EPIDEMIOLOGICAL MODELS FOR MUTATING PATHOGENS*

JIA LI†, YICAN ZHOU‡, ZHIEN MA‡, AND JAMES M. HYMAN§

Abstract. We formulate epidemiological models for the transmission of a pathogen that can mutate in the host to create a second infectious mutant strain. The models account for mutation rates that depend on how long the host has been infected. We derive explicit formulas for the reproductive number of the epidemic based on the local stability of the infection-free equilibrium. We analyze the existence and stability of the boundary equilibrium, whose infection components are zero and positive, respectively, and the endemic equilibrium, whose components are all positive. We establish the conditions for global stability of the infection-free and boundary equilibria and local stability of the endemic equilibrium for the case where there is no age structure for the pathogen in the infected population. We show that under certain circumstances, there is a Hopf bifurcation where the endemic equilibrium loses its stability, and periodic solutions appear. We provide examples and numerical simulations to illustrate the Hopf bifurcation.

Key words. epidemic model, pathogen, mutation, infection age, reproductive number, global stability, Hopf bifurcation

1. Introduction.

One of the biggest challenges in preventing the spread of infectious diseases is the genetic variations of pathogens. Pathogen mutations that circumvent the protective effects of a patient's immune response are common in infectious diseases such as measles [5], hepatitis B [20], HIV [9], West Nile virus [8], and influenza [18, 23, 24, 25].

The generation or selection of mutants that are a reflection of attempts of the pathogen to resist immune attacks of the host and to survive may occur naturally or in response to treatment with antibodies or antiviral drugs. Pathogens frequently alter their antigen expression to escape the immune defense and ensure the persistent infection in a host [10, 19].

There were only a few existing mathematical models accounting for genetic mutations of a pathogen [2, 3, 11, 17, 21], and little has been done to directly model dynamics of mutations which describe the attempts of the pathogen, after its infection in a host, to escape the immune defense of the host. In this paper, we propose an infection-age-structured dynamic model for a pathogen that can mutate into a second infectious strain in the host. The mutation could be the effect of selective immunologic pressure or possibly adaptation to a more efficiently transmitted or a better replicating pathogen resulting from conversion of the original viral pathogen.

The model formulation for the origin of the pathogen strain is based on a susceptible-infective-recovered (SIR) model with variable infection ages and is governed by partial differential equations (PDEs). The dynamics of the mutant are based on

an ordinary differential equation (ODE) SIR model. We characterize the threshold conditions of the model epidemic with an explicit formula for the reproductive number of infection, which determines the stability of the infection-free equilibrium. We analyze the stability of boundary equilibria of the model, where some, but not all, of the infection components are zero. We then investigate the existence and stability of the endemic equilibrium, whose components are all positive. We obtain explicit formulas for the endemic equilibrium and the characteristic equation of this equilibrium, which determines its stability. We then consider the special case where the rate at which the pathogen converts to its mutant and the transmission rate of the original pathogen are both independent of infection age. In this simplified situation, the model equations reduce to a system of ODEs. We obtain global stability of the infection-free equilibrium and a unique boundary equilibrium. We show that under certain conditions, the unique endemic equilibrium may undergo a Hopf bifurcation resulting in a periodic solution. We provide examples and numerical simulations to illustrate the stability change of the endemic equilibrium and the Hopf bifurcation.

2. Model formulation. We base our SIR model on the spread of a pathogen that can mutate in the host to create a second, cocirculating, mutant strain. We assume that after a certain period of infection, the original strain, referred to as Strain 1, is selected against in the intrahost selection process and is converted to a mutant, referred to as Strain 2, such that a proportion of the individuals infected by Strain 1 are then carrying Strain 2. Let $S(t)$ be the susceptibles and $i(t,\tau)$ the distribution of infectives infected by Strain 1 with infection stage, or time since infection, τ, such that $\int_{\tau_1}^{\tau_2} i(t,\tau)d\tau$ is the total number of infectives with infection ages between τ_1 and τ_2 [1, 7, 13, 14, 22]. Let $J(t)$ be the infectives infected by Strain 2 and $R(t)$ the group of individuals who are recovered and immune to both strains. We further assume that the genetic difference between the two strains, or the drift of the mutation, is relatively small so that there is perfect cross-immunity; that is, once an individual is recovered from infection by one of the two strains, the individual is immune to both strains.

The dynamics of the transmission in this model are governed by the system

$$
\begin{aligned}
\frac{dS(t)}{dt} &= \mu(S^0 - S(t)) - \left(\int_0^\infty \beta_1(\tau) i(t,\tau)d\tau + \beta_2 J(t)\right) S(t),\\
\frac{\partial i(t,\tau)}{\partial t} + \frac{\partial i(t,\tau)}{\partial \tau} &= -(\mu+\gamma_1) i(t,\tau) - \kappa(\tau) i(t,\tau),\\
i(t,0) &= S(t)\int_0^\infty \beta_1(\tau) i(t,\tau)d\tau,\\
i(0,\tau) &= \psi(\tau),\\
\frac{dJ(t)}{dt} &= \beta_2 J(t) S(t) - (\mu+\gamma_2) J(t) + \int_0^\infty \kappa(\tau) i(t,\tau)d\tau,\\
\frac{dR(t)}{dt} &= \gamma_1 \int_0^\infty i(t,\tau)d\tau + \gamma_2 J(t) - \mu R(t),
\end{aligned}
\tag{2.1}
$$

where μS^0 is the input flow into the susceptible population, μ is the total removal rate which accounts for both natural death and people moving in and out of the susceptible population, γ_1 and γ_2 are the recovery rates from the infection, $\beta_1(\tau)$ and β_2 are the transmission rates of Strain 1 and Strain 2, respectively, $\kappa(\tau)$ is the mutation rate, or the rate at which Strain 1 is converted to Strain 2, and $\psi(\tau)$ is the initial distribution of infectives infected by Strain 1.

3. Thresholds of the epidemic. Assume that the initial distribution of the infectives is zero. Then $E_0 := (S^0, 0, 0)$ is the infection-free equilibrium. As is well known, its stability determines the thresholds of the epidemic [6, 7, 13, 15, 16]. We investigate the local stability of E_0 as follows.

Since the dynamics of $R(t)$ do not affect the evolution of S, i, and J, we omit the equation for $R(t)$ when studying the growth of the epidemic. Linearizing system (2.1) about E_0, by defining the perturbation variables $x(t) = S(t) - S^0$, $y(t,\tau) = i(t,\tau)$, $z(t) = J(t)$, we obtain the system

$$
\begin{aligned}
&\frac{dx(t)}{dt} = -\mu x(t) - \left(\int_0^\infty \beta_1(\tau) y(t,\tau)\, d\tau + \beta_2 z(t)\right) S^0, \\
&\begin{cases} \dfrac{\partial y(t,\tau)}{\partial t} + \dfrac{\partial y(t,\tau)}{\partial \tau} &= -(\mu+\gamma_1) y(t,\tau) - \kappa(\tau) y(t,\tau), \\ y(t,0) &= S^0 \displaystyle\int_0^\infty \beta_1(\tau) y(t,\tau)\, d\tau, \end{cases} \qquad (3.1) \\
&\frac{dz(t)}{dt} = \beta_2 z(t) S^0 - (\mu+\gamma_2) z(t) + \int_0^\infty \kappa(\tau) y(t,\tau)\, d\tau.
\end{aligned}
$$

Let $x(t) = x_0 e^{\rho t}$, $y(t,\tau) = p(\tau) e^{\rho(t-\tau)}$, and $z(t) = z_0 e^{\rho t}$, where x_0, $p(\tau)$, z_0, and ρ are to be determined. Substituting them into (3.1), we obtain the equations

$$\rho x_0 = -\mu x_0 - S^0 \int_0^\infty \beta_1(\tau) p(\tau) e^{-\rho\tau}\, d\tau - \beta_2 S^0 z_0, \tag{3.2}$$

$$\frac{dp(\tau)}{d\tau} = -(\mu+\gamma_1) p(\tau) - \kappa(\tau) p(\tau), \tag{3.3}$$

$$p(0) = S^0 \int_0^\infty \beta_1(\tau) p(\tau) e^{-\rho\tau}\, d\tau, \tag{3.4}$$

$$\rho z_0 = (\beta_2 S^0 - \mu - \gamma_2) z_0 + \int_0^\infty \kappa(\tau) p(\tau) e^{-\rho\tau}\, d\tau \tag{3.5}$$

for $p(\tau) \not\equiv 0$, $x_0 \neq 0$, $z_0 \neq 0$, and ρ.

Equations (3.3) and (3.4) are decoupled from (3.2) and (3.5). Integrating (3.3) from 0 to τ gives

$$p(\tau) = p(0) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}, \tag{3.6}$$

where $\Delta(\tau) := \int_0^\tau \kappa(v)\, dv$. Substituting (3.6) into (3.4) yields the characteristic equation

$$p(0) = S^0 p(0) \int_0^\infty \beta_1(\tau) e^{-\rho\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}\, d\tau. \tag{3.7}$$

Defining

$$C(\rho) = S^0 \int_0^\infty \beta_1(\tau) e^{-\rho\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}\, d\tau,$$

we note that (3.7) has a nonzero solution $p(0)$ if and only if there exists ρ such that $C(\rho) = 1$.

We first consider the case where ρ is a real number. Since

$$C'(\rho) = -S^0 \int_0^\infty \tau \beta_1(\tau) e^{-\rho\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}\, d\tau < 0,$$

$C(\rho)$ is a decreasing function of ρ. Noticing $\lim_{\rho\to-\infty} C(\rho) = \infty$ and $\lim_{\rho\to\infty} C(\rho) = 0$, if we define the number

$$R_1 := C(0) = S^0 \int_0^\infty \beta_1(\tau) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau, \tag{3.8}$$

then there exists a unique real solution ρ to the equation $C(\rho) = 1$, which is negative if $R_1 < 1$ and positive if $R_1 > 1$.

If $\rho := \rho_1 + i\rho_2$ is a complex number, where $i = \sqrt{-1}$, then by separating the real and imaginary parts of $C(\rho) = 1$, the real part ρ_1 satisfies

$$1 = S^0 \int_0^\infty \beta_1(\tau) e^{-\rho_1\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} \cos(\rho_2\tau) d\tau. \tag{3.9}$$

However, since

$$S^0 \int_0^\infty \beta_1(\tau) e^{-\rho_1\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} \cos(\rho_2\tau) d\tau \le S^0 \int_0^\infty \beta_1(\tau) e^{-\rho_1\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau,$$

solution ρ_1 to (3.9) must be negative if $R_1 < 1$. That is, equation $C(\rho) = 1$ can have solutions with negative real part only if $R_1 < 1$.

The solution ρ of $C(\rho) = 1$ can be used to determine $p(\tau)$. The initial values, x_0 and z_0, can now be defined from (3.2) and (3.5). The number R_1 defined in (3.8) is a threshold value for Strain 1 because if $R_1 > 1$ the epidemic for Strain 1 grows, while if $R_1 < 1$ it delays. It is also the number of secondary infective cases generated by infection of Strain 1. We refer to R_1 as the reproductive number for Strain 1.

If initially no one is infected with Strain 1, i.e., $i(t, \tau) = 0$, then $p(\tau) = 0$ for all τ. Equations (3.2) and (3.5) can be reduced to

$$\begin{aligned} \rho x_0 &= -\mu x_0 - \beta_2 S^0 z_0, \\ \rho z_0 &= (\beta_2 S^0 - \mu - \gamma_2) z_0, \end{aligned} \tag{3.10}$$

and they determine threshold conditions for Strain 2. Define

$$R_2 := \frac{\beta_2 S^0}{\mu + \gamma_2}. \tag{3.11}$$

All solutions ρ of system (3.10) are negative if and only if $R_2 < 1$. Therefore, R_2 is a threshold value for Strain 2 and is the number of secondary infective cases generated by infection of Strain 2. We refer to R_2 as the reproductive number of Strain 2.

The thresholds for the epidemic can be summarized as follows.

THEOREM 3.1. *Define the reproductive number, R_0, of infection in the total population by*

$$R_0 := \max\{R_1, R_2\},$$

that is,

$$R_0 = \max\left\{ S^0 \int_0^\infty \beta_1(\tau) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau, \quad \frac{\beta_2 S^0}{\mu + \gamma_2} \right\}.$$

Then the infection-free equilibrium E_0 is asymptotically stable if $R_0 < 1$ and is unstable if $R_0 > 1$.

4. Boundary equilibrium. Cocirculating strains of the pathogen compete with each other to infect the susceptible population. When only one strain is present, the solution is on the boundary of the feasibility solution space and we call the stationary solution a boundary equilibrium.

An equilibrium of system (2.1), $(S, i(\tau), J)$, satisfies the system

$$\mu(S^0 - S) - \left(\int_0^\infty \beta_1(\tau) i(\tau) d\tau + \beta_2 J\right) S = 0, \tag{4.1a}$$

$$\frac{di(\tau)}{d\tau} = -(\mu + \gamma_1) i(\tau) - \kappa(\tau) i(\tau), \tag{4.1b}$$

$$i(0) = S \int_0^\infty \beta_1(\tau) i(\tau) d\tau, \tag{4.1c}$$

$$\beta_2 JS - (\mu + \gamma_2) J + \int_0^\infty \kappa(\tau) i(\tau) d\tau = 0. \tag{4.1d}$$

It follows from (4.1d) that if $J = 0$, then $i(\tau) = 0$ for all τ. That is, there does not exist a boundary equilibrium with $i(\tau) \geq 0$ and $J = 0$, and the only boundary equilibrium has $i(\tau) = 0$ for all τ and $J \neq 0$. We denote it as $E_1 := (S_1, i_1(\tau), J_1)$.

Solving (4.1a) and (4.1d), we have

$$S_1 = \frac{\mu + \gamma_2}{\beta_2}, \quad J_1 = \frac{\mu}{\beta_2}\left(\frac{S^0 \beta_2}{\mu + \gamma_2} - 1\right) = \frac{\mu}{\beta_2}(R_2 - 1). \tag{4.2}$$

Thus the boundary equilibrium E_1 exists if and only if $R_2 > 1$.

To study stability of this boundary equilibrium, we linearize system (2.1) about E_1 by letting $x(t) = S(t) - S_1$, $y(t) = J(t) - J_1$, $z(t, \tau) = i(t, \tau)$, and we obtain the system

$$\begin{aligned}
&\frac{dx(t)}{dt} = -\mu x(t) - \beta_2 J_1 x(t) - \beta_2 S_1 y(t) - S_1 \int_0^\infty \beta_1(\tau) z(t, \tau) d\tau, \\
&\frac{dy(t)}{dt} = \beta_2 J_1 x(t) - (\mu + \gamma_2) y(t) + \beta_2 S_1 y(t) + \int_0^\infty \kappa(\tau) z(t, \tau) d\tau, \\
&\begin{cases} \dfrac{\partial z(t, \tau)}{\partial t} + \dfrac{\partial z(t, \tau)}{\partial \tau} = -(\mu + \gamma_1) z(t, \tau) - \kappa(\tau) z(t, \tau), \\ z(t, 0) = S_1 \displaystyle\int_0^\infty \beta_1(\tau) z(t, \tau) d\tau. \end{cases}
\end{aligned} \tag{4.3}$$

Using the same approach as in section 3, we first derive the characteristic equation for E_1,

$$1 = S_1 \int_0^\infty \beta_1(\tau) e^{-\rho\tau} e^{-(\mu + \gamma_1)\tau - \Delta(\tau)} d\tau, \tag{4.4}$$

and define

$$R_b := S_1 \int_0^\infty \beta_1(\tau) e^{-(\mu + \gamma_1)\tau - \Delta(\tau)} d\tau.$$

If $R_b < 1$, then $\lim_{t \to \infty} z(t, \tau) = 0$.

Next we locate the eigenvalues of the following matrix from system (4.3):

$$\begin{bmatrix} -\mu - \beta_2 J_1 & -\beta_2 S_1 \\ \beta_2 J_1 & -(\mu + \gamma_2 - \beta_2 S_1) \end{bmatrix} = \begin{bmatrix} -\mu - \beta_2 J_1 & -\beta_2 S_1 \\ \beta_2 J_1 & 0 \end{bmatrix}.$$

The trace and determinant of this matrix are negative and positive, respectively. Therefore, its eigenvalues both have negative real part.

In summary we have the following.

THEOREM 4.1. *The unique boundary equilibrium*

$$E_1 = (S_1, i_1(\tau), J_1) = \left(\frac{\mu + \gamma_2}{\beta_2},\ 0,\ \frac{\mu}{\beta_2} \left(\frac{S^0 \beta_2}{\mu + \gamma_2} - 1 \right) \right)$$

exists if and only if $R_2 > 1$. *It is locally asymptotically stable if*

$$R_b = \frac{\mu + \gamma_2}{\beta_2} \int_0^\infty \beta_1(\tau) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau < 1$$

and is unstable if $R_b > 1$.

If $R_2 > 1$, then $S^0 > (\mu + \gamma_2)/\beta_2 := \tilde{S}_1$. Notice that R_b can be rewritten as $R_b = \tilde{S}_1/S^0 R_1 = R_1/R_2$. When the boundary equilibrium E_1 exists, $R_2 > 1$, and hence $S^0 > \tilde{S}_1$ and $R_b < R_1$. If $R_2 > 1 > R_1$, then $R_b < 1$, which implies that the boundary equilibrium E_1 is asymptotically stable. In the situation where $R_2 > 1$ and $R_1 > 1$, the infection-free equilibrium is unstable and the two strains cannot both die out. If $R_2 > R_1 > 1$, then $R_b < 1$ and the boundary equilibrium E_1 exists and is asymptotically stable. In the last possible case, if $R_1 > R_2 > 1$, then although the boundary equilibrium E_1 exists, it is unstable. This situation may lead to the existence and stability of an endemic equilibrium or other dynamical features of system (2.1).

5. Endemic equilibrium. The cocirculating strains of the pathogen can coexist. The stationary coexistence solution is an endemic equilibrium whose components are all positive.

5.1. Existence of the endemic equilibrium. Let $E^* := (S^*, i^*(\tau), J^*)$ be an endemic equilibrium of system (2.1). It follows from (4.1b) that

$$i^*(\tau) = i^*(0) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}.$$

By substituting this into (4.1c), we arrive at the equation

$$i^*(0) = i^*(0) S^* \int_0^\infty \beta_1(\tau) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau = i^*(0) \frac{S^* R_1}{S^0}. \tag{5.1}$$

Equation (5.1) has a solution $i^*(0) > 0$ if and only if

$$S^* = \frac{S^0}{R_1}. \tag{5.2}$$

It follows from (4.1c) that

$$i^*(0) = S^* W_1,$$

where we define $W_1 := \int_0^\infty \beta_1(\tau) i^*(\tau) d\tau$. Then

$$i^*(\tau) = S^* W_1 e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}. \tag{5.3}$$

Define

$$W_2 := \int_0^\infty \kappa(\tau) i^*(\tau) d\tau = S^* W_1 \int_0^\infty \kappa(\tau) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau = S^* W_1 K, \tag{5.4}$$

where

$$K := \int_0^\infty \kappa(\tau) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau.$$

The equilibrium equations (4.1a) and (4.1d) can be expressed as

$$\mu S^0 = (\mu + W_1 + \beta_2 J^*)\, S^*, \tag{5.5}$$

$$W_2 = ((\mu + \gamma_2) - \beta_2 S^*)\, J^*. \tag{5.6}$$

Substituting (5.2) into (5.6) yields

$$(\mu + \gamma_2)\left(1 - \frac{\beta_2 S^*}{\mu + \gamma_2}\right) J^* = (\mu + \gamma_2)\left(1 - \frac{R_2}{R_1}\right) J^* = W_2. \tag{5.7}$$

Since $W_2 > 0$, there exists a positive solution J^* of (5.7) if and only if

$$\frac{R_2}{R_1} < 1.$$

Suppose $R_2 < R_1$. Then solving (5.7) for J^* yields

$$J^* = \frac{W_2}{(\mu + \gamma_2)\left(1 - \frac{R_2}{R_1}\right)}. \tag{5.8}$$

Substituting (5.8) into (5.5) gives

$$\mu + W_1 + \beta_2 \frac{W_2}{(\mu + \gamma_2)\left(1 - \frac{R_2}{R_1}\right)} = \frac{\mu S^0}{S^*} = \mu R_1. \tag{5.9}$$

We then substitute (5.4) into (5.9) to obtain

$$W_1 + \frac{\beta_2 S^0 K}{(\mu + \gamma_2)(R_1 - R_2)} W_1 = \mu(R_1 - 1), \tag{5.10}$$

which implies that $W_1 > 0$ if $R_1 > 1$.

Solving (5.10) for W_1 yields

$$W_1 = \frac{\mu\,(R_1 - 1)\,(R_1 - R_2)\,(\mu + \gamma_2)}{((\mu + \gamma_2)\,(R_1 - R_2) + \beta_2 K S^0)}. \tag{5.11}$$

W_2 can be determined by substituting (5.11) into (5.4). Finally, substituting W_2 and W_1 into (5.3) and (5.8), we obtain the expression for the unique positive endemic equilibrium.

THEOREM 5.1. *If $R_1 > 1$ and $R_1 > R_2$, then there exists a unique endemic equilibrium $E^* = (S^*, i^*(\tau), J^*)$ given by*

$$S^* = \frac{S^0}{R_1}, \quad i^*(\tau) = \frac{S^0 W_1}{R_1} e^{-(\mu+\gamma_1)\tau - \int_0^\tau \kappa(v)dv}, \quad J^* = \frac{K S^0 W_1}{(\mu + \gamma_2)\,(R_1 - R_2)}, \tag{5.12}$$

where W_1 is defined in (5.11).

5.2. Stability of the endemic equilibrium. We investigate the local stability of the endemic equilibrium, E^*, by linearizing system (2.1) about E^*. Let $x(t) = S(t) - S^*$, $y(t,\tau) = i(t,\tau) - i^*(\tau)$, and $z(t) = J(t) - J^*$. The linearization results in the perturbation equations

$$
\begin{aligned}
&\frac{dx(t)}{dt} = -\left(\mu + W_1 + \beta_2 J^*\right) x(t) - \beta_2 S^* z(t) - S^* \int_0^\infty \beta_1(\tau) y(t,\tau) d\tau, \\
&\begin{cases} \dfrac{\partial y(t,\tau)}{\partial t} + \dfrac{\partial y(t,\tau)}{\partial \tau} &= -(\mu+\gamma_1) y(t,\tau) - \kappa(\tau) y(t,\tau), \\ y(t,0) &= S^* \displaystyle\int_0^\infty \beta_1(\tau) y(t,\tau) d\tau + W_1 x(t), \end{cases} \qquad (5.13) \\
&\frac{dz(t)}{dt} = \beta_2 J^* x(t) - (\mu+\gamma_2) z(t) + \beta_2 S^* z(t) + \int_0^\infty \kappa(\tau) y(t,\tau) d\tau.
\end{aligned}
$$

Suppose $x = x_0 e^{\rho t}$, $y = \hat{y}(\tau) e^{\rho(t-\tau)}$, and $z = z_0 e^{\rho t}$. Substituting these variables into system (5.13) and solving for $\hat{y}(\tau)$, with initial condition $\hat{y}(0)$, leads to the system

$$
\begin{aligned}
&(\rho + \mu + W_1 + \beta_2 J^*) x_0 + \beta_2 S^* z_0 + S^* \int_0^\infty \beta_1(\tau) \hat{y}(\tau) e^{-\rho\tau} d\tau = 0, \\
&-\beta_2 J^* x_0 + (\rho + \mu + \gamma_2 - \beta_2 S^*) z_0 - \int_0^\infty \kappa(\tau) \hat{y}(\tau) e^{-\rho\tau} d\tau = 0, \qquad (5.14) \\
&\hat{y}(\tau) = \left(S^* \int_0^\infty \beta_1(\tau) \hat{y}(\tau) e^{-\rho\tau} d\tau + W_1 x_0 \right) e^{-(\mu+\gamma_1)\tau - \Delta(\tau)}.
\end{aligned}
$$

We simplify these notations by defining the functions

$$
\begin{aligned}
H(\rho) &:= \int_0^\infty \beta_1(\tau) \hat{y}(\tau) e^{-\rho\tau} d\tau, & Q(\rho) &:= \int_0^\infty \kappa(\tau) \hat{y}(\tau) e^{-\rho\tau} d\tau, \\
P_1(\rho) &:= \int_0^\infty \beta_1(\tau) e^{-\rho\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau, & P_2(\rho) &:= \int_0^\infty \kappa(\tau) e^{-\rho\tau} e^{-(\mu+\gamma_1)\tau - \Delta(\tau)} d\tau.
\end{aligned}
$$

Multiplying $\hat{y}(\tau)$ in (5.14) by $\beta_1(\tau)e^{-\rho\tau}$ and $\kappa(\tau)e^{-\rho\tau}$, respectively, and then integrating from 0 to ∞ yields

$$
H(\rho) = \frac{W_1 P_1(\rho)}{1 - S^* P_1(\rho)} x_0 \qquad (5.15)
$$

and

$$
Q(\rho) = \left(S^* H(\rho) + W_1 x_0\right) P_2(\rho) = \left(\frac{S^* W_1 P_1(\rho)}{1 - S^* P_1(\rho)} + W_1 \right) P_2(\rho) x_0. \qquad (5.16)
$$

Substituting (5.15) and (5.16) into system (5.14), we obtain the characteristic equation

$$
\left(\rho + \mu + \beta_2 J^* + \frac{W_1}{1 - S^* P_1(\rho)} \right) (\rho + \mu + \gamma_2 - \beta_2 S^*) + \left(\beta_2 J^* + \frac{W_1 P_2(\rho)}{1 - S^* P_1(\rho)} \right) \beta_2 S^* = 0 \qquad (5.17)
$$

and arrive at the following result.

THEOREM 5.2. *The endemic equilibrium, given in* (5.12)*, is locally asymptotically stable if all roots, ρ, of the characteristic equation* (5.17) *have negative real part.*

The results obtained for the two-strain SIR model (2.1) are summarized in Table 1. The stability of the endemic equilibrium is not listed because it requires knowledge of the roots of the characteristic equation (5.17) and we have not established the explicit criterion.

TABLE 1

The existence conditions for the boundary and endemic equilibria, E_1 and E^*, and stability conditions for the infection-free and boundary equilibria, E_0 and E_1. These conditions are based on the relations between the two reproductive numbers, R_1 and R_2, for the two strains.

	$R_1 < 1$, $R_2 < 1$	$R_2 < 1 < R_1$	$R_1 < 1 < R_2$	$1 < R_1 < R_2$	$1 < R_2 < R_1$
E_0	stable	unstable	unstable	unstable	unstable
E_1	does not exist	does not exist	stable	stable	unstable
E^*	does not exist	exists	does not exist	does not exists	exists

6. Constant mutation rate. Because (5.17) is a transcendental equation, it is difficult to determine when all the roots of the characteristic equation have negative real part and, hence, whether the endemic equilibrium is stable. To gain insight into the transmission dynamics of the disease governed by system (2.1), we consider the special case where the mutation rate from Strain 1 to Strain 2 is constant and where the infection rate of Strain 1 is independent of the infection stages. We define these constant rates as $\kappa(\tau) := k$ and $\beta_1(\tau) := \beta_1$.

Let the total infectives be $I(t) := \int_0^\infty i(t,\tau)d\tau$. Integrating the equation for $i(t,\tau)$ in (2.1) with respect to τ and using the initial condition $i(t,0)$ reduces the system of PDEs to the system of ODEs,

$$\frac{dS}{dt} = \mu(S^0 - S) - \beta_1 IS - \beta_2 JS, \tag{6.1a}$$

$$\frac{dI}{dt} = \beta_1 SI - (\mu + \gamma_1 + k)I, \tag{6.1b}$$

$$\frac{dJ}{dt} = \beta_2 SJ - (\mu + \gamma_2)J + kI. \tag{6.1c}$$

The reproductive numbers of Strains 1 and 2, R_1 and R_2, for system (6.1) are

$$R_1 = \frac{S^0\beta_1}{\mu + \gamma_1 + k}, \qquad R_2 = \frac{S^0\beta_2}{\mu + \gamma_2}. \tag{6.2}$$

The only boundary equilibrium with $I = 0$ and $J > 0$ exists if $R_2 > 1$ and it has the same expression as in section 4. This boundary equilibrium is stable if $R_1 < R_2$ and is unstable if $R_1 > R_2$.

We now establish existence and local stability of the endemic equilibrium of system (6.1).

For $\kappa(\tau) = k$, the term K defined in (5.4) becomes

$$K = \frac{k}{\mu + \gamma_1 + k}. \tag{6.3}$$

Substituting (6.2) and (6.3) into (5.12), we obtain the endemic equilibrium, $E^* = (S^*, I^*, J^*)$, with

$$\begin{aligned} S^* &= \frac{\mu + \gamma_1 + k}{\beta_1}, \\ I^* &= \frac{\mu\big(S^0\beta_1 - (\mu + \gamma_1 + k)\big)\big(\beta_1(\mu + \gamma_2) - \beta_2(\mu + \gamma_1 + k)\big)}{\beta_1\big(\beta_1(\mu + \gamma_2) - \beta_2(\mu + \gamma_1)\big)(\mu + \gamma_1 + k)}, \\ J^* &= \frac{\mu k\big(S^0\beta_1 - (\mu + \gamma_1 + k)\big)}{\big(\beta_1(\mu + \gamma_2) - \beta_2(\mu + \gamma_1)\big)(\mu + \gamma_1 + k)}. \end{aligned} \tag{6.4}$$

By solving (6.1) for an endemic equilibrium, we have the equivalent solution

$$\begin{aligned} S^* &= \frac{S^0}{R_1}, \\ I^* &= \frac{\mu(\mu+\gamma_1+k)(R_1-1)(R_1-R_2)}{\beta_1\big(kR_1+(\mu+\gamma_1)(R_1-R_2)\big)}, \\ J^* &= \frac{\mu k S^0(R_1-1)}{(\mu+\gamma_2)\big(kR_1+(\mu+\gamma_1)(R_1-R_2)\big)}. \end{aligned}$$

Hence E^* exists if and only if $R_1 > 1$ and $R_1 > R_2$.

Based on $\mu + \beta_2 J^* = \mu S^0/S^* - \beta_1 I^*$, the characteristic equation for system (6.1) has the form

(6.5)
$$\left(\rho + \mu R_1 + \frac{\gamma_1+\mu+k}{\rho}\beta_1 I^*\right)(\rho+\mu+\gamma_2-\beta_2 S^*) + \left(\beta_2 J^* + \frac{k}{\rho}\beta_1 I^*\right)\beta_2 S^* = 0.$$

This can be expressed as

$$\rho^3 + a_1\rho^2 + a_2\rho + a_3 = 0,$$

where

$$\begin{aligned} a_1 &:= \mu R_1 + \mu + \gamma_2 - \beta_2 S^* = \mu\frac{S^0}{S^*} + k\frac{I^*}{J^*}, \\ a_2 &:= \mu R_1(\mu+\gamma_2-\beta_2 S^*) + (\mu+\gamma_1+k)\beta_1 I^* + \beta_2^2 J^* S^* \\ &= \beta_1^2 S^* I^* + \beta_2^2 S^* J^* + \mu\frac{S^0}{S^*}k\frac{I^*}{J^*}, \\ a_3 &:= \left((\mu+\gamma_2)\beta_1 - \beta_2(\mu+\gamma_1)\right)(\mu+\gamma_1+k)I^* = \beta_1 S^* k\frac{I^*}{J^*}\left(\beta_1 I^* + \beta_2 J^*\right). \end{aligned}$$

Since $a_1 > 0$ and $a_3 > 0$, it follows from the Routh–Hurwitz criterion that all characteristic roots of (6.5) have negative real part if and only if $a_1 a_2 > a_3$.

A straightforward calculation yields

(6.6)
$$\begin{aligned} a_1 a_2 - a_3 &= \mu\frac{S^0}{S^*}\left(\beta_1^2 S^* I^* + \beta_2^2 S^* J^* + \mu\frac{S^0}{S^*}k\frac{I^*}{J^*}\right) + \mu\frac{S^0}{S^*}\left(k\frac{I^*}{J^*}\right)^2 + kS^* I^*\beta_2(\beta_2-\beta_1) \\ &= \frac{\mu(R_1-1)(R_1-R_2)}{(\sigma_1+k)R_1-\sigma_1 R_2}\left(\mu R_1(\sigma_1+k)^2 + \frac{\mu\sigma_2 R_2^2 k}{R_1-R_2}\right. \\ &\qquad\qquad \left. - \frac{k\sigma_2 R_2\big(R_1(\sigma_1+k)-R_2\sigma_2\big)}{R_1^2}\right) \\ &\quad + \frac{\mu(R_1-R_2)}{R_1^2}(\mu\sigma_2 R_1^3 + \sigma_2^2(R_1-R_2)R_1) \\ &= \frac{\mu(R_1-1)(R_1-R_2)}{R_1^2\big((\sigma_1+k)R_1-\sigma_1 R_2\big)}(c_2k^2 + c_1 k + c_0), \end{aligned}$$

where

$$\sigma_1 := \mu + \gamma_1, \quad \sigma_2 := \mu + \gamma_2,$$

$$c_0 := \mu\sigma_1^2 R_1^3 + \sigma_2 R_1\big(\mu R_1^2 + \sigma_2(R_1 - R_2)\big)\frac{\sigma_1(R_1 - R_2)}{R_1 - 1},$$

$$c_1 := 2\mu\sigma_1 R_1^3 + \frac{\mu\sigma_2 R_1^2 R_2^2}{R_1 - R_2} + \frac{\sigma_2 R_1^2\big(\mu R_1^2 + \sigma_2(R_1 - R_2)\big)}{R_1 - 1} - \sigma_2 R_2(\sigma_1 R_1 - \sigma_2 R_2),$$

$$c_2 := \mu R_1^3 - \sigma_2 R_1 R_2.$$

Hence all roots of (6.5) have negative real part if $c_2k^2 + c_1k + c_0 > 0$, and at least one of the roots of (6.5) has positive real part if $c_2k^2 + c_1k + c_0 < 0$.

We summarize the results in the following theorem.

THEOREM 6.1. *When the mutation rate is constant, the dynamical behavior of epidemic model* (6.1) *can be described as one of the following cases:*

1. *If we define* $R_0 := \max\{R_1, R_2\}$ *and* $R_0 < 1$, *then the infection-free equilibrium,* $E_0 := (S^0, 0, 0)$, *is the only equilibrium and is locally asymptotically stable. If* $R_0 > 1$, *then* E_0 *is unstable.*
2. *If* $R_1 < 1 < R_2$, *or* $1 < R_1 < R_2$, *the only boundary equilibrium, given by*

$$E_1 := \left(\tilde{S}, 0, \tilde{J}\right) = \left(S^0 R_2,\ 0,\ \frac{\mu S^0}{\sigma_2 R_2}(R_2 - 1)\right), \tag{6.7}$$

   exists and is locally asymptotically stable. In this case, the endemic equilibrium, E^*, *does not exist.*
3. *If* $R_2 < 1 < R_1$, *the endemic equilibrium,* E^*, *exists and is the only nontrivial equilibrium. It is locally asymptotically stable if* $c_2k^2 + c_1k + c_0 > 0$ *and unstable if* $c_2k^2 + c_1k + c_0 < 0$.
4. *If* $1 < R_2 < R_1$, *the boundary equilibrium,* E_1, *exists but is unstable. The endemic equilibrium,* E^*, *exists and is locally asymptotically stable if* $c_2k^2 + c_1k + c_0 > 0$ *and unstable if* $c_2k^2 + c_1k + c_0 < 0$.

6.1. The global stability of the equilibria. In this section we establish that when the infection-free equilibrium and the boundary equilibrium of system (6.1) are locally asymptotically stable, they are globally stable.

THEOREM 6.2.

1. *If the infection-free equilibrium,* E_0, *is locally asymptotically stable, then it is globally stable; that is,* E_0 *is globally asymptotically stable if* $R_0 < 1$.
2. *If* $R_1 < 1 < R_2$, *the only boundary equilibrium,* E_1, *given in* (6.7), *is globally asymptotically stable.*

Proof. It follows from (6.1b) that

$$I(t) = I(0)e^{\int_0^t \beta_1 S(\tau)d\tau - (\mu+\gamma_1+k)t}$$

for all $t \geq 0$. Hence, the hyperplane $I = 0$ is invariant for system (6.1).

If $R_1 < 1$, we can further show that the hyperplane attracts all solutions started in the first octant, $S \geq 0$, $I \geq 0$, $J \geq 0$. That is, $\lim_{t\to\infty} I(t) = 0$. It can be seen from (6.1a) that $dS/dt \leq \mu(S^0 - S)$ and hence $S(t) \leq S^0 + S(0)e^{-\mu t}$ and from (6.1b) that

$$\begin{aligned} I(t) &\leq I(0)e^{\int_0^t \beta_1\left(S^0 + S(0)e^{-\mu\tau}\right)d\tau - (\mu+\gamma_1+k)t} = I(0)e^{(\mu+\gamma_1+k)(R_1-1)t + \frac{\beta_1 S(0)}{\mu}\left(1-e^{-\mu t}\right)} \\ &\leq I(0)e^{\frac{\beta_1 S(0)}{\mu}}e^{(\mu+\gamma_1+k)(R_1-1)t} \to 0 \end{aligned}$$

as $t \to \infty$.

Based on the attractiveness of the hyperplane $I = 0$, to prove the global asymptotic stability of the infection-free equilibrium E_0 or the boundary equilibrium E_1 in the first octant, it suffices to show that these two equilibria are globally asymptotically stable in the hyperplane $I = 0$.

We first show that all the solutions of (6.1) in the hyperplane $I = 0$ approach E_0 if $R_0 < 1$. We use the Lyapunov function V_1 defined by

$$V_1(S, J) := J + S - S^0 - S^0 \ln \frac{S}{S^0}$$

for system (6.1). Along the trajectories of system (6.1) in the hyperplane $I = 0$ we have

$$\begin{aligned}
\left.\frac{dV_1}{dt}\right|_{(6.1)} &= (\beta_2 S - (\mu + \gamma_2))\, J + \frac{S - S^0}{S}\left(\mu(S^0 - S) - \beta_2 JS\right) \\
&= -\frac{\mu(S - S^0)^2}{S} + \left(S^0\beta_2 - (\mu + \gamma_2)\right) J \\
&= -\frac{\mu(S - S^0)^2}{S} + J(R_2 - 1)\sigma_2 < 0
\end{aligned}$$

if $R_2 < 1$. Hence it follows from Lyapunov stability theory that E_0 is globally asymptotically stable.

We next assume $R_1 < 1 < R_2$ and show the global stability of the boundary equilibrium $E_1 = (\tilde{S}, 0, \tilde{J})$. We use

$$V_2(S, J) = J - \tilde{J} - \tilde{J} \ln \frac{J}{\tilde{J}} + S - \tilde{S} - \tilde{S} \ln \frac{S}{\tilde{S}}$$

as a Lyapunov functions for system (6.1). In the hyperplane $I = 0$,

$$\begin{aligned}
\left.\frac{dV_2}{dt}\right|_{(6.1)} &= (\beta_2 S - (\mu + \gamma_2))\,(J - \tilde{J}) + \frac{\mu(S^0 - S)(S - \tilde{S})}{S} - (S - \tilde{S})\beta_2 J \\
&= \beta_2(S - \tilde{S})(J - \tilde{J}) + \frac{\mu(S^0 - S)(S - \tilde{S})}{S} - (S - \tilde{S})\beta_2 J \\
&= -\beta_2(S - \tilde{S})\tilde{J} + \frac{\mu(S^0 - S)(S - \tilde{S})}{S} \\
&= -\frac{S - \tilde{S}}{S}\left(S\beta_2\tilde{J} - \mu(S^0 - S)\right) = -\frac{S - \tilde{S}}{S}\left((\beta_2\tilde{J} + \mu)S - \mu S^0\right) \\
&= -\frac{S - \tilde{S}}{S}\left(\frac{\mu S^0}{\tilde{S}}S - \mu S^0\right) = -\frac{\mu S^0(S - \tilde{S})^2}{\tilde{S}S} \le 0.
\end{aligned}$$

The maximum invariant subset of the set $\left\{(S, I, J) \;\middle|\; \frac{dV}{dt} = 0\right\}$ in the hyperplane $I = 0$ contains only E_1. Then it follows from the LaSalle invariance principle that E_1 is globally asymptotically stable on the hyperplane $I = 0$. □

Note that we have not been able to prove the global stability of the boundary equilibrium E_1 for the case $1 < R_1 < R_2$.

6.2. Hopf bifurcation near the endemic equilibrium. We know from Theorem 6.1 that if $R_2 < 1 < R_1$ or $1 < R_2 < R_1$, the boundary equilibrium either does not exist or is unstable, and the positive endemic equilibrium is asymptotically stable if $c_2k^2 + c_1k + c_0 > 0$ and is unstable if $c_2k^2 + c_1k + c_0 < 0$. We now show that as the

endemic equilibrium loses stability, periodic solutions can bifurcate from the endemic equilibrium.

To investigate the bifurcation and to simplify the mathematical analysis, we study the bifurcation in terms of the mutation rate k and the two basic reproductive numbers R_1 and R_2 and assume that individuals infected by the two strains have the same recovery rate $\gamma_1 = \gamma_2 := \gamma$, and hence $\sigma_1 = \sigma_2 := \sigma$. Under these assumptions, and after some tedious algebraic manipulations, (6.6) becomes

(6.8)
$$a_1a_2 - a_3 = \mu(R_1 - 1)(R_1 - R_2)\Big(\mu - \frac{\sigma R_2}{R_1^2}\Big)k + \sigma\mu^2 R_1(2R_1 - R_2 - 1) + \frac{\mu\sigma^2(R_1 - R_2)^2}{R_1}.$$

All terms in (6.8) are positive except $\mu - \sigma R_2/R_1^2$. If $\mu R_1^2 \geq \sigma R_2$, then $a_1a_2 > a_3$. It follows from the Routh–Hurwitz criterion that the endemic equilibrium E^* is locally asymptotically stable.

Suppose $\mu R_1^2 < \sigma R_2$. We define a critical number k_0 as

$$k_0 = \frac{\sigma\mu R_1^3(2R_1 - R_2 - 1) + \sigma^2(R_1 - R_2)^2 R_1}{(R_1 - 1)(R_1 - R_2)(\sigma R_2 - \mu R_1^2)} \tag{6.9}$$

such that E^* is locally asymptotically stable if $k < k_0$ and is unstable if $k > k_0$. For $k = k_0$, the characteristic equation (6.5) for the linearization of system (6.1) has two pure imaginary roots. The parameter k can be used as a bifurcation parameter such that as k passes through k_0, a Hopf bifurcation occurs and a periodic solution bifurcates from the endemic equilibrium.

The reproductive numbers R_1 and R_2 can also be used as bifurcation parameters. Rewrite $a_1a_2 - a_3$ as a quadratic function of $R_1 - R_2$:

$$a_1a_2 - a_3 = \mu d_2(R_1 - R_2)^2 + \mu d_1(R_1 - R_2) + \mu d_0,$$

where

$$\begin{aligned} d_0 &:= \sigma\mu R_1(R_1 - 1), \\ d_1 &:= (R_1 - 1)(\mu - \sigma/R_1)k + \sigma\mu R_1, \\ d_2 &:= \sigma^2/R_1 + \sigma(R_1 - 1)k/R_1^2. \end{aligned}$$

Fixing R_1 and then solving the equation $d_2(R_1 - R_2)^2 + d_1(R_1 - R_2) + d_0 = 0$ for R_2 yields the two solutions

$$R_2^+ = R_1 + \frac{d_1 + \sqrt{d_1^2 - 4d_2d_0}}{2d_2}, \qquad R_2^- = R_1 + \frac{d_1 - \sqrt{d_1^2 - 4d_2d_0}}{2d_2}.$$

For $R_1 > 1$, $d_2 > 0$ and $d_0 > 0$. If $R_1 > R_2$ and $d_1^2 < 4d_2d_0$, the inequality $a_1a_2 - a_3 > 0$ always holds. The endemic equilibrium, E^*, is locally asymptotically stable. If $d_1^2 > 4d_2d_0$, E^* is locally asymptotically stable provided $0 < R_2 < R_2^-$ or $R_2^+ < R_2 < R_1$ and is unstable provided $R_2^- < R_2 < R_2^+$. As R_2 passes through R_2^- or R_2^+, periodic solutions bifurcate from the endemic equilibrium.

The dynamics of system (6.1) are summarized, based on R_1 and R_2, in Figure 1. We divide the R_1-R_2 plane into five regions. In Region I, $R_1 < 1$ and $R_2 < 1$. The infection-free equilibrium, E_0, is the only equilibrium and is globally asymptotically stable. In both Regions II and III, the boundary equilibrium, E_1, is globally asymptotically stable, whereas the endemic equilibrium, E^*, does not exist in Region II

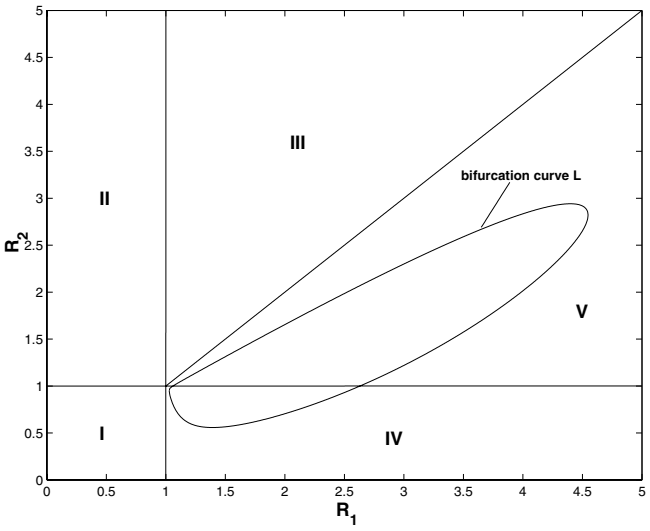

FIG. 1. *Schematic illustrations of dynamical behavior of system* (6.1) *based on the reproductive numbers,* R_1 *and* R_2*. The infection-free equilibrium,* E_0*, is the only equilibrium in Region* I *and is globally asymptotically stable. The boundary equilibrium,* E_1*, exists in Regions* II, III, *and* V*. It is globally asymptotically stable in both Regions* II *and* III *but is unstable in Region* V*. The endemic equilibrium,* E^**, exists in Regions* III, IV, *and* V*. It is unstable in Region* III *and in the interior of the region enclosed by the bifurcation curve* L*. It is locally asymptotically stable in the complement of the region enclosed by curve* L *in* IV *and* V*. For a fixed* R_1 *in the interval of the projection of curve* L *on the* R_1*-axis, as* R_2 *crosses through curve* L*, periodic solutions are bifurcated.*

and exists but is unstable in Region III. While E^* exists in both Regions IV and V and is the only nontrivial equilibrium in Region IV, and E_1 exists but is unstable in Region V, the stability of E^* is determined by the closed bifurcation curve L in these two regions. E^* is unstable and a Hopf bifurcation takes place in the interior of the region enclosed by L. E^* is asymptotically stable elsewhere in Regions IV and V.

We illustrate these results by examples using k, or R_1 and R_2, as bifurcation parameters.

Example 6.1. We use k as a bifurcation parameter and let $\sigma_1 = \sigma_2 = 1/2$, $\mu = 1/100$, $R_1 = 3$, and $R_2 = 2$. System (6.1) becomes

$$\begin{aligned} \frac{dS}{dt} &= \frac{1}{100}(S^0 - S) - \left(\frac{3+6k}{2S^0}I + \frac{1}{S^0}J\right)S, \\ \frac{dI}{dt} &= \frac{3+6k}{2S^0}SI - \frac{1+2k}{2}I, \\ \frac{dJ}{dt} &= \frac{1}{S_0}SJ - \frac{1}{2}J + kI \end{aligned} \tag{6.10}$$

and has the endemic equilibrium

$$E^* = \left(\frac{S^0}{3}, \frac{S^0}{75(1+6k)}, \frac{2kS^0}{25(1+6k)}\right) = (S^*, I^*, J^*).$$

The linearization of system (6.10) at E^* has the characteristic equation

$$f(\rho) = \rho^3 + \frac{59}{300}\rho^2 + \left(\frac{k}{150} + \frac{3}{200}\right)\rho + \frac{k}{300} + \frac{1}{600} = 0. \tag{6.11}$$

The critical number k_0 defined in (6.9) can be determined as $k_0 = 33/52$. Then, if $k < 33/52$, all roots of (6.11) have negative real part, and hence the endemic equilibrium of (6.10) is stable. If $k > 33/52$, there exist two roots with positive real part, and hence the endemic equilibrium of system (6.10) is unstable. For $k = 33/52$, (6.11) has a negative real root and two pure imaginary conjugates:

$$\rho_1 = -\frac{59}{300}, \quad \rho_2 = \frac{\sqrt{13}}{26}i, \quad \rho_3 = -\frac{\sqrt{13}}{26}i.$$

For k greater than, but near $33/52$, (6.11) has a negative real root $\rho_1(k)$ and a pair of complex conjugates $\rho_2(k) = \bar{\rho}_3(k) := \xi(k) + i\eta(k)$. Substituting the complex conjugates into (6.11) and then separating the real and imaginary parts yields the equations for $\xi(k)$ and $\eta(k)$:

$$\begin{aligned} &\xi^3 - 3\xi\eta^2 + \frac{59}{300}\xi^2 - \frac{59}{300}\eta^2 + \frac{k}{150}\xi + \frac{3}{200}\xi + \frac{k}{300} + \frac{1}{600} = 0, \\ &3\xi^2\eta - \eta^3 + \frac{59}{150}\xi\eta + \frac{k}{150}\eta + \frac{3}{200}\eta = 0. \end{aligned} \tag{6.12}$$

By differentiating (6.12) with respect to k, we have

$$\begin{aligned} &\left(3\xi^2 - 3\eta^2 + \frac{59}{150}\xi + \frac{k}{150} + \frac{3}{200}\right)\frac{d\xi}{dk} - \left(6\xi\eta + \frac{59}{150}\eta\right)\frac{d\eta}{dk} + \frac{1}{150}\xi + \frac{1}{300} = 0, \\ &\left(6\xi\eta + \frac{59}{150}\eta\right)\frac{d\xi}{dk} + \left(3\xi^2 - 3\eta^2 + \frac{59}{150}\xi + \frac{k}{150} + \frac{3}{200}\right)\frac{d\eta}{dk} + \frac{1}{150}\eta = 0. \end{aligned} \tag{6.13}$$

Solving (6.13) for $d\xi/dk$ and substituting $k = 33/52$, $\xi = 0$, and $\eta = \sqrt{13}/26$ into the expression of $d\xi/dk$ yields $d\xi/dk = 169/9679 > 0$. Therefore, system (6.10) undergoes a Hopf bifurcation and a periodic solution is bifurcated near $k = 33/52$.

To determine the bifurcation direction, we first discuss the stability of the endemic equilibrium of system (6.10) as $k = 33/52$. Let $x_1 = S - S^*$, $y_1 = I - I^*$, and $z_1 = J - J^*$ to transform the endemic equilibrium to the origin of a new system. Using the linear transformation

$$\begin{aligned} x_1 &= \frac{3125\sqrt{13}}{767}y - \frac{125}{6}z, \\ y_1 &= x + z, \\ z_1 &= \frac{639}{236}x - \frac{1125\sqrt{13}}{3068}y - \frac{539}{39}z, \end{aligned}$$

and rescaling $t = 2\sqrt{13}\,\hat{t}$, we transform the resulting system into

$$\begin{aligned} \frac{dx}{d\hat{t}} &\approx y + 319.95\left(S^0\right)^{-1}xy - 453.74\left(S^0\right)^{-1}xz - 6.93\left(S^0\right)^{-1}y^2 \\ &\quad + 243.20\left(S^0\right)^{-1}yz - 330.96\left(S^0\right)^{-1}z^2, \\ \frac{dy}{d\hat{t}} &\approx -x + 13.55\left(S^0\right)^{-1}xy - 19.22\left(S^0\right)^{-1}xz + 19.36\left(S^0\right)^{-1}y^2 \\ &\quad + 228.07\left(S^0\right)^{-1}yz - 362.37\left(S^0\right)^{-1}z^2, \\ \frac{dz}{d\hat{t}} &\approx -1.42z + 40.63\left(S^0\right)^{-1}xy - 57.62\left(S^0\right)^{-1}xz + 6.93\left(S^0\right)^{-1}y^2 \\ &\quad + 117.39\left(S^0\right)^{-1}yz - 180.40\left(S^0\right)^{-1}z^2. \end{aligned} \tag{6.14}$$

The nonlinear terms of the right-hand side of system (6.14) are quadratic and satisfy the existence conditions of the center manifold theorem [4, 12]. Hence, there exists a manifold $z = h(x, y)$ of system (6.14) which can be expanded as

$$z = h_{20}x^2 + h_{11}xy + h_{02}y^2 + o(r^2), \quad r = \sqrt{x^2 + y^2}, \tag{6.15}$$

where $o(r^2)$ denotes higher order terms and h_{ij} are to be determined.

Substituting (6.15) into system (6.14), we obtain

$$h_{20} = 8.38\left(S^0\right)^{-1}, \quad h_{11} = 11.89\left(S^0\right)^{-1}, \quad h_{02} = -3.50\left(S^0\right)^{-1}.$$

Substituting (6.15) with these h_{ij} again into the first two equations of system (6.14), we have the following equations on the center manifold:

(6.16)

$$\begin{aligned}
\frac{dx}{d\hat{t}} &= y - 6.93\left(S^0\right)^{-1} y^2 + 319.95\left(S^0\right)^{-1} xy - 3802.35\left(S^0\right)^{-2} x^3 - 3357.04\left(S^0\right)^{-2} x^2 y \\
&\quad + 4479.62\left(S^0\right)^{-2} xy^2 - 851.17\left(S^0\right)^{-2} y^3 + o(r^3), \\
\frac{dy}{d\hat{t}} &= -x + 13.55\left(S^0\right)^{-1} xy + 19.36\left(S^0\right)^{-1} y^2 - 161.06\left(S^0\right)^{-2} x^3 \\
&\quad + 1682.70\left(S^0\right)^{-2} x^2 y + 2779.06\left(S^0\right)^{-2} xy^2 - 798.25\left(S^0\right)^{-2} y^3 + o(r^3).
\end{aligned}$$

Consider the function

$$\begin{aligned}
V(x, y) = x^2 + y^2 &- 239.10\left(S^0\right)^{-1} x^3 - 38.71\left(S^0\right)^{-1} xy^2 + 4.42\left(S^0\right)^{-1} y^3 \\
&+ 59133.80\left(S^0\right)^{-2} x^4 - 6381.38\left(S^0\right)^{-2} x^3 y - 151.46\left(S^0\right)^{-2} xy^3 \\
&- 2462.13\left(S^0\right)^{-2} y^4.
\end{aligned}$$

It is positive definite in a small neighborhood of the origin. Along the trajectories of system (6.16),

$$\left.\frac{dV(x, y)}{dt}\right|_{(6.16)} = -1223.33\left(S^0\right)^{-2}(x^2 + y^2)^2 + o(r^4) < 0.$$

Therefore, V is a Lyapunov function for system (6.16) and the trivial solution of system (6.16) is asymptotically stable. It follows from the reducible principle of the center manifold theorem that the trivial solution of system (6.14), and hence the endemic equilibrium of system (6.10), is asymptotically stable for $k = 33/52$. Since the endemic equilibrium is unstable for $k > 33/52$, it follows from the Hopf bifurcation theorem that there exists a stable periodic solution in the neighborhood of the endemic equilibrium of system (6.10).

We illustrate the stable endemic equilibrium ($k < k_0$) and the stable periodic solutions ($k > k_0$) in Figures 2 and 3. In Figure 2, $k = 0.135 < k_0 = 0.6346$, and the endemic equilibrium $E^* = (3.3363, 0.0074, 0.0059)$ is asymptotically stable. In Figure 3, $k = 0.9846 > k_0 = 0.6346$, and the endemic equilibrium E^* is unstable. The solutions quickly converge to the stable periodic solution.

Example 6.2. In this example, we use R_1 and R_2 as bifurcation parameters. Let

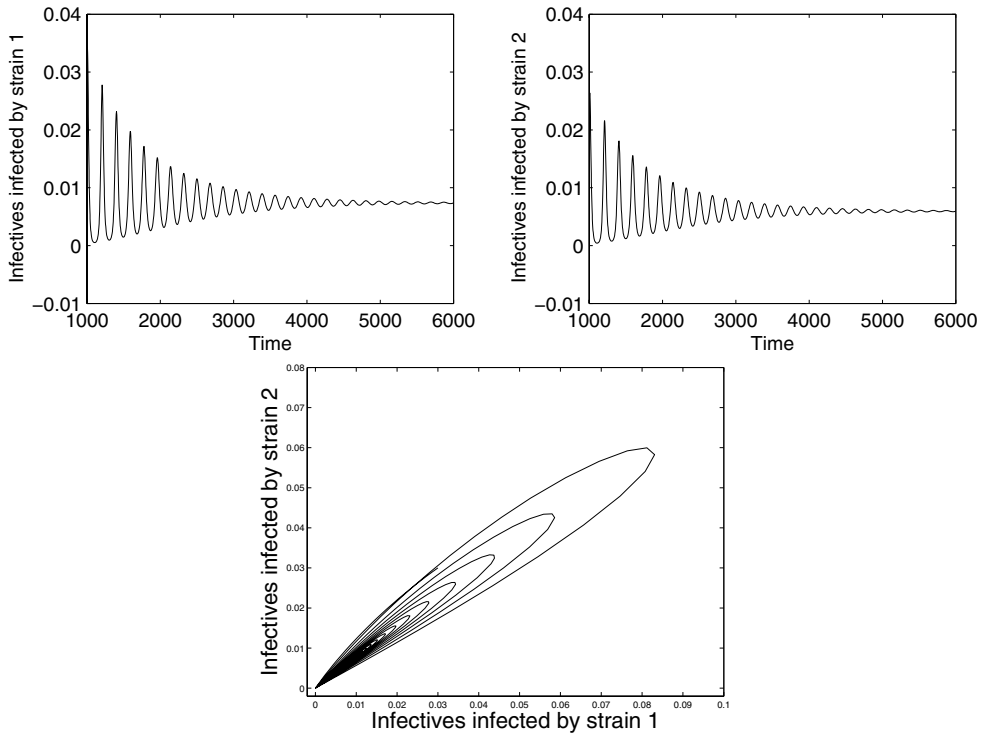

FIG. 2. *The solutions of system* (6.1) *for* $\mu = 0.01$, $\gamma_1 = \gamma_2 = 0.49$, $R_1 = 3$, *and* $R_2 = 2$. *The mutation rate* $k = 0.135$ *is used as a bifurcation parameter and is less than the critical value* $k_0 = 33/52$. *The endemic equilibrium* $(3.3363, 0.0074, 0.0059)$ *is asymptotically stable. The top two figures are the solutions of* I *and* J *versus time* t. *The bottom figure is the projected* I-J *phase plane of the phase space.*

$\sigma_1 = \sigma_2 = 1/10$, $\mu = 1/100$, and $k = 9/10$ in system (6.1), so that we have

$$\begin{aligned} \frac{dS}{dt} &= \frac{1}{100}(S^0 - S) - \left(\frac{R_1}{S^0}I + \frac{R_2}{10S^0}J\right)S, \\ \frac{dS}{dt} &= \frac{R_1}{S^0}SI - I, \\ \frac{dS}{dt} &= \frac{R_2}{10S_0}SJ - \frac{1}{10}J + \frac{9}{10}I. \end{aligned} \tag{6.17}$$

In region $D := \{(R_1, R_2) \mid R_1 > R_2,\ R_1 > 1\}$, the endemic equilibrium of system (6.17) is given by

$$E^* = \left(\frac{S^0}{R_1}, \frac{S^0(R_1 - 1)(R_1 - R_2)}{10(10R_1 - R_2)R_1}, \frac{9S^0(R_1 - 1)}{10(10R_1 - R_2)}\right).$$

The characteristic equation of the linearization of system (6.17) at E^* is

$$f(\rho) = \rho^3 + a_1\rho^2 + a_2\rho + a_3 = 0, \tag{6.18}$$

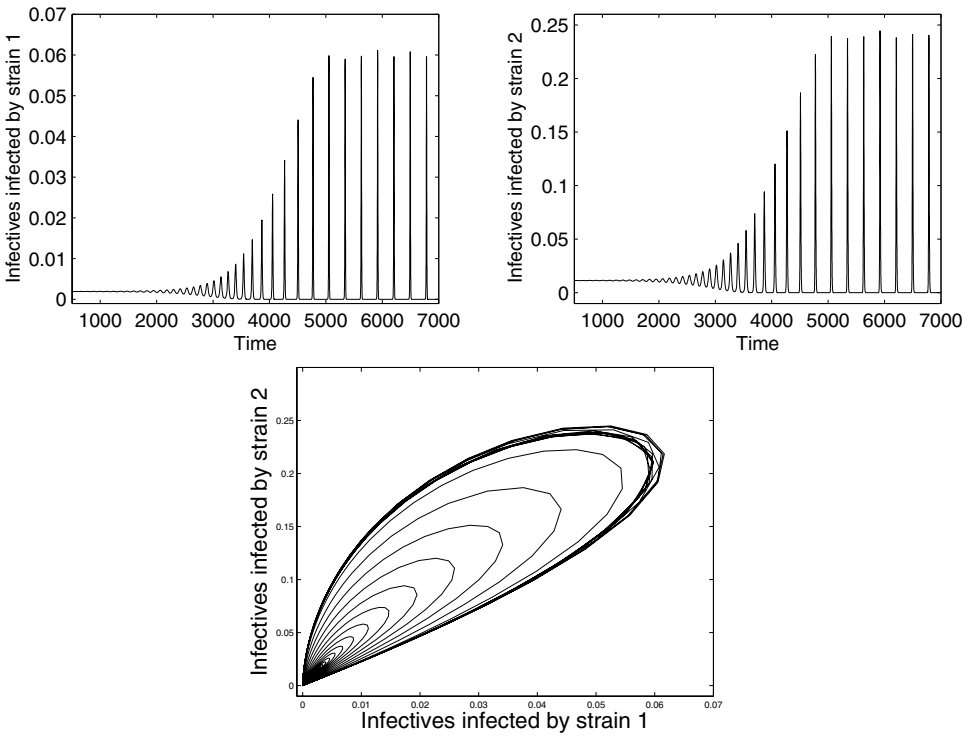

FIG. 3. *All parameters are the same as those in Figure* 2*, except the mutation rate* $k = 0.9846$ *is greater than the critical value* $k_0 = 33/52$*. The endemic equilibrium is unstable and a stable periodic solution is bifurcated from the endemic equilibrium. The top two figures show how the solutions with initial values near the unstable endemic equilibrium rapidly converge to the stable periodic solution. This can be also seen in the bottom figure of the I-J phase plane.*

where

$$a_1 = \frac{R_1^2 + 10R_1 - 10R_2}{100R_1},$$
$$a_2 = \frac{11R_1^2 - 10R_1R_2 - 10R_1 + 9R_2}{1000R_1},$$
$$a_3 = \frac{(R1-1)(R1-R2)}{1000R_1}.$$

E^* is asymptotically stable if

$$a_1a_2 - a_3 = \frac{100R_2^2R_1 - 90R_2^2 - 101R_2R_1^2 + 90R_1R_2 - 10R_1^3R_2 + 11R_1^4}{100000R_1^2} > 0. \tag{6.19}$$

Define function $H(R_2)$ as the numerator in (6.19). Then

$$H(R_2) = (100R_1 - 90)\,R_2^2 - \left(10R_1^3 + 101R_1^2 - 90R_1\right)R_2 + 11R_1^4.$$

The two zeros $R_2^{(1)} < R_2^{(2)}$, for R_1 and R_2, are in D, if

$$Q(R_1) := \left(10R_1^3 + 101R_1^2 - 90R_1\right)^2 - 44R_1^4\,(100R_1 - 90) > 0.$$

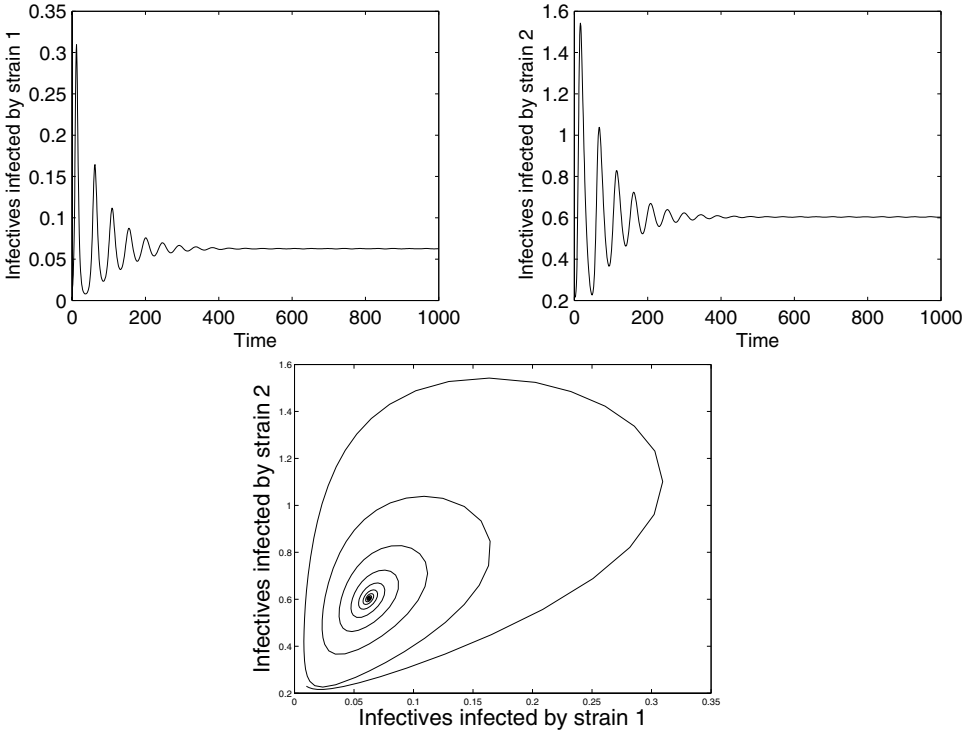

FIG. 4. *The reproductive numbers R_1 and R_2 are used as bifurcation parameters. The parameters $R_1 = 3$, $R_2^{(1)} = 1.5$, and $R_2 = 0.2$ are chosen so that $R_2 < R_2^{(1)}$. Then R_1 and R_2 are in Region* IV *in Figure* 1. *The endemic equilibrium exists and is asymptotically stable.*

Numerical computations verify that $Q(R_1)$ has two zeros, $R_1^{(1)} < R_1^{(2)}$, in the intervals $(1.01, 1.04)$ and $(4.50, 4.60)$, respectively. If $R_1 < R_1^{(1)}$ or $R_1 > R_1^{(2)}$, then $Q(R_1) < 0$, and if $R_1^{(1)} < R_1 < R_1^{(2)}$, then $Q(R_1) > 0$.

Suppose $R_1 < R_1^{(1)}$ or $R_1 > R_1^{(2)}$. Then $Q(R_1) < 0$ and $H(R_2)$ is always positive. If $R_1^{(1)} < R_1 < R_1^{(2)}$, then $Q(R_1) > 0$ and there are two zeros of $H(R_1)$, $R_2^{(1)} < R_2^{(2)}$ in D. If, moreover, $R_2 < R_2^{(1)}$ or $R_2 > R_2^{(2)}$, then $H(R_2) > 0$. Hence, in either case, $H(R_2) > 0$ and E^* is asymptotically stable. However, if $R_1^{(1)} < R_1 < R_1^{(2)}$ but $R_2^{(1)} < R_2 < R_2^{(2)}$, then $H(R_2) < 0$, for R_2 in D, and the endemic equilibrium is unstable.

For each R_1 in the interval $(R_1^{(1)}, R_1^{(2)})$, E^* changes its stability as R_2 increases from 0 to R_1. E^* is stable for R_2 in $(0, R_2^{(1)})$, unstable for R_2 in $(R_2^{(1)}, R_2^{(2)})$, and stable again for R_2 in $(R_2^{(2)}, R_1)$. At $R_2 = R_2^{(1)}$ or $R_2 = R_2^{(2)}$, the roots of characteristic equation (6.18) are imaginary indicating the existence of a periodic solution by Hopf bifurcation theory.

In numerical simulations, we fix $R_1 = 3$. The two roots of $H(R_2) = 0$ are $R_2^{(1)} = 3/2$ and $R_2^{(2)} = 99/35$. The characteristic roots of (6.18), with $R_2^{(1)} = 3/2$, are $\rho = -2/25$, $\rho = \sqrt{5}/20i$, and $\rho = -\sqrt{5}/20i$. The characteristic roots of (6.18), for $R_2^{(2)} = 99/35$, are $\rho = -1/28$, $\rho = \sqrt{2}/25i$, and $\rho = -\sqrt{2}/25i$.

In Figure 4, $\beta_1 = 0.3$ and $\beta_2 = 0.002$, and $R_2 = 0.2 < R_2^{(1)}$. The endemic equilib-

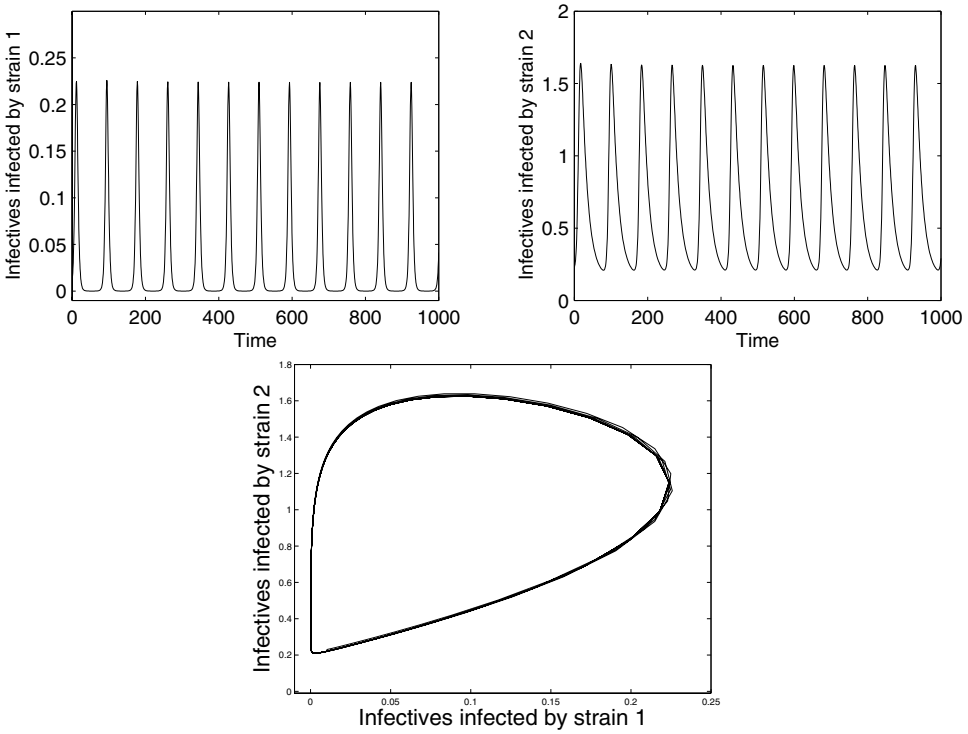

FIG. 5. *The parameters are chosen as in Figure* 4*, except* $R_2 = 2$ *by increasing* β_2 *to* 0.02 *whereas* $\beta_2 = 0.002$ *in Figure* 4*. Then* $R_2^{(1)} < R_2 < R_2^{(2)} = 2.829$*, and* R_1 *and* R_2 *are in the interior of the region enclosed by the bifurcation curve L, in Figure* 1*. The endemic equilibrium loses its stability. A periodic solution is bifurcated and is asymptotically stable.*

rium $E^* = (3.3348, 0.02627, 0.6032)$ is locally asymptotically stable, as is shown. We then increase β_2 to 0.02 so that $R_2 = 2$, which is between $R_2^{(1)}$ and $R_2^{(2)}$. The endemic equilibrium loses its stability and a periodic solution is bifurcated from the endemic equilibrium, as is shown in Figure 5. We continue increasing β_2 to 0.0286 such that $R_2 = 2.8571 > R_2^{(2)}$. The periodic solution disappears and the endemic equilibrium, $E^* = (3.3358, 0.0035, 0.6621)$, regains its stability, as is shown in Figure 6.

7. Concluding remarks. One of the challenges in modeling the spread of infectious diseases is to understand and predict the spread of competing strains of the same pathogen. After a strain of a pathogen infects a host, the mutation can be caused by an attempt of a pathogen to evade the immune defense of the host, the effect of selective immunologic pressure, or possibly adaptation to a more efficiently transmitted or better replicating pathogen.

We have formulated a simple compartmental mathematical model for the competition, mutation, and spread of a pathogen and its mutant strain. The model accounts for a continuous infection-age structure for the original pathogen, and the mutation rate of the pathogen depends on how long the host has been infected.

We model the transmission dynamics of pathogens by a system of partial differential-integral equations. We established conditions for the existence and stability of the infection-free equilibrium, the boundary equilibrium, and the endemic equilibrium. We derived formulas for the reproductive numbers, R_1 and R_2, for the two strains

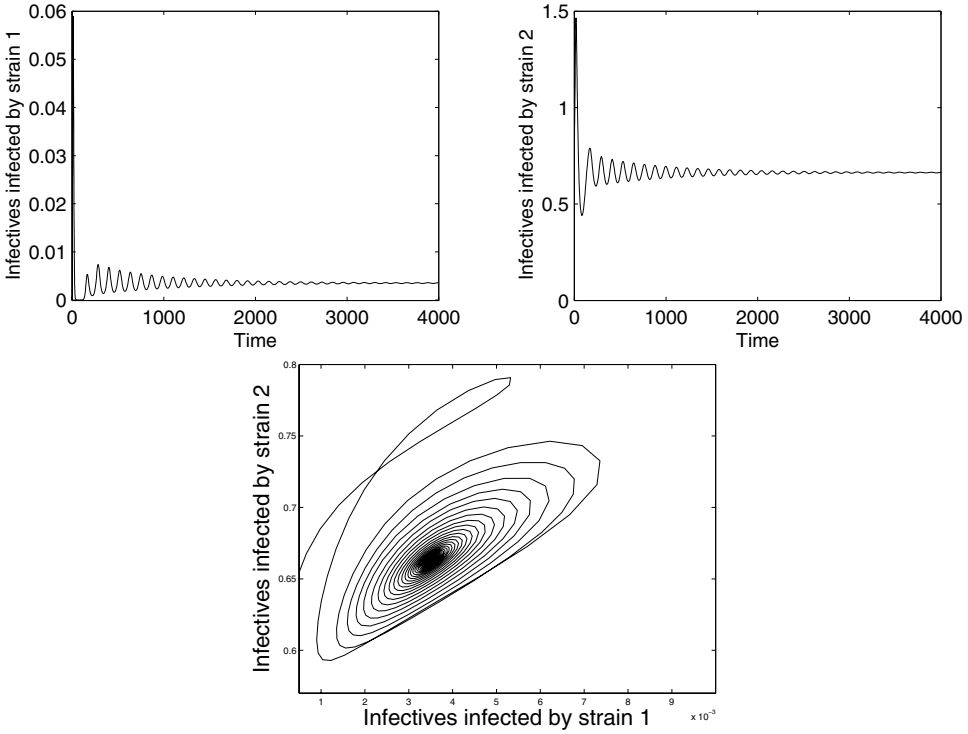

FIG. 6. *The parameters are chosen as in Figure* 4 *except* $\beta_2 = 0.0286$ *so that* $R_2 = 2.857 > R_2^{(2)}$. *Then* R_1 *and* R_2 *are in Region* V *and above the region enclosed by the bifurcation curve* L. *The endemic equilibrium regains its stability.*

based on the local stability of the infection-free equilibrium. We established the conditions for existence of the boundary equilibrium, E_1, where only one strain of the pathogen is in circulation, and the endemic equilibrium, E^*, where both the strain and its mutant are in circulation. We obtained stability conditions for E_1. These conditions, listed in Table 1, are expressed in terms of the two reproductive numbers. We investigated the stability of E^* and derived the characteristic equation of the linearization about E^*. The roots of this transcendental equation determine the stability of E^*.

To gain insight into transmission dynamics of the diseases with mutating strains, we simplified the model to make it more analytically tractable. By assuming the pathogen mutates with a constant rate, the PDE system is reduced into a system of ODEs. For pathogens with a constant mutation rate, we extended the local stability results for the infection-free and boundary equilibria of the ODE system, to prove that if $R_0 < 1$, E_0 is not only locally but also globally asymptotically stable. We also proved that if $R_1 < 1 < R_2$, then E_1 is globally asymptotically stable.

We established explicit conditions for the stability of the endemic equilibrium E^* when the mutation rate is constant. Furthermore, we identified the regions for the parameters where E^* loses its stability and periodic solutions bifurcate from E^*. For the special case where the two strains have the same recovery rate, we proved Hopf bifurcations using either the mutation rate, k, or the reproductive numbers, R_1 and R_2, as bifurcation parameters.

For the case where $R_1 = 3 > R_2 = 2 > 1$, we used k as a bifurcation parameter and identified regions where E_0 and E_1 are both unstable. In Example 6.1, we established a critical value, k_0, such that if $k < k_0$, the endemic equilibrium is asymptotically stable, and if $k > k_0$, the endemic equilibrium is unstable and periodic solutions appear through a Hopf bifurcation. We presented numerical simulations to illustrate that if both reproductive numbers exceed the threshold value, then the mutant cannot completely wipe out the original pathogen strain. We also showed that if the mutation rate is below the critical value, k_0, the two strains can coexist and eventually stay at a constant steady state level. On the other hand, if the mutation rate is above the critical value, k_0, there can be sustained periodic oscillations of the two pathogen strains. This phenomenon may furnish us with an interpretation of periodic appearance of pathogen strains of some diseases, such as influenza, and can provide useful guidance for disease intervention programs. Note that in this example we fixed R_2. Since R_2 is a function of the mutation rate, k, as we vary k we must also adjust the infection rate β_2 in the bifurcation analysis.

We also used R_1 and R_2 as bifurcation parameters, while fixing other parameters, including the mutation rate. Figure 1 illustrates the regions in the R_1-R_2 plane where the equilibria have different dynamics. We identified a closed bifurcation curve, L, for $R_1^{(1)} < R_1 < R_1^{(2)}$, where if R_1 and R_2 are within the curve, the endemic solution is periodic. We showed that for R_1 in the interval $(R_1^{(1)}, R_1^{(2)})$, as R_2 increases and passes through curve L, the stable steady state equilibrium changes its stability and becomes unstable. As R_2 continues to increase and passes through curve L the second time, the steady state equilibrium regains its stability. That is, the curve L identifies the parameter values where the solution undergoes a Hopf bifurcation.

Example 6.2 illustrates the Hopf bifurcation for $R_1^{(1)} < R_1 < R_1^{(2)}$. In Figure 4, (R_1, R_2) is outside the region enclosed by L with R_2 below L. In this case, the endemic equilibrium is asymptotically stable and the two strains eventually coexist at a steady state level with $I^* = 0.0035$. Figure 5 shows how when (R_1, R_2) is within the L the endemic solutions are periodic. In Figure 6, (R_1, R_2) are again outside L, but R_2 is above L. Once again, the two strains can coexist, but the steady state level $I^* = 0.02627$ is much higher than in Figure 4 because the mutant in the latter case has a larger reproductive number.

These examples illustrate the wide range of behavior that can exist when a pathogen mutates in the host to create a second infectious mutant strain. The explicit formulas for the reproductive numbers and the detailed analysis for the existence and stability of the boundary equilibrium can provide insight into the complexity of these epidemics. For the simplified cases where the mutation rate is not infection-age dependent, we were able to establish conditions for the global stability of the infection-free and boundary equilibria. Our analysis of the situation where the steady state equilibrium loses its stability through a Hopf bifurcation, and periodic solutions appear, may also help in understanding similar transitions in epidemics with mutating pathogens.

COMPLETE TRANSMISSION THROUGH A TWO-DIMENSIONAL DIFFRACTION GRATING*

G. A. KRIEGSMANN†

Abstract. The propagation of a normally incident electromagnetic plane wave through a two-dimensional metallic grating is modeled and analyzed. The period of the structure A is on the order of the incident wave length λ, but the height of the channel H separating the blocks is very small. Exploiting the small parameter H/A, an approximate transmission coefficient is obtained for the grating. For a fixed frequency this coefficient is $O(H/A)$ except near resonant lengths where it is $O(1)$. That is, for certain widths the structure is transparent. Similarly, for a fixed length the transmission coefficient has the same resonant features as a function of frequency.

1. Introduction.

There has been considerable recent interest in the study of electromagnetic propagation through a particular grating structure [1, 2]. This structure is taken at first approximation to be an infinite slab in the X-Y plane, but with a finite thickness L in the Z-direction. A periodic array of identical holes are bored through the slab, parallel to the Z-axis. The period of the structure A in the X-Y plane is on the order of the wavelength λ of the incident electromagnetic plane wave, the holes are very small in comparison, and the thickness $L \sim \lambda$. Experimental results [1, 2] show that very little of the wave propagates through the slab. This makes sense due to the size of the holes compared to λ. However, at certain resonant frequencies, there is significant transmission. It is precisely this feature that has generated interest in this structure as an element in photonic and microwave circuits. For example, the complete transmission at select frequencies makes this grating structure useful as a highly selective filter. On the other hand, utilizing its almost complete reflection for bands of frequencies suggests that the grating can be used as a mirror in Fabry–Perot resonators.

Although the electromagnetic boundary value problem describing this physical problem is easy to state, it has no closed form solution even for simply shaped holes such as circles [1], squares, and cross-like geometries [2]. This is basically because there is a mismatch between the geometries of the hole and the fundamental cell in the X-Y plane, and the complication of requiring continuity of tangential electromagnetic fields across the hole boundary. An approximate method, based on heuristic reasoning, has been employed to study this structure and to explain the phenomenon of complete transmittance [3].

In this paper we consider a two-dimensional version of this problem in which the structure is composed of perfectly conducting metal brick cylinders separated by thin channels which take the place of the holes. A schematic of the structure is shown

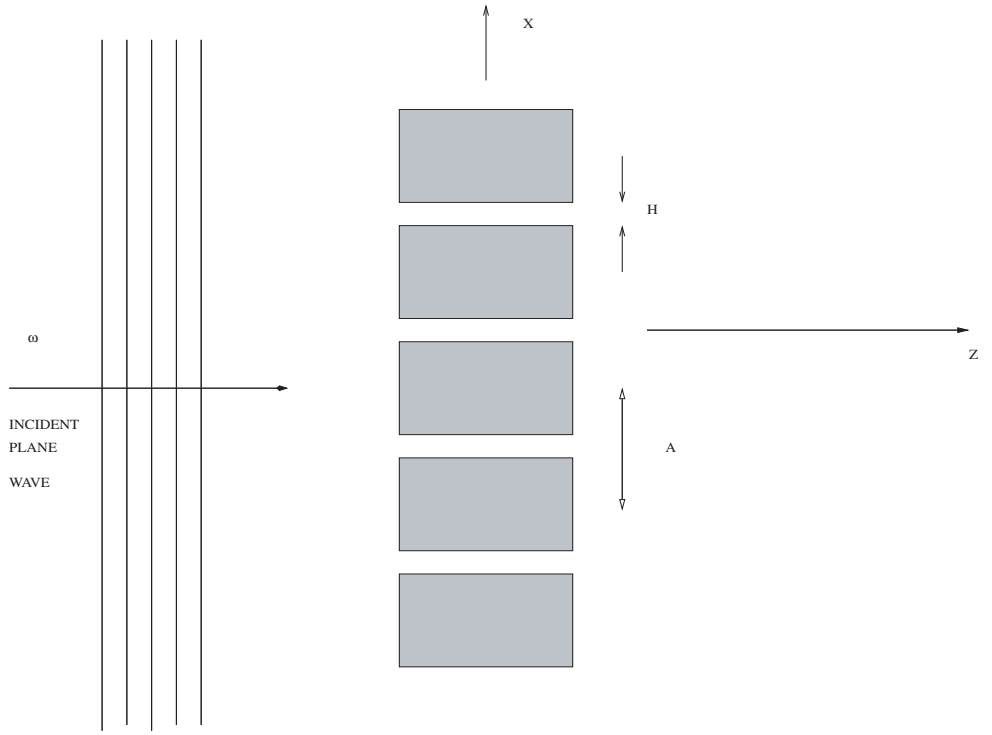

FIG. 1(a).

in Figure 1(a). The incident electromagnetic field is polarized so that the magnetic field is parallel to the Z-axis. The boundary value problem describing this physical configuration is scalar and amenable to analysis. We will show that this grating structure has the property of complete transmission at certain resonant frequencies.

We attack this problem by using S-matrix theory; we divide the problem into two pieces, analyze each separately, and then recombine the results to obtain a simple, explicit representation of the transmission coefficient. This approach is similar in spirit to the technique we employed to study large resonant structures [4]. Our analysis of the present problem shows that the transmission coefficient for the grating depends, remarkably, upon only a single real number $t(\lambda, H)$ which is a function of the wavelength of the incident plane wave and the height of the channel. This is the mathematical underpinning of the physics of the grating structure. The determination of t requires the solution of a single auxiliary scattering problem which involves the same grating structure with $L = \infty$. We solve this problem using a modal expansion procedure that is similar to the one used in [5]. It yields a single infinite system of algebraic equations. We make explicit use of the smallness of the channel height and derive an asymptotic approximation of the solution to these equations from which we deduce t. Our approximate transmission coefficient has the property seen in the three-dimensional grating structures. It is essentially zero for small channel heights, except at and near a discrete set of resonant frequencies.

A grating structure very similar to the one shown in Figure 1(a) was studied using a straightforward modal analysis [5]. By matching the modal expansions of the tangential electric and magnetic fields, which are valid inside the channel, with similar

expansions outside the channel, the authors arrived at two coupled infinite systems of linear equations whose solution yielded the required transmission and reflection coefficients. This approach can be modified to handle our grating, and the results can be simplified by considering a very narrow channel. The results of such an approach have recently been stated [6]. Another approach has been used to study a similar grating [7]. It involves a coordinate transformation, which reduces the grating to a flat surface, and a Fourier analysis of the resulting periodic Helmholtz equation. The novelty of our approach, compared to these, is its simplicity and its ability to produce a simple formula for the transmission coefficient of the grating which depends upon only $t(\lambda, H)$.

We finish this section by briefly outlining the remainder of this paper. In section 2 we formulate the scattering problem in dimensionless quantities. Section 3 contains the description of our S-matrix method. Specifically, we consider two auxiliary scattering problems and discuss their individual S-matrices. We show that both of these can be described by a single complex number τ_0 which physically is the transmission coefficient for the first auxiliary problem. Exploiting the unitary character of either S-matrix we show that τ_0 lies on a circle, C_0, in the complex plane whose center and radius are known. The number t described in the above paragraph is essentially the angle pinning τ_0 down. Using connection formulae, which ignore the effects of evanescent modes in the channel, the formula for the transmission coefficient is derived.

In section 4 the boundary value problem required to determine τ_0 is presented and a normal mode method is described to solve the problem. We derive an asymptotic approximation of the solution of these equations in the limit as $H/A \to 0$. From this result we obtain an approximation of t and hence τ_0. We find that this approximation of τ_0 lies on the circle C_0.

In section 5 we put all the ingredients together to obtain our approximation of the transmission coefficient. From this simple formula we are able to easily deduce the resonant structure of the problem. Specifically, we obtain a formula for the resonant lengths, for a fixed frequency, at which the grating is essentially transparent. We also show that there is very little transmission through the grating for other lengths, especially for $H/A \ll 1$. Similarly, when the length is fixed, we deduce a formula for the resonant frequencies of the structure. At these frequencies the grating is again transparent, and for others it is opaque.

In section 6 we briefly discuss the case when the incident wave obliquely strikes the grating. The problem is more difficult in general but asymptotically the same for $H/A \ll 1$. There is one slight modification which does not significantly alter our formulae and the resonant structure of the grating. Finally, in section 7 we offer a short conclusion and further discussion.

2. Formulation. A TM polarized electromagnetic plane wave impinges, normally, upon the periodic structure shown in Figure 1(a). The shaded regions indicate a perfectly conducting material. In all that follows the spatial variables have been scaled with respect to the period of the structure A and are denoted by lower case letters; the magnetic field P has been scaled with respect to the amplitude of the incident wave.

Since the structure is periodic, it is sufficient to study the wave propagation and scattering in the fundamental cell shown, in dimensionless form, in Figure 1(b). The magnetic field within this region satisfies the Helmholtz equation

$$\frac{\partial^2}{\partial x^2}P + \frac{\partial^2}{\partial z^2}P + k^2 P = 0, \tag{1a}$$

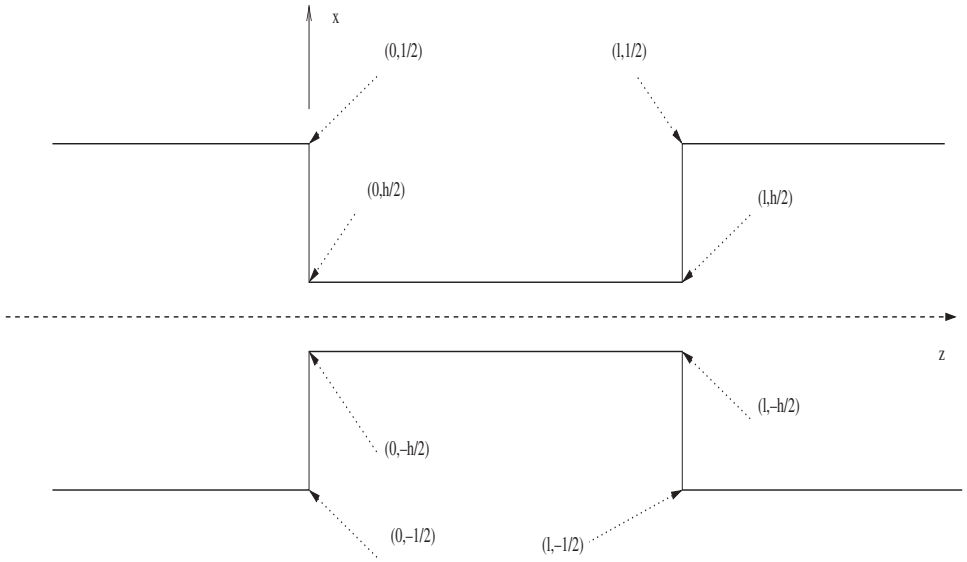

FIG. 1(b).

where $k = \omega A/c_0$, ω is the frequency in radians of the incident wave, and c_0 is the speed of light in air. The length of the structure, $l = L/A$, is order one in this scaling, and the height of the air-filled channel, $h = H/A \ll 1$, is very small. On the walls of the channel, the normal derivative of the magnetic field is zero; i.e.,

$$\frac{\partial}{\partial z} P = 0. \tag{1b}$$

On the boundaries of the fundamental cell the field is taken to periodic.

The field to the left of the structure, $z < 0$, is given by

$$P = e^{ikz}\psi_0 + \sum_{n=0}^{\infty} R_n \psi_n(x) e^{-i\beta_n z} \tag{2a}$$

and to the right of the structure, $z > l$,

$$P = \sum_{n=0}^{\infty} T_n \psi_n(x) e^{i\beta_n z}, \tag{2b}$$

where R_n and T_n are the unknown reflection and transmission coefficients, respectively. The orthonormal eigenfunctions and propagation constants are

$$\psi_0 = 1, \qquad \psi_n = \sqrt{2}\cos(2n\pi x), \quad n \neq 0, \tag{2c}$$

$$\beta_n = \sqrt{k^2 - 4n^2\pi^2}, \tag{2d}$$

where the sines have been omitted due to the symmetry of the incident wave about the z-axis. The field inside the channel is given by

$$P = \sum_{n=0}^{\infty} [A_n e^{-ik_n z} + B_n e^{ik_n z}]\phi_n, \tag{3a}$$

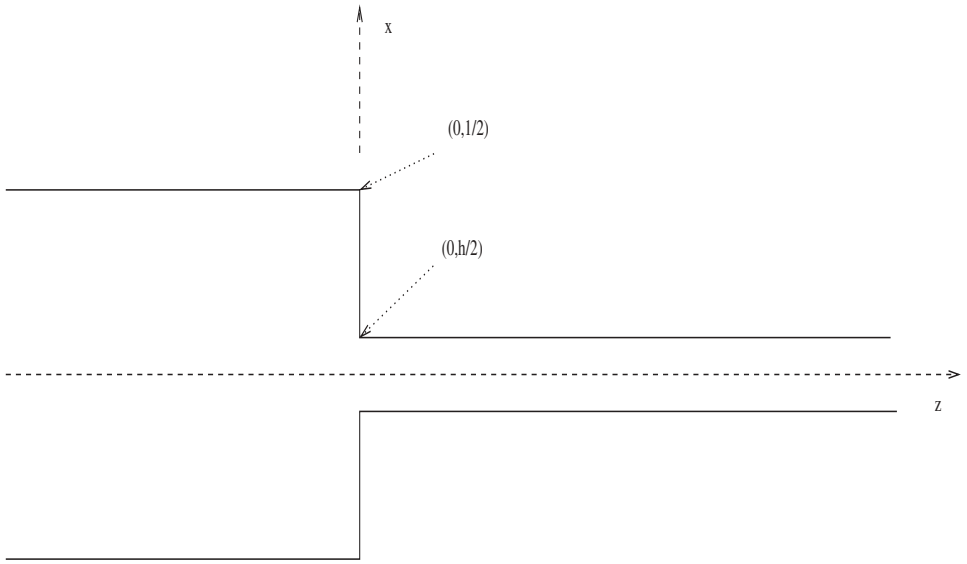

FIG. 2(a).

where the A_n and B_n are unknown constants, and the orthonormal eigenfunctions and propagation constants are

$$\phi_0 = \frac{1}{\sqrt{h}}, \qquad \phi_n = \sqrt{\frac{2}{h}} \cos \frac{2n\pi}{h} \left(x + \frac{h}{2} \right), \quad n \geq 1, \tag{3b}$$

$$k_n = \sqrt{k^2 - \frac{4n^2\pi^2}{h^2}}, \tag{3c}$$

where the sines again are omitted because of the symmetry of the incident field. It is assumed here that the wave number $k < 2\pi$ so that only β_0 is real and hence all of the other modes outside of the structure are evanescent. With this restriction on k and the fact that $h \ll 1$ it follows that only k_0 is real and all the other modes in the channel are evanescent, too. Finally, from their definitions it is clear that $\beta_0 = k_0 = k$.

3. The method. We shall begin this section by considering two auxiliary problems whose solutions can be used to construct an approximate solution to (1)–(3). These problems involve the same Helmholtz equation and boundary conditions, but now we let $l \to \infty$ so that the structure becomes semi-infinite. Accordingly, the fundamental cell becomes semi-infinite; its geometry is shown in Figure 2(a). These problems are two-dimensional versions of the three-dimensional acoustic cases studied in [8].

The auxiliary problems. In the first problem we consider an incident mode of unit strength striking this structure from the left; this corresponds to a normally incident plane wave. The field is given there by

$$P_1 = e^{ikz}\psi_0 + \sum_{n=0}^{\infty} r_n \psi_n(x) e^{-i\beta_n z}, \quad z < 0. \tag{4a}$$

The resulting field within the channel is

$$P_1 = \sum_{n=0}^{\infty} \tau_n \phi_n(x) e^{ik_n z}, \quad z > 0, \tag{4b}$$

where there are only modes propagating to the right. The determination of r_n and τ_n must be determined approximately by a numerical method; we shall describe a particular method in section 4.

At this stage we shall quickly derive a relationship between r_0 and τ_0 which will become very useful. It is

$$1 - r_0 = \sqrt{h}\,\tau_0. \tag{5}$$

This is derived by taking the partial derivative of (4a) with respect to z at $z = -\delta$, where $\delta \ll 1$, i.e., just to the left of the channel. Then multiplying this result by ψ_0, integrating with respect to x, and using the orthonormality of the eigenfunctions, we obtain

$$\int_{-1/2}^{1/2} \frac{\partial}{\partial z} P_1(x, -\delta)\psi_0 \, dx = ik(1 - r_0)e^{ik\delta}. \tag{6a}$$

A similar calculation applied to (4b) at $z = +\delta$ yields

$$\int_{-h/2}^{h/2} \frac{\partial}{\partial z} P_1(x, \delta)\phi_0 \, dx = ik\tau_0 e^{ik\delta}. \tag{6b}$$

We now let $\delta \to 0$ in (6a) and recall from (1b) that $P_{1z} = 0$ on the metal portion of the structure. This implies that the range of integration is now $(-h/2, h/2)$ in (6a). The exponential on the right-hand side goes to one. A similar limiting process applied to (6b) removes the exponential from its right-hand side. Since P_{1z} is continuous at $z = 0$ within the channel and $\phi_0 = \psi_0/\sqrt{h}$, (6a) and (6b) can be combined to arrive at (5).

In the second auxiliary problem we consider an incident mode of unit strength striking the structure from the right. This corresponds to an incident mode in the channel. The field is given by

$$P_2 = \sum_{n=0}^{\infty} \gamma_n \psi_n(x) e^{-i\beta_n z}, \quad z < 0, \tag{7a}$$

and

$$P_2 = e^{-ikz}\phi_0(x) + \sum_{n=0}^{\infty} \rho_n \phi_n(x) e^{ik_n z}, \quad z > 0. \tag{7b}$$

There is an analogous relation between γ_0 and ρ_0 that is very similar to (5) and is obtained along parallel lines of reasoning. It is

$$\sqrt{h}\,\rho_0 + \gamma_0 = \sqrt{h}. \tag{8}$$

The determination of ρ_0 and γ_0 must be found numerically.

There is a final and very useful relationship between γ_0 and τ_0; it is simply

$$\gamma_0 = \tau_0. \tag{9}$$

This follows from integrating the identity $\nabla\cdot\{P_1\nabla P_2 - P_2\nabla P_1\} = 0$ in the region $|z| < z_\infty$, applying the divergence theorem, using the boundary conditions, and neglecting the evanescent modes. Here $z_\infty \gg 1$ is a fixed number.

Finally, we note that the relationships contained in (5), (8), and (9) can be combined to express r_0, ρ_0, and γ_0 in terms of τ_0. Omitting the algebraic details, we list them here as

$$r_0 = 1 - \sqrt{h}\tau_0, \quad \gamma_0 = \tau_0, \tag{10a}$$

$$\rho_0 = 1 - \frac{\tau_0}{\sqrt{h}}. \tag{10b}$$

Thus, only the first auxiliary problem needs to be solved numerically to determine the reflection and transmission coefficients, of the propagating mode, for the second problem.

The S-matrix. The results of the proceeding subsection can be combined into two simple linear statements that constitute classical S-matrix theory used to characterize microwave circuits [9]. Let the semi-infinite structure, shown in Figure 2(a), be excited by a normally incident plane wave of strength a_0 from the left and by the lowest mode with strength c_0 from the right. A few wavelengths to the left of $z = 0$, where the evanescent modes may be neglected, the field is given by

$$P = \{a_0 e^{ikz} + b_0 e^{-ikz}\}\psi_0(x) \tag{11a}$$

and a few wavelengths to the right of $z = 0$ by

$$P = \{d_0 e^{ikz} + c_0 e^{-ikz}\}\phi_0(x). \tag{11b}$$

By the linearity of the Helmholtz equation and the boundary conditions (1), it follows that

$$b_0 = r_0\, a_0 + \gamma_0\, c_0, \tag{12a}$$

$$d_0 = \tau_0\, a_0 + \rho_0\, c_0. \tag{12b}$$

These can be rewritten with the aid of (10) as

$$b_0 = \left(1 - \sqrt{h}\tau_0\right)\, a_0 + \tau_0\, c_0, \tag{13a}$$

$$d_0 = \tau_0\, a_0 + \left(1 - \frac{\tau_0}{\sqrt{h}}\right)\, c_0. \tag{13b}$$

The coefficients in (13) form the S-matrix for our semi-infinite structure. We show in Appendix A that this matrix is unitary and, accordingly, that τ_0 must lie on the circle

$$\left|\tau_0 - \frac{\sqrt{h}}{1+h}\right| = \frac{\sqrt{h}}{1+h} \tag{14a}$$

in the complex plane, which has the equivalent representation

$$\tau_0 = \frac{2\sqrt{h}}{(1+h)+i\eta}, \quad -\infty < \eta < \infty. \tag{14b}$$

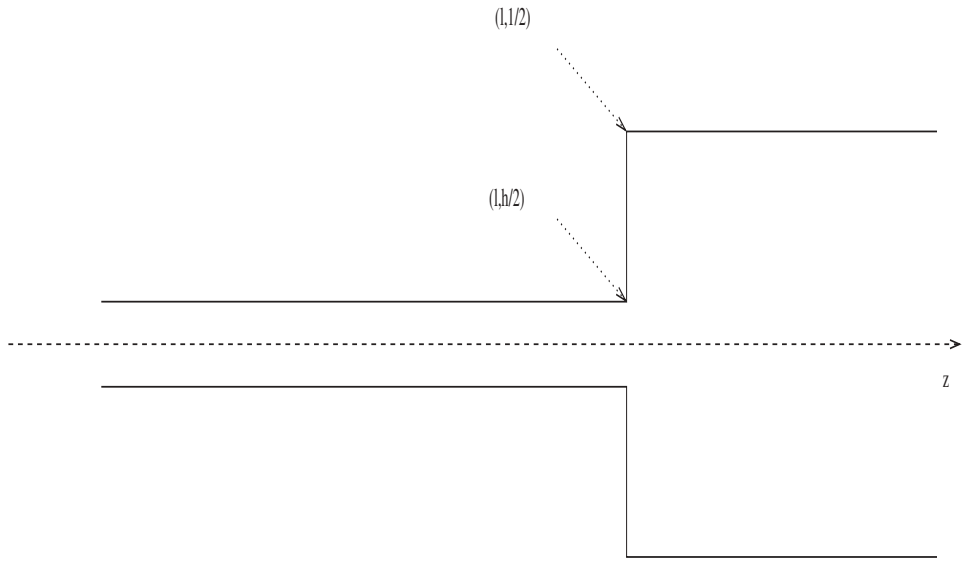

FIG. 2(b).

The real number η depends upon h and k: Remarkably, all of the scattering physics of our semi-infinite structure is contained in this number.

Finally, we state the S-matrix for the related structure shown in Figure 2(b), which is just the semi-infinite structure of Figure 2(a) shifted l units along the z-axis and reflected. If $\hat{c}_0$ is the strength of the incident mode to the left of $z = l$ and $\hat{a}_0$ is the amplitude of the plane wave striking from the right, then P is given by

$$P = \left\{ \hat{a}_0 e^{-ikz} + \hat{b}_0 e^{ikz} \right\} \psi_0(x) \tag{15a}$$

a few wavelengths to the right of $z = l$, and by

$$P = \left\{ \hat{d}_0 e^{-ikz} + \hat{c}_0 e^{ikz} \right\} \phi_0(x) \tag{15b}$$

a few to the left. The linear relationship analogous to (13) is

$$\hat{b}_0 = \left(1 - \sqrt{h}\tau_0\right) e^{-2ikl}\, \hat{a}_0 + \tau_0\, \hat{c}_0, \tag{16a}$$

$$\hat{d}_0 = \tau_0\, \hat{a}_0 + \left(1 - \frac{\tau_0}{\sqrt{h}}\right) e^{2ikl}\, \hat{c}_0, \tag{16b}$$

where the exponential factors take into account the shifted and reflected location of the channel.

Connection formulae. We shall now return to our original problem and begin the construction of its approximate solution. First, we reinterpret the modal structure of the field given by (3a) at the hypothetical plane $z = l/2$. At this plane only the propagating mode is present. This occurs because the evanescent modes are heavily damped, due to the fact that their propagation constants are purely imaginary and large in moduli; i.e., $\beta_m \sim \mathrm{Im}\pi/h$ for $m \geq 1$. For example, the largest evanescent

mode occurs when $m = 1$, and it is $O(e^{-\pi l/2h})$ as $h \to 0$. Thus in the vicinity of the hypothetical plane at $z = l/2$, we neglect these exponentially small terms and take

$$P = \{A_0 e^{-ikz} + B_0 e^{ikz}\}\phi_0. \tag{17}$$

From the perspective of an observer near the aperture at $z = 0$, a mode of unit strength impinges from the left and a mode of strength A_0 impinges from the right. The wave reflected to the left has an amplitude R_0 and to the right the amplitude is B_0. These amplitudes are connected via the S-matrix (13). Setting $a_0 = 1$, $b_0 = R_0$, $c_0 = A_0$, and $d_0 = B_0$, (13) becomes

$$R_0 = \left(1 - \sqrt{h}\tau_0\right) + \tau_0 A_0, \tag{18a}$$

$$B_0 = \tau_0 + \left(1 - \frac{\tau_0}{\sqrt{h}}\right) A_0. \tag{18b}$$

From the perspective of an observer near the aperture at $z = l$, there is no mode impinging from the right, just a mode of strength B_0 striking from the left. The wave transmitted to the right has an amplitude T_0 and reflected to the left A_0. These amplitudes are connected via the S-matrix (16). Setting $\hat{a}_0 = 0$, $\hat{b}_0 = T_0$, $\hat{c}_0 = B_0$, and $\hat{d}_0 = A_0$, (16) becomes

$$T_0 = \tau_0 B_0, \tag{19a}$$

$$A_0 = \left(1 - \frac{\tau_0}{\sqrt{h}}\right) e^{2ikl} B_0. \tag{19b}$$

Inserting (19b) into (18b) and solving for B_0 yields

$$B_0 = \frac{\tau_0}{1 - \left(1 - \frac{\tau_0}{\sqrt{h}}\right)^2 e^{2ikl}}. \tag{20}$$

Combining this result with (19a) gives

$$T_0 = \frac{\tau_0^2}{1 - \left(1 - \frac{\tau_0}{\sqrt{h}}\right)^2 e^{2ikl}}, \tag{21a}$$

the transmission coefficient for our periodic structure. Finally, inserting (20) into (19b) and the resulting expression into (18a) yields

$$R_0 = \left(1 - \sqrt{h}\tau_0\right) + T_0 \left(1 - \frac{\tau_0}{\sqrt{h}}\right) e^{2ikl}, \tag{21b}$$

the reflection coefficient of our periodic structure.

In closing this section it is interesting to note that the reflection and transmission coefficients for our periodic structure are determined completely by τ_0, the transmission coefficient for our first auxiliary problem. Remarkably then by (14b), the scattering properties of our grating are completely contained in the parameter η. All that is left now is to find an accurate approximation of this number.

4. An approximation of τ_0. The solution of the first auxiliary problem and the determination of τ_0 cannot be determined exactly; a numerical approximation must be sought. The approach we use here employs a Green's function argument and a normal mode expansion, using the ϕ_n as a basis, to obtain a system of equations for the τ_n. We then exploit the fact that $h \ll 1$ to obtain an approximation of τ_0.

We begin by representing the field P_1 in the region $z < 0$ by $P_1 = 2\cos(kz) + P_S$, where the first term incorporates the incident field and its rigid reflection and ignores the presence of the channel. The scattered field P_S takes this into account. It is clear from this representation that $\frac{\partial}{\partial z}P_1 = \frac{\partial}{\partial z}P_S$ on $z = 0$. It then follows from (1a) that $\frac{\partial}{\partial z}P_S = 0$ for $z = 0$ with $|x| > h/2$. Using this information we deduce, using standard Green's functions arguments, that

$$P_1(x,z) = 2\cos(kz) - \int_{-h/2}^{h/2} G(x,z|x',0)\,\frac{\partial}{\partial z'}P_1(x',0)\,dx', \tag{22a}$$

$$G(x,z|x',0) = \sum_{n=-\infty}^{\infty} \frac{1}{i\beta_n} e^{2n\pi i(x-x')}\, e^{-i\beta_n z}. \tag{22b}$$

Here G is the Green's function for the Helmholtz equation in $z < 0$ which is periodic in x, and satisfies $\frac{\partial}{\partial z'}G = 0$ when $z' = 0$.

We next set $z = 0$ in (22) and use the representation of P_1 given by (4b) in the resulting expression. This can be done because both the field and its z derivative are continuous across $z = 0$ with $|x| < h/2$. The result is

$$\sum_{m=0}^{\infty} \tau_m\phi_m = 2 - i\int_{-h/2}^{h/2} G_0(x,0|x',0) \sum_{m=0}^{\infty} k_m\tau_m\phi_m(x')\,dx'. \tag{23}$$

Multiplying this expression by ϕ_n, integrating between $\pm h/2$, and using the orthonormality of the $\{\phi_n\}$, we arrive at the linear system

$$\tau_n = 2\sqrt{h}\,\delta_{n0} - i\sum_{m=0}^{\infty} k_m\tau_m Z_{nm}, \tag{24a}$$

$$Z_{nm} = \int_{-h/2}^{h/2}\int_{-h/2}^{h/2} G(x,0|x',0)\phi_n(x)\phi_m(x')\,dx'\,dx, \tag{24b}$$

where δ_{n0} is the Kronecker delta function. Before proceeding to exhibit the formulae for the Z_{nm} we rewrite the system (24a) in two pieces, singling out the leading order coefficient τ_0:

$$\tau_0 = 2\sqrt{h} - ikZ_{00}\tau_0 + \sum_{m=1}^{\infty} |k_m| Z_{0m}\tau_m, \tag{25a}$$

$$\tau_n = -ikZ_{n0}\tau_0 + \sum_{m=1}^{\infty} |k_m| Z_{nm}\tau_m. \tag{25b}$$

Here we have recalled and used the fact that $k_m = i|k_m| \equiv i\sqrt{m^2\pi^2/h^2 - k^2}$ for $m \geq 1$.

We now make the substitution $\tau_n = -ik\tau_0\alpha_n$, for $n \geq 1$, into (25b) and find that the α_n must satisfy

$$\alpha_n = Z_{n0} + \sum_{m=1}^{\infty} |k_m| Z_{nm}\alpha_m, \quad n \geq 1. \tag{26a}$$

Once this system is solved for the α_n, then the τ_n are known for $n \geq 1$. Making the same substitution into (25a) and solving for τ_0 we find that

$$\tau_0 = \frac{2\sqrt{h}}{1 + ikZ_{00} + ik\sum\limits_{m=1}^{\infty} |k_m| Z_{m0}\,\alpha_m}. \tag{26b}$$

Thus, once the α_m are known, τ_0 is known, too.

The matrix elements are obtained by substituting (22b) into (24b) and interchanging the order of summation and integration. The resulting integrals are elementary, and we find that

$$Z_{00} = -i\frac{h}{k} - 2hS_{00}, \tag{27a}$$

$$Z_{n0} = Z_{0n} = 2hS_{0n}, \quad n \geq 1, \tag{27b}$$

$$Z_{nm} = hS_{nm}, \quad n, m \geq 1, \tag{27c}$$

where the S_{nm} are real and are defined by

$$S_{00} = \sum_{l=1}^{\infty} \frac{1}{|\beta_l|} \frac{\sin^2(l\pi h)}{(l\pi h)^2}, \tag{28a}$$

$$S_{0n} = \sqrt{2}\sum_{l=1}^{\infty} \frac{1}{|\beta_l|} \frac{\sin^2(l\pi h)}{[(n\pi)^2 - (l\pi h)^2]}, \quad n \geq 1, \tag{28b}$$

$$S_{nm} = -4\sum_{l=1}^{\infty} \frac{(l\pi h)^2 \sin^2(l\pi h)}{|\beta_l|[n^2\pi^2 - (lh\pi)^2][m^2\pi^2 - (lh\pi)^2]}, \quad m, n \geq 1. \tag{28c}$$

Finally, inserting (27a) and (27b) into (26b) we obtain the result

$$\tau_0 = \frac{2\sqrt{h}}{(1+h) + ih\,t}, \tag{29a}$$

$$t = 2\,k\left\{-S_{00} + \sum_{m=1}^{\infty} |k_m| S_{0m}\alpha_m\right\}. \tag{29b}$$

Thus, τ_0 satisfies (14b) with $\eta = h\,t$.

Now any approximation of τ_0 using the above formulation requires an approximation of the α_n. This is done by first truncating the infinite system (26a), so that

$1 \le n \le N$. Then for a fixed h and k the series defining the Z_{nm}, (28a)–(28c), can be truncated to yield a prescribed accuracy. Once this is done we can invert the finite system to determine the approximations of α_n , $1 \le n \le N$. These will be denoted by $\hat{\alpha}_n$. Next, the infinite sum in (29b) is likewise truncated, so that $1 \le m \le N$. We denote this approximation by $\hat{t}$. Finally, we insert this result into (29a) and obtain our approximation of the transmission coefficient

$$\hat{\tau}_o = \frac{2\sqrt{h}}{(1+h) + i\,h\,\hat{t}}. \tag{30}$$

Remarkably, this approximation satisfies (14b) regardless of N and the errors induced by truncating the series.

Up to this point we have not exploited the small channel width, $h \ll 1$, except in neglecting the exponentially small contributions of the evanescent modes to (17). From (27b) and (27c) we observe that the matrix elements Z_{nm}, $n \ge 1$ and $m \ge 0$, are formally $O(h)$ as $h \to 0$. To show this is true we need to demonstrate that the corresponding S_{nm} are $O(1)$. These sums are slowly convergent when $h \ll 1$. However, careful numerical computations on (28b) and (28c) show that they are order one, and a qualitative argument to this effect is presented in Appendix B.

Using the facts that Z_{n0} and Z_{nm} are small, it follows from (26a), truncated at $m = N$, that

$$\hat{\alpha}_n = 2\,h\,S_{n0} + O(h^2), \quad 1 \le n \le N, \tag{31a}$$

as $h \to 0$. Inserting this estimate into (29b), also truncated at $m = N$, and noting that $|k_m| \sim m\pi/h$, we deduce that

$$\hat{t} = 2k\left\{-S_{00} + 4\,\pi \sum_{m=1}^{N} m\,S_{0m}^2\right\}. \tag{31b}$$

Now the sum (28a) defining S_{00} is also slowly convergent, and we present a qualitative argument in Appendix B that $S_{00} \sim \ln(1/h)$; careful numerical computations bear this out, too. This suggests that the first term in (31b) is dominant and accordingly

$$\hat{t} = -2\,k\,S_{00}. \tag{31c}$$

Inserting (31c) into (30) yields our approximation $\hat{\tau}_0$ of the transmission coefficient of our first auxiliary problem.

The above approximations of $\hat{\alpha}_n$ and $\hat{t}$ are formal. To make them rigorous we must prove that the $O(h^2)$ estimate in (31a) remains valid as $N \to \infty$. Moreover, we must show $S_{0m} = O(1/m^p)$, where $p > 1$, so that the sum in (31b) converges in this limit. Of these two problems the second is intuitive due to the presence of $n^2\pi^2$ in the denominator of (28b). The first problem is not intuitive as it requires an estimate of the effects of the terms $\infty > m > N$. This is a difficult issue which we do not address here. We have, however, done careful numerical experiments on (26a) and the effects of truncation. We have found that for $h < 0.25$ and $0 < k < 2\pi$, choosing $N \ge 5$ gives accurate approximations of the α_n to six decimal places. Increasing N further changed the results in the higher decimal places. Furthermore, the estimate (31c) agreed to a similar degree of accuracy with (31b).

5. Transparency. All the ingredients are now in place to determine an approximation of the transmission coefficient T_0 for our periodic structure. This is done by inserting (30), with $\hat{t}$ given by (31c), into (21a); we denote the result by $\hat{T}_0$. The magnitude of this complex number is found, after some algebraic and trigonometric simplifications, to be

$$|\hat{T}_0| = \frac{4h}{\sqrt{16h^2A_1^2 + 4A_2^2}}, \tag{32a}$$

$$A_1 = \cos kl - 2kh^2 S_{00} \sin kl, \tag{32b}$$

$$A_2 = (1 + h^2 - 4k^2h^2S_{00}^2)\sin kl + 2khS_{00}\cos kl. \tag{32c}$$

Now if A_1 and A_2 are both $O(1)$, then $|T_0| = O(h)$. Since the channel width $h \ll 1$, the field will be quite small in the region $z > l$. On the other hand, if A_2 is small, then $|T_0|$ may be order one and the field will be substantial in $z > l$. In fact, for a fixed k and h we can force A_2 to be zero by choosing the length of our structure to satisfy

$$\tan kl = \frac{-2khS_{00}}{1 + h^2(1 - 4k^2S_{00}^2)}. \tag{33}$$

The approximate solution to this equation is

$$l = \frac{M\pi}{k} - 2hS_{00} + O(h^2\, S_{00}^2), \tag{34a}$$

as $h \to 0$, where M is an integer and the $O(h^2S_{00}^2)$ represents the error which is very small, even though $S_{00} = O(\ln(1/h))$, as $h \to 0$. For these choices of resonant l we find that $|\hat{T}_0| = 1 - O(h^2\, S_{00}^2)$; that is, our periodic structure is virtually transparent.

In Figure 3(a) we have plotted $|\hat{T}_0|$ as a function of l for $k = \pi/2$ and $h = 0.1$. The peaks of this function are slightly less than 1, and occur for values of l slightly less than $2, 4, 6$, and 8, completely in agreement with (34a). The value of this function away from these resonant lengths is relatively small and clearly on the order of h. Figure 3(b) contains the plot of $|\hat{T}_0|$ as a function of l for $k = \pi/2$ and $h = 0.01$. For this smaller channel width the peaks of this function are much more localized and occur even closer to $l = 2, 4, 6$, and 8. Furthermore, away from these peaks it is again on the order of h which is now even smaller.

Now for a fixed l we can rewrite (34a), neglecting the error term, to obtain

$$k = \frac{M\pi}{l + 2h\, S_{00}(k, h)}, \tag{34b}$$

where the dependence of S_{00} on k and h is explicitly shown. This is an implicit equation for the resonant k for our grating. However, the term involving hS_{00} is small so that the resonant k will be slightly less than $M\pi/l$. This is borne out in Figure 4(a), where $|\hat{T}_0|$ is plotted as a function of k for $h = 0.01$ and $l = 2$. Here we have restricted k to the interval $(0, 2\pi)$ to ensure single mode propagation in the regions $z < 0$ and $z > l$. We note that if l is increased from 2 to 4, then the function $|\hat{T}_0|$ will have 8 resonant spikes. This follows from (34b) and implies that the grating

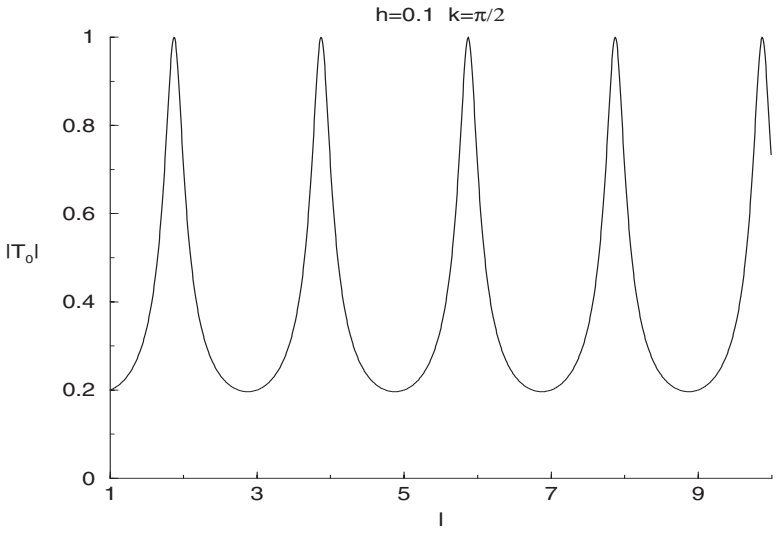

FIG. 3(a).

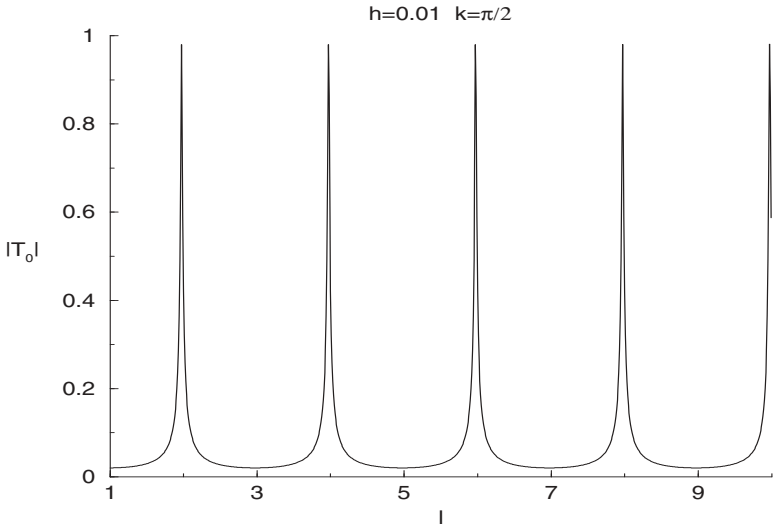

FIG. 3(b).

will be transparent at many frequencies as l increases, or equivalently as the structure becomes wider. We also observe that the pass bands for this grating structure are extremely localized about $k = k_M \sim M\pi/l$. This localization is mitigated somewhat when losses in the metallic grating are taken into account. Nonetheless this resonant structure suggests that the grating might be suitable as a highly selective filter.

In Figure 4(b) we plot $\hat{R}_0$ as a function of k for $h = 0.01$ and $l = 2$. This approximate reflection coefficient is obtained by combining (21a), (21b), (30), and (31c). It is evident from this plot that the grating stop bands are very broad, in the absence of grating losses. It is this feature of the grating that might make it a candidate for a lossy mirror in a Fabry–Perot resonator.

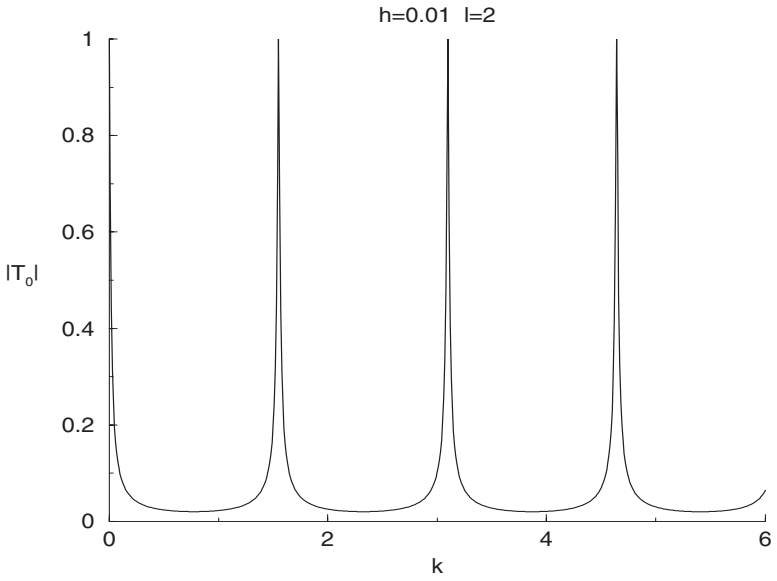

FIG. 4(a).

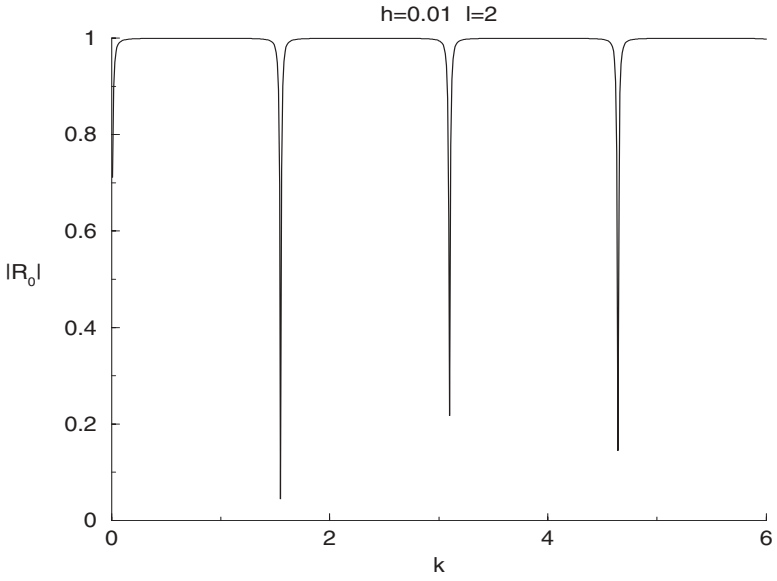

FIG. 4(b).

Finally, we offer a comparison of our results with those given in [6], where the transmission coefficient was determined from a full-modal solution of the entire grating problem. Using $A = 3.5\,\mu m$, $L = 4\,\mu m$, and $H = 0.5\,\mu m$, we find that $l = 1.14$ and $h = 1/7$. The full-modal solution predicted resonances at $4.9\,\mu m$ and $9.7\,\mu m$ which correspond to $k = 4.3$ and $k = 2.3$, respectively. Our approximation transmission coefficient for this case has resonances at $k = 2.4$ and $k = 4.7$ which differ by 4% and 8%. These errors are completely consistent with our asymptotic theory, which is accurate to $O(h)$.

6. Nonnormal incidence. The procedure developed and discussed in the previous sections can be modified to handle the case of an incident plane wave

$$P_{inc} = e^{ik(x\sin\theta_0 + z\cos\theta_0)}, \tag{35}$$

where θ_0 is the angle the wave makes with the positive z-axis. For an arbitrary channel height the simple results given in (10) are no longer true. Higher order reflection and transmission coefficients must be taken into account in these expressions. For example, the simple relationship $r_0 = 1 - \sqrt{h}\,\tau_0$ now becomes

$$r_0 = 1 - \sqrt{h}\tau_0 \operatorname{sinc}\left(\frac{kh\sin\theta_0}{2}\right) - \frac{i2\sqrt{h}}{k}\sum_{n=1}^{\infty} |k_n|\tau_n I_n \tag{36a}$$

where

$$\operatorname{sinc}(x) = \frac{\sin x}{x}, \qquad I_n = \int_0^1 e^{-ikht\sin\theta_0}\cos n\pi t\, dt. \tag{36b}$$

Thus, our simple theory based upon the single scalar number t no longer holds. However, if we exploit the fact that $h \ll 1$, then the sinc function and the I_n in (36a) all become $1 + O(h)$ and we obtain $r_0 = 1 - \sqrt{h}\tau_0 + O(h^{3/2})$. Ignoring the correction term we arrive at our original relationship. Similar reasoning shows that the other statements in (10) hold asymptotically and the rest of our argument proceeds accordingly until we arrive at the approximation of τ_0. A modified Green's function must be introduced at this point which takes into account the quasi-periodic nature of the solution in x. The analysis here follows along the same path and the results are the same with one exception. The formula for S_{00} must be modified by replacing $|\beta_l|$ by $\sqrt{(2l\pi - k\sin\theta_0)^2 - k^2}$ which takes into account the nonnormal incidence. The formulae (34a) and (34b) for the resonant length and wave number, respectively, still remain valid with this change.

7. Conclusion. We have derived a simple approximation of the transmission coefficient for the two-dimensional periodic structure shown in Figure 1. The assumptions used in our analysis were threefold. First, the incident wave was taken to be normally incident upon the structure. Second, the frequency of the incident wave was restricted to ensure that only a single mode propagated in the regions $z < 0$ and $z > l$. Third, the air filled channels were taken to be very small compared to the period of the structure. Our results show that for a fixed frequency and channel width h, the magnitude of the transmission coefficient is $O(h)$ except at certain resonant lengths where it is almost 1. Moreover, the smaller h is made, the more localized is this resonant behavior. The same phenomenon occurs when the length of the structure and the channel width are fixed. Then the magnitude of the transmission coefficient is $O(h)$ except in the neighborhood of resonant frequencies. These phenomena will be mitigated somewhat in actual gratings with finite conductivity. Nonetheless, our approximate transmission coefficient still gives accurate estimates for resonant lengths and the resonant frequencies for highly conductive gratings.

Our approximate transmission coefficient depends fundamentally upon τ_0, the transmission coefficient of a related auxiliary problem. This coefficient is deduced from the solution to an infinite system of linear algebraic equations. We have developed an asymptotic approximation of the solution of these equations, and hence of τ_0, in the limit $h \to 0$. Although these calculations were formal, careful numerical studies of the

system and of the resulting approximation of τ_0 strongly indicate that our asymptotic results are highly accurate.

We have also briefly addressed the case of nonnormal incidence and have provided the necessary changes. Finally, we note that removing the restriction on k so that more modes are present in the region exterior to our structure will cause the analyses to become much more involved. The dependence of the scattering physics on one number, regardless of the small channel height, will no longer be true. However, we conjecture that the resonant phenomena illustrated in this present work still will remain.

Appendix A. In this appendix we show that the matrix given in (13) is unitary and, accordingly, that τ_o satisfies (14a). We begin by letting P denote the solution to the Helmholtz equation which satisfies the boundary conditions enumerated in the text and behaves according to (11) away from $z = 0$. It follows from the former that $\mathrm{Im}\{\nabla \cdot \bar{P}\nabla P)\} = 0$. Integrating this relationship in the region $|z| < z_\infty$, applying boundary conditions, and using (11) we obtain

$$l|a_0|^2 + |c_0|^2 = |b_0|^2 + |d_0|^2. \tag{A.1}$$

This is a statement of the conservation of power. We now insert the expressions for b_0 and d_0 given by (13) into (A.1) and obtain

$$\begin{aligned} 0 = \{|1-\sqrt{h}\tau_0|^2 + |\tau_0|^2 - 1\}|a_0|^2 + \left\{\left|1-\frac{\tau_0}{\sqrt{h}}\right|^2 + |\tau_0|^2 - 1\right\}|c_0|^2 \\ +2\,\mathrm{Re}\left[\left\{\tau_0\left(1-\sqrt{h}\bar{\tau}_0\right) + \bar{\tau}_0\left(1-\frac{\tau_0}{\sqrt{h}}\right)\right\}\right]\bar{a}_0 c_0. \end{aligned} \tag{A.2}$$

Setting $a_0 = 1$ and $c_0 = 0$, we deduce from (A.2) that $|1-\sqrt{h}\tau_0|^2 + |\tau_0|^2 = 1$. This can be rearranged to give (14a). Similarly, setting $a_0 = 0$ and $c_0 = 1$ gives $|1-\frac{\tau_0}{\sqrt{h}}|^2 + |\tau_0|^2 = 1$. This too can be rearranged to give (14a). Using these two pieces of information it follows from (A.2) that $2\,\mathrm{Re}[\{\tau_0(1-\sqrt{h}\bar{\tau}_0) + \bar{\tau}_0(1-\frac{\tau_0}{\sqrt{h}})\}] = 0$. These results show that the matrix defined in (13) is unitary.

Appendix B. In this appendix we shall give a qualitative argument that S_{0n}, defined by (28b), is $O(1)$ as $h \to 0$. That is, S_{0n} is bounded in this limit. An analogous argument for S_{nm} has been developed, but for brevity will not be presented here.

We begin by rewriting (28b) as

$$S_{0n} = \frac{\sqrt{2}}{\pi}\sum_{l=1}^{\infty} \frac{\Delta x}{\sqrt{(2l\Delta x)^2 - (k\Delta x)^2}} \frac{\sin^2(l\Delta x)}{[(n\pi)^2 - (l\Delta x)^2]},$$

where $\Delta x = h\pi$. Now for small Δx the sum above can be interpreted as the Riemann sum which approximates the integral

$$I_{0n} = \frac{\sqrt{2}}{\pi}\int_{\Delta x}^{\infty} \frac{1}{\sqrt{4x^2 - (k\Delta x)^2}} \frac{\sin^2 x}{[(n\pi)^2 - x^2]}\, dx.$$

This integral can be split into three pieces:

$$I_{0n} = \frac{\sqrt{2}}{\pi}\{J_1 + J_2 + J_3\},$$

where

$$J_1 = \int_{k\Delta x/2}^{1} \frac{\sin^2 x}{\sqrt{4x^2 - (k\Delta x)^2}\,[(n\pi)^2 - x^2]}\,dx,$$

$$J_2 = -\int_{k\Delta x/2}^{\Delta x} \frac{\sin^2 x}{\sqrt{4x^2 - (k\Delta x)^2}\,[(n\pi)^2 - x^2]}\,dx,$$

$$J_3 = \int_{1}^{\infty} \frac{\sin^2 x}{\sqrt{4x^2 - (k\Delta x)^2}\,[(n\pi)^2 - x^2]}\,dx.$$

Now J_1 and J_3 can be approximated to $O(\Delta x)$ by replacing Δx by 0, yielding

$$J_1 \sim \int_{0}^{1} \frac{\sin^2 x}{2x\,[(n\pi)^2 - x^2]}\,dx,$$

$$J_3 \sim \int_{1}^{\infty} \frac{\sin^2 x}{2x\,[(n\pi)^2 - x^2]}\,dx.$$

Both of these integrals are finite. After making the substitution $x = (k\Delta x/2)p$ and using $\Delta x \ll 1$ the integral defining J_2 becomes

$$J_2 \sim -\left(\frac{k\Delta x}{2n\pi}\right)^2 \int_{1}^{2/k} \frac{p^2}{\sqrt{p^2 - 1}}\,dp.$$

Combining these three estimates we have

$$S_{0n} \sim I_{0n} = \frac{\sqrt{2}}{\pi}\{J_1 + J_2 + J_3\} = O(1)$$

as $h \to 0$.

Using similar reasoning on S_{00} we obtain

$$S_{00} \sim \frac{1}{\pi}\{K_1 + K_2 + K_3\},$$

where

$$K_1 = \int_{\Delta x}^{1} \frac{\sin^2 x}{\sqrt{4x^2 - (k\Delta x)^2}}\,\frac{dx}{x^2},$$

$$K_2 = \int_{k\Delta x/2}^{\Delta x} \frac{\sin^2 x}{\sqrt{4x^2 - (k\Delta x)^2}}\,\frac{dx}{x^2},$$

$$K_3 = \int_{1}^{\infty} \frac{\sin^2 x}{\sqrt{4x^2 - (k\Delta x)^2}}\,\frac{dx}{x^2}.$$

Now K_3 can be approximated to $O(h)$ by replacing Δx by 0, giving

$$K_3 = \int_1^\infty \frac{\sin^2 x}{2x^3}\, dx,$$

which is finite. Making the same substitution, as above in J_2, into K_2 we deduce that

$$K_2 = \int_1^{2/k} \frac{1}{\sqrt{p^2-1}}\, dp,$$

which is also finite. Now the integral defining K_1 is rewritten as

$$K_1 = \int_{\Delta x}^1 \frac{dx}{\sqrt{4x^2-(k\Delta x)^2}} - \int_{\Delta x}^1 \left(\frac{\sin^2 x}{x^2} - 1\right) \frac{dx}{\sqrt{4x^2-(k\Delta x)^2}}.$$

We observe that the second integral is bounded as $\Delta x \to 0$ and it can be approximated, to $O(\Delta x)$, by just setting $\Delta x = 0$. The first integral can be solved exactly and as $\Delta x \to 0$ it becomes $\frac{1}{2}\ln(\frac{4}{k\Delta x})$. Thus, we finally have

$$S_{00} \sim \frac{1}{2\pi} \ln(4/kh).$$

NUMERICAL HOMOGENIZATION AND CORRECTORS FOR NONLINEAR ELLIPTIC EQUATIONS*

Y. EFENDIEV† AND A. PANKOV‡

Abstract. In this paper we consider numerical homogenization and correctors for nonlinear elliptic equations. The numerical correctors are constructed for operators with homogeneous random coefficients. The construction employs two scales, one a physical scale and the other a numerical scale. A numerical homogenization technique is proposed and analyzed. This procedure is developed within finite element formulation. The convergence of the numerical procedure is presented for the case of general heterogeneities using G-convergence theory. The proposed numerical homogenization procedure for elliptic equations can be considered as a generalization of multiscale finite element methods to nonlinear equations. Using corrector results we construct an approximation of oscillatory solutions. Numerical examples are presented.

Key words. homogenization, multiscale, upscaling, scale-up, random, nonlinear, elliptic, finite element

1. Introduction.

Consider the nonlinear elliptic equations

$$-\mathrm{div}(a_\epsilon(x, u_\epsilon, Du_\epsilon)) + a_{0,\epsilon}(x, u_\epsilon, Du_\epsilon) = f, \qquad u_\epsilon \in W_0^{1,p}(Q). \tag{1}$$

Here ϵ denotes the small scale of the problem. Direct numerical simulations of these kinds of problems are difficult because of scale disparity. Our objective is to find the approximation of the homogenized solution without solving the fine scale problem; i.e., (1) is solved on a grid of size h, where $h \gg \epsilon$. The numerical procedure introduced for this purpose can be regarded as numerical homogenization. The numerical homogenization procedure for (1) should account for the functional dependence of the macroscopic quantities on the solution and its gradients. Our motivation in considering (1) mostly stems from the applications of flow in porous media (multiphase flow in saturated porous media and flow in unsaturated porous media) and enhanced diffusion due to nonlinear heterogeneous convection, though many applications of nonlinear elliptic equations of these kinds occur in transport problems.

In this paper we consider two issues: (1) the calculation of the correctors and (2) the computation of the homogenized solution. The homogenization of nonlinear elliptic equations in a random media has been studied previously (see, e.g., [17]). It was shown that a solution u_ϵ converges (up to a subsequence) to u in an appropriate norm and where $u \in W_0^{1,p}(Q)$ is a solution of

$$-\mathrm{div}(a^*(x, u, Du)) + a_0^*(x, u, Du) = f. \tag{2}$$

The homogenized coefficients can be computed if we make an additional assumption on the heterogeneities such as periodicity, almost periodicity, or when the fluxes are

strictly stationary fields with respect to spatial variables. In these cases one has an auxiliary problem of calculating a^* and a_0^*. The numerical homogenization procedure presented in this paper does not use the auxiliary problem for the calculation of the approximation of homogenized solutions.

To construct the numerical correctors we use two scales, a physical scale and a numerical scale that is much larger than the physical one, and construct the correctors in each numerical coarse block. The convergence for the corrector is obtained. These results show us a way to obtain numerically the fine scale features of the solution. We would like to note that the computation of the oscillation of solutions is important for the application to flow in porous media and other transport problems.

We present a procedure for calculating a coarse solution, the solution at the length scales h, $1 \gg h \gg \epsilon$. Our numerical homogenization procedure is based on general finite element computations of the coarse scale equations. It selectively solves the required local problems that reduce overall computations even in the periodic case. The solutions of the local problems are uniquely determined, which makes our discrete operator single-valued. The convergence of the numerical method is presented for general kinds of heterogeneities using G-convergence theory. Moreover, we show that the numerical homogenization approach presented in this paper can be considered as a generalization of multiscale finite element methods introduced in [10]. A related work in multiscale computations involves generalized finite element methods [2], residual free bubbles [3, 19], the variational multiscale method [12], two-scale finite element methods [15], two-scale conservative subgrid approaches [1], and the heterogeneous multiscale method (HMM) [6].

Some numerical examples are considered in this paper. We study numerically the effect of enhanced diffusion due to heterogeneous nonlinear convection,

$$\frac{\partial u_\epsilon}{\partial t} + \frac{1}{\epsilon} v_\epsilon(x) \cdot DF(u_\epsilon) - d\Delta u_\epsilon = f.$$

Since the elliptic part does not depend on t, the theory developed previously can be applied. In this application we are interested in the effect of the enhanced diffusion due to heterogeneous nonlinear convection. More precisely, assuming the existence of homogeneous stream function for the velocity field and zero mean drift, we calculate the approximation of the enhanced diffusion due to the convection using Buckley–Leverett flux that describes the convection. Other numerical examples for Richards equations are also studied.

The paper is organized as follows. In the next section we present some basic facts that are used later in the analysis. Section 3 is devoted to the construction of a numerical corrector and its convergence. Section 4 is devoted to the calculation of the homogenized solution and its analysis. In section 5 we present numerical results.

2. Preliminaries. We start with a description of random homogeneous fields on R^d, which are shown to be useful in homogenization problems (see, e.g., [13]). Let (Ω, Σ, μ) be a probability space. A random homogeneous field is a measurable function on Ω and $f(T(x)\omega)$ are realizations of the random field. The realizations are well-defined measurable functions on R^d for almost all $\omega \in \Omega$. Consider a d dimensional dynamical system on Ω, $T(x) : \Omega \to \Omega$, $x \in R^d$, that satisfies the following conditions: (1) $T(0) = I$, and $T(x + y) = T(x)T(y)$; (2) $T(x) : \Omega \to \Omega$ preserve the measure μ on Ω; (3) for any measurable function $f(\omega)$ on Ω, the function $f(T(x)\omega)$ defined on $R^d \times \Omega$ is also measurable (see [13, 18]). Let $L^p(\Omega)$ denote the space of all p-integrable

functions on Ω. Then $U(x)f(\omega) = f(T(x)\omega)$ defines a d-parameter group of isometries in the space $L^p(\Omega)$, and $U(x)$ is strongly continuous [13, 17]. Further, we assume that the dynamical system T is ergodic; i.e., any measurable T-invariant function on Ω is constant. Denote by $\langle\cdot\rangle$ the mean value over Ω,

$$\langle f\rangle = \int_\Omega f(\omega)d\mu(\omega) = E(f).$$

Now we explain briefly the relation between the standard definition of random homogeneous fields and the one we introduced here following, e.g., [17]. Let Ξ be a probability space endowed with a probability measure P. Let f be a random vector valued function, i.e., a measurable map $f : \Xi \times R^d \to R^N$. f is a random homogeneous field if all its finite dimensional distributions are translation invariant. The latter means that for any x^1, x^2, ..., $x^k \in R^d$, and any Borel subsets B_1, B_2, ..., $B_k \subset R^N$,

$$P\{\xi \in \Xi : f(\xi, x^1 + h) \in B_1, \dots, f(\xi, x^k + h) \in B_k\}$$

is independent of $h \in R^d$. Consider a new probability space Ω and a dynamical system $T(x)$ acting on Ω. We define Ω to be the set of all measurable functions $\omega : R^d \to R^N$ and set $T(x)\omega(y) = \omega(x + y)$, $x, y \in R^d$. Let $\mathcal{F}$ be the σ-algebra generated by "cylinder" sets, i.e., the sets of the form $B = \{\omega : \omega(x^1) \in B_1, \dots, \omega(x^k) \in B_k\}$, where x^1, x^2, ..., $x^k \in R^d$ and B_1, B_2, ..., B_k are Borel subsets in R^N. We define the measure μ on "cylinder" sets by $\mu(B) = P\{\xi \in \Xi : f(\xi, \cdot) \in B\}$ and then extend it to $\mathcal{F}$ by σ-additivity. Thus, the probability space Ω and the measure-preserving dynamical system $T(x)$, $x \in R^d$, on Ω are constructed. Moreover, consider the μ-measurable function $\hat{f} : \Omega \to R^N$ defined by the formula $\hat{f}(\omega) = \omega(0)$. Then $f(\xi, x) = \hat{f}(T(x)\omega)$, where $\omega(\cdot) = f(\xi, \cdot)$. More examples regarding the construction of T can be found in [13].

Denote by ∂^i_ω the generator of $U(x)$ along the ith coordinate direction, i.e.,

$$\partial^i_\omega = \lim_{\delta\to 0} \frac{f(T(\delta e_i)\omega) - f(\omega)}{\delta}.$$

The domains D^i of ∂^i_ω are dense in $L^2(\Omega)$, and the intersection of all D^i is also dense.

Next, following [17], we define potential and solenoidal fields. A vector field $f \in L^p(\Omega)$ is said to be potential (or solenoidal, respectively) if its generic realization $f(T(x)\omega)$ is a *potential* (or *solenoidal*, respectively) vector field in R^d. Denote by $L^p_{pot}(\Omega)$ (respectively, $L^p_{sol}(\Omega)$) the subspace of $L^p(\Omega)$ that consists of all potential (respectively, solenoidal) vector fields. Introduce the following notation:

$$V^p_{pot} = \{f \in L^p_{pot}(\Omega), \langle f\rangle = 0\}, \qquad V^p_{sol} = \{f \in L^p_{sol}(\Omega), \langle f\rangle = 0\}.$$

The following properties are known (see [17, page 138]):

$$L^p_{pot}(\Omega) = V^p_{pot} \oplus R^d, \quad L^p_{sol}(\Omega) = V^p_{sol} \oplus R^d, \quad L^q_{sol}(\Omega) = (V^p_{pot})^\perp, \quad L^q_{pot}(\Omega) = (V^p_{sol})^\perp.$$

Consider $u_\epsilon \in W^{1,p}_0(Q)$,

$$-\mathrm{div}(a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon)) + a_0(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon) = f \ \text{ in } Q, \tag{3}$$

where f is a deterministic function that does not depend on ϵ and is sufficiently smooth, and $Q \subset R^d$ is a domain with Lipschitz boundaries.

Assume for all $\omega \in \Omega$

$$(a(\omega,\eta,\xi_1) - a(\omega,\eta,\xi_2),\xi_1-\xi_2) \geq C(1+|\xi_1|+|\xi_2|)^{p-\beta}|\xi_1-\xi_2|^{\beta}, \tag{4}$$

$$|a(\omega,\eta,\xi)| + |a_0(\omega,\eta,\xi)| \leq C(1+|\eta|+|\xi|)^{p-1}, \tag{5}$$

$$\begin{aligned} &|a(\omega,\eta_1,\xi_1) - a(\omega,\eta_2,\xi_2)| + |a_0(\omega,\eta_1,\xi_1) - a_0(\omega,\eta_2,\xi_2)| \\ &\quad \leq C(1+|\eta_1|^{p-1}+|\eta_2|^{p-1}+|\xi_1|^{p-1}+|\xi_2|^{p-1})\nu(|\eta_1-\eta_2|) \\ &\qquad + C(1+|\eta_1|^{p-1-s}+|\eta_2|^{p-1-s}+|\xi_1|^{p-1-s}+|\xi_2|^{p-1-s})|\xi_1-\xi_2|^s, \end{aligned} \tag{6}$$

where $0 < s \leq 1$, $\beta \geq \max(p,2)$, $p > 1$. Here $\nu(r)$ is a continuity modulus; i.e., $\nu(r)$ is a nondecreasing continuous function on $[0,+\infty)$ such that $\nu(0) = 0$, $\nu(r) > 0$ if $r > 0$ and $\nu(r) = 1$ if $r > 1$, and $\nu(r_1 + r_2) \leq C(\nu(r_1) + \nu(r_2))$. For the existence of the solution we need a coercivity condition,

$$(a(\omega,\eta,\xi),\xi) + a_0(\omega,\eta,\xi)\eta \geq C|\xi|^p - C_1. \tag{7}$$

It is known (e.g., [17]) that, as $\epsilon \to 0$, Du_ϵ converges to Du weakly in $L^p(Q)^d$ for almost every ω, and u is the solution of

$$-\mathrm{div}(a^*(u,Du)) + a_0^*(u,Du) = f, \qquad u \in W_0^{1,p}(Q). \tag{8}$$

Further, a^* and a_0^* can be constructed using the solution of the following auxiliary problem. Given $\eta \in R$ and $\xi \in R^d$, define $w_{\eta,\xi} \in V_{pot}^p$ such that

$$a(\omega,\eta,\xi + w_{\eta,\xi}(\omega)) \in L_{sol}^q(\Omega)^d. \tag{9}$$

Then $a^*(\eta,\xi)$ and $a_0(\eta,\xi)$ are defined as

$$\begin{aligned} a^*(\eta,\xi) &= \langle a(\omega,\eta,\xi + w_{\eta,\xi}(\omega))\rangle, \\ a_0^*(\eta,\xi) &= \langle a_0(\omega,\eta,\xi + w_{\eta,\xi}(\omega))\rangle. \end{aligned} \tag{10}$$

Moreover, $a^*(\eta,\xi)$ and $a_0^*(\eta,\xi)$ satisfy estimates similar to those of a and a_0 with different constants [17].

Remark 2.1. We would like to note that G-convergence and homogenization results presented in [17] were formulated under weaker than (4) conditions. In particular, it is assumed that

$$(a(\omega,\eta,\xi_1) - a(\omega,\eta,\xi_2),\xi_1-\xi_2) \geq C(1+|\eta|+|\xi_1|+|\xi_2|)^{p-\beta}|\xi_1-\xi_2|^{\beta}. \tag{11}$$

It turns out that G-convergence and homogenization results hold under more general assumptions such as (4). The proof is identical to the one presented in [17]. Moreover, following [17], it can be easily shown that the homogenized operator is also coercive and satisfies (7).

Throughout the paper C denotes a generic constant, $\|\cdot\|_p$ denotes $L^p(Q)$ (or the broken norm), and $L^p(Q)^d$ norms and q are defined by $1/p + 1/q = 1$. The notation a.e. (almost every) is often omitted.

3. Two-scale correctors. The corrector results obtained in this section will be used in the approximation of solution gradients. The importance of this approximation is motivated by some applications in which details of the fluxes play a key role in a physical phenomenon (e.g., flow in porous media). For the construction we assume that the homogenized solution is computed with a reliable accuracy in an appropriate norm which will be specified later. In the next section we will propose a numerical procedure for the computation of the homogenized solution for more general heterogeneities. For the construction of the correctors we introduce two scale correctors, where one scale represents the numerical scale h and the other the physical scale ϵ.

Define $M_h\phi(x)$ in the following way:

$$M_h\phi(x) = \sum_i 1_{Q_i} \frac{1}{|Q_i|} \int_{Q_i} \phi(y)dy,$$

where $\bigcup Q_i = Q$. Here Q_i are domains with diameter of order h, e.g., finite element triangles or some unions of the triangles. Note that $M_h\phi \to \phi$ in $L^p(Q)$ as $h \to 0$ (see [22]). Further, define

$$P(T(y)\omega, \eta, \xi) = \xi + w_{\eta,\xi}(T(y)\omega), \tag{12}$$

where $w_{\eta,\xi} \in V^p_{pot}(\Omega)$ is the solution of the auxiliary problem $a(\omega, \eta, \xi + w_{\eta,\xi}(\omega)) \in L^q_{sol}(\Omega)^d$. Here $w_{\eta,\xi}(T(y)\omega)$ satisfies

$$-\mathrm{div}(a(T(y)\omega, \eta, \xi + w_{\eta,\xi}(T(y)\omega))) = 0$$

in the sense of distribution [17, p. 155].

The main result of this section regarding the convergence of the correctors is the following.

THEOREM 3.1. *Let u_ϵ and u be solutions of* (3) *and* (8)*, respectively, and let P be defined by* (12) *in each Q_i. Then*

$$\lim_{h\to 0} \lim_{\epsilon\to 0} \int_Q |P(T(x/\epsilon)\omega, M_h u, M_h Du) - Du_\epsilon|^p dx = 0 \tag{13}$$

μ-a.e.

We will omit μ-a.e. notation in further analysis. To make the expressions in the proof more concise we introduce the notation

$$\mathcal{P}_\epsilon = P(T(x/\epsilon)\omega, M_h u, M_h Du).$$

Theorem 3.1 indicates that the gradient of solutions can be approximated by $P(T(x/\epsilon)\omega, M_h u, M_h Du)$. This quantity can be computed based on $M_h Du$ and $M_h u$, i.e., the gradient of the coarse solution in each coarse block, as we will show later. The following lemma [4] will be used in the proof.

LEMMA 3.2. *For any ϕ_1 and ϕ_2 belonging to $L_p(Q)$ we have*

$$\begin{aligned}\|\phi_1 - \phi_2\|_{p,Q} \le C \left(\int_Q |\phi_1 - \phi_2|^\beta (1 + |\phi_1| + |\phi_2|)^{p-\beta} dx \right)^{1/\beta} \\ \times (|Q|^{1/p} + \|\phi_1\|_{p,Q} + \|\phi_2\|_{p,Q})^{(\beta-p)/\beta}.\end{aligned} \tag{14}$$

For the proof of Theorem 3.1 we need the following lemma.

LEMMA 3.3. *For every $\eta \in R$ and $\xi \in R^d$*

$$\|P(\omega,\eta,\xi)\|_{p,\Omega}^p \le C(1+|\eta|^p+|\xi|^p).$$

Proof. Using Lemma 3.2 and (4), we obtain

$$\begin{aligned}\|P\|_{p,\Omega}^p &\le C(1+\|P\|_{p,\Omega}^p)^{(\beta-p)/\beta}\left(\int_\Omega |P|^\beta(1+|P|)^{p-\beta}d\mu(\omega)\right)^{p/\beta}\\ &\le C\delta^{(p-\beta)/p}\int_\Omega |P|^\beta(1+|P|)^{p-\beta}d\mu(\omega)+C\delta(1+\|P\|_{p,\Omega}^p).\end{aligned}$$

With a suitable choice of δ and using (4) and (5), we get

$$\begin{aligned}\|P\|_{p,\Omega}^p &\le C+C\int_\Omega |P|^\beta(1+|P|)^{p-\beta}d\mu(\omega)\le C+C\int_\Omega (a(\omega,\eta,P)-a(\omega,\eta,0),P)d\mu(\omega)\\ &\le C+C\left|\int_\Omega (a(\omega,\eta,P),P)d\mu(\omega)\right|+\left|\int_\Omega (a(\omega,\eta,0),P)d\mu(\omega)\right|\\ &\le C+\left|\int_\Omega (a(\omega,\eta,P),\xi)d\mu(\omega)\right|+(1+|\eta|^{p-1})\left|\int_\Omega P d\mu(\omega)\right|\\ &\le C+C\delta_1\|P\|_{p,\Omega}^p+C\delta_1^{-1/(p-1)}|\eta|^p+C\int_\Omega (1+|\eta|+|P|)^{p-1}|\xi|d\mu(\omega)\\ &\le C\delta_2\|P\|_{p,\Omega}^p+C\delta_2^{-1/(p-1)}(1+|\xi|^p)+C+C\delta_1(|\eta|^p+\|P\|_{p,\Omega}^p)+C\delta_1^{-1/(p-1)}|\eta|^p.\end{aligned}$$

With an appropriate choice of δ_1 and δ_2, we obtain the desired result. ∎

It follows from Lemma 3.3 that $P(T(y)\omega,\eta,\xi)\in L^p_{loc}(R^d)^d$ for a.e. ω and for each $\eta\in R$, $\xi\in R^d$. The next lemma will be also used in the proof of Theorem 3.1.

LEMMA 3.4. *If $u_k\to 0$ in $L^r(Q)$ $(1<r<\infty)$ as $k\to\infty$, then*

$$\int_Q \nu(u_k)|v_k|^p dx\to 0 \text{ as } k\to\infty$$

for all v_k either (1) *compact in $L^p(Q)$ or* (2) *bounded in $L^{p+\alpha}(Q)$, $\alpha>0$. Here $\nu(r)$ is the continuity modulus defined previously* (*see* (6)) *and $1<p<\infty$.*

Proof. Since u_k converges in L^r, it converges in measure. Consequently, for any $\delta>0$ there exists Q_δ and k_0 such that $\mathrm{meas}(Q\setminus Q_\delta)<\delta$ and $\nu(u_k)<\delta$ in Q_δ for $k>k_0$. Thus

$$\begin{aligned}\int_Q \nu(u_k)|v_k|^p dx &= \int_{Q_\delta}\nu(u_k)|v_k|^p dx+\int_{Q\setminus Q_\delta}\nu(u_k)|v_k|^p dx\\ &\le C\delta+C\int_{Q\setminus Q_\delta}|v_k|^p dx.\end{aligned}\tag{15}$$

Next we use the fact that if (1) or (2) is satisfied, then the set v_k has equi-absolute continuous norm [14] (i.e., for any $\epsilon>0$ there exists $\zeta>0$ such that $\mathrm{meas}(Q_\zeta)<\zeta$ implies $\|P_{Q_\zeta}v_k\|_{p,Q}<\epsilon$, where $P_Df=\{f(x) \text{ if } x\in D; 0 \text{ otherwise}\}$. Consequently, the second term on the right-hand side (r.h.s.) of (15) converges to zero as $\delta\to 0$. ∎

The proof of Theorem 3.1 will be based on the following estimate:

$$\begin{aligned}\int_Q |\mathcal{P}_\epsilon-Du_\epsilon|^p dx &\le \int_Q |\mathcal{P}_\epsilon-Du_\epsilon|^\beta(1+|\mathcal{P}_\epsilon|+|Du_\epsilon|)^{p-\beta}dx(|Q|^{1/p}\\ &\quad+\|\mathcal{P}_\epsilon\|_{p,Q}+\|Du_\epsilon\|_{p,Q})^{(\beta-p)/p}.\end{aligned}\tag{16}$$

$\|Du_\epsilon\|_{p,Q}$ is uniformly bounded for a.e. ω. $\|\mathcal{P}_\epsilon\|_{p,Q}$ is also uniformly bounded since $M_h u$ and $M_h Du$ are bounded in $L^p(Q)$ and $L^p(Q)^d$, respectively. Thus it remains to estimate $\int_Q |\mathcal{P}_\epsilon - Du_\epsilon|^\beta (1 + |\mathcal{P}_\epsilon| + |Du_\epsilon|)^{p-\beta} dx$. For this term, using (4), we have

$$
\begin{aligned}
&\int_Q |\mathcal{P}_\epsilon - Du_\epsilon|^\beta (1 + |\mathcal{P}_\epsilon| + |Du_\epsilon|)^{p-\beta} dx \\
&\qquad \le C \left| \int_Q (a(T(x/\epsilon)\omega, u_\epsilon, \mathcal{P}_\epsilon) - a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), \mathcal{P}_\epsilon - Du_\epsilon) dx \right| \\
&\qquad \le C \left| \int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon) - a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), \mathcal{P}_\epsilon - Du_\epsilon) dx \right| \\
&\qquad\quad + C \left| \int_Q (a(T(x/\epsilon)\omega, u_\epsilon, \mathcal{P}_\epsilon) - a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), \mathcal{P}_\epsilon - Du_\epsilon) dx \right|.
\end{aligned} \tag{17}
$$

To prove Theorem 3.1 we will need to estimate the first and second terms on the r.h.s. of (17). For the first term we have

$$
\begin{aligned}
&C \int_Q \big(a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon) - a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), \mathcal{P}_\epsilon - Du_\epsilon\big) dx \\
&\qquad = C \int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), \mathcal{P}_\epsilon) dx - C \int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), Du_\epsilon) dx \\
&\qquad\quad - C \int_Q (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), \mathcal{P}_\epsilon) dx + C \int_Q (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), Du_\epsilon) dx.
\end{aligned} \tag{18}
$$

We will investigate the r.h.s. of (18) in the limit as $\epsilon \to 0$. For the first term of the r.h.s. of (18) we have the following convergence.

LEMMA 3.5.

$$
\int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), \mathcal{P}_\epsilon) dx \to \int_Q (a^*(M_h u, M_h Du), M_h Du) dx
$$

as $\epsilon \to 0$.

Proof.

$$
\begin{aligned}
&\int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), \mathcal{P}_\epsilon) dx \\
&\qquad = \sum_i \int_{Q_i} \big(a(T(x/\epsilon)\omega, \eta_i, \xi_i + w_{\eta_i,\xi_i}(T(x/\epsilon)\omega)), \xi_i + w_{\eta_i,\xi_i}(T(x/\epsilon)\omega)\big) dx \\
&\qquad = \sum_i \int_{Q_i} \big(a(T(x/\epsilon)\omega, \eta_i, \xi_i + w_{\eta_i,\xi_i}(T(x/\epsilon)\omega)), \xi_i\big) dx \\
&\qquad\quad + \sum_i \int_{Q_i} \big(a(T(x/\epsilon)\omega, \eta_i, \xi_i + w_{\eta_i,\xi_i}(T(x/\epsilon)\omega)), w_{\eta_i,\xi_i}(T(x/\epsilon)\omega)\big) dx \\
&\qquad \to \sum_i \int_{Q_i} 1_{Q_i} (a^*(\eta_i, \xi_i), \xi_i) dx
\end{aligned}
$$

as $\epsilon \to 0$. In the last step we have used the Birkhoff ergodic theorem (see [13]) as well as (9), (10), and $w_{\eta,\xi} \in V^p_{pot}$. Next we note that the limit can be written as

$$
\sum_i \int_{Q_i} 1_{Q_i} (a^*(\xi_i), \xi_i) dx = \int_Q (a^*(M_h u, M_h Du), M_h Du) dx. \qquad \square
$$

For the second term of the r.h.s. of (18) we have the following convergence.

LEMMA 3.6.

$$\int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), Du_\epsilon)dx \to \int_Q (a^*(M_h u, M_h Du), Du)dx$$

as $\epsilon \to 0$.

Proof.

$$\int_Q (a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), Du_\epsilon)dx = \sum_i \int_{Q_i} (a(T(x/\epsilon)\omega, \eta_i P(T(x/\epsilon)\omega, \eta_i, \xi_i)), Du_\epsilon)dx.$$

Du_ϵ is bounded in $L^p(Q)^d$ for a.e. ω. To show that $a(T(x/\epsilon)\omega, P(T(x/\epsilon)\omega, \eta_i, \xi_i))$ is bounded in $L^r(Q_i)^d$, where $r > q$, we will use Meyers' theorem [16]. Since $-\mathrm{div}(a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i))) = 0$ in $3 \times Q_i$ (where $3 \times Q_i$ is a domain that contains Q_i and is surrounded with a ring of size Q_i), using Meyers' theorem we can conclude that

$$\|P(T(x/\epsilon)\omega, \eta_i, \xi_i)\|_{p+\eta, Q_i} \le C\|P(T(x/\epsilon)\omega, \eta_i, \xi_i)\|_{p, 3\times Q_i},$$

where C is independent of ω and depends only on operator constants. Note that $P \in L^p_{loc}(R^d)^d$. Since $\|P(T(x/\epsilon)\omega, \eta_i, \xi_i)\|_{p,3\times Q_i}$ is bounded for a.e. ω (see Lemma 3.3), $\|P(T(x/\epsilon)\omega, \eta_i, \xi_i)\|_{p+\alpha, Q_i}$ is also bounded for a.e. ω. From here, using bounds for $a(T(y)\omega, \eta, \xi)$, we can easily obtain that $a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i))$ is bounded in $L^r(Q_i)^d$, where $r > q$ for a.e. ω. Indeed,

$$\begin{aligned}
&\int_{Q_i} |a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i)) - a(T(x/\epsilon)\omega, \eta_i, 0)|^r dx \\
&\quad \le C \int_{Q_i} (|1 + \eta_i + P(T(x/\epsilon)\omega, \eta_i, \xi_i)|)^{(p-2)r} |P(T(x/\epsilon)\omega, \eta_i, \xi_i)|^r dx \\
&\quad \le C(\|P\|_{r,Q_i} + \|P\|_{(p-1)r,Q_i}).
\end{aligned}$$

Since P is in $L^{p+\alpha}(Q_i)^d$ for a.e. ω, we can pick $r = q + \alpha/(p-1)$. Consequently, $(a(T(x/\epsilon)\omega, \eta_i, \xi_i + w_{\eta_i,\xi_i}(T(x/\epsilon)\omega)), Du_\epsilon)$ is bounded in $L^\sigma(Q_i)^d$, $\sigma > 1$, for every η_i and ξ_i. Thus it contains a subsequence that weak* converges to g_i for any i and a.e. ω. Since $-\mathrm{div}(a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i))) = 0$ in Q_i, using a compensated compactness argument we can obtain that as $\epsilon \to 0$, $g_i = (a^*(\eta_i, \xi_i), Du)$. The latter is true because Du_ϵ weakly converges to Du in $L^p(Q)^d$ for a.e. ω and $a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i))$ weakly converges to $a^*(\eta_i, \xi_i)$ in $L^r(Q)$. The fact that Du_ϵ weakly converges to Du for a.e. ω follows from general G-convergence results [17], and the weak convergence of $a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i))$ is a consequence of the Birkhoff ergodic theorem. Consequently,

$$\begin{aligned}
&\sum_i \int_{Q_i} (a(T(x/\epsilon)\omega, \eta_i, P(T(x/\epsilon)\omega, \eta_i, \xi_i)), Du_\epsilon)dx \\
&\quad \to \sum_i \int_{Q_i} (a^*(\eta_i, \xi_i), Du)dx = \int_Q (a^*(M_h u, M_h Du), Du)dx. \qquad \square
\end{aligned}$$

For the third term of the r.h.s. of (18) we have the following convergence.

LEMMA 3.7.

$$\int_Q (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), \mathcal{P}_\epsilon)dx \to \int_Q (a^*(u, Du), M_h Du)dx$$

as $\epsilon \to 0$.

Proof.

$$\int_Q (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), \mathcal{P}_\epsilon)dx = \sum_i \int_{Q_i} (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), P(T(x/\epsilon)\omega, \eta_i, \xi_i))dx.$$

Since $|a(\omega, \eta, \xi)| \le C(1 + |\eta|^{p-1} + |\xi|^{p-1})$ and $P(T(x/\epsilon)\omega, \eta_i, \xi_i)$ converges to ξ_i in $L^p(Q)^d$ and is bounded in $L^{p+\eta}(Q)^d$, similar to the analysis for the Lemma 3.6 we can obtain that

$$\begin{aligned}&\sum_i \int_{Q_i} (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), P(T(x/\epsilon)\omega, \eta_i, \xi_i))dx \\ &\quad \to \sum_i \int_{Q_i} (a^*(u, Du), \xi_i)dx = \int_Q (a^*(u, Du), M_h Du)dx. \qquad \square\end{aligned}$$

For the fourth term of the r.h.s. of (18), we have the following.

LEMMA 3.8.

$$\int_Q (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), Du_\epsilon)dx \to \int_Q (a^*(u, Du), Du)dx$$

as $\epsilon \to 0$.

Proof.

$$\begin{aligned}&\int_Q (a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon), Du_\epsilon)dx \\ &\quad = -\int_Q (\mathrm{div}(a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon)), u_\epsilon)dx = -\int_Q f u_\epsilon dx \\ &\quad \to -\int_Q f u dx = \int_Q (a^*(u, Du), Du)dx. \qquad \square\end{aligned}$$

Next for the second term on the r.h.s. of (17), using (6), we have

(19)

$$\begin{aligned}&C\left|\int_Q (a(T(x/\epsilon)\omega, u_\epsilon, \mathcal{P}_\epsilon) - a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon), \mathcal{P}_\epsilon - Du_\epsilon)dx\right| \\ &\quad \le \frac{C}{\delta_1}\left|\int_Q a(T(x/\epsilon)\omega, u_\epsilon, \mathcal{P}_\epsilon) - a(T(x/\epsilon)\omega, M_h u, \mathcal{P}_\epsilon)\right|^q dx + C\delta_1 \int_Q |\mathcal{P}_\epsilon - Du_\epsilon|^p dx \\ &\quad \le \frac{C}{\delta_1}\sum_i \int_{Q_i} \nu(|u_\epsilon - \eta_i|)^q (1 + |\xi_i|^p)dx \\ &\qquad + \frac{C}{\delta_1}\sum_i \int_{Q_i} \nu(|u_\epsilon - \eta_i|)^q (1 + |w_{\eta_i,\xi_i}|^p)dx + C\delta_1 \int_Q |\mathcal{P}_\epsilon - Du_\epsilon|^p dx,\end{aligned}$$

where $\nu(r)$ is a continuity modulus defined earlier (see (6)). Here we have used the uniform boundedness of Du_ϵ as well as u_ϵ in $L^p(Q)^d$ and $L^p(Q)$, respectively. The first term on the r.h.s. converges to $\int_Q \nu(|u - M_h u|)^q (1 + |M_h Du|^p)dx$ by Lemma 3.4. For the second term, using Meyers' theorem (cf. Lemma 3.6), we obtain that w_{η_i,ξ_i} is bounded in $L^{p+\alpha}(Q_i)^d$, $\alpha > 0$. Thus, using Lemma 3.4, we have that the second term for each i converges to $\int_{Q_i} \nu(|u - \eta_i|)^q (1 + \langle |w_{\eta_i,\xi_i}|^p \rangle)dx$, which is not

greater than $\int_{Q_i} \nu(|u-\eta_i|)^q(1+|\eta_i|^p+|\xi_i|^p)dx$. Summing this over all i, we get $\int_Q \nu(|u-M_hu|)^q(1+|M_hu|^p+|M_hDu|^p)dx$. Thus (19) is not greater than

$$\int_Q \nu(|u-M_hu|)^q(1+|M_hu|^p+|M_hDu|^p)dx + C\delta_1 \int_Q |\mathcal{P}_\epsilon - Du_\epsilon|^p dx.$$

With an appropriate choice of δ_1, combining all the estimates, we have for (17) (cf. (16))

$$\begin{aligned}
&\lim_{\epsilon\to 0}\int_Q |\mathcal{P}_\epsilon - Du_\epsilon|^p dx \\
&\quad \le C\left(\int_Q (a^*(M_hu, M_hDu), M_hDu)dx - \int_Q (a^*(M_hu, M_hDu), Du)dx\right. \\
&\qquad \left. - \int_Q (a^*(u, Du), M_hDu)dx + \int_Q (a^*(u, Du), Du)dx\right) \\
&\qquad + \int_Q \nu(|u-M_hu|)^q(1+|M_hu|^p+|M_hDu|^p)dx.
\end{aligned} \tag{20}$$

Next it is not difficult to show that the r.h.s. of (20) approaches zero as $h \to 0$. For this reason we write

$$\begin{aligned}
&\int_Q (a^*(M_hu, M_hDu), M_hDu)dx - \int_Q (a^*(M_hu, M_hDu), Du)dx \\
&\qquad - \int_Q (a^*(u, Du), M_hDu)dx + \int_Q (a^*(u, Du), Du)dx \\
&\qquad = \int_Q (a^*(u, Du) - a^*(M_hu, M_hDu), Du - M_hDu)dx.
\end{aligned} \tag{21}$$

Next, using the estimate $|a^*(\eta_1,\xi_1) - a^*(\eta_2,\xi_2)| \le C(1+|\eta_1|^{p-1}+|\eta_2|^{p-1}+|\xi_1|^{p-1}+|\xi_2|^{p-1})\nu(|\eta_1-\eta_2|) + C(1+|\eta_1|^{p-1-\tilde{s}}+|\eta_2|^{p-1-\tilde{s}}+|\xi_1|^{p-1-\tilde{s}}+|\xi_2|^{p-1-\tilde{s}})|\xi_1-\xi_2|^{\tilde{s}}$, $0<\tilde{r}\le 1$ (see [17]), we can obtain that the r.h.s. of (21) converges to zero as $h\to 0$. Indeed,

$$\begin{aligned}
&\int_Q (a^*(u, Du) - a^*(M_hu, M_hDu), Du - M_hDu)dx \\
&\le C\int_Q (1+|u|^{p-1}+|Du|^{p-1}+|M_hu|^{p-1}+|M_hDu|^{p-1})\nu(|u-M_hu|)|Du-M_hDu|dx \\
&+ C\int_Q (1+|u|^{p-1-\tilde{s}}+|Du|^{p-1-\tilde{s}}+|M_hu|^{p-1-\tilde{s}}+|M_hDu|^{p-1-\tilde{s}})|Du-M_hDu|^{\tilde{s}}dx.
\end{aligned} \tag{22}$$

Using the Holder inequality, it can be easily shown that the second term here converges to zero as $h\to 0$. Since M_hu converges to u in $L^p(Q)$ and M_hDu converges to Du in $L^p(Q)^d$ from Lemma 3.4, the first term in (22) also converges to zero. Similarly one can show that the last term on the r.h.s. of (20) converges to zero as $h\to 0$. This completes the proof of Theorem 3.1.

As an example we consider the correctors for

$$\operatorname{div}(a(T(x/\epsilon)\omega)k_r(u_\epsilon)Du_\epsilon) = f. \tag{23}$$

We assume that the operator satisfies the conditions stated previously. In this case $P(T(y)\omega,\eta,\xi)=\xi+w_{\eta,\xi}(T(y)\omega)$, where $w_{\eta,\xi}\in L^p_{pot}(\Omega)$ satisfies

$$-\mathrm{div}(a(T(x/\epsilon)\omega)k_r(\eta)(\xi+w_{\eta,\xi}))=0.$$

Introducing a notation N such that $w^i_{\eta,\xi}(\omega)=N_{ij}(\omega)\xi_j$, we have the classical equation (see [13]) for $N(\omega)$, i.e., $a(\omega)(I+N)\in L^q_{sol}(\Omega)$. Consequently, the correctors for (23) have the form

$$P(T(y)\omega,\eta,\xi)=\xi(I+N(T(y)\omega)).$$

From this we conclude that u satisfies

$$\mathrm{div}(a^*k_r(u)Du)=f,$$

where a^* is the homogenized tensor corresponding to a linear elliptic operator. The approximation for the gradient of the solution is defined by

$$P(T(x/\epsilon)\omega,M_hu,M_hDu)=M_hDu(I+N(T(x/\epsilon)\omega)).$$

Theorem 3.1 shows a way to compute an approximation for the gradient of u_ϵ, although this computation is difficult since it involves the solution of the auxiliary problem. In the next section we will present the numerical computation of the oscillatory solution.

4. Numerical computation of the homogenized solution.

4.1. Numerical homogenization method. Consider $u_\epsilon\in W^{1,p}_0(Q)$,

$$-\mathrm{div}(a_\epsilon(x,u_\epsilon,Du_\epsilon))+a_{0,\epsilon}(x,u_\epsilon,Du_\epsilon)=f, \tag{24}$$

where $a_\epsilon(x,\eta,\xi)$ and $a_{0,\epsilon}(x,\eta,\xi)$, $\eta\in R$, $\xi\in R^d$, satisfy (4)–(6) and (7). As we mentioned in the introduction, the numerical homogenization procedure and its analysis can be studied for more general heterogeneities using G-convergence theory. The main idea of the numerical homogenization procedure is to find the homogenized solution without using the auxiliary problem. Consider a finite dimensional space over the standard triangular partitions K of $Q=\bigcup K$, and let

(25)
$$S^h=\{v_h\in C^0(\overline{Q})\colon \text{the restriction } v_h \text{ is linear for each element } K \text{ and } v_h=0 \text{ on } \partial Q\},$$

$\mathrm{diam}(K)\le Ch$. Here we assume that $h\gg\epsilon$ is chosen for the approximation of the homogenized solution. The numerical homogenization procedure consists of finding an approximation, $u_h\in S^h$, of a homogenized solution u such that

$$(A_{\epsilon,h}u_h,v_h)=\int_Q fv_h\,dx, \tag{26}$$

where

$$(A_{\epsilon,h}u_h,v_h)=\sum_K\int_K((a_\epsilon(x,\eta^{u_h},Du_{\epsilon,h}),Dv_h)+a_{0,\epsilon}(x,\eta^{u_h},Du_{\epsilon,h})v_h)dx. \tag{27}$$

Here $u_{\epsilon,h}$ satisfies

$$-\mathrm{div}(a_\epsilon(x,\eta^{u_h},Du_{\epsilon,h}))=0 \text{ in } K, \tag{28}$$

$u_{\epsilon,h}=u_h$ on ∂K, and $\eta^{v_h}(=M_hv_h)=\frac{1}{|K|}\int_K v_h dx$ in each K. Our numerical homogenization procedure consists of (26), (27), and (28). In some sense, (27) attempts to approximate $\int_Q[(a^*(x,u_h,Du_h),Dv_h)+a_0^*(x,u_h,Du_h)v_h]dx$, which is a finite element formulation of the homogenized equation. Note that solutions, u_h, of (26) depend on ϵ, which we do not explicitly write because $u_h\in S^h$. We would like to point out that different boundary conditions can be chosen; e.g., one can use an oversampling technique [10], where the solution of the larger problem is used in the calculation of the solution of local problems. We have implemented and shown the advantages of an oversampling technique in our recent work [7]. In the next subsection we will show that the numerical homogenization approach can be considered as a generalization of MsFEM.

Next we briefly describe the numerical implementation of MsFEM for nonlinear elliptic problems. For each $u_h=\sum_i\theta_i\phi_0^i(x)\in S^h$, where $\phi_0^i(x)$ is a basis in S^h, (26) is equivalent to solving

$$F(\theta)=b, \tag{29}$$

where $F(\theta)$ is defined by (27) with $v_h=\phi_0^i(x)$ and $b_i=\int_Q f\phi_0^i(x)dx$. Equation (29) can be solved using Newton's method or its modifications. This involves the inversion of the Jacobian corresponding to $F(\theta)$. When using MsFEM, the Jacobian is a matrix assembled on the coarse grid, which gives us the advantage in the computations.

The following convergence result will be shown.

THEOREM 4.1. *Let u_h and u be solutions of* (26) *and* (2)*, respectively. Then*

$$\lim_{h\to 0}\lim_{\epsilon\to 0}\|u_h-u\|_{W_0^{1,p}(Q)}=0 \tag{30}$$

(up to a subsequence) under some nonrestrictive assumptions on $a^*(x,\eta,\xi)$.

Remark 4.1. Since the proof uses G-convergence theory, the limiting a^* (as well as a_0^*) is not unique, and the convergence of the numerical solutions is up to a subsequence in ϵ; i.e., u_h converges to *a* solution of *a* homogenized equation. We note that for the random homogeneous case the limiting operator is unique and the whole sequence converges. In later analysis, all the limits are taken up to a subsequence.

Note that because of the lack of scale separation, the above result cannot be improved, because there are all the scales $\alpha(\epsilon)$, such that $\alpha(\epsilon)\to 0$ as $\epsilon\to 0$ are present. We have observed significant improvement in the numerical calculation when an oversampling technique is used for problems without scale separation. To show that $u_{\epsilon,h}$ approximates u_ϵ in $W_0^{1,p}(Q)$ we will use the corrector results presented in the previous section.

4.2. Numerical homogenization method and MsFEM. To present the relation between the numerical homogenization approach and MsFEM we introduce the multiscale mapping, $E^{MsFEM}: S^h\to V_\epsilon^h$, a one-to-one operator which is constructed in the following way. For each $v_h\in S^h$, $v_{\epsilon,h}$ is the solution of

$$-\mathrm{div}(a_\epsilon(x,\eta^{v_h},Dv_{\epsilon,h}))=0 \quad \text{in } K; \tag{31}$$

in each K, $v_{\epsilon,h} = v_h$ on ∂K, and $\eta^{v_h} = \frac{1}{|K|}\int_K v_h dx$. In [11] the authors introduce MsFEM, where a basis for V_ϵ^h is constructed by mapping a basis of S^h. The extension of this approach to nonlinear problems yields a nonlinear space for the approximation of heterogeneities. Note that $v_{\epsilon,h}$ are uniquely determined because (31) enjoys the monotonicity property. Now the numerical homogenization procedure can be written in the following way. Find $u_h \in S^h$ (consequently, $u_{\epsilon,h} = E^{MsFEM} u_h \in V_\epsilon^h$) such that

$$(A_{\epsilon,h} u_h, v_h) = \int_Q f v_h dx \qquad \forall v_h \in S^h, \tag{32}$$

where $A_{\epsilon,h}$ is given by (26). Later on we will show that $Du_{\epsilon,h}$ approximates Du_ϵ in $L^p(Q)^d$, assuming that the fluxes $a_\epsilon(x,\eta,\xi)$ and $a_{0,\epsilon}(x,\eta,\xi)$ are random homogeneous fields. Clearly, for periodic problems, (31) can be solved in a period of size ϵ and extended periodically to K. This solution will approximate the solution of (31) and can be used in the construction of $A_{\epsilon,h}$ and in setting up (32) (cf. HMM [6]). The convergence analysis for this case can be easily carried out using periodic correctors, and this will be presented elsewhere. Finally, we would like to note that one can adopt the oversampling technique [10] for nonlinear multiscale finite element methods.

4.3. Proof of Theorem 4.1. The proof of Theorem 4.1 will be carried out in the following way. First we show the coercivity of $A_{\epsilon,h}$ defined by (27). Next we study the limit as $\epsilon \to 0$ of (26) and show that the solution of the limiting equation approximates homogenized solutions. For the sake of simplification of the proof, we assume $\beta = p$ in (4).

LEMMA 4.2. *Let $A_{\epsilon,h}$ be defined by* (27). *Then for sufficiently small h, there exists a constant $C > 0$ such that for any $v_h \in S^h$*

$$(A_{\epsilon,h} v_h, v_h) \geq C \|Dv_h\|_{p,Q}^p - C_1.$$

Proof. Let $\tilde{v}_{\epsilon,h} = v_{\epsilon,h} - v_h$. It follows that $\tilde{v}_{\epsilon,h} \in W_0^{1,p}(K)$ satisfies the following problem:

$$-\text{div } a_\epsilon(x, \eta^{v_h}, D\tilde{v}_{\epsilon,h} + Dv_h) = 0 \quad \text{ in } K. \tag{33}$$

Using (33) and applying Green's theorem and (7), we have the following estimate:

$$\begin{aligned}
(A_{\epsilon,h} v_h, v_h) &= \sum_K \int_K [(a_\epsilon(x, \eta^{v_h}, Dv_{\epsilon,h}), Dv_h) + a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h}) v_h] dx \\
&= \sum_K \int_K [(a_\epsilon(x, \eta^{v_h}, Dv_h + D\tilde{v}_{\epsilon,h}), Dv_h + D\tilde{v}_{\epsilon,h}) + a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h}) v_h] dx \\
&= \sum_K \int_K [(a_\epsilon(x, \eta^{v_h}, Dv_h + D\tilde{v}_{\epsilon,h}), Dv_h + D\tilde{v}_{\epsilon,h}) + a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h}) \eta^{v_h}] dx \\
&\quad + \sum_K \int_K a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h})(v_h - \eta^{v_h}) dx \\
&\geq C \sum_K \int_K |Dv_h + D\tilde{v}_{\epsilon,h}|^p dx - Ch \left(1 + \sum_K \int_K |Dv_h|^p dx\right) - C_1.
\end{aligned}$$

Here we have also used the fact that $\int_K |\eta^{v_h}|^p dx \le C \int_K |v_h|^p dx$. Next we will show that

$$\sum_K \int_K |Dv_h + D\tilde{v}_{\epsilon,h}|^p dx = \sum_K \int_K |Dv_{\epsilon,h}|^p \, dx \ge C \sum_K \int_K |Dv_h|^p dx.$$

We note that v_h is piecewise linear on ∂K for triangular mesh, i.e., $v_{\epsilon,h}|_{\partial K} = v_h = \beta + (Dv_h, x - x_0)$, for some constants β and x_0 independent of Dv_h. We set $\bar{v}_{\epsilon,h} = v_{\epsilon,h} - \beta$. Then, by change of variable and homogeneity argument and applying the trace theorem, we have

$$\begin{aligned}\sum_K \int_K |Dv_{\epsilon,h}|^p dx &\ge C \sum_K \frac{h^d}{h^p} \int_{K_r} |D_y \bar{v}_{\epsilon,h}|^p dy \\ &\ge C \sum_K \frac{h^d}{h^p} \int_{\partial K_r} |(Dv_h, y\, h)|^p dy = C \sum_K h^d |Dv_h|^p C(e_{Dv_h}),\end{aligned}$$

where K_r is a reference triangle of size of order 1, e_{Dv_h} is the unit vector in the direction of Dv_h, and

$$C(e_{Dv_h}) = \int_{\partial K_r} |(e_{Dv_h}, y)|^p dy.$$

Here we have used the trace inequality, $\|u\|_{L^p(\partial Q)} \le C \|u\|_{W^{1,p}(Q)}$, and taken into account the equivalence of finite dimensional norms for every h. One can further show that $C(e_\xi)$ is bounded from below independent of ξ and h. By contradiction, suppose that the claim is not true. Then there exists a sequence $\{e_{\xi_n}\}$ which has a subsequence (denoted by the same notation) such that $e_{\xi_n} \to e_*$ and $C(e_{\xi_n}) \to 0$ as $n \to \infty$. Since $C(e_\xi)$ is continuous, it follows that $C(e_*) = 0$. This further implies that $(e_*, y) = 0$ on ∂K_r, and hence $e_* = 0$. This is a contradiction. ∎

Next we show that $A_{\epsilon,h}$ is equicontinuous for any h in any compact set.

LEMMA 4.3. *For any $v_h \in S^h$ and $w_h \in S^h$ in a compact set we have*

$$\|A_{\epsilon,h} v_h - A_{\epsilon,h} w_h\|^p \le C \left(\sum_K \int_K (|D(v_h - w_h)|^p + \nu(|\eta^{v_h} - \eta^{w_h}|)) dx \right)^{1/p},$$

where C does not depend on ϵ.

Since this result is for fixed h (i.e., finite dimensional), we do not specify the norm.

Proof.

$$\begin{aligned}\|A_{\epsilon,h} v_h - A_{\epsilon,h} w_h\| &= \sum_K \int_K |a_\epsilon(x, \eta^{v_h}, Dv_{\epsilon,h}) - a_\epsilon(x, \eta^{w_h}, Dw_{\epsilon,h})| dx \\ &\quad + \sum_K \int_K |a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h}) - a_{0,\epsilon}(x, \eta^{w_h}, Dw_{\epsilon,h})| dx.\end{aligned} \tag{34}$$

Next we will estimate the first term on the r.h.s. of (34). The estimate for the second

term is analogous.

$$
\begin{aligned}
&\sum_K \int_K |a_\epsilon(x,\eta^{v_h},Dv_{\epsilon,h}) - a_\epsilon(x,\eta^{w_h},Dw_{\epsilon,h})|dx \\
&\quad \le C\sum_K \int_K (1+|\eta^{v_h}|+|\eta^{w_h}|+|Dv_{\epsilon,h}|+|Dw_{\epsilon,h}|)^{p-1}\nu(|\eta^{v_h}-\eta^{w_h}|) \\
&\quad + C\sum_K \int_K (1+|\eta^{v_h}|+|\eta^{w_h}|+|Dv_{\epsilon,h}|+|Dw_{\epsilon,h}|)^{p-1-s}|Dv_{\epsilon,h}-Dw_{\epsilon,h}|^s \\
&\quad \le C\left(\sum_K \int_K \nu(|\eta^{v_h}-\eta^{w_h}|)^p dx\right)^{1/p} + C\left(\sum_K \int_K |Dv_{\epsilon,h}-Dw_{\epsilon,h}|^p\right)^{1/p}.
\end{aligned} \tag{35}
$$

Here we have used the Cauchy inequality along with the facts that $\|Dv_{\epsilon,h}\|_{p,K} \le C\|Dv_h\|_{p,K}$, $\|Dw_{\epsilon,h}\|_{p,K} \le C\|Dw_h\|_{p,K}$, and $\|Dv_h\|_{p,Q} \le C$, $\|Dw_h\|_{p,Q} \le C$. It remains to estimate the second term on the r.h.s. of (35).

(36)

$$
\begin{aligned}
&\sum_K \int_K |Dv_{\epsilon,h}-Dw_{\epsilon,h}|^p \\
&\quad \le C\sum_K \int_K (a_\epsilon(x,\eta^{v_h},Dv_{\epsilon,h}) - a_\epsilon(x,\eta^{v_h},Dw_{\epsilon,h}), Dv_{\epsilon,h}-Dw_{\epsilon,h})dx \\
&\quad \le \sum_K \int_K (a_\epsilon(x,\eta^{v_h},Dw_{\epsilon,h}) - a_\epsilon(x,\eta^{w_h},Dw_{\epsilon,h}), Dv_{\epsilon,h}-Dw_{\epsilon,h})dx \\
&\qquad + \sum_K \int_K (a_\epsilon(x,\eta^{w_h},Dw_{\epsilon,h}) - a_\epsilon(x,\eta^{v_h},Dw_{\epsilon,h}), Dv_{\epsilon,h}-Dw_{\epsilon,h})dx \\
&\quad \le C\sum_K \int_K (a_\epsilon(x,\eta^{v_h},Dv_{\epsilon,h}) - a_\epsilon(x,\eta^{w_h},Dw_{\epsilon,h}), Dv_h + D\tilde{v}_{\epsilon,h} - Dw_h - D\tilde{w}_{\epsilon,h})dx \\
&\qquad + C\sum_K \int_K (a_\epsilon(x,\eta^{w_h},Dw_{\epsilon,h}) - a_\epsilon(x,\eta^{v_h},Dw_{\epsilon,h}), Dv_{\epsilon,h}-Dw_{\epsilon,h})dx \\
&\quad \le C\sum_K \int_K (a_\epsilon(x,\eta^{v_h},Dv_{\epsilon,h}) - a_\epsilon(x,\eta^{w_h},Dw_{\epsilon,h}), Dv_h - Dw_h)dx \\
&\qquad + C\sum_K \int_K \nu(|\eta^{w_h}-\eta^{v_h}|)^p dx \\
&\quad \le C\left(\sum_K \int_K |Dv_h-Dw_h|^p dx\right)^{1/p} + C\sum_K \int_K \nu(|\eta^{w_h}-\eta^{v_h}|)^p dx.
\end{aligned}
$$

Here we have used Holder and Cauchy inequalities along with the facts that $\|Dv_{\epsilon,h}\|_{p,K} \le C\|Dv_h\|_{p,K}$, $\|Dw_{\epsilon,h}\|_{p,K} \le C\|Dw_h\|_{p,K}$, and $\|Dv_h\|_{p,Q} \le C$, $\|Dw_h\|_{p,Q} \le C$, and that $v_{\epsilon,h} = v_h + \tilde{v}_{\epsilon,h}$, where $\tilde{v}_{\epsilon,h} \in W_0^{1,p}(K)$ satisfies $-\text{div } a_\epsilon(x,\eta^{v_h}, Dv_h + D\tilde{v}_{\epsilon,h}) = 0$. The estimates (35) and (36) give us the estimate for the first term of the r.h.s. of (34). A similar estimate for the second term can be obtained in a very analogous manner. □

The coercivity and continuity of $A_{\epsilon,h}$ guarantee the existence of a solution for the

discrete equation

$$(A_{\epsilon,h}u_{\epsilon,h}, w_h) = \int_Q f w_h dx. \tag{37}$$

LEMMA 4.4. *For any $v_h \in S^h$ and $w_h \in S^h$*

$$\lim_{\epsilon\to 0}(A_{\epsilon,h}v_h, w_h) = (A_h v_h, w_h)$$

(up to a sub-sequence), where the r.h.s. is defined as

$$(A_h v_h, w_h) = \sum_K \int_K [(a^*(x, \eta^{v_h}, Dv_0), Dw_h) + a_0^*(x, \eta^{v_h}, Dv_0)w_h]dx$$

and v_0 is the solution of $v_0 - v_h \in W_0^{1,p}(K)$,

$$-\mathrm{div}(a^*(x, \eta^{v_h}, Dv_0)) = 0.$$

Here $a^*(x, \eta, \xi)$ is a G-limit of the corresponding limit operator.

Proof. Using the theorem on G-convergence of arbitrary solutions [17, p. 87], we obtain that solutions $v_{\epsilon,h}$ of (31) weakly converge to v_0 in $W^{1,p}(K)$, and $a_\epsilon(x, \eta^{v_h}, Dv_{\epsilon,h})$ weakly converges to $a^*(x, \eta^{v_h}, Dv_0)$ in $L^q(K)^d$, and $a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h})$ weakly converges to $a_0^*(x, \eta^{v_h}, Dv_0)$ in $L^q(K)$ (up to a subsequence), where $a^*(x, \eta, \xi)$ and $a_0^*(x, \eta, \xi)$ are the fluxes corresponding to a G-limit of the original operators. Thus,

$$\lim_{\epsilon\to 0}(A_{\epsilon,h}v_h, w_h) = \lim_{\epsilon\to 0}\sum_K \int_K [(a_\epsilon(x, \eta^{v_h}, Dv_{\epsilon,h}), Dw_h) + a_{0,\epsilon}(x, \eta^{v_h}, Dv_{\epsilon,h})w_h]dx$$

$$= \sum_K \int_K [(a^*(x, \eta^{v_h}, Dv_0), Dw_h) + a_0^*(x, \eta^{v_h}, Dv_0)w_h]dx = (A_h v_h, w_h). \qquad \square$$

It can be easily shown that A_h is coercive for small h. Since $A_{\epsilon,h}$ is equicontinuous in any compact set, the results of Lemma 4.4 hold for any $v_h \in S^h$ and $w_h \in S^h$ that are uniformly bounded (finite dimensional). Thus, taking the limit $\epsilon \to 0$ of (37) (up to a subsequence), we obtain

$$(A_h u_h, w_h) = \int_Q f w_h dx.$$

From Lemma 4.2 and the continuity of A_h (which can be easily verified) it follows that u_h exists and is uniformly bounded in $W_0^{1,p}(Q)$, and thus $u_h \to u$ (up to a subsequence) weakly in $W_0^{1,p}(Q)$. Our task to show that u is a solution of the homogenized equation. The following lemma is needed for this purpose.

LEMMA 4.5. *Assume that $v_h \in S^h$ and Dv_h are uniformly bounded in $L^{p+\alpha}(Q)^d$ (with $\alpha > 0$) and $w_h \in S^h$ and Dw_h are uniformly bounded in $L^p(Q)^d$. Then*

$$\lim_{h\to 0}(A_h v_h - A^* v_h, w_h) = 0,$$

where

$$(A^* v_h, w_h) = \sum_K \int_K [(a^*(x, v_h, Dv_h), Dw_h) + a_0^*(x, v_h, Dv_h)w_h]dx.$$

Proof.

$$(A_h v_h - A^* v_h, w_h) = \sum_K \int_K [(a^*(x, \eta^{v_h}, Dv_0) - a^*(x, v_h, Dv_h), Dw_h) + (a_0^*(x, \eta^{v_h}, Dv_0) - a_0^*(x, v_h, Dv_h))w_h]dx. \tag{38}$$

Next we will show that the first and second terms on the r.h.s. of (38) converge to zero. For the first term we have

(39)

$$\begin{aligned}
&\sum_K \int_K (a^*(x, \eta^{v_h}, Dv_0) - a^*(x, v_h, Dv_h), Dw_h)dx \\
&\quad \le C \sum_K \int_K \nu(|v_h - \eta^{v_h}|)(1 + |\eta^{v_h}|^{p-1} + |v_h|^{p-1} + |Dv_0|^{p-1} + |Dv_h|^{p-1})|Dw_h|dx \\
&\qquad + C \sum_K \int_K (1 + |\eta^{v_h}| + |v_h| + |Dv_0| + |Dv_h|)^{p-1-s}|Dv_h - Dv_0|^s |Dw_h|dx \\
&\quad \le C \sum_K \left(\int_K \nu(|v_h - \eta^{v_h}|)^q (1 + |Dv_h|^p)dx \right)^{1/q} \left(\int_K |Dw_h|^p dx \right)^{1/p} \\
&\qquad + C \sum_K \left(\int_K (1 + |Dv_h|^p)dx \right)^{(p-qs)/pq} \left(\int_K |D(v_h - v_0|^p dx \right)^{s/p} \left(\int_K |Dw_h|^p dx \right)^{1/p} \\
&\quad = C \left(\int_Q \nu(|v_h - \eta^{v_h}|)^q (1 + |Dv_h|^p)dx \right)^{1/q} + C \left(\int_Q |D(v_h - v_0)|^p dx \right)^{s/p}.
\end{aligned}$$

Here we have used the Cauchy inequality along with the facts that $\|Dw_h\|_{p,Q} \le C$, $\int_K |Dv_0|^p dx \le C \int_K |Dv_h|^p dx$, $\int_K |v_h|^p dx \le C \int_K |Dv_h|^p dx$, and $\int_K |\eta^{v_h}|^p dx \le C \int_K |Dv_h|^p dx$. Next we will show that $\|Dv_h - Dv_0\|_{p,Q} \to 0$ as $h \to 0$ under some assumptions regarding the regularity of $a^*(x, \eta, \xi)$ with respect to spatial variables. Moreover, this convergence is uniform for a uniformly bounded family of Dv_h. Define $\overline{a^*}_K(x, \eta, \xi)$ as a piecewise constant function on each K and η, ξ defined in each K by

$$\overline{a^*}_K(\eta, \xi) = \frac{1}{|K|} \int_K a^*(x, \eta, \xi).$$

We assume that in each K

$$|a^*(x, \eta, \xi) - \overline{a^*}_K(\eta, \xi)| \le \alpha_h (1 + |\eta|^{p-1} + |\xi|^{p-1}), \tag{40}$$

where α_h is a generic sequence such that $\alpha_h \to 0$ as $h \to 0$ and is independent of K. For example, this condition is satisfied if $a^*(x, \eta, \xi)$ is a Holder function with respect to spatial variables. Note that for random homogeneous operators, (40) trivially holds because a^* is independent of x.

Then

$$\begin{aligned}
\|Dv_h - Dv_0\|^p_{p,Q} &\le C\sum_K \int_K (a^*(x,\eta^{v_h},Dv_h) - a^*(x,\eta^{v_h},Dv_0), Dv_h - Dv_0)dx \\
&= C\sum_K \int_K (a^*(x,\eta^{v_h},Dv_h) - \overline{a^*}_K(\eta^{v_h},Dv_h), Dv_h - Dv_0)dx \\
&\quad + C\sum_K \int_K (\overline{a^*}_K(\eta^{v_h},Dv_h) - a^*(x,\eta^{v_h},Dv_0), Dv_h - Dv_0)dx \\
&= C\sum_K \int_K (a^*(x,\eta^{v_h},Dv_h) - \overline{a^*}_K(\eta^{v_h},Dv_h), Dv_h - Dv_0)dx \\
&\le C\alpha_h \sum_K \int_K (1 + |\eta^{v_h}|^{p-1} + |Dv_h|)^{p-1}|Dv_h - Dv_0|dx \\
&\le C\alpha_h (1 + \|Dv_h\|^{p/q}_{p,Q})\|Dv_h - Dv_0\|_{p,Q}.
\end{aligned}$$

From here it follows that $\|Dv_h - Dv_0\|_{p,Q} \to 0$ as $h \to 0$.

We note that the r.h.s. of (39) converges to zero because $\|Dv_h - Dv_0\|_{p,Q} \to 0$ as $h \to 0$ and because of Lemma 3.4. Thus, the first term on the r.h.s. of (38) converges to zero.

For the second term on the r.h.s. of (38) we have

(41)

$$\begin{aligned}
&\sum_K \int_K (a_0^*(x,\eta^{v_h},Dv_0) - a_0^*(x,v_h,Dv_h))w_h dx \\
&\quad \le C\sum_K \int_K \nu(|v_h - \eta^{v_h}|)(1 + |\eta^{v_h}|^{p-1} + |v_h|^{p-1} + |Dv_0|^{p-1} + |Dv_h|^{p-1})|w_h|dx \\
&\qquad + C\sum_K \int_K (1 + |\eta^{v_h}| + |v_h| + |Dv_0| + |Dv_h|)^{p-1-s}|Dv_h - Dv_0|^s|w_h|dx.
\end{aligned}$$

Clearly one can do the same manipulations as the those for the first term of the r.h.s. of (38) to show that the r.h.s. of (41) converges to zero as $h \to 0$. □

For the proof of Theorem 4.1 we assume that Du_h is uniformly bounded in $L^{p+\alpha}(Q)^d$ for some $\alpha > 0$. One can assume additional nonrestrictive regularity assumptions [16] for input data and obtain Meyers-type estimates, $\|Du\|_{p+\alpha,Q} \le C$, for the homogenized solutions. In this case it is reasonable also to assume that the discrete solutions are uniformly bounded in $L^{p+\alpha}(Q)^d$. We have obtained results on Meyers-type estimates for our approximate solutions in the case $p = 2$ (see [8]). We are currently studying the generalization of these results to arbitrary p. One can impose different kinds of assumptions for which the Lemma 4.5 holds without assuming that Du_h is uniformly bounded in $L^{p+\alpha}(Q)^d$, e.g.,

$$|a^*(x,\eta,\xi) - a^*(s,\eta',\xi)| \le C(1 + |\eta|^{p-1} + |\eta'|^{p-1} + |\xi|^{p-1-r})|\eta - \eta'|^r$$

$(0 < r < 1)$.

To conclude the proof of Theorem 4.1 we note that $u_h \to u$ (up to a sub-sequence) weakly in $W_0^{1,p}(Q)$, and our goal is to show that u is a solution of the homogenized equation. Using Lemma 4.5, we obtain that

$$(A_h u_h - A^* u_h, v_h) = \int_Q f v_h dx - (A^* u_h, v_h).$$

Thus it follows from Lemma 4.5 that $A^*u_h \to f$ weakly in $W^{-1,p}(Q)$. Moreover, using Lemma 4.5, we obtain that $(A^*u_h, u_h) \to \int_Q f v_h dx$. Since the operator A^* is of type M (see [20]), we obtain that $A^*u = f$; i.e., u is a solution of a homogenized equation. Moreover, A^* is also of type S_+ (see [21]), which allows us to state that $u_h \to u$ *strongly* in $W_0^{1,p}(Q)$.

Remark 4.2. We would like to note that in the periodic and random homogeneous cases Theorem 4.1 holds in the limit $\epsilon/h \to 0$; i.e., $h = h(\epsilon) \gg \epsilon$. This will be presented elsewhere.

Remark 4.3. Finally we would like to note that Theorem 4.1 is proved under the assumptions (40) and $\|Du_h\|_{p+\alpha,Q} \le C$, $\alpha > 0$. The latter has been shown for $p = 2$ in [8].

4.4. Approximation of the oscillations. In order to approximate solutions u_ϵ in the $W^{1,p}$-norm, we assume $a_\epsilon(x,\eta,\xi) = a(T(x/\epsilon),\eta,\xi)$ and $a_{0,\epsilon}(x,\eta,\xi) = a_0(T(x/\epsilon),\eta,\xi)$. Then the following theorem holds.

THEOREM 4.6.

$$\lim_{h\to 0}\lim_{\epsilon\to 0}\|D(u_{\epsilon,h} - u_\epsilon)\|_{p,Q} = 0,$$

where $u_{\epsilon,h} = E^{MsFEM}u_h$, *defined by* (31) *(or* (28) *in each* K*).*

Proof. Because of Theorem 3.1 we need to show only that

$$\lim_{h\to 0}\lim_{\epsilon\to 0}\|Du_{\epsilon,h} - P(T(x/\epsilon)\omega, M_h u, M_h Du)\|_{p,Q} = 0.$$

Similarly,

$$\lim_{\epsilon\to 0}\|Du_{\epsilon,h} - P(T(x/\epsilon)\omega, M_h u_h, M_h Du_h)\|_{p,K} = 0. \tag{42}$$

Equation (42) follows from the fact that $-\mathrm{div}(a^*(\eta^{u_h}, D_x u_h)) = 0$, i.e., the homogenized solution for $u_{\epsilon,h}$ is u_h. Consequently,

$$\lim_{\epsilon\to 0}\|Du_{\epsilon,h} - P(T(x/\epsilon)\omega, M_h u_h, M_h Du_h)\|_{p,Q} = 0.$$

It remains to show that

$$\lim_{h\to 0}\lim_{\epsilon\to 0}\|P(T(x/\epsilon)\omega, M_h u_h, M_h Du_h) - P(T(x/\epsilon)\omega, M_h u, M_h Du)\|_{p,Q} = 0.$$

To show this we need the estimate for $\int_\Omega |P(\omega,\eta_1,\xi_1) - P(\omega,\eta_2,\xi_2)|^p d\mu(\omega)$. Define $P_1 = P(\omega,\eta_1,\xi_1)$ and $P_2 = P(\omega,\eta_2,\xi_2)$. Then

$$\begin{aligned}
\int_\Omega |P_1 - P_2|^p d\mu(\omega) &\le C\int_\Omega (a(\omega,\eta_1,P_1) - a(\omega,\eta_1,P_2), P_1 - P_2) d\mu(\omega)\\
&= \int_\Omega (a(\omega,\eta_1,P_1) - a(\omega,\eta_2,P_2), P_1 - P_2) d\mu(\omega)\\
&\quad + \int_\Omega (a(\omega,\eta_2,P_2) - a(\omega,\eta_1,P_2), P_1 - P_2)) d\mu(\omega)\\
&\le \int_\Omega (a(\omega,\eta_1,P_1) - a(\omega,\eta_2,P_2), \xi_1 - \xi_2) d\mu(\omega)\\
&\quad + \frac{C}{\delta_1}\int_\Omega (1 + |\eta_1|^p + |\eta_2|^p + |P_2|^p)\nu(|\eta_1 - \eta_2|) d\mu(\omega)\\
&\quad + C\delta_1 \int_\Omega |P_1 - P_2|^p d\mu(\omega).
\end{aligned}$$

Choosing δ_1 appropriately small and using (10), we have

(43)
$$\int_\Omega |P_1 - P_2|^p d\mu(\omega)$$
$$\leq (a^*(\eta_1,\xi_1) - a^*(\eta_2,\xi_2), \xi_1 - \xi_2) + C\int_\Omega (1 + |\eta_1|^p + |\eta_2|^p + |P_2|^p)\nu(|\eta_1 - \eta_2)d\mu(\omega).$$

Using (43), we have

$$\lim_{h\to 0}\lim_{\epsilon\to 0} \|P(T(x/\epsilon)\omega, M_h u_h, M_h Du_h) - P(T(x/\epsilon)\omega, M_h u, M_h Du)\|_{p,Q}$$
$$\leq \lim_{h\to 0}\sum_K \int_K (a^*(M_h u_h, M_h Du_h) - a^*(M_h u, M_h Du), M_h Du_h - M_h Du)dx$$
$$+ C\lim_{h\to 0}\sum_K \int_K (1 + |M_h u_h| + |M_h u| + |M_h Du|)^p \nu(|M_h u_h - M_h u|)dx.$$

The r.h.s. of (4.4) converges to zero, which can be established in a manner similar to the convergence analysis of the r.h.s. of (20). □

5. Numerical results. Our first numerical example is a nonlinear convection diffusion equation in two dimensions:

$$\frac{1}{\epsilon} v(T(x/\epsilon)\omega)\cdot DF(u_\epsilon) - d\Delta u_\epsilon = f, \tag{44}$$

where div$v = 0$. Assuming that there exists a homogeneous stream function $\mathcal{H}(T(x/\epsilon)\omega)$,

$$\mathcal{H} = \begin{pmatrix} 0 & H(T(x/\epsilon)\omega) \\ -H(T(x/\epsilon)\omega) & 0 \end{pmatrix},$$

such that div$\mathcal{H} = v$, we obtain

$$\text{div}(-d\delta_{ij} Du_\epsilon + \mathcal{H}(T(x/\epsilon)\omega)DF(u_\epsilon)) = f$$

or

$$-\text{div}(a(T(x/\epsilon)\omega, u_\epsilon)Du_\epsilon) = f,$$

where

$$a = \begin{pmatrix} -d & H(T(x/\epsilon)\omega)F'(u) \\ -H(T(x/\epsilon)\omega)F'(u) & -d \end{pmatrix}.$$

We assume that a satisfies the assumptions imposed in previous sections. The auxiliary problem is defined as follows: $w_{\eta,\xi}(\omega) \in V^p_{pot}$ is the solution of

$$\text{div}(a(T(y)\omega, \eta)(\xi + w_{\eta,\xi}(T(y)\omega))) = 0.$$

Introducing $N^j_\eta(T(y)\omega) \in V^p_{pot}$ such that $w^i_{\eta,\xi}(T(y)\omega) = N^{ij}_\eta(T(y)\omega)\xi_j$, we have

$$\text{div}(a(T(y)\omega, \eta)(I + N_\eta(T(y)\omega))) = 0,$$

where I is the identity matrix. Using $w_{\eta,\xi}$, we can compute the homogenized operator that is given by

$$\operatorname{div}(a^*(u)Du) = f,$$

where $a^*_{ij}(\eta) = -d\delta_{ij} + \langle H_{ik}F'(\eta)N^{kj}_\eta\rangle$. Here we have taken into account that $\langle N\rangle = 0$ since $N \in V^p_{pot}$. The term $\langle H_{ik}F'(\eta)N^{kj}_\eta\rangle$ can be regarded as an enhanced diffusion due to heterogeneous convection, similar to the linear case [9]. A numerical corrector is defined as

$$\mathcal{P}_\epsilon = M_h Du(I + w_{M_h u}(T(x/\epsilon)\omega)).$$

Next we present numerical examples where the enhanced diffusivity is approximately computed locally. It is more transparent for this purpose to use a parabolic equation,

$$\frac{\partial u_\epsilon}{\partial t} + \frac{1}{\epsilon}v(T(x/\epsilon)\omega)\cdot DF(u_\epsilon) = d\Delta u_\epsilon. \tag{45}$$

Using general G-convergence theory, we have the following equation for the homogenized solution:

$$\frac{\partial u}{\partial t} = \operatorname{div}(a^*(u)u), \tag{46}$$

where $a^*(\eta)$ is the homogenized operator derived from the elliptic problem shown above. In particular, $a^*_{ij} = d\delta^{ij} + a^c_{ij}$, where $a^c_{ij}(\eta) = -\langle H_{ik}F'(\eta)N^{kj}_\eta\rangle$ is the enhanced diffusion due to nonlinear heterogeneous convection. It can be shown that the corrector has the same form as in the elliptic case

$$P(T(x/\epsilon)\omega, M_h u(t,x), M_h Du(t,x)) = M_h Du(t,x)(I + w_{M_h u(t,x)}(T(x/\epsilon)\omega)),$$

i.e., all the time dependence is in the homogenized solution. The proof is the same as in the elliptic case.

To illustrate the significance of the enhanced diffusion, we present some numerical examples. Numerical tests are performed using the finite element method. First we present the total diffusivity as a function of η (i.e., average of the solution) for two different heterogeneous velocity fields given by the stream functions $H = \sin(2\pi y/\epsilon) + \sin(2\sqrt{(}2)\pi y/\epsilon)$. We take $\epsilon = 0.1$ and $d = 0.1$ (molecular diffusion). The flux function is chosen to be the Buckley–Leverett function $F(u) = u^2/(u^2 + 0.2(1-u)^2))$ motivated by porous media flows. The enhanced diffusion is computed by solving the problem in a unit square, and thus it is only an approximate value of it. In Figure 1 we plot the total diffusivity. The left plot in this figure represents the total diffusivity in the horizontal direction (along the layers), and the right plot represents the total diffusivity in the vertical direction. Clearly, the diffusion is enhanced dramatically in the horizontal direction, that is, along the convection (note the ten-fold difference between the y-axis scales). As we see for $\eta \approx 0.4$, there is a 15-fold increase in the diffusion relative to molecular diffusion, d. Moreover, since $F'(0) = F'(1) = 0$, there is no enhancement if $\eta = 0$ or $\eta = 1$ (this corresponds to pure phases). For the cellular flow, $H(x,y) = \sin(2\pi y/\epsilon)\sin(2\pi x/\epsilon)$, we obtain isotropic diffusion, which is shown in Figure 2.

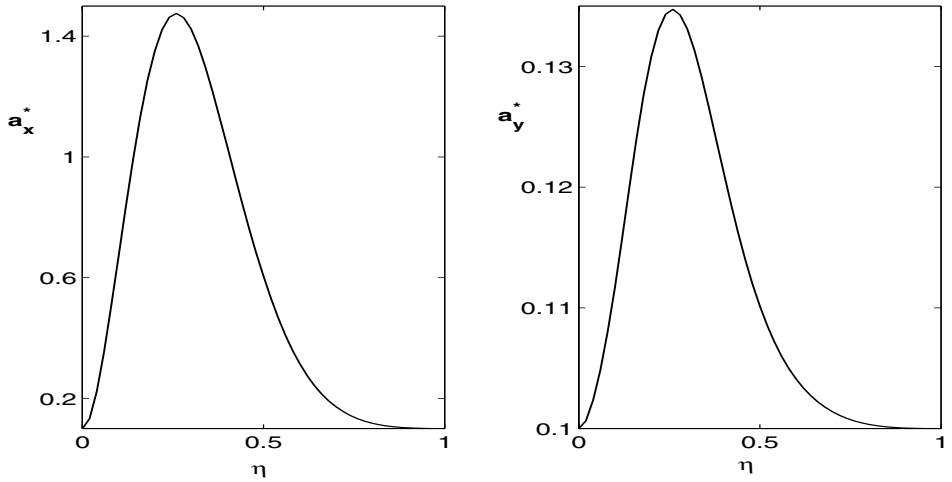

FIG. 1. *Horizontal (left) and vertical (right) effective diffusivity for the layered media with stream function* $H(x,y) = \sin(2\pi y/\epsilon)$ *and flux function* $F(u) = u^2/(u^2 + 0.2(1-u)^2)$.

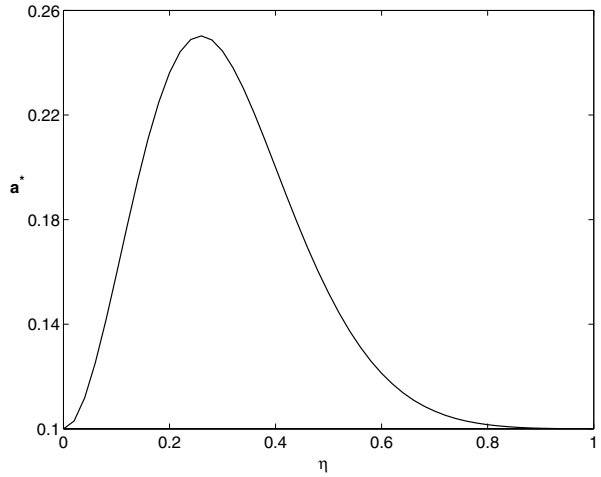

FIG. 2. *Effective diffusivity for the isotropic media with stream function* $H(x,y) = \sin(2\pi y/\epsilon) \times \sin(2\pi x/\epsilon)$ *and flux function* $F(u) = u^2/(u^2 + 0.2(1-u)^2)$.

The next set of numerical examples is designed to compare the solutions of the original (fine scale equation) with the solutions of the equations obtained using numerical homogenization with and without enhanced diffusion. Our goal here is to illustrate the importance of nonlinear enhanced diffusion. We consider

$$\frac{\partial u_\epsilon}{\partial t} + \frac{1}{\epsilon} v_\epsilon \cdot DF(u_\epsilon) = d\Delta u_\epsilon \tag{47}$$

in a unit square domain with boundary and initial conditions as follows: $u_\epsilon = 1$ at the inlet ($x_1 = 0$), $u_\epsilon = 0$ at the outlet ($x_1 = 1$), and no flow boundary conditions on the lateral sides $x_2 = 0$ and $x_2 = 1$. We have tested various heterogeneous fields for the velocity, and we present here a result for the layered flow, $H = \sin(2\pi y/\epsilon)$.

In Figure 3 we plot the average (over the whole domain) of the solutions of (47) ($\frac{1}{Q}\int_Q u_\epsilon(x,t)dx$) as a function of time. We compare the fine scale solution with the

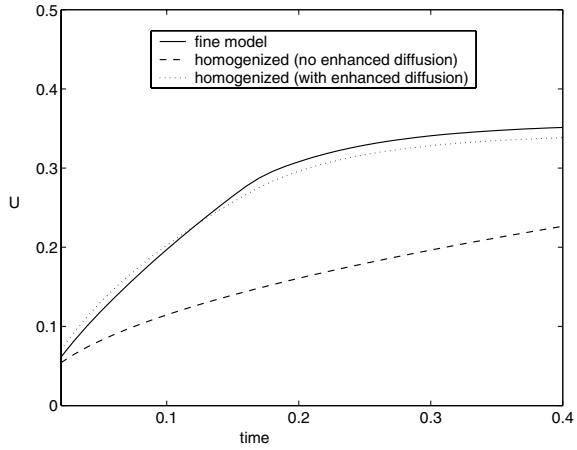

FIG. 3. *Comparison of the average u over the whole domain for three problems:* (1) *fine scale (designated with a solid line),* (2) *homogenized solution with no enhanced diffusion (designated with a dashed line), and* (3) *homogenized solution with enhanced diffusion (designated with a dotted line). In this case* $H(x,y) = \sin(2\pi y/\epsilon)$ *and* $F(u) = u^2/(u^2 + 0.2(1-u)^2)$.

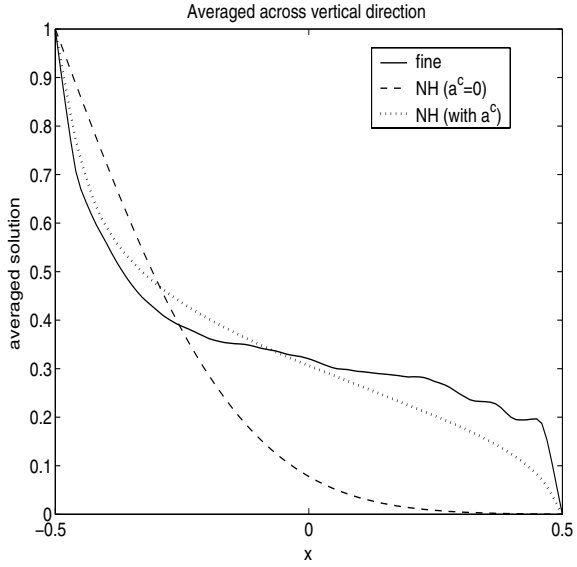

FIG. 4. *Vertical average (across the heterogeneities) of the solution for the layered media with stream function* $H(x,y) = \sin(2\pi y/\epsilon)$ *and flux function* $F(u) = u^2/(u^2 + 0.2(1-u)^2)$ *at time* 0.4.

coarse scale solutions where the enhanced diffusivity is taken into account; i.e., it can be considered as a numerical homogenization procedure with one coarse block. We also consider the coarse scale solution where the enhanced diffusion is neglected, i.e, $u_t = d\Delta u$. As we see from this figure, the solution computed with enhanced diffusion performs well and gives a reasonable approximation of the fine scale solution. On the other hand, the average solution that does not account for enhanced diffusion performs very poorly. In Figure 4 we plot the average along the horizontal direction (x_2)

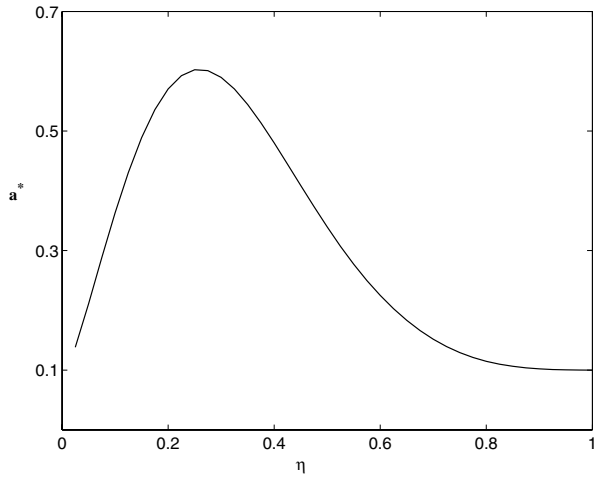

FIG. 5. *Effective diffusivity for the isotropic media with Gaussian stream function which has correlation lengths* $l_x = l_y = 0.1$*, mean zero, and variance* 0.5*. The flux function is chosen as* $F(u) = u^2/(u^2 + 0.2(1-u)^2)$ *and* $d = 0.1$ *(see* (44)*).*

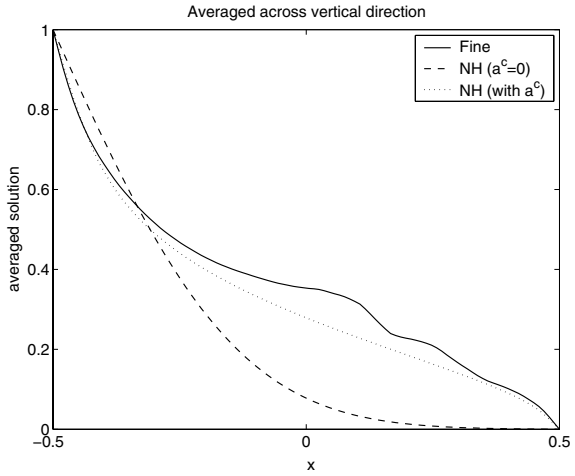

FIG. 6. *Average of the solution along the horizontal direction at* $t = 0.4$ *for Gaussian stream function which has correlation lengths* $l_x = l_y = 0.1$*, mean zero, and variance* 0.5*. The flux function is chosen as* $F(u) = u^2/(u^2 + 0.2(1-u)^2)$ *and* $d = 0.1$ *(see* (44)*).*

(across heterogeneities) of the solutions at time 0.4. The figure clearly indicates the importance of having enhanced diffusion in the homogenized setting of the problem. Next we present an example where the stream function $H(x, y)$ is a realization of the random field with Gaussian distribution. To generate a realization of the random field with prescribed correlation lengths, we use GSLIB [5]. In particular, $H(x, y)$ is a realization of a Gaussian field with correlation lengths $l_x = l_y = 0.1$, and with mean zero and variance 0.5. Here $d = 0.1$ and $F(u) = u^2/(u^2+0.2(1-u)^2)$ are used in (44). In Figure 5 we plot the total diffusivity. As we see, the enhancement of the diffusion can be up to 6 times the molecular diffusion, d. Since the stream field is isotropic, it is sufficient to consider total diffusion in one direction. In Figure 6 we plot a cross section

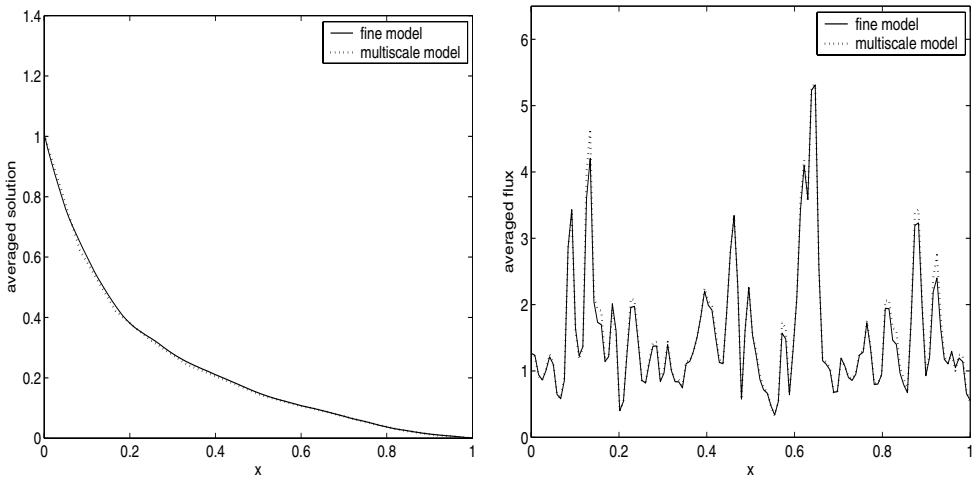

FIG. 7. *Left: the solutions are averaged in the vertical direction. Right: the fluxes are averaged in the vertical direction.*

of the solution at time 0.4. These results clearly indicate the importance of enhanced diffusion. For different realizations of the random field we have observed similar results. We note that this example can be easily generalized to nonlinear convection diffusion of more general form, $\frac{1}{\epsilon}v(T(x/\epsilon)\omega)\cdot DF(u_\epsilon) - \mathrm{div}(a(T(x/\epsilon)\omega, u_\epsilon, Du_\epsilon)) = f$.

Finally, we consider an application of the numerical homogenization procedure to Richards equations, $\mathrm{div}(a_\epsilon(x,u_\epsilon)D_x u_\epsilon) = 0$, where $a_\epsilon(x,\eta) = k_\epsilon(x)/(1+\eta)^{\alpha_\epsilon(x)}$. $k_\epsilon(x) = \exp(\beta_\epsilon(x))$ is chosen such that $\beta_\epsilon(x)$ is a realization of a random field with the spherical variogram [5], correlation lengths $l_x = 0.2$, $l_y = 0.02$, and variance $\sigma = 1.5$. Here $\alpha_\epsilon(x)$ is chosen such that $\alpha_\epsilon(x) = k_\epsilon(x) + const$ with the spatial average of 2. In Figure 7 we compare the solutions (u_ϵ) and the fluxes $(-a_\epsilon(x,u_\epsilon)D_x u_\epsilon)$ corresponding to this equation with boundary and initial conditions given as previously. The solutions are rescaled for comparison purposes. The solid line designates the fine scale model results computed on a 120×120 grid, and the dotted line designates the coarse scale results computed using the numerical homogenization procedure on a 12×12 coarse grid. These results demonstrate the robustness of our approach for anistropic fields where h and ϵ are nearly the same. For different realizations of the random field we have observed similar results. Currently, we are studying the application of the oversampling technique to the numerical homogenization procedure.

ANALYSIS OF A CANARD MECHANISM BY WHICH EXCITATORY SYNAPTIC COUPLING CAN SYNCHRONIZE NEURONS AT LOW FIRING FREQUENCIES*

JONATHAN DROVER†, JONATHAN RUBIN†, JIANZHONG SU‡, AND BARD ERMENTROUT†

Abstract. A population of oscillatory Hodgkin–Huxley (HH) model neurons is shown numerically to exhibit a behavior in which the introduction of excitatory synaptic coupling synchronizes and dramatically slows firing. This effect contrasts with the standard theory that recurrent synaptic excitation promotes states of rapid, sustained activity, independent of intrinsic neuronal dynamics. The observed behavior is not due to simple depolarization block nor to standard elliptic bursting, although it is related to these phenomena. We analyze this effect using a reduced model for a single, self-coupled HH oscillator. The mechanism explained here involves an extreme form of delayed bifurcation in which the development of a vortex structure through interaction of fast and slow subsystems pins trajectories near a surface that consists of unstable equilibria of a certain reduced system, in a canard-like manner. Using this vortex structure, a new passage time calculation is used to approximate the interspike time interval. We also consider how changes in the synaptic opening rate can modulate oscillation frequency and can lead to a related scenario through which bursting may occur for the HH equations as the synaptic opening rate is reduced.

Key words. neuronal oscillations, Hodgkin–Huxley equations, synaptic excitation, slow passage, canard

1. Introduction.

Recurrent excitatory networks of neurons are purported to underlie persistent activity in the nervous system. Such networks have been used as models for wave propagation and short-term memory [2, 17]. Long-lasting excitatory synaptic connectivity is generally sufficient to enable such densely coupled neurons to fire repetitively at high rates after some transient input, even when the individual neurons do not intrinsically oscillate. The ability of an excitatory network to maintain a persistent state depends on several interacting factors. In many types of cortical neuron models, excitatory coupling leads to asynchronous firing when the synaptic time course lasts long enough [10]. Shortening the time constant leads to two effects; first, the neurons can synchronize, and second, thus synchronized, the network cannot reignite due to the refractory period of the neurons. Studies of persistent activity have not generally focused on differences from this standard scenario that arise due to the intrinsic dynamics of individual neurons.

In this paper we report on a new mechanism through which persistent activity is drastically slowed by excitatory coupling in a network of Hodgkin–Huxley (HH) neurons. In fact, even if the neurons are intrinsically active (say, through current injection), the excitatory coupling dramatically slows them down. We will show that the mechanism for this slowing down is a consequence of an interesting mathematical

structure (a canard) in which a trajectory passes close to a curve of points that are critical points for the intrinsic neuronal dynamics without coupling and that switch from attracting to repelling with respect to these dynamics as synaptic excitation decays [3, 22]. While delayed bifurcation resulting from slow passage infinitesimally close to such a critical curve has been studied previously [3, 15, 16, 4], we shall see that the extreme slowing that we observe involves a novel "vortex" structure and does not fit into the standard class of slow passage problems that have been considered. Indeed, the dynamics controlling the slow passage here, namely, the synaptic decay, do not need to be particularly slow for the extreme delay in activity to occur. Moreover, the slowing phenomenon occurs over a broad parameter range, which distinguishes it from typical canard scenarios.

Our results relate to those of Guckenheimer et al. [8, 9], who found prolonged interspike intervals in a model of the lateral pyloric (LP) cell of the lobster stomatogastric ganglion (see Figure 5 in [8]) and analyzed a normal form of the subcritical Hopf-homoclinic bifurcation that gives rise to this phenomenon in the LP model. To compare our work to theirs, we note that the system we study has a unique, unstable critical point, at which the synaptic variable is zero. This critical point can be made to undergo a subcritical Hopf bifurcation as certain parameters are varied, although we do not do this. It is also quite possible that we are working in a parameter regime that is near a homoclinic bifurcation curve, although we do not consider this aspect of the dynamics directly. What Guckenheimer et al. analyze, however, is not a slow passage problem. Indeed, a crucial difference arising in the present work is that the decay of the synaptic variable sweeps a critical point of a reduced subsystem through a Hopf bifurcation, whereas their analysis treats periodic orbits with the full system held at a fixed distance from bifurcation. The slow passage that we consider leads to a delayed escape from a repelling branch of critical points for the subsystem; the normal form asymptotic analysis in [9] does not involve delayed bifurcation, multiple timescales, or reduced subsystems, although a slow variable does bring trajectories closer to the Hopf bifurcation on successive oscillation cycles in the LP model. Further, we give a directly computable estimate for the change in the synaptic variable during the passage through the vortex structure that traps it, which translates directly into an estimate of passage time, and we analyze the contribution of the synaptic decay rate to the delay. The work in [9] does give an estimate for oscillation period, but this is stated in terms of normal form variables and includes some abstract constants. We note that a prolonged silent phase in the HH equations was also observed in the thorough numerical study of Doi and Kumagai [5]. There, the slowing down was attributed simply to a decrease in the instability of the unstable equilibrium of a certain fast subsystem; no further analysis was given, and the vortex phenomenon was not uncovered.

In section 2 of this paper, we begin by demonstrating the extreme delay effect, first in a large network of HH neurons, then in a reduced model, and finally in a single self-coupled neuron. Since we show that the HH networks oscillate in near synchrony, the self-coupled neuron represents a reasonable approximation of the full network behavior. In the self-coupled neuron, we show how the slowed firing rate depends on the coupling strength, the time constant of the synapses, and the reversal potential of the synapses. In section 3, we review the phase plane for the reduced HH model for a single self-coupled neuron and illustrate the slowing mechanism there. In section 4, we introduce a polynomial approximation of the model that encapsulates the behavior of the reduced HH neuron in the silent phase. We analyze this model in some detail, first showing that the usual approach to delayed bifurcations [3, 15, 16] does

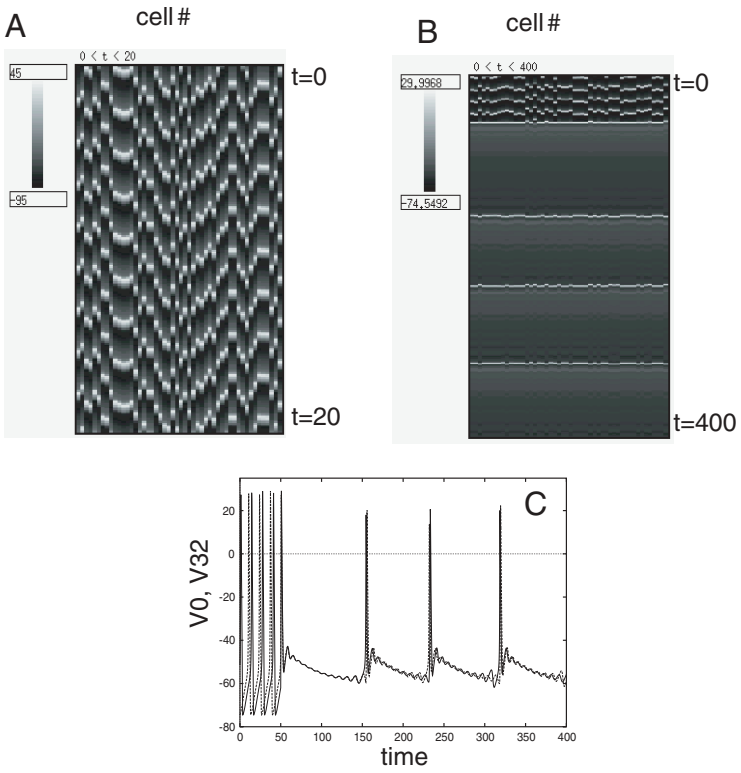

FIG. 1.1. *Behavior of networks of excitatorily coupled neurons depends on the intrinsic dynamics.* (a) *Persistent activity in a network of* 50 *cells with Traub's pyramidal cell dynamics. The first* 50 *milliseconds show the behavior of the uncoupled network; coupling is then turned on showing rapid synchronization and a* 10*-fold increase in the oscillation period.* (c) *Voltage traces from cells* 0 *and* 32 *(out of* 50*) from the simulation in* (b).

not capture the slowing down that we observe and then deriving a novel approach to analyze the delay, including its dependence on the synaptic decay rate. This approach focuses on the effect of a vortex structure in which the interaction of fast and slow subsystems pins trajectories in a certain neighborhood of the critical curve mentioned above. More specifically, we use this structure to derive an appropriate way-in–way-out function [3, 15, 16] that can be used to compute a good estimate of the change in the synaptic variable as a trajectory passes through the vortex. In section 5, we show how this vortex mechanism carries over to the HH system, and we explore the role of the active phase in the slow oscillations. In particular, we see how the slowing mechanism can contribute to a form of bursting, or alternation of sustained silent periods with periods of spiking, in the HH equations. Finally, in section 6, we give a further discussion of how this work relates to some earlier results and of the open questions that remain.

2. Numerical simulations of networks. If a network of excitatory cells is coupled together, often the network activity is asynchronous and has a much higher frequency than the individual cell [11, 12]. This is illustrated in Figure 1.1(a) for 50 cells coupled together in an all-to-all manner using a biophysical model for the fast

currents in a hippocampal neuron and synapses with a decay constant of 5 milliseconds [23]. Note that simulations shown in this figure, as well as all other simulations in this paper, were done using XPPAUT [7]. In the model simulated, individual cells do not fire on their own; the applied current is below threshold. However, coupled together, they produce a rhythm that is nearly 400 Hz. This is an example of strong persistent activity in an excitatory network. Contrast this behavior with another biophysical model based on the HH equations [13], with the same initial conditions and all-to-all coupling. The upper part of Figure 1.1(b) shows asynchronous output of the network when there is no coupling; the frequency is around 100 Hz. Here the neurons receive drive so that they fire spontaneously. After the first 50 milliseconds, the coupling is turned on and the network rapidly synchronizes and fires at a frequency of only about 10 Hz. Stronger coupling or longer decay rates lead to even lower frequencies. Both networks contain only three currents: a transient sodium current, a potassium current, and a leak. The individual voltage traces of two cells in Network B are shown in Figure 1.1(c). They are nearly synchronous, with out-of-phase subthreshold oscillations.

The difference in synchronization properties between these two example networks is fairly well understood, at least in the weak coupling limit. It is known that excitatory coupling can synchronize or desynchronize coupled neurons depending on many factors, such as the synaptic time constant. A very important factor is the nature of the individual neuron. In models for which the onset of repetitive firing is through a saddle node on a limit cycle (e.g., Figure 1.1(a)), excitatory coupling desynchronizes [6], while in models for which the onset is through a Hopf bifurcation (e.g., Figure 1.1(b)), excitatory coupling synchronizes [11]. As it turns out, the extreme slowing observed in the HH network also contributes to the synchronization through a form of fast threshold modulation [20]. We will return to this point in the discussion.

Our goal in much of the rest of this paper is to understand how the frequency of the synchronized oscillations is reduced to the extremely low rates observed in the HH simulations. To understand this, we first reduce the four-variable model to a two-variable system in the manner of Rinzel [18]. This will make the analysis simpler in the subsequent sections. The same network of 50 cells for the reduced system exhibits the same behavior as the full model (not shown); however, the cells synchronize perfectly, unlike in the four-variable cell model. Since synchrony (or near synchrony) appears to be a stable state of the network, we can understand the slowing down of the full network by studying a single self-coupled reduced HH cell:

$$

\end{aligned} \tag{2.1}
$$

The specific values of the gating functions and parameters in (2.1) are given in Appendix A. Note that the synapse has dynamics gated by the potential, V, and the reversal potential of the synapse is V_{syn}. Figure 2.1(a) shows the period of the self-coupled cell as a function of the strength of coupling, g_{syn}, for several different synaptic

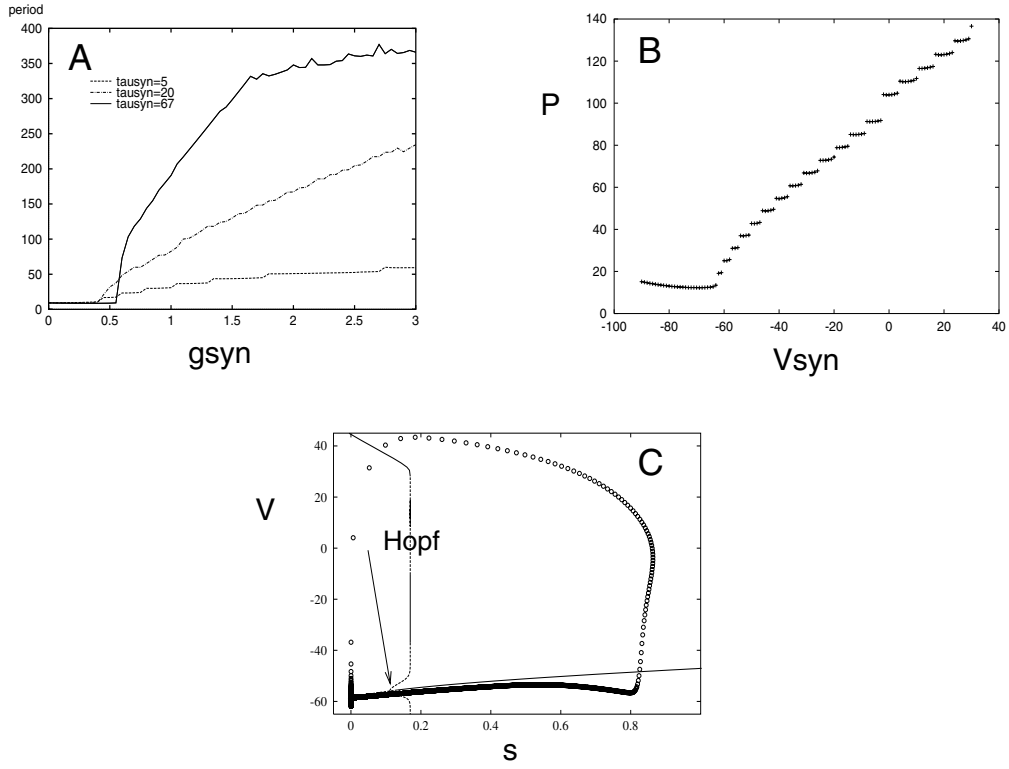

FIG. 2.1. *Properties of the self-coupled reduced HH model.* (a) *The variation of the period as a function of the maximal synaptic conductance for different synaptic decay times.* (b) *Dependence of the period on the reversal potential of the synapse;* $g_{syn} = 4\frac{ms}{cm^2}$ *and* $\tau_{syn} = 10s$. *The resting potential of the neuron is about* $-65\ mV$. *The discontinuities in the curve occur because the trajectory cannot release until after an integral number of subthreshold oscillations (see Figure* 1.1(c)*).* (c) $V-s$ *phase plane during a slow oscillation (trajectory shown with circles and thick solid line) superimposed on the bifurcation diagram (thin solid and dashed lines) for which* s *is treated as a parameter. The arrow depicts the value of* s *at which there is a Hopf bifurcation. To compute the bifurcation diagram, we replaced the piecewise linear definition of* n *in* (2.1) *with a smooth approximation.*

decay rates, τ_{syn}. This dramatic slowing down is not due to simple depolarization; the period is a monotonically decreasing function of the applied current, I_0. Furthermore, for g_{syn} fixed and s held constant as a parameter, the period is roughly constant as s increases. The mechanism for slowing down depends on the transient nature of $s(t)$ and its interplay with the intrinsic dynamics of the reduced HH model. Furthermore, synaptic *excitation* is required for this; Figure 2.1(b) shows the period as a function of the reversal potential of the synapse V_{syn}.

We can give a rather crude explanation for the behavior by treating the synapse as a slow variable. Thus, in (2.1), we treat s as a parameter in the voltage dynamics. For sufficiently large values of s and for g_{syn} large, the membrane dynamics have a stable fixed point corresponding to depolarization block of the sodium current. (The resting potential is so large that the sodium channels are inactivated by the synapse.) As s is decreased, there is a Hopf bifurcation leading to large amplitude periodic solutions. Figure 2.1(c) shows the $V - s$ phase plane with the bifurcation diagram superimposed. The trajectory winds around in a clockwise motion. Essentially, the

slow oscillation is a one-spike elliptic burster [19, 24, 14]. That is, for large values of s, the resting state is stable and the neuron cannot fire. Thus, the synaptic gating variable decays. As this variable gets smaller, the trajectory passes through the Hopf bifurcation (shown by the arrow) and the resting state becomes unstable. However, as can be seen in the figure and is known to occur in elliptic bursting, the trajectory continues along the curve of unstable fixed points, to s-values well below the Hopf point, before jumping away.

While this explanation seems somewhat satisfactory, it cannot account for the drastic slowing down and extreme decay (to nearly 0) of s that we observe. Moreover, the time constant of the decay in the figure ($\tau_{syn} = 10$ msec) is not particularly slow; in this range it is about twice the decay rate of the inactivation variable, h. The mechanism for the extended period is actually quite subtle, and it turns out to be better to treat the recovery variable, h, as the slow variable and to study the dynamics in the $V-h$ plane. Moreover, we shall see that standard treatment of elliptic bursting and associated delay does not predict the extent to which the period increases with τ_{syn} here, as seen in Figure 2.1(a).

3. The $V-h$ plane. We rewrite the equations for the reduced HH model:

$$C\frac{dV}{dt} = f(V,h) - g_{syn}s(V - V_{syn}), \tag{3.1}$$

$$\frac{dh}{dt} = \alpha_h(V)(1-h) - \beta_h(V)h, \tag{3.2}$$

where

$$f(V,h) = I_0 - g_{Na}h(V - V_{Na})m_\infty^3(V) - g_K(V - V_K)n^4(h) - g_L(V - V_L).$$

The equation for the synapse is

$$\frac{ds}{dt} = \alpha(V)(1-s) - s/\tau_{syn}. \tag{3.3}$$

While h and s have similar time courses, h evolves much more slowly than V, so we refer to (3.1) as the fast equation and (3.2) as the slow equation, and we refer to this pair of equations as (PS), for projected system. For each fixed value of s, the solution to the equation $dV/dt = 0$ forms a triple-branched curve in (V,h)-phase space, which constitutes the fast nullcline (Figure 3.1). We will also refer to the slow nullcline, given by $dh/dt = 0$ (Figure 3.1(b)). Note that as s evolves, the fast nullcline of system (3.1)–(3.2) evolves correspondingly, while the slow nullcline is independent of s. Alternatively, for the full system (3.1)–(3.3), there exist two-dimensional fast and slow nullsurfaces in (V,h,s)-phase space.

Solutions to the system (3.1)–(3.3) are strongly attracted to the left and right branches of the fast nullsurface, except during fast jumps between branches (see Figure 3.1(a)). We refer to a time period when a solution is near the left (right) branch as a silent phase (active phase). For our analysis, we will make use of projections of solutions to (V,h)-phase space, but it is important to note that s continues to evolve along with V and h.

3.1. Attraction to the intersection of nullclines and extended delay. The left panel of Figure 3.1 shows a numerically generated trajectory of (3.1)–(3.3),

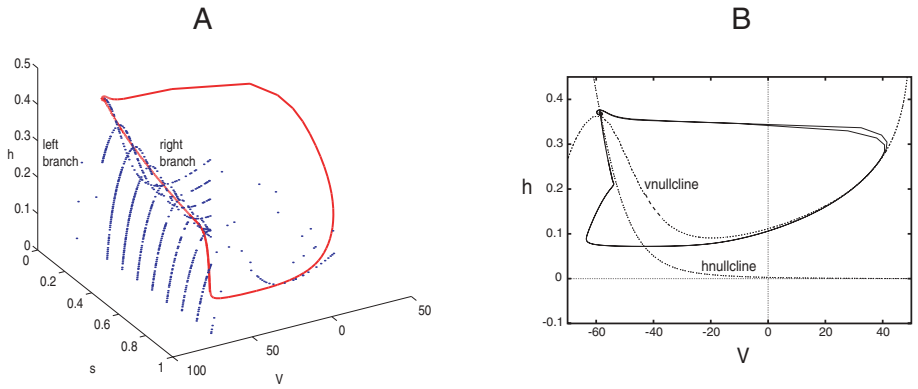

FIG. 3.1. *An orbit of* (3.1)–(3.3) *together with relevant nullclines. In the left panel, it is apparent that the orbit spends a long time in the silent phase near the left knees of the V-nullclines. In the right panel, it is clear that the orbit hugs the h-nullcline until s decays very near to zero, and then there is a small oscillation followed by a jump up to the active phase. $\tau_{syn} = 20s$ in this figure.*

superimposed on V-nullclines of (PS) that were numerically generated for several different values of s. A projection of this trajectory into (V, h)-phase space appears in the right panel, along with the V- and h-nullclines for an arbitrary fixed s near 0. In Figure 3.1, we see that after jumping down to the left surface of the fast nullcline, the orbit travels very close to this surface, although this is not apparent in the right panel of Figure 3.1 because we have only plotted the fast nullcline for a single, very small value of s. The orbit also appears to hug the slow nullcline as the synaptic variable s slowly decays; in other words, the orbit is very close to the intersection of the fast and slow nullclines for each fixed s. After a long delay, the orbit spirals away from the intersection of the nullclines as if this intersection point, treated as a critical point of (PS), had suddenly become unstable through a Hopf bifurcation at some small s. This is not the case; although there is a Hopf bifurcation and a loss of stability as s decays, the orbit remains near the nullcline until s reaches values well below the bifurcation point.

The intersection of the nullclines may be viewed as a critical point of (PS) with s fixed as a parameter. The stability of the critical point changes when $s \approx 0.222$ for the default parameter set, while the escape seen in Figure 3.1 occurs when $s \approx 0.003$. This means that the orbit is attracted toward the intersection (or not repelled) while that intersection represents an unstable fixed point of (PS). The objectives for this and the following section are to explain why this delayed exit occurs and to derive an analytical expression that gives a good estimate of the duration of this delay.

3.2. Ingredients for the delay. The problem presented here is that orbits appear to be attracted to a curve of unstable critical points. However, each critical point is only unstable for fixed s. For the full system (3.1)–(3.3), s decays during the silent phase, and so there are no true critical points with $s > 0$. Thus, we cannot immediately assume that the intersection will repel the orbit once it is unstable with respect to (PS). Linear stability analysis for critical points of (PS) may not be appropriate for the system (3.1)–(3.3). Somehow, one needs to take into account the dynamics of s to explain the delay in escape from the silent phase. Previous authors have contended with this issue in slow passage problems [3, 15, 16, 1, 4] and in elliptic bursting in particular [19, 24, 14, 21]. Unless $1/\tau_{syn} \ll dh/dt$, however, (3.1)–(3.3)

do not fit the standard slow passage assumptions.

Also, the h-coordinate of the fast nullcline increases as s decreases, and the slow nullcline has negative slope with respect to the variable V (in the (V, h)-plane). Thus, the intersection of the nullclines is moving up and to the left in the phase plane as s decreases. Trajectories also move in this direction, as they approach the negatively sloped slow nullcline. Thus, trajectories may approach the intersection of the nullclines, even if the linearization about the intersection of the nullclines with fixed s yields eigenvalues with positive real parts. Below, we will discuss an additional trapping mechanism that holds trajectories near this intersection.

Finally, for a value of s near the Hopf bifurcation, the nullclines are in the fold canard configuration [3]. Although this lasts for only a short period, it may provide a mechanism for a canard to arise in the full system. In this paper we will not use a singular slow-fast decomposition, and we will not use the tools of nonstandard analysis [3]. Nevertheless, the canard configuration appears to be an imperative structural feature in any system that demonstrates this extended delay, for reasons that we shall see below.

4. A simple system. To do any analysis directly, a model simpler than (3.1)–(3.3) is useful to characterize the relevant dynamics in the silent phase, although the conclusions of the analysis are expected to hold for more general systems. For the sake of analysis, the system ideally will have nullclines that are represented by polynomials. Based on the observations from the previous subsection, our model must incorporate the following characteristics:

- The slow nullcline has a negative slope with respect to the fast variable, provided the trajectory approaches the slow nullcline from the left after it enters the silent phase (see Figure 3.1). If the approach is from the right, then the slope of the curve must be positive.
- The intersection of the fast and slow nullclines is a stable critical point (when parameterized by s) of the intrinsic equations for large values of s, and then changes stability via a Hopf bifurcation induced by a transversal crossing of a conjugate pair of eigenvalues through the imaginary axis, away from the origin, as s decays. For a value of s near the Hopf bifurcation, the nullclines must be in the regular fold canard configuration, discussed in [3].
- The vector field of the system is analytic [15, 16] and autonomous during the silent phase.

4.1. The model. The model used for all analysis during the silent phase is

$$\frac{dx}{dt} = -f(x) + y - I(s)x, \tag{4.1}$$

$$\frac{dy}{dt} = -\epsilon\left(y + \frac{1}{4}x^5\right), \tag{4.2}$$

$$\frac{ds}{dt} = -\frac{s}{\tau_{syn}}, \tag{4.3}$$

where $0 < \epsilon \ll 1$; note that we consider only $x < 0$. For simulations in this paper, the function f in (4.1) is

$$f(x) = \frac{1}{4}x^3 - 2x$$

and the synaptic current function I is

$$I(s) = \frac{3}{2}s.$$

Note that this model does not oscillate, but trajectories do jump up from the silent phase. This is sufficient for consideration of behavior during the silent phase. It is not necessary to consider the active phase (when spikes occur) to explain the slow release; however, we will return to the study of the role of the active phase for the HH equations, and bursting in particular, later in the paper.

4.2. Some notation. For the remainder of the paper, the following notation will be used. $N_f(x,s)$ is the y-coordinate of the fast nullcline ($\frac{dx}{dt} = 0$) for a given x and s. Similarly, $N_s(x)$ is the y-coordinate of the slow nullcline ($\frac{dy}{dt} = 0$) for a given value of x. Note that $\partial N_f/\partial s < 0$ for $x < 0$, that $N_s(x)$ does not depend on s, and that these two curves intersect for each fixed s. Let $(\tilde{x}(s), \tilde{y}(s))$ denote the curve of intersection points.

For the system given in (4.1), (4.2), the functions $N_f(x,s)$ and $N_s(x)$ are given by

$$N_f(x,s) = f(x) + I(s)x,$$

$$N_s(x) = -\frac{1}{4}x^5.$$

The intersection of these curves is easily found for each value of s.

4.3. The usual approach. Though the trajectory is visibly separated from the intersection of the fast and slow nullclines in the right panel of Figure 3.1, it is still possible that the release value of s can be approximated using the variational equation around $(\tilde{x}(s), \tilde{y}(s))$. Indeed, this approach has been taken previously to analyze delayed escape in slow passage through a Hopf bifurcation through use of a way-in–way-out function [3, 15, 16]. This function relates the attraction of the orbit before the Hopf bifurcation to the repelling of the orbit after the change of stability has taken place. We shall see that in our case, this approach is not necessarily appropriate.

We now demonstrate the poor performance of the standard way-in–way-out, computed using the equation of first variation along the curve $(\tilde{x}(s), \tilde{y}(s))$. Let J be the Jacobian matrix of the system defined by (4.1)–(4.2) along $(\tilde{x}(s), \tilde{y}(s))$. We have that

$$J(s) = \begin{pmatrix} -\frac{3}{4}\tilde{x}^2(s) + 2 - I(s), & 1 \\ -\epsilon\frac{5}{4}\tilde{x}^4(s), & -\epsilon \end{pmatrix}. \tag{4.4}$$

The equation of first variation is

$$\frac{d}{ds}\begin{pmatrix} x \\ y \end{pmatrix} = -\frac{\tau_{syn}}{s} J(s) \begin{pmatrix} x \\ y \end{pmatrix}. \tag{4.5}$$

The solution to (4.5), taken from a starting point (x_0, y_0, s_{enter}), is

$$\begin{pmatrix} x \\ y \end{pmatrix} = \exp\left(\int_{s_{enter}}^{s} -\frac{\tau_{syn}}{\omega} J(\omega) d\omega \right) \begin{pmatrix} x_0 \\ y_0 \end{pmatrix}. \tag{4.6}$$

Given an s_{enter}, we may solve the equation

$$\left\| \exp\left(\int_{s_{enter}}^{s} -\frac{\tau_{syn}}{\omega} J(\omega) d\omega \right) \begin{pmatrix} x_0 \\ y_0 \end{pmatrix} \right\|_2 = \left\| \begin{pmatrix} x_0 \\ y_0 \end{pmatrix} \right\|_2 \tag{4.7}$$

for $s = s_{exit}$. The value s_{exit} is an approximation of the value of s such that

$$\left\| \begin{pmatrix} x \\ y \end{pmatrix} \right\|_2 = \left\| \begin{pmatrix} x_0 \\ y_0 \end{pmatrix} \right\|_2,$$

where x, y are functions of s since they solve (4.5).

In typical slow passage problems [3, 15, 16, 4], this s_{exit} provides a good approximation for the release value of s. The results for the system under consideration here are not good, especially for the lower values of τ_{syn} tested. This poor performance does not contradict the standard theory; this approach breaks down precisely when the passage rate determined by the decay of s in (4.3) is not sufficiently slow in comparison with the rate of change in (4.2). The value of the approximated value of s_{exit} over a range of τ_{syn} is shown in Figure 4.1. The standard way-in–way-out analysis overestimates s_{exit}. Since s decays in the silent phase, this means that this approach underestimates the amount of time spent in the silent phase.

Notice further that the s_{exit} curve generated here is rather flat. This is expected because the linearization of the system when s is used as a parameter does not depend on τ_{syn}. The slight curvature of the s_{exit} curve that is visible in Figure 4.1 is due to the fact that different values of s_{enter} satisfy the entrance criterion (see caption) for different τ_{syn}. Simulations (solid line in Figure 4.1) suggest that the true value of s_{exit} varies as the logarithm of τ_{syn}. Correspondingly, the passage time from s_{enter} to s_{exit} grows linearly with τ_{syn}, and spike frequency decreases as $1/\tau_{syn}$ as τ_{syn} increases.

It is now apparent this is not a standard way-in–way-out problem about the curve of critical points of a slow-fast system. In the following sections, we will propose a mechanism for the increased delay, perform the corresponding analysis, and demonstrate that this approach gives a much better estimate of the observed delay than that given by the usual analysis done in this section, up to values of τ_{syn} for which $1/\tau_{syn} \ll \epsilon$. For values of τ_{syn} greater than this, the usual approach is sufficient, and as $\tau_{syn} \to \infty$ the two approaches are identical.

4.4. The trapping mechanism. As $s \to 0$, the fast nullcline moves upward in the y-coordinate, since $x < 0$ and thus $\partial N_f / \partial s < 0$. In simulations, it appears as if orbits of (4.1)–(4.3) (or of (3.1)–(3.3)) track very close to the intersection curve of the fast and slow nullclines. To understand what organizes the flow near this curve, it is useful to define the following set:

$$A(s) = \left\{ (x_0, y_0) \middle| \frac{dy}{dt}(x_0, y_0) < \frac{dN_f}{ds}(x_0, s) \frac{ds}{dt} \right\}. \tag{4.8}$$

This set consists simply of the points in the (x, y)-plane such that a trajectory that passes through the point $(x_0, y_0) \in A$ travels more slowly in the vertical direction (y-direction) than does the point on the fast nullcline with the same x-coordinate. Because $N_f(x, s)$ increases as s decreases for fixed $x < 0$, we have that $\frac{dN_f}{ds}(x_0, s)\frac{ds}{dt} > 0$, which guarantees that $A(s)$ is nonempty for each s. As $x \to -\infty$, $\frac{dy}{dt} \to \infty$ as well (see (4.2)), so for each fixed y, there exists x sufficiently negative such that $\frac{dy}{dt} > \frac{dN_f}{ds}\frac{ds}{dt}$; similarly, for each fixed $x < 0$, there exists y sufficiently negative such

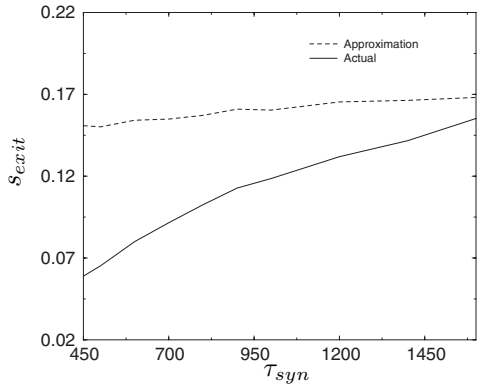

FIG. 4.1. *Values of s_{exit} computed numerically versus those computed from the usual way-in–way-out function, as τ_{syn} varies. The approximation obtained by solving* (4.7) *(dotted line) appears to be fairly invariant with respect to τ_{syn}, but simulations of* (4.1)–(4.3) *strongly suggest that this is not the case (solid line). Here, $\epsilon = .01$ and the entrance criterion used in* (4.7) *is $||x||_2 = 0.1$.*

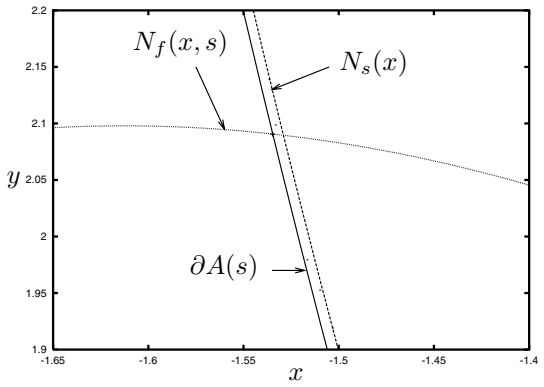

FIG. 4.2. *The curves N_f and N_s along with the boundary of the set $A(s)$ for $s = .0326$. The set $A(s)$ also includes a region to the right of $N_s(x)$, but only the shaded region is relevant.*

that this inequality holds. Thus, $A(s)$ is bounded to the left and below, and the boundary $\partial A(s)$ is a curve, which we denote $y_{\partial A(s)}(x)$, in the (x, y) plane. For the simple system (4.1)–(4.2), we can express the boundary curve $\partial A(s)$ as the graph of a function:

$$y_{\partial A(s)}(x) = -\frac{1}{4}x^5 + \frac{3xs}{2\epsilon\tau_{syn}}. \tag{4.9}$$

Notice that $y_{\partial A(0)}(x) = N_s(x)$, and that as $\tau_{syn} \to \infty$, $y_{\partial A(s)}(x) \to N_s(x)$.

Figure 4.2 shows the curve $\partial A(s)$ for $s = .0326$, along with $N_f(x, s)$ and $N_s(x)$. For the value of s in Figure 4.2, if the trajectory lies to the right of the curve $\partial A(s)$, then $N_f(x, s)$ will be moving upward faster than the trajectory. Likewise, if the trajectory lies to the left of the curve, then the nullcline will be moving upward slower than the trajectory.

The intersection of the curves $\partial A(s)$ and $N_f(x, s)$ turns out to be extremely important for the delay phenomenon under study. The curve defined by these intersection points for a range of s values forms an attractor for values of s for which, from the perspective of the analysis done in section 4.3, the intersection of N_f and N_s

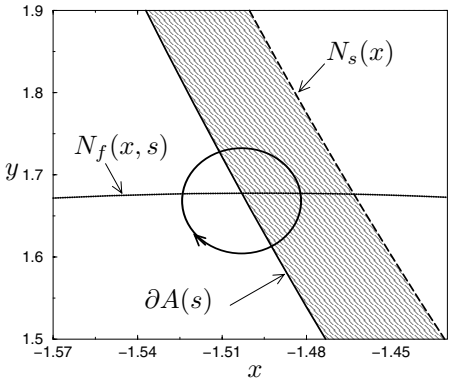

FIG. 4.3. *A sample trajectory as viewed by an observer riding the intersection of $\partial A(s)$ and $N_f(x,s)$. Trajectories to the left of $\partial A(s)$ pass to y-values above the observer, trajectories to the right fall behind. The left and right movement is dependent on whether the trajectory is above or below the curve $N_f(x,s)$.*

corresponds to a repelling set. Suppose that a trajectory lies below $N_f(x,s)$ and to the right of $\partial A(s)$. Thus, the trajectory and $N_f(x,s)$ are separating, but $\frac{dx}{dt} < 0$, and so eventually the trajectory crosses $\partial A(s)$ and then begins to catch up to $N_f(x,s)$. This may result in a net contraction toward $\partial A(s) \cap N_f(x,s)$. The y-coordinate of the trajectory will eventually increase through $N_f(x,s)$, such that $\frac{dx}{dt} > 0$ results. This causes the trajectory to again cross the curve $\partial A(s)$, and another contraction toward $\partial A(s) \cap N_f(x,s)$ may occur as $N_f(x,s)$ catches up to the trajectory. Thus, the intersection curve of $\partial A(s)$ and $N_f(x,s)$, while not itself invariant under the flow, creates a moving vortex, or core about which the flow spirals. The flow diagram around this core, projected to the (V,h)-phase plane, is shown in Figure 4.3.

This moving vortex structure generates a trapping mechanism within the flow. Simulations show that trajectories follow the vortex curve very closely during the silent phase. Using a change of variables, we next explore the stability of the vortex curve and its impact on delayed escape from the silent phase.

4.5. Equations of the moving vortex. To focus on the moving vortex, we will shift the system so that the intersection, say, $(\hat{x}(s), \hat{y}(s))$, of $\partial A(s)$ and $N_f(x,s)$ occurs at the origin for all s. For the simplified model, note that one can obtain explicit expressions for this intersection point. A linear change of variables, $z_1 = x - \hat{x}(s)$ and $z_2 = y - \hat{y}(s)$, yields the following system:

$$\frac{dz_1}{dt} = \frac{dx}{dt} - \frac{d\hat{x}}{ds}\frac{ds}{dt}, \tag{4.10}$$

$$\frac{dz_2}{dt} = \frac{dy}{dt} - \frac{d\hat{y}}{ds}\frac{ds}{dt}, \tag{4.11}$$

which can also be written

$$\frac{dz_1}{dt} = f_1(z_1, z_2, s), \tag{4.12}$$

$$\frac{dz_2}{dt} = f_2(z_1, z_2, s), \tag{4.13}$$

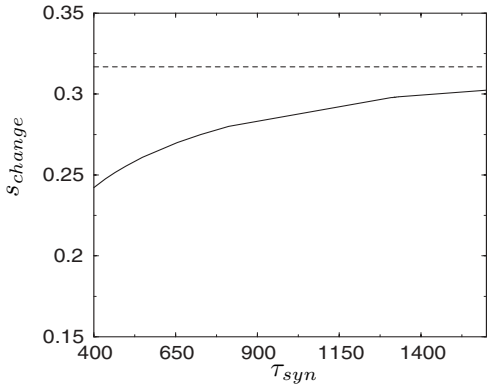

FIG. 4.4. *Change of stability. The solid line represents the value of s where the sign of the real part of the complex conjugate pair of eigenvalues changes along the curve $(\hat{x}(s), \hat{y}(s))$. The dotted line shows the value of s when the curve of critical points for* (4.1)–(4.2) *changes stability. This value is not dependent on τ_{syn}.*

where s is governed by (4.3).

If s is fixed as a parameter, then we may compute the linearization of system (4.12)–(4.13) about the vortex point $(z_1, z_2) = (0, 0)$. Although $(0, 0)$ is not a critical point for system (4.12)–(4.13), the sign of the real part of the complex conjugate pair of eigenvalues of the linearized system will still yield information about to what extent the neighborhood around the point acts as an attractor, as discussed above. Also, because the parameter τ_{syn} was incorporated into the linear component of the system during the change of variables, the value of s where the eigenvalues' real part changes sign is not invariant with respect to τ_{syn}, as it is using the regular approach discussed in section 4.3. The value of s where the eigenvalues' real part changes sign is shown in Figure 4.4. This is encouraging because it demonstrates a lower value for the change of stability in addition to a dependence on τ_{syn}, both of which are apparent in simulations but lacking in the analysis in section 4.3.

4.6. Release value for *s*. Because the real part of the eigenvalues crosses through zero for a smaller value of s in the linearization of system (4.12)–(4.13) about $(0, 0)$ than observed in the linearization of (4.1)–(4.2), we expect that the linearization of system (4.12)–(4.13) will provide an improved estimate of the exit value for s, relative to the analysis in section 4.3, at least until τ_{syn} becomes extremely large. In addition to the geometric argument given in section 4.4, an analytical justification for this expectation is given in Appendix B.

Now that we have transformed to the frame of the moving vortex, the analysis itself proceeds as in section 4.3. We rewrite (4.12)–(4.13) in vector form as

$$\frac{d\vec{z}}{ds} = -\frac{\tau_{syn}}{s}\vec{f}(\vec{z}, s). \tag{4.14}$$

The equation of first variation on the vortex curve $(z_1, z_2) = (0, 0)$ is

$$\frac{d\vec{z}}{ds} = -\frac{\tau_{syn}}{s}\vec{f}_{\vec{z}}(0, 0, s)\vec{z}. \tag{4.15}$$

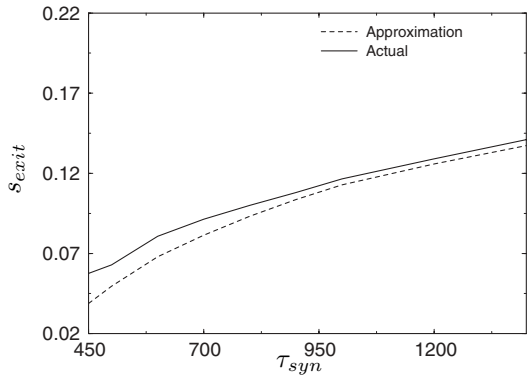

FIG. 4.5. *Improved estimate of s_{exit}. As a function of τ_{syn}, the exit value s_{exit} is derived from solution of* (4.17) *(dashed line) and numerical solution of the full translated model* (4.12)–(4.13) *(solid line). The entrance criterion for this figure was $||z||_2 = 0.03$, and again $\epsilon = 0.01$.*

The solution to (4.15) is given by

$$\vec{z}(s) = \exp\left(-\tau_{syn}\int_{s_0}^{s}\frac{1}{w}\vec{f}_{\vec{z}}(0,0,w)dw\right)\vec{z}(s_0). \tag{4.16}$$

To approximate the value of s where release begins to occur, we choose a value s_{enter} satisfying an entrance criterion, $||z||_2 = \eta$. We solve the equation

$$||\vec{z}(s)||_2 = \left\|\exp\left(-\tau_{syn}\int_{s_{enter}}^{s}\frac{1}{w}\vec{f}_{\vec{z}}(0,0,w)dw\right)\vec{z}(s_{enter})\right\|_2 = \eta. \tag{4.17}$$

The results of this estimation for a range of τ_{syn} are shown, along with results from full numerical simulations, in Figure 4.5. The approximation is much better than the one obtained in section 4.3 for low to moderately high values of τ_{syn}.

Remark 4.1. In principle, there exists some curve, say, $(x_{opt}(s), y_{opt}(s))$, such that linearization about this curve yields an optimal estimate of s_{exit}. Numerical simulation suggests that system (4.12)–(4.13) has a fixed point for each s, and this is the natural candidate about which to linearize this translated system. (In terms of Appendix B, linearization about this curve would yield a truly linear system in (8.8).) However, it is not clear how to access this curve numerically, and the geometric arguments and numerical computations done here, along with the analytical calculation in Appendix B, show that the moving vortex curve is a good approximation to $(x_{opt}(s), y_{opt}(s))$ to use for estimation of s_{exit}.

Remark 4.2. Unfortunately, for very large values of τ_{syn}, the approximation loses accuracy and gives a similar, but slightly less accurate, performance to the standard approach. Recall that the moving vortex point is defined as the intersection of $\partial A(s)$ with the fast nullcline $N_f(x,s)$ for each s. The boundary $\partial A(s)$ is given by $\frac{dy}{dt} = \frac{\partial N_f}{\partial s}\frac{ds}{dt} = -\frac{\partial N_f}{\partial s}\frac{s}{\tau_{syn}}$. As τ_{syn} increases, $\partial A(s)$ therefore approaches the slow nullcline, and correspondingly the moving vortex point approaches the intersection of the fast and slow nullclines, which is exactly the moving critical point used in the standard analysis. This explains why the moving vortex analysis is similar to the standard analysis for sufficiently large τ_{syn}. However, the transformation (4.10)–(4.11) brings τ_{syn} into (4.12)–(4.13), so the two approaches remain nonidentical.

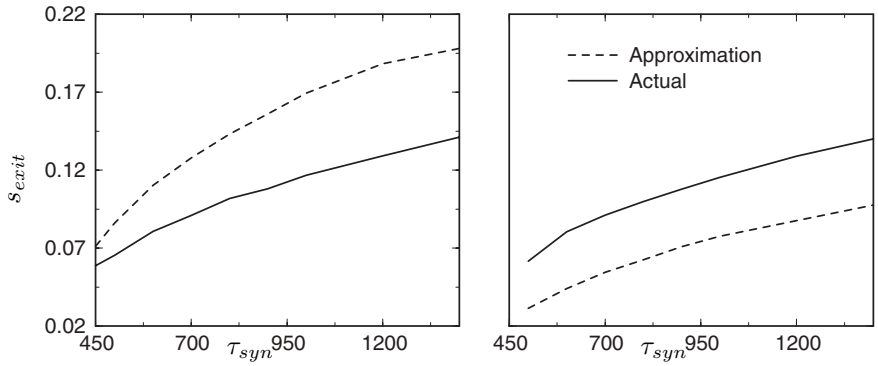

FIG. 4.6. *The approximation curve and the actual curve using the value* $\eta = 0.025$ *(left panel) or* $\eta = 0.035$ *(right panel) as the entrance criterion. The results are not as good as those in Figure* 4.5.

Remark 4.3. It is important to note that the results of our approach do depend on the value of η chosen for the entrance criterion. Because we take the equation of first variation of (4.12)–(4.13) about the vortex curve $(z_1, z_2) = (0, 0)$, rather than about the translated version of the optimal curve (x_{opt}, y_{opt}) discussed in Remark 4.1, we cannot choose η arbitrarily small. The behavior in a very small neighborhood of the origin, and the time to exit this neighborhood, do not perfectly capture the behavior near the optimal curve. Also, η cannot be chosen too large. Large η will result in failure of the approximation provided by the equation of first variation, and nonlinear terms may dominate. There must be an ideal entrance value, in the sense that the results obtained provide the most accurate approximations. Figure 4.6 shows the results derived from less appropriate values of η than that used in Figure 4.5. Note, however, that these results are still better than the standard approach (Figure 4.1) over the lower range of τ_{syn} values considered.

5. The HH equations.

5.1. Mechanism for slow oscillations. In section 4, a simplified model was used to elucidate a mechanism, involving trapping of trajectories near a vortex curve, by which slow synaptic decay results in an oscillation with a very long period. Because our simplified model satisfies the conditions listed at the start of section 4, this model is an appropriate subject for analysis, and we expect that the argument and findings from sections 4.4–4.6 carry over directly to the reduced HH model (3.1)–(3.3).

Indeed, numerical study strongly suggests that the mechanism for slow oscillations in the HH equations is identical to that of the simple model. Again, there is a vortex curve which is stable longer (for smaller s) than is the fixed-point curve created by the intersection of the fast and slow nullsurfaces. Figure 5.1 shows the analogue to Figure 4.2 for the reduced HH equations.

5.2. The active phase. Up to this point, our analysis has concerned only what occurs during the silent phase of oscillations. By changing the recovery capability of the synapse, either we can make the slow behavior discussed above more pronounced or we can eliminate the silent phase completely. The latter results in high-frequency oscillations, and for appropriate values of τ_{syn} this can induce bursting. Before discussing bursting, however, we take a closer look at how the recovery of the synapse depends on parameters in the model, assuming that a prolonged silent phase has occurred.

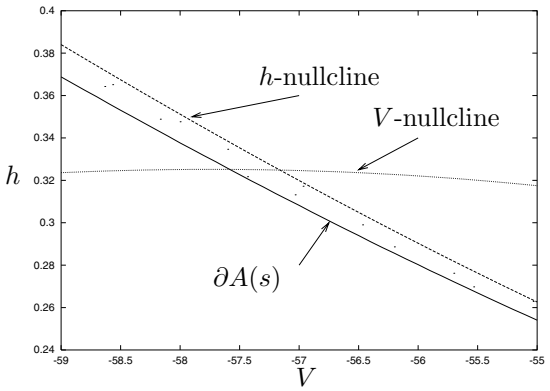

FIG. 5.1. *The set $A(s)$ for the HH equations (3.1)–(3.3) for fixed s. The shaded region is the numerically computed set of (V, h) (to the left of the slow h-nullcline) where the trajectory is moving more slowly in the direction of increasing h than is the fast V-nullcline.*

Under the flow of the reduced HH system (3.1)–(3.3), the synapse recovers (s increases) during the active phase, which begins when the cell jumps up from the vicinity of a left knee of the fast V-nullsurface and terminates when the cell jumps down from a right knee of this nullsurface. If we let $F(V, h, s)$ denote $f(V, h) - g_{syn}s(V - V_{syn})$, then the knees are the two solutions of $F(V, h, s) = \partial F(V, h, s)/\partial V = 0$, parametrized by s. More precisely, we can solve $F(V, h, s) = 0$ for $V = V(h, s)$, and then solve $\partial F(V(h, s), h, s)/\partial V = 0$ for $h = h(s)$, such that $V = V(h(s), s)$.

We can implicitly differentiate the equation

$$f(V(h(s), s), h(s)) - g_{syn}s(V(h(s), s) - V_{syn}) = 0$$

with respect to s to obtain

$$\frac{\partial f}{\partial V}\left[\frac{\partial V}{\partial h}\frac{dh}{ds} + \frac{\partial V}{\partial s}\right] + \frac{\partial f}{\partial h}\frac{dh}{ds} - g_{syn}s\left(\frac{\partial V}{\partial h}\frac{dh}{ds} + \frac{\partial V}{\partial s}\right) - g_{syn}(V(h(s), s) - V_{syn}) = 0. \tag{5.1}$$

Substitution of $\partial F(V(h(s), s), h(s), s)/\partial V = 0$ into (5.1) yields $\frac{\partial f}{\partial h}\frac{dh}{ds} = g_{syn} \times (V(h(s), s) - V_{syn})$. Rewriting this as a formula for dh/ds and substituting the currents in f from Appendix A, as well as $V_{syn} = 0$, yields

$$\frac{dh}{ds} = \frac{g_{syn}V}{-g_{Na}m^3(V)(V - V_{na}) - 4g_K n^3(h)(V - V_k)\frac{dn}{dh}}, \tag{5.2}$$

where $V = V(h(s), s)$ and $h = h(s)$. If we insert parameter values from Appendix A, as well as the range of V values found in the silent phase (say, $h = h_L(s)$) or the active phase (say, $h = h_R(s)$), into (5.2), we find that both dh_L/ds and dh_R/ds are quite small, at most about .02. Thus, we will assume that there is a fixed value h_L of h at the jump up from the silent phase to the active phase and a fixed value h_R of h at the jump down from the active phase to the silent phase.

Now, in the active phase, we have

$$\frac{dh}{ds} = \frac{\alpha_h(V)(1 - h) - \beta_h(V)h}{\alpha(V)(1 - s) - s/\tau_{syn}}. \tag{5.3}$$

Make the further approximations that $\alpha(V) \approx \alpha$ and $dh/dt \approx -\beta h$, for α, β constant, in the active phase, and let $\tau = \alpha + 1/\tau_{syn}$. Then direct integration of (5.3) from $(h, s) = (h_L, 0)$ to $(h, s) = (h_R, s_{max})$ yields

$$s_{max} = \frac{\alpha}{\tau}(1 - H^{\tau/\beta}), \tag{5.4}$$

where $H = h_R/h_L$. Equation (5.4) gives an estimate of how the level to which the synaptic variable s recovers in the active phase depends on the parameters of the HH equations, particularly α (the approximate value of $\alpha(V)$ in (3.3)), the synaptic decay rate τ_{syn}, and the active phase decay rate of h from (3.2), approximated by β.

In Figure 5.2, we compare this approximation of s_{max} to the value obtained from numerical simulation of (3.1)–(3.3) and to an alternative, naive approximation to s_{max}, namely, $\alpha/(\alpha + \tau_{syn}^{-1})$. This corresponds to the value of s that would be reached if synapses responded instantaneously to voltage. We show how s_{max} depends on α for several values of τ_{syn}, and also how s_{max} depends on τ_{syn} for $\alpha = 2$, corresponding to the default value of α_0 for the simulations in the other sections of this paper (see Appendix A). Note that there is some ambiguity in how to select the approximate decay rate β for h, since this rate typically remains near a constant value throughout much of the active phase but then decreases near the right knee, as the decay of h slows. We neglect the slowing near the right knee, which accounts for some of the error in Figure 5.2.

It is interesting to note that for fixed α, the value of s_{max} is roughly independent of τ_{syn}, such that the active phase contributes little to the slowing that occurs as τ_{syn} is increased, as discussed in the previous sections. As α increases, s_{max} increases correspondingly. This leads to a larger s_{enter} in (4.17), which in turn yields a smaller s_{exit}. Hence, the duration of the silent phase increases with α. We explore a further implication of this dependence in section 5.3.

5.3. Bursting. Consider Figure 5.3(a). This figure shows the bifurcation structure for (3.1)–(3.2) as s varies for $g_{syn} = 2$, while Figure 5.3(b) shows the voltage trace of a two-spike burst solution to (3.1)–(3.3). This solution was obtained by greatly reducing the function $\alpha(V)$, thereby reducing the turn-on of the synapse during the active (spiking) phase. Any number of spikes can be seen in a burst by scaling the recovery function appropriately.

As we have seen, during the time that a cell spends in the silent phase, its synaptic variable decays beyond the point where the fixed point (intersection of fast and slow nullclines) of the system (3.1)–(3.2) becomes unstable (s lies below the Hopf point at $s \approx 0.22$ in Figure 5.3(a)). During the active phase, the synaptic variable s increases as specified in (3.3). If s does not recover enough to reach a value for which the fixed point of (3.1)–(3.2) is stable ($s > 0.22$ in our example), then after it jumps down to the silent phase, it will not be attracted toward the slow nullcline or the vortex structure. Instead, the orbit tends toward the fast nullcline and the phase plane looks like a standard (oscillatory) relaxation oscillator. This results in a subsequent rapid jump to the active phase when the left knee of the fast nullcline is reached, corresponding to a rapid second spike, as seen, for example, at the start of the simulation in the right panel of Figure 5.3. Alternatively, if s does increase beyond the bifurcation point, then the silent phase becomes prolonged again; however, if it is still close to the bifurcation point, the silent phase duration is still reduced relative to that seen for large s, based on (4.17). Figure 5.3 shows the recovery of the synaptic variable, s, during the two-spike burst shown in the right panel of Figure 5.3.

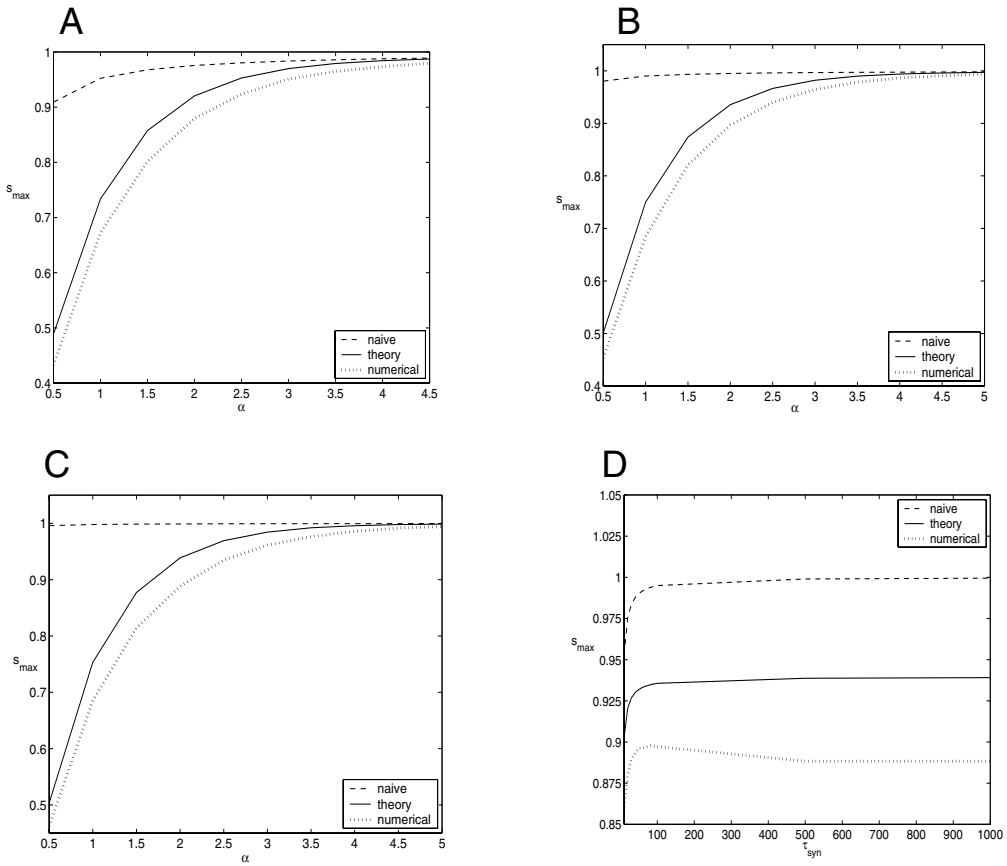

FIG. 5.2. *The dependence of synaptic recovery level,* s_{max}*, on the rate of synaptic rise* (α) *and decay* (τ_{syn})*. In each panel, the dashed line corresponds to the naive approximation* $s_{max} \approx \alpha/(\alpha + \tau_{syn}^{-1})$*, the solid line corresponds to* (5.4)*, and the thick dotted line corresponds to the actual value of* s_{max} *attained in numerical simulations of* (3.1)–(3.3). (a) $\tau_{syn} = 20$, (b) $\tau_{syn} = 100$, (c) $\tau_{syn} = 500$, (d) $\alpha = 2$.

6. Discussion. It is generally assumed that synaptic connections between excitatory neurons have the effect of strengthening and accelerating neuronal firing. Indeed, part of the accepted theory of computation in cortical circuitry is that if input is strong enough to make some excitatory cells fire, then recurrent excitation among excitatory cells amplifies this activity, whereas if inhibitory input comes in before the excitatory cells can become active, then this inhibition shuts them down. In this paper, we explore a scenario in which recurrent excitation instead causes a drastic slowing of firing. We find this effect, over a broad range of parameter values, in a network of standard, biophysically derived HH model neurons, coupled with slowly decaying synaptic excitation. This highlights the important point that the effects of synaptic inputs in neuronal networks depend on the intrinsic dynamics of the cells in the network, together with the timescale of the synaptic inputs. It remains to explore the functional consequences of this result, particularly in a network of interconnected excitatory cells and inhibitory interneurons.

Since we find that synaptic excitation is strongly synchronizing in this model network (up to small differences in subthreshold oscillations), we study the mechanism behind this synaptic slowing in a self-coupled neuron. The synchronization seen here

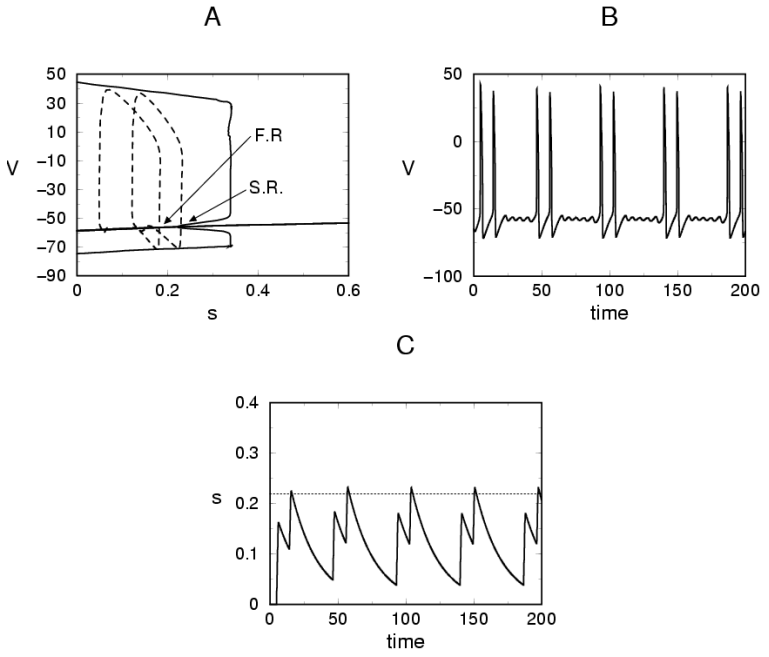

FIG. 5.3. *Bursting in the HH model.* (a) *Bifurcation diagram for the HH equations with s as the bifurcation parameter (as shown in Figure* 2.1(c)*). The curve at* $V \approx -60$ *corresponds to the critical point of system* (3.1)–(3.2) *formed by the intersection of the fast and slow nullclines. This becomes unstable via a subcritical Hopf bifurcation as s decreases. Here, F.R. and S.R. refer to the first and second return to the silent phase, respectively, of the dashed trajectory shown.* (b) *Two-spike burst solution. During the first spike of a two-spike burst, the s value does not recover enough to exit the regime where the critical point is unstable. The second recovery brings s into the stable regime, which yields a prolonged silent phase.* (c) *Synaptic variable,* $s(t)$ *during this burst. The dashed horizontal line is the value of s where the critical point (parametrized by s) changes stability. Because this stability is necessary to obtain a cycle with an arbitrarily long period, the oscillator experiences a prolonged silent phase only once s has exceeded this threshold. Parameter values for this plot are* $\tau_{syn} = 20$ *and* $\alpha_0 = 0.15$.

in part results from the phase response properties of HH neurons [11]. Further, the extreme slowing in the silent phase enhances the synchronization tendency. We have seen that this slowing involves a prolonged residence near the left knee curve of a fast nullsurface. In a population of many cells in a near-synchronized state, a strong spatial compression occurs during this residence. As soon as one cell jumps up to the active phase, fast threshold modulation (FTM) [20] will pull the other cells up as well. This compression and FTM easily overwhelm any desynchronization that may occur in the other stages of an oscillation.

We use a simplified model to elucidate the moving vortex canard mechanism by which slowly decaying synaptic excitation prolongs the silent phase between spikes, and this mechanism carries over to the HH model. The scenario that we study truly meets the criteria for a canard, since the fast (V) and slow (h) nullclines of the HH model, with s taken as a parameter, are in a regular fold canard configuration for an s-value near that at which the intersection of the nullclines loses stability via a Hopf bifurcation [3]; see also [22]. Moreover, the solutions to the full system spend a significant period of time traveling along the middle branch of the V-nullsurface

(although they remain extremely close to the curve of knees; see Figure 3.1). Unlike typical canards, however, the delayed solutions that we study are easy to find, occurring over a broad range of synaptic decay rates. We do not discuss the precise size of the region in phase space from which trajectories are drawn to the vortex region, for fixed parameter values. This may relate to attraction to a stable manifold of the $s = 0$ critical point of the HH model in the vicinity of a homoclinic bifurcation, as discussed in [9], but we have not explored this issue.

According to previous analytical results, one should be able to estimate the change in the slow variable s that will occur during the silent phase by using a way-in–way-out function [3, 15, 16]. This function incorporates information from the projected system derived by treating s as a parameter. Specifically, it involves the eigenvalues of the linearization of the projected system about an appropriate curve of critical points (parametrized by s). The eigenvalues correspond to rates of decay and growth toward this critical point curve. This approach was used previously in neuronal networks to study elliptic bursting, in which there is a delayed escape from a curve of critical points that are unstable with respect to a fast subsystem [19, 24, 14, 21]. However, the novel vortex phenomenon that we have identified causes this approach to underestimate the change in s in the silent phase, and correspondingly the time spent there, for a large range of synaptic decay rates.

The vortex structure develops through a breakdown in the distinction between fast and slow dynamics in the vicinity of the critical point curve for the projected system. The corresponding flow pins trajectories near a vortex curve, which itself lies close to the curve of critical points, for a prolonged period, as the synaptic strength gradually decays. We use the vortex curve to approximate a release threshold for the synaptic variable s, relative to a specified criterion for entrance into the trapping regime. This approach makes use of a set A, determined by the dynamics of the system, that is central to the vortex effect. In particular, A relates to the relative rates of change of the nonsynaptic slow variable and the position of the fast nullcline. Note that the position of the fast nullcline depends on the size of the synaptic variable s. Further, while there are three possible timescales corresponding to the rates of change of the three dependent variables (V, h, s) in the problem, the rate of change of the nonsynaptic slow variable (characterized by ϵ) and the synaptic decay rate $1/\tau_{syn}$ are comparable over much of the range of τ_{syn} that we consider. A full mathematical analysis of the vortex mechanism, and in particular the types of vector fields and range of timescales for which computations based on the vortex curve will always give small errors, remains open for consideration.

While we introduce the vortex mechanism and perform relevant calculations in the context of a simplified model related qualitatively to the silent phase features of the HH system, we illustrate numerically that the same ingredients are also present in the reduced HH equations (e.g., Figure 5.1). Numerical simulations of the full HH model show a similar prolongation of the silent phase, with a strong dependence on the synaptic decay rate τ_{syn}; indeed, such simulations led us to note and seek an explanation for the delay mechanism in the first place. In the reduced HH equations, we connect the active phase of oscillations to the silent phase by considering how the synaptic recovery rate α affects the level to which s recovers. This affects the level of s at which trajectories enter the trapping region (quantified by our choice of η), in turn affecting our estimation of s at release from the silent phase (see (4.17)); however, as discussed in section 5.2, the level of s at release feeds back little effect on the level to which s recovers in the active phase. By exploiting our understanding of the interaction of intrinsic and synaptic dynamics, we also describe how the fast-slow

structure allows for bursting in the HH equations. While this can be considered as elliptic bursting, the burst frequency can be quite slow, as the prolonged silent phase again occurs in the intervals between bursts of spikes.

7. Appendix A. The gating functions for h in (3.2) are

$$\alpha_h(V) = .07\exp(-(V+65)/20),$$

$$\beta_h(V) = 1/(1+\exp(-(V+35)/10)).$$

The m and n gating variables are slaved to V and h, respectively, by

$$m = \frac{\alpha_m(V)}{\alpha_m(V)+\beta_m(V)},$$

$$n = \max(.801 - 1.03h, 0),$$

where

$$\alpha_m(V) = \frac{0.1(V+40)}{1-\exp(-(V+40)/10)},$$

$$\beta_m(V) = 4\exp(-(V+65)/18).$$

The synaptic recovery function, $\alpha(V)$, is given by

$$\alpha(V) = \frac{\alpha_0}{1+\exp(-V/V_{shp})}.$$

Parameter values for all simulations are $V_{Na} = 50$, $V_K = -77$, $V_L = -54.4$, $g_{Na} = 120$, $g_K = 36$, $g_L = 0.3$, $C = 1$, $I_o = 13$, $V_{shp} = 5$, $g_{syn} = 2$, and $V_{syn} = 0$. Also, $\alpha_0 = 2$ in all sections except section 5.2, where it is varied, and section 5.3, where bursting is discussed. The units for the voltages are mV, the conductances (g_*) have units mS/cm^2, and the current (I_o) has units $\mu A/cm^2$.

