$$\begin{aligned}\dot{J}(\varphi) \;=\; & \frac{d\varphi}{dt}(\overline{\tau})\beta\big(\varphi(\overline{\tau})\big)\varphi(\overline{\tau}) \\ & + \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\big((\beta\big(\varphi(\overline{\tau})\big)\varphi(\overline{\tau}))^2 - (\beta\big(\varphi(\overline{\tau}-\tau)\big)\varphi(\overline{\tau}-\tau))^2\big)d\tau.\end{aligned} \tag{3.3}$$

Using (2.12a), we have

$$\frac{d\varphi}{dt}(\overline{\tau}) = -\Big(\delta + \beta\big(\varphi(\overline{\tau})\big)\Big)\varphi(\overline{\tau}) + 2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\beta\big(\varphi(\overline{\tau}-\tau)\big)\varphi(\overline{\tau}-\tau)d\tau.$$

Therefore, (3.3) becomes

$$\begin{aligned}\dot{J}(\varphi) &= -\Big(\delta + \beta\big(\varphi(\overline{\tau})\big)\Big)\beta\big(\varphi(\overline{\tau})\big)\varphi^2(\overline{\tau}) + \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\Big[\Big(\beta\big(\varphi(\overline{\tau})\big)\varphi(\overline{\tau})\Big)^2 \\ &\quad + 2\beta\big(\varphi(\overline{\tau})\big)\varphi(\overline{\tau})\beta\big(\varphi(\overline{\tau}-\tau)\big)\varphi(\overline{\tau}-\tau) - \Big(\beta\big(\varphi(\overline{\tau}-\tau)\big)\varphi(\overline{\tau}-\tau)\Big)^2\Big]d\tau \\ &= -\Big(\delta + \beta\big(\varphi(\overline{\tau})\big)\Big)\beta\big(\varphi(\overline{\tau})\big)\varphi^2(\overline{\tau}) + 2\Big(\beta\big(\varphi(\overline{\tau})\big)\varphi(\overline{\tau})\Big)^2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau \\ &\quad - \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\Big[\beta\big(\varphi(\overline{\tau})\big)\varphi(\overline{\tau}) - \beta\big(\varphi(\overline{\tau}-\tau)\big)\varphi(\overline{\tau}-\tau)\Big]^2 d\tau.\end{aligned}$$

Hence,

$$\dot{J}(\varphi) \leq -u(\varphi(\overline{\tau})),$$

where the function u is defined, for $x \geq 0$, by

$$u(x) = r(x)\beta(x)x^2 \tag{3.4}$$

with

$$r(x) = \delta - \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau - 1\right)\beta(x).$$

Since β is decreasing, r is a monotone function. Moreover, (3.1) leads to $r(0) > 0$, and $\lim_{x\to\infty} r(x) = \delta \geq 0$. Therefore, r is positive on $[0, +\infty)$.

Consequently, the function u defined by (3.4) is nonnegative on $[0, +\infty)$ and $u(x) = 0$ if and only if $x = 0$. We deduce that every solution of (2.12a), with $\varphi \in C^+$, tends to zero as t tends to $+\infty$.

We suppose now that (3.2) holds. The linearization of (2.12a) around $x \equiv 0$ leads to the characteristic equation

$$\Delta_0(\lambda) := \lambda + \delta + \beta(0) - 2\beta(0)\int_{\underline{\tau}}^{\overline{\tau}} e^{-(\lambda+\gamma)\tau} f(\tau)d\tau = 0. \tag{3.5}$$

We consider Δ_0 as a real function. Since

$$\frac{d\Delta_0}{d\lambda} = 1 + 2\beta(0)\int_{\underline{\tau}}^{\overline{\tau}} \tau e^{-(\lambda+\gamma)\tau} f(\tau)d\tau > 0,$$

it follows that Δ_0 is an increasing function. Moreover, (3.5) yields

$$\lim_{\lambda\to-\infty} \Delta_0(\lambda) = -\infty, \qquad \lim_{\lambda\to+\infty} \Delta_0(\lambda) = +\infty,$$

and (3.2) implies that

$$\Delta_0(0) = \delta - \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau - 1\right)\beta(0) < 0.$$

Hence, $\Delta_0(\lambda)$ has a unique real root which is positive. Consequently, (3.5) has at least one characteristic root with positive real part. Therefore, the equilibrium $x \equiv 0$ of (2.12a) is not stable. This completes the proof. □

The inequality (3.1) is satisfied when δ or γ (the mortality rates) is large or when $\beta(0)$ is small. Biologically, these conditions correspond to a population which cannot survive, because the mortality rates are too large or, simply, because not enough cells are introduced in the proliferating phase and, then, the population renewal is not supplied.

Remark 1. One can notice that when

$$\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau < \frac{1}{2},$$

the trivial equilibrium E_0 is the only equilibrium of (2.12) and is globally asymptotically stable. When

$$\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau = \frac{1}{2},$$

then E_0 is globally asymptotically stable if $\delta > 0$. When the equality

$$\left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(0) = \delta$$

holds, one can check that $\lambda = 0$ is a characteristic root of (3.5) and all other characteristic roots have negative real parts. Hence, we cannot conclude on the stability or instability of the trivial equilibrium E_0 of (2.12) without further analysis. However, this is not the subject of this paper.

3.2. Stability of the nontrivial equilibrium. We concentrate, in this section, on the equilibrium $E^* = (x^*, y^*)$ defined by (2.23)–(2.24). Hence, throughout this section, we assume that (2.25) holds, that is,

$$0 < \delta < \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(0).$$

Since $\delta > 0$ and $\beta(0) > 0$, (2.25) implies, in particular, that

$$\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau > \frac{1}{2}. \tag{3.6}$$

From Lemma 2.1, we only need to focus on the stability of the nontrivial equilibrium $x \equiv x^*$ of (2.12a). To that aim, we linearize (2.12a) around x^*. Denote by $\beta^* \in \mathbb{R}$ the quantity

$$\beta^* := \frac{d}{dx}\Big(x\beta(x)\Big)\Big|_{x=x^*} = \beta(x^*) + x^*\beta'(x^*) \tag{3.7}$$

and set $u(t) = x(t) - x^*$. The linearization of (2.12a) is given by

$$\frac{du}{dt} = -(\delta + \beta^*)u(t) + 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) u(t-\tau) d\tau.$$

Then, the characteristic equation is

$$\Delta(\lambda) := \lambda + \delta + \beta^* - 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-(\lambda+\gamma)\tau} f(\tau) d\tau = 0. \tag{3.8}$$

One can notice that the function $x \mapsto x\beta(x)$ is usually not monotone. For example, if β is given by (2.1) with $n > 1$, the function $x \mapsto x\beta(x)$ is increasing for $x \le \theta/(n-1)^{1/n}$ and decreasing for $x > \theta/(n-1)^{1/n}$. In this case, β^* is nonnegative when x^* is close to zero and negative when x^* is large enough.

The following theorem deals with the asymptotic stability of E^*.

THEOREM 3.2. *Assume that* (2.25) *holds. If*

$$\beta^* \ge -\frac{\delta}{2\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau + 1}, \tag{3.9}$$

then E^* is locally asymptotically stable.

Proof. We first prove that the equilibrium $x \equiv x^*$ is locally asymptotically stable when $\beta^* \geq 0$. We consider the mapping $\Delta(\lambda)$, given by (3.8), as a real function of λ. Then $\Delta(\lambda)$ is continuously differentiable on $\mathbb{R}$ and its first derivative is given by

$$\frac{d\Delta}{d\lambda} = 1 + 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} \tau e^{-(\lambda+\gamma)\tau} f(\tau) d\tau > 0. \tag{3.10}$$

Hence, $\Delta(\lambda)$ is an increasing function of λ satisfying

$$\lim_{\lambda \to -\infty} \Delta(\lambda) = -\infty \qquad \text{and} \qquad \lim_{\lambda \to +\infty} \Delta(\lambda) = +\infty.$$

Then, there exists a unique $\lambda_0 \in \mathbb{R}$ such that $\Delta(\lambda_0) = 0$. Moreover, since

$$\Delta(0) = \delta - \left(2 \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1 \right) \beta^*,$$

we deduce, by using (2.23), (3.6), and (3.7), that

$$\Delta(0) = -\left(2 \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1 \right) x^* \beta'(x^*) > 0.$$

Consequently, $\lambda_0 < 0$.

Let $\lambda = \mu + i\omega$ be a characteristic root of (3.8) such that $\mu > \lambda_0$. Considering the real part of (3.8), we obtain that

$$\mu = -(\delta + \beta^*) + 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-(\mu+\gamma)\tau} f(\tau) \cos(\omega\tau) d\tau. \tag{3.11}$$

Using (3.8), with $\lambda = \lambda_0$, together with (3.11), we then obtain

$$\mu - \lambda_0 = 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) \left[e^{-\mu\tau} \cos(\omega\tau) - e^{-\lambda_0\tau} \right] d\tau.$$

However,

$$e^{-\mu\tau} \cos(\omega\tau) - e^{-\lambda_0\tau} < 0$$

for all $\tau \in [\underline{\tau}, \overline{\tau}]$. So we obtain that $\mu - \lambda_0 < 0$, which leads to a contradiction. This implies that all characteristic roots of (3.8) have negative real part and the equilibrium $x \equiv x^*$ of (2.12a) is locally asymptotically stable.

Now, assume that $\beta^* < 0$ and

$$\beta^* > -\frac{\delta}{2 \displaystyle\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau + 1}. \tag{3.12}$$

Let $\lambda = \mu + i\omega$ be a characteristic root of (3.8) such that $\mu > 0$. Since

$$\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) \left(e^{-\mu\tau} \cos(\omega\tau) + 1 \right) d\tau \geq 0,$$

we have

$$2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-(\mu+\gamma)\tau} f(\tau)\cos(\omega\tau)d\tau \leq -2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau.$$

So, (3.11) and (3.12) lead to

$$\mu \leq -(\delta+\beta^*) - 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau < 0,$$

a contradiction. Therefore, $\mu \leq 0$.

Suppose now that (3.8) has a purely imaginary characteristic root $i\omega$, with $\omega \in \mathbb{R}$. Then, (3.11) leads to

$$\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\cos(\omega\tau)d\tau = \frac{\delta+\beta^*}{2\beta^*}.$$

However,

$$\left| \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\cos(\omega\tau)d\tau \right| \leq \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau$$

and (3.12) yields

$$\frac{\delta+\beta^*}{2\beta^*} < -\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau.$$

Hence, (3.8) has no purely imaginary root. Consequently, all characteristic roots of (3.8) have negative real part and the nontrivial equilibrium $x \equiv x^*$ of (2.12a) is locally asymptotically stable.

Finally, assume that

$$\beta^* = -\frac{\delta}{2\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau + 1}. \tag{3.13}$$

Consider a characteristic root $\lambda = \mu + i\omega$ of (3.8), which reduces, with (3.13), to

$$\lambda - 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)(1+e^{-\lambda\tau})d\tau = 0. \tag{3.14}$$

Suppose, by contradiction, that $\mu > 0$. By considering the real part of (3.14), we have

$$\mu = 2\beta^* \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)(1+e^{-\mu\tau}\cos(\omega\tau))d\tau < 0.$$

We obtain a contradiction; therefore $\mu \leq 0$. If we suppose now that $\mu = 0$, then we easily obtain that

$$\cos(\omega\tau) = -1 \qquad \text{for all } \tau \in [\underline{\tau}, \overline{\tau}],$$

which is impossible. It follows that all characteristic roots of (3.8) have negative real parts when (3.13) holds and the equilibrium $x \equiv x^*$ is locally asymptotically stable.

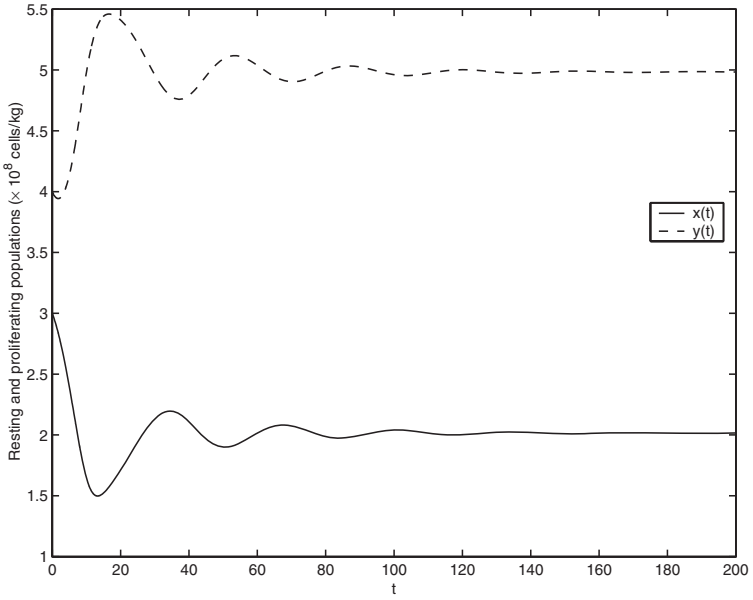

FIG. 3.1. *The solutions $x(t)$ (solid curve) and $y(t)$ (dashed curve) of system* (2.12) *are drawn for values of the parameters β_0, δ, and γ given by* (2.2), *$n = 2.42$, $\underline{\tau} = 0$, and $\overline{\tau} = 7$ days. In this case, the nontrivial equilibrium E^* is locally asymptotically stable, although the solutions oscillate transiently.*

From Lemma 2.1, we conclude that E^* is locally asymptotically stable when (3.9) holds. □

The asymptotic stability of E^* is shown in Figure 3.1. Values of the parameters are given by (2.2), except $n = 2.42$, $\underline{\tau} = 0$ and $\overline{\tau} = 7$ days. The function f is defined by

$$f(\tau) = \begin{cases} \dfrac{1}{\overline{\tau} - \underline{\tau}} & \text{if } \tau \in [\underline{\tau}, \overline{\tau}], \\ 0 & \text{otherwise.} \end{cases} \tag{3.15}$$

The MATLAB solver for delay differential equations, dde23 [32], is used to obtain Figure 3.1, as well as illustrations in sections 4 and 5.

When (3.9) does not hold, we have necessarily $\beta^* < 0$. In this case, we cannot obtain the stability of E^* for all values of β^*. In fact, in the next section we are going to show that the equilibrium E^* can be destabilized, in this case, via a Hopf bifurcation.

4. Hopf bifurcation and periodic solutions. In this section, we show that the equilibrium $x \equiv x^*$ of (2.12a) can become unstable when (3.9) does not hold anymore. Throughout this section, we assume that

$$\underline{\tau} = 0$$

and (2.25) holds, that is,

$$0 < \delta < \left(2 \int_0^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1 \right) \beta(0).$$

From Proposition 2.2, the solutions of (2.12a) are bounded. Consequently, instability in (2.12a) occurs only via oscillatory solutions.

We assume that

$$\beta^* < -\frac{\delta}{2\int_0^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau + 1} := \widetilde{\delta}. \tag{4.1}$$

Otherwise, the nontrivial equilibrium $x \equiv x^*$ of (2.12a) is locally asymptotically stable (see Theorem 3.2).

If instability occurs for a particular value $\beta^* < \widetilde{\delta}$, a characteristic root of (3.8) must intersect the imaginary axis. Hence, we look for purely imaginary characteristic roots $i\omega$, $\omega \in \mathbb{R}$, of (3.8). If $i\omega$ is a characteristic root of (3.8), then ω is a solution of the system

$$\begin{cases} \delta + \beta^*(1 - 2C(\omega)) = 0, \\ \omega + 2\beta^* S(\omega) = 0, \end{cases} \tag{4.2}$$

where

$$C(\omega) := \int_0^{\overline{\tau}} e^{-\gamma\tau} f(\tau) \cos(\omega\tau) d\tau \quad \text{and} \quad S(\omega) := \int_0^{\overline{\tau}} e^{-\gamma\tau} f(\tau) \sin(\omega\tau) d\tau.$$

One can notice that $\omega = 0$ is not a solution of (4.2). Otherwise,

$$\delta = \left(2\int_0^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta^* < 0,$$

which gives a contradiction. Moreover, if ω is a solution of (4.2), then $-i\omega$ is also a characteristic root. Thus, we look only for positive solutions ω.

LEMMA 4.1. *Assume that the function $\tau \mapsto e^{-\gamma\tau} f(\tau)$ is decreasing. Then, for each δ such that* (2.25) *is satisfied,* (4.2) *has at least one solution (β_c^*, ω_c) with $\beta_c^* < \widetilde{\delta}$ and $\omega_c > 0$. It follows that* (3.8) *has at least one pair of purely imaginary roots $\pm i\omega_c$ for $\beta^* = \beta_c^*$. Moreover, $\pm i\omega_c$ are simple characteristic roots of* (3.8). *Consider the branch of characteristic roots $\lambda(-\beta^*)$ such that $\lambda(-\beta_c^*) = i\omega_c$. Then*

$$\left.\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)}\right|_{\beta^*=\beta_c^*} > 0 \quad \textit{if and only if} \quad -\delta\left(\frac{S(\omega_c)}{\omega_c}\right)' > C'(\omega_c). \tag{4.3}$$

Proof. First, we show by induction that $S(\omega) > 0$ for $\omega > 0$. It is clear that $S(\omega) > 0$ if $\omega\overline{\tau} \in (0, \pi]$. Suppose that $\omega\overline{\tau} \in (\pi, 2\pi]$. Then

$$\begin{aligned} S(\omega) &= \frac{1}{\omega}\int_0^{\omega\overline{\tau}} e^{-\gamma\frac{\tau}{\omega}} f\left(\frac{\tau}{\omega}\right)\sin(\tau) d\tau \\ &= \frac{1}{\omega}\int_0^{\pi} e^{-\gamma\frac{\tau}{\omega}} f\left(\frac{\tau}{\omega}\right)\sin(\tau) d\tau + \frac{1}{\omega}\int_{\pi}^{\omega\overline{\tau}} e^{-\gamma\frac{\tau}{\omega}} f\left(\frac{\tau}{\omega}\right)\sin(\tau) d\tau. \end{aligned}$$

Since f is supported on the interval $[0, \overline{\tau}]$, it follows that

$$\int_{\omega\overline{\tau}}^{2\pi} e^{-\gamma\frac{\tau}{\omega}} f\left(\frac{\tau}{\omega}\right)\sin(\tau) d\tau = 0.$$

So, we obtain

$$S(\omega) = \frac{1}{\omega}\int_0^{\pi} e^{-\gamma\frac{\tau}{\omega}} f\Big(\frac{\tau}{\omega}\Big)\sin(\tau)d\tau + \frac{1}{\omega}\int_{\pi}^{2\pi} e^{-\gamma\frac{\tau}{\omega}} f\Big(\frac{\tau}{\omega}\Big)\sin(\tau)d\tau$$
$$= \frac{1}{\omega}\int_0^{\pi}\left(e^{-\gamma\frac{\tau}{\omega}} f\Big(\frac{\tau}{\omega}\Big) - e^{-\gamma\frac{\tau+\pi}{\omega}} f\Big(\frac{\tau+\pi}{\omega}\Big)\right)\sin(\tau)d\tau.$$

Since the function $\tau \mapsto e^{-\gamma\tau} f(\tau)$ is decreasing, we finally get $S(\omega) > 0$. Using a similar argument for $\omega\overline{\tau} \in (k\pi, (k+1)\pi]$, with $k \in \mathbb{N}$, $k \geq 2$, we deduce that $S(\omega) > 0$ for all $\omega > 0$.

Consider the equation

$$g(\omega) := \frac{\omega\big(1 - 2C(\omega)\big)}{2S(\omega)} = \delta, \qquad \omega > 0. \tag{4.4}$$

The function g is continuous with

$$\lim_{\omega\to 0} g(\omega) = \frac{1 - 2C(0)}{2\displaystyle\int_0^{\overline{\tau}} \tau e^{-\gamma\tau} f(\tau)d\tau} < 0 \tag{4.5}$$

because (2.25) leads to $1 - 2C(0) < 0$. Moreover, the Riemann–Lebesgue lemma implies that

$$\lim_{\omega\to+\infty} C(\omega) = \lim_{\omega\to+\infty} S(\omega) = 0.$$

This yields

$$\lim_{\omega\to+\infty} g(\omega) = +\infty.$$

We conclude that there exists a solution $\omega_c > 0$ of (4.4). Since $S(\omega_c) > 0$ and $g(\omega_c) = \delta > 0$, we obtain $1 - 2C(\omega_c) > 0$. Set

$$\beta_c^* = -\frac{\delta}{1 - 2C(\omega_c)} < 0. \tag{4.6}$$

Since $|C(\omega_c)| < C(0)$, it follows that

$$\beta_c^* < -\frac{\delta}{2C(0) + 1} = \widetilde{\delta}.$$

One can check that (β_c^*, ω_c) is a solution of (4.2). It follows that $\pm i\omega_c$ are characteristic roots of (3.8) for $\beta^* = \beta_c^*$.

Define a branch of characteristic roots $\lambda(-\beta^*)$ of (3.8) such that $\lambda(-\beta_c^*) = i\omega_c$. We use the parameter $-\beta^*$ because $\beta^* < \widetilde{\delta} < 0$.

Using (3.8), we obtain

$$\left[1 + 2\beta^*\int_0^{\overline{\tau}} \tau e^{-(\lambda+\gamma)\tau} f(\tau)d\tau\right]\frac{d\lambda}{d(-\beta^*)} = 1 - 2\int_0^{\overline{\tau}} e^{-(\lambda+\gamma)\tau} f(\tau)d\tau. \tag{4.7}$$

If we assume, by contradiction, that $i\omega_c$ is not a simple root of (3.8), then (4.7) leads to

$$C(\omega_c) = \frac{1}{2} \qquad \text{and} \qquad S(\omega_c) = 0.$$

Since $S(\omega_c) > 0$, we obtain a contradiction. Thus, $i\omega_c$ is a simple root of (3.8).

Moreover, using (4.7), we have

$$\left(\frac{d\lambda}{d(-\beta^*)}\right)^{-1} = \frac{1 + 2\beta^* \displaystyle\int_0^{\overline{\tau}} \tau e^{-(\lambda+\gamma)\tau} f(\tau) d\tau}{1 - 2\displaystyle\int_0^{\overline{\tau}} e^{-(\lambda+\gamma)\tau} f(\tau) d\tau}.$$

Since λ is a characteristic root of (3.8), we also have

$$1 - 2\int_0^{\overline{\tau}} e^{-(\lambda+\gamma)\tau} f(\tau) d\tau = -\frac{\lambda + \delta}{\beta^*}.$$

So, we deduce

$$\left(\frac{d\lambda}{d(-\beta^*)}\right)^{-1} = -\beta^* \frac{1 + 2\beta^* \displaystyle\int_0^{\overline{\tau}} \tau e^{-(\lambda+\gamma)\tau} f(\tau) d\tau}{\lambda + \delta}.$$

Then,

$$\begin{aligned}
\operatorname{sign}\left\{\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)}\right\}\Big|_{\beta^*=\beta_c^*} &= \operatorname{sign}\left\{\mathrm{Re}\left(\frac{d\lambda}{d(-\beta^*)}\right)^{-1}\right\}\Big|_{\beta^*=\beta_c^*} \\
&= \operatorname{sign}\left\{\mathrm{Re}\left(-\beta^* \frac{1 + 2\beta^* \displaystyle\int_0^{\overline{\tau}} \tau e^{-(\lambda+\gamma)\tau} f(\tau) d\tau}{\lambda + \delta}\right)\right\}\Big|_{\beta^*=\beta_c^*} \\
&= \operatorname{sign}\left\{ -\beta_c^* \frac{\delta(1 + 2\beta_c^* S'(\omega_c)) + 2\beta_c^* \omega_c C'(\omega_c)}{\delta^2 + \omega_c^2}\right\} \\
&= \operatorname{sign}\left\{\delta(1 + 2\beta_c^* S'(\omega_c)) + 2\beta_c^* \omega_c C'(\omega_c)\right\}.
\end{aligned}$$

From (4.6) and the fact that $1 - 2C(\omega_c) > 0$, this leads to

$$\begin{aligned}
\operatorname{sign}\left\{\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)}\right\}\Big|_{\beta^*=\beta_c^*} &= \operatorname{sign}\left\{1 - 2C(\omega_c) - 2\delta S'(\omega_c) - 2\omega_c C'(\omega_c)\right\} \\
&= \operatorname{sign}\left\{2\omega_c\left(- C'(\omega_c) - \delta\left(\frac{S(\omega_c)}{\omega_c}\right)'\right)\right\} \\
&= \operatorname{sign}\left\{ - C'(\omega_c) - \delta\left(\frac{S(\omega_c)}{\omega_c}\right)'\right\}.
\end{aligned}$$

This concludes the proof. □

Remark 2. Consider the function g defined by (4.4) and denote by α the quantity

$$\alpha := \left(2\int_0^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(0).$$

Define the sets

$$\Omega := \{\omega > 0;\ 0 < g(\omega) < \alpha \ \text{ and } \ g'(\omega) = 0\} \qquad \text{and} \qquad \Lambda := g(\Omega).$$

One can notice that Λ is finite (or empty). If $\delta \in (0,\alpha) \setminus \Lambda$, then

$$\left.\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)}\right|_{\beta^*=\beta_c^*} \neq 0.$$

Indeed, we have

$$g'(\omega) = -\frac{\omega}{S(\omega)}\left(g(\omega)\left(\frac{S(\omega)}{\omega}\right)' + C'(\omega)\right), \qquad \omega > 0.$$

Since $\delta \notin \Lambda$, we have $g'(\omega_c) \neq 0$. Moreover, $g(\omega_c) = \delta$. Thus

$$C'(\omega_c) \neq -\delta\left(\frac{S(\omega_c)}{\omega_c}\right)'.$$

We conclude by using (4.3).

Lemma 4.1, together with Remark 2, allows us to state and prove the following theorem.

THEOREM 4.2. *Assume that the function $\tau \mapsto e^{-\gamma\tau} f(\tau)$ is decreasing. Then, for each $\delta \notin \Lambda$ satisfying* (2.25)*, there exists $\beta_c^* < \widetilde{\delta}$ such that the equilibrium $x \equiv x^*$ is locally asymptotically stable when $\beta_c^* < \beta^* \leq \widetilde{\delta}$ and a Hopf bifurcation occurs at $x \equiv x^*$ when $\beta^* = \beta_c^*$.*

Proof. First, recall that $x \equiv x^*$ is locally asymptotically stable when $\beta^* = \widetilde{\delta}$ (see Theorem 3.2). We recall that, from the properties of the function g, (4.4) has a finite number of solutions (see Lemma 4.1). We set

$$\beta_c^* = -\frac{\delta}{1 - 2C(\omega_c^*)},$$

where ω_c^* is the smaller positive real such that

$$C(\omega_c^*) = \min\{C(\omega);\ \omega \text{ is a solution of (4.4)}\}.$$

Then, β_c^* is the maximum value of β^* (as defined in Lemma 4.1) which gives a solution of (4.2). From Lemma 4.1, (3.8) has no purely imaginary roots while $\beta_c^* < \beta^* \leq \widetilde{\delta}$. Consequently, Rouché's theorem [10, p. 248] leads to the local asymptotic stability of $x \equiv x^*$.

When $\beta^* = \beta_c^*$, (3.8) has a pair of purely imaginary roots $\pm i\omega_c$, $\omega_c > 0$ (see Lemma 4.1). Moreover, since $\delta \notin \Lambda$, Remark 2 implies that

$$\left.\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)}\right|_{\beta^*=\beta_c^*} \neq 0.$$

Assume, by contradiction, that

$$\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)} < 0$$

for $\beta^* > \beta_c^*$, β^* close to β_c^*. Then there exists a characteristic root $\lambda(-\beta^*)$ such that $\mathrm{Re}\lambda(-\beta^*) > 0$. This contradicts the fact that $x \equiv x^*$ is locally asymptotically stable when $\beta^* > \beta_c^*$. Thus, we obtain

$$\left.\frac{d\mathrm{Re}(\lambda)}{d(-\beta^*)}\right|_{\beta^*=\beta_c^*} > 0.$$

This implies the existence of a Hopf bifurcation at $x \equiv x^*$ for $\beta^* = \beta_c^*$. ∎

With the values of δ, γ and β_0 given by (2.2), and $\overline{\tau} = 7$ days, (2.12) has periodic solutions for $\beta_c^* = -0.3881$ with a period about 33 days. This value of β_c^* corresponds to $n = 2.53$ (see Figures 4.1 and 4.2). The function f is given by (3.15).

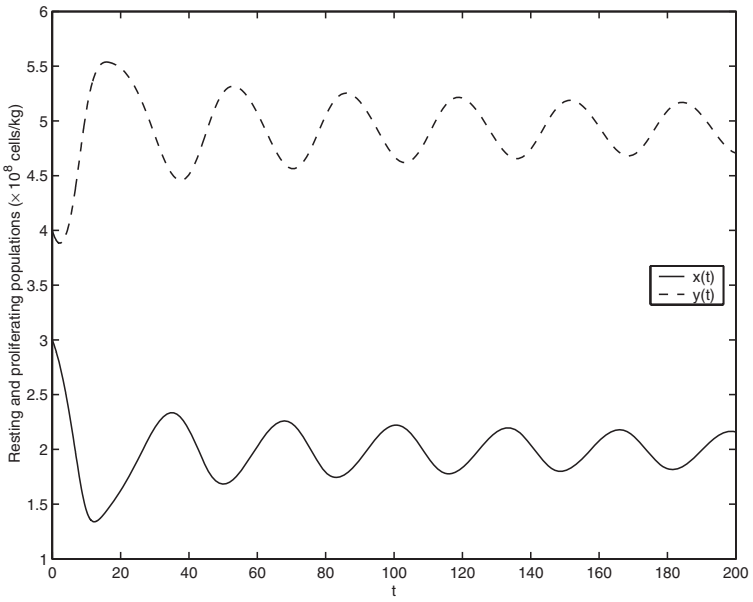

FIG. 4.1. *The solutions of system* (2.12), $x(t)$ (*solid curve*) *and* $y(t)$ (*dashed curve*), *are drawn when the Hopf bifurcation occurs. This corresponds to* $n = 2.53$ *with the other parameters given by* (2.2) *and* $\overline{\tau} = 7$ *days. Periodic solutions appear with period of the oscillations about* 33 *days.*

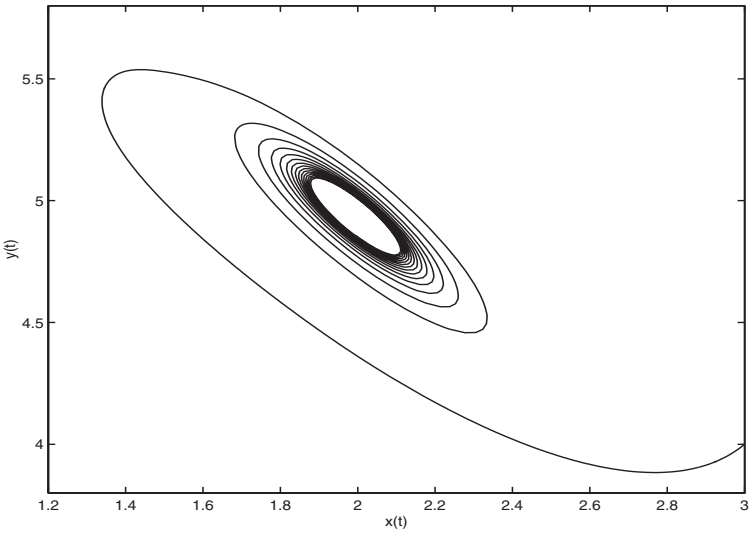

FIG. 4.2. *For the values used in Figure* 4.1, *the solutions are shown in the* (x, y)*-plane: the trajectories reach a limit cycle, surrounding the equilibrium.*

The bifurcation parameter was chosen to be β^* in this study, and the values of β^* depend strongly on the sensitivity n of the function $\beta(x)$, since all other parameters are fixed by (2.25). In this model, the sensitivity n plays a crucial role in the appearance of periodic solutions. Pujo-Menjouet and Mackey [27] already noticed the influence of this parameter on system (2.12) when the delay is constant (or equivalently, when f is a Dirac measure). The sensitivity n describes the way the rate of introduction in the proliferating phase reacts to changes in the resting phase population produced by external stimuli: a release of erythropoietin, for example, or the action of some growth factors.

Of course, the influence of other parameters (like mortality rates δ and γ, or the minimum and maximum delays $\underline{\tau}$ and $\overline{\tau}$) on the appearance of periodic solutions could be studied. However, since periodic hematological diseases—defined and described in section 5—are supposed to be due to hormonal control destabilization (see [11]), then the parameter n, among other parameters, seems to be appropriate to identify causes leading to periodic solutions in (2.12).

5. Discussion. Among the wide range of diseases affecting blood cells, periodic hematological diseases (Haurie, Dale, and Mackey [14]) are of main importance because of their intrinsic nature. These diseases are characterized by significant oscillations in the number of circulating cells, with periods ranging from weeks (19 to 21 days for cyclical neutropenia [14]) to months (30 to 100 days for chronic myelogenous leukemia [14]) and amplitudes varying from normal to low levels or normal to high levels, depending on the cells types [14]. Because of their dynamic character, periodic hematological diseases offer an opportunity to understand some of the regulating processes involved in the production of hematopoietic cells, which are still not well understood.

Some periodic hematological diseases involve only one type of blood cells, for example, red blood cells in periodic autoimmune hemolytic anemia (Bélair, Mackey, and Mahaffy [4]) or platelets in cyclical thrombocytopenia (Santillan et al. [31]). In these cases, periods of the oscillations are usually between two and four times the bone marrow production delay. However, other periodic hematological diseases, such as cyclical neutropenia (Haurie, Dale, and Mackey [14]) or chronic myelogenous leukemia (Fortin and Mackey [11]), show oscillations in all of the circulating blood cells, i.e., white cells, red blood cells, and platelets. These diseases involve oscillations with quite long periods (on the order of weeks to months). A destabilization of the pluripotential stem cell population (from which all of the mature blood cells types are derived) seems to be at the origin of these diseases.

We focus, in particular, on chronic myelogenous leukemia (CML), a cancer of the white cells, resulting from the malignant transformation of a single pluripotential stem cell in the bone marrow (Pujo-Menjouet, Bernard, and Mackey [26]). As described in Morley, Baikie, and Galton [24], oscillations can be observed in patients with CML, with the same period for white cells, red blood cells and platelets. This is called periodic chronic myelogenous leukemia (PCML). The period of the oscillations in PCML ranges from 30 to 100 days [14], [11] depending on patients. The difference between these periods and the average pluripotential cell cycle duration (between 1 and 4 days, as observed in mice [18]) is still not well understood.

Recently, to understand the dynamics of periodic chronic myelogenous leukemia, Pujo-Menjouet, Bernard, and Mackey [26] considered a model for the regulation of stem cell dynamics and investigated the influence of parameters in this stem cell model on the oscillations period when the model becomes unstable and starts to

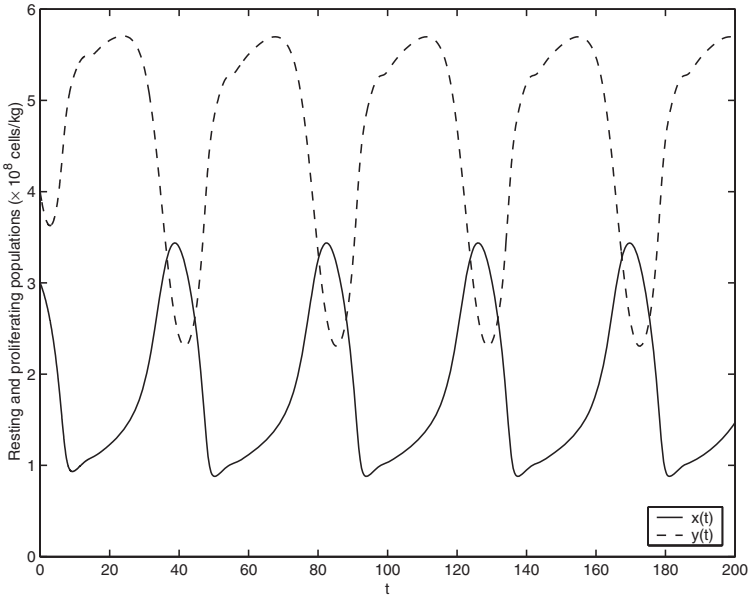

FIG. 5.1. *Solutions $x(t)$ (solid curve) and $y(t)$ (dashed curve) of system* (2.12) *oscillate with periods close to* 45 *days; the parameters are the same as in Figure* 4.1*, with $n = 3$. The amplitudes of the oscillations range from low values to normal values.*

oscillate. In this paper, taking into account the fact that a cell cycle has two phases, that is, stem cells in process are either in a resting phase or actively proliferating, and assuming that cells divide at different ages, we proposed a system of differential equations with distributed delay to model the dynamics of hematopoietic stem cells. By constructing a Lyapunov functional, we gave conditions for the trivial equilibrium to be globally asymptotically stable. Local stability and Hopf bifurcation of the nontrivial equilibrium were studied, the existence of a Hopf bifurcation leading to the appearance of periodic solutions in this model, with a period around 30 days at the bifurcation.

Numerical simulations show that periodic solutions occur after the bifurcation, with periods increasing as the bifurcation parameter (the sensitivity n) increases. In Figure 5.1, solutions oscillate around the equilibrium values with periods around 45 days. Moreover, amplitudes of the oscillations range from low values to normal values. The sensitivity is equal to $n = 3$; that is, the parameters are given by (2.2). This corresponds to values given by Mackey [16], values for which abnormal behavior (periodic) is usually observed in all circulating blood cells types.

When n continues to increase, longer oscillations periods are observed with amplitudes varying from low values to high values (see Figure 5.2). This situation characterizes periodic chronic myelogenous leukemia, with periods in the order of 2 months (70 days).

Moreover, the oscillations observed in Figures 5.1 and 5.2 look very much like relaxation oscillations. Experimental data from patients with PCML suggest that the shape of oscillations is of a relaxation oscillator type [11, 14]. Furthermore, Fowler and Mackey [12] showed that a model for hematopoiesis with a discrete delay may also exhibit relaxation oscillations. Therefore, it seems that not only periods and

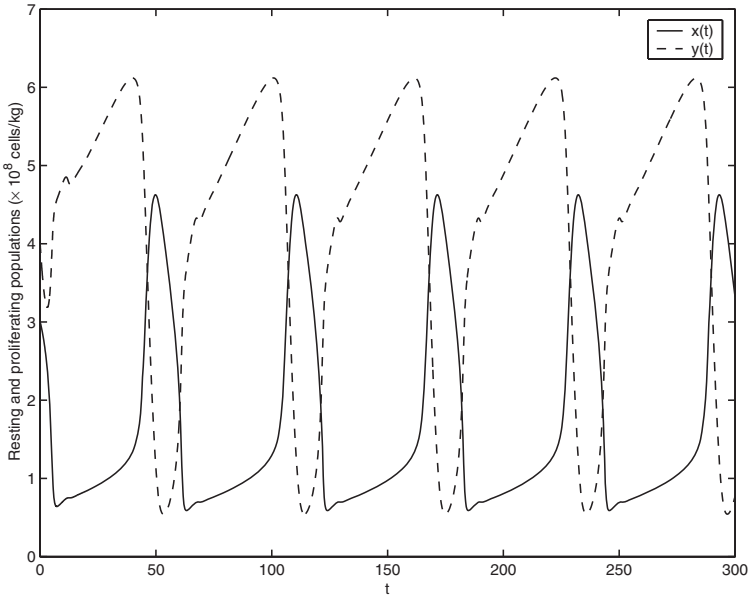

FIG. 5.2. *Solutions $x(t)$ (solid curve) and $y(t)$ (dashed curve) of system* (2.12) *oscillate with periods close to* 70 *days; the parameters are the same as in Figure* 4.1*, with $n = 4$. The amplitudes of the oscillations range from low values to high values.*

amplitudes of the oscillations correspond to the ones observed in PCML but also the shape of the oscillations.

Numerical simulations demonstrated that long period oscillations in the circulating cells are possible in our model even with short duration cell cycles. Thus, we are able to characterize some hematological diseases, especially those that exhibit a periodic behavior of all the circulating blood cells.

ON THE SOUND IN UNBOUNDED AND DUCTED VORTEX FLOWS*

L. M. B. C. CAMPOS† AND P. G. T. A. SERRÃO†

Abstract. The propagation of sound is considered in a potential cylindrical vortex, with superimposed axial flow, by means of explicit analytical solutions. The sound waves are sinusoidal in time and in the axial and azimuthal directions; the convected wave equation leads to a radial dependence specified by an ordinary second-order differential equation, with two singularities, at the origin and at infinity. Both singularities are irregular, implying that the acoustic fields have an essential singularity. In the neighborhood of the vortex axis, the essential singularity of the acoustic field is specified by an exponential of the integrated Doppler shift; using the latter as a factor, the acoustic fields are specified by asymptotic expansions in ascending powers of the radius. In the neighborhood of the point at infinity, where the tangential mean flow velocity vanishes, the leading terms are outward or inward propagating cylindrical waves; these factors multiply asymptotic expansions in descending powers of the radius. The two pairs of solutions, around the vortex axis and the point at infinity, are valid in all space or overlapping regions, as far as the asymptotic expansions can be calculated. The case of an annular nozzle, with uniform axial flow, and potential swirl is used as an example; the eigenvalues are obtained for rigid wall boundary conditions and the corresponding eigenfunctions are plotted.

1. Introduction. The propagation of sound in swirling flows [9, 7, 8, 12, 5] is relevant to the acoustics of turbomachinery and has important engineering applications in propulsion and power generation, e.g., jet engines and power turbines. The best known case is the rigid body rotation, for which the angular velocity is constant. It is of some interest to consider less simple cases, e.g., with radially varying angular velocity, of which the potential vortex is the only case, for which an acoustic potential exists, satisfying the convected wave equation [10, 1, 2]. The present paper concerns the exact solution of the convected wave equation in a cylindrical duct in the presence of a uniform axial flow with a superimposed potential vortex.

A vortex has a core where the tangential velocity remains finite, e.g., it should be sufficient to match the present solution to a small core with rigid body rotation. Taking the limit of zero core radius leads to a vortex with an algebraic singularity for the mean flow velocity and an essential singularity for the acoustic field. The latter singularity specifies the leading term of the acoustic field, viz., a Doppler factor on the vortex axis; at infinity, where the mean flow velocity vanishes, the leading term is a cylindrical wave. In both cases, viz., the solution around the vortex axis or the solution at infinity, the exact solution beyond the leading term is an asymptotic expansion; since the vortex is unstable, its perturbation could not be expected to lead to a convergent series. The summation of the asymptotic expansion is accurate for low azimuthal orders, and it shows that the leading terms dominate the acoustic fields.

The acoustic wave equation in cylindrical coordinates in a potential vortex is harmonic in time and in the circumferential and axial coordinates and thus leads to a linear ordinary differential equation in the radial direction (section 2.1), which has two irregular singularities. The singularity on the vortex axis can be represented by a Doppler effect associated with the mean flow velocity (section 2.2); once this factor is inserted the exact solution can be obtained as an ascending power series (section 2). The mean flow velocity tends to uniform at infinity, and thus the limit of the cylindrical wave specifies the singularity there (section 3.1); inserting this factor leads to an asymptotic expansion for the acoustic field at large radius (section 3). The combination of the two solutions specifies the acoustics of nozzles with axial flow and swirl (section 3.2), including the eigenvalues (section 4.1) and the radial eigenfunctions (section 4.2). These are discussed for several axial and tangential Mach numbers, dimensionless frequencies, and circumferential wavenumbers.

2. Acoustic fields in the neighborhood of the vortex axis. The convected wave equation, which describes sound propagation in a potential vortex (appendix), has an irregular singularity on the vortex axis (section 2.1), because the mean flow velocity is infinite there. This corresponds to an essential singularity for the acoustic potential, which is specified by the integrated Doppler shift (section 2.2); using this singularity as a factor, a pair of linearly independent solutions is obtained as a power series of the radius.

2.1. Convected wave equation for a vortex flow. The acoustic potential Φ satisfies the convected wave equation

$$\left\{ c^{-2} \left(\partial/\partial t + \overrightarrow{V} \cdot \nabla \right)^2 - \nabla^2 \right\} \Phi \left(\overrightarrow{x}, t \right) = 0 \tag{2.1}$$

in a nonuniform, incompressible flow for which the sound speed c is constant. A cylindrical vortex corresponds to a potential flow if the circulation per unit length Γ is a constant, corresponding to the tangential velocity,

$$V_\theta = \Gamma/(2\pi r) = \gamma/r, \tag{2.2a}$$

$$\gamma \equiv \Gamma/2\pi, \tag{2.2b}$$

where γ is the circulation per radian. If a uniform axial velocity U is added, the mean flow velocity

$$\overrightarrow{V} = U \overrightarrow{e_z} + (\gamma/r) \overrightarrow{e_\theta} \tag{2.3}$$

is still potential, and the convected wave equation (2.1) becomes

$$\begin{aligned} &\{c^{-2}[\partial/\partial t + U\, \partial/\partial z + (\gamma/r^2)\partial/\partial\theta]^2 - r^{-1} \left(\partial/\partial r\right) r \left(\partial/\partial r\right) \\ &- r^{-2}\partial^2/\partial\theta^2 - \partial^2/\partial z^2\}\Phi(r,\theta,z,t) = 0 \end{aligned} \tag{2.4}$$

in cylindrical coordinates.

Since the mean flow is steady and the velocity depends only on r, it is convenient to use Fourier decompositions in t, θ, z, i.e., the acoustic potential is represented

$$\Phi(r,\theta,z,t) = \sum_{m=-\infty}^{+\infty} e^{im\theta} \iint_{-\infty}^{+\infty} d\omega dk\, e^{i(kz-\omega t)} \Psi(r;m,k,\omega) \tag{2.5}$$

by (i) a Fourier series in the azimuthal direction θ, with integral wavenumber m; (ii) a Fourier integral in time t, with frequency ω; (iii) a Fourier integral in the axial direction z, with a continuous wavenumber k spectrum for an infinite vortex (or a Fourier series with wavenumber $2\pi l/L$ for a vortex of length L, with l integer). Substitution of (2.5) into (2.3) leads to an ordinary differential equation for the radial r dependence of the acoustic potential spectrum

(2.6)
$$r^2\Psi'' + r\Psi' + \left\{ \left[(\omega - k\,U)^2 / c^2 - k^2 \right] r^2 - 2m\gamma\,(\omega - k\,U)/c^2 - m^2 + (m\gamma/cr)^2 \right\} \Psi = 0,$$

where appear the transverse wavenumber (2.7a)

$$K^2 \equiv (\omega - k\,U)^2 / c^2 - k^2, \tag{2.7a}$$

$$q^2 \equiv m^2 + 2m\gamma\,(\omega - k\,U)/c^2 \tag{2.7b}$$

and the azimuthal constant (2.7b). The differential equation

$$r^2\Psi'' + r\Psi' + \left[K^2 r^2 - q^2 + (m\gamma/c)^2 / r^2 \right] \Psi = 0 \tag{2.8}$$

is similar to a Bessel equation, except for the last term in the square brackets, which involves the circulation.

Introducing the dimensionless variable incorporating the transverse wavenumber,

$$s \equiv Kr, \tag{2.9a}$$

$$\Psi(r; m, k, \omega) \equiv F(s), \tag{2.9b}$$

leads to the differential equation

$$s^2F'' + sF' + \left(s^2 - q^2 + a^2/s^2 \right) F = 0, \tag{2.10}$$

similar to the Bessel equation of order q, apart from the term involving the constant:

$$a \equiv m\gamma K/c. \tag{2.11}$$

This constant vanishes ($a = 0$) in the absence of the vortex $\gamma = 0$, in which case $q = m$ in (2.7b) is the azimuthal wavenumber, and the acoustic potential which is finite on axis is specified by a Bessel function:

$$\gamma = 0: \quad F(s) = J_m(s) = J_m(K\,r). \tag{2.12}$$

The other solution is a Neumann function $Y_m(s) \sim \log s$ which has a logarithmic singularity on the axis. These two solutions apply in the absence of a vortex $\gamma = 0$, i.e., for $a = 0$, when the origin $s = 0$ is a regular singularity of the differential equation, i.e., the case of cylindrical waves. They also apply in the presence of the vortex $\gamma \neq 0$, but only to the axisymmetric mode [9] $m = 0$, since then $a = 0$ in (2.11). For nonaxisymmetric modes $m \geq 1$, and in the presence of the vortex $\gamma \neq 0$, then $a \neq 0$ in (2.11), and the differential equation (2.10) has an irregular singularity at the origin $s = 0$, implying that the solution has an essential singularity. This corresponds to a singular phase for the acoustic field on the vortex axis, which is specified by the integrated Doppler shift, as shown next.

2.2. Singular Doppler shift on the vortex axis. The Doppler shift of a sound wave of wave vector $\overrightarrow{K}$ in a mean flow of velocity $\overrightarrow{V}$ is given by an integral along the ray path dl, viz.,

$$\phi = \int \left[\left(\overrightarrow{K}.\overrightarrow{V}\right)\Big/c\right] dl = (m/c)\int V_\theta dr = m\,\gamma/cr = m\,\gamma\,K/c\,s = a/s, \tag{2.13}$$

where the mean velocity is tangential (2.2a), and thus multiplies the azimuthal wavenumber m, and (2.9a), (2.11) were used. Thus the acoustic potential should be of the form

$$F(s) = e^{\Omega(s)}G(s), \tag{2.14}$$

where $\Omega(s) = i\,\phi = ia/s$ is the singular phase term, corresponding to the essential singularity in the solution, and $G(s)$ should be an ascending power series. Note that the differential equation (2.10) will not have an ascending power series solution, unless the factor $e^{\Omega(s)}$ is inserted. A solution of the type (2.14) is called a normal integral [6], and it will be shown next that a solution of this type exists, with essential singularity $e^{\Omega(s)}$ specified $\Omega(s) = i\,\phi$ by the integrated Doppler shift (2.13). To prove this, (2.14) is substituted in the differential equation (2.10), leading to

$$s^2\,G'' + s\,[1 + 2\Omega' s]\,G' + \left[s^2\left(\Omega'' + \Omega'^2\right) + s\,\Omega' + s^2 - q^2 + a^2/s^2\right] G = 0. \tag{2.15}$$

The origin $s = 0$ will be a regular singularity, and $G(s)$ will have solution as an ascending power series of Frobenius–Fuchs type if the coefficients in square brackets are analytic at $s = 0$,

$$X_1 \equiv 2\,\Omega'\,s = O(1) = s^2(\Omega'^2 + \Omega'') + s\,\Omega' + a^2/s^2 \equiv X_2. \tag{2.16}$$

Thus, if $\Omega(s)$ can be found such that both X_1 and X_2 in (2.16) are analytic functions of s at $s = 0$, then $s = 0$ is a regular singularity of (2.15), and $G(s)$ is an ascending power series, which substituted in (2.14) specifies the normal integral as solution of (2.10).

It turns out that it is not necessary to make both X_1 and X_2 analytical at $s = 0$, but it is sufficient to choose $\Omega(s)$ so as to eliminate the most singular term, viz., the double pole a^2/s^2, by taking this to cancel with $s^2\,\Omega'^2$, viz.,

$$\Omega'(s) = \pm i\,a/s^2; \tag{2.17}$$

this implies

$$\Omega(s) = \mp i\,a/s \tag{2.18}$$

that, as predicted before, the integrated Doppler shift (2.13) appears in the normal integral (2.14) in the form

$$F_\pm(s) = e^{\mp i\,a/s}\,G_\pm(s), \tag{2.19}$$

where $G_\pm(s)$ satisfies the differential equation

$$s^2\,G''_\pm + s(1 \pm 2i\,a/s)G'_\pm + (s^2 - q^2 \mp i\,a/s)G_\pm = 0, \tag{2.20}$$

obtained by substituting (2.18) in (2.15).

The origin $s = 0$ would be a regular singularity of (2.20) if the coefficients in parentheses were analytic at $s = 0$, in which case two ascending Frobenius–Fuchs power series would exist for each of $G_+$and G_-. In fact both coefficients in parentheses in (2.20) have simple poles, but this is an improvement over the double pole in the coefficient in parentheses in (2.10). The latter has no solutions in power series, as could be found by trying the Frobenius–Fuchs method. In contrast, substituting a Frobenius–Fuchs series

$$G_\pm(s) = \sum_{J=0}^{\infty} g_j^\pm \, s^{j+\sigma_\pm} \tag{2.21}$$

in (2.20), it will be shown that one solution exists; it could not have two, so it could have none or one, and the latter is the case. This follows from the recurrence formula for the coefficients,

$$\left[(j+\sigma_\pm)^2 - q^2\right] g_j^\pm + g_{j-2}^\pm = \mp i\, a\, (2j + 2\sigma_\pm + 1)\, g_{j+1}^\pm, \tag{2.22}$$

which could be identical to that for Bessel functions in the absence of the vortex $a = 0$, and otherwise $a \neq 0$ is triple instead of double. Setting $j = -1$ leads to the indicial equation

$$j = -1 : \quad (2\sigma_\pm - 1) g_0^\pm = 0, \tag{2.23}$$

which has one root, corresponding to

$$\sigma_\pm = 1/2 : \quad \left[(j+1/2)^2 - q^2\right] g_j^\pm + g_{j-2}^\pm = \mp 2i\, a\, (j+1)\, g_{j+1}^\pm, \tag{2.24}$$

as recurrence relation for the coefficients. Thus (2.24), (2.21) specify one solution for each of the two differential equations (2.20), yielding in total the two linearly independent solutions (2.19) needed for the second-order differential equation (2.10).

The two Frobenius–Fuchs series (2.21),

$$g_0^\pm \equiv 1 : \quad G_\pm(s) = \sum_{j=0}^{\infty} g_j^\pm \, s^{j+1/2}, \tag{2.25}$$

multiplied (2.19) by the Doppler shift (2.13) specify the normal integrals

$$F_\pm(s) = e^{\mp i\, a/s} s^{1/2} \sum_{j=0}^{\infty} g_j^\pm \, s^j, \tag{2.26}$$

corresponding to the acoustic potentials

$$\Psi_\pm(r; m, k, \omega) = e^{\mp i\, m\gamma/c\, r} \sum_{j=0}^{\infty} g_j^\pm \, (Kr)^{j+1/2}, \tag{2.27}$$

which are linearly independent. The total acoustic potential is a linear combination

$$r < \infty : \quad \Psi(r; m, k, \omega) = A_+ \Psi_+(r; m, k, \omega) + A_- \Psi_-(r; m, k, \omega), \tag{2.28}$$

where the arbitrary constants of integration $A_\pm$ incorporate the coefficients $g_0^\pm$, which can thus be set to unity in (2.25). The two arbitrary constants of integration $A_\pm$ are determined by two conditions, i.e., (i) the acoustic potential at a given radius $\Psi(r_0; m, k, \omega)$; (ii) a radiation condition at infinity $r = \infty$. Since the solution (2.28) holds only for finite r, to apply the radiation condition, the solution of (2.10) around the point at infinity must be obtained.

3. Asymptotic acoustic fields and radiation condition. Besides the origin, the other singularity of the convected wave equation in a potential vortex is the point at infinity; the latter is also an irregular singularity of the differential equation, implying an essential singularity for the acoustic field, which is simply a cylindrical wave, since the mean flow velocity vanishes at infinity. Using the asymptotic cylindrical wave as a factor, two solutions of the convected wave equation are obtained as descending power series of the radius (section 3.1). Since these solutions represent inward and outward propagating waves, they allow the application of the Sommerfeld radiation condition. The pair of asymptotic solutions (section 3.1) overlaps with the pair of solutions around the vortex axis (section 3.2), allowing the application of boundary conditions for a potential vortex plus axial flow in a cylindrical or annular nozzle (section 3.2).

3.1. Sound radiation in a cylindrical vortex flow. The point at infinity $s = \infty$ is mapped to the origin $\zeta = 0$ using the inversion as a change variable,

$$\zeta = 1/s, \tag{3.1a}$$

$$F(s) = H(\zeta), \tag{3.1b}$$

which transforms the differential equation (2.10) to

$$\zeta^2 H'' + \zeta H' + (1/\zeta^2 - q^2 + a^2\zeta^2)H = 0. \tag{3.2}$$

It is clear from the double pole in the coefficient in parentheses that the origin $\zeta = 0$ is an irregular singularity of the differential equation (3.2), and thus the point at infinity $s = \infty$ or $r = \infty$ is an irregular singularity of (2.10) or (2.8). In this case the search for a solution as a normal integral is facilitated by noting that the vortex does not produce a mean flow at infinity, i.e., a in (3.2) does not affect the singularity at $\zeta = 0$. This means that the acoustic potential at infinity consists of cylindrical waves propagating inward and outward, implying solutions of the form $\exp(\pm iKr) = \exp(\pm is) = \exp(\pm i/\zeta)$; this specifies the essential singularity in the normal integral,

$$H_\pm(\zeta) = e^{\pm i/\zeta} J_\pm(\zeta), \tag{3.3}$$

which substituted in (3.2) leads to

$$\zeta^2 J_\pm'' + (\zeta \mp 2i)\, J_\pm' + \left(i/\zeta - q^2 + a^2\zeta^2\right) J_\pm = 0. \tag{3.4}$$

Note that although the origin $\zeta = 0$ is not a regular singularity of the differential equation (3.4), because there is a simple pole in the second coefficient in parentheses, this is better than the double pole in the coefficient in parentheses in (3.2).

It can be checked by substituting a Frobenius–Fuchs series in (3.2) that no solution in ascending power series exists. Substituting in (3.4) a Frobenius–Fuchs series,

$$J_\pm(\zeta) = \sum_{l=0}^{\infty} j_l^\pm\, \zeta^{l+\vartheta_\pm}, \tag{3.5}$$

leads to the recurrence formula for the coefficients

$$\left[(l+\vartheta_\pm)^2 - q^2\right] j_l^\pm \mp (2l + 2\vartheta_\pm + 1)\, i\, j_{l+1}^\pm + a^2 j_{l-2}^\pm = 0 \tag{3.6}$$

and indicial equation

$$l = -1: \quad (2\vartheta_\pm - 1)\, j_0^\pm = 0, \tag{3.7}$$

which has one root:

$$\vartheta_\pm = 1/2: \quad \left[(l+1/2)^2 - q^2\right] j_l^\pm \mp 2(l+1) i\, j_{l+1}^\pm + a^2 j_{l-2}^\pm = 0. \tag{3.8}$$

This specifies (3.8), (3.5) one solution for each of the differential equations (3.4), and thus in total two solutions (3.3) for the differential equation (3.2). These solutions represent inward and outward propagating waves at infinity and thus allow the application of a radiation condition. By matching the solutions around the point at infinity with the solutions around the origin (2.27), other types of boundary conditions may be applied, e.g., for a vortex in a cylindrical duct.

Before proceeding to consider several kinds of boundary conditions, it is convenient to make explicit the two solutions at infinity, corresponding to outward and inward propagating waves. The power series (3.5),

$$j_0^\pm \equiv 1: \quad J_\pm(\zeta) = \sum_{l=0}^{\infty} j_l^\pm\, \zeta^{l+1/2}, \tag{3.9}$$

multiplied by the phase term (3.3),

$$H_\pm(\zeta) = e^{\pm i/\zeta} \sum_{l=0}^{\infty} j_l^\pm\, \zeta^{l+1/2}, \tag{3.10}$$

specify the acoustic potential around (3.1a), (3.1b) the point-at-infinity,

$$F^\pm(s) = e^{\pm is} \sum_{l=0}^{\infty} j_l^\pm\, s^{-l-1/2}, \tag{3.11}$$

which corresponds,

$$\Psi^\pm(r; m, k, \omega) = e^{\pm iKr} \sum_{l=0}^{\infty} j_l^\pm\, (Kr)^{-l-1/2}, \tag{3.12}$$

to, respectively, outward Ψ^+ and inward Ψ^- propagating waves.

3.2. Application to nozzles with axial flow and swirl. The total acoustic potential is a linear combination of the two,

$$r > 0: \quad \Psi(r; m, k, \omega) = B_+ \Psi^+(r; m, k, \omega) + B_- \Psi^-(r; m, k, \omega), \tag{3.13}$$

where the arbitrary constants of integration $B_\pm$ incorporate the coefficient $j_0^\pm$, which may be set to unity (3.9). The outward Ψ^+ and inward Ψ^- propagating acoustic potentials for all distances except for duct axis $r > 0$ are a linear combination of the acoustic potential $\Psi_\pm$ valid (2.27) at all finite distances $r < \infty$, in the region of overlap,

$$0 < r < \infty: \quad \Psi^\pm(r; m, k, \omega) = D_+^\pm \Psi_+(r; m, k, \omega) + D_-^\pm \Psi_-(r; m, k, \omega), \tag{3.14}$$

where the constants $D_{\pm}^{\pm}$ can be determined at any point. The radiation condition, specifying outward propagating waves Ψ^+ at infinity, requires selecting the first term of the right-hand side of (3.13), viz.,

$$r > 0: \quad \Psi(r;m,k,\omega) = B_+ \Psi^+(r;m,k,\omega), \tag{3.15a}$$

$$r < \infty: \quad \Psi(r;m,k,\omega) = B_+ [D_+^+ \Psi_+(r;m,k,\omega) + D_-^+ \Psi_-(r;m,k,\omega)]. \tag{3.15b}$$

The remaining constant of integration is determined,

$$0 < r_0 < \infty: \quad \Psi(r_0;m,k,\omega) = B_+ \Psi^+(r_0;m,k,\omega), \tag{3.16}$$

from the wave field at a given position. All these results concern acoustic propagation in an unbounded cylindrical vortex with axial flow.

It is also possible to confine the vortex into a cylindrical duct of radius R. In this case the problem concerns the acoustic modes in a cylindrical duct, with (2.3) uniform axial flow and a vortex on its axis with constant circulation Γ per unit length. The two solutions (2.27) around the duct vortex axis cover the whole duct. They are complex conjugates, as can be seen from (2.27), (2.24),

$$\Psi_+^* = \Psi_-: \quad \Psi_n(r;m,k,\omega) = A \operatorname{Re} \left\{ e^{\mp i\, m\gamma/c\, r} \sum_{j=0}^{\infty} g_j^{\pm} (Kr)^{j+1/2} \right\}, \tag{3.17}$$

and thus a real acoustic potential is obtained by taking the real part of either of them, which is equivalent to choosing $A_+ = A_- = 2A$ in (2.28). The eigenfrequencies are given by (2.7a), viz.,

$$\omega_n = KU + c\sqrt{K^2 + K_n^2}, \tag{3.18}$$

in terms of the radial wavenumbers K_n, which also specify the eigenfunctions (3.17). The wavenumbers K_n are determined by a boundary condition at the duct wall $r = R$. The simplest is a rigid wall boundary condition

$$0 = \partial\Psi/\partial r|_{r=R} = \operatorname{Re} \left\{ e^{\frac{im\gamma}{cR}} (KR)^{-1/2} K\, F(K) \right\}, \tag{3.19}$$

where

$$F_0 \prod_{n=0}^{\infty} (K - K_n) \equiv F(K) \equiv \sum_{j=0}^{\infty} g_j (KR)^j (j + 1/2 - im\gamma/cR); \tag{3.20}$$

thus the roots of (3.20) specify the eigenvalues K_n for the transverse wavenumber, substitution in (3.18) specifies the eigenfrequencies, and substitution in (3.17) specifies the eigenfunctions.

For an axial vortex and a uniform mean flow confined in an annular duct, the acoustic potential is a linear combination of the two solutions at infinity,

$$r_i < r < r_e: \quad \Psi_n(r;m,k,\omega) = B_+ \Psi_n^+(r;m,k,\omega) + B_- \Psi_n^-(r;m,k,\omega), \tag{3.21}$$

which cover the annular duct between inner radius r_i and outer radius r_e. In this case the problem concerns acoustic modes in an annular duct with potential swirling flow with eigenfunctions

$$\Psi_n^{\pm}(r;m,k,\omega) = e^{\pm iK_n r} \sum_{l=0}^{\infty} j_l^{\pm} (K_n r)^{-l-1/2}, \tag{3.22}$$

and radial eigenvalues K_n related to axial eigenvalues k_n in a dispersion relation,

$$K_n^2 = (\omega - k\,U)^2/c^2 - k_n^2, \tag{3.23}$$

where n represents the integer radial modal number.

The wavenumbers K_n are determined from the two rigid wall conditions

$$\partial\Psi/\partial r|_{r=r_i} = 0, \quad \partial\Psi/\partial r|_{r=r_e} = 0, \tag{3.24}$$

leading to

$$\begin{vmatrix} \Psi_n^{+\prime}(r_i; m, k_n, \omega) & \Psi_n^{-\prime}(r_i; m, k_n, \omega) \\ \Psi_n^{+\prime}(r_e; m, k_n, \omega) & \Psi_n^{-\prime}(r_e; m, k_n, \omega) \end{vmatrix} = 0. \tag{3.25}$$

4. Application to the acoustics of an annular nozzle with a potential swirl. The preceding results can be used to calculate the eigenvalues (section 4.1) and eigenfunctions (section 4.2) for sound in an annular nozzle containing an axially uniform mean flow, on which is superimposed a potential vortex swirl.

4.1. Effect of axial and swirling flow on radial wavenumbers. As an application an annular duct with inner radius $r_i = 4$ and outer radius $r_e = 6$ is considered. The dimensionless frequency $\varpi = \omega r_m/c$ is introduced, where $r_m = (r_i + r_e)/2$ is the mean radius. The calculations were performed for a dimensionless frequency $\varpi = 2.5$, an axial Mach number $M_z = 0.3$, and a tangential Mach number $M_\theta = 0.5$ specified at the mean radius r_m. The axial wavenumbers k_n as given by (3.23), (3.25) are represented in Figure 1 for the lowest integral wavenumber $m = 1, -1$. As m increases so does a in (2.11), and the asymptotic expansion (3.12), (3.13) deteriorates in accuracy. For the first circumferential mode $|m| = 1$ rotating in the same direction as the swirl of the mean flow $m = +1$, the axial wavenumbers are complex conjugate pairs,

$$k_n = \alpha_n \pm i\,\beta_n, \quad \exp(i\,k_n\,z) = \exp(i\,\alpha_n\,z)\exp(\mp\beta_n z), \tag{4.1}$$

with a small positive real part α_n almost independent of n representing propagation; in this case $m = +1$ of corotation the imaginary part increases with n, corresponding to a decay $+i\beta_n$ or instability $-i\beta_n$. In the case $m = -1$ of counterrotation, the first eigenvalue is real and of negative sign representing a wave of constant amplitude, propagating in the negative z-direction; the higher-order modes $n = 2, 3, 4$ are again complex conjugate pairs, with imaginary parts increasing with n, implying spatial decay or instability, as in the case of corotation. Also as in the case of corotation the real part α_n is almost independent of $n = 2, 3, \ldots$, but in contrast it has small negative (instead of positive) values $\alpha_n < 0$, implying propagation against the axial mean flow, in the negative z-direction. The larger propagation speed of corotating relative to counterrotating modes corresponds to the fast and slow acoustic-vortical modes in the axisymmetric case [9].

To each eigenvalue k_n, specified by a root of (3.25), corresponds an eigenfunction (3.21) with zero radial derivative at the wall. Each eigenfunction is a linear combination of inward and outward propagating waves (3.22) with amplitudes $B^\pm$. Since the rigid wall boundary conditions (3.24) only determine the ratios of amplitudes B^+/B^-, the choice $B^+ = 1$ is made for the plots in Figures 2 to 5. Each wave consists (3.12) of a sinusoidal radial oscillation multiplying an asymptotic expansion (3.9). Note that if the point at infinity were a regular singularity, the solution would

be a series expansion, whose convergence is assured by the Fuchs theorem. Since, in the present case, the point at infinity is an irregular singularity, the Fuchs theorem does not apply, and the Frobenius–Fuchs method leads to an asymptotic expansion (3.9), whose convergence or accuracy is not assured a priori. The asymptotic expansion was summed as long as the terms decreased; it was truncated when the sum of the absolute value of the last 10 terms did not exceed 10^{-7}. This criterion is quite demanding and is similar to that used for convergent series [3]. In the cases where this criterion was not met, the asymptotic expansion was summed up to the smallest term; if this term was less than 10^{-2} of the sum, the result was deemed acceptable. Otherwise, the result was discarded. Our choice of the inner and outer radius, mean flow, and swirl Mach numbers and dimensionless frequency coincides with [7, 8], whose authors have considered the same problem numerically; we have chosen to represent in Figure 1 the modes for $m = \pm 1$ and increasing $n = 1, 2, 3, 4, \ldots$; [7, 8] do not plot the waveforms in this case. For some of their other choices of dimensionless frequency and Mach number our asymptotic expansions do not meet the acceptance criteria. Thus an extensive comparison is not possible. The vortex flow $v_\theta = \gamma/r$ is unstable [11, 4], and therefore it could be expected that the solutions of the wave equation be asymptotic expansions rather than convergent series.

4.2. Radial eigenfunctions for acoustic modes in an annular nozzle. The eigenfunctions are plotted in Figures 2 and 3 for three radial modes. Mode $n = 1$ was excluded from Figure 2 plots by the accuracy criterion. All the eigenmodes in Figures 2 and 3 have zero slopes at the rigid walls; the number of zeros of the amplitude (left-hand side) increases with the order n, and the phases change sign at the zeros. In cases of both corotation (Figure 2) and counterrotation (Figure 3) the nth mode has $n - 1$ zeros. The zeros in the eigenfunctions (3.22) are due to the sinusoidal factor with unit amplitude, because the asymptotic expansions (3.9) are slowly varying monotonic functions in all cases shown in Figures 4 and 5. The asymptotic expansions for outward J_+ and inward J_- propagation in the case of corotation are shown in Figure 4: (i) in the case of outward propagation J_+ there is a decreasing amplitude for $n = 2, 3, 4$, and a phase of opposite sign (positive) for $n = 2, 4$ and $n = 3$ (negative); (ii) in the case of inward propagation J_- there is a small amplitude and phase, the latter being negative only for $n = 3$. In the case of counterrotation (Figure 5) the outward propagating asymptotic expansion J_+ has larger amplitude than the inward propagating asymptotic expansion J_- for $n = 2, 3$, with the exception of $n = 1$, when the amplitudes of $J_\pm$ are comparable. The phases are small and positive in all cases except for $n = 2, 3$ in outward propagation, when they are negative.

The phase corrections introduced by the asymptotic expansions (3.9) in the waveforms (3.22) are small relative to the sinusoidal factor; since the latter has unit modulus, the amplitude is determined by the modulos of the asymptotic expansions (3.9), which are dominant and all-important in this respect. The original eigenfunctions Ψ_n in (3.22) are plotted in Figures 2 and 3 as sets of six panels ($|\Psi_n|$ right-hand side, $\arg(\Psi_n)$ left-hand side) for integral wavenumber $m = 1, -1$. Removing the exponential leading term from the eigenfunctions $\Psi_n^\pm$ in (3.22) leaves the reduced eigenfunctions $J_\pm$ specified by the power series (3.8), (3.9) which are plotted in Figures 4 and 5 using the same reference values. Having shown how the eigenvalues and eigenfunctions can be obtained for the radial acoustic modes in an annular nozzle with uniform axial flow and potential vortex swirl, the main features of the method, the results are now reviewed and discussed.

5. Discussion. The problem considered is that of superposition of a line source of sound and a potential flow due to a coincident line vortex. It is well known that a line acoustic source generates a cylindrical wave, whose amplitude would be infinite on the axis; in reality dissipation limits the amplitude near the axis, but the singularity still determines the asymptotic decay of the amplitude of the cylindrical wave at large distances, like the inverse square root $1/\sqrt{r}$ of radial distance r. Likewise, a potential vortex would lead to an infinite velocity on the axis, which is excluded by matching a vortex core, e.g., in rigid body rotation; however the singularity on the vortex axis determines the asymptotic decay of the tangential velocity, at large distance from the vortex core, as the inverse of the radius $1/r$. The coincidence of a line-source sound and a line-vortex leads to an essential singularity because there are infinite phase oscillations near the axis, and thus the nondissipative solution is valid only in an annulus, whose inner radius is not too small. Despite this the nature of the essential singularities of the wave field, both at the origin and at infinity, still affects the acoustic field at all finite radial distances. The acoustic field can thus be represented at all finite radial distances, either by a linear combination of a pair of solutions $\Psi_\pm$ around the origin $r = 0$ or by a pair of solutions $\Psi^\pm$ around the point at infinity $r = \infty$.

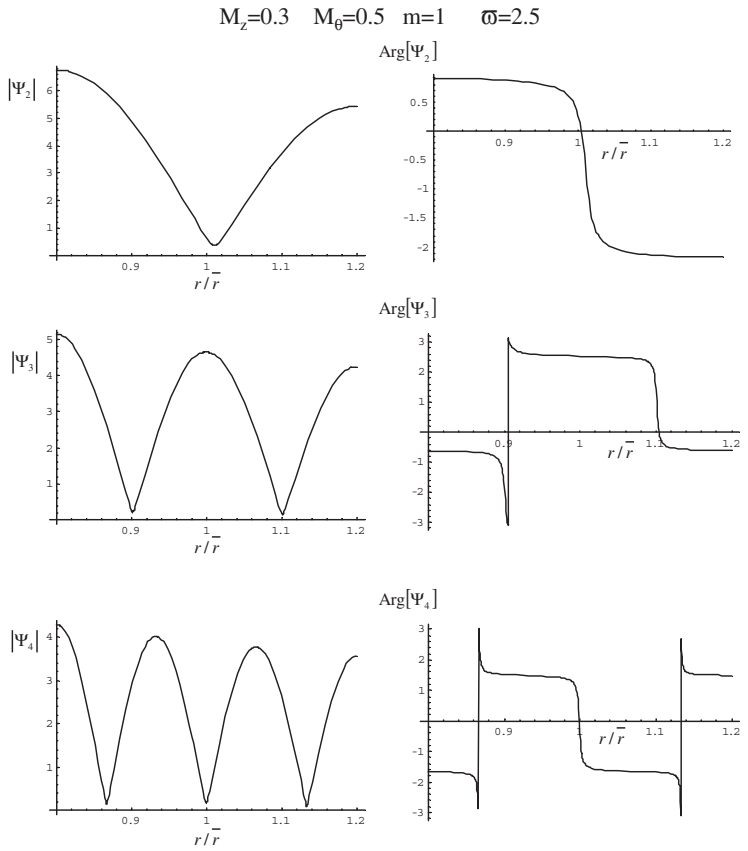

FIG. 2. *Amplitude (left) and phase (right) of the acoustic potential eigenfunctions* Ψ_n *radial modes* $n = 2$ *(top),* $n = 3$ *(middle),* $n = 4$ *(bottom) for integral azimuthal wavenumber* $m = 1$.

Since the wave equation is a differential equation of the second order, it can have only two linearly independent solutions; thus either function in the pair (Ψ_-, Ψ_+) and (Ψ^-, Ψ^+) is a linear combination of the other pair, e.g., $\Psi_- = C_-^- \Psi^- + C_-^+ \Psi^+$. The constant coefficients C_-^-, C_-^+ can be determined by matching the solutions at any two points in their common region of validity. Thus the consideration of the two essential singularities at the origin and infinity allows an exact analytical solution to be obtained, as an alternative to the numerical methods in the literature. The identification of the nature of the singularity is not a purely mathematical problem and is, in fact, guided by physical considerations: (i) the singularity at the origin is due to the integrated Doppler shift associated with the mean flow velocity; (ii) since at large distance the mean flow velocity is small the acoustic field must tend to a cylindrical wave. These simple considerations are used to obtain the exact analytical solutions of the problem of acoustic propagation in a potential vortex flow.