8. Appendix B. Consider the model system (4.1)–(4.3), which we express as

$$\begin{aligned} \frac{dx}{dt} &= y - N_f(x,s), \\ \frac{dy}{dt} &= -\epsilon(y - N_s(x)), \\ \frac{ds}{dt} &= -\frac{s}{\tau_{syn}}. \end{aligned} \tag{8.1}$$

Note that we can express (8.1) as a pair of equations:

$$\begin{aligned} -\frac{s}{\tau_{syn}}\frac{dx}{ds} &= y - N_f(x,s), \\ \frac{s}{\epsilon\tau_{syn}}\frac{dy}{ds} &= y - N_s(x). \end{aligned} \tag{8.2}$$

To find the vortex point $(\hat{x}(s), \hat{y}(s))$ about which to linearize, we solve

$$\hat{y} = N_f(\hat{x}, s) \tag{8.3}$$

and

$$dy(\hat{x}, \hat{y})/ds = \partial N_f(\hat{x}, s)/\partial s. \tag{8.4}$$

Together with (8.4), the second equation of (8.2) gives

$$\epsilon\tau_{syn}(\hat{y} - N_s(\hat{x}))/s = \partial N_f(\hat{x}, s)/\partial s. \tag{8.5}$$

Implicit differentiation of (8.3) along the solution $(\hat{x}(s), \hat{y}(s))$ gives

$$\partial N_f(\hat{x}, s)/\partial s = d\hat{y}/ds - (\partial N_f(\hat{x}, s)/\partial x)(d\hat{x}/ds). \tag{8.6}$$

Together, (8.5) and (8.6) yield

$$\frac{d\hat{y}}{ds} = \frac{\epsilon\tau_{syn}}{s}(\hat{y} - N_s(\hat{x})) + \frac{\partial N_f(\hat{x}, s)}{\partial x}\frac{d\hat{x}}{ds}. \tag{8.7}$$

Substitute $(\hat{x}(s) + u(s), \hat{y}(s) + v(s))$ into (8.2) and linearize about $(\hat{x}, \hat{y})$ to obtain

$$\begin{aligned} -\frac{s}{\tau}\frac{du}{ds} &= \frac{s}{\tau}\frac{d\hat{x}}{ds} + \hat{y} + v - N_f(\hat{x}, s) - u(\partial N_f(\hat{x}, s)/\partial x), \\ \frac{s}{\epsilon\tau}\frac{dv}{ds} &= -\frac{s}{\epsilon\tau}\frac{d\hat{y}}{ds} + \hat{y} + v - N_s(\hat{x}) - u(dN_s(\hat{x})/dx). \end{aligned} \tag{8.8}$$

In the first equation of (8.8), $\hat{y} = N_f(\hat{x}, s)$. From (8.7), we have

$$\frac{s}{\epsilon\tau}\frac{d\hat{y}}{ds} = \hat{y} - N_s(\hat{x}) + \frac{s}{\epsilon\tau}\frac{\partial N_f(\hat{x}, s)}{\partial x}\frac{d\hat{x}}{ds}.$$

Thus, (8.8) becomes

$$\begin{aligned} -\frac{s}{\tau}\frac{du}{ds} &= \frac{s}{\tau}\frac{d\hat{x}}{ds} + v - u(\partial N_f(\hat{x}, s)/\partial x), \\ \frac{s}{\epsilon\tau}\frac{dv}{ds} &= v - u(dN_s(\hat{x})/dx) - \frac{s}{\epsilon\tau}(\partial N_f(\hat{x}, s)/\partial x)(d\hat{x}/ds). \end{aligned} \tag{8.9}$$

Note that while this is a linearized equation, the right-hand side is not linear in (u, v) because the vortex point is not a critical point of (8.2).

At this point, we make a key assumption. Since the trajectory lies in the vicinity of the knee during the time over which the vortex calculation is done, we henceforth assume that $\partial N_f(\hat{x}, s)/\partial x = 0$. In some sense, this amounts to assuming that the system is in a vortex canard configuration, since it specifies that the boundary $\partial A(s)$ should intersect $N_f(x, s)$ at the knee of $N_f(x, s)$. Clearly this assumption is not precisely satisfied; however, a straightforward generalization of the calculation below shows that any error resulting from the violation of this assumption will be of the same order of magnitude as $(\partial N_f(\hat{x}, s)/\partial x)(d\hat{x}/ds)$.

Next, we express $(u(s), v(s)) = (u_1(s), v_1(s)) + (\tilde{u}(s), \tilde{v}(s))$, where (u_1, v_1) is a zero of the right-hand side of (8.9) with $\partial N_f/\partial x = 0$; that is, (u_1, v_1) solves

$$\begin{aligned} 0 &= \frac{s}{\tau}\frac{d\hat{x}}{ds} + v, \\ 0 &= v - u(dN_s(\hat{x})/dx). \end{aligned} \tag{8.10}$$

Note that $(u_1(s), v_1(s)) = O(1/\tau_{syn})$, while $(u_1'(s), v_1'(s)) = O(1/\tau_{syn})$ as well since the determinant of coefficients $(dN_s(\hat{x})/dx) \neq 0$. Substitution of this decomposition of $(u(s), v(s))$ into (8.9) yields

$$\begin{aligned}
-\frac{s}{\tau}\frac{d\tilde{u}}{ds} &= \frac{s}{\tau}\frac{du_1}{ds} + \frac{s}{\tau}\frac{d\hat{x}}{ds} + v_1 + \tilde{v} \\
&= \frac{s}{\tau}\frac{du_1}{ds} + \tilde{v} \\
&= O(1/\tau_{syn}^2) + \tilde{v}, \\
\frac{s}{\epsilon\tau}\frac{d\tilde{v}}{ds} &= -\frac{s}{\epsilon\tau}\frac{dv_1}{ds} + v_1 - u_1(dN_s(\hat{x})/dx) + \tilde{v} - \tilde{u}(dN_s(\hat{x})/dx) \\
&= -\frac{s}{\epsilon\tau}\frac{dv_1}{ds} + \tilde{v} - \tilde{u}(dN_s(\hat{x})/dx) \\
&= O(1/\tau_{syn}) + \tilde{v} - \tilde{u}(dN_s(\hat{x})/dx),
\end{aligned}$$

where we have assumed in the final line that $\epsilon\tau_{syn} = O(1)$. Thus, when $\epsilon\tau_{syn} = O(1)$, the error in using the equation of variations in the vortex approach is of $O(1/\tau_{syn})$.

Contrast this with the usual approach, Here one solves $0 = y - N_f(x, s)$ and $0 = y - N_s(x)$ to obtain $(\tilde{x}(s), \tilde{y}(s))$. As previously (see (8.2)), we have

$$\begin{aligned}
-\frac{s}{\tau}\frac{dx}{ds} &= y - N_f(x, s), \\
\frac{s}{\epsilon\tau}\frac{dy}{ds} &= y - N_s(x),
\end{aligned}$$

and we now linearize about $(\tilde{x}(s) + u(s), \tilde{y}(s) + v(s))$ to obtain, after cancellations,

$$\begin{aligned}
-\frac{s}{\tau}\frac{du}{ds} &= \frac{s}{\tau}\frac{d\tilde{x}}{ds} + v - u(\partial N_f(\tilde{x}, s)/\partial x), \\
\frac{s}{\epsilon\tau}\frac{dv}{ds} &= -\frac{s}{\epsilon\tau}\frac{d\tilde{y}}{ds} + v - udN_s(\tilde{x})/dx.
\end{aligned}$$

We can apply the same decomposition of $(u(s), v(s)) = (u_1(s), v_1(s)) + (\tilde{u}(s), \tilde{v}(s))$ as above. However, if we again assume that $\epsilon\tau_{syn} = O(1)$, then we will have $(u_1, v_1) = O(1)$ from the $d\tilde{y}/ds$ term, and an $O(1)$ error can result from calculation with the equation of variations.

COMPUTATION OF THE EFFECTIVE DIFFUSIVITY TENSOR FOR TRANSPORT OF A PASSIVE SCALAR IN A TURBULENT INCOMPRESSIBLE FLOW*

T. KOMOROWSKI†‡ AND P. WIDELSKI‡

Abstract. We consider the passive scalar transport in an incompressible random flow. Our basic result is a proof of the convergence of a certain numerical scheme for the computation of the eddy diffusivity tensor. The scheme leads to the formula for the diffusivity expressed in terms of an infinite series. We give a rigorous proof of the geometric bounds on the magnitude of the terms of the series, provided that the Eulerian field is Markovian and Gaussian and its temporal dynamics has a sufficiently large spectral gap. The principal tools used in the proofs are the decomposition of the space of square integrable fields formed over the possible realizations of the Eulerian velocity field in the Gaussian chaos and the hypercontractivity properties of Gaussian measures.

Key words. Gaussian Ornstein–Uhlenbeck field, mixing, convection-diffusion equation, passive scalar

1. Introduction.

The transport of a passive scalar field $T(\cdot,\cdot)$ in a turbulent flow can be modeled by the convection-diffusion equation with a random drift,

$$\begin{cases} \partial_t T(t,\mathbf{x}) + \mathbf{u}\,(t,\mathbf{x}) \cdot \nabla_{\mathbf{x}} T(t,\mathbf{x}) = \kappa \Delta_{\mathbf{x}} T(t,\mathbf{x}), \\ T(0,\mathbf{x}) = T_0(\mathbf{x}). \end{cases} \tag{1.1}$$

Here $\mathbf{u} = (u_1, \ldots, u_d) : \mathbb{R} \times \mathbb{R}^d \times \Omega \to \mathbb{R}^d$ is a d-dimensional, $d \geq 2$, random field, usually called *the Eulerian velocity*, given over a certain probability space $\mathcal{T} := (\Omega, \mathcal{V}, \mathbb{P})$, and $T_0(\cdot)$ is a deterministic initial condition. The drift models the turbulent convection by a flow of a certain fluid. It is therefore assumed to be time-space homogeneous, ergodic, centered, and incompressible, i.e., $\nabla_{\mathbf{x}} \cdot \mathbf{u}(t,\mathbf{x}) := \sum_{i=1}^{d} \partial_{x_i} u_i(t,\mathbf{x}) \equiv 0$. The parameter $\kappa > 0$, called *the molecular diffusivity*, describes the strength of the diffusive dispersion of the medium.

The passage from the microscopic to macroscopic description of transport is obtained by an appropriate change of scales. For example, under the diffusive scaling the macroscopic coordinates $(t', \mathbf{x}')$ are given by $t \sim t'/\varepsilon^2$ and $\mathbf{x} \sim \mathbf{x}'/\varepsilon$, where $\varepsilon \ll 1$ is a certain small parameter. Suppose also that the initial data varies on the macroscopic scale, so it is of the form $T_0(\varepsilon \mathbf{x})$. Then, in the macroscopic coordinates the rescaled field $T_\varepsilon(t,\mathbf{x}) = T(t/\varepsilon^2, \mathbf{x}/\varepsilon)$ (we omit primes here) satisfies

$$\begin{cases} \partial_t T_\varepsilon(t,\mathbf{x}) + \frac{1}{\varepsilon} \mathbf{u}\left(\frac{t}{\varepsilon^2}, \frac{\mathbf{x}}{\varepsilon}\right) \cdot \nabla_{\mathbf{x}} T_\varepsilon(t,\mathbf{x}) = \kappa \Delta_{\mathbf{x}} T_\varepsilon(t,\mathbf{x}), \\ T_\varepsilon(0,\mathbf{x}) = T_0(\mathbf{x}). \end{cases} \tag{1.2}$$

One feature that can be proved about the scaled solution, under appropriate assumptions on the statistics of the drift, is the self-averaging property of the scaled scalar

field. In the weak form it can be stated as follows:

$$\lim_{\varepsilon\to 0+}\left\langle\left[\int_{\mathbb{R}^d} T_\varepsilon(t,\mathbf{x})\varphi(\mathbf{x})d\mathbf{x}-\int_{\mathbb{R}^d} T^*(t,\mathbf{x})\varphi(\mathbf{x})d\mathbf{x}\right]^2\right\rangle=0\quad\forall\,\varphi\in C_0^\infty(\mathbb{R}^d). \tag{1.3}$$

Here $\langle\cdot\rangle$ denotes the averaging over the realizations of the drift and T^* is a (deterministic) solution of a constant coefficient heat equation

$$\begin{cases}\partial_t T^*(t,\mathbf{x})=\sum_{i,j=1}^d K^*_{i,j}\partial^2_{x_i,x_j}T^*(t,\mathbf{x}),\\ T^*(0,\mathbf{x})=T_0(\mathbf{x}).\end{cases} \tag{1.4}$$

$\mathbf{K}^*=[K^*_{i,j}]$—*the effective diffusivity* tensor—is a constant matrix. Since the procedure described above eliminates the inhomogeneity that appears in the convection-diffusion equation on the microscopic level and leads to a space-time homogeneous equation (1.4), it is sometimes referred to as *homogenization*. To substantiate the averaging property claimed in (1.3) one could first rewrite (1.2) in the divergence form. Since the drift $\mathbf{u}(t,\mathbf{x})$ is divergence-free, there exists an antisymmetric tensor-valued potential $\mathbf{H}(t,\mathbf{x})=[H_{p,q}(t,\mathbf{x})]$, $H_{p,q}(t,\mathbf{x})=-H_{q,p}(t,\mathbf{x})$ such that $\mathbf{u}(t,\mathbf{x})=\nabla_{\mathbf{x}}\cdot\mathbf{H}(t,\mathbf{x})$ and the equation in question takes the form $\partial_t T_\varepsilon(t,\mathbf{x})-\nabla_{\mathbf{x}}\cdot(a(t/\varepsilon^2,\mathbf{x}/\varepsilon)\nabla_{\mathbf{x}}T_\varepsilon(t,\mathbf{x}))=0$, where the diffusivity matrix $a(t,\mathbf{x})=[a_{p,q}(t,\mathbf{x})]$ is given by $a_{p,q}(t,\mathbf{x})=\kappa\delta_{p,q}-H_{p,q}(t,\mathbf{x})$. A rigorous proof of self-averaging for parabolic operators of this form, when the stream matrix $\mathbf{H}(t,\mathbf{x})$ is an L^∞ bounded, time-space homogeneous, and ergodic random field, follows from the results obtained by Zhikov, Kozlov, and Olejnik in [13, Theorem 1, p. 187]. However, if $\mathbf{H}(t,\mathbf{x})$ admits unbounded realizations but possesses an absolute pth moment, where $p>d+2$, as is the case in the present paper, then the averaging in the sense of (1.2) can be concluded from the quenched version of the invariance principle for random characteristics of (1.2) and has been shown in [1, 2]. The aforementioned homogenization results hold in both time dependent and static (time independent) cases. In [7] self-averaging is also shown for Gaussian time dependent drifts, for which the stream matrix need not exist. The temporal dynamics of the field is assumed to be Markovian and uniformly mixing on all spatial scales, i.e., possesses *a spectral gap*; see [7, Theorem 1, p. 528].

Because the proof of the existence of the effective diffusivity matrix is a result of an application of an appropriate ergodic theorem, what is usually left unanswered by the homogenization theorems is how to calculate the effective diffusivity tensor from the statistics of the Eulerian velocity. In this paper we take up the task of providing a formula for computing the effective diffusivity. We consider random drifts that are space-time homogeneous, Gaussian, and Markov and whose spectral dynamics possesses sufficiently strong spectral gap.

For the family of the Eulerian velocity fields described above we present a rigorous scheme for calculation of the effective diffusivity matrix that results in an infinite series expansion; see (3.18) below. In addition, we provide a geometric bound for the nth term of this series (see Theorem 3.1 below), which results in the control of the series tails (see Corollary 3.2). This control holds provided the spectral gap of the Eulerian field dynamics is sufficiently large. The precise estimate of the size of the spectral gap is possible thanks to formula (3.6).

Another interesting question pertaining to the model with a Gaussian drift is how to relate $\mathbf{K}^*$ to the autocovariance tensor

$$\mathbf{R}(t-s,\mathbf{x}-\mathbf{y}):=[\langle u_i(t,\mathbf{x})u_j(s,\mathbf{y})\rangle], \tag{1.5}$$

which, as is well known, characterizes the Gaussian drift $\mathbf{u}(\cdot,\cdot)$. To simplify our calculations we suppose further that the field is spatially isotropic and its spectral gap is identical for all spatial scales. The specific form of the spectrum of the covariance matrix is presented in (2.1) below. However, as becomes apparent during the course of the argument, our proofs do not depend on isotropy of the drift. We could also admit fields whose mixing rates vary on different scales, so long as they are bounded away from zero by a certain constant that is not too small. In section 4 we give a formula for the nth term of the series for the effective diffusivity in terms of the spectrum of the velocity field; see (4.10). Due to the fact that this term is in principle, i.e., discarding some possible cancellations, a sum of $n!$ terms, the computational value of this formula would be severely limited. Thanks to Theorem 3.1, however, we are able to control the size of a particular term of the series.

Let us describe briefly the main ideas used in the derivation of the formula for the effective diffusivity. The computation is contingent on finding, in an appropriate space, the solution of the cell problem (2.14); in the literature of the subject it is called *the corrector field*. In section 3 below we propose a numerical scheme for computing this field; see the formulas (3.1) and (3.5) for the definition of the scheme. The corrector field is then given by (3.17), and the eddy diffusivity can be calculated using (3.18). To gain appropriate estimates on the L^2-norm of the nth term ψ_n appearing in the scheme (see (3.4) for its definition), we use the decomposition of the space of square integrable functionals formed over the Eulerian velocity field at the given snapshot of time (say, when $t = 0$) into the Gaussian chaos. This together with the hypercontractivity property of Gaussian measure and the spectral gap estimate for the dynamics of the Eulerian field produce geometric bounds for the respective term; see Proposition 3.1 for the precise statement of the bounds.

Finally, in section 4 we provide an explicit formula for the nth term of the series (3.18); see Proposition 4.3. The formula is stated using the language of Feynman graphs. As we have already mentioned, in practical calculations, this formula should be coupled with the estimate (3.19) on the tails of the series expansion for the effective diffusivity.

2. The description of the model.

2.1. Homogeneous Gaussian random drifts. We suppose the following:

(V1) $\mathbf{u} : \mathbb{R} \times \mathbb{R}^d \times \Omega \to \mathbb{R}^d$ is a zero mean, space-time homogeneous, spatially isotropic, Gaussian random field over the probability space $\mathcal{T}$.

(V2) The autocovariance matrix of the field (cf. (1.5)) is given by

$$\mathbf{R}(t-s, \mathbf{x}-\mathbf{y}) = b \int_{\mathbb{R}^d} \cos((\mathbf{x}-\mathbf{y})\cdot\mathbf{k})\, e^{-a|t-s|} \mathcal{E}(|\mathbf{k}|)|\mathbf{k}|^{1-d} \hat{\Gamma}(\mathbf{k})\, d\mathbf{k}. \tag{2.1}$$

Here $a, b > 0$, $\hat{\Gamma}(\mathbf{k}) = [\hat{\Gamma}_{i,j}(\mathbf{k})]$, with $\hat{\Gamma}_{i,j}(\mathbf{k}) := \delta_{i,j} - k_i k_j |\mathbf{k}|^{-2}$. We assume that the power energy spectrum satisfies the power law

$$\mathcal{E}(k) := \mathbf{1}_{[0,K_0]}(k) k^{1-2\alpha}, \tag{2.2}$$

where $K_0 > 0$ is fixed and $\alpha < 1$, to ensure the L^2-integrability of the field.

Remark 2.1. It is well known that, thanks to (2.2), such a random field possesses a modification that is $\mathbb{P}$ a.s. jointly locally Hölder continuous in $(t, \mathbf{x}) \in \mathbb{R} \times \mathbb{R}^d$ and C^∞ smooth in $\mathbf{x}$ for any fixed $t \in \mathbb{R}$.

Remark 2.2. A direct calculation yields

$$\langle|\mathbf{u}(0,\mathbf{0})|^2\rangle = b(d-1)\omega_{d-1}\int_0^{K_0}\frac{dk}{k^{2\alpha-1}} = \frac{b}{2}(d-1)\omega_{d-1}K_0^{2(1-\alpha)}(1-\alpha)^{-1}, \tag{2.3}$$

where ω_{d-1} denotes the surface measure of $\mathbb{S}^{d-1}$—the unit sphere in $\mathbb{R}^d$.

Remark 2.3. The presence of the factor $\hat{\Gamma}(\cdot)$ in the formula ensures that the spatial realizations of the field are incompressible. The parameter $a > 0$, called *the spectral gap*, controls the rate at which the field decorrelates in the temporal variable. In our model we assume that this rate is constant on all spatial scales. Let us mention here one particular case that has been widely studied in the literature. When $a = b$ and $a \to +\infty$, the autocovariance matrix converges (in the distribution sense) to the autocovariance matrix of a δ-correlated velocity field, the so-called Kraichnan model (see [10]) given by

$$\mathbf{R}(t-s,\mathbf{x}-\mathbf{y}) = \delta(t-s)\int_{\mathbb{R}^d}\cos((\mathbf{x}-\mathbf{y})\cdot\mathbf{k})\,\mathcal{E}(|\mathbf{k}|)|\mathbf{k}|^{1-d}\,\hat{\Gamma}(\mathbf{k})\,d\mathbf{k}. \tag{2.4}$$

The effective diffusivity in this case is given explicitly and equals

$$\kappa_* = \kappa + \frac{1}{2}\int_{|\mathbf{k}|\le K_0}\mathcal{E}(|\mathbf{k}|)|\mathbf{k}|^{1-d}\hat{\Gamma}_{11}(\mathbf{k})d\mathbf{k} = \kappa + \frac{1}{4}\omega_{d-1}\left(1-\frac{1}{d}\right)K_0^{2(1-\alpha)}(1-\alpha)^{-1}.$$

2.2. Formula for effective diffusivity. An abstract cell problem. Thanks to isotropy of the Eulerian velocity field $\mathbf{u}(\cdot,\cdot)$, the effective diffusivity tensor must commute with any rotation. Hence it is of the form

$$\mathbf{K}^* = \kappa_*\mathbf{I}, \text{ where } \kappa_* = \kappa + d_* \tag{2.5}$$

and d_* is called *eddy diffusivity*. In order to determine eddy diffusivity, one needs to solve an auxiliary *cell problem for the corrector*; see, e.g., [7, (4.16), p. 537]. To formulate this problem, we need to introduce an appropriate functional space that is big enough to contain all possible spatial realizations of the velocity field at any given time instant; see also [8].

Suppose that m is a positive integer and $\vartheta_\rho(\mathbf{x}) := (1+|\mathbf{x}|^2)^{-\rho}$, $\mathbf{x}\in\mathbb{R}^d$, where $\rho > d/2$. Let $\mathcal{H}$ be the Hilbert space of d-dimensional incompressible vector fields that is the completion of $C^\infty_{0,div} := \{f\in C^\infty_0(\mathbb{R}^d;\mathbb{R}^d) : \nabla_{\mathbf{x}}\cdot f = 0\}$ w.r.t. the norm

$$||f||^2_{\mathcal{H}} := \int_{\mathbb{R}^d}(|f(\mathbf{x})|^2 + |\nabla_{\mathbf{x}}f(\mathbf{x})|^2 + \cdots + |\nabla^m_{\mathbf{x}}f(\mathbf{x})|^2)\vartheta_\rho(\mathbf{x})\,d\mathbf{x}.$$

We can always assume that m is big enough (e.g., $m > d/2+1$), so, thanks to the Sobolev embedding, any $f\in\mathcal{H}$ is of the C^1 class of regularity. The presence of a weight $\vartheta_\rho(\cdot)$ follows from the fact that for a given t the spatial realizations of the Gaussian field $\mathbf{u}(t,\cdot)$ grow, as $C\log^{1/2}|\mathbf{x}|$, for $|\mathbf{x}|\gg 1$; see, e.g., [12].

Let μ be the law in $\mathcal{H}$ of the Gaussian velocity field $\mathbf{u}(0,\cdot)$. Denote $L^2 := L^2(\mu)$, L^2_0 its subspace consisting of F such that $\int F\,d\mu = 0$. The measure μ is Gaussian of zero mean; i.e., $\int f(\mathbf{0})\mu(df) = \mathbf{0}$, with autocovariance

$$\int f(\mathbf{x})\otimes f(\mathbf{y})\mu(df) = b\int_{\mathbb{R}^d}\cos((\mathbf{x}-\mathbf{y})\cdot\mathbf{k})\,\frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d-1}}\,\hat{\Gamma}(\mathbf{k})\,d\mathbf{k}. \tag{2.6}$$

For any two vectors $\mathbf{a} = (a_1, \dots, a_d)$, $\mathbf{b} = (b_1, \dots, b_d)$ the symbol $\mathbf{a} \otimes \mathbf{b}$ denotes a $d \times d$ matrix $[a_i b_j]$. Equation (2.6) implies homogeneity of μ, i.e., $\mu \tau_{\mathbf{x}} = \mu \ \forall \mathbf{x} \in \mathbb{R}^d$, where $\tau_{\mathbf{x}} : \mathcal{H} \to \mathcal{H}$ is given by $\tau_{\mathbf{x}} f(\cdot) := f(\mathbf{x} + \cdot)$. We define *the abstract spatial gradient operator* ∇ as follows. Let

$$D_p F(f) := \partial_{x_p | \mathbf{x}=\mathbf{0}} F(\tau_{\mathbf{x}}(f)), \quad p = 1, \dots, d, \tag{2.7}$$

for $F \in L^2$, such that all the partial derivatives on the right-hand side of (2.7) exist in the L^2 sense. Let $\nabla F := (D_1 F, \dots, D_d F)$. The abstract Laplace operator Δ can be defined as

$$\Delta F = \sum_{p=1}^{d} D_p^2 F$$

for those F for which the second partials exist in the L^2 sense.

Remark 2.4. Observe that, due to incompressibility of $\mathbf{u}$, we have

$$(\tilde{\mathbf{u}} \cdot \nabla F, G)_{L^2} = -(\tilde{\mathbf{u}} \cdot \nabla G, F)_{L^2}. \tag{2.8}$$

Here

$$\tilde{\mathbf{u}}(f) = (\tilde{u}_1(f), \dots, \tilde{u}_d(f)) := f(\mathbf{0}). \tag{2.9}$$

Remark 2.5. The operator $\kappa\Delta$ is the generator of a semigroup of symmetric Markov contractions on L^2, given by

$$S(t)F(f) = \int_{\mathbb{R}^d} r_\kappa(t, \mathbf{y}) F(\tau_{\mathbf{y}} f) d\mathbf{y}, \quad F \in L^2, \tag{2.10}$$

where

$$r_\kappa(t, \mathbf{x}) := \frac{1}{(4\kappa\pi t)^{d/2}} \exp\left\{ -\frac{|\mathbf{x}|^2}{4\kappa t} \right\}. \tag{2.11}$$

It is therefore a self-adjoint, negative definite operator.

To introduce the temporal derivative $D_0 F$ we need to describe in more detail the dynamics of the $\mathcal{H}$-valued stochastic process $(\mathbf{u}(t, \cdot))_{t \geq 0}$. This process can be thought of as the time stationary solution of an $\mathcal{H}$-valued linear stochastic differential equation

$$du(t) = -au(t)dt + \sqrt{2a} B dW(t), \tag{2.12}$$

with $u(0) = \mathbf{u}(0, \cdot)$. Here $W(\cdot)$ is a cylindrical Wiener process on $L^2_{div}(\mathbb{R}^d, \mathbb{R}^d)$—the space of all square integrable incompressible d-dimensional vector fields—defined over the probability space $\mathcal{T}$, and $B : L^2_{div}(\mathbb{R}^d, \mathbb{R}^d) \to \mathcal{H}$ is a Hilbert–Schmidt operator given by

$$\widehat{B\psi}(\mathbf{k}) = \sqrt{\mathcal{E}\left(|\mathbf{k}|\right)} |\mathbf{k}|^{(1-d)/2} \hat{\psi}(\mathbf{k}). \tag{2.13}$$

Both here and below $\hat{\psi}$ denotes the Fourier transform of a given function ψ. We refer the reader to [7] for details of this construction.

The Eulerian velocity field $\mathbf{u}(t, \mathbf{x})$ can be then identified with $u(t)(\mathbf{x})$. Let $D_0 : D(D_0) \to L^2$ be the generator of $u(\cdot)$ and $(P(t))_{t \geq 0}$ the corresponding semigroup of

Markov operators. It can easily be shown that the dynamics described by (2.12) and (2.13) is *reversible*; i.e., each $P(t)$ is self-adjoint (see [7, (3.4), p. 530]).

The abstract cell problem can be formulated as

$$\kappa\Delta\chi + D_0\chi - \tilde{\mathbf{u}}\cdot\nabla\chi = \tilde{u}; \tag{2.14}$$

see [7, (4.16), p. 537]. Here $\tilde{\mathbf{u}}$ is given by (2.9) and $\tilde{u}$ denotes one of the components of $\tilde{\mathbf{u}}$. To fix our attention we shall admit $\tilde{u} := \tilde{u}_1$. The unknown field χ is called a *corrector*. Thanks to the assumed isotropy of the field, *the eddy diffusivity* d_* is given by

$$d_* := -(\tilde{u}, \chi)_{L^2}; \tag{2.15}$$

see [7, (5.10), p. 544]. Unfortunately, (2.14) does not need to have a solution in L^2. This is, for instance, a typical situation in the case of static fields. Then, one can only guarantee the existence of χ in a distribution sense. However, under the assumption that the dynamics of $\mathbf{u}(\cdot)$ possesses a spectral gap, i.e., its spectral measure is of the form (2.1) with $a > 0$, one can show that there exists a unique $\chi \in L^2$ solving (2.14) and satisfying $\int \chi d\mu = 0$; see [7, (4.16), p. 537].

It is immensely difficult in general to perform explicit calculations of eddy diffusivity with the help of formula (2.15). This is due to the fact that the cell problem (2.14) is formulated for functionals defined over an infinite dimensional Hilbert space and it is very seldom possible to solve it explicitly. However, in the Gaussian case it is possible to give a numerical scheme for calculating eddy diffusivity with the help of a decomposition of L^2 into Gaussian chaos.

2.3. The decomposition of L^2 using Gaussian chaos. Let $\mathcal{P}_n$ be the L^2 closure of the linear space spanned by the monomials $f \mapsto \langle\varphi_1, f\rangle \dots \langle\varphi_m, f\rangle$, where $m \le n$, $\varphi_1, \dots, \varphi_m \in \mathcal{S}_d$. Here $\mathcal{S}_d$ is the space of incompressible fields belonging to the Schwartz class and $\langle g, f\rangle := \int_{\mathbb{R}^d} f(\mathbf{x})\cdot g(\mathbf{x}) d\mathbf{x}$ for any $f \in \mathcal{S}_d$, $g \in \mathcal{H}$. $H_n := \mathcal{P}_n \ominus \mathcal{P}_{n-1}$ is called *the space of nth degree Hermite polynomials*. We denote by Π_n the orthogonal projection of L^2 onto H_n. It is well known (see, e.g., [6, Theorem 2.6, p. 16]) that $L^2 = \bigoplus_{n\ge 0} H_n$. Thanks to the fact that the group induced by shift $U^{\mathbf{x}}F := F\tau_{\mathbf{x}}$ leaves each H_n invariant, we see from (2.10) that $S(t)(H_n) = H_n$ for each n.

The Hermite polynomials also provide for a neat description of the operator D_0. Namely, for any $F \in H_n$ we have $F \in D(D_0)$ and

$$D_0 F = -anF. \tag{2.16}$$

Equation (2.16) can be seen by using the formula for the generator of $(\mathbf{u}(t,\cdot))_{t\ge 0}$ contained on p. 207 of [9]. A simple consequence of (2.16) is the following *spectral gap estimate* of D_0:

$$-(D_0F, F)_{L^2} \ge a\|F\|^2_{L^2} \quad \text{for any } F \in L^2 \text{ s.t. } \int F d\mu = 0. \tag{2.17}$$

Another consequence of (2.16) and the fact that each H_n is invariant under semigroup $S(\cdot)$ is commutation relation $P(t)S(s) - S(s)P(t) = 0$ for arbitrary $t, s \ge 0$. Hence $R(t) := S(t)P(t)$, $t \ge 0$, defines a semigroup of self-adjoint operators, whose generator equals $\kappa\Delta + D_0$ on a sufficiently large subspace $\mathcal{C}$ that constitutes a core for both $\kappa\Delta$, D_0. One can, for instance, take

$$\mathcal{C} := \bigcap_{p\in(2,\infty)} W^{2,p} \cap D(D_0),$$

where $W^{m,p}$ denotes the closure of those F, for which $\mathbf{x} \mapsto F\tau_{\mathbf{x}}$ possesses m derivatives at $\mathbf{0}$ in the norm given by $\|F\|^p_{m,p} := \sum_{i_1+\cdots+i_d\le m} \|D_1^{i_1} \dots D_d^{i_d} F\|^p_{L^p}$.

2.4. The integral representation of the corrector. Let $\mathcal{L}F := \kappa\Delta F + D_0 F - \tilde{\mathbf{u}} \cdot \nabla F$, $F \in \mathcal{C}$. It can be shown (see [7, Proposition 3, p. 536]) that the closure of $\mathcal{L}$ is a generator of a semigroup $(Q(t))_{t\ge 0}$ of Markov operators on L^2 that leaves $\mathcal{C}$ invariant. This semigroup is exponentially stable with $\|Q(t)F\|_{L^2} \le e^{-at}\|F\|_{L^2}$ for any F satisfying $\int F d\mu = 0$ (see [7, (4.5), p. 536]). Using the semigroup, we can write the unique zero mean solution to the Poisson equation (2.14) (cf. [7, (4.16), p. 537]):

$$\chi := -\int_0^\infty Q(t)\tilde{u}dt. \tag{2.18}$$

Since $\tilde{u} \in \mathcal{C}$ we conclude that also $\chi \in \mathcal{C}$. From (2.14) and the spectral gap estimate (2.17) we can also infer that for a nontrivial Eulerian velocity field

$$d_* = -(\mathcal{S}\chi, \chi)_{L^2} = \kappa\|\nabla\chi\|^2_{L^2} - (D_0\chi, \chi)_{L^2} > \kappa\|\nabla\chi\|^2_{L^2} > 0,$$

and in consequence $\kappa_* > \kappa$. The latter inequality highlights a well-known physical fact that in an incompressible medium a turbulent convection enhances diffusive properties of the medium.

Remark 2.6. Note that in our case the "time derivation operator" D_0 is self-adjoint and satisfies the spectral gap estimate (2.17). A differentiation w.r.t. to time operator D_0 can be in fact introduced for environments that are only stationary in t (with no additional assumption on the structure of their temporal dynamics); cf. [13, p. 193]. However, when D_0 is defined in such a general way, discarding additional information about the dissipative properties of the evolution of the environment in time, it is an anti-self-adjoint operator (conditioning on the environment up to a given moment of time becomes averaging w.r.t. a trivial, deterministic, probability measure), and the spectral gap inequality (2.17) fails to be true. In fact, then $(D_0F, F)_{L^2} = 0 \ \forall\ F$. In consequence, the definition of χ via (2.18) would not make sense in L^2 under such general circumstances, but one can make sense of it in an appropriate distribution space (see [13, p. 194]).

3. Numerical scheme for calculation of the effective diffusivity. Since $\tilde{u} \in \mathcal{P}_1$, $\int \tilde{u}d\mu = 0$, and the spectrum of $\kappa\Delta + D_0$ restricted to L^2_0 has a gap of size at least $a > 0$, we can find a unique $\psi_1 \in \mathcal{P}_1$ that is the solution of

$$(\kappa\Delta + D_0)\psi_1 = \tilde{u} \tag{3.1}$$

and satisfies $\int \psi_1 d\mu = 0$. In fact

$$\psi_1 := -\int_0^\infty R(t)\tilde{u}dt. \tag{3.2}$$

Suppose we have already defined $\psi_n \in \mathcal{P}_n$, $n = 1, \dots, N$, for a certain N. Set

$$u_N := \tilde{\mathbf{u}} \cdot \nabla\psi_N \in \mathcal{P}_{N+1}. \tag{3.3}$$

Note that

$$\int u_N d\mu = \int \nabla \cdot (\tilde{\mathbf{u}}\psi_N)d\mu = -\int \nabla\mathbf{1} \cdot \tilde{\mathbf{u}}\psi_N d\mu = 0,$$

so

$$\psi_{N+1} := -\int_0^\infty R(t)u_N dt \in \mathcal{P}_{N+1} \tag{3.4}$$

is the unique zero mean solution of

$$(D_0 + \kappa\Delta)\psi_{N+1} = u_N. \tag{3.5}$$

THEOREM 3.1. *Let*

$$q := \left(\frac{6}{a\kappa}\right)^{1/2} \|\tilde{\mathbf{u}}\|_{L^2}. \tag{3.6}$$

Then,

$$\|\psi_N\|_{L^2} \le q^{N-1}\|\psi_1\|_{L^2} \quad \forall\, N \ge 1. \tag{3.7}$$

Proof. Denote $\psi_{N,k} := \Pi_k\psi_N$ (the projection onto the space of kth degree Hermite polynomials) and

$$|\!|\!|F|\!|\!|^2 := \sum_{k=1}^{+\infty} k\|\Pi_k F\|_{L^2}^2.$$

Obviously $\psi_{N,k} = 0$ for $k > N$. Projecting both sides of (3.5) onto H_k and taking the scalar product against $\psi_{N+1,k}$, we obtain

$$ak\|\psi_{N+1,k}\|_{L^2}^2 + \kappa\|\nabla\psi_{N+1}\|_{L^2}^2 \tag{3.8}$$

$$= -(\tilde{\mathbf{u}}\cdot\nabla\psi_{N,k+1}, \psi_{N+1,k})_{L^2} - (\tilde{\mathbf{u}}\cdot\nabla\psi_{N,k-1}, \psi_{N+1,k})_{L^2}.$$

The last equality is a consequence of the following two observations. First, note that $\Pi_k(\tilde{\mathbf{u}}\cdot\nabla\psi_{N,l}) \neq 0$ only when $l = k-1, k, k+1$. In addition, thanks to (2.8),

$$(\Pi_k(\tilde{\mathbf{u}}\cdot\nabla\psi_{N,k}), \psi_{N,k})_{L^2} = (\tilde{\mathbf{u}}\cdot\nabla\psi_{N,k}, \psi_{N,k})_{L^2} = 0.$$

To estimate the right-hand side of (3.8), we consider two cases. First, when $k = 1$, the second term on the right-hand side vanishes. On the other hand, thanks to incompressibility of $\mathbf{u}(\cdot,\cdot)$, the first term equals $(\tilde{\mathbf{u}}\cdot\nabla\psi_{N+1,1}, \psi_{N,2})_{L^2}$. Its absolute value is, by virtue of the Cauchy–Schwarz inequality, less than or equal to

$$\begin{aligned}
&\|\psi_{N,2}\|_{L^2}\left[\sum_{i,j=1}^d \int \tilde{u}_i^2 (D_j\psi_{N+1,1})^2 d\mu\right]^{1/2} \\
&\le \|\psi_{N,2}\|_{L^2}\left[\sum_{i,j=1}^d \left(\int \tilde{u}_i^4 d\mu\right)^{1/2}\left(\int (D_j\psi_{N+1,1})^4 d\mu\right)^{1/2}\right]^{1/2} \\
&\le \sqrt{3}\|\psi_{N,2}\|_{L^2}\|\mathbf{u}\|_{L^2}\|\nabla\psi_{N+1,1}\|_{L^2}.
\end{aligned}$$

In the last inequality we used the fact that, for any centered Gaussian random variable X, its fourth moment $EX^4 = 3(EX^2)^2$.

For $k \geq 2$ we estimate as follows. The first term on the right-hand side of (3.8) equals $(\tilde{\mathbf{u}} \cdot \nabla \psi_{N+1,k}, \psi_{N,k+1})_{L^2}$, and its absolute value can be estimated from above by

$$\|\nabla \psi_{N+1,k}\|_{L^2} \left[\int (|\tilde{\mathbf{u}}||\psi_{N,k+1}|)^2 d\mu \right]^{1/2} \tag{3.9}$$

$$\leq \sqrt{d}\, \|\nabla \psi_{N+1,k}\|_{L^2} \|\tilde{u}\|_{L^{2m}} \|\psi_{N,k+1}\|_{L^{2m/(m-1)}}$$

for an arbitrary $m > 1$. The hypercontractivity property of Gaussian measures on L^p spaces (see [6, Theorem 5.10, p. 62]) allows us to estimate

$$\|\psi_{N,k+1}\|_{L^{2m/(m-1)}} \leq \left(\frac{2m}{m-1} - 1 \right)^{(k+1)/2} \|\psi_{N,k+1}\|_{L^2} \tag{3.10}$$

$$= \left(\frac{m+1}{m-1} \right)^{(k+1)/2} \|\psi_{N,k+1}\|_{L^2}.$$

On the other hand, $\tilde{u}$ is a Gaussian random variable under μ; hence

$$\|\tilde{u}\|_{L^{2m}} = [(2m-1)!!]^{1/(2m)} \|\tilde{u}\|_{L^2}. \tag{3.11}$$

Here $(2m-1)!! := 1 \cdot 3 \cdot \cdots \cdot (2m-1)$. Using Stirling's formula (see, e.g., [5, paragraph 406]), $n! = \sqrt{2\pi n}(ne^{-1})^n e^{\theta/(12n)}$ for some $\theta \in (0,1)$, we conclude from (3.11) that

$$[(2m-1)!!]^{1/(2m)} = \left[\frac{(2m-1)!}{2^{m-1}(m-1)!} \right]^{1/(2m)} \tag{3.12}$$

$$\leq (2e)^{-1/2} (2m-1)(m-1)^{-1/2} 2^{1/(4m)} \left(1 - \frac{1}{2m-1} \right)^{1/(4m)} \exp\left\{ [24m(2m-1)]^{-1} \right\}.$$

Summarizing, from (3.9)–(3.12) we conclude that

$$|(\tilde{\mathbf{u}} \cdot \nabla \psi_{N,k+1}, \psi_{N+1,k})_{L^2}| \leq C\left(\frac{k+1}{2}, m \right) \|\tilde{\mathbf{u}}\|_{L^2} (k+1)^{1/2} \|\psi_{N,k+1}\|_{L^2} \|\nabla \psi_{N+1,k}\|_{L^2}$$

$$\leq \frac{1}{2\kappa} C^2 \left(\frac{k+1}{2}, m \right) \|\tilde{\mathbf{u}}\|_{L^2}^2 (k+1) \|\psi_{N,k+1}\|_{L^2}^2 + \frac{\kappa}{2} \|\nabla \psi_{N+1,k}\|_{L^2}^2. \tag{3.13}$$

Here

$$C(p,m) := (2ep)^{-1/2} (2m-1)(m-1)^{-1/2} \left(\frac{m+1}{m-1} \right)^{p/2} \tag{3.14}$$

$$\times\ 2^{1/(4m)} \left(1 - \frac{1}{2m-1} \right)^{1/(4m)} \exp\left\{ [24m(2m-1)]^{-1} \right\}.$$

Likewise,

$$|(\tilde{\mathbf{u}} \cdot \nabla \psi_{N,k-1}, \psi_{N+1,k})_{L^2}| \tag{3.15}$$

$$\leq \frac{1}{2\kappa} C^2 \left(\frac{k-1}{2}, m' \right) \|\tilde{\mathbf{u}}\|_{L^2}^2 (k-1) \|\psi_{N,k-1}\|_{L^2}^2 + \frac{\kappa}{2} \|\nabla \psi_{N+1,k}\|_{L^2}^2.$$

Note that for $m = 2k + 1$ we have

$$C((k+1)/2, 2k+1) \le 2^{1/12} e^{-1/2+1/360} \left(2 + \frac{1}{2k}\right) \left(1 + \frac{1}{k}\right)^{k/2} < 1.0595 \left(2 + \frac{1}{2k}\right);$$

hence $C^2((k+1)/2, 2k+1) < 6$ for $k \ge 2$. A direct calculation also shows that $C^2(1,3) \approx 5.1620$. Likewise, for $m' = 2k-1$ we have $C^2((k-1)/2, 2k-1) < 6$, $k \ge 2$. Summing up (3.8) over k and using (3.13), (3.16), we conclude therefore that

$$a \sum_{k=1}^{N+1} k \|\psi_{N+1,k}\|_{L^2}^2 + \kappa \|\nabla \psi_{N+1}\|_{L^2}^2 \tag{3.16}$$

$$\le \kappa \|\nabla \psi_{N+1}\|_{L^2}^2 + \frac{6}{\kappa} \|\tilde{\mathbf{u}}\|_{L^2}^2 \sum_{k=1}^{N+1} k \|\psi_{N,k+1}\|_{L^2}^2.$$

Hence, from (3.16) we get

$$a |\!|\!| \psi_{N+1} |\!|\!|^2 \le \frac{6}{\kappa} \|\tilde{\mathbf{u}}\|_{L^2}^2 |\!|\!| \psi_N |\!|\!|^2,$$

and (3.7) follows. □

The solution to (2.14) is given by

$$\chi := \sum_{n=1}^{+\infty} \psi_n. \tag{3.17}$$

The series in (3.17) converges in the L^2 sense provided that $q < 1$; cf. (3.6). Also, as we shall show in Proposition 4.1, we have $(\psi_n, \tilde{u})_{L^2} = 0$ if n is even. From (2.15) we can write therefore that

$$d_* = -\sum_{n=0}^{+\infty} (\psi_{2n+1}, \tilde{u})_{L^2}; \tag{3.18}$$

thus, using (3.7), we conclude the following.

Corollary 3.2.

$$\left| d_* + \sum_{n=0}^{M} (\psi_{2n+1}, \tilde{u})_{L^2} \right| \le q^{2M+2} (1 - q^2)^{-1} \|\psi_1\|_{L^2} \|\tilde{u}\|_{L^2}. \tag{3.19}$$

To calculate $\|\psi_1\|_{L^2}$ we use the spectral representation of $\tilde{u}$,

$$\tilde{u}(\tau_{\mathbf{x}} f) = \int e^{i\mathbf{k}\cdot\mathbf{x}} \hat{u}(d\mathbf{k}; f),$$

where $\hat{u}(\cdot)$ is its spectral measure that satisfies $\hat{u}^*(d\mathbf{k}) = \hat{u}(-d\mathbf{k})$ (because $\tilde{u}$ is real-valued) and

$$\langle \hat{u}^*(d\mathbf{k}) \hat{u}(d\mathbf{k}') \rangle = b\delta(\mathbf{k} - \mathbf{k}') \frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d-1}} \hat{\Gamma}_{11}(\mathbf{k}) d\mathbf{k} d\mathbf{k}'.$$

Also, because $\mathbf{x} \mapsto \hat{u}(\tau_{\mathbf{x}} f)$ is a real Gaussian field, we have that (Re $\hat{u}(\cdot)$, Im $\hat{u}(\cdot)$) is jointly Gaussian. Hence,

$$\psi_1 = (\kappa\Delta + D_0)^{-1}\tilde{u} = -\int \frac{\hat{u}(d\mathbf{k})}{\kappa|\mathbf{k}|^2 + a}$$

and

$$\|\psi_1\|_{L^2}^2 = \int\int \frac{\langle \hat{u}^*(d\mathbf{k})\hat{u}(d\mathbf{k}')\rangle}{(\kappa|\mathbf{k}|^2 + a)(\kappa|\mathbf{k}'|^2 + a)} = b\omega_{d-1}\left(1 - \frac{1}{d}\right)\int_0^{K_0} \frac{dk}{(\kappa k^2 + a)^2 k^{2\alpha-1}}. \tag{3.20}$$

4. Calculation of $(\psi_n, \tilde{u})_{L^2}$. We start with some auxiliary notation. For any function $F(t_1, \dots, t_n, \mathbf{x}_1, \dots, \mathbf{x}_n)$ of n temporal and spatial variables we define

$$DF(t_1, \dots, t_{2n}, \mathbf{x}_1, \dots, \mathbf{x}_n) := \nabla_{\mathbf{y}|\,\mathbf{y}=\mathbf{0}} F(t_1, \dots, t_n, \mathbf{x}_1 + \mathbf{y}, \dots, \mathbf{x}_n + \mathbf{y}).$$

$\mathbf{W}_n(\cdot)$ is defined inductively by

$$\mathbf{W}_0(s_1, \mathbf{x}_1) := \mathbf{u}(s_1, \mathbf{x}_1), \tag{4.1}$$

$$\mathbf{W}_n(s_1, \dots, s_{n+1}, \mathbf{x}_1, \dots, \mathbf{x}_{n+1}) := \mathbf{u}(s_{n+1}, \mathbf{x}_{n+1}) \cdot D\mathbf{W}_{n-1}(s_1, \dots, s_n, \mathbf{x}_1, \dots, \mathbf{x}_n). \tag{4.2}$$

Let also $\Delta_n := [(s_1, \dots, s_n) : s_1 \geq \cdots \geq s_n \geq 0]$.

PROPOSITION 4.1. *We have*

$$-(\psi_n, \tilde{u})_{L^2} = \int_{\Delta_n}\dots\int \int_{(\mathbb{R}^d)^n}\dots\int \langle W_{n-1,1}(\mathbf{s}, \mathbf{x}) u_1(0, \mathbf{0})\rangle R_{n-1}(\mathbf{s}, \mathbf{x}) d\mathbf{s} d\mathbf{x}. \tag{4.3}$$

Here $\mathbf{s}$, $\mathbf{x}$ *stand for the abbreviations of the ensemble of variables* $\mathbf{s} = (s_1, \dots, s_n)$, $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$, $d\mathbf{s} = ds_1 \dots ds_n$, $d\mathbf{x} = d\mathbf{x}_1 \dots d\mathbf{x}_n$,

$$R_{n-1}(\mathbf{s}, \mathbf{x}) := \prod_{m=1}^{n} r_\kappa(s_m - s_{m+1}, \mathbf{x}_m - \mathbf{x}_{m+1}), \tag{4.4}$$

where $r_\kappa(\cdot, \cdot)$ *is the heat kernel defined in* (2.11) *and* $s_{n+1} := 0$, $\mathbf{x}_{n+1} := \mathbf{0}$.

Proof. To show (4.3) we prove that

$$\psi_n = -\int_{\Delta_n}\dots\int \int_{(\mathbb{R}^d)^n}\dots\int \mathbb{E}_0[W_{n-1,1}(\mathbf{s}, \mathbf{x})] R_{n-1}(\mathbf{s}, \mathbf{x}) d\mathbf{s} d\mathbf{x}, \tag{4.5}$$

where $\mathbb{E}_t$ denotes the conditional expectation w.r.t. σ-algebra $\mathcal{U}_t$ generated by $\mathbf{u}(s, \cdot)$, $s \leq t$. We use an induction argument. For $n = 1$, (4.5) is a consequence of (3.2) and the definition of the semigroup $R(t)$.

Suppose that we have established (4.5) for a certain $n \geq 1$. Note that

$$\psi_{n+1} = -\int_0^{+\infty} R(t) u_n dt. \tag{4.6}$$

Recalling the definition of u_n (see (3.3)), we get

$$u_n = -\int\!\!\dots\!\!\int_{\Delta_n} \int\!\!\dots\!\!\int_{(\mathbb{R}^d)^n} \mathbf{u}(0,\mathbf{0}) \cdot \mathbb{E}_0[DW_{n-1,1}(\mathbf{s},\mathbf{x})] R_{n-1}(\mathbf{s},\mathbf{x}) d\mathbf{s} d\mathbf{x},$$

and in consequence

$$R(t)u_n = -\int\!\!\dots\!\!\int_{\Delta_n} \int\!\!\dots\!\!\int_{(\mathbb{R}^d)^{n+1}} \mathbb{E}_0[\mathbf{u}(t,\mathbf{z}) \cdot DW_{n-1,1}(\mathbf{s}+t,\mathbf{x}+\mathbf{z})] R_{n-1}(\mathbf{s},\mathbf{x}) r_\kappa(t,\mathbf{z}) d\mathbf{s} d\mathbf{x} d\mathbf{z}.$$

Here $\mathbf{s}+t := (s_1+t,\dots,s_n+t)$, $\mathbf{x}+\mathbf{z} := (\mathbf{x}_1+\mathbf{z},\dots,\mathbf{x}_n+\mathbf{z})$. Setting $s'_{n+1} := t$, $s'_i := s_i + t$, $\mathbf{x}'_{n+1} := \mathbf{z}$, $\mathbf{x}'_i := \mathbf{x}_i$, $i = 1,\dots,n$, it is clear from (4.6) and definitions (4.3), (4.4) that formula (4.5) holds for $n+1$. □

Remark 4.2. From (4.3) and elementary properties of Gaussian variables we conclude that $(\psi_{2n}, \tilde{u})_{L^2} = 0 \; \forall\, n$.

To calculate $\langle W_{2n,1}(\mathbf{s},\mathbf{x}) u_1(0,\mathbf{0})\rangle$ appearing in the formula for $(\psi_{2n+1}, \tilde{u})_{L^2}$ (cf. Proposition 4.1), we need to compute the mathematical expectation of a multiple product of Gaussian random variables (cf. [4]). For that purpose it is convenient to use a graphical representation, borrowed from the quantum field theory; see, e.g., [6]. A *Feynman diagram* $\mathcal{G}$ of order $n \geq 0$ and rank $r \geq 0$ is a graph consisting of n vertices made of elements of $\mathbb{Z}_n := \{1,\dots,n\}$ that are positive integers and a set $E(\mathcal{G})$ of $r \leq n/2$ edges without common endpoints. So there are r pairs of vertices, each joined by an edge, and $n-2r$ unpaired vertices, called *free vertices*. An edge whose endpoints are $m, m' \in B$ is represented by $\widehat{mm'}$; we always assume that $m < m'$. Denote the set of all free vertices by $A(\mathcal{G})$. The diagram is *complete* if $A(\mathcal{G})$ is empty and *incomplete* otherwise. Denote by $\mathfrak{F}_n$ the family of all complete Feynman diagrams based on $\mathbb{Z}_n$ (n must then be even). For a given $\mathcal{G} \in \mathfrak{F}_n$ and any $l \leq n$ we denote by $V_l(\mathcal{G})$ all those vertices $m \leq l$ for which there is $n > l$ such that $\widehat{mn} \in E(\mathcal{G})$.

Suppose that $\mathcal{G}$, $\mathcal{G}'$ are Feynman diagrams based on $\mathbb{Z}_n$, $\mathbb{Z}_{n-1}$, respectively. We call $\mathcal{G}'$ *an immediate predecessor* of $\mathcal{G}$ and denote this $\mathcal{G}' \hookrightarrow \mathcal{G}$ if $E(\mathcal{G}') \subseteq E(\mathcal{G})$. Diagram $\mathcal{G}$ is called *admissible* if $A(\mathcal{G}) \neq \emptyset$. For $n \geq 1$ we define a class $\mathfrak{S}_n$ that consists of all sequences $\mathcal{F} := (\mathcal{F}_k)_{k=1}^n$ of Feynman diagrams $\mathcal{F}_1 \hookrightarrow \mathcal{F}_2 \dots \hookrightarrow \mathcal{F}_n$, such that each $\mathcal{F}_k$, based on $\mathbb{Z}_k$, is admissible. For n even we denote by $\mathfrak{S}_n^c$ the class of those sequences $\mathcal{F}_1 \hookrightarrow \mathcal{F}_2 \dots \hookrightarrow \mathcal{F}_n$ for which $(\mathcal{F}_k)_{k=1}^{n-1} \in \mathfrak{S}_{n-1}$ and $\mathcal{F}_n \in \mathfrak{F}_n$. Let $\mathcal{F} \in \mathfrak{S}_n$ or $\mathfrak{S}_n^c$. Denote by $A_k(\mathcal{F}) := A(\mathcal{F}_k)$, $E_k(\mathcal{F}) := E(\mathcal{F}_k)$, $k = 1,2,\dots,n$. We also let $a_k(\mathcal{F})$ denote the cardinality of $A_k(\mathcal{F})$. Let $e_1(\mathcal{F}) := 0$ and $e_{k+1}(\mathcal{F}) := 1/2[a_k(\mathcal{F}) + 1 - a_{k+1}(\mathcal{F})]$, $k = 1,\dots,n-1$.

LEMMA 4.1. *Let $n \geq 0$ and $\mathbf{s} = (s_1,\dots,s_{2n+1}) \in \Delta_{2n+1}$, $\mathbf{x} = (\mathbf{x}_1,\dots,\mathbf{x}_{2n+1})$, $\mathbf{k} = (\mathbf{k}_1,\dots,\mathbf{k}_{2n+1})$. We have then*

$$\langle W_{2n,1}(\mathbf{s},\mathbf{x}) u_1(0,\mathbf{0})\rangle \tag{4.7}$$

$$= (-1)^n b^{n+1} \sum \int\!\!\dots\!\!\int \exp\left\{ \mathrm{i} \sum_{m=1}^{2n+1} \mathbf{k}_m \cdot \mathbf{x}_m \right\} P_{\mathbf{j}}(\mathbf{s},\mathbf{k};\mathcal{F}) Q_{\mathbf{j}}(\mathbf{k};\mathcal{F}_{2n+2}) d\mathbf{k}.$$

The summation extends over all integer-valued multi-indices $\mathbf{j} = (j_1,\dots,j_{2n+2})$ of length $2n+2$, such that $j_1 = j_{2n+2} = 1$ and all sequences $\mathcal{F} \in \mathfrak{S}_{2n+2}^c$. Also, for a given $\mathcal{F}$

$$P_{\mathbf{j}}(\mathbf{s},\mathbf{k};\mathcal{F}) = \exp\{-aa_{2n+1}(\mathcal{F})s_{2n+1}\} \tag{4.8}$$

$$\times \prod_{l=1}^{2n} \left\{ \left(\sum_{m\in A_l(\mathcal{F})} k_{m,j_{l+1}} \right) \exp\{-aa_l(\mathcal{F})(s_l - s_{l+1})\}[1-\exp\{-2a(s_l-s_{l+1})\}]^{e_l(\mathcal{F})} \right\},$$

$$Q_{\mathbf{j}}(\mathbf{k};\mathcal{F}_{2n+2}) = \prod_{\widehat{mm'}\in E(\mathcal{F}_{2n+2})} \frac{\mathcal{E}(|\mathbf{k}_m|)}{|\mathbf{k}_m|^{d-1}} \hat{\Gamma}_{j_m,j_{m'}}(\mathbf{k}_m)\delta(\mathbf{k}_m+\mathbf{k}_{m'}). \tag{4.9}$$

Here, for abbreviation's sake, $d\mathbf{k} := d\mathbf{k}_1 \dots d\mathbf{k}_{2n+2}$.

This lemma follows from an argument analogous to that used in the proof of Lemma 1 of [4]. For the reader's convenience we present it in the appendix below.

Using Proposition 4.1 and Lemma 4.1, contained in the following section we have the following formula.

PROPOSITION 4.3. *We have*

$$(\psi_{2n+1},\tilde{u})_{L^2} = (-1)^{n+1}b^{n+1}(2a)^{-2n-1}\sum \prod_{l=1}^{2n+1} e_l(\mathcal{F})! \int\dots\int \prod_{l=1}^{2n} \left(\sum_{m\in V_l(\mathcal{F}_{2n+2})} k_{m,j_{l+1}} \right) \tag{4.10}$$

$$\times \prod_{l=1}^{2n+1} \left[\prod_{p=0}^{e_l(\mathcal{F})} \left(\frac{1}{2}a_l(\mathcal{F}) + p + \frac{\kappa}{2a} \left| \sum_{m\in V_l(\mathcal{F}_{2n+2})} \mathbf{k}_m \right|^2 \right) \right]^{-1} Q_{\mathbf{j}}(\mathbf{k}_1,\dots,\mathbf{k}_{2n+2};\mathcal{F}_{2n+2})d\mathbf{k}.$$

The summation range is the same as in Lemma 4.1.

Proof. Using the Fourier transform, we can write

$$R_{2n}(\mathbf{s},\mathbf{x}) = \int\dots\int \prod_{m=1}^{2n+1} \exp\left\{-\kappa|\mathbf{q}_m|^2(s_m-s_{m+1}) + \mathrm{i}\mathbf{q}_m\cdot(\mathbf{x}_m-\mathbf{x}_{m+1})\right\} d\mathbf{q},$$

with $d\mathbf{q} = d\mathbf{q}_1\dots d\mathbf{q}_{n+1}$. Applying formula (4.3) to represent $(\psi_{2n+1},\tilde{u})_{L^2}$ and substituting from (4.7) for $\langle W_{2n,1}(\mathbf{s},\mathbf{x})u_1(0,\mathbf{0})\rangle$, we obtain that

$$(\psi_{2n+1},\tilde{u})_{L^2} = (-1)^{n+1}b^{n+1}\sum \int_{\Delta_n}\dots\int\int\dots\int \prod_{m=1}^{2n+1} \exp\left\{-\kappa|\mathbf{q}_m|^2(s_m-s_{m+1})\right\} \tag{4.11}$$

$$\times \prod_{m=1}^{2n+1} \exp\left\{\,\mathrm{i}(\mathbf{k}_m+\mathbf{q}_m-\mathbf{q}_{m-1})\cdot\mathbf{x}_m\right\} P_{\mathbf{j}}(\mathbf{k}_1,\dots,\mathbf{k}_{2n+1};\mathcal{F})$$

$$\times Q_{\mathbf{j}}(\mathbf{k}_1,\dots,\mathbf{k}_{2n+2};\mathcal{F}_{2n+2})d\mathbf{s}d\mathbf{x}d\mathbf{k}d\mathbf{q};$$

here $\mathbf{q}_0 := \mathbf{0}$ and the summation range is the same as in Lemma 4.1. Performing the integration over $\mathbf{x}$ variables yields the expression $\prod_{m=1}^{2n+1}\delta(\mathbf{k}_m+\mathbf{q}_m-\mathbf{q}_{m-1})$, which in turn implies that $\mathbf{q}_1 = -\mathbf{k}_1$, $\mathbf{q}_m = \mathbf{q}_{m-1}-\mathbf{k}_m$. Hence $\mathbf{q}_l = -\sum_{m=1}^{l}\mathbf{k}_m$. Changing variables $s'_m := s_m - s_{m+1}$, $m = 1,\dots,2n+1$ ($s_{2n+2}=0$), and substituting for $P_{\mathbf{j}}(\mathbf{k}_1,\dots,\mathbf{k}_{2n+1};\mathcal{F})$ from (4.8), we get

$$(\psi_{2n+1},\tilde{u})_{L^2}=(-1)^{n+1}b^{n+1}\sum\int\dots\int\prod_{l=1}^{2n}\left(\sum_{m\in A_l(\mathcal{F})}k_{m,j_{l+1}}\right)Q_{\mathbf{j}}(\mathbf{k}_1,\dots,\mathbf{k}_{2n+2};\mathcal{F}_{2n+2})$$

$$\times\prod_{l=1}^{2n+1}\left[\int_0^{+\infty}\exp\left\{-\left(aa_l(\mathcal{F})+\kappa\left|\sum_{m=1}^{l}\mathbf{k}_m\right|^2\right)s_l'\right\}\left(1-e^{-2as_l'}\right)^{e_l(\mathcal{F})}ds_l'\right]d\mathbf{k}.$$

Substituting $t_l:=e^{-2as_l'}$ into the integral w.r.t. s_l', we conclude that

$$(\psi_{2n+1},\tilde{u})_{L^2}=(-1)^{n+1}b^{n+1}(2a)^{-2n-1}\sum\int\dots\int\prod_{l=1}^{2n}\left(\sum_{m\in A_l(\mathcal{F})}k_{m,j_{l+1}}\right)$$
$$\times Q_{\mathbf{j}}(\mathbf{k}_1,\dots,\mathbf{k}_{2n+2};\mathcal{F}_{2n+2})$$

$$\times\prod_{l=1}^{2n+1}B\left(\frac{1}{2}a_l(\mathcal{F})+\frac{\kappa}{2a}\left|\sum_{m=1}^{l}\mathbf{k}_m\right|^2,e_l(\mathcal{F})+1\right)d\mathbf{k}.$$

Here $B(\cdot,\cdot)$ denotes the Euler beta function. Note that for a fixed $l\le 2n+1$ for any $m,m'\le l$ such that $\widehat{mm'}\in E(\mathcal{F}_{2n+2})$ we necessarily have $\mathbf{k}_m+\mathbf{k}_{m'}=\mathbf{0}$; thus the summation range in the sum of $\mathbf{k}$'s reduces to $V_l(\mathcal{F}_{2n+2})$. Using the classical formula

$$B(x,n+1)=n!\left[\prod_{p=0}^{n}(x+p)\right]^{-1}$$

valid for any positive integer n, we conclude (4.10). □

Computations of the terms appearing in (4.10). For $n=0$ the class $\mathfrak{S}_2^c$ consists of a single diagram sequence $1\hookrightarrow\widehat{12}$. From (4.10), after a simple calculation, we obtain

$$(\psi_1,\tilde{u})_{L^2}=-b\int_{|\mathbf{k}|\le K_0}\left(1-\frac{k_1^2}{|\mathbf{k}|^2}\right)\frac{1}{a+\kappa|\mathbf{k}|^2}\times\frac{d\mathbf{k}}{|\mathbf{k}|^{2\alpha+d-2}} \tag{4.12}$$

$$=-\omega_{d-1}b\left(1-\frac{1}{d}\right)\int_0^{K_0}\frac{dk}{(a+\kappa k^2)k^{2\alpha-1}}.$$

The second equality in (4.12) is a consequence of isotropy. For $n=1$ there are only four sequences of diagrams from $\mathfrak{S}_4^c$ for which the corresponding terms of (4.10) are nonvanishing. They are (A) $1\hookrightarrow 12\hookrightarrow 123\hookrightarrow\widehat{14}\,\widehat{23}$, (B) $1\hookrightarrow 12\hookrightarrow 123\hookrightarrow\widehat{13}\,\widehat{24}$, (C) $1\hookrightarrow 12\hookrightarrow\widehat{13}\,2\hookrightarrow\widehat{13}\,\widehat{24}$, and (D) $1\hookrightarrow 12\hookrightarrow\widehat{23}\,1\hookrightarrow\widehat{23}\,\widehat{14}$. The corresponding terms of the sum appearing on the right-hand side of (4.10), after using isotropy, can be calculated as follows:

$$A=b^2\left(1-\frac{1}{d}\right)\int\int_{|\mathbf{k}_1|,|\mathbf{k}_2|\le K_0}|\mathbf{k}_1|^2\left[1-\left(\frac{\mathbf{k}_1\cdot\mathbf{k}_2}{|\mathbf{k}_1||\mathbf{k}_2|}\right)^2\right]$$
$$\times\frac{1}{a+\kappa|\mathbf{k}_1|^2}\times\frac{1}{2a+\kappa|\mathbf{k}_1+\mathbf{k}_2|^2}\times\frac{1}{3a+\kappa|\mathbf{k}_1|^2}\times\frac{d\mathbf{k}_1d\mathbf{k}_2}{(|\mathbf{k}_1||\mathbf{k}_2|)^{2\alpha+d-2}},$$

$$B = \frac{b^2}{d} \int\int_{|\mathbf{k}_1|,|\mathbf{k}_2| \le K_0} \mathbf{k}_1 \cdot \mathbf{k}_2 \left[\left(\frac{\mathbf{k}_1 \cdot \mathbf{k}_2}{|\mathbf{k}_1||\mathbf{k}_2|} \right)^2 - 1 \right] \times \frac{1}{a + \kappa |\mathbf{k}_1|^2} \times \frac{1}{2a + \kappa |\mathbf{k}_1 + \mathbf{k}_2|^2} \times \frac{1}{3a + \kappa |\mathbf{k}_2|^2} \times \frac{d\mathbf{k}_1 d\mathbf{k}_2}{(|\mathbf{k}_1||\mathbf{k}_2|)^{2\alpha + d - 2}},$$

$$C = \frac{2ab^2}{d} \int\int_{|\mathbf{k}_1|,|\mathbf{k}_2| \le K_0} \mathbf{k}_1 \cdot \mathbf{k}_2 \left[\left(\frac{\mathbf{k}_1 \cdot \mathbf{k}_2}{|\mathbf{k}_1||\mathbf{k}_2|} \right)^2 - 1 \right] \times \frac{1}{a + \kappa |\mathbf{k}_1|^2} \times \frac{1}{a + \kappa |\mathbf{k}_2|^2} \times \frac{1}{2a + \kappa |\mathbf{k}_1 + \mathbf{k}_2|^2} \times \frac{1}{3a + \kappa |\mathbf{k}_2|^2} \times \frac{d\mathbf{k}_1 d\mathbf{k}_2}{(|\mathbf{k}_1||\mathbf{k}_2|)^{2\alpha + d - 2}},$$

$$D = 2ab^2 \left(1 - \frac{1}{d} \right) \int\int_{|\mathbf{k}_1|,|\mathbf{k}_2| \le K_0} |\mathbf{k}_1|^2 \left[1 - \left(\frac{\mathbf{k}_1 \cdot \mathbf{k}_2}{|\mathbf{k}_1||\mathbf{k}_2|} \right)^2 \right] \times \frac{1}{(a + \kappa |\mathbf{k}_1|^2)^2} \times \frac{1}{2a + \kappa |\mathbf{k}_1 + \mathbf{k}_2|^2} \times \frac{1}{3a + \kappa |\mathbf{k}_1|^2} \times \frac{d\mathbf{k}_1 d\mathbf{k}_2}{(|\mathbf{k}_1||\mathbf{k}_2|)^{2\alpha + d - 2}}.$$

Adding all these terms, we conclude that

$$(\psi_3, \tilde{u})_{L^2} = \frac{b^2}{d} \int\int_{|\mathbf{k}_1|,|\mathbf{k}_2| \le K_0} \left[1 - \left(\frac{\mathbf{k}_1 \cdot \mathbf{k}_2}{|\mathbf{k}_1||\mathbf{k}_2|} \right)^2 \right] \left[\frac{(d-1)|\mathbf{k}_1|^2}{a + \kappa |\mathbf{k}_1|^2} - \frac{\mathbf{k}_1 \cdot \mathbf{k}_2}{a + \kappa |\mathbf{k}_2|^2} \right] \times \frac{1}{a + \kappa |\mathbf{k}_1|^2} \times \frac{1}{2a + \kappa |\mathbf{k}_1 + \mathbf{k}_2|^2} \times \frac{d\mathbf{k}_1 d\mathbf{k}_2}{(|\mathbf{k}_1||\mathbf{k}_2|)^{2\alpha + d - 2}}.$$

A simple calculation shows that the approximation of the eddy diffusivity obtained by using (3.19), with $M = 1$, has an error bounded by $0.1 d^{-1/2} \|\mathbf{u}\|_{L^2}^{3/2} \|\psi_1\|_{L^2}$ provided that $a\kappa \approx 22$.

When $n \ge 2$ we try to transform formula (4.10) a bit in order to drop the summation over multi-indices $\mathbf{j}$ and replace the summation over sequences of Feynman diagrams by the sum over the complete diagrams of length $2n + 2$. Let us fix then a sequence of Feynman diagrams $\mathcal{F} \in \mathfrak{S}^c_{2n+2}$ and denote by $I(\mathcal{F})$ its corresponding term appearing on the right-hand side of (4.10). Let us consider two cases.

Case 1, *when bond* $\widehat{1, 2n+2} \in E(\mathcal{F}_{2n+2})$. Let $\widehat{m\, m'} \in E(\mathcal{F}_{2n+2})$ be such that $1 < m < m' < 2n + 2$. Performing the summation over the respective multi-indices, we get

$$\sum_{j_m, j_{m'}} \left(\sum_{p \in V_{m-1}(\mathcal{F}_{2n+2})} k_{p, j_m} \right) \left(\sum_{p' \in V_{m'-1}(\mathcal{F}_{2n+2})} k_{p', j_{m'}} \right) \Gamma_{j_m, j'_m}(\mathbf{k}_m)$$

$$= \sum_{\substack{p \in V_{m-1}(\mathcal{F}_{2n+2}) \\ p' \in V_{m'-1}(\mathcal{F}_{2n+2})}} \left(\mathbf{k}_p \cdot \mathbf{k}_{p'} - \frac{(\mathbf{k}_p \cdot \mathbf{k}_m)(\mathbf{k}_{p'} \cdot \mathbf{k}_m)}{|\mathbf{k}_m|^2} \right).$$

Denote by $\widehat{m(p), m'(p)}$, $p = 1, \dots, n+1$, all the edges of $E(\mathcal{F}_{2n+2})$ whose left endpoints are enumerated in increasing order. We can write then that

(4.13)
$$I(\mathcal{F}) = \frac{(-b)^{n+1}}{(2a)^{2n+1}} \prod_{l=1}^{2n+1} e_l(\mathcal{F})! \int\limits_{|\mathbf{k}_1|,\dots,|\mathbf{k}_{n+1}|\le K_0} \dots \int \left(1 - \frac{k_{1,1}^2}{|\mathbf{k}_1|^2}\right) \mathcal{J}(\mathbf{k}_1, \dots, \mathbf{k}_{n+1}; \mathcal{F}_{2n+2})$$
$$\times \prod_{l=1}^{2n+1} \left[\prod_{p=0}^{e_l(\mathcal{F})} \left(\frac{1}{2} a_l(\mathcal{F}) + p + \frac{\kappa}{2a} \left| \sum_{m(q)\in V_l(\mathcal{F}_{2n+2})} \mathbf{k}_q \right|^2 \right) \right]^{-1} \frac{d\mathbf{k}_1 \dots d\mathbf{k}_{n+1}}{(|\mathbf{k}_1| \dots |\mathbf{k}_{n+1}|)^{2\alpha+d-2}}.$$

Here for a given $\mathcal{G} \in \mathfrak{F}_{2n+2}$ such that $\widehat{1, 2n+2} \in E(\mathcal{G})$, we set

$$\mathcal{J}(\mathbf{k}_1, \dots, \mathbf{k}_{n+1}; \mathcal{G}) := \prod_{l=1}^{n+1} \sum_{\substack{m(p)\in V_{m(l)-1}(\mathcal{F}_{2n+2}) \\ m(p')\in V_{m'(l)-1}(\mathcal{F}_{2n+2})}} \left(\mathbf{k}_p \cdot \mathbf{k}_{p'} - \frac{(\mathbf{k}_p \cdot \mathbf{k}_l)(\mathbf{k}_{p'} \cdot \mathbf{k}_l)}{|\mathbf{k}_l|^2} \right). \tag{4.14}$$

As above we let $1 = m(1) < \dots < m(n+1)$ denote the left vertices of all the edges from $E(\mathcal{G})$.

Using isotropy, we can further simplify the formula and obtain that

$$I(\mathcal{F}) = \left(1 - \frac{1}{d}\right) \frac{(-b)^{n+1}}{(2a)^{2n+1}} \prod_{l=1}^{2n+1} e_l(\mathcal{F})! \int\limits_{|\mathbf{k}_1|,\dots,|\mathbf{k}_{n+1}|\le K_0} \dots \int \mathcal{J}(\mathbf{k}_1, \dots, \mathbf{k}_{n+1}; \mathcal{F}_{2n+2})$$
$$\times \prod_{l=1}^{2n+1} \left[\prod_{p=0}^{e_l(\mathcal{F})} \left(\frac{1}{2} a_l(\mathcal{F}) + p + \frac{\kappa}{2a} \left| \sum_{m(q)\in V_l(\mathcal{F}_{2n+2})} \mathbf{k}_q \right|^2 \right) \right]^{-1} \frac{d\mathbf{k}_1 \dots d\mathbf{k}_{n+1}}{(|\mathbf{k}_1| \dots |\mathbf{k}_{n+1}|)^{2\alpha+d-2}}.$$

Case 2, when bond $\widehat{1, 2n+2} \notin E(\mathcal{F}_{2n+2})$. Let $q > 1$ be such that $\widehat{m(q), 2n+2} \in E(\mathcal{F}_{2n+2})$. After a calculation similar to the one in the previous case, we obtain that

$$I(\mathcal{F}) = \frac{(-b)^{n+1}}{d(2a)^{2n+1}} \prod_{l=1}^{2n+1} e_l(\mathcal{F})! \int\limits_{|\mathbf{k}_1|,\dots,|\mathbf{k}_{n+1}|\le K_0} \dots \int \mathcal{J}(\mathbf{k}_1, \dots, \mathbf{k}_{n+1}; \mathcal{F}_{2n+2})$$
$$\times \prod_{l=1}^{2n+1} \left[\prod_{p=0}^{e_l(\mathcal{F})} \left(\frac{1}{2} a_l(\mathcal{F}) + p + \frac{\kappa}{2a} \left| \sum_{m(q)\in V_l(\mathcal{F}_{2n+2})} \mathbf{k}_q \right|^2 \right) \right]^{-1} \frac{d\mathbf{k}_1 \dots d\mathbf{k}_{n+1}}{(|\mathbf{k}_1| \dots |\mathbf{k}_{n+1}|)^{2\alpha+d-2}}.$$

Here for a given $\mathcal{G} \in \mathfrak{F}_{2n+2}$ such that $\widehat{m(q), 2n+2} \in E(\mathcal{G})$ for some $q > 1$, we set

$$\mathcal{J}(\mathbf{k}_1, \dots, \mathbf{k}_{n+1}; \mathcal{G}) := \prod_{l\notin\{1,q\}} \sum_{\substack{m(p)\in V_{m(l)-1}(\mathcal{G}) \\ m(p')\in V_{m'(l)-1}(\mathcal{G})}} \left(\mathbf{k}_p \cdot \mathbf{k}_{p'} - \frac{(\mathbf{k}_p \cdot \mathbf{k}_l)(\mathbf{k}_{p'} \cdot \mathbf{k}_l)}{|\mathbf{k}_l|^2} \right) \tag{4.15}$$

$$\times \sum_{\substack{m(p)\in V_{m'(1)-1}(\mathcal{G})\\ m(p')\in V_{m(q)-1}(\mathcal{G})}} \Bigg[\mathbf{k}_p\cdot\mathbf{k}_{p'} + \frac{(\mathbf{k}_q\cdot\mathbf{k}_{p'})(\mathbf{k}_1\cdot\mathbf{k}_p)(\mathbf{k}_1\cdot\mathbf{k}_q)}{(|\mathbf{k}_1||\mathbf{k}_q|)^2} - \frac{(\mathbf{k}_p\cdot\mathbf{k}_q)(\mathbf{k}_{p'}\cdot\mathbf{k}_q)}{|\mathbf{k}_q|^2} - \frac{(\mathbf{k}_p\cdot\mathbf{k}_1)(\mathbf{k}_{p'}\cdot\mathbf{k}_1)}{|\mathbf{k}_1|^2}\Bigg].$$

Fix a Feynman diagram $\mathcal{G}\in\mathfrak{F}_{2n+2}$ and a sequence $(e_l)_{l=1}^{2n+2}$ such that $e_l\ge 0$ and $\sum e_l = n+1$. Let $\mathcal{F}\in\mathfrak{S}^c_{2n+2}$ be such that

$$e_l(\mathcal{F}) = e_l,\quad l\in\{1,\dots,2n+1\},\ \text{and}\ \mathcal{F}_{2n+2}=\mathcal{G}. \tag{4.16}$$

Since $\mathcal{F}$ is admissible, $(e_l)_{l=1}^{2n+1}$ must belong to the set $\mathcal{S}_n$ of all sequences satisfying $e_1+\dots+e_{2n+1}\le n$, $e_1+\dots+e_{2p}\le p-1$ and $e_1+\dots+e_{2p-1}\le p-1$, $p\in\{1,\dots,n\}$. Let a_l be given by $a_1=1$ and $a_{l+1}:=a_l+1-2e_l$, $l\ge 1$. With a given $(e_l)_{l=1}^{2n+1}$ and $\mathcal{G}$ let us calculate the number of $\mathcal{F}$'s satisfying (4.16). The diagram $\mathcal{F}_{2n+1}$ may be obtained from $\mathcal{G}$ by removing the bond containing $2n+2$ and $e_{2n+2}-1$ out of the remaining n bonds. There are $\binom{n}{e_{2n+2}-1}$ ways of doing that. Out of the remaining $n+1-e_{2n+2}$ bonds we can remove e_{2n+1} in $\binom{n+1-e_{2n+2}}{e_{2n+1}}$ ways, etc. One can see therefore that the number of sequences $\mathcal{F}$ corresponding to a given $\mathcal{G}\in\mathfrak{F}_{2n+2}$ and $(e_l)_{l=1}^{2n+1}\in\mathcal{S}_n$ equals $n!/[e_1!\dots e_{2n+1}!(n-e_1-\dots-e_{2n+1})!]$. Summarizing the above, we can rewrite (4.10) in the form

$$(\psi_{2n+1},\tilde{u})_{L^2} = (-1)^{n+1}b^{n+1}(2a)^{-2n-1}\sum\frac{n!}{(n-\sum_{l=1}^{2n+1}e_l)!}\int\dots\int \mathcal{J}(\mathbf{k}_1,\dots,\mathbf{k}_{n+1};\mathcal{G}) \tag{4.17}$$

$$\times\prod_{l=1}^{2n+1}\left[\prod_{p=0}^{e_l(\mathcal{F})}\left(\frac{1}{2}a_l+p+\frac{\kappa}{2a}\left|\sum_{m(q)\in V_l(\mathcal{G})}\mathbf{k}_q\right|^2\right)\right]^{-1}\frac{d\mathbf{k}_1\dots d\mathbf{k}_{n+1}}{(|\mathbf{k}_1|\dots|\mathbf{k}_{n+1}|)^{2\alpha+d-2}}.$$

The summation extends over all $\mathcal{G}\in\mathfrak{F}_{2n+2}$ and sequences $(e_l)_{l=1}^{2n+1}\in\mathcal{S}_n$. The cardinality D_{2n-1} of the set $\mathcal{S}_n$ can be calculated using the counting method presented in [11]; see, in particular, Lemma 1 on p. 16. We have the following recursive formula, $D_0:=1$, and

$$D_k=\sum_{i=0}^{k-1}(-1)^i\binom{[(k-i+1)/2]+k}{i+1}D_{k-i-1},\quad k=1,\dots,2n-1. \tag{4.18}$$

The number of terms that may, in principle, appear in the sum on the left-hand side of (4.17) equals, therefore, $(2n+1)!!D_{2n-1}$; here $(2n+1)!!$ stands for the number of complete Feynman diagrams of length $2n+2$. Note, however, that in fact the number of nonvanishing terms is necessarily smaller than the one given above. All terms corresponding to Feynman diagrams for which at least one of the sets $V_l(\mathcal{G})$, $l=1,\dots,2n$, is empty are equal to 0 (cf. (4.10)). Any $\mathcal{G}$ having that property shall be called a null diagram.

For example, when $n=2$, one calculates from (4.18) that $D_3=7$. Out of 15 Feynman diagrams belonging to $\mathfrak{F}_6$, all three diagrams containing bond $\widehat{5\,6}$ are null

diagrams. In addition, one can see that $\widehat{1\,2}\,\widehat{3\,5}\,\widehat{4\,6}$, $\widehat{1\,2}\,\widehat{3\,6}\,\widehat{4\,5}$ are also null. The sum in (4.17) involves therefore at most $7 \times 10 = 70$ nonvanishing terms.

An estimate of D_{2n-1} for a general n can also be obtained from [11]. Namely, using the counting argument contained on p. 14 and the upper bound (1.41) of [11], one can see that $D_{2n-1} \le 5\binom{3n+1}{2n-1}/(3n+1)$.

Appendix. The proof of Lemma 4.1. Using the Fourier transform in the spatial variable, we can write that

$$\mathbf{u}(t,\mathbf{x}) = \int e^{\mathrm{i}\mathbf{x}\cdot\mathbf{k}}\hat{\mathbf{u}}(t,d\mathbf{k}), \tag{A.1}$$

where $\hat{\mathbf{u}}(t,d\mathbf{k}) = (\hat{u}_1(t,d\mathbf{k}),\dots,\hat{u}_d(t,d\mathbf{k}))$ is a real-valued Gaussian spectral measure with the structure function

$$\langle \hat{\mathbf{u}}^*(t,d\mathbf{k}) \otimes \hat{\mathbf{u}}(s,d\mathbf{k}')\rangle = be^{-a|t-s|}\,\frac{\mathcal{E}(|\mathbf{k}|)}{|\mathbf{k}|^{d-1}}\,\hat{\Gamma}(\mathbf{k})\delta(\mathbf{k}-\mathbf{k}')\,d\mathbf{k}d\mathbf{k}' \tag{A.2}$$

satisfying $\hat{\mathbf{u}}^*(t,d\mathbf{k}) = \hat{\mathbf{u}}(t,-d\mathbf{k})$.

To show the lemma it suffices only to prove that for arbitrary $\mathbf{s} = (s_1,\dots,s_{n+1}) \in \Delta_{n+1}$, $s_{n+2} \le s_{n+1}$, we have

$$\mathbb{E}_{s_{n+2}} W_{n,1}(\mathbf{s},\mathbf{x}) \tag{A.3}$$

$$= \mathrm{i}^n \sum \int\dots\int b^{f_{n+1}(\mathcal{F})} \exp\left\{\mathrm{i}\sum_{m=1}^{n+1}\mathbf{k}_m\cdot\mathbf{x}_m\right\} \widehat{P}_{\mathbf{j}}(\mathbf{s},\mathbf{k};s_{n+2},\mathcal{F})\widehat{Q}_{\mathbf{j}}(d\mathbf{k};s_{n+2},\mathcal{F}).$$

Here $f_m(\mathcal{F}) = \sum_{l\le m} e_l(\mathcal{F})$ denotes the cardinality of $E(\mathcal{F}_m)$. The summation extends over all integer-valued multi-indices $\mathbf{j} = (j_1,\dots,j_{n+1})$, such that $j_1 = 1$ and all Feynman diagrams $\mathcal{F} \in \mathfrak{S}_{n+1}$. As we recall, $\mathbb{E}_t$ is the conditional expectation w.r.t. the σ-algebra $\mathcal{U}_t$ generated by $\mathbf{u}(s,\cdot)$, $s \le t$, and

$$\widehat{P}_{\mathbf{j}}(\mathbf{s},\mathbf{k};s_{n+2},\mathcal{F}) := \exp\{-aa_{n+1}(\mathcal{F})(s_{n+1}-s_{n+2})\} \tag{A.4}$$

$$\times\prod_{l=1}^{n}\left\{\left(\sum_{m\in A_l(\mathcal{F})} k_{m,j_{l+1}}\right)\exp\{-aa_l(\mathcal{F})(s_l-s_{l+1})\}[1-\exp\{-2a(s_l-s_{l+1})\}]^{e_l(\mathcal{F})}\right\},$$

$$\widehat{Q}_{\mathbf{j}}(d\mathbf{k};s_{n+2},\mathcal{F}) \tag{A.5}$$

$$:= \prod_{\widehat{mm'}\in E_{n+1}(\mathcal{F})} \frac{\mathcal{E}(|\mathbf{k}_m|)}{|\mathbf{k}|^{d-1}}\hat{\Gamma}_{j_m,j_{m'}}(\mathbf{k}_m)\delta(\mathbf{k}_m+\mathbf{k}_{m'})d\mathbf{k}_m d\mathbf{k}_{m'} \prod_{m\in A_{n+1}(\mathcal{F})}\hat{u}_{j_m}(s_{n+2},d\mathbf{k}_m).$$

We use the induction argument. Formula (A.3) obviously holds for $n = 0$. Suppose that it holds for a certain n. Then

$$\mathbb{E}_{s_{n+3}} W_{n+1,1}(\mathbf{s},\mathbf{x}) = \mathbb{E}_{s_{n+3}}\left[\mathbf{u}(s_{n+2},\mathbf{x}_{n+2})\cdot D\mathbb{E}_{s_{n+2}} W_{n,1}(s_1,\dots,s_{n+1},\mathbf{x}_1,\dots,\mathbf{x}_{n+1})\right].$$

Calculate $\mathbb{E}_{s_{n+2}}\mathbf{W}_n(\cdot)$ using (A.3). Note that

$$\mathbb{E}_{s_{n+3}} W_{n+1,1}(\mathbf{s},\mathbf{x}) = \mathrm{i}^n \sum \int\dots\int b^{f_{n+1}(\mathcal{F})} \exp\left\{\mathrm{i}\sum_{m=1}^{n+2}\mathbf{k}_m\cdot\mathbf{x}_m\right\} \widehat{P}_{\mathbf{j}}(\mathbf{s},\mathbf{k};s_{n+2},\mathcal{F}) \tag{A.6}$$

$$\times\, \mathbb{E}_{s_{n+3}}\left[\hat{u}_{j_{n+2}}(s_{n+2},\mathbf{k}_{n+2})\frac{\partial}{\partial y_{j_{n+2}}}_{|\,\mathbf{y}=\mathbf{0}}\exp\left\{\,\mathrm{i}\sum_{m=1}^{n+1}\mathbf{k}_m\cdot\mathbf{y}\right\}\widehat{Q}_{\mathbf{j}}(d\mathbf{k};s_{n+2},\mathcal{F})\right].$$

The summation extends over all integer-valued multi-indices $\mathbf{j}=(j_1,\dots,j_{n+2})$, such that $j_1=1$ and all Feynman diagrams $\mathcal{F}\in\mathfrak{S}_{n+1}$. Differentiating w.r.t. $y_{j_{n+2}}$ and using the identification rule $\mathbf{k}_m=-\mathbf{k}_{m'}$, when $\widehat{mm'}\in E_{n+1}(\mathcal{F})$, we obtain that the right-hand side of (A.6) equals

$$\text{(A.7)}\qquad \mathrm{i}^{n+1}\sum\int\dots\int b^{f_{n+1}(\mathcal{F})}\exp\left\{\,\mathrm{i}\sum_{m=1}^{n+2}\mathbf{k}_m\cdot\mathbf{x}_m\right\}\widehat{P}_{\mathbf{j}}(\mathbf{s},\mathbf{k};s_{n+2},\mathcal{F})$$

$$\times\left(\sum_{m\in A_{n+1}(\mathcal{F})}k_{m,j_{n+2}}\right)\mathbb{E}_{s_{n+3}}\left[\hat{u}_{j_{n+2}}(s_{n+2},\mathbf{k}_{n+2})\widehat{Q}_{\mathbf{j}}(d\mathbf{k};s_{n+2},\mathcal{F})\right].$$

From elementary properties of Gaussian variables we conclude that

$$\hat{u}_j(s_{n+2},d\mathbf{k};s_{n+3}):=\mathbb{E}_{s_{n+3}}\hat{u}_j(s_{n+2},d\mathbf{k})=e^{-a(s_{n+2}-s_{n+3})}\hat{u}_j(s_{n+3},d\mathbf{k}).$$

The spectral measure

$$\hat{u}_j^{\perp}(s_{n+2},d\mathbf{k};s_{n+3}):=\hat{u}_j(s_{n+2},d\mathbf{k})-\mathbb{E}_{s_{n+3}}\hat{u}_j(s_{n+2},d\mathbf{k})$$

is independent of the σ-algebra $\mathcal{U}_{s_{n+2}}$. Moreover, note that

$$\langle\hat{u}_j^{\perp}(s_{n+2},d\mathbf{k};s_{n+3})\hat{u}_{j'}^{\perp}(s_{n+2},d\mathbf{k}';s_{n+3})\rangle=\left[1-e^{-2a(s_{n+2}-s_{n+3})}\right]\langle\hat{u}_j(0,d\mathbf{k})\hat{u}_{j'}(0,d\mathbf{k}')\rangle.$$

Replace each $\hat{u}_{j_m}(s_{n+2},d\mathbf{k}_m)$ appearing in (A.7), i.e., $\hat{u}_{j_{n+2}}(s_{n+2},\mathbf{k}_{n+2})$ and the spectral measures that occur in $\widehat{Q}_{\mathbf{j}}(d\mathbf{k};s_{n+2},\mathcal{F})$, by

$$e^{-a(s_{n+2}-s_{n+3})}\hat{u}_{j_m}(s_{n+3},d\mathbf{k}_m)+\hat{u}_{j_m}^{\perp}(s_{n+2},d\mathbf{k}_m;s_{n+3}).$$

The conditional expectation $\mathbb{E}_{s_{n+3}}$ can be expressed using the expectation of the product of the terms in the form $\hat{u}_{j_m}^{\perp}(s_{n+2},d\mathbf{k}_m;s_{n+3})$ times the product of $e^{-a(s_{n+2}-s_{n+3})}\times\hat{u}_{j_m}(s_{n+3},d\mathbf{k}_m)$. In order to finish the induction argument we apply the rules of calculating the expectation of products of Gaussian random variables using Feynman diagrams. To prove that out of the diagrams generated in that way we need only to take into account those belonging to $\mathfrak{S}_{n+2}$, it suffices only to show that

$$\text{(A.8)}\qquad \mathrm{i}^{n+1}\sum\int\dots\int b^{f_{n+1}(\mathcal{F})}\exp\left\{\,\mathrm{i}\sum_{m=1}^{n+2}\mathbf{k}_m\cdot\mathbf{x}_m\right\}\widehat{P}_{\mathbf{j}}(\mathbf{s},\mathbf{k};s_{n+2},\mathcal{F})$$

$$\times\left(\sum_{m\in A_{n+1}(\mathcal{F})}k_{m,j_{n+2}}\right)\left\langle\hat{u}_{j_{n+2}}^{\perp}(s_{n+2},\mathbf{k}_{n+2};s_{n+3})\widehat{Q}_{\mathbf{j}}^{\perp}(d\mathbf{k};s_{n+2},s_{n+3},\mathcal{F})\right\rangle=0.$$

Here

$$\widehat{Q}_{\mathbf{j}}^{\perp}(d\mathbf{k};s_{n+2},s_{n+3},\mathcal{F})$$

$$:=\prod_{\widehat{mm'}\in E_{n+1}(\mathcal{F})}\frac{\mathcal{E}(|\mathbf{k}_m|)}{|\mathbf{k}_m|^{d-1}}\hat{\Gamma}_{j_m,j_{m'}}(\mathbf{k}_m)\delta(\mathbf{k}_m+\mathbf{k}_{m'})d\mathbf{k}_m d\mathbf{k}_{m'}\prod_{m\in A_{n+1}(\mathcal{F})}\hat{u}_{j_m}^{\perp}(s_{n+2},d\mathbf{k}_m;s_{n+3}).$$

To do so note that since $\sum_{j_{n+2}} k_{n+2,j_{n+2}} \hat{u}^{\perp}_{j_{n+2}}(s_{n+2}, d\mathbf{k}_{n+2}; s_{n+3}) = 0$, the expression appearing on the left-hand side of (A.8) equals

$$\text{(A.9)} \qquad \mathrm{i}^n \sum b^{f_{n+1}(\mathcal{F})} \widehat{P}_{\mathbf{j}}(\mathbf{s}, \mathbf{k}; s_{n+2}, \mathcal{F}) \left\langle \hat{u}^{\perp}_{j_{n+2}}(s_{n+2}, d\mathbf{k}_{n+2}; s_{n+3}) \right.$$

$$\left. \times \frac{\partial}{\partial y_{j_{n+2}}}{}_{|\mathbf{y}=0} \left[\int \dots \int \exp\left\{ \mathrm{i} \sum_{m=1}^{n+2} \mathbf{k}_m \cdot (\mathbf{x}_m + \mathbf{y}) \right\} \widehat{Q}^{\perp}_{\mathbf{j}}(d\mathbf{k}; s_{n+2}, s_{n+3}, \mathcal{F}) \right] \right\rangle$$

$$= \mathrm{i}^n \sum b^{f_{n+1}(\mathcal{F})} \widehat{P}_{\mathbf{j}}(\mathbf{s}, \mathbf{k}; s_{n+2}, \mathcal{F}) \frac{\partial}{\partial y_{j_{n+2}}}{}_{|\mathbf{y}=0} \left\langle \int \dots \int \exp\left\{ \mathrm{i} \sum_{m=1}^{n+2} \mathbf{k}_m \cdot \mathbf{x}_m \right\} \right.$$

$$\left. \times \hat{u}^{\perp}_{j_{n+2}}(s_{n+2}, d\mathbf{k}_{n+2}; s_{n+3}) \widehat{Q}^{\perp}_{\mathbf{j}}(d\mathbf{k}; s_{n+2}, s_{n+3}, \mathcal{F}) \right\rangle = 0.$$

The last equality in (A.9) is a consequence of spatial stationarity of the field.

APPLICATION OF SYMMETRY ANALYSIS TO A PDE ARISING IN THE CAR WINDSHIELD DESIGN*

NICOLETA BÎLĂ†

Abstract. A new approach to parameter identification problems from the point of view of symmetry analysis theory is given. A mathematical model that arises in the design of car windshield represented by a linear second order mixed type PDE is considered. Following a particular case of the direct method (due to Clarkson and Kruskal), we introduce a method to study the group invariance between the parameter and the data. The equivalence transformations associated with this inverse problem are also found. As a consequence, the symmetry reductions relate the inverse and the direct problem and lead us to a reduced order model.

Key words. symmetry reductions, parameter identification problems

1. Introduction.

Symmetry analysis theory links differential geometry to PDEs theory [18], symbolic computation [9], and, more recently, to numerical analysis theory [3], [6]. The notion of continuous transformation groups was introduced by Sophus Lie [14], who also applied them to differential equations. Over the years, Lie's method has been proven to be a powerful tool for studying a remarkable number of PDEs arising in mathematical physics (more details can be found for example in [2], [10], and [21]). In the last several years a variety of methods have been developed in order to find special classes of solutions of PDEs, which cannot be determined by applying the classical Lie method. Olver and Rosenau [20] showed that the common theme of all these methods has been the appearance of some form of group invariance. On the other hand, parameter identification problems arising in the inverse problems theory are concerned with the identification of physical parameters from observations of the evolution of a system. In general, these are ill-posed problems, in the sense that they do not fulfill Hadamard's postulates for all admissible data: a solution exists, the solution is unique, and the solution depends continuously on the given data. Arbitrary small changes in data may lead to arbitrary large changes in the solution. The iterative approach of studying parameter identification problems is a functional-analytic setup with a special emphasis on iterative regularization methods [8].

The aim of this paper is to show how parameter identification problems can be analyzed with the tools of group analysis theory. This is a new direction of research in the theory of inverse problems, although the symmetry analysis theory is a common approach for studying PDEs. We restrict ourselves to the case of a parameter identification problem modeled by a PDE of the form

$$F(x, w^{(m)}, E^{(n)}) = 0, \tag{1.1}$$

where the unknown function $E = E(x)$ is called *parameter*, and, respectively, the arbitrary function $w = w(x)$ is called *data*, with $x = (x_1, \ldots, x_p) \in \Omega \subset R^p$ a given

domain (here $w^{(m)}$ denotes the function w together with its partial derivatives up to order m). Assume that the parameters and the data are analytical functions. The PDE (1.1) sometimes augmented with certain boundary conditions is called *the inverse problem* associated with a *direct problem*. The direct problem is the same equation but the unknown function is the data, for which certain boundary conditions are required.

The *classical Lie method* allows us to find the *symmetry group* related to a PDE. This is a (local) Lie group of transformations acting on the space of the independent variables and the space of the dependent variables of the equation with the property that it leaves the set of all analytical solutions invariant. Knowledge of these *classical symmetries* allows us to reduce the order of the studied PDE and to determine *group-invariant solutions* (or *similarity solutions*) which are invariant under certain subgroups of the full symmetry group (for more details see [18]). Bluman and Cole [1] introduced the *nonclassical method* that allows one to find the *conditional symmetries* (also called *nonclassical symmetries*) associated with a PDE. These are transformations that leave only a subset of the set of all analytical solutions invariant. Note that any classical symmetry is a nonclassical symmetry but not conversely. Another procedure for finding symmetry reductions is the *direct method* (due to Clarkson and Kruskal [5]). The relation between these last two methods has been studied by Olver [19]. Moreover, for a PDE with coefficients depending on an arbitrary function, Ovsiannikov [21] introduced the notion of *equivalence transformations*, which are (local) Lie group of transformations acting on the space of the independent variables, the space of the dependent variables and the space of the arbitrary functions that leave the equation unchanged. Notice that these techniques based on group theory do not take into account the boundary conditions attached to a PDE.

To find symmetry reductions associated with the parameter identification problem (1.1) one can seek classical and nonclassical symmetries related to this equation. Two cases can occur when applying the classical Lie method or the nonclassical method, depending if the data w is known or not. From the symbolic computation point of view, the task of finding symmetry reductions for a PDE depending on an arbitrary function might be a difficult one, due to the lack of the symbolic manipulation programs that can handle these kind of equations. Another method to determine symmetry reductions for (1.1) might be a particular case of the direct method, which has been applied by Zhdanov [24] to certain multidimensional PDEs arising in mathematical physics. Based on this method and taking into account that (1.1) depends on an arbitrary function, we introduce a procedure to find the relation between the data and the parameter in terms of a similarity variable (see section 2). As a consequence, the equivalence transformations related to (1.1) must be considered as well. These final symmetry reductions are found by using any symbolic manipulation program designed to determine classical symmetries for a PDE system—now both the data and the parameter are unknown functions in (1.1). The equivalence transformations relate the direct problem and the inverse problem. Moreover, one can find special classes of data and parameters, respectively, written in terms of the invariants of the group action, the order of the studied PDE can be reduced at least by one, and analytical solutions of (1.1) can be found.

At the first step, the group approach of the free boundary problem related to (1.1) can be considered and, afterwards, the invariance of the boundary conditions under particular group actions has to be analyzed (see [2]). In the case of parameter identification problems we sometimes have to deal with two pairs of boundary conditions, for data and the parameter as well, otherwise we might only know the boundary

conditions for the data. Thus, the problem of finding symmetry reductions for a given data can be more complicated. At least by finding the equivalence transformations related to the problem, the invariants of the group actions can be used to establish suitable domains Ω on which the order of the model can be reduced.

In this paper we consider a mathematical model arising in the car windshield design. Let us briefly explain the *gravity sag bending process*, one of the main industrial processes used in the manufacture of car windshields. A piece of glass is placed over a rigid frame, with the desired edge curvature and heated from below. The glass becomes viscous due to the temperature rise and sags under its own weight. The final shape depends on the viscosity distribution of the glass obtained from varying the temperature. It has been shown that the sag bending process can also be controlled (in a first approximation) in the terms of Young's modulus E, a spatially varying glass material parameter, and the displacement of the glass w can be described by the thin linear elastic plate theory (see [11], [16], and [17] and references from there). The model is based on the linear plate equation

(1.2)
$$\left(E\left(w_{xx}+\nu w_{yy}\right)\right)_{xx}+2(1-\nu)\left(Ew_{xy}\right)_{xy}+\left(E\left(w_{yy}+\nu w_{xx}\right)\right)_{yy}=\tfrac{12(1-\nu^2)f}{h^3} \quad \text{on} \quad \Omega,$$

where $w=w(x,y)$ represents the displacement of the glass sheet (the target shape) occupying a domain $\Omega\subset R^2$, $E=E(x,y)$ is Young's modulus, a positive function that can be influenced by adjusting the temperature in the process of heating the glass, f is the gravitational force, $\nu\in\left(0,\frac{1}{2}\right]$ is the glass Poisson ratio, and h is thickness of the plate. The *direct problem* (or the *forward problem*) is the following: for a given Young modulus E, find the displacement w of a glass sheet occupying a domain Ω before the heating process. Note that the PDE (1.2) is an elliptic fourth order linear PDE for the function w. Until now, two problems related to (1.2) have been studied: the *clamped plate case* and the *simply supported plate case* (more details can be found for example in [15]). In this paper we consider the clamped case, in which the following boundary conditions are required: the plate is placed over a rigid frame, i.e.,

$$w(x,y)|_{\partial\Omega}=0, \tag{1.3}$$

and, respectively,

$$\frac{\partial w}{\partial n}|_{\partial\Omega}=0, \tag{1.4}$$

which means the (outward) normal derivative of w must be zero, i.e., the sheet of glass is not allowed to freely rotate around the tangent to $\partial\Omega$. The associated *inverse problem* consists of finding Young's modulus E for a given data w in (1.2). This is a linear second order PDE for Young's modulus that can be written as

$$\begin{aligned}(w_{xx}+\nu w_{yy})E_{xx}+2(1-\nu)w_{xy}E_{xy}+(w_{yy}+\nu w_{xx})E_{yy}\\ +2(\Delta w)_xE_x+2(\Delta w)_yE_y+(\Delta^2 w)E=1\end{aligned} \tag{1.5}$$

after the scaling transformations $w\to\frac{1}{k}w$ or $E\to\frac{1}{k}E$, with $k=\frac{12(1-\nu^2)f}{h^3}$. In (1.5), Δ denotes the Laplace operator. The main problem in the car windshield design is that the prescribed target shape w is frequent such that the discriminant

$$D=(1-\nu)^2w_{xy}^2-(w_{xx}+\nu w_{yy})(w_{yy}+\nu w_{xx})$$

of (1.5) changes sign in the domain Ω, so that we get a mixed type PDE. This is one of the reasons for which optical defects might occur during the process. Note that (1.5) would naturally call for boundaries conditions for E on $\partial\Omega$ in the purely elliptic case (when $D < 0$), and Cauchy data on a suitable (noncharacteristic part) $\Gamma \subset \partial\Omega$ in the purely hyperbolic part (for $D > 0$). There is a recent interest in studying this inverse problem (see, e.g., [13]). It is known [15] that a constant Young's modulus corresponds to a data which satisfies the nonhomogeneous biharmonic equation (2.29). A survey on this subject can be found in [23]. Salazar and Westbrook [22] studied the case when the data and the parameter are given by radial functions; Kügler [12] used a derivative free iterative regularization method for analyzing the problem on rectangular frames; and a simplified model for the inverse problem on circular domains was considered by Engl and Kügler [7].

So far it is not obvious which shapes can be made by using this technique. Hence, we try to answer this question by finding out the symmetry reductions related to the PDE (1.5) hidden by the nonlinearity that occurs between the data and the parameter. In this sense, we determine (see section 3) the group of transformations that leave the equation unchanged, and so, its mixed type form. Knowledge of the invariants of these group actions allows us to write the target shape and the parameter in terms of them, and, therefore, to reduce the order of the studied equation. We find again the obvious result that a Young's modulus constant corresponds to data which is a solution of a nonhomogeneous biharmonic equation. The circular case problem considered by Salazar and Westbrook is, in fact, a particular case of our study. We show that other target shapes which are not radial functions can be considered. We prove that (1.5) is invariant under scaling transformations. It follows that target shapes modeled by homogeneous functions can be analyzed as well. In particular, we are interested in target shapes modeled by homogeneous polynomials defined on elliptical domains or square domains with rounded corners.

The paper is structured as follows. To reduce the order of the PDE (1.5) we propose in section 2 a method for studying the relation between the data and the parameter in terms of the similarity variables. The equivalence transformations related to this equation are given in section 3. The symbolic manipulation program DESOLV, authors Carminati and Vu [4] has been used for this purpose. Table 1 contains a complete classification of these symmetry reductions. In the last section, we discuss the PDE (1.5) augmented with the boundary conditions (1.3) and (1.4), namely, how to use the invariants of the group actions (on suitable bounded domains Ω) in order to incorporate the boundary conditions. In this sense, certain examples of exact and of numerical solutions of the reduced ODEs are given.

2. Conditional symmetries. The direct method approach to a second order PDE

$$\mathcal{F}(x, y, E^{(2)}) = 0$$

consists of seeking solutions written in the form

$$E(x, y) = \Phi(x, y, F(z)), \quad \text{where} \quad z = z(x, y), \quad (x, y) \in \Omega. \tag{2.1}$$

In this case the function z is called *similarity variable* and its level sets $\{z = k\}$ are named *similarity curves*. After substituting (2.1) into the studied second order PDE, we require that the result to be an ODE for the arbitrary function $F = F(z)$. Hence, certain conditions are imposed upon the functions Φ, z and their partial derivatives.

The particular case

$$E(x,y) = F(z(x,y)) \tag{2.2}$$

consists of looking for solutions depending only on the similarity variable z. If z is an invariant of the group action then the solutions of the form (2.2) are as well. Assume that the similarity variable is such that $\|\nabla z\| \neq 0$ on $\bar{\Omega}$.

In this section we apply this particular approach to (1.5) in order to study if the parameter and the data are functionally independent, which means whether or not they can depend on the same similarity variable. Assume that Young's modulus takes the form (2.2). In this case we get the relation

$$\begin{aligned} &F''(z)\left[z_x^2(w_{xx}+\nu w_{yy})+2z_xz_y(1-\nu)w_{xy}+z_y^2(w_{yy}+\nu w_{xx})\right] \\ &\quad + F'(z)\left[z_{xx}(w_{xx}+\nu w_{yy})+2(1-\nu)z_{xy}w_{xy}++z_{yy}(w_{yy}+\nu w_{xx})\right. \\ &\qquad \left. +2z_x(\Delta w)_x+2z_y(\Delta w)_y\right]+F(z)(\Delta^2 w)=1, \end{aligned} \tag{2.3}$$

which must be an ODE for the unknown function $F = F(z)$. This condition is satisfied if the coefficients of the partial derivatives of F are function of z only (note that these coefficients are also invariant under the same group action). Denote them by

$$\begin{aligned} \Gamma_1(z) &= z_x^2(w_{xx}+\nu w_{yy})+2z_xz_y(1-\nu)w_{xy}+z_y^2(w_{yy}+\nu w_{xx}), \\ \Gamma_2(z) &= z_{xx}(w_{xx}+\nu w_{yy})+2(1-\nu)z_{xy}w_{xy}+z_{yy}(w_{yy}+\nu w_{xx}) \\ &\quad +2z_x(\Delta w)_x+2z_y(\Delta w)_y, \\ \Gamma_3(z) &= \Delta^2 w. \end{aligned} \tag{2.4}$$

If these relations hold, then the PDE (1.5) is reduced to the second order linear ODE

$$\Gamma_1(z)F''(z)+\Gamma_2(z)F'(z)+\Gamma_3(z)F(z)=1. \tag{2.5}$$

2.1. Data and parameter invariant under the same group. If the target shape is invariant under the same group action as Young's modulus, then

$$w(x,y) = G(z(x,y)), \tag{2.6}$$

where $G = G(z)$. Substituting (2.6) into the relations (2.4) we get

$$\begin{aligned} \Gamma_1 &= G''(z_x^2+z_y^2)^2+G'\left[(z_x^2+\nu z_y^2)z_{xx}+2(1-\nu)z_xz_yz_{xy}+(z_y^2+\nu z_x^2)z_{yy}\right], \\ \Gamma_2 &= 2G'''(z_x^2+z_y^2)^2+G''\left\{[7z_x^2+(\nu+2)z_y^2]z_{xx}+2(5-\nu)z_xz_yz_{xy}\right. \\ &\quad \left.+[7z_y^2+(\nu+2)z_x^2]z_{yy}\right\}+G'\left\{(\Delta z)^2+2(1-\nu)(z_{xy}^2-z_{xx}z_{yy})\right. \\ &\quad \left.+2\left[z_x(\Delta z)_x+z_y(\Delta z)_y\right]\right\}, \\ \Gamma_3 &= G''''(z_x^2+z_y^2)^2+2G'''\left[(3z_x^2+z_y^2)z_{xx}+4z_xz_yz_{xy}+(z_x^2+3z_y^2)z_{yy}\right. \\ &\quad \left.+G''\left\{3(\Delta z)^2+4(z_{xy}^2-z_{xx}z_{yy})+4\left[z_x(\Delta z)_x+z_y(\Delta z)_y\right]\right\}+G'\Delta^2 z.\right. \end{aligned} \tag{2.7}$$

Next, the coefficients of the partial derivatives of the function G, denoted by Γ_i, must depend only on z, i.e.,

$$\begin{aligned} \Gamma_1 &= \alpha^4 G''+a_1G', \\ \Gamma_2 &= 2\alpha^4 G'''+a_2G''+a_3G', \\ \Gamma_3 &= \alpha^4 G''''+2a_4G'''+a_5G''+a_6G', \end{aligned}$$

where

$$
\begin{aligned}
&\alpha^2(z) = z_x^2 + z_y^2,\\
&a_1(z) = (z_x^2 + \nu z_y^2) z_{xx} + 2(1-\nu) z_x z_y z_{xy} + (z_y^2 + \nu z_x^2) z_{yy},\\
&a_2(z) = \left[7z_x^2 + (\nu+2) z_y^2\right] z_{xx} + 2(5-\nu) z_x z_y z_{xy} + \left[7z_y^2 + (\nu+2) z_x^2\right] z_{yy},\\
&a_3(z) = (\Delta z)^2 + 2(1-\nu)(z_{xy}^2 - z_{xx} z_{yy}) + 2\left[z_x (\Delta z)_x + z_y (\Delta z)_y\right],\\
&a_4(z) = (3z_x^2 + z_y^2) z_{xx} + 4 z_x z_y z_{xy} + (z_x^2 + 3z_y^2) z_{yy},\\
&a_5(z) = 3(\Delta z)^2 + 4(z_{xy}^2 - z_{xx} z_{yy}) + 4\left[z_x (\Delta z)_x + z_y (\Delta z)_y\right],\\
&a_6(z) = \Delta^2 z.
\end{aligned}
\tag{2.8}
$$

The first relation in (2.8) is a two-dimensional (2D) eikonal equation. From this we get

$$
\begin{aligned}
&z_x^2 z_{xx} + 2 z_x z_y z_{xy} + z_y^2 z_{yy} = \alpha^3(z)\alpha'(z),\\
&z_{xx} = \alpha(z)\alpha'(z) - \tfrac{z_y}{z_x} z_{xy},\\
&z_{yy} = \alpha(z)\alpha'(z) - \tfrac{z_x}{z_y} z_{xy}.
\end{aligned}
$$

The last two equations imply

$$
z_y^2 z_{xx} - 2 z_x z_y z_{xy} + z_x^2 z_{yy} = \alpha^3(z)\alpha'(z) - \alpha^4(z)\frac{z_{xy}}{z_x z_y}. \tag{2.9}
$$

Assume that there is a function $\beta = \beta(z)$ such that

$$
z_{xy} = \beta(z) z_x z_y. \tag{2.10}
$$

Indeed, since the left-hand side in (2.9) depends only on z, one can easily check if z satisfies both the 2D eikonal equation in (2.8) and (2.10), then all the functions $a_i = a_i(z)$ defined by (2.8) are written in terms of α and β. Therefore, the problem of finding the similarity variable z is reduced to that of integrating the 2D eikonal equation and the PDE system

$$
\begin{cases}
z_{xx} = \alpha\alpha' - \beta z_y^2,\\
z_{xy} = \beta z_x z_y,\\
z_{yy} = \alpha\alpha' - \beta z_x^2.
\end{cases}
\tag{2.11}
$$

The system (2.11) is compatible if the following relation holds:

$$
\alpha\alpha'' + \alpha'^2 - 3\beta\alpha\alpha' + \alpha^2\left(\beta^2 - \beta'\right) = 0.
$$

Denote $\mu = \frac{1}{2}\alpha^2$. In this case, the above compatibility condition can be written as

$$
\mu'' - 3\beta\mu' + 2\mu\left(\beta^2 - \beta'\right) = 0. \tag{2.12}
$$

On the other hand, if the function β is given by

$$
\beta(z) = -\frac{\lambda''(z)}{\lambda'(z)}, \tag{2.13}
$$

where λ is a nonconstant function, then (2.10) turns into

$$(\lambda(z))_{xy} = 0.$$

The general solution of this equation is given by

$$\lambda(z(x,y)) = a(x) + b(y), \tag{2.14}$$

with a and b being arbitrary functions. Substituting β from (2.13) into the compatibility condition (2.12) and after integrating once, we get

$$\mu'\lambda' + 2\mu\lambda'' = k, \tag{2.15}$$

where k is an arbitrary constant.

Case 1. If $k \neq 0$, then after integrating (2.15) and substituting back $\mu = \frac{1}{2}\alpha^2$, we get

$$\alpha^2(z) = \frac{2k\lambda(z) + C_1}{\lambda'^2(z)}. \tag{2.16}$$

The relation (2.14) implies $\lambda'(z)z_x = a'(x)$, and $\lambda'(z)z_y = b'(y)$. We substitute these relations, (2.14) and (2.16), into the 2D eikonal equation (see (2.8)). It follows that the functions $a = a(x)$ and $b = b(y)$ are solutions of the following respective ODEs:

$$a'^2(x) - 2ka(x) = C_2 \quad \text{and} \quad b'^2(y) - 2kb(y) = C_3,$$

with $C_2 + C_3 = C_1$ (here C_i are real constants). The above ODEs admit the nonconstant solutions

$$a(x) = \frac{1}{2k}\left[k^2(x - C_4)^2 - C_2\right] \quad \text{and} \quad b(y) = \frac{1}{2k}\left[k^2(y - C_5)^2 - C_3\right],$$

and so (2.14) takes the form

$$\lambda(z(x,y)) = \frac{k}{2}\left[(x - C_4)^2 + (y - C_5)^2\right] - \frac{C_1}{2k}. \tag{2.17}$$

Notice that $\frac{1}{k_1}\lambda$ or $\lambda + k_2$ defines the same function β as the function λ does. Moreover, since the PDE (1.5) is invariant under translations in the (x, y)-space, we can consider

$$\lambda(z(x,y)) = x^2 + y^2. \tag{2.18}$$

If $\sqrt{\lambda}$ is a bijective function on a suitable interval, and if we denote by $\Phi = (\sqrt{\lambda})^{-1}$ its inverse function, then the similarity variable written in the polar coordinates (r, θ) (where $x = r\cos(\theta)$, $y = r\sin(\theta)$) is given by

$$z(x,y) = \Phi(r). \tag{2.19}$$

For simplicity, we consider $\Phi = \mathrm{Id}$, and from that we get

$$E = F(r) \quad \text{and} \quad w = G(r), \quad \text{where} \quad z(x,y) = r. \tag{2.20}$$

Hence, the ODE (2.5) turns into

$$\left(G'' + \frac{\nu}{r}G'\right)F'' + \left(2G''' + \frac{\nu+2}{r}G'' - \frac{1}{r^2}G'\right)F' + \left(G'''' + \frac{2}{r}G''' - \frac{1}{r^2}G'' + \frac{1}{r^3}G'\right)F = 1, \tag{2.21}$$

which can be reduced to the first order ODE

$$\left(G'' + \frac{\nu}{r}G'\right)F' + \left(G''' + \frac{1}{r}G'' - \frac{1}{r^2}G'\right)F = \frac{r^2 - r_0^2}{2r} + \frac{\gamma}{r}, \tag{2.22}$$

where $r_0 \in [0,1]$ with the property that

$$\gamma = \left[\left(rG'' + \nu G'\right)F' + \left(rG''' + G'' - \frac{1}{r}G'\right)F\right]|_{r=r_0}$$

is finite. The smoothness condition $G'(0) = 0$ implies that (2.22) can be written as [15]

$$\left(G'' + \frac{\nu}{r}G'\right)F' + \left(G''' + \frac{1}{r}G'' - \frac{1}{r^2}G'\right)F = \frac{r}{2}. \tag{2.23}$$

Case 2. If $k = 0$, similarly we get

$$z(x,y) = \Phi(k_1 x + k_2 y), \tag{2.24}$$

where k_1 and k_2 are real constants such that $k_1^2 + k_2^2 > 0$. In this case, for $\Phi = \mathrm{Id}$, the parameter and the data are written as

$$E = F(z) \quad \text{and} \quad w = G(z), \quad \text{where} \quad z(x,y) = k_1 x + k_2 y, \tag{2.25}$$

and the ODE (2.5) turns into

$$G''(z)F''(z) + 2G'''(z)F'(z) + G''''(z)F(z) = \frac{1}{(k_1^2 + k_2^2)^2}, \tag{2.26}$$

with $\{z|G''(z) = 0\}$ the associated set of singularities. Integrating the above ODE on the set $\{z|G''(z) \neq 0\}$ we obtain that Young's modulus is given by

$$E(x,y) = \frac{(k_1 x + k_2 y)^2 + C_1(k_1 x + k_2 y) + C_2}{2(k_1^2 + k_2^2)^2 G''(k_1 x + k_2 y)},$$

where C_i are arbitrary constants.

2.2. Data and parameter invariant under different groups. Consider two functionally independent functions on Ω, say, $z = z(x,y)$ and $v = v(x,y)$, and let

$$w = H(v(x,y)) \tag{2.27}$$

be the target shape. In this case, the data and the parameter do not share the same invariance. Similar to the above, substituting (2.27) into the relations (2.4) we get

(2.28)

$$\begin{aligned}
\Gamma_1 &= H''\left[(z_x v_x + z_y v_y)^2 + \nu(z_y v_x - z_x v_y)^2\right] \\
&\quad + H'\left[z_x^2 v_{xx} + 2z_x z_y v_{xy} + z_y^2 v_{yy} + \nu\left(z_x^2 v_{yy} - 2z_x z_y v_{xy} + z_y^2 v_{xx}\right)\right], \\
\Gamma_2 &= H'''(v_x^2 + v_y^2)(z_x v_x + z_y v_y) + H''\left[v_x^2 z_{xx} + 2v_x v_y z_{xy} + v_y^2 z_{yy}\right. \\
&\quad \left. + \nu\left(v_y^2 z_{xx} - 2v_x v_y z_{xy} + v_x^2 z_{yy}\right) + 2z_x v_x v_{xx} + 2(z_x v_y + z_y v_x)v_{xy} + 2z_y v_y v_{yy}\right. \\
&\quad \left. + (z_x v_x + z_y v_y)(\Delta v)\right] + H'\left[z_{xx} v_{xx} + 2z_{xy} v_{xy} + z_{yy} v_{yy} + \nu\left(z_{xx} v_{yy} - 2z_{xy} v_{xy}\right.\right. \\
&\quad \left.\left. + z_{yy} v_{xx}\right) + z_x(\Delta v)_x + z_y(\Delta v)_y\right], \\
\Gamma_3 &= H''''(v_x^2 + v_y^2)^2 + 2H'''\left[(3v_x^2 + v_y^2)v_{xx} + 4v_x v_y v_{xy} + (v_x^2 + 3v_y^2)v_{yy}\right] \\
&\quad + H''\left[3v_{xx}^2 + 4v_{xy}^2 + 3v_{yy}^2 + 2v_{xx}v_{yy} + 4v_x(\Delta v)_x + 4v_y(\Delta v)_y\right] + H'\Delta^2 v.
\end{aligned}$$

Recall that Γ_i's are functions of $z = z(x, y)$ only. Since each right-hand side in the above relations contains the function $H = H(v)$ and its derivatives, we require that the coefficients of the derivatives of H to be functions of v. It follows that Γ_i must be constant and denote them by γ_i. Therefore, the last condition in (2.28) becomes

$$\Delta^2(w) = \gamma_3, \tag{2.29}$$

which is the biharmonic equation. According to the above assumption, we seek solutions of (2.29) that are functions of v only. Similar to section 2.1, we get

$$v(x, y) = \Psi(r), \quad \text{or} \quad v(x, y) = \Psi(k_1 x + k_2 y), \tag{2.30}$$

and thus, for $\Psi = \mathrm{Id}$, the target shape is written as

$$w(x, y) = H(r), \quad \text{or} \quad w(x, y) = H(k_1 x + k_2 y). \tag{2.31}$$

Since $z = z(x, y)$ and $v = v(x, y)$ are functionally independent, we get

$$z(x, y) = k_1 x + k_2 y, \quad v(x, y) = \sqrt{x^2 + y^2} \tag{2.32}$$

or

$$z(x, y) = \sqrt{x^2 + y^2}, \quad v(x, y) = k_1 x + k_2 y. \tag{2.33}$$

One can prove that if the coefficients γ_i are constant, and if z and v are given by (2.32) or (2.33), respectively, then $\gamma_1 = \gamma_2 = 0$, and $\gamma_3 \neq 0$. On the other hand, the solutions of the biharmonic equation (2.29) of the form (2.31) are the following:

$$w(x, y) = \frac{\gamma_3}{64} z^4 + C_1 z^2 + C_2 \ln(z) + C_3 z^2 \ln(z) + C_4 \quad \text{for} \quad z = \sqrt{x^2 + y^2},$$

and, respectively,

$$w(x, y) = \frac{\gamma_3}{24(k_1^2 + k_2^2)^2} v^4 + C_1 v^3 + C_2 v^2 + C_3 v + C_4 \quad \text{for} \quad v = k_1 x + k_2 y,$$

and these correspond to the constant Young's modulus

$$E(x, y) = \frac{1}{\gamma_3}. \tag{2.34}$$

Notice that only particular solutions of the biharmonic equation have been found in this case (i.e., solutions invariant under rotations and translations). Since this PDE is also invariant under scaling transformations, which act not only on the space of the independent variables but on the data space as well, it is obvious to extend our study and to seek other types of symmetry reductions.

3. Equivalence transformations. Consider a one-parameter Lie group of transformations acting on an open set $\mathcal{D} \subset \Omega \times \mathcal{W} \times \mathcal{E}$, where $\mathcal{W}$ is the space of the data functions, and $\mathcal{E}$ is the space of the parameter functions, given by

$$\begin{cases} x^* = x + \varepsilon \zeta(x, y, w, E) + \mathcal{O}(\varepsilon^2), \\ y^* = y + \varepsilon \eta(x, y, w, E) + \mathcal{O}(\varepsilon^2), \\ w^* = w + \varepsilon \phi(x, y, w, E) + \mathcal{O}(\varepsilon^2), \\ E^* = E + \varepsilon \psi(x, y, w, E) + \mathcal{O}(\varepsilon^2), \end{cases} \tag{3.1}$$

where ε is the group parameter. Let

$$V=\zeta(x,y,w,E)\partial_x+\eta(x,y,w,E)\partial_y+\phi(x,y,w,E)\partial_w+\psi(x,y,w,E)\partial_E \tag{3.2}$$

be its associated general infinitesimal generator. The group of transformations (3.1) is called an *equivalence transformation* associated to the PDE (1.5) if this leaves the equation invariant. This means that the form of the equation in the new coordinates remains unchanged and the set of the analytical solutions is invariant under this transformation. The equivalence transformations can be found by applying the classical Lie method to (1.5), with E and w both considered as unknown functions (for more details see [10] and [21]). Following this method we obtain

$$\begin{cases}\zeta(x,y,w,E)=k_1+k_5x-k_4y,\\ \eta(x,y,w,E)=k_2+k_4x+k_5y,\\ \phi(x,y,w,E)=k_3+k_7x+k_6y+(4k_5-k_8)w,\\ \psi(x,y,w,E)=k_8E,\end{cases} \tag{3.3}$$

where k_i are real constants. The vector field (3.2) is written as $V=\sum_{i=1}^{8}k_iV_i$, where

$$\begin{gathered}V_1=\partial_x,\quad V_2=\partial_y,\quad V_3=\partial_w,\quad V_4=-y\partial_x+x\partial_y,\quad V_5=x\partial_x+y\partial_y+4w\partial_w,\\ V_6=y\partial_w,\quad V_7=x\partial_w,\quad V_8=-w\partial_w+E\partial_E.\end{gathered} \tag{3.4}$$

PROPOSITION 3.1. *The equivalence transformations related to the PDE* (1.5) *are generated by the infinitesimal generators* (3.4)*. Thus, the equation is invariant under translations in the x-space, y-space, w-space, rotations in the space of the independent variables (x,y), scaling transformations in the (x,y,w)-space, Galilean transformations in the (y,w) and (x,w) spaces, and scaling transformations in the (w,E)-space, respectively.*

Notice that the conditional symmetries found in section 2 represent particular cases of the equivalence transformations. Since each one-parameter group of transformations generated by V_i is a symmetry group, if ($w=G(x,y)$, $E=F(x,y)$) is a pair of known solutions of (1.5), so are the following:

$$\begin{aligned}
&w^{(1)}=G(x-\varepsilon_1,y), && E^{(1)}=F(x-\varepsilon_1,y),\\
&w^{(2)}=G(x,y-\varepsilon_2), && E^{(2)}=F(x,y-\varepsilon_2),\\
&w^{(3)}=G(x,y)+\varepsilon_3, && E^{(3)}=F(x,y),\\
&w^{(4)}=G(\tilde{x},\tilde{y}), && E^{(4)}=F(\tilde{x},\tilde{y}),\\
&w^{(5)}=e^{4\varepsilon_5}G(e^{-\varepsilon_5}x,e^{-\varepsilon_5}y), && E^{(5)}=F(e^{-\varepsilon_5}x,e^{-\varepsilon_5}y),\\
&w^{(6)}=G(x,y)+\varepsilon_6y, && E^{(6)}=F(x,y),\\
&w^{(7)}=G(x,y)+\varepsilon_7x, && E^{(7)}=F(x,y),\\
&w^{(8)}=e^{-\varepsilon_8}G(x,y), && E^{(8)}=e^{\varepsilon_8}F(x,y),
\end{aligned} \tag{3.5}$$

where $\tilde{x} = x\cos(\varepsilon_4) + y\sin(\varepsilon_4)$, $\tilde{y} = -x\sin(\varepsilon_4) + y\cos(\varepsilon_4)$, and ε_i are real constants. Moreover, the general solution of (1.5) constructed from a known one is given by

$$w(x,y) = e^{4\varepsilon_5-\varepsilon_8} G(e^{-\varepsilon_5}(\tilde{x}-\tilde{k}_1), e^{-\varepsilon_5}(\tilde{y}-\tilde{k}_2)) + e^{4\varepsilon_5-\varepsilon_8}\varepsilon_6 y + e^{4\varepsilon_5-\varepsilon_8}\varepsilon_7 x + e^{4\varepsilon_5-\varepsilon_8}\varepsilon_3,$$
$$E(x,y) = e^{\varepsilon_8} F(e^{-\varepsilon_5}(\tilde{x}-\tilde{k}_1), e^{-\varepsilon_5}(\tilde{y}-\tilde{k}_2)),$$

where $\tilde{k}_1 = \varepsilon_1\cos(\varepsilon_4) + \varepsilon_2\sin(\varepsilon_4)$, and $\tilde{k}_2 = \varepsilon_1\sin(\varepsilon_4) - \varepsilon_2\cos(\varepsilon_4)$.

The equivalence transformations form a Lie group $\mathcal{G}$ with an eight-dimensional associated Lie algebra $\mathcal{A}$. Using the adjoint representation of $\mathcal{G}$, one can find the optimal system of one-dimensional subalgebras of $\mathcal{A}$ (more details can be found in [18, pp. 203–209]). This optimal system is spanned by the vector fields given in Table 1. Denote by z, I, and J the invariants related to the one-parameter group of transformations generated by each vector field V_i. Here F and G are arbitrary functions, (r,θ) are the polar coordinates, and a, b, c are nonzero constants. To reduce the order of the PDE (1.5) one can also integrate the first order PDE system

$$\begin{cases} \zeta(x,y,w,E)w_x + \eta(x,y,w,E)w_y &= \phi(x,y,w,E), \\ \zeta(x,y,w,E)E_x + \eta(x,y,w,E)E_y &= \psi(x,y,w,E), \end{cases} \tag{3.6}$$

which defines the characteristics of the vector field (3.2). In Table 1, the associated reduced ODEs are listed. The invariance of (1.5) under the one-parameter groups of transformations generated by V_1, V_2, $V_1 + cV_6$, and $V_2 + cV_7$, respectively, leads us to the same ODE,

$$F''(z)G''(z) + 2F'(z)G'''(z) + F(z)G''''(z) = 1, \tag{3.7}$$

with the general solution

$$F(z) = \frac{z^2 + C_1 z + C_2}{2G''(z)} \tag{3.8}$$

on the set $\{z | G''(z) \neq 0\}$. The invariance under the scaling transformation generated by the vector field V_5 yields the reduced ODE

$$\begin{aligned} &\left[G''\left(z^2+1\right)^2 - 6z(z^2+1)G' + 12(z^2+\nu)G\right]F'' \\ &+ 2\left[\left(z^2+1\right)^2 G''' - 5z(z^2+1)G'' + 3(4z^2+\nu+1)G' - 12zG\right]F' \\ &+ \left[\left(z^2+1\right)^2 G'''' - 4z(z^2+1)G''' + 4(3z^2+1)G'' - 24zG' + 24G\right]F = 1. \end{aligned} \tag{3.9}$$

The ODE

$$\begin{aligned} &\left[\left(z^2+1\right)^2 G'' + 2(c-3)z(z^2+1)G' + (c-3)(c-4)(z^2+\nu)G\right]F'' \\ &+ \Big\{2\left(z^2+1\right)^2 G''' + 2(2c-5)z(z^2+1)G'' + 2(c-3)[z^2(c-4) + \nu(c-1) - 1]G' \\ &-2(c-3)(c-4)zG\Big\}F' + \Big\{\left(z^2+1\right)^2 G'''' + 2(c-2)z(z^2+1)G''' + \big[(c-3)(c-4)z^2 \\ &-2(c-2) + \nu c(c-1)\big]G'' - 2(c-4)(c-3)zG' + 2(c-4)(c-3)G\Big\}F = 1 \end{aligned} \tag{3.10}$$

TABLE 1

	Infintesimal generator	Invariants	$w = w(x,y)$	$E = E(x,y)$	ODE
1.	V_1	$z = y$ $I = w$ $J = E$	$w = G(z)$	$E = F(z)$	(3.7)
2.	V_2	$z = x$ $I = w$ $J = E$	$w = G(z)$	$E = F(z)$	(3.7)
3.	V_4	$z = r$ $I = w$ $J = E$	$w = G(z)$	$E = F(z)$	(2.21)
4.	V_5	$z = \frac{y}{x}$ $I = x^{-4}w$ $J = E$	$w = x^4 G(z)$	$E = F(z)$	(3.9)
5.	$cV_3 + V_4$	$z = r$ $I = w - c\theta$ $J = E$	$w = c\theta + G(z)$	$E = F(z)$	(2.21)
6.	$V_5 + cV_8$	$z = \frac{y}{x}$ $I = x^{c-4}w$ $J = x^{-c}E$	$w = x^{4-c}G(z)$	$E = x^c F(z)$	(3.10)
7.	$V_4 + cV_8$	$z = r$ $I = e^{c\theta}w$ $J = e^{-c\theta}E$	$w = e^{-c\theta}G(z)$	$E = e^{c\theta}F(z)$	(3.11)
8.	$V_4 + cV_5$	$z = re^{-c\theta}$ $I = r^{-4}w$ $J = E$	$w = r^4 G(z)$	$E = F(z)$	(3.13)
9.	$V_4 + cX_5 + bV_8$	$z = re^{-c\theta}$ $I = r^{\frac{b}{c}-4}w$ $J = r^{-\frac{b}{c}}E$	$w = r^{4-\frac{b}{c}}G(z)$	$E = r^{\frac{b}{c}}F(z)$	(3.14)
10.	$V_1 + cV_6$	$z = y$ $I = w - cxy$ $J = E$	$w = cxy + G(z)$	$E = F(z)$	(3.7)
11.	$V_2 + cV_7$	$z = x$ $I = w - cxy$ $J = E$	$w = cxy + G(z)$	$E = F(z)$	(3.7)
12.	$V_1 + cV_8$	$z = y$ $I = e^{cx}w$ $J = e^{-cx}E$	$w = e^{-cx}G(z)$	$E = e^{cx}F(z)$	(3.15)
13.	$V_2 + cV_8$	$z = x$ $I = e^{cy}w$ $J = e^{-cy}E$	$w = e^{-cy}G(z)$	$E = e^{cy}F(z)$	(3.15)

is obtained in case 6 of Table 1. The reduced equation

(3.11)
$$\left[G'' + \frac{\nu}{r}G' + \frac{\nu c^2}{r^2}G\right]F'' + \left[2G''' + \frac{\nu+2}{r}G'' + \frac{2\nu c^2 - 1}{r^2}G' - \frac{c^2(1+2\nu)}{r^3}G\right]F'$$

$$+ \left[G'''' + \frac{2}{r}G''' + \frac{c^2\nu - 1}{r^2}G'' + \frac{1 - c^2(2\nu+1)}{r^3}G' + \frac{2c^2(\nu+1)}{r^4}G\right]F = 1$$

is related to case 7. This can be written as the first order ODE

(3.12)
$$\left(G'' + \frac{\nu}{r}G' + \frac{\nu c^2}{r^2}G\right)F' + \left(G''' + \frac{1}{r}G'' + \frac{c^2\nu - 1}{r^2}G' - \frac{c^2(1+\nu)}{r^3}G\right)F = \frac{r^2 - r_0^2}{2r} + \frac{\gamma^*}{r},$$

where $r_0 \in [0,1]$ with the property that

$$\gamma^* = \left[F'\left(rG'' + \nu G' + \frac{\nu}{r}G\right) + F\left(rG''' + G'' + \frac{c^2\nu - 1}{r}G' - \frac{c^2(1+\nu)}{r^2}G\right)\right]|_{r=r_0}$$

is finite. In cases 8 and 9, after the change of the variable $z = \exp(t)$, the reduced ODEs are the following:

(3.13)
$$\begin{aligned}
&\left\{(c^2+1)^2G'' + (c^2+1)(\nu+7)G' + 4\left[\nu(3c^2+1) + c^2 + 3\right]G\right\}F'' \\
&+ \left\{2(c^2+1)^2G''' + (c^2+1)(\nu+19)G'' + 2[16 + (c^2+1)(3\nu+13)]G' + 8(\nu+7)G\right\}F' \\
&+ \left\{(c^2+1)^2G'''' + 12(c^2+1)G''' + 4(5c^2+13)G'' + 96G' + 64G\right\}F = 1,
\end{aligned}$$

and, respectively,

(3.14)
$$\begin{aligned}
&\left\{(c^2+1)^2G'' + \left(\frac{1}{c} + c\right)[c(\nu+7) - 2b]G' + \left(\frac{4}{c} - \frac{b}{c^2}\right)[c^3(1+3\nu) - c^2\nu b\right. \\
&\left. + c(\nu+3) - b]G\right\}F'' + \left\{2(c^2+1)^2G''' + \left(\frac{1}{c} + c\right)[c(\nu+19) - 4b]G''\right. \\
&+ 2\left[\frac{b^2}{c^2} + \nu b^2 + c^2(3\nu+13) - 4bc(\nu+1) - 12\frac{b}{c} + 3\nu + 29\right]G' \\
&\left. + \left(\frac{4}{c} - \frac{b}{c^2}\right)[2c(\nu+7) + b(\nu-5)]G\right\}F' + \left\{(c^2+1)^2G'''' \right. \\
&+ 2\left(c + \frac{1}{c}\right)(6c - b)G''' + \left[\frac{b^2}{c^2} + \frac{b}{c}(\nu - 17) + 20c^2 - bc(\nu+7) + \nu b^2 + 52\right]G'' \\
&\left. + \left(\frac{6}{c} - \frac{b}{c^2}\right)[16c + b(\nu-5)]G' + 2\left(\frac{4}{c} - \frac{b}{c^2}\right)[8c + b(\nu-3)]G\right\}F = 1.
\end{aligned}$$

In cases 12 and 13 we get the same equation,

$$\left(G'' + \nu c^2 G\right)F'' + 2\left(G''' + \nu c^2 G'\right)F' + \left(G'''' + \nu c^2 G''\right)F = 1, \tag{3.15}$$

with the general solution given by

$$F(z) = \frac{z^2 + C_1 z + C_2}{G''(z) + \nu c^2 G(z)} \tag{3.16}$$

on the set $\{z | G''(z) + \nu c^2 G(z) \neq 0\}$, where C_1 and C_2 are arbitrary real constants.

4. Conclusions. The data w is the function that models the target shape of a car windshield. Hence, we seek data with relevant physical and geometrical properties, such as smoothness and a positive curvature graph at least in the center of the bounded domain Ω, for which the boundary condition (1.3) is satisfied—which means that the sheet of glass is placed over a rigid frame. Moreover, if there is no free rotation of the plate around the tangent to $\partial\Omega$, then the condition (1.4) is required. Applying symmetry reductions theory to the PDE (1.5), we have shown that the data w and Young's modulus E can be expressed in terms of the invariants z, I, and J associated with a certain group action, i.e., $I = G(z)$ and $J = F(z)$, where w occurs in I, and E in J, respectively. Since now the technique of reducing the PDE (1.5) to an ODE has been applied only in the case of the radial functions ([15], [22], and [23]). Other symmetry reductions related to the studied model can be derived and these are listed in Table 1. The data given by homogeneous polynomials can be related to the invariance of the equation with respect to the scaling transformations (see cases 4 and 6, Table 1). The first two and last four cases in Table 1 allow us to construct other kind of data (see (3.5)). Since Ω must be bounded, the most interesting cases correspond to the rotational and the scaling symmetries. The problem of finding exact solutions of the reduced equations, which are second order linear nonhomogeneous ODEs, might be a difficult task depending on the form of the data. These equations are also, in general, ill-posed, as the initial problem is, and hence, regularization methods might be required in order to be studied, which is our current research.

One can make the following remarks: assume that $\partial\Omega = \{(x,y)|\ z(x,y) = k\}$ is the k-level set of the function z (here k being a nonzero constant) and $||\nabla z|| > 0$ on $\bar{\Omega}$. If the target shape is given by $w(x,y) = a(x,y)G(z(x,y))$, where $a = a(x,y)$ is a suitable function according to Table 1, then the boundary conditions (1.3) and (1.4) are equivalent to $G(k) = 0$ and $G'(k) = 0$. Therefore, the data might have the form $w(x,y) = a(x,y)\left(z(x,y) - k\right)^2 H(z(x,y))$. This corresponds to the case when the data and the bounded domain Ω are invariant under the same symmetry reduction. In our case, this can be applied to rotational symmetries. For scaling invariance, we have to incorporate the noninvariant boundary conditions in invariant solutions. As a consequence, we can extend the study of the problem on elliptical domains and on square domains with rounded corners. For instance, the class of target shapes of the form $w(x,y) = z^m(x,y) - k^m$, where $m \geq 1$ is a natural number, satisfies the boundary condition (1.3). In this case, the normal derivative of the data on the boundary is $\frac{\partial w}{\partial n}|_{\partial\Omega} = mk^{m-1}\|\nabla z\||_{\partial\Omega}$. If this quantity is small then the condition (1.4) is almost satisfied (i.e., there is a small free rotation of the plate around the tangent to $\partial\Omega$). In the following examples, we assume that the glass Poisson ration $\nu = 0.5$.

Example 1. *Rotational invariant data and parameter.* Consider the target shape of the form [23]

$$w(x,y) = G(r) = -\frac{1}{6}\left(r-1\right)^2\left(2r+1\right), \quad r = \sqrt{x^2+y^2},$$

defined on the unit disc (see Figure 4.1) which satisfies the boundary conditions (1.3) and (1.4). Since $G'(0) = 0$, the reduced ODE is (2.23) and this has a singularity at $r = \frac{3}{5}$. Since $E > 0$, we consider the constant of integration $C_1 = 1$, and so,

$$E(x,y) = F(r) = -\frac{1}{11}\left(r + \frac{1}{2}\right) + (5r-3)^{-\frac{6}{5}}.$$

The PDE (1.5) is elliptic for $r \in \left(\frac{3}{5}, \frac{3}{4}\right)$, hyperbolic for $r \in \left[0, \frac{3}{5}\right) \bigcup \left(\frac{3}{5}, 1\right]$, and parabolic if $r = \frac{3}{5}$ or $r = \frac{3}{4}$, respectively.

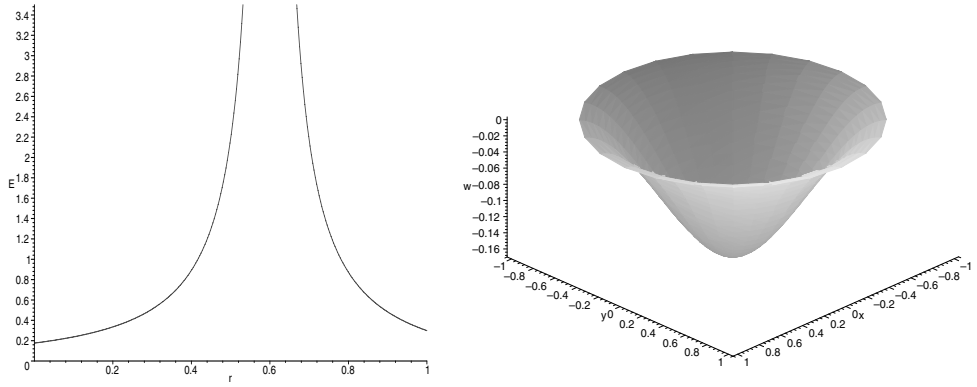

FIG. 4.1. *The parameter* $E(x,y) = F(r) = -\frac{1}{11}\left(r+\frac{1}{2}\right) + (5r-3)^{-\frac{6}{5}}$ *and the target shape* $w(x,y) = G(r) = -\frac{1}{6}(r-1)^2(2r+1)$, *with* $r = \sqrt{x^2+y^2}$, *defined on the unit disc.*

Example 2. *Particular target shapes on rounded square domains.*

(a) Suppose the Lamé oval $\partial\Omega = \{(x,y)|\ x^{2n} + y^{2n} = 1\}$ is the boundary of the domain (here $n \geq 2$ is a natural number). For a target shape of the form

$$w(x,y) = \left(x^{2n} + y^{2n}\right)^m - 1, \tag{4.1}$$

$m \geq 1$ being a natural number, (1.5) is elliptic on $\Omega - \{(0,0)\}$ and parabolic in $(0,0)$. These target shapes are invariant with respect to $V_5 + cV_8 + (4-c)V_3$, where $c = 4 - 2mn$. For $x > 0$ or $x < 0$, the functions (4.1) can be written as

$$w(x,y) = x^{2mn}G(z) - 1, \quad G(z) = \left(1 + z^{2n}\right)^m, \quad z = \frac{y}{x}.$$

According to case 6 in Table 1, the associated Young's modulus has the form

$$E(x,y) = x^{4-2mn}F(z), \quad z = \frac{y}{x}.$$

Since $w(x,y) = w(y,x) = w(-x,y) = w(x,-y) = w(-x,-y)$, Young's modulus also shares these discrete symmetries. Thus, the reduced ODE (3.10) can be integrated for $z \in [0,1]$. In particular, for $n = 2$ and $m = 1$, the data is a solution of the biharmonic equation and Young's modulus is $E = 48^{-1}$. For $n = 3$ and $m = 1$, the data and the numerical solution F satisfying $F(0) = 0.002$ and $F'(0) = 0$ are given in Figure 4.2.

(b) Assume that $\partial\Omega = \{(x,y)|\ x^{2n} + y^2 = 1\}$, where $n \geq 1$ is a natural number. Consider the class of target shapes

$$w(x,y) = x^{2n} + y^2 - 1,$$

invariant under the vector field $V_2 + 2V_6$. Hence, (1.5) is reduced to the ODE (3.7). For $n = 3$, the associated Young's modulus is given by

$$E(x,y) = F(x) = \frac{x^2 + C_1x + C_2}{2(30x^4+1)},$$

and since $E > 0$, we can set $C_1 = 0$ and $C_2 = 2$ (see Figure 4.3). Equation (1.5) is elliptic on $\Omega - Oy$ and parabolic on the y-axis.

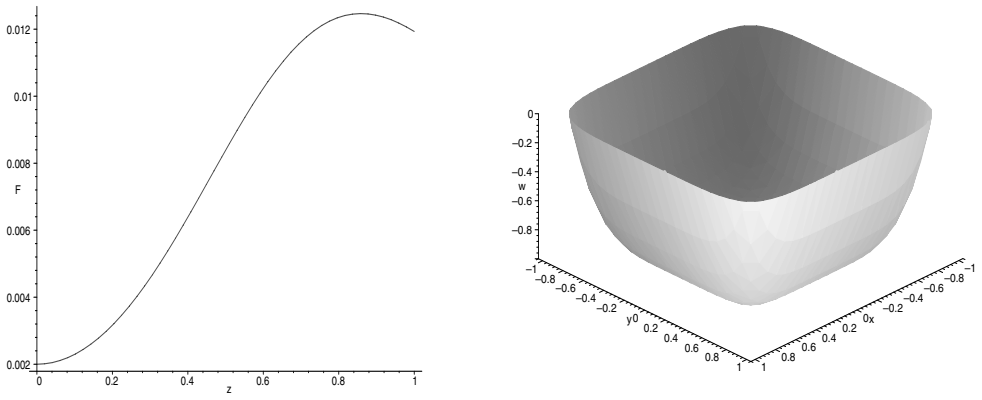

FIG. 4.2. *The parameter* $E(x,y) = x^{-2}F(z)$, *with* $z = \frac{y}{x}$, *and the data* $w(x,y) = x^6 + y^6 - 1$ *defined on the rounded square domain* $\{(x,y)|\ x^6 + y^6 < 1\}$.

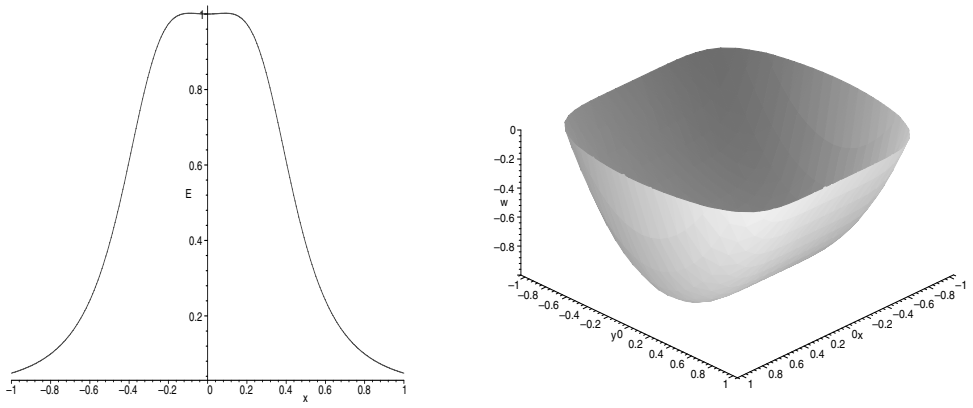

FIG. 4.3. *The parameter* $E(x,y) = \frac{x^2+2}{2(30x^4+1)}$ *and the data* $w(x,y) = x^6 + y^2 - 1$ *defined on the rounded square domain* $\{(x,y)|\ x^6 + y^2 < 1\}$.

Example 3. *Particular target shapes on elliptic domains.* Consider the data

$$w(x,y) = \left(\frac{x^2}{a^2} + \frac{y^2}{b^2}\right)^m - 1, \tag{4.2}$$

on the elliptic domain $\Omega = \{(x,y)|\ \frac{x^2}{a^2} + \frac{y^2}{b^2} < 1\}$, where $m \geq 1$ is a natural number. These target shapes are obtained from the invariance of the studied PDE with respect to $V_5 + cV_8 + (4-c)V_3$, where $c = 4 - 2m$. The PDE (1.5) is elliptic on $\Omega - \{(0,0)\}$ and parabolic in the origin. For $x > 0$ or $x < 0$, the functions (4.2) can be written as

$$w(x,y) = x^{2m}G(z) - 1, \quad G(z) = \left(\frac{1}{a^2} + \frac{z^2}{b^2}\right)^m, \quad z = \frac{y}{x}.$$

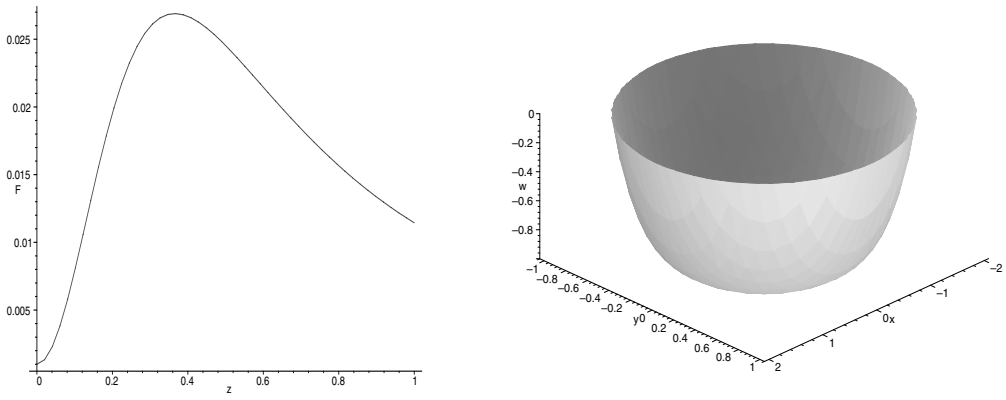

FIG. 4.4. *The parameter* $E(x,y) = x^{-2}F(z)$, *with* $z = \frac{y}{x}$, *and the data* $w(x,y) = \left(\frac{x^2}{4} + y^2\right)^3 - 1$ *defined on the elliptical domain* $\{(x,y) | \ \frac{x^2}{4} + y^2 = 1\}$.

In this case, we look for solutions to (1.5) of the form

$$E(x,y) = x^{4-2m}F(z), \quad z = \frac{y}{x}.$$

If $m = 2$, the data is a solution of the biharmonic equation, and the related Young's modulus is $E = 24\left(a^{-4} + b^{-4}\right) + 16a^{-2}b^{-2}$. If $m \geq 3$, the reduced ODE is (3.9). For $m = 3$, the data and the numerical solution F of (3.9) satisfying $F(0) = 0.001$ and $F'(0) = 0$ are plotted in Figure 4.4.

In brief, suppose that the target shape w on a domain Ω is given. In order to see if this is an invariant function with respect to the equivalence transformations related to the studied model, we should check if this is a solution of the first equation in (3.6), where the functions ζ, η, and ϕ are given by (3.3). Next, by integrating the second PDE in (3.6) we can determine the form of the parameter in terms of the similarity variables. The geometrical significance of the nonlinearity occurring between the data and the parameter in the inverse problem (1.1) is reflected by the group analysis tools. Investigating special groups of transformations connected to this equation, the order of the model can be reduced. The equation will be then written in terms of the invariants of the group actions. Another advantage of this approach is that of relating the direct and inverse problems through these symmetry reductions. It might be interesting for future study to link these results to the common approach of the inverse problems theory, especially in expressing the regularization methods in terms of the similarity variables. For other target shapes defined by functions which are not invariant under the listed symmetry reductions, the classical theory of the linear second order PDEs can be applied, but this might be quite difficult due to the form of the discriminant.

Acknowledgments. I would like to thank Prof. Heinz W. Engl and Dr. Philipp Kügler, Institute for Industrial Mathematics at Johannes Kepler University, for encouraging my research in applying the symmetry analysis to parameter identification problems, for interesting discussions, and for guiding me through this subject. I am grateful to Prof. Peter Olver, School of Mathematics, Institute of Technology at the University of Minnesota, for helpful comments which improved the presentation of this paper.

FRONT BIFURCATIONS IN AN EXCITATORY NEURAL NETWORK*

PAUL C. BRESSLOFF† AND STEFANOS E. FOLIAS†

Abstract. We show how a one-dimensional excitatory neural network can exhibit a symmetry breaking front bifurcation analogous to that found in reaction diffusion systems. This occurs in a homogeneous network when a stationary front undergoes a pitchfork bifurcation leading to bidirectional wave propagation. We analyze the dynamics in a neighborhood of the front bifurcation using perturbation methods, and we establish that a weak input inhomogeneity can induce a Hopf instability of the stationary front, leading to the formation of an oscillatory front or breather. We then carry out a stability analysis of stationary fronts in an exactly solvable model and use this to derive conditions for oscillatory fronts beyond the weak input regime. In particular, we show how wave propagation failure occurs in the presence of a large stationary input due to the pinning of a stationary front; a subsequent reduction in the strength of the input then generates a breather via a Hopf instability of the front. Finally, we derive conditions for the locking of a traveling front to a moving input, and we show how locking depends on both the amplitude and velocity of the input.

Key words. traveling waves, neural networks, cortical models, front bifurcations, inhomogeneous media

1. Introduction.

Nonlinear integro-differential equations of the form

$$\tau_s \frac{\partial u(x,t)}{\partial t} = -u(x,t) + \int_{-\infty}^{\infty} w(x-x') f(u(x',t)) dx' - \beta v(x,t) + I(x),$$

$$\frac{1}{\varepsilon}\frac{\partial v(x,t)}{\partial t} = -v(x,t) + u(x,t) \tag{1.1}$$

have arisen as continuum models of one-dimensional cortical tissue [1, 12], in which $u(x,t)$ is a neural field that represents the local activity of a population of excitatory neurons at position $x \in \mathbf{R}$, $I(x)$ is an external input current, τ_s is a synaptic time constant (assuming first-order synapses), $f(u)$ denotes the output firing rate function, and $w(x-x')$ is the strength of connections from neurons at x' to neurons at x. The distribution $w(x)$ is taken to be a positive, even function of x. The neural field $v(x,t)$ represents some form of negative feedback mechanism such as spike frequency adaptation or synaptic depression, with β, ε determining the relative strength and rate of feedback. If additional nonlocal terms in v are introduced, then v represents instead the activity of a population of inhibitory neurons [17, 1]. The nonlinear function f is usually taken to be a smooth sigmoid function

$$f(u) = \frac{1}{1+\mathrm{e}^{-\gamma(u-\kappa)}} \tag{1.2}$$

with gain γ and threshold κ. The units of time are fixed by setting $\tau_s = 1$; a typical value of τ_s is 10 msec. It can be shown [12] that there is a direct link between the above model and experimental studies of wave propagation in cortical slices where synaptic inhibition is pharmacologically blocked [4, 7, 18]. Since there is strong vertical

coupling between cortical layers, it is possible to treat a thin cortical slice as an effective one-dimensional medium. Analysis of the model provides valuable information regarding how the speed of a traveling wave, which is relatively straightforward to measure experimentally, depends on various features of the underlying cortical circuitry.

A number of previous studies have considered the existence and stability of traveling wave solutions of (1.1) in the case of a uniform input I, which is equivalent to a shift in the threshold κ. In particular, it has been shown that in the absence of any feedback ($\beta = 0$), the resulting scalar network can support the propagation of traveling fronts [5, 10], whereas traveling pulses tend to occur when there is significant negative feedback [17, 1, 12]. In this paper, we show that such feedback can also have a nontrivial effect on the propagation of traveling fronts. This is due to the occurrence of a symmetry breaking front bifurcation analogous to that found in reaction diffusion systems [14, 8, 16, 9, 2, 15, 13, 11]. We begin by deriving conditions for the existence of traveling wavefronts in the case of a homogeneous network (section 2). We then carry out a perturbation expansion in powers of the wavespeed c to show that a stationary front can undergo a supercritical pitchfork bifurcation at a critical rate of negative feedback, leading to bidirectional front propagation (section 3). As in the case of reaction diffusion systems, the front bifurcation acts as an organizing center for a variety of nontrivial dynamics including the formation of oscillatory fronts or breathers. We show how the latter can occur through a Hopf bifurcation from a stationary front in the presence of a weak stationary input inhomogeneity (section 4). Finally, we analyze the existence and stability of stationary fronts in an exactly solvable model, which is obtained by taking the high gain limit $\gamma \to \infty$ of the sigmoid function f such that $f(u) = H(u - \kappa)$, where H is the Heaviside function (section 5). As briefly reported elsewhere [3], the exactly solvable model allows us to study oscillatory fronts beyond the weak input regime. Rather than perturbing about the homogeneous case, we now consider a large input amplitude for which wave propagation failure occurs due to the pinning of a stationary front. A subsequent reduction in the amplitude of the input then induces a Hopf instability, leading to the formation of a breather. We conclude our analysis of the exactly solvable model by deriving conditions for the locking of a traveling front to a moving input, and we show how locking depends on both the amplitude and speed of the input.

The major advantage of the exactly solvable model is that it allows us to explicitly determine the existence and stability of stationary and traveling fronts in the presence of external inputs, without any restrictions on the size of the input. However, it has the disadvantage of restricting the nonlinear function f to be a step function. This is less realistic than the smooth nonlinearity (1.2), which matches quite well the input–output characteristics of populations of neurons. The lack of smoothness also makes it difficult to carry out a nonlinear analysis in order to determine whether or not the Hopf instability is supercritical, for example. As we show in this paper, such an analysis can be carried out for smooth f provided that the input amplitude is sufficiently weak. The fact that the nonlocal integro-differential equation (1.1) exhibits behavior similar to a reaction–diffusion system might not be surprising, particularly given that for the exponential weight distribution $w(x) = \mathrm{e}^{-|x|}$, equation (1.1) can be reduced to a PDE of the reaction–diffusion type. It is important to emphasize, however, that our results hold for a more general class of weight distribution $w(x)$ for which a corresponding (finite-order) PDE cannot be constructed. Hence, the analysis is a nontrivial extension of known results for reaction–diffusion equations.

2. Traveling fronts in a homogeneous network. In this section we investigate the existence of traveling front solutions of (1.1) for homogeneous inputs by combining results on scalar networks [5] with an extension of the analysis of front bifurcations in nonscalar reaction–diffusion equations [8, 2].

2.1. The scalar case. The existence of traveling front solutions in scalar, homogeneous networks was previously analyzed by Ermentrout and McLeod [5]. Their analysis can be applied to a scalar version of (1.1) obtained by taking $\varepsilon \to \infty$ so that $v = u$ and setting $I(x) = -h$ with h a constant input. This leads to the scalar integro-differential equation

$$\frac{\partial u(x,t)}{\partial t} = -(1+\beta)u(x,t) + \int_{-\infty}^{\infty} w(x-x')f(u(x',t))dx' - h. \tag{2.1}$$

Without loss of generality we choose h such that $\kappa = 0$ in the sigmoid function (1.2). The weight distribution w is assumed to be a positive, even, continuously differentiable function of x with unit normalization $\int_{-\infty}^{\infty} w(y)dy = 1$. Suppose that the function

$$F_{h,\beta}(u) = f(u) - (1+\beta)u - h \tag{2.2}$$

has precisely three zeros at $u = U_{\pm}(h,\beta), U_0(h,\beta)$ with $U_- < U_0 < U_+$ and $F'_{h,\beta}(U_{\pm}) < 0$. It can then be shown that (modulo uniform translations) there exists a unique traveling front solution of (2.1) such that $u(x,t) = U(\xi)$, $\xi = x - ct$, with $U(\xi) \to U_{\pm}$ as $\xi \to \mp\infty$ [5]. Moreover, the speed of the wave satisfies

$$c = c(h,\beta) = \frac{\Gamma_{h,\beta}}{\int_{-\infty}^{\infty} u'^2 f'(u)d\xi}, \tag{2.3}$$

where

$$\Gamma_{h,\beta} = \int_{U_-}^{U_+} F_{h,\beta}(u)du. \tag{2.4}$$

Since the denominator of (2.3) is positive definite, the sign of c is determined by the sign of the coefficient $\Gamma_{h,\beta}$. In particular, suppose that $h = 0.5$ and f is given by the sigmoid function (1.2) so that $f(u) - h = \tanh(u/2\gamma)/2$. It follows that, for $0 < 1+\beta < \gamma/4$, there exists a pair of stable homogeneous fixed points with $U_- = -U_+$, which in turn implies that $\Gamma_{h,\beta} = 0$ and the front solution is stationary; see Figure 2.1. The corresponding function $F_{h,\beta}(u)$ has the inflection symmetry $F_{h,\beta}(-u) = -F_{h,\beta}(u)$. Note that the stationary solution of (2.1) is also an ε-independent solution of the full system (1.1) with $I(x) = -h$, but it is not necessarily the only solution (see below).

2.2. The regime $\varepsilon \gg 1$. In the large ε regime, the neural field v varies on a much faster time scale than u. Introducing the stretched time coordinate $\tau = t/\delta$ with $\delta = \varepsilon^{-1} \ll 1$, we have

$$\frac{\partial u(x,\tau)}{\partial \tau} = \delta\left(-u(x,\tau) + \int_{-\infty}^{\infty} w(x-x')f(u(x',\tau))dx' - \beta v(x,\tau) - h\right),$$

$$\frac{\partial v(x,\tau)}{\partial \tau} = -v(x,\tau) + u(x,\tau). \tag{2.5}$$

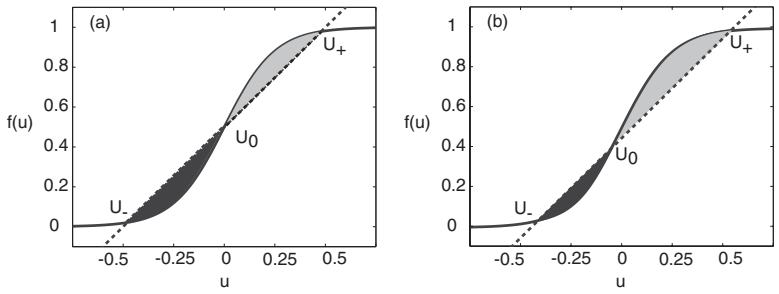

FIG. 2.1. *Balance condition for the speed of a traveling wavefront in a scalar excitatory network with* $u(x,t) = U(x-ct)$ *such that* $U(\mp\infty) = U_\pm$. *The solid curve is* $f(u) = 1/(1+\mathrm{e}^{-\gamma u})$ *with* $\gamma = 8$, *and the dashed line is* $g(u) = (1+\beta)u + h$. *The wavespeed* c *is positive (negative) if the gray shaded area is larger (smaller) than the black shaded area.* (a) $h = 0.5$, $\beta = 0.5$ *such that* $c = 0$. (b) $h = 0.4$, $\beta = 0.5$ *such that* $c > 0$.

To leading order in δ, u is independent of τ so that we can explicitly solve for v according to

$$v(x,t) = v_0(x)\mathrm{e}^{-\varepsilon t} + u(x,t)(1-\mathrm{e}^{-\varepsilon t}). \tag{2.6}$$

Thus after an initial transient of duration $t \sim \mathcal{O}(\varepsilon^{-1})$, the field v adiabatically follows the field u, with the latter evolving according to the scalar equation (2.1). It follows that in the large ε regime there exists a unique traveling wave solution of the full system with $(u(x,t), v(x,t)) = (U(x-ct), V(x-ct))$ such that $(U,V) \to (U_\pm, U_\pm)$ as $\xi \to \mp\infty$ and $c = c(h,\beta)$, $U_\pm = U_\pm(h,\beta)$. The front is stable in the large ε regime provided that the solution of the corresponding scalar equation is stable, which is found to be the case numerically. If $\Gamma_{h,\beta} = 0$, then the front is stationary and persists for all ε but may become unstable as ε is reduced.

2.3. The regime $0 < \varepsilon \ll 1$. In the small ε regime, additional front solutions can be constructed that connect the two fixed points $(u,v) = (U_\pm(h,\beta), U_\pm(h,\beta))$. This follows from the observation that the neural field v remains approximately constant on the length scale over which u varies, that is, within the transition layer of the front. Suppose that the system is prepared in the down state (U_-, U_-) and is perturbed on its left-hand side to induce a transition to the upper state (U_+, U_+). In this case $v \approx U_-$ within the transition layer, and this generates a front propagating to the right whose speed is approximately given by (2.3) with $h \to h + \beta U_-$, that is, $c = c(h + \beta U_-, 0)$. If, on the other hand, the system is prepared in the up state (U_+, U_+) and is perturbed on its right-hand side to induce a transition to the down state (U_-, U_-), then a left-propagating front is generated with $c = c(h + \beta U_+, 0)$. Note from (2.4) that

$$\Gamma_{h+\beta U_-,0} > \Gamma_{h,\beta} + \beta \int_{U_-}^{U_+} (u - U_-)du, \quad \Gamma_{h+\beta U_+,0} < \Gamma_{h,\beta} + \beta \int_{U_-}^{U_+} (u - U_+)du \tag{2.7}$$

so that $\Gamma_{h+\beta U_-,0} > \Gamma_{h,\beta} > \Gamma_{h+\beta U_+,0}$. Hence, the existence of fronts propagating in opposite directions clearly holds when h, β are chosen such that $\Gamma_{h,\beta} = 0$.

3. Front bifurcation. The above analysis suggests that if $\Gamma_{h,\beta} = 0$, then at some critical rate of feedback $\varepsilon = \varepsilon_c$, a pair of counterpropagating fronts bifurcate

from a stationary front. Moreover, all the front solutions have the same asymptotic behavior $(U(\xi),V(\xi)) \to (U_\pm,U_\pm)$ as $\xi \to \mp\infty$. Following along lines analogous to Hagberg and Meron [8], we carry out a perturbation expansion in powers of the speed c about this critical point, and we show that the stationary solution undergoes a pitchfork bifurcation.

First, set $I(x) = -h$ and $(u(x,t),v(x,t)) = (U(x-ct),V(x-ct))$ in (1.1) to obtain the pair of equations

$$\begin{aligned} -cU' &= -U + w * f(U) - \beta V, \\ -cV' &= \varepsilon[-V+U], \end{aligned} \tag{3.1}$$

where $U' = dU/d\xi$ and $*$ denotes the convolution operator,

$$w * U = \int_{-\infty}^{\infty} w(\xi-\xi')U(\xi')d\xi'. \tag{3.2}$$

Suppose that β and h are fixed such that $\Gamma_{h,\beta} = 0$, and denote the corresponding stationary solution by $(\overline{U},\overline{V})$. Expand the fields U,V as power series in c:

$$\begin{aligned} U(\xi) &= \overline{U}(\xi) + cU_1(\xi) + c^2U_2(\xi) + \cdots, \\ V(\xi) &= \overline{V}(\xi) + cV_1(\xi) + c^2V_2(\xi) + \cdots. \end{aligned} \tag{3.3}$$

Note that the higher order terms $U_n(\xi), V_n(\xi)$, $n \geq 1$, should all decay to zero as $\xi \to \pm\infty$, since the stationary solution already has the correct asymptotic behavior. Also expand ε according to

$$\varepsilon = \varepsilon_c + c\varepsilon_1 + c^2\varepsilon_2 + \cdots. \tag{3.4}$$

Substitute these expansions into (3.1) and Taylor expand the nonlinear function $f(U)$ about $\overline{U}$:

$$f(U) = f(\overline{U}) + \sum_{n\geq 1} \overline{f}_n(U-\overline{U})^n, \quad \overline{f}_n = \frac{1}{n!}\frac{d^nf}{dU^n}\bigg|_{U=\overline{U}}. \tag{3.5}$$

Collecting all terms at successive orders of c then generates a hierarchy of equations for the perturbative corrections U_n, V_n. The lowest order equation recovers the conditions for a stationary solution:

$$\begin{aligned} (1+\beta)\overline{U} + h &= w * f(\overline{U}), \\ \overline{V} &= \overline{U}. \end{aligned} \tag{3.6}$$

At order c we have

$$\begin{aligned} -\overline{U}' &= -U_1 + w * [\overline{f}_1U_1] - \beta V_1, \\ -\overline{V}' &= \varepsilon_c[-V_1+U_1] + \varepsilon_c[-\overline{V}+\overline{U}]. \end{aligned} \tag{3.7}$$

The term $-\beta V_1$ in the first line can be eliminated using the second. Since $\overline{V} = \overline{U}$, we thus find that

$$\mathcal{M}U_1 = \left(\frac{\beta}{\varepsilon_c} - 1\right)\overline{U}', \quad V_1 = U_1 + \frac{\overline{U}'}{\varepsilon_c}, \tag{3.8}$$

where $\mathcal{M}$ is the linear operator

$$\mathcal{M}U = -(1+\beta)U + w * [\overline{f}_1 U]. \tag{3.9}$$

Since the functions $U_n(\xi), V_n(\xi)$ decay to zero as $\xi \to \pm\infty$, we will assume that $\mathcal{M}$ acts on the space $L^2(\mathbf{R})$ and introduce the generalized inner product

$$\langle U|V\rangle = \int_{-\infty}^{\infty} f'(\overline{U}(\xi))U(\xi)V(\xi)d\xi \tag{3.10}$$

for all $U, V \in L^2(\mathbf{R})$. With respect to this space, $\mathcal{M}$ is self-adjoint and has the null vector $\overline{U}'$[1]:

$$\mathcal{M}\overline{U}' = \mathcal{M}^\dagger \overline{U}' = 0. \tag{3.11}$$

Applying the Fredholm alternative to (3.8) then gives the solvability condition

$$\langle \overline{U}'|\overline{U}'\rangle \left(\frac{\beta}{\varepsilon_c} - 1\right) = 0. \tag{3.12}$$

Since $f'(\overline{U}(\xi)) > 0$ for all ξ, it follows that $\langle \overline{U}'|\overline{U}'\rangle > 0$ and thus $\varepsilon_c = \beta$. This in turn means that $\mathcal{M}U_1 = 0$ and hence $U_1 = A\overline{U}'$ for some constant A. Since $\overline{U}'$ is the generator of uniform translations, we are free to choose the origin such that $A = 0$. Under this choice,

$$U_1 = 0, \quad V_1 = \frac{\overline{U}'}{\varepsilon_c}. \tag{3.13}$$

At order c^2 we obtain

$$\begin{aligned} -U_1' &= \mathcal{M}U_2 + \beta[-V_2 + U_2] + w * [\overline{f}_2 U_1^2], \\ -V_1' &= \varepsilon_c[-V_2 + U_2] + \varepsilon_1[-V_1 + U_1] + \varepsilon_2[-\overline{V} + \overline{U}]. \end{aligned} \tag{3.14}$$

Substituting for $-V_2 + U_2$ in the first line, taking $\overline{V} = \overline{U}$, $\beta = \varepsilon_c$, and using equation (3.13) then gives

$$\mathcal{M}U_2 = \frac{1}{\varepsilon_c}\left(\overline{U}'' - \varepsilon_1 \overline{U}'\right), \quad V_2 = U_2 + \frac{1}{\varepsilon_c^2}(\overline{U}'' - \varepsilon_1 \overline{U}'). \tag{3.15}$$

Applying the Fredholm alternative to (3.15) yields the solvability condition

$$\langle \overline{U}'|\overline{U}''\rangle = \varepsilon_1 \langle \overline{U}'|\overline{U}'\rangle. \tag{3.16}$$

In order to evaluate the inner product $\langle \overline{U}'|\overline{U}''\rangle$, we use the result

$$(1+\beta)\frac{d^2\overline{U}}{d\xi^2} = \int_{-\infty}^{\infty} w(\xi - \xi')\frac{d^2 f(\overline{U}(\xi'))}{d{\xi'}^2}d\xi', \tag{3.17}$$

[1] We could equally well proceed by taking the standard inner product $\langle U|V\rangle = \int_{-\infty}^{\infty} U(\xi)V(\xi)d\xi$. The adjoint of $\mathcal{M}$ is then given by $\mathcal{M}^\dagger U = -(1+\beta)U + \overline{f}_1 w * U$, which has the null vector $\overline{f}_1\overline{U}'$ where $\overline{f}_1 = f'(\overline{U})$.

which follows from differentiating (3.6) with respect to ξ and using the asymptotic properties of w. Then

$$\begin{aligned}\langle \overline{U}' | \overline{U}'' \rangle &= \int_{-\infty}^{\infty} f'(\overline{U}(\xi))\overline{U}'(\xi)\overline{U}''(\xi)d\xi \\ &= \int_{-\infty}^{\infty} \frac{df(\overline{U}(\xi))}{d\xi}\overline{U}''(\xi)d\xi \\ &= \frac{1}{1+\beta}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \frac{df(\overline{U}(\xi))}{d\xi} w(\xi-\xi')\frac{d^2 f(\overline{U}(\xi'))}{d\xi'^2}d\xi' d\xi \\ &= \frac{1}{1+\beta}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \frac{df(\overline{U}(\xi))}{d\xi} w'(\xi-\xi')\frac{df(\overline{U}(\xi'))}{d\xi'}d\xi' d\xi \\ &= 0, \end{aligned} \tag{3.18}$$

since $w'(\xi)$ is an odd function of ξ. Hence, $\varepsilon_1 = 0$ and

$$\mathcal{M}U_2 = \frac{\overline{U}''}{\varepsilon_c}, \quad V_2 = U_2 + \frac{\overline{U}''}{\varepsilon_c^2}. \tag{3.19}$$

At order c^3 we obtain

$$\begin{aligned} -U_2' &= \mathcal{M}U_3 + \beta[-V_3 + U_3] + 2w * [\overline{f}_2 U_1 U_2] + w * [\overline{f}_3 U_1^3], \\ -V_2' &= \varepsilon_c[-V_3 + U_3] + \varepsilon_1[-V_2 + U_2] + \varepsilon_2[-V_1 + U_1] + \varepsilon_3[-\overline{V} + \overline{U}]. \end{aligned} \tag{3.20}$$

Substituting for $-V_2 + U_2$ in the first line, taking $\overline{V} = \overline{U}$, $\beta = \varepsilon_c$, $\varepsilon_1 = 0$, and using (3.13) and (3.19) then gives

$$\mathcal{M}U_3 = \frac{1}{\varepsilon_c^2}\left(\overline{U}''' - \varepsilon_2\varepsilon_c\overline{U}'\right), \quad V_3 = U_3 + \frac{1}{\varepsilon_c^3}(\overline{U}''' + \varepsilon_c^2 U_2' - \varepsilon_2\varepsilon_c\overline{U}'). \tag{3.21}$$

Applying the Fredholm alternative to (3.21) yields the solvability condition

$$\varepsilon_2 = \frac{\langle \overline{U}' | \overline{U}''' \rangle}{\varepsilon_c \langle \overline{U}' | \overline{U}' \rangle} < 0. \tag{3.22}$$

The sign of ε_2 can be determined using (3.17),

$$\begin{aligned}\langle \overline{U}' | \overline{U}''' \rangle &= \int_{-\infty}^{\infty} f'(\overline{U}(\xi))\overline{U}'(\xi)\overline{U}'''(\xi)d\xi \\ &= \int_{-\infty}^{\infty} \frac{df(\overline{U}(\xi))}{d\xi}\overline{U}'''(\xi)d\xi \\ &= -\int_{-\infty}^{\infty} \frac{d^2 f(\overline{U}(\xi))}{d\xi^2}\overline{U}''(\xi)d\xi \\ &= -\frac{1}{1+\beta}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \frac{d^2 f(\overline{U}(\xi))}{d\xi^2} w(\xi-\xi')\frac{d^2 f(\overline{U}(\xi'))}{d\xi'^2}d\xi' d\xi \\ &< 0, \end{aligned} \tag{3.23}$$

since $w(\xi)$ is an even, monotonically decreasing function of $|\xi|$. Hence $\varepsilon_2 < 0$.

Combining these various results, we find that

$$\begin{aligned} U(\xi) &= \overline{U}(\xi) + \mathcal{O}(c^2), \\ V(\xi) &= \overline{U}(\xi) + \frac{c}{\varepsilon_c}\overline{U}'(\xi) + \mathcal{O}(c^2), \end{aligned} \tag{3.24}$$

and

$$\varepsilon = \varepsilon_c + c^2\varepsilon_2 + \mathcal{O}(c^3). \tag{3.25}$$

Equation (3.25) implies that the stationary front undergoes a pitchfork bifurcation, which is supercritical since $\varepsilon_2 < 0$. (This assumes of course that the stationary front is stable for $\varepsilon > \varepsilon_c$. This can be confirmed numerically, and also proven analytically in the high gain limit; see section 5.) Close to the bifurcation point the shape of the propagating fronts is approximately the same as the stationary front, except that the recovery variable V is shifted relative to U by an amount proportional to the speed c, that is,

$$U(\xi) \approx \overline{U}(\xi), \quad V(\xi) \approx \overline{U}(\xi + c/\varepsilon_c). \tag{3.26}$$

An analogous result was previously obtained for reaction–diffusion equations [8]. It is important to emphasize that the occurrence of a pitchfork bifurcation from a stationary front does not require any underlying inflection symmetries of the nonlinear function f (see also [2]). We only require that the scalar equation (2.1) supports a stationary front for appropriate choices of h, β. The fact that the weight distribution $w(x)$ is even means that there must be a pitchfork bifurcation from a stationary solution rather than a transcritical bifurcation as in the case of a nonsymmetric w.

4. The effect of a weak input inhomogeneity. Now suppose that both ε and h are allowed to vary. We then expect a codimension 2 cusp bifurcation in which the pitchfork bifurcation unfolds into a saddle-node bifurcation, with the stationary front replaced by a traveling front in the large ε regime. More interestingly, as in the case of reaction–diffusion systems [16, 9, 2], the pitchfork bifurcation acts as an organizing center for a variety of dynamical phenomena, including the formation of breathers due to the presence of a weak input inhomogeneity or due to curvature (in the case of two spatial dimensions). These breathers consist of periodic reversals in propagation that can be understood in terms of a dynamic transition between the pair of counterpropagating fronts that is induced by the weak intrinsic perturbation. Such a transition involves an interaction between a translational degree of freedom and an order parameter that determines the direction of propagation. In order to unravel this interaction, it is necessary to extend the perturbation analysis of section 3 along lines analogous to previous treatments of reaction–diffusion systems [16, 9, 2].

Suppose that the system (1.1) undergoes a pitchfork bifurcation from a stationary state when $\varepsilon = \varepsilon_c = \beta$ and $I(x) = -h$. Introduce the small parameter δ according to $\varepsilon - \varepsilon_c = \delta^2\chi$ and introduce a weak input inhomogeneity by taking $I(x) = -h + \delta^3\eta(x)$. Since any fronts are slowly propagating, we rescale time according to $\tau = \delta t$ so that (1.1) becomes

$$\begin{aligned} \delta\frac{\partial u(x,\tau)}{\partial \tau} &= -u(x,t) + \int_{-\infty}^{\infty} w(x-x')f(u(x',\tau))dx' - \beta v(x,\tau) - h + \delta^3\eta(x), \\ \delta\frac{\partial v(x,\tau)}{\partial \tau} &= (\varepsilon_c + \delta^2\chi)\left[-v(x,\tau) + u(x,\tau)\right]. \end{aligned} \tag{4.1}$$

Motivated by (3.24), we introduce the ansatz that, sufficiently close to the pitchfork bifurcation, the solutions of (4.1) can be expanded in the form

$$\begin{aligned} u(x,\tau) &= \overline{U}(x-p(\tau)) + \delta^2 u_2(x,\tau) + \delta^3 u_3(x,\tau) + \cdots, \\ v(x,\tau) &= \overline{U}(x-p(\tau)) + \delta\frac{a(\delta\tau)}{\varepsilon_c}\overline{U}'(x-p(\tau)) + \delta^2 v_2(x,\tau) + \delta^3 v_3(x,\tau) + \cdots. \end{aligned} \tag{4.2}$$

Here p is identified with the translational degree of freedom, whereas a represents the order parameter associated with changes in propagation direction. Note that a is assumed to evolve on a slower time scale than p. We now substitute the ansatz (4.2) into (4.1) and expand in powers of δ along lines similar to the perturbation calculation of section 3.

At order δ we find that

$$p_\tau = a, \tag{4.3}$$

where $p_\tau = dp/d\tau$. At order δ^2 we obtain the pair of equations

$$\mathcal{M}u_2 = a^2\frac{\overline{U}''}{\varepsilon_c}, \qquad v_2 = u_2 + a^2\frac{\overline{U}''}{\varepsilon_c^2} \tag{4.4}$$

after setting $p_\tau = a$. The solvability condition for (4.4) is automatically satisfied. At order δ^3 we have

$$\begin{aligned} \frac{\partial u_2}{\partial\tau} &= \mathcal{M}u_3 + \beta[-v_3 + u_3] + \eta, \\ \frac{\partial v_2}{\partial\tau} + \frac{\overline{U}'a_{\hat\tau}}{\varepsilon_c} &= \varepsilon_c[-v_3 + u_3] - a\chi\frac{\overline{U}'}{\varepsilon_c} \end{aligned} \tag{4.5}$$

with $\hat\tau = \delta\tau$. Using (4.4), the following equation for u_3 is obtained:

$$\mathcal{M}u_3 = \frac{1}{\varepsilon_c^2}\left(a^3\overline{U}''' - a\chi\varepsilon_c\overline{U}' - a_{\hat\tau}\varepsilon_c\overline{U}'\right) - \eta. \tag{4.6}$$

Applying the Fredholm alternative to (4.6) yields an amplitude equation for a:

$$a_{\hat\tau} = -\chi a + a^3\frac{\langle\overline{U}'|\overline{U}'''\rangle}{\varepsilon_c\langle\overline{U}'|\overline{U}'\rangle} - \varepsilon_c\frac{\langle\overline{U}'|\eta\rangle}{\langle\overline{U}'|\overline{U}'\rangle}. \tag{4.7}$$

Finally, rescaling p, a, and η, we obtain the pair of equations

$$\begin{aligned} p_t &= a, \\ a_t &= (\varepsilon_c - \varepsilon)a + \frac{\langle\overline{U}'|\overline{U}'''\rangle}{\varepsilon_c\langle\overline{U}'|\overline{U}'\rangle}a^3 - \varepsilon_c\frac{\langle\overline{U}'|\eta\rangle}{\langle\overline{U}'|\overline{U}'\rangle}. \end{aligned} \tag{4.8}$$

Note that $\overline{U} = \overline{U}(x-p)$, so that the final coefficient on the right-hand side of (4.8) will be p-dependent in the case of an inhomogeneous input $\eta = \eta(x)$.

Cusp bifurcation for homogeneous inputs. It is clear from (4.8) that when $\eta = 0$ we recover the pitchfork bifurcation of a stationary front as found in section 3. In particular, for $\varepsilon < \varepsilon_c$ there are three constant speed solutions of (4.8) such that

$a_t = 0, P_t = a = c$, corresponding to an unstable stationary front and a pair of stable counterpropagating fronts with speeds

$$c = \pm\sqrt{(\varepsilon_c - \varepsilon)\varepsilon_c \frac{\langle \overline{U}' | \overline{U}' \rangle}{|\langle \overline{U}' | \overline{U}''' \rangle|}}. \tag{4.9}$$

If η is nonzero but constant, on the other hand, the final term on the right-hand side of (4.8) reduces to the constant coefficient $\varepsilon_c \eta (f(U_+) - f(U_-))/\langle \overline{U}' | \overline{U}' \rangle$, and the pitchfork bifurcation unfolds to a saddle-node bifurcation. There are two saddle-node lines in the (η, ε)-plane corresponding to the condition $dG(a)/da = 0$, where $a_t = G(a)$:

$$\eta_{sn} = \pm \frac{2}{3\sqrt{3}} \frac{(\varepsilon_c - \varepsilon)^{3/2}}{\varepsilon_c^{1/2}} \frac{\langle \overline{U}' | \overline{U}' \rangle^{3/2}}{(f(U_+) - f(U_-))|\langle \overline{U}' | \overline{U}''' \rangle|^{1/2}}, \tag{4.10}$$

and the corresponding speed along these lines is

$$c_{sn} = \pm\sqrt{(\varepsilon_c - \varepsilon)\varepsilon_c \frac{\langle \overline{U}' | \overline{U}' \rangle}{3|\langle \overline{U}' | \overline{U}''' \rangle|}}. \tag{4.11}$$

Hopf bifurcation for a weak inhomogeneity. The introduction of a weak input inhomogeneity can lead to a Hopf instability of the stationary front. We shall illustrate this by considering the particular example of the step inhomogeneity

$$\eta(x) = \begin{cases} s/2 & \text{if } x \leq 0, \\ -s/2 & \text{if } x > 0 \end{cases} \tag{4.12}$$

with $s > 0$. For such an input we find that

$$\langle \overline{U}' | \eta \rangle = \frac{s}{2}[2f(\overline{U}(-p)) - f(U_+) - f(U_-)]. \tag{4.13}$$

Recall from section 2 that when $h = 0.5$ the homogeneous network with f given by (1.2) supports a stationary front solution for which $U_\pm = \pm 0.5/(1+\beta)$, and $\overline{U}(0) = 0$ such that $f(U_+) + f(U_-) = 2f(0)$. Hence, (4.8) has a fixed point at $p = 0, a = 0$. Linearization about this fixed point shows that there is a Hopf bifurcation of the stationary front at $\varepsilon = \varepsilon_c$ with Hopf frequency

$$\omega_H = \sqrt{\frac{s\varepsilon_c f'(0)|\overline{U}'(0)|}{\langle \overline{U}' | \overline{U}' \rangle}}. \tag{4.14}$$

The supercritical or subcritical nature of the Hopf bifurcation can then be determined by evaluating higher order terms in a, p. However, this is complicated by the fact that we do not have an analytical expression for the stationary front solution $\overline{U}$, in contrast to the case of a reaction–diffusion equation with a cubic nonlinearity [2]. (Note that, as in the case of reaction–diffusion equations [2], one can develop a more intricate perturbation analysis that takes into account $\mathcal{O}(\delta^2)$ inhomogeneities and corresponding shifts in the Hopf bifurcation point. Here we have followed a simpler approach in order to illustrate the basic ideas underlying the perturbative treatment of the integro-differential equation (1.1).)

5. Exactly solvable model. We now consider the high gain limit $\gamma \to \infty$, for which (1.2) reduces to $f(u) = H(u-\kappa)$, where H is the Heaviside function $H(u) = 1$ if $u > 0$ and $H(u) = 0$ if $u \le 0$. The advantage of using a threshold nonlinearity is that explicit analytical expressions for front solutions can be obtained, which allows us to derive conditions for the Hopf instability of a stationary front without any restrictions on the size of the input inhomogeneity. Numerical simulations of the full system establish that the bifurcation is supercritical and that it generates an oscillatory modulation of the stationary front in the form of a breather [3]. (For a corresponding analysis of reaction–diffusion equations, see Prat and Li [13].)

5.1. Traveling fronts (homogeneous case). We begin by deriving exact traveling front solutions of (1.1) for $f(u) = H(u-\kappa)$ and a homogeneous input $I(x) = 0$. That is, we seek a solution of the form $u(x,t) = U(\xi)$, $\xi = x - ct$, $c > 0$, such that $U(0) = \kappa$, $U(\xi) < \kappa$ for $\xi > 0$ and $U(\xi) > \kappa$ for $\xi < 0$. Setting $v(x,t) = V(\xi)$, we then have

$$-cU'(\xi) + U(\xi) = \int_{-\infty}^{0} w(\xi - \xi')d\xi' - \beta V(\xi), \tag{5.1}$$

$$-\frac{c}{\varepsilon}V'(\xi) = -V(\xi) + U(\xi). \tag{5.2}$$

Differentiating the first equation and substituting into the second, we obtain a second-order ODE with boundary conditions at $\xi = 0$ and $\pm\infty$:

$$\begin{aligned} -c^2U''(\xi) + c[1+\varepsilon]U'(\xi) - \varepsilon[1+\beta]U(\xi) &= -cw(\xi) - \varepsilon W(\xi), \\ U(0) &= \kappa, \\ U(\mp\infty) &= U_{\pm}, \end{aligned} \tag{5.3}$$

where

$$W(\xi) = \int_{\xi}^{\infty} w(y)dy. \tag{5.4}$$

Here $U_{\pm}$ are the homogeneous fixed point solutions

$$U_+ = \frac{1}{1+\beta}, \quad U_- = 0. \tag{5.5}$$

We have used the fact that w has unit normalization, $W(-\infty) \equiv \int_{-\infty}^{\infty} w(y)dy = 1$. It follows that a necessary condition for the existence of a front solution is $\kappa < U_+$.

In order to establish the existence of a traveling front, we solve the boundary value problem in the domains $\xi \le 0$ and $\xi \ge 0$ and match the solutions at $\xi = 0$. For further mathematical convenience, we take the weight distribution to be an exponential function

$$w(x) = \frac{1}{2d}\mathrm{e}^{-|x|/d}, \tag{5.6}$$

where d determines the range of the synaptic interactions. We fix the spatial scale by setting $d = 1$; a typical value of d is 1 mm. We first consider the case of right-moving

waves ($c > 0$). On the domain $\xi \geq 0$, the particular solution is $U_>(\xi) = \kappa e^{-\xi}$, with κ related to the speed c according to the self-consistency condition

$$\kappa = \frac{c+\varepsilon}{2(c^2 + c[1+\varepsilon] + \varepsilon[1+\beta])}, \qquad c \geq 0. \tag{5.7}$$

In the domain $\xi \leq 0$ the solution consists of complementary and particular parts:

$$U_<(\xi) = \mathcal{A}_+ e^{\mu_+ \xi} + \mathcal{A}_- e^{\mu_- \xi} + \mathcal{A} e^{\xi} + U_+, \tag{5.8}$$

where

$$\mu_\pm = \frac{1}{2c}\left[1 + \varepsilon \pm \sqrt{(1+\varepsilon)^2 - 4\varepsilon(1+\beta)}\right]. \tag{5.9}$$

The coefficient $\mathcal{A}$ is obtained by direct substitution into the differential equation for U, whereas the coefficients $\mathcal{A}_\pm$ are determined by matching solutions at the boundary $\xi = 0$, that is, $U_<(0) = \kappa$ and $U_<'(0) = -\kappa$. Thus we find

$$\mathcal{A} = \frac{c-\varepsilon}{2(c^2 - c[1+\varepsilon] + \varepsilon[1+\beta])}, \tag{5.10}$$

$$\mathcal{A}_+ = \frac{\mu_- U_+ + (\mu_- - 1)\mathcal{A} - (1+\mu_-)\kappa}{\mu_+ - \mu_-}, \tag{5.11}$$

$$\mathcal{A}_- = \frac{-\mu_+ U_+ + (1-\mu_+)\mathcal{A} + (1+\mu_+)\kappa}{\mu_+ - \mu_-}. \tag{5.12}$$

In the limit $\beta \to 0$ we recover the standard result for an excitatory network without feedback [5]:

$$U(\xi) = \begin{cases} \dfrac{1}{2(c+1)} e^{-\xi} & \text{for } \xi > 0, \\ 1 + (\kappa - 1)e^{\xi/c} + \dfrac{1}{2(c-1)}\left[e^{\xi} - e^{\xi/c}\right] & \text{for } \xi < 0 \end{cases} \tag{5.13}$$

with

$$\kappa = \frac{1}{2(c+1)}, \qquad c \geq 0. \tag{5.14}$$

A similar analysis can be carried out for left-moving waves. Now the speed c is determined by the particular solution in the domain $\xi \leq 0$, which takes the form $U_<(\xi) = -\hat{\kappa} e^{\xi} + U_+$ with $\hat{\kappa} = (1+\beta)^{-1} - \kappa$. This leads to the self-consistency condition

$$\hat{\kappa} = -\frac{c-\varepsilon}{2(c^2 - c[1+\varepsilon] + \varepsilon[1+\beta])}, \qquad c \leq 0. \tag{5.15}$$

The existence of traveling front solutions can now be established by finding positive real solutions of (5.7) and negative real solutions of (5.15). For concreteness, we will assume that the threshold κ is fixed and determine the solution branches as a

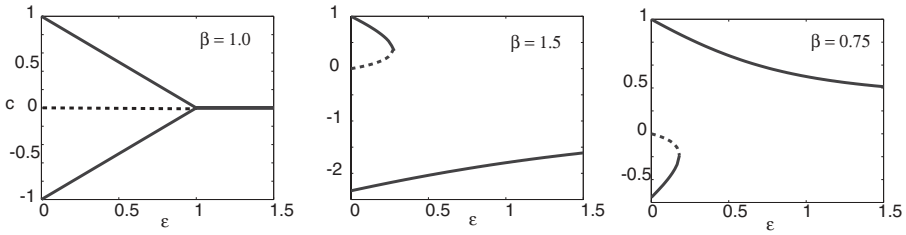

FIG. 5.1. *Plot of wavefront speed c as a function of ε for various values of β and a fixed threshold $\kappa = 0.25$: (i) $2\kappa(1+\beta) = 1$, (ii) $2\kappa(1+\beta) > 1$, (iii) $2\kappa(1+\beta) < 1$. Stable (unstable) branches are shown as solid (dashed) curves.*

function of the feedback parameters ε, β with $1/\kappa - 1 > \beta > 0$. The roots of (5.7) and (5.15) can be written explicitly as

$$c = \frac{1}{2}\left[-\left(1+\varepsilon-\frac{1}{2\kappa}\right) \pm \sqrt{\left(1+\varepsilon-\frac{1}{2\kappa}\right)^2 - 4\varepsilon\left(1+\beta-\frac{1}{2\kappa}\right)}\right] \tag{5.16}$$

and

$$c = \frac{1}{2}\left[\left(1+\varepsilon-\frac{1}{2\hat{\kappa}}\right) \pm \sqrt{\left(1+\varepsilon-\frac{1}{2\hat{\kappa}}\right)^2 - 4\varepsilon\left(1+\beta-\frac{1}{2\hat{\kappa}}\right)}\right]. \tag{5.17}$$

Using the fact that $\operatorname{sign}\left(1+\beta-\frac{1}{2\kappa}\right) = -\operatorname{sign}\left(1+\beta-\frac{1}{2\hat{\kappa}}\right)$, we find that there are three bifurcation scenarios, as shown in Figure 5.1:

(i) If $2\kappa(1+\beta) = 1$, then there exists a stationary front for all ε. At a critical value of ε the stationary front undergoes a pitchfork bifurcation, leading to the formation of a left- and a right-moving wave. This is the high gain limit of the front bifurcation analyzed in section 3 for smooth f.

(ii) If $2\kappa(1+\beta) > 1$, then there is a single left-moving wave for all ε. There also exists a pair of right-moving waves that annihilate in a saddle-node bifurcation at a critical value of ε that approaches zero as $\beta \to 0$.

(iii) If $2\kappa(1+\beta) < 1$, then there is a single right-moving wave for all ε. There also exists a pair of left-moving waves that annihilate in a saddle-node bifurcation at a critical value of ε that approaches zero as $\beta \to 0$.

5.2. Stability analysis of stationary fronts (inhomogeneous case). Stationary front solutions of (1.1) with $f(u) = H(u-\kappa)$ in the case of an inhomogeneous input $I(x)$ satisfy the equation

$$(1+\beta)U(x) = \int_{-\infty}^{x_0} w(x-x')dx' + I(x). \tag{5.18}$$

Suppose that $I(x)$ is a monotonically decreasing function of x. Since the system is no longer translation invariant, the position of the front is pinned to a particular location x_0, where $U(x_0) = \kappa$. Monotonicity of $I(x)$ ensures that $U(x) > \kappa$ for $x < x_0$ and $U(x) < \kappa$ for $x > x_0$. The center x_0 satisfies

$$(1+\beta)\kappa = \frac{1}{2} + I(x_0) \tag{5.19}$$

under the normalization $\int_0^\infty w(y)dy = 1/2$. Equation (5.19) implies that in contrast to the homogeneous case, there exists a stationary front over a range of threshold values (for fixed β); changing the threshold κ simply shifts the position of the center x_0. In the particular case of the exponential weight distribution (5.6), we have

$$(1+\beta)U(x) = \begin{cases} \dfrac{\mathrm{e}^{x_0-x}}{2} + I(x), & x > x_0, \\ 1 - \dfrac{\mathrm{e}^{x-x_0}}{2} + I(x), & x < x_0. \end{cases} \tag{5.20}$$

If the stationary front is stable, then it will prevent wave propagation. Stability is determined by writing $u(x,t) = U(x) + p(x,t)$ and $v(x,t) = V(x) + q(x,t)$ with $V(x) = U(x)$ and expanding (1.1) to first-order in $(p,\ q)$:

$$\frac{\partial p(x,t)}{\partial t} = -p(x,t) + \int_{-\infty}^{\infty} w(x-x')H'(U(x'))p(x',t)dx' - \beta q(x,t),$$

$$\frac{1}{\varepsilon}\frac{\partial q(x,t)}{\partial t} = -q(x,t) + p(x,t). \tag{5.21}$$

We assume that $p, q \in L^2(\mathbf{R})$. The spectrum of the associated linear operator is found by taking $p(x,t) = \mathrm{e}^{\lambda t}p(x)$ and $q(x,t) = \mathrm{e}^{\lambda t}q(x)$. Using the identity

$$\frac{dH(U(x))}{dU} = \frac{\delta(x-x_0)}{|U'(x_0)|} \tag{5.22}$$

we obtain the equation

$$(\lambda+1)p(x) = \frac{w(x-x_0)}{|U'(x_0)|}p(x_0) - \frac{\varepsilon\beta p(x)}{\lambda+\varepsilon}. \tag{5.23}$$

Equation (5.23) has two classes of solution. The first consists of any function $p(x)$ such that $p(x_0) = 0$, for which $\lambda = \lambda_\pm^{(0)}$, where

$$\lambda_\pm^{(0)} = \frac{-(1+\varepsilon) \pm \sqrt{(1+\varepsilon)^2 - 4\varepsilon(1+\beta)}}{2}. \tag{5.24}$$

Note that $\lambda_\pm^{(0)}$ belong to the essential spectrum since they have infinite multiplicity. The second class of solution is of the form $p(x) = Aw(x-x_0)$, $A \neq 0$, for which λ is given by the roots of the equation

$$\lambda + 1 + \frac{\varepsilon\beta}{\lambda+\varepsilon} = \frac{1}{2|U'(x_0)|}. \tag{5.25}$$

Since

$$U'(x_0) = \frac{1}{1+\beta}\left[I'(x_0) - \frac{1}{2}\right], \tag{5.26}$$

it follows that $\lambda = \lambda_\pm$, where

$$\lambda_\pm = \frac{-\Lambda \pm \sqrt{\Lambda^2 - 4(1-\Gamma)\varepsilon(1+\beta)}}{2} \tag{5.27}$$

with

$$\Lambda = 1 + \varepsilon - (1+\beta)\Gamma \tag{5.28}$$

and

$$\Gamma = \frac{1}{1+2D}, \quad D = |I'(x_0)|. \tag{5.29}$$

We have used the fact that $I'(x_0) \leq 0$. The eigenvalues $\lambda_\pm$ determine the discrete spectrum.

5.3. Hopf bifurcation to a breathing front. Equation (5.27) implies that the stationary front is locally stable, provided that $\Lambda > 0$ or, equivalently, the gradient of the inhomogeneous input at x_0 satisfies

$$D > D_c \equiv \frac{1}{2}\frac{\beta - \varepsilon}{1+\varepsilon}. \tag{5.30}$$

Since $D \geq 0$, it follows that the front is stable when $\beta < \varepsilon$, that is, when the feedback is sufficiently weak or fast. On the other hand, if $\beta > \varepsilon$, then there is a Hopf bifurcation at the critical gradient $D = D_c$. The corresponding critical Hopf frequency is

$$\omega_H = \sqrt{\frac{2D_c\varepsilon(1+\beta)}{2D_c+1}} = \sqrt{\varepsilon(\beta-\varepsilon)}. \tag{5.31}$$

Note that the frequency depends only on the size and rate of the negative feedback but is independent of the details of the synaptic weight distribution and the size of the input. This should be contrasted with the corresponding Hopf frequency in the case of a smooth nonlinearity f and a weak step-inhomogeneity; see (4.14). The latter depends on the input amplitude and the form of the stationary solution $\overline{U}$, which itself depends on the weight distribution w.

In order to investigate the nature of solutions around the Hopf bifurcation point, we consider the particular example of a smooth ramp inhomogeneity

$$I(x) = -\frac{s}{2}\tanh(\gamma x), \tag{5.32}$$

where s is the size of the step and γ determines its steepness. A stationary front will exist provided that

$$s > \bar{s} \equiv |1 - 2\kappa(1+\beta)|. \tag{5.33}$$

The gradient $D = s\gamma\,\mathrm{sech}^2(\gamma x_0)/2$ depends on x_0, which is itself dependent on β and κ through (5.19). Using the identity $\mathrm{sech}^2 x = 1 - \tanh^2 x$, it follows that

$$D = \frac{\gamma}{2s}\left(s^2 - \bar{s}^2\right). \tag{5.34}$$

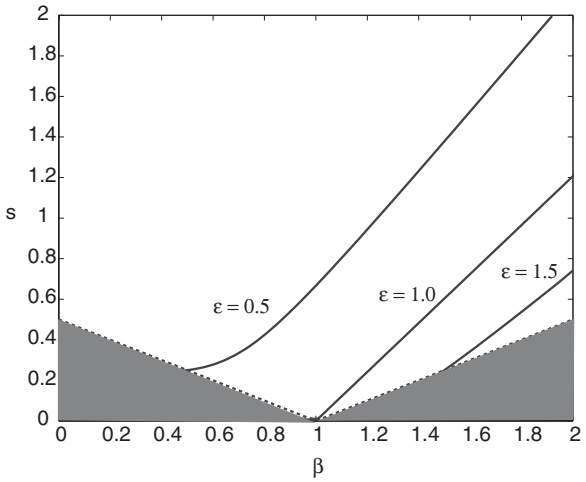

FIG. 5.2. *Stability phase diagram for a stationary front in the case of a step input* $I(x) = -s\tanh(\gamma x)/2$, *where* γ *is the steepness of the step and* s *its height. Hopf bifurcation lines (solid curves) in* $s-\beta$ *parameter space are shown for various values of* ε. *In each case the stationary front is stable above the line and unstable below it. The shaded area denotes the region of parameter space where a stationary front solution does not exist. The threshold* $\kappa = 0.25$ *and* $\gamma = 0.5$.

Combining (5.30) and (5.34), we obtain an expression for the critical value of s that determines the Hopf bifurcation points:

$$s_c = \frac{1}{2\gamma}\left[\frac{\beta-\varepsilon}{1+\varepsilon} + \sqrt{\left(\frac{\beta-\varepsilon}{1+\varepsilon}\right)^2 + 4\bar{s}^2\gamma^2}\right]. \tag{5.35}$$

The critical height s_c is plotted as a function of β for various values of ε and fixed κ, γ in Figure 5.2. Note that in the homogeneous case ($s = 0$) a stationary solution exists only at the particular value of β given by $\beta = 1/(2\kappa) - 1$. This solution is stable for $\varepsilon > \beta$ and unstable for $\varepsilon < \beta$, which is consistent with the pitchfork bifurcation shown in Figure 5.1. Close to the front bifurcation $\varepsilon = \beta$, the Hopf bifurcation occurs in the presence of a weak input inhomogeneity, which is the case considered in section 2. Now, however, it is possible to determine the bifurcation curve without any restrictions on the size of the input.

Numerically solving the full system of equations (1.1) for a step input $I(x)$, exponential weights $w(x)$, and threshold nonlinearity $f(u) = H(u-\kappa)$ shows that the Hopf bifurcation is supercritical, in which there is a transition to a small amplitude breather whose frequency of oscillation is approximately equal to the Hopf frequency ω_H. As the input amplitude s is reduced beyond the Hopf bifurcation point, the amplitude of the oscillation increases until the breather itself becomes unstable and there is a secondary bifurcation to a traveling front. This is illustrated in Figure 5.3, which shows a space-time plot of the developing breather as the input amplitude is slowly reduced. Note that analogous results have been obtained for pulses in the presence of stationary Gaussian inputs, where a reduction in the input amplitude induces a Hopf bifurcation to a pulse-like breather [3, 6]. Interestingly, the localized breather can itself undergo a secondary instability leading to the periodic emission of traveling waves. In one dimension such waves consist of pairs of counterpropagating pulses, whereas in two dimensions the waves are circular target patterns [6].

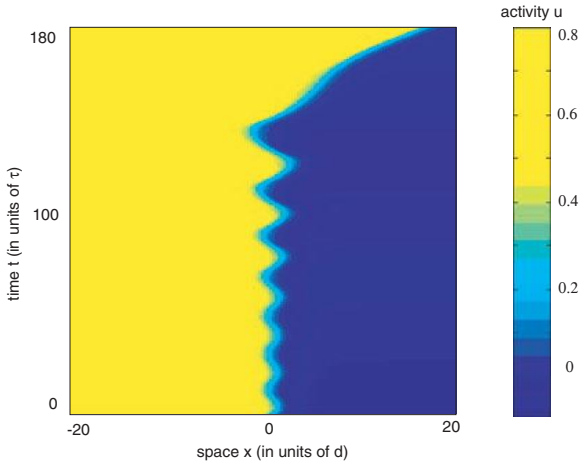

FIG. 5.3. *Breather-like solution arising from a Hopf instability of a stationary front due to a slow reduction in the size s of the step input inhomogeneity* (5.32). *Here* $\varepsilon = 0.5, \gamma = 0.5, \beta = 1, \kappa = 0.25$. *The input amplitude* $s = 2$ *at* $t = 0$ *and* $s = 0$ *at* $t = 180$. *The amplitude of the oscillation steadily grows until it destabilizes at* $s \approx 0.05$, *leading to the generation of a traveling front.*

5.4. Locking to a moving input. We conclude our analysis of the exactly solvable model by considering the effects of a moving input stimulus. This is interesting from a number of viewpoints. First, introducing a persistent stationary input into an in vitro cortical slice can damage the tissue, whereas a moving input (at least if it is localized) will not. Second, in vivo inputs into the intact cortex are typically nonstationary, as exemplified by inputs to the visual cortex induced by moving visual stimuli. We consider the particular problem of whether or not a traveling front can lock to a step-like input $I(x) = I_0\chi(x - vt)$ traveling with constant speed v, where

$$\chi(x) = \begin{cases} -1, & x > 0, \\ 0, & x = 0, \\ +1, & x < 0. \end{cases}$$

Such a front moves at the same speed as the input but may be shifted in space relative to the input.

We proceed by introducing the traveling wave coordinate $\xi = x - vt$ and deriving existence conditions for a front solution $U(\xi)$ satisfying $U(\xi) \to 0$ as $\xi \to \infty$, $U(\xi) \to (1+\beta)^{-1}$ as $\xi \to -\infty$, and $U(\xi_0) = \kappa$. Substituting into (1.1) gives

$$-vU'(\xi) = -U(\xi) + \int_{-\infty}^{\xi_0} w(\xi - \eta)d\eta - \beta V(\xi) + I_0\chi(\xi), \tag{5.36}$$

$$-vV'(\xi) = \epsilon(-V(\xi) + U(\xi)). \tag{5.37}$$

Setting $W(\xi) = \int_{\xi}^{\infty} w(\eta)d\eta$, we can rewrite this pair of equations in the matrix form

$$\mathbf{LS} \equiv \begin{pmatrix} vU' - U - \beta V \\ vV' + \epsilon U - \epsilon V \end{pmatrix} = -\begin{pmatrix} N_{\mathrm{E}} \\ 0 \end{pmatrix}, \tag{5.38}$$

where

$$\mathbf{S} = (U, V)^T, \qquad N_{\mathrm{E}}(\xi) = W(\xi - \xi_0) + I_0\chi(\xi). \tag{5.39}$$

We use variation of parameters to solve this linear equation. The homogeneous problem $\mathbf{L}S = 0$ has the two linearly independent solutions,

$$\mathbf{S}_+(\xi) = \begin{pmatrix} \beta \\ m_+ - 1 \end{pmatrix} \exp(\mu_+ \xi), \tag{5.40}$$

$$\mathbf{S}_-(\xi) = \begin{pmatrix} \beta \\ m_- - 1 \end{pmatrix} \exp(\mu_- \xi), \tag{5.41}$$

where

$$\mu_\pm = \frac{m_\pm}{v}, \qquad m_\pm = \frac{1}{2}\Big(1 + \epsilon \pm \sqrt{(1-\epsilon)^2 - 4\epsilon\beta}\Big).$$

By variation of parameters we define

$$\mathbf{S}(\xi) = [\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)] \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix},$$

where $[\mathbf{A}|\mathbf{B}]$ denotes the matrix whose first column is defined by the vector $\mathbf{A}$ and whose second column is defined by the vector $\mathbf{B}$. Then

$$\begin{aligned} \mathbf{LS} &= v\frac{\partial}{\partial \xi}\left([\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)] \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix}\right) - \begin{pmatrix} 1 & \beta \\ -\epsilon & \epsilon \end{pmatrix}\left([\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)] \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix}\right) \\ &= v[\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)]\frac{\partial}{\partial \xi} \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix}, \end{aligned} \tag{5.42}$$

since $\mathbf{LS}_\pm = 0$. Thus (5.38) reduces to

$$[\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)]\frac{\partial}{\partial \xi} \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = -\frac{1}{v} \begin{pmatrix} N_{\rm E} \\ 0 \end{pmatrix}. \tag{5.43}$$

The matrix $[\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)]$ is invertible. Introducing the vector-valued functions

$$\mathbf{Z}_+(\xi) = \begin{pmatrix} 1 - m_- \\ \beta \end{pmatrix} \exp(-\mu_+ \xi), \tag{5.44}$$

$$\mathbf{Z}_-(\xi) = -\begin{pmatrix} 1 - m_+ \\ \beta \end{pmatrix} \exp(-\mu_- \xi), \tag{5.45}$$

we have

$$[\mathbf{S}_+|\mathbf{S}_-][\mathbf{Z}_+|\mathbf{Z}_-]^{\rm T} = [\mathbf{Z}_+|\mathbf{Z}_-]^{\rm T}[\mathbf{S}_+|\mathbf{S}_-] = \beta(m_+ - m_-)\mathrm{I},$$

where I denotes the identity matrix. Multiplying (5.43) by $[\mathbf{Z}_+|\mathbf{Z}_-]^{\rm T}$ finally yields the first-order equation

$$\frac{\partial}{\partial \xi} \begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = -\frac{1}{v\beta(m_+ - m_-)}[\mathbf{Z}_+(\xi)|\mathbf{Z}_-(\xi)]^{\rm T} \begin{pmatrix} N_{\rm E}(\xi) \\ 0 \end{pmatrix}. \tag{5.46}$$

In order to solve (5.46) we need to specify the sign of v. First, suppose that $v > 0$, which corresponds to a right-moving front. Integrating over the interval $[\xi, \infty)$ gives

$$\begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = \begin{pmatrix} a_\infty \\ b_\infty \end{pmatrix} + \frac{1}{v\beta(m_+ - m_-)} \int_\xi^\infty [\mathbf{Z}_+(\eta)|\mathbf{Z}_-(\eta)]^{\rm T} \begin{pmatrix} N_{\rm E}(\eta) \\ 0 \end{pmatrix} d\eta,$$

where a_∞, b_∞ denote the values of a, b at ∞. Since we seek a bounded solution $\mathbf{S}(\xi)$, we must require that $a_\infty = b_\infty = 0$. Hence the solution is

$$\begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = \frac{1}{v\beta(m_+ - m_-)} \int_\xi^\infty [\mathbf{Z}_+(\eta)|\mathbf{Z}_-(\eta)]^{\mathrm{T}} \begin{pmatrix} N_{\mathrm{E}}(\eta) \\ 0 \end{pmatrix} d\eta,$$

so that

$$\mathbf{S}(\xi) = \frac{1}{v\beta(m_+ - m_-)} [\mathbf{S}_+(\xi)|\mathbf{S}_-(\xi)] \int_\xi^\infty [\mathbf{Z}_+(\eta)|\mathbf{Z}_-(\eta)]^{\mathrm{T}} \begin{pmatrix} N_{\mathrm{E}}(\eta) \\ 0 \end{pmatrix} d\eta. \tag{5.47}$$

Further simplification occurs by introducing the functions

$$M_\pm(\xi) = \frac{1}{v} \left(\frac{1}{m_+ - m_-} \right) \int_\xi^\infty e^{\mu_\pm(\xi - \eta)} N_{\mathrm{E}}(\eta) d\eta.$$

We can then express the solution for $(U(\xi), V(\xi))$ as follows:

$$U(\xi) = (1 - m_-)M_+(\xi) - (1 - m_+)M_-(\xi), \tag{5.48}$$

$$V(\xi) = \beta^{-1}(m_+ - 1)(1 - m_-) \left[M_+(\xi) - M_-(\xi) \right]. \tag{5.49}$$

To ensure that such a front exists we require that $U(\xi_0) = \kappa$, i.e.,

$$\kappa = (1 - m_-)M_+(\xi_0) - (1 - m_+)M_-(\xi_0). \tag{5.50}$$

Taking $w(x) = \mathrm{e}^{-|x|}/2$ so that

$$W(\xi) = \begin{cases} 1 - \dfrac{1}{2} e^{\xi}, & \xi < 0, \\ \\ \dfrac{1}{2} e^{-\xi}, & \xi \geq 0, \end{cases}$$

we can calculate $M_\pm(\xi_0)$ explicitly as

$$M_\pm(\xi_0) = \frac{1}{(m_+ - m_-)} \left(\frac{1}{2(v + m_\pm)} - \frac{1}{m_\pm} F(\xi_0) \right),$$

where

$$F(\xi_0) = \begin{cases} I_0(2e^{\mu_\pm \xi_0} - 1), & \xi_0 < 0, \\ \\ I_0, & \xi_0 \geq 0. \end{cases}$$

The case of a left-moving front for which $v < 0$ follows along similar lines by integrating (5.46) over $(-\infty, \xi_0]$:

$$U(\xi) = (m_- - 1)\breve{M}_+(\xi) - (m_+ - 1)\breve{M}_-(\xi), \tag{5.51}$$

$$V(\xi) = \beta^{-1}(m_+ - 1)(1 - m_-) \left[\breve{M}_+(\xi) - \breve{M}_-(\xi) \right], \tag{5.52}$$

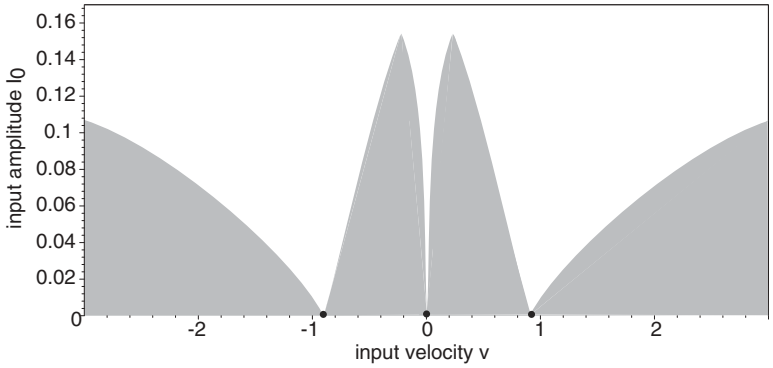

FIG. 5.4. *Locking of a traveling front to a moving step input with velocity v and amplitude I_0. Other parameter values are $\beta = 1, \varepsilon = 0.1, \kappa = 0.25$. Unshaded regions show where locking can occur in the (v, I_0)-plane. When $I_0 = 0$ there are three front solutions corresponding to a stationary front ($v = 0$) and two counterpropagating fronts, which is consistent with the front bifurcation shown in Figure* 5.1. *Each of these solutions forms the vertex of a distinct locking region whose width increases monotonically with I_0 so that ultimately the locking regions merge.*

where

$$\breve{M}_{\pm}(\xi_0) = \frac{1}{(m_+ - m_-)} \left(\frac{1}{2} \frac{m_{\pm} - 2v}{m_{\pm}(v - m_{\pm})} - \frac{1}{m_{\pm}} G(\xi_0) \right)$$

and

$$G(\xi_0) = \begin{cases} -I_0, & \xi_0 < 0, \\ I_0(1 - 2e^{\mu_{\pm}\xi_0}), & \xi_0 \geq 0. \end{cases}$$

This leads to the following threshold condition for $v < 0$:

$$\kappa = (m_- - 1)\breve{M}_+(\xi_0) - (m_+ - 1)\breve{M}_-(\xi_0). \tag{5.53}$$

We can now numerically solve (5.50) and (5.53) to determine the range of input velocities v and input amplitudes I_0 for which locking occurs. For the sake of illustration, we assume the threshold condition $2\kappa(1 + \beta) = 1$ and take $\varepsilon < \beta$. This ensures that, in the absence of any input, there exists an unstable stationary front and a pair of stable counterpropagating waves (see Figure 5.1). The continuation of these stationary and traveling fronts as I_0 increases from zero is shown in Figure 5.4. Since $2\kappa(1+\beta) = 1$, equations (5.50) and (5.53) are equivalent under the interchange $v \to -v$ and $\xi_0 \to -\xi_0$. This implies that the locking regions are symmetric with respect to v. For nonzero v the traveling front is shifted relative to the input such that $\xi_0 < 0$ when $v > 0$ and $\xi_0 > 0$ when $v < 0$. In other words, the wave is dragged by the input.

Figure 5.4 determines where locking can occur but not whether the resulting traveling wave is stable or unstable. Indeed, the stability analysis of traveling fronts is considerably more involved than that of stationary fronts. Nevertheless, we expect that for sufficiently small I_0 the locking regions around the counterpropagating fronts are stable, whereas the central region containing the stationary front is unstable. On the other hand, since $\beta > \varepsilon$, we know that the stationary front is stable for large inputs I_0 and undergoes a Hopf bifurcation as I_0 is reduced. This suggests that the Hopf bifurcation point at $v = 0$ lies on a Hopf curve within the locking region so that

a traveling front locked to a moving input can also be destabilized as the strength of the input is reduced (or as the input velocity changes relative to the intrinsic velocity of waves in the homogeneous network). Recently, Zhang [19] analyzed the asymptotic stability of traveling wave solutions of (1.1) in the case of homogeneous inputs by deriving the associated Evans function and evaluating it in the singular limit $\varepsilon \ll 1$. In future work we will extend this analysis to the case of inhomogeneous inputs and finite ε, thus determining the stability of the locking regions shown in Figure 5.4. We will also construct corresponding locking regions for traveling pulses in the presence of moving Gaussian inputs, and numerically explore the types of oscillatory solutions bifurcating from these waves.

Acknowledgment. We would like to thank Yue-Xian Li (University of British Columbia) for many helpful discussions regarding his work on wavefront instabilities in reaction–diffusion equations.

SWARMING PATTERNS IN A TWO-DIMENSIONAL KINEMATIC MODEL FOR BIOLOGICAL GROUPS*

CHAD M. TOPAZ† AND ANDREA L. BERTOZZI†

Abstract. We construct a continuum model for the motion of biological organisms experiencing social interactions and study its pattern-forming behavior. The model takes the form of a conservation law in two spatial dimensions. The social interactions are modeled in the velocity term, which is nonlocal in the population density and includes a parameter that controls the interaction length scale. The dynamics of the resulting partial integrodifferential equation may be uniquely decomposed into incompressible motion and potential motion. For the purely incompressible case, the model resembles one for fluid dynamical vortex patches. There exist solutions which have constant population density and compact support for all time. Numerical simulations produce rotating structures which have circular cores and spiral arms and are reminiscent of naturally observed phenomena such as ant mills. The sign of the social interaction term determines the direction of the rotation, and the interaction length scale affects the degree of spiral formation. For the purely potential case, the model resembles a nonlocal (forwards or backwards) porous media equation. The sign of the social interaction term controls whether the population aggregates or disperses, and the interaction length scale controls the balance between transport and smoothing of the density profile. For the aggregative case, the population clumps into regions of high and low density. The characteristic length scale of the density pattern is predicted and confirmed by numerical simulations.

1. Introduction.

Examples of collective motion abound in nature. Swarming, schooling, flocking, and herding have been observed among zooplankton, locusts, fish, birds, wolves, and other organisms; see [2, 21, 24] for discussions of some of these groups. These biological aggregations all consist of individuals moving in a coordinated manner, and yet they still represent a rich spectrum of phenomena [23]. For instance, length scales of different swarms may vary widely, ranging up to 100 km^2 in cross-sectional area for African migratory locust swarms [11]. Groups may also have different dimensionalities, from the three-dimensional rolling structure formed by the locusts [11] to the flat, two-dimensional structure of vortex-like ant mills [26]. Aggregations also vary in their degree of organization. Some groups, such as fish schools, are made up of individuals with highly correlated velocities, while other groups, such as mosquito swarms, accomplish their movement in a more disorganized manner [21]. Nonetheless, a common, remarkable aspect of these aggregations is that coordinated movement is achieved even though interactions between individuals via sight, smell, hearing, or other senses are typically limited to much shorter distances than the size of the group. Swarming, then, constitutes an example of how a global structure can arise from more localized rules.

While studies of emergent global structure and pattern formation have a long history in the realm of physics [7], the corresponding endeavors in biology are more

nascent. It is only over the past few decades that scientists have begun to address swarming from a mathematical perspective. The mathematical investigations are of interest not only because swarming is a widespread phenomenon, and not only because it provides a rich example of biological pattern formation, but because ideas from swarming have applications to other fields. For instance, swarming has recently been used by engineers, computer scientists, and others as a paradigm for developing efficient algorithms to accomplish routing, cooperative transport, and other tasks [5].

Previous theoretical investigations of swarms have been carried out in a wide variety of mathematical settings. We briefly mention some of these here; an overview of modeling issues is also available in sources such as [10, 19, 21]. One fruitful approach to modeling swarms has been to treat each individual as a discrete particle. These "individual-based" models have been employed in quite a few biological and mathematical studies, including [1, 8, 12, 13, 15, 18, 27, 29, 30]. These works begin with simple rules of motion for each individual, involving some combination of self-propulsion, random movement, and interaction with neighboring organisms. The models typically take the form of coupled nonlinear difference or differential equations, which may be stochastic or deterministic, depending on the particular ingredients of each model. Numerical simulations have indeed revealed collective behavior. However, a principal disadvantage of such models is that, for realistic numbers of individuals, analytical results for the collective motion are difficult or impossible to obtain. It is worth mentioning that some progress has been made in obtaining analytical results for *stationary* groups. In [18], a discrete model is formulated, and a Lyapunov functional is used to successfully predict an equilibrium state of equally spaced organisms. However, to our knowledge, analytical (nonstatistical) descriptions of nonequilibrium states in discrete swarming models are scarce.

Other investigations of swarming have been carried out in a continuum setting, in which relevant quantities are described as scalar or vector fields. This approach was perhaps first popularized in [20]; reviews are provided in [14, 19]. Continuum models, such as those in [11, 15, 17, 29], may be constructed a priori or by coarse-graining a particle model. In general, continuum models provide a convenient setting in which to study large populations, since one may apply machinery from the analysis of partial differential equations. In the context of swarming, the focus has generally been on models in which the population density satisfies a convection-diffusion equation of the form

$$\rho_t + \nabla \cdot (\vec{v}\rho) = \nabla \cdot (D \nabla \rho). \tag{1.1}$$

Here, $\rho(\vec{x}, t)$ is the population density, $\vec{v}(\vec{x}, t)$ is the velocity field, and $\vec{x}$ is the (one-, two-, or three-dimensional) spatial coordinate. This equation states that the density is conserved while individuals travel with average velocity $\vec{v}$. The motion may involve diffusion, whose strength is measured by $D \equiv D(\vec{x}, \vec{v}, \rho)$.

Swarming models may also be classified as either dynamic or kinematic, depending on how velocities are determined. In dynamic models, velocities are determined by Newton's second law. For continuum models, a dynamic rule would couple (1.1) to a momentum equation for the velocity field, such as

$$\vec{v}_t + \vec{v} \cdot \nabla \vec{v} = \vec{f}(\vec{v}) - \vec{k}(\rho, \vec{v}) + \nu \nabla^2 \vec{v} + \vec{F}_{ext}. \tag{1.2}$$

Here, the left-hand side is the material (or convective) derivative; i.e., the time derivative in a reference frame moving with the velocity field $\vec{v}$. The right-hand side is simply a sum of forces. The force $\vec{f}$ represents the self-propulsion of individuals, and $\vec{k}$ is a

nonlocal force due to interactions with other members of the population, to be discussed momentarily. The remaining terms on the right-hand side of (1.2) represent a "viscosity," with strength proportional to ν, and an external (environmental) force $\vec{F}_{ext}$. An example of a dynamic model for swarming may be found in [15]. In that work, $\nu = 0, \vec{F}_{ext} = \vec{0}$, and $\vec{f}(\vec{v}) = \alpha\vec{v}/|\vec{v}| - \beta\vec{v}$, so that in the absence of social interactions, individuals experience a self-propulsion of strength α in their direction of motion and a frictional drag of strength β.

In contrast, in kinematic models such as that in [17], inertial effects are not important. The motion of bodies is determined without consideration of the forces acting upon them. For continuum models, then, the velocity does not satisfy a momentum equation, but rather is simply a functional of the population density, i.e.,

$$\vec{v} = \vec{V}(\rho). \tag{1.3}$$

The functional $\vec{V}$ may include effects like those captured in (1.2), such as self-propulsion, social interactions, and environmental influence.

The essence of animal aggregations is the presence of social interactions. (Here we distinguish from animal "congregations," which may arise when organisms gather at a common attractant, such as a food or light source.) For the velocity equation (1.2), these interactions are represented by the term $\vec{k}(\rho, \vec{v})$, and for (1.3), they are contained in the functional $\vec{V}(\rho)$. The social interaction terms might describe effects such as attraction or repulsion between individuals sufficiently close to each other (a brief review of attraction/repulsion between organisms is provided in [21]) or the tendency of individuals to orient themselves similarly to their neighbors. Within the context of continuum models, then, the social term takes the form of an integral operator (most often of convolution form), and the governing equations are actually partial integrodifferential equations, as in [15, 17].

One challenge associated with continuum models has been the difficulty of obtaining swarm solutions with biologically realistic characteristics such as sharp boundaries, relatively constant internal population densities, and long lifetimes [23]. For swarms in one spatial dimension, some progress was made in [17], which also contains extensive background and an associated literature review on this issue. We believe that a related issue is the dimensionality of the model. Most continuum swarm models, such as those in [11, 17, 31], have been investigated in only one spatial dimension. We expect swarming dynamics in higher-dimensional models to be qualitatively different, since those cases allow for organisms to vary their orientations continuously, as in the "mill" or "vortex" states that have been observed in fish schools, ant colonies, and other groups [3, 22, 23, 25, 26].

In this paper, we consider a two-dimensional continuum kinematic model for the motion of biological organisms experiencing nonlocal social interactions, characterize the dynamics which may occur, and explore the pattern-forming behavior. Our model is general and abstract, since one of our goals in this paper is to highlight a difference between the swarming problems for one and two dimensions. The possibility of rotational motion in two spatial dimensions allows for cohesively moving swarms with sharp boundaries and infinite lifetimes, even in the absence of a local drift velocity, which is a key ingredient for one-dimensional models. Another goal is to demonstrate a natural way of classifying swarming dynamics in two spatial dimensions, namely by using the Hodge decomposition theorem. Our final goal is to determine explicitly how properties of the social interaction terms (for instance, their associated length scales and signs) affect the large-scale dynamics of the population. Throughout, we

highlight connections between our continuum swarming model and fluid-dynamical phenomena such as vortex patches and flow through porous media.

This paper is organized as follows. In section 2 we mention some results for constant density traveling band solutions of a class of one-dimensional swarm models. These solutions, which are the appropriate mathematical descriptions of one-dimensional swarms, rely on the presence of local drift in the model. These results are presented for contrast with the two-dimensional case, the study of which constitutes the bulk of this paper.

In section 3 we formulate an abstract kinematic model for the motion of biological organisms experiencing nonlocal social interactions. We also discuss how the Hodge decomposition theorem provides a useful way of understanding the two-dimensional motion of the group, namely by decomposing it into incompressible motion and potential motion.

In section 4 we focus on the case of incompressible motion. The resulting problem bears many similarities to fluid-dynamical vortex patches. Since we wish to study the motion of a biologically realistic swarm, we assume the initial condition to be a finite group with constant internal population density and sharp edges (compact support). We show that such a swarm retains these characteristics for all time. Numerical simulations demonstrate that the dynamics of the swarm are rotational, and that the asymptotic states are vortex-like structures with circular cores and a potentially complex arrangement of spiral arms. The sign of the social interaction term determines the direction of rotation of the swarm, and the characteristic length scale of the interactions determines the degree of spiral formation. The spiral states we observe are qualitatively similar to the mill states observed in [3, 22, 23, 25, 26].

In section 5 we consider the complementary case of potential motion. In this case, the resulting problem resembles a (forwards or backwards) porous media equation. The sign of the social interaction term determines whether the interaction represents nonlocal repulsion or attraction. These effects lead, respectively, to dispersion or aggregation of the population. For the dispersive case, shorter interaction length scales result in smoothing of the population density profile, while larger interaction length scales lead to motion which is more convective. For the case of aggregation, a simple linear stability analysis enables us to identify a maximally unstable wavelength and thus to make a prediction about the characteristic length scale of the clumped population distribution that will form. We demonstrate these results by means of numerical simulations.

Finally, we conclude in section 6 with a brief summary and a discussion of directions for future investigation.

2. Elementary results for one-dimensional kinematic swarms. A detailed investigation of a swarming model in one spatial dimension has been carried out in [17]. In that work, the population density ρ is assumed to obey (1.1). The kinematic velocity rule is

$$v = a_e\rho + (A_a - A_r\rho)(K * \rho), \quad a_e, A_a, A_r \in \mathbb{R}. \tag{2.1}$$

Here, the first term represents a local density-dependent drift. The remaining terms are nonlocal components describing attraction and repulsion, with the asterisk operator having the meaning of convolution. Note that the repulsive effects are higher order in the population density than are the attractive ones. The interaction kernel

K is odd, piecewise constant, and has compact support. It is given by

$$K(x) = \begin{cases} \frac{1}{2d} & \text{if } |x| \le r, \\ 0 & \text{otherwise,} \end{cases} \tag{2.2}$$

where d is an interaction length scale parameter that may be freely chosen.

Analysis and numerical simulations in [17] reveal that the model supports swarm solutions with biologically realistic characteristics, namely, a nearly constant internal population density and sharp edges. For density-independent diffusion, the cohesive swarm has an exponentially long lifetime before the population is lost through "tails" in the density profile. For the case of small density-dependent diffusion, the model has true "traveling band" solutions which have compact support. In either case, the cohesive motion of the swarm is achieved by an effective cancellation of the social interactions. The internal density of the swarm is precisely that at which the attractive and repulsive effects cancel each other, so that the only remaining component of the velocity is local drift. We mention this for contrast with the results to be presented later in this paper, which demonstrate a nonlocal, i.e., cooperative, means by which a constant density swarm may move cohesively.

With purely nonlocally determined velocities, traveling band solutions are difficult to obtain even in the absence of diffusion. We now mention some simple existence and uniqueness results for one-dimensional swarms with no diffusion. The population density ρ satisfies the convection equation

$$\rho_t + \partial_x(v\rho) = 0. \tag{2.3}$$

We will show how, in one dimension, realistic velocity rules that are purely nonlocal cannot lead to a constant-speed translation of the population, and thus cohesive swarms cannot be maintained. Again, these results are presented for contrast with the two-dimensional results given later in this paper.

Since we are interested in making statements about constant density swarms with sharp boundaries, we make the constant-density traveling band (CDTB) ansatz

$$\rho(x,t) = \rho_0 W_L(x - ct), \tag{2.4}$$

$$W_L(x - ct)v(x,t) = cW_L(x - ct). \tag{2.5}$$

Here, ρ_0 is the constant population density, c is the speed of the traveling band, and $W_L(x)$ is the window function defined without loss of generality as

$$W_L(x) = \begin{cases} 1 & \text{if } x \in \Omega_L,\ \Omega_L = [0, L], \\ 0 & \text{otherwise.} \end{cases} \tag{2.6}$$

The ansatz (2.4)–(2.5) automatically satisfies the governing equation (2.3) in Ω_L, the support of ρ. Note that we have not placed any restrictions on the velocity field outside the support of ρ since the velocity in unpopulated areas is irrelevant to the propagation of the swarm.

We must also consider an equation defining the velocity field. For contrast, we consider two velocity rules, each of which may be written as a (degenerate) version of the generalized kinematic velocity rule

$$v(x,t) = F(\rho) + G_1(\rho)\left[K_1 * H_1(\rho)\right] + G_2(\rho)\left[K_2 * H_2(\rho)\right]. \tag{2.7}$$

This rule is a generalization of (2.1) from [17]. F is a functional which captures the local density-dependence of the velocity. It represents the drift velocity of organisms, irrespective of social forces. K_1 and K_2 are interaction kernels, and thus the $G[K*H]$ terms represent nonlocal effects which arise from repulsion and attraction between organisms. G represents the strength of the interaction, and H represents the dependence of the convolution on the population density. We will further assume that K_1 and K_2 are integrable. In contrast to [17], we will also assume that these interaction kernels are decreasing in their arguments, so that the influence of the population on a given organism's velocity weakens with distance. We allow the functionals F, G, H to be nonlinear for generality. We assume that F, G_1, G_2, H_1, H_2 are smooth, and that $H_1(0) = H_2(0) = 0$, so that velocities from social interactions are induced only by nonzero population.

The swarm density ρ_0 and the constant band speed c must satisfy a consistency condition via the velocity equation (2.7) in order for the ansatz (2.4)–(2.5) to be a solution to (2.3).

We first consider the case $F = 0$, $G_2 = 0$, so that (2.7) becomes

$$v = G_1(\rho)\left[K_1 * H_1(\rho)\right], \tag{2.8}$$

where the argument of ρ is understood to be $z = x - ct$. Equivalently, we may obtain a rule of this form by choosing $F = 0,\ G_1 = G_2,\ H_1 = H_2$, so that

$$v = G_1(\rho)\left[(K_1 + K_2) * H_1(\rho)\right], \tag{2.9}$$

and both attractive and repulsive effects are represented. Note that for these velocity rules, in the absence of interactions, there is no underlying (i.e., local) drift velocity.

Combining (2.4)–(2.5) and (2.8), we obtain the consistency condition

$$W_L c = W_L G_1(\rho_0 W_L)\left[K_1 * H(\rho_0 W_L)\right], \tag{2.10}$$

which may be rewritten as

$$c = G_1^0 H_1^0 \int_{z-L}^{z} K_1(\zeta)\, d\zeta \quad \text{for } z \in \Omega_L, \tag{2.11}$$

where

$$G_1^0 \equiv G_1(\rho_0) \tag{2.12}$$

and

$$H_1^0 \equiv H_1(\rho_0). \tag{2.13}$$

By differentiating (2.11) with respect to z and applying the first fundamental theorem of calculus, we see that

$$K_1(z) = K_1(z - L) \quad \text{for } z \in \Omega_L. \tag{2.14}$$

Thus, K_1 satisfying (2.14) must be L-periodic on $[-L, L]$ in order to admit a CDTB solution. (The structure of K_1 outside of $[-L, L]$ is not relevant.) We will call the set of such kernels Υ. The logical implication goes in the reverse direction as well, as can be seen from writing down a Fourier series for $K_1 \in \Upsilon$, so that (2.11) is satisfied if and only if $K_1 \in \Upsilon$. In this case, (2.11) becomes

$$c = G_1^0 H_1^0 K_1^a, \tag{2.15}$$

where

$$K_1^a \equiv \int_0^L K(\zeta)\, d\zeta. \tag{2.16}$$

There may be families of traveling band solutions parameterized by c, which bifurcate depending on the structure of the nonlinear functions G_1 and H_1.

It is important to realize that the choice $K_1 \in \Upsilon$ is not biologically meaningful and contradicts our earlier assumption regarding the spatial decay of interaction kernels. As discussed above, biologically realistic kernels are expected to satisfy $dK_1/d|z| \leq 0$, so that, for a given individual, the effect of other individuals does not increase with distance. However, $K_1 \in \Upsilon$ cannot satisfy $dK_1/d|z| < 0$, so at best the kernel would be a constant, but even this choice is not expected to be a good biological model, except perhaps for very small L.

In contrast to the results just mentioned, we may now consider the case $G_2 = 0$, so that (2.7) becomes

$$v = F(\rho) + G_1(\rho)\left[K_1 * H_1(\rho)\right]. \tag{2.17}$$

Equivalently, we may choose $K_1 = K_2$, $H_1 = H_2$. (The velocity rule (2.1) in [17] takes this form.) Note that now there is a local drift, a self-induced contribution to the velocity, which is captured by F. Combining (2.4)–(2.5) and (2.17), we obtain the consistency condition

$$W_L c = W_L\left\{F(\rho_0 W_L) + G_1(\rho_0 W_L)\left[K_1 * H(\rho_0 W_L)\right]\right\}, \tag{2.18}$$

which may be rewritten as

$$c = F_1^0 + G_1^0 H_1^0 \int_{z-L}^{z} K_1(\zeta)\, d\zeta \quad \text{for } z \in \Omega_L. \tag{2.19}$$

Here,

$$F_1^0 \equiv F_1(\rho_0), \tag{2.20}$$

and H_1^0 and G_1^0 are given by (2.13) and (2.12).

There are two cases to consider. If $H_1^0 G_1^0 \neq 0$, then (2.19) becomes

$$\frac{c - F_1^0}{G_1^0 H_1^0} = \int_{z-L}^{z} K_1(\zeta)\, d\zeta \quad \text{for } z \in \Omega_L. \tag{2.21}$$

This is similar to the previous case. The condition (2.21) may be met only for $K_1 \in \Upsilon$, in which case the existence and uniqueness of solutions depend on the structure of $(c - F_1^0)/(G_1^0 H_1^0)$. For $K_1 \notin \Upsilon$, CDTB solutions are not possible.

On the other hand, if $H_1^0 G_1^0 = 0$, then CDTBs are possible for *any* choice of kernel K_1. In this case, the number of possible CDTB solutions depends on the number of roots of $H_1^0 G_1^0$ for positive ρ, of which there are expected to be a finite number. Looking at the problem from the forward (rather than inverse) perspective, for biologically realistic choices of K_1, the velocity rule (2.17) will lead to a finite number of CDTB solutions. The densities correspond to the solutions $\rho_0^* > 0$ of $H_1^0 G_1^0 = 0$, and the wave speeds are given by $F_1(\rho_0^*)$. Thus, the combination of local and nonlocal velocity terms selects particular densities and band speeds, rather than allowing entire families of solutions, as in the purely nonlocal case. The allowed CDTB densities are those at which the nonlocal interactions disappear. Further, since we imagine the total population to be fixed in number, this velocity rule actually dictates preferred swarm sizes L. These conclusions are similar to those reached in [17] for the particular choice of F_1, G_1, H_1, K_1 given by (2.1).

3. A kinematic two-dimensional swarm model. For the remainder of this paper, we study the dynamics of a two-dimensional swarming model. In constructing our model, we make the following assumptions:

1. The population is conserved; birth, death, immigration, and emigration of organisms are negligible on the time scale of the swarming dynamics.
2. The motion of organisms is due solely to social interactions, and thus velocities depend nonlocally on the population density.
3. Interactions between organisms are pairwise.
4. The social interactions are a linear functional of the population density.
5. The social interactions depend only on the distance between organisms, and become weaker with increasing distance.

Implicit in the second assumption is the supposition that random movement (e.g., due to fluctuations in the organisms' medium, or noise in their ability to move) is negligible. The third, fourth, and fifth assumptions are made for tractability of the model. The third assumption is made so that interaction effects on a given organism will be summable, and this will lead to a convolution in our model, similar to that of the model in [17].

In the spirit of the work in [17], we construct an abstract model, and thus we do not incorporate many biological specifics. Our model might be interpreted as a one for "flat" (two-dimensional) groups in the absence of disturbances such as predators or food sources. Even with the simple assumptions we have made, the dynamics are complex. As discussed in section 6, relaxing some of our assumptions to obtain a more biologically realistic model will be interesting for future work.

Under the assumptions described above, the model takes the form

$$\rho_t + \nabla \cdot (\vec{v}\rho) = 0, \tag{3.1}$$

$$\vec{v} = \int_{\mathbb{R}^2} \vec{K}(|\vec{x} - \vec{y}|)\rho(\vec{y})\, d\vec{y} \equiv \vec{K} * \rho. \tag{3.2}$$

Here, $\vec{x} = (x, y)$ is the two-dimensional spatial coordinate. Note that (3.1) is simply (1.1) with $D = 0$, and (3.2) is a two-dimensional analogue of a degenerate case of the velocity rule (2.7). $\vec{K}$ is our two-dimensional social interaction kernel, which is spatially decaying and isotropic.

Since our model includes no drift term, velocities decay in the far field, and we may apply the Hodge decomposition theorem (see, for instance, [16]). This theorem states that a vector field in the plane may be uniquely decomposed into a divergence-free component and a gradient component. That is to say, the velocity may be written as

$$\vec{v} = \psi + \nabla\Phi, \qquad \nabla \cdot \psi = 0. \tag{3.3}$$

For smooth vector fields decaying at infinity, the divergence-free part has a scalar stream function Ψ satisfying $\nabla^\perp\Psi = 0$. Thus, we can write

$$\vec{v} = \nabla^\perp\Psi + \nabla\Phi. \tag{3.4}$$

Using an analogy to fluid flow, we may think of Ψ as a stream function for the incompressible part of the flow and Φ as a pressure due to interactions. For functions with integrable gradients, convolution commutes with derivatives; i.e., $(\nabla P) * \rho = \nabla(P * \rho)$. Thus, for the model (3.1)–(3.2), we can directly apply the Hodge decomposition to the interaction kernel $\vec{K}$:

$$\vec{K} = \nabla^\perp N + \nabla P, \tag{3.5}$$

where P models the interaction pressure (motion towards and away from concentrations of density) and N models additional motion, which, as we will see, allows for rotation and a cohesive swarm.

To better understand the model (3.1)–(3.2), we separate the dynamics into the two cases which we have just discussed, namely incompressible motion and potential motion. In the following two sections we study each case in turn, and demonstrate how the macroscopic motion of the population is affected by the interaction kernel $\vec{K}$.

4. Incompressible motion. In this case,

$$\vec{K} = \nabla^{\perp} N \tag{4.1}$$

so that $\nabla \cdot \vec{v} = 0$. Incompressible motion in two spatial dimensions is the analogue of translational drift in one dimension, in that they both allow for cohesive movement of a swarm. However, while drift terms such as $F(\rho)$ in (2.7) cannot lead to pattern formation, incompressible velocities do lead to pattern formation (in particular, vortex patterns, as we demonstrate below) for the two-dimensional case.

The governing equations (3.1)–(3.2) may be written compactly as

$$\rho_t + \nabla \cdot [\rho(\nabla^{\perp} N * \rho)] = 0. \tag{4.2}$$

We take the scalar interaction function N to be a Gaussian of width d; i.e.,

$$G_d(|\vec{x}|) \equiv \frac{1}{d^2} e^{\frac{-|\vec{x}|^2}{d^2}}. \tag{4.3}$$

One might include an additional constant prefactor, but this would represent a velocity scale and may be removed by rescaling the time variable in the equations. The length scale d could also be removed by rescaling, in which case the only parameter remaining in the problem would be the initial condition. We choose to retain the length scale parameter d since it has a clear biological interpretation and since it is more convenient to vary than the length scale of the initial condition.

A Gaussian interaction was also considered for a linear stability analysis in [17]. Other works have used power functions or decaying exponentials [15, 18]. Our interaction function has a somewhat different meaning than the ones used in those previous works since it will be applied in two dimensions and thus has a rotationally symmetric structure. We choose Gaussian interaction functions since they are biologically realistic (in terms of being spatially decaying) and because they have convenient mathematical properties such as bounded norms and infinite differentiability. Many of our qualitative results will hold true for other classes of smooth spatially decaying interaction functions with normalized integral.

We begin by making some general statements about the effect of varying the interaction length scale d. For very small values of d, the interaction function N resembles a δ-function of strength π. For the limiting case $d \to 0$, (4.2) may be written as

$$\rho_t + \pi \nabla \cdot [\rho \nabla^{\perp} \rho] = 0 \tag{4.4}$$

since $\nabla^{\perp}$ commutes with convolution and the δ-function acts as the identity under convolution. A little algebra reveals that (4.4) is actually $\rho_t = 0$, and thus the swarm will be stationary. This makes intuitive sense. In the case that motion is perpendicular to population gradients in a completely local sense, the population

density profile cannot change, by construction. Of course, in a Lagrangian frame (tracking the coordinates of individual organisms) motion is possible, as long as it is perpendicular to the gradient.

On the other hand, for very large values of d, N is nearly a constant, namely zero. In the formal limit $d \to \infty$, $\nabla^{\perp} N = 0$, and once again (4.2) becomes $\rho_t = 0$. This result also makes intuitive sense. In this case, organisms can sense population gradients infinitely far away, but these gradients have no influence on velocity since social interactions are infinitely weak, and thus the organisms are stationary.

For simplicity, and for analogy with the results mentioned in section 2 and in [17], we now focus on constant density solutions of compact support. That is to say, we assume that the initial condition is a *swarm patch* with finite area and constant population density ρ_0. By making such a choice, we are not modeling the initial formation of a constant-density swarm. Rather, this model should be interpreted as a macroscopic description of a swarm in which attractive and repulsive forces have already come into balance. We will study the subsequent movement of such a swarm.

We use Green's formula to rewrite (3.1)–(3.2) as an integral over the boundary:

$$\vec{v}(\vec{x}) = \rho_0 \int_{\partial\Omega} N(|\vec{x} - \vec{y}|)\vec{t}(\vec{y}) ds(\vec{y}), \tag{4.5}$$

where Ω is the support of ρ and the boundary $\partial\Omega$ is parameterized in a clockwise orientation. Here s is the arc length, and $\vec{t}$ is the unit tangent vector to the boundary. Following the strategy from fluid dynamics, we adopt a Lagrangian framework and track points on the boundary of the swarm patch. That is to say, we write down a Lagrangian formulation of (4.5) which will be useful for numerical simulations. Taking α to parameterize the boundary of the swarm, we have the equation for $\vec{z}(\alpha, t)$, the patch boundary:

$$\frac{d\vec{z}(\alpha, t)}{dt} = \int_0^{2\pi} N(\vec{z}(\alpha, t) - \vec{z}(\alpha', t))\vec{z}_{\alpha}(\alpha', t) d\alpha', \tag{4.6}$$

where the subscript α indicates a derivative along the boundary.

This equation describes a self-deforming curve (which encloses a constant area). From a computational standpoint, this formulation is convenient because the dimension of the problem has been reduced by one. More importantly, we see that since the boundary is a self-deforming curve, *the swarm patch retains constant internal density and compact support for all time.* Equation (4.6) is similar to the contour-dynamics formulation of the two-dimensional Euler equations [33], which describe how a fluid region of constant vorticity, or a *vortex patch*, evolves in time. The difference is that for the swarm patch case, the interaction function N is expected to be spatially decaying in order to be biologically meaningful (cf. our modeling assumptions at the start of section 3, and our choice in (4.3)), while for the vortex patch problem, $N = \frac{1}{2\pi} \log |\vec{x}|$.

Before presenting numerical results for our model, we remark on the smoothness of the patch boundary, which historically, for the fluid vortex patches, has been a subject of interest. It is now known that, for the fluid vortex patches, solutions of (4.6) with smooth initial data stay smooth for all time [4, 6]. This turns out to be the case for our present swarm patch problem as well. See the appendix for a sketch of the proof.

Equation (4.6) may be solved numerically to find the evolution of the swarm patch boundary. We now briefly describe our simple numerical algorithm. An initial swarm patch shape is selected, and the boundary is discretized into n nodes. Depending on

our initial condition, we take the initial number of Lagrangian nodes to be between $n = 40$ and $n = 60$. The shape of the patch is evolved by using the discretized version of (4.6). The position of each node may be updated by computing its velocity and then using a time-stepping rule. We perform the spatial integral in (4.6) using Simpson's rule, which is an $\mathcal{O}(n^2)$ operation. As a start-up procedure, we take three time steps using a fourth-order Runge–Kutta method. However, since the Runge–Kutta method involves many evaluations of the right-hand side of (4.6), it is computationally expensive. Thus, we use a fourth-order multistep Adams–Bashforth rule for the remainder of the time steps. We take a time step of size $\Delta t = 0.02$. Checks are performed with smaller time steps and varying initial discretizations of the swarm patch boundary to verify that our solutions are sufficiently well converged.

Despite the fact that the boundary stays smooth, numerical simulations reveal that it develops complex structure (as we show below), which is also a feature of vortex patches. As the swarm patch evolves, it may be necessary to rediscretize the boundary in order to have an accurate solution, i.e., to have a fine enough mesh to capture new spatial complexity. Sophisticated "contour surgery" techniques have been developed to address this issue for vortex patches; see, for example, [9]. We use a simpler technique, which we apply at every time step. Nodes which are adjacent with respect to the Lagrangian parameter α are checked for spacing. If the Euclidean distance becomes too large, a node is inserted between them using linear interpolation. Similarly, if nodes become too close together, they are replaced with a node whose position is the spatial average of the original ones. While this latter step discards detail below a certain length scale, we perform it nonetheless so that the total number of nodes does not grow so quickly as to make the computation prohibitively slow. Finally, we periodically perform a check to verify that the swarm-patch boundary is not self-intersecting. (Self-intersection of the boundary would break the uniqueness of particle paths which the problem must obey.) If the boundary is found to self-intersect, the simulation is aborted and must be repeated with a finer threshold of spatial detail.

We note that, by symmetry arguments, a rotating disk is an exact solution to (4.2) (though the rotation is not solid-body rotation). This is true for fluid vortex patches as well; see [16] for a discussion. We assume that N is the Gaussian interaction function given by (4.3) and calculate the resulting velocity of points on the swarm boundary, a circle of radius R. After some algebra, we find the velocity $|\vec{v}(R)|$, from which we may compute the period of rotation

$$T(D) = \frac{2\pi R}{|\vec{v}(R)|} = \frac{d^2}{\rho_0} e^{\frac{2R^2}{d^2}} \left\{ I_1\left(\frac{2R^2}{d^2}\right) \right\}^{-1}, \tag{4.7}$$

where I_1 is the modified Bessel function of the first kind of order one. Figure 4.1 shows the period of rotation of the boundary, $T(d)$, for a swarm patch of radius $R = 1$ and population density $\rho_0 = 1$. The exact expression (4.7) is plotted as a line, while data from a numerical simulation, obtained by tracking one of the Lagrangian nodes, is plotted as dots. These results not only serve as a check on our algorithm, but also demonstrate our previous conclusions about the behavior of (4.2) in the limits $d \to 0$ and $d \to \infty$ for the particular case of a circular patch.

This example also illustrates the effect of the interaction function N on the direction of rotation. Since the boundary of the patch has a direction associated with its parameterization, the rotation is clockwise or counterclockwise according to whether the interaction function N is chosen to have, respectively, a positive or negative sign. This limitation results from our choice of kinematic velocity rule. In the case of a

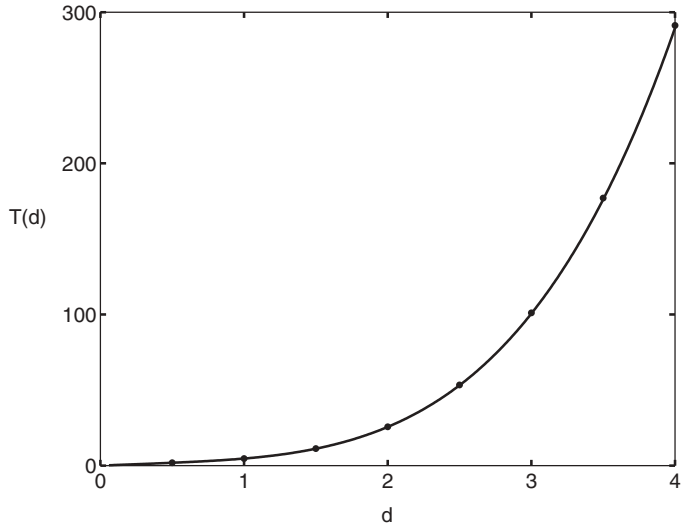

FIG. 4.1. *Period of rotation T for the boundary of a circular swarm patch under the model* (4.2) *with the interaction function* (4.3). *Here, T is shown as a function of d, the interaction length scale in* (4.3). *The line corresponds to the exact expression $T = 2\pi R/|\vec{v}(R)|$ given by* (4.7). *The dots correspond to a numerical simulation of the contour dynamics equation* (4.6). *For this example, the radius of the patch is $R = 1$, and the constant population density is $\rho_0 = 1$.*

dynamic velocity rule, inertial effects would give any initial swarm patch a natural direction of rotation. That is to say, for a dynamic rule, the swarm will have the freedom to nucleate a rotational state, for instance, as seen in simulations of the model in [15]. For simplicity, we present simulations in which N has a positive sign, resulting in clockwise rotation.

We now turn to a discussion of the behavior of the model for other (noncircular) initial conditions and for intermediate values of d when some nontrivial evolution occurs. We find that for the present case of incompressible velocity the dynamics are characterized by an overall rotational motion. The solutions at sufficiently long times are vortex-like, as we now illustrate with several examples.

Figure 4.2 shows the evolution of a swarm patch using the interaction function (4.3) with $d = 1$. The initial boundary of the population is the polar curve $r(\theta) = 1 + (1/10)(\cos 4\theta)$. The square-like initial swarm patch experiences clockwise rotation. At time $t = 1$, the beginnings of spiral arms are visible at the corners of the patch, where the initial curvature was greatest. By time $t = 3$, the spirals have grown longer and the core of the patch is becoming circular. This trend continues through the end of the simulation at $t = 10$, at which point the spiral arms have grown even longer and the core is nearly a perfect circle.

The evolution is qualitatively similar even for swarm patches whose initial shape is far from circular. For instance, Figure 4.3 shows the evolution of an elongated swarm patch, again with the interaction function (4.3) and $d = 1$. The boundary of the initial shape is an ellipse with a major semiaxis of 1 and a minor semiaxis of 0.1. As with the previous example, the swarm patch rotates in a clockwise direction. Spiral arms develop at the points of greatest curvature, and there is a movement of the population towards a developing circular core, which is noticeable at time $t = 8$ and well defined by $t = 10$.

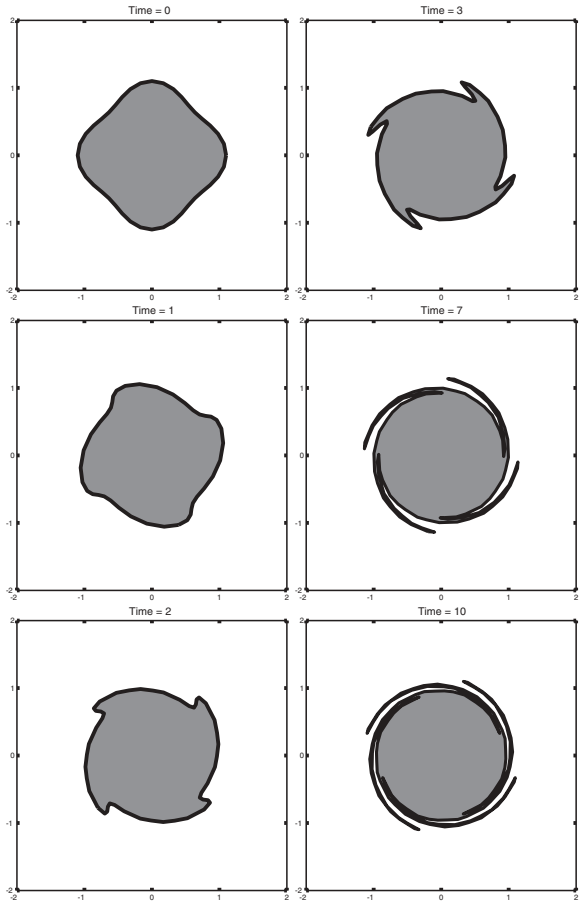

FIG. 4.2. *Evolution of a swarm patch under model* (4.2). *The boundary of the initial shape is a polar curve with radius given by* $r(\theta) = 1 + (1/10)(\cos 4\theta)$. *The constant population density is* $\rho_0 = 1$. *The interaction function* N *is the Gaussian given by* (4.3) *with interaction length scale* $d = 1$. *The constant density swarm patch rotates clockwise and develops spiral arms.*

Finally, we comment that a similar evolution occurs even for irregularly shaped swarm patches. Figure 4.4 shows the evolution of such a patch with the same interaction function as in the previous two examples. The initial shape is generated by the polar function $r = f(\theta)$, where f is a superposition of cosine components with randomly chosen amplitudes and randomly chosen low-integer frequencies. As with the previous examples, the patch rotates clockwise, developing a circular core and an irregular arrangement of spiral arms.

We have shown in this section that, in the case of incompressible motion, our simple nonlocal kinematic model has constant density solutions of compact support. It was seen directly from (4.2) that the evolution of any initial swarm patch slows for very large or very small values of the interaction length scale d. For intermediate values of d, numerical simulations demonstrated that the evolution of these swarm patches is rotational, with the direction of motion set a priori by the sign on the interaction function N. There is a movement of population towards the rotational center of the swarm, where a circular core develops. Spiral arms form at regions of the boundary

where the curvature is very high. We saw that all of our numerical simulations resulted in asymptotic vortex states reminiscent of those observed in bacteria [3], fish [23], ants [26], cellular slime molds [25], and zooplankton [22]. Similar vortex-like states have also been observed in discrete dynamic swarming models such as those in [15, 8]. Of course, these discrete dynamic models are quite different from the model we study here. As previously discussed, the direction of swarm rotation is necessarily determined by the sign of the kernel in our kinematic model, whereas in dynamic models, the swarm has the capability to nucleate a natural direction of rotation. The work in [17] alludes to this difference between kinematic and dynamic models in the context of one-dimensional motion; the difference is more dramatically highlighted by considering the more general two-dimensional case.

We close this section by discussing the biological significance of incompressible velocities. A common characteristic of biological swarms is their ability to move and evolve in shape while maintaining a constant density. Within the class of kinematic models, the general incompressible type of model we consider here is the only one

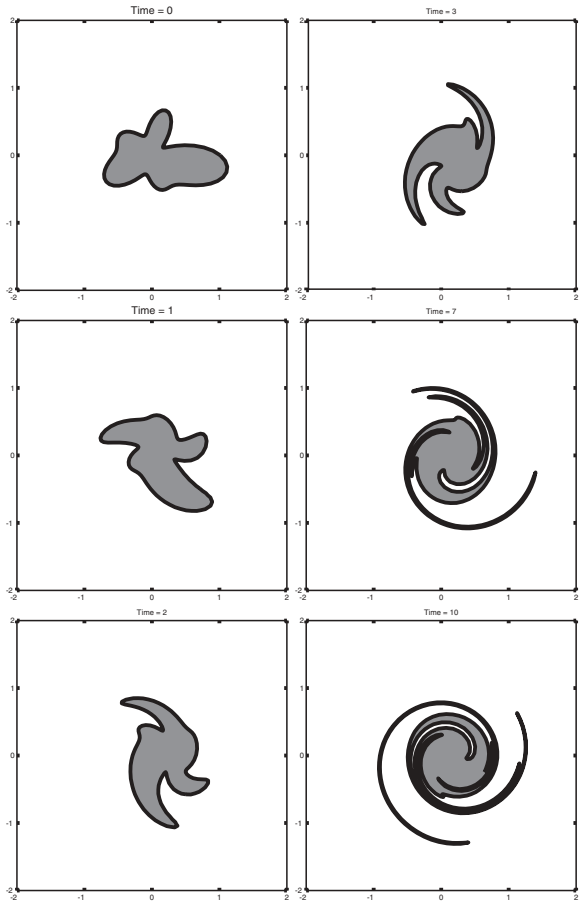

FIG. 4.4. *Evolution of an irregular swarm patch under model* (4.2). *The interaction function* N *is the Gaussian given by* (4.3) *with interaction length scale* $d = 1$. *The constant population density is* $\rho_0 = 1$. *The initial shape is generated by the polar function* $r = f(\theta)$, *where* f *is a superposition of cosine components with randomly chosen amplitudes and randomly chosen low-integer frequencies. which captures precisely this effect. Stated differently: for a constant density swarm in which attractive and repulsive effects are in balance, organisms wishing to maintain constant population density *must* move with incompressible velocities. Potential velocities, discussed in the next section, will lead to variations in population density. Thus, one may think of the incompressible velocity terms as those which model the aggregate cooperative dynamics of organisms striving to maintain equal spacing.

5. Potential motion. Some models based on potential forces are reviewed in [21, 19]. For our model, potential motion means that

$$\vec{K} = \nabla P, \tag{5.1}$$

so that the model (3.1)–(3.2) may be written compactly as

$$\rho_t + \nabla \cdot [\rho(\nabla P * \rho)] = 0. \tag{5.2}$$

We take the scalar interaction function $P = \mp G_d$, where G_d is the Gaussian distribution of width d given by (4.3). In section 4, we made the same choice for the scalar interaction function N. In that case, the sign of N simply determined the direction of rotation of the swarm. For the present case, we will see that the sign of P has a much more dramatic effect on the evolution of the population. Specifically, it will determine whether organisms disperse or aggregate, as we discuss in the following two subsections.

5.1. Dispersion. Here, we take $P = -G_d$. Note that (5.2) has an analogy to Darcy's law for flow in porous media. In fact, in the limit $d \to 0$, $-G_d$ becomes a δ-function of strength π, and the governing equation (5.2) is the porous media equation. This is a well studied partial differential equation, and it possesses an exact self-similar solution, called Barenblatt's solution. For an initial population of size Q placed at the origin, Barenblatt's solution is

$$\rho(r,t) = \begin{cases} \frac{1}{2\pi}\sqrt{\frac{Q}{t}} - \frac{r^2}{8\pi t}, & r \le 2\,(Qt)^{1/4}, \\ 0, & r > 2\,(Qt)^{1/4}. \end{cases} \tag{5.3}$$

A discussion of the porous media equation as it relates to biological dispersal, along with a more general statement of Barenblatt's solution, may be found in [19]. In the opposite limit $d \to \infty$, i.e., when social interactions are extremely nonlocal, a bit of algebra again reveals that the equation becomes simply the steady state $\rho_t = 0$. The intuitive statement of this limiting case is similar to that in the previous section: organisms can sense population gradients infinitely far away, but these gradients have no influence on velocity because the strength of the social interactions is infinitely weak.

For intermediate values of the interaction length scale d, the population density profile experiences diffusion and convection. We may understand this better by writing the governing equation (5.2) in an alternate form. After some algebra, we obtain

$$\rho_t = \nabla\rho \cdot (\nabla G_d * \rho) + \rho(\nabla^2 G_d * \rho). \tag{5.4}$$

The first term on the right-hand side of (5.4) is convective and, due to the single derivative on G, scales like $1/d^4$. In contrast, the second term is diffusive and scales like $1/d^6$. Thus, for a given population density profile, as d is increased, we expect that convection will be more dominant than diffusion.

We demonstrate the role played by the interaction length scale d by means of numerical simulations. For these examples, we focus on a radially symmetric model, so that the density $\rho(r,t)$ is a function of the radial coordinate r, and the velocity v is as given above. Note that if ρ is radially symmetric and P is also radially symmetric, then the velocity field for this gradient flow points in the radial direction and is itself radially symmetric. We solve the governing equation on the unit disk with boundary condition $\rho = 0$ on the circumference. We use MacCormack's method, which is second-order accurate in space and time; see, for instance, [28]. We use $n = 64$ grid points with time steps of $\Delta t = 1 \times 10^{-5} - 5 \times 10^{-4}$. Checks are performed with finer meshes in space and time to verify that solutions are sufficiently well converged.

Two example simulations are shown in Figure 5.1. We choose as a random initial condition the function

$$\rho(r,0) = f(r)\left\{\frac{1}{2} + \frac{1}{2}\tanh(5 - 15r)\right\}. \tag{5.5}$$

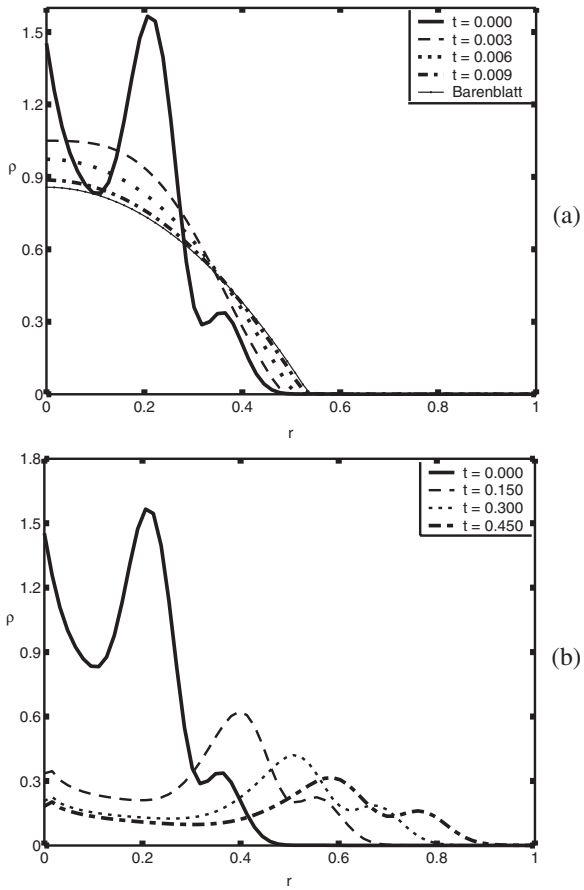

FIG. 5.1. *Time evolution of an identical random initial condition under* (5.2) *for two different social interaction length scales in a radially symmetric geometry with the potential interaction function* $P = -G_d$ *given by* (4.3). *The graphs show the population density* ρ *versus the radial coordinate* r. (a) *Interaction length scale* $d = 0.01$. *Interactions are very localized, and the dynamics are similar to those of the porous media equation. The curve labeled "Barenblatt" is a snapshot of the self-similar solution to the porous media equation given by* (5.3) *and should be compared to the numerical solution at time* $t = 0.009$. *(See text for details).* (b) *Interaction length scale* $d = 0.5$. *For this case of more nonlocal interactions, the population is convected away from the origin, and the smoothing of the population density profile occurs more slowly.*

Here, $f(r)$ is created by superposing Fourier modes with low integer wave numbers and random coefficients. Multiplication by the bracketed combination is carried out so that the initial condition decays smoothly towards zero. For the first example, this state is evolved with $d = 0.01$, so that social interactions are only very slightly nonlocal. In this case, (5.2) is nearly the porous media equation, and the "bumpy" initial condition quickly smooths out and approaches the parabolic profile given by Barenblatt's solution, which we verify in the following manner. We fit the numerical solution at time $t = 0.006$ to (5.3). Then the numerical solution is evolved numerically, and the fit to Barenblatt's solution is evolved analytically. The two are compared again at time $t = 0.009$. Both curves are contained in Figure 5.1(a). The curves nearly overlay each other, and the maximum error between the two is 3%.

For contrast, we have taken the same random initial condition and integrated it

with the more nonlocal interaction length scale $d = 0.5$. In this case, shown in Figure 5.1(b), Fourier modes are damped much more slowly, and the bumpy initial conditions retain their shape much longer. The motion of the swarm is much more convective, and the population is transported away from the origin.

5.2. Aggregation. In this case, we take $P = G_d$. Whereas P was strictly negative in the previous subsection, it is now strictly positive, and this change has dramatic consequences for the dynamics. Now the governing equation states that velocities are up, rather than down, population gradients (nonlocally), so that the population will tend to form groups.

We may understand this grouping by means of a linear stability analysis. To do so, we consider small perturbations $\hat{\rho}$ to a constant density steady state ρ_0. Linearizing (5.2), we obtain

$$\hat{\rho}_t = -\rho_0 G_d * \nabla^2 \hat{\rho}, \tag{5.6}$$

and thus we see that the perturbation obeys a nonlocal backwards heat equation. Taking a Fourier ansatz for the perturbation, i.e., $\hat{\rho} = \hat{\rho}_0 e^{i(\vec{k}\cdot\vec{x}+\sigma t)}$, we find that the linear growth rate is given by

$$\sigma(k) = \pi \rho_0 k^2 e^{\frac{-k^2}{(4d^2)}}, \tag{5.7}$$

where $k = |\vec{k}|$. By computing the critical points of (5.7), we see that the most unstable modes are those with wave number $k_u = 2/d$. The growth of this most unstable mode provides a mechanism for the clumping of organisms. We expect that extremely localized interactions will lead to the formation of a larger number of small groups, i.e., a density distribution pattern with a small characteristic length scale. On the other hand, more nonlocal interactions will result in a smaller number of large groups, i.e., a density distribution pattern with a larger characteristic length scale.

We confirm this prediction by means of numerical simulations. Using a pseudospectral Fourier method with 128 modes on each axis, we integrate (5.2) on a $2\pi \times 2\pi$ box with periodic boundary conditions. We choose the initial density distribution to be $\rho = 1$ plus a small random perturbation constructed by superposing low wave number ($k < 15$) Fourier modes with random coefficients. For time-stepping, we initialize with a forward Euler step and then use a second-order Adams–Bashforth method. Depending on the value of the interaction length scale d, we take time steps of $\Delta t = 4 \times 10^{-5} - 1 \times 10^{-3}$. Checks are performed with different numbers of modes and different time steps to verify convergence.

Our results are shown in Figure 5.2. Figure 5.2(a) shows the initial condition used for the two simulations. Dark patches correspond to regions of higher density. Figure 5.2(b) shows the center of the power spectrum of the initial perturbation, which is noisy. Figure 5.2(c) shows the evolution of the state in Figure 5.2(a) at time $t = 0.132$ with interaction length scale $d = 0.4$. Notice the patches of high population density. By the linear stability arguments given above, the characteristic wave number of the grouping pattern is predicted to be $k_u = 2/d = 5$. Figure 5.2(d) shows a blow-up of the center part of the power spectrum of the evolution of the perturbation. As predicted, the strongest peaks are centered around the circle $k = 5$. Figures 5.2(e) and 5.2(f) are analogous to 5.2(c) and 5.2(d), but at time $t = 2.74$ and with the more nonlocal interaction length scale $d = 1$. In this case, fewer groups form, and they are larger. The most unstable wave number from linear analysis is $k_u = 2$, and indeed

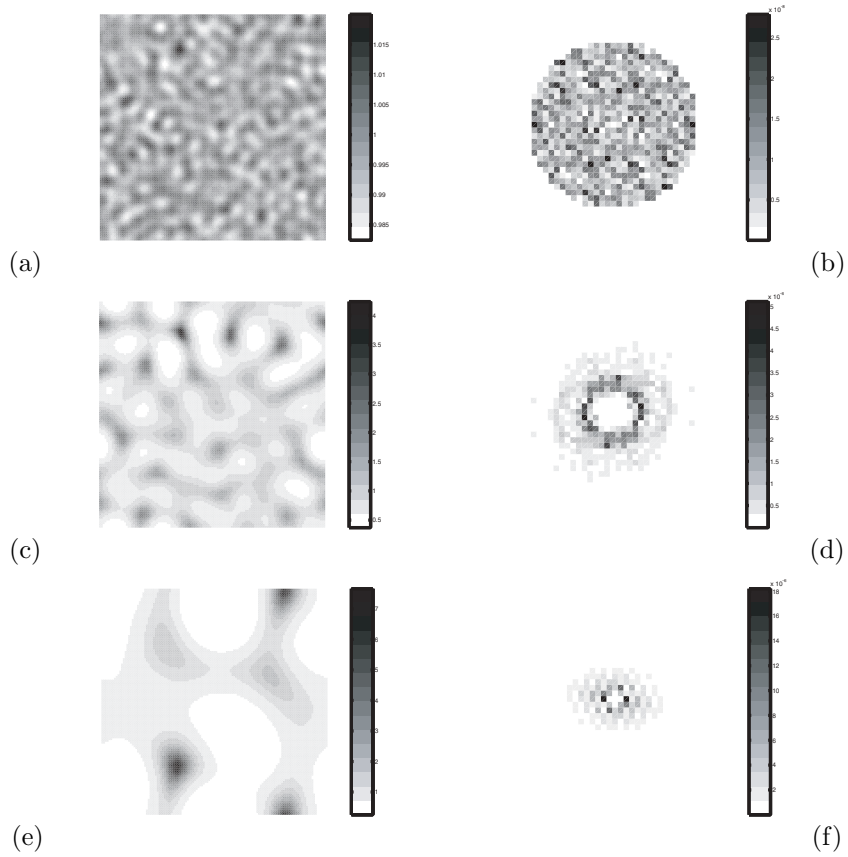

FIG. 5.2. *Results from integrating* (5.2) *on a* $2\pi \times 2\pi$ *periodic box with interaction function* $P = G_d$ *given by* (4.3). (a) *Initial population density, given by* $\rho = 1$ *plus a small random perturbation.* (b) *Center of the power spectrum of the initial perturbation.* (c) *Population density at* $t = 0.132$ *with interaction length scale* $d = 0.4$. *Note the formation of small, high-density groups.* (d) *Center of the power spectrum of the perturbation at* $t = 0.132$. *The strongest peaks are at wave number* $k = 5$, *which is the most unstable mode as predicted by linear analysis. Figures* (e) *and* (f) *are analogous to* (c) *and* (d), *but data is taken at* $t = 2.74$, *and the longer interaction length scale* $d = 1$ *is used. this is the wave number corresponding to the strongest peaks in the power spectrum. Finally, we comment that these simulations are not continued for longer times because they experience exponential blow-up, due to the lack of any effects to counterbalance the attractive forces in the model. See the appendix for a mathematical discussion of the blow-up. Modifications to the model to prevent blow-up will be a key aspect of future work, as mentioned in the next section.

6. Conclusions. Our work on biological groups in two dimensions is in the spirit of the one-dimensional study in [17]. The overarching goal in this paper is to make specific statements about how social interactions between organisms affect the large-scale motion of a biological group. In summary, we formulated and studied a simple kinematic continuum model which includes nonlocal spatially decaying social interactions between individuals. We decomposed the dynamics of our model into

incompressible motion and potential motion, or alternatively, motion perpendicular to population gradients and motion along gradients.

Whereas a constant drift and cancellation of nonlocal effects are necessary for maintaining a cohesive swarm in one dimension, this is not the case in two dimensions. For the special case of an incompressible kernel, where organisms move perpendicular to population gradients (in a nonlocal sense), the equations have constant density solutions of compact support. Through numerical simulations beginning with a variety of initial conditions, we showed that the dynamics for incompressible interactions are rotational, and that swarm patches eventually develop vortex-like structure. This rotational motion is a cooperative mechanism by which a swarm may maintain motion and cohesion once potential (attractive and repulsive) effects have come into balance. The sign of the social interaction term determines the direction of rotation, and the social interaction length scale determines the degree of macroscopic group movement. The observed asymptotic vortex states are intriguingly similar to actual mill vortices seen in biological systems [3, 22, 23, 25, 26].

In contrast, potential kernels model repulsion or attraction between organisms. For the repulsive case, the interaction length scale determines a balance between diffusive motion and convective motion. Very localized interactions lead to greater smoothing, while more nonlocal interactions result in slower smoothing but more outward convection motion. For the attractive case, the length scale determines a most-unstable mode, the growth of which results in the clumping of the population into regions of high and low density.

This work leaves open many possibilities for future research using nonlocal continuum models and ideas from fluid dynamics. One route would be to conduct fully two-dimensional simulations of biological groups under the simultaneous influence of incompressible and potential interactions. Another would be to relax some of the simplifying modeling assumptions made in section 3. The focus would be on more complicated velocity rules containing both nonlocal and local components, each of which may be nonlinear. Additional future work might consider dynamic, rather than kinematic, velocity rules. These rules would take into account inertial forces that might capture "phase changes" in animal group behaviors such as the transition from milling to translational motion.

While a model ultimately should base interaction rules on specific biological socialization functions of the organisms, field and laboratory data leading to such models is, unfortunately, very limited. We hope that the general discussion of this paper will help to focus further research in this direction. Furthermore, our results do suggest some additional measurements for future experimental work. One such measurement is motivated by our observation that (at least within the simple class of kinematic models we have considered here) we see quite different kinds of patterns depending on whether we consider incompressible or compressible motion. Thus, measuring local density variations for different swarm morphologies might elucidate the relationship between typical swarming patterns (like the vortex states) and the mechanisms that create them. Additionally, careful measurements of the nucleation of such patterns will also help in understanding the dynamics of their creation and their robustness to disturbances and other influences.

Appendix. In this appendix we sketch proofs for two results mentioned in the body of this paper, namely regularity of a swarm-patch boundary for the model examined in section 4 and an exponential upper bound for the blow-up of the model examined in section 5.2.

A.1. Regularity of the boundary of swarm patches. In this subsection we discuss the swarm-patch model of section 4 and the regularity of the swarm-patch boundary. The boundary parametrized by $\vec{z}(\alpha,t)$ is a solution of the integrodifferential equation

$$\frac{d\vec{z}}{dt} = \vec{v}(\vec{z},t), \quad \vec{v}(\vec{x},t) = \vec{K} * \rho(\vec{x},t), \quad \rho(\vec{x},t) = \chi_\Omega, \tag{A.1}$$

where $\Omega(t)$ is the interior of the swarm patch.

If we consider the problem as an integrodifferential equation for ρ,

$$\frac{d\rho}{dt} + \vec{v}\cdot\nabla\rho = 0, \qquad \vec{v} = \vec{K} * \rho, \tag{A.2}$$

where $\vec{K} = \nabla^\perp N$ for a smooth radial function N decaying at infinity, then the swarm patch is an example of a weak solution of this problem with initial condition $\rho_0 \in L^1 \cap L^\infty(\mathbb{R}^2)$. Existence and uniqueness of this problem can be proved following the classical theory of Yudovich for vortex patches [32] which is also detailed in [16]. Such a discussion is beyond the scope of this paper. However, we present some straightforward estimates that can be used to prove that the boundary of the patch remains smooth if initially smooth, as in the case of vortex patches for which the kernel $\vec{K}$ is more singular (and the proof is correspondingly more difficult).

If the swarm density persists as the characteristic function of a domain $\Omega(t)$, then it is uniformly bounded in $L^1 \cap L^\infty$ for all time. Since $\vec{v} = \vec{K} * \rho$ with $\vec{K} \in C^\infty$, then we have an a priori bound for all derivatives of $\vec{v}$, $D^k\vec{v} < \infty$ for all multi-indices k. Smoothness of the patch boundary then follows from the fact that the map $\vec{z}$ satisfies the ODE (A.1) with initial condition

$$\vec{z}|_{t_0} = \vec{z}_0(\alpha) \tag{A.3}$$

for smooth $\vec{z}_0$. Since $\vec{v}$ is C^∞ by standard regularity theory for solutions of ODEs, we see that $\vec{z}$ itself is smooth. Note that the mapping $\vec{z}$ cannot develop a critical point at a later time t because the Lagrangian derivative of $\vec{z}$, $\vec{z}_\alpha$ satisfies the ODE

$$\frac{d\vec{z}_\alpha}{dt} = \nabla\vec{v}\,|_{\vec{z}(\alpha,t)}\ \vec{z}_\alpha. \tag{A.4}$$

Since $\nabla\vec{v}$ is bounded for all time, $\vec{z}_\alpha$ remains bounded away from zero and infinity if it is so bounded at time zero, by Grönwall's lemma.

A.2. Boundedness of the swarm density for a general velocity rule. In section 5.2 we presented numerical computations that showed $\rho(\vec{x},t)$ can exhibit blow-up when the convolution kernel $\vec{K} = \nabla P = \nabla G_d$ is positive. In the limit as $d \to 0$ this formally corresponds to a backward time porous media equation.

Here we derive an a priori bound that shows that, for a smooth kernel of any sign, the maximum of ρ is bounded by an exponential in time. Thus the blow-up seen numerically must be an infinite time blow-up, not finite time. The bound we derive depends on the L^∞ norm of the convolution kernel. Thus as $d \to 0$, the bound itself becomes unbounded, as it should because we are approaching the ill-posed limit in the positive kernel case.

In Eulerian coordinates, ρ satisfies a reaction convection equation

$$\rho_t + \vec{v}\cdot\nabla\rho = -\rho\nabla\cdot\vec{v}. \tag{A.5}$$

This problem can be transformed to Lagrangian coordinates using the method of characteristics. Let $\vec{X}(\alpha, t)$ denote the solution of the ODE

$$\frac{d\vec{X}}{dt} = \vec{v}(\vec{X}, t), \quad \vec{X}|_{t=0} = \alpha. \tag{A.6}$$

Then in the Lagrangian coordinate α, ρ satisfies

$$\frac{d\rho}{dt} = -(\nabla \cdot \vec{v})|_{\vec{X}(\alpha,t)}\rho. \tag{A.7}$$

Thus we have a differential inequality for the L^∞ norm of ρ,

$$\frac{d}{dt}\|\rho\|_{L^\infty} \le C\|\nabla \cdot \vec{v}\|_{L^\infty}\|\rho\|_{L^\infty}. \tag{A.8}$$

Since ρ is a density, it has an a priori L^1 bound,

$$\int \rho(\vec{x}, t)d\vec{x} = \int \rho(\vec{x}, 0)d\vec{x} = \|\rho\|_{L^1}. \tag{A.9}$$

Since $\vec{v} = \vec{K} * \rho$ for smooth $\vec{K}$, we have

$$\|\nabla \cdot \vec{v}\|_{L^\infty} \le \|\nabla \cdot \vec{K}\|_{L^\infty}\|\rho\|_{L^1}. \tag{A.10}$$

Combining this with (A.8) and the a priori bound on the L^1 norm of ρ, we have

$$\frac{d}{dt}\|\rho\|_{L^\infty} \le C\|\rho\|_{L^1}\|\rho\|_{L^\infty}, \quad C = \|\nabla \cdot \vec{K}\|_{L^\infty}. \tag{A.11}$$

Grönwall's lemma then gives

$$\|\rho\|_{L^\infty} \le \exp\,(C\|\rho_0\|_{L^1}t)\|\rho_0\|_{L^\infty}. \tag{A.12}$$

Acknowledgments. We are grateful to Daniel Marthaler for providing input on numerical simulations, and to Anke Ordemann for numerous helpful comments.

STABILITY OF STATIONARY SOLUTIONS OF THE MULTIFREQUENCY RADIATION DIFFUSION EQUATIONS*

OLE H. HALD† AND ALEKSEI I. SHESTAKOV‡

Abstract. A nondimensional model of the multifrequency radiation diffusion equation is derived. A single material ideal gas equation-of-state is assumed. Opacities are proportional to the inverse of the cube of the frequency. Inclusion of stimulated emission implies a Wien spectrum for the radiation source function. It is shown that the solutions are uniformly bounded in time and that stationary solutions are stable. The spatially independent solutions are asymptotically stable, while the spatially dependent solutions of the linearized equations approach zero.

Key words. stationary solutions, multifrequency radiation diffusion

1. Introduction. This paper derives asymptotic stability properties for a system of equations modeling the frequency dependent radiation diffusion equation coupled to the matter energy balance equation. In order to obtain a tractable system, we simplify the equations and first derive a system in nondimensional form. Our derived system preserves the salient features of the original dimensional set of equations—in particular, frequency dependent opacities and a nonlinear relationship between the matter temperature and the radiation emission term. We assume matter to consist of a single material characterized by an ideal gas equation-of-state, i.e., a specific energy proportional to temperature. In the analysis, we impose zero flux boundary conditions on the radiation field. However, since we are interested in studying how the two fields (radiation and temperature) equilibrate, and since the radiation diffusion equation is itself derived assuming near isotropy, i.e., short mean free paths, our boundary condition is not overly restrictive.

We begin with the multifrequency radiation diffusion equations (CGS units)

$$\partial_t u_\nu = \nabla D_\nu \nabla u_\nu + c\,\kappa_\nu\,(\,B_\nu - u_\nu\,)\,, \tag{1}$$

$$\rho \partial_t e = -\,c\int_0^\infty d\nu\,\kappa_\nu\,(\,B_\nu - u_\nu\,)\,. \tag{2}$$

Equations (1)–(2) simulate diffusive transport and emission-absorption. The equations do not contain scattering or effects due to fluid motion (advection and spectral shifts.) The variable u_ν (erg sec cm^{-3}) represents the spectral energy density of the

radiation field, ν ($\sec^{-1}$) is the frequency coordinate, ρ is the mass density (assumed fixed), and e is the matter specific energy density. The latter's temporal derivative is expressed in terms of the specific heat $c_{\rm v}$ and the matter temperature T,

$$\partial_t e = \frac{\partial e}{\partial T}\,\partial_t T \doteq c_{\rm v}\partial_t T. \tag{3}$$

On the right side of (1), the diffusion coefficient $D_\nu = c/3\kappa_\nu$, where c is the speed of light and κ_ν (cm^{-1}) is the inverse mean free path.[1] (In most applications, D_ν is modified by including the total scattering cross-section (Mihalas and Weibel-Mihalas [9]) and a flux limiter (Lund and Wilson [7].) Section 6 discusses how such generalizations impact our model. The coefficient κ_ν is a complicated function of frequency. In this paper, we consider one valid for free-free transitions [12],

$$\kappa_\nu = (2\pi/3m_e^3k)^{1/2}\,(4Z_e^2e^6N_+N_e/3hc)\,T^{-1/2}\,\nu^{-3}\,, \tag{4}$$

where m_e is the electron mass, k is the Boltzmann constant, Z_e is the ionic charge, e is the fundamental charge, N_+ and N_e are the number densities (# cm^{-3}) of the ions and free electrons, and h is the Planck constant. We focus our attention on a fully ionized hydrogen plasma of density ρ. Thus, $Z_e = 1$, and $N_+ = N_e = \rho\mathcal{A}$, where $\mathcal{A}$ is the Avogadro constant. This implies that

$$\kappa_\nu = \kappa_0\ \nu^{-3}\ \ ,\quad \kappa_0 = 1.34\cdot 10^{56}\,\rho^2/\sqrt{T}. \tag{5}$$

In order to obtain a tractable set of equations, we ignore the weak temperature dependence of κ_0 and, since ρ is assumed to be fixed, absorb $\rho^2/\sqrt{T}$ into κ_0.[2] Thus, taking characteristic values for ρ and T, we let $\kappa_0\rho^2/\sqrt{T} \to \kappa_0$. Since κ_ν has units of cm^{-1}, κ_0 now has units of $\mathrm{cm}^{-1}\ \sec^{-3}$.

Last, we define the radiation emission term B_ν. To simplify the algebra, instead of the usual Planck function we assume a Wien distribution and write

$$B_\nu = (8\pi h/c^3)\,\nu^3\,\exp(-h\nu/kT). \tag{6}$$

The difference between (6) and the Planck function is that the latter replaces the exponential term with $[\exp(h\nu/kT)-1]^{-1}$. For our purposes, this is of little consequence. Both distributions, Planck and Wien, have the same exponential decay at high frequencies. At low frequencies, (6) and the Planck function are proportional to ν^3 and ν^2, respectively. Equation (6) and the Planck function peak at $h\nu/kT = 3$ and 2.82, respectively. Also, the frequency integrated emission term

$$\int_0^\infty d\nu\, B_\nu = 7.00\cdot 10^{-15}\,T^4\,,$$

which is approximately 8% less than the Planck result, $7.56\cdot 10^{-15}\,T^4$. The relative error of the two distributions, (Planck − Wien)/Planck $= \exp(-h\nu/kT)$. Thus, the error is greatest at $\nu = 0$, but at the peak of the Planck function, the error is less than 6%.

We now derive the nondimensional system of equations and begin by choosing characteristic values for the density ρ, specific heat $c_{\rm v}$, and temperature T_0. As

[1] Some authors express the mean free path as $(\rho\kappa_\nu)^{-1}$, where κ_ν (cm^2/g) is the opacity.

[2] Section 6 discusses the effect of keeping the $1/\sqrt{T}$ dependence of κ_ν.

mentioned above, incorporating these values into (5) yields $\kappa_\nu = \kappa_0 \nu^{-3}$. Denoting the normalization values with zero subscripts and the normalized variables with primes, we define $\nu' = \nu/\nu_0$, $T' = T/T_0$, $u' = u/u_0$, $t' = t/t_0$, and if x is the spatial coordinate, $x' = x/x_0$. This implies that $\kappa_\nu = \kappa_0(\nu_0\nu')^{-3}$, $\partial_t = (1/t_0)\,\partial_{t'}$, $\nabla = (1/x_0)\nabla'$, etc. The constants ν_0, t_0, etc. may be expressed in terms of the original three, ρ, c_v, and T_0. The choices

$$
\begin{aligned}
\nu_0 &= kT_0/h\ , \\
t_0 &= \nu_0^3/(c\,\kappa_0)\ , \\
x_0 &= \nu_0^3/(\sqrt{3}\,\kappa_0)\ , \\
u_0 &= 8\pi\, h\,\nu_0^3/c^3\ , \\
R &= \rho\, c_\mathrm{v}\, c^3/(8\pi\, k\,\nu_0^3)
\end{aligned}
\tag{7}
$$

yield the desired system,

$$
\partial_t u = \nabla \cdot \nu^3\, \nabla u + \left(\nu^3 e^{-\nu/T} - u\right)/\nu^3\,, \tag{8}
$$

$$
R\partial_t T = -T + \int_0^\infty (u/\nu^3)\, d\nu\,, \tag{9}
$$

where $u = u(x,t,\nu)$ and $T = T(x,t)$. In (8)–(9) and henceforth, we drop the primes from the nondimensional variables, t, ν, u, etc. Note that the first term on the right side of (9) stems from integrating over frequency, i.e.,

$$
\int_0^\infty d\nu\, (\nu^3 e^{-\nu/T})/\nu^3 = \int d\nu\, e^{-\nu/T} = T\,.
$$

It is instructive to choose characteristic values for T_0, ρ, and c_v and evaluate the normalization constants in (7). For example, the choices $T_0 = 10^5$ °K, $\rho = 10^{-6}$ g cm^{-3}, and $c_\mathrm{v} = 10^8$ erg/(g °K) imply $\nu_0 = 2.08 \cdot 10^{15}$ Hz (≈ 10 eV), $t_0 = 7.12 \cdot 10^{-7}$ sec, $x_0 = 1.24 \cdot 10^4$ cm, $u_0 = 5.59 \cdot 10^{-11}$ erg sec/cm^3, and $R = 85.8$. Note that the above value for ν_0 corresponds to a wavelength $\lambda_0 = 1.44 \cdot 10^{-5}$ cm, which lies just outside the so-called near UV range $2\text{–}4 \cdot 10^{-5}$ cm.

The nondimensional equations (8)–(9) preserve important properties of the original system (1)–(2). Conservation of total energy follows by ignoring boundary fluxes (e.g., by imposing homogeneous Neumann boundary conditions on u) and integrating the total energy density $RT + \int d\nu\, u$ over the spatial domain. The high frequency photons, i.e., u with large ν, in (8)–(9) are characterized by fast transport and slow absorption. In (8), $1/\nu^3$ plays the role of a coupling coefficient, the low frequencies coupling the fastest. Matter preferentially emits radiation into frequencies where $\nu^3\, e^{-\nu/T}$ is maximal.

Before launching into our theme, we summarize previously published related work. Andreev, Kozmanov, and Rachilov [1] consider the system coupling the matter energy equation to either the equation of radiative transfer (i.e., for the radiation intensity I) or to the radiation diffusion equation. They examine the grey, i.e., frequency-integrated, as well as the spectral cases. Andreev, Kozmanov, and Rachilov assume Dirichlet boundary conditions; that is, the incoming intensity is specified, or, in the diffusion limit, the radiation energy density. Isotropic scattering is included in the transfer equation. Assuming existence of solutions, the paper proves a maximum principle (MP), viz., that the solution is bounded by the initial data and the boundary values. The paper does not discuss whether the equilibrium solution is an attractor.

Mercier [8] considers the system coupling the spectral radiative transfer and matter energy equations. The system includes Thomson scattering, i.e., no energy exchange due to scattering. By applying the theory of accretive operators, Mercier shows that (1) a solution exists, (2) the solution is bounded by the initial and boundary data, and (3) as time progresses, the distance between the solution and the equilibrium point decreases, i.e., the latter is an attractor. Mercier makes the following assumptions regarding the behavior of the coefficients of the equations: The matter internal energy has a positive minimum and the specific heat has a finite upper bound. For the opacity κ, there is Lipschitz continuity with respect to T, a finite upper bound for all frequency, and κ decreases with T. And radiation emission κB increases with T. These assumptions are largely satisfied by our model, with the exceptions that our κ diverges with decreasing frequency (as ν^{-3}) and that κ is independent of T.

The existence of an MP has implications for the design of numerical methods for these equations. Ideally, the schemes should also satisfy an MP. In [6], Larsen and Mercier apply the theoretical work of [1] and [8] to analyze the Monte Carlo method of Fleck and Cummings [5]. Larsen and Mercier prove that for sufficiently small time steps, the algorithm does satisfy the MP but that it fails to do so for large time steps. The analysis is confirmed by their numerical simulations and by Fleck and Cummings's own results [5, Figure 4, p. 332].

There are two competing Monte Carlo schemes for the equations of radiative transfer. One is the previously mentioned one of Fleck and Cummings [5]; another is the method of Carter and Forest [2]. Both schemes rewrite the matter energy equation in terms of the integrated radiation energy density function $u_r(T) = aT^4$, where a is the radiation constant. The schemes require a value of u_r throughout the course of the time step, but they differ in how that term is approximated. The choice of approximation impacts the stability of the scheme, i.e., whether or not the numerical solution satisfies the MP. In [3], Densmore and Larsen apply the Larsen and Mercier analysis [6] to the Carter–Forest scheme. Densmore and Larsen's analysis shows that the Fleck–Cummings scheme appears to allow larger time steps than the Carter–Forest scheme before the numerical solution violates the MP. The analysis is confirmed by numerical results on a problem simulating radiative flow into initially cold matter.

In this paper, we extend the work just cited by analyzing the rate at which solutions equilibrate. Since our interests lie with the multifrequency radiation diffusion equations, we restrict our attention to the normalized system derived above.

We now summarize the rest of the paper. Section 2 confirms that solutions are positive and uniformly bounded by the initial conditions. Section 3 shows that the stationary solution is unique and if the initial conditions of a given problem lie within an envelope about the stationary solution, so does the solution for all time. In section 4, we consider a linearized form of (8)–(9) and prove that a small perturbation about the stationary solution decays to zero exponentially fast if the perturbation is spatially varying. Section 5 considers the nonlinear system (8)–(9) and shows that nonspatially varying perturbations also decay to zero. However, we are unable to give an estimate for the rate of decay and surmise that the decay may be slow. A summary, motivation for this work, and a description of ongoing related research appear in section 6. Section 6 also discusses the impact that more realistic assumptions, e.g., nonideal gases, have on our model.

2. A priori bounds. Let U be an open, bounded, and connected subset of $\mathbb{R}^3$ with smooth boundary. We consider the equations

$$\partial_t u(x,t,\nu) + \frac{1}{\nu^3} u(x,t,\nu) = \nu^3 \Delta u(x,t,\nu) + e^{-\nu/T(x,t)}, \tag{10}$$

$$R\,\partial_t T(x,t) + T(x,t) = \int_{\nu=0}^{\infty} \frac{u(x,t,\nu)}{\nu^3} d\nu \tag{11}$$

for $x \in U$, $t > 0$, and $0 < \nu < \infty$ with boundary conditions

$$\frac{\partial u}{\partial n}(x,t,\nu) = 0, \qquad x \in \partial U, \tag{12}$$

and initial conditions

$$u(x,0,\nu) = u_0(x,\nu), \qquad T(x,0) = T_0(x), \qquad x \in U.$$

Here $T(x,t)$ is the matter temperature at position x and time t, $u(x,t,\nu)$ denotes the radiation energy density at frequency ν, and $\Delta u = \sum_{i=1}^{3} \partial_{x_i}^2 u$. The constant R is positive.

LEMMA 1. *Let $u(x,t,\nu)$, $T(x,t)$ be smooth solutions of* (10)–(12). *If*

$$0 \le u(x,0,\nu) \le \nu^3 e^{-\nu/T_2} \qquad \textit{and} \qquad 0 < T(x,0) < T_2,$$

then, for $t > 0$,

$$0 < u(x,t,\nu) < \nu^3 e^{-\nu/T_2} \qquad \textit{and} \qquad 0 < T(x,t) < T_2.$$

Remark. Lemma 1 shows that the solutions of (10)–(12) are uniformly bounded in time. This is to be expected as the temperature and the radiation energy are nonnegative quantities and there is no energy flowing through the boundary. The result is also valid when U is a box with periodic boundary conditions.

Proof. The idea is to rewrite (10)–(11) as integral equations and use proof by contradiction. It follows from (10) that for each $\nu > 0$,

$$\partial_t (e^{t/\nu^3} u) = \nu^3 \Delta (e^{t/\nu^3} u) + e^{t/\nu^3} e^{-\nu/T}.$$

Using Duhamel's principle [4, p. 49], we obtain

$$\begin{aligned} u(x,t,\nu) = {} & e^{-t/\nu^3} \int_U G_\nu(x,y,t)\, u(y,0,\nu) dy \\ & + \int_{s=0}^{t} e^{-(t-s)/\nu^3} \int_U G_\nu(x,y,t-s) e^{-\nu/T(y,s)} dy\, ds\,. \end{aligned} \tag{13}$$

Here $G_\nu(x,y,t)$ is the Green's function for $\partial_t w = \nu^3 \Delta w$ with Neumann boundary conditions. From (11) we see that

$$\partial_t (e^{t/R} T) = \frac{e^{t/R}}{R} \int_{\nu=0}^{\infty} \frac{u}{\nu^3} d\nu.$$

Integrating with respect to t and using (13) yield

$$
\begin{aligned}
T(x,t) &= e^{-t/R}\,T(x,0) \\
&\quad + \int_{\tau=0}^{t} \frac{e^{-(t-\tau)/R}}{R} \int_{\nu=0}^{\infty} \frac{e^{-\tau/\nu^3}}{\nu^3} \int_U G_\nu(x,y,\tau) u(y,0,\nu)\,dy\,d\nu\,d\tau \\
&\quad + \int_{\tau=0}^{t} \frac{e^{-(t-\tau)/R}}{R} \int_{\nu=0}^{\infty} \int_{s=0}^{\tau} \frac{e^{-(\tau-s)/\nu^3}}{\nu^3} \int_U G_\nu(x,y,\tau-s) e^{-\nu/T(y,s)}\,dy ds d\nu d\tau. \qquad (14)
\end{aligned}
$$

To bound T we assume that either $\min_{\bar U} T(x,t) = 0$ or $\max_{\bar U} T(x,t) = T_2$ for some $t > 0$. Let t_2 be the smallest such t. Then $0 < T(x,t) < T_2$ for $0 \le t < t_2$. Since $T_0 > 0$, $G_\nu > 0$, $u_0 \ge 0$, $R > 0$, and $e^{-\nu/T} > 0$, for $t < t_2$ we conclude from (14) that $T(x,t_2) > 0$. Thus, the upper bound must hold at $t = t_2$. Let x_2 define the point where $T(x_2,t_2) = T_2$. Recall that $\int G_\nu dy \equiv 1$. Since $u(y,0,\nu) \le \nu^3 e^{-\nu/T_2}$ and $e^{-\nu/T(y,s)} < e^{-\nu/T_2}$, for $s < t_2$ it follows from (14), after integrating over s, that

$$
\begin{aligned}
T_2 = T(x_2,t_2) &\le e^{-t_2/R} T(x_2,0) \\
&\quad + \int_{\tau=0}^{t_2} \frac{e^{-(t_2-\tau)/R}}{R} \int_{\nu=0}^{\infty} e^{-\tau/\nu^3} e^{-\nu/T_2}\,d\nu d\tau \\
&\quad + \int_{\tau=0}^{t_2} \frac{e^{-(t_2-\tau)/R}}{R} \int_{\nu=0}^{\infty} (1 - e^{-\tau/\nu^3}) e^{-\nu/T_2}\,d\nu d\tau\,.
\end{aligned}
$$

Cancelling the terms involving $e^{-\tau/\nu^3}$ and evaluating the remaining integrals yield the contradiction

$$
T_2 \le e^{-t_2/R}\,[T(x_2,0) - T_2] + T_2 < T_2\,.
$$

Thus, the bounds for $T(x,t)$ hold for all time.

To bound $u(x,t,\nu)$, we let $t > 0$ be given and choose $\epsilon > 0$ such that

$$
\epsilon < \min_{y\in\bar U,\ 0\le s\le t} T(y,s) \le \max_{y\in\bar U,\ 0\le s\le t} T(y,s) < T_2 - \epsilon\,.
$$

Since $u(x,0,\nu) \ge 0$, $G_\nu > 0$, and $\int G_\nu dy \equiv 1$, it follows from (13) that $u(x,t,\nu) \ge (1 - e^{-t/\nu^3}) e^{-\nu/\epsilon} > 0$, which establishes the lower bound. For the upper bound, we use the inequalities $u(x,0,\nu) \le \nu^3 e^{-\nu/T_2}$ and $e^{-\nu/T(y,s)} < e^{-\nu/(T_2-\epsilon)}$. Doing the integrals in (13) gives

$$
\begin{aligned}
u(x,t,\nu) &\le e^{-t/\nu^3}\nu^3 e^{-\nu/T_2} + (1 - e^{-t/\nu^3})\nu^3 e^{-\nu/(T_2-\epsilon)} \\
&\le \nu^3 e^{-\nu/T_2} - (1 - e^{-t/\nu^3})\nu^3 e^{-\nu/T_2}\big(\,1 - e^{-\nu\epsilon/[T_2(T_2-\epsilon)]}\,\big) \\
&< \nu^3 e^{-\nu/T_2}\,.
\end{aligned}
$$

This completes the proof. □

3. Stationary solutions. In this section we consider stationary solutions of (10)–(12). We shall show that such solutions cannot depend on x and that they are stable. The problem of asymptotic stability is discussed in sections 4 and 5.

LEMMA 2. *Let $u(x,\nu)$, $T(x)$ be a stationary solution of* (10)–(12) *and satisfy the bounds in Lemma* 1. *Then u, T are independent of x, and there is a constant M such that*

$$
u(\nu) = \nu^3 e^{-\nu/M}, \qquad T = M.
$$

Proof. It is clear that $u = \nu^3 e^{-\nu/M}$, $T = M$ is a stationary solution of (10)–(12). We will show that there are no others. It follows from (10)–(12) that

$$-\nu^6 \Delta u(x,\nu) + u(x,\nu) = \nu^3 e^{-\nu/T(x)},$$

$$T(x) = \int_{\nu=0}^{\infty} \frac{u(x,\nu)}{\nu^3} d\nu, \tag{15}$$

where u satisfies the boundary condition (12). Since $-\nu^6 \Delta w + w = f$ with $\partial w/\partial n = 0$ has a unique solution and $w = 1$ if $f = 1$, we see that

$$u(x,\nu) = \int_U g_\nu(x,y) \nu^3 e^{-\nu/T(y)} dy, \tag{16}$$

$$1 = \int_U g_\nu(x,y) dy. \tag{17}$$

One can show that the Green's function satisfies $g_\nu(x,y) = g_\nu(y,x) > 0$ when $x \neq y$ and is singular when $x = y$. Let $M = \max_{\bar{U}} T(y)$. Then $M = T(x)$ for some x in $\bar{U}$ and by using (17), (15), and (16), we find

$$\begin{aligned} 0 &= M - T(x) \\ &= \int_{\nu=0}^{\infty} e^{-\nu/M} \int_U g_\nu(x,y) dy d\nu - \int_{\nu=0}^{\infty} \frac{1}{\nu^3} \int_U g_\nu(x,y) \nu^3 e^{-\nu/T(y)} dy d\nu \\ &= \int_{\nu=0}^{\infty} \int_U g_\nu(x,y) \left[e^{-\nu/M} - e^{-\nu/T(y)} \right] dy d\nu \,. \end{aligned}$$

Since $g_\nu > 0$ and $[e^{-\nu/M} - e^{-\nu/T(y)}] \geq 0$, we conclude that $T(y) = M$ for all y in U. Equations (16)–(17) then imply that $u(x,\nu) = \nu^3 e^{-\nu/M}$ for all x in U. This completes the proof. □

How do we determine the stationary solution corresponding to particular initial data? Let

$$K(t) = \int_U \left[R\,T(x,t) + \int_{\nu=0}^{\infty} u(x,t,\nu) d\nu \right] dx \tag{18}$$

define the total (matter and radiation) energy for the system. Differentiating with respect to t and using (10)–(12), we see that $K(t)$ is independent of time. If $T(x,t) \to M$ and $u(x,t,\nu) \to \nu^3 e^{-\nu/M}$ as $t \to \infty$, we can find M by solving

$$R\,M + 6M^4 = K(0) \,/\, \mathrm{vol}(U) \,. \tag{19}$$

If $K(0) > 0$, this equation has a unique solution. We will now show that the stationary solution is stable.

THEOREM 1. *Let $u(x,t,\nu)$, $T(x,t)$ be a smooth solution of* (10)–(12). *If*

$$\nu^3 e^{-\nu/T_1} \leq u(x,0,\nu) \leq \nu^3 e^{-\nu/T_2} \qquad \textit{and} \qquad T_1 < T(x,0) < T_2,$$

then for $t > 0$

$$\nu^3 e^{-\nu/T_1} < u(x,t,\nu) < \nu^3 e^{-\nu/T_2} \qquad \textit{and} \qquad T_1 < T(x,t) < T_2.$$

Remark. Equations (18)–(19) show that if u and T satisfy the assumptions in Theorem 1, then $R\,T_1+6T_1^4 < R\,M+6M^4 < R\,T_2+6T_2^4$. Therefore, the temperature M for the stationary solution lies in the interval $T_1 < M < T_2$.

Proof. We have already established the upper bounds in Lemma 1. Our proof for the lower bounds is similar. Assume $\min_{\bar U} T(x,t) = T_1$ for some $t > 0$, and let t_1 be the first such t. Then, $T_1 = T(x_1,t_1)$ for some $x_1 \in \bar U$, and $T(y,s) > T_1$ for $y \in U$ and $s < t$. Since $\int G_\nu dy \equiv 1$, $u(y,0,\nu) \geq \nu^3 e^{-\nu/T_1}$, and $e^{-\nu/T(y,s)} > e^{-\nu/T_1}$ for $s < t_1$, it follows from (14), after integrating over s, that

$$\begin{aligned} T_1 = T(x_1,t_1) &\geq e^{-t_1/R}T(x_1,0) \\ &\quad + \int_{\tau=0}^{t_1} \frac{e^{-(t_1-\tau)/R}}{R} \int_{\nu=0}^{\infty} e^{-\tau/\nu^3} e^{-\nu/T_1} d\nu d\tau \\ &\quad + \int_{\tau=0}^{t_1} \frac{e^{-(t_1-\tau)/R}}{R} \int_{\nu=0}^{\infty} (1-e^{-\tau/\nu^3}) e^{-\nu/T_1} d\nu d\tau. \end{aligned}$$

Cancelling the $e^{-\tau/\nu^3}$ terms and evaluating the remaining integrals, we get

$$T_1 \geq e^{-t_1/R}\,[T(x_1,0) - T_1] + T_1 > T_1\,.$$

The contradiction shows that the lower bound for $T(x,t)$ holds for all time.

To bound $u(x,t,\nu)$ from below we let $t > 0$ be given and choose $\epsilon > 0$ such that

$$T_1 + \epsilon < \min_{y\in\bar U,\ 0\leq s\leq t} T(y,s)\,.$$

Since $u(x,0,\nu) \geq \nu^3 e^{-\nu/T_1}$ and $e^{-\nu/T(y,s)} > e^{-\nu/(T_1+\epsilon)}$, it follows from (13) that

$$\begin{aligned} u(x,t,\nu) &\geq e^{-t/\nu^3}\nu^3 e^{-\nu/T_1} + (1-e^{-t/\nu^3})\nu^3 e^{-\nu/(T_1+\epsilon)} \\ &\geq \nu^3 e^{-\nu/T_1} + (1-e^{-t/\nu^3})\nu^3 e^{-\nu/(T_1+\epsilon)}(1-e^{-\nu\epsilon/[T_1(T_1+\epsilon)]}) \\ &> \nu^3 e^{-\nu/T_1}\,. \end{aligned}$$

This completes the proof. □

4. Linearized equations. In section 3 we have shown that (10)–(12) have a stable stationary solution. The important question is whether the stationary solution is asymptotically stable; i.e., will nearby solutions tend to the stationary solution as time increases? We approach this from two directions. In this section we linearize (10)–(12) around the stationary solution and prove that the linearized equation is asymptotically stable when the initial data are orthogonal to constant functions. In the next section we show that (10)–(12) are asymptotically stable if the initial data are expressed in terms of constant functions.

To get the linearized equations we assume that $u = \nu^3 e^{-\nu/M} + u'$ and $T = M + T'$, where u' and T' are small. Inserting (10)–(12), expanding $e^{-\nu/T}$ in a Taylor series, and discarding the higher order terms lead to the linearized equations

$$\partial_t u'(x,t,\nu) + \frac{1}{\nu^3}u'(x,t,\nu) = \nu^3\Delta u'(x,t,\nu) + \frac{\nu e^{-\nu/M}}{M^2}T'(x,t), \tag{20}$$

$$R\,\partial_t T'(x,t) + T'(x,t) = \int_{\nu=0}^{\infty} \frac{u'(x,t,\nu)}{\nu^3} d\nu, \tag{21}$$

where u' satisfies the original boundary condition (12). Since M satisfies (19), we conclude from (18) that for every $t \geq 0$,

$$\int_U \left[R\,T'(x,t) + \int_{\nu=0}^{\infty} u'(x,t,\nu)d\nu \right] dx = 0.$$

We solve (20)–(21) by separation of variables. Let

$$u'(x,t,\nu) = \sum_{k=0}^{\infty} a_k(t,\nu)e_k(x), \qquad T'(x,t) = \sum_{k=0}^{\infty} \alpha_k(t)e_k(x), \tag{22}$$

where $\Delta e_k + \lambda_k e_k = 0$ in U, $(\partial/\partial n)e_k = 0$ on ∂U, and $\int_U e_i e_j dx = \delta_{ij}$. It can be shown that $\lambda_0 = 0 < \lambda_1 \leq \lambda_2 \leq \cdots$ with $e_0 = 1/\sqrt{\mathrm{vol}(U)}$. Inserting (22) into (20)–(21), we get

$$\frac{d}{dt}a_k(t,\nu) + \left(\frac{1}{\nu^3} + \lambda_k \nu^3\right) a_k(t,\nu) = \frac{\nu e^{-\nu/M}}{M^2}\alpha_k(t), \tag{23}$$

$$R\frac{d}{dt}\alpha_k(t) + \alpha_k(t) = \int_{\nu=0}^{\infty} \frac{a_k(t,\nu)}{\nu^3}\, d\nu, \tag{24}$$

$$R\alpha_0(t) + \int_{\nu=0}^{\infty} a_0(t,\nu)d\nu = 0.$$

Note that the last equation, which follows from energy conservation, (18)–(19), and the orthogonality property of the e_k, does not constrain the coefficients α_k, a_k for $k \geq 1$. Following the proof of Lemma 1, we can show that solutions of (23)–(24) satisfy $|a_k(t,\nu)| \leq \nu^4 M^{-2} e^{-\nu/M} B$ and $|\alpha_k(t)| < B$ for $t > 0$ if the conditions hold at $t = 0$.

To analyze the solutions of (23)–(24) we need the following result.

LEMMA 3. *Let $M, R > 0$. For every $\lambda > 0$ there exist a $\sigma = \sigma(\lambda) > 0$ such that*

$$\int_{\nu=0}^{\infty} \frac{\nu e^{-\nu/M}}{M^2(1 + \lambda\nu^6 - \sigma\nu^3)}\, d\nu = 1 - R\sigma.$$

The function $\sigma(\lambda)$ is an increasing function of λ, and there is an $\eta > 0$ such that $1 + \lambda\nu^6 - \sigma(\lambda)\nu^3 > \eta^2$ for all $\lambda > 0$, $\nu > 0$.

Proof. Since $1 + \lambda\nu^6 - \sigma\nu^3 = 1 - \sigma^2/(4\lambda) + \lambda[\nu^3 - \sigma/(2\lambda)]^2$, we see that the integral—call it $f(\sigma)$—is positive and well defined for $\sigma < 2\sqrt{\lambda}$. It is a smooth increasing function of σ and becomes unbounded as $\sigma \to 2\sqrt{\lambda}$. Using the property that $1 - R\sigma$ decreases with σ and the inequality $0 < f(0) < 1$, we can find a $\sigma = \sigma(\lambda) > 0$ such that $f(\sigma) = 1 - R\sigma$. Note that $\sigma < \min(1/R, 2\sqrt{\lambda})$. Differentiating the identity in Lemma 3 with respect to λ, we obtain

$$\frac{d}{d\lambda}\sigma(\lambda) = \int_{\nu=0}^{\infty} \frac{\nu^7 e^{-\nu/M}\, d\nu}{M^2(1 + \lambda\nu^6 - \sigma\nu^3)^2} \Bigg/ \left(R + \int_{\nu=0}^{\infty} \frac{\nu^4 e^{-\nu/M}\, d\nu}{M^2(1 + \lambda\nu^6 - \sigma\nu^3)^2} \right)$$

and $(d^2/d\lambda^2)\sigma(\lambda) < 0$. This implies that $\sigma(\lambda)$ is an increasing function of λ and concave down. If λ is small and positive, we have

$$\sigma(\lambda) = 0 + \frac{5040M^6}{R + 24M^3}\lambda - \cdots.$$

Let $g(\lambda) = 1 - \sigma^2(\lambda)/(4\lambda)$ with $g(0) = 1$. Then, $g(\lambda) > 0$ for all $\lambda > 0$. Since $\sigma^2(\lambda)/(4\lambda) \to 0$ as $\lambda \to 0$ and $g(\lambda) \geq 3/4$ when $\lambda \geq 1/R^2$, we see that $g(\lambda)$ is continuous at $\lambda = 0$ and conclude that $g(\lambda) > \eta^2$ for all $\lambda \geq 0$. But $1+\lambda\nu^6-\sigma(\lambda)\nu^3 \geq g(\lambda)$. This completes the proof. □

THEOREM 2. *Let $a_k(t,\nu)$, $\alpha_k(t)$ be solutions of (23)–(24) satisfying*

$$|a_k(0,\nu)| \leq \frac{\nu^4 e^{-\nu/M}}{M^2} b_k\,, \qquad |\alpha_k(0)| \leq b_k\,,$$

for $k = 0, 1, \ldots$ and $\nu > 0$. Let $\sigma > 0$ satisfy the nonlinear equation in Lemma 3 with $\lambda = \lambda_1$, where λ_1 is the smallest nonzero eigenvalue of $\Delta e(x) + \lambda e(x) = 0$, $x \in U$, with $(\partial/\partial n)e(x) = 0$ for $x \in \partial U$. If $b_0 = 0$ and $\sum_{k=1}^{\infty} b_k^2 < \infty$, there is a $C > 0$ such that for $t \geq 0$

$$\|u'(x,t,\nu)\|_{L^2(U)} \leq \frac{\nu^4 e^{-\nu/M}}{M^2} C e^{-0.9\sigma t}\,, \qquad \|T'(x,t)\|_{L^2(U)} \leq C e^{-0.9\sigma t}\,.$$

Remarks. (1) The theorem asserts that if u', T' initially consist of only spatially varying components, i.e., $a_0(0,\nu) = \alpha(0) = 0$, the a_k, α_k modes for $k \geq 1$ decay to zero exponentially. Thus, for such perturbations about the stationary solution, the latter is an attractor. (2) If $a_0(0,\nu)$, $\alpha(0) \neq 0$, it is possible to show that $a_0(t,\nu)$ and $\alpha_0(t)$ tend to zero. However, the decay is very slow and requires a different proof. We discuss this in section 5.

Proof. To prove Theorem 2, we derive bounds for a_k, α_k as functions of time. One might think that the higher Fourier coefficients go to zero rapidly, but this is not the case. The relaxation to equilibrium depends on R and the size of the domain and can be slow for large R and large domains.

Let $k \geq 1$ be fixed and replace a_k, α_k, λ_k in (23)–(24) by a, α, λ. We will show that a particular linear combination of a and α goes to zero. Let $\sigma > 0$ be determined as in Lemma 3. If we subtract σa from both sides of (23), divide throughout by $1 + \lambda\nu^6 - \sigma\nu^3$, integrate for $\nu > 0$, and apply Lemma 3, we obtain

$$\begin{aligned}
&\frac{d}{dt}\int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{1+\lambda\nu^6-\sigma\nu^3} + \int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{\nu^3} \\
&= \int_{\nu=0}^{\infty} \frac{(\nu/M^2)\,e^{-\nu/M}\,d\nu}{1+\lambda\nu^6-\sigma\nu^3}\,\alpha(t) - \sigma\int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{1+\lambda\nu^6-\sigma\nu^3} \\
&= (1-R\sigma)\alpha(t) - \sigma\int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{1+\lambda\nu^6-\sigma\nu^3}\,.
\end{aligned}$$

Combining this result with (24) leads to

$$\frac{d}{dt}\left[R\alpha(t) + \int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{1+\lambda\nu^6-\sigma\nu^3}\right] = -\sigma\left[R\alpha(t) + \int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{1+\lambda\nu^6-\sigma\nu^3}\right].$$

We can solve this differential equation and get

$$R\alpha(t) + \int_{\nu=0}^{\infty} \frac{a(t,\nu)\,d\nu}{1+\lambda\nu^6-\sigma\nu^3} = C_1 e^{-\sigma t}, \tag{25}$$

where C_1 is the initial value of the left-hand side.

Our next goal is to derive a differential inequality for

$$A(t) = \int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M} a^2(t,\nu)\,d\nu}{\nu(1+\lambda\nu^6-\sigma\nu^3)}\,. \tag{26}$$

This time we multiply both sides of (23) by $2\nu^{-1}M^2e^{\nu/M}a/(1+\lambda\nu^6-\sigma\nu^3)$, integrate for $\nu>0$, and obtain

$$\begin{aligned}&\frac{d}{dt}A(t)+2\int_{\nu=0}^{\infty}\frac{M^2e^{\nu/M}a^2(t,\nu)}{\nu^4}\,d\nu\\ &=2\int_{\nu=0}^{\infty}\frac{a(t,\nu)}{1+\lambda\nu^6-\sigma\nu^3}\,d\nu\,\alpha(t)\;-2\sigma A(t)\,.\end{aligned}\tag{27}$$

Using (25) and completing the square, we write the penultimate term as

$$\begin{aligned}&2\int_{\nu=0}^{\infty}\frac{a(t,\nu)}{1+\lambda\nu^6-\sigma\nu^3}\,d\nu\,\alpha(t)\\ &=-\frac{2}{R}\left(\int_{\nu=0}^{\infty}\frac{a(t,\nu)}{1+\lambda\nu^6-\sigma\nu^3}\,d\nu\;-\frac{1}{2}C_1e^{-\sigma t}\right)^2+\frac{C_1^2}{2R}e^{-2\sigma t}\,.\end{aligned}\tag{28}$$

Inserting (26) and (28) into (27) yields

$$\begin{aligned}&\frac{d}{dt}A(t)+2\sigma A(t)+2\int_{\nu=0}^{\infty}\frac{M^2e^{\nu/M}a^2(t,\nu)}{\nu^4}\,d\nu\\ &+\frac{2}{R}\left(\int_{\nu=0}^{\infty}\frac{a(t,\nu)}{1+\lambda\nu^6-\sigma\nu^3}\,d\nu\;-\frac{1}{2}C_1e^{-\sigma t}\right)^2=\frac{C_1^2}{2R}e^{-2\sigma t}\,.\end{aligned}$$

Neglecting the integral terms gives a differential inequality for $A(t)$ with the solution

$$A(t)\le\left(A(0)+\frac{C_1^2}{2R}\,t\right)e^{-2\sigma t}\,.$$

In the arguments below it is inconvenient to carry the term proportional to t. However, as $te^{-\sigma t/5}\le 5/(\sigma e)$ for $t\ge 0$ we can use the weaker result

$$A(t)\le\left(A(0)+\frac{C_1^2}{R\sigma}\right)e^{-1.8\sigma t}\,.\tag{29}$$

Our next task is to estimate $\alpha(t)$ and $a(t,\nu)$. Using Cauchy–Schwarz in (25), we see that

$$\begin{aligned}|\alpha(t)|&=\frac{1}{R}\left|C_1e^{-\sigma t}-\int_{\nu=0}^{\infty}\frac{a(t,\nu)}{1+\lambda\nu^6-\sigma\nu^3}\,d\nu\right|\\ &\le\frac{1}{R}\left[|C_1|e^{-\sigma t}+\left(\int_{\nu=0}^{\infty}\frac{M^2e^{\nu/M}a^2(t,\nu)}{\nu(1+\lambda\nu^6-\sigma\nu^3)}\,d\nu\right)^{1/2}\right.\\ &\qquad\left.\times\left(\int_{\nu=0}^{\infty}\frac{\nu e^{-\nu/M}}{M^2(1+\lambda\nu^6-\sigma\nu^3)}\,d\nu\right)^{1/2}\right].\end{aligned}$$

In the product, the first integral is $A(t)$, while the second is $1-R\sigma$; see (26) and Lemma 3. Since $R\sigma<1$ and $\sqrt{a+b}\le\sqrt{a}+\sqrt{b}$, we find from (29) that

$$\begin{aligned}|\alpha(t)|&\le\frac{1}{R}\left[|C_1|e^{-\sigma t}+\left(A(0)+\frac{C_1^2}{R\sigma}\right)^{1/2}e^{-0.9\sigma t}(1-R\sigma)^{1/2}\right]\\ &\le\frac{1}{R}\left[\sqrt{A(0)}+\frac{2|C_1|}{\sqrt{R\sigma}}\right]e^{-0.9\sigma t}\\ &=C_2e^{-0.9\sigma t}\,.\end{aligned}\tag{30}$$

To estimate $a(t,\nu)$ we rewrite (23) as

$$a(t,\nu) = e^{-(\nu^{-3}+\lambda\nu^3)t}a(0,\nu) + \int_{s=0}^{t} \frac{\nu e^{-\nu/M}}{M^2} e^{-(\nu^{-3}+\lambda\nu^3)(t-s)}\alpha(s)ds\,.$$

Using (30) and integrating with respect to s, we obtain

$$|a(t,\nu)| \le e^{-(\nu^{-3}+\lambda\nu^3)t}|a(0,\nu)| + \frac{\nu e^{-\nu/M}}{M^2}\, C_2\, \frac{e^{-0.9\sigma t} - e^{-(\nu^{-3}+\lambda\nu^3)t}}{\nu^{-3}+\lambda\nu^3 - 0.9\sigma}\,.$$

Since $1+\lambda\nu^6-\sigma\nu^3 > \eta^2$ (see Lemma 3), it follows that $-(\nu^{-3}+\lambda\nu^3) < -0.9\sigma$ and

$$\begin{aligned} |a(t,\nu)| &\le \frac{\nu^4 e^{-\nu/M}}{M^2}\left(b_k + \frac{C_2}{\eta^2}\right) e^{-0.9\sigma t} \\ &= \frac{\nu^4 e^{-\nu/M}}{M^2}\, C_3\, e^{-0.9\sigma t}\,. \end{aligned} \tag{31}$$

Next, we derive bounds for $A(0)$, C_1, C_2, and C_3. After setting $t=0$ in (26) and recalling the assumption $|a(0,\nu)| \le \nu^4 M^{-2} e^{-\nu/M} b_k$, it follows from Lemma 3 that

$$\begin{aligned} |A(0)| &\le \int_{\nu=0}^{\infty} \frac{\nu^7\, e^{-\nu/M} b_k^2}{M^2(1+\lambda\nu^6-\sigma\nu^3)}\, d\nu \\ &\le \frac{7!\, M^6\, b_k^2}{\eta^2}\,. \end{aligned}$$

Similar arguments applied to (25) give

$$\begin{aligned} |C_1| &\le R|\alpha(0)| + \int_{\nu=0}^{\infty} \frac{|a(0,\nu)|}{1+\lambda\nu^6-\sigma\nu^3}\, d\nu \\ &\le \left(R + \frac{24\, M^3}{\eta^2}\right) b_k. \end{aligned}$$

Combining these bounds, we conclude from (30) and (31) that

$$\begin{aligned} C_2 &\le \frac{1}{R}\left[\frac{71M^3}{\eta} + \frac{2}{\sqrt{R\sigma}}\left(R + \frac{24\, M^3}{\eta^2}\right)\right] b_k \quad \text{and} \\ C_3 &\le \left(1 + \frac{1}{R\eta^2}\left[\frac{71M^3}{\eta} + \frac{2}{\sqrt{R\sigma}}\left(R + \frac{24\, M^3}{\eta^2}\right)\right]\right) b_k. \end{aligned} \tag{32}$$

So far we have assumed that k is fixed. However, note that M, R, and η are independent of k. Since $\lambda_1 \le \lambda_2 \le \cdots$ and $\sigma(\lambda)$ is an increasing function of λ, we see that $\sigma(\lambda_1) \le \sigma(\lambda_k)$ for $k \ge 1$. Thus, if we replace σ by $\sigma(\lambda_1)$ in the bounds for C_2, C_3, we find that $C_2,\, C_3 \le C_4\, b_k$, where C_4 is independent of k. Observe also that the slowest decay in (30), (31) occurs for $\sigma = \sigma(\lambda_1)$, where λ_1 is the eigenvalue of the lowest spatially varying eigenmode.

Finally, we must reassemble the Fourier series for u', T'. Since $\sum_{k=1}^{\infty} b_k^2 < \infty$, it follows from (22), (31), and (32) that

$$\begin{aligned} \|u'(x,t,\nu)\|_{L^2(U)} &= \left\| \sum_{k=1}^{\infty} a_k(t,\nu)\, e_k(x) \right\|_{L^2(U)} \\ &= \left(\sum_{k=1}^{\infty} a_k^2(t,\nu) \right)^{1/2} \\ &\le \frac{\nu^4 e^{-\nu/M}}{M^2}\, C\, e^{-0.9\sigma t}\,, \end{aligned}$$

where $C = C_4 \left(\sum b_k^2\right)^{1/2}$. We can use the same arguments for T'. This completes the proof. □

5. Asymptotic stability. In section 4, we linearized (10)–(12) around a stationary solution and showed that the solution of the linearized equations tends to zero exponentially. We therefore expect that for every ν the solutions of the original equations will be approximately constant as times increases. In this section we consider a class of functions which are independent of x and show that they tend to a stationary solution. The stationary solution is therefore asymptotically stable for this class of initial data.

THEOREM 3. *Let $u(t,\nu)$, $T(t)$ be independent of x and satisfy* (10)–(11) *and the bounds in Lemma* 1. *If*

$$R\,T(0) + \int_{\nu=0}^{\infty} u(0,\nu)\,d\nu \;=\; R\,M + 6M^4 \tag{33}$$

and

$$\left(\int_{\nu=0}^{\infty} \frac{M^2\,e^{\nu/M}}{\nu}\,|u(0,\nu) - \nu^3 e^{-\nu/M}|^2\,d\nu\right)^{1/2} < \frac{RM}{7}, \tag{34}$$

then

$$\begin{aligned} u(t,\nu) &\to \nu^3 e^{-\nu/M} \qquad && as\ t \to \infty,\ \nu > 0\ fixed, \\ T(t) &\to M && as\ t \to \infty\,. \end{aligned}$$

Proof. As in the proof of Theorem 2 we set $u' = u - \nu^3 e^{-\nu/M}$ and $T' = T - M$, but now we do not assume that u', T' are small. It follows from (10)–(11) and the constraint (33) that

$$\frac{\partial}{\partial t}u'(t,\nu) + \frac{1}{\nu^3}u'(t,\nu) = e^{-\nu/[M+T'(t)]} - e^{-\nu/M}, \tag{35}$$

$$R\frac{d}{dt}T'(t) + T'(t) = \int_{\nu=0}^{\infty} \frac{u'}{\nu^3}\,d\nu, \tag{36}$$

$$R\,T'(t) + \int_{\nu=0}^{\infty} u'(t,\nu)\,d\nu = 0. \tag{37}$$

Equation (37) follows from the energy conservation property. We proceed as in the previous proof. This time we derive a differential inequality for

$$A(t) = \int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M}}{\nu}|u'(t,\nu)|^2\,d\nu \tag{38}$$

and show that $A(t)$ decays. The function $A(t)$ defined in (38) is the analogue of the one defined in (26), except now we are considering the $\lambda = 0$ case, which according to Lemma 3 corresponds to $\sigma = 0$. Note that (34) and (38) imply that

$$0 < A(0) < (RM/7)^2\,. \tag{39}$$

Using Cauchy–Schwarz in (37) yields

$$\begin{aligned} R|T'(t)| &\le \int_{\nu=0}^{\infty} |u'(t,\nu)|\, d\nu \\ &\le \left(\int_{\nu=0}^{\infty} \frac{\nu e^{-\nu/M}}{M^2}\, d\nu\right)^{1/2} \left(\int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M}}{\nu} |u'(t,\nu)|^2\, d\nu\right)^{1/2} \\ &= 1 \cdot \sqrt{A(t)}\,. \end{aligned} \tag{40}$$

To analyze (35), we expand the right-hand side using Taylor's formula,

$$\begin{aligned} e^{-\nu/(M+T')} - e^{-\nu/M} &= \frac{\nu e^{-\nu/M}}{M^2}\, T' \\ &+ \frac{1}{2}\, e^{-\nu/(M+\theta T')} \left[\frac{\nu^2}{(M+\theta T')^4} - \frac{2\nu}{(M+\theta T')^3}\right] (T')^2\,, \end{aligned} \tag{41}$$

where $0 < \theta < 1$.

We now prove that $|T'(t)| < M/7$ for all t and do this by contradiction. Equations (40), (38), and (39) show that at least for small t,

$$|T'(t)| \;\le\; R^{-1}\sqrt{A(t)} < M/7.$$

Let $t = t_2$ be the first time for which the inequality fails; thus, $|T'(t_2)| = M/7$. Since $|T'(t)| \le M/7$ for $t \le t_2$, we see that the absolute value of the term multiplying $(T')^2$ in (41) is bounded by

$$N(\nu) = \frac{1}{2}\, e^{-7\nu/(8M)} \left[\frac{\nu^2}{(6M/7)^4} + \frac{2\nu}{(6M/7)^3}\right].$$

Hence, there exists a $\gamma(\nu)$ with $|\gamma| \le 1$ such that

$$e^{-\nu/(M+T')} - e^{-\nu/M} = \frac{\nu e^{-\nu/M}}{M^2}\, T' + \gamma\, N(\nu)\, (T')^2\,.$$

Inserting this expression in (35), multiplying both sides by $\nu^{-1} M^2 e^{\nu/M} u'(t,\nu)$, and integrating over $\nu > 0$, we find

$$\begin{aligned} &\frac{1}{2}\,\frac{d}{dt} \int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M}}{\nu} |u'|^2\, d\nu + \int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M}}{\nu^4} |u'|^2\, d\nu \\ &= \left(\int_{\nu=0}^{\infty} u' d\nu\right) T' + \left(\int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M}}{\nu}\, u'\, \gamma\, N(\nu)\, d\nu\right) (T')^2\,. \end{aligned} \tag{42}$$

Note that the first term is $(1/2)dA/dt$. Let E_1, E_2 denote the terms on the right-hand side of (42). It is clear from (37) that $E_1 = -R\,[\,T'(t)\,]^2$. To estimate E_2, we recall that $|\gamma| \le 1$, apply Cauchy–Schwarz, and get

$$\begin{aligned} |E_2| &\le \left(\int_{\nu=0}^{\infty} \frac{M^2 e^{\nu/M}}{\nu} |u'(t,\nu)|^2\, d\nu\right)^{1/2} \\ &\quad \times \left(\int_{\nu=0}^{\infty} \left[\frac{M\, e^{\nu/(2M)}}{\sqrt{\nu}}\, N(\nu)\right]^2 d\nu\right)^{1/2} (T')^2\,. \end{aligned}$$

The first integral is $A(t)$ (see (38)), while an elementary but tedious calculation shows that the second integral is less than $36/M^2$. Thus, $|E_2| \le (6/M)\sqrt{A(t)}$. Inserting the expressions for E_1, E_2 in (42), we obtain the desired differential inequality

$$\frac{1}{2}\frac{d}{dt}A(t) + \int_{\nu=0}^{\infty} \frac{M^2\, e^{\nu/M}}{\nu^4} |u'(t,\nu)|^2\, d\nu + \left(R - \frac{6}{M}\sqrt{A(t)}\right) |\, T'(t)\,|^2 \le 0. \tag{43}$$

We note that for the linearized problem discussed in the previous section, we would have arrived at the same inequality, but without the term $(6/M)\sqrt{A(t)}$ and with u', T' replaced by a_0, α_0.

Equations (39) and (43) show that $A(t)$ is a decreasing function of t for $t \le t_2$. Thus, $A(t)^2 \le A(0)^2 < RM/7$. However, (40) shows that $|T'(t)| \le R^{-1}\sqrt{A(t)} < M/7$ for $0 \le t \le t_2$, which contradicts the definition of t_2. Thus, the bound

$$|T'(t)| \le M/7 \tag{44}$$

holds for all time.

We now show that $T'(t)$ decays to zero. If in (43) we ignore the middle term, note that $R - 6\sqrt{A(t)}/M > R/7$, and integrate, we obtain

$$A(t) + 2\int_{\tau=0}^{t} \frac{R}{7}\, |T'(\tau)|^2\, d\tau \le A(0)\,.$$

The function $|T'(t)|^2$ is therefore integrable on $(0,\infty)$. However, this is insufficient for our purposes since we wish to show that $T'(t) \to 0$ as $t \to \infty$ (which implies $T \to M$).

To prove $T' \to 0$, we first show that $|(d/dt)[T'(t)]^2|$ is bounded. Equation (44) leads to

$$\left|\frac{d(T')^2}{dt}\right| \le 2\,|T'(t)|\, \left|\frac{dT'}{dt}\right| \le \frac{2M}{7}\, \left|\frac{dT'}{dt}\right|. \tag{45}$$

Using (36), (44), and the definition of $u'(x,\nu)$, we obtain

$$\left|\frac{dT'}{dt}\right| \le \frac{1}{R}\, \left[\frac{M}{7} + \left|\int \nu^{-3}\,(u - \nu^3 e^{-\nu/M})\, d\nu\right|\right].$$

If T_2 is the upper bound defined in Lemma 1, then $\max(\,M,\, T_2 - M) < T_2$ bounds the last integral. Substituting these results into (45) yields

$$|(d/dt)[T'(t)]^2| \le (2M/7)\,(1/R)\,(T_2 + M/7) \doteq c\,.$$

Thus, the function $|T'(t)|^2$ is integrable and has a uniformly bounded derivative. Clearly, $|T'(t)|^2$, for large t, cannot stray too far from zero. In fact, for any $\epsilon > 0$, $|T'(t)|^2$ can only have a finite number of spikes above ϵ no less than $2\epsilon/c$ apart, because every neighborhood with radius ϵ/c of a spike contributes at least ϵ^2/c toward the area under the curve. Thus $|T'(t)|^2 < \epsilon$ for t sufficiently large.

To show that $u' \to 0$ when ν is fixed and $t \to \infty$, we solve (35) and get

$$\begin{aligned} u'(t,\nu) &= e^{-t/\nu^3}\, u'(0,\nu) + \int_{\tau=0}^{t} e^{-(t-\tau)/\nu^3}\, \left(e^{-\nu/[M+T'(\tau)]} - e^{-\nu/M}\right) d\tau \\ &\doteq E_3 + E_4\,. \end{aligned}$$

Clearly $E_3 \to 0$ as $t \to \infty$. For E_4 we use l'Hôpital. Since $e^{t/\nu^3} \to \infty$ and $T'(t) \to 0$ as $t \to \infty$, it follows that

$$\lim_{t\to\infty} E_4(t) = \lim_{t\to\infty} \frac{\int_{\tau=0}^{t} e^{\tau/\nu^3} \left(e^{-\nu/[M+T'(\tau)]} - e^{-\nu/M} \right) d\tau}{e^{t/\nu^3}}$$

$$= \lim_{t\to\infty} \frac{e^{-\nu/[M+T'(t)]} - e^{-\nu/M}}{(1/\nu^3)} = 0\,.$$

Combining the results for E_3, E_4 completes the argument. Our proof is nonconstructive and gives no rate of convergence. However, numerical experiments indicate very slow convergence. This completes the proof. □

6. Concluding remarks. We have derived a nondimensional form of the system that couples the multifrequency radiation diffusion equations to the matter energy balance equation. In deriving the nonlinear system, we strived for equations that preserve the salient properties of the underlying physics yet are amenable to analysis. Our equations may be applied in multiple spatial dimensions and arbitrarily sized domains on which one may impose boundary conditions appropriate to parabolic systems.

Our nondimensional system conserves total energy and a unique stationary solution is eventually established. For homogeneous Neumann boundary conditions, the stationary solution is spatially constant. We have shown that the decay to equilibrium is constrained by an envelope whose extent depends on the initial conditions. Spatially varying perturbations about the stationary solution decay to zero exponentially. Spatially constant perturbations also decay. However, we are unable to estimate the speed of decay; it may be very slow.

Although our nondimensional system is a valid model for multifrequency radiation diffusion, it is instructive to recall how it differs from equations typically used in high energy density computer codes.

We assume the matter to be composed of a single material, of constant density, characterized by an ideal gas equation-of-state. For "real" materials, the internal energy is a nonlinear function of temperature [12, p. 177]. This implies a temperature dependence for the specific heat, $c_{\rm v} = c_{\rm v}(T)$. Recalling (7), we obtain the dependence $R = R(T)$ for our model.

If matter density were to vary with position, so would the opacities. This implies spatial variations for the diffusion coefficient ν^3 in (8), the coupling coefficient $1/\nu^3$ in (8)–(9), and the coefficient R in (9). For real materials, especially for those of high atomic number and/or at low temperatures, the opacity is a complicated nonmonotonic function of frequency [12, p. 246]. Most notably, it features occasional spikes corresponding to the "bound-bound" transitions of the electrons.

Our model ignores the $1/\sqrt{T}$ dependence of the opacity. As we show below, including $1/\sqrt{T}$ leads to spatial variations of the diffusion and coupling coefficients. This complicates the analysis significantly. We are then unable to invoke Duhamel's principle since a general Green's function $G_\nu(x, y, t)$ does not exist.

We chose a Wien $\nu^3 e^{-\nu/T}$ rather than a Planck $\nu^3/(e^{\nu/T} - 1)$ distribution for radiation emission. The difference between the two is most pronounced for small ν yielding a smaller radiation source. However, since our absorption opacity ignores induced emission [12], multiplying our κ_ν by a Wien distribution gives the correct total radiation source if we ignore the $1/\sqrt{T}$ dependence of the opacity. To see this,

recall that to include induced emission, one multiplies κ_ν by the factor $(1 - e^{-y})$, where $y = h\nu/kT$. Then, if instead of (6) we use the Planck function, the exponential is replaced by the factor $1/(e^y - 1)$. Hence, if B_ν denotes the Planck function and κ'_ν the absorption coefficient corrected for stimulated emission, the $(e^y - 1)$ factors cancel and we obtain the same total radiation source,

$$c \int_0^\infty d\nu\, \kappa'_\nu\, B_\nu = \text{const}\, T.$$

Choosing a Wien rather than a Planck function brings an additional benefit when the system is discretized in the frequency direction in order to derive the "multigroup" equations. For this endeavor, one defines a spectral mesh

$$0 = \nu_0 < \nu_1 < \cdots < \nu_N.$$

If B_ν is the Wien function, integrals of the form

$$\int_{\nu_{j-1}}^{\nu_j} d\nu\, \nu^n\, B_\nu$$

can be done analytically. If B_ν is the Planck function, the integrals can only be approximated.

Last, we did not include a flux limiter in the diffusion coefficient. This leads to unphysically large photon speeds for our model, especially for those with high frequencies. To incorporate a flux limiter into our model, we note that (physically) the distance x that radiation can travel in a time interval t is limited by $x \le c\,t$. Recalling the nondimensional variables x' and t', the inequality reduces to $x' \le \sqrt{3}\, t'$. Hence, if we introduce a Lund–Wilson-type flux limiter, our nondimensional flux becomes

$$-\nu^3\, \nabla u \to \frac{-1}{1/(\nu^3\, \sqrt{T}) + |\nabla u|/(\sqrt{3}\, u)}\, \nabla u \doteq -D_\nu\, \nabla u. \tag{46}$$

Note that we have kept the dependence of κ_ν on $1/\sqrt{T}$.

We conclude the discussion of how to modify our model to account for some of the above effects. If we include the $\sqrt{T}$ dependence of the opacity, allow for a nonconstant c_v, write the emission function in the general form $B_\nu = B_0\, \nu^3\, g(\nu/T)$, but do not include effects of stimulated emission, the nondimensional equations become

$$\partial_t u = \nabla \cdot D_\nu \nabla u + \left(\nu^3\, g(\nu/T) - u\right) / \sqrt{T}\, \nu^3,$$
$$R(T)\, \partial_t T = -\frac{1}{\sqrt{T}} \left(\int_0^\infty d\nu\, \frac{1}{\nu^3} (\nu^3\, g(\nu/T) - u) \right),$$

where D_ν may be defined as in (46), with or without the flux limiter and/or the $\sqrt{T}$ factor, and $g(y)$ is chosen appropriate to either the Wien or Planck distribution.

The analysis described in this paper was motivated by an unexpected result from simulations and [10] and [11], which solve the multigroup system derived from (8)–(9). The papers simulate the relaxation to steady state of an initial condition in which the two fields, u and T, are wildly out of equilibrium.

In the problem of interest, the spatial domain is $|x| < 1$. Initially, T is sharply peaked:

$$T|_{t=0} = \begin{cases} 6.4775 & \text{if } |x| < 0.04, \\ 0.0027 & \text{otherwise.} \end{cases}$$

Using a "specific heat" $R = 2.0$ yields an initial matter energy $\mathcal{E}_m(t)|_{t=0} = 1.0469$. The spectral radiation energy density u is initialized with a Wien profile characterized with a spatially constant "radiation temperature" $T_r = 0.0172$. Hence, the initial radiation energy $\mathcal{E}_r(0) = 1.0469 \cdot 10^{-6}$. The conditions imply that initially 99% of the total energy $\mathcal{E}_m + \mathcal{E}_r$ is contained in the central region $|x| < 0.04$. The problem is designed so that the stationary solution consists of spatially uniform fields with the matter energy equal to 1, i.e., with $T = 0.25$.

In the simulation, the hot central region pumps a prodigious amount of energy into the high frequencies. (This is a result consistent with the Wien profile which peaks at $\nu/T = 3$.) The high frequencies are characterized by fast transport. Thus, this energy quickly diffuses away from the hot spot. However, the high frequency energy is slow to absorb since the coupling coefficient is $1/\nu^3$. In effect, the high frequency energy is trapped for a time proportional to ν^3. Because of the trapping, the ratio $\mathcal{E}_r(t)/\mathcal{E}_m(t)$ exhibits a surprising behavior. It quickly rises to approximately 0.6 (more than 10 times the equilibrium value), then gradually decays, albeit very slowly. That very slow relaxation to equilibrium is the subject of section 5. During the slow-relaxation phase, the fields have little spatial variation.

Acknowledgments. Aleksei I. Shestakov is extremely grateful to Prof. Alexandre Chorin of the Mathematics Department of the University of California at Berkeley and the Lawrence Berkeley Laboratory for numerous discussions, suggestions, and the opportunity to pursue this work in the intellectually stimulating environment of the Mathematics Department of the Lawrence Berkeley Laboratory. We also thank the referee(s) for numerous suggestions. When we started the project, we were unaware of the analytical work of Andreev, Kozmanov, and Rachilov [1], Mercier [8], Larsen and Mercier [6], and Densmore and Larsen [3]. We hope that our contribution will complement those papers.

ON THE FRÉCHET DERIVATIVE FOR OBSTACLE SCATTERING WITH AN IMPEDANCE BOUNDARY CONDITION*

HOUSSEM HADDAR† AND RAINER KRESS‡

Abstract. A technique introduced by Kress and Päivärinta to establish differentiability of the solution to obstacle scattering problems with respect to the boundary is extended to the case of the impedance boundary condition. For acoustic scattering an alternative proof of a differentiability result due to Hettlich is provided, and in electromagnetic scattering a new differentiability result is proven.

Key words. Helmholtz equation, Maxwell equations, acoustic scattering, electromagnetic scattering, obstacle scattering, impedance condition, far field pattern, inverse scattering, Fréchet derivative

1. Introduction.

In time-harmonic inverse obstacle scattering, for the mathematical foundation and implementation of approximate solution methods by regularized iteration schemes via linearization, it is necessary to investigate the differentiability of the boundary to far field operator that maps the boundary of the obstacle onto the far field pattern of the scattered wave. In acoustic scattering, differentiability with respect to the boundary was considered by Roger [18], who first employed Newton-type iterations for inverse obstacle scattering problems. Rigorous foundations for the Fréchet differentiability including characterizations of the derivative both for the Dirichlet and Neumann boundary condition, i.e., for sound-soft and sound-hard obstacles, were given by Kirsch [7] and Hettlich [3] in the sense of a domain derivative via variational methods and by Potthast [15, 16] via boundary integral equation techniques. Alternative proofs were contributed by Hohage [6] and Schormann [19] via the implicit function theorem and by Kress and Päivärinta [11] via Green's theorems and a factorization of the difference of the far field for neighboring domains. Hettlich [3] also established differentiability for the impedance boundary condition.

In electromagnetic obstacle scattering from perfect conductors Fréchet differentiability was considered by Potthast [17] via boundary integral equations. Hettlich [5] treated the transmission problem for penetrable obstacles via variational methods. The technique due to Kress and Päivärinta was extended to the Maxwell equations for the perfect conductor case in [9]. The impedance boundary condition for electromagnetic obstacle scattering has not yet been considered in the literature.

It is the purpose of the present paper to extend the method introduced by Kress and Päivärinta to the case of the impedance boundary condition. In section 2 we will reestablish the results of Hettlich through an alternative proof, and in section 3 we will establish Fréchet differentiability with respect to the boundary for the electromagnetic impedance problem and provide a characterization of the derivative. In principle, one of the key ideas of the method is to extend the continuous dependence of the

solution on the boundary that can be obtained via boundary integral equations to differentiability via the application of Green's integral and Green's representation theorems.

The paper will be concluded with a few remarks on the difficulties that arise in connection with investigating the nullspace of the linearization, i.e., the Fréchet derivative.

2. Impedance problem in acoustic scattering. Let $D \subset \mathbb{R}^3$ be a bounded domain with a connected boundary ∂D of class C^2 and outward unit normal ν. Consider the exterior impedance boundary value problem for acoustic waves: Given a continuous function f on ∂D and a constant $\lambda \in \mathbb{C}$ find a solution $v \in C^2(\mathbb{R}^3 \setminus \bar{D}) \cap C^1(\mathbb{R}^3 \setminus D)$ to the Helmholtz equation

$$\triangle v + k^2 v = 0 \quad \text{in } \mathbb{R}^3 \setminus \bar{D} \tag{2.1}$$

with wave number $k > 0$ that satisfies the impedance boundary condition

$$\frac{\partial v}{\partial \nu} + ik\lambda v = f \quad \text{on } \partial D \tag{2.2}$$

and the Sommerfeld radiation condition

$$\lim_{r\to\infty} r\left(\frac{\partial v}{\partial r} - ikv\right) = 0, \quad r = |x|, \tag{2.3}$$

uniformly for all directions. The impedance coefficient λ is assumed to satisfy the condition

$$\operatorname{Re}\lambda \geq 0 \tag{2.4}$$

that ensures uniqueness of a solution via Rellich's lemma. For existence of a solution we refer to [1, 2].

For an impedance obstacle D the scattering problem for time-harmonic waves is, given an incident field u^i as an entire solution of the Helmholtz equation, to find the total field $u = u^i + u^s$ as a solution to the Helmholtz equation in the exterior $\mathbb{R}^3 \setminus \bar{D}$ of D, such that u satisfies the impedance boundary condition

$$\frac{\partial u}{\partial \nu} + ik\lambda u = 0 \quad \text{on } \partial D$$

and u^s fulfills the Sommerfeld radiation condition. Clearly, this scattering problem is a special case of the above boundary value problem (2.1)–(2.3).

We introduce the fundamental solution to the Helmholtz equation in $\mathbb{R}^3$ by

$$\Phi(x,y) := \frac{1}{4\pi}\,\frac{e^{ik|x-y|}}{|x-y|}\,, \quad x \neq y.$$

For $x \in \mathbb{R}^3 \setminus \bar{D}$ let $w^s(x,\cdot)$ be the solution of (2.1)–(2.3) for the boundary values

$$f = -\frac{\partial \Phi(x,\cdot)}{\partial \nu} - ik\lambda\Phi(x,\cdot) \quad \text{on } \partial D$$

and let $w(x,\cdot) := \Phi(x,\cdot) + w^s(x,\cdot)$; that is, $w^s(x,\cdot)$ and $w(x,\cdot)$ are the scattered and the total field, respectively, for the scattering of a point source located at $x \in \mathbb{R}^3 \setminus \bar{D}$.

Note that the function w is the Green function for the boundary value problem (2.1)–(2.3) and that it enjoys the symmetry, i.e., the reciprocity

$$w(x,y) = w(y,x), \quad x, y \in \mathbb{R}^3 \setminus \bar{D},\ x \neq y,$$

which can be easily derived from Green's integral theorem. From Green's representation theorem and Green's integral formula it follows that (see also the proof of the following lemma) the unique solution of the impedance boundary value problem (2.1)–(2.3) can be represented in the form

$$v(x) = -\int_{\partial D} w(x,y) f(y)\, ds(y), \quad x \in \partial D. \tag{2.5}$$

We now consider a family of scatterers D_h with boundaries represented in the form

$$\partial D_h = \{x + h(x) : x \in \partial D\}, \tag{2.6}$$

where $h : \partial D \to \mathbb{R}^3$ is of class C^2. Provided h is sufficiently small in the C^2 norm on ∂D, then ∂D_h is well defined and the boundary of a C^2 domain D_h. By ν_h we denote its exterior unit normal and, in what follows, we will distinguish the above quantities related to the impedance scattering problem for the domain D_h through the subscript h.

LEMMA 2.1. *Assume that $\bar{D} \subset D_h$. Then*

$$u_h^s(x) - u^s(x) = \int_{\partial D_h} u_h \left\{ \frac{\partial w(x,\cdot)}{\partial \nu_h} + ik\lambda w(x,\cdot) \right\} ds \tag{2.7}$$

for $x \in \mathbb{R}^3 \setminus \bar{D}_h$.

Proof. Let $x \in \mathbb{R}^3 \setminus \bar{D}_h$. Combining Green's integral theorem for the incident field u^i and Green's representation theorem for the scattered field u^s we have that

$$u^s(x) = \int_{\partial D} \left\{ u\, \frac{\partial \Phi(x,\cdot)}{\partial \nu} - \Phi(x,\cdot)\, \frac{\partial u}{\partial \nu} \right\} ds. \tag{2.8}$$

From the impedance boundary condition for u and $w(x,\cdot)$ by straightforward calculations we obtain

$$u\, \frac{\partial \Phi(x,\cdot)}{\partial \nu} - \Phi(x,\cdot)\, \frac{\partial u}{\partial \nu} = -u\, \frac{\partial w^s(x,\cdot)}{\partial \nu} + w^s(x,\cdot)\, \frac{\partial u}{\partial \nu} \quad \text{on } \partial D.$$

Hence, using Green's integral theorem and the radiation condition, (2.8) implies that

$$u^s(x) = -\int_{\partial D} \left\{ u^i\, \frac{\partial w^s(x,\cdot)}{\partial \nu} - w^s(x,\cdot)\, \frac{\partial u^i}{\partial \nu} \right\} ds \tag{2.9}$$

and then again via Green's theorem

$$u^s(x) = -\int_{\partial D_h} \left\{ u^i\, \frac{\partial w^s(x,\cdot)}{\partial \nu_h} - w^s(x,\cdot)\, \frac{\partial u^i}{\partial \nu_h} \right\} ds. \tag{2.10}$$

From this, once again using Green's integral theorem and the radiation condition, we find that

$$u^s(x) = -\int_{\partial D_h} \left\{ u_h\, \frac{\partial w^s(x,\cdot)}{\partial \nu_h} - w^s(x,\cdot)\, \frac{\partial u_h}{\partial \nu_h} \right\} ds$$

and in view of the boundary condition for u_h we finally arrive at

$$u^s(x) = -\int_{\partial D_h} u_h \left\{ \frac{\partial w^s(x,\cdot)}{\partial \nu_h} + ik\lambda w^s(x,\cdot) \right\} ds.$$

On the other hand, from (2.8) applied to u_h and ∂D_h and the boundary condition for u_h we have that

$$u_h^s(x) = \int_{\partial D_h} u_h \left\{ \frac{\partial \Phi(x,\cdot)}{\partial \nu_h} + ik\lambda \Phi(x,\cdot) \right\} ds \tag{2.11}$$

and the statement (2.7) follows by combining the last two equations. □

Remark 2.2. We note that (2.7) remains valid for $x \notin \bar{D} \cup \bar{D}_h$ if we drop the assumption that $\bar{D} \subset D_h$ and assume that w^s can be extended as a solution to the Helmholtz equation in the exterior of D_h. By Theorem 5.7.1′ in [13, p. 169], this can be assured if ∂D is analytic and D_h does not differ too much from D. In this case, obviously, (2.10) follows from (2.9) via Green's theorem by introducing the corresponding integral over a sufficiently large sphere as an intermediate step. □

In a neighborhood of ∂D we introduce a coordinate system via

$$z = x + t\nu(x), \quad x \in \partial D,\ t \in [-T, T], \tag{2.12}$$

with some sufficiently small $T > 0$. Straightforward calculations show that the determinant G of the metric in the neighborhood

$$U_T := \{z = x + t\nu(x) : x \in \partial D,\ t \in [-T, T]\}$$

and the determinant g of the metric on ∂D are related via

$$G(z) = g(x)[1 - 2tH(x) + t^2 K(x)]^2, \tag{2.13}$$

where H denotes the mean curvature and K the Gaussian curvature of the surface ∂D (with respect to the exterior normal direction). In the neighborhood U_T we define an extension ν of the exterior unit normal ν to ∂D by setting

$$\nu(x + t\nu(x)) := \nu(x), \quad x \in \partial D,\ t \in [-T, T].$$

If we chose an orthonormal coordinate system at the point $x \in \partial D$, then we have that

$$\operatorname{div} \nu(x) = \frac{1}{\sqrt{G(z)}} \left. \frac{\partial \sqrt{G(z)}}{\partial t} \right|_{t=0}$$

and therefore (2.13) implies that

$$\operatorname{div} \nu = -2H \quad \text{on } \partial D. \tag{2.14}$$

We would like to point out that, in the literature, there is some ambiguity for the sign in the definition of the mean curvature. In this paper, in order to be consistent with [1, 3, 5] we choose the sign according to the classical definition in differential geometry. However, other authors prefer a definition where the sign in (2.14) is reversed (see, for example, Nédélec [14]).

We assume that h is small enough to ensure that ∂D_h is contained in U_T. For the further analysis we need to relate the normal ν_h to ∂D_h and the extended normal ν. To achieve this, we consider a fixed point $x_0 \in \partial D$ and a local parameterization

$$\partial D \cap V = \{\varphi(\xi) : \xi \in U\}$$

for a neighborhood V of x_0 and an open set $U \subset \mathbb{R}^2$. For convenience, we may assume that $\varphi(0) = x_0$ and that the tangential vectors satisfy

$$\left|\frac{\partial \varphi}{\partial \xi_1}(0)\right| = \left|\frac{\partial \varphi}{\partial \xi_2}(0)\right| = 1, \quad \frac{\partial \varphi}{\partial \xi_1}(0) \cdot \frac{\partial \varphi}{\partial \xi_2}(0) = 0,$$

and

$$\nu(x_0) = \frac{\partial \varphi}{\partial \xi_1}(0) \times \frac{\partial \varphi}{\partial \xi_2}(0).$$

The perturbed boundary ∂D_h is locally described by

$$\psi(\xi) = \varphi(\xi) + \tilde{h}(\xi), \quad \xi \in U,$$

where $\tilde{h} = h \circ \varphi$. We compute

$$\frac{\partial \psi}{\partial \xi_1}(0) \times \frac{\partial \psi}{\partial \xi_2}(0) = \nu(x_0) + \delta + O\left(\|h\|^2_{C^1(\partial D)}\right),$$

where we have set

$$\delta := \frac{\partial \tilde{h}}{\partial \xi_1}(0) \times \frac{\partial \varphi}{\partial \xi_2}(0) + \frac{\partial \varphi}{\partial \xi_1}(0) \times \frac{\partial \tilde{h}}{\partial \xi_2}(0).$$

From this it follows that

$$\nu_h(x_0 + h(x_0)) = \nu(x_0) + \delta - [\nu(x_0) \cdot \delta]\, \nu(x_0) + O\left(\|h\|^2_{C^1(\partial D)}\right).$$

Straightforward computations exploiting the orthonormality of the tangent vectors at x_0 yield that

$$\begin{aligned}
\delta - [\nu(x_0) \cdot \delta]\, \nu(x_0) &= \nu(x_0) \times [\delta \times \nu(x_0)] \\
&= -\sum_{j=1}^{2} \left[\nu(x_0) \cdot \frac{\partial \tilde{h}}{\partial \xi_j}(0)\right] \frac{\partial \varphi}{\partial \xi_j}(0) \\
&= \sum_{j=1}^{2} \left[h(x_0) \cdot \frac{\partial \nu}{\partial \xi_j}(0)\right] \frac{\partial \varphi}{\partial \xi_j}(0) - \mathrm{Grad}[\nu \cdot h](x_0),
\end{aligned}$$

where Grad denotes the surface gradient on ∂D. Combining this with the previous equation we find that

$$\begin{aligned}
\nu_h(x_0 + h(x_0)) - \nu(x_0) &= \sum_{j=1}^{2} \left[h(x_0) \cdot \frac{\partial \nu}{\partial \xi_j}(0)\right] \frac{\partial \varphi}{\partial \xi_j}(0) \\
&\quad - \mathrm{Grad}[\nu \cdot h](x_0) + O\left(\|h\|^2_{C^1(\partial D)}\right).
\end{aligned} \tag{2.15}$$

From Taylor's formula and $\nabla\nu \cdot \nu = 0$, using the coordinate system (2.12) we obtain

$$\begin{aligned}\nu(x_0 + h(x_0)) - \nu(x_0) &= [\nabla\nu](x_0)h(x_0) + O\left(\|h\|^2_{C^1(\partial D)}\right) \\ &= \sum_{j=1}^{2}\left[h(x_0)\cdot\frac{\partial\varphi}{\partial\xi_j}(0)\right]\frac{\partial\nu}{\partial\xi_j}(0) + O\left(\|h\|^2_{C^1(\partial D)}\right).\end{aligned}$$

Subtracting this from (2.15) yields

$$\begin{aligned}\nu_h(x_0 + h(x_0)) - \nu(x_0 + h(x_0)) &= \sum_{j=1}^{2}\left[\frac{\partial\nu}{\partial\xi_j}(0)\times\frac{\partial\varphi}{\partial\xi_j}(0)\right]\times h(x_0) \\ &\quad - \operatorname{Grad}[\nu\cdot h](x_0) + O\left(\|h\|^2_{C^1(\partial D)}\right).\end{aligned}$$

From this, in view of

$$\nu\cdot\frac{\partial\varphi}{\partial\xi_j} = 0, \quad j = 1, 2,$$

and

$$\frac{\partial\nu}{\partial\xi_j}\cdot\frac{\partial\varphi}{\partial\xi_\ell} = -\nu\cdot\frac{\partial^2\varphi}{\partial\xi_j\,\partial\xi_\ell} = \frac{\partial\nu}{\partial\xi_\ell}\cdot\frac{\partial\varphi}{\partial\xi_j}, \quad j, \ell = 1, 2,$$

we finally obtain the following technical lemma.

LEMMA 2.3. *The normal ν_h to ∂D_h and the extended normal ν are related by the estimate*

$$\nu_h(x + h(x)) - \nu(x + h(x)) = -\operatorname{Grad}[\nu\cdot h](x) + O\left(\|h\|^2_{C^1(\partial D)}\right) \tag{2.16}$$

uniformly for all $x \in \partial D$.

In particular, from (2.16) we can conclude that

$$\nu\cdot(\nu_h - \nu) = O\left(\|h\|^2_{C^1(\partial D)}\right). \tag{2.17}$$

LEMMA 2.4. *Let ∂D be analytic and K be a compact subset of $\mathbb{R}^3 \setminus \bar{D}$. Then*

$$u^s_h(x) - u^s(x) = -\int_{\partial D} w(x, y)\,(Bu)(y)\,ds(y) + o\left(\|h\|_{C^2(\partial D)}\right) \tag{2.18}$$

uniformly for x in K, where

$$Bu := [k^2(1 - \lambda^2) + 2ik\lambda H u](\nu\cdot h) + \operatorname{Div}[(\nu\cdot h)\operatorname{Grad} u]$$

and Div *and* Grad *denote the surface divergence and surface gradient, respectively.*

Proof. From (2.11), with the aid of the jump relations we obtain the boundary integral equation

$$u_h(x) = 2u^i(x) + 2\int_{\partial D_h}\left\{\frac{\partial\Phi(x,\cdot)}{\partial\nu_h} + ik\lambda\Phi(x,\cdot)\right\}u_h\,ds, \quad x \in \partial D_h. \tag{2.19}$$

Employing a perturbation argument based on pointwise convergence and collective compactness of the single- and double-layer boundary integral operators as $h \to 0$, from (2.19) it can be deduced that

$$|u_h(y + h(y)) - u(y)| \to 0, \quad \|h\|_{C^2(\partial D)} \to 0,$$

uniformly for all $y \in \partial D$. From this, in view of (2.7), using the impedance boundary condition for w together with Taylor's formula and the continuity of the second derivatives of w up to the boundary ∂D it follows that

$$u_h^s(x) - u^s(x) = \int_{\partial D_h} u \left\{ \frac{\partial w(x,\cdot)}{\partial \nu_h} + ik\lambda w(x,\cdot) \right\} ds + o\left(\|h\|_{C^2(\partial D)}\right) \tag{2.20}$$

uniformly for x on compact subsets of $\mathbb{R}^3 \setminus \bar{D}$. Abbreviating $w = w(x,\cdot)$, from (2.20) and the divergence theorem in view of (2.17) and the boundary condition for w we obtain

$$u_h^s(x) - u^s(x) = \int_{D_h^*} \operatorname{div} \{u \operatorname{grad} w + ik\lambda uw\nu\} \chi \, dy + o\left(\|h\|_{C^2(\partial D)}\right). \tag{2.21}$$

Here

$$D_h^* := \{y \in D_h : y \notin D\} \cup \{y \in D : y \notin D_h\}$$

and $\chi(y) = 1$ if $y \in D_h$ and $y \notin D$ and $\chi(y) = -1$ if $y \in D$ and $y \notin D_h$. Approximating the integral over D_h^* in (2.21) by an integral over ∂D, with the aid of (2.13) and Taylor's formula, we readily obtain that

$$u_h^s(x) - u^s(x) = \int_{\partial D} \operatorname{div} \{u \operatorname{grad} w + ik\lambda uw\nu\} (\nu \cdot h) \, ds + o\left(\|h\|_{C^2(\partial D)}\right).$$

Straightforward computations using the Helmholtz equation for w, the impedance boundary conditions for u and w, and (2.14) yield that

$$\operatorname{div} \{u \operatorname{grad} w + ik\lambda uw\nu\} = \operatorname{Grad} u \cdot \operatorname{Grad} w - k^2(1-\lambda^2)uw - 2ik\lambda H uw.$$

Inserting this into the previous equation and applying the Gauss surface divergence theorem we finally arrive at (2.18). □

The Sommerfeld radiation condition (2.3) implies an asymptotic behavior in the form of a spherical wave

$$v(x) = \frac{e^{ik|x|}}{|x|} \left\{ v_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \to \infty,$$

uniformly for all directions $\hat{x} = x/|x|$ where the function v_∞, defined on the unit sphere $\Omega := \{z \in \mathbb{R}^3 : |z| = 1\}$, is known as the far field pattern.

For a fixed incident field u^i, we define the operator

$$F : \partial D_h \to u_{\infty,h}$$

that maps the boundary ∂D_h onto the far field pattern $u_{\infty,h}$ of the scattered wave for scattering from the impedance obstacle D_h. For this operator we now are ready to prove the following result on Fréchet differentiability.

THEOREM 2.5. *Let ∂D be analytic. Then the boundary to far field operator $F : C(\partial D) \to L^2(\Omega)$ is Fréchet differentiable with the Fréchet derivative given through*

$$F'(\partial D)h = v_{\infty,h},$$

where $v_{\infty,h}$ is the far field pattern of the solution v_h to the Helmholtz equation in $\mathbb{R}^3 \setminus \bar{D}$ that satisfies the Sommerfeld radiation condition and the impedance boundary condition

$$\frac{\partial v_h}{\partial \nu} + ik\lambda v_h = [k^2(1-\lambda^2) + 2ik\lambda Hu](\nu \cdot h) + \operatorname{Div}[(\nu \cdot h)\operatorname{Grad} u] \quad \text{on } \partial D.$$

Proof. This is an immediate consequence of Lemma 2.4 and the representation formula (2.5). □

We expect that proceeding as in [11] Theorem 2.5 can be extended to the case of C^2 boundaries.

3. Impedance problem in electromagnetic scattering. Now we consider the exterior impedance boundary value problem for electromagnetic waves: Given a Hölder continuous tangential field c on ∂D and a constant $\lambda \in \mathbb{C}$ find a solution $E, H \in C^1(\mathbb{R}^3 \setminus \bar{D}) \cap C(\mathbb{R}^3 \setminus D)$ to the time-harmonic Maxwell equations

$$\operatorname{curl} E - ikH = 0, \quad \operatorname{curl} H + ikE = 0 \quad \text{in } \mathbb{R}^3 \setminus \bar{D} \tag{3.1}$$

that satisfies the impedance or Leontovich boundary condition

$$\nu \times H - \lambda(\nu \times E) \times \nu = c \quad \text{on } \partial D \tag{3.2}$$

and the Silver–Müller radiation condition

$$\lim_{r\to\infty} (H \times x - rE) = 0, \tag{3.3}$$

where $r = |x|$ and the limit holds uniformly for all directions $x/|x|$. The impedance coefficient λ is assumed to satisfy the condition

$$\operatorname{Re} \lambda \geq 0 \tag{3.4}$$

that ensures uniqueness and existence of a solution to (3.1)–(3.3) (see [1]). The limiting case $\lambda = 0$ corresponds to the case of a perfectly conducting obstacle with the roles of the fields E and H interchanged. We note that in this case the existence of a classical solution requires the existence and Hölder continuity of the surface divergence $\operatorname{Div} c$ of the given boundary data.

For an impedance obstacle D the scattering problem for time-harmonic waves is, given an incident field E^i, H^i as an entire solution of the Maxwell equations, to find the total field $E = E^i + E^s, H = H^i + H^s$ as a solution to the Maxwell equations in the exterior $\mathbb{R}^3 \setminus \bar{D}$ of D, such that E, H satisfies the impedance boundary condition

$$\nu \times H - \lambda(\nu \times E) \times \nu = 0 \quad \text{on } \partial D$$

and E^s, H^s satisfies the Silver–Müller radiation condition. Clearly, this scattering problem is a special case of the above boundary value problem (3.1)–(3.3).

On occasion, as an abbreviation we will use

$$E_T := (\nu \times E) \times \nu$$

for the tangential component of E on the boundary ∂D. For a matrix $M=(m_1,m_2,m_3)$ in $\mathbb{C}^3\times\mathbb{C}^3$ with columns m_1, m_2, m_3 we define matrices $\nu\times M$ and $M\times\nu$ by $\nu\times M := (\nu\times m_1, \nu\times m_2, \nu\times m_3)$ and $M\times\nu := -\nu\times M$.

Describing the electromagnetic field of an electric dipole with polarization $p\in\mathbb{R}^3$ located at a point $y\in\mathbb{R}^3$ we introduce matrices E_e^i, H_e^i through

$$E_e^i(x,y)p := \frac{i}{k}\,\mathrm{curl}_x\,\mathrm{curl}_x\,p\Phi(x,y), \quad H_e^i(x,y)p := \mathrm{curl}_x\,p\Phi(x,y)$$

in terms of the fundamental solution Φ to the Helmholtz equation. Note the symmetries

$$E_e^i(x,y) = [E_e^i(x,y)]^\top = E_e^i(y,x) \quad \text{and} \quad H_e^i(x,y) = [H_e^i(y,x)]^\top, \quad x\neq y.$$

For $z\in\mathbb{R}^3\setminus\bar{D}$ denote by $E_e^s(\cdot,z), H_e^s(\cdot,z)$ the matrices for which the pairs of corresponding columns are the solution of (3.1)–(3.3) for the boundary values given by the columns of

$$c = -\nu\times H_e^i(\cdot,z) + \lambda(\nu\times E_e^i(\cdot,z))\times\nu \quad \text{on } \partial D.$$

Then define $E_e := E_e^i + E_e^s, H_e := H_e^i + H_e^s$; that is, E_e^s, H_e^s and E_e, H_e describe the scattered and the total field, respectively, for the scattering of an electric dipole located at $x\in\mathbb{R}^3\setminus\bar{D}$. In view of the symmetry

$$E_e(x,y) = [E_e(y,x)]^\top, \quad x,y\in\mathbb{R}^3\setminus\bar{D},\ x\neq y,$$

that can be shown with the aid of the Gauss divergence theorem (see also section 7 in [8]), from the Stratton–Chu representation theorem it follows that (see also the proof of the following lemma) the unique solution of the impedance boundary value problem (3.1)–(3.3) can be represented in the form

$$E(x) = -\int_{\partial D} E_e(x,y)c(y)\,ds(y), \quad x\in\mathbb{R}^3\setminus\bar{D}. \tag{3.5}$$

As in the previous section we consider a family of domains D_h as defined in (2.6) and distinguish the above quantities related to the impedance scattering problem for the domain D_h through the subscript h.

LEMMA 3.1. *Assume that $\bar{D}\subset D_h$. Then*

$$E_h^s(x) - E^s(x) = -\int_{\partial D_h} \left\{[H_e(\cdot,x)]^\top + \lambda\,[\nu_h\times E_e(\cdot,x)]^\top\right\}[\nu_h\times E_h]\,ds \tag{3.6}$$

for $x\in\mathbb{R}^3\setminus\bar{D}_h$.

Proof. Let $x\in\mathbb{R}^3\setminus\bar{D}_h$. Combining the Stratton–Chu representation theorem for the incident field E^i, H^i and for the scattered field E^s, H^s we have that

$$E^s(x) = -\int_{\partial D} \left\{[E_e^i(\cdot,x)]^\top[\nu\times H] + [H_e^i(\cdot,x)]^\top[\nu\times E]\right\} ds \tag{3.7}$$

(see Corollary 2.2 in [8]). From the impedance boundary condition for E, H, and $E_e(\cdot,x), H_e(\cdot,x)$ by straightforward calculations we obtain

$$[E_e^i(\cdot,x)]^\top[\nu\times H] + H_e^i(\cdot,x)]^\top[\nu\times E] = -[E_e^s(\cdot,x)]^\top[\nu\times H] - [H_e^s(\cdot,x)]^\top[\nu\times E]$$

on ∂D. Hence, using the Gauss divergence theorem (see Lemma 2.1 in [8]) and the Silver–Müller radiation condition, (3.7) implies that

$$E^s(x) = \int_{\partial D} \left\{ [E_e^s(\cdot,x)]^\top [\nu \times H^i] + [H_e^s(\cdot,x)]^\top [\nu \times E^i] \right\} ds \tag{3.8}$$

and then again via the Gauss divergence theorem

$$E^s(x) = \int_{\partial D_h} \left\{ [E_e^s(\cdot,x)]^\top [\nu_h \times H^i] + [H_e^s(\cdot,x)]^\top [\nu_h \times E^i] \right\} ds. \tag{3.9}$$

From this, applying once again the Gauss divergence theorem and the radiation condition, we obtain that

$$E^s(x) = \int_{\partial D_h} \left\{ [E_e^s(\cdot,x)]^\top [\nu_h \times H_h] + [H_e^s(\cdot,x)]^\top [\nu_h \times E_h] \right\} ds,$$

and in view of the boundary condition for E_h, H_h we finally arrive at

$$E^s(x) = \int_{\partial D_h} \left\{ [H_e^s(\cdot,x)]^\top + \lambda\, [\nu_h \times E_e^s(\cdot,x)]^\top \right\} [\nu_h \times E_h]\, ds.$$

On the other hand, from (3.7) applied to $E_h, H_h, \partial D_h$ and the boundary condition for E_h, H_h we have that

$$E_h^s(x) = -\int_{\partial D_h} \left\{ [H_e^i(\cdot,x)]^\top + \lambda\, [\nu_h \times E_e^i(\cdot,x)]^\top \right\} [\nu_h \times E_h]\, ds \tag{3.10}$$

and the statement (3.6) follows by combining the last two equations. □

Remark 3.2. Again (3.6) remains valid for $x \notin \bar{D} \cup \bar{D}_h$ if we drop the assumption that $\bar{D} \subset D_h$ and assume that E^s, H^s can be extended as a solution to the Maxwell equations in the exterior of D_h. By the regularity results on elliptic boundary value problems this can be assured if ∂D is analytic and D_h does not differ too much from D. This follows from sections 6.1 and 6.6 in [13] by considering the impedance boundary value problem for the Maxwell equation equivalently as a boundary value problem for the vector Helmholtz equation.

In the neighborhood of ∂D we define the curvature operator R by the matrix with the columns

$$R := \left(\frac{\partial \nu}{\partial x_1}\,,\ \frac{\partial \nu}{\partial x_2}\,,\ \frac{\partial \nu}{\partial x_3} \right).$$

Then the curl operator trace on ∂D can be expressed in terms of surface operators in the form

$$\operatorname{curl} E = [\operatorname{Div}(E \times \nu)]\nu + \operatorname{Grad}(E \cdot \nu) \times \nu + \left(R + 2H_{\partial D} - \frac{\partial}{\partial \nu} \right) (E \times \nu) \quad \text{on } \partial D,$$

where we use the subscript ∂D to distinguish the mean curvature $H_{\partial D}$ from the magnetic field (see Theorem 2.5.20 in [14]). From this we derive

$$\operatorname{curl}(\nu \times E) = [\operatorname{Div} E_T]\nu + \left(R + 2H_{\partial D} - \frac{\partial}{\partial \nu} \right) E_T \quad \text{on } \partial D, \tag{3.11}$$

and, in particular, since E_T is tangential

$$\nu \cdot \operatorname{curl} E = \operatorname{Div}(E \times \nu) \quad \text{on } \partial D \tag{3.12}$$

and

$$\nu \cdot \operatorname{curl}(\nu \times E) = \operatorname{Div} E_T \quad \text{on } \partial D. \tag{3.13}$$

LEMMA 3.3. *Let ∂D be analytic and let K be a compact subset of $\mathbb{R}^3 \setminus \bar{D}$. Then*

$$E_h^s(x) - E^s(x) = -\int_{\partial D} [E_e(y,x)]^\top (NE)(y)\, ds(y) + o\left(\|h\|_{C^2(\partial D)}\right) \tag{3.14}$$

uniformly for x in K, where

$$\begin{aligned} NE :=\ & -\nu \times \{\operatorname{Grad}[(\nu \cdot H)(\nu \cdot h)] + \lambda\, E \times \operatorname{Grad}(\nu \cdot h)\} \\ & +(\nu \cdot h)\left[ik - \lambda\left(R + 2H_{\partial D} - \frac{\partial}{\partial \nu}\right)\right] E_T. \end{aligned}$$

Proof. From (3.10), with the aid of the jump relation we obtain the hypersingular boundary integral equation

$$\begin{aligned} &\nu_h(x) \times E_h(x) = 2\,\nu_h(x) \times E^i(x) \\ &-2\,\nu_h(x) \times \int_{\partial D_h} \left\{[H_e^i(\cdot,x)]^\top + \lambda\,[\nu_h \times E_e^i(\cdot,x)]^\top\right\}[\nu_h \times E_h]\, ds, \quad x \in \partial D_h. \end{aligned}$$

From this, regularizing the integral equation and employing a perturbation argument it can be deduced that

$$|\nu_h(y + h(y)) \times E_h(y + h(y)) - \nu(y) \times E(y)| \to 0, \quad \|h\|_{C^2(\partial D)} \to 0,$$

uniformly for all $y \in \partial D$. Hence, in view of (3.6), using the impedance boundary condition for E_e, H_e together with Taylor's formula and the estimate $\nu_h(y + h(y)) - \nu(y) = O(\|h\|_{C^2(\partial D)})$ (see (2.15)) it follows that

$$\begin{aligned} E_h^s(x) - E^s(x) \ =\ & -\int_{\partial D_h} \left\{[H_e(\cdot,x)]^\top + \lambda\,[\nu_h \times E_e(\cdot,x)]^\top\right\}[\nu_h \times E]\, ds \\ & +o\left(\|h\|_{C^2(\partial D)}\right) \end{aligned}$$

uniformly for x on compact subsets of $\mathbb{R}^3 \setminus \bar{D}$. From this, abbreviating $E_e = E_e(x,\cdot)$ and $H_e = H_e(x,\cdot)$, and using the Gauss divergence theorem in view of (2.17), the boundary condition for E_e, H_e, and the Maxwell equations we obtain

$$\begin{aligned} E_h^s(x) - E^s(x) \ =\ & -\lambda \int_{\partial D_h} [\nu \times E_e]^\top [(\nu_h - \nu) \times E]\, ds \\ & -\int_{D_h^*} ik \left\{H_e^\top [H + \lambda\,\nu \times E] + E_e^\top E^*\right\} \chi\, dy \\ & +o\left(\|h\|_{C^2(\partial D)}\right), \end{aligned} \tag{3.15}$$

where D_h^* and χ are defined as in the proof of Lemma 2.4 and

$$E^* := E - \frac{\lambda}{ik}\,\mathrm{curl}[\nu \times E]. \tag{3.16}$$

In (3.15), we estimate the integral over ∂D_h with the aid of (2.16) and approximate the integral over D_h^* by an integral over ∂D. Then with the aid of (2.13), Taylor's formula, and the boundary condition for E, H we obtain that

$$\begin{aligned} E_h^s(x) - E^s(x) \;=\; & \int_{\partial D} \left\{ \lambda E_e^\top [\nu \times \{E \times \mathrm{Grad}(\nu \cdot h)\}] \right. \\ & \left. - ik \left[H_e^\top \{(H \cdot \nu)\,\nu\} + E_e^\top E^* \right] (\nu \cdot h) \right\} ds \\ & + o\left(\|h\|_{C^2(\partial D)} \right). \end{aligned} \tag{3.17}$$

With the aid of Maxwell's equation for E, the vector identities (3.12) and (3.13), and the boundary condition for E, H, we observe that

$$E^* \cdot \nu = \frac{1}{ik}\,\mathrm{Div}(\nu \times H - \lambda E_T) = 0 \quad \text{on } \partial D.$$

Using the Maxwell equation for H_e, the identity (3.12), and the Gauss surface divergence theorem we can transform

$$\int_{\partial D} ik\, H_e^\top (\nu \cdot H)(\nu \cdot h)\nu\, ds = -\int_{\partial D} E_e^\top [\nu \times \mathrm{Grad}\{(\nu \cdot H)(\nu \cdot h)\}]\, ds.$$

Inserting this into (3.17) we conclude that

$$\begin{aligned} E_h^s(x) - E^s(x) \;=\; & \int_{\partial D} \left\{ E_e^\top [\nu \times \{\mathrm{Grad}[(\nu \cdot H)(\nu \cdot h)] + \lambda\, E \times \mathrm{Grad}(\nu \cdot h)\}] \right. \\ & \left. - ik\, E_e^\top [\nu \times (E^* \times \nu)(\nu \cdot h)] \right\} ds \\ & + o\left(\|h\|_{C^2(\partial D)} \right). \end{aligned}$$

From this, the statement (3.14) follows with the help of the definition (3.16) and the identity (3.11). □

The Silver–Müller radiation condition (3.3) implies an asymptotic behavior in the form of a spherical wave

$$E(x) = \frac{e^{ik|x|}}{|x|} \left\{ E_\infty(\hat{x}) + O\left(\frac{1}{|x|} \right) \right\}, \quad |x| \to \infty,$$

uniformly for all directions $\hat{x} = x/|x|$ where the tangential field E_∞ on the unit sphere Ω is known as the electric far field pattern.

For a fixed incident field E^i, H^i, we define the operator

$$F : \partial D_h \to E_{\infty,h}$$

that maps the boundary ∂D_h onto the electric far field pattern $E_{\infty,h}$ of the scattered wave for scattering from the impedance obstacle D_h. For this operator we now are ready to prove the following result on Fréchet differentiability.

THEOREM 3.4. *Let ∂D be analytic. Then the boundary to far field operator $F : C(\partial D) \to L^2(\Omega)$ is Fréchet differentiable with the Fréchet derivative given through*

$$F'(\partial D)h = E_{\infty,h},$$

where $E_{\infty,h}$ is the far field pattern of the solution E_h, H_h to the Maxwell equations in $\mathbb{R}^3 \setminus \bar{D}$ that satisfies the Silver–Müller radiation condition and the impedance boundary condition

$$\begin{aligned} &\nu \times H_h - \lambda(\nu \times E_h) \times \nu \\ &\quad = -\nu \times \{\mathrm{Grad}[(\nu \cdot H)(\nu \cdot h)] - \lambda\, E \times \mathrm{Grad}(\nu \cdot h)\} \\ &\qquad +(\nu \cdot h)\left[ik - \lambda\left(R + 2H_{\partial D} - \frac{\partial}{\partial \nu}\right)\right][(\nu \times E) \times \nu] \quad \text{on } \partial D. \end{aligned} \tag{3.18}$$

Proof. This is an immediate consequence of Lemma 3.3 and the representation formula (3.5). □

We expect that, proceeding as in [11], Theorem 3.4 can be extended to the case of C^2 boundaries.

We will conclude with a few remarks on the injectivity of the Fréchet derivative as given in the previous theorem, i.e., the characterization of the nullspace of the derivative as the space of tangential fields $\nu \cdot h = 0$. In acoustic scattering, on one hand for the Dirichlet condition this result is an immediate consequence of the characterization of the derivative via Holmgren's uniqueness theorem (see Theorem 5.15 in [2]). On the other hand, the injectivity for the Neumann problem based on the characterization of Theorem 2.5 for $\lambda = 0$ remains an open problem. For the impedance problem for large λ, i.e., for the impedance condition close to the Dirichlet case, Kress and Rundell [12] (see also [10]) have settled the injectivity of the linearization.

The ideas for proving injectivity as applied in [12] fail for the Neumann boundary condition due to the occurrence of two definite integrals with opposite signs. Unfortunately the same happens in the electromagnetic case for $\lambda = 0$. In this case, in view of (3.18) we would want to conclude from

$$\nu \times \mathrm{Grad}[(\nu \cdot H)(\nu \cdot h)] - ik\, \nu \times [E \times \nu]\,(\nu \cdot h) = 0 \quad \text{on } \partial D \tag{3.19}$$

that $\nu \cdot h = 0$. Taking the dot product of (3.19) with the conjugate complex $\bar{E}$ and integrating over

$$U := \{x \in \partial D : \nu(x) \cdot h(x) \geq 0\}$$

with the aid of (3.12), the Maxwell equations and the Gauss divergence theorem yields

$$\int_U \left\{|\nu \times E|^2 - |\nu \cdot H|^2\right\}(\nu \cdot h)\, ds = 0$$

and no further conclusions are possible from this equation.

The following example actually shows that further assumptions on the incident field are required for establishing that the nullspace of the derivative consists only of the tangential fields. Consider as the incident field the vector spherical wave function

$$E^i(x) = \mathrm{curl}\left\{x j_n(k|x|) Y_n\left(\frac{x}{|x|}\right)\right\}, \quad H^i(x) = \frac{1}{ik}\,\mathrm{curl}\, E^i(x),$$

where j_n is the spherical Bessel function of order n and Y_n a spherical harmonic of order n. Elementary computations (see Theorem 6.24 in [2]) show that for D a ball of radius R centered at the origin the scattered wave is given by

$$E^s(x) = A_n(R)\,\mathrm{curl}\left\{x h_n^{(1)}(k|x|)Y_n\left(\frac{x}{|x|}\right)\right\}, \quad H^s(x) = \frac{1}{ik}\,\mathrm{curl}\,E^s(x), \tag{3.20}$$

where $h_n^{(1)}$ is the spherical Hankel function of order n and

$$A_n(R) = -\frac{(1+ik\lambda R)j_n(kR) + k\,j_n'(kR)}{(1+ik\lambda R)h_n^{(1)}(kR) + k\,h_n^{(1)\prime}(kR)}\,. \tag{3.21}$$

The denominator in (3.21) is nonzero, since for the radiating solution

$$u_n(x) = h_n^{(1)}(k|x|)Y_n\left(\frac{x}{|x|}\right)$$

to the Helmholtz equation we have the impedance boundary values

$$\frac{\partial u_n}{\partial \nu} + (1+ikR\lambda)u_n = \left\{k\,h_n^{(1)\prime}(kR) + (1+ik\lambda R)h_n^{(1)}(kR)\right\}Y_n \tag{3.22}$$

on ∂D. Therefore, due to the uniqueness result for the acoustic impedance boundary value problem as mentioned in section 2 the right-hand side of (3.22) cannot vanish identically.

The tangential component of the total electric field on ∂D is of the form

$$\nu \times E = a_n(R)\,\mathrm{Grad}\,Y_n,$$

where

$$a_n(R) := j_n(kR) + A_n(R)\,h_n^{(1)}(kR).$$

Then, with the aid of the Maxwell equations, the identities (3.12), and

$$\mathrm{Div}\,\mathrm{Grad}\,Y_n + n(n+1)Y_n = 0$$

for $R = 1$, $\lambda = 0$, and $\nu \cdot h = 1$, the right-hand side of (3.18) becomes

$$\nu \times \mathrm{Grad}[(\nu\cdot H)(\nu\cdot h)] - ik\,\nu\times[E\times\nu]\,(\nu\cdot h) = \frac{a_n(1)}{ik}\,[n(n+1)-k^2]\,\nu\times\mathrm{Grad}\,Y_n.$$

Hence, for $k^2 = n(n+1)$ we have vanishing boundary data and consequently a vanishing Fréchet derivative for a nontangential field h.

This observation, of course, can also be based on differentiating with respect to the radius R. The far field pattern E_∞ of (3.20) is given by

$$E_\infty = \frac{A_n(R)}{k\,i^{n+1}}\;\mathrm{Grad}\,Y_n \times \nu$$

with the exterior unit normal ν to the unit sphere Ω (see Theorem 6.26 in [2]). Straightforward calculations using the differential equation and the Wronskian for the spherical Bessel and Hankel functions (see section 2.4 in [2]) shows that

$$A_n'(1) = \frac{i[k^2(1-\lambda^2) - n(n+1)]}{k[(1+ik\lambda)h_n^{(1)}(k) + k\,h_n^{(1)\prime}(k)]^2}\,,$$

i.e., the derivative vanishes for $k^2(1-\lambda^2) = n(n+1)$ leading to vanishing Fréchet derivatives for a nontangential field h if λ is real and less than one. However, according to the symmetry of the Maxwell equations, if E, H solves the impedance boundary value problem with impedance constant λ, then $H, -E$ solves the impedance boundary value problem with impedance $1/\lambda$. Hence, our example also provides vanishing Fréchet derivatives for impedance values larger than one. These counter examples suggest that for proving injectivity of the derivative, for example, for plane wave incidence, the special structure of the plane waves has to be incorporated.

A MATHEMATICAL MODEL OF COMPETITION FOR TWO ESSENTIAL RESOURCES IN THE UNSTIRRED CHEMOSTAT*

JIANHUA WU†, HUA NIE,†, AND GAIL S. K. WOLKOWICZ‡

Abstract. A mathematical model of competition between two species for two growth-limiting, essential (complementary) resources in the unstirred chemostat is considered. The existence of a positive steady-state solution and some of its properties are established analytically. Techniques include the maximum principle, the fixed point index, and numerical simulations. The simulations also seem to indicate that there are regions in parameter space for which a globally stable positive equilibrium occurs and that there are other regions for which the model admits bistability and even multiple positive equilibria.

Key words. chemostat, essential or complementary resources, steady-state solution, fixed point index, numerical simulation

1. Introduction.

An apparatus called the chemostat, used for the continuous culture of microorganisms, has played an important role in ecology. It has been thought of as a *lake in a laboratory.* See [9, 25, 29] for a description of the apparatus and the general theory.

In the basic set up, the culture vessel is assumed to be well stirred. One or more populations of microorganisms grow and/or compete exploitatively for a single, nonreproducing, growth-limiting nutrient that is supplied at a constant rate. The contents of the culture vessel are removed at the same constant rate as the medium containing the nutrient is supplied, and thus the volume of the culture vessel remains constant. Species-specific parameters can be measured one species at a time, and based on these parameters the theory predicts the qualitative outcome in advance of actual competition. In particular, the theory predicts that the species with the lowest *break-even* concentration excludes all other competitors (see [6, 14, 29]). Experiments confirmed this prediction in the case of auxotrophic bacterial strains competing for limiting tryptophan [11].

Mathematical analysis of chemostat models involving two limiting resources under the assumption that the culture vessel is *well stirred* can be found, for example, in [2, 3, 7, 13, 12, 17, 18, 19, 28]. When more than one resource is limiting, it is necessary to consider how these resources promote growth. At one extreme are resources that are sources of different essential substances that must be taken together, because each substance fulfills different physiological needs with respect to growth, for example, a

carbon source and a nitrogen source. Such resources are called complementary by Leon and Tumpson [17], Rapport [22], and Baltzis and Fredrickson [4]; essential by Tilman [28]; and heterologous by Harder and Dijkhuizen [12].

The model of exploitative competition for two essential resources in the well-stirred case is given by

$$\begin{aligned} S_t &= (S^0 - S)D - \tfrac{1}{y_{s_1}} g_1(S,R)u - \tfrac{1}{y_{s_2}} g_2(S,R)v, \\ R_t &= (R^0 - R)D - \tfrac{1}{y_{r_1}} g_1(S,R)u - \tfrac{1}{y_{r_2}} g_2(S,R)v, \\ u_t &= [-D + g_1(S,R)]u, \\ v_t &= [-D + g_2(S,R)]v. \end{aligned}$$

$S(t)$, $R(t)$ denote the nutrient concentrations at time t, and $u(t)$ and $v(t)$ denote the biomass of each population in the culture vessel. $S^0 > 0$ and $R^0 > 0$ are constants that represent the input concentrations of nutrients S and R, respectively, D is the dilution rate, and y_{s_i} and y_{r_i}, $i = 1, 2$, are the corresponding growth yield constants. The response functions are denoted $g_i(S,R) = \min(p_i(S), q_i(R))$, $i = 1, 2$, where $p_i(S)$ denotes the response function of the ith population when only resource S is limiting and $q_i(R)$ denotes the response function of the ith population when only resource R is limiting. We will consider the case that the Monod model for exploitative competition for one resource is generalized to the two essential resources case, i.e., $p_i(S) = \frac{m_{s_i} S}{K_{s_i} + S}$, $q_i(R) = \frac{m_{r_i} R}{K_{r_i} + R}$, $i = 1, 2$, where m_{s_i}, m_{r_i}, K_{s_i}, K_{r_i}, are positive constants.

In this paper, we study the *unstirred* chemostat and consider *two species' competition* for *two*, growth-limiting, nonreproducing *essential* resources. Motivated by the work on the unstirred chemostat in the case of one limiting resource (see [5, 8, 15, 16, 20, 23, 24, 25, 26, 30, 31]) and in the case of two limiting resources in [32], the model takes the form of the following reaction-diffusion equations:

$$\begin{aligned} S_t &= dS_{xx} - \tfrac{1}{y_{s_1}} g_1(S,R)u - \tfrac{1}{y_{s_2}} g_2(S,R)v, && 0 < x < 1,\ t > 0, \\ R_t &= dR_{xx} - \tfrac{1}{y_{r_1}} g_1(S,R)u - \tfrac{1}{y_{r_2}} g_2(S,R)v, && 0 < x < 1,\ t > 0, \\ u_t &= du_{xx} + g_1(S,R)u, && 0 < x < 1,\ t > 0, \\ v_t &= dv_{xx} + g_2(S,R)v, && 0 < x < 1,\ t > 0, \end{aligned}$$

with boundary conditions

$$\begin{aligned} &S_x(0,t) = -S^0, && R_x(0,t) = -R^0,\ u_x(0,t) = 0,\ v_x(0,t) = 0, \\ &S_x(1,t) + \gamma S(1,t) = 0, && R_x(1,t) + \gamma R(1,t) = 0, \\ &u_x(1,t) + \gamma u(1,t) = 0, && v_x(1,t) + \gamma v(1,t) = 0. \end{aligned}$$

The boundary conditions are very intuitive. Readers may refer to [5, 16, 26] for their derivation.

These equations can be simplified using the nondimensional variables and parameters defined as follows: $\bar{S} = \frac{S}{S^0}$, $\bar{R} = \frac{R}{R^0}$, $\alpha = \frac{S^0 y_{s_1}}{R^0 y_{r_1}}$, $\beta = \frac{R^0 y_{r_2}}{S^0 y_{s_2}}$, $\bar{g}_i(\bar{S}, \bar{R}) = \min(\frac{m_{s_i}\bar{S}}{\bar{K}_{s_i} + \bar{S}}, \frac{m_{r_i}\bar{R}}{\bar{K}_{r_i} + \bar{R}})$, $i = 1, 2$, $\bar{u} = \frac{u}{y_{s_1} S^0}$, $\bar{v} = \frac{v}{y_{r_2} R^0}$, where $\bar{K}_{s_i} = \frac{K_{s_i}}{S^0}$, $\bar{K}_{r_i} = \frac{K_{r_i}}{R^0}$, $i = 1, 2$. For more convenient notation, we drop the bars on the nondimensional

variables and parameters, yielding the following model:

$$
\begin{aligned}
S_t &= dS_{xx} - g_1(S,R)u - \beta g_2(S,R)v, && 0<x<1,\ t>0,\\
R_t &= dR_{xx} - \alpha g_1(S,R)u - g_2(S,R)v, && 0<x<1,\ t>0,\\
u_t &= du_{xx} + g_1(S,R)u, && 0<x<1,\ t>0,\\
v_t &= dv_{xx} + g_2(S,R)v, && 0<x<1,\ t>0,
\end{aligned}
\tag{1}
$$

with boundary conditions

$$
\begin{aligned}
&S_x(0,t) = -1,\ \ R_x(0,t) = -1,\ \ u_x(0,t) = 0,\ v_x(0,t) = 0,\\
&S_x(1,t) + \gamma S(1,t) = 0,\ \ R_x(1,t) + \gamma R(1,t) = 0,\\
&u_x(1,t) + \gamma u(1,t) = 0,\ \ v_x(1,t) + \gamma v(1,t) = 0,
\end{aligned}
$$

and initial conditions

$$
S(x,0) = S_0(x) \ge 0,\ R(x,0) = R_0(x) \ge 0,\ u(x,0) = u_0(x) \ge 0,\ v(x,0) = v_0(x) \ge 0.
$$

Denote $\varphi_1 = S + u + \beta v,\ \varphi_2 = R + \alpha u + v$, where $\varphi_i,\ i = 1,2$, is the solution of

$$
\begin{aligned}
&\varphi_{it} = d\varphi_{ixx}, && 0<x<1,\ t>0,\\
&\varphi_{ix}(0,t) = -1,\ \ \varphi_{ix}(1,t) + \gamma\varphi_i(1,t) = 0,\\
&\varphi_i(x,0) = \varphi_{i0}(x).
\end{aligned}
$$

Then u and v satisfy

$$
\begin{aligned}
u_t &= du_{xx} + ug_1(\varphi_1 - u - \beta v, \varphi_2 - \alpha u - v), && 0<x<1,\ t>0,\\
v_t &= dv_{xx} + vg_2(\varphi_1 - u - \beta v, \varphi_2 - \alpha u - v), && 0<x<1,\ t>0,\\
&u_x(0,t) = 0,\ \ u_x(1,t) + \gamma u(1,t) = 0, && t>0,\\
&v_x(0,t) = 0,\ \ v_x(1,t) + \gamma v(1,t) = 0, && t>0.
\end{aligned}
\tag{1$'$}
$$

This paper is devoted to determining the positive solution of this two-species model of exploitative competition for *two essential resources* in the *unstirred chemostat*. Since the reaction terms are Lipschitz continuous, but not C^1, many methods used to analyze elliptic systems do not apply. This makes the analysis more difficult. Some methods used to prove the existence of the positive equilibrium in the region $D = \{(\hat{\lambda}_1, \hat{\lambda}_2) : \hat{\lambda}_1 > 1,\ \hat{\lambda}_2 > 1\}$ occupy a major portion of the paper, where $\hat{\lambda}_i,\ i = 1,2$, is defined in the next section. The main result is established in Theorem 3. The other related results are also obtained in section 2. Extensive numerical studies were run, and some conclusions are summarized in section 3. The simulations convince us that much more complex dynamics can occur in region D.

The paper is organized as follows. In section 2, the existence of a positive steady-state solution and some of its properties are established by using the maximum principle and fixed point index theory, which is closely related to bounding the principal eigenvalues of certain differential operators. Some results on extensive numerical studies are reported in section 3, complementing the mathematical results in section 2, and a number of typical figures chosen from many simulations are also given in this section.

2. The positive steady-state solution. First, we consider the steady state of system (1):

$$
\begin{aligned}
&dS_{xx} - g_1(S,R)u - \beta g_2(S,R)v = 0, && 0 < x < 1,\\
&dR_{xx} - \alpha g_1(S,R)u - g_2(S,R)v = 0, && 0 < x < 1,\\
&du_{xx} + g_1(S,R)u = 0, && 0 < x < 1,\\
&dv_{xx} + g_2(S,R)v = 0, && 0 < x < 1,
\end{aligned} \tag{2}
$$

with boundary conditions

$$
\begin{aligned}
&S_x(0) = -1,\ \ R_x(0) = -1,\ \ u_x(0) = 0,\ v_x(0) = 0,\\
&S_x(1) + \gamma S(1) = 0,\ \ R_x(1) + \gamma R(1) = 0,\ \ u_x(1) + \gamma u(1) = 0,\ \ v_x(1) + \gamma v(1) = 0.
\end{aligned}
$$

It follows that $S + u + \beta v = z$, $R + \alpha u + v = z$, where $z = z(x) = \frac{1+\gamma}{\gamma} - x$. Then u and v satisfy

$$
\begin{aligned}
&du_{xx} + ug_1(z - u - \beta v, z - \alpha u - v) = 0, && 0 < x < 1,\\
&dv_{xx} + vg_2(z - u - \beta v, z - \alpha u - v) = 0, && 0 < x < 1,\\
&u_x(0) = 0,\ \ u_x(1) + \gamma u(1) = 0,\\
&v_x(0) = 0,\ \ v_x(1) + \gamma v(1) = 0.
\end{aligned} \tag{3}
$$

Let λ_i be the principal eigenvalue and let $\phi_i(x) > 0$ on $[0,1]$, $i = 1, 2$, be the corresponding eigenfunction, normalized as $\max_{x\in[0,1]} \phi_i(x) = 1$, of the following problem:

$$
d\phi_{ixx} + \lambda_i \phi_i g_i(z,z) = 0, \quad 0 < x < 1, \quad \phi_{ix}(0) = 0, \quad \phi_{ix}(1) + \gamma\phi_i(1) = 0. \tag{4}
$$

Let $U(x)$ be the solution of

$$
\begin{aligned}
&dU_{xx} + Ug_1(z - U, z - \alpha U) = 0, && 0 < x < 1,\\
&U_x(0) = 0,\ \ U_x(1) + \gamma U(1) = 0,
\end{aligned} \tag{5}
$$

and let $U(x,t)$ be the solution of

$$
\begin{aligned}
&U_t = dU_{xx} + Ug_1(\varphi_1 - U, \varphi_2 - \alpha U), && 0 < x < 1,\ t > 0,\\
&U_x(0,t) = 0,\ \ U_x(1,t) + \gamma U(1,t) = 0,\\
&U(x,0) = U_0(x) \geq 0.
\end{aligned} \tag{6}
$$

From Lemmas 2.2–2.4 and Theorem 2.5 in [32] we have the following lemma.

LEMMA 1. *If $\lambda_1 < 1$, then there exists a unique positive solution $U(x)$ of (5), satisfying $0 < U < \min\{1, \frac{1}{\alpha}\}z$ on $[0,1]$. If $\lambda_1 \geq 1$, the only nonnegative solution of (5) is $U = 0$. Furthermore, $\lim_{t\to\infty} U(x,t) = U(x)$ if $\lambda_1 < 1$, and $\lim_{t\to\infty} U(x,t) = 0$ if $\lambda_1 > 1$.*

Remark 1. If $\lambda_2 < 1$, a similar result holds for $V(x)$, where $V(x)$ is the unique positive solution of

$$
\begin{aligned}
&dV_{xx} + Vg_2(z - \beta V, z - V) = 0, && 0 < x < 1,\\
&V_x(0) = 0,\ \ V_x(1) + \gamma V(1) = 0.
\end{aligned}
$$

Since we are only concerned with the nonnegative steady-state solutions of (3), there is no loss of generality if we redefine

$$p_i(S) = \begin{cases} \frac{m_{s_i} S}{K_{s_i}+S}, & S \geq 0, \\ 0, & S < 0, \end{cases} \quad q_i(R) = \begin{cases} \frac{m_{r_i} R}{K_{r_i}+R}, & R \geq 0, \\ 0, & R < 0. \end{cases}$$

LEMMA 2. *Suppose* (u, v) *is the nonnegative solution of* (3). *Then* (i) $u > 0$ *or* $u \equiv 0$, *and* $v > 0$ *or* $v \equiv 0$; (ii) $u + \beta v < z$, $\alpha u + v < z$; (iii) $u \leq U, v \leq V$. *Moreover,* $u < U$ *or* $u \equiv U$, *and* $v < V$ *or* $v \equiv V$.

Proof. (i) This part can be proved by the maximum principle, in the usual way, and the details are omitted here.

(ii) Define $w = u + \beta v - z$. Note that by (3) it follows that

$$dw_{xx} + ug_1(-w, z - \alpha u - v) + \beta v g_2(-w, z - \alpha u - v) = 0,$$
$$w_x(0) = 1 \quad \text{and} \quad w_x(1) + \gamma w(1) = 0.$$

First we show that $w \leq 0$ on $[0, 1]$. Suppose not. If $w(1) > 0$, then $w_x(1) < 0$. Therefore, there exists $a \in [0, 1)$ so that for all $x \in (a, 1]$, $w(x) > 0$, and either $a = 0$ or $w(a) = 0$. But then for all $x \in [a, 1]$, $w_{xx} = 0$ and so $w_x(x) = w_x(1) < 0$, i.e., $w(x)$ is decreasing there. Since $w_x(0) = 1 > 0$, $a \neq 0$. But $a > 0$ is also impossible since then $w(a) = 0$, $w(x)$ is decreasing in $[a, 1]$, and $w(1) > 0$. Therefore, $w(1) \leq 0$. Next, assume there exists $\bar{x} \in [0, 1)$ with $w(\bar{x}) > 0$. Then there exist $\delta_1 \geq 0$ and $\delta_2 > 0$ such that $w(x) > 0$ for all $x \in (\bar{x} - \delta_1, \bar{x} + \delta_2) \subset (0, 1)$, $w(\bar{x} + \delta_2) = 0$, and either $\bar{x} - \delta_1 = 0$ or $w(\bar{x} - \delta_1) = 0$. But then for all $x \in [\bar{x} - \delta_1, \bar{x} + \delta_2]$, $w_{xx}(x) = 0$ and so $w_x(x)$ is constant. Since $w(\bar{x} + \delta_2) = 0$, it follows that $w_x(\bar{x} + \delta_2) \leq 0$, and so $w(x)$ is nonincreasing on $[\bar{x} - \delta_1, \bar{x} + \delta_2]$. Then $\bar{x} - \delta_1 \neq 0$, since $w_x(0) = 1$, and so $w(\bar{x} - \delta_1) = 0$. Therefore, $w(x) \equiv 0$ on $[\bar{x} - \delta_1, \bar{x} + \delta_2]$, a contradiction. Hence, $u + \beta v \leq z$ on $[0, 1]$. That $\alpha u + v \leq z$ follows similarly. It is easy to see that $u + \beta v \not\equiv z$, $\alpha u + v \not\equiv z$; otherwise we have $du_{xx} = 0$, $dv_{xx} = 0$, with the usual boundary condition, which gives $u \equiv 0$, $v \equiv 0$, a contradiction. Let $w_1 = z - u - \beta v$, $w_2 = z - \alpha u - v$. Then $w_i \geq 0, \not\equiv 0$, and w_1 satisfies

$$-dw_{1xx} + ug_1(w_1, w_2) + \beta v g_2(w_1, w_2) = 0,$$
$$w_{1x}(0) = -1, \quad w_{1x}(1) + \gamma w_1(1) = 0,$$

which leads to

$$-dw_{1xx} + w_1 \left(\frac{m_{s_1} u}{K_{s_1}+w_1} + \frac{m_{s_2} \beta v}{K_{s_2}+w_1} \right) \geq 0,$$
$$w_{1x}(0) = -1, \quad w_{1x}(1) + \gamma w_1(1) = 0.$$

If $w_1(x_0) = 0$ for some point $x_0 \in [0, 1]$, by applying the strong maximum principle (see [21]) we obtain a contradiction. Hence $w_1 > 0$ on $[0, 1]$. The proof that $w_2 > 0$ on $[0, 1]$ is similar.

(iii) It follows by the monotone method and the uniqueness of U that $u \leq U \leq \min\{1, \frac{1}{\alpha}\} z$. By the Lipschitz continuity of $g_1(S, R)$, there exists a constant $L > 0$, such that $0 \leq g_1(z - u, z - \alpha u) - g_1(z - U, z - \alpha U) \leq L(U - u)$. Let $\hat{U} = U - u$. Then $\hat{U} \geq 0$ satisfies

$$d\hat{U}_{xx} + \hat{U}[g_1(z - U, z - \alpha U) - uL] \leq 0, \quad 0 < x < 1,$$
$$\hat{U}_x(0) = 0, \quad \hat{U}_x(1) + \gamma \hat{U}(1) = 0.$$

If $\hat{U} \not\equiv 0$, then the maximum principle leads to $\hat{U} > 0$. Thus either $u < U$ or $u \equiv U$. The proof for v is similar. ∎

Remark 2. It follows from Lemmas 1 and 2 that, for $\lambda_i \geq 1$, $i = 1, 2$, the only nonnegative solution of (3) is $(0, 0)$. In order to guarantee the existence of a positive solution of (3), we must assume that $\lambda_i < 1$ for $i = 1, 2$.

Let $\hat{\lambda}_i$ be the principal eigenvalues and let $\hat{\phi}_i(x) > 0,\ x \in [0, 1],\ i = 1, 2$, be the corresponding eigenfunctions of the problem

$$d\hat{\phi}_{1xx} + \hat{\lambda}_1\hat{\phi}_1 g_1(z - \beta V, z - V) = 0, \quad 0 < x < 1, \quad \hat{\phi}_{1x}(0) = 0,\ \ \hat{\phi}_{1x}(1) + \gamma\hat{\phi}_1(1) = 0,$$

$$d\hat{\phi}_{2xx} + \hat{\lambda}_2\hat{\phi}_2 g_2(z - U, z - \alpha U) = 0, \quad 0 < x < 1, \quad \hat{\phi}_{2x}(0) = 0,\ \ \hat{\phi}_{2x}(1) + \gamma\hat{\phi}_2(1) = 0.$$

THEOREM 1. *Suppose* $\hat{\lambda}_i < 1$ *for* $i = 1, 2$. *Then there exists a positive steady-state solution* (u, v) *of* (3) *satisfying* $0 < u(x) < U(x),\ 0 < v(x) < V(x)$ *for* $x \in [0, 1]$.

Proof. It is easy to check that (U, V) is the sup-solution of (3). Let $(\underline{u}, \underline{v}) = (\delta\hat{\phi}_1, \delta\hat{\phi}_2)(\delta > 0)$. Then for δ sufficiently small, we have

$$\begin{aligned}
&d\underline{u}_{xx} + \underline{u}g_1(z - \underline{u} - \beta V, z - \alpha\underline{u} - V)\\
&= [\underline{u}g_1(z - \underline{u} - \beta V, z - \alpha\underline{u} - V) - \hat{\lambda}_1\underline{u}g_1(z - \beta V, z - V)]\\
&= \underline{u}[(1 - \hat{\lambda}_1)g_1(z - \beta V, z - V)\\
&\qquad + (g_1(z - \underline{u} - \beta V, z - \alpha\underline{u} - V) - g_1(z - \beta V, z - V))] > 0.
\end{aligned}$$

Hence there exists a solution (u, v) of (3) satisfying $(\delta\hat{\phi}_1, \delta\hat{\phi}_2) \leq (u, v) \leq (U, V)$ for small δ. By Lemma 2 we obtain the strict inequalities in Theorem 1. □

Now we consider the special case that $g_1 = g_2 = g$, and we find that there exist infinitely many positive solutions of (3).

THEOREM 2. *Suppose that* $\lambda_i < 1$ *for* $i = 1, 2$ *and* $g_1 = g_2 = g$. *Then there exist infinitely many positive solutions* (u_ρ, v_ρ) $(\rho > 0)$ *of* (3) *satisfying* $0 < v_\rho \leq \min\{\frac{1}{\rho+\beta}, \frac{1}{\alpha\rho+1}\}z,\ u_\rho = \rho v_\rho$.

Proof. Set $\omega = \frac{u}{v}$. Then ω satisfies

$$-d\omega_{xx} - \frac{2dv_x}{v}\omega_x = 0, \quad \omega_x(0) = \omega_x(1) = 0.$$

By the maximum principle it follows that $\omega \equiv \rho$, a positive constant, i.e., $u = \rho v$. Thus v satisfies

$$dv_{xx} + vg(z - (\rho + \beta)v, z - (\alpha\rho + 1)v) = 0, \quad v_x(0) = 0,\ \ v_x(1) + \gamma v_x(1) = 0.$$

For $\rho > 0$ fixed, arguing as for the existence of U or V, and noting that $\lambda_2 < 1$, it follows that there exists a unique positive solution of the above problem, say, v_ρ, satisfying $0 < v_\rho \leq \min\{\frac{1}{\rho+\beta}, \frac{1}{\alpha\rho+1}\}z$. Thus (u_ρ, v_ρ) $(\rho > 0)$, where $u_\rho = \rho v_\rho$, is the positive solution of (3). This completes the proof. □

Remark 3. Suppose that $g_1 \leq g_2$, $g_1 \not\equiv g_2$ or $g_1 \geq g_2$, $g_1 \not\equiv g_2$. Then there exists no positive solution of (3). This conclusion is consistent with the analysis in [9] for the pure and simple competition model. In fact, suppose $u > 0,\ v > 0$ satisfy (3). We consider the first case, since the second case can be proved similarly. Denoting $\omega = \frac{u}{v}$, we have

$$\begin{aligned}
&-d\omega_{xx} - \frac{2dv_x}{v}\omega_x + \omega[g_2(z - u - \beta v, z - \alpha u - v) - g_1(z - u - \beta v, z - \alpha u - v)] = 0,\\
&\omega_x(0) = \omega_x(1) = 0.
\end{aligned}$$

Then $\omega =$ constant, and hence $\omega = 0$, a contradiction.

THEOREM 3. *Suppose* $\lambda_i < 1$ *and* $\hat{\lambda}_i > 1$ *for* $i = 1, 2$. *Then there exists a positive solution* (u, v) *of* (3).

Proof. Let $C_B[0,1] = \{u(x) \in C[0,1] : u_x(0) = 0,\ u_x(1) + \gamma u(1) = 0\}$ be the Banach space, with the usual maximum norm, denoted by $\|\cdot\|$, $X = C_B[0,1] \times C_B[0,1]$, $K = C_B^+[0,1] \times C_B^+[0,1]$, the positive cone of X. Let $N = (-d\Delta)^{-1}$, the inverse operator of $-d\Delta$ in $C_B[0,1]$. Then system (3) can be written as

$$u - N(ug_1(z - u - \beta v, z - \alpha u - v)) = 0,$$
$$v - N(vg_2(z - u - \beta v, z - \alpha u - v)) = 0.$$

Let $T(u,v) = (N(ug_1(z - u - \beta v, z - \alpha u - v)), N(vg_2(z - u - \beta v, z - \alpha u - v)))$. Then the fixed points of T in K are the corresponding nonnegative solutions of (3). Define $D = \{(u,v) \in K : \|u\| + \|v\| \le R_0\}$, where $R_0 = 2\max\{1, \frac{1}{\alpha}, \frac{1}{\beta}\}\|z\|$, and let $\dot{D}$ denote the interior of D in K. Since the proof is long, we divide it into three lemmas.

LEMMA 3. *For* $\lambda \ge 1$, *the equation* $T(u,v) = \lambda(u,v)$ *has no solution in* K *satisfying* $\|u\| + \|v\| = R_0$.

Proof. Suppose $(u,v) \in K$ satisfies $T(u,v) = \lambda(u,v)$. Then we have

$$du_{xx} + \lambda^{-1} ug_1(z - u - \beta v, z - \alpha u - v) = 0,$$
$$dv_{xx} + \lambda^{-1} vg_2(z - u - \beta v, z - \alpha u - v) = 0,$$

with the boundary conditions as above. As in the proof of Lemma 2, it follows that $u + \beta v < z, \alpha u + v < z$. Thus $u + v < \max\{1, \frac{1}{\alpha}, \frac{1}{\beta}\}z$. Hence there exists no fixed point of $T(u,v) = \lambda(u,v)$ in K satisfying $\|u\| + \|v\| = R_0$. □

Remark 4. It follows from Lemma 12.1 in [1] that $index_K(T, \dot{D}) = 1$.

Let $P_\sigma(0,0) = \{(u,v) \in K : \|u\| + \|v\| < \sigma\}$ be the neighborhood of $(0,0)$ in K with radius σ.

LEMMA 4. *For* $\sigma > 0$ *small enough,* $index_K(T, P_\sigma(0,0)) = 0$.

Proof. Given $\epsilon_0 > 0$ sufficiently small, noting the definition of U, V, we can take $0 < \sigma < \sigma_0 \ll 1$ such that $\frac{\sigma}{\gamma} < \min\{U - \epsilon_0, V - \epsilon_0\}$. Denote $S_\sigma^+ = \{(u,v) \in K : \|u\| + \|v\| = \frac{\sigma}{\gamma}\}$. Thus $\|u\| \le \sigma z,\ \|v\| \le \sigma z$ whenever $(u,v) \in S_\sigma^+$.

Let $\psi = (2 + \gamma) - \gamma x^2$. Then $\psi > 0$ on $[0,1]$ and satisfies

$$\psi_{xx} < 0, \quad 0 < x < 1, \quad \psi_x(0) = 0, \quad \psi_x(1) + \gamma\psi(1) = 0.$$

Take $p = (\psi, \psi)(\in K)$. We show next (by contradiction) that for $\lambda \ge 0$, $(u,v) - T(u,v) = \lambda(\psi, \psi)$ has no solution on S_σ^+ for small σ. Assume that this problem has a solution (u,v) on S_σ^+. Then (u,v) satisfies

$$du_{xx} + ug_1(z - u - \beta v, z - \alpha u - v) = d\lambda\psi_{xx}, \quad 0 < x < 1,$$
$$dv_{xx} + vg_2(z - u - \beta v, z - \alpha u - v) = d\lambda\psi_{xx}, \quad 0 < x < 1.$$

Hence by the definition of ψ, we have

$$du_{xx} + ug_1((1 - \sigma\beta)z - u, (1 - \sigma)z - \alpha u) \le 0, \quad 0 < x < 1,$$
$$dv_{xx} + vg_2((1 - \sigma)z - \beta v, (1 - \sigma\alpha)z - v) \le 0, \quad 0 < x < 1.$$

Since $\lambda_i < 1$, we can take sufficiently small σ, say, $\sigma < \sigma_1 \ll 1$, such that $\lambda_1(g_1((1 - \sigma\beta)z, (1 - \sigma)z)) < 1,\ \lambda_2(g_2((1 - \sigma)z, (1 - \sigma\alpha)z)) < 1$, where $\lambda_1(g_1((1 - \sigma\beta)z, (1 - \sigma)z))$, $\lambda_2(g_2((1 - \sigma)z, (1 - \sigma\alpha)z))$ are the principal eigenvalues of (4) with g_1 and g_2

replaced by $g_1((1-\sigma\beta)z,(1-\sigma)z)$ and $g_2((1-\sigma)z,(1-\sigma\alpha)z)$, respectively. As in the proof of Lemma 3.2 in [31] we can prove the existence and uniqueness of U^*, V^* of the following problem:

$$\begin{aligned} dU^*_{xx} + U^* g_1((1-\sigma\beta)z - U^*, (1-\sigma)z - \alpha U^*) = 0, \qquad 0 < x < 1,\\ dV^*_{xx} + V^* g_2((1-\sigma)z - \beta V^*, (1-\sigma\alpha)z - V^*) = 0, \qquad 0 < x < 1, \end{aligned}$$

with the usual boundary conditions. By an L^p estimate and the Sobolev embedding theorem (see [27]), we proceed as in the proof of Theorem 2.5 in [32] to obtain

$$\lim_{\sigma\to 0} U^* = U, \ \lim_{\sigma\to 0} V^* = V.$$

Thus there exists $\sigma_2 > 0$, such that for $\sigma < \sigma_2$, $U^* > U - \epsilon_0$, $V^* > V - \epsilon_0$. It follows from the monotone method and the uniqueness of U^*, V^* that $u \geq U^*$, $v \geq V^*$. Now take $\sigma < \bar{\sigma} = \min\{\sigma_0, \sigma_1, \sigma_2\}$. Then for $\sigma < \bar{\sigma}$, we have $u > \frac{\sigma}{\gamma}, v > \frac{\sigma}{\gamma}$, which contradicts $(u,v) \in S^+_\sigma$. Lemma 12.1 of [1] can be applied to complete the proof of this lemma. □

Let $O^+(U,0)$ be a small neighborhood of $(U,0)$ in K. Then we have the following lemma.

LEMMA 5. *Suppose that T has no fixed point in $\dot{D}$. Then $index_K(T, O^+(U,0)) = 1$ if $\hat{\lambda}_2 > 1$, $\lambda_1 < 1$.*

Proof. Define $T(\theta)(u,v) = (N(ug_1(z-u-\theta\beta v, z-\alpha u-\theta v)), N(vg_2(z-u-\theta\beta v, z-\alpha u-\theta v)))$. It follows from $(u,v) = T(\theta)(u,v)$ that

$$\begin{aligned} du_{xx} + ug_1(z-u-\theta\beta v, z-\alpha u-\theta v) = 0,\\ dv_{xx} + vg_2(z-u-\theta\beta v, z-\alpha u-\theta v) = 0. \end{aligned}$$

If (u,v) is a fixed point of $T(\theta)$ on $\partial O^+(U,0)$, the boundary of $O^+(U,0)$ in K, it is easy to see that $u > 0$, $v \geq 0$. Furthermore, we have $v > 0$; otherwise we have $(u,v) = (U,0)$, contradicting $(u,v) \in \partial O^+(U,0)$. We claim that for $\theta \in [0,1]$, $T(\theta)$ has no fixed point on $\partial O^+(U,0)$. Otherwise, for $\theta = 0$, by noting $\hat{\lambda}_2 > 1$ and $\lambda_1 < 1$, we find $u = U$, $v = 0$, a contradiction; for $\theta > 0$, this implies that $(u, \theta v) > (0,0)$ is a fixed point of T in $\dot{D}$, contradicting a hypothesis of this lemma. It follows from the homotopy invariance of topological degree that

$$index_K(T, O^+(U,0)) = index_K(T(1), O^+(U,0)) = index_K(T(0), O^+(U,0)), \tag{7}$$

where $T(0)(u,v) = (N(ug_1(z-u, z-\alpha u)), N(vg_2(z-u, z-\alpha u)))$.

The fixed point (u,v) of $T(0)$ in $O^+(U,0)$ satisfies

$$\begin{aligned} du_{xx} + ug_1(z-u, z-\alpha u) = 0, \quad 0 < x < 1,\\ dv_{xx} + vg_2(z-u, z-\alpha u) = 0, \quad 0 < x < 1, \end{aligned} \tag{8}$$

with the boundary conditions

$$u_x(0) = 0, \ \ v_x(0) = 0, \ \ u_x(1) + \gamma u(1) = 0, \ \ v_x(1) + \gamma v(1) = 0.$$

Since $\lambda_1 < 1$, we have $u = U$. Noting $\hat{\lambda}_2 > 1$, we determine that the principal eigenvalue λ'_2 of the following problem is negative:

$$d\phi'_{xx} + \phi' g_2(z-U, z-\alpha U) = \lambda'_2 \phi', \quad \phi'_x(0) = 0, \quad \phi'_x(1) + \gamma\phi'(1) = 0.$$

Substituting $u = U$ into the second equation of (8), we have $v = 0$. Hence $(U, 0)$ is the unique fixed point of $T(0)$ in $O^+(U, 0)$; thus

$$index_K(T(0), O^+(U, 0)) = index_K(T(0), (U, 0)). \tag{9}$$

Let $I(\theta)$ $(\theta \in [0, 1])$ be defined by $I(\theta)(u, v) = (N(ug_1(z - u, z - \alpha u)), N(vg_2(z - (\theta U + (1 - \theta)u), z - \alpha(\theta U + (1 - \theta)u))))$. Then $(u, v) = I(\theta)(u, v)$ satisfies

$$\begin{aligned} &du_{xx} + ug_1(z - u, z - \alpha u) = 0, && 0 < x < 1, \\ &dv_{xx} + vg_2(z - (\theta U + (1 - \theta)u), z - \alpha(\theta U + (1 - \theta)u)) = 0, && 0 < x < 1, \end{aligned} \tag{10}$$

with the usual boundary conditions. We claim that $I(\theta)$ has no fixed point on $\partial O^+(U, 0)$ in K. Otherwise, from the first equation of (10), we have $u = U$, and substituting this into the second equation of (10), we find $v = 0$, so the only fixed point of $I(\theta)$ on $\partial O^+(U, 0)$ is $(U, 0)$, a contradiction. By the definition of $I(\theta)$, we obtain

$$T(0) = I(0), \quad I(1) = T_1 \times T_2, \tag{11}$$

where $T_1 u = N(ug_1(z - u, z - \alpha u))$, $T_2 v = N(vg_2(z - U, z - \alpha U))$, $(T_1 \times T_2)(u, v) = (T_1 u, T_2 v)$. $(u, v) = I(1)(u, v)$ satisfies

$$\begin{aligned} &du_{xx} + ug_1(z - u, z - \alpha u) = 0, && 0 < x < 1, \\ &dv_{xx} + vg_2(z - U, z - \alpha U) = 0, && 0 < x < 1. \end{aligned}$$

It follows from (7)–(11) and the product theorem for fixed points (see [33]) that

$$\begin{aligned} index_K(T(0), (U, 0)) &= index_K(I(0), (U, 0)) = index_K(I(1), (U, 0)) \\ &= index_{C_B}(T_1, U) \cdot index_{C_B^+}(T_2, 0). \end{aligned} \tag{12}$$

Since T_2 is a linear compact operator and $\hat{\lambda}_2 > 1$, then T_2 has no eigenvalue > 1 with positive eigenfunction in C_B^+. It follows from Lemma 13.1 of [1] that $index_{C_B^+}(T_2, 0) = 1$.

We show next that $index_{C_B}(T_1, U) = 1$. Let $\tau = 2 \min\{1, \frac{1}{\alpha}\}\|z\|$, $P_\tau = \{u \in C_B^+ : \|u\| \le \tau\}$, $\partial P_\tau = \{u \in C_B^+ : \|u\| = \tau\}$. For $\lambda \ge 1$, if $T_1 u = \lambda u$, $d\lambda u_{xx} + ug_1(z - u, z - \alpha u) = 0$. Arguing as in the proof of Lemma 1, we have $u \le \min\{1, \frac{1}{\alpha}\}z < \tau$. Hence for $\lambda \ge 1$, $T_1 u = \lambda u$ has no solution on ∂P_τ. It follows from Lemma 12.1 of [1] that $index_{C_B^+}(T_1, P_\tau) = 1$. Let $0 < \tau_0 \le \frac{1}{2} \min_{[0,1]}\{U(x)\}$. Suppose that for $\lambda \ge 0$, $p = \psi(x)$, such that $u - T_1 u = \lambda p$ has a solution u on ∂P_{τ_0}, where $\psi(x)$ is defined as in the proof of Lemma 4. Then, $du_{xx} + ug_1(z - u, z - \alpha u) = d\lambda\psi_{xx} \le 0$. Thus u is a sup-solution of (5). From the monotone method and the uniqueness of U it follows that $u \ge U$, a contradiction to $\|u\| = \tau_0$. Hence, $index_{C_B^+}(T_1, P_{\tau_0}) = 0$. Since $u = U$ is the unique fixed point of T_1 in $P_\tau \backslash \bar{P}_{\tau_0}$, we obtain $index_{C_B}(T_1, U) = index_{C_B^+}(T_1, P_\tau \backslash \bar{P}_{\tau_0}) = index_{C_B^+}(T_1, P_\tau) - index_{C_B^+}(T_1, P_{\tau_0}) = 1$.

Combining the above result with equations (7), (9), and (12), it follows that $index_K(T, O^+(U, 0)) = 1$. □

Remark 5. Suppose that T has no fixed point in $\dot{D}$. We can proceed as above to obtain $index_K(T, O^+(0, V)) = 1$ if $\hat{\lambda}_1 > 1$, $\lambda_2 < 1$.

Now we turn to the proof of Theorem 3. Suppose that T has no fixed point in $\dot{D}$. Then the following equation holds:

$$index_K(T, \dot{D}) = index_K(T, O^+(0, 0)) + index_K(T, O^+(U, 0)) + index_K(T, O^+(0, V)),$$

contradicting Lemmas 3–5. This completes the proof of Theorem 3. □

Noting Lemma 1, and using the same process as in the proof of Theorem 3.6 in [15], we have the following theorem.

THEOREM 4. *If* $\lambda_1 > 1$ *and* $\lambda_2 > 1$, *then the solution of system* (1) *satisfies*

$$\lim_{t\to\infty}(S,R,U,V) = (z,z,0,0).$$

If $\lambda_1 > 1$ *and* $\lambda_2 < 1$, *then the solution of system* (1) *satisfies*

$$\lim_{t\to\infty}(S,R,U,V) = (z-\beta V, z-V, 0, V).$$

If $\lambda_1 < 1$ *and* $\lambda_2 > 1$, *then the solution of system* (1) *satisfies*

$$\lim_{t\to\infty}(S,R,U,V) = (z-U, z-\alpha U, U, 0).$$

THEOREM 5. *Suppose* $\hat{\lambda}_i < 1$, $i = 1,2$. *Then the solution of system* (1) *is uniformly persistent* ([10]).

Proof. It follows from system (1′) that $v(x,t) \le V(x,t)$, where $V(x,t)$ is the solution of the problem

$$\begin{aligned} &V_t = dV_{xx} + Vg_2(\varphi_1 - \beta V, \varphi_2 - V), \quad 0 < x < 1, \quad t > 0,\\ &V_x(0,t) = 0, \quad V_x(1,t) + \gamma V(1,t) = 0,\\ &V(x,0) = v_0(x). \end{aligned}$$

Since $\hat{\lambda}_2 < 1$, then $\lambda_2 < 1$. We can proceed as in Theorem 2.5 in [32] to show that if $\lambda_2 < 1$, then $\lim_{t\to\infty} V(x,t) = V(x)$, where $V(x) < \min\{1, \frac{1}{\beta}\}z$ is the unique positive solution of

$$\begin{aligned} &dV_{xx} + Vg_2(z-\beta V, z-V) = 0, \quad 0 < x < 1,\\ &V_x(0) = 0, \;\; V_x(1) + \gamma V(1) = 0. \end{aligned}$$

Since $\hat{\lambda}_1 < 1$, we can take $0 < \epsilon \ll 1$, such that for the following principal eigenvalue $\tilde{\lambda}_1 < 1$,

$$\begin{aligned} &d\tilde{\phi}_{1xx} + \tilde{\lambda}_1\tilde{\phi}_1 g_1((1-\epsilon(1+\beta)/2)z - \beta V(x), (1-\epsilon)z - V(x)) = 0, \quad 0 < x < 1,\\ &\tilde{\phi}_{1x}(0) = 0, \quad \tilde{\phi}_{1x}(1) + \tilde{\phi}_1(1) = 0. \end{aligned}$$

There exists $\tau' > 0$ such that for $x \in [0,1]$, $t \ge \tau'$, the following inequalities hold:

$$\varphi_1 \ge z - (\epsilon/2)z, \quad \varphi_2 \ge z - (\epsilon/2)z, \quad v(x,t) \le V(x) + (\epsilon/2)z.$$

Using the comparison theorem, it follows that for $t \ge \tau'$, $u(x,t) \ge \underline{u}(x,t)$, where $\underline{u}(x,t)$ is the solution of

$$\begin{aligned} &\underline{u}_t = d\underline{u}_{xx} + \underline{u}g_1((1-(\epsilon(1+\beta)/2))z - \underline{u} - \beta V(x), \quad (1-\epsilon)z - \alpha\underline{u} - V(x)),\\ &\qquad\qquad 0 < x < 1, t > \tau',\\ &\underline{u}_x(0,t) = 0, \quad \underline{u}_x(1,t) + \gamma\underline{u}(1,t) = 0,\\ &\underline{u}(x,\tau') = \min\{(1-\epsilon(1+\beta)/2)z - \beta V(x), \quad ((1-\epsilon)z - V(x))/\alpha, u(x,\tau')\}. \end{aligned}$$

Noting $\tilde{\lambda}_1 < 1$, we have $\lim_{t\to\infty} \underline{u}(x,t) = \underline{u}_\epsilon(x)$, where $\underline{u}_\epsilon(x)$ is the unique positive solution of

$$d\underline{u}_{\epsilon xx} + \underline{u}_\epsilon g_1((1-\epsilon(1+\beta)/2)z - \underline{u}_\epsilon - \beta V(x), (1-\epsilon)z - \alpha\underline{u}_\epsilon - V(x)) = 0$$

with the usual boundary conditions. It follows from an L^p estimate and the embedding theorem (see [27]) that $\lim_{\epsilon\to 0} \underline{u}_\epsilon(x) = \hat{u}(x)$, where $\hat{u}(x)$ is the unique positive solution of the following problem on $[0,1]$:

$$d\hat{u}_{xx} + \hat{u}g_1(z - \hat{u} - \beta V(x), z - \alpha\hat{u} - V(x)) = 0 \tag{13}$$

with the usual boundary conditions. A similar result holds for v if $\hat{\lambda}_2 < 1$. Hence, there exist constants $\eta_1 > 0,\ \tau_1 \geq \tau'$ such that $u(x,t) \geq \eta_1,\ v(x,t) \geq \eta_1$ for $x \in [0,1],\ t \geq \tau_1$.

By the equation of S in system (1) and the definition of $g_i,\ i = 1,2$, we have

$$\begin{aligned} S_t &= dS_{xx} - g_1(S,R)u - \beta g_2(S,R)v \\ &\geq dS_{xx} - \max\left\{\tfrac{m_{s_1}}{K_{s_1}}, \tfrac{m_{s_2}}{K_{s_2}}\right\} S(u+\beta v). \end{aligned}$$

Then there exists $\tau'' > 0$, and for $t \geq \tau''$, the following inequality holds:

$$S_t \geq dS_{xx} - \max\left\{\frac{m_{s_1}}{K_{s_1}}, \frac{m_{s_2}}{K_{s_2}}\right\} S(z+\varepsilon - S).$$

A similar result holds for R. Thus we can proceed as in Lemma 3.8 in [15] to show that there exist $\eta_2 > 0,\ \tau_2 > 0$ such that $S(x,t) \geq \eta_2,\ R(x,t) \geq \eta_2$ for $x \in [0,1],\ t \geq \tau_2$. Denote $\tau = \max\{\tau_1, \tau_2\},\ \eta = \max\{\eta_1, \eta_2\}$. Then we have $S \geq \eta,\ R \geq \eta,\ u \geq \eta,\ v \geq \eta$ for $x \in [0,1],\ t \geq \tau$. This completes the proof. □

3. Numerical simulations. The goal of this section is to present the results of numerical simulations that complement the analytic results of the previous section. The simulations reported below represent a small fraction of those made. We wish to make a few general comments based on our observations. First, in most simulations performed, convergence to equilibrium was observed. Second, competitive exclusion, the elimination of one population by another, was observed. Finally, nonuniqueness of the positive equilibrium and bistability of the semitrivial equilibrium were observed. Our simulations are consistent with the analytic results of the previous sections. Furthermore, the simulations reveal that much more complicated dynamics are also possible in the region D defined below. Our numerical simulations also seemed to indicate that coexistence is more likely in the case of competition for two limiting complementary resources in the unstirred chemostat, than in the case of competition for a single limiting resource in the unstirred chemostat (see [26]).

Define $A = \{(\hat{\lambda}_1, \hat{\lambda}_2) : 0 < \hat{\lambda}_1 < 1,\ 0 < \hat{\lambda}_2 < 1\}$, $B = \{(\hat{\lambda}_1, \hat{\lambda}_2) : 0 < \hat{\lambda}_1 < 1,\ \hat{\lambda}_2 > 1\}$, $C = \{(\hat{\lambda}_1, \hat{\lambda}_2) : \hat{\lambda}_1 > 1,\ 0 < \hat{\lambda}_2 < 1\}$, and $D = \{(\hat{\lambda}_1, \hat{\lambda}_2) : \hat{\lambda}_1 > 1,\ \hat{\lambda}_2 > 1\}$.

Our numerical simulations seem to indicate the following:

(1) Coexistence in the form of a positive equilibrium can be observed when $(\hat{\lambda}_1, \hat{\lambda}_2) \in A \cup B \cup C$ (see Figures 1–2 and Tables 1–2), and apparently a globally stable positive equilibrium can always be observed when $(\hat{\lambda}_1, \hat{\lambda}_2) \in A$;

(2) Competitive exclusion in the form of an apparently globally stable semitrivial positive equilibrium can occur when $(\hat{\lambda}_1, \hat{\lambda}_2) \in B \cup C$ (see Figures 1–2 and Tables 1–2);

(3) Both stable and unstable positive equilibria can exist, and there can be bistability with two stable semitrivial equilibria and an unstable positive equilibrium, resulting in initial condition dependent outcomes when $(\hat{\lambda}_1, \hat{\lambda}_2) \in D$ (see Figures 3–4);

(4) Existence of multiple stable and/or unstable positive equilibria can be observed when $(\hat{\lambda}_1, \hat{\lambda}_2) \in D$ (see Figures 4–5);

(5) The parameters have an apparent effect on the density of both organisms, i.e., the density u can be nondecreasing and the density v can be nonincreasing as α increases (see Figures 6(a)–6(c)). Similar results for v and u hold as β increases. But the density of both organisms can decrease as γ increases (see Figures 6(b) and 6(d)).

Now we describe an indirect method used for determining either $\hat{\lambda}_i > 1$ or $\hat{\lambda}_i < 1$ from numerical simulations. The method will be described for determining the sign of $\hat{\lambda}_1 - 1$ only, since the other case is similar. Consider the following system:

$$
\begin{aligned}
&u_t = du_{xx} + ug_1(z - u - \beta v, z - \alpha u - v), && 0 < x < 1,\ t > 0,\\
&v_t = dv_{xx} + vg_2(z - \beta v, z - v), && 0 < x < 1,\ t > 0,\\
&u_x(0,t) = 0,\ \ u_x(1,t) + \gamma u(1,t) = 0,\\
&v_x(0,t) = 0,\ \ v_x(1,t) + \gamma v(1,t) = 0,\\
&u(x,0) = u_0(x) \geq 0,\ \ v(x,0) = v_0(x) \geq 0, \not\equiv 0,
\end{aligned}
\tag{14}
$$

where $u_0 + \beta v_0 \leq z,\ \alpha u_0 + v_0 \leq z$. Taking initial conditions characterized by a very small density of u_0, we can prove and observe numerically that v rapidly approaches the equilibrium $V(x)$. Hence for large times, t, we take $v(x,t)$ as $V(x)$ in the first equation of (14). Then we have

$$
u_t = du_{xx} + ug_1(z - u - \beta V, z - \alpha u - V), \quad 0 < x < 1,\ t > 0 \tag{15}
$$

with the usual boundary and initial conditions. We can use the comparison theorem and the Liapunov function method to prove that the solution $u(x,t)$ of (15) satisfies $\lim_{t\to\infty} u(x,t) = 0$ if $\hat{\lambda}_1 \geq 1$ and $\lim_{t\to\infty} u(x,t) = \hat{u}$ if $\hat{\lambda}_1 < 1$, where $\hat{u}$ is the unique positive solution of (13). Therefore, what happens to u depends essentially on the sign of $\hat{\lambda}_1 - 1$. If $\hat{\lambda}_1 \geq 1$, we observed the decay of the solution u of (15) to very small values; if $\hat{\lambda}_1 < 1$, we observed the growth of the solution u of (15) to the value of the solution of (13). Therefore, we can determine the sign of $\hat{\lambda}_1 - 1$ numerically by observing whether there is decay to very small values or growth to the value of the solution of (13).

We next simulate the corresponding time-dependent system of (3), which determines the limiting system of (1):

$$
\begin{aligned}
&u_t = du_{xx} + ug_1(z - u - \beta v, z - \alpha u - v), && 0 < x < 1,\ t > 0,\\
&v_t = dv_{xx} + vg_2(z - u - \beta v, z - \alpha u - v), && 0 < x < 1,\ t > 0,\\
&u_x(0,t) = 0,\ \ u_x(1,t) + \gamma u(1,t) = 0,\\
&v_x(0,t) = 0,\ \ v_x(1,t) + \gamma v(1,t) = 0,\\
&u(x,0) = u_0(x) \geq 0,\ \ v(x,0) = v_0(x) \geq 0.
\end{aligned}
$$

We have chosen to discretize the spatial variables in the above system using a second-order finite-difference scheme. The derivative terms in the boundary conditions are approximated using second-order centered differencing. The temporal variable is approximated using the Crank–Nicholson method. In all of the simulations the domain is divided uniformly into 40 cells.

TABLE 1

The equilibria corresponding to the parameters given in Tables 1 *and* 2 *are shown in Figures* 1 *and* 2.

m_s	$\hat{\lambda}_1$	$\hat{\lambda}_2$	Area	Equilibrium
$(2.06, 2.04)$	< 1	> 1	B	$(U, 0)$
$(2.045, 2.055)$	< 1	> 1	B	Coexistence
$(2.04, 2.06)$	< 1	< 1	A	Coexistence

$(2.1, 6.9)$	> 1	< 1	C	Coexistence
$(1.95, 7.05)$	> 1	< 1	C	$(0, V)$

In the following, we denote $m_s = (m_{s_1}, m_{s_2})$, $m_r = (m_{r_1}, m_{r_2})$, $K_s = (K_{s_1}, K_{s_2})$, $K_r = (K_{r_1}, K_{r_2})$.

Coexistence and competitive exclusion. In Figures 1 and 2 a sequence of simulations is reported where different growth rates were used, but all of the other parameter values remain fixed. The parameter values used were $\alpha = \beta = 0.5, \gamma = 1, K_s = (1, 1), K_r = (1, 1.2)$. In Figure 1 and Table 1, $m_r = (3, 3)$, and in Figure 2 and Table 2, $m_r = (6, 6)$. In Figure 1, m_s took the values indicated in Table 1, and in Figure 2, m_s took the values indicated in Table 2. In each simulation in Figures 1 and 2, the densities were plotted at the final time, $t = 1000$. This appeared to be long enough to allow the solutions to be very close to steady state. A similar procedure was used in the other figures. We observed from Figures 1 and 2, as well as from many other simulations, that at the highest growth rate of u and the lowest growth rate of v, u is dominant with v barely present for any initial conditions. In this case, we checked that $(\hat{\lambda}_1, \hat{\lambda}_2) \in B$. As the growth rate of u is decreased or the growth rate of v is increased, the amount of v increases at the expense of the amount of u. Both organisms coexist at a positive equilibrium. In this case, we also checked that $(\hat{\lambda}_1, \hat{\lambda}_2) \in A$ or B or C. All the simulations show that the coexistence is unique and an apparently globally stable positive equilibrium exists when $(\hat{\lambda}_1, \hat{\lambda}_2) \in A$. As the growth rate of u is further decreased or the growth rate of v is further increased, v is dominant with u barely present for any initial condition. In addition, we checked $(\hat{\lambda}_1, \hat{\lambda}_2) \in C$ in this case. Coexistence in the form of a positive equilibrium can occur when $(\hat{\lambda}_1, \hat{\lambda}_2) \in A$ or B or C. The nonexistence of a positive equilibrium can also occur when $(\hat{\lambda}_1, \hat{\lambda}_2) \in B$ or C.

Bistability and the existence of positive equilibria. (i) In Figure 3, we provide numerical evidence of bistability; i.e., each of the two semitrivial equilibria is stable to invasion by its rival and attracts solutions corresponding to nearby initial data. As well, an unstable positive equilibrium is observed. We took $m_s = (3, 2)$, $m_r = (2.4, 3.6)$, and the other parameter values as in Figure 1. In this case we checked that $(\hat{\lambda}_1, \hat{\lambda}_2) \in D$. The simulations in Figures 3(a) and 3(b) show a plot of the L_1 norms of u and of v versus time t. In Figure 3(a) the initial conditions used were $u_0 = 0.5$ and

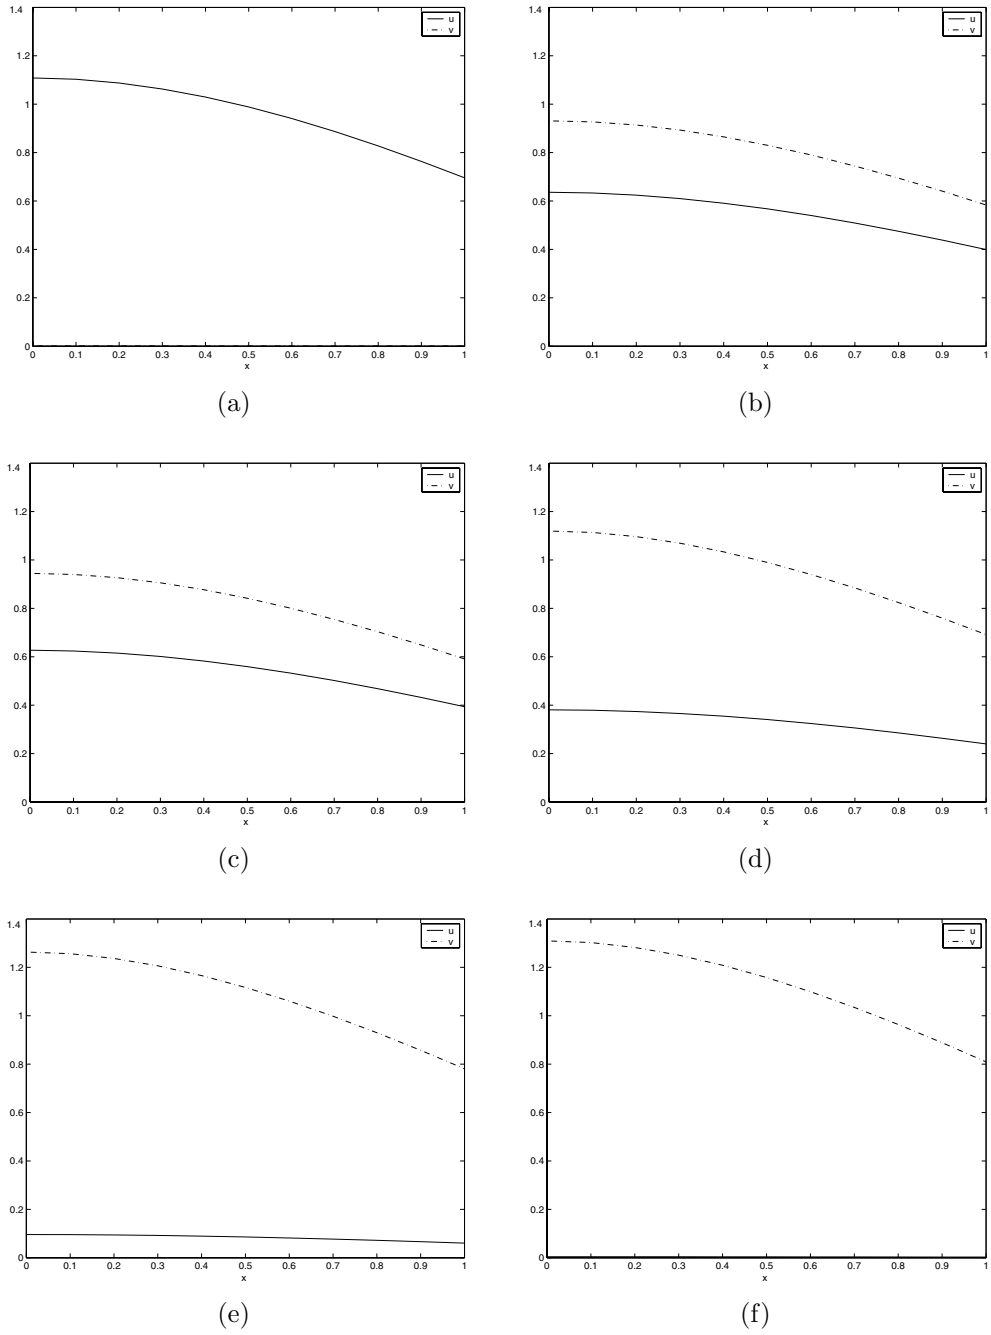

FIG. 1. *Equilibria for* $m_r = (3, 3)$ *and the different values of* m_s *from Table* 1 *(in the order given in that table). The other parameters used are* $K_s = (1, 1)$, $K_r = (1, 1.2)$, $\alpha = \beta = 0.5$, *and* $\gamma = 1$.

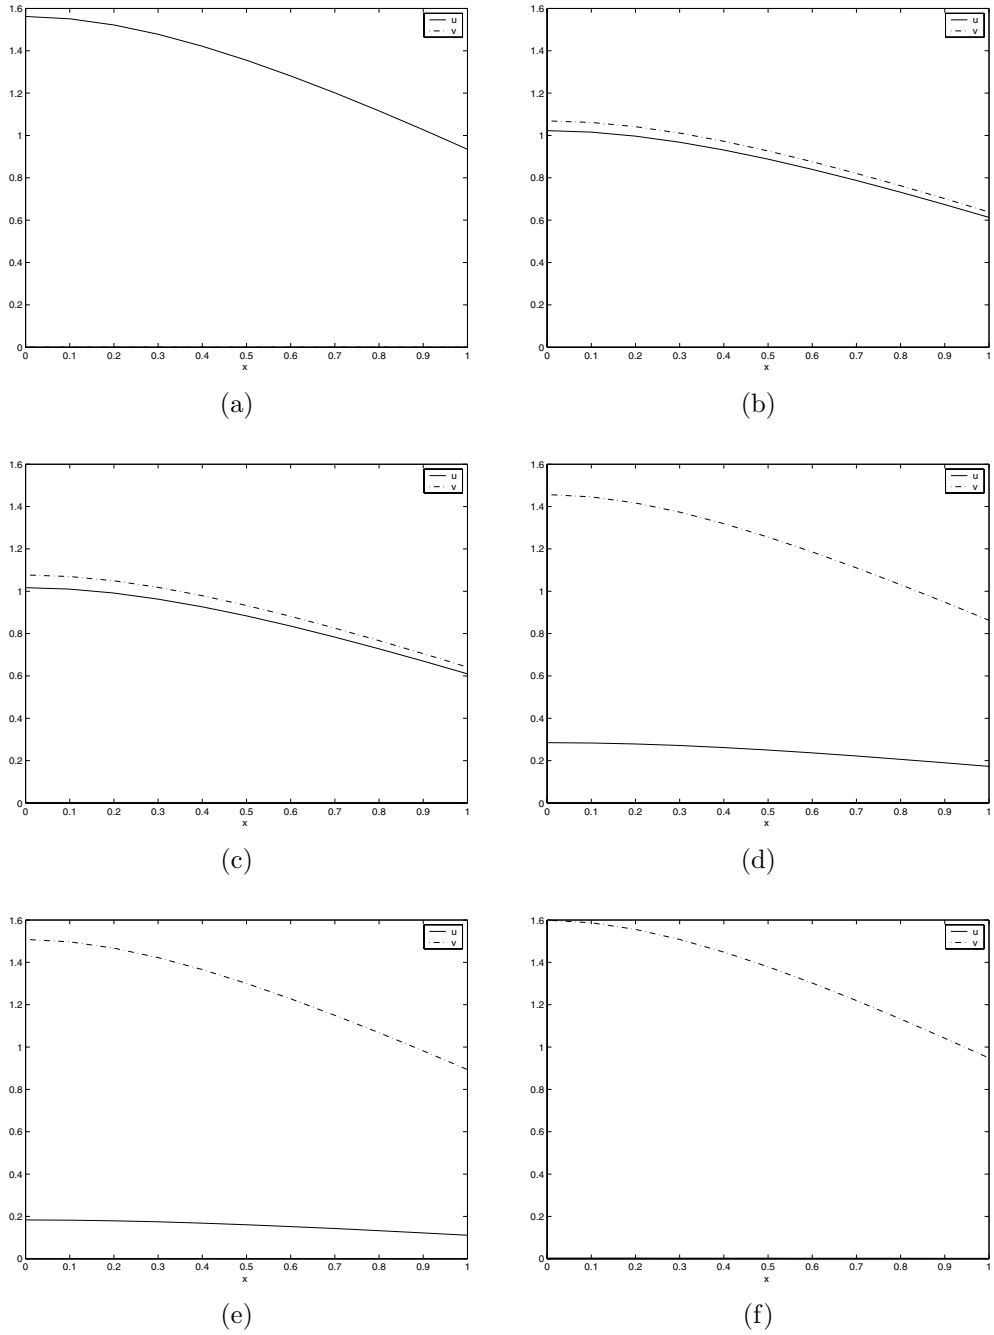

FIG. 2. *Equilibria for* $m_r = (6, 6)$ *and the different values of* m_s *from Table* 2 *(in the order given in that table). All the other parameters are the same as those in Figure* 1.

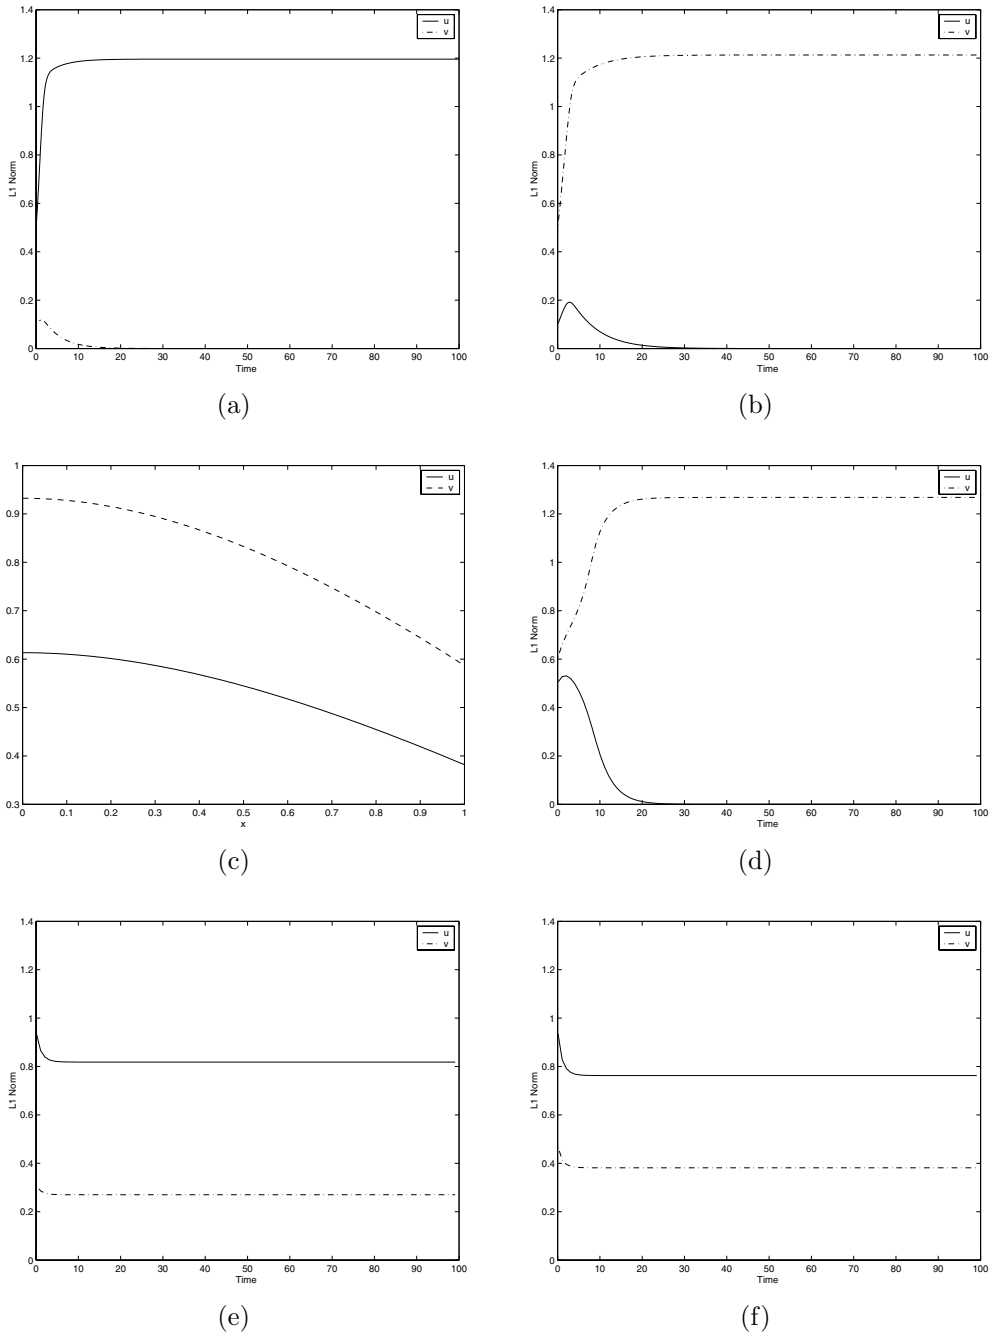

FIG. 3. *Convergence to equilibria. All parameters except m_s and m_r are the same as those in Figure* 1. *In* (a)–(c) $m_s = (3, 2)$ *and* $m_r = (2.4, 3.6)$. *In* (a)–(b) *the* L_1 *norms of* u *and of* v *versus time are shown for two semitrivial equilibria. In* (c) *a plot of the positive equilibrium for each* $x \in [0, 1]$ *is shown. In* (d)–(f) $m_s = (2, 2)$ *and* $m_r = (2, 4)$. *The* L_1 *norms of* u *and of* v *versus time are shown for several different equilibria.*

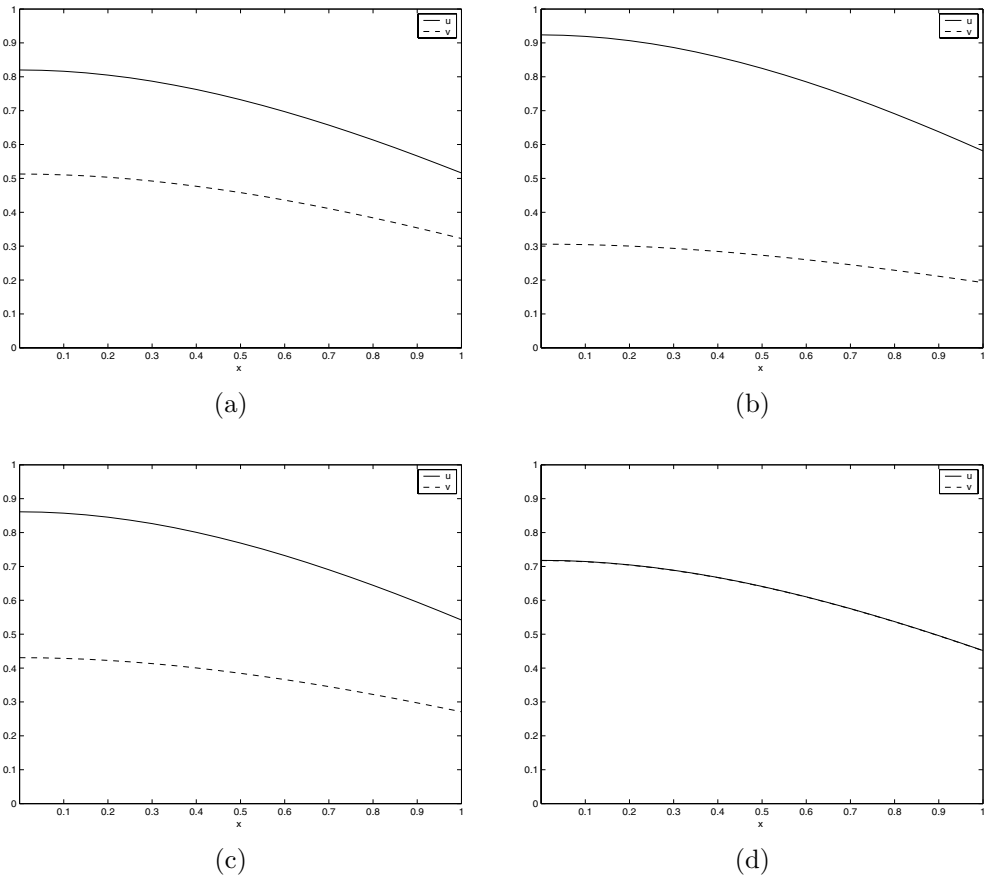

FIG. 4. *Several positive equilibria. All parameters are the same as those in Figure* 1*, except* $m_s = (2, 2)$ *and* $m_r = (2, 4)$*. Note that* u *and* v *are indistinguishable in* (d).

$v_0 = 0.1$. In Figure 3(b) the initial conditions used were $u_0 = 0.1$ and $v_0 = 0.5$. The positive equilibrium is plotted in Figure 3(c). After many simulations, in this case we believe that this is the only positive equilibrium and that it is unstable.

(ii) In Figures 3(d)–(f), we took $m_s = (2, 2)$ and $m_r = (2, 4)$. All other parameters are the same as in Figure 1. Both semitrivial equilibria are stable. Only one of them is shown (see Figure 3(d)). As well, nonuniqueness and stability of more than one positive equilibrium are observed. In this case, we checked that $(\hat{\lambda}_1, \hat{\lambda}_2) \in D$.

Existence of multiple positive equilibria. Based on extensive simulations, we believe that much more complicated dynamical behavior can occur when $(\hat{\lambda}_1, \hat{\lambda}_2) \in D$.

(i) In Figure 4 we took the same parameters as in Figures 3(d)–(f) and used continuation (numerical analysis) to find the equilibria. Simulations (not shown) seem to indicate that there are at least four positive equilibria in this case, and strongly suggest that one of them is unstable (see Figure 4(d), where u and v are indistinguishable), and that the other three are stable (see Figures 4(a)–(c)). Note that the equilibria depicted in Figures 4(b)–(c) correspond to those in Figures 3(e)–(f), respectively.

(ii) In Figures 5(a)–(c) we took $m_s = (1.5, 1.8)$ and $m_r = (1.75, 1.42)$. In Figures 5(d)–(f) we took $m_s = (2.1, 2.75)$ and $m_r = (2.8, 2.13)$. The other parameters

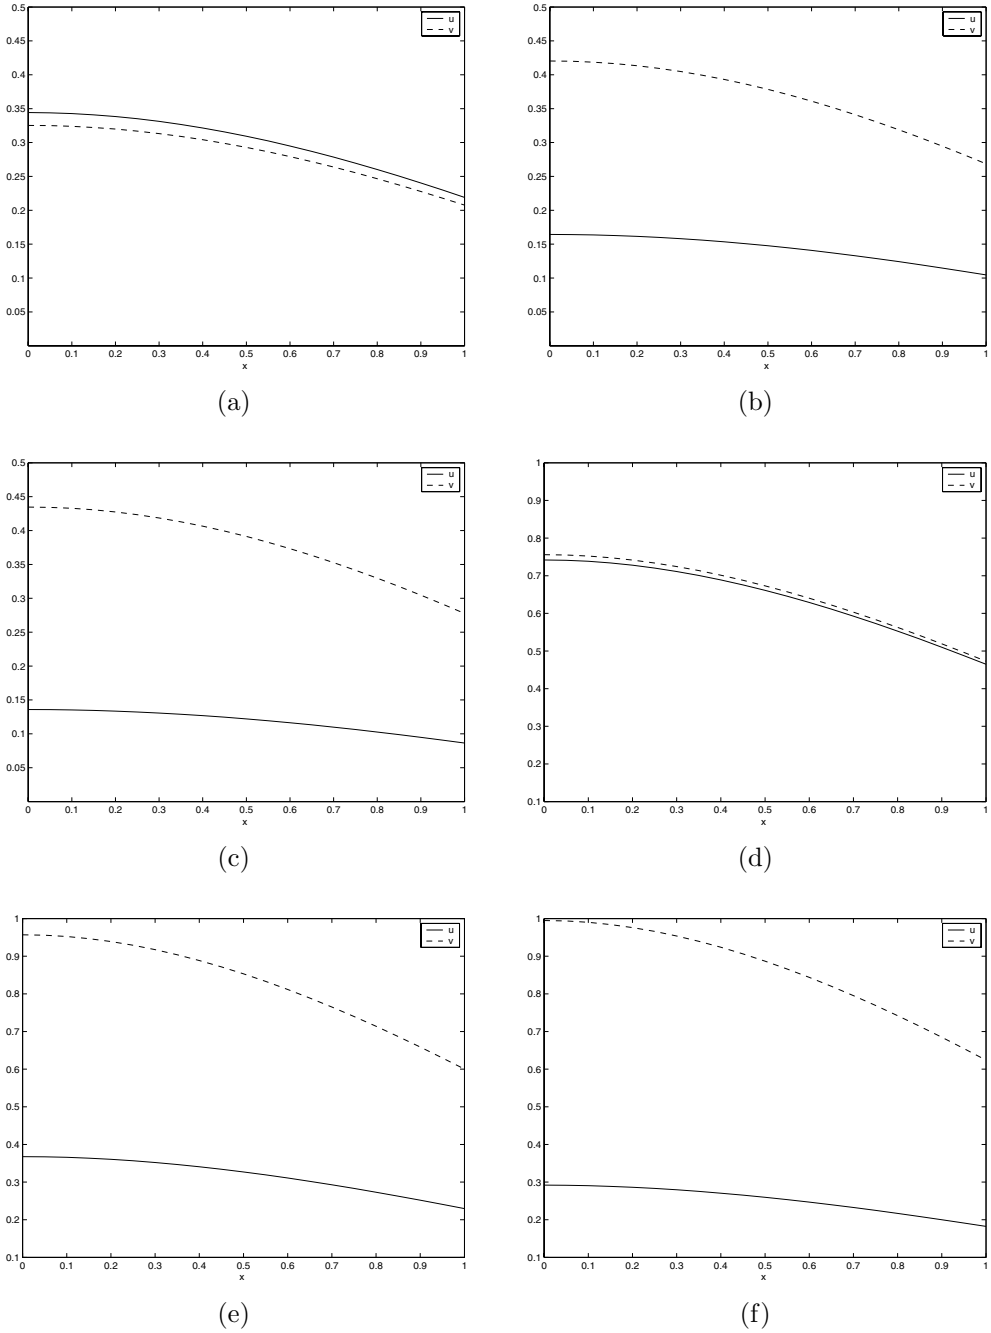

FIG. 5. *Positive equilibria. All parameters are the same as those in Figure* 1*, except that in* (a)–(c) $m_s = (1.5, 1.8)$ *and* $m_r = (1.75, 1.42)$*, and in* (d)–(f) $m_s = (2.1, 2.75)$ *and* $m_r = (2.8, 2.13)$.

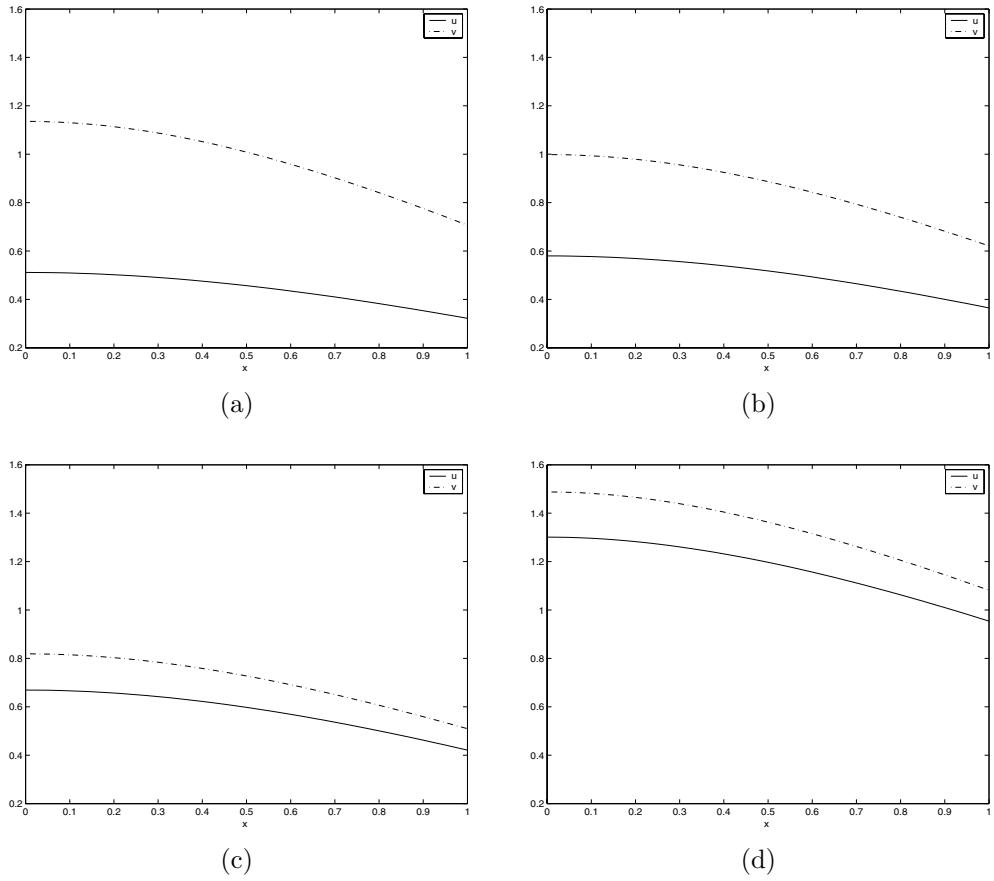

FIG. 6. *Parameters α and γ have an effect on the densities of the equilibria. In* (a)–(d) $m_s = (2, 2.1)$, $m_r = (3, 3)$, $K_s = (1, 1)$, $K_r = (1, 1.2)$, *and* $\beta = 0.5$. *In* (a)–(c) $\gamma = 1$, *and in* (d) $\gamma = 0.6$. *In* (a) $\alpha = 0.3$, *in* (b) $\alpha = 0.5$, *in* (c) $\alpha = 0.7$, *and in* (d) $\alpha = 0.5$.

were taken as in Figure 1. In both cases, we checked that $(\hat{\lambda}_1, \hat{\lambda}_2) \in D$. For each case, we used numerical analysis to find the three positive equilibria depicted in Figure 5. Subsequent simulations strongly indicated that all these positive equilibria are unstable.

Effects of the parameters. In Figure 6 a sequence of simulations shows that the parameters α, β, γ have an apparent effect on the density of both populations. Parameter values taken are $m_s = (2, 2.1)$, $m_r = (3, 3)$, $K_s = (1, 1)$, $K_r = (1, 1.2)$. Values for α, β, and γ are given in the caption of Figure 6. The initial data are $u_0 = 1$ and $v_0 = 1$. We observed that the density of u can be nondecreasing and the density of v can be nonincreasing as α increases (see Figures 6(a)–6(c)). A similar result holds for v and u as β increases. We also observed that the density of both u and v can decrease as γ increases (see Figures 6(b) and 6(d)).

Acknowledgment. The authors would like to express their sincere thanks to the anonymous referees of this paper for their careful reading and valuable suggestions leading to an improvement of the paper.

INSTABILITIES OF WAVY PATTERNS GOVERNED BY COUPLED BURGERS EQUATIONS*

E. A. GLASMAN†, A. A. GOLOVIN‡, AND A. A. NEPOMNYASHCHY§

Abstract. Wave dynamics in a system of coupled Burgers equations is studied. This model describes the long-wave nonlinear evolution of an oscillatory pattern-forming system in the presence of the Goldstone mode caused by the translation symmetry, for example, the oscillatory instability of a propagating combustion front. It is shown that the system of coupled Burgers equations reveals several new types of instabilities, which are studied both analytically and numerically. In some limiting cases, secondary amplitude equations governing these instabilities are derived. The nonlinear development of these instabilities is studied by numerical simulations.

Key words. waves, Burgers equation, instability, combustion

1. Introduction.

In the last decades, the spontaneous formation of spatially inhomogeneous patterns was a subject of extensive investigations [1]. A deep understanding of various phenomena was achieved by studying nonlinear *amplitude equations* valid near the onset of instability. The role of these equations in the description of bifurcations in distributed systems is similar to the role of normal forms in the description of bifurcations in systems with a finite number of degrees of freedom. In the case of *short-wavelength instabilities* (i.e., those occurring with a nonzero wavenumber at the threshold), a complex Ginzburg–Landau (CGL) equation [2, 3, 4, 5] turns out to be a generic equation for an envelope function governing the evolution of patterns near the instability threshold. In the case of *long-wavelength instabilities* (i.e., those occurring with a zero wavenumber at the threshold) the situation is much more intricate. Depending on the features of the linear dispersion relation and the symmetries of the problem, the nonlinear dynamics of patterns is governed by different kinds of amplitude equations [6]. Among them are the CGL equation [7], the Kuramoto–Sivashinsky equation [8, 9, 10, 11], the perturbed Korteweg–de Vries equation [12, 13, 14], and others.

A basic problem, which is typically solved by means of amplitude equations, is the stability of spatially periodic waves generated by the primary instability. In many cases, there exists a *stability interval* of periodic waves ("Busse balloon"). Specifically, such an interval was revealed for wavy patterns governed by the Ginzburg–Landau equation [3, 15], the Kuramoto–Sivashinsky equation [8, 16, 17], and the perturbed Korteweg–de Vries equation [18, 19]. The boundaries of this interval are determined by long-wavelength *modulational instabilities*. The growth rate σ of these instabilities usually depends on the perturbation wavenumber k as $\sigma = O(k^2)$ ("negative

viscosity"), but sometimes as $\sigma = O(k)$ (see [6, 17, 19]). The nonlinear development of modulational instabilities is governed by secondary amplitude equations (see [4, 10, 14, 20]). It leads either to a change of the pattern wavelength or to the appearance of more complicated, e.g., spatially quasi-periodic, or chaotic, dynamics.

Recently, a new class of pattern-forming systems started attracting considerable attention. The dynamics of these systems is characterized by the nonlinear interaction of an unstable mode coupled with a *stable* but slow Goldstone mode (see [21, 22] for review) associated with the symmetry of the problem or a conservation law. An interesting example of such a system in which the long-wave oscillatory mode is coupled to the slow Goldstone mode caused by the translation symmetry is a uniformly propagating planar flame front governed by sequential reactions [23, 24]. The nonlinear dynamics of this system near the instability threshold is governed by two coupled equations: a CGL equation for the frontal oscillation amplitude P and a Burgers equation for the frontal deformation Q [23],

$$\begin{aligned} \partial_t P + \nabla P \cdot \nabla Q &= P + (1+iu)\nabla^2 P - (1+iv)|P|^2 P - sP\nabla^2 Q, \\ \partial_t Q &= m\nabla^2 Q - \frac{1}{2}|\nabla Q|^2 - w|P|^2, \end{aligned} \tag{1.1}$$

where $s = s_r + is_i$ is a complex constant, and u, v, m, and w are real constants. The parameter m is assumed to be positive; otherwise the deformational mode is intrinsically unstable and should be described by the Kuramoto–Sivashinsky equation rather than by the Burgers equation [23]. Although the system of equations (1.1) was derived for a particular physical system it should be considered as *generic* for a class of systems that have left-right symmetry and the same linear dispersion relation and are characterized by the presence of the Goldstone mode associated with the translation symmetry. Evolution equations for the interaction between an unstable mode and the zero mode in systems with other symmetries were studied, for example, in [21, 22, 25].

In [23], the stability of spatially uniform pulsations of the front was investigated, and some new types of nonlinear dynamics were revealed, including modulated standing waves, blinking states, and intermittent states. In [24] it was found that the long-wave instabilities of spatially periodic patterns, essentially different from the usual Benjamin–Feir instability, are of major importance. They can produce either modulated waves or oscillating cells separated by domain walls.

In the present paper we investigate long waves governed by the system (1.1). These waves are generated by the long-wavelength instabilities caused by the coupling between the phase $\theta = \arg(P)$ and the slow mode Q. We will show that in the long-wave limit, the problem is governed, to the leading order, by two *coupled Burgers equations* and has an additional symmetry with respect to the scaling transformation. A similar approach was used in [26] for the investigation of a secondary Hopf bifurcation of a stationary periodic structure possessing a translation symmetry. Note that several other systems of coupled Burgers-type equations were studied in different contexts in [27, 28, 29, 30, 31, 32]. Linear stability analysis presented below reveals a new type of modulational instability of traveling waves, which does not have its analogy for homogeneous oscillations. It leads to an unusual situation when the Busse balloon includes the single wavenumber $k_0 = 0$ rather than an interval of wavenumbers. Depending on the parameters, this instability is characterized by the growth rate dependence $\sigma = O(k^2)$ or $\sigma = O(k)$. In some limiting cases, we derive secondary amplitude equations governing both types of instabilities. The nonlinear development of these instabilities is studied by numerical simulations.

2. Instabilities of patterns governed by coupled Burgers equations.

2.1. Derivation of the system of coupled Burgers equations. Consider *large-scale* solutions of the system (1.1). Define $P = \rho \exp(i\theta)$ and rewrite the system (1.1) in the form

$$\rho_t + \nabla\rho\cdot\nabla Q = \nabla^2\rho - \rho|\nabla\theta|^2 - u(2\nabla\rho\cdot\nabla\theta + \rho\nabla^2\theta) + \rho(1 - \rho^2 - s_r\nabla^2 Q), \tag{2.1}$$

$$\rho\theta_t + \rho\nabla\theta\cdot\nabla Q = u(\nabla^2\rho - \rho|\nabla\theta|^2) + 2\nabla\rho\cdot\nabla\theta + \rho\nabla^2\theta - \rho(v\rho^2 + s_i\nabla^2 Q), \tag{2.2}$$

$$Q_t = m\nabla^2 Q - \frac{1}{2}|\nabla Q|^2 - w\rho^2. \tag{2.3}$$

The system (2.1)–(2.3) has the solution

$$\rho = 1, \qquad \theta = -vt, \qquad Q = -wt, \tag{2.4}$$

which corresponds to a planar front moving with the velocity $-w$ and pulsating with the frequency v.

In the case of a pure CGL equation, it is known that the behavior of long-wave solutions is of major importance. They are responsible for the Benjamin–Feir instability of homogeneous oscillations [3, 4, 7] that leads to the development of spatiotemporal chaos ("phase turbulence") [10]. The goal of the present section is to analyze the behavior of long waves governed by the system (2.1)–(2.3).

Introduce a formal small parameter $\epsilon \ll 1$, and assume that the characteristic wavenumbers in the Fourier expansion of the solution are small, $k = O(\epsilon)$, i.e., the solution slowly depends on the spatial coordinates. Also, we assume that the solution slowly evolves in time. Define new variables, $\mathbf{X} = \epsilon\mathbf{x}$, $T = \epsilon^2 t$, so that $\partial_t \to \partial_t + \epsilon^2\partial_T$, $\nabla \to \epsilon\nabla_{\mathbf{X}}$, and consider

$$\rho = \rho_0 + \epsilon^2\tilde\rho(\mathbf{X}, T), \qquad \theta = -\omega_0 t + \tilde\theta(\mathbf{X}, T), \qquad Q = c_0 t + \tilde Q(\mathbf{X}, T), \tag{2.5}$$

where the functions $\tilde\rho$, $\tilde\theta$, and $\tilde Q$ are expanded in series as

$$\tilde\rho = \tilde\rho_0 + \epsilon^2\tilde\rho_2 + \ldots, \qquad \tilde\theta = \tilde\theta_0 + \epsilon^2\tilde\theta_2 + \ldots, \qquad \tilde Q = \tilde Q_0 + \epsilon^2\tilde Q_2 + \ldots. \tag{2.6}$$

Substitute (2.5)–(2.6), together with (2.4) into (2.1)–(2.3) and equate the terms of the same order in ϵ. In the leading order one obtains $\rho_0 = 1$, $\omega_0 = v$, $c_0 = -w$, which coincides with (2.4). In the next order, one obtains

$$(\nabla\tilde\theta)^2 + u\nabla^2\tilde\theta + 2\tilde\rho_0 + s_r\nabla^2\tilde Q = 0, \tag{2.7}$$

$$-\omega_0\tilde\rho_0 + \tilde\theta_T + \nabla\tilde\theta\cdot\nabla\tilde Q = -u(\nabla\tilde\theta)^2 + \nabla^2\tilde\theta - (2v\tilde\rho_0 + s_i\nabla^2\tilde Q) - v\tilde\rho_0\,, \tag{2.8}$$

$$\tilde Q_T = m\nabla^2\tilde Q - \frac{1}{2}(\nabla\tilde Q)^2 - 2w\tilde\rho_0\,, \tag{2.9}$$

where the subscripts are omitted in $\tilde\theta_0$, $\tilde Q_0$, and $\nabla_{\mathbf{X}}$. From (2.7) one gets

$$\tilde\rho_0 = -\frac{1}{2}\left[(\nabla\tilde\theta)^2 + u\nabla^2\tilde\theta + s_r\nabla^2\tilde Q\right]. \tag{2.10}$$

Substitute (2.10) into (2.8), (2.9) to obtain the *coupled Burgers equations* for $\tilde\theta$ and $\tilde Q$:

$$\begin{aligned} \tilde\theta_T &= A\nabla^2\tilde\theta + C(\nabla\tilde\theta)^2 + B\nabla^2\tilde Q - \nabla\tilde\theta\cdot\nabla\tilde Q, \\ \tilde Q_T &= D\nabla^2\tilde Q - \frac{1}{2}(\nabla\tilde Q)^2 + w(\nabla\tilde\theta)^2 + E\nabla^2\tilde\theta, \end{aligned} \tag{2.11}$$

where

$$A = 1 + uv, \quad B = vs_r - s_i, \quad C = (v - u), \quad D = m + ws_r, \quad E = wu, \tag{2.12}$$

and the subscripts have been dropped.

The system (2.11) describes the interaction between long-wave phase disturbances and long-wave modulations of the zero mode; in the case of a flame instability the latter corresponds to the large-scale deformations of the flame front. Note that for $w = 0$ the equation for Q in the system (2.11) is decoupled from the equation for the phase disturbances. It is important that the system (2.11), unlike the original system (1.1), is invariant with respect to (the group of) scaling transformations $\mathbf{X} \to \mathbf{X}' = \alpha\mathbf{X}$, $T \to T' = \alpha^2 T$. Note also the specific nonlinear coupling in the system (2.11); it is related to the particular form of the system (1.1). In other systems the coupling can be different [27, 28, 29, 30, 31, 32].

2.2. Linear stability of traveling waves. The system (2.11) has a class of traveling wave solutions,

$$\tilde{\theta}_0 = \mathbf{F} \cdot \mathbf{X} - \omega T, \qquad \tilde{Q}_0 = \mathbf{G} \cdot \mathbf{X} - cT, \tag{2.13}$$

corresponding to planar waves ($\mathbf{F} \neq 0$) propagating on the background of an inclined front ($\mathbf{G} \neq 0$), where $\omega = \mathbf{F} \cdot \mathbf{G} - CF^2$, $c = G^2/2 - wF^2$. In this section we study the instabilities of these solutions in the framework of the system (2.11).

Consider the perturbed solution, $\tilde{\theta} = \tilde{\theta}_0 + \widehat{\theta}$, $\tilde{Q} = \tilde{Q}_0 + \widehat{Q}$, with $(\hat{\theta}, \hat{Q}) = (\hat{A}, \hat{B})\, e^{i\mathbf{k}\cdot\mathbf{X} + \sigma T}$, and linearize the system (2.11) to obtain the dispersion relation

$$\begin{vmatrix} \sigma + Ak^2 - i(2C\mathbf{k}\cdot\mathbf{F} - \mathbf{k}\cdot\mathbf{G}) & Bk^2 + i\mathbf{k}\cdot\mathbf{F} \\ Ek^2 - i2w\mathbf{k}\cdot\mathbf{F} & \sigma + Dk^2 + i\mathbf{k}\cdot\mathbf{G} \end{vmatrix} = 0. \tag{2.14}$$

For homogeneous frontal oscillations, $\mathbf{F} = \mathbf{G} = 0$, one finds $\sigma = \Sigma k^2$ [23], where Σ satisfies the quadratic equation $\Sigma^2 + \mathrm{tr}(M) \cdot \Sigma + \det(M) = 0$, with $\mathrm{tr}(M) = 1 + uv + m + ws_r$ and $\det(M) = m(1 + uv) + w(s_r + us_i)$ being the trace and the determinant of the matrix

$$M = \begin{pmatrix} A & B \\ E & D \end{pmatrix}. \tag{2.15}$$

Spatially homogeneous oscillations of the planar front, corresponding to $\mathbf{F} = \mathbf{G} = 0$, are monotonically unstable ($\mathrm{Im}\Sigma = 0, \mathrm{Re}\Sigma > 0$) if $\det(M) < 0$, and oscillatory unstable ($\mathrm{Im}\Sigma \neq 0$, $\mathrm{Re}\Sigma > 0$) if $\mathrm{tr}(M) < 0$, $\det(M) > [\mathrm{tr}(M)]^2/4$. Both the *monotonic instability boundary*,

$$1 + uv = -\frac{w}{m}(s_r + us_i), \tag{2.16}$$

and the *oscillatory instability boundary*,

$$1 + uv = -(m + ws_r), \qquad (m + ws_r) < \frac{w}{m}(s_r + us_i), \tag{2.17}$$

can be considered as modifications of the Benjamin–Feir instability boundary, $1 + uv = 0$, of the CGL equation, caused by the coupling with the Burgers equation. The homogeneous oscillations are stable with respect to long-wave perturbations if $\mathrm{tr}(M) > 0$, $\det(M) > 0$, i.e., for

$$1 + uv > \max\left\{-(m + ws_r), \qquad -\frac{w}{m}(s_r + us_i)\right\}. \tag{2.18}$$

Let us emphasize that the nonlinear development of the Benjamin–Feir instability *cannot* be studied in the framework of the system (2.11) because the latter has no short-wave cut-off and becomes ill-posed when the Benjamin–Feir instability appears. To describe the saturation of the Benjamin–Feir instability, the terms with fourth-order derivatives are necessary [7, 10]. Later on, we shall assume that there is no instability of the homogeneous oscillations, i.e., $\det(M) > 0$, $\mathrm{tr}(M) > 0$.

Consider now the stability of traveling wave solutions with $\mathbf{F} \neq 0$, which is determined by the dispersion relation (2.14). Since $\sigma(\mathbf{k}; \mathbf{F}, \mathbf{G}) = \sigma(\mathbf{k}; \mathbf{F}, 0) - i\mathbf{k}\cdot\mathbf{G}$, the stability of traveling waves is not affected by the inclination of the front characterized by the vector $\mathbf{G}$, and we shall further consider $\mathbf{G} = 0$. In this case, the dispersion relation (2.14) can be written as

$$\Sigma^2 + [\mathrm{tr}(M) - 2iC\alpha]\Sigma + \det(M) - i\alpha\zeta - 2w\alpha^2 = 0, \tag{2.19}$$

where $\Sigma \equiv \sigma/k^2$, $\alpha \equiv \mathbf{k}\cdot\mathbf{F}/k^2$, $\zeta = 2m(v-u) + w[2s_i + u(1-2s_r)]$. If $\mathbf{k} = 0$, then $\sigma = 0$ independently of $\mathbf{F}$; thus, traveling waves are neutrally stable with respect to homogeneous perturbations with $\mathbf{k} = 0$. If $\mathbf{k}$ and $\mathbf{F}$ are orthogonal, the dispersion relation coincides with that for $\mathbf{F} = 0$. Thus, if the condition (2.18) is not satisfied, traveling wave solutions with any $\mathbf{F}$ are unstable at least with respect to *transverse* perturbations, with $\mathbf{k} \perp \mathbf{F}$. Later on, we shall investigate the stability of traveling wave solutions with $\mathbf{F} \neq 0$ with respect to disturbances with $\mathbf{k} \neq 0$ for the parameter region defined by (2.18).

In the limit $\alpha \to 0$ (i.e., for $k_n F \ll k^2$) (2.19) is reduced to the quadratic equation for Σ corresponding to $\mathbf{F} = 0$; thus there is no instability for small α if $\mathrm{tr}(M) > 0$, $\det(M) > 0$. For finite values of α, the instability can occur for

$$2w - C^2 + \frac{Z^2}{[\mathrm{tr}(M)]^2} > 0, \tag{2.20}$$

when there exists a solution of the equation $\mathrm{Re}(\Sigma(\alpha_*)) = 0$,

$$\alpha_*^2 = \frac{[\mathrm{tr}(M)]^2 \det(M)}{[\mathrm{tr}(M)]^2(2w - C^2) + Z^2}, \qquad Z = \zeta - C\,\mathrm{tr}(M). \tag{2.21}$$

If (2.20) is satisfied, a traveling wave is unstable with respect to the disturbances with $|\,\alpha\,| > \alpha_*$. Thus, the solution characterized by the wavevector $\mathbf{F}$ is unstable with respect to perturbations with the wavevector $\mathbf{k}$ within the region

$$\left(\frac{\mathbf{k}}{F} \pm \frac{\mathbf{n}}{2\alpha_*}\right)^2 < \frac{1}{4\alpha_*^2}, \tag{2.22}$$

where $\mathbf{n} = \mathbf{F}/F$, i.e., within two disks of the radius $1/2\alpha_*$ with the centers in the points $\mathbf{k} = \pm\mathbf{n}F/2\alpha_*$ (see Figure 1; $k_n = \mathbf{k}\cdot\mathbf{n}$, $k_\tau = \mathbf{k}\cdot\boldsymbol{\tau}$, $\mathbf{n}\cdot\boldsymbol{\tau} = 0$). At the instability boundary, $\sigma = i\Omega k^2$, $\Omega = \alpha_*\zeta/\mathrm{tr}(M)$.

The instability inside the region (2.22) is a new type of instability which is absent in the case of the pure CGL equation. Indeed, if the CGL equation is decoupled from the Burgers equation ($w = 0$), the condition (2.20) is not satisfied for $1 + uv > 0$, $m > 0$. An unusual feature of this new kind of long-wave instability is the fact that if the conditions (2.18), (2.20) hold, then *all* traveling wave solutions with $F \neq 0$ are unstable, while homogeneous oscillations with $F = 0$ are stable; therefore the Busse balloon contains the *single* wavenumber $F = 0$. This property is not the result of the

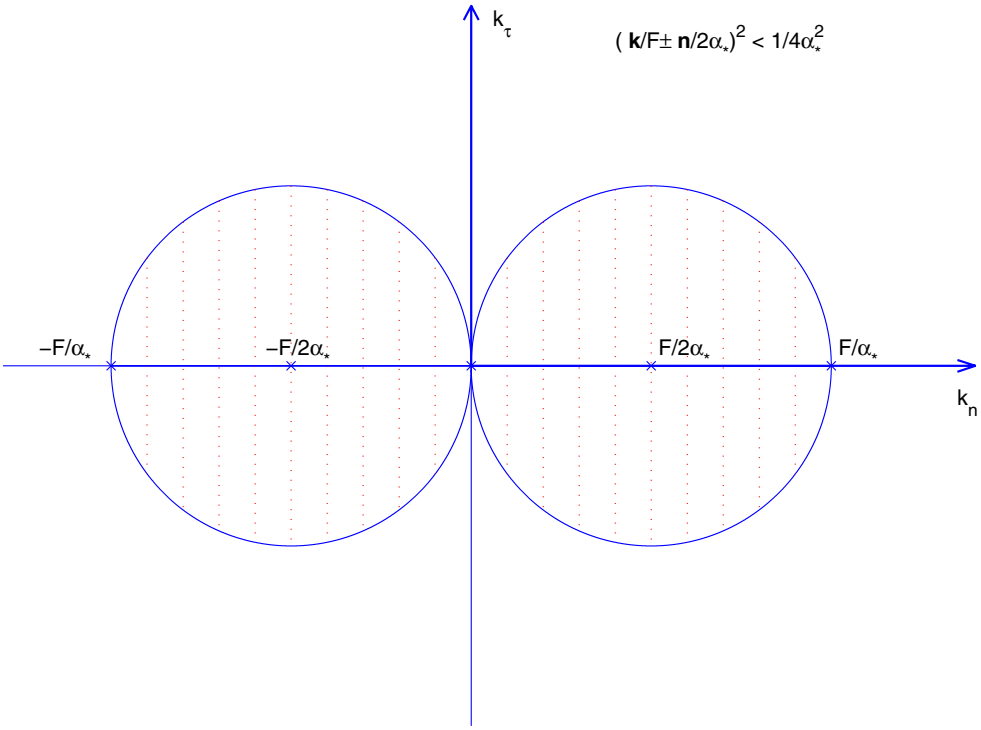

FIG. 1. *Regions of instability (dashed) of the traveling wave* (2.13) *with the wavevector* $\mathbf{F}$, $k_n = \mathbf{k}\cdot\mathbf{n}$, $k_\tau = \mathbf{k}\cdot\boldsymbol{\tau}$; $\mathbf{n}$ *and* $\boldsymbol{\tau}$ *are orthogonal unit vectors;* $\mathbf{n} = \mathbf{F}/\mathrm{F}$.

long-wave approximation of the system (1.1) by the coupled Burgers equations (2.11) but it also remains in the full system (1.1) [24]. The same property was obtained for modulated waves governed by a generalized Ginzburg–Landau equation [33] and [34]. Note that the inequality (2.22) contains only the *ratio* $\mathbf{k}/F$, which is the result of the similarity properties of the system of coupled Burgers equations.

It is instructive to analyze the asymptotics of the solution $\Sigma(\alpha)$ defined by (2.19) in the limit $\alpha \to \infty$, i.e., for $k_n F \gg k^2$ (note that in this case $(k_\tau/F)^2 \ll k_n/F \ll 1$). For $2w - C^2 \neq 0$, one expands $\Sigma(\alpha) \sim \Sigma_1\alpha + \Sigma_0 + \Sigma_{-1}\alpha^{-1} + \dots$, where

$$\Sigma_1 = iC \pm \sqrt{2w - C^2}, \qquad \Sigma_0 = -\frac{1}{2}\mathrm{tr}(M) \pm \frac{Z}{2\sqrt{C^2 - 2w}}. \tag{2.23}$$

If $2w - C^2 < 0$ (specifically, near the instability boundary, where $2w - C^2 = -Z^2/[\mathrm{tr}(M)]^2$), then Σ_1 is purely imaginary and Σ_0 is real. It is easy to show that in the case $\mathrm{tr}(M) > 0$ the instability condition $\Sigma_0 > 0$ is equivalent to (2.20). In this case, $\mathrm{Re}(\sigma) = \Sigma_0 k^2$ to the leading order; i.e., the instability is of the negative viscosity type.

If $2w - C^2 > 0$, one of the roots Σ_1 has a positive real part. In this case, the growth rate $\mathrm{Re}(\sigma) = \pm\sqrt{(2w - C^2)}\cdot\mathbf{k}\cdot\mathbf{F}$ depends *linearly* on the perturbation wavenumber. In the order $O(k)$, the frequency of the disturbances, $\omega(\mathbf{k}) = i\sigma(\mathbf{k})$, is determined by the eigenvalues of the matrix (2.14). Since the matrix is not symmetric it can have a pair of complex conjugate eigenvalues that corresponds to the instability.

This phenomenon is known to be the origin of similar instabilities in several hydrodynamic problems, e.g., the Kelvin–Helmholtz instability in ideal fluid flows [35] and kinetic instability of viscous flows with two or more interfaces ("kinetic α-effect") [36] (see also [37]). Note that on the boundary $2w - C^2 = -Z^2/[\mathrm{tr}(M)]^2$ the instability always appears as a negative-viscosity one, while the kinetic α-effect develops only in the interior of the instability region in the parameter space where $2w - C^2 > 0$ (see Figure 2).

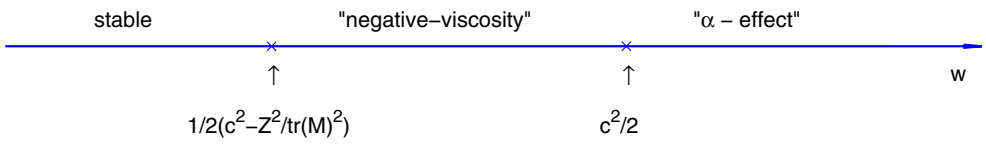

FIG. 2. *Instability types.*

On the boundary $2w - C^2 = 0$, the growth rate of the unstable mode is described by the relation $\mathrm{Re}(\Sigma(\alpha)) \sim \sqrt{\frac{|\alpha|Z}{2}}$; thus $\mathrm{Re}(\sigma(k^2)) \sim k(\mathbf{k}\cdot\mathbf{F})^{1/2}$.

2.3. Weakly nonlinear amplitude equations for long-wave disturbances. In this section we analyze the nonlinear evolution of the new type of instability of the traveling wave solutions described in the previous section, in the case when the size of the instability region in the plane (k_n, k_τ) is small. Consider finite-amplitude perturbations of the traveling wave solution (2.13), $\hat\theta = \theta - \theta_0$, $\hat Q = Q - Q_0$, and choose a new reference frame, $\mathbf{X}' = \mathbf{X} - \mathbf{G}T$. In the new frame of reference, the evolution of $\hat\theta$ and $\hat Q$ is described by the following system of equations:

$$\widehat{\theta_T} = A\nabla^2\widehat\theta + B\nabla^2\widehat Q + 2C\mathbf{F}\cdot\nabla\widehat\theta - \mathbf{F}\cdot\nabla\widehat Q + C\left(\nabla\widehat\theta\right)^2 - \nabla\widehat\theta\cdot\nabla\widehat Q,$$
$$\widehat Q_T = D\nabla^2\widehat Q + E\nabla^2\widehat\theta + 2w\mathbf{F}\cdot\nabla\widehat\theta + w\left(\nabla\widehat\theta\right)^2 - \frac{1}{2}\left(\nabla\widehat Q\right)^2. \tag{2.24}$$

In the present section, we derive the weakly nonlinear amplitude equations valid near the instability boundary determined by (2.20), where the instability takes place only with respect to disturbances with $k/F \ll 1$. In order to obtain the asymptotic equation equally valid for the negative viscosity instability and for the α-effect instability, we will consider in the present section the case when the boundaries of both types of the instabilities mentioned above are close to each other. According to the results of the linear stability analysis (see Figure 2) the two boundaries are close to each other if $[Z/\mathrm{tr}(M)]^2 \ll 1$. Below we consider the case $|Z| \ll 1$, $\mathrm{tr}(M) = O(1)$. Also, we assume that the parameter w is close to the two boundaries, so that the instability takes place with respect to perturbations with $|k_n| \ll 1$ and $|k_\tau| \ll 1$. Below we derive a long-wave asymptotic limit for the system (2.24).

Define $s_i^0 = -2m/C + u(s_r - 1/2)$ and assume $s_i = s_i^0 + R\varepsilon$, $w = C^2/2 + W\varepsilon^2$. Under these assumptions, the width of the instability interval $\frac{F}{\alpha_*}$ (see Figure 1) is $O(\varepsilon)$. Introduce slow time variables, $T_1 = \varepsilon T$, $T_2 = \varepsilon^2 T$, and a new, long-scale spatial variable, $\mathbf{z} = \varepsilon\mathbf{X}' + \mathbf{F}CT_1$; expand $\widehat\theta = \varepsilon^{-1}\widehat\theta_{-1} + \widehat\theta_0 + \varepsilon\widehat\theta_1 + \ldots$, $\widehat Q = \varepsilon^{-1}\widehat Q_{-1} + \widehat Q_0 + \varepsilon\widehat Q_1 + \ldots$; and substitute this expansion in the system (2.24) to obtain the series of problems for $\hat\theta_i$, $\hat Q_i$, $i = -1, 0, 1, \ldots$, in the successive orders of the small

parameter ε. Using solvability conditions for $i = -1, 0$ one obtains the following system of equations for renormalized functions θ and ϕ (see Appendix A for details):

$$\begin{aligned} \frac{\partial\ \theta}{\partial T_2} &= D_1 {\nabla_z}^2 \theta - \nabla_z \theta \cdot \nabla_z \phi, \\ \frac{\partial \phi}{\partial T_2} &= D_2 {\nabla_z}^2 \phi - \frac{1}{2}(\nabla_z \phi)^2 + {\nabla_z}^2 \theta + \mu (\nabla_z \theta)^2. \end{aligned} \tag{2.25}$$

The function θ has a nonzero average gradient and therefore is unbounded for $|\mathbf{z}| \to \infty$; the function ϕ has a nonzero average time derivative and thus is unbounded for $T_2 \to \infty$. It is convenient to introduce new functions, $\widetilde{\theta} = \theta - \mathfrak{z} \cdot \mathbf{n}$ and $\widetilde{\phi} = \phi - \mu \mathfrak{t}$, where $\mathfrak{z} = C^2 RF\mathbf{z}$, $T_2 = \mathfrak{t}/(C^2 R\mathbf{F})^2$, $\mathbf{n} = \mathbf{F}/F$, that will be bounded for $|\mathfrak{z}| \to \infty$ and $\mathfrak{t} \to \infty$. The system (2.25) will then become

$$\begin{aligned} \widetilde{\theta}_{\mathfrak{t}} &= D_1 {\nabla_{\mathfrak{z}}}^2 \widetilde{\theta} - (\mathbf{n} + \nabla_{\mathfrak{z}} \widetilde{\theta}) \cdot \nabla_{\mathfrak{z}} \widetilde{\phi}, \\ \widetilde{\phi}_{\mathfrak{t}} &= D_2 {\nabla_{\mathfrak{z}}}^2 \widetilde{\phi} - \frac{1}{2}(\nabla_{\mathfrak{z}} \widetilde{\phi})^2 + {\nabla_{\mathfrak{z}}}^2 \widetilde{\theta} + \mu (\nabla_{\mathfrak{z}} \widetilde{\theta})^2 + 2\mu \mathbf{n} \cdot \nabla_{\mathfrak{z}} \widetilde{\theta}. \end{aligned} \tag{2.26}$$

The system (2.26) can be considered as a simplified version of the system (2.24) which is still capable of describing both types of the long-wave instabilities. Indeed, the linear dispersion relation for the system (2.26),

$$\begin{vmatrix} \sigma + D_1 k^2 & ik_n \\ -2\mu i k_n + k^2 & \sigma + D_2 k^2 \end{vmatrix} = 0, \tag{2.27}$$

keeps all characteristic features of the general dispersion relation (2.14). The oscillatory instability of the negative viscosity type occurs in the region

$$\mu > \mu_* = -\frac{1}{2(D_1 + D_2)^2}, \tag{2.28}$$

with the boundary of the instability region in $\mathbf{k}$-space described by

$$(\mathbf{k} \pm k_m \cdot \mathbf{n})^2 = {k_m}^2 \equiv \frac{\mu - \mu_*}{2D_1 D_2}. \tag{2.29}$$

The α-effect occurs for $\mu > 0$.

2.4. Absolute and convective instability. At this point one needs to distinguish between the absolute instability and the convective instability [38, 39]. Consider the one-dimensional version of the dispersion relation for the system (2.26),

$$\sigma^2 + D_1 D_2 k^4 + (D_1 + D_2) k^2 \sigma - 2\mu k^2 - ik^3 = 0. \tag{2.30}$$

In order to find the boundary of the absolute instability, consider the roots $k(\sigma)$ for $\mathrm{Re}\sigma \gg 1$, separate them into two classes: $\mathrm{Im}k(\sigma) > 0$ and $\mathrm{Im}k(\sigma) < 0$, and follow the appearance of double roots $k_i = k_i(\sigma)$, $i = 1, 2, \dots$, with the decrease of $\mathrm{Re}\sigma$. The double roots correspond to $d\sigma/dk = 0$, but only those that appear by merging of the roots corresponding to *different* classes are relevant to the development of the absolute instability. The latter takes place for $\mathrm{Re}\sigma(k_i) > 0$.

For $|\mu| \ll 1$ dispersion relation (2.30) is simplified under the assumption $k = O(|\mu|)$, $\sigma = O(|\mu|^{3/2})$, and in the leading order becomes

$$-ik^3 - 2\mu k^2 + \sigma^2 = 0. \tag{2.31}$$

Similar to [38], we shall use the complex frequency $\omega(k) = \omega'(k) + i\omega''(k) = i\sigma(k)$. Let us analyze the "motion" of roots in the complex k-plane with the decrease of ω''. In the limit $\omega'' \gg 1$, the equation (2.31) has three roots $k(\omega)$: one pure imaginary root with $\mathrm{Im}k > 0$ and two roots of the type $\pm a + ib$ in the lower half-plane ($b < 0$).

For $\mu < 0$, one obtains that the two roots in the lower half plane can merge on the imaginary axis, but this is not a sign of the appearance of an absolute instability, because both merging roots belong to the same class.

For $\mu > 0$, one gets that neither of the two roots $\pm a + ib$ crosses the imaginary axis and, therefore, cannot merge. The double root can occur in the upper half-plane, $\mathrm{Im}k > 0$, due to merging of one of these roots and the pure imaginary root. Positive values of $\mathrm{Re}\sigma$ for these double roots show that an absolute instability appears.

Finally, one comes to the conclusion that $\mu = 0$ is the boundary of the absolute instability which coincides with the transition from the negative viscosity instability type to the α-effect instability type in the long-wave limit, so that for $-|\mu_*| < \mu < 0$ the instability is *convective* and of the negative viscosity type, and for $\mu > 0$ the instability is *absolute* and of the α-effect type.

2.5. Nonlinear waves near the threshold $\boldsymbol{\mu = \mu_*}$. Now we study the spontaneous generation of nonlinear waves near the threshold $\mu = \mu_*$, described by (2.26), in more detail. For small deviations of the parameter μ near the threshold, $\mu = \mu_* + \mu_2\delta^2 + \ldots$, we expand $\widetilde{\theta} = \delta\theta_1 + \delta^2\theta_2 + \delta^3\theta_3 + \ldots$, $\widetilde{\phi} = \delta\phi_1 + \delta^2\phi_2 + \delta^3\phi_3 + \ldots$ and use $\nabla_z = \delta\nabla_\mathfrak{z}$, $\partial_\mathfrak{t} = \delta\partial_{t_1} + \delta^2\partial_{t_2} + \delta^3\partial_{t_3} + \delta^4 t_4 + \ldots$.

For the lowest order, one obtains

$$\frac{\partial\theta_1}{\partial t_1} = -\mathbf{n}\cdot\nabla_\mathfrak{z}\phi_1, \qquad \frac{\partial\phi_1}{\partial t_1} = 2\mu_*\mathbf{n}\cdot\nabla_\mathfrak{z}\theta_1, \tag{2.32}$$

which can be transformed to

$$\frac{\partial^2\theta_1}{\partial {t_1}^2} + 2\mu_*(\mathbf{n}\cdot\nabla_\mathfrak{z})^2\theta_1 = 0. \tag{2.33}$$

Introduce the coordinates (x, y) as $x = \mathbf{n}\cdot\mathbf{z}$, $y = \boldsymbol{\tau}\cdot\mathbf{z}$. Then (2.33) becomes $\partial_{t_1 t_1}\theta_1 + 2\mu_*\partial_{xx}\theta_1 = 0$, whose solution is

$$\theta_1 = \theta_1^+(x + \sqrt{2|\mu_*|}t_1, y) + \theta_1^-(x - \sqrt{2|\mu_*|}t_1, y), \tag{2.34}$$

$$\phi_1 = \sqrt{2|\mu_*|}[-\theta_1^+(x + \sqrt{2|\mu_*|}t_1, y) + \theta_1^-(x - \sqrt{2|\mu_*|}t_1, y)]. \tag{2.35}$$

In the next order, $O(\delta^3)$, one obtains

$$\theta_2 = \theta_2^+(x_+, y) + \theta_2^-(x_-, y), \qquad \phi_2 = \phi_2^+(x_+, y) + \phi_2^-(x_-, y), \tag{2.36}$$

where $x_\pm = x \pm \sqrt{2|\mu_*|}t_1$. Using solvability conditions in the successive orders of δ, after appropriate rescaling, one finally obtains the following evolution equation for a single function $\Theta \propto \theta_1^+ + \delta\theta_2^+$:

$$\begin{aligned}&\frac{\partial\Theta}{\partial T} + \widetilde{C}\frac{\partial\Theta}{\partial X} + \mathcal{I}[\nabla^2\Theta] + 3(\nabla\Theta)^2 \\ &+\widetilde{\delta}\left\{\nabla^2\Theta + \mathcal{I}^2[\nabla^2\Theta] + \widetilde{D}\mathcal{I}[(\nabla\Theta)^2] + \widetilde{E}\nabla\Theta\cdot\mathcal{I}[\nabla\Theta]\right\} + O(\widetilde{\delta}^2) = 0,\end{aligned} \tag{2.37}$$

where $\mathcal{I}[f(X, Y)] \equiv \int_0^X \nabla^2 f(X', Y)\, dX'$. The coefficients and other details of the derivation are given in Appendix B.

In the one-dimensional case, $\Theta = \Theta(X,T)$, (2.37) is reduced to the *perturbed Korteweg–de Vries equation* for the function $U = \frac{\partial \Theta}{\partial X}$:

$$\frac{\partial U}{\partial T} + \widetilde{C}\frac{\partial U}{\partial X} + \frac{\partial^3 U}{\partial X^3} + 6U\frac{\partial U}{\partial X} + \widetilde{\delta}\left[\frac{\partial^2 U}{\partial X^2} + \frac{\partial^4 U}{\partial X^4}\right] = 0. \tag{2.38}$$

This equation has been derived formerly in different physical problems (see [12, 13, 14]). Several two-dimensional generalizations of (2.38) are known (see [40, 41, 42, 43, 44]). However, to our knowledge, (2.37) is obtained here for the first time.

2.6. Numerical simulations. Far from the threshold $\mu = \mu_*$, full equations (2.26) should be used. The advantage of the system (2.26) is that it governs both the negative viscosity instability and the α-effect instability.

First, we have performed numerical simulations of the system (2.26) in one dimension by means of a pseudospectral code, with periodic boundary conditions. The time-integration has been carried out in the Fourier space using the Crank–Nicolson scheme for the linear operator, and the Adams–Bashford scheme for the nonlinear one. Figure 3 shows typical snapshots of traveling wave solutions obtained numerically for different values of the parameter μ. For $\mu < 0$, as well as for very small positive values of μ, we have observed the formation of spatially periodic uniformly traveling waves; see Figure 3(a). These waves correspond to spatiotemporal periodic modulations of the original wave (2.13) coupled to the traveling wave of the zero mode (frontal deformations). With the increase of the parameter $\mu > 0$ (corresponding to the α-effect-type instability of the original wave (2.13)), this wave structure becomes unstable with respect to spatial modulations; see Figures 3(b) and 3(c). Patterns shown in Figures 3(b) and 3(c) are snapshots of waves that travel from right to left and also undergo very small modulations on a very slow time scale. Note that these modulated wave structures resulted from a very slow evolution of a spatially irregular system of typical "Burgers shocks" that forms initially from random initial data. This intermediate system of Burgers shocks is similar to that shown in Figure 3(d) for $\mu = 0.15$; it produces spatially irregular modulations of the original wave (2.13) coupled to the modulations of the zero mode. On the fast time scale, the pattern shown in Figure 3(d) travels from right to left as a whole with almost constant speed, while it also changes on a very slow time scale. For example, in the case $\mu = 0.1$, this evolution results in a spatially modulated wave structure shown in Figure 3(c). With the increase of the parameter μ, the time required for the formation of a modulated wave pattern from the spatially irregular one increases drastically. Probably, with the increase of μ, the attractor corresponding to a modulated wave pattern becomes unstable and transition to chaos occurs. However, in order to verify this assumption, one needs to perform extremely long computations which are beyond the scope of this paper. Note that the characteristic spatial scale of the wave patterns increases with the increase of μ. At the same time, once established, the characteristic spatial scale does not change, so no coarsening has been observed when the value of the parameter μ is fixed.

Our numerical simulations of the system (2.26) in two dimensions (by means of a pseudospectral code with periodic boundary conditions), both for $\mu_* < \mu < 0$ and $\mu > 0$, exhibit two-dimensional wavy patterns shown in Figure 4. Here, the pattern is rapidly moving along the x-axis in the negative direction and undergoes slow evolution in the transversal direction: the cells shown in Figure 4 slowly merge together and then split, forming new cells. The average spatial scale of the cells remains the same, so no coarsening has been observed in the two-dimensional case either.

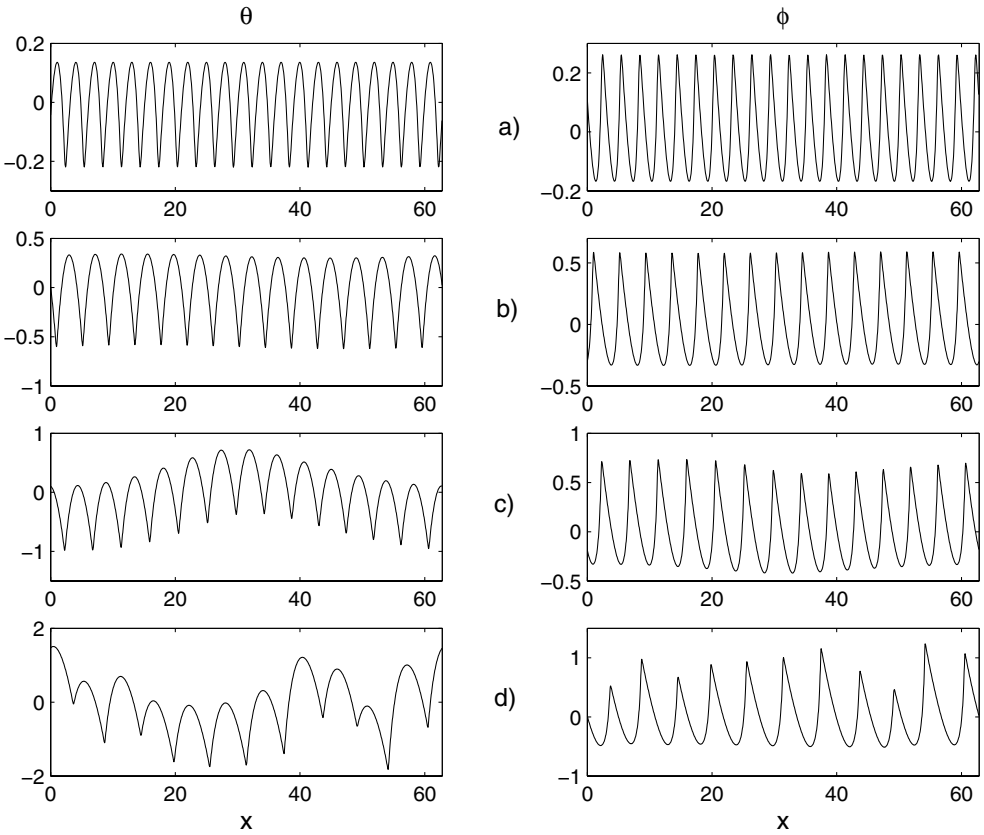

FIG. 3. *Typical traveling wave structures (travel from right to left): numerical solutions of the system* (2.26) *in one dimension for* $D_1 = 0.1$, $D_2 = 0.6$ *and various values of* μ*:* (a) $\mu = -0.3$*;* (b) $\mu = 0.051$*;* (c) $\mu = 0.1$*;* (d) $\mu = 0.15$.

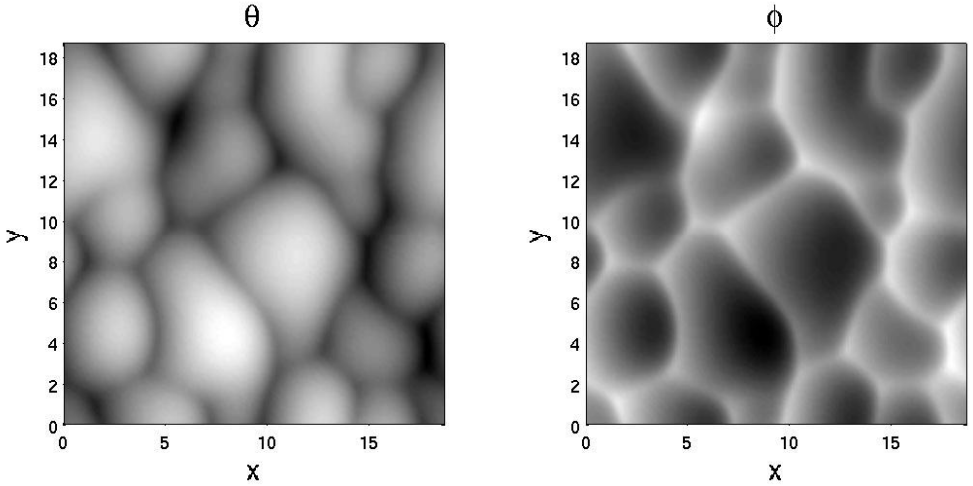

FIG. 4. *Numerical solution of the system* (2.26) *in two dimensions at a particular moment of time;* $D_1 = 0.1$, $D_2 = 0.6$*;* $\mu = -0.3$.

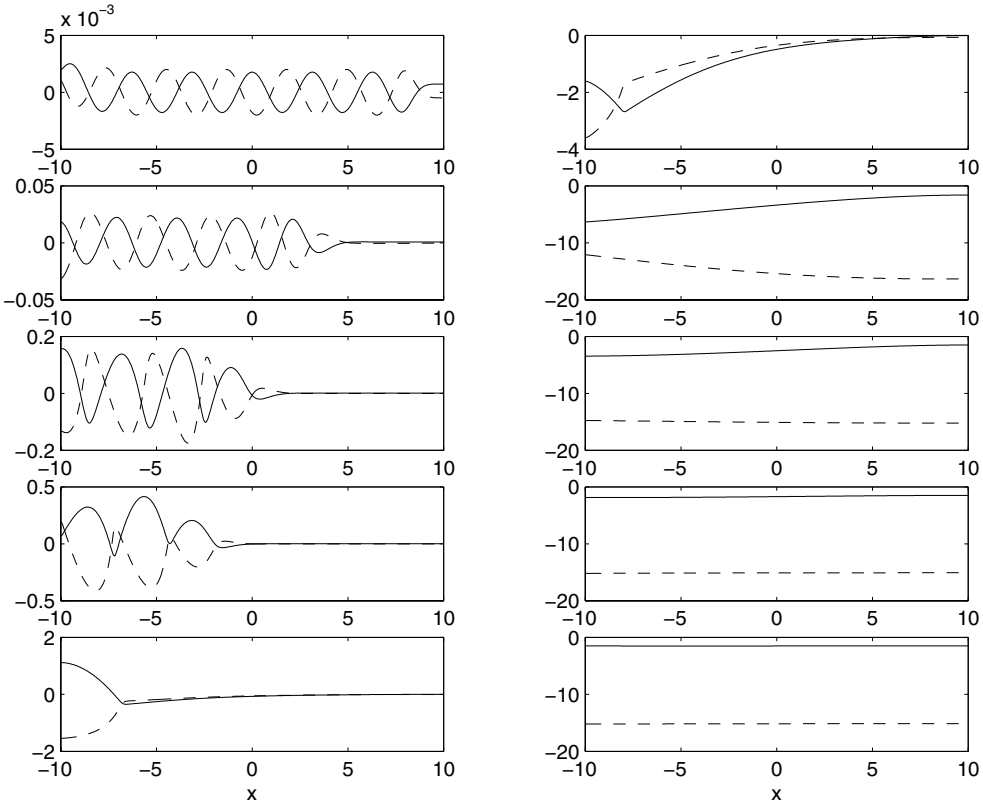

FIG. 5. *Numerical solutions of the system* (2.26) *in one dimension with Neumann boundary conditions, at different moments of time (time increases from top to bottom and from left to right), demonstrating the* convective *instability. Solid lines—*$\theta(z)$*; dashed lines—*$\phi(z)$.

Note that the formation of the modulated traveling wave structure is caused by the periodic boundary conditions. With these conditions, no difference between the absolute and convective instabilities can be observed since the wave leaving the computational domain comes back from the other side. In order to demonstrate the difference between these two instability types, we have performed numerical simulations of the system (2.26) in one dimension by means of a finite-difference code (using the semi-implicit Crank–Nicolson scheme) with Neumann boundary conditions. The results of the simulations are presented in Figures 5 and 6. Figure 5 shows the development of the *convective* instability for $\mu_* < \mu < 0$. One can see that growing perturbations are transported by the convective terms from right to left but gradually escape from the domain and leave behind a trivial steady state, $\theta = \text{const}$, $\phi = \text{const}$. On the contrary, in the case of $\mu > 0$ corresponding to the *absolute* instability, shown in Figure 6, one can see that, although the perturbations are still transported to the left by the convective terms, they are too slow to leave the domain so that finally they grow in the whole domain and form a nontrivial spatially nonuniform structure. This structure is not stationary but continues to evolve in time.

In concluding this section we present some typical results of numerical simulations of the full system (2.24) in one dimension, with periodic boundary conditions. Figure 7 shows a snapshot of a wave, traveling from right to left, resulting from the instability

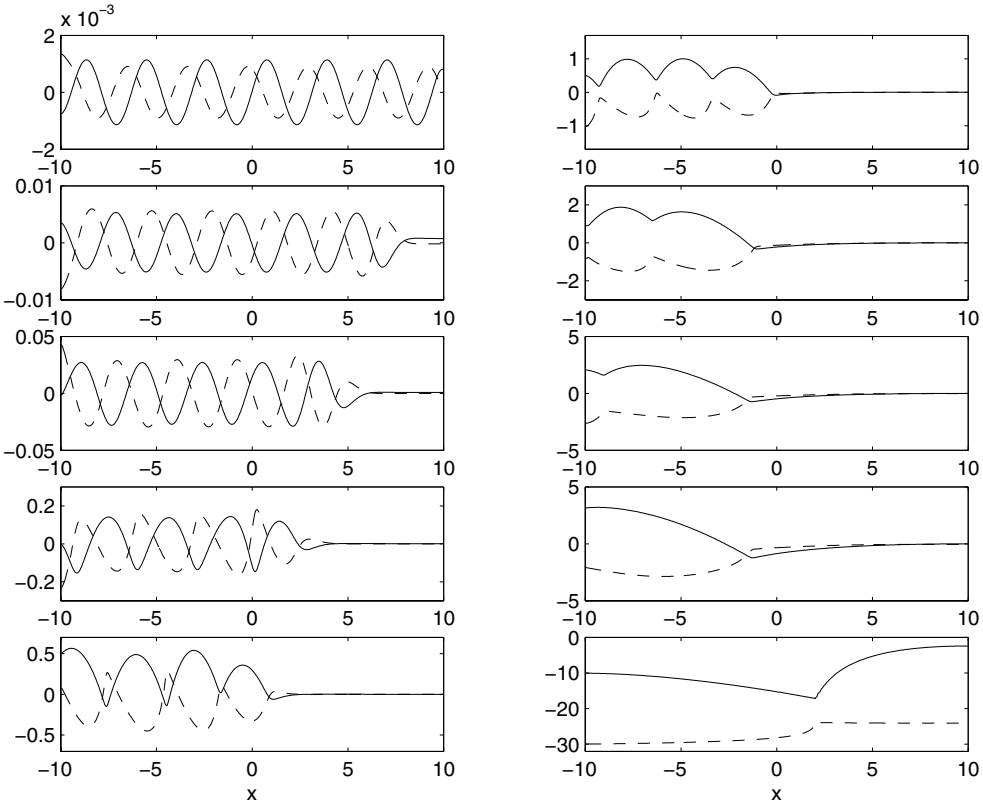

FIG. 6. *Numerical solutions of the system* (2.26) *in one dimension with Neumann boundary conditions, at different moments of time (time increases from top to bottom and from left to right), demonstrating the* absolute *instability. Solid lines—$\theta(z)$; dashed lines—$\phi(z)$.*

of the solution (2.13) with $F = 4.0$. Other parameters have been taken equal to those used in the computations of the full system of CGL–Burgers equations (1.1) performed in [24] that showed the instability of a harmonic traveling wave resulting in a modulated traveling wave. One can see that it corresponds to the formation of a modulated traveling wave that was observed in the numerical simulations of the full system (1.1) performed in [24].

3. Domain wall solutions. In the previous section, we investigated the stability of solutions (2.13) with the constant values of **F** and **G**. One can think of a situation when several waves with different wavevectors **F** and different front-slope vectors **G** develop in different parts of the domain. In this case, regions occupied by the waves with different wavevectors will be divided by domain walls.

In the present section, we investigate a particular case of a one-dimensional stationary domain wall between traveling waves with equal values of the parameters ω and c (see (2.13)). Consider the one-dimensional version of the system (2.25) and define $\theta_z = F(z)$, $\phi_z = H(z)$ and consider solutions with $F(+\infty) = -F(-\infty)$ and $H(+\infty) = -H(-\infty)$. Such solutions correspond to the *domain walls* between two traveling waves with the opposite wavenumbers, each wave traveling on the background of an inclined front.

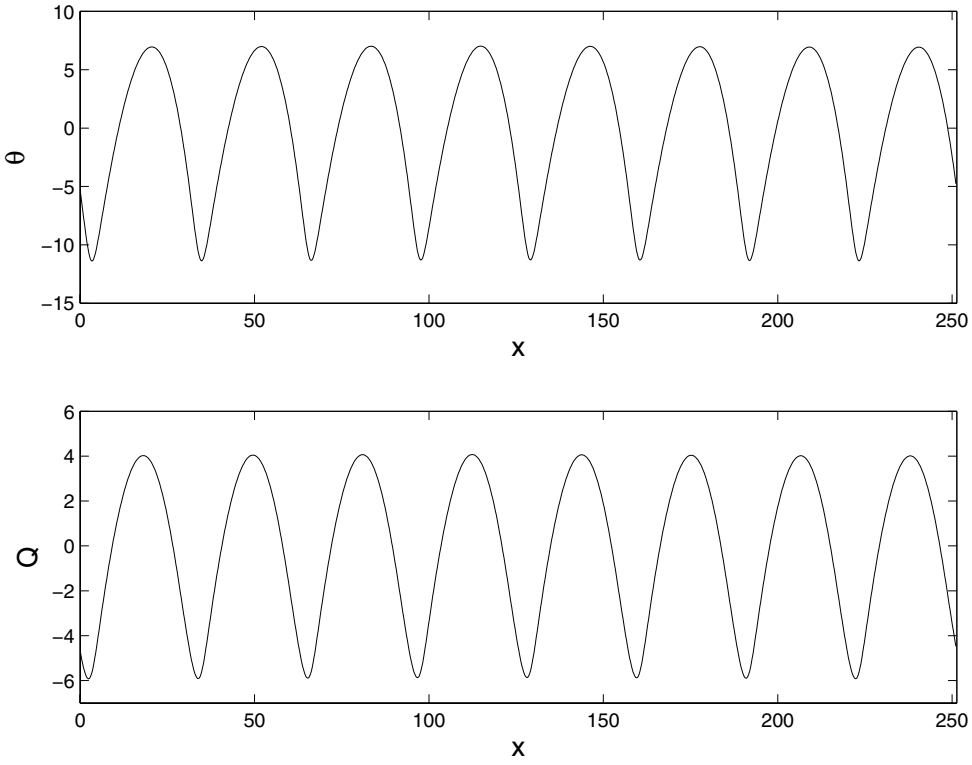

FIG. 7. *Numerical solution of the system* (2.24) *for* $A = 3.0$, $B = -3.0$, $C = 1.0$, $D = 10.45$, $E = -0.9$, $w = 0.45$*: Spatially periodic wave traveling from right to left.*

Assume that $\theta_{T_2} = \Omega$, $\phi_{T_2} = \Phi$ are constants and rewrite the system (2.25) in the form

$$D_1 F_z = \Omega + FH, \tag{3.1}$$
$$D_2 H_z + F_z = \Phi + \frac{1}{2}H^2 - \mu F^2.$$

The dynamical system (3.1) determines stationary profiles $F(z)$, $H(z)$. The critical points of this dynamical system correspond to traveling waves, while the domain walls are governed by the separatrices joining different critical points.

For $\Phi \neq 0$, $\Omega \neq 0$, the critical points of system (3.1), $F(z) = f = \text{const}$, $H(z) = h = \text{const}$, must satisfy the conditions

$$f^2 = f_\pm^2 \equiv \frac{-\Phi \pm \sqrt{\Phi^2 + 2\mu\Omega^2}}{(-2\mu)}, \qquad h = h_\pm \equiv -\frac{\Omega}{f_\pm}. \tag{3.2}$$

Thus, for $\mu < -\Phi^2/(2\Omega^2)$, the dynamical system (3.1) has no critical points. For $\mu = -\Phi^2/(2\Omega^2)$, a pair of critical points appears in the case $\Phi < 0$; otherwise, there are no critical points. For $-\Phi^2/(2\Omega^2) < \mu < 0$ and $\Phi < 0$ there exist two pairs of critical points. In the special case $\mu = 0$, there is one pair of critical points while the other pair of critical points approaches infinity. For $\mu > 0$, there is one pair of critical points for *any* Φ. Thus, the critical points always appear in pairs $(f_\pm, h_\pm)$, $(-f_\pm, -h_\pm)$. Later on, we shall define $f_\pm > 0$.

The analysis of the eigenvalues of the linearized system (3.1) near the critical points leads to the following conclusions. For $\Phi < 0$, $\Omega > 0$, $-\Phi^2/2\Omega^2 < \mu < 0$, the points $(\pm f_+, \pm h_+)$ are saddles, and the point (f_-, h_-) is a stable node, while the point $(-f_-, -h_-)$ is an unstable node. For $\Phi < 0$, $\Omega < 0$, $-\Phi^2/2\Omega^2 < \mu < 0$, the points $(\pm f_+, \pm h_+)$ are saddles, and for $\mu < -1/[2(D_1 - D_2)^2]$, the points $(\pm f_-, \pm h_-)$ are nodes. However, for $-1/[2(D_1 - D_2)^2] < \mu < 0$, there always exists such an interval of $|\Phi/\Omega|$ that the point (f_-, h_-) is a focus. This focus is unstable for $|\mu| > 1/[2(D_1 + D_2)^2]$ and stable otherwise.

Consider now solutions corresponding to the domain walls. The trajectories in the phase plane (F, H) are governed by the equation

$$\frac{D_2}{D_1}\frac{dH}{dF} = -\frac{1}{D_1} + \frac{\Phi + H^2/2 - \mu F^2}{\Omega + FH}. \tag{3.3}$$

Any trajectory that leads from one critical point to another corresponds to a domain wall. There exists a class of symmetric domain walls that are described by trajectories invariant with respect to the transformation $F \to -F$, $H \to -H$. Such a trajectory connects the critical points $(-f, -h)$ and (f, h) passing through the point $(0, 0)$.

A trajectory that leaves the point $(0, 0)$ is generically attracted to the stable critical point or leads to infinity. However, there exists a codimension-1 manifold in the parameter space (Ω, Φ, μ) where the trajectory is "nongeneric" and leads to a saddle critical point. This manifold separates the region of the attraction to the stable critical point and the region where the trajectory tends to infinity.

Generally, (3.3) is not analytically integrable. However, some classes of analytical exact solutions can be found. There exist surfaces in the parameter space (Ω, Φ, μ) where a trajectory that passes through the point $(0, 0)$ is just $H(z) = kF(z)$, $k \neq 0$. These surfaces are determined by the conditions

$$\frac{\Phi}{\Omega} = \frac{sD_2 + D_1}{D_1}, \qquad s = \frac{1 \pm \sqrt{1 - 2\mu D_1(2D_2 - D_1)}}{2D_2 - D_1}, \tag{3.4}$$

where $1 - 2\mu D_1(2D_2 - D_1) > 0$. The corresponding solutions are

$$F = f^{\pm} \tanh \beta(z - z_0), \qquad H = h \tanh \beta(z - z_0), \tag{3.5}$$

where

$$f^{\pm} = \frac{1 \pm \sqrt{1 - 2\mu D_1(2D_2 - D_1)}}{2\mu}\beta, \qquad h = -D_1\beta, \tag{3.6}$$

and $\mu < 0$, β and z_0 are arbitrary constants (β can be taken positive without loss of generality).

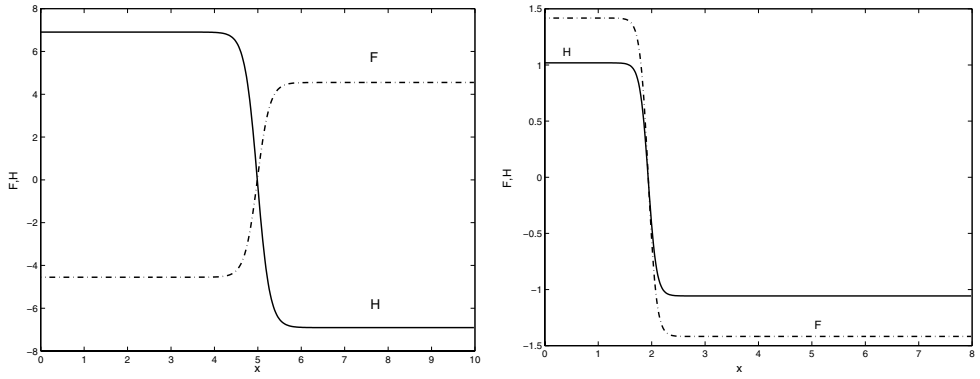
One can show that for $(2D_2 - D_1) > 0$, $\Omega < 0$, the exact solution (3.5) corresponds to a nongeneric trajectory that leads to the saddle critical point (f^-, h) if $\mu < -1/[2(D_2 - D_1)^2]$. Otherwise, the point (f^-, h) determined by (3.6) corresponds to a node. For $2D_2 - D_1 < 0$, $|\mu| > 1/[2{D_1}^2]$, $\Omega < 0$, the trajectory (3.5) leads to a saddle for $\mu > -1/[2(D_2 - D_1)^2]$, and to a node for $\mu < -1/[2(D_2 - D_1)]^2$. For $\Omega < 0$, $|\mu| > 1/[2{D_1}^2]$, $D_2 - D_1 < 0$, the point (f^+, h) is a node for $\mu < -1/[2(D_2 - D_1)^2]$. For $2D_2 - D_1 = 0$, the point (f^-, h) is a node, and the point (f^+, h) is a saddle for $\mu > -2/D_1^2$. Otherwise, the point (f^+, h) is a node. In the case $\Omega > 0$, $D_2 > D_1$ the point (f, h) is a node for $\mu > -1/[2(D_2 - D_1)^2]$. Otherwise, the trajectory (3.5) leads to a saddle.

Note that there is one more class of exact solutions, corresponding to the case $\Omega = 0$,

$$F = 0, \qquad H(z) = h \tanh \beta z, \tag{3.7}$$

where $h = -2D_2\beta, \beta > 0$. In this case, the point $(0, h)$ is a node.

We have studied the family of solutions that correspond to the domain walls between two traveling waves with the opposite wavenumbers by rewriting the system (2.25) in one dimension for $\chi(z,t) = \theta_z$ and $\psi(z,t) = \phi_z$, and solving it numerically, by means of a finite-difference, semi-implicit Crank–Nicholson scheme, with Neumann boundary conditions. We have found that, depending on the initial conditions and the values of the parameters D_1, D_2, and μ, the solutions evolve either toward stationary domain walls described above or tend to constant solutions, $\chi = \text{const}$, $\psi = \text{const}$, corresponding to a single traveling wave on a slant planar front. Examples of stable domain wall solutions are shown in Figure 8. We have checked that they compare very well with the analytical solutions (3.5), (3.6).



(a) (b)

FIG. 8. *Numerical solution of the system* (2.25) *in one dimension for* $\theta_z = F$ *and* $\phi_z = H$ *in the form of stationary domain walls:* (a) $D_1 = 2.0$, $D_2 = 6.0$, $\mu = -5.0$; (b) $D_1 = 0.2$, $D_2 = 0.6$, $\mu = -5.0$.

In concluding this section we note that there also exists a family of solutions in the form of moving domain walls: indeed, if $F_0(z) = \theta_z$, $H_0(z) = \phi_z$ is a solution of (3.1) that describes a stationary domain wall with the definite values of $\Omega_0 = \theta_{T_2}$, $\Phi_0 = \phi_{T_2}$, then a moving domain wall $F(z,T_2) = \theta_z(z,T_2) = F_0(z - cT_2)$, $H(z,T_2) = \phi_z(z,T_2)_z = c + H_0(z - cT_2)$ with $\Omega = \Omega_0$, $\Phi = \Phi_0 + c^2/2$ ($\theta(z,T_2) = \int F(z,T_2)\,dz + \Omega T_2$, $\phi(z,T_2) = \int H(z,T_2)\,dz + \Phi T_2$) is a solution of (2.25) (in one dimension).

4. Conclusions. We have investigated the stability and nonlinear dynamics of traveling waves in a system with translation symmetry that exhibits a long-wave oscillatory instability. Near the instability threshold, the nonlinear dynamics of this system is governed by a CGL equation for the unstable mode coupled to the Burgers equation for the Goldstone mode generated by the translation symmetry. We have demonstrated that, in the long-wave limit, this system of coupled nonlinear evolution equations is reduced to the system of two *coupled Burgers equations*—for the *phase* of

the unstable mode and for the Goldstone mode—and we have studied the nonlinear dynamics of waves described by this system.

We have shown that the derived system of coupled Burgers equations captures well the main effect of the coupling between the unstable oscillatory mode and the Goldstone mode, namely, the change of the Benjamin–Feir stability region as well as the unique situation when all waves, except the one with the zero wavenumber (planar oscillations), are unstable. Also, the derived system of the coupled Burgers equations describes the two main instability types: the convective instability of the negative viscosity type, and the absolute instability of the α-effect type. At the boundaries of these instabilities we have derived the weakly nonlinear evolution equations describing the weakly nonlinear dynamics of unstable waves near the instability thresholds. We have also performed numerical simulations of the coupled Burgers equations and studied the strongly nonlinear dynamics of the discovered instabilities. We have observed the formation of periodically and chaotically modulated traveling waves, in both one and two dimensions. The similar type of nonlinear behavior was also observed earlier in simulating the coupled CGL and Burgers equations. Finally, we have shown that the derived system of coupled Burgers equations also describes the domain boundaries between waves with different wavenumbers.

Thus, the derived system of coupled Burgers equations can be considered as a *generic* system that describes the *long-wave* dynamics of waves in systems that exhibit an oscillatory instability at a zero wavenumber in the presence of the Goldstone mode associated with the translation symmetry. This situation is typical of physical systems with uniformly propagating fronts, such as planar flame fronts in combustion [23], [24], solidification in a hypercooled melt [45], as well as in general reaction-diffusion systems [46]. In this paper we considered combustion fronts as an example, but the results obtained also can be applied to any other system of this class. Waves on uniformly propagating fronts were observed in experiments on premixed-flame gaseous combustion [47], solid combustion (self-propagating high-temperature synthesis) [48], as well as frontal polymerization [49]. These systems would be natural candidates for experimental verification of theoretical conclusions presented in this paper.

Appendix A. Derivation of (2.25). We introduce slow time variables, $T_1 = \varepsilon T$, $T_2 = \varepsilon^2 T$, and a new, long-scale spatial variable, $\mathbf{z} = \varepsilon \mathbf{X}' + \mathbf{F} C T_1$; we expand $\widehat{\theta} = \varepsilon^{-1}\widehat{\theta}_{-1} + \widehat{\theta}_0 + \varepsilon\widehat{\theta}_1 + \dots, \widehat{Q} = \varepsilon^{-1}\widehat{Q}_{-1} + \widehat{Q}_0 + \varepsilon\widehat{Q}_1 + \dots$; and we substitute this expansion in the system (2.24). As a leading-order problem, one obtains

$$\frac{\partial \widehat{\theta}_{-1}}{\partial T_1} = C(\nabla_z \widehat{\theta}_{-1})^2 - \nabla_z \widehat{\theta}_{-1} \cdot \nabla_z \widehat{Q}_{-1} + C\mathbf{F} \cdot \nabla_z \widehat{\theta}_{-1} - \mathbf{F} \cdot \nabla_z \widehat{Q}_{-1}, \tag{A.1}$$

$$\frac{\partial \widehat{Q}_{-1}}{\partial T_1} = \frac{C^2}{2}(\nabla_z \widehat{\theta}_{-1})^2 - \frac{1}{2}(\nabla_z \widehat{Q}_{-1})^2 + C^2 \mathbf{F} \cdot \nabla_z \widehat{\theta}_{-1} - C\mathbf{F} \cdot \nabla_z \widehat{Q}_{-1},$$

where ∇_z is the gradient with respect to the new long-scale variable $\mathbf{z}$. Taking $\widehat{Q}_{-1} = C\widehat{\theta}_{-1} + \phi_{-1}$, one obtains from (A.1)

$$\frac{\partial \phi_{-1}}{\partial T_1} = -\frac{1}{2}(\nabla_z \phi_{-1})^2. \tag{A.2}$$

If ϕ_{-1} is initially nonzero, $|\nabla_z \phi_{-1}|$ becomes infinite in a finite time.[1] Thus, in order

[1] Indeed, the equation $u_t + uu_z = 0$, $u = \frac{\partial \phi_{-1}}{\partial z}$ for any initial condition has an exact solution $z = f(u) + ut$; therefore $u_z = \frac{1}{f'(u)+t}$. Except the case when $f'(u) > 0$ everywhere, $u_z \to \infty$ in a finite time.

to describe smooth solutions we have to assume $\phi_{-1} = 0$. Therefore,

$$\widehat{Q}_{-1} = C\widehat{\theta}_{-1}. \tag{A.3}$$

From (A.3) and (A.1) one finds $\partial\widehat{\theta}_{-1}/\partial T_1 = \partial\widehat{Q}_{-1}/\partial T_1 = 0$, and hence the solution does not depend on T_1.

In the next order one obtains

$$\frac{\partial\widehat{\theta}_{-1}}{\partial T_2} = (A + B^0C)\nabla_z{}^2\widehat{\theta}_{-1} + C(\nabla_z\widehat{\theta}_{-1} + \mathbf{F})\cdot\nabla_z\widehat{\theta}_0 - (\nabla_z\widehat{\theta}_{-1} + \mathbf{F})\cdot\nabla_z\widehat{Q}_0, \tag{A.4}$$

$$C\frac{\partial\widehat{\theta}_{-1}}{\partial T_2} = (CD + E)\nabla_z{}^2\widehat{\theta}_{-1} + C^2(\nabla_z\widehat{\theta}_{-1} + \mathbf{F})\cdot\nabla_z\widehat{\theta}_0 - C(\nabla_z\widehat{\theta}_{-1} + \mathbf{F})\cdot\nabla_z\widehat{Q}_0,$$

where $B^0 = vs_r - s_i^0$, and we take $\widehat{Q}_0 = C\widehat{\theta}_0 + \phi_0$. The solvability condition for the problem (A.4) is

$$E - 2w_0B^0 - C(A - D) = 0, \tag{A.5}$$

where $C^2 = 2w_0$. One can see that the solvability condition (A.5) is automatically satisfied. From (A.4) one obtains

$$\frac{\partial\widehat{\theta}_{-1}}{\partial T_2} = (A + B^0C)\nabla_z{}^2\widehat{\theta}_{-1} - (\nabla_z\widehat{\theta}_{-1} + \mathbf{F})\cdot\nabla_z\phi_0. \tag{A.6}$$

Taking a corresponding linear combination of the equations for $\hat{\theta}_0$ and $\hat{Q}_0$, which are obtained in the next order, one gets the following problem:

$$\frac{\partial\phi_0}{\partial T_2} = (D - CB^0)\nabla_z{}^2\phi_0 - \frac{1}{2}(\nabla_z\phi_0)^2 + RC^2\nabla_z{}^2\widehat{\theta}_{-1} + W(\nabla_z\widehat{\theta}_{-1} + 2\mathbf{F})\cdot\nabla_z\widehat{\theta}_{-1}. \tag{A.7}$$

Define $D_1 = A + CB^0$, $D_2 = D - CB^0$, $\phi = \phi_0 + WF^2T_2$, $\theta = C^2R(\widehat{\theta}_{-1} + \mathbf{F}\cdot\mathbf{z})$, $\mu = W/(RC^2)^2$. Since $\mathrm{tr}(M) > 0$, $\det(M) > 0$, the coefficients D_1 and D_2 are positive. Note that if the function $\widehat{\theta}_{-1}$ is bounded for $|\mathbf{z}| \to \infty$, the asymptotics of the function θ is $\theta \sim \mathbf{F}\cdot\mathbf{z}$. Then (A.6) and (A.7) can be written in the form of the system (2.25).

Appendix B. Derivation of (2.37). The functions ${\theta_2}^{\pm}$, ${\phi_2}^{\pm}$ from (2.36) satisfy the following equations:

$$\pm\sqrt{2|\mu_*|}\frac{\partial\theta_2^{\pm}}{\partial x_{\pm}} + \frac{\partial\theta_1^{\pm}}{\partial t_2} = D_1\left(\frac{\partial^2\theta_1^{\pm}}{\partial {x_{\pm}}^2} + \frac{\partial^2\theta_1^{\pm}}{\partial y^2}\right) - 2\frac{\partial\phi_2^{\pm}}{\partial x_{\pm}}, \tag{B.1}$$

$$\pm\sqrt{2|\mu_*|}\frac{\partial\phi_2^{\pm}}{\partial x_{\pm}} \mp \sqrt{2|\mu_*|}\frac{\partial\theta_1^{\pm}}{\partial t_2} = \left(1 \mp \sqrt{2|\mu_*|}D_2\right)\left(\frac{\partial^2\theta_1^{\pm}}{\partial {x_{\pm}}^2} + \frac{\partial^2\theta_1^{\pm}}{\partial y^2}\right) - 2|\mu_*|\frac{\partial\theta_2^{\pm}}{\partial x_{\pm}}, \tag{B.2}$$

which can be transformed to

$$\mp 2\sqrt{2|\mu_*|}\frac{\partial\theta_1^{\pm}}{\partial t_2} = \left[1 \mp (D_1 + D_2)\sqrt{2|\mu_*|}\right]\left(\frac{\partial^2\theta_1^{\pm}}{\partial x_{\pm}^2} + \frac{\partial^2\theta_1^{\pm}}{\partial y^2}\right). \tag{B.3}$$

Taking into account the definition of μ_* in (2.28), one finds that θ_1^+ does not depend on t_2, while θ_1^- is governed by the equation

$$\frac{\partial \theta_1^-}{\partial t_2} = (D_1 + D_2)\left(\frac{\partial^2 \theta_1^-}{\partial x_-^2} + \frac{\partial^2 \theta_1^-}{\partial y^2}\right), \tag{B.4}$$

where $(D_1 + D_2) = (A + D) > 0$. Therefore, $\theta_1^- \to 0$, $\phi_1^- \to 0$ on the time scale t_2, and one obtains from (B.1) the following problem:

$$\frac{\partial}{\partial x_+}\left[\phi_2^+ + \sqrt{2|\mu_*|}\theta_2^+\right] = D_1 \nabla^2 \theta_1^+, \tag{B.5}$$

$$\frac{\partial}{\partial x_-}\left[\phi_2^- - \sqrt{2|\mu_*|}\theta_2^-\right] = 0, \tag{B.6}$$

where $\nabla^2 \theta_1^+ = \partial^2 \theta_1^+ / \partial x_+^2 + \partial^2 \theta_1^+ / \partial y^2$. The solution of (B.6) is

$$\phi_2^- = \sqrt{2|\mu_*|}\theta_2^- + c_-(t_3, \ldots), \tag{B.7}$$

and the solution of (B.5) can be written formally as

$$\phi_2^+ = D_1 \mathcal{I}[\theta_1^+] - \sqrt{2|\mu_*|}\theta_2^+ + c_+(t_3, \ldots), \tag{B.8}$$

where

$$\mathcal{I}[f(x_+, y)] \equiv \int_0^{x_+} dx'_+ \nabla^2 f(x'_+, y). \tag{B.9}$$

In the next order, $O(\delta^4)$, one obtains

$$\theta_3 = \theta_3^+(x_+, y) + \theta_3^-(x_-, y), \qquad \phi_3 = \phi_3^+(x_+, y) + \phi_3^-(x_-, y), \tag{B.10}$$

where the functions ${\theta_3}^{\pm}$, ${\phi_3}^{\pm}$ satisfy the following equations:

$$\pm\sqrt{2|\mu_*|}\frac{\partial \theta_3^\pm}{\partial x_\pm} + \frac{\partial \phi_3^\pm}{\partial x_\pm} = D_1(\nabla^2 \theta_2^\pm) \pm \sqrt{2|\mu_*|}(\nabla^2 \theta_1^\pm)^2 - \frac{\partial \theta_1^\pm}{\partial t_3}, \tag{B.11}$$

$$\pm\sqrt{2|\mu_*|}\frac{\partial \phi_3^\pm}{\partial x_\pm} \mp \sqrt{2|\mu_*|}\frac{\partial \theta_1^\pm}{\partial t_3} + 2|\mu_*|\frac{\partial \theta_3^\pm}{\partial x_\pm} = D_2 \nabla^2 \phi_2^\pm + \nabla^2 \theta_2^\pm + 2\mu_2 \frac{\partial \theta_1^\pm}{\partial x_\pm} + 2|\mu_*|(\nabla^2 \theta_1^\pm)^2. \tag{B.12}$$

Equations (B.11) and (B.12) can be transformed to

$$\frac{\partial \theta_1^+}{\partial t_3} = \sqrt{2|\mu_*|}(\nabla \theta_1^+)^2 - \frac{\mu_2}{\sqrt{2|\mu_*|}}\frac{\partial \theta_1^+}{\partial x_+} - \frac{D_1 D_2}{2\sqrt{2|\mu_*|}}\mathcal{I}[\nabla^2 \theta_1^+] + c_+(t_3, \ldots), \tag{B.13}$$

$$\nabla^2 \theta_2^- = 0. \tag{B.14}$$

Also, one obtains from (B.11), (B.12) the following problem for $\phi_3^\pm$:

$$\frac{\partial}{\partial x_+}\left[\phi_3^+ + \sqrt{2|\mu_*|}\theta_3^+\right] = D_1 \nabla^2 \theta_2^+ + \frac{\mu_2}{\sqrt{2|\mu_*|}}\frac{\partial \theta_1^+}{\partial x_+} + \frac{D_1 D_2}{2\sqrt{2|\mu_*|}}\mathcal{I}\left[\nabla^2 \theta_1^+\right], \tag{B.15}$$

$$\frac{\partial}{\partial x_-}\left[\phi_3^- - \sqrt{2|\mu_*|}\theta_3^-\right] = 0. \tag{B.16}$$

The solutions of (B.15), (B.16) are

$$\phi_3^+ = -\sqrt{2|\mu_*|}\theta_3^+ + D_1\mathcal{I}\left[\theta_2^+\right] + \frac{\mu_2\theta_1^+}{\sqrt{2|\mu_*|}} + \frac{D_1D_2}{2\sqrt{2|\mu_*|}}\mathcal{I}\left[\nabla^2\theta_2^+\right], \tag{B.17}$$
$$\phi_3^- = \sqrt{2|\mu_*|}\theta_3^- + \tilde{c}_-(t_3,\ldots).$$

In the next order, $O(\delta^5)$, one obtains

$$\theta_4 = \theta_4^+(x_+,y) + \theta_4^-(x_-,y), \qquad \phi_4 = \phi_4^+(x_+,y) + \phi_4^-(x_-,y), \tag{B.18}$$

where the functions ${\theta_4}^{\pm}$ and ${\phi_4}^{\pm}$ satisfy the two equations:

(B.19)
$$\pm\sqrt{2|\mu_*|}\frac{\partial\theta_4^\pm}{\partial x_\pm} + \frac{\partial\phi_4^\pm}{\partial x_\pm} + \frac{\partial\theta_1^\pm}{\partial t_4} + \frac{\partial\theta_2^\pm}{\partial t_3} = D_1\left(\nabla^2\theta_3^\pm\right) - \nabla\theta_1^\pm\cdot\nabla\phi_2^\pm - \nabla\theta_2^\pm\cdot\nabla\phi_1^\pm,$$
$$\pm\sqrt{2|\mu_*|}\left(\frac{\partial\phi_4^\pm}{\partial x_\pm} - \frac{\partial\theta_1^\pm}{\partial t_4}\right) + \frac{\partial\phi_2^\pm}{\partial t_3} = D_2\nabla^2\phi_3^\pm + \nabla^2\theta_3^\pm + 2\mu_2\frac{\partial\theta_2^\pm}{\partial x_\pm}$$

(B.20)
$$-2|\mu_*|\left(\frac{\partial\theta_4^\pm}{\partial x_\pm} + \nabla\theta_1^\pm\cdot\nabla\theta_2^\pm\right) - \nabla\phi_1^\pm\cdot\nabla\phi_2^\pm\,.$$

Using (2.35), (B.7), (B.8), (B.17) one gets

$$\frac{\partial\theta_1^+}{\partial t_4} + \frac{\partial\theta_2^+}{\partial t_3} = \frac{-1}{2\sqrt{2|\mu_*|}}\left(2\mu_2\frac{\partial\theta_2^+}{\partial x_+} + D_1D_2\mathcal{I}[\nabla^2\theta_2^+] + \frac{D_1D_2}{4|\mu_*|}\mathcal{I}^2[\nabla^2\theta_1^+] + \frac{\mu_2}{2|\mu_*|}\nabla^2\theta_1^+\right)$$
$$+2\sqrt{2|\mu_*|}\nabla\theta_1^+\cdot\nabla\theta_2^+ - D_1\nabla\theta_1^+\mathcal{I}[\nabla\theta_1^+] + \frac{D_1}{2}\mathcal{I}[(\nabla\theta_1^+)^2]\,, \tag{B.21}$$

$$\frac{\partial\theta_2^-}{\partial t_3} = \frac{1}{\sqrt{2|\mu_*|}}\left(\nabla^2\theta_3^- + \mu_2\frac{\partial\theta_2^-}{\partial x_-}\right). \tag{B.22}$$

Equations (B.13) and (B.21) can be combined as the following single equation:

$$\frac{\partial\vartheta}{\partial\tau} = -\frac{\mu_2}{\sqrt{2|\mu_*|}}\frac{\partial\vartheta}{\partial x_+} - \frac{D_1D_2}{2\sqrt{2|\mu_*|}}\mathcal{I}[\nabla^2\vartheta] + \sqrt{2|\mu_*|}(\nabla\vartheta)^2$$
$$+\delta\left(-\frac{\mu_2}{4|\mu_*|\sqrt{2|\mu_*|}}\nabla^2\vartheta + \Psi) + O(\delta^2\right), \tag{B.23}$$

where

$$\Psi = -\frac{D_1D_2}{8|\mu_*|\sqrt{2|\mu_*|}}\mathcal{I}^2[\nabla^2\vartheta] + \frac{D_1}{2}\mathcal{I}[(\nabla\vartheta)^2] - D_1\nabla\vartheta\cdot\mathcal{I}[\nabla\vartheta]\,,$$
$$\mathcal{I}[f(x_+,y)] \equiv \int_0^{x_+} dx'_+\nabla^2 f(x'_+,y)\,,$$

and $\vartheta = \theta_1^+ + \delta\theta_2^+ + \ldots\,,\ \partial_\tau = \partial_{\tau_3} + \delta\partial_{\tau_4} + \ldots.$

By means of the scaling transformation $\vartheta = C_1\Theta,\ x_+ = C_2\tilde{X},\ y = C_2\tilde{Y},\ \tau = C_3\tilde{T}$, where

$$C_1 = -\frac{3\sqrt{2\mu_2D_1D_2}}{4|\mu_*|}, \qquad C_2 = \left(\frac{D_1D_2}{2\mu_2}\right)^{1/2}, \qquad C_3 = \frac{2\sqrt{2|\mu_*|D_1D_2}}{(2\mu_2)^{3/2}},$$

(B.23) can be written in the form (2.37), where $\nabla = \vec{e}_X \partial_X + \vec{e}_Y \partial_Y$, the coefficients are

$$\widetilde{C} = 1,\ \widetilde{\delta} = \delta \frac{(2|\mu_*|)^{3/2}}{6\mu_2^2},\ \widetilde{D} = -\frac{D_1}{2}\left(\frac{3\mu_2}{2|\mu_*|}\right)^2 \sqrt{\frac{2\mu_2}{D_1 D_2}},\ \widetilde{E} = D_1 \left(\frac{3\mu_2}{2|\mu_*|}\right)^2 \sqrt{\frac{2\mu_2}{D_1 D_2}},$$

and tildes in $\tilde{X}$, $\tilde{Y}$, $\tilde{\nabla}$, $\tilde{T}$ have been dropped.

T-SCAN ELECTRICAL IMPEDANCE IMAGING SYSTEM FOR ANOMALY DETECTION*

HABIB AMMARI†, OHIN KWON‡, JIN KEUN SEO§, AND EUNG JE WOO¶

Abstract. We consider an inverse conductivity problem arising in anomaly detections with its mathematical model based on the T-Scan system (breast cancer detection system). In this model, we try to detect an anomaly D from one or two sets of measured data that are available only on a small portion Γ of the boundary of the subject Ω. In practice, Ω differs in each subject, so our detection algorithm should not depend much on the global geometry of Ω. The purpose of this work is to provide a mathematical ground for the reconstruction of a rough feature of D which is stable against any measurement noise and any change of geometry $\partial\Omega$. Based on rigorous estimates with a simplified model, we found an approximation that gives a noniterative detection algorithm of finding a useful feature of anomaly. We also present a multifrequency approach to handling the case where the complex conductivity of the background is not homogeneous and is not known a priori.

Key words. breast cancer detection, electrical conductivity, T-Scan, anomaly estimation algorithm

1. Introduction.

Bioimpedance techniques such as electrical impedance tomography (EIT) have been used as a diagnostic tool for breast cancer detection due to the high contrast of the complex conductivity between cancerous and healthy tissues. Among them, the T-Scan is one of the most successful systems that has received FDA approval for adjunctive clinical uses with X-ray mammography [3]. Use of the T-Scan is to decrease equivocal findings and thereby reduce unnecessary biopsies. However, diagnostic information from the currently available T-Scan system lacks a sophisticated reconstruction method of finding lesions. Increasing the ability to accurately detect breast cancer requires improvements in the sensitivity and accuracy of the T-Scan system. Although some observations on processing data from the T-Scan system have been published [3, 21], rigorous mathematical theory for supporting their results has not been presented. Systematic studies are essential to achieve higher performance in breast cancer detection, and it is necessary to derive agreements between experimental results and mathematical theory that provide the relationship between lesions and measured data acquired by a scanning probe through the breast skin.

The mathematical model of the T-Scan can be viewed essentially as a realistic or practical version of a general EIT system, so any developed theory from this model can be applied to other areas in EIT, especially in anomaly detection problems. In the T-Scan system, a patient holds in one hand a metallic cylindrical reference electrode through which a constant voltage of 1 to 2.5 V is applied with frequencies spanning

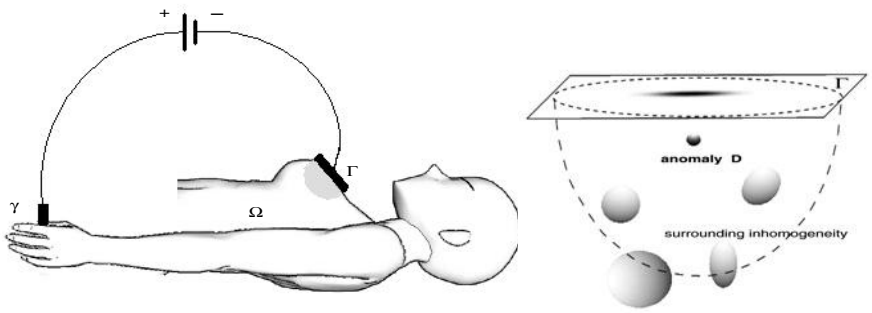

FIG. 1.1. *T-Scan configuration (left) and the breast region of interest (right).*

100 Hz to 100 KHz. A scanning probe with a planar array of electrodes kept at the ground potential is placed on the breast as shown in Figure 1.1. The voltage difference between the hand and the breast skin produces current flows from the reference electrode to each electrode of the probe through the breast. We can extract some information of the complex conductivity distribution within a breast region under the probe by measuring the exit current through each electrode of the probe.

Let the human body occupy a three-dimensional region Ω bounded by a smooth surface $\partial\Omega$. Let Γ and γ be portions of $\partial\Omega$, denoting the probe plane placed on the breast and the surface of the metallic reference electrode contacting the hand, respectively. Since Γ is a planar domain, without loss of generality, we let x_3 be the label of the axis normal to Γ so that Γ is in the plane $\{\mathbf{x} = (x_1, x_2, x_3) \in \mathbb{R}^3 : x_3 = 0\}$. Suppose the diameter of Γ is between 4ρ and 6ρ; $\{x_3 = 0\} \cap B_{2\rho} \subset \Gamma \subset \{x_3 = 0\} \cap B_{3\rho}$, where $B_\rho := \{\mathbf{x} \in \mathbb{R}^3 \mid |\mathbf{x}| < \rho\}$ and denote $\Gamma_\rho = \Gamma \cap B_\rho$. Then the breast region of interest is the half ball $\Omega_\rho := \Omega \cap B_\rho$. If we apply a boundary voltage f with a frequency ω on $\Gamma \cup \gamma$, the resulting internal complex voltage $u(\mathbf{x})$ at the position $\mathbf{x}$ in Ω satisfies the following mixed boundary value problem:

$$\begin{cases} \nabla \cdot ((\sigma + i\omega\epsilon)\nabla u(\mathbf{x})) = 0, & \mathbf{x} \in \Omega, \\ u(\mathbf{x}) = f, & \mathbf{x} \in \Gamma \cup \gamma, \\ (\sigma + i\omega\epsilon)\nabla u(\mathbf{x}) \cdot \nu(\mathbf{x}) = 0, & \mathbf{x} \in \partial\Omega \setminus \Gamma \cup \gamma. \end{cases} \tag{1.1}$$

Here, ν is the unit outward normal vector to the boundary, $\sigma = \sigma(\mathbf{x}, \omega)$ is the conductivity, and $\epsilon = \epsilon(\mathbf{x}, \omega)$ is the permittivity. As in the T-Scan system, we use $f = 0$ on Γ and $f = 1$ to 2.5 V on γ with $\omega = 2\pi \times 10^2$ to $2\pi \times 10^5$ rad/s. The goal is to extract some core information of the complex conductivity $(\sigma + i\omega\epsilon)$ in the breast region Ω_ρ from the Cauchy data given only on the small portion Γ.

Let us denote a breast tumor by D and suppose $D \subset \Omega_\rho$. Since there is an abrupt change in the complex conductivity across ∂D, it is convenient to write

$$\sigma + i\omega\epsilon = \begin{cases} \sigma_1 + i\omega\epsilon_1 := \tau_1 & \text{in } \Omega \setminus \overline{D}, \\ \sigma_2 + i\omega\epsilon_2 := \tau_2 & \text{in } D. \end{cases} \tag{1.2}$$

Our anomaly detection problem is to identify D near Γ from the exit current data $g := (\sigma + i\omega\epsilon)\nabla u(\mathbf{x}) \cdot \nu(\mathbf{x})|_\Gamma$ under the following limitations:

- We measure the data only in a small surface Γ instead of the whole surface $\partial\Omega$.
- Since Ω differs for each subject, our detection algorithm should not depend much on the global geometry of Ω.
- Electrical safety regulations limit the amount of the total current flowing through the human subject and therefore the range of the applied voltage is also limited.

Although this type of anomaly detection problem has been studied in many papers [1, 2, 4, 5, 6, 7, 11, 12, 16, 17, 18], these limitations are indispensable in practice and raise serious difficulties in applying previous techniques. The challenge of this problem is to develop a proper analysis for a quantitative information of D in the breast region with some measured data in such a way that a reconstruction formula for D is reasonably stable to any change of the conductivity distributions outside the breast region. In this work we fix the voltage $f = 0$ on Γ as in the T-Scan system instead of applying various voltages f. Keeping $f = 0$ on Γ has a great advantage because it forces the level surface of the voltage in the breast region to be approximately parallel to the probe plane Γ and its electric field $-\nabla u$ will be in the direction perpendicular to the level surface, so more current will flow along D of which the conductivity σ_2 is much higher than the surrounding. Although one could apply many different f on Γ to acquire additional information of D, technical difficulties related with measurement noise make us hesitate to use various patterns of voltages f.

The purpose of this work is to provide a mathematical ground for reconstruction of a rough feature of D which is stable against any measurement noise and any change of geometry $\partial\Omega$. We carry out some quantitative analysis for a simplified model with a single applied voltage $f = 0$ on Γ. We relate D to $(g - g_0)$, where g_0 is the corresponding Neumann data of (1.1) in the absence of D. This analysis provides the reconstruction method of extracting a rough feature of D, although we do not know the overall structure of the complex conductivity distribution in Ω.

To end this section, let us review some previous results toward the T-Scan model. Assenheimer et al. [3] and Scholtz [21] studied the model, and their results were based on the physical insight that an anomaly can be viewed as a distribution of aligned dipoles. However, their expressions lack generality and flexibility without a rigorous mathematical theory. To perform a quantitative analysis of the T-Scan model and increase the accuracy of lesion detection, we need to develop a rigorous mathematical theory counting on the effects of the anomaly. In the recent paper by Seo et al. [22], a framework for analyzing the mathematical model of the T-Scan system was presented, providing a stable reconstruction algorithm for locating D, and numerical simulations showed that their methods can extract key features of D. However, rigorous mathematical theory has not yet been provided to support all these results and so their accuracy has not been confirmed.

We should also note that there have been different approaches to detecting breast cancers based on the current-injection EIT system. Kerner et al. placed a circular array of electrodes around the breast and produced cross-sectional conductivity images [15]. Larson-Wiseman [19], Mueller, Isaacson, and Newell [20], and Kao et al. [14] investigated the usefulness of planar electrode arrays instead of conventional circular electrode arrays. They studied the optimal injection current patterns, distinguishability, and image reconstruction algorithms using the measured voltage data on the electrode arrays. Cherepenin et al. used a planar array of 256 electrodes to reconstruct so-called electrical impedance mammograms by sequentially injecting currents through chosen electrodes and measuring voltage data on other electrodes in the array [8, 9].

Although there could be various approaches in breast cancer detection using EIT techniques, we focus on the T-Scan model in this paper. Although we deal only with the problem in three-dimensional space, all results in this paper work for general dimension $n \geq 2$ with minor modifications.

2. Anomaly detection in half space. The problem we consider in this section is a simplified version of the T-Scan model in (1.1). Let Ω be the lower half space $\Omega = \mathbb{R}^3_- := \{\mathbf{x} = (x_1, x_2, x_3) \mid x_3 < 0\}$. Let $B_r(\mathbf{x}) = \{\mathbf{y} \in \mathbb{R}^3 : |\mathbf{x} - \mathbf{y}| < r\}$ and simply $B_r = B_r(0)$. Let ρ be a fixed positive number and let D be a domain contained in $\Omega_\rho = \Omega \cap B_\rho$ with connected C^2-boundary. Let Γ be a portion of the plane $\partial\Omega$ such that $\{x_3 = 0\} \cap B_{2\rho} \subset \Gamma \subset \{x_3 = 0\} \cap B_{3\rho}$ and let $\Gamma_\rho = \Gamma \cap B_\rho$.

We consider the following mixed boundary value problem:

$$\text{(2.1)} \qquad \begin{cases} \nabla \cdot ((1 + \mu\chi_D)\nabla v(\mathbf{x})) = 0, \quad \mathbf{x} \in \Omega = \mathbb{R}^3_-, \\ v(\mathbf{x}) = 1, \quad \mathbf{x} \in \Gamma, \\ \frac{\partial v}{\partial x_3}(\mathbf{x}) = 0, \quad \mathbf{x} \in \Gamma^{ext} := \partial\Omega \setminus \Gamma, \end{cases}$$

where μ is a positive constant. The $H^1(\Omega)$-solution u of (1.1) is related to the solution v of (2.1) in such a way that $u = 1 - v$ when $\tau_1 = 1$, $\tau_2 = 1 + \mu$, and $\gamma = \infty$. For related works of this simplified model, see [3] and [21].

The inverse problem is to determine D from the Neumann data $g = \frac{\partial v}{\partial x_3}|_\Gamma$. We assume that

$$\xi \in D \subset \Omega_\rho, \qquad \operatorname{diam}(D) \leq r_0, \qquad \text{and} \qquad r_0 \leq \operatorname{dist}(D, \Gamma) \leq A r_0,$$

where A is a fixed positive constant. We assume that the ratio r_0/ρ is small. Here, we exclude two possible cases; (i) $\operatorname{dist}(D, \Gamma) < r_0$ and (ii) D is far away from Γ. For the first case where D is very close to Γ, the Neumann data g manifest the presence of D that was used in the original T-Scan system, so any aid of mathematical analysis is not necessary. For the second case where D is far away from Γ, the change of the Neumann data g due to D will be negligibly small so that any analysis in this case may not have practical meaning if we consider inevitable measurement noise and ill-posedness of this inverse problem.

Let v_0 be the solution of (2.1) in the absence of D and $g_0 = \frac{\partial v_0}{\partial x_3}|_\Gamma$. We try to find a relation between D and the difference $(g - g_0)$. Recall that v and v_0 satisfy the following integral representations [13]: for $\mathbf{x} \in \Omega$,

(2.2)

$$v_0(\mathbf{x}) = -\int_\Gamma \Phi(\mathbf{x}, \mathbf{y}) g_0(\mathbf{y}) ds_{\mathbf{y}} + \int_{\Gamma \cup \Gamma^{ext}} \partial_{x_3} \Phi(\mathbf{x}, \mathbf{y})\, v_0(\mathbf{y}) ds_{\mathbf{y}},$$

$$v(\mathbf{x}) = -\int_\Gamma \Phi(\mathbf{x}, \mathbf{y}) g(\mathbf{y}) ds_{\mathbf{y}} + \int_{\Gamma \cup \Gamma^{ext}} \partial_{x_3} \Phi(\mathbf{x}, \mathbf{y}) v(\mathbf{y}) ds_{\mathbf{y}} + \int_D \mu \nabla_{\mathbf{y}} \Phi(\mathbf{x}, \mathbf{y}) \cdot \nabla v(\mathbf{y}) d\mathbf{y}.$$

The next theorem enables us to approximate

$$\frac{1}{2\mu}[g(\mathbf{x}) - g_0(\mathbf{x})] \approx \int_D \nabla_{\mathbf{y}} \frac{\partial}{\partial x_3} \Phi(\mathbf{x}, \mathbf{y}) \cdot \nabla v(\mathbf{y}) d\mathbf{y}, \quad \mathbf{x} \in \Gamma_\rho.$$

Here, $\Phi(\mathbf{x}, \mathbf{y})$ denotes the fundamental solution to Laplace's equation: $\Phi(\mathbf{x}, \mathbf{y}) = \frac{-1}{4\pi|\mathbf{x}-\mathbf{y}|}$. Throughout this section, the constant C will be different in each occurrence, but all Cs are independent of r_0, ρ, and Γ.

THEOREM 2.1. *The difference* $(g - g_0)$ *on* Γ *can be expressed as*

$$\frac{1}{2\mu}[g(\mathbf{x}) - g_0(\mathbf{x})] = \int_D \nabla_{\mathbf{y}} \left[\frac{\partial}{\partial x_3} \Phi(\mathbf{x}, \mathbf{y}) + T(\mathbf{x}, \mathbf{y}) \right] \cdot \nabla v(\mathbf{y}) d\mathbf{y}, \quad \mathbf{x} \in \Gamma_\rho, \tag{2.3}$$

where $T(\mathbf{x}, \mathbf{y})$ *satisfies the following estimate:*

$$|\nabla_{\mathbf{y}} T(\mathbf{x}, \mathbf{y})| \leq C \, \rho^{-3}, \qquad \mathbf{y} \in D, \ \mathbf{x} \in \Gamma_\rho. \tag{2.4}$$

Proof. Using (2.2) and $v = v_0$ on Γ, we have

$$\begin{aligned} v(\mathbf{x}) - v_0(\mathbf{x}) = &- \int_\Gamma \Phi(\mathbf{x}, \mathbf{y})[g - g_0](\mathbf{y}) ds_{\mathbf{y}} + \int_D \mu \nabla_{\mathbf{y}} \Phi(\mathbf{x}, \mathbf{y}) \cdot \nabla v(\mathbf{y}) d\mathbf{y} \\ &+ \int_{\Gamma^{ext}} \partial_{x_3} \Phi(\mathbf{x}, \mathbf{y})[v(\mathbf{y}) - v_0(\mathbf{y})] ds_{\mathbf{y}} \end{aligned} \tag{2.5}$$

for $\mathbf{x} \in \Omega$. Applying $\frac{\partial}{\partial x_3}$ over both sides of the identity (2.5) for $\mathbf{x} \in \Gamma$ yields

$$\begin{aligned} g(\mathbf{x}) - g_0(\mathbf{x}) = \frac{\partial}{\partial x_3}[v(\mathbf{x}) - v_0(\mathbf{x})] &= - \lim_{x_3 \to 0^-} \frac{\partial}{\partial x_3} \int_\Gamma \Phi(\mathbf{x}, \mathbf{y})[g - g_0](\mathbf{y}) ds_{\mathbf{y}} \\ &+ \frac{\partial}{\partial x_3} \int_D \mu \nabla_{\mathbf{y}} \Phi(\mathbf{x}, \mathbf{y}) \cdot \nabla v(\mathbf{y}) d\mathbf{y} + \int_{\Gamma^{ext}} (v(\mathbf{y}) - v_0(\mathbf{y})) \partial_{y_3}^2 \Phi(\mathbf{x}, \mathbf{y}) ds_{\mathbf{y}}. \end{aligned} \tag{2.6}$$

Since $\lim_{x_3 \to 0^-} \frac{\partial}{\partial x_3} \int_\Gamma \Phi(\mathbf{x}, \mathbf{y})[g - g_0](\mathbf{y}) ds_{\mathbf{y}} = -\frac{1}{2}[g - g_0](\mathbf{x})$ for $\mathbf{x} \in \Gamma$ from the trace formula for the single layer potential in [10], the identity (2.6) becomes

$$\begin{aligned} \frac{1}{2}[g(\mathbf{x}) - g_0(\mathbf{x})] = \mu \frac{\partial}{\partial x_3} &\int_D \nabla_{\mathbf{y}} \Phi(\mathbf{x}, \mathbf{y}) \cdot \nabla v(\mathbf{y}) d\mathbf{y} \\ &+ \int_{\Gamma^{ext}} (v(\mathbf{y}) - v_0(\mathbf{y})) \partial_{y_3}^2 \Phi(\mathbf{x}, \mathbf{y}) ds_{\mathbf{y}}, \quad \mathbf{x} \in \Gamma. \end{aligned} \tag{2.7}$$

Now, we investigate $[v - v_0]|_{\Gamma^{ext}}$. For a fixed $\mathbf{x} \in \mathbb{R}^3 \setminus \Gamma$, let $h(\mathbf{x}, \cdot)$ be the $H^1(\mathbb{R}^3 \setminus \Gamma)$-solution of the following:

$$\begin{cases} \Delta_{\mathbf{y}} h(\mathbf{x}, \mathbf{y}) = 0, \quad \mathbf{y} \in \mathbb{R}^3 \setminus \Gamma, \\ h(\mathbf{x}, \mathbf{y}) = \frac{1}{2\pi |\mathbf{x} - \mathbf{y}|}, \quad \mathbf{y} \in \Gamma, \\ h(\mathbf{x}, \mathbf{y}) = 0, \quad \text{as } |\mathbf{y}| \to \infty. \end{cases}$$

Let $N(\mathbf{x}, \mathbf{y})$ denote the Neumann function for the half space $\mathbb{R}^3_-$; $N(\mathbf{x}, \mathbf{y}) := \Phi(\mathbf{x}, \mathbf{y}) + \Phi(\mathbf{x}, \mathbf{y}^+)$, where $\mathbf{y}^+ = (y_1, y_2, -y_3)$ is the reflection point of $\mathbf{y}$ by the plane $\{y_3 = 0\}$. Then $\Psi(\mathbf{x}, \mathbf{y}) := N(\mathbf{x}, \mathbf{y}) + h(\mathbf{x}, \mathbf{y})$ satisfies

$$\begin{cases} \Delta_{\mathbf{x}} \Psi(\mathbf{x}, \mathbf{y}) = \delta(\mathbf{x} - \mathbf{y}), \quad \mathbf{x}, \mathbf{y} \in \Omega, \\ \Psi(\mathbf{x}, \mathbf{y}) = 0, \quad \mathbf{x} \in \Gamma, \ \mathbf{y} \in \Omega, \\ \frac{\partial}{\partial x_3} \Psi(\mathbf{x}, \mathbf{y}) = 0, \quad \mathbf{x} \in \Gamma^{ext}, \ \mathbf{y} \in \mathbb{R}^3_-, \\ \Psi(\mathbf{x}, \mathbf{y}) \to 0 \quad \text{as } |\mathbf{x} - \mathbf{y}| \to \infty. \end{cases}$$

It is easy to see from the standard argument in PDE that $\Psi(\mathbf{x}, \mathbf{y}) = \Psi(\mathbf{y}, \mathbf{x})$, $\mathbf{x}, \mathbf{y} \in \Omega$. Since $-N(\mathbf{x}, \mathbf{y}) = h(\mathbf{x}, \mathbf{y})$ for $\mathbf{y} \in \Gamma$ and $\mathbf{x} \in \Omega$, in view of the maximum principle, we have $|h(\mathbf{x}, \mathbf{y})| \leq |N(\mathbf{x}, \mathbf{y})|$ for $\mathbf{x}, \mathbf{y} \in \Omega$, and so

$$|\Psi(\mathbf{x}, \mathbf{y})| \leq 2|N(\mathbf{x}, \mathbf{y})|, \qquad \mathbf{x}, \mathbf{y} \in \Omega. \tag{2.8}$$

Using Ψ and following the process in (2.5), the difference $v - v_0$ can be expressed as

$$v(\mathbf{y}) - v_0(\mathbf{y}) = \mu \int_D \nabla_{\mathbf{z}} \Psi(\mathbf{y}, \mathbf{z}) \cdot \nabla_{\mathbf{z}} v(\mathbf{z}) d\mathbf{z}, \qquad \mathbf{y} \in \Omega.$$

Hence, the second term in (2.7) can be written as

$$\int_{\Gamma^{ext}} (v(\mathbf{y}) - v_0(\mathbf{y})) \partial_{y_3}^2 \Phi(\mathbf{x}, \mathbf{y}) ds_{\mathbf{y}} = \mu \int_D \nabla_{\mathbf{z}} T(\mathbf{x}, \mathbf{z}) \cdot \nabla v(\mathbf{z}) d\mathbf{z},$$

where

$$T(\mathbf{x}, \mathbf{z}) = \int_{\Gamma^{ext}} \Psi(\mathbf{y}, \mathbf{z}) \partial_{y_3}^2 \Phi(\mathbf{x}, \mathbf{y}) ds_{\mathbf{y}}.$$

The term $\nabla_{\mathbf{z}} T(\mathbf{x}, \mathbf{z})$ can be estimated as

$$|\nabla_{\mathbf{z}} T(\mathbf{x}, \mathbf{z})| \le \int_{\Gamma^{ext}} |\nabla_{\mathbf{z}} \Psi(\mathbf{y}, \mathbf{z})| \frac{1}{|\mathbf{x} - \mathbf{y}|^3} ds_{\mathbf{y}} \qquad \text{for } \mathbf{z} \in D, \mathbf{x} \in \Gamma^{ext}.$$

For a fixed $\mathbf{y} \in \Gamma^{ext}$, $\Psi(\mathbf{y}, \cdot)$ is harmonic in the lower half ball $\Omega_{2\rho}$ and zero on Γ, so $\Psi(\mathbf{y}, \cdot)$ has the harmonic extension $\bar{\Psi}(\mathbf{y}, \cdot)$ to the entire ball $B_{2\rho}$. Using (2.8) and the interior estimate, we have

$$\begin{aligned} |\nabla_{\mathbf{z}} \Psi(\mathbf{y}, \mathbf{z})| &= \frac{1}{|B_\rho(\mathbf{z})|} \left| \int_{B_\rho(\mathbf{z})} \nabla_{\mathbf{z}} \Psi(\mathbf{y}, \tilde{\mathbf{z}}) d\tilde{\mathbf{z}} \right| = \frac{1}{|B_\rho(\mathbf{z})|} \left| \int_{\partial B_\rho(\mathbf{z})} \nu(\tilde{\mathbf{z}}) \Psi(\mathbf{y}, \tilde{\mathbf{z}}) ds_{\tilde{\mathbf{z}}} \right| \\ &\le C \frac{1}{\rho |\mathbf{y} - \mathbf{z}|}, \qquad \mathbf{z} \in D,\ \mathbf{y} \in \Gamma^{ext}. \end{aligned}$$

Since $\Gamma^{ext} \subset \partial\Omega \setminus B_{2\rho}$, we obtain

$$|\nabla_{\mathbf{z}} T(\mathbf{x}, \mathbf{z})| \le \int_{\Gamma^{ext}} \frac{1}{\rho |\mathbf{y} - \mathbf{z}|} \frac{1}{|\mathbf{x} - \mathbf{y}|^3} ds_{\mathbf{y}} \le C \rho^{-3}, \qquad \mathbf{z} \in D,\ \mathbf{x} \in \Gamma_\rho.$$

This completes the proof. □

In the next theorem, we provide a more precise estimate by investigating $\nabla v|_D$.