Appendix. Deduction of the convected wave equation for sound in a vortex with constant circulation. Consider a mean flow consisting of a uniform axial velocity U and a rotation with angular velocity $\Omega(r)$, so that the mean flow

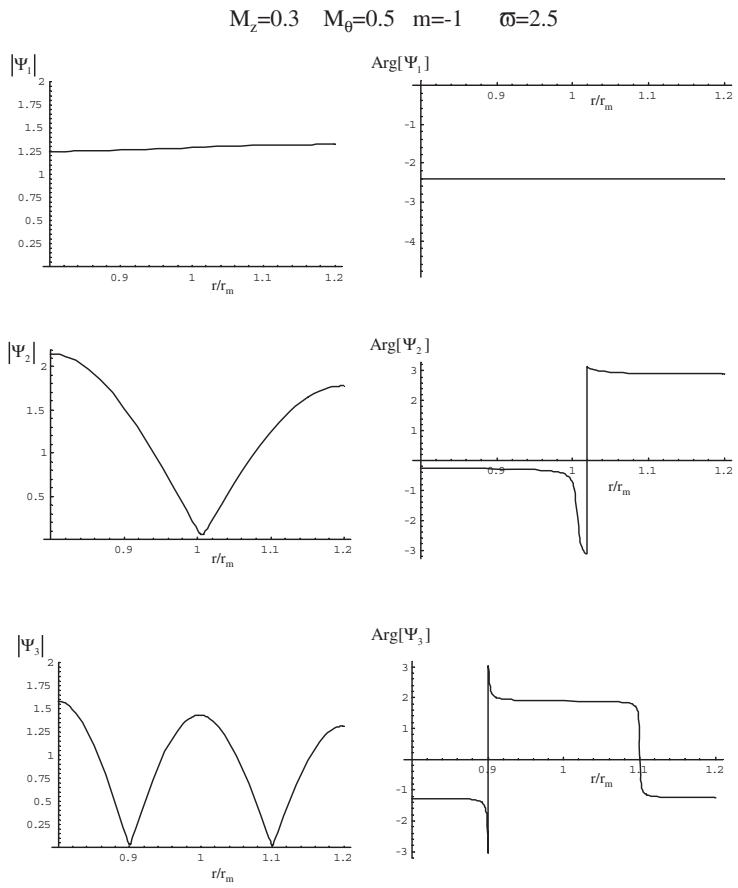

FIG. 3. *Amplitude (left) and phase (right) of the acoustic potential eigenfunctions* Ψ_n *radial modes* $n = 1$ *(top),* $n = 2$ *(middle),* $n = 3$ *(bottom) for integral azimuthal wavenumber* $m = -1$.

velocity is specified in cylindrical coordinates by

$$V_r = 0, \tag{A.1a}$$

$$V_z = U, \tag{A.1b}$$

$$V_\theta = r\,\Omega(r). \tag{A.1c}$$

The curl of the velocity or vorticity of the mean flow

$$\nabla \wedge \overrightarrow{V} = \overrightarrow{e_z}\frac{1}{r}\frac{\partial}{\partial r}\,(rV_\theta) = \overrightarrow{e_z}\frac{1}{r}\frac{d}{dr}\left[r^2\Omega(r)\right] \tag{A.2}$$

lies in the axial direction and vanishes only if the angular velocity varies like the inverse square of the radius (A.3a),

$$\nabla \wedge \overrightarrow{V} = 0: \quad \Omega(r) \sim r^{-2}, \tag{A.3a}$$

$$V_\theta \sim r^{-1}, \tag{A.3b}$$

which implies that the tangential velocity varies inversely with radius (A.3b), and thus the circulation Γ or γ is constant (2.2a), (2.2b). Note that from (A.1a), (A.1b),

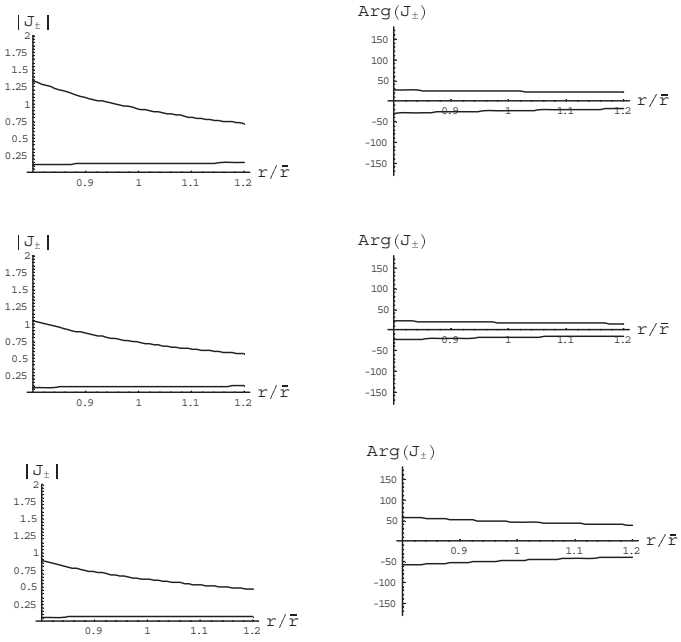

FIG. 4. *Power series outward J_+ and inward J_- for integral wavenumber $m = 1$. Radial mode $n = 2$ (top), $n = 3$ (middle), $n = 4$ (bottom).*

(A.1c) it follows that $\nabla . \overrightarrow{V} = 0$ for arbitrary uniform axial velocity U and angular velocity $\Omega(r)$, so that the mean flow is incompressible; it will be shown that in this case the propagation of sound is specified by the convected wave equation provided that the angular velocity $\Omega \sim r^{-2}$ corresponds to a potential vortex of any strength γ or Γ in (2.2a), (2.2b).

For a homentropic, inviscid flow, the linearized vorticity equation reads

$$\partial \left(\nabla \wedge \overrightarrow{v} \right) / \partial t - \nabla \wedge \left[\overrightarrow{V} \wedge \left(\nabla \wedge \overrightarrow{v} \right) \right] - \nabla \wedge \left[\overrightarrow{v} \wedge \left(\nabla \wedge \overrightarrow{V} \right) \right] = 0, \tag{A.4}$$

where $\overrightarrow{v}$ is the perturbation velocity. If the mean flow is irrotational,

$$\nabla \wedge \overrightarrow{V} = 0 : \quad \partial \left(\nabla \wedge \overrightarrow{v} \right) / \partial t + \nabla \wedge \left[\overrightarrow{V} \wedge \left(\nabla \wedge \overrightarrow{v} \right) \right] = 0, \tag{A.5}$$

a solution is that the velocity perturbation is irrotational (A.6),

$$\nabla \wedge \overrightarrow{v} = 0 \Rightarrow \overrightarrow{v} = \nabla \Phi, \tag{A.6}$$

and thus an acoustic potential exists in nondissipative conditions. Since both mean flow velocity and velocity perturbation are irrotational, the Bernoulli equation for an incompressible or compressible fluid reads (A.7a)

$$p = -\rho \frac{d\Phi}{dt}, \tag{A.7a}$$

$$d/dt \equiv \partial / \partial t + \overrightarrow{V} \cdot \nabla, \tag{A.7b}$$

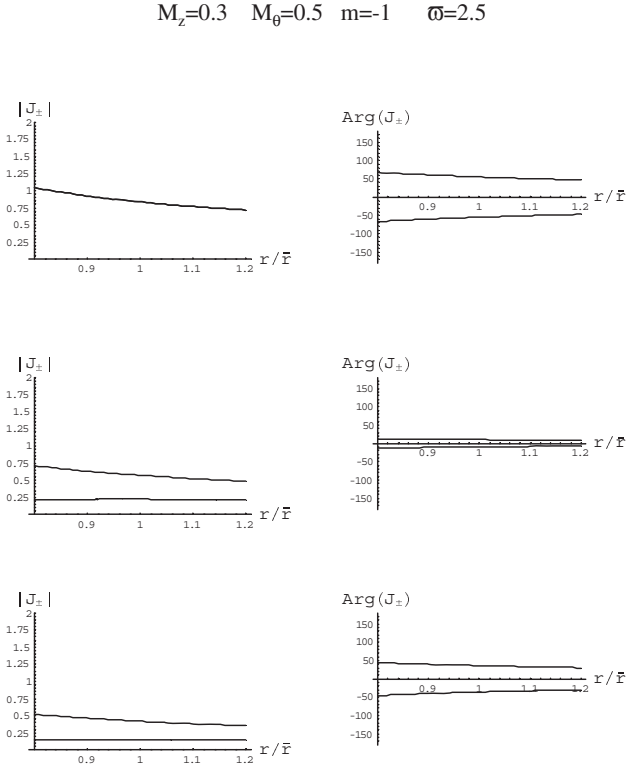

FIG. 5. *Power series outward J_+ and inward J_- for integral wavenumber $m = -1$. Radial mode $n = 1$ (top), $n = 2$ (middle), $n = 3$ (bottom).*

where p is the pressure perturbation, ρ is the constant mean flow density, and the linearized material derivative (A.7b) involves only the mean flow velocity.

The linearized equation of continuity is

$$d\rho'/dt + \rho\nabla \cdot \overrightarrow{v} = 0, \tag{A.8}$$

where the density perturbation is related to the pressure perturbation by the adiabatic condition,

$$dp/dt = c^2 d\rho'/dt, \tag{A.9}$$

where the sound speed is constant for an incompressible mean flow. Substitution of (A.9) in (A.8) yields

$$c^{-2} dp/dt + \rho\nabla \cdot \overrightarrow{v} = 0. \tag{A.10}$$

Substitution of (A.6), (A.7a) leads to the convected wave equation for the acoustic potential,

$$c^{-2} d^2\Phi/dt^2 - \nabla^2\Phi = 0, \tag{A.11}$$

in agreement with (2.3).

The swirl in the mean flow causes a centrifugal force, compensated by a radial pressure gradient,

$$dp_0/dr = \rho \left[V_\theta (r)\right]^2 / r = \rho\gamma^2/r^3; \tag{A.12}$$

thus the pressure in the mean flow is given by

$$p_0(r) = p_\infty + \rho\gamma^2/(2r^2), \tag{A.13}$$

where p_∞ is the pressure at infinity. Denoting by $\overline{\gamma}$ the ratio of specific heats, since the mass density is constant, the sound speed

$$\left[c\,(r)\right]^2 = \overline{\gamma} p(r)/\rho = c_\infty^2 + \overline{\gamma}\gamma^2/(2r^2) \tag{A.14}$$

is approximately constant, and equal to the sound speed at infinity, if

$$c_\infty^2 \equiv \overline{\gamma} p_\infty/\rho = \left[c\,(r)\right]^2 : \quad r^2 \gg \overline{\gamma}\gamma^2/(2c_\infty^2). \tag{A.15}$$

Thus the solution of the wave equation in the text, which assumed constant sound speed, is valid only at some distance from the axis. The singularity of the wave equation at the origin, although outside the physical region of interest, remains important, because it affects the wave field for finite radius, beyond (A.15).

Acknowledgment. The authors are grateful for the comments of the two referees, which helped improve the paper.

ON A REGULARIZATION SCHEME FOR LINEAR OPERATORS IN DISTRIBUTION SPACES WITH AN APPLICATION TO THE SPHERICAL RADON TRANSFORM*

THOMAS SCHUSTER† AND ERIC TODD QUINTO‡

Abstract. This article provides a framework to regularize operator equations of the first kind where the underlying operator is linear and continuous between distribution spaces, the dual spaces of smooth functions. To regularize such a problem, the authors extend Louis' method of approximate inverse from Hilbert spaces to distribution spaces. The idea is to approximate the exact solution in the weak topology by a smooth function, where the smooth function is generated by a mollifier. The resulting regularization scheme consists of the evaluation of the given data at so-called reconstruction kernels which solve the dual operator equation with the mollifier as right-hand side. A nontrivial example of such an operator is given by the spherical Radon transform which maps a function to its mean values over spheres centered on a line or plane. This transform is one of the mathematical models in sonar and radar. After establishing the theory of the approximate inverse for distributions, we apply it to the spherical Radon transform. The article also contains numerical results.

1. Introduction.

We apply the method of approximate inverse to the problem of reconstructing a function from integrals over spheres. Applications of this mathematical problem include sonar when the source and detector are at the same point [15], thermoacoustic tomography for cancer detection [14], seismic testing [23], and radar. The article [5] provides an excellent introduction to synthetic aperture radar and the relation between spherical integrals and radar and sonar.

The approximate inverse was originally developed by Louis as a general method to regularize ill-posed operators on Hilbert spaces [17]. It has been applied to integral equations of the first kind [18] and tomography [27, 28]. However, the inversion formula for our problem is valid not on Hilbert spaces but on distributions. Therefore, we will generalize the approximate inverse to the setting of distributions. It is hoped this generalization will be useful for other inverse problems for which the ambient spaces are not Hilbert spaces.

In seismology or sonar the acoustic wave equation is

$$n^2(x)u_{tt} = \Delta u + \delta(t)\delta(x - a_0), \text{ where } a_0 \in A,$$

and A is a small section of the surface of the earth. After linearization, the determination of $n^2(x)$ from back-scattered data is equivalent to recovering n^2 from integrals

over spheres with centers on A [15]. Knowing n^2 or at least an approximation to n^2 can show boundaries of objects in the water. This linearized model is reasonable from a practical standpoint when the speed of sound in the ambient water is fairly constant. This would occur in water of depth less than 100 feet with fairly constant temperature [3]. Since the speed of sound is constant in shallow water with constant temperature, a pulse travels from a point source, a, making a spherical wavefront. The sound that is reflected back to the source at time t gives the amount reflected back from the sphere centered at a and radius $t/2$ times the speed of sound (assuming no multiple reflections). See [12] for practical information about sonar.

The mathematical problem can be described as trying to recover a function by its integrals over all spheres centered on a given line (in $\mathbb{R}^2$), plane (in $\mathbb{R}^3$), or hyperplane (in $\mathbb{R}^n$).

We first discuss the inversion methods that have been implemented numerically and then the pure mathematical results behind them. Denisjuk has an inversion method based on a transformation that changes the spherical transform into a limited data line transform [9]. He has implemented his method with good results. Klein [13] has developed and numerically tested a promising inversion method based on the ideas of Andersson discussed below. Beltukov proposed a numerical inversion method using a discrete SVD for the sonar transform [4]. He showed that the singular values are fairly flat and then drop off precipitously, which reflects the ill-posedness of the problem.

Our numerical reconstructions are given in section 6 and they show the potential of our method.

Many authors have proven injectivity and inversion methods for this transform. Courant and Hilbert [7, p. 699] proved injectivity for functions that are even about the hyperplane. Fawcett [10] and Andersson [2] provide inversion formulas in $\mathbb{R}^n$. Norton provides an inversion method for the circular transform if the center set is a circle in the plane [22] and if the center set is a line [21], and [23] gives three-dimensional results. Ranges and inversion formulas on a subspace of Schwartz functions are given in [20].

Finch, Patch, and Rakesh [11] develop an explicit inversion formula for recovering a function from spherical integrals when the center set is the boundary of a bounded, connected, open set in $\mathbb{R}^n$. Ramm proves injectivity and inversion theorems in [26]. Fairly general uniqueness theorems are given in [1].

Louis and Quinto [19] develop the microlocal analysis of the transform when A is a real-analytic surface (e.g., an open subset of a hyperplane), and they prove the local transform is injective under fairly general hypotheses. They characterize singularities (jumps, etc.) of the object that are stably visible from the data. Palamodov [24] and Denisjuk [8] continue this microlocal analysis when S is a hyperplane, providing instability results, inversion methods, and range theorems. Beltukov has proven an inversion method for the transform on hyperbolic space.

Section 2 contains the extension of the method of approximate inverse to distribution spaces. In particular, we define what we mean by a mollifier in the distributional sense. In section 3, we apply this concept to the inverse problem of inverting the spherical Radon transform. Section 4 deals with the design of a mollifier for this problem. The computation of the corresponding reconstruction kernel is outlined in section 5. Section 6 provides a couple of numerical tests using synthetic Radon data, and the proof that our functions satisfy the conditions to be mollifiers is in the appendix.

2. Approximate inverse in distribution spaces. In this section we extend the method of approximate inverse as introduced by Louis and Maass [18] and Louis [16, 17] to distribution spaces.

To this end let $\Omega_1 \subset \mathbb{K}^n$, $\Omega_2 \subset \mathbb{K}^m$ be open sets, $\mathbb{K} = \mathbb{R}$ or $\mathbb{K} = \mathbb{C}$, and $V \subset \mathcal{C}^\infty(\Omega_1)$, $W \subset \mathcal{C}^\infty(\Omega_2)$ be subspaces which are closed in their own topology. We denote the dual spaces (continuous linear functionals) for V and W by V', W', respectively. Furthermore we assume $\mathsf{A} : V' \to W'$ to be a linear mapping which is one-to-one. The inverse problem under consideration is as follows. Given a $g \in W'$ lying in the range $\mathsf{A}(V')$ of A, find $f \in V'$ such that

$$\mathsf{A}f = g. \tag{2.1}$$

The concept of approximate inverse involves so called *mollifiers*. The aim is to calculate convolutions of them with the sought solution f rather than to calculate f itself. To extend this concept to distribution spaces V', W' we first define what we mean by a mollifier.

DEFINITION 2.1. *For $\gamma > 0$ let $e_\gamma(\cdot, y) \in V''$ for all $y \in \Omega_1$ such that*

$$\langle \varphi, e_\gamma(\cdot, y)\rangle_{V'\times V''} \in V' \quad \text{for all } \varphi \in V'. \tag{2.2}$$

We call e_γ a mollifier *if and only if*

$$\langle\langle \varphi, e_\gamma(\cdot, y)\rangle_{V'\times V''}, \beta\rangle_{V'\times V} \to \langle \varphi, \beta\rangle_{V'\times V} \tag{2.3}$$

as $\gamma \to 0$ for all $\beta \in V$.

Let $V_1 \subset V'$ and let $V_2 \subset V$. Then, e_γ is a (V_1, V_2)-mollifier if and only if (2.2) *holds for all $\varphi \in V_1$ and* (2.3) *holds for all $\varphi \in V_1$ and $\beta \in V_2$.*

In Definition 2.1 we denote the double dual of V by V'', and $\langle\cdot,\cdot\rangle_{V'\times V}$, $\langle\cdot,\cdot\rangle_{V'\times V''}$ are the corresponding dual pairings.

If e_γ is a mollifier in the sense of Definition 2.3, then for $f \in V'$,

$$f_\gamma(y) := \langle f, e_\gamma(\cdot, y)\rangle_{V'\times V''}, \quad y \in \Omega_1, \tag{2.4}$$

is a distribution in V' which converges to f in the (weak) topology of V'. Because $V \subset V''$, e_γ can be chosen from V. Thus, f_γ is a kind of smooth version of f. If e_γ is a (V_1, V_2)-mollifier, then (2.4) holds for all $f \in V_1$ and convergence holds when tested against all $\beta \in V_2$.

To obtain f_γ from Af we consider the adjoint operator of A. Since $\mathsf{A} : V' \to W'$ is linear, continuous, and one-to-one, it has a linear and continuous adjoint $\mathsf{A}^* : W'' \to V''$ with dense range. Suppose that for each $y \in \Omega_1$ we have an element $\Psi_\gamma(y) \in W''$ satisfying

$$\mathsf{A}^*\Psi_\gamma(y) = e_\gamma(\cdot, y). \tag{2.5}$$

Then, f_γ can be expressed as

$$\begin{aligned} f_\gamma(y) &= \langle f, e_\gamma(\cdot, y)\rangle_{V'\times V''} = \langle f, \mathsf{A}^*\Psi_\gamma(y)\rangle_{V'\times V''} \\ &= \langle \mathsf{A}f, \Psi_\gamma(y)\rangle_{W'\times W''} = \langle g, \Psi_\gamma(y)\rangle_{W'\times W''}, \end{aligned}$$

where $g = \mathsf{A}f$ are the given data. The mapping $S_\gamma : W' \to V'$ defined by

$$S_\gamma g = \langle g, \Psi_\gamma(y)\rangle_{W'\times W''} \tag{2.6}$$

is called the *approximate inverse* of A; the element $\Psi_\gamma(y)$ is the *reconstruction kernel* corresponding to e_γ. Thus, the approximate inverse consists of evaluations of dual pairings of the given data g and the reconstruction kernels $\Psi_\gamma(y)$.

Three main features of the approximate inverse are as follows:

- The reconstruction kernels $\Psi_\gamma(y)$ can be precomputed before the measurement process starts.
- Equation (2.5) is independent of the data g and hence not influenced by noise.
- Invariance properties of A^* help to improve the efficiency of the method, if (2.5) has to be solved only for one single $y \in \Omega_1$. We will demonstrate this in section 3.

REMARK 2.2. *In general, it does not follow that choosing a mollifier e_γ from V results in a reconstruction kernel $\Psi_\gamma(y) \in W$. The key is that* (2.5) *must have a solution in W. If $\mathsf{A}^*(W) \cap V$ is dense in V, then this is more likely. This density condition will happen if the adjoint A^* maps W to $V \subset V''$.*

In practical situations we have only finitely many measurement data available rather than a distribution g. For this reason investigating the semidiscrete operator equation

$$\mathsf{A}_N f = g_N, \tag{2.7}$$

where $\mathsf{A}_N = \Phi_N \mathsf{A}$, $g_N = \Phi_N g \in \mathbb{K}^N$, may fit better to that situation. Here, the observation operator $\Phi_N \in W''$ can be, e.g., point evaluations, if $\mathsf{A}(V')$ consists of continuous, not necessarily integrable, functions. But following the outlines of Rieder and Schuster [27, 28] we formulate the approximate inverse of (2.7) by

$$S_{\gamma,N} g_N(y) = \langle g_N, G_N \, \Phi_N \Psi_\gamma(y) \rangle_{\mathbb{K}^N}, \tag{2.8}$$

where $\Psi_\gamma(y)$ is a reconstruction kernel for (2.1) and $G_N \in \mathbb{K}^{N \times N}$ is a matrix containing the weights of a numerical integration rule which is applied to get the discrete version (2.8) of the dual pairing $\langle \cdot, \cdot \rangle_{W' \times W''}$. Thus, we continue in this article to focus on the continuous problem.

REMARK 2.3. *Compared to the concept of approximate inverse in Hilbert spaces as established by Louis* [16]*, Definition* 2.1 *applies to more general spaces and requires less restrictive assumptions on an element e_γ to be a mollifier. The L^2-theory requires convergence of $f_\gamma(y) = \langle f, e_\gamma(\cdot, y) \rangle \to f(y)$ in L^2 as $\gamma \to 0$, but this distributional setup requires only weak convergence. We should point out that our theory is meant for distribution spaces and does not directly subsume the L^2- or H^s-theory since these Hilbert spaces are not closed subspaces of distribution spaces, the topologies are too different, and their standard duals are not their duals as distribution spaces. It should also be pointed out that this generalization to distributions is necessary for the spherical transform since the transform does not map L^2 into L^2 and the inversion formula we use applies to distributions.*

3. Approximate inverse meets the spherical Radon transform. In this section we apply the method of approximate inverse established in section 2 to the spherical Radon transform. We use the mathematical setup of Andersson's article [2] and formulate some of his main results first.

We start with some notation. Throughout the paper a scalar product $\langle \cdot, \cdot \rangle$ or norm $\| \cdot \|$ without subscript always means the Euclidean scalar product or norm, respectively. We denote the space of all rapidly decreasing, smooth functions by $\mathcal{S}(\mathbb{R}^n)$ and give this space the usual seminorms [29, section 7.3]. This topology turns $\mathcal{S}(\mathbb{R}^n)$ into a Fréchet space. The Fourier transform $\mathsf{F} : \mathcal{S}(\mathbb{R}^n) \to \mathcal{S}(\mathbb{R}^n)$ and its inverse are given by

$$\mathsf{F}f(\xi) = \hat{f}(\xi) = \int_{\mathbb{R}^n} f(x) \, \mathrm{e}^{-\imath \langle \xi, x \rangle} \, dx, \qquad \mathsf{F}^{-1} f(x) = (2\pi)^{-n} \int_{\mathbb{R}^n} f(\xi) \, \mathrm{e}^{\imath \langle x, \xi \rangle} \, d\xi.$$

The dual space $\mathcal{S}'(\mathbb{R}^n)$ of $\mathcal{S}(\mathbb{R}^n)$ is called the set of *tempered distributions*. Each distribution $\varphi \in \mathcal{S}'(\mathbb{R}^n)$ is of finite order [29] and can be written as the derivative of a continuous function of polynomial growth [6].

The Fourier transform gives isomorphisms on $\mathcal{S}(\mathbb{R}^n)$ and on $\mathcal{S}'(\mathbb{R}^n)$. Finally, we often write a vector $x \in \mathbb{R}^{n+1}$ in the form $x = (x', x_{n+1})^\top$, where $x' = (x_1, \dots, x_n)^\top \in \mathbb{R}^n$ contains the first n components of x and x_{n+1} is the last component. We will drop the $\top$ when this correspondence is clear.

The *spherical Radon transform* R assigns a function $f \in \mathcal{S}(\mathbb{R}^{n+1})$ its mean values over all spheres centered about $(z, 0) \in \mathbb{R}^{n+1}$, $z \in \mathbb{R}^n$ with radius $r \geq 0$:

$$\mathsf{R}f(z, r) = \frac{1}{\omega_n} \int_{S^n} f(z + r\,\xi, r\,\eta)\, dS_n(\xi, \eta) = g(z, r). \tag{3.1}$$

Here, ω_n is the area of the n-dimensional sphere $S^n = \{(\xi, \eta) \in \mathbb{R}^{n+1} : \xi \in \mathbb{R}^n, \eta \in \mathbb{R}, \|\xi\|^2 + \eta^2 = 1\}$ and dS_n is the surface measure on S^n.

Obviously $\mathsf{R}f = 0$ holds true for every $f \in \mathcal{S}(\mathbb{R}^{n+1})$ that is odd in the last variable: $f(x', -x_{n+1}) = -f(x', x_{n+1})$. Courant and Hilbert [7] proved that the kernel of R consists exactly of all such functions. This suggests restricting R to the subspace of even functions in the last variable,

$$\mathcal{S}_{\mathrm{e}} := \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1}) = \{f \in \mathcal{S}(\mathbb{R}^{n+1}) : f(x', -x_{n+1}) = f(x', x_{n+1})\}.$$

Unfortunately, even if $f \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})$, the image $\mathsf{R}f$ does not have to be in $L^2(\mathbb{R}^{n+1})$. In fact, if f is the characteristic function of a circle, then $\mathsf{R}f$ has infinite support and does not decrease at infinity. Furthermore, one can show (e.g., using ideas in [19, 24]) that R^{-1} is not continuous in any range of Sobolev norms, at least with data for bounded centers or radii (see Remark 2.3).

Identifying the radius r in (3.1) with the norm $\|w\|$ of a vector $w \in \mathbb{R}^{n+1}$, we introduce the following subspace of $\mathcal{S}(\mathbb{R}^{2n+1})$:

$$\begin{aligned}\mathcal{S}_{\mathrm{r}} &:= \mathcal{S}_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1}) \\ &= \{f \in \mathcal{S}(\mathbb{R}^{2n+1}) : f(z, w) = \check{f}(z, \|w\|) \text{ for a function } \check{f} \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})\}.\end{aligned}$$

Thus, $\mathcal{S}_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1})$ consists of the functions in $\mathcal{S}(\mathbb{R}^{2n+1})$ which are radially symmetric in the last $n+1$ variables. We will often view functions in $\mathcal{S}_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1})$ as functions on $\mathbb{R}^n \times \mathbb{R}$ where we write $f(z, r) = f(z, w)$ with $r = \|w\|$, but when we take the Fourier transform, it will be the Fourier transform on $\mathbb{R}^{2n+1}$.

As mentioned before, we cannot expect that $\mathsf{R}f \in \mathcal{S}_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1})$ even when $f \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})$. But it is easy to show that $\mathsf{R}f \in \mathcal{S}'_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1})$, the dual space of $\mathcal{S}_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1})$. By a density argument we may extend R to domain $\mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})'$. The following theorem summarizes some properties of R considered as mapping between $\mathcal{S}'_{\mathrm{e}}$ and $\mathcal{S}'_{\mathrm{r}}$. The proofs are in [2] or [13].

THEOREM 3.1 (see [2, Theorem 2.1 and Proposition 2.2]). *The spherical Radon transform $\mathsf{R} : \mathcal{S}'_{\mathrm{e}} \to \mathcal{S}'_{\mathrm{r}}$ is a linear, continuous operator which is one-to-one and has range*

$$\mathsf{R}(\mathcal{S}'_{\mathrm{e}}) = \mathcal{S}'_{r,cone} := \left\{ g \in \mathcal{S}'_{\mathrm{r}} : \operatorname{supp} \hat{g} \subset \{(\sigma, \rho) \in \mathbb{R}^n \times [0, \infty) : \rho \geq \|\sigma\|\} \right\} \subset \mathcal{S}'_{\mathrm{r}}. \tag{3.2}$$

If the Fourier transform of $f \in \mathcal{S}'_{\mathrm{e}}$ is equal to an integrable function $\hat{f}(\sigma, \omega)$, then the inversion formula

$$\hat{f}(\sigma, \omega) = c_n\, |\omega|\, (\|\sigma\|^2 + \omega^2)^{(n-1)/2}\, \hat{g}(\sigma, \sqrt{\|\sigma\|^2 + \omega^2}) \tag{3.3}$$

is valid with $c_n = \omega_n / (2\,(2\pi)^n)$ and $g = \mathsf{R}f$.

The adjoint operator $\mathsf{R}^* : \mathcal{S}_{\mathrm{r}} \to \mathcal{S}_{\mathrm{e}}$ *has dense range and is given by*

$$\mathsf{R}^* g(x', x_{n+1}) = \int_{\mathbb{R}^n} g\left(z, \sqrt{\|z - x'\|^2 + x_{n+1}^2}\right) dz; \tag{3.4}$$

its Fourier transform is

$$\mathsf{F}\,\mathsf{R}^* g(\sigma, \rho) = \hat{g}(\sigma, \sqrt{\|\sigma\|^2 + \rho^2}). \tag{3.5}$$

Note that the right-hand side of (3.3) is the Fourier transform of the function g in $\mathbb{R}^{2n+1}$ that is radial in the last $n+1$ variables. The reason to consider R as a map into $\mathcal{S}'_{\mathrm{r}}(\mathbb{R}^n \times \mathbb{R}^{n+1})$ rather than $\mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1})$ is that the relationship between the Fourier transform and spherical transform is easier in these spaces. The constant c_n in (3.3) differs from the corresponding constant in Andersson's article by a factor of $(2\pi)^{-n}$. This inaccuracy was found by Klein [13].

In order to apply the approximate inverse (section 2) to solve the inverse problem of finding a distribution $f \in \mathcal{S}'_{\mathrm{e}}$ satisfying

$$\mathsf{R} f = g \tag{3.6}$$

for a given $g \in \mathcal{S}'_{\mathrm{r}}$ in the range of R, we identify $V = \mathcal{S}_{\mathrm{e}}$, $W = \mathcal{S}_{\mathrm{r}}$, and $\mathsf{A} = \mathsf{R}$. Note that due to Theorem 3.1, R^* maps $\mathcal{S}_{\mathrm{r}}$ into $\mathcal{S}_{\mathrm{e}}$ and we have the situation mentioned in Remark 2.2 and may choose a mollifier $e_\gamma(\cdot, y) \in \mathcal{S}_{\mathrm{e}}$ for every $y \in \mathbb{R}^{n+1}$. Once having a mollifier e_γ at hand, the following extension lemma, whose proof also can be found in [2], helps us to find a solution of the equation

$$\mathsf{R}^* \Psi_\gamma(y) = e_\gamma(\cdot, y), \tag{3.7}$$

which is our reconstruction kernel; see (2.5).

Lemma 3.2 (see [2, Extension Lemma 2.4 and Corollary 2.5]). *There exists a continuous linear mapping* $\mathsf{E} : \mathcal{S}_{\mathrm{e}} \to \mathcal{S}_{\mathrm{r}}$ *such that*

$$\mathsf{R}^*\,\mathsf{E} = id_{\mathcal{S}_{\mathrm{e}}}. \tag{3.8}$$

For $\rho \geq \|\sigma\|$ *the mapping* E *satisfies*

$$\mathsf{F}\,\mathsf{E} f(\sigma, \rho) = \hat{f}(\sigma, \sqrt{\rho^2 - \|\sigma\|^2}). \tag{3.9}$$

If $e_\gamma(\cdot, y) \in \mathcal{S}_{\mathrm{e}}$ is a mollifier in the sense of Definition 2.1, then the reconstruction kernel $\Psi_\gamma(y)$ belonging to e_γ is given by

$$\Psi_\gamma(y) = \mathsf{E} e_\gamma(\cdot, y). \tag{3.10}$$

With the help of (3.8) we easily see that $\Psi_\gamma(y)$ from (3.10) is a solution of (3.7).

From (3.5), it is clear that any continuous E that satisfies (3.9) will satisfy (3.8). We will choose E so that for a mollifier $e_\gamma(\cdot, y)$ in $\mathcal{S}_{\mathrm{e}}$, $\mathsf{E} e_\gamma(\cdot, y)$ is in $\mathcal{S}_{\mathrm{r}}$.

So far we know how to get the reconstruction kernel once we have chosen a mollifier. Theorem 4.1 will provide general criteria that will allow us to construct mollifiers, and with the help of Lemma 3.2 we know how to find a corresponding solution of (3.7). But it would be very time-consuming if we had to solve (3.7) for all reconstruction points y. To this end we prove an invariance property of R^*, Lemma 3.3, which allows us to solve (3.7) only once and to generate *all* reconstruction kernels by applying the invariance to that *one* solution.

For a given $M > 1$, we denote

$$\mathcal{H}^M = \mathcal{H}^M(\mathbb{R}^{n+1}) = \{y = (y', y_{n+1}) \in \mathbb{R}^{n+1} : 1/M < |y_{n+1}|\},$$

$$\mathcal{H}^{M,M} = \mathcal{H}^{M,M}(\mathbb{R}^{n+1}) = \{y = (y', y_{n+1}) \in \mathbb{R}^{n+1} : 1/M < |y_{n+1}| < M\}. \tag{3.11}$$

Furthermore, if $U \subset \mathbb{R}^{n+1}$ is open, we define

$$\begin{aligned}
\mathcal{S}_{\mathrm{e}}(U) &= \{f \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1}) : \operatorname{supp} f \subset U\},\\
\mathcal{S}'_{\mathrm{e}}(U) &= \{f \in \mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1}) : \operatorname{supp} f \subset U\},\\
\mathcal{E}'_{\mathrm{e}}(U) &= \{f \in \mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1}) : \operatorname{supp} f \subset U \text{ is compact}\}.
\end{aligned}$$

Note that, in general, $\mathcal{S}'_{\mathrm{e}}(U)$ is a proper subspace of the dual space of $\mathcal{S}_{\mathrm{e}}(U)$.

We define mappings $\mathsf{S}^y_{\mathrm{e}} : \mathcal{S}_{\mathrm{e}} \to \mathcal{S}_{\mathrm{e}}$ and $\mathsf{S}^y_{\mathrm{r}} : \mathcal{S}_{\mathrm{r}} \to \mathcal{S}_{\mathrm{r}}$ by

$$\mathsf{S}^y_{\mathrm{e}} f(x) = \begin{cases} |y_{n+1}|^{-n-1} f\Big(\frac{x'-y'}{|y_{n+1}|}, \frac{x_{n+1}}{|y_{n+1}|}\Big), & y \in \mathcal{H}^M(\mathbb{R}^{n+1}),\\ 0, & y \notin \mathcal{H}^M(\mathbb{R}^{n+1}), \end{cases} \tag{3.12}$$

$$\mathsf{S}^y_{\mathrm{r}} g(z, r) = \begin{cases} |y_{n+1}|^{-2n-1} g\Big(\frac{z-y'}{|y_{n+1}|}, \frac{r}{|y_{n+1}|}\Big), & y \in \mathcal{H}^M(\mathbb{R}^{n+1}),\\ 0, & y \notin \mathcal{H}^M(\mathbb{R}^{n+1}). \end{cases} \tag{3.13}$$

Because $\mathsf{S}^y_{\mathrm{e}}$ and $\mathsf{S}^y_{\mathrm{r}}$ are compositions of dilations and translations, they are linear and continuous mappings on $\mathcal{S}_{\mathrm{e}}$ and $\mathcal{S}_{\mathrm{r}}$, respectively. Moreover, both operators intertwine with the adjoint R^*. It is also clear that $\mathsf{S}^y_{\mathrm{e}} f$ and $\mathsf{S}^y_{\mathrm{r}} g$ can be discontinuous in y for $y_{n+1} = \pm 1/M$.

LEMMA 3.3. *Let $\mathsf{S}^y_{\mathrm{e}} : \mathcal{S}_{\mathrm{e}} \to \mathcal{S}_{\mathrm{e}}$ and $\mathsf{S}^y_{\mathrm{r}} : \mathcal{S}_{\mathrm{r}} \to \mathcal{S}_{\mathrm{r}}$ be defined as in* (3.12) *and* (3.13)*, respectively. Then,*

$$\mathsf{S}^y_{\mathrm{e}}\, \mathsf{R}^* = \mathsf{R}^*\, \mathsf{S}^y_{\mathrm{r}}. \tag{3.14}$$

Proof. Let $y \in \mathcal{H}^M(\mathbb{R}^{n+1})$. Using representation (3.4) together with the definitions (3.12) and (3.13) gives

$$\begin{aligned}
\mathsf{R}^*\mathsf{S}^y_{\mathrm{r}} g(x', x_{n+1}) &= |y_{n+1}|^{-2n-1} \int_{\mathbb{R}^n} g\Big(\frac{z-y'}{|y_{n+1}|}, |y_{n+1}|^{-1} \sqrt{\|z-x'\|^2 + x_{n+1}^2}\Big)\, dz\\
&= |y_{n+1}|^{-n-1} \int_{\mathbb{R}^n} g\Big(z, \sqrt{\|z - |y_{n+1}|^{-1}(x'-y')\|^2 + |y_{n+1}|^{-2} x_{n+1}^2}\Big)\, dz\\
&= \mathsf{S}^y_{\mathrm{e}}\, \mathsf{R}^* g(x', x_{n+1})
\end{aligned}$$

for all $g \in \mathcal{S}_{\mathrm{r}}$. For $y \notin \mathcal{H}^M(\mathbb{R}^{n+1})$ assertion (3.14) follows immediately, since both sides are equal to zero. ∎

Lemma 3.3 tells us that under certain conditions we may restrict ourselves to solving (3.7) only for *one single* $y \in \mathbb{R}^{n+1}$.

COROLLARY 3.4. *For each $\gamma > 0$ let $\bar{e}_\gamma \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})$ and $e_\gamma(\cdot, y) \in \mathcal{S}_{\mathrm{e}}$ be defined by $\mathsf{S}^y_{\mathrm{e}}$:*

$$e_\gamma(x, y) = \mathsf{S}^y_{\mathrm{e}} \bar{e}_\gamma(x). \tag{3.15}$$

Assume e_γ is a mollifier. Then, we get all corresponding reconstruction kernels by solving

$$\mathsf{R}^* \bar{\Psi}_\gamma = \bar{e}_\gamma \tag{3.16}$$

and setting

$$\Psi_\gamma(y) = \Psi_\gamma(y; z, r) = \mathsf{S}_{\mathrm{r}}^y \bar{\Psi}_\gamma(z, r). \tag{3.17}$$

If e_γ is an $(\mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M}), \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M}))$-mollifier, then

$$S_\gamma \mathsf{R} f := \langle Rf, \Psi_\gamma \rangle_{\mathcal{S}'_{\mathrm{r}} \times \mathcal{S}_{\mathrm{r}}} \to f$$

for $f \in \mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M})$. This means that

$$\langle \langle Rf, \Psi_\gamma \rangle_{\mathcal{S}'_{\mathrm{r}} \times \mathcal{S}_{\mathrm{r}}}, \beta \rangle_{\mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M}) \times \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M})} \to \langle f, \beta \rangle_{\mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M}) \times \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M})}$$

for all $\beta \in \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M})$.

We will construct a general class of $\bar{e}_\gamma$ in section 4 and show that the resulting e_γ satisfy the definition. We now prove the corollary.

Proof. Taking into account (3.17) and (3.14), statement (3.16) is a consequence of

$$e_\gamma(x, y) = \mathsf{S}_{\mathrm{e}}^y \bar{e}_\gamma(x) = \mathsf{S}_{\mathrm{e}}^y \mathsf{R}^* \bar{\Psi}_\gamma(x) = \mathsf{R}^* \mathsf{S}_{\mathrm{r}}^y \bar{\Psi}_\gamma(x) = \mathsf{R}^* \{\Psi_\gamma(y)\}(x). \qquad \square$$

Considering (3.8) a solution of (3.16) is given by $\bar{\Psi}_\gamma = \mathsf{E}\bar{e}_\gamma$.

REMARK 3.5. *Putting*

$$f_\gamma(y) = \langle f, \mathsf{S}_{\mathrm{e}}^y \bar{e}_\gamma \rangle_{\mathcal{S}'_{\mathrm{e}} \times \mathcal{S}_{\mathrm{e}}}$$

it becomes clear from (3.12) *that* $\operatorname{supp} f_\gamma \subset \mathcal{H}^M(\mathbb{R}^{n+1})$. *Thus, using the invariance $\mathsf{S}_{\mathrm{e}}^y$ to generate mollifiers, we can only recover objects $f \in \mathcal{S}'_{\mathrm{e}}$ with support in $\mathcal{H}^M(\mathbb{R}^{n+1})$. But this is not a restriction in applications, e.g., in sonar or radar, since the support of any object to be reconstructed is always a positive distance from the line $y_{n+1} = 0$. For technical reasons, our mollifiers satisfy the convergence assumption* (2.3) *for bounded $|y_{n+1}|$, so we will reconstruct f_γ only on $\mathcal{H}^M$ or $\mathcal{H}^{M,M}$. This is not a serious practical restriction since M can be chosen arbitrarily large. Therefore, we will construct $(\mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M}), \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M}))$-mollifiers.*

To use the method of approximate inverse for inverting R, we

- choose a mollifier e_γ fulfilling the conditions of Theorem 4.1 defined by $\mathsf{S}_{\mathrm{e}}^y$: $e_\gamma(x, y) = \mathsf{S}_{\mathrm{e}}^y \bar{e}_\gamma(x)$ and calculate $\bar{\Psi}_\gamma = \mathsf{E}\bar{e}_\gamma$;
- compute the approximate inverse of R as

$$S_\gamma g(y) = \langle g, \mathsf{S}_{\mathrm{r}}^y \bar{\Psi}_\gamma \rangle_{\mathcal{S}'_{\mathrm{r}} \times \mathcal{S}_{\mathrm{r}}}, \tag{3.18}$$

  where $g = \mathsf{R}f$ are the given data.

Considering (3.9), we have only an explicit representation for $\mathsf{F}\,\mathsf{E}\bar{e}_\gamma$ when $\rho \geq \|\sigma\|$. We want to obtain $\bar{\Psi}_\gamma$ rather than its Fourier transform because a discrete Fourier transform would extend the data, which are given in applications only on a bounded domain, periodically and could cause large artifacts. Furthermore even in the two-dimensional case ($n = 1$) we would have to compute a three-dimensional Fourier transform of the data. Therefore, we need an explicit representation of $\mathsf{F}\,\mathsf{E}\bar{e}_\gamma$ for *all* $\rho \geq 0$ and $\sigma \in \mathbb{R}^n$. (Andersson uses an extension method from Stein [30] which is fairly arbitrary and not explicit for calculations.) We will present an idea in section 4 that will circumvent these difficulties.

4. Design of a mollifier for R. Due to Corollary 3.4 we let the mollifier e_γ be defined $e_\gamma(x,y) = \mathsf{S}_{\mathrm{e}}^y \bar{e}_\gamma(x)$ as in (3.12).

Since we will need the Fourier transform of $\bar{e}_\gamma$ to compute the reconstruction kernel (see (3.9)) it is appropriate to choose $\bar{e}_\gamma$ as a tensor product

$$\bar{e}_\gamma(x) = e_\gamma^1(x') \otimes e_\gamma^2(x_{n+1}), \tag{4.1}$$

where $e_\gamma^1 \in \mathcal{S}(\mathbb{R}^n)$, $e_\gamma^2 \in \mathcal{S}(\mathbb{R})$, e_γ^2 even. Defining $e_\gamma(x,y)$ as in (3.15), (4.1) it is obvious that $e_\gamma(\cdot, y) \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})$ for all $y \in \mathbb{R}^{n+1}$.

In view of (3.9) and Theorem 4.1 below we want e_γ and $\bar{e}_\gamma$ to have the following properties:

1. $\int_{\mathbb{R}^n} e_\gamma^1(z)\,dz = 1 = \int_{\mathbb{R}} e_\gamma^2(t)\,dt$.
2. $\mathsf{F} e_\gamma^1$ is easy to calculate.
3. $\mathsf{F} e_\gamma^2(\sqrt{\xi})$ has a nice extension for $\xi < 0$.

By "nice" in 3, we mean that the extension is explicitly known since we do not want to apply an extension lemma [30] like Andersson did it in his article [2]. Moreover we need an explicit expression for that extension to calculate the corresponding reconstruction kernel.

Now we get more explicit with our choices for e_γ^1 and e_γ^2. We define

$$e_\gamma^1(x') = \gamma^{-n}\, e^1(x'/\gamma) \quad \text{for } e^1(x') \in \mathcal{S}(\mathbb{R}^n), \quad \int_{\mathbb{R}^n} e^1(z)\,dz = 1. \tag{4.2}$$

We have to be careful with respect to the choice of e_γ^2. Let $F \in \mathcal{S}_e(\mathbb{R})$ have mean value 1. To guarantee the mollifier property, because of the dilation by y_{n+1} in $\mathsf{S}_{\mathrm{e}}^y$ (see (3.12) and (3.15)), we define

$$e_\gamma^2(q) = \frac{1}{2\,\gamma}\left\{F\left(\frac{q+1}{\gamma}\right) + F\left(\frac{q-1}{\gamma}\right)\right\} \quad \text{for } F \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}), \quad \int_{\mathbb{R}} F(t)\,dt = 1. \tag{4.3}$$

We will show that property 3 is fulfilled when we define F as in (4.5) below.

The following key theorem asserts that these properties guarantee e_γ is a mollifier. The proof will be given in the appendix.

THEOREM 4.1. *Let $M > 1$ and let functions e_γ^1 and e_γ^2 be given by* (4.2) *and* (4.3). *Then, e_γ defined by* (3.15) *and* (4.1) *is an $(\mathcal{E}_{\mathrm{e}}'(\mathcal{H}^{M,M}), \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M}))$-mollifier.*

We will now construct specific functions e_γ^1 and e_γ^2 that we will use in our algorithm. We define

$$e_\gamma^1(x') = \gamma^{-n} e^1(x'/\gamma), \quad e^1(x') = (2\,\pi)^{-n/2}\,\exp(-\|x'\|^2/2), \quad x' \in \mathbb{R}^n, \tag{4.4}$$

which obviously is a function in $\mathcal{S}(\mathbb{R}^n)$ with mean value 1, since $\int_{\mathbb{R}^n} e_\gamma^1(x')\,dx' = \hat{e}_\gamma^1(0) = 1$.

We have to be more careful in the choice of e_γ^2. The desirable extension property 3 for e_γ^2 is fulfilled if there exists a function $g \in \mathcal{S}(\mathbb{R})$ satisfying

$$\mathsf{F} e_\gamma^2(\sqrt{\xi}) = g(\xi^2). \tag{4.5}$$

The function

$$F(q) := 2\,\mathsf{F}^{-1}\{\exp(-|\xi|^4)\}(2\,q) \tag{4.6}$$

satisfies (4.5) with $g(\xi) = \exp(-|\xi|^2)$. So, F is an even function in $\mathcal{S}(\mathbb{R})$ with mean value equal to 1. We define e_γ^2 using (4.3) and the specific function (4.6).

REMARK 4.2. *Since the inverse Fourier transform of* $\exp(-|\xi|^4)$ *does not decrease as rapidly as* $\exp(-|\xi|^2)$ *near* $\xi = 0$*, we introduced the dilation factor* 2 *in* (4.6) *to make the decay behavior the same in both variables (see also Figure* 1*).*

COROLLARY 4.3. *Let* $M > 1$*. The function* $e_\gamma = e^1_\gamma \otimes e^2_\gamma$ *defined using* (4.4) *and* (4.3) *with* F *defined by* (4.6) *satisfies the assumptions of Theorem* 4.1 *and therefore is an* $(\mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M}), \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M}))$*-mollifier.*

Proof. All we need to do is observe that our specific e^1 and F satisfy $\int_{\mathbb{R}^n} e^1(z)\,dz = 1 = \int_{\mathbb{R}} F(t)\,dt$ and that e_γ is constructed according to Theorem 4.1. ∎

Figure 1 displays $\bar{e}_\gamma$ in the case of $n = 1$, $\gamma = 0.06$. It has its peak in $(0, 1)$.

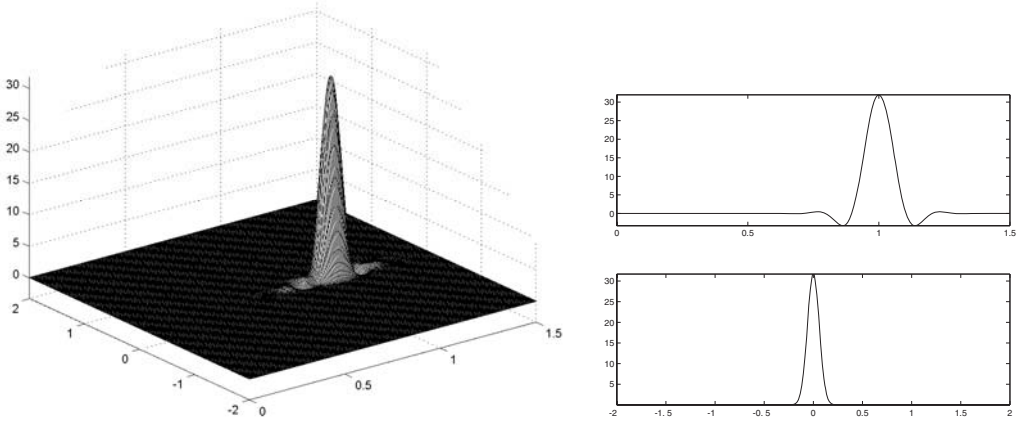

FIG. 1. *Plot of* $e_\gamma(x_1, x_2)$ *in the two-dimensional case* ($n = 1$) *for* $\gamma = 0.06$ *(left picture). On the right-hand side is the graph of* e^1_γ *(bottom) and* e^2_γ *(top). The width of the peak is about* 0.5 *units in each case (note the different scales), which is achieved by the dilation in* (4.6)*.*

5. Computation of the reconstruction kernel $\bar{\Psi}_\gamma$. Throughout this section we assume $\bar{e}_\gamma$ to be given as in (4.1), (4.2), (4.3), (4.4), and (4.6) and $e_\gamma(x, y) = \mathsf{S}^y_{\mathrm{e}}\bar{e}_\gamma(x)$. Our aim is to compute $\bar{\Psi}_\gamma = \mathsf{E}\bar{e}_\gamma$.

From Lemma 3.2 we know that

$$\mathsf{F}\bar{\Psi}_\gamma(\sigma, \rho) = \mathsf{F}\,\mathsf{E}\bar{e}_\gamma = \mathsf{F}\bar{e}_\gamma(\sigma, \sqrt{\rho^2 - \|\sigma\|^2}) \quad \text{if } \rho \geq \|\sigma\|, \tag{5.1}$$

where $\rho \geq 0$, $\sigma \in \mathbb{R}^n$. Thus, we have to compute the Fourier transform of $\bar{e}_\gamma$ at first.

LEMMA 5.1. *We have that*

$$\mathsf{F}\bar{e}_\gamma(\sigma, \rho) = \hat{e}^1_\gamma(\sigma)\,\hat{e}^2_\gamma(\rho) = \cos(\rho)\,\mathrm{e}^{-\gamma^2\|\sigma\|^2/2}\,\mathrm{e}^{-\gamma^4\rho^4/16}, \tag{5.2}$$

where $\sigma \in \mathbb{R}^n$*,* $\rho \in \mathbb{R}$*.*

Proof. The proof follows from a straightforward calculation using the definition of $\bar{e}_\gamma$. ∎

So far by Lemma 5.1 we have the representation

$$\mathsf{F}\bar{\Psi}_\gamma(\sigma, \rho) = \cos(\sqrt{\rho^2 - \|\sigma\|^2})\,\mathrm{e}^{-\gamma^2\|\sigma\|^2/2}\,\mathrm{e}^{-\gamma^4(\rho^2 - \|\sigma\|^2)^2/16} \quad \text{if } \rho \geq \|\sigma\|. \tag{5.3}$$

To get $\bar{\Psi}_\gamma$ for *all* $\rho \geq 0$ and $\sigma \in \mathbb{R}^n$, we have to find an extension of $\cos\sqrt{\xi}$ for $\xi < 0$ that turns (5.3) into a function in $\mathcal{S}_{\mathrm{r}}$. The natural extension involves $\cosh\sqrt{-\xi}$ for $\xi < 0$. As noted in section 3, we can extend $\bar{\Psi}_\gamma$ arbitrarily, and for computational

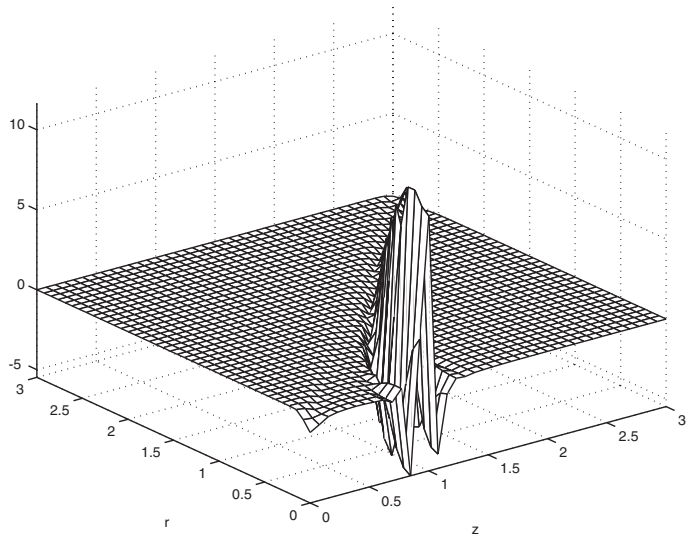

FIG. 2. *The reconstruction kernel* $\bar{\Psi}_\gamma$ *given as in* (5.6) *for* $\gamma = 0.06$ *and* $n = 1$. *The integrals have been computed using numerical integration.*

reasons, we will cut this function off away from $\xi = 0$. Let $\chi \in \mathcal{C}^\infty(\mathbb{R})$ be zero on $(-\infty, -1]$ and 1 on $[0, \infty)$ and let

$$G(\xi) = \begin{cases} \cos\sqrt{\xi}, & \xi \geq 0, \\ \chi(\xi)\,\cosh(\sqrt{|\xi|}), & \xi < 0. \end{cases} \tag{5.4}$$

The Fourier transform $\mathsf{F}\bar{\Psi}_\gamma$ is given by

$$\mathsf{F}\bar{\Psi}_\gamma(\sigma, \rho) = G(\rho^2 - \|\sigma\|^2)\,\mathrm{e}^{-\gamma^2\,\|\sigma\|^2/2}\,\mathrm{e}^{-\gamma^4\,(\rho^2 - \|\sigma\|^2)^2/16} \tag{5.5}$$

and we get $\bar{\Psi}_\gamma$ by applying the inverse Fourier transform.

LEMMA 5.2. *Let* $\bar{e}_\gamma$ *be given as in* (4.1), (4.2), (4.3), (4.4), *and* (4.6). *Then, a solution of* $\mathsf{R}^*\bar{\Psi}_\gamma = \bar{e}_\gamma$ *is represented by*

$$\begin{aligned} \bar{\Psi}_\gamma(z, r) = 2^n\,(2\,\pi)^{-\frac{3}{2}\,n - \frac{1}{2}} \int_{\mathbb{R}^n_+} \int_0^\infty \Big\{ & G(\rho^2 - \|\sigma\|^2)\,\mathrm{e}^{-\gamma^2\,(\frac{\|\sigma\|^2}{2} + \frac{\gamma^2}{16}\,(\rho^2 - \|\sigma\|^2)^2)} \\ & \cdot \rho^{(n+1)/2}\,\mathcal{J}_{(n-1)/2}(\rho\,r)\,\cos(\langle \sigma, z\rangle) \Big\}\,d\rho\,d\sigma. \end{aligned} \tag{5.6}$$

Here, $\mathbb{R}^n_+ = \{x = (x_1, \ldots, x_n)^\top \in \mathbb{R}^n : x_j \geq 0\}$, $\mathcal{J}_\nu$ *is the Bessel function of first kind of order* ν, *and* G *is given as in* (5.4).

Proof. The proof follows by a simple application of an inverse Fourier transform of dimension $2n + 1$ to (5.5) in which one uses Lemma 5.1, spherical coordinates, and the identity

$$\int_{S^n} \mathrm{e}^{\imath\,\rho\,r\,\langle \omega, \theta\rangle}\,d\omega = (2\,\pi)^{(n+1)/2}\,(\rho\,r)^{(1-n)/2}\,\mathcal{J}_{(n-1)/2}(\rho\,r),$$

which can be found, e.g., in [10]. ∎

Figure 2 displays a picture of $\bar{\Psi}_\gamma$ for $\gamma = 0.06$ and $n = 1$ corresponding to the two-dimensional case. The integrals in (5.6) have been computed using numerical integration, where the integrals were cut off when the absolute value of the integrand was less then 10^{-12}. The reconstruction kernel in Figure 2 belongs to the mollifier shown in Figure 1 and has its absolute maximum point in $(0, 1)$, just as the mollifier $\bar{e}_\gamma$.

6. Implementation and numerical results. We now have all the ingredients to implement the approximate inverse for the spherical Radon transform. We present results for the two-dimensional case ($n = 1$). The reconstruction kernel $\bar{\Psi}_\gamma$ (5.6) belonging to the mollifier (4.1), (4.2), (4.3) has the representation

(6.1)
$$\bar{\Psi}_\gamma(z,r) = \frac{2}{(2\,\pi)^2}\left\{\int_0^\infty\!\!\int_0^\infty \tau\,\mathcal{J}_0(\sqrt{\tau^2+\sigma^2}\,r)\,\cos\tau\,\mathrm{e}^{-\gamma^2\,(\frac{\sigma^2}{2}+\frac{\gamma^2\,\tau^4}{16})}\,\cos(\sigma\,z)\,d\tau\,d\sigma \right.$$
$$\left. + \int_0^\infty\!\!\int_0^\sigma \tau\,\mathcal{J}_0(\sqrt{\sigma^2-\tau^2}\,r)\,\chi(-\tau^2)\,\cosh\tau\,\mathrm{e}^{-\gamma^2\,(\frac{\sigma^2}{2}+\frac{\gamma^2\,\tau^4}{16})}\,\cos(\sigma\,z)\,d\tau\,d\sigma\right\},$$

where we used the substitutions $\rho = \sqrt{\tau^2+\sigma^2}$ and $\rho = \sqrt{\sigma^2-\tau^2}$, respectively.

Throughout this section we suppose that f has compact support in $\mathcal{H}^{M,M}(\mathbb{R}^2)$ for a certain $M > 1$. The method of approximate inverse used to solve the problem $\mathsf{R}f = g$ for $n = 1$ has the form $S_\gamma \mathsf{R}f(y) = \langle \mathsf{R}f, \mathsf{S}_{\mathrm{r}}^y \bar{\Psi}_\gamma\rangle_{\mathcal{S}'_{\mathrm{r}}\times\mathcal{S}_{\mathrm{r}}}$.

We now adjust the algorithm to practical situations where only finitely many data on a bounded domain are available. Assume that equally spaced centers $z_k \in [\lambda, \Lambda]$, $\lambda < \Lambda$, $k = 0, \ldots, P$, and equally spaced radii $r_m \in [0, R]$, $R > 0$, $m = 0, \ldots, Q$, are given, so we have $N = (P+1)\,(Q+1)$ spherical averages of f at hand. More explicitly, instead of $\mathsf{R}f$ itself we have only the vector $\phi_N\,\mathsf{R}f \in \mathbb{R}^N$ as data, where $\phi_N : \mathcal{C}(\mathbb{R}\times[0,\infty)) \to \mathbb{R}^N$ are the point evaluations

$$(\phi_N v)_{k,m} = v(z_k, r_m), \quad 0 \le k \le P, \quad 0 \le m \le Q.$$

Remark 6.1. *The observation operator ϕ_N, which contains all information about the measurement geometry, is well defined only if the function to be evaluated is continuous. Since $\mathsf{R}f \in \mathcal{S}'_{\mathrm{r}}$ we have to postulate that $\mathsf{R}f$ is a continuous, but not necessarily integrable, function in order to apply ϕ_N properly. Thus, we assume $\mathsf{R}f \in \mathcal{C}(\mathbb{R}\times[0,\infty))$ which is not a large restriction since R smooths of order $n/2$ in Sobolev scales.*

To recover f from $\phi_N \mathsf{R}f$ we apply the trapezoidal sum corresponding to the nodes $\{z_k\}, \{r_m\}$ and obtain

$$\begin{aligned} S_{\gamma,N}\,\phi_N\,\mathsf{R}f(y) &= \langle \phi_N\,\mathsf{R}f, Q_N\,\phi_N\,\mathsf{S}_{\mathrm{r}}^y\bar{\Psi}_\gamma\rangle_{\mathbb{R}^N} \\ &= \frac{2\,\pi}{|y_2|^3}\,h_z\,h_r \sum_{k=0}^{P}\sum_{m=0}^{Q} r_m\,\bar{\Psi}_\gamma\!\left(\frac{z_k - y_1}{|y_2|}, \frac{r_m}{|y_2|}\right)\mathsf{R}f(z_k, r_m) \end{aligned} \tag{6.2}$$

for $y \in \mathcal{H}^M(\mathbb{R}^2)$, $Q_N = h_z\,h_r\,I_{N,N}$ (compare (2.8)).

Formula (6.2) was applied to get the reconstructions in Figures 3 and 4.

As mentioned in section 5 we compute $\bar{\Psi}_\gamma$ by applying numerical integration to (6.1) choosing convenient integration boundaries. Moreover we determine $\bar{\Psi}_\gamma(z,r)$ on the square $[0, 15]^2$ on an equidistant mesh grid consisting of 128×128 grid points. Since the kernel is rapidly decreasing, the absolute value of $\bar{\Psi}_\gamma$ outside the square

$[0,15]^2$ is rather small, so we can extend the kernel by 0 there. Using the symmetry $\bar{\Psi}_\gamma(z,r) = \bar{\Psi}_\gamma(-z,r)$ and linear interpolation we get $\bar{\Psi}_\gamma(z,r)$ for every $z \in \mathbb{R}$, $r \geq 0$.

To check the performance of the above algorithm we implemented it to reconstruct several objects. All reconstructions were computed for $(y_1, y_2) \in [0,7] \times [1,8]$ using an equidistant mesh grid with 64×64 grid points. The objects are assumed to have their support in $\mathcal{H}^1(\mathbb{R}^2)$. The data are given on equally spaced points with $\lambda = -36$, $\Lambda = 36$, $P = 384$, $R = 50$, and $Q = 256$. *Note that in all pictures the y_2-axis is the horizontal one, whereas the y_1-axis (the sonar sources, circle centers) is the vertical one.*

First, we recovered the characteristic function of a circle centered at $(4,4)$ with radius 1 and density 2. Figure 3 shows the original circle as well as the approximate inverse $S_{\gamma,N}\phi_N \mathsf{R}f$. We used the reconstruction kernel (6.1) with $\gamma = 0.06$ which was precomputed for $(z,r) \in [0,15]^2$ using 128×128 equally distributed grid points.

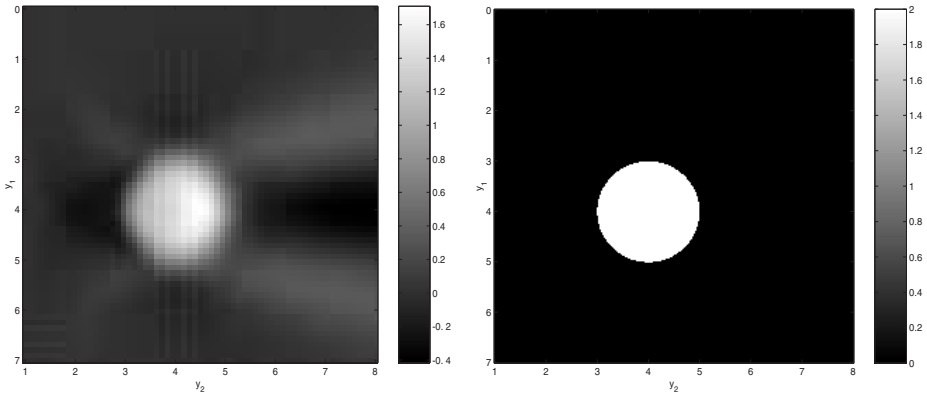

FIG. 3. *Reconstruction of the characteristic function of a circle (left) and original object function (right),* $\gamma = 0.06$.

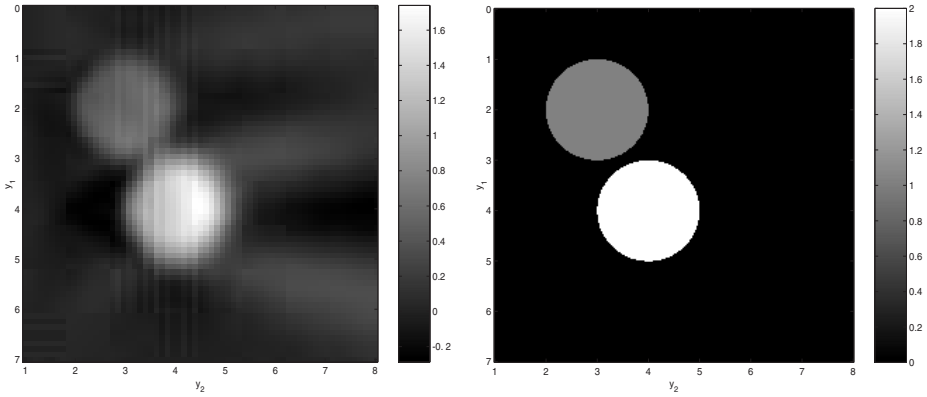

FIG. 4. *Reconstruction of two circles f_1 and f_2 (left) and original object function (right),* $\gamma = 0.06$.

Second, we applied the algorithm to the sum of the function in Figure 3 and the characteristic function of a disk centered at $(2,3)$ and of radius 1. The reconstruction as well as the original object can be seen in Figure 4; the parameters are the same as

in Figure 3.

These tests show that the method of approximate inverse works fine, and the reconstructions are comparable to those in [9]. Some blurring in the reconstructions is probably caused by the numerical calculation of the reconstruction kernel and truncation error. However, some ill-posedness is inherent in the problem.

REMARK 6.2. *Some of the fuzzy reconstruction boundaries in Figures* 3 *and* 4 *are intrinsic to the problem. As shown in* [19, 24]*, the object boundaries that are most difficult to reconstruct are those not tangent to circles in the data set. This means that horizontal boundaries in Figures* 3 *and* 4 *will be intrinsically hardest to reconstruct since the set of circle centers is the vertical axis. Since more-or-less vertical boundaries are tangent to spheres in the data set, the microlocal analysis predicts they will be easiest to reconstruct. This is analogous to limited angle X-ray tomography in which some boundaries are "invisible" in the data* [25].

7. Conclusions. In this paper we extended the method of approximate inverse, a regularization scheme for operators between Hilbert spaces, to distribution spaces. We applied the method to the inversion problem of the spherical Radon transform which appears in sonar as well as in radar. This algorithm allows one to solve inverse problems for linear operators which are not bounded mappings between Hilbert or Banach spaces.

We presented a representation for a reconstruction kernel $\bar{\Psi}_\gamma$ in arbitrary dimensions (5.6). Unfortunately, in the three-dimensional case ($n = 2$) numerical integration to get $\bar{\Psi}_\gamma$ is too time consuming and we are working on other ways to get the reconstruction kernel. In this case a modified inversion formula presented by Klein [13] might be useful. This inversion formula could also be helpful to obtain an *analytic* expression for the reconstruction kernel $\bar{\Psi}_\gamma$, which would also increase the accuracy of the reconstructed solution. This and stability and error analysis (as for Hilbert space in [27]) will be part of future research.

Appendix A. Proof of Theorem 4.1. Let $M > 1$. We recall the general construction of e_γ given in section 4. Let $e_\gamma(x, y) = \mathsf{S}_{\mathrm{e}}^y \bar{e}_\gamma(x)$, where

$$\bar{e}_\gamma(x) = \mathrm{e}_\gamma^1(x') \otimes \mathrm{e}_\gamma^2(x_{n+1}), \tag{A.1}$$

$$e_\gamma^1(x') = \gamma^{-n} e^1(x'/\gamma), \quad \int_{\mathbb{R}^n} e^1(x')\,dx' = 1, \quad e^1 \in \mathcal{S}(\mathbb{R}^n), \tag{A.2}$$

$$e_\gamma^2(q) = \frac{1}{2\,\gamma}\left\{F\left(\frac{q+1}{\gamma}\right) + F\left(\frac{q-1}{\gamma}\right)\right\} \quad \text{for } F \in \mathcal{S}_{\mathrm{e}}(\mathbb{R}), \quad \int_{\mathbb{R}} F(t)\,dt = 1. \tag{A.3}$$

We will use several steps to show that e_γ is an $(\mathcal{E}'_{\mathrm{e}}(\mathcal{H}^{M,M}), \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M}))$-mollifier. First, we will prove (2.2) using Lemma A.1. Then, we will prove a distributional Fubini's theorem, Lemma A.2, and finally, we will prove the convergence result (2.3) which concludes the proof of Theorem 4.1.

LEMMA A.1. *Let $\gamma > 0$ be fixed, e_γ be defined by* (A.1)–(A.3)*, and $\varphi \in \mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1})$. Then, the function $\langle \varphi, e_\gamma(\cdot, y)\rangle_{\mathcal{S}'_{\mathrm{e}} \times \mathcal{S}_{\mathrm{e}}}$ is a continuous function of polynomial growth for $y \in \mathcal{H}^M$ and is 0 for $y \notin \mathcal{H}^M$. Therefore $\langle \varphi, e_\gamma(\cdot, y)\rangle_{\mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1}) \times \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})} \in \mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1})$.*

Proof. First, using the definition of e_γ, one proves the map $y \mapsto e_\gamma(\cdot, y)$ is a continuous map from $\mathcal{H}^M$ to $\mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})$. Therefore, $\langle \varphi, e_\gamma(\cdot, y)\rangle_{\mathcal{S}'_{\mathrm{e}} \times \mathcal{S}_{\mathrm{e}}}$ is continuous for $y \in \mathcal{H}^M$ and is 0 if not.

We simplify the problem by reducing the calculation to integrals of functions. By [6] there exists a multi-index $\alpha \in \mathbb{N}_0^{n+1}$ and a continuous function P_φ of polynomial

growth such that

$$\varphi = D^\alpha P_\varphi, \tag{A.4}$$

where $\alpha = (\alpha', \alpha_{n+1})$ and $D^\alpha = \partial_{x_1}^{\alpha_1} \cdots \partial_{x_{n+1}}^{\alpha_{n+1}}$.

For $y \in \mathcal{H}^M$, we obtain

(A.5)

$$\begin{aligned}\varphi_\gamma(y) &:= \langle \varphi, e_\gamma(\cdot, y)\rangle_{\mathcal{S}_e' \times \mathcal{S}_e} = (-1)^{|\alpha|} \int_{\mathbb{R}^{n+1}} P_\varphi(x)\, D_x^\alpha e_\gamma(x, y)\, dx \\ &= \frac{1}{2(-\gamma\,|y_{n+1}|)^{|\alpha|}} \int_{\mathbb{R}^n} \int_{\mathbb{R}} \Big[P_\varphi(\gamma\,|y_{n+1}|\, z' + y', \gamma\,|y_{n+1}|\, z_{n+1} + |y_{n+1}|) \\ &\quad + P_\varphi(\gamma\,|y_{n+1}|\, z' + y', \gamma\,|y_{n+1}|\, z_{n+1} - |y_{n+1}|) \Big] D^{\alpha'} e^1(z')\, D^{\alpha_{n+1}} F(z_{n+1})\, dz_{n+1}\, dz',\end{aligned}$$

where we used the substitutions $z' = (x' - y')/(\gamma\,|y_{n+1}|)$ and $z_{n+1} = (x_{n+1}/|y_{n+1}| \pm 1)/\gamma$, as well as the symmetry of F. Since P_φ is polynomially increasing, there exists a constant $C_\varphi > 0$ and a $\kappa > 0$ such that

$$|P_\varphi(x)| \le C_\varphi\,(1 + \|x\|^2)^\kappa \quad \text{as } \|x\| \to \infty, \quad x \in \mathbb{R}^{n+1}. \tag{A.6}$$

Using (A.6) and some simple estimates, we show

$$\Big| P_\varphi\big(\gamma\,|y_{n+1}|\, z' + y', \gamma\,|y_{n+1}|\, z_{n+1} \pm |y_{n+1}|\big) \Big| \le C_\varphi\, 2^\kappa\, (1 + \gamma^2\,|y_{n+1}|^2\,\|z\|^2)^\kappa\, (1 + \|y\|^2)^\kappa.$$

This allows us to estimate (A.5) as

$$|\varphi_\gamma(y)| \le C_\varphi\, 2^\kappa\, q_\gamma\, (\gamma\,|y_{n+1}|)^{-|\alpha|}\, (1 + \|y\|^2)^\kappa, \qquad y \in \mathcal{H}^M,$$

with $q_\gamma := \int_{\mathbb{R}^n} \int_{\mathbb{R}} (1 + \gamma^2\,|y_{n+1}|^2\,\|z\|^2)^\kappa\, D^{\alpha'} e^1(z')\, D^{\alpha_{n+1}} F(z_{n+1})\, dz_{n+1}\, dz' < \infty$, which finishes the proof. ∎

Our next task is to prove a distributional Fubini's theorem that will allow us to examine the pairing $\langle e_\gamma(x, \cdot), \beta\rangle$ to show the convergence result (2.3) in Definition 2.1.

LEMMA A.2 (distributional Fubini's theorem). *Let $\gamma > 0$ be fixed and e_γ be defined by* (A.1)–(A.3). *Further assume that $\varphi \in \mathcal{S}_e'(\mathbb{R}^{n+1})$ and $\beta \in \mathcal{S}_e(\mathcal{H}^M)$. Then,*

$$\begin{aligned}&\big\langle \langle \varphi, e_\gamma(\cdot, y)\rangle_{\mathcal{S}_e'(\mathbb{R}^{n+1}) \times \mathcal{S}_e(\mathbb{R}^{n+1})}, \beta \big\rangle_{\mathcal{S}_e'(\mathbb{R}^{n+1}) \times \mathcal{S}_e(\mathcal{H}^M)} \\ &\qquad = \big\langle \varphi, \langle e_\gamma(x, \cdot), \beta\rangle_{\mathcal{S}_e'(\mathbb{R}^{n+1}) \times \mathcal{S}_e(\mathcal{H}^M)} \big\rangle_{\mathcal{S}_e'(\mathbb{R}^{n+1}) \times \mathcal{S}_e(\mathbb{R}^{n+1})}.\end{aligned} \tag{A.7}$$

Furthermore,

$$\beta_\gamma(x) := \langle e_\gamma(x, \cdot), \beta\rangle_{\mathcal{S}_e'(\mathbb{R}^{n+1}) \times \mathcal{S}_e(\mathcal{H}^M)} \in \mathcal{S}_e(\mathbb{R}^{n+1})\,. \tag{A.8}$$

Note that here, β_γ is a function of x, and in section 2, f_γ is a function of y.

Proof. We reduce this to a Fubini theorem for functions. Since $\varphi = D^\alpha P_\varphi$ for a function P_φ with polynomial growth by (A.4), we can again use (A.5) to write

(A.9)

$$\langle \varphi_\gamma, \beta\rangle_{\mathcal{S}_e'(\mathbb{R}^{n+1}) \times \mathcal{S}_e(\mathcal{H}^M)} = \int_{\mathcal{H}^M} \int_{\mathbb{R}^n} \int_{\mathbb{R}} I_\varphi^\gamma(y', y_{n+1}, x', x_{n+1})\, dx_{n+1}\, dx'\, dy_{n+1}\, dy',$$

where

$$I^{\gamma}_{\varphi}(y', y_{n+1}, x', x_{n+1}) := \frac{(-1)^{|\alpha|}}{2} \left(\gamma\,|y_{n+1}|\right)^{-n-1-|\alpha|} \beta(y', y_{n+1})\, P_{\varphi}(x', x_{n+1})$$
$$\cdot\, (D^{\alpha'} e^1)\left(\frac{x'-y'}{\gamma\,|y_{n+1}|}\right) \left\{ (D^{\alpha_{n+1}} F)\left(\frac{x_{n+1}-|y_{n+1}|}{\gamma\,|y_{n+1}|}\right) + (D^{\alpha_{n+1}} F)\left(\frac{x_{n+1}+|y_{n+1}|}{\gamma\,|y_{n+1}|}\right)\right\}.$$

Using (A.6), $y \in \mathcal{H}^M$, the fact that F, β, and e^1 are in $\mathcal{S}_{\mathrm{e}}$, and some basic inequalities (e.g., $(1+\|a-b\|^2)^{-q} \le 2^q\,(1+\|b\|^2)^q\,(1+\|a\|^2)^{-q}$, $a, b \in \mathbb{R}^n$, $q \in \mathbb{N}$), we may estimate

$$|I^{\gamma}_{\varphi}(y', y_{n+1}, x', x_{n+1})| \le (C_{\varphi}/2)\ (1+\|x\|^2)^{\kappa}\,(\gamma/M)^{-n-1-|\alpha|}\,|\beta(y', y_{n+1})|$$
$$\cdot \left(1+\frac{\|x'-y'\|^2}{\gamma^2\, y_{n+1}^2}\right)^{-q_1} \left\{ \left(1+\frac{(x_{n+1}-|y_{n+1}|)^2}{\gamma^2\, y_{n+1}^2}\right)^{-q_2} + \left(1+\frac{(x_{n+1}+|y_{n+1}|)^2}{\gamma^2\, y_{n+1}^2}\right)^{-q_2}\right\}$$
$$\le \frac{C_{\varphi}}{2}\,\frac{(1+\|x\|^2)^{\kappa}}{(1+\|y\|^2)^{q_3}} \left(\frac{\gamma}{M}\right)^{-n-1-|\alpha|} \frac{(1+\|y'\|^2)^{q_1}}{(1+\|x'\|^2)^{q_1}}\,\frac{(1+|y_{n+1}|^2)^{q_2}}{(1+|x_{n+1}|^2)^{q_2}}\,[2(1+\gamma^2\, y_{n+1}^2)]^{q_1+q_2}$$

for arbitrary $q_1, q_2, q_3 \in \mathbb{N}$.

We see for sufficiently large q_1, q_2, q_3 that the integrand in (A.9) is bounded by an integrable function in $(x, y) \in \mathbb{R}^{n+1} \times \mathcal{H}^M$.

This allows us to switch the order of integration in (A.9). Since the integral in this switched version is smooth with uniformly integrable derivatives in $y \in \mathcal{H}^M$ for x in any compact set, we can pull the D^{α} out of the inner integral. Finally, we use the definition of derivative on $\mathcal{S}'_{\mathrm{e}}$ to prove (A.7).

To show (A.8), we let $\alpha \in \mathbb{N}_0^{n+1}$ be an arbitrary multi-index. We will prove that $D^{\alpha}\beta_{\gamma}$ decreases rapidly. We bring the D^{α} inside the integral for β_{γ} and use estimates as above, and we find a constant $\tilde{c}_{\gamma} > 0$ such that

$$|D^{\alpha}\beta_{\gamma}(y)| \le \tilde{c}_{\gamma}\,(1+\|y'\|^2)^{-q_1}\,(1+y_{n+1}^2)^{-q_2}, \qquad (y', y_{n+1}) \in \mathbb{R}^{n+1},$$

for arbitrary numbers $q_1, q_2 \in \mathbb{N}$ since $\beta \in \mathcal{S}_{\mathrm{e}}(\mathcal{H}^M)$ and γ is fixed. Now, using similar arguments as for the bound on $|I^{\gamma}_{\varphi}|$, we prove assertion (A.8). ∎

The final key is the following important convergence result.

LEMMA A.3. *Let e_{γ} be defined by* (A.1)–(A.3). *Let $\beta \in \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M})$ and $\alpha \in \mathbb{N}_0^{n+1}$ be a multi-index. Assume that β_{γ} is defined by* (A.8). *Then, $D^{\alpha}\beta_{\gamma} \to D^{\alpha}\beta(x)$ pointwise in $\mathcal{H}^{M,M}$, and $D^{\alpha}\beta_{\gamma}$ is uniformly bounded in $(x, \gamma) \in \mathcal{H}^{M,M} \times (0, 1)$.*

Proof. We first use the symmetry of F to write

(A.10)
$$\beta_{\gamma}(x) = \int_{\mathcal{H}^{M,M}} \frac{1}{(\gamma\,|y_{n+1}|)^{n+1}}\, e^1\left(\frac{x'-y'}{\gamma\,|y_{n+1}|}\right) F\left(\left(\frac{x_{n+1}}{y_{n+1}}-1\right)\Big/\gamma\right)\beta(y)\,dy_{n+1}\,dy'.$$

We assume $(x, y) \in \mathcal{H}^{M,M} \times \mathcal{H}^{M,M}$ and then we use the change of variables

$$z' = (x'-y')/(|y_{n+1}|\gamma), \qquad z_{n+1} = \left(\frac{x_{n+1}}{y_{n+1}}-1\right)\Big/\gamma, \tag{A.11}$$

and we have the following simple but important estimate:

$$\frac{1}{M^2} < \frac{1}{M|x_{n+1}|} < \frac{1}{|\gamma z_{n+1}+1|} < \frac{M}{|x_{n+1}|} < M^2. \tag{A.12}$$

Then, the integral in (A.10) becomes

$$\beta_\gamma(x) = \int_{\mathbb{R}^n}\int_{1/|\gamma z_{n+1}+1|<M^2} e^1(z')F(z_{n+1}) \cdot \beta\left(x' - \frac{\gamma|x_{n+1}|}{|\gamma z_{n+1}+1|}z', \frac{x_{n+1}}{\gamma z_{n+1}+1}\right)\frac{1}{|\gamma z_{n+1}+1|}dz'dz_{n+1}, \tag{A.13}$$

where the limits of integration in (A.13) are determined because $1/M < |y_{n+1}| < M$ and $\operatorname{supp}\beta \subset \mathbb{R}^n \times [1/M, M]$.

In order to subtract $\beta(x)$ within the integral (A.13), we define an auxiliary function that simplifies the calculation,

$$b_\gamma(x) = \beta(x)\int_{1/|\gamma z_{n+1}+1|<M^2} e^1(z')\,F(z_{n+1})\,\frac{1}{|\gamma z_{n+1}+1|}\,dz_{n+1}.$$

We must calculate $D^\alpha[\beta_\gamma - b_\gamma]$ and show this difference goes to zero as $\gamma \to 0$. To do this, we take the derivative inside the integral:

$$D^\alpha[\beta_\gamma(x) - b_\gamma(x)] = \int_{\mathbb{R}^n}\int_{1/|\gamma z_{n+1}+1|<M^2} e^1(z')\,F(z_{n+1}) \cdot D_x^\alpha\left\{\beta\left(x' - \frac{\gamma|x_{n+1}|}{|\gamma z_{n+1}+1|}z', \frac{x_{n+1}}{\gamma z_{n+1}+1}\right) - \beta(x)\right\}\frac{1}{|\gamma z_{n+1}+1|}\,dz'\,dz_{n+1}. \tag{A.14}$$

To show that (A.14) converges to zero, we must do two things:

1. We need to show for each $x \in \mathcal{H}^{M,M}$ that the integrand in (A.14) is bounded by an integrable function uniformly in $\gamma \in (0,1)$.
2. We need to show $D^\alpha\beta_\gamma$ is bounded by an integrable function, uniformly in $\gamma \in (0,1)$.

To show 1, we need to examine the derived integrand. The $D_{x'}^{\alpha'}$ terms are evaluated on β in both terms of (A.14) and they do not cause a problem, so we will evaluate them first. This gives an expression

$$D_x^\alpha\left\{\beta\left(x' - \frac{\gamma\,|x_{n+1}|}{|\gamma\,z_{n+1}+1|}\,z', \frac{x_{n+1}}{\gamma\,z_{n+1}+1}\right) - \beta(x)\right\} = D_{x_{n+1}}^{\alpha_{n+1}}(D_{x'}^{\alpha'}\beta)\left(x' - \frac{\gamma\,|x_{n+1}|}{|\gamma\,z_{n+1}+1|}\,z', \frac{x_{n+1}}{\gamma z_{n+1}+1}\right) - D_x^\alpha\beta(x). \tag{A.15}$$

However, because x_{n+1} appears in both coordinates of the first β in (A.15), some of the derivatives in $D_{x_{n+1}}^{\alpha_{n+1}}$ fall on the first coordinate. We will let $\delta' = (\delta_1, \ldots, \delta_n)$ denote a multi-index in $\mathbb{N}_0^n$. An explicit calculation shows that the integrand in (A.14) can be written for $x_{n+1} > 1/M > 0$ as a sum of terms in which some derivatives in x_{n+1} fall on the first coordinates of β and then the term in which all derivatives fall on the last coordinate, the integrand in (A.14) becomes

(A.16)

$$\frac{e^1(z')\,F(z_{n+1})}{|\gamma\,z_{n+1}+1|}\left[\sum_{0<|\delta'|\le\alpha_{n+1}}\left(\frac{\gamma^{|\delta'|}\,(-z)^{\delta'}}{|\gamma\,z_{n+1}+1|^{|\delta'|}\,(\gamma\,z_{n+1}+1)^{\alpha_{n+1}-|\delta'|}} \cdot \left(\partial_{x_{n+1}}^{\alpha_{n+1}-|\delta'|}\,D_{x'}^{\delta'+\alpha'}\beta\right)\left(x' - \frac{\gamma\,|x_{n+1}|}{|\gamma\,z_{n+1}+1|}z', \frac{x_{n+1}}{\gamma\,z_{n+1}+1}\right)\right) + \left\{(\gamma\,z_{n+1}+1)^{-\alpha_{n+1}}\,(D^\alpha\beta)\left(x' - \frac{\gamma\,|x_{n+1}|}{|\gamma\,z_{n+1}+1|}z', \frac{x_{n+1}}{\gamma\,z_{n+1}+1}\right) - D^\alpha\beta(x)\right\}\right].$$

A similar formula is obtained for $x_{n+1} < -1/M < 0$.

Because $1/|\gamma z_{n+1} + 1| \leq M^2$, it can be seen from (A.16) that the integrand of (A.14) can be bounded by an integrable function uniformly in $\gamma \in (0,1)$. Hence, an application of Lebesgue's dominated convergence theorem shows $D^\alpha(\beta_\gamma - b_\gamma) \to 0$ pointwise for $x \in \mathcal{H}^{M,M}$. This is valid for two reasons: the sum in (A.16) is a factor of γ times a bounded function, and the difference in braces goes to zero as $\gamma \to 0$. Since $(b_\gamma - \beta) \to 0$ in $\mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M})$ we thus have $D^\alpha(\beta_\gamma - \beta) \to 0$ pointwise in $\mathcal{H}^{M,M}$.

A similar boundedness argument shows that $D^\alpha \beta_\gamma$ is bounded by an integrable function uniformly in $\gamma \in (0,1)$. ∎

At last, we finish the proof of Theorem 4.1. Recall that in the statement of this theorem, φ has compact support in $\mathcal{H}^{M,M}$ and $\varphi = D^\alpha P_\varphi$ for a function P_φ of polynomial growth (A.4). Thus, there are compactly supported functions $\psi_1(x')$ and $\psi_2(x_{n+1})$ such that ψ_2 is one on $[-M, -1/M] \cup [1/M, M]$ and supported in $[-2M, -1/2M] \cup [1/2M, 2M]$ and $\psi(x) = \psi_1(x')\psi_2(x_{n+1})$ is one on a neighborhood of $\operatorname{supp}\varphi$. Then, $\varphi = \psi\, D^\alpha P_\varphi$.

By Lemma A.2,

$$\begin{aligned} \langle \varphi_\gamma, \beta \rangle_{\mathcal{S}'_{\mathrm{e}}(\mathbb{R}^{n+1}) \times \mathcal{S}_{\mathrm{e}}(\mathcal{H}^{M,M})} &= \langle \varphi, \beta_\gamma \rangle_{\mathcal{S}'_{\mathrm{e}}(\mathcal{H}^{M,M}) \times \mathcal{S}_{\mathrm{e}}(\mathbb{R}^{n+1})} \\ &= (-1)^{|\alpha|} \int_{\mathcal{H}^{M,M}} P_\varphi(x)\, D^\alpha \big\{ \psi(x)\, \beta_\gamma(x) \big\}\, dx. \end{aligned} \tag{A.17}$$

By the product rule for derivatives and the convergence result Lemma A.3, we see that the derivative in (A.17) converges pointwise on any compact set in x, and it is uniformly bounded. Therefore, we can use Lebesgue's dominated convergence theorem again to finish the proof of Theorem 4.1.

Acknowledgments. The authors are indebted to Jens Klein, Aleksei Beltukov, and Alfred Louis for very useful conversations. The authors are grateful to the referees and editors, in particular Adel Faridani, for thoughtful comments that improved the article.

MODELING OF SEISMIC DATA IN THE DOWNWARD CONTINUATION APPROACH*

CHRISTIAAN C. STOLK† AND MAARTEN V. DE HOOP‡

Abstract. Seismic data are commonly modeled by a high-frequency single scattering approximation. This amounts to a linearization in the medium coefficient about a smooth background. The discontinuities are contained in the medium perturbation. The high-frequency part of the wavefield in the background medium is described by a geometrical optics representation. It can also be described by a one-way wave equation. Based on this we derive a downward continuation operator for seismic data. This operator solves a pseudodifferential evolution equation in depth, the so-called double-square-root equation. We consider the modeling operator based on this equation. If the rays in the background that are associated with the reflections due to the perturbation are nowhere horizontal, the singular part of the data is described by the solution to an inhomogeneous double-square-root equation.

Key words. seismic modeling, microlocal analysis, double-square-root equation

1. Introduction.

In reflection seismology one places point sources and point receivers on the earth's surface. The source generates acoustic waves in the subsurface, which are reflected where the medium properties vary discontinuously. In seismic imaging, one tries to reconstruct the properties of the subsurface from the reflected waves that are observed. There are various approaches to seismic imaging, each based on a different mathematical model for seismic reflection data with underlying assumptions. In general, seismic scattering and inverse scattering have been formulated in the form of a linearized inverse problem for the medium coefficient in the acoustic wave equation. The linearization is around a smoothly varying background, called the velocity model, which is a priori also unknown.

In this paper and a companion paper [24] we study a method of seismic imaging introduced by Clayton [6] and Claerbout [5]. The key concept in this method is the construction of data of fictitious experiments carried out in the subsurface, at increasing depths, from data observed at the earth's surface. These so-called downward continued data are then used for imaging the medium contrast as well as for a reflection tomographic procedure to estimate the smoothly varying background (known as migration velocity analysis). The downward continuation approach to seismic imaging has received much attention in the geophysical research literature, and it is currently widely used in practice in various approximations [3, 19, 16].

The downward continuation of data is derived from the factorization of the wave equation into two one-way wave equations. This factorization is closely connected to the notion of wave splitting [28]. One-way wave equations, in various approximations,

have been extensively used in applications other than seismics: for integrated optics (see, e.g., [12]) and for underwater acoustics (see, e.g., [25, 7]).

There are basically two categories of seismic imaging methods. One category is associated with the evolution of waves and data in time; the other is associated with the evolution in depth (or another principal spatial direction). The first category contains approaches known under the collective names of Kirchhoff migration [4] or generalized Radon transform inversion, and reverse-time migration [21]; the second category comprises the downward continuation approach. There are great computational advantages of the downward continuation approach to seismic imaging over the Kirchhoff approaches. There are fundamental, theoretical advantages as well, in particular with a view to the problem of estimating the smoothly varying background. These are analyzed in a separate paper [24]. For the Kirchhoff approach to seismic imaging there is a solid mathematical theory, which treats seismic imaging as an inverse problem and shows that singularities can be reconstructed [2, 20]. For the downward continuation approach much research has gone into the development of numerical one-way wave equations, but little is known from an analysis point of view. For a constant coefficient background, the downward continuation method was cast into an inverse problem in [1]. For the case of variable coefficients, which of course is the case of interest in practice, there has been no such theory.

The purpose of this paper is to develop a mathematical theory for modeling seismic reflection data in the downward continuation approach. As was done in the analysis of Kirchhoff methods, we make use of techniques and concepts from microlocal analysis, such as wave front set, denoted by $\mathrm{WF}(\cdot)$, and Fourier integral operators; see, e.g., [10] for background information on these concepts. We introduce the main concepts and operators involved in the method. We then study the double-square-root modeling operator. This modeling operator and its properties will be the point of departure for the development of an inverse scattering theory [24].

In our notation we will distinguish the vertical coordinate $z \in \mathbb{R}$ from the horizontal coordinates $x \in \mathbb{R}^{n-1}$ and write $(z, x) \in \mathbb{R}^n$. In these coordinates the scalar acoustic wave equation with wave speed function $c_0(z, x)$ is given by

$$Pu = f, \qquad P = c_0(z,x)^{-2}\partial_t^2 - \partial_z^2 - \sum_{j=1}^{n-1} \partial_{x_j}^2, \tag{1.1}$$

where $u = u(z, x, t)$ is the acoustic pressure. The equation is considered for t in a time interval $]0, T[$, together with an initial condition $u(\cdot, \cdot, 0) = 0$. The solution to (1.1) can be written as

$$u(z,x,t) = \int_0^t \int G(z,x,t-t_0,z_0,x_0) f(z_0,x_0,t_0)\, \mathrm{d}z_0 \mathrm{d}x_0 \mathrm{d}t_0, \tag{1.2}$$

where G is the Green's function of (1.1). The source f can be a distribution.

To model the scattering of waves, we adopt the linearized scattering or Born approximation. The linearization is in the wavespeed, around a smooth (C^∞) background c_0; for the full wavespeed function we write $c = c_0 + \delta c$. The perturbation δc may contain singularities. The perturbation in G at the acquisition surface $z = 0$ is given by (see, e.g., [2])

$$\begin{aligned} \delta G(0,r,t,0,s) = \int_{\mathbb{R}_+ \times \mathbb{R}^{n-1}} \int_0^t G(0,r,t-t_0,z_0,x_0)\, 2c_0^{-3}(z_0,x_0)\delta c(z_0,x_0) \\ \times \partial_{t_0}^2 G(z_0,x_0,t_0,0,s)\, \mathrm{d}t_0 \mathrm{d}z_0 \mathrm{d}x_0, \end{aligned} \tag{1.3}$$

where both $s, r \in \mathbb{R}^{n-1}$. We assume that the acquisition manifold Y, which contains the set of values of (s, r, t) used in the acquisition, is a bounded open subset of $\mathbb{R}^{2n-2} \times \mathbb{R}_+$. The modeled data are then a function of $(s, r, t) \in Y$ given by (1.3). We define the Born modeling map F through (1.3) as the map from δc to δG evaluated at $z = 0$. Since Y is bounded and the waves propagate with finite speed we may assume that δc is supported in a bounded open subset X of $\mathbb{R}_+ \times \mathbb{R}^{n-1}$. Furthermore, we assume that $\overline{X} \cap \{z = 0\} = \emptyset$. Naturally, (1.3) is, in general, not a complete model for raw data measured in seismic experiments. It models data that are the input for imaging and inversion and have undergone some processing.

We summarize some results in the literature about the modeling map, F. The solution operator (1.2) is such that singularities in the solution propagate along bicharacteristics. Denote by $p(z, x, \zeta, \xi, \tau) = -c(z, x)^{-2}\tau^2 + \zeta^2 + \|\xi\|^2$ the principal symbol of P. Propagating singularities are in the characteristic set, given by the points $(z, x, t, \zeta, \xi, \tau) \in T^*\mathbb{R}^{n+1}$ with

$$p(z, x, \zeta, \xi, \tau) = -c(z, x)^{-2}\tau^2 + \zeta^2 + \|\xi\|^2 = 0. \tag{1.4}$$

The bicharacteristics are the solution curves of a Hamilton system with Hamiltonian given by p,

$$\frac{\mathrm{d}(z, x, t)}{\mathrm{d}\lambda} = \frac{\partial p}{\partial(\zeta, \xi, \tau)}, \quad \frac{\mathrm{d}(\zeta, \xi, \tau)}{\mathrm{d}\lambda} = -\frac{\partial p}{\partial(z, x, t)}. \tag{1.5}$$

Assuming that $\tau \neq 0$, the time t is strictly increasing or decreasing with λ and can be used as parameter for the solution curve. To parameterize points on the solution curves, we use the initial position (z_0, x_0), the take-off direction $\alpha \in S^{n-1}$, the frequency τ, which together define the initial cotangent vector $(\zeta_0, \xi_0) = -\tau c(z_0, x_0)^{-1}\alpha$, and the time t (instead of λ). Points on the solution curves will be denoted by

$$\begin{aligned}\eta(t, z_0, x_0, \alpha, \tau) = (&\eta_z(t, z_0, x_0, \alpha, \tau), \eta_x(t, z_0, x_0, \alpha, \tau), t,\\ &\eta_\zeta(t, z_0, x_0, \alpha, \tau), \eta_\xi(t, z_0, x_0, \alpha, \tau), \tau).\end{aligned} \tag{1.6}$$

The variable τ is invariant along the Hamilton flow. We take $t = 0$ as the initial value for t (note that (1.5) are time translation invariant).

To ensure that δG defines a continuous map from $\mathcal{E}'(X)$ to $\mathcal{D}'(\mathbb{R}^n \times \mathbb{R}^n \times]0, T[)$ and that the restriction of δG to Y is a Fourier integral operator we make the following assumption on c_0.

ASSUMPTION 1. *There are no rays from $(0, s)$ to $(0, r)$ with travel time t such that $(s, r, t) \in Y$. For all ray pairs connecting $(0, r)$ via some $(z, x) \in X$ to $(0, s)$ with total time t such that $(s, r, t) \in Y$, the rays intersect the plane $z = 0$ transversally at r and s.*

We also assume that rays from such a point $(z, x) \in X$ intersect the surface $z = 0$ only once, because all reflections must come from the region $z > 0$ (the subsurface). The first part of the assumption excludes direct rays, or a pair of incident and reflected rays with scattering angle π. The second part of the assumption excludes rays grazing the plane $z = 0$. Concerning the second part, strictly only caustics grazing the plane $z = 0$ have to be excluded. In practice the wave speed near the surface is much lower than in the interior of the earth, and waves from the interior arrive under small angles with the vertical. So from a geophysical point of view one is only interested in incoming rays that intersect the measurement surface transversally. We have the following theorem. (See [10] for a general reference on Fourier integral operators.)

THEOREM 1.1 (see [20, 17]). *With Assumption* 1 *the map* F *is a Fourier integral operator* $\mathcal{E}'(X) \to \mathcal{D}'(Y)$ *of order* $(n-1)/4$ *with canonical relation*

(1.7)
$$\big\{(\eta_x(t_{\rm s},z,x,\beta,\tau),\eta_x(t_{\rm r},z,x,\alpha,\tau),t_{\rm s}+t_{\rm r},\eta_\xi(t_{\rm s},z,x,\beta,\tau),\eta_\xi(t_{\rm r},z,x,\alpha,\tau),\tau;z,x,\zeta,\xi)|$$
$$t_{\rm s},t_{\rm r}>0,\ \eta_z(t_{\rm s},z,x,\beta,\tau)=\eta_z(t_{\rm r},z,x,\alpha,\tau)=0,\ (\zeta,\xi)=-\tau c_0(z,x)^{-1}(\alpha+\beta),$$
$$(z,x,\alpha,\beta,\tau)\in \textit{ subset of } X\times(S^{n-1})^2\times\mathbb{R}\backslash 0\big\}\subset T^*\mathbb{R}^{2n-1}_{(s,r,t)}\times T^*\mathbb{R}^n_{(z,x)}.$$

In this paper, we express F in terms of a depth-continuation operator, and we study the properties of this operator. The main contributions of this paper are the following:

(i) We define an *upward continuation operator* $H(z,z_0)$ using the solution operators to one-way wave equations. Its adjoint will be the downward continuation operator. Intuitively this operator maps data from a fictitious experiment carried out at depth z_0 to data from an experiment carried out at depth z, $z<z_0$. Subject to Assumption 2 in the main text—stating, essentially, that the rays in the background that are associated with the reflections are nowhere tangent to horizontal—we prove that the data $F\delta c$ are given by $\int_0^\infty(\dots)H(0,z)(\dots)g(z,\cdot,\cdot,\cdot)\,{\rm d}z$, where the dots are pseudodifferential factors specified below and $g=g(z,s,r,t)$ is given by mapping $c_0^{-3}\delta c$ to a function $E_2E_1(c_0^{-3}\delta c)$ of (z,s,r,t) using the maps

(1.8)
$$E_1:\mathcal{D}'(\mathbb{R}^n)\to\mathcal{D}'(\mathbb{R}^{2n-1})\ :\ (c_0^{-3}\delta c)(z,x)\mapsto h(z,\bar x,x)=\delta(x-\bar x)(c_0^{-3}\delta c)(z,\tfrac{\bar x+x}{2}),$$
$$E_2:\mathcal{D}'(\mathbb{R}^{2n-1})\to\mathcal{D}'(\mathbb{R}^{2n})\ :\ h(z,\bar x,x)\mapsto\delta(t)h(z,\bar x,x)$$

(Theorem 5.1).

(ii) We show that the operator $H(z,z_0)$ solves the initial value problem for a first-order pseudodifferential evolution equation in depth, known as the *double-square-root (DSR) equation*. The data can be identified with the solution to an inhomogeneous DSR equation, with inhomogeneous term g (section 3). The computation of the map from g to data and the computation of its adjoint can be done by marching in depth using the DSR equation. This is the basis of DSR modeling and imaging methods in geophysics.

(iii) The modeling operator can be written as the composition of a Fourier integral operator representing *depth-to-time conversion*, with a locally invertible canonical relation (Theorem 4.2) and the operator E_1.

It should be mentioned that our Assumption 2 can be quite restrictive. However, the limited aperture of seismic acquisition yields a natural cutoff so that, in general, a large part of the *observed* data can be modeled with the approach presented in this paper.

In general, the downward continuation approach results in a more complete computation of the wave propagation and diffraction in the modeling of seismic reflection data than the one based on the geometrical optics approximation underlying the Kirchhoff approach. Fast algorithms have been designed to solve the DSR equation; as compared with numerical algorithms solving the full wave equation, the advantage of using the DSR equation becomes significant in space dimension 3 (and higher).

The outline of the paper is as follows. In section 2 we discuss one-way acoustic equations. In section 3 we use these to define the upward/downward continuation operator H, and we describe some of its properties. Section 4 contains our result on

depth-to-time conversion. In section 5 we show that the data can be modeled using the downward continuation method. The last section is about the relation between our assumption and the Bolker condition that occurs in the inversion.

2. Directional decomposition, single-square-root equations. Singularities of solutions to the wave equation, which propagate with velocity with nonzero vertical (z) component, are described by a first-order pseudodifferential evolution equation in z. This follows from a well-known factorization argument; see, e.g., [26]. In [22] the approximation of solutions to the wave equation by solutions to an evolution equation in z is discussed. Such an equation is called a one-way wave equation or single-square-root (SSR) equation. We summarize the structure and properties of this one-way wave equation that we need for the upward/downward continuation approach to seismic data processing.

To determine whether the velocity vector at some point of a ray (cf. (1.5)) is close to horizontal, we use the angle with the vertical, defined to be in $[0, \pi/2]$ and given by $\tan(\theta) = \frac{\|\xi\|}{|\zeta|}$. We recall that the propagating singularities are microlocally in the characteristic set given by (1.4). Given a point (z, x, ξ, τ) with $\|\xi\| < c(z,x)^{-1}|\tau|$, there are two solutions ζ to (1.4), given by $\zeta = \pm b$, where $b = b(z, x, \xi, \tau)$ is defined by

$$b(z, x, \xi, \tau) = -\tau\sqrt{c(z,x)^{-2} - \tau^{-2}\xi^2}. \tag{2.1}$$

The sign is chosen such that $\zeta = \pm b$ corresponds to propagation with $\pm\frac{\mathrm{d}z}{\mathrm{d}t} > 0$. There is also an angle associated with (z, x, ξ, τ) given by the solution $\theta \in [0, \pi/2]$ of the equation

$$\sin(\theta) = c(z,x)\|\tau^{-1}\xi\|. \tag{2.2}$$

When this angle is smaller than $\pi/2$ along a ray segment, then the vertical velocity $\frac{\mathrm{d}z}{\mathrm{d}t}$ does not change sign, and the ray segment can be parameterized by z. The maximal z-interval such that $\arcsin(c(z,x)\|\tau^{-1}\xi\|) < \theta$ for given θ along the bicharacteristic determined by the initial values $(z, x, \pm b, \xi, \tau)$ will be denoted by

$$]z_{\min,\pm}, z_{\max,\pm}[=]z_{\min,\pm}(z, x, \xi, \tau, \theta), z_{\max,\pm}(z, x, \xi, \tau, \theta)[; \tag{2.3}$$

see also Figure 1. Furthermore, we define a set

$$I_\theta = \{(z, x, t, \zeta, \xi, \tau) \mid \arcsin(c(z,x)\|\tau^{-1}\xi\|) < \theta, |\zeta| < C|\tau|\}, \tag{2.4}$$

where C is some constant that is everywhere larger than $c(z,x)^{-1}$.

The SSR equation. To obtain a one-way wave equation, the wave equation is written as the following first-order system in z:

$$\frac{\partial}{\partial z}\begin{pmatrix} u \\ \frac{\partial u}{\partial z}\end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -A(z, x, D_x, D_t) & 0\end{pmatrix}\begin{pmatrix} u \\ \frac{\partial u}{\partial z}\end{pmatrix} + \begin{pmatrix} 0 \\ f\end{pmatrix}, \tag{2.5}$$

where $D_x = -\mathrm{i}\frac{\partial}{\partial x}, D_z = -\mathrm{i}\frac{\partial}{\partial z}$, and $A(z, x, D_x, D_t) = c_0(z,x)^{-2}D_t^2 - D_x^2$. Then the system is transformed by using a family of matrix pseudodifferential operators $\mathsf{Q}(z) = \mathsf{Q}(z, x, D_x, D_t)$ with

$$\begin{pmatrix} u_+ \\ u_-\end{pmatrix} = \mathsf{Q}(z)\begin{pmatrix} u \\ \frac{\partial u}{\partial z}\end{pmatrix}, \qquad \begin{pmatrix} f_+ \\ f_-\end{pmatrix} = \mathsf{Q}(z)\begin{pmatrix} 0 \\ f\end{pmatrix}. \tag{2.6}$$

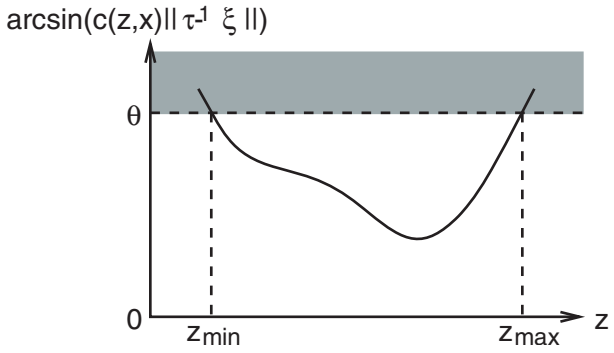

FIG. 1. *Definition of $z_{\min,\pm}$ and $z_{\max,\pm}$, which give the maximal interval where* $\arcsin(c(z,x)\|\tau^{-1}\xi\|)$ *is in the interval* $[0,\theta]$. *Here,* (z,x,ξ,τ) *lies on a bicharacteristic.*

The functions (u_+,u_-) satisfy a pseudodifferential system of equations. Let $\theta_2<\pi/2$ be a given angle. (In the next subsection we need another angle, θ_1, with $0<\theta_1<\theta_2<\pi/2$, hence the subscript 2.) With suitably chosen Q it is shown in [22] that the system that results from applying the transformation (2.6) to (2.5) is diagonal on I_{θ_2}. It then follows that (2.5) is equivalent to two equations of the form

$$\left(\frac{\partial}{\partial z}-\mathrm{i}B_\pm(z,x,D_x,D_t)\right)u_\pm=f_\pm, \tag{2.7}$$

microlocally on I_{θ_2}. These are called the one-way wave or SSR equations. The principal part of $B_\pm$ is equal to $\pm b$, while its subprincipal part depends on the normalization of $\mathsf{Q}(z)$. We choose the normalization such that $B_\pm$ are self-adjoint and Q satisfies

$$\begin{aligned}\mathsf{Q}(z,x,\xi,\tau)&=\tfrac{1}{2}\begin{pmatrix}a^{1/4}&-\mathrm{i}\,\mathrm{sgn}(\tau)a^{-1/4}\\ a^{1/4}&\mathrm{i}\,\mathrm{sgn}(\tau)a^{-1/4}\end{pmatrix}+\text{order}\begin{pmatrix}-\frac12&-\frac32\\-\frac12&-\frac32\end{pmatrix},\\ \mathsf{Q}(z,x,\xi,\tau)^{-1}&=\begin{pmatrix}a^{-1/4}&a^{-1/4}\\ \mathrm{i}\,\mathrm{sgn}(\tau)a^{1/4}&-\mathrm{i}\,\mathrm{sgn}(\tau)a^{1/4}\end{pmatrix}+\text{order}\begin{pmatrix}-\frac32&-\frac32\\-\frac12&-\frac12\end{pmatrix}\end{aligned} \tag{2.8}$$

with $a=a(z,x,\xi,\tau)=c_0(z,x)^{-2}\tau^2-\xi^2$.

It appears that only two components of $\mathsf{Q}(z)$ and $\mathsf{Q}(z)^{-1}$ are needed in the analysis. To clarify this, we first observe that multiplication by $\mathrm{i}\,\mathrm{sgn}(\tau)$ in the frequency domain corresponds to the application of a Hilbert transform with respect to the time variable, which we denote by $\mathcal{H}$. Next, we use the relation between $\mathsf{Q}(z)^*$ and $\mathsf{Q}(z)^{-1}$,

$$\begin{pmatrix}1&0\\0&-1\end{pmatrix}\mathsf{Q}(z)^{-1*}=2\mathsf{Q}(z)\begin{pmatrix}0&-\mathcal{H}\\ \mathcal{H}&0\end{pmatrix},$$

shown to hold microlocally in [22, (59)]. (This relation also appears in [8, (II.49)].) We let

$$Q_+=Q_+(z,x,D_x,D_t)=2\mathsf{Q}_{1,2}\mathcal{H},\ Q_-=Q_-(z,x,D_x,D_t)=-2\mathsf{Q}_{2,2}\mathcal{H},$$

where we choose a convenient normalization such that both $Q_\pm$ have principal symbol $a^{1/4}$. It follows with these definitions that

$$u=Q_+^*u_++Q_-^*u_-, \tag{2.9}$$

$$f_\pm=\mp\tfrac{1}{2}\mathcal{H}Q_\pm f. \tag{2.10}$$

The above procedure does not prescribe the symbol of the operator B_- for $\arcsin(c(z,x)\|\tau^{-1}\xi\|) > \theta_2$. We will assume that B_- is a first-order family of pseudodifferential operators with real homogeneous principal symbol. This implies that the evolution problem (2.7) has well-defined solutions satisfying energy estimates.

Propagation of singularities and introduction of a microlocal cutoff. Here, we discuss how the wave field is approximated by solutions of (2.7). This approximation is valid microlocally on part of the cotangent bundle $T^*\mathbb{R}^{n+1}_{(z,x,t)}$. We consider the approximation of upward traveling waves using the equation for u_-, where we assume that there are only upward traveling singularities at depth z_0, hence $u_+(z_0,\cdot) \in C^\infty$. The treatment of downward traveling waves using the equation for u_+ is analogous.

Consider the initial value problem for $P_{0,-} \stackrel{\text{def}}{=} \partial_z - \mathrm{i}B_-$,

$$P_{0,-}u_- = 0, \quad z < z_0, \quad Q_-^* u_-(z_0,\cdot) = u(z_0,\cdot). \tag{2.11}$$

Let $J_-(z_0,\theta)$ be defined by

$$J_-(z_0,\theta) = \{(z,x,t,\zeta,\xi,\tau) \in I_\theta \,|\, \tau^{-1}\zeta > 0 \text{ and } z_{\max,-}(z,x,\xi,\tau,\theta) \geq z_0\}. \tag{2.12}$$

The solutions to (2.11) agree with the solutions to the original wave equation microlocally on the set $J_-(z_0,\theta_2)$ in the following way. Suppose that $\mathrm{WF}(u) \cap \{z = z_0, \tau^{-1}\zeta < 0\} = \emptyset$ (i.e., at depth z_0 all singularities are propagating in the $-$ direction), and let u_- be a solution to (2.11); then it follows from the propagation of regularity/propagation of singularities result that

$$u \equiv Q_-^* u_- \tag{2.13}$$

microlocally on the set $J_-(z_0,\theta_2)$ [22]. Here, we say that $u \equiv v$ microlocally on a set $\Gamma \subset T^*\mathbb{R}^n$ if $\mathrm{WF}(u-v) \cap \Gamma = \emptyset$.

The solutions to (2.11) have propagating singularities, also in the part of the phase space where $\arcsin(c(z,x)\|\tau^{-1}\xi\|) \geq \theta_2$, but there the singularities of the solution are in general incorrect in the sense that they do not correspond to solutions of the original wave equation. For such singularities we introduce a pseudodifferential cutoff. Let θ_1 be given with $0 < \theta_1 < \theta_2$. We assume we have a pseudodifferential cutoff $\psi_1 = \psi_1(z,z_0,x,D_x,D_t)$ with symbol satisfying

$$\psi_1(z,z_0,x,\xi,\tau) \sim 1 \text{ on } J_-(z_0,\theta_1), \tag{2.14}$$

$$\psi_1(z,z_0,x,\xi,\tau) \in S^\infty \text{ outside } J_-(z_0,\theta_2), \text{ if } z - z_0 > \delta > 0. \tag{2.15}$$

Then we have

$$\psi_1 u \equiv \psi_1 Q_-^* u_-. \tag{2.16}$$

We reformulate this result in terms of the solution operators, the propagators. By $G_{0,-}(z,z_0)$ we will denote the solution operator to the evolution problem (2.11), defined to map $u_-(z_0,\cdot)$ to $u_-(z,\cdot)$. We assume that the full one-way propagator is then given by

$$G_-(z,z_0) = \psi_1(z,z_0) G_{0,-}(z,z_0). \tag{2.17}$$

Here, we let $z < z_0$. This can also be written as a pseudodifferential cutoff applied prior to $G_{0,-}$. We denote this different cutoff also by ψ_1 but with the order of z, z_0 interchanged, so that

$$G_-(z, z_0) = G_{0,-}(z, z_0)\psi_1(z_0, z). \tag{2.18}$$

In this paper this is all we need to know about the pseudodifferential cutoff ψ_1. But it raises the question of an explicit recipe for computing ψ_1: Can it, for example, be computed with a modified evolution equation in depth? This is indeed the case. It was established in [22, 23] that such a pseudodifferential cutoff can be generated by adding a dissipative term to $P_{0,-}$. Instead of $P_{0,-}$ one considers the operator

$$P_- = \partial_z - \mathrm{i}B_\pm(z, x, D_x, D_t) - C(z, x, D_x, D_t) \tag{2.19}$$

with C a first-order pseudodifferential operator with homogeneous, nonnegative real principal symbol, satisfying certain conditions. The operator $\psi_1(z, z_0)$ is then a (z, z_0)-family of pseudodifferential operators with symbol in $S^0_{\rho,1-\rho}(\mathbb{R}^n \times \mathbb{R}^n)$, such that the derivatives $\frac{\partial^{j+k}\psi_1}{\partial z_0^j \partial_z^k}$ are in $S^{(j+k)(1-\rho)}_{\rho,1-\rho}(\mathbb{R}^n \times \mathbb{R}^n)$ for $z \neq z_0$, where ρ can be any number satisfying $\frac{1}{2} < \rho < 1$ (see [23]). For the theory of such operators, see, e.g., [27, 14].

Let the elements $(z, x, t, \zeta, \xi, \tau)$ of the wave front set of f be such that $\tau^{-1}\zeta > 0$ (corresponding to propagation direction $\frac{\partial z}{\partial t} < 0$). Consider u_- defined by

$$u_-(z, \cdot) = \int_z^\infty G_-(z, z_0) \left(\frac{1}{2}\mathcal{H}Q_-(z_0)\right) f(z_0, \cdot)\, \mathrm{d}z_0, \tag{2.20}$$

assuming also that $f = 0$ on a neighborhood of the plane given by z. We have that $Q_-^* u_-(z, \cdot) \equiv u(z, \cdot)$, where u is the solution to (1.1) with f replaced by $(\psi_1(z_0, z) - Q_-^{-1}[Q_-, \psi_1(z_0, z)])f$. Here the square brackets denote a commutator.

We use the notation $\gamma(z, z_0, x_0, t_0, \xi_0, \tau)$ for the bicharacteristic of $P_{0,-}$ parameterized by z. In components we write them as (note that they are time translation invariant)

$$\begin{aligned}\gamma(z, z_0, x_0, t_0, \xi_0, \tau) = (&z, \gamma_x(z, z_0, x_0, \xi_0, \tau), \gamma_t(z, z_0, x_0, \xi_0, \tau) + t_0,\\ &- b(z, \gamma_x, \gamma_\xi, \tau), \gamma_\xi(z, z_0, x_0, \xi_0, \tau), \tau).\end{aligned} \tag{2.21}$$

Properties of G_-. The operator $G_-(z, z_0)$ is a Fourier integral operator with canonical relation

$$\{(\gamma_x, t_0 + \gamma_t, \gamma_\xi, \tau; x_0, t_0, \xi_0, \tau)\} \subset T^*\mathbb{R}^n \times T^*\mathbb{R}^n, \tag{2.22}$$

where $\gamma_x = \gamma_x(z, z_0, x_0, \xi_0, \tau)$ and the same for γ_t, γ_ξ as in (2.21).

The operators $B_\pm$ are self-adjoint. It follows that $G_{0,-}(z, z_0)$ is unitary. But then

$$G_-(z, z_0)^* G_-(z, z_0) = \psi_1(z_0, z)^* \psi_1(z_0, z), \tag{2.23}$$

and $G_-(z, z_0)^* G_-(z, z_0)$ is one microlocally where $\psi_1(z_0, z)$ is one.

Numerical methods for one-way wave propagation are described, e.g., in [9] and [13] and in the references given in those papers.

3. Downward/upward continuation and the DSR equation. In this section we construct the data downward/upward continuation operator, and we establish some of its properties.

Data model. In preparation of the downward/upward continuation approach to seismic data modeling, we rewrite (1.3) in the form

$$\begin{aligned}\delta G(0,r,t,0,s) = \int_{\mathbb{R}^{n-1}\times\mathbb{R}_+}\int_{\mathbb{R}^{n-1}}\int_{-\infty}^{t}\int_{\mathbb{R}_+} & G(0,r,t-t_0,z,x)\\ & \times 2\partial_{t_0}^2 R(z,x,\bar{x},t_0-\bar{t}_0)\\ & \times G(z,\bar{x},\bar{t}_0,0,s)\,\mathrm{d}\bar{t}_0\,\mathrm{d}t_0\,\mathrm{d}\bar{x}\,\mathrm{d}x\mathrm{d}z,\end{aligned} \tag{3.1}$$

where

$$R(z,x,\bar{x},t_0) = \delta(t_0)\delta(x-\bar{x})\left(\frac{\delta c}{c_0^3}\right)\left(z,\frac{\bar{x}+x}{2}\right) \tag{3.2}$$

so that

$$R = E_2E_1c_0^{-3}\delta c \tag{3.3}$$

with the definitions in (1.8). Changing variables of integration, i.e., $t_0 \mapsto t_0' = t_0 - \bar{t}_0$, (3.1) can be written in the form of an integral operator acting on the distribution R,

$$\begin{aligned}\delta G(0,r,t,0,s) = \int_{\mathbb{R}_+}\Big\{\int_{\mathbb{R}}\int_{\mathbb{R}^{n-1}}\int_{\mathbb{R}^{n-1}}\Big(\int_{\mathbb{R}_+} & G(0,r,t-t_0'-\bar{t}_0,z,x)\\ & \times G(z,\bar{x},\bar{t}_0,0,s)\,\mathrm{d}\bar{t}_0\Big)\\ & \times 2\partial_{t_0'}^2 R(z,x,\bar{x},t_0')\,\mathrm{d}\bar{x}\,\mathrm{d}x\,\mathrm{d}t_0'\Big\}\mathrm{d}z,\end{aligned} \tag{3.4}$$

in between the braces, the contributions of which are integrated over depth z.

Using the reciprocity relation of the time-convolution type for the Green's function, we arrive at the integral representation

$$\begin{aligned}\delta G(0,r,t,0,s) = \int_{\mathbb{R}_+}\Big\{\int_{\mathbb{R}^{n-1}}\int_{\mathbb{R}^{n-1}}\int_{\mathbb{R}}\Big(\int_0^{t-t_0} & G(0,r,t-t_0-\bar{t}_0,z,x)\\ & \times G(0,s,\bar{t}_0,z,\bar{x})\,\mathrm{d}\bar{t}_0\Big)\\ & \times 2\partial_{t_0}^2 R(z,x,\bar{x},t_0)\,\mathrm{d}\bar{x}\,\mathrm{d}x\,\mathrm{d}t_0\Big\}\mathrm{d}z.\end{aligned} \tag{3.5}$$

Upon substituting (3.3) into this representation we obtain a mapping $\delta c(z,x) \to \delta G(0,r,t,0,s)$ as encountered in Theorem 1.1. The associated operator kernel appears to propagate singularities from two different scattering points, $\bar{x}$ and x, at each depth z, to the surface at $z=0$.

To arrive at an upward continuation formulation of data modeling, the idea is to substitute in (3.5) for the Green's functions their upward propagating constituents. Thus we replace these Green's functions in accordance with (2.9), (2.10), using only the u_- constituent. So, for the Green's functions $G(z,x,t-t_0,z_0,x_0)$ in (3.5) we substitute the kernel of the operator

$$\frac{1}{2}\mathcal{H}Q_-^*(z,x,D_x,D_t)G_-(z,z_0)Q_-(z_0,x_0,D_{x_0},D_{t_0}), \tag{3.6}$$

viewed as a function of (z, x, t, z_0, x_0, t_0). Naturally, a time convolution of two one-way Green's functions appears. This is the motivation of the definition, by its kernel, of an operator $H(z, z_0), z < z_0$ on functions of (s, r, t),

$$(H(z,z_0))(s,r,t,s_0,r_0,t_0) = \int_{\mathbb{R}} (G_-(z,z_0))(s,t-t_0-\bar{t}_0,s_0)(G_-(z,z_0))(r,\bar{t}_0,r_0)\,\mathrm{d}\bar{t}_0. \tag{3.7}$$

Here $(G_-(z,z_0))(r,\bar{t}_0,r_0,0)$ denotes the distribution kernel of $G_-(z,z_0)$, and $(H(z,z_0))(s,r,t,s_0,r_0,t_0)$ denotes the distribution kernel of $H(z,z_0)$.

As an alternative formulation, we can write the operator $H(z,z_0)$ as the composition of two operators obtained by a tensor product. We recall that if ψ_1, ψ_2 are two operators with kernels $K_{\psi_1}(x,\bar{x})$, $K_{\psi_2}(y,\bar{y})$, then their tensor product $\psi_1 \otimes \psi_2$ has kernel given by the product $K_{\psi_1}(x,\bar{x})K_{\psi_2}(y,\bar{y})$ and maps functions of $(\bar{x},\bar{y})$ to functions of (x,y). We denote the identity operator acting on functions of s by Id_s and similarly for Id_r. If ψ is an operator acting in the (x,t) variables, then we will write ψ_s, ψ_r for the operator acting in the (s,t) variables or the (r,t) variables, respectively. Then we can also write (3.7) as

$$H(z,z_0) = (\mathrm{Id}_s \otimes G_{-,r}(z,z_0)) \circ (G_{-,s}(z,z_0) \otimes \mathrm{Id}_r). \tag{3.8}$$

Since the tensor product of two operators is a well-defined operator, this shows that $H(z,z_0)$ is well defined. If ψ is an operator on functions of (x,t), then we will often simply write ψ_s instead of $\psi_s \otimes \mathrm{Id}_r$. The map $H(z,z_0)$, $z < z_0$, is the upward continuation operator.

If ψ_1 and ψ_2 are operators on functions of (x,t) and are time translation invariant, then $\psi_{1,s}$ and $\psi_{2,r}$ commute, which can be derived by writing out the distribution kernel of the compositions. The factors $G_{-,s}$ and $G_{-,r}$ can be written as compositions $\psi_{1,s}G_{0,-,s}$, $G_{0,-,s}\psi_{1,s}$ (and similarly for r) using (2.17), (2.18). It follows that the operator H can be written as a composition $\psi_2(z,z_0)H_0(z,z_0)$, where H_0 is given by (3.7) with G_- replaced by $G_{-,0}$ and $\psi_2(z,z_0) = \psi_{1,s}(z,z_0)\psi_{1,r}(z,z_0)$. The operator $\psi_2(z,z_0)$ is pseudodifferential with symbol

$$\psi_2(z,z_0,s,r,\sigma,\rho,\tau) = \psi_1(z,z_0,s,\sigma,\tau)\psi_1(z,z_0,r,\rho,\tau). \tag{3.9}$$

We can also write $H(z,z_0) = H_0(z,z_0)\psi_2(z_0,z)$ with ψ_2 defined by (3.9) as well, but with z, z_0 interchanged.

Replacing both source and receiver Green's functions, the result is the replacement of the integral in the parentheses of (3.5) by $-\frac{1}{4}Q^*_{-,s}(0)Q^*_{-,r}(0)H(0,z)Q_{-,s}(z)Q_{-,r}(z)$, where we denote $Q_{-,s}(z) = Q_-(z,s,D_s,D_t)$, and similarly for $Q_{-,r}(z)$. Therefore, we define the DSR modeling operator as

$$F_{\mathrm{D}}\delta c = Q^*_{-,s}(0)Q^*_{-,r}(0)\int_0^Z H(0,z)Q_{-,s}(z)Q_{-,r}(z)\tfrac{1}{2}D_t^2(E_2E_1c_0^{-3}\delta c)(z,\cdot,\cdot,\cdot)\mathrm{d}z, \tag{3.10}$$

where Z is some large number such that $\mathrm{supp}(\delta c)$ is contained in $]0,Z[\times\mathbb{R}^{n-1}$.

In Theorem 5.1 we will show that, in general, F_{D} differs from F by a pseudodifferential cutoff and that under a certain assumption F_{D} models the singular part of the data. We first derive some important properties of H.

The DSR equation. It follows from differentiating expression (3.8) for H with respect to z, using the fact that $B_-(z,r,D_r,D_t)$ and $G_{-,s}(z,z_0)$ commute, that the operator $H_0(z,z_0)$ is a solution operator for the Cauchy initial value problem for the so-called DSR equation, given by

$$\left(\frac{\partial}{\partial z} - \mathrm{i}B_-(z,s,D_s,D_t) - \mathrm{i}B_-(z,r,D_r,D_t)\right) u = 0. \tag{3.11}$$

Using Duhamel's principle (cf. (1.2)), it follows that

$$u(z,s,r,t) = \int_z^Z (H(z,z_0)g(z_0,\cdot,\cdot,\cdot))(s,r,t)\,\mathrm{d}z_0 \tag{3.12}$$

solves the inhomogeneous DSR equation,

$$\begin{aligned}&\left(\frac{\partial}{\partial z} - \mathrm{i}B_-(z,s,D_s,D_t) - \mathrm{i}B_-(z,r,D_r,D_t) - C(z,s,D_s,D_t) - C(z,r,D_r,D_t)\right) u\\ &\quad = g(z,s,r,t), \quad 0 \le z < Z,\end{aligned} \tag{3.13}$$

with zero initial condition, $u(Z,s,r,t) = 0$. It follows from (3.10) that $F_{\mathrm{D}}\delta c$ is given by $Q^*_{-,s}(0)Q^*_{-,r}(0)$ acting on the solution u at $z = 0$ of an inhomogeneous DSR equation with

$$g = Q_{-,s}(z)Q_{-,r}(z)\tfrac{1}{2}D_t^2 R \tag{3.14}$$

and Z such that δc is supported in $0 < \delta < z < Z$ as before.

The bicharacteristics associated with (3.13) are, in the notation of (2.21), given by

$$\begin{aligned}&\Gamma(z,z_0;s_0,r_0,t_0,\sigma_0,\rho_0,\tau) = (\gamma_x(z,z_0,s_0,\sigma_0,\tau),\gamma_x(z,z_0,r_0,\rho_0,\tau),t_0\\ &\quad + \gamma_t(z,z_0,s_0,\sigma_0,\tau) + \gamma_t(z,z_0,r_0,\rho_0,\tau),\gamma_\xi(z,z_0,s_0,\sigma_0,\tau),\gamma_\xi(z,z_0,r_0,\rho_0,\tau),\tau).\end{aligned} \tag{3.15}$$

They are defined on the intersection of the maximal intervals associated with source ray coordinates (z,s,σ,τ) and receiver ray coordinates (z,r,ρ,τ); let θ be given as in the previous section. The intersection will be denoted by $]Z_{\min},Z_{\max}[=]Z_{\min}(z,s,r,\sigma,\rho,\tau,\theta),Z_{\max}(z,s,r,\sigma,\rho,\tau,\theta)[$, where we have

$$Z_{\min}(z,s,r,\sigma,\rho,\tau,\theta) = \max(z_{\min,-}(z,s,\sigma,\tau,\theta),z_{\min,-}(z,r,\rho,\tau,\theta)), \tag{3.16}$$

$$Z_{\max}(z,s,r,\sigma,\rho,\tau,\theta) = \min(z_{\max,-}(z,s,\sigma,\tau,\theta),z_{\max,-}(z,r,\rho,\tau,\theta)). \tag{3.17}$$

Let $g(z,s,r,t)$ be supported in the set $0 < \delta < z < Z$. As mentioned, the map $g \mapsto u$ given by (3.12) maps g to the solution of the inhomogeneous DSR equation (3.13) at $z = 0$. Motivated by (3.10), we define an operator L by modifying (3.12) with pseudodifferential factors $Q_{-,s}, Q_{-,r}$ and setting $z = 0$ as follows:

$$Lg = Q^*_{-,s}(0)Q^*_{-,r}(0)\int_0^Z H(0,z)Q_{-,s}(z)Q_{-,r}(z)g(z,\cdot,\cdot,\cdot)\,\mathrm{d}z. \tag{3.18}$$

Our next result states that H and L are Fourier integral operators and gives a representation of the kernel of H as an oscillatory integral. Consider the following set:

$$\begin{aligned}&\{(\Gamma(0,z,s,r,t,\sigma,\rho,\tau);z,s,r,t,-b(z,s,\sigma,\tau) - b(z,r,\rho,\tau),\sigma,\rho,\tau)\,|\\ &\quad (s,r,t,\sigma,\rho,\tau) \in T^*\mathbb{R}^{2n-1}_{(s,r,t)}, 0 > Z_{\min}(z,s,r,t,\sigma,\rho,\tau,\theta_2)\}.\end{aligned} \tag{3.19}$$

As will be clear from the proof below, this set is a canonical relation. Let $y_0 = (s_0, r_0, t_0)$, $\eta_0 = (\sigma_0, \rho_0, \tau)$. A convenient choice of phase function for the canonical relation is described by Maslov and Fedoriuk [18]. They state that one can always use a subset of the cotangent vector components as phase variables. There is always a set of local coordinates for the canonical relation of the form

$$(z, y_{0I}, \eta_{0J}, s, r, t), \tag{3.20}$$

where $I \cup J$ is a partition of $\{1, \dots, 2n-1\}$. It follows from Theorem 4.21 in Maslov and Fedoriuk [18] that there is a function $S = S(z, y_{0I}, \eta_{0J}, s, r, t)$, such that locally the canonical relation (3.19) is given by

$$y_{0J} = -\frac{\partial S}{\partial \eta_{0J}}, \qquad \zeta = \frac{\partial S}{\partial z}, \tag{3.21}$$

$$\eta_{0I} = \frac{\partial S}{\partial y_{0I}}, \qquad (\sigma, \rho, \tau) = -\frac{\partial S}{\partial (s, r, t)}. \tag{3.22}$$

Here we take into account the fact that we have a canonical relation, which introduces a minus sign for (σ, ρ, τ).

LEMMA 3.1. *$H(z, z_0)$ is a Fourier integral operator with canonical relation*

$$\{(\Gamma(z, z_0, s, r, t, \sigma, \rho, \tau); s, r, t, \sigma, \rho, \tau) \mid (s, r, t, \sigma, \rho, \tau) \in T^*\mathbb{R}^{2n-1}_{(s,r,t)} \backslash 0,\ z_0 > Z_{\min}(z, s, r, t, \sigma, \rho, \tau, \theta_2)\}. \tag{3.23}$$

The operator L is a Fourier integral operator with canonical relation (3.19). *The kernel of $H(0, z)$ admits microlocally an oscillatory integral representation with phase variables η_{0J}, given by*

$$(H(0, z))(s_0, r_0, t_0, s, r, t) = (2\pi)^{-(2n-1+|I|)/2} \int A(z, y_0, \eta_{0J}, s, r, t) \exp[\mathrm{i}(S(z, y_{0I}, \eta_{0J}, s, r, t) + \langle \eta_{0J}, y_{0J} \rangle)] \, \mathrm{d}\eta_{0J} \tag{3.24}$$

such that the principal part a of the amplitude A satisfies

$$|a(z, y_0, \eta_{0J}, s, r, t)| = \left| \frac{\partial(\sigma, \rho, \tau)}{\partial(y_{0I}, \eta_{0J})} \right|^{1/2} \tag{3.25}$$

with

$$(\sigma(z, y_{0I}, \eta_{0J}, s, r, t), \rho(z, y_{0I}, \eta_{0J}, s, r, t), \tau(z, y_{0I}, \eta_{0J}, s, r, t)) = -\frac{\partial S}{\partial (s, r, t)}(z, y_{0I}, \eta_{0J}, s, r, t) \tag{3.26}$$

in accordance with (3.22).

Proof. The operators $G_{-,s}(z, z_0)$ and $G_{-,r}(z, z_0)$ are Fourier integral operators as noted at the end of section 2 (subject to the substitution of x by s or r, respectively). We consider $G_{-,s}(z, z_0)$. Locally there are Maslov phase functions for its canonical relation (cf. (2.22)), similar to the one described above, here with phase variables $(\tau, \sigma_{0J'})$, where $I' \cup J'$ is a partition of $\{1, \dots, n-1\}$. Thus $G_{-,s}(z, z_0)$ is a locally

finite sum $\sum_j G^{(j)}_{-,s}(z,z_0)$, where the kernels of $G^{(j)}_{-,s}(z,z_0)$ admit oscillatory integral representations of the form

$$(3.27)\quad (G^{(j)}_{-,s}(z,z_0))(s,t,s_0) = \int A'(s,s_0,\sigma_{0,J'},\tau)\exp[\mathrm{i}(S'(z,z_0,s,s_{0I'},\sigma_{0J'},\tau)-\langle\sigma_{0J'},s_{0J'}\rangle-\tau t)]\mathrm{d}\sigma_{0J'}\mathrm{d}\tau.$$

We denote the canonical relation of $G^{(j)}_{-,s}(z,z_0)$ by $\Lambda^{(j)}_s$ (cf. (2.22)). Similarly, we have $G_{-,r}(z,z_0)=\sum_k G^{(k)}_{-,r}(z,z_0)$ in which the kernels of $G^{(k)}_{-,r}(z,z_0)$ admit oscillatory integral representations of the above type with phase variables $(\tau,\rho_{0J''})$, amplitude A'', and phase function $S''(z,z_0,r,r_{0I''},\rho_{0J''},\tau)-\langle\rho_{0J''},r_{0J''}\rangle-\tau t$. We denote the canonical relation of $G^{(k)}_{-,r}(z,z_0)$ by $\Lambda^{(k)}_r$. But then the kernel of $H(z,z_0)$ is given by a sum $\sum_{j,k}H^{(j,k)}(z,z_0)$. Entering expressions of the type (3.27) for $G^{(j)}_{-,s}(z,z_0)$ and $G^{(k)}_{-,r}(z,z_0)$ into (3.7), and performing the $\bar{t}_0$ integration, we find the following expression for the kernel of $H^{(j,k)}(z,z_0)$:

$$\begin{aligned}(3.28)\quad (H^{(j,k)}(z,z_0))(s,r,t,s_0,r_0,t_0) = \int 2\pi A'(s,s_0,\sigma_{0,J'},\tau)A''(r,r_0,\rho_{0,J''},\tau)\\ \times\exp[\mathrm{i}(S'(z,z_0,s,s_{0I'},\sigma_{0J'},\tau)-\langle\sigma_{0J'},s_{0J'}\rangle\\ +S''(z,z_0,r,r_{0I''},\rho_{0J''},\tau)-\langle\rho_{0J''},r_{0J''}\rangle-\tau t)]\,\mathrm{d}\sigma_{0J'}\,\mathrm{d}\rho_{0J''}\,\mathrm{d}\tau.\end{aligned}$$

It is not difficult to verify that $-\mathrm{i}$ times the argument in the exponent is a nondegenerate phase function. Because A' and A'' are symbols supported inside a region with $\|\sigma\|<C|\tau|$ and $\|\rho\|<C|\tau|$ it follows that $A'A''$ is a symbol and that (3.28) is a Fourier integral operator. From the phase function it follows that the canonical relation of $H^{(j,k)}(z,z_0)$ is given by the points

$$(s,r,t_0+t_1+t_2,\sigma,\rho,\tau;s_0,r_0,t_0,\sigma_0,\rho_0,\tau)$$

with

$$(s,t_1,\sigma,\tau;s_0,0,\sigma_0,\tau)\in\Lambda^{(j)}_s \text{ and } (r,t_2,\rho,\tau;r_0,0,\rho_0,\tau)\in\Lambda^{(k)}_r.$$

Taking the union over (j,k) results in (3.23).

Using (3.18) and the fact that H is given by a sum of terms of the form (3.28), it also follows that L is a Fourier integral operator with canonical relation (3.19), as usual for the solution operators of first-order hyperbolic equations.

The phase function $S(z,y_{0I},\eta_{0J},s,r,t)-\langle\eta_{0J},y_{0J}\rangle)$, with S as described in (3.21)–(3.22), describes locally the canonical relation of $H(0,z)$. Therefore the kernel of $H(0,z)$ has microlocally an oscillatory integral representation of the form

$$\begin{aligned}(3.29)\quad (H(0,z))(y_0,s,r,t) = (2\pi)^{-(2n-1+|I|)/2}\\ \times\int A(z,y_0,\eta_{0J},s,r,t)\exp[\mathrm{i}(S(z,y_{0I},\eta_{0J},s,r,t)+\langle\eta_{0J},y_{0J}\rangle)]\,\mathrm{d}\eta_{0J}.\end{aligned}$$

Then the adjoint $H(0,z)^*$ has amplitude $\overline{A(z,y_0,\eta_{0J},s,r,t)}$ and phase $-S(z,y_{0I},\eta_{0J},s,r,t)-\langle\eta_{0J},y_{0J}\rangle$. Hence, the kernel of the composition $H(0,z)^*H(0,z)$ has the

oscillatory integral representation

$$(3.30)\quad (2\pi)^{-(2n-1)}\int \overline{A(z,y_0,\eta_{0J},s',r',t')}A(z,y_0,\eta_{0J},s,r,t)\\ \times\exp(\mathrm{i}[-S(z,y_{0I},\eta_{0J},s',r',t')+S(z,y_{0I},\eta_{0J},s,r,t)])\,\mathrm{d}y_{0I}\mathrm{d}\eta_{0J}.$$

We expand the phase as a function of (s',r',t') in a Taylor series about (s,r,t) and identify the gradient

$$(3.31)\quad -\frac{\partial S}{\partial(s,r,t)}(z,y_{0I},\eta_{0J},s,r,t)\\ =(\sigma(z,y_{0I},\eta_{0J},s,r,t),\rho(z,y_{0I},\eta_{0J},s,r,t),\tau(z,y_{0I},\eta_{0J},s,r,t)).$$

Applying a change of variables, $(y_{0I},\eta_{0J})\mapsto(\sigma,\rho,\tau)$, the phase takes the form

$$(3.32)\qquad \langle(\sigma,\rho,\tau),(s'-s,r'-r,t'-t)\rangle.$$

In the text preceding (2.23) it was noted that $G_{0,-}(z,z_0)$ is unitary. It follows using (3.8) that $H_0(z,z_0)$ is also unitary. Therefore, the operator $H(0,z)^*H(0,z)$ must be a pseudodifferential operator (in (s,r,t)) with symbol 1 in the set of (s,r,t,σ,ρ,τ), where ψ_2 is equal to 1. We conclude that the principal part a of the amplitude A is given by

$$(3.33)\qquad |a(z,y_0,\eta_{0J},s,r,t)|=\left|\frac{\partial(\sigma,\rho,\tau)}{\partial(y_{0I},\eta_{0J})}\right|^{1/2}. \qquad \square$$

4. Depth-to-time conversion. For $h=h(z,s,r)$ we consider the mapping

$$(4.1)\qquad K\ :\ h\mapsto Q^*_{-,s}(0)Q^*_{-,r}(0)\int_0^Z H(0,z)Q_{-,s}(z)Q_{-,r}(z)(E_2h)(z,\cdot,\cdot,\cdot)\mathrm{d}z;$$

we have $K=LE_2$ (cf. (3.18)). The DSR modeling operator (cf. (3.10)) is then given by

$$(4.2)\qquad F_{\mathrm{D}}\delta c=\frac{1}{2}D_t^2KE_1c_0^{-3}\delta c.$$

This factorization is exploited in seismic applications such as imaging.

First we make the following observation. We use the notation $\Theta=\Theta(z,s,r,\sigma,\rho,\tau)$ for the sum $-b(z,s,\sigma,\tau)-b(z,r,\rho,\tau)$ appearing in the canonical relation (3.19) of L,

$$(4.3)\qquad \Theta(z,s,r,\sigma,\rho,\tau)=-b(z,s,\sigma,\tau)-b(z,r,\rho,\tau).$$

Because of expression (2.1) the map $\tau\mapsto\zeta=\Theta$ is strictly monotone when Θ is real. Taking as domain only the τ where the two square roots are real, we find the following lemma. The inverse of this map will be denoted by Θ^{-1}.

LEMMA 4.1. *Suppose (z,s,r,σ,ρ) are given, let $c=\max(c(z,s)\|\sigma\|,c(z,r)\|\rho\|)$, and let $d=\sqrt{|\sigma^2\frac{c(z,s)^2}{c(z,r)^2}-\rho^2|}$ if $c(z,s)\|\sigma\|\geq c(z,r)\|\rho\|$ and $d=\sqrt{|\rho^2\frac{c(z,r)^2}{c(z,s)^2}-\sigma^2|}$ otherwise. The map $\tau\mapsto\Theta(z,s,r,\sigma,\rho,\tau)$ is a diffeomorphism $]-\infty,-c[\cup]c,\infty[\ \to\ ]-\infty,-d[\cup]d,\infty[$.*

The maximal depth $Z_{\max}$ associated with $(z,s,r,\sigma,\rho,\tau,\theta)$ also has an associated maximal time, given by

$$(4.4)\qquad T_{\max}(z,s,r,\sigma,\rho,\tau,\theta)=-\Gamma_t(Z_{\max}(z,s,r,\sigma,\rho,\tau,\theta),s,r,\sigma,\rho,\tau).$$

We define a subset Ω_θ of $T^*\mathbb{R}^{2n-1}_{(s,r,t)}$, such that t is bounded by $T_{\max}$,

$$\Omega_\theta = \{(s,r,t,\sigma,\rho,\tau)\,|\,0<t<T_{\max}(0,s,r,\sigma,\rho,\tau,\theta)\}. \tag{4.5}$$

We have the following result about K.

THEOREM 4.2. *The operator K is microlocally a Fourier integral operator with canonical relation consisting of a set of points,*

$$\{(\Gamma(0,z,s,r,0,\sigma,\rho,\tau);z,s,r,\Theta(z,s,r,\sigma,\rho,\tau),\sigma,\rho)\,| \\ z,s,r,\sigma,\rho,\tau\in\mathbb{R}^{4n-2}, 0<Z_{\min}(z,s,r,\sigma,\rho,\tau,\theta_2)\}. \tag{4.6}$$

This canonical relation is the graph of an invertible map Σ:

$$\{(z,s,r,\zeta,\sigma,\rho)\,|\,0\langle z,0\rangle Z_{\min}(z,s,r,\sigma,\rho,\Theta^{-1}(z,s,r,\zeta,\sigma,\rho),\theta_2)\}\to\Omega_{\theta_2}. \tag{4.7}$$

The map K converts depth to time, which is indeed the way seismologists often look at modeling.

Proof. The operator K is the composition of (3.18) and E_2. The first is a Fourier integral operator with canonical relation given by (3.19). The operator E_2 is a Fourier integral operator with canonical relation given by

$$\{(z,s,r,0,\zeta,\sigma,\rho,\tau;z,s,r,\zeta,\sigma,\rho)\,|\,(z,s,r,\zeta,\sigma,\rho)\in T^*\mathbb{R}^{2n-1}_{(z,s,r)}\backslash 0,\tau\in\mathbb{R}\backslash\{0\}\}. \tag{4.8}$$

In general, the composition of two canonical relations $\Lambda_1\subset T^*(X\times Y)\backslash 0$, $\Lambda_2\subset T^*(Y\times Z)\backslash 0$, X,Y,Z open subsets of $\mathbb{R}^{n_X},\mathbb{R}^{n_Y}$, respectively, $\mathbb{R}^{n_Z}$, is said to be transversal if

$$\Lambda_1\times\Lambda_2 \text{ intersects } T^*X\times(\operatorname{diag}T^*Y)\times T^*Z \text{ transversally.}$$

In the particular case of the canonical relations of L and E_2, their composition is transversal if at the solution τ of

$$-b_s-b_r=\zeta \tag{4.9}$$

we have $\frac{\mathrm{d}\Theta}{\mathrm{d}\tau}\neq 0$; see, e.g., Theorem 2.4.1 in [10]. Because by the previous lemma this is the case, it then follows that the composition LE_2, hence K, is a Fourier integral operator. The composition of the canonical relations is equal to (4.6).

The canonical relation of K is parameterized by (z,s,r,σ,ρ,τ) in a subset of $\mathbb{R}^{4n-2}$. To show that it is invertible we must show that the projections of (4.6) on the two sets given in (4.7) are both diffeomorphisms. By the previous lemma this is clear for the projection on the right-hand side of (4.7). For the projection on the left-hand side of (4.7) it follows from Lemma 25.3.6 of [15] and the fact that the right projection has maximal rank that the linearization of this projection is invertible. Thus it remains to be shown that the equation

$$(s_0,r_0,t_0,\sigma_0,\rho_0,\tau_0)=\Gamma(0,z,s,r,0,\sigma,\rho,\tau) \tag{4.10}$$

determines a unique point (z,s,r,σ,ρ,τ) when $(s_0,r_0,t_0,\sigma_0,\rho_0,\tau_0)$ is in Ω_{θ_2}, the right-hand side of (4.7). The point $(s_0,r_0,t_0,\sigma_0,\rho_0,\tau_0)$ determines a DSR bicharacteristic $\Gamma(z,0,s_0,r_0,t_0,\sigma_0,\rho_0,\tau_0)$. The t component will be denoted here by $\Gamma_t = t_0-\gamma_t(z,0,s_0,\sigma_0,\tau)-\gamma_t(z,0,r_0,\rho_0,\tau)$. We have a solution to (4.10) if and only if

$$\Gamma(z,0,s_0,r_0,t_0,\sigma_0,\rho_0,\tau_0)-(s,r,0,\sigma,\rho,\tau)=0. \tag{4.11}$$

In particular, we have that $\Gamma_t(z, 0, s_0, r_0, t_0, \sigma_0, \rho_0, \tau_0) = 0$. Because Γ_t depends strictly monotonically on z, this equation uniquely determines z. The other equations uniquely determine s, r, σ, ρ, τ. If $z < Z_{\max}(0, s_0, r_0, \sigma_0, \rho_0, \tau)$, then there is a DSR bicharacteristic connecting $(s_0, r_0, t_0, \sigma_0, \rho_0, \tau)$ at depth 0 with $(s, r, t, \sigma, \rho, \tau) = \Gamma(z, 0, s, r, t_0, \sigma, \rho, \tau)$ at depth z; hence it follows that then $0 > Z_{\min}(z, s, r, \sigma, \rho, \tau)$, and vice versa. So using definition (4.4) this point $(z, s, r, \sigma, \rho, \tau)$ is such that $0 > Z_{\min}(z, s, r, \sigma, \rho, \tau, \theta_2)$ precisely when $t < T_{\max}(0, s_0, r_0, \sigma_0, \rho_0, \tau_0, \theta_2)$. This completes the proof of the theorem. □

5. Modeling in the single-scattering approximation. The replacement of the wave equation Green's function by a pair of one-way Green's functions leads to a cutoff in the modeling of the scattered wave field. To describe when all the singularities of the data are modeled by the DSR method, we need the following assumption. We use some angle θ, $0 < \theta < \pi/2$, with the vertical as introduced in section 2.

ASSUMPTION 2 (DSR assumption). *If $(z, x) \in X$ and $\alpha, \beta \in S^{n-1}$, $t_s, t_r > 0$ depending on (z, x, α, β) are such that $\eta_z(t_s, z, x, \beta, \tau) = \eta_z(t_r, z, x, \alpha, \tau) = 0$, then*

$$c(z, x)^{-1} \frac{\partial \eta_z}{\partial t}(t, z, x, \beta, \tau) < -\cos(\theta), t \in [0, t_s], \tag{5.1}$$

$$c(z, x)^{-1} \frac{\partial \eta_z}{\partial t}(t, z, x, \alpha, \tau) < -\cos(\theta), t \in [0, t_r]. \tag{5.2}$$

It is clear that this assumption is stronger than Assumption 1. In general the set of rays violating this assumption is not small, but it can contain an open subset of the canonical relation (1.7), depending on the properties of the background medium. This limits the applicability of the method discussed here, which however is still useful in many cases, as discussed in the introduction.

In the following theorem we give the DSR modeling formula, and we give the result in terms of a cutoff acting on $F\delta c$. The symbol $\psi_2(0, z, s, r, 0, \sigma, \rho, \tau)$ can be pulled back to a symbol that is a function of $(s, r, t, \sigma, \rho, \tau)$ by the inverse of the map Σ given by (4.6), (4.7).