THEOREM 2.2. *Let $\xi^* = (\xi_1, \xi_2, 0)$, the projection of ξ to Γ. Then*

(2.9)
$$\frac{1}{2\mu}[g(\mathbf{x}) - g_0(\mathbf{x})] = g_0(\xi^*) \int_D \frac{\partial}{\partial x_3} \frac{(\mathbf{x} - \mathbf{y}) \cdot [\mathbf{e}_3 + \mu \nabla V(\mathbf{y})]}{4\pi |\mathbf{x} - \mathbf{y}|^3} d\mathbf{y} + Err(\mathbf{x}), \quad \mathbf{x} \in \Gamma_\rho,$$

where the error term $Err(\mathbf{x})$ satisfies the estimate

$$|Err(\mathbf{x})| \le C g_0(\xi^*) |D| \left(\frac{r_0}{\rho |\mathbf{x} - \xi|^3} + \frac{1}{\rho^3} \right), \quad \mathbf{x} \in \Gamma_\rho. \tag{2.10}$$

Here, V is the $H^1(\Omega)$-solution of

$$\begin{cases} \Delta V = 0 \quad \text{in } \Omega \setminus \partial D, \\ V^+ = V^- \quad \text{on } \partial D, \\ (1 + \mu) \dfrac{\partial V^+}{\partial \nu} - \dfrac{\partial V^-}{\partial \nu} = -\nu \cdot \mathbf{e}_3 \quad \text{on } \partial D, \\ \chi_\Gamma V + (1 - \chi_\Gamma) \dfrac{\partial V}{\partial \nu} = 0 \quad \text{on } \partial\Omega, \end{cases}$$

where $V^+ = V|_{\Omega \setminus \bar{D}}$ and $V^- = V|_D$.

Proof. The v can be decomposed into

$$v(\mathbf{x}) = v_0(\mathbf{x}) + \mu g_0(\xi^*)V(\mathbf{x}) + \mu w(\mathbf{x}), \quad \mathbf{x} \in \Omega, \tag{2.11}$$

where w is the $H^1(\Omega)$-solution of

$$\begin{cases} \Delta w = 0 \quad \text{in } \Omega \setminus \bar{D}, \\ (1+\mu)\dfrac{\partial w^+}{\partial \nu} - \dfrac{\partial w^-}{\partial \nu} = [-\nabla v_0 + g_0(\xi^*)] \cdot \nu \quad \text{on } \partial D, \\ w\chi_\Gamma + \dfrac{\partial w}{\partial \nu}(1-\chi_\Gamma) = 0 \quad \text{on } \partial\Omega. \end{cases}$$

Substituting $v = v_0 + \mu g_0(\xi^*)V + \mu w$ into (2.3), the error term in (2.9) is

$$\begin{aligned} Err(\mathbf{x}) = &\int_D \nabla_{\mathbf{x}} \frac{\partial}{\partial x_3}\Phi(\mathbf{x},\mathbf{y}) \cdot [\nabla v_0(\mathbf{y}) - g_0(\xi^*)\mathbf{e}_3]d\mathbf{y} + \mu \int_D \nabla_{\mathbf{x}} \frac{\partial}{\partial x_3}\Phi(\mathbf{x},\mathbf{y}) \cdot \nabla w(\mathbf{y}) d\mathbf{y} \\ &+ \int_D \nabla_{\mathbf{y}} T(\mathbf{x},\mathbf{y}) \cdot \nabla v(\mathbf{y}) d\mathbf{y} := I_1(\mathbf{x}) + I_2(\mathbf{x}) + I_3(\mathbf{x}). \end{aligned}$$

To estimate I_1, we begin with proving the estimate

$$|\nabla v_0(\mathbf{y}) - g_0(\xi^*)\mathbf{e}_3| \le C\frac{r_0}{\rho} g(\xi^*). \tag{2.12}$$

Since $\frac{\partial v_0}{\partial x_3}$ is harmonic in Ω and $\frac{\partial v_0}{\partial x_3}|_{\partial\Omega} \ge 0$, from the maximum principle $\frac{\partial v_0}{\partial x_3} > 0$ in Ω. Let $\bar{v}_0$ be the harmonic extension of v_0 from $\Omega_{2\rho}$ to $B_{2\rho}$ across Γ in such a way that $\bar{v}_0(x_1, x_2, -x_3) = 2 - v_0(\mathbf{x})$ for $\mathbf{x} \in \Omega_{2\rho}$. It is easy to see $\frac{\partial \bar{v}_0}{\partial x_3} > 0$ in $\Omega_{2\rho}$. Now, let $\mathbf{y} \in D$ be fixed and $\mathbf{y}^* = (y_1, y_2, 0)$. Note that $\nabla v_0(\mathbf{y}^*) = \frac{\partial \bar{v}_0}{\partial y_3}(\mathbf{y}^*)\mathbf{e}_3 = g(y^*)\mathbf{e}_3$ because $v_0 = 1$ on Γ. We have

$$\begin{aligned} |\nabla v_0(\mathbf{y}) - g(\xi^*)\mathbf{e}_3| &= \left| \nabla v_0(\mathbf{y}) - \nabla v_0(\mathbf{y}^*) + \mathbf{e}_3 \left[\frac{\partial v_0}{\partial y_3}(\mathbf{y}^*) - \frac{\partial v_0}{\partial y_3}(\xi^*) \right] \right| \\ &\le C|y_3| \int_0^1 \left| \frac{\partial}{\partial y_3} \nabla v_0(t\mathbf{y} + (1-t)\mathbf{y}^*) \right| dt \\ &\quad + |\mathbf{y}^* - \xi^*| \int_0^1 \left| \frac{\partial}{\partial y_3} \nabla v_0(t\mathbf{y}^* + (1-t)\xi^*) \right| dt \\ &\le Cr_0 \left\| \nabla \frac{\partial}{\partial y_3} v_0 \right\|_{L^\infty(\Omega_\rho)} \le C\frac{r_0}{\rho} \left\| \frac{\partial}{\partial y_3} \bar{v}_0 \right\|_{L^\infty(B_{3\rho/2})}. \end{aligned} \tag{2.13}$$

In the above inequalities, we use that $|y_3|, |\mathbf{y}^* - \xi^*| < r_0$ and the standard interior estimate for the harmonic function $\nabla \frac{\partial}{\partial y_3}\bar{v}_0$. Since $\frac{\partial}{\partial y_3}\bar{v}_0 > 0$ in $B_{2\rho}$, from the Harnack inequality we have

$$\left\| \frac{\partial}{\partial y_3} \bar{v}_0 \right\|_{L^\infty(B_{3\rho/2})} \le C g_0(\xi^*),$$

and so (2.12) follows from (2.13) and the above estimate. From (2.12), we have

$$|I_1(\mathbf{x})| \le C\frac{1}{|\mathbf{x}-\xi|^3} \int_D |\nabla v_0(\mathbf{y}) - g(\xi^*)\mathbf{e}_3| d\mathbf{y} \le C g_0(\xi^*) \frac{r_0|D|}{\rho|\mathbf{x}-\xi|^3}, \quad \mathbf{x} \in \Gamma_\rho.$$

Next, we will estimate I_2. Using (2.12) and the definition of w, we have

$$(1+\mu)\int_D |\nabla w|^2 d\mathbf{y} + \int_{\Omega\setminus\bar{D}} |\nabla w|^2 d\mathbf{y} = \int_{\partial D} w[-\nabla v_0 + g_0(\xi^*)\mathbf{e}_3]\cdot \nu ds_{\mathbf{y}}$$
$$= \int_D \nabla w\cdot[\nabla v_0 - g_0(\xi^*)\mathbf{e}_3]d\mathbf{y} \le C g_0(\xi^*)\frac{r_0\sqrt{|D|}}{\rho}\left(\int_D |\nabla w|^2\right)^{1/2}$$

and so

$$\left(\int_D |\nabla w|^2\right)^{1/2} \le C g_0(\xi^*)\frac{r_0\sqrt{|D|}}{(1+\mu)\rho}. \tag{2.14}$$

Hence, we have

$$|I_2(\mathbf{x})| \le C\frac{1}{|\mathbf{x}-\xi|^3}\int_D |\nabla w| d\mathbf{y} \le C\frac{\sqrt{|D|}}{|\mathbf{x}-\xi|^3}\left(\int_D |\nabla w|^2\right)^{1/2}$$
$$\le C g(\xi^*)\frac{r_0|D|}{\rho|\mathbf{x}-\xi|^3}, \quad \mathbf{x}\in\Gamma_\rho.$$

Finally, I_3 can be estimated using (2.4) and the previous estimates (2.12) and (2.14):

$$|I_3| \le C\frac{1}{\rho^3}\int_D |\nabla v| d\mathbf{y} \le C\frac{1}{\rho^3}\int_D |\nabla v_0| + |g(\xi^*)||\nabla V| + |\nabla w| d\mathbf{y} \le C g(\xi^*)\frac{|D|}{\rho^3}.$$

This completes the proof. □

The theorem suggests an idea of reconstructing D approximately. Since D is small and $\xi\in D$, (2.9) can be expressed roughly as follows. For $\mathbf{x}\in\Gamma_\rho$,

$$\frac{1}{2\mu}[g(\mathbf{x}) - g_0(\mathbf{x})] \approx \frac{|D| g_0(\xi^*)}{4\pi|\mathbf{x}-\xi|^3}\begin{pmatrix} \dfrac{-2\xi_3^2 + (x_1-\xi_1)^2 + (x_2-\xi_2)^2}{|\mathbf{x}-\xi|^2}\left[1+\mu\dfrac{\partial V}{\partial y_3}(\xi)\right] \\ + 3\mu\dfrac{\xi_3(x_1-\xi_1)\frac{\partial V}{\partial y_1} + \xi_3(x_2-\xi_2)\frac{\partial V}{\partial y_2}}{|\mathbf{x}-\xi|^2} \end{pmatrix} \tag{2.15}$$

because, according to the estimate (2.10), the term $Err(\mathbf{x})$ does not contribute to the distribution of $\frac{1}{2\mu}[g(\mathbf{x})-g_0(\mathbf{x})]$ significantly compared with the major term described in the above approximation; $\frac{r_0}{\rho}$ is small and $\frac{1}{|\mathbf{x}-\xi|^3} \gtrsim \{\frac{r_0}{\rho|\mathbf{x}-\xi|^3} + \frac{1}{\rho^3}\}$ for $\mathbf{x}\in\Gamma_\rho$ and $|\mathbf{x}-\xi| < \rho/2$.

Next, we will roughly estimate V. Suppose that $D = B_r(\xi)$ and $r < r_0$. Define

$$\tilde{V}(\mathbf{y}) = \frac{1}{3+\mu}\int_D \frac{z_3 - y_3}{4\pi|\mathbf{z}-\mathbf{y}|^3}\, d\mathbf{z},$$

which satisfies the following properties:

$$\tilde{V}(\mathbf{y}) = \frac{1}{3+\mu}(\xi_3 - y_3) \quad \text{for } \mathbf{y}\in D, \qquad \tilde{V}(\mathbf{y}) = \frac{r^3}{3+\mu}\frac{\xi_3 - y_3}{|\xi-\mathbf{y}|^3} \quad \text{for } \mathbf{y}\in\mathbb{R}^3\setminus\bar{D},$$
$$(1+\mu)\frac{\partial\tilde{V}^+}{\partial\nu}(\mathbf{y}) - \frac{\partial\tilde{V}^-}{\partial\nu}(\mathbf{y}) = -\nu\cdot\mathbf{e}_3 \quad \text{for } \mathbf{y}\in\partial D,$$

where $\tilde{V}^+ = V|_D$ and $\tilde{V}^- = V|_{\mathbb{R}^3\setminus\bar{D}}$ (see [18]). Hence, V can be decomposed into $V(\mathbf{y}) = \tilde{V}(\mathbf{y}) + U(\mathbf{y})$, where U satisfies

$$\nabla((1+\mu\chi_D)\nabla U) = 0 \qquad \text{in } \Omega, \qquad U|_\Gamma = \frac{r^3}{3+\mu}\frac{-\xi_3}{|\mathbf{y}-\xi|^3}.$$

Then U can be expressed as

$$U(\mathbf{y}) = U_0(\mathbf{y}) + \mu\int_D \nabla_{\mathbf{z}}[\Phi(\mathbf{y},\mathbf{z}) - \Phi(\mathbf{y}^+,\mathbf{z})]\cdot\nabla U(\mathbf{z})d\mathbf{z}, \quad \mathbf{y}\in\Omega, \tag{2.16}$$

where U_0 is the $H^1(\Omega)$-solution of the Dirichlet problem:

$$\Delta U_0 = 0 \quad \text{in } \Omega, \qquad U_0|_{\partial\Omega} = U|_{\partial\Omega}.$$

From the boundary condition $U_0|_\Gamma$, U_0 can be approximated as

$$U_0(\mathbf{y}) \approx \frac{r^3}{3+\mu}\frac{-y_3-\xi_3}{|\mathbf{y}^+-\xi|^3}, \quad \mathbf{y}\in\Omega_\rho,$$

and so $\nabla U_0(\xi) \approx \frac{r^3}{(3+\mu)16\pi|\xi_3|^3}\mathbf{e}_3$. Therefore, in view of (2.16) we may approximate

$$\nabla V(\xi) \approx \frac{\mathbf{e}_3}{3+\mu}\left(-1+\frac{r^3}{16\pi|\xi_3|^3}\right). \tag{2.17}$$

This leads to the approximation

$$\frac{1}{2\mu}[g(\mathbf{x})-g_0(\mathbf{x})] \approx \frac{|D|g_0(\xi^*)}{3+\mu}\left(1-\frac{r^3}{16\pi|\xi_3|^3}\right)\frac{2\xi_3^2-(x_1-\xi_1)^2-(x_2-\xi_2)^2}{4\pi|\mathbf{x}-\xi|^5}, \quad \mathbf{x}\in\Gamma_\rho,$$

or simply

$$\frac{1}{2}[g(\mathbf{x})-g_0(\mathbf{x})] \approx \frac{\mu|D|g(\xi^*)}{3+\mu}\,\frac{2\xi_3^2-(x_1-\xi_1)^2-(x_2-\xi_2)^2}{4\pi|\mathbf{x}-\xi|^5}, \quad \mathbf{x}\in\Gamma_\rho, \tag{2.18}$$

since $\frac{r^3}{16\pi|\xi_3|^3} < \frac{1}{16\pi}$ is small. This approximation gives an accurate reconstruction algorithm for finding the location ξ and the size $|D|$. This will be discussed in the following sections.

3. Anomaly detection algorithm in the T-Scan model. In this section, based on the mathematical analysis for the simplified model given in the previous section, we will derive a rough detection algorithm for the T-Scan model. With a realistic model, the background complex conductivity τ_1 may not be homogeneous, and we met many technical difficulties in carrying out rigorous mathematical analysis that requires various approximations. We will not do all the analysis with the complicated model but will suggest several desired estimates to the reader.

Let Ω be a bounded domain in $\mathbb{R}^3$ with a smooth boundary $\partial\Omega$. The real and imaginary parts of complex conductivities $\tau_1 = \sigma_1 + i\omega\epsilon_1$ and $\tau_2 = \sigma_2 + i\omega\epsilon_2$ are positive and bounded. As in the previous section, let $\Gamma \subset \partial\Omega$ be a smooth planar domain lying on the plane $\partial\mathbb{R}^3_-$ such that $B_{2\rho}(0)\cap\{x_3=0\} \subset \Gamma \subset B_{3\rho}(0)$, where $B_\rho(\mathbf{z}) = \{\mathbf{x}\in\mathbb{R}^3 : |\mathbf{x}-\mathbf{z}| < \rho\}$. We denote $\Omega_\rho = \Omega\cap B_\rho(0)$ and $\Gamma_\rho = \Gamma\cap B_\rho(0)$. As before, assume that D is a simply connected smooth domain and

$$\xi\in D \subset \Omega_\rho, \qquad \operatorname{diam}(D)\le r_0, \qquad \text{and} \qquad r_0 \le \operatorname{dist}(D,\Gamma) \le Ar_0.$$

The mathematical model of the T-Scan system is the following:

$$\text{(3.1)}\qquad \begin{cases} \nabla\cdot(\tau_1+(\tau_2-\tau_1)\chi_D)\nabla u(\mathbf{r}))=0, & \mathbf{r}\in\Omega,\\ u(\mathbf{r})=0, & \mathbf{r}\in\Gamma,\\ u(\mathbf{r})=1, & \mathbf{r}\in\gamma,\\ \tau_1\nabla u(\mathbf{r})\cdot\nu(\mathbf{r})=0, & \mathbf{r}\in\partial\Omega\setminus\Gamma\cup\gamma. \end{cases}$$

For a fixed frequency ω, let u be the $H^1(\Omega)$-solution of (3.1) and $g=\frac{\partial u}{\partial z}|_\Gamma$, $f=u|_{\partial\Omega}$. Our goal is to reconstruct D from g.

To derive a reconstruction algorithm, we need to introduce layer potentials over a smooth surface Υ. The single and double layer potentials are defined by

$$\mathcal{S}_\Upsilon[\varphi](\mathbf{x})=\int_\Upsilon \Phi(\mathbf{x},\mathbf{y})\varphi(\mathbf{y})ds_{\mathbf{y}},\quad \mathbf{x}\in\mathbb{R}^3,$$
$$\mathcal{D}_\Upsilon[\varphi](\mathbf{x}):=\int_\Upsilon \nu(\mathbf{y})\cdot\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\varphi(\mathbf{y})\,ds_{\mathbf{y}},\quad \mathbf{y}\in\mathbb{R}^3\setminus\Upsilon.$$

Suppose that u_0 is the solution of (3.1) in the absence of D and $g_0=\frac{\partial u_0}{\partial x_3}|_\Gamma$. It must be noted that we cannot compute u_0 explicitly because the background complex conductivity τ_1 is unknown. However, let us begin by finding a relation between D and $(g-g_0)$.

THEOREM 3.1. *Let $\Lambda_{2\rho}=\partial\Omega_{2\rho}\setminus\Gamma$. Then*

$$\text{(3.2)}\qquad \frac{1}{2}[g(\mathbf{x})-g_0(\mathbf{x})]=\frac{\partial}{\partial x_3}\int_D(\tau_2-\tau_1)\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}+E_1(\mathbf{x})+E_2(\mathbf{x}),\quad \mathbf{x}\in\Gamma_{2\rho},$$

where

$$E_1(\mathbf{x})=\frac{\partial}{\partial x_3}\int_{\Omega_{2\rho}}[u(\mathbf{y})-u_0(\mathbf{y})]\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla\tau_1(\mathbf{y})d\mathbf{y},$$
$$\text{and } E_2(x)=\frac{\partial}{\partial x_3}\mathcal{S}_{\Lambda_{2\rho}}\left[\frac{\partial(u-u_0)}{\partial\nu}\right](\mathbf{x})-\frac{\partial}{\partial x_3}\mathcal{D}_{\Lambda_{2\rho}}[\tau_1(u-u_0)](\mathbf{x}).$$

Moreover,

$$E_1(\mathbf{x})\le C\|\nabla\tau_1\|_{L^p(\Omega_{2\rho})}\quad \text{for } \mathbf{x}\in\Gamma_{2\rho},$$

where $p>3$.

Proof. For $\mathbf{x}\in\Omega_{2\rho}$, we have

$$\begin{aligned}\tau_1u(\mathbf{x})&=-\int_{\Omega_{2\rho}}\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla[\tau_1u(\mathbf{y})]d\mathbf{y}+\mathcal{D}_{\Lambda_{2\rho}}[\tau_1\,u](\mathbf{x})\\ &=-\int_{\Omega_{2\rho}}\tau_1(\mathbf{y})\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}+\mathcal{D}_{\partial\Omega_{2\rho}}[\tau_1\,u](\mathbf{x})\\ &\quad+\int_{\Omega_{2\rho}}\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla\tau_1(\mathbf{y})\,u(\mathbf{y})d\mathbf{y}\\ &=-\int_\Omega[\tau_1+(\tau_2-\tau_1)\chi_D]\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}+\int_D[\tau_2-\tau_1]\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}\\ &\quad+\mathcal{D}_{\partial\Omega_{2\rho}}[\tau_1\,u](\mathbf{x})+\int_{\Omega_{2\rho}}\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla\tau_1(\mathbf{y})\,u(\mathbf{y})d\mathbf{y}\end{aligned}$$

$$= -\mathcal{S}_\Gamma g(\mathbf{x}) - \mathcal{S}_{\Lambda_{2\rho}}\left[\tau_1 \frac{\partial u}{\partial \nu}\right](\mathbf{x}) + \int_D [\tau_2 - \tau_1]\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}$$
$$+ \mathcal{D}_{\partial\Omega_{2\rho}}[\tau_1\, u](\mathbf{x}) + \int_{\Omega_{2\rho}} \nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla\tau_1(\mathbf{y})\, u(\mathbf{y})d\mathbf{y}.$$

Similarly, u_0 can be expressed as

$$\tau_1 u_0(\mathbf{x}) = -\mathcal{S}_\Gamma g_0(\mathbf{x}) - \mathcal{S}_{\Lambda_{2\rho}}\left[\tau_1 \frac{\partial u_0}{\partial \nu}\right](\mathbf{x}) + \mathcal{D}_{\partial\Omega_{2\rho}}[\tau_1\, u_0](\mathbf{x}) + \int_{\Omega_{2\rho}} \nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla\tau_1(\mathbf{y})\, u_0(\mathbf{y})d\mathbf{y}, \qquad \mathbf{x}\in\Omega_{2\rho}.$$

Since $(u-u_0)=0$ on Γ, for $\mathbf{x}\in\Omega_{2\rho}$

$$\tau_1[u(\mathbf{x})-u_0(\mathbf{x})] = \mathcal{S}_\Gamma[g_0-g](\mathbf{x}) + \int_D [\tau_2-\tau_1]\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}$$
$$+ \mathcal{S}_{\Lambda_{2\rho}}\left[\tau_1\frac{\partial(u_0-u)}{\partial\nu}\right](\mathbf{x}) + \mathcal{D}_{\Lambda_{2\rho}}[\tau_1(u-u_0)](\mathbf{x})$$
$$+ \int_{\Omega_{2\rho}} \nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla\tau_1(\mathbf{y})\,[u(\mathbf{y})-u_0(\mathbf{y})]d\mathbf{y}.$$

Hence, by applying $\frac{\partial}{\partial x_3}$ through the above identity at $\mathbf{x}\in\Gamma_{2\rho}$ and using the standard trace formula for single layer potentials, we have

$$\frac{\partial}{\partial x_3}[\tau_1(u(\mathbf{x})-u_0(\mathbf{x})] = \frac{1}{2}[g(\mathbf{x})-g_0(\mathbf{x})] + \frac{\partial}{\partial x_3}\int_D [\tau_2-\tau_1]\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}$$
$$+ E_1(\mathbf{x}) + E_2(\mathbf{x}), \qquad \mathbf{x}\in\Gamma_{2\rho}.$$

Moreover, for $\mathbf{x}\in\Gamma_{2\rho}$,

$$\frac{\partial}{\partial x_3}[\tau_1(u(\mathbf{x})-u_0(\mathbf{x})] = \frac{\partial\tau_1}{\partial x_3}(u(\mathbf{x})-u_0(\mathbf{x})) + [g(\mathbf{x})-g_0(\mathbf{x})] = [g(\mathbf{x})-g_0(\mathbf{x})].$$

The E_1 can be estimated by

$$|E_1(\mathbf{x})| \le \int_{\Omega_{2\rho}} \frac{|u(\mathbf{y})-u_0(\mathbf{y})|}{|\mathbf{x}-\mathbf{y}|^3}|\nabla\tau_1(\mathbf{y})|d\mathbf{y}, \qquad \mathbf{x}\in\Gamma_{2\rho}.$$

Since $\frac{u(\mathbf{y})}{y_3}$ and $\frac{u_0(\mathbf{y})}{y_3}$ are bounded in $\Omega_{2\rho}$ due to $u=0=u_0$ on Γ,

$$|E_1(\mathbf{x})| \le C\|\nabla\tau_1\|_{L^p(\Omega_{2\rho})},$$

where $p>3$ and C depends only on p and $\|\frac{u-u_0}{y_3}\|_{L^\infty(\Omega_{2\rho})}$. This completes the proof. □

In our reconstruction algorithm, we will neglect the terms $E_1(\mathbf{x})$ and $E_2(\mathbf{x})$ in the identity (3.2). Since the background complex conductivity τ_1 is a small perturbation of a constant inside the region $\Omega_{2\rho}$, $\|\nabla\tau_1\|_{L^2(\Omega_{2\rho})}$ is small and so is $E_1(\mathbf{x})$ for $\mathbf{x}\in\Gamma_\rho$. The term $E_2(x) = \frac{\partial}{\partial x_3}\mathcal{S}_{\Lambda_{2\rho}}[\frac{\partial(u-u_0)}{\partial\nu}](\mathbf{x}) - \frac{\partial}{\partial x_3}\mathcal{D}_{\Lambda_{2\rho}}[\tau_1(u-u_0)](\mathbf{x})$ is a sum of integral over $\Lambda_{2\rho}$ that sustains a distance larger than ρ from the observation point $\mathbf{x}\in\Gamma_\rho$. Furthermore, the difference $(u-u_0)|_{\Lambda_{2\rho}}$ is small, and so $E_2(\mathbf{x}), \mathbf{x}\in\Gamma_\rho$ can be viewed as a negligibly small term. Hence, the identity (3.2) can be approximated as

$$\frac{1}{2}[g(\mathbf{x})-g_0(\mathbf{x})] \approx \frac{\partial}{\partial x_3}\int_D (\tau_2-\tau_1)\nabla_{\mathbf{y}}\Phi(\mathbf{x},\mathbf{y})\cdot\nabla u(\mathbf{y})d\mathbf{y}, \quad \mathbf{x}\in\Gamma_\rho, \tag{3.3}$$

which is essentially the same as (2.15).

Under the assumption that τ_1 and τ_2 are small perturbations of two constants, we have the following approximation that corresponds to the approximation (2.18):

$$\frac{1}{2}[g(\mathbf{x}) - g_0(\mathbf{x})] \approx \frac{3\alpha(\tau_1 - \tau_2)}{2\tau_1 + \tau_2}|D|\frac{2\xi_3^2 - (x_1 - \xi_1)^2 - (x_2 - \xi_2)^2}{4\pi|\mathbf{x} - \xi|^5}, \quad \mathbf{x} \in \Gamma_\rho,$$

where $\alpha = \frac{1}{|\Gamma_\rho|}\int_{\Gamma_\rho} g$ denotes the average of g over Γ_ρ.

This rough estimate leads us to derive the following anomaly detection algorithm via simple elementary algebra:

- *Transversal position.* The anomaly D lies below the point ξ^* at which the absolute value $|g(\mathbf{x}^*) - g_0(\mathbf{x}^*)|$ has the greatest quantity:

$$|g(\xi^*) - g_0(\xi^*)| = \max_{\mathbf{x}\in\Gamma_\rho} |g(\mathbf{x}) - g_0(\mathbf{x})|. \tag{3.4}$$

- *Depth.* Let $\mathbf{x}_0$ be any chosen point in Γ_ρ near ξ^* and let l be the distance between ξ^* and $\mathbf{x}_0$, that is, $l = |\xi^* - \mathbf{x}_0|$. The depth d is determined by the identity

$$\left| \frac{g(\xi^*) - g_0(\xi^*)}{g(\mathbf{x}_0) - g_0(\mathbf{x}_0)} \right| = \frac{|2 - \frac{l^2}{d^2}|}{2(\frac{l^2}{d^2} + 1)^{5/2}}. \tag{3.5}$$

Remark 3.2 (multifrequency). We often do not have a priori knowledge of the background complex conductivity τ_1, and so we cannot compute the data g_0. In this case, we may use more than two different frequencies for the detection algorithm provided that the frequency dependencies of conductivity and permittivity values for background and anomaly are significantly different. Suppose $\tilde{\omega}$ is a frequency such that the corresponding $\tilde{\tau}_2$ is quite different from τ_2, while $\tilde{\tau}_1$ is close to τ_1. Let $\tilde{u}$ be the solution of (3.1) for the frequency $\tilde{\omega}$ and let $\tilde{g} = \frac{\partial u}{\partial \nu}|_\Gamma$. Suppose now that the difference $\tau_2 - \tilde{\tau}_2$ in cancerous region D is much larger than the difference $\tau_1 - \tilde{\tau}_1$ in the normal region. Then the expression corresponding to (2.18) is

$$\frac{1}{2}[\tilde{g}(\mathbf{x}) - g(\mathbf{x})] \approx \frac{9\alpha\tau_1(\tau_2 - \tilde{\tau}_2)}{(2\tau_1 + \tau_2)(2\tau_1 + \tilde{\tau}_2)}|D|\frac{2\xi_3^2 - (x_1 - \xi_1)^2 - (x_2 - \xi_2)^2}{4\pi|\mathbf{x} - \xi|^5}, \quad \mathbf{x} \in \Gamma_\rho.$$

This rough estimate leads to the similar anomaly detection formula as (3.4) and (3.5).

4. Numerical experiments. In this section, we present results of numerical simulations using the anomaly estimation algorithm derived in the previous section. We set the scanning probe region as $\Gamma = [-25, 25] \times [-25, 25] \times \{0\}$ mm^2 including 16×16 electrodes. The total amount of current through all 256 electrodes is assumed to be 0.2 mA. The inhomogeneous background complex conductivity τ_1 is set as

$$\tau_1 = \begin{cases} 0.005 + 100w\epsilon_0 i & \text{if } \mathbf{x} \in E\ [(-12.5, -12.5, -35); (7.5, 5, 5)] \text{ in mm}, \\ 0.01 + 500w\epsilon_0 i & \text{if } \mathbf{x} \in E\ [(12.5, 12.5, -30); (5, 7.5, 5)] \text{ in mm}, \\ 0.3 + 40000w\epsilon_0 i & \text{if } \mathbf{x} \in E\ [(-12.5, 12.5, -40); (7.5, 7.5, 7.5)] \text{ in mm}, \\ 0.05 + 30000w\epsilon_0 i & \text{if } \mathbf{x} \in E\ [(0, -2.5, -32.5); (7.5, 2.5, 2.5)] \text{ in mm}, \\ 0.003 + 800w\epsilon_0 i & \text{otherwise}, \end{cases}$$

where $\omega = 2\pi \times 10^3$ rad/s, $\epsilon_0 = 8.854 \times 10^{-12}$ F/m is the permittivity of the free space, and $E\ [\mathbf{z}; (\lambda_1, \lambda_2, \lambda_3)] := \left\{\mathbf{x} = (x_1, x_2, x_3) \mid \sum_{i=1}^3 \left(\frac{x_j - z_j}{\lambda_j}\right)^2 \le 1\right\}$. We set the anomaly D to be reconstructed as

$$D = E[\mathbf{z}_0; (2.5, 2.5, 2.5)] \text{ in mm}$$

with its center at $\mathbf{z}_0$ and complex conductivity $\tau_2 = 0.2 + 2000\omega\epsilon_0 i$.

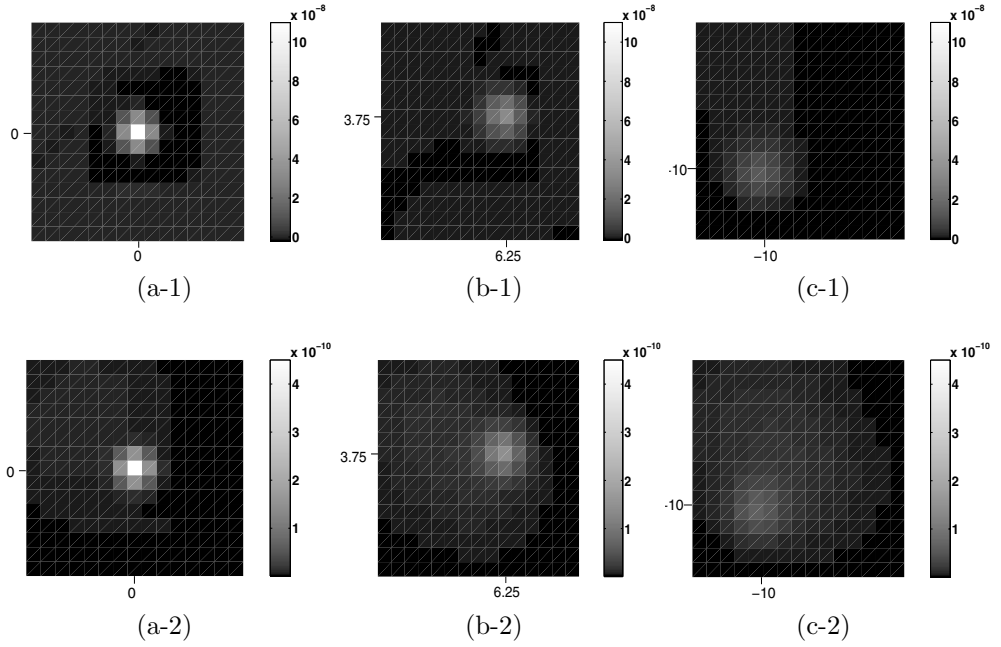

FIG. 4.1. *Plots* (a-1,2), (b-1,2), *and* (c-1,2) *are real and imaginary parts of* $(g - g_0)$ *in mA corresponding to* D *having three different centers* $\mathbf{z} = (0, 0, -5)$, $(6.25, 3.75, -7.5)$, $(-10, -10, -10)$ *in mm, respectively.*

TABLE 4.1
Performance of the proposed detection algorithm.

True center of $D(:= \mathbf{z})$	(0,0,-5)	(6.25,3.75,-7.5)	(-10,-10,-10)
Detected center of $D(:= \mathbf{z}^*)$	(0,0,-4.73)	(6.65,3.36,-7.05)	(-10,-10,-9.50)
Error$(:= \| \mathbf{z} - \mathbf{z}^* \|)$	0.27	0.72	0.5

Since we do not know the exact background complex conductivity τ_1 in practice, we compute g_0 by solving (3.1) in the absence of D with the homogeneous background $\hat{\tau}_1 = 0.003 + 800w\epsilon_0 i$ instead of the inhomogeneous τ_1. We compute g from (3.1) in the presence of D with the inhomogeneous τ_1. Notice that $(g - g_0)$ contains some unavoidable noise due to the unknown inhomogeneity $(\tau_1 - \hat{\tau}_1)$. Now we try to detect D from the difference $(g - g_0)$.

Figure 4.1 shows the real and imaginary parts of $(g - g_0)$ with D having three different centers $\mathbf{z} = (0, 0, -5), (6.25, 3.75, -7.5)$, and $(-10, -10, -10)$ in mm. First we determine the transversal position (ξ^*) using (3.4). For the depth estimate of the anomaly, we can choose any point $\mathbf{x}_0$ near ξ^*. However, if we choose a point far away from ξ^*, the difference $|g(\xi^*) - g_0(\xi^*)|$ may not be distinguished from noise. Therefore, we select four different nearest electrodes around ξ^* for the choice of the point $\mathbf{x}_0$ in (3.5) and take the average value to determine the depth using (3.5). Table 4.1 shows the results of the proposed detection algorithm.

We now test the noise tolerance of the algorithm by adding a random noise on g. We generate noised data g_n by

$$g_n = g + \| g \|_2 * NL * RN,$$

where $\| g \|_2$ is the L^2 norm of g on Γ_ρ, NL is a noise level, and RN is a ran-

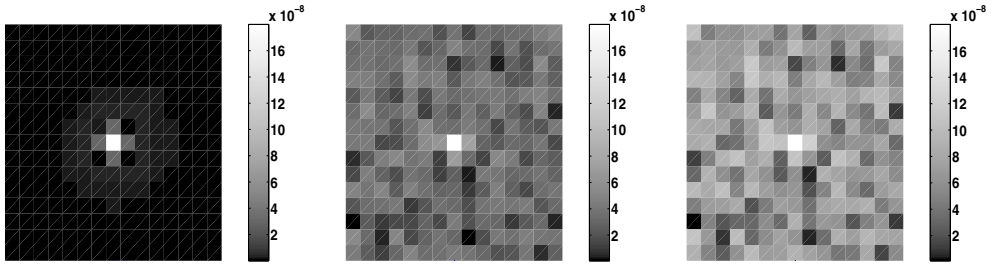

FIG. 4.2. *Noised data* $(g-g_n)$*:* (a) *noise* 0%, (b) *noise* 0.5%, *and* (c) *noise* 1% *for the anomaly* $D_1 = E[(0,0,-3.75);(2.5,2.5,2.5)]$ *in mm.*

TABLE 4.2
Detection of centers of anomalies with noised data.

Noise level	0%	0.5%	1%
Detected center of D_1	(0,0, -3.62)	(0, 0, -4.40)	(0, 0, -5.18)
Detected center of D_2	(0,0, -4.73)	(0, 0, -6.34)	(0, 0, -7.07)
Detected center of D_3	(0,0, -5.88)	(0, 0, -7.74)	(0, 0, -9.85)

dom number uniformly distributed on the interval $(-1,1)$. For the anomaly $D_1 = E[(0,0,-3.75);(2.5,2.5,2.5)]$ in mm, noised data $(g-g_n)$ with 0.5% and 1% noise are shown in Figure 4.2(b) and (c), respectively. We also apply the algorithm for anomalies $D_2 = E[(0,0,-5);(2.5,2.5,2.5)]$ and $D_3 = E[(0,0,-6.25);(2.5,2.5,2.5)]$ in mm with different depths from D_1. The detected centers of D_1, D_2, and D_3 are summarized in Table 4.2. From the results in Tables 4.1 and 4.2, we can see that the performance of the algorithm is quite good in terms of both transversal position and depth estimates. Experimental verification of these results will be a part of our future studies.

RESONANCE TONGUE INTERACTION IN THE PARAMETRICALLY EXCITED COLUMN*

A. R. CHAMPNEYS† AND W. B. FRASER‡

Abstract. This paper concerns a codimension-two analysis of the interaction between various resonances that occur in an upright flexible rod subject to sinusoidal parametric excitation. Particular attention is paid to rods that are just longer than their critical length for self-weight buckling, and their possible stabilization by the excitation. Previous work has identified three small dimensionless parameters in this problem: the closeness of the length (divided by the cube root of bending stiffness) to the critical one, the amplitude of excitation, and the reciprocal of the frequency of excitation. Multiple timescale analysis is used to show how the asymptotics of resonance tongues in the amplitude-versus-bending-stiffness plane becomes of lower order at certain special values of the frequency ratio where two resonances interact. In particular, an $O(1)$ change in the shape of the parameter region of the stabilized supercritical rod occurs through interaction with the pure harmonic resonance of some other mode of vibration of the rod. It is also shown how to include material damping within the analysis. The results help explain why earlier theories failed to qualitatively explain experimental observation, and are also likely to be of relevance in other three-parameter parametric resonance problems for continuous structures.

1. Introduction.

It is well known that if a column exceeds a certain critical length it will, when placed upright, buckle under its own weight. A recent experiment by Mullin, reported in [14] (see also [1, 2]), has demonstrated that a piece of "curtain wire" that is longer than its critical length can be stabilized by subjecting its bottom support point to a vertical vibration of appropriate amplitude and frequency. In two previous papers, [5, 8], henceforth referred to as Part I and Part II, respectively, we made a numerical and asymptotic study of the linear and nonlinear equations that govern the behavior of such a column.

In Part I we noted that there are three key dimensionless parameters in this problem: B, the ratio of the column's bending stiffness to the cube of its length; η (called $1/\delta$ in that paper), the square of the ratio of the frequency of excitation to that of the pendulum of the same length ($\sqrt{g/\ell}$); and ε, the amplitude of excitation. By looking in the (B, ε) plane for fixed η, one can then analyze the stability of the upright position using Floquet analysis and double scale asymptotics, in much the same way as one does for the single-degree-of-freedom Mathieu equation (e.g., [11, 16]). The result for the fundamental instability curve is to show that for "most" η-values it is possible to stabilize, for small ε, a column that is just longer ($B < B_c$) than its critical length for self-weight buckling. In fact, this criterion gives a lower bound on the frequency of excitation that is required in order to stabilize a column

of a given length. However, this lower bound is too conservative when compared with experiments [14], nor does this criterion give the observed upper bound.

Part II concerns an attempt to answer these deficiencies by considering, in addition, harmonic and subharmonic instabilities. In that paper the analysis was also extended to include a fully geometrically nonlinear formulation, but the ensuing weakly nonlinear asymptotic analysis in essence held no surprises. However, it was observed that the quadratic-in-ε coefficient of the B-value bounding the fundamental stability region can undergo singularities as η varies. These occur precisely when a first harmonic resonance has the same B-value as the self-weight buckling $B = B_c$. In fact, in the analyses of both the fundamental and harmonic instabilities, the asymptotic expansions became invalid at these special values of the excitation frequency. This breakdown appears to be an artifact of the particular expansions used there. In this paper we offer an alternative expansion procedure that avoids this difficulty.

The key is to think of this as a genuinely three-parameter problem, and expand both B and η in powers of ε in a neighborhood of these codimension-two *resonance tongue interaction* points. In what follows we shall consider only the linear equations of motion of the column, since the tongue interaction we wish to describe involves the (loss of) linear stability of an upright column. As in Part II, the results can be extended to include geometrically nonlinear terms to give the amplitude and stability of the bifurcating motion. But since our prime objective is to describe the shape of stability regions in a neighborhood of codimension-two points, we shall omit such complications here.

The rest of the paper is outlined as follows. Section 2 contains a brief review of the mathematical formulation and some new insight into the behavior of eigenmodes and resonances as parameters are varied. Section 3 then considers the possibility of two instabilities occurring at once and introduces a general asymptotic expansion procedure for unfolding such a situation. The details of all the asymptotics are relegated to various appendices. It is argued how only a few of these interactions lead to a qualitatively significant change in the stability regions, including the case where there is a singularity in the coefficient of the subharmonic resonance boundary (with dimensionless frequency 1/2), due to its interaction with the tongue corresponding to frequency 3/2. Section 4 then studies the important special case where the fundamental buckling instability interacts with a first harmonic resonance of any one of the higher-order eigenmodes. Section 5 shows how the results are modified in the presence of damping. Section 6 compares the analysis of this paper to the results of the curtain wire experiments, and, finally, section 7 draws conclusions and discusses the results in a wider context.

2. Mathematical formulation. Consider an initially straight column of length ℓ, with a uniform circular cross-section of radius $a \ll \ell$ and mass linear density m per unit length (see Figure 2.1). The column is assumed to be inextensible, unshearable, and linearly elastic with bending stiffness $\bar{B}$. It is further assumed that the lower end is clamped upright and is displaced by a vertical harmonic oscillation equal to $\Delta \cos \omega_0 \bar{t}$. The upper end is assumed to be free. The derivation of the geometrically nonlinear equations that govern the motion of the centerline $\bar{\mathbf{R}}(\bar{s}, \bar{t})$ and tension $\bar{T}(\bar{s})$ of such a column was detailed in Parts I and II. There it was shown that the effects of rotary inertia and torsional waves in the angular momentum equation can be neglected. Also, in [9] it is shown, via homogenization of a system of links with stiff, damped joints, how to include a dimensionless coefficient of material damping Γ into the linearized equations. This leads to material damping that is proportional to the time derivative

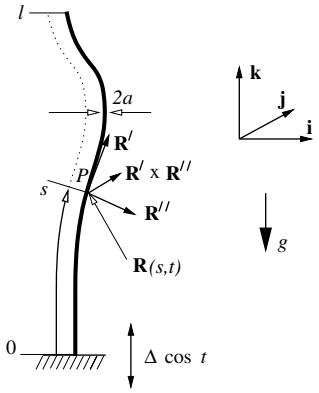

FIG. 2.1. *Definition sketch in which* $\mathbf{R}(s,t) = \ell\mathbf{r}(s,t) + \ell s\mathbf{k} + \Delta\cos(t)\mathbf{k}$, *where* ℓs *is the arclength parameter for the inextensible centerline of the circular column.*

of the fourth-derivative bending stiffness term. Note that this form of damping also occurs in models used in structural geology [13].

2.1. Linearized equations. The dimensionless form of the linearized equations and boundary conditions governing small amplitude motion $\mathbf{r}(s,t)$ of the column about the oscillating upright position are (cf. Part II, (2.5), (2.6), and (2.7))

$$\eta\{\gamma \mathrm{D}\mathbf{r}^{IV} + \mathrm{D}^2\mathbf{r} - \varepsilon\cos t[(1-s)\mathbf{r}']'\} = -\mathcal{M}\mathbf{r} + T'\mathbf{k}, \tag{2.1}$$

where $()' = \partial/\partial s$, $D = \partial/\partial t$, and

$$\mathcal{M}\mathbf{r} := B\mathbf{r}^{IV} + [(1-s)\mathbf{r}']', \quad \text{subject to} \tag{2.2}$$

$$\mathbf{r} = \mathbf{r}' = \mathbf{0} \quad \text{at } s = 0, \qquad \mathbf{r}'' = \mathbf{r}''' = \mathbf{0}, \quad T = 0 \quad \text{at } s = 1. \tag{2.3}$$

Furthermore, upon linearization, inextensibility implies

$$\mathbf{r}' \cdot \mathbf{k} = 0. \tag{2.4}$$

The dimensionless variables are defined in terms of the dimensional variables by the following relations:

$$\left.\begin{aligned} s = \frac{\bar{s}}{\ell}, \quad \mathbf{r} = \frac{\bar{\mathbf{R}}}{\ell} - (\varepsilon\cos t + s)\mathbf{k}, \quad t = \omega_0\bar{t}, \quad \gamma = \frac{\Gamma\ell\omega}{mg} \\ T = \frac{\bar{T}}{mg\ell} - (1 - \eta\varepsilon\cos t)(1-s), \quad B = \frac{\bar{B}}{mg\ell^3}, \quad \eta = \frac{\omega_0^2\ell}{g}, \quad \varepsilon = \frac{\Delta}{\ell}. \end{aligned}\right\} \tag{2.5}$$

In fact, we can eliminate T immediately by considering the $\mathbf{k}$ component of (2.1) subject to condition (2.4), which gives the result $T \equiv 0$. Moreover, without loss of generality at this linearized level, we can assume that the motion is restricted to the $(\mathbf{i},\mathbf{k})$-plane and write $\mathbf{R}(s,t) = u(s,t)\mathbf{i}$, where u satisfies the scalar inhomogeneous, parametrically forced linear PDE

$$\mathrm{M}u + \eta\{\gamma \mathrm{D}u^{IV} + \mathrm{D}^2u - \varepsilon\cos t[(1-s)u']'\} = 0, \tag{2.6}$$

where

$$\mathrm{M}u := Bu^{IV} + [(1-s)u']' \quad \text{subject to} \tag{2.7}$$

$$u = u' = 0 \quad \text{at } s = 0, \qquad u'' = u''' = 0 \quad \text{at } s = 1. \tag{2.8}$$

This completes the formulation of the linear stability problem for the vertically oscillated column. For the majority of this paper we shall consider the perfect rod without the presence of material damping.

2.2. Eigenmodes of the unforced, undamped problem. Consider $\varepsilon = \gamma = 0$. This is the unforced problem. The general linear solution for a given B-value is a superposition of eigenmodes

$$\sum_n \{A_n \cos \sqrt{\lambda_n/\eta_n}\, t + B_n g_n \sin \sqrt{\lambda_n/\eta_n}\, t\}\phi_n(s;B),$$

where ϕ_n is the eigenmode of M corresponding to λ_n. That is, (ϕ_n, λ_n) satisfy

$$\mathrm{M}\phi_n - \lambda_n \phi_n = 0 \tag{2.9}$$

together with boundary conditions (2.8). Note that for each B-value the operator M is self-adjoint and so the eigenfunctions form a complete orthonormal basis for L^2 subject to the boundary conditions (2.8), where we choose to normalize each eigenfunction such that its L^2-norm is unity. Then, upon defining

$$\langle a, b\rangle = \int_0^1 a(s)b(s)ds,$$

we have

$$\langle \phi_i, \phi_j\rangle = \delta_{i,j}, \qquad \langle \phi_i, \mathrm{M}\phi_j\rangle = \lambda_j \delta_{i,j} \tag{2.10}$$

and

$$\langle \phi_i^{IV}, v\rangle = \langle \phi_i'', v''\rangle, \qquad \langle \phi_i, \mathrm{L}v\rangle = \langle v, \mathrm{L}\phi_i\rangle = -B\langle \phi_i'', v''\rangle + \lambda_i \langle \phi_i, v\rangle \tag{2.11}$$

for any function $v(s)$ satisfying the boundary conditions (2.8). Here

$$\mathrm{L}v(s) := [(1-s)v'' - v']. \tag{2.12}$$

These identities will prove useful in what follows.

The eigenmodes $\phi_n(s;B)$ are in general not expressible in closed form except at the special values of B at which $\lambda_n(B) = 0$, in which case (see Part II, section 3) there is a solution in terms of the Bessel function $J_{-1/3}$. The same analysis shows that there are infinitely many such B-values, $B_{0,n}$, $n = 1, 2, 3, 4, \ldots$, accumulating at $B = 0$, the first few values of which are $B_{0,1} = 0.127594$, $B_{0,2} = 0.017864$, $B_{0,3} = 0.0067336$, and $B_{0,4} = 0.0003503$. These correspond, respectively, to where each eigenvalue locus $\lambda_n(B)$, for $n = 1, 2, 3, 4$, crosses the B-axis, with the corresponding eigenmode there having $n-1$ internal zeros. The lowering of B through each $B_{0,n}$-value implies that the nth mode becomes linearly unstable. Hence for $B > B_c := B_{0,1}$ the unforced rod is stable to self-weight buckling (a result known to Greenhill [10]). Numerically, in Part I it was found that each eigenmode $\phi_n(s)$ retains a qualitatively similar mode shape for $B > B_{0,n}$ and that the corresponding loci $\lambda_n(B)$ are approximately straight lines (see Part I, Figure 2 and the schematic diagram in the upper part of Figure 2.2 below). In fact, we can now identify the slopes of those lines via the following asymptotic analysis.

Consider a rod for a specific length $B = B_0$ with eigenvalue and eigenmode (λ_n, ϕ_n) for some n. Let us expand in a small parameter δ via

$$B = B_0 + \delta B_1, \qquad \phi = \phi_n + \delta f_1 + \delta^2 f_2 + \cdots,$$
$$\lambda = \lambda_n + \delta\sigma_1 + \delta^2\sigma_2 + \cdots.$$

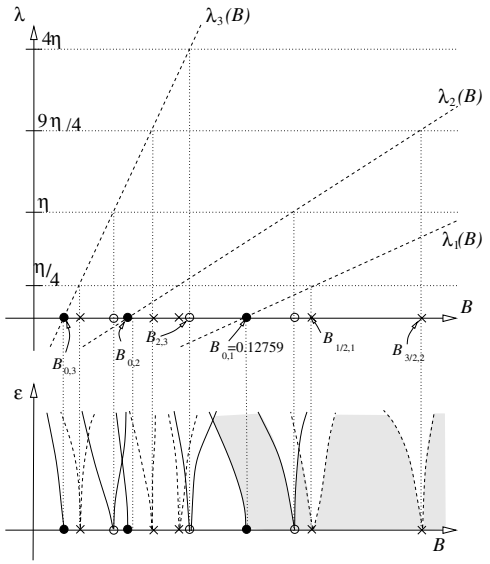

FIG. 2.2. *Summarizing schematically the results from Part* I *and the formula* (2.17). *The upper part shows eigenvalue loci* $\lambda_n(B)$ *and the definition of the points* $B_{\alpha,n}$, $\alpha = 0, 1/2, 1, 3/2, \ldots$. *In the lower part instability tongues in the* (B, ε)*-plane are shown to occur with root points* $B_{\alpha,n}$ *and to have width* $\varepsilon^{2\alpha}$. *The shaded regions correspond to where the vertical solution is stable. Solid lines represent neutral stability curves with Floquet multiplier* $+1$ *(where* α *is an integer) and dashed lines correspond to multiplier* -1 *(where* α *is half an odd integer).*

Taking these expansions and substituting them into the eigenvalue equation (2.9), and collecting powers of δ, we obtain

$$(\mathrm{M}_0 - \lambda_n) f_1 = -B_1 \phi_n^{IV} + \sigma_1 \phi_n, \tag{2.13}$$

$$(\mathrm{M}_0 - \lambda_n) f_2 = -B_1 f_1^{IV} + \sigma_1 f_1 + \sigma_2 \phi_n, \tag{2.14}$$

where M_0 is the operator M evaluated at $B = B_0$. The solvability condition for the $O(\delta)$ equation is that the right-hand side of (2.13) should be orthogonal to the eigenfunction ϕ_n of the left-hand side. Using the first identity in (2.11), this yields

$$\sigma_1 = B_1 \langle \phi_n'', \phi_n'', \rangle \quad \text{and} \quad \langle f_1, \phi_n \rangle = 0.$$

At the next order, the same solvability condition applied to (2.14) yields

$$\sigma_2 = B_1 \langle \phi_n'', f_1'' \rangle,$$

where f_1 is the solution of

$$\mathrm{M}_0 f_1 - \lambda_n f_1 = \sigma_1 \left(\phi_n - \frac{1}{\langle \phi_n'', \phi_n'' \rangle} \phi_n^{IV} \right) \tag{2.15}$$

subject to the boundary conditions (2.8). Combining these results we obtain the following asymptotic expression for dependence of any eigenvalue on B:

$$\lambda = \lambda_n + \delta B_1 \langle \phi_n'', \phi_n'' \rangle + \delta^2 B_1 \langle \phi_n'', f_1'' \rangle + O(\delta^3), \tag{2.16}$$

where we have used explicitly $\langle \phi_n, \phi_n \rangle = 1$. Note that the linear term is a positive definite quantity for all B. Hence the slopes of the loci $\lambda(B)$ are strictly positive for

all n and B. This proves a property that was observed only numerically in Part I. In fact, we found there numerically that for $\lambda_n(B) > 0$ each locus is in fact well approximated by a straight line.

2.3. Dynamic resonances. Consider now the parametrically excited problem $\varepsilon \neq 0$. It is not difficult to see that in the limit $\varepsilon \to 0$, the dimensionless drive angular frequency η will be in resonance with a natural vibration frequency λ_n whenever $\lambda_n(B) = p^2\eta$ for some $n > 0$, $p \geq 0$. Such B-values we label as $B = B_{p,n}$. Similarly, subharmonic resonances occur in the limit $\varepsilon \to 0$ at points $B = B_{p/2,n}$ defined for odd integers p such that $\lambda_n(B) = p^2\eta/2$.

Using Floquet theory (see Part I) one can deduce that for $\varepsilon > 0$, each of these resonance points $B_{\alpha,n}$ for nonnegative half-integers α is the root point of an instability tongue in the (B, ε)-plane (see Figure 2.2). One branch of the tongue corresponds to neutral modes whose leading-order term is $\phi_n(s)\cos\alpha t$ (in phase with the excitation) and the other to modes with leading-order term $\phi_n(s)\sin\alpha t$ (out of phase with the excitation). The case $\alpha = 0$ is special. This corresponds to the instability resulting from one of the pure buckling modes. From such a root point $B = B_{0,n}$ there is thus a single curve in the (B, ε)-plane corresponding to an instability whose mode shape is time independent to leading order. Figure 2.3 shows actual tongue boundaries in the (B, ε)-plane computed using the numerical Floquet theory method presented in Part I.

In fact, following the general asymptotics laid out in section 3, we can add to this result. Specifically, any instability with root point $B_{\alpha,n}$ which is a resonance whose neutral modes are like $\cos\alpha t$ or $\sin\alpha t$, leads to a tongue the boundaries of which are (under certain nondegeneracy assumptions) given by

$$B = B_{\alpha,m} + \sum_{j=2}^{2\alpha-1} B_j\varepsilon^j + B_{2\alpha}^{\pm}\varepsilon^{2\alpha} \tag{2.17}$$

for some coefficients B_j and $B_{2\alpha}^{\pm}$. Here the superscript "+" represents a neutral stability curve corresponding to motion whose time variation is $\cos\alpha t$, i.e., in phase with the drive, and the superscript "−" corresponds to the neutral stability of out-of-phase motion whose time variation is $\sin\alpha t$. See Appendix D for the details.

Thus the simplest family of subharmonic resonances, corresponding to $\alpha = 1/2$, leads to linear instability tongues, whereas the simplest harmonic instability, corresponding to $\alpha = 1$, gives quadratic tongues. Higher-order tongues have width $\varepsilon^{2\alpha}$, albeit with a generically nonzero quadratic lean in the (B, ε)-plane. Thus $\alpha = 3/2$ leads to tongues with width $O(\varepsilon^3)$ in the (B, ε)-plane; $\alpha = 2$ leads to tongues with widths varying to the fourth power of ε, etc. Therefore, for small amplitude of excitation ε, only instabilities corresponding to lower values of α are likely to lead to any significant regions of instability provided the amplitude of excitation ε is small (an observation that is further vindicated by the presence of damping; see section 5). The case $\alpha = 0$ is once again special, and it was shown in Part I that this leads to a single boundary between instability and stability that is to leading order quadratic in B.

The general result (2.17) confirms and extends what we found by detailed multiple timescale asymptotics in Parts I and II. Before proceeding to a codimension-two analysis of when the nondegeneracy conditions leading to (2.17) fail, let us extract from Part II the leading-order expressions for the coefficients in the simplest few cases.

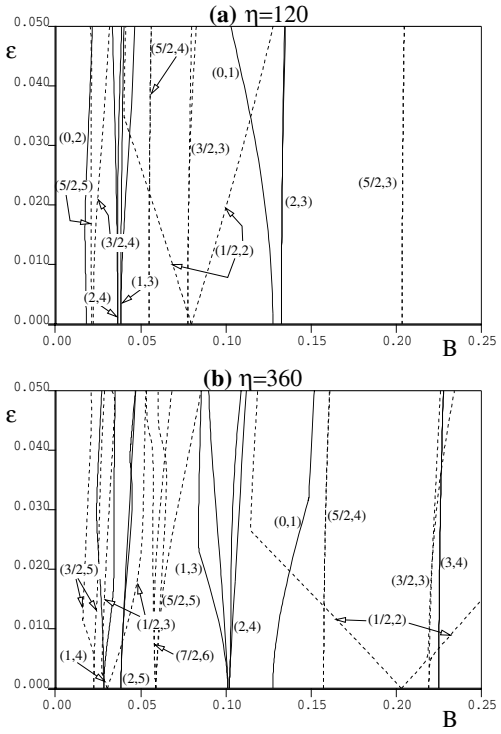

FIG. 2.3. *Resonance tongue boundaries computed using numerical Floquet analysis with* $N = 4$ *for* (a) $\eta = 120$ *and* (b) $\eta = 360$. *Depicted are all resonance tongues (labelled by* (α, n)*) with root points corresponding to* $B_{\alpha,n}$ *with* $\alpha \leq 5/2$ *and* $n \leq 4$ *and* $0.02 < B < 0.25$. *Note that the order of the resonance tongues changes between the figures (but the instability curve* $(0, 2)$ *is omitted from panel* (b) *for clarity). This is because at intermediate* η*-values there have been codimension-two resonance tongue interactions which form the subject of this paper. Note that each tongue other than the instability boundary coming out of* $B_{0,n}$ *has nonzero width which is sometimes not apparent on the scale depicted.*

Taking $\alpha = 0$, the single neutral curve is defined by

$$B = B_{0,n} + B_2\varepsilon^2 + O(\varepsilon^3)$$

where (Part II, equation (4.11), interpreted in the notation of this paper)

$$B_2 = \frac{\eta\langle\phi_n, \mathrm{L}H_1\rangle}{2\langle\phi_n'', \phi_n''\rangle}, \tag{2.18}$$

with H_1 being the solution to

$$\mathrm{M}_{0,n}H_1 - \eta H_1 = \eta\mathrm{L}\phi_n \tag{2.19}$$

subject to the usual boundary conditions (2.8).

Taking $\alpha = 1/2$, the neutral stability curves are defined by

$$B = B_{1/2,n} + B_1^{\pm}\varepsilon + O(\varepsilon^2),$$

where (Part II, equation (4.19))

$$B_1^{\pm} = \pm\frac{\eta\langle\phi_n, \mathrm{L}\phi_n\rangle}{2\langle\phi_n'', \phi_n''\rangle}. \tag{2.20}$$

In the case $\alpha = 1$, neutral stability occurs along the curves

$$B = B_{1,n} + B_2^{\pm}\varepsilon^2 + O(\varepsilon^3),$$

where (upon solving for $\alpha_1 = \pm\alpha_2$ in Part II, equation (4.26))

$$B_2^+ = \eta\frac{2\langle\phi_n, \mathrm{L}H_4\rangle + \langle\phi_n, \mathrm{L}H_3\rangle}{2\langle\phi_n'', \phi_n''\rangle}, \tag{2.21}$$

$$B_2^- = \frac{\eta\langle\phi_n, \mathrm{L}H_3\rangle}{2\langle\phi_n'', \phi_n''\rangle}, \tag{2.22}$$

with H_3 and H_4 being the solutions to

$$\mathrm{M}_{1,n}H_3 - 4\eta H_3 = \frac{\eta}{2}\mathrm{L}\phi_n, \tag{2.23}$$

$$\mathrm{M}_{1,n}H_4 = \frac{\eta}{2}\mathrm{L}\phi_n, \tag{2.24}$$

subject to the usual boundary conditions (2.8).

We now notice several anomalies from Figure 2.3. First the instability curve $(0, 1)$ representing the fundamental falling-over instability, bends back to the left for $\eta = 120$ (as indeed it does for "most" η-values, as was argued in Part I to explain the stabilization effect observed in the experiment). However, for $\eta = 360$, this curve bends to the right, thus showing that increasing ε does not lead to a region of stability of the forced rod that failed to exist for the unforced problem. This anomaly forms the subject of section 4 below. Second, the instability tongue $(1/2, 2)$ undergoes, for $\eta \approx 360$, a strange interaction process with the $(3/2, 3)$-tongue in the bottom right of Figure 2.3(b). An explanation of this and similar interactions forms the subject of section 3 below.

3. Resonance tongue interaction. The general expression (2.17) giving the leading-order expression for resonance tongues is subject to nondegeneracy conditions. These nondegeneracy conditions fail at special values of η for which

$$B_{\alpha,n} = B_{\beta,m} \quad \text{for } n \neq m, \tag{3.1}$$

and values of α and β that are related by certain conditions as we shall now explain.

It was noted in Part II that the coefficient B_2 given by (2.18) becomes singular precisely when $\lambda_m = \eta$ is another eigenvalue of M, corresponding to eigenmode ϕ_m. That is, there is the coexistence of resonances (3.1) corresponding to $\alpha = 1$ and $\beta = 0$. We can see why this is so since (2.19) becomes such that the left-hand side is solved by eigenfunction ϕ_m and hence the solution becomes unbounded unless the right-hand side function is orthogonal to ϕ_m. This will occur at a special pair of values (η_0, B_0) of η and B for which $M_0\phi_n = M_0\phi_m - \eta_0\phi_m = 0$. At such points we can see that the coefficient of the quadratic coefficient B_2^+ of the resonance tongue corresponding to $\phi_m \cos t$ also becomes unbounded, since H_4 given by (2.24) becomes unbounded. Similarly both coefficients B_2^+ and B_2^- of the $\phi_m \cos t$ and $\phi_m \sin t$ boundaries become singular when $B_{(1,n)} = B_{(2,m)}$, because the function H_3 given by (2.23) becomes unbounded. This leads to two questions: Precisely which pairs of values of frequencies α and β can lead to such singularities? and, How can one unfold these codimension-two resonance tongue interactions, allowing both η and B to vary?

3.1. Multiple timescale asymptotic expansion. In order to answer these questions, we shall develop a general multiple timescale asymptotic expansion about a given pair of values (B_0, η_0). Suppose that $B_0 = B_{\alpha,n}$ is the root point in the (B, ε)-plane of a resonance tongue corresponding to motion with angular frequency α. We shall consider the possibility that at precisely (B_0, η_0) there is the root point of a second resonance tongue so that $B_0 = B_{\alpha,n} = B_{\beta,m}$ for $m \neq n$. For the time being we do not assume any relation between the half-integers α and β, except of course the relation between the eigenvalues

$$\eta_0 = \frac{\lambda_n}{\alpha^2} = \frac{\lambda_m}{\beta^2}. \tag{3.2}$$

Since we do not know a priori which time scales will lead to a distinguished limit for this problem we will now consider all functions to be functions of a hierarchy of time scales (t, $\tau_1 = \delta t$, $\tau_2 = \delta^2 t$, ...) and introduce the following expansions:

$$\left.\begin{aligned} u(s) &= \delta u_1(s,t,\tau_1,\tau_2) + \delta^2 u_2(s,t,\tau_1,\tau_2) + \delta^3 u_3(s,t,\tau_1,\tau_2) + \cdots, \\ \eta &= \frac{\lambda_n}{\alpha^2} + \delta\eta_1 + \delta^2\eta_2 + \cdots, \\ B &= B_0 + \delta B_1 + \delta^2 B_2 + \cdots, \\ \varepsilon &= \delta\varepsilon_1, \quad \gamma = \delta\gamma_1. \end{aligned}\right\} \tag{3.3}$$

Here, for future use in section 5, we have retained the material damping γ at the same order $O(\delta)$ as the amplitude of excitation ε. By keeping the small parameter δ separate from ε we allow for the possibility of having nonzero damping at zero excitation; that is, $\varepsilon_1 = 0$, $\gamma_1 \neq 0$.

When these series are substituted into (2.6)–(2.8) and the coefficients of the terms up to δ^3 are set to zero, the result is

$$\frac{\lambda_n}{\alpha^2}\frac{\partial^2 u_1}{\partial t^2} + \mathrm{M}_0 u_1 = 0, \tag{3.4}$$

$$\frac{\lambda_n}{\alpha^2}\frac{\partial^2 u_2}{\partial t^2} + \mathrm{M}_0 u_2 = \varepsilon_1 \frac{\lambda_n}{\alpha^2}\cos t \mathrm{L} u_1 - \eta_1 \frac{\partial^2 u_1}{\partial t^2} - \frac{2\lambda_n}{\alpha^2}\frac{\partial^2 u_1}{\partial t \partial \tau_1} - B_1 u_1^{IV} - \gamma_1 \frac{\lambda_n}{\alpha^2}\frac{\partial u_1^{IV}}{\partial t}, \tag{3.5}$$

$$\begin{aligned} \frac{\lambda_n}{\alpha^2}\frac{\partial^2 u_3}{\partial t^2} + \mathrm{M}_0 u_3 = {} & \varepsilon_1 \frac{\lambda_n}{\alpha^2}\cos t \mathrm{L} u_2 - \eta_1 \frac{\partial^2 u_2}{\partial t^2} - \frac{2\lambda_n}{\alpha^2}\frac{\partial^2 u_2}{\partial t \partial \tau_1} - B_1 u_2^{IV} \\ & - \gamma_1 \frac{\lambda_n}{\alpha^2}\frac{\partial u_2^{IV}}{\partial t} + \varepsilon_1 \eta_1 \cos t \mathrm{L} u_1 - \eta_2 \frac{\partial^2 u_1}{\partial t^2} - 2\eta_1 \frac{\partial^2 u_1}{\partial t \partial \tau_1} \\ & - \frac{2\lambda_n}{\alpha^2}\frac{\partial^2 u_1}{\partial t \partial \tau_2} - \frac{\lambda_n}{\alpha^2}\frac{\partial^2 u_1}{\partial \tau_1^2} - B_2 u_1^{IV} \\ & - \gamma_1 \frac{\lambda_n}{\alpha^2}\frac{\partial u_1^{IV}}{\partial \tau_1} - \gamma_1 \eta_1 \frac{\partial u_1^{IV}}{\partial t}. \end{aligned} \tag{3.6}$$

Here the linear operator M_0 is M (defined in (2.7)) evaluated at $B = B_0$:

$$\mathrm{M}_0 u = B_0 u^{IV} + \mathrm{L} u \quad \text{with } \mathrm{L} u = [(1-s)u']',$$

and $u_1(s), u_2(s), u_3(s)$ are each subject to the boundary conditions (2.8).

Following assumptions (3.2) on coexistent resonances, we shall take the $O(\delta)$ solution to be

$$u_1 = [f(\tau_1, \tau_2, \dots)\cos\alpha t + g(\tau_1, \tau_2, \dots)\sin\alpha t]\phi_n(s) + [d(\tau_1, \tau_2, \dots)\cos\beta t + e(\tau_1, \tau_2, \dots)\sin\beta t]\phi_m(s). \tag{3.7}$$

The functions f, g, e, d will be determined at higher-order by nonresonance conditions.

Appendix A contains the general solution to the problem at $O(\delta^2)$ together with solvability conditions that can be expressed as fourth-order boundary-value problems involving the operator M_0.

In this section and the next we are interested in the zero-damping case, and so we now set

$$\gamma_1 = 0, \quad \varepsilon_1 = 1; \quad \text{hence } \delta \equiv \varepsilon,$$

and we shall use ε rather than δ as our expansion parameter.

Let us assume for now that we are not in the special case where α or $\beta = 1/2$. Appendix B then shows that the solvability condition at $O(\varepsilon^2)$ gives that the zero solution is stable except at the two isolated values

$$B_1 = \frac{\eta_1\alpha^2}{\langle\phi_n'', \phi_n''\rangle} \quad \text{or} \quad \frac{\eta_1\beta^2}{\langle\phi_n'', \phi_m''\rangle}. \tag{3.8}$$

However, note that these two conditions (3.8) can be written more simply as

$$\sigma_1 = B_1\langle\phi_p'', \phi_p''\rangle, \quad \text{where } \lambda = \lambda_p + \varepsilon\sigma_1,$$

for $p = n$ or m. We recognize immediately that this is the first-order-in-ε correction to the curve (2.16) for the eigenvalues as a function of B if we demand that either the condition $\lambda = \eta\alpha^2$ or $\lambda = \eta\beta^2$ remains true at nearby (B, η)-values. In other words, this moves the underlying B and η values to new ones that satisfy the appropriate eigenvalue condition (either of the two equalities in (3.2)). Since we are interested in expanding about η_0 and B_0, we must therefore choose

$$\eta_1 = B_1 = 0. \tag{3.9}$$

Equations (A.9) and (A.10) have a unique bounded solution unless $(\beta \pm 1)^2 = \alpha^2$. That is, unless

$$\beta = \alpha \pm 1. \tag{3.10}$$

If (3.10) is satisfied, then the above asymptotic expansion becomes invalid and we note that the function F_3 or F_4 must be combined with H_1 or H_2, respectively. Then the nonresonance conditions (B.2) and (B.3) lead to nontrivial expressions for B_1 as a function of η_1. We shall treat these on a case-by-case basis in sections 3.2, 3.3, and 4.

For the time being let us continue by assuming that (3.10) is *not* satisfied. Then, Appendix C gives the form of the general equation at $O(\varepsilon^3)$, and we now proceed to analyze its various special cases. First note that the asymptotics is now in place to derive the general description 2.17 of each codimension-one resonance tongue (where β is unrelated to α); see Appendix D.

3.2. Resonance interaction at $O(\varepsilon^2)$. Consider what happens at $O(\varepsilon^2)$ when (3.10) is satisfied, which without loss of generality we assume occurs with

$$\beta = \alpha + 1 \tag{3.11}$$

(avoiding for the time being the special cases $\alpha = 0$ or $\alpha = 1/2$). As we already remarked, the asymptotic expansion we have introduced above becomes invalid when (3.11) is satisfied. In particular we can no longer assume $B_1 = \eta_1 = 0$. Instead we find stability at this order except on a single neutral curve in the (B_1, η_1)-plane

$$(\eta_1\alpha^2 - B_1\langle\phi_n'', \phi_n''\rangle)(\eta_1(\alpha+1)^2 - B_1\langle\phi_m'', \phi_m''\rangle) = \frac{\lambda_n^2}{4\alpha^4}\langle\phi_m, \mathrm{L}\phi_n\rangle^2; \tag{3.12}$$

see appendix E.

Note that the right-hand side of (3.12) is strictly positive, whereas the left-hand side is the product of two linear functions of η_1 and B_1. This is the equation for a hyperbola in the (η_1, B_1)-plane; see Figure 3.1(a). In the limit that $|\eta_1|$ is large, the locus of solutions becomes two straight lines with slopes $\frac{1}{\alpha^2}\langle\phi_n'', \phi_n''\rangle$ and $\frac{1}{(\alpha+1)^2}\langle\phi_m'', \phi_m''\rangle$, which according to (2.16) are precisely the linear approximations to the loci $B_{\alpha,n}(\eta)$ and $B_{\alpha+1,m}(\eta)$. Hence a long way from the resonance tongue interaction there is no correction at $O(\varepsilon)$ to the root points of the resonance tongues (as expected). Note, however, as shown in Figure 3.1, the solution at finite values of the excitation ε that was attached to the (α, n) tongue for $\eta_1 \ll 0$ switches over to become associated with the $(\alpha+1, m)$ tongue for $\eta_1 \gg 0$.

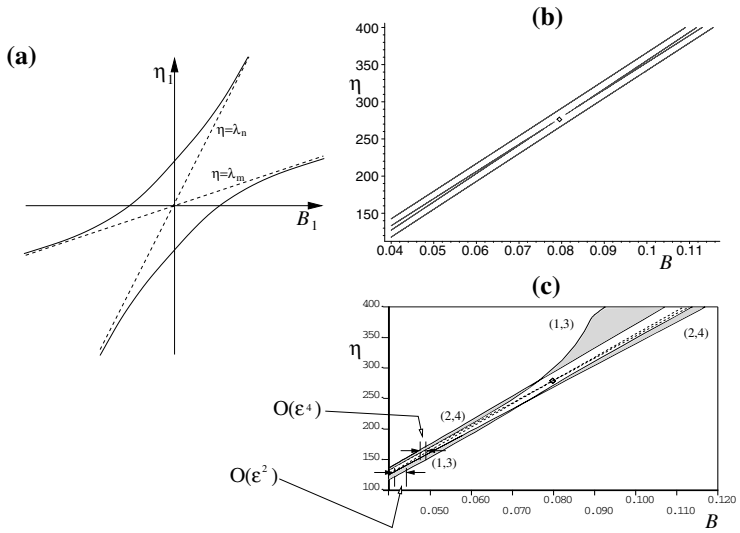

FIG. 3.1. (a) *Schematic diagram of the interaction at $O(\varepsilon)$ of the resonance tongues corresponding to α and $\beta = \alpha + 1$ according to* (3.12). *The dashed lines represent the eigenvalue loci $B_{\alpha,n}(\eta)$ and $B_{\beta,m}(\eta)$, and the solid line gives the $O(\varepsilon)$ correction. Note that at this order both tongues have zero width, provided $\alpha \geq 1$.* (b), (c) *Numerical illustration in the case $(\alpha, n) = (1, 3)$, $(\beta, m) = (2, 4)$, and $\varepsilon = 0.02$. Panel* (b) *shows the evaluation of the formula* (3.12) *(outer two curves) together with the eigenvalue loci $B = B_{1,3}(\eta)$ and $B = B_{2,4}(\eta)$ which cross at $\eta = 278.808$ (marked by a diamond). Panel* (c) *shows the numerically computed stability boundaries using Floquet theory with $N = 4$. The eigenvalue loci are dashed. Shaded regions correspond to instability inside the resonance tongue.*

Figure 3.1 numerically illustrates a particular resonance tongue interaction between the tongues $(1,3)$ and $(2,4)$. Note from Figure 2.3 that these two resonance tongues switch their order (the relative B-values for which they occur) between $\eta = 120$ and $\eta = 360$. In fact we find numerically that these two resonances interact at

$$\eta_0 = 278.809, \qquad B_0 = 0.0798242,$$

from which we have calculated that

$$\langle \phi_3'', \phi_3'' \rangle = 3807.75, \qquad \langle \phi_4'', \phi_4'' \rangle = 14618.8, \qquad \langle \phi_4'', \mathrm{L}\phi_3'' \rangle = 8.55440.$$

Using these quantities, the loci of the $O(\varepsilon)$ behavior of the tongues, (3.12) is calculated and plotted in Figure 3.1(b). Note that the slopes of the loci $\eta = B_{1,3}$ and $\eta = B_{2,4}$ are much closer than in the schematic panel (a). Finally, panel (c) of the figure shows how these results compare with a full numerical evaluation of the resonance tongues using Floquet theory for fixed amplitude $\varepsilon = 0.02$. Note that the tongues, which are $O(\varepsilon^2)$ and $O(\varepsilon^4)$ in theory away from the interaction (marked at the left-hand edge of the figure) undergo an abrupt change as they pass through a neighborhood of the resonance tongue interaction point. There are several features to this change. First, as predicted and in broad quantitative agreement with the results in panel (b), the resonance tongues do not cross, but each tongue becomes attached to the opposite instability. Second, there is a point close to the codimension-two point at which each tongue (at this value of ε) "pinches off." The result is that the cosine and sine boundaries switch sides. This pinching off of the resonance tongue is not part of the above $O(\varepsilon)$ theory, but can be seen here as a necessary consequence of the resonance tongue interaction process. Note that such pinching of resonance tongues has been described before for one-degree-of-freedom parametrically excited systems [4]. (It is also in evidence in Figure 2.3, where for $\eta = 360$, both the (1,3) and (2,4) resonance tongues become narrower for ε-values toward the top of the graph, suggesting that they pinch off for higher ε still (indeed they do); also the tongue (2,5) can be seen to undergo just such a pinching at $\varepsilon \approx 0.035$.) Finally, note that beyond the codimension-two point the $(1,3)$ tongue suddenly becomes much fatter. This is because of its interaction with the buckling mode instability at $B = B_{0,1} = 0.127594$ which was discussed in Part II, section 4(e), and will be treated further in section 4 below.

3.3. The case $\alpha = 1/2$, $\beta = 3/2$; singularity in the subharmonic resonance. This case is special because the $O(\varepsilon)$ correction due to the resonance tongue interaction is at the same order as the $O(\varepsilon)$ width of the resonance tongue itself. From Appendix E we obtain the stability boundary (B_1, η_1)-plane

$$\left(\frac{\eta_1}{4} - B_1\langle \phi_n'', \phi_n'' \rangle \pm 2\lambda_n \langle \phi_n, \mathrm{L}\phi_n \rangle\right)\left(\frac{9\eta_1}{4} - B_1\langle \phi_m'', \phi_m'' \rangle\right) = \frac{4}{9}\lambda_n^2 \langle \phi_m, \mathrm{L}\phi_n \rangle^2. \tag{3.13}$$

This describes two hyperbolae which bound the shaded region of stability shown schematically in Figure 3.2(a). For large η_1 and B_1 they asymptote to the straight lines

$$\begin{aligned} B_1 &= B_{n,1/2} \pm B_1^{\pm} = \frac{\eta_1}{4\langle \phi_n'', \phi_n'' \rangle} \pm \frac{\langle \phi_n, \mathrm{L}\phi_n \rangle}{\langle \phi_n'', \phi_n'' \rangle} \quad \text{and} \\ B_1 &= B_{m,3/2} = \frac{9\eta_1}{4\langle \phi_n'', \phi_n'' \rangle}, \end{aligned} \tag{3.14}$$

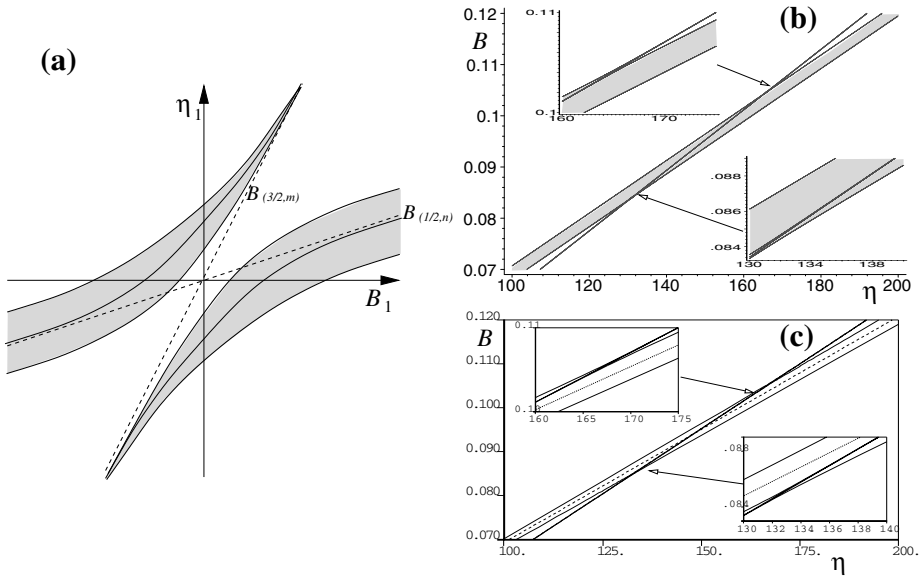

FIG. 3.2. *The interaction at $O(\varepsilon)$ of the resonance tongues corresponding to $\alpha = 1/2$ and $\beta = 3/2$.* (a) *Schematic picture; the shaded region corresponds to that of instability.* (b) *Evaluation of the formula* (3.13) *for $n = 2$, $m = 3$, using numerically calculated eigenfunctions ϕ_n and ϕ_m and $\varepsilon = 0.001$.* (c) *Numerically computed stability boundaries using Floquet theory with $N = 4$. The dashed line, as in part* (a)*, corresponds to the locus $B = B_{1/2,2}(\eta)$. The locus $B = B_{3/2,3}$ is indistinguishable in this plot from the corresponding tongue boundary with finite ε.*

which are the $O(\varepsilon)$ expressions for the two stability boundaries in the absence of their interaction. The region of instabilities for a finite ε are shaded in Figure 3.2(a), and are obtained by noting the inequalities that must be true in order for (E.11)–(E.14) to have bounded solutions. The resonance conditions $B_1 = B_{n,1/2}$ and $B_{m,3/2}$, valid when $\varepsilon = 0$, are depicted as dashed lines in the figure. Observe that the interaction between the two instabilities causes a small region of *stability* for finite ε in a neighborhood of the critical point $\eta_1 = B_1 = 0$, where the two resonance curves $B_{n,1/2}$ and $B_{m,3/2}$ cross.

By numerical computation we have found numerous examples of resonance tongue interaction of this kind. For example, taking $n = 2$ and $m = 3$ we find that $\lambda_n = \eta/4$ and $\lambda_m = 9\eta/4$ at $(B, \eta) = (0.0941064, 148.084)$. Note that this B-value is a little less than $B_c = 0.127594$, which implies that this interaction of instabilities is occurring for rods which are already marginally unstable to self-weight buckling. At those parameter values, computation of the eigenfunctions reveals

$$\begin{aligned} \langle \phi_n'', \phi_n'' \rangle &= 485.765, \qquad \langle \phi_m'', \phi_m'' \rangle = 3807.41, \\ \langle \phi_n, \mathrm{L}\phi_n \rangle &= -8.69181, \qquad \langle \phi_m, \mathrm{L}\phi_n \rangle = -1.946423. \end{aligned} \tag{3.15}$$

Using these precise values, Figure 3.2(b) shows the evaluation of the loci (3.13) with $\varepsilon = 0.001$, which are compared in Figure 3.2(c) to the computation of the same stability boundaries using the numerical Floquet theory introduced in Part I. Note from the values (3.15) that the straight lines $B_{1/2,2}$ and $B_{3/2,3}$ given by (3.14) with $n = 2$ and $m = 3$ have slopes that differ by less than 10%. Hence the stability region caused by the interaction between these two resonances is very small compared to the width of the instability tongues around $B = B_{1/2,2}$ (see insets).

3.4. Resonance interaction at higher order. The above analysis can be continued to $O(\varepsilon^3)$ to obtain the $O(\varepsilon^2)$ corrections to the four solid lines in Figure 3.2(a). Carrying out the expansion to $O(\varepsilon^4)$ would show how to couple the shapes of the shaded instability boundaries to the $O(\varepsilon^3)$-thick resonance tongue around the locus $B = B_{m,3/2}$ which itself would be a curve with nonzero coefficients of ε^2 and ε^3. There is little extra qualitative information to be obtained by carrying out these expansions explicitly. Instead, let us focus on other resonance-tongue interactions which can be captured only by going to $O(\varepsilon^3)$ or higher.

Suppose first that (3.10) is not satisfied, but instead

$$\beta = \alpha \pm 2; \quad \text{without loss of generality} \quad \beta = \alpha + 2.$$

The analysis at $O(\varepsilon^2)$ now proceeds as in Appendix A and we have $B_1 = \eta_1 = 0$. Consider the $O(\varepsilon^3)$ equation (C.1). Then the coefficients of $\cos(\beta-2)t$ and $\sin(\beta-2)t$ are also resonant and must be added to the coefficients of $\cos\alpha t$ and $\sin\alpha t$ to form solvability conditions. Also the coefficients of $\cos(\alpha+2)t$ and $\sin(\alpha+2)t$ should be added to those for $\cos\beta t$ and $\sin\beta t$. Again there will be two pairs of relations, from orthogonality to ϕ_n and ϕ_m separately. This will lead to a nontrivial equation linking B_2 and η_2, like (3.12) for η_1 and B_1 in the case of a lower-order resonance tongue interaction.

So we find in general that the coefficient of ε^3 in the asymptotics of the resonance tongues undergoes a singularity which is patched up by this correction to the $O(\varepsilon^2)$ coefficient B_2 as η passes through η_0. Similarly, by extrapolation of the above argument to higher powers of ε in our asymptotic expansion, we find that if

$$\beta = \alpha + n,$$

then there is a singularity in the $O(\varepsilon^{n+1})$ coefficient of the resonance tongues which is resolved by showing that there is a nontrivial contribution to the $O(\varepsilon^n)$ coefficient as η passes through the critical value at which the interaction occurs.

4. The case $\alpha = 1$, $\beta = 0$; first-harmonic buckling interaction. The case $\alpha = 1$, $\beta = 0$ leads to quite different results since instead of a resonance tongue, we have a single neutral stability curve corresponding to the rod "falling over" into one of its buckling modes. The bookkeeping in section 3.2 above shows that this interaction causes a singularity in the $O(\varepsilon^2)$ coefficient B_2 of this instability curve in the (B, ε)-plane. Clearly this can have a profound effect on the stability analysis of the slightly longer than critical column because it was precisely the negativity of this coefficient B_2 that gave the stabilization effect referred to colloquially as the "Indian rope trick" in Parts I and II.

Consider a neighborhood of a special η-value $\eta = \lambda_n$ at which $B_{1,n} = B_{0,m}$. Particular physical interest is in the case $m = 1$, in which case we consider the column that is only slightly longer (or shorter) than the length of column that will just stand under its own weight. That is $B \approx B_c = B_{0,1}$, the critical value of the dimensionless parameter B for self-weight buckling. We shall denote the critical eigenmode corresponding to B_c as ϕ_c and the eigenmode corresponding to the pure dynamic instability ϕ_n. In fact, the analysis below works equally well for $B_c = B_{0,m}$ for any $m \geq 2$, except that "stability" implies then "stable to vibration mode m" rather than absolute stability since such a rod is statically unstable to modes ϕ_p, $p = 1, \ldots, n-1$.

Thus the solution of the $O(\varepsilon)$ equation (3.4) we take is

$$u_1 = \{h(\tau_1,\tau_2)\phi_c(s) + [f(\tau_1,\tau_2)\cos t + g(\tau_1,\tau_2)\sin t]\phi_n(s)\}, \tag{4.1}$$

with $\phi_m(s)$ and $\phi_c(s)$ subject to the boundary conditions (2.8).

4.1. The $O(\varepsilon^2)$ interaction equation. In Appendix F the following condition for stability at $O(\varepsilon^2)$ is derived:

$$\left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'',\phi_n''\rangle}{2\lambda_n}\right)\left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'',\phi_n''\rangle}{2\lambda_n} + \frac{\lambda_n B_c^2\langle\phi_n'',\phi_c''\rangle^2}{4B_1\langle\phi_c'',\phi_c''\rangle}\right) > 0, \tag{4.2}$$

with the stability boundaries in (η, B, ε)-space determined by the zeros of this expression.

One boundary is determined by

$$\left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'',\phi_n''\rangle}{2\lambda_n}\right) := \sigma_1 = 0; \quad \text{hence } \eta_1 = B_1\langle\phi_n'',\phi_n''\rangle. \tag{4.3}$$

In this case f is independent of τ_1 by (F.9) and, unless $f \equiv 0$, g will be a linear function of τ_1 by (F.8) and hence unbounded as $\tau_1 \to \infty$. Thus g is constant as a function of τ_1, which implies the motion is $\sin t$, out of phase with the drive.

The other boundary is determined by

$$\left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'',\phi_n''\rangle}{2\lambda_n} + \frac{\lambda_n B_c^2\langle\phi_n'',\phi_c''\rangle^2}{4B_1\langle\phi_c'',\phi_c''\rangle}\right) := \sigma_2 = 0; \tag{4.4}$$

hence

$$\eta_1 = B_1\langle\phi_n'',\phi_n''\rangle - \frac{\lambda_n^2 B_c^2\langle\phi_n'',\phi_c''\rangle^2}{2B_1\langle\phi_c'',\phi_c''\rangle}.$$

In this case g is independent of τ_1 by (F.8) and therefore unless $g \equiv 0$, f will be a linear function of τ_1, and unbounded on this boundary. With this choice f and h are at most functions of τ_2, which implies a motion that is in phase with the drive, but with a nonzero lean (proportional to a constant plus $\cos t$).

To determine on which side of these boundaries solutions are stable we simply observe that for stability we must have $\sigma_1\sigma_2 > 0$ so that σ_1 and σ_2 must be either both negative or both positive. The regions of stability are shown as shaded in Figure 4.1(a).

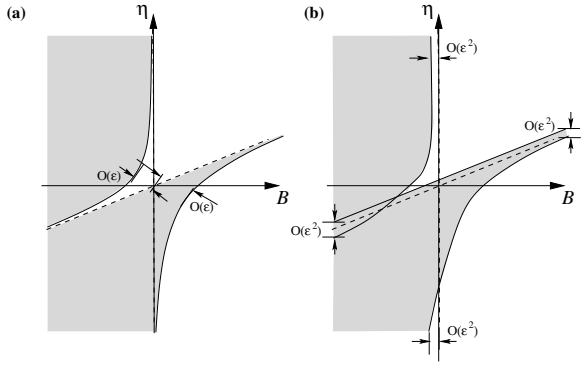

FIG. 4.1. *Schematic figure of the resonance tongue interaction process between the falling-over and first-harmonic instabilities.* (a) *at* $O(\varepsilon)$; (b) *including* $O(\varepsilon^2)$.

4.2. Correction at $O(\varepsilon^3)$. We now construct the correction $B_2\varepsilon^2$ and $\eta_2\varepsilon^2$ to these stability boundaries. This is necessary in order to see how the above $O(\varepsilon)$ correction matches the limit when the two resonances are a long way from interaction. In that case, both the falling-over and harmonic instabilities are quadratic to leading order (formulae (2.18), (2.22) and (2.21)). We shall consider a neighborhood of the boundaries $\sigma_1 = 0$ and $\sigma_2 = 0$ separately.

The case $\sigma_1 = 0$ is dealt with in Appendix G. The result is that one can combine the results for B_1 and B_2 into the single expression

$$B = B_c + \frac{(\eta - \lambda_n)}{\langle \phi_n'', \phi_n'' \rangle} - \varepsilon(\eta - \lambda_n)\frac{\langle \phi_n'', H_2'' \rangle}{\langle \phi_n'', \phi_n'' \rangle^2} + \varepsilon^2 \frac{1}{2}\lambda_n \frac{\langle \phi_n, \mathrm{L}H_3 \rangle}{\langle \phi_n'', \phi_n'' \rangle} + O(\varepsilon^3). \tag{4.5}$$

Note that the first three terms of (4.5) are precisely the expansion of the locus $B = B_{1,m}(\eta)$ up to $O(\varepsilon^2)$ that defines the condition that there is an eigenvalue $\lambda = \eta$. To see this, take $\delta = \varepsilon$, $n = m$, $\lambda = \eta$, $B_1 = B - B_c$ in (2.16) and invert the expansion up to $O(\varepsilon^2)$, noting that (2.14) satisfied by f_1 is a scalar multiple of that satisfied by H_2, which is (F.5) with $\eta_1 \equiv \sigma_1$ and $f = 0$. The fourth term of (4.5) is just the $O(\varepsilon^2)$ coefficient B_2^- given by (2.22) of the $\sin t$ boundary of the resonance tongue when it does not interact with the falling-over mode. We conclude that this boundary of the resonance tongue does not become singular as it passes through the resonance tongue interaction point.

Consider now the boundary $\sigma_2 = 0$, which contains a discontinuity. The results in Appendix H show that the correction B_2 and η_2 can be expressed in terms of B_1 and η_1:

$$B_2 = \frac{1}{2G_n\langle \phi_c'', \phi_c'' \rangle}(2B_1K_n\langle \phi_c'', H_0'' \rangle - K_n\lambda_n\langle \phi_c, \mathrm{L}H_1 \rangle - B_1\eta_1\langle \phi_c, \mathrm{L}\phi_n \rangle), \tag{4.6}$$

$$\begin{aligned}\eta_2 = {} & \frac{1}{B_1}\left[\eta_1 G_n\langle \phi_c'', \phi_n'' \rangle - K_n\lambda_n\left(\langle \mathrm{L}H_0, \phi_n \rangle + \frac{1}{2}\langle \mathrm{L}H_3, \phi_n \rangle\right)\right] \\ & + K_n\langle H_1'', \phi_n'' \rangle + B_2\langle \phi_n'', \phi_n'' \rangle.\end{aligned} \tag{4.7}$$

Now we have to decide how to interpret these results. At $O(\varepsilon)$ we have a neutral stability curve (4.4) in the (B, η)-plane that asymptotes to $\eta = \infty$ as $B \to 0$. However, the above formulae (4.6) and (4.7) provide corrections to both η and B_2 at each point on this curve. The most meaningful way of applying this asymptotic correction is to take only those components that are normal to the curve. To that end we can define a new coordinate

$$\hat{\eta} = \eta - B\langle \phi_n'', \phi_n'' \rangle$$

so that the straight line $\eta_1 = B_1\langle \phi_n'', \phi_n'' \rangle$ to which the curve (4.4) asymptotes as $\eta_1 \to \infty$ becomes the B_1-axis. Also, the second $O(\varepsilon^2)$-correction equation (4.7), which involves both B_2 and η_2, becomes just a condition for $\hat{\eta}_2$. Then taking B_1 as a single independent coordinate and, according to (4.4)

$$\hat{\eta}_1 = -\frac{\lambda_n^2 B_c^2 \langle \phi_n'', \phi_c'' \rangle^2}{2B_1\langle \phi_c'', \phi_c'' \rangle}, \tag{4.8}$$

we can write that the second-order corrections $\tilde{B}_2, \tilde{\hat{\eta}}_2$ should satisfy

$$(\tilde{B}_2, \tilde{\hat{\eta}}_2) = \frac{(B_2, \hat{\eta}_2) \cdot (-\hat{\eta}_1, B_1)}{B_1^2 + \hat{\eta}_1^2}(-\hat{\eta}_1, B_1). \tag{4.9}$$

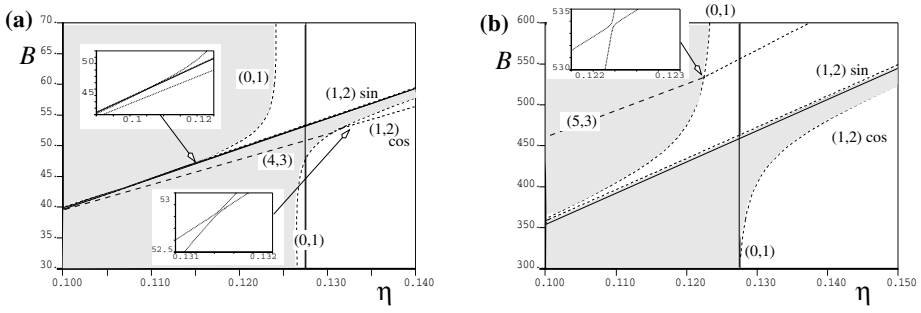

FIG. 4.2. *Numerical evaluation in the* (B, η) *parameter-plane of resonance tongue interaction. Solid lines depict the curves* $B_{(0,1)}$ *and* $B_{(1,n)}$*, and dashed lines represent the stability boundaries for finite* ε*. Shaded regions depict the areas of instability. Insets show blowups of various regions.* (a) $n = 2$ *for* $\varepsilon = 0.02$*;* (b) $n = 3$ *for* $\varepsilon = 0.005$.

The results are presented schematically in Figure 4.1(b). In order to sketch Figure 4.1(b), we have used the fact that (4.9) can be matched into the limits $B_1 \to 0$ and $B_1 \gg 1$. With the correct interpretation, the former limit yields the falling-over instability boundary, whereas the latter yields the first-harmonic resonance tongue, as shown in Appendix I.

4.3. Numerical evaluation. Figure 4.2 shows resonance tongues calculated using numerical Floquet theory with $N = 4$. Two cases of the resonance tongue interaction studied in this section are shown corresponding, respectively, to the cases $n = 2$ (for which $\eta_0 = 53.285$) and $n = 3$ ($\eta_0 = 460.68$) interacting with the fundamental falling-over instability at $B_c = 0.127594$. In both cases, the general shape of the qualitative picture in Figure 4.1 predicted by the above theory is indeed found to occur. Specifically, we find

$$\langle \phi_c'', \phi_c'' \rangle = 12.4182, \tag{4.10}$$

$$\eta = 53.285 : \langle \phi_2'', \phi_2'' \rangle = 3807.01, \quad \langle \phi_c'', \phi_2'' \rangle = 8.9822, \tag{4.11}$$

$$\eta = 460.68 : \langle \phi_3'', \phi_3'' \rangle = 14617.8, \quad \langle \phi_c'', \phi_3'' \rangle = 6.9483. \tag{4.12}$$

Moreover we also found that the mode shape corresponding to each stability boundary is also as predicted by the analysis. The mode shape of the cosine boundary of the $(1, n)$ tongue is found to pick up a large component of the $(0, 1)$ mode as it approaches B_c, whereupon the $\phi_n \cos t$ term starts to diminish in size until as $\eta \to |\infty|$ the mode becomes pure ϕ_c to leading order in ε.

Note from Figure 4.2(a) that there is an interaction with the $(4, 3)$-boundary for an η-value just greater than the critical one, such that at $\ll O(\varepsilon^2)$ these two boundaries exchange positions (see the inset to that figure). Similarly, in Figure 4.2(b), there is an interaction between the $(1, 3)$-mode and the $(5, 3)$ at higher-order in ε (again blown up in an inset). However, the existence of these remarkably thin $(4, 3)$ and $(5, 4)$ resonance tongues makes virtually no difference to the size of the (in)stability region.

5. The effect of damping. Let us now consider the effect on the above analysis of including damping. Recall the assumption made in section 3.3 that both damping and amplitude of excitation are small parameters at $O(\delta)$, but with independent coefficients ε_1 and γ_1 to allow for the possibility of allowing one of these effects to be

zero independent of the other. So we now consider the general asymptotic expansion (3.5)–(3.6) with γ_1 and ε_1 both being $O(1)$ and δ as the perturbation parameter.

5.1. Codimension-one resonances. It is well known that positive linear damping increases the size of stability regions and lifts the root points of resonance tongues off the $\varepsilon = 0$ axis (e.g., [16]). In fact, damping enters at $O(\delta)$ and so makes its first nontrivial contribution in the $O(\delta^2)$ equation derived in section A. Consider taking just a single codimension-one resonance $\eta \equiv \lambda_n/\alpha^2$. Then if $\alpha > 1/2$, we have that the $O(\delta)$ stability equation (B.6) gets replaced with the pair of equations

$$\frac{\partial g}{\partial \tau_1} + \frac{1}{2}\gamma_1 \langle \phi_n'', \phi_n'' \rangle g - K_\alpha \gamma_1 f = 0,$$
$$\frac{\partial f}{\partial \tau_1} + \frac{1}{2}\gamma_1 \langle \phi_n'', \phi_n'' \rangle f + K_\alpha \gamma_1 g = 0,$$

where now,

$$K_\alpha = -B_1 \frac{\alpha \langle \phi_n'', \phi_n'' \rangle}{2\lambda_n}.$$

Note that the eigenvalues of such a system are $-(\gamma_1/2)\langle \phi_n'' \phi_n'' \rangle \pm i K_\alpha$, so that the origin is stable for all B_1 at this order. This shows that the resonance tongue is "lifted off" from the $\varepsilon = 0$ axis by more than an $O(\delta)$ amount (see Figure 5.1(a)).

To get a nontrivial resonance tongue at $O(\delta)$ we must consider the case $\alpha = 1/2$. Then (E.11) and (E.12) become (in the absence of a codimension-two interaction so that $d = e = 0$)

$$\frac{\partial g}{\partial \tau_1} + \left(\frac{B_1 \langle \phi_n'', \phi_n'' \rangle}{4\lambda_n} - \frac{\varepsilon_1}{2} \langle \phi_n, \mathrm{L}\phi_n \rangle \right) f + \frac{\gamma_1}{2} \langle \phi_n'', \phi_n'' \rangle g = 0, \tag{5.1}$$

$$\frac{\partial f}{\partial \tau_1} - \left(\frac{B_1 \langle \phi_n'', \phi_n'' \rangle}{4\lambda_n} + \frac{\varepsilon_1}{2} \langle \phi_n, \mathrm{L}\phi_n \rangle \right) g + \frac{\gamma_1}{2} \langle \phi_n'', \phi_n'' \rangle f = 0. \tag{5.2}$$

When $\varepsilon_1 = 0$ the origin is stable. It becomes unstable along the neutral curve

$${\varepsilon_1}^2 \langle \phi_n, \mathrm{L}\phi_n \rangle^2 = \left(\gamma_1^2 + \frac{B_1^2}{4\lambda_n^2} \right) \langle \phi_n'', \phi_n'' \rangle^2, \tag{5.3}$$

which is depicted in Figure 5.1(b).

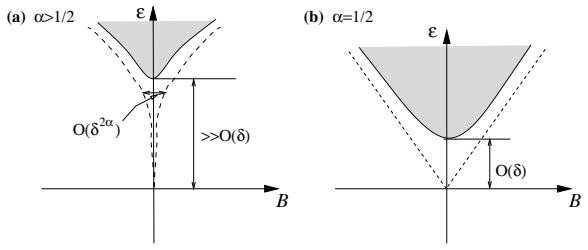

FIG. 5.1. *Sketch of resonance tongues in the presence of nonzero forcing $\varepsilon = \varepsilon_1 \delta$ and damping $\gamma_1 \delta$ (solid line) compared with that of $\gamma_1 = 0$ (dashed). Shaded regions correspond to instability.*

5.2. Codimension-two resonance tongue interaction. We can also include damping in all of the above codimension-two analyses and find its effect on resonance tongue interaction. We shall, however, present only the effect on the calculation in section 4, as this was the most involved and appears the most physically significant to explain the experimental results in [14]. To that end, we consider u_1 given by (4.1) and see the adjustment that the extra linear terms in (3.5)–(3.6) for nonzero γ_1 make on the stability boundaries.

Proceeding as in section 4, at $O(\delta^2)$, when damping is included, (F.8) and (F.9) become

$$\frac{\partial g}{\partial \tau_1} + \frac{\gamma_1}{2}\langle \phi_n'', \phi_n''\rangle g - \left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle \phi_n'', \phi_n''\rangle}{2\lambda_n} + \varepsilon_1 \frac{\lambda_n B_c^2 \langle \phi_n'', \phi_c''\rangle^2}{4B_1\langle \phi_c'', \phi_c''\rangle} \right) f = 0,$$

$$\frac{\partial f}{\partial \tau_1} + \frac{\gamma_1}{2}\langle \phi_n'', \phi_n''\rangle f + \left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle \phi_n'', \phi_n''\rangle}{2\lambda_n} \right) g = 0,$$

and (F.7) is unchanged.

Writing such a system as

$$\frac{\partial g}{\partial \tau_1} + \Gamma g - ((A/B_1) + C) f = 0, \qquad \frac{\partial g}{\partial \tau_1} + \Gamma f - C g = 0, \tag{5.4}$$

where

$$\Gamma = \frac{\gamma_1}{2}\langle \phi_n'', \phi_n''\rangle, \qquad A = \frac{\varepsilon_1}{4}\frac{\lambda_n B_c \langle \phi_n'', \phi_0''\rangle^2}{\langle \phi_0'', \phi_0''\rangle}, \qquad C = \frac{\eta_1 - B_1\langle \phi_n'', \phi_n''\rangle}{2\lambda_n}, \tag{5.5}$$

we note that $\Gamma > 0$ is a rescaled damping parameter and $A > 0$ is a rescaled amplitude parameter. On the other hand, C can be thought of as a shifted version of η_1 so that the B_1 and C axes, respectively, represent the $O(\varepsilon)$ loci of the bifurcation loci $B_{0,n}$ and $B_{1,m}$.

From (5.4) and (5.5), straightforward calculation shows that the region of stability is given by

$$C(C + A/B_1) + \Gamma^2 > 0, \tag{5.6}$$

which gives the shaded region in Figure 5.2. Note that in the limit $\Gamma \to 0$, we recover the undamped $O(\varepsilon)$ stability curve (4.2) sketched in Figure 4.1(a). Also if $A = 0$

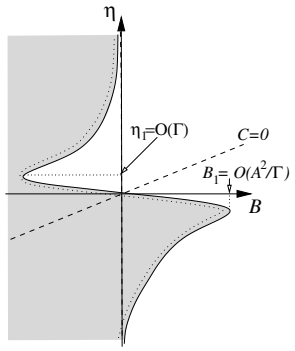

FIG. 5.2. *Schematic figure of the resonance tongue interaction process between the falling-over and first-harmonic instabilities according to* (5.6)*, in the presence of damping* $\gamma_1 > 0$*. Here the* $O(\delta)$ *curve is plotted as a solid line bounding a shaded region of instability in the* (B_1, η_1)*-plane. The dotted curve represents the* $O(\delta^2)$ *correction.*

(corresponding to $\varepsilon_1 = 0$), then we are solving the unforced problem in the presence of nonzero damping; then the only instability is that given by B_1, which is the buckling instability $B_{0,n}$. In between these two extremes we see the curve sketched. Note that the $B_{1,m}$ tongue does not lead to an instability with finite damping at $O(\delta)$ (because of the construction in Figure 5.1), but it does have a very strong influence on the shape of the falling-over instability boundary. Figure 5.2 also shows schematically the result of adding an $O(\delta^2)$ correction to this curve, which can be seen as a secondary effect. See Figure 6.1(b) for actual calculations of the $O(\delta)$ curves, based on the numerical evaluation of Γ, A, and C in (5.5).

6. Experimental comparison. In [14] the quantitative details of the experimental results using a piece of domestic curtain wire are given. A wire of critical buckling length $\ell_c = 55.3\,\text{cm}$ is held in a clamp and subjected to vertical sinusoidal oscillation with peak-to-peak amplitude of 2.2 mm and frequency between 0 and 35 Hz. In terms of the dimensionless parameters of this paper this equates to $\varepsilon = 0.02$ and $0 < \eta < 1000$. The parameter B may be varied by allowing different lengths of wire through the holding clamp. The wire is clearly damped although it is hard to estimate the true value of the dimensionless parameter γ. It is observed that for lengths of wire a little longer than ℓ_c ($B < B_c$), the upright position of the wire is unstable for lower frequencies (η-values), becomes stable at higher η, and becomes unstable again beyond a second η threshold. The nature of the instability at the lower-η stability boundary is a pure falling-over mode ($(0,1)$ in the notation of our theory). The upper boundary is a dynamic instability, at the same frequency of the drive, with a large component of the third spatial mode $(1,3)$. The shape of the stability region is shown in Figure 6.1. There is no evidence of any appreciable subharmonic instability.

Figure 6.1 also compares these results with two separate theories from this paper. First in panel (a) we compare with the results in section 4. This is essentially the same comparison that was shown in [14, Figure 2(b)], although in this paper we have developed a rational explanation for the resonance tongue interaction process that

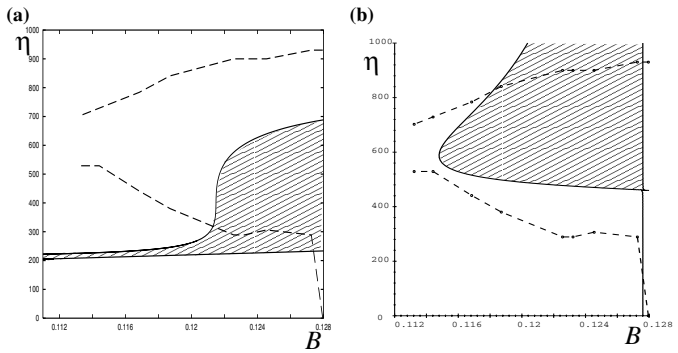

FIG. 6.1. *Comparison between theory (solid line and shading) and the experimental results of* [14] *(dashed line), for the* stability *region as a function of the dimensionless parameters B and η with $\delta = 0.02$, $\varepsilon_1 = 1$. The theory is based on two different calculations close to the resonance tongue interaction between* $(0,1)$ *and* $(1,3)$*, for which $B_{0,1} = B_{1,3}$ when $\eta = \eta_0 = 460.7$.* (a) *Using the theoretical results from Part* II*, which computes the $O(\delta^2)$ coefficients B_2 and B_2^+ given by* (2.18) *and* (2.21) *which undergo singularities in accord with the theory of section* 4 *above. In this case there is no damping.* (b) *Plotting the zeros of* (5.6)*, the $O(\delta)$ coefficient of the resonance tongue interaction in the presence of damping, evaluated using the values* (4.10), (4.12)*, with $\gamma_1 = 0.01$ being used as a representative damping value.*

underlies the shape of the stability region. Note that these results in part explain the experiments, in that the interaction between modes $(0,1)$ and $(1,3)$ leads to a wedge-shaped region in the (B,η)-plane.

Panel (b) compares the experimental data with the results of section 5, where damping is included. Here we have used $\delta = 0.02$ with $\varepsilon_1 = 1$ and have set damping to the plausible value of $\gamma_1 = 0.01$. No other fitting is employed. Also, these results do not include any $O(\varepsilon^2)$ correction to the curves. The agreement is now very good. Note that at this level of δ, the tongue corresponding to the $(1,3)$-instability has zero width. However, its presence is strongly felt in the shape of the instability curve of the $(0,1)$ instability. In particular, the large wedge-shaped region of stability for $B > B_c$ (corresponding to the unshaded wedge within the shaded instability regions in Figure 5.2) is due precisely to the resonance tongue interaction between the buckling instability and the first-harmonic resonance of the third spatial mode.

7. Discussion. The idea that parametric resonance in continuous structures can cause energy to be transferred between modes is a well-established concept, due to the pioneering work of Nayfeh (see [15]) and others (e.g., [6]). This paper has expounded a somewhat different idea, namely, that the combination of resonances corresponding to different spatial modes of a structure can have surprising effects. We have illustrated our results for the canonical model of a straight, vertically mounted elastic column subject to simple sinusoidal parametric excitation. Nevertheless many of the results are likely to have profound implications for other continuous or multi-degree-of-freedom problems subject to parametric excitation.

Let us summarize the main findings. First we studied the undamped problem. The key idea has been to study the genuinely three-parameter problem and to think of *each* degree of freedom as providing a generalized Hill or Mathieu stability diagram in two parameters (B and ε). Each diagram has a buckling (zero-harmonic) instability and a resonance tongue corresponding to every possible multiple of a half-frequency of the drive. The third parameter (η) we think of as sliding each of these diagrams over one another, the result being that instabilities or resonance tongues corresponding to different modes pass through each other; i.e., they *interact*. See Figures 2.2 and 2.3.

Via multiple-scale asymptotic methods, backed up by numerical Floquet theory, we have studied each possible codimension-two interaction in detail. The cases of most interest are when the harmonic corresponding to each of the two tongues differs by unity, that is, in the notation of this paper, when $B_{\alpha,i} = B_{\alpha+1,j}$ for different spatial modes i and j. If $\alpha > 1$, then we have shown that the interaction occurs at first order in the asymptotic parameter ε, such that there is an $O(\varepsilon)$ gap between the two instability tongues, while the width of the tongues themselves remains $\ll O(\varepsilon)$ (see Figure 3.1). In fact, as can be seen from the numerically calculated Figure 2.3(a) in the case of tongues $(5/2,4)$ and $(1/2,2)$, it appears that no two tongues that both correspond to integer (or half-integer) α and β can cross each other, other than at $\varepsilon = 0$. There is always an interaction process where the boundary of one tongue evolves into the boundary of another with the consequent gap being $\ll O(\varepsilon)$ if $\beta \neq \alpha \pm 1$. In this problem, because the mode coupling is through a $\cos t$ term only, tongues where α and β are respectively half-integer and integer (corresponding to the existence of 4π-periodic and 2π-periodic motion, respectively) are unrelated and can pass through each other without interaction (see Figure 2.3).

We then dealt with two special cases. The first was when $\alpha = 1/2$. In this case, the leading-order resonance tongue interaction with modes for which $\beta = 3/2$ occurs

at the same order as the width of the tongue. This leads to the special shape of the two-parameter bifurcation diagram calculated and computed in Figure 3.2.

The second, and most important, special case we studied, in section 4, is when $\alpha = 0$, corresponding to a static buckling instability of the column. Here surprising things happen near η-values for which a pure harmonic instability $\beta = 1$ occurs for the same B-value when $\varepsilon = 0$. In particular we showed that the cosine boundary of the harmonic tongue and the buckling instability curve, which are both ordinarily quadratic in ε, undergo a singularity of their $O(\varepsilon^2)$ coefficients which we have resolved in a new form of asymptotic expansion. The result is the shapes of the instability regions shown in Figures 4.1 and 4.2, which have a large "blob" of stability above the line $B = B_{1,j}$ for $B < B_c$ and a corresponding area of instability below $B = B_{1,j}$ for $B > B_c$. It is this blob of stability which we claim explains the qualitative shape of the stability region in the curtain wire experiment reproduced in Figure 6.1(a).

To get qualitative agreement with the experiments, though, we found it necessary to include material damping. It is well known that linear damping lifts resonance tongues off from zero amplitude in Mathieu-type stability diagrams, and this problem is no exception (Figure 5.1). The key to understanding the experimental parameter regime, though, is to include damping in the interaction between the buckling instability and the harmonic resonance. This leads to the asymptotic results in section 6, which according to Figure 6.1(b) gives good quantitative agreement with the experiments.

Now, as remarked in the conclusions to our earlier papers, we are really only scratching at the surface of the complete nonlinear dynamics of a parametrically excited vertical column. In Part II we showed how to introduce a nonlinear formulation of the problem, which leads to a differential algebraic equation formulation, with the tension in the column acting as a Lagrange multiplier. Also, as remarked in [14], the curtain wire used in the experiment is anything but linearly elastic. Even for the one-degree-of-freedom simple pendulum under parametric excitation, the dynamics of the fully nonlinear system are remarkably rich [17]. For small amplitude nonlinear motion in a neighborhood of the codimension-two instabilities we study, one could presumably infer information on the presence of (both rotating and oscillating) periodic and quasi-periodic solutions from a center manifold and normal form approach, e.g., as in [7]. Yet, even for the linear problem we have studied we have not explored the implications of many finite-amplitude effects such as the "pinching off" of resonance tongues which seemed to occur as a consequence of the interaction between (α, i) and $(\alpha + 1, j)$ resonance tongues for $\alpha > 1$, as was remarked upon in section 3. There are also questions of rigor that we have not addressed. Even for one-degree-of-freedom parametrically excited systems, whether linear stability implies nonlinear stability is a nontrivial question [3]. There are also clearly small-divisor problems, and KAM theory may be able to shed some light; see, for example, the book [12] for infinite dimensional systems.

Nevertheless we hope that this paper has provided a rational and mathematically consistent explanation for the "upside down" stability of a wire under vertical excitation, previously reported in the popular media (e.g., [2]). More seriously, we have explained what we believe to be a new universal mechanism for creation of finite regions of stability (and instability) in parametrically excited systems. Importantly this does *not* involve subharmonic resonance, but rather the interaction of first-harmonic resonance with a steady-state instability.

Appendix A. The general solution at $O(\delta^2)$. Substituting the form (3.7) into the left-hand side of the $O(\delta^2)$ equation (3.5), we obtain

(A.1)
$$\begin{aligned}
&\frac{\lambda_n}{\alpha^2}\frac{\partial^2 u_2}{\partial t^2} + \mathrm{M}_0 u_2 \\
&\quad = \varepsilon_1 \frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_n \{f[\cos(\alpha+1)t + \cos(\alpha-1)t] + g[\sin(\alpha+1)t + \sin(\alpha-1)t]\} \\
&\qquad + \left\{\eta_1\alpha^2\phi_n f - \frac{2\lambda_n}{\alpha}\frac{\partial g}{\partial \tau_1}\phi_n - B_1\phi_n^{IV} f - \gamma_1\frac{\lambda_n}{\alpha}\phi_n^{IV} g\right\}\cos\alpha t \\
&\qquad + \left\{\eta_1\alpha^2\phi_n g + \frac{2\lambda_n}{\alpha}\frac{\partial f}{\partial \tau_1}\phi_n - B_1\phi_n^{IV} g + \gamma_1\frac{\lambda_n}{\alpha}\phi_n^{IV} f\right\}\sin\alpha t \\
&\qquad + \text{similar expressions with } \alpha \mapsto \beta,\ (f,g) \mapsto (d,e),\ n \mapsto m.
\end{aligned}$$

The particular integral for u_2 can in general be expressed as

(A.2)
$$\begin{aligned}
u_2 &= H_1\cos\alpha t + H_2\sin\alpha t + F_1\cos\beta t + F_2\sin\beta t \\
&\quad + H_3[f\cos(\alpha+1)t + g\sin(\alpha+1)t] + H_4[f\cos(\alpha-1)t + g\sin(\alpha-1)t] \\
&\quad + F_3[d\cos(\beta+1)t + e\sin(\beta+1)t] + F_4[d\cos(\beta-1)t + e\sin(\beta-1)t],
\end{aligned}$$

where

$$M_0H_1 - \lambda_n H_1 = (\eta_1\alpha^2\phi_n - B_1\phi_n^{IV})f - \frac{2\lambda_n}{\alpha}\phi_n\frac{\partial g}{\partial\tau_1} - \gamma_1\frac{\lambda_n}{\alpha}\phi_n g, \tag{A.3}$$

$$M_0H_2 - \lambda_n H_2 = (\eta_1\alpha^2\phi_n - B_1\phi_n^{IV})g + \frac{2\lambda_n}{\alpha}\phi_n\frac{\partial f}{\partial\tau_1} + \gamma_1\frac{\lambda_n}{\alpha}\phi_n f, \tag{A.4}$$

$$M_0H_3 - \frac{\lambda_n(\alpha+1)^2}{\alpha^2}H_3 = \varepsilon_1\frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_n, \tag{A.5}$$

$$M_0H_4 - \frac{\lambda_n(\alpha-1)^2}{\alpha^2}H_4 = \varepsilon_1\frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_n, \tag{A.6}$$

$$M_0F_1 - \lambda_m F_1 = (\eta_1\beta^2\phi_m - B_1\phi_m^{IV})d - \frac{2\lambda_m}{\beta}\phi_m\frac{\partial e}{\partial\tau_1} - \gamma_1\frac{\lambda_m}{\beta}\phi_m e, \tag{A.7}$$

$$M_0F_2 - \lambda_m F_2 = (\eta_1\alpha^2\phi_m - B_1\phi_m^{IV})e + \frac{2\lambda_m}{\beta}\phi_m\frac{\partial d}{\partial\tau_1} + \gamma_1\frac{\lambda_m}{\beta}\phi_m d, \tag{A.8}$$

$$M_0F_3 - \frac{\lambda_n(\beta+1)^2}{\alpha^2}F_3 = \varepsilon_1\frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_m, \tag{A.9}$$

$$M_0F_4 - \frac{\lambda_n(\beta-1)^2}{\alpha^2}F_4 = \varepsilon_1\frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_m. \tag{A.10}$$

Appendix B. Trivial solution at $O(\varepsilon^2)$. We assume $\alpha, \beta \neq 1/2$. (The case $\alpha = 1/2$ leads to the fact that the $\sin(\alpha-1)t$ and $\cos(\alpha-1)t$ terms are included in the equations for the $\sin\alpha t$ and $\cos\alpha t$ coefficients so that the function H_4 is combined with functions H_1 and H_2). The solvability condition then gives the linear terms in $B_1^{\pm}$ given by (2.20). So, assuming

$$\alpha, \beta \geq 1, \tag{B.1}$$

we find that (A.5) and (A.6) have unique bounded solutions. The solvability condition comes from demanding that the right-hand sides of (A.3) and (A.4) should be orthogonal to ϕ_n, and the right-hand sides of (A.7) and (A.8) orthogonal to ϕ_m, which are eigenfunctions of the respective left-hand side operators. Hence, using the orthonormality of ϕ_n and ϕ_m, we obtain

$$\frac{\partial g}{\partial \tau_1} - (\eta_1\alpha^2 - B_1\langle\phi_n'', \phi_n''\rangle)\frac{\alpha}{2\lambda_n} f = 0, \tag{B.2}$$

$$\frac{\partial f}{\partial \tau_1} + (\eta_1\alpha^2 - B_1\langle\phi_n'', \phi_n''\rangle)\frac{\alpha}{2\lambda_n} g = 0, \tag{B.3}$$

$$\frac{\partial e}{\partial \tau_1} - (\eta_1\beta^2 - B_1\langle\phi_m'', \phi_m''\rangle)\frac{\beta}{2\lambda_m} d = 0, \tag{B.4}$$

$$\frac{\partial d}{\partial \tau_1} + (\eta_1\beta^2 - B_1\langle\phi_m'', \phi_m''\rangle)\frac{\beta}{2\lambda_m} e = 0. \tag{B.5}$$

These four equations can be simplified to read that f and g must both satisfy the equation

$$\frac{\partial^2 f}{\partial \tau_1^2} = -K_\alpha^2 f, \tag{B.6}$$

and both d and e satisfy

$$\frac{\partial^2 e}{\partial \tau_1^2} = -K_\beta^2 e, \tag{B.7}$$

where

$$K_\alpha = (\eta_1\alpha^2 - B_1\langle\phi_n'', \phi_n''\rangle)\frac{\alpha}{2\lambda_n}, \qquad K_\beta = (\eta_1\beta^2 - B_1\langle\phi_m'', \phi_m''\rangle)\frac{\beta}{2\lambda_m}. \tag{B.8}$$

We are looking for stability boundaries, that is, where the functions f, g, d, and e have neutrally stable solutions. Thinking of η as fixed, we find from (B.6)–(B.7) that this happens for an isolated B_1-value for each of (B.6) and (B.7), given by $K_\alpha = 0$ and $K_\beta = 0$, respectively.

Appendix C. The $O(\varepsilon^3)$ equation. Assuming that (B.1) holds and (3.10) is not satisfied, so that (3.9) holds, the $O(\varepsilon^2)$ solution to (3.6) is given by (A.2), where f, g, d, and e are all independent of τ_1. Substitution of this form for u_2 into (3.6) yields

$$\begin{aligned}
&\frac{\lambda_n}{\alpha^2}\frac{\partial^2 u_3}{\partial t^2} + \mathrm{M}_0 u_3 \\
&\quad = \cos(\alpha-2)t\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_4 f \; + \sin(\alpha-2)t\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_4 g \\
&\qquad + \cos(\alpha-1)t\left\{\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_1 f + \eta_1(\alpha_1-1)^2 H_4 f - B_1 H_4^{IV} f + \frac{1}{2}\eta_2 \mathrm{L}\phi_n f\right\} \\
&\qquad + \sin(\alpha-1)t\left\{\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_2 g + \eta_1(\alpha-1)^2 H_4 g - B_1 H_4^{IV} g + \frac{1}{2}\eta_2 \mathrm{L}\phi_n g\right\} \\
&\qquad + \cos\alpha t\left\{\frac{\lambda_n}{2\alpha^2}(\mathrm{L}H_3 + \mathrm{L}H_4) f + \eta_1\alpha^2 H_1 f - B_1 H_1^{IV}\right. \\
&\qquad\qquad \left. + \eta_2\alpha^2\phi_n f - 2\frac{\lambda_n}{\alpha}\phi_n\frac{\partial g}{\partial \tau_2} - B_2\phi_n^{IV} f\right\}
\end{aligned}$$

$$
\begin{aligned}
&+\sin\alpha t\left\{\frac{\lambda_n}{2\alpha^2}(\mathrm{L}H_3 g+\mathrm{L}H_4 g)+\eta_1\alpha^2 H_2 g-B_1 H_2^{IV} g+\eta_2\alpha^2\phi_n g\right.\\
&\qquad\left.+\frac{2\lambda_n}{\alpha}\phi_n\frac{\partial f}{\partial\tau_2}-B_2\phi_n^{IV} g\right\}\\
&+\cos(\alpha+1)t\left\{\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_1 f+\eta_1(\alpha+1)^2 H_3 f-B_1 H_3^{IV} f+\frac{1}{2}\eta_2\mathrm{L}\phi_n f\right\}\\
&+\sin(\alpha+1)t\left\{\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_2 g+\eta_1(\alpha+1)^2 H_3 g-B_1 H_3^{IV} g+\frac{1}{2}\eta_2\mathrm{L}\phi_n g\right\}\\
&+\cos(\alpha+2)t\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_3 f\ +\sin(\alpha+2)t\frac{\lambda_n}{2\alpha^2}\mathrm{L}H_3 g \qquad \text{(C.1)}\\
&+\text{similar expressions with } \alpha\mapsto\beta,\quad (f,g)\mapsto(d,e),\quad n\mapsto m,\quad H_i\mapsto F_i.
\end{aligned}
$$

Appendix D. Codimension-one resonance; derivation of (2.17). In order to obtain the "linearized" results from Parts I and II, valid for undistinguished values of η, we drop all of the β terms in the above and set $\lambda_n/\alpha=\eta$. This describes the asymptotics of resonance tongues away from their codimension-two interactions. Furthermore we set $\eta=\lambda_n/\alpha^2$; i.e., $\eta_1=\eta_2=\cdots 0$. Failure to do this will result in the corrections (2.16) for the η-values that define the resonance condition as B_0 varies. From (3.9) we have, provided $\alpha\neq 1/2$, that $B_1=0$. Consider now the α-dependent terms of (C.1). The solvability condition at this level is that the coefficients of $\cos\alpha t$ and $\sin\alpha t$ must be orthogonal to the eigenfunction ϕ_n. Now, provided that we do *not* satisfy

$$
\alpha\pm 1=\pm\alpha\quad\text{or}\quad\alpha\pm 2=\pm\alpha,\quad\text{i.e., }\alpha=\frac{1}{2}\text{ or }1, \tag{D.1}
$$

this leads to the conditions (making use of (2.10), (2.11))

$$
\frac{\partial f}{\partial\tau_2}=\left[\frac{B_2\alpha}{2\lambda_n}\langle\phi_n'',\phi_n''\rangle-\frac{1}{4\alpha}(\langle\phi_n,\mathrm{L}H_3\rangle+\langle\phi_n,\mathrm{L}H_4\rangle)\right]g, \tag{D.2}
$$

$$
\frac{\partial g}{\partial\tau_2}=-\left[\frac{B_2\alpha}{2\lambda_n}\langle\phi_n'',\phi_n''\rangle-\frac{1}{4\alpha}(\langle\phi_n,\mathrm{L}H_3\rangle+\langle\phi_n,\mathrm{L}H_4\rangle)\right]f. \tag{D.3}
$$

Like (B.2) and (B.3), these equations can be expressed more simply by saying that both f and g satisfy

$$
\frac{\partial f^2}{\partial\tau^2}=-K^2 f,\quad\text{where } K=\frac{B_2\alpha}{2\lambda_n}\langle\phi_n'',\phi_n''\rangle-\frac{1}{4\alpha}(\langle\phi_n,\mathrm{L}H_3\rangle+\langle\phi_n,\mathrm{L}H_4\rangle).
$$

Hence solutions are bounded, apart from at the single neutral stability point $K=0$ given by

$$
B_2=\frac{\lambda_n}{2\alpha^2}\,\frac{\langle\phi_n,\mathrm{L}H_3\rangle+\langle\phi_n,\mathrm{L}H_4\rangle}{\langle\phi_n'',\phi_n''\rangle}. \tag{D.4}
$$

This shows that the width of the resonance tongue is not resolved at this level, but both boundaries of the tongue have the same quadratic coefficient $B_2\varepsilon^2$ given by (D.4).

Now suppose that one of (D.1) *is* satisfied. Consider first $\alpha = 1/2$, which case we have already shown leads to a nontrivial width of resonance tongue at $O(\varepsilon)$: $B = B_0 + \varepsilon B_1^{\pm} + O(\varepsilon^2)$. From the $O(\varepsilon^3)$ equation (C.1), we see that the coefficient of $\cos(\alpha-1)t$ must be added to that of $\cos\alpha t$ when seeking the orthogonality condition, and similarly the coefficient of $\sin(\alpha-1)t$ must be *subtracted* from that of $\sin\alpha t$. This will lead to different equations for B_2 and separate nontrivial corrections to the two boundaries of the resonance tongue $B = B_0 + \varepsilon B_1^{\pm} + \varepsilon^2 B_2^{\pm} + O(\varepsilon^3)$.

Consider now $\alpha = 1$. Here the coefficient of $\cos(\alpha-2)t$ in (C.1) must be added to that of $\cos\alpha t$ when seeking the orthogonality condition, and similarly the coefficient of $\sin(\alpha-2)t$ must be *subtracted* from that of $\sin\alpha t$. This will lead to different equations for B_2 and separate nontrivial corrections to the two boundaries corresponding to $\cos\alpha t$ and $\sin\alpha t$. In fact, it is easy to see that we get $B = B_0 + \varepsilon^2 B_2^{\pm}$, where $B_2^{\pm}$ are given by (2.21), (2.22) with $\eta = \lambda_n$.

Returning to the general case $\alpha \neq 1/2$ or 1, suppose we carry out the expansion to $O(\varepsilon^4)$. We would then get contributions to the particular integral u_4 from terms which come from the expansion of

$$\left\{ \begin{array}{c} \cos \\ \sin \end{array} \right\}(\alpha \pm 1)t \cdot \cos t \quad \text{and} \quad \left\{ \begin{array}{c} \cos \\ \sin \end{array} \right\}(\alpha \pm 2)t \cdot \cos t,$$

which we lead to terms proportional to

$$\left\{ \begin{array}{c} \cos \\ \sin \end{array} \right\}(\alpha \pm 3)t.$$

Therefore, provided we do *not* satisfy

$$\alpha \pm 3 = \pm\alpha, \quad \text{i.e., } \alpha = 3/2 \text{ (since } \alpha > 0),$$

then the orthogonality condition applied to the $\sin\alpha t$ and $\cos\alpha t$ equations leads to a unique condition for B_3, which is third-order correction to both resonance tongues $B = B_0 + \varepsilon^2 B_2 + \varepsilon^3 B_3$. If, however, $\alpha = 3/2$, then we get a different contribution from the $\sin(\alpha-3)t$ and $\cos(\alpha-3)t$ terms, leading to nonequal corrections $B_3^{\pm}$. Hence the first nontrivial width of the resonance tongue is $O(\varepsilon^3)$.

Extrapolating this argument we see that the first nontrivial width of any resonance tongue is always at $O(\varepsilon^{2\alpha})$, and we recover the general expression (2.17). The asymptotic procedure we have developed can in principle calculate all the coefficients B_j, $j = 2, \ldots, 2\alpha - 1$, and $B_{2\alpha}^{\pm}$ for any arbitrary half-integer α, but the expressions become rather cumbersome beyond $O(\varepsilon^3)$.

Appendix E. Neutral curves for $O(\varepsilon^2)$ interaction. The assumption $\beta = \alpha + 1$ leads to the contradiction that the $O(\varepsilon^2)$ solvability condition equation (A.10) has a solution that is an eigenfunction, but the right-hand side is not orthogonal to ϕ_m. Instead we must combine F_4 (which is the coefficient of $d\cos(\beta-1)t$ and $e\sin(\beta-1)t$) into the functions H_1 and H_2 via

$$\tilde{H}_1 = H_1 + F_4, \qquad \tilde{H}_2 = H_2 + F_4.$$

Then $\tilde{H}_1$ and $\tilde{H}_2$ satisfy

$$M_0\tilde{H}_1 - \lambda_n\tilde{H}_1 = \eta_1\alpha^2\phi_n f - B_1\phi_n^{IV} f + \frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_m d - \frac{\partial g}{\partial \tau_1}\left(\frac{2\lambda_n}{\alpha}\phi_n\right), \tag{E.1}$$

$$M_0\tilde{H}_2 - \lambda_n\tilde{H}_2 = \eta_1\alpha^2\phi_n g - B_1\phi_n^{IV} g + \frac{\lambda_n}{2\alpha^2}\mathrm{L}\phi_m e + \frac{\partial f}{\partial \tau_1}\left(\frac{2\lambda_n}{\alpha}\phi_n\right). \tag{E.2}$$

Similarly, the term H_3 proportional to $f\cos(\alpha+1)t$ and $g\sin(\alpha+1)t$ must be added to the functions F_1 and F_2 via

$$\tilde{F}_1 = F_1 + H_3, \qquad \tilde{F}_2 = F_2 + H_3,$$

where $\tilde{F}_1$ and $\tilde{F}_2$ satisfy

$$M_0\tilde{F}_1 - \lambda_m\tilde{F}_1 = \eta_1\beta^2\phi_m d - B_1\phi_m^{IV}d + \frac{\lambda_m}{2\beta^2}\mathrm{L}\phi_n f - \frac{\partial e}{\partial\tau_1}\left(\frac{2\lambda_m}{\beta}\phi_m\right), \tag{E.3}$$

$$M_0\tilde{F}_2 - \lambda_m\tilde{F}_2 = \eta_1\alpha^2\phi_m e - B_1\phi_m^{IV}e + \frac{\lambda_m}{2\beta^2}\mathrm{L}\phi_n g + \frac{\partial d}{\partial\tau_1}\left(\frac{2\lambda_m}{\beta}\phi_m\right). \tag{E.4}$$

The solvability condition is now that the right-hand sides of (E.1) and (E.2) should both be orthogonal to ϕ_n and that the right-hand sides of (E.3) and (E.4) should be orthogonal to ϕ_m. This gives

$$\frac{\partial g}{\partial\tau_1} - \frac{\alpha}{2\lambda_n}(\eta_1\alpha^2 - B_1\langle\phi_n'',\phi_n''\rangle)f - \frac{1}{4\alpha}\langle\phi_n,\mathrm{L}\phi_m\rangle d = 0, \tag{E.5}$$

$$\frac{\partial f}{\partial\tau_1} + \frac{\alpha}{2\lambda_n}(\eta_1\alpha^2 - B_1\langle\phi_n'',\phi_n''\rangle)g + \frac{1}{4\alpha}\langle\phi_n,\mathrm{L}\phi_m\rangle e = 0, \tag{E.6}$$

$$\frac{\partial e}{\partial\tau_1} - \frac{(\alpha+1)}{2\lambda_m}(\eta_1(\alpha+1)^2 - B_1\langle\phi_m'',\phi_m''\rangle)d - \frac{1}{4(\alpha+1)}\langle\phi_n,\mathrm{L}\phi_m\rangle f = 0, \tag{E.7}$$

$$\frac{\partial d}{\partial\tau_1} + \frac{(\alpha+1)}{2\lambda_m}(\eta_1(\alpha+1)^2 - B_1\langle\phi_m'',\phi_m''\rangle)e + \frac{1}{4(\alpha+1)}\langle\phi_n,\mathrm{L}\phi_m\rangle g = 0. \tag{E.8}$$

From the form of these equations we note that they are expressible as a system

$$\frac{\partial x}{\partial\tau_1} = A(x), \quad \text{where } x = \begin{bmatrix} f \\ d \\ g \\ e \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 0 & -a_1 & -a_2 \\ 0 & 0 & -a_3 & -a_4 \\ a_1 & a_2 & 0 & 0 \\ a_3 & a_4 & 0 & 0 \end{bmatrix},$$

with

$$\begin{aligned} a_1 &= \frac{\alpha}{2\lambda_n}(\eta_1\alpha^2 - B_1\langle\phi_n'',\phi_n''\rangle), \qquad a_2 = \frac{1}{4\alpha}\langle\mathrm{L}\phi_m,\phi_n\rangle, \\ a_3 &= \frac{1}{4(\alpha+1)}\langle\mathrm{L}\phi_m,\phi_n\rangle, \qquad a_4 = \frac{(\alpha+1)}{2\lambda_m}(\eta_1(\alpha+1)^2 - B_1\langle\phi_m'',\phi_m''\rangle). \end{aligned} \tag{E.9}$$

From the form of A we conclude that its eigenvalues are all double and purely imaginary unless

$$a_1a_4 - a_2a_3 = 0. \tag{E.10}$$

Hence the zero solution to the system (E.5)–(E.8) is stable unless we sit precisely on this neutral stability curve defined by (E.10). The fact that all eigenvalues of A are then zero implies that (E.10) is the neutral stability condition for both the cosine mode (corresponding to coefficients f and d) and the sine mode (with coefficients g and e). Hence at this $O(\varepsilon)$ level the resonance tongue has zero width.

It remains to express the neutral stability condition as a curve in the (B_1,η_1)-plane. Substitution of (E.9) into (E.10) results in (3.12), where we have used $\lambda_m = \lambda_n(\alpha+1)^2/\alpha^2$.

Finally, we treat the special case where $\alpha = 1/2$, $\beta = 3/2$. Here, we find that the term $H_3 f \cos(\alpha+1)$ in (A.2) must be added to $\tilde{H}_1$, and the term $H_3 g \sin(\alpha+1)$ subtracted from $\tilde{F}_1$. Hence the solvability condition becomes

$$\frac{\partial g}{\partial \tau_1} - \left(\frac{\eta_1}{16\lambda_n} - \frac{B_1\langle \phi_n'', \phi_n''\rangle}{4\lambda_n} + \frac{\langle \phi_n, \mathrm{L}\phi_n\rangle}{2} \right) f - \frac{\langle \phi_m, \mathrm{L}\phi_n\rangle}{2} d = 0, \tag{E.11}$$

$$\frac{\partial f}{\partial \tau_1} + \left(\frac{\eta_1}{16\lambda_n} - \frac{B_1\langle \phi_n'', \phi_n''\rangle}{4\lambda_n} - \frac{\langle \phi_n, \mathrm{L}\phi_n\rangle}{2} \right) g + \frac{\langle \phi_m, \mathrm{L}\phi_n\rangle}{2} e = 0, \tag{E.12}$$

$$\frac{\partial e}{\partial \tau_1} - \left(\frac{9\eta_1}{48\lambda_n} - \frac{B_1\langle \phi_m'', \phi_m''\rangle}{12\lambda_n} \right) d - \frac{\langle \phi_m, \mathrm{L}\phi_n\rangle}{6} f = 0, \tag{E.13}$$

$$\frac{\partial d}{\partial \tau_1} + \left(\frac{9\eta_1}{48\lambda_n} - \frac{B_1\langle \phi_n'', \phi_n''\rangle}{12\lambda_n} \right) e + \frac{\langle \phi_m, \mathrm{L}\phi_n\rangle}{6} g = 0. \tag{E.14}$$

The neutral mode solution of this equation can be written similarly to (E.10) in the form

$$9(a_1 \pm a_5)a_4 - a_2 a_3 = 0, \quad \text{where } a_5 = \frac{\langle \phi_n, \mathrm{L}\phi_n\rangle}{2}, \tag{E.15}$$

$a_1, \ldots, a_4$ are given by (E.9), and the sign "+" corresponds to the cosine mode and "−" to the sine mode. Expanding (E.15), we obtain the pair of loci in the (B_1, η_1)-plane given by (3.13).

Appendix F. Neutral curves for the first-harmonic buckling interaction. When the solution (4.1) is substituted into the right-hand side of the $O(\varepsilon^2)$ equation (3.5), the result is

$$\begin{aligned} \lambda_n \frac{\partial^2 u_2}{\partial t^2} + \mathrm{M}_0 u_2 = {} & \frac{1}{2}\lambda_n [f(1+\cos 2t) + g \sin 2t] \mathrm{L}\phi_n - B_1 h \phi_c^{IV} \\ & + \left[\left(\eta_1 f - 2\lambda_n \frac{\partial g}{\partial \tau_1} \right) \phi_n + \lambda_n h \mathrm{L}\phi_c - B_1 f \phi_n^{IV} \right] \cos t \\ & + \left[\left(\eta_1 g + 2\lambda_n \frac{\partial f}{\partial \tau_1} \right) \phi_n - B_1 g \phi_n^{IV} \right] \sin t. \end{aligned} \tag{F.1}$$

The particular integral of (F.1) is

$$\begin{aligned} u_2 = \{ & H_0(s, \tau_1, \tau_2) + H_1(s, \tau_1, \tau_2) \cos t + H_2(s, \tau_1, \tau_2) \sin t \\ & + H_3(s)(f \cos 2t + g \sin 2t)\}, \end{aligned} \tag{F.2}$$

where

$$\mathrm{M}_0 H_0 = \frac{1}{2}\lambda_n f \mathrm{L}\phi_n - B_1 h \phi_c^{IV}, \tag{F.3}$$

$$\mathrm{M}_0 H_1 - \lambda_n H_1 = -\left(2\lambda_n \frac{\partial g}{\partial \tau_1} - \eta_1 f \right) \phi_n + \lambda_n h \mathrm{L}\phi_c - B_1 f \phi_n^{IV}, \tag{F.4}$$

$$\mathrm{M}_0 H_2 - \lambda_n H_2 = \left(2\lambda_n \frac{\partial f}{\partial \tau_1} + \eta_1 g \right) \phi_n - B_1 g \phi_n^{IV}, \tag{F.5}$$

$$\mathrm{M}_0 H_3 - 4\lambda_n H_3 = \frac{1}{2}\lambda_n \mathrm{L}\phi_n, \tag{F.6}$$

and H_0, H_1, H_2, and H_3 must satisfy boundary conditions (2.8). Applying orthogonality with respect to ϕ_c to the right-hand side of (F.3), we obtain

$$\frac{1}{2}\lambda_n\langle\phi_c, \mathrm{L}\phi_n\rangle f - B_1\langle\phi_c'', \phi_c''\rangle h = 0,$$

which, using (2.11), we can rewrite as

$$h = -\left(\frac{\lambda_n B_c\langle\phi_n'', \phi_c''\rangle}{2B_1\langle\phi_c'', \phi_c''\rangle}\right) f := -\frac{G_n}{B_1} f. \tag{F.7}$$

Applying orthogonality with respect to ϕ_m to the right-hand sides of (F.4) and (F.5) yields

$$\frac{\partial g}{\partial \tau_1} - \left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'', \phi_n''\rangle}{2\lambda_n} + \frac{\lambda_n B_c^2\langle\phi_n'', \phi_c''\rangle^2}{4B_1\langle\phi_c'', \phi_c''\rangle}\right) f = 0, \tag{F.8}$$

$$\frac{\partial f}{\partial \tau_1} + \left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'', \phi_n''\rangle}{2\lambda_n}\right) g = 0. \tag{F.9}$$

Thus f and g both satisfy the differential equation

$$\frac{\partial^2 f}{\partial \tau_1^2} + \left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'', \phi_n''\rangle}{2\lambda_n}\right)\left(\frac{\eta_1}{2\lambda_n} - \frac{B_1\langle\phi_n'', \phi_n''\rangle}{2\lambda_n} + \frac{\lambda_n B_c^2\langle\phi_n'', \phi_c''\rangle^2}{4B_1\langle\phi_c'', \phi_c''\rangle}\right) f = 0. \tag{F.10}$$

The condition for this equation to have bounded sinusoidal solutions on time scale τ_1 is given by (4.2).

Appendix G. The $O(\varepsilon^3)$ correction to the boundary $\sigma_1 = 0$. On this boundary $f \equiv 0$ so that $h \equiv 0$ by (F.7), and $g = g(\tau_2)$. The right-hand sides of (F.3) and (F.4) are zero in this case so that H_0 and H_1 are proportional to ϕ_c and ϕ_n, respectively. Thus, this part of the $O(\varepsilon^2)$ solution can be absorbed into the $O(\varepsilon)$ solution, and without loss of generality we can set $H_0 = H_1 \equiv 0$. The solution (F.2) can now be written as

$$\left.\begin{aligned} u_1 &= \phi_n(s)\sin t\, g(\tau_2), \\ u_2 &= \{H_2(s)\sin t + H_3(s)\sin 2t\} g(\tau_2), \end{aligned}\right\} \tag{G.1}$$

where $H_3(s)$ is the solution of (F.6) and H_2 satisfies (F.5) with $f = 0$ and the relationship (4.3) holding between B_1 and η_1 in order to ensure orthogonality of the right-hand side to the eigenfunction ϕ_n of the operator on the left.

When the form (G.1) is substituted into the right-hand side of (3.6) one obtains

$$\begin{aligned} &\lambda_n\frac{\partial^2 u_3}{\partial t^2} + \mathrm{M}_0 u_3 \\ &\quad = \left\{\frac{1}{2}\lambda_n \mathrm{L}H_3 + \eta_1\left(H_2 - \frac{1}{\langle\phi_n'', \phi_n''\rangle} H_2^{IV}\right) + \eta_2\phi_n - B_2\phi_n^{IV}\right\} g(\tau_2)\sin t \\ &\qquad -2\lambda_n\phi_n\frac{\partial g}{\partial \tau_2}\cos t + \text{terms involving } \sin 2t \text{ and } \sin 3t, \end{aligned} \tag{G.2}$$

where (4.3) has been used to eliminate B_1 in favor of η_1 from the above equations. Finally, when we require that the right-hand side of this equation be orthogonal to the ϕ_m, we see that g must be independent of τ_2 and that

$$B_2 = \frac{1}{2}\lambda_n\frac{\langle\phi_n, \mathrm{L}H_3\rangle}{\langle\phi_n'', \phi_n''\rangle} - \eta_1\frac{\langle\phi_n, \mathrm{L}H_2\rangle}{\langle\phi_n'', \phi_n''\rangle^2} + \frac{\eta_2}{\langle\phi_n'', \phi_n''\rangle}. \tag{G.3}$$

Note that $\langle \phi_n, H_2 \rangle = 0$ has been used to obtain this result.

From these results the shape of this stability boundary in the space of the original variables B, η, ε in the neighborhood of the singular point $(B_c, \lambda_n, \varepsilon = 0)$ can be constructed as follows.

First, note that from the second power series in (3.3) we may write

$$\begin{aligned} \varepsilon\eta_1 &= (\eta - \lambda_n) - \varepsilon^2\eta_2 + O(\varepsilon^3), \\ \varepsilon^2\eta_1 &= \varepsilon(\eta - \lambda_n) + O(\varepsilon^3). \end{aligned}$$

Now, when these expressions for $\varepsilon\eta_1$ and $\varepsilon^2\eta_1$ are substituted into the above expressions for B_1 and B_2 and the results are substituted into the third series in (3.3), we obtain (4.5).

Appendix H. The $O(\varepsilon^3)$ correction to the boundary $\sigma_2 = 0$. On this boundary $g \equiv 0$, $f = f(\tau_2)$, and

$$h(\tau_2) = -\frac{\lambda_n B_c \langle \phi_n'', \phi_c'' \rangle}{2B_1 \langle \phi_c'', \phi_c'' \rangle} f(\tau_2) := -\frac{G_n}{B_1} f(\tau_2). \tag{H.1}$$

We require the solution to $O(1)$ even as $B_1 \to 0$ or ∞. Hence we set

$$k(\tau_2) := \sqrt{f^2 + g^2}, \quad \text{so that } f = \frac{B_1}{K_n} k, \qquad h = \frac{-G_n}{K_n} k, \quad \text{where } K_n = \sqrt{B_1^2 + G_n^2}.$$

Also by reasoning similar to that above we may set $H_2 \equiv 0$ so that on this boundary we have

$$\left.\begin{aligned} u_1 &= (-G_n \phi_c(s) + B_1 \phi_n(s) \cos t) \frac{k(\tau_2)}{K_n}, \\ u_2 &= \{H_0(s) + H_1(s) \cos t + H_3(s) \cos 2t\} k(\tau_2), \end{aligned}\right\} \tag{H.2}$$

where in this case

$$\mathrm{M}_0 H_0 = \frac{B_1}{K_n} \left(\frac{1}{2} \lambda_n \mathrm{L}\phi_n + G_n \phi_c^{IV} \right), \tag{H.3}$$

$$\mathrm{M}_0 H_1 - \lambda_n H_1 = \frac{1}{K_n} (\eta_1 B_1 \phi_n - \lambda_n G_n \mathrm{L}\phi_c - B_1^2 \phi_n^{IV}), \tag{H.4}$$

$$\mathrm{M}_0 H_3 - 4\lambda_n H_3 = \frac{B_1 \lambda_n}{2K_n} \mathrm{L}\phi_n. \tag{H.5}$$

When the results (H.2) are substituted into the right-hand side of (3.6) we obtain

$$\begin{aligned} \lambda_n \frac{\partial^2 u_3}{\partial t^2} + \mathrm{M}_0 u_3 = &\left\{ \frac{1}{2} \lambda_n \mathrm{L} H_1 + \frac{B_1}{2K_n} \eta_1 \mathrm{L}\phi_n - B_1 H_0^{IV} + B_2 \frac{G_n}{K_n} \phi_c^{IV} \right\} k(\tau_2) \\ &+ \left\{ \lambda_n \left(\mathrm{L} H_0 + \frac{1}{2} \mathrm{L} H_3 \right) + \eta_1 \left(H_1 - \frac{G_n}{K_n} \mathrm{L}\phi_c \right) \right. \\ &\left. - B_1 H_1^{IV} + \frac{B_1}{K_n} \eta_2 \phi_n - \frac{B_1}{K_n} B_2 \phi_n^{IV} \right\} k(\tau_2) \cos t \\ &+ 2\lambda_n \phi_n \frac{B_1}{K_n} \frac{\partial k}{\partial \tau_2} \sin t + \text{ terms involving } \cos 2t \text{ and } \cos 3t. \end{aligned} \tag{H.6}$$

Applying orthogonality conditions to the various groups of terms on the right-hand side of this equation, we see that f is independent of τ_2 and hence obtain the expressions (4.6) and (4.7).

Appendix I. Matching to the codimension-one results. We consider the expression (4.9) in the two limits (i) $B_1 \to 0$ (and hence $|\hat{\eta}_1| \gg 1$, but $\ll 1/\varepsilon$) and (ii) $B_1 \gg 1$ (and hence $\hat{\eta}_1 \to 0$, but $B_1 \ll 1/\varepsilon$).

(i) Consider first $B_1 \to 0$. Taking B_1 as a small parameter, then (4.8) shows $\hat{\eta_1} = O(1/B_1)$. The leading-order term of (4.9) we then find to be in the B_2-direction and to be given by

$$\tilde{B}_2 = B_2 - \hat{\eta}_2 \frac{B_1}{\hat{\eta}_1} = -\frac{\lambda_n}{2}\langle \phi_c, \mathrm{L}H_1\rangle - (1+B_c)G_n\langle \phi_c'', \phi_n''\rangle + O(B_1), \tag{I.1}$$

where H_1 satisfies

$$\mathrm{M}_0 H_1 - \lambda_n H_1 = -2\lambda_n B_c \langle \phi_n'', \phi_c''\rangle \phi_n - \lambda_n \mathrm{L}\phi_c + O(B_1^2). \tag{I.2}$$

Now we are interested in matching to the asymptotics of the pure falling-over instability, away from the codimension-two interaction, for which ϕ_m is not a resonant mode. Setting ϕ_m to zero in (I.1) and (I.2) we obtain precisely (dropping the tilde)

$$B_2 = \frac{\lambda_n}{2}\frac{\langle \mathrm{L}H_1, \phi_c\rangle}{\langle \phi_c'', \phi_c''\rangle},$$

which is precisely the boundary B_2^+ defined by (2.21) (with η replaced by its $O(1)$ value λ_m, for the same function H_1, where now ϕ_m is called ϕ_c). Hence we recover the correct asymptotic expression well away from the resonance tongue interaction.

(ii) Now consider $B_1 \gg 1$. Then (4.8) shows $\hat{\eta}_1 = O(1/B_1)$. Then we find the leading-order term of (4.9) to be in the $\hat{\eta}$-direction and to be given by

$$\tilde{\hat{\eta}}_2 = \hat{\eta}_2 + O(1/B_1),$$

where $\hat{\eta}_2$ is given by the right-hand side of (4.7) without the B_2-term. Now, to match to the limit of just the $(1,n)$ resonance, away from its interaction with the falling-over instability, we must set $\phi_c = 0$, since this is no longer resonant, and also set $H_1 = 0$, since it is now resonant (it defines the coefficient of $\cos t$) and therefore can be subsumed into the $O(1)$ solution. We then obtain to leading order that (dropping tildes)

$$\hat{\eta}_2 = \eta_2 - B_2\langle \phi_n'', \phi_n''\rangle = -\lambda_n\left(\langle \mathrm{L}H_0, \phi_n\rangle + \frac{1}{2}\langle LH_3, \phi_n\rangle\right).$$

Hence, allowing η_2 to be zero, to model the codimension-one case, we get

$$B_2 = \frac{2\lambda_n}{\langle \phi_n'', \phi_n''\rangle}(2\langle \mathrm{L}H_0, \phi_n\rangle + \langle LH_3, \phi_n\rangle),$$

where now

$$\mathrm{M}_0 H_3 - 4\lambda_n H_3 = \frac{\lambda_n}{2}\mathrm{L}\phi_n,$$
$$\mathrm{M}_0 H_0 = \frac{\lambda_n}{2}\mathrm{L}\phi_n.$$

Hence we see that this is identical to that defined by (2.21) (with H_4 now called H_0), and we obtain perfect matching in this case also.

BOUNDS AND EXTREMAL CONFIGURATIONS FOR THE TORSIONAL RIGIDITY OF COATED FIBER REINFORCED SHAFTS*

ROBERT LIPTON† AND TUNGYANG CHEN‡

Abstract. In this paper we derive bounds on the torsional rigidity for coated fiber reinforced shafts. The bounds are used to assess the optimality or suboptimality of fiber reinforcement configurations. This investigation focuses on coated fiber reinforcements with circular cross section. It is shown how the effective antiplane shear modulus and torsional rigidity of each coated fiber are used to determine whether the configuration provides reinforcement above or below that of a homogeneous shaft containing no coated fibers. Simply connected shaft cross sections of arbitrary shape reinforced with any configuration of coated fibers are considered. Precise conditions on the effective antiplane shear modulus and torsional rigidity of each coated fiber are given under which the circular shaft reinforced with a single centered circular coated fiber is either optimal or suboptimal.

Key words. torsion, coated fibers

1. Introduction.

The problem of extremizing the torsional rigidity of prismatic shafts has been the focus of many investigations. For homogeneous shafts made from elastically isotropic material, de Saint-Venant [10] proposed that among all prismatic shafts with a given cross-sectional area that the greatest torsional rigidity is obtained by a shaft with a circular cross section. This proposition was proven by Polya [7]. For multiply connected cross sections of a given cross-sectional area, Polya and Weinstein [8] showed that the optimal cross section is given by the annulus. Alvino and Trombetti [1] considered composite shaft cross sections made up of perfectly bonded elastic materials. Here each phase is a cylindrical fiber of arbitrary cross section with generators parallel to the shaft. In this context they showed that circular cross sections with a radially nonincreasing arrangement of compliance delivers the maximum torsional rigidity among all cross sections with given cross-sectional area and fixed area fraction of the constituent phases.

When the materials are imperfectly bonded the elastic displacement may suffer jumps across the interface betweendifferent elastic phases. To first order one models the imperfect bonding in terms of a linear constitutive law relating tangential stress to the jump in the warping displacement. This model for imperfect bonding is well known and is referred to as the spring layer model; see Jones and Whittier [4]. In this context one considers shafts reinforced with fibers of greater shear stiffness than the matrix. One is interested in extremizing the torsional rigidity over fiber configurations and understanding how the imperfect interface compromises the benefits of the stiffer reinforcement. It is found that the degree of imperfect bonding relative to the contrast in compliance between matrix and fiber explicitly determines the type of

fiber configuration that maximizes the torsional rigidity; see Lipton [5, Theorems 1.1 through 1.7]. The relative degree of imperfect bonding is given by the parameter

$$\mathrm{R}_{cr} = \frac{\alpha^{-1}}{\mathrm{G}_m^{-1} - \mathrm{G}_f^{-1}}, \tag{1.1}$$

where G_f is the shear modulus of the fiber reinforcement, G_m is the shear modulus of the matrix, and α is the interfacial shear stiffness having dimensions of shear stiffness per unit length. For a shaft with a circular cross section of radius R containing N reinforcement fibers of circular cross section with common radii given by R_{cr}, the imperfect interface balances the reinforcing effect of the fibers and the warping function outside the fibers is precisely zero. For this case the torsional rigidity is independent of the location of the fibers and is given by

$$\frac{\pi \mathrm{G_m}}{2}(R^4 - N\mathrm{R}_{cr}^4) + \frac{\pi \mathrm{G_f}}{2} N\mathrm{R}_{cr}^4 \tag{1.2}$$

and is precisely the torsional rigidity of a circular shaft of radius R reinforced with a single centered fiber of radius $N^{1/4}\mathrm{R}_{cr}$; see Lipton [5].

In many composites a third phase or inter-phase separating fiber and matrix is present. The inter-phase or coating phase often has elastic properties that are distinct from the fiber or matrix. In this context the recent work of Chen, Benveniste, and Chuang [2] treats a system of N fibers with circular cross section and radii a_i, $i = 1, \ldots, N$. The fibers are coated by a shell of uniform thickness and the outer radius of the coated fiber is b_i, $i = 1, \ldots, N$. The shear modulus of the ith fiber is denoted by G_f^i and the shear modulus of the associated coating is denoted by G_c^i. The area fraction of the fiber phase in the ith coated fiber system is denoted by ν_i and $\nu_i = a_i^2/b_i^2$. One recalls the formula for the effective antiplane shear modulus for the concentric coated cylinders assemblage of Hashin and Rosen [3] given by

$$G_{CCA}^i = \mathrm{G}_c^i \left(\frac{\mathrm{G}_c^i(1-\nu_i) + \mathrm{G}_f^i(1+\nu_i)}{\mathrm{G}_c^i(1+\nu_i) + \mathrm{G}_f^i(1-\nu_i)} \right). \tag{1.3}$$

Here G_{CCA}^i gives the effective shear stiffness of each coated fiber. Chen, Benveniste, and Chuang [2] show that when the effective shear stiffness of each coated fiber equals the matrix shear stiffness G_m, i.e.,

$$G_{CCA}^i = \mathrm{G}_m, \;\; i = 1, \ldots, N, \tag{1.4}$$

then the warping function outside the coated fibers is zero and the torsional rigidity is given by

$$\mathcal{A}^N = \frac{\pi}{2}\mathrm{G}_m R^4 + \sum_{i=1}^{N} \left(\frac{\pi}{2}(\mathrm{G}_c^i(b_i^4 - a_i^4) + \mathrm{G}_f^i a_i^4) - \frac{\pi}{2}\mathrm{G}_m\, b_i^4 \right). \tag{1.5}$$

When all fibers have the same radius and coating thickness ℓ one passes to the distinguished limit given by

$$\lim_{\ell \to 0} \lim_{\mathrm{G}_c^i \to 0} \frac{\ell}{\mathrm{G}_c^i} = \alpha^{-1} \tag{1.6}$$

in (1.4) and (1.5) to see that $\mathcal{A}^N$ is given by (1.2).

The relations given by (1.4) express the balance between the shear moduli of the matrix, fiber, coating, and coating thickness that renders the warping function zero outside the inclusions. Furthermore, under the hypotheses leading to (1.5) it is evident that if the torsional rigidity of each coated fiber given by

$$T_f^i = \frac{\pi}{2}(\mathrm{G}_c^i(b_i^4 - a_i^4) + \mathrm{G}_f^i a_i^4) \tag{1.7}$$

equals the torsional rigidity $\frac{\pi}{2}\mathrm{G}_m\, b_i^4$, obtained by replacing coating and fiber shear moduli with the matrix shear moduli, then there is complete neutrality; i.e., the torsional rigidity equals the torsional rigidity of the unreinforced shaft given by $\frac{\pi}{2}\mathrm{G}_m R^4$ (see Chen, Benveniste, and Chuang [2]). A recent summary of results involving neutral inclusions in the context of the theory of effective properties is given in Milton [6].

In this article we examine the effect of the coating phase on the torsional rigidity of coated fiber reinforced shafts. We build on the previous results and develop a variational methodology to assess the optimality or suboptimality of coated fiber configurations. Here the cross section of each coated fiber is taken to be circular, the radius of the ith fiber cross section is denoted by a_i, and the outer radius of the coating is given by b_i. The union of the coated fibers is denoted by A. The remaining part of the cross section containing matrix material is denoted by A_m. The shaft cross section is denoted by Ω and $\Omega = A \cup A_m$. The results given in this paper follow easily from a set of bounds on the torsional rigidity derived using the variational principles given by (2.1) and (2.2).

We provide a brief outline of the bounds derived in this paper. Upper and lower bounds on the torsional rigidity for shafts with circular cross section reinforced with coated fibers are given in Proposition 2.1. These bounds are given in terms of the effective shear moduli and torsional rigidity of each coated fiber. Next we consider shafts with arbitrary simply connected cross section. Here upper bounds are given in terms of the polar moment of inertia of the shaft cross section $I_0(\Omega)$ and the effective shear moduli and torsional rigidity of each coated fiber; see Proposition 3.1. If, in addition, one knows that $\mathrm{G}_c^i \le \mathrm{G}_f^i$ for $i = 1, \ldots, N$, then it is shown that one can derive a tighter upper bound given in terms of the torsional rigidity $\mathcal{T}_0(\Omega)$ of the shaft cross section and the effective shear moduli and torsional rigidity of each coated fiber; see Proposition 5.2. When $\mathrm{G}_c^i \ge \mathrm{G}_f^i$ for $i = 1, \ldots, N$, a lower bound is derived and is given in terms of $\mathcal{T}_0(\Omega)$ and the effective shear moduli and torsional rigidity of each coated fiber; see Proposition 6.2.

The bounds are used to establish the three reinforcement inequalities and three geometric inequalities presented in section 2. The reinforcement inequalities provide explicit criteria that determine when the torsional rigidity of a single coated fiber centered inside a shaft with circular cross section is either optimal or suboptimal among all coated fiber configurations for shafts with cross sections satisfying prescribed isoperimetric constraints; see Propositions 2.2, 2.3, and 2.4. The geometric inequalities provide explicit criteria that determine when the torsional rigidity of the coated fiber reinforced shaft is either greater than or less than the torsional rigidity of the same shaft in the absence of the coated fiber reinforcement; see Propositions 2.5, 2.6, and 2.7. In all cases the optimality conditions are expressed in terms of the effective shear modulus and torsional rigidity of each coated fiber.

2. Inequalities on the torsional rigidity. We begin by introducing the variational formulations for the torsional rigidity used in the subsequent analysis. The

torsional rigidity for a system of N coated fibers inside a shaft with cross section Ω is denoted by $\mathcal{T}^N(\Omega)$. Points inside Ω are denoted by $\mathbf{x} = (x_1, x_2)$, and the coordinate system is chosen such that the origin lies inside Ω. The first variational principle is given in terms of virtual stress potentials φ that vanish on the boundary of the shaft cross section that are square integrable and have square integrable gradients. It is given by

$$\mathcal{T}^N(\Omega) = -2 \min_{\varphi} \left\{ \frac{1}{2} \int_\Omega G^{-1}(\mathbf{x}) |\nabla \varphi|^2 \, d\mathbf{x} \, - \, 2 \int_\Omega \varphi \, d\mathbf{x} \right\}, \tag{2.1}$$

where the piecewise constant shear modulus $G(\mathbf{x})$ is G_m in the matrix and takes the values G_f^i and G_c^i in the ith fiber and coating, respectively. Next we define the vector $\mathbf{x}^\perp$ to be given by $(-x_2, x_1)$. The second variational principle is given in terms of virtual warping functions $\tilde{w}$ that are square integrable and have square integrable gradients. It is given by

$$\mathcal{T}^N(\Omega) = \min_{\tilde{w}} \left\{ \int_\Omega G(\mathbf{x}) |\nabla \tilde{w} + \mathbf{x}^\perp|^2 \, d\mathbf{x} \right\}. \tag{2.2}$$

Motivated by (1.4) and (1.5), we start by considering shafts with a circular cross section of radius R. For this case we denote the shaft cross section by D_R. The torsional rigidity of D_R reinforced with N coated fibers is written as $\mathcal{T}^N(D_R)$. Here the coordinates are chosen such that the center of the shaft is the origin. The method presented here is simple. The trial fields are designed so that they become the actual stress potential or warping field in the composite when $G^i_{CCA} = \mathrm{G}_m$ for $i = 1, \ldots, N$. Otherwise, these fields are admissible trials and when substituted into the variational principles give upper and lower bounds on the torsional rigidity. In this way the upper and lower bounds match when $G^i_{CCA} = \mathrm{G}_m$ for $i = 1, \ldots, N$. For a system of N coated fibers with centers located at the points $\mathbf{x}_i$, $i = 1, \ldots, N$, the bounds are given by the following proposition.

PROPOSITION 2.1.

$$\begin{aligned} \mathcal{A}^N + \pi \sum_{i=1}^N |\mathbf{x}_i|^2 b_i^2 \frac{\mathrm{G}_m}{G^i_{CCA}} (G^i_{CCA} - \mathrm{G}_m) &\le \mathcal{T}^N(D_R) \\ &\le \mathcal{A}^N + \pi \sum_{i=1}^N |\mathbf{x}_i|^2 b_i^2 (G^i_{CCA} - \mathrm{G}_m), \end{aligned} \tag{2.3}$$

where $\mathcal{A}^N$ is given by (1.5). *The upper and lower bounds agree when $G^i_{CCA} = \mathrm{G}_m$ for $i = 1, \ldots, N$.*

These upper and lower bounds are derived in sections 3 and 4, respectively.

In what follows we apply Proposition 2.1 to obtain the basic reinforcement inequality for shafts of circular cross section reinforced with a finite number N of coated fibers. Here we suppose that the shear moduli of each fiber and coating are the same, i.e., $\mathrm{G}_f^i = \mathrm{G}_f$ and $\mathrm{G}_c^i = \mathrm{G}_c$. In addition, it is supposed that the ratio of outer and inner coating radius is the same for each coated fiber, i.e., $\nu_i = \nu$, $i = 1, \ldots, N$. For this case $G^i_{CCA} = G_{CCA}$, where

$$G_{CCA} = \mathrm{G}_c \left(\frac{\mathrm{G}_c(1-\nu) + \mathrm{G}_f(1+\nu)}{\mathrm{G}_c(1+\nu) + \mathrm{G}_f(1-\nu)} \right) \tag{2.4}$$

and for $G_{CCA} = \mathrm{G}_m$ the torsional rigidity given by (1.5) becomes

$$\mathcal{A}^N = \overline{\mathcal{A}} = \frac{\pi}{2}\left(\mathrm{G}_m R^4 - \mathrm{G}_m \overline{b}^4 + \mathrm{G}_c \overline{b}^4(1-\nu^2) + \mathrm{G}_f \nu^2 \overline{b}^4\right), \tag{2.5}$$

where $\overline{b}^4 = \sum_{i=1}^N b_i^4$. Here $\overline{\mathcal{A}}$ is precisely the torsional rigidity of a single coated fiber with outer coating radius $\overline{b}$ and fiber radius $\overline{a} = \nu^{1/2}\overline{b}$ when the centers of the coated fiber cross section and shaft cross section are the same. The torsional rigidity of the concentric coated fiber shaft configuration is given by the right-hand side of (2.5) for all values of G_m, G_f, G_c, and $\overline{a} \le \overline{b} \le R$. We note here that the area of the fiber cross section is given by $\pi\overline{a}^2 = \pi\sqrt{\sum_{i=1}^N a_i^4}$.

The following reinforcement inequalities follow from Proposition 2.1 and give conditions for which the concentric coated fiber and circular shaft cross section is either optimal or suboptimal.

PROPOSITION 2.2 (reinforcement inequalities I). *If $G_{CCA} \le \mathrm{G}_m$, then the torsional rigidity associated with N coated fibers is less than or equal to the rigidity associated with a single centered circular coated fiber with fiber radius $\overline{a} = \nu^{1/2}\overline{b}$, i.e.,*

$$\mathcal{T}^N(D_R) \le \overline{\mathcal{A}}. \tag{2.6}$$

Otherwise, if $G_{CCA} \ge \mathrm{G}_m$, then the torsional rigidity associated with N coated fibers is greater than or equal to that of a single centered circular coated fiber with fiber radius $\overline{a} = \nu^{1/2}\overline{b}$, i.e.,

$$\mathcal{T}^N(D_R) \ge \overline{\mathcal{A}}. \tag{2.7}$$

These inequalities are independent of the number and location of the coated fibers.

When all fibers have the same radius a and coating thickness ℓ, one easily passes to the distinguished limit given by (1.6) in Proposition 2.2 to recover Theorem 1.3 of Lipton [5] for imperfectly bonded fiber reinforced shafts.

Next we consider the more general case where the shaft can have an arbitrary simply connected cross section Ω. Here we consider all configurations of N coated fibers with prescribed fiber radii a_i, $i = 1, \ldots, N$, and consider all cross sections Ω with prescribed polar moment of inertia. We apply the upper bound on the torsional rigidity given by Proposition 3.1 to obtain the following.

PROPOSITION 2.3 (reinforcement inequality II). *Consider any shaft with polar moment of inertia with respect to the origin equal to $\pi R^4/2$ reinforced with N circular coated fibers. If $G_{CCA} \le \mathrm{G}_m$, then the torsional rigidity $\mathcal{T}^N(\Omega)$ is less than or equal to the torsional rigidity associated with a shaft with circular cross section of radius R reinforced with a single centered circular coated fiber with fiber radius $\overline{a}$ given by*

$$\pi\overline{a}^2 = \pi\sqrt{\sum_{i=1}^N a_i^4} \tag{2.8}$$

and $\overline{b} = \nu^{-1/2}\overline{a}$.

When $\mathrm{G}_c \le \mathrm{G}_f$ we can appeal to the tighter upper bound on the torsional rigidity given by Proposition 5.2 to obtain a reinforcement inequality that holds for all shaft cross sections Ω with prescribed cross-sectional area.

PROPOSITION 2.4 (reinforcement inequality III). *Consider any shaft with cross-sectional area equal to πR^2 reinforced with N circular coated fibers. If $G_{CCA} \le \mathrm{G}_m$*

and $\mathrm{G}_c \leq \mathrm{G}_f$*, then the torsional rigidity* $\mathcal{T}^N(\Omega)$ *is less than or equal to the torsional rigidity associated with a shaft with a circular cross section of radius* R *reinforced with a single centered circular coated fiber with fiber radius* $\overline{a}$ *given by*

$$\pi\overline{a}^2 = \pi\sqrt{\sum_{i=1}^{N} a_i^4} \tag{2.9}$$

and $\overline{b} = \nu^{-1/2}\overline{a}$*.*

It is evident from the inequality $\sqrt{\sum_{i=1}^N a_i^4} \leq \sum_{i=1}^N a_i^2$ that the cross-sectional area of the single centered circular fiber appearing in Propositions 2.2, 2.3, and 2.4 is less than or equal to the joint cross-sectional area of the N fibers.

Now we consider the more general case where the shear moduli of the fiber and coating and the ratio of the inner radius and outer radius of the coating are allowed to differ between coated fibers. In this context we present explicit conditions on the effective shear modulus and torsional rigidity of each coated fiber that show when the torsional rigidity of the coated fiber reinforced shaft is either greater or less than the torsional rigidity of the shaft without reinforcement.

For shafts with circular cross sections of radius R, i.e., $\Omega = D_R$, we have the following.

PROPOSITION 2.5 (geometric inequalities I). *If* $\sum_{i=1}^N T_f^i \leq \sum_{i=1}^N \frac{\pi}{2}\mathrm{G}_m\, b_i^4$ *and* $G_{CCA}^i \leq \mathrm{G}_m$*, then*

$$\mathcal{T}^N(D_R) \leq \frac{\pi}{2}\mathrm{G}_m R^4. \tag{2.10}$$

If $\sum_{i=1}^N T_f^i \geq \sum_{i=1}^N \frac{\pi}{2}\mathrm{G}_m\, b_i^4$ *and* $G_{CCA}^i \geq \mathrm{G}_m$*, then*

$$\mathcal{T}^N(D_R) \geq \frac{\pi}{2}\mathrm{G}_m R^4. \tag{2.11}$$

The inequalities (2.10) *and* (2.11) *are independent of the number and location of the coated fibers.*

These inequalities follow immediately from Proposition 2.1.

Now we extend these results to simply connected cross sections Ω and denote the torsional rigidity for simply connected shaft cross sections with shear modulus unity by $\mathcal{T}_0(\Omega)$. The following geometric inequality shows when a system of coated fibers always decreases the torsional rigidity below that of the unreinforced shaft.

PROPOSITION 2.6 (geometric inequality II). *Suppose that* $\mathrm{G}_c^i \leq \mathrm{G}_f^i$*,* $i=1,\ldots,N$*. If* $\sum_{i=1}^N T_f^i \leq \sum_{i=1}^N \frac{\pi}{2}\mathrm{G}_m\, b_i^4$ *and* $G_{CCA}^i \leq \mathrm{G}_m$*, then*

$$\mathcal{T}^N(\Omega) \leq \mathrm{G}_m\mathcal{T}_0(\Omega). \tag{2.12}$$

The equality holds in (2.12) *when the shaft cross section is circular,* $\sum_{i=1}^N T_f^i = \sum_{i=1}^N \frac{\pi}{2}\mathrm{G}_m\, b_i^4$ *and* $G_{CCA}^i = \mathrm{G}_m$ *for* $i = 1,\ldots,N$*.*

This result follows from the upper bound on the torsional rigidity given by Proposition 5.2.

The following geometric inequality shows when a system of coated fibers always increases the torsional rigidity above that of the unreinforced shaft.

PROPOSITION 2.7 (geometric inequality III). *Suppose that* $\mathrm{G}_c^i \geq \mathrm{G}_f^i$*,* $i=1,\ldots,N$*. If* $\sum_{i=1}^N T_f^i \geq \sum_{i=1}^N \frac{\pi}{2}\mathrm{G}_m\, b_i^4$ *and* $G_{CCA}^i \geq \mathrm{G}_m$*, then*

$$\mathcal{T}^N(\Omega) \geq \mathrm{G}_m\mathcal{T}_0(\Omega). \tag{2.13}$$

The equality holds in (2.13) *when the shaft cross section is circular,* $\sum_{i=1}^{N} T_f^i = \sum_{i=1}^{N} \frac{\pi}{2} \mathrm{G}_m\, b_i^4$ *and* $G_{CCA}^i = \mathrm{G}_m$ *for* $i = 1, \ldots, N$.

This result follows from the lower bound on the torsional rigidity given by Proposition 6.2.

3. Upper bounds on the torsional rigidity for shafts reinforced with circular coated fibers. In this section we develop trial warping functions for configurations of circular coated fibers. These are substituted into the variational principle (2.2) and deliver the upper bound presented in Proposition 2.1. The trial warping functions constructed here will be admissible for shaft cross sections of any shape. For circular shaft cross sections it is shown that the trial warping functions become the actual warping displacement in the shaft when $G_{CCA}^i = \mathrm{G}_m$ for $i = 1, \ldots, N$.

Consider a shaft of arbitrary cross section Ω reinforced with N circular coated fibers with centers at the points $\mathbf{x}_i$, $i = 1, \ldots, N$. The radius of the ith fiber is a_i, and the outer radius of the coated fiber is b_i. The coating occupies the annular shell with inner and outer radii a_i and b_i. The trial warping function $\tilde{w}$ is chosen such that $\tilde{w} = 0$ outside the coated fibers. In each coated fiber the function $\tilde{w}$ is required to be harmonic inside the fiber and harmonic inside the coating. It is required that $\tilde{w}$ be continuous across the interface separating the fiber and coating and

$$\mathrm{G}_f^i(\nabla \tilde{w}_{|_f} + \mathbf{x}^{\perp}) \cdot \mathbf{n} = \mathrm{G}_c^i(\nabla \tilde{w}_{|_c} + \mathbf{x}^{\perp}) \cdot \mathbf{n} \tag{3.1}$$

across the fiber–coating interface. Here the subscripts indicate the side of the interface over which the quantities are evaluated and $\mathbf{n}$ is the outward directed unit normal in the fiber–coating interface. The final requirement is that $\tilde{w}$ vanish on the boundary of the coated fiber. It is clear that the continuity conditions for $\tilde{w}$ at material interfaces ensure that it is an admissible trial field for (2.2).

We solve the transmission boundary value problem inside each coated fiber to obtain the explicit formula for $\tilde{w}$. The polar coordinates (θ, r) are chosen such that the axis $\theta = 0$ coincides with the direction given by $\mathbf{x}^{\perp}{}_i$ and origin with $\mathbf{x}_i$. In these coordinates, the transmission condition (3.1) on the ith fiber–coating interface becomes

$$\mathrm{G}_c^i \partial_r \tilde{w}_{|_c} - \mathrm{G}_f^i \partial_r \tilde{w}_{|_f} = (\mathrm{G}_f^i - \mathrm{G}_c^i)|\mathbf{x}_i| \cos\theta \text{ on } r = a_i. \tag{3.2}$$

Since $\tilde{w}$ is required to be harmonic inside each fiber and coating it follows that

$$\tilde{w} = C_1 r \cos\theta \text{ for } r \le a_i \tag{3.3}$$

and

$$\tilde{w} = (C_2 r + C_3 r^{-1}) \cos\theta \text{ for } a_i \le r \le b_i. \tag{3.4}$$

The transmission conditions at $r = a_i$ and boundary condition at $r = b_i$ require that

$$\begin{gathered} C_2 b_i^2 + C_3 = 0, \\ C_1 a_i^2 - C_2 a_i^2 - C_3 = 0, \\ \mathrm{G}_c^i a_i^2 C_2 - \mathrm{G}_c^i C_3 - \mathrm{G}_f^i a_i^2 C_1 = (\mathrm{G}_f^i - \mathrm{G}_c^i) a_i^2 |\mathbf{x}_i|. \end{gathered} \tag{3.5}$$

The solution of (3.5) shows that inside each coated fiber the trial warping function is given by

$$\tilde{w} = C_1^i r \cos\theta \text{ for } r = |\mathbf{x} - \mathbf{x}_i| \le a_i \tag{3.6}$$

and

$$\tilde{w} = (C_2^i r + C_3^i r^{-1})\cos\theta \text{ for } a_i \le r = |\mathbf{x} - \mathbf{x}_i| \le b_i, \tag{3.7}$$

where $\Delta_i = \mathrm{G}_c^i(a_i^2 + b_i^2) + \mathrm{G}_f^i(b_i^2 - a_i^2)$ and

$$\begin{aligned} C_1^i &= (\mathrm{G}_c^i - \mathrm{G}_f^i)|\mathbf{x}_i|(b_i^2 - a_i^2)/\Delta_i, \\ C_2^i &= (\mathrm{G}_f^i - \mathrm{G}_c^i)|\mathbf{x}_i|a_i^2/\Delta_i, \\ C_3^i &= (\mathrm{G}_c^i - \mathrm{G}_f^i)|\mathbf{x}_i|b_i^2 a_i^2/\Delta_i. \end{aligned} \tag{3.8}$$

Outside the coated fibers $\tilde{w} = 0$.

The polar moment of inertia of the shaft cross section Ω with respect to the origin is written $I_0(\Omega)$. Here $I_0(\Omega) = \int_\Omega |\mathbf{x}|^2 d\mathbf{x}$. Substitution of $\tilde{w}$ into (2.2) delivers the upper bound given in the following.

PROPOSITION 3.1 (upper bound on rigidity for arbitrary shaft cross section).

$$\begin{aligned} \mathcal{T}^N(\Omega) \le \mathrm{G}_m I_0(\Omega) + \sum_{i=1}^N \Big(\frac{\pi}{2} T_f^i - \frac{\pi}{2}\mathrm{G}_m\, b_i^4\Big) \\ + \pi \sum_{i=1}^N |\mathbf{x}_i|^2 b_i^2 (G_{CCA}^i - \mathrm{G}_m). \end{aligned} \tag{3.9}$$

Next we consider shafts with a circular cross section of radius R. In order for the trial warping field $\tilde{w}$ to be the actual warping displacement in the shaft it must also satisfy the transmission condition on the coating–matrix interface $|\mathbf{x} - \mathbf{x}_i| = b_i$ given by

$$\mathrm{G}_m \mathbf{x}^\perp \cdot \mathbf{n} = \mathrm{G}_c^i(\nabla \tilde{w}_{|_c} + \mathbf{x}^\perp) \cdot \mathbf{n}. \tag{3.10}$$

This gives the extra condition

$$\mathrm{G}_c^i C_2^i b_i^2 - \mathrm{G}_c^i C_3^i = (\mathrm{G}_m - \mathrm{G}_c^i)|\mathbf{x}_i| b_i^2. \tag{3.11}$$

This condition together with the conditions given by (3.5) provide an overdetermined system of equations for the coefficients C_1^i, C_2^i, C_3^i in each coated fiber. It is easily seen that the overdetermined system has a solution when $G_{CCA}^i = \mathrm{G}_m$. For this case the function $\tilde{w}$ becomes the warping displacement in the shaft and we recover the formula

$$\mathcal{T}^N(D_R) = \mathcal{A}^N, \tag{3.12}$$

where $\mathcal{A}^N$ is given by (1.5).

4. Lower bounds on the torsional rigidity for circular shafts reinforced with circular coated fibers. In this section we develop trial stress potentials for configurations of circular coated fibers. These are substituted into the variational principle (2.1) to obtain the lower bound given in Proposition 2.1.

We consider a circular shaft cross section of radius R reinforced with N coated fibers. Outside the coated fibers the trial stress potential φ is taken to be $\varphi = \frac{1}{2}\mathrm{G}_m(R^2 - |\mathbf{x}|^2)$. The trial potential is taken to be continuous across the matrix–coating interface specified by $|\mathbf{x} - \mathbf{x}_i| = b_i$. It is easily seen that

$$\varphi = h(\mathbf{x}) = -\mathrm{G}_m(\mathbf{x} - \mathbf{x}_i)\cdot \mathbf{x}_i + \frac{1}{2}\mathrm{G}_m(R^2 - b_i^2 - |\mathbf{x}_i|^2) \tag{4.1}$$

on this interface in view of the condition $|\mathbf{x}-\mathbf{x}_i| = b_i$. The trial is taken to be continuous inside the coated fiber and is given by $\varphi = \psi^i + r^i$ in the ith fiber. Here ψ^i is chosen to be the stress potential generated inside the coated fiber when it is subject to torsion loading. It is the solution of the transmission problem inside the coated fiber given by

$$\mathrm{G}_f^{i\,-1}(x)\Delta\psi^i = -2 \text{ in the fiber, } |\mathbf{x}-\mathbf{x}_i| < a_i, \tag{4.2}$$

$$\mathrm{G}_c^{i\,-1}(x)\Delta\psi^i = -2 \text{ in the coating, } a_i < |\mathbf{x}-\mathbf{x}_i| < b_i. \tag{4.3}$$

ψ^i is continuous across the fiber–coating interface,

$$\mathrm{G}_f^{i\,-1}\nabla\psi^i_{|_f}\cdot\mathbf{n} = \mathrm{G}_c^{i\,-1}\nabla\psi^i_{|_c}\cdot\mathbf{n} \text{ on } |\mathbf{x}-\mathbf{x}_i| = a_i, \tag{4.4}$$

and $\psi^i = 0$ on $|\mathbf{x}-\mathbf{x}_i| = b_i$. It is easily seen that ψ^i is given by

$$\begin{aligned}
\psi^i &= -\frac{1}{2}\left(\mathrm{G}_f^i|\mathbf{x}-\mathbf{x}_i|^2 - \mathrm{G}_c^i(b_i^2-a_i^2) - \mathrm{G}_f^i a_i^2\right) \text{ for } |\mathbf{x}-\mathbf{x}_i| < a_i,\\
\psi^i &= -\frac{1}{2}\left(\mathrm{G}_c^i|\mathbf{x}-\mathbf{x}_i|^2 - \mathrm{G}_c^i b_i^2\right) \text{ for } a_i < |\mathbf{x}-\mathbf{x}_i| < b_i.
\end{aligned} \tag{4.5}$$

The function $r^i = h$ on the coating–matrix interface and is continuous inside the coated fiber. It is the solution to the transmission problem given by

$$\mathrm{G}_f^{i\,-1}(x)\Delta r^i = 0 \text{ in the fiber, } |\mathbf{x}-\mathbf{x}_i| < a_i, \tag{4.6}$$

$$\mathrm{G}_c^{i\,-1}(x)\Delta r^i = 0 \text{ in the coating, } a_i < |\mathbf{x}-\mathbf{x}_i| < b_i, \tag{4.7}$$

and

$$\mathrm{G}_f^{i\,-1}\nabla r^i_{|_f}\cdot\mathbf{n} = \mathrm{G}_c^{i\,-1}\nabla r^i_{|_c}\cdot\mathbf{n} \text{ on } |\mathbf{x}-\mathbf{x}_i| = a_i. \tag{4.8}$$

In the polar coordinates (θ, r) chosen such that the axis $\theta = 0$ coincides with the vector $\mathbf{x}_i$ and $r = |\mathbf{x}_i - \mathbf{x}|$, the solution of the transmission problem for r^i is given by

$$\begin{aligned}
r^i &= C_1^i r\cos\theta + k^i \text{ for } |\mathbf{x}-\mathbf{x}_i| < a_i,\\
r^i &= \left(C_2^i r + C_3^i r^{-1}\right)\cos\theta + k^i \text{ for } a_i < |\mathbf{x}-\mathbf{x}_i| < b_i,
\end{aligned} \tag{4.9}$$

where

$$\begin{aligned}
k^i &= \frac{\mathrm{G}_m}{2}\left(R^2 - b_i^2 - |\mathbf{x}_i|^2\right),\\
C_1^i &= -\mathrm{G}_m|\mathbf{x}_i|b_i^2 2\mathrm{G}_f^i/D_i,\\
C_2^i &= -\mathrm{G}_m|\mathbf{x}_i|b_i^2(\mathrm{G}_f^i + \mathrm{G}_c^i)/D_i,\\
C_3^i &= -\mathrm{G}_m|\mathbf{x}_i|a_i^2 b_i^2(\mathrm{G}_f^i - \mathrm{G}_c^i)/D_i,
\end{aligned} \tag{4.10}$$

and $D_i = (b_i^2+a_i^2)\mathrm{G}_f^i + (b_i^2-a_i^2)\mathrm{G}_c^i$. The lower bound in (2.3) follows from substitution of this trial potential into the variational principle (2.1).

In order for the trial potential field φ to be the actual stress potential in the shaft it must also satisfy the transmission condition on the coating–matrix interface given by

$$\mathrm{G}_m^{-1}\nabla\varphi_{|_m}\cdot\mathbf{n} = {\mathrm{G}_c^i}^{-1}(\nabla\psi^i_{|_c}+\nabla r^i_{|_c})\cdot\mathbf{n}. \tag{4.11}$$

Substitution and working in polar coordinates show that (4.11) gives the extra condition

$$ {\mathrm{G}_c^i}^{-1}\left(C_2^i - C_3^i b_i^{-2}\right) = -|\mathbf{x}_i|. \tag{4.12}$$

This condition together with the system of equations (4.10) overdetermines the coefficients C_1^i, C_2^i, C_3^i in each coated sphere. It is easily seen that the overdetermined system has a solution when $G^i_{CCA} = \mathrm{G}_m$. For this case the function φ becomes the stress potential in the shaft and we recover the formula

$$\mathcal{T}^N(D_R) = \mathcal{A}^N, \tag{4.13}$$

where $\mathcal{A}^N$ is given by (1.5).

5. Upper bounds on the torsional rigidity for $\mathbf{G_c^i \le G_f^i}$. In this section we focus on the case where $\mathrm{G}_c^i \le \mathrm{G}_f^i$, $i = 1, \ldots, N$. Here we are able to get tighter upper bounds on the torsional rigidity for shaft cross sections of arbitrary shape. Our approach follows the methodology developed in Lipton [5]. We fix the cross section of the shaft Ω and investigate the effects of adding a circular coated fiber to an already existing configuration of $N-1$ coated fibers. At present no assumptions on the geometry or shear moduli of the $N-1$ coated fibers are made. We denote the part of the shaft cross section already occupied by the coated fibers by A and the cross section of the circular coated fiber to be added by Σ. Here Σ is composed of a circular fiber of radius a_N with shear modulus G_f^N surrounded by a coating of outer radius b_N with shear modulus G_c^N. The torsional rigidity of the original configuration is denoted by $\mathcal{T}(A,\Omega)$. The rigidity associated with the added fiber is written as $\mathcal{T}(A\cup\Sigma,\Omega)$. We recall that the torsional rigidity obtained by replacing coating and fiber shear moduli with the matrix shear moduli in Σ is given by $\frac{\pi}{2}\mathrm{G}_m\, b_N^4$. Here b_N is the outer radius of the coating. The torsional rigidity of the coated fiber is $T_f^N = \frac{\pi}{2}(\mathrm{G}_c^N(b_N^4 - a_N^4) + \mathrm{G}_f^N a_N^4)$.

PROPOSITION 5.1 (upper rigidity inequality). *If* $\mathrm{G}_c^N \le \mathrm{G}_f^N$ *and if*

$$G^N_{CCA} \le \mathrm{G}_m, \tag{5.1}$$

then

$$\mathcal{T}(A\cup\Sigma,\Omega) \le \mathcal{T}(A,\Omega) + T_f^N - \frac{\pi}{2}\mathrm{G}_m\, b_N^4. \tag{5.2}$$

Proposition 5.1 is established with the aid of the variational principle given by (2.1). We remark that the methods used to establish this inequality apply to the case when the fiber cross section is multiply connected. One writes (2.1) as $\mathcal{T}(A,\Omega) = -2\mathcal{E}(A,\Omega)$, where

$$\mathcal{E}(A,\Omega) = \min_{\varphi}\left\{\frac{1}{2}\int_\Omega G^{-1}(\mathbf{x})|\nabla\varphi|^2\,d\mathbf{x} \;-\; 2\int_\Omega \varphi\,d\mathbf{x}\right\}. \tag{5.3}$$

Here the piecewise constant shear modulus $G(\mathbf{x})$ takes the value G_m in the matrix and takes the values G_f^i and G_c^i in the ith fiber and coating, respectively. The idea of the proof is to estimate the quantity $\mathcal{E}(A,\Omega)$ in terms of $\mathcal{E}(A\cup\Sigma,\Omega)$ associated with the additional fiber. We let $\mathcal{G}(\mathbf{x})$ denote the piecewise constant shear modulus for the configuration $A\cup\Sigma$. Here $\mathcal{G}(\mathbf{x})=G(\mathbf{x})$ outside of Σ and inside Σ the shear modulus $\mathcal{G}(\mathbf{x})=\mathrm{G}_f^N$ in the fiber and $\mathcal{G}(\mathbf{x})=\mathrm{G}_c^N$ in the coating. We regroup terms in the variational principle (5.3) and write

$$\begin{aligned}\mathcal{E}(A,\Omega)=\min_{\varphi}\Bigg\{&\frac{1}{2}\int_\Omega \mathcal{G}^{-1}(\mathbf{x})|\nabla\varphi|^2 d\mathbf{x}-2\int_\Omega\varphi d\mathbf{x}\\&+\frac{1}{2}\left(\int_\Sigma(\mathrm{G}_m^{-1}-\mathcal{G}^{-1}(\mathbf{x}))\right)|\nabla\varphi|^2 d\mathbf{x}\Bigg\}.\end{aligned}\tag{5.4}$$

We obtain an estimate by substitution of a suitable trial field in (5.4). Our choice is made as follows: We introduce the stress potential $\tilde{\Phi}$ for the configuration $A\cup\Sigma$. Here $\tilde{\Phi}$ is continuous in Ω,

$$-\mathcal{G}^{-1}(\mathbf{x})\Delta\tilde{\Phi}=2,\tag{5.5}$$

and satisfies the transmission conditions

$$\mathrm{G}_f^{i\,-1}\nabla\tilde{\Phi}_{|_f}\cdot\mathbf{n}=\mathrm{G}_c^{i\,-1}\nabla\tilde{\Phi}_{|_c}\cdot\mathbf{n}\ \text{on the fiber–coating interface}\ |\mathbf{x}-\mathbf{x}_i|=a_i\tag{5.6}$$

and

$$\mathrm{G}_f^{i\,-1}\nabla\tilde{\Phi}_{|_c}\cdot\mathbf{n}=\mathrm{G}_m{}^{-1}\nabla\tilde{\Phi}_{|_m}\cdot\mathbf{n}\ \text{on the matrix–coating interface}\ |\mathbf{x}-\mathbf{x}_i|=b_i.\tag{5.7}$$

The trial field φ is chosen to match $\tilde{\Phi}$ outside the coated fiber cross section Σ but inside we suppose that $\varphi=\tilde{\Phi}+\delta$, where δ is continuous, vanishes on the boundary of Σ, is square integrable inside Σ, and has a square integrable gradient over Σ. One easily checks that

$$\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})\nabla\tilde{\Phi}\cdot\nabla\delta\,d\mathbf{x}=2\int_\Sigma\delta\,d\mathbf{x}.\tag{5.8}$$

Substitution of φ into (5.4) gives

$$\begin{aligned}\mathcal{E}(A,\Omega)\le\frac{1}{2}&\left(\int_{\Omega/\Sigma}\mathcal{G}^{-1}(\mathbf{x})|\nabla\tilde{\Phi}|^2 d\mathbf{x}+\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})|\nabla\tilde{\Phi}+\nabla\delta|^2 d\mathbf{x}\right)\\&-2\int_\Omega\tilde{\Phi}d\mathbf{x}-2\int_\Sigma\delta d\mathbf{x}\\&+\frac{1}{2}\left(\int_\Sigma(\mathrm{G}_m^{-1}-\mathcal{G}^{-1}(\mathbf{x}))\right)|\nabla\varphi|^2 d\mathbf{x}.\end{aligned}\tag{5.9}$$

We apply (5.8) and expand the second term on the right-hand side of (5.9) to find

$$\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})|\nabla\tilde{\Phi}+\nabla\delta|^2 d\mathbf{x}=\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})|\nabla\tilde{\Phi}|^2 d\mathbf{x}+\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})|\nabla\delta|^2 d\mathbf{x}+4\int_\Sigma\delta d\mathbf{x}.\tag{5.10}$$

Substitution of (5.10) into (5.9) yields

$$\mathcal{E}(A,\Omega) \leq \mathcal{E}(A\cup\Sigma,\Omega) + \frac{1}{2}\int_\Sigma \mathcal{G}^{-1}(\mathbf{x})|\nabla\delta|^2 d\mathbf{x} + \frac{1}{2}\left(\int_\Sigma (\mathrm{G}_m^{-1} - \mathcal{G}^{-1}(\mathbf{x}))\right)|\nabla\varphi|^2 d\mathbf{x}. \tag{5.11}$$

Multiplying by -2 and arranging terms, we find that

$$\mathcal{T}(A\cup\Sigma,\Omega) \leq \mathcal{T}(A,\Omega) + \int_\Sigma \mathcal{G}^{-1}(\mathbf{x})|\nabla\delta|^2 d\mathbf{x} + \int_\Sigma (\mathrm{G}_m^{-1} - \mathcal{G}^{-1}(\mathbf{x}))|\nabla\varphi|^2 d\mathbf{x}. \tag{5.12}$$

Next we minimize the right-hand side of (5.12) with respect to δ to obtain

$$\mathcal{T}(A\cup\Sigma,\Omega) \leq \mathcal{T}(A,\Omega) + \mathcal{U}, \tag{5.13}$$

where

$$\mathcal{U} = \int_\Sigma (\mathrm{G}_m^{-1} - \mathcal{G}^{-1}(\mathbf{x}))\nabla\hat{\varphi}\cdot\nabla\tilde{\Phi}\, d\mathbf{x}. \tag{5.14}$$

Here $\hat{\varphi} = \hat{\delta} + \tilde{\Phi}$ in Σ and $\hat{\delta}$ solves

$$\int_\Sigma \mathrm{G}_m^{-1}\nabla\hat{\delta}\cdot\nabla u\, d\mathbf{x} = \int_\Sigma (\mathcal{G}^{-1}(\mathbf{x}) - \mathrm{G}_m^{-1})\nabla\tilde{\Phi}\cdot\nabla u\, d\mathbf{x} \tag{5.15}$$

for every trial u vanishing on the boundary of Σ. From (5.15) and (5.5)–(5.7) we see that $\hat{\varphi}$ solves

$$\int_\Sigma \mathrm{G}_m^{-1}\nabla\hat{\varphi}\cdot\nabla u\, d\mathbf{x} = 2\int_\Sigma u\, d\mathbf{x} \tag{5.16}$$

for every trial u vanishing on the boundary of Σ. This is equivalent to the differential equation $-\mathrm{G}_m^{-1}\Delta\hat{\varphi} = 2$ over Σ.

We decompose the trial $\hat{\varphi}$ into two parts: $\hat{\varphi} = r + \psi^h$, where the function r satisfies

$$\Delta r = 0 \text{ in } \Sigma \text{ and } r = \tilde{\Phi} \text{ on the boundary of } \Sigma, \tag{5.17}$$

and ψ^h satisfies

$$\Delta\psi^h = -2\mathrm{G}_m \text{ in } \Sigma \text{ and } \psi^h = 0 \text{ on the boundary of } \Sigma. \tag{5.18}$$

Next we decompose $\tilde{\Phi}$ into two components over Σ. We write $\tilde{\Phi} = \psi - h$. Here ψ is continuous, vanishes on the boundary of Σ, and solves the torsion problem

$$-\mathcal{G}^{-1}(\mathbf{x})\Delta\psi = 2 \tag{5.19}$$

with the transmission condition

$$(\mathrm{G}_f^N)^{-1}\nabla\psi_{|_f}\cdot\mathbf{n} = (\mathrm{G}_c^N)^{-1}\nabla\psi_{|_c}\cdot\mathbf{n} \text{ on the fiber–coating interface } |\mathbf{x}-\mathbf{x}_N| = a_N. \tag{5.20}$$

The function h is continuous on Σ and $h = -\tilde{\Phi}$ on the boundary of Σ. It is the solution of

$$-\mathcal{G}^{-1}(\mathbf{x})\Delta h = 0 \tag{5.21}$$

and h satisfies the transmission condition

$$(\mathrm{G}_f^N)^{-1}\nabla h_{|_f} \cdot \mathbf{n} = (\mathrm{G}_c^N)^{-1}\nabla h_{|_c} \cdot \mathbf{n} \text{ on the fiber–coating interface } |\mathbf{x} - \mathbf{x}_N| = a_N. \tag{5.22}$$

Substitution of the functions ψ^h, ψ, r, and h into $\mathcal{U}$ and (5.13) gives

$$\begin{aligned}\mathcal{T}(A \cup \Sigma, \Omega) \leq \mathcal{T}(A, \Omega) + T_f^N - \frac{\pi}{2}\mathrm{G}_m\, b_N^4 \\ + \int_\Sigma \mathrm{G}_m^{-1}|\nabla r|^2\, d\mathbf{x} - \int_\Sigma \mathcal{G}^{-1}(\mathbf{x})|\nabla h|^2\, d\mathbf{x} - 4\int_\Sigma r + h\, d\mathbf{x}.\end{aligned} \tag{5.23}$$

For circular fiber cross sections calculation shows that $\int_\Sigma r + h\, d\mathbf{x} = 0$ and we obtain

$$\begin{aligned}\mathcal{T}(A \cup \Sigma, \Omega) \leq \mathcal{T}(A, \Omega) + T_f^N - \frac{\pi}{2}\mathrm{G}_m\, b_N^4 \\ + \int_\Sigma \mathrm{G}_m^{-1}|\nabla r|^2\, d\mathbf{x} - \int_\Sigma \mathcal{G}^{-1}(\mathbf{x})|\nabla h|^2\, d\mathbf{x}.\end{aligned} \tag{5.24}$$

It is clear that Proposition 5.1 holds when the indefinite term

$$\begin{aligned}D &= \int_\Sigma \mathrm{G}_m^{-1}|\nabla r|^2\, d\mathbf{x} - \int_\Sigma \mathcal{G}^{-1}(\mathbf{x})|\nabla h|^2\, d\mathbf{x} \\ &= \mathrm{G}_m^{-1}\left(\int_\Sigma |\nabla r|^2\, d\mathbf{x} - \int_\Sigma \frac{\mathrm{G}_m}{\mathcal{G}(\mathbf{x})}|\nabla h|^2\, d\mathbf{x}\right) \leq 0.\end{aligned} \tag{5.25}$$

If $\tilde{\Phi} = \text{const}$ on the boundary of Σ, then $r = \text{const}$ and $h = -\text{const}$ and $D = 0$. We now examine conditions for which $D \leq 0$ and $r \neq \text{const}$ and $h \neq -\text{const}$. To do this we search for the largest number β for which

$$\beta \int_\Sigma |\nabla r|^2\, d\mathbf{x} - \int_\Sigma \frac{\mathrm{G}_m}{\mathcal{G}(\mathbf{x})}|\nabla h|^2\, d\mathbf{x} \leq 0 \tag{5.26}$$

for every choice of r and h such that $h = -r$ on the boundary of Σ, r is harmonic inside Σ, and h is harmonic in the fiber and in the coating, and satisfies the transmission conditions

$$\frac{\mathrm{G}_m}{\mathrm{G}_f^N}\nabla h_{|_f} \cdot \mathbf{n} = \frac{\mathrm{G}_m}{\mathrm{G}_c^N}\nabla h_{|_c} \cdot \mathbf{n} \tag{5.27}$$

on the fiber–coating interface. The set of all such r and h for which $r \neq \text{const}$ and $h \neq \text{const}$ is denoted by $\mathcal{C}$. The largest β is given by

$$\hat{\beta} = \mathrm{G}_m \inf_{\mathcal{C}} \frac{\int_\Sigma \mathcal{G}(\mathbf{x})^{-1}|\nabla h|^2\, d\mathbf{x}}{\int_\Sigma |\nabla r|^2\, d\mathbf{x}}. \tag{5.28}$$

The stationary values for the quotient given in (5.28) are denoted by β_n, and the stationary conditions for the stationary functions (r_n, h_n) in $\mathcal{C}$ are given by

$$(\mathrm{G}_c^N)^{-1}\nabla h_n \cdot \mathbf{n} = -\beta_n \nabla r_n \cdot \mathbf{n} \tag{5.29}$$

on the coating matrix boundary $|\mathbf{x}-\mathbf{x}_N| = b_N$. Choosing polar coordinates (θ, r) such that the $\theta = 0$ axis is along $\mathbf{x}_N$ and $r = |\mathbf{x}-\mathbf{x}_N|$, one finds that the stationary functions are given by

$$\begin{aligned} r_n &= K_1^n r^n \exp(jn\theta) \text{ for } 0 \le r \le b_N, \\ h_n &= (K_2^n r^n) \exp(jn\theta) \text{ for } 0 \le r \le a_N, \\ h_n &= \left(K_3^n r^n + K_4^n r^{-n}\right) \exp(jn\theta) \text{ for } a_N \le r \le b_N. \end{aligned} \tag{5.30}$$

Here $j = \sqrt{-1}$ and both real and imaginary parts of r_n and h_n are stationary functions. The constants K_1^n are arbitrary and the remaining constants are given by

$$\begin{aligned} K_2^n &= -K_1^n \left(\frac{2\mathrm{G}_f^N}{\mathrm{G}_f^N - \mathrm{G}_c^N}\right) \frac{b_N^{2n}}{b_N^{2n}\frac{\mathrm{G}_c^N+\mathrm{G}_f^N}{\mathrm{G}_f^N-\mathrm{G}_c^N} + a_N^{2n}}, \\ K_3^n &= -K_1^n \left(\frac{\mathrm{G}_c^N + \mathrm{G}_f^N}{\mathrm{G}_f^N - \mathrm{G}_c^N}\right) \frac{b_N^{2n}}{b_N^{2n}\frac{\mathrm{G}_c^N+\mathrm{G}_f^N}{\mathrm{G}_f^N-\mathrm{G}_c^N} + a_N^{2n}}, \\ K_4^n &= -K_1^n \frac{a_N^{2n} b_N^{2n}}{b_N^{2n}\frac{\mathrm{G}_c^N+\mathrm{G}_f^N}{\mathrm{G}_f^N-\mathrm{G}_c^N} + a_N^{2n}}. \end{aligned} \tag{5.31}$$

The stationary values are given by

$$\beta_n = (\mathrm{G}_c^N)^{-1} \left(\frac{\mathrm{G}_f^N(b_N^{2n} - a_N^{2n}) + \mathrm{G}_c^N(b_N^{2n} + a_N^{2n})}{\mathrm{G}_f^N(b_N^{2n} + a_N^{2n}) + \mathrm{G}_c^N(b_N^{2n} - a_N^{2n})}\right). \tag{5.32}$$

One readily checks for $\mathrm{G}_f^N \ge \mathrm{G}_c^N$ that β_n is increasing with n and that $\beta_1 = 1/G_{CCA}^N$. It can also be easily checked that (5.32) gives all of the stationary values. Indeed one supposes there exists a stationary value $\tilde{\beta}$ not given by (5.32) to find that the only associated stationary functions are of the form $r = \text{const}$, $h = -\text{const}$. Thus we find that $\hat{\beta} = \mathrm{G}_m\beta_1 = \mathrm{G}_m/G_{CCA}^N$ to conclude that

$$\text{if } \frac{\mathrm{G}_m}{G_{CCA}^N} \ge 1, \text{ then } D \le 0, \tag{5.33}$$

and Proposition 5.1 follows.

The torsional rigidity for an arbitrary simply connected cross section reinforced with N circular coated fibers is denoted by $\mathcal{T}^N(\Omega)$ and repeated application of Proposition 5.1 gives the following.

PROPOSITION 5.2 (upper bound). *If* $\mathrm{G}_c^i \le \mathrm{G}_f^i$, $i = 1, \ldots, N$, *and*

$$G_{CCA}^i \le \mathrm{G}_m \text{ for } i = 1 \ldots, N, \tag{5.34}$$

then

$$\mathcal{T}^N(\Omega) \le \mathrm{G}_m \mathcal{T}_0(\Omega) + \sum_{i=1}^{N} \left(T_f^i - \frac{\pi}{2}\mathrm{G}_m\, b_i^4\right), \tag{5.35}$$

where $\mathcal{T}_0(\Omega)$ *is the torsional rigidity of the homogeneous cross section containing material with unit shear modulus.*

Proposition 2.6 follows directly from Proposition 5.2. To establish Proposition 2.4 one recalls the isoperimetric inequality

$$\mathcal{T}_0(\Omega) \leq \frac{\pi}{2} R^4, \tag{5.36}$$

which holds for all cross sections Ω with area πR^2; see Polya [7]. Proposition 2.4 then follows from (5.36) and (5.35) when $\mathrm{G}_f^i = \mathrm{G}_f$ and $\mathrm{G}_c^i = \mathrm{G}_c$, and $a_i/b_i = \nu^{1/2}$ for $i = 1, \ldots, N$.

6. Lower bounds on the torsional rigidity for $\mathbf{G_f^i \leq G_c^i}$. We focus on the case where $\mathrm{G}_f^i \leq \mathrm{G}_c^i$, $i = 1, \ldots, N$. We proceed as in the last section and investigate the effects of adding a circular coated fiber to an already existing configuration of $N-1$ coated fibers. At present no assumptions on the geometry or shear moduli of the $N-1$ coated fibers are made. The part of the shaft cross section already occupied by the coated fibers is denoted by A and the cross section of the circular coated fiber to be added by Σ. Here Σ is composed of a circular fiber of radius a_N with shear modulus G_f^N surrounded by a coating of outer radius b_N with shear modulus G_c^N. The torsional rigidity of the original configuration is denoted by $\mathcal{T}(A, \Omega)$. The rigidity associated with the added fiber is written as $\mathcal{T}(A \cup \Sigma, \Omega)$.

PROPOSITION 6.1 (lower rigidity inequality). *If* $\mathrm{G}_f^N \leq \mathrm{G}_c^N$ *and if*

$$\mathrm{G}_m \leq G_{CCA}^N, \tag{6.1}$$

then

$$\mathcal{T}(A, \Omega) + T_f^N - \frac{\pi}{2} \mathrm{G}_m \, b_N^4 \leq \mathcal{T}(A \cup \Sigma, \Omega). \tag{6.2}$$

Proposition 6.1 is established with the aid of the variational principle given by (2.1). One writes (2.1) as $\mathcal{T}(A \cup \Sigma, \Omega) = -2\mathcal{E}(A \cup \Sigma, \Omega)$, where

$$\mathcal{E}(A \cup \Sigma, \Omega) = \min_{\varphi} \left\{ \frac{1}{2} \int_\Omega \mathcal{G}^{-1}(\mathbf{x}) |\nabla \varphi|^2 \, d\mathbf{x} \, - \, 2 \int_\Omega \varphi \, d\mathbf{x} \right\}, \tag{6.3}$$

where the piecewise constant shear modulus $\mathcal{G}(\mathbf{x})$ is G_m in the matrix and takes the values G_f^i and G_c^i in the ith fiber and coating, respectively, for $i = 1, \ldots, N$. The idea of the proof is to estimate the quantity $\mathcal{E}(A \cup \Sigma, \Omega)$ in terms of $\mathcal{E}(A, \Omega)$ associated with the original configuration of $N-1$ fibers. We let $G(\mathbf{x})$ denote the piecewise constant shear modulus for the original configuration A of $N-1$ fibers. Here $G(\mathbf{x}) = \mathcal{G}(\mathbf{x})$ outside of Σ and inside Σ the shear modulus $G(\mathbf{x}) = \mathrm{G}_m$. We regroup terms in the variational principle (6.3) and write

$$\begin{aligned} \mathcal{E}(A \cup \Sigma, \Omega) = \min_{\varphi} \Bigg\{ & \frac{1}{2} \int_\Omega G^{-1}(\mathbf{x}) |\nabla \varphi|^2 d\mathbf{x} - 2 \int_\Omega \varphi d\mathbf{x} \\ & + \frac{1}{2} \left(\int_\Sigma (\mathcal{G}^{-1}(\mathbf{x}) - \mathrm{G}_m^{-1}) \right) |\nabla \varphi|^2 d\mathbf{x} \Bigg\}. \end{aligned} \tag{6.4}$$

We obtain an estimate by substitution of a suitable trial field in (6.4). Our choice is made as follows: We introduce the stress potential Φ_A for the configuration A. Here Φ_A is continuous in Ω,

$$-G^{-1}(\mathbf{x}) \Delta \Phi_A = 2, \tag{6.5}$$

and satisfies the transmission conditions

(6.6)
$$\mathrm{G}_f^{i\,-1}\nabla\tilde{\Phi}_{|_f}\cdot\mathbf{n}=\mathrm{G}_c^{i\,-1}\nabla\tilde{\Phi}_{|_c}\cdot\mathbf{n} \text{ on the fiber–coating interface } |\mathbf{x}-\mathbf{x}_i|=a_i, i=1,\dots,N-1,$$

and

(6.7)
$$\mathrm{G}_f^{i\,-1}\nabla\tilde{\Phi}_{|_c}\cdot\mathbf{n}=\mathrm{G}_m{}^{-1}\nabla\tilde{\Phi}_{|_m}\cdot\mathbf{n} \text{ on the matrix–coating interface, } |\mathbf{x}-\mathbf{x}_i|=b_i,\dots,N-1.$$

The trial field φ is chosen to match Φ_A outside the coated fiber cross section Σ but inside we suppose that $\varphi=\Phi_A+\delta$, where δ is continuous, vanishes on the boundary of Σ, is square integrable inside Σ, and has square integrable gradient over Σ. One easily checks that

$$\int_\Sigma \mathrm{G}_m{}^{-1}\nabla\Phi_A\cdot\nabla\delta\,d\mathbf{x}=2\int_\Sigma\delta\,d\mathbf{x}. \tag{6.8}$$

Application of (6.8) and rearranging terms as in the previous section yield

$$\begin{aligned}\mathcal{T}(A\cup\Sigma,\Omega)\geq\mathcal{T}(A,\Omega)&-\int_\Sigma \mathrm{G}_m{}^{-1}|\nabla\delta|^2d\mathbf{x}\\ &+\int_\Sigma(\mathrm{G}_m^{-1}-\mathcal{G}^{-1}(\mathbf{x}))|\nabla\varphi|^2d\mathbf{x}.\end{aligned}\tag{6.9}$$

On maximizing the right-hand side of (6.9) with respect to δ, we obtain

$$\mathcal{T}(A\cup\Sigma,\Omega)\geq\mathcal{T}(A,\Omega)+\mathcal{U}, \tag{6.10}$$

where

$$\mathcal{U}=\int_\Sigma(\mathrm{G}_m^{-1}-\mathcal{G}^{-1}(\mathbf{x}))\nabla\hat{\varphi}\cdot\nabla\Phi_A\,d\mathbf{x}. \tag{6.11}$$

Here $\hat{\varphi}=\hat{\delta}+\Phi_A$ in Σ and $\hat{\delta}$ solves

$$\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})\nabla\hat{\delta}\cdot\nabla u\,d\mathbf{x}=\int_\Sigma(\mathrm{G}_m^{-1}-\mathcal{G}^{-1}(\mathbf{x}))\nabla\Phi_A\cdot\nabla u\,d\mathbf{x} \tag{6.12}$$

for every trial u vanishing on the boundary of Σ. From (6.8) and (6.12) we see that $\hat{\varphi}$ solves

$$\int_\Sigma\mathcal{G}^{-1}(\mathbf{x})\nabla\hat{\varphi}\cdot\nabla u\,d\mathbf{x}=2\int_\Sigma u\,d\mathbf{x} \tag{6.13}$$

for every trial u vanishing on the boundary of Σ. Proceeding as in the last section we introduce the continuous functions ψ, r, ψ^h, and h such that $\hat{\varphi}=\psi-h$ and $\Phi_A=r+\psi^h$. Here ψ^h and ψ are the same functions introduced in section 5. The function ψ^h is the solution of (5.18) and ψ solves the transmission problem given by (5.19) and (5.20). The function r is harmonic in Σ and $r=\Phi_A$ on the boundary of Σ. The function h is continuous on Σ and $h=-\Phi_A$ on the boundary of Σ. It is the solution of the transmission problem given by (5.21) and (5.22).

Substitution of the functions ψ^h, ψ, r, and h into $\mathcal{U}$ gives

$$\mathcal{T}(A\cup\Sigma,\Omega)\geq\mathcal{T}(A,\Omega)+T_f^N-\frac{\pi}{2}\mathrm{G}_m\,b_N^4+D, \tag{6.14}$$

where the indefinite quantity D is given by (5.25). Its clear that (6.2) holds when $D \geq 0$. We find conditions for which $D \geq 0$ when $r \neq$ const and $h \neq$ const. To do this we search for the largest number ρ for which

$$\int_\Sigma |\nabla r|^2 \, d\mathbf{x} - \rho \int_\Sigma \frac{\mathrm{G}_m}{\mathcal{G}(\mathbf{x})} |\nabla h|^2 \, d\mathbf{x} \geq 0 \tag{6.15}$$

for every choice of r and h in $\mathcal{C}$ and $r \neq$ const and $h \neq -$ const. The largest ρ is given by

$$\hat{\rho} = \inf_{\mathcal{C}} \frac{\int_\Sigma |\nabla r|^2 \, d\mathbf{x}}{\int_\Sigma \frac{\mathrm{G}_m}{\mathcal{G}(\mathbf{x})} |\nabla h|^2 \, d\mathbf{x}}. \tag{6.16}$$

Proceeding as in the previous section, we find that $\hat{\rho} = G^N_{CCA}/\mathrm{G}_m$. Thus $D \geq 0$ when $G^N_{CCA}/\mathrm{G}_m \geq 1$ and the proposition follows.

The torsional rigidity for an arbitrary simply connected cross section reinforced with N circular coated fibers is denoted by $\mathcal{T}^N(\Omega)$ and repeated application of Proposition 6.1 gives the following.

PROPOSITION 6.2 (lower bound). *If* $\mathrm{G}^i_f \leq \mathrm{G}^i_c$, $i = 1, \ldots, N$, *and*

$$\mathrm{G}_m \leq G^i_{CCA} \text{ for } i = 1 \ldots, N, \tag{6.17}$$

then

$$\mathrm{G}_m \mathcal{T}_0(\Omega) + \sum_{i=1}^{N} \left(T^i_f - \frac{\pi}{2} \mathrm{G}_m \, b_i^4 \right) \leq \mathcal{T}^N(\Omega). \tag{6.18}$$

Proposition 2.7 follows directly from Proposition 6.2.

DELAYED COUPLING BETWEEN TWO NEURAL NETWORK LOOPS*

SUE ANN CAMPBELL†, R. EDWARDS‡, AND P. VAN DEN DRIESSCHE§

Abstract. Coupled loops with time delays are common in physiological systems such as neural networks. We study a Hopfield-type network that consists of a pair of one-way loops each with three neurons and two-way coupling (of either excitatory or inhibitory type) between a single neuron of each loop. Time delays are introduced in the connections between loops, and the effects of coupling strengths and delays on the network dynamics are investigated. These effects depend strongly on whether the coupling is symmetric (of the same type in both directions) or asymmetric (inhibitory in one direction and excitatory in the other). The network of six delay differential equations is studied by linear stability analysis and bifurcation theory. Loops having inherently stable zero solutions cannot be destabilized by weak coupling, regardless of the delay. Asymmetric coupling is weakly stabilizing but easily upset by delays. Symmetric coupling (if not too weak) can destabilize an inherently stable zero solution, leading to nontrivial fixed points if the gain of the neuron response function is not too negative or to oscillation otherwise. In the oscillation case, intermediate delays can restabilize the zero solution. At the borderline of the weak coupling region (symmetric or asymmetric), stability can change with delay ranges. When the coupling strengths are of the same magnitude, the oscillations of corresponding neurons in the two loops can be in phase, antiphase (symmetric coupling), or one quarter period out of phase (asymmetric coupling) depending on the delay.

1. Introduction.

Interacting loops that are capable of sustaining oscillation are common in physiological systems. One approach to modeling such systems is via coupled oscillators [13]. However, this approach does not lend itself to studying the patterns of connections between oscillators when each oscillator is itself a network. Furthermore, such networks may not be inherently oscillatory, but oscillations may arise as a result of the coupling between them. If the coupling between networks is slower than each network's internal dynamics, then additional effects can arise from the delay in the coupling. The coupling may also be faster than the internal dynamics, in which case each network could be modeled with internal delays, or both the internal connections and coupling between networks could have delays.

These questions arise in models of the brain's motor circuitry, where there are many interacting loops and feedback systems. For example, functionally separate parallel loops operate through the basal ganglia (e.g., through matrisomes in the striatum [10]) but may interact through crosstalk [2]. These loop interactions have been implicated in the generation of tremor oscillations in Parkinson's disease. The effect of the particular patterns of connections between parallel copies of a network was studied by Edwards and Gill [5], where synchrony of the network copies occurred

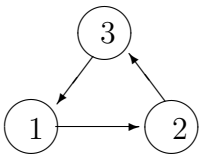
with appropriate crosstalk, but only when each network was in a periodic regime.

Previous work on these problems has not explicitly allowed for delays in connections. While analysis becomes more difficult with delays, their effects may be important for the applications. Research on Hopfield-type neural networks with delays, first introduced by Marcus and Westervelt [15], has shown that delays can modify dynamics in interesting ways. Delays have been inserted into various simple loop structures. Some work [14, 17, 18] has considered systems of two neurons with delayed connections. Shayer and Campbell [18] gave a detailed analysis of dynamics of two coupled units with delayed coupling and also delayed self-input, showing in particular how oscillation occurs when the interactions are strong enough, but also depending on the delays. A number of authors have studied loops of three or more neurons with delays, showing various types of behavior including oscillations, waves, steady states, and even chaos [1, 3, 7, 16, 21]. Other work has dealt with conditions for stability of steady states in Hopfield-type networks of arbitrary structure (see, for example, [4, 9, 18, 19, 20] and references therein).

The current study is an initial attempt to determine the effects of coupling (or crosstalk) between parallel copies of a network structure in the presence of delays. We focus on the simplest example that uses Hopfield network equations and in which each network copy is capable of oscillation, namely, a pair of simple loops of three neurons with one-way connections, with coupling between only one neuron of each loop. We consider the case in which the coupling between the loops, rather than the connections within the loops, is delayed. Of the previous studies mentioned above, this is perhaps most similar to that of Shayer and Campbell [18], in which the concern was also with delayed coupling between two potential oscillators, though the oscillators were single neurons with self-input rather than small loops. A single (one-way) loop of three Hopfield neurons can oscillate if their connections are inhibitory and sufficiently strong. The coupling between the loops can change this behavior, but we seek to determine how the behavior depends on the strength of coupling, the delay in coupling, and the internal gain or connection strengths within each loop.

We begin in section 2 with the dynamics of a single 3-loop (loop of three neurons with one-way connections). In section 3 we look at a pair of coupled 3-loops, giving results on stability of the trivial equilibrium and the presence of oscillation over the parameter space defined by the internal gain parameter (positive or negative) and a coupling strength parameter, allowing either inhibitory or excitatory coupling in either direction. Section 4 deals with delayed coupling between the loops. Most of the analysis is local, but where we do not have global results, numerical experiments support the conclusions. We summarize our results with a discussion (section 5).

2. Isolated 3-loop without delay. Consider a Hopfield-type network of three neurons connected in a (one-way) loop as in the following figure:



This can be described by the system of ordinary differential equations (with subscripts interpreted mod 3)

$$\frac{dx_j}{dt} = -x_j + \tanh(bx_{j-1}), \qquad j = 1, 2, 3, \tag{2.1}$$

together with initial condition $x(0) = (x_1(0), x_2(0), x_3(0))^t$. Here x_j represents the normalized voltage of neuron j and $b \in \mathbb{R}$ is the gain of the response function, assumed equal for each neuron. Interactions are inhibitory if $b < 0$ and excitatory if $b > 0$. System (2.1) always has the trivial equilibrium $(0, 0, 0)^t$, i.e., at the origin. The existence of nontrivial equilibria depends on the value of b, as in the following result.

THEOREM 2.1. *If $b > 1$, then system (2.1) has one positive symmetric and one negative symmetric equilibrium. If $b \leq 1$, then there is no nontrivial equilibrium.*

Proof. At an equilibrium of (2.1), $x_1 = \tanh(bx_3) \equiv f(x_3)$; thus $x_2 = \tanh(bx_1) = f(f(x_3))$ and $x_3 = \tanh(bx_2) = F(x_3)$, where $F(x) \equiv f(f(f(x)))$. Consider

$$h(x_3) \equiv x_3 - F(x_3) = 0. \tag{2.2}$$

Since $f'(0) = b$, $h'(0) = 1 - b^3$. Also $\lim_{x_3 \to \pm\infty} h(x_3) = \pm\infty$. From (2.2)

$$h'(x_3) = 1 - b^3 \operatorname{sech}^2(b\tanh(b\tanh(bx_3))) \operatorname{sech}^2(b\tanh(bx_3)) \operatorname{sech}^2(bx_3). \tag{2.3}$$

Thus $h'(x_3) \geq 1 - b^3$ for $b \geq 0$, which is nonnegative (for all x_3) if $b \leq 1$. Since $h(0) = 0$, there is no nontrivial equilibrium for $0 \leq b \leq 1$. For $b < 0$, (2.3) gives $h'(x_3) \geq 1$, which again shows that there is no nontrivial equilibrium.

If $b > 1$, then (2.3) gives $h''(x_3) > 0$ for all $x_3 > 0$, showing that $h(x_3)$ is concave up. This, together with $h(0) = 0$, $h'(0) < 0$, and $h(x_3) > 0$ for sufficiently large $x_3 > 0$, shows that there is a unique positive solution $x_3 = \overline{x_3} > 0$ to (2.2). The corresponding equilibrium values $\overline{x_1} > 0$, $\overline{x_2} > 0$ are determined from $\overline{x_3}$ and (2.1). Since (2.2) holds also for x_1 and x_2, it must be that $\overline{x_1} = \overline{x_2} = \overline{x_3} = \overline{x}$, giving the unique symmetric positive equilibrium as $(x_1, x_2, x_3)\,t = (\overline{x}, \overline{x}, \overline{x})^t$, with $0 < \overline{x} < 1$ from the equilibrium equation $\overline{x} = \tanh(b\overline{x})$. By symmetry, there is also a unique negative equilibrium $(x_1, x_2, x_3)\,t = (-\overline{x}, -\overline{x}, -\overline{x})^t$ if $b > 1$. ∎

The linear stability of an equilibrium $(\overline{x}, \overline{x}, \overline{x})\,t$ is governed by $\frac{dx}{dt} = Ax$, with

$$A = \begin{bmatrix} -1 & 0 & b\operatorname{sech}^2(b\overline{x}) \\ b\operatorname{sech}^2(b\overline{x}) & -1 & 0 \\ 0 & b\operatorname{sech}^2(b\overline{x}) & -1 \end{bmatrix}. \tag{2.4}$$

The following result shows that a Hopf bifurcation can occur at the trivial equilibrium.

THEOREM 2.2. *The trivial solution of (2.1) is locally asymptotically stable iff $-2 < b < 1$. At $b = -2$, the system undergoes a Hopf bifurcation and has stable limit cycle solutions for $b \lesssim -2$.*

Proof. The characteristic equation of A at $\overline{x} = 0$ in (2.4) is $-(1+\lambda)^3 + b^3 = 0$. For $-2 < b < 1$, all eigenvalues have negative real parts; thus the system is linearly stable. When $b = 1$, there is a zero eigenvalue, and for $b > 1$ there is a real positive eigenvalue. When $b = -2$, the eigenvalues are -3, $\pm\sqrt{3}i$, and for $b < -2$ there is a complex pair of eigenvalues with positive real part. At $b = -2$, matrix A is diagonalized by a matrix P of eigenvectors. Approximating $\tanh(bx_j)$ by $bx_j - b^3x_j^3/3$ (ignoring terms

of order ≥ 5) system (2.1) with $x = (x_1, x_2, x_3)^t$ is transformed by $y = P^{-1}x$ with $y = (y_1, y_2, y_3)^t$ at $b = -2$ to

$$\frac{dy}{dt} = \begin{bmatrix} 0 & -\sqrt{3} & 0 \\ \sqrt{3} & 0 & 0 \\ 0 & 0 & -3 \end{bmatrix} y + P^{-1}\left(\frac{8}{3}\right) \begin{bmatrix} (y_1 + y_3)^3 \\ \left(-y_1/2 - \sqrt{3}y_2/2 + y_3\right)^3 \\ \left(-y_1/2 + \sqrt{3}y_2/2 + y_3\right)^3 \end{bmatrix}. \tag{2.5}$$

The center manifold is given by $y_3 = H(y_1, y_2)$, with H third order because the third equation of (2.5) has no quadratic term. On the center manifold, (2.5) becomes

$$\begin{bmatrix} \frac{dy_1}{dt} \\ \frac{dy_2}{dt} \end{bmatrix} = \begin{bmatrix} 0 & -\sqrt{3} \\ \sqrt{3} & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} + \begin{bmatrix} p(y_1, y_2) \\ q(y_1, y_2) \end{bmatrix}, \tag{2.6}$$

where p and q are determined by substituting $y_3 = H(y_1, y_2)$ in the first two equations of (2.5). The standard formula for the criticality coefficient ((3.4.11) of Guckenheimer and Holmes [11]) gives $a = -1 < 0$. Since $\mathrm{Re}\,(\partial\lambda/\partial b) = -1/2$ when evaluated at $\lambda = \pm\sqrt{3}i$, $b = -2$, the supercritical Hopf bifurcation gives rise to stable periodic solutions occurring for $b \lesssim -2$. □

For a Hopfield 2-loop, the corresponding characteristic equation, $-(1+\lambda)^2 + b^2 = 0$, cannot have pure imaginary solutions. Thus a Hopfield 3-loop without delay is the smallest that can undergo a Hopf bifurcation at the origin.

Global results for the trivial equilibrium when $-2 < b \leq 1$ are now stated. Theorem 2.1 of van den Driessche and Zou [20] can be used to show easily that if $|b| < 1$, then the origin is globally asymptotically stable. For system (2.1), a Lyapunov function $V = \sum_{j=1}^{3} x_j^2$ can be used to extend the range of global stability of the origin to $-\sqrt{2} \leq b \leq 1$. Note that $b = 1$ is included here, whereas it was not in Theorem 2.2. Numerical results indicate that the full range of global stability is $-2 < b \leq 1$.

Global results for the existence and stability of periodic solutions for $b < -2$ are more difficult to obtain. However, in the limit $b \to -\infty$, when the hyperbolic tangents become step functions, the problem is easier. Glass and Pasternack [8] showed that n-dimensional networks similar to (2.1) but with step functions have globally asymptotically stable periodic solutions for $n \geq 3$. Numerical simulations of (2.1) with $b < -2$ indicate that there is a unique globally asymptotically stable periodic solution for each $b \in (-\infty, -2)$.

Consider now the stability of the nontrivial equilibria (when they exist).

THEOREM 2.3. *For $b > 1$, the positive and negative symmetric equilibria of* (2.1) *are locally asymptotically stable.*

Proof. From (2.4), the characteristic equation of A is $-(1+\lambda)^3 + b^3\,\mathrm{sech}^6(b\overline{x}) = 0$, where $(\overline{x}, \overline{x}, \overline{x})^t$ with $\overline{x} > 0$ is the positive symmetric equilibrium of (2.1) that exists for $b > 1$ (by Theorem 2.1). Thus the eigenvalues are

$$\lambda_1(\overline{x}) = -1 + b\,\mathrm{sech}^2(b\overline{x}), \quad \lambda_{2,3}(\overline{x}) = -1 - \left(\frac{1}{2} \pm i\sqrt{\frac{3}{2}}\right) b\,\mathrm{sech}^2(b\overline{x}).$$

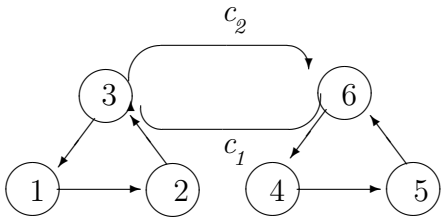
Since $b\,\mathrm{sech}^2(b\overline{x}) > 0$, local stability follows if $\lambda_1(\overline{x}) < 0$. By (2.1), $b\overline{x} = \tanh^{-1}(\overline{x})$ and $\mathrm{sech}^2(b\overline{x}) = 1 - \overline{x}^2$, giving $\lambda_1(\overline{x}) = -1 + \tanh^{-1}(\overline{x})\left(1 - \overline{x}^2\right)/\overline{x}$ for $0 < \overline{x} < 1$, which is equivalent to $1 < b < \infty$. Also, $\lambda_1(0) = 0$ at $b = 1$. Differentiating gives

$$\frac{d\lambda_1}{d\overline{x}}(\overline{x}) = \left(\overline{x} - \left(1 + \overline{x}^2\right)\tanh^{-1}(\overline{x})\right)/\overline{x}^2,$$

which is negative, since $\tanh^{-1}(\overline{x}) > \overline{x}$. Thus $\lambda_1(\overline{x}) < 0$, showing that the positive symmetric equilibrium is locally stable. Stability for $\overline{x} < 0$ follows by symmetry. ∎

Note that $\overline{x} \to 0^+$ as $b \to 1^+$, showing that the linearly stable positive and negative equilibria bifurcate from the trivial equilibrium as it loses stability. Thus the system has a supercritical pitchfork bifurcation at $b = 1$.

3. Coupled loops without delay. Consider a pair of coupled 3-loops:



The individual loops each follow the form of (2.1). Coupling strengths are given by c_1 and c_2, where $bc_j > 0$ implies excitatory and $bc_j < 0$ implies inhibitory coupling. The system of equations for the entire system is then

$$
\begin{aligned}
&\frac{dx_1}{dt} = -x_1 + \tanh(bx_3), \quad \frac{dx_2}{dt} = -x_2 + \tanh(bx_1),\\
&\frac{dx_3}{dt} = -x_3 + \tanh(bx_2) + c_1 \tanh(bx_6),\\
&\frac{dx_4}{dt} = -x_4 + \tanh(bx_6), \quad \frac{dx_5}{dt} = -x_5 + \tanh(bx_4),\\
&\frac{dx_6}{dt} = -x_6 + \tanh(bx_5) + c_2 \tanh(bx_3),
\end{aligned}
\tag{3.1}
$$

together with initial condition $x(0) = (x_1(0), x_2(0), x_3(0), x_4(0), x_5(0), x_6(0))^t$.

Equilibria of (3.1) satisfy $x_2 = f(x_1) = f(f(x_3))$ and $x_5 = f(x_4) = f(f(x_6))$, where $f(x_j) \equiv \tanh(bx_j)$. Using the other two equations gives

$$
x_3 = F(x_3) + c_1 f(x_6), \quad x_6 = F(x_6) + c_2 f(x_3), \tag{3.2}
$$

where $F(x) = f(f(f(x)))$ as before. This can be reduced (for $c_1 \neq 0$) to

$$
g(x_3) \equiv [x_3 - F(x_3)] - c_1 f\left(f\left(f\left(\frac{1}{c_1}[x_3 - F(x_3)]\right)\right) + c_2 f(x_3)\right) = 0. \tag{3.3}
$$

Any x_3 satisfying (3.3) determines x_6 and hence all the variables at an equilibrium. Clearly the origin $x_j = 0$, $j = 1, \ldots, 6$, is an equilibrium, and our interest mostly focuses on its stability properties. However, we first show the existence of nontrivial equilibria for some b values. Define $d \equiv b^2 c_1 c_2$ and $\beta \equiv b^3$. When $d > 0$, the coupling is either excitatory or inhibitory in both directions (symmetric coupling); when $d < 0$, the coupling is excitatory in one direction and inhibitory in the other (asymmetric coupling).

THEOREM 3.1. *If $d > (1-\beta)^2$, then system* (3.1) *has nontrivial equilibria. If either* (i) $0 < \beta < 1$ *and* $d < (1-\beta)^2$, *or* (ii) $\beta < 0$ *and* $d < 1$, *then system* (3.1) *has no nontrivial equilibrium.*

Proof. Assuming $c_1 \neq 0$, differentiating (3.3) gives

$$g'(x_3) = (1 - F'(x_3))\left(1 - \beta s_1^2 s_2^2 s_3^2\right) - d s_1^2 s_4^2,$$

where s_k^2, $k = 1, \ldots, 4$, represents $\operatorname{sech}^2(\cdot)$ evaluated at some point; thus $0 < s_k^2 \leq 1$. Since $F'(0) = \beta$, it follows from the derivative above that $g'(0) = (1-\beta)^2 - d$; thus $g(x_3)$ is strictly decreasing at the origin if $d > (1-\beta)^2$. Clearly $g(0) = 0$ and $\lim_{x\to\infty} g(x_3) = \infty$ because f (and therefore F) is bounded. Thus by continuity there is at least one positive value of x_3, namely, $\overline{x}_3 > 0$, such that $g(\overline{x}_3) = 0$. By symmetry, $g(-\overline{x}_3) = 0$ and these values determine the other variables at a nontrivial equilibrium.

For $x_3 > 0$ if $\beta > 0$, then $0 < F'(x_3) < \beta$. Thus $0 < \beta < 1$ implies that $(1-\beta)^2 - d < g'(x_3)$ if $d \geq 0$, and $(1-\beta)^2 < g'(x_3) < 1 - d$ if $d \leq 0$. Thus in case (i), $g(x_3)$ is strictly increasing for all $x_3 > 0$. Similarly $\beta < 0$ implies that $\beta < F'(x_3) < 0$ and $1 - d < g'(x_3) < (1-\beta)^2$ if $d \geq 0$, and $1 < g'(x_3) < (1-\beta)^2 - d$ if $d \leq 0$. Thus in case (ii), $g(x_3)$ is strictly increasing for all $x_3 > 0$. In both cases there is no nontrivial positive equilibrium and, by symmetry, no nontrivial negative equilibrium. If $c_1 = 0$ but $c_2 \neq 0$, then reversing the roles of x_3 and x_6 leads to the same conclusions. If $c_1 = c_2 = 0$, then the results follow from Theorem 2.1. □

Note that Theorem 3.1 does not specify all regions of parameter space in which nontrivial equilibria occur. It does not provide information about the regions where β is large and positive or where β is large and negative with $d > 1$. Moreover, the number and signs of equilibria may depend on the values of c_1 and c_2 for a given d. For example, if $b = 2$ (so that $\beta = 8$) and $c_1 = c_2 = 0$, then there is one positive and one negative nontrivial equilibrium for each uncoupled loop (see Theorem 2.1) so that for the full system (3.1) there are nine equilibria, three of which have x_3 positive. However, if the coupling goes only one way, e.g., $c_1 > 0$ but $c_2 = 0$, then there can be two or four different positive equilibrium values for x_3 when $b > 1$.

The special case of symmetric coupling $c_1 = c_2$ is now considered.

THEOREM 3.2. *Let $b > 1$. If $c_1 = c_2 > 0$, then system (3.1) has a positive equilibrium $x^* = (\overline{x}_1, \overline{x}_2, \overline{x}_3, \overline{x}_1, \overline{x}_2, \overline{x}_3)^t$ and an equilibrium $-x^*$; if $c_1 = c_2 < 0$, then it has equilibria $\tilde{x}^* = (\overline{x}_1, \overline{x}_2, \overline{x}_3, -\overline{x}_1, -\overline{x}_2, -\overline{x}_3)^t$ with $\overline{x}_j > 0$, $j = 1, 2, 3$, and $-\tilde{x}^*$.*

Proof. Consider $c_1 = c_2 > 0$ and suppose that $x_3 = x_6$; then (3.2) reduces to

$$G(x_3) \equiv x_3 - F(x_3) - c_1 f(x_3) = 0$$

at an equilibrium. Note that $G(0) = 0$, $\lim_{x_3\to\infty} G(x_3) = \infty$ and $G'(0) = 1 - b^3 - c_1 b < 0$. Thus there is at least one positive zero $\overline{x}_3$ of $G(x_3)$. Since $\overline{x}_3 = \overline{x}_6 > 0$, it follows that $\overline{x}_1 = \overline{x}_4 > 0$ and $\overline{x}_2 = \overline{x}_5 > 0$. By symmetry, the negative equilibrium follows.

Consider $c_1 = c_2 < 0$ and suppose that $x_3 = -x_6$; then (3.2) reduces to

$$\tilde{G}(x_3) \equiv x_3 - F(x_3) + c_1 f(x_3) = 0$$

at an equilibrium. By the above there is at least one positive zero $\overline{x}_3$ of $\tilde{G}(x_3)$. Then $\overline{x}_1, \overline{x}_2 > 0$ and $\overline{x}_4, \overline{x}_5, \overline{x}_6 < 0$. Symmetry gives the second equilibrium. □

Numerical solutions demonstrate that additional equilibria can occur: for $c_1 = c_2 > 0$ (respectively, < 0) there may be one or three equilibria with $\overline{x}_3 > 0$, $\overline{x}_6 < 0$ (respectively, $\overline{x}_3 < 0$, $\overline{x}_6 > 0$) and an equal number of symmetric equilibria.

The linear stability of the trivial equilibrium $x_j = 0$, $j = 1, \ldots, 6$, can be determined from $\frac{dx}{dt} = Ax$ with $x = (x_1, \ldots, x_6)^t$ and

$$A = \begin{bmatrix} -1 & 0 & b & 0 & 0 & 0 \\ b & -1 & 0 & 0 & 0 & 0 \\ 0 & b & -1 & 0 & 0 & bc_1 \\ 0 & 0 & 0 & -1 & 0 & b \\ 0 & 0 & 0 & b & -1 & 0 \\ 0 & 0 & bc_2 & 0 & b & -1 \end{bmatrix}. \tag{3.4}$$

The characteristic equation for this system at $x_j = 0$ with $d \equiv b^2 c_1 c_2$ and $\beta \equiv b^3$ is

$$\left[(1+\lambda)^3 - \beta\right]^2 - d\,(1+\lambda)^4 = 0. \tag{3.5}$$

First consider the case $d \geq 0$. The characteristic equation then factors as follows:

$$\Delta_+^+(\lambda)\Delta_-^+(\lambda) \equiv \left[(1+\lambda)^3 - \beta + \sqrt{d}\,(1+\lambda)^2\right]\left[(1+\lambda)^3 - \beta - \sqrt{d}\,(1+\lambda)^2\right] = 0. \tag{3.6}$$

From the single-loop results (see Theorem 2.2), if $d = 0$, then the origin is locally asymptotically stable for $-8 < \beta < 1$ and unstable for $\beta < -8$ and $\beta > 1$. To find the stability region for $\sqrt{d} > 0$, look for curves in the βd-plane on which there is a zero or pure imaginary eigenvalue.

From (3.6), zero eigenvalues occur when $1 - \beta = \pm\sqrt{d}$. Pure imaginary eigenvalues $\lambda = i\omega$ with $\omega > 0$ make $\Delta_+^+(\lambda) = 0$ when their real and imaginary parts are zero, namely,

$$1 - 3\omega^2 - \beta + \sqrt{d}\left(1 - \omega^2\right) = 0 \quad \text{and} \quad \omega\left(3 - \omega^2 + 2\sqrt{d}\right) = 0.$$

The second condition above gives $\omega^2 = 3 + 2\sqrt{d}$, which can be substituted into the first condition to yield $\beta = -2(2 + \sqrt{d})^2$. To make $\Delta_-^+(\lambda) = 0$, there is an analogous condition where $\sqrt{d}$ is replaced by $(-\sqrt{d})$, as long as $\omega^2 = 3 - 2\sqrt{d} > 0$, i.e., $\sqrt{d} < \frac{3}{2}$, namely, $\beta = -2(2 - \sqrt{d})^2$. Note that this curve intersects the parabola of zero eigenvalues at $\beta = -\frac{1}{2}$, $d = \frac{9}{4}$. These curves are shown in Figure 3.1. It is clear by continuity from the single-loop results ($d = 0$) that the region labeled "STABLE" in the figure corresponds to linear stability of the origin. By picking points in the other regions, it can easily be checked that the origin is unstable there.

In the case where $d \leq 0$ in (3.5), factor the characteristic equation as

$$\Delta_+^-(\lambda)\Delta_-^-(\lambda) \equiv \left[(1+\lambda)^3 - \beta + i\sqrt{-d}\,(1+\lambda)^2\right]\left[(1+\lambda)^3 - \beta - i\sqrt{-d}\,(1+\lambda)^2\right] = 0. \tag{3.7}$$

Now, $\lambda = 0$ when $1 - \beta \pm i\sqrt{-d} = 0$, i.e., only at the point $\beta = 1$ and $d = 0$. Working with $\Delta_+^-(\lambda) = 0$, $\lambda = i\omega$ implies that

$$\beta = 1 - 2\sqrt{-d}\omega - 3\omega^2 \quad \text{and} \quad \sqrt{-d} = \frac{\omega\left(\omega^2 - 3\right)}{\left(1 - \omega^2\right)} \quad (\text{if } \omega^2 \neq 1), \tag{3.8}$$

giving $\beta = 1 - 3\omega^2 - 2\omega^2\left(\omega^2 - 3\right)/\left(1 - \omega^2\right)$. Working with $\Delta_-^-(\lambda) = 0$ gives this same equation in β and ω.

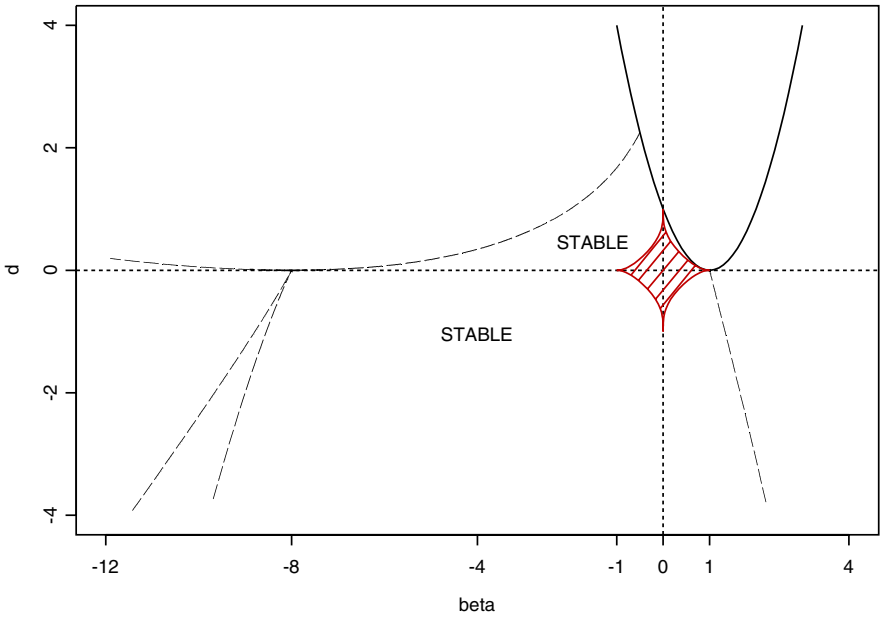


FIG. 3.1. *Regions in the parameter plane indicating stability of the origin in the coupled loop system (see* (3.1)*). The solid parabolic curve indicates parameter values where there is a zero eigenvalue. Dashed curves indicate parameter values where there are pure imaginary eigenvalues. The linearly stable regions defined by these boundaries are marked. The shaded area indicates where global stability of the origin has been proved.*

The fact that $\sqrt{-d} \geq 0$ implies that ω is in one of the intervals $\left(-\infty, -\sqrt{3}\right]$, $(-1, 0]$, or $\left(1, \sqrt{3}\right]$. In these intervals, (3.8) can be considered parametric equations for curves in the βd-plane. The curves are shown in Figure 3.1. Linear stability can again be checked by examining eigenvalues at points within each region. In the regions where $d > 0$ and $\beta > 1 - \sqrt{d}$, there are real positive eigenvalues, so the origin is an unstable node. Everywhere else outside the stability region it can be verified that there are complex conjugate pairs of eigenvalues with positive real parts, suggesting the existence of stable oscillations. Note that the pair of positive real eigenvalues becomes a complex pair with positive real part as d becomes negative $(\beta > 1)$.

For equal coupling strengths, as in the case of the single loop, global stability of the origin can be shown on a subset of the linear stability region.

THEOREM 3.3. *The origin is globally asymptotically stable for system* (3.1) *with* $|c_1| = |c_2| \equiv c > 0$ *when* $|b| < \frac{2}{\gamma}$, *where* $\gamma = 1 + 2c\,(B_1 + 1)$ *and* B_1 *is the positive root of the cubic* $8c^3 B_1\,(1 + B_1)^2 = 1$.

The proof uses the Lyapunov function $V = \sum_{j=1}^{6} a_j\, x_j^2$, where $a_j > 0$ are given as $a_1 = a_4 = \frac{B_1 + B_2}{2}$, $a_2 = a_5 = \frac{1}{4c} + \frac{B_2}{2}$, $a_3 = a_6 = \frac{1}{4c} + \frac{B_1 + 1}{2}$, and $B_2 = \sqrt{B_1/2c}$. Details of the proof are omitted. The condition $|b| < \frac{2}{\gamma}$ can be interpreted in terms of β and d by taking $d = \pm b^2 c_1^2$ (the sign depending on the sign of $c_1 c_2$, with $|c_1| = |c_2|$), and the resulting global stability region is the diamond-shaped region in Figure 3.1. Note that it covers most of the local stability region in the positive quadrant.

4. Coupled loops with delay. The case with delayed coupling connections between the 3-loops leads to the following system of delay differential equations:

$$
\begin{aligned}
&\frac{dx_1}{dt} = -x_1(t) + \tanh\left(bx_3(t)\right), \quad \frac{dx_2}{dt} = -x_2(t) + \tanh\left(bx_1(t)\right), \\
&\frac{dx_3}{dt} = -x_3(t) + \tanh\left(bx_2(t)\right) + c_1 \tanh\left(bx_6(t-\tau)\right), \\
&\frac{dx_4}{dt} = -x_4(t) + \tanh\left(bx_6(t)\right), \quad \frac{dx_5}{dt} = -x_5(t) + \tanh\left(bx_4(t)\right), \\
&\frac{dx_6}{dt} = -x_6(t) + \tanh\left(bx_5(t)\right) + c_2 \tanh\left(bx_3(t-\tau)\right),
\end{aligned} \tag{4.1}
$$

where $\tau \geq 0$ is the time delay, and when $\tau = 0$ this reduces to (3.1). To pose an initial value problem at $t = 0$, we must specify data for each variable on the interval $[-\tau, 0]$, i.e., $x_j(t) = \phi_j(t),\ -\tau \leq t \leq 0,\ j = 1, \ldots, 6$.

The equilibria for (4.1) are the same as for (3.1); in particular, Theorem 3.1 is also valid for (4.1). Using Theorem 2.1 of van den Driessche and Zou [20], we give one global stability result for system (4.1): If $|b| \max_i\{1 + |c_i|\} < 1$, then the origin is globally asymptotically stable for all values of delay $\tau \geq 0$. However, for other parameter ranges the stability of the equilibria may change due to the delay. In the next subsection we focus on the linear stability analysis of the trivial equilibrium. This then leads us to a discussion of the bifurcations of the trivial equilibrium.

4.1. Stability regions. Linearization of (4.1) about the origin gives

$$x'(t) = A_1 x(t) + A_2 x(t-\tau), \tag{4.2}$$

where

$$
A_1 = \begin{bmatrix}
-1 & 0 & b & 0 & 0 & 0 \\
b & -1 & 0 & 0 & 0 & 0 \\
0 & b & -1 & 0 & 0 & 0 \\
0 & 0 & 0 & -1 & 0 & b \\
0 & 0 & 0 & b & -1 & 0 \\
0 & 0 & 0 & 0 & b & -1
\end{bmatrix}, \quad
A_2 = \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & bc_1 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & bc_2 & 0 & 0 & 0
\end{bmatrix}. \tag{4.3}
$$

The characteristic equation for this system with $d \equiv b^2 c_1 c_2$ and $\beta \equiv b^3$ is

$$\left[(1+\lambda)^3 - \beta\right]^2 - d(1+\lambda)^4 e^{-2\tau\lambda} = 0. \tag{4.4}$$

Section 3 describes the stability region of the trivial equilibrium when $\tau = 0$ (see Figure 3.1). To determine the stability region for $\tau > 0$, we determine curves in the $d\tau$-plane along which (4.4) has a zero root or a pair of pure imaginary roots. Given values of β and d for which the trivial equilibrium is stable at $\tau = 0$, it remains so for $0 \leq \tau \leq \tau_{crit}$, where τ_{crit} is the lowest value of τ on one of these curves.

First consider the case $d \geq 0$. The characteristic equation then factors as

$$
\begin{aligned}
&\Delta_+^+(\lambda)\Delta_-^+(\lambda) \\
&\quad \equiv \left[(1+\lambda)^3 - \beta + (1+\lambda)^2\sqrt{d}e^{-\tau\lambda}\right]\left[(1+\lambda)^3 - \beta - (1+\lambda)^2\sqrt{d}e^{-\tau\lambda}\right] = 0.
\end{aligned} \tag{4.5}
$$

As for the nondelayed case, zero roots occur when $d = (1-\beta)^2 \equiv d_0$.

LEMMA 4.1. *Let β and τ be fixed.*

(i) *If $\beta < 1$ and $\tau \neq 2 + \frac{3}{\beta-1}$, then $\Delta_-^+(\lambda)$ has a simple zero root when $d = d_0$; the number of roots of* (4.4) *with positive real part increases (decreases) by one as d increases through d_0 with $\tau > 2 + \frac{3}{\beta-1}$ ($\tau < 2 + \frac{3}{\beta-1}$).*

(ii) *If $\beta > 1$ and $\tau \neq 2 + \frac{3}{\beta-1}$, then $\Delta_+^+(\lambda)$ has a simple zero root when $d = d_0$; the number of roots of* (4.4) *with positive real part increases (decreases) by one as d increases through d_0 with $\tau > 2 + \frac{3}{\beta-1}$ ($\tau < 2 + \frac{3}{\beta-1}$).*

(iii) *If $\beta = 1$, both factors of* (4.5) *have a simple zero root when $d = d_0 = 0$.*

(iv) *If $\beta < 1$ ($\beta > 1$) and $\tau = 2 + \frac{3}{\beta-1}$, then $\Delta_-^+(\lambda)$ ($\Delta_+^+(\lambda)$) has a double zero root when $d = d_0$.*

Proof. The presence of zero roots follows from the facts that $\Delta_+^+(0) = 0$ when $\sqrt{d} = \beta - 1$ and $\Delta_-^+(0) = 0$ when $\sqrt{d} = 1 - \beta$. For case (iv), note that

$$\frac{d}{d\lambda}\Delta_\pm^+(\lambda) = 3(1+\lambda)^2 \pm 2(1+\lambda)\sqrt{d}e^{-\tau\lambda} \mp \tau(1+\lambda)^2\sqrt{d}e^{-\tau\lambda}.$$

Thus, if $\sqrt{d} = \pm(\beta - 1)$ and $\tau = 2 + \frac{3}{\beta-1}$, then $\frac{d}{d\lambda}\Delta_\pm^+(0) = 0$. The fact that zero is a simple root in cases (i)–(iii) also follows from this derivative.

To study the rate of change of the real part of a root, λ, of (4.5), consider either factor of this equation. For $d > 0$, differentiating with respect to d, keeping in mind that λ is a function of d, and rearranging give

$$\frac{d\lambda}{d\,d} = \frac{\pm(1+\lambda)^2\sqrt{d}e^{-\tau\lambda}}{-6d(1+\lambda)^2 \mp 4d(1+\lambda)\sqrt{d}e^{-\tau\lambda} \pm 2d\tau(1+\lambda)^2\sqrt{d}e^{-\tau\lambda}},$$

where the upper sign in $\pm$, $\mp$ refers to Δ_+^+ and the lower sign to Δ_-^+. Using (4.5) to eliminate $\pm\sqrt{d}e^{-\tau\lambda}$ and setting $\lambda = 0$ and $d = d_0$ yield

$$\left.\frac{d\lambda}{d\,d}\right|_{\lambda=0} = \frac{1}{2(\beta-1)[(\tau-2)(\beta-1)-3]}.$$

Consideration of the sign of the right-hand side completes the proofs of (i) and (ii). ∎

For $d > 0$, to find the curves where pure imaginary roots exist, set $\lambda = i\omega$ in each factor of (4.5) and separate into real and imaginary parts. Without loss of generality, take $\omega > 0$. For $\Delta_+^+(\lambda)$, isolating $\sin(\omega\tau)$ and $\cos(\omega\tau)$ yields

$$\begin{aligned} (1+\omega^2)^2\sqrt{d}\cos(\omega\tau) &= -\left((1+\omega^2)^2 - \beta(1-\omega^2)\right) \equiv -\mathcal{C}(\omega), \\ (1+\omega^2)^2\sqrt{d}\sin(\omega\tau) &= \omega\left((1+\omega^2)^2 + 2\beta\right) \equiv \mathcal{S}(\omega). \end{aligned} \tag{4.6}$$

To find d and τ in terms of β and ω, square the equations in (4.6) and add to give

$$d = d_{im}(\omega) \equiv \frac{(1+\omega^2)^3 + 2\beta(3\omega^2-1) + \beta^2}{(1+\omega^2)^2}. \tag{4.7}$$

Dividing the second equation of (4.6) by the first gives $\tan(\omega\tau) = -\mathcal{S}(\omega)/\mathcal{C}(\omega)$. However, this loses information about the signs of $\cos(\omega\tau)$ and $\sin(\omega\tau)$ that is in (4.6). Thus we introduce $y = \mathrm{Arctan}(u)$ as the branch of the arctangent function with range $(-\frac{\pi}{2}, \frac{\pi}{2})$. Note that this corresponds to $\cos(y) > 0$ and that the function

$\text{Arctan}(u) + \pi$ corresponds to $\cos(y) < 0$. The other branches of the arctangent function are obtained from these two by adding multiples of 2π. As can be seen from (4.6), the sign of $\cos(\omega\tau)$ is determined by $\mathcal{C}(\omega)$, and thus we define

$$\tau = \tau^+_{k+}(\omega) \equiv \frac{1}{\omega}\begin{cases} \text{Arctan}\left(-\frac{\mathcal{S}(\omega)}{\mathcal{C}(\omega)}\right) + 2k\pi, & \mathcal{C}(\omega) < 0, \\ \text{Arctan}\left(-\frac{\mathcal{S}(\omega)}{\mathcal{C}(\omega)}\right) + (2k+1)\pi, & \mathcal{C}(\omega) > 0, \end{cases} \tag{4.8}$$

where $k = 0, 1, \ldots$. (We do not take $k < 0$ as these branches always yield $\tau < 0$.)

In a similar manner it can be shown that the curves along which the second factor, $\Delta^+_-(\lambda)$, of (4.5) has a pair of pure imaginary roots are given by $(d, \tau) = (d_{im}(\omega), \tau^+_{k-}(\omega))$, where d_{im} is as above and

$$\tau^+_{k-}(\omega) \equiv \frac{1}{\omega}\begin{cases} \text{Arctan}\left(-\frac{\mathcal{S}(\omega)}{\mathcal{C}(\omega)}\right) + 2k\pi, & \mathcal{C}(\omega) > 0, \\ \text{Arctan}\left(-\frac{\mathcal{S}(\omega)}{\mathcal{C}(\omega)}\right) + (2k+1)\pi, & \mathcal{C}(\omega) < 0. \end{cases} \tag{4.9}$$

The zeros of $\mathcal{C}(\omega)$ define the points where the branches join. To see how the sign of $\mathcal{C}(\omega)$ varies with β and ω, rewrite the first equation of (4.6) as a quartic in ω, namely, $\mathcal{C}(\omega) = \omega^4 + (2+\beta)\omega^2 + 1 - \beta$. The roots of this quartic are $\pm\omega^+_{\mathcal{C}}, \pm\omega^-_{\mathcal{C}}$, where

$$\omega^\pm_{\mathcal{C}} = \sqrt{-1 - \frac{\beta}{2} \pm \frac{1}{2}\sqrt{\beta(\beta+8)}}. \tag{4.10}$$

All four roots exist if $\beta \le -8$ (with $\omega^+_{\mathcal{C}} = \omega^-_{\mathcal{C}}$ when $\beta = -8$), no roots exist if $-8 < \beta < 1$, and only $\pm\omega^+_{\mathcal{C}}$ exists if $\beta \ge 1$ ($\omega^+_{\mathcal{C}} = 0$ when $\beta = 1$). This yields the following ranges:

$$\begin{aligned} \beta < -8 \quad &: \quad \mathcal{C}(\omega) > 0 \quad \text{for} \quad 0 < \omega < \omega^-_{\mathcal{C}},\ \omega^+_{\mathcal{C}} < \omega, \\ &\quad\ \ \mathcal{C}(\omega) < 0 \quad \text{for} \quad \omega^-_{\mathcal{C}} < \omega < \omega^+_{\mathcal{C}}, \\ -8 \le \beta \le 1 \quad &: \quad \mathcal{C}(\omega) > 0 \quad \text{for} \quad 0 < \omega, \omega \ne \omega^\pm_{\mathcal{C}}, \\ 1 < \beta \quad &: \quad \mathcal{C}(\omega) < 0 \quad \text{for} \quad 0 < \omega < \omega^+_{\mathcal{C}}, \\ &\quad\ \ \mathcal{C}(\omega) > 0 \quad \text{for} \quad \omega^+_{\mathcal{C}} < \omega. \end{aligned}$$

Now consider the case $d < 0$. The characteristic equation factors as

$$\begin{aligned} &\Delta^-_+(\lambda)\Delta^-_-(\lambda) \\ &\quad \equiv \left[(1+\lambda)^3 - \beta + i(1+\lambda)^2\sqrt{-d}e^{-\tau\lambda}\right]\left[(1+\lambda)^3 - \beta - i(1+\lambda)^2\sqrt{-d}e^{-\tau\lambda}\right] = 0. \end{aligned} \tag{4.11}$$

Clearly, neither factor has a zero root. Note that λ is a root of $\Delta^-_+(\lambda)$ iff $\bar{\lambda}$ is a root of $\Delta^-_-(\lambda)$. This is a consequence of the fact that the roots of the unfactored characteristic equation (4.4) come in complex conjugate pairs. Following a similar procedure to that for $d > 0$, pure imaginary roots $i\omega, -i\omega$ with $\omega > 0$, of the first and second factors, respectively, exist along the curves $(d, \tau) = (-d_{im}(\omega), \tau^-_{k+}(\omega))$. Similarly, pure imaginary roots $-i\omega, i\omega$ with $\omega > 0$, of the first and second factors,

respectively, exist along the curves $(d,\tau)=(-d_{im}(\omega),\tau^-_{k\,-}(\omega))$. Here

$$\tau^-_{k\,+}(\omega)\equiv\frac{1}{\omega}\begin{cases}\operatorname{Arctan}\left(\frac{\mathcal{C}(\omega)}{\mathcal{S}(\omega)}\right)+2k\pi, & \mathcal{S}(\omega)<0,\\ \operatorname{Arctan}\left(\frac{\mathcal{C}(\omega)}{\mathcal{S}(\omega)}\right)+(2k+1)\pi, & \mathcal{S}(\omega)>0,\end{cases}\tag{4.12}$$

$$\tau^-_{k\,-}(\omega)\equiv\frac{1}{\omega}\begin{cases}\operatorname{Arctan}\left(\frac{\mathcal{C}(\omega)}{\mathcal{S}(\omega)}\right)+2k\pi, & \mathcal{S}(\omega)>0,\\ \operatorname{Arctan}\left(\frac{\mathcal{C}(\omega)}{\mathcal{S}(\omega)}\right)+(2k+1)\pi, & \mathcal{S}(\omega)<0.\end{cases}\tag{4.13}$$

The zeros of $\mathcal{S}(\omega)$ define the points where the branches join. To make the definitions of $\tau^-_{k\pm}$ more precise, the sign of $\mathcal{S}(\omega)$ with $\omega_{\mathcal{S}}=\sqrt{\sqrt{-2\beta}-1}$ is given as follows:

$$\begin{array}{rcll}\beta<-\frac{1}{2} & : & \mathcal{S}(\omega)<0 & \text{for}\quad 0<\omega<\omega_{\mathcal{S}},\\ & & \mathcal{S}(\omega)>0 & \text{for}\quad \omega_{\mathcal{S}}<\omega,\\ \beta\geq-\frac{1}{2} & : & \mathcal{S}(\omega)>0 & \text{for}\quad 0<\omega.\end{array}$$

To determine what these curves look like, we use the following results that are derived by using L'Hôpital's rule. Note that we consider only $\tau\geq 0$.

LEMMA 4.2. *For the functions in* (4.7)–(4.9), (4.12), (4.13),

$$d_{im}(0)=d_0,\ \lim_{\omega\to\infty}d_{im}(\omega)=\infty;\ \lim_{\omega\to\infty}\tau^{\pm}_{k\,\pm}=0;$$

$$\lim_{\omega\to0^+}\tau^+_{k\,\pm}=\infty,\ k>0;\quad \lim_{\omega\to0^+}\tau^+_{0\,+}=\begin{cases}2+\frac{3}{\beta-1}, & \beta>1,\\ \infty, & \beta\leq1;\end{cases}$$

$$\lim_{\omega\to0^+}\tau^+_{0\,-}=\begin{cases}\infty, & \beta>1,\\ -\infty, & \beta=1,\\ 2+\frac{3}{\beta-1}, & \beta<1;\end{cases}$$

$$\lim_{\omega\to0^+}\tau^-_{k\,\pm}=\infty,\ k>0;\quad \lim_{\omega\to0^+}\tau^-_{0\,+}=\begin{cases}-\infty, & \beta<-\frac{1}{2},\\ \infty, & \beta\geq-\frac{1}{2};\end{cases}$$

$$\lim_{\omega\to0^+}\tau^-_{0\,-}=\begin{cases}\infty, & \beta<1,\\ 1, & \beta=1,\\ -\infty, & \beta>1.\end{cases}$$

LEMMA 4.3. *For* $\frac{1}{2}(5-3\sqrt{3})\leq\beta\leq12-4\sqrt{5}$, *i.e.,* β *approximately* $\in[-0.0981, 3.0557]$, $d_{im}(\omega)$ *is a nondecreasing function of* ω. *Outside this interval it is nonmonotone and has the following behavior. For* $\beta<\frac{1}{2}(5-3\sqrt{3})$ *or* $\beta\geq\frac{1}{2}(5+3\sqrt{3})\approx5.0981$, *there exists* $\omega_c>0$ *such that* $d_{im}(\omega)$ *is decreasing for* $0<\omega<\omega_c$ *and increasing for* $\omega>\omega_c$. *For* $12-4\sqrt{5}<\beta<\frac{1}{2}(5+3\sqrt{3})$, *there exist* $0<\omega_{c1}<\omega_{c2}$ *such that* $d_{im}(\omega)$ *is increasing for* $0<\omega<\omega_{c1}$ *and* $\omega>\omega_{c2}$ *and decreasing for* $\omega_{c1}<\omega<\omega_{c2}$.

Proof. From (4.7) it is clear that

$$\frac{d\,d_{im}}{d\omega}=2\omega\frac{\omega^6+3\omega^4+3(1-2\beta)\omega^2+2\beta(5-\beta)+1}{(1+\omega^2)^3};\tag{4.14}$$

thus the sign of $\frac{d\,d_{im}}{d\omega}$ is determined by $\Omega^3+3\Omega^2+3(1-2\beta)\Omega+2\beta(5-\beta)+1$, where $\Omega=\omega^2$. Consideration of the sign of the constant term shows that the cubic has an

even number of positive roots if $\beta \in [\frac{1}{2}(5-3\sqrt{3}), \frac{1}{2}(5+3\sqrt{3}))$ and an odd number otherwise. The discriminant of this cubic is a positive multiple of $-\beta^2(\beta^2-24\beta+64)$, which is nonnegative for $\beta \in [12-4\sqrt{5}, 12+4\sqrt{5}]$ and negative otherwise. Thus outside this interval the cubic has one real root, and inside it has three. For $\beta \in [\frac{1}{2}(5-3\sqrt{3}), 12-4\sqrt{5})$, the cubic has no positive roots and at $\beta = 12-4\sqrt{5}$ it has a double positive root. Consideration of the graph of the cubic in Ω shows that $\frac{d\,d_{im}}{d\omega} \geq 0$ for $\beta \in [\frac{1}{2}(5-3\sqrt{3}), 12-4\sqrt{5}]$, and hence $d_{im}(\omega)$ is a nondecreasing function of ω. For $\beta < \frac{1}{2}(5-3\sqrt{3})$ or $\beta \geq \frac{1}{2}(5+3\sqrt{3})$ the cubic has one positive root, Ω_c. Let $\omega_c = \sqrt{\Omega_c}$. For $12-4\sqrt{5} < \beta < \frac{1}{2}(5+3\sqrt{3})$, the cubic has two positive roots $\Omega_{c1} < \Omega_{c2}$. Let $\omega_{cj} = \sqrt{\Omega_{cj}}$. The results follow from the graph of the cubic. ∎

LEMMA 4.4. *For fixed β, τ, the number of roots of* (4.4) *with positive real part increases (decreases) by two as τ increases through one of the curves $(d,\tau) = (d_{im}, \tau^+_{k\pm})$, where d_{im} is an increasing (decreasing) function of ω. The number of roots of* (4.4) *with positive real part increases (decreases) by two as τ increases through one of the curves $(d,\tau) = (-d_{im}, \tau^-_{k\pm})$, where $-d_{im}$ is a decreasing (increasing) function of ω.*

Proof. Consider the first factor of (4.5). Differentiating with respect to τ gives

$$\frac{d\lambda}{d\tau} = \frac{\lambda(1+\lambda)\sqrt{d}e^{-\tau\lambda}}{3(1+\lambda)+\sqrt{d}e^{-\tau\lambda}(2-\tau(1+\lambda))}.$$

Using (4.5) to eliminate $e^{-\tau\lambda}$ and setting $\lambda = i\omega$ yield

$$\left.\frac{d\lambda}{d\tau}\right|_{\lambda=i\omega} = \frac{i\omega\left[\beta+4\omega^2-(1-\omega^2)^2+i\omega(\beta-4(1-\omega^2))\right]}{1-3\omega^2+2\beta-\tau(\beta+4\omega^2-(1-\omega^2)^2)+i\omega[3-\omega^2-\tau(\beta-4(1-\omega^2))]}.$$

Taking the real part gives

$$\left.\frac{d\,[\mathrm{Re}(\lambda)]}{d\tau}\right|_{\lambda=i\omega} = \frac{\omega^2}{K_1^2+K_2^2}\left(\omega^6+3\omega^4+3(1-2\beta)\omega^2+2\beta(5-\beta)+1\right),$$

where

$$K_1 = 1-3\omega^2+2\beta-\tau(\beta+4\omega^2-(1-\omega^2)^2), \qquad K_2 = \omega[3-\omega^2-\tau(\beta-4(1-\omega^2))].$$

The second factor of (4.5) or either factor of (4.11) yields the same expression. Using (4.14) gives

$$\left.\frac{d\,[\mathrm{Re}(\lambda)]}{d\tau}\right|_{\lambda=i\omega} = \frac{\omega(1+\omega^2)^3}{2(K_1^2+K_2^2)}\,\frac{d\,d_{im}}{d\omega},$$

along the curves associated with pure imaginary roots of (4.5). Along the curves associated with pure imaginary roots of (4.11), d_{im} is replaced by $-d_{im}$ so the derivative is of opposite sign. The result follows. ∎

From section 3, when $\tau = 0$ and $\beta < -\frac{1}{2}$ the characteristic equation has a pair of pure imaginary roots $\lambda = \pm i\sqrt{-1+\sqrt{-2\beta}} = \pm i\omega_{\mathcal{S}}$ at the positive value $d = d^+ \equiv (2-\sqrt{-\beta/2})^2$. Similarly, when $\tau = 0$ and $\beta \leq -8$ the characteristic equation has pairs of pure imaginary roots $\lambda = \pm i\omega_{\mathcal{C}}^+, \pm i\omega_{\mathcal{C}}^-$, as defined in (4.10), at the following negative values of d:

$$d^-_{\pm} \equiv -\frac{\omega_{\mathcal{C}}^{\pm\,2}(\omega_{\mathcal{C}}^{\pm\,2}-3)^2}{(1-\omega_{\mathcal{C}}^{\pm\,2})^2}.$$

The roots at d_+^- also occur when $\beta > 1$. Note that d^+ must correspond to the value of d_{im} when $\tau = 0$ and $d_\pm^-$ to values of $-d_{im}$ when $\tau = 0$. More specifically, the definitions (4.8)–(4.9) and (4.12)–(4.13) of $\tau_{k\pm}^{\pm}$ give the following. For $\beta \le -8$, d^+ is the d intercept of the curve $(d_{im}(\omega), \tau_{0+}^{+}(\omega))$ and $d_\mp^-$ are the d intercepts of the curves $(-d_{im}(\omega), \tau_{0\pm}^{-}(\omega))$. For $-8 < \beta < -\frac{1}{2}$, d^+ is the d intercept of the curve $(d_{im}(\omega), \tau_{0-}^{+}(\omega))$. For $\beta > 1$, d_+^- is the d intercept of the curve $(-d_{im}(\omega), \tau_{0-}^{-}(\omega))$.

We now describe the region of stability of the trivial equilibrium in the $d\tau$-plane for intervals of values of β by finding bifurcation curves on which an eigenvalue has zero real part. This is the content of the rest of this section. Theorem 4.5 is illustrated (using Maple) in Figure 4.1(a) with $\beta = 1.5$, Theorem 4.6 is illustrated in Figure 4.1(b) with $\beta = 0.1$, and Theorem 4.7 is illustrated in Figure 4.4 with $\beta = -10$.

THEOREM 4.5. *Let $1 \le \beta \le 12 - 4\sqrt{5}$ be fixed. Then the trivial solution of* (4.1) *is linearly asymptotically stable for $d < d_+^-$, $0 \le \tau < \tau_{0-}^{-}$.*

Proof. From section 3, for $\tau = 0$ and $\beta \ge 1$, all roots of the characteristic equation have negative real parts if $d < d_+^-$ (see Figure 3.1). For fixed β and d, as τ is increased the number of roots with positive real parts remains the same until τ reaches the smallest value for which the characteristic equation has a pair of pure imaginary roots. This value is τ_{0-}^{-}. To see this, note from Lemma 4.4 that d_{im} is a continuous nondecreasing function of ω with $0 \le d_0 \le d_{im} < \infty$ and that $d_+^- < -d_0$. Thus for any fixed $d < d_+^-$ there is one positive value of ω such that $-d_{im}(\omega) = d$. Further, it is straightforward to show that, for any value of ω, $\tau_{0-}^{-}(\omega) < \tau_{0+}^{-}(\omega) < \tau_{k\pm}^{-}(\omega)$ for $k = 1, 2, \ldots$. Thus all the roots of the characteristic equation have negative real parts in the given range of d and τ. Applying the results of Lemma 4.4 shows there is at least one root of the characteristic equation with positive real part everywhere else in the $d\tau$-plane. ∎

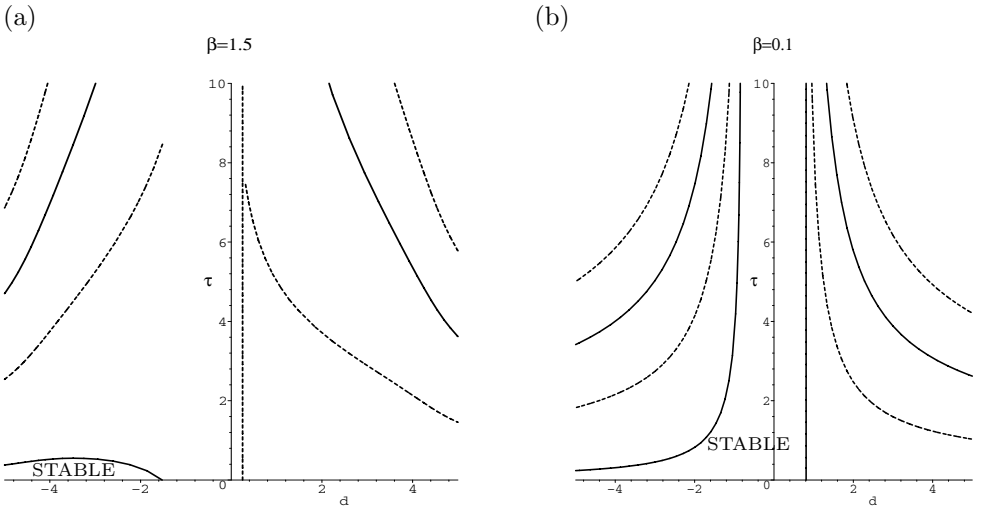

FIG. 4.1. *Bifurcation curves for the trivial solution of* (4.1) *for* (a) $\beta = 1.5$, (b) $\beta = 0.1$. *The stability region is qualitatively the same for* (a) $1 \le \beta \le 12 - 4\sqrt{5}$, (b) $\frac{1}{2}(5 - 3\sqrt{3}) \le \beta < 1$. *Along the solid (dashed) curves with $d > 0$, $\Delta_-^+(\lambda)$ ($\Delta_+^+(\lambda)$) has a pair of pure imaginary roots. Along the solid (dashed) vertical line $d = d_0$, $\Delta_-^+(\lambda)$ ($\Delta_+^+(\lambda)$) has a zero root. Along the solid (dashed) curves with $d < 0$, $\Delta_-^-(\lambda)$ ($\Delta_+^-(\lambda)$) has a root $i\omega$ with $\omega > 0$ and $\Delta_+^-(\lambda)$ ($\Delta_-^-(\lambda)$) has the complex conjugate root $-i\omega$.*

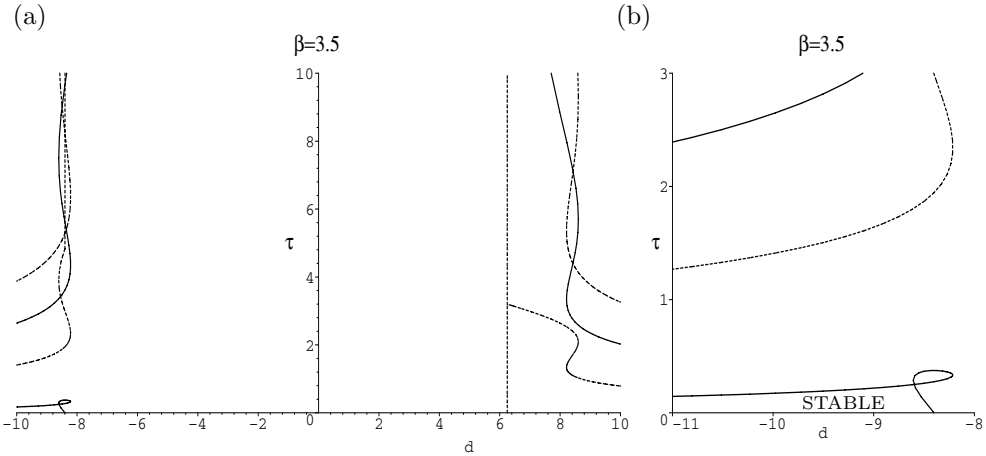

FIG. 4.2. (a) *Bifurcation curves for the trivial solution of* (4.1) *for* $\beta = 3.5$. (b) *Close-up showing stability region. The meaning of the solid and dashed curves are as described for Figure* 4.1.

THEOREM 4.6. *Let* $\frac{1}{2}(5-3\sqrt{3}) \le \beta < 1$ *be fixed. Then the trivial solution of* (4.1) *is linearly asymptotically stable for* $-d_0 \le d < d_0$, $0 \le \tau$ *or* $d < -d_0$, $0 \le \tau < \tau_{0-}^{-}$.

Proof. From section 3, for $\tau = 0$ and $\frac{1}{2}(5 - 3\sqrt{3}) \le \beta < 1$, all roots of the characteristic equation have negative real parts if $d < d_0$ (see Figure 3.1). Using the same argument as in the proof of Theorem 4.5, it can be shown that all roots of the characteristic equation have negative real parts for $d < -d_0$ and $0 \le \tau < \tau_{0-}^{-}$. From Lemma 4.3, d_{im} is a monotone function of ω for the assumed β range. Thus, using Lemma 4.2 for $\omega > 0$, $d_{im}(\omega) \ge d_{im}(0) = d_0$ and $-d_{im}(\omega) \le -d_{im}(0) = -d_0$. Hence for $-d_0 \le d < d_0$ and $\tau \ge 0$ all roots of the characteristic equation have negative real parts. The rest of the proof is the same as for Theorem 4.5. □

When β no longer lies in the first range given in Lemma 4.3, the curves along which the characteristic equation has pure imaginary roots become nonmonotone. This has two consequences. First, there will be values of ω such that $d_{im}(\omega) < d_0$, and second, there may exist intersection points of the curves $(d_{im}(\omega), \tau_{j\pm}^{+}(\omega))$ and $(-d_{im}(\omega), \tau_{j\pm}^{-}(\omega))$ with each other and with the line $d = d_0$. In this situation, the boundary of the stability region is made up of pieces of the curves $(d_{im}(\omega), \tau_{j\pm}^{+}(\omega))$ and $(-d_{im}(\omega), \tau_{j\pm}^{-}(\omega))$ and of the line $d = d_0$.

Consider first the case $\beta > 12 - 4\sqrt{5}$. For this range of β, we observe that $(d, \tau) = (-d_{im}, \tau_{0-}^{-})$ intersects itself. The stability region is still bounded by the d axis for $d < d_{+}^{-}$ and the curve $(-d_{im}(\omega), \tau_{0-}^{-}(\omega))$. However, part of the curve now forms a loop, inside which the trivial solution is unstable (this may be verified by applying Lemma 4.4). This is illustrated in Figure 4.2 with $\beta = 3.5$. We believe that the stability region is qualitatively the same for any $\beta > 12 - 4\sqrt{5}$.

Now consider the range $\beta < \frac{1}{2}(5 - 3\sqrt{3})$. For $\beta \le -\frac{1}{2}$ part of the curve of pure imaginary eigenvalues $(d_{im}(\omega), \tau_{0-}^{+}(\omega))$ enters the nonnegative τ region (this can be seen from the limits in Lemma 4.2). Using this fact, the discussion above, and the results of Lemmas 4.2 and 4.3, it can be shown that for $-\frac{1}{2} \le \beta < \frac{1}{2}(5 - 3\sqrt{3})$ the stability region looks qualitatively as depicted in Figure 4.3(a) and for $-8 < \beta < -\frac{1}{2}$ it looks qualitatively as depicted in Figure 4.3(b).

As β is decreased, the curves of pure imaginary eigenvalues approach the τ axis (and the stability region shrinks) until at $\beta = -8$ their points of minimal d value actually touch the τ axis. Recall that for $\beta < -8$, the curves $(-d_{im}(\omega), \tau_{0-}^{-}(\omega))$

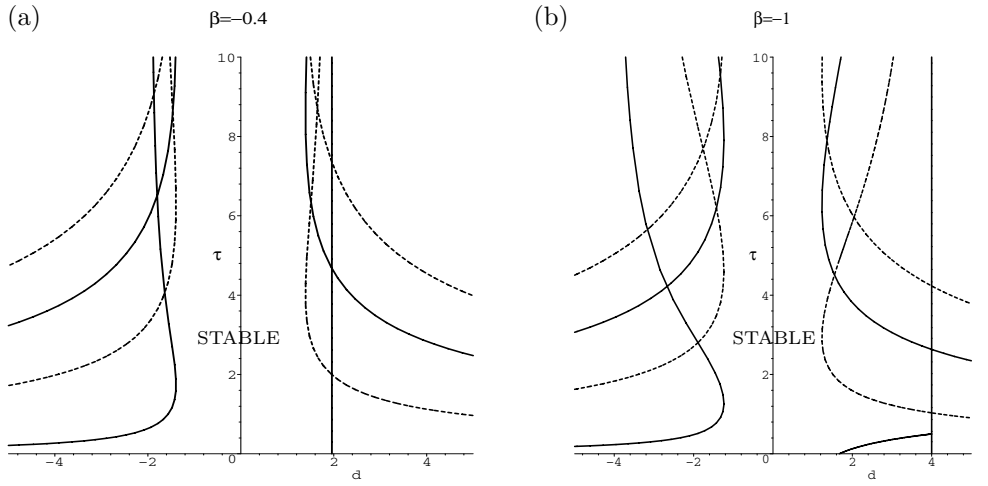

FIG. 4.3. *Bifurcation curves for the trivial solution of* (4.1) *for* (a) $\beta = -0.4$, (b) $\beta = -1$. *The stability region is qualitatively the same for* (a) $-\frac{1}{2} \le \beta < \frac{1}{2}(5 - 3\sqrt{3})$, (b) $-8 < \beta < -\frac{1}{2}$. *The meaning of the solid and dashed curves is as described for Figure* 4.1.

and $(-d_{im}(\omega), \tau_{0+}^{-}(\omega))$ intersect the d axis at d_+^- and d_-^-, respectively. From their definitions, (4.12)–(4.13), and the fact that $d_-^- < d_+^-$, these curves must have an intersection point. We denote this point by (d_{int}, τ_{int}) and have the following result, illustrated in Figure 4.4, for $\beta = -10$.

THEOREM 4.7. *Let $\beta \le -8$ be fixed. Then the trivial solution of* (4.1) *is linearly asymptotically stable for $d < d_-^-$, $0 \le \tau < \tau_{0-}^{-}$ or $d_-^- \le d < d_{int}$, $\tau_{0+}^{-} < \tau < \tau_{0-}^{-}$.*

Proof. From section 3, for $\tau = 0$ and $\beta \le -8$, all the roots of the characteristic equation have negative real parts if $d < d_-^-$ (see Figure 3.1). Using the same argument as in the proof of Theorem 4.5, it can be shown that all roots of the characteristic equation have negative real parts for $d < d_-^-$ and $0 \le \tau < \tau_{0-}^{-}$. For $\tau = 0$ and $d_-^- < d < d_+^-$, the characteristic equation has two roots with positive real parts.

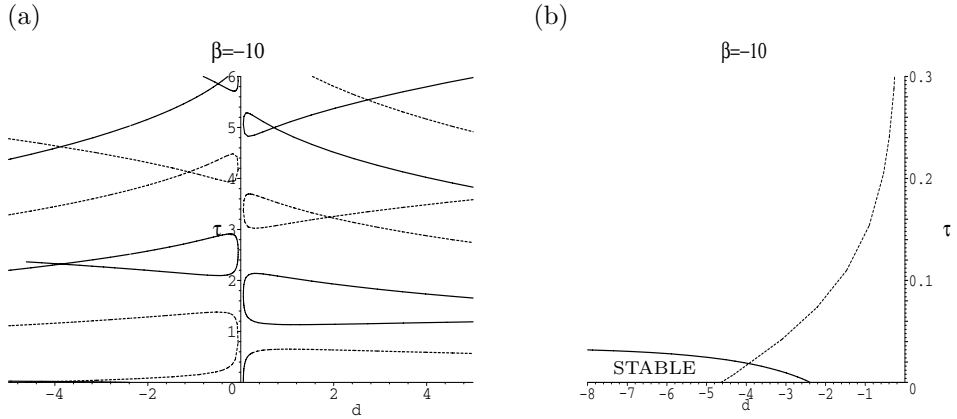

FIG. 4.4. (a) *Bifurcation curves for the trivial solution of* (4.1) *for* $\beta = -10$. (b) *Close-up showing stability region. The stability region is qualitatively the same for any* $\beta \le -8$. *The meaning of the solid and dashed curves is as described for Figure* 4.1.

Applying Lemma 4.4 shows that the number of roots with positive real parts decreases by two along the part of $(-d_{im}(\omega), \tau_{0+}^{-}(\omega))$, where $-d_{im}$ is increasing, and increases by two along the part of $\left(-d_{im}(\omega), \tau_{0-}^{-}(\omega)\right)$, where $-d_{im}$ is decreasing. The rest of the proof is the same as for Theorem 4.5. □

4.2. Bifurcations. In the previous subsection, we determined all points in parameter space where the trivial solution of (4.2) has eigenvalues with zero real parts. The bifurcations that may occur at such points as a system parameter is varied are important, particularly when they lie on the boundary of the stability region, as they determine the observable behavior of the system.

Consider first the case when a zero root of (4.4) exists. This occurs for parameter values along the line $d = d_0$. For $\beta \neq 1$, it can be shown that the conditions for a pitchfork bifurcation to occur are satisfied at almost all points on this line. In particular, taking d as the bifurcation parameter, Lemma 4.1 shows that the root is simple for $\beta \neq 1$ and $\tau \neq 2 + \frac{3}{\beta - 1}$. To ensure that the characteristic equation has no other roots with zero real part, the points of intersection of the line $d = d_0$ with the curves $(d_{im}(\omega), \tau_{\pm}^{+}(\omega))$ and $(-d_{im}(\omega), \tau_{\pm}^{-}(\omega))$ must also be excluded. In terms of the original model parameters, taking d as the bifurcation parameter is equivalent to fixing b, τ, and one of the c_j and using the other c_j as the bifurcation parameter.

Consider now the case when a pair of pure imaginary roots of (4.4) exists. This occurs for parameter values on the curves $(d_{im}(\omega), \tau_{\pm}^{+}(\omega))$ and $(-d_{im}(\omega), \tau_{\pm}^{-}(\omega))$. A statement of the Hopf bifurcation theorem for delay equations can be found in [12, Chapter 11]. It can be shown that this theorem is satisfied at almost all points on these curves. In particular, taking τ as the bifurcation parameter, Lemma 4.4 shows that the roots are simple at all points where $\frac{dd_{im}}{d\omega} \neq 0$. To ensure that the characteristic equation has no other roots with zero real part, the points of intersection of each curve with $d = d_0$ and the other curves where pure imaginary roots exist must be excluded.

If there is slightly more symmetry in the model, then some interesting patterns in the bifurcating solutions emerge. Suppose that $c_1 = c_2 = c$, as in parts of section 3 (e.g., Theorem 3.2), implying that $d = b^2c^2 > 0$. In this case, only the pitchfork bifurcation and the Hopf bifurcations along $(d_{im}(\omega), \tau_{\pm}^{+}(\omega))$ can occur. Consider the bifurcations that occur at a point in parameter space where $\Delta_{-}^{+}(\lambda)$ has a root with zero real part. (This corresponds to the solid curves in the figures of the previous subsection.) When $bc > 0$ it is straightforward to show that the solution of (4.2) corresponding to a root λ of $\Delta_{-}^{+}(\lambda)$ has the form $e^{\lambda t}(y_1, y_2, y_3, y_1, y_2, y_3)^t$. Thus we expect that the bifurcating solutions have a similar property—namely, the corresponding elements of the two loops are in phase, or synchronized. Similarly, when $bc < 0$ the solution of (4.2) corresponding to a root λ of $\Delta_{-}^{+}(\lambda)$ has the form $e^{\lambda t}(y_1, y_2, y_3, -y_1, -y_2, -y_3)^t$, and we expect the bifurcating solutions have corresponding elements of the two loops antiphase (or half a period out of phase). The solutions corresponding to roots of $\Delta_{+}^{+}(\lambda)$ have just the opposite property. When $bc > 0$ they are antiphase and when $bc < 0$ they are in-phase. When $c_1 \neq c_2$ but $c_1 \approx c_2$, we expect that bifurcating solutions are almost in-phase or almost antiphase. Such behavior was observed in [18].

Now suppose that $c_1 = -c_2 = c$, implying that $d = -b^2c^2 < 0$. In this case, only Hopf bifurcations along the curves $(-d_{im}(\omega), \tau_{\pm}^{-}(\omega))$ occur. When the characteristic equation has a pair of roots $\lambda = \pm i\omega$, corresponding solutions of (4.2) have the form $e^{\lambda t}(y_1, y_2, y_3, \pm iy_1, \pm iy_2, \pm iy_3)^t$. Thus corresponding elements of the bifurcating periodic orbits are one quarter period out of phase. When $c_1 \neq -c_2$ but $c_1 \approx -c_2$,

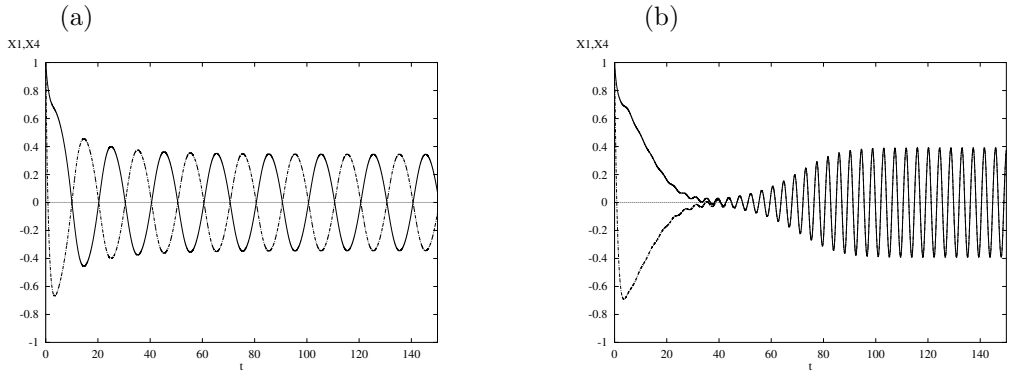

FIG. 4.5. *Numerical simulations of* (4.1) *with* $b = -1$, $c_1 = c_2 = 1.75$. *The plots in each case show* x_1 *(solid line) and* x_4 *(dot-dash line) vs.* t. (a) $\tau = 0.3$*; periodic orbit with* $x_4(t) = -x_1(t)$. (b) $\tau = 1.5$*; periodic orbit with* $x_4(t) = x_1(t)$. *Initial conditions for both cases* $x(t) = (1, -0.7, -0.9, 1.1, 0.8, 1.2)^t$, $-\tau \le t \le 0$.

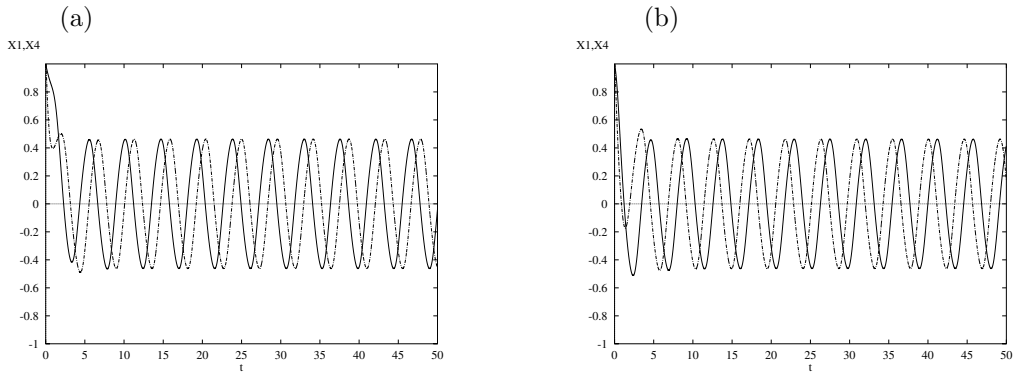

FIG. 4.6. *Numerical simulations of* (4.1) *with* $b = -1$, $\tau = 0.5$, *and* $c_1 = -c_2$. *The plots in each case show* x_1 *(solid line) and* x_4 *(dot-dash line) vs.* t. (a) $c_1 = 1.75$*; periodic orbit with* $x_4(t) = x_1(t - \frac{T}{4})$, *where* T *is the period.* (b) $c_1 = -1.75$*; periodic orbit with* $x_4(t) = x_1(t + \frac{T}{4})$. *Initial conditions as for Figure* 4.5.

we expect that bifurcating solutions are close to one quarter period out of phase.

These results are illustrated in Figures 4.5–4.6, showing numerical simulations of (4.1), with $b = -1$ and other parameters as indicated, which correspond to points in the stability diagram of Figure 4.3(b). Only x_1 and x_4 are shown in Figures 4.5–4.6; solutions for other pairs are similar. Simulations were performed in XPPAUT [6] using a fourth order Runge–Kutta integrator adapted for delay differential equations.

5. Discussion. Combining local and global results with numerical evidence, we arrive at the following summary of the dynamics of these loops. Results are given in terms of $\beta = b^3$ and $d = b^2 c_1 c_2$, where b is the gain of the response function for each neuron and c_i are the coupling strengths between the 3-loops. The loops are inherently (i.e., in isolation) oscillatory for $\beta < -8$. The origin is proved to be globally stable for $\beta \in (-2\sqrt{2}, 1)$, and numerical evidence extends this to $(-8, 1)$. For

$\beta > 1$ the solutions approach a nontrivial stable fixed point (the origin is unstable).

The effect of coupling depends on whether it is symmetric (excitatory in both directions or inhibitory in both directions) or asymmetric (excitatory in one direction and inhibitory in the other). It is interesting that the linear stability analysis is identical for excitatory and inhibitory coupling, as long as it is the same in both directions, as it depends essentially on the product of the two coupling coefficients. This was also noted in the somewhat similar situation studied by Shayer and Campbell [18]. Symmetric coupling of sufficient strength (not necessarily very strong) can destabilize the origin in the middle (inherently stable) β range. When $\beta \in (-\frac{1}{2}, 1)$, the system goes to nontrivial fixed points, but when $\beta \in (-8, -\frac{1}{2})$, it first goes to oscillation as coupling is increased. Asymmetric coupling of sufficient strength (and here it needs to be quite strong) can stabilize the origin in either of the two inherently unstable ranges. The further β is from the inherently stable range, the stronger the coupling needs to be to accomplish this stabilization. In the case of symmetric coupling, nontrivial equilibria exist when β is large enough, but there are no nontrivial equilibria for smaller β when the coupling is weak. In the case of asymmetric coupling, there are no nontrivial equilibria for $\beta < 1$. It is not clear whether nontrivial equilibria occur for other regions of parameter space. For most regions, oscillation of the system is suggested when the linear results show that the origin is unstable.

We have observed five main delay-related phenomena in this system.

1. When coupling is asymmetric ($d < 0$) and large, the stability of the origin is weak in the sense that only a small delay is needed to destabilize it and produce oscillation. This is delay-induced oscillation or delay-induced instability, which has commonly been observed in delayed networks since the early work of Marcus and Westervelt [15].
2. In the inherently stable range $\beta \in (-8, 1)$, delay independent stability exists for weak enough coupling ($|d|$ small) whether symmetric or asymmetric.
3. For intermediate values of $|d|$ and $\beta \in (-8, -0.098)$, whether the system oscillates or settles at the origin depends on the delay in a complex way. For some delay ranges, the origin is stable, and for others it is unstable, and there can be stability/instability switches as the delay increases.
4. For $\beta \in (-8, -\frac{1}{2})$, if coupling is symmetric and fairly strong ($d > 0$ and large but still $< (1-\beta)^2$), in the region where coupling has destabilized the origin to create oscillation, there is an intermediate range of delays (not including zero but not too large) that stabilizes the origin again and suppresses the oscillations. This is delay-induced stability or *oscillator death*.
5. For equal and symmetric coupling strengths, oscillatory solutions in the two loops bifurcating from the origin may be in phase or antiphase depending on the value of the delay. For asymmetric coupling with equal strengths, corresponding neurons in the two loops oscillate one quarter period out of phase.

Some of these results are similar to those found by Shayer and Campbell [18] for a simpler coupled system. However, their work focused on the symmetric coupling case.

Some properties of coupled systems that can each potentially oscillate begin to emerge from these studies—in particular, the ways in which oscillation or instability depends on the interaction between coupling strength and coupling delay. Although the system studied here is too simple to draw definite conclusions about physiological systems, results do show that complicated effects can occur even in the simplest

coupled loops with delay. This study could be extended by investigating other patterns of coupling between two loops, such as "lateral" coupling between each corresponding pair of units in the two loops (if the loops have the same structure), or "forward" coupling as studied without delays by Edwards and Gill [5]. For applications in which the units are far apart, it would be worthwhile to include delays in connections within each loop.

SINGULARITY FORMATION IN CHEMOTAXIS— A CONJECTURE OF NAGAI*

HOWARD A. LEVINE† AND JOANNA RENCŁAWOWICZ†‡

Abstract. Consider the initial-boundary value problem for the system (S) $u_t = u_{xx} - (uv_x)_x$, $v_t = u - av$ on an interval $[0,1]$ for $t > 0$, where $a > 0$ with $u_x(0,t) = u_x(1,t) = 0$. Suppose μ, v_0 are positive constants. The corresponding spatially homogeneous global solution $U(t) = \mu$, $V(t) = \mu/a + (v_0 - \mu/a)\exp(-at)$ is stable in the sense that if (μ', v_0') are positive constants, the corresponding spatially homogeneous solution will be uniformly close to $(U(\cdot), V(\cdot))$.

We consider, in sequence space, an approximate system (S') which is related to (S) in the following sense: The chemotactic term $(uv_x)_x$ is replaced by the inverse Fourier transform of the finite part of the convolution integral for the Fourier transform of $(uv_x)_x$. (Here the finite part of the convolution on the line at a point x of two functions, f, g, is defined as $\int_0^x (f(y)g(y-x)\,dy$.) We prove the following:

(1) If $\mu > a$, then in every neighborhood of (μ, v_0) there are (spatially nonconstant) initial data for which the solution of problem (S') blows up in finite time in the sense that the solution must leave $L^2(0,1) \times H^1(0,1)$ in finite time T. Moreover, the solution components $u(\cdot,t), v(\cdot,t)$ each leave $L^2(0,1)$.

(2) If $\mu > a$, then in every neighborhood of (μ, v_0) there are (spatially nonconstant) initial data for which the solution of problem (S) on $(0,1) \times (0, T_{max})$ must blow up in finite time in the sense that the coefficients of the cosine series for (u,v) become unbounded in the sequence product space $\ell^1 \times \ell^1_1$.

A consequence of (2) states that in every neighborhood of (μ, v_0), there are solutions of (S) which, if they are sufficiently regular, will blow up in finite time. (Nagai and Nakaki [*Nonlinear Anal.*, 58 (2004), pp. 657–681] showed that for the original system such solutions are unstable in the sense that if $\mu > a$, then in every neighborhood of $(\mu, \mu/a)$, there are spatially nonconstant solutions which blow up in finite *or* infinite time. They conjectured that the blow-up time must be finite.) Using a recent regularity result of Nagai and Nakaki, we prove this conjecture.

1. Introduction.

The classical equations of chemotaxis were introduced in [15, 16, 22]. A variant of them, which was later discussed in [14], takes the form

$$\begin{aligned} u_t &= D_1(\Delta u - \nabla \cdot (u\chi(v)\nabla v)), \\ v_t &= D_2 \Delta v + \lambda u - av \end{aligned} \tag{1.1}$$

when the diffusivities D_j are constant. The constants in (1.1) are presumed to be positive. Generally speaking, $u(\cdot,t)$ represents the cell concentration (or local population) of some species, while $v(\cdot,t)$ corresponds to the concentration of a chemotactic agent such as cyclic adenosine monophosphate (cAMP). The function $\chi(v)$ is called the chemotactic sensitivity.

This system is not of standard reaction-diffusion type since the first equation will involve the Laplacian of the second dependent variable. Typically, the boundary conditions are of Neumann type for the first equation and of either mixed or Dirichlet type for the second equation. Precise conditions will be given later.

In the growing literature on singularity formation in chemotaxis, the problems studied tend to fall into one of two types.[1]

In the first type, the time scale of the second equation is assumed to be much smaller than that of the first, i.e., $D_2 \gg D_1$, or the cell species has infinite propagation speed, while the chemical species has diffused so rapidly that it has come to a steady state. In this case, the system simplifies into one of elliptic-parabolic type, namely,

$$\begin{aligned} u_t &= D_1(\Delta u - \nabla \cdot (u\chi(v)\nabla v)), \\ 0 &= D_2\Delta v + \lambda u - av. \end{aligned} \tag{1.2}$$

A number of papers have been concerned with the phenomenon of blowup for such systems. See [2, 1, 5, 9, 10, 8, 19], for example. The first such result in this direction seems to be contained in [13]. The rough idea of the approach to this system is to solve, at least in principle, the second (elliptic) equation in (1.2) for v as a nonlocal, but linear, function of u and then eliminate v from the first equation leaving a nonlinear, nonlocal dynamical equation for u.

In the second, and probably less well studied form, the time scale of the second equation is assumed to be much larger than that of the first, so fast in fact that the diffusion of the chemical species can be neglected. (That is, $D_2 \ll D_1$.) In this case the spatial movement of the chemical is being controlled by the movement of the particles which the chemical influences through its gradient. This was used as an example to illustrate the modelling approach to *Dictyostelium discoideum* movement taken in [21].

The reaction term $\lambda u - av$ is the cAMP saturated limit approximation of a reaction term that more accurately reflects Michealis–Menten reaction kinetics. A model of *D. discoideum* movement which views the cell receptors as the catalyzing agent for cAMP production can be found in [6, pp. 498ff.]. However, if cAMP is not in excess, then one must replace the reaction term by a term of the form $\frac{k_1 uv}{k_2+v} - av$, where $\lambda = k_1/k_2$, in order to more accurately describe the cell receptor kinetics involved (see [6, pp. 273ff.]). The system then takes the form

$$\begin{aligned} u_t &= D_1\nabla \cdot \left\{ u\nabla\left[\ln \frac{u}{\psi(v)}\right]\right\}, \\ v_t &= R(u,v) = \frac{k_1 uv}{k_2+v} - av. \end{aligned} \tag{1.3}$$

The advantage of writing the system in this form is that one can see that if the system is tending toward a steady state, u should follow $\psi(v)$.

Indeed, by using the principles of reinforced random walk [4], the authors of [21] derived the first of equations (1.3) ab initio. However, by writing the flux vector $\overrightarrow{J}$ as

$$\overrightarrow{J} = -D_1(\overrightarrow{\nabla} u - \chi(v)u\overrightarrow{\nabla} v),$$

[1] If one sets $\tau = D_1 t$, then D_1 drops out of the first equation, while the second equation becomes $D_1\partial_\tau v = D_2\Delta v + \lambda u - av$. One then lets $D_1 \to 0$ in this equation in the first case. In the second case, one lets $D_1, a, \lambda \to \infty$ in such a way that $a/D_1, \lambda/D_1$ remain constant.

defining $\psi(v)$ by the equation $\psi'(v)/\psi(v) = \chi(v)$, and using the continuity equation $u_t = -\overrightarrow{\nabla} \cdot \overrightarrow{J}$, we obtain the first equation in (1.3) by continuum mechanical considerations.

Here the solution approach, taken, for example in [17], is to solve the second equation for u as a nonlinear function of v, v_t and then eliminate it from the first equation, leaving a rather messy third order equation in v. Reference [17] is devoted to a detailed discussion and interpretation of the numerical results obtained there and earlier in [21] for the resulting equation.

In [17], the discussion begins with consideration of the following special case of (1.3) on an interval $[0, 1]$ for $t > 0$ with $\psi(v) = v$:

$$\begin{aligned} u_t &= \nabla \cdot \left\{ u \nabla \left[\ln \frac{u}{v} \right] \right\}, \\ v_t &= R(u, v) = uv \end{aligned} \tag{1.4}$$

with $u_x(0,t) = u_x(1,t) = 0$ and $v_x(0,t) = v_x(1,t) = 0$ (which then imply the zero flux conditions $u_x = uv_x$ at $x = 0, 1$). The vector $[\mu(x,t), v_0(x,t)]^t \equiv [1, e^t]^t$ is a spatially homogeneous solution of (1.4) with $[1, 1]$ as initial datum. The following statement is a consequence of the results of [17]: Let c be the positive root of $c^2 + Nc - 1 = 0$ and let $0 < \epsilon < 1$. Given any mode number N, there is a direction $[u_N, v_N]^t \equiv [Nc, 1]^t \cos(Nx)$ in the closed subspace of $L^2(0,1) \times H^1(0,1)$ consisting of the closure of functions which satisfy $u[\log(u/v)]_x = 0$ at $x = 0, 1$, and a curve given by $\overrightarrow{R}(\varepsilon) \equiv [u(\cdot, 0, \varepsilon), v(\cdot, 0, \varepsilon)]^t$ in $L^2(0,1) \times H^1(0,1)$ of initial data passing through $[1, 1]$ with the property that any solution initially emanating from this curve will blow up in a finite time.

This solution is given by $u = \psi_t(x,t)$, $v = \exp(\psi)$, where

$$\psi(x,t) = t - \ln[1 - 2\varepsilon \exp(Nct) \cos(N\pi x) + \varepsilon^2 \exp(2Nct)].$$

Moreover, this solution has the important biological property that it leaves the above space by aggregation, in particular, by virtue of the fact that $\|u(\cdot,t)\|_{L^2(0,1)}$ blows up in finite time. It is conceivable that for such systems, $\|u(\cdot,t)\|_{L^2(0,1)}$ can remain bounded, while $\|u_x(\cdot,t)\|_{L^2(0,1)}$ blows up in finite time. In [21], this possibility was demonstrated numerically, while in [17], a plausibility argument was given to show that these numerical results were not just artifacts of the simulations and were to be expected from the underlying dynamical system.

The result tells us that in every neighborhood of the initial data for the spatially homogeneous solution $[1, e^t]^t$, there are solutions of arbitrarily high initial total variation which begin in this neighborhood and blow up in finite time. The numerical evidence suggests that *every* arbitrarily small nonconstant perturbation of the initial data for $[1, e^t]^t$ (which must have a nontrivial projection onto at least one of the directions $[Nc, 1]^t \cos(Nx)$ for some N) must blow up in finite time. (This interpretation was not spelled out in [17].)

Clearly if we replace v by $\exp(v)$ in the system (1.4), there results

$$\begin{aligned} u_t &= u_{xx} - (uv_x)_x, \\ v_t &= u, \end{aligned} \tag{1.5}$$

which, when $\epsilon \geq 0$, is a special case of

$$\begin{aligned} u_t &= u_{xx} - (uv_x)_x, \\ v_t &= \epsilon v_{xx} + u - av. \end{aligned} \tag{1.6}$$

Equation (1.6) is the classical system studied in [3]. In its turn, this system contains as a special case the system of Nagai and Nakaki taken up in section 2. However, it is important to note that in [20], the authors establish the well posedness of the initial-boundary value problem for this system (with homogeneous Neumann boundary conditions) as well as the existence of a global attractor. Their proof demands that $\epsilon > 0$ in order to establish the existence of a global Lyapunov functional. An alternate proof of this result has been given in [12]. There the authors also provide an asymptotic profile of the solution.

Thus we are left with the question of what happens to solutions when the dissipation in v is weak, i.e., when $\epsilon = 0$ and $a > 0$. This is the problem raised by Nagai and partially addressed by him and Nakaki in [18].

The plan of the paper is as follows. In section 2 we discuss their system and the results they established recently [18]. There we also discuss a related initial value problem for their system and introduce a closely related approximate initial value problem. In section 3 we reformulate the Nagai–Nakaki system as an infinite system of nonlinear ordinary differential equations. In section 4, we introduce a second infinite system of ordinary differential equations which is closely related to the system of ordinary differential equations in section 3. This second system is related to the first in much the same way as the approximate initial value problem is related to the full initial value problem for their system.

In section 5 we establish the local existence and uniqueness of solutions of their system when $\mu > a$ in the sequence space $\ell_1 \times \ell_1^1$, i.e., in the space of pairs of sequences $(\{a_i\}, \{b_i\})$ such that $\sum_{i\geq 1}(|a_i| + i|b_i|)$ is finite. (This sequence space is continuously and injectively imbedded in $L^1(0,1) \times W^{1,1}(0,1)$. However, the inverse of the injection (restricted to the image) is not continuous. We discuss this point in more detail in section 7.)

In section 6, we demonstrate that the spatially homogeneous solutions of the system of ordinary differential equations for the approximate problem are unstable in the sense that in every neighborhood of the spatially homogeneous solution there are solutions in $L^2(0,1) \times H^1(0,1)$ with spatially inhomogeneous data which blow up in finite time in this space.

In section 7, we establish this conjecture. That is, if $\mu > a$, then in every neighborhood of (μ, v_0) there are (spatially nonconstant) initial data for which the corresponding solution of the Nagai–Nakaki problem in the cylinder must blow up in finite time (in a sense to be made precise below). This result will yield the Nagai–Nakaki conjecture for solutions that are sufficiently regular.

2. The system of Nagai and Nakaki [18]. Nagai, in a talk given at the International Conference on Partial Differential Equations and Mathematical Biology, Wuhan, China, 2001, considered the following initial-boundary value problem:

$$\begin{aligned} u_t &= u_{xx} - (uv_x)_x, \\ v_t &= u - av \end{aligned} \tag{2.1}$$

with $a \geq 0$. As boundary conditions he took

$$\begin{aligned} u_x(0,t) &= v_x(0,t)u(0,t), \\ u_x(1,t) &= v_x(1,t)u(1,t). \end{aligned} \tag{2.2}$$

These boundary conditions follow from the conditions $u_x(0,t) = u_x(1,t) = 0$ and $v_x(0,0) = v_x(1,0) = 0$ because the second equation of (2.1) implies that $v_x(0,t), v_x(1,t)$

satisfy $y'(t) = -ay(t)$. (In what follows we will refer to (2.1) and (2.2) as Nagai's problem or the Nagai–Nakaki problem.)

To set the notational stage for what follows, we introduce a potential function $\psi(x,t)$ as follows: We let $v(x,t) \equiv V(t)+\psi(x,t)$, $u(x,t) \equiv U(t)+\tilde{u}(x,t)$. The spatially homogeneous solution of Nagai's problem is

$$(V(t), U(t)) = (\mu/a + (v_0 - \mu/a)\exp(-at), \mu).$$

This and the second equation force the choice for $\tilde{u} = \psi_t + a\psi$ so that

$$(\psi, \psi_t + a\psi)^t = (v - V(t), u - \mu) = (v,u)^t - (V(t), U(t))^t. \tag{2.3}$$

In particular, in what follows, the reader is cautioned that $(\psi, \psi_t + a\psi)^t$ corresponds to the pair $(v, u + a\psi)^t$. (That is, with reference to [18], the pairing is (u,v), while in the theorems and proofs here, the pairing is (v,u).)

We are interested in those potential functions for which

$$\int_0^1 \psi\, dx = \int_0^1 \psi_t\, dx = 0 \tag{2.4}$$

in order to ensure that the mass, $\int_0^1 u\, dx$, is conserved.

Recently Nagai and Nakaki [18] have established the following statements for a restricted class of initial data perturbations for which the corresponding solutions are more regular than $L^2(0,1) \times H^1(0,1)$.

To save the reader a bit of time, we give a rough summary of their results. (By initial values, we mean initial values for which the mean value of u is μ and which are not identical with the stationary solution $(\mu, \mu/a)$.)

1. If the initial values are sufficiently regular (in particular if they are analytic functions) and if they satisfy the boundary conditions, then the solution components u, v will be in $H^2(0,1)$ and will be continuous or continuously differentiable in time into the appropriate range on the interval of existence.
2. If $\mu < a$ and the initial values are sufficiently regular, then (u,v) approaches $(\mu, \mu/a)$ exponentially rapidly in the norm of $H^1(0,1) \times H^2(0,1)$.
3. Suppose $\mu > a$ and suppose that the initial values are sufficiently regular.
   a. If the initial data satisfy

$$W(u(,\cdot,0), v(\cdot,0)) < \mu \ln \mu - \frac{\mu^2}{2a},$$

   where $f > 0, g \geq 0$ and where

$$W(f,g) \equiv \int_0^1 (f \ln f - fg + ag^2/2)\, dx,$$

   and if the solution exists for all time, then each component of (u,v) blows up in the H^1 norm as $t \to +\infty$.
   b. If the blow-up time is finite, then each component blows up in L^∞, i.e., pointwise.
3. There are also solutions in each such neighborhood which converge to the steady state solutions in infinite time in the norm of $H^1(0,1) \times H^2(0,1)$.

Stability results for related problems have been established in [7, 23]. All of the exact solutions found in [23] were found earlier in [17] in rescaled form, contrary to

the implication in [23, p. 776]. (The solutions in [23] follow from those of [17] after a shift in the time axis.)

In his talk, Nagai mentioned that he and Nakaki were unable to resolve whether or not the blowup occurred in finite time. Therefore, we shall refer to the following statement as *Nagai's conjecture.* There are choices of initial data $(u(\cdot,0), v(\cdot,0))$ for which the blow-up time must be finite.

In view of the results of [17], when $a = 0$, the blowup must occur in finite time. Motivated by this simple observation, we set about trying to establish this for Nagai's problem. However, we were unable to establish this claim in $L^2(0,1) \times H^1(0,1)$.

In the course of our investigations, we happened upon a problem, which is, in a sense, close to that of the problem of Nagai, for which Nagai's conjecture holds for $(u, v) \in L^2(0,1) \times H^1(0,1)$. Moreover, this result allows us to prove the conjecture of Nagai in a Banach space different from that proposed by Nagai. More precisely, if we denote by $\{(a_n(t), b_n(t))\}_{n=1}^{\infty}$ the sequence of cosine coefficients for the pair (ψ, ψ_t), we show that $\sum_n (n|a_n(t)| + |b_n(t)|)$ must blow up in finite time.

As remarked above, blowup in sequence space in this sense does *not* imply blowup of the L^1 norm of ψ, ψ_x, or ψ_t.

We see that ψ satisfies

$$\psi_{tt} + (\mu - a)\psi_{xx} = (\psi_{tx} - \psi_t\psi_x)_x - a(\psi_t + (\psi\psi_x)_x). \tag{2.5}$$

In order to motivate the approximate problem, we digress for a moment and consider the pure initial value problem for (2.5). If we compute the Fourier transform $\varphi(\xi, t) = \widehat{\psi(x,t)} = \int_{-\infty}^{\infty} e^{-i\xi x}\psi(x,t)dx$ and assume that ψ, ψ_x vanish at $x = \pm\infty$ on any interval $[0, T)$ where the solution of the initial value problem exists, we find (suppressing the second argument on the right)

$$\begin{aligned}
\varphi_{tt} + (a + \xi^2)\varphi_t + \xi^2(a - \mu)\varphi &= \frac{a\xi^2}{2}\varphi * \varphi(\xi) + \xi\varphi_t * (\eta\varphi) \\
&= \frac{1}{2}\int_0^{\xi} [a\xi^2\varphi(\xi - \eta)\varphi(\eta) + 2\xi(\xi - \eta)\varphi(\xi - \eta)\varphi_t(\eta)]\, d\eta \\
&\quad + \frac{1}{2}\int_{\xi}^{\infty} \{a\xi^2\varphi(\xi - \eta)\varphi(\eta) + \xi[(\xi - \eta)\varphi(\xi - \eta)\varphi_t(\eta) \\
&\qquad + \eta\varphi(\eta)\varphi_t(\xi - \eta)]\}\, d\eta.
\end{aligned} \tag{2.6}$$

If ψ, ψ_x are sufficiently regular, then

$$\lim_{|\xi|\to+\infty} \int_{\xi}^{\infty} a\xi^2\varphi(\xi - \eta)\varphi(\eta) + \xi[(\xi - \eta)\varphi(\xi - \eta)\varphi_t(\eta) + \eta\varphi(\eta)\varphi_t(\xi - \eta)]\, d\eta = 0. \tag{2.7}$$

We can estimate the terms in (2.7) as follows:

$$\left| \int_{\xi}^{\infty} \xi^2\varphi(\xi - \eta)\varphi(\eta)\, d\eta \right| \le \xi^2 \|\varphi\|_{L^\infty} \int_{\xi}^{\infty} |\varphi(\eta)|\, d\eta,$$

while

$$\frac{1}{2}\left| \int_{\xi}^{\infty} \xi[(\xi - \eta)\varphi(\xi - \eta)\varphi_t(\eta) + \eta\varphi(\eta)\varphi_t(\xi - \eta)]\, d\eta \right| \le |\xi| \|\eta\varphi(\eta)\|_{L^\infty} \int_{\xi}^{\infty} |\varphi_t(\eta)|\, d\eta.$$

These inequalities give us an idea of how rapidly the transform of the solution should decay.

The Fourier transform of the partial differential equation which approximates Nagai's problem is the equation

$$\varphi_{tt} + (a+\xi^2)\varphi_t + \xi^2(a-\mu)\varphi = \frac{1}{2}\int_0^\xi [a\xi^2\varphi(\xi-\eta)\varphi(\eta) + 2\xi(\xi-\eta)\varphi(\xi-\eta)\varphi_t(\eta)]\,d\eta \equiv \Phi(\phi,\phi_t)(\xi,t). \tag{2.8}$$

The nonlinear partial differential equation itself can be recovered from (2.8) in the form

$$\psi_{tt} + [a\psi + \psi_{xx}]_t + (\mu-a)\psi_{xx} = \widehat{\Phi}(\phi,\phi_t)(x,t), \tag{2.9}$$

where $\widehat{\Phi}$ denotes the inverse Fourier transform of Φ. We call Φ the finite part of the Fourier transform of $(uv_x)_x$. (Notice that, except for the factor ξ^2, Φ is the sum of the finite parts of two convolutions, one of ϕ with itself and the other of $\phi_t(\xi)$ with $\xi\phi(\xi)$.)

In section 4, we derive a system of ordinary differential equations for the cosine coefficients of the initial-boundary value problem for (2.9). This initial-boundary value problem corresponds to the natural initial-boundary value problem for (2.5) which arises from Nagai's problem, i.e., $\psi_x = \psi_{xt} = 0$ at $x = 0, 1$ and $t > 0$ with ψ, ψ_t prescribed at $t = 0$. The resulting system of ordinary differential equations for the cosine coefficients of the solution of (2.9) is related to the corresponding system of ordinary differential equations for the cosine coefficients of the solution of Nagai's problem in much the same way that (2.8) is related to (2.6).

In order to see how the former system comes about, we next derive the corresponding system of ordinary differential equations for Nagai's problem.

3. Reformulation of the Nagai–Nakaki system as a system of ordinary differential equations. We introduce some notation. Let $\beta \geq 0$ and $i \in \{1, 2\}$. We work in the spaces $\ell^i_\beta([0,T))$ of sequences of real valued functions $\{g_n(t)\}_{n=1}^\infty$ on $[0,T)$ for which $\sum_{n=1}^\infty n^\beta |g_n(t)|^i < \infty$. When $\beta = 0$ we omit the subscript. That is, $\ell^i_\beta = \ell^i_0 = \ell^i$.

We say that a sequence of differentiable functions $\{g_n(t)\}_{n=1}^\infty$ is in $\ell^i_\beta([0,T)) \times \ell^j_{\beta'}([0,T))$ if the sequence $\{g_n(t)\}_{n=1}^\infty$ is in $\ell^i{}_\beta([0,T))$ and the sequence $\{g_n'(t)\}_{n=1}^\infty$ is in $\ell^j_{\beta'}([0,T))$.

Assuming that $\mu > a$, we seek a solution of this equation in the form

$$\psi(x,t) = \sum_{n=1}^\infty g_n(t)\cos(Cnx), \tag{3.1}$$

where $C = 2\pi M$ for some integer M. With this choice of M the conservation conditions (2.4) hold.

Consequently,

$$(\psi_t\psi_x)_x = -C\sum_{n=2}^{\infty}\sum_{k+l=n} kg_kg_l'(\cos(Clx)\sin(Ckx))_x$$

$$= -\frac{1}{2}C^2\sum_{n=2}^{\infty}\sum_{k+l=n} kg_kg_l'[(k+l)\cos(C(k+l)x) + (k-l)\cos(C(k-l)x)] \tag{3.2}$$

$$= -\frac{1}{2}C^2\sum_{n=2}^{\infty}\sum_{k=1}^{n-1} kg_kg_{n-k}'[n\cos(Cnx) + (2k-n)\cos(C(2k-n)x)],$$

and

$$(\psi\psi_x)_x = -C\sum_{n=2}^{\infty}\sum_{k+l=n} kg_kg_l(\cos(Clx)\sin(Ckx))_x$$

$$= -\frac{1}{2}C^2\sum_{n=2}^{\infty}\sum_{k+l=n} kg_kg_l[(k+l)\cos(C(k+l)x) + (k-l)\cos(C(k-l)x)] \tag{3.3}$$

$$= -\frac{1}{4}C^2\sum_{n=2}^{\infty}\sum_{k=1}^{n-1} g_kg_{n-k}[n^2\cos(Cnx) + (2k-n)^2\cos(C(2k-n)x)].$$

Then (2.5) can be rewritten in the form

$$\sum_{n=1}^{\infty}(g_n'' + (C^2n^2+a)g_n' - (\mu-a)C^2n^2g_n)\cos(Cnx)$$

$$= \frac{1}{2}C^2\sum_{n=2}^{\infty}\sum_{k=1}^{n-1}\{kg_kg_{n-k}'\,[n\cos(Cnx) + (2k-n)\cos(C(2k-n)x)]$$

$$+\frac{a}{2}g_kg_{n-k}\left[n^2\cos(Cnx) + (2k-n)^2\cos(C(2k-n)x)\right]\}.$$

The terms involving $\cos(C(2k-n)x)$ on the right-hand side can be rewritten by switching the order of summation and setting $l = 2k-n$ to obtain

$$\sum_{n=2}^{\infty}\sum_{k=1}^{n-1}(2k-n)kg_kg_{n-k}'\cos(C(2k-n)x) = \sum_{k=1}^{\infty}\sum_{n=k+1}^{\infty}(2k-n)kg_kg_{n-k}'\cos(C(2k-n)x)$$

$$= \sum_{k=1}^{\infty}\sum_{l=-\infty}^{k-1} lkg_kg_{k-l}'\cos(Clx)$$

$$= \sum_{k=1}^{\infty}\sum_{l=1}^{\infty}(-l)kg_kg_{k+l}'\cos(Clx)$$

$$+\sum_{k=1}^{\infty}\sum_{l=1}^{k-1} lkg_kg_{k-l}'\cos(Clx)$$

$$= -\sum_{l=1}^{\infty}\sum_{k=1}^{\infty} lkg_kg_{k+l}'\cos(Clx)$$

$$+\sum_{l=1}^{\infty}\sum_{k=l+1}^{\infty} lkg_kg_{k-l}'\cos(Clx).$$

Likewise,

$$\begin{aligned}\sum_{n=2}^{\infty}\sum_{k=1}^{n-1} g_k g_{n-k}(2k-n)^2\cos(C(2k-n)x) &= \sum_{k=1}^{\infty}\sum_{n=k+1}^{\infty} g_k g_{n-k}(2k-n)^2\cos(C(2k-n)x)\\ &= \sum_{k=1}^{\infty}\sum_{l=-(k-1)}^{\infty} g_k g_{l+k} l^2\cos(Clx)\\ &= 2\sum_{l=1}^{\infty}\left(l^2\sum_{k=1}^{\infty} g_k g_{l+k}\right)\cos(Clx),\end{aligned}$$

the third line following from the second by breaking up the inner sum on the right of the second line into an infinite sum over positive integers and a finite sum over negative integers $l=-1,\dots,-(k-1)$. The latter inner sum is then rewritten as a finite sum over positive indices and the order changed in the resultant double sum.

Therefore, we have

$$\begin{aligned}&\sum_{n=1}^{\infty}(g_n''+(C^2n^2+a)g_n'-(\mu-a)C^2n^2g_n)\cos(Cnx)\\ &\quad=\frac{1}{2}C^2\sum_{n=2}^{\infty}\sum_{k=1}^{n-1}\left(nkg_kg_{n-k}'+\frac{a}{2}n^2g_kg_{n-k}\right)\cos(Cnx)\\ &\qquad+\frac{1}{2}C^2\sum_{n=1}^{\infty}n\left[\sum_{k=n+1}^{\infty}kg_kg_{k-n}'-\sum_{k=1}^{\infty}kg_kg_{k+n}'+an\sum_{k=1}^{\infty}g_kg_{n+k}\right]\cos(Cnx).\end{aligned}\tag{3.4}$$

We obtain the following (infinite) system of ordinary differential equations:

$$\begin{aligned}\mathfrak{L}_n g_n &\equiv g_n''+(C^2n^2+a)g_n'-(\mu-a)C^2n^2g_n\\ &=\frac{1}{2}C^2n\left\{\sum_{k=1}^{n-1}\left(kg_kg_{n-k}'+\frac{a}{2}ng_kg_{n-k}\right)\right.\\ &\qquad\left.+\sum_{k=1}^{\infty}\left[(n+k)g_{n+k}g_k'-kg_kg_{k+n}'+ang_kg_{n+k}\right]\right\}\quad\text{for}\quad n=1,2,\dots.\end{aligned}\tag{3.5}$$

In order to rewrite (3.5) in a more compact form, we introduce the notation

$$\begin{aligned}|g| &= \{|g_k|\}_{k=1}^{\infty},\\ T_ng &= \{g_{n+k}\}_{k=1}^{\infty}\ \text{(shift operator)},\\ g' &= \{g_k'\}_{k=1}^{\infty}\quad\text{(differentiation)},\\ \mathcal{M}g &= \{kg_k\}_{k=1}^{\infty}\quad\text{(multiplication by the transform variable)},\\ g*h &= \left\{\sum_{k=1}^{n-1}g_kh_{n-k}\right\}_{n=1}^{\infty}\quad\text{(convolution)},\\ (g,h) &= \sum_{k=1}^{\infty}g_kh_k\ \ \text{(scalar product in } \ell^2).\end{aligned}$$

Then one can solve the Nagai–Nakaki system in the aforementioned function space if and only if one can solve the initial value problem for the following system in the

corresponding sequence space:

$$\begin{aligned}\mathfrak{L}_n g_n &\equiv g_n'' + (C^2n^2 + a)g_n' - (\mu - a)C^2n^2 g_n \\ &= \frac{1}{2}C^2 n\Big\{(\mathcal{M}g * g')_n + n\frac{a}{2}(g*g)_n + [(T_n\mathcal{M}g, g') - (\mathcal{M}g, T_n g')] + an(g, T_n g)\Big\}.\end{aligned} \tag{3.6}$$

4. A system of ordinary differential equations related to the Nagai–Nakaki system. If we consider (3.6) without the last three terms on the right-hand side, we obtain the following system of ordinary differential equations:

$$\begin{aligned}\mathfrak{L}_n g_n &\equiv g_n'' + (C^2n^2 + a)g_n' - (\mu - a)C^2n^2 g_n \\ &= \frac{1}{2}C^2 n\left\{\sum_{k=1}^{n-1}\left(k g_k g_{n-k}' + \frac{a}{2}n g_k g_{n-k}\right)\right\} \\ &\equiv \frac{1}{2}C^2 n\Big\{(\mathcal{M}g * g')_n + n\frac{a}{2}(g*g)_n\Big\}.\end{aligned} \tag{4.1}$$

That is, (4.1) is the discrete version of (2.8). It is the system satisfied by the cosine coefficients of solutions of (2.9).

Comparing (4.1) and (2.8), we infer that the three terms in (3.6) that do not appear in (4.1) can be viewed as "tail ends" of integrals. That is, they are analogous to the three integrals that have been dropped in passing from (2.6) to (2.8) under the assumption that ψ, ψ_x are sufficiently regular.

This suggests that $(T_n\mathcal{M}g, g')$, $(\mathcal{M}g, T_n g')$, $na(g, T_n g)$ can be neglected in comparison with the remaining terms on the right-hand side of (3.6).

Such a statement needs rigorous proof.

5. Local existence and uniqueness of solutions of the initial value problem for the Nagai–Nakaki system. We prove the following result in $\ell_1^1 \times \ell^1$ which was proved in [18] in a product of smoother spaces.

LEMMA 1. *The solution $\{g_n(\cdot)\}_{n=1}^{\infty}$ of the system* (3.5) *exists locally in time and is unique in $\ell_1^1 \times \ell^1$ on the interval of local existence. Moreover, the solution is uniformly bounded in the $\ell_1^1 \times \ell^1$ norm on compact subsets of the existence interval.*

Proof. First consider the question of uniqueness. Set $w_n = g_n - h_n$, where g_n and h_n are two solutions of the above system for $n \geq 2$ for which $g(0) = h(0)$, $g'(0) = h'(0)$. The difference w_n satisfies the equation

$$\begin{aligned}\mathfrak{L}_n w_n &\equiv w_n'' + (C^2n^2 + a)w_n' - (\mu - a)C^2n^2 w_n \\ &= \frac{1}{2}C^2 n\left\{\sum_{k=1}^{n-1}\left[k(w_k g_{n-k}' + h_k w_{n-k}') + ak(w_k g_{n-k} + h_k w_{n-k})\right]\right. \\ &\qquad + \sum_{k=1}^{\infty}\left[(n+k)(w_{n+k}g_k' + h_{n+k}w_k') - k(w_k g_{n+k}' + h_k w_{n+k}')\right] \\ &\qquad \left. + 2a\sum_{k=1}^{\infty}k(w_k g_{n+k} + h_k w_{n+k})\right\},\end{aligned} \tag{5.1}$$

which, in the above notation, becomes

$$\begin{aligned}\mathfrak{L}_n w_n = \frac{1}{2}C^2 n\{&(\mathcal{M}w * g')_n + (\mathcal{M}h * w')_n + a[(\mathcal{M}w * g)_n + (\mathcal{M}h * w)_n] \\ &+ (T_n\mathcal{M}w, g') + (T_n\mathcal{M}h, w') - (\mathcal{M}w, T_n g') \\ &- (\mathcal{M}h, T_n w') + 2a[(\mathcal{M}w, T_n g) + (\mathcal{M}h, T_n w)]\}.\end{aligned}$$

We abbreviate this as

$$\mathfrak{L}_n w_n = \mathcal{F}_n(w, w'), \tag{5.2}$$

where we suppress the dependence of the right-hand side on g, h, g', h' for the moment. The characteristic equation for each of the linear second order operators $\mathfrak{L}_n$ is

$$r^2 + (C^2n^2 + a)r - (\mu - a)C^2n^2 = 0.$$

The roots r_n^+, r_n^- are real with $r_n^+ > 0 > r_n^-$, with $r_n^+ \to 2(\mu - a) \equiv r^+$ as $n \to \infty$, and with $r_n^+ \le r^+$ for all n while $r_n^- \to -\infty$. Since the initial values for w vanish, the solution of (5.1) can be written as

$$w_n = A_n(\mathcal{F}_n, t)e^{r_n^+ t} + B_n(\mathcal{F}_n, t)e^{r_n^- t}, \tag{5.3}$$

where

(5.4)

$$A_n(\mathcal{F}_n, t) = \int_0^t \frac{-e^{r_n^- s}\mathcal{F}_n(s)}{W} ds = \frac{1}{\sqrt{(C^2n^2 + a)^2 + 4(\mu - a)C^2n^2}} \int_0^t e^{-r_n^+ s}\mathcal{F}_n(s)ds,$$
$$B_n(\mathcal{F}_n, t) = \int_0^t \frac{e^{r_n^+ s}\mathcal{F}_n(s)}{W} ds = \frac{-1}{\sqrt{(C^2n^2 + a)^2 + 4(\mu - a)C^2n^2}} \int_0^t e^{-r_n^- s}\mathcal{F}_n(s)ds.$$

Because

$$\max\{|B_n(\mathcal{F}_n, t)e^{r_n^- t}|,\ |A_n(\mathcal{F}_n, t)e^{r_n^+ t}|\} \le \frac{c}{n^2} e^{r_n^+ t} \int_0^t e^{-r_n^+ s}|\mathcal{F}_n(s)|ds$$

for some computable constant c, we have

$$\begin{aligned} \|\mathcal{M}w(t)\|_{\ell^1} = \sum_{n=1}^{\infty} n|w_n(t)| &\le \sum_{n=1}^{\infty} \frac{c}{n} e^{r_n^+ t} \int_0^t e^{-r_n^+ s}|\mathcal{F}_n(s)|ds \\ &\le e^{r^+ t} \int_0^t \sum_{n=1}^{\infty} \frac{c}{n}|\mathcal{F}_n(s)|ds. \end{aligned} \tag{5.5}$$

We need to estimate the terms in the last integral. For each index n, there are 10 sums arising from the 10 terms in the definition of $\mathcal{F}_n/n$. After use of the convolution inequality, we have that

$$\sum_{n=1}^{\infty} |(\mathcal{M}w * g')_n| \le \sum_{n=1}^{\infty} \sum_{k=1}^{n-1} k|w_k||g'_{n-k}| = \||\mathcal{M}w| * |g'|\|_{\ell^1} \le \|\mathcal{M}w(t)\|_{\ell^1} \|g'(t)\|_{\ell^1}.$$

The next three sums are bounded above by a constant multiple of $\|w'(t)\|_{\ell^1}\|\mathcal{M}h(t)\|_{\ell^1}$, $\|\mathcal{M}w(t)\|_{\ell^1}\|\mathcal{M}g(t)\|_{\ell^1}$, and $\|\mathcal{M}w(t)\|_{\ell^1}\|\mathcal{M}h(t)\|_{\ell^1}$, respectively.

The terms involving T_n are a bit trickier to estimate. We have, for the first of them,

$$\sum_{n=1}^{\infty} |(T_n\mathcal{M}w, g')| \le \sum_{k=1}^{\infty} \sum_{n=1}^{\infty} (n+k)|w_{n+k}||g'_k| = \sum_{k=1}^{\infty} |g'_k| \sum_{l=k+1}^{\infty} l|w_l| \le \sum_{k=1}^{\infty} |g'_k| \|T_k\mathcal{M}w\|_{\ell^1}.$$

Since $\|T_k\mathcal{M}w\|_{\ell^1}$ is decreasing in k, we obtain

$$\sum_{k=1}^{\infty}|g_k'||T_k\mathcal{M}w|_{\ell^1}\le\|\mathcal{M}w(t)\|_{\ell^1}\|g'(t)\|_{\ell^1}.$$

In a similar fashion, the remaining five sums are found to be bounded above by a constant multiple of $\|w'(t)\|_{\ell^1}\|\mathcal{M}h(t)\|_{\ell^1}$, $\|\mathcal{M}w(t)\|_{\ell^1}\|g'(t)\|_{\ell^1}$, $\|w'(t)\|_{\ell^1}\|\mathcal{M}h(t)\|_{\ell^1}$, $\|\mathcal{M}w(t)\|_{\ell^1}\|\mathcal{M}g(t)\|_{\ell^1}$, and $\|\mathcal{M}w(t)\|_{\ell^1}\|\mathcal{M}h(t)\|_{\ell^1}$, respectively.

Thus, for some constant B

$$\|\mathcal{M}w(t)\|_{\ell^1}\le Be^{r^+t}\int_0^t(\|\mathcal{M}w(s)\|_{\ell^1}+\|w'(s)\|_{\ell^1})(\|\mathcal{M}g(s)\|_{\ell^1}+\|g'(s)\|_{\ell^1}+\|\mathcal{M}h(s)\|_{\ell^1}+\|h'(s)\|_{\ell^1})ds.$$

Assume that $g(\cdot),h(\cdot)$ are in $\ell^1_1([0,T])$ and g',h' are in $\ell^1([0,T])$; i.e., on every compact subset K of $[0,T)$ there is a finite constant $M(K)$ such that

$$\max\left\{\sum_{k=1}^{\infty}(k|g_k|+|g_k'|),\sum_{k=1}^{\infty}(k|h_k|+|h_k'|)\right\}<M(K). \tag{5.6}$$

There results

$$\|\mathcal{M}w(t)\|_{\ell^1}\le Be^{r^+t}\int_0^t(\|\mathcal{M}w(s)\|_{\ell^1}+\|w'(s)\|_{\ell^1})ds \tag{5.7}$$

for some new computable constant $B=B(M(K))$.

Next we estimate $\|w'(t)\|_{\ell^1}$. Using the representation formula (5.3) we obtain

$$w_n'(t)=\frac{1}{\sqrt{(C^2n^2+a)^2+4(\mu-a)C^2n^2}}\left\{r_n^+\int_0^t e^{r_n^+(t-s)}\mathcal{F}_n(s)ds-r_n^-\int_0^t e^{r_n^-(t-s)}\mathcal{F}_n(s)ds\right\}. \tag{5.8}$$

Consequently, for some positive computable constants c,d we have, noting that $r_n^-\approx -dn^2$,

$$|w_n'(t)|\le c\left\{\frac{r^+}{n^2}\int_0^t e^{r^+(t-s)}|\mathcal{F}_n(s)|ds+\int_0^t\left[ne^{-dn^2(t-s)}\right]\frac{|\mathcal{F}_n(s)|}{n}ds\right\}. \tag{5.9}$$

The first term on the right-hand side is treated exactly as above. We note that for $c_1=1/\sqrt{2ed}$, all positive integers n, and all $s\le t$,

$$ne^{-dn^2(t-s)}\le\frac{c_1}{\sqrt{t-s}}.$$

Using this in (5.9) and summing over n we obtain

$$\|w'(t)\|_{\ell^1}\le c\left\{\int_0^t r^+e^{r^+(t-s)}\sum_{n=1}^{\infty}\frac{|\mathcal{F}_n(s)|}{n^2}ds+\int_0^t\frac{c_1}{\sqrt{t-s}}\sum_{n=1}^{\infty}\frac{|\mathcal{F}_n(s)|}{n}ds\right\}. \tag{5.10}$$

Since we have already estimated the integrand sums $\sum_{n=1}^{\infty}\frac{|\mathcal{F}_n(s)|}{n}$ above, we obtain

$$\|w'(t)\|_{\ell^1}\le c_1\left\{e^{r^+t}\int_0^t\frac{c}{\sqrt{t-s}}(\|\mathcal{M}w(s)\|_{\ell^1}+\|w'(s)\|_{\ell^1})\,ds\right\}. \tag{5.11}$$

Setting $\varphi(t) = \|\mathcal{M}w(t)\|_{\ell^1} + \|w'(t)\|_{\ell^1}$, we have, with $c = c(T) = (cc_1 + B)e^{r^+T}$,

$$\varphi(t) \le c \int_0^t \frac{\varphi(s)}{\sqrt{t-s}}\, ds, \tag{5.12}$$

a Volterra integral inequality of Gronwall type with a weakly singular kernel. Thus, after an application of the Hölder inequality, it is easily shown that φ^q, with $1/p + 1/q = 1$ and $1 < p < 2$, satisfies a standard Gronwall inequality. That is,

$$\varphi^q(t) \le c^q \left(\frac{2}{2-p}\right)^{\frac{q}{p}} t^{\frac{q}{p}-\frac{q}{2}} \int_0^t \varphi^q(s)\, ds.$$

Thus, for $\phi(t) = \int_0^t \varphi^q(s)\, ds$ and $\tilde{c}(s) = c^q(\frac{2}{2-p})^{\frac{q}{p}} s^{\frac{q}{p}-\frac{q}{2}}$, we obtain

$$\frac{d}{dt}\left(\phi(t) e^{-\int_0^t \tilde{c}(s)\, ds}\right) \le 0.$$

Then

$$0 \le \phi(t) \le \phi(0) e^{\int_0^t \tilde{c}(s)\, ds}.$$

Since $\phi(0) = 0$, it follows that $\phi(t) \equiv 0$.

Consequently, $\varphi(t) \equiv 0$, and hence $g \equiv h$ on the existence interval.

Next, consider local existence. Since most of the estimates needed here have been worked through above, we will be brief.

Abbreviate (3.6) as $\mathfrak{L}g = F(g, g'), g(0) = g_0, g'(0) = g_0'$. Then the homogeneous solution $G(t)$ with inhomogeneous initial values solves

$$\begin{aligned} &\mathfrak{L}G = 0, \\ &G(0) = g_0, \quad G'(0) = g_0', \end{aligned}$$

while the function $H = g - G$ satisfies the nonlinear problem with homogeneous initial data:

$$\begin{aligned} &\mathfrak{L}H = F(G + H, G' + H'), \\ &H(0) = 0, \quad H'(0) = 0. \end{aligned}$$

Thus it suffices to show that the integral equation $H = \mathfrak{L}^{-1}F(G + H, G' + H')$ has a fixed point on some interval $[0, T_{exist})$. We see from the variation of parameters formula (5.3) that the components satisfy

$$H_n = A_n(\mathcal{F}_n, t)e^{r_n^+ t} + B_n(\mathcal{F}_n, t)e^{r_n^- t}.$$

Define the sequence of iterates $\{H^k\}_{k=1}^\infty$ as follows with $H^1(t) = \{H_n^1(t) = 0\}_{n=1}^\infty$ and, for $k \ge 1$,

$$H^{k+1} = \mathfrak{L}^{-1}F(G + H^k, G' + H^{k\prime}).$$

To construct a fixed point, we need to show that sequence $(\{H^k\}, \{H^{k\prime}\})$ is convergent in $\ell_1^1 \times \ell^1$. We do this by showing that we can apply the contraction mapping principle to the sequence. The argument usually goes in two steps.

1. There is a small time interval $[0,T]$ such that the sequence (of sequences) $(\{H^k\},\{H^{k'}\})_{k=1}^{\infty}$ is uniformly bounded in the norm on $\ell_1^1\times\ell^1$.
2. This sequence is contracting on this (or possibly smaller) time interval; i.e., there exists a constant $0\le\theta<1$ such that

$$\sup_{0\le s\le T}\|\mathcal{M}(H^{k+1}(s)-H^k(s))\|_{\ell^1}+\|(H^{k+1}-H^k)'(s)\|_{\ell^1}$$
$$\le\theta\sup_{0\le s\le T}\|\mathcal{M}(H^k-H^{k-1})(s))\|_{\ell^1}+\|(H^k-H^{k-1})'(s)\|_{\ell^1}.$$

To establish step 1, we find, as in the uniqueness proof, an inequality of the form

$$\|\mathcal{M}H^{k+1}(t)\|_{\ell^1}+\|(H^{k+1})'(t)\|_{\ell^1}$$
$$\le c\int_0^t\frac{1}{\sqrt{t-s}}(\|\mathcal{M}((G+H^k)(s))\|_{\ell^1}+\|(G+H^k)'(s)\|_{\ell^1})^2\,ds.$$

Because the roots $r_n^{\pm}$ are bounded above, we can assume that

$$\sup[0,T](\|\mathcal{M}G(s)\|_{\ell^1}+\|(G'(s)\|_{\ell^1})\le G_0(T)$$

for some constant G_0 depending only on T. Consequently, we have the estimate

$$\|\mathcal{M}H^{k+1}(t)\|_{\ell^1}+\|(H^{k+1})'(t)\|_{\ell^1}\le c\sqrt{t}\left\{G_0^2+[\|\mathcal{M}H^k(t)\|_{\ell^1}+\|(H^k)'(t)\|_{\ell^1}]^2\right\}.$$

If we set $Z_n=\sup_{[0,T]}[\|\mathcal{M}H^n(t)\|_{\ell^1}+\|(H^n)'(t)\|_{\ell^1}]$, then $Z_{n+1}\le c\sqrt{T}(G_0^2+Z_n^2)$. Let $G_1>0$ be any constant such that $Z_1\le G_1$. Then $Z_{n+1}\le G_1$ for all $n=1,2,3,\dots$, provided that T is so small that

$$\sqrt{T}\le\frac{G_1}{c(G_0^2+G_1^2)}.$$

Since both G_0,G_1 depend on the initial values for the free solution, we have the desired a priori bound on the iterates. For step 2, we examine the difference:

$$\mathfrak{L}(H^{k+1}-H^k)=F(G+H^k,G'+H^{k'})-F(G+H^{k-1},G'+H^{k-1'})\equiv\mathcal{F}(W^k,W^{k'}),$$

where $W^k=H^k-H^{k-1}$ and $\mathcal{F}$ depends in fact on $H^k,H^{k'},H^{k-1},G,G'$. That is,

$$\begin{aligned}\mathfrak{L}_nW_n^{k+1}=\frac{1}{2}C^2n\{&(\mathcal{M}W^k*(G+H^k)')_n+(\mathcal{M}(G+H^{k-1})*W^{k'})_n\\&+a[(\mathcal{M}W^k*(G+H^k))_n+(\mathcal{M}(G+H^{k-1})*W^k)_n]\\&+(T_n\mathcal{M}W^k,(G+H^k)')+(T_n\mathcal{M}(G+H^{k-1}),W^{k'})\\&-(\mathcal{M}W^k,T_n(G+H^k)')-(\mathcal{M}(G+H^{k-1}),T_nW^{k'})\\&+2a[(\mathcal{M}W^k,T_n(G+H^k))+(\mathcal{M}(G+H^{k-1}),T_nW^k)]\}.\end{aligned}$$

Consequently, as in the previous proof, after obtaining a similar expression for $W^{k'}$ we can then use the estimates in the previous part of the proof to derive the estimate of the form

$$\|\mathcal{M}W^{k+1}(t)\|_{\ell^1}+\|(W^{k+1})'(t)\|_{\ell^1}\le c\int_0^t\frac{1}{\sqrt{t-s}}(\|\mathcal{M}W^k(s)\|_{\ell^1}+\|(W^k)'(s)\|_{\ell^1})\,ds,$$

where

$$c = c(\|\mathcal{M}(G + H^{k-1})\|_{\ell^1}, \|G + H^k\|_{\ell^1}, \|(G + H^k)'\|_{\ell^1}).$$

By step 1, we may assume that c is uniformly bounded above by a constant $\tilde{c}(T, G(0), G'(0))$ for a sufficiently small time interval $[0, T]$. We proceed as in the previous proof, using the Hölder inequality to obtain the Gronwall inequality. From this, we easily show that on a sufficiently small time interval one can apply the contraction mapping principle to the sequence $(\{H^k\}, \{H^{k'}\})$ in $\ell_1^1 \times \ell^1$. We omit the details. □

6. Local existence and blowup of solutions of the approximate system. We turn next to the local existence theorem and blow-up theorem for the initial value problem for the approximate system (4.1). We choose the special initial sequence $g_n(0) = a_n$, $g_n'(0) = n\lambda a_n$, where a_n and λ are to be chosen in such a manner that $\{g_n(t) = a_n e^{n\lambda t}\}_{n=1}^{\infty}$ is a solution of the approximate system which must blow up in finite time.

In what follows, we adopt the following notation. Let M be a positive integer such that $\frac{a}{4\pi^2 M^2} \equiv a_* \leq 1$. Suppose that ε, δ are such that

$$0 < 2\varepsilon \leq a_1 \leq \frac{\lambda}{\lambda + a}\delta,$$

where λ is given by (6.3) below.

We establish the following theorems.

THEOREM 1 (local existence). *Suppose $\mu > a$ and the sequence $\{a_n\}_{n=2}^{\infty}$ solves the recurrence relation given by* (6.1) *below. Then the sequence $\{g_n(t) = a_n e^{n\lambda t}\}_{n=1}^{\infty}$ solves* (4.1) *on an interval $[0, T_e]$, where $T_e \geq T_* = -\frac{\ln \delta}{\lambda}$. Moreover, $(\psi(\cdot, t), \psi_t(\cdot, t))$ is in $H^1(0,1) \times L^2(0,1)$ on $[0, T_*)$, where $(\psi(\cdot, t))$ is given by* (3.1). *The function ψ is analytic on $(0,1) \times [0, T_*)$.*

THEOREM 2 (finite time blowup). *The function $(\psi(\cdot, t), \psi_t(\cdot, t))$ of the previous theorem must leave $H^1(0,1) \times L^2(0,1)$ in finite time $T_\infty \leq -\frac{\ln \varepsilon}{\lambda}$.*

Before proving these theorems, we show that for $n \geq 2$

$$\lambda(4\pi^2 M^2 n - a)(n-1)a_n = 2\pi^2 M^2 \sum_{k=1}^{n-1} [\lambda(n-k) + a] k a_k a_{n-k}. \tag{6.1}$$

This recurrence formula defines the sequence a_n. However, unlike the situation in [11, 17], we cannot find a simple expression for the coefficients a_n in terms of a_1 and n. Nonetheless, we can find upper and lower bounds for the series which sum to the related solutions found in [17] for the case $a = 0$. These estimates provide the necessary comparison functions for the existence and blowup of ψ in $H^1(0,1) \times L^2(0,1)$.

For convenience of notation, we use $\xi = x - 1/2$ in (3.1) instead of x. Then $\partial_x = \partial_\xi$ and single point blowup at $\xi = 0$ corresponds to blowup at $x = 1/2$. Therefore, if $g_n = a_n e^{n\lambda t}$ and $C = 2\pi M$, equation (4.1) reads

$$\begin{aligned} &\sum_{n=1}^{\infty} a_n \{4\pi^2 M^2 \lambda n^3 + \lambda^2 n^2 - (\mu - a)4\pi^2 M^2 n^2 + a\lambda n\} e^{n\lambda t} \cos(2\pi M n \xi) \\ &\qquad = 2\pi^2 M^2 \sum_{n=2}^{\infty} n \left\{ \sum_{k=1}^{n-1} (\lambda(n-k) + a) k a_k a_{n-k} \right\} e^{n\lambda t} \cos(2\pi M n \xi). \end{aligned} \tag{6.2}$$

Comparing coefficients for $n \geq 2$,

$$[4\pi^2 M^2 \lambda n^2 + n\left(\lambda^2 - (\mu - a)4\pi^2 M^2\right) + a\lambda]a_n = 2\pi^2 M^2 \sum_{k=1}^{n-1} [\lambda(n-k) + a]k a_k a_{n-k}.$$

For $n = 1$,

$$a_1\{\lambda^2 + \lambda(4\pi^2 M^2 + a) - (\mu - a)4\pi^2 M^2\} = 0.$$

Since $\mu > a$, the roots are real. Let

$$\lambda = \frac{1}{2}(\sqrt{(4\pi^2 M^2 + a)^2 + 16\pi^2 M^2(\mu - a)} - 4\pi^2 M^2 - a) \tag{6.3}$$

denote the positive root.[2] Then the relation for a_n, $n \geq 2$, simplifies to (6.1) as claimed. With the values of λ, a_* above, we have that

$$2\lambda(n - a_*)(n-1)a_n = \sum_{k=1}^{n-1} (\lambda(n-k) + a)k a_k a_{n-k}. \tag{6.4}$$

We are now in a position to prove the theorems. We begin with Theorem 1.

Proof. From (6.1), since $n \geq k + 1$,

$$\begin{aligned} 2\lambda(n - a_*)(n-1)a_n &\leq \sum_{k=1}^{n-1} (\lambda(n-k) + a)k a_k a_{n-k} \\ &\leq (\lambda + a) \sum_{k=1}^{n-1} k(n-k)\, a_k a_{n-k}. \end{aligned}$$

If $a_1 \leq b_1$, by induction it follows that $a_n \leq b_n$, where

$$2(n - a_*)(n-1)b_n = \frac{\lambda + a}{\lambda} \sum_{k=1}^{n-1} k(n-k) b_k b_{n-k}.$$

Because $n \geq 2$, we have $a_* \leq n/2$ and

$$n(n-1)b_n \leq \frac{\lambda + a}{\lambda} \sum_{k=1}^{n-1} k(n-k) b_k b_{n-k}.$$

Comparing this sequence with b'_n, it again follows that if $b_1 = b'_1$, then $b_n \leq b'_n$, where

$$n(n-1)b'_n = \frac{\lambda + a}{\lambda} \sum_{k=1}^{n-1} k(n-k) b'_k b'_{n-k}.$$

[2] As in [17], the choice of the negative root yields a global solution which converges to the spatially homogeneous solution as $t \to +\infty$. Notice also that if $\mu < a$, both roots have negative real part and the constructed solution must not only be global, it must converge to the spatially homogeneous solution, an observation consistent with the results of Nagai and Nakaki [18]. When $\mu = a$, $\lambda = 0$ and the constructed solution will be global but will not converge to the spatially homogenous solution.

This recurrence relation can be solved explicitly with $b'_n = \frac{1}{n}\left(\frac{\lambda+a}{\lambda}\right)^{n-1}(b'_1)^n$. For $b'_1 = \frac{\lambda}{\lambda+a}\delta$, we have $b'_n = \frac{\lambda}{\lambda+a}\frac{\delta^n}{n}$. The sequence $\{b'_n\}$ defines a convergent series of the form

$$\begin{aligned}\overline{\psi}(x,t) &= \sum_{n=1}^{\infty} b'_n e^{n\lambda t}\cos(2\pi Mn\xi) = \frac{\lambda}{\lambda+a}\sum_{n=1}^{\infty}\frac{1}{n}\delta^n e^{n\lambda t}\cos(2\pi Mn\xi)\\ &= -\frac{\lambda}{\lambda+a}\ln[1-2\delta e^{\lambda t}\cos(2\pi M\xi)+\delta^2 e^{2\lambda t}]\end{aligned}$$

for $t < -\frac{\ln\delta}{\lambda}$. Consequently, the upper bound for ψ in L^2 holds by the comparison of the coefficients a_n and b'_n of series for ψ and $\overline{\psi}$. A similar norm estimate holds for ψ_t, $\bar{\psi}_t$. Thus ψ exists for all $t < T_*$. That is, the existence interval $[0, T_e] \supset [0, T_*)$ or $T_e \geq T_*$. □

We now turn to the proof of Theorem 2.

Proof. To obtain the lower bound, note that if $a_1 \geq c_1$, then $a_n \geq c_n$, where the c_n satisfy

$$2(n-a_*)(n-1)c_n = \sum_{k=1}^{n-1} k(n-k)c_k c_{n-k}.$$

Thus

$$2n(n-1)c_n \geq \sum_{k=1}^{n-1} k(n-k)c_k c_{n-k} + 2a_*(n-1)c_n \geq \sum_{k=1}^{n-1} k(n-k)c_k c_{n-k}.$$

Hence if $c_1 \geq c'_1 > 0$, then $c_n \geq c'_n$, where

$$2n(n-1)c'_n = \sum_{k=1}^{n-1} k(n-k)c'_k c'_{n-k}.$$

However, $c'_n = \frac{1}{n2^{n-1}}(c'_1)^n$. Setting $c'_1 = 2\varepsilon$, it follows that $a_n \geq c'_n = 2\frac{\varepsilon^n}{n}$.

The function

$$\begin{aligned}\underline{\psi}(x,t) &= 2\sum_{n=1}^{\infty}\frac{1}{n}\varepsilon^n e^{n\lambda t}\cos(2\pi Mn\xi)\\ &= -\ln[1-2\varepsilon e^{\lambda t}\cos(2\pi M\xi)+\varepsilon^2 e^{2\lambda t}]\end{aligned}$$

exists as long as $t < -\frac{\ln\varepsilon}{\lambda}$ because the series converges absolutely and uniformly. The function $\underline{\psi}$ blows up pointwise at those points for which $\cos(2\pi M\xi) = 1$. Although we cannot compare these functions pointwise, we can compare them in H^1. To see this, note that from Parseval's identity, it follows that $|\underline{\psi_x}|_{L^2}(t)$ blows up in finite time.

Again, from Parseval and the inequalities $a_n \geq 2\frac{\varepsilon^n}{n}$, we have

$$|\underline{\psi_x}|_{L^2(0,1)}(t) \leq |\psi_x|_{L^2(0,1)}(t)$$

and

$$|\underline{\psi_t}|_{L^2(0,1)}(t) \leq |\psi_t|_{L_2(0,1)}(t).$$

Thus, ψ "blows up" at $T_\infty \le -\frac{\ln \varepsilon}{\lambda}$ in the sense that the functions $t \to |\psi_x|_{L^2}(t)$ and $t \to |\psi_t|_{L^2}(t)$ cannot be locally bounded on $[0,\infty)$ and hence (u,v) cannot remain in $H^1(0,1) \times L^2(0,1)$ for all time.

We next require that

$$2\varepsilon \le a_1 \le \frac{\lambda}{\lambda + a}\delta$$

so that

$$\varepsilon \le \frac{\lambda}{2(\lambda + a)}\delta. \tag{6.5}$$

Then the blow-up time must satisfy $-\frac{\ln \delta}{\lambda} \le T_\infty \le -\frac{\ln \varepsilon}{\lambda}$.

To prove the last claim of the theorem, note that since $u = \mu + \psi_t + a\psi$, it follows yet again from Parseval that

$$|u(\cdot,t) - \mu|_{L^2(0,1)} = \sum_1^\infty |a_n|^2(1+n^2)e^{2n\lambda t} \ge 4\sum_1^\infty \varepsilon^{2n}(1+n^{-2})e^{2n\lambda t}.$$

Consequently u must leave L^2 in finite time. Notice that this blow-up time is at least as large as the time of escape from H^1.

Finally, note that $\psi(x,0)$ and $\psi_t(x,0)$ are uniformly bounded above by $[2\lambda/(\lambda + a)]\ln(1-\delta)$ and $[2\lambda/(\lambda+a)](\lambda\delta(2+\lambda\delta)/(1-\delta))$, respectively. Hence for sufficiently small δ the initial values for the perturbed solution are positive and uniformly close to those for the spatially homogeneous solution. □

COROLLARY 1. *If $a_n \ge 2\frac{\varepsilon^n}{n}$, the function $(\psi(\cdot,t), \psi_t(\cdot,t))$ in the theorem also blows up in finite time in the sense that the sequence $\{(g_n(t), g_n'(t))\}_{n=1}^\infty$ with $g_n(0) = a_n$ and $g_n'(0) = na_n\lambda$ must leave $\ell_1^1 \times \ell^1$ in finite time.*

Since $|ng_n(t)| + |g_n'(t)| \ge 4\varepsilon^n e^{n\lambda t}$, the result follows.

Remark 1. We give an argument in the next section that shows that in every neighborhood of the spatially homogeneous solution, there are solutions of Nagai's problem, which, if they agree initially with solutions of the approximate problem and are sufficiently regular, cannot be global. The key to this argument is the demonstration that one may neglect the terms which we have identified as "tail ends."

To explain why this might be reasonable, if we evaluate $(T_n\mathcal{M}g, g'), (\mathcal{M}g, T_ng'), na(g, T_ng)$ for $g_n(t) = \beta^n e^{n\lambda t}$ for $\beta \in (0,1)$ and $\lambda > 0$, one has $g_n' = n\lambda g_n$ so that the sum of the three neglected terms is bounded above by a constant multiple of $\beta^{n+2}e^{\lambda(n+2)t}/(1-\beta^2e^{2\lambda t})$, while the sum of the convolution terms behaves like $n\beta^n e^{n\lambda t}$. Therefore on any compact subinterval of $[0, -\ln\beta/\lambda)$ the terms involving T_n are small in comparison to the convolution terms for all sufficiently large n. Elementary calculations with series for which $g_n(t),\ g_n'(t) \approx A/n^{(2+\delta)}$ show that the terms involving the T_n are not necessarily small when compared with the convolution terms.

A loose interpretation of this is the following: The partial differential equation $\psi_{tt} + (\mu - a)\psi_{xx} = (\psi_{tx} - \psi_t\psi_x)_x - a(\psi_t + (\psi\psi_x)_x)$ can be written in the form

$$\psi_{tt} + [a\psi - \psi_{xx}]_t + a(\psi\psi_x)_x + (\psi_t\psi_x)_x + (\mu - a)\psi_{xx} = 0,$$

which can be viewed as a quasi-linear second order partial differential equation with a strong damping term $(a\psi - \psi_{xx})_t$. Suppose that $\mu > a$. Linearizing this equation about $\psi = 0$ yields $\psi_{tt} + (a\psi - \psi_{xx})_t + (\mu - a)\psi_{xx} = 0$, an equation which is of

elliptic type in the second derivative terms. Without the damping term, the solutions are very regular, but the initial-boundary value problem is highly unstable. Even with the damping term, solutions of the linear equation can blow up in infinite time. The introduction of the nonlinear terms $a(\psi\psi_x)_x + (\psi_t\psi_x)_x$ can lend a hyperbolic character to the problem and force blowup in finite time by a focusing effect. See [17] for a discussion of this when $a = 0$.

7. Nagai's conjecture. From the local existence and uniqueness theorem we know that the cosine series for ψ, ψ_t satisfies the condition that

$$(\|\mathcal{M}h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1}) \tag{7.1}$$

is uniformly bounded on $[0, \tau]$ for all τ in the existence interval of the solution.

We also know that in every neighborhood of the homogeneous initial data, there is a solution of the approximate problem (4.1) with spatially nonconstant initial data for which the solution blows up in $\ell^1_1 \times \ell^1$ in finite time.

We establish the following theorem.

THEOREM 3 (Nagai's conjecture in $\ell^1_1 \times \ell^1$). *Suppose $\mu > a$. Then the corresponding solution of the Nagai–Nakaki problem, for which the cosine coefficients agree initially with the cosine coefficients of the aforementioned approximate problem, cannot be global. That is, Nagai's conjecture (in our sense) holds; i.e., such spatially inhomogeneous solutions become unstable by blowing up in finite time in $\ell^1_1 \times \ell^1$.*

Proof. Suppose that $h(t) \equiv \{h_n(t)\}_{n=1}^{\infty}$ satisfies $h(0) = a_n$, $h'(0) = n\lambda a_n$ and the system of ordinary differential equations (3.6) on some interval, say, $[0, T_{\max})$. Let $g(t) \equiv \{g_n(t)\}_{n=1}^{\infty}$ satisfy $g(0) = a_n$, $g'(0) = n\lambda a_n$ and satisfy (4.1) on $[0, T^*)$. Then $T_{\max} \le T^*$, and the solution of Nagai's problem must blow up in finite time $T_{\max}$ in $\ell^1_1 \times \ell^1$.

Suppose we could show that, on any time interval $[0, \tau)$ where $\{h_n(t)\}_{n=1}^{\infty}$ exists in the sense of the local existence theorem,

$$\sup_{[0,\tau]} \|\mathcal{M}(h(t) - g(t))\|_{\ell^1} + \sup_{[0,\tau]} \|h'(t) - g'(t)\|_{\ell^1} < C(h, \tau), \tag{7.2}$$

where $C(h, \tau)$ does not depend on g. Then this inequality, together with Theorem 2 and the triangle inequality, would lead to a lower bound for the $\ell^1_1 \times \ell^1$ norm of $\{h_n(t)\}_{n=1}^{\infty}$ in terms of the corresponding norm for $\{g_n(t)\}_{n=1}^{\infty}$ and thus would permit the establishment of Nagai's conjecture in the space $\ell^1_1 \times \ell^1$.

To this end, suppose that $\tau < T^* < T_{\max}$. We need to estimate $w_n(t) = h_n(t) - g_n(t)$ in the same fashion that we did in the proof of local existence and uniqueness where once again, $w_n(0) = w_n'(0) = 0$. Define, for any sequence $\{z_n(t)\}$,

$$\begin{aligned} \mathcal{G}_n(z, z') &= \frac{1}{2} C^2 n\{(\mathcal{M}z * z')_n + n\frac{a}{2}(z * z)_n\}, \\ \mathcal{H}_n(z, z') &= \frac{1}{2} C^2 n\{[(T_n\mathcal{M}z, z') - (\mathcal{M}z, T_n z')] + an(z, T_n z)\}. \end{aligned} \tag{7.3}$$

Then

$$
\begin{aligned}
\mathfrak{L}_n w_n &= \mathcal{G}_n(h,h') - \mathcal{G}_n(g,g') + \mathcal{H}_n(h,h') \\
&= \mathcal{G}_n(h,h') - \mathcal{G}_n(w+h,(w+h)') + \mathcal{H}_n(h,h') \\
&= \frac{1}{2}C^2 n\{-(\mathcal{M}w * h')_n - (\mathcal{M}h * w')_n - a[(\mathcal{M}w * h)_n + (\mathcal{M}h * w)_n]\} \\
&\quad + \mathcal{H}_n(h,h') \\
&\equiv \mathcal{K}_n(w,w';h,h') + \mathcal{H}_n(h,h') \\
&\equiv \mathcal{F}_n(w,w';h,h').
\end{aligned} \tag{7.4}
$$

This is the value of $\mathcal{L}_n$ that replaces the right-hand side of (5.2), (5.4)–(5.8). Notice that the terms in the definition of $\mathcal{K}_n$ can be estimated as in the local existence and uniqueness theorem. That is,

$$|\mathcal{K}_n(w,w';h,h')(s)| \le (\|\mathcal{M}w(s)\|_{\ell^1} + \|w'(s)\|_{\ell^1})(\|\mathcal{M}h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1}).$$

Likewise, we have

$$\sum_{n=1}^{\infty} \frac{|\mathcal{H}_n(h,h')|(s)}{n} \le \max\{a,1\} \sum_{k=1}^{\infty}\sum_{j=1}^{\infty} [|h_k'(s)|j|h_j(s)| + |h_k(s)|j|h_j'(s)| + |h_k(s)|j|h_j(s)|].$$

For such functions, the conservation conditions (2.4) hold. Consequently,

$$\sum_{n=1}^{\infty} \frac{|\mathcal{H}_n(h,h')|(s)}{n} \le \max\{a,1\}(\|h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1})\|\mathcal{M}h(s)\|_{\ell^1}$$

by using estimates similar to those used for the estimates on the tail-end terms in the proof of uniqueness.

Thus we obtain an inequality of the form

$$
\begin{aligned}
&\|\mathcal{M}w(t)\|_{\ell^1} + \|w'(t)\|_{\ell^1} \\
&\le \int_0^t \frac{A(\|\mathcal{M}w(s)\|_{\ell^1} + \|w'(s)\|_{\ell^1}) + \sum_{n=1}^{\infty} |\mathcal{H}_n(h,h')|(s)/n}{\sqrt{t-s}}\, ds \\
&\le \int_0^t \frac{A(\|\mathcal{M}w(s)\|_{\ell^1} + \|w'(s)\|_{\ell^1}) + B(\|\mathcal{M}h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1})\|\mathcal{M}h(s)\|_{\ell^1}}{\sqrt{t-s}}\, ds
\end{aligned} \tag{7.5}
$$

for some constant A depending on $\tau, \|\mathcal{M}h\|_{\ell^1}, \|h'\|_{\ell^1}$ and for some constant B depending perhaps on τ but not on w, w', h, h'.

This inequality, (7.1), and an application of the Gronwall inequality will give us the estimate (7.2). Combining this observation with its consequence (7.2) and the triangle inequality gives the result. □

Remark 2. The injection $I : \ell^1 \to L^1(0,1)$ given by

$$I(\{a_n\}_{n=1}^{\infty})(x) = \sum_{n=1}^{\infty} a_n \cos{(n-1)\pi x}$$

is certainly continuous. However, the inverse is not. To see this, let

$$P(x,\epsilon) = \frac{1}{2}\frac{1-\epsilon^2}{1+\epsilon^2-2\epsilon\cos(\pi x)}$$

denote the Poisson kernel for $0 \leq \epsilon < 1$. The Poisson kernel is nonnegative, satisfies

$$\int_0^1 P(x,\epsilon)\,dx = 1 = \|P(\cdot,\epsilon)\|_{L^1},$$

and has Fourier cosine series

$$\sum_{n=1}^{\infty} a_n \cos{(n-1)\pi x} = \frac{1}{2} + \sum_{n=1}^{\infty} \epsilon^n \cos n\pi x$$

whose coefficient sequence satisfies

$$\|\{a_n\}_{n=1}^{\infty}\|_{\ell^1} = \frac{1+\epsilon}{1-\epsilon}.$$

Therefore, as ϵ increases to unity, the ℓ^1 norm of the coefficient sequence increases without bound, while the L_1 norms of $P(\cdot,\epsilon)$ remain bounded. (Indeed, they converge in measure to Dirac measure).

If $\mu \geq 0$, then we know from the first equation of the system that $\int_0^1 u(x,t)\,dx = \int_0^1 \mu(x)\,dx$ and hence must remain in $L^1(0,1)$ on the existence interval. The second equation tells us that the second component must likewise remain bounded in $L^1(0,1)$.

The remark tells us that it is possible for the solution to blow up in sequence space in finite time but remain bounded in the $H^1 \times L^1$ norm. If one knew that the solution components blow up in finite time in $\ell^2_\beta \times \ell^2_{\beta'}$, for large enough β, β', then Parseval's identity would tell us that the solution would blow up in $H^{\beta'}(0,1) \times H^{\beta'}(0,1)$. Thus we have the following corollary.

COROLLARY 2. *Let $\delta, \delta' > 0$. Suppose a solution of Nagai's problem blows up in finite time T in $\ell^1_1 \times \ell^1$. If the solution components belong to $H^{3/2+\delta}(0,1) \times H^{1/2+\delta'}(0,1)$ and are bounded on compact subsets of the existence interval in the norm of this product space, then the solution blows up in $H^{3/2+\delta}(0,1) \times H^{1/2+\delta'}(0,1)$ in finite time no larger than T.*

Proof. This result follows from Schwarz's inequality and Parseval's identity. ∎

Remark 3. The corollary states that certain very smooth solutions of Nagai's problem cannot be global. That is, they must lose regularity in finite time.

We can use the results of [18] to establish Nagai's conjecture.

COROLLARY 3. *Suppose $\mu > a$. Then in every neighborhood of the stationary solution, there are solutions which blow up in finite time in the sense that the $H^2 \times H^1$ norm blows up in finite time.*

Proof. In [18, Proposition 4.1] the authors prove that if the initial data for u, v are sufficiently smooth (in particular, if they are analytic) and satisfy the boundary conditions, then both components are continuous from $[0, T_{exist})$ into $H^2(0,1)$, while the first (corresponding to v in the notation of [18]) is continuously differentiable from $[0, T_{exist})$ into $H^2(0,1)$.

The initial data for the approximate problem which give a solution of the approximate problem that blows up in finite time are in fact analytic (the Fourier coefficients are bounded above by $Cn\epsilon^n$ for small ϵ) and consequently must satisfy the smoothness criteria of the initial data needed for [18, Proposition 4.1]. If we take the same initial values for solution of Nagai's problem, its components must belong to the same spaces.

Thus, by the preceding corollary, the solution cannot be global. This, together with the preceding corollary and $\delta = \delta' = 1/2$, establishes Nagai's conjecture for certain sufficiently smooth data in every neighborhood of the stationary data. ∎

Remark 4. These results say nothing about the pointwise finite time blowup for the solution components.

COROLLARY 4. *Suppose* $\mu > a$ *and* $0 < \varepsilon \le a_1 \le \frac{\lambda}{\lambda+a}\delta$, *where* λ *is given in* (6.3). *Then both components of the solution constructed in the preceding corollary blow up in* L^∞.

Proof. In [18, Theorem 7.1], the authors show that *if* the global existence time is finite, then both components blow up in L^∞. □

An illustrative computation is given in Figures 3 and 4.

Remark 5. If we replace λ by the negative root of the quadratic it satisfies, then we can use the arguments of section 6 to obtain solutions of the approximate problem which decay uniformly and exponentially rapidly to zero. It is then possible, by appropriately modifying the arguments in Theorem 3, to show that the corresponding solution of the Nagai–Nakaki problem, *for which the cosine coefficients agree initially with the cosine coefficients of the aforementioned approximate problem*, must be global. That is, Nagai's conjecture (in our sense) holds; i.e., such spatially inhomogeneous solutions (ψ, ψ_t) exist for all time and must converge to the steady state $(\mu/a, \mu)$ in $\ell_1^1 \times \ell^1$ as $t \to \infty$. We omit the details.

8. Illustrative computations. One might well ask whether or not solutions of (6.1) are asymptotically of the form $A\epsilon^n$ for some $|\epsilon| \in (0,1)$ in the sense that there is $\epsilon \in [0,1)$ such that $\lim a_n/\epsilon^n = A$ for some constant A. We have shown that the solutions of (6.1) are bounded above and below by terms of this form but we have not yet established the asymptotics. However, the computations below provide a powerful argument for these asymptotics.

The dependence of the blow-up time on $M, \mu - a$ for the function ψ in Theorem 1 can be investigated numerically as follows. It is worth noting that $\lambda \to 0^+$ as $M \to +\infty$ for fixed $\mu - a$ or $\mu - a \to 0^+$ for fixed $M \ge 1$.

We begin by examining the growth of the terms of the sequence defined by (6.1). If we set $a_n(a) = b_n(a)\sigma^n/n$ with $b_1 = 1$ and $\sigma > 0$, it is not too hard to see that when $a = 0$, $b_n = 1$ for all $n \ge 1$. However, when $0 < a < \mu$, the terms b_n grow remarkably rapidly. As an illustrative example, with $M = \mu = 1$ and $a = 0.6$, $b_1 = 1$, $\ln b_{1000} \approx 656.9587$. In fact, numerical evidence suggests that $\ln b_n \approx 0.657616(n-1)(1+o(1/n))$. Let τ be this coefficient of $n-1$ (assuming it exists). If we take $\sigma = \exp(-\tau(1+\delta))$ for any small, positive δ, then the solution should blow up in finite time $t = \tau\delta/\lambda$. This will be the case if one can prove that the asymptotics for the b_n are as indicated by the numerical evidence. The numerical evidence indicates that as a increases to μ from below, τ increases without bound, and hence the blow-up time will increase without bound also. This is to be expected. (See Figure 1.) Likewise, the numerical evidence indicates that as the integer M is increased for fixed a, τ approaches a limiting value (which is to be expected since as M increases, $\lambda \to 0$). This corresponds to $a_* = 0$ so that the sequence behaves like the exact solution when $a = 0$. The solution for $a = 0$ has the smallest blow-up time possible for fixed ε, δ, μ and all $a \ge 0$. (See Figure 2.)

In Figures 3 and 4 we present a numerical simulation for the Nagai–Nakaki problem with $u_t = D(u_{xx} - (uv_x)_x)$, $v_t = u - av$ for $0 < x < 1, t > 0$ and zero flux boundary conditions. We took $D = 0.02$, $\mu = 4.0$, and $a = 1.0$. For initial values we used $u(x,0) = \mu - \epsilon\cos(2\pi x)$ where $\epsilon = 0.4$ and $v(x,0) = v_0 = \mu/a$. These figures provide some evidence that the solution does blow up pointwise in finite time as well as in the $\ell_1^1 \times \ell^1$ norm.

FROM INDIVIDUAL TO COLLECTIVE BEHAVIOR IN BACTERIAL CHEMOTAXIS*

RADEK ERBAN† AND HANS G. OTHMER†

Abstract. Bacterial chemotaxis is widely studied from both the microscopic (cell) and macroscopic (population) points of view, and here we connect these very different levels of description by deriving the classical macroscopic description for chemotaxis from a microscopic model of the behavior of individual cells. The analysis is based on the velocity jump process for describing the motion of individuals such as bacteria, wherein each individual carries an internal state that evolves according to a system of ordinary differential equations forced by a time- and/or space-dependent external signal. In the problem treated here the turning rate of individuals is a functional of the internal state, which in turn depends on the external signal. Using moment closure techniques in one space dimension, we derive and analyze a macroscopic system of hyperbolic differential equations describing this velocity jump process. Using a hyperbolic scaling of space and time, we obtain a single second-order hyperbolic equation for the population density, and using a parabolic scaling, we obtain the classical chemotaxis equation, wherein the chemotactic sensitivity is now a known function of parameters of the internal dynamics. Numerical simulations show that the solutions of the macroscopic equations agree very well with the results of Monte Carlo simulations of individual movement.

Key words. chemotaxis equations, velocity-jump process, internal dynamics, transport equations, aggregation, bacterial chemotaxis

1. Introduction.

The ability to detect and respond to changes in the environment is a basic necessity for survival of all organisms, and as a result, a variety of mechanisms have evolved by which organisms sense their environment and respond to signals they detect. Often the response involves movement toward a more favorable environment or away from a noxious substance. The movement response can entail changing the speed of movement and the frequency of turning, which is called *kinesis*; it may involve directed movement, which is called *taxis*; or it may involve a combination of these. Taxes and kineses may be characterized as positive or negative, depending on whether they lead to accumulation at high or low points of the external stimulus that triggers the motion. A variety of both modes are known, and include responses to gradients of oxygen and other chemicals, gradients of adhesion to the substrate, and other effects. Both tactic and kinetic responses involve two major steps: (i) detection of the signal and (ii) transduction of the external signal into an internal signal that triggers the response. From the modeling and analysis standpoint, an important characteristic of both modes of response is whether or not the individual merely detects the signal or alters it as well, for example by amplifying it so as to relay the signal. When there is no significant alteration, the individual simply responds to the spatio-temporal distribution of the signal. However, when the individual produces

or degrades the signal, there is coupling between the local density of individuals and the intensity of the signal. This occurs, for example, when individuals aggregate in response to a signal from "organizers" and relay the signal as well.

In several systems, including the flagellated bacterium *Escherichia coli* and the amoeboid cell *Dictyostelium discoideum*, a detailed understanding of how extracellular signals are transduced into behavioral changes is emerging from experimental work, while at the macroscopic level a great deal is known about solutions of the classical chemotaxis equations. However, the chemotaxis equations to date have been based on phenomenological descriptions of how cells respond to signals, and at present there is little understanding of how microscopic properties translate into the macroscopic parameters. The motion of *E. coli* has been studied for forty years, and much is known about how they sense and process environmental signals. *E. coli* alternates two basic behavioral modes, a more or less linear motion, called a run, and a highly erratic motion, called tumbling, the purpose of which is to reorient the cell. During a run the bacteria move at approximately constant speed in the most recently chosen direction. Run times are typically much longer than the time spent tumbling, and when bacteria move in a favorable direction (i.e., either in the direction of foodstuffs or away from harmful substances) the run times are increased further. These bacteria are too small to detect spatial differences in the concentration of an attractant on the scale of a cell length, and during a tumble they simply choose a new direction essentially at random, although it has some bias in the direction of the preceding run [7, 4]. The effect of alternating these two modes of behavior, and in particular, of increasing the run length when moving in a favorable direction, is that a bacterium executes a three-dimensional (3D) random walk with drift in a favorable direction when observed on a sufficiently long time scale [4, 25, 5]. Models for signal transduction and adaptation in this system are given in [40, 2, 28].

In the absence of external cues, many organisms use a random walk strategy to determine their pattern of movement. In this case the movement of organisms released at a point in a uniform environment can be described as an uncorrelated, unbiased random walk of noninteracting particles on a sufficiently long time scale. In an appropriate continuum limit the cell density n, measured in units of cells/L^N, where L denotes length and $N = 1, 2$, or 3, satisfies the diffusion equation

$$\frac{\partial n}{\partial t} = D\Delta n. \tag{1.1}$$

Here the cell flux is given by $j = -D\nabla n$, and the simplest description of cell motion in the presence of an attractant or repellent is obtained by adding a directed component to the diffusive flux to obtain

$$j = -D\nabla n + nu_c, \tag{1.2}$$

where u_c is the macroscopic chemotactic velocity. The taxis is positive or negative according to whether u_c is parallel or antiparallel to the direction of increase of the chemotactic substance. The resulting evolution equation for n is

$$\frac{\partial n}{\partial t} = \nabla \cdot (D\nabla n - nu_c), \tag{1.3}$$

and this is called a chemotaxis equation. In a phenomenological approach one postulates a constitutive relation for the chemotactic velocity of the form

$$u_c = \chi(S)\,\nabla S, \tag{1.4}$$

where S is the concentration of the chemotactic substance and the function $\chi(S)$ is called the chemotactic sensitivity. When $\chi > 0$, the tactic component of the flux is in the direction of ∇S and the taxis is positive. With this postulate, (1.3) takes the form

$$\frac{\partial n}{\partial t} = \nabla \cdot (D\nabla n - n\,\chi(S)\,\nabla S). \tag{1.5}$$

We call equations of this type classical chemotaxis equations, though frequently that term is used for a system of equations comprising (1.5) and a reaction-diffusion equation for the evolution of the signal substance. A recent review of the mathematical aspects of chemotaxis equations is given in [21].

A problem in using equations such as (1.5) to describe chemotaxis is how one justifies the constitutive assumption (1.4) and, in particular, how one incorporates microscopic responses of individual cells into the chemotactic sensitivity. A number of phenomenological approaches to the derivation of the chemotactic sensitivity or chemotactic velocity have been taken, including simply postulating the form in (1.4) [23, 33] or deriving the velocity directly in terms of forces exerted by the cell [35]. Other more fundamental approaches have also been used to relate the chemotactic velocity or sensitivity to a microscopic description of movement. In the first, one begins with a lattice walk or space jump process, either in discrete or continuous time, and postulates how the transition probabilities depend on the external signal. For a discrete time walk the chemotaxis equation is derived in the diffusion limit of this process, by letting the space step size h and the time step δt go to zero in such a way that the ratio $h^2/\delta t$ is a constant, namely D. A more general approach leads to a renewal equation, from which a partial differential equation is obtained by particular choices of the jump kernel and the waiting time distribution [29]. Another method, based on a continuous time reinforced random walk in which the walker modifies the transition probabilities of an interval for successive crossings, is developed in [31] for a single tactic substance.

A space jump process is suitable for certain organisms, but an alternative stochastic process that may be more appropriate for describing the motion of cells is called the velocity jump process [29]. In this process the velocity, rather than the spatial position, changes by random jumps at random instants of time. The governing evolution equation for the simplest version of this process is

$$\frac{\partial}{\partial t}p(x,v,t) + v \cdot \nabla p(x,v,t) = -\lambda p(x,v,t) + \lambda \int_V T(v,v')p(x,v',t)dv', \tag{1.6}$$

where $p(x,v,t)$ denotes the density of particles at spatial position $x \in \Omega \subset R^N$, moving with velocity $v \in V \subset R^N$ at time $t \geq 0$ [29]. Here λ is the (constant) turning rate, and $1/\lambda$ is a measure of the mean run length between velocity jumps. In general, the turning frequency λ must depend on the extracellular signal, as transduced through the signal transduction network and the motility control system. The turning kernel $T(v,v')$ gives the probability of a velocity jump from v' to v if a jump occurs, and implicit in the above formulation is the assumption that the choice of a new velocity is independent of the run length.

The forward equation (1.6) for a velocity jump process is similar to the Boltzmann equation, wherein the right-hand side is an integral operator that describes the collision of two particles, and is therefore quadratic in p [11]. The kernel of the integral operator is specified by the dynamics, and it is well known that an appropriate

scaling of space and time leads at least formally from the Boltzmann equation to a diffusion process [26, 17]. This also holds for transport equations and more general transport processes (see, e.g., [18, 34, 36]). The earliest derivation of the chemotactic sensitivity from a velocity jump process was done by Patlak [36], who used kinetic theory arguments to express u_c in terms of averages of the velocities and run times of individual cells. Alt [1] significantly extended Patlak's approach to the analysis of taxis and his results have been applied to *E. coli* using a phenomenological description of signal transduction [12].

In [19, 30] the kinetic equation approach for deriving chemotactic equations was further developed using a kernel T that may include an external bias. A general Perron–Frobenius property of the turning operator $\mathcal{T}$ defined by the right-hand side of (1.6) and a proper scaling of space and time lead to a Hilbert expansion of the long-term dynamics that produces a parabolic limiting equation. In certain cases there is no taxis, and the parabolic limit is anisotropic, in that the resulting equation for the macroscopic density,

$$n(x,t) = \int_V p(x,v,t)\mathrm{d}v, \tag{1.7}$$

is

$$\frac{\partial n}{\partial t} = \nabla \cdot D\nabla n, \tag{1.8}$$

where D is an $N \times N$ nondiagonal matrix. Necessary and sufficient conditions under which the diffusion matrix D reduces to a scalar times the identity were also obtained. In previous work the external bias enters the turning kernel and turning rate as an order ε term [1, 30], and the perturbation analysis done in [30] shows that the chemotaxis equation is obtained only in this case. In the approach used in [30] an external bias of order one in the turning kernel can be admitted, but with suitable restrictions this leads to (1.8) rather than the chemotaxis equation in the diffusion limit.

The prototypical organisms whose motion can be described as a velocity jump process are the flagellated bacteria such as *E. coli*. A bacterium runs at a constant velocity for a random length of time, then tumbles for a random length of time, chooses a new direction at random, and repeats the cycle. When motion is restricted to one space dimension and the tumble phase is neglected, this leads to a telegraph process described by the hyperbolic system

$$\begin{aligned} \frac{\partial p^+}{\partial t} + s\frac{\partial p^+}{\partial x} &= -\lambda p^+ + \lambda p^-, \\ \frac{\partial p^-}{\partial t} - s\frac{\partial p^-}{\partial x} &= \lambda p^+ - \lambda p^-, \end{aligned} \tag{1.9}$$

where $p^{\pm}(x,t)$ are the probabilities densities of particles that are at (x,t) and are moving to the right $(+)$ and left $(-)$ and s is the speed. This model was first analyzed by Goldstein [16], and subsequently by others [22, 27, 29]. It can be shown that if λ is a constant, the system reduces to a damped wave equation called the telegraph equation for the total density $p \equiv p^+ + p^-$, and on a finite domain with reflecting boundary conditions, solutions are asymptotically constant in space and time. Even if there is a fixed background signal and the turning rate depends on the signal but is

independent of the direction of travel, still there is no aggregation at extrema of the signal: all solutions are asymptotically constant [32].

It is not difficult to see formally that the turning rate for left-moving particles must be different from that for right-moving particles in order to produce a nonzero chemotactic velocity [32], and this has been analyzed in detail in [20]. However, at present there is little understanding of the interplay between the intracellular dynamical system that describes signal transduction and quantities such as the turning rate and turning kernel in a macroscopic, population-level description of motion. Our objective here is to develop a mathematical framework in which one can systematically extract information about population-level behavior for adapting walkers from microscopic models of individual behavior, and to apply it to a caricature of adapting intracellular dynamics. We use *E. coli* as a prototype system, but the methodology and the results apply more generally.

The paper is organized as follows. In the following section we briefly describe the signal transduction network in *E. coli* to motivate the simplified description used herein. Next we introduce the transport equations for systems with internal dynamics, which are the starting point for the derivation of the macroscopic limit. We derive the macroscopic moment equations (section 4), the modified version of the classical chemotaxis equation (section 6), and the classical chemotaxis equation (section 7). Finally, we show some illustrative numerical results, we apply our results to experiments with an exponential signal gradient, and we discuss generalizations of our approach. The extension of the results herein to higher space dimensions is done in [15].

2. Internal dynamics. *E. coli* have 4–6 flagella distributed uniformly over the cell surface and move by rotating them in a corkscrew-like manner [37, 41]. When rotated counterclockwise, the flagella coalesce into a propulsive bundle, resulting in a relatively straight "run" [8]. When rotated clockwise they fly apart, resulting in a "tumble" which reorients the cell but causes no significant change of location. The cell thus alternates between runs and reorienting tumbles. In the absence of stimuli, the bias or probability per unit time of a tumble (P_{CW}) is essentially independent of when the last tumble occurred [41]. The mean run interval is about 1 sec in the absence of chemotaxis, the mean tumble interval is about 0.1 sec, and both are distributed exponentially [6]. A chemoeffector (attractant or repellent) alters the probabilities that the flagella will rotate in a given direction, thus changing the frequencies and duration of runs and tumbles. *E. coli* respond chemotactically to a variety of attractants and repellents over a wide range of concentrations [6]. A typical response, which we define as a measurable change in bias from baseline following a transient increase in the concentration of an attractant or a decrease in that of a repellent, is as follows. After a brief latency period there is an increase in P_{CCW} (probability per unit time of a run) above the baseline probability of approximately 0.64 [8]. This early response, which is typically rapid, constitutes the excitation, and it is followed by a period of relatively slow adaptation to the stimulus. Adaptation eventually returns the bias to baseline, allowing the cell to respond to further changes.

The magnitude of the change in bias in response to an exponentially increasing attractant concentration increases approximately linearly with the ramp rate [9]. Assuming equilibrium binding, the fraction of receptors occupied is $\theta = S/(K_D + S)$, where S is the concentration and K_D is the dissociation constant. Therefore $\dot{\theta} = K_D S/(K_D + S)^2 \cdot d\ \mathrm{ln}S/dt$, and if $S \sim K_D$, then $4\dot{\theta} \sim d\ \mathrm{ln}S/dt$, which is the ramp rate. Thus the magnitude of the response is an approximately linear function of the *rate of change* in occupancy, which provides a superficial explanation of the observed

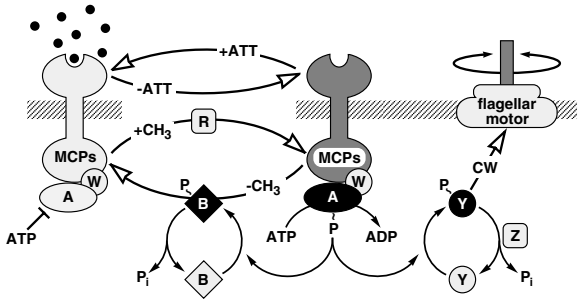

FIG. 2.1. *Signaling components and pathways for* E. coli *chemotaxis. Chemoreceptors (MCPs) span the cytoplasmic membrane (hatched lines), with a ligand-binding domain on the outside and a catalytic domain on the cytoplasmic side. MCP complexes have two alternative signaling states. In the attractant-bound form, the receptor inhibits CheA autokinase activity; in the unliganded form, the receptor stimulates CheA (A) activity. The overall flux of phosphoryl groups P to CheB (B) and CheY (Y) reflects the proportion of signaling complexes in the inhibited and stimulated states. Changes in attractant concentration shift this distribution, triggering a flagellar response. Adaptation occurs when the ensuing changes in the CheB phosphorylation state alter its methylesterase activity, producing a net change in the MCP methylation state that cancels the stimulus signal (cf.* [42] *for a review; figure reproduced from* [40]*, with permission).*

adaptation. Because of adaptation, the response is not directly dependent on the absolute concentration of chemoeffector [41], but instead the sensory system functions as a derivative detector.

E. coli is also extremely sensitive to small changes in chemoeffector levels. The cells can respond to slow exponential increases in attractant levels that correspond to rates of change in the fractional occupancy of chemoreceptors as small as 0.1% per second [9, 38]. Thus a cell can respond even when there is only a small change in the receptor occupancy over a typical sampling period. High sensitivity is also seen when cells are subjected to small impulses or step increases in attractant concentration, though the evidence is mixed. Segall, Block, and Berg [38] report that a change in receptor occupancy of 0.42% elicits a 23% change in bias—a ratio, or gain, of 55—but Khan et al. [24] report a maximum gain of only 6.

The main features of the *E. coli* chemotaxis excitation and adaptation pathways are as follows [10] (see Figure 2.1). Chemical stimuli are detected by transmembrane receptors, which in turn generate cytoplasmic signals that control the flagellar motors. Aspartate, the attractant chemoeffector most commonly used in experiments, binds directly to the periplasmic domain of its transducer, Tar. This initiates a complicated sequence of biochemical steps, the net effect of which is to temporarily reduce the level of the motor control protein CheY_P following an increase in attractant, thereby temporarily increasing $P_{CCW} = 1 - P_{CW}$ and increasing the fraction of time spent running as opposed to tumbling. Detailed models of this network are now available [40, 2, 28], and we refer the reader to the original literature. For our purposes we wish to abstract the essential features of the signal transduction and response processes.

2.1. Cartoon internal dynamics. The essential aspects that a simplified description must reproduce in order to make it useful for studying macroscopic phenomena are (i) it must exhibit excitation, which here means a change in bias in response to a stimulus, (ii) the bias must return to baseline levels (i.e., the response must adapt) on a time scale that is slow compared to excitation, and (iii) the signal transduction network should amplify signals appropriately. Let $y = (y_1, y_2, \ldots, y_m) \in \mathbb{R}^m$

denote the internal state variables, which can include the concentrations of receptors, proteins, etc., and let $S(x,t) = (S_1, S_2, \ldots, S_M) \in \mathbb{R}^M$ denote the signals in the environment. Then all current deterministic models of bacterial signal transduction pathways can be cast in the form of a system of ordinary differential equations that describe the evolution of the intracellular state, forced by the extracellular signal. Thus

$$\frac{\mathrm{d}y}{\mathrm{d}t} = f(y, S), \tag{2.1}$$

where $f : \mathbb{R}^m \times \mathbb{R}^M \to \mathbb{R}^m$ describes the particular model. The question is, given an accurate microscopic model, can we derive a macroscopic description, and can we use it to predict the effect on macroscopic behavior of changes in the microscopic parameters? At present this is very difficult to do with a full description of the internal dynamics for *E. coli*, which may involve 20 or more variables, and as a first step we use a simpler cartoon description of signal transduction that was developed in [32], which incorporates the essential features described above.

We describe the internal dynamics with two internal variables, i.e., $y \in Y \subset \mathbb{R}^2$, and we suppose that the internal state evolves according to the system of ordinary differential equations

$$\frac{\mathrm{d}y_1}{\mathrm{d}t} = \frac{g(S(x,t)) - (y_1 + y_2)}{t_e}, \tag{2.2}$$

$$\frac{\mathrm{d}y_2}{\mathrm{d}t} = \frac{g(S(x,t)) - y_2}{t_a}, \tag{2.3}$$

where t_e and t_a are constants, x is the current position of a cell, $S : \mathbb{R}^N \times [0,\infty) \to [0,\infty)$ is the concentration of the chemoattractant, and $g : [0,\infty) \to [0,\infty)$ models the first step of signal transduction. For any constant signal S these equations have the property that

$$\lim_{t\to\infty} y_1 = 0 \quad \text{and} \quad \lim_{t\to\infty} y_2 = g(S), \tag{2.4}$$

and therefore y_1 adapts perfectly to any constant stimulus. The time constants t_e and t_a are labeled in anticipation of using y_1 for the internal response and y_2 as the adaptation variable, and therefore we call t_e and t_a the excitation and adaptation time constants, respectively. In order to obtain the desired response, one must have $t_e < t_a$. In *E. coli* the excitation is much faster than adaptation, and we have $t_e \ll t_a$.

Since y_1 adapts perfectly, any continuous function $h : \mathbb{R} \to \mathbb{R}$ of y_1 can be used to model the response to changes in the extracellular signal, and the response will adapt; i.e., the steady state response will be independent of the magnitude of the stimulus S. In Figure 2.2 we compare the response of the cartoon model with the response predicted by a detailed model of the entire signal transduction pathway. It is clear that the cartoon model can capture the essential changes in the bias in *E. coli* using a suitable definition of the response. For the simplest velocity jump process in which tumbling is ignored, we identify the response with the turning frequency $\lambda(y)$. In a more detailed description in which the tumble phase is accounted for, one can relate the internal state more directly to experimental results on the switching frequency [13]. This will be done in section 9.1; here we use $\lambda(y) \equiv \mathit{Response} = h(y_1)$. Moreover,

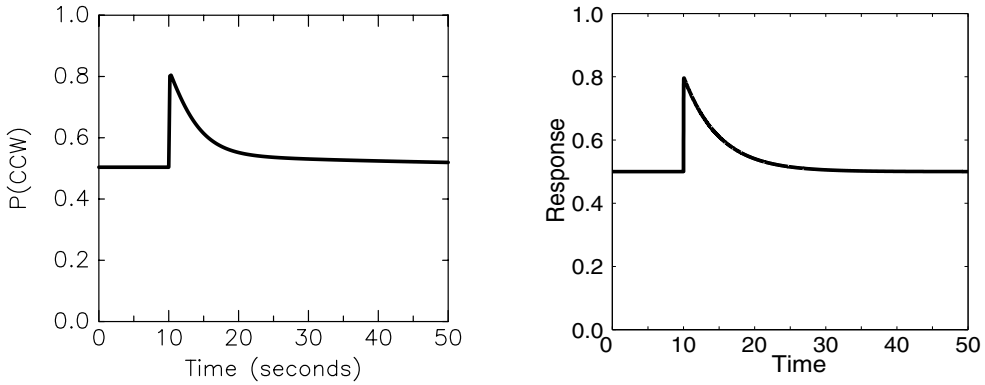

FIG. 2.2. *(left) The computed change in bias in response to a step change in attractant for a complete signal transduction model* [40]. *(right) The graph of the response of the internal dynamics* (2.2)–(2.3)*, given a step change of the signal. Here the response is defined as* $Response = 0.5 + y_1$; *moreover,* $g = Identity$, $t_e = 0.01$, *and* $t_a = 5$. *The signal function is* 0 *in the time interval* $[0, 10]$, *and the signal is equal to* 0.3 *in the time interval* $[10, 50]$.

for simplicity we will assume that h is a linear function of y_1 (which is always true for small responses y_1); i.e., we suppose that

$$\lambda(y) \equiv Response = \lambda_0 - by_1, \tag{2.5}$$

where λ_0 is the basal turning frequency for a fully adapted cell and b is a positive constant. The term by_1 describes the change in the turning frequency in response to a signal, and the negative sign accounts for the fact that an increase of y_1 should produce a decrease in the turning rate.

The function g in (2.2) and (2.3) describes the transduction of the signal, and a reasonable choice for this is to suppose that it depends on the fraction of receptors occupied, in which case

$$g(S) = G\left(\frac{S}{K_D + S}\right)$$

for some other function G, where K_D is the dissociation constant for the attractant [9]. We shall assume in the derivation that $g = \text{Identity}$, and that $t_e = 0$ in (2.2). The results for a general function g and $t_e \neq 0$ can be derived similarly, and we state them at the end of the corresponding sections (see (6.34), (7.12), etc.).

Whatever the choice of g, the formal solution to (2.2) and (2.3) can be obtained explicitly. However, because $x = x(t)$ is the cell position at time t in a given external concentration field, the integration must be along the cell trajectory, which is a biased random walk. Hence, $S(x, t)$ is a stochastic input to the signal transduction system.

3. Individual behavior. We suppose that the extracellular signal is specified as $S(x, t)$, and for the present we neglect the time spent tumbling; the tumble phase is incorporated in section 9.1. Let $p(x, v, y, t)$ be the density function of bacteria in a $(2N + m)$-dimensional phase space with coordinates (x, v, y), where $x \in \mathbb{R}^N$ is the position of a cell, $v \in V \subset \mathbb{R}^N$ is its velocity, and $y \in Y \subset \mathbb{R}^m$ is its internal state, which evolves according to (2.1). Thus $p(x, v, y, t)\mathrm{d}x\mathrm{d}v\mathrm{d}y$ is the number of cells with position between x and $x + \mathrm{d}x$, velocity between v and $v + \mathrm{d}v$, and internal state

between y and $y + \mathrm{d}y$. The evolution of p is governed by the following transport equation:

$$\frac{\partial p}{\partial t} + \nabla_x \cdot vp + \nabla_v \cdot Fp + \nabla_y \cdot fp = \mathcal{Q}, \tag{3.1}$$

where F denotes the external force acting on the individuals and $\mathcal{Q}$ is the rate of change of p due to reactions, random choices of velocity, collisions, etc. Here we ignore external forces and set $F \equiv 0$. Moreover, we assume that there is only one process represented in $\mathcal{Q}$: that which generates the random velocity change, and we assume that the changes are the result of a Poisson process of intensity $\lambda(y)$. Then

$$\mathcal{Q} = -\lambda(y)p(x, v, y, t) + \int_V \lambda(y)T(v, v', y)p(x, v', y, t)\mathrm{d}v',$$

where the kernel $T(v, v', y)$ gives the probability of a change in velocity from v' to v, given that a reorientation occurs. The kernel T is nonnegative and satisfies the normalization condition $\int_V T(v, v', y)\mathrm{d}v = 1$.

Consequently, the transport equation (3.1) takes the following form:

$$\frac{\partial p}{\partial t} + \nabla_x \cdot vp + \nabla_y \cdot fp = -\lambda(y)p + \int_V \lambda(y)T(v, v', y)p(x, v', y, t)\mathrm{d}v'. \tag{3.2}$$

The objective of this paper is to derive a macroscopic description for chemotaxis from the microscopic model, i.e., an evolution equation for the macroscopic density of individuals

$$n(x, t) = \int_Y \int_V p(x, v, y, t)\mathrm{d}v\mathrm{d}y. \tag{3.3}$$

Since we are primarily concerned with how the internal dynamics (2.1) influence the macroscopic behavior, we will only consider movement in one dimension. Considering 2D and 3D models does not alter the process of incorporating the internal dynamics into the macroscopic equations, but it does raise technical issues that will be discussed elsewhere [15]. Moreover, we assume that the speed is constant, and therefore we analyze the following generalization of the simple telegraph process described by (1.9): let $p^{\pm}(x, y, t)$ be the density of the particles that are at (x, t) with the internal state y and are moving to the right $(+)$ or left $(-)$, and suppose that the internal state evolves according to the system of equations (2.1). Then $p^{\pm}(x, y, t)$ satisfy the equations

$$\frac{\partial p^+}{\partial t} + s\frac{\partial p^+}{\partial x} + \sum_{i=1}^{m} \frac{\partial}{\partial y_i}\left[f_i(y, S)p^+\right] = \lambda(y)\left[-p^+ + p^-\right], \tag{3.4}$$

$$\frac{\partial p^-}{\partial t} - s\frac{\partial p^-}{\partial x} + \sum_{i=1}^{m} \frac{\partial}{\partial y_i}\left[f_i(y, S)p^-\right] = \lambda(y)\left[p^+ - p^-\right]. \tag{3.5}$$

Written as a system, this takes the form

$$\begin{aligned} &\frac{\partial}{\partial t}\begin{pmatrix} p^+ \\ p^- \end{pmatrix} + s\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\frac{\partial}{\partial x}\begin{pmatrix} p^+ \\ p^- \end{pmatrix} + \nabla_y \cdot \left[f(y, S)\begin{pmatrix} p^+ \\ p^- \end{pmatrix}\right] \\ &\quad = \lambda(y)\begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix}\begin{pmatrix} p^+ \\ p^- \end{pmatrix}. \end{aligned} \tag{3.6}$$

This is a hyperbolic system in diagonal form that has two independent characteristics for $s > 0$, and it is therefore strictly hyperbolic for $s > 0$.

To analyze the system (3.4)–(3.5), we must specify the internal dynamics (2.1) and the turning rate $\lambda(y)$. Here we shall use the internal dynamics (2.2)–(2.3) and the turning rate given by (2.5). Moreover, for simplicity we suppose that the signal $S(x)$ is a time-independent scalar function, that $t_e = 0$, and that $g =$ Identity. (The results for a general function g and $t_e \neq 0$ can be derived similarly, and we state them at the end of the corresponding sections; see (6.34), (7.12), etc.) Then the internal dynamics and the response are given as follows:

$$\frac{\mathrm{d}y_2}{\mathrm{d}t} = \frac{S(x) - y_2}{t_a}, \tag{3.7}$$

$$\lambda(y) \equiv \textit{Response} = \lambda_0 - b(S(x) - y_2). \tag{3.8}$$

It is convenient to define the new internal state variable z_2 as

$$z_2 = y_2 - S(x), \tag{3.9}$$

and then

$$\frac{\mathrm{d}z_2}{\mathrm{d}t} = \frac{S(x) - y_2}{t_a} - S'(x)\frac{\mathrm{d}x}{\mathrm{d}t} = -\frac{z_2}{t_a} \mp S'(x)s, \tag{3.10}$$

where the sign of the last term is determined by the sign of the velocity of the particle. Moreover,

$$\lambda(z_2) \equiv \lambda(y) = \lambda_0 - b(S(x) - y_2) = \lambda_0 + bz_2. \tag{3.11}$$

Later we will make use of an estimate on the internal state derived in the following lemma, and to avoid repetition, we introduce the following definition. Suppose that the cell moves in one dimension according to a velocity jump process with internal dynamics, and that the internal state z_2 of the cell evolves according to (3.10). We call this the *standard process*.

LEMMA 3.1. *Suppose that the cells execute the standard process, and suppose that*

$$|S'(x)| \leq K \ \text{ for } x \in \mathbb{R} \qquad \textit{and} \qquad |z_2(0)| \leq st_aK.$$

Then we have

$$|z_2(t)| \leq st_aK \ \text{ for } \ t \geq 0.$$

Proof. If $z_2(t) = -st_aK$, then the estimate $|S'(x)| \leq K$ implies $\frac{\mathrm{d}z_2}{\mathrm{d}t} \geq 0$. Similarly, if $z_2(t) = st_aK$, then the estimate $|S'(x)| \leq K$ implies $\frac{\mathrm{d}z_2}{\mathrm{d}t} \leq 0$. As $|z_2(0)| \leq st_aK$, we have $|z_2(t)| \leq st_aK$ for all $t \geq 0$. ∎

For a physically reasonable model we must ensure that the turning rate $\lambda(z_2)$ is always nonnegative, and for this we introduce the following *standing hypothesis*:

$$\text{Assume that} \quad |S'(x)| \leq \overline{C}, \quad \text{where } \overline{C} \text{ is given by} \quad \overline{C} = \frac{\lambda_0}{bst_a}. \tag{3.12}$$

Given (3.12), we have the following lemma.

LEMMA 3.2. *Suppose that the cells execute the standard process and that* (3.12) *is satisfied. Suppose that initially* $\lambda(z_2(0)) \geq 0$. *Then we have*

$$\lambda(z_2(t)) \geq 0 \qquad \text{for all } \ t \geq 0.$$

Proof. The linear turning rate (3.11) is nonnegative if and only if $z_2 \geq -\frac{\lambda_0}{b}$. As $\lambda(z_2(0)) \geq 0$, we have $z_2(0) \geq -\frac{\lambda_0}{b}$. Then Lemma 3.1 implies that $z_2(t) \geq -\frac{\lambda_0}{b}$ for $t \geq 0$. Consequently, the turning rate $\lambda(y)$ is nonnegative for all $t \geq 0$. ∎

In view of the preceding assumptions and simplifications, the evolution equations (3.4)–(3.5) for the densities $p^{\pm}(x, z_2, t)$ can be written as

$$\frac{\partial p^+}{\partial t} + s\frac{\partial p^+}{\partial x} + \frac{\partial}{\partial z_2}\left[\left(-\frac{z_2}{t_a} - sS'(x)\right)p^+\right] = (\lambda_0 + bz_2)\left[-p^+ + p^-\right], \tag{3.13}$$

$$\frac{\partial p^-}{\partial t} - s\frac{\partial p^-}{\partial x} + \frac{\partial}{\partial z_2}\left[\left(-\frac{z_2}{t_a} + sS'(x)\right)p^-\right] = (\lambda_0 + bz_2)\left[p^+ - p^-\right]. \tag{3.14}$$

In the following sections we use (3.13)–(3.14) to derive macroscopic equations. First, however, we address the question of existence and nonnegativity of the densities $p^{\pm}(x, z_2, t)$. In the following lemma we establish these properties for the general system (3.4)–(3.5), and this implies the result for (3.13)–(3.14).

LEMMA 3.3. *Suppose that* $f \in C^1(\mathbb{R}^m \times \mathbb{R}^M)$, *and let* $S : \mathbb{R} \times [0, \infty) \to \mathbb{R}^M$ *be continuous. Moreover, suppose that* $\lambda(y)$ *in* (3.4)–(3.5) *is always nonnegative, and that* $p_0^+ : \mathbb{R}^{m+1} \to [0, \infty)$ *and* $p_0^- : \mathbb{R}^{m+1} \to [0, \infty)$ *are given nonnegative compactly supported* C^1*-functions. Then there exists a domain* $Q \subset \mathbb{R}^{m+1} \times [0, \infty)$ *containing the entire plane* $t = 0$ *such that the system of equations* (3.4)–(3.5) *with initial conditions* $p^{\pm}(x, y, 0) = p_0^{\pm}(x, y)$ *has a unique* C^1*-solution in* Q. *Moreover, the functions* $p^{\pm}$ *are nonnegative wherever they are defined.*

Proof. As remarked earlier, the general system (3.6) has two independent characteristics, and this applies to (3.4)–(3.5) as well. Consequently, we can apply the modified implicit function theorem to show local existence of a unique classical solution (see [3, section 2.4.4]). To prove nonnegativity, let us consider that the solution is NOT nonnegative and define

$$t^0 = \inf\{\, \tau \ : \text{ there exists } (x, y) \text{ such that } p^+(x, y, \tau) < 0 \text{ or } p^-(x, y, \tau) < 0 \,\};$$

i.e., t^0 is the last time for which the nonnegativity of solutions is satisfied. In particular, we have $p^{\pm}(\cdot, \cdot, t^0) \geq 0$.

Let $\chi^+_{x,y,t^0}(\tau)$ be a characteristic through the point (x, y, t^0) for (3.4), and let $\chi^-_{x,y,t^0}(\tau)$ be a characteristic through the point (x, y, t^0) for (3.5). Thus $\chi^{\pm}_{x,y,t^0}(\tau)$ are curves in the $(m + 2)$-dimensional (x, y, t)-space along which (3.4)–(3.5) read as

$$\frac{d}{d\tau}p^+(\chi^+_{x,y,t^0}(\tau)) = -c(\chi^+_{x,y,t^0}(\tau))p^+(\chi^+_{x,y,t^0}(\tau)) + \lambda(\chi^+_{x,y,t^0}(\tau))p^-(\chi^+_{x,y,t^0}(\tau)), \tag{3.15}$$

$$\frac{d}{d\tau}p^-(\chi^-_{x,y,t^0}(\tau)) = \lambda(\chi^-_{x,y,t^0}(\tau))p^+(\chi^-_{x,y,t^0}(\tau)) - c(\chi^-_{x,y,t^0}(\tau))p^-(\chi^-_{x,y,t^0}(\tau)), \tag{3.16}$$

wherein

$$c(x,y,t) = \lambda(y) + \sum_{i=1}^{m} \frac{\partial f_i(y, S(x,t))}{\partial y_i}.$$

Let us suppose that $p^+(x,y,t^0) = 0$. Then (3.15) implies (using $\tau = t^0$, $\lambda(y) \geq 0$ and $p^-(x,y,t^0) \geq 0$)

$$\frac{d}{d\tau} p^+(x,y,t^0) \geq 0. \tag{3.17}$$

Similarly, if $p^-(x,y,t^0) = 0$, then (3.16) gives $\frac{d}{d\tau} p^-(x,y,t^0) \geq 0$. Consequently, there exists a constant $c > 0$ such that the solutions $p^{\pm}$ are nonnegative in the time interval $[t^0, t^0 + c)$. This is a contradiction with the choice of t^0. □

4. Moment equations. The next step is to derive evolution equations for macroscopic variables from the simplified system (3.13)–(3.14). Since there are only two velocities and one internal state variable, the density $n(x,t)$ is given by (cf. (3.3))

$$n(x,t) = \int_{\mathbb{R}} p^+(x,z_2,t) + p^-(x,z_2,t) \mathrm{d}z_2. \tag{4.1}$$

The objective is to derive an evolution equation involving only n, if possible. For this purpose define $\mathcal{N} = p^+(x,z_2,t) + p^-(x,z_2,t)$ and $\mathcal{J} = s(p^+(x,z_2,t) - p^-(x,z_2,t))$; the former is the microscopic particle density, obtained by integrating p over v, while the latter is a microscopic flux obtained similarly. In this notation, (4.1) can be written

$$n(x,t) = \int_{\mathbb{R}} \mathcal{N}(x,z_2,t) \mathrm{d}z_2, \tag{4.2}$$

and we define the additional moments

$$j(x,t) = \int_{\mathbb{R}} \mathcal{J}(x,z_2,t) \mathrm{d}z_2, \tag{4.3}$$

$$n_1(x,t) = \int_{\mathbb{R}} z_2 \mathcal{N}(x,z_2,t) \mathrm{d}z_2, \tag{4.4}$$

$$j_1(x,t) = \int_{\mathbb{R}} z_2 \mathcal{J}(x,z_2,t) \mathrm{d}z_2, \tag{4.5}$$

and

$$j_2(x,t) = \int_{\mathbb{R}} (z_2)^2 \mathcal{J}(x,z_2,t) \mathrm{d}z_2. \tag{4.6}$$

The quantity j is the macroscopic particle flux, n_1 and j_1 are first moments with respect to the slow component of the internal state of the microscopic density and flux, respectively, and j_2 is the second moment of the microscopic flux with respect to the slow component of the internal state. All moments with respect to z_2 are well defined by virtue of Lemma 3.1 and the standing assumption (3.12), which implies that p vanishes identically outside some sufficiently large interval in $|z_2|$.

Next, by multiplying (3.13) and (3.14) by 1 or z_2, integrating with respect to z_2, and adding or subtracting the resulting equations, we obtain the following four moment equations:

$$\frac{\partial n}{\partial t} + \frac{\partial j}{\partial x} = 0, \tag{4.7}$$

$$\frac{\partial j}{\partial t} + s^2 \frac{\partial n}{\partial x} = -2\lambda_0 j - 2b j_1, \tag{4.8}$$

$$\frac{\partial n_1}{\partial t} + \frac{\partial j_1}{\partial x} = -S'(x) j - \frac{1}{t_a} n_1, \tag{4.9}$$

$$\frac{\partial j_1}{\partial t} + s^2 \frac{\partial n_1}{\partial x} = -s^2 S'(x) n - \left(2\lambda_0 + \frac{1}{t_a}\right) j_1 - 2b j_2. \tag{4.10}$$

We see that the moment equations for a density-flux pair introduce a higher-order flux via the change in turning rate, as measured by b. If $S(x)$ is constant, the effect of the signal disappears and the second pair is uncoupled from the first. In section 6 we rescale the variables and then close the system of four moment equations with the assumption that

$$j_2 = 0; \tag{4.11}$$

i.e., we simply neglect the second-order flux. The moment closure (4.11) will be rigorously justified in the case of shallow gradients of the signal. The moment closures for arbitrary signal functions will be discussed in section 9.2.

Of course one can ask what a lower-order closure (i.e., the closure assumption on j_1) leads to, and it is easy to see that if we assume that $j_1 = 0$, we obtain the telegraph equation

$$\frac{1}{2\lambda_0} \frac{\partial^2 n}{\partial t^2} + \frac{\partial n}{\partial t} = \frac{s^2}{2\lambda_0} \frac{\partial^2 n}{\partial x^2}. \tag{4.12}$$

Since the external signal S is completely absent from this equation, this approximation is not suitable for studying the dependence of n on the signal. Clearly (4.12) applies if there is no effect of the signal on the turning rate, and in this case there can be no taxis.

From (4.7)–(4.10) we can derive evolution equations for various statistics of the motion that give insight into the asymptotics of solutions of the system of moment equations. These are derived in the following section.

5. Evolution of certain statistics of the motion. We denote by n_0 the total number of particles in the domain. This is a conserved quantity and is given by

$$n_0 = \int_{\mathbb{R}} n(x,t) \mathrm{d}x.$$

The mean position of the particles $\langle x \rangle(t)$ and the mean square displacement $\langle x^2 \rangle(t)$ are given by

$$\langle x \rangle(t) = \frac{1}{n_0} \int_{\mathbb{R}} x n(x,t) \mathrm{d}x, \qquad \langle x^2 \rangle(t) = \frac{1}{n_0} \int_{\mathbb{R}} \left(x - \langle x \rangle\right)^2 n(x,t) \mathrm{d}x. \tag{5.1}$$

We define the spatial moments of j, j_1, and j_2 as follows:

$$j^0 = \int_{\mathbb{R}} j(x,t)\mathrm{d}x, \quad j^x = \int_{\mathbb{R}} xj(x,t)\mathrm{d}x, \quad j_1^0 = \int_{\mathbb{R}} j_1(x,t)\mathrm{d}x, \quad j_2^0 = \int_{\mathbb{R}} j_2(x,t)\mathrm{d}x.$$

Then, multiplying (4.7) by x and by $(x - \langle x\rangle(t))^2$, and integrating the resulting equations with respect to x, we find that

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle = \frac{j^0}{n_0} \qquad \text{and} \qquad \frac{\mathrm{d}}{\mathrm{d}t}\langle x^2\rangle = \frac{2j^x - 2\langle x\rangle j^0}{n_0}. \tag{5.2}$$

Integrating (4.8) and (4.10) with respect to x, we obtain the evolution equations for j^0 and j_1^0:

$$\frac{\mathrm{d}}{\mathrm{d}t}j^0 = -2\lambda_0 j^0 - 2bj_1^0, \tag{5.3}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}j_1^0 = -s^2\int_{\mathbb{R}} S'(x)n(x,t)\mathrm{d}x - \left(2\lambda_0 + \frac{1}{t_a}\right)j_1^0 - 2bj_2^0. \tag{5.4}$$

We can solve (5.3)–(5.4) explicitly for j^0 as a function of the quantities $\int_{\mathbb{R}} S'(x)n(x,t)\mathrm{d}x$ and j_2^0. Then the evolution equation (5.2) for $\langle x\rangle$ reads

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle = \frac{e^{-2\lambda_0 t}}{n_0}\Bigg[j^0(0) + \int_0^t e^{t'/t_a}2b\Bigg(- j_1^0(0) + \int_0^{t'} e^{2\lambda_0 t'' + t''/t_a}\left\{s^2\int_{\mathbb{R}} S'(x)n(x,t)\mathrm{d}x + 2bj_2^0\right\}\mathrm{d}t''\Bigg)\mathrm{d}t'\Bigg].$$

Thus the mean displacement is driven by the flux j^0, which is in turn forced by the projection of the local density onto the gradient, as given by the integral term in S', as well as by the higher-order flux j_2^0. From the foregoing one can conclude that if $\langle x\rangle$ tends to a constant as $t \to \infty$, then the total flux j^0 must vanish as $t \to \infty$, and this in turn requires that the term $s^2\int_{\mathbb{R}} S'(x)n(x,t)\mathrm{d}x + 2bj_2^0$ must tend to zero. Thus this is a necessary, but not sufficient, condition for steady patterns. Similarly, one can derive the system of evolution equations for the mean square displacement.

In order to gain further insight into the evolution of the statistics of motion, let us suppose that

$$S'(x) = C = \text{constant} \qquad \text{and} \qquad j_2 = 0.$$

To derive equations for the mean position $\langle x\rangle$ and the mean square displacement $\langle x^2\rangle$ under this restriction we introduce some additional moments

$$n_1^0 = \int_{\mathbb{R}} n_1(x,t)\mathrm{d}x, \qquad n_1^x = \int_{\mathbb{R}} xn_1(x,t)\mathrm{d}x, \qquad \text{and} \qquad j_1^x = \int_{\mathbb{R}} xj_1(x,t)\mathrm{d}x.$$

Then, integrating (4.8), (4.9), and (4.10) with respect to x, we obtain the system

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} j^0 \\ n_1^0 \\ j_1^0 \end{pmatrix} = \begin{pmatrix} -2\lambda_0 & 0 & -2b \\ -C & -\frac{1}{t_a} & 0 \\ 0 & 0 & -\left(2\lambda_0 + \frac{1}{t_a}\right) \end{pmatrix}\begin{pmatrix} j^0 \\ n_1^0 \\ j_1^0 \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ -s^2Cn_0 \end{pmatrix}. \tag{5.5}$$

Similarly, multiplying (4.8), (4.9), and (4.10) by x and integrating with respect to x, we obtain

(5.6)
$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} j^x \\ n_1^x \\ j_1^x \end{pmatrix} = \begin{pmatrix} -2\lambda_0 & 0 & -2b \\ -C & -\frac{1}{t_a} & 0 \\ 0 & 0 & -\left(2\lambda_0 + \frac{1}{t_a}\right) \end{pmatrix}\begin{pmatrix} j^x \\ n_1^x \\ j_1^x \end{pmatrix} + \begin{pmatrix} s^2 n_0 \\ j_1^0 \\ s^2 n_1^0 - s^2 C\langle x\rangle n_0 \end{pmatrix}.$$

Together (5.5) and (5.6) form a system of six linear nonhomogeneous equations. The eigenvalues of the matrix of this 6×6 system, which has the 3×3 blocks of the separate system along the diagonal, are in fact just the diagonal entries, and are therefore real and negative. Since n_0 is constant, it follows that the system has a unique stable steady state given by

$$j^0 = \frac{bs^2 C t_a}{\lambda_0 + 2\lambda_0^2 t_a} n_0 \qquad \text{and} \qquad 2j^x - 2\langle x\rangle j^0 = \left(\frac{s^2}{\lambda_0} + \frac{2b^2 s^4 C^2 t_a^3}{(\lambda_0 + 2\lambda_0^2 t_a)^2}\right) n_0.$$

Thus, (5.2) implies that, asymptotically for $t \to \infty$, we have

$$\langle x\rangle(t) = \frac{bs^2 C t_a}{\lambda_0 + 2\lambda_0^2 t_a} t \qquad \text{and} \qquad \langle x^2\rangle(t) = \left(\frac{s^2}{\lambda_0} + \frac{2b^2 s^4 C^2 t_a^3}{(\lambda_0 + 2\lambda_0^2 t_a)^2}\right) t. \tag{5.7}$$

The second of these shows that when the gradient $S'(x) = C$, the standard process is asymptotically a diffusion process with diffusion constant

$$D = \frac{s^2}{2\lambda_0} + \frac{b^2 s^4 C^2 t_a^3}{(\lambda_0 + 2\lambda_0^2 t_a)^2}. \tag{5.8}$$

Later, using the scaling in (6.8), we will see that the second term in (5.8) is smaller than the first, and thus in (5.8) $D \sim s^2/2\lambda_0$.

6. The hyperbolic scaling and derivation of a hyperbolic chemotaxis equation. The macroscopic equations for n and j that can be obtained from the moment equations depend on the time and space scales of interest. In this section we use a hyperbolic scaling of space and time, which can capture the initial time evolution of the system. Using this scaling, we give a heuristic derivation of a hyperbolic version of the classical chemotaxis equation. Moreover, we also give an alternate random walk interpretation to the derived hyperbolic chemotaxis equation in section 6.1. In section 7, we use a parabolic scaling valid for large times, which leads to the classical chemotaxis equation. This equation is also a parabolic limit of the hyperbolic chemotaxis equation derived here in cases where the signal is fixed. When the signal itself evolves in time, this need not be true.

Let L, T, and s_0 be scale factors for the length, time, and velocity, respectively; let N_0 be a scale factor for the particle density; and define the dimensionless variables

$$\hat{x} = \frac{x}{L}, \qquad \hat{t} = \frac{t}{T}, \qquad \hat{n} = \frac{n}{N_0}, \qquad \hat{j} = \frac{j}{N_0 s_0},$$
$$\hat{n}_1 = \frac{n_1}{N_0}, \qquad \hat{j}_1 = \frac{j_1}{N_0 s_0}, \qquad \text{and} \qquad \hat{j}_2 = \frac{j_2}{N_0 s_0}. \tag{6.1}$$

Then the moment equations (4.7)–(4.10) can be written in the dimensionless form

$$\frac{\partial \hat{n}}{\partial \hat{t}} + \varepsilon \frac{\partial \hat{j}}{\partial \hat{x}} = 0, \tag{6.2}$$

$$\frac{\partial \hat{j}}{\partial \hat{t}} + \varepsilon \hat{s}^2 \frac{\partial \hat{n}}{\partial \hat{x}} = -2\hat{\lambda}_0 \hat{j} - 2\hat{b}\hat{j}_1, \tag{6.3}$$

$$\frac{\partial \hat{n}_1}{\partial \hat{t}} + \varepsilon \frac{\partial \hat{j}_1}{\partial \hat{x}} = -\varepsilon \hat{S}'(\hat{x})\hat{j} - \frac{1}{\hat{t}_a}\hat{n}_1, \tag{6.4}$$

$$\frac{\partial \hat{j}_1}{\partial \hat{t}} + \varepsilon \hat{s}^2 \frac{\partial \hat{n}_1}{\partial \hat{x}} = -\varepsilon \hat{s}^2 \hat{S}'(\hat{x})\hat{n} - \left(2\hat{\lambda}_0 + \frac{1}{\hat{t}_a}\right)\hat{j}_1 - 2\hat{b}\hat{j}_2, \tag{6.5}$$

where

$$\varepsilon \equiv \left(\frac{s_0 T}{L}\right), \quad \hat{s} \equiv \frac{s}{s_0}, \quad \hat{\lambda}_0 \equiv \lambda_0 T, \quad \hat{b} \equiv bT, \quad \hat{t}_a \equiv \frac{t_a}{T}, \quad \text{and} \quad \hat{S}'(\hat{x}) \equiv LS'(x). \tag{6.6}$$

In order to derive the macroscopic equations, we have to specify L, T, and s_0 and estimate the dimensionless parameters. The typical space scale of macroscopic experiments is several millimeters or centimeters, a typical speed of bacterium is $s = 10$ – 20 μm/sec, and a characteristic time scale depends on our interests. Here, we choose

$$T = 1 \text{ sec}, \qquad L = 1 \text{ mm}, \quad \text{and} \quad s_0 = 10\mu\text{m/sec}; \tag{6.7}$$

i.e., we use a time scale that is of the same order as the mean time between directional changes, since this characterizes the initial evolution. Assuming that the adaptation time and the bias are also of the same order as the mean run time, we get

$$\varepsilon \approx 10^{-2} \quad \text{and} \quad \hat{s} \sim \hat{\lambda}_0 \sim \hat{b} \sim \hat{t}_a \sim \mathcal{O}(1). \tag{6.8}$$

Using an approximation given later, this scaling will lead to a hyperbolic chemotaxis equation. For simplicity, we drop the hats on x, t, s, λ_0, b, t_a, S and the hats on moments, and use the same symbols for the dimensionless variables. Then the moment equations (6.2)–(6.5) read as follows:

$$\frac{\partial n}{\partial t} + \varepsilon \frac{\partial j}{\partial x} = 0, \tag{6.9}$$

$$\frac{\partial j}{\partial t} + \varepsilon s^2 \frac{\partial n}{\partial x} = -2\lambda_0 j - 2b j_1, \tag{6.10}$$

$$\frac{\partial n_1}{\partial t} + \varepsilon \frac{\partial j_1}{\partial x} = -\varepsilon S'(x) j - \frac{1}{t_a} n_1, \tag{6.11}$$

$$\frac{\partial j_1}{\partial t} + \varepsilon s^2 \frac{\partial n_1}{\partial x} = -\varepsilon s^2 S'(x) n - \left(2\lambda_0 + \frac{1}{t_a}\right) j_1 - 2b j_2. \tag{6.12}$$

In order to close this system we have to specify

$$j_2 = \mathcal{F}(n, j, n_1, j_1), \tag{6.13}$$

where the functional $\mathcal{F}$ is to be determined. To do that, we first rewrite our standing assumption (3.12) using hyperbolic scaling (6.7)–(6.8). We denote the dimensionless constant $\overline{C}$ again as $\overline{C}$ for simplicity, and then (3.12) for the dimensionless signal gradient reads as follows:

$$|S'(x)| \le \overline{C}, \qquad \text{where} \qquad \overline{C} \sim \mathcal{O}\left(\frac{1}{\varepsilon}\right). \tag{6.14}$$

Thus the maximal possible gradient that satisfies (3.12) is $\mathcal{O}(1/\varepsilon)$ on the hyperbolic scale. In other words, the restriction on the gradients that guarantees positivity of the turning rate is very weak, and we strengthen it as follows.

DEFINITION 6.1. *We call the signal gradient shallow on the hyperbolic scale if*

$$|S'(x)| \le \overline{K}, \qquad \textit{where} \qquad \overline{K} \sim \mathcal{O}(1). \tag{6.15}$$

In the following, we investigate the case of shallow gradients, and to do that, we have to estimate the moments in (6.9)–(6.12).

LEMMA 6.2. *Suppose that the signal gradient is shallow. Then the moments in* (6.9)–(6.12) *can be estimated as follows:*

$$\frac{j}{n} \le K_1, \qquad \frac{n_1}{n} \le \varepsilon K_2, \qquad \frac{j_1}{n} \le \varepsilon K_3, \qquad \frac{j_2}{n} \le \varepsilon^2 K_4, \tag{6.16}$$

where the constants K_1, K_2, K_3, and K_4 are $\mathcal{O}(1)$.

Proof. We use (4.6) rescaled by (6.1), (6.6), the nonnegativity of $p^{\pm}$, Lemma 3.1, (4.1), and (6.8) to estimate

$$\begin{aligned} j_2 &= \frac{s}{N_0}\int_{\mathbb{R}} (z_2)^2 \left[p^+(x,z_2,t) - p^-(x,z_2,t)\right] \mathrm{d}z_2 \\ &\le \frac{s}{N_0}\int_{\mathbb{R}} (z_2)^2 \left[p^+(x,z_2,t) + p^-(x,z_2,t)\right] \mathrm{d}z_2 \\ &\le \varepsilon^2(\overline{K}s\,t_a)^2 \frac{s}{N_0}\int_{\mathbb{R}} \left[p^+(x,z_2,t) + p^-(x,z_2,t)\right] \mathrm{d}z_2 = \varepsilon^2(\overline{K}t_a)^2 s^3\, n = \varepsilon^2 K_4\, n, \end{aligned}$$

where $K_4 \sim \mathcal{O}(1)$. This proves the last inequality in (6.16), and the proof of the other inequalities is similar. ∎

Therefore the term $2bj_2$ in equation (6.12) is $\mathcal{O}(\varepsilon^2)$ when the gradient is shallow, and we can close the moment equations (6.9)–(6.12) with the moment closure assumption

$$j_2 = 0. \tag{6.17}$$

This will introduce the error of order $\mathcal{O}(\varepsilon^2)$ into (6.12). The corresponding orders of the remaining moments are given in Lemma 6.2.

Next we show that one can obtain a hyperbolic chemotaxis equation for n, provided a certain assumption on the decay of modes holds. To do that, we write the system (6.9)–(6.12) in the matrix form

$$\frac{\partial v}{\partial t} + \varepsilon \frac{\partial}{\partial x}(Av) = B(x,\varepsilon)v + r, \tag{6.18}$$

where

$$v = \begin{pmatrix} n \\ j \\ n_1 \\ j_1 \end{pmatrix}, \qquad A = \begin{pmatrix} 0 & 1 & 0 & 0 \\ s^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & s^2 & 0 \end{pmatrix}, \qquad r = \begin{pmatrix} 0 \\ 0 \\ 0 \\ -2bj_2 \end{pmatrix}, \tag{6.19}$$

and

$$B(x,\varepsilon) = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -2\lambda_0 & 0 & -2b \\ 0 & -\varepsilon S'(x) & -\frac{1}{t_a} & 0 \\ -\varepsilon s^2 S'(x) & 0 & 0 & -\left(2\lambda_0 + \frac{1}{t_a}\right) \end{pmatrix}. \tag{6.20}$$

Equation (6.18) holds for any signal function satisfying the standing assumption (3.12), since it is just a different formulation of the system (6.9)–(6.12). Assuming (6.17), the system (6.18) can be written in the form

$$\frac{\partial v}{\partial t} + \varepsilon \frac{\partial}{\partial x}(Av) = B(x,\varepsilon)v. \tag{6.21}$$

This is a hyperbolic system of four linear PDEs with nonconstant coefficients for four unknowns: n, j, n_1, and j_1. The matrix $B(x,\varepsilon)$ has the interesting property that its eigenvalues do not depend on the signal $S(x)$, and consequently the eigenvalues of $B(x,\varepsilon)$ are independent of ε and x. An easy calculation gives the following four (not necessarily distinct) eigenvalues of $B(x,\varepsilon)$:

$$\lambda_1 = 0, \quad \lambda_2 = -2\lambda_0, \quad \lambda_3 = -\frac{1}{t_a}, \quad \lambda_4 = -\frac{1+2\lambda_0 t_a}{t_a}. \tag{6.22}$$

Let us note that three of the eigenvalues, λ_2, λ_3, and λ_4, are negative. Moreover, $\lambda_4 < \lambda_2$ and $\lambda_4 < \lambda_3$.

System (6.21) cannot be solved explicitly, so we simplify it heuristically as follows. First consider the system (6.21) with $\varepsilon = 0$, in which case (6.21) reduces to the system of ordinary differential equations

$$\frac{\partial w}{\partial t} = B(x,0)w,$$

where the matrix $B(x,0)$ has four eigenvalues given by (6.22). Consequently, the long time behavior is given by the eigenvectors corresponding to the largest eigenvalues. Next, let us consider the system (6.21) with $\varepsilon \neq 0$. As ε is a small parameter, we use the following heuristic argument to derive a hyperbolic chemotaxis equation.

The eigenvectors of $B(x,\varepsilon)$ are

$$\lambda_1 = 0: \quad \vartheta_1 = \begin{pmatrix} \lambda_0 + 2\lambda_0^2 t_a \\ b\varepsilon s^2 S'(x) t_a \\ -b(\varepsilon s S'(x) t_a)^2 \\ -\varepsilon s^2 S'(x) t_a \lambda_0 \end{pmatrix}, \qquad \lambda_2 = -2\lambda_0: \quad \vartheta_2 = \begin{pmatrix} 0 \\ -1 + 2\lambda_0 t_a \\ \varepsilon S'(x) t_a \\ 0 \end{pmatrix}, \tag{6.23}$$

$$\lambda_3 = -\frac{1}{t_a}: \quad \vartheta_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \qquad \lambda_4 = -\frac{1+2\lambda_0 t_a}{t_a}: \quad \vartheta_4 = \begin{pmatrix} 0 \\ 2b\lambda_0 t_a \\ \varepsilon S'(x) b t_a \\ \lambda_0 \end{pmatrix}. \tag{6.24}$$

Let us suppose that $2\lambda_0 \neq \frac{1}{t_a}$. Then we can write the unknown vector function $v(x,t)$ as a linear combination of the eigenvectors ϑ_i, $i = 1, \ldots, 4$, i.e.,

$$v(x,t) = c_1(x,t)\vartheta_1 + c_2(x,t)\vartheta_2 + c_3(x,t)\vartheta_3 + c_4(x,t)\vartheta_4. \tag{6.25}$$

We are interested in the evolution of the first component of v, which is n. The first component is nonzero only for the vector ϑ_1, and consequently we have

$$n(x,t) = (\lambda_0 + 2\lambda_0^2 t_a)c_1(x,t).$$

Then (6.25) reads as follows:

$$v(x,t) = \frac{n(x,t)}{(\lambda_0 + 2\lambda_0^2 t_a)}\vartheta_1 + c_2(x,t)\vartheta_2 + c_3(x,t)\vartheta_3 + c_4(x,t)\vartheta_4. \tag{6.26}$$

The parameter ε is small compared with $2\lambda_0 + \frac{1}{t_a}$ (see (6.8)). Consequently, the major dynamical features will be given by the eigenvectors corresponding to the zero eigenvalue and the eigenvalues with lower absolute value. We have the inequalities

$$\lambda_4 < \lambda_2 < \lambda_1 = 0 \quad \text{and} \quad \lambda_4 < \lambda_3 < \lambda_1 = 0, \tag{6.27}$$

and therefore we consider the projection

$$v(x,t) = \frac{n(x,t)}{(\lambda_0 + 2\lambda_0^2 t_a)}\vartheta_1 + c_2(x,t)\vartheta_2 + c_3(x,t)\vartheta_3,$$

to obtain (from the fourth component of the vector v)

$$j_1(x,t) = -\frac{\varepsilon s^2 S'(x) t_a}{1 + 2\lambda_0 t_a} n(x,t). \tag{6.28}$$

This can be used to reduce the system (6.21) to the following system of two equations:

$$\frac{\partial n}{\partial t} + \varepsilon \frac{\partial j}{\partial x} = 0, \tag{6.29}$$

$$\frac{\partial j}{\partial t} + \varepsilon s^2 \frac{\partial n}{\partial x} = -2\lambda_0 j + 2b \frac{\varepsilon s^2 S'(x) t_a}{1 + 2\lambda_0 t_a} n. \tag{6.30}$$

The last step is to reduce these two equations to one equation for n. To this end, we differentiate (6.29) with respect to t and (6.30) with respect to x to obtain

$$\frac{\partial^2 n}{\partial t^2} + \varepsilon \frac{\partial^2 j}{\partial t \partial x} = 0, \qquad \frac{\partial^2 j}{\partial x \partial t} + \varepsilon s^2 \frac{\partial^2 n}{\partial x^2} = -2\lambda_0 \frac{\partial j}{\partial x} + 2b \frac{\partial}{\partial x} \frac{\varepsilon s^2 S'(x) t_a}{1 + 2\lambda_0 t_a} n. \tag{6.31}$$

Then, solving (6.31) for n, we obtain the hyperbolic version of the classical chemotaxis equation (compare with (1.5)):

$$\frac{\partial^2 n}{\partial t^2} + 2\lambda_0 \frac{\partial n}{\partial t} = \frac{\partial}{\partial x}\left(\varepsilon^2 s^2 \frac{\partial n}{\partial x} - \frac{2\, b\, \varepsilon^2 s^2 t_a}{1 + 2\lambda_0 t_a} S'(x) n \right). \tag{6.32}$$

Finally, let us note that s (or $\hat{s}$) given by (6.6) is the value of the speed of bacteria in units of s_0. On the other hand, if we give the values for characteristic time T and length L by (6.7), then the characteristic speed can be also considered as $L/T = 1$

mm/sec. In these units, the value of bacterial speed is simply given by $\overline{s} = \varepsilon s$. Using $\overline{s}$ instead of s, we can rewrite (6.32) in the following form:

$$\frac{\partial^2 n}{\partial t^2} + 2\lambda_0 \frac{\partial n}{\partial t} = \frac{\partial}{\partial x}\left(\overline{s}^2 \frac{\partial n}{\partial x} - \frac{2\, b\, \overline{s}^2\, t_a}{1 + 2\lambda_0 t_a} S'(x) n\right). \tag{6.33}$$

Here, the chemotactic sensitivity is given as a function of bacterial speed $\overline{s}$, adaptation time t_a, and turning parameters λ_0 and b, namely,

$$\chi = \frac{b\, \overline{s}^2\, t_a}{\lambda_0 + 2\lambda_0^2 t_a},$$

which we have already derived for the case in which the signal gradient is constant (see (5.7)). Equation (6.33) was derived for the simplified cartoon model (3.7), but a similar analysis can be done for the full model (2.2)–(2.3) with $t_e \neq 0$ and a general function g. This leads to the following hyperbolic chemotaxis equation (cf. (6.33)),

$$\frac{\partial^2 n}{\partial t^2} + 2\lambda_0 \frac{\partial n}{\partial t} = \frac{\partial}{\partial x}\left(\overline{s}^2 \frac{\partial n}{\partial x} - g'(S(x)) \frac{2\, b\, \overline{s}^2\, t_a}{(1 + 2\lambda_0 t_a)(1 + 2\lambda_0 t_e)} S'(x) n\right), \tag{6.34}$$

and the chemotactic sensitivity is now given by

$$\chi = g'(S(x)) \frac{b\, \overline{s}^2\, t_a}{\lambda_0 (1 + 2\lambda_0 t_a)(1 + 2\lambda_0 t_e)}. \tag{6.35}$$

Note that we can derive (6.33) as the limit $t_e \to 0$ of (6.34) for $g = \text{Identity}$. It should also be noted that in either case (and those that follow) the chemotactic sensitivity vanishes as $t_a \to 0$, which is to be expected since the system adapts instantaneously in this case. In this limit one sees, via (3.12) and Lemma 6.2, the interplay between the adaptation time and the allowable magnitude of the gradient: as $t_a \to 0$ we can allow the bound $\bar{K}$ on $|S'(x)|$ in Definition 6.1 to grow as long as $|\bar{K} t_a| \sim \mathcal{O}(1)$, and we obtain the same conclusions as in Lemma 6.2.

In contrast, one cannot extract from (6.35) the effect of letting $t_a \to \infty$, because the derivation of (6.34) or its simplified version (6.33) make use of the inequalities (6.27) to conclude that the projection of the solution onto the eigenvector ϑ_4 dies out faster than other modes. The spectral gap in (6.27) between λ_4 and other eigenvalues does not persist in the limit $t_a \to \infty$, and in addition the constant $\overline{C}$ tends to zero in the standing assumption (3.12). Consequently, we need a model for large t_a in which the turning rate is given by some nonlinear nonnegative function of the signal. Let us also note for later reference that the hyperbolic chemotaxis equation (6.34) gives the same parabolic limit as we will derive in section 7 from the full system (6.21).

6.1. A different random walk interpretation of the hyperbolic chemotaxis equation. As we observed in the discussion in the introduction and in [15], biasing the turning rates depending on the direction of travel will lead to a nonzero chemotactic velocity, and in this section we show that one can explicitly extract that bias from the chemotactic sensitivity derived from the cartoon internal dynamics. This leads back to a system of equations for left- and right-moving particles, but now without internal dynamics. One could obtain this by inverting the procedure that leads from the hyperbolic system without internal dynamics to the second-order scalar equation for the total density, but we proceed directly. The advantage of this system is that it provides a direct step to a microscopic model that bypasses the internal dynamics, and hence may be better suited for stochastic simulations. It also

suggests a model for chemotaxis in eukaryotic cells, which can measure gradients over their length.

Consider a random walk in which a particle moves along the x-axis at a constant speed $\overline{s}$ but at random instants of time reverses its direction according to a Poisson process with the turning frequency

$$\lambda = \lambda_0 \pm \frac{b\,\overline{s}\,t_a g'(S(x))}{(1+2\lambda_0 t_a)(1+2\lambda_0 t_e)} S'(x). \tag{6.36}$$

Here the sign depends on the direction of the particles: plus for particles moving to the left and minus for particles moving to the right. Let $u^{\pm}(x,t)$ be the density of particles at (x,t) that are moving to the right (plus) or left (minus) (note that here, and only in this section, there are no internal variables). Then $u^{\pm}(x,t)$ satisfy the equations

$$\begin{aligned} \frac{\partial u^+}{\partial t} + \overline{s}\frac{\partial u^+}{\partial x} = &-\left(\lambda_0 - \frac{b\,\overline{s}\,t_a g'(S(x))}{(1+2\lambda_0 t_a)(1+2\lambda_0 t_e)} S'(x)\right) u^+ \\ &+\left(\lambda_0 + \frac{b\,\overline{s}\,t_a g'(S(x))}{(1+2\lambda_0 t_a)(1+2\lambda_0 t_e)} S'(x)\right) u^-, \end{aligned} \tag{6.37}$$

$$\begin{aligned} \frac{\partial u^-}{\partial t} - \overline{s}\frac{\partial u^-}{\partial x} = &\left(\lambda_0 - \frac{b\,\overline{s}\,t_a g'(S(x))}{(1+2\lambda_0 t_a)(1+2\lambda_0 t_e)} S'(x)\right) u^+ \\ &-\left(\lambda_0 + \frac{b\,\overline{s}\,t_a g'(S(x))}{(1+2\lambda_0 t_a)(1+2\lambda_0 t_e)} S'(x)\right) u^-. \end{aligned} \tag{6.38}$$

The density of particles at (x,t) is given by the sum $n(x,t) = u^+(x,t) + u^-(x,t)$. Then, adding and subtracting (6.37) and (6.38), one can rewrite them as a system of two equations of the form (6.29)–(6.30) for the variables $n = u^+ + u^-$ and $j = u^+ - u^-$. Then one can follow the same procedure as before to show that the density n of these direction-sensing random walkers is described by (6.34). In this case, (6.34) is valid for all times for all biologically reasonable parameter regimes.

7. The parabolic scaling and derivation of the classical chemotaxis equation. The previous analysis used the scaling (6.7)–(6.8) and led to the hyperbolic chemotaxis equation (6.33), but the arguments are formal in several places. This equation formally reduces for large times to the classical chemotaxis equation (1.5), but to derive the latter rigorously we introduce a parabolic scaling that leads directly from the moment equations (4.7)–(4.10) to the classical chemotaxis equation. For this purpose we define a long time scale, as was done in [19], by setting

$$\hat{t} = \frac{t}{T_p}, \qquad \text{where} \qquad T_p = \frac{1}{\varepsilon^2} T, \tag{7.1}$$

where $T = 1$ sec is the time scale used in the hyperbolic scaling. All other parameters remain the same as in (6.1), (6.6), (6.7), and (6.8), and therefore the dimensionless

equations (6.2)–(6.5) take the form

$$\varepsilon^2 \frac{\partial \hat{n}}{\partial \hat{t}} + \varepsilon \frac{\partial \hat{j}}{\partial \hat{x}} = 0, \tag{7.2}$$

$$\varepsilon^2 \frac{\partial \hat{j}}{\partial \hat{t}} + \varepsilon \hat{s}^2 \frac{\partial \hat{n}}{\partial \hat{x}} = -2\hat{\lambda}_0 \, \hat{j} - 2\,\hat{b}\,\hat{j}_1, \tag{7.3}$$

$$\varepsilon^2 \frac{\partial \hat{n}_1}{\partial \hat{t}} + \varepsilon \frac{\partial \hat{j}_1}{\partial \hat{x}} = -\varepsilon \, \hat{S}'(\hat{x}) \, \hat{j} - \frac{1}{\hat{t}_a} \hat{n}_1, \tag{7.4}$$

$$\varepsilon^2 \frac{\partial \hat{j}_1}{\partial \hat{t}} + \varepsilon \hat{s}^2 \frac{\partial \hat{n}_1}{\partial \hat{x}} = -\varepsilon \hat{s}^2 \, \hat{S}'(\hat{x}) \, \hat{n} - \left(2\hat{\lambda}_0 + \frac{1}{\hat{t}_a} \right) \hat{j}_1 - 2\,\hat{b}\,\hat{j}_2. \tag{7.5}$$

For simplicity, we drop the hats in (7.2)–(7.5), and we consider the case of shallow gradients $S'(x) \sim \mathcal{O}(1)$ as before (see Definition 6.1). Therefore we can use the moment closure $j_2 = 0$ as before, and (7.2)–(7.5) can be written in the following matrix form

$$\varepsilon^2 \frac{\partial v}{\partial t} + \varepsilon \frac{\partial}{\partial x} (Av) = \varepsilon Q(x) v + Rv, \tag{7.6}$$

where v and A are given by (6.19) and

$$Q(x) = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & -S'(x) & 0 & 0 \\ -s^2 S'(x) & 0 & 0 & 0 \end{pmatrix}$$

$$\text{and} \quad R = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & -2\lambda_0 & 0 & -2b \\ 0 & 0 & -\frac{1}{t_a} & 0 \\ 0 & 0 & 0 & -\left(2\lambda_0 + \frac{1}{t_a} \right) \end{pmatrix}.$$

Here all the entries of the matrices A, $Q(x)$, and R are $\mathcal{O}(1)$. Assuming the regular perturbation expansion

$$v = v^0 + \varepsilon v^1 + \varepsilon^2 v^2 + \cdots, \qquad \text{where} \quad v^0 = \begin{pmatrix} n^0 \\ j^0 \\ n_1^0 \\ j_1^0 \end{pmatrix} \quad \text{and} \quad v^1 = \begin{pmatrix} n^1 \\ j^1 \\ n_1^1 \\ j_1 \end{pmatrix};$$

substituting this into (7.6); and comparing terms of equal order in ε, we obtain

$$\varepsilon^0 \ : \qquad Rv^0 = 0, \tag{7.7}$$

$$\varepsilon^1 \ : \qquad \frac{\partial}{\partial x} \left(Av^0 \right) - Q(x) v^0 = Rv^1, \tag{7.8}$$

$$\varepsilon^2 \ : \qquad \frac{\partial v^0}{\partial t} + \frac{\partial}{\partial x} \left(Av^1 \right) - Q(x) v^1 = Rv^2. \tag{7.9}$$

The first equation, (7.7), implies that

$$v_0 = (\, n^0,\, 0\,,\, 0\,,\, 0\,)^T;$$

consequently, the second equation, (7.8), implies

$$j^1 = -\frac{s^2}{2\lambda_0}\frac{\partial n^0}{\partial x} + \frac{bs^2 t_a}{\lambda_0 + 2\lambda_0^2 t_a} S'(x) n^0. \tag{7.10}$$

Finally, (7.9) implies that the left-hand side

$$\frac{\partial v^0}{\partial t} + \frac{\partial}{\partial x}\left(Av^1\right) - Q(x)v^1$$

is in the range of the operator $\mathcal{R} : w \to Rw$. Consequently, using a Fredholm alternative, the left-hand side must be orthogonal to the vector $(1, 0, 0, 0)^T$. Hence,

$$\frac{\partial n^0}{\partial t} + \frac{\partial j^1}{\partial x} = 0.$$

Finally, using (7.10), we derive the classical chemotaxis equation in the following form:

$$\frac{\partial n^0}{\partial t} = \frac{\partial}{\partial x}\left(\frac{s^2}{2\lambda_0}\frac{\partial n^0}{\partial x} - \frac{bs^2 t_a}{\lambda_0 + 2\lambda_0^2 t_a} S'(x) n^0\right). \tag{7.11}$$

Equation (7.11) was derived for the simplified cartoon model (3.7), but a similar analysis can be done for the full cartoon model (2.2)–(2.3). This leads to the classical chemotaxis equation

$$\frac{\partial n}{\partial t} = \frac{\partial}{\partial x}\left(\frac{s^2}{2\lambda_0}\frac{\partial n}{\partial x} - g'(S(x))\frac{bs^2 t_a}{\lambda_0(1 + 2\lambda_0 t_a)(1 + 2\lambda_0 t_e)} S'(x) n\right). \tag{7.12}$$

This is the parabolic counterpart of the hyperbolic equation (6.34) and leads once again to the formula (6.35) for the chemotactic sensitivity. Rigorous estimates on how well the solution of the parabolic equation approximates the solution of the moment equations can be obtained using arguments analogous to those in [19].

8. Numerical examples. The macroscopic descriptions of chemotaxis embodied in either the modified classical chemotaxis equation (6.33) or the classical chemotaxis equation (7.11) are approximations of the original transport equation and the stochastic process describing movement that underlies it. In this section we present two numerical examples that illustrate how well the macroscopic descriptions approximate the solution of the microscopic process. We start by describing our numerical methods.

8.1. Numerical methods. The parameters in our computations are assumed to be dimensionless, and we choose $b = 1$, $t_a = 1$, $\lambda_0 = 1$, and $s = 0.1$; i.e., s is small compared to other parameters (compare with scaling (6.7)–(6.8)).

To solve the system (6.9)–(6.12), closed by (6.17), numerically, we first transform this system to the diagonal form

$$\frac{\partial v}{\partial t} + D_1 \frac{\partial}{\partial x} v = C_1(x) v.$$

Here D_1 is a diagonal 4×4 matrix. Then we use an explicit finite difference method with upwinding. To solve the hyperbolic modified chemotaxis equation (6.33) numerically, we first transform it to the system of two first-order equations in the diagonal form

$$\frac{\partial w}{\partial t} + D_2 \frac{\partial}{\partial x} w = C(x) w,$$

where D_2 is a diagonal 2×2 matrix. Again, we use an explicit finite difference method with upwinding.

To solve the classical chemotaxis equation (7.11) numerically, we use an implicit finite difference method (backward difference approximation in time and centered difference approximation for spatial derivatives).

Finally, to simulate the random walk of individuals, we consider an ensemble of 2000 or 8000 particles. Each particle is described by three variables—position x, velocity $\pm s$, and the internal state y. We use a small time step $dt = 0.01$ (i.e., the unbiased turning frequency divided by 100). During each time step the particle moves with speed s in the chosen direction, and we integrate the internal dynamics to find the change of y. At the end of each time step, a random number from $[0, 1]$ is generated and compared with the probability of the turn $\lambda(y)\mathrm{d}t$. If the turn occurs, the bacterium will move during the next time step in the opposite direction.[1]

8.2. Traveling bands. In this example we analyze the motion of the individuals in the interval $[0, 20]$ with the signal $S(x)$ given by

$$S(x) = 28 - 2|x - 14|. \tag{8.1}$$

The signal has a global maximum at the point 14, and its derivative is $S'(x) = -2\,\mathrm{sign}\,(x-14)$ for $x \neq 14$. We assume the same initial condition for all computations, namely,

$$n(x,0) = \begin{cases} 1 & \text{for } x \in [5,6], \\ 0 & \text{for } x \notin [5,6]; \end{cases} \tag{8.2}$$

we assume that all individuals are perfectly adapted at $t = 0$; and we use no-flux boundary conditions.

In Figure 8.1 we compare the results of the stochastic simulation of the random walk with the solutions of the macroscopic system (6.9)–(6.12) closed by (6.17). It happens that the solution of the modified chemotaxis equation (6.33) and the solution of the classical chemotaxis equation (7.11) are indistinguishable on the plots from the solution of (6.9)–(6.12). Thus the macroscopic results presented can be viewed as plots of the solution of any of these macroscopic equations.

In Figure 8.1 we see that the band travels to the right (i.e., toward the maximum of the signal), as expected, and then the individuals who arrive at the maximum first aggregate there. Eventually all individuals aggregate around the maximum of the signal. From the plots we also see that numerically the macroscopic equations give very good results in comparison with the Monte Carlo simulations. Finally, if we use the results for the time interval $[0, 600]$, i.e., under the influence of the constant gradient, we can compute the average speed of the bacteria in this interval and find that

$$V \doteq \frac{1}{150} = \frac{|b|s^2 S'(x) t_a}{\lambda_0 + 2\lambda_0^2 t_a},$$

which agrees with the result in (5.7).

[1] A Monte Carlo simulation that incorporates the internal dynamics used here, as well as a more detailed description of the motor behavior, is given in [39].

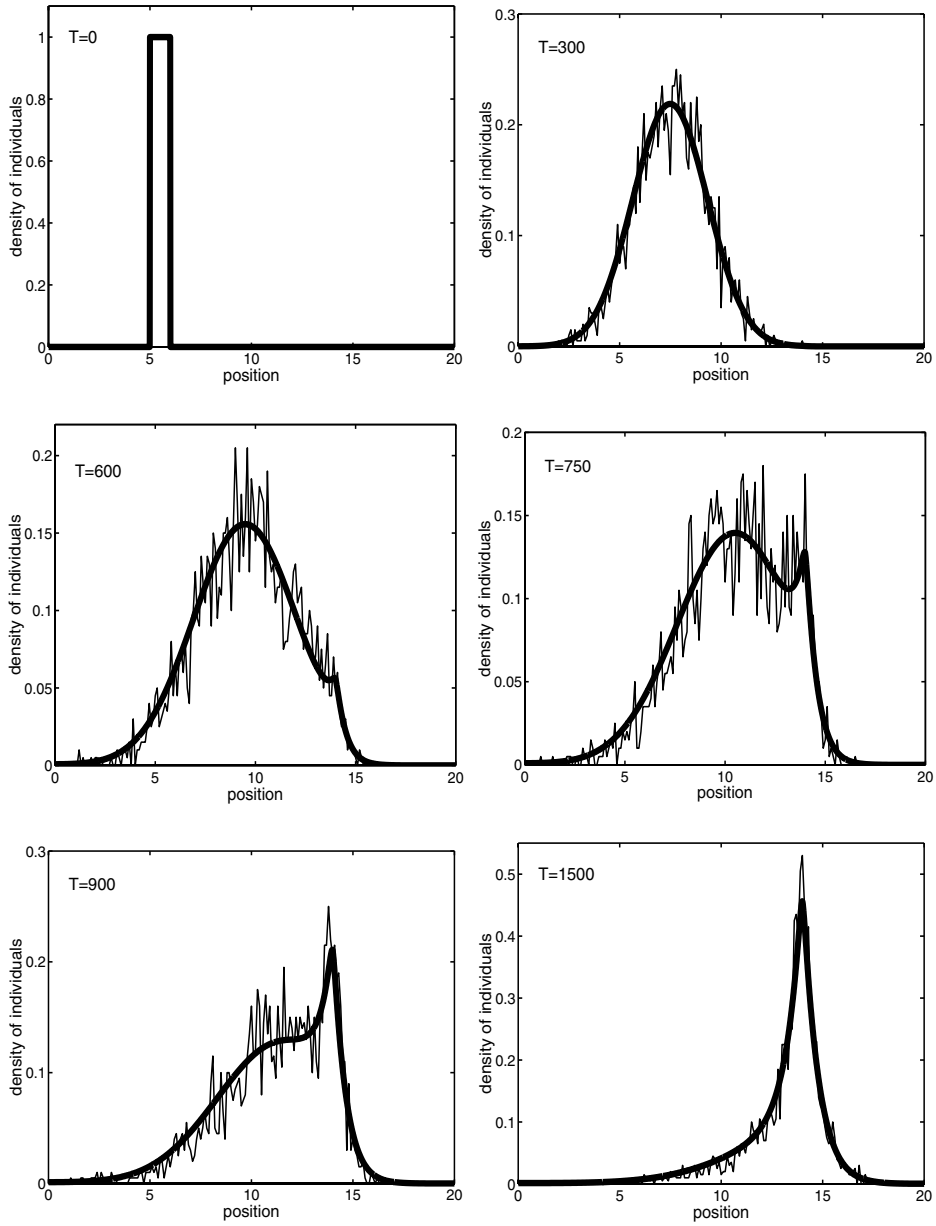

FIG. 8.1. *The graphs show the solutions of the macroscopic system* (6.9)–(6.12) *closed by* (6.17) *(thick smooth line) and the results of stochastic simulations of the velocity jump process with internal state variables (thin line). Moreover, the thick line can also be viewed as a solution of the modified chemotaxis equations* (6.33) *and the solution of the classical chemotaxis equation* (7.11)*, since the solutions of* (6.33)*,* (7.11)*, and* (6.9)–(6.12) *closed by* (6.17) *are indistinguishable on this scale. We used* 2000 *particles for the Monte Carlo simulations, and the parameters* $b = 1$, $t_a = 1$, $\lambda_0 = 1$, *and* $s = 0.1$.

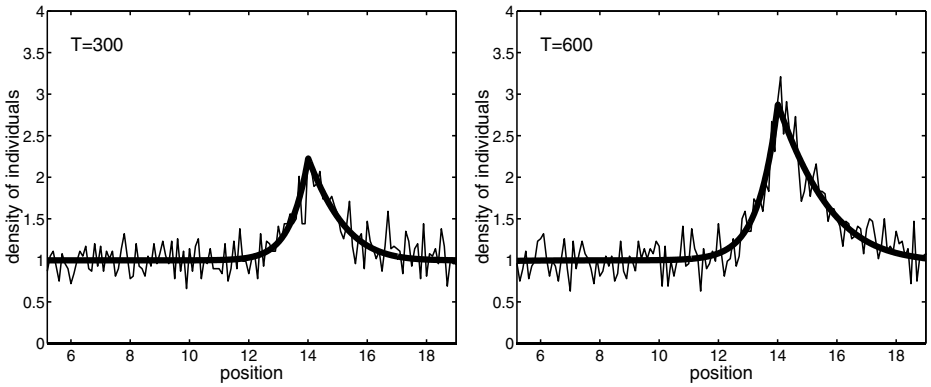

FIG. 8.2. *The graphs of the density of bacteria under the influence of the exponential signal function* (8.3) *with* $x_0 = 14$ *and* $C = 1$. *Initially the bacteria were uniformly distributed at a density equal to* 1. *The figure shows the density of bacteria at time* $T = 300$ *(left) and* $T = 600$ *(right). The bacteria aggregate around the point* $x = 14$, *as expected. In this figure we use the internal dynamics* (2.2)–(2.5) *with* $g(S) = 2\ln(S)$, $t_a = b = \lambda_0 = 1$, $t_e = 0$, *and* $s = 0.1$. *The solution of the classical chemotaxis equation* (7.11) *(thick line) and the Monte Carlo simulation (thin line) are shown.*

8.3. Exponential signal ramp. Various chemotaxis experiments have been done with exponential signal functions [14, 43]. The standard setup is that initially there is a uniform concentration of bacteria in the medium with an exponential signal ramp of the form

$$S(x) = \begin{cases} Ce^x & x \le x_0, \\ Ce^{x_0} & x \ge x_0. \end{cases} \tag{8.3}$$

After several minutes, bacteria aggregate at the top of the exponential ramp, i.e., around the point x_0.

As a second numerical example and test of the macroscopic equations, we reproduce these experiments with the exponential signal ramp. We again use here the internal dynamics (2.2)–(2.5) with a suitable choice of g. The exponential signal ramp was used experimentally because a cell swimming in one direction sees a constant *rate of increase of the signal*, and therefore the bias should remain approximately constant. To take this into account, we could choose

$$g(S) = C\frac{S(x)}{K_D + S(x)}. \tag{8.4}$$

However, as we only want to reproduce the experimental results qualitatively, we can approximate (8.4) by the logarithmic function. The numerical results for this are shown in Figure 8.2. We plot the solution of the classical chemotaxis equation (7.11), but the solutions of (6.9)–(6.12) and (6.33) again give the same results. Moreover, we also qualitatively reproduce the behavior observed in experiments (cf. [14, 43]).

9. Extensions of the analysis. In this section, we discuss two extensions of our analysis—the inclusion of a finite-duration tumbling state and the moment closure for arbitrary signal gradients.

9.1. Inclusion of a finite-duration tumbling state. As we mentioned earlier, the movement of *E.coli* consists of "running" smoothly with a speed s and "tumbling"

randomly. Tumbles cause the bacterium to reorient and swim in a new random direction. The duration of both runs and tumbles are exponentially distributed with means of 1 sec and 10^{-1} sec, respectively, in the absence of an extracellular signal. Thus cells spend 10 percent of the total time in the tumbling state. Earlier we neglected this time by assuming an instantaneous reversal of direction, but we now include it. We again restrict the analysis to one space dimension, since the generalization to higher dimensions only introduces some technical issues. We denote by

- $p^0(x, y, t)$ the number density of tumbling bacteria at time t and at point x with internal state y;
- $p^{\pm}(x, y, t)$ the number density of bacteria running to the *right* (resp., *left*) at time t and at point x with internal state y.

Suppose that a cell with internal state y moves along the x-axis at a constant speed s and at random instants of time stops with stopping time governed by a Poisson process of intensity $\alpha(y)$, and that a cell with internal state y tumbling at the point x to move at random instants of time starts according to a Poisson process with the intensity $\beta(y)$. Further, suppose that the direction of movement is unbiased, i.e., that the tumbling particle will go with probability 0.5 to the right and with probability 0.5 to the left, given that movement starts.

For simplicity we consider the simplified cartoon internal dynamics (3.7)–(3.8). Using the change of internal variables $y_2 = S(x) + z_2$, the movement of bacteria can be described by the following equations:

$$\frac{\partial p^+}{\partial t} + s\frac{\partial p^+}{\partial x} + \frac{\partial}{\partial z_2}\left[\left(-\frac{z_2}{t_a} - sS'(x)\right)p^+\right] = -\alpha(y)p^+ + \frac{1}{2}\beta(y)p^0, \tag{9.1}$$

$$\frac{\partial p^0}{\partial t} + \frac{\partial}{\partial z_2}\left[\left(-\frac{z_2}{t_a}\right)p^0\right] = \alpha(y)(p^+ + p^-) - \beta(y)p^0, \tag{9.2}$$

$$\frac{\partial p^-}{\partial t} - s\frac{\partial p^-}{\partial x} + \frac{\partial}{\partial z_2}\left[\left(-\frac{z_2}{t_a} + sS'(x)\right)p^-\right] = -\alpha(y)p^- + \frac{1}{2}\beta(y)p^0. \tag{9.3}$$

In order to compare this model with the previous one, we will specify $\alpha(y)$ and $\beta(y)$ as follows:

$$\alpha(y) = 2\lambda_0 + 2bz_2, \qquad \beta(y) = \beta_0 - \beta_1 z_2, \tag{9.4}$$

where

$$\lambda_0 > 0, \quad b > 0, \quad \beta_0 > 0, \quad \beta_1 \geq 0.$$

Then this model is equivalent to the model in section 4 in the limit $\beta_0 \to \infty$. One can show, using techniques similar to those used before, that the average position of the particles under the influence of a constant gradient $S'(x) = C$ is given by (cf. (5.7))

$$\langle x\rangle(t) = \frac{bs^2Ct_a}{\lambda_0 + 2\lambda_0^2 t_a}\left(\frac{\beta_0}{2\lambda_0 + \beta_0}\right)t. \tag{9.5}$$

Thus the tumbling state slows down the movement by the factor $\beta_0/(2\lambda_0 + \beta_0)$, and we recover (5.7) as $\beta_0 \to \infty$. Moreover, one can derive the following modified classical chemotaxis equation (cf. (6.33)):

$$\frac{\partial^2 n}{\partial t^2} + 2\lambda_0\frac{\partial n}{\partial t} = \frac{\partial}{\partial x}\left(s^2\frac{\partial n}{\partial x} - \frac{2s^2bt_a}{1 + 2\lambda_0 t_a}\left(\frac{\beta_0}{2\lambda_0 + \beta_0}\right)S'(x)n\right).$$

9.2. Moment closure for arbitrary signal gradients. Heretofore we have used the approximation (6.17), which is appropriate for shallow signal gradients. The question arises as to what can be done for large signal gradients, i.e., for signals that satisfy the standing assumption (3.12). Can we also find a moment closure of the form (6.13)?

To do that, we have to approximate the neglected term

$$2bj_2 = 2bs\int_{\mathbb{R}}(z_2)^2\big[p^+(x,z_2,t)-p^-(x,z_2,t)\big]\mathrm{d}z_2 = 2b\int_{\mathbb{R}}(z_2)^2\mathcal{J}(x,z_2,t)\mathrm{d}z_2. \tag{9.6}$$

Recall that the internal variable $z_2 \in \mathbb{R}$ evolves according to (3.10), i.e., according to the differential equation

$$\frac{\mathrm{d}z_2}{\mathrm{d}t} = -\frac{z_2}{t_a} \mp S'(x)s, \tag{9.7}$$

where the sign of the last term is determined by the sign of the velocity of the particle. Equation (9.7) suggests that we can assume $z_2 \approx \mp S'(x)st_a$. This is simply an assumption, but it leads to the following two naive moment closures:

$$\begin{aligned}
2bj_2 &= 2bs\int_{\mathbb{R}}(z_2)^2\big[p^+(x,z_2,t)-p^-(x,z_2,t)\big]\mathrm{d}z_2\\
&= 2bs\int_{\mathbb{R}}(z_2)(z_2)p^+(x,z_2,t)\mathrm{d}z_2 - 2bs\int_{\mathbb{R}}(z_2)(z_2)p^-(x,z_2,t)\mathrm{d}z_2\\
&\doteq 2bs\int_{\mathbb{R}}(-S'(x)st_a)(z_2)p^+(x,z_2,t)\mathrm{d}z_2 - 2bs\int_{\mathbb{R}}(S'(x)st_a)(z_2)p^-(x,z_2,t)\mathrm{d}z_2\\
&= -2bS'(x)t_as^2\int_{\mathbb{R}}z_2\big[p^+(x,z_2,t)+p^-(x,z_2,t)\big]\mathrm{d}z_2 = -2bS'(x)t_as^2n_1, \qquad (9.8)
\end{aligned}$$

$$2bj_2 = 2b\int_{\mathbb{R}}(z_2)^2\mathcal{J}(x,z_2,t)\mathrm{d}z_2 \doteq 2b\int_{\mathbb{R}}(\mp S'(x)st_a)^2\mathcal{J}(x,z_2,t)\mathrm{d}z_2 = 2b(S'(x))^2t_a^2s^2j. \tag{9.9}$$

These are both consistent with the moment closure (6.17) for shallow gradients of the signal, and consequently they lead to the same equations (6.33) and (7.11) in that case. On the other hand, they are much better than (6.17) for arbitrary signal gradients, which we illustrate here numerically.

To this end, suppose that the derivative of the signal function $S(x)$ is constant, i.e., $S'(x) = C$ and, as in section 5, we derive the corresponding average velocity of the individuals V (i.e., the average velocity which is approached asymptotically; cf. (5.7)). Surprisingly, the result is the same for both moment closures (9.8) and (9.9), namely,

$$V = \frac{bt_as^2S'(x)}{\lambda_0 + 2\lambda_0^2t_a - 2b^2t_a^3s^2(S'(x))^2}.$$

As in section 8, we set $b = \lambda_0 = t_a = 1$ and $s = 0.1$, and then have $\overline{C} = 10$ and

$$V = \frac{S'(x)}{300 - 2(S'(x))^2} \tag{9.10}$$

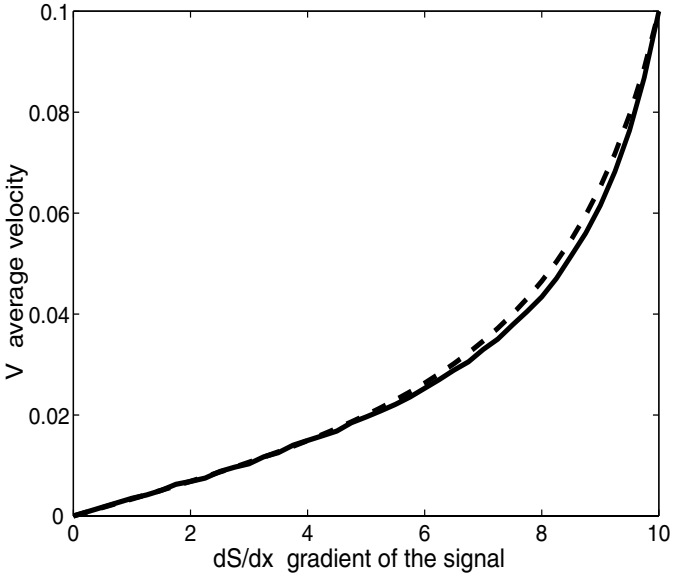

FIG. 9.1. *The dashed line shows the average velocity V given by the formula* (9.10) *as a function of the gradient of the signal. The solid line presents the average velocities of the bacteria obtained by the stochastic simulation.*

for $S'(x) \in [-10, 10]$. To verify this formula numerically, we make several stochastic simulations of the velocity jump process with internal variables, with the same parameters $b = \lambda_0 = t_a = 1$ and $s = 0.1$ for the constant gradients of the signal from the interval [0,10].

Figure 9.1 shows the graph of V (dashed line) as a function of gradient $S'(x)$. The solid line presents the velocities obtained by the stochastic simulation of the velocity jump process with internal variables. We see that, for the maximum possible signal function $S'(x) = 10$, all individuals move to the right with the speed $s = 0.1$, as expected. Moreover, we also see that the macroscopic equations obtained by the moment closure (9.8) or by moment closure (9.9) can give good macroscopic moment equations when used in (6.9)–(6.12).

10. Discussion and conclusions. We have shown how information about microscopic intracellular processes such as signal transduction and response can be translated into the macroscopic chemotactic sensitivity that appears in the macroscopic description of chemotaxis. This was done for a highly simplified description of intracellular dynamics, one which is based on linear dynamics for the response to an extracellular signal, but which nonetheless incorporates the two most important characteristics of any detailed signal transduction network, namely, excitation and adaptation. Linear dynamics and linear response may well be adequate for describing the type of signal changes a swimming bacterium normally sees, but that remains to be established. In addition, a great deal of further work is needed to identify the essential response modes in a general signal transduction network, even if a near-equilibrium assumption is used. A difficult part of that will be to determine how the extracellular signal feeds into the linearized response of the cell.

The moment approach used here leads firstly to a system of hyperbolic equations, and then via a hyperbolic (resp., parabolic) scaling of space and time to a single

hyperbolic (6.34) (resp., parabolic (7.12)) equation for the density of individuals. One can also use other scalings of space and time. For example, the parabolic scaling uses $T \sim \mathcal{O}(1/\varepsilon^2)$, but if one uses $T \sim \mathcal{O}(1/\varepsilon^3)$, the result is the elliptic equation for the steady states of (6.34).

The first systematic derivation of a chemotaxis equation from a velocity jump process is due to Patlak [36], who considers both internal and external biases in detail, but these biases are imposed. A basic assumption in [36] is that the run length is chosen and fixed whenever the particle turns, which is quite different from the stochastic process treated here. As was observed elsewhere [30], the particle motion between turns is deterministic, and thus, were the speed and run length constant, the process would be formally equivalent to a space jump process [29]. In general one can show that this process leads to a renewal equation that generalizes the renewal equation (15) derived in [29], from which a diffusion equation is obtained by suitable choice of the waiting time and jump distributions. Others have treated a process similar to the one treated here without the internal dynamics since Patlak's work, and the reader is referred to [30] for a review of the literature.

SYNCHRONY IN A POPULATION OF HYSTERESIS-BASED GENETIC OSCILLATORS*

ALEXEY KUZNETSOV†, MADS KÆRN‡, AND NANCY KOPELL†

Abstract. Oscillatory behavior has been found in different specialized genetic networks. Previous work has demonstrated nonsynchronous, erratic single-cell oscillations in a genetic network composed of nonspecialized regulatory components and based entirely on negative feedback. Here, we present the construction of a more robust, hysteresis-based genetic relaxation oscillator and provide a theoretical analysis of the conditions necessary for single-cell and population synchronized oscillations. The oscillator is constructed by coupling two subsystems that have previously been implemented experimentally. The first subsystem is the toggle switch, which consists of two mutually repressive genes and can display robust switching between bistable expression states and hysteresis. The second subsystem is an intercell communication system involved in quorum-sensing. This subsystem drives the toggle switch through a hysteresis loop in single cells and acts as a coupling between individual cellular oscillators in a cell population. We demonstrate the possibility of both population synchronization and suppression of oscillations (cluster formation), depending on diffusion strength and other parameters of the system. We also propose the optimal choice of the parameters and small variations in the architecture of the gene regulatory network that substantially expand the oscillatory region and improve the likelihood of observing oscillations experimentally.

Key words. coupled oscillators, relaxation oscillations, stability, intercell communication, gene networks

1. Introduction.

The variation in gene expression in response to internal or external signals is one of the most important means of cellular regulation. The rate at which a gene is transcribed into messenger RNA and subsequently translated into protein is influenced by many factors but is primarily controlled by how well the RNA polymerase complex can bind to and initiate transcription from a regulatory region of the DNA called the promoter. Signals that modulate transcription are often mediated through transcription factor proteins that bind to target sites within or near the promoter where they increase (activation) or decrease (repression) the probability of RNA polymerase complex binding and/or initiation of transcription. The manipulation of DNA sequence to create novel promoters containing customized transcription factor target sites and to mix and match such promoters with genes that encode the corresponding transcription factor proteins has allowed the construction of artificial gene regulatory networks with customizable functionality [1, 2, 3, 4, 5]. Such networks can be used to achieve complex and multifaceted control of cellular function and have promising scientific, medicinal, and biotechnological applications [6, 7, 8].

Mathematical modeling and analysis is becoming increasingly important as a tool to organize and to interpret vast amounts of experimental data and as a predictive tool in the construction of artificial gene networks [1, 2, 9]. The first step in the construction of an artificial gene network is to investigate if the proposed network architecture supports the desired functionality. In this paper, we use mathematical techniques to model and analyze an artificial gene network that is currently being implemented experimentally in the bacterium *Escherichia coli* [10]. The network is intended to regulate a population synchronous periodic oscillation in the levels of cellular protein in a constant density, well-stirred bio-reactor. The goals of the mathematical analysis are (1) to investigate if the network architecture supports single-cell and population synchronous oscillations, (2) to identify the parameter values and the experimental conditions where this behavior is supported, and (3) to suggest modifications to the network that optimize the robustness of single-cell and population oscillations.

The oscillator is to be constructed by combining two engineered gene networks that have previously been implemented experimentally in *E. coli*: the toggle switch [1] and an intercell communication system [11, 12, 13]. The engineered gene networks are carried on multicopy, self-replicating plasmids that interfere minimally with the host cell. As a result, the dynamics of the engineered networks may be considered independently of the dynamics of the cell's natural regulatory circuitry. The toggle switch is composed of two transcription factor proteins: the lac repressor, encoded by the gene *lacI*, and a temperature-sensitive variant of the λ *cI* repressor, encoded by the gene *cI857*. The synthesis of the two repressor proteins is regulated in such a way that expression of the *cI857* and *lacI* genes are mutually exclusive: The promoter P_{trc} that controls the expression of *cI857* is attenuated by the lac repressor while the promoter P_{L*} that controls the expression of *lacI* is attenuated by the λ repressor. Thus, a cell can be either in a state where λ repressor is abundant and lac repressor scarce (the *cI* on state) or in a state where lac repressor is abundant and λ repressor scarce (the *lacI* on state).

It has been demonstrated experimentally [1] that the state of cells harboring the toggle switch network can be changed permanently by transient inactivation of the dominant repressor protein. The λ repressor is inactivated at elevated temperature and the state can be changed from the *cI* ON to the *lacI* ON state by a transient increase in temperature. Conversely, the transition from the *lacI* ON to *cI* ON state ensues when the lac repressor protein is inactivated by the addition of sufficient amounts of the chemical isopropyl-β-D-thiogalactopyranoside (IPTG). At subcritical levels of IPTG, both states exist and are stable. Variation in IPTG has demonstrated hysteresis of these two steady states [1]. We exploit the presence of hysteresis in the toggle switch to construct an oscillator network by linking the toggle switch to a second network that autonomously drives cells through the hysteresis loop (Figure 1.1(A)).

The gene network intended to drive the oscillation involves components of the quorum-sensing system from *Vibrio fischeri* [14]. Quorum-sensing enables cells to sense population density through a transcription factor protein LuxR, which acts as a transcriptional activator of genes expressed from the P_{lux} promoter when a small organic molecular, the autoinducer (AI), binds to it. The AI is synthesized by the protein encoded by the gene *luxI*, and the AI can diffuse across the cell membrane causing the extracellular concentration of AI, as well as the AI concentration in individual cells, to depend on the density of AI-producing cells. These properties of the quorum-sensing system has been exploited experimentally to construct biosensors (see, e.g., [15, 16, 17]) to transfer information from one cell to another [11] and can,

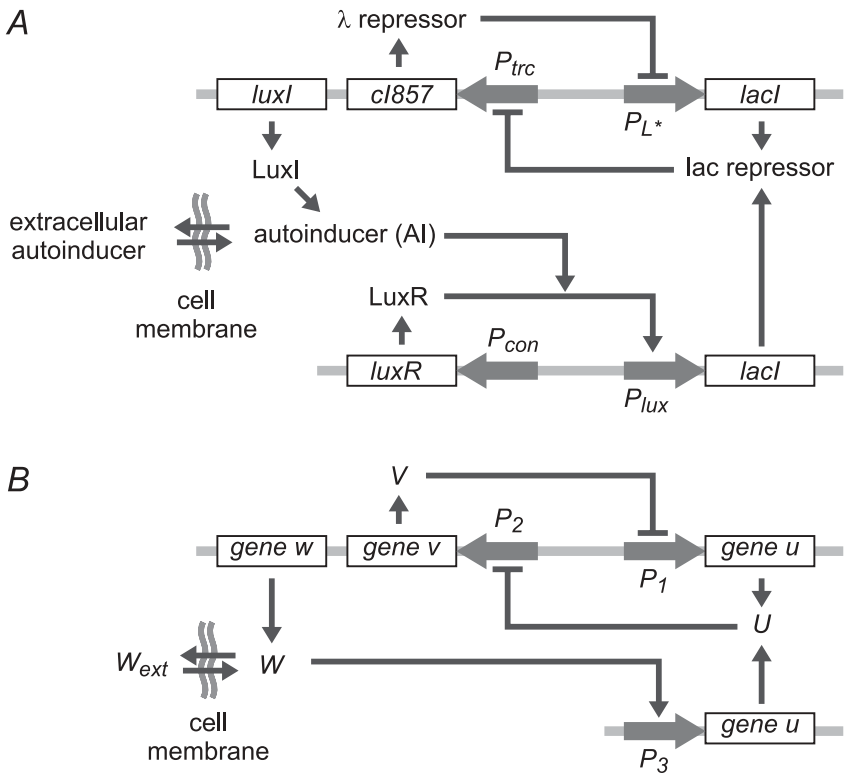

FIG. 1.1. *Schematic diagrams of the genetic oscillator network in isolated cells.* (A) *Full network composed of the toggle switch genes* cI857 *and* lacI *and their respective promoters* P_{trc} *(lac repressed) and* P_{L*} *(*λ *repressed) and the quorum-sensing genes* luxI *and* luxR*. Autoinducer* (AI) *is synthesized by the LuxI protein and activates expression of* lacI *from the* P_{lux} *promoter through binding to the LuxR transcription factor.* (B) *Minimal model. It is assumed that the activation of expression of the repressor gene u (*lacI*) occurs in a single step binding of W (AI) to the promoter* P_3 *(*P_{lux}*).*

in theory, be used to achieve synchronization across a cell population [18]. It was recently shown experimentally [10] that a variant of the network in Figure 1.1 lacking the *luxI* gene can respond to AI and be driven through a saddle-node bifurcation by increasing AI concentration.

This paper is organized as follows. In section 2, we discuss the structure of the genetic network and derive the equations that govern the dynamics of a minimal description of the network. In section 3, we investigate the dynamics of isolated cells and establish the condition for the organization of single-cell oscillations. In section 5, we consider the dynamics of an ensemble of cells and demonstrate the possibility of both population synchronization and suppression of oscillations, depending on diffusion strength and other parameters of the system. In section 4, we investigate the effect on the ability of isolated cells to oscillate when molecular details left out of the minimal model are taken into consideration. In particular, production of the autoinducer in two steps, rather than just one as assumed in the minimal model, improves the likelihood of observing oscillations experimentally. We also show that oscillatory behavior can be made much more robust by adding an additional connectivity to the network.

2. Minimal model. The molecular details of the genetic oscillator network that we wish to construct is illustrated schematically in Figure 1.1(A). It is a slight variant of a network constructed by Kobayashi et al. [10], where *luxI* is inserted downstream of *cI857* rather than downstream of *luxR*. The expression of the *cI857* is controlled by the promoter P_{trc}, and the expression of the *lacI* gene is controlled by the P_{L*} promoter. As a result, the AI is synthesized when the cell is in the *cI* ON/*lacI* OFF state. The AI binds to the LuxR protein, whose gene is expressed at a constant rate from the P_{con} promoter, and the LuxR-AI complex increases the rate of expression of the *lacI* gene by activation of the P_{lux} promoter. Hence, when cells are in the *lacI* OFF state, the AI will gradually accumulate and activate the production of λ repressor protein. The λ repressor eventually shuts down expression of *cI* and *luxI* from the P_{trc} promoter, causing a transition from the *cI* ON to the *lacI* ON state and a down-regulation of AI production. To complete the cycle, it is required that a cell returns to the *cI* ON state once AI production ceases in the *lacI* ON state. Therefore, oscillations require that the toggle switch component of the network is bistable at intermediate levels of AI and monostable when the level of AI is either high (*lacI* ON) or low (*cI* ON).

To ease the mathematical analysis, we initially employ a simplified model of the full system, illustrated in Figure 1.1(B). In this model, the promoters are renamed P_1 (P_{L*}), P_2 (P_{trc}), and P_3 (P_{lux}) and the transcription factors renamed U (lac repressor), V (λ repressor), and W (the LuxR-AI activator). The difference between the full (Figure 1.1(A)) and the simplified system (Figure 1.1(B)) lies in the regulation of the P_3 promoter. We assume for simplicity that the activator of P_3 is encoded by a single gene w rather than being the complex between LuxR and the AI. This assumption ignores a potential time delay introduced by the two-step synthesis of the LuxR-AI complex (i.e., LuxI $\rightarrow$ AI $\rightarrow$ LuxR-AI) and the titration and saturation of free LuxR by the AI. The effects of these assumptions on oscillations in single cells are investigated further in section 4.

2.1. Regulation of gene expression. The simplest model of gene expression involves only two steps: the transcription of a gene into mRNA and the translation of the mRNA into protein [19]. Consider the expression of a gene x that encodes the protein X and is regulated by the promoter P. When each cell harbors n_A active promoters from which the mRNA of gene x is transcribed at an average rate k, the approximation of the rate of mRNA change gives us the following differential equation:

$$\frac{dn_m}{dt} = n_A k - d_m n_m, \tag{2.1}$$

where d_m is the effective first-order rate constant associated with degradation of the mRNA within cells. This equation is, of course, only an approximation since it assumes that the number of mRNA molecules is continuous rather than discrete and since many additional steps are involved in both transcription and degradation of mRNA [21]. Messenger RNA molecules are usually degraded rapidly compared to other cellular processes, and it is often assumed that the concentration of mRNA rapidly reaches a pseudo-steady state where $n_m = n_A k/d_m$ such that dn_m/dt is zero. In some cases, the delay introduced by mRNA synthesis is important for oscillatory dynamics [2]. However, mRNA half-lives are difficult to manipulate experimentally, which makes it difficult to exploit these control parameters in vivo.

The mRNA is translated into a protein by ribosomes, and it is assumed that each x mRNA molecule gives rise to $b_x = k_{tl,x}/d_m$ copies of the protein X, where

$k_{tl,x}$ is the averaged translation rate. The parameter b_x is referred to as the burst parameter of the protein and depends on the efficiency of translation and the mRNA half-life [19]. The value of the translational efficiency depends, among several factors, on the nucleotide sequence of the ribosome binding sites (RBS) located within the upstream, noncoding part of the mRNA. The RBS is encoded by the DNA sequence immediately upstream of the start codon of the gene and is an independent regulatory element that can be manipulated experimentally. The sequence of the DNA encoding the RBS is one of the principal tools by which the parameters of an engineered gene network can be adjusted (see, e.g., [1]).

The equation that governs the evolution of the number of proteins, n_X, produced from n_m mRNA molecules is in the continuous approximation given by

$$\frac{dn_X}{dt} = k_{tl,x} n_m - k_X n_X, \tag{2.2}$$

where $k_{tl,x}$ is the averaged translation rate, introduced above and k_X is the effective first-order rate constant associated with the degradation of the protein within cells. When a pseudo-steady state approximation is invoked for mRNA ($n_m = n_A k/d_m$), it is obtained that $k_{tl,x} n_m = k_{tl,x} n_A k/d_m = b_x n_A k$. The equation for the number of proteins takes the form

$$\frac{dn_X}{dt} = b_x n_A k - k_X n_X. \tag{2.3}$$

The rate of protein decay, k_X, is a second experimental control parameter that can be altered by augmenting, or tagging, the protein with additional amino acids, which makes the protein a target of proteases that break down the protein into amino acids [2].

It is convenient to convert the equation for the evolution of the total number of proteins per cell into an equation for the evolution of cellular protein concentration, $[X](t) = n_X(t)/v(t)$, where $v(t)$ is the cell volume. Cells divide at regular time intervals T, and the cell volume is assumed to increase exponentially in accordance with the growth law $v(t) = v_0 \exp(k_g t)$, where v_0 is the cell volume immediately after division and $k_g = \ln(2)/T$. Cell division occurs when $v(t = T) = 2v_0$. The evolution equation for protein concentration is then obtained as

$$\frac{d[X]}{dt} = \frac{1}{v(t)} \left(\frac{dn_X}{dt} - [X] \frac{dv(t)}{dt} \right) = b_x k [A](t) - (k_X + k_g)[X], \tag{2.4}$$

where $[A](t)$ is the concentration of active promoters, $[A](t) = n_A(t)/v(t)$. It is noted that an exponential increase in cell volume is only an approximation of the quite complicated process of cell growth and division.

The concentration of active promoters, $[A](t)$, depends on the concentration of transcription factors that are bound to the promoter region at a given time. Consider the formation of a complex PE between the promoter, P, and a transcriptional effector E of that promoter through the cooperative binding of β effector molecules to the unoccupied promoter. This scheme can be represented by the reversible chemical reaction of the Hill type with the equilibrium constant K:

$$\beta E + P \leftrightarrows PE, \quad K = \frac{[PE]}{[E]^\beta [P]}, \tag{2.5}$$

where $[P]$, $[PE]$, and $[E]$ are the concentrations of unoccupied promoters, occupied promoters, and effector molecules, respectively. The parameter β is the Hill coefficient associated with the binding of the effector to the promoter.

The total concentration of promoters is proportional to the concentration $[P_{tot}]$ of the plasmid that carries the promoter. Plasmids are self-replicating, and the total number of plasmids (and, hence, of promoters) change as a cell progresses through the division cycle. The control of the plasmid copy number is quite elaborate [20] and must be balanced with the cell's growth and division. As a first approximation, it is assumed that the number of plasmids per cell scales proportionally with the cell volume such that the plasmid concentration remains fairly constant throughout the cell division cycle, i.e., that $[P_{tot}] = [P](t) + [PE](t)$ is constant. Combined with the equilibrium relation in (2.5), the conservation of plasmid concentration can be used to derive the concentration of active promoters $[A]$ used in (2.4). The effector can be either a transcriptional repressor or a transcriptional activator. In the case when the effector is the repressor, the unoccupied promoters are supposed to be active, and $[A]^R \equiv [P]$, where the superscript R stands for the repression case. Deriving concentration of the repressed promoters, $[PE]$, from (2.5) as a function of $[P]$, we have $[P_{tot}] = [P] + K[E]^\beta[P]$, or, taking into account the equivalence of $[P]$ and $[A]^R$, $[P_{tot}] = [A]^R + K[E]^\beta[A]^R$. Then, in the case of transcriptional repression, the concentration of active promoters is given by

$$[A]^R = \frac{[P_{tot}]}{1 + K[E]^\beta}. \tag{2.6}$$

In the case when the effector is the activator, the unoccupied promoters are assumed to be passive, and $[A]^A \equiv [PE]$, where the superscript A stands for the activation case. We derive concentration of unoccupied promoters from (2.5) as $[P] = [A]^A/K[E]^\beta$, then $[P_{tot}] = [A]^A/K[E]^\beta + [A]^A$. From this equation, the concentrations of active promoters is given by

$$[A]^A = \frac{[P_{tot}]K[E]^\beta}{1 + K[E]^\beta}. \tag{2.7}$$

Introducing the exponent a, we can write down the common formula for these two cases:

$$[A] = \frac{[P_{tot}]\left\{K[E]^\beta\right\}^a}{1 + K[E]^\beta}, \tag{2.8}$$

where the case of repression (R) corresponds to $a = 0$ and the case of activation (A) corresponds to $a = 1$.

Equation (2.4) can be generalized for the case of multiple promoters, controlling the production of the same protein. Suppose we have several protein effectors E_j, each of which influences production of the protein X, binding the corresponding promoter P_j ($j = 1, \ldots, M$). By summation of the contribution from each promoter P_j in the network, the evolution of the protein concentration $[X]$ can be written as

$$\frac{d[X]}{dt} = \sum_{j=1}^{M} \frac{b_{jx}k_j[P_{tot,j}][K_j[E_j](t)^{\beta_j}]^{a_j}}{1 + K_j[E_j](t)^{\beta_j}} - (k_X + k_g)[X]. \tag{2.9}$$

We also need to take into account that X may be able to penetrate the cell membrane by passive or active transport. An additional term for (2.9), which corresponds

to the passive transport, is $D_X([X] - [X_{ext}])$. Here, $[X_{ext}]$ is the extracellular concentration of X and D_X is an effective diffusion coefficient. The parameter D_X, in its simplest form, is defined by $D_X = S(t)p_X/v(t)$, where $S(t)$ is the cell surface area and p_X is the membrane permeability of X [22]. While D_X depends slightly on the stage of the cell division cycle, we will assume for simplicity that D_X is a constant. The resulting equation for a protein, which is synthesized from multiple promoters and can penetrate the cell membrane, is given by

$$\frac{d[X]}{dt} = \sum_{j=1}^{M} \frac{b_{jx}k_j[P_{tot,j}][K_j[E_j](t)^{\beta_j}]^{a_j}}{1 + K_j[E_j](t)^{\beta_j}} - (k_X + k_g)[X] - D_X([X] - [X_{ext}]). \tag{2.10}$$

Most proteins within the cell are unable to penetrate the cell membrane, and the diffusive term is in the present case only relevant for the AI.

2.2. The genetic oscillator model. The network diagram in Figure 1.1(B) can be converted into a system of evolution equations by using (2.10) for each of the three proteins U, V, and W synthesized from the three promoters. We use $[U]_i$, $[V]_i$, and $[W]_i$ to denote the concentrations of U, V, and W in cell i and $[W_{ext}]$ to denote the extracellular concentration of the AI:

$$\begin{aligned}
\frac{d[U]_i}{dt} &= \frac{b_{1u}k_1[P_{tot,1}]}{1 + K_1[V]_i^{\beta}} + \frac{b_{3u}k_3[P_{tot,3}]K_3[W]_i^{\eta}}{1 + K_3[W]_i^{\eta}} - (k_U + k_g)[U]_i, \\
\frac{d[V]_i}{dt} &= \frac{b_{2v}k_2[P_{tot,2}]}{1 + K_2[U]_i^{\gamma}} - (k_V + k_g)[V]_i, \\
\frac{d[W]_i}{dt} &= \frac{b_{2w}k_2[P_{tot,2}]}{1 + K_2[U]_i^{\gamma}} - (k_W + k_g)[W]_i - D_W([W]_i - [W_{ext}]),
\end{aligned} \tag{2.11}$$

where β, γ, and η denote the Hill coefficients of the P_1, P_2, and P_3 promoter, respectively.

Since the AI is able to penetrate the cell membrane, it is necessary to consider how the production of AI in an ensemble of N cells changes the extracellular AI concentration. The flux ϕ_i (in number/time unit) of W across the membrane of an individual cell is $\phi_i = S(t)p_W([W]_i - [W_{ext}])$ [22], and the evolution of the extracellular autoinducer concentration is given by

$$\frac{d[W_{ext}]}{dt} = \frac{v_c D_W}{v_{ext}} \frac{1}{N} \sum_{i=1}^{N} ([W]_i - [W_{ext}]) - k_0[W_{ext}], \tag{2.12}$$

where v_{ext} is the volume of the extracellular space, v_c is the total volume of N cells, and k_0 is the effective first-order constant of removal of AI from the extracellular medium. We assume that the experiments are carried out in a continuously stirred, constant volume flow reactor where the extracellular medium is homogeneous and the number of cells is kept constant by continuous dilution of the cell culture by a steady inflow of fresh growth medium and outflow of extracellular medium and cells. It is the rate of this dilution that determines the value of the parameter k_0.

To reduce the number of parameters in the system, we assume that U and V have identical half-lives, $k_d = k_U = k_V$. This assumption is based on the fact that the protein decay rate can be controlled in experiments. The identical half-lives are determined by identical protease tags added to these proteins. However, this assumption is not a constraint for design of the network but just a simplification for

our analysis. To normalize the equations, we introduce the following dimensionless variables:

$$u_i = \sqrt[\gamma]{K_2}[U]_i, \quad v_i = \sqrt[\beta]{K_1}[V]_i, \quad w_i = \sqrt[\eta]{K_3}[W]_i,$$
$$w_e = \sqrt[\eta]{K_3}[W_{ext}], \quad \tau = (k_d + k_g)t. \tag{2.13}$$

With these assumptions, the system is governed by the dimensionless system:

$$\begin{aligned}
\frac{du_i}{d\tau} &= \alpha_1 f(v_i) + \alpha_3 h(w_i) - u_i,\\
\frac{dv_i}{d\tau} &= \alpha_2 g(u_i) - v_i,\\
\frac{dw_i}{d\tau} &= \bar{\alpha}_2 g(u_i) - \delta w_i - D(w_i - w_e),\\
\frac{dw_e}{d\tau} &= \frac{D_e}{N}\sum_{i=1}^{N}(w_i - w_e) - \delta_e w_e,
\end{aligned} \tag{2.14}$$

where the functions are defined by

$$f(v) = \frac{1}{1+v^\beta}, \quad g(u) = \frac{1}{1+u^\gamma}, \quad h(w) = \frac{w^\eta}{1+w^\eta}, \tag{2.15}$$

and the dimensionless parameters are defined by

$$\begin{aligned}
\alpha_1 &= \frac{\sqrt[\gamma]{K_2} b_{1u} k_1 [P_{tot,1}]}{k_d + k_g}, \quad \alpha_2 = \frac{\sqrt[\beta]{K_1} b_{2v} k_2 [P_{tot,2}]}{k_d + k_g},\\
\bar{\alpha}_2 &= \frac{\sqrt[\eta]{K_3} b_{2w} k_2 [P_{tot,2}]}{k_d + k_g}, \quad \alpha_3 = \frac{\sqrt[\gamma]{K_2} b_{3u} k_3 [P_{tot,3}]}{k_d + k_g},\\
\delta &= \frac{k_W + k_g}{k_d + k_g}, \quad \delta_e = \frac{k_0}{k_d + k_g}, \quad D = \frac{D_W}{(k_d + k_g)}, \quad D_e = \frac{v_c D_W}{v_{ext}(k_d + k_g)}.
\end{aligned} \tag{2.16}$$

3. Isolated element. We first establish the conditions for oscillations in isolated cells. Cells can be considered as isolated elements in the limit $D_e \ll \delta_e$, corresponding to a vanishing cell density, where the contribution from cellular autoinducer production to the extracellular autoinducer concentration is vanishing and $w_e \to 0$. The evolution of protein content in an isolated cell is thus determined by

$$\begin{aligned}
&\frac{du}{d\tau} = \alpha_1 f(v) + \alpha_3 h(w) - u, \quad \frac{dv}{d\tau} = \alpha_2 g(u) - v,\\
&\frac{dw}{d\tau} = \bar{\alpha}_2 g(u) - (D+\delta)w = \varepsilon\left(\alpha_4 g(u) - w\right),
\end{aligned} \tag{3.1}$$

where $\varepsilon = D + \delta = (D_W + k_g)/(k_d + D_W)$ and $\alpha_4 = \bar{\alpha}_2(k_d + D_W)/(D_W + k_g)$. We suppose also that $\bar{\alpha}_2$ is of the same order as $(D+\delta)$, i.e., $\alpha_4 = O(1)$ because otherwise dynamics becomes trivial (the only stationary state).

When the parameter ε is small ($\varepsilon \ll 1$), the evolution of the system splits into two well-separated time-scales. In the fast time-scale, changes of the coordinates per unit of time τ are of order 1. Here, we can assume w to be stationary, since $dw/d\tau \sim \varepsilon \ll 1$. The fast motion ceases in the vicinity of the curve, where $du/d\tau = 0$ and $dv/d\tau = 0$, which is called the manifold of slow motion. On the manifold, changes of the coordinates per unit of time τ are of order ε, and we can introduce the slow time $\tau_1 = \varepsilon\tau$, where the changes are of order 1.

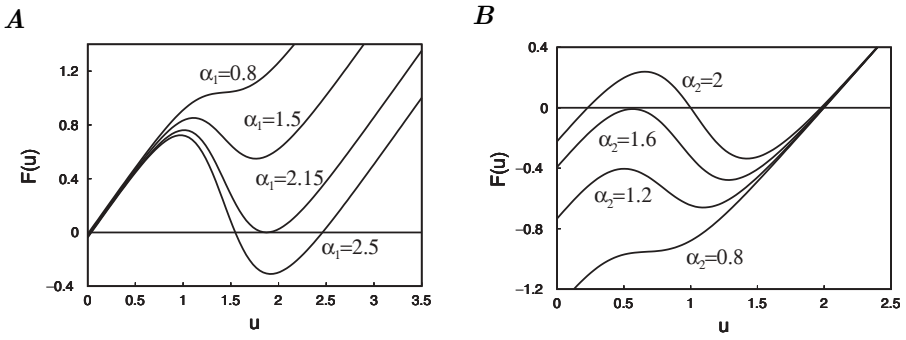

FIG. 3.1. *Geometrical investigation of equilibrium states in the fast subsystem with* $\alpha_w = 0$. *Equilibrium states are located where* $F(u) = 0$. (A) *Increasing the value of* α_1 *causes a transition from one to three equilibrium states, with a new equilibrium with high* u *being created through a saddle-node bifurcation. Parameter values are* $\alpha_2 = 4$, $\beta = \gamma = 3$. (B) *Creation of an equilibrium state with low* u *through a saddle-node bifurcation by an increase in* α_2. *Parameter values are* $\alpha_1 = 2$, $\beta = \gamma = 3$.

3.1. The fast subsystem. The first step in our analysis is to establish the conditions where the fast subsystem can be driven through a bistability region by varying the autoinducer concentration. Two conditions must be satisfied by the fast subsystem. (1) Two saddle-node bifurcations that define a region of bistability must exist and (2) the bifurcations must occur as the autoinducer concentration is varied. To establish the analytical conditions, we look for equilibria on the fast time-scale for $\varepsilon \to 0$, where the full system reduces to the toggle switch equations [1] augmented with a constant production term α_w arising from a constant concentration of autoinducer:

$$\begin{aligned} \frac{du}{d\tau} &= \alpha_1 f(v) + \alpha_w - u = P(u,v), \\ \frac{dv}{d\tau} &= \alpha_2 g(u) - v = Q(u,v), \end{aligned} \tag{3.2}$$

where $\alpha_w = \alpha_3 h(w)$. These equations correspond to those used by Kobayashi et al. to guide the construction of a toggle-based AI biosensor [10]. By Bendixson's criterion [23], the system in (3.2) has no closed orbit since the divergence of the vector field $P_u' + Q_v' = -2$ does not change sign.

3.1.1. Absence of autoinducer. In the absence of the autoinducer ($\alpha_w = 0$), the equilibrium states (u_0, v_0) of the system in (3.2) can be found by setting $v = \alpha_2 g(u)$ as the zeros of the function $F(u)$ given by

$$F(u) = u - \alpha_1 f\left(\alpha_2 g(u)\right) = u - \frac{\alpha_1 (1+u^\gamma)^\beta}{\alpha_2^\beta + (1+u^\gamma)^\beta}. \tag{3.3}$$

Since $F(u) \to -\alpha_1/(\alpha_2^\beta + 1) < 0$ for $u \to 0$ and $F(u) \to u - \alpha_1 > 0$ for $u \to \infty$, the existence of at least one steady state is guaranteed.

A necessary, but not sufficient, condition for the existence of multiple equilibrium states is that $F(u)$ be an N-shaped function such that there exist local extrema (where $F'(u) = 0$). Figure 3.1 illustrates the transition from monostability when α_1 is varied for $\alpha_2 = 4$, $\beta = \gamma = 3$. At very low values of α_1, the function $F(u)$ is monotonically increasing and there exists a single equilibrium state where u_0 is low and v_0 is high.

When α_1 increases, a local maximum and a local minimum emerge, but there is still only a single equilibrium state. As α_1 increases further, the local minimum of $F(u)$ is shifted downward, and it coincides with $F(u) = 0$ when α_1 reaches a critical value α_1^c (at approximately $\alpha_1 = 2.14925$ in Figure 3.1). This critical point corresponds to a saddle-node bifurcation where the two conditions $F(u) = 0$ and $F'(u) = 0$ are simultaneously fulfilled and a new equilibrium state is created. For α_1 higher than the critical value, the function $F(u)$ has three zeros corresponding to three equilibrium states. Two of these states are destroyed when α_1 is very high (greater than approximately 22.9767 for $\alpha_2 = 4$, $\beta = \gamma = 3$) where the local maximum is shifted to negative values of $F(u)$ (not shown). The system is again monostable, this time with an equilibrium state where u_0 is high and v_0 is low. As illustrated in Figure 3.1(B), a similar bifurcation scenario is observed when α_2 is varied.

The characteristic polynomial that determines stability of the equilibrium states of the fast subsystem is given by

$$\begin{aligned} \lambda^2 + 2\lambda + F'(r) &= 0, \\ F'(r) &= 1 - \alpha_1\alpha_2 f_v'(v_0(r))g_u'(r), \end{aligned} \tag{3.4}$$

where we have introduced the parameter r to represent the equilibrium state (u_0, v_0). This parameter is obtained from (3.1) by setting $du/d\tau = 0$ and $dv/d\tau = 0$:

$$r = u_0, \quad v_0 = \alpha_2 g(r). \tag{3.5}$$

It can be shown that when a single equilibrium state exists, it is always stable (monostability), and when three equilibrium states exist, one of them is unstable and the remaining two are stable (bistability).

As described above, the transition from monostability to bistability occurs through saddle-node bifurcations. Their location can be predicted from (3.4) by finding solutions where $\lambda = 0$, i.e., from $F'(r) = 0$. This equation can be written in a parametric form (Appendix A) to obtain sets of critical parameter values $(\alpha_1^c(r), \alpha_2^c(r))$ that determine the location of the saddle-node bifurcations in the α_1, α_2 phase plane:

$$\begin{aligned} \alpha_1^c(r) &= \tfrac{\beta\gamma r^{\gamma+1}}{1+r^\gamma} \Big/ \left(\tfrac{\beta\gamma r^\gamma}{1+r^\gamma} - 1\right), \\ \alpha_2^c(r) &= (1+r^\gamma)\left(\tfrac{\beta\gamma r^\gamma}{1+r^\gamma} \Big/ \left(\tfrac{\beta\gamma r^\gamma}{1+r^\gamma} - 1\right) - 1\right)^{1/\beta}. \end{aligned} \tag{3.6}$$

In these equations, r is in the range $(r_l : \infty)$ with r_l defined by $r_l^\gamma = (\beta\gamma - 1)^{-1}$ (implying that $\beta\gamma > 1$ since r_l must be positive). Note that $\alpha_1^c(r) < 0$ when $r < r_l$, which violates the condition that all the parameters must be positive reals.

3.1.2. Presence of autoinducer. In the presence of autoinducer ($\alpha_w > 0$), the equilibrium states are obtained as the solution of $F(u) = \alpha_w$ rather than $F(u) = 0$. In order to use variation in α_w to drive the fast subsystem through a bistability region, it is essential that an increase (or decrease) in α_w causes the fast subsystem to pass through the two saddle-node bifurcations. Therefore, the system must be monostable when α_w is lower than a critical value $\alpha_w^+ > 0$, having the only equilibrium with low u (denoted r^-), monostable when α_w is greater than the second critical value $\alpha_w^- > \alpha_w^+$, having the only equilibrium with high u (denoted r^+), and bistable when $\alpha_w^- > \alpha_w > \alpha_w^+$. This scenario is depicted in Figure 3.2(A), where one, two, or three equilibrium states arises as α_w is varied. The critical values in α_w, where the fast

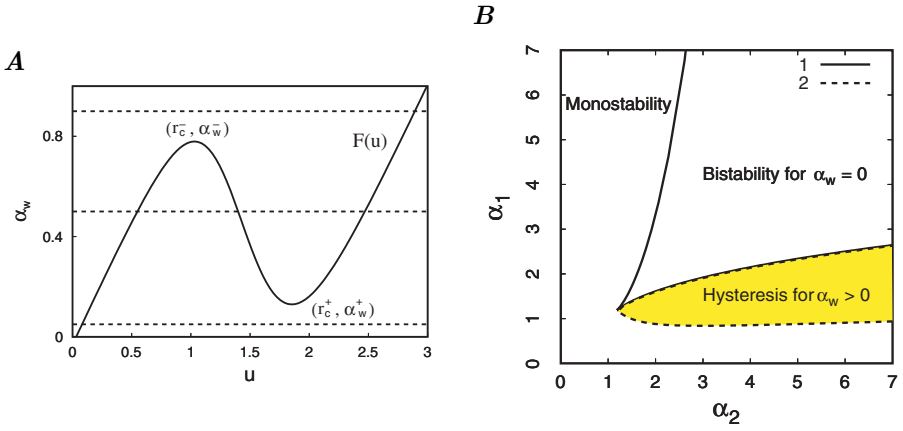

FIG. 3.2. (A) *Changes in the number of equilibrium states by variation in* α_w. *At* $\alpha_w = 0.05$ *there is a single equilibrium state at low* u. *There are three equilibrium states at* $\alpha_w = 0.5$ *and a single equilibrium state for* $\alpha_w = 0.9$. *The points labeled* (r_c^-, α_w^-) *and* (r_c^+, α_w^+) *correspond to the values of* α_w *at the saddle-node bifurcations. Parameter values are* $\alpha_1 = 2, \alpha_2 = 4$, $\beta = \gamma = 3$. (B) *Different regions of the* α_1, α_2 *phase plane showing different behavior for* $\beta = \gamma = 3$. *The solid curve encloses a region where the system is bistable in the absence of autoinducer. The solid and the dashed curve enclose a region where bistability can occur in the presence of autoinducer, i.e., a hysteresis loop for* $\alpha_w > 0$.

subsystem has two equilibrium states (a stable node and a saddle-node), satisfy the conditions

$$\alpha_w^- = F(r_c^-), \quad \alpha_w^+ = F(r_c^+), \quad F'(r_c^\pm) = 0, \tag{3.7}$$

where $r_c^\pm$ are the values of u corresponding to the extrema of $F(u)$.

To achieve hysteresis when α_w is varied, $F(u)$ must have two extrema and they must be located in the positive quadrant, i.e., $F(r_c^\pm) > 0$. The section of parameter plane where the fast subsystem satisfies the required conditions are thus bounded by two curves: one where bistability ceases to exist, corresponding to the merger of extrema of $F(u)$, and one where the minimum of $F(u)$ crosses into negative values. As derived in Appendix B, the merging extrema of the function $F(u)$ defines a curve $(\alpha_1^m(r), \alpha_2^m(r))$ in the α_1, α_2 phase plane given by

$$\alpha_1^m(r) = \frac{(1+r^\gamma)[1+R_1(r)]^2}{\gamma\beta R_1(r) r^{\gamma-1}}, \quad \alpha_2^m(r) = (1+r^\gamma) R_1(r)^{1/\beta}, \tag{3.8}$$

where

$$R_1(r) = -\frac{(\gamma-1) - r^\gamma(1+\beta\gamma)}{(\gamma-1) - r^\gamma(1-\beta\gamma)}. \tag{3.9}$$

The curve $(\alpha_1^m(r), \alpha_2^m(r))$ is in addition subject to the condition that the system is monostable in the absence of autoinducer. In other words, $F(u) = \alpha_w$ must have a single solution for $\alpha_w = 0$ and the saddle-node bifurcations must therefore occur at values of $\alpha_w = F(u) > 0$. The boundary of this condition coincides with that of emergence of bistability in the unperturbed toggle switch, which is determined by the curves of saddle-node bifurcations in (3.6). Figure 3.2(B) illustrates the regions of different dynamics in the α_1, α_2 parameter space. The solid curve is obtained

from (3.6), and the dashed curve shows the merging of extrema (3.8). The area enclosed by the solid curves corresponds to the region in parameter space where the fast subsystem shows bistability in the absence of autoinducer, and the shaded area corresponds to the region of parameter space where there exists a bistable region for $0 < \alpha_w^+ < \alpha_w < \alpha_w^-$, where α_w^+ and α_w^-, as previously defined in this section, are the critical values of autoinducer at the saddle-node bifurcations (see Figure 3.2(A)).

3.2. The slow subsystem. Given sufficient time-scale separation, the fast subsystem reaches a point on the manifold of slow motion, where the dynamics is governed by

$$\frac{dw}{d\tau} = \varepsilon(\alpha_4 g(u) - w). \tag{3.10}$$

Here u satisfies the condition $F(u) = \alpha_3 h(w)$ obtained from (3.2). When the parameters of the fast subsystem are such that there exist two extrema of $F(u)$ at $u = r_c^-$ (the local maximum) and $u = r_c^+$ (the local minimum), the slow subsystem can drive the fast subsystem through a bistability region if $\alpha_w = \alpha_3 h(w)$ can assume values on either side of the interval $[\alpha_w^-, \alpha_w^+]$ where $\alpha_w^\pm = F(r_c^\pm)$, as was illustrated in Figure 3.2(A).

The equilibrium states of the whole system are given by the intersection in u, α_w space between $F(u)$ and the curve

$$\alpha_w(w(u)) \equiv \alpha_3 h(w), \quad w(u) = \alpha_4 g(u). \tag{3.11}$$

The curve $\alpha_w(w(u))$ is a monotonically decreasing function of u since $w(u)$ is a monotonically decreasing function of u and h is monotonic. In order for the slow subsystem to meet the above conditions, it is required that

$$\alpha_w(w(r_c^-)) > F(r_c^-), \quad \alpha_w(w(r_c^+)) < F(r_c^+). \tag{3.12}$$

This condition implies that $\alpha_w(w(u))$ and $F(u)$ must intersect for values of u where $F'(u) < 0$. Figure 3.3(A) illustrates the different scenarios that are possible for different values of the parameters of the slow subsystem. When the parameters are appropriately adjusted, the curves $\alpha_w(w(u))$ and $F(u)$ intersect once in the region where $F'(u) < 0$ and the conditions in (3.12) are satisfied. For other parameter values, there may be one, two, or three intersections of the curves, which violates one of the conditions in (3.12).

The limits of the inequalities in (3.12) can be used to obtain the regions in the parameter space, where the slow subsystem satisfies the required conditions. In particular, equation $\alpha_w(w(r_c^-)) = F(r_c^-)$ requires that $\alpha_w(w(u))$ and $F(u)$ intersect in the point where $F'(u) = 0$, i.e., in the maximum of the function $F(u)$. Hence, the critical values of the parameters where $\alpha_w(w(u))$ intersects an extremum of $F(u)$ satisfies the following condition:

$$\alpha_w(w(r_c^\pm)) = F(r_c^\pm), \quad F'(r_c^\pm) = 0. \tag{3.13}$$

We apply this condition to obtain the region in the (α_3, α_4) parameter plane for different values of η where the slow subsystem satisfies the requirements for relaxation oscillations. These curves are plotted in Figure 3.3(B) and show an increase of the oscillatory region (filled) with increasing η.

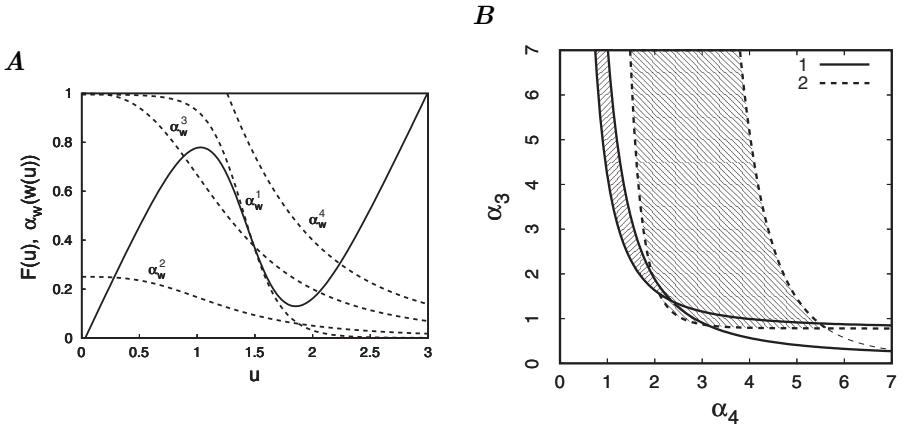

FIG. 3.3. *Geometrical analysis of equilibrium states as the parameters of the slow subsystem are varied.* (A) *Oscillations are possible* (3.12) *when the curves* $F(u)$ *and* $\alpha_w(w(u))$ *intersect only in the region where* $F'(u) < 0$ *(curve* α_w^1*,* $\eta = 4$*,* $\alpha_3 = 1$*,* $\alpha_4 = 3.8$*). The curves* α_w^2*,* α_w^3*, and* α_w^4 *are obtained for* $\eta = 1$*,* $\alpha_4 = 1$*, and* $\alpha_3 = 0.5$*, 2, 4, respectively. They illustrate monostability (*α_w^2 *and* α_w^4*) and multistability (*α_w^3*) in the system. Other parameters are* $\alpha_1 = 2$*,* $\alpha_2 = 4$*,* $\beta = \gamma = 3$*.* (B) *Regions in the* α_3*,* α_4 *parameter space where the conditions* (3.12) *are satisfied for different values of* η*:* (1) $\eta = 2$*;* (2) $\eta = 6$*.*

The condition in (3.13) is solved with respect to α_1 and α_2 (Appendix C) to give a set of bifurcation points (α_1^H, α_2^H) in the limit $\varepsilon = 0$:

$$\alpha_1^H(r) = \frac{1 + R_2(r)}{r - R_3(r)}, \quad \alpha_2^H(r) = (1 + r^\gamma)\,(R_2(r))^{1/\beta}, \tag{3.14}$$

where

$$\begin{aligned} R_2(r) =& \frac{\beta\gamma r^{\gamma-1}\,(r - R_3(r))}{(\beta\gamma r^\gamma - r^\gamma - \beta\gamma r^{\gamma-1} R_3(r) - 1)} - 1, \\ R_3(r) =& \alpha_3 \left(\frac{\alpha_4}{1 + r^\gamma}\right)^\eta \Bigg/ \left(1 + \left(\frac{\alpha_4}{1 + r^\gamma}\right)^\eta\right). \end{aligned} \tag{3.15}$$

As illustrated in Figure 3.4(A), the bifurcation curve has a loop structure and defines two distinct regions of parameter space. The region R is the set of α_1, α_2 values where system (3.1) can display oscillations for sufficiently low values of ε . The region labeled M defines a set of α_1, α_2 values where system (3.1) displays multistability.

3.3. Bifurcation analysis. The positions of equilibrium states $S = (u_0, v_0, w_0)$ in the full system in (3.1) are determined by the equations

$$\alpha_1 f(v_0) - u_0 + \alpha_3 h(w_0) = 0, \quad \alpha_2 g(u_0) - v_0 = 0, \quad \alpha_4 g(u_0) - w_0 = 0. \tag{3.16}$$

The stability of the equilibrium states are obtained from the Jacobian matrix,

$$J = \begin{pmatrix} -1 & \alpha_1 f_v'(v_0) & \alpha_3 h_w'(w_0) \\ \alpha_2 g_u'(u_0) & -1 & 0 \\ \varepsilon\alpha_4 g_u'(u_0) & 0 & -\varepsilon \end{pmatrix}, \tag{3.17}$$

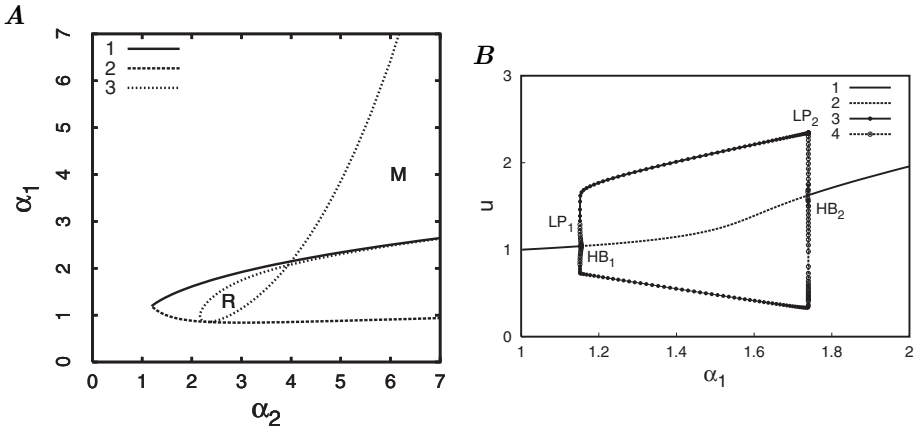

FIG. 3.4. *Bifurcation analysis of the full system.* (A) *Regions of different dynamic behavior in the* α_1, α_2 *parameter plane for* $\alpha_3 = 1, \alpha_4 = 3, \beta = \gamma = \eta = 3$. *Oscillations can occur in the region labeled R for sufficiently low* ε. *The system is bistable in the region labeled M and monostable everywhere else.* (B) *An example of bifurcation diagram obtained by variation in* α_1 *for a fixed value of* α_2 *(*$\alpha_2 = 3$*).*

by evaluation of the characteristic equation given by

$$\lambda^3 + \lambda^2(2+\varepsilon) + \lambda\left(1 - \alpha_1\alpha_2 f_v'(v_0)g_u'(u_0) + 2\varepsilon - \varepsilon\alpha_3\alpha_4 h_w'(w_0)g_u'(u_0)\right) + \varepsilon - \varepsilon\alpha_1\alpha_2 f_v'(v_0)g_u'(u_0) - \varepsilon\alpha_3\alpha_4 h_w'(w_0)g_u'(u_0) = 0. \tag{3.18}$$

The Andronov–Hopf bifurcation, which gives birth to a limit cycle, occurs when a pair of complex conjugate eigenvalues crosses the imaginary axis. If we write down the characteristic equation in the form $\lambda^3 + a\lambda^2 + b\lambda + c = 0$, then the condition for the Andronov–Hopf bifurcation takes the form $ab - c = 0$. From (3.18), this implies that the bifurcation occurs when the following condition is fulfilled:

$$1 - \alpha_1\alpha_2 f_v'(v_0)g_u'(u_0) + \varepsilon\left(2 - \frac{\alpha_3\alpha_4}{2} g_u'(u_0)h_w'(w_0)\right) + \varepsilon^2\left(1 - \frac{\alpha_3\alpha_4}{2} g_u'(u_0)h_w'(w_0)\right) = 0. \tag{3.19}$$

In the limit $\varepsilon \to 0$, we recover condition (3.13) for $\alpha_w(w(u))$ intersecting an extremum of $F(u)$. This is because a solution of the system (3.16), u_0, fits the equation $\alpha_w(w(u_0)) = F(u_0)$, and (3.19) for $\varepsilon = 0$ takes the form $1 - \alpha_1\alpha_2 f_v'(v_0)g_u'(u_0) = 0$, which is equivalent to $F'(u_0) = 0$. In other words, oscillations are constrained to be in the region where the conditions imposed by the slow subsystem (3.13) are satisfied, which, in turn, lies inside the region of hysteresis of the fast subsystem (Figure 3.2(B)).

Figure 3.4(B) illustrates in more detail the bifurcation structure of the full system when α_1 is varied at constant values of α_2. Here, Andronov–Hopf bifurcations, which correspond to entering and exiting from the oscillatory region, are labeled as HB_1 and HB_2. These bifurcations are subcritical and accompanied by saddle-node bifurcations of limit cycles LP_1 and LP_2. The points of Andronov–Hopf bifurcations agree well with the points of intersection of curve 3 of Figure 3.4(A) with the line that corresponds to the given value of α_2. This agreement shows that the region R in Figure 3.4(A) gives a good approximation for the oscillatory region of the full system if ε is small.

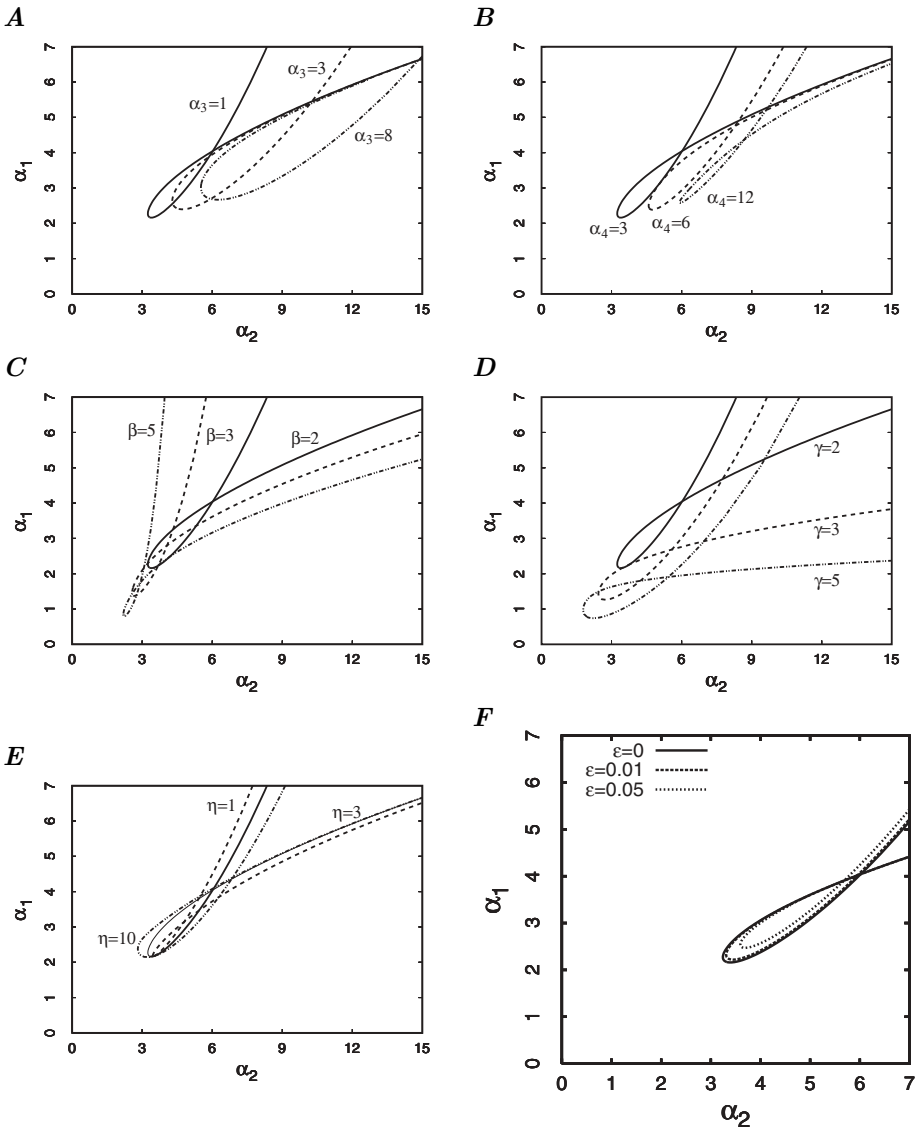

FIG. 3.5. *Increasing the oscillatory region in the α_1, α_2 parameter plane. All plots show the bifurcation curve $(\alpha_1^H(r), \alpha_2^H(r))$ for the reference parameters $\alpha_3 = 1$, $\alpha_4 = 3$, $\beta = \gamma = 2, \eta = 3$, $\varepsilon = 0$ in full. The six plots show the effect of variation in* (A) α_3, (B) α_4, (C) β, (D) γ, (E) η, *and* (F) ε *relative to the reference parameters.*

3.4. Parameter dependence. In this section we are optimizing conditions for oscillations by variation of all of the model parameters. In Figure 3.5(A)–(E), we plot the bifurcation curve $(\alpha_1^H(r), \alpha_2^H(r))$ defined in (3.14), i.e., for $\varepsilon = 0$. Increasing ε decreases the region in the α_1, α_2 parameter plane where oscillations are observed (Figure 3.5(F)). Comparing different curves in Figure 3.5(A), the range of both α_1 and α_2 values where oscillation can occur is seen to expand as α_3 is increased, indicating that larger values of α_3 increase the likelihood of oscillations. In Figure 3.5(B), it is seen that the region of oscillations is maximized at intermediate values of α_4. Therefore, the rate of AI synthesis must be carefully chosen to observe oscillations.

This can be done experimentally by manipulating the *luxI* RBS. Interestingly, Figure 3.5(C) shows a counterintuitive result, namely that the region of oscillations expands as β is decreased, i.e., when the degree of nonlinearity is decreased. Figure 3.5(D) and (E) shows the opposite effect for different nonlinearity exponents, namely that the oscillatory region shrinks when γ and η are decreased.

The exponents β and η have opposite influence because these two parameters change slopes of the function $F(u)$ and $a_w(u)$ independently. In the case where $a_w(u)$ coincides with the middle (decreasing) branch of $F(u)$, the system is very sensitive to changing other parameters. This is because very small variations of a parameter may cause an intersection outside the middle branch of $F(u)$, which corresponds to a stable equilibrium state. When the slope of $a_w(u)$ is less than of the middle branch of $F(u)$, relaxation oscillations cannot occur (see Figure 3.3, curve a_w^3). Thus, the larger the η, the larger the slope of $a_w(u)$, and the larger the tolerance of other parameters for oscillatory dynamics. By contrast, the larger the β, the larger the slope of $F(u)$, and the smaller the region of relaxation oscillations for given η. Parameter γ changes both $F(u)$ and $a_w(u)$, which results in an increase of the oscillatory region with increase of this parameter.

4. Oscillations in more detailed models. In this section, we consider how details left out during the derivation of the minimal model affect the ability of the single cells to display oscillatory behavior. We consider three important assumptions: (1) titration and saturation of the LuxR transcription factor by the AI, (2) two-step synthesis of the AI, and (3) the effect of "leaky" promoters. We also consider how oscillatory behavior can be made more robust by adding an additional connectivity to the network.

4.1. Taking LuxI synthesis into account increases the oscillatory region. As mentioned in the Introduction, the AI is not a gene product, but a small molecule synthesized by the protein encoded by the *luxI* gene (see Figure 1.1A). A more realistic description of the network would therefore involve production of AI in two steps, synthesis of the LuxI protein by the transcription and the translation of *luxI* and subsequent synthesis of the AI by the LuxI protein. This can be accounted for by introducing a new dimensionless variable, x, for the concentration of the LuxI protein and a rate of AI production that is proportional to x. The minimal model (3.1) is recovered when x is assumed to be in a quasi-steady state, $dx/d\tau = 0$. This assumption, however, is not justified since LuxI is a stable protein whose evolution occurs on the same time-scale as the slow variable w. Assuming the time-scales are the same, we take degradation rates of LuxI and AI to be equal and denote both of them as δ. When δ is small, the location of the oscillatory region is slightly shifted in the parameter space (data not shown), indicating that the model where LuxI synthesis is ignored, i.e., (3.1), is a reasonable approximation for this case. On the other hand, when δ is not small, the effect of time lag introduced by the two-step synthesis of the AI is significant. In the minimal model (3.1), oscillations are suppressed when the value of δ exceeds roughly 0.08 for all value of α_4. In the model that incorporates LuxI, oscillations cease when δ exceeds 0.3. This a major improvement for the likelihood of observing oscillations experimentally since smallness of the parameter δ is a major experimental challenge. It requires that the protein half-life, which typically is roughly 30 min or longer, is roughly 20 times shorter than the cell division time. Fortunately, the production of AI in two steps allows for a significant increase in the value of δ where oscillations can be observed. If other parameters are adjusted appropriately, it is possible to get oscillations for δ as high as 0.3.

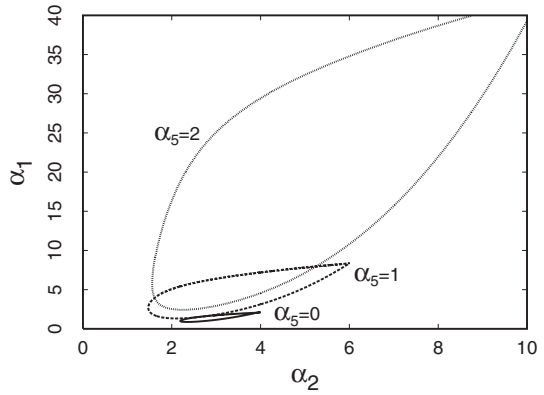

FIG. 4.1. *Increasing robustness of oscillations. The boundary of the oscillatory region in the α_1, α_2 parameter plane for different values of α_5. Parameter values: $\alpha_3 = 1$, $\alpha_4 = 0.03$, $\beta = \gamma = \eta = \zeta = 3$, $\delta = 0.01$, $D = 0$.*

4.2. Adding connectivity to the network increases the oscillatory region. The previous sections have demonstrated that the organization of oscillations in isolated cells requires that most of the parameters are precisely adjusted to a fairly narrow region of parameter space. We investigated if small changes to the system may enhance the region of parameter space where oscillations can be observed. One change that has a dramatic effect on the system is to express the gene coding for the V repressor from a promoter, denoted P_{W2}, that is repressed by AI.

$$\begin{aligned} \frac{du}{d\tau} &= \alpha_1 f(v) + \alpha_3 h(w) - u, \\ \frac{dv}{d\tau} &= \alpha_2 g(u) + \alpha_5 j(w) - v, \\ \frac{dw}{d\tau} &= \bar{\alpha}_2 g(u) - (\delta + D)w, \end{aligned} \tag{4.1}$$

where $\alpha_5 j(w) = \alpha_5/(1 + w^\zeta)$ represents expression of the protein V via the promoter P_{W2}. The model in (3.1) is recovered in the limit $\alpha_5 = 0$.

The addition of an AI-repressed promoter synthesizing the V repressor has a significant impact on the ability of isolated cells to oscillate since it favors the V high state in the absence of autoinducer without making the U high state harder to achieve in the presence of autoinducer. As a result, as α_5 increases, there is an increase in the region of parameter space where the fast subsystem has no stable equilibrium states and, thus, is able to oscillate. In Figure 4.1, we compare the region in the α_1, α_2 parameter plane where oscillations are observed for different values of α_5. It is evident that increased α_5 causes the region of oscillations to expand considerably, thus making oscillatory behavior in isolated cells more robust.

4.3. LuxR synthesis. As mentioned in the Introduction, the transcription factor that activates expression from the P_{lux} promoter is not the AI, as was assumed in the minimal model, but a complex comprised of LuxR and AI (Figure 1.1(A)). This complex is formed in a bimolecular reaction:

$$LuxR + AI \leftrightarrows LuxR - AI, \quad K_4 = \frac{k_{4f}}{k_{4b}}, \tag{4.2}$$

where K_4 is the equilibrium constant and k_{4b} and k_{4f} are the rate constants for the dissociation and association reaction, respectively. The *luxR* gene is assumed to be expressed at a constant rate from a plasmid-borne, constitutive promoter P_{con}, such that the LuxR protein is synthesized at a constant rate v_R. To obtain the minimal model (3.1), we need to assume here that the concentration of free autoinducer [AI] is negligible. That is, we assume that LuxR synthesis rate is large ($v_R \gg 1$) to provide LuxR for binding with AI, and the association reaction (4.2) is fast ($k_{4f} \gg k_{4b}$ and $k_{4f} \gg 1$). Our simulations reveal (data not shown) that, for smaller v_R, the oscillatory region shrinks and shifts to smaller α_1 and α_2. Violation of the other inequalities (e.g., $k_{4f} \ll k_{4b}$) makes the changes more significant. Hence, the details of formation of this effector complex may make oscillations more difficult to obtain.

4.4. Promoter leakage. In all of the models investigated, we have assumed that the promoters are fully repressible or fully silenced meaning that there is no expression from the promoter when repressor concentration is high or when activator is absent. In reality, many bacterial promoters are "leaky," and expression occurs at a basal level even under conditions where repressor is present in excess or activator is completely absent from the system.

To evaluate the effect of promoter leakage on the ability of isolated cells to oscillate, we introduced a constant synthesis term in each of the variables u and v that is proportional to maximal synthesis rate α_j. For simplicity, we use the same proportionality factor μ, corresponding to identical relative basal synthesis rates for all promoters. For large Hill coefficients $\eta = \zeta = 3$, the oscillations were observed at a fairly high value of leakage $\mu = 0.1$, i.e., 10% of the maximal synthesis rate for all promoters (data not shown). Decreasing the values of η and ζ causes the oscillatory region to be confined to lower values of μ. This indicates that organization of oscillations in isolated elements does not require the very tightly regulated promoters.

5. Ensemble of cells. We now study collective dynamics of the cell population. Introduction of coupling between elements of an ensemble can lead to qualitative changes of their dynamics. We are interested in providing synchronous oscillations, which would correspond to macroscopic oscillations of a protein concentration over the whole population. We demonstrate the possibility of both population synchronization and suppression of oscillations, depending on coupling strength and other parameters of the system.

First we make a transformation of the coordinates and parameters to combine intra- and extracellular degradation of the autoinducer into single term, thereby decreasing the number of parameters in the system. Then the system (2.14), describing the population of $i = 1, \dots, N$ cells, takes the form

$$
\begin{aligned}
\frac{du_i}{dt} &= \alpha_1 f(v_i) - u_i + \alpha_3 h(w_i),\\
\frac{dv_i}{dt} &= \alpha_2 g(u_i) - v_i,\\
\frac{dw_i}{dt} &= \bar{\varepsilon}\,(\bar{\alpha}_4 g(u_i) - w_i) + 2d(\bar{w}_e - w_i),\\
\frac{d\bar{w}_e}{dt} &= \frac{d_e}{N}\sum_{i=1}^{N}(w_i - \bar{w}_e).
\end{aligned}
\tag{5.1}
$$

Here, $\bar{w}_e = w_e\,(1 + \delta_e/D_e)$, $\bar{\varepsilon} = D + \delta - \frac{D}{(1+\delta_e/D_e)}$, $d = \frac{D}{2(1+\delta_e/D_e)}$, $d_e = D_e + \delta_e$, and $\bar{\alpha}_4 = \bar{\alpha}_2/\bar{\varepsilon}$.

Let us consider the simplest synchronous solution, i.e., identical synchronization of all elements of the ensemble: $u_i = u(t), v_i = v(t), w_i = w(t)$, $i = \overline{1,N}$. These equalities give the manifold of identity of corresponding coordinates: $M\{u_i, v_i, w_i : u_i = u_j, v_i = v_j w_i = w_j \forall i = \overline{1,N}, j = \overline{1,N}\}$. Now we study two matters: (1) dynamics on this manifold and (2) its stability. We show that if the isolated element displays relaxation oscillations, then the ensemble has the solution of identical synchronization for both small and large coupling strength. However, for the latter, the synchronous state may not be stable.

5.1. Identical synchronization. Dynamics on the manifold of identity of corresponding coordinates, M, is given by the following system:

$$\begin{aligned}
\frac{du}{dt} &= \alpha_1 f(v) - u + \alpha_3 h(w),\\
\frac{dv}{dt} &= \alpha_2 g(u) - v,\\
\frac{dw}{dt} &= \bar{\varepsilon}\,(\bar{\alpha}_4 g(u) - w) + 2d(\bar{w}_e - w),\\
\frac{d\bar{w}_e}{dt} &= d_e(w - \bar{w}_e).
\end{aligned} \tag{5.2}$$

Suppose that we have relaxation oscillations in each isolated element (for which $D_e \ll \delta_e$), i.e., we have the oscillations in this system with $d \to 0$ and $\bar{\varepsilon} \to \varepsilon = D + \delta$. We also assumed $\varepsilon \ll 1$ to obtain the oscillations.

We show first that the oscillations persist for small nonzero coupling strength $0 < d \ll 1$. We suppose also that the extracellular coupling coefficient is not small: $d_e \sim 1$. Then the system can be divided into fast and slow parts. The fast subsystem

$$\frac{du}{dt} = \alpha_1 f(v) - u + \alpha_3 h(w), \tag{5.3}$$

$$\frac{dv}{dt} = \alpha_2 g(u) - v, \tag{5.4}$$

$$\frac{d\bar{w}_e}{dt} = d_e(w - \bar{w}_e) \tag{5.5}$$

gives dynamics of three variables in the fast time-scale, where w is a constant. The u, v equations and the $\bar{w}_e$ equation do not depend on one another, so the fast subsystem splits into two independent parts. The u, v part is identical to the fast subsystem of the isolated element, in which all trajectories on the (u, v) plane converge to one of the equilibria. Trajectories of the $\bar{w}_e$ equation converge to the equilibrium state $\bar{w}_e = w$.

The slow subsystem is determined on the manifold of slow motion, i.e., in the intersection of all nullclines of the fast subsystem. This implies that we need to consider the equation for w on the manifold $\{\bar{w}_e = w, F(u) = \alpha_3 h(w)\}$. Substitution of the first constraint in the third equation of the system (5.2) gives

$$\frac{dw}{dt} = \bar{\varepsilon}(\bar{\alpha}_4 g(u) - w), \tag{5.6}$$

where u is a function of w, taken from the second constraint ($u = F^{-1}(\alpha_3 h(w))$). This equation has the same form as the slow equation obtained for the isolated element

(3.10), with parameters $\bar{\varepsilon}$ and $\bar{\alpha}_4$ representing other combinations of the initial parameters. Thus, for a given set of initial parameters D, δ, D_e, and δ_e, the slow dynamics of the system (5.2) with weak coupling strength d differs from the slow dynamics of the isolated element, but the parametric portrait of the isolated element with respect to parameters ε, α_4 coincides with the portrait for the system (5.2) with respect to parameters $\bar{\varepsilon}$ and $\bar{\alpha}_4$. If we have a solution for an isolated element with some values of ε and α_4, we can obtain the same solution in the system (5.2) with weak coupling strength d by tuning the parameters D, δ, D_e, and δ_e so that $\bar{\varepsilon}$ and $\bar{\alpha}_4$ take values ε and α_4. Thus, if a solution exists for the isolated element, then the same solution exists for the ensemble on the manifold of identical synchronization. Thus, we have shown, in particular, that there exists a regime of relaxation oscillations for a nonzero but weak coupling strength ($0 < d \ll 1$).

Next we consider the existence of a relaxation oscillation solution for large coupling strength $d \gg 1$. A shift in the frequency of the oscillation is obtained below for this case. The analysis can be performed analogously to that in [24]. There, the authors have proved that, for large coupling strength, the coupling term remains $O(1)$. Analogously, in our case, the coupling term $d(\bar{w}_e - w)$ is $O(\bar{\varepsilon})$ for large d, because the remaining part of the equation for w_i in system (5.2) is of that order (this follows from our analysis below). As $d \to \infty$, $w \to \bar{w}_e$, so $d(\bar{w}_e - w)$ is essentially a function of either one of the coordinates which enter the term. (This was proved rigorously in [24] for a related set of equations.) Using this, as in [24], we introduce $c(w) = d(\bar{w}_e - w)$.

We derive $\bar{w}_e$ from the definition of $c(w)$:

$$\bar{w}_e = w + \frac{1}{d} c(w). \tag{5.7}$$

Taking the derivative of this equation, we get

$$\frac{d\bar{w}_e}{dt} = \frac{dw}{dt}\left(1 + \frac{1}{d}\frac{dc(w)}{dw}\right). \tag{5.8}$$

Substituting this derivative and $c(w)$ into the third and fourth equation of system (5.2), we can rewrite them in the form

$$\frac{dw}{dt} = \bar{\varepsilon}(\bar{\alpha}_4 g(u) - w) + 2c(w), \tag{5.9}$$

$$\frac{dw}{dt}\left(1 + \frac{1}{d}\frac{dc(w)}{dw}\right) = -\frac{d_e}{d} c(w). \tag{5.10}$$

Excluding dw/dt from these equations, we get

$$[\bar{\varepsilon}(\bar{\alpha}_4 g(u) - w) + 2c(w)]\left(1 + \frac{1}{d}\frac{dc(w)}{dw}\right) = -\frac{d_e}{d} c(w). \tag{5.11}$$

The left-hand side of this equation is $O(\bar{\varepsilon})$. For a nonzero result in the leading order, $O(\bar{\varepsilon})$, we suppose that $\frac{d_e}{d} \sim 1$ and obtain

$$c_0(w) = -\frac{\bar{\varepsilon}(\bar{\alpha}_4 g(u) - w)}{2 + d_e/d}. \tag{5.12}$$

Note that we have not assumed $\bar{\varepsilon}$ small. The above result is valid for $\bar{\varepsilon} \sim 1$ whenever $d \gg \bar{\varepsilon}$.

Substituting $c_0(w)$ for $d(\bar{w}_e - w)$ in (5.2), we have the following three-dimensional system for synchronous oscillations in the limit of large coupling:

$$\begin{aligned} \frac{du}{dt} &= \alpha_1 f(v) - u + \alpha_3 h(w), \\ \frac{dv}{dt} &= \alpha_2 g(u) - v, \\ \frac{dw}{dt} &= \bar{\varepsilon} \frac{d_e}{2d + d_e} \left(\bar{\alpha}_4 g(u) - w \right). \end{aligned} \tag{5.13}$$

Hence, increasing the coupling strength d perturbs the parameter in front of the slow equation, changing the rate of change of the autoinducer, i.e., the slow timescale of the system. It follows from (5.11) that this perturbation is negligible if $d_e \gg d$ (to leading order $c(w) = 0$). But in the intermediate case $d_e \sim d$, the perturbation slows down the oscillations. In the limiting case $d_e \ll d$, (5.11) gives $c_0(w) = -\bar{\varepsilon}(\bar{\alpha}_4 g(u) - w)/2$, and, substituting $d(\bar{w}_e - w)$ in (5.2) by this formula, we obtain $dw/dt = o(\bar{\varepsilon})$. Thus, in the case $d_e \ll d$, the rate of change of the slow variable, w, is decreased by an order of magnitude, and so is the frequency of oscillations.

5.2. Stability of the synchronous solution. Now we examine stability of the solution obtained above with respect to small perturbations of the equalities of corresponding coordinates of the elements. We show that the synchrony may become unstable for large coupling strength. Let us define the perturbations in the following way: $u_i = u + \xi, u_j = u - \xi, v_i = v + \nu, v_j = v - \nu, w_i = w + \zeta, w_j = w - \zeta$, where i and j are any two numbers from 1 to N. Thus, we are perturbing any two elements of the ensemble in such a way that the perturbation does not affect the remaining elements. These perturbations are called transversal (or evaporational [25]) and test stability of the manifold of identical coordinates of the elements. The linearized equations for these perturbations are

$$\begin{aligned} \frac{d\xi}{dt} &= \alpha_1 f'(v)\nu - \xi + \alpha_3 h'(w)\zeta, \\ \frac{d\nu}{dt} &= \alpha_2 g'(u)\xi - \nu, \\ \frac{d\zeta}{dt} &= \bar{\varepsilon} \left(\bar{\alpha}_4 g'(u)\xi - \zeta \right) - 2d\zeta, \end{aligned} \tag{5.14}$$

where u, v, and w are taken in identity manifold with dynamics, governed by system (5.2). We solve this system numerically, calculating its Lyapunov exponents. They reveal stability of the synchronous solution with respect to the transversal perturbations and are therefore called transversal Lyapunov exponents. Figure 5.1 presents curves of the maximal transversal Lyapunov exponent vs. the coupling strength d for several sets of the other parameters. A negative value of the exponent implies transversal stability. The first curve corresponds to a set of parameters for which synchrony remains stable for any coupling strength. The second curve shows the maximal transversal Lyapunov exponent when only the parameter $\bar{\varepsilon}$ is changed. For this case, a fivefold increase in $\bar{\varepsilon}$ causes loss of stability with increasing coupling strength. The third curve illustrates the influence of another parameter on stability: changing α_1 shifts the manifold of slow motion so that the intersection with the nullcline of slow motion is shifted far apart from the extrema of the manifold. This shift makes the limit cycle more symmetric (see Figure 5.2) and leads to stability of this solution for any coupling strength even with a higher value of $\bar{\varepsilon}$, for which the oscillations are not

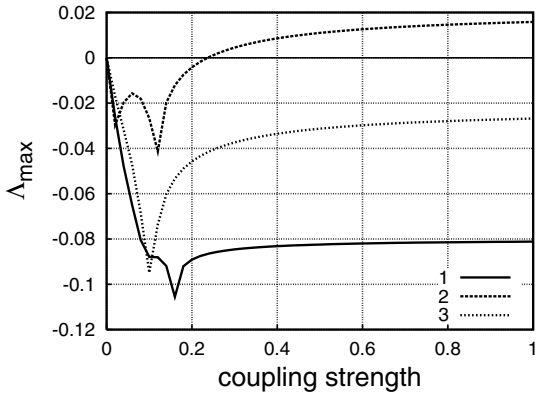

FIG. 5.1. *The largest transversal Lyapunov exponent vs. coupling strength for different sets of the parameters. Curve* (1) *corresponds to* $\bar{\varepsilon} = 0.01, \alpha_1 = 3$. *Curve* (2) *corresponds to* $\bar{\varepsilon} = 0.05, \alpha_1 = 3$, *so the nullclines are the same (see Figure* 5.2(A)*), and shows instability for large coupling strength. Curve* (3) *shows that oscillations can be stable even for such a high value of* $\bar{\varepsilon}$ *(*$\bar{\varepsilon} = 0.05$*) if the limit cycle is more symmetric (*$\alpha_1 = 3.2$ *as in Figure* 5.2(B)*).*

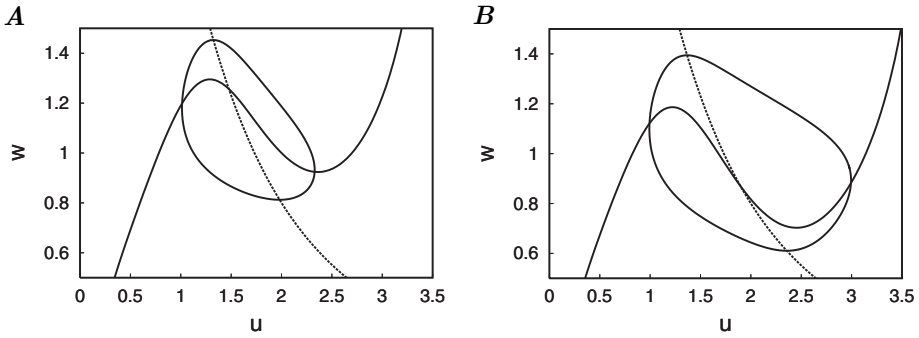

FIG. 5.2. *Position of the nullclines and form of limit cycles for* (A) *unstable and* (B) *stable synchrony. The only different parameter for these two cases is* α_1, *which is equal to* 3 *in the case* (A) *and* 3.2 *in the case* (B). *The other parameters are* $\alpha_2 = 5, \alpha_3 = 1, \bar{\alpha}_4 = 4, \beta = \gamma = \eta = 2$.

of relaxation type ($\bar{\varepsilon} = 0.05$). The illustrations of time series for the ensemble of 20 elements in the cases of stable and unstable identical synchronization solutions are presented in Figure 5.3. Thus, depending on the parameters of the element, we can keep the synchronous solution stable for any positive coupling strength or destabilize it for a large coupling strength.

The dependence of stability of a synchronous solution on parameters of the element can be explained qualitatively. The manifold of identical synchronization, M, has stable and unstable regions. Stability of a trajectory on this manifold is determined by the Lyapunov exponents, which measure whether perturbations decay or grow. As can be seen from computer simulations of this system, the perturbations grow during the fast motion, i.e., in the region, where u corresponds to the negative slope of the manifold of slow motion, $F'(u) < 0$ (see, e.g., Figure 5.2). By contrast, the perturbations decrease during the slow motion. If the time-scales are well separated, then the interval of time on the slow motion is much longer and contraction wins. Increasing $\bar{\varepsilon}$ leads to faster dynamics of the autoinducer (see (5.2)) and decreases intervals of time with slow motion. Thus, a synchronous solution may lose stability with

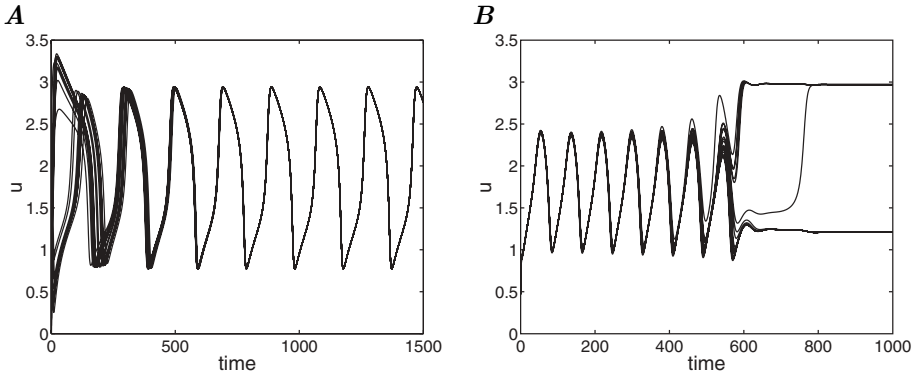

FIG. 5.3. *Examples of time series for the ensemble of* 20 *elements in the cases of* (A) *stable and* (B) *unstable synchronous solution.* $\alpha_1 = 3, \alpha_2 = 5, \alpha_3 = 1, \bar{\alpha}_4 = 4, \beta = \gamma = \eta = 2$*;* (A) $\bar{\varepsilon} = 0.01, d = 0.005$*;* (B) $\bar{\varepsilon} = 0.05, d = 0.3$.

respect to the transversal perturbations when dynamics of the autoinducer becomes faster.

The same argument can be applied to explain dependence of stability on the form of the limit cycle. Given the same time separation ($\bar{\varepsilon}$) for both trajectories in Figure 5.2, in the case (A), the major part of the trajectory lies in the middle region of u, where $F'(u) < 0$. Here, the transversal perturbations grow, giving divergence of the close trajectories from the limit cycle. In the case (B), the limit cycle has much larger parts outside the middle region, which contributes to the decrease of the perturbations and causes convergence in average along the limit cycle.

5.3. Stable equilibria for large coupling strength. In this section we show that large diffusion may cause emerging steady states of the protein concentrations and ceasing of the oscillations in the population. We are going to show existence and stability of new equilibria in the phase space of the ensemble (5.1) for large coupling strength. Taking into account our result on synchronization of this population, the new equilibria may coexist with the stable synchronous periodic solution, dividing the phase space into basins of attraction.

We conduct the analysis analogous to [26] and [27]. Consider for simplicity a pair of the elements

$$
\begin{aligned}
\frac{du_1}{dt} &= \alpha_1 f(v_1) - u_1 + \alpha_3 h(w_1),\\
\frac{dv_1}{dt} &= \alpha_2 g(u_1) - v_1,\\
\frac{dw_1}{dt} &= \bar{\varepsilon}\,(\bar{\alpha}_4 g(u_1) - w_1) + 2d(\bar{w}_e - w_1),\\
\frac{du_2}{dt} &= \alpha_1 f(v_2) - u_2 + \alpha_3 h(w_2),\\
\frac{dv_2}{dt} &= \alpha_2 g(u_2) - v_2,\\
\frac{dw_2}{dt} &= \bar{\varepsilon}\,(\bar{\alpha}_4 g(u_2) - w_2) + 2d(\bar{w}_e - w_2),\\
\frac{d\bar{w}_e}{dt} &= \frac{d_e}{2}(w_1 + w_2 - 2\bar{w}_e).
\end{aligned}
\tag{5.15}
$$

Equilibrium states of the system are given by

$$\begin{aligned}
\alpha_1 f(v_1) - u_1 + \alpha_3 h(w_1) &= 0,\\
\alpha_2 g(u_1) - v_1 &= 0,\\
\bar{\varepsilon}(\bar{\alpha}_4 g(u_1) - w_1) + 2d(\bar{w}_e - w_1) &= 0,\\
\alpha_1 f(v_2) - u_2 + \alpha_3 h(w_2) &= 0,\\
\alpha_2 g(u_2) - v_2 &= 0,\\
\bar{\varepsilon}(\bar{\alpha}_4 g(u_2) - w_2) + 2d(\bar{w}_e - w_2) &= 0,\\
w_1 + w_2 - 2\bar{w}_e &= 0.
\end{aligned} \tag{5.16}$$

Again, we derive v_i from these equations as $v_i = \alpha_2 g(u_i)$, and substituting them into the remaining equations, we can write u_i as a function of w_i: $u_i = F^{-1}(\alpha_3 h(w_i))$, where, as before, $F(u) = u - \alpha_1 f(\alpha_2 g(u))$. The extracellular autoinducer concentration can also be presented as a function of w_i: $\bar{w}_e = (w_1 + w_2)/2$. Since u_i, v_i, and $\bar{w}_e$ are determined by w_i, the equilibria of the system can be found from a two-dimensional system presented in the following form:

$$\begin{aligned}
w_2 &= w_1 - \frac{\bar{\varepsilon}}{d} R(w_1),\\
w_1 &= w_2 - \frac{\bar{\varepsilon}}{d} R(w_2),
\end{aligned} \tag{5.17}$$

where

$$R(w) = \bar{\alpha}_4 g\left(F^{-1}(\alpha_3 h(w))\right) - w. \tag{5.18}$$

This system gives two curves in the (w_1, w_2) plane, intersections of which correspond to equilibria of the pair of elements.

Consider the case where each isolated element displays relaxation oscillations. In particular, let us take the same parameters of the element as in Figure 5.2(A). The curves given by system (5.17) are shown in Figure 5.4 for two different values of the coupling parameter d. Here, with increasing coupling strength, two new intersections of these curves emerge. The intersections correspond to equilibria, the stability of which is shown below.

To explain the emergence of the new equilibria, we divide the dynamics of the system into fast and slow motion, taking $\bar{\varepsilon} \sim d \ll 1$. Consider first the fast subsystem of system (5.15):

$$\begin{aligned}
\frac{du_1}{dt} &= \alpha_1 f(v_1) - u_1 + \alpha_3 h(w_1),\\
\frac{dv_1}{dt} &= \alpha_2 g(u_1) - v_1,\\
\frac{du_2}{dt} &= \alpha_1 f(v_2) - u_2 + \alpha_3 h(w_2),\\
\frac{dv_2}{dt} &= \alpha_2 g(u_2) - v_2,\\
\frac{d\bar{w}_e}{dt} &= \frac{d_e}{2}(w_1 + w_2 - 2\bar{w}_e),
\end{aligned} \tag{5.19}$$

where w_1 and w_2 can be taken to be constant ($\dot{w}_1 = \dot{w}_2 = 0$) and equal to their initial values. This system has three independent parts: for (u_1, v_1), (u_2, v_2), and for $\bar{w}_e$

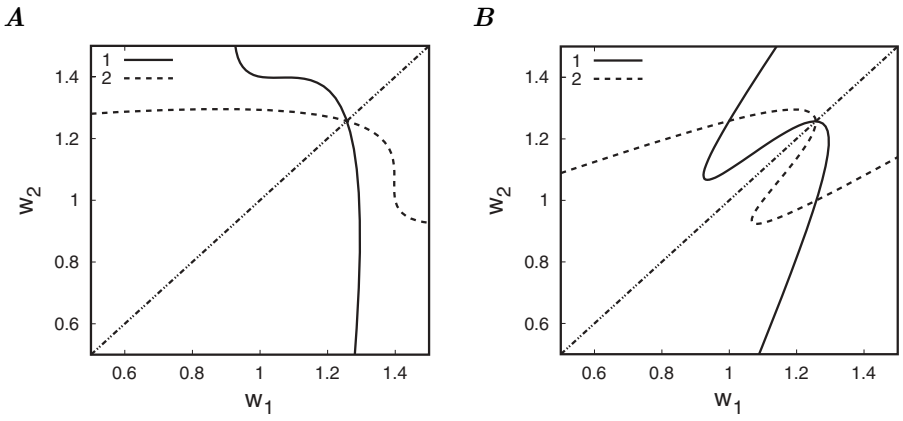

FIG. 5.4. *Equilibrium states of the pair of elements are in the points of intersection of the two curves given by system* (5.17)*, which are plotted for* (A) $\bar{\varepsilon}/d = 2$*;* (B) $\bar{\varepsilon}/d = 0.5$*. Curves* 1 *and* 2 *correspond to the first and the second equations in* (5.17)*. The dashed diagonal line is the manifold of identity of the w coordinates. In case* (B) *we have two intersections of the nullclines outside the diagonal, which are stable equilibria.*

(each part does not include variables from other parts). The equation for $\bar{w}_e$ has the equilibrium $\bar{w}_e = (w_1 + w_2)/2$, which is stable. The remaining two systems for (u_i, v_i) coincide with the fast subsystems for the isolated element (3.2), i.e., the elements are effectively uncoupled with respect to fast motion. Hence, these systems cannot have closed orbits. The only trajectories which attract or repel all others nearby are equilibrium states, defined, as before, by

$$-F(u_i) + \alpha_3 h(w_i) = 0, \qquad v_i = \alpha_2 g(u_i), \quad i = 1, 2. \tag{5.20}$$

The position of the equilibria, depending on w_i, constitutes the manifold of slow motion for the whole system (5.15), where the fast equations do not contribute to the motion, and the motion is governed entirely by the slow subsystem. The manifold for each of the elements of the coupled system (5.15) is given by the same curve (Figure 5.5), which is identical to the one obtained for the isolated element (3.2). Figure 5.5 shows trajectories for the two elements from their initial conditions $(u_1, \alpha_{w,1})$ and $(u_2, \alpha_{w,2})$, where $\alpha_{w,i} = \alpha_3 h(w_i)$. Once the elements come to their manifolds of slow motion, fast motion ceases and the trajectory moves along the manifold, governed by the slow subsystem

$$\begin{aligned} \frac{dw_1}{dt} &= \bar{\varepsilon}\,(\bar{\alpha}_4 g(u_1) - w_1) + d(w_2 - w_1), \\ \frac{dw_2}{dt} &= \bar{\varepsilon}\,(\bar{\alpha}_4 g(u_2) - w_2) + d(w_1 - w_2), \end{aligned} \tag{5.21}$$

where $u_i = F^{-1}(\bar{\alpha}_4 h(w_i)), i = 1, 2$. For $d = 0$, w_i increases along the left-hand branch of $F(u)$ and decreases on the right-hand branch. In the case plotted in Figure 5.5, by providing attraction of the w_i coordinates to each other, the coupling term speeds up motion along the manifold until $w_1 = w_2$. After that, the coupling slows down the motion. If the coupling strength is high enough, it can stop the motion along the manifold, compensating for the slow dynamics of the individual elements, as plotted in Figure 5.5.

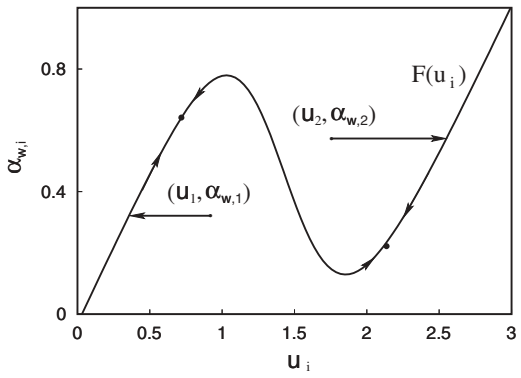

FIG. 5.5. *Fast motion in the pair of elements. The manifolds of slow motion for these two elements coincide with each other. The fast motion attracts the trajectory to one of the outer branches of the manifold. The middle branch is unstable with respect to fast motion.*

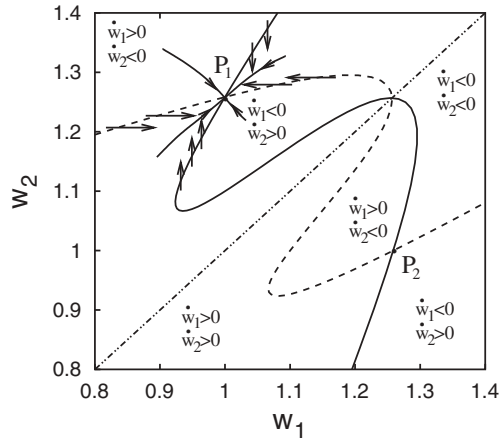

FIG. 5.6. *Phase diagram of slow system* (5.22) *near equilibria* P_1 *and* P_2.

5.4. Stability of the new equilibria. We are going to show that the equilibrium states are stable with respect to both fast and slow motion. Consider first the slow subsystem (5.21), which, using the function $R(w)$ defined in (5.18), can be presented as

$$\begin{aligned} \frac{dw_1}{dt} &= \bar{\varepsilon} R(w_1) + d(w_2 - w_1), \\ \frac{dw_2}{dt} &= \bar{\varepsilon} R(w_2) + d(w_1 - w_2). \end{aligned} \tag{5.22}$$

The curves (5.17), plotted in Figure 5.4, are nullclines of this system. Determining the sign of $\dot{w}_1$ and $\dot{w}_2$ from (5.22) in different regions of the (w_1, w_2) plane, we can qualitatively plot directions of trajectories for the slow subsystem. This gives us the picture in Figure 5.6, which shows stability with respect to slow motion of the equilibrium states P_1 and P_2.

Next consider stability with respect to the fast motion. We know that, in the singular limit $\bar{\varepsilon} \to 0$, the middle branch of the manifold of slow motion for the isolated element is unstable (Figure 5.5). Even in the case when there is an equilibrium in the middle branch and the slow motion converges to it, the fast motion provides divergence (see Figure 3.2(A) curve α_{w3}). Thus, we can determine stability of an equilibrium state with respect to the fast motion based only upon its position on the manifold of slow motion. In particular, if the equilibrium state is situated in the middle branch of the manifold, then it is unstable.

This rule helps us to determine stability of the equilibria in the intersections of the curves in the (w_1, w_2) plane (Figure 5.4). The curves have three monotonic branches, which correspond to the branches of the manifold of slow motion, given by $F(u)$. The middle branch of the manifold, which is unstable with respect to fast motion, corresponds to the middle branch of the curves $w_1(w_2)$ and $w_2(w_1)$. Hence, the equilibrium state in the diagonal in Figure 5.4(A) and (B) is unstable, but the pair of new equilibria in Figure 5.4(B) is stable with respect to fast motion. This suggests the new equilibrium states are stable for large coupling strength.

Stability of the equilibria can be shown rigorously by the standard characteristic equation method. The characteristic equation for the pair of interacting elements (5.15) can be written in the following form:

$$\Omega_1\Omega_2(-d_e-\lambda) - \Omega_1\Delta_2 d_e d - \Omega_2\Delta_1 d_e d = 0. \tag{5.23}$$

Here, $\Delta_i = (1+\lambda)^2 - \alpha_2 g'(u_i)\alpha_1 f'(v_i)$, $\Omega_i = \Delta_i(-\bar{\varepsilon}-2d-\lambda)+(1+\lambda)\alpha_3 h'(w_i)\bar{\varepsilon}\alpha_4 g'(u_i)$. This is a seventh order equation with respect to λ.

To carry out stability analysis for the case considered above in a more rigorous way, we suppose $d \sim \bar{\varepsilon} \ll 1$. We are looking first for eigenvalues of the order one, $\lambda \sim 1$. To leading order of magnitude, (5.23) gives

$$\Delta_1\Delta_2\lambda^2(-d_e-\lambda) = 0.$$

The first root of this equation is $\lambda_1 = -d_e$; the other four roots, $\lambda_{2,3}$ and $\lambda_{4,5}$, come from the quadratic equations $\Delta_1 = 0$ and $\Delta_2 = 0$, respectively. All of them are negative if $1 - \alpha_2 g'(u_i)\alpha_1 f'(v_i) > 0$, which is equivalent to $F'(u_i) > 0$ (see section 3.3). The remaining two eigenvalues, $\lambda_{6,7}$, obtained from this equation are zero. We need to consider a lower order of magnitude of equation (5.23) to determine their signs. Thus next we suppose $\lambda \sim \bar{\varepsilon}$. Then the leading order of (5.23) is $O(\bar{\varepsilon}^2)$:

$$\begin{aligned}
&\Big[F'(u_1)(-\bar{\varepsilon}-2d-\lambda) + \bar{\varepsilon}\alpha_3 h'(w_1)\alpha_4 g'(u_1)\Big] \\
&\quad\times\Big[F'(u_2)(-\bar{\varepsilon}-2d-\lambda) + \bar{\varepsilon}\alpha_3 h'(w_2)\alpha_4 g'(u_2)\Big](-d_e) \\
&\quad-\Big[F'(u_1)(-\bar{\varepsilon}-2d-\lambda) + \bar{\varepsilon}\alpha_3 h'(w_1)\alpha_4 g'(u_1)\Big]F'(u_2)d_e d \\
&\quad-\Big[F'(u_2)(-\bar{\varepsilon}-2d-\lambda) + \bar{\varepsilon}\alpha_3 h'(w_2)\alpha_4 g'(u_2)\Big]F'(u_1)d_e d = 0,
\end{aligned} \tag{5.24}$$

where we take only $O(1)$ terms in Δ_i and $O(\bar{\varepsilon})$ terms in Ω_i. This is a quadratic equation, which can be written in the form $a\lambda^2 + b\lambda + c = 0$ with the coefficients $a = -F'(u_1)F'(u_2)$, $b = -2(\bar{\varepsilon}+d)F'(u_1)F'(u_2)+\bar{\varepsilon}\alpha_3\alpha_4[F'(u_1)h'(w_2)g'(u_2)+F'(u_2)\times h'(w_1)g'(u_1)]$, $c = -(\bar{\varepsilon}+2d)\bar{\varepsilon}F'(u_1)F'(u_2) + (\bar{\varepsilon}+d)\bar{\varepsilon}\alpha_3\alpha_4[F'(u_1)h'(w_2)g'(u_2)+F'(u_2)h'(w_1)g'(u_1)] - \bar{\varepsilon}^2\alpha_3^2\alpha_4^2 h'(w_1)h'(w_2)g'(u_1)g'(u_2)$. We need to show that $\lambda_{6,7} = (-b \pm \sqrt{b^2-4ac})/2a$ are negative or, equivalently, that $-b \pm \sqrt{b^2-4ac} > 0$. Consider the region where all the eigenvalues of the leading order, $O(1)$, are negative, i.e.,

$F'(u_i) > 0$. Then it is obvious that the first coefficient, a, is negative. All three terms of c coefficient are negative because $h'(w_i) \geq 0$ and $g'(u_i) \leq 0$ everywhere. Thus, $ac > 0$, $b^2 - 4ac < b^2$, or $\sqrt{b^2 - 4ac} < |b|$. The coefficient b is also negative; hence the latter inequality gives $\sqrt{b^2 - 4ac} < -b$, or $-b - \sqrt{b^2 - 4ac} > 0$. Thus, all eigenvalues are negative under conditions $F'(u_i) > 0$, showing stability of the equilibria in the outer branches of the function $F(u)$.

Analogously, one can show stability of the equilibria for the case of large or moderate coupling strength d.

5.5. Impact of the collective dynamics. We now discuss how requirements for obtaining oscillations are changed in the case of a population of interacting cells. One of the key experimental problems is to achieve a sufficiently slow dynamics of the autoinducer. The time-scale of autoinducer dynamics is determined by the coefficient in front of the right part of the equation for autoinducer concentration—a rate constant. For the isolated element (3.1), this coefficient is ε; for the system on the manifold of identical synchronization (5.2), it is $\bar{\varepsilon}$. We have shown that the lower the rate constant (the slower dynamics of autoinducer) the larger the oscillatory region (see Figure 3.5(F)). For population dynamics, the rate constant depends on the coupling strength (see, e.g., (5.13)). It follows from (5.11) that the autoinducer dynamics is much slower than in isolated element if $d_e \ll d$ and $d \gg \bar{\varepsilon}$. Hence, we can slow down dynamics of the autoinducer using properties of the collective dynamics. The assumption that $d_e \ll d$ ($d = \frac{D}{2(1+\delta_e/D_e)}$, $d_e = D_e + \delta_e$) is quite plausible for the experiment because D_e is presented usually as $D_e = \frac{D\rho}{1-\rho}$, where ρ is cell density, and $\rho \ll 1$. Then $D_e \ll D$, and if we suppose that $\delta_e \sim D_e$, we come to the inequality $d_e \ll d$. The other assumption ($d \gg \bar{\varepsilon}$) is also plausible because the permeability of the cell membrane to the autoinducer molecules is expected to be relatively high ($D \gg 1$).

Stability of the synchronous solution also depends on the time-scale of the autoinducer dynamics. We have shown that synchrony may be stable for a small rate constant $\bar{\varepsilon}$ and unstable for larger $\bar{\varepsilon}$ (see Figure 5.1). Those computations were made for $d_e \gg d$ so that the period of oscillations was not changed significantly with increasing coupling strength. Now, if $d_e \ll d$, increasing coupling strength also slows down the oscillations (5.13), causing stabilization of the synchronous solution (data not shown).

On the other hand, increasing coupling strength also causes emergence of the new equilibria. The higher the coupling strength, the larger the domains of attraction of the new equilibria and the larger the probability of obtaining a steady state instead of synchronous oscillations in the experiment. The effect is very strong because the coupling strength sufficient for the formation of the equilibria is of the same order of magnitude as $\bar{\varepsilon}$. To avoid formation of the equilibria, we need to keep $\bar{\varepsilon}$ larger than d, which contradicts the conditions used above. Thus, our theoretical study of the simplified model (5.1) predicts a potential problem for the experimental implementation of the synchronous oscillatory dynamics.

6. Solving experimental problems (discussion). In this section we summarize the results of our investigations and discuss the conditions required for population synchronous oscillations in the light of constraints imposed by experimental considerations. Our study of a simplified model shows that population synchronous oscillations are theoretically possible. However, there may be some difficulties in achieving population synchronous oscillations experimentally. First of all, a strong

interaction between cells (e.g., high permeability of the membrane to the autoinducer) may result in the suppression of synchronous oscillations and a transition to a stable heterogeneous population state where individual cells are locked in different stable equilibrium states. On the other hand, if the cell-to-cell interactions are too weak, individual cells may oscillate but will be unable to achieve synchrony. Therefore, the parameters that determine the coupling strength between cells must be finely adjusted. Cell-to-cell variations in parameter values and initial conditions increase the likelihood that the population synchronous oscillation will be suppressed. As our study has shown, mere difference in initial conditions for different cells may be sufficient to obtain a stationary population state and suppression of individual cellular oscillators, even though the synchronous solution is asymptotically stable.

Fortunately, the system provides a possibility for attracting a very broad distribution of initial conditions to the synchronous solution. This requires the dynamics of the extracellular autoinducer to be much slower than the intracellular ones, which corresponds to the condition $d_e \ll d$ discussed in the end of the previous section. In this case (and for large coupling strength d), the motion from the initial conditions starts with relaxation of the concentrations of the intracellular autoinducer in different cells toward the state where the concentrations are equal to the extracellular concentration. If the extracellular autoinducer is washed out at the onset of the experiment, then the initial state will have the extracellular concentration that is close to zero. Thus, the concentrations inside the cells approach a low value. Once the low concentration has been achieved, the concentrations of the repressor proteins inside all cells approach the same state: low u and high v. This state is in the domain of attraction of the synchronous solution, and synchrony can be achieved even when other attractors exist.

Moreover, if the parameters of individual cells are different, the identical synchronization solution does not exist at all. Our computational study of the model of the population shows that the introduction of inhomogeneity in parameters increases the probability of obtaining a stationary state starting from random initial conditions. Generally speaking, a larger variation in the parameter values of individual elements (e.g., a larger difference in the individual cellular oscillators and high cell-to-cell variability) will decrease the likelihood of observing a population synchronized oscillatory state. This is particularly important since many engineered gene regulatory networks, including the toggle switch and the Lux-based cell-to-cell communication system, are carried on self-replicating plasmids. The number of plasmids per cell (and hence the number of genes and promoters they carry) is know to vary quite dramatically [20], and it will probably be necessary to minimize this source of cell-cell variability in order to achieve population synchronous oscillations. This could be achieved by using plasmids with more elaborate mechanisms of copy-number and partitioning control or by integrating the engineered network into the bacterial chromosome.

In addition to parameter differences caused by fluctuations in the number of genes per cell, there are other sources of cell-to-cell variability that cannot easily be minimized. These include variation in growth rates, differences in the concentration of polymerases and of ribosomes, and others. Moreover, genetic manipulations usually introduce rather coarse changes, and it is generally difficult to fine-tune the parameter values that govern the dynamics of individual cells. Therefore, to increase the likelihood of population synchronous oscillations, it is important to have a rather large parameter region where oscillatory dynamics for the isolated element is observed.

We have shown that this can be achieved by increasing the maximal rate (α_3)

of synthesis of one of the repressors (u) from the promoter that is regulated by the autoinducer. The expansion of the oscillatory region also requires an increase of the maximal rate (α_2) of synthesis of the second repressor (v). Our investigation indicates that an increased nonlinearity, i.e., the parameters for promoter cooperativity β, γ, and η, does not significantly expand the region of parameter space where oscillations in isolated elements can be observed. Increasing the value of β (cooperativity for promoter that synthesizes u repressor) actually causes a contraction of the oscillatory region. In addition, to achieve the largest oscillatory region possible, the rate of decay of the autoinducer ε must be as small as possible (of a smaller order of magnitude, $\varepsilon \ll 1$). This may pose an experimental challenge because it implies that the rates of autoinducer synthesis ($\varepsilon \times \alpha_4$) and decay ($\varepsilon$) are at least an order of magnitude lower than the rates of the repressors synthesis (α_1 and α_2) and decay (which is equal to 1). While the maximal rate of autoinducer synthesis could be made low by genetic manipulations, the rate of decay is primarily determined by dilution due to the cell growth. This dilution of course affects all cellular components identically. Moreover, the autoinducer is able to penetrate the cell membrane, and the value of the rate parameter ε depends linearly on the diffusion coefficient D of the autoinducer, which may be large.

For mathematical tractability, our simplified model ignores the fact that the synthesis of the autoinducer is a two-step process that requires the synthesis of the protein LuxI. Taking this step into consideration partially solves the problem with the smallness of ε. First, the additional step introduces a delay in production of the autoinducer. Second, the degradation rate of LuxI is the same as that of the repressors since the LuxI protein is unable to penetrate the cell membrane. As shown by numerical simulations, it is possible to achieve oscillations when the decay rate of the autoinducer is only three times smaller than the decay rates of the repressor proteins. This is in contrast to the simplified model, where an order of magnitude difference was required. In other words, the simplified model may actually underestimate the likelihood of achieving oscillatory dynamics. Further improvement of the gene network toward the ability to oscillate was achieved by the introduction of a promoter that is repressible by the autoinducer and synthesizes protein v, i.e., a negative feedback from the autoinducer to one of the repressors (see section 4.2). Such a promoter has previously been described in the literature [28]. Our simulations demonstrate that the oscillatory region can be substantially increased when this negative feedback is added. It is our belief that this slight variation in the architecture of gene regulatory network would be very useful experimentally as it increases the robustness of single-cell oscillations quite dramatically.

The problem of new equilibria also can be overcome in the experiment if we take into account the LuxI synthesis step and/or introduce the additional network connectivity. In the simplified model, the degradation rate constant of the autoinducer $\bar{\varepsilon}$ must be larger than the coupling coefficient d to avoid the presence of equilibria. On the other hand, $\bar{\varepsilon}$ must be small to provide relaxation type of oscillations, and d must be large enough to synchronize the ensemble. This contradiction is resolved if the second slow process, LuxI synthesis, is taken into account. This introduces an additional delay in production of the autoinducer and allows the rate constants of the autoinducer to take higher values without losing the oscillations. Moreover, these rate constants are expected to take much higher values than the rate constants of the LuxI synthesis because the effective rate of degradation for the autoinducer includes the diffusion coefficient D ($\bar{\varepsilon}_w = D + \delta - \frac{D}{(1+\delta_e/D_e)}$), but the rate of degradation

for LuxI does not ($\bar{\varepsilon}_x = \delta$). Hence, the LuxI dynamics has the function of slowing down the oscillations; its rate constant must be several times smaller than those of the other proteins. The rate constants of the autoinducer can be chosen large enough so that the degradation rate constant is larger than the coupling coefficient: $\bar{\varepsilon}_w > d$. Thus, it is theoretically possible to simultaneously achieve absence of the equilibria and strongly enough attracting synchronous oscillations.

Appendix. Derivation of parametric formula for approximations of bifurcation boundaries.

Appendix A. The saddle-node bifurcation for the toggle switch. We are solving the system which gives the curve of the saddle-node bifurcation for the fast subsystem in the absence of the autoinducer:

$$F(u) = 0, \qquad F'(u) = 0.$$

Substituting the function $F(u)$, defined as (3.3), we can rewrite it in the form

$$\frac{\alpha_1}{1+\left(\frac{\alpha_2}{1+u^\gamma}\right)^\beta} = u, \qquad \left(1+\left(\frac{\alpha_2}{1+u^\gamma}\right)^\beta\right)^2 = \left(\frac{\alpha_2}{1+u^\gamma}\right)^\beta \frac{\alpha_1\beta\gamma u^{\gamma-1}}{1+u^\gamma}. \tag{A.1}$$

We define $R = (\frac{\alpha_2}{1+u^\gamma})^\beta$. From the first equation of the latter system, we have $R = \frac{\alpha_1}{u} - 1$. Using this combination in the second equation of system (A.1), we obtain

$$\left(\frac{\alpha_1}{u}\right)^2 = \left(\frac{\alpha_1}{u} - 1\right)\frac{\alpha_1\beta\gamma u^{\gamma-1}}{1+u^\gamma}, \tag{A.2}$$

or

$$\alpha_1 = \frac{\beta\gamma u^{\gamma+1}}{\beta\gamma u^\gamma - (1+u^\gamma)}. \tag{A.3}$$

R has appeared to be a function of u and depends on γ and β, but it does not depend on α_1 and α_2:

$$R(u) = \frac{\beta\gamma u^\gamma}{\beta\gamma u^\gamma - (1+u^\gamma)} - 1. \tag{A.4}$$

Then, from the definition of R, we have

$$\alpha_2 = (R(u))^{1/\beta}(1+u^\gamma). \tag{A.5}$$

We introduce a parameter $r > 0$, replacing u in the obtained formulas, to show that we have obtained a bifurcation boundary in the space (α_1, α_2) parametrized by an independent parameter. The resulting formulas of the saddle-node bifurcation curve for the fast subsystem in absence of the autoinducer are

$$\begin{aligned} \alpha_1^c &= \frac{\beta\gamma r^{\gamma+1}}{1+r^\gamma} \Big/ \left(\frac{\beta\gamma r^\gamma}{1+r^\gamma} - 1\right), \\ \alpha_2^c &= (1+r^\gamma)\left(\frac{\beta\gamma r^\gamma}{1+r^\gamma} \Big/ \left(\frac{\beta\gamma r^\gamma}{1+r^\gamma} - 1\right) - 1\right)^{1/\beta}. \end{aligned} \tag{A.6}$$

Appendix B. Merging extrema of the function $F(u)$. We have the following condition for merging extrema of a function:

$$F^{'}(u) = 0, \quad F^{''}(u) = 0,$$

which, in our case, takes the form

$$\left(1 + \left(\frac{\alpha_2}{1+u^\gamma}\right)^\beta\right) = \left(\frac{\alpha_2}{1+u^\gamma}\right)^\beta \frac{\alpha_1\beta\gamma u^{\gamma-1}}{1+u^\gamma},$$

$$\left(\frac{\alpha_2}{1+u^\gamma}\right)^\beta = -\frac{(\gamma-1) - u^\gamma(1+\beta\gamma)}{(\gamma-1) + u^\gamma(\beta\gamma-1)}. \tag{B.1}$$

We define $R = (\frac{\alpha_2}{1+u^\gamma})^\beta$. From the second equation of the latter system, we have

$$R = -\frac{(\gamma-1) - u^\gamma(1+\beta\gamma)}{(\gamma-1) + u^\gamma(\beta\gamma-1)}. \tag{B.2}$$

This formula shows again that R has appeared to be a function of u, which depends on γ and β, but does not depend on α_1 and α_2. Performing analogous calculations as in the previous case and introducing an independent parameter r instead of u, we obtain the following parametric representation of the boundary:

$$\alpha_1^m = \left(1 + R_1(r)\right)^2 \left(1 + r^\gamma\right) \Big/ \left(R_1(r)\gamma\beta r^{\gamma-1}\right),$$

$$\alpha_2^m = \left(R_1(r)\right)^{1/\beta} \left(1 + r^\gamma\right), \tag{B.3}$$

where r is the parameter and

$$R_1(r) = -\frac{(\gamma-1) - r^\gamma(1+\beta\gamma)}{(\gamma-1) - r^\gamma(1-\beta\gamma)}. \tag{B.4}$$

Appendix C. The approximation for the Andronov–Hopf bifurcation. The Andronov–Hopf bifurcation curve for vanishing ε is approximated by the curve in the parameter space that corresponds to the intersection of the nullcline of slow motion with the manifold of slow motion in an extremum of the latter:

$$-F(u) + \alpha_3 h(\alpha_4 g(u)) = 0, \quad F'(u) = 0.$$

Let us solve this condition with respect to the parameters α_1 and α_2. This case is very similar to the condition of the boundary for the saddle-node bifurcation for the fast subsystem in the absence of the autoinducer (see Appendix A) because the only difference is the additive term $\alpha_3 h(\alpha_4 g(u))$. This term depends only on u and parameters α_3 and α_4, which gives us a possibility to apply the same steps as in the previous case, defining $R_3(u) = \alpha_3 h(\alpha_4 g(u))$. These calculations give the following curve in (α_1, α_2) parameter plane:

$$\alpha_1^H = \left(1 + R_2(r)\right) / \left(r - R_3(r)\right), \quad \alpha_2^H = \left(R_2(r)\right)^{1/\beta} \left(1 + r^\gamma\right), \tag{C.1}$$

where r is an independent parameter and

$$R_2(r) = \frac{\beta\gamma r^{\gamma-1}\left(r - R_3(r)\right)}{\left(\beta\gamma r^\gamma - r^\gamma - \beta\gamma r^{\gamma-1} R_3(r) - 1\right)} - 1,$$

$$R_3(r) = \alpha_3 \left(\frac{\alpha_4}{1+r^\gamma}\right)^\eta \Big/ \left(1 + \left(\frac{\alpha_4}{1+r^\gamma}\right)^\eta\right). \tag{C.2}$$

THE RIEMANN PROBLEM FOR REVERSIBLE REACTIVE FLOWS WITH METASTABILITY*

ANDREA CORLI† AND HAITAO FAN‡

Abstract. A hyperbolic model for dynamic phase transitions is studied. The model involves three phases: liquid, vapor, and a mixture of them. Metastable regions are present both in the liquid and in the vapor phase.