THEOREM 5.1. *If Assumption 2 is satisfied with $\theta = \theta_1$, then $F_D \delta c \equiv F\delta c$. There is a pseudodifferential operator $\psi_D = \psi_D(s, r, t, D_s, D_r, D_t)$ with principal symbol given by the pull back mentioned just above of ψ_2, that is, 1 on Ω_{θ_1}, and is in $S^{-\infty}$ outside Ω_{θ_2}, such that*

$$F_D \delta c \equiv \psi_D F \delta c. \tag{5.3}$$

Proof. We reconsider the modeling operator F of Theorem 1.1 and use its description by (3.5). In this proof, we denote by G_s the map from a function $f(z, s, t)$ to $(G_s f)(z, s, t) = \int_{\mathbb{R}\times\mathbb{R}^{n-1}\times\mathbb{R}} G(z, s, t - t_0, z_0, s_0) f(z_0, s_0, t_0)\, dz_0 ds_0 dt_0$; cf. (1.2). Motivated by (3.5) and the introduction of H in (3.8), we consider the operator $M = (\mathrm{Id}_r \otimes G_s) \circ (G_r \otimes \mathrm{Id}_s)$, which maps functions of (z_s, z_r, s, r, t) to functions of (z_s, z_r, s, r, t). In our application, we consider M as a map of functions in $z > \delta$ to functions on a small neighborhood of $z_s = 0, z_r = 0$. By an argument similar to the first part of the proof of Lemma 3.1, it follows that M is a Fourier integral operator, with canonical relation consisting of a set of points

$$\{(\eta_{z,s}, \eta_{z,r}, \eta_{x,s}, \eta_{x,r}, t + t_s + t_r, \eta_{\zeta,s}, \eta_{\zeta,r}, \eta_{\xi,s}, \eta_{\xi,r}, \tau; z_s, z_r, s, r, t, \zeta_s, \zeta_r, \rho, \sigma, \tau)\}, \tag{5.4}$$

where $(\zeta_s,\sigma) = -\tau c(z_s,s)^{-1}\beta$, $(\zeta_r,\rho) = -\tau c(z_r,r)^{-1}\alpha$, $\eta_{z,s} = \eta_z(t_s,z_s,s,\beta,\tau)$, and similar for the other components, and for the r-components, cf. (1.6); $\alpha,\beta \in S^{n-1}$ as in Theorem 1.1.

Denote by $R_4(z)$ the restrictions to $z_s = z$ and $z_r = z$ of functions $f(z_s,z_r,s,r,t)$ and by $E_4(z)$ the map that maps a function $f(s,r,t)$ to $(E_4(z)f)(z_s,z_r,s,r,t) = \delta(z_s - z)\delta(z_r - z)f(s,r,t)$. It follows, from writing out the distribution kernel of M, and using the remark below (2.20), that for distributions in (z_s,z_r,s,r,t) with singularities with $\tau^{-1}\zeta_s > 0$ and $\tau^{-1}\zeta_r > 0$, we have

$$R_4(0)ME_4(z)\psi_2'(z,0) = -\frac{1}{4}Q_{-,s}^*(0)Q_{-,r}^*(0)H(0,z)Q_{-,s}(z)Q_{-,r}(z), \tag{5.5}$$

modulo a regularizing operator, where $\psi_2' = \psi_2 - Q_{-,s}^{-1}Q_{-,r}^{-1}[Q_{-,s}Q_{-,r},\psi_2]$. Since for F the rays come from one side of the surface $z = 0$, we can apply this to (3.5). Denote by E_5 the map that maps a function $f(z,s,r,t)$ to $(E_5(z)f)(z_s,z_r,s,r,t) = \delta(z_s - z_r)f(\frac{z_s+z_r}{2},s,r,t)$. It follows that we have

$$R_4(0)ME_5\psi_2'(z,0)E_2E_1(c_0^{-3}\delta c) \equiv \tfrac{1}{4}KE_1(c_0^{-3}\delta c), \tag{5.6}$$

modulo a regularizing operator.

We can find an operator $\psi'(z,s,r,D_z,D_s,D_r)$ such that the principal symbol $\psi_2' - \psi'$ is zero on the set $\zeta = -b(z,s,\sigma,\tau) - b(z,r,\rho,\tau)$. Namely, first set (for the principal symbol) $\psi'(z,s,r,\zeta,\sigma,\rho) = \psi_2'(z,0,s,r,\sigma,\rho,\Theta^{-1})$. Then the map $ME_5(\psi_2' - \psi')$ is a Fourier integral operator with highest-order amplitude equal to zero. With lower-order terms in ψ' we find that we can replace ψ_2' in (5.6) by an operator $\psi' = \psi'(z,s,r,D_z,D_s,D_r)$. The operator ψ' commutes with E_2. Hence, if $h = h(z,s,r)$, we have that

$$R_4(0)ME_5E_2\psi'h = Kh, \tag{5.7}$$

modulo a smoothing operator. Because of equality (5.7), $R_4(0)ME_5E_2$ is an invertible Fourier integral operator with canonical relation given by (4.6), microlocally on a neighborhood of the set where ψ' is not in $S^{-\infty}$. Now define microlocally on a neighborhood of the set where ψ' is not in $S^{-\infty}$,

$$\psi_{\mathrm{D}} = R_4(0)ME_5E_2\psi'(R_4(0)ME_5E_2)^{-1}. \tag{5.8}$$

By Egorov's theorem this is a pseudodifferential operator with symbol as in the theorem and we have

$$\psi_{\mathrm{D}}R_4(0)ME_5E_2 = K, \tag{5.9}$$

modulo a smoothing operator. It follows that (5.3) is satisfied. □

6. The Bolker condition. It follows from (4.2) and from Theorem 4.2 that the canonical relation of F_{D} in (3.10) satisfies Guillemin's [11] Bolker condition: The projection of the canonical relation (1.7) on $T^*Y\backslash 0$ is an embedding.

Indeed, Assumption 2 is stronger than this condition, as can be seen from the

arguments in the proof of Theorem 4.2. This fact will be important for the inverse scattering based on modeling data by F_{D}.

Acknowledgments. We thank Margaret Cheney for her interest in the work presented in this paper and for encouraging us to write up the results in the present form. We also thank the members of the Mathematical Sciences Research Institute, and in particular Gunther Uhlmann, for providing a very stimulating environment during the Inverse Problems program in Fall 2001.

SOME PROPERTIES OF THE CAPACITY VALUE FUNCTION*

B. A. CHIERA†, A. E. KRZESINSKI‡, AND P. G. TAYLOR†

Abstract. In a previous paper [B. A. Chiera and P. G. Taylor, *Probab. Engrg. Inform. Sci.*, 16 (2002), pp. 513–522], two of the authors developed a method for ascribing a value to an extra unit of capacity on a telecommunications link. Specifically, they expressed the value of an extra unit of capacity as a function of current capacity, current occupancy, and a planning horizon. The intention was to use this function as an ingredient in a bandwidth reallocation scheme for ensuring efficient operation of a telecommunications network.

Unfortunately, direct evaluation of the function requires numerical inversion of a Laplace transform expressed in terms of Charlier polynomials, a task that is beyond the processing capabilities of typical switches in today's telecommunications networks. Because of this, it is desirable to have more easily computable methods of either calculating or approximating the capacity value function. We develop two approaches to this problem: the first is a recursive method of computing the Laplace transform of the capacity value function, and the second is a linear approximation to the capacity value function itself.

Key words. Erlang loss system, capacity value function, approximation

1. Introduction.

A topical issue in recent telecommunications literature revolves around the problem of how network resources should be reallocated from underutilized to overutilized links. One possible way to approach this problem is by calculating the expected amount of extra revenue that would be earned on a specified end-to-end link over some planning horizon if extra capacity were present on that link. A reallocation scheme can then be designed in which capacity is transferred from places in the network where its earning capacity is temporarily low to places where it is high. We would expect that such a scheme should maximize the overall rate at which the network earns revenue.

Previous approaches to allocating a value to capacity in a telecommunications context cover an extensive range. They include a simple model in which the value of capacity is an exponential function of the amount of free capacity [8], a model that values customers in a dynamic loss system [10], multimarket pricing scenarios that price resources on the basis of current and future usage [7], and constrained producer-consumer linear programming models requiring simultaneous solution [11].

For any capacity valuation model to be implementable in practice, it must satisfy the following criteria:

1. It must require only local information; that is, knowledge of the current state of the entire network should not be required to compute the value of capacity on any given route.

*Received by the editors July 2, 2003; accepted for publication (in revised form) September 8, 2004; published electronically April 26, 2005. This research was supported by Australian Research Council grant A10033153.

‡Department of Computer Science, University of Stellenbosch, 7600 Stellenbosch, South Africa (aek1@cs.sun.ac.za).

2. It should be scalable. This means that the model must allow for, and be easily adaptable to, changes in network size.
3. It should involve calculations that can be efficiently implemented by network switches.

Some of the above pricing schemes satisfy the first two requirements. However, with the exception of the exponential pricing function given in [8], it is not always clear that these schemes can be implemented and run in real time on network switches. In particular, the WALRAS model proposed by Wellman [11] possesses the disadvantage that the time for computation can potentially exceed the time it takes for the underlying market to change.

While the pricing function suggested by [8] does satisfy all three requirements, it is not derived from a realistic model for the value of capacity. Thus it is unlikely that a reallocation scheme based on this valuation would maximize the overall good of either the subnetwork to which the link belongs or the network as a whole.

An alternative method for valuing capacity was proposed by two of the authors in [4]. This model, derived from the basic tenets of renewal theory, is designed to reflect the difference between the amount of lost revenue that would ensue if a particular link were allocated an extra unit of capacity and if it were not. This difference can be thought of as the "value to the link" of the extra capacity.

In ongoing work, the authors are planning to incorporate this value function into a capacity reallocation scheme. The method allows for reallocations to occur between multiple-link routes and their constituent single-link routes, with the result that the model is decentralized and scalable while at the same time able to maximize the revenue in each part of the network.

A potential drawback, however, is that the calculation of the value function involves numerical computations that are beyond the capacity of today's switches. The numerical problems manifest themselves at two stages. First, it is necessary to calculate the Laplace transform of the capacity value function, which is expressed in terms of Charlier polynomials, in a stable and efficient manner. Second, it is necessary to invert the Laplace transform numerically.

In this paper, we shall address both of the above-mentioned difficulties. By concentrating on computing ratios of the Charlier polynomials, rather than the polynomials themselves, we shall develop a stable recursive method for computing the Laplace transform of the capacity value function. This can be used in conjunction with an efficient method of transform inversion if one is available. For situations when no such method is available, we propose a linear approximation to the capacity value function itself, together with a bound on its accuracy. Furthermore, we present efficient recursions for calculating the coefficients in the linear approximation. The value of capacity as given by the linear approximation can be thought of as consisting of an initial set-up cost and then a fixed per-unit cost. As such, it may prove to be useful in formulating optimization problems involving the allocation of capacity.

In section 2 we shall give a brief description of the value function of [4] and establish a preliminary result. In section 3 we shall introduce our recursion for the Laplace transform of the capacity value function. Section 4 contains our approximation of the capacity value function itself together with a discussion of the approximation error and how the various coefficients might be efficiently calculated, while section 5 presents a numerical comparison of the approximate model compared with the original pricing model. Finally, some conclusions are presented in section 6.

2. The valuation model. The model of [4] is calculated on the assumption that an end-to-end link in a telecommunications network is well modeled by an M/M/C/C loss system. This is a continuous-time birth-and-death process with state space $\{0, 1, \ldots, C\}$ [9]. For $0 \leq n \leq C$, the state n denotes the number of connections present at any one time. We assume that the arrival rate λ and mean holding time μ^{-1} of connections are known. In practice, this may not be true in any a priori sense. However, methods for online evaluation of these parameters are currently a subject of great interest in the literature (see, for example, [3]) and it is reasonable to expect that estimates will be available. We denote the expected amount of revenue earned per connection by θ.

In [4], two of the authors derived the function $R_{n,C}(T)$ that gives the expected revenue lost in the interval $[0, T]$ due to arriving connections being rejected, when the capacity is C and the occupancy at time 0 is n. This model can be converted to a set of value functions for capacity via the relations

$$B_n(T) = R_{n,C}(T) - R_{n,C+1}(T), \tag{2.1}$$

$$S_n(T) = \begin{cases} R_{n,C-1}(T) - R_{n,C}(T) & \text{when} \quad n < C, \\ R_{C-1,C-1}(T) - R_{C,C}(T) & \text{when} \quad n = C, \end{cases} \tag{2.2}$$

respectively. The function $B_n(T)$ gives the amount that the link should "pay" for an extra unit of capacity. The logic behind (2.1) is that the value of an extra unit of capacity is given by the expected difference between the revenue that would be lost over the planning horizon $[0, T]$ if the extra capacity were present at time 0 and if it were not. Similarly, the function $S_n(T)$ gives the expected amount of extra revenue that would be lost over the planning horizon $[0, T]$ if the link were to give up a unit of capacity at time 0.

The formula (2.2) was not explicitly given in [4] for the case $n = C$. In this case, if the link were to give up a unit of capacity, it would also have to eject one of its current customers. The issue then arises as to whether an extra penalty value should be added to reflect the negative consequences of such a decision. The right-hand side of (2.2) reflects the situation in which no such penalty is added. The opposite extreme would be to incorporate an infinite penalty, which would have the effect of precluding any capacity reallocation away from a full link.

We might envisage a capacity reallocation scheme in which the links act in a cooperative manner. If $S_n(T)$ for one link is less than or equal to $B_n(T)$ for another link with whom it shares physical capacity, then a unit of capacity will be reallocated from the first link to the second. Via this mechanism, capacity is moved to that part of the network in which it can have the greatest effect in reducing loss of revenue.

To evaluate $R_{n,C}(T)$, it is necessary to compute the numerical inversion of the Laplace transform,

$$\widetilde{R}_{n,C}(s) = \left(\frac{1}{s}\right)\left(\frac{\theta\lambda}{(s + C\mu)P_C\left(s/\lambda\right) - C\mu P_{C-1}\left(s/\lambda\right)}\right) P_n\left(\frac{s}{\lambda}\right), \tag{2.3}$$

where

$$P_n(s/\lambda) = (-\mu/\lambda)^n C_n^{(\lambda/\mu)}\left(-s/\mu\right) \tag{2.4}$$

and

$$C_n^{(\lambda/\mu)}\left(-s/\mu\right) = \sum_{k=0}^{n} \binom{n}{k}\binom{-s/\mu}{k}\left(\frac{-\lambda}{\mu}\right)^{n-k} k! \tag{2.5}$$

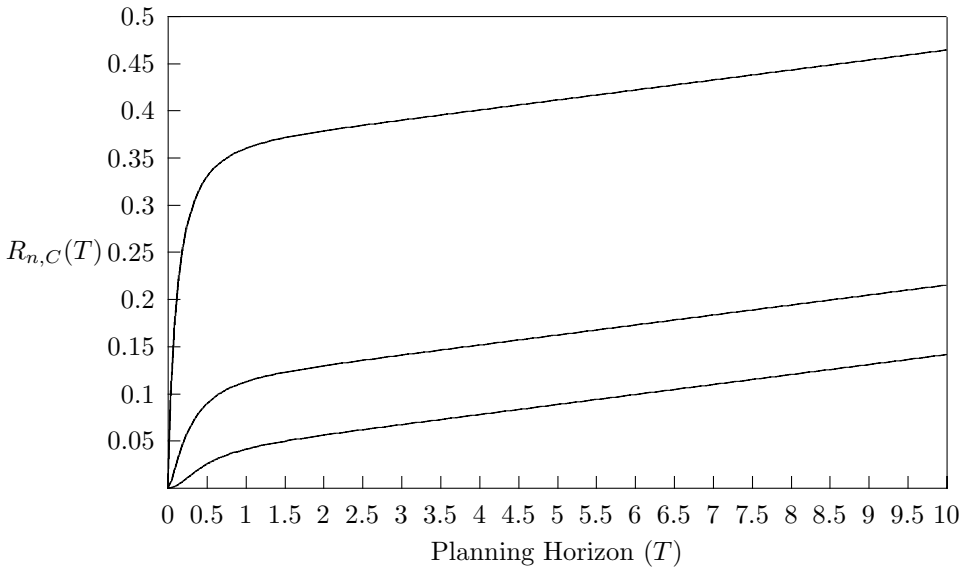

FIG. 1. $R_{n,C}(T)$ *with* $n = 4, 5, 6, C = 6, \lambda = 3$, *and* $\mu^{-1} = 0.5$.

is a Charlier polynomial as defined in [5]. For some purposes below it will be convenient to write $P_n(s/\lambda)$ in the form

$$P_n(s/\lambda) = \sum_{k=0}^{n} \binom{n}{k} \left(\frac{1}{\lambda}\right)^k s(s+\mu)\dots(s+(k-1)\mu), \tag{2.6}$$

which is easily derived by substituting (2.5) into (2.4). In [4] it was recommended that the Euler method (see Abate and Whitt [1]) be used for the numerical inversion of $\widetilde{R}_{n,C}(s)$ to yield $R_{n,C}(T)$. This involves numerical integration of the function $\widetilde{R}_{n,C}(s)$ along a contour which lies in the right complex half-plane. Thus, to implement the method, we need to be able to evaluate the right-hand side of (2.3) for complex numbers s with $\Re(s) > 0$.

An example of the lost revenue curves described by $R_{n,C}(T)$ is given in Figure 1. This example is adapted from one presented in [4]. Here the expected loss revenue curves are given for the case where $C = 6, n \in \{4, 5, 6\}, \lambda = 3$, and $\mu^{-1} = 0.5$.

In practice, it is difficult to evaluate both the expression on the right-hand side of (2.3) and its inverse Laplace transform. The calculation of the Charlier polynomials and $\widetilde{R}_{n,C}(s)$, if not done carefully, may be subject to arithmetic overflow, while the Euler method, although straightforward from an implementation viewpoint, is numerically complex. It is therefore of interest to develop stable and efficient methods for the calculation of $\widetilde{R}_{n,C}(s)$ and $R_{n,C}(T)$. In the following sections, we develop a recursion for $\widetilde{R}_{n,C}(s)$ and a linear approximation for $R_{n,C}(T)$. Furthermore, we give a stable recursion for computing the coefficients and bounds on the accuracy of the approximation. To conclude this section, we prove the following lemma, which will be useful in the rest of the paper.

LEMMA 2.1. *Let*

$$G_C(s) = (s + C\mu)P_C(s/\lambda) - C\mu P_{C-1}(s/\lambda) \tag{2.7}$$

so that the denominator of the right-hand side of (2.3) *is* $sG_C(s)$. *Then*

(i) $G_C(s)$ *has a zero at* $s = 0$, *which implies that* $G_C(s) = sF_C(s)$, *where* $F_C(s)$ *is a polynomial of degree* C;

(ii) *the zeros* $-\sigma_C < -\sigma_{C-1} \cdots < -\sigma_1$ *of* $F_C(s)$ *are all real and negative; and*

(iii) *the maximal zero* $-\sigma_1$ *of* $F_C(s)$ *is less than* $-\mu$.

Proof. Clearly $G_C(s)$ is a polynomial of degree $C + 1$. To get (i), observe that

$$G_C(s) = (s + C\mu)\left(\frac{-\mu}{\lambda}\right)^C C_C^{(\lambda/\mu)}(-s/\mu) - C\mu\left(\frac{-\mu}{\lambda}\right)^{C-1} C_{C-1}^{(\lambda/\mu)}(-s/\mu), \tag{2.8}$$

where $C_n^{(\lambda/\mu)}(-s/\mu)$ is defined in (2.5). Substituting $s = 0$ in (2.5), we see that $C_n^{(\lambda/\mu)}(0) = (\frac{-\lambda}{\mu})^n$ and thus the right-hand side of (2.8) is zero at $s = 0$. This gives (i).

Now let us think about (ii). It is known [5] that the zeros of $C_n^{(\lambda/\mu)}(x)$ are all real and positive. Moreover they interleave, that is, with $x_{n,i}$ the ith zero of $C_n^{(\lambda/\mu)}(x)$,

$$0 < x_{n,1} < x_{n-1,1} < \cdots x_{n,i} < x_{n-1,i} < x_{n,i+1} < \cdots < x_{n-1,n-1} < x_{n,n} < \infty. \tag{2.9}$$

By (2.4), we can see that the zeros of $P_n(s/\lambda)$ occur at the points $s_{n,i} = -x_{n,i}\mu$, which are all real and negative. From (2.9) it thus follows that

$$-\infty < s_{n,n} < s_{n-1,n-1} < \cdots < s_{n,i+1} < s_{n-1,i} < s_{n,i} < \cdots < s_{n-1,1} < s_{n,1} < 0. \tag{2.10}$$

For notational convenience, define $s_{n,0} = 0$ and $s_{n,n+1} = -\infty$. From (2.6), it is easy to see that the lead coefficient of $P_n(s/\lambda)$ is positive and so $P_n(s/\lambda)$ is negative in intervals of the form $(s_{n,2k}, s_{n,2k-1})$ for $k = 1, \lceil n/2 \rceil$ and positive in intervals of the form $(s_{n,2k+1}, s_{n,2k})$ for $k = 0, \lfloor n/2 \rfloor$.

It is clear from the representation (2.6) that $-C\mu$ is not a zero of $P_{C-1}(s/\lambda)$, so the point $-C\mu$ must lie in one of the intervals $(s_{C-1,i+1}, s_{C-1,i})$ for $i = 0, \ldots, C-1$. Define $j \in \{0, \ldots, C-1\}$ to be such that the interval that contains $-C\mu$ is $(s_{C-1,j+1}, s_{C-1,j})$. It follows from the interleaving property (2.10) that for $i \neq j$, $(s + C\mu)P_C(s/\lambda)$ changes sign exactly once in each of the intervals $(s_{C-1,i+1}, s_{C-1,i})$. Since $F_C(s) = (s + C\mu)P_C(s/\lambda)$ at the zeros of $P_{C-1}(s/\lambda)$, it too must change sign at least once in each of the intervals $(s_{C-1,i+1}, s_{C-1,i})$ for $i \neq j$. Thus there is at least one zero of $F_C(s)$ in each of the intervals $(s_{C-1,i+1}, s_{C-1,i})$ for $i \neq j$.

Now consider the behavior of $F_c(s)$ in the interval $(s_{C-1,j+1}, s_{C-1,j})$. The function $(s + C\mu)P_C(s/\lambda)$ changes sign twice in this interval. Assume that j is odd and not equal to $C - 1$. Then, by the interleaving property (2.10) and by the fact that $s_{C-1,j+1} < -C\mu < s_{C-1,j}$, it follows that $F_C(s_{C-1,j}) = (s_{C-1,j} + C\mu)P_C(s_{C-1,j}/\lambda)$ and $F_C(s_{C-1,j+1}) = (s_{C-1,j+1} + C\mu)P_C(s_{C-1,j+1}/\lambda)$ must both be negative. Moreover, $P_{C-1}(s/\lambda)$ is negative for $s \in (s_{C-1,j+1}, s_{C-1,j})$, which gives us that $F_C(s_{C,j+1})$ and $F_C(-C\mu)$ are both positive. There must therefore exist two zeros of $F_C(s)$ in the interval $(s_{C-1,j+1}, s_{C-1,j})$. A similar argument holds if j is even, equal to 0, or equal to $C - 1$.

We have thus shown that the degree-C polynomial $F_C(s)$ has C real and negative zeros, $C - 2$ of them in intervals of the form $(s_{C-1,i+1}, s_{C-1,i})$, for $i \neq j$, and two of them in the interval $(s_{C-1,j+1}, s_{C-1,j})$. Part (ii) of the lemma is proved.

To prove part (iii), we substitute the form (2.6) of $P_n(s/\lambda)$ into (2.7). We have

$$\begin{aligned} G_C(s) &= s\sum_{k=0}^{C}\binom{C}{k}\left(\frac{1}{\lambda}\right)^k s(s+\mu)\dots(s+(k-1)\mu) \\ &\quad + C\mu\sum_{k=0}^{C-1}\left[\binom{C}{k}-\binom{C-1}{k}\right]\left(\frac{1}{\lambda}\right)^k s(s+\mu)\dots(s+(k-1)\mu) \\ &\quad + C\mu\left(\frac{1}{\lambda}\right)^C s(s+\mu)\dots(s+(C-1)\mu) \end{aligned}$$

and so $F_C(s) = G_C(s)/s$ can be expressed as

$$\begin{aligned} F_C(s) &= \sum_{k=0}^{C}\binom{C}{k}\left(\frac{1}{\lambda}\right)^k s(s+\mu)\dots(s+(k-1)\mu) \\ &\quad + C\mu\sum_{k=1}^{C-1}\binom{C-1}{k-1}\left(\frac{1}{\lambda}\right)^k (s+\mu)\dots(s+(k-1)\mu) \\ &\quad + C\mu\left(\frac{1}{\lambda}\right)^C (s+\mu)\dots(s+(C-1)\mu) \\ &= 1+\sum_{k=1}^{C-1}\binom{C-1}{k-1}[C(s/k+\mu)]\left(\frac{1}{\lambda}\right)^k (s+\mu)\dots(s+(k-1)\mu) \\ &\quad + \left(\frac{1}{\lambda}\right)^C (s+\mu)\dots(s+C\mu), \end{aligned}$$

which is easily seen to be positive for $s > -\mu$. All the zeros of $F_c(s)$ are thus less than $-\mu$ and part (iii) is proved. □

3. A stable method for computing $\widetilde{\boldsymbol{R}}_{\boldsymbol{n,C}}(\boldsymbol{s})$. In (11) of [4], it was shown that the polynomials $P_n(s/\lambda)$ satisfy the recurrence relation

$$P_{n+1}(s/\lambda) = \left(\frac{s}{\lambda}+\frac{\mu n}{\lambda}+1\right)P_n(s/\lambda) - \frac{\mu n}{\lambda}P_{n-1}(s/\lambda) \tag{3.1}$$

for $n \geq 1$. With $H_n(s) \equiv P_{n-1}(s/\lambda)/P_n(s/\lambda)$, it follows that

$$1 = \left(\frac{s}{\lambda}+\frac{\mu n}{\lambda}+1\right)H_{n+1}(s) - \frac{\mu n}{\lambda}H_n(s)H_{n+1}(s)$$

and so

$$H_{n+1}(s) = \frac{1}{\left(\frac{s}{\lambda}+\frac{\mu n}{\lambda}+1\right) - \left(\frac{\mu n}{\lambda}\right)H_n(s)}. \tag{3.2}$$

With the initial condition

$$H_0(s) = \frac{1}{s/\lambda+1}, \tag{3.3}$$

we can use (3.2) to calculate $H_n(s)$ for s with $\Re(s) > 0$.

Moreover, Lemma 3.1 below shows that $H_n(s)$ remains bounded for s with $\Re(s) > 0$ and so the recursion is stable. Having calculated $H_n(s)$ for $n = 1, \ldots, C$, we can then calculate $\widetilde{R}_{C,C}(s)$ via the equation

$$\widetilde{R}_{C,C}(s) = \left(\frac{1}{s}\right)\left(\frac{\theta}{\frac{s}{\lambda} + \frac{\mu C}{\lambda} - \frac{\mu C}{\lambda} H_C(s)}\right), \tag{3.4}$$

which is easily derived from (2.3), and $\widetilde{R}_{n,C}(s)$ from the relation

$$\widetilde{R}_{n,C}(s) = \widetilde{R}_{C,C}(s) \prod_{j=n+1}^{C} H_j(s). \tag{3.5}$$

LEMMA 3.1. *For s with $\Re(s) > 0$ and $n \geq 1$, the ratios $H_n(s)$ are such that $|H_n(s)| < 1$.*

Proof. From (3.3), it follows that $|H_0(s)|$ is clearly less than one for s with $\Re(s) > 0$. Now assume that $|H_n(s)|$ is less than one for s with $\Re(s) > 0$. Then, from (3.2),

$$\begin{aligned} |H_{n+1}(s)| &= \left| \frac{1}{\left(\frac{s}{\lambda} + \frac{\mu n}{\lambda} + 1\right) - \left(\frac{\mu n}{\lambda}\right) H_n(s)} \right| \\ &\leq \frac{1}{\left|\frac{s}{\lambda} + \frac{\mu n}{\lambda} + 1\right| - \left|\frac{\mu n}{\lambda} H_n(s)\right|} \\ &\leq \frac{1}{\left|\frac{s}{\lambda} + 1\right|}, \end{aligned}$$

which is less than one for s with $\Re(s) > 0$. The lemma is thus proved by mathematical induction. □

4. An approximation to $R_{n,C}(T)$. As $T \to \infty$, the occupancy of the M/M/C/C loss system will be distributed according to the system's stationary distribution. Hence, as pointed out in [4] we would expect that the loss curves described by $R_{n,C}(T)$ will have asymptotic slope $\theta\lambda\pi_{\rho,C}$, where the Erlang-B function

$$\pi_{\rho,C} = \frac{\rho^C/C!}{\sum_{i=0}^{C} \rho^i/i!} \tag{4.1}$$

gives the stationary probability that the link is full when the traffic is $\rho \equiv \lambda/\mu$ and the capacity is C.

In this section, we shall verify that this is indeed the case and develop a straight-line approximation to $R_{n,C}(T)$ of the form

$$\hat{R}_{n,C}(T) = \theta\lambda\pi_{\rho,C}T + a_{n,C} \tag{4.2}$$

that can be used to compute approximate buying and selling prices following a process similar to that used in (2.1) and (2.2), that is,

$$\hat{B}_n(T) = \hat{R}_{n,C}(T) - \hat{R}_{n,C+1}(T), \tag{4.3}$$

$$\hat{S}_n(T) = \begin{cases} \hat{R}_{n,C-1}(T) - \hat{R}_{n,C}(T) & \text{when} \quad n < C, \\ \hat{R}_{C-1,C-1}(T) - \hat{R}_{C,C}(T) & \text{when} \quad n = C. \end{cases} \tag{4.4}$$

As with (2.2), it may be appropriate to add a penalty function to the right-hand side of (4.4) when $n = C$.

A key step in the development of the approximation is given in the following theorem.

THEOREM 4.1. *The function $R_{n,C}(T)$ defined in section 2 satisfies the following:*

$$\lim_{T\to\infty} [R_{n,C}(T) - \theta\lambda\pi_{\rho,C}T] \tag{4.5}$$

$$= \frac{2\theta\lambda g_1(n) - \theta\lambda\pi_{\rho,C}\left[2g_1(C) + C\mu\left[g_2(C) - g_2(C-1)\right]\right]}{2\left[1 + C\mu[g_1(C) - g_1(C-1)]\right]}, \tag{4.6}$$

where, for $n \in \{0, 1, \ldots, C\}$,

$$g_1(n) = \frac{1}{\mu}\sum_{k=1}^{n}\binom{n}{k}\left(\frac{\mu}{\lambda}\right)^k (k-1)! \tag{4.7}$$

and

$$g_2(n) = \frac{2}{\mu^2}\sum_{k=2}^{n}\binom{n}{k}\left(\frac{\mu}{\lambda}\right)^k (k-1)! \sum_{m=1}^{k-1}\frac{1}{m}. \tag{4.8}$$

Proof. It is easily established by differentiating (2.6) that

$$g_1(n) = \left.\frac{dP_n(s/\lambda)}{ds}\right|_{s=0} \tag{4.9}$$

and

$$g_2(n) = \left.\frac{d^2P_n(s/\lambda)}{ds^2}\right|_{s=0}. \tag{4.10}$$

We also recall the previously used fact that $P_n(0) = 1$.

By parts (i) and (ii) of Lemma 2.1, the rational function $s\widetilde{R}_{n,C}(s)$ has one pole at $s = 0$ with all the other poles real and negative. Hence, as long as the function

$$A_{n,C}(s) \equiv \left[s\widetilde{R}_{n,C}(s) - \frac{\theta\lambda\pi_{\rho,C}}{s}\right] \tag{4.11}$$

does not have a pole at $s = 0$, all its poles are in the left half-plane; in particular, they are real and negative. It then follows by the final value theorem (see, for example, [6, pp. 110–111]) that the limit (4.5) exists and is equal to $\lim_{s\to 0} A_{n,C}(s)$.

Expansion of $A_{n,C}(s)$ gives

$$A_{n,C}(s) = \frac{s\theta\lambda P_n(\frac{s}{\lambda}) - \theta\lambda\pi_{\rho,C}\left[(s + C\mu)P_C(\frac{s}{\lambda}) - C\mu P_{C-1}(\frac{s}{\lambda})\right]}{s\left[(s + C\mu)P_C(\frac{s}{\lambda}) - C\mu P_{C-1}(\frac{s}{\lambda})\right]}.$$

Both the numerator and the denominator of this are equal to zero at $s = 0$. The derivative of the denominator is also equal to zero at $s = 0$, which implies that for the limit as $s \to 0$ to exist, the derivative of the numerator must be equal to zero at $s = 0$. Using (4.9), this derivative is equal to

$$\theta\lambda - \theta\lambda\pi_{\rho,C}\left[1 + C\mu\left[g_1(C) - g_1(C-1)\right]\right]. \tag{4.12}$$

Consider the factor $1 + C\mu\,[g_1(C) - g_1(C-1)]$. By (4.7), this is equal to

$$\begin{aligned}
&1 + C\left[\sum_{k=1}^{C}\binom{C}{k}\left(\frac{\mu}{\lambda}\right)^k (k-1)! - \sum_{k=1}^{C-1}\binom{C-1}{k}\left(\frac{\mu}{\lambda}\right)^k (k-1)!\right] \\
&= 1 + C\sum_{k=1}^{C-1}\binom{C-1}{k-1}\left(\frac{\mu}{\lambda}\right)^k (k-1)! + C!\left(\frac{\mu}{\lambda}\right)^C \\
&= 1 + C!\sum_{k=0}^{C-1}\left(\frac{\mu}{\lambda}\right)^{C-k}/k! \\
&= 1 + \frac{\sum_{k=0}^{C-1}\left(\frac{\lambda}{\mu}\right)^k/k!}{\left(\frac{\lambda}{\mu}\right)^C/C!} \\
&= \frac{1}{\pi_{\rho,C}}
\end{aligned} \tag{4.13}$$

by (4.1). It follows that (4.12) is equal to zero as required. This argument shows further that if the coefficient of T in (4.2) were anything other than $\theta\lambda\pi_{\rho,C}$, then $\lim_{s\to 0} A_{n,C}(s)$ would not exist. This verifies that the approximation (4.2) has the correct asymptotic slope.

Now, using a further application of l'Hôpital's rule, together with (4.9) and (4.10), it is easily seen that $\lim_{s\to 0} A_{n,C}(s)$ is equal to the right-hand side of (4.6), which gives us the result. □

Theorem 4.1 tells us that we should take the constant $a_{n,C}$ in (4.2) equal to the right-hand side of (4.6). Specifically, our linear approximation to $R_{n,C}(T)$ is given by

$$\hat{R}_{n,C}(T) = \theta\lambda\pi_{\rho,C}T + \frac{2\theta\lambda g_1(n) - \theta\lambda\pi_{\rho,C}\,[2g_1(C) + C\mu\,[g_2(C) - g_2(C-1)]]}{2\,[1 + C\mu[g_1(C) - g_1(C-1)]]}. \tag{4.14}$$

For large problems, we need to be careful in computing the coefficients in this linear approximation. There is certainly the potential for numerical problems if we attempt to calculate them directly using (4.1), (4.9), and (4.10). Fortunately, it is possible to design stable and efficient recursive methods for their evaluation.

It is well known (see, for example, [2]) that $\pi_{\rho,C}$ is most efficiently calculated using the recursion

$$\pi_{\rho,C+1} = \frac{\rho\pi_{\rho,C}}{C + 1 + \rho\pi_{\rho,C}} \tag{4.15}$$

with $\pi_{\rho,C+1} = 1$. This gives us the linear term in the approximation (4.14) and also, along with (4.13), the denominator of the constant term. Moreover, we can use (4.13) to derive the fact that, for $n \geq 1$,

$$g_1(n) = \frac{1}{\mu}\sum_{j=1}^{n}\frac{1 - \pi_{\rho,j}}{j\pi_{\rho,j}}, \tag{4.16}$$

which can be computed at the same time as we generate the terms in the recursion (4.15). This gives us both $g_1(n)$ and $g_1(C)$ in the constant term. Finally, let $\psi_{\rho,n} = [n\mu\,[g_2(n) - g_2(n-1)]]$.

Differentiating (3.1) twice and putting $s = 0$, we get, for $n \geq 2$,

$$\psi_{\rho,n+1} = \frac{n+1}{\rho} \left[2g_1(n) + \psi_{\rho,n} \right]. \tag{4.17}$$

This recursion can be initialized by observing that $\psi_{\rho,2} = 2/\lambda^2$.

Generally a link will be dimensioned so that $\lambda/C\mu$ is close to one. Thus the coefficient of the multiplicative part of the recursion in (4.17) will be less than one for the values of interest. The recursion can thus be expected to remain stable for these values.

The above observations demonstrate that we can compute both coefficients in the linear approximation (4.2) in a stable and efficient manner. The final question of interest concerns the accuracy of the approximation. We can use the information in Lemma 2.1 about the roots of $G_c(s)$ to approach this question. The result is contained in the following lemma.

LEMMA 4.2. *The difference between the functions* $R_{n,C}(T)$ *and* $\hat{R}_{n,C}(T)$, *as defined in* (4.14), *satisfies*

(i)

$$\lim_{T\to\infty} \frac{R_{n,C}(T) - \hat{R}_{n,C}(T)}{e^{-\sigma_1 T}} = K_1, \tag{4.18}$$

where

$$K_1 = \lim_{s\to-\sigma_1} (s+\sigma_1) \left[s\tilde{R}_{n,C}(s) - \frac{\theta\lambda\pi_{\rho,C}}{s} \right]; \tag{4.19}$$

(ii)

$$\lim_{T\to\infty} \frac{R_{n,C}(T) - \hat{R}_{n,C}(T)}{e^{-\mu T}} = 0. \tag{4.20}$$

Proof. Using Lemma 2.1 and the proof of Theorem 4.1, we see that the partial fraction expansion of

$$D_{n,C}(s) \equiv \tilde{R}_{n,C}(s) - \frac{\theta\lambda\pi_{\rho,C}}{s^2} - \frac{a_{n,C}}{s}$$

is of the form

$$D_{n,C}(s) = \sum_{i=1}^{C} \frac{K_i}{s+\sigma_i}, \tag{4.21}$$

where

$$K_i = \lim_{s\to-\sigma_i} (s+\sigma_i) \left[s\tilde{R}_{n,C}(s) - \frac{\theta\lambda\pi_{\rho,C}}{s} \right]. \tag{4.22}$$

From this we can see that

$$R_{n,C}(T) - \hat{R}_{n,C}(T) = \sum_{i=1}^{C} K_i e^{-\sigma_i T} \tag{4.23}$$

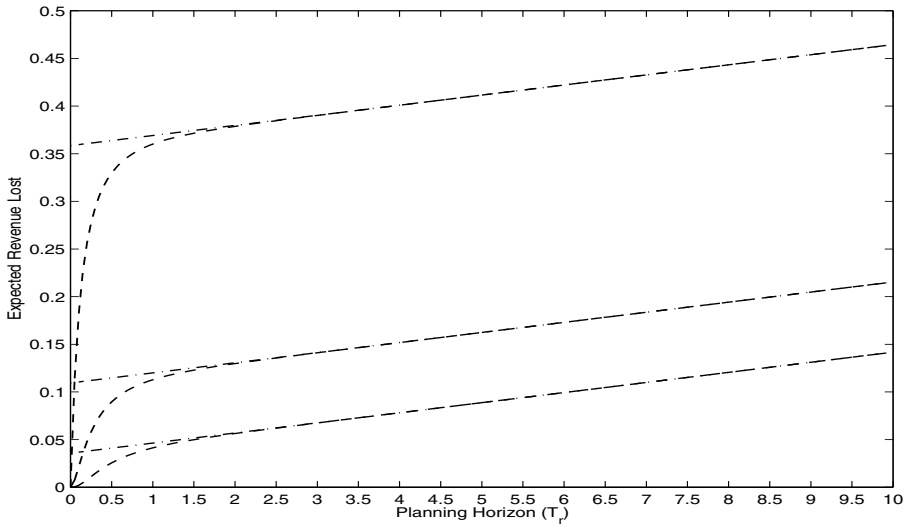

FIG. 2. *$R_{n,C}(T)$ (- -) versus $\hat{R}_{n,C}(T)$ (· -) with $n = 4, 5, 6, C = 6, \lambda = 3$, and $\mu^{-1} = 0.5$.*

and part (i) follows because $-\sigma_1$ is the largest root of $G_c(s)$. Part (iii) of Lemma 2.1 tells us that $-\sigma_1 < -\mu$ and so part (ii) of this lemma is an easy consequence of part (i). □

Lemma 4.2 tells us that the linear approximation $\hat{R}_{n,C}(T)$ approaches the actual function $R_{n,C}(T)$ at a rate that is better than exponential with coefficient $-\mu$. This gives us a useful indication as to the quality of the approximation.

5. A comparison of $R_{n,C}(T)$ and $\hat{R}_{n,C}(T)$. As an illustration of the behavior of our approximation function $\hat{R}_{n,C}(T)$, we revisit the example presented in section 2. Figure 2 depicts the original loss curves $R_{n,C}(T)$ and also $\hat{R}_{n,C}(T)$ for $C = 6, n \in [4, 6], \lambda = 3$, and $\mu^{-1} = 0.5$. Note that $R_{4,6}(T) < R_{5,6}(T) < R_{6,6}(T)$ and that similarly $\hat{R}_{4,6}(T) < \hat{R}_{5,6}(T) < \hat{R}_{6,6}(T)$.

From Figure 2 we immediately see that the curves $\hat{R}_{n,c}(T)$ are very good approximations for $R_{n,C}(T)$ for large T.

Next, we compare $\hat{B}_{n,C}(T)$ against $B_{n,C}(T)$ for a larger network where $C = 100, n = \{50, 100\}, \lambda = 85$, and $\mu^{-1} = 1$. Both functions are displayed in Figure 3. We observe that the original and approximated functions coincide once the system has reached equilibrium.

Of particular interest in this example is the linear function described by $\hat{B}_{50,100}(T)$. We see that in this instance the approximation results in a negative value for the intercept. Moreover, $B_{50,100}(T)$ is very close to zero for T such that $\hat{B}_{50,100}(T)$ is negative. In practice, this suggests that when $\hat{B}_{50,100}(T)$ is negative, we should treat the value of an extra unit of capacity as equal to zero. If we compare the negative values of $\hat{B}_{50,100}(T)$ with the corresponding values produced by $B_{50,100}(T)$, we see that this approximation is likely to be accurate.

Similar observations can be made with respect to Figure 4, where we compare $\hat{S}_{n,C}(T)$ against $S_{n,C}(T)$ for the larger network. In this instance we would once again interpret all negative values as zero in practice.

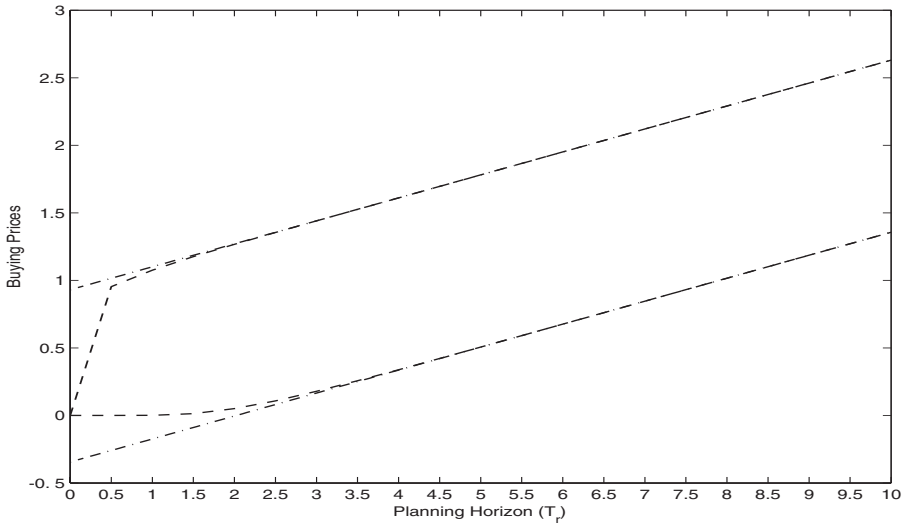

FIG. 3. $B_{n,C}(T)$ *(- -) versus* $\hat{B}_{n,C}(T)$ *(· -) with* $n = 50, 100, \lambda = 85$*, and* $\mu^{-1} = 1$.

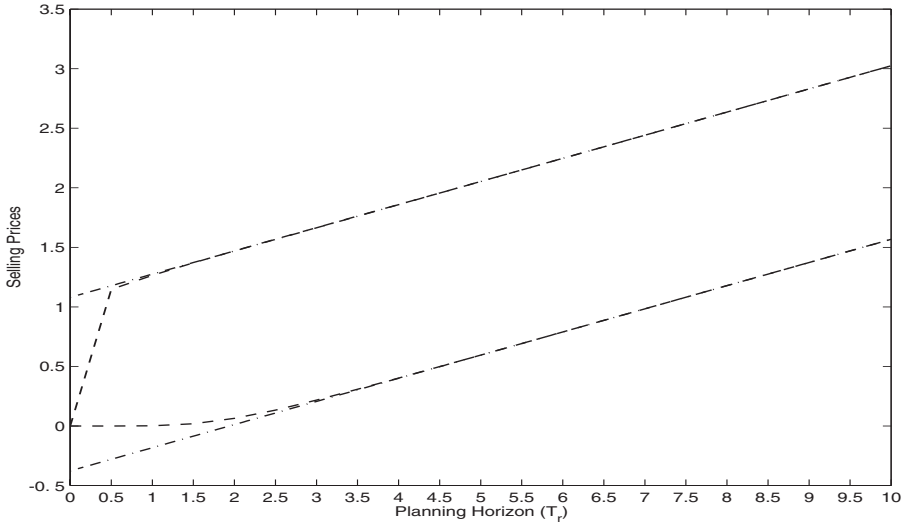

FIG. 4. $S_{n,C}(T)$ *(- -) versus* $\hat{S}_{n,C}(T)$ *(· -) with* $n = 50, 100, \lambda = 85$*, and* $\mu^{-1} = 1$.

6. Conclusions. Of considerable importance in telecommunications is the ability to transfer capacity between network flows according to some scheme that ascribes a value to capacity, in order to alleviate network congestion. The value function must meet three specific criteria: it is decentralized, scalable, and able to be implemented by a simple network switch.

In this paper, we have considered the valuation model presented in [4] which satisfied the first two criteria, and we developed a suitable approximate equivalent. The calculations involved are sufficiently simple to be implemented by a network switch.

Further implementation issues, such as the online estimation of the traffic param-

eters required for these pricing models, are still to be explored. This topic has already attracted considerable interest in the field and will be the subject of future research.

Acknowledgment. The authors would like to thank an anonymous referee for pointing out the recursion (4.17).

DIFFUSIVE AND CHEMOTACTIC CELLULAR MIGRATION: SMOOTH AND DISCONTINUOUS TRAVELING WAVE SOLUTIONS*

K. A. LANDMAN†, M. J. SIMPSON†, J. L. SLATER†, AND D. F. NEWGREEN‡

Abstract. A mathematical model describing cell migration by diffusion and chemotaxis is considered. The model is examined using phase plane, numerical, and perturbation techniques. For a proliferative cell population, traveling wave solutions are observed regardless of whether the migration is driven by diffusion, chemotaxis, or a combination of the two mechanisms. For pure chemotactic migration, both smooth and discontinuous solutions with shocks are shown to exist using phase plane analysis involving a curve of singularities, and identical results are obtained numerically. Alternatively, pure diffusive migration and combinations of diffusive and chemotactic migration yield smooth solutions only. For all cases the wave speed depends on the exponential decay rate of the initial cell density, and it is bounded by a minimum value which is numerically observed whenever the initial cell distribution has compact support. The minimum wave speed c_{min} is proportional to $\sqrt{\chi}$ or $\sqrt{D}$ for pure chemotaxis and pure diffusion cases, respectively. The value of c_{min} for combined diffusion and chemotactic migration is examined numerically. The rate at which the mixed migration system approaches either a diffusion-dominated or chemotaxis-dominated system is investigated as a function of a dimensionless parameter involving D/χ. Finally, a perturbation analysis provides details of the steep critical layer when $D/\chi \ll 1$, and these are confirmed with numerical solutions. This analysis provides a deeper qualitative and quantitative understanding of the interplay between diffusion and chemotaxis for invading cell populations.

1. Introduction.

Cell migration is an essential feature of many important biological systems, including wound healing, tumor invasion, and several developmental biology processes [12, 27, 37]. Typically, to model cell migration, a system of conservation equations is proposed which incorporates the migratory processes in conjunction with kinetic terms to simulate proliferation of the migratory population. Additional kinetic processes (e.g., cell death, cell-receptor binding) can be included in the kinetic terms where required. Diffusion and chemotaxis are two common cell migration mechanisms [5].

Diffusion simulates random walk processes of cells. The Fisher equation [6] is the archetypal pure diffusion model which considers diffusive migration together with proliferation of cells via a logistic process.

Chemotaxis describes the movement of cells in the direction of a spatial gradient of a signaling species called the chemoattractant. The chemoattractant kinetics may be specified in several ways. An early chemotactic model was developed by Keller and Segel [13] describing bacterial motion. Other important contributions have been

made by Tranquillo [39], Tranquillo and Alt [40], Hillen [10], Othmer and Stevens [29], and Horstmann and Stevens [11], as well as those reviewed by Ford and Cummings [7].

The classical Fisher model and several pure chemotaxis models [1, 18, 24, 25, 31, 32] are known to support traveling wave solutions moving with a constant speed. For the Fisher model, the wave speed is bounded by a minimum value [25]. For pure chemotactic migration, Landman, Pettet, and Newgreen [18] recently demonstrated the existence of traveling wave solutions with a minimum wave speed. It should be noted that haptotaxis, which is based on migration along adhesive extracellular matrix gradients, is mathematically equivalent to chemotaxis; hence a pure haptotactic model can also support traveling wave solutions with a minimum wave speed [20, 22, 30]. The focus of these previous analyses has been to examine the characteristics of traveling wave solutions for cell migration in response to a single mechanism. The more complex case of multimechanism migration has received less attention and is therefore poorly understood.

In this article we consider a model of diffusive and chemotactic cell migration. The model is motivated by migration processes during embryological development. The rostral-to-caudal migration of neural crest cells along the developing avian and mammalian intestine is one of the most extensive migration paths known in developmental biology [15]. Neural crest cells show a variety of responses including chemotactic attraction to growth factors, which are thought to be produced uniformly along the intestine mesenchymal tissue (e.g., glial derived neurotrophic factor (GDNF) [43]). Local gradients in the chemoattractant concentration are postulated to arise from the binding of the chemoattractant to receptors on the migrating cells, rather than from diffusion of growth factors from a source. In addition to promoting migration, the chemoattractant also acts as a survival factor for the migrating population [9, 26, 43]. Interest in the migration of enteric neural crest cells stems from hypotheses which have linked neural crest cell migration to a common birth defect in humans called Hirschsprung's disease or aganglionic megacolon. This defect occurs when the caudal part of the gut lacks intrinsic nerve cells. Hirschsprung's disease is thought to occur when the rostral-to-caudal migration of the neural crest cells fails to completely colonize the developing intestine [17, 28].

This paper constructs a mathematical framework for the analysis of the combined diffusive and chemotactic migration, relevant to developmental biology processes. We utilize a holistic approach incorporating both analytical and numerical analyses of traveling wave solutions for the proposed model. For the case of purely chemotactic migration, the results presented here extend the previous work of Landman, Pettet, and Newgreen [18] in two significant ways. First, the relationship between the wave speed and the transition from smooth to discontinuous solutions is examined in detail. Second, an analysis of the functional dependence of the minimum wave speed for pure chemotaxis migration is presented. This analysis provides a useful relationship similar to the well-known expression for the Fisher equation.

For the more complex case of combined diffusion and chemotaxis migration we use a specifically designed numerical algorithm to examine the traveling wave solutions. In particular, the numerical results are used to show how the combined diffusive and chemotactic migration model approaches the limits of diffusion-only and chemotaxis-only cases as the relative contributions of diffusion and chemotaxis are altered. This kind of analysis is unexplored in previous studies [18, 21]. We use the numerically determined wave speeds to conjecture some useful bounds on the minimum wave speed

for the combined diffusion and chemotaxis problem.

The mathematical model for this problem is a coupled system of partial differential equations for cell density and chemoattractant concentration. A traveling wave coordinate system is introduced with an unknown wave speed to convert the system into a coupled system of ordinary differential equations. Phase plane and singular perturbation methods are then used to explore the solutions of the system. The numerical algorithm is applicable to pure hyperbolic problems including the formation of shock-fronted solutions as well as parabolic problems.

2. Diffusive and chemotactic cell migration in one dimension. A system of equations is introduced to describe the diffusive and chemotactic migration of cells in one dimension. Let $n(x,t)$ and $g(x,t)$ denote the cell density and chemoattractant concentration per unit length, respectively; x and t are position and time coordinates. A conservation-of-mass argument for a diffusion and chemotaxis transport of cells gives

$$\frac{\partial n}{\partial t} = D\frac{\partial^2 n}{\partial x^2} - \chi\frac{\partial}{\partial x}\left(n\frac{\partial g}{\partial x}\right) + f(n,g), \tag{2.1}$$

$$\frac{\partial g}{\partial t} = h(n,g), \tag{2.2}$$

where the diffusion coefficient D and the chemotactic factor χ are assumed to be constant [20, 21, 22]. The assumption of a constant chemotactic factor ignores saturation effects. Although alternative forms for $\chi(g)$ that incorporate saturation have been proposed [8], the specific relationship relevant to the system of interest is unknown and therefore a constant value is adopted. Preliminary investigations indicate that the results of this study are qualitatively insensitive to this assumption. The f and h terms in (2.1)–(2.2) represent the kinetic terms. Equation (2.2) reflects our assumption that the distribution of chemoattractant is governed by kinetic processes rather than diffusion. This is particularly relevant for the migration of neural crest cells where the chemoattractant GDNF is produced uniformly within the underlying tissues and not from diffusion from some external source [43]. For this case, the distribution of chemoattractant is governed by a balance between the underlying production of chemoattractant, the natural decay of chemoattractant, and also the uptake of chemoattractant by the migrating cells. Furthermore, care must be taken to ensure that the steady state of (2.2) does not permit a zero solution as the chemoattractant is a trophic factor necessary for the survival of the migratory population. Therefore, the chemoattractant concentration must be strictly positive at all times to sustain the migratory species.

In keeping with these biologically motivated considerations, the kinetic terms are chosen to reflect the following assumptions. The cells n proliferate by mitosis and have a carrying capacity density; these characteristics can be described by a logistic-type term for f. The chemoattractant g is produced uniformly at a constant rate throughout the domain and decays with time. Furthermore, the chemoattractant binds to the cells. Therefore a localized initial distribution of cells creates a gradient of chemoattractant, which produces a chemoattractant migration velocity. These effects are described with the following choice of f and h:

$$f = \lambda_1 n\left(1 - \frac{n}{k_1}\right), \tag{2.3}$$

$$h = \lambda_2 - \lambda_3 g - \lambda_4 n g. \tag{2.4}$$

For simplicity, a constant mitotic index λ_1 is assumed rather than a more complex form with $\lambda_1(g)$.

The system (2.1)–(2.4) reduces to some special cases. When the chemotactic factor χ is zero, the equation describing the cell population n reduces to the Fisher equation [6, 25]. Alternatively, when the diffusivity D is zero, cell migration is driven by chemotaxis alone. Several authors (e.g., [2, 18, 32]) have studied some aspects of simple chemotaxis models, or mathematically equivalent haptotaxis models, with a different choice of kinetic term h. The choice of h here is governed by considerations relevant to developmental biology problems as discussed.

We are interested in cells at their maximum density migrating into a region without such cells, giving rise to an invading profile with a constant shape and moving at a constant speed. The well-studied Fisher equation allows such traveling wave solutions, while purely chemotactic systems also support such solutions [18]. The nature of such solutions, whether they are smooth or discontinuous functions, and their minimum wave speed will be investigated here.

Scaling time with the mitotic index and introducing a length scale L, all the variables can be made dimensionless using the definitions as shown:

$$n = k_1 n^*, \qquad g = \frac{\lambda_2}{\lambda_3} g^*, \qquad t = \frac{1}{\lambda_1} t^*, \qquad x = L x^*, \tag{2.5}$$

$$D^* = \frac{D}{L^2 \lambda_1}, \qquad \chi^* = \frac{\chi \lambda_2}{L^2 \lambda_1 \lambda_3}, \qquad \beta = \frac{\lambda_3}{\lambda_1}, \qquad \gamma = \frac{\lambda_4 k_1}{\lambda_1}. \tag{2.6}$$

In later sections we choose L so that one of the dimensionless parameters D^* or χ^* is equal to unity. Omitting the asterisk notation, the dimensionless system is

$$\frac{\partial n}{\partial t} = D \frac{\partial^2 n}{\partial x^2} - \chi \frac{\partial}{\partial x}\left(n \frac{\partial g}{\partial x} \right) + n(1-n), \tag{2.7}$$

$$\frac{\partial g}{\partial t} = \beta(1-g) - \gamma n g. \tag{2.8}$$

To explore the nature of the dynamics of the system (2.7)–(2.8), we consider numerical solutions in conjunction with phase plane and perturbation analyses.

3. Numerical solution. Numerical solutions to the full system (2.7)–(2.8) are sought. We are interested in obtaining results under a wide range of conditions where diffusion or chemotaxis can either dominate or be absent. Therefore, the numerical scheme must be sufficiently robust to solve either a purely hyperbolic system ($D = 0$) or the simpler diffusion-reaction system ($\chi = 0$). An operator splitting technique is used to overcome this difficulty [16, 38, 36, 41]. Within each time increment, temporal integration of the system (2.7)–(2.8) is split into two steps. First the purely hyperbolic system (2.7)–(2.8) with $D = 0$, namely,

$$\frac{\partial n}{\partial t} = -\chi \frac{\partial}{\partial x}\left(n \frac{\partial g}{\partial x} \right) + n(1-n), \tag{3.1}$$

$$\frac{\partial g}{\partial t} = \beta(1-g) - \gamma n g, \tag{3.2}$$

is solved to yield intermediate solutions. Second, these intermediate solutions are used as initial conditions to solve the remaining parabolic system

$$\frac{\partial n}{\partial t} = D \frac{\partial^2 n}{\partial x^2}, \tag{3.3}$$

$$\frac{\partial g}{\partial t} = 0. \tag{3.4}$$

Obtaining numerical solutions of linear hyperbolic problems using standard numerical schemes has been referred to as an "embarrassingly difficult problem" [42]. Therefore, the greatest of care must be exercised in obtaining numerical solutions of the nonlinear hyperbolic system (3.1)–(3.2). To this end, we spatially discretize (3.1)–(3.2) with the semidiscrete scheme described by Kurganov and Tadmor [14]. The resulting system of ordinary differential equations is explicitly integrated with a fourth-order Runge–Kutta algorithm using a constant time step [33]. The solution to the parabolic system (3.3)–(3.4) is obtained using a linear finite element mesh composed of uniformly spaced elements. Temporal integration of the discretized finite element equations is achieved with a mass-lumped backward Euler scheme [34]. Both spatial and temporal discretizations are uniform. We choose to include the kinetic terms in the hyperbolic step of the splitting scheme since this step is solved using an explicit method convenient for solving nonlinear kinetic terms; alternatively, if the kinetic terms are included in the parabolic step, then the implicit Euler stepping would require further iterations to solve the resulting nonlinear system of equations. From this point of view the splitting regime (3.1)–(3.4) is computationally efficient.

It should be noted that the main limitation with this numerical scheme is imposed through the hyperbolic solution method [14] which requires sufficiently small time steps so that the Courant condition is satisfied,

$$Cr = \max \frac{\mid \lambda_i \mid \Delta t}{\Delta x} \leq M, \tag{3.5}$$

where the λ_i are the eigenvalues associated with the Jacobian of the flux vector [14] and M is some constant. The λ_i relate to the speed of propagation of information for the system. Fortunately, since we are interested in traveling wave solutions which move with a constant wave speed, it is clear that a uniformly optimal time step Δt exists for a particular uniform spatial mesh. The optimal time step can be determined using a straightforward trial-and-error approach. The finite element solution of the parabolic system (3.3)–(3.4) is not subject to any numerical stability limitation since the mass-lumped implicit Euler scheme is known to be unconditionally stable [34].

The numerical scheme outlined here is particularly convenient for analyzing general solutions of the system (2.7)–(2.8). The inclusion of Kurganov and Tadmor's central scheme is necessary so that the nonlinear hyperbolic term associated with chemotactic migration can be solved accurately without incurring any high Peclet number-induced oscillations and numerical diffusion associated with standard numerical techniques [44]. Furthermore, incorporating diffusion through an operator splitting scheme is required to maintain generality of the algorithm. Previous attempts at simulating a combined haptotactic and diffusive migration system discretized the diffusion term explicitly within the central scheme [21]. This previous approach is very restrictive as explicit solutions of the diffusion equation are subject to well-known stability criteria [4] which are satisfied only for small values of the diffusion coefficient. These limitations are completely overcome in this work as the diffusion term is split and solved implicitly thereby yielding an algorithm valid for any value of χ and D.

The problem is modeled on the infinite x domain. However, for numerical computations the finite domain $[0, X]$ is selected with X chosen to be sufficiently large to avoid boundary effects. Zero-flux conditions are specified for both boundaries. Since we are interested in the invasion of cells into the domain, the initial data are chosen to be primarily localized near the left boundary as discussed in section 4.

After a particular time, the numerical solution converges to a fixed profile moving with a constant speed. The traveling wave speed c is computed by selecting a particular contour, say, $n(x,t) = N$, and locating the position of that contour at each time interval using a linear interpolation scheme. Once the position of the contour is known over successive time intervals, the wave speed can be approximated by

$$c_n = \frac{x^{n+1} - x^n}{\Delta t} \tag{3.6}$$

for large n, where x^n and x^{n+1} are the positions of the contour at the n and $n+1$ time step, respectively, and Δt is the time step. The speed of convergence varies with initial conditions and parameter values. Consequently, the domain length X must be chosen sufficiently large if the convergence is slow. When $D = 0$, the chemotactic migration cell profile is expected to develop a shock in the low-concentration region of the profile for some choices of initial condition [22]. It is impractical to use linear interpolation to determine the position of the contour within the shock because of the discontinuity. This complication is circumvented by choosing a concentration away from the shock region to compute the wave speed. Therefore, it is best to use a sufficiently large contour value N.

4. Traveling wave speed and dependence on the initial conditions. Traveling wave solutions with a range of possible wave speeds greater than some minimum value are known to occur for purely diffusive or purely chemotactic migration [6, 25, 18]. We expect the same behavior when both diffusion and chemotaxis are present. Here we investigate how various types of initial data evolve to traveling wave solutions with different wave speeds. To determine the minimum wave speed numerically, it is necessary to know the relationship between the initial conditions and the wave speed so that the appropriate initial conditions are specified.

It is possible to investigate the speed of the traveling waves by examining the leading edge of the wave, assuming it decays exponentially in space [25]. McKean [23] and Marchant [19] determine relationships between exponential decay rates of initial data and the wave speed of solutions for the Fisher equation (purely parabolic) and a haptotactic invasion (purely hyperbolic) system, respectively. We extend this work to our system with both diffusion and chemotaxis.

Consider initial conditions, where for large x

$$n(x,0) = A_1 e^{-\xi_1 x}, \tag{4.1}$$

$$g(x,0) = 1 - A_2 e^{-\xi_2 x} \tag{4.2}$$

for arbitrary positive constant A_1, A_2, ξ_1 and ξ_2. Looking at the evolving wave near the leading edge and writing $n = \tilde{n}, g = 1 - \tilde{g}$, assuming that $\tilde{n}$ and $\tilde{g}$ are small, the system (2.7)–(2.8) simplifies to the linear system

$$\frac{\partial \tilde{n}}{\partial t} = D\frac{\partial^2 \tilde{n}}{\partial x^2} + \tilde{n}, \tag{4.3}$$

$$-\frac{\partial \tilde{g}}{\partial t} = \beta \tilde{g} - \gamma \tilde{n} \tag{4.4}$$

with the initial conditions (for large x)

$$\tilde{n}(x,0) = A_1 e^{-\xi_1 x}, \tag{4.5}$$

$$\tilde{g}(x,0) = A_2 e^{-\xi_2 x}. \tag{4.6}$$

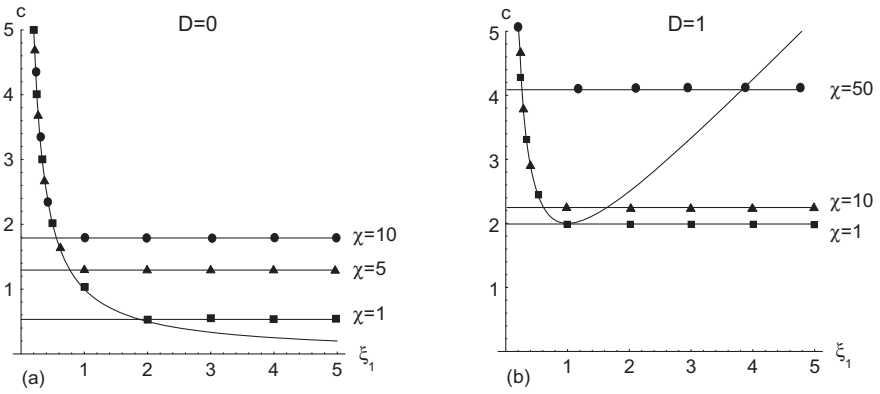

FIG. 4.1. *Numerical wave speed c versus ξ_1 for initial data of the form* (4.1)–(4.2). *Numerical results are shown in squares, circles, and triangles. These results were generated using* $\Delta x = 0.05$ *and* $\Delta t = 0.01$. *The continuous curves are given by* (4.7). *The horizontal lines represent* c_{min}. *Here* $\beta = 1$ *and* $\gamma = 1$. (*a*) *With* $D = 0$ *and increasing values of* χ. (*b*) *With* $D = 1$ *and increasing values of* χ.

A solution of the form $\tilde{n} = A_1 e^{-\xi_1(x-ct)}$ is sought. Substitution into (4.3)–(4.4) requires

$$c = \frac{1}{\xi_1} + D\xi_1 \tag{4.7}$$

for large values of x. Then solving (4.4) with (4.6), the leading edge of chemoattractant concentration is

$$\tilde{g} = e^{-\beta t}\left[A_2 e^{-\xi_2 x} - \frac{\gamma A_1}{\beta + \xi_1 c} e^{-\xi_1 x}\right] + \frac{\gamma A_1}{\beta + \xi_1 c} e^{-\xi_1(x-ct)}. \tag{4.8}$$

For large values of t, both $\tilde{n}$ and $\tilde{g}$ are functions of the traveling wave coordinate $x - ct$, where c is given by (4.7). This condition is independent of ξ_2 and hence independent of the initial conditions imposed on g.

The analytical result for c given by (4.7) is confirmed by the numerical results illustrated in Figure 4.1. Two cases are described. In the first, $D = 0$, so that the cells are purely chemotactically driven. For fixed values of the kinetic parameters β and γ and chemotactic factor χ, Figure 4.1(a) shows that a traveling wave solution with wave speed satisfying (4.7) is realized when $\xi_1 < 1/c_{min}$. Alternatively, when $\xi_1 > 1/c_{min}$ a traveling wave of fixed wave speed develops where $c = c_{min}$. Furthermore Figure 4.1(a) shows that c_{min} increases proportional to $\sqrt{\chi}$. In section 6.2, both smooth and discontinuous solutions will be found numerically using initial data of the form (4.1)–(4.2) (with $\xi_2 = 0$). (Note that (4.7) is also valid when both $D = \chi = 0$; under these conditions a traveling wave results from the initial nonzero cell density distribution in conjunction with the kinetics.) The second case, $D = 1$, $\chi > 0$, illustrated in Figure 4.1(b), has the same qualitative behavior as the case $D = 0$. The solution with $\chi = 0$ corresponds to the Fisher equation ($c_{min} = 2$, [25]) and is not shown here. As χ increases the value of c_{min} again increases, but for the case of nonzero D, it clearly does not scale with $\sqrt{\chi}$.

In summary, numerical computations yield a suite of traveling waves with the wave speed dependent on the exponential decay rate of the initial cell population

$n(x,0)$. There is a maximum exponential decay rate such that for ξ_1 larger than the maximum value, the initial data develops into a traveling wave moving with a minimum wave speed c_{min}. Further discussion of c_{min} will appear in section 6.3.2.

The asymptotic form of the initial conditions given by (4.1)–(4.2) is useful for numerically investigating the dependence of the wave speed on the decay rate ξ_1. However, in the limit $\xi_1 \to \infty$ the initial cell distribution tends towards having semi-compact support, a typical choice being

$$n(x,0) = \begin{cases} 1, & x < x_1, \\ q(x), & x_1 < x < x_2, \\ 0, & x > x_2, \end{cases} \tag{4.9}$$

where $q(x)$ is monotonic and continuous. Since all such functions decay faster than any exponential function, $n(x,t)$ will evolve to a traveling wave with speed $c = c_{min}$. Numerical solutions with such initial data confirm this result.

In light of this discussion, initial conditions used in this study take the form

$$n(x,0) = \begin{cases} 1, & x < 10, \\ e^{-\xi_1(x-10)}, & x \geq 10, \end{cases} \tag{4.10}$$

$$g(x,0) \equiv 1. \tag{4.11}$$

Altering the value of ξ_1 in (4.10) enables the leading front of the cell density distribution to decay exponentially with a variable rate. In the limit $\xi_1 \to \infty$ the initial conditions (4.10) approach a step function at $x = 10$. This is a particular case of the more general initial condition (4.9) with $x_1 = x_2 = 10$. The location of the transition point to exponential decay is arbitrary as identical traveling wave behavior results regardless of the point chosen.

5. Traveling wave solution. Introducing the traveling wave coordinate transformation $z = x - ct$, where c is the dimensionless wave speed, and the variable $v = \frac{\partial n}{\partial x}$, the dimensionless system (2.7)–(2.8) becomes the following first-order system of equations:

$$c\frac{dg}{dz} = -\left[\beta(1-g) - \gamma n g\right], \tag{5.1}$$

$$\frac{dn}{dz} = v, \tag{5.2}$$

$$\begin{aligned} D\frac{dv}{dz} = {} & \frac{\chi n}{c^2}\left[\gamma n + \beta\right]\left[\gamma n g - \beta(1-g)\right] - n(1-n) \\ & - \left[1 + \frac{\chi}{c^2}(\beta(1-g) - 2\gamma n g)\right] cv. \end{aligned} \tag{5.3}$$

There are two steady states of this system, namely, $(g,n,v) = (\frac{\beta}{\beta+\gamma}, 1, 0)$ and $(1,0,0)$. The first state corresponds to cells at their carrying capacity density and therefore can be thought of as the colonized or invaded state, whereas the second is the uncolonized state. We seek traveling wave solutions connecting the colonized to the uncolonized state. Note that $\frac{\beta}{\beta+\gamma}$ is a function which depends only on the ratio γ/β; it is an increasing function of the production rate β, is a decreasing function of binding rate γ, and is always less than unity, the value of the chemoattractant concentration in the absence of cells.

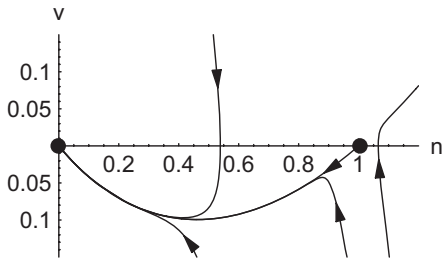

FIG. 6.1. *Phase plane for the Fisher equation. Here* $D = 1$, $c = 2.5$. *The steady states are marked* (•).

6. Phase plane, perturbation analysis, and numerical solutions. We first investigate phase plane and numerical solutions corresponding to the two special cases when one of D or χ is zero and discuss the nature of the solutions and the minimum wave speed c_{min}. For the remaining case, when both migration mechanisms are active, the transition from Fisher type solutions to chemotactic solutions (and vice versa) is investigated, and the solutions and c_{min} are determined numerically. In addition, perturbation analysis provides some insight into any rapid transition zones.

6.1. Diffusion-driven migration, no chemotaxis. If the chemotactic coefficient is zero, then the model equations reduce to the Fisher equation which describes cell migration driven by diffusion and proliferation. Then the system (2.7)–(2.8), in the traveling wave coordinate, reduces to the differential equation system

$$\frac{dn}{dz} = v, \tag{6.1}$$

$$D\frac{dv}{dz} = -n(1-n) - cv. \tag{6.2}$$

It is well known that traveling waves exist and can be found by phase plane analysis in the (n, v) plane, as illustrated in Figure 6.1. The state $(n, v) = (1, 0)$ is a saddle for all values of c. The other steady state (0,0) is a stable node if $c^2 > 4D$ and a stable spiral if $c^2 < 4D$. The population density n is required to be nonnegative and hence cannot be oscillatory around zero; therefore, the wave speed must be restricted to $c^2 \geq 4D$ giving a minimum wave speed $c_{min} = 2\sqrt{D}$. The traveling wave solutions are smooth. Clearly, the cell density is independent of the chemoattractant kinetics.

Numerical solutions to (2.7)–(2.8) with $\chi = 0$ are shown in Figure 6.2 with both rapid and slowly decaying initial conditions. In both cases, the profiles of $n(x, t)$ show clear traveling wave behavior characterized by a constant wave speed. For rapidly decaying initial conditions, Figure 6.2(a) demonstrates a minimum wave speed of $c_{min} = 2.0$, which agrees with the theoretical result. Alternatively for slowly decaying initial conditions, Figure 6.2(b) illustrates an increased wave speed of $c = 2.5$, as given by (4.7). This example confirms the result that the traveling wave speed c depends on the exponential decay rate of the initial distribution of the cell population.

6.2. Chemotactically driven migration, no diffusion. If the diffusion coefficient is zero, then the variable v does not need to be introduced. As discussed in section 2, when there is no diffusion, we can choose the length scale L so that the dimensionless χ is identically equal to unity. Then equations (5.1)–(5.3) reduce to the

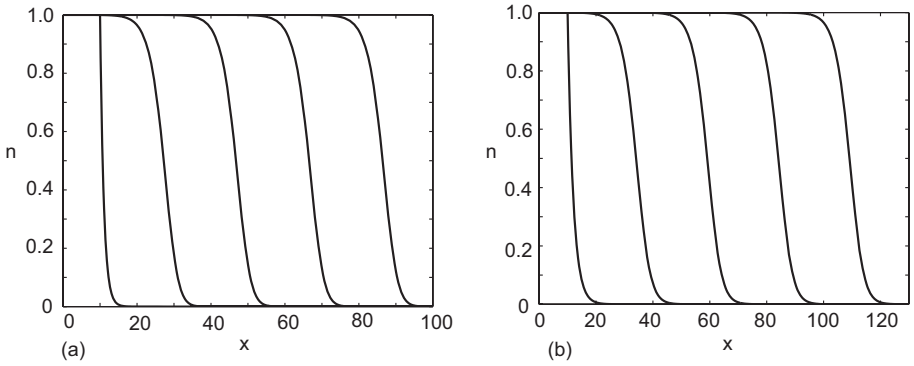

FIG. 6.2. *Numerical solutions of $n(x,t)$ for the Fisher equation with $D = 1$, $\Delta x = 0.05$, and $\Delta t = 0.01$. (a) Solutions at $t = 0, 10, 20, 30$, and 40 left to right with $\xi_1 = 10$. The computed wave speed is $c = c_{min} = 2$. (b) Solutions at $t = 0, 10, 20, 30$, and 40 left to right with $\xi_1 = 0.5$. The computed wave speed is $c = 2.5$.*

following system:

$$c\frac{dg}{dz} = -\left[\beta(1-g) - \gamma n g\right], \tag{6.3}$$

$$c\left[1 + \frac{1}{c^2}(\beta(1-g) - 2\gamma n g)\right]\frac{dn}{dz} = \frac{n}{c^2}\left[\gamma n + \beta\right]\left[\gamma n g - \beta(1-g)\right] - n(1-n). \tag{6.4}$$

The chemoattractant kinetic term h chosen here differs from that in [18], resulting in a different system with different steady states. The steady states of (6.3)–(6.4) are $(g,n) = (\frac{\beta}{\beta+\gamma}, 1)$ and (1,0). The point $(\frac{\beta}{\beta+\gamma}, 1)$ is an unstable focus when $c^2 > \frac{\beta\gamma}{\beta+\gamma}$ and is a saddle when $c^2 < \frac{\beta\gamma}{\beta+\gamma}$, while the point (1,0) is always a saddle. It is worth noting that with no diffusion, the stability of the steady states does not provide a minimum for the wave speed, since the eigenvalues are always real.