Results on the behavior of traveling wave profiles of the model, involving viscosity, species diffusion and relaxation, are obtained. These behaviors are consistent with physical intuitions. Admissibility criteria (kinetic relations) that mimic the behavior of traveling wave profiles are then proposed. Admissible basic waves of the model are liquefaction, evaporation, and isobaric waves, in addition to Lax shock and rarefaction waves. Based on these waves, solutions of the Riemann problem for the model are constructed for general Riemann initial data. Most of the physical phenomena are embodied in the solver. For some Riemann initial data solutions are expected to be nonunique. Which solutions actually appear depends on whether nucleation already occurred or not. The model admits both solutions, as it should.

The model also has two other types of waves, collapsing and explosion waves. More complicated solutions involving these two waves are also proposed and discussed.

Key words. Riemann problem, phase transitions, hyperbolic conservation laws

1. Introduction.

In the study of liquid-vapor phase transitions in fluids, one often encounters an intermediate regime where the pure phases are mixed together. The pure phase regions contain metastable subregions. The aim of this paper is to study a simple hyperbolic model of phase transitions that involves all three configurations above as well as metastability. The model in one space dimension for isothermal flow in Lagrangian coordinates is

$$\begin{cases} v_t - u_x = 0, \\ u_t + p(v,\lambda)_x = \epsilon u_{xx}, \\ \lambda_t = \dfrac{a}{\epsilon}(p - p_e)\lambda(\lambda - 1) + b\epsilon\lambda_{xx}. \end{cases} \tag{1.1}$$

Here v denotes the specific volume, u the velocity, $p = p(v,\lambda)$ the pressure, and p_e a fixed equilibrium pressure. The number ϵ denotes a positive viscosity coefficient, and a and b denote two real positive parameters; the ratio ϵ/a is the typical reaction time. The quantity $\lambda \in [0,1]$ is the mass density fraction of vapor in the fluid; therefore $\lambda = 0$ identifies a liquid regime, $\lambda = 1$ a vapor regime, and $\lambda \in (0,1)$ a mixture of two pure phases. The system (1.1) is shown, in [9, 10], to exhibit all major wave patterns observed in shock tube experiments on retrograde fluids [5, 15].

We assume that the pressure p is defined in $(0,+\infty) \times [0,1]$ and satisfies the following essential assumptions:

$$p_v < 0, \qquad p_{vv} > 0, \tag{1.2}$$

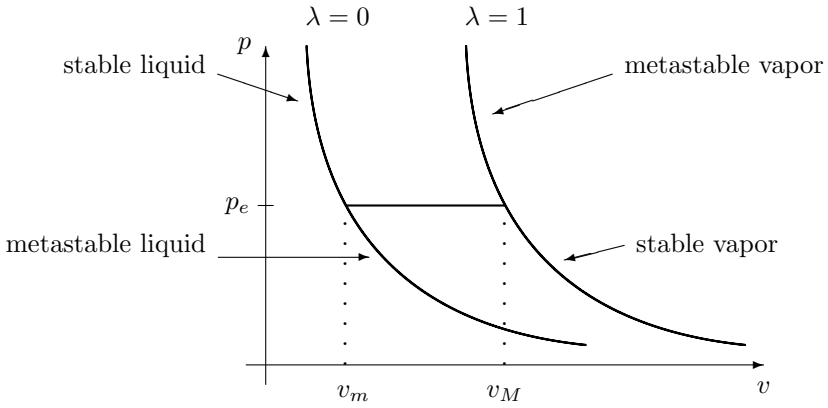

FIG. 1. *Pressure curves.*

$$p_\lambda > 0. \tag{1.3}$$

However, in order to simplify the analysis below, we also require

$$p > 0, \quad \lim_{v \to 0+} p(v, \lambda) = +\infty, \tag{1.4}$$

$$\int^{+\infty} \sqrt{-p_v(v, \lambda)}\, dv = +\infty. \tag{1.5}$$

Both assumptions (1.4) and (1.5) could be dropped by modifying slightly the following. In particular (1.5) prevents the formation of vacuum. An example of pressure satisfying (1.2)–(1.5) is

$$p(v, \lambda) = \frac{1 + \lambda}{v}. \tag{1.6}$$

We define on the v axis the points v_m, respectively, v_M, as the abscissas of the intersections of the curves $p = p(v, 0)$, $p = p_e$ and $p = p(v, 1)$, $p = p_e$; see Figure 1. The part of the graph of the function $p = p(v, 0)$ lying below the line $p = p_e$ is called the *metastable liquid region*, while that of function $p = p(v, 1)$ lying above the line $p = p_e$ is called the *metastable vapor region*. For example, the liquid in metastable liquid region tends to vaporize. But the evaporation will not start until seeds for evaporation, typically tiny vapor bubbles or particles of impurities, are present. The remaining parts of the curves are the *stable liquid* and *stable vapor region*.

Consider then the following initial value problem for system (1.1):

$$\begin{cases} v_t - u_x = 0, \\ u_t + p(v, \lambda)_x = \epsilon u_{xx}, \\ \lambda_t = \dfrac{a}{\epsilon}(p - p_e)\lambda(\lambda - 1) + b\epsilon\lambda_{xx}, \\ (u, v, \lambda)(x, 0) = (u_0, v_0, \lambda_0)(x) = \begin{cases} (u_-, v_-, \lambda_-) & \text{if } x < 0, \\ (u_+, v_+, \lambda_+) & \text{if } x > 0. \end{cases} \end{cases} \tag{1.7}$$

Assume that the problem (1.7) has a solution $(u^\epsilon, v^\epsilon, \lambda^\epsilon)(x, t)$; assume moreover that there is a sequence ϵ_n, $n = 1, 2, \ldots$, with $\epsilon_n \to 0+$ as $n \to \infty$, such that the limit

$$(u, v, \lambda)(x, t) := \lim_{n \to \infty} (u^{\epsilon_n}, v^{\epsilon_n}, \lambda^{\epsilon_n})(x, t)$$

exists in some strong sense, such as pointwise. Then the limit satisfies the Riemann problem

$$\begin{cases} v_t - u_x = 0, \\ u_t + p(v,\lambda)_x = 0, \\ (p(v,\lambda) - p_e)\,\lambda(\lambda-1) = 0, \\ (u,v,\lambda)(x,0) = (u_0,v_0,\lambda_0)(x). \end{cases} \tag{1.8}$$

Remark that under assumption (1.2), the first two equations of (1.8) form a strictly hyperbolic system of conservation laws with eigenvalues $-\sqrt{-p_v(v,\lambda)}$, $\sqrt{-p_v(v,\lambda)}$. The third equation imposes some constraints on the states under consideration. The Riemann problem (1.8) is the object of our investigations. Remark that analogously to [2, 3] the first three equations in (1.8) can be understood by eliminating λ as

$$\begin{cases} v_t - u_x = 0, \\ u_t + p(v,0)_x = 0, \\ (v,u) \in \Omega_0, \end{cases} \qquad \begin{cases} v_t - u_x = 0, \\ u_t = 0, \\ (v,u) \in \Omega_*, \end{cases} \qquad \begin{cases} v_t - u_x = 0, \\ u_t + p(v,1)_x = 0, \\ (v,u) \in \Omega_1, \end{cases} \tag{1.9}$$

where $\Omega_0 = \Omega_1 = (0,+\infty)\times(-\infty,+\infty)$, $\Omega_* = [v_m, v_M]\times(-\infty,+\infty)$.

The structure of solutions of (1.8) is easier to obtain than that of (1.7). Nevertheless, we want to keep track as much as possible of the derivation of the latter from the former system, and we shall focus on solutions of (1.8) that are some type of strong limits of solutions of (1.7) as $\epsilon_n \to 0$ for some sequence $\{\epsilon_n\}$.

From the third equation in (1.8) it is clear that piecewise smooth solutions of (1.8) consist of smooth pieces satisfying either

$$\lambda = 0 \quad \text{or} \quad \lambda = 1 \tag{1.10}$$

or

$$p = p_e. \tag{1.11}$$

In order to have solutions to the Riemann problem (1.8) which mimic as far as possible solutions of (1.7), we choose waves of (1.8) which have traveling wave profiles of (1.7). This choice is a way to impose kinetic relations [1, 12], which imposes admissibility restrictions on waves of conservation laws. However, the results about traveling waves at our disposal (see [7, 9]) are not sufficient to guarantee the existence of a solution for every set of initial data. Nevertheless, the behavior of traveling waves, carrying physical meanings, can serve as a guide for kinetic relations for (1.8). To guarantee the existence of solutions for general Riemann initial data, we shall supplement (1.8) with kinetic relations whose behaviors are consistent with the relevant behavior of traveling waves of (1.7).

One should not expect one kinetic relation that is independent of time to be valid for all time $t > 0$. Consider Shearer's type of nonunique solutions [13]: The Riemann initial data represents a tube of metastable vapor, i.e., $\lambda = 1$, $p > p_e$, flowing at a given speed towards the center. For this type of data, the system (1.8) has two Riemann solutions, one without phase boundary and the other with two phase boundaries moving apart from the center. The center is occupied by liquid. There are studies utilizing different kinetic relations that favor one of them over the other. We want to say that both solutions are good, but good at different time periods: As time t starts to increase from 0, there is no seed, such as a liquid drop, to start

the condensation; the vapor will stay as vapor for a sizable period of time. Thus, at the early stage, the solution without phase boundary is appropriate. As $t \to \infty$, liquid drops will form through nucleation and the condensation will eventually happen, resulting in phase boundaries, and the fluid will eventually settle down in the stable phase. This clearly shows that the solution without phase boundary is valid only up to a certain finite time, so is the kinetic relation that picks this solution. The process as t increases from 0 is as follows: After some time, a liquid drop is formed though a random fluctuation (or nucleation) process. This liquid drop serves as a seed for condensation. Since the surrounding vapor is in the metastable region, further condensation will occur around this liquid drop, resulting in the growth of the liquid or liquid/vapor mixture region. For this time period, the solution with two phase boundaries moving out, with the liquid drop in the center and metastable vapor on outer sides, is appropriate. This example illustrates that for a different time period, different Riemann solvers should be employed. Thus, any admissibility criterion that favors one of the solutions over the other is applicable only for one of time intervals:

$$[0, T_{\text{initiation of the 1st drop}}),$$

$$[T_{\text{initiation of the 1st drop}}, T_{\text{initiation of the 2nd drop}}), \dots$$

The nucleation is a random process, and hence $T_{\text{initiation of the 1st drop}}$ is a random variable. Since the model does not include the nucleation mechanism directly in the equations, the model should allow both solutions, with additional admissibility criterion stating when and which one of them is admissible.

In this paper, we proposed the admissibility criterion applicable in the first time interval. Under this kinetic condition, we can finally prove the existence of a global Riemann solver which singles out solutions uniquely.

Riemann solutions involve many kinds of elementary waves. First of all, liquefaction and evaporation waves may arise in the connection of two different pure phases; they can be either subsonic or sonic. In the latter case, our solver admits rarefaction waves attached to them. This pattern appears also in solution of systems where genuinely nonlinearity fails [12] as well as in combustion theory [11, 2]. A selection criterion is imposed to both liquefaction and evaporation waves in order to find a unique solution to the Riemann problem; if profiles exist, the criterion amounts to choosing the wave traveling with the slowest speed (in absolute value). Moreover it is required that, if we fix a state in back of the phase transition, then the speed of the phase boundary increases if $|p(v_-, \lambda_-) - p_e|$ increases; here (v_-, λ_-) is the state in the back. This requirement has a physical ground and is satisfied by the traveling wave profile having the slowest speed. We refer to [3] for a Riemann solver that applies to deflagration waves having both rarefaction waves attached to a sonic phase boundary and a superimposed kinetic condition. Liquefaction and evaporation waves may arise also in the connection of a pure phase with a mixture phase; also in this case they can be either subsonic or sonic. No selection condition is needed for this case.

Another kind of waves are the isobaric waves, along which the pressure equals the equilibrium pressure p_e; they are stationary and require no kinetic condition. Lax shocks and rarefaction waves in the pure phases complete the set of elementary waves.

This paper is organized as follows. In section 2 we list all possible elementary waves of (1.8). They are reacting or nonreacting shock waves, nonreacting rarefaction waves, and isobaric waves. The existence of traveling wave profiles to some reacting shocks, namely liquefaction and evaporation waves, was established in [7, 9]; in

section 3 we continue the analysis started with those papers. We show first that liquefaction (and evaporation) profiles are monotone; moreover, if the state v_- in the back is fixed, then among these profiles there is a slowest one. Our main result in this section is that the speed of the slowest profile is a decreasing (respectively, increasing) function of v_-. Kinetic conditions are given in section 4. In section 5, using the elementary waves and the related kinetic conditions, we construct solutions to the Riemann problem (1.8) for arbitrary Riemann data; comments about our Riemann solver are gathered at the end of this section. Numerical works in [10] indicated the existence of another two kinds of reacting shocks. They are explosion waves and collapsing waves. In section 6 we show through some examples how these waves may be used to obtain a different Riemann solver.

2. Basic admissible waves. In this section we introduce the elementary waves to be used in the following. We state as well some results proved elsewhere about the existence of traveling wave profiles. If a wave has such a profile, we call it *admissible*.

We review now some simple facts about solutions to (1.8), (1.7). Recall that we consider only states (v, u, λ) satisfying either (1.10) or (1.11).

Let us fix two states (v_-, u_-, λ_-) and (v_+, u_+, λ_+). If they are connected by a wave having a jump discontinuity with speed c, then the Rankine–Hugoniot conditions must hold:

$$\begin{cases} -c[v] - [u] = 0, \\ -c[u] + [p] = 0. \end{cases} \tag{2.1}$$

From these equations it follows that

$$c^2 = -\frac{p(v_+, \lambda_+) - p(v_-, \lambda_-)}{v_+ - v_-}. \tag{2.2}$$

Remark then that a necessary condition for a jump to take place is that in the plane (v, p) the line joining $(v_-, p(v_-))$ and $(v_+, p(v_+))$ has negative slope.

Traveling waves of (1.7) are solutions of

$$\begin{cases} -cv' - u' = 0, \\ -cu' + p(v, \lambda)' = u'', \\ -c\lambda' = aw(v, \lambda) + b\lambda'', \\ (v, u, \lambda)(\pm\infty) = (v_\pm, u_\pm, \lambda_\pm), \quad (v', u', \lambda')(\pm\infty) = (0, 0, 0), \end{cases} \tag{2.3}$$

where $w(v, \lambda) = (p - p_e)\lambda(\lambda - 1)$ and prime ($'$) denotes $d/d\xi$ with $\xi = (x - ct)/\epsilon$. Here the data $(v_\pm, u_\pm, \lambda_\pm)$ satisfy the Rankine–Hugoniot conditions (2.1). Remark that (2.3) implies

$$\begin{cases} -cv' = c^2(v - v_-) + p - p_-, \\ -c\lambda' = a(p - p_e)\lambda(\lambda - 1) + b\lambda''. \end{cases} \tag{2.4}$$

For simplicity in the rest of this section we refer only to the case of phase boundaries with *nonnegative* wave speeds. Then the speed of a phase boundary joining (v_-, u_-, λ_-) and (v_+, u_+, λ_+) is

$$c = \sqrt{-\frac{p(v_+, \lambda_+) - p(v_-, \lambda_-)}{v_+ - v_-}}\,. \tag{2.5}$$

Phase boundaries with negative speeds can be obtained by interchanging the left and right side of phase boundaries with positive speeds.

(i) *Liquefaction waves.* After a liquefaction wave passes, the state of fluid changes from vapor or vapor/liquid mixture ($v_+, \lambda_+ \neq 0$) to liquid ($v_-, \lambda_- = 0$); see Figure 2(a)–(b). Further requirements on the data are
(a) either

$$\lambda_- = 0,\ \lambda_+ = 1, \qquad v_- < v_+, \qquad p(v_-, \lambda_-) > p(v_+, \lambda_+) \geq p_e \tag{2.6}$$

(b) or

$$\lambda_- = 0,\ 0 < \lambda_+ < 1, \qquad v_- < v_+, \qquad p(v_-, \lambda_-) > p(v_+, \lambda_+) = p_e. \tag{2.7}$$

Under either (2.6) or (2.7), it is shown in [7] and [9] that admissible waves exist if

$$c \geq 2\sqrt{ab|p(v_-, \lambda_-) - p_e|}, \tag{2.8}$$

$$c^2 + p_v\,(v_\pm, \lambda_\pm) < 0, \tag{2.9}$$

and there is no other equilibrium point of (2.3), with v value between v_- and v_+. On the other hand, if the speeds satisfy

$$c < 2\sqrt{ab|p(v_+, \lambda_+) - p_e|}, \tag{2.10}$$

then there are no admissible liquefaction waves.
Condition (2.9) means that a liquefaction wave is subsonic or sonic with respect to both side states. The absolute value in (2.8) and (2.10) is not necessary in this case, but it has been put in order to have a unique condition valid also for the next case. Note that in case (i)(b), the condition (2.10) does not impose any restriction.
We further observe through numerical computation that for case (i)(b), there is always a traveling wave as long as $\lambda_+ \in (0, 1)$, even if (2.8) is not satisfied.

(ii) *Evaporation waves.* The state in front of an evaporation wave is metastable liquid: $(v_+, \lambda_+ = 0)$ with $p_+ < p_e$. In the back of the evaporation shock is vapor: $(v_-, \lambda_- = 1)$ with $v_- > v_+$ and $p_- < p_+ < p_e$; see Figure 2(c)–(d). We require moreover that
(a) either

$$\lambda_- = 1,\ \lambda_+ = 0,\ v_- > v_+,\ p(v_-, \lambda_-) < p(v_+, \lambda_+) \leq p_e \tag{2.11}$$

(b) or

$$\lambda_- = 1,\ 0 < \lambda_+ < 1,\ v_- > v_+,\ p(v_-, \lambda_-) < p(v_+, \lambda_+) = p_e\ .$$

Results about the admissibility of evaporation waves are given in [7], [9]: if conditions (2.8), (2.9) hold and there is no other equilibrium point of (2.3) with v value between v_- and v_+, then the evaporation wave is admissible. Similarly, under the condition (2.10), there is no admissible evaporation wave. Our numerical tests show that there is a traveling wave for case (ii)(b) as long as $\lambda_+ \in (0, 1)$, even if (2.8) is not satisfied.

(iii) *Isobaric waves.* Smooth isobaric waves are solutions of (1.8) with

$$p\,(v(x,t), \lambda(x,t)) = p_e \tag{2.12}$$

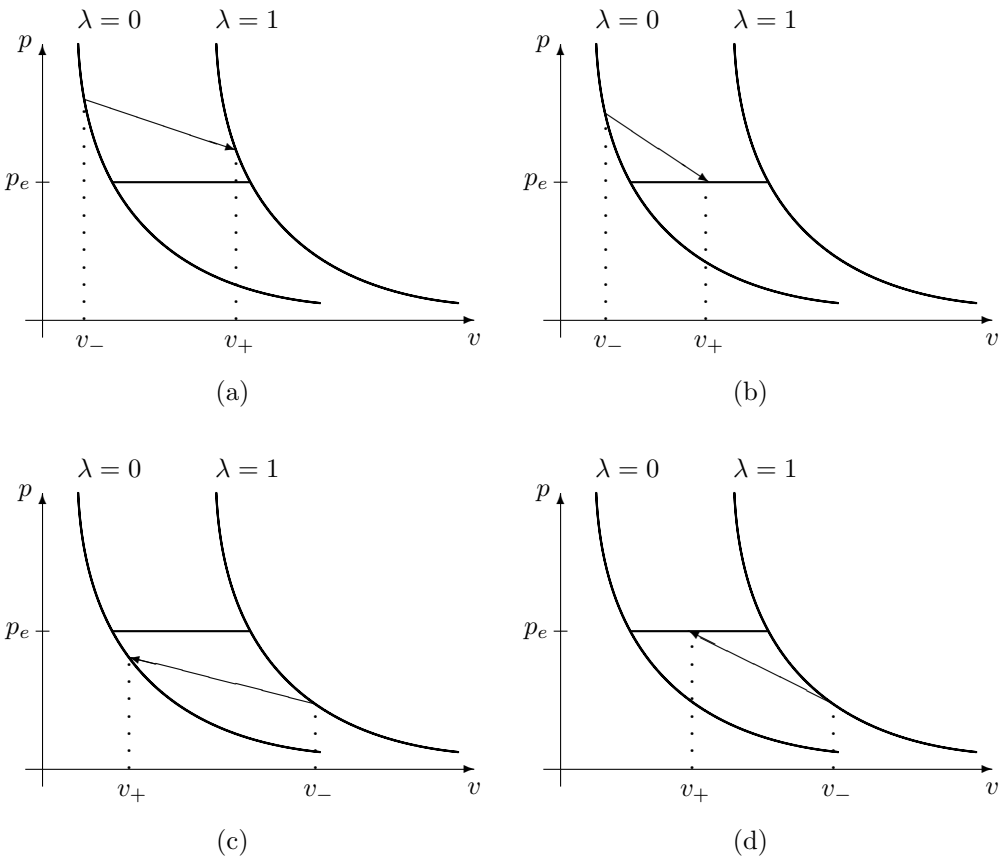

FIG. 2. *Admissible waves.* (a) *and* (b), *liquefaction shocks;* (c) *and* (d), *evaporation shocks.*

for (x,t) in some region D called isobaric region. For convenience, suppose D contains a rectangle $[a,b]\times[t_0,t_1]$. Then in this rectangle we have

$$\begin{cases} u = u(x,t_0), \\ v = u_x(x,t_0)(t-t_0) + v(x,t_0), \\ \lambda = \lambda_e(v(x,t)), \end{cases} \tag{2.13}$$

where the last equation is the explicit form of (2.12), which exists due to $p_\lambda > 0$. Two constant states (v_-,u_-,λ_-), (v_+,u_+,λ_+) are connected by an isobaric wave only if $p(v_-,\lambda_-) = p(v_+,\lambda_+) = p_e$; as a consequence the wave is stationary and $u_+ = u_-$.

(iv) *Nonreacting compressive shock waves.* Under the assumption (1.2) the nonreacting shocks must satisfy $\lambda_- = \lambda_+ = 0$ or 1 and the Lax admissibility conditions

(a) either (1-shocks)

$$-\sqrt{-p_v(v_-,\lambda_-)} > c > -\sqrt{-p_v(v_+,\lambda_+)}$$

(b) or (2 shocks)

$$\sqrt{-p_v(v_-,\lambda_-)} > c > \sqrt{-p_v(v_+,\lambda_+)},$$

where c is the speed of the wave determined by the Rankine–Hugoniot conditions. Due to the assumption $p_{vv} > 0$, we have $\text{sign}\partial_{v_\pm} c = -\text{sign}c$ for both Lax shocks. We shall use these inequalities when solving Riemann problems.

(v) *Nonreacting rarefaction waves.* These are continuous solutions of (1.8) of the form $(u, v, \lambda)(x, t) = (u, v, \lambda)(x/t)$ with $\lambda =$ constant. By the third equation in (1.8), we have $\lambda(x, t) \equiv \lambda_\pm = 0$ or 1, and the system (1.8) is reduced to the nonreacting p-system for gas dynamics. Thus, the nonreacting rarefaction waves are the same as the classical rarefaction waves in gas dynamics:

(a) first family of rarefaction waves,

$$u_+ - u_- = \int_{v_-}^{v_+} \sqrt{-p_v(v,\lambda_-)}dv, \quad v_- < v_+; \tag{2.14}$$

(b) second family of rarefaction waves,

$$u_+ - u_- = -\int_{v_-}^{v_+} \sqrt{-p_v(v,\lambda_-)}dv, \quad v_- > v_+. \tag{2.15}$$

Remark 2.1. We consider again the case of a right-moving liquefaction wave; see (i) above. For a *fixed* v_- we denote the speed of the liquefaction wave connecting v_- with v_+ by $c(v_+)$. It is easy to check that the function $c(v_+)$ is increasing when (2.9) holds. We define v^* by the relation $c(v^*) = 2\sqrt{ab(p(v_-, 0) - p_e)}$. Moreover, consider the line joining $(v_-, p(v_-, 0))$ with $(v_+, p(v_+, 1))$ and let $(v^T, p(v^T, 1))$ be the point in which this line is tangent to the curve $p(v, 1)$. As a consequence of the conditions (2.8) and (2.9), we see that the existence of liquefaction waves connecting v_- with v_+ is ensured if $v_+ \in [v^*, \min\{v^T, v_M\}]$. In the case that the pressure has the form (1.6) then a simple calculation shows that the interval $[v^*, \min\{v^T, v_M\}]$ is never empty for any $v_- \le v_m$ if ab is sufficiently small. In other words, for these values of ab for every v_- we have, in the state space, a whole curve of admissible liquefaction waves.

For the evaporation shocks, the situation is somewhat different: For any fixed $ab > 0$ and as $v_- \to \infty$, the $c(v^*) = 2\sqrt{ab(p(v_-, 1) - p_e)}$ will become bigger than the slope of the tangent of $p(v, 1)$, destroying the possibility of a direct traveling wave link from (v_-, λ_-) to (v_+, λ_+). Thus, for any fixed $ab > 0$, there is an upper bound for v_- so that there is no evaporation wave with v_- above this bound.

The class of admissible waves could be enlarged by admitting the collapsing and explosion waves introduced below. One side of these waves is an equilibrium mixture of liquid and vapor, while the other side is metastable liquid or vapor. Such waves are numerically verified to exist by computing some initial value problems of (1.7) for t not small. The numerical results revealed the following: For these kinds of waves to appear, the pressure of the metastable side must differ from equilibrium by a certain amount. Such waves cannot appear in a Riemann solver when the Riemann initial data consist of a piece of liquid and a piece of vapor unless the initial data is set such that the pressure of the metastable side differs sufficiently from equilibrium. The reason for this phenomenon is left for future investigation. It is clear that if these waves appear in Riemann solvers for such Riemann data, a severe loss of uniqueness will occur. For these reasons we consider the following waves separately.

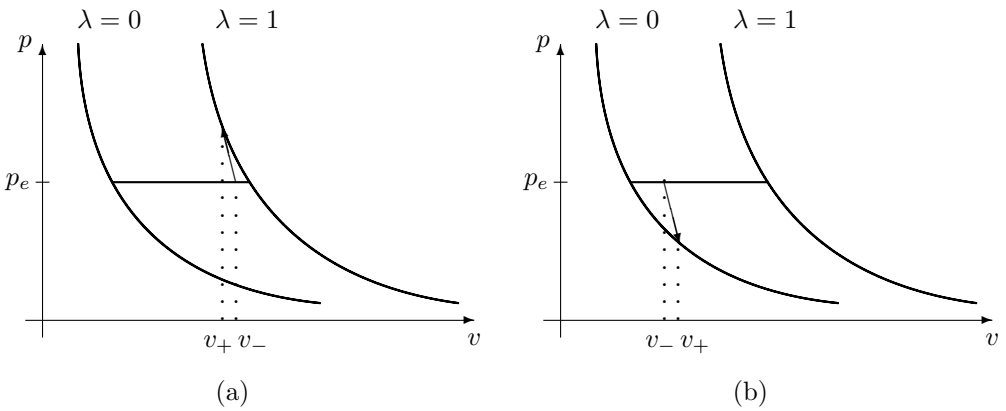

FIG. 3. *Other waves.* (a) *collapsing shock;* (b) *explosion shock.*

(vi) *Collapsing waves.* As a collapsing wave passes through the metastable vapor, $\lambda_+ = 1$, $p_+ > p_e$, the fluid changes to a liquid/vapor mixture at equilibrium pressure, $p_- = p_e$, $\lambda_- \in (0,1)$; see Figure 3(a). Although this is also a kind of liquefaction shock, we single it out to emphasize that it is supersonic relative to its front and that the pressure drops after the shock passes.

(vii) *Explosion waves.* In the front of an explosion wave there is metastable liquid, $\lambda_+ = 0$, $p_+ < p_e$. Behind the wave is a liquid/vapor mixture at equilibrium pressure, $p_- = p_e$, $\lambda_- \in (0,1)$. The Rankine–Hugoniot condition then requires $v_+ > v_-$. See Figure 3(b). Also these waves are supersonic with respect to the state in front.

3. Properties of admissible waves. In this section we study some properties of the admissible waves listed in section 2; these properties provide motivations for the kinetic conditions that are given in section 4.

Throughout this section we denote (v_-, λ_-) the state behind a shock, (v_+, λ_+) the state in front, while $c = c(v_-, v_+)$ is given by (2.5). For simplicity we deal only with the case $c > 0$.

LEMMA 3.1. *If* $c^2 + p_v(v_\pm, \lambda_\pm) < 0$, *with* $\lambda_- = 0$, $\lambda_+ = 1$, *then the equation*

$$R(v, \lambda; c) := c^2(v - v_-) + p(v, \lambda) - p(v_-, 0) = 0 \tag{3.1}$$

has a unique solution $v := v(\lambda)$. *This solution satisfies*

$$R_v\left(v(\lambda), \lambda; c\right) < 0. \tag{3.2}$$

Proof. Existence of a solution $v(\lambda)$ of $R(v, \lambda; c) = 0$ follows from $R_\lambda = p_\lambda > 0$ and then, for $\lambda \in (0,1)$,

$$R(v_-, \lambda; c) > R(v_-, 0; c) = 0 = R(v_+, 1; c) > R(v_+, \lambda; c).$$

To prove the uniqueness of the solution $v(\lambda)$, assume its contrary, i.e., that there are two solutions of the equation $R(v, \lambda_0; c) = 0$ for some $\lambda_0 \in (0,1)$, $v_1(\lambda_0)$, and $v_2(\lambda_0)$. Without loss of generality, let $v_1(\lambda_0) < v_2(\lambda_0)$ denote the smallest two such solutions.

Thus, there are no other zeros between $v_1(\lambda_0)$ and $v_2(\lambda_0)$. Note that $R_{vv} = p_{vv} > 0$ and $R_v(v_-, 0; c) = c^2 + p_v(v_-, 0) < 0$. Then

$$R_v(v_1, \lambda_0; c) < 0 < R_v(v_2, \lambda_0; c) \tag{3.3}$$

and hence

$$R_v(v, \lambda_0; c) > 0 \quad \text{for } v \in (v_2, v_+) \tag{3.4}$$

holds. It leads to a contradiction:

$$0 = R(v_+, 1; c) > R(v_+, \lambda_0; c) > R(v_2, \lambda_0; c) = 0, \tag{3.5}$$

which establishes the uniqueness of $v(\lambda)$.

If there was a point $\lambda_0 \in (0, 1)$ such that $R_v(v(\lambda_0), \lambda_0; c) \geq 0$ holds, then the argument from (3.3) to (3.5) would apply to yield a contradiction. This shows that $R_v(v(\lambda), \lambda; c) < 0$ for $\lambda \in [0, 1]$, as desired. □

LEMMA 3.2. *Under the assumptions of the previous lemma, every liquefaction (evaporation) traveling wave connecting (v_-, λ_-) with (v_+, λ_+) is monotone.*

Proof. We deal with the case of a liquefaction wave. In the (λ, v)-plane, consider the strip $S = \{(\lambda, v) : \ 0 \leq \lambda \leq 1, v > 0\}$. Denote $\mathcal{R}_0 = \{(\lambda, v);\ R(v, \lambda) = 0\}$ and

$$\mathcal{R}_- = \{(\lambda, v) \in S;\ R(v, \lambda) < 0\},$$
$$\mathcal{R}_+ = \{(\lambda, v) \in S;\ R(v, \lambda) > 0\}.$$

For contradiction, assume that there exists a profile $(v(\xi), \lambda(\xi))$ with $v'(\xi_0) = 0$ for some ξ_0. When $(v(\xi), \lambda(\xi))$ starts from $(v_-, 0)$ it must enter the region $\mathcal{R}_-$; otherwise $v'(\xi) < 0$ for every ξ and then it could not reach the point $(v_+, 1)$. From (2.4), when $\xi = \xi_0$ the trajectory $(v(\xi), \lambda(\xi))$ meets the curve $\mathcal{R}_0$. The curve $\mathcal{R}_0$, parameterized as $v(\lambda)$, is increasing as λ increases, as shown by

$$\frac{dv}{d\lambda} = -\frac{R_\lambda}{R_v} = -\frac{p_\lambda}{R_v} > 0$$

in view of Lemma 3.1. Thus, $v'(\xi) < 0$ for every $\xi > \xi_0$ and so the point $(v_+, 1)$ cannot be reached, a contradiction.

If λ is not monotone, then there exists the smallest critical point ξ_0, which must be a local maximum, and then a critical point ξ_1, adjacent to ξ_0, which must be a local minimum point. From the second equation of (2.4) we have $p(v(\xi_0), \lambda(\xi_0)) \leq p_e$. If $\xi \in (\xi_0, \xi_1)$, then $\lambda(\xi)$ is decreasing while $v(\xi)$ is increasing; then $p(v(\xi_1), \lambda(\xi_1)) < p_e$ from the first equation of (2.4). But then at ξ_1 we should have $0 = a(p - p_e)\lambda(\lambda - 1) + b\lambda'' > 0$, a contradiction. □

Remark that in the plane (λ, v) the curve $\{(\lambda, v);\ p(v, \lambda) = p_e\}$ lies all above the curve $\mathcal{R}_0$; see Figure 4. In fact, if $v(\lambda)$ is as in Lemma 3.1, then $v'(\lambda) > 0$. By differentiating (3.1) with respect to λ we obtain $c^2 v'(\lambda) + d/d\lambda[p\,(v(\lambda), \lambda)] = 0$, and thus p is decreasing along the curve $\mathcal{R}_0$. Since $v_- < v_m$ and $v_+ < v_M$, the claim is proved.

LEMMA 3.3. *Fix a state (v_-, λ_-), $\lambda_- = 0$ (or 1). If there are liquefaction (evaporation) waves having (v_-, λ_-) as the back state, then there is one with the least speed.*

Proof. We now consider the case for liquefaction waves. The proof for evaporation waves is the same.

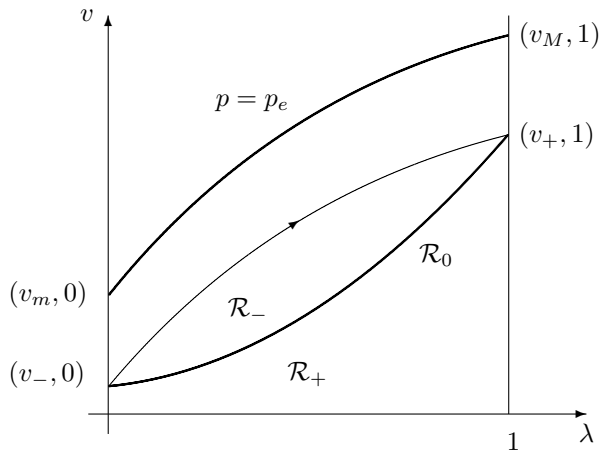

FIG. 4. *Profile in the plane* (λ, v). *The curves* $\mathcal{R}_0$ *and* $p = p_e$ *are represented by thickness, the profile with a thin line.*

Fix a state $(v_-, 0)$ and consider the set $\mathcal{P}(v_-)$ of all states $(v_+, 1)$ that can be connected to $(v_-, 0)$ with a liquefaction wave. These traveling waves satisfy (2.4), and from Lemma 3.2 they are monotone. Let

$$\omega = \inf_{v_+ \in \mathcal{P}(v_-)} c(v_-, v_+) \, .$$

Take a sequence $v_n \in \mathcal{P}(v_-)$ such that $c(v_-, v_n) \to \omega$ as $n \to +\infty$, and let

$$(v(\xi; v_-, v_n), \lambda(\xi; v_-, v_n))$$

be the related traveling waves. Note that a shift of a traveling wave solution of (2.3) is still a traveling wave with the same speed. By shifting we can assume that for every n

$$\lambda(0; v_-, v_n) = 1/2 \, .$$

Due to (1.3), $v_n \le v_1$ for large n to make possible $c(v_-, v_n) \to \omega$, as $n \to \infty$. We have that for large n, $\mathrm{TV}(v(\cdot; v_-, v_n)) \le |v_+ - v_1|$, $\mathrm{TV}(\lambda(\cdot; v_-, v_n)) = 1$ since they are monotone. Then there exists a subsequence converging a.e. to some functions $(v_*(\xi), \lambda_*(\xi))$.

The functions $v_*(\xi)$, $\lambda_*(\xi)$ still satisfy (2.4) and are monotone. They are not constant because $\lambda_*(0) = 1/2$ is not an equilibrium point of (2.4). Then they satisfy the conditions $v_*(\pm\infty) = v_\pm$, $\lambda_*(-\infty) = 0$, $\lambda_*(+\infty) = 1$. Thus, $(v_*(\xi), \lambda_*(\xi))$ is a traveling wave with the minimum speed. □

We denote the lowest speed of a liquefaction (evaporation) wave by $\omega(v_-, \lambda_-)$.

THEOREM 3.1. *The function* $v_- \to \omega(v_-, \lambda_-)$ *introduced above is decreasing in the case of a liquefaction wave, increasing in the case of an evaporation wave.*

Proof. For definiteness, we prove the statement for a liquefaction wave. For an evaporation wave the proof is analogous.

In the case of a liquefaction wave, the state λ behind the wave is $\lambda_- = 0$. Consider v_- in the domain of definition of the function $\omega(v_-, 0)$. By the definition of $\omega(v_-, 0)$, there is a solution of (2.4) starting at $v(-\infty) = v_-$, and the slowest nonnegative speed of such traveling waves is $\omega(v_-, 0)$, which connects $(v_\pm, \lambda_\pm)$ as depicted in Figure 2(a). We denote this slowest traveling wave by $(v_1, \lambda_1)(\xi; v_-)$.

We want to prove that

$$\omega := \omega(v_-, 0) \geq \omega(v_-^*, 0) \tag{3.6}$$

if $v_- < v_-^* < v_m$ with v_-^* sufficiently close to v_-. It suffices to prove that for such v_-^*, there is a solution of (2.4) with speed $c = \omega$ starting from $v(-\infty) = v_-^*$. The other side of the traveling wave $v(\infty) = v_+^*$ must satisfy the Rankine–Hugoniot condition

$$\omega^2(v_+^* - v_-^*) + p(v_+^*, 1) - p(v_-^*, 0) = 0. \tag{3.7}$$

Due to the subsonicity at $(v_\pm, p(v_\pm, \lambda_\pm))$, the smallness of $|v_- - v_-^*|$, and the shape of $p(v, \lambda)$ given by (1.2) and (1.3), there must be the smallest solution of (3.7) satisfying $v_+^* > v_+$. We rewrite and modify the system (2.4) of traveling waves connecting $v_\pm^*$ as

$$\begin{cases} -\omega v' = \omega^2(v - v_-^*) + p - p_-^* + \eta v'', \\ -\omega \lambda' = aw(v, \lambda) + b\lambda'', \\ (v, \lambda)(\pm\infty) = (v_\pm^*, \lambda_\pm), \quad (v', \lambda')(\pm\infty) = (0, 0). \end{cases} \tag{3.8}$$

We shall take the limit $\eta \to 0+$ later. By Theorems 3.1 and 3.1′ in [9] and the analysis therein, a necessary and sufficient condition for (3.8) with data given in (i) and (ii) of section 2 to have a solution is

$$\omega \geq \inf_{U \in K} \sup_{x,j} \frac{a_j U_j'' + F_j(U, \omega)}{-U_j'}, \tag{3.9}$$

where

$$\begin{aligned} U &= (v, \lambda), \\ F(U, \omega) &= \left(\omega^2(v - v_-^*) + p - p_-^* \;\; a(p - p_e)\lambda(\lambda - 1)\right), \end{aligned}$$

with $a_1 = \eta$, $a_2 = b$, and

$$K := \{U \in C^2 \;:\; U \text{ is monotone and } U(\pm\infty) = (v_\pm^*, \lambda_\pm)\}. \tag{3.10}$$

We now apply Lemma 3.1; then denote by $v_2 := v(\lambda)$ the unique solution of the equation

$$R(v, \lambda; \omega) := \omega^2(v - v_-^*) + p(v, \lambda) - p(v_-^*, 0) = 0. \tag{3.11}$$

We consider the function

$$v_2^*(\xi) := v_2(\lambda_1(\xi)).$$

It is clear that $v_2^*(\pm\infty) = v_\pm^*$. Let $\delta > 0$ be a sufficiently small constant. The intervals $(-\infty, \xi_-)$ over which $v_2^*(\xi) > v_1(\xi) + \delta$ are nonempty since $v_2^*(-\infty) = v_-^* > v_- = v_1(-\infty)$. Let $(-\infty, \xi_-)$ denote the largest such interval, and hence either $\xi_- = \infty$ or $v_1(\xi_-) + \delta = v_2^*(\xi_-)$ holds. If it is the later case, then there is an interval (ξ_+, ∞) over which $v_1(\xi) + \delta < v_2^*(\xi)$ and $v_1(\xi_+) + \delta = v_2^*(\xi_+)$ hold. Due to (3.2), the function $v_2^*(\xi)$ is strictly increasing since $\lambda_1' > 0$. We can construct a function $v_3^* \in C^2$ satisfying

$$v_3^*(\xi) = \begin{cases} v_2^*(\xi) & \text{if } \xi < \xi_- - 1, \\ \text{joining the left and right branches in } C^2 & \text{if } \xi_- - 1 < \xi < \xi_-, \\ v_1(\xi) + \delta & \text{if } \xi_- < \xi < \xi_+, \\ \text{joining the left and right branches in } C^2 & \text{if } \xi_+ < \xi < \xi_+ + 1, \\ v_2^*(\xi) & \text{if } \xi > \xi_+ + 1. \end{cases} \tag{3.12}$$

The joining pieces in (3.12) can be made to satisfy $v_3^{*'} > 0$ and $v_1 + \delta < v_3^* < v_2^*$ for $\xi \in (\xi_- - 1, \xi_-) \cup (\xi_+, \xi_+ + 1)$.

It is clear that $(v_3^*, \lambda_1) \in K$ as defined in (3.10). Also, the function v_3^* is independent of η. Since $(v_1, \lambda_1)(\xi, v_-)$ is a traveling wave of speed ω joining $(v_\pm, \lambda_\pm)$, it follows that

$$\begin{aligned} \omega &= \frac{-b\lambda_1'' - a(p(v_1, \lambda_1) - p_e)\lambda_1(\lambda_1 - 1)}{\lambda_1'} \\ &> \frac{-b\lambda_1'' - a(p(v_1 + \delta, \lambda_1) - p_e)\lambda_1(\lambda_1 - 1)}{\lambda_1'} \\ &\geq \frac{-b\lambda_1'' - a(p(v_3^*, \lambda_1) - p_e)\lambda_1(\lambda_1 - 1)}{\lambda_1'} \end{aligned} \tag{3.13}$$

since $v_3^* \geq v_1 + \delta$. To estimate the other component of (3.9), we consider

$$\frac{\eta v_3^{*''} + \omega^2(v_3^* - v_-^*) + p(v_3^*, \lambda_1) - p_-^*}{-v_3^{*'}}. \tag{3.14}$$

Over the range $(-\infty, \xi_-) \cup (\xi_+, \infty)$, we use $v_3^* \leq v_2^*$ and (3.11) to derive

$$\begin{aligned} \omega^2(v_3^* - v_-^*) + p(v_3^*, \lambda_1) - p_-^* &= \omega^2(v_3^* - v_2^*) + p(v_3^*, \lambda_1) - p(v_2^*, \lambda_1) \\ &= R_v(\theta, \lambda_1; \omega)(v_3^* - v_2^*) \geq 0. \end{aligned}$$

Here, we used the smallness of $|v_2^* - v_3^*|$ and Lemma 3.1. Then the inequality $v_3^{*\prime} > 0$ yields

$$\frac{\eta v_3^{*''} + \omega^2(v_3^* - v_-^*) + p(v_3^*, \lambda_1) - p_-^*}{-v_3^{*'}} \leq -\eta \frac{v_3^{*''}}{v_3^{*'}}. \tag{3.15}$$

On intervals $(-\infty, \xi_- - 1)$ and $(\xi_+ + 1, \infty)$, the definition of v_3^* implies that

$$\frac{v_3^{*''}}{v_3^{*'}} = O(1) + O(1)\frac{\lambda_1''}{\lambda_1'}.$$

For the traveling wave $(v_1, \lambda_1)(\xi)$, we can prove that

$$\frac{\lambda_1''}{\lambda_1'} = O(1)$$

by investigating the decay rate of $\lambda_1(\xi)$ at $\xi = \pm\infty$ and by $v_1' > 0$ proved in the proof of Lemma 3.2. Over the intervals $[\xi_- - 1, \xi_-)$ and $(\xi_+, \xi_+ + 1]$, $v_3^{*''}/v_3^{*'}$ changes smoothly by $O(1)$ from $v_2^{*''}(\xi_\pm \pm 1)/v_2^{*'}(\xi_\pm \pm 1) = O(1)$ to $v_1^{*''}(\xi_\pm)/v_1^{*'}(\xi_\pm) = O(1)$. Hence $v_3^{*''}/v_3^{*'}$ is also bounded on the intervals $[\xi_- - 1, \xi_-)$ and $(\xi_+, \xi_+ + 1]$. Therefore we have

$$\frac{\eta v_3^{*''} + \omega^2(v_3^* - v_-^*) + p(v_3^*, \lambda_1) - p_-^*}{-v_3^{*'}} = O(1)\eta \tag{3.16}$$

for $\xi \in (-\infty, \xi_-) \cup (\xi_+, \infty)$.

On the interval $[\xi_-, \xi_+]$, we have $v_3^* = v_1 + \delta$ and

$$\begin{aligned}
&\frac{\eta v_3^{*\prime\prime} + \omega^2(v_3^* - v_-^*) + p(v_3^*, \lambda_1) - p_-^*}{-v_3^{*\prime}} \\
&= \frac{\eta v_1'' + \omega^2(v_1 + \delta - v_-^*) + p(v_1 + \delta, \lambda_1) - p_-^*}{-v_1'} \\
&= \frac{\omega^2(v_1 - v_-) + p(v_1, \lambda_1) - p_-}{-v_1'} \\
&\quad + \frac{\eta v_1'' + \omega^2\delta + p(v_1 + \delta, \lambda_1) - p(v_1, \lambda_1) + \omega^2(v_- - v_-^*) + p_- - p_-^*}{-v_1'} \\
&= \omega + \frac{\eta v_1'' + \omega^2\delta + p(v_1 + \delta, \lambda_1) - p(v_1, \lambda_1) + \omega^2(v_- - v_-^*) + p_- - p_-^*}{-v_1'}.
\end{aligned} \tag{3.17}$$

The part

$$F(v_1, \lambda_1, \delta) := \eta v_1'' + \omega^2\delta + p(v_1 + \delta, \lambda_1) - p(v_1, \lambda_1) + \omega^2(v_- - v_-^*) + p_- - p_-^*$$

in (3.17) satisfies

$$F(v_1, \lambda_1, 0) = \eta v_1'' + \omega^2(v_- - v_-^*) + p_- - p_-^* > 0$$

when $\eta > 0$ is sufficiently small, due to $\omega^2 + p_v(v_-, \lambda_-) < 0$ and the smallness of $v_-^* - v_- > 0$. Then, by the continuity of F, $F(v_1, \lambda_1, \delta) > 0$ for any (v_1, λ_1) in the bounded closed set $[v_-, v_+] \times [0, 1]$ if $\delta > 0$ is sufficiently small. This, together with (3.17) and $v_1' > 0$, implies that, for $\xi \in [\xi_-, \xi_+]$,

$$\frac{\eta v_3^{*\prime\prime} + \omega^2(v_3^* - v_-^*) + p(v_3^*, \lambda_1) - p_-^*}{-v_3^{*\prime}} < \omega. \tag{3.18}$$

Combining estimates (3.13)–(3.18), we see that the condition (3.9) is satisfied when $\eta > 0$ is sufficiently small. Thus, the system (3.8) has a solution with speed ω when $\eta > 0$ is sufficiently small.

Let $(v, \lambda)(\xi, v_\pm^*; \eta)$ be solutions of (3.8) with the speed ω. They are monotone in ξ. Since (3.8) is invariant under shifting, $\xi \mapsto \xi + \xi_0$, we can assume $v(0, v_\pm^*; \eta) = (v_+^* + v_-^*)/2$. By the monotoneness of these solutions, there is a sequence $\{\eta_n\}_1^\infty$ such that

$$(v, \lambda)(\xi, v_\pm^*; 0) := \lim_{n\to\infty} (v, \lambda)(\xi, v_\pm^*; \eta_n)$$

exist for a.e. $\xi \in (-\infty, \infty)$. The limit $(v, \lambda)(\xi, v_\pm^*; 0)$ satisfies the differential equations in (2.4) with speed ω in the sense of distribution, and hence in the strong sense. It also satisfies the boundary conditions in (2.4) since there is no other equilibrium point between $(v, \lambda) = (v_-^*, 0)$ and $(v_+^*, 1)$. In other words, the system (2.4) has a traveling wave with speed $\omega = \omega(v_-, 0)$, starting at $v(-\infty) = v_-^*$. Therefore, the minimum speed $\omega(v_-^*, 0)$ of all traveling waves starting at v_-^* is no greater than $\omega(v_-, 0)$. The proof is complete. □

Remark 3.1. The above proof can be further improved to yield strict monotonicity of $\omega(v_-, \lambda_-)$.

4. Kinetic relations. At this stage, the existence results on traveling wave profiles listed in section 2 are not strong enough to guarantee the solvability of the Riemann problem for (1.8). On the other hand, for each given v_-, there are too many liquefaction and vaporization traveling waves listed in section 2, cases (i) and (ii). If we admit all these waves, then many solutions can exist for the same initial data. Admitting collapsing and explosion waves introduce more solution configurations for Riemann solvers; see section 6. When to use which waves remains to be investigated more thoroughly in future studies. For this reason, instead of strictly using traveling wave admissibility criterion, we shall impose the following selection criteria for admissible waves that mimics the properties of traveling wave profiles. The selection criteria are also called kinetic relations in most mathematical literature.

In the solution of the Riemann problem for (1.8) we admit every liquefaction or evaporation wave connecting a pure phase with a mixture phase, isobaric waves, and Lax-shock and rarefaction waves, as defined in section 2, disregarding the existence results of their traveling waves profiles. Of course each of these waves must satisfy the Rankine–Hugoniot conditions (2.1) when a discontinuity occurs.

Moreover we admit both liquefaction and evaporation waves connecting *two pure phases*. The selection criterion for these liquefaction and evaporation waves are as follows: Let (v_-, u_-, λ_-) be the state in the back of a shock, (v_+, u_+, λ_+) the state in the front. For simplicity we consider only the case of waves with positive speeds.

(i) For each liquid state $(v_-, u_-, 0)$ with $p(v_-, 0) > p_e$ there is only one vapor state $(v_+, u_+, 1)$, satisfying (2.6), that can be connected to $(v_-, u_-, 0)$ with a liquefaction wave. The speed $s = s(v_-)$ of the liquefaction wave is a decreasing C^1 function satisfying $s^2(v_-) + p_v(v_\pm, \lambda_\pm) \le 0$.

(ii) For each vapor state $(v_-, u_-, 1)$ with $p(v_-, 1) < p_e$ there is only one liquid state (v_+, u_+0), satisfying (2.11), that can be connected to $(v_-, u_-, 1)$ with an evaporation wave. The speed $s = s(v_-)$ of the evaporation wave is an increasing C^1 function; it satisfies $s^2(v_-) + p_v(v_\pm, \lambda_\pm) \le 0$.

There are physical reasons for imposing conditions (i) and (ii): for example, let us consider the case of liquefaction waves. The speeds of liquefaction waves depend on the density of liquid drops in front of the waves, which is determined by the nucleation effects [8]. The larger the density of liquid drops in front of the waves is, the faster the liquefaction wave moves. The nucleation term is typically very small and takes a long time to have some effect in a metastable vapor. Thus, when t is not large, the liquefaction shock travels at the lowest possible speed. The first part of condition (i) then can be justified furthermore because the nucleation effect is not included in (1.8). The approximation of the hyperbolic regime to the parabolic one is then to be understood for $O(1)$-order time intervals, in which the nucleation changes little the value of λ in the front of the liquefaction and evaporation traveling waves. Furthermore, if every liquefaction shock is allowed, then the Riemann solvers are not unique.

The second part of condition (i) is quite intuitive, since if v_- decreases then the difference $p(v_-, 0) - p_e > 0$ increases, speeding up the phase changes. Hence it is natural to assume that the liquefaction waves proceed faster. Moreover, in terms of traveling waves, we showed in Theorem 3.1 that the liquefaction shock moving with the slowest speed satisfies this assumption. At last, the condition $s^2(v_-) + p_v(v_\pm, \lambda_\pm) \le 0$ means simply that the wave can be either subsonic or sonic.

Condition (ii) is motivated on the same basis. But, there is a difference from the case of a liquefaction wave: The assumption $s^2(v_-) + p_v(v_-, 1) \le 0$ implies that the

connection exists only if $v_- \le v_-^T$, where v_-^T is the abscissa of the point where the line joining $(v_-, p(v_-, 1))$ with $(v_+, p(v_+, 0))$ is tangent to the curve $p(v, 1)$. Such a point v_-^T exists and is unique because of the assumption $s'(v_-) > 0$.

5. Solutions of the Riemann problem. In this section we show how to solve the Riemann problem (1.8) for any data (v_-, u_-, λ_-), (v_+, u_+, λ_+) with $v_\pm > 0$, $u_\pm \in (-\infty, +\infty)$, $\lambda_\pm \in [0, 1]$. This is done by considering several different sets of initial data; cases are classified according to the difference in speeds $u_- - u_+$. The waves considered in the Riemann problems below are always listed from the left to the right.

We define $v_+^T > v_M$, $v_-^T > v_M$ as the points that satisfy, respectively, the equations

$$p_v(v_+^T, 1) = \frac{p(v_+, \lambda_+) - p(v_+^T, 1)}{v_+ - v_+^T}\,, \tag{5.1}$$

$$p_v(v_-^T, 1) = \frac{p(v_-^T, 1) - p(v_-, \lambda_-)}{v_-^T - v_-}\,. \tag{5.2}$$

The point v_+^T (respectively, v_-^T) is the abscissa of the tangency point of the line passing through $(v_+, p(v_+, \lambda_+))$ (respectively, $(v_-, p(v_-, \lambda_-))$) with the curve $p(v, 1)$.

5.1. Data in two mixture phases. We assume about data $\lambda_- \in (0, 1)$, $\lambda_+ \in (0, 1)$, $p(v_-, \lambda_-) = p(v_+, \lambda_+) = p_e$.

5.1.1. $u_+ - u_- < 0$. In this case the solution has a transition

$$\text{mixture} \to \text{liquid} \to \text{mixture}.$$

See Figure 5(a) in the case $v_- < v_+$. We claim that there exists a unique $v_1 < v_m$ such that the Riemann problem has a solution made of a left-moving liquefaction shock (from v_- to v_1) followed by a right-moving liquefaction shock (from v_1 to v_+).

In fact the jump conditions require

$$\begin{cases} -s_1(v_1 - v_-) &= u_1 - u_-, \\ -s_2(v_+ - v_1) &= u_+ - u_1. \end{cases} \tag{5.3}$$

As both s_1 and s_2 are functions of v_1, summing up the previous equations we find $F(v_1) := -s_1(v_1 - v_-) - s_2(v_+ - v_1) = u_+ - u_-$. We remark first that

$$\inf_{v \le v_m} F(v_1) = -\infty, \quad \max_{v \le v_m} F(v_1) = F(v_m) = 0.$$

Moreover,

$$\frac{dF}{dv_1}(v_1) = -s_1 + s_2 - \frac{ds_1}{dv_1}(v_1 - v_-) - \frac{ds_2}{dv_1}(v_+ - v_1). \tag{5.4}$$

From (2.2) we see that $ds_1/dv_1 > 0$, $ds_2/dv_1 < 0$; then $dF/dv_1 > 0$. Therefore for every $u_+ - u_- < 0$ there exists a unique v_1 such that $F(v_1) = u_+ - u_-$.

5.1.2. $u_+ - u_- = 0$. In this case the solution is simply given by an isobaric wave from v_- to v_+. Velocity and pressure are constant through the wave.

Following the pattern of case 5.1.1, for $v_1 \to v_m$ one could argue that the solution consists of two jumps: v_- to v_m, v_m to v_+. However, both waves are stationary, so they coincide, and the jump is directly from v_- to v_+.

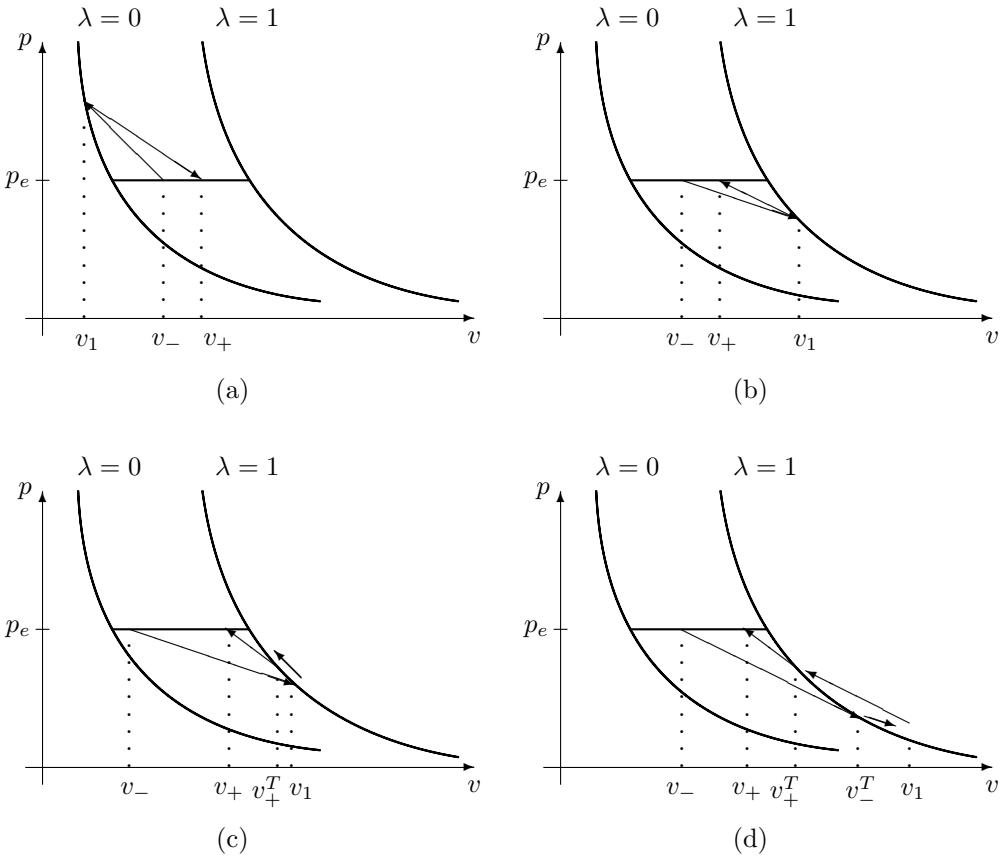

FIG. 5. *Two mixture phases data.* (a) $u_+ - u_- < 0$; (b) $0 < u_+ - u_- < u_*$; (c) $u_* < u_+ - u_- < u^*$; (d) $u_+ - u_- > u^*$. *In case* (c) *the small wave is a* 2*-rarefaction wave attached to the evaporation shock; in case* (d) *the small waves are first a* 1*-rarefaction then a* 2*-rarefaction wave.

5.1.3. $u_+ - u_- > 0$. In this case the solution has a transition (see Figures 5(b)–(d))

$$\text{mixture} \to \text{vapor} \to \text{mixture}.$$

Define

$$u_* = \sqrt{-\frac{p(v_+^T, 1) - p(v_-, \lambda_-)}{v_+^T - v_-}}(v_+^T - v_-) - \sqrt{-p_v(v_+^T, 1)}(v_+ - v_+^T),$$

$$u^* = \sqrt{-p_v(v_-^T, 1)}(v_-^T - v_-) - \int_{v_-^T}^{v_+^T} \sqrt{-p_v(v, 1)}\, dv - \sqrt{-p_v(v_+^T, 1)}(v_+ - v_+^T).$$

It is easy to check that $0 < u_* < u^*$.
Consider first the case $v_- < v_+$. Three patterns arise.

(i) $0 < u_+ - u_- \le u_*$: The solution consists of a left-moving evaporation shock (from v_- to v_1) followed by a right-moving evaporation shock (from v_1 to v_+); see Figure 5(b). As in case 5.1.1 the equations (5.3) must be satisfied. Now, however, $ds_1/dv_1 < 0$, $ds_2/dv_1 > 0$ and from (5.4) we again have $dF/dv_1 > 0$. As $F(v_M) = 0$, this means that we can solve uniquely the equation $F(v_1) = u_+ - u_-$ until the line joining $(v_1, p(v_1, 1))$ and $(v_+, p(v_+, \lambda_+))$ becomes tangent to the graph of $p(v, 1)$, i.e., for $v_1 \in (v_M, v_+^T]$. This concludes this case, because $F(v_+^T) = u_*$.

(ii) $u_* \le u_+ - u_- \le u^*$: The solution consists of a left-moving evaporation shock (from v_- to v_1), followed by a 2-rarefaction wave (from v_1 to v_+^T) ending on a right-moving evaporation shock (from v_+^T to v_+). We call s_2^T the speed of this last shock; see Figure 5(c). Then

$$\begin{cases} -s_1(v_1 - v_-) = u_1 - u_-, \\ -\displaystyle\int_{v_1}^{v_+^T} \sqrt{-p_v(v,1)}\, dv = u_+^T - u_-, \\ -s_2^T(v_+ - v_+^T) = u_+ - u_+^T. \end{cases}$$

Summing up we define the function

$$G(v_1) = -s_1(v_1 - v_-) - \int_{v_1}^{v_+^T} \sqrt{-p_v(v,1)}\, dv - s_2^T(v_+ - v_+^T).$$

We already proved that $ds_1/dv_1 < 0$, moreover $ds_2^T/dv_1 = 0$; then $dG/dv_1 > 0$. Therefore we can solve uniquely the equation $G(v_1) = u_+ - u_-$ until the line joining $(v_-, p(v_-, \lambda_-))$ and $(v_1, p(v_1, 1))$ becomes tangent to the graph of $p(v, 1)$, that is, for $v_1 \in [v_+^T, v_-^T]$. This concludes this case, since $G(v_-^T) = u^*$ and $G(v_+^T) = F(v_+^T)$.

(iii) $u^* \le u_+ - u_- < +\infty$: The solution consists of a left-moving evaporation shock (from v_- to v_-^T, whose speed we call s_1^T) followed by a 1-rarefaction wave (from v_-^T to v_1), coinciding at the left with the evaporation shock; then it follows a 2-rarefaction wave (from v_1 to v_+^T) ending on a right-moving evaporation shock (from v_+^T to v_+). See Figure 5(d). Then

$$\begin{cases} -s_1^T(v_-^T - v_-) = u_-^T - u_-, \\ \displaystyle\int_{v_-^T}^{v_1} \sqrt{-p_v(v,1)}\, dv = u_-^T - u_1, \\ -\displaystyle\int_{v_1}^{v_+^T} \sqrt{-p_v(v,1)}\, dv = u_+^T - u_-, \\ -s_2^T(v_+ - v_+^T) = u_+ - u_+^T. \end{cases}$$

Summing up we define the function

$$H(v_1) = -s_1^T(v_-^T - v_-) + \int_{v_-^T}^{v_1} \sqrt{-p_v(v,1)}\, dv - \int_{v_1}^{v_+^T} \sqrt{-p_v(v,1)}\, dv - s_2^T(v_+ - v_+^T).$$

We see that $dH(v_1)/dv_1 = 2\sqrt{-p_v(v_1, 1)} > 0$; moreover $H(v_-^T) = G(v_-^T)$ and $\sup_{v \ge v_-^T} H(v) = +\infty$ because of (1.5). Then we can solve uniquely the equation $H(v_1) = u_+ - u_-$ for $u_+ - u_- \in [u^*, +\infty)$.

This concludes the discussion of case 5.1.3 if $v_- < v_+$. The case $v_- > v_+$ is analogous and goes as follows. If $u_+ - u_-$ is positive and sufficiently small, we find a solution consisting of a left-moving evaporation shock followed by a right-moving evaporation shock, as in case (i); for larger values of $u_+ - u_-$ the solution consists of an evaporation shock moving toward the left with fixed speed, and it is sonic on the right. Then it follows a 1-rarefaction wave coinciding on the left with the shock and then a right-moving evaporation shock. For still larger values of $u_+ - u_-$ the pattern is as in case (iii). Details are left to the reader.

5.2. Data in one mixture, one pure phase. In this section we solve the Riemann problem in the case that one data is in a pure phase and the other in a mixture phase. More precisely we treat in detail the case of data (v_-, u_-, λ_-), (v_+, u_+, λ_+) with $\lambda_- = 0, 1$ and $\lambda_+ \in (0, 1)$. The mirror case $\lambda_- \in (0, 1)$, $\lambda_+ = 0, 1$ is easily deduced by the transformation $x \mapsto -x$.

5.2.1. $\boldsymbol{\lambda_- = 0}$, $\boldsymbol{\lambda_+ \in (0,1)}$, $\boldsymbol{-\infty < u_+ - u_- \le u_*}$. The threshold u_* is defined by

$$u_* = \begin{cases} \displaystyle\int_{v_-}^{v_m} \sqrt{-p_v(v,0)}\, dv & \text{if } v_- \le v_m, \\ \displaystyle\sqrt{-\frac{p(v_m,0) - p(v_-,0)}{v_m - v_-}}(v_m - v_-) & \text{if } v_- > v_m. \end{cases}$$

The solution has a transition

$$\text{liquid} \to \text{mixture}.$$

The solution consists of a 1-wave from v_- to v_1, then a right-moving liquefaction shock from v_1 to v_+ (an isobaric wave if $u_+ - u_- = u_*$); see Figure 6(a). This construction can be made if $v_1 \le v_m$, and for $v_1 = v_m$ we have an isobaric wave; if $v_1 > v_m$, the liquefaction shock is no more admissible. Then

$$\begin{cases} -\chi_{(-\infty,v_-)}(v_1) \cdot s_1(v_1 - v_-) + \chi_{[v_-,+\infty)}(v_1) \cdot \displaystyle\int_{v_-}^{v_1} \sqrt{-p_v(v,0)} dv = u_1 - u_-, \\ -s(v_+ - v_1) = u_+ - u_1. \end{cases}$$

The function

$$F(v_1) = -\chi_{(-\infty,v_-)}(v_1) \cdot s_1(v_1 - v_-) + \chi_{[v_-,+\infty)}(v_1) \cdot \int_{v_-}^{v_1} \sqrt{-p_v(v,0)} dv \\ -s(v_+ - v_1)$$

satisfies $dF/dv_1 > 0$ because $ds_1/dv_1 > 0$, $ds/dv_1 < 0$. Since $v_1 \le v_m$ we have a solution if $u_+ - u_- \in (-\infty, F(v_m)]$. It is then sufficient to remark that $F(v_m) = u_*$ to complete the proof.

5.2.2. $\boldsymbol{\lambda_- = 0}$, $\boldsymbol{\lambda_+ \in (0,1)}$, $\boldsymbol{u_* < u_+ - u_- \le u^*}$. The value u^* is defined in (5.11). In this case the solution has a transition

$$\text{liquid} \to \text{vapor} \to \text{mixture}.$$

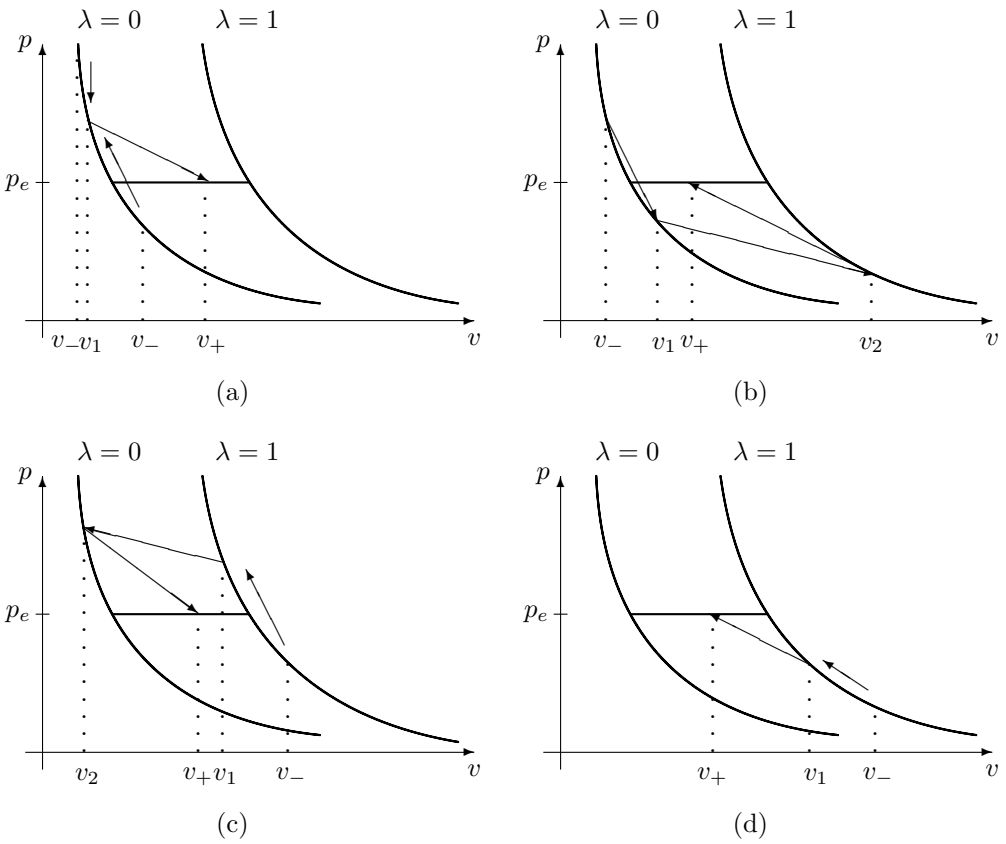

FIG. 6. *One pure phase, one mixture phase data. Liquid-mixture cases:* (a) $-\infty < u_+ - u_- < u_*$; (b) $u_* < u_+ - u_- < u^*$. *In case* (a) *both a* 1*-rarefaction and a* 1*-shock are drawn; if* $u_+ - u_- > u^*$ *the pattern is analogous to that in Figure* 5(d) *(two rarefactions in the vapor phase) and is not shown. Vapor-mixture cases:* (c) $-\infty < u_+ - u_- < u_\sharp$; (d) $u_\sharp < u_+ - u_- < u^\sharp$. *In case* (c) *a* 1*-Lax wave followed by a left-moving liquefaction shock, then a right-moving liquefaction shock; in case* (d) *a* 1*-Lax wave followed by an evaporation shock. Also in this case if* $u_+ - u_- > u^\sharp$ *the pattern is analogous to that in Figure* 5(d) *(two rarefactions in the vapor phase) and is not shown.*

It consists of a 1-Lax wave from v_- to v_1, then a left-moving evaporation shock from v_1 to v_2, at last a right-moving evaporation shock from v_2 to v_+; see Figure 6(b). Here $v_1 > v_m$, different from the previous case. We have

$$\begin{cases} -\chi_{(-\infty,v_-)}(v_1)\cdot s_1(v_1 - v_-) + \chi_{[v_-,+\infty)}(v_1)\cdot \displaystyle\int_{v_-}^{v_1} \sqrt{-p_v(v,0)}dv = u_1 - u_-, \\ -s(v_2 - v_1) = u_2 - u_1, \\ -s_2(v_+ - v_2) = u_+ - u_2. \end{cases} \tag{5.5}$$

Remark 5.1. If every evaporation and liquefaction wave connecting two pure phases were admissible then it is clear that uniqueness of solutions to the Riemann problem would fail: we should have two free parameters in system (5.5). This is why we imposed the kinetic condition (ii), section 4; then $s = s(v_2)$ and $v_1 = v_1(v_2)$. More

precisely, let us call $(v_{2-}^T, p(v_{2-}^T, 1))$ the point where the line joining $(v_1, p(v_1, 0))$ and $(v_2, p(v_2, 1))$ becomes tangent to the curve $p(v, 1)$. Then for any $v_2 \in [v_M, v_{2-}^T]$ there exist unique $v_1 > v_m$ and s such that v_1 and v_2 are connected by an evaporation shock of speed s.

Consider, however, for the moment v_2, s as independent variables in (5.5) and define the function

$$F(v_2, s) = -\chi_{(-\infty, v_-)}(v_1) \cdot s_1(v_1 - v_-) + \chi_{[v_-, +\infty)}(v_1) \cdot \int_{v_-}^{v_1} \sqrt{-p_v(v, 0)}dv$$

$$-s(v_2 - v_1) - s_2(v_+ - v_2); \tag{5.6}$$

see [6] for a similar procedure. Then $v_1 = v_1(v_2, s)$, $s_1 = s_1(v_1(v_2, s))$, $s_2 = s_2(v_2)$; for simplicity we omit the dependence on v_2, s in the following calculations.

LEMMA 5.1. *For the function $F(v_2, s)$ defined in (5.6), with $v_1 = v_1(v_2, s)$, $s_1 = s_1(v_1(v_2, s))$, $s_2 = s_2(v_2)$, we have*

$$\frac{\partial F}{\partial v_2}(v_2, s) > 0, \quad \frac{\partial F}{\partial s}(v_2, s) < 0. \tag{5.7}$$

Proof. We begin with some preliminary calculations. By differentiating with respect to v_2 and to s the formula

$$s^2 = -\frac{p(v_2, 1) - p(v_1, 0)}{v_2 - v_1},$$

we find

$$\frac{\partial v_1}{\partial v_2} = \frac{p_v(v_2, 1) + s^2}{p_v(v_1, 0) + s^2}, \qquad \frac{\partial v_1}{\partial s} = \frac{2s(v_2 - v_1)}{p_v(v_1, 0) + s^2}. \tag{5.8}$$

Then $\partial v_1/\partial v_2 > 0$, $\partial v_1/\partial s > 0$ because of the subsonic condition (ii) in section 4. On the other hand, by differentiating with respect to v_2 the formula

$$s_2^2 = -\frac{p(v_+, \lambda_+) - p(v_2, 1)}{v_+ - v_2},$$

we obtain

$$\frac{\partial s_2}{\partial v_2} = \frac{p_v(v_2, 1) + s_2^2}{2s_2(v_+ - v_2)} \tag{5.9}$$

that is positive again because of (ii). At last

$$\frac{ds_1}{dv_1} = -\frac{1}{2s_1(v_1 - v_-)} \left(p_v(v_1, 0) + s_1^2\right). \tag{5.10}$$

Next we compute

$$\frac{\partial F}{\partial v_2}(v_2, s) = \begin{cases} -\left(\dfrac{\partial s_1}{\partial v_1}\dfrac{\partial v_1}{\partial v_2} \cdot (v_1 - v_-) + s_1 \dfrac{\partial v_1}{\partial v_2}\right) + (s_2 - s) - \dfrac{\partial s_2}{\partial v_2}(v_+ - v_2) & \text{if } v_1 < v_-, \\ \left(\sqrt{-p_v(v_1, 0)} + s\right) \dfrac{\partial v_1}{\partial v_2} + (s_2 - s) - \dfrac{\partial s_2}{\partial v_2}(v_+ - v_2) & \text{if } v_1 \geq v_-. \end{cases}$$

We note that $ds_1/dv_1 > 0$, $ds_2/dv_2 > 0$, $s - s_1 > 0$, $s_2 - s > 0$, and $\sqrt{-p_v(v_1,0)} + s > 0$. The first inequality in (5.7) then follows from (5.8), (5.9).

We now compute

$$\frac{\partial F}{\partial s}(v_2,s) = -\chi_{(-\infty,v_-)}(v_1)\cdot\left(\frac{\partial s_1}{\partial s}(v_1-v_-)+s_1\frac{\partial v_1}{\partial s}\right) + \chi_{[v_-,+\infty)}(v_1)\cdot\sqrt{-p_v(v_1,0)}\frac{\partial v_1}{\partial s} - (v_2-v_1) + s\frac{\partial v_1}{\partial s}.$$

Since $\partial s_1/\partial s = (ds_1/dv_1)(\partial v_1/\partial s)$, from (5.8), (5.10) we have

$$\frac{\partial F}{\partial s}(v_2,s) = \begin{cases} \dfrac{v_2-v_1}{s_1(p_v(v_1,0)+s^2)}(s-s_1)\left(p_v(v_1,0)+ss_1\right) & \text{if } v_1 < v_-\,, \\ \dfrac{v_2-v_1}{p_v(v_1,0)+s^2}\left(\sqrt{-p_v(v_1,0)}+s\right)^2 & \text{if } v_1 \geq v_-. \end{cases}$$

Both expressions are negative. This proves the second inequality in (5.7). □

Recall now that we have only one free parameter in the resolution (5.5), i.e., v_2. Therefore

$$\frac{d}{dv_2}\left[F\left(v_2,s(v_2)\right)\right] = \frac{\partial F}{\partial v_2}\left(v_2,s(v_2)\right) + \frac{\partial F}{\partial s}\left(v_2,s(v_2)\right)\cdot\frac{ds}{dv_2}(v_2)\ .$$

Because of assumption (ii) in section 4, we have $\partial s/\partial v_2 < 0$, and from Lemma 5.1 we deduce

$$\frac{d}{dv_2}\left[F\left(v_2,s(v_2)\right)\right] > 0\ .$$

Then define $G(v_2) = F\left(v_2,s(v_2)\right)$. The function G is increasing and

$$\min_{v\geq v_M} G(v_2) = G(v_M) = u_*.$$

This case then matches with the previous one. This wave structure is valid until v_2 reaches the point v_{2+}^T, when the line joining $(v_2,p(v_2,1))$ with $(v_+,p(v_+,\lambda_+))$ becomes tangent to the curve $p(v,1)$ at $(v_2,p(v_2,1))$. The situation is entirely analogous to case 5.1.3. Therefore the upper limit of $u_+ - u_-$ for this case is

$$u^* = G(v_+^T)\ . \tag{5.11}$$

5.2.3. $\boldsymbol{\lambda_- = 0}$, $\boldsymbol{\lambda_+ \in (0,1)}$, $\boldsymbol{u^* \leq u_+ - u_- < +\infty}$. This case is the continuation of the previous one; the solution has again a transition

$$\text{liquid} \to \text{vapor} \to \text{mixture}.$$

The patterns of the solutions are analogous to case 5.1.3. Let v_{2-}^T be the abscissa of the tangency point of the line joining $(v_1,p(v_1,0))$ and $(v_2,p(v_2,1))$ with the curve $p(v,1)$. When $v_2 \in [v_+^T, v_{2-}^T]$ we need to introduce in the solution a 2-rarefaction wave ending with the right-moving evaporation shock; this happens for $u^* \leq u_+ - u_- \leq u^{**}$, for some u^{**}. When finally $v_2 \in [v_{2-}^T, +\infty)$ (that is, $u_+ - u_- \geq u^{**}$), we add also a 1-rarefaction wave beginning with the left-moving evaporation shock. Details are left to the reader.

5.2.4. $\lambda_- = 1$, $\lambda_+ \in (0,1)$, $-\infty < u_+ - u_- \le u_\sharp$. The threshold $u_\sharp$ is defined by

$$u_\sharp = \begin{cases} \displaystyle\int_{v_-}^{v_M} \sqrt{-p_v(v,1)}\,dv & \text{if } v_- \le v_M, \\ \displaystyle\sqrt{-\frac{p(v_M,1)-p(v_-,1)}{v_M - v_-}}(v_M - v_-) & \text{if } v_- \ge v_M. \end{cases} \tag{5.12}$$

In this case we have a transition

$$\text{vapor} \to \text{liquid} \to \text{mixture}.$$

The solution consists of a left-moving Lax wave from v_- to v_1, a left-moving liquefaction wave (uniquely determined by the kinetic condition (i)) from v_1 to v_2, and a right-moving liquefaction wave from v_2 to v_+; see Figure 6(c). This requires $v_1 \le v_M$; otherwise the left-moving liquefaction wave is not admissible. If $v_1 = v_M$ (i.e., $u_+ - u_- = u_\sharp$), the two liquefaction waves are replaced by a single isobaric wave from v_M to v_+. Therefore

$$\begin{cases} \chi_{(-\infty,v_-)}(v_1)\cdot s_1(v_1 - v_-) + \chi_{[v_-,+\infty)}(v_1)\cdot \displaystyle\int_{v_-}^{v_1} \sqrt{-p_v(v,1)}\,dv = u_1 - u_-, \\ -s(v_2 - v_1) = u_2 - u_1, \\ -s_2(v_+ - v_2) = u_+ - u_2. \end{cases}$$

We proceed as in case 5.2.2, the only differences being that 0 and 1 are interchanged for the Lax curves and we have liquefaction instead of evaporation waves. In order to prove estimates analogous to (5.7) we use v_2 and s as independent variables, set $v_1 = v_1(v_2,s)$, $s_1 = s(v_1(v_2,s))$, $s_2 = s_2(v_2)$ and define

$$\begin{aligned} F(v_2,s) = {} & \chi_{(-\infty,v_-)}(v_1)s_1(v_1 - v_-) + \chi_{[v_-,+\infty)}(v_1)\int_{v_-}^{v_1} \sqrt{-p_v(v,1)}\,dv \\ & -s(v_2 - v_1) - s_2(v_+ - v_2). \end{aligned}$$

Now, however, $v_2 - v_1 < 0$ and

$$\frac{\partial v_1}{\partial v_2}(v_2,s) = \frac{p_v(v_2,0) + s^2}{p_v(v_1,1) + s^2} > 0, \quad \frac{\partial v_1}{\partial s}(v_2,s) = \frac{2s(v_2 - v_1)}{p_v(v_1,1) + s^2} < 0.$$

Then

$$\frac{\partial F}{\partial v_2}(v_2,s) > 0, \quad \frac{\partial F}{\partial s}(v_2,s) < 0$$

hold and since $s = s(v_2)$ we have $d/dv_2[F(v_2,s(v_2))] > 0$. Notice that if $v_2 = v_m$, then $v_1 = v_M$. The function F satisfies $\inf_{v_2 \le v_m} F(v_2,s(v_2)) = -\infty$ and reaches its maximum at point v_m. If $v_- \le v_M$, the maximum is reached when the 1-wave is a shock; if $v_- \ge v_M$, it is reached when it is a 1-rarefaction wave. Therefore $\max_{v_2 \le v_M} F(v_2) = u_\sharp$, where $u_\sharp$ is defined in (5.12).

5.2.5. $\lambda_- = 1$, $\lambda_+ \in (0,1)$, $u_\sharp < u_+ - u_- \le u^\sharp$. Here $u^\sharp$ is defined by

$$u^\sharp = \int_{v_-}^{v_+^T} \sqrt{-p_v(v,1)}\,dv - \sqrt{-p_v(v_+^T,1)}(v_+ - v_+^T)$$

for v_+^T defined in (5.1). In this case the solution has a transition

$$\text{vapor} \to \text{mixture}.$$

The solution consists of a 1-Lax wave from v_- to v_1 followed by a right-moving evaporation shock from v_1 to v_+; see Figure 6(d). This construction holds under the following two conditions on v_1. First, the line joining $(v_1, p(v_1, 1))$ and $(v_+, p(v_+, \lambda_+))$ cannot go beyond the tangent to the curve $p(v, 1)$ at point $(v_1, p(v_1, 1))$, i.e., $v_1 < v_+^T$; this position can be reached only if the 1-wave is a rarefaction wave. Second, $v_1 > v_M$; this may happen either if the 1-wave is a shock or a 1-rarefaction wave.

The proof is analogous to case 5.2.1, using the function

$$F(v_1) = -\chi_{(-\infty, v_-)}(v_1) \cdot s_1(v_1 - v_-) + \chi_{[v_-, +\infty)}(v_1) \cdot \int_{v_-}^{v_1} \sqrt{-p_v(v, 1)} dv \\ -s(v_+ - v_1).$$

The function F is increasing and $F(v_M) = u_\sharp$, $F(v_+^T) = u^\sharp$. This case is therefore proved.

5.2.6. $\boldsymbol{\lambda_- = 1}$, $\boldsymbol{\lambda_+ \in (0, 1)}$, $\boldsymbol{u^\sharp \le u_+ - u_- < +\infty}$. Again the solution has a transition

$$\text{vapor} \to \text{mixture}.$$

With respect to the previous case, the solution refers to $v_1 > v_+^T$. It consists of a 1-rarefaction wave from v_- to v_1; a 2-rarefaction wave from v_1 to v_+^T; and a right-moving evaporation shock from v_+^T to v_+. The proof of this case is similar to the proof of case 5.1.3(iii), the only difference being that the 1-rarefaction starts from a generic point v_- and not just from v_-^T. The proof is omitted.

5.3. Data in two pure different phases. In this section we consider the case of initial data (v_-, u_-, λ_-), (v_+, u_+, λ_+) in two different pure phases, that is, either $\lambda_- = 0$ and $\lambda_+ = 1$ or $\lambda_- = 1$ and $\lambda_+ = 0$. For simplicity we treat only the first case; the second case is dealt analogously.

5.3.1. $\boldsymbol{\lambda_- = 0}$, $\boldsymbol{\lambda_+ = 1}$, $\boldsymbol{-\infty < u_+ - u_- \le u_\star}$. Here $u_\star$ is defined in (5.13). The solution consists of a 1-Lax wave from v_- to v_1, a right-moving liquefaction wave from v_1 to v_2, and a 2-Lax wave from v_2 to v_+; see Figure 7(a). The liquefaction wave is replaced by an isobaric wave in the case $u_+ - u_- = u_\star$. This means that

$$\begin{cases} -\chi_{(-\infty, v_-)}(v_1) \cdot s_1(v_1 - v_-) + \chi_{[v_-, +\infty)}(v_1) \cdot \displaystyle\int_{v_-}^{v_1} \sqrt{-p_v(v, 0)}\, dv = u_1 - u_-, \\ -s(v_2 - v_1) = u_2 - u_1, \\ -\chi_{(-\infty, v_+)}(v_2) \cdot s_2(v_+ - v_2) - \chi_{[v_+, +\infty)}(v_2) \cdot \displaystyle\int_{v_2}^{v_+} \sqrt{-p_v(v, 1)}\, dv = u_+ - u_2. \end{cases}$$

Arguing as we did in case 5.2.2 we take for the moment, however, v_1 and s as independent variables, so that $v_2 = v_2(v_1, s)$, $s_1 = s_1(v_1)$, $s_2 = s_2(v_2(v_1, s))$. Denote

$$F(v_1, s) \;=\; -\chi_{(-\infty, v_-)}(v_1) \cdot s_1(v_1 - v_-) + \chi_{[v_-, +\infty)}(v_1) \cdot \int_{v_-}^{v_1} \sqrt{-p_v(v, 0)}\, dv, \\ -s(v_2 - v_1) - \chi_{(-\infty, v_+)}(v_2) \cdot s_2(v_+ - v_2) - \chi_{[v_+, +\infty)}(v_2) \cdot \int_{v_2}^{v_+} \sqrt{-p_v(v, 1)}\, dv.$$

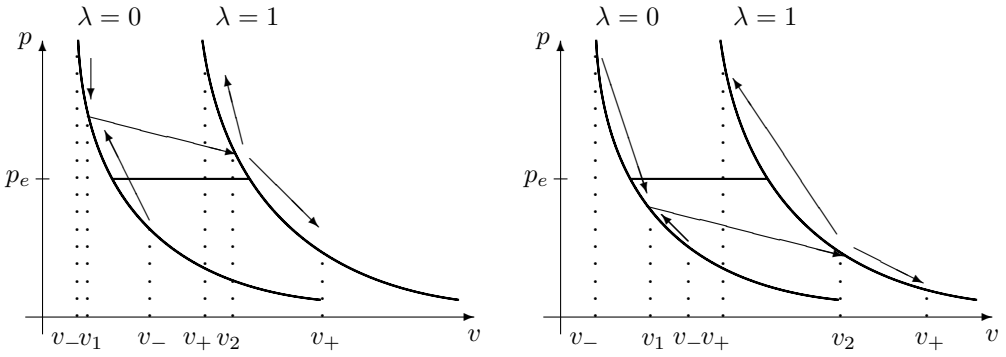

FIG. 7. *Two pure different phases data.* (a) $-\infty < u_+ - u_- < u_\star$; (b) $u_\star < u_+ - u_- \leq u^\star$. *In case* (a) *the phase boundary is a right-moving evaporation wave, in case* (b) *a left-moving liquefaction wave.*

Then

$$\frac{\partial F}{\partial v_1}(v_1, s) = \chi_{(-\infty, v_-)}(v_1)\left(-\frac{\partial s_1}{\partial v_1}(v_1 - v_-) - s_1\right) + \chi_{[v_-, +\infty)}(v_1)\sqrt{-p_v(v_1, 0)}$$
$$-s \cdot \left(\frac{\partial v_2}{\partial v_1} - 1\right)$$
$$+\chi_{(-\infty, v_+)}(v_2)\left(-\frac{\partial s_2}{\partial v_1}(v_+ - v_2) + s_2\frac{\partial v_2}{\partial v_1}\right) + \chi_{[v_+, +\infty)}(v_2)\sqrt{-p_v(v_2, 1)}\frac{\partial v_2}{\partial v_1}\ .$$

We remark now that because of the kinetic condition (i)

$$\frac{\partial v_2}{\partial v_1} = \frac{p_v(v_1, 0) + s^2}{p_v(v_2, 0) + s^2} > 0, \quad \frac{\partial s_1}{\partial v_1} > 0, \quad \frac{\partial s_2}{\partial v_1} = \frac{\partial s_2}{\partial v_2}\frac{\partial v_2}{\partial v_1} < 0.$$

We need only to control the term $-s \cdot \partial v_2/\partial v_1$. But if $v_2 < v_+$, then $s < s_2$, while if $v_2 \geq v_+$, then $s < \sqrt{-p_v(v_2, 1)}$. All that proves that

$$\frac{\partial F}{\partial v_1}(v_1, s) > 0\ .$$

Next compute

$$\frac{\partial F}{\partial s}(v_1, s) = -(v_2 - v_1) - s \cdot \frac{\partial v_2}{\partial s} - \chi_{(-\infty, v_+)}(v_2) \cdot \left(\frac{\partial s_2}{\partial v_2}\frac{\partial v_2}{\partial s}(v_+ - v_2) - s_2 \cdot \frac{\partial v_2}{\partial s}\right)$$
$$+\chi_{[v_+, +\infty)}(v_2) \cdot \sqrt{-p_v(v_2, 1)}\frac{\partial v_2}{\partial s}\ .$$

Moreover

$$\frac{\partial v_2}{\partial s} = -\frac{2s(v_2 - v_1)}{p_v(v_2, 1) + s^2} > 0.$$

If $v_2 < v_+$, then

$$\frac{\partial F}{\partial s}(v_1, s) = \frac{(v_2 - v_1)}{s_2\left(p_v(v_2, 1) + s^2\right)}\left(s_2 - s\right)\left(s_2 s - p_v(v_2, 1)\right) < 0,$$

while if $v_2 \geq v_+$, then

$$\frac{\partial F}{\partial s}(v_1, s) = (v_2 - v_1)\frac{s - \sqrt{-p_v(v_2, 1)}}{s + \sqrt{-p_v(v_2, 1)}} < 0.$$

Recalling the kinetic condition (i) for $s = s(v_1)$, we have $d/dv_1\left[F(v_1, s(v_1))\right] > 0$. So $F(v_1, s(v_1))$ is an increasing function and in the current case has

$$u_\star = F(v_m, 0) \tag{5.13}$$

as maximum. This value can be explicitly computed from above, as in the previous cases, and depends on the four possible configurations of (v_-, v_+): $v_- < v_m$, $v_- > v_m$ or $v_+ < v_M$, $v_+ > v_M$. This concludes the case.

5.3.2. $\boldsymbol{\lambda_- = 0}$, $\boldsymbol{\lambda_+ = 1}$, $\boldsymbol{u_\star < u_+ - u_- \leq u^\star}$. This case is analogous to the previous one, but now a left-moving evaporation wave replaces the liquefaction wave. More precisely the solution consists of a 1-Lax wave, the evaporation shock, and a 2-Lax wave. Now $v_1 > v_m$ (and then $v_2 > v_M$); see Figure 7(b). This pattern is, however, possible for $v_2 \in [v_M, v_+^T]$; the state v_+^T was defined in (5.1).

We define the function

$$\begin{aligned} F(v_2, s) \;=\; & -\chi_{(-\infty, v_-)}(v_1)\cdot s_1(v_1 - v_-) + \chi_{[v_-, +\infty)}(v_1)\cdot \int_{v_-}^{v_1} \sqrt{-p_v(v, 0)}\, dv \\ & -s(v_2 - v_1) - \chi_{(-\infty, v_+)}(v_2)\cdot s_2(v_+ - v_2) - \chi_{[v_+, +\infty)}(v_2)\cdot \int_{v_2}^{v_+} \sqrt{-p_v(v, 1)}\, dv, \end{aligned}$$

where the independent variables are now v_2 and s. Then $v_1 = v_1(v_2, s)$, $s_1 = s_1(v_1(v_2, s))$, $s_2 = s_2(v_2)$. The function $F(v_2, s(v_2))$ is easily proved to be increasing. The critical speed $u^\star$ is then defined as

$$u^\star = F\left(v_+^T, s(v_+^T)\right).$$

Call $(v_*, p(v_*, 0))$ the intersection of the tangent line to the curve $p(v, 1)$ at point $(v_+^T, p(v_+^T, 1))$ with the curve $p(v, 0)$.

5.3.3. $\boldsymbol{\lambda_- = 0}$, $\boldsymbol{\lambda_+ = 1}$, $\boldsymbol{u^\star \leq u_+ - u_- < +\infty}$. Now $v_2 \in [v_+^T, +\infty)$ and the solution consists of a 1-Lax wave from v_- to v_*, an evaporation wave from v_* to v_+^T, a 1-rarefaction wave from v_+^T to v_2 (attached to the evaporation wave on the left), and a 2-rarefaction wave from v_2 to v_+.

The proof of this case is lengthy and is a combination of the cases 5.3.2 and 5.1.3(iii). The details are left to the reader.

5.4. Data in two same pure phases. In this case data (v_-, u_-, λ_-) and (v_+, u_+, λ_+) satisfy either $\lambda_- = \lambda_+ = 0$ or $\lambda_- = \lambda_+ = 1$. We solve the Riemann problem simply using two Lax waves, without phase changes; see [14].

5.5. Comments on the Riemann solver. The Riemann solver defined in the previous sections has many interesting features that we emphasize now.

First, many nonclassical waves arise [2, 3, 12]—for instance, rarefaction waves attached to phase boundaries as in case 5.1.3 (Figures 5(c)–(d)). Also, the case of two phase boundaries with two attached rarefaction waves is present.

Second, the structure of the solution may change abruptly under small changes of the Riemann data. Consider, for instance, case 5.1.2 (Figure 5(b)) and the two near cases 5.1.1 and 5.1.3 (Figures 5(a), (c)). If $u_+ - u_- = 0$, then the solution is an isobaric wave from v_- to v_+. However, if $u_+ - u_-$ is small but nonvanishing, then the solution suffers two phase transitions. In this case the solution has a total variation of order $|v_- - v_m| + |v_+ - v_m|$ (or $|v_- - v_M| + |v_+ - v_M|$) that may be much larger than $|v_+ - v_-|$. The reason for this abrupt change of structure is that when $u_+ - u_-$ go across 0, the phase transition in the solution changes from condensation to evaporization.

A Riemann solver is said to be consistent [4] if the following holds. Take any three state U_-, U_0, U_+, and solve the Riemann problems of initial data (U_-, U_0) and (U_0, U_+); if it is possible to paste horizontally the two solutions (there are no interactions of waves), then the result of the pasting is the solution for the Riemann problem of data (U_-, U_+). Our solutions are easily proved to be consistent if, under the previous notations, $\lambda_- = \lambda_0 = \lambda_+$. In general, however, they are not consistent: For instance, take $\lambda_- = 1$, $\lambda_0 = 0$, $\lambda_+ = 1$. Fix U_-, connect it to U_0 with a left-moving liquefaction wave, and then connect U_0 to some U_+ with a right-moving liquefaction wave. The pasting gives a solution to the Riemann problem of data (U_-, U_+) with two phase boundaries, while our Riemann solver prescribes the Lax solution. This gives two solutions for the same Riemann problem. Intuitively, both solutions are good, but they are good at different times. At first, there are no liquid drops in the initial data, and it takes time for such liquid drops to form through nucleation process. Without seeds for condensation, i.e., liquid drops, the vapor will stay as vapor, and hence the good solution at the early stage is the one without phase changes. After some time, a liquid drop appears in the vapor due to nucleation. Then condensation will occur around the drop, and we will see the second solution with two phase boundaries. Since we are interested in Riemann solvers in the early stages, we picked the one without phase changes as our Riemann solver.

6. Collapsing and explosion waves in the Riemann problem. In section 5 we uniquely solved the Riemann problem by using the waves introduced in section 4. We emphasized, however, in section 2 that other kinds of waves can be considered, namely collapsing and explosion waves. Here we introduce first a selection criterion in order to consider collapsing and explosion waves for system (1.8). Second, we show how collapsing and explosion waves can be used to construct a Riemann solver different from the one defined above. How to deal with the loss of uniqueness introduced by these new waves is left for future investigations. Here we limit ourselves to consider some examples.

The following selection criteria for collapsing and explosion waves are analogous to (i), (ii) in section 4. For simplicity we state the criteria only for waves with positive speed.

(iii) There exists a critical threshold p_{co} such that for each metastable state (v_+, λ_+) with $\lambda_+ = 0$ and $|p(v_+, \lambda_+) - p_e| \geq p_{co}$ there is only one mixture state (v_-, λ_-), $0 < \lambda < 1$, that can be connected to (v_+, λ_+) with a collapsing wave.

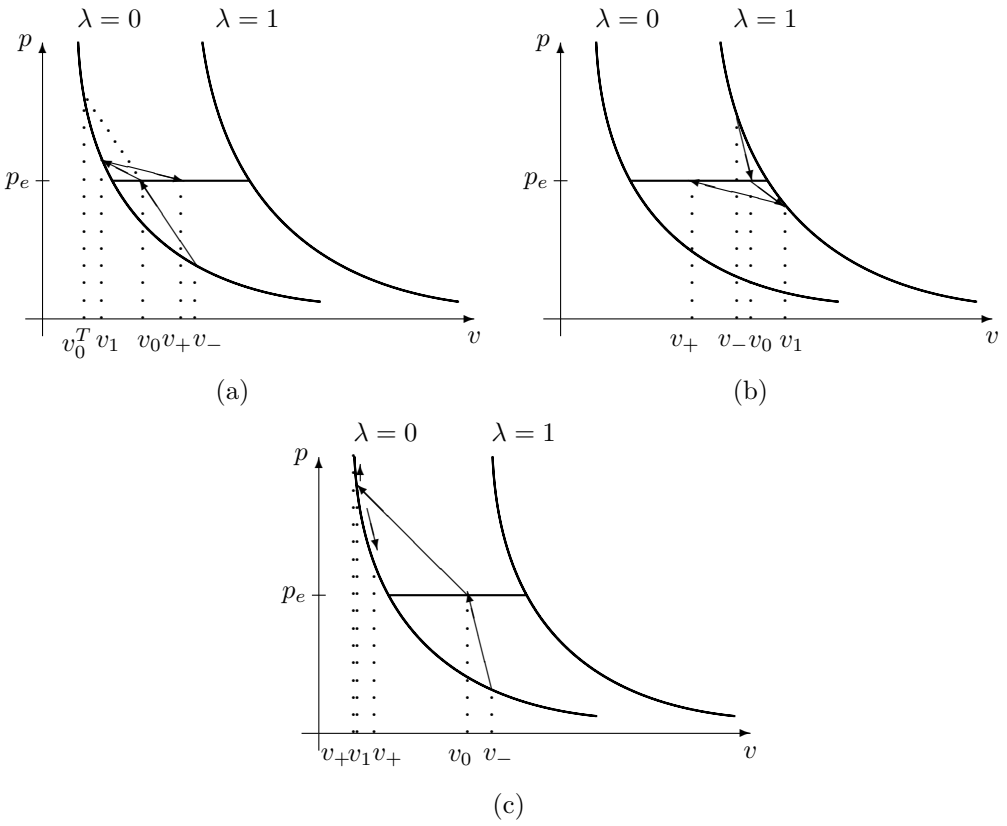

FIG. 8. *Collapsing and explosion waves in the solution of the Riemann problem.*

(iv) There is a critical threshold p_{ex} such that for each metastable state (v_+, λ_+) with $\lambda_+ = 1$ and $|p(v_+, \lambda_+) - p_e| \geq p_{ex}$ there is only one mixture state (v_-, λ_-), $0 < \lambda < 1$, that can be connected to (v_+, λ_+) with an explosion wave.[1]

We consider now some cases that can be solved collapsing or explosion waves.

Example 6.1. This example concerns the case of data (v_-, u_-, λ_-), (v_+, u_+, λ_+) one in a pure phase and one in a mixture. More precisely we assume

$$\lambda_- = 0, \quad \lambda_+ \in (0,1), \quad p_e - p(v_-, 0) \geq p_{ex}, \quad u_\circ \leq u_+ - u_- \leq u^\circ$$

for $u_\circ, u^\circ$ defined below. This case overlaps with case 5.2.1. The solution has a transition

$$\text{liquid} \to \text{mixture} \to \text{liquid} \to \text{mixture}. \tag{6.1}$$

It consists of a left-moving explosion wave from v_- to v_0, then a left-moving liquefaction wave from v_0 to v_1, and finally a right-moving liquefaction wave from v_1 to v_+; see Figure 8(a). When $u_+ - u_- = u^\circ$ the liquefaction waves are replaced by a single

[1] Our numerical tests on (1.7) indicate that at $|p(v_-, 1) - p_e| = p_{co}$, the speed of the collapsing wave is sonic.

isobaric wave. Because of condition (iv) we have $v_0 = v_0(v_-)$; let $\lambda_0 = \lambda_0(v_-)$ be the related mass density fraction and $s_0 = s_0(v_-)$ be the speed of the collapsing wave. Therefore

$$\begin{cases} -s_0(v_0 - v_-) = u_0 - u_-, \\ -s_1(v_1 - v_0) = u_1 - u_0, \\ -s_2(v_+ - v_1) = u_+ - u_1. \end{cases}$$

If we define $F(v_1) = -s_0(v_0 - v_-) - s_1(v_1 - v_0) - s_2(v_+ - v_1)$, then $dF/dv_1 > 0$ (the first summand is constant; for the sum of the other two see case 5.1.1). Now notice that this construction holds until the lines joining $(v_-, p(v_-, 0))$ with $(v_0, p(v_0, \lambda_0))$ and $(v_0, p(v_0, \lambda_0))$ with $(v_1, p(v_1, 0))$ are parallel, that is, until the liquefaction overtakes the explosion wave, so $s_0 = s_1$. Let us define v_0^T as the intersection point of the curve $p = p(v, 0)$ and the line joining $(v_-, p(v_-, 0))$ with $(v_0, p(v_0, \lambda_0))$:

$$\sqrt{-\frac{p(v_0, \lambda_0) - p(v_-, 0)}{v_0 - v_-}} = \sqrt{-\frac{p(v_-^T, 0) - p(v_0, \lambda_0)}{v_0^T - v_0}}\ .$$

From that point on the order of the liquefaction and explosion waves is no more respected. It suffices then to define

$$u_\circ = F(v_0^T), \quad u^\circ = F(v_m).$$

Remark that when $u_+ - u_- = u_\diamond$ the solution with the explosion and the liquefaction shock traveling with equal speed matches with the solution having a single 1-Lax shock, traveling with the same speed. We stress, however, the different behavior of this solution and the one provided by the previous Riemann solver when v_1 is close to v_0^T.

The solution given in Example 6.1 has three phase boundaries. On the other hand, for the same initial data, Figure 6(a) gives a solution of the form

$$\text{liquid} \to \text{liquid with higher pressure} \to \text{mixture} \tag{6.2}$$

with only one phase boundary. One point of Example 6.1 is that a physically relevant solution need not be the one with least number of phase boundaries. For example, when the liquid side of the initial data of Example 6.1 is at or beyond the spinodal limit, the liquid will very quickly evaporate into vapor or liquid/vapor mixture when in contact with the vapor drops of the other side of the initial data. This process is much faster than the sound speed as indicated by the explosion wave. In contrast, the liquid-to-liquid Lax shock in (6.2) is about the sound speed. When solution (6.1) and (6.2) compete, the process that proceeds faster will occur, eliminating the base for the slower process to occur, leading to (6.1). Thus, we choose solution (6.1), which has three phase boundaries, rather than the solution (6.2) with only one phase boundary.

Example 6.2. This example concerns again the case of data one in a pure phase and one in a mixture. We assume, however,

$$\lambda_- = 1, \quad \lambda_+ \in (0, 1), \quad p(v_+, 1) - p_e \geq p_{co}, \quad \tilde{u} \leq u_+ - u_- < +\infty$$

for $\tilde{u}$ defined below. This case overlaps with cases 5.2.4 and 5.2.5.

By using a collapsing wave we define now a solution which has transitions

$$\text{vapor} \to \text{mixture} \to \text{vapor} \to \text{mixture}.$$

The solution consists of a left-moving collapsing wave from v_- to v_0, a left-moving evaporation shock from v_0 to v_1, and a right-moving evaporation shock from v_1 to v_+; see Figure 8(b). If $u_+ - u_- = \tilde{u}$, then the two evaporation waves are replaced by a single isobaric wave from v_1 to v_+. Then

$$\begin{cases} -s_0(v_0 - v_-) = u_0 - u_-, \\ -s_1(v_1 - v_0) = u_1 - u_0, \\ -s_2(v_+ - v_1) = u_+ - u_1. \end{cases}$$

The function $F(v_1) = -s_0(v_0 - v_-) - s_1(v_1 - v_0) - s_2(v_+ - v_1)$ is easily proved to be increasing and reaches its minimum for $v_1 = v_M$; in that case $s_1 = s_2 = 0$ and

$$F(v_M) = \tilde{u} = -s_0(v_-) \cdot (v_0(v_-) - v_-)\,.$$

This pattern changes when the line joining $(v_0, p(v_0, \lambda_0))$ and $(v_1, p(v_1, 1))$ becomes tangent to the curve $p(v, 1)$ at point $(v_1, p(v_1, 1))$, that is, for $v_1 = v_0^T$. From that point on the pattern is as follows: a left-moving collapsing wave from v_- to v_0, a left-moving evaporation shock from v_0 to v_0^T, a 1-rarefaction wave from v_0^T to v_1, and a right-moving evaporation shock from v_1 to v_+. The pattern changes once more when $v_1 = v_+^T$ (defined in (5.1)). From that point on the pattern is as follows: a left-moving collapsing wave from v_- to v_0, a left-moving evaporation shock from v_0 to v_0^T, a 1-rarefaction wave from v_0^T to v_1, a 2-rarefaction wave from v_1 to v_+^T, and a right-moving evaporation shock from v_+^T to v_+.

The proof of these three last cases is analogous to that of case 5.1.3. The details are left to the reader.

Example 6.3. The following example refers to the case of two states both in a same pure phase; see subsection 5.4. We assume

$$\lambda_- = \lambda_+ = 0, \quad p_e - p(v_-, 0) \geq p_{ex}, \quad u_\diamond \leq u_+ - u_- \leq u^\diamond$$

for $u_\diamond$ and $u^\diamond$ defined below. The solution involves a transition

$$\text{liquid} \to \text{mixture} \to \text{liquid}.$$

It consists of a left-moving explosion wave connecting v_- to v_0, a left-moving liquefaction wave from v_0 to v_1, and a 2-Lax wave from v_1 to v_+; see Figure 8(c). The liquefaction wave becomes an isobaric wave if $u_+ - u_- = u^\diamond$. Therefore

$$\begin{cases} -s_0(v_0 - v_-) = u_0 - u_-, \\ -s(v_1 - v_0) = u_1 - u_0, \\ -\chi_{(-\infty, v_+)}(v_1) \cdot s_2(v_+ - v_1) - \chi_{[v_+, +\infty)}(v_1) \displaystyle\int_{v_1}^{v_+} \sqrt{-p_v(v, 0)}\, dv = u_+ - u_1. \end{cases}$$

Define then

$$\begin{aligned} &F(v_1) = -s_0(v_0 - v_-) - s(v_1 - v_0) \\ &-\chi_{(-\infty, v_+)}(v_1) \cdot s_2(v_+ - v_1) - \chi_{[v_+, +\infty)}(v_1) \int_{v_1}^{v_+} \sqrt{-p_v(v, 0)}\, dv. \end{aligned}$$

We have that $ds/dv_1 > 0$, $ds_2/dv_1 < 0$ and so $dF/dv_1 > 0$. As in Example 6.1, this construction fails when the liquefaction overtakes the explosion shock, i.e., when

the lines joining, respectively, $(v_-, p(v_-, 0))$ with $(v_0, p(v_0, 0))$ and $(v_0, p(v_0, 0))$ with $(v_1, p(v_1, 0))$ become parallel, that is, $s_0 = s$. Define $v_0^T < v_m$ by

$$\sqrt{-\frac{p(v_0(v_-), \lambda_0(v_-)) - p(v_-, 0)}{v_0(v_-) - v_-}} = \sqrt{-\frac{p(v_0^T, 0) - p(v_0(v_-), \lambda_0(v_-))}{v_0^T - v_0(v_-)}}.$$

We then define

$$u_\diamond = F(v_0^T), \quad u^\diamond = F(v_m).$$

For $u_+ - u_- \le u_\diamond$ the construction of solutions to the Riemann problem can be continued proceeding as in subsection 5.4.

Example 6.4. Consider again the case of two pure states, same phase. Assume $\lambda_- = \lambda_+ = 1$, $p(v_-, 1) - p_e \ge p_{co}$; for simplicity we omit the bounds for $u_+ - u_-$. The solution has a transition

$$\text{vapor} \to \text{mixture} \to \text{vapor}.$$

It connects v_- to v_0 with a left-moving collapsing wave, v_0 to v_1 with a left-moving evaporation wave, and, finally, v_1 to v_+ with a 2-Lax wave. This construction, however, can be done until the line joining $(v_0, p(v_0, 1))$ and $(v_1, p(v_1, 1))$ becomes tangent to the graph of the function $p(v, 1)$. From that point on a construction similar to the one of Example 6.2 can be done. We omit the details.

Acknowledgment. This work was partly accomplished while A. Corli and H. Fan visited the Isaac Newton Institute for Mathematical Sciences, Cambridge, UK, during the programme Nonlinear Hyperbolic Waves in Phase Dynamics and Astrophysics.

SPATIAL DECAY BOUNDS IN TIME DEPENDENT PIPE FLOW OF AN INCOMPRESSIBLE VISCOUS FLUID*

CHANGHAO LIN† AND LAWRENCE E. PAYNE‡

Abstract. In this paper, the authors investigate the flow of an incompressible viscous fluid in a semi-infinite cylindrical pipe. If the net entrance flow is nonzero, then the fluid velocity will not tend to zero as the distance from the entrance end tends to infinity when the fluid adheres at the cylinder wall and the fluid is initially at rest. Assuming that the entrance velocity data are small enough and that the fluid flow converges to a laminar flow as the distance down the pipe tends to infinity, it is shown that the convergence in energy measure is at least exponential.

Key words. viscous pipe flow, decay bounds, Saint-Venant's principle, Navier–Stokes equation

1. Introduction.

A number of papers in the literature have dealt with the transient flow of an incompressible viscous fluid in a semi-infinite pipe or channel. If the net flow into the finite end of the pipe or channel at any time is not zero, then the flow velocity cannot go to zero as the distance from the finite end tends to infinity. If the flow is governed by the linear Stokes equations, then the case in which the net entry flow is zero has been considered in $\mathbb{R}^2$ by Lin [14] and in $\mathbb{R}^3$ by Ames, Payne, and Schaefer [2]. The case of nonzero channel entry flow has been investigated by Song [22]. When the flow is governed by the Navier–Stokes equation, the general entry flow problem in $\mathbb{R}^2$ has been treated by Lin and Payne [15]. In this paper, we study the analogous problem in $\mathbb{R}^3$.

It is well known that unless there is some restriction on data, coefficients, and geometry, a global solution may not exist. Also if the net entry flow in the pipe is nonzero, we expect the velocity profile to converge to that of transient laminar flow as the distance from the finite end of the cylinder tends to infinity. The object of this paper is to derive explicit conditions on the data, coefficients, and geometry that will imply exponential decay of the transient flow to transient laminar flow in some appropriate weighted measure. We should point out, however, that there are various ways of handling boundary terms that appear in the computations as well as various ways of combining the inequalities. We have not attempted to derive optimal results, since that would excessively lengthen the already involved computations.

For related work on steady solutions of the Navier–Stokes equations for flows in channels and pipes, see, for instance, [1, 2, 3, 4, 7, 12]. These pipe and channel flow results may be regarded as Saint-Venant type decay results. In fact, the first paper to point out this connection was that of Horgan and Wheeler [12]. For other results of Saint-Venant type, see [8, 9, 10]. Of interest also are the papers [16, 17].

In section 2 we give a formulation of the problem. In section 3 we present some auxiliary inequalities used throughout the paper. In section 4 we derive the energy decay bounds in terms of total weighted energies and properties of the limiting solution. The laminar flow bounds are obtained in section 5 and the required total energies are obtained in section 6.

2. Formulation of the problem. In this section we introduce the boundary value problem that provides the basis for our investigation of the pipe flow of an incompressible viscous fluid.

Let R denote the interior of a semi-infinite three-dimensional cylindrical pipe and let ∂R denote its boundary. The uniform cross section is denoted by D. We assume the generators of the cylinder are parallel to the x_3 axis and that the entry section of the cylinder lies in the plane $x_3 = 0$. The symbol R_z designates the subdomain of R for which $x_3 > z \geq 0$, i.e.,

$$R_z = \{(x_1, x_2, x_3) \mid (x_1, x_2) \in D, x_3 \geq z \geq 0\}.$$

Clearly $R \equiv R_0$. Furthermore, we denote the cross section D with $x_3 = z$ by the symbol D_z, i.e.,

$$D_z = \{(x_1, x_2, x_2) \mid (x_1, x_2) \in D, x_3 = z\}.$$

The velocity field $u_i(x_1, x_2, x_3, t)$, $(i = 1, 2, 3)$ and the pressure $p(x_1, x_2, x_3, t)$ for the transient Navier–Stokes flow of an incompressible viscous fluid in the pipe are assumed to be classical solutions of the following initial-boundary value problem:

$$u_{i,t} - \nu \Delta u_i + u_j u_{i,j} = p_{,i} \quad \text{in } R \times \{t > 0\}, \tag{2.1}$$

$$u_{i,i} = 0 \quad \text{in } R \times \{t > 0\} \tag{2.2}$$

with

$$u_i = 0 \quad \text{on } \partial D \times \{t \geq 0\}, \tag{2.3}$$

$$u_i = f_i(x_1, x_2, t) \quad \text{on } D_0 \times \{t > 0\}, \tag{2.4}$$

$$u_i = 0 \quad \text{in } R \times \{t = 0\}, \tag{2.5}$$

where Δ denotes the Laplace operator and ν is the constant kinematic viscosity. We have used the comma to denote partial differentiation and have adopted the summation convention of summing over a repeated Latin subscript from 1 to 3 and over a repeated Greek index (unless otherwise specified) from 1 to 2. By rescaling the space and time variables, we may take the constant ν to be 1. In general we shall assume that time lies in some finite interval $[0, T]$.

It is well known that a global bounded solution for $t \in [0, T]$ may not exist. However, if the data f_i are sufficiently small in L_2, a bounded solution will exist. In fact, if the mean value of f_3 over D is zero, we expect the solution in some appropriate measure to vanish exponentially. However, if f_3 does not have mean value zero, we expect that for sufficiently small data, the velocity field (u_1, u_2, u_3) will tend exponentially to $(0, 0, V)$ as $x_3 \to \infty$, where $V(x_1, x_2, t)$ satisfies

$$V_{,t} - V_{,\alpha\alpha} = P(t) \quad \text{in } D \times \{t > 0\}, \tag{2.6}$$

$$V = 0 \quad \text{on } \partial D \times \{t > 0\}, \tag{2.7}$$

$$V = 0 \quad \text{in } D \times \{t = 0\}. \tag{2.8}$$

The function $P(t)$ is not prescribed but is determined by the condition

$$\int_D V(x_1, x_2, t)dA = \int_D f_3(x_1, x_2, t)dA = Q(t). \tag{2.9}$$

The problem (2.6)–(2.8) may be viewed as an inverse problem for determining $P(t)$ and V.

We now set

$$w_i = u_i - v_i, \quad q_{,i} = p_{,i} - P(t)\delta_{i3}, \tag{2.10}$$

where

$$(v_1, v_2, v_3) = (0, 0, V).$$

Then (w_i, q) will satisfy the following initial-boundary value problem:

$$w_{i,t} - \Delta w_i + (w_j + v_j)(w_{i,j} + v_{i,j}) = q_{,i} \quad \text{in } R \times \{t > 0\}, \tag{2.11}$$

$$w_{i,i} = 0 \quad \text{in } R \times \{t > 0\}, \tag{2.12}$$

$$w_i = 0 \quad \text{on } \partial D \times \{t \geq 0\}, \tag{2.13}$$

$$w_i = f_i - V\delta_{i3} \quad \text{in } D_0 \times \{t \geq 0\}, \tag{2.14}$$

$$w_i = 0 \quad \text{in } R \times \{t = 0\}. \tag{2.15}$$

We suppose further that for any finite positive constant K, the energy expression

$$E(0, t) = \int_0^t \int_{R_0} x_3^2 w_{i,j} w_{i,j} dx d\eta + K \int_0^t \int_{R_0} x_3^2 w_{i,\eta} w_{i,\eta} dx d\eta \tag{2.16}$$

is bounded. Here η is a running time variable, and there is no summation over η.

We note that

$$\int_{D_z} w_3 dA = \int_{D_0} w_3 dA + \int_0^z \int_{D_\xi} w_{i,i} dA d\xi = 0. \tag{2.17}$$

3. Auxiliary results. We list in this section a number of standard inequalities used throughout this paper.

Let w be a Dirichlet integrable function defined on a bounded plane domain D and vanishing on the boundary ∂D; then

$$\int_D w_{,\alpha} w_{,\alpha} dA \geq \lambda_1 \int_D w^2 dA, \tag{3.1}$$

where λ_1 is the smallest eigenvalue of the problem

$$\Delta\varphi + \lambda\varphi = 0 \quad \text{in } D,$$
$$\varphi = 0 \quad \text{on } \partial D.$$

Lower bounds for λ_1 are well known; see, e.g., [6, 18, 19].

We also make use of the following representation theorem attributed to Babuška and Aziz [5].

THEOREM A. *Let D be a plane Lipschitz domain and let w be a differentiable function in D which satisfies $\int_D w dA = 0$. Then there exists a vector function φ_α such that*

$$\begin{aligned} \varphi_{\alpha,\alpha} &= w \quad \text{in } D, \\ \varphi_\alpha &= 0 \quad \text{on } \partial D, \end{aligned}$$

and a positive constant C depending only on the geometry of D such that

$$\int_D \varphi_{\alpha,\beta}\varphi_{\alpha,\beta} dA \le C \int_D \varphi_{\alpha,\alpha}^2 dA. \tag{3.2}$$

This theorem was first applied to viscous flow problems by Horgan and Wheeler [12]. In fact, an explicit upper bound for the optimal value of C was found by Horgan and Payne [11] if D is star-shaped. The analogue of Theorem A also holds in $\mathbb{R}^3$ (see [23]). This inequality will allow us to eliminate the pressure function difference term q, since w_3 satisfies the hypothesis of this theorem.

In addition to inequalities (3.1), (3.2), we also make use of the following Sobolev inequalities which hold for $w \in C_0^1(D)$ and $w \in C_0^1(R)$, respectively:

$$\int_D w^4 dA \le \frac{1}{2}\left[\int_D w^2 dA\right]\left[\int_D w_{,\alpha} w_{,\alpha} dA\right], \tag{3.3}$$

$$\int_{R_z} w^6 dx \le \Omega \left[\int_{R_z} w_{,i} w_{,i} dx\right]^3. \tag{3.4}$$

For (3.4), we assume that w vanishes appropriately as $x_3 \to \infty$. A derivation of (3.3) is given by Serrin [20] and Payne [17], while (3.4) follows as a special case of results of [13, 21], where the optimal value of Ω was determined to be

$$\Omega = \frac{1}{27}\left(\frac{3}{4}\right)^4.$$

In what follows, we also make frequent use of the fact that if $w \in C^1(R_z)$ and w_i vanishes on ∂D for $x_3 \ge z$, then, if w_i vanishes as $x_3 \to \infty$,

$$\begin{aligned} \int_{D_z} (w_i w_i)^2 dA &= -4 \int_{R_z} w_i w_{i,3} w_j w_j dx \\ &\le 4 \left[\int_{R_z} w_{i,3} w_{i,3} dx\right]^{1/2} \left[\int_{R_z} (w_j w_j)^3 dx\right]^{1/2} \\ &\le 4\sqrt{\Omega}\left[\int_{R_z} w_{i,j} w_{i,j} dx\right]^2. \end{aligned} \tag{3.5}$$

4. Energy decay bounds. In this section we derive the main exponential decay result for problems (2.1)–(2.15).

First, for arbitrary $z > 0$ and $t > 0$, we define a weighted energy integral

$$\begin{aligned} E(z,t) &= \int_0^t \int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx d\eta + K \int_0^t \int_{R_z} (\xi - z)^2 w_{i,\eta} w_{i,\eta} dx d\eta \\ &= E_1(z,t) + K E_2(z,t). \end{aligned} \tag{4.1}$$

We also define

$$E_3(z,t) = \int_0^t \int_{R_z} (\xi - z)^2 w_{i,j\eta} w_{i,j\eta} dx d\eta, \tag{4.2}$$

where there is no summation on the η subscript and K is a positive parameter. Note that (2.16) has been assumed, but now we further require that $E_3(0,t)$ be bounded. Clearly then

$$\frac{\partial E}{\partial z} = -2\int_0^t \int_{R_z} (\xi - z) w_{i,j} w_{i,j} dx d\eta - 2K \int_0^t \int_{R_z} (\xi - z) w_{i,\eta} w_{i,\eta} dx d\eta,$$
$$\frac{\partial^2 E}{\partial z^2} = 2\int_0^t \int_{R_z} w_{i,j} w_{i,j} dx d\eta + 2K \int_0^t \int_{R_z} w_{i,\eta} w_{i,\eta} dx d\eta.$$

Upon integrating by parts in (4.1) and using equations (2.11) and (2.12), we obtain

$$\begin{aligned} &E(z,t) + \frac{1}{2}\int_{R_z} (\xi - z)^2 w_i w_i dx\big|_{\eta=t} + \frac{K}{2}\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx\big|_{\eta=t} \\ &\quad = -2\int_0^t \int_{R_z} (\xi - z) w_i w_{i,3} dx d\eta - \int_0^t \int_{R_z} (\xi - z)^2 w_i [w_j w_{i,j} + v_j w_{i,j} + w_j v_{i,j}] dx d\eta \\ &\qquad - 2\int_0^t \int_{R_z} (\xi - z) w_3 q dx d\eta - 2K \int_0^t \int_{R_z} (\xi - z) w_{i,\eta} w_{i,3} dx d\eta \\ &\qquad - 2K \int_0^t \int_{R_z} (\xi - z) w_{3,\eta} q dx d\eta \\ &\qquad - K \int_0^t \int_{R_z} (\xi - z)^2 w_{i,\eta} [w_j w_{i,j} + v_j w_{i,j} + w_j v_{i,j}] dx d\eta \\ &\quad = \sum_{i=1}^{6} I_i. \end{aligned} \tag{4.3}$$

We now proceed to bound each integral I_i. Using Schwarz's inequality and (3.1), we obtain

$$\begin{aligned} I_1 &\le 2\left(\int_0^t \int_{R_z} (\xi - z) w_i w_i dx d\eta\right)^{1/2} \left(\int_0^t \int_{R_z} (\xi - z) w_{i,3} w_{i,3} dx d\eta\right)^{1/2} \\ &\le \lambda_1^{-1/2} \left(-\frac{\partial E}{\partial z}\right). \end{aligned} \tag{4.4}$$

We next look at

$$\begin{aligned} I_2 &= \int_0^t \int_{R_z} (\xi - z) w_i w_i w_3 dx d\eta - \int_0^t \int_{R_z} (\xi - z)^2 w_i w_{i,3} V dx d\eta \\ &\qquad - \int_0^t \int_{R_z} (\xi - z)^2 w_3 w_\alpha V_{,\alpha} dx d\eta \\ &= I_{21} + I_{22} + I_{23}. \end{aligned} \tag{4.5}$$

By using Schwarz's inequality and (3.3), (3.5), we obtain

$$
\begin{aligned}
I_{21} &\le \int_0^t \int_z^\infty (\xi - z) \left(\int_{D_\xi} (w_i w_i)^2 dA \right)^{1/2} \left(\int_{D_\xi} w_3^2 dA \right)^{1/2} d\xi d\eta \\
&\le \frac{2^{1/4} \Omega^{1/8}}{\lambda_1^{3/4}} \int_0^t \left(\int_{R_z} w_{i,j} w_{i,j} dx \right)^{1/2} \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} \\
&\qquad \cdot \left(\int_{R_z} w_{i,j} w_{i,j} dx \right)^{1/2} d\eta \\
&\le \frac{2^{1/4} \Omega^{1/8}}{\lambda_1^{3/4}} \max_t \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} \left[\frac{\partial^2 E_1}{\partial z^2}(0,t) \right]^{1/2} \left[\frac{\partial^2 E}{\partial z^2} \right]^{1/2} \\
&\le \frac{\varepsilon_1}{2} \max_t \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} + \frac{\Omega^{1/4}}{2^{1/2} \lambda_1^{3/2} \varepsilon_1} \left[\frac{\partial^2 E_1}{\partial z^2}(0,t) \right] \left[\frac{\partial^2 E}{\partial z^2} \right] \qquad (4.6)
\end{aligned}
$$

for arbitrary positive constant ε_1.

For I_{22}, we have

$$
\begin{aligned}
I_{22} &= -\int_0^t \int_{R_z} (\xi - z)^2 w_i w_{i,3} V dx d\eta \\
&= \int_0^t \int_{R_z} (\xi - z) w_i w_i V dx d\eta \\
&\le \frac{1}{\lambda_1} |V|_{\max} \left[-\frac{\partial E}{\partial z} \right]. \qquad (4.7)
\end{aligned}
$$

Similarly, we have

$$
\begin{aligned}
I_{23} &= -\int_0^t \int_{R_z} (\xi - z)^2 w_3 w_\alpha V_{,\alpha} dx d\eta \\
&= \int_0^t \int_{R_z} (\xi - z)^2 w_{3,\alpha} w_\alpha V dx d\eta - \int_0^t \int_{R_z} (\xi - z)^2 w_3 w_{3,3} V dx d\eta \\
&\le \frac{1}{2} \lambda_1^{-1/2} |V|_{\max} E(z,t) + \frac{1}{\lambda_1} |V|_{\max} \left[-\frac{\partial E}{\partial z} \right]. \qquad (4.8)
\end{aligned}
$$

To seek a bound for I_3, we note that, for any $z > 0$,

$$
\int_{D_z} w_3 dA = 0. \qquad (4.9)
$$

Accordingly by Theorem A, there exists a vector function (φ_1, φ_2) such that

$$
\begin{cases} \varphi_{\alpha,\alpha} = w_3 & \text{in } D_z, \\ \varphi_\alpha = 0 & \text{on } \partial D_z, \end{cases}
$$

and for φ_α inequality (3.2) holds. Introducing φ_α into I_3, we obtain

$$
\begin{aligned}
I_3 &= -2 \int_0^t \int_{R_z} (\xi - z) \varphi_{\alpha,\alpha} q dx d\eta \\
&= 2 \int_0^t \int_{R_z} (\xi - z) \varphi_\alpha [w_{\alpha,\eta} + w_j w_{\alpha,j} + v_j w_{\alpha,j} - \Delta w_\alpha] dx d\eta \\
&= I_{31} + I_{32} + I_{33} + I_{34}. \qquad (4.10)
\end{aligned}
$$

Obviously, by using Schwarz's inequality and (3.2), we have

$$I_{31} \le \frac{2}{\sqrt{K}} \left(\int_0^t \int_{R_z} (\xi - z) \varphi_\alpha \varphi_\alpha dx d\eta \right)^{1/2} \left(K \int_0^t \int_{R_z} (\xi - z) w_{\alpha,\eta} w_{\alpha,\eta} dx d\eta \right)^{1/2}$$

$$\le \frac{1}{\lambda_1} (C/K)^{1/2} \left[-\frac{\partial E}{\partial z} \right]. \tag{4.11}$$

For I_{32}, with a derivation similar to (4.6), we obtain

$$\begin{aligned} I_{32} &\le 2 \int_0^t \int_z^\infty (\xi - z) \left(\int_{D_\xi} (\varphi_\alpha \varphi_\alpha)^2 dA \right)^{1/4} \left(\int_{D_\xi} (w_i w_i)^2 dA \right)^{1/4} \\ &\qquad \cdot \left(\int_{D_\xi} w_{\alpha,j} w_{\alpha,j} dA \right)^{1/2} d\xi d\eta \\ &\le \frac{2(2C)^{1/2} \Omega^{1/8}}{2^{1/4} \lambda_1^{1/2}} \int_0^t \left(\int_{R_z} w_{i,j} w_{i,j} dx \right)^{1/2} \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} \\ &\qquad \cdot \left(\int_{R_z} w_{i,j} w_{i,j} dx \right)^{1/2} d\eta \\ &\le \frac{2(2C)^{1/2} \Omega^{1/8}}{2^{1/4} \sqrt{\lambda_1}} \max_t \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} \left[\frac{\partial^2 E_1}{\partial z^2}(0,t) \right]^{1/2} \left[\frac{\partial^2 E}{\partial z^2} \right]^{1/2} \\ &\le \frac{\varepsilon_2}{2} \max_t \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right) + \frac{2^{3/2} \Omega^{1/4}}{\lambda_1 \varepsilon_2} \left[\frac{\partial^2 E}{\partial z^2}(0,t) \right] \left[\frac{\partial^2 E}{\partial z^2} \right]. \end{aligned} \tag{4.12}$$

Using (3.2), we find

$$\begin{aligned} I_{33} &\le 2 \int_0^t \int_{R_z} (\xi - z) \varphi_\alpha w_{\alpha,3} V dx d\eta \\ &\le 2 |V|_{\max} \left(\int_0^t \int_{R_z} (\xi - z) \varphi_\alpha \varphi_\alpha dx d\eta \right)^{1/2} \left(\int_0^t \int_{R_z} (\xi - z) w_{\alpha,3} w_{\alpha,3} dx d\eta \right) \\ &\le \frac{C^{1/2}}{\lambda_1} |V|_{\max} \left[-\frac{\partial E}{\partial z} \right], \end{aligned} \tag{4.13}$$

and

$$\begin{aligned} I_{34} &= -2 \int_0^t \int_{R_z} (\xi - z) \varphi_\alpha w_{\alpha,jj} dx d\eta \\ &= 2 \int_0^t \int_{R_z} \varphi_\alpha w_{\alpha,3} dx d\eta + 2 \int_0^t \int_{R_z} (\xi - z) \varphi_{\alpha,j} w_{\alpha,j} dx d\eta \\ &\le \frac{C^{1/2}}{\lambda_1} \left[\frac{\partial^2 E}{\partial z^2} \right] + (C/\lambda_1)^{1/2} \left[-\frac{\partial E}{\partial z} \right]. \end{aligned} \tag{4.14}$$

By using Schwarz's inequality, we obtain

$$I_4 = -2K \int_0^t \int_{R_z} (\xi - z) w_{i,\eta} w_{i,3} dx d\eta \le K^{1/2} \left[-\frac{\partial E}{\partial z} \right]. \tag{4.15}$$

For I_5, since

$$\int_{D_z} w_{3,t} dA = 0,$$

by Theorem A, there exists a vector function (ψ_1, ψ_2) that satisfies the boundary value problem

$$\begin{cases} \psi_{\alpha,\alpha} = w_{3,t} & \text{in } D_z, \\ \psi_\alpha = 0 & \text{on } \partial D_z. \end{cases}$$

Introducing ψ_α, we can write

$$\begin{aligned} I_5 &= -2K \int_0^t \int_{R_z} (\xi - z) \psi_{\alpha,\alpha} q dx d\eta \\ &= 2K \int_0^t \int_{R_z} (\xi - z) \psi_\alpha [w_{\alpha,\eta} + w_j w_{\alpha,j} + v_j w_{\alpha,j} - \Delta w_\alpha] dx d\eta \\ &= I_{51} + I_{52} + I_{53} + I_{54}. \end{aligned} \tag{4.16}$$

It is easy to see that

$$\begin{aligned} I_{51} &\le 2K \left(\int_0^t \int_{R_z} (\xi - z) \psi_\alpha \psi_\alpha dx d\eta \right)^{1/2} \left(\int_0^t \int_{R_z} (\xi - z) w_{\alpha,\eta} w_{\alpha,\eta} dx d\eta \right)^{1/2} \\ &\le (C/\lambda_1)^{1/2} \left[-\frac{\partial E}{\partial z} \right]. \end{aligned} \tag{4.17}$$

In a manner similar to (4.6), (4.11), we find

$$\begin{aligned} I_{52} &= 2K \int_0^t \int_{R_z} (\xi - z) \psi_\alpha w_\alpha w_{\alpha,j} dx d\eta \\ &\le 2K \int_0^t \int_z^{+\infty} (\xi - z) \left(\int_{D_\xi} (\psi_\alpha \psi_\alpha)^2 dA \right)^{1/4} \left(\int_{D_\xi} (w_\alpha w_\alpha)^2 dA \right)^{1/4} \\ &\qquad \cdot \left(\int_{D_\xi} w_{\alpha,j} w_{\alpha,j} dA \right)^{1/2} d\xi d\eta \\ &\le \frac{2(2CK)^{1/2} \Omega^{1/8}}{(2\lambda_1)^{1/4}} \max_t \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} \left[\frac{\partial^2 E_1}{\partial z^2}(0,t) \right]^{1/2} \left[\frac{\partial^2 E}{\partial z^2} \right]^{1/2} \\ &\le \frac{\varepsilon_3}{2} \max_t \left(\int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx \right)^{1/2} + \frac{2^{3/2} CK \Omega^{1/4}}{\lambda_1^{1/2} \varepsilon_3} \left[\frac{\partial^2 E_1}{\partial z^2}(0,t) \right] \left[\frac{\partial^2 E}{\partial z^2} \right]. \end{aligned} \tag{4.18}$$

Similarly, we have

$$\begin{aligned} I_{53} &= 2K\int_0^t\int_{R_z}(\xi-z)\psi_\alpha w_{\alpha,3}V dxd\eta \\ &= (KC/\lambda_1)^{1/2}|V|_{\max}\left[-\frac{\partial E}{\partial z}\right], \end{aligned} \tag{4.19}$$

$$\begin{aligned} I_{54} &= 2K\int_0^t\int_{R_z}\psi_\alpha w_{\alpha,3}dxd\eta + 2K\int_0^t\int_{R_z}(\xi-z)\psi_{\alpha,j}w_{\alpha,j}dxd\eta \\ &\le (KC/\lambda_1)^{1/2}\left[\frac{\partial^2 E}{\partial z^2}\right] + (CK)^{1/2}\left[-\frac{\partial E}{\partial z}\right]. \end{aligned} \tag{4.20}$$

Finally, we derive a bound for I_6:

$$\begin{aligned} I_6 &= -K\int_0^t\int_{R_z}(\xi-z)^2 w_{i,\eta}[w_j w_{i,j} + v_j w_{i,j} + w_j v_{i,j}]dxd\eta \\ &= -K\int_0^t\int_{R_z}(\xi-z)^2 w_{i,\eta}w_j w_{i,j}dxd\eta - K\int_0^t\int_{R_z}(\xi-z)^2 w_{i,\eta}w_{i,3}V dxd\eta \\ &\quad - K\int_0^t\int_{R_z}(\xi-z)^2 w_{3,\eta}w_\alpha V_{,\alpha}dxd\eta \\ &= I_{61}+I_{62}+I_{63}. \end{aligned} \tag{4.21}$$

With a derivation similar to (4.11), we have

$$\begin{aligned} I_{61} &\le K\int_0^t\int_z^\infty(\xi-z)^2\left(\int_{D_\xi}(w_i w_i)^2 dA\right)^{1/4}\left(\int_{D_\xi}(w_{,i\eta}w_{i,\eta})^2 dA\right)^{1/4} \\ &\qquad\cdot\left(\int_{D_\xi}w_{i,j}w_{i,j}dA\right)^{1/2}d\xi d\eta \\ &\le (2/\lambda_1)^{1/4}\Omega^{1/8}K\int_0^t\left(\int_{R_z}w_{,ij\eta}w_{,ij\eta}dx\right)^{1/2}\left(\int_{R_z}(\xi-z)^2 w_{i,j}w_{i,j}dx\right)d\eta \\ &\le (2/\lambda_1)^{1/4}\Omega^{1/8}K\max_t\left[\int_{R_z}(\xi-z)^2 w_{i,j}w_{i,j}dx\right]^{1/2}\left[\frac{\partial^2 E_3(0,t)}{\partial z^2}\right]^{1/2}[E(z,t)]^{1/2} \\ &\le \frac{\varepsilon_4}{2}\max_t\int_{R_z}(\xi-z)^2 w_{i,j}w_{i,j}dx + \frac{\Omega^{1/4}}{(2\lambda_1)^{1/2}}\,\frac{K}{\varepsilon_4}\left[\frac{\partial^2 E_3(0,t)}{\partial z^2}\right]\cdot E(z,t). \end{aligned} \tag{4.22}$$

It is easy to bound I_{62}, i.e.,

$$I_{62} \le \frac{K^{1/2}}{2}|V|_{\max}E(z,t). \tag{4.23}$$

For I_{63}, we observe that

$$\begin{aligned} I_{63} &= K\int_0^t\int_{R_z}(\xi-z)^2 w_{3,\alpha\eta}w_\alpha V dxd\eta - K\int_0^t\int_{R_z}(\xi-z)^2 w_{3,\eta}w_{3,3}V dxd\eta \\ &= K\int_{R_z}(\xi-z)^2 w_{3,\alpha}w_\alpha V dx - K\int_0^t\int_{R_z}(\xi-z)^2 w_{3,\alpha}w_{\alpha,\eta}V dxd\eta \\ &\quad - K\int_0^t\int_{R_z}(\xi-z)^2 w_{3,\alpha}w_\alpha V_{,\eta}dxd\eta - K\int_0^t\int_{R_z}(\xi-z)^2 w_{3,\eta}w_{3,3}V dxd\eta \\ &\le \frac{K|V|_{\max}}{2\lambda_1^{1/2}}\left(\int_{R_z}(\xi-z)^2 w_{i,j}w_{i,j}dx\right) + \frac{1}{2}(K/\lambda_1)^{1/2}|V_{,t}|_{\max}E(z,t) \\ &\quad + K^{1/2}|V|_{\max}E(z,t). \end{aligned} \tag{4.24}$$

We now sum up the results established in this section to obtain

$$\begin{aligned} &E(z,t) + \frac{1}{2}\int_{R_z}(\xi-z)^2 w_i w_i dx + \frac{K}{2}\left(1-\frac{|V|_{\max}}{\lambda_1^{1/2}}\right)\int_{R_z}(\xi-z)^2 w_{i,j}w_{i,j}dx \\ &\quad \le M_1 E(z,t) + M_2\left(-\frac{\partial E}{\partial z}\right) + M_3\frac{\partial^2 E}{\partial z^2} \\ &\quad\quad + \frac{1}{2}(\varepsilon_1+\varepsilon_2+\varepsilon_3+\varepsilon_4)\max_t\int_{R_z}(\xi-z)^2 w_{i,j}w_{i,j}dx, \end{aligned} \tag{4.25}$$

where

$$\begin{aligned} M_1 &= \left(\frac{1}{\lambda_1}+K^{1/2}\right)|V|_{\max} + \frac{1}{2}(K/\lambda_1)^{1/2}|V_{,t}|_{\max} \\ &\quad + \left(\frac{\Omega^{1/2}}{2\lambda_1}\right)^{1/2}\frac{K}{\varepsilon_4}\left[\frac{\partial^2 E_3(0,t)}{\partial z^2}\right], \end{aligned} \tag{4.26}$$

$$\begin{aligned} M_2 &= \left[\left(\frac{1}{\lambda_1}\right)^{1/2} + \frac{2}{\lambda_1}|V|_{\max} + \frac{C^{1/2}}{\lambda_1}|V|_{\max} + \frac{1}{\lambda_1}(C/K)^{1/2} + 2(C/\lambda_1)^{1/2}\right. \\ &\quad \left. + K^{1/2} + (KC)^{1/2}\right], \end{aligned} \tag{4.27}$$

and

$$\begin{aligned} M_3 &= \Omega^{1/4}\left[\frac{1}{(2\lambda_1^3)^{1/2}\varepsilon_1} + \frac{2^{3/2}C}{\lambda_1\varepsilon_2} + \frac{2^{3/2}CK}{\lambda_1^{1/2}\varepsilon_3}\right]\left[\frac{\partial^2 E_1}{\partial z^2}(0,t)\right] \\ &\quad + \left(\frac{CK}{\lambda_1}\right)^{1/2} + \frac{C^{1/2}}{\lambda_1}. \end{aligned} \tag{4.28}$$

Explicit bounds for $|V|_{\max}$ and $|V_{,t}|_{\max}$ as well as bounds for the total energies $E(0,t)$, $\frac{\partial^2 E_1}{\partial z^2}(0,z)$, and $\frac{\partial^2 E_3}{\partial z^2}(0,z)$ in terms of data are derived in sections 5 and 6, respectively.

Suppose now that the quantity $\int(\xi - z)^2 w_{i,j} w_{i,j} dx$ takes its maximum value at $t^* \in [0, T]$. Then, evaluating (4.25) at $t = t^*$, we have

$$\gamma \int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx\big|_{t=t^*}$$
$$\leq (M_1 - 1)E(z, t^*) + M_2 \left(-\frac{\partial}{\partial z} E(z, t^*)\right) + M_3 \left(\frac{\partial^2}{\partial z^2} E(z, t^*)\right), \tag{4.29}$$

where

$$\gamma = \frac{1}{2}\left[K\left(1 - \frac{|V|_{\max}}{\lambda_1^{1/2}}\right) - (\varepsilon_1 + \varepsilon_2 + \varepsilon_3 + \varepsilon_4)\right]. \tag{4.30}$$

At this point, we require that the data be small enough to satisfy

$$|V|_{\max} < \lambda_1^{1/2}, \tag{4.31}$$

in which case the ε_i can be chosen small enough that $\gamma > 0$. We further restrict the data by requiring that

$$M_1 < 1, \tag{4.32}$$

and since $E(z, t)$ and its first and second derivatives are monotone functions of t, we have

$$\gamma \int_{R_z} (\xi - z)^2 w_{i,j} w_{i,j} dx\big|_{t=t^*} \leq M_2 \left(-\frac{\partial}{\partial z} E(z, t)\right) + M_3 \left(\frac{\partial^2}{\partial z^2} E(z, t)\right). \tag{4.33}$$

Inserting (4.33) back into (4.25), we conclude that

$$\frac{K}{2\delta}\left(1 - \frac{|V|_{\max}}{\lambda_1^{1/2}}\right)\left[M_3 \frac{\partial^2 E}{\partial z^2} + M_2 \left(-\frac{\partial E}{\partial z}\right)\right] - (1 - M_1)E \geq 0. \tag{4.34}$$

We rewrite this expression as

$$\frac{\partial^2 E}{\partial z^2} - a\frac{\partial E}{\partial z} - bE \geq 0, \tag{4.35}$$

where

$$a = M_2/M_3, \quad b = \frac{(1 - M_1)}{M_3}\left[\frac{K}{2\delta}\left(1 - \frac{|V|_{\max}}{\lambda_1^{1/2}}\right)\right]^{-1}. \tag{4.36}$$

We further rewrite (4.35) as

$$\left(\frac{\partial}{\partial z} - k_1\right)\left(\frac{\partial E}{\partial z} + k_2 E\right) \geq 0, \tag{4.37}$$

where

$$k_1 = \frac{a}{2} + \frac{1}{2}\sqrt{a^2 + 4b}, \quad k_2 = -\frac{a}{2} + \frac{1}{2}\sqrt{a^2 + 4b}. \tag{4.38}$$

It is well known that (4.37) leads to the conclusion that

$$E(z, t) \leq E(0, t)e^{-k_2 z}. \tag{4.39}$$

Inequalities (4.31) and (4.32) may be regarded as Reynold's number type restrictions for our problem.

5. Bounds for laminar flow V. In this section we derive explicit bounds for the laminar flow V and its time derivative in terms of the geometry of domain and prescribed data.

We recall that the fully developed laminar flow V satisfies the initial-boundary value problem (2.6)–(2.8), i.e.,

$$\begin{aligned} V_{,t} - \Delta V &= P(t) \quad \text{in } D_z \times \{t > 0\}, \\ V(x,0) &= 0 \quad \text{in } D_z \times \{t = 0\}, \\ V(x,t) &= 0 \quad \text{on } \partial D_z \times \{t > 0\}, \end{aligned}$$

where $P(t)$ is an unknown function but is determined from the condition

$$\int_D V(x,t)dA = \int_D f_3(x,t)dA = Q(t), \tag{5.1}$$

and $f_3(x,t)$ is the f_3 of (2.4).

From (5.1), we readily obtain

$$\frac{1}{2}\frac{\partial}{\partial t}\int_D V^2 dA + \int_D V_{,\alpha}V_{,\alpha}dA = P(t)Q(t), \tag{5.2}$$

$$\frac{1}{2}\int_D V_{,\alpha}V_{,\alpha}dA + \int_0^t \int_D (V_{,\eta})^2 dA d\eta = \int_0^t P(\eta)Q_{,\eta}(\eta)d\eta. \tag{5.3}$$

Now let ψ be a solution of the problem

$$\begin{cases} \Delta\psi = -1 & \text{in } D, \\ \psi = 0 & \text{on } \partial D. \end{cases} \tag{5.4}$$

Then we have

$$Q(t) = \int_D V dA = -\int_D V\Delta\psi dA = -\int_D V_{,t}\psi dA + SP(t), \tag{5.5}$$

where

$$S = \int_D \psi dA = \int_D \psi_{,\alpha}\psi_{,\alpha}dA > 0. \tag{5.6}$$

From (5.5) we obtain

$$P(t) = \frac{1}{S}\left[Q(t) + \int_D \psi V_{,t}dA\right]. \tag{5.7}$$

Inserting (5.7) into (5.3) leads to

$$\begin{aligned} &\frac{1}{2}\int_D V_{,\alpha}V_{,\alpha}dA + \int_0^t \int_D (V_{,\eta})^2 dA d\eta = \frac{1}{S}\int_0^t Q_{,\eta}(\eta)\left[Q(\eta) + \int_D \psi V_{,\eta}dA\right]d\eta \\ &= \frac{1}{2S}[Q^2(t) - Q^2(0)] + \frac{1}{S}\int_0^t Q_{,\eta}\left(\int_D \psi V_{,\eta}dA\right)d\eta. \end{aligned} \tag{5.8}$$

But $Q(0)=0$, since $V(x,0)=0$, so (5.8) further reduces to

$$\begin{aligned}&\frac{1}{2}\int_D V_{,\alpha}V_{,\alpha}dA+\int_0^t\int_D (V_{,\eta})^2 dAd\eta\\ &\quad\le \frac{1}{2S}Q^2(t)+\frac{1}{S}\left[\int_0^t\int_D (V_{,\eta})^2 dAd\eta\int_0^t (Q_{,\eta})^2 d\eta\int_D \psi^2 dA\right]^{1/2}.\end{aligned}\tag{5.9}$$

Using the arithmetic-geometric mean inequality in (5.9) yields, finally,

$$\begin{aligned}&\int_D V_{,\alpha}V_{,\alpha}dA+\int_0^t\int_D (V_{,\eta})^2 dAd\eta\\ &\quad\le \frac{1}{S}Q^2(t)+\frac{1}{S^2}\int_0^t (Q_{,\eta})^2 d\eta\int_D \psi^2 dA=:\overline{M}_1.\end{aligned}\tag{5.10}$$

We remark that S is a monotone function of domain as is ψ, so that bounds for S and for $\int_D \psi^2 dA$ are easily obtained (see, e.g., [6]).

By a similar derivation, using (5.7) and (5.10) in (5.2) we obtain

$$\begin{aligned}&\frac{1}{2}\int_D V^2 dA+\int_0^t\int_D V_{,\alpha}V_{,\alpha}dAd\eta=\frac{1}{S}\int_0^t Q(\eta)\left[Q(\eta)+\int_D \psi V_{,\eta}dA\right]d\eta\\ &\quad\le \frac{1}{S}\int_0^t Q^2(\eta)d\eta+\frac{1}{S}\left[\int_0^t\int_D (V_{,\eta})^2 dAd\eta\int_D \psi^2 dA\int_0^t Q^2(\eta)d\eta\right]^{1/2}\\ &\quad\le \frac{1}{S}\int_0^t Q^2(\eta)d\eta+\frac{1}{S}\left\{\left[\frac{1}{S}Q^2(t)+\frac{1}{S^2}\int_0^t Q_{,\eta}^2 d\eta\int_D \psi^2 dA\right]\right.\\ &\qquad\qquad\left.\cdot\int_D \psi^2 ds\int_0^t Q^2(\eta)d\eta\right\}^{1/2}\\ &\quad=:\overline{M}_2.\end{aligned}\tag{5.11}$$

From (5.11) it follows that

$$\int_D V^2(x,t)dA\le 2\overline{M}_2.\tag{5.12}$$

To derive a bound for $|V|_{\max}$, we observe that

$$\begin{aligned}V(x)&=-\int_D G(V_{,t}-P(t))dA\\ &=-\int_D GV_{,t}dA+P(t)\int_D GdA\\ &=-\int_D GV_{,t}dA+\psi(x)P(t),\end{aligned}\tag{5.13}$$

where G is the harmonic Green's function for D. Using Schwarz's inequality in (5.13), we obtain

$$|V|\le\left(\int_D G^2 dA\right)^{1/2}\left(\int_D V_{,t}^2 dA\right)^{1/2}+|\psi|_{\max}|P(t)|.\tag{5.14}$$

As a limiting expression of results of Weinberger [24], we have

$$\int_D G^2 dA \le \frac{|D|}{8\pi^2}, \tag{5.15}$$

where $|D|$ is the area of domain D. Using (5.9), (5.7), and the monotonicity of ψ, we obtain a bound for $|V|_{\max}$. The bound for $|V_{,t}|_{\max}$ may be found in an analogous way by substituting $V_{,t}$ for V and $P'(t)$ for $P(t)$ in the preceding arguments.

6. Bounds for the total weighted energies. In this section we sketch how one can derive the total weighted energy bounds needed to complete our decay results. Since we need it in subsequent arguments, we first show how to bound $\partial^2 E(0,t)/\partial z^2$.

Let $\widehat{u}_i$ be the solution of the associated Stokes flow problem

$$\widehat{u}_{i,t} = \Delta \widehat{u}_i + \widehat{p}_{,i} \quad \text{in } R \times \{t > 0\}, \tag{6.1}$$

$$\widehat{u}_{i,i} = 0 \quad \text{in } R \times \{t > 0\}, \tag{6.2}$$

$$\widehat{u}_i = 0 \quad \text{on } \partial D \times \{t \ge 0\}, \tag{6.3}$$

$$\widehat{u}_i = f_i(x_1, x_2, t) \quad \text{in } D_0 \times \{t > 0\}, \tag{6.4}$$

$$\widehat{u}_i = 0 \quad \text{in } R \times \{t = 0\}. \tag{6.5}$$

Suppose now that we set

$$w_i = (u_i - \widehat{u}_i) + (\widehat{u}_i - v_i) = \chi_i + \theta_i,$$
$$q_i = (p_{,i} - \widehat{p}_i) + (\widehat{p}_{,i} - P(t)\delta_{i3}) = \sigma_{,i} + \gamma_{,i}.$$

Clearly (χ_i, σ) is the solution of the initial-boundary value problem

$$\chi_{i,t} - \Delta \chi_i + u_j u_{i,j} = \sigma_{,i} \quad \text{in } R \times \{t > 0\}, \tag{6.6}$$

$$\chi_{i,i} = 0 \quad \text{in } R \times \{t > 0\}, \tag{6.7}$$

$$\chi_i = 0 \quad \text{on } \partial D \times \{t \ge 0\}, \tag{6.8}$$

$$\chi_i = 0 \quad \text{in } D_0 \times \{t > 0\}, \tag{6.9}$$

$$\chi_i = 0 \quad \text{in } R \times \{t = 0\}. \tag{6.10}$$

Furthermore, by the triangle inequality we have

$$[E(0,t)]^{1/2} \le [\widehat{E}(0,t)]^{1/2} + [\widetilde{E}(0,t)]^{1/2}, \tag{6.11}$$

where

$$\widehat{E}(0,t) = \int_0^t \int_R \xi^2 [\chi_{i,j}\chi_{i,j} + K\chi_{i,\eta}\chi_{i,\eta}] dx d\eta,$$
$$\widetilde{E}(0,t) = \int_0^t \int_R \xi^2 [\theta_{i,j}\theta_{i,j} + K\theta_{i,\eta}\theta_{i,\eta}] dx d\eta.$$

The same triangle inequality holds for E_1 and E_2 separately as well as for their z derivatives. Bounds for $-\frac{\partial \widetilde{E}(0,t)}{\partial z}$ and $\frac{\partial^2 \widetilde{E}(0,t)}{\partial z^2}$ were derived in [2, section 6]. Note, however, that the $E(0,t)$ of [2] is our $-\frac{\partial \widetilde{E}(0,t)}{\partial z}$.

We start by deriving a bound for $\frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2}$. Upon integration by parts, we obtain

$$\frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} = -2 \int_0^t \int_R \chi_i [\chi_{i,\eta} + (\chi_j + \widehat{u}_{,j})(\chi_i + \widehat{u}_i)_{,j} - \sigma_{,i}] dx d\eta. \tag{6.12}$$

In a manner analogous to that of section 4, it is readily seen that

$$\begin{aligned}
&\frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} + \int_R \chi_i \chi_i dx\big|_{\eta=t} = -2\int_0^t \int_R \chi_i(\chi_j + \widehat{u}_j)\widehat{u}_{i,j} dx d\eta \\
&= 2\int_0^t \int_R \chi_{i,j}[\chi_j(\theta_i + v_i) + (\theta_j + v_j)(\theta_i + v_i)] dx d\eta \\
&= 2\int_0^t \int_R \chi_{i,j}\chi_j \theta_i dx d\eta + 2\int_0^t \int_R \chi_{3,j}\chi_j V dx d\eta \\
&\quad + 2\int_0^t \int_R \chi_{i,j}\theta_i\theta_j dx d\eta + 2\int_0^t \int_R \chi_{i,3}\theta_i V dx d\eta + 2\int_0^t \int_R \chi_{3,j}\theta_j V dx d\eta \\
&\quad + 2\int_0^t \int_R \chi_{3,3} V^2 dx d\eta \\
&\le C_1 \max_t \left[\int_r \theta_{i,j}\theta_{i,j} dx\right]^{1/2} \frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} + C_2 |V|_{\max} \frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} \\
&\quad + C_3 \max_t \left[\int_R \theta_{i,j}\theta_{i,j} dx\right]^{1/2} \left[\frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} \cdot \frac{\partial^2 \widetilde{E}_1(0,t)}{\partial z^2}\right]^{1/2} \\
&\quad + C_4 |V|_{\max} \left[\frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} \cdot \frac{\partial^2 \widetilde{E}(0,t)}{\partial z^2}\right]^{1/2} \\
&\quad + C_5 |V|_{\max}^2 \left[\frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2}\right]^{1/2}
\end{aligned} \tag{6.13}$$

for computable C_i $(i = 1, 2, \ldots, 5)$. Applying the arithmetic-geometric mean inequality, (6.13) yields the bound

$$\left\{1 - C_1 \max_t \left[\int_R \theta_{i,j}\theta_{i,j} dx\right]^{1/2} - C_2 |V|_{\max} - \varepsilon\right\} \frac{\partial^2 \widehat{E}_1(0,t)}{\partial z^2} \le \text{data}, \tag{6.14}$$

provided the term in brackets is positive for some positive ε.

A bound for $\int_R \theta_{i,j}\theta_{i,j} dx$ in terms of data was derived in [2] for general t. Again, if the maximum value of $\int_R \theta_{i,j}\theta_{i,j} dx$ occurs at $t^* \in (0,t)$, we may employ the bounds of [2] for $t = t^*$. By use of Schwarz's inequality, if necessary, these data bounds may be made monotone in t and thus yield a bound for $\max_t \int_R \theta_{i,j}\theta_{i,j} dx$ that is independent of the unknown t^*. If the data terms are small enough, we can then satisfy

$$C_1 \max_t \left[\int_R \theta_{i,j}\theta_{i,j} dx\right]^{1/2} + C_2 |V|_{\max} \le 1 - \varepsilon. \tag{6.15}$$

It can be shown that if $u_{3,t}$ is continuous on ∂D at $t = 0$, the same arguments yield a bound for $\frac{\partial^2 \widehat{E}_3(0,t)}{\partial z^2}$, since we already have a bound for $|V_{,t}|_{\max}$. The key is to show that $\int_R \chi_{i,t}\chi_{i,t} dx\big|_{t=0}$ is zero. This follows since

$$\int_R \chi_{i,t}\chi_{i,t} dx\big|_{t=0} = \int_R \chi_{i,t}\sigma_{,i} dx\big|_{t=0} = -\int_{D_0} \chi_{3,t}\sigma dA = 0, \tag{6.16}$$

recalling that $\chi_i = 0$ in D_0.

We next indicate how to find a bound for $\frac{\partial^2 \widehat{E}_2(0,t)}{\partial z^2}$ and then complete our bound for $\frac{\partial^2 \widehat{E}(0,t)}{\partial z^2}$. Clearly, we have

$$\frac{\partial^2 \widehat{E}_2(0,t)}{\partial z^2} + \int_R \chi_{i,j}\chi_{i,j}dx\big|_{\eta=t} = -2\int_0^t \int_R \chi_{i,\eta}(\chi_j+\theta_j+v_j)(\chi_i+\theta_i+v_i)_{,j}dxd\eta. \tag{6.17}$$

The arguments of section 4 allow us to bound $\frac{\partial^2 \widehat{E}_2(0,t)}{\partial z^2}$ in terms of data and $\frac{\partial^2 \widehat{E}_3(0,t)}{\partial z^2}$ provided data terms are small enough. This then provides a bound for $\frac{\partial^2 \widehat{E}(0,t)}{\partial z^2}$. But the bound for $\frac{\partial^2 \widetilde{E}(0,t)}{\partial z^2}$ is known from [2]. It follows then that we have a bound for $\frac{\partial^2 E(0,t)}{\partial z^2}$. This yields a bound for $E(0,t)$ as follows. Evaluating (4.34) at $z=0$, we find

$$E(0,t) = \frac{1}{b}\,\frac{\partial^2 E(0,t)}{\partial z^2} - \frac{a}{b}\,\frac{\partial E(0,t)}{\partial z}. \tag{6.18}$$

By Schwarz's inequality, we have

$$-\frac{\partial E(0,t)}{\partial z} \le \sqrt{2}\left[E(0,t)\cdot\frac{\partial^2 E(0,t)}{\partial z^2}\right]^{1/2}. \tag{6.19}$$

Combining (6.18) and (6.19) and using the arithmetic-geometric mean inequality yields

$$E(0,t) \le 2\left[\frac{1}{b}+\frac{a^2}{b^2}\right]\frac{\partial^2 E(0,t)}{\partial z^2}. \tag{6.20}$$

Finally, with the bounds for $E(0,t)$ and $\frac{\partial^2 E_3(0,t)}{\partial z^2}$ we can make (4.39) explicit provided the data terms are sufficiently small. These data terms depend on f_i and its derivatives, the time interval, and the size of D. So our results will hold not only if the f_i and its derivatives are small enough but also for general data if the time interval or the size of the domain is sufficiently small.

HOMOGENIZATION THEORY AND THE ASSESSMENT OF EXTREME FIELD VALUES IN COMPOSITES WITH RANDOM MICROSTRUCTURE*

ROBERT LIPTON†

Abstract. Suitable macroscopic quantities are identified and used to assess the field distribution within a composite specimen of finite size with random microstructure. Composites made of N anisotropic dielectric materials are considered. The characteristic length scale of the microstructure relative to the length scale of the specimen is denoted by ε, and realizations of the random composite microstructure are labeled by ω. Consider any cube C_0 located inside the composite. The function $P^\varepsilon(t, C_0, \omega)$ gives the proportion of C_0 where the square of the electric field intensity exceeds t. The analysis focuses on the case when $0 < \varepsilon \ll 1$. Rigorous upper bounds on $\lim_{\varepsilon\to 0} P^\varepsilon(t, C_0, \omega)$ are found. They are given in terms of the macrofield modulation functions. The macrofield modulation functions capture the excursions of the local electric field fluctuations about the homogenized or macroscopic electric field. Information on the regularity of the macrofield modulations translates into bounds on $\lim_{\varepsilon\to 0} P^\varepsilon(t, C_0, \omega)$. Sufficient conditions are given in terms of the macrofield modulation functions that guarantee polynomial and exponential decay of $\lim_{\varepsilon\to 0} P^\varepsilon(t, C_0, \omega)$ with respect to "t." For random microstructure with oscillation on a sufficiently small scale we demonstrate that a pointwise bound on the macrofield modulation function provides a pointwise bound on the actual electric field intensity. These results are applied to assess the distribution of extreme electric field intensity for an L-shaped domain filled with a random laminar microstructure.

Key words. random composite materials, field fluctuations, material breakdown

1. Introduction.

Failure of composite materials can often be attributed to the presence of large local fields. This includes extreme temperature gradients and large electric and current fields as well as mechanical stresses [9]. These fields are strongly influenced by the local microgeometry inside the composite. It is often the case that the microgeometry of heterogeneous specimens is known only in a statistical sense. Motivated by these considerations, we examine the distribution of extreme field values in random heterogeneous media. The focus here is to assess the likelihood that the magnitude of the electric field inside the composite exceeds a prescribed nominal value for almost every realization of the random microstructure.

Here we consider a random composite made up of N anisotropic dielectric materials with dielectric tensors $A_1, A_2, \ldots, A_N$. To describe the dielectric tensor for a finite size sample of random composite, we begin with the description of a random medium of infinite extent. The dielectric tensor field $A(\mathbf{y}, \omega)$ associated with the composite is a function of both position $\mathbf{y}$ and geometric realization ω taken from the sample space Ω. For each realization ω, the tensor field $A(\mathbf{y}, \omega)$ is piecewise constant taking

only the values $A_1, A_2, \ldots, A_N$ for different points $\mathbf{y}$ in R^3. The random medium is assumed to be stationary, i.e., for any finite choice of points $\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_k$ and any vector $\mathbf{h}$, the distribution of the random tensor

$$A(\mathbf{y}_1 + \mathbf{h}, \omega), A(\mathbf{y}_2 + \mathbf{h}, \omega), \ldots, A(\mathbf{y}_k + \mathbf{h}, \omega) \tag{1.1}$$

does not depend on $\mathbf{h}$. The finite size composite specimen occupies the bounded domain $\mathcal{D}$, and points inside it are denoted by $\mathbf{x}$. The dielectric tensor for a composite with a random microstructure of characteristic length scale ε relative to the size of $\mathcal{D}$ is given by

$$A^\varepsilon(\mathbf{x}, \omega) = A\left(\frac{\mathbf{x}}{\varepsilon}, \omega\right). \tag{1.2}$$

The potential inside the composite is denoted by $\phi^\varepsilon(\mathbf{x}, \omega)$. For a prescribed charge distribution $f = f(\mathbf{x})$ and prescribed values of the electric potential on the boundary of the domain $\mathcal{D}$ given by $\phi^\varepsilon(\mathbf{x}, \omega) = \phi_0(\mathbf{x})$, the potential is the solution of

$$-\mathrm{div}(A^\varepsilon(\mathbf{x}, \omega)\nabla\phi^\varepsilon(\mathbf{x}, \omega)) = f \tag{1.3}$$

in $\mathcal{D}$. Here (1.3) holds in the sense of distributions. The associated electric field $\mathbf{E}^\varepsilon(\mathbf{x}, \omega) = -\nabla\phi^\varepsilon(\mathbf{x}, \omega)$ is not necessarily a stationary random field; this is due to the finite size of the domain $\mathcal{D}$ and the prescribed charge distribution.

Failure initiation criteria are often given in terms of a critical field strength such that if a significant portion of the sample has field strength above this value, then the failure process is initiated [7]. Motivated by this observation, we focus on the subset of the composite where $|\mathbf{E}^\varepsilon|^2$ exceeds the value $t > 0$, and we denote it by $S_t^\varepsilon(\omega)$. Consider any cube C_0 inside the composite. It is assumed here that the boundary of the cube does not intersect the boundary of the specimen. The field distribution function $\lambda^\varepsilon(t, C_0, \omega)$ gives the volume of the intersection of $S_t^\varepsilon(\omega)$ with C_0, i.e., $\lambda^\varepsilon(t, C_0, \omega) = |S_t^\varepsilon(\omega) \cap C_0|$. Here $|S|$ denotes the volume of the set S. Division of $\lambda^\varepsilon(t, C_0, \omega)$ by the volume of the cube gives the function $P^\varepsilon(t, C_0, \omega)$. Here $P^\varepsilon(t, C_0, \omega)$ gives the proportion of the cube experiencing field strength greater than t. One also defines the electric field distribution inside the part of the ith phase contained in the cube C_0. The volume of the set in the ith phase contained in C_0 where $|\mathbf{E}^\varepsilon|^2$ exceeds the value $t > 0$ is denoted by $\lambda_i^\varepsilon(t, C_0, \omega)$. The set occupied by the ith phase is denoted by $S_i^\varepsilon(\omega)$. Analogously $P_i^\varepsilon(t, C_0, \omega) \equiv \lambda_i^\varepsilon(t, C_0, \omega)/|S_i^\varepsilon(\omega) \cap C_0|$ gives the proportion if the ith phase contained in C_0 with field strength greater than t.

In this paper we obtain bounds on $P^\varepsilon(t, C_0, \omega)$ and $P_i^\varepsilon(t, C_0, \omega)$ in the limit of vanishing ε. These bounds are expressed in terms of suitable macroscopic quantities dubbed macrofield modulation functions. To illustrate the ideas, one applies the Chebyshev inequality to obtain the bound on $P^\varepsilon(t, C_0, \omega)$ given by

$$P^\varepsilon(t, C_0, \omega) \leq t^{-p} \frac{1}{|C_0|} \int_{C_0} |\mathbf{E}^\varepsilon(\mathbf{x}, \omega)|^{2p}\, d\mathbf{x}. \tag{1.4}$$

In section 2 we state the homogenized version of (1.4) given by

$$\lim_{\varepsilon \to 0} P^\varepsilon(t, C_0, \omega) \leq t^{-p} A_p(C_0). \tag{1.5}$$

Here $A_p(C_0)$ is independent of ω and is described in terms of the macrofield modulation functions. The macrofield modulation of order p is the L^p norm of the square

of the electric field intensity for the associated corrector problem (2.2) posed on the infinite random medium when the random medium is subjected to an imposed macroscopic electric field; see (2.9). Proposition 2.1 explicitly shows how integrability of order p at the level of the corrector problem contributes to the t^{-p} order decay of $\lim_{\varepsilon\to 0} P^{\varepsilon}(t, C_0, \omega)$. Similarly, Proposition 2.3 shows how L^{∞} regularity of the square of the electric field intensity for the associated corrector problem allows $\lim_{\varepsilon\to 0} P^{\varepsilon}(t, C_0, \omega)$ to vanish above a critical value of t. For this case we can pass to a subsequence, if necessary, to derive a pointwise bound on the local electric field intensity for almost every realization of the random microstructure when the scale of the microstructure is sufficiently small; see Proposition 2.4. When the macrofield modulation function has bounded mean oscillation, an explicit upper bound is obtained that is exponential in $-t$ and is given in terms of the BMO norm of the macrofield modulation function; see Proposition 2.5. The corrector problem that is used to define the macrofield modulation functions is well known and naturally arises in the definition of the effective dielectric tensor [1, 10, 17, 18].

It is pointed out that the main results given by Propositions 2.1 through 2.6 are strong limit theorems in that they hold for almost all realizations of the random medium. Propositions 2.1 through 2.6 are a direct consequence of the homogenization constraints given in Proposition 3.1. These constraints relate the macrofield modulation functions to the distribution of states for the square of the electric field intensity. This type of constraint is introduced in [11, 14] for the case of graded locally periodic microstructures and in the context of G convergence for multiphase linearly elastic composites. The results reported here apply to the mathematically identical situations appearing in the contexts of thermal conductivity and DC electric conductivity.

The paper is organized as follows: In section 2 the macrofield modulation functions are introduced and the main results are presented. The homogenization constraint is introduced and derived in section 3. The homogenized version of Chebyshev's inequality is established in section 4. The bounds on the support of $\lim_{\varepsilon\to 0} P_i^{\varepsilon}(t, C_0, \omega)$ and $\lim_{\varepsilon\to 0} P^{\varepsilon}(t, C_0, \omega)$ are obtained in section 5. These are given in terms of the L^{∞} norm of the macrofield modulation functions. The pointwise upper bounds are derived in section 6. The exponentially decaying bound on $\lim_{\varepsilon\to 0} P^{\varepsilon}(t, C_0, \omega)$ is derived in section 7. In section 8 we consider a highly oscillatory, randomly layered dielectric occupying an L-shaped domain. The dielectric is subjected to a prescribed charge density and the electric potential satisfies homogeneous Dirichlet boundary conditions. The macrofield modulation functions together with the results of section 2 are applied to assess the distribution of the electric field intensity inside the domain.

2. The macrofield modulation functions and main results. To introduce the macrofield modulation functions, we consider a random composite of infinite extent. For stationary random media it is shown in [17] that one can regard the dielectric tensor $A(\mathbf{y}, \omega)$ as the realization of a random function $\tilde{A}$ with respect to a three-dimensional dynamical system T acting on a suitable sample space; see also [2] for a more recent discussion. In view of this let $(\Omega, \mathcal{F}, \mathcal{P})$ be a probability space. For a given partition of Ω into N measurable subsets $\Omega_1, \Omega_2, \ldots, \Omega_N$ we introduce the indicator functions $\tilde{\chi}_i$ taking the values 1 in Ω_i and zero outside and set $\tilde{A}(\omega) = \sum_{i=1}^{N} A_i \tilde{\chi}_i(\omega)$. Following [5, 10, 17] we regard the dielectric $A(\mathbf{y}, \omega)$ as a realization of $\tilde{A}$ with respect to a three-dimensional dynamical system T on Ω, i.e., $A(\mathbf{y}, \omega) = \tilde{A}(T(\mathbf{y})\omega)$ for $(\mathbf{y}, \omega)$ in $R^3 \times \Omega$. Here the family of mappings $T = T(\mathbf{y})$, $\mathbf{y}$ in R^3 from Ω into Ω, is one to one and preserves the measure $\mathcal{P}$ on Ω; i.e., for any A in $\mathcal{F}$ one has $\mathcal{P}(T(-\mathbf{y})A) = \mathcal{P}(A)$. The family of transforms is a group with $T(0)\omega = \omega$, $T(\mathbf{y} + \mathbf{h}) = T(\mathbf{y})T(\mathbf{h})$, and

for any $\mathcal{P}$ measurable function $\tilde{f}$ on Ω, the function $\tilde{f}(T(\mathbf{y})\omega)$ defined on $R^3 \times \Omega$ is also measurable with respect to $\mathcal{L} \times \mathcal{F}$, where $\mathcal{L}$ stands for the σ-algebra of Lebesgue-measurable subsets of R^3. Lastly, it is assumed that the dynamical system is ergodic.

Let $\mathbf{e}^1$, $\mathbf{e}^2$, $\mathbf{e}^3$ represent unit vectors along the coordinate directions in R^3. A constant electric field $\mathbf{e}^k$ is imposed on the infinite random medium. The dielectric response in the composite is given by an electric field that can be decomposed into the imposed electric field $\mathbf{e}^k$ and a stationary random fluctuation $-\nabla\varphi^k(\mathbf{y},\omega) = \mathbf{G}^k(T(\mathbf{y})\omega)$, where $\mathbf{G}^k$ is in $L^2(\Omega,\mathcal{P})$ with zero mean, i.e., $\langle \mathbf{G}^k \rangle = \int_\Omega \mathbf{G}^k d\mathcal{P} = 0$; see [5, 10, 17, 8]. From the Birkhoff ergodic theorem it follows that for any sequence of cubes $Q(r)$ of side length $2r$ and volume $|Q(r)|$,

$$\lim_{r\to\infty} \frac{1}{|Q(r)|} \int_{Q(r)} (-\nabla\varphi^k(\mathbf{y},\omega))\, d\mathbf{y} = \langle \mathbf{G}^k \rangle = 0. \tag{2.1}$$

The fluctuation solves

$$-\mathrm{div}(A(\mathbf{y},\omega)(\nabla\varphi^k(\mathbf{y},\omega) + \mathbf{e}^k)) = 0 \tag{2.2}$$

for $\mathbf{y}$ in R^3. For an imposed constant electric field of the general form $\overline{\mathbf{E}} = (E_1\mathbf{e}^1 + E_2\mathbf{e}^2 + E_3\mathbf{e}^3)$, the stationary random fluctuation is obtained by superposition and is given by $-\nabla\varphi(\mathbf{y},\omega) = \sum_{k=1}^3 E_k \mathbf{G}^k(T(\mathbf{y})\omega)$. For future reference we introduce the matrix with column vectors $\mathbf{G}^k$ given by $\underline{\tilde{\mathbf{G}}}(\omega) = (\mathbf{G}^1(\omega), \mathbf{G}^2(\omega), \mathbf{G}^3(\omega))$. Then $-\nabla\varphi(\mathbf{y},\omega) = \underline{\tilde{\mathbf{G}}}(T(\mathbf{y})\omega)\overline{\mathbf{E}}$ and $\mathbf{E}(\mathbf{y},\omega) = (I + \underline{\tilde{\mathbf{G}}}(T(\mathbf{y})\omega))\overline{\mathbf{E}}$. The dielectric displacement is a stationary random field, and its mean is given by

$$\langle \mathbf{D} \rangle = \int_\Omega \tilde{A}(\omega)(I + \underline{\tilde{\mathbf{G}}}(\omega))\overline{\mathbf{E}}\, d\mathcal{P}(\omega) = \lim_{r\to\infty} \frac{1}{|Q(r)|} \int_{Q(r)} A(\mathbf{y},\omega)\mathbf{E}(\mathbf{y},\omega)\, dy. \tag{2.3}$$

The effective dielectric tensor A^E provides the linear relation between the imposed electric field $\overline{\mathbf{E}}$ and the mean dielectric displacement $\langle \mathbf{D} \rangle$, i.e., $\langle \mathbf{D} \rangle = A^E\overline{\mathbf{E}}$; see [5, 10, 17, 8].

When considering failure initiation it is important to assess the magnitude of the local electric field inside the random medium arising from the imposed electric field $\overline{\mathbf{E}}$. Here one is interested in the probability that the square of the electric field intensity $|\mathbf{E}|^2$ in the ith phase exceeds a nominal value t. For the stationary random case this probability is the same for every point and is given by $\theta_{t,i} = \mathcal{P}(\tilde{\chi}_i(\omega)|(I + \underline{\tilde{\mathbf{G}}}(\omega))\overline{\mathbf{E}}|^2 > t)$. Other quantities that are useful for local field assessment are given by the L^p norms, $1 \le p \le \infty$. The $L^p(\Omega)$ norm of a $\mathcal{P}$ measurable function $\tilde{g}$ is denoted by $\|\tilde{g}\|_{L^p(\Omega)}$. Since $T(\mathbf{y})$ preserves the measure $\mathcal{P}$ on Ω, it follows that

$$\|\chi_i(\mathbf{y},\omega)|\mathbf{E}(\mathbf{y},\omega)|^2\|_{L^p(\Omega)} = \|\tilde{\chi}_i(\omega)|(I + \underline{\tilde{\mathbf{G}}}(\omega))\overline{\mathbf{E}}|^2\|_{L^p(\Omega)} \quad \text{for every } \mathbf{y} \text{ in } R^3. \tag{2.4}$$

Motivated by these considerations, we introduce moments of the local electric field of order p.

Definition: Moments of the local electric field.

$$f_p^i(\overline{\mathbf{E}}) = \|\tilde{\chi}_i(\omega)|(I + \underline{\tilde{\mathbf{G}}}(\omega))\overline{\mathbf{E}}|^2\|_{L^p(\Omega)} = \left(\int_\Omega \tilde{\chi}_i(\omega)|(I + \underline{\tilde{\mathbf{G}}}(\omega))\overline{\mathbf{E}}|^{2p}\, d\mathcal{P}(\omega) \right)^{1/p} \tag{2.5}$$

for $1 \le p \le \infty$.

Moments of the electric field have been calculated for two-dimensional random dispersions of disk-, needle-, and square-shaped inclusions in [4].

It is pointed out that the electric field generated by a constant imposed electric field is self-similar under a rescaling of the infinite random medium. Indeed, set $\varepsilon_k = 1/k$ and rescale the material properties by $A^{\varepsilon_k}(\mathbf{y},\omega) = A(\mathbf{y}/\varepsilon_k,\omega)$. It is easily checked that the electric field also rescales as $\mathbf{E}^{\varepsilon_k}(\mathbf{y},\omega) = \mathbf{E}(\mathbf{y}/\varepsilon_k,\omega)$. Thus the analysis of electric field distribution for the ε_k scale microstructure reduces to an analysis for the unrescaled random media. However, this symmetry is broken for generic situations when the specimen is finite in extent and the loading is not uniform throughout the sample. Because of this the electric field in the composite is not obtained directly through an analysis of the electric field in an infinite random medium. Instead, it is shown here that a suitable multiscale analysis using macrofield modulation functions provides rigorous bounds on the field distributions $P^{\varepsilon}(t,C_0,\omega)$ and $P_i^{\varepsilon}(t,C_0,\omega)$ for almost every realization in the limit of vanishing ε.

Consider a finite size specimen $\mathcal{D}$ filled with random composite with characteristic length scale $\varepsilon_k = 1/k$. Here the composite is described by $A^{\varepsilon_k}(\mathbf{x},\omega) = \tilde{A}(T(\mathbf{x}/\varepsilon_k)\omega)$, and the electric potential $\phi^{\varepsilon_k}(\mathbf{x},\omega)$ solves the boundary value problem described in the introduction with equilibrium condition given by (1.3). The electric field is given by $\mathbf{E}^{\varepsilon_k} = -\nabla(\phi^{\varepsilon_k})$. The multiscale analysis proceeds in two steps. The first step is the up scaling or homogenization step where the macroscopic electric field is determined. From the theory of random homogenization, the fields $\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)$ and $\mathbf{D}^{\varepsilon_k}(\mathbf{x},\omega) = \mathbf{A}^{\varepsilon_k}(\mathbf{x},\omega)\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)$ converge to the deterministic macroscopic fields $\mathbf{E}(\mathbf{x})^M$ and $\mathbf{D}^M(x)$ as ε_k goes to zero for almost every ω; see [10, 17]. Here the convergence of the sequences of electric and displacement fields is given by weak convergence in $L^2(\mathcal{D})^3$. The deterministic macroscopic potential $\phi^M(\mathbf{x})$ satisfies the boundary condition $\phi^M(\mathbf{x}) = \phi_0(\mathbf{x})$. The macroscopic dielectric displacement satisfies the equilibrium equation

$$\text{div}\mathbf{D}^M = f \tag{2.6}$$

and $\mathbf{E}^M = -\nabla\phi^M$. The displacement and electric field are related through the homogenized constitutive law

$$\mathbf{D}^M(\mathbf{x}) = A^E\mathbf{E}^M(\mathbf{x}). \tag{2.7}$$

The second step is a down scaling step and gives the interaction between the macroscopic electric field $\mathbf{E}^M(\mathbf{x})$ and the microstructure. For each $\mathbf{x}$, the microscopic dielectric response is given by

$$\mathbf{E}(\mathbf{x},\mathbf{y},\omega) = (I + \underline{\tilde{\mathbf{G}}}(T(\mathbf{y})\omega))\mathbf{E}^M(\mathbf{x}). \tag{2.8}$$

The relevant interaction is described by the macrofield modulation function $f_p^i(\mathbf{E}^M(\mathbf{x}))$ given by the following definition.

Definition: Macrofield modulation function.

$$f_p^i(\mathbf{E}^M(\mathbf{x})) = \|\tilde{\chi}_i(\omega)|(I + \underline{\tilde{\mathbf{G}}}(\omega))\mathbf{E}^M(\mathbf{x})|^2\|_{L^p(\Omega)} \tag{2.9}$$

for $1 \le p \le \infty$. The macrofield modulation function $f_p^i(\mathbf{E}^M(\mathbf{x}))$ provides a measure of the amplification or diminution of $\mathbf{E}^M(\mathbf{x})$ by the random medium. Explicit formulas for the macrofield modulation functions for randomly layered two-phase dielectrics are given in section 8.

Consider any cube C_0 inside the composite. The L^1 norm of a function $g(\mathbf{x})$ over the cube C_0 is denoted by $\|g\|_{L^1(C_0)}$. In what follows, it is always assumed that

$\theta_i = \int_\Omega \tilde{\chi}_i(\omega)\, d\mathcal{P} > 0$, and from ergodicity the volume occupied by the ith phase in the cube C_0 tends to the nonzero limit $\lim_{\varepsilon_k \to 0} \int_{C_0} \tilde{\chi}_i(T(\mathbf{x}/\varepsilon_k)\omega)\, d\mathbf{x} = \theta_i |C_0|$ as ε_k tends to zero. Passing to a subsequence, if necessary, we consider $\lim_{\varepsilon_k \to 0} P_i^{\varepsilon_k}(t, C_0, \omega)$.

If it is known that $\| |f_p^i(\mathbf{E}^M(\mathbf{x}))|^p \|_{L^1(C_0)} < \infty$ for some p, then the following proposition shows that $\lim_{\varepsilon_k \to 0} P_i^{\varepsilon_k}(t, C_0, \omega)$ decays on the order of t^{-p}.

PROPOSITION 2.1 (homogenization of Chebyshev's inequality). *Given that*

$$\| |f_p^i(\mathbf{E}^M(\mathbf{x}))|^p \|_{L^1(C_0)} < \infty$$

for some p with $1 \le p < \infty$, then for almost every realization ω one has

$$\begin{aligned} \lim_{\varepsilon_k \to 0} P_i^{\varepsilon_k}(t, C_0, \omega) &\le t^{-p} \frac{1}{\theta_i |C_0|} \| |f_p^i(\mathbf{E}^M(\mathbf{x}))|^p \|_{L^1(C_0)} \\ &= t^{-p} \frac{1}{\theta_i |C_0|} \int_{C_0} \int_\Omega \tilde{\chi}_i(\omega) |(I + \underline{\tilde{\mathbf{G}}}(\omega)) \mathbf{E}^M(\mathbf{x})|^{2p}\, d\mathcal{P}(\omega)\, d\mathbf{x}. \end{aligned} \tag{2.10}$$

If $\| |f_p^i(\mathbf{E}^M(\mathbf{x}))|^p \|_{L^1(C_0)} < \infty$ for all $i = 1, 2, \ldots, N$, then

$$\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) \le t^{-p} \frac{1}{|C_0|} \int_{C_0} \int_\Omega |(I + \underline{\tilde{\mathbf{G}}}(\omega)) \mathbf{E}^M(\mathbf{x})|^{2p}\, d\mathcal{P}(\omega)\, d\mathbf{x} \tag{2.11}$$

for almost every realization ω.

It is clear that the coefficients of t^{-p} in (2.10) and (2.11) depend upon the Dirichlet data ϕ_0, charge density f, and the domain $\mathcal{D}$ through the solution of the homogenized problem (2.6). The proof of Proposition 2.1 is given in section 4.

The L^∞ norm of a function $g(\mathbf{x})$ over the cube C_0 is denoted by $\|g\|_{L^\infty(C_0)}$. A characterization of the set of parameters t where $\lim_{\varepsilon_k \to 0} P_i^{\varepsilon_k}(t, C_0, \omega)$ vanishes for almost every realization is given in the following proposition.

PROPOSITION 2.2. *If $t > \|f_\infty^i(\mathbf{E}^M(\mathbf{x}))\|_{L^\infty(C_0)}$, then $\lim_{\varepsilon_k \to 0} P_i^{\varepsilon_k}(t, C_0, \omega) = 0$ for almost every ω in Ω*

From the proposition it is evident that if $t > \|f_\infty^i(\mathbf{E}^M(\mathbf{x}))\|_{L^\infty(C_0)}$, then the volume of the subsets in the ith phase for which $|\mathbf{E}^{\varepsilon_k}(\mathbf{x}, \omega)|^2 > t$ vanishes as ε_k tends to zero with probability one. The proof of Proposition 2.2 is given in section 5.

We introduce the macrostress modulation $M(\mathbf{E}^M(\mathbf{x}))$ given by

$$M(\mathbf{E}^M(\mathbf{x})) = \max_{i=1,\ldots,N} f_\infty^i(\mathbf{E}^M(\mathbf{x})) \tag{2.12}$$

and characterize $\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega)$ in a way analogous to Proposition 2.2. This is stated in the following proposition.

PROPOSITION 2.3. *If $t > \|M(\mathbf{E}^M(\mathbf{x}))\|_{L^\infty(C_0)}$, then $\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) = 0$ for almost every realization.*

For random microstructure with oscillation on a sufficiently small scale, it is found that a pointwise bound on the macrofield modulation function delivers a pointwise bound on the actual electric field intensity for almost every realization of the microstructure.

PROPOSITION 2.4 (pointwise bounds on the electric field intensity). *Suppose that*

$$t > M(\mathbf{E}^M(\mathbf{x})) \tag{2.13}$$

on C_0. Then one can pass to a subsequence $\{\varepsilon_{k'}\}_{k'=1}^\infty$ if necessary to find that there is a critical ε_0 such that for every $\varepsilon_{k'} < \varepsilon_0$,

$$|\mathbf{E}^{\varepsilon_{k'}}(\mathbf{x}, \omega)|^2 \le t \tag{2.14}$$

for almost every $\mathbf{x}$ *in* C_0 *and for almost every realization* ω. *Here* ε_0 *can depend upon* $\mathbf{x}$ *and* ω.

The proof of Proposition 2.4 is given in section 6.

Last, we give conditions for which $\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega)$ decreases exponentially with t. To do this we introduce the BMO norm of $M(\mathbf{E}^M(\mathbf{x}))$ over the cube C_0 given by

$$\|M\|_{BMO} = \sup_{C \subset C_0} \left(\frac{1}{|C|} \int_C |M(\mathbf{E}^M(\mathbf{x})) - M_C| \, d\mathbf{x} \right), \tag{2.15}$$

where M_C is the average of $M(\mathbf{E}^M(\mathbf{x}))$ over C and the supremum is taken over all subcubes C of C_0. The BMO norm and the space of functions of bounded mean oscillation were introduced by John and Nirenberg [6]. The space of functions with bounded L^∞ norm are a subspace of the functions with bounded BMO norm since $\|M(\mathbf{E}^M)\|_{BMO} \le c\|M(\mathbf{E}^M)\|_{L^\infty(C_0)}$, where c is a constant depending on C_0.

For any positive number α between zero and one, we define the constant $C(\alpha)$ by

$$C(\alpha) = \frac{\alpha |\ln \alpha|}{8\|M\|_{BMO}}. \tag{2.16}$$

With the average of $M(\mathbf{E}^M(\mathbf{x}))$ over the cube C_0 denoted by M_{C_0}, the bound on $\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega)$ is given in the following proposition.

PROPOSITION 2.5. *If* $t > 8\|M\|_{BMO}\alpha^{-1} + M_{C_0}$, *then*

$$\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) \le \alpha^{-1} e^{-C(\alpha) \times (t - M_{C_0})} \tag{2.17}$$

for almost every realization.

For t fixed the proposition shows that $P^{\varepsilon_k}(t, C_0, \omega)$ approaches or drops below

$$\alpha^{-1} e^{-C(\alpha) \times (t - M_{C_0})}$$

for ε_k sufficiently small for almost every realization. It also shows that the upper bound is exponentially decreasing for large t. Optimization over α (see section 7) provides the tighter upper bound given by the following proposition.

PROPOSITION 2.6. *If* $t > 8\|M\|_{BMO} + M_{C_0}$, *then for almost every realization of the random medium*

$$\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) \le (\alpha(t))^{-1} e \times e^{[-\alpha(t)(t - M_{C_0})/(8\|M\|_{BMO})]}, \tag{2.18}$$

where the factor $\alpha(t)$ *lies in the interval* $e^{-1} < \alpha(t) < 1$ *and is the root of the equation*

$$\kappa^{-1} - \alpha(1 + \ln \alpha) = 0, \tag{2.19}$$

with $\kappa = (t - M_{C_0})/(8\|M\|_{BMO})$.

It is pointed out that if the macroscopic electric field $\mathbf{E}^M$ is constant inside C_0, then $\|M\|_{BMO} = 0$, $M_{C_0} = M(\mathbf{E}^M) = \|M(\mathbf{E}^M)\|_{L^\infty(C_0)}$, and Propositions 2.3, 2.5, and 2.6 reduce to the observation that if $t > M(\mathbf{E}^M)$, then $\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) = 0$ for almost all ω.

Propositions 2.1 through 2.6 provide the opportunity to recover information on the behavior of the electric field intensity $|\mathbf{E}^\varepsilon(\mathbf{x}, \omega)|$ inside the random microstructure from knowledge of the behavior of the macrofield modulation functions. An application is given in section 8 where the electric field distribution inside an L-shaped domain containing a highly oscillatory random laminate is analyzed.

3. Homogenization constraints. The homogenization constraints are motivated by considering the case of a random composite of infinite extent. For the $p = \infty$ case the homogenization constraint follows immediately from the definition of $f^i_\infty(\overline{\mathbf{E}})$. Indeed, it is clear from the definition of the L^∞ norm that $t \geq f^i_\infty(\overline{\mathbf{E}})$ implies that $\theta_{t,i} = 0$, and equivalently, if $\theta_{t,i} > 0$, it follows that $f^i_\infty(\overline{\mathbf{E}}) > t$. This delivers the homogenization constraints given by

$$\theta_{t,i}(f^i_\infty(\overline{\mathbf{E}}) - t) \geq 0. \tag{3.1}$$

For $1 \leq p < \infty$, Chebyshev's inequality implies

$$t^{-p}(f^i_p(\overline{\mathbf{E}}))^p \geq \theta_{t,i}. \tag{3.2}$$

Inequalities (3.1) and (3.2) are the specialization of the homogenization constraints to stationary random composites of infinite extent. In the general context the macroscopic electric field is not uniform and the composite specimen has finite size. For general specimen shapes and nonuniform loading, the constraints analogous to (3.1) and (3.2) are given in terms of $f^i_\infty(\mathbf{E}^M(\mathbf{x}))$ and $f^i_p(\mathbf{E}^M(\mathbf{x}))$. In order to complete the description of the homogenization constraint, a suitable generalization of $\theta_{t,i}$ is needed. For this case, one considers a realization of the random composite $A^{\varepsilon_k}(\mathbf{x},\omega)$ and the set in the ith phase where the square of the electric field intensity $|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2$ exceeds t is denoted by $S^{\varepsilon_k}_{t,i}(\omega)$. Consider any subdomain Q of the specimen such that the boundary of Q does not intersect the boundary of the specimen. The distribution function $\lambda^{\varepsilon_k}_i(t,Q,\omega)$ is defined by $\lambda^{\varepsilon_k}_i(t,Q,\omega) = |S^{\varepsilon_k}_{t,i}(\omega) \cap Q|$. The indicator function for the set $S^{\varepsilon_k}_{t,i}(\omega)$ is written $\chi^{\varepsilon_k}_{t,i}(\mathbf{x},\omega)$ taking the value 1 in $S^{\varepsilon_k}_{t,i}(\omega)$ and 0 outside and we write $\lambda^{\varepsilon_k}_i(t,Q,\omega) = \int_Q \chi^{\varepsilon_k}_{t,i} d\mathbf{x}$. From the theory of weak convergence there exists a (Lebesgue measurable) density $\theta_{t,i}(\mathbf{x},\omega)$ taking values in the interval $[0,1]$ such that (on passage to a subsequence if necessary) $\lim_{k\to\infty} \lambda^{\varepsilon_k}_i(t,Q,\omega) = \int_Q \theta_{t,i}(\mathbf{x},\omega)dx$. The density $\theta_{t,i}(\mathbf{x},\omega)$ is the local distribution of states of the square of the electric field intensity $|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2$ in the ith phase as ε_k goes to zero. Here, the random fields $\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)$ and $\theta_{t,i}(\mathbf{x},\omega)$ can no longer be regarded as stationary; this is due to the finite size of the domain and nonuniform charge distribution within the dielectric. However, for almost every realization one has the homogenization constraints given in the following proposition.

PROPOSITION 3.1 (homogenization constraints). *For almost every point* $\mathbf{x}$ *in* Q *and almost every realization* ω *in* Ω*, one has*

$$\theta_{t,i}(\mathbf{x},\omega)(f^i_\infty(\mathbf{E}^M(\mathbf{x})) - t) \geq 0, \quad i = 1,\ldots,N, \tag{3.3}$$

and for $1/q + 1/p = 1$*,*

$$\theta^{1/q}_{t,i}(\mathbf{x},\omega) f^i_p(\mathbf{E}^M(\mathbf{x})) \geq t\theta_{t,i}(\mathbf{x},\omega), \quad i = 1,\ldots,N. \tag{3.4}$$

It is clear that (3.3) and (3.4) are the extensions of (3.1) and (3.2) to situations where the macroscopic electric field is no longer uniform.

Proof. For a given realization ω, it follows from the definition of the set $S^{\varepsilon_k}_{t,i}(\omega)$ that

$$\chi^{\varepsilon_k}_{t,i}(\mathbf{x},\omega)|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2 - t\chi^{\varepsilon_k}_{t,i}(\mathbf{x},\omega) > 0. \tag{3.5}$$

Multiplying (3.5) by any nonnegative test function $p(\mathbf{x})$ and integrating over $\mathcal{D}$ gives

$$\int_{\mathcal{D}} p(\mathbf{x})(\chi^{\varepsilon_k}_{t,i}(\mathbf{x},\omega)|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2 - t\chi^{\varepsilon_k}_{t,i}(\mathbf{x},\omega))\, d\mathbf{x} > 0. \tag{3.6}$$

Taking limits and passing to subsequences if necessary gives

$$\lim_{\varepsilon_k \to 0} \int_{\mathcal{D}} p(\mathbf{x}) \chi_{t,i}^{\varepsilon_k}(\mathbf{x}, \omega) |\mathbf{E}^{\varepsilon_k}(\mathbf{x}, \omega)|^2 \, d\mathbf{x} \geq t \int_{\mathcal{D}} p(\mathbf{x}) \theta_{t,i}(\mathbf{x}, \omega) \, d\mathbf{x}. \tag{3.7}$$

We will use the following lemma.

LEMMA 3.2.

$$\int_{\mathcal{D}} p(\mathbf{x}) f_\infty^i(\mathbf{E}^M(\mathbf{x})) \theta_{t,i}(\mathbf{x}, \omega) \, d\mathbf{x} \geq \lim_{\varepsilon_k \to 0} \int_{\mathcal{D}} p(\mathbf{x}) \chi_{t,i}^{\varepsilon_k}(\mathbf{x}, \omega) |\mathbf{E}^{\varepsilon_k}(\mathbf{x}, \omega)|^2 \, d\mathbf{x}, \tag{3.8}$$

and for $1/q + 1/p = 1$,

$$\int_{\mathcal{D}} p(\mathbf{x}) f_p^i(\mathbf{E}^M(\mathbf{x})) \theta_{t,i}^{1/q}(\mathbf{x}, \omega) \, d\mathbf{x} \geq \lim_{\varepsilon_k \to 0} \int_{\mathcal{D}} p(\mathbf{x}) \chi_{t,i}^{\varepsilon_k}(\mathbf{x}, \omega) |\mathbf{E}^{\varepsilon_k}(\mathbf{x}, \omega)|^2 \, d\mathbf{x} \tag{3.9}$$

for all nonnegative $p(\mathbf{x})$ *in* $C_0^\infty(\mathcal{D})$ *and for almost every* ω.

Applying the inequality (3.7) together with Lemma 3.2 delivers

$$\int_{\mathcal{D}} p(\mathbf{x}) f_\infty^i(\mathbf{E}^M(\mathbf{x})) \theta_{t,i}(\mathbf{x}, \omega) \, d\mathbf{x} \geq t \int_{\mathcal{D}} p(\mathbf{x}) \theta_{t,i}(\mathbf{x}, \omega) \, d\mathbf{x} \tag{3.10}$$

and

$$\int_{\mathcal{D}} p(\mathbf{x}) f_p^i(\mathbf{E}^M(\mathbf{x})) \theta_{t,i}^{1/q}(\mathbf{x}, \omega) \, d\mathbf{x} \geq t \int_{\mathcal{D}} p(\mathbf{x}) \theta_{t,i}(\mathbf{x}, \omega) \, d\mathbf{x} \tag{3.11}$$

for almost every ω. The proposition now follows since (3.10) and (3.11) hold for every nonnegative test function. □

Proof of Lemma 3.2. We write

$$A^{\varepsilon_k}(\mathbf{x}, \omega) = A^{\varepsilon_k}(A_1, A_2, \ldots, A_N, \mathbf{x}, \omega) = \sum_{\ell=1}^{N} \tilde{\chi}_\ell(T(\mathbf{x}/\varepsilon_k)\omega) A_\ell. \tag{3.12}$$

We introduce the $N+1$ phase composite identical to the previous except that in $S_{t,i}^{\varepsilon_k}(\omega)$ it has dielectric constant P_{N+1}. The piecewise constant dielectric tensor for this composite is given by

$$\begin{aligned} \hat{A}^{\varepsilon_k}(\mathbf{x}, \omega) &= \hat{A}^{\varepsilon_k}(A_1, A_2, \ldots, A_N, P_{N+1}, \mathbf{x}, \omega) \\ &= \sum_{\substack{\ell=1 \\ \ell \neq i}}^{N} \tilde{\chi}_\ell(T(\mathbf{x}/\varepsilon_k)\omega) A_\ell \\ &\quad + \tilde{\chi}_i(T(\mathbf{x}/\varepsilon_k)\omega)(1 - \chi_{t,i}^{\varepsilon_k}(\mathbf{x}, \omega)) A_i + \tilde{\chi}_i(T(\mathbf{x}/\varepsilon_k)\omega) \chi_{t,i}^{\varepsilon_k}(\mathbf{x}, \omega) P_{N+1}. \end{aligned} \tag{3.13}$$

For P_{N+1} in a neighborhood of A_i, we invoke the compactness property of G-convergence with respect to the sequence $\{\hat{A}^{\varepsilon_k}(A_1, A_2, \ldots, A_N, P_{N+1}, \mathbf{x}, \omega)\}_{k=1}^\infty$ [19, 16] to assert the existence of a G-converging subsequence also denoted by

$$\{\hat{A}^{\varepsilon_k}(A_1, A_2, \ldots, A_N, P_{N+1}, \mathbf{x}, \omega)\}_{k=1}^\infty$$

and a G-limit denoted by $\hat{A}^E(A_1, A_2, \ldots, A_N, P_{N+1}, \mathbf{x}, \omega)$. The partial derivatives of $\hat{A}^E(A_1, A_2, \ldots, A_N, P_{N+1}, \mathbf{x}, \omega)$ with respect to each element of P_{N+1} evaluated at $P_{N+1} = A_i$ are given by [11, 12, 13]:

$$\begin{aligned} &\nabla_{mn}^{N+1} \hat{A}_{op}^E(A_1, A_2, \ldots, A_N, A_i, \mathbf{x}, \omega) \\ &\quad = \lim_{r \to 0} \lim_{\varepsilon_k \to 0} \left(\frac{1}{|Q(\mathbf{x}, r)|} \int_{Q(\mathbf{x}, r)} \chi_{t,i}^{\varepsilon_k}(\mathbf{y}, \omega)(\partial_m w_o^{k,r} + \mathbf{e}_m^o)(\partial_n w_p^{k,r} + \mathbf{e}_n^p) \, d\mathbf{y} \right). \end{aligned} \tag{3.14}$$

Here $Q(\mathbf{x},r)$ is a cube of side length $2r$ inside $\mathcal{D}$ centered at $\mathbf{x}$ with volume given by $|Q(\mathbf{x},r)|$, and the functions $w_p^{k,r}$ vanish on the boundary of the cube and are the solutions of

$$-\mathrm{div}(A^{\varepsilon_k}(\mathbf{y},\omega)(\nabla w_p^{k,r}(\mathbf{y})+\mathbf{e}^p))=0,\quad p=1,2,3, \tag{3.15}$$

for $\mathbf{y}$ in $Q(\mathbf{x},r)$. From [11, 12, 13] one has for every test function p vanishing on the boundary of $\mathcal{D}$ that

$$\begin{aligned}&\lim_{\varepsilon_k\to 0}\int_{\mathcal{D}} p(\mathbf{x})\chi_{t,i}^{\varepsilon_k}(\mathbf{x},\omega)|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2\,d\mathbf{x}\\ &\quad=\int_{\mathcal{D}} p(\mathbf{x})\left(\sum_{m=1}^{3}\nabla_{mm}^{N+1}\hat{A}^E(A_1,A_2,\ldots,A_N,A_i,\mathbf{x},\omega)\right)\mathbf{E}^M(\mathbf{x})\cdot\mathbf{E}^M(\mathbf{x})\,d\mathbf{x}.\end{aligned} \tag{3.16}$$

Here

$$\begin{aligned}&\left(\sum_{m=1}^{3}\nabla_{mm}^{N+1}\hat{A}^E(A_1,A_2,\ldots,A_N,A_i,\mathbf{x},\omega)\right)\mathbf{E}^M(\mathbf{x})\cdot\mathbf{E}^M(\mathbf{x})\\ &\quad=\sum_{op}\left(\lim_{r\to 0}\lim_{\varepsilon_k\to 0}\left(\frac{1}{|Q(\mathbf{x},r)|}\int_{Q(\mathbf{x},r)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)(\nabla w_o^{k,r}+\mathbf{e}^o)\right.\right.\\ &\qquad\left.\left.\cdot(\nabla w_p^{k,r}+\mathbf{e}^p)\,d\mathbf{y}\right)\mathbf{E}_o^M(\mathbf{x})\mathbf{E}_p^M(\mathbf{x})\right).\end{aligned} \tag{3.17}$$

From the appendix of [5] it follows, on passing to a subsequence, if necessary, that for every $r>0$

$$\lim_{\varepsilon_k\to 0}\int_{Q(\mathbf{x},r)}|(-\nabla w_p^{k,r}(\mathbf{y}))-\mathbf{G}^p(T(\mathbf{y}/\varepsilon_k)\omega)|^2\,d\mathbf{y}=0 \tag{3.18}$$

for almost every ω. From this we deduce that for a denumerable sequence $\{r_j\}_{j=1}^{\infty}$, $r_j\to 0$

$$\begin{aligned}&\left(\sum_{m=1}^{3}\nabla_{mm}^{N+1}\hat{A}^E(A_1,A_2,\ldots,A_N,A_i,\mathbf{x},\omega)\right)\mathbf{E}^M(\mathbf{x})\cdot\mathbf{E}^M(\mathbf{x})\\ &\quad=\lim_{r_j\to 0}\lim_{\varepsilon_k\to 0}\left(\frac{1}{|Q(\mathbf{x},r_j)|}\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y}/\varepsilon_k)\omega))\mathbf{E}^M(\mathbf{x})|^2\,d\mathbf{y}\right)\end{aligned} \tag{3.19}$$

for almost every ω. Applying the Hölder inequality gives

$$\begin{aligned}&\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y}/\varepsilon_k)\omega))\mathbf{E}^M(\mathbf{x})|^2\,d\mathbf{y}\\ &\quad\le\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)\,d\mathbf{y}\|\tilde{\chi}_i(T(\mathbf{y})\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y})\omega))\mathbf{E}^M(\mathbf{x})|^2\|_{L^\infty(R^3)}\\ &\quad\le\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)\,d\mathbf{y}\|\tilde{\chi}_i(\omega)|(I+\underline{\tilde{\mathbf{G}}}(\omega))\mathbf{E}^M(\mathbf{x})|^2\|_{L^\infty(\Omega)}.\end{aligned} \tag{3.20}$$

The last inequality in (3.20) follows from a straightforward argument given in the appendix. Noting that

$$\lim_{r_j\to 0}\lim_{\varepsilon_k\to 0}\frac{1}{|Q(\mathbf{x},r_j)|}\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)\,d\mathbf{y}=\theta_{t,i}(\mathbf{x},\omega) \tag{3.21}$$

for almost all $\mathbf{x}$ and applying (3.20) to (3.19), we arrive at the estimate

$$\begin{aligned}&\left(\sum_{m=1}^{3}\nabla_{mm}^{N+1}\hat{A}^E(A_1,A_2,\ldots,A_N,A_i,\mathbf{x},\omega)\right)\mathbf{E}^M(\mathbf{x})\cdot\mathbf{E}^M(\mathbf{x})\\&\qquad\le\theta_{t,i}(\mathbf{x},\omega)f_\infty^i(\mathbf{E}^M(\mathbf{x}))\end{aligned} \tag{3.22}$$

for almost every ω in Ω, and the proof of (3.8) of Lemma 3.2 is complete. To prove (3.9) we return to (3.19) and apply the Hölder inequality with $1/p+1/q=1$ to obtain

$$\begin{aligned}&\lim_{\varepsilon_k\to 0}\frac{1}{|Q(\mathbf{x},r_j)|}\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y}/\varepsilon_k)\omega))\mathbf{E}^M(\mathbf{x})|^2\,d\mathbf{y}\\&\quad\le\lim_{\varepsilon_k\to 0}\left(\frac{1}{|Q(\mathbf{x},r_j)|}\int_{Q(\mathbf{x},r_j)}\chi_{t,i}^{\varepsilon_k}(\mathbf{y},\omega)\,d\mathbf{y}\right)^{1/q}\\&\qquad\times\lim_{\varepsilon_k\to 0}\left(\frac{1}{|Q(\mathbf{x},r_j)|}\int_{Q(\mathbf{x},r_j)}\tilde{\chi}_i(T(\mathbf{y}/\varepsilon_k)\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y}/\varepsilon_k)\omega))\mathbf{E}^M(\mathbf{x})|^{2p}d\mathbf{x}\right)^{1/p}.\end{aligned} \tag{3.23}$$

From the Birkhoff ergodic theorem it follows that

$$\begin{aligned}&f_p^i(\mathbf{E}^M(\mathbf{x}))\\&\quad=\lim_{\varepsilon_k\to 0}\left(\frac{1}{|Q(\mathbf{x},r_j)|}\int_{Q(\mathbf{x},r_j)}\tilde{\chi}_i(T(\mathbf{y}/\varepsilon_k)\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y}/\varepsilon_k)\omega))\mathbf{E}^M(\mathbf{x})|^{2p}d\mathbf{x}\right)^{1/p},\end{aligned} \tag{3.24}$$

and the proof of (3.9) is complete. □

4. Homogenization of Chebyshev's inequality. In this section we establish Proposition 2.1. We start by providing the relationship between the limits $\lim_{\varepsilon_k\to 0}P_i^{\varepsilon_k}(t,C_0,\omega)$, $\lim_{\varepsilon_k\to 0}P^{\varepsilon_k}(t,C_0,\omega)$ and the distribution of states for the square of the electric field intensity in the ith phase. The volume of the subset of the ith phase contained in C_0 where the equivalent stress exceeds t is given by $\lambda_i^{\varepsilon_k}(t,C_0,\omega)=\int_{C_0}\chi_{t,i}^{\varepsilon_k}(\mathbf{x},\omega)d\mathbf{x}$. Passing to a subsequence if necessary, the theory of weak convergence delivers the distribution of states $\theta_{t,i}(\mathbf{x},\omega)$ for which $\lim_{\varepsilon_k\to 0}\lambda_i^{\varepsilon_k}(t,C_0,\omega)=\int_{C_0}\theta_{t,i}(\mathbf{x},\omega)d\mathbf{x}$. For fixed ε_k the volume of the ith phase in the cube C_0 is denoted by $V_i^{\varepsilon_k}$ and $P_i^{\varepsilon_k}(t,C_0,\omega)=\lambda_i^{\varepsilon_k}(t,C_0,\omega)/V_i^{\varepsilon_k}$. From ergodicity, $\lim_{\varepsilon_k\to 0}V_i^{\varepsilon_k}=\theta_i|C_0|$. It is clear that

$$\lim_{\varepsilon_k\to 0}P_i^{\varepsilon_k}(t,C_0,\omega)=\left(\frac{1}{\theta_i|C_0|}\right)\int_{C_0}\theta_{t,i}(\mathbf{x},\omega)\,d\mathbf{x}. \tag{4.1}$$

Set $\theta_t(\mathbf{x},\omega)=\sum_{i=1}^{N}\theta_{t,i}(\mathbf{x},\omega)$; then one has

$$\lim_{\varepsilon_k\to 0}P^{\varepsilon_k}(t,C_0,\omega)=(1/|C_0|)\int_{C_0}\theta_t(\mathbf{x},\omega)\,d\mathbf{x}. \tag{4.2}$$

It follows easily from the homogenization constraint (3.4) that

$$\theta_{t,i}(\mathbf{x},\omega) \leq t^{-p}|f_p^i(\mathbf{E}^M(\mathbf{x}))|^p, \qquad i=1,\ldots,N. \tag{4.3}$$

Taking averages of both sides gives

$$\lim_{\varepsilon_k\to 0} P_i^{\varepsilon_k}(t,C_0,\omega) \leq t^{-p}\left(\frac{1}{\theta_i|C_0|}\right)\int_{C_0}|f_p^i(\mathbf{E}^M(\mathbf{x}))|^p\,d\mathbf{x}, \tag{4.4}$$

and (2.10) of Proposition 2.1 is proved. The inequality (2.11) of Proposition 2.1 follows immediately upon summation of the left and right sides of (4.3) over $i=1,\ldots,N$ and averaging both sides.

5. Bounds on the support set of the electric field intensity distribution function. This section contains the proofs of Propositions 2.2 and 2.3. The homogenization constraint (3.3) is used to prove Proposition 2.2. Integration of (3.3) gives

$$\int_{C_0}\theta_{t,i}(\mathbf{x},\omega)f^i(\mathbf{E}^M(\mathbf{x}))\,d\mathbf{x} - t\int_{C_0}\theta_{t,i}(\mathbf{x},\omega)\,d\mathbf{x} \geq 0, \quad i=1,\ldots,N. \tag{5.1}$$

Application of Hölder's inequality to the first term and division by $\theta_i|C_0|$ gives

$$\lim_{\varepsilon_k\to 0} P_i^{\varepsilon_k}(t,C_0,\omega)(\|f^i(\mathbf{E}^M)\|_{L^\infty(C_0)} - t) \geq 0, \quad i=1,\ldots,N, \tag{5.2}$$

and Proposition 2.2 follows.

To prove Proposition 2.3 we add the constraints (5.1) to get

$$\sum_{i=1}^N\left(\int_{C_0}\theta_{t,i}(\mathbf{x},\omega)f^i(\mathbf{E}^M(\mathbf{x}))\,d\mathbf{x}\right) - t\int_{C_0}\theta_t(\mathbf{x},\omega)\,d\mathbf{x} \geq 0. \tag{5.3}$$

Noting that $M(\mathbf{E}^M(\mathbf{x})) \geq f^i(\mathbf{E}^M(\mathbf{x}))$ gives

$$\int_{C_0}\theta_t(\mathbf{x},\omega)M(\mathbf{E}^M(\mathbf{x}))\,d\mathbf{x} - t\int_{C_0}\theta_t(\mathbf{x},\omega)\,d\mathbf{x} \geq 0. \tag{5.4}$$

Application of Hölder's inequality to the first term and division by $|C_0|$ gives

$$\lim_{\varepsilon_k\to 0} P^{\varepsilon_k}(t,C_0,\omega)(\|M(\mathbf{E}^M(\mathbf{x}))\|_{L^\infty(C_0)} - t) \geq 0, \tag{5.5}$$

and Proposition 2.3 follows.

6. Pointwise bounds on the electric field intensity. In this section we give the proof of Proposition 2.4. From the hypothesis of Propositions 2.4 and 2.3 it follows that $\lim_{k\to\infty}|S_t^{\varepsilon_k}(\omega)\cap C_0| = 0$. We choose a subsequence $\{\varepsilon_{k'}\}_{k'=1}^\infty$ such that $|S_t^{\varepsilon_{k'}}(\omega)\cap C_0| < 2^{-k'}$. Then if $\mathbf{x}$ doesn't belong to $\cup_{k'\geq\tilde{K}}^\infty S_t^{\varepsilon_{k'}}(\omega)\cap C_0$, one has that $|\mathbf{E}^{\varepsilon_{k'}}|^2 \leq t$ for every $k' > \tilde{K}$. Hence for any $\mathbf{x}$ not in $A = \cap_{K=1}^\infty \cup_{k'\geq K}^\infty S_t^{\varepsilon_{k'}}(\omega)\cap C_0$ there is an index K for which $|\mathbf{E}^{\varepsilon_{k'}}|^2 \leq t$ for every $k' > K$. But

$$|A| \leq \left|\cup_{k'\geq\tilde{K}}^\infty S_t^{\varepsilon_{k'}}(\omega)\cap C_0\right| \leq \sum_{k'=\tilde{K}}^\infty |S_t^{\varepsilon_{k'}}(\omega)\cap C_0| \leq 2^{-\tilde{K}+1}.$$

Hence $|A| = 0$. Thus for almost every $\mathbf{x}$ in C_0 there is a finite index K (that may depend upon $\mathbf{x}$ and ω) for which $|\mathbf{E}^{\varepsilon_{k'}}|^2 \leq t$ for every $k' > K$, and the proposition follows.

7. Upper bounds on the stress distribution function. In this section Propositions 2.5 and 2.6 are derived. For a cube C_0 contained inside the composite, the set of points where $M(\mathbf{E}^M(\mathbf{x})) \geq t$ is denoted by $\{\mathbf{x} \text{ in } C_0;\ M(\mathbf{E}^M(\mathbf{x})) \geq t\}$. We start by establishing the inequality

$$\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) \leq \frac{|\{\mathbf{x} \text{ in } C_0;\ M(\mathbf{E}^M(\mathbf{x})) \geq t\}|}{|C_0|}. \tag{7.1}$$

Adding the homogenization constraints gives

$$\theta_t(\mathbf{x}, \omega)(M(\mathbf{E}^M(\mathbf{x})) - t) \geq 0. \tag{7.2}$$

Thus from (7.2) it is evident that at almost every point for which $\theta_t(\mathbf{x}, \omega) > 0$, one has that $M(\mathbf{E}^M(\mathbf{x})) \geq t$. The set of points in C_0 for which $\theta_t(\mathbf{x}, \omega) > 0$ is denoted by $\{\mathbf{x} \text{ in } C_0;\ \theta_t(\mathbf{x}, \omega) > 0\}$, and it is clear that

$$|\{\mathbf{x} \text{ in } C_0;\ \theta_t(\mathbf{x}, \omega) > 0\}| \leq |\{\mathbf{x} \text{ in } C_0;\ M(\mathbf{E}^M(\mathbf{x})) \geq t\}|. \tag{7.3}$$

Since $0 \leq \theta_t(\mathbf{x}, \omega) \leq 1$, one has the estimate

$$\int_{C_0} \theta_t(\mathbf{x}, \omega)\, d\mathbf{x} \leq |\{\mathbf{x} \text{ in } C_0;\ \theta_t(\mathbf{x}, \omega) > 0\}|, \tag{7.4}$$

and (7.1) follows from (7.3).

We will apply the John–Nirenberg theorem [6] to estimate the right-hand side of (7.1). To do this we show first that

$$|\{\mathbf{x} \text{ in } C_0;\ M(\mathbf{E}^M(\mathbf{x})) \geq t\}| \leq |\{\mathbf{x} \text{ in } C_0;\ |M(\mathbf{E}^M(\mathbf{x})) - M_{C_0}| \geq t - M_{C_0}\}|. \tag{7.5}$$

To see this, note that $M(\mathbf{E}^M(\mathbf{x})) \leq |M(\mathbf{E}^M(\mathbf{x})) - M_{C_0}| + M_{C_0}$, so

$$\{\mathbf{x} \text{ in } C_0;\ M(\mathbf{E}^M(\mathbf{x})) \geq t\} \subset \{\mathbf{x} \text{ in } C_0;\ |M(\mathbf{E}^M(\mathbf{x})) - M_{C_0}| \geq t - M_{C_0}\}, \tag{7.6}$$

and (7.5) follows. Application of the John–Nirenberg theorem gives

$$\frac{|\{\mathbf{x} \text{ in } C_0;\ |M(\mathbf{E}^M(\mathbf{x})) - M_{C_0}| \geq s\}|}{|C_0|} \leq \begin{cases} 1 & \text{for } 0 < s \leq 8\|M\|_{BMO}\alpha^{-1}, \\ \alpha^{-1} e^{[-(C(\alpha)\times(s))]} & \text{for } 8\|M\|_{BMO}\alpha^{-1} < s. \end{cases} \tag{7.7}$$

Proposition 2.5 follows immediately from the change of variables $s = t - M_{C_0}$ and the inequalities (7.1), (7.5), and (7.7). The function obtained by the change of variables $s = t - M_{C_0}$ in (7.7) is denoted by $\overline{P}_\alpha(t, C_0)$, and

$$\overline{P}_\alpha(t, C_0) = \begin{cases} 1 & \text{for } 0 < t - M_{C_0} \leq 8\|M\|_{BMO}\alpha^{-1}, \\ \alpha^{-1} e^{[-(C(\alpha)\times(t - M_{C_0}))]} & \text{for } 8\|M\|_{BMO}\alpha^{-1} < t - M_{C_0}. \end{cases} \tag{7.8}$$

It is evident from the estimates that $\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) \leq \overline{P}_\alpha(t, C_0)$ for $M_{C_0} < t$. Tighter upper bounds are given by optimizing over α, i.e.,

$$\lim_{\varepsilon_k \to 0} P^{\varepsilon_k}(t, C_0, \omega) \leq \overline{U}(t, C_0) = \inf_{0 < \alpha < 1} \overline{P}_\alpha(t, C_0). \tag{7.9}$$

Here $\overline{U}(t, C_0)$ is continuous and decreasing and is given by

(7.10)
$$\overline{U}(t, C_0) = \begin{cases} 1 & \text{for } 0 < t - M_{C_0} \leq 8\|M\|_{BMO}, \\ (\alpha(t))^{-1} e \times e^{[-\alpha(t)(t-M_{C_0})/(8\|M\|_{BMO})]} & \text{for } 8\|M\|_{BMO} + M_{C_0} < t. \end{cases}$$

The factor $\alpha(t)$ lies in the interval $e^{-1} < \alpha(t) < 1$ and is the root of the equation

$$\kappa^{-1} - \alpha(1 + \ln \alpha) = 0, \tag{7.11}$$

where $\kappa = (t - M_{C_0})/(8\|M\|_{BMO})$. Proposition 2.6 now follows immediately from (7.10).

8. Macrofield modulation functions for random two-phase layered composites. In this section we treat randomly layered media and give an example of how the macrofield modulation functions are used to assess the field distribution inside a finite size sample. We start by considering a two-dimensional electrostatic problem on the plane R^2 and derive explicit formulas for the moments of the electric field. The plane is partitioned into layers of unit thickness parallel to the y_2 axis. Each layer contains an isotropic dielectric material having either dielectric constant α or β with $\alpha < \beta$. The particular value of the dielectric constant in each layer is given by a Bernoulli process; i.e., a biased coin that takes heads with probability θ and tails with probability $1 - \theta$ is used to assign the dielectric constant in each layer. Over each layer the coin is flipped, and if the coin lands heads up, the layer is assigned the β dielectric; otherwise it assigned the α dielectric. In section 8.1 we calculate the moments of the electric field directly using the strong law of large numbers. In section 8.2 we apply these results and use Proposition 2.2 to assess the distribution of the electric field intensity inside an L-shaped domain filled with a highly oscillatory random laminate in the presence of a prescribed electric charge density.

8.1. Moments of the electric field for random two-phase layered composites. For a given infinite sequence of biased coin flips, we arrive at a realization of the random medium. The indicator function ω of the β phase is a function of the y_1 coordinate and takes the value one in the β phase and zero outside it. For convenience we choose the origin of the $y_1 - y_2$ coordinate system to lie on a two-phase interface, with the β phase on the left and the α phase on the right. The coordinates of the interfaces between α and β phases on the positive y_1 axis are given by the sequence $\{N_n\}_{n=1}^{\infty}$ and $N_0 = 0$. The coordinates of the interfaces between phases on the negative y_1 axis are given by $\{N_n\}_{n=-1}^{-\infty}$. Let $\mathbf{e}^1$ and $\mathbf{e}^2$ be unit vectors pointing in the directions of the y_1 axis and y_2 axis, respectively. For imposed electric field gradients $\mathbf{e}^k$, $k = 1, 2$, the fluctuating part of the electric potential φ^k is continuous and solves the two-dimensional version of the field problem (2.2) given by

$$\begin{aligned} &\Delta\varphi^k = 0 \quad \text{inside each layer,} \\ &\beta(\partial_{y_1}\varphi^k_{|_L} + \mathbf{e}^k_1) = \alpha(\partial_{y_1}\varphi^k_{|_R} + \mathbf{e}^k_1) \text{ on interfaces.} \end{aligned} \tag{8.1}$$

It is clear from the above that $\varphi^1 = \varphi^1(y_1)$ and $\varphi^2 = \text{const}$. In this context the analogue of (2.1) is given by

$$\lim_{r\to\infty} \frac{\int_{-r}^{r} \partial_{y_1}\varphi^1 dy_1}{2r} = \lim_{r\to\infty} \frac{\varphi^1(r) - \varphi^1(-r)}{2r} = 0 \tag{8.2}$$

and $\varphi^k(0) = 0$. Clearly $\varphi^2 = 0$, and the potential φ^1 is a continuous piecewise linear function of y_1, i.e., in each phase φ^1 is of the form $\varphi^1(y_1) = ay_1 + b$ where the constants a and b change between phases. Application of (8.1), the continuity conditions at two-phase interfaces, and (8.2) together with the strong law of large numbers shows that $\varphi^1(y_1)$ is given a.s. by the following formulas.

For $N_n \le y_1 < N_{n+1}$ and $n+1$ even, the potential is given by

$$\varphi^1(y_1) = (k_2 - 1)y_1 + k_1(N_1 - N_2 + N_3 - N_4 + \cdots + N_n), \tag{8.3}$$

and for $n+1$ odd

$$\varphi^1(y_1) = (k_3 - 1)y_1 + k_1(N_1 - N_2 + N_3 - N_4 + \cdots - N_n). \tag{8.4}$$

For $N_{-(n+1)} < y_1 \le N_{-n}$ and $n+1$ even, the potential is given by

$$\varphi^1(y_1) = (k_3 - 1)y_1 + k_1(-N_{-1} + N_{-2} - N_{-3} + N_{-4} + \cdots - N_{-n}), \tag{8.5}$$

and for $n+1$ odd

$$\varphi^1(y_1) = (k_2 - 1)y_1 + k_1(-N_{-1} + N_{-2} - N_{-3} + N_{-4} + \cdots + N_{-n}), \tag{8.6}$$

where the constants k_1, k_2, and k_3 are defined by

$$\begin{aligned} k_1 &= \frac{\beta - \alpha}{\alpha + (\beta - \alpha)(1 - \theta)}, \\ k_2 &= \frac{\alpha}{\alpha + (\beta - \alpha)(1 - \theta)}, \\ k_3 &= \frac{\beta}{\alpha + (\beta - \alpha)(1 - \theta)}. \end{aligned} \tag{8.7}$$

The derivative $\partial_{y_1}\varphi^1$ is given by the following formula:

$$\begin{aligned} \partial_{y_1}\varphi^1 = \gamma_\alpha &= \frac{\theta(\beta - \alpha)}{\alpha + (\beta - \alpha)(1 - \theta)} \text{ in the } \alpha \text{ phase}, \\ \partial_{y_1}\varphi^1 = \gamma_\beta &= \frac{-(1 - \theta)(\beta - \alpha)}{\alpha + (\beta - \alpha)(1 - \theta)} \text{ in the } \beta \text{ phase}. \end{aligned} \tag{8.8}$$

For an imposed constant applied field of the general form $\overline{\mathbf{E}} = E_1\mathbf{e}^1 + E_2\mathbf{e}^2$, the local electric field $\mathbf{E}(\mathbf{y}, \omega)$ is given by

$$\mathbf{E}(\mathbf{y}, \omega) = (1 - \omega(y_1))((1 + \gamma_\alpha)E_1\mathbf{e}^1 + E_2\mathbf{e}^2) + \omega(y_1)((1 + \gamma_\beta)E_1\mathbf{e}^1 + E_2\mathbf{e}^2). \tag{8.9}$$

We average over the plane and apply the strong law of large numbers to obtain the moments of the local electric field given by

$$\begin{aligned} f_p^1(\overline{\mathbf{E}}) &= \lim_{r\to\infty}\left(\frac{1}{2r}\int_{-r}^{r}(1 - \omega(y_1))|\mathbf{E}(\mathbf{y}, \omega)|^{2p}\,dy_1\right)^{1/p} \\ &= (1 - \theta)^{1/p}((1 + \gamma_\alpha)^2E_1^2 + E_2^2), \end{aligned} \tag{8.10}$$

$$\begin{aligned} f_p^2(\overline{\mathbf{E}}) &= \lim_{r\to\infty}\left(\frac{1}{2r}\int_{-r}^{r}\omega(y_1)|\mathbf{E}(\mathbf{y}, \omega)|^{2p}\,dy_1\right)^{1/p} \\ &= \theta^{1/p}((1 + \gamma_\beta)^2E_1^2 + E_2^2). \end{aligned} \tag{8.11}$$

FIG. 8.1. *A realization for* $\theta = 1/3$.

The local dielectric constant in the random laminate is given by

$$A(\mathbf{y},\omega) = \alpha(1-\omega(y_1)) + \beta\omega(y_1), \tag{8.12}$$

and the effective tensor A^E is given by

$$\begin{aligned} A^E\overline{\mathbf{E}} &= \lim_{r\to\infty}\frac{1}{2r}\int_{-r}^{r} A(\mathbf{y},\omega)\mathbf{E}(\mathbf{y},\omega)\,dy_1 \\ &= (\alpha^{-1}(1-\theta)+\beta^{-1}\theta)^{-1}E_1 + (\alpha(1-\theta)+\beta\theta)E_2. \end{aligned} \tag{8.13}$$

The random laminate described above is an example of a symmetric cell material [15]. A standard construction delivers the probability space $(\Omega,\mathcal{F},\mathcal{P})$ and dynamical system associated with the symmetric cell material; see [8, 17]. Using this, one rewrites the averages given in (8.10), (8.11), and (8.13) in terms of the ensemble averages used to define the moments of the local electric field and effective dielectric constant in section 2.

8.2. Electric field assessment for a randomly layered dielectric in an *L*-shaped domain. In this subsection we apply the theory presented in section 2 to assess the electric field distribution inside an L-shaped domain containing a highly oscillatory random laminate with length scale $\varepsilon_k = 1/k$, $k = 1, 2, \ldots$. Here the L-shaped domain is taken to have side length one. The dielectric constant for the highly oscillatory random laminate inside the L-shaped domain is given by

$$A^{\varepsilon_k}(\mathbf{x},\omega) = A(x_1/\varepsilon_k,\omega), \tag{8.14}$$

where $A(\mathbf{y},\omega)$ is given by the Bernoulli process (8.12) with $\theta = 1/3$. A realization of the random laminate with characteristic length scale ε_{40} is given in Figure 8.1. Here the subdomain in white is the α dielectric and the subdomain in black is the β dielectric.

The electric potential $\phi^{\varepsilon_k}(\mathbf{x},\omega)$ is the solution of

$$-\mathrm{div}(A^{\varepsilon_k}(\mathbf{x},\omega)\nabla\phi^{\varepsilon_k}(\mathbf{x},\omega)) = 10 \tag{8.15}$$

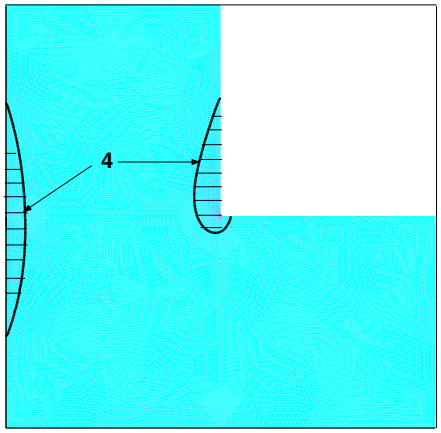

FIG. 8.2. *Distribution of the electric field intensity in the α dielectric.*

inside the L-shaped domain and $\phi^{\varepsilon_k}(\mathbf{x},\omega) = 0$ on the boundary. The associated electric field is given by $\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega) = -\nabla\phi^{\varepsilon_k}(\mathbf{x},\omega)$. The goal of this application is to characterize the distributions $\lim_{\varepsilon_k\to 0} P_i^{\varepsilon_k}(t, C_0, \omega)$, $i = 1, 2$. Here C_0 can be any square contained inside the L-shaped domain. To do this we solve numerically for the macroscopic potential and electric field and construct the macrofield modulation functions. The macroscopic electric potential $\phi^M(\mathbf{x})$ satisfies the boundary condition $\phi^M(\mathbf{x}) = 0$ and

$$-\mathrm{div}(A^E \nabla\phi^M(\mathbf{x})) = 10. \tag{8.16}$$

The macroscopic electric field is given by $\mathbf{E}^M(\mathbf{x}) = -\nabla\phi^M(\mathbf{x})$. The macrofield modulation functions are given by

$$f_p^1(\mathbf{E}^M(\mathbf{x})) = (1-\theta)^{1/p}((1+\gamma_\alpha)^2|\partial_{x_1}\phi^M(\mathbf{x})|^2 + |\partial_{x_2}\phi^M(\mathbf{x})|^2), \tag{8.17}$$

$$f_p^2(\mathbf{E}^M(\mathbf{x})) = \theta^{1/p}((1+\gamma_\beta)^2|\partial_{x_1}\phi^M(\mathbf{x})|^2 + |\partial_{x_2}\phi^M(\mathbf{x})|^2). \tag{8.18}$$

For the computation we choose $\alpha = 2$ and $\beta = 10$ and restrict our attention to $f_\infty^1(\mathbf{E}^M(\mathbf{x}))$ and $f_\infty^2(\mathbf{E}^M(\mathbf{x}))$. To illustrate the ideas, the level curves given by $f_\infty^1(\mathbf{E}^M(\mathbf{x})) = 4$ are plotted in Figure 8.2. The lined regions indicate where $f_\infty^1(\mathbf{E}^M(\mathbf{x})) > 4$ and $f_\infty^1(\mathbf{E}^M(\mathbf{x})) < 4$ outside these. For any square C_0 that doesn't intersect the lined regions, Proposition 2.2 implies that

$$\lim_{\varepsilon_k\to 0} P_1^{\varepsilon_k}(t, C_0, \omega) = 0 \quad \text{for } t > 4 \tag{8.19}$$

for almost every realization ω. In this way it is seen that the lined regions provide an asymptotically exact bound on the set where $|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2 > 4$ in the α dielectric.

The level curves given by $f_\infty^2(\mathbf{E}^M(\mathbf{x})) = 1$ are plotted in Figure 8.3. The lined regions indicate where $f_\infty^2(\mathbf{E}^M(\mathbf{x})) > 1$ and $f_\infty^1(\mathbf{E}^M(\mathbf{x})) < 1$ outside these. For any square C_0 that doesn't intersect the lined regions, Proposition 2.2 implies that

$$\lim_{\varepsilon_k\to 0} P_2^{\varepsilon_k}(t, C_0, \omega) = 0 \quad \text{for } t > 1 \tag{8.20}$$

for almost every realization ω. It is seen as before that the lined regions provide an asymptotically exact bound on the set where $|\mathbf{E}^{\varepsilon_k}(\mathbf{x},\omega)|^2 > 1$ in the β dielectric.

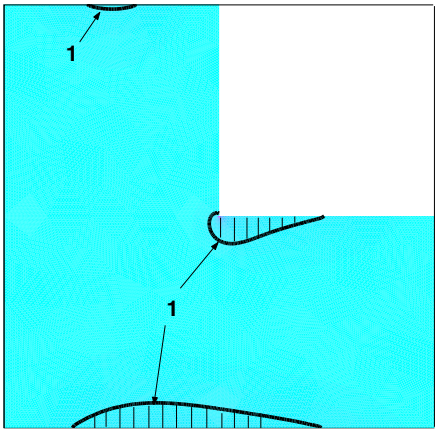

FIG. 8.3. *Distribution of the electric field intensity in the β dielectric.*

Appendix. Here we establish the inequality stated in (3.20) given by

$$\begin{aligned} &\|\tilde{\chi}_i(T(\mathbf{y})\omega)|(I+\underline{\tilde{\mathbf{G}}}(T(\mathbf{y})\omega))\mathbf{E}^M(\mathbf{x})|^2\|_{L^\infty(R^3)} \\ &\quad\le \|\tilde{\chi}_i(\omega)|(I+\underline{\tilde{\mathbf{G}}}(\omega))\mathbf{E}^M(\mathbf{x})|^2\|_{L^\infty(\Omega)} \end{aligned} \tag{A.1}$$

for almost every ω. To establish (A.1) put $\alpha = \|\tilde{\chi}_i(\omega)|(I+\underline{\tilde{\mathbf{G}}}(\omega))\mathbf{E}^M(\mathbf{x})|^2\|_{L^\infty(\Omega)}$ and introduce the set $\mathcal{G} = \{\omega : \tilde{\chi}_i(\omega)|(I+\underline{\tilde{\mathbf{G}}}(\omega))\mathbf{E}^M(\mathbf{x})|^2 \le \alpha\}$. From Lemma 7.1 of [8] there exists a set $\mathcal{G}_1 \subset \mathcal{G}$ for which $\mathcal{P}(\mathcal{G}_1) = 1$, and for any fixed ω in $\mathcal{G}_1$, one has that $T(\mathbf{y})\omega$ is in $\mathcal{G}$ for almost every $\mathbf{y}$ in R^3, and (A.1) follows.

PARAMETRIC RESONANCE IN IMMERSED ELASTIC BOUNDARIES*

RICARDO CORTEZ†, CHARLES S. PESKIN‡,
JOHN M. STOCKIE§, AND DOUGLAS VARELA¶

Abstract. In this paper, we investigate the stability of a fluid-structure interaction problem in which a flexible elastic membrane immersed in a fluid is excited via periodic variations in the elastic stiffness parameter. This model can be viewed as a prototype for active biological tissues such as the basilar membrane in the inner ear, or heart muscle fibers immersed in blood. Problems such as this, in which the system is subjected to internal forcing through a parameter, can give rise to "parametric resonance." We formulate the equations of motion in two dimensions using the immersed boundary formulation. Assuming small amplitude motions, we can apply Floquet theory to the linearized equations and derive an eigenvalue problem whose solution defines the marginal stability boundaries in parameter space. The eigenvalue equation is solved numerically to determine values of fiber stiffness and fluid viscosity for which the problem is linearly unstable. We present direct numerical simulations of the fluid-structure interaction problem (using the immersed boundary method) that verify the existence of the parametric resonances suggested by our analysis.

Key words. immersed boundary, fluid-structure interaction, parametric resonance

1. Introduction.

Fluid-structure interaction problems abound in industrial applications as well as in many natural phenomena. Owing to the potentially complex, time-varying geometry and the nonlinear interactions that arise between fluid and solid, such problems represent a major challenge to both mathematical modelers and computational scientists.

This paper deals with a model for fluid-structure interaction known as the immersed boundary (IB) formulation [20], which has proven particularly effective for dealing with complex problems in biological fluid mechanics. In this formulation, the immersed structure is treated as an elastic surface or interwoven mesh of elastic fibers that exert a singular force on a surrounding viscous fluid, while also moving with the velocity of adjacent fluid particles. The associated immersed boundary method has been used to solve a wide range of problems such as blood flow in the heart and arteries [2, 21], swimming microorganisms [8], biofilms [7], and insect flight [16]. More recently, the IB method has also been extended to a much wider range of nonbiological problems involving flow past solid cylinders [12], flapping filaments [29], parachutes [10], and suspensions of flexible particles [25].

While a significant body of literature has developed around numerical simulations using the IB method (as well as related methods such as the blob projection method [4]), comparatively little work has been done on analyzing the stability behavior of solutions to the underlying equations of motion. Beyer and LeVeque [3] were the first to perform an analysis of the IB formulation in one spatial dimension. Stockie and Wetton [26] investigated the linear stability of a flat fiber in two dimensions which is subjected to a small sinusoidal perturbation, and presented asymptotic results on the frequency and rate of decay for the resulting oscillations. Cortez and Varela [5] performed a nonlinear analysis for a perturbed circular elastic membrane immersed in an inviscid fluid.

In all of this previous work, the immersed boundary was assumed to be passive, moving along with the flow and generating forces only in response to elastic deformation. However, there are many problems in which the immersed boundary is an active material, generating time-dependent forces to drive its motion. Examples include beating heart muscle fibers and flagellated cells, both of which apply periodic forces to direct their motion and that of the surrounding fluid.

It is then natural to ask whether periodic forcing at various frequencies will give rise to resonance. In the case of immersed boundaries, the applied force is *internal*, in the sense that the system is forced through a periodic variation in a system parameter (namely, the elastic properties of the solid material) rather than through an external body force. In contrast to externally forced systems, these internally or parametrically forced systems are known to exhibit parametric resonance, in which the response for linear systems (i.e., assuming small amplitude motions) can become unbounded even in the presence of viscous damping. Once nonlinearities are taken into account, however, the response remains bounded, but the system can still exhibit large-amplitude motion when forced at certain resonant frequencies. Analyses of parametric resonance have appeared for various fluid flows involving surface or interfacial waves wherein the system is forced through gravitational modulation [11, 14, 17] or time-dependent heating [15]. However, to our knowledge there has been no analysis performed on fluid-structure problems that captures the two-way interaction between a fluid and an immersed, flexible structure. In a recent study by Wang [28], an analysis is performed of flutter and buckling instabilities in a paper making headbox, in which a long, flexible vane is driven to vibrate under the influence of periodic forcing from turbulent fluid jets. However, the author assumes a given fluid velocity and that the solid structure has no influence on the fluid motion.

In this paper, we perform an analysis of parametric resonance in a two-dimensional, circular, elastic membrane immersed in Navier–Stokes flow, which is driven by a time-periodic variation in its elastic stiffness parameter. The elastic membrane is under tension due to the incompressible fluid it encloses, and the changes in the elastic stiffness parameter are equivalent to changes in the tension of the membrane that mimic the contraction of biological fibers. The novelty of this work is that it includes the full, two-way interaction between the fluid and the membrane. In sections 2 and 3, we present the linearized equations of motion for the IB formulation and reduce them to a suitable nondimensional form. In sections 4, 5, and 6, we perform a Floquet analysis of the problem and derive a system of equations that relate the amplitude, frequency, and wavenumber of the internal forcing to the physical parameters in the problem. The natural modes for the unforced system are derived in section 7 and compared to the asymptotic expressions for the natural modes in a flat fiber that were derived in [26]. We also compare the natural modes to those observed in computations using the blob projection method, an alternate method for solving the IB problem that

affords higher spatial accuracy. In section 8 we consider the periodically forced problem and determine the conditions under which parametric resonance can occur. The results are verified using numerical simulations with the IB method.

2. Problem definition. Consider an elastic fiber immersed in a two-dimensional, viscous, incompressible fluid of infinite extent. The fiber is a closed loop with resting length of zero, so that in the absence of fluid the fiber would shrink to a point. However, because an incompressible fluid occupies the region inside the fiber, the equilibrium state is a circle of constant radius R, in which the pressure drop across the fiber is balanced by the tension force. Our aim is to investigate a *parametric excitation* of the fiber, in which the elastic stiffness is varied periodically in time.

The equations of motion for the fluid and immersed boundary can be written in terms of the vorticity $\xi(\boldsymbol{x},t)$ and stream function $\psi(\boldsymbol{x},t)$ as [19, p. 1]:

$$\rho\left(\xi_t + \boldsymbol{u}\cdot\nabla\xi\right) = \mu\nabla^2\xi + \hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{f}, \tag{2.1a}$$

$$\boldsymbol{u} = -\hat{\boldsymbol{z}}\times\nabla\psi, \tag{2.1b}$$

$$-\nabla^2\psi = \xi, \tag{2.1c}$$

$$\boldsymbol{f}(\boldsymbol{x},t) = \int_0^{2\pi} (K\boldsymbol{X}_s)_s\,\delta(\boldsymbol{x}-\boldsymbol{X})\,ds, \tag{2.1d}$$

$$\boldsymbol{X}_t = \boldsymbol{u}(\boldsymbol{X},t), \tag{2.1e}$$

where $\boldsymbol{x} = (x,y)$ and $\hat{\boldsymbol{z}} = (0,0,1)$. The fluid velocity $\boldsymbol{u}(\boldsymbol{x},t)$ and fiber force $\boldsymbol{f}(\boldsymbol{x},t)$ are functions of position and time, whereas the fiber position $\boldsymbol{X}(s,t) = (X^r(s,t), X^\theta(s,t))$ is a function of time and the Lagrangian fiber parameter $0 \le s \le 2\pi$ (which is the same as the angle θ when the fiber's reference state is a circle). We assume in this paper that the stiffness is a periodic function of time,

$$K = K(s,t) = K_c(1 + 2\tau\sin\omega_o t), \tag{2.2}$$

which has no dependence on the spatial variable s.

We point out that s is a Lagrangian parameter and is not necessarily proportional to arclength since the fiber is allowed to stretch and shrink tangentially. The force density $(K\boldsymbol{X}_s)_s$ thus includes components normal and tangential to the fiber. If we identify the tension $T(s) = K\|\boldsymbol{X}_s\|$ and the unit tangent vector $\hat{\tau}(s) = \boldsymbol{X}_s/\|\boldsymbol{X}_s\|$, we may write the force density term as

$$(K\boldsymbol{X}_s)_s = (T(s)\hat{\tau}(s))_s = T_s(s)\hat{\tau}(s) + T(s)\hat{\tau}_s(s),$$

which shows explicitly that the force resolves itself into normal and tangential components. We also remark that spatial dependence in K can be easily incorporated into our analysis provided that the spatial variations are small (that is, on the order of the parameter ϵ introduced in the following section).

Our motivation comes from active muscle fibers that may contract and relax to generate fluid motion. For this reason we will focus on nonnegative values of the stiffness and we will be concerned mostly with the range $0 \le \tau \le \frac{1}{2}$ in (2.2). However, our analysis does not require this restriction and the results apply to values of $\tau > 1/2$ as well. This is important because there are instances in which a negative stiffness plays an important role as is the case of hair bundles in the bullfrog inner ear [9].

3. Nondimensionalization. We first simplify the problem by scaling the variables and forming dimensionless groups. For now, variables with a tilde will be dimensionless. Let

$$\begin{aligned} \boldsymbol{x} &= R\,\tilde{\boldsymbol{x}}, \\ \boldsymbol{u} &= U\,\tilde{\boldsymbol{u}} \qquad (U \text{ will be determined later}), \\ t &= R/U\,\tilde{t}, \\ K &= K_c\,\tilde{K}, \end{aligned}$$

which imply that

$$\begin{aligned} \boldsymbol{f}(\boldsymbol{x},t) = \frac{K_c}{R}\,\tilde{\boldsymbol{f}}(\tilde{\boldsymbol{x}},\tilde{t}) &= \int_0^{2\pi} (\tilde{K}\tilde{\boldsymbol{X}}_s)_s\,\delta(\tilde{\boldsymbol{x}}-\tilde{\boldsymbol{X}})\,ds, \\ \xi = \frac{U}{R}\,\tilde{\xi}, \\ \psi = UR\,\tilde{\psi}. \end{aligned}$$

With these scalings the vorticity equation becomes

$$\tilde{\xi}_{\tilde{t}} + \tilde{\boldsymbol{u}}\cdot\tilde{\nabla}\,\tilde{\xi} = \left(\frac{\mu}{\rho U R}\right)\tilde{\nabla}^2\tilde{\xi} + \left(\frac{K_c}{\rho U^2}\right)\,(\hat{\boldsymbol{z}}\cdot\tilde{\nabla}\times\tilde{\boldsymbol{f}}).$$

In view of this and (2.2), we now define

$$U = R\omega_o, \qquad \nu = \frac{\mu}{\rho U R} = \frac{\mu}{\rho R^2\omega_o}, \qquad \kappa = \frac{K_c}{\rho U^2} = \frac{K_c}{\rho R^2\omega_o^2}, \tag{3.1}$$

so that the unperturbed fiber configuration is the unit circle ($\boldsymbol{X} = \hat{\boldsymbol{r}}(s)$) and we can write the dimensionless equations (omitting the tildes) as

$$\xi_t + \boldsymbol{u}\cdot\nabla\,\xi = \nu\nabla^2\xi + \kappa(\hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{f}), \tag{3.2a}$$

$$\boldsymbol{u} = -\hat{\boldsymbol{z}}\times\nabla\psi, \tag{3.2b}$$

$$-\nabla^2\psi = \xi, \tag{3.2c}$$

$$\boldsymbol{f}(\boldsymbol{x},t) = \int_0^{2\pi} (K\boldsymbol{X}_s)_s\,\delta(\boldsymbol{x}-\boldsymbol{X})\,ds, \tag{3.2d}$$

$$\boldsymbol{X}_t = \boldsymbol{u}(\boldsymbol{X},t), \tag{3.2e}$$

with

$$K = (1 + 2\tau\sin t), \tag{3.3a}$$

$$\boldsymbol{X} = \hat{\boldsymbol{r}}(s) + \epsilon\boldsymbol{X}_1^{(1)}(s,t) + \cdots. \tag{3.3b}$$

Our aim is now to solve (3.2a)–(3.2e) with the only two remaining parameters, ν and κ, defined in (3.1). We point out that ν is the reciprocal of the Reynolds number and κ is the square of the natural frequency divided by the driving frequency.

4. Small-amplitude approximation. For the linear analysis, assume the fiber force can be written as

$$\boldsymbol{f} = \boldsymbol{f}^{(0)}(\boldsymbol{x},t) + \epsilon\boldsymbol{f}^{(1)}(\boldsymbol{x},t) + \cdots,$$

so that the term $(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f})$ in (3.2a) can be expanded as

$$(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}) = (\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(0)}) + \epsilon(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(1)}) + \cdots.$$

CLAIM 1. *Given the expansions in* (3.3a) *and* (3.3b),

$$(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(0)}) = 0 \qquad \textit{and}$$
$$(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(1)}) = K(t)\left(X^{\theta}_{ss} + X^{r}_{s}\right)\left(\frac{\delta(r-1)}{r}\right)_r - K(t)\left(X^{r}_{sss} - X^{\theta}_{ss}\right)\frac{\delta(r-1)}{r}.$$

The proof is found in Appendix B.

Since the leading-order term in the curl of the force is zero, the corresponding flow is simply the trivial solution $\xi^{(0)} = \psi^{(0)} = 0$. Therefore, we look for a series solution expanded in terms of powers of a small parameter ϵ:

$$\xi = \epsilon\, \xi^{(1)}(\boldsymbol{x}, t) + \cdots,$$
$$\psi = \epsilon\, \psi^{(1)}(\boldsymbol{x}, t) + \cdots.$$

In the remainder of this work, we assume ϵ is small and consider the $O(\epsilon)$ equations

$$\text{(4.1a)}\quad \xi_t = \nu\nabla^2\xi + \kappa K(t)\left(X^{\theta}_{ss} + X^{r}_{s}\right)\left[\frac{\delta(r-1)}{r}\right]_r - \kappa K(t)\left(X^{r}_{sss} - X^{\theta}_{ss}\right)\frac{\delta(r-1)}{r},$$
$$\text{(4.1b)}\quad \nabla^2\psi = -\xi,$$
$$\text{(4.1c)}\quad X^{r}_{t} = \psi_{\theta}\big|_{r=1},$$
$$\text{(4.1d)}\quad X^{\theta}_{t} = -\psi_{r}\big|_{r=1},$$

where we have omitted the superscript $^{(1)}$ on most variables because we will be working solely with these quantities from now on.

It is worthwhile mentioning that in the above expansions, the influence of the time-dependent stiffness coefficient is felt solely at first order in ϵ, and so we need only consider the forcing terms up to $O(\epsilon)$. The derivation can be easily extended to include the case where the stiffness is spatially dependent, for which the s-variation appears as an order ϵ perturbation of a time-dependent stiffness,

$$K = K(s,t) = K^{(0)}(t) + \epsilon K^{(1)}(s,t) + O(\epsilon^2).$$

When a Floquet-type expansion is assumed for $K^{(1)}(s,t)$ (refer to the next section), correction terms appear in the $O(\epsilon)$ equations, and these corrections complicate the analysis somewhat by coupling together the various spatial modes. We do not consider a spatially dependent stiffness in this paper.

It is quite striking that a spatially homogeneous $K(t)$ can have any interesting effects in this problem. This is because such $K(t)$ would have no effect at all on the equilibrium state in which the fiber is a circle. Starting with that equilibrium state as initial data and imposing time-periodic $K(t)$ will produce only an oscillation of the pressure and no motion of the fiber at all. But if instead we start with an initial condition that is arbitrarily close but not exactly equal to a circular equilibrium state, we can nevertheless build up a large-amplitude and spatially inhomogeneous oscillation of the fiber through the application of spatially homogeneous but time-periodic $K(t)$ at the right driving frequency. This is actually typical of parametric

resonance. A pendulum that is initially at rest hanging straight down cannot be made to swing by imposing periodic changes in its length, but a pendulum that is initially swinging ever so slightly can indeed be made to swing violently by the application of precisely such changes in length, as every child who swings in the playground knows [6].

5. Floquet analysis. Since we are not simply looking for natural modes but rather are investigating the response of the system to a periodic forcing with a given frequency, we must look for a solution in the form of an infinite series. This is a very general approach in Floquet theory [18], and our derivation parallels the analysis of Kumar and Tuckerman [11] for a horizontal fluid interface consisting of two fluids with different densities. It is worth mentioning that other approaches have also been used to study parametric resonances. For example, Semler and Païdoussis [23] analyze the case of a tubular beam filled with fluid whose velocity contains sinusoidal fluctuations. They use separation of variables and nonlinear dynamics techniques to solve the perturbation equations for small amplitude fluctuations. We will see that our approach will result in a system of equations in block form that is very similar to the equations derived in [23].

We assume that the unknown functions can be written as series of the following form:

$$\begin{aligned}
\xi(r,\theta,t) &= e^{ip\theta}\sum_{n=-\infty}^{\infty}\xi_n(r)e^{(\gamma+in)t},\\
\psi(r,\theta,t) &= e^{ip\theta}\sum_{n=-\infty}^{\infty}\psi_n(r)e^{(\gamma+in)t},\\
X^r(\theta,t) &= e^{ip\theta}\sum_{n=-\infty}^{\infty}X^r_n e^{(\gamma+in)t},\\
X^\theta(\theta,t) &= e^{ip\theta}\sum_{n=-\infty}^{\infty}X^\theta_n e^{(\gamma+in)t},
\end{aligned}$$

where $i=\sqrt{-1}$, p is an integer with $p>1$, and $\gamma=\alpha+i\beta$ with α and β real. To simplify the notation, we define $\mathcal{E}_n \doteq e^{(\gamma+in)t+ip\theta}$ and then write the equation for the vorticity from (4.1a) as

$$\begin{aligned}
\sum_{n=-\infty}^{\infty}\left((\gamma+in)+\frac{\nu p^2}{r^2}\right)\xi_n\mathcal{E}_n \;=\; \sum_{n=-\infty}^{\infty}\Bigg\{&\frac{\nu}{r}(r\xi_n')' + \kappa K(-p^2X_n^\theta + ipX_n^r)\left(\frac{\delta(r-1)}{r}\right)'\\
&+\kappa K(ip^3X_n^r - p^2X_n^\theta)\,\frac{\delta(r-1)}{r}\Bigg\}\mathcal{E}_n. \qquad (5.1)
\end{aligned}$$

Except for the stiffness $K(t)$, all of the t- and θ-dependence is now encompassed by the factor $\mathcal{E}_n$. Note that ξ_n and ψ_n are functions of r, while X_n^r and X_n^θ are constants. The primes in the equations denote derivatives with respect to r. If we take advantage of the fact that the stiffness from (3.3a) can be rewritten as

$$K(t) = 1 - i\tau e^{it} + i\tau e^{-it} \qquad (5.2)$$

and then rearrange terms in the series in (5.1) and divide by $\mathcal{E}_n$, we obtain

$$-\frac{1}{r}(r\xi_n')' + \left(\frac{(\gamma+in)}{\nu} + \frac{p^2}{r^2}\right)\xi_n \tag{5.3}$$
$$= \frac{\kappa}{\nu}\left(\frac{\delta(r-1)}{r}\right)'\left[-p^2\left(X_n^\theta - i\tau X_{n-1}^\theta + i\tau X_{n+1}^\theta\right) + ip\left(X_n^r - i\tau X_{n-1}^r + i\tau X_{n+1}^r\right)\right]$$
$$+ \frac{\kappa}{\nu}\frac{\delta(r-1)}{r}\left[-p^2\left(X_n^\theta - i\tau X_{n-1}^\theta + i\tau X_{n+1}^\theta\right) + ip^3\left(X_n^r - i\tau X_{n-1}^r + i\tau X_{n+1}^r\right)\right]$$

for all integer values of n. The equations for the remaining unknowns in (4.1b)–(4.1d) do not involve $K(t)$, and so for the nth coefficient functions we have

$$-\frac{1}{r}(r\psi_n')' + \frac{p^2}{r^2}\psi_n = \xi_n,$$
$$(\gamma+in)X_n^r = ip\psi_n(1),$$
$$(\gamma+in)X_n^\theta = -\psi_n'(1).$$

A more useful formulation of the problem is in terms of jump conditions across the fiber. The delta function terms in (5.3) are nonzero only on the fiber, and so the following two equations hold on either side of the fiber:

$$-\frac{1}{r}(r\xi_n')' + \left(\frac{(\gamma+in)}{\nu} + \frac{p^2}{r^2}\right)\xi_n = 0, \tag{5.4a}$$
$$-\frac{1}{r}(r\psi_n')' + \frac{p^2}{r^2}\psi_n = \xi_n. \tag{5.4b}$$

The fiber evolution equations hold on the fiber (at $r = 1$):

$$(\gamma+in)X_n^r = ip\psi_n(1), \tag{5.4c}$$
$$(\gamma+in)X_n^\theta = -\psi_n'(1). \tag{5.4d}$$

At the same time, the jump conditions connect the solutions on either side of the fiber (see Appendix C):

$$[\![\xi_n]\!] = \frac{\kappa}{\nu}\left[p^2\left(X_n^\theta - i\tau X_{n-1}^\theta + i\tau X_{n+1}^\theta\right) - ip\left(X_n^r - i\tau X_{n-1}^r + i\tau X_{n+1}^r\right)\right], \tag{5.4e}$$
$$[\![\xi_n']\!] = -\frac{i\kappa p(p^2-1)}{\nu}\left(X_n^r - i\tau X_{n-1}^r + i\tau X_{n+1}^r\right), \tag{5.4f}$$
$$[\![\psi_n]\!] = 0, \tag{5.4g}$$
$$[\![\psi_n']\!] = 0, \tag{5.4h}$$

where we denote the jump in a quantity q by $[\![q]\!] = q|_{r=1^+} - q|_{r=1^-}$. These jump conditions were found in the same way as in [13, 22], by integrating the equations for vorticity across the fiber. We point out that this system of equations cannot be reduced to a Mathieu equation (see [11]).

6. Solution of the vorticity and stream function equations. The equations (5.4) from the previous section can be solved explicitly for each integer value of n, both inside and outside the fiber. Due to (5.4c) and (5.4d), the character of the solution will be different depending on whether the quantity $(\gamma + in)$ is zero. This will happen for $n = 0$ whenever $\gamma = 0$. We therefore solve the equations considering two cases.

6.1. Case $(\gamma+in) \neq 0$. If we make the change of variables $z^2 = -r^2(\gamma+in)/\nu$, then (5.4a) turns into the Bessel equation

$$z^2\xi_n''(z) + z\xi_n'(z) + [z^2 - p^2]\xi_n(z) = 0.$$

The appropriate solution, rewritten in terms of r, is [27]

$$\xi_n(r) = \begin{cases} b_n J_p(i\Omega_n r) & \text{if } r < 1 \qquad \text{(inner)}, \\ a_n H_p(i\Omega_n r) & \text{if } r > 1 \qquad \text{(outer)}, \end{cases}$$

where $\Omega_n \doteq \sqrt{(\gamma+in)/\nu}$ is chosen as the square root with positive real part, $J_p(z)$ is the Bessel function of the first kind, $H_p(z) = J_p(z) + iY_p(z)$ is the Hankel function of the first kind, and a_n and b_n are arbitrary constants (see Appendix A).

The corresponding stream function is given by (see Appendix D)

$$\psi_n(r) = \frac{1}{2ip\Omega_n} \begin{cases} b_n r\Big[J_{p-1}(i\Omega_n r) + J_{p+1}(i\Omega_n r)\Big] \\ \qquad + r^p\Big[a_n H_{p-1}(i\Omega_n) - b_n J_{p-1}(i\Omega_n)\Big] \text{ if } 0 \le r < 1, \\ a_n r\Big[H_{p-1}(i\Omega_n r) + H_{p+1}(i\Omega_n r)\Big] \\ \qquad - r^{-p}\Big[a_n H_{p+1}(i\Omega_n) - b_n J_{p+1}(i\Omega_n)\Big] \text{ if } r > 1. \end{cases}$$

One can easily check that $\psi_n(r)$ and $\psi_n'(r)$ are continuous across the boundary and that

$$\psi_n(1) = \frac{1}{2ip\Omega_n}\Big[a_n H_{p-1}(i\Omega_n) + b_n J_{p+1}(i\Omega_n)\Big],$$
$$\psi_n'(1) = \frac{1}{2i\Omega_n}\Big[a_n H_{p-1}(i\Omega_n) - b_n J_{p+1}(i\Omega_n)\Big].$$

Turning now to (5.4c) and (5.4d), we find the fiber position to be

$$X_n^r = \frac{1}{2\nu\Omega_n^3}\Big[a_n H_{p-1}(i\Omega_n) + b_n J_{p+1}(i\Omega_n)\Big],$$
$$X_n^\theta = \frac{-1}{2i\nu\Omega_n^3}\Big[a_n H_{p-1}(i\Omega_n) - b_n J_{p+1}(i\Omega_n)\Big].$$

We can solve for a_n and b_n from these equations to find

$$a_n = \frac{\nu\Omega_n^3}{H_{p-1}(i\Omega_n)}\left(X_n^r - iX_n^\theta\right),$$
$$b_n = \frac{\nu\Omega_n^3}{J_{p+1}(i\Omega_n)}\left(X_n^r + iX_n^\theta\right).$$

We now substitute these expressions into the jump conditions (5.4e)–(5.4f) to get the following system of equations:

$$\begin{aligned} 0 = {} & i\left\{\phi\ \Omega_n^3\left[\frac{H_p(i\Omega_n)}{H_{p-1}(i\Omega_n)} - \frac{J_p(i\Omega_n)}{J_{p+1}(i\Omega_n)}\right] + ip\right\} X_n^r \\ & + \left\{\phi\ \Omega_n^3\left[\frac{H_p(i\Omega_n)}{H_{p-1}(i\Omega_n)} + \frac{J_p(i\Omega_n)}{J_{p+1}(i\Omega_n)}\right] - ip^2\right\} X_n^\theta \\ & + i\tau p\left(X_{n-1}^r - X_{n+1}^r\right) - \tau p^2\left(X_{n-1}^\theta - X_{n+1}^\theta\right), \end{aligned} \tag{6.1}$$

$$
\begin{aligned}
0 = i\left\{\phi\ \Omega_n^4\left[2 - \frac{H_{p+1}(i\Omega_n)}{H_{p-1}(i\Omega_n)} - \frac{J_{p-1}(i\Omega_n)}{J_{p+1}(i\Omega_n)}\right] + 2p(p^2-1)\right\} X_n^r \\
- \phi\ \Omega_n^4\left[\frac{H_{p+1}(i\Omega_n)}{H_{p-1}(i\Omega_n)} - \frac{J_{p-1}(i\Omega_n)}{J_{p+1}(i\Omega_n)}\right] X_n^\theta \\
+ 2\tau p(p^2-1)\left(X_{n-1}^r - X_{n+1}^r\right),
\end{aligned} \tag{6.2}
$$

where we define ϕ as the grouping $\phi = \nu^2/\kappa$. It is these last two equations, (6.1) and (6.2), that determine the coefficients X_n^r and X_n^θ in the case when $(\gamma + in) \neq 0$.

6.2. Case $(\gamma + in) = 0$. For this case, the vorticity equation becomes

$$r^2\xi_n''(r) + r\xi_n'(r) - p^2\xi_n(r) = 0,$$

whose appropriate solution is

$$\xi_o(r) = \begin{cases} b_o r^p & \text{if } r < 1 \qquad \text{(inner)}, \\ a_o r^{-p} & \text{if } r > 1 \qquad \text{(outer)}, \end{cases}$$

while the corresponding solution for the stream function is

$$\psi_o(r) = \begin{cases} \dfrac{1}{4p}\left(b_o - \dfrac{a_o}{1-p}\right) r^p - \dfrac{b_o}{4(1+p)} r^{2+p} & \text{if } r < 1, \\ \dfrac{1}{4p}\left(\dfrac{b_o}{1+p} - a_o\right) r^{-p} - \dfrac{a_o}{4(1-p)} r^{2-p} & \text{if } r > 1. \end{cases}$$

One can easily check that $\psi_o(r)$ and $\psi_o'(r)$ are continuous across the boundary and that

$$\psi_o(1) = \frac{1}{4p}\left[\frac{a_o}{p-1} + \frac{b_o}{p+1}\right],$$
$$\psi_o'(1) = \frac{1}{4}\left[\frac{a_o}{p-1} - \frac{b_o}{p+1}\right].$$

Turning now to (5.4c) and (5.4d), we find that in this case, the above equations reduce to $\psi_o(1) = \psi_o'(1) = 0$, which implies that $a_o = b_o = 0$. This means that when $(\gamma + in) = 0$ we obtain the trivial solution $\xi_o(r) \equiv 0$ and $\psi_o(r) \equiv 0$. The jump conditions (5.4e) and (5.4f) then give the system of equations

$$0 = ip^2\left(X_n^\theta - i\tau X_{n-1}^\theta + i\tau X_{n+1}^\theta\right) + p\left(X_n^r - i\tau X_{n-1}^r + i\tau X_{n+1}^r\right), \tag{6.3}$$

$$0 = ip(p^2-1)\left(X_n^r - i\tau X_{n-1}^r + i\tau X_{n+1}^r\right), \tag{6.4}$$

which are used instead of (6.1)–(6.2) for the case $(\gamma + in) = 0$.

7. Natural modes for the unforced fiber. When there is no forcing applied to the fiber, then $\tau = 0$ and there is no need to look for a solution in the form of an infinite series. Instead, we can consider a single mode by taking $n = 0$, for which the problem reduces to the following single pair of equations for X^r and X^θ:

$$
\begin{aligned}
0 = i\left\{\phi\ \Omega_o^3\left[\frac{H_p(i\Omega_o)}{H_{p-1}(i\Omega_o)} - \frac{J_p(i\Omega_o)}{J_{p+1}(i\Omega_o)}\right] + ip\right\} X^r \\
+ \left\{\phi\ \Omega_o^3\left[\frac{H_p(i\Omega_o)}{H_{p-1}(i\Omega_o)} + \frac{J_p(i\Omega_o)}{J_{p+1}(i\Omega_o)}\right] - ip^2\right\} X^\theta,
\end{aligned} \tag{7.1}
$$

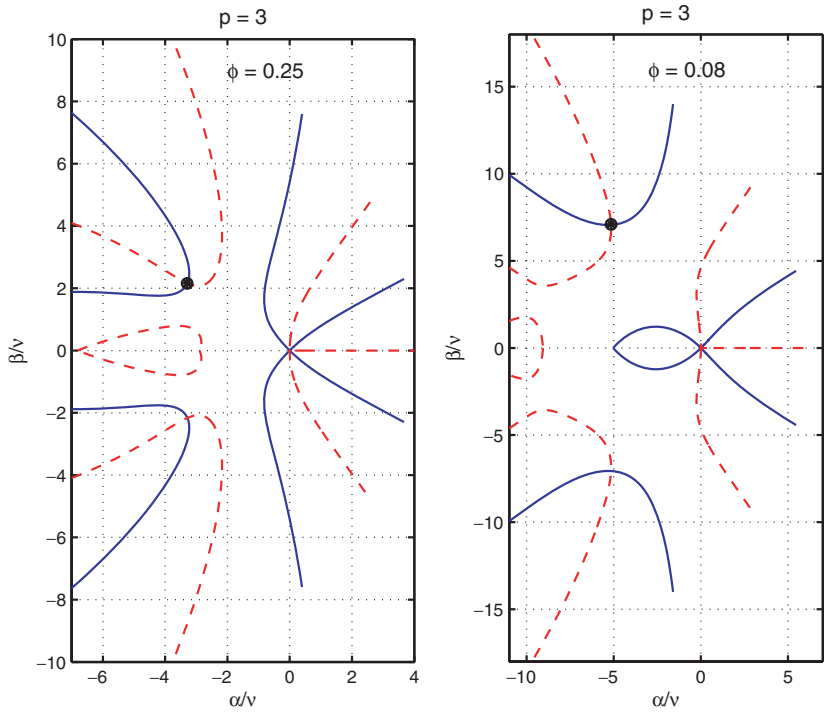

FIG. 7.1. *Zero-level contours of $\mathcal{D}(\Omega_o;\phi,p)$ for $p=3$ and two values of ϕ. The solid lines correspond to the real part and the dashed lines to the imaginary parts. Intersection points represent the natural modes of oscillation of the fiber.*

$$0 = i\left\{\phi\,\Omega_o^4\left[2-\frac{H_{p+1}(i\Omega_o)}{H_{p-1}(i\Omega_o)}-\frac{J_{p-1}(i\Omega_o)}{J_{p+1}(i\Omega_o)}\right]+2p(p^2-1)\right\}X^r \\ -\phi\,\Omega_o^4\left[\frac{H_{p+1}(i\Omega_o)}{H_{p-1}(i\Omega_o)}-\frac{J_{p-1}(i\Omega_o)}{J_{p+1}(i\Omega_o)}\right]X^\theta, \tag{7.2}$$

where $\Omega_o^2=\gamma/\nu=(\alpha/\nu)+i(\beta/\nu)$ and $\phi=\nu^2/\kappa$. Consequently, the above equations can be rewritten as a 2×2, homogeneous, linear system

$$\mathcal{M}\begin{pmatrix}X^r\\X^\theta\end{pmatrix}=0,$$

which has a nontrivial solution only if $\det(\mathcal{M})=0$. For notational convenience we define the function $\mathcal{D}(\Omega_o;\phi,p)=\det(\mathcal{M})$. The roots of $\mathcal{D}(\Omega_o;\phi,p)=0$, which is a *dispersion relation*, correspond to the natural modes of oscillation of the immersed boundary for a given set of parameters ϕ and p.

From the left plot of Figure 7.1, which corresponds to $p=3$ and $\phi=0.25$, a possible value of the natural response is $(\gamma/\nu)=(\alpha/\nu,\beta/\nu)\approx(-3.29,2.16)$. The right plot of Figure 7.1 shows that for $\phi=0.08$ the root is $(\alpha/\nu,\beta/\nu)\approx(-5.15,7.1)$ instead. These roots are in dimensionless form, and the dimensional frequency γ is obtained by multiplying these roots by $\mu/\rho R^2$. Note that in both cases, the natural mode of oscillation is stable (i.e., α is negative), as would be expected from an unforced immersed fiber (see [26]).

7.1. Collapse of the curves. The condition $\mathcal{D}(\Omega_o; \phi, p) = 0$ defines implicitly the root

$$\frac{\gamma}{\nu} = F(\phi, p) \tag{7.3}$$

as a function of the parameters. This suggests that the same root can be obtained with different values of damping ν and stiffness κ, provided the ratio $\phi = \nu^2/\kappa$ is held constant.

We corroborated this with the numerical solution of the nonlinear equations (3.2a)–(3.2e) for different combinations of (ν, κ) that yield the same value of ϕ. The blob projection method described in [4] was used in these calculations, which solves the IB problem using high-order regularized delta functions and fourth-order finite differences and time stepping. We have chosen to use this approach (rather than the IB method described in section 9) since the blob projection method affords higher accuracy, particularly when ϕ is small.

The initial condition of the fiber was the unit circle augmented by a single p-mode perturbation with amplitude ϵ, so that the fiber configuration can be written in polar coordinates as

$$r(\theta, t) = 1 + \epsilon B(t) \cos(p\theta) + O(\epsilon^2).$$

After each run, the amplitude $B(t)$ was assumed to have the form $B(t) = e^{\alpha t}[\cos(\beta t) + (\alpha/\beta)\sin(\beta t)]$ because this function has zero slope at $t = 0$ and it oscillates with decaying amplitude. The values of (α, β) can then be estimated numerically using least squares. These values were then compared with the roots of (7.3). This procedure was repeated for several values of ϕ with perturbed modes $p = 2$, 3, and 4, and the results are summarized in Figure 7.2.

The analytical results (plotted as solid lines) correspond very well with the numerical calculations (plotted as points). Two simulations corresponding to different combinations of ν and κ are performed for every ϕ. The observed values of α and β corresponding to a given ϕ are nearly identical, so that the points cannot be distinguished visually in Figure 7.2. Consequently, ϕ is an appropriate parameter for characterizing the fiber oscillations.

The correspondence between the analytical and computed results is very good for most values of the parameters, except for relatively large values of ϕ. This is mostly due to the fact that the blob projection method is implemented with periodic boundary conditions in a box about twice as large as the fiber's diameter. For large values of ϕ, the diffusion is significant over the time scale of the runs, and the dynamics are affected by the periodicity. Nonetheless, the results clearly show that different values of (ν, κ) that yield the same ϕ give the same root.

7.2. The small viscosity limit. We consider the limit of small viscosity by assuming a fixed value of the stiffness κ and small value of ν. It will be convenient to define a natural response frequency by $\omega_N \doteq \sqrt{p(p^2-1)/2}$, which is displayed in the frequency plot in Figure 7.2 as a dashed line for comparison with the analytical and computed results discussed in the preceding section. In the small viscosity case, (7.3), whose roots represent the dispersion relation, can be expanded as a series in powers of ν. The results show that the first few terms in the expansion of the natural response of the fiber are

$$\alpha = -\frac{p}{2\sqrt{2}}\omega_N^{1/2}\kappa^{1/4}\sqrt{\nu} + \frac{(p^3 - 3p^2 - p + 1)}{4}\nu + \cdots, \tag{7.4}$$

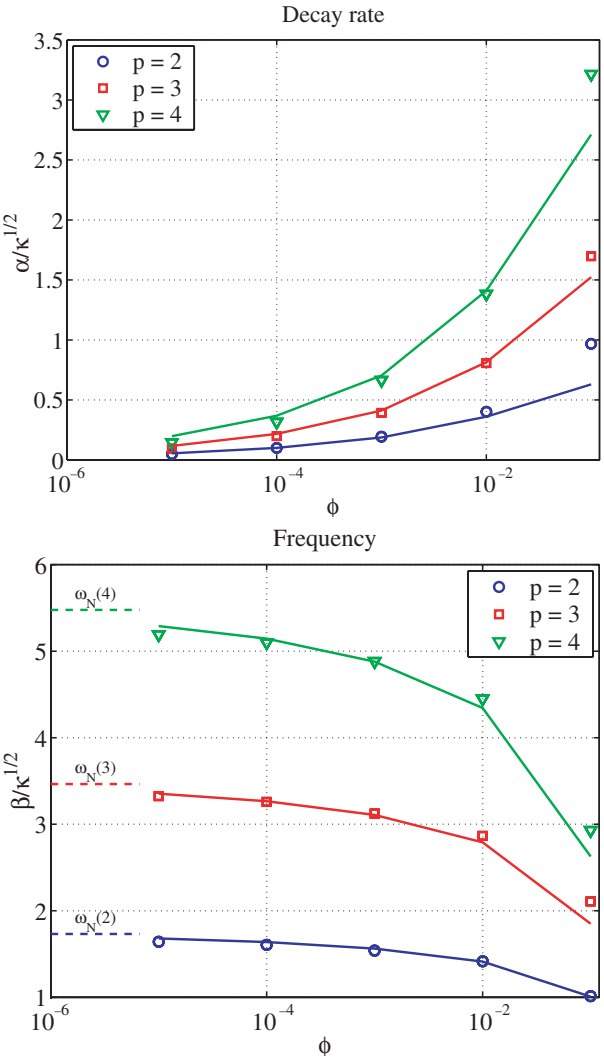

FIG. 7.2. *Roots $\gamma = \alpha + i\beta$ of the dispersion relation $\mathcal{D}(\Omega_o; \phi, p) = 0$, plotted as scaled values of α and β versus ϕ. The analytical results are displayed as solid lines, while the numerical approximations are plotted as points, with multiple points corresponding to simulations done using different values of κ and ν corresponding to the same ϕ. The results are presented for initial fiber perturbations corresponding to three different modes: $p = 2$, 3, and 4. The zero-viscosity ($\phi = 0$) limit, $\omega_N(p) = \sqrt{p(p^2-1)/2}$, is also shown for comparison.*

$$\beta = \omega_N\sqrt{\kappa} - \frac{p}{2\sqrt{2}}\omega_N^{3/4}\kappa^{1/4}\sqrt{\nu} - \frac{p(4p^3 - 39p^2 - 4p + 8)}{64\sqrt{2}}\omega_N^{1/4}\kappa^{-1/4}\nu^{3/2} + \cdots. \tag{7.5}$$

In the limit as $\nu \to 0$, these become $\alpha = 0$ and $\beta = \omega_N\sqrt{\kappa}$, which is precisely the linear dispersion relation found by other methods in [5] for a closed membrane in Euler flow.

It is also possible to compare the above expressions to the asymptotic expansions derived in [26] for an unforced, horizontal fiber immersed in a viscous fluid. The normal mode of oscillation for the flat fiber initialized with a p-mode obeys the following

to leading order:

$$\alpha \sim -2^{-7/4}\,\rho^{-3/4}\,\mu^{1/2}\,K_c^{1/4}\,p^{7/4}\,R^{-3/2} = -p\left(\frac{p^3}{2^7}\right)^{1/4}\left(\frac{\mu}{\rho R^2}\right)^{1/2}\left(\frac{K_c}{\rho R^2}\right)^{1/4},$$

$$\beta \sim 2^{-1/2}\,\rho^{-1/2}\,K_c^{1/2}\,p^{3/2}\,R^{-1} = \left(\frac{p^3}{2}\right)^{1/2}\left(\frac{K_c}{\rho R^2}\right)^{1/2}.$$

Substituting the nondimensional variables from (3.1) into (7.4) and (7.5), it is possible to show that the parameter dependence in the first term in each of α and β is identical to that in the expressions above, provided that we take $\omega_o \equiv 1$. We note that the natural frequency of the flat fiber is different from ω_N above due to the differences in the geometry of the problems. Furthermore, the linear theory for the circular fiber excludes the $p = 1$ mode, since to leading order this perturbation results only in a translation of the fiber.

8. Stability of the periodically forced fiber. In Floquet stability theory, the standard approach is to determine solutions with $\mathrm{Re}(\gamma) = \alpha = 0$, which correspond to the boundary of the stability region. In general, we expect the coefficients in (6.1) and (6.2) to decrease in magnitude as n increases, and so it is reasonable to truncate the series expansions at some finite number of terms, say, $-N \le n \le N$ (this is an assumption that will be checked later on). Equations (6.1) and (6.2) are written for $n = \pm 1, \pm 2, \ldots, \pm N$, and (6.3) and (6.4) are written for $n = 0$, which results in a linear system of dimension $(4N + 4) \times (4N + 4)$ for the unknown coefficients X_n^r and X_n^θ.

8.1. The reality condition. In general, the coefficients arising from the solution to the linear system are complex-valued, but the position of the fiber must be a real quantity. We therefore need to impose additional constraints to guarantee that the Floquet expansion

$$X^r(t) = \sum_n X_n^r e^{int}$$

is real. This will also allow the series to be written for positive index only. Consequently,

$$\overline{X}^r(t) = \sum_n \overline{X}_n^r e^{-int} = \sum_n \overline{X}_{-n}^r e^{int} = \sum_n X_n^r e^{int} = X^r(t),$$

which implies that

$$X_{-n}^r = \overline{X}_n^r \quad \text{for every } n.$$

This is the called the *reality condition* (see [11]), and it allows us to consider (6.1) and (6.2) for strictly positive values of n, thereby eliminating the coefficients for $n < 0$. The condition also implies that $X_o^r = \overline{X}_o^r$, for use in (6.3) and (6.4) with $n = 0$. The same reality condition applies to X_n^θ.

8.2. Formulation as an eigenvalue problem. Equations (6.1)–(6.2) now take the form

$$0 = A_n X_n^r + B_n X_n^\theta + \tau\left[C_n X_{n-1}^r + D_n X_{n-1}^\theta + E_n X_{n+1}^r + F_n X_{n+1}^\theta\right].$$

By setting the real part and the imaginary part of the equation to zero independently, we can write the final system as

$$(\mathcal{D} + \tau\, \mathcal{C})\boldsymbol{v} = 0,$$

where $\mathcal{D}$ and $\mathcal{C}$ are *real-valued* matrices, each of dimension $(4N+4)\times(4N+4)$. The vector is $\boldsymbol{v} = [v_0, v_1, v_2, \ldots, v_N]^T$, where each component has four elements, $v_n = [\mathrm{Re}(X_n^r), \mathrm{Im}(X_n^r), \mathrm{Re}(X_n^\theta), \mathrm{Im}(X_n^\theta)]$, with the difference now being that the reality condition ensures that all solution components are real values. The matrices $\mathcal{D}$ and $\mathcal{C}$ have the following block form:

$$\mathcal{D} = \begin{pmatrix} D_0 & 0 & & \ldots & 0 \\ 0 & D_1 & 0 & \ldots & 0 \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & & 0 & D_{N-1} & 0 \\ 0 & \ldots & & 0 & D_N \end{pmatrix},$$

$$\mathcal{C} = \begin{pmatrix} 0 & C_{01} & & \ldots & 0 \\ C_{10} & 0 & C_{12} & \ldots & 0 \\ 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & & C_{N-1,N-2} & 0 & C_{N-1,N} \\ 0 & \ldots & & C_{N,N-1} & 0 \end{pmatrix},$$

where each element shown is a 4×4 matrix. The first row of each matrix corresponds to $n = 0$ and is derived from (6.3)–(6.4).

An eigenvalue problem is formed by rewriting the system as

$$-\mathcal{D}^{-1}\mathcal{C}\boldsymbol{v} = \frac{1}{\tau}\,\boldsymbol{v}, \tag{8.1}$$

where the eigenvalue $1/\tau$ must be real. Since the matrices have real entries, all eigenvalues are either real or occur in complex conjugate pairs.

For a given value of the wavenumber p, as well as parameters ν and κ from (3.1), the eigenvalue equation (8.1) yields a sequence of values for the forcing amplitude τ. In practice, we have found that choosing $N = 60$ terms in the series expansions is sufficient to ensure that the neglected coefficients are small (that is, the computed eigenvalues do not change appreciably when N is taken any larger than 60). The choices $\gamma = 0$ or $\gamma = \frac{1}{2}i$ are known as the harmonic and subharmonic cases, respectively, and any complex value of τ is discarded. These are the two cases that correspond to real Floquet multipliers, $e^{2\pi\gamma} = e^{2\pi(\alpha+i\beta)}$. When $0 < \beta < \frac{1}{2}$ on the other hand, the Floquet multipliers are complex and always correspond to solutions that are damped; hence, they are of no interest in our stability analysis.

The resulting harmonic and subharmonic eigenvalues correspond to physical modes of oscillation of the fiber which are *marginally stable*. We can then vary the wave number p, and produce a plot of each real value of τ, which traces out the boundary of the stability region of the linearized problem in parameter space. Furthermore, if we concentrate on the range $\tau \le \frac{1}{2}$, we need only consider stability boundaries that drop below the curve $\tau = \frac{1}{2}$.

Figures 8.1–8.3 depict the stability regions for various parameter values, with both harmonic (H) and subharmonic (S) modes shown. The stability boundaries separate

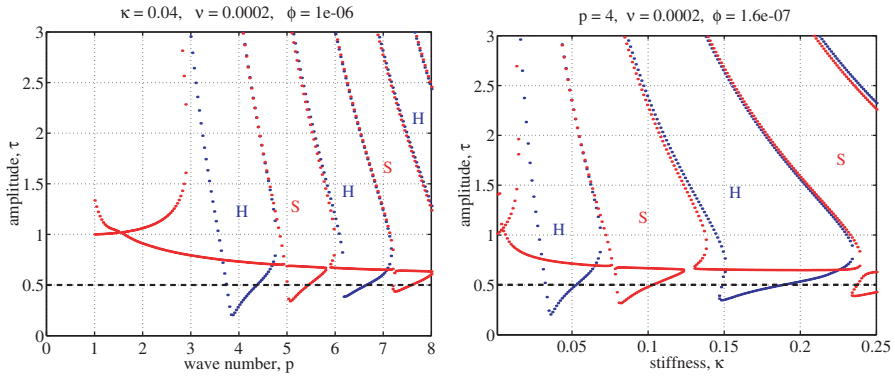

FIG. 8.1. *Stability diagrams, depicting plots of the fiber amplitude τ as a function of (left) wave number p, holding $\kappa = 0.04$; and (right) stiffness κ, holding $p = 4$. The other parameter values are $\nu = 0.0002$ and $\alpha = 0$. The curves traced out by the individual points represent the stability boundaries, and the regions above and inside each "tongue" correspond to unstable oscillations of the linearized IB problem. Regions of instability corresponding to harmonic modes (with $\gamma = 0$) are denoted "H" and are drawn with blue points, while the subharmonic modes (with $\gamma = \frac{1}{2}i$) are denoted "S" and are drawn with red points. The dashed horizontal line corresponds to $\tau = \frac{1}{2}$, and only portions of the tongues lying below this line correspond to oscillations with positive stiffness.*

parameter space into regions where the solution is stable and regions where it is unstable. Because of their distinctive shape, the regions of instability are usually referred to as "tongues." The unstable tongues alternate between harmonic and subharmonic modes, moving from left to right, with no overlap between the successive tongues.

Figure 8.1 shows two views of the stability regions for $\nu = 0.0002$: the first in the p, τ-plane with κ held constant at 0.04, and the second in the κ, τ-plane with $p = 4$. In both views, the tongue-like structure of the stability regions is apparent. The first unstable mode occurring for $\kappa = 0.04$ is a $p = 4$ mode, which corresponds to the left-most tongue that falls below the line $\tau = \frac{1}{2}$. Only tongues that correspond to integer values of the angular wavenumber p are physical. Notice in the right plot that increasing the stiffness has a stabilizing influence in the sense that the tongues migrate upward as κ is increased and therefore require higher-amplitude forcing in order to generate parametric resonance.

Figure 8.2 demonstrates more clearly the influence of changes in the stiffness parameter, by depicting the stability boundaries in the p, τ-plane for $\kappa = 0.02$, 0.04, and 0.08. As κ is increased (corresponding to a stiffer fiber), the regions of instability move towards the left, causing the wavenumber of the first unstable mode to decrease, periodically moving in and out of the "physical" regime.

The effect of changes in viscosity for constant stiffness is investigated in Figure 8.3, where plots for $\nu = 0.00005$, 0.0002, and 0.001 are given for $\kappa = 0.04$. As viscosity increases, the unstable regions migrate vertically upwards, so that the minimum value of τ corresponding to a linear instability increases, and some modes that were unstable no longer lead to parametric resonance. As a result, larger-amplitude forcing is necessary to cause onset of parametric resonance in fibers with larger viscosity. If ν is taken large enough that all tongues lift above the $\tau = \frac{1}{2}$ line, then the system is no longer subject to parametric resonance. These results are evidence of the fact that viscosity has a stabilizing influence on the system.

In the limit as $\nu \to 0$, the tongues extend down to the p-axis, where they touch the

line $\tau = 0$, corresponding to unforced oscillations of the immersed fiber. Therefore, the points where the tongues touch down in the $\nu = 0$ limit represent the natural modes of oscillation which were discussed in detail in section 7.

9. Comparison with IB computations. In this section, we use several immersed boundary computations to demonstrate the validity of the preceding Floquet analysis. The numerical method is based on a straightforward discretization of the IB equations in terms of velocity and pressure variables. An alternating direction implicit (ADI) approach is used to apply the convection, diffusion, and forcing terms to obtain an intermediate velocity field. The resulting velocity is then made divergence-free through the use of a split-step pressure projection procedure. The standard cosine approximation to the Dirac delta function is employed [20], which is smoothed over a square box with side length of four fluid grid points. The resulting method is second-order accurate in space, except for the approximate delta function interpolation which limits the spatial accuracy to first order. The method is explicit and has first-order accuracy in time. There are many variants of the IB method that increase both spatial and temporal accuracy, but we have chosen instead to demonstrate the presence of parametric resonance using this simplest and most common implementation. For complete details of the numerical technique, refer to [20] or [24].

All computations were performed on an immersed boundary whose rest configuration is a circle, immersed in a periodic box of dimension 2.5 times the size of the circular boundary. The analysis strictly applies only to an infinite fluid domain, but we found that this domain size was large enough in practice to avoid significant

TABLE 9.1
Parameters for the two resonant cases, one with a first unstable mode with angular wavenumber $p = 2$, and the other with $p = 4$.

Case I	Case II
$\kappa = 0.5$ $\nu = 0.004$ $\phi = 3.2 \times 10^{-5}$	$\kappa = 0.04$ $\nu = 0.00056$ $\phi = 7.84 \times 10^{-6}$
$\rho = 1$ $\mu = 0.4$ $R = 0.2$ $K_c = 125000$ $\omega_o = 2500$ $\tau = 0.45$ $p = 2$ unstable	$\rho = 1$ $\mu = 0.5$ $R = 1$ $K_c = 40000$ $\omega_o = 900$ $\tau = 0.45$ $p = 4$ unstable

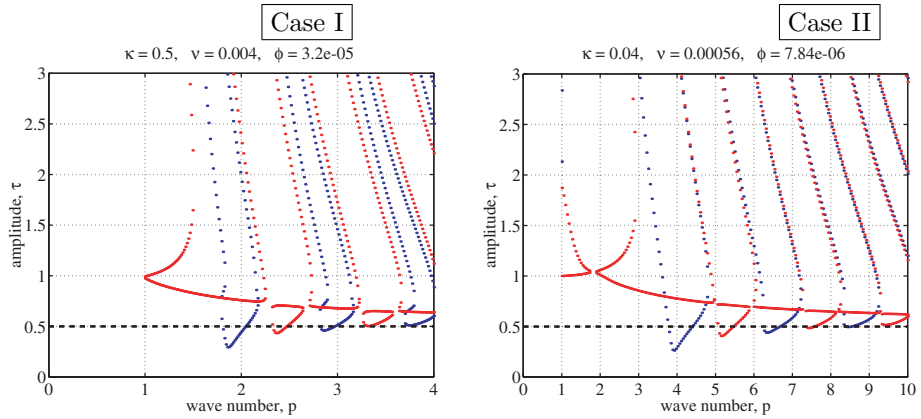

FIG. 9.1. *Stability diagrams for Case* I *($\kappa = 0.5$, $\nu = 0.004$) and Case* II *($\kappa = 0.04$, $\nu = 0.00056$).*

interference from neighboring periodic copies. The fluid domain is divided into a 64×64 grid with 192 immersed boundary points, ensuring that there is significant resolution of the boundary within each fluid grid cell. Finer grid computations were also performed with a 128×128 fluid grid and 384 fiber points to validate the results. The time step was selected to be well within the stability restriction imposed by the explicit method.

We chose to focus on two specific sets of parameters for which the stability plots suggested different resonant p-modes. The parameters are listed in Table 9.1, and the corresponding stability regions are displayed in Figure 9.1. In Case I, the first unstable tongue corresponds to a harmonic mode of oscillation at $p = 2$, while the lowest-wavenumber unstable mode for the second case is $p = 4$ (also harmonic).

We next present numerical evidence that supports the existence of these two instances of parametric resonance. In both cases, the immersed boundary is initially in the shape of a circle of radius R with a radial perturbation of the form $r = R(1 + 0.05\cos(p\theta))$. The results of a given simulation are reported as plots of $\hat{r}_p(t)$, which represents the amplitude of the p-mode of oscillation in the fiber versus time, and is calculated as follows:

1. we convert the (x, y) position of each point on the immersed fiber to radial coordinates;

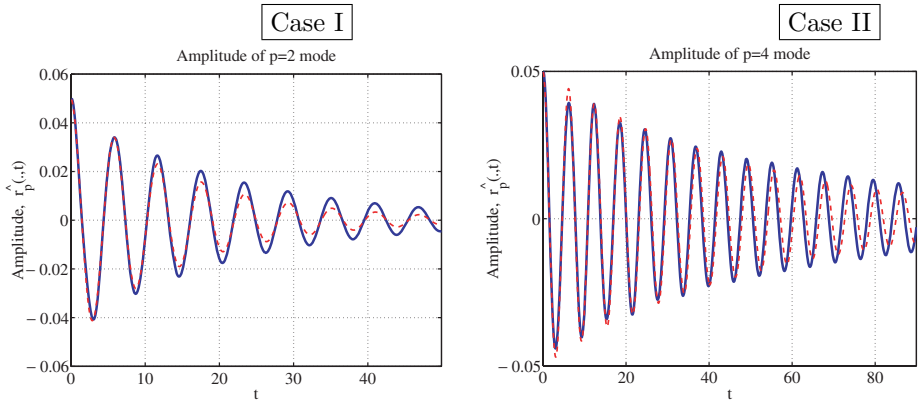

FIG. 9.2. *Amplitude of the unforced immersed boundary for Case* I *($p = 2$) and Case* II *($p = 4$). The dashed curve is an approximate fit to the computed results using a function of the form $e^{\alpha t}\cos(\beta t)$.*

2. using cubic splines, we interpolate the points representing the fiber positions onto a set of points that are equally spaced in θ;
3. we calculate $\hat{r}_p(t) = FFT_\theta(r(\theta, t))$, the fast Fourier transform of the radius in θ, which then yields the amplitude of the desired p-mode.

First, we present plots of the unforced solution (with $\tau = 0$) in Figure 9.2 that represent the natural mode of oscillation for the fiber in each case. The rate of decay and frequency of the natural modes of oscillation for the unforced fiber are as follows:

$$\text{Case I:} \quad \alpha = -0.066, \qquad \beta = 1.071,$$
$$\text{Case II:} \quad \alpha = -0.020, \qquad \beta = 1.016.$$

When the immersed boundary is then forced internally at a frequency equal to the resonant frequency suggested by the plots in Figure 9.1 (i.e., $\omega_o = 2500$ in Case I and $\omega_o = 900$ in Case II), amplitude of oscillation grows far beyond the initial amplitude of 0.05 cm. The motion never actually becomes unstable, but the fiber instead exhibits sustained, large-amplitude oscillations (see Figure 9.3 and compare to Figure 9.2).

In order to verify that this behavior is truly arising from a parametric resonance, we consider changes to either κ or ν that move the resonant tongue in the eigenvalue plot outside the range of parameters being considered. The results are summarized in Figures 9.4 and 9.5. the As the viscosity is increased, the oscillations either decrease in amplitude or decay in time, though not at as rapid a rate as for the unforced case. Because an increase in viscosity acts to raise the "tongues" in the eigenvalue plot, this is precisely the behavior we would expect.

Alternately, if we increase or decrease the value of κ in relation to the resonant value, the resulting oscillations are pictured in Figure 9.5. The amplitude of oscillation for the resonant mode has a maximum value close to the resonant value of κ, which represents the movement of the resonant tongues either to the left or to the right as κ is increased or decreased, respectively.

The effect of varying the stiffness perturbation amplitude τ is displayed in Figure 9.6 for Case II. For $\tau \leq 0.40$, there is no longer a sustained oscillation in the fiber, and as τ is reduced the amplitude of the fiber motion decreases.

At this point, it is important to emphasize that in our numerical simulations, resonance is indicated by sustained, large-amplitude motions, rather than any actual

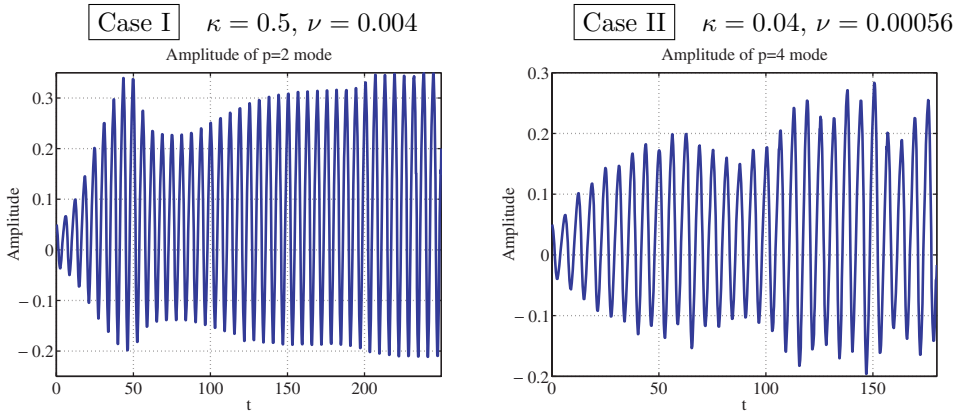

FIG. 9.3. *Amplitude of the resonant p-mode, when the immersed boundary is forced at the resonant frequency ($p = 2$ for Case* I *and $p = 4$ for Case* II*). Both cases display a sustained, large-amplitude oscillation.*

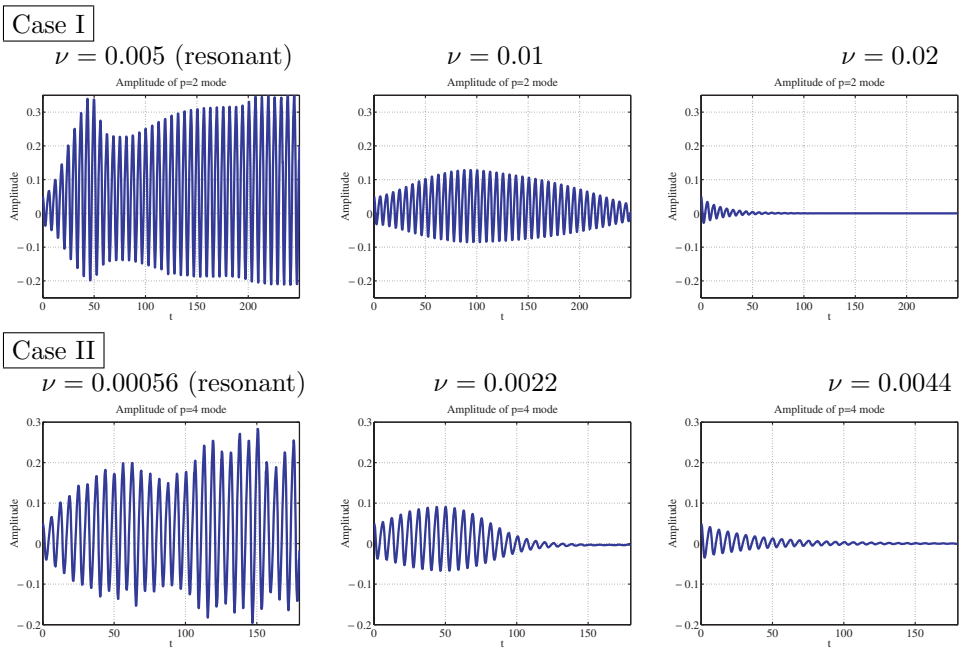

FIG. 9.4. *Amplitude of the resonant p-mode in Cases* I *and* II*, as ν is increased. The stabilizing influence of viscosity is exhibited by the inability of the fiber to sustain large-amplitude oscillations for even small increases in the viscosity.*

instability (i.e., unbounded oscillations). This discrepancy arises from both numerical errors and simplifications to the model, namely:

- the numerical scheme is only first order in space and time and introduces a significant level of artificial viscosity;
- although the fiber force term in the linearized Navier–Stokes equations was also linearized in the forgoing analysis, it is actually nonlinear, which acts to

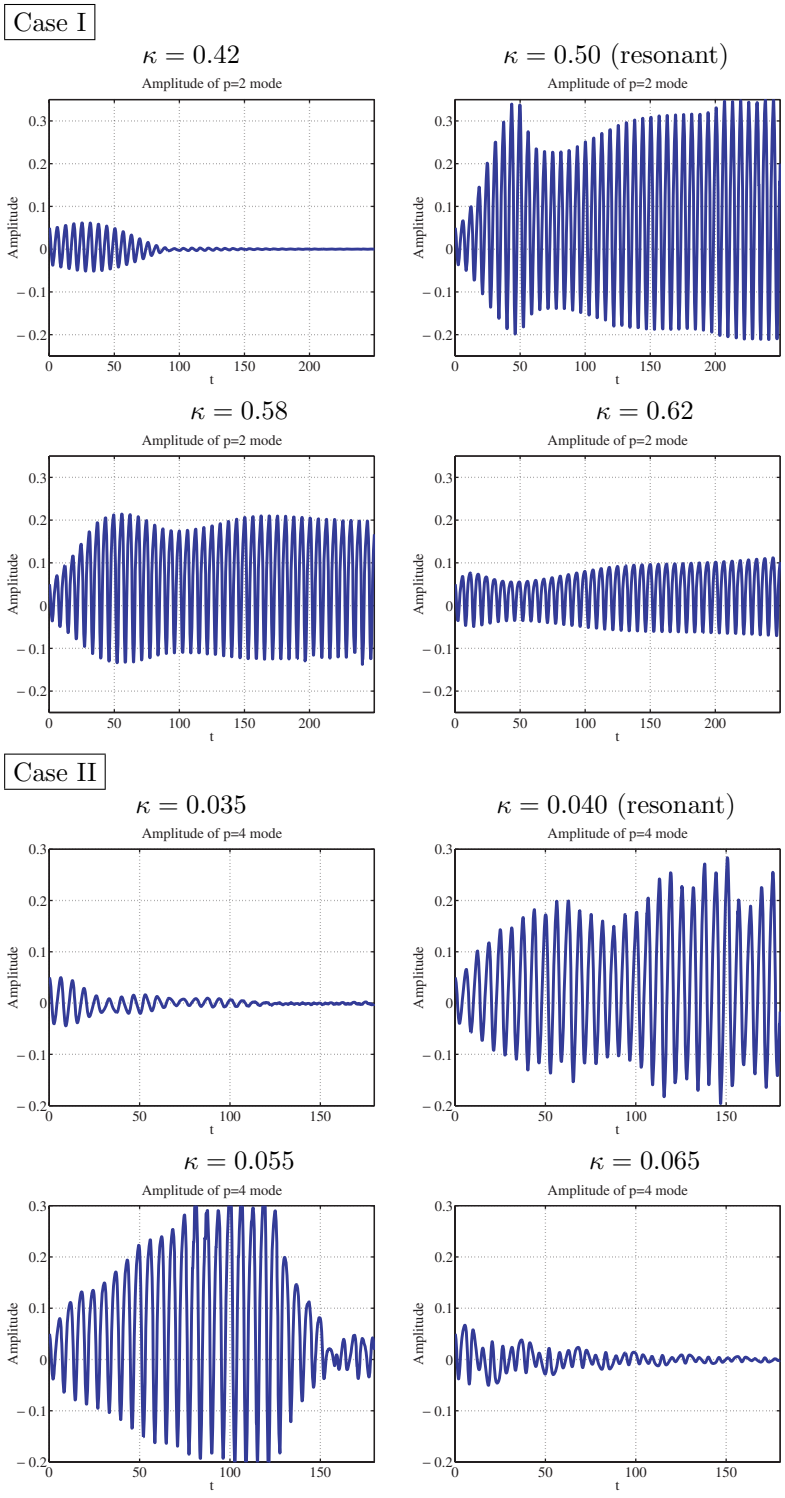

FIG. 9.5. *Amplitude of the resonant p-mode in Cases* I *and* II, *as* κ *is varied. When the stiffness is taken either smaller or larger than the resonant value, the amplitude of the oscillations decreases to the point that they can no longer be sustained.*

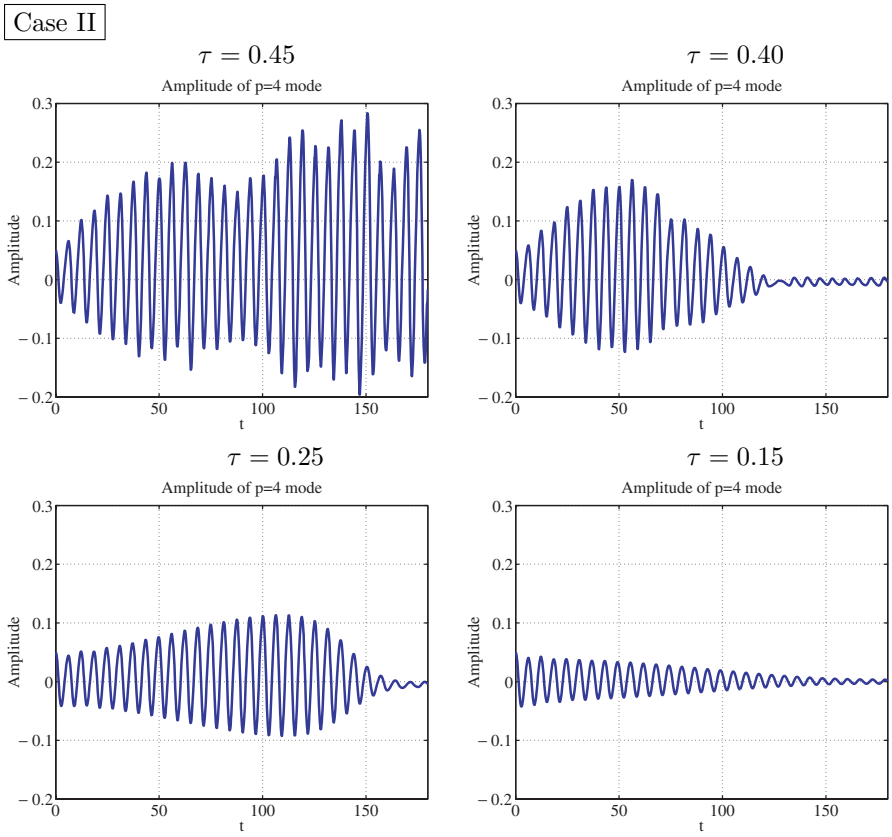

FIG. 9.6. *Amplitude of the resonant p-mode in Case* II*, as the forcing amplitude, τ, is varied. As the forcing is reduced, the amplitude of the fiber oscillations also diminishes.*

stabilize the numerical results;

- the analysis assumed an infinite fluid domain, while our numerical simulations use periodic boundary conditions. Discrepancies owing to interference from periodic copies of the immersed fiber are therefore unavoidable, though we have attempted to choose the size of our computational domain large enough so that these errors are minimized.

A further symptom of these errors is the fact that the stability boundaries in parameter space demonstrated in the simulations are not nearly as sharp, or located in exactly the same locations, as indicated by the plots in section 8. Nonetheless, the correspondence between analytical and numerical results is still quite convincing evidence of the presence of parametric resonance in the linearized IB problem.

The final set of results indicates what transpires when a mode other than the resonant mode is excited initially. We restrict ourselves to Case II and initialize the fiber position with modes having wavenumber $p = 2$ or $p = 3$, while still forcing the stiffness through a $p = 4$ mode. The other parameters remain the same as in the resonant case. Figure 9.7 shows that in both cases, the given 2- and 3-modes do not grow; however, energy transfers over time into the resonant $p = 4$ mode which eventually dominates the fiber oscillation.

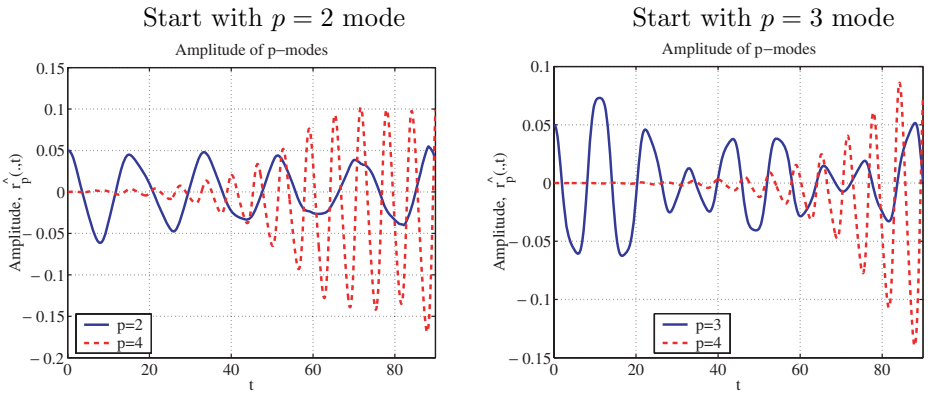

FIG. 9.7. *The amplitude of various fiber modes in Case* II *when wavenumbers* $p = 2$ *and* $p = 3$ *are excited initially instead of the* $p = 4$ *mode. Numerical errors give rise to phase-shifted oscillations which, when combined linearly with the initial conditions, perturb the* $p = 4$ *mode and hence feed energy into the resonant mode over time.*

10. Conclusions. Floquet analysis has proven to be an extremely useful tool in examining parametric resonance and the stability behavior of a wide variety of flows involving interfaces and fluid-structure interaction. In this paper, we study parametric resonances arising from an elastic membrane immersed in a viscous fluid in two dimensions, which is driven by periodic variations in the stiffness parameter of the elastic material. The underlying mathematical model, known as the immersed boundary formulation, captures not only the flow-induced deformations of the elastic membrane but also the influence of the immersed structure on the surrounding fluid flow. To our knowledge, this is the first study of its kind that captures this two-way interaction between fluid and fiber in a parametrically forced system.

Our Floquet analysis leads to an eigenvalue problem that can be solved in order to determine the stability boundaries in parameter space that separate the regions in which the motion is stable from those in which it is unstable. Using asymptotic expansions of the resulting solutions, we demonstrate that our results are consistent with previous analyses of unforced immersed fibers. The decay rates and frequencies of oscillation for the forced system are also shown to match closely those found in full numerical simulations of the fluid-fiber system for small-wavenumber perturbations. We also present numerical results that verify the existence of resonances in parametrically forced immersed boundaries.

This study opens the door for several avenues of further investigation. First of all, while we have demonstrated the existence of parametric resonances numerically in periodically forced immersed fibers, we have yet to find a biological system in which the parameters lie within the unstable regime. In the heart, for example, the muscle fiber stiffness appears to be too small to lead to parametric resonance, according to our analysis. However, we intend to investigate other biological systems with different parameter ranges to determine if resonances are possible.

There are also several natural extensions to the analysis that would allow us to investigate much more interesting fiber dynamics. For example, introducing a spatial dependence in the stiffness, $K(s,t)$, would better mimic biological systems in which an active fiber is pulsed via a wave of contraction that travels around the fiber. However, this form of the stiffness complicates the Floquet analysis significantly by coupling the various fiber modes, and hence would require an extension of our analytical technique.

We also intend to investigate the use of optimal control to see whether it is possible to eliminate parametric resonances by introducing an additional periodic forcing term in the system.

Appendix A. Some useful Bessel function formulas. The following identities are taken from [27] and [1]:

$$J_p(z) = \frac{z}{2p}(J_{p-1}(z) + J_{p+1}(z)), \tag{A.1}$$

$$J_p'(z) = \frac{1}{2}(J_{p-1}(z) - J_{p+1}(z)), \tag{A.2}$$

$$\int z^{p+1} J_p(az)dz = \frac{z^{p+1}}{a} J_{p+1}(az), \tag{A.3}$$

$$\int z^{1-p} J_p(az)dz = \frac{-z^{1-p}}{a} J_{p-1}(az). \tag{A.4}$$

Equations (A.1)–(A.4) are written for the Bessel function of the first kind, $J_p(z)$, but are also valid for the various other Bessel functions, $Y_p(z)$, $H_p(z)$, etc.

Appendix B. Proof of Claim 1.

CLAIM 1. *Given the expansions in* (3.3a) *and* (3.3b)*,*

$$(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(0)}) = 0 \qquad \textit{and}$$
$$(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(1)}) = K\left(X^{\theta}_{ss} + X^{r}_{s}\right)\left(\frac{\delta(r-1)}{r}\right)_r - K\left(X^{r}_{sss} - X^{\theta}_{ss}\right)\frac{\delta(r-1)}{r}.$$

Proof. Since

$$\begin{aligned}(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}) &= -\hat{\boldsymbol{z}} \cdot \int_0^{2\pi} (K\boldsymbol{X}_s)_s \times \nabla\delta(\boldsymbol{x} - \boldsymbol{X})\, ds \\ &= -\int_0^{2\pi} [\hat{\boldsymbol{z}} \times (K\boldsymbol{X}_s)_s] \cdot \nabla\delta(\boldsymbol{x} - \boldsymbol{X})\, ds,\end{aligned}$$

we have that (3.3a)–(3.3b) imply that

$$\begin{aligned}(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(0)}) &= -\int_0^{2\pi} [\hat{\boldsymbol{z}} \times (K(t)\hat{\boldsymbol{r}}_s)_s] \cdot \nabla\delta(\boldsymbol{x} - \boldsymbol{X}(s,t))\, ds \\ &= -K(t)\int_0^{2\pi} [\hat{\boldsymbol{z}} \times \hat{\boldsymbol{r}}_{ss}] \cdot \nabla\delta(\boldsymbol{x} - \boldsymbol{X}(s,t))\, ds \\ &= -K(t)\int_0^{2\pi} \frac{d}{ds}\delta(\boldsymbol{x} - \boldsymbol{X}(s,t))\, ds \; = 0.\end{aligned}$$

We also have that

$$\begin{aligned}(\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{f}^{(1)}) &= -\int_0^{2\pi} \left[\hat{\boldsymbol{z}} \times (K\boldsymbol{X}^{(1)}_s)_s\right] \cdot \nabla\delta(\boldsymbol{x} - \boldsymbol{X}^{(0)})\, ds \\ &\quad + \int_0^{2\pi} \left\{\left[\hat{\boldsymbol{z}} \times (K\boldsymbol{X}^{(0)}_s)_s\right] \cdot \nabla\right\}\left(\boldsymbol{X}^{(1)} \cdot \nabla\right)\delta(\boldsymbol{x} - \boldsymbol{X}^{(0)})\, ds \\ &= I_1 + I_2.\end{aligned} \tag{B.1}$$

The second term can be simplified:

$$\begin{aligned} I_2 &= K\int_0^{2\pi}\left(\boldsymbol{X}^{(1)}\cdot\nabla\right)\left\{\left[\hat{\boldsymbol{z}}\times\boldsymbol{X}_{ss}^{(0)}\right]\cdot\nabla\right\}\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds \\ &= K\int_0^{2\pi}\left(\boldsymbol{X}^{(1)}\cdot\nabla\right)\frac{d}{ds}\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds \\ &= -K\int_0^{2\pi}\boldsymbol{X}_s^{(1)}\cdot\nabla\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds, \end{aligned}$$

so that so far we have that (B.1) is

$$(\hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{f}^{(1)}) = -K\int_0^{2\pi}\left[\hat{\boldsymbol{z}}\times\boldsymbol{X}_{ss}^{(1)}+\boldsymbol{X}_s^{(1)}\right]\cdot\nabla\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds.$$

Now it is convenient to write $\boldsymbol{X}^{(1)}$ in polar coordinates

$$\boldsymbol{X}^{(1)} = X^r(s,t)\hat{\boldsymbol{r}}(s)+X^\theta(s,t)\hat{\boldsymbol{\theta}}(s),$$

so that

$$\hat{\boldsymbol{z}}\times\boldsymbol{X}_{ss}^{(1)}+\boldsymbol{X}_s^{(1)} = -\left(X_{ss}^\theta+X_s^r\right)\hat{\boldsymbol{r}}+\left(X_{ss}^r-X_s^\theta\right)\hat{\boldsymbol{\theta}}.$$

Now we can write

$$\begin{aligned} (\hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{f}^{(1)}) &= K\int_0^{2\pi}\left[X_{ss}^\theta+X_s^r\right]\hat{\boldsymbol{r}}\cdot\nabla\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds \\ &\quad - K\int_0^{2\pi}\left[X_{ss}^r-X_s^\theta\right]\hat{\boldsymbol{\theta}}\cdot\nabla\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds. \end{aligned}$$

The last term can be integrated by parts and we arrive at

$$\begin{aligned} (\hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{f}^{(1)}) &= \int_0^{2\pi}K\left(X_{ss}^\theta+X_s^r\right)\hat{\boldsymbol{r}}\cdot\nabla\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds \\ &\quad - \int_0^{2\pi}K\left(X_{sss}^r-X_{ss}^\theta\right)\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)})\,ds. \end{aligned}$$

If we now write

$$\delta(\boldsymbol{x}-\boldsymbol{X}^{(0)}) = \frac{\delta(r-1)\delta(\theta-s)}{r},$$

we get

$$\begin{aligned} (\hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{f}^{(1)}) &= \left[K\left(X_{ss}^\theta+X_s^r\right)\right](\theta,t)\left(\frac{\delta(r-1)}{r}\right)_r \\ &\quad - \left[K\left(X_{sss}^r-X_{ss}^\theta\right)\right](\theta,t)\,\frac{\delta(r-1)}{r}. \qquad \square \end{aligned}$$

Appendix C. Jump conditions. The derivation of the jump conditions for vorticity will make use of the following result.

CLAIM 2. *In the sense of distributions*

$$r\left(\frac{\delta(r-R)}{r}\right)' = \delta'(r-R) - \frac{\delta(r-R)}{R}.$$

Proof. Let $\phi(r)$ be a smooth function. Then

$$\begin{aligned}\int \phi(r)\, r\left(\frac{\delta(r-R)}{r}\right)' dr &= -\int \left(r\phi(r)\right)_r \left(\frac{\delta(r-R)}{r}\right) dr \\ &= -\int \left(\phi'(r) + \frac{\phi(r)}{r}\right)\delta(r-R)\, dr \\ &= -\phi'(R) - \frac{\phi(R)}{R}.\end{aligned}$$

The result follows. ∎

The jump conditions for an equation of the form

$$-\frac{1}{r}(r\xi')' + \left(\frac{(\gamma+in)}{\nu} + \frac{p^2}{r^2}\right)\xi = A\left(\frac{\delta(r-1)}{r}\right)' + B\left(\frac{\delta(r-1)}{r}\right),$$

where A and B are independent of r, can be derived as follows. We first multiply the equation by r:

$$-(r\xi')' + \left(\frac{(\gamma+in)}{\nu}r + \frac{p^2}{r}\right)\xi = Ar\left(\frac{\delta(r-1)}{r}\right)' + B\delta(r-1),$$

and use the claim to write it as

$$-(r\xi')' + \left(\frac{(\gamma+in)}{\nu}r + \frac{p^2}{r}\right)\xi = A\delta'(r-1) + (B-A)\delta(r-1).$$

We now integrate from $1-\epsilon$ to some point r to get

$$-\big[r\xi'(r) - (1-\epsilon)\xi'(1-\epsilon)\big] + \int_{1-\epsilon}^{r}\left(\frac{(\gamma+in)}{\nu}q + \frac{p^2}{q}\right)\xi(q)\, dq = A\delta(r-1) + (B-A)H(r-1). \tag{C.1}$$

We can use (C.1) in two ways. First, set $r = 1+\epsilon$ and take the limit $\epsilon \to 0$:

$$-[\![\xi']\!] = (B-A). \tag{C.2}$$

Second, we divide (C.1) by r, integrate from $1-\epsilon$ to $1+\epsilon$, and let $\epsilon \to 0$ to get

$$-[\![\xi]\!] = A. \tag{C.3}$$

Equations (C.2)–(C.3) are the two jump conditions.

Appendix D. Solution of the stream function equation. In this section we describe the method for finding the solution of the stream function equation

$$-\frac{1}{r}\left(r\psi_r\right)_r + \frac{p^2}{r^2}\psi = \xi(r),$$

where $\xi(r)$ is given by

$$\xi(r) = \begin{cases} bJ_p(i\Omega_n r) & \text{if } r < 1 \qquad \text{(inner)}, \\ aH_p(i\Omega_n r) & \text{if } r > 1 \qquad \text{(outer)}. \end{cases}$$

The general solution may be written as

$$\psi(r) = \int_0^\infty \xi(r)\mathcal{G}(r,z)dz.$$

Here, the Green's function $\mathcal{G}(r,z)$ is the solution of

$$-\frac{1}{r}\left(r\mathcal{G}_r\right)_r + \frac{p^2}{r^2}\mathcal{G} = \delta(r-z). \tag{D.1}$$

Multiplying this equation by r, integrating from $z-\epsilon$ to $z+\epsilon$, and taking the limit $\epsilon \to 0$, we find that $\mathcal{G}(r,z)$ satisfies the jump conditions

$$[\![\mathcal{G}]\!] = 0 \qquad \text{and} \qquad [\![\mathcal{G}_r]\!] = -1.$$

Since solutions of equation (D.1) are of the form r^p and r^{-p}, we have that

$$\mathcal{G}(r,z) = \frac{z}{2p}\begin{cases} \dfrac{r^p}{z^p} & \text{if } r < z, \\ \dfrac{z^p}{r^p} & \text{if } r > z. \end{cases}$$

The stream function is then found by piecewise integration. For the interior solution, $r < 1$, we obtain

$$\begin{aligned} \psi(r) &= \frac{b}{2pr^p}\int_0^r J_p(i\Omega_n r')(z)^{p+1}\,dz + \frac{br^p}{2p}\int_r^1 J_p(i\Omega_n r')(z)^{1-p}\,dz \\ &\quad + \frac{ar^p}{2p}\int_1^\infty H_p(i\Omega_n r')(z)^{1-p}\,dz \\ &= \frac{br}{2ip\Omega_n}\Big[J_{p-1}(i\Omega_n r) + J_{p+1}(i\Omega_n r)\Big] + \frac{r^p}{2ip\Omega_n}\Big[aH_{p-1}(i\Omega_n) - bJ_{p-1}(i\Omega_n)\Big], \end{aligned}$$

making use of the identities (A.3) and (A.4). The solution for $r > 1$ is found in the same way.

DYNAMICS IN A ROD MODEL OF SOLID FLAME WAVES*

J. H. PARK†, A. BAYLISS†, AND B. J. MATKOWSKY†

Abstract. We consider gasless solid fuel combustion in a cylinder of radius $\tilde{R}$, associated with the SHS (self-propagating high-temperature synthesis) process, which employs combustion waves to synthesize materials. A powder mixture of reactants is cold pressed into a sample, typically a cylinder, and ignited at one end. A high-temperature combustion wave then propagates along the sample, converting the unreacted powder into the desired product. It has recently become popular to model systems governed by partial differential equations as an array of interacting oscillators. Here, we extend this approach by considering an array of interacting rods, each of which supports propagating waves. Thus, we employ an array of interacting one-dimensional (1D) rods connected via heat transfer. The heat transfer terms correspond to a discretization of the transverse Laplacian.

Both the full 3D model and the rod model allow for a uniformly propagating planar combustion wave. The dispersion relation for this solution is determined for both models and shown to be equivalent when certain parameters in the two models are identified. The rod model is able to describe a number of the features of the 3D model, thus allowing numerical simulations with significantly reduced computational resources. In this paper we consider a rod model consisting of an outer ring of three rods equally spaced along the ring, together with an axial rod. Clearly, this limits the 3D modes of wave propagation which can be described, and the results below have to be considered within this basic limitation. The 3/1 model admits analogues of spin and radial modes which are known to exist experimentally and as solutions of the 3D model. We propose that the new modes of solution behavior that we find are also related to modes of the 3D model.

We determine solution behavior as a function of R, the nondimensionalized cylindrical radius. We consider three cases characterized by the Zeldovich number $Z = N(1-\sigma)/2$, where N is a nondimensionalized activation energy and σ is the ratio of the unburned to the burned temperature. For Z sufficiently small, the uniformly propagating planar solution is stable to planar, i.e., rod independent, perturbations. In this case, analysis of the dispersion relation predicts that for sufficiently small and sufficiently large R, only the uniformly propagating solution is stable. Spin modes, seen in experiments as hot spots spinning periodically around the cylinder as the wave propagates, occur for small R, and radial modes, periodically oscillating solutions independent of the cylindrical angle, occur for larger R. We find analogues of these modes for the rod model and describe the transition from spin to radial modes via a family of quasiperiodic (QP) modes, manifested by periodic variations in the temperature and rotation speed of the spot.

For a larger value of Z, the uniformly propagating solution is unstable to planar perturbations. In this case, we find that for sufficiently small values of R, the singly periodic pulsating planar (PP) solution is the only stable solution. For larger values of R, there is bistability between PP solutions and spin solutions. As R increases further, both solutions lose stability, and the only stable solution is a QP mode. This mode is a combination of spin and radial behavior. Unlike the smaller Z case, stable radial solutions are not found. As R increases, the two generator frequencies of the QP solutions converge to the dominant frequency of the PP solution. In the time domain the solution in each rod is approximately the PP solution on intermediate time scales, with a long time envelope corresponding to the small difference between the two generator frequencies. There is a phase difference between adjacent outer rods which is essentially constant over intermediate time scales, but which varies over longer time scales. The intermediate time scale increases as R increases. Thus, we find QP spin-like behavior which on intermediate time scales appears as a spinning manifestation of the PP solution. We refer to this behavior as spinning PP (SPP) behavior.

We also consider a yet larger value of Z. We find a PP solution which is now period doubled. In addition, we find spin and QP spin solutions as before. We also find an interval in R where spinning-type solutions reverse direction in a periodic or QP fashion.

Key words. combustion wave dynamics, self-propagating high-temperature synthesis, solid flames

1. Introduction. We consider modes of solid flame propagation associated with the SHS (self-propagating high-temperature synthesis) process of materials synthesis. In this process reactants are ground into a powder, cold pressed into a solid sample, typically a cylinder, and ignited at one end. Synthesis ensues as a high-temperature self-sustaining combustion wave propagates through the sample, converting reactants to products. When gas plays no significant role in the process, the resulting gasless combustion wave is referred to as a "solid flame" [12]. The SHS process enjoys a number of advantages over conventional technology, in which the sample is placed in a furnace and "baked" until it is "well done." The advantages include (i) simpler equipment; (ii) significantly shorter synthesis times; (iii) greater economy, since the internal energy of the chemical reactions is employed rather than the costly external energy of the furnace; (iv) greater product purity, due to volatile impurities being burned off by the very high temperatures of the propagating combustion wave; and (v) no intrinsic limit on the size of the sample to be synthesized, as exists in conventional technology.

In many instances, synthesis does not proceed in a uniform manner. Rather, nonuniform structures appear in the synthesized samples, corresponding to nonuniformly propagating combustion waves. A variety of dynamical modes of propagation have been found both from analysis and computations (see, e.g., [1, 2, 7, 8, 10, 12]), including planar pulsating (PP) modes, in which waves independent of the radial and angular coordinates, $\tilde{r}$ and ψ, exhibit time periodic oscillations; spinning modes, where one or more hot spots rotate periodically around the cylindrical axis as the wave propagates, so that a helical pattern is visible on the cylindrical surface; and radial modes, where a periodically oscillating wave depends on $\tilde{r}$ but not ψ, i.e., there are radial pulsations as the wave propagates axially. We note that it is difficult to visually determine the internal structure of spin and radial waves, as only the surface of the sample is visible. The internal structure can only be ascertained from a dissection of the synthesized product in controlled experiments. Thus, it is useful to obtain information on these modes from computations.

We consider solid flame waves in a cylindrical geometry. A full simulation of this problem would require three-dimensional (3D) computations. In order to reduce the required computational resources, we introduce a simplified model consisting of an array of 1D rods aligned along the cylindrical axis and connected to each other via heat transfer. The model simulates the 3D sample, but with coarse angular and radial grids. It has recently become popular to model systems governed by partial differential equations using an array of interacting oscillators. Here, we extend this approach by considering an array of interacting rods, each of which supports propagating waves. Our model generalizes the model introduced in [1], where surface spin modes were studied via a discrete number of interacting layers on the surface of the cylinder. In particular, spin modes were identified as pulsating solutions in each layer with a constant phase difference between adjacent layers. In this paper we consider a 3/1 model in which three equally spaced outer rods are located on the surface of the cylinder and an axial rod is located on the axis. All rods are connected to one another via heat transfer. This very simple rod model clearly limits the 3D modes that can be described. For example, it does not allow for a description of multiheaded spin solutions. However, it does allow an examination of the behavior of one-headed (one rotating hot spot) spins for large R, the nondimensional cylindrical radius. In addition, it allows the description of radial waves and of spin-like and radial-like quasiperiodic (QP) waves.

Since the activation energy of the reaction is typically large, the region between the burned and unburned material is generally very thin. Therefore, the reaction term is sometimes replaced by a δ-function of appropriate strength. This is referred to as the *reaction sheet approximation*. The resulting temperature profile is continuous, though its derivative is discontinuous at the reaction site (the site of the δ-function), which separates the burned from the unburned region. Here, we employ the distributed Arrhenius reaction term. We will use the descriptive term *front* to describe the thin region separating the burned and unburned regions.

A key parameter in describing solution behavior is the Zeldovich number $Z = N(1-\sigma)/2$, where N is a nondimensionalized activation energy and $\sigma = \tilde{T}_u/\tilde{T}_b$, where $\tilde{T}_u$ and $\tilde{T}_b$ are the unburned and adiabatic burned temperatures, respectively. Both the full 3D model and the rod model admit a uniformly propagating solution. In the rod model it is characterized by a uniformly propagating combustion wave in each rod, all propagating in phase. For all values of R the uniform solution loses stability to planar, i.e., rod independent, perturbations at a critical value Z_c, leading to a planar pulsating (PP) solution, characterized by a pulsating wave in each rod, all propagating in phase. In the reaction sheet approximation, $Z_c = 2+\sqrt{5}$ (see [11]). For Arrhenius kinetics as considered here, Z_c is slightly different. The dispersion relations for the uniformly propagating solution of the full 3D model in the reaction sheet approximation and of the rod model are shown to be equivalent when appropriate parameter identifications are made.

We consider solution behavior for selected values of Z, as R increases. The parameter R is technologically important, as the objective often is to synthesize large samples. We determine detailed solution behavior as a function of R for three values of Z, one less than Z_c and two greater than Z_c. The largest value of Z corresponds to the case when the PP solution is period doubled.

Preliminary results for $Z < Z_c$ were presented in [13]. It was shown that only uniformly propagating solutions are found for small values of R ($R < R_{sp}$). For $R > R_{sp}$, stability is transferred to a family of spin modes, characterized by periodically pulsating waves of period T in each rod, with a constant $(T/3)$ phase difference between adjacent outer rods. The spin modes lose stability above $R = R_s$. For large R ($R > R_r$) there exist radial modes, characterized by pulsating propagating waves in each rod, with the oscillations in the outer rods being in phase with each other but out of phase with the axial rod. Radial modes lose stability below $R = R_r > R_s$. The transitions at R_s and R_r are supercritical Hopf bifurcations. As R increases above R_s or decreases below R_r, a new frequency enters, and as R increases in $R_s < R < R_r$, a family of QP modes was found which continuously evolved from spin-like to radial-like character. The QP solutions are combinations of radial and spin modes, with the radial component entering with zero amplitude as the spin modes lose stability at $R = R_s$. Similarly, the spin component enters with zero amplitude when the radial mode loses stability at $R = R_r$. Depending on R, two different types of QP modes were found. For R near R_s the QP modes are characterized by spin behavior for the outer rods; i.e., the rods always fire in a fixed order, though there is a modulation in both the firing amplitude as well as the interval between successive firings. For R near R_r where radial behavior predominates, while there is still a modulation in the amplitude of the firings, the outer rods no longer fire in a fixed order. The former behavior can be described as spin-type QP behavior, while the latter are nonspin QP modes.

It is known that as Z increases the uniformly propagating solution becomes unstable and stable PP modes exist. As Z increases further, the PP solution undergoes

a bifurcation from singly periodic to doubly periodic ($2T$) [5]. We have considered two values of $Z > Z_c$, Z_T and Z_{2T}. For $Z = Z_T$ the PP solution is singly periodic, while for $Z = Z_{2T}$ the PP solution is period doubled. For $Z = Z_T$, stable PP solutions are found for $R < R_p$. Spin modes are found for $R_{sp} < R < R_s$, where the same notation is used for the spin mode boundary R_s, for both values of Z, though the numerical values are different. We note that $R_{sp} < R_p$, so that there is a region of bistability between the pulsating planar and spin modes. Spin modes lose stability at $R = R_s$ where stability is transferred to a family of QP solutions. No further transitions are found for the range of values of R considered. In particular, for $Z > Z_c$ we do not find stable radial solutions. Furthermore, all QP solutions found for this value of Z are spin-type QP solutions. However, examination of the frequency content of the QP solutions shows that their spectra are generated by two distinct generator frequencies. By examining the behavior associated with each of these frequencies, we show that the QP modes are combinations of spin and radial behavior as in the $Z < Z_c$ case. Calling these frequencies f_{sp} and f_r, we find that as R increases, the two frequencies coalesce, i.e., $f_{sp} - f_r \to 0$. Furthermore, the limiting frequency is the dominant frequency of the PP solution, f_p. We note that since the equations are autonomous, the term PP solution encompasses a family of solutions differing from each other by a constant phase shift in time. For large values of R, the QP solutions exhibit spin-like behavior, where for each rod the solution is approximately periodic over intermediate time scales which increase as R increases, with a period corresponding to the period of the PP solution and with a long period modulation in amplitude and phase corresponding to the difference frequency $f_d = \mid f_{sp} - f_r \mid$. The amplitude modulation decays to 0 as $R \to \infty$. There is a phase difference between adjacent outer rods which is essentially constant on intermediate time scales, but which varies over longer time scales. The phase modulation does not vanish as $R \to \infty$. The solution remains QP, though the quasiperiodicity is manifested only by a persistent modulation in the phase difference between temperature maxima of adjacent rods over long time scales. These time scales become infinite as $R \to \infty$. Thus, for large R we find an approximate spin mode where the behavior in each rod, over intermediate time scales, is close to that of an appropriately phase shifted PP solution. That is, the solution behaves as a multidimensional form, specifically a spinning form, of the 1D pulsating planar solution. We refer to this behavior as a spinning form of the PP (SPP) solution.

We have not traced the behavior for $Z = Z_{2T}$ in as much detail. Analogous to the case for $Z = Z_T$, we find that for small values of R only PP solutions are found, with the PP solution being $2T$. As R increases, we find periodic and QP spin modes. We note that the periodic spin modes are singly periodic. The dynamics of the spin modes do not appear to be affected by the period doubled nature of the pulsating planar solution, i.e., by the presence of the subharmonic in the PP mode. The QP spin mode is a combination of a spin and radial mode as is the case for smaller values of Z.

As R increases, we find QP spin modes where a subharmonic of one of the generator frequencies develops. These are spin modes which have the character of period doubled solutions; i.e., the front temperature exhibits a high temperature firing followed by a low temperature firing. There is also an interval of apparently chaotic behavior as R is increased further. Beyond a critical value of R we find periodic direction reversing modes which exhibit the character of both T and $2T$ solutions. In these modes the outer rods fire in a clockwise sequence and then a counterclockwise sequence. If the outer rods are numbered 2, 3, and 4, the rods fire in the sequence 324 followed by 423, with this behavior repeated periodically. Thus, the direction of spin

reverses periodically, and two of the rods (in this case rods 3 and 4) fire successively. The successive firings are at different amplitudes, while the intermediate rod (rod 2) always fires at the same amplitude. Thus, rod 2 and the axial rod exhibit singly periodic behavior, while the remaining two outer rods exhibit a period doubled behavior with firings at two different amplitudes within each cycle. Increasing R further leads to QP direction reversing modes.

Dynamical modes of solid fuel combustion were studied in [2] for the case that burning was confined to the surface. We showed that spin modes evolved into QP spins as R increased, as occurs in our rod model. The transition from spin modes to QP spin-type modes was accompanied by an increasing localization of the hot spots as R increased, thus leading to nearly planar behavior over a large fraction of the front on the cylindrical surface.

Three-dimensional computations of spinning modes are presented in [7, 8] for adiabatic combustion with $Z > Z_c$. Generally, the computational requirements for full 3D computations preclude the detailed, high resolution, studies presented here. Results were presented for one-headed spins, exhibiting both a rigid rotation of the hot spot, i.e., a traveling wave in the angular coordinate, and variable spot behavior where the spot exhibits a variability in brightness, size, and speed (possible QP behavior). Furthermore, the amplitude of the pulsations on the axis increased with R. These results are qualitatively similar to the results for the simplified rod model presented here. Furthermore, we identify the QP behavior as due to an interaction between spin and radial modes and demonstrate that axial pulsations increase as the amplitude of the radial component increases. This is a different mechanism for the transition to quasiperiodicity than that observed for surface combustion [2], where radial modes are not present. The mechanism identified for surface combustion was the increasing localization of the spot, leading to nearly uniform behavior over a large portion of the front, together with the fact that, for the parameters considered, the uniform solution is unstable. The spot extends radially into the sample, and even if it is localized on the surface, it will not necessarily be localized in the interior. Thus, the breakdown of periodic spins is due not to localization, but rather to the interaction of spin with radial modes. A preliminary analysis of the nature of the quasiperiodicity in three dimensions is presented in [13].

Since all the results presented in this paper are for the 3/1 rod model, it is still an open question as to which dynamical behaviors that we find are qualitatively similar to those which would be observed in the full 3D problem. While this model does not allow for a description of multiheaded spin modes, it does allow for a description of modes involving one hot spot. As shown in [2] for surface combustion, such modes may persist stably for relatively large values of R. Spin, radial, and QP spin modes which are combinations of spin and radial modes are found for models involving a larger number of rods, suggesting that this behavior is not an artifact of this particular rod model. In addition, SPP behavior is observed for more extensive rod models, thus suggesting that such behavior would also be observed in the continuous system. However, this has yet to be verified.

2. The mathematical model. We consider a model consisting of an array of 1D rods coupled via heat transfer. We denote dimensional quantities by $\tilde{\cdot}$. We also employ this notation for the mass fraction, even though it is nondimensional, in order to distinguish it from the normalized mass fraction employed in the nondimensional model. We consider a configuration with three rods symmetrically located on a cylindrical surface of radius $\tilde{R}$ and one rod located on the cylindrical axis. A similar model was employed in [1] to simulate the case when burning is confined to the surface of

the cylinder.

Let $\tilde{T}_i$ and $\tilde{Y}_i$ be the temperature and mass fraction, respectively, of a deficient component of the reaction in rod i. Suppose that rod 1 is located on the cylindrical axis, while rods 2, 3, and 4 are symmetrically located on $\tilde{r} = \tilde{R}$. For $i = 2, 3, 4$ we have

$$\frac{\partial \tilde{T}_i}{\partial \tilde{t}} = \tilde{\lambda}\frac{\partial^2 \tilde{T}_i}{\partial \tilde{z}^2} + \tilde{q}\tilde{W}(\tilde{T}_i, \tilde{Y}_i) - \tilde{\alpha}_\psi(\tilde{T}_i - \tilde{T}_{i+}) - \tilde{\alpha}_\psi(\tilde{T}_i - \tilde{T}_{i-}) - \tilde{\alpha}_{ri1}(\tilde{T}_i - \tilde{T}_1), \tag{1}$$

$$\frac{\partial \tilde{Y}_i}{\partial \tilde{t}} = -\tilde{W}(\tilde{T}_i, \tilde{Y}_i),$$

where $i+ = 3, 4, 2$ and $i- = 4, 2, 3$. Here, $\tilde{\lambda}$ is the thermal diffusivity and $\tilde{q} = \tilde{Q}/(\tilde{c}\tilde{\rho})$, where $\tilde{Q}$, $\tilde{c}$, and $\tilde{\rho}$ are the heat of reaction, specific heat, and solid density, respectively (all assumed to be constant and independent of i), is the scaled heat of reaction. The coefficients $\tilde{\alpha}_\psi$ and $\tilde{\alpha}_{ri1}$ represent heat transfer between the rods in the angular and radial directions (from rod i to the axial rod), respectively. The reaction rate $\tilde{W}$ is given by

$$\tilde{W}(\tilde{T}_i, \tilde{Y}_i) = \tilde{A}g(\tilde{T}_i)\tilde{Y}_i \exp\left(\frac{-\tilde{E}}{\tilde{R}_g \tilde{T}_i}\right), \tag{2}$$

where $\tilde{A}, \tilde{E}, \tilde{R}_g$ are the frequency factor, activation energy, and universal gas constant, respectively, and

$$g(\tilde{T}_i) = 0,\ \tilde{T}_i < \tilde{T}_{cut}, \qquad g(\tilde{T}_i) = 1,\ \tilde{T}_i > \tilde{T}_{cut},$$

where $\tilde{T}_{cut}$ is chosen to cut off the reaction far ahead of the combustion zone.

The equations for the axial rod $\tilde{T}_1$ are

$$\frac{\partial \tilde{T}_1}{\partial \tilde{t}} = \tilde{\lambda}\frac{\partial^2 \tilde{T}_1}{\partial \tilde{z}^2} + \tilde{q}\tilde{W}(\tilde{T}_1, \tilde{Y}_1) - \sum_{i=2}^{i=4} \tilde{\alpha}_{r1i}(\tilde{T}_1 - \tilde{T}_i), \quad \frac{\partial \tilde{Y}_1}{\partial \tilde{t}} = -W(\tilde{T}_1, \tilde{Y}_1), \tag{3}$$

where $\tilde{\alpha}_{r1i}$ represents heat transfer from the axial rod to the outer rod i.

For all rods the solutions satisfy the boundary conditions

$$\lim_{\tilde{z}\to-\infty} \tilde{T}_i = \tilde{T}_u, \qquad \lim_{\tilde{z}\to-\infty} \tilde{Y}_i = \tilde{Y}_u, \qquad \lim_{\tilde{z}\to\infty} \frac{\partial \tilde{T}_i}{\partial \tilde{z}} = 0, \tag{4}$$

where $\tilde{T}_u, \tilde{Y}_u$ are the unburned temperature and mass fraction, respectively. We note that $\tilde{T}_i \to \tilde{T}_b$ as $\tilde{z} \to \infty$, where $\tilde{T}_b$ is the adiabatic burned temperature; however, we employ the Neumann condition in our computations. Finally, we note that $\tilde{T}_b$ is derivable from thermodynamical considerations as $\tilde{T}_b = \tilde{T}_u + \tilde{q}\tilde{Y}_u$.

The heat transfer coefficients $\tilde{\alpha}_\psi, \tilde{\alpha}_{ri1}, \tilde{\alpha}_{r1i}$ correspond to a coarse grained approximation to the transverse Laplacian, i.e., the terms $\tilde{T}_{\psi\psi}/\tilde{r}^2$ and $(\tilde{r}\tilde{T}_{\tilde{r}})_{\tilde{r}}/\tilde{r}$, with periodicity in ψ assumed, thus establishing a relationship between the rod model and the fully 3D model. Approximating these expressions by finite differences leads to unique heat transfer terms. For example, interpreting rod i as a grid point and approximating the angular diffusion term at rod i gives

$$\frac{\tilde{T}_{\psi\psi}}{\tilde{r}^2} \simeq -\frac{\tilde{T}_i - \tilde{T}_{i+}}{(\Delta\psi\tilde{R})^2} - \frac{\tilde{T}_i - \tilde{T}_{i-}}{(\Delta\psi\tilde{R})^2}, \qquad \text{so that } \tilde{\alpha}_\psi = \frac{\tilde{\lambda}}{(\Delta\psi\tilde{R})^2},$$

where $\Delta\psi = 2\pi/3$ since we take three outer rods. For radial heat transfer, $\tilde{\alpha}_{ri1}$ can be determined by employing a finite difference approximation for radial diffusion together with the no flux boundary condition $\tilde{T}_r = 0$ at $\tilde{r} = \tilde{R}$, giving

$$\frac{(\tilde{r}\tilde{T}_{\tilde{r}})_{\tilde{r}}}{\tilde{r}} \simeq -2\frac{\tilde{T}_i - \tilde{T}_1}{(\Delta\tilde{r})^2}, \qquad \text{so that } \tilde{\alpha}_{ri1} = \frac{2\tilde{\lambda}}{(\Delta\tilde{r})^2},$$

where $\Delta\tilde{r} = \tilde{R}$. For heat transfer from the axis, we approximate the Laplacian by a suitably averaged five point difference in Cartesian coordinates with $\Delta\tilde{x} = \Delta\tilde{y} = \Delta\tilde{r}$ to get

$$\nabla^2\tilde{T} \simeq \frac{4}{3\Delta\tilde{r}^2}\sum_{i=2}^{i=4}(\tilde{T}_i - \tilde{T}_1), \qquad \text{so that } \tilde{\alpha}_{r1i} = \frac{4\tilde{\lambda}}{3(\Delta\tilde{r})^2},$$

where $\Delta\tilde{r} = \tilde{R}$.

Although this model is very coarse-grained, it allows a qualitative description of the fully 3D problem at a small fraction of the computational cost. We nondimensionalize as in [11] by introducing

$$Y_i = \frac{\tilde{Y}_i}{\tilde{Y}_u}, \qquad \Theta_i = \frac{\tilde{T}_i - \tilde{T}_u}{\tilde{T}_b - \tilde{T}_u}, \qquad t = \frac{\tilde{t}\tilde{U}^2}{\tilde{\lambda}}, \qquad z = \frac{\tilde{z}\tilde{U}}{\tilde{\lambda}},$$

$$\sigma = \frac{\tilde{T}_u}{\tilde{T}_b}, \qquad N = \frac{\tilde{E}}{\tilde{R}_g\tilde{T}_b},$$

where

$$\tilde{U}^2 = \frac{\tilde{\lambda}\tilde{A}}{2Z}\exp(-N),$$

$Z = N(1-\sigma)/2$ is the Zeldovich number, and $\tilde{U}$ is the velocity of the uniformly propagating front in the reaction sheet approximation [9]. Note that lengths are scaled by the size of the preheat zone. Finally, letting $\tilde{\alpha}$ (α) generically denote any of the dimensional (nondimensional) heat transfer coefficients, we have

$$\alpha = \tilde{\alpha}\frac{\tilde{\lambda}}{\tilde{U}^2}.$$

We will describe combustion waves propagating in the axial ($-z$) direction. We introduce the moving coordinate system [2, 11]

$$x = z - \phi(t),$$

where $\phi(t)$ is defined by $Y_1(\phi(t), t) = 0.5$. Here, the choice of the particular rod at which the mass fraction is fixed is arbitrary. Thus, ϕ_t is the approximate velocity of the wave, so that the transformation to the moving coordinate system enables us to localize the front to a neighborhood of $x = 0$.

In terms of the nondimensionalized quantities we have, for $i = 2, 3, 4$,

$$\frac{\partial\Theta_i}{\partial t} = \frac{\partial^2\Theta_i}{\partial x^2} + W(\Theta_i, Y_i) - \alpha_\psi(\Theta_i - \Theta_{i+}) - \alpha_\psi(\Theta_i - \Theta_{i-}) - \alpha_{ri1}(\Theta_i - \Theta_1), \tag{5}$$

$$\frac{\partial Y_i}{\partial t} = -W(\Theta_i, Y_i),$$

where

$$W(\Theta_i, Y_i) = 2Zg(\Theta_i)Y_i \exp\left(\frac{N(1-\sigma)(\Theta_i - 1)}{\sigma + (1-\sigma)\Theta_i}\right).$$

For the axial rod we have

$$\frac{\partial \Theta_1}{\partial t} = \frac{\partial^2 \Theta_1}{\partial x^2} + W(\Theta_1, Y_1) - \sum_{i=2}^{i=4} \alpha_{r1i}(\Theta_1 - \Theta_i), \quad \frac{\partial Y_1}{\partial t} = -W(\Theta_1, Y_1). \tag{6}$$

The boundary conditions are

$$\begin{gathered} Y_i \to 1, \quad \Theta_i \to 0 \ \text{ as } \ x \to -\infty, \\ \frac{\partial \Theta_i}{\partial x} \to 1 \ \text{ as } \ x \to \infty. \end{gathered} \tag{7}$$

These boundary conditions are specified at finite points far from the front which is located in the vicinity of $x = 0$. The computations presented here were obtained with the boundary conditions imposed at $x = \pm 12$. There is virtually no effect of further increasing the size of the computational domain.

Our numerical method employs an adaptive Chebyshev pseudospectral method, described in detail in [2, 3]. We solve the initial value problem, marching forward in time until steady state is achieved, so that we compute only stable solutions.

3. The uniformly propagating planar solution and its stability. As shown in [13], the system (5)–(7) admits a planar uniformly propagating solution. In the reaction sheet approximation this solution (see [11, 10]) is

$$\Theta_{unif} = \begin{cases} \exp(x), & x \le 0, \\ 1, & x \ge 0, \end{cases} \qquad Y = \begin{cases} 1, & x < 0, \\ 0, & x > 0, \end{cases} \qquad \phi(t) = -t + C,$$

where $\Theta_1 = \Theta_2 = \Theta_3 = \Theta_4 = \Theta_{unif}$ and C is an arbitrary constant. Note that for this solution the heat transfer between the rods vanishes. A linear stability analysis shows that three different types of instabilities can occur. The dispersion relation requires that the product of three terms vanishes, so that instability sets in when any of the factors vanishes. In terms of Z the three stability boundaries are given by

$$Z = 2 + \sqrt{5}, \tag{8}$$

$$Z = \frac{4 + 12(3\beta + 2)\alpha_R + \sqrt{\left[4 + 12(3\beta + 2)\alpha_R\right]^2 + 4\left[1 + 4(3\beta + 2)\alpha_R\right]^3}}{2[1 + 4(3\beta + 2)\alpha_R]}, \tag{9}$$

$$Z = \frac{4 + 12(6)\alpha_R + \sqrt{\left[4 + 12(6)\alpha_R\right]^2 + 4\left[1 + 4(6)\alpha_R\right]^3}}{2[1 + 4(6)\alpha_R]}, \tag{10}$$

where $\beta = 1/(\Delta\psi)^2 = 9/(4\pi^2)$, $\alpha_R = 1/R^2$, and $R = \tilde{R}U/\tilde{\lambda}$ is the nondimensional cylindrical radius. The eigenvectors indicate that (8) corresponds to a PP solution where all rods pulsate in phase and describes the well-known PP stability boundary, while (9) corresponds to a one-headed spin mode (the outer rods exhibit identical pulsations with a phase difference of $T/3$ where T is the period), and (10) represents

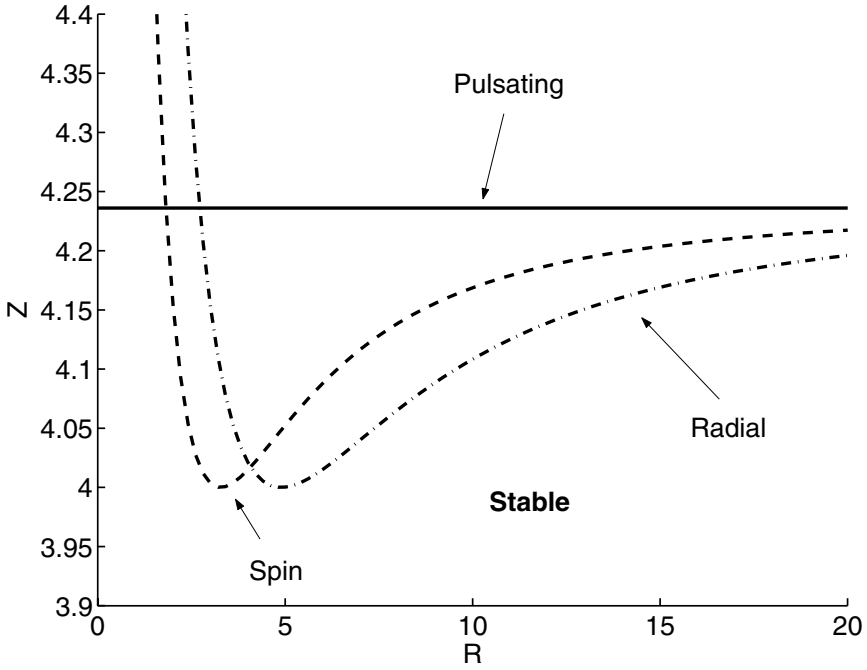

FIG. 1. *Stability boundaries for the uniform solution.*

a radial mode where the outer rods pulsate in phase, but are out of phase with the axial rod, the analogue of 3D radial modes where the solution depends on r but not on ψ. The three stability boundaries are shown in Figure 1.

The dispersion relation for the nondimensionalized continuous 3D problem is

$$Z_{3D} = \frac{4 + 12k^2 + \sqrt{\left[4 + 12k^2\right]^2 + 4\left[1 + 4k^2\right]^3}}{2[1 + 4k^2]}, \quad k = \frac{\xi_m^{(n)}}{R}. \tag{11}$$

Here, $\xi_m^{(n)}$ is the mth root of $J_n'(\xi) = 0$, where J_n is the Bessel function of order n, with n the angular wavenumber [10].

Since in our model we consider rods located at only three angular and two radial locations, only wave numbers $n = 0, 1$ and $m = 1, 2$ are relevant for comparison between the full model and our rod model. Since $\xi_1^{(0)} = 0$ $(m = 1, n = 0)$, the dispersion relations for the pulsating solutions are identical for the two models. The spin $(m = 1, n = 1)$ and radial $(m = 2, n = 0)$ modes are equivalent to the rod model if we identify k^2 with $(3\beta + 2)\alpha_R$ and $6\alpha_R$, respectively. This equivalence serves as a partial justification for the assumption that the behavior of the rod model is qualitatively similar to that of the full 3D model.

4. Results. We first consider results for a value of Z below the pulsating stability boundary Z_c, e.g., $Z \simeq 4.1$, for which the linear stability analysis suggests the sequence of transitions uniform → spin → transition region → radial → uniform as R increases. However, Figure 1 is based on a δ-function reaction term, while the results presented here are for the Arrhenius reaction term, leading to a slightly different dispersion

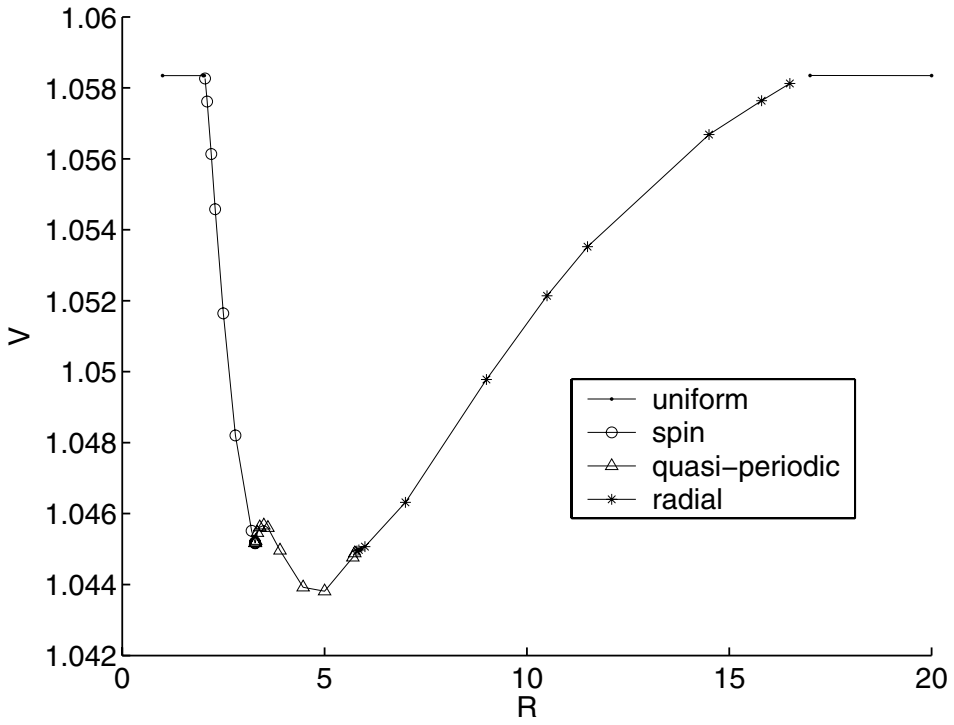

FIG. 2. *Mean speed V for different solution branches for $Z = 3.916$.*

relation. Our computations are for $Z = 3.916$, $N = 17.7$, $\sigma = .5575$, conditions which exhibit behavior analogous to $Z = 4.1$ in Figure 1.

In order to visualize the solution, we compute the temperature as a function of time at the flame front $\Theta_{Fi}(t)$, in each of the rods. Since we do not employ the reaction sheet model, there is not, strictly speaking, a front separating the burned and unburned regions. Nevertheless, we can determine the spatial location at which the reaction term is maximal and use it as an approximate flame front location. Computing this quantity as a function of time and then doing a least squares fit enables us to compute the mean flame speed V. The temperature on the front, $\Theta_{Fi}(t)$ can then be obtained by evaluating the Chebyshev polynomial approximation of Θ at this location [1]. Typically, the time history of $\Theta_{Fi}(t)$ will be oscillatory (though not necessarily periodic). Peaks in $\Theta_{Fi}(t)$ can be interpreted as a firing of the rod. As an analogue of the continuous 3D problem, a peak in $\Theta_{Fi}(t)$ can also be interpreted as a hot spot passing over the angle corresponding to the rod's location. Since this paper deals with the rod model, we will primarily refer to the firing of each rod in describing the dynamics of the solutions that we find.

Preliminary results for $Z = 3.916$ were presented in [13]. These results are summarized in Figure 2, which shows the mean front speed V as a function of R for the different solution branches that we have found. The spin modes are connected to the radial modes via a family of solutions exhibiting QP dynamics where the behavior continuously varies from spin-like (for smaller R) to near-radial (for larger R). There is no indication of bistability.

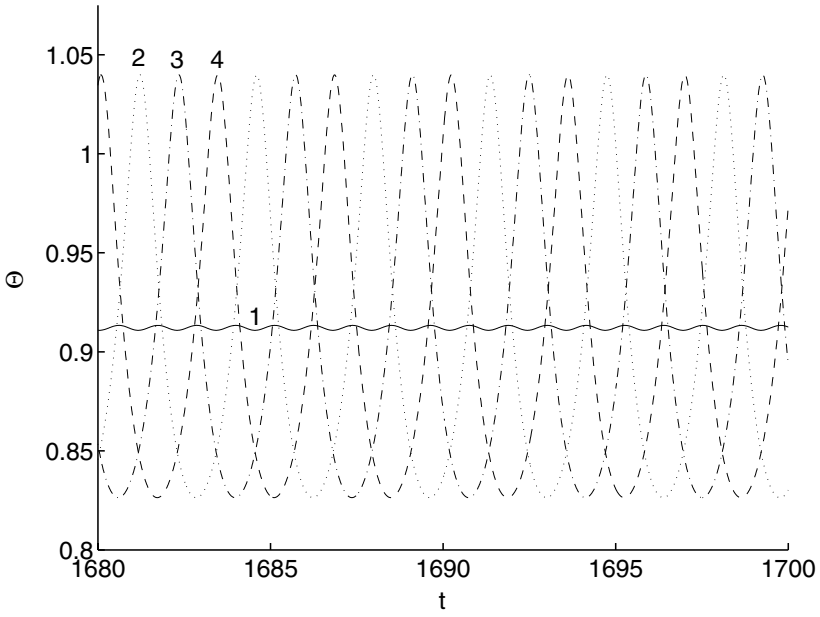

FIG. 3. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for spin solution for* $Z = 3.916$ *and* $R = 3.2$.

For the rod model a spin mode is represented by pulsating waves that are identical in each of the three outer rods except for the constant $T/3$ phase shift, with $\Theta_{Fi}(t)$ periodic of period T for $i = 2, 3, 4$. This is exactly what would be observed by examining the temperature of a spin mode at three angular locations separated by $2\pi/3$. When $\Theta_{Fi}(t)$ attains a maximum in time, one can think of a rotating hot spot passing over the spatial location corresponding to the rod, i.e., for the three outer rods the angles $k2\pi/3$ $(k = 0, 1, 2)$. Alternatively, in terms of the rod model, one can think of such a temperature maximum as a "firing" of the rod. We note that while the linear stability analysis predicts uniform temperature on the axis, there is a low level periodic temperature pulsation due to nonlinear effects neglected in the linear analysis. This axial pulsation will grow as R increases along the spin branch. Near the onset of spin modes the axial rod fires at a period $1/3$ that of the outer rods; i.e., it fires with the firing of each outer rod though with a slight phase shift, behavior clearly dependent on the choice of three outer rods and one axial rod in the model.

For the spin modes, the firing of the outer rods is synchronized. The rods fire in a fixed order with a constant time interval between firings. Note that the reverse firing order can also occur (corresponding to clockwise and counterclockwise rotating spots), with the order depending on initial conditions. The axial rod also fires periodically, but at a significantly lower level than the surface rods. For larger values of R, radial behavior is found. For a radial mode all outer rods fire simultaneously; i.e., there is no angular behavior to the firing, while the axial rod fires out of phase with the outer rods. Spin and radial modes were found in [13] and are illustrated in Figures 3 and 4, respectively, where the numbers 1–4 refer to the flame front temperatures in rods 1–4, respectively.

Near $R = 3.285$, the spin modes lose stability, and a transition to QP behavior is

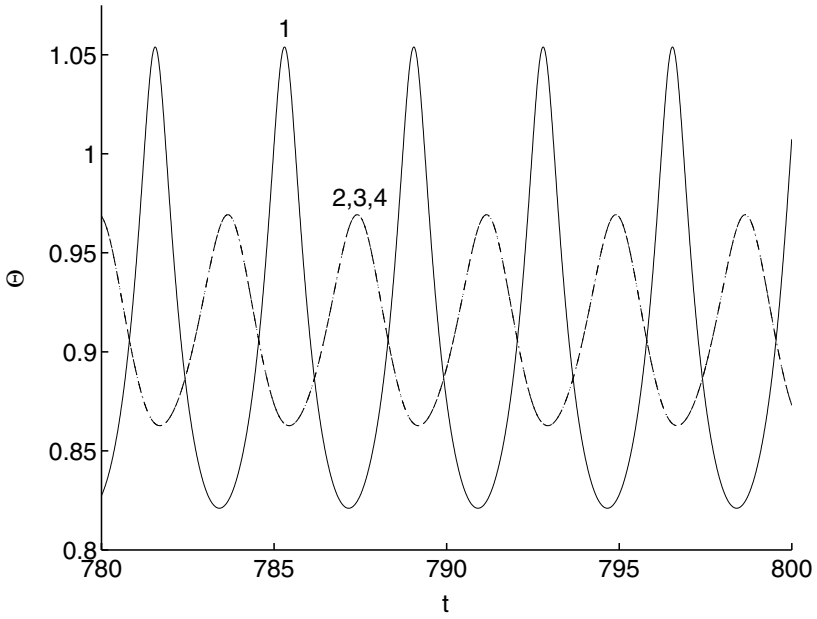

FIG. 4. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for radial solution for* $Z = 3.916$ *and* $R = 5.8$.

observed. Near the transition point the solution exhibits approximate spin behavior, in that the firing order is preserved. However, the firings are no longer synchronized; the phase shift between firings becomes periodic, corresponding to continuous spin modes in which adjacent hot spots periodically approach and then withdraw from each other, as seen in [2].

The QP modes are best described by analyzing the frequency spectrum of $\Theta_{Fi}(t)$. The spin and radial solutions are periodic in time. Thus, their frequency spectrum is composed of a single dominant frequency and its harmonics. The QP modes have two dominant frequencies which generate all other frequencies in the spectrum via linear combinations. Analysis of the frequency spectrum for the QP solutions indicates that the two generator frequencies correspond to spin and radial behavior, respectively. Thus, the QP modes are combinations of spin and radial modes. At the transition from spin to QP behavior a new frequency, corresponding to radial behavior, enters with zero amplitude. As R increases, the amplitude of the radial spectral component increases while the amplitude of the spin component decreases, so that at the transition from QP to radial behavior, the amplitude of the spin component vanishes.

This behavior was described in [13] and can be seen in Figure 5, where we exhibit the dominant frequencies for spin (S), QP, and radial (R) modes as a function of R. For the spin and radial modes there is only one dominant frequency. For the QP modes there are two dominant frequencies. The figure clearly shows that in the QP regime the two generator frequencies emanate continuously from the spin and radial frequencies, respectively. For $R \leq R_a$ (indicated by point a in the figure) the frequency corresponding to the largest spectral amplitude is the spin frequency, while for $R \geq R_b$ (indicated by point b in the figure), the frequency corresponding to the largest spectral amplitude is the radial frequency. The most dominant frequency

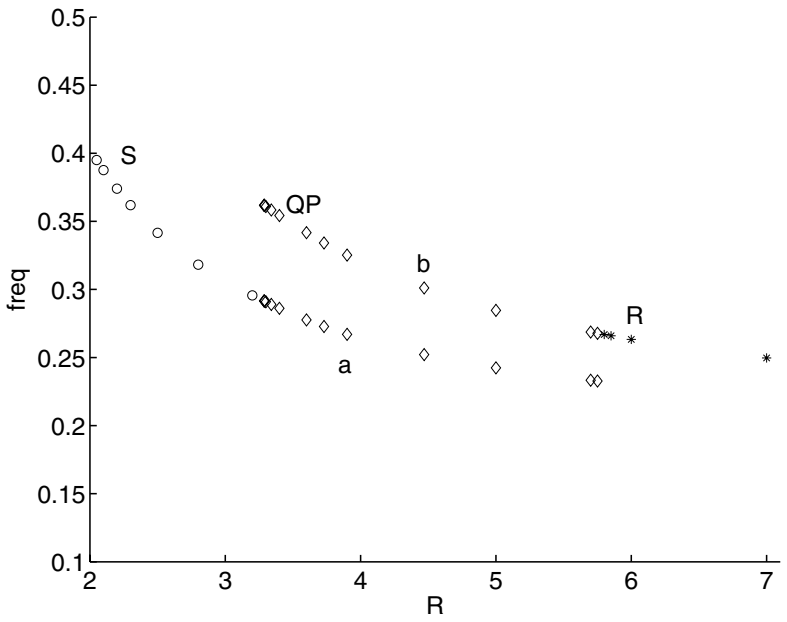

FIG. 5. *Principal frequency components for* $\Theta_{F2}(t)$ *for* $Z = 3.916$ *and* $R = 3.3$.

shifts from the spin frequency to the radial frequency as R increases. Thus, at least in terms of spectral content, for small R the QP modes take on a spin character, while for larger values of R the QP modes take on a radial character.

The time domain behavior, described in [13], is illustrated in the time domain in Figure 6, where we consider a QP mode near the spin-QP transition. For this figure, $\Theta_{Fi}(t)$ was Fourier transformed, the amplitudes of all frequencies except the secondary generator frequency and its harmonics were set to zero, and the resulting spectral representation was transformed back to the time domain. The resulting time domain behavior shown in the figure clearly exhibits radial behavior, including the simultaneous firings of the outer rods and the constant phase shift (near π) between the outer rods and the axial rod. A similar analysis near the transition from QP to radial behavior (Figure 7) indicates that the new frequency corresponds to spin behavior. We note that the solution shown in Figure 7 corresponds to a nonspin QP mode, where the firing order of the outer rods is not fixed. Such modes are connected to the transition to radial behavior. These modes are not found for larger values of Z since we cannot find stable radial modes for values of Z above the pulsating stability boundary.

Behavior near the spin-QP transition was discussed in [13]. Flame front temperatures for a QP mode near the spin-QP transition point are shown in Figure 8. The behavior is close to that of the spin modes. The rods fire in the same firing order; however, the time interval between successive firings is no longer constant, and the temperature maxima exhibit a nonconstant envelope. A QP mode near the QP-radial transition is shown in Figure 9. The outer rods fire nearly simultaneously; however, there is an amplitude modulation, and the time delay between successive firings is nonzero and nonconstant. Up to $R \simeq 3.7$, the outer rods fire in a fixed firing order (that of the spin modes). As R increases, the outer rods fire closer together in time,

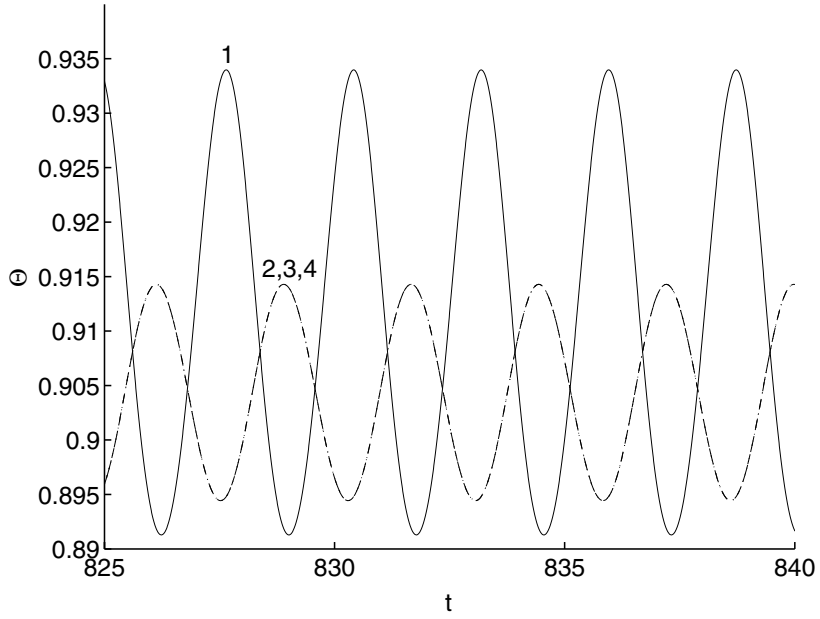

FIG. 6. *Radial component of* $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for QP mode for* $Z = 3.916$ *and* $R = 3.3$.

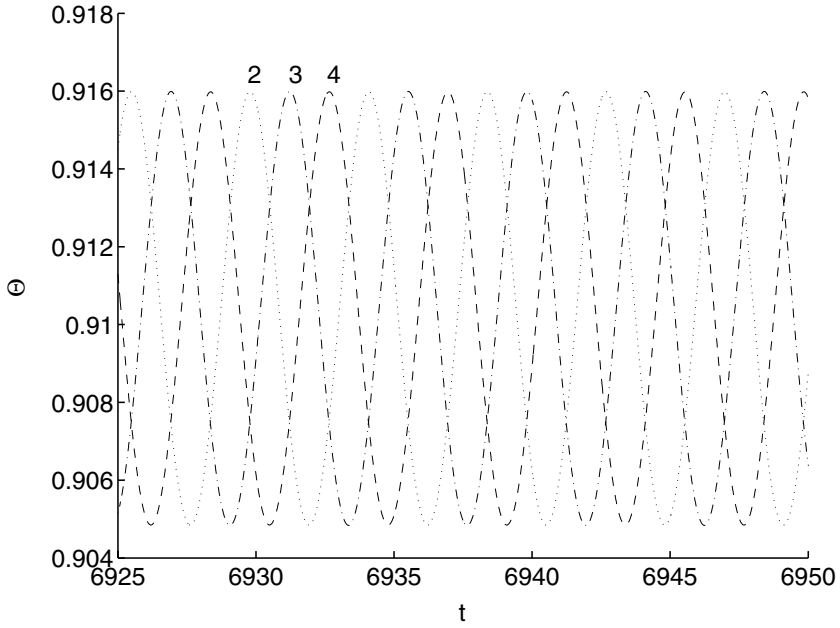

FIG. 7. *Spinning component of* $\Theta_{Fi}(t)$ $(i = 2, 3, 4)$ *for QP mode for* $Z = 3.916$ *and* $R = 5.75$.

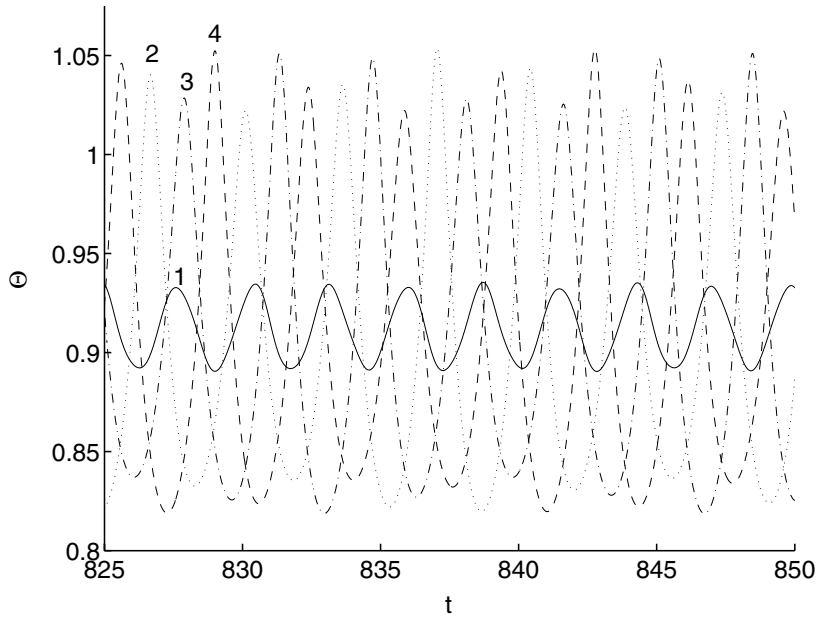

FIG. 8. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for QP solution for* $Z = 3.916$ *and* $R = 3.3$.

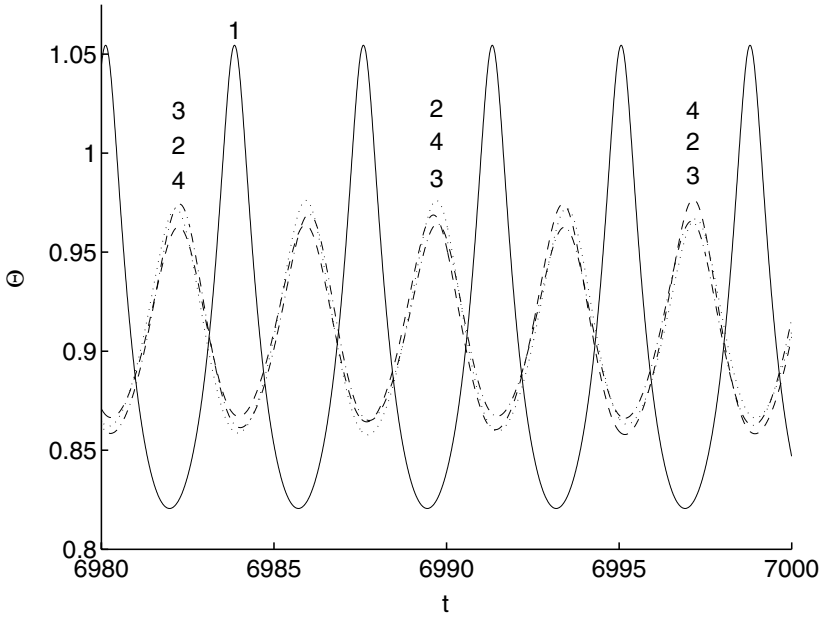

FIG. 9. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for QP solution for* $Z = 3.916$ *and* $R = 5.75$.

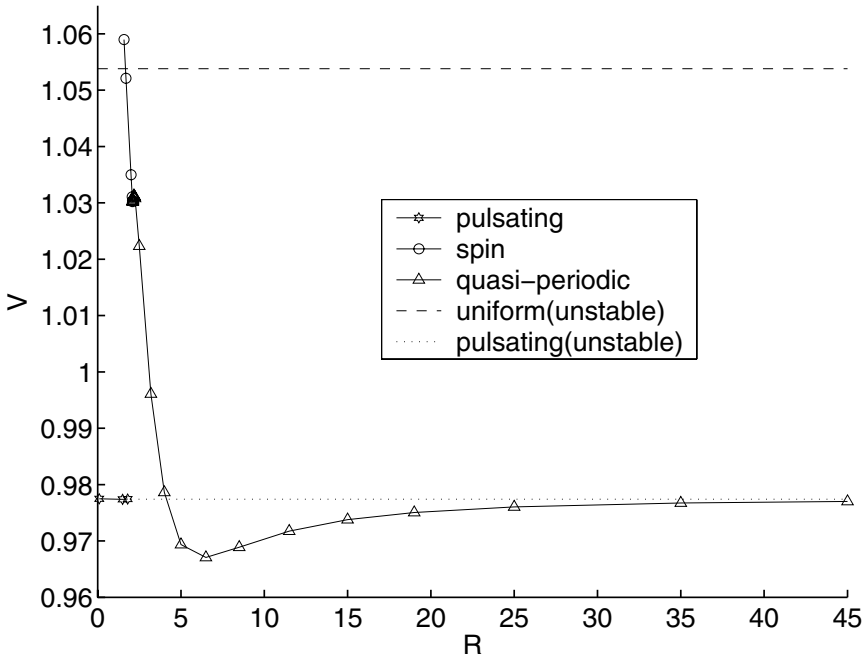

FIG. 10. *Mean speed for different solution branches for* $Z = 4.3$.

with the firing order no longer fixed, as the QP solutions take on more of a radial mode (simultaneous firing) character. In addition, the amplitude of the axial rod grows. Such a solution is shown in Figure 9. Near the transition to radial behavior, the firing of the outer rods occurs nearly simultaneously. Firings occur in groups of three, separated by a time interval close to the period of the radial solution.

Thus, for Z below the pulsating stability boundary there are three branches of nonuniform solutions, a spin branch for small values of R, a radial branch for larger values of R, and a connecting QP branch, where the behavior of the solution continuously changes from spin-like to radial-like as R increases. There is no indication of bistability.

We next consider behavior for Z above the pulsating stability boundary so that the uniformly propagating solution is unstable for all values of R. Specifically, we consider $Z = Z_T = 4.3$. A summary of our results is shown in Figure 10, where we plot V for the different solution branches as a function of R. While the PP solution, involving no heat transfer between the rods, exists for all values of R, we find that it is stable only for small values of R ($R < R_p \simeq 2$). Stable spin modes develop at $R = R_{sp} < R_p$, where $R_{sp} \simeq 1.58$. Since $R_{sp} < R_p$, there is a region of bistability between the spin and PP solutions. Examples of these modes in the bistable region are shown in Figures 11 and 12, where we plot $\Theta_{Fi}(t)$ for a spin (Figure 11) and PP (Figure 12) solution for $R = 1.7$. For $R > R_p$ only spin and QP spin-type modes are found.

Spin modes lose stability at $R = R_{QP} \simeq 2.0994$, and QP spin-type modes develop. This is accompanied by an increase in the amplitude of the axial pulsation. An example of such a QP spin mode is shown in Figure 13, where we plot $\Theta_{Fi}(t)$ for all rods for $R = 2.102$. The frequency spectrum of $\Theta_{F2}(t)$, shown in Figure 14, exhibits

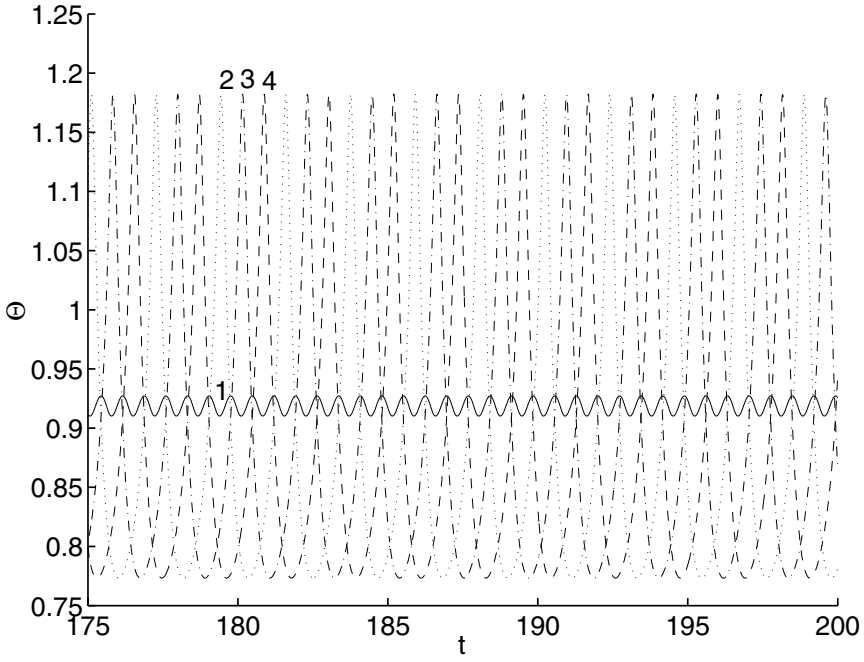

FIG. 11. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for spin solution for* $Z = 4.3$ *and* $R = 1.7$.

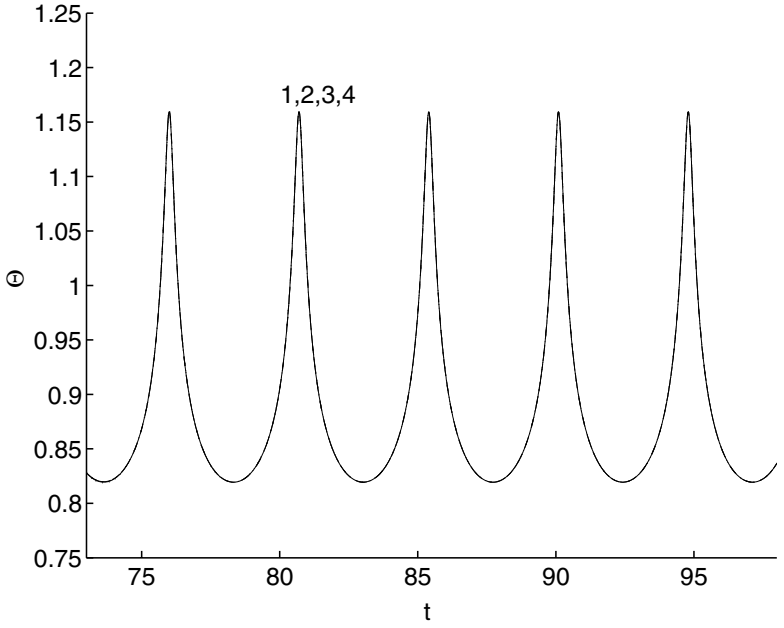

FIG. 12. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for PP solution for* $Z = 4.3$ *and* $R = 1.7$.

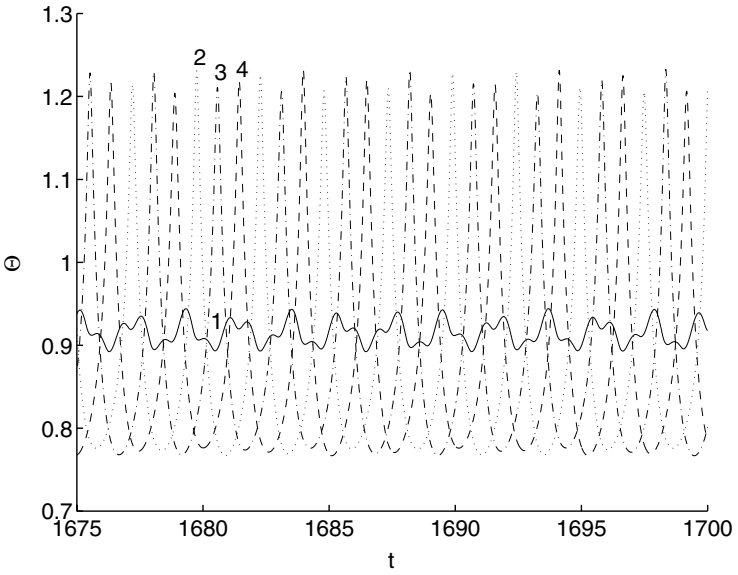

FIG. 13. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for QP solution for* $Z = 4.3$ *and* $R = 2.102$.

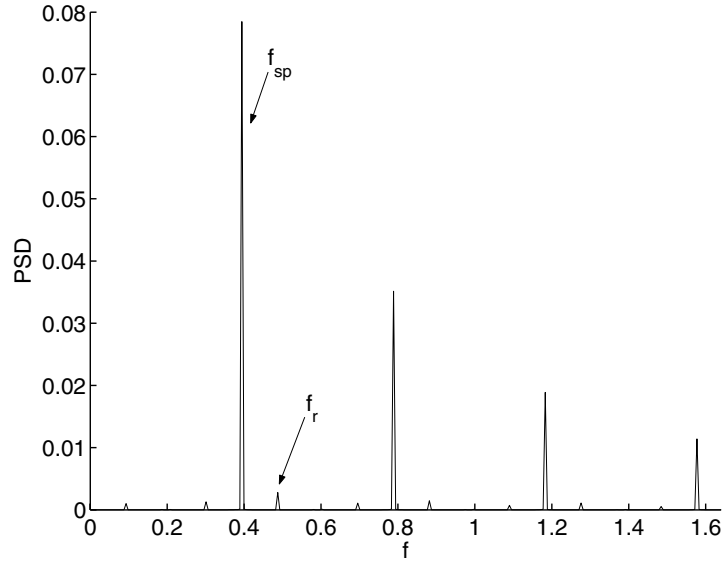

FIG. 14. *Frequency spectrum of* $\Theta_{F2}(t)$ *for QP solution for* $Z = 4.3$ *and* $R = 2.102$.

two clear generator frequencies together with linear combinations. Reconstructing time domain behavior corresponding to each of the two generator frequencies, denoted by f_{sp} and f_r in the figure, as described above, shows that they correspond to spin and radial behavior, respectively. This is shown in Figures 15 and 16.

We next consider the behavior of the QP modes as R increases. Unlike the previous case, we do not find stable radial solutions. For all values of $R > R_{QP}$ that we have considered the only stable solution that we find is the QP spin-type mode,

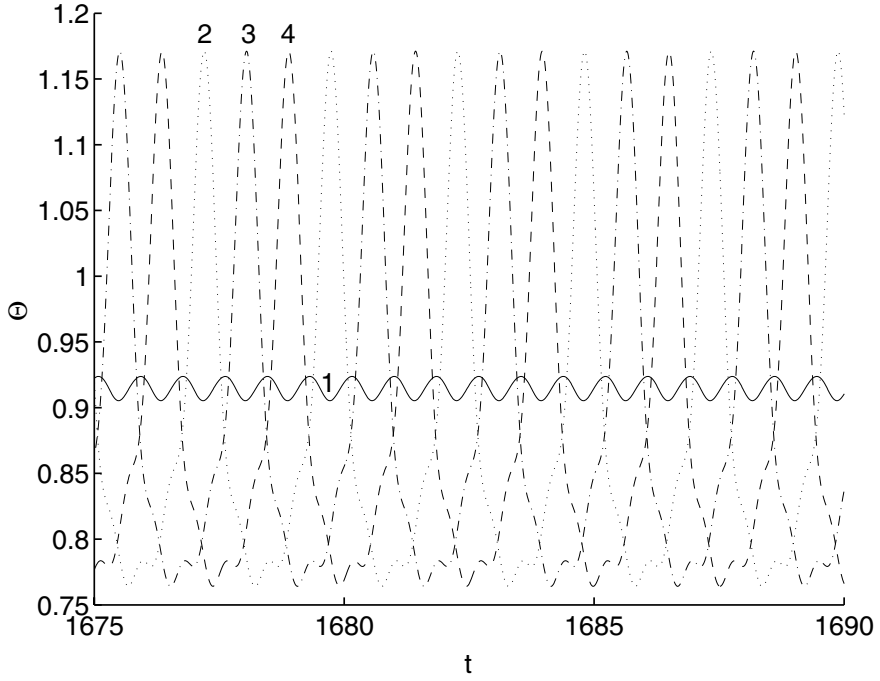

FIG. 15. *Spin component of QP solution for* $Z = 4.3$ *and* $R = 2.102$.

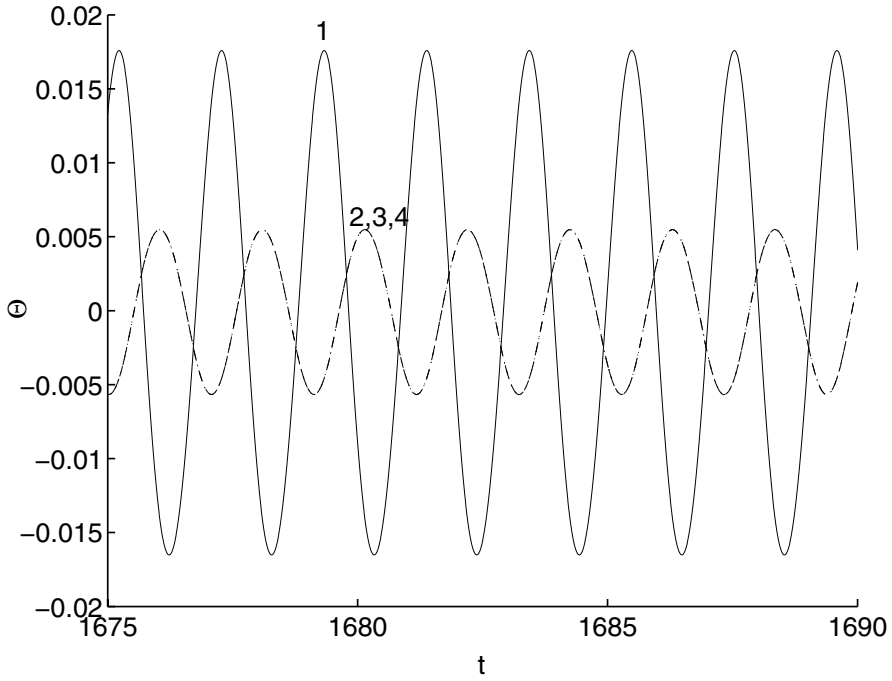

FIG. 16. *Radial component of QP mode for* $Z = 4.3$ *and* $R = 2.102$.

though like all QP spin modes it has a radial component. Furthermore, there is no breakdown in the firing order as occurred previously when there was a transition to radial behavior. For all values of R that we consider, the outer rods fire in a fixed order, characteristic of a spin mode.

As R increases, the QP modes are characterized by an asymptotic coalescence of the dominant spin and radial frequencies to the dominant frequency of the PP solution, f_p. In addition, the front temperatures in the time domain approach that of the PP solution, appropriately shifted in time. The solution varies over three distinct time scales. Over short time scales, of the order of the period T of the PP solution, the QP solution is essentially identical to the PP solution (appropriately phase shifted). Over intermediate time scales, which increase with R, the QP solutions are characterized as SPP solutions; i.e., the time history at each rod is approximately that of the PP solution appropriately phase shifted. Furthermore, adjacent outer rods are phase shifted with respect to each other, by a shift which is nearly constant in time, though the shift is different for different pairs of rods. Thus, over intermediate time scales the solution behaves as a spinning form of the PP solution, with a nonconstant rotation rate. We refer to this behavior as SPP behavior.

In addition, there is a longer time scale determined by the inverse of the difference frequency $f_d = \mid f_{sp} - f_r \mid$. Since $f_d \to 0$ as $R \to \infty$, this time scale grows as R increases. On this time scale there is a phase and an amplitude modulation. The amplitude modulation decreases as R increases and appears to vanish as $R \to \infty$. However, there is a phase variation between any two outer rods which appears to persist as R increases. Thus, for large R the front temperature appears to be QP, but without a noticeable amplitude modulation.

An indication of the SPP behavior can be seen from Figure 10, where V asymptotically approaches the mean speed of the PP solution as R increases. Note that our computations indicate that the PP solution is unstable for large values of R. The only stable solutions that we find are the SPP modes.

The frequency coalescence is shown in Figure 17 where we plot the two generator frequencies for the QP spin mode as a function of R. As R increases, the two generator frequencies converge to the dominant frequency of the PP solution, f_p. We note that even for large R, reconstruction of the time history employing only f_{sp} (f_r) and harmonics shows that these frequencies still correspond to spin (radial) behavior. Thus, for large values of R, spin and radial behavior occur with frequencies which converge to the frequency of the PP solution.

Figure 17 shows only the frequencies corresponding to the largest amplitudes of the spectrum. However, there is convergence in the time domain as well. The front temperature varies over three different time scales. Over time scales comparable to the period T of the PP solution (short time scale), Θ_{Fi} are almost identical to the PP solution (appropriately phase shifted). This behavior is maintained over intermediate time scales, of the order of $10T$, for the values of R considered here. Furthermore, there is a nearly constant phase difference between any two outer rods (though not necessarily $T/3$ as would be expected for a purely spinning mode). Thus, over the intermediate time scale, the QP spin mode behaves as an SPP solution, thus establishing a connection between spin modes and the PP solution which is stable only for small R.

Finally, there is a long time scale in which there is a modulation in the phase difference between two successive firings as well as in the amplitude of the pulsation. This time scale is proportional to f_d^{-1} and thus approaches ∞ as $R \to \infty$. The am-

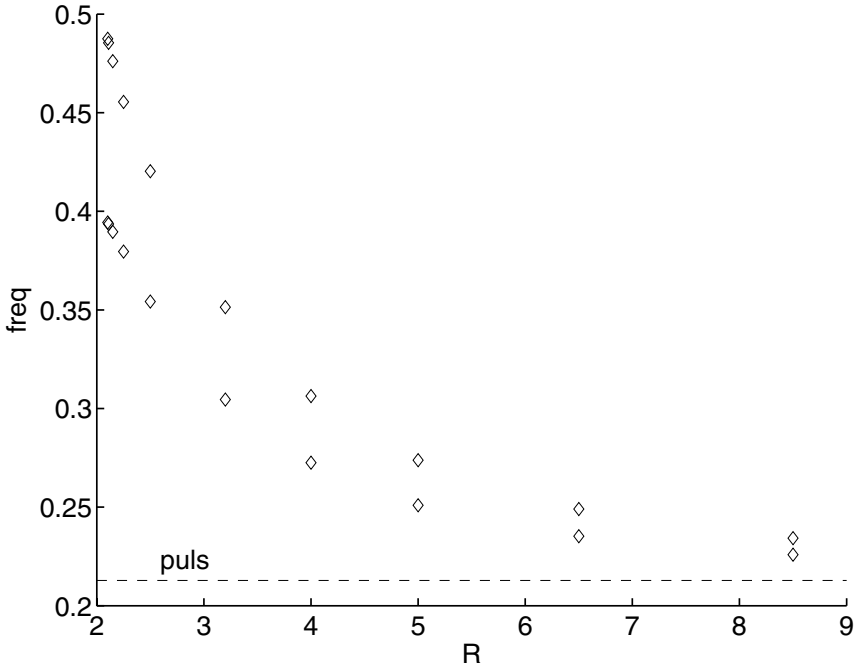

FIG. 17. *Generator frequencies for* $\Theta_{F2}(t)$.

plitude modulation appears to decay to 0 as $R \to \infty$. However, the phase modulation persists and does not decay to 0, even for large values of R.

We first illustrate behavior for intermediate values of R, where there are indications of SPP behavior, although it is not pronounced. In Figure 18 we plot $\Theta_{Fi}(t)$ and the PP solution (appropriately phase shifted) for $R = 19$. The data is plotted over approximately 100 time units. The amplitude and phase modulation can be seen from the figures, although for each rod the QP temperature is close to that of the PP solution (appropriately phase shifted).

In Figure 19 we plot the same quantities for $R = 35$. In this case there are essentially no visible differences between the QP and the PP solution over this time scale, and the QP solution can be considered as an SPP form of the solution. The intermediate time scale on which this occurs increases with R. The phase modulation is illustrated in Figures 20 and 21, where we plot $\Theta_{F2}(t)$ and $\Theta_{F3}(t)$ over roughly three PP periods. Figures 20 and 21 are separated by roughly 1000 units of time, a time interval where the phase modulation is evident. We note that in Figure 20 the time difference between the firings of rods 2 and 3 is approximately one unit, while in Figure 21 the time difference is approximately three units. There is virtually no change in amplitude between the pulsations in the two figures. Furthermore, all time histories in these two figures would be indistinguishable from appropriately phase shifted PP solutions. Thus, the quasiperiodicity of the QP mode for large R is manifested by a long time phase modulation between adjacent rods of a time signal that exhibits essentially no amplitude modulation and is essentially identical to that of the PP solution. The persistence of the phase modulation is further shown

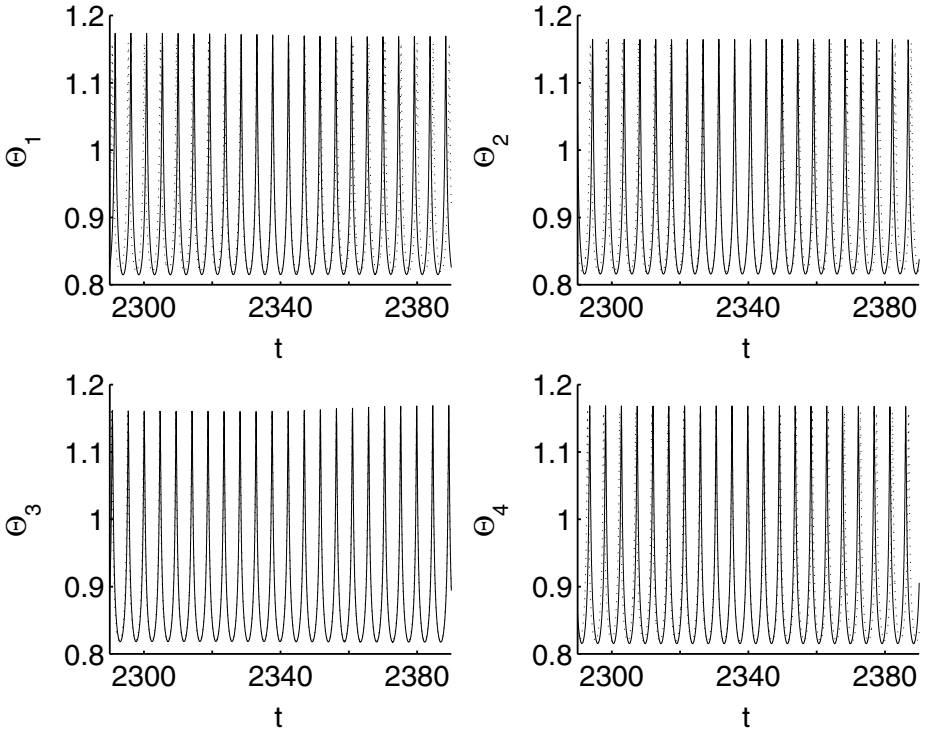

FIG. 18. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *(solid) and an appropriately phase shifted PP solution (dotted) for* $Z = 4.3$ *and* $R = 19$.

in Figure 22, where the maximum and minimum times between the firings of rods 2 and 3 is plotted against R. We note that these extrema asymptotically approach nonzero values (approximately 2.8 and 0.8, respectively). Though we have described the firings of rods 2 and 3, we note that the same behavior is observed for the phase modulation between any pair of adjacent outer rods.

Thus, these results suggest that at least for one-headed spin modes, the behavior for large sample sizes is dominated by a dynamical transformation of the PP solution, which manifests itself as a QP spin mode, with the outer rods exhibiting approximately PP behavior with a phase shift between neighboring rods.

We next describe results for $Z = Z_{2T} = 4.6$. For this value of Z, the pulsating planar solution is period doubled, exhibiting both large amplitude and small amplitude bursts within one cycle. Analogous to the $Z = Z_T$ case, for small values of R ($R \leq 1.3$) the only stable solution that we find is the $2T$ pulsating planar solution; i.e., the subharmonic is now present for the PP solution. For $1.3 < R < 1.5$ we find a region of bistability with both PP solutions and spin solutions. As R increases, we find that the PP solution becomes unstable and there is a branch of spin solutions ($1.3 \leq R \leq 1.7$). Increasing R further, we find a transition to QP spin modes ($1.75 \leq R \leq 4$). These solutions are very similar to those found for $Z = Z_T$ (see Figures 11 and 13) and will not be described further, except to note that the behavior for these modes is singly periodic as opposed to the $2T$ PP solution. Thus, for this range of R there is no indication in the spin modes that the PP solution is $2T$. This is similar to the behavior found for surface combustion in [2].

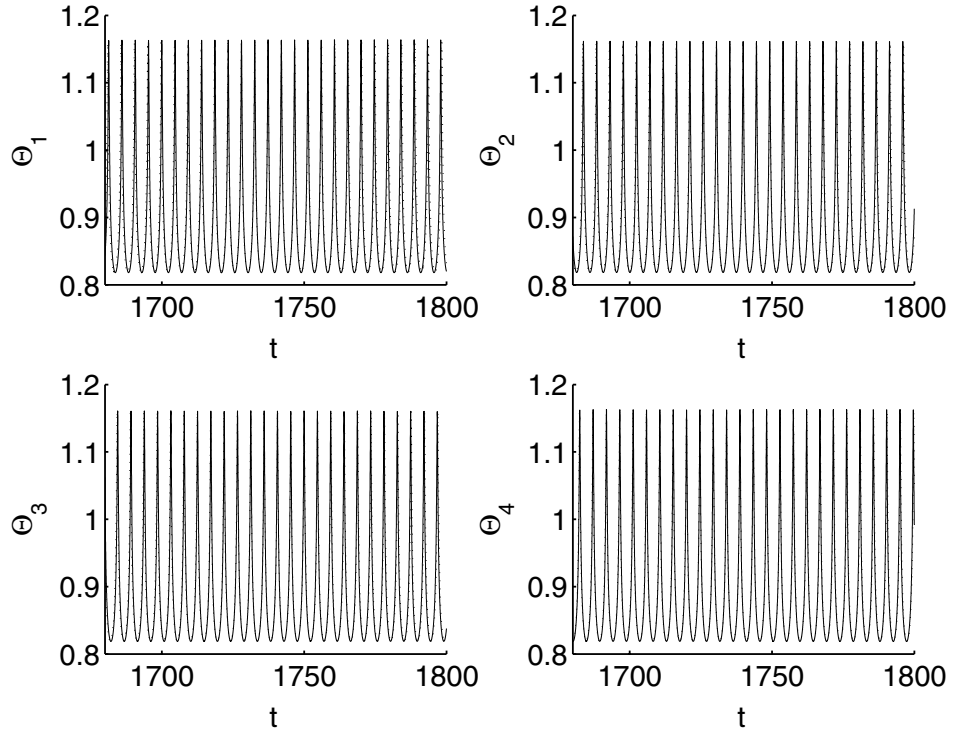

FIG. 19. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *(solid) and an appropriately phase shifted PP solution (dotted) for* $Z = 4.3$ *and* $R = 35$.

As R increases, subharmonics of the generator frequencies develop, giving the solution something of the character of a period doubled solution ($R \simeq 4.8$). We also find intervals where the solution is apparently chaotic, ($5 \leq R \leq 5.6$) and ($6 \leq R \leq 6.78$).

For $6.8 \leq R \leq 9.1$ we find direction reversing modes where two rods exhibit T behavior while the other two exhibit $2T$ behavior, and we observe a reversal of the spin direction around the cylinder. Note that the case of four coupled oscillators with the property that two of them exhibit period $2T$ behavior, though out of phase with each other by T, while the remaining two oscillators exhibit period T behavior, was discussed in [6], though the relation of such a mode to direction reversing behavior was not discussed. In order to describe these solutions we recall the numbering convention whereby rod 1 is located on the axis and rods 2, 3, and 4 are on the cylindrical surface. For the direction reversing modes the axial rod is singly periodic with period T, say. The surface rods are also periodic, but two of them, rods 3 and 4, exhibit period doubled behavior due to a direction reversal of the firing order. Note that rods 3 and 4 are out of phase by T.

In order to understand the dynamics of this mode, suppose for concreteness that rod 2 has period T while rods 3 and 4 have periods $2T$. Consider a sequence of firings commencing with a firing of rod 3, and suppose that rod 2 is the next rod to fire. An ordinary spin mode would then fire in the order 324, 324, ..., thus describing a specific direction to the spin around the cylinder, i.e., clockwise or counterclockwise. The period would be the time interval between two consecutive firings of any of the

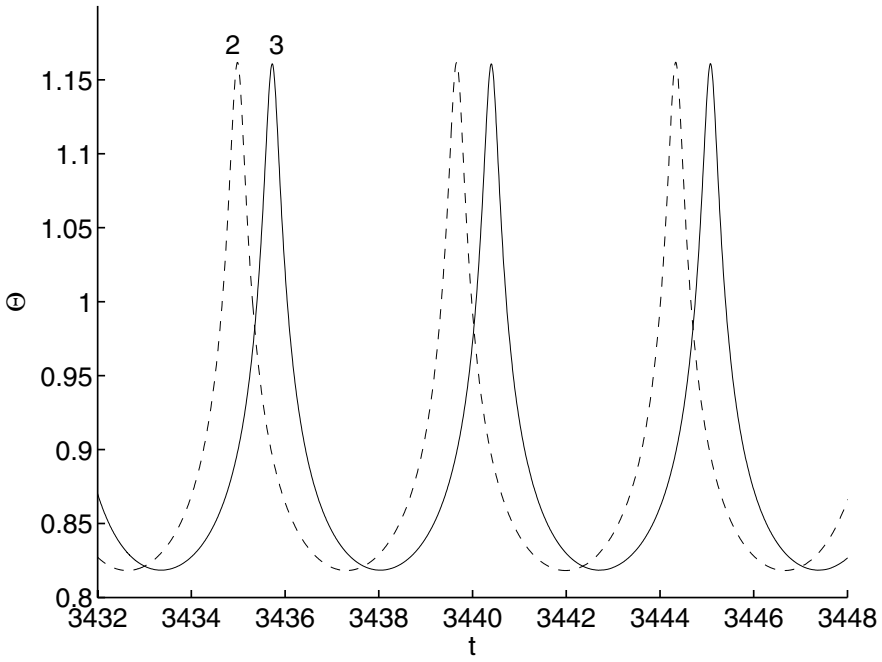

FIG. 20. $\Theta_{F2}(t)$ *and* $\Theta_{F3}(t)$ *plotted for small time interval near* $t = 3440$ *for* $Z = 4.3$ *and* $R = 35$.

rods. In the direction reversing mode, the firing direction reverses after one complete circuit around the cylinder. Thus, the firing order would be 324, 423, 324, 423, ... Rods 3 and 4 fire *twice* in succession, signaling a reversal of direction. Furthermore, the two successive firings are at different amplitudes, whereas rod 2 always fires at the same amplitude. An overall period consists of two groups of three, or equivalently two circuits around the cylinder, with a direction reversal. If we denote the period between successive firings of rod 2 as T, then rods 3 and 4 have periods $2T$. The axial rod (rod 1), which has period T, fires between successive firings of rods 3 and 4, so that a firing of the axial rod can be thought of as triggering the reversal. We illustrate this mode for $R = 7$ in Figure 23, where we plot $\Theta_{Fi}(t)$ for rods 3, 2, 4, and 1 over a time interval containing a complete cycle. The figure illustrates the firing sequence 324, 423. The first firing shown is for rod 3 (denoted by A in the figure). Then, rods 2 and 4 fire in order (B and C, respectively). Prior to the direction reversal, the axial rod (rod 1) fires (D). The firing order reverses as rod 4 fires again, but at a smaller amplitude (E). Then, rod 2 fires at the same amplitude at which it previously fired, indicating its period T (F). Finally, rod 3 fires at a larger amplitude than it previously did (G). The figure includes the start of the next reversal, with the subsequent axial firing (H) followed by another firing of rod 3 (I) at the same level as its initial firing. The time between firings A and I is $2T$.

Thus, there are two frequencies associated with this solution, the period between successive firings and the period of the reversal. For this value of R, the two frequencies are commensurate and the solution is periodic. For larger values of R, the two frequencies no longer appear to be commensurate, and we find QP direction reversing

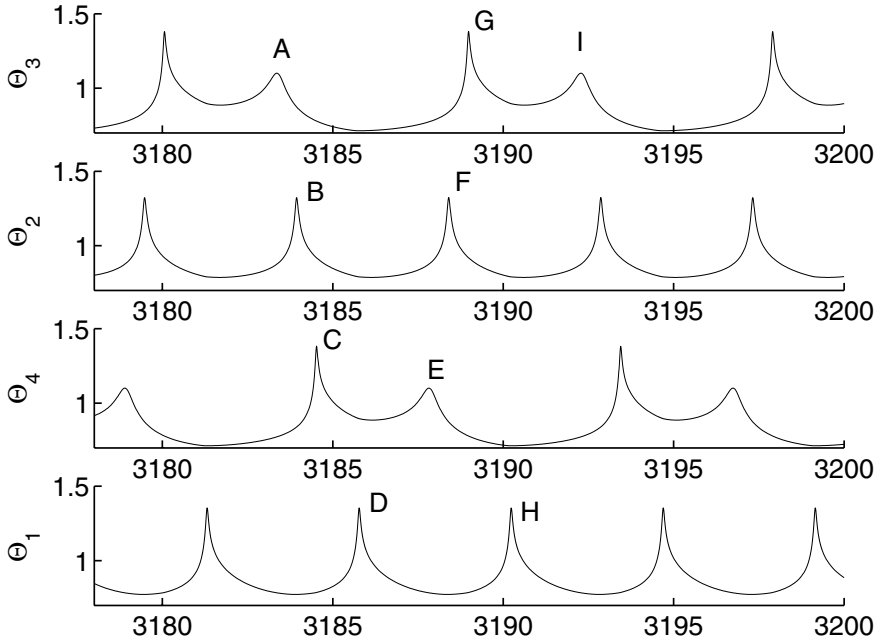

FIG. 23. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for periodic direction reversing mode for* $Z = 4.6$ *and* $R = 7$.

modes which exhibit similar dynamics to those described above but in a QP rather than periodic fashion. Upon increasing R yet further, we find a window of apparently chaotic solutions. Thus, the direction reversing mode represents an isolated window (in R) of laminar behavior, surrounded on both sides by intervals of apparently chaotic behavior.

Finally, for $R = 19$, we find a QP solution whose oscillations are periodically modulated. The envelopes, corresponding to the modulation frequency, exhibit a symmetry like that observed in [6] for a periodic solution. Specifically, the envelopes of $\Theta_{F3}(t)$ and $\Theta_{F4}(t)$ oscillate in synchrony with period T; thus, they have a common waveform. The envelopes of $\Theta_{F1}(t)$ and $\Theta_{F2}(t)$ also oscillate with period T, but they are not synchronous with each other nor with the envelopes of $\Theta_{F3}(t)$ or $\Theta_{F4}(t)$; they have different waveforms. This solution is shown in Figure 24. As R is increased, the amplitudes of the modulation oscillations decrease while their period increases.

5. Summary. We have numerically simulated 3D modes of solid flame waves employing limited computational resources, by employing a rod model in which a small number of appropriately located 1D rods interact with each other via heat transfer. The heat transfer coefficients correspond to a coarse-grained discretization of the transverse Laplacian. Both the rod model and the full 3D model allow uniformly propagating planar waves. By appropriately relating the heat transfer coefficients in the rod model to the radius R in the full 3D model, the dispersion relations for the two models can be shown to be identical.

We consider a simple rod model involving three outer rods and one axial rod, thus limiting the class of modes that can be described and for which analogies can be drawn with the modes of the 3D model. Clearly, additional modes, e.g., multiheaded spin modes, can be described by a rod model with a larger number of rods.

We have described the detailed behavior of the model as the sample size increases

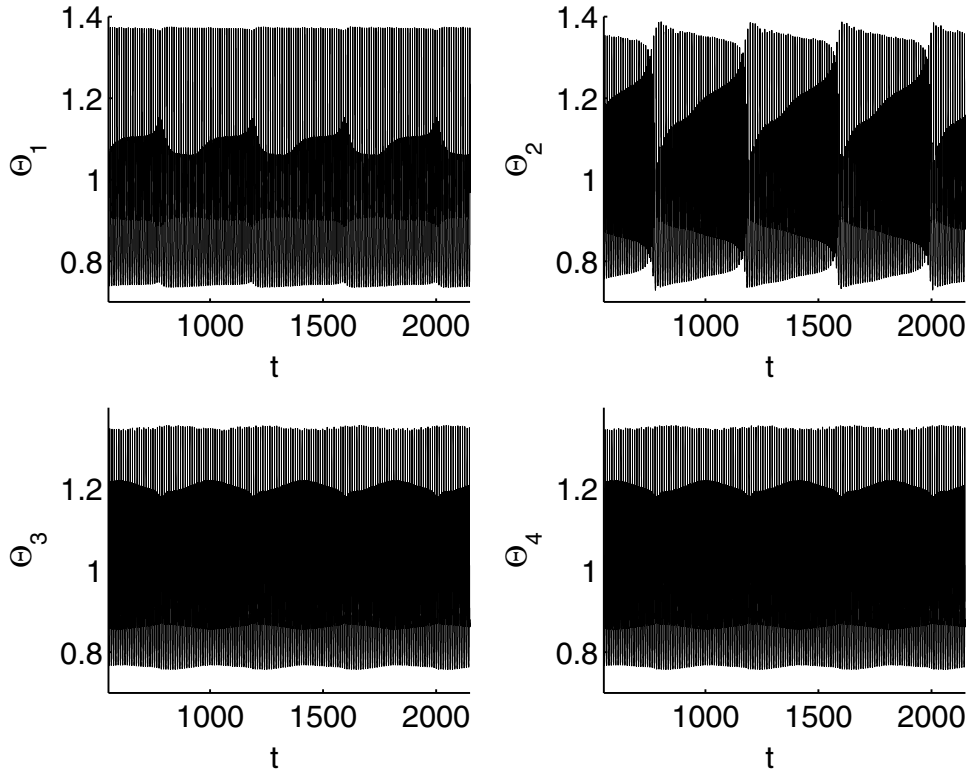

FIG. 24. $\Theta_{Fi}(t)$ $(i = 1, 2, 3, 4)$ *for QP solution with* $Z = 4.6$ *and* $R = 19$.

for three values of Z, one below and two above the pulsating stability boundary. When Z is below the stability boundary, there are transitions from the uniform mode to spin behavior as R increases. For larger values of R periodic radial modes are found. There is a branch of QP modes connecting the spin and radial branches, which involve an interaction between spin and radial behavior. Spin behavior dominates for smaller values of R (near the spin-QP transition), and radial behavior dominates for larger values of R (near the QP-radial transition). There is no indication of bistability for this value of Z.

For Z above the pulsating stability threshold, we find PP solutions for small R and spin modes for larger values of R, with a region of bistability between them. For larger values of R, only QP spin modes are found. Spectral analysis of the QP modes indicates that they represent the interaction of spin and radial modes. As R increases, the frequency spectrum of the QP modes approaches that of the PP solution, with a phase shift between adjacent outer rods. Thus, the pulsation within each rod is approximately that of the PP solution. We term this behavior SPP behavior. The behavior for large R can be described as a dynamical transformation of the PP mode, stable for small R, into a QP spin mode. This behavior persists over intermediate time scales which increase with R. Over long time scales there is persistent phase modulation between successive firings of the outer rods while the amplitude modulation decays to 0. Thus, the solutions remain QP with phase modulations manifested over progressively longer time scales as $R \to \infty$.

For yet larger values of Z, so that the PP solution is period doubled, we find spin and QP spin modes as before. We also find a window (in R) where direction reversing modes exist and are stable. These modes are characterized by a firing sequence which reverses direction, either periodically or quasi-periodically. Thus, outer rods fire in a sequence, e.g., 324, 423, 324, 423,..., so that the direction of firings is reversed. The middle rod in this sequence, in this case rod 2, is periodic with period T, say. The end rods, rods 3 and 4, fire consecutively as the sequence reverses. These firings are at different amplitude levels, so that these rods are periodic with period $2T$. The axial rod fires between two consecutive firings of rods 3 and 4. Thus, a firing on the axis can be thought of as triggering the reversal.

Our rod model is designed to provide insight into the qualitative behavior of the full 3D problem, employing vastly reduced computational resources. The computations presented here are for a primitive rod model, consisting of only four rods in total. The model is very computationally efficient, although it is incapable of reproducing multiheaded spins and standing wave–type solutions exhibiting, e.g., creation and annihilation, as is found in, e.g., surface gasless combustion [2]. Thus, the model can reproduce at most a limited subset of the solutions that can occur for the full 3D problem, although the results in [2] suggest that branches involving primarily one spot may extend stably for relatively large values of R and thus describe behavior for large diameter samples. The equivalence of the dispersion relation between the model and the full 3D problem suggests that 1-headed spin and radial-type behavior is reproduced at least qualitatively by the model. Whether the nonlinear behavior that we have observed is in fact also observed in the 3D problem has not yet been determined, though some of the computations described in [7, 8] may exhibit QP spin behavior. We should point out that the SPP mode (observed for large R) and the direction reversing mode (observed for large Z) occur in the regimes where numerical computations are most difficult and computationally intensive. Of course, if the number of rods is sufficiently large, the results for the rod model will surely closely approximate those for the full 3D model. However, our interest is in employing a finite, indeed a relatively small, number of rods. In addition to the question regarding the discretization, i.e., the use of a small number of rods, there is also the question of whether certain dynamical behaviors are a reflection of the symmetries of the rod arrangement. In view of this, it is important to ascertain whether such modes are observed for rod models involving a larger number of rods, arranged to exhibit different symmetries. We have obtained preliminary results with models involving more rods, which indicate that many of the modes reported here persist as the number of rods is increased, thus suggesting that they occur in the full 3D model as well.

A DELAY REACTION-DIFFUSION MODEL OF THE SPREAD OF BACTERIOPHAGE INFECTION*

STEPHEN A. GOURLEY† AND YANG KUANG‡

Abstract. This paper is a continuation of recent attempts to understand, via mathematical modeling, the dynamics of marine bacteriophage infections. Previous authors have proposed systems of ordinary differential delay equations with delay dependent coefficients. In this paper we continue these studies in two respects. First, we show that the dynamics is sensitive to the phage mortality function, and in particular to the parameter we use to measure the density dependent phage mortality rate. Second, we incorporate spatial effects by deriving, in one spatial dimension, a delay reaction-diffusion model in which the delay term is rigorously derived by solving a von Foerster equation. Using this model, we formally compute the speed at which the viral infection spreads through the domain and investigate how this speed depends on the system parameters. Numerical simulations suggest that the minimum speed according to linear theory is the asymptotic speed of propagation.

Key words. reaction-diffusion, delay, stage structure, through-stage death rate, traveling wave

1. Introduction.

It is known that bacteriophage infection can be a significant mechanism of mortality in marine prokaryotes (Bergh et al. [6], Proctor and Fuhrman [16]). These mortality mechanisms are critical in understanding the marine production processes. The constituents released by cell lysis can be an important pathway of nutrient recycling. This has direct bearing on issues such as global warming and topics of geochemical cycles. Viral infection also has direct implications for genetic exchange in the sea (Lenski and Levin [14], Bohannan and Lenski [7]).

Although we do not yet have a good understanding of the temporal or spatial scales at which host-virus encounters occur, it is clear that viral mortality must be explicitly considered in most models of the marine system. A case in point, recent experimental work suggests that the contamination of algal cells by viruses can serve as a regulatory mechanism in its bloom dynamics. Beltrami and Carroll [1] formulated a simple trophic model including virus-induced mortality. Their model succeeded in mimicking the actual algal bloom patterns of several species.

Our main interest in this paper is to explore how viral mortality affects both the temporal and spatial dynamics of marine bacteria and cyanobacteria. Recently, Beretta and Kuang [4] formulated and carried out a detailed study of the temporal viral-bacteria model

$$\begin{aligned}
\frac{dS}{dt} &= \alpha S(t)\left(1-\frac{S(t)+I(t)}{C}\right) - KS(t)P(t),\\
\frac{dI}{dt} &= -\mu_i I(t) + KS(t)P(t) - e^{-\mu_i T}KS(t-T)P(t-T),\\
\frac{dP}{dt} &= \beta - \mu_p P(t) - KS(t)P(t) + be^{-\mu_i T}KS(t-T)P(t-T).
\end{aligned} \tag{1.1}$$

This system of delay differential equations models a population of marine bacteria in which the individuals are subject to infection by viruses, also known as bacteriophages. Prior to that, these authors (Beretta and Kuang [2]) modeled and studied the same process by a set of nonlinear ordinary differential equations, and Carletti [10] has studied the stochastic extension of that model. In system (1.1), S is the density (i.e., number of bacteria per liter) of susceptible bacteria, I is the density of infected bacteria, and P is the density (number of viruses per liter) of viruses (phages). Viruses P attack the susceptible bacteria S, and a bacterium becomes infected I when a virus successfully injects itself through the bacterial membrane. The virus then starts replicating inside the bacterium, and then all the bacterium's resources are directed to replication of the virus. The infected bacterium does not replicate itself by division; only susceptible bacteria are capable of doing so. After a latency time T, an infected bacterium will die by lysis; i.e., the bacterium explodes releasing b copies ($b > 1$) of the virus into the solution, which are then free to attack other susceptible bacteria. An infected bacterium may die other than by viral lysis; we allow for this by the term $-\mu_i I(t)$. The differential equation for $I(t)$ is derived from the fact that $I(t)$ is given by

$$I(t) = \int_0^T e^{-\mu_i \tau} KS(t-\tau)P(t-\tau)\, d\tau, \tag{1.2}$$

which expresses the fact that the number of recruits into the infected class between times $t-(\tau+d\tau)$ and $t-\tau$ is $KS(t-\tau)P(t-\tau)\,d\tau$, the number of these still alive at time t is obtained by multiplying by $e^{-\mu_i\tau}$, and then the integral totals up the contributions from all relevant previous times, i.e., up to T time units ago.

In the virus equation, the third equation of (1.1), all mortalities of viruses are accounted for by the term $-\mu_p P(t)$. The β term, where $\beta > 0$, models a constant inflow of phages from outside the system. In the absence of viruses the bacteria grow logistically. The rate of infection is given by the law of mass action to be $KS(t)P(t)$.

Beretta and Kuang [4] assumed that infected bacteria still compete with susceptible bacteria for common resources. This is represented by the $-(S+I)/C$ term in the first equation of (1.1). This is clearly a disputed subject. For example, a model by Campbell [8] consists of the following equations:

$$\begin{aligned} \frac{dS(t)}{dt} &= \alpha S(t)\left(1-\frac{S(t)}{C}\right) - KS(t)P(t), \\ \frac{dP(t)}{dt} &= bKS(t-T)P(t-T) - \mu_p P(t) - KS(t)P(t), \end{aligned} \tag{1.3}$$

where

$$I(t) = \int_{t-T}^{t} KS(\theta)P(\theta)d\theta. \tag{1.4}$$

Clearly, in (1.3) the competition for common resources and additional mortality rate endured by infected bacteria is neglected. The equations (1.3), (1.4) can be obtained from (1.1) by setting $\beta = 0$, $\mu_i = 0$. Extensions of the above Campbell model can be found in Beretta, Carletti, and Solimano [3] (taking into account environmental fluctuations) and Carletti [9] (replacing b by $be^{-\mu_i T}$).

In the present paper, like the model of Campbell [8], we assume that once a bacterium becomes infected by a virus, it no longer competes with susceptibles for

resources. We will allow the possibility of a density dependent mortality term in the phage equation. In Beretta and Kuang [4], and also in the present paper, it is assumed that T and b are constant and the same for the whole population. Modifications of this assumption (e.g., replacing the constant incubation time T by a distribution of incubation times modeled using a probability density function) are the subject of further work presently in progress.

In the next section, we will present our delay model of bacteriophage infection and a simple preliminary result on the positivity of its solutions. This is followed by a short section on the global stability of the disease-free equilibrium. The analysis of endemic equilibrium is highly nontrivial and we provide only generic conditions for its stability switch. To complement this analytic work, we present some carefully designed and data-based simulation results. We then proceed to formulate and study a delay reaction-diffusion model of the spread of bacteriophage infection. The paper ends with a discussion.

2. Preliminaries. Most of our effort will be devoted to understanding the system

$$\begin{aligned} S'(t) &= \alpha S(t)\left(1-\tfrac{S(t)}{\gamma}\right) - KS(t)P(t), \\ P'(t) &= -\mu_p P(t) - mP^2(t) - KS(t)P(t) + bKe^{-\mu_i T}S(t-T)P(t-T), \end{aligned} \tag{2.1}$$

and with a reaction-diffusion version of (2.1). The initial conditions for (2.1) are

$$\begin{aligned} S(s) &= S^0(s) \geq 0,\ s \in [-T,0], \quad \text{with } S^0(0) > 0, \\ P(s) &= P^0(s) \geq 0,\ s \in [-T,0], \quad \text{with } P^0(0) > 0, \end{aligned} \tag{2.2}$$

where S^0 and P^0 are prescribed continuous functions. Our system (2.1) differs from that studied in [4] in three respects: (i) we do not have an inflow of phages from outside the system, (ii) we allow the possibility of a density dependent mortality term (the term $-mP^2$ in (2.1)), and (iii) we assume that an infected bacterium no longer competes with the susceptibles for resources. The latter assumption means that we do not need the differential equation for $I(t)$ for the analysis (though $I(t)$ is still given by (1.2)). An additional difference is that in the present paper we shall consider the effects of including diffusion to model the motion of the phages and bacteria.

If we had $P^0(s) \equiv 0$ on $[-T,0]$, the method of steps would immediately yield $P(t) = 0$ for all $t > 0$. The dynamics of $S(t)$ would then be governed by the logistic equation. Similarly, if $S^0(s) \equiv 0$, then clearly $S(t)$ remains zero for all $t > 0$ and thus $P(t) \to 0$ as $t \to \infty$. These trivial cases are removed from consideration by the assumptions in (2.2).

PROPOSITION 1. *Solutions of* (2.1), (2.2) *satisfy* $S(t) > 0$, $P(t) > 0$ *for all* $t > 0$.

Proof. The equation for $S(t)$ in (2.1) contains a factor of $S(t)$ and therefore positivity for $S(t)$ follows by the standard argument. For $P(t)$, note that on $t \in [0,T]$ we have $P'(t) \geq -\mu_p P(t) - mP^2(t) - KS(t)P(t)$ so that $P(t) \geq \tilde{P}(t)$, where $\tilde{P}$ is the solution of $\tilde{P}'(t) = -\mu_p \tilde{P}(t) - m\tilde{P}^2(t) - KS(t)\tilde{P}(t)$ satisfying $\tilde{P}(0) = P(0) > 0$. Clearly $\tilde{P}(t) > 0$ for all $t > 0$, and so we conclude that $P(t) > 0$ for all $t > 0$. The proof is complete. ∎

3. Equilibria and their stability. The equilibria of (2.1) are $(S,P) = (0,0)$, the disease-free equilibrium $(\gamma, 0)$, and possibly an endemic equilibrium

$$(S^*, P^*) := \left(\frac{m\gamma\alpha + K\gamma\mu_p}{m\alpha + K^2\gamma(be^{-\mu_i T} - 1)},\ \frac{\alpha\gamma K(be^{-\mu_i T} - 1) - \alpha\mu_p}{m\alpha + K^2\gamma(be^{-\mu_i T} - 1)} \right). \tag{3.1}$$

The latter is ecologically relevant if and only if

$$be^{-\mu_i T} > 1 + \frac{\mu_p}{\gamma K}, \tag{3.2}$$

which, of course, can only possibly hold for T up to a finite value. As long as (3.2) holds, there is an endemic equilibrium. Note that as $m \to \infty$ the endemic equilibrium approaches the disease-free equilibrium $(\gamma, 0)$.

We shall first prove that, if condition (3.2) does not hold, then any positive solution approaches the disease-free equilibrium $(\gamma, 0)$.

THEOREM 1. *Assume that*

$$be^{-\mu_i T} \leq 1 + \frac{\mu_p}{\gamma K}.$$

Then any solution of (2.1), (2.2) *satisfies*

$$\lim_{t \to \infty} (S(t), P(t)) = (\gamma, 0).$$

Proof. Consider the positive definite functional

$$V = S - \gamma - \gamma \ln \frac{S}{\gamma} + \frac{\gamma K}{\mu_p} P + \frac{b\gamma K^2}{\mu_p} e^{-\mu_i T} \int_{t-T}^{t} S(s)P(s)\, ds.$$

Differentiating along solutions of (2.1) yields

$$\begin{aligned} V' &= -\frac{\alpha}{\gamma}(S-\gamma)^2 - \frac{\gamma m K}{\mu_p} P^2 + K\left(\frac{b\gamma K}{\mu_p} e^{-\mu_i T} - \frac{\gamma K}{\mu_p} - 1\right) SP \\ &\leq -\frac{\alpha}{\gamma}(S-\gamma)^2. \end{aligned}$$

Thus

$$V(t) + \frac{\alpha}{\gamma} \int_0^t (S(s) - \gamma)^2\, ds \leq V(0),$$

and, letting $t \to \infty$, we conclude that $|S(t) - \gamma| \in L^2(0, \infty)$ so that $S(t) \to \gamma$ as $t \to \infty$. The differential equations (2.1) then yield $P(t) \to 0$. The proof is complete. ∎

3.1. The endemic equilibrium: Linearized analysis. Let us investigate the endemic equilibrium (S^*, P^*) given by (3.1). In this subsection we shall assume, of course, that (3.2) holds, so that the equilibrium is feasible. The linearized analysis about the endemic equilibrium is algebraically quite complicated. The main reason for this is that the delay T appears not only in the $S(t-T)P(t-T)$ term in the second equation of (2.1), but also in the factor $e^{-\mu_i T}$ in front of that term. The paper by Wolkowicz, Xia, and Wu [20] shows how such additional factors involving time delay can appear in distributed delay equations. Surprisingly, this represents a significant complication and prevents us from analytically computing the precise parameter regimes in which the endemic equilibrium can change stability as the delay T is increased, or the actual values of T when stability switches occur. Note further that the equilibrium itself depends on T and exists only for T up to a finite value. This renders many of the existing stability switch methods (see Kuang [12]) powerless. However, a method has recently been developed by Beretta and Kuang [5] to address the problem of computing stability switches for delay equations which do not lend

themselves to classical methods because of these complications. We shall use this method in this section.

To linearize about (S^*, P^*) we set $S = S^* + \tilde{S}$ and $P = P^* + \tilde{P}$. Ignoring higher order terms in $\tilde{S}, \tilde{P}$ gives us the linearized system

$$\begin{aligned} \tilde{S}'(t) &= -\tfrac{\alpha}{\gamma} S^* \tilde{S}(t) - K S^* \tilde{P}(t), \\ \tilde{P}'(t) &= -K P^* \tilde{S}(t) - (\mu_p + 2mP^* + KS^*)\tilde{P}(t) \\ &\quad + bKe^{-\mu_i T}(P^* \tilde{S}(t-T) + S^* \tilde{P}(t-T)). \end{aligned} \tag{3.3}$$

We shall find it convenient to introduce the parameter

$$\rho_T = \frac{\gamma K}{\mu_p}(be^{-\mu_i T} - 1). \tag{3.4}$$

Then the endemic equilibrium (S^*, P^*) exists if and only if

$$\rho_T > 1.$$

In terms of ρ_T,

$$(S^*, P^*) = \left(\frac{\gamma(m\alpha + K\mu_p)}{m\alpha + K\mu_p \rho_T}, \ \frac{\alpha \mu_p (\rho_T - 1)}{m\alpha + K\mu_p \rho_T} \right).$$

Nontrivial solutions of the linearized system of the form $(\tilde{S}(t), \tilde{P}(t)) = e^{\lambda t}(c_1, c_2)$ exist if and only if

$$D(\lambda; T) = 0,$$

where

$$D(\lambda; T) = \lambda^2 + a(T)\lambda + b(T)\lambda e^{-\lambda T} + c(T) + d(T)e^{-\lambda T} \tag{3.5}$$

and

$$a(T) = \frac{\alpha(m\alpha + K\mu_p) + m\alpha(K\gamma + 2\mu_p\rho_T - \mu_p) + K\mu_p(K\gamma + \mu_p\rho_T)}{m\alpha + K\mu_p\rho_T}, \tag{3.6}$$

$$b(T) = -\frac{b\gamma K e^{-\mu_i T}(m\alpha + K\mu_p)}{m\alpha + K\mu_p\rho_T}, \tag{3.7}$$

$$c(T) = \frac{\alpha(m\alpha + K\mu_p)\left\{m\alpha(K\gamma + (2\rho_T - 1)\mu_p) + K\mu_p(\mu_p\rho_T + (2 - \rho_T)K\gamma)\right\}}{(m\alpha + K\mu_p\rho_T)^2}, \tag{3.8}$$

$$d(T) = \frac{bK\gamma\alpha e^{-\mu_i T}(m\alpha + K\mu_p)\left\{K\mu_p(\rho_T - 2) - m\alpha\right\}}{(m\alpha + K\mu_p\rho_T)^2}. \tag{3.9}$$

Keeping in mind that $b > 1$, it is straightforward to see that when $T = 0$ the equilibrium (S^*, P^*), if feasible, is linearly stable. This is because when $T = 0$, (3.5) becomes a quadratic in λ, and it is easy to see that $a(0) + b(0) > 0$ and $c(0) + d(0) > 0$. The question is whether the equilibrium can undergo any stability switch as T is increased, remembering that the equilibrium is only feasible up to a finite value of T. To identify a stability switch we seek solutions of the characteristic equation $D(\lambda; T) = 0$ of the

form $\lambda = \pm i\omega$, with ω a real positive number. We find that it is necessary for ω to satisfy

$$\omega^4 + (a^2(T) - 2c(T) - b^2(T))\omega^2 + c^2(T) - d^2(T) = 0. \tag{3.10}$$

However, the existence for a particular T of a real root $\omega(T)$ of (3.10) does not in itself imply that a stability switch occurs at that value of T, since T also has to satisfy (3.11) and (3.12) below. Nonetheless, certain general analytical conclusions can be drawn in spite of the algebra. Straightforward but tedious computations show that, for any parameter values consistent with $\rho_T > 1$ (i.e., with existence of the endemic equilibrium (S^*, P^*)), we have

$$a^2(T) - 2c(T) - b^2(T) > 0.$$

In light of this fact, and assuming that (S^*, P^*) is feasible when $T = 0$, certain conclusions follow.

(i) A stability switch cannot occur in an interval of T throughout which $c^2(T) > d^2(T)$.

(ii) If there are values of T with $c^2(T) < d^2(T)$, then a stability switch may occur as T is varied. Pairs of eigenvalues cross the imaginary axis as T passes through certain critical values. The critical values of T and the corresponding purely imaginary eigenvalues $\pm i\omega(T)$, $\omega(T) > 0$, are given implicitly by

$$\sin(\omega(T)\,T) = \frac{b(T)\omega(T)(\omega^2(T) - c(T)) + \omega(T)a(T)d(T)}{\omega^2(T)b^2(T) + d^2(T)}, \tag{3.11}$$

$$\cos(\omega(T)\,T) = \frac{d(T)(\omega^2(T) - c(T)) - \omega^2(T)a(T)b(T)}{\omega^2(T)b^2(T) + d^2(T)}, \tag{3.12}$$

$$\begin{aligned}\omega^2(T) = \frac{1}{2}\Big(&- a^2(T) + 2c(T) + b^2(T) \\ &+ \sqrt{a^4(T) - 4a^2(T)c(T) - 2a^2(T)b^2(T) + 4c(T)b^2(T) + b^4(T) + 4d^2(T)}\Big),\end{aligned} \tag{3.13}$$

where $a(T)$, $b(T)$, $c(T)$, and $d(T)$ are given by (3.6), (3.7), (3.8), and (3.9) above. It is impossible to solve these equations for T explicitly, so we shall use the procedure described in Beretta and Kuang [5]. According to this procedure, we define $\theta(T) \in [0, 2\pi)$ such that $\sin\theta(T)$ and $\cos\theta(T)$ are given by the right-hand sides of (3.11) and (3.12), respectively, with $\omega(T)$ given by (3.13). This defines $\theta(T)$ in a form suitable for numerical evaluation using standard software. Then T is given (still implicitly) by

$$T = \frac{\theta(T) + 2n\pi}{\omega(T)}, \qquad n = 0, 1, 2, \ldots,$$

and the idea is to identify the roots of this equation for various n, i.e., to solve numerically the equation $S_n(T) = 0$ for $n = 0, 1, 2$, where

$$S_n(T) = T - \left(\frac{\theta(T) + 2n\pi}{\omega(T)}\right), \qquad n = 0, 1, 2, \ldots. \tag{3.14}$$

Accurate plots of these functions $S_n(T)$ quickly reveal whether stability switches can occur or not, but one must remember to keep track of the feasibility of the equilibrium (S^*, P^*) since it disappears completely (by coalescing with the disease-free equilibrium $(\gamma, 0)$) at a finite value of the delay T.

By reference to (i) above, it is possible to obtain sufficient and easily verifiable conditions for the equilibrium (S^*, P^*) to remain locally stable. Indeed, the condition $c^2(T) > d^2(T)$ amounts to

(3.15)
$$\begin{aligned} &m^2\left\{\alpha^2(K\gamma+(2\rho_T-1)\mu_p)^2-\alpha^2b^2K^2\gamma^2e^{-2\mu_iT}\right\}\\ &+2\alpha K\mu_pm\left\{(K\gamma+(2\rho_T-1)\mu_p)(\mu_p\rho_T+(2-\rho_T)K\gamma)+(\rho_T-2)b^2K^2\gamma^2e^{-2\mu_iT}\right\}\\ &+K^2\mu_p^2(\mu_p\rho_T+(2-\rho_T)K\gamma)^2-K^2\mu_p^2(\rho_T-2)^2b^2K^2\gamma^2e^{-2\mu_iT}>0. \end{aligned}$$

Thus, if (3.15) holds, then (S^*, P^*), if feasible, is locally stable. The coefficient of m^2 in (3.15) is automatically positive if $\rho_T > 1$ (the condition for feasibility of (S^*, P^*)), and therefore one parameter regime in which (3.15) is satisfied is that the parameter m be large.

For the convenience of comparison and computation, we perform the same dimensionless analysis as was carried out in Beretta and Kuang [4]. We choose the dimensionless time as $\tau = K\gamma t$. Note that one unit of the dimensionless time scale, i.e., $\tau = 1$, corresponds to $t_\tau = (1/K\gamma)$ in the original time unit. We also need the dimensionless variables

$$s = \frac{S}{\gamma}, \quad p = \frac{P}{\gamma}.$$

Below are the dimensionless parameters:

$$a = \frac{\alpha}{K\gamma}, \quad m_p = \frac{\mu_p}{K\gamma}, \quad m_i = \frac{\mu_i}{K\gamma}, \quad m_q = \frac{m}{K}.$$

Equations (2.1) have the dimensionless form

(3.16)
$$\begin{cases} \dfrac{ds(\tau)}{d\tau} = as(\tau) - as^2(\tau) - s(\tau)p(\tau), \\ \dfrac{dp(\tau)}{d\tau} = -m_pp(\tau) - m_qp^2(\tau) - s(\tau)p(\tau) + be^{-m_iT_\tau}s(\tau - T_\tau)p(\tau - T_\tau). \end{cases}$$

The values for the dimensionless parameters and the dimensionless time scale are taken from the model of Beretta and Kuang [4] (the original parameter estimates are due to Okubo). They are

(3.17)
$$a = 10, \quad m_p = 14.925,$$

with $t_\tau = (1/K\gamma) = 7.4627$ days and an average latency time $T \simeq 0.303$ days. We have no estimates for $m_i = (\mu_i/K\gamma)$, but it seems reasonable to assume it is smaller than m (since the main cause of mortality is the lysis of infected cells). We assume $m_i \simeq 0.1m_p$. In addition, we do not have an estimate on m_q. In the following computational work, we assume that $m_q \simeq 0.1$, a value close to zero. Figure 1 is the result of an application of the stability switch theory of Beretta and Kuang [5] for this set of parameters (except that we vary the latency period).

Figure 2 provides simulation results for the above set of parameters with four representative values of latency periods. Clearly Figure 2 confirms the findings embodied in Figure 1.

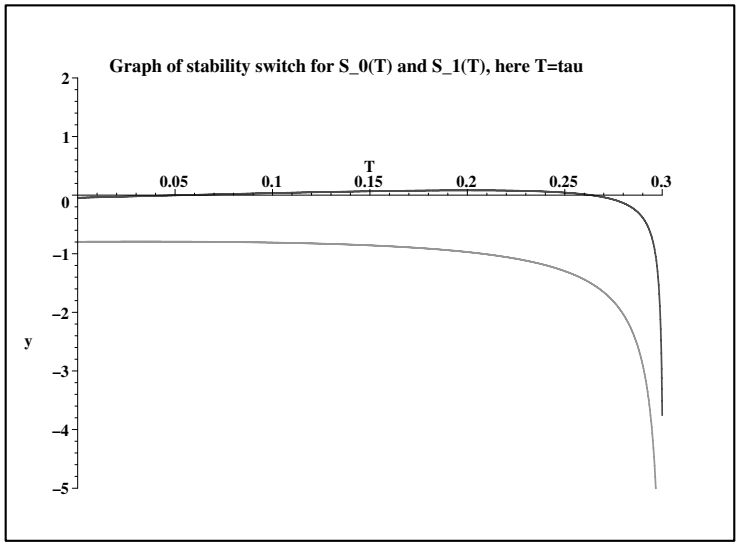

FIG. 1. *Plots of the functions* $S_0(\tau)$ *(upper curve) and* $S_1(\tau)$ *(lower curve). Parameter values used are* $\mu_p = 14.925$, $b = 75$, $\mu_i = 1.5$, $\alpha = 10$, *and* $m = 0.1$. *The equilibrium is feasible for* $0 \le \tau < \ln(b/(1+\mu_p))/\mu_i \equiv \tau_e \approx 1.033$.

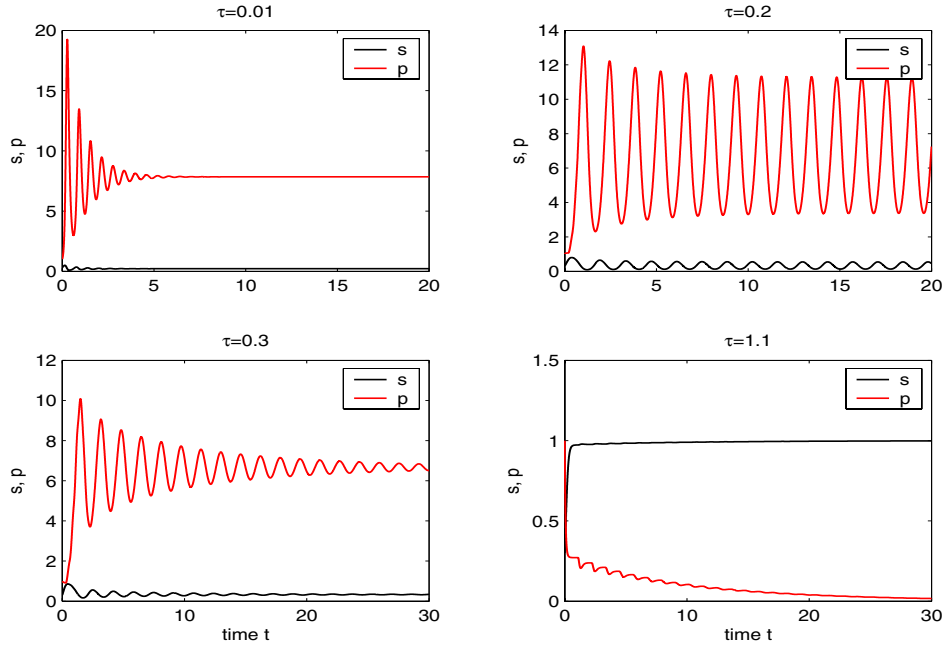

FIG. 2. *A solution of model* (3.16) *with* $s(\theta) = 0.3$, $p(\theta) = 1$, $\theta \in [-\tau, 0]$, *where* $\mu_p = 14.925$, $b = 75$, $\mu_i = 1.5$, $\alpha = 10$, $m = 0.1$, *and* τ *varies from* 0.01 *to* 1.1.

4. Diffusive models. In this section we propose some reaction-diffusion extensions of system (2.1). The main issues here are (i) what types of diffusion are appropriate, and (ii) derivation of the time-delay terms for the case when there is diffusion. The latter point is important because infectives can move during the period between infection and lysis, so that when an infective dies by lysis it will release the b copies of the virus into the water at a different location from where it originally became infected. We shall show how this can be accounted for in the modeling by including time and age as independent variables and using an age-structured model approach. The approach described here has also been used by many other investigators (see, e.g., Smith [17], So, Wu, and Zou [18], and Gourley and So [11]).

For the simplest case of Fickian diffusion, and working on an infinite one-dimensional domain $-\infty < x < \infty$, system (2.1) becomes

$$\begin{aligned} \frac{\partial S(x,t)}{\partial t} &= D_s \frac{\partial^2 S(x,t)}{\partial x^2} + \alpha S(x,t)\left(1 - \frac{S(x,t)}{\gamma}\right) - KS(x,t)P(x,t), \\ \frac{\partial P(x,t)}{\partial t} &= D_p \frac{\partial^2 P(x,t)}{\partial x^2} - \mu_p P(x,t) - mP^2(x,t) - KS(x,t)P(x,t) \\ &\quad + b \times \{\text{rate of death of infectives by lysis}\}, \end{aligned} \tag{4.1}$$

where D_s and D_p are the diffusivities of the susceptibles and the phages. The last term in the P equation reflects the fact that each time an infective dies by lysis, it releases b copies of the virus, and we must now compute an expression for the term in curly brackets. As a first step in doing so, we shall indicate how to compute the density $I(x,t)$ of infectives at (x,t). This will be achieved by using a standard age-structured model approach. Let $i(x,t,a)$ be the density of infectives at (x,t) of age a. We assume that i satisfies the von Foerster-type equation

$$\frac{\partial i}{\partial t} + \frac{\partial i}{\partial a} = D_i \frac{\partial^2 i}{\partial x^2} - \mu_i i, \tag{4.2}$$

where D_i is the diffusivity of the infectives. The age of an infective will be measured from its time of infection so that, by the law of mass action,

$$i(x,t,0) = KS(x,t)P(x,t). \tag{4.3}$$

We want to solve (4.2) subject to (4.3) to obtain $i(x,t,a)$. The total density of infectives at (x,t) will then be obtained by totaling all those of "age" less than T (since older ones will have died by lysis); thus

$$I(x,t) = \int_0^T i(x,t,a)\, da. \tag{4.4}$$

Expression (4.4) can then be used to find the rate of death of infectives by lysis which is required for model (4.1).

Let

$$i^r(x,a) = i(x,a+r,a).$$

Then

$$\frac{\partial i^r}{\partial a} = \left[\frac{\partial i}{\partial t} + \frac{\partial i}{\partial a}\right]_{t=a+r} = \left[D_i \frac{\partial^2 i}{\partial x^2} - \mu_i i\right]_{t=a+r}$$

so that

$$\frac{\partial i^r}{\partial a} = D_i \frac{\partial^2 i^r}{\partial x^2} - \mu_i i^r. \tag{4.5}$$

Applying the Fourier transform

$$\widehat{i^r}(s,a) = \mathcal{F}\{i^r(x,a);\, x \to s\} = \int_{-\infty}^{\infty} i^r(x,a) e^{-isx}\, dx$$

to (4.5) gives

$$\frac{\partial \widehat{i^r}(s,a)}{\partial a} = -(D_i s^2 + \mu_i)\widehat{i^r}(s,a),$$

the solution of which is

$$\begin{aligned}
\widehat{i^r}(s,a) &= \widehat{i^r}(s,0) e^{-(D_i s^2 + \mu_i)\, a} \\
&= \mathcal{F}\left\{KS(x,r)P(x,r);\, x \to s\right\} e^{-(D_i s^2 + \mu_i)\, a} \\
&= \mathcal{F}\left\{KS(x,r)P(x,r);\, x \to s\right\} \mathcal{F}\left\{\frac{e^{-\mu_i a}}{2\sqrt{\pi D_i a}} e^{-x^2/4D_i a};\, x \to s\right\}
\end{aligned}$$

since

$$\widehat{i^r}(s,0) = \mathcal{F}\left\{i(x,r,0);\, x \to s\right\} = \mathcal{F}\left\{KS(x,r)P(x,r);\, x \to s\right\}$$

and

$$e^{-(D_i s^2 + \mu_i)\, a} = \mathcal{F}\left\{\frac{e^{-\mu_i a}}{2\sqrt{\pi D_i a}} e^{-x^2/4D_i a};\, x \to s\right\}.$$

By the convolution theorem for Fourier transforms,

$$i(x, a+r, a) = i^r(x,a) = \int_{-\infty}^{\infty} \frac{e^{-\mu_i a}}{2\sqrt{\pi D_i a}} e^{-(x-y)^2/4D_i a} KS(y,r)P(y,r)\, dy.$$

Hence

$$i(x,t,a) = \int_{-\infty}^{\infty} \frac{e^{-\mu_i a}}{2\sqrt{\pi D_i a}} e^{-(x-y)^2/4D_i a} KS(y, t-a)P(y, t-a)\, dy,$$

and so

$$I(x,t) = \int_0^T \int_{-\infty}^{\infty} \frac{e^{-\mu_i a}}{2\sqrt{\pi D_i a}} e^{-(x-y)^2/4D_i a} KS(y, t-a)P(y, t-a)\, dy\, da$$

or, after the substitution $a = t - \tau$,

$$I(x,t) = \int_{t-T}^{t} \int_{-\infty}^{\infty} \frac{e^{-\mu_i (t-\tau)}}{2\sqrt{\pi D_i (t-\tau)}} e^{-(x-y)^2/4D_i (t-\tau)} KS(y,\tau)P(y,\tau)\, dy\, d\tau.$$

From this, we see that $I(x,t)$ obeys

$$\begin{aligned}
\frac{\partial I(x,t)}{\partial t} &= D_i \frac{\partial^2 I(x,t)}{\partial x^2} - \mu_i I(x,t) + KS(x,t)P(x,t) \\
&\quad - Ke^{-\mu_i T} \int_{-\infty}^{\infty} \frac{e^{-(x-y)^2/4D_i T}}{2\sqrt{\pi D_i T}} S(y, t-T)P(y, t-T)\, dy,
\end{aligned}$$

and it is clear that the last term of this is the rate of death of infectives by lysis. Thus, system (4.1) becomes

$$
\begin{aligned}
\frac{\partial S(x,t)}{\partial t} &= D_s \frac{\partial^2 S(x,t)}{\partial x^2} + \alpha S(x,t)\left(1 - \frac{S(x,t)}{\gamma}\right) - KS(x,t)P(x,t), \\
\frac{\partial P(x,t)}{\partial t} &= D_p \frac{\partial^2 P(x,t)}{\partial x^2} - \mu_p P(x,t) - mP^2(x,t) - KS(x,t)P(x,t) \\
&\quad + bKe^{-\mu_i T}\int_{-\infty}^{\infty} \frac{e^{-(x-y)^2/4D_i T}}{2\sqrt{\pi D_i T}} S(y,t-T)P(y,t-T)\,dy.
\end{aligned} \tag{4.6}
$$

The formulation of a simple reaction-diffusion extension of (2.1) is complete. Like (2.1), system (4.6) does not involve the infectives $I(x,t)$ directly, but it does involve the parameter D_i which measures their diffusivity.

System (4.6) is to be solved on the domain $-\infty < x < \infty$. Reaction-diffusion systems with delay are quite difficult to study, and in this paper we will not attempt a systematic study of all the dynamics of (4.6). It is of interest to investigate what (4.6) tells us about the spatial spread of a virus infection in a population of bacteria. Mathematically, it is therefore reasonable to look for traveling wave solutions of (4.6) connecting the disease-free equilibrium $(\gamma, 0)$ with the endemic equilibrium (S^*, P^*) given by (3.1), assuming (3.2) holds so that an endemic equilibrium exists. A traveling front solution connecting these equilibria can model an invasion by the virus into the domain.

A traveling wave solution is one that travels at a constant speed c without changing shape. Mathematically, it is a solution that depends on x and t through the single variable $z = x + ct$, with $c \geq 0$ without loss of generality (this gives a leftward moving wave). In terms of the variable z, system (4.6) becomes

$$
\begin{aligned}
c\,S'(z) &= D_s S''(z) + \alpha S(z)\left(1 - \frac{S(z)}{\gamma}\right) - KS(z)P(z), \\
c\,P'(z) &= D_p P''(z) - \mu_p P(z) - mP^2(z) - KS(z)P(z) \\
&\quad + bKe^{-\mu_i T}\int_{-\infty}^{\infty} \frac{e^{-y^2/4D_i T}}{2\sqrt{\pi D_i T}} S(z - cT - y)P(z - cT - y)\,dy,
\end{aligned} \tag{4.7}
$$

where prime denotes differentiation with respect to z, and we need to solve (4.7) for $S(z)$ and $P(z)$ subject to

$$
(S,P)(-\infty) = (\gamma, 0) \quad \text{and} \quad (S,P)(+\infty) = (S^*, P^*). \tag{4.8}
$$

System (4.7), (4.8) remains a difficult mathematical problem, and we have not been able to establish the existence of a solution, even with the most recently developed methods for proving existence of traveling front solutions of delay reaction-diffusion systems such as those of Wu and Zou [21]. We shall therefore assume that such a solution exists and concentrate on finding out as much as possible about the speed c at which the virus infection spreads through the spatial domain. On the further assumption that the infection spreads at the minimum speed consistent with having an ecologically realistic solution satisfying $S(z), P(z) \geq 0$ for all $z \in (-\infty, \infty)$, we shall formally calculate this minimum speed by examining the situation as $z \to -\infty$, where $P(z) \to 0$, and obtaining conditions on c which are necessary for the convergence of $P(z)$ to 0 to be nonoscillatory. Linearizing as $z \to -\infty$, when $P \to 0$ and $S \to \gamma$, the

second equation of (4.7) becomes, approximately,

$$c\,P'(z) = D_p P''(z) - \mu_p P(z) - \gamma K P(z) + b\gamma K e^{-\mu_i T} \int_{-\infty}^{\infty} \frac{e^{-y^2/4D_i T}}{2\sqrt{\pi D_i T}} P(z - cT - y)\,dy$$

and has solutions of the form $P(z) = \exp(\lambda z)$ whenever λ satisfies

$$c\lambda - D_p\lambda^2 + \mu_p + \gamma K = b\gamma K e^{-\mu_i T} e^{-\lambda c T} e^{\lambda^2 D_i T}. \tag{4.9}$$

Since this analysis is for $z \to -\infty$, it is necessary that (4.9) have at least one real positive root if $P(z)$ is to approach 0 in a nonoscillatory manner. Whether (4.9) has real positive roots or not depends on the value of c, as can be easily seen by plotting the left- and right-hand sides of (4.9) against λ and remembering that $b\gamma K e^{-\mu_i T} > \mu_p + \gamma K$, since this is the condition for the existence of (S^*, P^*). If c is very small, then (4.9) has no real positive roots, but if c is gradually increased, there is a critical value of c which we shall call $c_{\min}$ (depending on T) such that when $c = c_{\min}$ (4.9) has one positive root (a double root), and when $c > c_{\min}$ the equation has precisely two real distinct positive roots. Only traveling fronts for which $c \geq c_{\min}$ are ecologically realistic, and we assume that the virus infection travels with speed $c_{\min}$ since it is usually the case in reaction-diffusion equations that the front one actually sees is the one with minimum speed (those with $c > c_{\min}$ usually have very small basins of attraction that rule out all but special initial conditions having very specific exponential decay rates).

Our aim now is to find out more about $c_{\min}$ and its dependence on the parameters. It is not possible to find an explicit expression for $c_{\min}$, but we can find some information about it. Indeed, $c_{\min}$ is the value of c for which (4.9) has a double root λ_*. Therefore, $c_{\min}$ and the double root λ_* must satisfy the simultaneous equations

$$\begin{aligned} c_{\min}\lambda_* - D_p\lambda_*^2 + \mu_p + \gamma K &= b\gamma K \exp(-\mu_i T - \lambda_* c_{\min} T + \lambda_*^2 D_i T), \\ c_{\min} - 2D_p\lambda_* &= b\gamma K(2\lambda_* D_i T - c_{\min} T)\exp(-\mu_i T - \lambda_* c_{\min} T + \lambda_*^2 D_i T). \end{aligned} \tag{4.10}$$

From these equations, we see that λ_* must satisfy $f(\lambda) = 0$, where

$$\begin{aligned} f(\lambda) := 2D_i D_p T\lambda^3 - (2c_{\min} D_i T + c_{\min} D_p T)\lambda^2 - (2D_i T(\mu_p + \gamma K) - c_{\min}^2 T + 2D_p)\lambda \\ + c_{\min} + c_{\min} T(\mu_p + \gamma K). \end{aligned}$$

Now f is a cubic and is such that $f(0) > 0$ and

$$f\left(\frac{c_{\min} + \sqrt{c_{\min}^2 + 4D_p(\mu_p + \gamma K)}}{2D_p}\right) = -\sqrt{c_{\min}^2 + 4D_p(\mu_p + \gamma K)} < 0.$$

These facts imply that the equation $f(\lambda) = 0$ has one real negative root and two real distinct positive roots. The larger of the two positive roots cannot satisfy the first equation of (4.10). Therefore, λ_* is the smaller of the two real positive roots of $f(\lambda) = 0$. Furthermore,

$$0 < \lambda_* < \frac{c_{\min} + \sqrt{c_{\min}^2 + 4D_p(\mu_p + \gamma K)}}{2D_p}. \tag{4.11}$$

The roots of a cubic equation are difficult to write down in general terms because there are numerous cases depending on the signs of various quantities defined in terms of the coefficients in the equation. An appendix to the book by Murray [15] gives all the

details. Although the coefficients of our particular cubic equation are complicated, we know a priori that our cubic equation has only real roots, and this narrows down the possibilities considerably. In fact, if we let

$$a_* = -\frac{c_{\min}\,(2D_i + D_p)}{6D_iD_p},$$

$$\alpha_* = \frac{4c_{\min}^2 TD_i^2 - 2c_{\min}^2 TD_iD_p + c_{\min}^2 TD_p{}^2 + 12D_i^2D_pT\mu_p + 12D_i^2D_pT\gamma K + 12D_iD_p^2}{36D_i^2D_p^2T}$$

(it is easily shown that $\alpha_* > 0$),

$$N = 8c_{\min}^2 TD_i^2 + 36D_i^2D_pT\mu_p + 36D_i^2D_pT\gamma\,K + 2c_{\min}^2 TD_i\,D_p - 18D_iD_p^2 - c_{\min}^2 TD_p^2,$$

$$\beta_* = \frac{c_{\min}\,(D_p - D_i)\,N}{108D_i{}^3D_p{}^3T},$$

and

$$\phi = (1/3)\sin^{-1}\left(\frac{\beta_*}{2\alpha_*^{3/2}}\right), \qquad \phi \in [-\pi/6, \pi/6],$$

then the only root of $f(\lambda) = 0$ satisfying (4.11) can be shown to be

$$\lambda_* = 2\alpha_*^{1/2}\sin\phi - a_*. \tag{4.12}$$

Substituting λ_* into either equation of (4.10) then gives a single, but very complicated, equation determining the speed $c_{\min}$.

We define the function $g(c)$ to be the left-hand side minus the right-hand side of the second equation of (4.10), with λ_* given by (4.12) and $c_{\min}$ replaced by c. The resulting function is too complicated to write out explicitly but is easily handled in MAPLE. Of course, $c_{\min}$ solves $g(c_{\min}) = 0$ and can easily be found either by reading off the root from an accurate plot of $g(c)$ or by using MAPLE commands for finding roots numerically. Figure 3 shows a plot of $g(c)$ for typical parameter values (see caption). We investigated how $c_{\min}$ depends on the values of all the parameters, and our main observations were as follows:

- If μ_i, μ_p, or T is increased, the result is a decrease in $c_{\min}$.
- If K, γ, b, D_i, or D_p is increased, the result is an increase in $c_{\min}$.
- If the delay T is large, then the value of $c_{\min}$ is much more sensitive to D_i than to D_p. Presumably this is because virus particles with a host are transported at the diffusivity of the infectives. To illustrate this, let $T = 7$ and other parameters retain their Figure 3 values. Then $c_{\min} = 1.265$. Keeping $T = 7$, if D_i is then raised to 100, $c_{\min}$ rises to 5.623. But if instead $D_i = 5$ and D_p is raised to 100, then $c_{\min}$ rises only to 1.976.

Analytical estimates for $c_{\min}$ can be obtained from other arguments, involving consideration of the graphs of the left- and right-hand sides of (4.9) as functions of λ. When $c = c_{\min}$ these two graphs just touch, at the value λ_* just discussed. Consider first the case when $D_i < D_p$ (so the minimum of the right-hand side is to the right of the maximum of the left-hand side). In this situation the maximum of the left-hand

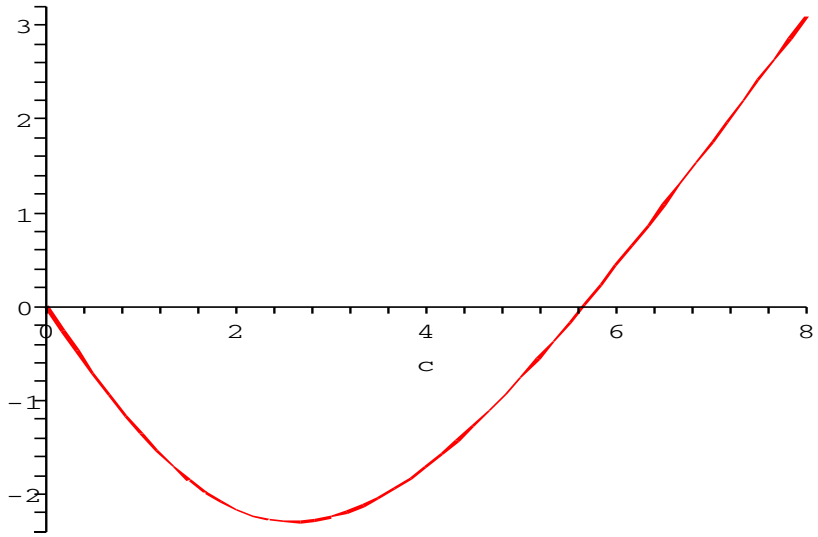

FIG. 3. *Plot of the function $g(c)$ defined in the text. The virus is predicted to spread at the speed $c_{\min} > 0$ such that $g(c_{\min}) = 0$. Parameter values used for this graph were $K = 0.134$, $\mu_i = 0.1$, $\mu_p = 2$, $T = 0.2$, $\gamma = 1$, $D_i = 5$, $D_p = 1$, and $b = 60$. For these values, $c_{\min} = 5.646$.*

side as a function of λ is $c_{\min}^2/(4D_p) + \mu_p + \gamma K$, and this must be less than the value of the right-hand side when $\lambda = 0$, which is $b\gamma K e^{-\mu_i T}$. This leads to the estimate

$$c_{\min} < 2\sqrt{D_p\{\gamma K(be^{-\mu_i T} - 1) - \mu_p\}} \quad \text{if } D_i < D_p.$$

If D_i is larger than D_p, but not too much larger, the above estimate on $c_{\min}$ will still hold.

We also carried out some numerical simulations of system (4.6) with a view to finding out whether the minimum speed $c_{\min}$ found from the linearized analysis is the speed which would be observed in practice. The question is whether the minimum speed wave is in some sense robust, attracting large classes of initial data. These questions are difficult to resolve analytically. In a recent paper, Thieme and Zhao [19] proved results on asymptotic speeds of spread for a class of nonlinear integral equations which include many reaction-diffusion models with delay, but their results do not include system (4.6). Figure 4 shows the results of a numerical simulation of system (4.6). For initial data, susceptibles S were set equal to γ throughout the domain, and some phages were introduced at $x = 0$ into an otherwise phage-free domain. Figure 4 shows how the phages spread out into the domain and the effect on the density of susceptible bacteria. Note that the traveling wave profiles are nonmonotone. Careful examination of the profiles suggests that the traveling fronts advance at the minimum speed $c_{\min}$ computed from the linearized analysis. The numerically computed front actually appears to travel at a slightly higher speed, but we are confident that this is purely a consequence of the discretization procedure. The speed varied slightly with the number of spatial grid points but seemed to approach $c_{\min}$ from above as

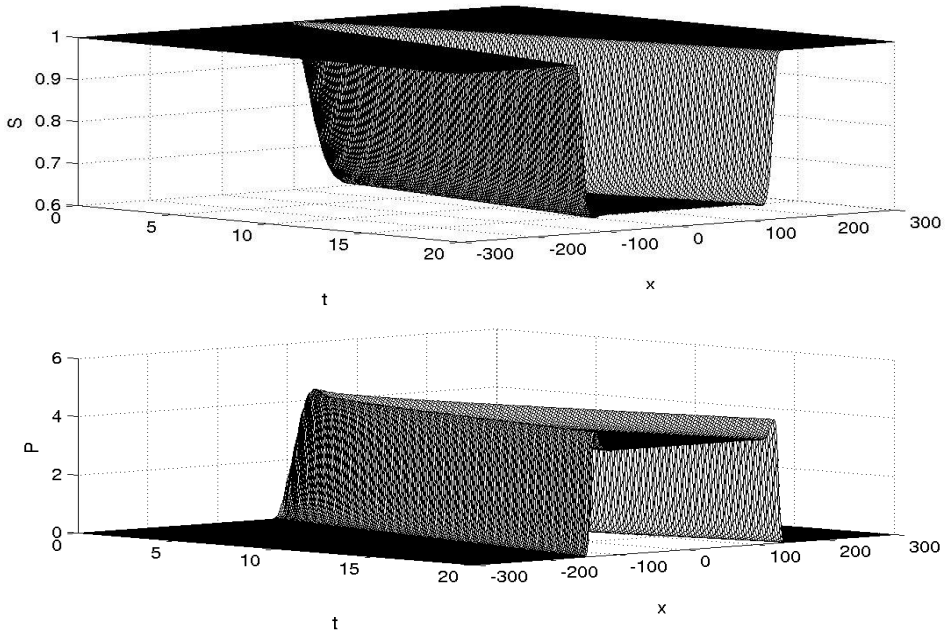

FIG. 4. *Numerical simulation of system* (4.6). *Parameter values were* $D_s = 5$, $m = 1$, $\alpha = 1.34$, *and the remaining parameters were as in Figure* 3. *The simulation suggests that the asymptotic speed of spread is* $c_{\min}$, *the minimum speed according to the linearized analysis.*

the number of grid points was increased. As a result, we suggest that the asymptotic speed of spread is indeed the speed $c_{\min}$ found from the linearized analysis.

5. Discussion. A key observation of Beretta and Kuang [2, 4] is the sensitivity of the dynamics on the phage reproduction rate b. This remains so for model (2.1). The novel observation of this work is the ultrasensitivity of the dynamics on the phage density dependent mortality rate m. This suggests that the density dependent mortality rate must be carefully measured to gain a better understanding of the bacteriophage infection dynamics in marine bacteria. Indeed, the recent work of Kuang, Fagan, and Loladze [13] contends that the predator death rate almost always positively correlates with the predator density in nature. To see this for model (2.1), we present Figures 5 and 6. Both figures use initial data and parameter values identical to those in Figure 2, except that in Figure 5, $m = 0$, while in Figure 6, $m = 0.2$.

The second novel aspect of our work is the rigorous derivation of a delay reaction-diffusion system to model the spatial spread of the virus infection and the use of this system to formally calculate the speed at which the infection spreads through a one-dimensional environment. The speed does not depend on the density dependent mortality parameter m just discussed. Unfortunately, it is not possible to find a simple expression for the speed, but it can be found from numerical computation. As we would expect, the speed depends on the diffusivity of both the infectives and the phages but is much more sensitive to the value of the former than the latter. This would be because virus replication takes place only inside a host, and therefore during replication the diffusivity of the viruses is effectively the host diffusivity D_i rather than D_p.

TWO-TIME-SCALE MARKOV CHAINS AND APPLICATIONS TO QUASI-BIRTH-DEATH QUEUES*

G. YIN† AND HANQIN ZHANG‡

Abstract. Aiming at reduction of complexity, this work is concerned with two-time-scale Markov chains and applications to quasi-birth-death queues. Asymptotic expansions of probability vectors are constructed and justified. Lumping all states of the Markov chain in each subspace into a single state, an aggregated process is shown to converge to a continuous-time Markov chain whose generator is an average with respect to the stationary measures. Then a suitably scaled sequence is shown to converge to a switching diffusion process. Extensions of the results are presented together with examples of quasi-birth-death queues.

Key words. Markov chain, singular perturbation, countable state space, asymptotic expansion, occupation measure, aggregation, switching diffusion, quasi-birth-death queue

1. Introduction.

Much effort has gone into evaluating performance measures of queueing systems in the past two decades; see, for example, [3, 22, 24, 26] and the references therein. Since exact solutions are difficult to obtain in many queueing problems, we are content with approximate solutions. To treat large-scale Markovian queueing systems, one of the most popular methods is decomposition, which consists of breaking the underlying network into smaller pieces (e.g., one station in each piece); see [3, 24, 26] among others. Although one often uses time-homogeneous Markovian models for approximating the actual systems, many queueing systems in real life are nonstationary (time-dependent); for example, the arrival and service rates in the systems are time-varying. Recently, time-inhomogeneous Markovian queueing networks have been widely used to model telecommunication systems; see [5]. Developing computational methods and approximation techniques for these quantities involved in *time-inhomogeneous* queueing problems has long been regarded as a challenging task (see [14] and [20]); see also [12, 18] and the references therein for earlier effort in this direction.

The motivation of our study stems from the recent advances in understanding asymptotic properties of singularly perturbed Markov chains aimed at reducing of complexity. We began our investigation in [13]. By combining matched asymptotic expansions and stochastic analysis, our effort was subsequently extended to treat more complex models and applications in control and optimization; see [29, 30]. These results are about Markov chains with finite-state spaces, and they are applicable to queues with a finite number of waiting rooms or finite capacity; see also [20] for a related work. Continuing our effort initiated in [28], using a model similar to that

presented in [26] as our starting point, we consider queueing systems in which the generator of the queue length process includes both a fast varying part and a slowly changing part reflecting both strong and weak interactions of states belonging to different irreducible classes. Compared with the methods used in [3, 24, 26], we adopt a singular perturbation approach via time-scale separation to model the different transition intensities. In [28], treating countable-state-space Markov chains, one of the main assumptions used is that the underlying Markov chain is irreducible. In the context of queueing theory, it basically corresponds to the consideration of a single queue. The goal of this paper is to treat multistation queueing networks and to develop decomposition and aggregation methods for queueing network problems. Motivated by queueing networks involving quasi-birth-death processes, we start with decomposition by splitting the entire state space into a number of subspaces. Usually, the transitions within each subspace are much more intensive and frequent than those among different subspaces. We introduce a small parameter $\varepsilon > 0$ to highlight the different rates of transition intensities. Then we proceed to derive the asymptotic expansions of the probability distribution of the queue length. By lumping all the states in each subspace into a single state, we obtain a sequence of aggregated processes. We demonstrate that this sequence converges to a Markov chain. Furthermore, we obtain limit results for suitably scaled sequences.

The rest of the paper is arranged as follows. Section 2 begins with the precise formulation of the problem. Section 3 provides asymptotic expansions. A sequence of occupation measures is defined in section 4; its probabilistic properties, including mean square estimate, aggregation, and switching diffusion limit of a suitably scaled sequence, are examined. Section 5 presents extensions of results and queueing examples. Finally, an appendix is provided to include some technical complements.

2. Formulation. Working with a finite time horizon $t \in [0, T]$ for some $T > 0$, our focus is on time-inhomogeneous Markov chains. Suppose that $\beta(t)$ is a continuous-time Markov chain with countable state space $\mathbb{N} = \{1, 2, \ldots\}$. An infinite dimensional matrix-valued function $Q(t) = (q^{ij}(t))$ defined on $[0, T]$ is a generator of the Markov chain $\beta(t)$ if $q^{ij}(\cdot)$ is Borel measurable and bounded for each $i, j \in \mathbb{N}$, $q^{ij}(t) \geq 0$ for all $i \neq j$, $\sum_{j=1}^{\infty} q^{ij}(t) = 0$ for all $i \in \mathbb{N}$, and for any bounded and Borel-measurable function $\widetilde{g}(\cdot)$ defined on $\mathbb{N}$, $\widetilde{g}(\beta(t)) - \int_0^t Q(s)\widetilde{g}(\cdot)(\beta(s))ds$ is a martingale, where

$$Q(t)\widetilde{g}(\cdot)(i) = \sum_{j=1}^{\infty} q^{ij}(t)\widetilde{g}(j) \quad \text{for each} \quad i \in \mathbb{N}. \tag{2.1}$$

Throughout the paper, we use K to denote a generic positive constant. The conventions $K + K = K$ and $KK = K$ are used for simplicity. We use $\mathbb{1}_{m_0}$ and $\mathbb{1}$ to denote an m_0-dimensional and infinite dimensional column vector with all components being 1. For a vector z and a matrix H, we use z' and H' to denote their transposes, and we use z^i and h^{ij} to denote the ith component of z and the ijth entry of $H = (h^{ij})$, respectively. For a given matrix $H = (h^{ij})_{\infty \times \infty}$ with infinite columns and infinite rows, H_a is an augmented matrix given by $H_a = (H \vdots \mathbb{1})$. In addition, we use a subscript to index a sequence.

A Markov chain $\beta(t)$ or its generator $Q(t)$ is weakly irreducible, if the system of equations $g(t)Q_a(t) = (0 \vdots 1)$ has a unique solution $g(t) = (g^i(t))$ with $g^i(t) \geq 0$ for each $i \in \mathbb{N}$, where $0 = (0, 0, \ldots)$ is an infinite dimensional 0 vector. The unique nonnegative solution is termed a quasi-stationary distribution. (An equivalent way to write the system of equations in the above definition is $g(t)Q(t) = 0$, $g(t)\mathbb{1} = 1$.) The

definition is an extension of the usual notion of irreducibility, and the weak irreducibility given in [13] for finite-state Markov chains. Compared with the usual definition of irreducibility, it deals with time-varying generators and allows some components of the quasi-stationary distribution to be 0.

Suppose that the Markovian queueing network has n_0 ($n_0 < \infty$) interconnected stations. Consider a vector-valued queue-length process taking values in $\mathbb{N}^{n_0} = \mathbb{N} \times \mathbb{N} \times \cdots \times \mathbb{N}_{n_0}$ (an n_0-fold product). We use $\alpha(\cdot)$, a continuous-time Markov chain, to model the queue length of the queueing network. Suppose that $\mathbb{N}^{n_0}$ can be divided into l subsets. Within each subset, the transitions (such as arrivals and departures of customers, etc.) take place an order of magnitude more frequent than that of among different subsets. To highlight this contrast, we introduce a small parameter $\varepsilon > 0$. Thus the continuous-time Markov chain is ε-dependent, i.e., $\alpha(\cdot) = \alpha_\varepsilon(\cdot)$. For $t \in [0, T]$, assume that the generator of the Markov chain $\alpha_\varepsilon(t)$ is given by

$$Q_\varepsilon(t) = \frac{A(t)}{\varepsilon} + B(t), \quad \text{with } A(t) = \operatorname{diag}(A^1(t), \ldots, A^l(t)), \tag{2.2}$$

where $A(t)$, $B(t)$, and $A^i(t)$ (for $i = 1, \ldots, l$) are all generators of certain countable-state space Markov chains, and $\operatorname{diag}(A^1(t), \ldots, A^l(t))$ denotes a block diagonal matrix, each of the entries of which has appropriate dimension. Note that $B(t)$ is a generator and there is no need to assume it has the same diagonal matrix form as that of $A(t)$.

There is a certain hierarchy in the underlying network. Within each subset, one observes detailed variations of the networks such as arrivals and services of customers, etc., whereas at an upper system management level, instead of these variations, one observes the transitions among different subsets. Thus from an upper management point of view, by lumping all the states in each subspace into a single one, the system may be regarded as if it were a queue with finite waiting rooms (l rooms). Nevertheless, the aggregated process is generally non-Markovian. Fortunately, as will be shown, the aggregated process converges weakly to a limit process that is a finite-state Markovian queue. The significance of such a result is that in lieu of examining the detailed variations, one can study the aggregated process.

To reflect the decomposition in the network, write the state space of the queueing network as $\mathcal{M} = \mathcal{M}_1 \cup \mathcal{M}_2 \cdots \cup \mathcal{M}_l$, where $\mathcal{M}_i = \{s_{i1}, s_{i2}, \ldots, \}$ for $i = 1, \ldots, l$. Following our approach for singularly perturbed Markov chains with finite-state spaces, we construct matched asymptotic expansions of the probability vector

$$p_\varepsilon(t) = (p_\varepsilon^{11}(t), \ldots, p_\varepsilon^{21}(t), \ldots, \ldots, p_\varepsilon^{l1}(t), \ldots), \quad p_\varepsilon^{ij}(t) = P(\alpha_\varepsilon(t) = s_{ij}). \tag{2.3}$$

For future use, partition an infinite dimensional vector v as $v = (v^1, \ldots, v^l)$ with $v^i = (v^{i1}, v^{i2}, \ldots)$. That is, v^i is an infinite dimensional vector corresponding to the subspace $\mathcal{M}_i$. Since we are dealing with countable state space Markov chains, we work with an infinite dimensional vector space. It is natural to consider the spaces $\ell_1 = \{(v^1, \ldots, v^l) : 1 \le i \le l,\ v^{ik} \in \mathbb{R} \text{ for each } k \in \mathbb{N}, \text{ and } \sum_{i=1}^{l} \sum_{k=1}^{\infty} |v^{ik}| < \infty\}$, $\ell_\infty = \{(v^1, \ldots, v^l)\colon 1 \le i \le l,\ v^{ik} \in \mathbb{R} \text{ for each } k \in \mathbb{N}, \text{ and } \sup_{1 \le i \le l} \sup_{1 \le k < \infty} |v^{ik}| < \infty\}$, equipped with $||v||_1 = \sum_{i=1}^{l} \sum_{k=1}^{\infty} |v^{ik}|$ and $||v||_\infty = \sup_{1 \le i \le l} \sup_{1 \le k < \infty} |v^{ik}|$, respectively; see [9, p. 11]. For a linear operator A defined on these spaces, we use its induced norm $||A|| = \sup_{||x||=1} ||Ax||$, where $||\cdot||$ is either norm $||\cdot||_1$ or $||\cdot||_\infty$. It is plain that $p_\varepsilon(t) \in \ell_1$ and that for each i ($1 \le i \le l$) and each k ($1 \le k < \infty$), $p_\varepsilon^{ik}(t) \ge 0$, and $\sum_{i=1}^{l} \sum_{k=1}^{\infty} p_\varepsilon^{ik}(t) = 1$. It is well known that $p_\varepsilon(t)$ satisfies the forward equation

$$\dot{p}_\varepsilon(t) = p_\varepsilon(t) Q_\varepsilon(t), \qquad p_\varepsilon(0) = p(0), \tag{2.4}$$

such that $p^{ik}(0) \geq 0$ and $\sum_{i=1}^{l} \sum_{k=1}^{\infty} p^{ik}(0) = 1$.

3. Asymptotic expansions. Following the approach of singular perturbation methods, we derive uniform (in the time variable t) asymptotic expansions of the probability vector as well as that of the transition probability matrices of the queue length processes. To proceed, we need the following conditions.

(A1) For each $t \in [0,T]$ and each $i = 1, \ldots, l$, $A^i(t)$ is weakly irreducible. There exists an integer n such that $(d^{n+2}/dt^{n+2})A^i(\cdot) \in \text{Lip}[0,T]$ and (d^{n+1}/dt^{n+1}) $B(\cdot) \in \text{Lip}[0,T]$, where $\text{Lip}[0,T]$ denotes the class of functions defined on $[0,T]$ that are Lipschitzian.

(A2) There is a $\kappa > 0$ such that for any real number $\tau > 0$,

$$\big|\big|\exp(A(0)\tau) - \text{diag}(\mathbb{1}\nu^1(0), \ldots, \mathbb{1}\nu^l(0))\big|\big|_\infty \leq K \exp(-\kappa\tau), \tag{3.1}$$

where $\nu^i(t) = (\nu^{i1}(t), \nu^{i2}(t), \ldots)$ is the quasi-stationary distribution corresponding to the generator $A^i(t)$.

Remark 3.1. From (A1) and the definition of weak irreducibility, $\nu^i(t)A^i_a(t) = (0 \vdots 1)$ has a unique solution. Furthermore, $\nu^i(t) = (0 \vdots 1)(A^i_a(t))'(A^i_a(t)(A^i_a(t))')^{-1}$. (A2) is a Doeblin-type condition. A condition in a slightly different form is given in [7, p. 192]. We will obtain the asymptotic expansions in two steps. The first step is a formal construction in which we (see [4, 10, 25] and [11, 13] among others) find the outer expansions and the initial layer corrections. The second step involves validating the formal expansions and deriving the desired error estimates.

3.1. Formal expansions. We seek matched asymptotic expansions of the form $\mathcal{O}_{\varepsilon,n}(t) + \mathcal{I}_{\varepsilon,n}(t) = \sum_{i=0}^{n} \varepsilon^i \phi_i(t) + \sum_{i=0}^{n} \varepsilon^i \psi_i(t/\varepsilon)$. For technical reasons, which will become clear in what follows, to justify the validity of the expansions, we also need to compute $\phi_{n+1}(t)$ and $\psi_{n+1}(t/\varepsilon)$. To make sure that the matching condition is satisfied, we use $\mathcal{O}_{\varepsilon,n+1}(0) + \mathcal{I}_{\varepsilon,n+1}(0) = p(0)$ or, more specifically, $\phi_0(0) + \psi_0(0) = p(0)$, $\phi_k(0) + \psi_k(0) = 0$ for $1 \leq k \leq n+1$. Our approach is based on constructions of the sequences $\{\phi_i(t)\}$ and $\{\psi_i(t/\varepsilon)\}$.

Substituting $\mathcal{O}_{\varepsilon,n+1}(t)$ into (2.4) and comparing coefficients of powers of ε^k, we obtain

$$\phi_0(t)A(t) = 0, \qquad \phi_k(t)A(t) = \dot{\phi}_{k-1}(t) - \phi_{k-1}(t)B(t), \quad 1 \leq k \leq n+1. \tag{3.2}$$

The outer expansions give us satisfactory approximation for $t > 0$ away from an initial layer of the order $O(\varepsilon)$, but it does not satisfy the initial condition and breaks down for sufficiently small t. To compensate, introduce a fast time variable $\tau = t/\varepsilon$. By the Lipschitz continuity given in (A1), taking Taylor expansions of $A(\varepsilon\tau)$ and $B(\varepsilon\tau)$ about 0 yields $A(\varepsilon\tau) = \sum_{i=0}^{n+1} \frac{(\varepsilon\tau)^i}{i!} \frac{d^iA(0)}{dt^i} + O((\varepsilon\tau)^{n+2})$, $\varepsilon B(\varepsilon\tau) = \sum_{i=0}^{n} \varepsilon \frac{(\varepsilon\tau)^i}{i!} \frac{d^iB(0)}{dt^i} + O((\varepsilon\tau)^{n+2})$. Substituting $\mathcal{I}_{\varepsilon,n+1}(t)$ into (2.4), using the above Taylor expansions of $A(t)$ and $B(t)$, and comparing powers of ε^i, we obtain the equations satisfied by the initial layer terms. We have $\psi_0(0) = p(0) - \phi_0(0)$, $\psi_k(0) = -\phi_k(0)$, and

$$\begin{aligned} &\frac{d\psi_0(\tau)}{d\tau} = \psi_0(\tau)A(0), \quad \frac{d\psi_k(\tau)}{d\tau} = \psi_k(\tau)A(0) + r_k(\tau), \quad 1 \leq k \leq n+1, \\ &r_k(\tau) = \sum_{i=0}^{k-1} \psi_{k-i-1}(\tau)\Big(\frac{\tau^{i+1}}{(i+1)!}\frac{d^{i+1}A(0)}{dt^{i+1}} + \frac{\tau^i}{i!}\frac{d^iB(0)}{dt^i}\Big), \ 1 \leq k \leq n+1. \end{aligned} \tag{3.3}$$

In [28], in which $A(t)$ consists of only one block, the outer expansions and initial layers can be obtained separately. Here, the constructions of $\{\phi_k(t)\}$ have to be done

in conjunction with the initial layer corrections. The equations in (3.3) together with the initial data are known as abstract Cauchy problems; see [17, p. 21]. It is well known that $\{\exp(A(0)\tau)\}$ is a uniformly continuous semigroup (see [17, 23]). With $\psi_k(0)$ to be determined, the representation of the solutions of (3.3) is given by

$$\begin{aligned}\psi_0(\tau) &= (p(0) - \phi_0(0))\exp(A(0)\tau),\\ \psi_k(\tau) &= \psi_k(0)\exp(A(0)\tau) + \int_0^\tau r_k(s)\exp(A(0)(\tau - s))ds,\ 1 \le k \le n+1.\end{aligned} \tag{3.4}$$

Step 1. Determine $\boldsymbol{\phi_0(t)}$ and $\boldsymbol{\psi_0(\tau)}$. We begin with the first equation in (3.2). Using the partitioned vector form introduced right after (2.3), we obtain $\phi_0^i(t)A^i(t) = 0$ for each $i = 1, \ldots, l$. These equations are not uniquely solvable since $A^i(t)$ have a 0 eigenvalue. However, by attaching $\sum_{j=1}^\infty \phi_0^{ij}(t) = \theta_0^i(t)$ to the equations, the resulting system of equations has a unique solution thanks to the weak irreducibility of $A^i(t)$. Thus, $\phi_0^i(t)$ must be proportional to $\nu^i(t)$, the quasi-stationary distribution corresponding to $A^i(t)$. That is, $\phi_0^i(t) = \theta_0^i(t)\nu^i(t)$, where $\theta_0^i(t) \in \mathbb{R}$ is to be determined. Define

$$\theta_0(t) = (\theta_0^1(t), \ldots, \theta_0^l(t)) \in \mathbb{R}^{1\times l},\ \widetilde{\mathbb{1}} = \operatorname{diag}(\mathbb{1}, \mathbb{1}, \ldots, \mathbb{1}),\ \nu(t) = \operatorname{diag}(\nu^1(t), \ldots, \nu^l(t)). \tag{3.5}$$

It is immediate that $A(t)$ is orthogonal to $\widetilde{\mathbb{1}}$ (i.e., $A(t)\widetilde{\mathbb{1}} = 0$) and $\phi_0(t) = \theta_0(t)\nu(t)$. For the equation with $k = 1$ in (3.2), multiplying from the right by $\widetilde{\mathbb{1}}$ leads to

$$\dot\theta_0(t) = \theta_0(t)\overline{B}(t), \quad \overline{B}(t) = \nu(t)B(t)\widetilde{\mathbb{1}}, \tag{3.6}$$

so $\overline{B}(t)$ is an average of $B(t)$ with respect to $\nu^1(t), \ldots, \nu^l(t)$. Note that $\overline{B}(t)$ is an $l \times l$ matrix-valued function. Note also that (3.6) is a linear system of differential equations and that it has a unique solution for each initial condition. Choose $\theta_0(0) = p(0)\widetilde{\mathbb{1}}$. Then the solution of (3.6) is uniquely determined. The $\phi_0^i(t)$ has the interpretation of total probability.

Concerning the initial layer correction $\psi_0(\tau)$, the solution is given by the first equation in (3.4) and is uniquely solved. We claim that $||\psi_0(\tau)||_\infty \le K\exp(-\kappa\tau)$ for some $\kappa > 0$ and $K > 0$. To prove this, note that $\widetilde{\mathbb{1}}\nu(0) = \operatorname{diag}(\mathbb{1}\nu^1(0), \ldots, \mathbb{1}\nu^l(0))$ and

$$\psi_0(0)\widetilde{\mathbb{1}}\nu(0) = [p(0) - \phi_0(0)]\widetilde{\mathbb{1}}\nu(0) = (0, 0, \ldots), \tag{3.7}$$

where $\phi_0(0) = \theta_0(0)\nu(0)$, $\phi_0(0)\widetilde{\mathbb{1}} = \theta_0(0)$, and $\theta_0(0) = p(0)\widetilde{\mathbb{1}}$ are used. By virtue of the orthogonality and (A2), $||\psi_0(\tau)||_\infty = ||\psi_0(0)(\exp(A(0)\tau) - \widetilde{\mathbb{1}}\nu(0))||_\infty \le K\exp(-\kappa\tau)$. To determine $\phi_i(t)$ and $\psi_i(t)$ for $i \ge 1$, we need the following lemma.

LEMMA 3.2. *Suppose that $Q(t)$ is a generator of a countable-state-space Markov chain such that $Q(t)$ is weakly irreducible for each $t \in [0, T]$ and $(d^{n+1}/dt^{n+1})Q(\cdot) \in Lip[0, T]$. Denote $\widetilde{Q}(t) = Q_a(t)Q_a'(t)$. Then for $k = 1, \ldots, n+1$, $(d^k/dt^k)\widetilde{Q}^{-1}(t)$ exists and belongs to C^{n+1-k} (the class of functions that are $(n+1-k)$-times continuously differentiable).*

Proof. Since $\widetilde{Q}(t)\widetilde{Q}^{-1}(t) = I$, differentiating both sides of the above equation leads to

$$\frac{d\widetilde{Q}^{-1}(t)}{dt} = -\widetilde{Q}^{-1}(t)\frac{d\widetilde{Q}(t)}{dt}\widetilde{Q}^{-1}(t), \tag{3.8}$$

so $\widetilde{Q}^{-1}(\cdot)$ is differentiable. Repeatedly differentiating equation (3.8) yields the desired result. ∎

Step 2. Determine $\phi_1(t)$ and $\psi_1(\tau)$. Lemma 3.2 and Remark 3.1 imply that $\phi_0(\cdot)$ is differentiable and is a function of class C^{n+1}. We proceed to determine $\phi_1(t)$ and $\psi_1(\tau)$. Note that the equation with $k=1$ in (3.2) is a nonhomogeneous equation whose right-hand side $\widetilde{\phi}_0(t) \stackrel{\text{def}}{=} \dot{\phi}_0(t) - \phi_0(t)B(t)$ is a known function since $\phi_0(t)$ has been found. Using (3.6), $[\dot{\phi}_0(t)-\phi_0(t)B(t)]\widetilde{\mathbb{1}} = \dot{\theta}_0(t)-\theta_0(t)\nu(t)B(t)\widetilde{\mathbb{1}} = (0,0,\ldots)$, and the Fredholm alternative yields that the equation with $k=1$ in (3.2) has a particular solution $\phi_{1,p}(t)$ being orthogonal to $\widetilde{\mathbb{1}}$. Assume the solution of $\phi_1(t)A(t) = \widetilde{\phi}_0(t)$ to be of the form $\phi_1(t) = \theta_1(t)\nu(t)+\phi_{1,p}(t)$. Since $\phi_{1,p}(t)$ is orthogonal to $\widetilde{\mathbb{1}}$, postmultiplying the equation with $k=2$ in (3.2) by $\widetilde{\mathbb{1}}$ leads to

$$\dot{\theta}_1(t) = \theta_1(t)\overline{B}(t) + \phi_{1,p}(t)B(t)\widetilde{\mathbb{1}}. \tag{3.9}$$

Once the initial condition is specified, (3.9) is uniquely solved. The initial condition $\theta_1(0)$ has to come from the initial layer correction term. With the selection of $\psi_1(0) = -\phi_1(0)$, by (3.4) with $k=1$, the unique solution is given by

$$\begin{aligned}\psi_1(\tau) = {} & \psi_1(0)\exp(A(0)\tau) + \int_0^\tau \psi_0(s)\exp(A(0)s)B(0)\exp(A(0)(\tau-s))ds \\ & + \int_0^\tau s\psi_0(s)\exp(A(0)s)\frac{dA(0)}{dt}\exp(A(0)(\tau-s))ds.\end{aligned} \tag{3.10}$$

By the exponential decay of $\psi_0(\tau)$, $\left|\left|\int_0^\tau \psi_0(s)\exp(A(0)s)ds\right|\right|_\infty = \int_0^\infty ||\psi_0(s)||_\infty\, ds < \infty$. Denote $\overline{\psi}_0 \stackrel{\text{def}}{=} \int_0^\infty \psi_0(s)\exp(A(0)s)dsB(0)$. Then from (A2),

$$\begin{aligned}\lim_{\tau\to\infty}\psi_1(0)\exp(A(0)\tau) &= \lim_{\tau\to\infty}\big(\psi_1(0)[\exp(A(0)\tau) - \widetilde{\mathbb{1}}\nu(0)] + \psi_1(0)\widetilde{\mathbb{1}}\nu(0)\big) \\ &= \psi_1(0)\widetilde{\mathbb{1}}\nu(0), \\ \lim_{\tau\to\infty}\int_0^\tau \psi_0(s)\exp(A(0)s)B(0)\exp(A(0)(\tau-s))ds &= \overline{\psi}_0\widetilde{\mathbb{1}}\nu(0).\end{aligned}$$

Note that

$$A(t)\widetilde{\mathbb{1}} = 0, \quad \frac{d^kA(t)}{dt^k}\widetilde{\mathbb{1}} = \frac{d^kA(t)\widetilde{\mathbb{1}}}{dt^k} = 0, \quad k = 1,\ldots,n+1. \tag{3.11}$$

Using the orthogonality (see (3.7) and (3.11)), we obtain

$$\left|\left|\int_0^\tau s\psi_0(s)\exp(A(0)s)\frac{dA(0)}{dt}\exp(A(0)(\tau-s))ds\right|\right|_\infty \le K\tau^2\exp(-\kappa\tau). \tag{3.12}$$

By demanding $\lim_{\tau\to\infty}\psi_1(\tau) = 0$, taking the limit as $\tau\to\infty$ in (3.10), and using the estimates above, we arrive at

$$\psi_1(0)\widetilde{\mathbb{1}}\nu(0) + \overline{\psi}_0\widetilde{\mathbb{1}}\nu(0) = 0. \tag{3.13}$$

An important observation indicates that there are only l unknowns in (3.13). Using the notation of partitioned vector given after (2.3), $\psi_1(0) = (\psi_1^1(0),\psi_1^2(0),\ldots,\psi_1^l(0))$ and $\overline{\psi}_0 = (\overline{\psi}_0^1,\overline{\psi}_0^2,\ldots,\overline{\psi}_0^l)$, the solution is given by $\psi_1^i(0)\mathbb{1} = -\overline{\psi}_0^i\mathbb{1}$, $i=1,\ldots,l$. Since $\psi_1(0)$ must be chosen so that $\phi_1(0)+\psi_1(0) = 0$, we obtain $\theta_1^i(0) = \overline{\psi}_0^i\mathbb{1}, i = 1,\ldots,l$. Thus both $\phi_1(t)$ and $\psi_1(\tau)$ have been determined. We claim that $\psi_1(\tau)$

decays exponentially fast. By adding and subtracting appropriate terms,

$$\begin{aligned}\psi_1(\tau) &= \psi_1(0)[\exp(A(0)\tau) - \widetilde{\mathbb{1}}\nu(0)] - \int_\tau^\infty \psi_0(s)\exp(A(0)s)dsB(0)\widetilde{\mathbb{1}}\nu(0)\\ &\quad + \psi_1(0)\widetilde{\mathbb{1}}\nu(0) + \int_0^\infty \psi_0(s)\exp(A(0)s)dsB(0)\widetilde{\mathbb{1}}\nu(0)\\ &\quad + \int_0^\tau \psi_0(s)\exp(A(0)s)B(0)[\exp(A(0)(\tau-s)) - \widetilde{\mathbb{1}}\nu(0)]ds\\ &\quad + \int_0^\tau s\psi_0(s)\exp(A(0)s)\frac{dA(0)}{dt}\exp(A(0)(\tau-s))ds.\end{aligned} \tag{3.14}$$

By (A2),

$$\begin{aligned}&\Big|\Big|\psi_1(0)[\exp(A(0)\tau) - \widetilde{\mathbb{1}}\nu(0)]\Big|\Big|_\infty \le K\exp(-\kappa\tau), \quad \text{and}\\ &\Big|\Big|\int_0^\tau \psi_0(s)\exp(A(0)s)B(0)[\exp(A(0)(\tau-s)) - \widetilde{\mathbb{1}}\nu(0)]ds\Big|\Big|_\infty\\ &\qquad\qquad \le K(1+\tau)\exp(-\kappa\tau).\end{aligned} \tag{3.15}$$

It then follows from the above estimates, $||\psi_1(\tau)||_\infty \le K(1+\tau+\tau^2)\exp(-\kappa\tau) \le K\exp(-\kappa_0\tau)$, for some $0 < \kappa_0 < \kappa$.

Step 3. Determine $\boldsymbol{\phi_k(t)}$ and $\boldsymbol{\psi_k(\tau)}$, for $\boldsymbol{1 < k \le n+1}$. We apply the same method for finding $\phi_1(t)$ and $\psi_1(\tau)$ to determine $\phi_k(t)$ and $\psi_k(\tau)$. For each $i = 1,\dots,l$, assume $\phi_k^i(t)$ is of the form $\phi_k^i(t) = \theta_k^i(t)\nu^i(t) + \phi_{k,p}^i(t)$, where $\phi_{k,p}(t) = (\phi_{k,p}^1(t),\dots,\phi_{k,p}^l(t))$ is a particular solution of the equation $\phi_k(t)A(t) = \dot\phi_{k-1}(t) - \phi_{k-1}(t)B(t)$, and $\phi_{k,p}(t)$ is orthogonal to $\widetilde{\mathbb{1}}$. We proceed to determine $\theta_k(t) = (\theta_k^i(t)) \in \mathbb{R}^{1\times l}$. By substitution, similar to (3.9), it is easily seen that $\theta_k(t)$ satisfies the differential equation

$$\dot\theta_k(t) = \theta_k(t)\overline{B}(t) + \phi_{k,p}(t)B(t)\widetilde{\mathbb{1}}. \tag{3.16}$$

To determine the initial condition $\theta_k(0)$, the definition of $r_k(\tau)$ in (3.4) gives us

$$\begin{aligned}\psi_k(\tau) &= \psi_k(0)\exp(A(0)\tau) + \int_0^\tau \sum_{j=0}^{k-1}\psi_{k-j-1}(s)\\ &\quad \times\Big(\frac{\tau^{j+1}}{(j+1)!}\frac{d^{j+1}A(0)}{dt^{j+1}} + \frac{\tau^j}{j!}\frac{d^jB(0)}{dt^j}\Big)\exp(A(0)(\tau-s))ds.\end{aligned} \tag{3.17}$$

Using the same techniques as that for $\theta_1(0)$, we obtain $\theta_k(0)$ and uniquely determine both $\phi_k(t)$ and $\psi_k(\tau)$. We then verify the exponential decay property of $\psi_k(\tau)$. The procedure is the same as for that of $\psi_1(\tau)$; we record the result as follows.

THEOREM 3.3. *Assume* (A1) *and* (A2). *Then the following assertions hold:*

(a) *The sequence $\{\phi_k(t)\}$ can be constructed by solving the system of equations*

$$\phi_k(t)A(t) = \dot\phi_{k-1}(t) - \phi_{k-1}(t)B(t) \stackrel{\text{def}}{=} \widetilde{\phi}_{k-1}(t) \tag{3.18}$$

for $k = 1,2,\dots,n$. The solution is $\phi_k(t) = \theta_k(t)\nu(t) + \phi_{k,p}(t)$, where $\phi_{k,p}(t)$ is a particular solution of (3.18)*, which is orthogonal to $\widetilde{\mathbb{1}}$, and $\theta_k(t)$ satisfies $\dot\theta_k(t) = \theta_k(t)\overline{B}(t) + \phi_{k,p}(t)B(t)\widetilde{\mathbb{1}}$.*

(b) *Find $\psi_k^i(0)\mathbb{1}$ from $\psi_k(0)\widetilde{\mathbb{1}}\nu(0) = -(\sum_{j=0}^{k-1}\int_0^\infty \frac{s^j}{j!}\psi_{k-j-1}(s)ds\frac{d^jA(0)}{dt^j})\widetilde{\mathbb{1}}\nu(0) \stackrel{\text{def}}{=} -\overline{\psi}_{k-1}\widetilde{\mathbb{1}}\nu(0)$. Choose $\theta_k^i(0) = -\psi_k^i(0)\mathbb{1} = \overline{\psi}_{k-1}^i\mathbb{1}$ for $i = 1,\dots,l$. Choose $\psi_k(0) = -\phi_k(0)$.*

(c) *For $k = 0, 1, \ldots, n+1$, $\theta_k(\cdot)$ and $\phi_k(\cdot)$ are $(n+1-k)$-times continuously differentiable on $[0, T]$; there exists a $\kappa_0 > 0$ such that $||\psi_k(\tau)||_\infty \le K \exp(-\kappa_0 \tau)$.*

3.2. Asymptotic justification. In this section, we obtain the desired error bounds and show that the asymptotic expansions hold uniformly in $t \in [0, T]$. Define an operator $\mathcal{L}_\varepsilon$ as

$$\mathcal{L}_\varepsilon f(t) = \varepsilon \frac{df(t)}{dt} - f(t)A(t) - \varepsilon f(t)B(t) \tag{3.19}$$

for a suitable smooth function $f(\cdot)$. First let us establish a lemma.

LEMMA 3.4. *Consider $\mathcal{L}_\varepsilon v_\varepsilon(t) = \Delta_{\varepsilon,k}(t)$, $v_\varepsilon(0) = 0$, with $\sup_{t\in[0,T]} ||\Delta_{\varepsilon,k}(t)||_\infty = O(\varepsilon^{k+1})$ for some k with $0 \le k \le n+1$. Then $\sup_{t\in[0,T]} ||v_\varepsilon(t)||_\infty = O(\varepsilon^k)$.*

Proof. Note that the initial value problem given above is a time-dependent abstract Cauchy problem or an evolution equation. The solution is given by $v_\varepsilon(t) = \frac{1}{\varepsilon}\int_0^t \Delta_{\varepsilon,k}(s) X_\varepsilon(t,s) ds$, where $X_\varepsilon(t,s)$ is a fundamental solution or an evolution operator. In fact (see Ladas and Lakshmikantham [17, p. 56]), $X_\varepsilon(t,s)$ is an operator-valued function with values in $L(\ell_1)$; the space of bounded linear operators, defined on ℓ_1 and strongly continuous in t, s for $0 \le s \le t \le T$ such that $(\partial/\partial t)X_\varepsilon(t,s)$ exists in strong topology of ℓ_1; $(\partial/\partial t)X_\varepsilon(t,s) \in L(\ell_1)$ for $0 \le s \le t \le T$ and $(\partial/\partial t)X_\varepsilon(t,s)$ is strongly continuous in t; the range of $X_\varepsilon(t,s)$ is in the domain of $Q_\varepsilon(t)$; and it satisfies the homogeneous problem $\varepsilon\frac{\partial X_\varepsilon(t,s)}{\partial t} - X_\varepsilon(t,s)A(t) - \varepsilon X_\varepsilon(t,s)B(t) = 0$, $X_\varepsilon(s,s) = I$, where the initial value I is the infinite dimensional identity matrix. Since it represents transition probabilities, $||X_\varepsilon(t,s)||_\infty$ is bounded uniformly in ε for all $t, s \in [0,T]$. Therefore, we have $\sup_{t\in[0,T]} ||v_\varepsilon(t)||_\infty \le \frac{K}{\varepsilon}\sup_{t\in[0,T]}\int_0^t ||\Delta_{\varepsilon,k}(s)||_\infty ds \le K\varepsilon^k$. The lemma is obtained. □

For each $k = 1, \ldots, n+1$, define a vector-valued error $e_{\varepsilon,k}(t)$

$$e_{\varepsilon,k}(t) = p_\varepsilon(t) - \sum_{i=0}^{k} \varepsilon^i \phi_i(t) - \sum_{i=0}^{k} \varepsilon^i \psi_i(t/\varepsilon), \tag{3.20}$$

where $p_\varepsilon(\cdot)$ is the solution of (2.4), $\phi_i(\cdot)$ and $\psi_i(\cdot)$ are the outer expansions and initial layer corrections, respectively. We must show that $e_{\varepsilon,n}(t) = O(\varepsilon^{n+1})$. For this purpose, we first derive a lemma whose proof is similar in spirit to the corresponding results for weakly irreducible generators [28] and is thus omitted.

LEMMA 3.5. *Under* (A1) *and* (A2), *for $k = 1, \ldots, n+1$, $\sup_{t\in[0,T]} ||\mathcal{L}_\varepsilon e_{\varepsilon,k}(t)||_\infty = O(\varepsilon^{k+1})$, and hence $\sup_{t\in[0,T]} ||e_{\varepsilon,k}(t)||_\infty = O(\varepsilon^k)$.*

Remark 3.6. Using Lemma 3.5, with $k = 1$, we obtain $\sup_{t\in[0,T]} ||e_{\varepsilon,1}(t)||_\infty = O(\varepsilon)$. However, $e_{\varepsilon,1}(t) = e_{\varepsilon,0}(t) - \varepsilon\phi_1(t) - \varepsilon\psi_1(t/\varepsilon)$. In view of the boundedness of $\phi_1(t)$ and $\psi_1(t/\varepsilon)$, $\varepsilon\phi_1(t) + \varepsilon\psi_1(t/\varepsilon) = O(\varepsilon)$. Thus, $e_{\varepsilon,0}(t) = O(\varepsilon)$ uniformly in $t \in [0,T]$. We can proceed inductively. By virtue of Lemma 3.5, with $k = n+1$, $\sup_{t\in[0,T]} ||\varepsilon_{\varepsilon,n+1}||_\infty = O(\varepsilon^{n+1})$. Going back one step and using $e_{\varepsilon,n+1}(t) = e_{\varepsilon,n}(t) + O(\varepsilon^{n+1})$, similar to the case of $k = 1$, we obtain $\sup_{t\in[0,T]} ||e_{\varepsilon,n}(t)||_\infty = O(\varepsilon^{n+1})$. We summarize the discussion thus far into the following theorem. This gives us the desired approximation results. Not only is the convergence of $P(\alpha_\varepsilon(t) = i)$ obtained, but also the rate of convergence is derived. Furthermore, a full asymptotic series is obtained.

THEOREM 3.7. *Under* (A1) *and* (A2), *we can construct two sequences $\{\phi_k(t)\}_{k=0}^n$ and $\{\psi_k(t/\varepsilon)\}_{k=0}^n$ by Theorem* 3.3 *such that $\phi_k(t) \in C^{n+1-k}$ and $\psi_k(t/\varepsilon)$ decay exponentially fast. Moreover with $e_{\varepsilon,n}(t)$ defined by* (3.20), $\sup_{t\in[0,T]} ||e_{\varepsilon,n}(t)||_\infty = O(\varepsilon^{n+1})$.

Using the same techniques, we can also obtain asymptotic expansions of transition probability matrices. Since the proofs are essentially the same, we will state only the results and omit the detailed argument. Let $P_\varepsilon(t_0,t)$ be the transition matrix $(p_\varepsilon^{in,jk}(t_0,t))$ with $p_\varepsilon^{in,jk}(t_0,t)=P(\alpha_\varepsilon(t)=s_{jk}|\alpha_\varepsilon(t_0)=s_{in})$ for all $s_{in},s_{jk}\in\mathcal{M}$.

THEOREM 3.8. *Assume* (A1) *and* (A2) *with* $n=1$. *Then*

$$P_\varepsilon(t_0,t)=\Phi_0(t_0,t)+\Psi_0(t_0,(t-t_0)/\varepsilon)+O(\varepsilon+\varepsilon\exp((t-t_0)/\varepsilon)) \tag{3.21}$$

uniformly in (t_0,t), *where* $0\le t_0\le t\le T$,

$$\Phi_0(t_0,t)=\widetilde{\mathbb{1}}\Theta(t_0,t)\nu(t),\qquad \frac{d\Psi_0(t_0,\tau)}{d\tau}=\Psi_0(t_0,\tau)A(t_0),\ \Psi_0(t_0,t_0)=I-\Phi_0(t_0,t_0), \tag{3.22}$$

where $\Theta(t_0,t)=(\theta^{ij}(t_0,t))\in\mathbb{R}^{l\times l}$ *is the solution of*

$$\frac{d}{dt}\Theta(t_0,t)=\Theta(t_0,t)\overline{B}(t),\quad \Theta(t_0,t_0)=I. \tag{3.23}$$

Remark 3.9. Owing to Theorems 3.7 and 3.8, for some $\kappa_0>0$, $p_\varepsilon(t)=\nu(t)+O(\varepsilon+\exp(-\kappa_0 t/\varepsilon))$, $P_\varepsilon(t_0,t)=\Phi_0(t_0,t)+O(\varepsilon+\exp(-\kappa_0(t-t_0)/\varepsilon))$.

4. Occupation measures, aggregation, and switching diffusion. This section presents further asymptotic results that are of probabilistic feature. The statements of the results are given, and the proofs are relegated to the appendix.

4.1. Occupations measures. For any $i=1,\dots,l$ and $j=1,2,\dots$, define sequences of occupation measures as

$$\mu_\varepsilon^{ij}(t)=\int_0^t z^{ij}(s,\alpha_\varepsilon(s))ds,\quad z^{ij}(t,\alpha_\varepsilon(t))=I_{\{\alpha_\varepsilon(t)=s_{ij}\}}-\nu^{ij}(t)I_{\{\alpha_\varepsilon(t)\in\mathcal{M}_i\}}, \tag{4.1}$$

where $\nu^{ij}(t)$ is the jth component of the quasi-stationary distribution $\nu^i(t)$ as defined in (A2). As a preparation, we first derive an order of magnitude estimate for $\mu_\varepsilon^{ij}(\cdot)$ defined in (4.1).

THEOREM 4.1. *Under the conditions of Theorem* 3.8, $\sup_{t\in[0,T]}E(\mu_\varepsilon^{ij}(t))^2=O(\varepsilon)$.

As alluded to in the introduction, we wish to reduce the complexity of the queueing network by aggregating states in each subspace as a single state. This leads to the definition of $\overline{\alpha}_\varepsilon(t)=i$ if $\alpha_\varepsilon(t)\in\mathcal{M}_i$.

THEOREM 4.2. *Under the conditions of Theorem* 3.8, $\overline{\alpha}_\varepsilon(\cdot)$ *converges weakly to* $\overline{\alpha}(\cdot)$, *a Markov chain generated by* $\overline{B}(t)$ *given in* (3.6).

4.2. Switching diffusion limit. Let $f(\cdot)$ be a real-valued function defined on $\mathcal{M}$ satisfying that $\{f(s_{ij}):1\le i\le l,\ 1\le j<\infty\}\in\ell_1$. For $t\in[0,T]$, define a sequence of real-valued functions by

$$x_\varepsilon(t)=\sum_{i=1}^{l}\sum_{j=1}^{\infty}\frac{1}{\sqrt{\varepsilon}}\int_0^t f(s_{ij})[I_{\{\alpha_\varepsilon(u)=s_{ij}\}}-\nu^{ij}(u)I_{\{\alpha_\varepsilon(u)\in\mathcal{M}_i\}}]du. \tag{4.2}$$

Our interest lies in the asymptotic properties of $x_\varepsilon(\cdot)$. To obtain the desired limit property, we consider a pair of processes $\{Y_\varepsilon(\cdot)\}=\{x_\varepsilon(\cdot),\overline{\alpha}_\varepsilon(\cdot)\}$ and aim to show that $Y_\varepsilon(\cdot)$ converges weakly to $Y(\cdot)$ with a suitable generator.

LEMMA 4.3. *Under the conditions of Theorem* 3.8, $\{Y_\varepsilon(\cdot)\}$ *is tight in* $D^2[0,T]$ (*the space of* $\mathbb{R}^2$*-valued functions that are right continuous and have left limits endowed with the Skorohod topology*).

Since $\{Y_\varepsilon(\cdot)\}$ is tight, by Prohorov's theorem, we can extract a weakly convergent subsequence. Select such a subsequence and still use ε as its index for notational simplicity. Denote the limit by $Y(\cdot) = (x(\cdot), \overline{\alpha}(\cdot))$. We proceed to characterize this limit process. Let C_L^2 be the collection of functions having bounded derivatives up to the second order with the second derivative being Lipschitz continuous. For each $i = 1, \ldots, l$, $g(\cdot, i) \in C_L^2$, define an operator $\mathcal{D}(t)$ by

$$\mathcal{D}(t)g(x,i) = \frac{1}{2}\sigma^2(t,i)\frac{\partial^2}{\partial x^2}g(x,i) + \overline{B}(t)g(x,\cdot)(i), \tag{4.3}$$

where $\sigma^2(t,i) > 0$ is a smooth function.

THEOREM 4.4. *Under the conditions of Theorem* 3.8, $Y_\varepsilon(\cdot)$ *converges weakly to* $Y(\cdot)$, *which is a solution of the martingale problem with operator* $\mathcal{D}(\cdot)$ *defined by* (4.3).

Using the above theorem, we can also get a weak convergence of a reflected process. Define $r_\varepsilon(t) = x_\varepsilon(t) - \inf_{0\le u\le t}\{x_\varepsilon(u)\}$. The weak convergence of $x_\varepsilon(t)$ and the continuous mapping theorem (see [2, p. 30, Theorem 5.1]) yield that $r_\varepsilon(\cdot)$ converges weakly to $r(\cdot)$, a reflected switching diffusion process.

5. Extensions and examples. In this section we give the extensions of the results and present examples of queueing problems.

5.1. Infinitely many blocks. We consider the case

$$Q_\varepsilon(t) = \frac{A(t)}{\varepsilon} + B(t) \quad \text{with } A(t) = \operatorname{diag}(A^1(t), A^2(t), \ldots). \tag{5.1}$$

That is, the matrix $A(t)$ given by (2.2) is a diagonal block one with infinitely many blocks. Instead of condition (A2), we assume (A2′).

(A2′) There is a $\kappa_l > 0$ such that for $\big|\big|\exp(A^l(0)\tau) - \mathbb{1}\nu^l(0)\big|\big|_\infty \le K\exp(-\kappa_l\tau)$, any real number $\tau > 0$, where $\nu^l(t) = (\nu^{l1}(t), \nu^{l2}(t), \ldots)$ is the quasi-stationary distribution corresponding to the generator $A^l(t)$, and $\inf_{l\ge 1}\kappa_l > 0$.

THEOREM 5.1. *Under* (A1) *and* (A2′), Theorem 3.7, Theorem 4.2, *and* Theorem 4.4 *hold.*

The proof of this theorem follows the same line of argument as that of Theorems 3.7, 4.2, and 4.4 and is thus omitted. A special case of the theorem is that $Q_\varepsilon(t)$ has the form (5.1) with $A(t)$ having infinitely many blocks such that each $A^i(t)$ is a generator of a finite-state Markov chain.

Example 5.2. Consider a two-station queueing system, where each station has a single server and an exogenous Poisson arrival process. For the first station, having completed service there, customers either proceed to a queue in front of the second station with probability p_1 or depart the system with probability $(1 - p_1)$. For the second station, after completing service there, they depart the system with probability $(1 - p_2)$ and go to a queue in front of the first station with probability p_2. Service is rendered in the order of the arrivals at each station. We assume that the first station can hold at most a total of m_0 customers (including the customer in service) and any further arriving customers from outside will in fact be refused entry and hence will depart immediately without service at the first station, while the second station

has an unlimited waiting room. Furthermore, we assume that the system is a time-dependent Markovian queueing network. Specifically, the rate of station i's customer arriving from outside is $\lambda_i(t)$, and the service rate is $\mu_i(t)$ $(i = 1, 2)$.

Assume that $\lambda_i(t)$ and $\mu_i(t)$ are smooth, positive, real analytic functions of time t. We let $\mathcal{Q}(t) = (\mathcal{Q}_2(t), \mathcal{Q}_1(t))$ be the Markovian queue length process that $\mathcal{Q}_i(t)$ equals the number of customers at station i at time t. Then the state space of the queueing system can be represented by $\{(k, i) : 0 \le k < \infty \text{ and } 0 \le i \le m_0\}$. To determine the generator $Q(t) = (q^{(j,n),(k,i)}(t))$, let

$$
\begin{aligned}
&\pi_1(t) = (1 - p_1)\mu_1(t),\ \pi_2(t) = (1 - p_2)\mu_2(t),\\
&\pi(t) = \lambda_1(t) + \pi_1(t),\ \tilde{\pi}(t) = \lambda_2(t) + p_1\mu_1(t) + \mu_2(t),\\
&A^1(t) = \begin{pmatrix}
-\lambda_1(t) & \lambda_1(t) & & & \\
\pi_1(t) & -\pi(t) & \lambda_1(t) & & \\
& \ddots & \ddots & \ddots & \\
& & \pi_1(t) & -\pi(t) & \lambda_1(t)\\
& & & \pi_1(t) & -\pi_1(t)
\end{pmatrix},\\
&B^1(t) = \operatorname{diag}(-\lambda_2(t), -[\lambda_2(t) + p_1\mu_1(t)], \ldots, -[\lambda_2(t) + p_1\mu_1(t)]),\\
&B^2(t) = \operatorname{diag}(-(\lambda_2(t) + \mu_2(t)), -\tilde{\pi}(t), \ldots, -\tilde{\pi}(t)),\\
&C(t) = \begin{pmatrix}
\lambda_2(t) & & & \\
p_1\mu_1(t) & \lambda_2(t) & & \\
& \ddots & \ddots & \\
& & p_1\mu_1(t) & \lambda_2(t)
\end{pmatrix},\\
&D(t) = \begin{pmatrix}
\pi_2(t) & p_2\mu_2(t) & & \\
& \ddots & \ddots & \\
& & \pi_2(t) & p_2\mu_2(t)\\
& & & \mu_2(t)
\end{pmatrix},
\end{aligned}
$$

where each matrix is a $(m_0 + 1) \times (m_0 + 1)$ matrix. Then some tedious calculations yield

$$
Q(t) = \operatorname{diag}(A^1(t), A^1(t), \ldots) + \begin{pmatrix}
B^1(t) & C(t) & & \\
D(t) & B^2(t) & C(t) & \\
& \ddots & \ddots & \ddots
\end{pmatrix}. \tag{5.2}
$$

For an initial time point t_0 with $t_0 \in [0, T]$, let $P(t_0, t)$ with $t > t_0$ be the transition matrix $P(t_0, t) = (p^{(j,n),(k,i)}(t_0, t))$ with

$$
p^{(j,n),(k,i)}(t_0, t) = P(\mathcal{Q}(t) = (k, i) | \mathcal{Q}(t_0) = (j, n)) \text{ for all } 0 \le j, k < \infty,\ 0 \le n, i \le m_0.
$$

Then we have the following system of equations for a quasi-birth-death process:

$$
\frac{d}{dt}P(t_0, t) = P(t_0, t)Q(t). \tag{5.3}
$$

Assume that

$$
(1 - p_1) \gg p_1, \quad \lambda_1(t) \gg p_1\mu_1(t), \quad \lambda_1(t) \gg \lambda_2(t), \quad \lambda_1(t) \gg \mu_2(t). \tag{5.4}
$$

Introduce $\varepsilon = \frac{1}{\inf_{t_0 \le t \le T} \lambda_1(t)}$. Then $\nu^i(t) = (\nu^{i0}(t), \nu^{i1}(t), \ldots, \nu^{im_0}(t))$ with

$$
\nu^{1j}(t) = \left(\frac{\lambda_1(t)}{\pi_1(t)}\right)^j p_0(t), \quad p_0(t) = 1 \Big/ \left[1 + \sum_{j=1}^{m_0} \left(\frac{\lambda_1(t)}{\pi_1(t)}\right)^j\right].
$$

Let $\widehat{\pi}(t) = [\lambda_2(t) + p_1\mu_1(t)] - p_1\mu_1(t)p_0(t)$. It follows from some tedious calculations that

$$\overline{B}(t) = \begin{pmatrix} -\widehat{\pi}(t) & \widehat{\pi}(t) & & \\ \mu_2(t) & -\widehat{\pi}(t) - \mu_2(t) & \widehat{\pi}(t) & \\ & \ddots & \ddots & \ddots \end{pmatrix}. \tag{5.5}$$

By Theorem 5.1,

$$\begin{aligned} P_\varepsilon(t_0, t) &= \Phi_0(t_0, t) + [I - \Phi(t_0, t_0)] \exp\left(A(t_0)\frac{t - t_0}{\varepsilon}\right) \\ &\quad + O\left(\varepsilon + \exp\left(\frac{t - t_0}{\varepsilon}\right)\right) \end{aligned} \tag{5.6}$$

uniformly in (t_0, t), where for $0 \le t_0 \le t \le T$, $\Phi_0(t_0, t)$ is given by (3.22) with $\Theta(t_0, t)$ satisfying (3.23). Using [23, Theorem 5.2, p. 128], the solution of (3.23) can be explicitly written as $\Theta(t_0, t) = U(t_0, t)$, where $U(t_0, t)$ is a solution operator. Consequently $\Phi(t_0, t)$ given in (5.6) takes the form $\Phi(t_0, t) = \widetilde{\mathbb{1}}U(t_0, t)\nu$. In particular, when the generators are time independent, $U(t_0, t)$ becomes a semigroup [23, Chapter 1] and may be expressed as $U(t_0, t) = \exp((t - t_0)\overline{B})$.

Next we consider the queue length process at the first station, $\mathcal{Q}_1(t)$. In general, $\mathcal{Q}_1(t)$ is not a Markov process. But from Theorem 5.1, $\mathcal{Q}_1(t)$ *can be approximated very well* by a Markov process $\overline{\alpha}(t)$ with generator $\overline{B}(t)$ defined by (5.5). Furthermore, we consider a refined approximation of $\mathcal{Q}(t) = (\mathcal{Q}_2(t), \mathcal{Q}_1(t))$. Define $\varpi_\varepsilon(t) = \sum_{i=0}^{\infty}\sum_{j=0}^{m_0}\int_0^t \left[I_{\{\mathcal{Q}(u)=(i,j)\}} - \nu^{(i,j)}(u)I_{\{\mathcal{Q}_1(u)=j\}}\right] du$. It follows from Theorem 5.1 that $(1/\sqrt{\varepsilon})\varpi_\varepsilon(t)$ can be well approximated by the switching diffusion process $\int_0^t \sigma(u, \overline{\alpha}(u))dw(u)$, where $w(\cdot)$ is a standard one-dimensional Brownian motion, $\sigma^2(t, i) = \sum_{k=0}^{m_0}\sum_{l=0}^{m_0}\left[\nu^{0k}(t)\int_0^\infty \psi_0^{kl}(i, t, u)du + \nu^{0l}(t)\int_0^\infty \psi_0^{lk}(i, t, u)du\right]$ for $0 \le i < \infty$, and $\psi_0^{kl}(i, s, t)$ is the (k, l)th entry of $\Psi_0(i, t, u)$ given by

$$\Psi_0(i, t, u) = \left(I - \begin{pmatrix} \nu^1(t) \\ \vdots \\ \nu^1(t) \end{pmatrix}\right) \exp(A^1(t)u).$$

Remark 5.3. References [12] and [18] establish asymptotic expansions for the queue length distribution of the time inhomogeneous single serve queue, a time-dependent *pure* birth-death process. Here we consider a *quasi*-birth-death process. Furthermore, the queue length process at the first station (generally non-Markovian) can be approximated well by a Markov process with generator $\overline{B}(t)$. In [20], uniform acceleration expansions for time-varying generators were treated, and in [28] diffusion approximation was also considered. In these references, the Markov chains have one ergodic class, whereas in the current paper, multiergodic classes are considered. Compared with the diffusion approximations in [19] and [27], the switching diffusion approximation given here is related to the queue length process on the interval $[0, t]$ and provides the evolution of the scaled sequence. The usual diffusion approximation leads to asymptotic normality, whereas switching diffusion limit yields Gaussian mixture distribution.

The $[\lambda_1(t) + p_2\lambda_2(t)]/[(1 - p_1p_2)\mu_1(t)]$ and $[\lambda_2(t) + p_1\mu_1(t)]/[(1 - p_1p_2)\mu_2(t)]$ are called the traffic intensities at station 1 and station 2, respectively. If $[\lambda_1(t) + p_2\lambda_2(t)]/[(1-p_1p_2)\mu_1(t)]$ and $[\lambda_2(t)+p_1\mu_1(t)]/[(1-p_1p_2)\mu_2(t)]$ are less than but close

to one, the system is regarded as in heavy traffic, whereas if $[\lambda_1(t) + p_2\lambda_2(t)]/[(1 - p_1p_2)\mu_1(t)]$ and $[\lambda_2(t) + p_1\mu_1(t)]/[(1 - p_1p_2)\mu_2(t)]$ are much less than one, the system is considered to be in light traffic. Our approximations are valid for either the heavy traffic case or the light traffic case as long as (5.4) holds. Using the Laplace transform technique, from the balance equation of the system, one may proceed as in [15] to carry out heavy traffic analysis for the sojourn time of time-homogeneous Markovian tandem queues with two servers.

Comparing with (5.2), we can consider a general quasi-birth-death process with state space $\{(i, j), i \geq 0, 1 \leq j \leq m_0\}$ with a generator $G(t)$ given by

$$\begin{pmatrix} A^1(t) - \operatorname{diag}(C^1(t)\mathbb{1}) & C^1(t) & & \\ B^1(t) & A^2(t) - \operatorname{diag}(B^1(t)\mathbb{1} + C^2(t)\mathbb{1}) & C^2(t) & \\ & \ddots & \ddots & \end{pmatrix}, \tag{5.7}$$

where i and j are called level and phase, respectively; see [22]. If the transitions between levels are much less frequent than the transitions between the phases inside the same level, then $Q(t)$ given by (5.7) can be written as

$$\operatorname{diag}(A^1(t), A^2(t), \ldots) + \varepsilon \begin{pmatrix} -\operatorname{diag}(C^1(t)\mathbb{1}) & C^1(t) & & \\ B^1(t) & -\operatorname{diag}(B^1(t)\mathbb{1} + C^2(t)\mathbb{1}) & C^2(t) & \\ & \ddots & \ddots & \ddots \end{pmatrix}.$$

Hence following Example 5.2, we can also get the asymptotic probability distribution of the process.

5.2. Asymptotic properties under γ-norm. For $v = (v^1, \ldots, v^l)$ with $v^i = (v^{i1}, v^{i2}, \ldots)$, the γ-norm (which was named ν-norm in [21]; see also [1]) is defined as $||v||_\gamma = \max_{1\leq i\leq l} \sup_{1\leq k<\infty} |v^{ik}|/\gamma^{ik}$. The corresponding induced γ-norm for any operator is given by $||A||_\gamma = \max_{1\leq k\leq l} \sup_{1\leq i<\infty} [\sum_{j=1}^{\infty} |A^k_{ij}|\gamma^{kj}]/\gamma^{ki}$. Replace (A2) with (A2″).

(A2″) There is a $\kappa > 0$ such that $\big|\big|\exp(A^l(0)\tau) - \mathbb{1}\nu^l(0)\big|\big|_\gamma \leq K \exp(-\kappa_l\tau)$ for any real number $\tau > 0$, where $\nu^l(t) = (\nu^{l1}(t), \nu^{l2}(t), \ldots)$ is the quasi-stationary distribution corresponding to the generator $A^l(t)$, and $\inf_{l\geq 1} \kappa_l > 0$.

Similar to Theorem 3.7, using essentially the same techniques, we obtain the following result.

THEOREM 5.4. *Under* (A1) *and* (A2″), *we construct two sequences* $\{\phi_k(t)\}_{k=0}^n$ *and* $\{\psi_k(t/\varepsilon)\}_{k=0}^n$ *by Theorem* 3.3 *such that* $\phi_k(t) \in C^{n+1-k}$ *and* $\psi_k(t/\varepsilon)$ *decay exponentially fast. Moreover, with* $e_{\varepsilon,n}(t)$ *defined by* (3.20), $\sup_{t\in[0,T]} ||e_{\varepsilon,n}(t)||_\gamma = O(\varepsilon^{n+1})$.

Example 5.5. Consider the queueing system given by Example 5.2, but allow the first station to have unlimited waiting rooms. Then the state space of $(\mathcal{Q}_2(t), \mathcal{Q}_1(t))$

can be represented by $\{(k,i): 0 \le k < \infty \text{ and } 0 \le i < \infty\}$. Let

$$\widehat{A}^1(t) = \begin{pmatrix} -\lambda_1(t) & \lambda_1(t) & & \\ (1-p_1)\mu_1(t) & -\pi(t) & \lambda_1(t) & \\ & \ddots & \ddots & \ddots \end{pmatrix},$$
$$\widehat{B}^1(t) = \operatorname{diag}(-\lambda_2(t), -[\lambda_2(t)+p_1\mu_1(t)], \ldots),$$
$$\widehat{B}^2(t) = \operatorname{diag}(-(\lambda_2(t)+\mu_2(t)), -\tilde{\pi}(t), \ldots),$$
$$\widehat{C}(t) = \begin{pmatrix} \lambda_2(t) & & \\ p_1\mu_1(t) & \lambda_2(t) & \\ & \ddots & \ddots \end{pmatrix}, \ \widehat{D}(t) = \begin{pmatrix} \pi_2(t) & p_2\mu_2(t) & \\ & \pi_2(t) & p_2\mu_2(t) \\ & & \ddots & \ddots \end{pmatrix}.$$

Then, some tedious calculations yield

$$\widehat{Q}(t) = \operatorname{diag}(\widehat{A}^1(t), \widehat{A}^1(t), \ldots) + \begin{pmatrix} \widehat{B}^1(t) & \widehat{C}(t) & & \\ \widehat{D}(t) & \widehat{B}^2(t) & \widehat{C}(t) & \\ & \ddots & \ddots & \ddots \end{pmatrix}. \tag{5.8}$$

Letting $\gamma^{1i}(0) = ((1-p_1)\mu_1(0)/\lambda_1(0))^i$, then we have (A2″) holds; see [21]. Therefore, by Theorem 5.4, we obtain the asymptotic probability distribution of $(\mathcal{Q}_2(t), \mathcal{Q}_1(t))$ under γ-norm.

Appendix A.

Proof of Theorem 4.1. Suppose that $0 \le s \le t$. For each $i = 1, \ldots, l$ and $j \in \mathbb{N}$, define

$$\begin{aligned} \zeta_\varepsilon^{1,ij}(s,t) &= P(\alpha_\varepsilon(s) = s_{ij}, \alpha_\varepsilon(t) = s_{ij}) - \nu^{ij}(t)P(\alpha_\varepsilon(s) = s_{ij}, \alpha_\varepsilon(t) \in \mathcal{M}_i), \\ \zeta_\varepsilon^{2,ij}(s,t) &= \nu^{ij}(s)\nu^{ij}(t)P(\alpha_\varepsilon(s) \in \mathcal{M}_i, \alpha_\varepsilon(t) \in \mathcal{M}_i) \\ &\quad -\nu^{ij}(s)P(\alpha_\varepsilon(s) \in \mathcal{M}_i, \alpha_\varepsilon(t) = s_{ij}). \end{aligned} \tag{A.1}$$

Theorem 3.8 and Remark 3.9 yield $\zeta_\varepsilon^{1,ij}(s,t) = O(\varepsilon + \exp(-\kappa_0(t-s)/\varepsilon))$. Similarly, $\zeta_\varepsilon^{2,ij}(s,t) = O(\varepsilon + \exp(-\kappa_0(t-s)/\varepsilon))$. It follows from $\mu_\varepsilon^{ij}(0) = 0$ that $E(\mu_\varepsilon^{ij}(t))^2 = 2\int_0^t \int_0^s (\zeta_\varepsilon^{1,ij}(r,s) + \zeta_\varepsilon^{2,ij}(r,s))drds$. The desired order estimates then follows. □

Proof of Theorem 4.2. The theorem will be proved in two steps. In the first step, we establish the tightness of $\{\overline{\alpha}_\varepsilon(\cdot)\}$, and in the second step, we characterize the limit process.

(1) Tightness. Note that $\overline{\alpha}_\varepsilon(t) = \sum_{i=1}^l iI_{\{\overline{\alpha}_\varepsilon(t)=i\}} = \sum_{i=1}^l iI_{\{\alpha_\varepsilon(t)\in\mathcal{M}_i\}}$. Define $\chi_\varepsilon(t) = (\chi_\varepsilon^1(t), \ldots, \chi_\varepsilon^l(t))$, $\chi_\varepsilon^i(t) = (I_{\{\alpha_\varepsilon(t)=s_{ij}\}})$, $\overline{\chi}_\varepsilon(t) = (I_{\{\overline{\alpha}_\varepsilon(t)=1\}}, \ldots, I_{\{\overline{\alpha}_\varepsilon(t)=l\}})$. In view of the definition of $\overline{\alpha}_\varepsilon(t)$ and the Cramér–Wold theorem [2, p. 49], to prove the tightness of $\{\overline{\alpha}_\varepsilon(\cdot)\}$, it suffices to derive that of $\{\overline{\chi}_\varepsilon(\cdot)\}$. For any $\delta > 0$, any $t > 0$, and any $s > 0$ with $\delta > s > 0$ and $t + s \in [0,T]$, owing to the Markov property, $E(\chi_\varepsilon(t+s) - \chi_\varepsilon(t) - \int_t^{t+s} \chi_\varepsilon(u)Q_\varepsilon(u)du|\mathcal{F}_{t,\varepsilon}) = 0$, where $\mathcal{F}_{t,\varepsilon}$ denotes the σ-algebra generated by $\{\alpha_\varepsilon(u): u \le t\}$. Postmultiplying by $\widetilde{\mathbb{1}}$ and noting $A(t)\widetilde{\mathbb{1}} = 0$ lead to $E(\overline{\chi}_\varepsilon(t+s) - \overline{\chi}_\varepsilon(t) - \int_t^{t+s} \chi_\varepsilon(u)B(u)\widetilde{\mathbb{1}}du|\mathcal{F}_{t,\varepsilon}) = 0$. Thus by (A1), $E(\overline{\chi}_\varepsilon(t+s)|\mathcal{F}_{t,\varepsilon}) - \overline{\chi}_\varepsilon(t) = O(s)$. This implies that $E(|\overline{\chi}_\varepsilon(t+s) - \overline{\chi}_\varepsilon(t)|^2|\mathcal{F}_{t,\varepsilon}) = E(|\int_t^{t+s} \chi_\varepsilon(u)B(u)\widetilde{\mathbb{1}}du|^2|\mathcal{F}_{t,\varepsilon}) = O(s)$. Consequently, for $0 < \delta \le s$, $\lim_{\delta\to 0} \limsup_{\varepsilon\to 0} E|\overline{\chi}_\varepsilon(t+s) - \overline{\chi}_\varepsilon(t)|^2 = 0$. The desired tightness then follows from [16, p. 47].

(2) Characterization of the limit. Since $\{\overline{\alpha}_\varepsilon(\cdot)\}$ is tight, by Prohorov's theorem, we can extract a weakly convergent subsequence. Select such a sequence and still use ε as its index for notational simplicity; denote its limit by $\overline{\alpha}(\cdot)$. We proceed to

characterize the limit process. We need to show that for any bounded function $\overline{g}(\cdot)$ defined on $\{1,\dots,l\}$,

$$\overline{g}(\overline{\alpha}(t)) - \int_0^t \overline{B}(u)\overline{g}(\cdot)(\overline{\alpha}(u))du \text{ is a martingale.} \tag{A.2}$$

To establish (A.2), it suffices that for any positive integers m, and $k \le m$, any bounded functions $h_k(\cdot)$ defined on $\{1,\dots,l\}$, and any $0 < t_k \le t \le t+s$,

$$E\prod_{k=1}^m h_k(\overline{\alpha}(t_k))\left(\overline{g}(\overline{\alpha}(t+s)) - \overline{g}(\overline{\alpha}(t)) - \int_t^{t+s}\overline{B}(u)\overline{g}(\cdot)(\overline{\alpha}(u))du\right) = 0. \tag{A.3}$$

To proceed, define $g(\alpha_\varepsilon(s)) = \sum_{i=1}^l \overline{g}(i)I_{\{\alpha_\varepsilon(s)\in\mathcal{M}_i\}}$. Then, $g(\alpha_\varepsilon(s)) = \overline{g}(\overline{\alpha}_\varepsilon(s))$. Thus, $g(\alpha_\varepsilon(t)) - \int_0^t Q_\varepsilon(u)g(\cdot)(\alpha_\varepsilon(u))du$ is a martingale. Consequently,

$$\prod_{k=1}^m Eh_k(\overline{\alpha}_\varepsilon(t_k))[g(\alpha_\varepsilon(t+s)) - g(\alpha_\varepsilon(t)) - \int_t^{t+s} Q_\varepsilon(u)g(\cdot)(\alpha_\varepsilon(u))du)] = 0. \tag{A.4}$$

By virtue of the weak convergence and the Skorohod representation, as $\varepsilon \to 0$,

$$E\prod_{k=1}^m h_k(\overline{\alpha}_\varepsilon(t_k))[g(\alpha_\varepsilon(t+s) - g(\alpha_\varepsilon(t))] \to E\prod_{k=1}^m h_k(\overline{\alpha}(t_k))[\overline{g}(\overline{\alpha}(t+s)) - \overline{g}(\overline{\alpha}(t))]. \tag{A.5}$$

The definition of $g(\cdot)$ leads to $A(u)g(\cdot)(\alpha_\varepsilon(u)) = 0$ for all $u \in [0,T]$. As a result,

$$\begin{aligned} &E\prod_{k=1}^m h_k(\overline{\alpha}_\varepsilon(t_k))\left(\int_t^{t+s} Q_\varepsilon(u)g(\cdot)(\alpha_\varepsilon(u))du\right)\\ &= \sum_{i=1}^l\sum_{j=1}^\infty E\prod_{k=1}^m h_k(\overline{\alpha}_\varepsilon(t_k))[\int_t^{t+s}\nu^{ij}(u)I_{\{\overline{\alpha}_\varepsilon(u)=i\}}B(u)g(\cdot)(s_{ij})du]\\ &\quad + \sum_{i=1}^l\sum_{j=1}^\infty E\prod_{k=1}^m h_k(\overline{\alpha}_\varepsilon(t_k))[\int_t^{t+s}[I_{\{\alpha_\varepsilon(u)=s_{ij}\}} - \nu^{ij}(u)I_{\{\overline{\alpha}_\varepsilon(u)=i\}}]B(u)g(\cdot)(s_{ij})du]. \end{aligned} \tag{A.6}$$

Using Theorem 4.1, the last term in (A.6) goes to 0 as $\varepsilon \to 0$. By virtue of the weak convergence of $\overline{\alpha}_\varepsilon(\cdot)$ and the Skorohod representation, (A.6) yields that

$$\begin{aligned} &E\prod_{k=1}^m h_k(\overline{\alpha}_\varepsilon(t_k))\left(\int_t^{t+s} Q_\varepsilon(u)g(\cdot)(\alpha_\varepsilon(u))du\right)\\ &\to E\prod_{k=1}^m h_k(\overline{\alpha}(t_k))\left(\int_t^{t+s}\overline{B}(u)\overline{g}(\cdot)(\overline{\alpha}(u))du\right). \end{aligned} \tag{A.7}$$

Combining (A.4), (A.5), and (A.7), (A.3) is verified. This completes the proof. □

Proof of Lemma 4.3. Note that $Y_\varepsilon(\cdot)$ is a sequence of vector-valued random processes with two components. Again, using the Crámer–Wold theorem, since $\{\overline{\alpha}_\varepsilon(\cdot)\}$ is tight, to prove the tightness of $\{Y_\varepsilon(\cdot)\}$, it suffices to verify the tightness of $\{x_\varepsilon(\cdot)\}$.

We claim that for any $\delta > 0$, $0 \le s \le t$, and $t - s \le \delta$,

$$\sup_{0\le s\le t\le T} E\left(|x_\varepsilon(t) - x_\varepsilon(s)|^2 \big| \mathcal{F}_{s,\varepsilon}\right) \le K(t-s).$$

First, for $u \in [s,t]$, $E(z^{ij}(u,\alpha_\varepsilon(u))\big|\mathcal{F}_{s,\varepsilon}) = O(\varepsilon + \exp(-\kappa_0(t-s)/\varepsilon))$ uniformly in i and j, by (4.2), the Markov property, and Theorem 3.8. Thus

$$\begin{aligned} E(x_\varepsilon(t) - x_\varepsilon(s)\big|\mathcal{F}_{s,\varepsilon}) &= \sum_{i=1}^{l}\sum_{j=1}^{\infty} f(s_{ij})\frac{1}{\sqrt{\varepsilon}}\int_s^t E(z^{ij}(u,\alpha_\varepsilon(u))\big|\mathcal{F}_{s,\varepsilon})du \\ &= \frac{1}{\sqrt{\varepsilon}} O(\varepsilon + \exp(-\kappa_0(t-s)/\varepsilon)) = O(\sqrt{\varepsilon}). \end{aligned} \tag{A.8}$$

Denote

$$\begin{aligned} \Delta_\varepsilon(s,t) &= E((x_\varepsilon(t) - x_\varepsilon(s))^2\big|\mathcal{F}_{s,\varepsilon}) \\ &= \frac{1}{\varepsilon}E\left(\left(\sum_{i=1}^{l}\sum_{j=1}^{\infty} f(s_{ij})\int_s^t z_\varepsilon^{ij}(\alpha_\varepsilon(u))du\right)^2 \Big|\mathcal{F}_{s,\varepsilon}\right). \end{aligned}$$

It then follows $\frac{d}{dt}\Delta_\varepsilon(s,t) = \frac{2}{\varepsilon}\sum_{i=1}^{l}\sum_{j=1}^{\infty} f(s_{ij})\int_s^t E(\zeta_\varepsilon^{1,ij}(u,t) + \zeta_\varepsilon^{2,ij}(u,t)\big|\mathcal{F}_{s,\varepsilon})du$, where $\zeta_\varepsilon^{1,ij}(u,t)$ and $\zeta_\varepsilon^{2,ij}(u,t)$ are defined in (A.1). Thus $(d/dt)\Delta_\varepsilon(s,t) = O(1)$, $\Delta_\varepsilon(s,s) = 0$. An integration then leads to $\Delta_\varepsilon(s,t) = O(t-s)$. Therefore,

$$\lim_{\delta\to 0}\limsup_{\varepsilon\to 0}\sup_{0\le t-s\le\delta} E(E(x_\varepsilon(t) - x_\varepsilon(s))^2\big|\mathcal{F}_{s,\varepsilon}) = 0.$$

Moreover, for each $\delta > 0$, and each rational $t \ge 0$, using the Chebyshev's inequality $\inf_\varepsilon P(|x_\varepsilon(t)| \le K_{t,\delta}) \ge \inf_\varepsilon(1 - E|x_\varepsilon(t)|^2/(K_{t,\delta})^2) \ge 1 - Kt/(K_{t,\delta})^2$. Select $K_{t,\delta} > \sqrt{KT/\delta}$. Then $\inf_\varepsilon P(|x_\varepsilon(t)| \le K_{t,\delta}) \ge 1-\delta$. This inequality, (A.8), and the criterion [16] then yield the desired tightness. □

Proof of Theorem 4.4. To prove the theorem, it suffices to show that

$$g(x(t),\overline{\alpha}(t)) - \int_0^t \mathcal{D}(u)g(x(u),\overline{\alpha}(u))du \text{ is a martingale.} \tag{A.9}$$

To verify this martingale property, we prove that for any positive integer m, any $k \le m$, any bounded and continuous function $h_k(\cdot,\alpha)$ for each α, and any $0 < t_k \le t \le t+s$,

$$\begin{aligned} \prod_{k=1}^{m} Eh_k(x(t_k),\overline{\alpha}(t_k))\ \Big(&g(x(t+s),\overline{\alpha}(t+s)) - g(x(t),\overline{\alpha}(t)) \\ &- \int_t^{t+s}\mathcal{D}(u)g(x(u),\overline{\alpha}(u))du\Big) = 0. \end{aligned}$$

To accomplish this, we begin with the process indexed by ε.

(1) Using an argument similar to [29, pp. 199–200], it can be verified that the martingale problem associated with operator $\mathcal{D}(t)$ has a unique (in the sense of distribution) solution.

(2) In what follows, we often need to carry out estimates involving $x_\varepsilon(t)$ and $\alpha_\varepsilon(t)$ intertwined. To untangle them, as a preparation, let $\eta(t,x)$ be a real-valued function

that is Lipschitz continuous in $(t,x)\in\mathbb{R}^2$. Using an argument similar to that of [29, Lemma 7.4, pp. 189–192], we can show

$$\lim_{\varepsilon\to 0}\sup_{0\le t\le T} E\left|\int_0^t z^{ij}(u,\alpha_\varepsilon(u))\eta(u,x_\varepsilon(u))du\right|^2=0. \tag{A.10}$$

(3) Define an operator $\mathcal{D}_\varepsilon(t)$ by

(A.11)
$$\begin{aligned}\mathcal{D}_\varepsilon(t)\rho(t,x,\alpha)=\frac{\partial\rho(t,x,\alpha)}{\partial t}\ &+\frac{1}{\sqrt{\varepsilon}}\left(\sum_{i=1}^{l}\sum_{j=1}^{\infty}f(s_{ij})z^{ij}(t,\alpha)\right)\frac{\partial\rho(t,x,\alpha)}{\partial x}\\ &+Q_\varepsilon(t)\rho(t,x,\cdot)(\alpha)\ \text{ for }\ \alpha\in\mathcal{M},\ \rho(\cdot,\cdot,\alpha)\in C^{1,1}.\end{aligned}$$

Then $\rho(t,x_\varepsilon(t),\alpha_\varepsilon(t))-\int_0^t\mathcal{D}_\varepsilon(u)\rho(u,x_\varepsilon(u),\alpha_\varepsilon(u))du$ is a martingale; see [6, Chapter 2].

Define $\overline{g}(x,\alpha)=\sum_{i=1}^{l}g(x,i)I_{\{\alpha\in\mathcal{M}_i\}}$. It is easily seen that $A(u)\overline{g}(x,\cdot)(\alpha_\varepsilon(u))=0$. Thus,

(A.12)
$$\mathcal{D}_\varepsilon(u)\overline{g}(x_\varepsilon(u),\alpha_\varepsilon(u))=\frac{1}{\sqrt{\varepsilon}}\widetilde{b}(u,\alpha_\varepsilon(u))\frac{\partial}{\partial x}\overline{g}(x_\varepsilon(u),\alpha_\varepsilon(u))+B(u)\overline{g}(x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u)),$$

where $\widetilde{b}(u,\alpha)=\sum_{i=1}^{l}\sum_{j=1}^{\infty}f(s_{ij})z^{ij}(u,\alpha)$. To obtain the desired limit, we use the techniques of perturbed test function methods [16], which require us to introduce a perturbation that is small in magnitude and that results in desired cancellations. To this end, define the perturbation by $\widehat{g}(t,x,\alpha)$ such that $\widehat{g}(\cdot,x,\alpha)$ is uniform Lipschitz in t; both $\widehat{g}(\cdot)$ and $(\partial/\partial x)\widehat{g}(\cdot)$ are bounded; $(\partial/\partial x)\widehat{g}(\cdot,\cdot,\alpha)$ is Lipschitz in (t,x) such that it is the solution of

$$A(t)\widehat{g}(t,x,\cdot)(\alpha)=-\widetilde{b}(t,\alpha)\frac{\partial\overline{g}(x,\alpha)}{\partial x}. \tag{A.13}$$

It can be shown that such a function exists similar to [29, Remark 7.16].

Next, define the perturbed test function $g_\varepsilon(\cdot)$ by

$$g_\varepsilon(t,x,\alpha)=\overline{g}(x,\alpha)+\sqrt{\varepsilon}\widehat{g}(t,x,\alpha). \tag{A.14}$$

Then using the definition of $\mathcal{D}_\varepsilon(t)$, $g_\varepsilon(t,x_\varepsilon(t),\alpha_\varepsilon(t))-\int_0^t\mathcal{D}_\varepsilon(u)g_\varepsilon(u,x_\varepsilon(u),\alpha_\varepsilon(u))du$ is a martingale. Consequently,

$$\begin{aligned}\prod_{k=1}^{m}Eh_k(x_\varepsilon(t_k),\overline{\alpha}_\varepsilon(t_k))\Bigg[&g_\varepsilon(t+s,x_\varepsilon(t+s),\alpha_\varepsilon(t+s))-g_\varepsilon(t,x_\varepsilon(t),\alpha_\varepsilon(t))\\ &-\int_t^{t+s}\mathcal{D}_\varepsilon(u)g_\varepsilon(u,x_\varepsilon(u),\alpha_\varepsilon(u))du\Bigg]=0.\end{aligned}$$

By the weak convergence of $Y_\varepsilon(\cdot)$ to $Y(\cdot)$, the Skorohod representation, and (A.14),

$$\begin{aligned}&\lim_{\varepsilon\to 0}\prod_{k=1}^{m}Eh_k(x_\varepsilon(t_k),\overline{\alpha}_\varepsilon(t_k))[g_\varepsilon(t+s,x_\varepsilon(t+s),\alpha_\varepsilon(t+s))-g_\varepsilon(t,x_\varepsilon(t),\alpha_\varepsilon(t))]\\ &\quad=\prod_{k=1}^{m}Eh_k(x(t_k),\overline{\alpha}(t_k))[g(x(t+s),\overline{\alpha}(t+s))-g(x(t),\overline{\alpha}(t))].\end{aligned}$$

Note that from (A.11),

$$\begin{aligned}\sqrt{\varepsilon}\mathcal{D}_\varepsilon(u)\widehat{g}(u,x_\varepsilon(u),\alpha_\varepsilon(u)) &= \sum_{i=1}^{l}\sum_{j=1}^{\infty} f(s_{ij})z^{ij}(u,\alpha_\varepsilon(u))\frac{\partial\widehat{g}(u,x_\varepsilon(u),\alpha_\varepsilon(u))}{\partial x}\\ &+\sqrt{\varepsilon}\frac{\partial\widehat{g}(u,x_\varepsilon(u),\alpha_\varepsilon(u))}{\partial u}\\ &+\sqrt{\varepsilon}B(u)\widehat{g}(u,x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u))+\frac{1}{\sqrt{\varepsilon}}A(u)\widehat{g}(u,x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u)).\end{aligned}\tag{A.15}$$

It follows from (A.12), (A.13), and (A.15), upon cancellation, that

(A.16)

$$\begin{aligned}\mathcal{D}_\varepsilon(u)g_\varepsilon(u,x_\varepsilon(u),\alpha_\varepsilon(u)) &= \sum_{i=1}^{l}\sum_{j=1}^{\infty} f(s_{ij})z^{ij}(u,\alpha_\varepsilon(u))\frac{\partial\widehat{g}(u,x_\varepsilon(u),\alpha_\varepsilon(u))}{\partial x}\\ &+B(u)\overline{g}(x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u))\\ &+\sqrt{\varepsilon}\frac{\partial\widehat{g}(u,x_\varepsilon(u),\alpha_\varepsilon(u))}{\partial u}+\sqrt{\varepsilon}B(u)\widehat{g}(u,x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u)).\end{aligned}$$

Thus again, by the weak convergence and the Skorohod representation,

$$\begin{aligned}&\lim_{\varepsilon\to0}\prod_{k=1}^{m}Eh_k(x_\varepsilon(t_k),\overline{\alpha}_\varepsilon(t_k))\left(\int_t^{t+s}\mathcal{D}_\varepsilon(u)g_\varepsilon(u,x_\varepsilon(u),\alpha_\varepsilon(u))du\right)\\ &=\lim_{\varepsilon\to0}\prod_{k=1}^{m}Eh_k(x_\varepsilon(t_k),\overline{\alpha}_\varepsilon(t_k))\left[\int_t^{t+s}\sum_{i=1}^{l}\sum_{j=1}^{\infty}f(s_{ij})z^{ij}(u,\alpha_\varepsilon(u))\frac{\partial\widehat{g}(u,x_\varepsilon(u),\alpha_\varepsilon(u))}{\partial x}du\right.\\ &\qquad\left.+\int_t^{t+s}B(u)\overline{g}(x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u))du\right].\end{aligned}$$

By virtue of the weak convergence of $Y_\varepsilon(\cdot)$ to $Y(\cdot)$, the Skorohod representation, and the boundedness of $\widehat{g}(\cdot)$, $(\partial/\partial x)\widehat{g}(\cdot)$, we have $\int_0^t B(u)\overline{g}(x_\varepsilon(u),\cdot)(\alpha_\varepsilon(u))du\to\int_0^t\overline{B}(u)g(x(u),\cdot)(\overline{\alpha}(u))du$.

Define

$$b(t,x,\alpha)=\widetilde{b}(t,\alpha)\frac{\partial\widehat{g}(t,x,\alpha)}{\partial x}.\tag{A.17}$$

Then

$$\begin{aligned}\int_0^t b(u,x_\varepsilon(u),\alpha_\varepsilon(u))du &= \int_0^t\sum_{i=1}^{l}\sum_{j=1}^{\infty}b(u,x_\varepsilon(u),s_{ij})\nu^{ij}(u)I_{\{\overline{\alpha}_\varepsilon(u)=i\}}du\\ &+\int_0^t\sum_{i=1}^{l}\sum_{j=1}^{\infty}[I_{\{\alpha_\varepsilon(u)=s_{ij}\}}-\nu^{ij}(u)I_{\{\overline{\alpha}_\varepsilon(u)=i\}}]b(u,x_\varepsilon(u),s_{ij})du.\end{aligned}\tag{A.18}$$

By (A.10), the last term in (A.18) goes to 0 in mean squares, so $\int_0^t b(u,x_\varepsilon(u),\alpha_\varepsilon(u))du$ converges to $\int_0^t\overline{b}(u,x(u),\overline{\alpha}(u))du$, where $\overline{b}(u,x,i)=\sum_{j=1}^{\infty}\nu^{ij}(u)b(u,x,s_{ij})$. Combining the estimates obtained so far, we arrive at

$$\begin{aligned}&Eh_k(x_\varepsilon(t_k),\overline{\alpha}_\varepsilon(t_k))\Big(\int_t^{t+s}\mathcal{D}_\varepsilon(t)g_\varepsilon(u,x_\varepsilon(u),\alpha_\varepsilon(u))du\Big)\\ &\quad\to Eh_k(x(t_k),\overline{\alpha}(t_k))\Big(\int_t^{t+s}\overline{b}(u,x(u),\overline{\alpha}(u))du+\int_t^{t+s}\overline{B}(u)g(x(u),\cdot)(\overline{\alpha}(u))du\Big).\end{aligned}$$

(4) In view of (A.13), for $i = 1, \ldots, l$,

$$A^i(t) \begin{pmatrix} \widehat{g}(t,x,s_{i1}) \\ \widehat{g}(t,x,s_{i2}) \\ \vdots \end{pmatrix} = \begin{pmatrix} \widetilde{b}(t,s_{i1}) \frac{\partial \overline{g}(x,i)}{\partial x} \\ \widetilde{b}(t,s_{i2}) \frac{\partial \overline{g}(x,i)}{\partial x} \\ \vdots \end{pmatrix},$$

which has a unique solution. This implies that $\widehat{g}(t,x,s_{ij})$ is a function of $(\partial/\partial x)\overline{g}(x,i)$. In view of (A.17), $b(t,x,s_{ij})$ is a function of $(\partial/\partial x)\widehat{g}(t,x,s_{ij})$. Thus $b(t,x,s_{ij})$ is a function of $(\partial^2/\partial x^2)\overline{g}(x,i)$.

Denote $\overline{b}(t,x,i) = (1/2)a(t,i)(\partial^2/\partial x^2)\overline{g}(x,i)$, where $a(t,i)$ is an appropriate function. Using an argument similar to that [29, pp. 200–203], it can be shown that $a(t,i) \geq 0$. Thus, $a(t,i)$ can be written as $a(t,i) = \sigma^2(t,i)$, where for each $i = 1, 2, \ldots, l$,

$$\sigma^2(t,i) = \sum_{k=1}^{\infty} \sum_{m=1}^{\infty} f(s_{ik}) f(s_{im}) \left[\nu^{ik}(t) \int_0^{\infty} \psi_0^{km}(i,u,t)du + \nu^{im}(t) \int_0^{\infty} \psi_0^{mk}(i,u,t)du \right], \tag{A.19}$$

and $\psi_0^{km}(i,s,t)$ is the (k,m)th entry of $\Psi_0(i,s,t)$ given by

$$\Psi_0(i,s,t) = (I - (\nu^i(s), \nu^i(s), \ldots)') \exp(A^i(s)t).$$

This specifies the covariance structure of the limit process and establishes the desired martingale property and hence the theorem follows. □

Acknowledgment. We thank the editor and the reviewers for detailed comments and suggestions on an early version of the manuscript, which have led to much improvement of the paper.

ACOUSTIC-ROTATIONAL INTERNAL FLOW CAUSED BY TRANSIENT SIDEWALL MASS ADDITION*

P. L. STAAB†, M. J. REMPE‡, AND D. R. KASSOY§

Abstract. Asymptotic and numerical methods are used to describe thermal transients in an internal flow caused by time-dependent, spatially distributed sidewall mass addition. Solutions are obtained for the temperature distribution and wall heat transfer, as well as the vorticity, in a high Reynolds number (Re), low Mach number (M), *compressible* flow in a cylinder. A multiple-scale analysis, valid in the limit of $M \to 0$ and $Re \to \infty$, is used to derive an equation for $O(M)$ acoustic disturbances arising from transient injection. The limit process is also used to obtain reduced equations for the rotational axial velocity field and the nonacoustic temperature variation arising from a balance of convection and transverse diffusion. The convection-diffusion equations are characterized by viscous and conductive transport on an $O(M)$ radial scale relative to the $O(1)$ nondimensional cylinder radius. These small-scale diffusive effects are pervasive throughout the entire cylinder in this large Re, injected flow. The thermal analysis presented here shows that the transient temperature disturbance consists of an $O(M)$ acoustic component and an $O(M)$ radially dependent "rotational" component arising from the convection and diffusion of large radial gradients. The latter are generated on the injection surface and then gradually fill the cylinder as time elapses. The radial gradient of temperature is $O(1)$, although the temperature disturbance is only $O(M)$. Results for the radial and axial variations of the instantaneous temperature distribution imply that the $O(M)$ acoustic and "rotational" temperature components make the largest contributions to the total energy transient. Smaller kinetic energy effects appear only at $O(M^2)$. These results emphasize the importance of modeling intense thermal transients, including the sidewall heat transfer, in addition to the more familiar vorticity distributions.

1. Introduction.

Time-dependent mass injection from the boundaries of cylinders and channels induces a transient internal flow characterized by the presence of coexisting rotational and irrotational (acoustic) phenomena. The velocity and vorticity dynamics in these high Reynolds number and low Mach number flows have been elucidated through the use of both linear and nonlinear mathematical models.

Linear analysis was initiated by Flandro [1] and later reviewed in Flandro [2]. More recent, related research advances are noted by Majdalani and Rienstra [3]. These studies focus on the evolution of very small, linear disturbances to the basic steady flow field induced by uniform mass addition at the boundary. Flow transients are driven by an assumed small quasi-steady pressure disturbance, independent of conditions on the flow boundary. The asymptotic methodology used to derive the disturbance equations implies that the magnitude of the assumed pressure field is smaller than the injection Mach number, typically $O(10^{-3})$. It follows that the disturbance is about 0.1 of commensurately small vorticity at the injection surface, resulting primarily from

an inviscid interaction between the imposed pressure gradient transients and the fluid injected from the boundary, as well as subsequent penetration of vorticity into the flow field. These models supplement classical acoustic stability theory for solid rocket motors, reviewed by Culick and Yang [4], valid only for irrotational flow dynamics. Related, more general linear stability analyses, including the rotational flow effects, are given by Casalis, Avalon, and Pineau [5] and Venugopal, Najjar, and Moser [6, 7].

Nonlinear velocity transients in channel and cylinder configurations have also been investigated [8, 9, 10, 11, 12, 13, 14]. These asymptotic and numerical studies use an initial-boundary value problem (IBVP) approach to investigate the effect of imposed time-dependent disturbances, located on a boundary surface, on the internal flow dynamics. The asymptotic methodology is based on the limit $M \to 0$, where M is the characteristic axial Mach number. In this case, the $O(M)$ pressure gradient transients, typically 1% to 10% of the baseline value and 10 to 100 times larger than those in the linear analyses, arise directly from the time-dependent boundary condition, often associated with variable mass addition. The evolution of $O(1/M)$ transient vorticity, generated by an inviscid mechanism at the boundary, is described by a fully nonlinear convection-diffusion equation for a relatively large rotational axial velocity disturbance.

The vorticity generation concept was used originally by Cole and Aroesty [15] to describe high Reynolds number, external steady flow past a flat plate with massive injection (a magnitude larger than that permitted in traditional boundary layer theory). This concept has been generalized in [8, 9, 10, 11, 12, 13, 14] to describe high Reynolds number, low Mach number, compressible transient internal flows. In contrast to the Cole and Aroesty theory, where viscosity is confined to a thin, separated shear layer, viscous effects are pervasive throughout the transient internal flow, affecting the diffusion of vorticity in a fundamental way.

An early asymptotic formulation for flow in a cylinder is described by Zhao [8] and more fully by Zhao et al. [9]. Significant transient endwall mass addition is the source of large disturbances in the flow field. A related computational study is given by Kirkkopru, Kassoy, and Zhao [10], where the source of large disturbances is an assumed pressure transient on the exit plane. Staab and Kassoy [11] extend the study in [9] to describe multidimensional flow in a cylinder arising from time-dependent endwall mass addition with an amplitude varying in the transverse direction.

The impact of sidewall mass addition transients are considered by Staab et al. [12]. In this case the acoustic field in a cylinder is directly attributable to the time-dependent component of the axially distributed injection velocity. A related computational study by Kirkkopru et al. [13] predicts flow transients arising from a similar injection distribution on the walls of a cylinder. Staab and Kassoy [14] impose a sidewall transient injection velocity with axial and azimuthal dependence to induce a fully three-dimensional transient internal flow disturbance. Results include an axial component of the vorticity vector, in addition to the more familiar azimuthal component found in cylinders with symmetric injection.

The consequences of sidewall vorticity generation in transient internal flows have been observed in many related computational studies. Vuillot and Avalon [16] and Vuillot [17] provide early examples of vorticity penetration into channel flow. Lupoglazoff and Vuillot [18] consider the presence of vorticity shed from the injection surface of a channel. Many other examples are cited in [8, 9, 10, 11, 12, 13, 14]. More recently, Venugopal, Najjar, and Moser [6, 7] described the appearance of vorticity striations on a channel sidewall and their penetration into a turbulent internal flow.

These results support the predictions of vorticity spreading discussed in [8, 9, 10, 11, 12, 13, 14] and [19].

Solutions in [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14] and [16, 17, 18] provide results for the pressure and velocity transients in the flow field, with little consideration of thermal effects. The latter have probably been relegated to secondary importance because the injected fluid is assumed to be isothermal. However, Staab et al. [12] show that unexpectedly large transient radial temperature gradients are generated at the injection surface by a nonconductive interaction between the local acoustic pressure transients and the injected fluid. These gradients are the source of unanticipated heat transfer at the surface, just as the radial gradients of axial velocity (vorticity) are the source of unanticipated shear stress on the surface. The radial temperature gradients will be convected into the internal flow field and diffused by conduction, analogous to the flow physics affecting the vorticity distribution in the internal flow field. Hegab's [19] computational model for channel flow with transient isothermal sidewall mass addition provides solutions for the time-history of the spatially varying temperature distribution in the channel and for the injection surface heat transfer.

The current work provides an asymptotic description of the temperature distribution and wall heat transfer for high Reynolds number (Re), low Mach number (M), compressible flow in a cylinder. An initial-boundary value approach is used to develop the model. When $t \leq 0$, a steady flow is generated by a steady, axially dependent, isothermal mass injection from the sidewall. Then for $t > 0$, a similar magnitude, isothermal component of mass is added with oscillatory time-dependence and spatial variation in the axial direction.

A formal multiple-scale analysis in the limit of $M \to 0$ and $Re \to \infty$ is used to derive an equation for the acoustic response to the transient injection. The axial acoustic velocity is of the same order of magnitude as that of the initial steady flow. The limit process is also used to obtain reduced equations for the rotational axial velocity field and the associated "rotational" temperature variation above and beyond the acoustic response. The latter is described by two compatible equations. The first is a wave equation which describes a nonconductive interaction between the $O(M)$ local pressure transient and the injected fluid, leading to the generation of $O(1)$ radial gradients in the "rotational" temperature field. The second is a *linear* convection-diffusion equation with coefficients dependent on both the acoustic and rotational velocities. Velocities are obtained from a solution to an analogous *nonlinear* convection-diffusion equation. Diffusion in either case occurs on a small radial scale, $O(M)$ compared to the $O(1)$ nondimensional cylinder radius. Diffusive effects in this large Re injected flow are pervasive throughout the entire cylinder.

The present temperature and velocity analysis incorporates an integral scaling transformation for the crucial small radial variable, used by Zhao [8] and Zhao et al. [9], in place of the linear scaling transformation used in [12]. Solutions written in terms of the former variable are valid for much longer time-scales than those in the latter.

The analysis presented here shows that the transient temperature disturbance consists of an acoustic component and a radially dependent "rotational" component arising from the convection and diffusion of large radial gradients. The latter are generated on the injection surface and then gradually fill the cylinder as time elapses. Results are given for the radial and axial variations of the instantaneous temperature distribution. Spatial waves in the radial coordinate are observed between the sidewall and an identifiable front, which moves toward the cylinder axis with increasing time.

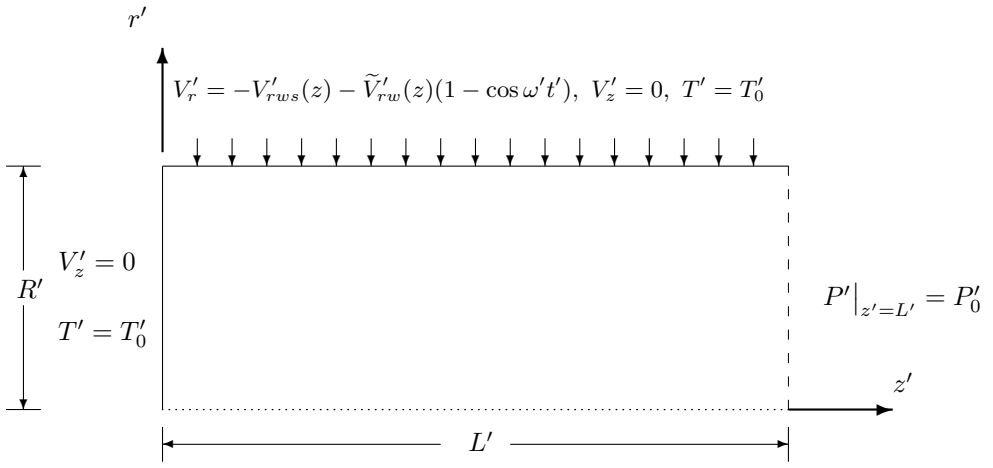

FIG. 1. *The geometric domain of the model is a cylinder of length L' and radius R', where the aspect ratio $\delta = \frac{L'}{R'} \gg 1$. Along the sidewall, $r' = R'$, a steady velocity, $V_{rws}'(z')$, and an unsteady velocity, $\widetilde{V}_{rw}(z')(1 - \cos\omega' t')$, are imposed, and the no-slip condition, $V_z' = 0$, is satisfied. A temperature T_0' is imposed along the sidewall and the endwall. A pressure node is imposed at the exit plane, $z' = L'$.*

Temperature solutions are developed for two different spatial distributions of the mass addition. A comparison shows that the details of the internal flow are sensitive to the characteristics of the mass addition.

A comparison is made of new, long-time solutions for the spatially distributed temperature and velocity. Differences in characteristic spatial waves are observed and attributed to basic properties of the linear (for temperature) and nonlinear (for velocity convection-diffusion) equations.

A study of energy partitioning shows that the $O(M)$ acoustic and "rotational" temperature components make the largest contributions to the total energy transient. Smaller kinetic energy effects appear only at (M^2). In addition, the long-time average of the largest acoustic temperature transient vanishes, while that associated with the "rotational" component is nonzero. This result emphasizes the importance of modeling the thermal transients, including the sidewall heat transfer in the cylinder.

2. Mathematical formulation. The flow occurs in a right circular cylinder of length L' and radius R'. A pressure node is imposed at the exit plane, as shown in Figure 1, to simplify the calculation of the acoustic field arising from unsteady wall injection. Other, more physically viable pressure conditions at the exit plane could be employed to find alternative acoustic responses. However, the basic modeling concepts, in particular, the role of acoustics in generating intense transient vorticity and heat transfer, will be unaffected.

The mathematical model is based on the nondimensional, compressible Navier–Stokes equations in cylindrical coordinates:

$$\frac{\partial \rho}{\partial t} + M\left(\frac{1}{r}\,\frac{\partial}{\partial r}\,\left(r\rho V_r\right) + \frac{\partial}{\partial z}\,\left(\rho V_z\right)\right) = 0, \tag{1}$$

$$\rho\frac{DV_r}{Dt} = -\frac{\delta^2}{\gamma\ M}\frac{\partial P}{\partial r} + \frac{M\ \delta^2}{Re}\left(2\frac{\partial}{\partial r}\left(\mu\left(\frac{\partial V_r}{\partial r} - \frac{1}{3}\nabla\cdot\overline{\mathbf{V}}\right)\right)\right.$$
$$\left. + \frac{\partial}{\partial z}\left(\mu\left(\frac{1}{\delta^2}\frac{\partial V_r}{\partial z} + \frac{\partial V_z}{\partial r}\right)\right) + 2\frac{\mu}{r}\left(\frac{\partial V_r}{\partial r} - \frac{V_r}{r}\right)\right), \tag{2}$$

$$\rho\frac{DV_z}{Dt} = -\frac{1}{\gamma M}\frac{\partial P}{\partial z} + 2\frac{M}{Re}\frac{\partial}{\partial z}\left(\mu\left(\frac{\partial V_z}{\partial z} - \frac{1}{3}\nabla\cdot\overline{\mathbf{V}}\right)\right)$$
$$+ \frac{M\ \delta^2}{Re}\frac{\partial}{\partial r}\left(\mu\left(\frac{1}{\delta^2}\frac{\partial V_r}{\partial z} + \frac{\partial V_z}{\partial r}\right)\right), \tag{3}$$

$$\rho C_V\frac{DT}{Dt} = -M(\gamma-1)P\nabla\cdot\overline{\mathbf{V}} + \frac{M^3(\gamma-1)\gamma}{Re}\Phi$$
$$+ \frac{M}{Pr}\frac{\delta^2}{Re}\left(\frac{1}{r}\frac{\partial}{\partial r}\left(r\kappa\frac{\partial T}{\partial r}\right) + \frac{1}{\delta^2}\frac{\partial}{\partial z}\left(\kappa\frac{\partial T}{\partial z}\right)\right), \tag{4}$$

$$P = \rho T, \tag{5}$$

where

$$\nabla\cdot\overline{\mathbf{V}} = \frac{\partial V_r}{\partial r} + \frac{V_r}{r} + \frac{\partial V_z}{\partial z},$$
$$\frac{D}{Dt} = \frac{\partial}{\partial t} + M\left(V_r\frac{\partial}{\partial r} + V_z\frac{\partial}{\partial z}\right),$$

and Φ is the dissipation function. The nondimensionalized variables in (1)–(5) are defined by the following:

$$\rho = \frac{\rho'}{\rho_0'}, \quad P = \frac{P'}{P_0'}, \quad T = \frac{T'}{T_0'}, \quad V_r = \frac{V_r'}{V_{r0}'}, \quad V_z = \frac{V_z'}{V_{z0}'},$$
$$r = \frac{r'}{R'}, \quad z = \frac{z'}{L'}, \quad t = \frac{t'}{t_a'}, \quad \kappa = \frac{\kappa'}{\kappa_0'}, \quad \mu = \frac{\mu'}{\mu_0'}, \quad C_V = \frac{C_V'}{C_{V0}'},$$

where P_0' is the initial static pressure in the cylinder and ρ_0' and T_0' are the density and temperature of the fluid being injected from the sidewall. The aspect ratio, given by $\delta = \frac{L'}{R'}$, where $\delta \gg 1$, is chosen to reflect the large aspect ratios found in typical large solid rocket motors. The induced characteristic axial velocity, V_{z0}', is defined with respect to the injection reference sidewall velocity, V_{r0}', by $\frac{V_{z0}'}{V_{r0}'} = \delta$, which is a global characteristic mass conservation statement.

Time is nondimensionalized by the axial acoustic time-scale, $t_a' = \frac{L'}{C_0'}$, where $C_0' = (\gamma\mathcal{R}'T_0')^{\frac{1}{2}}$ is the speed of sound, $\mathcal{R}'$ is the gas constant, and γ is the ratio of specific heats. Thermal diffusivity, viscosity, and specific heat at constant volume, κ_0', μ_0', and C_{V0}', are characteristic properties of the single-species injected fluid. Also the axial Reynolds number, Prandtl number, and axial Mach number are defined as

$$Re = \frac{\rho_0' V_{z0}' L'}{\mu_0'}, \quad Pr = \frac{\mu_0' C_{p0}'}{\kappa_0'}, \quad M = \frac{V_{z0}'}{C_0'}, \tag{6}$$

where $Re \gg 1, M \ll 1$, and $Pr = O(1)$. It is also assumed that hard blowing, defined in Cole and Aroesty [15] by $\delta^2/Re << 1$ prevails. The nondimensional parameter δ^2/Re represents the inverse of the radial Reynolds number with characteristic speed V_{r0}' and length R'.

2.1. Boundary conditions. Initially, for $t \leq 0$, a steady internal flow is generated by an axisymmetric time-independent sidewall radial velocity, $V_r = -V_{rws}(z)$. Subsequently, $t > 0$, a transient disturbance is added to the steady value such that $V_r = -V_{rws}(z) - \widetilde{V}_{rw}(z)(1 - \cos\omega t)$ for $\omega = O(1)$. The transient mass addition is of the same magnitude as the steady component and is always positive, e.g., $\tilde{V}_{rw}(z) > 0$.

The full boundary conditions for this axisymmetric problem are

$$z = 0; \quad V_z = 0, \quad V_r = 0, \quad T = 1, \tag{7}$$

$$z = 1; \quad P = 1, \tag{8}$$

$$r = 0; \quad V_r = 0, \quad \frac{\partial V_z}{\partial r} = \frac{\partial T}{\partial r} = \frac{\partial \rho}{\partial r} = \frac{\partial P}{\partial r} = 0, \tag{9}$$

$$r = 1; \quad V_r = \begin{cases} -V_{rws}(z), & t \leq 0, \\ -V_{rws}(z) - \widetilde{V}_{rw}(z)(1 - \cos\omega t), & t > 0, \end{cases} \tag{10}$$

$$r = 1; \quad V_z = 0, \quad T = 1. \tag{11}$$

The unsteady radial boundary velocity is chosen to ensure that the axial acoustic velocity, driven by the fluctuations in the radial injection velocity, is of the same amplitude as the mean axial velocity flow. As a consequence, the model accommodates nonlinear phenomena.

3. Steady flow solutions. The solution to the steady equations is a base flow arising from the first boundary condition in (10). The steady flow is then altered by imposing the second unsteady boundary condition in (10). The initial step in finding solutions is to divide the velocities and thermodynamic variables,

$$(V_r, V_z, P, \rho, T) = (V_{rs}, V_{zs}, P_s, \rho_s, T_s) + (\widetilde{V}_r, \widetilde{V}_z, \widetilde{P}, \widetilde{\rho}, \widetilde{T}), \tag{12}$$

where the subscript "s" represents the steady part of the flow and ($\tilde{}$) represents the unsteady flow.

The steady variables are then expanded as

$$\begin{aligned} (V_{rs}, V_{zs}) &\sim (V_{r0s}, V_{z0s}) + O(M), \\ (P_s, \rho_s, T_s) &\sim 1 + M^2(P_{0s}, \rho_{0s}, T_{0s}) + O(M^3) \end{aligned} \tag{13}$$

for the limit $M \to 0$ and $\delta^2/Re \to 0$ (see [9, 12]). The leading-order steady equations for the velocity and pressure are found by substitution of (13) into (1)–(5),

$$\frac{1}{r}\frac{\partial (rV_{r0s})}{\partial r} + \frac{\partial V_{z0s}}{\partial z} = 0, \tag{14}$$

$$P_{0s} = P_{0s}(z), \tag{15}$$

$$V_{r0s}\frac{\partial V_{z0s}}{\partial r} + V_{z0s}\frac{\partial V_{z0s}}{\partial z} = -\frac{1}{\gamma}\frac{\partial P_{0s}}{\partial z}, \tag{16}$$

$$V_{r0s}\frac{\partial T_{0s}}{\partial r} + V_{z0s}\frac{\partial T_{0s}}{\partial z} = 0, \tag{17}$$

$$P_{0s} = \rho_{0s} + T_{0s}, \tag{18}$$

and must satisfy the steady boundary conditions,

$$z = 0; \quad V_{z0s} = 0, \quad T_{0s} = 0, \tag{19}$$

$$z = 1; \quad P_{0s} = 0, \tag{20}$$

$$r = 0; \quad V_{r0s} = 0, \quad \frac{\partial V_{z0s}}{\partial r} = \frac{\partial P_{0s}}{\partial r} = \frac{\partial T_{0s}}{\partial r} = \frac{\partial \rho_{0s}}{\partial r} = 0, \tag{21}$$

$$r = 1; \quad V_{r0s} = -V_{rws}(z), \quad V_{z0s} = 0, \quad T_{0s} = 0. \tag{22}$$

Equation (14) shows that the steady flow is incompressible, and the lack of viscous terms in (16) is noted. As shown by Staab et al. [12], evaluation of (16) along the sidewall, $r = 1$, and use of the no-slip condition in (22) shows that a nonzero steady vorticity, Ω_{0s}, is generated on the sidewall,

$$\Omega_{0s}(r = 1, z) = \left(\frac{\partial V_{z0s}}{\partial r} - \frac{\partial V_{r0s}}{\partial z} \right)(r = 1, z) = -\frac{1}{\gamma\, V_{r0s}} \frac{\partial P_{0s}}{\partial z} + \frac{\partial V_{rws}(z)}{\partial z}. \tag{23}$$

In contrast, the steady heat transfer along the sidewall, found from (17) and (22), $\frac{\partial T_{0s}}{\partial r}(r = 1, z)$, is zero. Last, (15) shows that the steady pressure varies only with z, a result of the large aspect ratio assumption, $\delta \gg 1$.

The solutions to (14)–(22) can be written as

$$V_{r0s} = -\frac{V_{rws}(z)}{r} \sin\left(\frac{\pi}{2} r^2\right), \tag{24}$$

$$V_{z0s} = \left(\pi \int_0^z V_{rws}(\widehat{z}) d\widehat{z} \right) \cos\left(\frac{\pi}{2} r^2\right), \tag{25}$$

$$P_{0s} = \gamma \pi^2 \int_z^1 V_{rws}(\widehat{z}) \int_0^{\widehat{z}} V_{rws}(\tau) d\tau d\widehat{z}, \tag{26}$$

$$T_{0s} = 0, \tag{27}$$

$$\rho_{0s} = \gamma \pi^2 \int_z^1 V_{rws}(\widehat{z}) \int_0^{\widehat{z}} V_{rws}(\tau) d\tau d\widehat{z}. \tag{28}$$

The results in (24), (25), and (26), derived by Zhao et al. [9], reduce to those of Culick [20] and Taylor [21] when $V_{rws} = 1$. In the absence of conduction, (17) implies that the steady flow is isothermal.

The r-dependence of the steady radial velocity in (24) will be used in section 4 to define a useful coordinate transformation [9, 22], where

$$s(r) \equiv -\frac{\sin(\pi r^2/2)}{r}. \tag{29}$$

The steady solutions in (24)–(28) provide the initial conditions for the full transient flow. Thus, from (12),

$$t = 0, \quad (\widetilde{V}_r, \widetilde{V}_z, \widetilde{P}, \widetilde{\rho}, \widetilde{T}) = 0. \tag{30}$$

4. Integral transform. Zhao et al. [9] and Zhao and Kassoy [22] show that an integral transform of the radial variable facilitates solution development, particularly for the nonirrotational, transient flow components. The transformed radial variable,

$$\sigma(r) = \int_1^r \frac{1}{s(\hat{r})}\, d\hat{r} = -\frac{1}{\pi} \log\Big(\tan\left(\frac{\pi r^2}{4}\right)\Big), \tag{31}$$

is used to calculate partial derivatives in r,

$$\frac{\partial}{\partial r} = \frac{1}{s}\,\frac{\partial}{\partial \sigma}, \qquad \frac{\partial^2}{\partial r^2} = \frac{1}{s^2}\,\frac{\partial^2}{\partial \sigma^2} + \frac{d}{dr}\left(\frac{1}{s}\right)\frac{\partial}{\partial \sigma}, \tag{32}$$

where s is defined in (29). The transform maps the radial domain $0 \leq r \leq 1$ to $0 \leq \sigma \leq \infty$. The sidewall of the cylinder is at $\sigma = 0$, and the centerline is at $\sigma \to \infty$. The inverse of (31),

$$r(\sigma) = \frac{1}{\sqrt{\pi}}\,\sqrt{\tan^{-1}\left(e^{-\pi\sigma}\right)}, \tag{33}$$

is used to convert σ-dependent functions to the original variable dependence.