When the function premultiplying $\frac{dn}{dz}$ in (6.4) is identically zero, the derivative $\frac{dn}{dz}$ is no longer defined. Pettet, McElwain, and Norbury [32] defined such a curve as a *wall-of-singularities*. Here the wall-of-singularities can be written as

$$n = \frac{1}{2\gamma g}\left(c^2 + \beta(1-g)\right). \tag{6.5}$$

This wall is asymptotic to the n-axis, cutting the positive g-axis at

$$g = 1 + \frac{c^2}{\beta}$$

to the right of the steady state $(1,0)$. Hence when $c^2 > \frac{\beta\gamma}{\beta+\gamma}$ the two steady states (an unstable focus and a saddle) are to the left of the wall. Alternatively, when $c^2 < \frac{\beta\gamma}{\beta+\gamma}$, then the two steady states (both saddles) are on either side of the wall. The wall gets closer to the origin as c^2 decreases, and therefore it is possible for the wall to move below the steady state $(\frac{\beta}{\beta+\gamma}, 1)$.

Pettet, McElwain, and Norbury [32] showed that a solution approaching a wall-of-singularities could not cross the wall unless it passed through a special point called a *hole* in the wall. A hole is defined by both the function premultiplying $\frac{dn}{dz}$ and the

right-hand side of (6.4) being equal to zero simultaneously. Marchant, Norbury, and Perumpanani [20] and Landman, Pettet, and Newgreen [18] showed that for a system of equations (in the class of (2.1)–(2.2)) a trajectory exiting one steady state in the phase plane which passed through a hole in the wall could in fact recross the wall by way of a jump discontinuity to join up with the second steady state.

Similar behavior, where the two steady states are on same side of the wall, occurs for the system considered here. As noted, our system also allows the two steady states to be on the opposite sides of the wall. We will show that for this case the presence of a hole in the wall is irrelevant and all traveling wave solutions exhibit a shock or discontinuity. For this problem, there is at most one hole in the wall in the positive (g, n) quadrant.

In seeking a trajectory connecting $(\frac{\beta}{\beta+\gamma}, 1)$ to $(1, 0)$, two different types of behavior can occur, and these are explained with two examples.

Example 1. In our first example, Figure 6.3 illustrates the (g, n) phase plane with decreasing values of wave speed c, for one choice of the kinetic parameters β and γ. For sufficiently large wave speeds, the two steady states are below the wall as in Figure 6.3(a) and there is a unique trajectory to the left of the wall, connecting the two states; this gives a smooth traveling wave. However, as c is decreased, there is a value $c = c_{crit}$ where the wall begins to interfere with trajectories emanating from the unstable node. At this value the trajectory just touches the hole in the wall as in Figure 6.3(b). For $c < c_{crit}$, we must determine whether a trajectory emanating from $(\frac{\beta}{\beta+\gamma}, 1)$ can cross the wall and connect to the other steady state (1,0).

Marchant [19] and Landman, Pettet, and Newgreen [18] investigated a similar scenario. The arguments in section 4 of [18] for general kinetic terms apply to our system of equations, allowing us to summarize the results here. No smooth connection between the two states can be made; however, there is the possibility for the solution to be nonsmooth by containing a jump discontinuity. The method relies on hyperbolic partial differential equation theory, Lax entropy condition, and the Rankine–Hugoniot jump condition. A solution for n with a shock or discontinuity, traveling of course with the constant wave speed c, is shown to exist. Let the subscripts L and R denote the value of the variable on the left and right side of the shock, respectively. Then from (4.10)–(4.12) in [18], with $h = \beta(1 - g) - \gamma n g$, the shock conditions are

$$g_L = g_R = g, \tag{6.6}$$

$$n_L + n_R = \frac{1}{\gamma g}\left(c^2 + \beta(1 - g)\right), \tag{6.7}$$

$$u_L - u_R = \frac{\gamma g}{c}(n_L - n_R), \tag{6.8}$$

where $u = \frac{\partial g}{\partial x}$. These equations establish that g is continuous, while n and the spatial gradient of the chemoattractant concentration u support a discontinuity. The Lax entropy condition [3] is satisfied only if $n_L > n_R$. Recall that the wall-of-singularities satisfies (6.5). Hence, from (6.7) the geometric center of the jump $\frac{1}{2}(n_L + n_R)$ lies exactly on the wall-of-singularities, and therefore any jump takes the trajectory to the other side of the wall. In this way, it is possible for a trajectory to pass through the hole in the wall and then jump to a trajectory on the other side of the wall, thus connecting the colonized and uncolonized states when $c < c_{crit}$, although the wall prevents a smooth joining trajectory. Such a case is shown in Figure 6.3(c), where the discontinuity corresponds to the vertical portion of the trajectory that joins the colonized and uncolonized steady states. After the jump discontinuity, n will have a

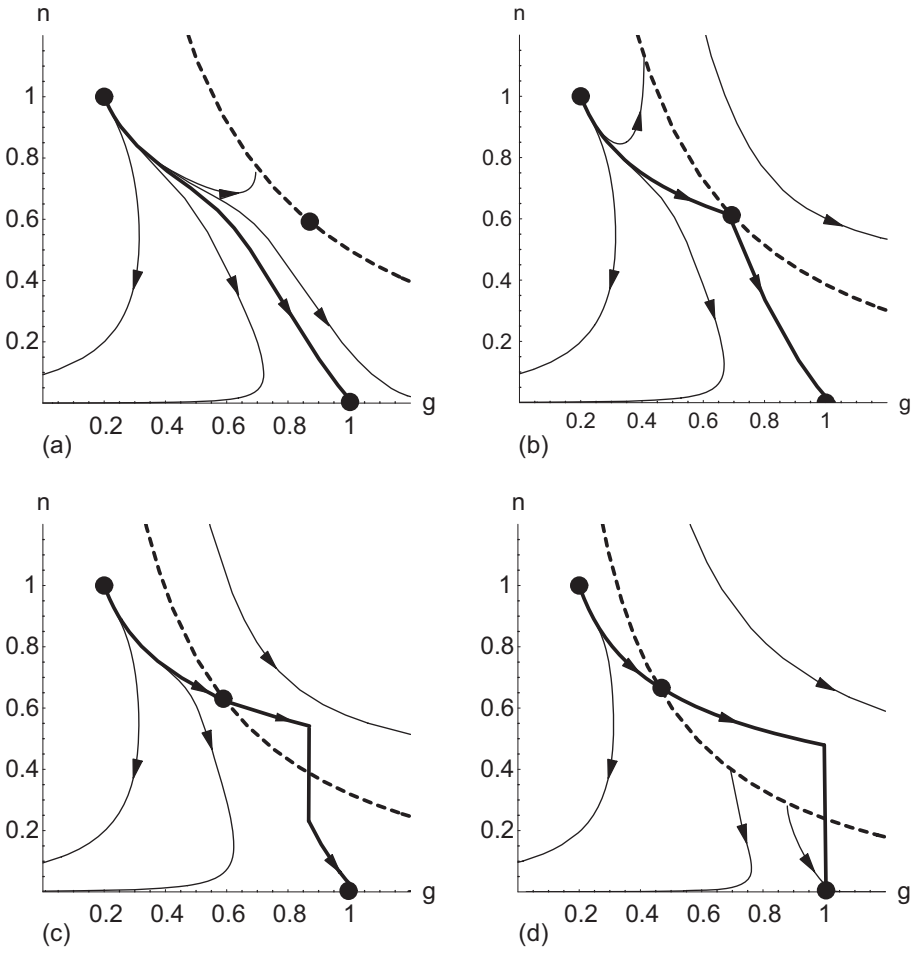

FIG. 6.3. *Phase plane for* (g, n) *for decreasing values of wave speed* c. *Here* $\beta = 0.25$, $\gamma = 1.0$. *The positions of the steady states* (•), *wall-of-singularities* (*dotted line*), *holes in the wall* (•), *and the trajectory joining the colonized and uncolonized steady states* (*thick line*) *are shown. The vertical lines in* (c) *and* (d) *correspond to the jump discontinuity in* n. (a) $c = 1.0$, (b) $c = c_{crit} \approx 0.88$, (c) $c = 0.8$, (d) $c = c_{min} \approx 0.69$.

smooth leading edge which asymptotes to zero.

However, for a realistic solution, $n_R > 0$, so the jump cannot be so large as to take the trajectory across the g-axis. As c decreases, the jump size becomes larger, until at some $c = c_{min}$, the trajectory jumps directly from $(g, n) = (1, c^2/\gamma)$ to $(1, 0)$, as illustrated in Figure 6.3(d). This solution with $c = c_{min}$ is the only solution with a zero leading edge and hence has compact support. If $c < c_{min}$, no smooth or nonsmooth traveling shock wave solution exists.

Therefore, our system supports traveling shock wave solutions with wave speed $c_{crit} > c > c_{min}$. Clearly for this example $c_{min}^2 > \frac{\beta\gamma}{\beta+\gamma}$, since both steady states remain on the same side of the wall. Example 2 considers the alternative case.

Example 2. In our second example, the value of the production rate β is increased sufficiently, so that $c_{min}^2 < \frac{\beta\gamma}{\beta+\gamma}$, allowing the possibility for the two steady states to lie on opposite sides of the wall, as shown in Figure 6.4. For sufficiently large wave

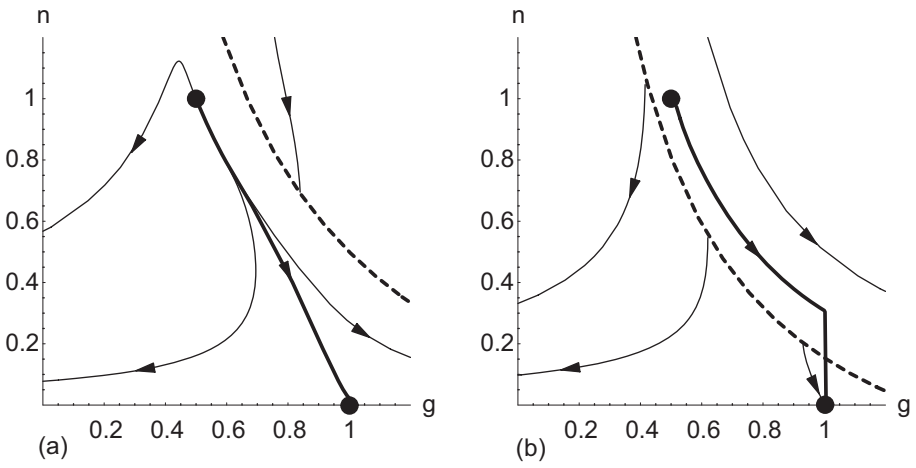

FIG. 6.4. *Phase plane for* (g, n) *for decreasing values of wave speed* c. *Here* $\beta = 1.0$, $\gamma = 1.0$. *The positions of the steady states* (•), *wall-of-singularities* (*dotted line*), *and the trajectory joining the colonized and uncolonized steady states* (*thick line*) *are shown. speeds, the two steady states are below the wall, as in Figure 6.4(a), and there is a unique trajectory to the left of the wall, connecting the two states; this gives a smooth traveling wave. However, as c is decreased to c_{crit} where

$$c_{crit}^2 = \frac{\beta\gamma}{\beta + \gamma}, \tag{6.9}$$

the steady state lies on the wall and so is also a hole in the wall. For $c < c_{crit}$, the steady state lies on the other side of the wall, as shown in Figure 6.4(b). The jump discontinuity theory can then be applied again, so that the trajectory emanating from $(\frac{\beta}{\beta+\gamma}, 1)$ can cross the wall to join with a trajectory which connects with the saddle at (1,0). Again, the requirement that $n_R > 0$ implies that as c decreases, the jump size becomes larger, until at some $c = c_{min}$, the trajectory jumps directly from $(g, n) = (1, c^2/\gamma)$ to $(1, 0)$. If $c < c_{min}$, no smooth or nonsmooth traveling shock wave solution exists. Note that, for this case, no hole is needed when the two steady states are on opposite sides of the wall, as shown here.

In addition to the phase plane analysis, a numerical solution to the system (2.7)–(2.8) with $D = 0$ illustrates the smooth and discontinuous solutions and their corresponding dependence on the wave speed. As discussed in section 4 the wave speed depends on the exponential decay rate of the initial data for n, and therefore the mechanism for generating the smooth and discontinuous traveling waves is through varying the rate of decay ξ_1.

With the same parameter values as in Figure 6.4, profiles of n and g at a fixed time for three cases where the initial cell density distribution decreases at a rapid, moderate, and slow exponential rate are given in Figure 6.5. The left-most profile corresponds to a rapidly decaying initial condition. The cell density profile shows that the cell front is discontinuous, with the discontinuity extending to $n = 0$, and therefore the profile has compact support. The gradient of the chemoattractant profile is also discontinuous at the same position, namely, the smallest value of x where $g = 1$. This corresponds to the case where the trajectory in the phase plane jumps across the

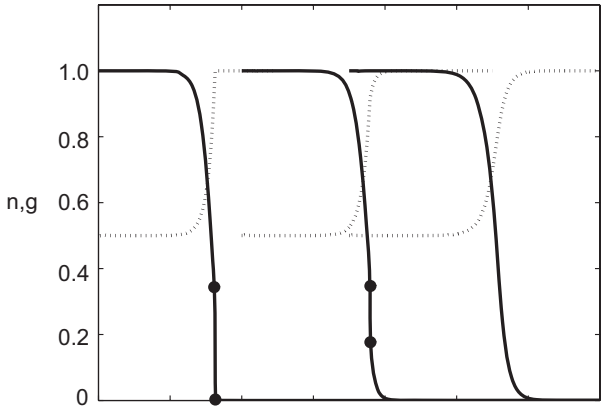

FIG. 6.5. *Numerical profiles for $n(x,t)$ (solid line) and $g(x,t)$ (dotted line) with $\gamma = 1.0$, $\beta = 1.0$. Left to right $n(x,t)$: Discontinuous solution with maximum shock length ($n_R = 0$) with $\xi_1 = 3.0$; discontinuous solution with smaller shock length ($n_R > 0$) with $\xi_1 = 1.5$; continuous solution with $\xi_1 = 1$. The end points of the shocks (•) are shown. Numerical computations were performed with $\Delta x = 0.05$ and $\Delta t = 0.01$.*

wall to the completely colonized steady state, as in Figure 6.4(b). The middle profile in Figure 6.5 corresponds to an initial condition where the decay is moderate. This profile shows a smaller discontinuity in the cell density; however, the discontinuity does not extend to the base of the profile as the toe of the profile is continuous. Again there is a discontinuity in the gradient of the chemoattractant at the same position where the discontinuity in the cell density occurs. Finally, with a slowly decaying initial condition, the distributions of the cell density, chemoattractant concentration, and the gradient of the chemoattractant concentration are continuous, as shown in the rightmost profile. The phase plane corresponding to this final case has the two steady states on the same side of the wall, as in Figure 6.4(a). With the parameter values used in Figure 6.3, the numerical solutions are qualitatively similar.

The profiles in Figure 6.5, together with the phase diagrams in Figures 6.3 and 6.4, give a comprehensive understanding of the behavior of the traveling wave solutions obtained from (2.7)–(2.8) when $D = 0$ and chemotaxis is the only cell migration process. Similar to the alternative diffusion-only case ($\chi = 0$), the existence of traveling wave solutions is established. In contrast, migration by pure diffusion cannot give rise to discontinuous solutions because of the smoothing nature of linear diffusion. However, both these limiting cases show that the speed of the resulting traveling wave solution is determined by the exponential decay rate of the initial distribution of the migrating cell population.

Finally, it follows from our scaling arguments (2.6), (6.3)–(6.4), that the minimum wave speed for the chemotaxis-only migration case scales with $\sqrt{\chi}$ and hence has the form

$$c_{min} = K(\beta,\gamma)\sqrt{\chi}, \tag{6.10}$$

where $K(\beta,\gamma)$ is a constant dependent on the kinetic parameters. This was anticipated in the earlier numerical simulations presented in Figure 4.1(a). Therefore c_{min} has a similar form to the minimum wave speed of $2\sqrt{D}$ for the diffusion driven migration as discussed in section 6.1. The major difference is that the coefficient $K(\beta,\gamma)$ is

not a constant but varies in a complicated way with the kinetic parameters β and γ. The two examples discussed above provide the criterion for determining K. As in Example 1, if $c_{min}^2 > \frac{\beta\gamma}{\beta+\gamma}$, then c_{min} is defined as that value of c such that the trajectory from the hole in the wall passes through $(1, c^2/\gamma)$. Alternatively, as in Example 2, if $c_{min}^2 < \frac{\beta\gamma}{\beta+\gamma}$, then c_{min} is defined as that value of c such that the trajectory from the steady state $(\frac{\beta}{\beta+\gamma}, 1)$ passes through $(1, c^2/\gamma)$.

An analytical solution for $K(\beta, \gamma)$ has been attempted but does not appear possible at the present time. Instead, numerical solutions are used to compute the minimum wave speed $K(\beta, \gamma)$ over a range of kinetic parameters β and γ. The form of $K(\beta, \gamma)$ is shown in Figure 6.6. In general, $K(\beta, \gamma)$ decreases with increasing β and increases with increasing γ, that is, $\frac{\partial K}{\partial \beta} < 0$ and $\frac{\partial K}{\partial \gamma} > 0$. These trends can be understood by considering the biological processes associated with the kinetic terms. The steady state concentration $g = \frac{\beta}{\gamma+\beta}$ increases with increasing β or with decreasing γ. As this steady concentration increases, the chemotactic gradient decreases giving rise to slower traveling wave speeds and a reduced value of $K(\beta, \gamma)$. This intuitive argument agrees with the form of $K(\beta, \gamma)$ deduced with the numerical solutions shown in Figure 6.6. We also investigated whether $K(\beta, \gamma)$ depended on a similarity variable, such as the ratio $\frac{\beta}{\gamma}$ alone, as illustrated in Figure 6.6(c). It appears that $K(\beta, \gamma)$ has a similar shape for the wide range of $\frac{\beta}{\gamma}$ investigated. However, the location of the curve can vary considerably for various choices of β.

Incorporating both numerical and phase plane analyses in this work reveals a remarkable advantage regarding the development and testing of the numerical algorithm. In general, testing numerical schemes for coupled nonlinear migration problems can be very difficult because of a lack of suitable analytical solutions [35]. Using the phase plane for the pure chemotaxis problem quantifies certain properties of the solution, such as the critical wave speed c_{crit}, the minimum wave speed c_{min}, and the size of the discontinuity. This unique information is useful in developing the numerical scheme as these quantitative checks are invoked to ensure that the numerical scheme is accurate.

6.3. Migration with both diffusion and chemotaxis. A three-dimensional phase plane analysis of (5.1)–(5.3) does not provide a productive way for seeking traveling wave solutions. A numerical study is convenient for examining both the shape of the invading profile as well as the minimum wave speeds. In particular, the robust numerical algorithm presented here has no difficulty in generating numerical solutions for any value of the diffusion coefficient and chemotactic factor. Therefore, it is of interest to investigate how this general case of combined chemotaxis and diffusive migration relates to the two limiting cases when either D or χ is zero.

6.3.1. Numerical solution profiles. Various solution profiles showing the influence of increasing the chemotactic factor χ for a fixed value of diffusivity $D = 1$ are shown in Figure 6.7(a). Comparison of these profiles shows that their smooth shape evolves to one with a developing discontinuity as χ increases. Moreover, the gradient of both the cell density and chemoattractant concentration increases with χ. Since the profiles are plotted at a fixed time starting from the same initial data, the wave speed clearly increases with χ from the minimum wave speed associated with the Fisher equation. This increase in wave speed with χ is expected because the inclusion of a second migration process enhances cell migration.

Similarly, the effect of increasing D on the numerical solutions is shown in Figure 6.7(b). Now the steep profiles evolve to smooth, flatter profiles as the diffusivity

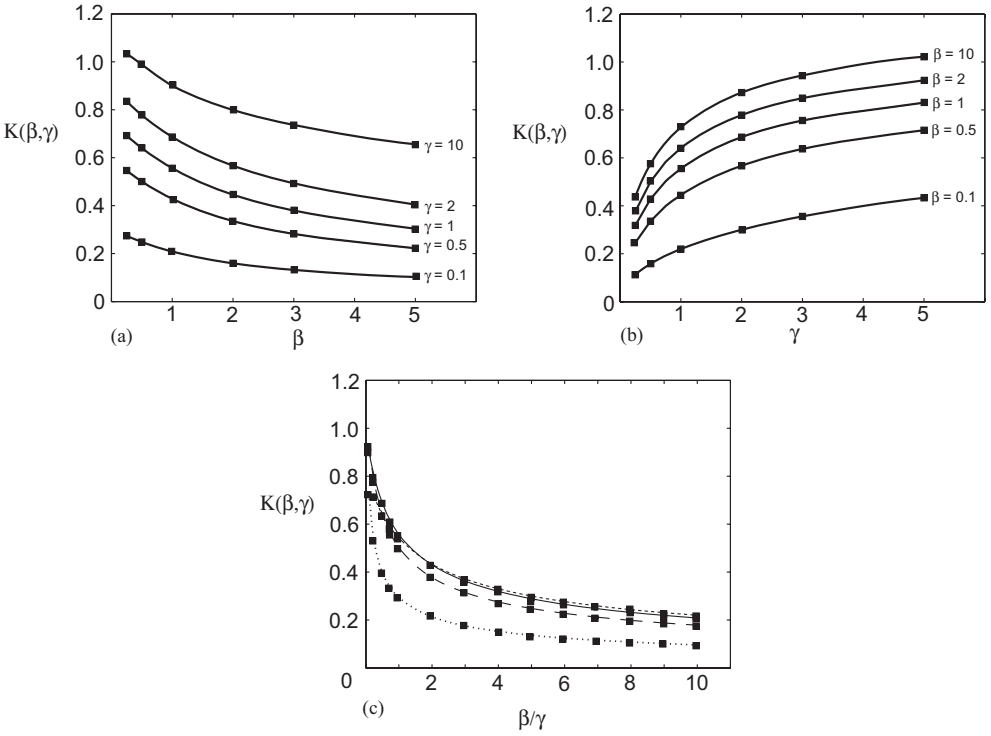

FIG. 6.6. *Dependence of $K(\beta,\gamma)$ on the kinetic parameters.* (*a*) *β for various γ values;* (*b*) *γ for various β values;* (*c*) *β/γ for $\beta = 10$ (short dashed line), $\beta = 1$ (solid line), $\beta = 0.5$ (long dashed line), and $\beta = 0.1$ (dotted line).*

increases, which reflect the smoothing nature of linear diffusion. These flatter profiles travel at a faster rate, as for the Fisher equation [25].

It is interesting to compare the rate at which the added migration processes competes with the underlying migration. In Figure 6.7(a), with the addition of chemotaxis to diffusive migration, the shape of the front steepens with increasing χ; however, the smooth shape is maintained fairly consistently up until $\chi = 50$ and it is not until $\chi = 100$ that the profile begins to tend toward the upper limit of chemotaxis-only migration with a discontinuous front. Conversely, in Figure 6.7(b), with the addition of diffusion to chemotactic migration, the shape of the front is very sensitive to the addition of a small amount of diffusion. The sharp front is smoothed with increasing D and tends toward the limit of diffusion-only migration for $D = 0.5$. These observations show that diffusion masks the influence of chemotaxis more efficiently than chemotaxis masks diffusion. These trends will now be more thoroughly explored in terms of the minimum wave speed c_{min}.

6.3.2. Minimum wave speed. For the system (5.1)–(5.3), a linear stability analysis of the steady state $(g, n, v) = (1, 0, 0)$ gives real eigenvalues if and only if $c \geq 2\sqrt{D}$, ensuring the point is a saddle point, just like for the Fisher equation. This condition provides a lower bound for the minimum wave speed. Numerical computations provide an extended analysis of the influence of mixed migration on the minimum wave speed. We examine the case where one of χ or D is held constant while simultaneously varying the other migration parameter. Numerical computations are

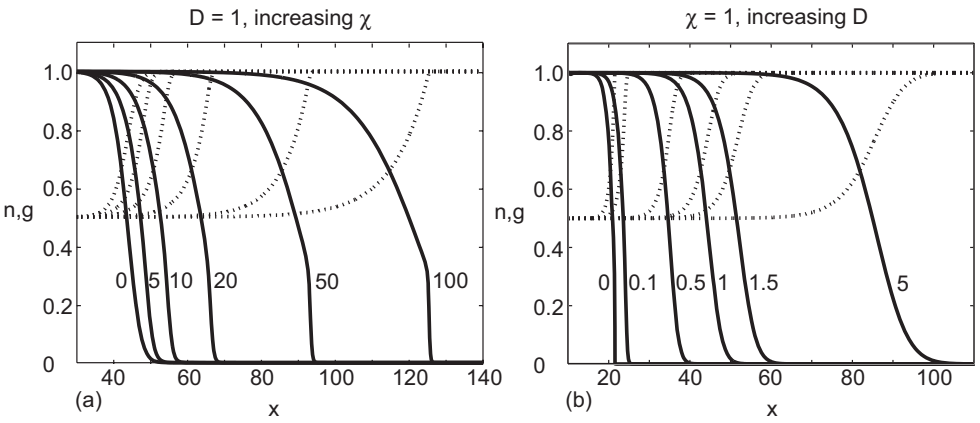

FIG. 6.7. *Numerical profiles of* $n(x, 20)$ (*solid line*) *and* $g(x, 20)$ (*dotted line*). (*a*) *The influence of increasing chemotaxis with fixed* $D = 1$, *with* χ *increasing from left to right with values indicated.* (*b*) *The influence of increasing diffusion with fixed* $\chi = 1$, *with* D *increasing from left to right with values indicated. conducted to determine the effect on c_{min}.

Fixing the value of the chemotactic factor, namely, $\chi = 1$, the minimum wave speed increases monotonically with the diffusion coefficient D, as shown in Figure 6.8(a). Furthermore, as the diffusion coefficient increases, the minimum wave speed asymptotes to $2\sqrt{D}$. For this choice of kinetic parameters, $2\sqrt{D}$ provides a good approximation to c_{min} when $D/\chi > 0.2$. In general, for sufficiently large D/χ, diffusion dominates over chemotaxis and the minimum wave speed is accurately approximated by the Fisher wave speed $c_{min} = 2\sqrt{D}$, while for smaller values of D/χ, chemotaxis dominates and c_{min} is greater than that associated with the Fisher equation or chemotaxis alone. The numerical results for large D lie a little below $2\sqrt{D}$; this trend was also found for haptotactic invasion with added diffusion [19].

Similarly, setting the diffusion coefficient as $D = 1$, the c_{min} monotonically increases with the chemotactic factor χ and asymptotes to $K(\beta, \gamma)\sqrt{\chi}$, as illustrated in Figure 6.8(b). In this example, $K(\beta, \gamma)\sqrt{\chi}$ gives a good approximation to c_{min} when $\chi/D > 50.0$. In general for sufficiently large χ/D, chemotaxis dominates over diffusion and the minimum wave speed is well approximated by $c_{min} = K(\beta, \gamma)\sqrt{\chi}$ as given in (6.10). Conversely, for smaller values of χ/D, diffusion dominates and c_{min} is greater than that associated with chemotaxis or diffusion alone.

An explicit formula for c_{min} as a function of χ and D (as well as the kinetic parameters) has not been determined at this stage. However, some descriptive comments can be made. The discussion above indicates a natural lower bound for c_{min} as $\max[K(\beta, \gamma)\sqrt{\chi}, 2\sqrt{D}]$. An upper bound can be conjectured, as indicated in Figure 6.8. These can be combined as

$$\max[K(\beta, \gamma)\sqrt{\chi}, 2\sqrt{D}] < c_{min} < \sqrt{4D + K^2(\beta, \gamma)\chi}. \tag{6.11}$$

This expression suggests that diffusion dominates over chemotaxis when $\frac{K^2(\beta,\gamma)\chi}{4D} \ll 1$, and alternatively that chemotaxis dominates over diffusion when $\frac{4D}{K^2(\beta,\gamma)\chi} \ll 1$.

6.3.3. Perturbation analysis. When chemotaxis is small compared to diffusive migration, namely, $\chi/D \ll 1$, a regular perturbation analysis could be undertaken to

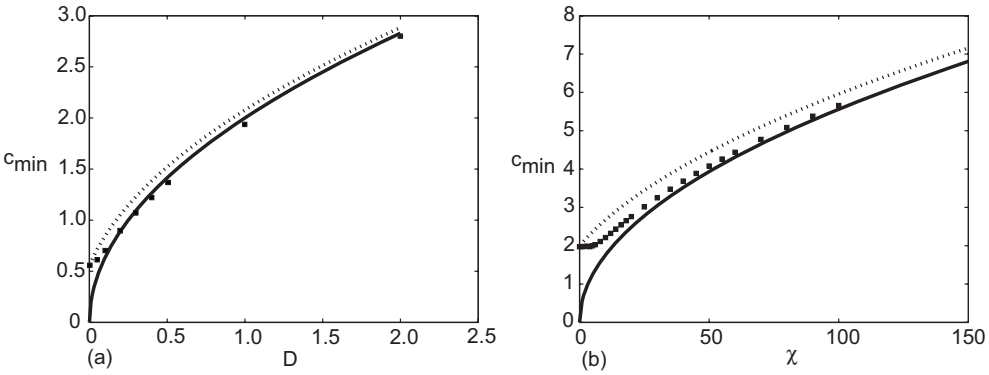

FIG. 6.8. *Numerically calculated minimum wave speed c_{min} shown with squares evolving from initial data with $\xi_1 = 10$. Results computed with $\beta = 1, \gamma = 1$. (a) Dependence on D with $\chi = 1$. The solid curve is $c_{min} = 2\sqrt{D}$. (b) Dependence on χ with $D = 1$. The solid curve is $c_{min} = K(\beta,\gamma)\sqrt{\chi}$; for this example $K(\beta,\gamma) \approx 0.556$. The dotted curves are the conjectured upper bound $c_{min} = \sqrt{4D + K^2(\beta,\gamma)\chi}$.*

give a solution valid for small χ/D. The first-order terms for n would just be the solution to the Fisher equation. This analysis is not very insightful and therefore is not shown here. A more illuminating analysis comes from the alternative case when D/χ is small.

Marchant [19] examined the case where a small amount of diffusion was added to a haptotactic invasion problem, using singular perturbation and phase plane arguments. A similar analysis is performed here but can be taken further and solved exactly. As discussed in section 6.2, when $D = 0$, our model supports discontinuous traveling wave solutions for a range of values of c. We know that a small amount of diffusion added to a purely chemotactic system has the effect of smoothing out any discontinuities. However, the gradients are expected to remain large in a small region. When D/χ is small, a perturbation analysis provides an understanding of the transition region. The analysis determines the evolution from a discontinuous traveling wave solution ($D = 0$) to one which is smooth, but has large derivative, in a small critical layer. Set $\chi = 1$ without any loss of generality. With $D \ll 1$, we seek solutions to (5.1)–(5.3) as an asymptotic expansion in terms of D as

$$g = g_0(z) + Dg_1(z) + D^2 g_2(z) + \cdots, \tag{6.12}$$

$$n = n_0(z) + Dn_1(z) + D^2 n_2(z) + \cdots, \tag{6.13}$$

$$v = v_0(z) + Dv_1(z) + D^2 v_2(z) + \cdots. \tag{6.14}$$

Hence g_0 and n_0 will satisfy (6.3)–(6.4). We choose to consider the traveling wave solution with the minimum wave speed c_{min}. We shift the origin so that the jump occurs at $z = 0$. This solution is the first term in the *outer* solution of the asymptotic expansion of the solution. At $z = 0$, for small D, there will be a narrow region where the rates of change of n are large, since n has to connect the left-hand limit n_L and right-hand limit $n_R = 0$. In this critical layer we seek a solution in the expanded variable $\xi = z/D$ as

$$g = G_0(\xi) + DG_1(\xi) + D^2 G_2(\xi) + \cdots, \tag{6.15}$$

$$n = N_0(\xi) + DN_1(\xi) + D^2 N_2(\xi) + \cdots, \tag{6.16}$$

$$v = \frac{1}{D}V_0(\xi) + V_1(\xi) + DV_2(\xi) + \cdots. \tag{6.17}$$

Substitution into (5.1)–(5.3) yields the highest-order terms satisfying

$$\frac{dG_0}{d\xi} = 0, \tag{6.18}$$

$$\frac{dN_0}{d\xi} = V_0, \tag{6.19}$$

$$\frac{dV_0}{d\xi} = -\left[1 + \frac{1}{c_{min}^2}(\beta(1-G_0) - 2\gamma N_0 G_0)\right] c_{min} V_0. \tag{6.20}$$

For the inner solution to match the outer solution, we require

$$G_0 = 1, \quad \xi \to \pm\infty, \tag{6.21}$$

$$N_0 = n_L = \frac{c_{min}^2}{\gamma}, \quad \xi \to -\infty\,, \qquad N_0 = n_R = 0, \quad \xi \to \infty, \tag{6.22}$$

$$V_0 = 0, \quad \xi \to \pm\infty. \tag{6.23}$$

Note that the value of n_L is obtained using the jump condition (6.7). Equations (6.18) and (6.21) give $G_0(\xi) = 1$ for all ξ. This simplifies the coupled system (6.19)–(6.20) as

$$\frac{dV_0}{d\xi} = -\left[1 - \frac{2\gamma}{c_{min}^2}N_0\right] c_{min}\frac{dN_0}{d\xi} = -c_{min}\left[\frac{dN_0}{d\xi} - \frac{2\gamma}{c_{min}^2}N_0\frac{dN_0}{d\xi}\right], \tag{6.24}$$

which integrates to

$$\frac{dN_0}{d\xi} = V_0 = -c_{min}\left(N_0 - \frac{\gamma}{c_{min}^2}N_0^2\right), \tag{6.25}$$

where the integration constant is zero from the conditions at $\xi \to \infty$. This is a logistic equation with solution

$$N_0 = \frac{c_{min}^2}{\gamma}\frac{e^{-c_{min}\xi}}{1 + e^{-c_{min}\xi}}, \tag{6.26}$$

where $N_0(0) = c_{min}^2/(2\gamma)$ with no loss of generality. Therefore, adding a small amount of diffusion introduces a steep transition region, of width D with exponential behavior depending on $c_{min}z/D$ (having set $\chi = 1$).

Figure 6.9 compares the numerically generated solutions to the perturbation analysis logistic solution (6.26). The region about the sharp front is stretched via the transformation $\xi = z/D$ so that the gradient is $\mathcal{O}(1)$ in the ξ coordinate. The numerical profile is translated so that $n(\xi, t) = c_{min}^2/(2\gamma)$ occurs at $\xi = 0$, as it does for N_0. The profiles of the leading order perturbation analysis and the numerically generated solution compare very well in the leading edge for $\xi > 0$ for small values of D as shown. The perturbation solution does not match as well in the region $\xi < 0$ for two reasons. First, we have matched with the jump density n_L as $\xi \to -\infty$, whereas the full numerical solution goes to the $n = 1$ state. Second, the slope of n as $\xi \to -\infty$ does not match at this dominant order of the approximation. The next order term, V_1, would be required to match the slope of the outer solution $\frac{\partial n_0}{\partial z}$ at the left of the shock as $\xi \to -\infty$.

7. Conclusions. This article considers a mathematical model of cell invasion, where both diffusion and chemotaxis are the migration mechanisms. The details of the model were developed such that the results of the analysis are applicable to certain cell migration processes which are known to occur in developmental biology. A suite of traveling wave solutions is shown to exist regardless of whether the migration is pure diffusive, pure chemotaxis, or a combination of diffusive and chemotaxis migration. For all three cases, the traveling wave speed is bounded from below. The minimum wave speed is always observed whenever numerical simulations are performed using initial data where the cell density has compact support. Since the initial distribution of invading cells usually falls to zero for x large enough, this seems to be the most biologically relevant situation. Therefore, in general the most biologically relevant solution for these cell migration models is the solution corresponding to the minimum wave speed.

An understanding of the nature of the minimum wave speed as a function of the migration parameters is important. Phase plane analysis can provide values for the minimum wave speed for the two limiting cases when either the migration is purely diffusive or chemotactic. These values and the explicit shapes of the solutions can also be found using numerical methods. In particular, a robust numerical algorithm is developed which gives stable traveling waves solutions including shocks. The numeri-

cal algorithm combines a high-accuracy explicit central scheme [14] for the nonlinear hyperbolic and reaction terms together with a standard implicit finite element solution of the diffusion term with an operator split approach. The use of operator splitting for this particular problem was critical in combining the numerical solutions of the chemotaxis and diffusion terms together in a way that conveniently minimized numerical stability issues. Therefore, the numerical algorithm presented in this work provides an extremely accurate and versatile means of solving combined chemotaxis and diffusive migration problems.

For the combined diffusion and chemotactic migration case, numerical results were used to determine an upper and a lower bound on the minimum wave speed. Numerical results also demonstrate how the diffusion and chemotaxis mechanisms interact in a combined migration problem. The rate at which the minimum wave speed for the mixed migration case approached the minimum wave speed for the two limiting cases indicated that diffusion dominates over chemotaxis for relatively small values of the ratio of $\frac{D^*}{\chi^*} = \frac{D\lambda_3}{\chi\lambda_2}$.

The results from the combined diffusion and chemotaxis case indicate that adding a small amount of diffusion to a pure chemotaxis problem can result in the chemotactic characteristics of the problem being completely masked by the added diffusion. This observation is particularly relevant for numerical computations, when parabolic solvers are often used for chemotaxis (or haptotaxis) dominated processes. Further, this result also implies that standard numerical solutions of chemotaxis problems might be extremely sensitive to numerical diffusion and so great care should be exercised in obtaining such solutions.

In summary, this analysis provides a deeper qualitative and quantitative understanding of the interplay between diffusion and chemotaxis for invading cell populations. Often, when modeling biological cell migration, parameter values are difficult to estimate. If the wave speed can be determined experimentally, and the diffusion rate estimated, then some reasonable estimates of the chemotactic term may be deduced from the results presented here.

ASYMPTOTIC THEORY OF ELECTROSEISMIC PROSPECTING*

BENJAMIN S. WHITE†

Abstract. In a porous medium such as the earth's subsurface, electromagnetic (EM) waves and mechanical waves are coupled through the phenomenon of electrokinetics, for which a complete set of partial differential equations was derived by S. Pride. In this paper, we derive from Pride's equations an asymptotic theory that enables forward modeling of the seismic response to an EM source in fully three-dimensional geometries on a scale that is relevant to exploration. For simplicity, we consider piecewise homogeneous media separated by interfaces which are curved surfaces in three dimensions. The following physical picture emerges: An EM source excites an EM wave which propagates into the earth, stirring up local mechanical movement. At an interface, EM energy is converted to seismic waves, which may be described by ray theory. Instantly, on the seismic time scale, every interface becomes a wavefront for both compressional and shear waves; that is, seismic P- and S-waves explode from both sides of each interface, at every point on it. The rays for these waves leave the interface in the orthogonal direction and propagate up and down into the homogeneous media on both sides of the surface. We derive formulas for the initial amplitudes of these waves. Conventional seismic ray theory then describes propagation of the P- and S-waves, including reflection, transmission, and mode conversion at any other interfaces that they may encounter. Thus, three-dimensional electroseismic modeling may be accomplished with conventional EM and conventional seismic modeling tools, using the present theory to provide the link between them.

1. Introduction.

In a porous medium such as the earth's subsurface, electromagnetic (EM) waves and mechanical waves are coupled through the phenomenon of electrokinetics [14]. Ions in the pore fluid are attracted to ions of the opposite sign in the solid at the pore walls, so that there is an electrical double layer, called the Debye layer, at the pore boundaries. An electric field acting on this double layer will move the ions relative to each other, creating movement of both the fluid and the solid. Conversely, a mechanical wave which moves the fluid and solid relative to each other will create an EM wave. This phenomenon was proposed as the basis of a hydrocarbon exploration method in 1936 by R. R. Thompson of Humble Oil Company, in volume 1 of *Geophysics* [19]. It was described theoretically 60 years ago [7] and has been demonstrated in the laboratory, where the magnitude of the coupling, called the electrokinetic mobility, has been measured (see [13] and references therein).

Starting with the microscopic description, Pride [14] derived from first principles a complete set of macroscopic equations describing electrokinetics. These are 19 scalar partial differential equations in which Maxwell's equations for EM are coupled with Biot's equations [1, 2, 3, 15] for movement of fluid and solid in a porous medium. Some general properties of these equations are known, including uniqueness, source/receiver reciprocity, energy conservation, and point source and plane wave responses in homogeneous media [17]. Also, computer codes have been written to compute the solution of Pride's equations in plane layered media [8], that is, media which are piecewise

homogeneous and which have material properties that vary only in one dimension, which is depth.

Techniques based on electrokinetics have been proposed for use in exploration of the earth's subsurface, and several groups have conducted field experiments [19, 18, 4, 11, 12]. All of these experiments were seismoelectric, i.e., a mechanical (seismic) source was used, and an EM wave was detected. In this paper, we will analyze the electroseismic method, where an EM source is used and a seismic wave is detected.

Electrokinetic prospecting methods are especially promising for detecting materials whose electrical resistivity varies markedly from that of the background, e.g., hydrocarbons. EM methods [20, 6] may also be used for this, but their spatial resolution is usually less than desirable because of the long wavelengths of EM waves in the earth. Seismic methods [6] have much better spatial resolution, but they respond to much smaller contrasts in material properties. It may be hoped that electrokinetic methods can combine the virtues of both approaches.

In this paper, we will derive an asymptotic theory that enables forward modeling of the electroseismic response in fully three-dimensional geometries on a scale that is relevant to exploration. For these problems, the cost of direct calculation, for instance with finite differences, is prohibitive. In deriving the theory, we use three basic assumptions: first, that the EM and mechanical coupling is weak; second, that, as is common in seismology, conventional elasticity theory may be used in place of Biot's theory; and third, that the scales are such that seismic ray theory is valid. Each of these assumptions is specified in terms of a single parameter that is assumed to be large or small. Our asymptotic theory is then derived from a systematic perturbation expansion of Pride's full system of equations for electrokinetics. For simplicity, we consider only piecewise homogeneous media separated by interfaces which are curved surfaces in three dimensions.

The physical picture that emerges from the perturbation expansion is as follows: An EM source excites an EM wave which propagates into the earth, stirring up local mechanical movement as it passes. At an interface, EM energy is converted to seismic waves, which may be described by ray theory. Instantly, on the seismic time scale, every interface becomes a wavefront for both compressional and shear waves; that is, seismic P- and S-waves explode from both sides of each interface, at every point on it. The rays for these waves leave the interface in the orthogonal direction, and propagate up and down into the homogeneous media on both sides of the surface. Conventional seismic ray theory [5, 10] then describes propagation of the P- and S-waves, including reflection, transmission, and mode conversion at any other interfaces that they may encounter.

All that is necessary to complete this picture are the initial amplitudes of the P- and S-waves when they originate at the interfaces. Formulas for these initial amplitudes are given below in section 8. These formulas depend on the material parameters and on values of the electric field on both sides of the interface where the seismic waves originate.

With this theory, a general computer program for three-dimensional electroseismic modeling can be constructed, using commercially available software for the major computational tasks. First, the EM field is computed using, say, a finite element EM solver. A small subroutine then uses the formulas of section 8, combined with the computed values of the electric field, to get the initial P- and S-wave amplitudes on every interface. Finally, a ray trace program may be used to follow the rays that are created. In this way, three-dimensional electroseismic modeling may be accomplished

with conventional EM and conventional seismic modeling tools, using the present theory to provide the link between them.

This paper is organized as follows.

In section 2, we nondimensionalize Pride's equations, and introduce the small and large parameters used for the perturbation analysis. In section 3 we show how the problem can be reduced to solving the usual homogeneous Biot's equations, but with inhomogeneous boundary conditions at all the interfaces. For each interface, we derive eight scalar jump conditions for Biot's equations, conditions that depend on the material parameters and on the computed values of the electric field on both sides of the interface.

In sections 4–7 we derive a two-parameter asymptotic expansion for Biot's equations. This approximation is applicable when seismic ray theory is valid, and when Biot's equations give rise to waves that look like the conventional seismic P- and S-waves which are derived from the theory of an elastic solid. Besides the P- and S-waves, we obtain the form, in our approximation, of the Biot slow wave.

The Biot slow wave is a diffusive wave, which decays rapidly to zero with propagation distance. It is therefore difficult to observe, and laboratory observation of it in real rocks has only been accomplished recently [9]. However, as is shown in section 8, EM energy is converted to Biot slow waves at an interface, and slow waves must be considered in order to calculate the amplitudes of the P- and S-waves which also originate there. The necessity of including the Biot slow waves for energy conversion at an interface is consistent with the results of Pride and Garambois [16] for conversions of seismic to EM energy.

In section 8, we combine our asymptotic Biot theory with the interface conditions of section 3 to derive the initial amplitudes of all the waves created at an interface by an EM source.

In section 9, we compare the asymptotic theory to the results of a computer program which is designed to compute the electroseismic response in plane layered media.

Concluding remarks are in section 10.

2. An EM source in the seismic band. For an EM source current $\mathbf{j_s}$ in a porous medium, Pride's equations for the electric and magnetic field vectors, $\mathbf{E}$ and $\mathbf{H}$, respectively, are

$$\nabla \mathbf{x} \mathbf{E} = i\omega\mu \mathbf{H}, \tag{1}$$

$$\nabla \mathbf{x} \mathbf{H} = (\sigma - i\epsilon\omega)\mathbf{E} + L(-\nabla p + \omega^2 \rho_f \mathbf{u}) + \mathbf{j_s}, \tag{2}$$

where ω is frequency, σ, ϵ, and μ are, respectively, conductivity, dielectric constant, and magnetic permeability, L is the electrokinetic mobility parameter, p is the pore pressure, ρ_f is the density of the pore fluid, and $\mathbf{u}$ is the solid displacement.

Pride's equations for $\mathbf{u}$ and the relative fluid displacement $\mathbf{w}$ are

$$-\omega^2(\rho \mathbf{u} + \rho_f \mathbf{w}) = \nabla \cdot \tau, \tag{3}$$

$$-i\omega \mathbf{w} = L\mathbf{E} + (\kappa/\eta)(-\nabla p + \omega^2 \rho_f \mathbf{u}), \tag{4}$$

$$\tau = (\lambda \nabla \cdot \mathbf{u} + C \nabla \cdot \mathbf{w})\mathbf{I} + G(\nabla \mathbf{u} + \nabla \mathbf{u}^{\mathbf{T}}), \tag{5}$$

$$-p = C\nabla \cdot \mathbf{u} + M\nabla \cdot \mathbf{w}, \tag{6}$$

where τ is the stress tensor, $\mathbf{I}$ is the 3×3 identity, κ is the permeability, η is the viscosity of the pore fluid, λ and G are the Lamé parameters of elasticity, and C and M are the Biot moduli parameters.

Note that in this theory, the electrokinetic mobility L provides coupling between the EM system (1), (2) and the mechanical system (3)–(6). That is, when $L = 0$ these systems are decoupled. We assume weak coupling so that to leading (i.e., zeroth) order in L, the EM field satisfies (1), (2) with $L = 0$. These equations are the conventional Maxwell equations, and can be solved independently of the mechanical system. Then to leading (i.e., first) order in L the mechanical system satisfies (3)–(6), which are Biot's equations with the EM field as a source.

We consider these equations in a homogeneous region of space, i.e., where all parameters are constant. Then putting (5) into (3) yields

$$-\omega^2(\rho\mathbf{u} + \rho_f\mathbf{w}) = (\lambda + G)\nabla(\nabla \cdot \mathbf{u}) + G\nabla^{\mathbf{2}}\mathbf{u} + C\nabla(\nabla \cdot \mathbf{w}). \tag{7}$$

Putting (6) into (4) yields

$$-\omega^2(\rho_f\mathbf{u} + \tilde{\rho}\mathbf{w}) = C\nabla(\nabla \cdot \mathbf{u}) + M\nabla(\nabla \cdot \mathbf{w}) - i\omega\tilde{\rho}L\mathbf{E}, \tag{8}$$

where the pure imaginary parameter

$$\tilde{\rho} = \frac{i\eta}{\omega\kappa} \tag{9}$$

has units of density.

The equations may be nondimensionalized by introducing typical values $\bar{\rho}$, $\bar{\lambda}$, $\bar{G}$, $\bar{L}$, $\bar{E}$, and a typical length scale of the geometry, $\bar{l}$. Define

$$\begin{aligned} \bar{v} &= \sqrt{\frac{(\bar{\lambda} + 2\bar{G})}{\bar{\rho}}}, \\ \bar{u} &= \frac{\bar{l}}{\bar{v}}\bar{L}\bar{E}. \end{aligned} \tag{10}$$

Note that $\bar{v}$ is a typical compressional wave speed in elasticity theory, i.e., a typical seismic P-wave speed.

Define the dimensionless variables

$$\begin{aligned} &\mathbf{x}' = \mathbf{x}/\bar{l}, \quad \omega' = \omega\bar{l}/\bar{v}, \quad L' = L/\bar{L}, \\ &\rho' = \rho/\bar{\rho}, \quad \rho_f' = \rho_f/\bar{\rho}, \quad \tilde{\rho}' = \tilde{\rho}/\bar{\rho}, \\ &\lambda' = \lambda/(\bar{\lambda} + 2\bar{G}), \quad G' = G/(\bar{\lambda} + 2\bar{G}), \quad M' = M/(\bar{\lambda} + 2\bar{G}), \quad C' = C/(\bar{\lambda} + 2\bar{G}), \\ &\mathbf{u}' = \mathbf{u}/\bar{u}, \quad \mathbf{w}' = \mathbf{w}/\bar{u}, \quad p' = \frac{\bar{l}}{\bar{u}(\bar{\lambda} + 2\bar{G})}p, \quad \tau' = \frac{\bar{l}}{\bar{u}(\bar{\lambda} + 2\bar{G})}\tau, \quad \mathbf{E}' = \mathbf{E}/\bar{E}. \end{aligned} \tag{11}$$

Use of (10) and (11) shows that (5)–(8) are also satisfied by the primed variables.

We consider the seismic ray theory regime when a typical seismic wavelength is much smaller than a typical dimension $\bar{l}$. Thus the dimensionless frequency ω' satisfies the high frequency condition

$$\omega' >> 1. \tag{12}$$

However, the frequency is assumed to be subcritical for the porous medium, i.e.,

$$|\tilde{\rho}'| >> 1. \tag{13}$$

As is shown in sections 4–7, condition (13) assures that the dynamics of the porous medium may in most regions of space be approximated by the dynamics of elasticity theory, as is commonly assumed in seismology. In particular, this condition is necessary to obtain wave modes that approximate those of seismic P- and S-waves. Condition (13) also plays a role in microscopic theory, where it guarantees that the frequency is much less than the transition frequency separating low frequency viscous flow in the pores from high frequency inertial flow [14]. Thus the present theory corresponds to that in [1] rather than that in [2].

Because a typical EM wavelength is much larger than a seismic wavelength, $\mathbf{E}$ is not rapidly varying on the length scale $\bar{l}$. Therefore, ray theory is not appropriate for the calculation of the EM field, and the full Maxwell equations (1), (2) with $L = 0$ must be solved.

Equations (7) and (8) are satisfied in each homogeneous region of space. Let $\mathcal{S}$ be an interface, i.e., a surface separating two homogeneous regions, and let $\mathbf{n}$ be a normal to $\mathcal{S}$. Then Pride's interface conditions [17] are

$$\text{Continuity of} \quad \mathbf{u},\ p,\ \mathbf{w}\cdot\mathbf{n},\ \tau\cdot\mathbf{n} \quad \text{across } \mathcal{S}. \tag{14}$$

Note that (14) comprises eight scalar boundary conditions that must be satisfied at any interface between two homogeneous regions. Of course Maxwell's equations also require continuity of the tangential components of $\mathbf{E}$ and $\mathbf{H}$ across $\mathcal{S}$.

For notational convenience, we drop primes in what follows and use nondimensional units.

3. Interface conditions for the converted waves. Let

$$\mathbf{u} = \mathbf{u}^{(\mathbf{p})} + \hat{\mathbf{u}} \qquad \mathbf{w} = \mathbf{w}^{(\mathbf{p})} + \hat{\mathbf{w}}, \tag{15}$$

where $\mathbf{u} = \mathbf{u}^{(\mathbf{p})}$ and $\mathbf{w} = \mathbf{w}^{(\mathbf{p})}$ are particular solutions of (7) and (8) that do not necessarily satisfy the interface conditions (14), and $\hat{\mathbf{u}}, \hat{\mathbf{w}}$ are solutions of the homogeneous equations, i.e., (7) and (8) with $\mathbf{E} = \mathbf{0}$.

Particular solutions are easy to find asymptotically by seeking $\mathbf{u} = \mathbf{u}^{(\mathbf{p})}$ and $\mathbf{w} = \mathbf{w}^{(\mathbf{p})}$ that are not rapidly varying in space. From (7) and (8) we obtain

$$\begin{aligned} -i\omega\mathbf{u}^{(\mathbf{p})} &= -\left(\frac{\rho_f}{\rho}\right) L\mathbf{E} + O\left(\frac{1}{\omega^2}\right) + O\left(\frac{1}{|\tilde{\rho}|}\right), \\ -i\omega\mathbf{w}^{(\mathbf{p})} &= L\mathbf{E} + O\left(\frac{1}{|\tilde{\rho}|}\right). \end{aligned} \tag{16}$$

In what follows, we neglect the small terms in this equation. Note, however, that this approximation is only valid in the far field of the source, where the interfaces are assumed to lie. Near the source, gradients of the electric field may be large, invalidating (16). This raises the possibility that some EM energy is converted directly to seismic waves where the EM source contacts the ground, but we will not investigate these near-source seismic waves in the present theory.

The particular solution given by (16) represents a mechanical disturbance that propagates along with the exciting EM wave. In a completely homogeneous space,

this represents the asymptotic solution. However, if there are interfaces, new waves must be generated at those interfaces in order for $\mathbf{u}$ and $\mathbf{w}$ to satisfy the conditions (14). Let $\mathbf{n}$ be a normal to the interface $\mathcal{S}$. Continuity of $\mathbf{u}$ across $\mathcal{S}$ yields the jump condition

$$[|\mathbf{u}|] = \left[\left|\mathbf{u^{(p)}} + \hat{\mathbf{u}}\right|\right] = \mathbf{0}, \tag{17}$$

where $[|\cdot|]$ represents the jump in the value of a quantity across the interface $\mathcal{S}$. That is, let the normal $\mathbf{n}$ point to the side of the interface $\mathcal{S}^+$ and let $\mathcal{S}^-$ be the other side. The jump in any quantity A is

$$[|\ A\ |] \equiv A\ |_{\mathcal{S}^+} - A\ |_{\mathcal{S}^-}\ . \tag{18}$$

From (16) and (17) we obtain the jump condition for $\hat{\mathbf{u}}$

$$[|-i\omega\hat{\mathbf{u}}|] = \left[\left|\left(\frac{\rho_f L}{\rho}\right)\mathbf{E}\right|\right]. \tag{19}$$

Similarly, from continuity of $\mathbf{w}\cdot\mathbf{n}$ across $\mathcal{S}$ and (15), (16), we obtain

$$[|-i\omega\hat{\mathbf{w}}\cdot\mathbf{n}\,|] = -[|\,L\mathbf{E}\cdot\mathbf{n}\,|]. \tag{20}$$

Next, pressure p is decomposed into parts corresponding to the particular and homogeneous solutions

$$p = p^{(p)} + \hat{p}, \tag{21}$$

where $p^{(p)}$ satisfies (6) with $\mathbf{u},\mathbf{w}$ replaced by $\mathbf{u^{(p)}},\mathbf{w^{(p)}}$ and $\hat{p}$ satisfies (6) with $\mathbf{u},\mathbf{w}$ replaced by $\hat{\mathbf{u}},\hat{\mathbf{w}}$. However, in a homogeneous region of space

$$\nabla\cdot\mathbf{u^{(p)}} = \nabla\cdot\mathbf{w^{(p)}} = \mathbf{0}. \tag{22}$$

Equation (22) follows from taking the divergence of (16) and using the fact that the divergence of the electric field vanishes in a source-free region of homogeneous space. From (22) and (6) it follows that $p^{(p)} = 0$ and so $p = \hat{p}$. Continuity of p across $\mathcal{S}$ then yields the condition

$$[|\hat{p}|] = 0. \tag{23}$$

Finally, the stress tensor τ is decomposed into parts corresponding to the particular and homogeneous solutions

$$\tau = \tau^{(\mathbf{p})} + \hat{\tau}, \tag{24}$$

where $\tau^{(\mathbf{p})},\hat{\tau}$ each satisfy (5) for $\mathbf{u},\mathbf{w}$ replaced by, respectively, the particular or homogeneous quantities. Substituting (16) into (5) and using (22) yields

$$\tau^{(\mathbf{p})} = \left(\frac{-iG\rho_f L}{\rho\omega}\right)\left(\nabla\mathbf{E} + \nabla\mathbf{E}^{\mathbf{T}}\right). \tag{25}$$

Now use of (24), (25) in the condition (14) that $\tau\cdot\mathbf{n}$ be continuous across $\mathcal{S}$ yields

$$[|-i\omega\hat{\tau}\cdot\mathbf{n}|] = \left[\left|\left(\frac{G\rho_f L}{\rho}\right)(\nabla\mathbf{E} + \nabla\mathbf{E}^{\mathbf{T}})\cdot\mathbf{n}\right|\right]. \tag{26}$$

In summary, new waves will be generated at an interface $\mathcal{S}$. These waves will satisfy the homogeneous equations (7) and (8) with the electric field set equal to zero. However, they will satisfy the inhomogeneous interface conditions (19), (20), (23), and (26). These jump conditions comprise eight scalar equations, with inhomogeneous terms that depend on the electric field and on the values of the material parameters on both sides of the interface.

For notational convenience, we will drop hats in what follows.

4. WKB expansion. The WKB ansatz [10] for a high frequency wave with phase ϕ is an asymptotic expansion, as $\omega \to \infty$, of the form

$$\begin{aligned} \mathbf{u} &\sim e^{i\omega\phi}\left(\mathbf{u_0} + \frac{1}{i\omega}\mathbf{u_1} + \frac{1}{(i\omega)^2}\mathbf{u_2} + \cdots\right), \\ \mathbf{w} &\sim e^{i\omega\phi}\left(\mathbf{w_0} + \frac{1}{i\omega}\mathbf{w_1} + \frac{1}{(i\omega)^2}\mathbf{w_2} + \cdots\right). \end{aligned} \tag{27}$$

From the form of the interface conditions derived in section 3, it may be anticipated that $-i\omega\mathbf{u}, -i\omega\mathbf{w}$ are of order $O(1)$, i.e., $\mathbf{u_j}, \mathbf{w_j}$ are of order $O(1/\omega)$. This is of no consequence in the expansion (27), since factors of ω may be divided through the homogeneous Biot equations. It will, however, insert an extra factor of $1/\omega$ in the error estimates of sections 5–7.

Substituting (27) into (7) and equating coefficients of $(i\omega)^k$ to zero yields a series of equations. Similarly, substituting (27) into (8) with $\mathbf{E} = \mathbf{0}$ yields a second sequence of equations. The results are summarized below in matrix-vector form, where $\mathcal{L}$ is a 6×6 matrix defined below in terms of its 3×3 blocks. Let

$$\mathcal{L} = \mathcal{L}(\nabla\phi) = \begin{bmatrix} \left(\rho - G(\nabla\phi)^2\right)\mathbf{I} - (\lambda+G)\nabla\phi\nabla\phi^T & \rho_f\mathbf{I} - C\nabla\phi\nabla\phi^T \\ \rho_f\mathbf{I} - C\nabla\phi\nabla\phi^T & \tilde{\rho}\mathbf{I} - M\nabla\phi\nabla\phi^T \end{bmatrix}, \tag{28}$$

$$\begin{aligned} \mathbf{R_1}(\nabla\phi, \mathbf{u}, \mathbf{w}) &= (\lambda+G)\left\{(\nabla\cdot\mathbf{u})\nabla\phi + \nabla(\nabla\phi\cdot\mathbf{u})\right\} \\ &\quad + G\left\{2(\nabla\phi\cdot\nabla)\mathbf{u} + (\nabla^2\phi)\mathbf{u}\right\} + C\left\{(\nabla\cdot\mathbf{w})\nabla\phi + \nabla(\nabla\phi\cdot\mathbf{w})\right\}, \end{aligned} \tag{29}$$

$$\mathbf{R_2}(\nabla\phi, \mathbf{u}, \mathbf{w}) = C\left\{(\nabla\cdot\mathbf{u})\nabla\phi + \nabla(\nabla\phi\cdot\mathbf{u})\right\} + M\left\{(\nabla\cdot\mathbf{w})\nabla\phi + \nabla(\nabla\phi\cdot\mathbf{w})\right\}. \tag{30}$$

Then we obtain

$$\mathcal{L}\begin{bmatrix} \mathbf{u_0} \\ \mathbf{w_0} \end{bmatrix} = \mathbf{0}, \tag{31}$$

$$\mathcal{L}\begin{bmatrix} \mathbf{u_1} \\ \mathbf{w_1} \end{bmatrix} = \begin{bmatrix} \mathbf{R_1}(\nabla\phi, \mathbf{u_0}, \mathbf{w_0}) \\ \mathbf{R_2}(\nabla\phi, \mathbf{u_0}, \mathbf{w_0}) \end{bmatrix}, \tag{32}$$

and for $j = 2, 3, 4, \ldots,$

$$\begin{aligned} \mathcal{L}\begin{bmatrix} \mathbf{u_j} \\ \mathbf{w_j} \end{bmatrix} &= \begin{bmatrix} \mathbf{R_1}(\nabla\phi, \mathbf{u_{j-1}}, \mathbf{w_{j-1}}) \\ \mathbf{R_2}(\nabla\phi, \mathbf{u_{j-1}}, \mathbf{w_{j-1}}) \end{bmatrix} \\ &\quad + \begin{bmatrix} (\lambda+G)\nabla(\nabla\cdot\mathbf{u_{j-2}}) + G\nabla^2\mathbf{u_{j-2}} + C\nabla(\nabla\cdot\mathbf{w_{j-2}}) \\ C\nabla(\nabla\cdot\mathbf{u_{j-2}}) + M\nabla(\nabla\cdot\mathbf{w_{j-2}}) \end{bmatrix}. \end{aligned} \tag{33}$$

From (31), $\mathcal{L}$ has a nontrivial null space, which contains the vector $[\mathbf{u_0}, \mathbf{w_0}]^{\mathbf{T}}$. Because $\mathcal{L}$ is complex symmetric, the complex conjugate $[\mathbf{u_0^*}, \mathbf{w_0^*}]^{\mathbf{T}}$ is in the null space of the adjoint of $\mathcal{L}$. The Fredholm alternative then implies that $[\mathbf{u_0^*}, \mathbf{w_0^*}]^{\mathbf{T}}$ is orthogonal to the right-hand side of (32), i.e.,

$$\mathbf{u_0} \cdot \mathbf{R_1}(\nabla\phi, \mathbf{u_0}, \mathbf{w_0}) + \mathbf{w_0} \cdot \mathbf{R_2}(\nabla\phi, \mathbf{u_0}, \mathbf{w_0}) = 0. \tag{34}$$

Similarly, $[\mathbf{u_0^*}, \mathbf{w_0^*}]^{\mathbf{T}}$ is orthogonal to the right-hand side of (33) for all $j = 2, 3, 4, \ldots$.

Equation (31) reduces to the Biot theory dispersion relations if $\nabla\phi$ is identified as the slowness vector. This is because a sinusoidal wave is a special case of the form (27), when ϕ is linear in $\mathbf{x}$. Of course, wave fields that are much more complicated than sinusoidal can be constructed from the general WKB expansion given here. However, analogous to the classification of wave modes, we can classify three distinct types of waves, which, for large $|\tilde{\rho}|$, correspond to seismic S-waves, seismic P-waves, and the Biot slow wave. This is done in the next three sections.

5. S-waves. First consider transverse waves $\mathbf{u_0} = \mathbf{u_S}, \mathbf{w_0} = \mathbf{w_S}$, $\phi = \phi_S$, satisfying

$$\mathbf{u_S} \cdot \nabla\phi_S = \mathbf{w_S} \cdot \nabla\phi_S = \mathbf{0}. \tag{35}$$

Substitution of (35) into (31) gives

$$\left(\rho - G(\nabla\phi_S)^2\right) \mathbf{u_S} + \rho_f \mathbf{w_S} = \mathbf{0}, \tag{36}$$

$$\rho_f \mathbf{u_S} + \tilde{\rho} \mathbf{w_S} = \mathbf{0}. \tag{37}$$

From (36) and (37) we get the dispersion relation for transverse waves

$$\rho - G(\nabla\phi_S)^2 = \rho_f^2/\tilde{\rho}, \tag{38}$$

which for $|\tilde{\rho}|$ large can be written as

$$(\nabla\phi_S)^2 = \frac{1}{V_S^2} + O\left(\frac{1}{|\tilde{\rho}|}\right), \tag{39}$$

where

$$V_S = \sqrt{\frac{G}{\rho}} \tag{40}$$

is the elastic shear wave (seismic S-wave) speed. The eikonal equation [5, 10], (39) with the small terms neglected, identifies the phase as approximately that of an S-wave. The S-wave ray system is derived as the subcharacteristic curves of this equation, which in a homogeneous medium are straight lines in the directions of $\nabla\phi_S$.

From (39), corrections to ϕ_S are of order $O(1/|\tilde{\rho}|)$. Because of the exponential factor in (27) these terms are negligible only if $\omega/|\tilde{\rho}| << 1$. Thus, this condition is necessary for elasticity theory without significant modification, e.g., with attenuation, to be valid.

From (37)

$$\mathbf{w_S} = -\frac{\rho_f}{\tilde{\rho}} \mathbf{u_S}. \tag{41}$$

From (41) note that for an S-wave, the fluid displacement relative to the solid is small, of order $O(1/|\tilde{\rho}|)$. Thus the fluid motion does not depart substantially from the solid motion, as would be expected if the porous medium is to approximate an elastic solid.

To get a transport equation for the S-wave amplitudes, assume that $\mathbf{w_S}$ is small compared to $\mathbf{u_S}$, so that the second term in (34) may be neglected. Then simplifying, using that $\mathbf{u_S}$ is orthogonal to $\nabla\phi_S$ and $\mathbf{w_S}$ is small yields

$$\mathbf{u_S}\cdot\mathbf{R_1} = G\mathbf{u_S}\cdot\left\{2(\nabla\phi_S\cdot\nabla)\mathbf{u_S} + (\nabla\phi_S)^2\mathbf{u_S}\right\} = 0. \tag{42}$$

This equation reduces to the usual transport equation in which energy is conserved in a ray tube [10]:

$$\nabla\cdot\left((\mathbf{u_S})^2\nabla\phi_S\right) = 0. \tag{43}$$

To determine the direction of $\mathbf{u_S}$, note that $\mathbf{u_0'} = \nabla\phi_S\times\mathbf{u_S}, \mathbf{w_0'} = -(\rho_f/\tilde{\rho})\mathbf{u_0'}$ is also a solution of (31). That is, $[\nabla\phi_S\times\mathbf{u_S}, -(\rho_f/\tilde{\rho})\nabla\phi_S\times\mathbf{u_S}]^T$ is in the null space of $\mathcal{L}$, and so the complex conjugate of this vector is in the null space of the adjoint of $\mathcal{L}$. Therefore, the Fredholm alternative implies that $[(\nabla\phi_S\times\mathbf{u_S})^*, (-(\rho_f/\tilde{\rho})\nabla\phi_S\times\mathbf{u_S})^*]^T$ is orthogonal to $[\mathbf{R_1}(\nabla\phi_S, \mathbf{u_S}, \mathbf{w_S}), \mathbf{R_2}(\nabla\phi_S, \mathbf{u_S}, \mathbf{w_S})]^T$. To leading order,

$$(\nabla\phi_S\times\mathbf{u_S})\cdot\{(\nabla\phi_S\cdot\nabla)\mathbf{u_S}\} = 0. \tag{44}$$

Thus changes in $\mathbf{u_S}$ in the direction of $\nabla\phi_S$ remain in the plane determined by $\nabla\phi_S$ and $\mathbf{u_S}$. Since, in a homogeneous medium, the rays are straight lines in the direction of $\nabla\phi_\mathbf{S}$, the direction of $\mathbf{u_S}$ remains constant along a ray.

To summarize, we will use the following approximation for S-waves when $-i\omega\mathbf{u_S}$ is of order $O(1)$:

$$\begin{aligned}\mathbf{u} &= e^{i\omega\phi_S}\left[\mathbf{u_S} + O\left(\frac{1}{\omega|\tilde{\rho}|}\right) + O\left(\frac{1}{\omega^2}\right)\right],\\ \mathbf{w} &= e^{i\omega\phi_S}\left[-\frac{\rho_f}{\tilde{\rho}}\mathbf{u_S} + O\left(\frac{1}{\omega|\tilde{\rho}|^2}\right) + O\left(\frac{1}{\omega^2}\right)\right].\end{aligned} \tag{45}$$

Here $\mathbf{u_S}$, with $\mathbf{u_S}\cdot\nabla\phi_S = 0$, is determined by (43) and (44), and ϕ_S is determined, with error of order $O(1/|\tilde{\rho}|)$, by (39).

6. P-waves. Next, consider longitudinal waves

$$\mathbf{u_0} = u_L\nabla\phi, \quad \mathbf{w_0} = w_L\nabla\phi\,, \tag{46}$$

where u_L, w_L are scalars. Putting (46) into (31) gives

$$\left(\rho - (\lambda+2G)(\nabla\phi)^2\right)u_L + \left(\rho_f - C(\nabla\phi)^2\right)w_L = 0, \tag{47}$$

$$\left(\rho_f - C(\nabla\phi)^2\right)u_L + \left(\tilde{\rho} - M(\nabla\phi)^2\right)w_L = 0. \tag{48}$$

From (47) and (48) we obtain the longitudinal dispersion relation

$$\left(\rho_f - C(\nabla\phi)^2\right)^2 = \left(\tilde{\rho} - M(\nabla\phi)^2\right)\left(\rho - (\lambda+2G)(\nabla\phi)^2\right). \tag{49}$$

There are two roots of the quadratic equation (49) for $(\nabla\phi)^2$. One root ϕ_P is obtained asymptotically by a power series expansion in $(\tilde{\rho})^{-1}$:

$$(\nabla\phi_P)^2 = \frac{1}{V_P^2} + O\left(\frac{1}{|\tilde{\rho}|}\right), \tag{50}$$

where

$$V_P = \sqrt{\frac{(\lambda + 2G)}{\rho}} \tag{51}$$

is the elastic compressional wave (seismic P-wave) speed. Neglecting the small terms in the eikonal equation (50) identifies these waves as, approximately, seismic P-waves. For this root, the solution is written as

$$\mathbf{u_0} = u_P V_P \nabla\phi_P, \quad \mathbf{w_0} = w_P V_P \nabla\phi_P. \tag{52}$$

The constant factor V_P is inserted in (52) because $V_p\nabla\phi_P$ is a unit vector.

The ray system for P-waves are the subcharacteristic curves of equation (50), i.e., straight lines in the direction of $\nabla\phi_P$.

As for S-waves, the condition $\omega/|\tilde{\rho}| << 1$ must be assumed for accuracy of $\exp\{i\omega\phi_P\}$, when terms of order $O(1/|\tilde{\rho}|)$ are dropped in determining ϕ_P. Also, as for S-waves, the fluid motion does not depart substantially from that of the solid. This can be seen by combining (48), (52), and (50) to get

$$w_P \sim \frac{1}{\tilde{\rho}}\left(\frac{C}{V_P^2} - \rho_f\right) u_P. \tag{53}$$

To derive the transport equation, let w_P be small compared to u_P, and substitute into (34). Then use of (50) yields again the transport equation for energy conservation in a ray tube:

$$\nabla \cdot (u_P^2 \nabla\phi_P) = 0. \tag{54}$$

To summarize, we will use the following approximation for P-waves when $-i\omega u_P$ is of order $O(1)$:

$$\begin{aligned} \mathbf{u} &= e^{i\omega\phi_P}\left[u_P \frac{\nabla\phi_P}{|\nabla\phi_P|} + O\left(\frac{1}{\omega|\tilde{\rho}|}\right) + O\left(\frac{1}{\omega^2}\right)\right], \\ \mathbf{w} &= e^{i\omega\phi_P}\left[\frac{1}{\tilde{\rho}}\left(\frac{C}{V_P^2} - \rho_f\right) u_P \frac{\nabla\phi_P}{|\nabla\phi_P|} + O\left(\frac{1}{\omega|\tilde{\rho}|^2}\right) + O\left(\frac{1}{\omega^2}\right)\right]. \end{aligned} \tag{55}$$

Here u_P is determined by (54) and ϕ_P is determined, with error of order $O(1/|\tilde{\rho}|)$, by (50).

7. Biot slow waves. To obtain asymptotically the second root of (49) let $\phi = \phi_B$ be written as

$$\phi_B = \sqrt{\tilde{\rho}}\,\bar{\phi}_B, \tag{56}$$

where the square root is in the first quadrant. Then asymptotically

$$(\nabla\bar{\phi}_B)^2 = \frac{1}{\tilde{M}^2} + O\left(\frac{1}{|\tilde{\rho}|}\right), \tag{57}$$

where

$$\tilde{M} = \sqrt{M - \frac{C^2}{(\lambda + 2G)}} \tag{58}$$

is real. The eikonal equation (57), with (56), identifies this wave as the Biot slow wave, which is slow because its speed, $V_B = Re\{\tilde{M}/\sqrt{\tilde{\rho}}\}$, is small. It is a diffusive wave, which decays rapidly as it propagates away from where it originates. This is because the exponential factor in the WKB. expansion is

$$e^{i\omega\phi_B} = e^{\frac{(-1+i)}{\sqrt{2}}\omega\sqrt{|\tilde{\rho}|}\bar{\phi}_B}, \tag{59}$$

which is transcendentally small unless $|\omega\sqrt{|\tilde{\rho}|}\bar{\phi}_B|$ is $O(1)$.

If $\bar{\phi}_B$ is determined from (57) with the error terms dropped, then $\bar{\phi}_B$ is accurate up to an error of order $O(1/|\tilde{\rho}|)$. In this case corrections to the argument of the exponential in (59) have an error of $O(\omega/\sqrt{|\tilde{\rho}|})$, and so higher order terms in $\tilde{\rho}^{-1}$ might be significant depending on the size of this ratio. Nevertheless, in what follows, we will not need to consider corrections to $\bar{\phi}_B$, because the leading order term is sufficient to determine when the slow wave is transcendentally small such that it need not be calculated at all; and because we will use the exponential only where $\bar{\phi}_B \equiv 0$ to all orders in $\tilde{\rho}$.

For the phase $\bar{\phi}_B$ the solution is written as

$$\mathbf{u_0} = u_B\tilde{M}\nabla\bar{\phi}_B, \quad \mathbf{w_0} = w_B\tilde{M}\nabla\bar{\phi}_B. \tag{60}$$

The constant factor $\tilde{M}$ is inserted in (60) because $\tilde{M}\nabla\bar{\phi}_B$ is a unit vector.

From (47), (57), and (58) we obtain that, dropping terms of order $O\,(1/|\tilde{\rho}|)$,

$$w_B \sim -\frac{(\lambda+2G)}{C}u_B. \tag{61}$$

Note that w_B is not small compared to u_B unlike the corresponding expressions for P- and S-waves. This is consistent with the fact that these waves have no analogue in elasticity theory. Thus differences from elasticity theory can occur, but only locally near where a Biot slow wave originates. We will show in the next section that at interfaces excited by an EM wave, Biot slow waves can play an important role in determining other wave amplitudes, even though the slow waves themselves are undetectably small away from the interfaces.

To obtain the transport equation for the slow wave amplitudes, substitute (60) (61) into (34) and use (56) and (57). After simplification, the result is again conservation of energy in a ray tube:

$$\nabla\cdot(u_B^2\nabla\bar{\phi}_B) = 0. \tag{62}$$

The above equations determine the amplitudes u_B and w_B to an error of order $O(1/|\tilde{\rho}|)$.

In the next section, we will need to differentiate $\mathbf{u}$ and $\mathbf{w}$ in order to calculate the pressure and stress tensor from (6) and (5). A subtlety then arises in the case of the Biot slow wave, since differentiation of the exponential in (59) brings down a large factor of $\sqrt{\tilde{\rho}}$. In this case the higher order terms such as $\mathbf{u_1}, \mathbf{w_1}$ appear to be significant if $\sqrt{|\tilde{\rho}|}/\omega$ is not small. To obtain the form of these higher order terms in ω, but to leading order in $|\tilde{\rho}|$, substitute (56) into (31)–(33) and write the result in matrix form. Let

$$\mathcal{L}^{(0)} = \mathcal{L}^{(0)}(\nabla\bar{\phi}_B) = \begin{bmatrix} -G(\bar{\phi}_B)^2\mathbf{I} - (\lambda+G)\nabla\bar{\phi}_B\nabla\bar{\phi}_B^T & -C\nabla\bar{\phi}_B\nabla\bar{\phi}_B^T \\ -C\nabla\bar{\phi}_B\nabla\bar{\phi}_B^T & \mathbf{I} - M\bar{\phi}_B\nabla\bar{\phi}_B^T \end{bmatrix}. \tag{63}$$

Then the equations can be written as

$$\mathcal{L}^{(0)} \begin{bmatrix} \mathbf{u_0} \\ \mathbf{w_0} \end{bmatrix} = O\left(\frac{1}{|\tilde{\rho}|}\right), \tag{64}$$

and for $j = 1, 2, \ldots,$

$$\mathcal{L}^{(0)} \begin{bmatrix} \mathbf{u_j} \\ \mathbf{w_j} \end{bmatrix} = \frac{1}{\sqrt{\tilde{\rho}}} \begin{bmatrix} \mathbf{R_1}(\nabla\bar{\phi}_B, \mathbf{u_{j-1}}, \mathbf{w_{j-1}}) \\ \mathbf{R_2}(\nabla\bar{\phi}_B, \mathbf{u_{j-1}}, \mathbf{w_{j-1}}) \end{bmatrix} + O\left(\frac{1}{|\tilde{\rho}|}\right). \tag{65}$$

The solution of (64) and (65) may be expanded as a power series in $(\tilde{\rho})^{-1/2}$:

$$\begin{aligned} \mathbf{u_j} &= \sum_{m=0}^{\infty} (\tilde{\rho})^{(-m/2)} \mathbf{u_{j,m}}, \\ \mathbf{w_j} &= \sum_{m=0}^{\infty} (\tilde{\rho})^{(-m/2)} \mathbf{w_{j,m}}. \end{aligned} \tag{66}$$

Letting $|\tilde{\rho}| \to \infty$, the leading order terms, $\mathbf{u_{j,0}}, \mathbf{w_{j,0}}$, satisfy, for $j = 0, 1, 2, \ldots,$

$$\mathcal{L}^{(0)} \begin{bmatrix} \mathbf{u_{j,0}} \\ \mathbf{w_{j,0}} \end{bmatrix} = \mathbf{0}. \tag{67}$$

Consideration of the null space of $\mathcal{L}^{(0)}$ shows that for $j = 0, 1, 2, \ldots$

$$\mathbf{u_{j,0}} = u_{B,j}\tilde{M}\nabla\bar{\phi}_B, \quad \mathbf{w_{j,0}} = w_{B,j}\tilde{M}\nabla\bar{\phi}_B, \tag{68}$$

where

$$w_{B,j} = -\frac{(\lambda + 2G)}{C} u_{B,j}. \tag{69}$$

Finally, the Fredholm condition for the jth term is that the vector $[\nabla\bar{\phi}_B, -C^{-1}(\lambda+2G)\nabla\bar{\phi}_B]^{*T}$ is orthogonal to $[\mathbf{R_1}(\nabla\bar{\phi}_B, \mathbf{u_{j,0}}, \mathbf{w_{j,0}}), \mathbf{R_2}(\nabla\bar{\phi}_B, \mathbf{u_{j,0}}, \mathbf{w_{j,0}})]$. As in the case of $j = 0$, which was first done separately above, we derive the expression for energy conservation in a ray tube:

$$\nabla \cdot (u_{B,j}^2 \nabla\bar{\phi}_B) = 0. \tag{70}$$

Therefore the same relations (68), (69), and (70) govern the slow wave amplitudes to leading order in $\tilde{\rho}^{-1/2}$ to all orders $j = 0, 1, 2, \ldots$ in $(i\omega)^{-j}$. These are the same relations (60), (61), and (62) that were first derived for $j = 0$. However, corrections to $\bar{\phi}_B$ and to the $j = 0$ amplitude terms are of order $O(1/|\tilde{\rho}|)$, while corrections to the amplitudes for $j \geq 1$ are larger, of order $O(1/\sqrt{|\tilde{\rho}|})$.

To summarize, we will use the following approximation for Biot slow waves when $-i\omega u_B$ and $-i\omega u_{B,j}$ are of order $O(1)$:

(71)

$$\mathbf{u} \sim e^{i\omega\sqrt{\bar\rho}\bar\phi_B}\left[u_B\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega|\tilde\rho|}\right)+\sum_{j=1}^{\infty}\left(\frac{u_{B,j}}{(i\omega)^j}\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega^{j+1}\sqrt{|\tilde\rho|}}\right)\right)\right],$$

$$\mathbf{w} \sim -\frac{(\lambda+2G)}{C}e^{i\omega\sqrt{\bar\rho}\bar\phi_B}\left[u_B\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega|\tilde\rho|}\right)\right.$$
$$\left.+\sum_{j=1}^{\infty}\left(\frac{u_{B,j}}{(i\omega)^j}\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega^{j+1}\sqrt{|\tilde\rho|}}\right)\right)\right].$$

Here $u_B, u_{B,j}$ are determined by (62) and (70), and $\tilde{\phi_B}$ is determined, with error of order $O(1/|\tilde\rho|)$, by (57).

8. Initial amplitudes of the seismic waves. Combining (45), (55), and (71), a wavefield with the three types of waves is written as

(72)

$$\mathbf{u} \sim e^{i\omega\phi_S}\left[u_{S1}\mathbf{e_1}+u_{S2}\mathbf{e_2}+O\left(\frac{1}{\omega|\tilde\rho|}\right)+O\left(\frac{1}{\omega^2}\right)\right]$$
$$+\ e^{i\omega\phi_P}\left[u_P\frac{\nabla\phi_P}{|\nabla\phi_P|}+O\left(\frac{1}{\omega|\tilde\rho|}\right)+O\left(\frac{1}{\omega^2}\right)\right]$$
$$+\ e^{i\omega\sqrt{\bar\rho}\bar\phi_B}\left[u_B\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega|\tilde\rho|}\right)+\sum_{j=1}^{\infty}\left(\frac{u_{B,j}}{(i\omega)^j}\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega^{j+1}\sqrt{|\tilde\rho|}}\right)\right)\right],$$

$$\mathbf{w} \sim e^{i\omega\phi_S}\left[-\frac{\rho_f}{\tilde\rho}(u_{S1}\mathbf{e_1}+u_{S2}\mathbf{e_2})+O\left(\frac{1}{\omega|\tilde\rho|^2}\right)+O\left(\frac{1}{\omega^2}\right)\right]$$
$$+\ e^{i\omega\phi_P}\left[\frac{1}{\tilde\rho}\left(\frac{C}{V_P^2}-\rho_f\right)u_P\frac{\nabla\phi_P}{|\nabla\phi_P|}+O\left(\frac{1}{\omega|\tilde\rho|^2}\right)+O\left(\frac{1}{\omega^2}\right)\right]\quad-\frac{(\lambda+2G)}{C}$$
$$\times\, e^{i\omega\sqrt{\bar\rho}\bar\phi_B}\left[u_B\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega|\tilde\rho|}\right)+\sum_{j=1}^{\infty}\left(\frac{u_{B,j}}{(i\omega)^j}\frac{\nabla\bar\phi_B}{|\nabla\bar\phi_B|}+O\left(\frac{1}{\omega^{j+1}\sqrt{|\tilde\rho|}}\right)\right)\right].$$

Here $\mathbf{e_1}$, $\mathbf{e_2}$ are orthogonal unit vectors, orthogonal to $\nabla\phi_S$, and u_{S1}, u_{S2}, u_P, u_B, $u_{B,j}$ are scalar wave amplitudes. As noted previously, each of these amplitudes is anticipated to be of order $O(1/\omega)$, because of the form of interface conditions (19), (20), (23), and (26).

In the expression for $\mathbf{w}$ in equation (72) the small terms of order $O(1/|\tilde\rho|)$ will dominate the exponentially small slow wave term, except when the slow wave phase $\bar\phi_B$ is near zero. However, as shown below, $\bar\phi_B = 0$ at an interface where waves originate, and it is then the slow wave term that dominates the expression for $\mathbf{w}$.

Consider an interface $\mathcal{S}$ separating two homogeneous media, and at each point of $\mathcal{S}$ let $\mathbf{n}$ be a unit normal pointing into the side $\mathcal{S}^+$, i.e., away from $\mathcal{S}^-$. We will show that the interface conditions of section 3 can be satisfied by introducing two waves, $\mathbf{u}^\pm, \mathbf{w}^\pm$, each of the form of (72), originating at $\mathcal{S}^\pm$ and subsequently propagating up and down into the two homogeneous media separated by $\mathcal{S}$.

First note that none of the interface conditions from section 3 have rapid spatial oscillations. Therefore all the phases must vanish on $\mathcal{S}$:

$$\phi_S^\pm = \phi_P^\pm = \bar{\phi}_B^\pm = 0 \quad \text{on}\, \mathcal{S}. \tag{73}$$

From (73), every interface is a wavefront for every type of wave. In particular, $\nabla\phi_S^\pm, \nabla\phi_P^\pm, \nabla\bar{\phi}_B^\pm$ are all orthogonal to $\mathcal{S}$. Since rays propagate in the direction of the phase gradients, it is apparent that all P-, S-, and Biot slow wave rays leave $\mathcal{S}$ in the orthogonal direction. That is, the rays for $\mathbf{u}^+, \mathbf{w}^+$ originating at $\mathcal{S}^+$ are in the direction $\mathbf{n}$, while those for $\mathbf{u}^-, \mathbf{w}^-$ originating at $\mathcal{S}^-$ are in the direction $-\mathbf{n}$. These observations are sufficient for determination of the phases to leading order in $\tilde{\rho}$, via conventional ray tracing.

Similarly, the transport (43), (54), and (62) are sufficient to determine the eight wave amplitudes, provided that their initial values $u_{S1}^\pm$, $u_{S2}^\pm$, $u_P^\pm$, $u_B^\pm$ are known on $\mathcal{S}^\pm$. We next determine those initial values by using the eight scalar interface conditions derived in section 3.

First, we obtain from (72) and (73) that to leading order

$$\mathbf{u}^\pm \sim u_{S1}^\pm \mathbf{e_1} + u_{S2}^\pm \mathbf{e_2} \pm u_P^\pm \mathbf{n} \pm u_B^\pm \mathbf{n} \quad \text{on}\, \mathcal{S}^\pm, \tag{74}$$

$$\mathbf{w}^\pm \cdot \mathbf{n} \sim \mp \frac{(\lambda^\pm + 2G^\pm)}{C^\pm} u_B^\pm \quad \text{on}\, \mathcal{S}^\pm, \tag{75}$$

since the slow wave dominates the expression for $\mathbf{w}$ on $\mathcal{S}$. In these equations λ^+ denotes the value of this parameter on $\mathcal{S}^+$, λ^- denotes the value of this parameter on $\mathcal{S}^-$, with a similar notation for the other parameters.

Next, differentiation of (72) yields

$$\nabla \cdot \mathbf{u}^\pm = \sqrt{\tilde{\rho}^\pm} \frac{(i\omega u_B^\pm)}{\tilde{M}^\pm} + \frac{\sqrt{\tilde{\rho}^\pm}}{\tilde{M}^\pm} \sum_{j=1}^{\infty} \frac{(i\omega u_{B,j}^\pm)}{(i\omega)^j} + \frac{(i\omega u_P^\pm)}{V_P} + o(1) \quad \text{on}\, \mathcal{S}^\pm,$$

$$\nabla \cdot \mathbf{w}^\pm = -\frac{\sqrt{\tilde{\rho}^\pm}}{\tilde{M}^\pm} \frac{(\lambda^\pm + 2G^\pm)}{C^\pm} \left[(i\omega u_B^\pm) + \sum_{j=1}^{\infty} \frac{(i\omega u_{B,j}^\pm)}{(i\omega)^j} \right] + o(1) \quad \text{on}\, \mathcal{S}^\pm. \tag{76}$$

Inserting (76) into (6) and use of (57) yields that to leading order

$$p^\pm \sim \sqrt{\tilde{\rho}^\pm} \tilde{M}^\pm \frac{(\lambda^\pm + 2G^\pm)}{C^\pm} (i\omega u_B^\pm) \quad \text{on}\, \mathcal{S}^\pm. \tag{77}$$

From (77) the Biot slow wave determines the fluid pressure on the boundary.

We next compute the normal stress on the interface. To do this, compute from (72),

(78)

$$\left(\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathbf{T}}\right)^{\pm}=\pm\frac{(i\omega u_{S1}^{\pm})}{V_S^{\pm}}\left(\mathbf{e_1n^T}+\mathbf{ne_1^T}\right)\pm\frac{(i\omega u_{S2}^{\pm})}{V_S^{\pm}}\left(\mathbf{e_2n^T}+\mathbf{ne_2^T}\right)$$
$$+2\frac{(i\omega u_P^{\pm})}{V_P^{\pm}}\mathbf{nn^T}\quad+\quad2\frac{\sqrt{\tilde{\rho}^{\pm}}}{\tilde{M}^{\pm}}\left((i\omega u_B^{\pm})+\sum_{j=1}^{\infty}\frac{\left(i\omega u_{B,j}^{\pm}\right)}{(i\omega)^j}\right)\mathbf{nn^T}+o(1).$$

Again, the Biot slow wave term dominates this expression, because of the factor of $\sqrt{\tilde{\rho}^{\pm}}$. However, on substitution of (76) and (78) into (5) and taking the dot product with $\mathbf{n}$ it is found that the slow wave contributions cancel out to all orders in ω in the expression for the normal stress. Because of this remarkable cancellation, it is not necessary to make assumptions about the size of the ratio of large parameters $\sqrt{|\tilde{\rho}|}/\omega^j$. The final expression for the normal stress is

$$\tau^{\pm}\cdot\mathbf{n}=\frac{(\lambda^{\pm}+2G^{\pm})}{V_P^{\pm}}(i\omega u_P^{\pm})\mathbf{n}\pm\frac{G^{\pm}}{V_S^{\pm}}(i\omega u_{S1}^{\pm})\mathbf{e_1}\pm\frac{G^{\pm}}{V_S^{\pm}}(i\omega u_{S2}^{\pm})\mathbf{e_2}+o(1). \tag{79}$$

Now substitution of (74) into (19), (75) into (20), (77) into (23), and (79) into (26) yields eight scalar equations for the eight amplitudes $u_{S1}^{\pm},u_{S2}^{\pm},u_P^{\pm},u_B^{\pm}$. After some algebra, and discarding higher order terms in $(i\omega)^{-1}$ the following formulas are obtained. Let

$$\gamma_1=\frac{\sqrt{\tilde{\rho}^{+}}\tilde{M}^{+}(\lambda^{+}+2G^{+})C^{-}}{\sqrt{\tilde{\rho}^{-}}\tilde{M}^{-}(\lambda^{-}+2G^{-})C^{+}}, \tag{80}$$

$$\gamma_2=\left[1+\frac{(\lambda^{+}+2G^{+})V_P^{-}}{(\lambda^{-}+2G^{-})V_P^{+}}\right]^{-1}, \tag{81}$$

$$\gamma_3=\left[1+\frac{V_S^{-}G^{+}}{V_S^{+}G^{-}}\right]^{-1}. \tag{82}$$

Then

$$-i\omega u_B^{+}=\left[\frac{(\lambda^{+}+2G^{+})}{C^{+}}+\frac{(\lambda^{-}+2G^{-})}{C^{-}}\gamma_1\right]^{-1}[\,|\,L\mathbf{E}\cdot\mathbf{n}\,|\,], \tag{83}$$

$$-i\omega u_P^{+}=\gamma_2\left[\left|\left(\frac{\rho_f}{\rho}\right)L\mathbf{E}\cdot\mathbf{n}\right|\right]-\gamma_2(1+\gamma_1)(-i\omega u_B^{+}), \tag{84}$$

$$-i\omega u_{Sj}^{+}=\gamma_3\left[\left|\left(\frac{\rho_f}{\rho}\right)L\mathbf{E}\cdot\mathbf{e_j}\right|\right]\quad\text{for}\quad j=1,2. \tag{85}$$

The corresponding formulas for $u_B^{-},u_P^{-},u_{Sj}^{-}$ may be obtained from those above by replacing $\mathbf{n}$ by $-\mathbf{n}$, and reversing the roles of + and –. Alternatively, the following

formulas may be used:

$$
\begin{aligned}
u_B^- &= \gamma_1 u_B^+, \\
u_P^- &= \frac{V_P^-}{V_P^+}\frac{(\lambda^+ + 2G^+)}{(\lambda^- + 2G^-)} u_P^+, \\
u_{Sj}^- &= -\frac{V_S^-}{V_S^+}\frac{G^+}{G^-} u_{Sj}^+ \quad \text{for} \quad j = 1, 2.
\end{aligned}
\tag{86}
$$

9. Comparison with an exact solution. To assess the accuracy of the asymptotic solution, we compared it to the results of a computer program designed to solve electroseismic problems in piecewise homogeneous media that are plane layered. For such media, where the material properties vary only with the depth dimension, special methods exist which are based on two-dimensional Fourier transformation of the lateral spatial dimensions. Consequently, plane layered media are the only class of piecewise homogeneous problems in electroseismic prospecting for which solutions that are exact, to within roundoff error and the numerical accuracy of the Fourier transforms, can be computed. One example of such a computer code for layered media is described in [8]. Details of the computer code used here will be described in a separate publication.

For simplicity, we ignored the earth-air boundary, considering a medium consisting of just two homogeneous half spaces joined at an interface at depth D. The source is a single, positive 1 amp point electrode at the origin $x = y = z = 0$, with the corresponding negative electrode at ∞. For comparison, conversions at the EM source were removed. For a negative electrode at a finite location on the surface $z = 0$, the solution computed here is translated spatially to the location of the electrode and the sign reversed. If both electrodes are at finite locations, i.e., the source is a bipole, then the solutions for the two electrodes are summed. Finally, from linearity of the equations, the results can be scaled for any current.

We computed a number of cases that fell well within the regime for which seismic ray tracing is valid. Figures 1 and 2 show the predicted geophone response, that is, the vertical velocity of the solid caused by seismic waves converted from EM at the interface, for one of these cases. Plotted are the amplitude vs. offset and phase vs. offset for geophones located on the surface $z = 0$ at a distance from the source corresponding to the offset coordinate. Note that the phase plotted here is just the phase of the complex number representing the geophone response at a point, not one of the WKB phases, as defined in previous sections. For many of the parameter values we investigated there were no discernible differences between the asymptotic solution and that of the layer code when the results were displayed graphically. However, for the example plotted in Figures 1 and 2 the amplitude vs. offset and phase vs. offset plots do show some small differences near zero offset. Still, the comparison is excellent, as would be expected if we were testing the accuracy of ray tracing for this example.

The parameter values used for Figures 1 and 2 were as follows: $D = 1000$ m; frequency is 30 Hz; $\sigma = 0.1\,(\text{ohm-m})^{-1}$ in the upper layer and $\sigma = 0.001\ (\text{ohm-m})^{-1}$ in the lower layer; $\epsilon = 0$ throughout, i.e., displacement currents have been neglected, as is common in geoelectric prospecting [20]; $\mu = 4\pi \times 10^{-7}\,\text{H/m}$ throughout, i.e., the magnetic permeability of free space; $\eta = 1.0 \times 10^{-3}\,\text{Pa-sec}$ in both layers; $\kappa = 1.0 \times 10^{-16}\,\text{m}^2$ in the upper layer and $\kappa = 1.0 \times 10^{-13}\,\text{m}^2$ in the lower layer; $L = 1.0 \times 10^{-9}\,\text{m}^2/\text{V-sec}$ in both layers.

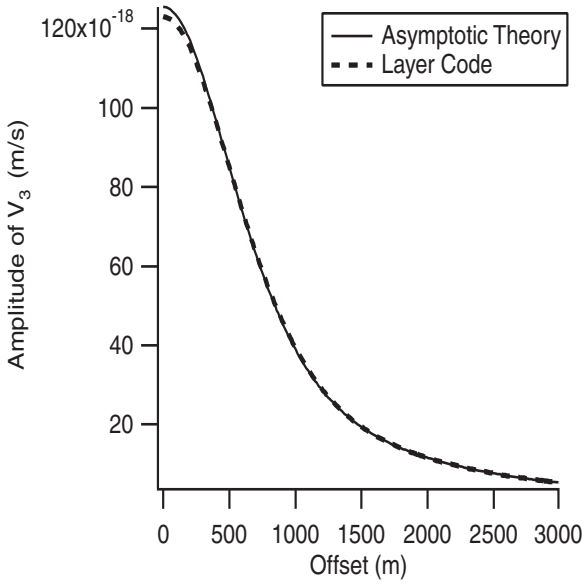

FIG. 1. *Vertical velocity, amplitude vs. offset.*

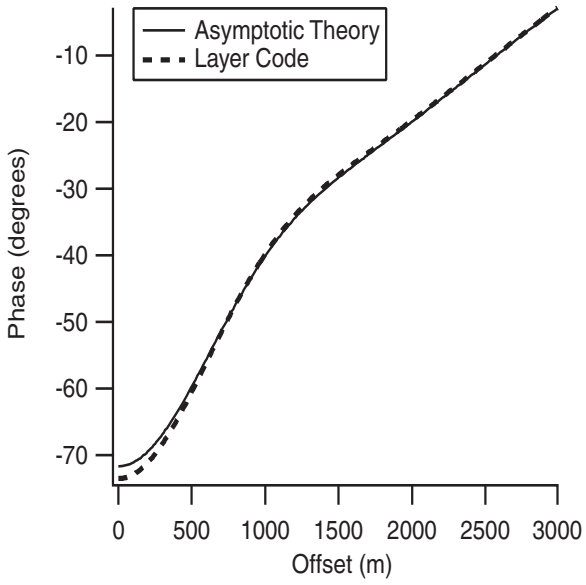

FIG. 2. *Vertical velocity, phase vs. offset.*

For both layers the solid density was taken as $\rho_s = 2650\,\mathrm{kg/m^2}$ and the porosity as 0.3. The fluid density was taken as $\rho_f = 980\,\mathrm{kg/m^2}$ in the upper layer and $\rho_f = 784\,\mathrm{kg/m^2}$. The density in each layer was then calculated as the porosity weighted average of the fluid and solid densities.

The Biot theory parameters were calculated using the theory of Pride, Gangi, and Morgan [15] and reasonable numbers for the variables. Values were $V_P = 1800\,\mathrm{m/sec}$

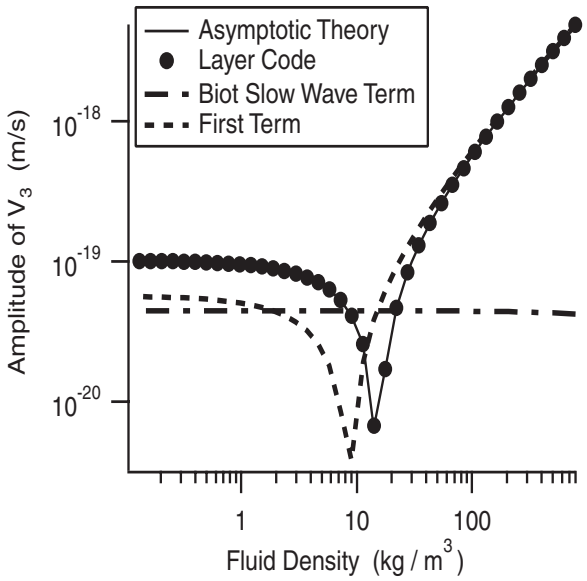

FIG. 3. *Vertical velocity at zero offset. Amplitude vs. density of reservoir fluid.*

and $V_S = 1080\,\mathrm{m/sec}$ for both layers. Then calculated values in $\mathrm{N/m^2}$ were $\lambda = 1,949,572,601$, $G = 2,506,593,700$, $M = 22,436,559$, and $C = 21,603,901$ in the upper layer and $\lambda = 1,896,229,249$, $G = 2,438,009,381$, $M = 22,436,554$, and $C = 21,626,820$ in the lower layer.

Comparison of the asymptotic theory with the geophone response for plane layered media is really only a test of the P-wave amplitude theory. This is because the Biot slow wave does not propagate back to the surface; moreover, since all rays are orthogonal to the plane of the layering, shear waves cannot contribute to the vertical velocity of the solid. However, from the derivation of the theory, it is expected that the S-wave accuracy will be comparable to that of the P-waves.

In Figure 3 the amplitude of the vertical velocity at zero offset is plotted as a function of fluid density in the lower layer, with excellent agreement of the asymptotic theory and the layer code over four orders of magnitude in fluid density. From (84) the vertical velocity, which is determined by the P-waves, is the sum of two terms: the first term in (84) and the second, i.e., the Biot slow wave term. As seen in Figure 3, for small fluid densities both terms contribute about equally, while for large fluid densities the first term dominates, and the slow wave term is unimportant. There is, however, a narrow range of fluid densities for which the Biot slow wave determines the response, and the first term is unimportant. Altogether, both terms are needed to cover the full range of possibilities.

10. Conclusions. As stated in section 1, the theory developed here can be used to link conventional EM modeling software with conventional seismic ray tracing software to model the electroseismic response of three-dimensional subsurface structures in the earth. The theory can also be used to obtain simple estimates of the electroseismic response if the electric field can be estimated at depth; then use can be made of the fact that the tangential component of the electric field is continuous across the interface, while the normal components on both sides of the interface are in inverse

proportion to the conductivities. For example, since conductivities of a hydrocarbon reservoir are often orders of magnitude less than that of other kinds of rock, good P-wave responses are to be expected from reservoir boundaries, because of the large discontinuities in the normal electric field there.

In addition, the amplitude formulas (80)–(85) can be used to estimate other parametric dependencies of the electroseismic response. For example, note from (84) and (85) that all permeability dependencies in both the P- and S-waves are contained in the Biot slow wave term, through the dependence of γ_1 on $\tilde{\rho}$. Thus there is no permeability information in the S-waves, and the P-waves will also lack permeability information in cases where the slow wave term is unimportant compared to the other term in (84). In general, determination of permeability using the type of electroseismic prospecting described here is expected to be problematic. This contrasts with the permeability estimates obtained from EM conversions in the near field of a Stonely wave, as described in [12].

The theory derived here is expected to be of about the same order of accuracy as seismic ray theory. It also suffers from naive ray theory's defects, which include, for instance, edge diffraction. While this phenomenon must surely occur in electroseismics, it and other diffraction phenomena have not been included in the present theory.

Acknowledgment. I would like to thank Minyao Zhou for his help with the numerical comparisons of section 9, and for many helpful conversations.

CURRENT-VOLTAGE RELATIONS FOR ELECTROCHEMICAL THIN FILMS*

MARTIN Z. BAZANT†, KEVIN T. CHU†, AND B. J. BAYLY‡

Abstract. The DC response of an electrochemical thin film, such as the separator in a microbattery, is analyzed by solving the Poisson–Nernst–Planck equations, subject to boundary conditions appropriate for an electrolytic/galvanic cell. The model system consists of a binary electrolyte between parallel-plate electrodes, each possessing a compact Stern layer, which mediates Faradaic reactions with nonlinear Butler–Volmer kinetics. Analytical results are obtained by matched asymptotic expansions in the limit of thin double layers and compared with full numerical solutions. The analysis shows that (i) decreasing the system size relative to the Debye screening length decreases the voltage of the cell and allows currents higher than the classical diffusion-limited current; (ii) finite reaction rates lead to the important possibility of a reaction-limited current; (iii) the Stern-layer capacitance is critical for allowing the cell to achieve currents above the reaction-limited current; and (iv) all polarographic (current-voltage) curves tend to the same limit as reaction kinetics become fast. Dimensional analysis, however, shows that "fast" reactions tend to become "slow" with decreasing system size, so the nonlinear effects of surface polarization may dominate the DC response of thin films.

Key words. Poisson–Nernst–Planck equations, electrochemical systems, thin films, polarographic curves, Butler–Volmer reaction kinetics, Stern layer, surface capacitance

Introduction. Microelectrochemical systems pose interesting problems for applied mathematics because traditional "macroscopic" approximations of electroneutrality and thermal equilibrium [1], which make the classical transport equations more tractable [2], break down at small scales, approaching the Debye screening length. Of course, the relative importance of surface phenomena also increases with miniaturization. Microelectrochemical systems of current interest include ion channels in biological membranes [3, 4, 5] and thin-film batteries [6, 7, 8, 9, 10], which could revolutionize the design of modern electronics with distributed on-chip power sources. In the latter context, the internal resistance of the battery is related to the nonlinear current-voltage characteristics of the separator, consisting of a thin-film electrolyte (solid, liquid, or gel) sandwiched between flat electrodes and interfacial layers where Faradaic electron-transfer reactions occur [11]. Under such conditions, the internal resistance is unlikely to be simply constant, as is usually assumed.

Motivated by the application to thin-film batteries, here we revisit the classical problem of steady conduction between parallel, flat electrodes, studied by Nernst [12] and Brunner [13, 14] a century ago. As in subsequent studies of liquid [15, 16] and solid [17, 18] electrolytes, we do not make Nernst's assumption of bulk electroneutrality and work instead with the Poisson–Nernst–Planck (PNP) equations, allowing

for diffuse charge in solution [1, 2]. What distinguishes our analysis from previous work on current-voltage relations (or "polarographic curves") is the use of more realistic nonlinear boundary conditions describing (i) Butler–Volmer reaction kinetics and (ii) the surface capacitance of the compact Stern layer, as in the recent paper of Bonnefont, Argoul, and Bazant [19]. Such boundary conditions, although complicating mathematical analysis, generally cannot be ignored in microelectrochemical cells, where interfaces play a crucial role. Diffuse-charge dynamics, which can be important for high-power applications, also complicates analysis [20], but in most cases it is reasonable to assume that electrochemical thin films are in a steady state, due to the short distances for electrodiffusion.

We stress, however, that steady state does not imply thermal equilibrium when the system sustains a current, driven by an applied voltage. In this paper, we focus on applied voltages small enough to justify the standard boundary-layer analysis of the PNP equations, which yields charge densities in thermal equilibrium at leading order in the limit of thin double layers [21]. In a companion paper [22], we extend the analysis to larger voltages, at [23] and above [24] the Nernst's diffusion-limited current, and show how more realistic boundary conditions affect diffuse charge, far from thermal equilibrium. In both cases, we obtain novel formulae for polarographic curves by asymptotic analysis in the limit of thin double layers, which we compare with numerical solutions, and we focus on a variety of dimensionless physical parameters: the reaction-rate constants (scaled to the typical diffusive flux) and the ratios of the Stern length to the Debye length to the electrode separation.

1. Mathematical model. Let us consider uniform conduction through a dilute, binary electrolyte between parallel-plate electrodes separated by a distance, L. Our goal is to determine the steady-state response of the electrochemical cell to either an applied voltage, V, or an applied current, I. Specifically, we seek the electric potential $\Phi(X)$ and the concentrations $C_+(X)$ and $C_-(X)$ of cations and anions in the region $0 \le X \le L$. The Faradaic current is driven by redox reactions occurring at the electrodes, and we neglect any other chemical reactions, such as dissociation/recombination in the bulk solution or hydrogen production. Since we do not assume electroneutrality, the region of integration extends to the point where the continuum approximation breaks down near each electrode, roughly a few molecules away. In other words, our integration region includes the "diffuse part" but not the "compact part" of the double layer [1, 11, 25, 26].

1.1. Transport equations. In the context of dilute solution theory [1, 2], the governing equations for this situation are the steady PNP equations:

$$\frac{d}{dX}\left(D_+\frac{dC_+}{dX} + \mu_+ z_+ F C_+ \frac{d\Phi}{dX}\right) = 0, \tag{1}$$

$$\frac{d}{dX}\left(D_-\frac{dC_-}{dX} + \mu_- z_- F C_- \frac{d\Phi}{dX}\right) = 0, \tag{2}$$

$$-\frac{d}{dX}\left(\epsilon_s \frac{d\Phi}{dX}\right) = (z_+ C_+ - z_- C_-)F, \tag{3}$$

where F is Faraday's constant (a mole of charge), $z_\pm$, $\mu_\pm$, and $D_\pm$ are the charge numbers, mobilities, and diffusivities of each ionic species, respectively, and ϵ_s is the permittivity of the solvent, all taken to be constant in the limit of infinite dilution. The first two equations set divergences of the ionic fluxes to zero in order to maintain the steady state, and the third is Poisson's equation relating the electric potential to

the charge density. In each flux expression, the first term represents diffusion and the second electromigration. The Einstein relation, $\mu_\pm = D_\pm/RT$, relates mobilities and diffusion coefficients via the absolute temperature, T, and the universal gas constant, R.

Due to the potentially large electric fields in thin films, as in interfacial double layers, these classical approximations could break down [1, 25, 26]. For example, the polarization of solvent molecules in large electric fields can lower the solvent dielectric permittivity by an order of magnitude, while also affecting diffusivity and mobility. The solution can also become locally so concentrated or depleted of certain ions as to make finite sizes and/or interactions (and thus ionic activities) important. In spite of these concerns, however, it is reasonable to analyze the PNP equations before considering more complicated transport models, especially because our focus is on the effect of boundary conditions.

1.2. Electrode boundary conditions. Although PNP equations constitute a well-understood and widely accepted approximation, appropriate boundary conditions for them are not so clear, and drastic approximations, such as constant concentration, potential or surface charge (or zeta potential), are usually made, largely out of mathematical convenience. On the other hand, in the context of electric circuit models for electrochemical cells [20, 27, 28], much effort has been made to describe the nonlinear response of the electrode-electrolyte interface, while describing the bulk solution as a simple circuit element, such as a resistor. Here, we formulate general boundary conditions based on classical models of the double layer [11, 25, 26], with a unified description of ion transport by the PNP equations.

Our first pair of boundary conditions sets the normal anion flux to zero at each electrode,

$$D_- \frac{dC_-}{dX}(0) + \mu_- z_- F C_-(0) \frac{d\Phi}{dX}(0) = 0, \tag{4}$$

$$D_- \frac{dC_-}{dX}(L) + \mu_- z_- F C_-(L) \frac{d\Phi}{dX}(L) = 0, \tag{5}$$

on the assumption that anions do not specifically adsorb onto the surfaces, which holds for many anions at typical metal surfaces (e.g., SO_4^{-2}, OH^-, F^-). The second pair relates the normal cation flux to the net deposition (or dissolution) flux, or reaction-rate density, $R(C_+, \Delta\Phi_S)$, which in the dilute limit is assumed to depend only on cation concentration and potential drop, $\Delta\Phi_S$, across the compact part of the double layer, originally proposed by Stern [29]. Following the convention in electrochemistry, we take $\Delta\Phi_S$ to be the potential of the electrode surface measured relative to the solution. The reference potential is chosen so that the cathode, located at $X = 0$, is at zero potential and the anode, located at $X = 1$, is at the applied cell voltage V. Therefore, we have the following two boundary conditions:

$$D_+ \frac{dC_+}{dX}(0) + \mu_+ z_+ F C_+(0) \frac{d\Phi}{dX}(0) = R\left(C_+(0), \Phi(0)\right), \tag{6}$$

$$-D_+ \frac{dC_+}{dX}(L) - \mu_+ z_+ F C_+(L) \frac{d\Phi}{dX}(L) = R\left(C_+(L), \Phi(L) - V\right). \tag{7}$$

For electrodes, it is typical to assume a balance of forward (deposition) and backward (dissolution) reaction rates biased by the Stern voltage with an Arrhenius temperature dependence,

$$R(C_+, \Delta\Phi_S) = K_c C_+ \exp\left(\frac{-\alpha_c z F \Delta\Phi_S}{RT}\right) - K_a C_M \exp\left(\frac{\alpha_a z F \Delta\Phi_S}{RT}\right), \tag{8}$$

where C_M is the (constant) density of electrode metal and K_c and K_a are rate constants for the cathodic and anodic reactions [1]. (Expressing the reaction rate in terms of the surface overpotential, $\eta_S = \Delta\Phi_S - \Delta\Phi_S^{eq}$, where $\Delta\Phi_S^{eq}$ is the Stern-layer voltage in the absence of current, $R = 0$, yields the more common form of the Butler–Volmer equation [1, 26].) The Stern-layer voltage contributes $-zF\Delta\Phi_S$ to the activation energy barriers multiplied by transfer coefficients α_c and α_a for the cathodic and anodic reactions, respectively, where $\alpha_c \approx \alpha_a \approx \frac{1}{2}$, for single electron transfer reactions [1, 26, 30].

Following Frumkin [31], we apply (8) just outside the Stern layer, in contrast to "macroscopic" models which postulate the Butler–Volmer equation as a purely empirical description of reactions between the electrode surface and the electrically neutral bulk solution. Physically, the Frumkin approach makes more sense since the activation energy barrier described by the Butler–Volmer equation actually exists at the atomic scale in the Stern layer, not across the entire "interface" including diffuse charge in solution. We are not aware of any prior analysis with the full, nonlinear Butler–Volmer equation as a boundary condition on the PNP equations other than that of Bonnefont, Argoul, and Bazant [19]. Earlier analyses by Chang and Jaffé [15], Jaffé and LeMay [16], and Itskovich, Kornyshev, and Vorotyntsev [17] also include electrode reactions, but only for small perturbations around equilibrium.

The final pair of boundary conditions determines the electric potential by specifying the voltage drop across the Stern layer in terms of the local electric field and concentrations,

$$0 - \Phi(0) = \Delta\Phi_S\left(\frac{d\Phi}{dX}(0), C_+(0), C_-(0)\right), \tag{9}$$

$$V - \Phi(L) = \Delta\Phi_S\left(-\frac{d\Phi}{dX}(L), C_+(L), C_-(L)\right). \tag{10}$$

In macroscopic electrochemistry, these boundary conditions are usually replaced by the assumption of electroneutrality (which eliminates the need to solve Poisson's equation) or by simple Dirichlet boundary conditions on the potential [1]. In colloidal science, they are likewise replaced by simple boundary conditions of constant surface charge (or zeta potential) [32, 33]. Here, we incorporate more realistic properties of the interface as follows: Neglecting the specific adsorption of anions, the Stern layer acts as a nonlinear capacitor in series with the diffuse layer. Grahame's celebrated electrocapillary measurements [34, 35] suggest that (i) the Stern-layer capacitance, C_S, is roughly independent of concentration, depending mainly on the (variable) total charge, σ,

$$\frac{d(\Delta\Phi_S)}{d\sigma} = \frac{1}{C_S(\sigma)}, \tag{11}$$

and (ii) dilute solution theory accurately describes the capacitance, $C_D(\sigma, C_+)$, of the diffuse layer, at least when the charge and current are small enough to be well described by the Poisson–Boltzmann theory (as derived below). Using Gauss's law, the surface charge density can be expressed in terms of the normal electric field, $\sigma = -\epsilon_S d\Phi/dX$, where ϵ_S is an effective permittivity of the compact layer. Therefore,

integrating (11), Grahame's model corresponds to the assumption

$$\Delta\Phi_S = \int_0^{-\epsilon_S d\Phi/dx} \frac{d\sigma}{C_S(\sigma)}, \tag{12}$$

which determines how the voltage across the compact layer (relative to the point of zero charge for which $\Delta\Phi_S = 0$) varies as the two capacitors become charged. The function, $C_S(\sigma)$, should be fit to experimental or theoretical electrocapillary curves at large concentrations (since $1/C_{total} = 1/C_D + 1/C_S \approx 1/C_S$ in that case).

The simplest model that captures this interplay between the compact and diffuse layers is the Stern model [11, 26], which assumes the capacitance of the compact layer, C_S, to be constant [29]. While more complicated models for the compact layer have been proposed [36, 37, 25], the Stern model suffices for our purposes, because it allows us to describe surface capacitance easily in the context of our model of Faradaic reactions. Following Itskovich, Kornyshev, and Vorotyntsev [17] and Bonnefont, Argoul, and Bazant [19], let us introduce an effective width, λ_S, for the compact layer, $\lambda_S = \epsilon_S/C_S$, so that (12) reduces to a linear extrapolation of the potential across the compact layer, $-\Delta\Phi_S = \lambda_S d\Phi/dx$. Substituting this expression into (9) and (10) yields two Robin boundary conditions,

$$\Phi(0) - \lambda_S \frac{d\Phi}{dX}(0) = 0, \tag{13}$$

$$\Phi(L) + \lambda_S \frac{d\Phi}{dX}(L) = V, \tag{14}$$

completing a set of six boundary conditions for our three second-order differential equations. Physically, the Stern layer, as an effective solvation shell for the electrode, is only a few molecules wide, so it is best to think of λ_S as simply a measure of the capacitance of the Stern layer. More generally, the same boundary condition could also describe a thin dielectric layer on the electrode [38, 39, 40], e.g., arising from surface contamination or a passivating monolayer.

Note that since the anion flux is zero, the current passing through the cell is proportional to the cation flux (everywhere in the cell, since it is constant),

$$I = z_+ FA \left(D_+ \frac{dC_+}{dX} + \mu_+ z_+ F C_+ \frac{d\Phi}{dX} \right), \tag{15}$$

where A is the electrode area and a current flow towards the cathode ($x = 0$) is taken to be positive. Under potentiostatic conditions, the cell voltage V is given, and the steady-state polarization curve $I(V)$ is determined by solving the equations. Conversely, under galvanostatic conditions, I is fixed, and we solve for $V(I)$.

1.3. An integral constraint. As formulated above, the boundary value problem is not well posed. Since the anion flux is constant throughout the cell according to (2), the two anion flux boundary conditions are degenerate, leaving one constant of integration undetermined. This is not surprising, as we have omitted one crucial physical parameter: the total number of anions. More precisely, because anions do not react, we must specify their total number, which remains constant as the steady state is reached. This corresponds to the constraint

$$\frac{1}{L} \int_0^L C_-(X) dX = C_{ref}, \tag{16}$$

where C_{ref} is the initial concentration of anions.

Note that the total number of cations (and hence the total charge) is not known a priori because the removal of cations at the cathode and the injection of cations at the anode may significantly alter their total number. This may seem counterintuitive since we are accustomed to assuming that we know the total cation concentration at all times based on the original molarity of the solution, but this "macroscopic" thinking does not apply when the physics at the microscopic level are explicitly being studied (e.g., diffuse charge layers or microelectrochemical systems). Mathematically, the reaction boundary conditions at the electrodes (6) and (7) are sufficient to determine the total cation concentration (and total charge), as long as the total anion concentration is specified.

1.4. Dimensionless formulation. To facilitate our analysis, we formulate the problem in dimensionless form. For simplicity we also assume that the electrolyte is symmetric, $z_+ = -z_- \equiv z$, which does not qualitatively affect any of our conclusions as long as $z_+/|z_-|$ is not too different from 1 (which holds for most simple, aqueous electrolytes). Scaling the basic variables

$$x \equiv X/L, \qquad c_\pm(x) \equiv C_\pm(xL)/C_{ref}, \qquad \phi(x) \equiv \frac{zF\Phi(xL)}{RT}, \tag{17}$$

equations (1)–(3) become

$$\frac{d^2c_+}{dx^2} + \frac{d}{dx}\left(c_+\frac{d\phi}{dx}\right) = 0, \tag{18}$$

$$\frac{d^2c_-}{dx^2} - \frac{d}{dx}\left(c_-\frac{d\phi}{dx}\right) = 0, \tag{19}$$

$$-\epsilon^2\frac{d^2\phi}{dx^2} = \frac{1}{2}(c_+ - c_-), \tag{20}$$

where $\epsilon \equiv \lambda_D/L$ is the ratio of the Debye screening length $\lambda_D \equiv \sqrt{\frac{\epsilon_s RT}{2z^2F^2C_{ref}}}$ to the distance between electrodes. The Debye length is typically on the order of nanometers, so ϵ is always extremely small for macroscopic electrochemical cells. This situation changes, however, as L or C_{ref} is decreased, and in the case of nanoelectrochemical systems ϵ could be as large as 10.

The two flux equations are easily integrated, using (4) to evaluate one constant and leaving the other constant expressed in terms of the current via (15),

$$\frac{dc_+}{dx} + c_+\frac{d\phi}{dx} = 4j, \tag{21}$$

$$\frac{dc_-}{dx} - c_-\frac{d\phi}{dx} = 0, \tag{22}$$

where we have defined a dimensionless current density, $j \equiv I/I_d$, scaled to the Nernst's diffusion-limited current density (see section 2.1), $I_d \equiv 4zFD_+C_{ref}A/L$. Since diffuse charge is of primary interest here, it is convenient to introduce

$$c = \frac{1}{2}(c_+ + c_-) \quad \text{and} \quad \rho = \frac{1}{2}(c_+ - c_-), \tag{23}$$

the average concentration of ions and (half) the charge density, respectively, which leaves us with a coupled set of one second-order and two first-order differential

equations,

$$\frac{dc}{dx} + \rho\frac{d\phi}{dx} = 2j, \tag{24}$$

$$\frac{d\rho}{dx} + c\frac{d\phi}{dx} = 2j, \tag{25}$$

$$-\epsilon^2\frac{d^2\phi}{dx^2} = \rho. \tag{26}$$

Nondimensionalizing the boundary conditions (remembering that there is an extra condition needed to determine the current-voltage relation, $j(v)$ or $v(j)$), we obtain

$$\phi(0) - \delta\epsilon\frac{d\phi}{dx}(0) = 0, \tag{27}$$

$$\phi(1) + \delta\epsilon\frac{d\phi}{dx}(1) = v, \tag{28}$$

$$k_c[c(0) + \rho(0)]e^{\alpha_c\phi(0)} - j_r e^{-\alpha_a\phi(0)} = j, \tag{29}$$

$$-k_c[c(1) + \rho(1)]e^{\alpha_c(\phi(1)-v)} + j_r e^{-\alpha_a(\phi(1)-v)} = j, \tag{30}$$

$$\int_0^1 [c(x) - \rho(x)]dx = 1, \tag{31}$$

where

$$k_c \equiv \frac{K_c L}{4D_+}, \quad j_r \equiv \frac{K_a L C_M}{4D_+ C_{ref}}, \quad v \equiv \frac{zFV}{RT}, \quad \text{and} \quad \delta \equiv \frac{\lambda_S}{\lambda_D}. \tag{32}$$

Keep in mind that the dimensionless rate constants decrease with system size, so that "fast reactions" ($k_c, j_r \gg 1$) may become "slow reactions" ($k_c, j_r = O(1)$) as L is reduced to the micron or submicron scale.

It is important to note that we have scaled the effective Stern-layer width, λ_S, with the Debye screening length, λ_D, rather than the electrode separation L, thus introducing the factor $\epsilon = \lambda_D/L$ in (27) and (28). This choice is important for our asymptotic analysis of the limit $\epsilon \to 0$ at fixed δ, which is intended to describe situations in which L is much larger than *both* λ_S and λ_D. Without it, our analysis would assume that as $\epsilon \to 0$ the Stern layer becomes infinitely wide compared to the diffuse layer, even though it is mainly the macroscopic electrode separation which varies. The limit of very small Stern layer capacitance, which amounts to the Helmholtz model of the double layer [41], is best studied by letting $\delta \to \infty$ *after* $\epsilon \to 0$. In contrast, because ϵ and δ would both be small, the limit of very large Stern-layer capacitance can be studied by simply letting $\delta = 0$, yielding the Dirichlet boundary conditions

$$\phi(0) = 0, \qquad \phi(1) = 1 \tag{33}$$

of the Gouy–Chapman model of the double layer [42, 43]. In our work, we shall consider both limits, starting with the assumption that $\delta = O(1)$, which corresponds to the Gouy–Chapman–Stern model of the double layer [11, 26].

For one-dimensional problems, galvanostatic conditions are more mathematically convenient than potentiostatic conditions. In the former case, j is given, and $v(j)$ is easily obtained from the Stern boundary condition at the anode (28). In the latter case, however, v is specified and $j(v)$ must be determined self-consistently to satisfy (28). Therefore, we shall assume that the current j is specified and solve (24)–(26) subject to the boundary conditions (29) and (30) and the integral constraint (31).

2. Boundary-layer analysis. In this section, we briefly review the classical asymptotic analysis of the PNP equations, pioneered independently by Chernenko [44], Newman [21], and MacGillivray [45], which involves boundary layers of width ϵ (corresponding to diffuse-charge layers of dimensional width, λ_D). As discussed below, the classical asymptotics breaks down at large currents approaching diffusion limitation. Unlike most previous authors, who assume either a fixed potential [42, 43] or fixed interfacial charge [21] at an isolated electrode or fixed concentrations at cell boundaries with ion-permeable membranes [4, 5, 24], we solve for the response of a complete, two-electrode galvanic cell with boundary conditions for Faradaic reactions and Stern-layer capacitance.

Throughout this section, the reader may refer to Figure 1, which compares the uniform asymptotic solutions derived below to numerical solutions at several values of ϵ. These figures illustrate the structure of the field variables in the cell as well as give an indication of the quality of the asymptotic solutions. The numerical solutions are obtained by a straightforward iterative spectral method, described in a companion paper [22].

2.1. Electroneutrality in the bulk solution. The most fundamental approximation in electrochemistry is that of bulk electroneutrality [1]. As first emphasized by Newman [21], however, this does not mean that the charge density is vanishing or unimportant, but rather that over macroscopic distances the charge density is small compared to the total concentration, $|C_+ - C_-| \ll C_+ + C_-$, or, in our dimensionless notation, $|\rho| \ll c$. Mathematically, the "macroscopic limit" corresponds to the limit $\epsilon = \lambda_D/L \to 0$. The electroneutral solution is just the leading order solution when asymptotic series of the form $f(x) = f^{(0)}(x) + \epsilon f^{(1)}(x) + \epsilon^2 f^{(2)}(x) + \cdots$ are substituted for the field variables in (24)–(26).

Carrying out these substitutions and collecting terms with like powers of ϵ, we obtain a hierarchy of differential equations for the expansion functions. At $O(1)$ we have

$$\frac{d\bar{c}^{(0)}}{dx} = 2j, \quad -\bar{c}^{(0)}\bar{E}^{(0)} = 2j, \quad \bar{\rho}^{(0)} = 0, \tag{34}$$

where the bar accent indicates that these expansions are valid in the "bulk region" $\epsilon \ll x \ll 1 - \epsilon$ (or $\lambda_D \ll X \ll L - \lambda_D$). Integrating these equations, we obtain the leading order bulk solution:

$$\bar{c}^{(0)}(x) = c_o + 2jx, \tag{35}$$

$$\bar{E}^{(0)}(x) = \frac{-1}{x + c_o/2j}, \tag{36}$$

$$\bar{\phi}^{(0)}(x) = \phi_o + \log\left(1 + \frac{2jx}{c_o}\right), \tag{37}$$

where the constants of integration c_o and ϕ_o are the values of the bulk concentration and potential extrapolated to the cathode surface at $x = 0$. Note that, despite quasi-electroneutrality, the electrostatic potential does not satisfy Laplace's equation at leading order in the bulk, as emphasized by Levich [46] and Newman [1]. Noting the presence of ϵ^2 in (26) for the dimensionless potential, it is clear that a negligible charge density, $\rho = O(\epsilon^2)$, is perfectly consistent with a nonvanishing Laplacian of the potential. More precisely, we have

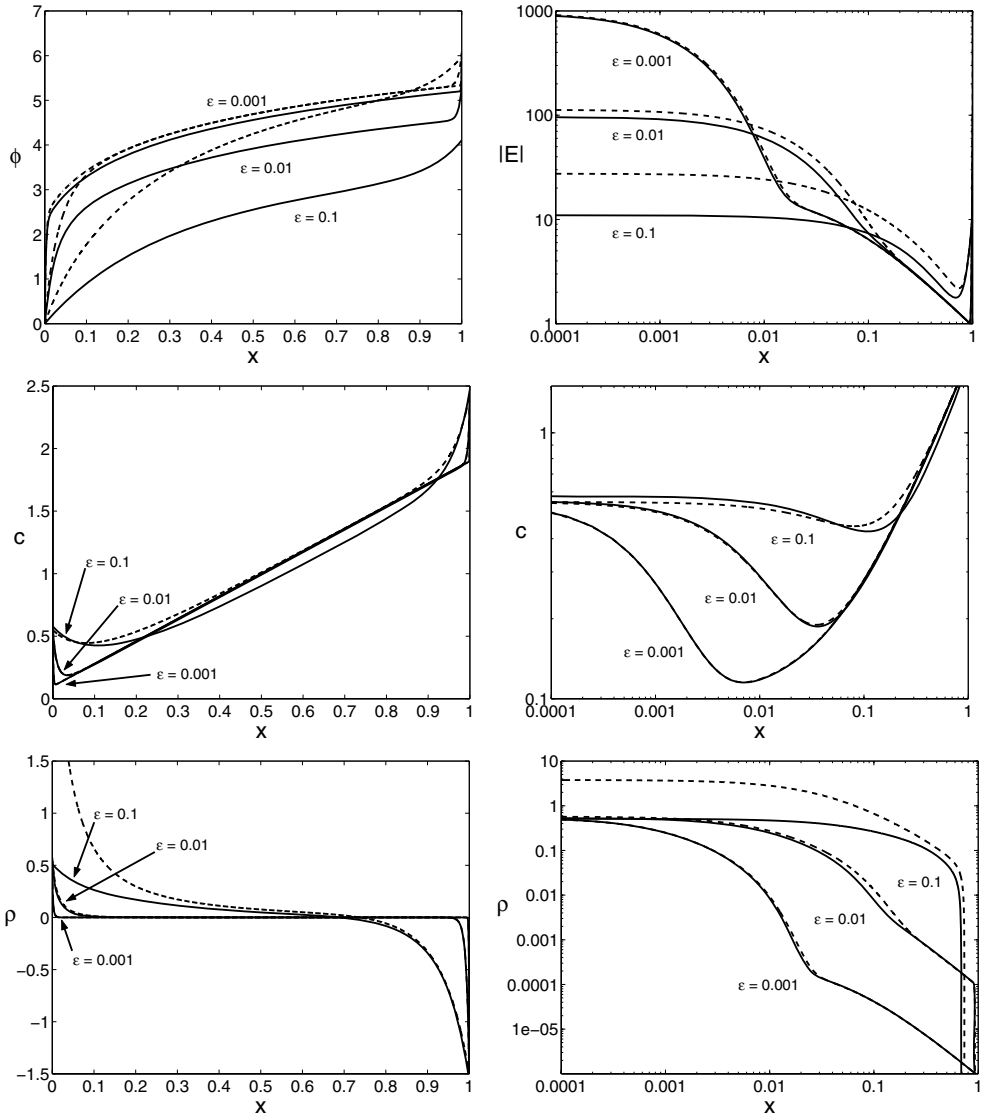

FIG. 1. *Numerical solutions (solid lines) compared with the leading order uniformly valid approximations (dashed lines) given by* (58)–(61) *for the dimensionless potential* $\phi(x)$*, electric field* $E(x)$*, concentration* $c(x)$*, and charge density* $\rho(x)$ *for the case* $j = 0.9$*,* $k_c = 10$*,* $j_r = 10$*,* $\delta = 0$*, and* $\epsilon = 0.001, 0.01, 0.1$*. Linear scales on the left show the entire cell, while log scales on the left zoom in on the cathodic region. Note that in the concentration and charge density profiles, the numerical and asymptotic solutions are barely distinguishable for* $\epsilon \leq 0.01$*.*

$$\bar{\rho}^{(2)}(x) = \frac{d^2\bar{\phi}^{(0)}}{dx^2}(x) = \frac{1}{(x + c_o/2j)^2} \tag{38}$$

at $O(\epsilon^2)$ in (26).

The integral constraint, (31), can be used to evaluate the constant c_o. If we assume that c_- in the boundary layers does not diverge as $\epsilon \to 0$, then they contribute only $O(\epsilon)$ to the total anion number. Therefore,

$$1 = \int_0^1 c_-(x)dx = \int_0^1 \bar{c}^{(0)}(x)dx + O(\epsilon) = c_o + j + O(\epsilon), \tag{39}$$

which implies that $c_o = 1 - j$.

At leading order in the bulk, we have recovered the classical theory dating back a century to Nernst [12, 13, 14]. The solution is electrically neutral with a linear concentration profile whose slope is proportional to the current. This approximation leads to one of the fundamental concepts in electrochemistry, that there exists a "limiting current," $j = 1$, or

$$I = I_d = \frac{4zFD_+C_{ref}A}{L}, \tag{40}$$

corresponding to zero concentration at the cathode, $c_o = 1 - j = 0$. The current is limited by the maximum rate of mass transfer allowed by diffusion, and larger currents would lead to unphysical and mathematically inconsistent negative concentrations (see the appendix).

Examination of the electric field exposes the same limitation on the current: a singularity exists at $j = 1$ that blocks larger currents from being attained. The leading-order bulk approximation to the electric field, $\bar{E}^{(0)} = 1/[x + (1 - j)/2j]$, diverges near the cathode like $1/x$ in the limit $j \to 1$. This would imply that the cell voltage v (calculated below) diverges as $j \to 1$, thus providing a satisfactory theory of the limiting current since an infinite voltage would be necessary to exceed (or even attain) it. Unfortunately, this classical picture due to Nernst [12], based on passing to the *singular* limit $\epsilon = 0$, is not valid for any *finite* value of ϵ because the solution is, in general, unable to satisfy all of the boundary conditions.

2.2. Diffuse charge layers in thermal equilibrium. We now derive the leading order description of the boundary layers in the standard way [21, 5, 26, 1], using (24)–(25). The singular perturbation in (26) can be eliminated with the rescaling $y = x/\epsilon$ indicating that the boundary layer at $x = 0$ has a width $O(\epsilon)$. In terms of this inner variable, the governing equations in the cathode boundary layer are

$$\frac{dc}{dy} + \rho\frac{d\phi}{dy} = 2j\epsilon, \tag{41}$$

$$\frac{d\rho}{dy} + c\frac{d\phi}{dy} = 2j\epsilon, \tag{42}$$

$$-\frac{d^2\phi}{dy^2} = \rho, \tag{43}$$

where ϵ now appears as a regular perturbation since solutions satisfying the cathode boundary conditions and the matching conditions still exist when $\epsilon = 0$. At the anode, the appropriate inner variable is $y = (1 - x)/\epsilon$, and the equations are the same as above except that j is replaced with $-j$, since current is leaving the anode layer, while it is entering the cathode boundary layer.

Expanding the cathode boundary-layer fields (indicated by the check accent) as asymptotic series in powers of ϵ, we obtain at leading order

$$\frac{d\check{c}^{(0)}}{dy} + \check{\rho}^{(0)}\frac{d\check{\phi}^{(0)}}{dy} = 0, \tag{44}$$

$$\frac{d\check{\rho}^{(0)}}{dy} + \check{c}^{(0)}\frac{d\check{\phi}^{(0)}}{dy} = 0. \tag{45}$$

Using (23) to rewrite these equations in terms of c_+ and c_-, we find that the flux of each ionic species in the boundary layer is zero at leading order:

$$\frac{d\check{c}_\pm^{(0)}}{dy} \pm \check{c}_\pm^{(0)} \frac{d\check{\phi}^{(0)}}{dy} = 0. \tag{46}$$

While this equation appears to contradict the fact that the current is nonzero, the paradox is resolved in the same way as electroneutrality is reconciled with a nonharmonic potential in the bulk region: tiny fluctuations about the boundary-layer equilibrium concentration profiles at $O(\epsilon)$ are amplified by a scaling factor of $1/\epsilon$ to sustain the $O(1)$ current. Thus, the leading order contribution to the current in the boundary layer is

$$\epsilon\left(\frac{d\check{c}_+^{(1)}}{dx} + \check{c}_+^{(1)}\frac{d\check{\phi}^{(0)}}{dx} + \check{c}_+^{(0)}\frac{d\check{\phi}^{(1)}}{dx}\right) = \frac{d\check{c}_+^{(1)}}{dy} + \check{c}_+^{(1)}\frac{d\check{\phi}^{(0)}}{dy} + \check{c}_+^{(0)}\frac{d\check{\phi}^{(1)}}{dy} = 4j. \tag{47}$$

Integrating (46) and matching with the bulk, we find that the leading order ionic concentrations are Boltzmann equilibrium distributions:[1]

$$\check{c}_\pm^{(0)}(y) = c_o e^{\pm[\phi_o - \check{\phi}^{(0)}(y)]}, \tag{48}$$

where $c_o = 1 - j$ and $\phi_o = \bar{\phi}^{(0)}(0)$ are obtained by matching with the solution in the bulk. Note that the Boltzmann distribution arises not from an assumption of thermal equilibrium in the boundary layer but as the leading order concentration distribution, even in the presence of a nonnegligible $O(1)$ current.

The general leading-order solution was first derived by Gouy [42] and Chapman [43] and appears in numerous books [1, 26, 32, 33] and recent papers [5, 19]:

$$\check{c}^{(0)}(y) = c_o \cosh[\phi_o - \check{\phi}^{(0)}(y)], \tag{49}$$

$$\check{\rho}^{(0)}(y) = c_o \sinh[\phi_o - \check{\phi}^{(0)}(y)], \tag{50}$$

$$\frac{d\check{\phi}^{(0)}}{dy} = 2\sqrt{c_o}\sinh\left(\frac{\phi_o - \check{\phi}^{(0)}(y)}{2}\right), \tag{51}$$

$$\check{\phi}^{(0)}(y) = \phi_o + 4\tanh^{-1}\left(\gamma_o e^{-\sqrt{c_o}y}\right), \tag{52}$$

where $\gamma_o \equiv \tanh(\zeta_o/4)$ and $\zeta_o \equiv \check{\phi}^{(0)}(0) - \phi_o$ is the leading-order "zeta potential" across the cathodic diffuse layer, which plays a central role in electrokinetic phenomena [32, 33]. Note that the magnitude of the diffuse layer electric field scales as $1/\epsilon$, as illustrated in Figure 1.

The value of $\check{\phi}^{(0)}(0)$ hidden in the zeta potential ζ_o is determined by the Stern boundary condition, (27). If $\delta = 0$ (Gouy–Chapman model), then $\check{\phi}^{(0)}(0) = 0$, or $\zeta_o = -\phi_o$, which means that the entire voltage drop ϕ_o across the cathodic double layer occurs in the diffuse layer. If $\delta = \infty$ (Helmholtz model), then $\check{\phi}^{(0)}(0) = \phi_o$, or $\zeta_o = 0$, in which case the Stern layer carries all the double-layer voltage. For finite $\delta > 0$ (Stern model), ζ_o is obtained in terms of ϕ_o by solving a transcendental algebraic equation,

$$-\zeta_o = 2\delta\sqrt{c_o}\sinh(\zeta_o/2) + \phi_o, \tag{53}$$

[1] The expression for energy in the Boltzmann equilibrium distribution includes only the energy due to electrostatic interactions. "Chemical" contributions to the energy are neglected.

which can be linearized about the two limiting cases and solved for ζ_o,

$$-\zeta_o \sim \begin{cases} \phi_o - 2\delta\sqrt{c_o}\sinh(\phi_o/2) & \text{if } \delta \ll \phi_o/2\sqrt{c_o}\sinh(\phi_o/2), \\ \phi_o/\delta\sqrt{c_o} & \text{if } \delta \gg \phi_o/2\sqrt{c_o}. \end{cases} \tag{54}$$

Note that if $\phi_o \ll 1$, then $-\zeta_o \approx \frac{\phi_o}{1+\delta\sqrt{c_o}}$ is a reasonable approximation for any value of $\delta \geq 0$. Finally, we solve for ϕ_o by applying the Butler–Volmer rate equation, (29), which yields a transcendental algebraic equation for ϕ_o:

$$k_c c_o e^{-\zeta_o + \alpha_c(\zeta_o+\phi_o)} - j_r e^{-\alpha_a(\zeta_o+\phi_o)} = j. \tag{55}$$

Simultaneously solving the pair of (53) and (55) exactly is not possible in general, but below we will analyze various limiting cases.

In the anodic boundary layer, we find the same set of equations as (41)–(43) except that j is replaced by $-j$. Therefore, since the fields do not depend on j at leading order, the anodic boundary layer has the same structure but with different constants of integration. Thus, we find that the leading order description of the anodic boundary layer is given by (49)–(52) with c_o, ϕ_o, γ_o, and ζ_o replaced by different constants c_1, ϕ_1, γ_1, and ζ_1, respectively. Moreover, it is straightforward to show that $c_1 = \bar{c}^{(0)}(1) = 1 + j$ and $\phi_1 = \phi_o + \log(\frac{1+j}{1-j})$.

The leading-order anodic zeta potential, ζ_1, and the potential drop across the entire anodic double layer, $v - \phi_1$, are found by solving another pair of transcendental algebraic equations resulting from the anode Stern and Butler–Volmer boundary conditions, (28) and (30),

$$-\zeta_1 = 2\delta\sqrt{c_1}\sinh(\zeta_1/2) + \phi_1 - v, \tag{56}$$

$$j = -k_c c_1 e^{-\zeta_1 + \alpha_c(\zeta_1+\phi_1-v)} + j_r e^{-\alpha_a(\zeta_1+\phi_1-v)}. \tag{57}$$

As before, the Gouy–Chapman and Helmholtz limits are $\zeta_1 = v - \phi_1$ and $\zeta_1 = 0$, respectively, and for small voltages (or currents) the approximation $\zeta_1 \approx (v-\phi_1)/(1+\delta\sqrt{c_1})$ is valid for all $\delta \geq 0$.

2.3. Leading order uniformly valid approximations. We obtain asymptotic approximations that are uniformly valid across the cell by adding the bulk and boundary-layer approximations and subtracting the overlapping parts:

$$c(x) = [\check{c}^{(0)}(x/\epsilon) - c_o] + \bar{c}^{(0)}(x) + [\hat{c}^{(0)}((1-x)/\epsilon) - c_1] + O(\epsilon), \tag{58}$$

$$\rho(x) = \check{\rho}^{(0)}(x/\epsilon) + \epsilon^2\bar{\rho}^{(2)}(x) + \hat{\rho}^{(0)}((1-x)/\epsilon) + O(\epsilon), \tag{59}$$

$$E(x) = \frac{1}{\epsilon}\frac{d\check{\phi}^{(0)}}{dy}(x/\epsilon) + \frac{d\bar{\phi}^{(0)}}{dx}(x) - \frac{1}{\epsilon}\frac{d\hat{\phi}^{(0)}}{dy}((1-x)/\epsilon) + O(\epsilon), \tag{60}$$

$$\phi(x) = [\check{\phi}^{(0)}(x/\epsilon) - \phi_o] + \bar{\phi}^{(0)}(x) + [\hat{\phi}^{(0)}((1-x)/\epsilon) - \phi_1] + O(\epsilon). \tag{61}$$

Note that we have kept the $O(\epsilon^2)$ term in the charge density since it is the leading-order contribution in the bulk region and is easily computed from (38). As shown in Figure 1, the leading-order uniformly valid solutions are very accurate for $\epsilon \leq 0.01$ (or $L \geq 100\lambda_D$) and reasonably good for $\epsilon = 0.1$. Since higher-order terms are not analytically tractable, it seems numerical solutions must suffice for nanolayers, where $\epsilon \approx 1$, or else other limits of various parameters must be considered, as below.

The discrepancy in electric potential profile at large ϵ in Figure 1 is particularly interesting because it arises from a constraint on the total potential drop across the cell.

To understand the origin of this voltage constraint, recall that the total cell voltage is determined by the current density flowing through the cell (via the voltage-current relationship). While ϵ is technically a parameter in the voltage-current relationship, a leading-order analysis does not capture the ϵ dependence. Thus, the leading-order cell voltage must be the same for all ϵ, which is what we observe in Figure 1. A close examination of the potential and electric field profiles reveals that most of the error in the asymptotic solution for the potential comes from an over-prediction of the electric field strength (and therefore the potential drop) in the cathode region.

3. Polarographic curves for thin double layers, $\epsilon \to 0$. The relationship between current and cell voltage is of primary importance in the study of any electrochemical system, so we now use the results from the previous section to calculate theoretical polarographic curves in several physically relevant regimes. We focus on the effects of the Stern capacitance and the reaction-rate constants through the dimensionless parameters, δ, k_c, and j_r, with $\alpha_c = \alpha_a = 1/2$. For a fixed voltage, the mathematical results are valid in the asymptotic limit of thin double layers, $\epsilon \to 0$.

3.1. Exact results at leading order. Using the uniformly valid approximation (61), we can write the leading-order approximation for the cell voltage as

$$v = \phi_o + 2\tanh^{-1}(j) + (v - \phi_1). \tag{62}$$

We can interpret this expression as a decomposition of the cell voltage into the potential drop across the cathode, bulk, and anode layers, respectively. Note the divergence in the bulk contribution to the cell voltage as $j \to 1$, which we expect from our earlier analysis. In the next section, we explore analytic solutions for several limiting cases and compare them to exact solutions given by (62) with the leading-order cathode and anode diffuse layer potential drops determined implicitly by (53), (55), (56). To make plots in our figures, we use Newton iteration to solve for ϕ_o and $v - \phi_1$ in this algebraic system.

3.2. Cell resistance at low current. Given the common practice of using linear circuit models to describe electrochemical systems [27, 28, 20], it is important to consider the low-current regime, where the cell acts as a simple resistance, $R = V/I$. First, we compute the potential drop across the double layers. Since the procedure is almost identical for the two boundary layers, we focus on the calculation for the cathode. By writing the boundary conditions (29) in the standard Butler–Volmer form involving the exchange current and surface overpotential [26, 1],

$$j = j_o^c\big(e^{-\alpha_c \eta_s^c} - e^{\alpha_a \eta_s^c}\big), \tag{63}$$

where $j_o^c = (k_c c_o e^{-\zeta_o})^{\alpha_a} j_r^{\alpha_c}$ and $\eta_s^c = \Delta\phi_S - \Delta\phi_S^{eq}$ are the cathode exchange current and surface overpotential, respectively. Note that the exchange current contains the Frumkin correction through the factor $e^{-\zeta_o}$ [26]. For low-current densities, we expect the surface overpotential to be small, so we can linearize this equation to obtain

$$j \sim -j_o^c \eta_s^c, \tag{64}$$

where we have used the fact that $\alpha_c + \alpha_a = 1$. Rewriting this equation in terms of $\check{\phi}(0)$, we find that

$$\check{\phi}(0) \sim \frac{j}{j_o^c} + \check{\phi}_{eq}(0), \tag{65}$$

where $\check{\phi}_{eq}(0)$ is the value of $\check{\phi}(0)$ calculated from the cathode Butler–Volmer rate equation when there is no current flowing through the electrode. The zeta potential ζ_o in the formula for the exchange current is determined by combining (65) with (53) to obtain a single equation for ζ_o:

$$-2\delta\sqrt{c_o}\sinh(\zeta_o/2) \sim \frac{j}{(k_c c_o e^{-\zeta_o})^{\alpha_a} j_r^{\alpha_c}} + \log\left(\frac{j_r}{k_c c_o}\right) + \zeta_o. \tag{66}$$

Finally, to compute the total double-layer potential drop, we add the potential drop across the diffuse layer to $\check{\phi}(0)$:

$$\phi_o = \check{\phi}(0) - \zeta_o \sim \frac{j}{j_o^c} + \log\left(\frac{j_r}{k_c c_o}\right). \tag{67}$$

A similar calculation at the anode results in

$$v - \phi_1 \sim \frac{j}{j_o^a} + \log\left(\frac{k_c c_1}{j_r}\right), \tag{68}$$

where $j_o^a = (k_c c_1 e^{-\zeta_1})^{\alpha_a} j_r^{\alpha_c}$ and ζ_1 is determined by the anode equivalent of (66).

Combining these results with the potential drop across the bulk solution, we find that the total cell voltage is given by

$$\begin{aligned} v(j) &\sim 4\tanh^{-1}(j) + \frac{j}{j_o^c} + \frac{j}{j_o^a} \\ &\approx j\left(4 + \frac{1}{j_o^c} + \frac{1}{j_o^a}\right) \\ &= j\ r. \end{aligned} \tag{69}$$

This result gives the dimensionless resistance, r, of the electrochemical thin film as a function of the physical properties of the electrodes and the electrolyte. Note that the Stern-layer capacitance is accounted for implicitly via the calculation of the electrode zeta potentials.

3.3. Simple analytical formulae. The exact leading-order current-voltage relation simplifies considerably in a variety of physically relevant limits. These approximate formulae provide insight into the basic physics and may be useful in interpreting experimental data.

3.3.1. The Gouy–Chapman limit ($\delta \to 0$). In this limit, the capacitance of the diffuse layer of the charged double layer is negligible compared to the capacitance of the compact layer. As a result, the voltage drop across the diffuse layer accounts for the entire potential drop across the charged double layer. Physically, this limit corresponds to the limits of low ionic concentration or zero ionic volume [26]. Since $\zeta_o = -\phi_o$ and $\zeta_1 = v - \phi_1$ when $\delta = 0$, the Butler–Volmer rate equations, (55) and (57), reduce to

$$k_c(1-j)e^{-\zeta_o} - j_r = j \quad \text{and} \quad -k_c(1+j)e^{-\zeta_1} + j_r = j. \tag{70}$$

Solving for ζ_o and ζ_1, we find that

$$\zeta_o = \ln(1-j) - \ln\left(\frac{j_r + j}{k_c}\right) \quad \text{and} \quad \zeta_1 = \ln(1+j) + \ln\left(\frac{k_c}{j_r - j}\right), \tag{71}$$

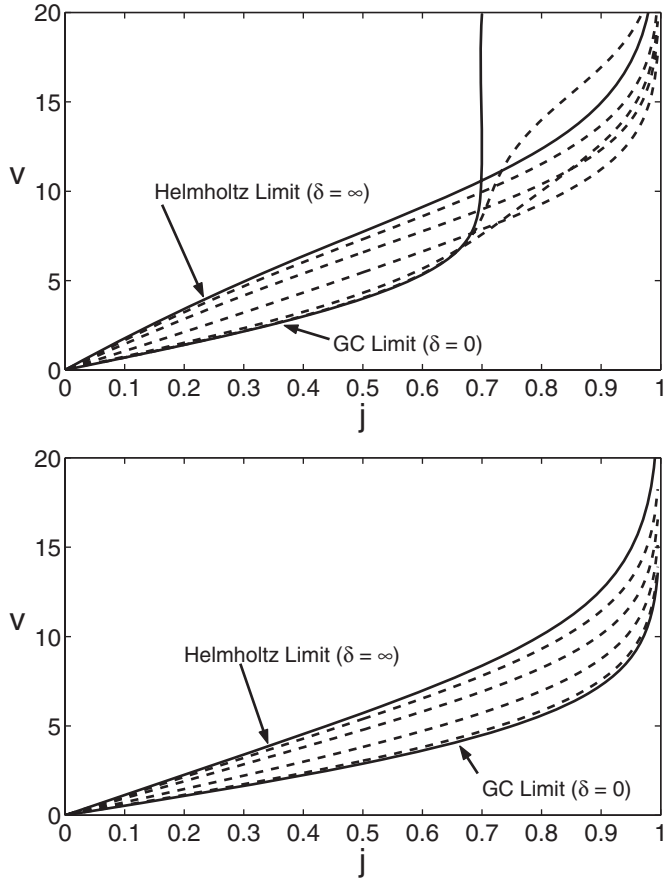

FIG. 2. *Exact polarographic curves (dashed lines) for varying δ values compared to polarographic curves for the Gouy–Chapman ($\delta = 0$) and Helmholtz ($\delta = \infty$) limits (solid lines). Top: a reaction-limited cell ($j_r < 1$) with physical parameters, $k_c = 0.03$, $j_r = 0.7$. Notice that above the reaction-limited current density, j_r, the highest cell voltages occur for δ values near 0. Bottom: a diffusion-limited cell ($j_r > 1$) with physical parameters, $k_c = 0.05$, $j_r = 1.5$. In both cases, δ increases as the curves move upwards.*

which can be substituted into (62) to obtain

$$v(j) = 4\tanh^{-1}(j) + 2\tanh^{-1}(j/j_r). \tag{72}$$

Notice that the boundary layers make a nontrivial contribution to the leading-order cell voltage. The $2\tanh^{-1}(j/j_r)$ term is especially interesting because it indicates the existence of a reaction-limited current when $j_r < 1$. In hindsight, it is obvious that reaction-limited currents exist in the Gouy–Chapman limit because the reaction kinetics at the anode do not permit a current greater than j_r. We emphasize, however, that the Gouy–Chapman limit is singular because there is no problem achieving current densities above j_r for any $\delta > 0$ (see Figure 2). For any finite $\delta > 0$, the shift of the anode double-layer potential drop to the Stern layer helps the dissolution reaction while suppressing the deposition reaction, which permits the current density to rise greater than j_r.