Zhao et al. [9] show that two disparate length scales are needed to describe the solution dynamics since physical phenomena are occurring simultaneously on two disparate radial length scales. A multiple-scale analysis can be carried out in terms of the independent variables σ_1 and σ_2 defined by

$$\sigma_1 = \sigma, \qquad \sigma_2 = \frac{\sigma}{M}. \tag{34}$$

The variable σ in (31) can be interpreted physically as the nondimensional time required for a fluid particle injected from a z-location on the wall ($r = 1$) to reach a radial location $r \geq 0$. As the centerline is approached ($r \to 0$), the value of σ becomes unbounded because the steady radial speed in (24) is proportional to $O(r)$. It follows that the σ-variable is used to describe physical variations experienced by an injected fluid particle as it traverses the entire radius of the cylinder, R'. In contrast, the second variable, σ_2, in (34) is used to describe physical variations occurring on the much shorter acoustic time $t'_A = L'/Co'$, during which a fluid particle will move only a small radial distance relative to R'. These simple physical interpretations of (31) and (34) stand in contrast to unsupported criticisms by Majdalani and Flandro [23] suggesting that the transformations are a "...conjectured set of scales found by intuition" and that they are "...different from the uniformly valid scales...prescribed by the problem's solvability condition." The latter remark refers to analysis found in their small disturbance theory and is not relevant to the nonlinear model considered in the present work.

In order to derive accurate reduced forms of the basic descriptive equations in the limit $M \to 0$, the radial variables in (34) must be introduced into (1)–(4) through the use of a chain rule

$$\frac{\partial}{\partial \sigma} = \frac{\partial}{\partial \sigma_1} + \frac{1}{M}\,\frac{\partial}{\partial \sigma_2} \tag{35}$$

prior to taking limits. This approach differs from that of Majdalani and Van Moorhem [23, 24], who introduce the short scale only after deriving reduced equations based on an asymptotic limit for large Reynolds number. This nested expansion approach makes it difficult to account for all appropriate terms in each order of reduced equations.

Figure 2 shows a comparison of the new radial variable, $\sigma_2(r)$, to r_2. Equation (34) defines $\sigma_2(r)$, while r_2 is defined in Staab et al. [12] as $r_2 = \frac{1-r}{M}$. The use of the radial variable r_2 in Staab et al. [12] restricts the maximum domain to $r_2 \leq 1/M$. The new variable's semi-infinite domain has no restriction. Both r_2 and $\sigma_2(r)$ are 0 at the sidewall and increase as they approach the centerline.

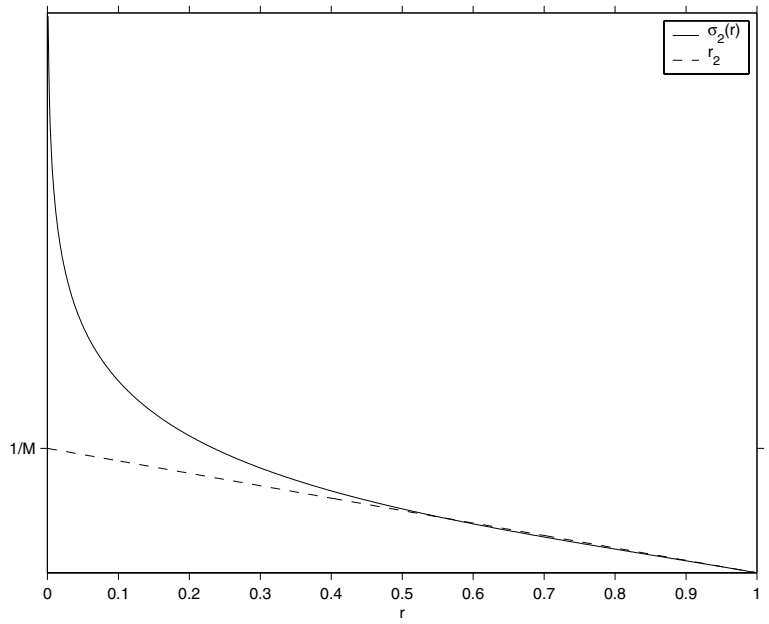

FIG. 2. *Comparison of the new radial variable, $\sigma_2(r)$, to r_2, the radial variable used by Staab et al.* [12].

Staab et al. [12] explain that the coupling between the time and radial direction, found from a method of characteristics solution (see section 5.5), implies a time restriction for a given spatial restriction. Analytic and numerical results in [12] show that $t \leq O(1/M)$. This restriction is absent in the present study.

5. Unsteady flow. The mathematical analysis described here is a generalization and extension of that in Staab et al. [12]. First, the integral transformation in (31) and (34) facilitates the development of solutions valid for extended time values relative to the solutions in [12]. Second, the primary objective of the present modeling is to describe thermal effects including density variations occurring in the flow field. In contrast, the results in [12] describe only the velocity and pressure responses to transient sidewall mass injection for limited values of the time variable.

The modeling paradigm and asymptotic concepts used in [12] are informative with respect to the current work. At the same time, the mathematical analyses differ considerably because the use of the integral transform alters the equations in a substantive way. In this respect, a reader is likely to benefit from a systematic exposition of the asymptotic analysis.

The boundary conditions for the unsteady axisymmetric flow are found using (12), (13), and the difference between (7)–(11) and (19)–(22):

$$z = 0; \quad \widetilde{V}_z = 0, \quad \widetilde{V}_r = 0, \tag{36}$$

$$z = 1; \quad \widetilde{P} = 0, \tag{37}$$

$$\sigma = 0; \quad \widetilde{V}_r = -\widetilde{V}_{rw}(1 - \cos \omega t), \quad \widetilde{V}_z = 0, \quad \tilde{T} = 0, \tag{38}$$

$$\sigma \to \infty; \quad \widetilde{V}_r \to 0, \quad \frac{\partial \widetilde{V}_z}{\partial \sigma} = \frac{\partial \widetilde{T}}{\partial \sigma} = \frac{\partial \widetilde{P}}{\partial \sigma} = \frac{\partial \widetilde{\rho}}{\partial \sigma} \to 0. \tag{39}$$

Asymptotic expansions for the velocity and thermodynamic variables, in the limit $M \to 0$, are

$$\begin{aligned} V_z &\sim V_{z0s}(z,r) + \sum_{n=0}^{\infty} M^n \widetilde{V}_{zn}(z,\sigma,t), \\ V_r &\sim V_{r0s}(z,r) + \sum_{n=0}^{\infty} M^n \widetilde{V}_{rn}(z,\sigma,t), \\ (P,\rho,T) &\sim 1 + \sum_{n=0}^{\infty} M^{n+1}(\widetilde{P}_n, \widetilde{\rho}_n, \widetilde{T}_n), \end{aligned} \tag{40}$$

where the tilde $(\widetilde{\ })$ denotes a time-dependent variable, as in (12). V_{r0s} and V_{z0s} are the steady solutions in (24) and (25).

The large aspect ratio and Reynolds number parameters are connected to the master asymptotic parameter, M, through the relations

$$\delta = \frac{k}{M}, \qquad Re = \frac{1}{CM^4}, \tag{41}$$

where k and C are $O(1)$ constants. The first relationship defines the size of the large aspect ratio chamber relative to a small Mach number. It can be rewritten as $\delta^2 = k/M_i$, where the typical size of the characteristic injection Mach number $M_i = V'_{ro}/C'_o = O(10^{-3})$ (see [2]). This implies that the theory is valid for cylindrical rocket motors with aspect ratios roughly in the range 10 to 30, values that are certainly found in practice.

The second relationship in (41) arises from the limit process analysis itself and is chosen to assure that the effects of viscosity and conductivity are pervasive in the cylinder and maximized with respect to the asymptotic limit, $M \to 0$.

Equation (41) is compatible with the hard blowing limit $\delta^2/Re \to 0$ as $M \to 0$. The relations in (41) permit one to accurately assess the order of magnitude of each and every term in (1)–(4) in the limit $M \to 0$, so that accurate reduced equation systems are derived at each order of M.

5.1. Leading-order equations in the limit $M \to 0$. The derivatives related to the transformation in (31) and (35), the multiple-scale relationships in (34), the unsteady expansions in (40), and the relationship between the parameters δ, Re, and M in (41) are substituted into (1)–(5) prior to applying the limit $M \to 0$. The resulting $O(M^0)$ to $O(M^2)$ approximations of (1) are

$$\frac{\partial \widetilde{V}_{r0}}{\partial \sigma_2} = 0, \tag{42}$$

$$\frac{\mathcal{D}\widetilde{\rho}_0}{\mathcal{D}t} = -\frac{\partial \widetilde{V}_{z0}}{\partial z} - \frac{1}{s}\frac{\partial \widetilde{V}_{r1}}{\partial \sigma_2} - \frac{\widetilde{V}_{r0}}{r} - \frac{1}{s}\frac{\partial \widetilde{V}_{r0}}{\partial \sigma_1}, \tag{43}$$

$$\begin{aligned} \frac{\mathcal{D}\widetilde{\rho}_1}{\mathcal{D}t} = \widetilde{\rho}_0 \frac{\mathcal{D}\widetilde{\rho}_0}{\mathcal{D}t} - \frac{\widetilde{V}_{r1}}{r} - \frac{1}{s}\left(\frac{\partial \widetilde{V}_{r1}}{\partial \sigma_1} + \frac{\partial \widetilde{V}_{r2}}{\partial \sigma_2} + \widetilde{V}_{r1}\frac{\partial \widetilde{\rho}_0}{\partial \sigma_2} + (V_{r0s} + \widetilde{V}_{r0})\frac{\partial \widetilde{\rho}_0}{\partial \sigma_1}\right) \\ - \frac{\partial \widetilde{V}_{z1}}{\partial z} - (V_{z0s} + \widetilde{V}_{z0})\frac{\partial \widetilde{\rho}_0}{\partial z}, \end{aligned} \tag{44}$$

where

$$\frac{\mathcal{D}}{\mathcal{D}t} \equiv \frac{\partial}{\partial t} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\frac{\partial}{\partial \sigma_2}. \tag{45}$$

The $\mathcal{D}$ symbol differentiates (45) from the substantial derivative below (5).

The $O(M^0)$ to $O(M^2)$ versions of the radial momentum equation (2),

$$\frac{\partial \widetilde{P}_0}{\partial \sigma_2} = 0, \tag{46}$$

$$\frac{\partial \widetilde{P}_1}{\partial \sigma_2} + \frac{\partial \widetilde{P}_0}{\partial \sigma_1} = 0, \tag{47}$$

$$\frac{\partial \widetilde{P}_2}{\partial \sigma_2} + \frac{\partial \widetilde{P}_1}{\partial \sigma_1} = 0, \tag{48}$$

result from the large aspect ratio assumption.

The $O(M^0)$ and $O(M)$ terms of the axial momentum equation (3) result in

$$\frac{\mathcal{D}\widetilde{V}_{z0}}{\mathcal{D}t} = -\frac{1}{\gamma}\frac{\partial \widetilde{P}_0}{\partial z}, \tag{49}$$

$$\begin{aligned}\frac{\mathcal{D}\widetilde{V}_{z1}}{\mathcal{D}t} = &-\frac{1}{\gamma}\frac{\partial \widetilde{P}_1}{\partial z} - \frac{1}{\gamma}\frac{\partial P_{0s}}{\partial z} + \frac{1}{\gamma}\widetilde{\rho}_0\frac{\partial \widetilde{P}_0}{\partial z} + \frac{Ck^2}{s^2}\frac{\partial^2 \widetilde{V}_{z0}}{\partial \sigma_2^2} - \frac{\widetilde{V}_{r1}}{s}\frac{\partial \widetilde{V}_{z0}}{\partial \sigma_2} \\ &-\frac{\widetilde{V}_{r0} + V_{r0s}}{s}\left(\frac{\partial \widetilde{V}_{z0}}{\partial \sigma_1} + \frac{\partial V_{z0s}}{\partial \sigma_1}\right) - \left(\widetilde{V}_{z0} + V_{z0s}\right)\left(\frac{\partial \widetilde{V}_{z0}}{\partial z} + \frac{\partial V_{z0s}}{\partial z}\right),\end{aligned} \tag{50}$$

where (49) has been used to simplify (50).

The $O(M)$ and $O(M^2)$ approximations to the energy equation (4) are

$$\frac{\mathcal{D}\widetilde{T}_0}{\mathcal{D}t} = \frac{\gamma - 1}{\gamma}\frac{\partial \widetilde{P}_0}{\partial t}, \tag{51}$$

$$\begin{aligned}\frac{\mathcal{D}\widetilde{T}_1}{\mathcal{D}t} = &-\left(\frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_1} + \frac{\widetilde{V}_{r1}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_2} + (V_{z0s} + \widetilde{V}_{z0})\frac{\partial \widetilde{T}_0}{\partial z}\right) \\ &+\frac{\gamma - 1}{\gamma}\left(\frac{\partial \widetilde{P}_1}{\partial t} + (V_{z0s} + \widetilde{V}_{z0})\frac{\partial \widetilde{P}_0}{\partial z}\right) + \frac{Ck^2}{\partial\ Pr}\,\frac{1}{s^2}\,\frac{\gamma^2 \widetilde{T}_0}{\gamma \sigma_2^2} \\ &-\frac{(\gamma - 1)^2}{\gamma^2}\left(\widetilde{P}_0\frac{\partial \widetilde{P}_0}{\partial t} - \widetilde{T}_0\frac{\partial \widetilde{P}_0}{\partial t}\right),\end{aligned} \tag{52}$$

The somewhat complicated derivation of the latter appears in the appendix.

The $O(M)$ and $O(M^2)$ equations of state, found from (5), are

$$\widetilde{P}_0 = \widetilde{\rho}_0 + \widetilde{T}_0, \tag{53}$$

$$\widetilde{P}_1 = \widetilde{\rho}_1 + \widetilde{T}_1 + \widetilde{\rho}_0\widetilde{T}_0. \tag{54}$$

The σ_1-dependence of the leading-order pressure, $\widetilde{P}_0$, is found by integration of (47) with respect to σ_2,

$$\widetilde{P}_1 = -\frac{\sigma_2}{s(\sigma_1)}\frac{\partial \widetilde{P}_0}{\partial \sigma_1} + \phi(\sigma_1, z, t).$$

The first term on the right-hand side contains unacceptable secular growth with respect to σ_2, typical of a multiple-scale analysis. It must be suppressed by choosing

$$\frac{\partial \widetilde{P}_0}{\partial \sigma_1} = 0, \tag{55}$$

which, together with (46), implies that the pressure, $\widetilde{P}_0 = \widetilde{P}_0(z,t)$, is planar throughout the cylinder. This result is typical of large aspect ratio cylinder geometries.

A similar analysis can be performed for $\widetilde{P}_1$ to show that

$$\frac{\partial \widetilde{P}_1}{\partial \sigma_2} = \frac{\partial \widetilde{P}_1}{\partial \sigma_1} = 0, \tag{56}$$

and hence the pressure $\widetilde{P}_1$ is also planar.

5.2. Leading-order solutions. Complete solutions for the variables $\widetilde{V}_{z0}$, $\widetilde{V}_{r0}$, $\widetilde{P}_0$, and $\widetilde{T}_0$, described by (42)–(53) and the boundary conditions in (36)–(39), can now be obtained.

The solution development is analogous to that of Zhao et al. [9], in which the variables are split into weak ($\overline{\ }$, implies radial dependence only on σ_1) and strong ($\widehat{\ }$, implies both σ_1 and σ_2 radial dependence) rotational components,

$$\begin{aligned}
\widetilde{V}_{r0} &= \overline{V}_{r0}(z,t,\sigma_1),\\
\widetilde{V}_{r1} &= \overline{V}_{r1}(z,t,\sigma_1) + \widehat{V}_{r1}(z,t,\sigma_1,\sigma_2),\\
\widetilde{V}_{z0} &= \overline{V}_{z0}(z,t,\sigma_1) + \widehat{V}_{z0}(z,t,\sigma_1,\sigma_2),\\
\widetilde{P}_0 &= \overline{P}_0(z,t),\\
\widetilde{\rho}_0 &= \overline{\rho}_0(z,t,\sigma_1) + \widehat{\rho}_0(z,t,\sigma_1,\sigma_2),\\
\widetilde{T}_0 &= \overline{T}_0(z,t,\sigma_1) + \widehat{T}_0(z,t,\sigma_1,\sigma_2).
\end{aligned} \tag{57}$$

The radial velocity $\widehat{V}_{r0}$ has no strong component due to (42), while (46) and (55) preclude any radial dependence for pressure.

The naming convention "strong" and "weak" rotational flow has been used in Staab et al. [12]. Upon substitution of (57) into (42)–(53), two sets of equations can be derived. The weak terms are dependent only on σ_1, z, and t. In contrast, the strong rotational terms depend on σ_1, σ_2, z, and t.

5.3. Weak rotational equations. The leading-order weak rotational unsteady equations, derived from (43), (49), (51), and (53), are

$$\frac{\partial \overline{\rho}_0}{\partial t} = -\frac{1}{r}\frac{\partial (r\overline{V}_{r0})}{\partial r} - \frac{\partial \overline{V}_{z0}}{\partial z}, \tag{58}$$

$$\frac{\partial \overline{V}_{z0}}{\partial t} = -\frac{1}{\gamma}\frac{\partial \overline{P}_0}{\partial z}, \tag{59}$$

$$\frac{\partial \overline{T}_0}{\partial t} = \frac{\gamma - 1}{\gamma}\frac{\partial \overline{P}_0}{\partial t}, \tag{60}$$

$$\overline{P}_0 = \overline{\rho}_0 + \overline{T}_0, \tag{61}$$

where the radial variable σ_1 has been replaced with the original radial variable, r, for convenience.

The boundary conditions for these equations are subsets of those in (36)–(39),

$$z = 0; \quad \overline{V}_{z0} = 0, \tag{62}$$

$$z = 1; \quad \overline{P}_0 = 0, \tag{63}$$

$$r = 0; \quad \overline{V}_{r0} = 0, \qquad \frac{\partial \overline{V}_{z0}}{\partial r} = \frac{\partial \overline{T}_0}{\partial r} = \frac{\partial \overline{P}_0}{\partial r} = \frac{\partial \overline{\rho}_0}{\partial r} = 0, \tag{64}$$

$$r = 1; \quad \overline{V}_{r0} = -\widetilde{V}_{rw}(z)(\cos \omega t - 1). \tag{65}$$

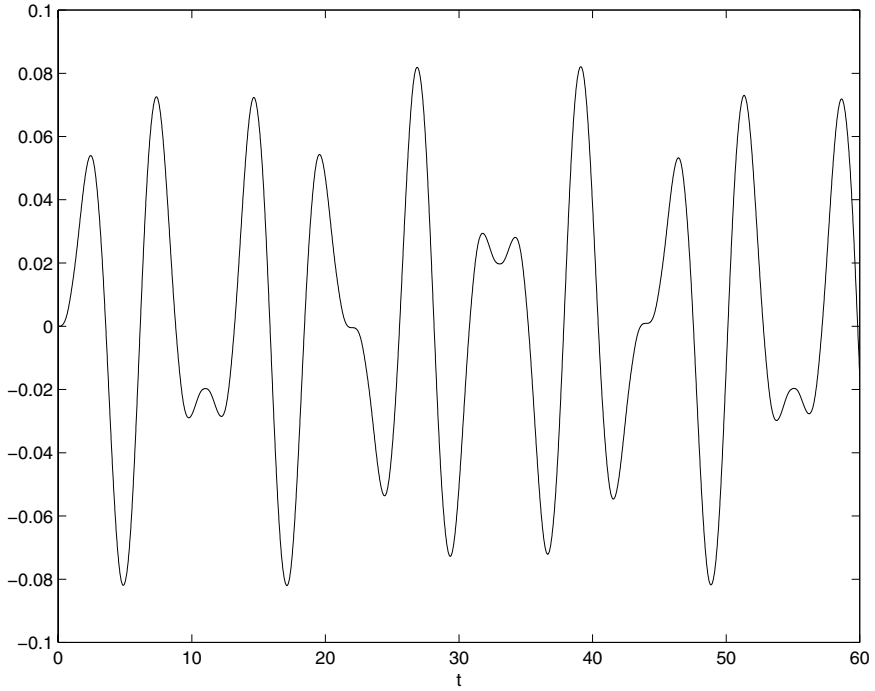

FIG. 3. *The temperature solution of* $\overline{T}_0$ *vs.* t *at* $z = 0.5$ *for* $\omega = 1$ *has a period roughly equal to* 45 *time units.*

The solutions to (58)–(65) are those found in Staab et al. [12],

$$\overline{P}_0 = \sum_{n=0}^{\infty} \frac{2c_n\gamma\omega}{\omega^2 - b_n^2} \left(\frac{\omega}{b_n} \sin b_n t - \sin \omega t \right) \cos b_n z, \tag{66}$$

$$\overline{V}_{z0} = \sum_{n=0}^{\infty} \frac{2\omega c_n}{\omega^2 - b_n^2} \left(\frac{\omega}{b_n}(1 - \cos b_n t) - \frac{b_n}{\omega}(1 - \cos \omega t) \right) \sin b_n z, \tag{67}$$

$$\overline{T}_0 = \sum_{n=0}^{\infty} \frac{2c_n(\gamma - 1)\omega}{\omega^2 - b_n^2} \left(\frac{\omega}{b_n} \sin b_n t - \sin \omega t \right) \cos b_n z, \tag{68}$$

$$\overline{\rho}_0 = \sum_{n=0}^{\infty} \frac{2\omega c_n}{\omega^2 - b_n^2} \left(\frac{\omega}{b_n} \sin b_n t - \sin \omega t \right) \cos b_n z, \tag{69}$$

$$\overline{V}_{r0} = -r\widetilde{V}_{rw}(z)(1 - \cos \omega t), \tag{70}$$

where

$$c_n = 2 \int_0^1 \widetilde{V}_{rw}(z) \cos b_n z \, dz, \tag{71}$$

and $b_n = (n + 1/2)\pi$.

The $\overline{T}_0$ solution is planar and contains both a boundary condition response ($\sin \omega t$) and eigenfunction ($\sin b_n t$) relevant to the exit plane pressure node boundary condition. The latter can be rewritten as a sum of two counter-propagating planar waves, while the boundary condition response represents a standing wave. A time

series plot of $\overline{T}_0$ is found in Figure 3 at $z = 0.5$ for $\omega = 1$. The period is roughly 45 time units. The relatively small positive and negative peaks near $t = 10, 33$, and 55 will be seen in the results for the full temperature field, showing a connection between the acoustic field and the overall temperature variation.

5.4. Steady parts of the weak rotational solutions. Equations (67) and (70) reveal that $\overline{V}_{z0}$ and $\overline{V}_{r0}$ contain both mean and fluctuating parts. It will be shown in section 6 that the means of $\overline{V}_{z0}$ and $\overline{V}_{r0}$, important in describing the temperature dynamics, can be written [12] as

$$\overline{V}_{z0s} = 2\int_0^z \widetilde{V}_{rw}(\hat{z})d\hat{z}, \tag{72}$$

$$\overline{V}_{r0s} = -r\widetilde{V}_{rw}(z). \tag{73}$$

5.5. Strong rotational equations. The leading-order strong rotational equations are found by subtracting (58)–(61) from (43), (49), (51), (53),

$$\frac{\mathcal{D}\widehat{\rho}_0}{\mathcal{D}t} = -\frac{\partial \widehat{V}_{z0}}{\partial z} - \frac{1}{s}\frac{\partial \widehat{V}_{r1}}{\partial \sigma_2}, \tag{74}$$

$$\frac{\mathcal{D}\widehat{V}_{z0}}{\mathcal{D}t} = 0, \tag{75}$$

$$\frac{\mathcal{D}\widehat{T}_0}{\mathcal{D}t} = 0, \tag{76}$$

$$\widehat{\rho}_0 + \widehat{T}_0 = 0, \tag{77}$$

where $\frac{\mathcal{D}}{\mathcal{D}t}$ is defined in (45).

Equations (76) and (77) can be combined to show that

$$\frac{\mathcal{D}\widehat{\rho}_0}{\mathcal{D}t} = 0, \tag{78}$$

and therefore (74) can be written as

$$\frac{\partial \widehat{V}_{z0}}{\partial z} + \frac{1}{s}\frac{\partial \widehat{V}_{r1}}{\partial \sigma_2} = 0. \tag{79}$$

Equations (75), (76), and (78) are first-order wave equations defining invariance along characteristics defined by the radial velocity field, $V_{r0s} + \widetilde{V}_{r0}$. The wave-like solutions to (75), (76), and (78) originate on the sidewall and convect toward the centerline with the local radial velocity. The solution to (76) for the temperature, $\widehat{T}_0$, is obtained following the procedures in Staab et al. [12].

The relevant initial/boundary conditions for (76) are

$$\begin{aligned} t = 0; \qquad & \widehat{T}_0 = 0, \\ \sigma_1 = 0 \quad \text{and} \quad \sigma_2 = 0; \qquad & \widehat{T}_0 = -\overline{T}_0, \end{aligned} \tag{80}$$

where $\overline{T}_0$ is the solution in (68). The second condition demonstrates that the acoustic solution in (68) is a forcing function for $\hat{T}_0$. Equation (76), with the substantial derivative represented by (45), can be solved along a set of characteristics found by integration of

$$\frac{d\sigma_2}{dt} = \frac{V_{r0s}(\sigma_1, z) + \overline{V}_{r0}(\sigma_1, z, t)}{s(\sigma_1)} = V_{rws}(z) + \frac{\overline{V}_{r0}}{s}, \tag{81}$$

where σ_1 and z are treated as constants in the multiple-scale analysis. It follows that (81) can be integrated from 0 to t with the integration constant found from $\sigma_2 = \xi$ at $t = 0$, and σ_1 and σ_2 treated as independent variables. The equation characteristics are described by the result

$$\xi - \sigma_2 = -tV_{rws}(z) - \frac{r^2\widetilde{V}_{rw}(z)}{\sin(\pi r^2/2)}\left(t - \frac{\sin\omega t}{\omega}\right), \tag{82}$$

where r is taken to be $r(\sigma_1)$ as defined by the inverse of the function in (31).

The characteristic, $\xi = 0$, represents the front of the strongly rotational temperature distribution described by (76), which convects away from the sidewall toward the centerline with the speed defined by (81).

An alternative representation of the characteristic curves in (82) can be found by integration of (81) from $t^\star$ to t with the integration constant found from $\sigma_2 = 0$ when $t = t^\star$,

$$\sigma_2 = V_{rws}(z)(t - t^\star) + \frac{r^2\widetilde{V}_{rw}(z)}{\sin(\pi r^2/2)}\left(t - t^\star + \frac{\sin\omega t^\star - \sin\omega t}{\omega}\right). \tag{83}$$

This representation is useful because the solution to (76) along $\sigma_1 = 0$ can be found by integration and the application of the boundary/initial conditions in (80),

$$\widehat{T}_0(t^\star; z) = \begin{cases} 0, & t^\star \le 0, \\ -\overline{T}_0(t^\star, z), & t^\star > 0. \end{cases} \tag{84}$$

The characteristic variable $t^\star$ is the solution of (83) for a given σ_2, z, and t when $\sigma_1 = 0$.

This analysis yields only $\widehat{T}_0(\sigma_1 = 0, \sigma_2, z, t)$, given in (84). As is typical of a multiple-scale analysis, higher-order equations must be considered to resolve behavior on the longer scale, in this case, σ_1.

6. Higher-order considerations. The $O(M^2)$ energy equation in (52) is used in the higher-order analysis to determine the σ_1-dependence of the temperature, $\widehat{T}_0(\sigma_1, \sigma_2, z, t)$.

Similar to the procedure used for the lower-order variables, the $O(M^2)$ unsteady pressure and $O(M)$ unsteady axial velocity are written in the form

$$\begin{aligned} \widetilde{P}_1 &= \overline{P}_1(z,t), \\ \widetilde{V}_{z1} &= \overline{V}_{z1}(\sigma_1, z, t) + \widehat{V}_{z1}(\sigma_1, \sigma_2, z, t), \\ \widetilde{T}_1 &= \overline{T}_1(\sigma_1, z, t) + \widehat{T}_1(\sigma_1, \sigma_2, z, t), \end{aligned} \tag{85}$$

where the weak and strong rotational components of the temperature are denoted by the bar and caret superscripts, respectively. The pressure $\widetilde{P}_1$ is shown to be planar in (56), and therefore no radially dependent pressure term exists.

Substitution of (57) and (85) into (52) yields two sets of energy equations. The first set contains all of the terms of (52) with dependence on σ_1, z, and t,

$$\begin{aligned} \frac{\partial\overline{T}_1}{\partial t} =& \frac{\gamma-1}{\gamma}\frac{\partial\overline{P}_1}{\partial t} - (V_{z0s} + \overline{V}_{z0})\frac{\partial\overline{T}_0}{\partial z} + \frac{\gamma-1}{\gamma}(V_{z0s} + \overline{V}_{z0})\frac{\partial\overline{P}_0}{\partial z} \\ & - \frac{(\gamma-1)^2}{\gamma^2}\left(\overline{P}_0\frac{\partial\overline{P}_0}{\partial t} - \overline{T}_0\frac{\partial\overline{P}_0}{\partial t}\right), \end{aligned} \tag{86}$$

while the second equation is the difference between (52) and (86),

$$\frac{\mathcal{D}\widehat{T}_1}{\mathcal{D}t} = -\left(\frac{V_{r0s}+\overline{V}_{r0}}{s}\frac{\partial\widehat{T}_0}{\partial\sigma_1} + \frac{\widetilde{V}_{r1}}{s}\frac{\partial\widehat{T}_0}{\partial\sigma_2} + (V_{z0s}+\overline{V}_{z0}+\widehat{V}_{z0})\frac{\partial\widehat{T}_0}{\partial z} + \widehat{V}_{z0}\frac{\partial\overline{T}_0}{\partial z}\right)$$
$$+\frac{\gamma-1}{\gamma}\widehat{V}_{z0}\frac{\partial\overline{P}_0}{\partial z} - \frac{(\gamma-1)^2}{\gamma^2}\widehat{T}_0\frac{\partial\overline{P}_0}{\partial t} + \frac{Ck^2}{\gamma\, Pr}\frac{1}{s^2}\frac{\partial^2\widehat{T}_0}{\partial\sigma_2^2}. \tag{87}$$

When (87) is integrated in time, several terms on the right-hand side are sources of unbounded solution behavior in time [12]. The unphysical secular behavior can be suppressed if

$$0 = \frac{V_{r0s}+\overline{V}_{r0s}}{s}\frac{\partial\widehat{T}_0}{\partial\sigma_1} + (V_{z0s}+\overline{V}_{z0s})\frac{\partial\widehat{T}_0}{\partial z} - \frac{Ck^2}{\gamma\, Pr}\frac{1}{s^2}\frac{\partial^2\widehat{T}_0}{\partial\sigma_2^2}, \tag{88}$$

which describes the complete solution $\widehat{T}_0(\sigma_1,\sigma_2,z,t)$. This convection-diffusion equation for the strongly rotational temperature field is analogous to that for the axial speed $\hat{V}_{z0}$,

$$0 = \frac{V_{r0s}+\overline{V}_{r0s}}{s}\frac{\partial\widehat{V}_{z0}}{\partial\sigma_1} + \frac{\partial}{\partial z}\left(\widehat{V}_{z0}\left(\frac{1}{2}\widehat{V}_{z0}+V_{z0s}+\overline{V}_{z0s}\right)\right) - \frac{Ck^2}{\gamma}\frac{1}{s^2}\frac{\partial^2\widehat{V}_{z0}}{\partial\sigma_2^2}. \tag{89}$$

Both the first and third terms in (88) have analogues in (89) for $Pr = 1$. However, the axial convection term in (89) is nonlinear, while that in (88) is linear. Also, the solutions to the two equations will have different properties arising from the boundary conditions imposed on each.

The boundary conditions for (88) have the form

$$\begin{aligned} z = 0, &\quad \widehat{T}_0 = 0; \\ \sigma_2 = 0, &\quad \widehat{T}_0 = \widehat{T}_0(t^\star, z); \\ \sigma_1,\sigma_2 \to \infty, &\quad \widehat{T}_0 \to 0. \end{aligned} \tag{90}$$

The physical solution, $\widehat{T}_0(r,z,t)$, is found by evaluating the function $\widehat{T}_0(\sigma_1,\sigma_2,z,t)$ along $\sigma_1 = M\sigma_2$ and returning to the original radial variable using (33). A numerical solution to (88) is described in section 11.

7. Density field dynamics. The complete leading-order temperature solution can be used to obtain the density. As with the temperature, the density is composed of a steady field, ρ_s, and an unsteady field, $\widetilde{\rho}$. The latter is defined by an asymptotic expansion in powers of M as in (40). In short, the leading-order density field is $\rho = 1 + M(\widehat{\rho}_0 + \overline{\rho}_0) + O(M^2)$, where $\overline{\rho}_0$ is the solution in (69) and $\widehat{\rho}_0$ is explained here.

The strongly rotational density, $\widehat{\rho}_0$, is found from (77), once $\widehat{T}_0$ is found from (88). The qualitative behavior of the density field is analogous to that of the temperature field. A large radial gradient of the density arising along the sidewall of the cylinder will be convected downstream and toward the centerline.

8. Heat transfer along the sidewall. The strongly rotational energy equation, (76) can be used to determine the heat transfer along the sidewall. The dimensional heat transfer per unit area,

$$q' = \kappa'\frac{\partial T'}{\partial r'}, \tag{91}$$

can be nondimensionalized using the definition

$$q_0' = \frac{\kappa_0' T_0'}{R'}$$

to find the first approximation

$$q' \sim \frac{q_0'}{V_{r0s}} \frac{\partial \widehat{T}_0}{\partial \sigma_2}, \tag{92}$$

where (32), (35), and (40) have been used. The characteristic radial heat flux q_0' is far larger than one might expect in a flow where the typical temperature variation is $O(MT_0')$. This $O(1)$, rather than $O(M)$, dependence arises from the presence of large radial gradients on the scale $O(MR')$.

The heat transfer along the sidewall can be found using the leading-order conservation of energy in (51), the sidewall boundary condition in (10), and the pressure solution in (66),

$$\begin{aligned}\left(\frac{q_{\text{wall}}'}{q_0'}\right) = q_{\text{wall}} \equiv \frac{1}{s}\frac{\partial \widehat{T}_0}{\partial \sigma_2}\bigg|_{\text{wall}} &= \frac{1}{\left(V_{r0s} + \widetilde{V}_{r0}\right)} \frac{\partial \overline{T}_0}{\partial t}\bigg|_{\text{wall}} \\ &= \frac{1}{V_{rws} + \widetilde{V}_{rw}(z)\sin\omega t} \sum_{n=0}^{\infty} \frac{2c_n(\gamma-1)\omega}{\omega^2 - b_n^2} (\cos b_n t - \cos\omega t)\cos b_n z. \end{aligned} \tag{93}$$

This surprising result shows that the basic heat transfer is determined by a nonconductive interaction between the acoustic field and the injected fluid.

It should be noted that the heat flux is found from a transport equation (51) in which conduction is absent. This property of the equations is analogous to that of the inviscid momentum equation in (75) which is compatible with the no-slip condition. Hard blowing problems ($\delta^2/Re \ll 1$) are characterized by relatively diminished influence of transport effects on near-surface gradients.

Related wall heat transfer analyses have been done by Staab et al. [12], who present results for different frequencies of the sidewall mass addition.

9. Properties of $\widehat{T}_0$. The effective conductivity for the $\widehat{T}_0$-equation (88) is proportional to $s^{-1}(V_{r0s} + \overline{V}_{r0s})^{-1}$. As the centerline is approached, $r \to 0$, the conductivity becomes unbounded like $1/r^2$. In a linear conduction problem, such conductivity behavior implies that in the limit $r- > 0$, $\widehat{T}_0 \to 0$.

Qualitatively, the linear convection-conduction equation (88) describes convection of thermal energy toward the centerline and downstream, and conduction in the radial direction. However, much more can be said about the properties of the equation. For example, (88) can be written as a linear conduction equation

$$\frac{\partial \widehat{T}_0}{\partial \sigma_1} = \frac{Ck^2}{\gamma Pr} \frac{1}{s(V_{r0s} + \overline{V}_{r0s})} \frac{\partial^2 \widehat{T}_0}{\partial \sigma_2^2} \tag{94}$$

along characteristic curves $z = z(\sigma_1)$ defined by

$$\frac{dz}{d\sigma_1} = \frac{s(V_{z0s} + \overline{V}_{z0s})}{V_{r0s} + \overline{V}_{r0s}}. \tag{95}$$

These curves are streamlines determined by the lowest-order total axial and radial speeds. The slope $dz/d\sigma_1 > 0$, as determined from the right-hand side of (95), which is positive for all σ_1 and z. The streamlines start on the sidewall, $\sigma_1 = 0$, and leave through the exit plane, $z = 1$. All solutions for $\widehat{T}_0$ can be described along these characteristics. Such curves will not cross due to the lack of $\widehat{T}_0$ in (95), a result of the linear form of (88). Equation (95) can be evaluated for $r \to 0$ to show that the streamlines become parallel to the axis ($r = 0$) as $r \to 0$.

The heat equation in (94) can be solved using Fourier transform techniques. A simplified version is solved in Staab et al. [12] and used to show that solutions near the centerline decay with form

$$\lim_{r\to 0} \widehat{T}_0 \sim \left(r\ \frac{\pi}{4}\right)^{\frac{Ck^2\omega^2}{\pi(1+A)^2}}, \tag{96}$$

where the original variable r has been used, C and k are the constants found in (41), and A is an average transverse vorticity wave speed used to simplify the boundary condition. Equation (96) shows that the strongly rotational temperature $\widehat{T}_0$ goes to zero at the centerline. Only the acoustic solution, $\overline{T}_0$ in (68), contributes to the centerline temperature.

10. Solution development and numerical methodology. Solutions to (88) and (89) are found using a procedure similar to that employed by Staab et al. [12]. However, in this case there is no upper limit on the transformed radial variable, σ_2, so the solution can be solved for a much larger time domain.

First the results in (80)–(84) are used to find $\widehat{T}_0(\sigma_1 = 0, \sigma_2 = 0, z, t)$, which is the initial condition for (88). The numerical solution of $\widehat{T}_0(\sigma_1, \sigma_2, z, t)$ at each z and t is evaluated along $\sigma_1 = M\sigma_2$ to yield the solution in (σ, z, t)-space. Finally, (33) is used to return to (r, z, t)-space.

It is noted that t is an implicit variable in (88), with σ_1 playing the role of the timelike variable. For a given value of t the solution to the wave equation (76) on $\sigma_1 = 0$ penetrates a distance defined by the front $\xi = 0$ in (82). Equation (88) describes the convection and diffusion effects on $\widehat{T}_0$ between the wall and the front.

Equation (88) is solved via the method of lines, a numerical technique which employs a spatial discretization to reduce a time-dependent partial differential equation (PDE) to a system of ordinary differential equations (ODEs) in the timelike variable. Since convection is downstream, a second-order backward finite difference formula in the z-direction is the basis for the axial spatial discretization. In this manner the finite differencing is stable since all information comes from the upstream direction. A fourth-order centered finite difference formula is used for the $\frac{\partial^2 \widehat{T}_0}{\partial \sigma_2^2}$ term. The discretization leads to a set of $N_{\sigma_2} \times N_z$ coupled ODEs, where N_z and N_{σ_2} are the number of gridpoints chosen in the z- and σ_2-directions, respectively. This set of ODEs is solved using an adaptive fourth-order Runge–Kutta solver, a stable method for solving a set of ODEs that arise from the discretization of equations with both parabolic and hyperbolic terms.

The computational results in the following section are produced using 150 grid points in the radial direction and 50 in the axial direction. The figures shown in that section were produced with 300 radial gridpoints, where the new points are found using a spline interpolation based on the original 150 points. This was done in order to save computing time in making the plots since running the solver with high grid density takes much longer than performing a spline interpolation. Solving (88)

with 300 radial gridpoints took 89 minutes of computing time, whereas 150 radial gridpoints and then splines took only 10 minutes. All computations were carried out on a SuperSparc workstation.

Before discussing the error generated at each extra gridpoint from using splines, it is necessary to define the following variables:

$$U_{150} = \widehat{T}_0 \quad \text{with } N_{\sigma_2} = 150, \tag{97}$$

$$U_{300} = \widehat{T}_0 \quad \text{with } N_{\sigma_2} = 300, \tag{98}$$

$$U_s = \text{spline}(U_{150}), \tag{99}$$

where U_s comes from taking U_{150} and spline interpolating it to 300 points. The notation N_{σ_2} denotes the number of gridpoints used in the σ_2-direction for the computational solution.

The error at each extra gridpoint is calculated using the following formula:

$$\epsilon = \frac{\|U_{300} - U_s\|_\infty}{\|U_{300}\|_\infty}. \tag{100}$$

The maximum error, ϵ, computed using (100) on a representative test problem is 1.78×10^{-2}. This is considered to be acceptable since the next term in the asymptotic expansion for the temperature is $O(M)$ smaller than $\widehat{T}_0$ and the Mach numbers used in this study are slightly larger than the error. Therefore, the error associated with the asymptotic series is larger than that due to the spline interpolation process.

11. Results. The spatial distribution of the instantaneous temperature and temperature gradient are discussed in this section in order to explain the origin and evolution of thermal disturbances for the sidewall boundary condition in (10), with $V_{rws}(z) = 1$ and $\tilde{V}_{rw}(z) = 0.2\cos\left(\frac{\pi z}{2}\right)$;

$$V_r = -1 - 0.2\cos\left(\frac{\pi z}{2}\right)(1 - \cos\omega t) \qquad \text{at} \quad r = 1. \tag{101}$$

It is noted that the additional unsteady mass increase is on the order of 20% of that due to uniform injection.

Figure 4 shows the instantaneous rotational temperature $\widehat{T}_0$ variation with r and z, for $M = 0.02$, $\delta = 20$, $Re = 3 \times 10^5$, $\omega = 1$, $Pr = 1$, and $\gamma = 1.4$ at $t = 20$. The temperature disturbances, which begin on the sidewall, are driven by the third condition in (90). Three spatial waves characterized by large radial gradients have propagated into the cylinder interior to about $r = 0.5$. Beyond this first wave the solution is $\widehat{T}_0 = 0$. The 0.001-contour nearest the centerline will hereafter be referred to as the "$\widehat{T}_0$-front."

Two mechanisms give the surface in Figure 4 its characteristic morphology. First, along the sidewall of the cylinder ($r = 1$) the solution is given in (84). The time-dependence of the solution along the edge is the negative of $\widehat{T}_0$ shown in Figure 3. The waves are generated along the sidewall and convected into the flow field by the radial velocity field as shown in (76), where the substantial derivative is defined in (45). The other mechanisms governing the shape of the solution are the convective and conductive effects in (88). The waves are convected toward the centerline and downstream and diffused on the length-scale associated with the σ_2-variable.

Observation of each temperature wave in Figure 4 shows that the magnitude decreases in the downstream direction. In contrast, the analogous rotational axial velocity increases with z (see [12]). The difference can be attributed to the mathematical

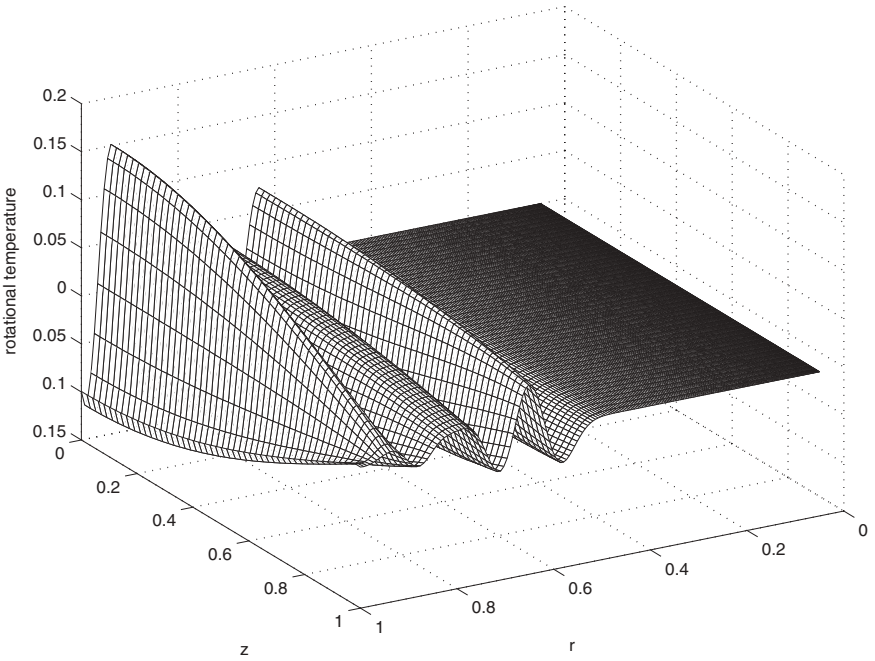

FIG. 4. *The variation of* $\widehat{T}_0$ *with* r *and* z *for* $M = 0.02$, $\delta = 20$, $Re = 3 \times 10^5$, $\omega = 1$, $Pr = 1$, $\gamma = 1.4$, *and at* $t = 20$. *Temperature disturbances originate on the sidewall and convect toward the centerline. The temperature front has reached about* $r = 0.5$ *at this time. The fluid ahead of the front remains at its initial temperature of* $T = 1$.

form of the acoustic solutions in (67) and (68). The acoustic axial velocity contains a $\sin\left(\frac{\pi z}{2}\right)$ term which increases with z, while the acoustic temperature has a $\cos\left(\frac{\pi z}{2}\right)$ term which decreases in the same region. These terms arise from the z-dependence of the sidewall radial velocity in (10). The radial sidewall velocity drives the acoustic temperature field that ultimately generates the strongly rotational temperature.

Figure 5 shows the (r, z) variation of the complete temperature $T \sim 1 + M(\widehat{T}_0 + \overline{T}_0) + O(M^2)$, where $\widehat{T}_0$ is the solution to (76) and (88) and $\overline{T}_0$ is defined in (68). The results are given at $t = 20$ and 30 for the parameter values in Figure 4. Since the boundary condition in (10) has a period of 2π when $\omega = 1$, at $t = 30$, one should expect to find about five spatial waves, as observed in Figure 5(b).

The instantaneous acoustic temperature, $\overline{T}_0$, is described by the "ramp" in Figures 5(a) and 5(b), where $\widehat{T}_0 = 0$. Also, since it is proportional to $\cos\left(\frac{\pi z}{2}\right)$, it always approaches 0 at $z = 1$. The variations with z and t differ according to the dependencies in (68). The impact of the $\widehat{T}_0$-solution can be observed in the region between the front location and $r = 1$. Note the different vertical scales used in Figures 5(a) and 5(b). The amplitude of the solution in Figure 5(a) is almost entirely greater than 1, while that in Figure 5(b) is mostly less than 1. Again, this difference arises from the instantaneous acoustic temperature field. It is noted from Figure 3 that $\widehat{T}_0$ is positive at $t = 20$ and negative at $t = 30$. Figure 6, a contour plot of Figure 5, shows clearly the axial shape of the waves and the radial location of the $\widehat{T}_0$-front near $r = 0.45$. The pure acoustic field is associated with horizontal contours on the left side of the figure. To the right of the $\widehat{T}_0$-front and extending to the sidewall, tightly packed contours

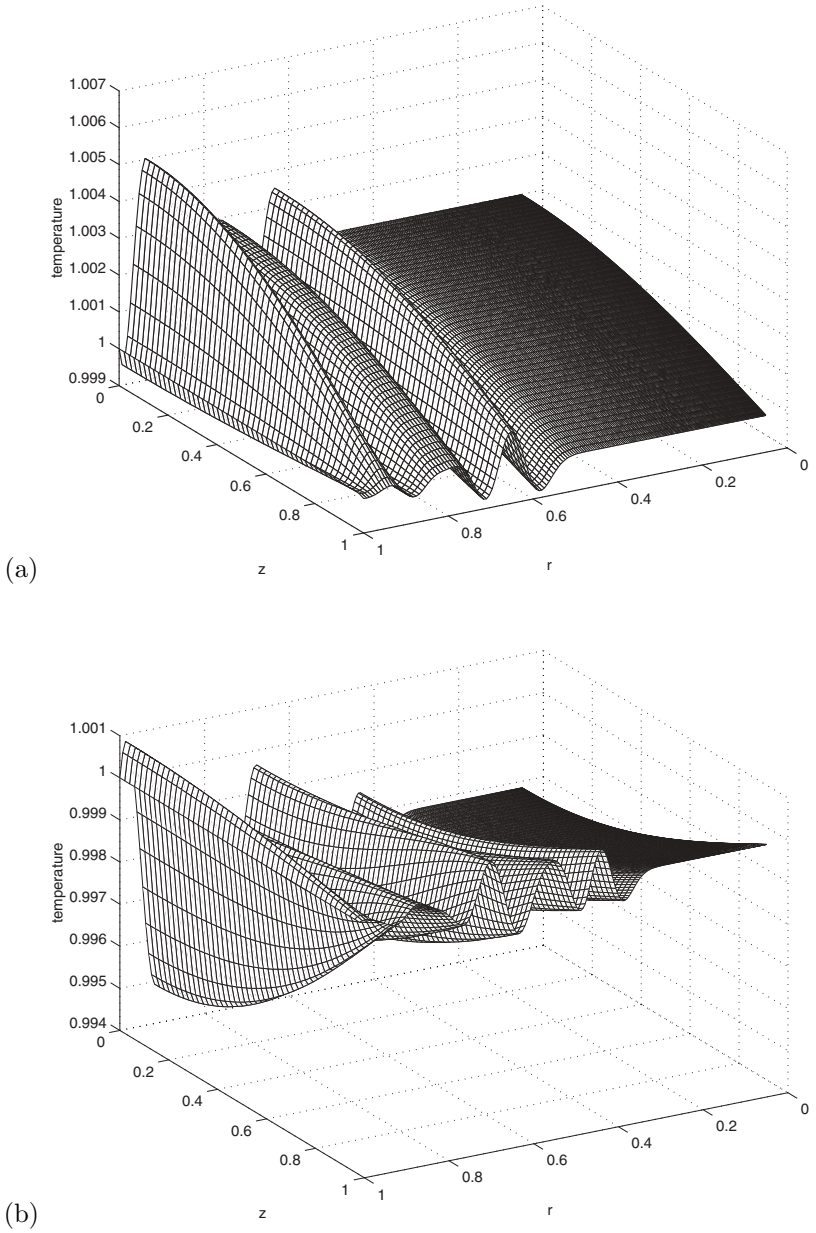

FIG. 5. *Variation of the complete temperature* $T \sim 1 + M(\widehat{T}_0 + \overline{T}_0)$ *with* r *and* z *for* $M = 0.02$, $\delta = 20$, $Re = 3 \times 10^5$, $\omega = 1$, $Pr = 1$, *and* $\gamma = 1.4$ *at* (a) $t = 20$ *and* (b) $t = 30$. *The characteristics of the field near* $r = 1$ *are dominated by* $\widehat{T}_0$, *while that near the centerline is dominated by* $\overline{T}_0$. *Note that different vertical scales have been used for the two plots.*

represent regions of large radial gradients. The shading depicts variations from the background of $T = 1$.

A surface plot of the radial temperature gradient, $\frac{\partial T}{\partial r}$, is shown in Figure 7 using the parameters in Figure 5(a). Pronounced gradients persist up to the location of

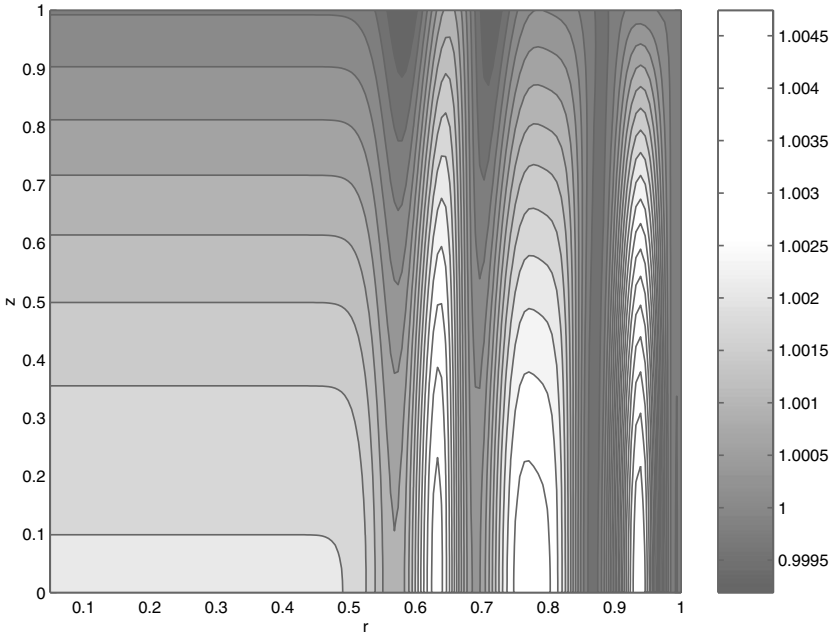

FIG. 6. *Contour plot of the complete temperature T for the parameters in Figure* 5(a).

the $\widehat{T}_0$-front. The variation in the temperature gradient, typically about 0.1, is of the same magnitude as that for $\widetilde{V}_{rw}$. This is in contrast to the leading-order temperature variation, $T-1 \sim M(\widehat{T}_0+\overline{T}_0)+O(M^2)$, roughly .005, as can be seen in Figure 5(a). The variation in the temperature gradient is roughly twenty times larger than that of the temperature in this case, a result of the short wavelength of the spatial oscillations in Figure 5(a). Since the conductive heat transfer is proportional to the temperature gradient, this means that surprisingly large amounts of heat transfer exist in the cylinder even though the temperature perturbations are small.

Figure 8(a) shows the (r,z) variation of the rotational temperature, $\widehat{T}_0$, at $t=60$ with all the other parameters the same as those in Figure 5. At any given axial location, it can be seen that the amplitude of the radial oscillations varies considerably as one moves between the sidewall and the axis of the cylinder. The monotonic variations arise because the solution to (88) along $r=1$ is $-\overline{T}_0$, as shown in (84). Since $-\overline{T}_0$ is not monotonic in time, as shown in Figure 3, the waves that originate on the sidewall are not strictly decreasing in time. However, if one follows a given spatial wave originating at the sidewall and convecting into the cylinder, it will be observed that the wave magnitude is diminished. Staab et al. [12] have shown that this is the result of accumulated convection and diffusion. One may note the smaller amplitude spatial waves near the cylinder axis.

Figure 8(b) describes the spatial dependence of the strong rotational axial velocity, $\overline{V}_{z0}$, for $t=60$ and the same parameter values as those for Figure 8(a). This long-time solution could not be obtained in the earlier work by Staab et al. [12] because of the limitations described earlier in section 4. The results in Figures 8(a) and 8(b) show that the $\widehat{V}_{z0}$ solution is damped more quickly in the radial direction than is the $\widehat{T}_0$ solution. This difference can be attributed to the characteristic of the

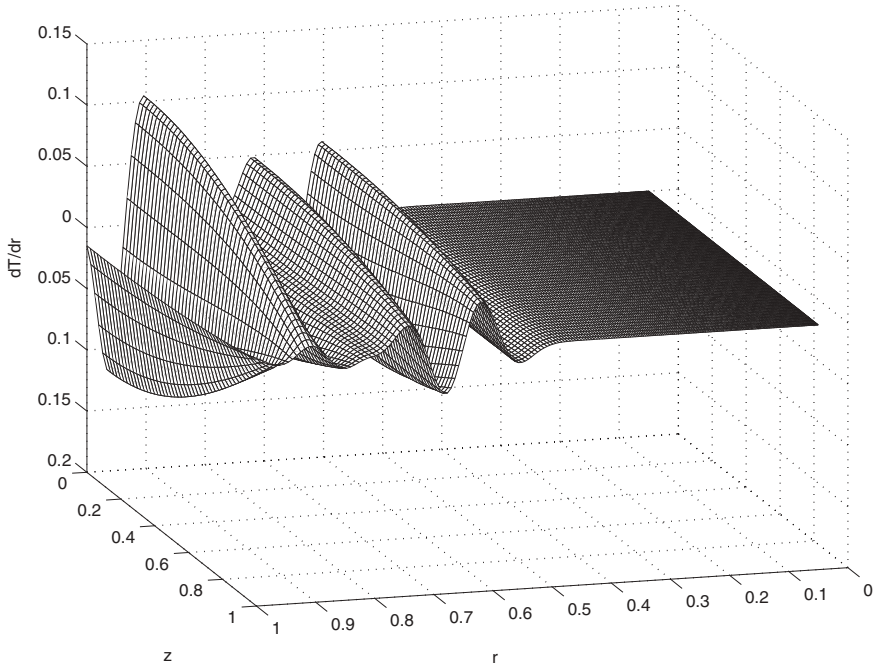

FIG. 7. *The spatial distribution of the temperature gradient,* $\frac{\partial T}{\partial r}$*, for the same parameter values as in Figure* 5(a)*. The temperature gradient is of the same magnitude as the radial velocity at the sidewall. Note that relatively large temperature gradients persist into the flow field, not just at the wall.*

different convective terms in (88) and (89), particularly the nonlinear properties of the latter.

The radial spatial wave variation for $\widehat{T}_0$ differs from that of $\widehat{V}_{z0}$, as shown at $t = 20$ and $z = 0.5$ in Figure 9. In part, this occurs because the acoustic solutions, $\overline{T}_0$ and $\overline{V}_{z0}$, the drivers for the strong rotational solutions, are out of phase, as can be seen from (67) and (68). Here again it can be seen that there is a difference between the damping of spatial oscillations in $\widehat{T}_0$ and those in the $\widehat{V}_{z0}$-waves as the centerline is approached.

Figures 10 and 11 describe the spatial variation of the complete temperature T for the parameter values used in Figure 5(a) when the injection boundary condition is given by

$$V_r = -1 - 0.2\cos^2\left(\frac{3\pi z}{2}\right)(1 - \cos\omega t) \qquad \text{at} \quad r = 1. \tag{102}$$

This injection distribution is employed to explore the impact of higher axial wave number variations on the internal flow dynamics. The z-dependence of this boundary condition is shown on the right-hand side of Figure 11, where positive velocity values are given to the right on the horizontal axis. A new acoustic solution was derived to satisfy (102).

The leading-order complete temperature solution is shown in Figure 10. The parameter values correspond to those in Figure 5(a). Three waves have propagated into the cylinder just as in Figure 5(a). Now, however, the waves contain a little more

(b)

FIG. 8. (a) *Variation of the strong rotational temperature* $\widehat{T}_0$ *with* r *and* z *at time* $t = 60$ *for the parameters used in Figure* 5. *The use of a radial variable integral transformation in* (31) *removes restrictions on the maximum time for which the solution can be found.* (b) *Variation of* $\hat{V}_{z0}$ *with* r *and* z, *the rotational axial velocity, for* $t = 60$.

axial variation, resulting from the higher wave number axial variation in the sidewall mass addition. The rate of radial wave propagation is axially dependent and directly related to variation in the mass addition, as implied by (76) and (81).

A comparison of the contour plots in Figures 6 and 11 is useful for observing the altered shape of the temperature waves for a given set of parameter values. The first

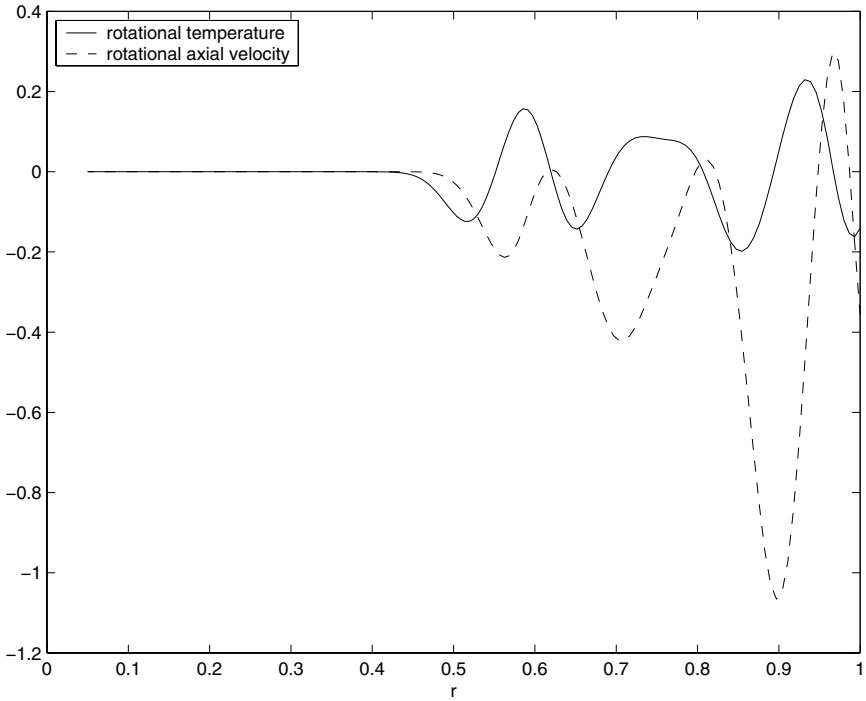

FIG. 9. *Comparison of the radial variation of* $\widehat{T}_0$ *and* $\widehat{V}_{z0}$ *at* $z = 0.5$ *for* $M = 0.02$, $\delta = 20$, $Re = 3 \times 10^5$, $\omega = 1$, $Pr = 1$, *and* $\gamma = 1.4$ *at* $t = 20$. *The radial locations of the peaks differ because the acoustic solutions,* $\overline{T}_0$ *and* $\overline{V}_{z0}$, *are qualitatively different, and the linear convective term in* (88) *differs from the nonlinear effect in* $\widehat{V}_{z0}$ ((see (89)).

waves adjacent to the sidewall have very little z-variation. However, the second and third waves in Figure 11 have crests with radial locations that vary considerably in the z-direction relative to those in Figure 6.

Figure 12 shows the location and shape of the .001-contour of the rotational temperature for 12 different times up to $t = 60$ reading from right to left. As the front propagates toward the centerline, regions of relatively large curvature are convected downstream and swept out of the cylinder. Downstream convection can be followed by noting that the local minimum in the front location, marked with an X near $z = 0.3$ at $t = 5$, moves to a larger axial location at each new time value. It moves out of the cylinder by the time $t = 30$ and leaves behind a front profile that has very little axial dependence.

The lack of axial variation near the centerline is similar to a result of Staab and Kassoy [14], who find that azimuthal variations along the sidewall driven by nonaxisymmetric wall injection are damped out near the centerline. Both the model in Staab and Kassoy [14] and that used here are without azimuthal and axial diffusion terms, respectively. These results show that axial convective terms are sufficient to produce these phenomena.

12. Summary of results and conclusions. A multiple-scale asymptotic analysis has provided the mathematical foundation for investigating the thermal properties of the compressible flow in a large aspect ratio cylinder with unsteady, axially

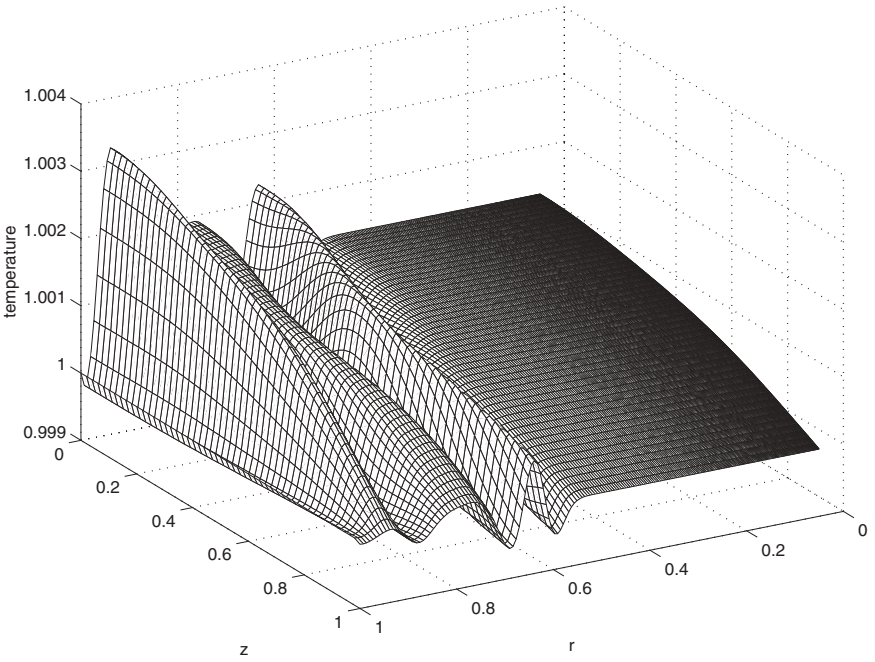

FIG. 10. *The* (r, z) *variation of* $T \sim 1 + M(\widehat{T}_0 + \overline{T}_0) + O(M^2)$ *for* $M = 0.02$, $\delta = 20$, $Re = 3 \times 10^5$, $\omega = 1$, $Pr = 1$, *and* $\gamma = 1.4$ *at* $t = 20$ *using the new radial sidewall velocity,* $\widetilde{V}_{rw}(z) = 0.2\left(\cos^2(\frac{3\pi z}{2})\right)$. *The curvature changes of the wave crests in the z-direction arise from the higher wave number axial variation of the sidewall mass addition in* (102).

distributed sidewall mass addition. The latter drives significant planar acoustic disturbances in the low Mach number and high Reynolds number fluid flow. Although the temperature variations in the flow field are only $O(M)$, one can find larger-than-expected $O(1)$ temperature gradients on the sidewall because the relevant radial length scale for gradients is $O(M)$ rather than $O(1)$. It follows that the transient heat transfer on the sidewall is rather more intense than one might expect and is controlled entirely by the injection-induced acoustic disturbances.

The current work extends the earlier study of Staab et al. [12], who predicted velocity and vorticity solutions for a limited range of time. This limitation is overcome by employing an integral transformation for the short-length–scale radial variable. When this transform is used in the asymptotic analysis, the time-scale for solution validity is extended considerably compared to the limitations found in Staab et al. [12]. As a result, long-time velocity and temperature results have been included here that were not possible previously.

Several interesting thermal phenomena have been observed in the cylinder.

1. The temperature gradient on the sidewall is $O(1)$, even though the fluctuations in the temperature are $O(M)$. This results in an unexpectedly large heat transfer on the sidewall.
2. The decay rate of the strongly rotational axial velocity waves is more pronounced and systematic than that of the corresponding rotational temperature waves. Since the results are for $Pr = 1$, the characteristic difference

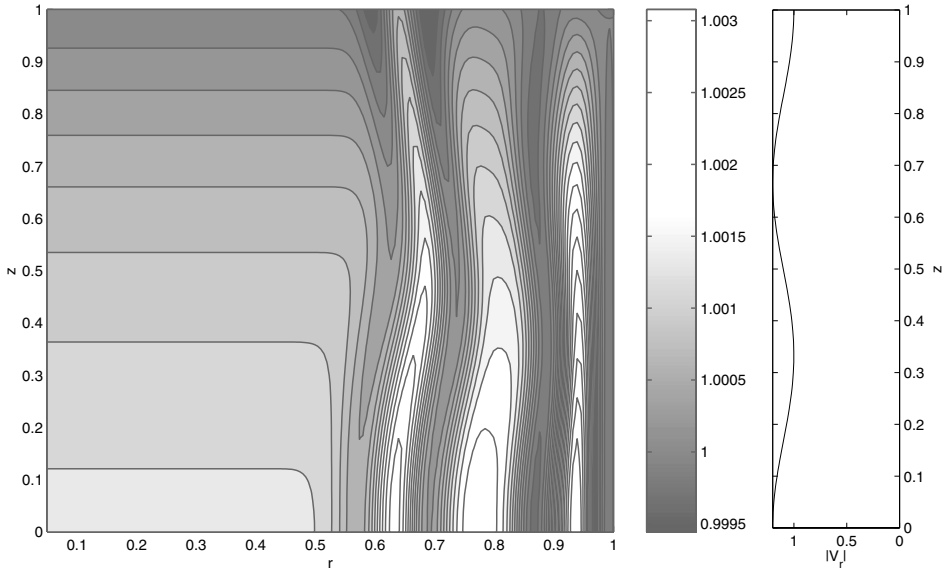

FIG. 11. *The contour plot of T for the parameter values in Figure* 10*, showing the curvature in the crest locations of the waves. The crest shapes become more varied in the z-direction as one moves away from the wall. The z-dependence of the sidewall mass addition in* (102) *is shown on the right-hand side. Axial variations in the sidewall mass addition create the curvature in the temperature contours.*

in structure must be due to the impact of the differing axial convection process.

3. Increasing the wave number of the axial variation in mass addition causes axial variations in the front separating the irrotational and "rotational" temperature distributions when the front is not too close to the center line. However, the axial structure is lost when the front approaches the center line. Since axial diffusion is not present in the model, the result can be explained by the axial convection that transports fluid downstream and out of the cylinder.

The transient mass addition on the boundary of the cylinder causes work to be done on the system as well as producing acoustic disturbances. The latter interact with the fluid at the injection surface to create vorticity. As a result, the energy of the fluid can be partitioned into acoustic and rotational components. A careful analysis of the asymptotic results shows that the $O(M)$ acoustic and "rotational" temperature disturbances make the largest contributions to the total energy transient. Kinetic energy effects appear only at $O(M^2)$. The presence of thermal energy in the "rotational" disturbance, and of course kinetic energy associated with the rotational velocity disturbance, suggest that a purely acoustical analysis cannot accurately describe the partitioning of the energy in the flow.

The wall injection boundary condition in (10) simulates the transverse speed of hot gaseous products of reaction exiting the very thin combustion zone, typically on the order of millimeters (O(mm.)) adjacent to the burning rocket motor propellant. The speed is known to be compatible with the hard blowing approximation [15] used in section 2. The axial gas speed at the edge of the combustion zone is likely to be small compared to the transverse value because the zone thickness is small in absolute

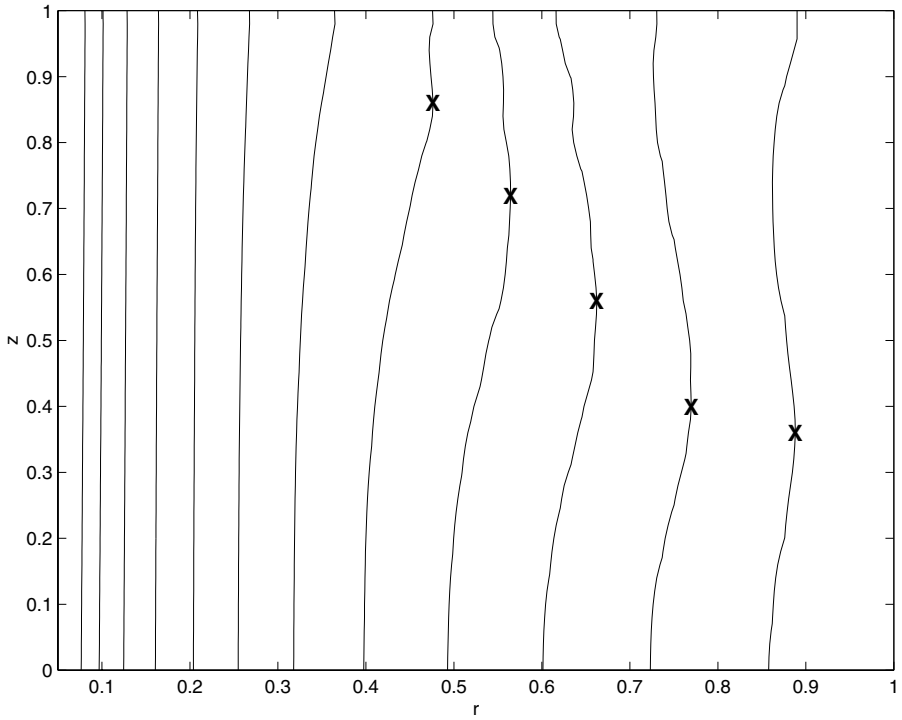

FIG. 12. *Front locations for* $\widehat{T}_0 = 0.001$ *at* $t = 5, 10, 15, 20, 23, \ldots, 60$. *The front near* $r = 0.85$ *corresponds to* $t = 5$, *and each successive front is to the left of the one before it. The X's mark a local minimum in the front which gets convected downstream.*

terms and the local transient, axial pressure gradient is $O(M)$. It follows that the no-slip condition imposed by (7) provides a reasonable first approximation to the model.

The isothermal boundary condition in (11) represents the temperature of the hot gaseous products, typically 2500K–3000K in dimensional value. The axial variation of the combustion zone flame temperature is likely to be small compared to the flame temperature because it is controlled primarily by gas phase exothermic chemical kinetics. Hence, the use of a spatially uniform temperature in (11) is a reasonable modeling approximation. In this respect the isothermal injection model provides a reasonable approximation of the physics occurring at the edge of the combustion zone.

The boundary condition on the radial speed in (7) is not satisfied by the solution provided. In fact a thin viscous boundary is required to provide a transition between the solutions given here and the endwall of the cylinder. This issue, discussed in [12], will not affect the solutions described here.

The model presented here does not include the effect of turbulent transition in the downstream portion of the cylinder, arising from hydrodynamic instability. Vorticity generated by turbulent flow will add to that arising from the deterministic mechanism explored in the current work. It would be worthwhile to ascertain the relative intensity of both components of the vorticity field. It should also be recognized that transient surface pressure fluctuations associated with the turbulent field will initiate additional vorticity via the deterministic process.

Appendix: Derivation of the higher-order energy equation. Derivations of (51) and (52) are given here to describe the algebraic manipulations. The complete set of $O(M)$ terms for the $\widetilde{T}_0$-equation is

$$\frac{\partial \widetilde{T}_0}{\partial t} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_2} = -(\gamma-1)\left(\frac{\widetilde{V}_{r0}}{r} + \frac{1}{s}\,\frac{\partial \widetilde{V}_{r0}}{\partial \sigma_1} + \frac{1}{s}\,\frac{\partial \widetilde{V}_{r1}}{\partial \sigma_2} + \frac{\partial \widetilde{V}_{r0}}{\partial z}\right). \tag{A1}$$

Equation (43) can be used to reduce (A1) to

$$\frac{\mathcal{D}\widetilde{T}_0}{\mathcal{D}t} = (\gamma-1)\,\frac{\mathcal{D}\widetilde{\rho}_0}{\mathcal{D}t}, \tag{A2}$$

which can be further simplified by introducing (53),

$$\frac{\mathcal{D}\widetilde{T}_0}{\mathcal{D}t} = \frac{\gamma-1}{\gamma}\,\frac{\partial \widetilde{P}_0}{\partial t}. \tag{A3}$$

The $O(M^2)$ energy equation for $\widetilde{T}_1$ is derived in much the same way. The complete set of $O(M^2)$ terms is

$$\begin{aligned}
&\frac{\partial \widetilde{T}_1}{\partial t} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_1}{\partial \sigma_2} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_1} + \frac{\widetilde{V}_{r1}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_2} + (V_{z0s} + \widetilde{V}_{z0})\,\frac{\partial \widetilde{T}_0}{\partial z} \\
&= \frac{Ck^2}{Pr}\,\frac{1}{s^2}\,\frac{\partial^2 \widetilde{T}_0}{\partial \sigma_2^2} - (\gamma-1)\left(\frac{\widetilde{V}_{r1}}{r} + \frac{1}{s}\,\frac{\partial \widetilde{V}_{r1}}{\partial \sigma_1} + \frac{\partial \widetilde{V}_{r2}}{s} + \frac{\partial \widetilde{V}_{z1}}{\partial z}\right) \\
&-(\gamma-1)\widetilde{P}_0\left(\frac{\widetilde{V}_{r0}}{r} + \frac{1}{s}\,\frac{\partial \widetilde{V}_{r0}}{\partial \sigma_1} + \frac{1}{s}\,\frac{\partial \widetilde{V}_{r1}}{\partial \sigma_2} + \frac{\partial \widetilde{V}_{z0}}{\partial z}\right).
\end{aligned} \tag{A4}$$

Then (43) and (44) can be used in (A4) to find

$$\begin{aligned}
&\frac{\partial \widetilde{T}_1}{\partial t} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_1}{\partial \sigma_2} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_1} + \frac{\widetilde{V}_{r1}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_2} + (V_{z0s} + \widetilde{V}_{z0})\,\frac{\partial \widetilde{T}_0}{\partial z} \\
&= (\gamma-1)\left(\frac{\mathcal{D}\widetilde{\rho}_1}{\mathcal{D}t} - \widetilde{\rho}_0\,\frac{\mathcal{D}\widetilde{\rho}_0}{\mathcal{D}t} + \widetilde{P}_0\,\frac{\mathcal{D}\widetilde{\rho}_0}{\mathcal{D}t} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{\rho}_0}{\partial \sigma_1}\right. \\
&\qquad \left. + \frac{\widetilde{V}_{r1}}{s}\,\frac{\partial \widetilde{\rho}_0}{\partial \sigma_2} + (V_{z0s} + \widetilde{V}_{z0})\,\frac{\partial \widetilde{\rho}_0}{\partial z}\right) \\
&+ \frac{Ck^2}{Pr}\,\frac{1}{s^2}\,\frac{\partial^2 \widetilde{T}_0}{\partial \sigma_2^2}.
\end{aligned} \tag{A5}$$

Next, (53) and (54) are used to replace $\widetilde{\rho}_0$ and $\widetilde{\rho}_1$, respectively:

$$\begin{aligned}
&\frac{\partial \widetilde{T}_1}{\partial t} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_1}{\partial \sigma_2} + \frac{V_{r0s} + \widetilde{V}_{r0}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_1} + \frac{\widetilde{V}_{r1}}{s}\,\frac{\partial \widetilde{T}_0}{\partial \sigma_2} + (V_{z0s} + \widetilde{V}_{z0})\,\frac{\partial \widetilde{T}_0}{\partial z} \\
&= (\gamma-1)\left(\frac{\partial \widetilde{P}_1}{\partial t} - \frac{\mathcal{D}\widetilde{T}_1}{\mathcal{D}t} - \frac{\mathcal{D}\widetilde{\rho}_0\widetilde{T}_0}{\mathcal{D}t} + \widetilde{T}_0\,\frac{\mathcal{D}\widetilde{\rho}_0}{\mathcal{D}t}\right) \\
&+(\gamma-1)\left(-\frac{V_{r0s} + \widetilde{V}_{r0}}{s}\frac{\partial \widetilde{T}_0}{\partial \sigma_1} - \frac{\widetilde{V}_{r1}}{s}\frac{\partial \widetilde{T}_0}{\partial \sigma_2} - (V_{z0s} + \widetilde{V}_{z0})\frac{\partial \widetilde{T}_0}{\partial z} + (V_{z0s} + \widetilde{V}_{z0})\frac{\partial \widetilde{P}_0}{\partial z}\right) \\
&+ \frac{Ck^2}{Pr}\,\frac{1}{s^2}\,\frac{\partial^2 \widetilde{T}_0}{\partial \sigma_2^2}.
\end{aligned} \tag{A6}$$

Further simplification leads to

$$\frac{\mathcal{D}\widetilde{T}_1}{\mathcal{D}t} = -\left(\frac{V_{r0s}+\widetilde{V}_{r0}}{s}\,\frac{\partial\widetilde{T}_0}{\partial\sigma_1}+\frac{\widetilde{V}_{r1}}{s}\,\frac{\partial\widetilde{T}_0}{\partial\sigma_2}+(V_{z0s}+\widetilde{V}_{z0})\frac{\partial\widetilde{T}_0}{\partial z}\right) + \frac{\gamma-1}{\gamma}\left(\frac{\partial\widetilde{P}_1}{\partial t}+(V_{z0s}+\widetilde{V}_{z0})\frac{\partial\widetilde{P}_0}{\partial z}\right)+\frac{Ck^2}{\gamma\ Pr}\,\frac{1}{s^2}\,\frac{\partial^2\widetilde{T}_0}{\partial\sigma_2^2} - \frac{(\gamma-1)^2}{\gamma^2}\left(\widetilde{P}_0\frac{\partial\widetilde{P}_0}{\partial t}-\widetilde{T}_0\frac{\partial\widetilde{P}_0}{\partial t}\right), \tag{A7}$$

which appears as (52) in section 5.1.

ON THE TURING PATTERNS IN ONE-DIMENSIONAL GRADIENT/SKEW-GRADIENT DISSIPATIVE SYSTEMS*

MASATAKA KUWAMURA†

Abstract. In this article, fundamental properties concerning the Turing patterns are considered in one-dimensional dissipative systems with gradient/skew-gradient structure introduced in [M. Kuwamura and E. Yanagida, *Phys. D*, 175 (2003), pp. 185–195]. It is a natural extension of free energy, which covers reaction-diffusion systems of activator-inhibitor type. The theory based on this concept provides a new perspective on a fundamental problem of what unique Turing pattern is to be selected among many.

Key words. (skew) free energy, Turing pattern, pattern selection

1. Introduction.

There are many self-organized spatial patterns appearing from uniform steady state as various organs with complex structures are formed and developed from a simple cell. The problem of clarifying the essential mechanism of such a pattern formation process has attracted much attention. For this problem, Rashevsky [33] and Turing [35] suggested that, under certain conditions, chemicals can react and diffuse in such a way as to produce steady state heterogeneous spatial patterns of chemical and morphogen concentration. This is, currently, known as the Turing instability mechanism, which provides a fundamental and universal concept for the study of pattern formation in dissipative systems; we refer to standard texts Nicolis and Prigogine [27], Haken [15], Manneville [22], Mori and Kuramoto [24], Murray [25], and the references therein. This theoretical concept was also demonstrated by real experiments and careful observations by Ouyang and Swinney [29], Kondo and Asai [18], De Kepper, Perraud, Rudovics, and Dulos [8], Yamaguchi [36], and so on. The progress of study of the Turing instability gives us a useful viewpoint to understand pattern formation in various phenomena; however, some natural questions still remain. A typical question is this: when one observes a pattern formation process due to the Turing instability, why does a particular pattern often selected though various patterns appear? This problem is known as pattern selection, one of the main subjects in various fields of sciences, and there are some approaches to study the pattern selection problem; we refer to Cross and Hohenberg [7] and Nishiura [28]. One useful approach is to find a free energy (potential system or variational principle), which determines direction of time evolution of systems. It is quite natural, however, and there are few examples to apply this approach explicitly. The purpose of this paper is to study fundamental properties of spatially periodic patterns induced by the Turing instability under the one-dimensional gradient/skew-gradient dissipative structure introduced in Kuwamura and Yanagida [20]. It is a natural extension of the notion of free energy, which covers reaction-diffusion systems of activator-inhibitor type such as modified FitzHugh–Nagumo systems and Gierer–Meinhardt systems. Our results

clarify universal properties of the Turing patterns in dissipative systems, and become a first step to study a fundamental problem of what unique Turing pattern is to be selected among many. The organization of this paper is as follows. In the next section, we introduce the concept of gradient/skew-gradient dissipative structure following [20]. In section 3, we give a necessary condition for existence of nontrivial spatially periodic patterns due to the Turing instability. In section 4, we give a sufficient condition for instability of spatially periodic patterns in terms of convexity of (skew) free energy per unit length of periodic patterns in its wavenumber; this is known as the Eckhaus instability criterion. In section 5, we consider a quantity introduced in the previous section, which plays a crucial role in determining the instability of the Turing patterns. It is shown that this quantity is closely related to the validity of amplitude equation which describes dynamics in a sufficiently small neighborhood of the Turing bifurcation point. In section 6, we consider structures of the (skew) free energy per unit length of the Turing patterns. Under a certain nondegeneracy condition, uniqueness of the extremum of (skew) free energy is shown. Moreover, we give a simple formula for computing the wavenumber corresponding to the unique extremum near the Turing bifurcation point. In section 7, we apply our results to concrete examples which are helpful to understand usefulness of the results obtained in previous sections. In section 8, combining the analytical results with numerical experiments, we study what Turing pattern is to be selected near a bifurcation point. The results suggest that the wavenumber corresponding to the unique extremum of (skew) free energy gives an upper bound for the wavenumber of the selected Turing pattern. Section 9 is devoted to a summary of this paper.

2. Gradient/skew-gradient dissipative structure. In this section, we introduce the concept of *gradient/skew-gradient dissipative structure* following [20]. Let us consider an n-component system on $\mathbf{R}$

$$Tu_t = Du_{xx} + f(u), \tag{2.1}$$

where $u(x,t) = (u_1, u_2, \dots, u_n)^T \in \mathbf{R}^n$. We assume that T is a nonnegative diagonal matrix and D is a regular matrix such that (2.1) is well posed in an appropriate sense. As for a nonlinear term, we assume that

$$f(u) = Q \bigtriangledown_u F(u), \tag{2.2}$$

where Q is a symmetric matrix with $Q^2 = I_n$, and that $F = F(u) : \mathbf{R}^n \to \mathbf{R}$ is a smooth function. In addition, we assume that D satisfies the condition

$$D^T Q = QD \tag{2.3}$$

which guarantees that QD is a nondegenerate symmetric matrix. We notice that the Jacobian matrix f_u of f satisfies

$$f_u(u)^T Q = Q f_u(u). \tag{2.4}$$

Under these assumptions, we introduce an energy-like functional

$$\mathcal{E}[u] = \int \left\{ \frac{1}{2} \langle Du_x, Qu_x \rangle - F(u) \right\} dx, \tag{2.5}$$

where $\langle\ ,\ \rangle$ stands for a usual inner product on $\mathbf{R}^n$. In fact, we can easily (formally) check

$$\frac{d}{dt}\mathcal{E}[u(x,t)] = -\int \langle u_t, QTu_t \rangle \, dx.$$

DEFINITION 2.1. *The system* (2.1) *is said to have gradient structure when* QT *is nonnegative symmetric and skew-gradient structure otherwise.*

Although (2.5) is not monotone decreasing when QT is not nonnegative definite, according to Definition 2.1, we naturally think of the functional (2.5) as an extended kind of free energy. This framework covers not only usual gradient (potential) systems such as the real Ginzburg–Landau equation but also systems without (in the usual sense) potential such as reaction-diffusion systems of activator-inhibitor type.

The equation for stationary solutions of (2.1) admits structures of Hamiltonian dynamical systems (e.g., Arnold [2], Goldstein [13]). In fact,

$$Du_{xx} + f(u) = 0 \tag{2.6}$$

is rewritten in the canonical form

$$JZ_x = \frac{\partial H(Z)}{\partial Z}, \tag{2.7}$$

where $Z = (u, u_x)^T$,

$$J = \begin{pmatrix} 0 & -QD \\ QD & 0 \end{pmatrix}$$

is a skew-symmetric matrix by virtue of (2.3), and $H(Z)$ is a first integral (Hamiltonian) given by

$$H(Z) = H(u, u_x) := \frac{1}{2}\langle Du_x, Qu_x\rangle + F(u).$$

We give typical examples of dissipative systems with gradient/skew-gradient structure.

Real Ginzburg–Landau equation:

$$u_t = u_{xx} + u(\mu - u^2 - v^2), \quad v_t = v_{xx} + v(\mu - u^2 - v^2),$$
$$T = D = Q = I_2, \qquad F = \mu(u^2 + v^2)/2 - (u^2 + v^2)^2/4.$$

Modified FitzHugh–Nagumo systems:

$$\tau_1 u_t = d_1 u_{xx} + \alpha u - u^3 - v, \quad \tau_2 v_t = d_2 v_{xx} + u - \gamma v,$$
$$T = \begin{pmatrix} \tau_1 & 0 \\ 0 & \tau_2 \end{pmatrix}, \quad D = \begin{pmatrix} d_1 & 0 \\ 0 & d_2 \end{pmatrix}, \quad Q = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$
$$F = F(u, v) = \frac{1}{2}\alpha u^2 - \frac{1}{4}u^4 - uv + \frac{1}{2}\gamma v^2.$$

Gierer–Meinhardt system:

$$u_t = \varepsilon^2 u_{xx} - \alpha u + \frac{u^p}{v^q} + \sigma, \quad \tau v_t = dv_{xx} - v + \frac{u^r}{v^s} \quad (p + 1 = r,\ q + 1 = s),$$
$$T = \begin{pmatrix} r & 0 \\ 0 & q\tau \end{pmatrix}, \quad D = \begin{pmatrix} r\varepsilon^2 & 0 \\ 0 & qd \end{pmatrix}, \quad Q = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$
$$F = F(u, v) = -\frac{\alpha r}{2}u^2 + \frac{q}{2}v^2 + \frac{u^r}{v^q} + r\sigma u.$$

As is verified in these two examples, in reaction-diffusion systems, diagonal entries of Q determine types of components—either activator or inhibitor type. An entry 1 indicates an activator and -1 an inhibitor. The following example is a fourth order differential equation with gradient structure.

Swift–Hohenberg equation:

$$u_t = \mu u - (1 + \partial_{xx})^2 u - u^3.$$

In fact, by putting $v = u + u_{xx}$, we find that the above equation is rewritten as (2.1) with

$$T = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad D = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad Q = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

$$F = F(u, v) = \frac{\mu}{2}u^2 - \frac{1}{4}u^4 - uv + \frac{1}{2}v^2.$$

For other examples, see [20].

3. Existence of Turing patterns. In this section, we briefly review construction of Turing patterns from a standard bifurcation theory (e.g., Iooss and Joseph [17], Murray [25]) and consider a necessary condition for existence of the Turing patterns.

A strategy was initiated by Turing [35] to study self-organized spatial patterns emerging from spatially homogeneous steady states and may be described as follows, in the framework of bifurcation theory: Let $\bar{u}$ be a spatially uniform steady state of (2.1), which is an onset of bifurcating patterns. We consider a situation in which $\bar{u}$ loses its stability and gives rise to the appearance of spatially periodic stationary solutions. Therefore, we begin with a linear stability analysis for $\bar{u}$. Let us consider the linearized equation of (2.1) at $u = \bar{u}$

$$Tw_t = Lw, \tag{3.1}$$

where

$$L = D\partial_x^2 + B \tag{3.2}$$

and $B = f_u(\bar{u})$. Let us choose a bifurcation parameter μ in the linear operator L, i.e., D or B. As usual, we are looking for solutions of the following form:

$$w = \Psi_k \exp(\lambda t + ikx), \qquad \Psi_k \in \mathbf{C}^n. \tag{3.3}$$

That is to say, we look for solutions that have a temporal growth rate $\exp(\mathrm{Re}(\lambda)t)$ for perturbations with wavenumber k. Substituting (3.3) into (3.1), we have a system of linear equations in Ψ_k

$$(\lambda T + k^2 D - B)\Psi_k = 0. \tag{3.4}$$

According to a standard bifurcation theory, in order for a stationary solution to bifurcate from $\bar{u}$ at $\mu = \mu_k$, it is necessary that (3.4) possesses a nontrivial solution for $\lambda = 0$. Hence it follows from

$$\det(k^2 D - B) = 0 \tag{3.5}$$

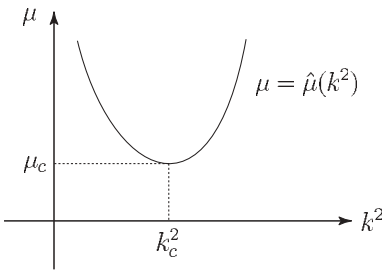

FIG. 1. *The graph of* $\mu = \hat{\mu}(k^2)$. *The bifurcating patterns appear for* $\mu > \hat{\mu}(k^2)$.

that μ_k is a function of k^2, denoted by

$$\mu_k = \hat{\mu}(k^2). \tag{3.6}$$

The bifurcation point μ_c is determined by

$$\frac{\partial}{\partial\theta}\,\hat{\mu}(\theta)|_{\theta=k_c^2} = 0, \quad \mu_c = \hat{\mu}(k_c^2), \tag{3.7}$$

where k_c is called the *critical wavenumber*. In what follows, we suppose that bifurcating patterns appear for $\mu > \mu_c$ without loss of generality (Figure 1). That is, in addition to (3.7), we assume

$$\frac{\partial}{\partial\theta^2}\,\hat{\mu}(\theta)|_{\theta=k_c^2} > 0,$$

and

$$\mathrm{Re}\lambda = \mathrm{Re}\lambda(k^2;\mu) < 0 \tag{3.8}$$

for $\mu < \mu_c$ and arbitrary k, where $\lambda = \lambda(k^2;\mu)$ is the dispersion relation defined by $\det(\lambda T + k^2 D - B) = 0$. Condition (3.8) means that the spatially homogeneous steady state $\bar{u}$ must be stable before bifurcation occurs.

Under suitable conditions, we can construct small bifurcating stationary solutions of (2.1) with wavenumber k close to k_c near the bifurcation point μ_c. From the above arguments, we expect that they are given by

$$\phi(x;k,\mu) = ae^{ikx}\Psi_k + c.c. + h.o.t., \tag{3.9}$$

where *c.c.* and *h.o.t.* denote the complex conjugate and higher order terms with respect to a, respectively. Moreover, $\Psi_k \in \mathbf{C}^n$ is defined by

$$(k^2 D - B)\Psi_k = 0 \tag{3.10}$$

for $\mu = \hat{\mu}(k^2)$ and $\langle \Psi_k, \Psi_k \rangle = 1$, where $\langle\ ,\ \rangle$ denotes the usual inner product in $\mathbf{C}^n$, and $a = a(k, \mu - \hat{\mu}(k^2)) \geq 0$ is sufficiently small with $a(k,0) = 0$. In what follows, $\langle\ ,\ \rangle$ denotes the usual inner product in $\mathbf{R}^n$ or $\mathbf{C}^n$, and we do not explicitly mention this notation unless any confusion occurs. (3.9) is a family of spatially periodic stationary solutions parameterized by its wavenumber k close to k_c.

DEFINITION 3.1. (3.9) *is called the Turing patterns when* $k_c \neq 0$.

From a standard bifurcation theory, a is determined by solving the following bifurcation equation in a:

$$[e^{ikx}\Psi_k^* + c.c., Lv + N(v)] = 0,$$

where $[\ ,\ ]$ denotes the usual inner product of periodic functions, $v = ae^{ikx}\Psi_k + c.c.$, $N(v) = f(\bar{u} + v) - Bv$, and $\Psi_k^* \in \mathbf{C}^n$ corresponds to the kernel of L^*, the adjoint operator of L for $\mu = \hat{\mu}(k^2)$, i.e.,

$$(k^2\, D^T - \, B^T)\Psi_k^* = 0 \quad \text{for} \quad \mu = \hat{\mu}(k^2).$$

Under the gradient/skew-gradient structure, we can verify

$$\Psi_k^* = Q\Psi_k. \tag{3.11}$$

In fact, noting (2.3), (2.4), and $B = f_u(\bar{u})$, it follows from (3.10) that

$$(k^2\, D^T - \, B^T)Q\Psi_k = Q(k^2 D - B)\Psi_k = 0.$$

Thus (under suitable approximation) we can solve

$$[e^{ikx}Q\Psi_k + c.c., Lv + N(v)] = 0$$

with the aid of (3.10) and obtain $a = a(k, \mu - \hat{\mu}(k^2))$. In this paper, we do not use any information about $a(k, \mu - \hat{\mu}(k^2))$.

We now consider a condition concerning the critical wavenumber k_c. The following theorem shows that when QD is definite, Turing patterns (characterized by $k_c \neq 0$) can never be observed under the gradient/skew-gradient structure.

THEOREM 3.2. *If QD is definite, then $k_c = 0$.*

As far as reaction-diffusion systems are concerned, it is well recognized, theoretically and experimentally, that the existence of *two types* of components such as activator and inhibitor with different diffusion rates is a sufficient condition to produce Turing patterns with spatial structure ([1], [12], [25], [33], [35], [37]). On the other hand, this theorem proves that the existence of two types of components such as activator and inhibitor (cf. section 2) is a necessary condition to produce Turing patterns. In other words, Turing patterns with spatial structure cannot be produced by using only one type of reacting component corresponding to activator or inhibitor.

Proof of Theorem 3.2. We consider the case when QD is positive because a negative case can be similarly treated. Since (3.4) has a nontrivial solution for $\lambda = 0$ at the bifurcation point, we consider a condition such that $\det(\nu D - B) = 0$ holds for some $\nu \geq 0$. From elementary linear algebra, there exists a symmetric regular matrix A with $A^2 = QD$ for positive QD. By using $Q^2 = I_n$, $B = f_u(\bar{u})$, and (2.2), we have

$$\begin{aligned}\det(\nu D - B) &= \det Q\ \det(\nu QD - \bigtriangledown_u^2 F(\bar{u})) \\ &= \pm \det(\nu A^2 - \bigtriangledown_u^2 F(\bar{u})) = \pm \det A\ \det(\nu I - A^{-1}\ \bigtriangledown_u^2\ F(\bar{u})A^{-1})\ \det A.\end{aligned}$$

It is easily verified that $A^{-1}\ \bigtriangledown_u^2\ F(\bar{u})A^{-1}$ is symmetric because A and $\bigtriangledown_u^2 F(\bar{u})$ are symmetric, so that all eigenvalues of $A^{-1}\ \bigtriangledown_u^2\ F(\bar{u})A^{-1}$ are real. On the other hand, there exists no wavenumber k satisfying $\det(k^2 D - B) = 0$ when uniform steady state $\bar{u}$ is stable. Hence, all eigenvalues of $A^{-1}\nabla_u^2 F(\bar{u})A^{-1}$ must be negative for a stable steady state $\bar{u}$. Thus, noting the fact that all eigenvalues of $A^{-1}\ \bigtriangledown_u^2\ F(\bar{u})A^{-1}$ are

continuous real functions in parameters, we see that critical wavenumber k_c at the bifurcation point must be equal to zero for any path in parameter space. □

From the above theorem, QD is not definite when we observe nontrivial spatially periodic patterns. Our next question is what periodic pattern is selected near the Turing bifurcation point. As a first step in considering this problem, in the next section we consider linear instability of the Turing patterns because selected patterns are not unstable.

4. Instability of Turing patterns. First, we give a general instability criterion for a family of spatially periodic stationary solutions of (2.1).

Let $u = \varphi(x;k)$ be a family of spatially periodic stationary solutions of (2.1) parameterized by its wavenumber k; that is, $\varphi(x;k)$ satisfies

$$\begin{aligned} D\varphi_{xx}(x;k) + f(\varphi(x;k)) &= 0, \\ \varphi(x;k) &= \varphi(x + l(k);k), \end{aligned} \tag{4.1}$$

where $l(k) = 2\pi/k$ denotes the minimal spatial period of $\varphi(x;k)$.

THEOREM 4.1. *$\varphi(x;k)$ is unstable if $sgn(I(k) \cdot d^2E(k)/dk^2) < 0$, where*

$$I(k) := \int_0^{l(k)} \langle T\varphi_x(x;k), Q\varphi_x(x;k)\rangle \, dx \tag{4.2}$$

and

$$E(k) := \frac{1}{l(k)} \int_0^{l(k)} \left\{ \frac{1}{2}\langle D\varphi_x(x;k), Q\varphi_x(x;k)\rangle - F(\varphi(x;k)) \right\} dx. \tag{4.3}$$

It should be noted that the above instability criterion does not require any other assumptions such as smallness and symmetry for $\varphi(x;k)$. Since $I(k) > 0$ from the definition of gradient systems, we immediately find that the following is true.

COROLLARY 4.2. *For gradient systems, $\varphi(x;k)$ is unstable if*

$$\frac{d^2E(k)}{dk^2} < 0.$$

Recalling (2.5), we regard $E(k)$ as (skew) free energy per unit length for $\varphi(x;k)$. Under the gradient/skew-gradient dissipative structure, instability of $\varphi(x;k)$ is dependent on the convex property of $E(k)$ with respect to wavenumber k.

On the other hand, $I(k)$ is related to the ODE dynamics of (2.1) as well as the spatial dynamics (2.6). $I(k)$ may be reminiscent of the (time) action functional of systems with multisymplectic structures [4]. However, this is not correct. In fact, (2.6) can be rewritten as (2.7) which expresses symplectic (Hamiltonian) structure, while (2.1) cannot be rewritten as a system with multisymplectic structure. For more details, see [4] and the references therein.

From a viewpoint of Hamiltonian dynamical systems theory, Theorem 4.1 corresponds to the well-recognized (in)stability criterion for solutions with periodic structure in terms of the convexity of the averaged Lagrangian with respect to its wavenumber. In fact, we can regard $E(k)$ as the averaged Lagrangian of $\varphi(x;k)$ because (2.6) (i.e., (4.1)) is the Euler–Lagrange equation for the Hamiltonian system (2.7) with Lagrangian

$$L(\varphi, \varphi_x) = \frac{1}{2}\langle D\varphi_x, Q\varphi_x\rangle - F(\varphi).$$

There is a wide range of literature concerning this topic; see well organized works by Bridges [4], Grillakis, Shatah, and Strauss [14], and the references therein.

Proof of Theorem 4.1. Let us consider the linearized eigenvalue problem

$$\lambda TW = DW_x x + f_u(\varphi(x;k))W.$$

We investigate the (local) dispersion relation with respect to the Fourier mode $e^{i\nu x}$ that describes the behavior of critical eigenvalues to determine sideband instability of $\varphi(x;k)$. According to [20], it is given by

$$\lambda = -D_{//}\nu^2 + h.o.t., \tag{4.4}$$

where

$$D_{//} = -\frac{l^2}{I}\frac{dH}{dl}, \tag{4.5}$$

$l = l(k) = 2\pi/k$ is the minimal spatial period, I is given by (4.2), and H is a first integral for (4.1) (see also (2.7)) given by

$$H := \frac{1}{2}\langle D\varphi_x, Q\varphi_x\rangle + F(\varphi). \tag{4.6}$$

Moreover, by [20], we have

$$\frac{dH}{dl} = \frac{1}{l}\frac{dK}{dl} \quad \text{and} \quad \frac{dE}{dl} = -\frac{K}{l^2}, \tag{4.7}$$

where E is given by (4.3), and

$$K := \int_0^l \langle D\varphi_x, Q\varphi_x\rangle\, dx.$$

Applying the chain rule of differentiation to (4.7), we have

$$\frac{dH}{dk} = \frac{1}{l}\frac{dK}{dk} \quad \text{and} \quad \frac{dE}{dk} = \frac{K}{2\pi}, \tag{4.8}$$

which yields

$$\frac{d^2E}{dk^2} = \frac{1}{2\pi}, \quad \frac{dK}{dk} = \frac{l}{2\pi}, \quad \frac{dH}{dk} = -\frac{l}{k^2}\frac{dH}{dl}. \tag{4.9}$$

Thus, it follows from (4.4) and (4.5) that $\varphi(x;k)$ is unstable if $sgn(I(k)\cdot d^2E(k)/dk^2) < 0$. □

We now apply Theorem 4.1 to $\phi(x;k,\mu)$ defined by (3.9). To do so, setting $\varphi(x;k) = \phi(x;k,\mu)$ for any fixed μ, we define

$$I(k,\mu) := \int_0^{l(k)} \langle T\phi_x(x;k,\mu), Q\phi_x(x;k,\mu)\rangle\, dx \tag{4.10}$$

and

$$E(k,\mu) := \frac{1}{l(k)}\int_0^{l(k)} \left\{\frac{1}{2}\langle D\phi_x(x;k,\mu), Q\phi_x(x;k,\mu)\rangle - F(\phi(x;k,\mu))\right\} dx, \tag{4.11}$$

where $\phi(x;k,\mu)$ is given by (3.9). Then it follows from Theorem 4.1 that $\phi(x;k,\mu)$ is unstable if $sgn(I(k,\mu)\cdot\partial_k^2 E(k,\mu))<0$. This is a general result regardless of $k_c\neq 0$ which gives the definition of the Turing patterns. Thus it turns out that $\mu=\mu_E(k)$ derived from $\partial_k^2 E(k,\mu)=0$ plays a crucial role in determining the instability of $\phi(x;k,\mu)$. In fact, as seen in section 7, it coincides with the *Eckhaus instability criterion* [10] with respect to perturbations having a large spatial period. Recalling the fact that Theorem 4.1 does not require smallness of $\phi(x;k,\mu)$, we see that the Eckhaus instability criterion is valid away from a bifurcation point in gradient/skew-gradient dissipative systems. There is a wide range of literature concerning the Eckhaus instability, and main references are given in [20].

To conclude this section, we prepare the following lemma for the subsequent analysis.

LEMMA 4.3. *For* (4.2) *and* (4.3)*, we have*

$$\frac{dE(k)}{dk}=\frac{1}{2\pi}\int_0^{l(k)}\langle D\varphi_x(x;k),\ Q\varphi_x(x;k)\rangle dx,$$

$$\frac{d^2E(k)}{dk^2}=\frac{l(k)}{2\pi}\left(\langle D\varphi_x(x;k),\ Q\varphi_{xk}(x;k)\rangle-\langle D\varphi_{xx}(x;k),\ Q\varphi_k(x;k)\rangle\right).$$

Proof. The first equality directly follows from (4.8). Moreover, it follows from (2.2), (2.3), (4.1), and (4.6) that

$$\begin{aligned}\frac{dH}{dk}&=\frac{1}{2}\langle D\varphi_{xk},Q\varphi_x\rangle+\frac{1}{2}\langle D\varphi_x,Q\varphi_{xk}\rangle+\langle\bigtriangledown F(\varphi),\varphi_k\rangle\\&=\frac{1}{2}\langle\varphi_{xk},\ D^TQ\varphi_x\rangle+\frac{1}{2}\langle D\varphi_x,Q\varphi_{xk}\rangle+\langle Q\bigtriangledown F(\varphi),Q\varphi_k\rangle\\&=\frac{1}{2}\langle\varphi_{xk},QD\varphi_x\rangle+\frac{1}{2}\langle D\varphi_x,Q\varphi_{xk}\rangle+\langle f(\varphi),Q\varphi_k\rangle\\&=\langle D\varphi_x,Q\varphi_{xk}\rangle-\langle D\varphi_{xx},Q\varphi_k\rangle,\end{aligned}$$

where we used $Q=Q^T$ and $Q^2=I_n$. Thus, by (4.9) we see that the second equality is true. ∎

5. Properties of $I(k,\mu)$. In this section, we consider properties of $I(k,\mu)$ defined by (4.10). The contents in this section are regardless of whether or not $k_c\neq 0$, which concerns the definition of the Turing patterns. First, we introduce the notion of the sign of $I(k,\mu)$ at the bifurcation point (k_c,μ_c).

DEFINITION 5.1.

$$I_c=\mathrm{Re}\langle T\Psi_k,\ Q\Psi_k\rangle|_{k=k_c},\tag{5.1}$$

where Ψ_k *is defined by* (3.10).

Since it follows from (3.9) and (4.10) that $\lim_{\mu\downarrow\mu_c} sgn I(k,\mu)|_{k=k_c}=sgn I_c$, we call the sign of I_c the sign of $I(k,\mu)$ at the bifurcation point (k_c,μ_c).

Remark 5.2. In gradient systems, $I_c>0$ from its definition.

In order to study the sign of I_c, we now derive the amplitude equation which describes dynamics of (2.1) in a sufficiently small neighborhood of the bifurcation point (k_c,μ_c). It was first derived by Newell and Whitehead [26] in the study of dynamics sufficiently close to the onset of thermal convection. The derivation presented here is

a standard one [7]. Let $\bar{u}$ be a spatially uniform steady state of (2.1). Since μ is a bifurcation parameter which is included in the linearized operator (3.2), we write

$$L = L_\mu(\partial_x) = D\partial_x^2 + B.$$

Then $L_c = L_{\mu_c}(\partial_x)$ has the following property:

$$L_c(e^{ik_c x}\Psi_{k_c}) = 0,$$

where

$$\det(k_c^2 D - B) = 0,$$

and

$$(k_c^2 D - B)\Psi_{k_c} = 0, \qquad \Psi_{k_c} \in \mathbf{C}^n. \tag{5.2}$$

On the other hand, substituting $u = \bar{u} + v$ into (2.1), we have

$$Lv = Kv - g(v), \tag{5.3}$$

where $K = T\partial_t$ and $g(v) = f(\bar{u} + v) - Bv = a_2 v^2 + a_3 v^3 + \cdots$. Let us set

$$\varepsilon = \frac{\mu - \mu_c}{\mu_c}$$

and suppose that

$$v = \varepsilon^{1/2} v_0 + \varepsilon v_1 + \varepsilon^{3/2} v_2 + \cdots, \tag{5.4}$$

where

$$v_0 = A(y, s)e^{ik_c x}\Psi_{k_c} + c.c.,$$

and $y = \varepsilon^{1/2}x$ and $s = \varepsilon t$. Here we suppose that the time dependence of dynamics of v is expressed by only rescaled time variable s, not original t. It is well known that the dynamics of A is given by the Ginzburg–Landau equation

$$\tau A_s = \alpha A_{yy} + \beta A - \gamma |A|^2 A, \tag{5.5}$$

where α, β, γ, and τ are some constants determined by the subsequent calculation. We are interested in τ, though we can compute other constants α, β, and γ. We now show that $sgn\tau = sgnI_c$. Noting $\partial_x \to \partial_x + \varepsilon^{1/2}\partial_y$ and $\mu = \mu_c + \varepsilon\mu_c$, the linear operator $L = L_\mu(\partial_x)$ in the left-hand side of (5.3) can be expanded in ε as follows:

$$L = L_0 + \varepsilon^{1/2} L_1 + \varepsilon L_2, \tag{5.6}$$

where $L_0 = L_{\mu_c}(\partial_x) = L_c$, $L_1 = L_1(\partial_x, \partial_y)$, and $L_2 = L_2(\partial_x, \partial_y)$. Here we do not need the concrete expressions of L_1 and L_2. On the other hand, since the time variable of v is only s, applying $\partial_t \to \varepsilon\partial_s$, the linear operator K in the right-hand side of (5.3) can be expanded in ε as follows:

$$K = \varepsilon T\partial_s. \tag{5.7}$$

Substituting (5.4), (5.6), and (5.7) into (5.3) and comparing each coefficient of powers in ε, we have

$$\begin{aligned} &L_c v_0 = 0, \\ &L_c v_1 = -L_1 v_0 - a_2 v_0^2, \\ &L_c v_2 = -L_1 v_1 - L_2 v_0 + T\partial_s v_0 - 2a_2 v_0 v_1 - a_3 v_0^3. \end{aligned} \tag{5.8}$$

As a consequence, the dynamics of A is determined by the solvability condition for v_2 in the third equation of (5.8). Since τ is determined by $T\partial_s v_0$ in the right-hand side of the third equation of (5.8), applying the solvability condition, we find that $sgn\tau = sgn\mathrm{Re}\langle T\Psi_{k_c}, \Psi^*_{k_c}\rangle$, where $\Psi^*_{k_c} \in \mathbf{C}^n$ corresponds to the kernel of L_c^*, the adjoint operator of L_c, i.e.,

$$(k_c^2\, D^T - \, B^T)\Psi^*_{k_c} = 0.$$

As was seen in (3.11), under the gradient/skew-gradient structure, we have $\Psi^*_{k_c} = Q\Psi_{k_c}$. Hence it follows from (5.1) that $sgn\tau = sgn\mathrm{Re}\langle T\Psi_{k_c}, Q\Psi_{k_c}\rangle = sgnI_c$.

Thus we see that I_c determines the sign of time constant coefficient of amplitude equation (5.5), so that it affects the well posedness of (5.5). Next, we reconsider properties of I_c from another viewpoint when $n = 2$.

Let us recall a system of linear equations (3.4). When $n = 2$, the determinant of coefficient matrix of (3.4) becomes a quadratic equation in λ:

$$\alpha_0\lambda^2 + \alpha_1\lambda + \alpha_2 = 0, \tag{5.9}$$

where

$$\begin{aligned} &\alpha_0 = \tau_1\tau_2 > 0, \\ &\alpha_1 = \tau_2(k^2 d_{11} - b_{11}) + \tau_1(k^2 d_{22} - b_{22}), \end{aligned}$$

$T = \mathrm{diag}(\tau_1, \tau_2)$, $B = (b_{ij})$, and $D = (d_{ij})$.

We now consider a relation between $sgn\alpha_1$ and $sgnI_c$ at the bifurcation point (k_c, μ_c). Let $A = k_c^2 D - B$ for $\mu = \mu_c$. Then, we have

$$\alpha_1 = \tau_2 a_{11} + \tau_1 a_{22},$$

where $A = (a_{ij})$. On the other hand, we calculate $\langle T\Psi_{k_c}, Q\Psi_{k_c}\rangle$ explicitly. In the following calculation, we consider a case when $Q = \mathrm{diag}(1, -1)$ because other cases can be similarly treated. Since it follows from (5.2) that

$$\begin{aligned} a_{11}p + a_{12}q = 0, \\ a_{21}p + a_{22}q = 0, \end{aligned}$$

where $(p, q)^T = \Psi_{k_c}$, we have

$$\langle T\Psi_{k_c}, Q\Psi_{k_c}\rangle = \tau_1|p|^2 - \tau_2|q|^2 = \tau_1|p|^2 - \tau_2|p|^2\,\frac{a_{11}}{a_{12}}\frac{a_{21}}{a_{22}} = \tau_1|q|^2\,\frac{a_{12}}{a_{11}}\frac{a_{22}}{a_{21}} - \tau_2|q|^2.$$

Noting that $a_{12} = -a_{21}$ because $A^TQ = QA$ by virtue of (2.3), (2.4), and $B = f_u(\bar{u})$, we have

$$\langle T\Psi_{k_c}, Q\Psi_{k_c}\rangle = |p|^2\,\frac{\tau_2 a_{11} + \tau_1 a_{22}}{a_{22}} = -|q|^2\,\frac{\tau_2 a_{11} + \tau_1 a_{22}}{a_{11}}.$$

Therefore, it follows from (5.1) that $sgn\,\alpha_1 = sgn\,I_c \cdot sgn\,a_{22} = -sgn\,I_c \cdot sgn\,a_{11}$.

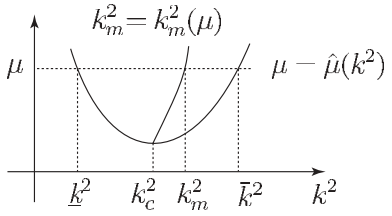

FIG. 2. *For $\mu > \hat{\mu}(k^2)$ near the Turing bifurcation point, there exists a unique extreme point of $E(k, \mu)$ given by $k_m = k_m(\mu)$.*

On the other hand, the quadratic equation (5.9) must have roots with $\mathrm{Re}\lambda < 0$ for $\mu < \mu_c$ and arbitrary k as in (3.8) because the homogeneous steady state $\bar{u}$ must be stable for $\mu < \mu_c$. Therefore, $\alpha_1 > 0$ must be true for $\mu < \mu_c$ near the bifurcation point (k_c, μ_c), so that $\alpha_1 > 0$ holds at the bifurcation point. This implies that the assumption (3.8) cannot be satisfied by changing the sign of I_c. Thus we see that the sign of I_c affects the instability of an underlying homogeneous steady state to be equipped with spatially periodic structure.

According to the justification theory of validity of amplitude equation (Collet and Eckmann [6], Eckhaus [11], Harten [16], Mielke and Schneider [23]), under certain conditions, the dynamics of (2.1) in a sufficiently small neighborhood of the bifurcation point (k_c, μ_c) is well approximated by (5.5) as long as (5.5) is well posed. Thus, recalling the definition of gradient systems, the above arguments lead us to the following observation.

OBSERVATION 5.3. *The sign of a time constant coefficient of amplitude equation is determined by I_c, the sign of $I(k, \mu)$ at the bifurcation point (k_c, μ_c). It is closely related to the well posedness of the amplitude equation and the instability of the underlying homogeneous steady state to be equipped with spatially periodic structure. Moreover, it is necessary that $I_c > 0$ so that the skew-gradient system can admit gradient structure in a sufficiently small neighborhood of the bifurcation point (k_c, μ_c).*

6. Properties of $E(k, \mu)$. In this section, we consider properties of (skew) free energy $E(k, \mu)$ defined by (4.11) for the Turing patterns near the bifurcation point and establish the uniqueness of the extremum of $E(k, \mu)$. First, we introduce a nondegeneracy condition at the bifurcation point (k_c, μ_c).

HYPOTHESIS 6.1. $E_c := \mathrm{Re}\,\partial_k \langle D\Psi_k, Q\Psi_k \rangle|_{k=k_c} \neq 0$, *where Ψ_k is defined by* (3.10).

We call this hypothesis the nondegeneracy condition at the bifurcation point (k_c, μ_c). The following result shows uniqueness of the extremum of (skew) free energy.

THEOREM 6.2. *Let us assume that the above hypothesis is met and $k_c \neq 0$.*

(1) *For any fixed $\mu > \mu_c$ near the Turing bifurcation point, there exists a unique extremum of $E(k) = E(k, \mu)$ in $(\underline{k}, \bar{k})$, where $\underline{k}$ and $\bar{k}$ are defined by $\hat{\mu}(\underline{k}^2) = \hat{\mu}(\bar{k}^2) = \mu$ with $\hat{\mu}$ given by* (3.6).

(2) *The wavenumber $k_m = k_m(\mu)$ corresponding to the extremum is approximately obtained by $\mathrm{Re}\langle D\Psi_k, Q\Psi_k \rangle = 0$ near the Turing bifurcation point* (*Figure* 2).

Remark 6.3. (1) Theorem 6.2 implies (cf. section 3) that if the Turing bifurcation parameter μ is in reaction term f (not in D), then $k_m(\mu)$ is approximately given by k_c (independent of μ). In this case, we denote $k_m(\mu) \approx k_c$.

(2) As seen in the next section, $k_c \leq k_m(\mu)$ holds for two component gradient/skew-gradient dissipative systems.

(3) The reader may expect that the above theorem can be proved by the theories in [6, 11, 16, 23] because the amplitude equation describes the dynamics in a sufficiently small neighborhood of the bifurcation point (k_c, μ_c). However, Theorem 6.2 is obtained by applying Theorem 4.1 and Lemma 4.3, which are valid away from the bifurcation point. It is essentially different from the results obtained by using the amplitude equation derived at the bifurcation point.

When the above assumption is satisfied, QD is not definite because of Theorem 3.2. It is necessary for existence of k satisfying $\mathrm{Re}\langle D\Psi_k, Q\Psi_k\rangle = 0$. Moreover, we notice that the above result does not require any other assumptions, and that the unique extremum is the (global) minimum when $E_c > 0$. In order to prove the above theorem, we prepare the following lemma.

LEMMA 6.4. *Under the assumption of Theorem* 6.2*, the following hold near the Turing bifurcation point* (k_c, μ_c):

(i) *When* $E_c > 0$, $d^2E/dk^2 > 0$ *if* $dE/dk = 0$.

(ii) *When* $E_c < 0$, $d^2E/dk^2 < 0$ *if* $dE/dk = 0$.

Proof. We consider case (i) because (ii) can be similarly treated. We suppose that $0 < \underline{k} < k_c < \bar{k}$ without loss of generality. In the following calculation, we neglect higher order terms of (3.9). By (3.9), we have

$$\phi_x = ikae^{ikx}\Psi_k + c.c.,$$

which yields

$$\begin{aligned}(6.1)\qquad \int_0^l \langle D\phi_x, Q\phi_x\rangle\, dx &= \int_0^l \langle\, D(ikae^{ikx}\Psi_k + c.c.),\, Q(ikae^{ikx}\Psi_k + c.c.)\,\rangle\, dx \\ &= 2lk^2a^2\mathrm{Re}\langle D\Psi_k,\, Q\Psi_k\rangle.\end{aligned}$$

Hence it follows from Lemma 4.3 that $\mathrm{Re}\langle D\Psi_k, Q\Psi_k\rangle = 0$ if $dE/dk = 0$. On the other hand, since

$$\begin{aligned}\phi_{xx} &= -k^2ae^{ikx}\Psi_k + c.c.,\\ \phi_{xk} &= iae^{ikx}\Psi_k + ik(\partial_k a)e^{ikx}\Psi_k - kxae^{ikx}\Psi_k + ikae^{ikx}(\partial_k\Psi_k) + c.c.,\\ \phi_k &= (\partial_k a)e^{ikx}\Psi_k + ixae^{ikx}\Psi_k + ae^{ikx}(\partial_k\Psi_k) + c.c.,\end{aligned}$$

we have

$$\begin{aligned}&\langle D\phi_x, Q\phi_{xk}\rangle\\ &= \langle D(ikae^{ikx}\Psi_k + c.c.),\ Q(iae^{ikx}\Psi_k + ik(\partial_k a)e^{ikx}\Psi_k\\ &\qquad\qquad - kxae^{ikx}\Psi_k + ikae^{ikx}(\partial_k\Psi_k) + c.c.)\rangle\end{aligned}$$

and

$$\begin{aligned}&\langle D\phi_{xx}, Q\phi_k\rangle\\ &= \langle\, D(-k^2ae^{ikx}\Psi_k + c.c.),\ Q(\,(\partial_k a)e^{ikx}\Psi_k + ixae^{ikx}\Psi_k + ae^{ikx}(\partial_k\Psi_k) + c.c.)\rangle.\end{aligned}$$

Therefore, when $\mathrm{Re}\langle D\Psi_k, Q\Psi_k\rangle = 0$, we have

$$\langle D\phi_x, Q\phi_{xk}\rangle - \langle D\phi_{xx}, Q\phi_k\rangle = 4k^2a^2\mathrm{Re}\langle D\Psi_k, Q\partial_k\Psi_k\rangle.$$

On the other hand, since $Q = Q^T$, QD is a symmetric matrix by (2.3) and $\partial_k(QD)|_{k=k_c} = 0$ by (3.7), we have

$$2\mathrm{Re}\langle D\Psi_k,\, Q\partial_k\Psi_k\rangle|_{k=k_c} = \mathrm{Re}\,\partial_k\langle QD\Psi_k,\, \Psi_k\rangle|_{k=k_c} = \mathrm{Re}\,\partial_k\langle D\Psi_k,\, Q\Psi_k\rangle|_{k=k_c}.$$

Thus, by (6.1) and Lemma 4.3, we see that near the Turing bifurcation point, $d^2E/dk^2 > 0$ holds if $dE/dk = 0$ when $E_c > 0$. □

Proof of Theorem 6.2. Since $\phi(x;\underline{k},\mu) = \phi(x;\bar{k},\mu) \equiv \bar{u}$, we have $E(\underline{k}) = E(\bar{k})$. Hence there exists $k_0 \in (\underline{k},\bar{k})$ such that $dE(k_0)/dk = 0$. Moreover, by Lemmas 4.3 and 6.4, we see that such a k_0 must be unique and approximately calculated by $\mathrm{Re}\langle D\Psi_k,\, Q\Psi_k\rangle = 0$ because of (6.1). □

7. Application. In this section, we apply our results to typical examples. They are helpful to understand the usefulness and meaning of our results.

First, we consider the real Ginzburg–Landau equation,

$$u_t = u_{xx} + u(\mu - u^2 - v^2), \quad v_t = v_{xx} + v(\mu - u^2 - v^2), \tag{7.1}$$

which can be rewritten as (2.1) with $T = D = Q = I_2$ and $F = \mu(u^2+v^2)/2 - (u^2+v^2)^2/4$. By using Theorem 3.2, we see that (7.1) does not have the Turing patterns (characterized by $k_c \neq 0$) because $QD = I_2$ is positive. It is well known, however, that (7.1) has a family of spatially periodic stationary solutions

$$\phi(x;k,\mu) = \sqrt{\mu - k^2}\,(\cos kx,\, \sin kx).$$

They are trivial patterns because the critical wavenumber k_c is equal to zero at the bifurcation point $\mu_c = 0$. On the other hand, recalling Definition 2.1, (7.1) is a gradient system because $QT = I_2$ is positive. Hence we apply Corollary 4.2 to the above family $\phi(x;k,\mu)$ for any fixed μ. It follows from direct calculation that

$$E(k) = E(k,\mu) = -\frac{1}{4}(\mu - k^2)^2,$$

which yields

$$E''(k) = \partial_k^2 E(k,\mu) = \mu - 3k^2.$$

Thus, an instability criterion is given by $\mu = \mu_E(k) = 3k^2$, so that $\phi(x;k,\mu)$ is unstable if $\mu < 3k^2$. This result is well known as the Eckhaus instability. For other examples of applications of Theorem 4.1 and Corollary 4.2; see [20].

Next, we apply Theorem 6.2 to the following model system with skew-gradient structure, which is studied in Ben-Jacob et al. [3]:

$$\tau_1 u_t = d_1 u_{xx} + \alpha(1-u^2)u - \beta v, \quad \tau_2 v_t = d_2 v_{xx} - \gamma(1+v^2)v + \beta u, \tag{7.2}$$

where $\alpha, \beta, \gamma, d_1, d_2, \tau_1$, and τ_2 are positive constants. This equation is rewritten as (2.1) with

$$T = \begin{pmatrix} \tau_1 & 0 \\ 0 & \tau_2 \end{pmatrix}, \quad D = \begin{pmatrix} d_1 & 0 \\ 0 & d_2 \end{pmatrix}, \quad Q = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

$$F = F(u,v) = \frac{\alpha}{4}(1-u^2)^2 - \beta uv + \frac{\gamma}{4}(1+v^2)^2.$$

As usual, we consider the linearized eigenvalue problem at the trivial steady state $\bar{u} = 0$ and obtain a system of linear equations

$$(\lambda T + k^2 D - B)\Psi_k = 0, \tag{7.3}$$

where $\langle \Psi_k, \Psi_k \rangle = 1$, and

$$B = \begin{pmatrix} \alpha & -\beta \\ \beta & -\gamma \end{pmatrix}.$$

It follows from $\det(k^2 D - B) = 0$ that

$$\beta^2 - (\alpha - k^2 d_1)(\gamma + k^2 d_2) = 0, \tag{7.4}$$

so that (7.3) has nontrivial solution $\Psi_k = (p_k, q_k)^T$ for $\lambda = 0$, where

$$p_k^2 = \frac{\beta^2}{\beta^2 + (\alpha - k^2 d_1)^2} := g_1(k^2),$$
$$q_k^2 = \frac{(\alpha - k^2 d_1)^2}{\beta^2 + (\alpha - k^2 d_1)^2} := g_2(k^2).$$

Hence, we have

$$\langle D\Psi_k, Q\Psi_k \rangle = d_1 p_k^2 - d_2 q_k^2 = d_1 g_1(k^2) - d_2 g_2(k^2), \tag{7.5}$$

$$\partial_k \langle D\Psi_k, Q\Psi_k \rangle = 2d_1 k g_1'(k^2) - 2d_2 k g_2'(k^2), \tag{7.6}$$

$$\langle T\Psi_k, Q\Psi_k \rangle = \tau_1 p_k^2 - \tau_2 q_k^2 = \tau_1 g_1(k^2) - \tau_2 g_2(k^2). \tag{7.7}$$

First, we choose d_2 as a Turing bifurcation parameter. By using (7.4), we have

$$d_2 = \hat{d}_2(k^2) = \frac{\beta^2}{k^2(\alpha - k^2 d_1)} - \frac{\gamma}{k^2}$$

for $0 < k^2 < \alpha/d_1$. By using $\hat{d}_2\,' = 0$, we have

$$k_c^2 = \frac{\alpha\sqrt{\beta^2 - \alpha\gamma}}{d_1(\beta + \sqrt{\beta^2 - \alpha\gamma})} > 0 \tag{7.8}$$

and

$$d_2^c = \hat{d}_2(k_c^2) = \frac{d_1(\beta + \sqrt{\beta^2 - \alpha\gamma})^2}{\alpha^2}. \tag{7.9}$$

As was explained in section 3, we can construct the Turing patterns $\phi(x; k, d_2)$ for $d_2 > \hat{d}_2(k^2)$ near the bifurcation point $(k_c^2, \hat{d}_2(k_c^2))$ provided

$$0 < \alpha < \gamma \quad \text{and} \quad \beta^2 - \alpha\gamma > 0. \tag{7.10}$$

By using (7.6), we can compute the value of $\partial_k \langle D\Psi_k, Q\Psi_k \rangle$ at $k = k_c$, which determines E_c. In fact, direct calculation yields

$$\partial_k \langle D\Psi_k, Q\Psi_k \rangle = \frac{4\beta^2 d_1(d_1 + d_2)k(\alpha - k^2 d_1)}{(\beta^2 + (\alpha - k^2 d_1)^2)^2} > 0,$$

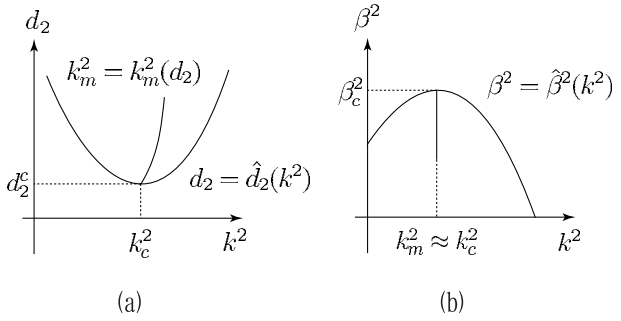

FIG. 3. *The minimizer of (skew) free energy for the Turing patterns of model equation* (7.2): (a) *The Turing bifurcation parameter* $\mu = d_2$; (b) $\mu = \beta^2$.

which implies $E_c > 0$. Thus we find that the Turing bifurcation point is nondegenerate and $E_c > 0$ when $n = 2$. Moreover, it follows from (7.5) and $\langle D\Psi_k, Q\Psi_k \rangle = 0$ that the minimizer of (skew) free energy per unit length is given by

$$k_m^2 = k_m^2(d_2) = \frac{\alpha}{d_1} - \frac{\beta}{\sqrt{d_1 d_2}}. \tag{7.11}$$

Furthermore, by using (7.9), we can easily verify that

$$k_c^2 < k_m^2(d_2)$$

holds provided $d_2 > d_2^c$. Since the above calculation can be used in general two component systems with gradient/skew-gradient structure, the above results are universal features of two component systems with gradient/skew-gradient structure. These results are presented in Figure 3(a).

On the other hand, by using (7.7), we can compute the value of $\langle T\Psi_k, Q\Psi_k \rangle$ at $k = k_c$, which determines the sign of I_c. In fact, it follows from (7.7) and (7.8) that

$$sgn\, I_c = sgn\, (2\beta\tau_1(\beta + \sqrt{\beta^2 - \alpha\gamma}) - \alpha(\gamma\tau_1 + \alpha\tau_2)).$$

Next, we choose β^2 as a Turing bifurcation parameter, which is a case treated in [3]. As was seen in section 3, we see that the Turing patterns appear for

$$\beta^2 < \hat{\beta}^2(k^2) = (\alpha - k^2 d_1)(\gamma + k^2 d_2)$$

near the bifurcation point (k_c^2, β_c^2), where

$$k_c^2 = \frac{\alpha d_2 - \gamma d_1}{2 d_1 d_2} > 0 \tag{7.12}$$

and

$$\beta_c^2 = \hat{\beta}^2(k_c^2) = \frac{(\alpha d_2 + \gamma d_1)^2}{4 d_1 d_2}. \tag{7.13}$$

In this case, while Turing patterns appear for $\beta^2 < \hat{\beta}^2(k^2)$, our results can also be applied. In a manner similar to the previous case, we obtain

$$k_m^2 = k_m^2(\beta^2) = \frac{\alpha d_2 - \gamma d_1}{2 d_1 d_2}.$$

Thus, as is shown in Figure 3(b), we verified that $k_m \approx k_c$ holds when the Turing bifurcation parameter is in the reaction term (not in D).

As we have observed in the arguments so far, the Turing bifurcation gives rise to a family of spatially periodic patterns with wavenumber k close to the critical wavenumber k_c. The (skew) free energy on these patterns has an extreme value only at the pattern with a uniquely determined wavenumber k_m. When Turing bifurcations occur in actual systems, it is expected that the wavenumber k_m plays an important role in determining which pattern, or, which wavenumber, is to be selected. In the next section, we investigate this problem for several concrete model systems by employing numerical experiments.

8. Pattern selection. In this section, combining numerical experiments with the analytical results obtained in the previous section, we investigate what pattern is to be uniquely selected among many near the Turing bifurcation point.

Let us explain our problem more specifically. We have discussed basic properties of the Turing patterns in an *infinite* domain. However, in real (numerical) experiments, they are observed in a *finite* domain. Thus we consider the gradient/skew-gradient systems (2.1) with (2.2) on a finite interval under the periodic boundary conditions

$$\begin{aligned} &Tu_t = Du_{xx} + f(u), \quad 0 < x < L, \\ &u(x,0) = \varepsilon u_0(x), \end{aligned} \tag{8.1}$$

where ε and $|D|/L$ are sufficiently small, $|D| = \max |d_{ij}|$, and $u_0(x)$ is bounded. For each fixed μ near the Turing bifurcation point μ_c, we numerically solve (8.1) by using the pseudospectral method and the discrete FFT. Then we study a spatial profile and the Fourier power spectrum of $u(x, T_1)$ for sufficiently large T_1. Notice that numerical computations sufficiently close to a (Turing) bifurcation point for sufficiently small $|D|/L$ are very delicate tasks.

According to [11], when μ is sufficiently close to μ_c, the power spectrum of $u(x, T_1)$ for sufficiently large T_1 has a (bell) shape such as Figure 5(e) centered at $k = k_c$ if the power spectrum of an initial data $u_0(x)$ takes the maximal peak only at $k = k_c$. It should be noted that this is valid for general systems regardless of whether they have gradient/skew-gradient dissipative structures.

Here we are interested in a spatial profile and the Fourier power spectrum of $u(x, T_1)$ for sufficiently large T_1 for a uniform distribution $u_0(x) \in (-1/2, 1/2)$ generated by pseudorandom numbers. Noting $k_m(\mu_c) = k_c$ and the above mentioned fact, we expect that the distribution of power spectrum of $u(x, T_1)$ is concentrated in a cluster centered at $k = k_c$ near the Turing bifurcation point $\mu = \mu_c$. We investigate the peak of distribution of power spectrum of $u(x, T_1)$ in the cluster.

Let us first consider the Swift–Hohenberg equation

$$u_t = \mu u - (1 + \partial_{xx})^2 u - u^3. \tag{8.2}$$

As seen in section 2, (8.2) is a gradient system that can be rewritten as (2.1). It is easy to see that (8.2) has a Turing bifurcation point $\mu_c = 0$ with a critical wavenumber $k_c = 1$. In fact, it is well known [5] that (8.2) has a family of spatially periodic stationary solutions

$$\phi(x; k, \mu) = \frac{2a}{\sqrt{3}} \cos(kx) + O(a^3),$$

where $a = \sqrt{\mu - (1 - k^2)^2}$. Applying the results in the previous section, we find that $k_m(\mu) \approx k_c$ holds. This suggests that the power spectrum of $u(x, T_1)$ for sufficiently

large T_1 takes the maximal peak at $k_c = 1$. We set $L = 200\pi$ so that L/λ_c is an integer, where $\lambda_c = 2\pi$ is wavelength of the Turing pattern with wavenumber k_c. In this case, the discrete FFT can capture a variation of wavenumber of the Turing pattern in the accuracy $\delta k = 2\pi/L = 0.01$. Notice that a relative variation of wavenumber to the basic pattern associated with $k_c = 1$ is given by $\delta k/k_c = 0.01$. For $\mu = 0.01$ and $\varepsilon = 0.0001$, Figures 4 and 5 show snapshots of spatial profiles and the Fourier power spectra of a numerical solution of (8.2). After sufficiently large time, the spatial profile in Figure 4(e) looks like a (meta)stable stationary pattern with spatially periodic structure. In what follows, T_1 is determined by the time when a solution of a system reaches a (meta)stable stationary pattern as in Figure 4(e). Notice that T_1 depends on an initial condition and all parameters in a system. In this case, we set $T_1 = 2000$. We regard a spatial pattern of $u(x, T_1)$ as the Turing pattern in our numerical experiments. Furthermore, we say that the Turing pattern with wavenumber 1.00 is selected because the Fourier power spectrum in Figure 5(e) has the maximal peak at $k = 1.00$.

In order to study what Turing pattern is to be uniquely selected among many, we numerically solve (8.2) for some other initial data. In general, the Fourier power spectrum of $u(x, T_1)$ does not necessarily have a clear (bell) shape (for example, see Figure 6). Therefore, we compute the power spectra of $u(x, T_1)$ for 30 random initial data and take their average. The result shows that the wavenumber $k = 1.00$ is selected with the highest probability. We call this wavenumber *the selected wavenumber* denoted by $k_s(\mu)$. In this case, $k_s(0.01) = 1.00$. The selected wavenumbers for various μ are shown in Table 1.

Thus we see that $k_s(\mu) \approx k_m(\mu) \approx k_c$ holds near the Turing bifurcation point in this example.

Next, we treat again the model system (7.2) from the previous section:

$$\tau_1 u_t = d_1 u_{xx} + \alpha(1 - u^2)u - \beta v, \quad \tau_2 v_t = d_2 v_{xx} - \gamma(1 + v^2)v + \beta u.$$

This system was used in Ben-Jacob et al. [3] for a study of patterns generated from small initial data with *compact support* in various dissipative systems. They studied the problem of front propagation of local Turing patterns generated by a small local perturbation into a linearly unstable steady state. For recent progress of this topic, we refer to Ebert and Saarloos [9] and Saarloos [34].

First, we consider a case $\mu = \beta^2$. As was seen in the previous section, in this case, $k_m(\mu) \approx k_c$ holds, and we may expect that $k_s(\mu) \approx k_m(\mu)$. In a manner similar to the previous example, we set $L = 200\pi$ for $k_c = 1$. We choose $\alpha = 1.0$, $\gamma = 2.0$, $d_1 = 0.25$, and $d_2 = 1.0$ satisfying (7.12). Then, it follows from (7.13) that $\beta_c = 1.5$. Moreover, noting (7.10), we choose $\beta = 1.48$, so that the distance from the bifurcation point is given by $|\mu - \mu_c|/\mu_c = (\beta_c^2 - \beta^2)/\beta_c^2 \approx 0.0264889$.

For $\tau_1 = \tau_2 = 1.0$, $\varepsilon = 0.0001$, and these parameter values, numerically solving (7.2), we have a spatial profile and the Fourier power spectrum of $u(x, T_1)$ for $T_1 = 3000$ as in Figure 6. In a manner similar to the previous example, computing the power spectra of $u(x, T_1)$ for 30 random initial data, and taking their average, we determine that $k_s((1.48)^2) = 0.97$. Moreover, the selected wavenumber $k_s(\mu)$ for various μ are shown in Table 2.

Contrary to our expectation, this statistical result shows that $k_s(\mu)$ does not necessarily coincide with $k_m(\mu)$. More precisely, $k_s(\mu) \approx k_m(\mu) \approx k_c$ holds in a sufficiently small neighborhood of the Turing bifurcation point, while $k_s(\mu) < k_m(\mu)$ holds slightly away from the bifurcation point. Similar results, as in Table 2, can also be obtained for other values of $\alpha, \gamma, d_1, d_2, \tau_1$, and τ_2.

$(1.49)^2$	0.0132889	1.00	0.99
$(1.485)^2$	0.0199	1.00	0.97
$(1.48)^2$	0.0264889	1.00	0.97
$(1.46)^2$	0.0526222	1.00	0.94

Next, we consider the case $\mu = d_2$. As was seen in section 7, in this case, $k_m = k_m(\mu)$ does not coincide k_c, and $k_m > k_c$ holds for $\mu > \mu_c$. In the following numerical experiments, we set $\tau_1 = \tau_2 = 1.0$, $\varepsilon = 0.0001$, and $L = 200\pi$ for $k_c = 1$ as in the previous case. Noting (7.10), we choose $\alpha = 1.0$, $\beta = 1.5$, and $\gamma = 2.0$. Then it follows from (7.8) and (7.9) that $d_1 = 0.25$ and $d_2^c = 1.0$. In order to compare k_c and k_m, by using (7.11), we choose $\mu = d_2$ such that $k_m(\mu)$ can be captured by the discrete FFT. In a manner similar to the previous case, we can obtain (see Table 3) the selected wavenumbers $k_s(\mu)$ for various $\mu = d_2$.

TABLE 3
$k_s(\mu)$ and $k_m(\mu)$ for various μ when $\alpha = 1.0$, $\beta = 1.5$, and $\gamma = 2.0$.

μ	$\lvert\mu - \mu_c\rvert/\mu_c$	k_c	$k_s(\mu)$	$k_m(\mu)$
1.01354	0.0135359	1.00	1.00	1.01
1.02749	0.0274873	1.00	1.00	1.02
1.072	0.0720021	1.00	1.01	1.05
1.1562	0.156203	1.00	1.01	1.10

TABLE 4
$k_s(\mu)$ and $k_m(\mu)$ for various μ when $\alpha = 1.0$, $\beta = 1.43$, $\gamma = 2.0$.

μ	$\lvert\mu - \mu_c\rvert/\mu_c$	k_c	$k_s(\mu)$	$k_m(\mu)$
0.352115	0.0120813	1.00	1.01	1.02
0.358726	0.0310831	1.00	1.03	1.05
0.370618	0.0652656	1.00	1.05	1.10
0.383708	0.102891	1.00	1.08	1.15

Similarly, Table 4 shows a case in which $\alpha = 1.0$, $\beta = 1.43$, $\gamma = 2.0$, $d_1 \approx 0.129056$, and $d_2^c \approx 0.347912$.

In this example, the above statistical results show that $k_s(\mu) \approx k_m(\mu) \approx k_c$ holds in a sufficiently small neighborhood of the Turing bifurcation point, while $k_s(\mu) \leq k_m(\mu)$ holds (slightly) away from the bifurcation point.

As expected, these numerical results show that $k_s(\mu) \approx k_c$ holds in a sufficiently small neighborhood of the Turing bifurcation point μ_c. This is certainly true for any general system. On the other hand, the above results clearly show that $k_s(\mu) \approx k_c$ is not always true, even if μ is rather close to the bifurcation point μ_c. Thus, the statement $k_s(\mu) \approx k_c$, which has been widely accepted as a working principle[1] in many previous references, has to be modified so that it is valid in a realistic parameter region near the bifurcation point. As for gradient/skew-gradient dissipative systems, keeping Remark 6.3(2) in mind, we propose the following conjecture as a general (modified version of) pattern selection principle which is consistent with the above experimental results.

CONJECTURE 8.1. *For gradient/skew-gradient dissipative systems, the inequality*

$$k_s(\mu) \leq k_m(\mu) \tag{8.3}$$

holds near the Turing bifurcation point.

The reader may wonder about the validity of the above conjecture because $k_s(\mu)$ has no precise definition; how can we predict $k_s(\mu)$? A partial answer for this problem is reported in a separate paper [21]. In fact, for two component gradient/skew-gradient systems, we can explain a mechanism which determines $k_s(\mu)$ and confirm the validity of (8.3) near the Turing bifurcation point. As for n-component systems, however, we do not know whether or not (8.3) is true because we have not yet performed analytical calculations and numerical experiments as in sections 7 and 8. In general,

[1] This principle and the definition of the pattern to be (uniquely) selected have not been explicitly expressed.

some nondegeneracy conditions such as $E_c > 0$ may be required, where E_c is defined in Hypothesis 6.1.

The inequality (8.3) turns out to be very important in selection problems for roll patterns in two-dimensional problems. In [21], we verify the validity of the marginal stability hypothesis [30, 31, 32], which asserts that the selected roll pattern is determined by $D_\perp = 0$ corresponding to the zigzag instability criterion. As seen in [20], $D_\perp = 0$ is given by $k_m(\mu)$ in gradient/skew-gradient dissipative systems. For roll patterns in two-dimensional problems, we can introduce $k_s(\mu)$ in a manner similar to the one-dimensional case, and we find that (8.3) plays a key role in studying marginal stability hypotheses for roll patterns in two-dimensional problems under the gradient/skew-gradient structure.

9. Summary. In this paper, we consider some fundamental properties of Turing patterns in gradient/skew-gradient dissipative systems. The results are summarized as follows:

(1) To prove that QD is definite, we cannot produce the Turing patterns (Theorem 3.2). This characterizes Turing patterns a little more precisely than commonly accepted explanations based on two types of components with opposing kinetics and different diffusion rates.

(2) To give an instability criterion for spatially periodic steady states (Theorem 4.1), it is represented in terms of $I(k)$ and $E(k)$. $E(k)$ is (skew) free energy per unit length of spatially periodic steady states and convexity of $E(k)$ in wavenumber k determines the instability. This is an extension of the Eckhaus instability criterion. Notice that this criterion is valid far from a bifurcation point.

For any fixed bifurcation parameter μ, we define $I(k, \mu)$ and $E(k, \mu)$ for spatially periodic patterns $\phi(x; k, \mu)$ with wavenumber k near a bifurcation point.

(3) The sign of $I(k, \mu)$ at a bifurcation point determines the sign of time constant coefficient of the amplitude equation, which describes dynamics in a sufficiently small neighborhood of the bifurcation point. Moreover, $I(k, \mu)$ affects the instability of the underlying homogeneous steady state to be equipped with spatially periodic structure (see Observation 5.3).

(4) Uniqueness of extremum of $E(k, \mu)$ in k is established under the nondegeneracy condition (Theorem 6.2). This condition can be easily verified at the Turing bifurcation point.

(5) The wavenumber corresponding to the unique extremum of $E(k, \mu)$ gives an upper bound for the wavenumber of the Turing pattern to be uniquely selected among many near the Turing bifurcation point (Conjecture 8.1). The intrinsic symmetric property in the gradient/skew-gradient structure gives a prohibition law in selection of the Turing patterns near a bifurcation point.

As seen in section 7, from a practical viewpoint we propose the following calculation procedure to obtain the Turing pattern with minimum (skew) free energy per unit length:

(1) To verify that QD is not definite.

(2) To determine Turing bifurcation point, choose a bifurcation parameter μ, seek the relation $\mu = \hat{\mu}(k^2)$ by solving $\det(k^2 D - f_u(\bar{u})) = 0$, and determine Turing bifurcation point μ_c and critical wavenumber k_c by $\partial_\theta \hat{\mu}(\theta)|_{\theta=k_c^2} = 0$ and $\mu_c = \hat{\mu}(k_c^2)$.

(3) To compute zero eigenvector Ψ_k by $(k^2 D - f_u(\bar{u}))\Psi_k = 0$ for $\mu = \hat{\mu}(k^2)$.

(4) To check the hypothesis

$$I_c := \mathrm{Re}\langle T\Psi_k, Q\Psi_k\rangle|_{k=k_c} > 0 \text{ and } E_c := \mathrm{Re}\,\partial_k\langle D\Psi_k, Q\Psi_k\rangle|_{k=k_c} > 0.$$

(5) To compute the wavenumber $k_m = k_m(\mu)$ corresponding to minimizer of (skew) free energy by $Re\langle D\Psi_k, Q\Psi_k\rangle = 0$.

In addition to the above summary, we mention some remarks. First, we notice that if the bifurcation parameter μ is in reaction term f (not in D), $k_m(\mu) \approx k_c$ holds (Remark 6.3(1)). In many practical problems, μ is often an external parameter such as temparature, which is in the reaction term. Thus, recalling Conjecture 8.1, this suggests that a wavenumber to be selected is likely to deviate from k_c to the left in one-dimensional problems.

Moreover, we notice that it is necessary that $I_c > 0$ so that skew-gradient dissipative systems can admit gradient structure near a bifurcation point. On the other hand, when we change the sign of I_c, the underlying homogeneous steady state to be equipped with spatial structure becomes unstable, so that the spatial patterns lose their stability.

Furthermore, from the analytical results of section 7, we find that in two component gradient/skew-gradient dissipative systems, the Turing bifurcation point is nondegenerate and $E_c > 0$. This is a universal feature of two component systems. The degenerate case $E_c = 0$ can be observed for $n \geq 3$, and the complex spatial patterns near the bifurcation point in this case will be reported in a separate paper.

Finally, we mention further problems that should be studied in the framework of our theory. They seem to be significant steps to understand pattern selection principle in various fields of science. First, we must clarify what mechanism determines the selected wavenumber $k_s(\mu)$ and verify Conjecture 8.1. In particular, we must clarify conditions to guarantee the validity of inequality (8.3) in general n-component gradient/skew-gradient systems. This study is now in progress and is treated in a forthcoming paper [21].

In section 8, we consider what Turing pattern is to be selected among many for small random initial data. We are also interested in small initial data with compact support which is natural from a practical viewpoint. In this case, a local Turing pattern generated by a small local perturbation propagates into a linearly unstable uniform steady state [9, 34]. According to [9, 34], the wavenumber of spatially periodic structure of propagating patterns is determined by the (linear) marginal stability criterion, which yields a different one from $k_c, k_m(\mu)$, and $k_s(\mu)$ introduced here. Comparisons of our theory and theirs should be studied in the future.

In this paper, we consider pattern selection problems in a uniform environment. It is an ideal situation in which standard analysis such as asymptotic expansion can be easily performed. We are also interested in various cases that we meet in realistic problems. For example, the Turing parameter μ is dependent on spatial variable x, i.e., $\mu = \mu(x)$. This is known as a ramp problem [7, 19] which describes a bifurcation phenomena in a spatially nonuniform environment. In addition, a case in which μ is dependent on time variable t should be studied to compare our theory with real experiments.

Although pattern selection problems attracted the attention of many researchers, convincing mathematical results are very few. In fact, they are essentially to classify basins of attraction for stable steady states, and it turns out to be quite difficult in many cases. Our strategy to study pattern selection problems is not to determine the basins of attraction for steady states. The aim of our theory is rather to order steady states by using an appropriate (energy) functional which provides useful and practical information to determine what steady state is to be selected. We believe that our approach is a first step in understanding pattern selection mechanisms in various dissipative systems.

Acknowledgments. The author expresses his sincere gratitude to Professors Yasumasa Nishiura, Eiji Yanagida, and Kunimochi Sakamoto for their helpful advice. Moreover, the author would like to give appreciation to the referees who carefully read the manuscript.

STABILITY AND BIFURCATIONS IN NEURAL FIELDS WITH FINITE PROPAGATION SPEED AND GENERAL CONNECTIVITY*

FATIHCAN M. ATAY† AND AXEL HUTT‡

Abstract. A stability analysis is presented for neural field equations in the presence of finite propagation speed along axons and for a general class of connectivity kernels and synaptic properties. Sufficient conditions are given for the stability of equilibrium solutions. It is shown that the propagation delays play a significant role in nonstationary bifurcations of equilibria, whereas the stationary bifurcations depend only on the connectivity kernel. In the case of nonstationary bifurcations, bounds are determined on the frequencies of the resulting oscillatory solutions. A perturbative scheme is used to calculate the types of bifurcations leading to spatial patterns, oscillations, and traveling waves. For high propagation speeds a simple method is derived that allows the determination of the bifurcation type by visual inspection of the Fourier transforms of the kernel and its first moment. Results are numerically illustrated on a class of neurologically plausible systems with combinations of Gaussian excitatory and inhibitory connections.

Key words. synaptic networks, nonlocal interaction, delay, bifurcations, spatiotemporal patterns, traveling waves

1. Introduction.

In recent years, there has been growing interest in the mechanisms of spatiotemporal activity in neural tissue. In this field, applications of various experimental techniques [37, 21, 39, 41] revealed formations of different spatial patterns, traveling waves, and pulses [28, 43, 48], standing pulses (e.g., [18]), or irregular spatial patterns [2, 40]. Since neural tissue exhibits multiscale properties in space and time, the analysis of such activity represents a challenging task. However, reduced biological models at fixed scales in time and space simplify the analysis and allow for analytical treatments (see, e.g., [5, 12, 42] for review). In this context, a well-known approach is to focus on neuronal ensembles [46, 47, 29], which allows for the successful reconstruction of empirical data measured on a macroscopic scale [24, 30, 35, 34, 25].

On a small spatial level ($\sim 50\mu m$), model neurons may consist of two compartments: synapses, which convert incoming action potentials to postsynaptic potentials, and a trigger zone, where these potentials sum up and are reconverted to outgoing action potentials. Due to the large spatial density of neurons ($\sim 10^4$ neurons/mm^3), one might consider ensemble activity on a larger spatial scale (> 1 mm), obtaining a coarse-grained description in space and time [46]. Consequently, macroscopic state variables of neuronal ensembles are mean pulse rates $P(x,t)$ and mean postsynaptic potentials $V(x,t)$, with x and t denoting the space and time coordinates, respectively. In the following, all quantities are meant to represent means of microscopic quantities.

Since the link between the microscopic description and the level of neural ensembles has been established in several previous works (e.g., [46, 38, 5, 4]), we only briefly

outline the basic mechanisms of activity conversion in neuronal fields. At chemical passive synapses, incoming pulse activity $J(x,t)$ is converted to postsynaptic potentials by convolution with an impulse response function $h(t)$, yielding

$$V(x,t) = \int_{-\infty}^{t} h(t-\tau)J(x,\tau)d\tau.$$

Since neuronal fields exhibit nonlocal interactions via axonal connections between synapses, incoming pulse activity obeys

$$J(x,t) = \beta \int_{\Omega} K(x,y)P(y,t-\Delta(x,y))dy \; + \; E(x,t),$$

where Ω is an appropriate spatial domain, K is the connectivity kernel, $\beta > 0$ is a scaling factor, and E is an additional external input. In the case of undamped axonal pulse propagation with finite velocity v and no additional constant delay, we get $\Delta(x,y) = |x-y|/v$. Essentially, the chain of activity conversion closes by the conversion of postsynaptic potentials to pulse rates

$$P(x,t) = S[V(x,t)],$$

where S is called the transfer function, which is taken to have a sigmoidal shape in most works. Considering all conversions, we obtain the integral equation

$$V(x,t) = \beta \int_{-\infty}^{t} \int_{\Omega} \left(h(t-\tau)K(x,y)S[V(y,\tau-|x-y|/v)] + E(x,\tau)\right)\, dy\, d\tau.$$

We then recast the impulse response function as a Green's function and thus stipulate

$$Lh(t) = \delta(t),$$

introducing a temporal differential operator L. Finally, we assume a homogeneous field where the connectivity $K(x,y)$ depends only on the distance $|x-y|$, and so we replace $K(x,y)$ by an even function $K(x-y)$. Hence, the final equation has the form

$$L(\partial/\partial t)V(x,t) = \beta \int_{\Omega} K(x-y)S(V(y,t-|x-y|/v))\, dy + E(x,t), \tag{1.1}$$

where L is a polynomial and $L(\partial/\partial t)$ denotes a temporal differentiation operator with constant coefficients. We shall refer to (1.1) as an nth-order system, where $n \geq 1$ is the order of L.

The model (1.1) has been treated in the literature in several contexts and with different choices for L. In most studies the effect of transmission speed has been neglected by letting $v = \infty$ in the model, the justification being that the signal propagation is sufficiently fast or the spatial scales of the problem are small [32]. Some recent works [5, 15, 19, 31, 23, 8] have addressed the case of finite v by numerical investigations for particular choices of the kernel K. Our aim is to give an analytical treatment of the effects of finite transmission speeds for general K and L, in relation to the stability and bifurcation of the equilibrium solutions.

In the next section we consider the equilibrium solutions of (1.1) and give a sufficient condition for their stability. Section 3 discusses the types of dynamics that may emerge when stability is lost. Here it is shown that the transmission speed needs to

be smaller than a certain threshold in order to have oscillatory bifurcations in first- and second-order systems. Furthermore, bounds are calculated for the frequencies of the oscillatory solutions. In section 4, a perturbative analysis is used to compute the bifurcating solutions, and a graphical method is given to determine the possible bifurcations for a given kernel. Applications to kernels derived from Gaussian distributions are presented in section 5, and the paper concludes with a discussion of the results.

2. Stability of equilibrium solutions. For the rest of the paper we make the following assumptions regarding (1.1). For the spatial domain we assume $\Omega = \mathbf{R}$, although the results remain valid virtually without modification when Ω is a circle. The polynomial L is stable; i.e., all its roots have negative real parts. The kernel $K : \mathbf{R} \to \mathbf{R}$ is continuous, integrable, and even; that is, $K(-z) = K(z)$ for all $z \in \mathbf{R}$. Finally, the transfer function $S : \mathbf{R} \to \mathbf{R}$ is differentiable and monotone increasing.

It is often convenient to normalize the time and space in (1.1). For instance, if l and τ are some characteristic length and time of the physical problem, then one can define $\bar{t} = t/\tau$, $\bar{x} = x/l$, $\bar{V}(\bar{x}, \bar{t}) = V(l\bar{x}, \tau\bar{t})$, $\bar{E}(\bar{x}, \bar{t}) = E(l\bar{x}, \tau\bar{t})$, $\bar{L}(\partial/\partial\bar{t}) = \tau^n L(\tau^{-1}\partial/\partial\bar{t})$, $\bar{K}(\bar{z}) = K(l\bar{z})$, and $\bar{v} = \tau v/l$ so that (1.1) becomes

$$\bar{L}(\partial/\partial\bar{t})\bar{V}(\bar{x}, \bar{t}) = l\tau^n\beta \int_\Omega \bar{K}(\bar{x} - \bar{y}) S(\bar{V}(\bar{y}, \bar{t} - |\bar{x} - \bar{y}|/\bar{v}))\, d\bar{y} + \bar{E}(\bar{x}, \bar{t}),$$

which has the same form as (1.1). A common choice for characteristic time is $\tau^n = 1/L(0)$, in which case $\bar{L}(0) = 1$. Thus, without loss of generality we consider (1.1) with the assumption that $L(0) = 1$. Most studies of neuronal fields assume first- or second-order time derivatives in (1.1). To address these models in a unified manner, we shall often refer to the following specific form:

$$L(\lambda) = \eta\lambda^2 + \gamma\lambda + 1, \quad \eta = 0 \text{ or } 1,\ \gamma > 0, \tag{2.1}$$

although certain results will be stated for arbitrary order stable polynomials L.

For a constant input $E(x, t) \equiv E^*$, an equilibrium solution $V(x, t) \equiv V^*$ satisfies

$$V^* = \beta \int_{-\infty}^{\infty} K(x - y) S(V^*)\, dy + E^*. \tag{2.2}$$

Let

$$\kappa = \int_{-\infty}^{\infty} K(z)\, dz = 2\int_0^{\infty} K(z)\, dz. \tag{2.3}$$

Then (2.2) can be written as

$$f(V^*) \stackrel{\text{def}}{=} V^* - \kappa\beta S(V^*) = E^*. \tag{2.4}$$

If S is bounded, then $f : \mathbf{R} \to \mathbf{R}$ is surjective; thus (2.4) has a solution V^* for any $E^* \in \mathbf{R}$. The uniqueness of V^* depends on the sign of κ and the shape of S. If S is positive and increasing on $\mathbf{R}$, such as a sigmoid function, and if $\kappa \le 0$, then f is increasing and hence also injective, in which case the solution V^* is unique. On the other hand, if $\kappa > 0$, then there may be multiple equilibria, as (2.4) can have more than one solution V^* for a given E^*.

The stability of the equilibrium solution V^* is determined by the linear variational equation

$$L(\partial/\partial t)u(x,t) = \alpha \int_{-\infty}^{\infty} K(x-y)u(y,t-|x-y|/v)\,dy, \tag{2.5}$$

where $u(x,t) = V(x,t) - V^*$ and $\alpha = \beta S'(V^*) \geq 0$. We shall use α as a bifurcation parameter in the following sections. Using the ansatz $u(x,t) = e^{\lambda t}\varphi(x)$ in (2.5) one obtains

$$L(\lambda)\varphi(x) = \alpha \int_{-\infty}^{\infty} K(x-y)\exp(-\lambda|x-y|/v)\varphi(y)\,dy. \tag{2.6}$$

Thus φ is an eigenfunction of an integral operator. Due to the difference kernel the eigenfunctions have the form $\varphi(x) = e^{ikx}$ for some $k \in \mathbf{R}$, and substituting into (2.6) followed by a change of variables $z = x - y$ in the integral gives

$$L(\lambda) = \alpha \int_{-\infty}^{\infty} K(z)\exp(-\lambda|z|/v)\exp(-ikz)\,dz. \tag{2.7}$$

The integral above is the Fourier transform of the function $K_\lambda(z) = K(z)\exp(-\lambda|z|/v)$ (up to a multiplicative factor, depending on which definition one uses), which is also equal to its cosine transform since $K_\lambda(z)$ is an even function of z. The dispersion relation (2.7) between the temporal and spatial modes λ and k is in general difficult to solve explicitly. A notable exception is the case of instantaneous information transmission, since when $v = \infty$, the right-hand side of (2.7) is independent of λ. In this paper we are interested in the effects of finite transmission speeds.

The solutions (λ, k) of (2.7) correspond to the perturbations $u(x,t) = e^{\lambda t}e^{ikx}$ about the equilibrium solution, which grow or decay in time depending on whether $\operatorname{Re}\lambda$ is positive or negative, respectively, thus determining the stability of V^*. We give sufficient conditions for asymptotic stability.

THEOREM 2.1. *Let $c = \alpha\int_{-\infty}^{\infty}|K(z)|\,dz$. If*

$$c < \min_{\omega\in\mathbf{R}} |L(i\omega)|, \tag{2.8}$$

then V^* is asymptotically stable. In particular, if $L(\lambda) = \lambda + 1$, then the condition

$$c < 1 \tag{2.9}$$

is sufficient for the asymptotic stability of V^*. If $L(\gamma) = \lambda^2 + \gamma\lambda + 1$ with $\gamma > 0$, then V^* is asymptotically stable provided that the condition

$$\frac{\gamma^2}{2} > 1 - \sqrt{1-c^2} \tag{2.10}$$

holds, in addition to (2.9).

The following lemma will be useful in the proof of the theorem.

LEMMA 2.2. *Let $L(\lambda)$ be a polynomial whose roots have nonpositive real parts. Then*

$$|L(\sigma + i\omega)| \geq |L(i\omega)|$$

for all $\sigma \geq 0$ and $\omega \in \mathbf{R}$.

Proof. If λ_k denote the roots of L, then $L(\lambda) = (\lambda - \lambda_1)(\lambda - \lambda_2)\cdots(\lambda - \lambda_n)$, where n is the order of L. Thus

$$\begin{aligned}|L(\sigma + i\omega)| &= \prod_{k=1}^{n} |\sigma + i\omega - \lambda_k| \\ &= \prod_{k=1}^{n} \left((\sigma - \mathrm{Re}[\lambda_k])^2 + (\omega - \mathrm{Im}[\lambda_k])^2\right)^{1/2}.\end{aligned}$$

By assumption, $\sigma \geq 0$ and $\mathrm{Re}[\lambda_k] \leq 0$ for all k, so

$$\begin{aligned}|L(\sigma + i\omega)| &\geq \prod_{k=1}^{n} \left((-\mathrm{Re}[\lambda_k])^2 + (\omega - \mathrm{Im}[\lambda_k])^2\right)^{1/2} \\ &= \prod_{k=1}^{n} |i\omega - \lambda_k| \\ &= |L(i\omega)|. \qquad \square\end{aligned}$$

Proof of Theorem 2.1. In the ansatz $u(x,t) = e^{\lambda t}e^{ikx}$, let $\lambda = \sigma + \mathrm{i}\omega$, where σ and ω are real numbers. We will prove that $\sigma < 0$ if (2.8) holds. Suppose by way of contradiction that (2.8) holds but $\sigma \geq 0$. From the dispersion relation (2.7) it follows that

$$\begin{aligned}|L(\sigma + i\omega)| &= \alpha \left| \int_{-\infty}^{\infty} K(z) \exp(-(\sigma + i\omega)|z|/v) \exp(-ikz)\, dz \right| \\ &\leq \alpha \int_{-\infty}^{\infty} |K(z)|\, |\exp(-(\sigma + i\omega)|z|/v)|\, dz \\ &\leq \alpha \int_{-\infty}^{\infty} |K(z)| dz = c. \qquad (2.11)\end{aligned}$$

On the other hand, by Lemma 2.2,

$$|L(i\omega)| \leq |L(\sigma + i\omega)|,$$

which together with (2.11) implies

$$|L(i\omega)| \leq c$$

for some $\omega \in \mathbf{R}$. This, however, contradicts (2.8). Thus $\sigma < 0$, and the equilibrium solution is asymptotically stable. This proves the first statement of the theorem. In the specific case when L is given by $L(\lambda) = \lambda + 1$, one has $|L(i\omega)|^2 = 1 + \omega^2$. Hence if (2.9) is satisfied, then

$$c^2 < 1 \leq 1 + \omega^2 = |L(i\omega)|^2 \quad \text{for all } \omega \in \mathbf{R},$$

which is a sufficient condition for stability by (2.8). Similarly, suppose that L has the form $L(\lambda) = \lambda^2 + \gamma\lambda + 1$ and that (2.9) and (2.10) are satisfied. Then

$$|L(i\omega)|^2 = (1 - \omega^2)^2 + (\gamma\omega)^2.$$

Now consider the function

$$\begin{aligned}g(\omega) &\stackrel{\mathrm{def}}{=} |L(i\omega)|^2 - c^2 \\ &= \omega^4 + (\gamma^2 - 2)\omega^2 + (1 - c^2). \qquad (2.12)\end{aligned}$$

If $\gamma^2 \geq 2$, then $g(\omega)$ is positive for all ω by (2.9). On the other hand, if $\gamma^2 < 2$, then by (2.10)

$$0 < 2 - \gamma^2 < 2\sqrt{1 - c^2},$$

implying that the discriminant $(\gamma^2 - 2)^2 - 4(1 - c^2)$ is negative; thus g has no real roots. Thus, in either case, $g(\omega)$ is positive, or, equivalently, $c < |L(i\omega)|$ for all ω, and stability again follows by the first statement of the theorem. □

3. Bifurcations. When $\alpha = 0$, the eigenvalues λ are simply given by the roots of L, so that $\operatorname{Re}\lambda < 0$ by the assumption that L is a stable polynomial, and the equilibrium point is asymptotically stable. As α is increased, stability can be lost if an eigenvalue λ crosses the imaginary axis. At the critical transition there is an eigenvalue of the form $\lambda = i\omega$, $\omega \in \mathbf{R}$, and the dispersion relation (2.7) has the form

$$L(i\omega) = \alpha \int_{-\infty}^{\infty} K(z) \exp(-i(kz + \omega|z|/v))\, dz. \tag{3.1}$$

The possibilities for the resulting behavior when α is near such a critical value can then be qualitatively classified as follows:

I. Stationary bifurcations
   a. $\omega = 0$ and $k = 0$: bifurcation to a spatially and temporally constant solution.
   b. $\omega = 0$ and $k \neq 0$: bifurcation to a spatially periodic solution which is constant in time, leading to spatial patterns (Turing modes).

II. Nonstationary bifurcations
   a. $\omega \neq 0$ and $k = 0$: Hopf bifurcation to periodic oscillations of a spatially uniform solution.
   b. $\omega \neq 0$ and $k \neq 0$: bifurcation to traveling waves, with wave speed equal to ω/k.

The conditions for stationary bifurcations are easily characterized by the relation (3.1), recalling the assumption that $L(0) = 1$. Thus for case Ia one has

$$1 = \alpha \int_{-\infty}^{\infty} K(z)\, dz = \alpha\kappa \tag{3.2}$$

with κ as defined in (2.3). This is only possible if $\kappa > 0$ and is the mechanism for appearance of multiple equilibrium solutions of (2.2). Similarly, the condition (2.7) for case Ib is

$$1 = \alpha \int_{-\infty}^{\infty} K(z) \exp(ikz)\, dz = \alpha \hat{K}(k), \quad k \neq 0, \tag{3.3}$$

where $\hat{K}$ denotes the Fourier transform of K. As α is increased from zero, the first mode that becomes unstable in the linearized equation is expected to give an indication of what would be observed in the full nonlinear system (1.1). Hence, spatial patterns are typically observed as bifurcations from equilibria if a nonzero k is the first mode that loses stability. From (3.3) it follows that a necessary condition for this is that the maximum value of the Fourier transform of K is positive and occurs at a nonzero frequency k.

It is clear from (3.2) and (3.3) that stationary bifurcations are independent of the order of the temporal differentiation operator L or the transmission speed v. Their

analysis only involves the properties of the Fourier transform of the kernel function. On the other hand, L and v turn out to be crucial in nonstationary bifurcations. Indeed, our next result shows that a sufficiently small transmission speed is actually a necessary condition for nonstationary bifurcations in first- and second-order systems.

THEOREM 3.1. *Suppose $L(\lambda) = \eta\lambda^2 + \gamma\lambda + 1$, where η may possibly be zero. If*

$$v > \frac{\alpha}{|\gamma|} \int_{-\infty}^{\infty} |zK(z)|\, dz, \tag{3.4}$$

then (2.5) *has no solutions of the form $u(x,t) = \exp i(\omega t + kx)$ with ω real and nonzero.*

Proof. From the dispersion relation (2.7),

$$\begin{aligned} L(\lambda) &= \alpha \int_{-\infty}^{\infty} K(z) \exp(-\lambda|z|/v)(\cos kz - i \sin kz)\, dz \\ &= \alpha \int_{-\infty}^{\infty} K(z) \exp(-\lambda|z|/v) \cos kz\, dz \end{aligned}$$

since the function $K(z)\exp(-\lambda|z|/v)$ is even in z. Separating the real and imaginary parts of the above expression at the bifurcation value $\lambda = i\omega$ gives

$$\operatorname{Re} L(i\omega) = \alpha \int_{-\infty}^{\infty} K(z) \cos(\omega z/v) \cos(kz)\, dz, \tag{3.5}$$

$$\operatorname{Im} L(i\omega) = -\alpha \int_{-\infty}^{\infty} K(z) \sin(\omega|z|/v) \cos(kz)\, dz. \tag{3.6}$$

Suppose $L(\lambda) = \eta\lambda^2 + \gamma\lambda + 1$. Then $\operatorname{Im} L(i\omega) = \gamma\omega$, and (3.6) implies

$$\begin{aligned} |\gamma\omega| &= \alpha \left| \int_{-\infty}^{\infty} K(z) \sin(\omega|z|/v) \cos(kz)\, dz \right| \\ &\le \alpha \int_{-\infty}^{\infty} |K(z) \sin(\omega z/v)|\, dz \\ &\le \alpha \int_{-\infty}^{\infty} |K(z)\omega z/v|\, dz, \end{aligned}$$

where we have used the estimate $|\sin(x)| \le |x|$ for all $x \in \mathbf{R}$. If $\omega \neq 0$, then $|\omega|$ may be cancelled in the last inequality to yield

$$|\gamma| \le \frac{\alpha}{v} \int_{-\infty}^{\infty} |zK(z)|\, dz.$$

This, however, contradicts the assumption (3.4). Hence $\omega = 0$, which proves the theorem. ∎

We note that the above result is valid for first- and second-order systems; in higher order systems, bifurcation values $\lambda = i\omega \neq 0$ may occur even with $v = \infty$ [12].

For bifurcating oscillatory solutions, it is possible to put a priori bounds on the possible values of the frequencies ω in terms of the kernel function and the operator L, as given by the next result.

THEOREM 3.2. *Let c be as defined in Theorem* 2.1. *Then there exists $B > 0$, depending only on L and c, such that*

$$|\omega| \le B \tag{3.7}$$

whenever $u(x,t) = \exp i(\omega t + kx)$, $\omega, k \in \mathbf{R}$, *is a solution of* (2.5). *Furthermore, if* $c < 1$, *then there exists* $A > 0$, *depending only on* L *and* c, *such that*

$$0 < A \leq |\omega|. \tag{3.8}$$

In particular, if $L(\lambda) = \lambda + 1$, *then*

$$\omega^2 \leq c^2 - 1, \tag{3.9}$$

and if $L(\lambda) = \lambda^2 + \gamma\lambda + 1$, *then*

$$\begin{array}{cc} (1 - \frac{1}{2}\gamma^2) - \delta \leq \omega^2 \leq (1 - \frac{1}{2}\gamma^2) + \delta & \text{if} \quad 0 \leq c < 1, \\ 0 \leq \omega^2 \leq (1 - \frac{1}{2}\gamma^2) + \delta & \text{if} \quad c \geq 1, \end{array} \tag{3.10}$$

where $\delta = \sqrt{(1 - \frac{1}{2}\gamma^2)^2 - 1 + c^2}$.

Remark. The existence of a solution of the form $u(x,t) = \exp i(\omega t + kx)$ implies that the equilibrium point is not asymptotically stable. It is then a consequence of Theorem 2.1 that the right sides of the inequalities in (3.9) and (3.10) are nonnegative.

Proof of Theorem 3.2. If $\lambda = i\omega$ satisfies the dispersion relation (2.7) for some k, then

$$|L(i\omega)| \leq \alpha \int_{-\infty}^{\infty} |K(z)|\, dz = c. \tag{3.11}$$

Since $|L(i\omega)| \to \infty$ as $\omega \to \pm\infty$ for any nonconstant polynomial L, the above inequality implies an upper bound B on $|\omega|$, which proves (3.7). For the particular case when $L(\lambda) = \lambda + 1$, (3.11) gives

$$|L(i\omega)|^2 = \omega^2 + 1 \leq c^2,$$

proving (3.9). Similarly, for $L(\lambda) = \lambda^2 + \gamma\lambda + 1$, (3.11) yields

$$|L(i\omega)|^2 = \omega^4 + (\gamma^2 - 2)\omega^2 + 1 \leq c^2. \tag{3.12}$$

If we let $u = \omega^2$, then the inequality above is equivalent to saying that possible values of $u \geq 0$ are those which render the function

$$h(u) \stackrel{\text{def}}{=} u^2 + (\gamma^2 - 2)u + (1 - c^2)$$

negative or zero. This is only possible if h has at least one root in the interval $[0, \infty)$, implying that the discriminant $(\gamma^2 - 2)^2 - 4(1 - c^2)$ is nonnegative. Letting $\delta = \sqrt{(1 - \frac{1}{2}\gamma^2)^2 - 1 + c^2}$, the roots of h can be written as $(1 - \frac{1}{2}\gamma^2) \pm \delta$. Thus $h(\omega^2) \leq 0$ for ω^2 satisfying

$$(1 - \tfrac{1}{2}\gamma^2) - \delta \leq \omega^2 \leq (1 - \tfrac{1}{2}\gamma^2) + \delta. \tag{3.13}$$

It remains to ensure that the interval above is a subset of $[0, \infty)$. If $c < 1$, then it is easy to see that both roots of h are nonnegative. For if the smaller root is negative, we have

$$0 > (1 - \tfrac{1}{2}\gamma^2) - \delta > (1 - \tfrac{1}{2}\gamma^2) - |1 - \tfrac{1}{2}\gamma^2|,$$

so $(1-\frac{1}{2}\gamma^2)<0$. But then both the conditions (2.9) and (2.10) are satisfied, and by Theorem 2.1 $\lambda = i\omega$ cannot be a solution to (2.7). On the other hand, if $c \geq 1$, then

$$(1-\tfrac{1}{2}\gamma^2) - \delta \leq (1-\tfrac{1}{2}\gamma^2) - |1-\tfrac{1}{2}\gamma^2| \leq 0$$

and

$$(1-\tfrac{1}{2}\gamma^2) + \delta \geq (1-\tfrac{1}{2}\gamma^2) + |1-\tfrac{1}{2}\gamma^2| \geq 0.$$

So, in this case the lower bound on ω^2 in (3.13) can be replaced by zero. This establishes (3.10). Finally, to prove (3.8) for arbitrary L assume that $c<1$. Then $1 = L(0) > c$. By the continuity of L there exists $A>0$ such that $|L(i\omega)| > c$ whenever $|\omega| \leq A$. Since (3.11) is not satisfied, (2.5) does not have a solution of the form $\exp i(\omega t + kx)$ with $|\omega| \leq A$, which completes the proof. ∎

4. Perturbative analysis. In order to study the type of bifurcations that may arise in a given situation, the dispersion relation (3.1) needs to be solved for ω and k. However, explicit solutions are difficult to obtain for general kernel functions. The results of the previous sections imply that in the absence of delays, one has a simpler case, where nonstationary bifurcations do not exist in first- and second-order systems. Consequently, the role of delays can be systematically examined by following the changes in the bifurcation structure as the value of the transmission speed is decreased from infinity. Hence we introduce the parameter $\varepsilon = 1/v$ and consider the change in dynamics as ε is increased from zero. This leads to an approximation scheme that provides valuable insight into the effects of axonal delays in the dynamics of the system.

Consider the power series estimate

$$\exp(-\lambda|z|/v) = \sum_{m=0}^{N} \frac{(-\lambda|z|/v)^m}{m!} + \mathcal{O}(v^{-(N+1)}).$$

Substitution in the dispersion relation (2.7) at the bifurcation value $\lambda = i\omega$ gives a finite series in powers of $\varepsilon = 1/v$,

$$\begin{aligned} L(i\omega) &= \alpha \int_{-\infty}^{\infty} K(z)\exp(-ikz)\left[\sum_{m=0}^{N}\frac{(-i\varepsilon\omega|z|)^m}{m!} + \mathcal{O}(\varepsilon^{N+1})\right] dz \\ &= \alpha \sum_{m=0}^{N} \frac{(-i\varepsilon\omega)^m}{m!}\hat{K}_m(k) + \mathcal{O}(\varepsilon^{N+1}), \end{aligned} \tag{4.1}$$

where the $\hat{K}_m$ denote the transforms of the moments of K:

$$\hat{K}_m(k) = \int_{-\infty}^{\infty} |z|^m K(z)\exp(-ikz)\,dz = 2\int_0^{\infty} z^m K(z)\cos(kz)\,dz \tag{4.2}$$

and the integrals are assumed to exist. Separating the real and imaginary parts of (4.1) then yields

$$\alpha^{-1}\operatorname{Re} L(i\omega) = \hat{K}_0(k) - \frac{\varepsilon^2}{2}\omega^2\hat{K}_2(k) + \frac{\varepsilon^4}{24}\omega^4\hat{K}_4(k) - \cdots, \tag{4.3}$$

$$\alpha^{-1}\operatorname{Im} L(i\omega) = -\varepsilon\omega\hat{K}_1(k) + \frac{\varepsilon^3}{6}\omega^3\hat{K}_3(k) - \frac{\varepsilon^5}{120}\omega^5\hat{K}_5(k) + \cdots. \tag{4.4}$$

The number of terms needed for the above series to be useful depends on the value of ε as well as the shape of the kernel K. If K is highly concentrated near the origin, then a few terms are sufficient. To make this precise, suppose that K is of exponential order, which is a reasonable assumption in most practical situations. In other words, suppose there exist positive numbers κ_1 and κ_2 such that

$$|K(z)| \leq \kappa_1 \exp(-\kappa_2|z|) \quad \text{for all } z \in \mathbf{R}.$$

Then, by (4.2),

$$\begin{aligned}\left|\hat{K}_m(k)\right| &\leq \int_{-\infty}^{\infty} |z|^m \kappa_1 \exp(-\kappa_2|z|)\, dz = 2\kappa_1 \int_0^{\infty} z^m \exp(-\kappa_2 z)\, dz \\ &= 2\kappa_1 \kappa_2^{-(m+1)} \Gamma(m+1) = 2\kappa_1 \kappa_2^{-(m+1)} m!,\end{aligned}$$

so the mth term in the series (4.1) is bounded in absolute value by

$$2\frac{\kappa_1}{\kappa_2}\left(\frac{\varepsilon|\omega|}{\kappa_2}\right)^m \leq 2\frac{\kappa_1}{\kappa_2}\left(\frac{B}{\kappa_2}\varepsilon\right)^m,$$

where we have used Theorem 3.2 to bound the values of ω. Hence, in case of small ε (large transmission speed) or B (e.g., small α) or a large value of κ_2 (fast decay of K away from the origin), the finite series has increased accuracy. We assume that at least one of these conditions is satisfied so that a small number of terms suffices to determine the general behavior.

In order to observe the qualitative effects of finite transmission speed, we thus neglect third- and higher order terms in ε in the series (4.1). Then, for L given by

$$L(\lambda) = \eta\lambda^2 + \gamma\lambda + 1, \quad \eta = 0 \text{ or } 1,\ \gamma > 0,$$

(4.3)–(4.4) become

$$\alpha^{-1}(1 - \eta\omega^2) = \hat{K}(k) - \tfrac{1}{2}\varepsilon^2\omega^2\hat{K}_2(k), \tag{4.5}$$

$$\alpha^{-1}\gamma\omega = -\varepsilon\omega\hat{K}_1(k), \tag{4.6}$$

where we have substituted the more conventional notation $\hat{K}$ for the Fourier transform $\hat{K}_0$ of the kernel. For stationary bifurcations ($\omega = 0$), one obtains from the first equation that

$$\hat{K}(k) = 1/\alpha, \tag{4.7}$$

which is the same as the conditions (3.2)–(3.3) given by exact calculation. For a nonstationary bifurcation, $\omega \neq 0$, so (4.6) implies that

$$\hat{K}_1(k^*) = -\gamma/\varepsilon\alpha. \tag{4.8}$$

If $\hat{K}_1(k)$ assumes negative values, then it has a minimum since it is continuous and tends to zero as $k \to \pm\infty$; this minimum value corresponds to the first mode that loses stability as ε or α is increased. More precisely, if

$$k^* = \min_k \hat{K}_1(k) = \min_k \int_{-\infty}^{\infty} |z| K(z) \exp(-ikz)\, dz \tag{4.9}$$

exists and $\hat{K}_1(k^*) < 0$, then k^* is the sought solution of (4.8). Substituting k^* into (4.5) gives

$$\omega^2 = \frac{\alpha\hat{K}(k^*) - 1}{\frac{1}{2}\alpha\varepsilon^2\hat{K}_2(k^*) - \eta}, \tag{4.10}$$

which has a solution for ω whenever the right-hand side is nonnegative. This gives a simple procedure to calculate the pairs (ω, k) satisfying the dispersion relation and corresponding to the bifurcating solution $\exp(\omega t + kx)$.

It remains to determine what type of bifurcation actually occurs. This depends on the mode by which the equilibrium solution, which is stable for $\alpha = 0$, loses its stability as the bifurcation parameter α is increased. The procedure described in the above paragraph gives a simple graphical method. Thus if one plots the curves $\hat{K}(k)$ and $-\hat{K}_1(k)/\gamma v$ in the same graph and thinks of $1/\alpha$ as a horizontal line being lowered from $+\infty$, then the first intersection point specifies the bifurcation type. If the horizontal line touches the graph of $\hat{K}(k)$ first, then (4.7) is satisfied and a stationary bifurcation occurs. If, on the other hand, it touches $-\hat{K}_1(k)/\gamma v$ first, then (4.8) is satisfied and a nonstationary bifurcation occurs. Furthermore, the value of k at the intersection point being zero or nonzero specifies whether the bifurcating solution is spatially constant or not, respectively. It is worthwhile to note that the types of bifurcations that can occur depends only the extremal values of $\hat{K}$ and $\hat{K}_1$ and not on the exact shapes of their graphs. This observation has two important consequences. First, the bifurcation structure depends on some general qualities of the kernel and not on its precise shape. And second, although our analysis is based on an approximation scheme, the qualitative conclusions regarding the type of bifurcations are generally robust, except for some degenerate cases, such as when the maximum values of $\hat{K}(k)$ and $-\hat{K}_1(k)/\gamma v$ are equal.

An example for the investigation of possible bifurcations is illustrated in Figure 1 for some typical kernel functions representing the possibilities for different types of inhibitory and excitatory interaction within the field. For each kernel type in the first column of the figure, the corresponding graphs of $\hat{K}(k)$ and $-\hat{K}_1(k)/\gamma v$ are plotted in the second column. By the argument outlined above, the possible bifurcations for each type of kernel can be directly read off from the graphs in the second column. The actual graphs in the figure are calculated from Gaussian distributions; however, it is clear that small variations in the graphs do not change the bifurcation types. In this way, it is possible to draw some general conclusions concerning different interaction kernels.

The analysis presented in this section is useful for understanding the relationship between the interactions within the field and the resulting dynamics. The stationary bifurcations of equilibria are determined by the Fourier transform $\hat{K}$ of the connectivity kernel. The nonstationary bifurcations, on the other hand, are characterized by the transforms of the moments of the kernel. For first- and second-order systems this characterization can be reduced to the consideration of the single term $\hat{K}_1/\gamma v$, over the parameter ranges where the approximation scheme is justified. Outside of this range, e.g., for very low transmission speeds, more terms need to be considered in the series (4.1), together with a numerical solution of the system (4.3)–(4.4). Nevertheless, already in the term $\hat{K}_1/\gamma v$ one can see the ingredients responsible for nonstationary bifurcations: the operator L (through γ) representing the local temporal behavior, the kernel (through $\hat{K}_1$) representing spatial interaction, and the transmission speed v connecting the two aspects of the dynamics. Figure 1 gives a summary of the bifurcations resulting from the interplay of these elements. In the next section we

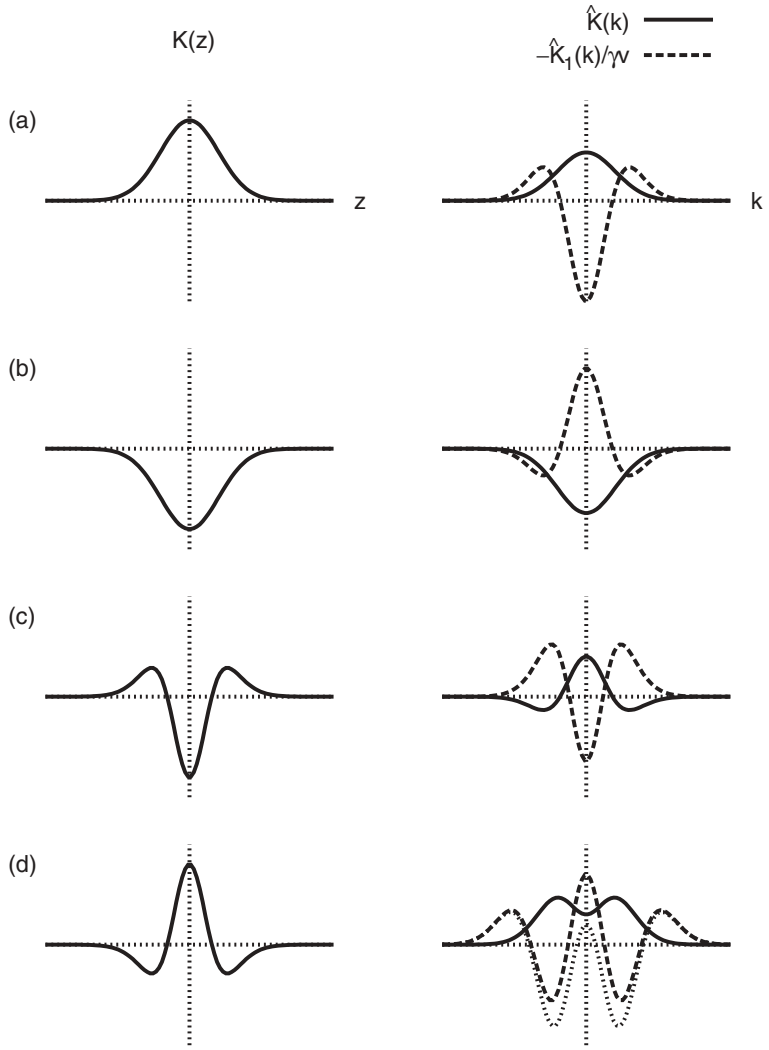

FIG. 1. *Typical interaction kernels and possible bifurcation types. The first column shows the kernels, with the corresponding Fourier transforms in the second column. The maxima of* $\hat{K}$ *and* $-\hat{K}_1/\gamma v$*, respectively, determine the stationary and oscillatory bifurcations, the largest peak giving the actual bifurcation taking place as* α *is increased. Hence, depending on the value of* γv*, some typical cases are* (a) *an excitatory field, possible bifurcations* Ia *and* IIb*;* (b) *an inhibitory field, possible bifurcation* IIa*;* (c) *local inhibition and lateral excitation, possible bifurcations* Ia *and* IIb*;* (d) *local excitation and lateral inhibition, possible bifurcations* Ib *and* IIa *or* IIb*. In the last subfigure, two distinct possibilities for* $-\hat{K}_1/\gamma v$ *are shown with dashed and dotted lines.*

present numerical simulations for the corresponding dynamical behavior in the nonlinear system (1.1), obtained on the basis of the foregoing analysis.

5. Applications. We now examine the previous results numerically for a particular model. To this end, we set the differential operator to

$$L\left(\frac{\partial}{\partial t}\right) = \frac{\partial^2}{\partial t^2} + \gamma\frac{\partial}{\partial t} + 1 \tag{5.1}$$

and further specify the connectivity kernel. Since a neuronal field might exhibit excitatory and inhibitory connections, the kernel K contains both excitatory and inhibitory distributions over space. In case of a homogeneous and isotropic neuronal field, a choice of K is

$$K(z) = \frac{1}{\sqrt{\pi}}(a_{\mathrm{e}} e^{-z^2} - a_{\mathrm{i}} r e^{-r^2 z^2}), \tag{5.2}$$

where $a_{\mathrm{e}}, a_{\mathrm{i}}$ denote excitatory and inhibitory synaptic weights and $r = \sigma_{\mathrm{e}}/\sigma_{\mathrm{i}}$ gives the relation of excitatory and inhibitory spatial connectivity ranges σ_{e} and σ_{i}. Since the present work treats dynamics on a mesoscopic spatial scale, it does not resolve single synapses and synaptic interaction is considered in terms of normalized distributions of excitatory and inhibitory connections as in (5.2). Thus a purely excitatory connection (Figure 1(a)) is obtained when $a_{\mathrm{i}} = 0$ and $a_{\mathrm{e}} > 0$, whereas the choice $a_{\mathrm{e}} = 0$ and $a_{\mathrm{i}} > 0$ gives an inhibitory connection (Figure 1(b)). Similarly, for $a_{\mathrm{e}} > a_{\mathrm{i}} > 0$, local inhibition and lateral excitation (Figure 1(c)) or local excitation and lateral inhibition (Figure 1(d)) can be obtained by choosing $r > a_{\mathrm{e}}/a_{\mathrm{i}}$ or $0 < r < 1$, respectively. We shall mostly focus on these last two cases. Finally, we take $\beta = 1$ and choose the transfer function in (1.1) as the sigmoid $S(y) = 1/(1 + \exp(-1.8(y - 3)))$ according to previous works [46, 36].

The subsequent temporal integration procedure applies a fourth-order Runge–Kutta algorithm, while the spatial integration algorithm discretizes the field into N intervals and applies

$$\int_0^l f(z)dz \approx \sum_{i=1}^{N} \frac{1}{2}(f(z_i) + f(z_{i+1}))\Delta x \tag{5.3}$$

for any function f, with l the field length and $\Delta x = l/N$. Further, for periodic boundary conditions, the integration obeys the circular rule

$$\int_{-\infty}^{\infty} K(|x - y|)f(y)dy \approx \int_0^l K(l/2 - |l/2 - |x - y||)f(y)dy. \tag{5.4}$$

5.1. Stability of V^*. The equilibria V^* are found from (2.4). Figure 2 shows solutions V^* of (2.4) with respect to the external input for various values of κ. In the case where $\kappa > 2.2$, there exist up to three solutions A, B, and C subject to the external input, whereas there is only a single solution for $\kappa \leq 2.2$. Theorem 2.1 gives a sufficient condition for the stability of these equilibria. Note that for $\gamma > \sqrt{2}$ the inequality (2.10) is automatically satisfied, so $c < 1$ is a sufficient condition for asymptotic stability by the theorem. From (5.2) we have

$$c = \alpha|2a_{\mathrm{e}}\Phi(x_0) - 2a_{\mathrm{i}}\Phi(x_0 r) - (a_{\mathrm{e}} - a_{\mathrm{i}})|, \quad x_0 = \sqrt{\frac{1}{1 - r^2}\ln\left(\frac{a_{\mathrm{e}}}{a_{\mathrm{i}} r}\right)}, \tag{5.5}$$

where Φ is the Gaussian error function and $0 < r < 1$ or $r > a_{\mathrm{e}}/a_{\mathrm{i}}$. The spatial distance x_0 marks the change of sign of the kernel function and thus separates inhibitory from excitatory connections. The external input E^* affects c through $\alpha = S'(V^*)$. In Figure 3, c is plotted with respect to the input E^* for $r = 0.5$ and various parameter values of $a_{\mathrm{e}}, a_{\mathrm{i}}$ at the different equilibria V^*. Stability is guaranteed by Theorem 2.1 at least in the region $c < 1$. In this line, Figure 4 shows a space-time plot of field

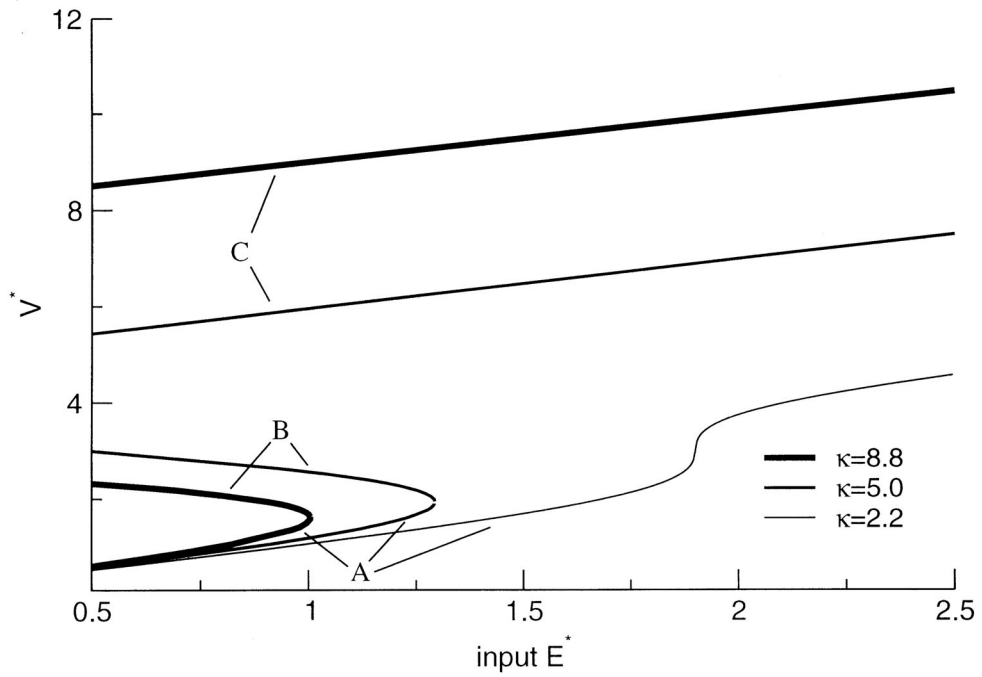

FIG. 2. *Stationary constant fields V^* plotted with respect to the external input E^* for various parameters κ. Up to three solutions A, B, and C may exist for a given input level.*

activity that relaxes to a lower solution A for $c = 0.85$ (cf. Figure 2). On the other hand, at sufficiently high values of α (and thus of c), stability is lost since when

$$\alpha = \frac{1}{\kappa}, \tag{5.6}$$

the condition (3.2) for a type Ia bifurcation, is satisfied. This bifurcation point is also indicated in Figure 3. Therefore, the constant solutions denoted B in Figures 2–3 are unstable. Interestingly, this general result shows accordance to findings in previous works for special connectivity kernels [36, 23]. Finally, in the region $c > 1$ and $\alpha < 1/\kappa$, additional bifurcations might occur, yielding loss of stability. These are discussed in the following section.

5.2. Bifurcations. Recall that the external input defines the set of constant fields V^*, which subsequently determine the value of α; hence α is an appropriate bifurcation parameter. For bifurcations to periodic patterns (Turing case Ib), the threshold condition from (3.3) reads

$$\alpha_{\text{thr}} = \frac{1}{a_{\text{e}} e^{-k_0^2/4} - a_{\text{i}} e^{-k_0^2/4r^2}}, \qquad k_0^2 = \frac{4r^2}{r^2 - 1} \ln \frac{a_{\text{e}} r^2}{a_{\text{i}}}, \tag{5.7}$$

where $k_0 = \arg\max_k \hat{K}(k)$. As $\alpha > 0$, we obtain directly from (5.7) that $r < 1$, i.e., there is no Turing instability for $r > 1$. Figure 5 displays thresholds α_{thr} with respect to parameters r, confirming this finding. Figure 6 displays a space-time plot of the corresponding Turing instability with $r = 0.5$.

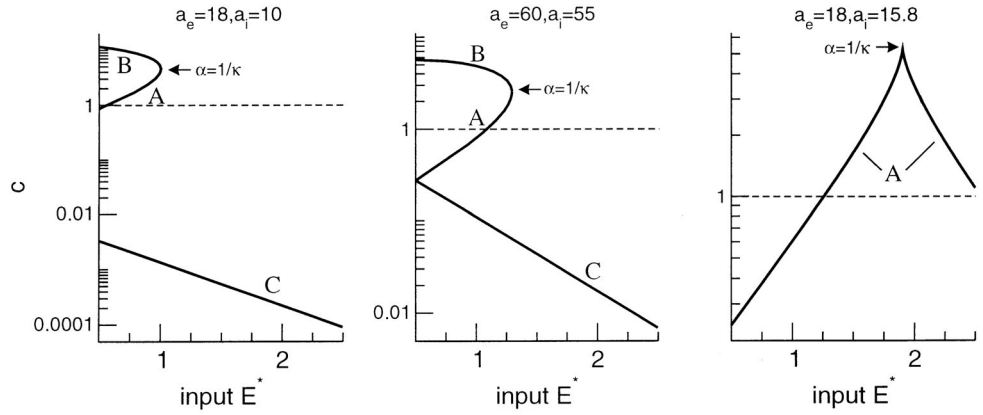

FIG. 3. *Parameter c from Theorem* 2.1 *plotted with respect to the external input* E^* *for various parameters* $a_\mathrm{e}, a_\mathrm{i}$ *and* $r = 0.5,\ \gamma > \sqrt{2}$. *The characters* $A, B,$ *and* C *denote stationary solutions (see Figure* 2*) and solutions in the region below the dashed line fulfill the sufficient condition of asymptotic stability. It turns out that stationary solutions* C *are asymptotically stable for all external inputs in case of* $a_\mathrm{e} = 18,\ a_\mathrm{i} = 10$ *and* $a_\mathrm{e} = 60,\ a_\mathrm{i} = 55$.

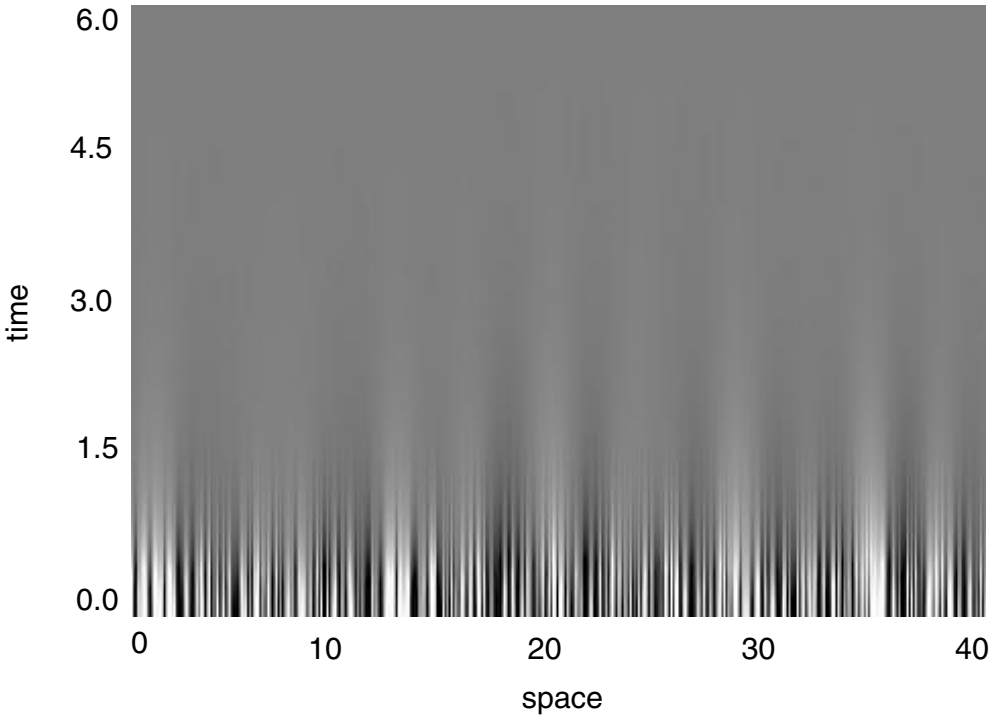

FIG. 4. *Space-time plot of an asymptotically stable field for the Gaussian connectivity kernel and parameters* $E^* = 0.5$, $r = 0.5$, $\gamma = 2$, $a_\mathrm{e} = 60$, $a_\mathrm{i} = 55$, $v = 100$, $\beta = 1$, $N = 400$. *Initial values* $V^0(x,t)$ *are chosen randomly from a uniform distribution on* $[V^* - 0.1, V^* + 0.1]$ *for* $t \in [-l/v, 0]$, *where* $l = 40$. *The gray scale encodes the deviations from the stationary solution.*

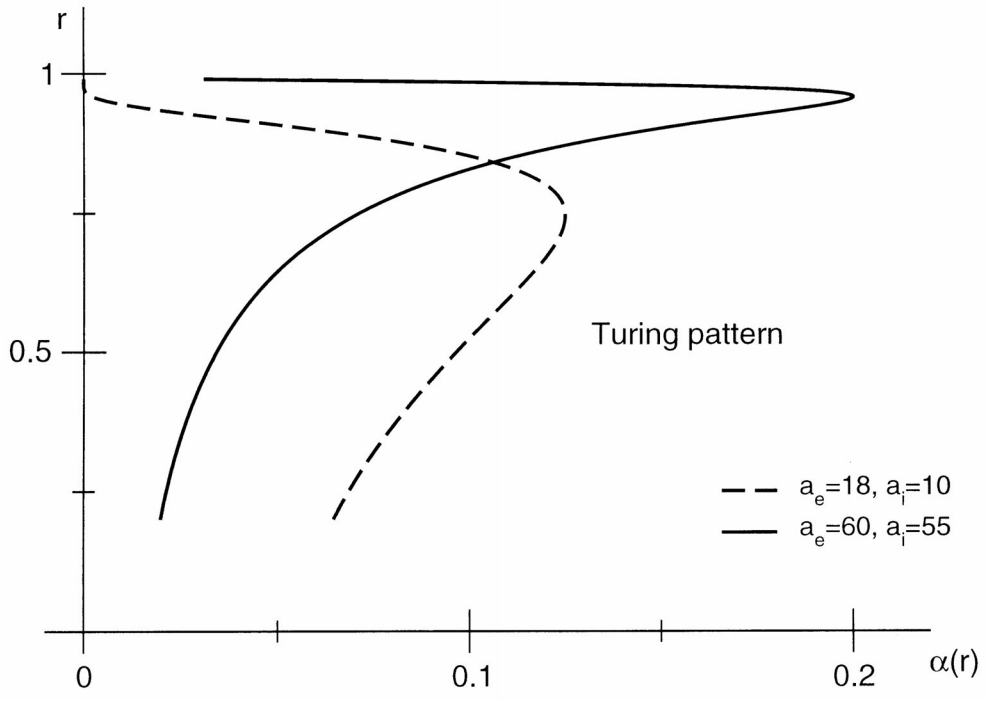

FIG. 5. *Thresholds of stationary Turing bifurcations* α_{thr} *plotted for two parameter sets* $a_{\mathrm{e}}, a_{\mathrm{i}}$. *The regime of the Turing instability obeys* $\alpha > \alpha_{\mathrm{thr}}$, *i.e., the right-hand side of each curve. The thresholds* α_{thr} *are independent from the synaptic parameter* γ *and the propagation speed* v, *while the external input* E^* *determines* α *implicitly.*

Next, we consider oscillatory phenomena. From Theorem 3.1, a necessary condition for oscillatory behavior is

$$v < v_{\mathrm{thr}} = \frac{\alpha}{|\gamma|\sqrt{\pi}} \left[\frac{a_{\mathrm{i}}}{r} - a_{\mathrm{e}} + 2 \left(a_{\mathrm{e}} e^{-x_0^2} - \frac{a_{\mathrm{i}}}{r} e^{-r^2 x_0^2} \right) \right], \tag{5.8}$$

with x_0 taken from (5.5). Figure 7 shows plots of thresholds v_{thr} with respect to the parameter r for two parameter couples of $a_{\mathrm{e}}, a_{\mathrm{i}}$. It turns out that condition (5.8) is fulfilled and oscillations are expected for a wide range of $r > 1$, whereas $r < 1$ (lateral inhibition) allows only for a small parameter regime. For appropriate parameters, the properties of the kernel and the temporal delays introduced by finite propagation speed interact in a way that destabilizes the stationary state and produces oscillations. Similar effects have also been found in previous works [6, 22].

Section 4 gives conditions for an oscillatory bifurcation in case of large propagation velocity. To obtain oscillating activity constant in space (case IIa), Figure 1(d) illustrates the conditions $r < 1$ and $-\hat{K}_1(0)/(\gamma v) > \max_k \hat{K}(k)$, implying

$$\frac{a_{\mathrm{e}} - a_{\mathrm{i}}/r}{\gamma v \sqrt{\pi}} > a_{\mathrm{e}} e^{-k_0^2/4} - a_{\mathrm{i}} e^{-k_0^2/4r^2}, \tag{5.9}$$

where k_0 is taken from (5.7). Figure 8 displays the corresponding spatiotemporal activity for appropriate parameters. From the figure, an oscillation frequency of about $\omega = 0.28$ can be observed. This agrees well with the theory, as from (3.10)

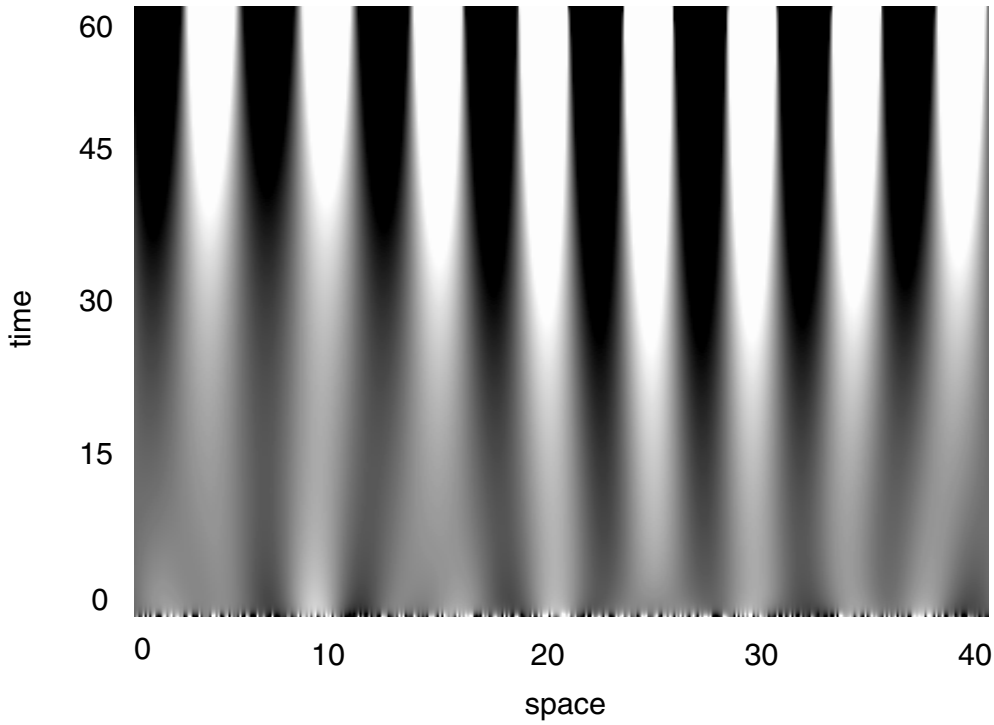

FIG. 6. *Space-time plot of the Turing instability, obtained for the Gaussian connectivity kernel and parameters* $E^* = 0.74$, $r = 0.5$, $\gamma = 2$, $a_e = 60$, $a_i = 55$, $v = 100$, $\beta = 1$, $N = 400$, *and* $1/\alpha = 0.727$. *Initial conditions* $V^0(x,t)$ *are chosen randomly from a uniform distribution on* $[V^* - 0.1, V^* + 0.1]$ *for* $t \in [-l/v, 0]$, *where* $l = 40$.

with $c \geq 1$ a frequency in the interval $[0, 0.26]$ is predicted at the bifurcation. The small discrepancy arises from choosing the simulation parameters somewhat beyond the bifurcation values in order to obtain reasonably high amplitude solutions for visualization.

On the other hand, for traveling waves (case IIb) $k \neq 0$ and Figure 1(c) gives the conditions $r > a_e/a_i$ and $\max_k -\hat{K}_1(k)/(\gamma v) > \hat{K}(0)$. A series expansion for $\hat{K}_1$ [20] yields a single implicit condition for parameters a_e, a_i, r and k. Figure 9 shows the corresponding space-time plot of the wave instability for appropriate parameters. Here $r > 1$, and the field activity is shifted from local to lateral spatial locations, facilitating traveling waves.

Finally we examine how the phase velocity of traveling waves depends on the propagation velocity v in the system. From (4.10) the phase velocity reads

$$v_{\mathrm{ph}} = \frac{\omega}{k^*} = \frac{v}{k^*}\sqrt{\frac{\alpha\hat{K}(k^*) - 1}{\frac{1}{2}\alpha\hat{K}_2(k^*) - v^2}}, \tag{5.10}$$

where k^* solves (4.8). In Figure 10, v_{ph} is plotted and exhibits a slightly nonlinear dependence on the propagation velocity for the applied parameters. We point to the small ratio of phase velocity to propagation velocity in accordance with previous findings [32, 23].

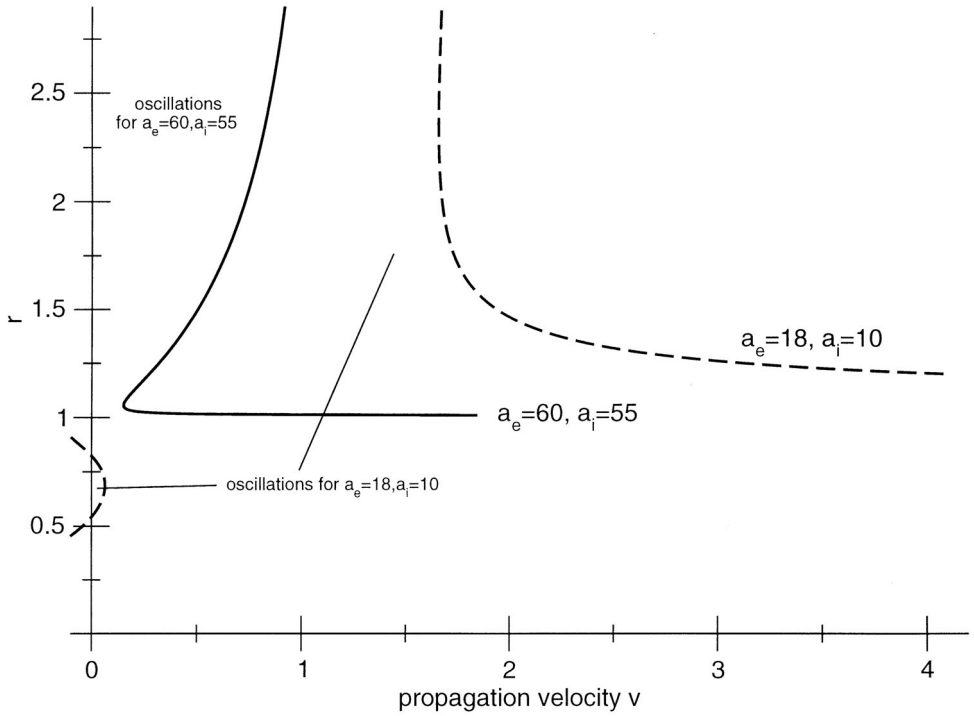

FIG. 7. *Thresholds of oscillatory phenomena v_{thr} for two parameter sets $a_{\mathrm{e}}, a_{\mathrm{i}}$. The sufficient condition for oscillations is fulfilled for $v < v_{\mathrm{thr}}$, i.e., the left-hand side of each curve.*

6. Conclusion. We have presented an analysis of the stability of equilibrium solutions for a general class of neural field equations on the real line. The details of bifurcations arising from loss of stability provide important information concerning a variety of dynamical behavior that is of neuroscientific interest, including spatial patterns and traveling waves. The stationary bifurcations and the resulting spatial patterns depend only on the connectivity kernel, and are completely determined by its Fourier transform $\hat{K}(k)$. On the other hand, the axonal delays due to finite propagation speed are shown to have significant effects on the nonstationary bifurcations. In fact, we have proved that in first- and second-order systems, nonstationary bifurcations of equilibria can occur only if the delays are sufficiently large, that is, when the transmission speed is sufficiently small. This behavior is different from that of higher order systems, where nonstationary bifurcations can occur even in the absence of delays. By a perturbation approach we have expressed the conditions for bifurcation in terms of the Fourier transforms of the moments of the kernel function. For high signal transmission speeds, only the first kernel moment needs to be considered to draw qualitative conclusions. For first- and second-order systems this leads to a simple method for determining the possible bifurcation types by comparing the Fourier transforms $\hat{K}(k)$ and $-\hat{K}_1(k)/v\gamma$. Furthermore, the bifurcations depend only on the extremal values of the transforms, rather than the precise shapes of the kernels.

The analysis presented here, being applicable to a broad range of connectivity and synaptic properties and transfer functions, suggests some general conclusions on the types of nonlinear dynamics that can be observed in a fairly wide class of systems.

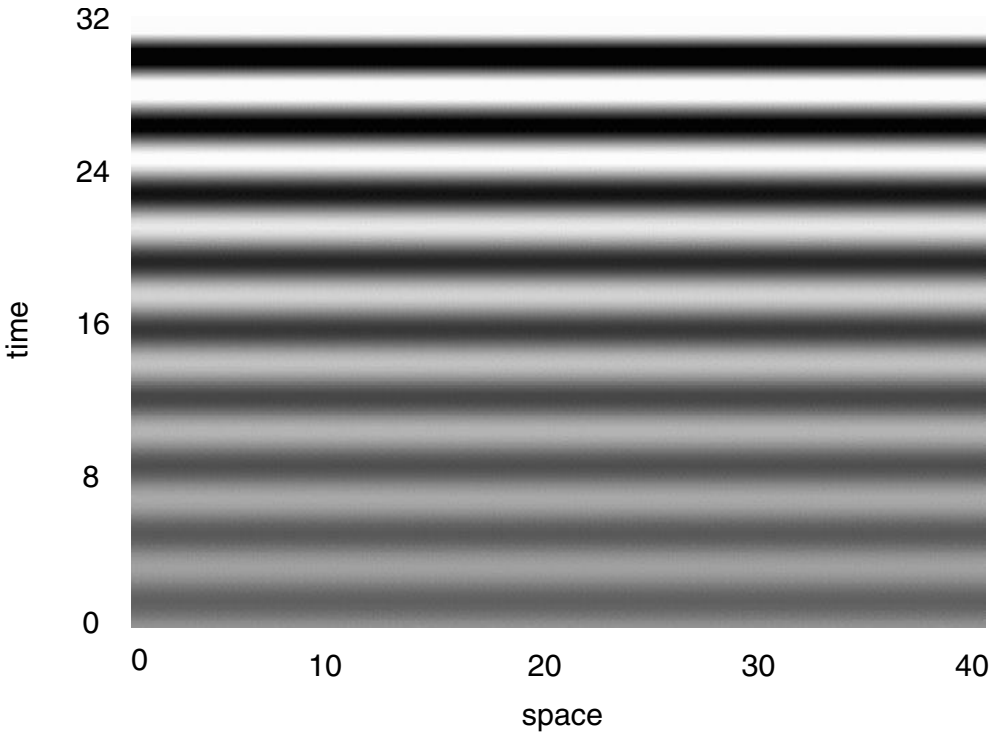

FIG. 8. *Space-time plot of the Hopf instability leading to periodic oscillations of a spatially constant solution (type* IIa *bifurcation), obtained for the Gaussian connectivity kernel and parameters* $E^* = 0.91$, $r = 0.2$, $\gamma = 0.5$, $a_\mathrm{e} = 18$, $a_\mathrm{i} = 10$, $v = 6$, $\beta = 1$, $N = 400$. *Initial conditions are* $V^0(x,t) = V^* + 0.02$ *for* $t \in [-l/v, 0]$, *with* $V^* = 0.11$ *and* $l = 40$.

For instance, one generally expects to see oscillatory behavior whenever the signal transmission speed is sufficiently small. In fact, for completely general kernels, the peaks of $\hat{K}(k)$ and $-\hat{K}_1(k)$ are more likely to occur at some nonzero k rather than at the precise value $k = 0$. This suggests that in first- and second-order systems the prevalent dynamics arising from bifurcations of equilibria will be either spatial patterns or traveling waves, depending on whether the transmission speed is large or small, respectively. Nevertheless, more specific kernel types may dictate different dynamical behavior depending on the application.

There are many studies of discrete networks which exhibit in-phase periodic behavior by increased constant delay (e.g., [49, 6]) and propagation delay (e.g., [17, 26, 22]). These studies consider specific network connectivities and obtain similar results with respect to the role of delays in oscillatory behavior. In this context, we would like to mention the recent work of Earl and Strogatz [9], who studied the stability of discrete, homogeneous oscillator networks with constant connection delays. They obtain a rather strong stability condition for global in-phase oscillations that is independent of the connectivity topology, provided each node has the same number of connections. The in-phase oscillations correspond to type IIa bifurcations in our study; however, we also have the possibility of other bifurcation types, indicating that the neural fields considered here can exhibit a richer range of dynamics. An important difference arises from the nature of the delays in the two models. In the discrete network with a constant connection delay, each unit knows the state of its neighbors

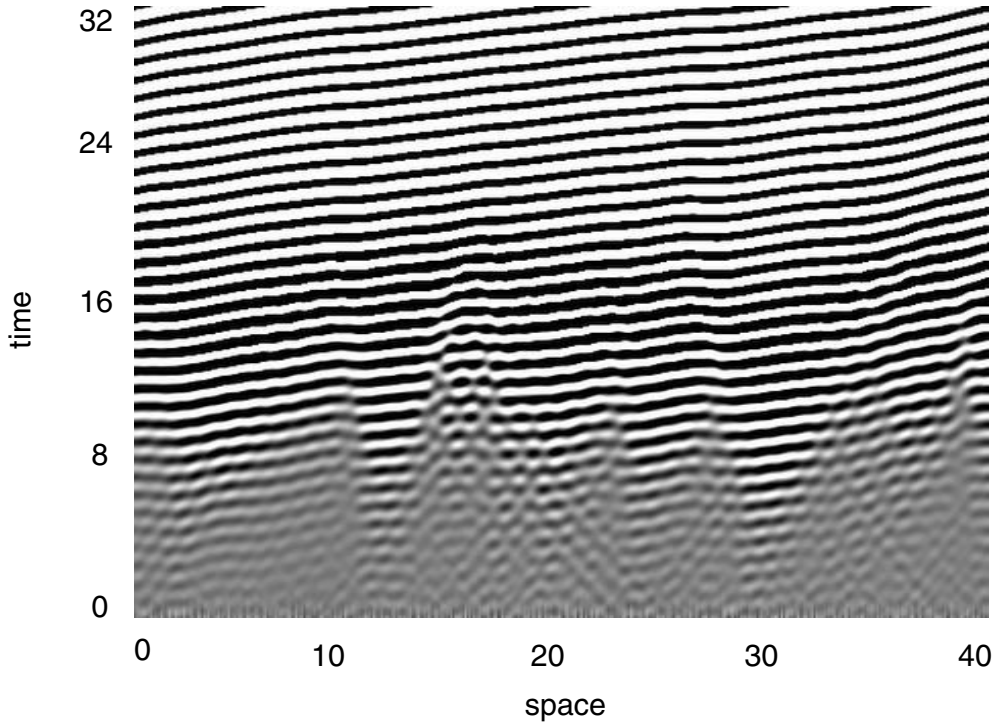

FIG. 9. *Space-time plot of the wave instability (type* IIb *bifurcation), obtained for the Gaussian connectivity kernel and parameters* $E^* = 1.29$, $r = 3$, $\gamma = 2$, $a_e = 60$, $a_i = 55$, $v = 1$, $\beta = 1$, $N = 400$. *Initial conditions* $V^0(x,t)$ *are chosen randomly from a uniform distribution on* $[V^* - 0.1, V^* + 0.1]$ *for* $t \in [-l/v, 0]$, *where* $l = 40$.

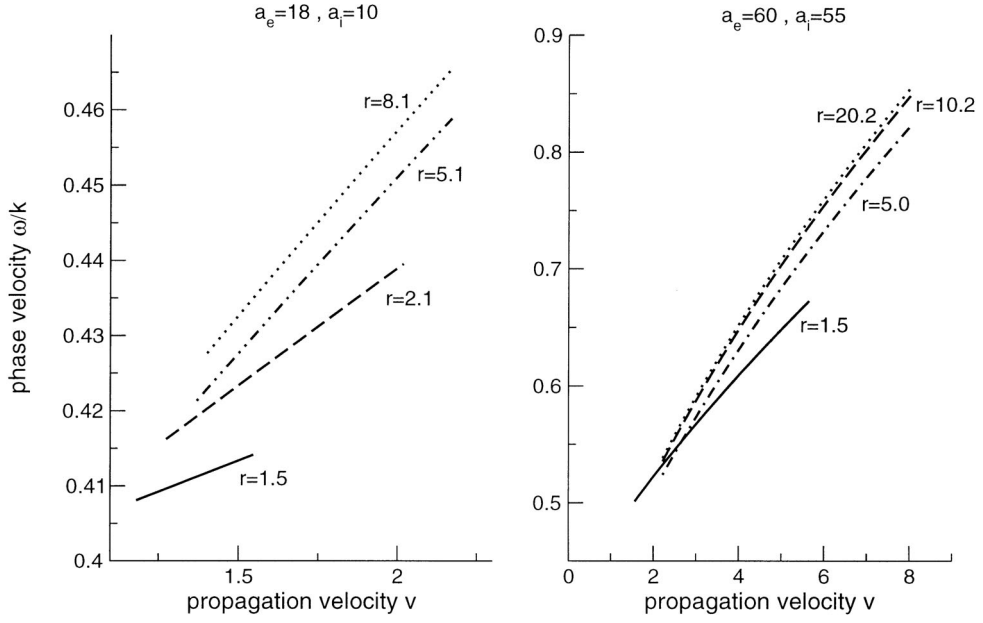

FIG. 10. *The wave velocity of traveling waves with respect to axonal propagation velocity. Parameters are* $\gamma = 0.2$, $0.03 \le \alpha \le 0.11$ *and* $\omega/v \approx 0.7$ *(left, for* $v \approx 2$*) and* $\omega/v \approx 0.3$ *(right, for* $v \approx 7$*), respectively.*

at the same time instant (although not at the present time), so it is plausible that this type of arrangement favors in-phase oscillations. On the other hand, our model involves distance-dependent delays, for which travelling waves may be the more natural type of oscillatory behavior. The details of this interesting connection will be given in a future paper.

Our work is mostly motivated by experimental findings (e.g., [29, 44, 16]). In this line, the presented study aims to generalize the analysis of synaptically coupled neuronal fields in order to gain a classification scheme for observed spatiotemporal patterns. Here, we would like to mention the important generalization of Amari [1] in lateral-inhibition-type fields without axonal delay. Since neurophysiological properties of observed neural tissue are not accessible precisely, a classification scheme might link model functionals with observed phenomena. For example, observed traveling waves necessitate an axonal propagation velocity below a certain threshold defined by connectivity kernel properties and synaptic response properties (Theorem 3.1), and furthermore, their frequencies are confined to a bounded band (Theorem 3.2). In addition, this classification might be important for estimating interaction parameters from multisite neuronal data (e.g., [14]). Due to the large number of different activity phenomena, further studies in this area could incorporate additional mechanisms like standing and traveling pulse fronts as in [32, 33], boundary effects in local neuronal areas (e.g., [7]), the influence of external inputs [45, 10] local in space and time, or the constant delayed feedback found experimentally in thalamocortical connections [41] and visual areas [27, 11] and which has been addressed in several theoretical studies (e.g., [13, 5, 3]). In particular, the mutual treatment of both constant delayed feedback and propagation delay proposes new insights into information processing between distant brain areas. Moreover, consideration of neural fields in higher space dimensions might yield further interesting results.

RESOLVENT ESTIMATES FOR PLANE COUETTE FLOW*

PABLO BRAZ E SILVA†

Abstract. We discuss the problem of deriving estimates for the resolvent of the linear operator associated with three-dimensional perturbations of plane Couette flow and determining its dependence on the Reynolds number R. Depending on the values of the parameters involved, we derive estimates analytically. For the remaining values of the parameters, we prove that deriving estimates for the resolvent can be reduced to estimating the solutions of a 4th-order linear homogeneous ordinary differential equation with nonhomogeneous boundary conditions. We study these boundary value problems numerically. Our results indicate the L_2 norm of the resolvent to be proportional to R^2.

1. Introduction.

It is well known that plane Couette flow is stable for infinitesimal perturbations for all values of the Reynolds number R [12]. In laboratory experiments, though, transition to turbulence is observed for Reynolds numbers as low as approximately 350 [4, 16]. This discrepancy may be caused by a small domain of attraction of the Couette flow. Therefore, it is of great interest to understand how this domain of attraction scales with the Reynolds number R.

The so-called resolvent technique for nonlinear differential equations allows one to derive nonlinear stability results from linear stability. To this end, one uses estimates for the resolvent of a linear operator. One of its advantages is the quantification of stability; that is, when successfully applied, the method gives information about the domain of attraction of a stable solution [7, 8].

For plane Couette flow, recent works use the resolvent technique to derive a threshold amplitude for perturbations of the base flow, that is, to give a lower bound on the size of perturbations that can lead to turbulence [9, 6, 2]. In this case, successful application of the method requires estimates for the resolvent $(s\mathcal{I} - \mathcal{L}_R)^{-1}$ of the linear operator $\mathcal{L}_R$ associated with perturbations of the base flow, for the parameter s belonging to the unstable half-plane $\mathrm{Re}(s) \geq 0$. These estimates should show exactly how the norm of the resolvent depends on R. Our aim is to study this dependence.

For large enough values of $|s|$, depending on the Reynolds number, analytical estimates for the L_2 norm of the resolvent have already been proved [1, 10]. To derive an estimate valid for the whole unstable half-plane, direct numerical computations have been used indicating the L_2 norm of the resolvent to be proportional to R^2 [6, 17]. In [10], R-dependent weighted norms are used. Direct numerical computations indicate that in one of the norms considered, the resolvent is proportional to R.

We study the three-dimensional case, with periodic boundary conditions in two of the directions. Our results indicate the L_2 norm of the resolvent to be proportional to R^2, agreeing with the computations in [6, 17]. Our main result is a theorem showing

†Departamento de Matemática, Universidade Federal de Pernambuco, CEP 50740-540, Recife, PE, Brazil (pablo@dmat.ufpe.br).

that the problem of proving the resolvent estimates can be reduced to estimating the solutions of a 4th-order homogeneous linear ordinary differential equation with nonhomogenous boundary conditions. Numerical computations, which are simple and reliable in this case, are used only to study the norms of the solutions of those boundary value problems. The analysis carried out here has other advantages. First of all, it clarifies the reasons for the R^2 growth of the L_2 norm of the resolvent, since it shows exactly where the extra factor of R comes into the game. It also gives some physical insight about the problem, showing that different components of perturbations of the base flow have different scales with respect to R. We also discuss the reasons for the better dependence of the resolvent on R when the weighted norm from [10] is used.

2. The problem. We first give some notations that will be used throughout this work.

In general, elements of $\mathbb{R}^3$ will be represented by boldface letters. The same letter may be used for one of the coordinates of the vector. For example, when convenient, we write $\mathbf{x} = (x, y, z) \in \mathbb{R}^3$. We denote by Ω the set

$$\Omega := [0, 2\pi] \times [0, 2\pi] \times [0, 1].$$

The Euclidean inner product in $\mathbb{R}^3$ is denoted by $\cdot$; that is, for $\mathbf{x} = (x_1, x_2, x_3)$, $\mathbf{y} = (y_1, y_2, y_3)$, we have

$$\mathbf{x} \cdot \mathbf{y} = \sum_{i=1}^{3} x_i y_i.$$

The L_2 inner product and norm over Ω are denoted, respectively, by

$$\langle \mathbf{u}_1, \mathbf{u}_2 \rangle = \int_\Omega \overline{\mathbf{u}}_1 \cdot \mathbf{u}_2 \, d\mathbf{x}, \quad \|\mathbf{u}\|^2 = \langle \mathbf{u}, \mathbf{u} \rangle.$$

In our choice of coordinates, the Couette flow is the vector field $\mathbf{U} = (0, z, 0)$, which is a steady solution of

$$\begin{aligned} &\mathbf{U}_t + (\mathbf{U} \cdot \nabla)\mathbf{U} + \nabla P = \frac{1}{R}\Delta \mathbf{U}, \\ &\nabla \cdot \mathbf{U} = 0, \\ &\mathbf{U}(x, y, 0, t) = (0, 0, 0), \\ &\mathbf{U}(x, y, 1, t) = (0, 1, 0), \\ &\mathbf{U}(x, y, z, t) = \mathbf{U}(x + 2\pi, y, z, t), \\ &\mathbf{U}(x, y, z, t) = \mathbf{U}(x, y + 2\pi, z, t) \end{aligned} \tag{2.1}$$

for P a constant. The positive parameter R is the Reynolds number. We consider $R \geq 1$, since this is the physically interesting case. We also note that there are no technical reasons for this assumption, only a slight simplification of the presentation. Problem (2.1) describes the flow of an incompressible fluid between the two parallel planes $z = 0$ and $z = 1$, the plane $z = 0$ at rest and the plane $z = 1$ moving in the y direction with constant velocity 1.

We want to analyze the resolvent of the linear operator associated with perturbations of the Couette flow $\mathbf{U}$. Therefore, we consider the initial boundary value

problem

$$
\begin{aligned}
&\mathbf{u}_t + (\mathbf{u}\cdot\nabla)\mathbf{U} + (\mathbf{U}\cdot\nabla)\mathbf{u} + \nabla p = \frac{1}{R}\Delta\mathbf{u} + \mathbf{F},\\
&\nabla\cdot\mathbf{u} = 0,\\
&\mathbf{u}(x,y,0,t) = \mathbf{u}(x,y,1,t) = (0,0,0),\\
&\mathbf{u}(x,y,z,t) = \mathbf{u}(x+2\pi,y,z,t),\\
&\mathbf{u}(x,y,z,t) = \mathbf{u}(x,y+2\pi,z,t),\\
&\mathbf{u}(x,y,z,0) = (0,0,0),
\end{aligned}
\tag{2.2}
$$

which is the linearization of the equations governing three-dimensional perturbations $\mathbf{u}(\mathbf{x},t) = (u(\mathbf{x},t), v(\mathbf{x},t), w(\mathbf{x},t))$ of $\mathbf{U}$. The forcing $\mathbf{F}(\mathbf{x},t) = (F(\mathbf{x},t), G(\mathbf{x},t), H(\mathbf{x},t))$ is a given C^∞ function, satisfying

$$
\int_0^\infty \|\mathbf{F}(\cdot,t)\|^2\,dt < \infty, \quad \nabla\cdot\mathbf{F} = 0. \tag{2.3}
$$

The pressure term $p(x,y,z,t)$ in (2.2) is determined up to a constant in terms of $\mathbf{u}$ by the linear elliptic problem

$$
\begin{aligned}
\Delta p = -\nabla\cdot((\mathbf{u}\cdot\nabla)\mathbf{U}) - \nabla\cdot((\mathbf{U}\cdot\nabla)\mathbf{u}) = -2w_y,\\
p_z(x,y,0,t) = \frac{1}{R}w_{zz}(x,y,0,t),\\
p_z(x,y,1,t) = \frac{1}{R}w_{zz}(x,y,1,t).
\end{aligned}
\tag{2.4}
$$

Moreover, if p is given by the problem above, the solution $\mathbf{u}$ of (2.2) remains divergence-free. Therefore, we drop the continuity equation and write (2.2) as the linear evolution equation

$$
\begin{aligned}
\mathbf{u}_t = \mathcal{L}_R\mathbf{u} + \mathbf{F},\\
\mathbf{u}(\mathbf{x},0) = (0,0,0),
\end{aligned}
\tag{2.5}
$$

where the linear operator $\mathcal{L}_R$ is defined by

$$
\mathcal{L}_R\mathbf{u} := \frac{1}{R}\Delta\mathbf{u} - (\mathbf{u}\cdot\nabla)\mathbf{U} - (\mathbf{U}\cdot\nabla)\mathbf{u} - \nabla p, \tag{2.6}
$$

with p given in terms of $\mathbf{u}$ by (2.4).

It was proven in [12] that all the eigenvalues of $\mathcal{L}_R$ have negative real part for all values of R and that the eigenvalue with the greatest real part is at least at a distance proportional to $\frac{1}{R}$ from the imaginary axis. Our aim is to estimate the L_2 norm of the resolvent $(s\mathcal{I}-\mathcal{L}_R)^{-1}$ of $\mathcal{L}_R$ on the unstable half-plane $\mathrm{Re}(s) \geq 0$, and to determine its dependence on R. Our results indicate the resolvent constant $\sup_{\mathrm{Re}(s)\geq 0}\|(s\mathcal{I}-\mathcal{L}_R)^{-1}\|$ to be proportional to R^2, which agrees with the direct numerical computations of [6, 17]. Our analysis clarifies the role played by each component of the function $\mathbf{u}$, and it allows us to determine the origin of the R^2 growth of the resolvent constant.

3. Estimates for the resolvent. For large $|s|$, estimates were already proved [1, 10]. We state Theorem 1 from [1].

THEOREM 3.1. *If* $\mathrm{Re}(s) \geq 0$, $|s| \geq 2\sqrt{2}(1+\sqrt{R})$, *then*

$$
\|(s\mathcal{I}-\mathcal{L}_R)^{-1}\|^2 \leq \frac{8}{|s|^2}(1+\sqrt{R})^2 \leq 1.
$$

Using these estimates and the maximum modulus theorem for holomorphic mappings in Banach spaces [3], one can prove (see [1]) that

$$\sup_{\mathrm{Re}(s)\geq 0} \|(s\mathcal{I}-\mathcal{L}_R)^{-1}\| = \sup_{\xi\in\mathbb{R}} \|(i\xi\mathcal{I}-\mathcal{L}_R)^{-1}\|. \tag{3.1}$$

Therefore, for our purposes, it is sufficient to consider $s = i\xi$ purely imaginary. Using this result one can easily prove (see [1]) the following corollary.

COROLLARY 3.2. *Let $s = i\xi$, $\xi \in \mathbb{R}$. If $|\xi| \geq 2(1+\sqrt{R})$, then*

$$\|(s\mathcal{I}-\mathcal{L}_R)^{-1}\|^2 \leq \frac{8}{|s|^2}(1+\sqrt{R})^2 \leq 1.$$

Hence, our aim is to estimate the resolvent $(s\mathcal{I}-\mathcal{L}_R)^{-1}$ for $s = i\xi$, $0 \leq |\xi| < 2(1+\sqrt{R})$. We write the problem (2.2) componentwise:

$$\begin{aligned} u_t + zu_y + p_x &= \frac{1}{R}\Delta u + F, \\ v_t + zv_y + w + p_y &= \frac{1}{R}\Delta v + G, \\ w_t + zw_y + p_z &= \frac{1}{R}\Delta w + H, \\ u_x + v_y + w_z &= 0, \\ u(\mathbf{x},0) = v(\mathbf{x},0) &= w(\mathbf{x},0) = 0, \end{aligned} \tag{3.2}$$

with u, v, w vanishing at $z = 0$, $z = 1$ and 2π periodic in both x and y directions. Taking the Laplace transform with respect to t of the equation in (2.5), we get the resolvent equation

$$s\widetilde{\mathbf{u}} = \mathcal{L}_R\widetilde{\mathbf{u}} + \widetilde{\mathbf{F}}. \tag{3.3}$$

Componentwise, the transformed problem is

$$\begin{aligned} s\widetilde{u} + z\widetilde{u}_y + \widetilde{p}_x &= \frac{1}{R}\Delta\widetilde{u} + \widetilde{F}, \\ s\widetilde{v} + z\widetilde{v}_y + \widetilde{w} + \widetilde{p}_y &= \frac{1}{R}\Delta\widetilde{v} + \widetilde{G}, \\ s\widetilde{w} + z\widetilde{w}_y + \widetilde{p}_z &= \frac{1}{R}\Delta\widetilde{w} + \widetilde{H}, \\ \widetilde{u}_x + \widetilde{v}_y + \widetilde{w}_z &= 0. \end{aligned} \tag{3.4}$$

Our aim is to get an estimate of the form

$$\|\widetilde{\mathbf{u}}(\cdot,s)\|^2 \leq CR^\gamma \|\widetilde{\mathbf{F}}(\cdot,s)\|^2 \tag{3.5}$$

for $\mathrm{Re}(s) \geq 0$, where C is an absolute constant. Since the most important part of the argument is to determine the exponent γ, we keep the notation simple by representing by C any absolute constant appearing in different parts of this work, possibly with different numerical values. We obtain $\gamma = 4$, which implies the norm of the resolvent to be proportional to R^2. Actually, our analysis shows that different components of the velocity have different dependence on R. We get

$$\begin{aligned} \|\widetilde{u}\|^2 &\leq CR^4\|\widetilde{\mathbf{F}}\|^2, \\ \|\widetilde{v}\|^2 &\leq CR^4\|\widetilde{\mathbf{F}}\|^2, \\ \|\widetilde{w}\|^2 &\leq CR^2\|\widetilde{\mathbf{F}}\|^2. \end{aligned} \tag{3.6}$$

The inequalities above provide some physical insight about the problem. For a given forcing, components of the perturbations which are parallel to the planes may grow as R^2, while the worst growth for the normal component is R.

To derive the estimates, we use the well-known equivalent formulation of the problem in terms of the normal velocity and the normal vorticity [13, 10]. The vorticity is defined by

$$\boldsymbol{\eta} = (\eta_1, \eta_2, \eta_3) := \mathbf{curl}\, \mathbf{u}. \tag{3.7}$$

The transformed normal component of the velocity $\widetilde{w}$ is the solution of

$$\begin{gathered} \left(s + z\frac{\partial}{\partial y}\right)\Delta\widetilde{w} = \frac{1}{R}\Delta^2\widetilde{w} + \Delta\widetilde{H}, \\ \widetilde{w}(x,y,0,s) = \widetilde{w}(x,y,1,s) = 0, \\ \widetilde{w}_z(x,y,0,s) = \widetilde{w}_z(x,y,1,s) = 0. \end{gathered} \tag{3.8}$$

The transformed normal component of the vorticity $\widetilde{\eta}_3$ satisfies

$$\begin{gathered} \left(s + z\frac{\partial}{\partial y}\right)\widetilde{\eta}_3 + \widetilde{w}_x = \frac{1}{R}\Delta\widetilde{\eta}_3 + \widetilde{G}_x - \widetilde{F}_y, \\ \widetilde{\eta}_3(x,y,0,s) = \widetilde{\eta}_3(x,y,1,s) = 0. \end{gathered} \tag{3.9}$$

Expand in a Fourier series in the x and y directions. We represent by k_1 and k_2 the respective parameters. Let $k^2 := k_1^2 + k_2^2$. The transformed functions $\widehat{w}$, $\widehat{\eta}_3$ are the solutions of the system

$$\begin{gathered} \frac{1}{R}\widehat{w}'''' - \left(s + \frac{2k^2}{R} + ik_2z\right)\widehat{w}'' + \left(sk^2 + \frac{k^4}{R} + ik_2k^2z\right)\widehat{w} = k^2\widehat{H} - \widehat{H}'', \\ \widehat{w}(k_1,k_2,0,s) = \widehat{w}(k_1,k_2,1,s) = \widehat{w}'(k_1,k_2,0,s) = \widehat{w}'(k_1,k_2,1,s) = 0, \end{gathered} \tag{3.10}$$

and

$$\begin{gathered} \frac{1}{R}\widehat{\eta}_3'' - \left(s + \frac{k^2}{R} + ik_2z\right)\widehat{\eta}_3 = ik_1\widehat{w} + ik_2\widehat{F} - ik_1\widehat{G}, \\ \widehat{\eta}_3(k_1,k_2,0,s) = \widehat{\eta}_3(k_1,k_2,1,s) = 0. \end{gathered} \tag{3.11}$$

In the problems above, $'$ denotes the derivative with respect to z. The equations in (3.10) and (3.11) are, respectively, the classical Orr–Sommerfeld and Squire equations [13, 11, 14, 15]. The transformed normal velocity $\widehat{w}$, solution of (3.10), acts as a forcing term in the equation of the transformed normal vorticity (3.11). To simplify the notation, we define the differential operators T, T_0 by

$$\begin{gathered} T := \frac{1}{R}\mathcal{D}^2 - \left(s + \frac{k^2}{R} + ik_2z\right), \\ T_0 := \mathcal{D}^2 - k^2, \end{gathered} \tag{3.12}$$

where $\mathcal{D}$ denotes the derivative with respect to z. Then, the differential equation in (3.10) is written as

$$TT_0\widehat{w} = N := k^2\widehat{H} - \widehat{H}''. \tag{3.13}$$

The equation for the transformed normal vorticity is

$$T\widehat{\eta}_3 = ik_1\widehat{w} + ik_2\widehat{F} - ik_1\widehat{G}. \tag{3.14}$$

Lemma 3.3 follows directly from Parseval's identity.

LEMMA 3.3. *If*

$$\|\widehat{\mathbf{u}}(k_1,k_2,\cdot,s)\|^2 \le CR^\gamma \|\widehat{\mathbf{F}}(k_1,k_2,\cdot,s)\|^2 \tag{3.15}$$

for all $(k_1,k_2)\in\mathbb{Z}\times\mathbb{Z}$ *and for all* $s\in\mathbb{C}$, $\mathrm{Re}(s)\ge 0$, *then*

$$\|(s\mathcal{I}-\mathcal{L}_R)^{-1}\|^2 \le CR^\gamma, \quad \forall s\in\mathbb{C},\ \mathrm{Re}(s)\ge 0. \tag{3.16}$$

Therefore, we aim for an estimate of the form (3.15). We begin by estimating the normal velocity.

3.1. Estimates for the normal velocity. We separate the analysis into three cases: $k^2 \ge \frac{R}{\sqrt{2}}$, $k=0$, and $0<k^2<\frac{R}{\sqrt{2}}$.

Case $k^2 \ge \frac{R}{\sqrt{2}}$. The transformed normal velocity is the solution of problem (3.10). By Corollary 3.2, we need only to consider $s=i\xi$, $\xi\in\mathbb{R}$, $0\le|\xi|<2(1+\sqrt{R})$. Therefore, (3.10) reads as

$$\begin{aligned} &\frac{1}{R}\widehat{w}'''' - \left(i\xi + \frac{2k^2}{R} + ik_2z\right)\widehat{w}'' + \left(i\xi k^2 + \frac{k^4}{R} + ik_2k^2z\right)\widehat{w} = N,\\ &\widehat{w}(k_1,k_2,0,\xi) = \widehat{w}(k_1,k_2,1,\xi) = \widehat{w}'(k_1,k_2,0,\xi) = \widehat{w}'(k_1,k_2,1,\xi) = 0, \end{aligned} \tag{3.17}$$

where $N = k^2\widehat{H} - \widehat{H}''$. We prove the following theorem.

THEOREM 3.4. *If* $k^2 \ge \frac{R}{\sqrt{2}}$, *then*

$$\begin{aligned} &\|\widehat{w}''(k_1,k_2,\cdot,s)\|^2 + (k^2+k_1^2)\|\widehat{w}'(k_1,k_2,\cdot,s)\|^2 + k^4\|\widehat{w}(k_1,k_2,\cdot,s)\|^2\\ &\quad\le CR^2\|\widehat{H}(k_1,k_2,\cdot,s)\|^2. \end{aligned}$$

Proof. Taking the inner product of the differential equation in (3.17) with $\widehat{w}$ and integrating by parts, one obtains

$$\begin{aligned} &\frac{1}{R}\|\widehat{w}''\|^2 + \left(\frac{2k^2}{R} + i\xi\right)\|\widehat{w}'\|^2 + \left(i\xi k^2 + \frac{k^4}{R}\right)\|\widehat{w}\|^2\\ &\qquad + ik_2\langle\widehat{w},\widehat{w}'\rangle + ik_2\langle\widehat{w}', z\widehat{w}'\rangle + ik_2k^2\langle\widehat{w}, z\widehat{w}\rangle = \langle\widehat{w}, N\rangle. \end{aligned} \tag{3.18}$$

As can be easily checked through integration by parts, $\langle\widehat{w},\widehat{w}'\rangle$ is purely imaginary, and $\langle\widehat{w}, z\widehat{w}\rangle$, $\langle\widehat{w}', z\widehat{w}'\rangle$ are both real. Hence, taking the real part of (3.18) and using the triangle inequality, one gets

$$\frac{1}{R}\|\widehat{w}''\|^2 + \frac{2k^2}{R}\|\widehat{w}'\|^2 + \frac{k^4}{R}\|\widehat{w}\|^2 - |k_2|\,|\langle\widehat{w},\widehat{w}'\rangle| \le |\langle\widehat{w}, N\rangle|. \tag{3.19}$$

We note that (3.19) is valid for all values of the parameters.

If $k_2\neq 0$, use the inequality

$$|\langle\widehat{w},\widehat{w}'\rangle| \le \frac{R}{4|k_2|}\|\widehat{w}\|^2 + \frac{|k_2|}{R}\|\widehat{w}'\|^2$$

to get

$$\frac{1}{R}\|\widehat{w}''\|^2 + \left(\frac{2k^2}{R} - \frac{k_2^2}{R}\right)\|\widehat{w}'\|^2 + \left(\frac{k^4}{R} - \frac{R}{4}\right)\|\widehat{w}\|^2 \le |\langle \widehat{w}, N\rangle|. \tag{3.20}$$

Since $k^2 \ge \frac{R}{\sqrt{2}}$ implies $\frac{k^4}{R} - \frac{R}{4} \ge \frac{k^4}{2R}$, inequality (3.20) gives

$$\frac{1}{R}\|\widehat{w}''\|^2 + \frac{k^2 + k_1^2}{R}\|\widehat{w}'\|^2 + \frac{k^4}{2R}\|\widehat{w}\|^2 \le |\langle \widehat{w}, N\rangle|. \tag{3.21}$$

The desired estimates follow from this inequality. To derive them, we first note that the differential equation in (3.17) is linear. Therefore, if $\widehat{w}_1$, $\widehat{w}_2$ are the solutions of

$$\begin{aligned} TT_0\widehat{w}_1 &= k^2\widehat{H}, \\ TT_0\widehat{w}_2 &= -\widehat{H}'', \end{aligned}$$

both satisfying the same boundary conditions as $\widehat{w}$, then $\widehat{w} = \widehat{w}_1 + \widehat{w}_2$. We prove estimates for $\widehat{w}_1$ and $\widehat{w}_2$.

Using inequality (3.21) for $\widehat{w}_1$, and the Cauchy–Schwarz inequality, one gets

$$\frac{1}{R}\|\widehat{w}_1''\|^2 + \frac{k^2 + k_1^2}{R}\|\widehat{w}_1'\|^2 + \frac{k^4}{2R}\|\widehat{w}_1\|^2 \le k^2\|\widehat{w}_1\|\|\widehat{H}\|. \tag{3.22}$$

This inequality implies

$$\|\widehat{w}_1''\|^2 + (k^2 + k_1^2)\|\widehat{w}_1'\|^2 + k^4\|\widehat{w}_1\|^2 \le CR^2\|\widehat{H}\|^2. \tag{3.23}$$

For $\widehat{w}_2$, first note that

$$\langle \widehat{w}_2, \widehat{H}''\rangle = \langle \widehat{w}_2'', \widehat{H}\rangle, \tag{3.24}$$

since the boundary conditions satisfied by $\widehat{w}_2$ imply that the boundary terms after integration by parts vanish. Therefore, using (3.21), and the Cauchy–Schwarz inequality, we get

$$\frac{1}{R}\|\widehat{w}_2''\|^2 + \frac{k^2 + k_1^2}{R}\|\widehat{w}_2'\|^2 + \frac{k^4}{2R}\|\widehat{w}_2\|^2 \le \|\widehat{w}_2''\|\|\widehat{H}\|. \tag{3.25}$$

This inequality implies

$$\|\widehat{w}_2''\|^2 + (k^2 + k_1^2)\|\widehat{w}_2'\|^2 + k^4\|\widehat{w}_2\|^2 \le CR^2\|\widehat{H}\|^2. \tag{3.26}$$

Since $\widehat{w} = \widehat{w}_1 + \widehat{w}_2$, inequalities (3.23) and (3.26) imply

$$\|\widehat{w}''\|^2 + (k^2 + k_1^2)\|\widehat{w}'\|^2 + k^4\|\widehat{w}\|^2 \le CR^2\|\widehat{H}\|^2. \tag{3.27}$$

If $k_2 = 0$, then $k_1 \ne 0$ and inequality (3.19) is

$$\frac{1}{R}\|\widehat{w}''\|^2 + \frac{2k_1^2}{R}\|\widehat{w}'\|^2 + \frac{k_1^4}{R}\|\widehat{w}\|^2 \le |\langle \widehat{w}, N\rangle|.$$

From this inequality, estimates follow by the same argument as above, with no restriction on k_1. □

Case $k = 0$. In this case, we prove the following.

THEOREM 3.5. *If $k = 0$, we have*

$$\|\widehat{w}''(0,0,\cdot,s)\|^2 + \|\widehat{w}'(0,0,\cdot,s)\|^2 + \|\widehat{w}(0,0,\cdot,s)\|^2 \le CR^2\|\widehat{H}(0,0,\cdot,s)\|^2. \tag{3.28}$$

Proof. For this case, problem (3.17) is

$$\begin{gathered} \frac{1}{R}\widehat{w}'''' - i\xi\widehat{w}'' = -\widehat{H}'', \\ \widehat{w}(0,0,0,s) = \widehat{w}(0,0,1,s) = \widehat{w}'(0,0,0,s) = \widehat{w}'(0,0,1,s) = 0, \end{gathered} \tag{3.29}$$

where $s = i\xi$. Taking the inner product of the equation with $\widehat{w}$ and integrating by parts, one gets

$$\frac{1}{R}\|\widehat{w}''\|^2 + i\xi\|\widehat{w}'\|^2 = -\langle\widehat{w}'', \widehat{H}\rangle. \tag{3.30}$$

Taking the real part of this equation, and using the Cauchy–Schwarz inequality on its right-hand side, we obtain

$$\|\widehat{w}''\|^2 \le R^2\|\widehat{H}\|^2. \tag{3.31}$$

Application of Poincaré's inequality twice gives us the estimate

$$\|\widehat{w}''\|^2 + \|\widehat{w}'\|^2 + \|\widehat{w}\|^2 \le CR^2\|\widehat{H}\|^2. \qquad \square \tag{3.32}$$

Case $0 < k^2 < \frac{R}{\sqrt{2}}$. For this case, we show that the problem can be reduced to estimating the solutions of linear homogeneous ordinary differential equations with nonhomogeneous boundary conditions. The method used here is similar to the approach in [1] to estimate the stream function for the case of two space dimensions.

THEOREM 3.6. *If, for all $R \ge 1$, the solutions $\phi_1(k_1,k_2,z,s)$ and $\phi_2(k_1,k_2,z,s)$ of*

$$\begin{array}{ll} TT_0\phi_1 = 0, & TT_0\phi_2 = 0, \\ \phi_1(k_1,k_2,0,s) = 0, & \phi_2(k_1,k_2,0,s) = 0, \\ \phi_1(k_1,k_2,1,s) = 0, & \phi_2(k_1,k_2,1,s) = 0, \\ \phi_1'(k_1,k_2,0,s) = 1, & \phi_2'(k_1,k_2,0,s) = 0, \\ \phi_1'(k_1,k_2,1,s) = 0, & \phi_2'(k_1,k_2,1,s) = 1 \end{array} \tag{3.33}$$

satisfy

$$\begin{array}{ll} |k|\|\phi_1(k_1,k_2,\cdot,s)\|^2 \le C & |k|\|\phi_2(k_1,k_2,\cdot,s)\|^2 \le C \\ \|\phi_1'(k_1,k_2,\cdot,s)\|^2 \le C & \|\phi_2'(k_1,k_2,\cdot,s)\|^2 \le C \end{array} \tag{3.34}$$

for some absolute constant $C > 0$ and for all $0 < k^2 < \frac{R}{\sqrt{2}}$, $s = i\xi$, $\xi \in \mathbb{R}$, $0 \le |\xi| < 2(1+\sqrt{R})$, then

$$|k|\|\widehat{w}'(k_1,k_2,\cdot,s)\|^2 + k^2\|\widehat{w}(k_1,k_2,\cdot,s)\|^2 \le CR^2\|\widehat{\mathbf{F}}\|^2 \tag{3.35}$$

for all $R \ge 1$, $0 < k^2 < \frac{R}{\sqrt{2}}$, $s = i\xi$, $\xi \in \mathbb{R}$, $0 \le |\xi| < 2(1+\sqrt{R})$.

Proof. The transformed normal velocity $\widehat{w}$ is the solution of

$$\begin{gathered} TT_0\widehat{w} = N, \\ \widehat{w}(0) = \widehat{w}(1) = \widehat{w}'(0) = \widehat{w}'(1) = 0, \end{gathered} \tag{3.36}$$

where $N = k^2\widehat{H} - \widehat{H}''$. To simplify the notation, we do not write explicitly the dependence of $\widehat{w}$ on all the parameters.

Let g and h be solution of the system

$$\begin{aligned} Th &= \left(\frac{1}{R}\mathcal{D}^2 - \left(i\xi + \frac{k^2}{R} + ik_2 z\right)\right) h = N, \quad h(0) = h(1) = 0, \\ T_0 g &= (\mathcal{D}^2 - k^2)g = h, \quad g(0) = g(1) = 0. \end{aligned} \tag{3.37}$$

Taking the inner product of the first equation with h, and integrating by parts, one gets

$$-\frac{1}{R}\|h'\|^2 - \frac{k^2}{R}\|h\|^2 - i\xi\|h\|^2 - ik_2\langle h, zh\rangle = \langle h, N\rangle. \tag{3.38}$$

Taking the real part of the equation above, and noting that $\langle h, zh\rangle \in \mathbb{R}$, we get

$$\frac{1}{R}\|h'\|^2 + \frac{k^2}{R}\|h\|^2 \leq |\langle h, N\rangle|. \tag{3.39}$$

As done before, since the equation satisfied by h in (3.37) is linear, we study separately h_1, h_2, the solutions of

$$\begin{aligned} Th_1 &= k^2\widehat{H}, \quad h_1(0) = h_1(1) = 0, \\ Th_2 &= -\widehat{H}'', \quad h_2(0) = h_2(1) = 0. \end{aligned} \tag{3.40}$$

For h_1, inequality (3.39) is

$$\frac{1}{R}\|h_1'\|^2 + \frac{k^2}{R}\|h_1\|^2 \leq |\langle h_1, k^2\widehat{H}\rangle| \leq k^2\|h_1\|\|\widehat{H}\|, \tag{3.41}$$

which implies

$$\|h_1\|^2 \leq R^2\|\widehat{H}\|^2. \tag{3.42}$$

For h_2, using inequality (3.39) and integrating by parts once, we have

$$\frac{1}{R}\|h_2'\|^2 + \frac{k^2}{R}\|h_2\|^2 \leq |\langle h_2, -\widehat{H}''\rangle| = |\langle h_2', -\widehat{H}'\rangle| \leq \|h_2'\|\|\widehat{H}'\|. \tag{3.43}$$

Therefore,

$$\|h_2'\|^2 + k^2\|h_2\|^2 \leq CR^2\|\widehat{H}'\|^2. \tag{3.44}$$

From (2.3), we have

$$\widehat{H}' = -ik_1\widehat{F} - ik_2\widehat{G}. \tag{3.45}$$

Therefore, (3.44) gives

$$\|h_2'\|^2 + k^2\|h_2\|^2 \leq CR^2(k_1^2\|\widehat{F}\|^2 + k_2^2\|\widehat{G}\|^2) \leq Ck^2R^2(\|\widehat{F}\|^2 + \|\widehat{G}\|^2), \tag{3.46}$$

which implies

$$\|h_2\|^2 \leq CR^2(\|\widehat{F}\|^2 + \|\widehat{G}\|^2). \tag{3.47}$$

Using (3.42) and (3.47), we conclude that $h = h_1 + h_2$ satisfies

$$\|h\|^2 \leq CR^2(\|\widehat{F}\|^2 + \|\widehat{G}\|^2 + \|\widehat{H}\|^2) = CR^2\|\widehat{\mathbf{F}}\|^2. \tag{3.48}$$

For g, estimates follow in a similar and simpler way. Taking the inner product of the second equation in (3.37) with g and integrating by parts, one can prove that

$$k^2\|g'\|^2 + k^4\|g\|^2 \leq C\|h\|^2. \tag{3.49}$$

Using the differential equation for g in (3.37), one can also bound g''. Therefore, one gets

$$\|g''\|^2 + k^2\|g'\|^2 + k^4\|g\|^2 \leq C\|h\|^2. \tag{3.50}$$

Using (3.48) and (3.50), we conclude that

$$\|g''\|^2 + k^2\|g'\|^2 + k^4\|g\|^2 \leq CR^2\|\widehat{\mathbf{F}}\|^2. \tag{3.51}$$

It follows from the definition of g that it satisfies

$$\begin{aligned} TT_0 g &= k^2\widehat{H} - \widehat{H}'', \\ g(0) &= g(1) = 0. \end{aligned} \tag{3.52}$$

Therefore, g satisfies the same differential equation satisfied by $\widehat{w}$, but with different boundary conditions, since $g'(0)$ and $g'(1)$ do not necessarily vanish. But those values can be estimated. Indeed, using the one-dimensional Sobolev inequality $|g'|_\infty^2 \leq \|g'\|^2 + 2\|g'\|\|g''\|$, and (3.51), we have

$$\begin{aligned} |k||g'(0)|^2 \leq |k||g'|_\infty^2 \leq |k|\|g'\|^2 + 2|k|\|g'\|\|g''\| \leq CR^2\|\widehat{\mathbf{F}}\|^2, \\ |k||g'(1)|^2 \leq |k||g'|_\infty^2 \leq |k|\|g'\|^2 + 2|k|\|g'\|\|g''\| \leq CR^2\|\widehat{\mathbf{F}}\|^2. \end{aligned} \tag{3.53}$$

Now, let ϕ be the solution of

$$\begin{aligned} &TT_0\phi = 0, \\ &\phi(0) = \phi(1) = 0, \\ &\phi'(0) = g'(0), \\ &\phi'(1) = g'(1). \end{aligned} \tag{3.54}$$

Then, $\widehat{w} = g - \phi$, as can be easily checked. Since we already have estimates for g, estimates for ϕ will imply estimates for $\widehat{w}$. Now, note that if ϕ_1 and ϕ_2 are the solutions of

$$\begin{array}{cc} TT_0\phi_1 = 0, & TT_0\phi_2 = 0, \\ \phi_1(0) = \phi_1(1) = 0, & \phi_2(0) = \phi_2(1) = 0, \\ \phi_1'(0) = 1, & \phi_2'(0) = 0, \\ \phi_1'(1) = 0, & \phi_2'(1) = 1, \end{array} \tag{3.55}$$

then $\phi = g'(0)\phi_1 + g'(1)\phi_2$. Therefore, if for some absolute constant C we have

$$\begin{array}{cc} |k|\|\phi_1(k_1,k_2,\cdot,s)\|^2 \leq C, & |k|\|\phi_2(k_1,k_2,\cdot,s)\|^2 \leq C, \\ \|\phi_1'(k_1,k_2,\cdot,s)\|^2 \leq C, & \|\phi_2'(k_1,k_2,\cdot,s)\|^2 \leq C, \end{array} \tag{3.56}$$

then, using (3.53), we get

$$\begin{aligned} k^2\|\phi\|^2 &\le 2k^2|g'(0)|^2\|\phi_1\|^2 + 2k^2|g'(1)|^2\|\phi_2\|^2 \le CR^2\|\widehat{\mathbf{F}}\|^2, \\ |k|\|\phi'\|^2 &\le 2|k||g'(0)|^2\|\phi_1'\|^2 + 2|k||g'(1)|^2\|\phi_2'\|^2 \le CR^2\|\widehat{\mathbf{F}}\|^2. \end{aligned} \tag{3.57}$$

Since $\widehat{w} = g - \phi$, inequalities (3.51) and (3.57) imply

$$|k|\|\widehat{w}'\|^2 + k^2\|\widehat{w}\|^2 \le CR^2\|\widehat{\mathbf{F}}\|^2, \tag{3.58}$$

which proves the theorem. ∎

We study the solutions ϕ_1 and ϕ_2 of (3.55) numerically. These problems are suitable for a numerical approach for two main reasons: First, they are homogeneous problems, with fixed nonhomogeneous boundary conditions for all values of the parameters k_1, k_2, ξ, R. Second, they need to be studied only for bounded values of k_1, k_2, and s, namely for $0 < k^2 < \frac{R}{\sqrt{2}}$, and $s = i\xi$, $\xi \in \mathbb{R}$, $0 \le |\xi| < 2(1 + \sqrt{R})$. The results are shown in section 4, providing evidence for the bounds (3.56).

Therefore, from the three cases studied above, we conclude that for all values of the parameters k_1, k_2, and s, we have

$$\begin{aligned} |k|\|\widehat{w}'\|^2 + k^2\|\widehat{w}\|^2 \le CR^2\|\widehat{\mathbf{F}}\|^2, \quad k^2 \neq 0, \\ \|\widehat{w}'\|^2 + \|\widehat{w}\|^2 \le CR^2\|\widehat{\mathbf{F}}\|^2, \quad k = 0. \end{aligned} \tag{3.59}$$

Having bounds for the normal velocity $\widehat{w}$, we now derive the bounds for the normal vorticity and use them to estimate $\widehat{u}$, $\widehat{v}$, the remaining components of the velocity.

3.2. Estimates for the normal vorticity. We prove the following theorem.

THEOREM 3.7. *If the estimates* (3.59) *hold, then*

$$\|\widehat{\eta}_3'\|^2 + k^2\|\widehat{\eta}_3\|^2 \le CR^4\|\widehat{\mathbf{F}}\|^2. \tag{3.60}$$

Moreover, inequality (3.60) *implies*

$$\|\widehat{u}\|^2 + \|\widehat{v}\|^2 \le CR^4\|\widehat{\mathbf{F}}\|^2. \tag{3.61}$$

Proof. The function $\widehat{\eta}_3$ is the solution of

$$\begin{aligned} T\widehat{\eta}_3 = \frac{1}{R}\widehat{\eta}_3'' - \left(i\xi + \frac{k^2}{R} + ik_2 z\right)\widehat{\eta}_3 = ik_1\widehat{w} + ik_2\widehat{F} - ik_1\widehat{G}, \\ \widehat{\eta}_3(k_1, k_2, 0, \xi) = \widehat{\eta}_3(k_1, k_2, 1, \xi) = 0. \end{aligned} \tag{3.62}$$

Taking the inner product of the differential equation with $\widehat{\eta}_3$, and integrating by parts the first term of the resulting equation once, we get

$$\frac{1}{R}\|\widehat{\eta}_3'\|^2 + \left(i\xi + \frac{k^2}{R}\right)\|\widehat{\eta}_3\|^2 + ik_2\langle\widehat{\eta}_3, z\widehat{\eta}_3\rangle = -ik_1\langle\widehat{\eta}_3, \widehat{w}\rangle - ik_2\langle\widehat{\eta}_3, \widehat{F}\rangle + ik_1\langle\widehat{\eta}_3, \widehat{G}\rangle.$$

Since $\langle\widehat{\eta}_3, z\widehat{\eta}_3\rangle \in \mathbb{R}$, taking the real part of the equation above and using the Cauchy–Schwarz inequality, we have

$$\frac{1}{R}\|\widehat{\eta}_3'\|^2 + \frac{k^2}{R}\|\widehat{\eta}_3\|^2 \le |k_1|\|\widehat{\eta}_3\|\|\widehat{w}\| + |k_2|\|\widehat{\eta}_3\|\|\widehat{F}\| + |k_1|\|\widehat{\eta}_3\|\|\widehat{G}\|. \tag{3.63}$$

If $k^2 = 0$, the desired estimates follow directly. For $k^2 \neq 0$, (3.63) implies

$$\frac{|k|}{R}\|\widehat{\eta}_3\| \leq \frac{|k_1|}{|k|}\|\widehat{w}\| + \frac{|k_2|}{|k|}\|\widehat{F}\| + \frac{|k_1|}{|k|}\|\widehat{G}\| \leq \|\widehat{w}\| + \|\widehat{F}\| + \|\widehat{G}\| \leq CR\|\widehat{\mathbf{F}}\|,$$

where we used (3.59) to bound $\|\widehat{w}\|$. Therefore,

$$k^2\|\widehat{\eta}_3\|^2 \leq CR^4\|\widehat{\mathbf{F}}\|^2. \tag{3.64}$$

Using (3.63) and (3.64), we can bound $\widehat{\eta}_3'$ by

$$\|\widehat{\eta}_3'\|^2 \leq CR^4\|\widehat{\mathbf{F}}\|^2. \tag{3.65}$$

Inequalities (3.64) and (3.65) together give

$$\|\widehat{\eta}_3'\|^2 + k^2\|\widehat{\eta}_3\|^2 \leq CR^4\|\widehat{\mathbf{F}}\|^2, \tag{3.66}$$

which proves the first part of the theorem.

We now use (3.64) to bound $\widehat{u}$, $\widehat{v}$, components of the velocity. The velocity components u and v can be recovered once one knows the normal velocity w and normal vorticity η_3 by solving, with appropriate boundary conditions, the equations

$$-u_{xx} - u_{yy} = \eta_{3y} + w_{xz}, \tag{3.67}$$

$$-v_{xx} - v_{yy} = w_{yz} - \eta_{3x}. \tag{3.68}$$

For the transformed functions, the equations above are

$$k^2\widehat{u} = ik_2\widehat{\eta}_3 + ik_1\widehat{w}', \tag{3.69}$$

$$k^2\widehat{v} = ik_2\widehat{w}' - ik_1\widehat{\eta}_3. \tag{3.70}$$

Using (3.59) and (3.64), the estimates

$$k^2\|\widehat{u}\| \leq CR^2\|\widehat{\mathbf{F}}\|, \tag{3.71}$$

$$k^2\|\widehat{v}\| \leq CR^2\|\widehat{\mathbf{F}}\| \tag{3.72}$$

follow. □

Inequalities (3.59), (3.71), (3.72) and Corollary 3.2 together imply

$$\begin{aligned}\|\widehat{\mathbf{u}}(k_1,k_2,\cdot,s)\|^2 &= \|\widehat{u}(k_1,k_2,\cdot,s)\|^2 + \|\widehat{v}(k_1,k_2,\cdot,s)\|^2 + \|\widehat{w}(k_1,k_2,\cdot,s)\|^2 \\ &\leq CR^4\|\widehat{\mathbf{F}}(k_1,k_2,\cdot,s)\|^2 + CR^4\|\widehat{\mathbf{F}}(k_1,k_2,\cdot,s)\|^2 + CR^2\|\widehat{\mathbf{F}}(k_1,k_2,\cdot,s)\|^2 \\ &\leq CR^4\|\widehat{\mathbf{F}}(k_1,k_2,\cdot,s)\|^2\end{aligned}$$

for all $(k_1,k_2) \in \mathbb{Z}\times\mathbb{Z}$ and for all $s \in \mathbb{C}$, $\mathrm{Re}(s) \geq 0$. By Lemma 3.3, this implies the resolvent estimate

$$\|(s\mathcal{I} - \mathcal{L}_R)^{-1}\|^2 \leq CR^4 \quad \forall s \in \mathbb{C},\ \mathrm{Re}(s) \geq 0. \tag{3.73}$$

Remarks about weighted norms. In [10], the authors define a weighted norm $\|\cdot\|_3$, which is given in our coordinate system by

$$\|\widetilde{\mathbf{u}}\|_3^2 := \|\widetilde{u}\|^2 + \|\widetilde{v}\|^2 + R^2\|\widetilde{w}\|^2. \tag{3.74}$$

Via direct numerical computations, they conclude that

$$\|\widetilde{\mathbf{u}}\|_3^2 \leq CR^2\|\widetilde{\mathbf{F}}\|_3^2. \tag{3.75}$$

Our analysis shows that, if one gets estimates of the type (3.27) for all values of k_1, k_2, (that is, estimating the normal velocity by the normal component of the forcing only), inequality (3.75) follows. Indeed, in this case, the estimates for the normal vorticity would be

$$\|\widehat{\eta}_3'\|^2 + k^2\|\widehat{\eta}_3\|^2 \leq CR^2\|\widehat{F}\|^2 + CR^2\|\widehat{G}\|^2 + CR^4\|\widehat{H}\|^2.$$

Then, using (3.69) and (3.70),

$$\|\widehat{u}\|^2 \leq CR^2\|\widehat{F}\|^2 + CR^2\|\widehat{G}\|^2 + CR^4\|\widehat{H}\|^2,$$
$$\|\widehat{v}\|^2 \leq CR^2\|\widehat{F}\|^2 + CR^2\|\widehat{G}\|^2 + CR^4\|\widehat{H}\|^2.$$

Therefore,

$$\|\widehat{u}\|^2 + \|\widehat{v}\|^2 + R^2\|\widehat{w}\|^2 \leq CR^2\|\widehat{F}\|^2 + CR^2\|\widehat{G}\|^2 + CR^4\|\widehat{H}\|^2 = CR^2\|\widehat{\mathbf{F}}\|_3^2.$$

We believe this to be the case. In our argument though, we need to use all the components of the forcing $\widehat{\mathbf{F}}$ to bound $\widehat{w}$ for $0 < k^2 < \frac{R}{\sqrt{2}}$. We do not see how to overcome this technical difficulty at the moment. To get a better R growth for the perturbations using our estimates, we could define a weighted norm $\|\cdot\|_R$, scaling the components of $\widehat{\mathbf{u}}$ in the obvious way:

$$\|\widehat{\mathbf{u}}\|_R^2 := \frac{1}{R^2}\|\widehat{u}\|^2 + \frac{1}{R^2}\|\widehat{v}\|^2 + \|\widehat{w}\|^2. \tag{3.76}$$

For this norm, we have

$$\|\widehat{\mathbf{u}}\|_R^2 \leq CR^2\|\widehat{\mathbf{F}}\|^2, \tag{3.77}$$

but this does not imply a resolvent estimate, since we do not have the same norms on both sides of the inequality.

4. Numerical results. The only part of the argument that relies on numerical computations are the estimates for ϕ_1 and ϕ_2, solutions of

$$\frac{1}{R}\phi_1'''' - \left(i\xi + \frac{2k^2}{R} + ik_2z\right)\phi_1'' + \left(i\xi k^2 + \frac{k^4}{R} + ik_2k^2z\right)\phi_1 = 0,$$
$$\phi_1(k_1,k_2,0,\xi) = \phi_1(k_1,k_2,1,\xi) = 0,$$
$$\phi_1'(k_1,k_2,0,\xi) = 1,$$
$$\phi_1'(k_1,k_2,1,\xi) = 0,$$

and

$$\frac{1}{R}\phi_2'''' - \left(i\xi + \frac{2k^2}{R} + ik_2z\right)\phi_2'' + \left(i\xi k^2 + \frac{k^4}{R} + ik_2k^2z\right)\phi_2 = 0,$$
$$\phi_2(k_1,k_2,0,\xi) = \phi_2(k_1,k_2,1,\xi) = 0,$$
$$\phi_2'(k_1,k_2,0,\xi) = 0,$$
$$\phi_2'(k_1,k_2,1,\xi) = 1,$$

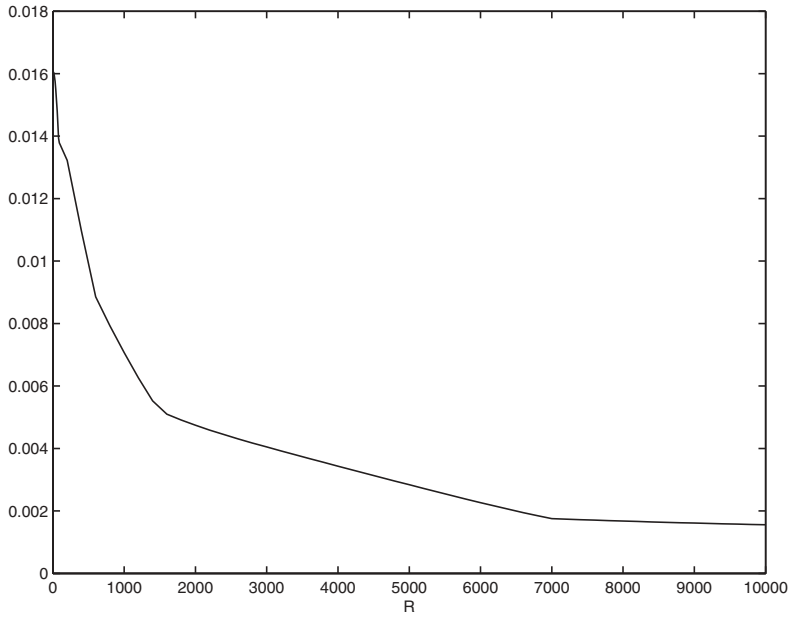

FIG. 1. $\max_{k_1,k_2,\xi} |k|\|\phi_1(k_1,k_2,\cdot,i\xi)\|^2$ *for* $0 < k_1^2 + k_2^2 < \frac{R}{\sqrt{2}}$, $0 \le |\xi| < 2(1+\sqrt{R})$.

for the parameter range

$$
\begin{aligned}
&(k_1,k_2) \in \mathbb{Z}, \quad 0 < k^2 = k_1^2 + k_2^2 < \frac{R}{\sqrt{2}},\\
&\xi \in \mathbb{R}, \quad 0 \le |\xi| < 2(1+\sqrt{R}).
\end{aligned}
\tag{4.1}
$$

We solved these problems using the MATLAB boundary value problem solver BVP4C, which makes use of a collocation method. A detailed description of the routine, and the methods used therein, can be found in [5]. For each value of R, we calculate the maximum of $|k|\|\phi_1(k_1,k_2,\cdot,\xi)\|^2$, $\|\phi_1'(k_1,k_2,\cdot,\xi)\|^2$, $\|\phi_2(k_1,k_2,\cdot,\xi)\|$, $\|\phi_2'(k_1,k_2,\cdot,\xi)\|$ for the parameter range (4.1). The results, for values of R up to 10000, are shown in Figures 1–4. The curves for ϕ_1 and ϕ_2 are very similar. Actually, for all considered values of R, the absolute value of the difference between the values in Figures 1 and 3 is of order 10^{-6}; the difference between the values in Figures 2 and 4 is of order 10^{-5}. These results are shown in Figures 5 and 6.

The numerical computations were performed with different absolute and relative tolerances, using continuation in the Reynolds number for the initial guess of the solution. The results were similar in all cases. Moreover, one just needs to ensure that the values of the norms above are bounded. Therefore, the results should be reliable. They indicate that, for all R,

$$
\begin{aligned}
|k|\|\phi_1(k_1,k_2,\cdot,s)\|^2 \le 1, \quad & |k|\|\phi_2(k_1,k_2,\cdot,s)\|^2 \le 1,\\
\|\phi_1'(k_1,k_2,\cdot,s)\|^2 \le 1, \quad & \|\phi_2'(k_1,k_2,\cdot,s)\|^2 \le 1
\end{aligned}
$$

for $0 < k^2 < \frac{R}{\sqrt{2}}$, $s = i\xi$, $\xi \in \mathbb{R}$, $0 \le |\xi| < 2(1+\sqrt{R})$.

5. Conclusions. The estimates derived here indicate the L_2 norm of the resolvent of the linear operator associated with three-dimensional perturbations of plane

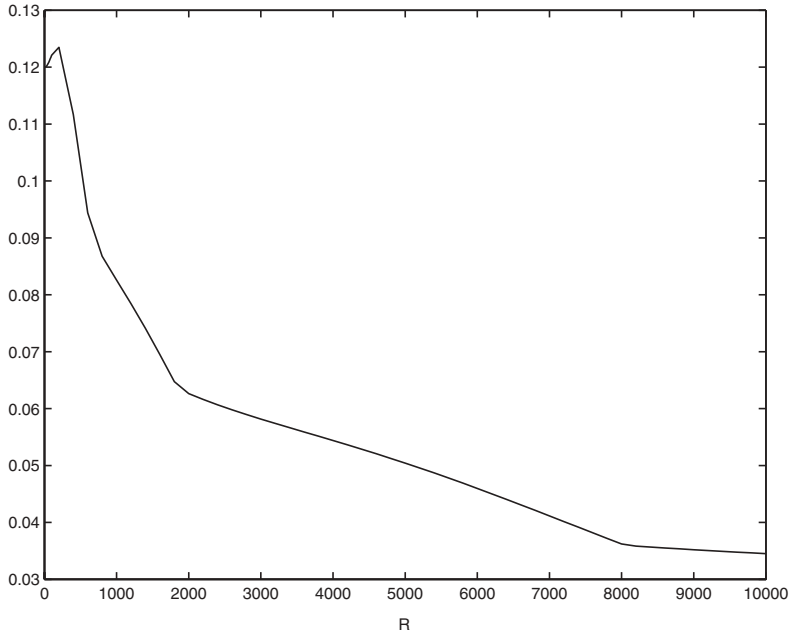

FIG. 2. $\max_{k_1,k_2,\xi} \|\phi_1'(k_1,k_2,\cdot,i\xi)\|^2$ *for* $0 < k_1^2 + k_2^2 < \frac{R}{\sqrt{2}}$, $0 \le |\xi| < 2(1+\sqrt{R})$.

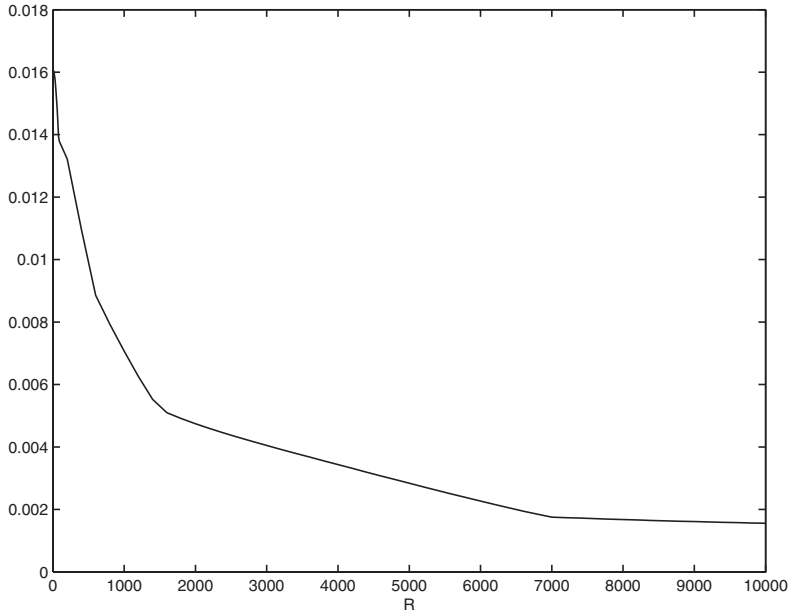

FIG. 3. $\max_{k_1,k_2,\xi} |k| \|\phi_2(k_1,k_2,\cdot,i\xi)\|^2$ *for* $0 < k_1^2 + k_2^2 < \frac{R}{\sqrt{2}}$, $0 \le |\xi| < 2(1+\sqrt{R})$.

Couette flow to be proportional to R^2 for the whole unstable half-plane $\mathrm{Re}(s) \ge 0$. They agree with previous numerical computations [6, 17]. In our argument though, numerical computations are used only to estimate the solutions of 4th-order

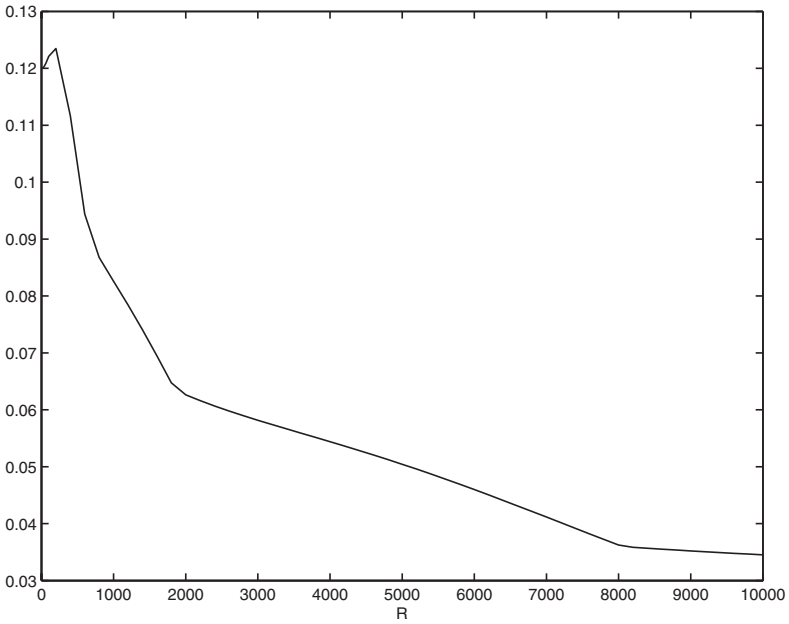

FIG. 4. $\max_{k_1,k_2,\xi} \|\phi_2'(k_1,k_2,\cdot,i\xi)\|^2$ *for* $0 < k_1^2 + k_2^2 < \frac{R}{\sqrt{2}}$, $0 \le |\xi| < 2(1+\sqrt{R})$.

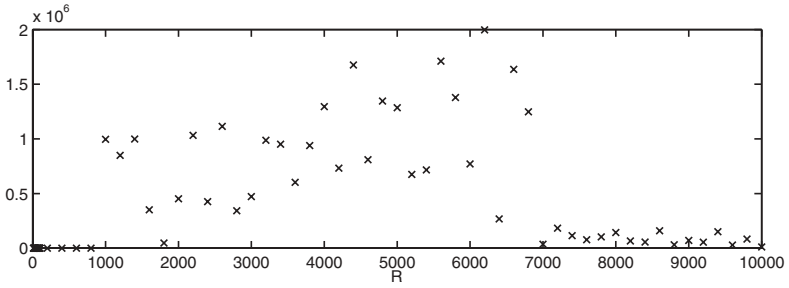

FIG. 5. $|\max_{k_1,k_2,\xi} |k| \|\phi_1(k_1,k_2,\cdot,i\xi)\|^2 - \max_{k_1,k_2,\xi} |k| \|\phi_2(k_1,k_2,\cdot,i\xi)\|^2|$.

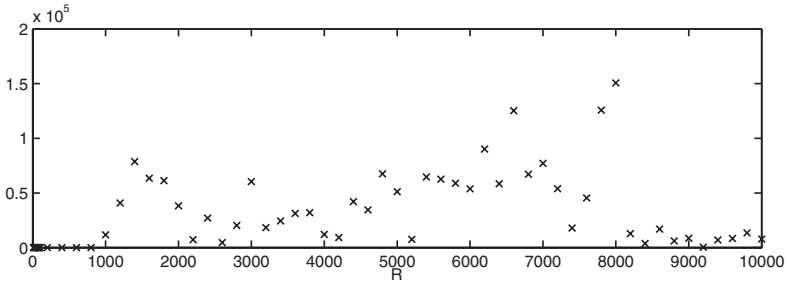

FIG. 6. $|\max_{k_1,k_2,\xi} \|\phi_1'(k_1,k_2,\cdot,i\xi)\|^2 - \max_{k_1,k_2,\xi} \|\phi_2'(k_1,k_2,\cdot,i\xi)\|^2|$.

homogeneous linear ordinary differential equations, with nonhomogeneous boundary conditions. Deriving the estimates analytically for the entire unstable half-plane is an

open problem, as far as we know. We believe that Theorem 3.6 may be useful towards a complete proof of the resolvent estimates. We hope to address this question in the future.

BOOMING AND CRASHING POPULATIONS AND EASTER ISLAND*

BILL BASENER† AND DAVID S. ROSS‡

Abstract. The population of Easter Island grew steadily for some time and then suddenly decreased dramatically. This is not the sort of behavior predicted by the usual logistic differential equation model of an isolated population or by the predator-prey model for a population using resources. We present a mathematical model that predicts this type of behavior when the growth rate of the resources, such as food and trees, is less than the rate at which resources are harvested. Our model is expressed mathematically as a system of two first-order differential equations, both of which are generalized logistic equations. Numerical solution of the equations, using realistic parameters, predicts values very close to archaeological observations of Easter Island. We analyze the model by using a coordinate transformation to blow up a singularity at the origin. Our analysis reveals surprisingly rich dynamics including a degenerate Hopf bifurcation.

Key words. Easter Island, population dynamics

1. The model.

At one time inhabitants of Easter Island prospered. They were sufficiently sophisticated, artistically and technologically, to build and transport the enormous mysterious statues for which the island is famous. Yet when westerners first came in contact with the island in the late eighteenth century, the inhabitants lived meagerly in flimsy huts and there were no trees left on the island. The island is extremely isolated, surrounded by over 1000 miles of ocean. Archaeological records indicate that a small group, about 50 to 150 people, sailed to Easter Island between 400 and 700 AD. The population grew to about 10,000 between 1200 and 1500 AD. It is thought that at this time the inhabitants built the biggest statues, had large boats, sailed on the ocean for fishing, and used the abundant large trees for building. The inhabitants overused the resources to the point of starvation and the island's human population decreased drastically. As a consequence of the population's actions, the large trees and other resources completely disappeared from the island. For a more detailed discussion of the history of Easter Island, see [4] and [8].

Neither of the standard elementary types of population models, logistic models and predator-prey models, predicts this sort of growth and decline. We present a system of differential equations for an isolated population that uses self-replenishing resources (such as trees, plants, and animals) which exhibits this booming and crashing behavior. We prove that if the population uses resources too quickly relative to the rate at which the resources replenish themselves, then the population will increase and then disappear in finite time. If the population uses the resources more slowly, then the population and resources do not disappear. A thorough characterization of solutions for various parameter values is given in Figure 5.

For our model, let P be a population and let R be the amount of resources. Our model is given by (1). To derive these equations, we assume that the resources would equilibrate in the absence of people. So when the population is zero the equation for the resources should be the standard logistic equation with $c, K > 0$. As in the standard logistic model we call c the growth rate of the resources and K the carrying capacity. The constant c has units of inverse time; it is the fraction by which the resource supply would increase per unit time were the resource supply far from the island's carrying capacity. The carrying capacity K has the same units as R; it is the maximum resource supply that the island can support.

The term $-hP$ accounts for the harvesting of the resources. The constant h, the harvesting constant, has units of reciprocal time; it is on the order of the reciprocal of the average lifetime of members of the population. The population P has units of persons, as does R; one unit of the resources is the amount of resources required to support a member of the population through his or her lifetime. We assume that the resources are accessible so that the amount of harvesting is proportional only to the population. This is a reasonable assumption for people on a small island.

At any given time the size of the population that our island can support depends on the amount of resources on the island. Given our choice of units, the island has the capacity to support R people. The evolution of the population is described by a logistic equation with the carrying capacity equal to R.

$$\begin{aligned} \frac{\mathrm{d}R}{\mathrm{d}t} &= cR\left(1-\frac{R}{K}\right) - hP, \\ \frac{\mathrm{d}P}{\mathrm{d}t} &= aP\left(1-\frac{P}{R}\right). \end{aligned} \tag{1}$$

The positive constant a has units of inverse time. The quantity aP is the net growth rate of the population in circumstances in which resources are abundant. Observe that when there are no resources ($R = 0$) the carrying capacity for the population is zero. This makes sense, but it causes mathematical trouble in the form of a singularity on the P-axis. The P/R term in (1) places our model in the class of ratio-dependent models, a class that has recently received much attention in the population biology literature. (See [9].) In fact, a discrete predator-prey model analogous to ours has been used by Eberhardt in [5].

The main virtues of this model are that it incorporates a variable carrying capacity for the population and that it is based on a simple but sensible account of the interaction between a population and its resources. Moreover, the predictions of this model match archeological data for the population of Easter Island; the predictions of standard models, such as the logistic model and the Lotka–Volterra model, do not. Of course a model's prediction matching data is not sufficient, though it is necessary, to establish the model's validity.

Our model is notable for the singularity in (1) when $R = 0$. Other models of populations similar to that of Easter Island do not involve such singularities; recent contributions to the literature have favored modified Lotka–Volterra models. Anderies [1] presents a general form for such models:

$$\begin{aligned} \frac{\mathrm{d}R}{\mathrm{d}t} &= \rho(R) - H(R,P), \\ \frac{\mathrm{d}P}{\mathrm{d}t} &= G(H,R)P. \end{aligned} \tag{2}$$

Here, $\rho(R)$ is the growth rate of the resources, $H = H(R, P)$ is the rate at which resources are harvested, and $G(H, R)P$ is the growth rate of the population; that is, G is the difference between the per person birth and death rates.

Brander and Taylor [3] choose the logistic form $\rho(R) = cR(1 - R/K)$ that we use in (1). Their harvesting rate is proportional to PR, while ours is simply proportional to P. For G, they use the linear function $G(H, R) = (b - d + \phi R)$, where b is the birth rate, d is the death rate, and ϕ is a constant. (The function $P(t)$, in Anderies's work and in the work of some other researchers in this field, is the labor pool, whereas we have considered, instead, the entire population.)

The harvesting model of Brander and Taylor accounts for the fact that as resources become scarce, less of the resources will be harvested per person. In our model, by contrast, the same amount of resources is harvested per person in all conditions. Consequently, our model does not capture details of low-resource conditions. The harvesting model, in which the harvesting rate is proportional to the amount of resources, seems to err in the other direction; it probably produces an underestimate of the harvesting rate in conditions of scarce resources. The truth is probably somewhere between the two models. While scarcity should diminish the harvesting rate, there will be a tendency for members of the population to maintain their standard of living at the cost of depleting resources. For conditions of plenty, our model seems sensible, and the assumption that the harvesting rate is proportional to the resources probably overestimates the harvesting rate.

Brander and Taylor use a population growth rate model in which the difference between the per person birth and death rates, $(b - d + \phi R)$, which is negative in the absence of resources, increases linearly with resources. In our population growth model, the difference between the per person birth and death rates is $a(1 - P/R)$, which is proportional to the unused fraction of the island's carrying capacity.

The per person growth rate of Brander and Taylor has the familiar mathematical form of an exponential decay model in conditions of scarcity. In the absence of resources, the population in the Brander and Taylor model dies out exponentially. Our model has the population, along with the resources, die out exponentially in some cases and in finite time in other cases. The appealing feature, in our model, of allowing the population to die out in finite time comes at the cost of an unbounded per person death rate. As resources increase, the model of Brander and Taylor has the difference between the per person birth and death rates become arbitrarily large. In our model, when resources are more than sufficient for the population, the difference between the per person birth and death rates approaches a finite positive constant.

Brander and Taylor derive their model in the framework of neoclassical economics; they justify the form of their harvesting rate by maximizing a Cobb–Douglas utility function. Anderies [2] takes a similar approach. He improves on their model by introducing a more general type of utility function, a Stone–Geary utility function. In this way, Anderies allows for a structural change in the culture when resources are scarce. He derives a continuous per person harvesting rate that is constant in conditions of scarcity and approaches a smaller constant asymptotically like $1/R$ in conditions of great abundance. This extra level of detail allows Anderies to fit the population data of Easter Island better than Brander and Taylor. (See graphs in [1] and [2].)