Note that the cathodic and anodic boundary layers do not evenly contribute to

the cell voltage near the limiting currents. In a diffusion-limited cell, the cathodic layer makes the greater contribution because as $j \to 1$, ζ_o diverges while ζ_1 approaches a finite limit. We expect this behavior because as $j \to 1$, the electric field diverges only at $x = 0$. However, when the cell is reaction-limited, the division of cell voltage between the boundary layers is reversed as j approaches the limiting current j_r. Even the voltage drop in the bulk becomes negligible compared to ζ_1 in the reaction-limited case. In this situation, the cell voltage diverges as $j \to j_r$ because the only way to achieve a current near j_r is to drastically reduce the deposition reaction at the anode. In other words, the cation concentration at the anode must be made extremely small, which requires a huge anodic zeta potential.

3.3.2. The Helmholtz limit ($\delta \to \infty$). This is the reverse of the Gouy–Chapman limit. Here, the capacitance of the compact layer is negligible, so the potential drop across the double layer resides completely in the compact layer. The Helmholtz limit holds for concentrated solutions or solvents with low dielectric constants and other situations where the Debye screening length becomes negligible [26]. It also describes a thick dielectric or insulating layer on an electrode [38, 20].

In the Helmholtz limit, $\zeta_o = 0 = \zeta_1$, so the Butler–Volmer rate equations take the form

$$k_c(1-j)e^{\alpha_c \phi_o} - j_r e^{-\alpha_a \phi_o} = j, \tag{73}$$

$$-k_c(1+j)e^{\alpha_c(\phi_1 - v)} + j_r e^{-\alpha_a(\phi_1 - v)} = j. \tag{74}$$

Solving these equations for ϕ_o and $v - \phi_1$ under the assumption of a symmetric electron-transfer reaction (i.e., $\alpha_c = 1/2 = \alpha_a$) and substituting into the formula for the cell voltage, we find that

$$v(j) = 6\tanh^{-1}(j) + 2\ln\left(\frac{j + \sqrt{j^2 + 4j_r k_c(1-j)}}{-j + \sqrt{j^2 + 4j_r k_c(1+j)}}\right). \tag{75}$$

While this expression appears to be more complicated than the one obtained for the Gouy–Chapman model, it is not very different when $j_r > 1$, as can be seen in Figures 2 and 3. In fact, the wide spread in the polarographic curves observed in Figure 2 requires that $k_c \ll j_r$; otherwise, all of the curves would be difficult to distinguish. Moreover, as we shall see in the next section, in the limit of fast reactions, both models lead to the same expression for the cell voltage for $j_r > 1$. On the other hand, when $j_r < 1$, the two models are qualitatively very different. While the Gouy–Chapman model gives rise to a reaction-limited current, the Helmholtz model does not.

3.3.3. The fast-reaction limit ($j_r \gg 1$, $(j_r)^{\alpha_a}(k_c)^{\alpha_c} \gg j/(1-j)^{\alpha_a}$). The polarographic curves for all δ values collapse onto each other in the limit of fast-reaction kinetics (Figure 3). Even the assumption of symmetry in the electron-transfer reaction is not required. When reaction rates are much larger than the current, the two reaction-rate terms in the Butler–Volmer equations, (55) and (57), must balance each other at leading order:

$$k_c(1-j)e^{-\zeta_o + \alpha_c(\zeta_o + \phi_o)} - j_r e^{-\alpha_a(\zeta_o + \phi_o)} \approx 0, \tag{76}$$

$$-k_c(1+j)e^{-\zeta_1 + \alpha_c(\zeta_1 + \phi_1 - v)} + j_r e^{-\alpha_a(\zeta_1 + \phi_1 - v)} \approx 0. \tag{77}$$

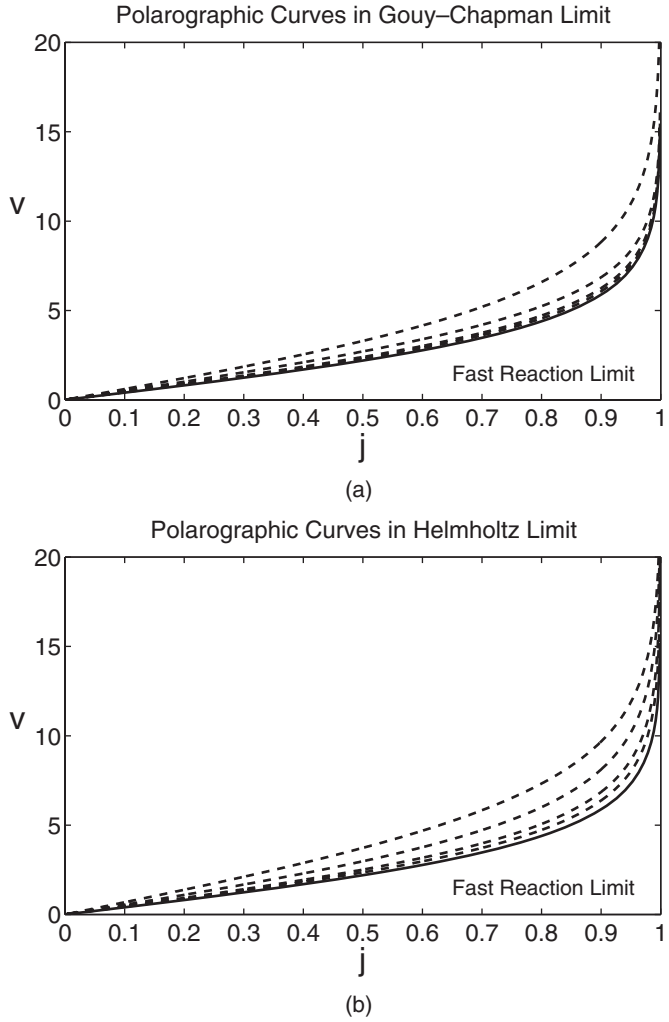

FIG. 3. *Polarographic curves in* (a) *the Gouy–Chapman limit and* (b) *the Helmholtz limit as the reaction-rate constants are increased (dashed lines). For these plots, the reaction-rate constants* ($j_r = 1, 2, 5,$ *and* 10) *increase as the curves shift towards the lower right and are related by* $k_c = j_r/2$. *It should be noted that the fast-reaction limit is reached very quickly; in both plots, the curve closest to the fast-reaction curve has a* j_r *value of only* 10.

Since $\alpha_c + \alpha_a = 1$ for theoretical models of single electron-transfer reactions [1, 11, 30], we can solve explicitly for ϕ_o and $v - \phi_1$ to obtain

$$\phi_o = \ln\left(\frac{j_r}{k_c(1-j)}\right), \qquad v - \phi_1 = \ln\left(\frac{k_c(1+j)}{j_r}\right). \tag{78}$$

Thus, for fast-reaction kinetics, the leading-order cell voltage is given by

$$v(j) = 4\tanh^{-1}(j). \tag{79}$$

Notice that this is exactly the fast-reaction limit of $v(j)$ that we find in both the Gouy–Chapman and Helmholtz limits. It is straightforward to check the validity of the

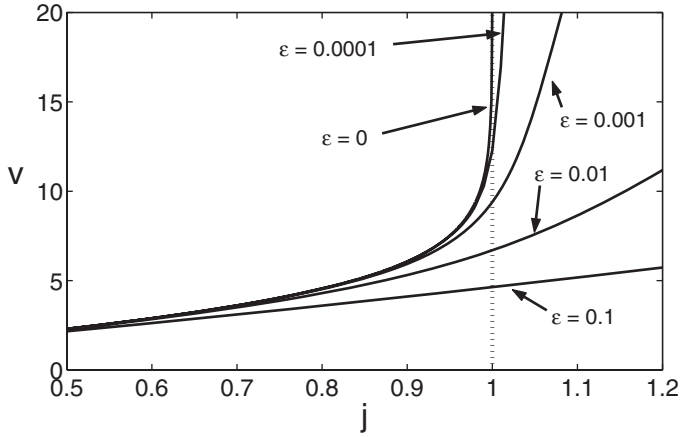

FIG. 4. *Polarographic curves for ϵ values of* 0, 0.0001, 0.001, 0.01, *and* 0.1 *(listed in order from uppermost to lowest curves) with the other physical parameters taken to be $\delta = 0$, $k_c = 10$, and $j_r = 10$. Notice that for any $\epsilon > 0$, the cell has no problem achieving current densities higher than the diffusion-limited current (dashed vertical line). All of these curves, with the exception of the exact $\epsilon = 0$ curve, were generated by numerically solving* (24)–(26) *subject to the boundary conditions* (27)–(31) *using the method of our companion paper* [22].

assumptions made in (76) and (77) by substituting these results into the expressions for the reaction rates and observing that the zeta potentials satisfy the bounds $\zeta_o \leq 0$ and $\zeta_1 \leq \ln(\frac{k_c(1+j)}{j_r - j})$, which follow from the monotonicity of ζ_o and ζ_1 as functions of δ.

4. Thick double layers, $\epsilon = O(1)$. Up to this point, we have examined only the current-voltage characteristics in the singular limit $\epsilon \to 0$, where the current density cannot exceed its diffusion-limited value, $j = 1$. The situation changes for any finite $\epsilon > 0$.

4.1. What limiting current? As is clearly evident in Figure 4, the cell has no problem breaking through the classical limiting current for $\epsilon > 0$. Figure 4 also shows that the ϵ dependence of the polarographic curves becomes significant only at currents approaching the diffusion-limited current; below $j \approx 0.5$, the curves are nearly indistinguishable. Moreover, as ϵ increases, the upper ends of the polarographic curves flatten out and shift downwards. This decrease in the cell voltage for large ϵ values arises because the diffuse charge layers overlap and are able to interact with each other. More precisely, the cell has become so small (relative to the Debye screening length) that the electric fields from the two diffuse layers partially cancel each other out throughout the cell, resulting in a lower total cell voltage. It should be emphasized that this effect is observable only because we are studying a two-electrode system. Single-electrode systems (in addition to being not physically achievable) are not capable of showing this behavior because they always implicitly assume an infinite system size, which effectively discards any interactions from "far away" electrodes.

4.2. Breakdown of the classical approximation. For a diffusion-limited cell, the classical nonlinear asymptotic analysis just presented leads to an aesthetically appealing theory that predicts a limiting current at $j = 1$. The existence of this limiting current fits nicely with our physical intuition that the concentration of cations in a solution must always remain nonnegative. In reality, however, the analysis breaks

down as the current approaches (and exceeds) its limiting value.

The breakdown of the classical asymptotics is evident upon examining the expansions for the bulk field variables as the current is increased toward its diffusion-limited value. Calculating a few of the higher-order terms in the bulk asymptotic expansion, we find that

$$-\bar{E}(x) = \frac{2j}{\bar{c}^{(0)}} + \frac{3}{2}\epsilon^2\frac{(2j)^3}{(\bar{c}^{(0)})^4} + \frac{111}{4}\epsilon^4\frac{(2j)^5}{(\bar{c}^{(0)})^7} + \frac{6045}{4}\epsilon^6\frac{(2j)^7}{(\bar{c}^{(0)})^{10}} + O(\epsilon^8), \tag{80}$$

$$\bar{c}(x) = \bar{c}^{(0)} + \frac{1}{2}\epsilon^2\frac{(2j)^2}{(\bar{c}^{(0)})^2} + \frac{3}{2}\epsilon^4\frac{(2j)^4}{(\bar{c}^{(0)})^5} + \frac{231}{8}\epsilon^6\frac{(2j)^6}{(\bar{c}^{(0)})^8} + O(\epsilon^8), \tag{81}$$

$$\bar{\rho}(x) = 0 + \epsilon^2\frac{(2j)^2}{(\bar{c}^{(0)})^2} + 6\epsilon^4\frac{(2j)^4}{(\bar{c}^{(0)})^5} + \frac{777}{4}\epsilon^6\frac{(2j)^6}{(\bar{c}^{(0)})^8} + O(\epsilon^8). \tag{82}$$

Since $\bar{c}^{(0)} \to 2x$ as $j \to 1$, the higher-order terms are clearly more singular than the leading-order term at the limiting current. Rubinstein and Shtilman make a similar observation from a potentiostatic perspective; they note that the asymptotic expansions are not uniform in the cell voltage [24].

The inconsistency in the classical approximation was apparently first noticed by Levich, who observed that the leading-order solution in the bulk predicts an infinite charge density when the current density reaches 1, which directly contradicts the assumption of bulk charge neutrality [46]. As $j \to 1$, the bulk charge density is given by

$$\bar{\rho} = -\epsilon^2\frac{d^2\bar{\phi}}{dx^2} = \frac{\epsilon^2}{[x + (1-j)/2j]^2} \approx \frac{\epsilon^2}{x^2}, \tag{83}$$

which diverges at the cathode.

Smyrl and Newman first showed that these paradoxical results are related to the breakdown of thermal equilibrium charge profiles near the cathode, leading to a significant expansion of the double layer into the bulk solution [23]. They argue that the assumption of electroneutrality breaks down when $\bar{\rho} \approx \bar{c}$. Since $\bar{c}$ is proportional to x at the limiting current, the bulk approximation fails to be valid for x smaller than $O(\epsilon^{2/3})$, which leads to a boundary layer that is thicker than the usual Debye length. From an alternative perspective, the problems begin when $\bar{\rho}(0)/\bar{c}(0) \approx 1$ (see Figure 5). Using this criterion, we find that the classical asymptotic theory is appropriate only when $c_o \gg (2j\epsilon)^{2/3}$ or, equivalently, $j \ll 1 - (2\epsilon)^{2/3}$. Since the cell voltage is approximately $4\tanh^{-1}(j)$ in many situations, this regime also corresponds to $v = O(|\ln\epsilon|)$. This shows that in thin films, where ϵ is not so small, it is easy to exceed the classical limiting current and achieve rather different charge profiles [22].

5. Conclusion. In summary, we have revisited the classical PNP equations, analyzing for the first time the effect of physically realistic boundary conditions for thin-film galvanic cells and other microelectrochemical systems. In particular, we focused on the effect of Stern-layer capacitance and Faradaic reactions with Butler–Volmer kinetics. Such boundary conditions contain new physics, such as the possibility of a reaction-limited current due to the slow injection of ions at the anode. We also find that the Stern layer generally allows the cell to exceed limiting currents by carrying diverging portions of the cell voltage, which would otherwise end up in the diffuse part of the double layer. We have provided analytical formulae for current-voltage relations that should prove useful in characterizing the differential resistance of thin films, such as those used in on-chip microbatteries. Here, we have focused on the classical nonlinear regime in which thin double layers remain in thermal equilibrium; the more

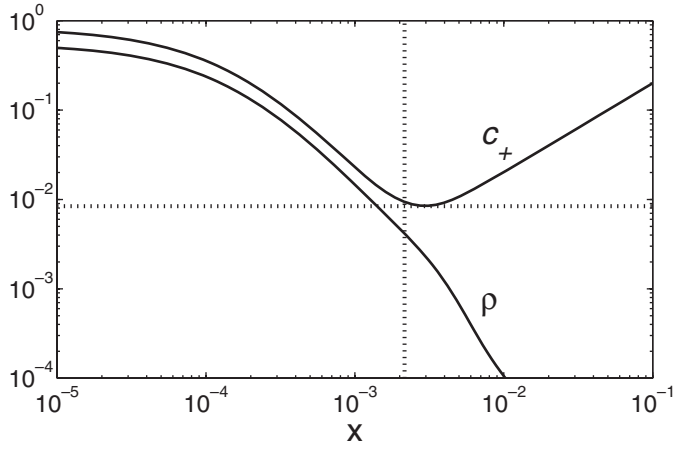

FIG. 5. *Numerical solutions for the dimensionless cation concentration $c_+(x)$ and (full) charge density $2\rho(x)$ at the diffusion-limited current ($j = 1.0$) with physical parameters $k_c = 10$, $j_r = 10$, $\alpha_c = \alpha_a = 0.5$, $\delta = 0.0$, and $\epsilon = 0.0001$. In the cathode region, electroneutrality breaks down as the solution becomes cation rich in order to satisfy the reaction boundary conditions. Note that when $x = O(\epsilon^{2/3})$, c_+ and ρ are both $O(\epsilon^{2/3})$. For reference, the dashed vertical line shows where $x = \epsilon^{2/3}$, and the dashed horizontal line shows where $y = \epsilon^{2/3}[(2+2^{2/3})+4/(2+2^{2/3})^2] \approx c_+(\epsilon^{2/3})$.*

exotic, nonequilibrium regime, which arises at and above the classical limiting current, is analyzed in the companion paper [22].

Appendix. Positivity of ion concentrations. The positivity of the ion concentrations follows directly from the mathematical formulation of the problem. For the anion concentration, (22) can be integrated exactly using the integrating factor e^{ϕ} to yield

$$c_-(x) = Ae^{\phi(x)}, \tag{84}$$

which implies that the sign of $c_-(x)$ is the same across the entire domain. Since the integral constraint (31) requires that $c_-(x)$ is positive somewhere in the domain, $c_-(x)$ must be positive *everywhere* in the domain.

For the cation concentration, we make use of the reaction boundary conditions. Integrating (21) with the integrating factor e^{ϕ}, we obtain

$$c_+(x) = c_+(0)e^{\phi(0)-\phi(x)} + 4je^{-\phi(x)} \int_0^x e^{\phi(y)} dy. \tag{85}$$

Clearly, the integral term is positive because e^{ϕ} is positive everywhere. Moreover, the reaction boundary condition (29) implies that $c_+(0) > 0$ because both j_r and k_c are positive. Thus, we find that the cation concentration is strictly positive.

ELECTROCHEMICAL THIN FILMS AT AND ABOVE THE CLASSICAL LIMITING CURRENT*

KEVIN T. CHU† AND MARTIN Z. BAZANT†

Abstract. We study a model electrochemical thin film at DC currents exceeding the classical diffusion-limited value. The mathematical problem involves the steady Poisson–Nernst–Planck equations for a binary electrolyte with nonlinear boundary conditions for reaction kinetics and Stern-layer capacitance, as well as an integral constraint on the number of anions. At the limiting current, we find a nested boundary-layer structure at the cathode, which is required by the reaction boundary condition. Above the limiting current, a depletion of anions generally characterizes the cathode side of the cell. In this regime, we derive leading-order asymptotic approximations for the (i) classical bulk space-charge layer and (ii) another nested highly charged boundary layer at the cathode. The former involves an exact solution to the Nernst–Planck equations for a single, unscreened ionic species, which may apply more generally to Faradaic conduction through very thin insulating films. By matching expansions, we derive current-voltage relations well into the space-charge regime. Throughout our analysis, we emphasize the strong influence of the Stern-layer capacitance on cell behavior.

Key words. Poisson–Nernst–Planck equations, electrochemical systems, limiting current, reaction boundary conditions, double-layer capacitance, polarographic curves

Introduction. Thin-film technologies offer a promising way to construct rechargeable microbatteries, which can be directly integrated into modern electronic circuits [1, 2, 3, 4, 5, 6]. Due to the power-density requirements of many applications, such as portable electronics, microbatteries are likely to be operated at high-current density, possibly exceeding diffusion limitation. In a thin film, very large electric fields are easily produced by applying only small voltages, due to the small electrode separation, which may be comparable to the Debye screening length. Under such conditions, the traditional postulates of macroscopic electrochemical systems [7, 8]—bulk electroneutrality and equilibrium double layers—break down near the classical diffusion-limited current [9]. The mathematical justification for these postulates is based on matched asymptotic expansions in the limit of thin double layers [10, 11, 12], which require subtle modifications at large currents.

The concept of a "limiting current," due to the maximum steady-state flux of diffusion across an electrochemical cell, was introduced by Nernst a century ago [13]. Consider the simplest case of a binary electrolyte between parallel plate electrodes with cation redox reactions and inert anions. Assuming neutrality, the bulk concentration is a linear function of distance (due to steady diffusion) with a gradient proportional to the current. Since the total number of anions is fixed, the total integral of the bulk concentration must also be fixed, which implies that the concentration at the cathode decreases linearly with current. The "diffusion-limited current" corre-

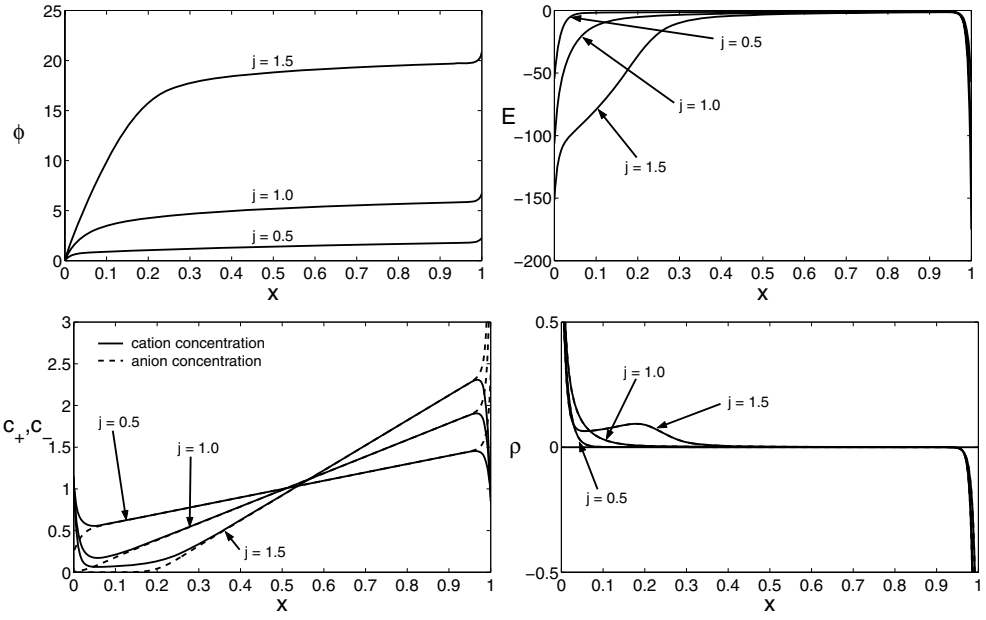

FIG. 1. *Profiles of the dimensionless potential (top left), electric field (top right), total ionic concentration (bottom left), and charge density (bottom right) in three regimes: below the classical diffusion-limited current ($j = 0.5$), at the limiting current ($j = 1$), and above the limiting current ($j = 1.5$). These are numerical solutions to our model problem with the following dimensionless parameters: $\epsilon = 0.01$, $\delta = 0$, $k_c = 10$, $j_r = 10$.*

sponds to a vanishing bulk concentration at the cathode, and, as the name suggests, it can never be reached, except with an infinite voltage.

It was eventually realized that the classical theory is flawed, as illustrated in Figure 1 by numerical solutions to our model problem below. The bulk concentration remains linear, but the system is clearly able to achieve and even exceed the classical limiting current (as shown in the lower left panel of the figure). Levich was perhaps the first to notice that the assumption of bulk electroneutrality yields approximate solutions to the Poisson–Nernst–Planck (PNP) equations, which are not self-consistent near the limiting current, since the predicted charge density eventually exceeds the salt concentration near the cathode [14]. This paradox was first resolved by Smyrl and Newman, who showed that the double layer expands at the limiting current as the Poisson–Boltzmann approximation of thermal equilibrium breaks down [15]. Rubinstein and Shtilman later pointed out that mathematical solutions also exist for larger currents, well above the classical limiting value, characterized by a region of nonequilibrium "space charge" extending significantly into the neutral bulk [16]. As shown in Figure 1, the space-charge layer exhibits anomalously large electric fields and charge densities, compared to the equilibrium double layers at smaller currents.

The possibility of superlimiting currents has been studied extensively in the different context of bulk liquid electrolytes, where a thin space-charge layer drives nonlinear electro-osmotic slip. This phenomenon of "electro-osmosis of the second kind" was introduced by Dukhin for the nonlinear electrophoresis of ion-selective, conducting colloidal particles [17], and Ben and Chang have recently studied it in microfluidics [18]. The mathematical analysis of second-kind electro-osmosis using matched asymptotic expansions, similar to the approach taken here, was first developed by Rubinstein

and Zaltzman for related phenomena at electrodialysis membranes [19, 20]. In earlier studies, the space-charge layer was also invoked by Bruinsma and Alexander [21] to predict hydrodynamic instability during electrodeposition and by Chazalviel [22] in a controversial theory of fractal electrochemical growth.

As in our companion paper on sublimiting currents [9], here we consider (typically solid or gel) thin films, e.g., arising in microbatteries, which approach the classical limiting current without hydrodynamic instability. At micron or smaller length scales, the space-charge layer need not be "thin" compared to the film thickness, so we also analyze currents well above the classical limiting current, apparently for the first time. In both regimes, close to and far above the classical limiting current, we derive matched asymptotic expansions for the concentration profiles and potential, which we compare against numerical solutions. In addition to our focus on superlimiting currents and small systems, a notable difference with the literature on second-kind electro-osmosis is our use of nonlinear boundary conditions for Faradaic electron-transfer reactions, assuming Butler–Volmer kinetics and a compact Stern layer. We also analyze the current-voltage relation, thus extending our analogous results for thin films below the limiting current [9].

1. Statement of problem. Before delving into the analysis (and to make the paper self-contained), we review governing equations and boundary conditions. We shall focus solely on the dimensionless formulation of the problem, derived and discussed in the companion paper [9].

The transport of cations and anions is described by the steady Nernst–Planck equations

$$\frac{d^2c_+}{dx^2} + \frac{d}{dx}\left(c_+\frac{d\phi}{dx}\right) = 0, \tag{1}$$

$$\frac{d^2c_-}{dx^2} - \frac{d}{dx}\left(c_-\frac{d\phi}{dx}\right) = 0, \tag{2}$$

while Poisson's equation relates the electric potential to the charge density,

$$-\epsilon^2\frac{d^2\phi}{dx^2} = \frac{1}{2}\left(c_+ - c_-\right). \tag{3}$$

Here ϵ is a small dimensionless parameter equal to the ratio of the Debye screening length to the electrode separation (or film thickness). Note that this formulation assumes constant material properties, such as diffusivity, mobility, and dielectric coefficient, and neglects any variations which may occur at large electric fields. The factor of $1/2$ multiplying the charge density $c_+ - c_-$ is present merely for convenience. The domain for the system of (1)–(3) is $0 < x < 1$.

The two Nernst–Planck equations are easily integrated under the physical constraint that the boundaries are impermeable to anions (i.e., zero flux of anions at $x = 0$) and taking the nondimensional current density at the electrodes to be $4j$:

$$\frac{dc_+}{dx} + c_+\frac{d\phi}{dx} = 4j, \tag{4}$$

$$\frac{dc_-}{dx} - c_-\frac{d\phi}{dx} = 0. \tag{5}$$

Then by introducing the average ion concentration and (half) the charge density,

$$c = \frac{1}{2}\left(c_+ + c_-\right) \quad \text{and} \quad \rho = \frac{1}{2}\left(c_+ - c_-\right), \tag{6}$$

we can derive a more symmetric form for the coupled PNP equations:

$$\frac{dc}{dx} + \rho\frac{d\phi}{dx} = 2j, \tag{7}$$

$$\frac{d\rho}{dx} + c\frac{d\phi}{dx} = 2j, \tag{8}$$

$$-\epsilon^2\frac{d^2\phi}{dx^2} = \rho. \tag{9}$$

For this system of one second-order and two first-order differential equations, we require four boundary conditions and one integral constraint:

$$\phi(0) - \delta\epsilon\frac{d\phi}{dx}(0) = 0, \tag{10}$$

$$\phi(1) + \delta\epsilon\frac{d\phi}{dx}(1) = v, \tag{11}$$

$$k_c\left[c(0)+\rho(0)\right]e^{\alpha_c\phi(0)} - j_r e^{-\alpha_a\phi(0)} = j, \tag{12}$$

$$-k_c\left[c(1)+\rho(1)\right]e^{\alpha_c(\phi(1)-v)} + j_r e^{-\alpha_a(\phi(1)-v)} = j, \tag{13}$$

$$\int_0^1 \left[c(x)-\rho(x)\right]dx = 1. \tag{14}$$

These conditions, which are often simplified or omitted in electrochemical modeling, are central to our analysis. A detailed discussion can be found in the companion paper [9], so here we simply give an overview.

The first two boundary conditions, (10)–(11), account for the intrinsic capacitance of the compact part of the electrode-electrolyte interface, which is taken to be linear (the "Stern model"). The compact-layer charge could contain solvated ions at the point of closest approach to the electrode, as well as adsorbed ions on the surface. The capacitance also accounts for the dielectric polarization of the solvation layer and/or impurities or coatings on the surface. In these boundary conditions, δ is a dimensionless parameter which measures the strength of the surface capacitance, and v is the total dimensionless voltage drop across the cell.

The next two boundary conditions, (12)–(13), are Butler–Volmer rate equations, which represent the kinetics of Faradaic electron-transfer reactions at each electrode, with an Arrhenius dependence on the compact-layer voltage. In these equations, k_c and j_r are dimensionless reaction-rate constants and α_c and α_a are transfer coefficients for the electrode reaction. It is worth noting that α_c and α_a do not vary too much from system to system; typically they have values between 0 and 1, and often both take on values near 1/2.

Finally, the integral constraint, (14), reflects the fact that the total number of anions is fixed, assuming that anions are not allowed to leave the electrolyte by Faradaic processes or specific adsorption. When solving time-dependent problems with the same mathematical model [23, 24], the constraint is not needed, since the total number of anions is set by the initial condition. Here, we solve for the steady state at different voltages (and currents), assuming the same average concentration of anions to allow a meaningful comparison for the same cell.

It is important to understand that the need for an extra constraint reflects that the current-voltage relationship, $j(v)$, or "polarographic curve," is not given a priori. As usual in one-dimensional problems [9], it is easier to assume galvanostatic forcing at fixed current, j, and then solve for the cell voltage, $v(j)$, by applying the boundary

condition (11), rather than the more common case of potentiostatic forcing at fixed voltage, v. For this reason, we take the former approach in our analysis. For steady-state problems, the two kinds of forcing are equivalent and yield the same (invertible) polarographic curve, $j(v)$ or $v(j)$.

For some of our analysis, it will be convenient to further simplify the problem by introducing the dimensionless electric field, $E \equiv -\frac{d\phi}{dx}$. This transformation is useful because three of the five independent constraints can be expressed in terms of these variables, without explicit dependence on $\phi(x)$, namely, the two Butler–Volmer rate equations,

$$k_c \left(c(0) + \rho(0)\right) e^{-\alpha_c \delta \epsilon E(0)} - j_r e^{\alpha_a \delta \epsilon E(0)} = j, \tag{15}$$

$$-k_c \left(c(1) + \rho(1)\right) e^{\alpha_c \delta \epsilon E(1)} + j_r e^{-\alpha_a \delta \epsilon E(1)} = j, \tag{16}$$

and the integral constraint on the total number of anions, (14). The potential is recovered by integrating the electric field and applying the Stern boundary conditions (10) and (11).

2. Unified analysis at all currents.

2.1. Master equation for the electrostatic potential. We begin our analysis by reducing the governing equations, (7) through (9), to a single master equation for the electrostatic potential. Substituting (9) into (7) and integrating, we obtain an expression for the average concentration:

$$c(x) = \underline{c}_o + 2jx + \frac{\epsilon^2}{2}\left(\frac{d\phi}{dx}\right)^2. \tag{17}$$

Then by applying the integral constraint, (14), we find that the integration constant, $\underline{c}_o$, is given by

$$\underline{c}_o = (1-j) - \epsilon^2 \left[\left(\frac{d\phi}{dx}\right)\Big|_{x=1} - \left(\frac{d\phi}{dx}\right)\Big|_{x=0} + \frac{1}{2}\int_0^1 \left(\frac{d\phi}{dx}\right)^2 dx \right]. \tag{18}$$

Note that when the electric field is $O(1)$, (17) and (18) reduce to the leading-order concentration in the bulk when j is sufficiently below the limiting current [9]. We can now eliminate ρ and c from (8) to arrive at a single master equation for ϕ,

$$\epsilon^2 \left[-\frac{d^3\phi}{dx^3} + \frac{1}{2}\left(\frac{d\phi}{dx}\right)^3 \right] + \left(\underline{c}_o + 2jx\right)\frac{d\phi}{dx} = 2j, \tag{19}$$

or, equivalently, for the electric field E,

$$\epsilon^2 \left[\frac{d^2E}{dx^2} - \frac{1}{2}E^3 \right] - \left(\underline{c}_o + 2jx\right) E = 2j. \tag{20}$$

Once this equation is solved, the concentration, c, and charge density, ρ, are computed using (17) and Poisson's equation, (9).

The master equation has been derived in various equivalent forms since the 1960s. Grafov and Chernenko [25] first combined (4), (5), and (9) to obtain a single nonlinear differential equation for the anion concentration, c_-, whose general solution they expressed in terms of Painlevé's transcendents. The master equation for the

electric field, (20), was first derived by Smyrl and Newman [15] in the special case of the classical limiting current, where $j = 1$ and $\underline{c}_o = 0$, where they discovered a nonequilibrium double layer of width $\epsilon^{2/3}$, which is apparent from the form of the master equation. We shall study the general electric-field and potential equations for an arbitrary current, j, focusing on boundary-layer structure in the limiting and superlimiting regimes.

2.2. Efficient numerical solution. To solve the master equation for the electric field with the boundary conditions and integral constraint, we use the Newton–Kantorovich method [26]. Specifically, we use a Chebyshev pseudospectral discretization to solve the linearized boundary-value problem at each iteration [26, 27]. Our decision to use this method is motivated by its natural ability to resolve boundary layers and its efficient use of grid points. We are able to get accurate results for many parameter regimes very quickly (typically less than a few minutes on a workstation) with only a few hundred grid points, which would not be possible at large currents and/or thin double layers using a naive finite-difference scheme. It is important to stress that the boundary conditions and the integral constraint are explicitly included as part of the Newton–Kantorovich iteration. Therefore, the linear boundary-value problem solved in each iteration is actually an *integrodifferential equation* with boundary conditions that are integroalgebraic equations.

To ensure convergence at high currents, we use continuation in the current density parameter, j, and start with a sufficiently low initial j that the bulk electroneutral solution is a reasonable initial guess; often, initial j values relatively high compared to the diffusion-limited current are acceptable. After a small increase in current, we check that the iteration converges to a correspondingly small perturbation of the previous solution. Analogous continuation in the δ parameter is also sometimes necessary to compute solutions at high δ values.

The results of the numerical method are presented in the figures below and in [9] to test our analytical approximations obtained by asymptotic analysis.

2.3. Recovery of classical results below the limiting current, $j \ll 1 - O(\epsilon^{2/3})$. In the low-current regime, the master equation admits the two distinguished limits around $x = 0$ that arise in the classical analysis: $x = O(1)$ and $x = O(\epsilon)$. When $x = O(1)$, we find the usual bulk electric field from (19) and the bulk concentration from (17). When $x = O(\epsilon)$, the master equation can be rescaled using $x = \epsilon y$ to obtain

$$-\frac{d^3\phi}{dy^3} + \frac{1}{2}\left(\frac{d\phi}{dy}\right)^3 + \underline{c}_o\frac{d\phi}{dy} + 2jy\epsilon\frac{d\phi}{dy} = 2j\epsilon, \tag{21}$$

which is equivalent to the classical theory at leading order [9]. In particular, the Gouy–Chapman structure of the double layer can be derived directly from the Smyrl–Newman equation in this limit [23].

The anode boundary layer comes from a similar $O(\epsilon)$ scaling around $x = 1$. Note that in the $j \ll 1 - \epsilon^{2/3}$ regime, the scaling $x = O(\epsilon^{2/3})$ is *not* a distinguished limit because the $\underline{c}_o(\frac{d\phi}{dx})$ term would dominate all other terms in (19).

3. Nested boundary layers at the limiting current, $j = 1 - O(\epsilon^{2/3})$. In this section, we show that a nontrivial nested boundary-layer structure emerges at the classical limiting current when general boundary conditions are considered.

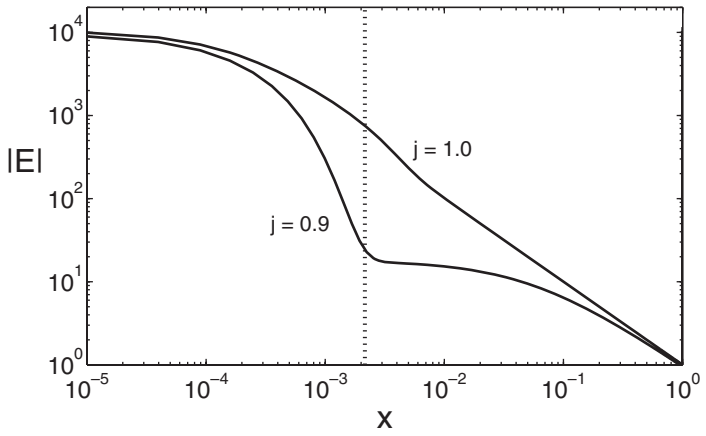

FIG. 2. *Numerical solutions for the dimensionless electric field $E(x)$ at current densities of $j = 0.9$ and $j = 1.0$ demonstrating the expansion of the diffuse layer at the limiting current ($k_c = 1$, $j_r = 2$, $\delta = 0.1$, and $\epsilon = 0.0001$). For reference, the vertical line shows where $x = \epsilon^{2/3}$.*

3.1. Expansion of the double layer out of equilibrium. As discussed in the companion paper [9], the classical analysis breaks down as the current approaches the diffusion-limited current, $j \to 1$. One sign of the problem is that the charge density at $j = 1$ grows near the cathode ($x \to 0$),

$$\rho = \epsilon^2 \frac{d^2\phi}{dx^2} \sim \frac{\epsilon^2}{x^2}. \tag{22}$$

The classical assumption of charged boundary layers of $O(\epsilon)$ width, therefore, fails because the charge density, $\rho = O(1)$, would be much larger than the salt concentration, $c \sim 2x = O(\epsilon)$, at $x = O(\epsilon)$, which violates bulk electroneutrality. This paradox, noted by Levich [14], was resolved by Smyrl and Newman [15], who realized that the structure of the double layer must change near the classical limiting current. In particular, the width of the diffuse part expands to $x = O(\epsilon^{2/3})$, beyond which the bulk charge density remains small, $\rho = O(\epsilon^{2/3})$, as shown in Figure 2. Here, we revisit this problem with more general boundary conditions and also consider currents above the classical limiting current.

Mathematically, the classical asymptotics fails because a new distinguished limit for the master equation appears as $j \to 1$. Rescaling the master equation using $x = \epsilon^{2/3} z$ gives us

$$-\frac{d^3\phi}{dz^3} + \frac{1}{2}\left(\frac{d\phi}{dz}\right)^3 + \frac{\underline{c}_o}{\epsilon^{2/3}}\frac{d\phi}{dz} + 2jz\frac{d\phi}{dz} = 2j, \tag{23}$$

which implies that we have a meaningful distinguished limit if $\underline{c}_o = O(\epsilon^{2/3})$ or, equivalently, $j = 1 - O(\epsilon^{2/3})$. In this regime, the double layer is no longer in Poisson–Boltzmann equilibrium at leading order, and the potential satisfies the more general equation, (23), for $z = O(1)$ or $x = O(\epsilon^{2/3})$.

Unfortunately, at this scale, *all* terms in (23) are $O(1)$, so we are forced to solve the full equation. Although general solutions can be expressed in terms of Painlevé's transcendents [8, 18, 25], these are not convenient for applying our nonlinear boundary conditions or obtaining physical insight. Even when $\underline{c}_o = o(\epsilon^{2/3})$, we are left with a

complicated differential equation which does not admit a simple analytical solution. However, in the case $\underline{c}_o = o(\epsilon^{2/3})$, it is possible to study the asymptotic behavior of the solution in the limits $z \to 0$ and $z \to \infty$ by considering the behavior of the *neighboring* asymptotic layers.

3.2. Nested boundary layers when $|1 - j| = o(\epsilon^{2/3})$. The appearance of the new distinguished limit for $j = 1 - O(\epsilon^{2/3})$ does not destroy the ones that exist in the classical analysis. In particular, the $O(\epsilon)$ boundary layer at $x = 0$ does *not* vanish. This inner layer was overlooked by Smyrl and Newman because they assumed a fixed surface charge density given by the equilibrium zeta potential [15], rather than more realistic boundary conditions allowing for surface charge variations and electrochemical reactions.

In the general case, a set of nested boundary layers must exist when the current is near (or above) the classical limiting current. For convenience, we shall refer to the $x = O(\epsilon^{2/3})$ and the $x = O(\epsilon)$ regions as the "Smyrl–Newman" and "inner diffuse" layers, respectively. It is important to realize that, without the inner layer, it would be impossible to satisfy any reasonable boundary conditions describing the electrochemical reactions which support the current. In the Smyrl–Newman layer, the concentration of the active species (here, cations) nearly vanishes at the limiting current, since $\underline{c}_0 = O(\epsilon^{2/3})$, but this would imply a very small reaction rate density. The paradox of the original Smyrl–Newman solution (which ignores reactions) is that there are very few ions available at the cathode, and yet there is a very large reaction rate and current. The resolution involves an inner layer where the cation concentration increases to $O(1)$.

In the context of our model of electrochemical reactions, we can also understand the nested boundary layers on mathematical grounds. Consider the reaction boundary condition at the cathode, (12). To estimate the c and ρ at the electrode surface, we rescale (17) and Poisson's equation using $x = \epsilon^{2/3} z$ to obtain

$$c = \underline{c}_o + 2j\epsilon^{2/3} z + \frac{\epsilon^{2/3}}{2}\left(\frac{d\phi}{dz}\right)^2, \tag{24}$$

$$\rho = -\epsilon^{2/3}\frac{d^2\phi}{dz^2}, \tag{25}$$

which means that the concentration and charge density are both $O(\epsilon^{2/3})$ since $\underline{c}_o = o(\epsilon^{2/3})$ when $|1 - j| = o(\epsilon^{2/3})$. Then, from the Stern boundary condition, we have $\phi(0) = -\delta\epsilon\bar{E} = -\delta\epsilon^{1/3}\grave{E} = O(\delta\epsilon^{1/3})$. Plugging these estimates into the reaction boundary condition, we find

$$k_c O(\epsilon^{2/3}) e^{\alpha_c \delta \epsilon^{1/3}\grave{E}(0)} = j + j_r e^{-\alpha_a \delta\epsilon^{1/3}\grave{E}(0)} = O(1). \tag{26}$$

This equation cannot be satisfied in the limit $\epsilon \to 0$ with $\delta \geq 0$ fixed, which implies the existence of the inner diffuse layer. In the Gouy–Chapman model without any compact layer ($\delta = 0$), (26) reduces to a contradiction, $O(\epsilon^{2/3}) = j = \text{constant}$, and thus implies the existence of the inner diffuse layer. In the Stern model ($\delta > 0$), it can only be satisfied for very large values, $\delta = O(|\log \epsilon^{2/3}|/\epsilon^{1/3})$, but, since δ is fixed, the nested inner layer must appear as $\epsilon \to 0$. However, this calculation predicts that the magnitude of the concentration at the cathode (within the inner layer) decreases with increasing δ, which is clearly seen in the numerical solutions of Figure 3.

To analyze (23), it is convenient to focus on the electric field rather than the

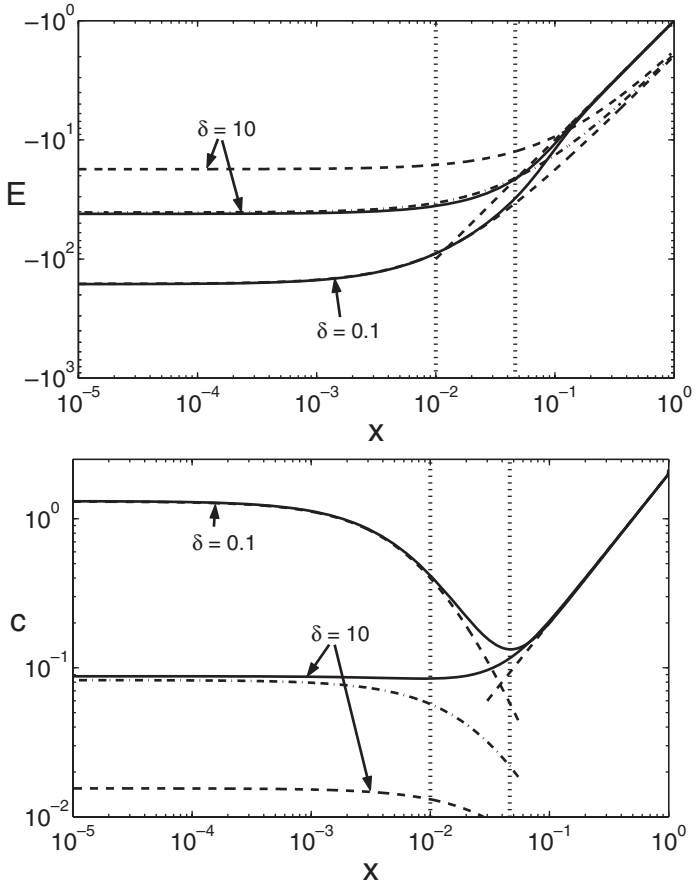

FIG. 3. *Numerical solutions (solid lines) for the dimensionless electric field $E(x)$ and concentration $c(x)$ at the classical diffusion-limited current ($j = 1$) compared with leading-order asymptotic approximations (dashed and dot-dashed lines) for $k_c = 1$, $j_r = 2$, $\epsilon = 0.01$, and $\delta = 0.1, 10$. The leading-order bulk approximations for $E(x)$ and $c(x)$ are given by* (28) *and $c(x) = 2jx$, respectively. In the diffuse layer, the leading-order approximations are given by* (30) *and* (31). *For the $\delta = 10$ curves, the difference between the dashed and dot-dashed curves is that the dashed curve uses an approximate value for B given by* (36), *while the dot-dashed curve uses a B value calculated by numerically solving* (33). *For reference, the vertical lines show where $x = \epsilon$ and $x = \epsilon^{2/3}$. The thin anode diffuse-layer field is not shown.*

potential. In terms of the scaled electric field, $\grave{E}(z) \equiv -\frac{d\phi}{dz} = \epsilon^{2/3} E(x)$, (23) becomes

$$\frac{d^2\grave{E}}{dz^2} - \frac{1}{2}\grave{E}^3 - 2j(z\grave{E} + 1) = \frac{\mathrm{c}_o}{\epsilon^{2/3}}\grave{E}, \tag{27}$$

which we shall refer to as the "Smyrl–Newman equation." From (71) in [9], we know that the first few terms in the expansion for the bulk electric field at the limiting current are

$$\begin{aligned} -\bar{E}(x) &= \frac{1}{x} + \frac{3\epsilon^2}{4x^4} + \frac{111\epsilon^4}{16x^7} + \frac{6045\epsilon^6}{32x^{10}} + \cdots \\ &= \frac{1}{\epsilon^{2/3}}\left(\frac{1}{z} + \frac{3}{4z^4} + \frac{111}{16z^7} + \frac{6045}{32z^{10}} + \cdots\right). \end{aligned} \tag{28}$$

Since the second series is asymptotic for $z \gg 1$, the expansion in the bulk is valid for $x \gg \epsilon^{2/3}$. In order to match the solution in the Smyrl–Newman layer to the bulk, we expect the asymptotic solution to (27) as $z \to \infty$ to be given by the expression in parentheses in (28). We could also have arrived at this result by directly substituting an asymptotic expansion in $1/z$ and matching coefficients. As we can see in Figure 3 the leading-order term in (28) is a good approximation to the exact solution in the bulk and is matched by the solution in the Smyrl–Newman layer as it extends into the bulk.

We now turn our attention towards the "inner diffuse" layer, which gives us the asymptotic behavior of the Smyrl–Newman equation in the limit $z \to 0$. Introducing the scaled variables $y = x/\epsilon = z/\epsilon^{1/3}$ and $\breve{E} = \epsilon\bar{E} = \epsilon^{1/3}\grave{E}$, (27) becomes

$$\frac{d^2\breve{E}}{dy^2} - \frac{1}{2}\breve{E}^3 - 2j\epsilon(y\breve{E} + 1) = \underline{c}_o\breve{E}. \tag{29}$$

Near the limiting current (i.e., $\underline{c}_o = O(\epsilon^{2/3})$), $\breve{E}$ satisfies $\frac{d^2\breve{E}}{dy^2} = \frac{1}{2}\breve{E}^3$ at leading order with the boundary condition $\breve{E} \to 0$ as $y \to \infty$ from the matching condition that $\grave{E}$ remains bounded as $z \to 0$. Integrating this equation twice with the observation that $\frac{d\breve{E}}{dy} > 0$ gives us

$$\breve{E}(y) \sim -\frac{2}{y+b}, \tag{30}$$

where b is a constant determined by applying the Butler–Volmer reaction boundary condition at the cathode. We can estimate $\breve{c}(y)$ and $\breve{\rho}(y)$ by substituting (30) into (17) and Poisson's equation to find

$$\breve{c}(y) = \underline{c}_o + 2jx + \frac{\epsilon^2}{2}\bar{E}(x)^2 = \underline{c}_o + 2j\epsilon y + \frac{1}{2}\breve{E}(y)^2 = \frac{2}{(y+b)^2} + O(\epsilon), \tag{31}$$

$$\breve{\rho}(y) = \epsilon^2\frac{d\bar{E}}{dx} = \frac{d\breve{E}}{dy} = \frac{2}{(y+b)^2} + O(\epsilon). \tag{32}$$

Therefore, b satisfies the following transcendental equation at leading order:

$$k_c\frac{4}{b^2}e^{2\alpha_c\delta/b} = j + j_r e^{-2\alpha_a\delta/b}. \tag{33}$$

While this equation does not admit a simple closed-form solution, we can compute approximate solutions in the limits of small and large δ values. In the small δ limit, we can linearize (33) and expand b in a power series in δ to obtain

$$b \sim 2\sqrt{\frac{k_c}{j+j_r}} + \delta\left(\alpha_c + \frac{\alpha_a j_r}{j+j_r}\right) + O(\delta^2). \tag{34}$$

At the other extreme, for $\delta \gg 1$, (33) can be approximated by

$$k_c\frac{4}{b^2}e^{2\alpha_c\delta/b} \approx j. \tag{35}$$

Then, using fixed-point iteration on the approximate equation, we find that

$$b \sim \frac{2\alpha_c\delta}{\log\kappa - 2\log\log\kappa + O\left(\log\log\log\delta^2\right)}, \tag{36}$$

where $\kappa \equiv j\alpha_c^2\delta^2/k_c$. Figure 3 shows that the leading-order approximation (30) is very good in the inner diffuse layer as long as an accurate estimate for b is used. While the small δ approximation for b is amazingly good (the asymptotic and numerical solutions are nearly indistinguishable), the large δ estimate for b is not as good but is only off by an $O(1)$ multiplicative factor.

Before moving on, it is worth noting that the asymptotic behavior of the concentration and charge density in the Smyrl–Newman layer as $z \to 0$ and $z \to \infty$ suggests that the charge density is low throughout the entire Smyrl–Newman layer. Figure 3 shows how the Smyrl–Newman layer acts as a transition layer, allowing the bulk concentration to become small near the cathode while still ensuring a sufficiently high cation concentration at the cathode surface to satisfy the reaction boundary conditions. The transitional nature of the Smyrl–Newman layer becomes even more pronounced for smaller values of ϵ.

4. Bulk space charge above the limiting current, $1 + O(\epsilon^{2/3}) \ll j \ll O(1/\epsilon)$. As current exceeds the classical limiting value, the overlap region between the inner diffuse and Smyrl–Newman layers grows to become a layer having $O(1)$ width. Following other authors [16, 22], we shall refer to this new layer as the "*space-charge*" layer because, as we shall see, it has a nonnegligible charge density compared to the rest of the bulk. Therefore, in this current regime, the central region of the electrochemical cell is split into two pieces having $O(1)$ width separated by an $o(1)$ transition layer.

In the bulk, the solution remains unchanged except that $\underline{c}_o$ cannot be approximated by $1 - j$; the contribution from the integral term is no longer negligible. The need for this correction arises from the high electric fields required to drive current through the electrically charged space-charge layer. With this minor modification, we find that the bulk solution is

$$\begin{aligned} \bar{c}(x) &= \underline{c}_o + 2jx, \\ \bar{E}(x) &= \frac{1}{x_o - x}, \end{aligned} \tag{37}$$

where $x_o \equiv -\underline{c}_o/2j$ is the point where the bulk concentration vanishes (see Figure 4).

Between the two $O(1)$ layers, there is a small transition layer. Rescaling the master equation using the change of variables $z = (x - x_o)/\epsilon^{2/3}$ and $\acute{E}(z) = \epsilon^{2/3}\bar{E}(x)$, we again obtain the Smyrl–Newman equation, (27), with right-hand side equal to zero. As before, we find that the solution in the transition layer approaches $-1/z$ as $z \to \infty$. In the other direction as $z \to -\infty$, we will find that the appropriate boundary condition is $\acute{E} \to -2\sqrt{j|z|}$ to match the electric field in space-charge layer.

4.1. Structure of the space-charge layer. Physically, we could argue that the concentration of ions in the space-charge layer is very small (i.e., zero at leading order) because the layer is essentially the result of stretching the ionic content of the overlap between the inner diffuse and Smyrl–Newman layers, which is small to begin with, over an $O(1)$ region. This physical intuition is confirmed by the numerical solutions shown in Figures 4, 5, and 6. Therefore, using (17), we obtain the leading-order solution for the electric field

$$\tilde{E} \sim \frac{-2\sqrt{j\,(x_o - x)}}{\epsilon}. \tag{38}$$

Note that the magnitude of the field is exactly what is required to make the integral term in $\underline{c}_o$ an $O(1)$ contribution. From this formula, it is easy to compute the charge

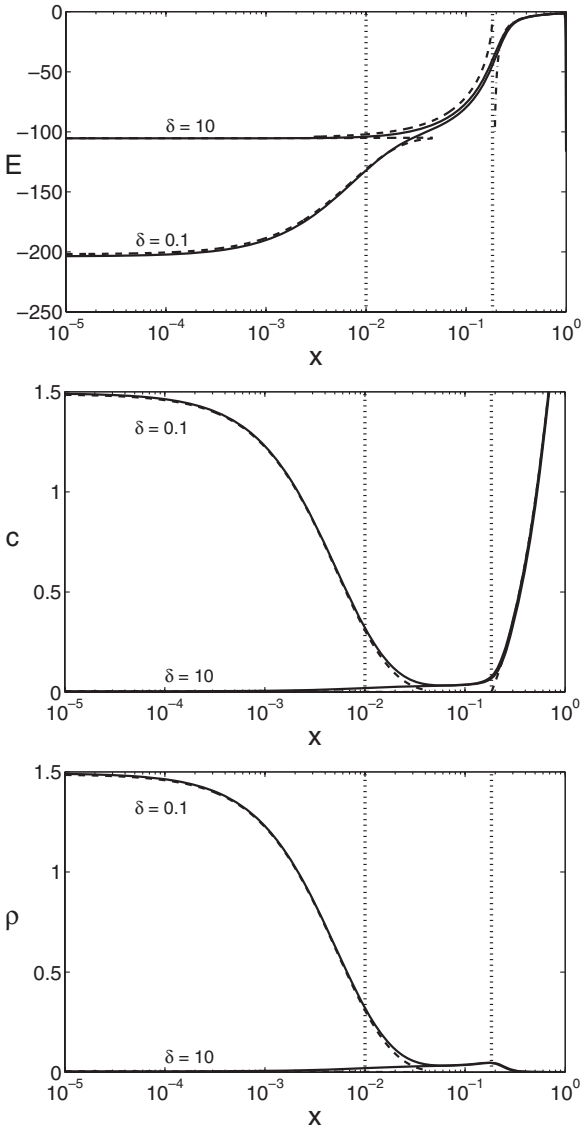

FIG. 4. *Numerical solutions (solid lines) for the dimensionless electric field $E(x)$, average concentration $c(x)$, and charge density $\rho(x)$ above the diffusion-limited current ($j = 1.5$) compared with leading-order asymptotic approximations (dashed lines) for $k_c = 1$, $j_r = 2$, $\epsilon = 0.01$, and $\delta = 0.1, 10$. The leading-order bulk approximations are given by* (37)*. In the space-charge layer, the leading-order electric field is given by* (38)*, and leading-order concentration is* 0*. Finally,* (58) *and* (59) *are the diffuse-layer asymptotic approximations for the electric field and concentration, respectively. For reference, the vertical lines show where $x = \epsilon$ and $x = x_o$.*

density in the space-charge layer:

$$\tilde{\rho} = \epsilon^2 \frac{d\tilde{E}}{dx} \sim \epsilon \sqrt{\frac{j}{x_o - x}}, \tag{39}$$

which is an order of magnitude larger than the $O(\epsilon^2)$ charge density in the bulk. The $O(\epsilon)$ charge density also implies that the concentration must be at least $O(\epsilon)$ because

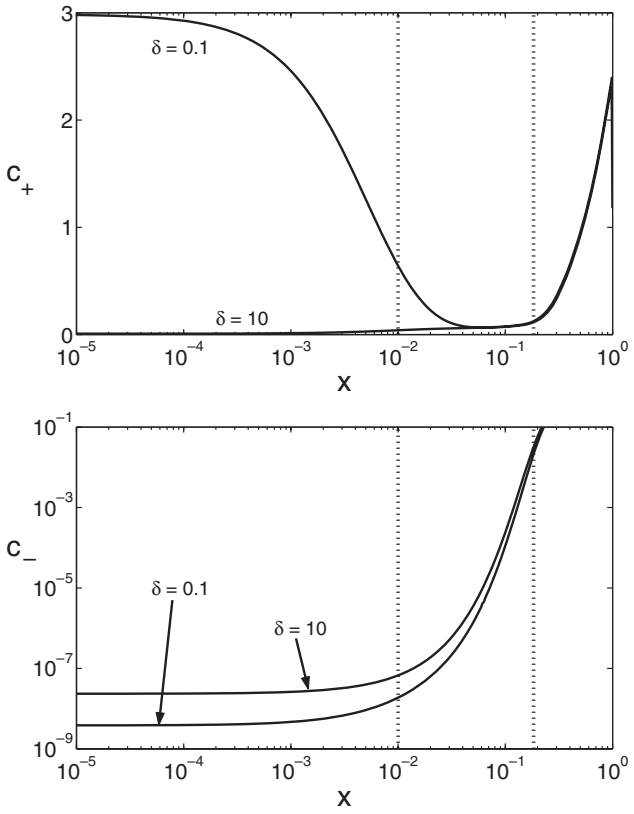

FIG. 5. *Numerical solutions for the dimensionless cation and anion concentrations above the diffusion-limited current ($j = 1.5$) for $k_c = 1$, $j_r = 2$, $\epsilon = 0.01$, and $\delta = 0.1, 10$. For reference, the vertical lines show where $x = \epsilon$ and $x = x_o$.*

the anion concentration, $c - \rho$, is positive.

With the electric field given by (38), we can determine the values of x_o and $\underline{c}_o$ by solving the system of equations given by the definition of x_o and $\underline{c}_o$. Using (18) to calculate $\underline{c}_o$ and noticing that the leading-order contribution to the integral comes from the space-charge layer, we obtain

$$\underline{c}_o \sim 1 - j\left(1 + x_o^2\right). \tag{40}$$

Combining this result with $x_o = -\underline{c}_o/2j$, we find that

$$x_o \sim 1 - j^{-1/2}, \qquad \underline{c}_o \sim 2(j^{1/2} - j), \tag{41}$$

which can be substituted into (37) and (38) to yield the leading-order solutions in the bulk and space-charge layers. It should be noted that the expression for x_o is consistent with the estimate for the width found by Bruinsma and Alexander [21] and Chazaviel [22] in the limits $j - 1 \ll 1$ and small space-charge layer ($x_o \ll 1$), although our analysis also applies to much larger voltages.

The results obtained via physical arguments in the previous few paragraphs motivate an asymptotic series expansion for E whose leading-order term is $O(1/\epsilon)$. Moreover, because we want to be able to balance the current density at second order, we

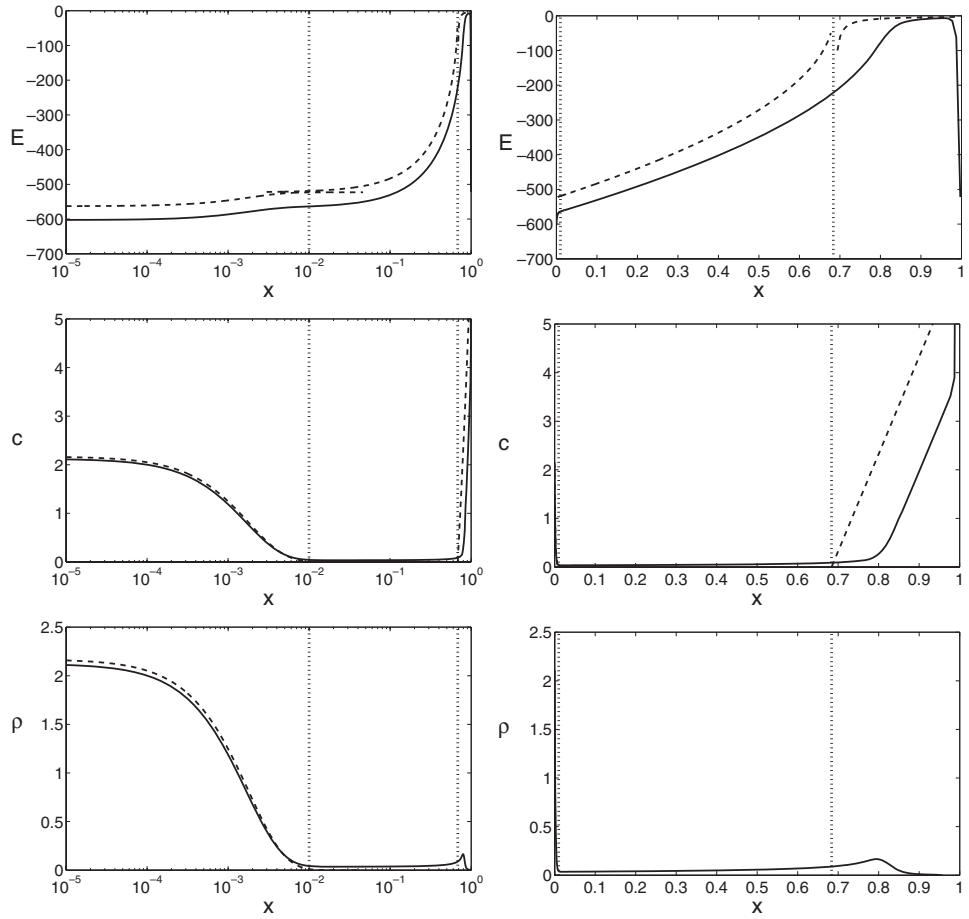

FIG. 6. *Numerical solutions (solid lines) for the dimensionless electric field $E(x)$, average concentration $c(x)$, and charge density $\rho(x)$ far above the diffusion-limited current ($j = 10.0$) compared with leading-order asymptotic approximations (dashed lines) for $k_c = 1$, $j_r = 2$, $\epsilon = 0.01$, and $\delta = 0.1$. Each field is shown twice:* (1) *with x on* log *scale to focus on the cathode region and* (2) *with x on a linear scale to emphasize the interior of the cell. Note that $j\epsilon = 0.1$, so the asymptotic approximations are not as good as at lower current densities. For reference, the vertical lines show where $x = \epsilon$ and $x = x_o$.*

choose the second-order term to be $O(j)$. Thus, we have

$$\tilde{E} = \frac{1}{\epsilon} E_{-1} + E_0 j + \cdots . \tag{42}$$

Note that in this asymptotic series, the first term dominates the second term only as long as $j \ll 1/\epsilon$, so the following analysis holds exclusively for current densities far below $O(1/\epsilon)$. Figure 6 illustrates the breakdown of the leading-order asymptotic solutions at very high current densities. While the qualitative features of the asymptotic approximation are correct (e.g., the shape of $E(x)$ in the diffuse layer and the slope of $c(x)$ in the bulk), the quality of the approximation is clearly less than at lower values of j.

The key advantage of a more systematic asymptotic analysis is that we are able to calculate the leading-order behavior of the space-charge layer concentration $\tilde{c}$, which

is not possible with only knowledge of the leading-order behavior for the electric field. Substituting (42) into the master equation (20), it is straightforward to obtain

$$\tilde{E} \sim -\frac{2}{\epsilon}\sqrt{j\,(x_o - x)} - \frac{1}{2\,(x_o - x)} + \cdots . \tag{43}$$

Using this expression in (17), we find the dominant contribution to $\tilde{c}$ is exactly the same as $\tilde{\rho}$:

$$\tilde{c} \sim \epsilon\sqrt{\frac{j}{x_o - x}}. \tag{44}$$

Since $c_- = c - \rho$, this result leads to an important physical conclusion: *The space-charge layer is essentially depleted of anions*, $c_- = o(\epsilon)$, as is clearly seen in Figures 4 and 5. This contradicts our macroscopic intuition about electrolytes, but, in very thin films, complete anion deplection might occur. For example, in a microbattery developed for on-chip power sources using the $Li/SiO_2/Si$ system, lithium ion conduction has recently been demonstrated in nanoscale films of silicon oxide, where there should not be any counterions or excess electrons [6].

At leading order as $\epsilon \to 0$, the anion concentration, c_-, can be set to zero in the space-charge layer, leaving the following two governing equations:

$$\frac{dc_+}{dx} + c_+\frac{d\phi}{dx} = 4j, \tag{45}$$

$$-\epsilon^2\frac{d^2\phi}{dx^2} = \frac{1}{2}c_+. \tag{46}$$

As with the binary electrolyte case, these equations can be reduced to a single equation for the electric potential:

$$\frac{d^3\phi}{dx^3} + \frac{d^2\phi}{dx^2}\frac{d\phi}{dx} = -\frac{2j}{\epsilon^2}. \tag{47}$$

Integrating this equation once, we obtain a Riccati equation for $\frac{d\phi}{dx}$:

$$\frac{d^2\phi}{dx^2} + \frac{1}{2}\left(\frac{d\phi}{dx}\right)^2 = -\frac{2j}{\epsilon^2}\,(x - x_o) + h, \tag{48}$$

where h is an integration constant. Using the transformations

$$u \equiv e^{\phi/2}, \qquad z \equiv -\frac{j^{1/3}}{\epsilon^{2/3}}\,(x - x_o) + \frac{\epsilon^{4/3}h}{2j^{2/3}}, \tag{49}$$

we find that u satisfies Airy's equation,

$$\frac{d^2u}{dz^2} - zu = 0. \tag{50}$$

Thus, the general solution for $\phi(x)$ is

$$\phi(x) = 2\log\left[a_1 Ai\left(\frac{j^{1/3}}{\epsilon^{2/3}}\,(x_o - x) + \beta h\right) + a_2 Bi\left(\frac{j^{1/3}}{\epsilon^{2/3}}\,(x_o - x) + \beta h\right)\right], \tag{51}$$

where a_1 and a_2 are constants determined by boundary conditions and $\beta = \frac{\epsilon^{4/3}}{2j^{2/3}}$.

To simplify this expression, note that in the limit $\epsilon \to 0$, the potential drop between $x = x_o$ and $x = 0$ is approximately

$$\phi(x_o) - \phi(0) \sim 2\log\left[\frac{a_1 Ai(0) + a_2 Bi(0)}{a_1 Ai\left(\frac{x_o j^{1/3}}{\epsilon^{2/3}}\right) + a_2 Bi\left(\frac{x_o j^{1/3}}{\epsilon^{2/3}}\right)}\right]. \tag{52}$$

Now, using the large argument behavior of the Airy functions, we see that as $\epsilon \to 0$, the argument of the logarithm approaches zero. Thus, we are lead to the conclusion that the electric potential at $x = x_o$ is less than at $x = 0$. However, this is completely inconsistent with our physical intuition and the numerical results, which show that $\phi(x_o) - \phi(0) > 0$. Therefore, it must be the case that $a_2 \approx 0$, so that

$$\phi(x) = 2\log\left[a_1 Ai\left(\frac{j^{1/3}}{\epsilon^{2/3}}(x_o - x) + \beta h\right)\right] \tag{53}$$

and

$$E(x) = \frac{2j^{1/3}}{\epsilon^{2/3}} \frac{Ai'\left(\frac{j^{1/3}}{\epsilon^{2/3}}(x_o - x) + \beta h\right)}{Ai\left(\frac{j^{1/3}}{\epsilon^{2/3}}(x_o - x) + \beta h\right)}. \tag{54}$$

In principle, the integration constants h and a_1 can be determined by matching to the inner diffuse layer, $x = O(\epsilon)$ (described below), and the bulk transition layer, $|x_0 - x| = O(\epsilon^{2/3})$ (described above). Here, the main point is that the leading-order approximation for the electric field when the region is depleted of anions is exactly (38), which follows from the asymptotic form of $Ai(z)$ and $Ai'(z)$ as $z \to \infty$ in (54). The equivalence of the single-ion equations and the full governing equations at leading order mathematically confirms the physically interpretation of the space-charge layer as a region of anion depletion.

4.2. Boundary layers above the limiting current. To complete our analysis of the high-current regime, $1 + O(\epsilon^{2/3}) \ll j \ll O(1/\epsilon)$, we must consider the boundary layers. At the anode, all fields are $O(1)$, so we recover the usual Gouy–Chapman solution with the minor modification that $c_1 = 2\sqrt{j}$, which is the value $\bar{c}$ takes as $x \to 1$. The cathode structure, however, is much more interesting because it is depleted of anions (see Figure 5). To our knowledge, this nonequilibrium inner boundary layer on the space-charge region, related to the reaction boundary condition at the cathode, has not been analyzed before.

As in the space-charge layer, the leading-order governing equations in this layer are those of a single ionic species with no counterions (45) and (46). Rescaling those equations using $x = \epsilon y$, we obtain

$$\frac{d\check{c}_+}{dy} + \check{c}_+ \frac{d\check{\phi}}{dy} = 4j\epsilon \approx 0, \tag{55}$$

$$-\frac{d^2\check{\phi}}{dy^2} = \frac{1}{2}\check{c}_+. \tag{56}$$

From these equations, it is immediately clear that the cations have a Boltzmann equilibrium profile at leading order: $c_+ \propto e^{-\phi(y)}$. As in the analysis for the space-charge layer, it is possible to find a general solution to (55) and (56). By combining

these equations and integrating, we find that the potential in the cathode boundary layer has the form

$$\check{\phi} \sim \log\left[\sinh^2(py+q)\right] + r, \tag{57}$$

where p, q, and r are integration constants. Therefore, the electric field and concentration are

$$\check{E}(y) \sim -2p\coth(py+q), \tag{58}$$

$$\check{c}(y) = \frac{1}{2}\check{c}_+(y) \sim \frac{2p^2}{\sinh^2(py+q)}. \tag{59}$$

Matching the electric fields in the diffuse and space-charge layers, we find that $p \sim \sqrt{jx_o}$. Note that because $p = O(\sqrt{j})$, the electric field in the diffuse charge layer is $O(\sqrt{j}/\epsilon)$, which is the same order of magnitude as in the space-charge layer. To solve for q, we use the expression for p in the cathode Stern and Butler–Volmer boundary conditions, which leads to the following nonlinear equation:

$$\frac{4k_c j x_o}{\sinh^2 q}\exp\left(2\alpha_c\delta\sqrt{jx_o}\coth q\right) - j_r\exp\left(-2\alpha_a\delta\sqrt{jx_o}\coth q\right) = j. \tag{60}$$

In the limit of small δ, we can use fixed-point iteration to obtain an approximate solution,

$$q \sim \sinh^{-1}\left(2\sqrt{\frac{k_c j x_o\exp\left(2\alpha_c\delta\sqrt{jx_o}\coth q_o\right)}{j + j_r\exp\left(-2\alpha_a\delta\sqrt{jx_o}\coth q_o\right)}}\right), \tag{61}$$

where q_o has the same form as q with $(\coth q_o)$ set equal to 1. For $\delta \gg 1$, the leading-order equation is

$$\frac{4k_c j x_o}{\sinh^2 q}\exp\left(2\alpha_c\delta\sqrt{jx_o}\coth q\right) \sim j, \tag{62}$$

which implies that $q \gg 1$, so that the left-hand side can be small enough to balance the current. Thus, by using $\coth q \approx 1$ and $\sinh q \approx \exp(q)/2$, we find that $q \sim \alpha_c\delta\sqrt{jx_o} + \frac{1}{2}\log(16k_c x_o)$. The agreement of these asymptotic approximations with the numerical solutions in the diffuse charge layer is illustrated in Figure 4.

5. Polarographic curves. We are now in a position to compute the leading-order behavior of the polarographic curve at and above the classical limiting current. Recall that the formula for the cell voltage is given by

$$v = -\delta\epsilon E(0) + \int_0^1 -E(x)dx - \delta\epsilon E(1). \tag{63}$$

The integral is the voltage drop through the interior of the cell, and the first and last terms account for the potential drop across the Stern layers.

At the limiting current, $j = 1$, we can estimate the voltage drop across the cell by using the bulk and diffuse-layer electric field to approximate the field in the Smyrl–Newman transition layer to obtain

$$v \sim -\delta\epsilon E(0) + \int_0^{\epsilon^{2/3}} -E(x)dx + \int_{\epsilon^{2/3}}^1 -E(x)dx - \delta\epsilon E(1) \tag{64}$$

$$\sim 2\frac{\delta}{b} + 2\log\left(\frac{\epsilon^{-1/3}+b}{b}\right) - \frac{2}{3}\log\epsilon. \tag{65}$$

Notice that in the small δ limit, this expression reduces to $v \sim -\frac{4}{3}\ln\epsilon$ as $\epsilon \to 0$. The

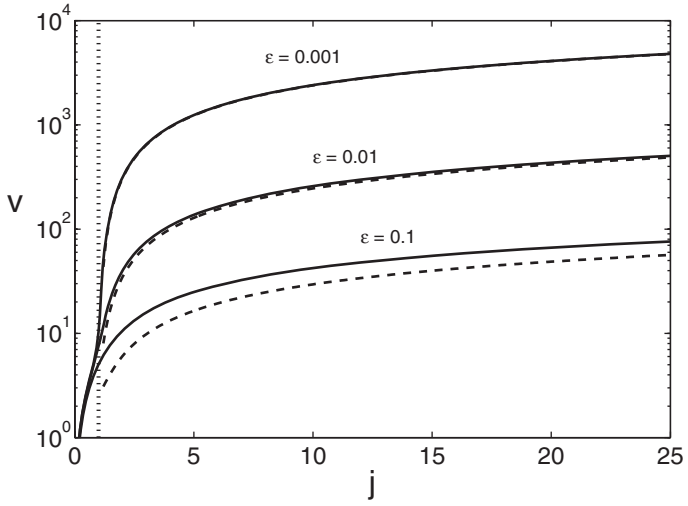

FIG. 7. *Comparison of numerical polarographic curves (dashed lines) with leading-order asymptotic approximations (solid lines) given in* (66) *for several values of* ϵ *with* $\delta = 1.0$, $k_c = 1$, *and* $j_r = 2$. *For* $\epsilon = 0.001$, *the numerical and asymptotic polarographic curves are indistinguishable on this graph. 1e-1	10.0	7.995	6.327	16.088	13.146

dependence, $v(j = 0) \propto \ln \epsilon$, is clear in the numerical polarographic curves shown in Figure 7. (See also Figure 4 of the companion paper [9].) Table 1 compares this approximation with the exact cell voltage for a few ϵ and δ values. For small ϵ values ($\epsilon \leq 0.01$), the asymptotic approximations are fairly good (within 5% to 10%).

Above the limiting current, the space-charge layer makes the dominant contribution to the cell voltage. Using (37) and (38) in the formula for the cell voltage, we find that

$$v \sim \frac{4\sqrt{j}}{3\epsilon}\left(1 - j^{-1/2}\right)^{3/2} + 2\delta\left(j - \sqrt{j}\right)^{1/2}\coth q - \frac{1}{2}\log j - 2/3\log\epsilon. \tag{66}$$

The first two terms in this expression estimate the voltage drop across the space-charge and the cathode Stern layers, respectively. The last two terms are the subdominant

contribution from the bulk where we have somewhat arbitrarily taken $x = x_o + \epsilon^{2/3}$ as the boundary between the bulk layer and the Smyrl–Newman transition layer. Notice that we ignore the contribution from the cathode diffuse and Smyrl–Newman layers. It is safe to neglect the diffuse layer because it is an $O(1)$ contribution. However, the Smyrl–Newman layer has a nonnegligible potential drop that we have to accept as error since we do not have an analytic form for the solution in that region.

Figure 7 shows that the asymptotic polarographic curves are quite accurate for sufficiently small ϵ values. In Table 1, we compare the results predicted by the asymptotic formula with numerical results for a few specific values of ϵ and δ. It is interesting that the approximation is also better for large δ values (we explain this observation in the next section). Also, while the $\log \epsilon$ term is subdominant, it makes a significant contribution to the cell voltage for ϵ values as small as 0.01.

As with the width of the space-charge layer, x_o, our expression for the cell voltage, (66), is consistent with the results of Bruinsma and Alexander [21] and Chazaviel [22] near the limiting current, $j \to 1^+$, while remaining valid at much larger currents, $j = O(1/\epsilon)$.

6. Effects of the Stern-layer capacitance. The inclusion of the Stern layer in the boundary conditions allows us to explore the effects of the intrinsic surface capacitance on the structure of the cell. From Figures 3 through 5, we can see that smaller Stern-layer capacitances (i.e., larger δ values) decrease the concentration and electric-field strength in the cathode diffuse layer. This behavior arises primarily from the influence of the electric field on the chemical kinetics at the electrode surfaces. When the capacitance of the Stern layer is low, small electric fields at the cathode surface translate into large potential drops across the Stern layer, (10), which help drive the deposition reaction, (12). As a result, neither the electric field nor the cation concentration need to be very large at the cathode to support high-current densities. These results confirm our physical intuition that it is only important to pay attention to the diffuse layer when the Stern-layer potential drop is negligible (i.e., $\delta \ll 1$).

At high currents, another important effect of the Stern-layer capacitance is that the total cell voltage becomes dominated by the potential drop across the Stern layer at large δ values (i.e., small capacitances). This behavior is clearly illustrated in Figure 8. Notice that for currents below the classical diffusion-limited current, the total cell voltage does not show a strong dependence on δ. However, for $j > 1$, the total cell voltage increases with δ—the increase being driven by the strong δ dependence of the Stern voltage.

7. Conclusion. In summary, we have studied the classical problem of direct current in an electrochemical cell, focusing on the exotic regime of high-current densities. A notable new feature of our study is the use of nonlinear Butler–Volmer and Stern boundary conditions to model a thin film passing a Faradaic current, as in a microbattery. We have derived leading-order approximations for the fields at and above the classical, diffusion-limited current, paying special attention to the structure of the cathodic boundary layer, which must be present to satisfy the reaction boundary conditions. In our analysis of superlimiting current, we have shown that the key feature of the bulk space-charge layer is the depletion of anions. Our exact solution of the leading-order problem in the space-charge region, (51), could thus also have relevance for Faradaic conduction through very thin insulating films.

Using the asymptotic approximations to the fields, we are able to derive a current-voltage relation, (66), which compares well with numerical results, far beyond the limiting current. Combined with the analogous formulae in the companion paper [9],

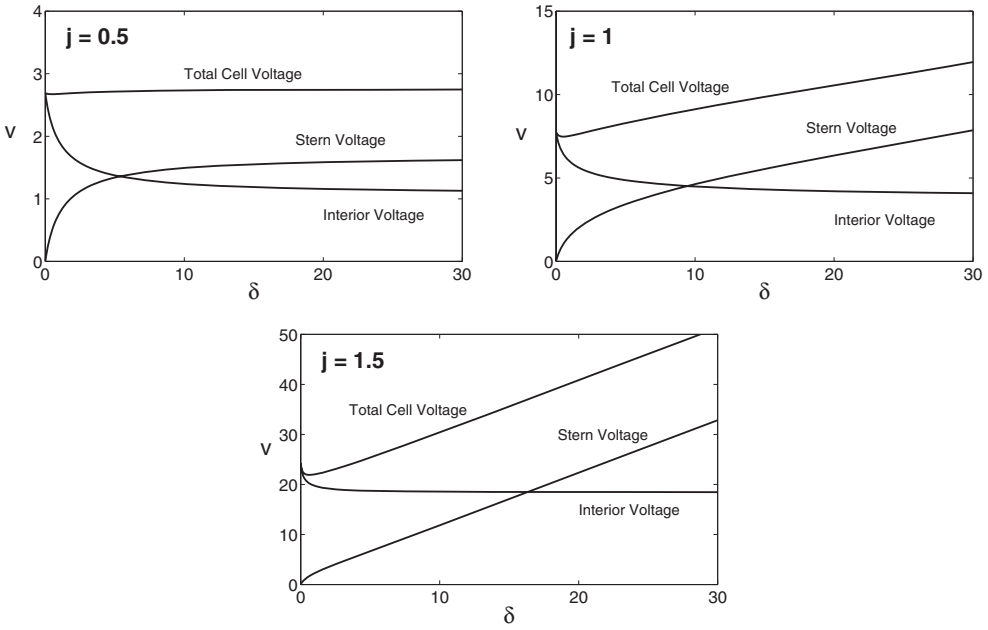

FIG. 8. *These graphs break the total cell voltage into contributions from the cell interior and the Stern layer as a function of* δ *for* $\epsilon = 0.01$, $k_c = 2$, *and* $j_r = 2$. *Note that at and above the classical limiting current, the Stern-layer voltage dominates the total cell voltage for large values of* δ.

which hold below the limiting current, we have essentially analyzed the full range of the current-voltage relation. These results could be useful in interpreting experimental data, e.g., on the internal resistance of thin-film microbatteries.

A general conclusion of this study is that boundary conditions strongly affect the solution. For example, the Stern-layer capacitance, often ignored in theoretical analysis, plays an important role in determining the qualitative structure of the cell near the cathode, as well as the total cell voltage. The nonlinear boundary conditions for Butler–Volmer reaction kinetics also profoundly affect charge distribution and current-voltage relation, compared to the ubiquitous case of Dirichlet boundary conditions. The latter rely on the assumption of surface equilibrium, which is of questionable validity at very large currents.

We leave the reader with a word of caution. The results presented here are valid mathematical solutions of standard model equations, but their physical relevance should be met with some skepticism under extreme conditions, such as superlimiting current. For example, the PNP equations are meant to describe infinitely dilute solutions in relatively small electric fields [7, 28, 29]. Even for quasi-equilibrium double layers, their validity is not so clear when the zeta potential greatly exceeds the thermal voltage, because co-ion concentrations may exceed the physical limit required by discreteness (accounting also for solvation shells) and counterion concentrations may become small enough to violate the continuum assumption. Large electric fields can cause the permittivity to vary, by some estimates up to a factor of ten, as solvent dipoles become aligned. Including such effects, however, introduces further ad hoc parameters into the model, which may be difficult to infer from experimental data. Instead, we suggest using our analytical results (especially current-voltage relations) to test the validity of the basic model equations in thin-film experiments.

THREE-DIMENSIONAL PROBABILITY DENSITY FUNCTIONS VIA TOMOGRAPHIC INVERSION*

JULES S. JAFFE†

Abstract. In many experimental observation systems where the goal is to record a three-dimensional observation of an object, or a set of objects, a lower-dimensional projection of the intended subject is obtained. In some situations only the statistical properties of such objects are desired: the three-dimensional probability density function. This article demonstrates that under special symmetries this function can be obtained from either a one- or two-dimensional probability density function which has been obtained from the observed, projected data. Standard tomographic theorems can be used to guarantee the uniqueness of this function, and a natural basis set can be used in computing the three-dimensional function from the one- or two-dimensional projection. The theory of this inversion is explored using theoretical and computational methods with examples of data taken from scientific experiments.

DOI. 10.1137/S003613990342390X

Introduction. In many experimental observation systems whose goal is to record a "true" three-dimensional observation of an object, or a set of objects, a lower-dimensional projection of the intended subject is obtained. In general, the tomographic inversion theorems for many such systems have been known for some time and have been used to expedite the inversion of projected data sets: one- and two-dimensional projections of such structures to obtain the three-dimensional data (Herman, 1980; Kak and Slaney, 1987). For the most part, the data collection and subsequent inversions have considered the reconstruction of individual three-dimensional structures whose unique features are desired.

An alternate problem which utilizes the exact same tomographic theory arises in a situation where the interest is in some statistical parameterization of a set of three-dimensional objects and where the data that have been measured are lower-dimensional projections of these three-dimensional structures. This is true in certain situations such as the x-ray diffraction of molecules in suspension, where the molecules are assumed to be randomly oriented and the observed diffraction patterns are a result of the incoherent superposition of the magnitude of the Fourier transforms of the various orientations. In this case, the correlation distances between atoms are the desirable parameter, and in favorable situations the relationships between the ensemble of projections and the observed data can be used to infer the average distances between such entities (Hukins, 1981).

Another example concerns the case treated in this article: the recording of the displacements of animals using either optical or acoustic systems. In this situation, one type of desired knowledge is the probability density function for velocities $pdf(\vec{v})$, that is to say, the probability that a given animal is moving with velocity between $\vec{v}$ and $\vec{v}+d\vec{v}$, where $\vec{v}$ is a three-dimensional velocity. Assuming that the system is temporally

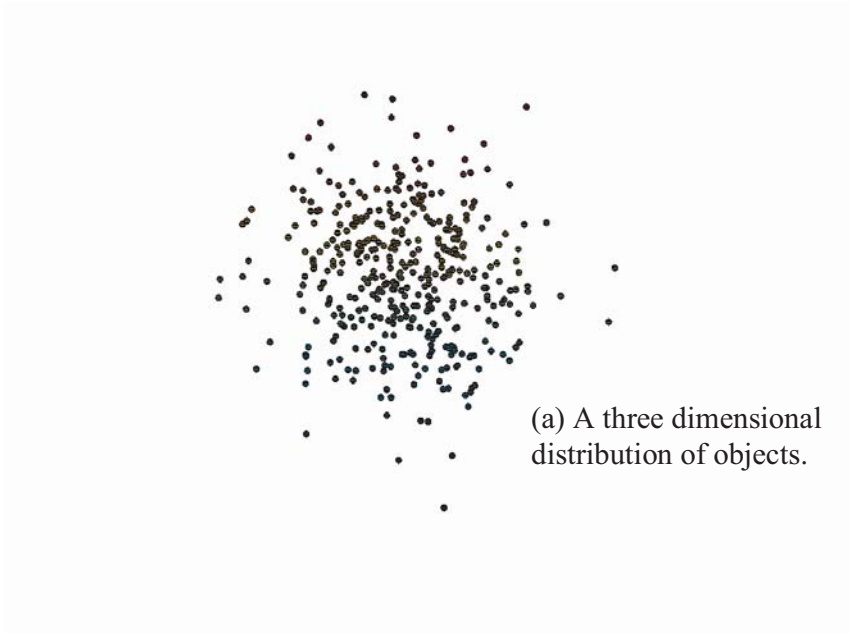

FIG. 1. *A diagram which illustrates the utility of the methodology developed.* (a) *shows a three-dimensional distribution of objects. The distribution can be measured with either* (b) *an essentially one-dimensional sonar system producing a record of animal reflectivity along a line or* (c) *an image of the same phenomenon observed with a camera system.*

stationary, this statistic provides an interesting parameterization of the state of the system. Valuable ecological information can be inferred from such a function which includes the metabolic energy level of the animal (Torres and Childress, 1983) as well as a knowledge of the animal's lifestyle and the factors which govern its success in either foraging or mating.

Two special cases that are treated in the article are illustrated in Figure 1. The native environment for many observational phenomena is three-dimensional. However, in many cases it is much easier to measure either one- or two-dimensional data sets in which the three-dimensional information is embedded. As one example, we remark that the inferences about the behavior of animal aggregations (swarms, flocks)

(Okubo, 1980; Parrish and Edelstein-Keshet, 1999; Parrish and Hamner, 1997) could benefit from the methodology described herein. The figure depicts reflections from an essentially one-dimensional sonar system (b) and images from a camera (c). In the case of the sonar, a very narrow beam can be used to measure the range-dependent locations of animals along a single line. In the case of the camera, the projected two-dimensional locations of the animals can be inferred.

Mathematical formulation. The starting point for our discussion of the algorithm concerns the existence of a data matrix of object positions as a function of time: $\mathcal{R} = \{\vec{r}_{i,j}\}$, where the i,jth element corresponds to the three-dimensional position of object i observed at time t_j. Considering this matrix, a set of displacements can be computed for a set of objects at two time instants, $\{t_j, t_k\}$ as $\{\Delta\vec{r}_i = \vec{r}_{ij} - \vec{r}_{ik} | t_j - t_k, i = 1, M\}$, where there are M objects. Computing this set of displacements over all objects and over all time intervals and assuming temporal stationarity allows the computation of a set of displacements as a function of time interval $\Delta\vec{r}(\Delta T) = \{\Delta\vec{r}_i | \Delta T, i = 1, M\}$. Dividing this data matrix by the time difference $\Delta T = t_j - t_k$ provides an estimate of the instantaneous velocities of the objects. However, we choose to leave the data as positions, as they are a bit easier to visualize.

Forming a histogram of the object displacements provides an estimate of the underlying probability density function for object displacement $pdf(\Delta\vec{r}|\Delta T)$ for a fixed time interval, ΔT. Dividing three-dimensional space into small three-dimensional boxes of dimensions, $\delta\Delta\vec{r}$, the approximate three-dimensional probability density function, derived from the measured data, can be computed by assuming, given $n(\Delta\vec{r})$ as the number of occurrences of the length $\Delta\vec{r}$ in the interval $\Delta\vec{r} - \frac{\delta\Delta\vec{r}}{2} < \Delta\vec{r} \leq \Delta\vec{r} + \frac{\delta\Delta\vec{r}}{2}$, that

$$pdf_{3d}(\Delta\vec{r}|\Delta T) = \lim_{N,t\to\infty} \frac{n(\Delta\vec{r})}{N}.$$

We next consider the data collection process and the consequences of a system that can measure only a subset of the vector components of the range displacement. In one case examined here a set of narrow sonar beams constituted the measurement which transformed the three-dimensional data vector into one that considered only range. A more common occurrence occurs when a conventional optical camera is used to obtain a two-dimensional picture of a set of three-dimensional objects. In this case, a conventional camera system provides a projected view of the animals' three-dimensional positions. In either case, a linear transformation projects the higher-dimensional data onto the measured lower-dimensional coordinates, resulting in a loss of information. For a single object or scene, a multitude of views can be obtained, resulting in a set of projections which can be used to invert for the true three-dimensional object (Kak and Slaney, 1987). In the special case when the object has some inherent degree of symmetry, the structure of the object can be obtained from a reduced set of data. So, for example, in the case of an object which displays complete three-dimensional symmetry, the three-dimensional structure can be obtained from a single projection.

The purpose of this article is to extend the theory of the reconstruction of projected functions to the case of probability density functions. As such, given an ensemble of objects with features $\{\Delta\vec{r}\}$, a probability density function $pdf_{3d}(\Delta\vec{r})$ is used to describe their characteristics. In our case, the resultant measurement of such objects is a new set of objects with reduced dimensionality. This set of objects has lower dimensionality, say ρ (a scalar), and a new and different probability density function

$pdf_{1d}(\rho)$ (in the one-dimensional case) is obtained which is dependent on measurement geometry.

Defining a new matrix $\mathcal{D} = \{\rho_{ij}\}$, where the i,jth element is the projected position of object i at time t_j, the treatment above can be extended in a similar way to obtain an estimate for the probability density function of this one-dimensional function. Given $n(\Delta\rho)$ as the number of occurrences of the length $\Delta\rho$ in the interval $\Delta\rho - \frac{\delta\Delta\rho}{2} < \Delta\rho \leq \Delta\rho + \frac{\delta\Delta\rho}{2}$, then

$$pdf_{1d}(\Delta\rho|\Delta T) = \lim_{N,t\to\infty} \frac{n(\Delta\rho)}{N}.$$

Although we suspect that this theory can be generalized to measurements other than displacements, only the straightforward relationships between the displacements in one, two and three dimensions and their respective probability density functions will be addressed here. In the case of displacement, under the assumption of three-dimensional isotropy, the inversion from $pdf_{3d}(\Delta\rho)$ to $pdf_{3d}(\Delta\vec{r})$ can be formulated using the theory of reconstruction of functions from their projections. The next section demonstrates that the one-dimensional probability density function obtained this way is a projection of the three-dimensional probability density function. Additional theorems are proved relating to our specific formulation as well.

Theorems.

The spherically symmetric case. Our first proof examines the relationship between the three-dimensional probability density function for a fixed time delay ΔT, $pdf_{3d}(\Delta\vec{r}|\Delta T)$, and a one-dimensional projection of it, $pdf_{1d}(\Delta\rho|\Delta T)$. Figure 2 illustrates that the formulation concerns the existence of two sets of data and their respective probability density functions. The two data sets are the "true" three-dimensional set of object displacements which would be obtained from a "true" three-dimensional imaging system $\{\Delta\vec{r}|\Delta T\}$. The measured data $\{\Delta\rho|\Delta T\}$ is obtained via the measurement process $M_{3d\to 1d}$ as shown in the diagram (as, for example, using a pencil sonar beam). The probability density functions, $pdf_{3d}(\Delta\vec{r}|\Delta T)$ and $pdf_{1d}(\Delta\rho|\Delta T)$ are obtained from each of these data sets via the binning transformations as above and represent the underlying statistics of the processes from one point of view. $Pdf_{3d\to 1d}$ is the resultant transformation that occurs when one computes $pdf_{1d}(\Delta\rho|\Delta T)$ from the inherent three-dimensional probability density function by projecting it to a one-dimensional function.

$$\begin{array}{ccc} & M_{3d\to 1d} & \\ \{\Delta\vec{r}|\Delta T\} & \Rightarrow & \{\Delta\rho|\Delta T\} \\ \Downarrow & & \Downarrow \\ & Pdf_{3d\to 1d} & \\ pdf_{3d}(\Delta\vec{r}|\Delta T) & \Rightarrow & pdf_{1d}(\Delta\rho|\Delta T) \end{array}$$

FIG. 2. *A diagram illustrating the relationships (clockwise from upper right) between the data* $\{\Delta\vec{r}|\Delta T\}$*, the projected data* $\{\Delta\rho|\Delta T\}$*, the probability density function for the one-dimensional data* $pdf_{1d}(\Delta\rho|\Delta T)$*, and the probability density function for the three-dimensional data* $pdf_{3d}(\Delta\vec{r}|\Delta T)$*. The transformations* $M_{3d\to 1d}$ *and* $pdf_{1d}(\Delta\rho|\Delta T)$ *are the projection operator on the data set and the projection operator on the three-dimensional data.*

The first theorem concerns the consistency of the above diagram. That is, the arrows indicate that the one-dimensional probability density function can be obtained

in one of two ways: by recording the three-dimensional data and computing the one-dimensional pdf via a projection of the three-dimensional probability density function, or by recording the one-dimensional data and computing the probability density function from this scalar data set. The two methods produce equivalent functions as indicated by the theorem.

THEOREM 1. *The one-dimensional probability density function obtained from the projected data is identical to that obtained via a projection of the three-dimensional probability density function.*

Proof. The question asked here is whether the diagram in Figure 2 "commutes." To demonstrate that this is so, assume an arbitrary three-dimensional probability density function $pdf_{3d}(\Delta\vec{r}|\Delta T)$ and consider a finite realization of this process in that a set of N three-dimensional vectors has been observed, $\{\Delta\vec{r}_1, \Delta\vec{r}_2, \ldots, \Delta\vec{r}_N\}$. From the definition of a probability density function, $pdf_{3d}(\Delta\vec{r}_i) = \lim_{N\to\infty} \frac{n(\Delta\vec{r}_i)}{N}$, where $n(\Delta\vec{r}_i)$ has been defined as the number of occurrences of event $\Delta\vec{r}_i$ in the interval $\Delta\vec{r}_i - \frac{\delta\Delta\vec{r}_i}{2} < \Delta\vec{r}_i \leq \Delta\vec{r}_i + \frac{\delta\Delta\vec{r}_i}{2}$. These cells also have dimensions $\delta\Delta x, \delta\Delta y, \delta\Delta z$, with the corresponding definition of the probability density function as above for $\delta\Delta\vec{r}$. Now the transformation $M_{3d\to 1d}$ maps the data vector $\{\Delta\vec{r}|\Delta T\}$ into $\{\Delta\rho|\Delta T\}$. Without loss of generality, consider the measurement system to be able to resolve objects in the direction Δz so that $\{\Delta\vec{r}|\Delta T\} \to \{\Delta z|\Delta T\}$ and the Δx and Δy components are lost in the measurement process. Then, for a given cell $\delta\Delta z$, $n(\Delta z|\Delta T) = \sum_{\Delta y}\sum_{\Delta x} n(\Delta z, \Delta x, \Delta y|\Delta t)$. Dividing by the total number of observations N and taking the limit $N \to \infty$ permits the integration to be approximated as $\sum_{\Delta y}\sum_{\Delta x} \frac{n(\Delta z,\Delta y,\Delta x|\Delta T)}{N} = \int pdf_{3d}(\Delta\vec{r})dxdy$, which is the marginal probability density function $pdf_{1d}(\Delta z)dxdy$, the projection of $pdf_{3d}(\Delta r)$ onto the z axis. In the limit as $N \to \infty$ the marginal distribution can be computed either directly from the three-dimensional probability density function or by projecting the data to one dimension and then performing the computation of the probability density function.

We next turn our attention to the class of three-dimensional functions which have some special symmetry. The simplest case is when the three-dimensional probability density function has spherical symmetry. In this case, assuming spherical coordinates, the entire function can be represented by a radial slice so that $pdf_{3d}(\Delta\vec{r}) = pdf_{3d}(\rho)$, where ρ is the distance from the origin. Although the ultimate interest is in reconstructing such functions from a single projection, we pause briefly to state and prove a simple theorem.

THEOREM 2. *Given a separable and isotropic probability density function, the projection of the three-dimensional function is identical to the one-dimensional probability density function.*

This theorem is almost trivial to prove; however, we present it for completeness and because it also illustrates the well-known and important fact that if the three-dimensional data are normally distributed, no inversion is necessary, as the one-dimensional probability density function and the three-dimensional probability density function are identical.

So, for example, if (for fixed ΔT)

$$pdf_{3d}(\rho) = pdf_{1d}(x)pdf_{1d}(y)pdf_{1d}(z), \tag{1}$$

then integrating with respect to y and z yields

$$pdf_{3d}(\rho) = pdf_{1d}(x)\int pdf_{1d}(y)dy \int pdf_{1d}(z)dz, \tag{2}$$

so that

$$pdf_{3d}(\rho) = pdf_{1d}(x). \tag{3}$$

As an example, consider a set of object displacements that are normally distributed in three dimensions with mean 0 and variance σ. The three-dimensional probability density function of the displacements can be represented as

$$pdf_{3d}(\Delta\vec{r}) = \frac{1}{2\pi\sigma^2} \exp^{-\frac{\Delta x^2+\Delta y^2+\Delta z^2}{2\sigma^2}}. \tag{4}$$

In this case, the projection of this function onto a one-dimensional axis (here taken to be the z axis with no loss of generality since this function is isotropic) is the marginal probability distribution function

$$pdf_{1d}(\Delta z) = \iint \frac{1}{2\pi\sigma^2} \exp^{-\frac{\Delta x^2+\Delta y^2+\Delta z^2}{2\sigma^2}} dxdy, \tag{5}$$

which is equivalent to

$$pdf_{1d}(\Delta z) = \frac{1}{2\pi\sigma^2} \exp^{-\frac{\Delta z^2}{2\sigma^2}}. \tag{6}$$

Evidently, since the projection of this normally distributed function onto a single axis results in a normally distributed function with equal variance, there is no need to invert for the "true" three-dimensional function.

We next continue to pursue our interest in the reconstruction of the three-dimensional probability density function from the projected data and hence the one-dimensional probability density function. In particular, our interest is in the invertibility of the projection operator $pdf_{3d\to 1d}$. We remark that this inversion is possible for the general class of centrosymmetric functions and can be obtained via some standard techniques such as the projection slice theorem and its ramifications. Therefore, given $\mathcal{F}$, a one-dimensional Fourier transform, and $\mathcal{H}$ as a Hankel transform, with $\mathcal{H}^{-1}$ as an inverse Hankel transform, the transformation $pdf_{1d}(\rho) \to pdf_{3d}(\rho)$ can be obtained neglecting normalization coefficients as

$$pdf_{3d}(\rho) = \mathcal{H}^{-1}\mathcal{F}[pdf_{1d}(\rho)]. \tag{7}$$

In order to pursue this interest we examine more closely the transformation between the three-dimensional centrosymmetric function and its one dimensional projection:

$$pdf_{3d}(\rho) \leftrightarrow pdf_{1d}(\rho). \tag{8}$$

Initially, assume that the three-dimensional probability density function is unimodal so that

$$pdf_{3d}(\rho) = \delta(\rho - \rho_0). \tag{9}$$

In a physical sense, this probability density function corresponds to a set of three-dimensional translations where the displacement is isotropic, though of a fixed value. Under this assumption the set of projected vector lengths, and hence the distribution of the projected lengths, can be computed. The following theorem expresses the relationship between this simple unimodal distribution and its projection.

THEOREM 3. *If* $pdf_{3d}(\rho) = \delta(\rho - \rho_0)$, *then*

$$pdf_{1d}(\rho) = \frac{\Pi(\frac{\rho}{2\rho_0})}{2\rho_0}, \tag{10}$$

where

$$\Pi(x) = 1 \quad \textit{if } |x| \leq 1/2, \tag{11}$$

$$\Pi(x) = 0 \qquad \textit{otherwise.} \tag{12}$$

As an outline of the proof, we first assume a spherical coordinate system with ϕ in the x, y plane and θ as the angle between a vector and the z axis. Next, we compute the probability distribution function for θ and ϕ which will lead to the construction of a set of three-dimensional isotropic vectors of length ρ_0. Following this, the one-dimensional probability density function $pdf_{1d}(\rho)$ is obtained by taking a set of projections and computing the probability density function. Since the distribution is isotropic, we choose the z axis for convenience.

In order to compute the probability density functions for θ and ϕ we first assume that an ensemble of values has been chosen for $0 \leq \theta' \leq \pi$ and $0 \leq \phi' \leq 2\pi$ that are uniformly distributed on these intervals. We seek a set of two functions $g(\theta')$ and $h(\phi')$ which will transform this θ' and ϕ' into a new set of variables, θ and ϕ. Imagine the end points of a set of three-dimensional vectors whose origin is at the coordinate system origin and of length ρ_0 as being uniformly distributed on the surface of a sphere of radius ρ_0. Points drawn from this isotropic distribution should sample the surface area of the sphere uniformly so that, as a function of θ and assuming that $h(\phi')$ is an identity mapping, an increment in total area A is equal to

$$\Delta A = \int_0^{\theta=g(\theta')} r^2 \sin(\theta) d\theta d\phi = 4\pi r^2 (\theta'/\pi). \tag{13}$$

The integral can be solved for θ so that

$$\cos(g(\theta')) = 1 - \frac{2\theta'}{\pi}, \tag{14}$$

yielding

$$\theta = g(\theta') = \cos^{-1}\left(1 - \frac{2\theta'}{\pi}\right). \tag{15}$$

Taking the projection of this distribution is particularly simple with respect to the z axis, since $z = \rho_0 \cos\theta$:

$$z = \rho_0 \left(1 - \frac{2\theta'}{\pi}\right). \tag{16}$$

Since θ' is uniformly distributed on the interval $0 \leq \theta' \leq \pi$, this implies that z is uniformly distributed on the interval $-\rho_0 < z < \rho_0$, and that

$$\begin{aligned} p(z) = 1/2\rho_0 \quad & \text{if } |z| \leq \rho_0, \\ 0 \qquad & \text{otherwise,} \end{aligned} \tag{17}$$

which proves the theorem.

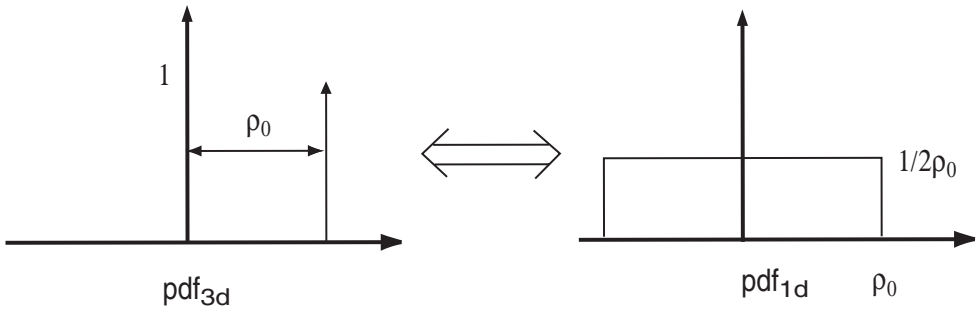

FIG. 3. *The relationship between pdf3d and pdf1d when* $pdf_{3d} = \delta(\rho - \rho_0)$.

We prefer to think of (10) as defining an "impulse response" of the transformation, as illustrated in Figure 3. Since, strictly, the response is a function of position, it is not spatially stationary. Nevertheless, it provides a particularly simple method for inverting the one-dimensional probability density function as shown. Assuming that $pdf_{3d}(\rho)$ can be represented by a set of discrete samples as

$$pdf_{3d}(\rho) = \{pdf_{3d}(\rho_i)|i = 1, N\} = \sum_{i=1}^{N} \int pdf_{3d}(\rho)\delta(\rho - \rho_i)d\rho \tag{18}$$

and noting that the transformation from pdf_{3d} to pdf_{1d} can be made as

$$pdf_{1d}(\rho) = \mathcal{P}[pdf_{3d}(\rho)], \tag{19}$$

where

$$\mathcal{P}\left[\sum_{i=1}^{N} \int pdf_{3d}(\rho)\delta(\rho - \rho_i)d\rho\right] = pdf_{3d}(\rho_i)\frac{\Pi(\frac{\rho}{2\rho_i})}{2\rho_i}, \tag{20}$$

implies that

$$pdf_{1d}(\rho) = \sum_{i=1}^{N} pdf_{3d}(\rho_i)\frac{\Pi(\frac{\rho}{2\rho_i})}{2\rho_i}. \tag{21}$$

This is a system of linear equations which, in principle, can be inverted to obtain an estimate for $pdf_{3d}(\rho)$ from $pdf_{1d}(\rho)$.

An interesting corollary guarantees that these functions are nonincreasing.

COROLLARY. *The one-dimensional probability density function, considered on the positive axis, is always a nonincreasing function.*

The proof follows from Theorem 3 as the final function is a set of nonincreasing functions via (22), and since a sum of nondecreasing functions is nondecreasing, the resultant function is also nondecreasing.

The cylindrically symmetric case. Next, we demonstrate the utility of the general methodology as applied to cylindrically symmetric functions. One example of its use is when a camera system monitors the movements of animals. In this case, a set of two-dimensional projections of the three-dimensional trajectories is obtained. The treatment here is motivated by the fact that many ecosystems can be regarded as

having a distribution of animal motions which are isotropic in the horizontal plane but not the vertical. This is a reasonable assumption when considering some terrestrial and aquatic ecosystems where the force of gravity can permit the animal to differentiate between vertical versus horizontal movement and the environment is azimuthally isotropic in the horizontal plane.

In this case the desired probability density function can be considered to have isotropy in the x, y plane so that the function has cylindrical symmetry, that is, $pdf_{3d}(\rho, \theta, z) = pdf_{3d}(\rho, z)$, where the z, θ, and ρ axes are the ones commonly associated with the cylindrical coordinate system (ρ being the length of a vector in the x, y plane and θ the angle between the vector and the x, y plane). Also, the set of three-dimensional trajectories are projected onto the x, z axes, resulting in the measurement of a set of vectors in the x, z plane. Accordingly, we seek a transform from $pdf_{2d}(x, z)$, the measured data to the "true" probability density function, $pdf_{3d}(\rho, z)$. Note that Δ has been dropped, as it is assumed that the functions are defined on physical variables that obey the geometric requirements of being "projected" via the measurement process.

If ρ and z are independent variables, the three-dimensional probability density function $pdf_{3d}(\rho, z)$ can be expressed as $pdf_{2d}(\rho)pdf_{1d}(z)$, a product of these lower-dimensional functions. In the case where the probability density function cannot be written as a product of the two probability density functions, an alternate strategy for data categorization can be used where the joint probability density function, $pdf_{3d}(\rho, z)$, can be estimated by creating a finite number of bins for the variable z, δz_i, and by observing the probability density function $pdf(x; \delta z_i)$ for each one of these δz_i. In either case, the goal here is to invert for the function $pdf_{2d}(\rho, z)$ given the function $pdf_{1d}(x)$ of measured data. Note that, as before, the one-dimensional function $pdf_{1d}(x)$ of measured (projected) data is not equivalent to $pdf_{3d}(x, 0, 0)$, a slice through the three-dimensional probability density function.

Considering the probability density function only in the plane, we state a theorem similar to Theorem 3, but this time for the two-dimensional to one-dimensional projection.

THEOREM 4. *If* $pdf_{2d}(\rho) = \delta(\rho - \rho_0)$, *then*

$$pdf_{1d}(\rho) = \frac{2}{\pi\rho_0(1 - \frac{\rho^2}{\rho_0^2})^{\frac{1}{2}}} \quad \textit{for } 0 \le \rho \le \rho_0, \tag{22}$$

$$0, \qquad \rho_0 < \rho. \tag{23}$$

The theorem states that if one has a unimodal two-dimensional probability density function which is circularly symmetric in the plane, then the probability density function for the projection of the set of vectors of length ρ_0 will be equal to the above $pdf_{1d}(\rho)$.

For this cylindrically symmetric case, the measurement process will "project" these vectors located in the x, y plane onto the x axis. Here, a linear transformation is derived between the probability density function for the set of projected lengths (uniformly distributed in θ, now assumed to be the angle between the vector ρ and the x axis) and the observed one-dimensional probability density function for their distribution, $pdf_{1d}(x)$.

The proof is as follows: Given a set of vectors in the x, y plane of length ρ_0 and uniformly distributed on $0 \le \theta \le 2\pi$ we seek the $pdf_{1d}(x)$ of their projected lengths. Geometrically, the cumulative distribution function of x in the positive quadrant ($x \ge 0$, $y \ge 0$) for uniform θ is proportional to the length of the arc of a circle

of radius ρ_0 for $0 \leq \theta \leq \pi/2$. Now, considering a new angle, $\theta' = \pi/2 - \theta$ (the angle between the vector and the y axis), the cumulative distribution function for the normalized length of the arc of the circle from $\theta' = 0$ to some value θ' is

$$CDF(\theta') = \frac{2}{\pi\rho_0} \int_0^{\theta'} \rho_0 d\theta = \frac{2\theta'}{\pi}. \tag{24}$$

Transforming back to the original polar angle θ via $\theta' = \frac{\pi}{2} - \theta$ yields

$$CDF(\theta) = 1 - \frac{2\theta}{\pi}. \tag{25}$$

Since $\cos(\theta) = \frac{\rho}{\rho_0}$,

$$CDF(\rho) = 1 - \frac{2}{\pi} \cos^{-1}\left(\frac{\rho}{\rho_0}\right), \tag{26}$$

where we limit

$$0 \leq \cos^{-1}\left(\frac{\rho}{\rho_0}\right) \leq \pi/2. \tag{27}$$

Taking the derivate with respect to x yields the probability density function, so that $pdf_{1d}(\rho) = \delta(\rho - \rho_0)$ is transformed to

$$\frac{2}{\pi\rho_0(1 - \frac{\rho^2}{\rho_0^2})^{\frac{1}{2}}} \quad \text{for} \quad 0 \leq \rho \leq \rho_0, \quad 0 \quad \text{otherwise} \tag{28}$$

by the measurement process.

Interestingly, this function goes to infinity at $\frac{\rho}{\rho_0} = 1$; however, its integral exists and can be used to define the probability of events over any finite interval. The consideration of the other quadrants is accomplished most easily by assuming first that the absolute value of the measurements $|\Delta x|$ are used. This simplifies the bookkeeping needed to keep track of the inverse cosine argument and renders the positive and negative x axes the same. Second, a similar treatment for the negative y axis which defines a new angle which goes from $-\frac{\pi}{2} \leq \theta \leq 0$ yields the same result. Thus, the theorem is proved.

In examining the probability density function, it can be noted that the transformation from two dimensions to one dimension, this time, is somewhat more merciful to the data interpretation in the absence of inversion. So, for example, the most likely value for the projected data is identical to the length of the vector (i.e., when $\frac{\rho}{\rho_0} = 1$). Nevertheless, the transformation does occur and it behooves the experimenter to examine the effects of this projection process in every case. This motivates the development of inversion techniques which will allow the computation of the radially symmetric function from the measured data. As before, a useful view of (22) is as a basis set for the observed data. In this view, the collected data is composed of a superposition of this set of stretched and renormalized functions. The development of inversion techniques that will allow the estimation of $pdf_{2d}(\rho)$ from $pdf_{1d}(\rho)$ will be considered in the next section.

Numerical analysis.

The spherically symmetric case. We next consider the numerical inversion of the set of equations that can be generated from Theorem 3. Assuming discrete

sampling of both the projected data and the proposed inverse solution, a set of matrix equations can be formulated using (21). Assuming the form $\vec{b} = A\vec{x}$, where $\vec{b}$ is the observed data (the one-dimensional probability density function) and $\vec{x}$ is the desired inverse (a radial slice through the three-dimensional probability density function), a numerical inversion can be performed.

A discrete version of the system of equations can be obtained by integrating the observed data $pdf_{1d}(\rho)$ over intervals $\delta\rho$ so that $pdf_{1d}(\delta\rho_j) = \sum_{i=1}^{N} pdf_{3d}(\rho_i)\Pi(\frac{\delta\rho_j}{2\rho_i})$. In addition, considering only positive displacements allows the distribution to be one-sided so that

$$pdf_{1d}(\delta\rho_j) = \sum_{i=1}^{N} pdf_{3d}(\rho_i)\Pi\left(\frac{\delta\rho_j}{\rho_i}\right), \text{ where } \rho_i, \rho_j \geq 0. \tag{29}$$

Assuming bin widths of unit value, the system of equations can be represented as

$$\begin{bmatrix} b_1 \\ b_2 \\ . \\ . \\ . \\ b_N \end{bmatrix} = \begin{bmatrix} 1 & \frac{1}{2} & . & . & . & \frac{1}{N} \\ & \frac{1}{2} & . & . & . & \frac{1}{N} \\ & & . & . & . & . \\ & & & . & . & . \\ & & & & . & . \\ & & & & & \frac{1}{N} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ . \\ . \\ . \\ x_N \end{bmatrix}.$$

Since this matrix is upper right triangular, a solution can be written down so that

$$\begin{aligned} x_N &= b_N N, \\ x_{N-1} &= (N-1)(b_{N-1} - b_N), \end{aligned}$$

which implies

$$\begin{aligned} x_i &= i(b_i - b_{i+1}) \quad \text{for } i < N \\ &= ib_i \qquad\qquad\ \ \text{for } i = N. \end{aligned}$$

Thus, the inverse matrix can be written as

$$A^{-1} = \begin{bmatrix} 1 & -1 & & & & \\ & 2 & -2 & & & \\ & & . & & & \\ & & & . & & \\ & & & & (N-1) & -(N-1) \\ & & & & & N \end{bmatrix}.$$

Computing the signal-to-noise of this inversion can be accomplished by adding noise to the observed data vector, $\vec{b}_{obs} = \vec{b} + \vec{\epsilon}$, where $\vec{\epsilon}$ is a noise vector, and then computing the inversion. Substituting back into the expression for x yields a computed $\vec{x}_c$, where

$$x_{c_i} = i((b_i + \epsilon_i) - (b_{i+1} + \epsilon_{i+1})), \tag{30}$$

or

$$x_{c_i} = i(b_{oi} - b_{oi+1}), \tag{31}$$

where b_{oi} and b_{oi+1} are random variables which consist of the observed values of the parameters. Therefore, x_{c_i} is a function of two random variables. If b_{oi} and b_{oi+1} can be described by probability density functions which are independent and, moreover, normally distributed with variance σ_i and σ_{i+1}, then the random variable x_{c_i} has a probability density function which is normal and has variance of

$$\sigma^2_{x_{c_i}} = i^2(\sigma_i^2 + \sigma_{i+1}^2), \tag{32}$$

which demonstrates that the variance increases with the square of value i and is a sum of the variances of the observed data values.

The cylindrically symmetric case. The cylindrically symmetric case can be treated in a manner almost identical to that of the spherically symmetric case. The situation is somewhat more complicated in this case due to the form of the transformation from two-dimensional to one-dimensional probability density function as represented by (22). The two-dimensional probability $pdf_{2d}(\rho)$ can be represented by a discretely sampled version as

$$pdf_{1d}(\rho) = \sum_{i=1}^{N} pdf_{2d}(\rho_i) \frac{2}{\pi\rho_i(1 - \frac{\rho^2}{\rho_i^2})^{\frac{1}{2}}}. \tag{33}$$

As before, we prefer to think of this as a "system response" to a unimodal probability density function ($pdf_{2d}(\rho) = \delta(\rho - \rho_i)$). Integrating this equation over finite bin widths of size $\Delta\rho$ to accommodate the data collection process yields

$$pdf_{1d}(\delta\rho_j) = \int_{\rho_j - \frac{\Delta\rho}{2}}^{\rho_j + \frac{\Delta\rho}{2}} \sum_{i=1}^{N} pdf_{2d}(\rho_i) \frac{2}{\pi\rho_i(1 - \frac{\rho_j^2}{\rho_i^2})^{\frac{1}{2}}} d\rho_j. \tag{34}$$

Taking the integral inside of the sum and noting that

$$\int_{\rho_j - \frac{\Delta\rho}{2}}^{\rho_j + \frac{\Delta\rho}{2}} \frac{2}{\pi\rho_i(1 - \frac{\rho_j^2}{\rho_i^2})^{\frac{1}{2}}} d\rho_j = CDF\left(\rho_j + \frac{\Delta\rho}{2}; \rho_i\right) - CDF\left(\rho_j - \frac{\Delta\rho}{2}; \rho_i\right), \tag{35}$$

where CDF stands for the cumulative distribution function for $pdf_{1d}(\rho)$ as in (26), implies that

$$pdf_{1d}(\delta\rho_j) = \sum_{i=1}^{N} pdf_{2d}(\rho_i) \left(CDF\left(\rho_j + \frac{\Delta\rho}{2}; \rho_i\right) - CDF\left(\rho_j + \frac{\Delta\rho}{2}; \rho_i\right)\right). \tag{36}$$

This equation can then be transformed into a more compact notation as

$$pdf_{1d}(\delta\rho_j) = \sum_{i=1}^{N} pdf_{2d}(\rho_i) \Delta CDF(\rho_j, \rho_i), \tag{37}$$

where

$$\Delta CDF(\rho_j, \rho_i) = CDF\left(\rho_j + \frac{\Delta\rho}{2}; \rho_i\right) - CDF\left(\rho_j + \frac{\Delta\rho}{2}; \rho_i\right) \tag{38}$$

$$= \frac{2}{\pi}\left(\cos\left(\frac{\rho_j - \frac{\Delta\rho}{2}}{\rho_i}\right) - \cos\left(\frac{\rho_j + \frac{\Delta\rho}{2}}{\rho_i}\right)\right). \tag{39}$$

The matrix is, again, upper right triangular because via (23)

$$\Delta CDF(\rho_j, \rho_i) = 0 \qquad \text{if } \rho_i > \rho_j. \tag{40}$$

Therefore, the numerical solution of the set of linear equations can be computed as before. The noise analysis can also be performed; however, we have not derived an analytic expression, as above, as the inverse matrix has a much more complicated structure. We defer these considerations to a future publication.

Experimental results.

The spherically symmetric case. As an example of the use of the method for the analysis of collected data we present results that utilize data generated from the FishTV sonar system (Jaffe et al., 1995). Briefly, the FishTV system is a multibeam sonar system which operates at a frequency of 445 kHz with bandwidth of 25 kHz and at frame rates of up to 4 Hz. The system provides acoustic backscatter from a set of 64 beams whose beam widths are 2 degrees by 2 degrees. The system resolves 512 range bins at a range increment of 0.75 cm, which yields a three-dimensional data set of dimensions 16 degrees by 16 degrees by 3.8 meters. The system has been used to measure the sonar reflectivity (Jaffe, Ohman, and De Robertis, 1998) and behavior (Jaffe, De Robertis, and Ohman, 1999) of small animals in the water column (zooplankton).

Given that the azimuthal resolution of the system is 2 degrees by 2 degrees, at a range of 3 m the cross-track resolution of the system is 10.5 cm by 10.5 cm. In contrast, the range resolution of the system, dictated by the bandwidth of the signal, in excellent signal-to-noise can be as small as 1 cm. Clearly, an algorithm which takes advantage of the superior range resolution in order to estimate the $pdf(\vec{v})$, the probability density function for velocity, is desired. This was especially appealing since the animal motions were suspected to be small, as they are quiescent during some of our observation times (daylight). In addition, during this time, there is good reason to believe that this probability density function is spherically symmetric. One advantage of the algorithm proposed here is that it permits use of this much better range resolution in order to compute the three-dimensional probability density function from the one-dimensional observations.

Data shown here were collected in a fjord in British Columbia over a period of approximately 10 minutes. The sonar was suspended below an anchored ship and oriented into the current via the use of a current vane which was placed on the data collection package. The sonar was operated at a rate of 2 Hz and was aimed slightly downward into the layer of animals that collects at depth during the daytime. Suspended at 85 meters, the system recorded the time varying reflections from targets that were between 7 and 10 meters in range. The recording process yielded a set of time varying reflections from each of the 64 sonar beams. Additional information describing the system can be found in Jaffe et al. (1995).

Extensive software development in conjunction with validation of the system's performance has been performed over a period of several years (De Robertis, 2001). The first step is to identify the presence of individual targets in each of the 64 sonar beams. This is accomplished via the use of a correlation receiver and also by inspecting the neighboring beams for side lobes as our targets are azimuthally spread. The output of this first step is an estimate for the three-dimensional voxel (horizontal and vertical bearing angle and range) in which the target is located, and its acoustic cross section (reflectivity). This set of three-dimensional locations, which are obtained over

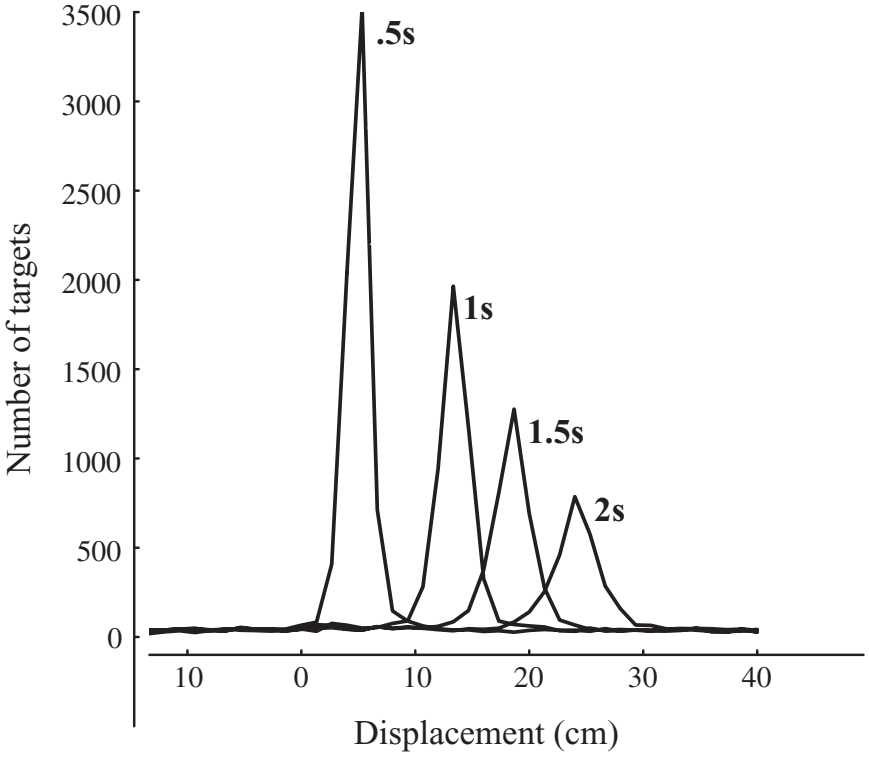

FIG. 4. *A set of displacement distribution functions: the number of targets that underwent translation ΔX in time interval ΔT as a function of time delay.*

a relatively short period of time for one complete system transmission-and-receive cycle, is referred to as a frame.

The next step in our treatment of the data, for the purposes of this article, is to consider the range displacements only. The histogram of these values provides the data from which the probability density function can be estimated. The histogram formed solely from the range estimates forms an estimate for $pdf_{1d}(\rho)$. In order to compute this function from the target lists as a function of frame number, various approaches can be used. Probably the most sophisticated approach would be to track the targets temporally and to estimate their range displacements accordingly. A simpler approach was taken here which should yield approximately the same results. That is, given a time interval, the range displacement vectors were computed for all targets in successive frames, which were separated by the given time interval from the two lists (with reflectivities above a certain value). This is computationally very simple, and under the assumption that the individual target locations are uncorrelated (among themselves), the extra displacements from targets that were not the same should produce a "dc value" or plateau upon which the true target displacements are observable. The displacements were binned into bins of width 1.5 cm. Although the data recording interval results in a range increment of .75 cm, this value was used, as it was closer to the "true" resolution of the system as measured by the width of the autocorrelated pulse.

Figure 4 contains a set of four histograms for these estimated range displacements from this data set. These displacement distributions can easily be converted into an

estimate for $pdf_{1d}(\rho)$ by simply dividing through by the total number of observations. The data indicate that there is a mean translation of the animals' positions (due to the current) which is superimposed upon a broadening of the distribution, which we have assumed is due to animal motion. It is evident that the majority of the animals are hardly moving at all, that is to say, the majority of their displacement is due to the current. This further motivated our interest in using this inversion algorithm to obtain a higher resolution estimate than could be obtained from just the three-dimensional positions, which suffer from poor azimuth resolution (relative to animal displacement).

The data in Figure 4 were obtained by forming the histograms for each of the individual beams for each of the time delays and then shifting them by small amounts in order to line them up. The reason that they had different modes for their displacements was due to the small differences in pointing angles for each of the 64 beams. This resulted in a different value for the projection of the current vector onto each of the beam-pointing angles. The correction assumes that the width of the peaks will change little as a function of this systematic correction.

Since these data were obtained by regarding only changes in animal position in range, the data reflects an estimate for $pdf_{1d}(\Delta\rho|\Delta T)$. Moreover, since it is likely that the "true" animal displacement probability density function is isotropic, the data were treated using the above analysis. Note that this probability density function might be due to both turbulence as well as animal movement. In the case that both of those are isotropic, the analysis considered here can be rightfully applied. In addition, since the current regime where the study was done was extremely laminar, the broadening of the probability density function was interpreted as due to animal movement. The inverse was computed by multiplying the data by the matrix A^{-1} to obtain an estimate for the radial slice through the three-dimensional function (here kept in the form of a displacement histogram). Figure 5 shows the result. An interesting feature of the inverse is that there is a significant decrease in the estimated number of targets that are simply drifting with the current, as contrasted with the estimate that would be obtained by simply taking the one-dimensional displacements histograms.

In order to test whether this inversion differs significantly from the measured data and to explore its stability, a simulation was done. Under the assumption that (1) the measured data was not subject to any systematic error and (2) the underlying probability density function for the measured data is Poisson distributed with expectation and standard deviation equal to the measured value, an ensemble of potential measured waveforms was simulated. Each member of the ensemble was then multiplied by the inverse matrix (as above) to compute a new inverse. This yielded an ensemble of inverses whose standard deviations are shown as dashed lines in Figure 5. The error curves indicate that, at the origin, the computed inverse is significantly different from the measured data; however, at larger displacements the inversion is not. This is an interesting and significant observation. Perhaps some degree of active swimming is needed for survival.

The cylindrically symmetric case. In this section we consider the utilization of the methodology which was developed for the cylindrically symmetric case. In the above spherically symmetric case we described the application of the methodology to data that were measured using a specially designed sonar system. Here, standard camera technology has been used to view the behavior of animals from a single direction. Under the assumption that the underlying probability density function for velocity has cylindrical symmetry, a temporally changing set of data from this sin-

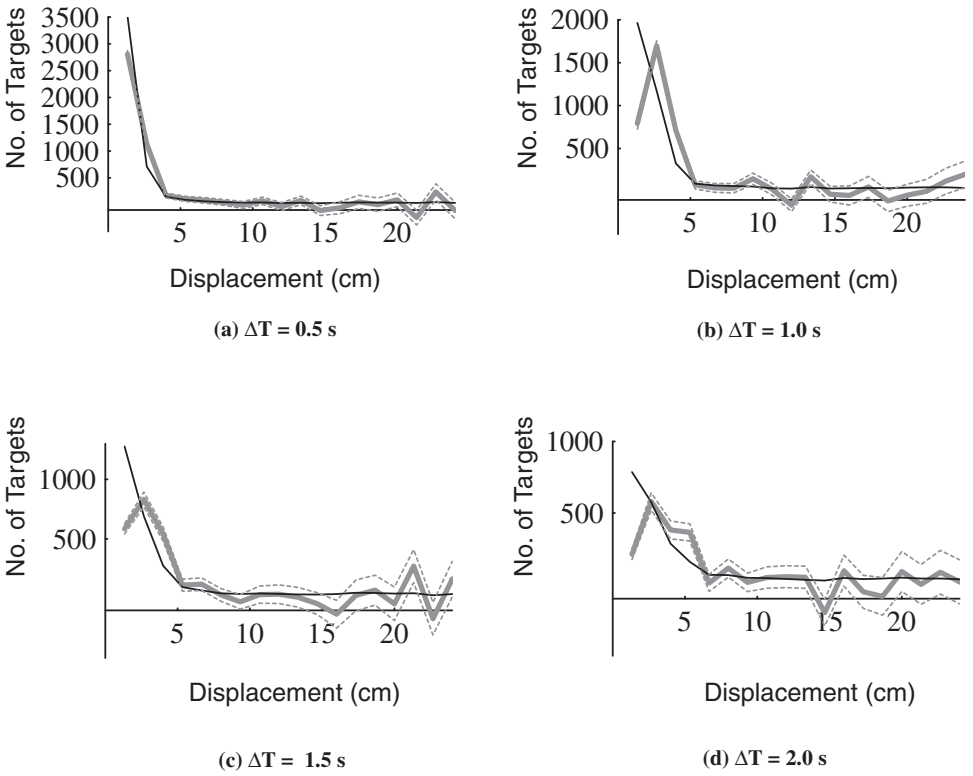

FIG. 5. *The result of performing the matrix inversion A^{-1} on the one-dimensional sonar data for different time delays. The solid black line is the observed histogram of the range displacement data. The gray line is the result obtained after multiplying by the inverse matrix. The dashed gray lines indicate plus or minus one standard deviation. The output of this process is an estimate for a radial slice through the spherically symmetric, three-dimensional histogram.*

gle camera can be used to infer a radial line through the cylindrically symmetric distribution.

Here we consider experiments that were performed to observe the behavior of small underwater animals (zooplankton of size 1 mm) in order to study the differences in their behavior in the presence and absence of food. The animals were placed in an aquarium and photographed with a video camera under dim red light. Postprocessing of the data yielded a set of displacement vectors for the animals $\{\Delta x_i, \Delta z_i; t, i = 1, N\}$ as a function of time.

This section contains the results of processing the set of five animal trajectories which consisted of approximately 100 positions each, yielding about 500 animal displacements (Leising and Franks, 2002). These vectors were then assembled into two histograms of displacements, one for Δx and the other for Δz, under the assumption that the two probability density functions are independent, as described above. The displacements for both positive and negative values were combined under the assumption that the distribution is symmetric.

As described above, the forward problem was modeled using a finite number of bins, and the algorithm was tested on several simulated distributions. Here, the experimental data of the recorded animal positions were used to obtain a set of animal displacements which were binned into 11 size classes. In order to compute the inver-

sion, an 11 by 11 matrix was created for the forward problem. The forward matrix was computed as

1.	.356	.227	.167	.132	.110	.093	.081	.072	.065	.059
0.	.644	.249	.174	.136	.111	.095	.082	.073	.066	.059

The inverse matrix will not be shown here; however, the inverted data set is shown in Figure 6, along with the original data histogram of the displacements. As the figure indicates, the estimate for the *true* data set is somewhat different than the observed data. Curves of plus or minus one standard deviation, computed in an identical way to the spherically symmetric case, are also shown. Interestingly, in the same way as in the spherically symmetric case, a decrease in targets that were practically still is evident. This inversion then also suggests that there are fewer targets moving with very small velocities than would be measured from just computing the probability density function from the projected data. In this case, it is widely known that the animals execute a "hop and sink" strategy for foraging, indicating that they indeed spend little of their time not moving at all. Since the animals are somewhat negatively buoyant, they cannot simply suspend movement and maintain their depth.

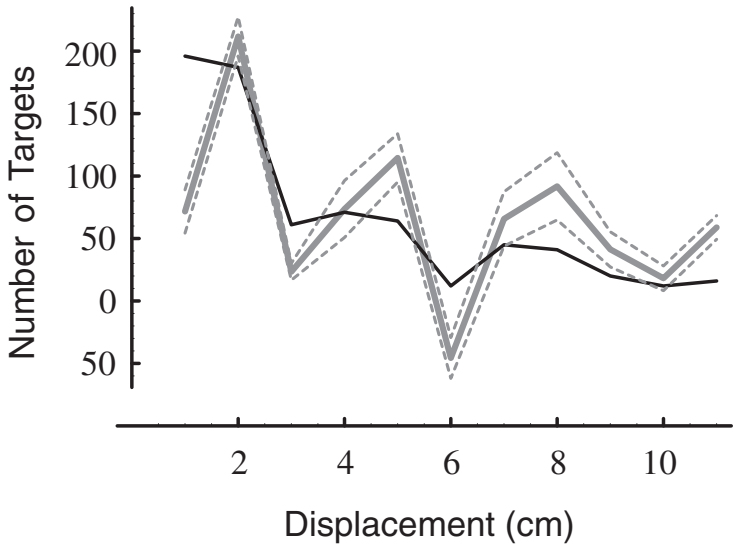

FIG. 6. *A histogram of observed animal displacements, proportional to* $pdf_{1d}(\Delta x)$ *(solid black), and the inversion for the "true" three-dimensional histogram, proportional to* $pdf_{3d}(\Delta r)$ *(gray). The dashed gray lines indicate plus or minus one standard deviation. The data was collected with a camera system which viewed animal displacements in dim red light.*

Discussion and conclusions. In this article a theory of tomographic inversions for probability density functions from observed data has been proposed. The theory is motivated by the many data collection systems that observe a lower-dimensional projection of the data where both one-dimensional and two-dimensional projections of three-dimensional vectors are observed. In the two cases considered here, a three-dimensional sonar system and an optical camera, animal displacement distributions were processed to obtain an estimate for radial slices through the two- and three-dimensional displacement probability density functions. The identical nature of this problem to the standard theories relating to tomographic inversion is emphasized. Several theorems are proved which demonstrate the utility of inverting symmetric marginal probability density functions using tomographic theorems. The utility of these ideas is demonstrated via the application of the numerical implications to experimentally collected data.

From the scientific point of view there are a host of interesting problems that could be explored using the methodology described here. In this regard, this author's primary interest has been in tracking individual animals in various aquatic environments. Other applications of the methodology may relate to tracking animals both on land and in the air. As demonstrated, even one-dimensional range information from a simple device can be transformed into a radial slice of a multidimensional probability density function using the methodology presented here. In the case of animals that fly, the similarities are clear between observing birds or insects and the aquatic examples in the applications given here. Other interesting probability moments exist as well. So, for example, one might be interested in the joint distribution of some predator and prey via their relative distances in some reduced-dimensional coordinate system. Inversion for the true joint probability density function from this joint distribution, under assumptions here of various symmetries, therefore seems like an interesting future application of the technique.

In a similar context, we remark that other work by this author involves the projection of fluorescent organisms onto a plane (Jaffe, Franks, and Leising, 1998; Franks and Jaffe, 2001). Under various assumptions about symmetry, the correlation distances can be computed.

From the point of view of the reconstruction of multidimensional functions from projections, there are a number of theoretical questions which arise as a result of this work. A significant issue concerns the underlying assumptions of isotropy, either in three dimensions or in two, and how strictly isotropic the distributions need to be in order for the results to apply. So, for example, in the analysis of the sonar system's measurements of one-dimensional displacements, it was assumed that the animals' movements could be described by an isotropic probability density function. However, since the animals remain at a depth strata during the day, it cannot be strictly true that their distribution is isotropic, as over time they would diffuse into the entire volume. If the underlying three- or two-dimensional probability density function is not strictly isotropic, the above theorems do not apply; however, if the distribution is "almost" isotropic, then one might hope that some variation of the theorems can be used. Moreover, when the system is not truly isotropic, perhaps one can use some fewer number of projections than would be required for a true multidimensional inversion without arbitrary assumptions about the underlying structure of the desired object. The application of the theory and methodology described here to situations of pragmatic interest is an interesting area for future research.

Additional issues which relate to the numerical solution of the system of equations remain. These issues are generic to the theory of the reconstruction of functions from

projections and thus relate to the field in general. Under the special symmetries considered here, the inversions would benefit from additional work. So, for example, only a straightforward multiplication by the matrix inverse was performed here. However, in the presence of noise, this inversion is probably neither a maximum likelihood nor maximum a priori estimate for the solution. So, for example, in both cases considered here, it is likely that there is some noise amplification as a result of the simplicity of the inversions.

Another issue relates to the numerical implementation of the inverse. Tomographic reconstructions are typically performed through the use of filtered backprojection. It would be interesting to characterize the performance of that algorithm in comparison to the more analytically based algorithms that capitalize on the symmetry which have been proposed here.

Finally, perhaps the most surprising and significant conclusion is that it is productive to perform tomographic inversions on marginal probability density functions. As shown, these inversions can provide an estimate for a true underlying two- or three-dimensional probability density function when performed on one- and two-dimensional projected data. Collection of these lower-dimensional data sets can vastly simplify an experimental setup, as the collection of true three-dimensional data requires both careful calibration and additional hardware when compared with the lower-dimensional case.

Acknowledgments. The author would like to thank both the National Science Foundation and the Office of Naval Research for supporting his work over the years. Thanks are also extended to A. Leising (National Marine Fisheries Service, Pacific Grove, CA) for providing the displacement data for cylindrically symmetric analysis and to Simon Levin (Princeton University) for encouraging remarks after reading an earlier version of this manuscript.

MULTIPLE EQUILIBRIA IN COMPLEX CHEMICAL REACTION NETWORKS: I. THE INJECTIVITY PROPERTY*

GHEORGHE CRACIUN† AND MARTIN FEINBERG‡

Abstract. The capacity for multiple equilibria in an isothermal homogeneous continuous flow stirred tank reactor is determined by the reaction network. Examples show that there is a very delicate relationship between reaction network structure and the possibility of multiple equilibria. We suggest a new method for discriminating between networks that have the capacity for multiple equilibria and those that do not. Our method can be implemented using standard computer algebra software and gives answers for many reaction networks for which previous methods give no information.

1. Introduction.

We are interested in studying the uniqueness of positive equilibrium points of a special but large class of systems of nonlinear ordinary differential equations (ODEs): those that derive from chemical reaction networks. In order to understand how these equations arise, we will first look informally at an example of a reaction network and see how it induces a system of ODEs.

Consider some chemical species A, B, C, D, W, X, Y, and Z, and suppose that the chemical reactions occurring among these species are

$$A + B \rightleftharpoons C, \quad X \rightleftharpoons 2A + D \rightleftharpoons Y, \quad D \rightleftharpoons C + W, \quad B + D \rightleftharpoons Z. \tag{1.1}$$

We will study a particular kind of reactor, called a continuous flow stirred tank reactor (CFSTR; see [3]) by chemical engineers. Think of a CFSTR as just some enclosed volume endowed with a feed stream and an outflow stream. Suppose that its contents are kept at constant temperature and are spatially uniform. Now imagine that a liquid mixture of species A, B, C, D, W, X, Y, and Z is continuously supplied to some CFSTR at a constant volumetric flow rate g (volume/time). Also, the contents of the CFSTR are continuously removed at the same volumetric flow rate g. Chemical reactions occur in the CFSTR, according to (1.1). We would like to investigate the temporal evolution of the composition of the mixture within the CFSTR. Let us denote by $c_A^f, c_B^f, \ldots, c_Z^f$ the molar concentrations (moles/volume) in the feed stream and by $c_A(t), c_B(t), \ldots, c_Z(t)$ the molar concentrations within the CFSTR (and effluent stream) at time t. We will denote the vector of all molar concentrations within the CFSTR by $c(t)$. We get the picture shown in Figure 1.1.

One source of change in composition is the occurrence of chemical reactions. It is generally assumed that the occurrence rate of each reaction at time t depends just

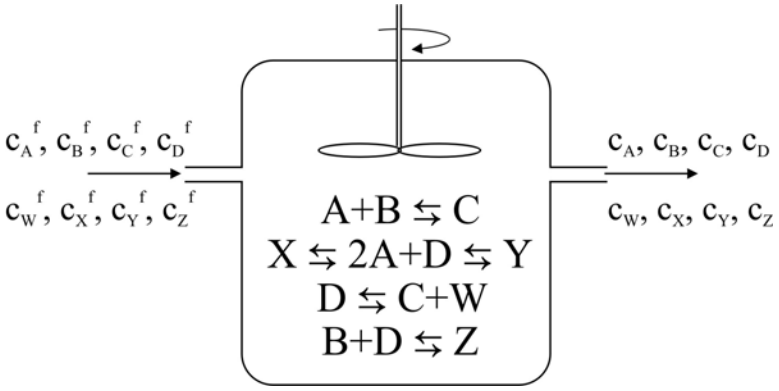

FIG. 1.1. *The CFSTR of the reaction network* (1.1).

on the mixture composition $c(t)$. For example, for the reaction $A + B \to C$ there exists a nonnegative real-valued *rate function* $K_{A+B\to C}$ such that $K_{A+B\to C}(c)$ is the occurrence rate of reaction $A + B \to C$ per unit volume of mixture when the mixture composition is given by the vector c. Let us now think about the instantaneous rate of change of c_A. Whenever the reaction $A + B \to C$ occurs we lose one molecule of A. Also, whenever the reaction $C \to A + B$ occurs we gain one molecule of A. Similarly, whenever the reaction $X \to 2A + C$ occurs we gain two molecules of A, and so on.

The other source of changes in composition is the difference between the composition c^f in the feed stream and the composition c in the effluent stream. (Note that the composition of the effluent stream is presumed to be identical to that of the homogeneous mixture within the vessel.) If V is the total volume of the mixture within the CFSTR,[1] we get

$$\begin{aligned} V\dot{c}_A = g(c_A^f - c_A) &- VK_{A+B\to C}(c) + VK_{C\to A+B}(c) \\ &- 2VK_{2A+D\to X}(c) + 2VK_{X\to 2A+D}(c) \\ &- 2VK_{2A+D\to Y}(c) + 2VK_{Y\to 2A+D}(c). \end{aligned} \tag{1.2}$$

We will now look more closely at the structure of the rate functions. In most cases chemists suppose the rate functions to be of *mass-action* type (see [26]). This means that, for example, for the reaction $A + B \to C$, the more A there is in the CFSTR, the more occurrences of the reaction there will be, and similarly for B. More precisely, we presume that the occurrence rate of the reaction $A + B \to C$ is proportional to the probability of A and B meeting in the CFSTR, which, in turn, is proportional to the value of $c_A c_B$. Thus, we write

$$K_{A+B\to C}(c) = k_{A+B\to C} c_A c_B,$$

where $k_{A+B\to C}$ is a positive *rate constant* for the reaction $A + B \to C$. For the reaction $2A + D \to X$ an occurrence requires two molecules of A and one molecule of D to meet in the CFSTR, and we consider the probability of this encounter to be proportional to $c_A^2 c_D$. Therefore we get

$$K_{2A+D\to X}(c) = k_{2A+D\to X} c_A^2 c_D,$$

[1] We assume hereafter that the densities of the feed and the effluent streams are identical and time-invariant. This implies that V is constant in time. We also assume throughout that the temperature of the reacting mixture is held constant.

where $k_{2A+D\to X}$ is the rate constant for the reaction $2A + D \to X$. In the case of a reaction such as $D \to C + W$ it is presumed that the occurrence rate is simply proportional to the molar concentration of D, i.e.,

$$K_{D\to C+W}(c) = k_{D\to C+W}c_D.$$

The rate constants are usually either approximated on the basis of chemical principles or are deduced from experiments. If we assume mass-action kinetics for the network (1.1), then we get the following *associated system of differential equations*:

$$\begin{aligned}
(1.3)\quad \dot{c}_A &= (g/V)(c_A^f - c_A) - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C - 2k_{2A+D\to X}c_A^2c_D \\
&\quad + 2k_{X\to 2A+D}c_X - 2k_{2A+D\to Y}c_A^2c_D + 2k_{Y\to 2A+D}c_Y, \\
\dot{c}_B &= (g/V)(c_B^f - c_B) - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C \\
&\quad + k_{Z\to B+D}c_Z - k_{B+D\to Z}c_Bc_D, \\
\dot{c}_C &= (g/V)(c_C^f - c_C) + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C \\
&\quad + k_{D\to C+W}c_D - k_{C+W\to D}c_Cc_W, \\
\dot{c}_D &= (g/V)(c_D^f - c_D) + k_{X\to 2A+D}c_X - k_{2A+D\to X}c_A^2c_D \\
&\quad + k_{Y\to 2A+D}c_Y - k_{2A+D\to Y}c_A^2c_D - k_{D\to C+W}c_D + k_{C+W\to D}c_Cc_W \\
&\quad - k_{B+D\to Z}c_Bc_D + k_{Z\to B+D}c_Z, \\
\dot{c}_W &= (g/V)(c_W^f - c_W) + k_{D\to C+W}c_D - k_{C+W\to D}c_Cc_W, \\
\dot{c}_X &= (g/V)(c_X^f - c_X) - k_{X\to 2A+D}c_X + k_{2A+D\to X}c_A^2c_D, \\
\dot{c}_Y &= (g/V)(c_Y^f - c_Y) + k_{2A+D\to Y}c_A^2c_D - k_{Y\to 2A+D}c_Y, \\
\dot{c}_Z &= (g/V)(c_Z^f - c_Z) + k_{B+D\to Z}c_Bc_D - k_{Z\to B+D}c_Z.
\end{aligned}$$

Therefore we obtain a system of ODEs where all equations are determined by the reaction network up to some constants: c_A^f, $c_B^f, \ldots, c_Z^f$, g/V, and $k_{A+B\to C}$, $k_{C\to A+B}, \ldots, k_{Z\to B+D}$. We are now going to ask the question: does this system of ODEs have no more than one positive equilibrium for all positive values of g/V, all positive values of the rate constants, and all nonnegative values of the feed concentrations c_A^f, $c_B^f, \ldots, c_Z^f$?

This question is motivated by experiments. For homogeneous liquid phase CFSTRs, there are very few reports of reaction networks with more than one positive equilibrium, despite hundreds of reaction networks being studied (see [9] for one such report). We are asking this question for *all* positive rate constants since in practice there is poor knowledge of the rate constants of reactions.

This question is not easy to answer, in general. Even if, for the simple example above, we could decide one way or the other by some ad-hoc method, there will be thousands of other reaction networks for which we will still not know the answer. There are important reaction networks with hundreds of reactions. Ideally, there will be a simple way to decide on the uniqueness of equilibria.

We say that a mass-action network *has the capacity for multiple positive equilibria* (in an isothermal homogeneous CFSTR context) if there are positive values of the flow rate, the volume, the rate constants, and nonnegative values of the feed concentrations such that the resulting differential equations admit two or more distinct positive equilibria.

According to [30], there are examples of very similar reaction networks with very different capacities for multiple positive equilibria (see Table 1.1). Networks (i) and

TABLE 1.1
Some examples of reaction networks and their capacity for multiple positive equilibria [30].

Reaction network		Has the capacity for multiple equilibria?
(i)	$A+B \rightleftharpoons P$ $B+C \rightleftharpoons Q$ $C \rightleftharpoons 2A$	Yes
(ii)	$A+B \rightleftharpoons P$ $B+C \rightleftharpoons Q$ $C+D \rightleftharpoons R$ $D \rightleftharpoons 2A$	No
(iii)	$A+B \rightleftharpoons P$ $B+C \rightleftharpoons Q$ $C+D \rightleftharpoons R$ $D+E \rightleftharpoons S$ $E \rightleftharpoons 2A$	Yes
(iv)	$A+B \rightleftharpoons P$ $B+C \rightleftharpoons Q$ $C \rightleftharpoons A$	No
(v)	$A+B \rightleftharpoons F$ $A+C \rightleftharpoons G$ $C+D \rightleftharpoons B$ $C+E \rightleftharpoons D$	Yes
(vi)	$A+B \rightleftharpoons 2A$	No
(vii)	$2A+B \rightleftharpoons 3A$	Yes
(viii)	$A+2B \rightleftharpoons 3A$	No

(iii) in Table 1.1 have the capacity for multiple positive equilibria, but the "middle case" network (ii) does not. Similarly, network (iv) is almost identical to (i), but does not have the capacity for multiple positive equilibria. Moreover, network (v) is an example that shows that we don't need two or more copies of the same species to appear in the same reaction for the network to admit multiple positive equilibria. Also, changing (vi) to (vii) does bring in multiple positive equilibria, but changing (vi) to (viii) does not. Therefore, a good theory of multiple positive equilibria in CFSTRs should be able to differentiate between these subtle differences.

Let us look again at the system of ODEs in (1.3). If we are just interested in equilibria, we set all the left-hand side terms equal to zero, and we get a system of polynomial (algebraic) equations. Let us also move the feed terms $c_A^f, \dots, c_Z^f$ to the other side of the equations. We choose units such that $g/V = 1$. If we now change signs in both sides and rearrange terms, then we get the following system of eight polynomial equations:

$$
\begin{aligned}
c_A^f &= c_A + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C + 2k_{2A+D\to X}c_A^2c_D \\
&\quad - 2k_{X\to 2A+D}c_X + 2k_{2A+D\to Y}c_A^2c_D - 2k_{Y\to 2A+D}c_Y, \\
c_B^f &= c_B + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C - k_{Z\to B+D}c_Z \\
&\quad + k_{B+D\to Z}c_Bc_D, \\
c_C^f &= c_C - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C - k_{D\to C+W}c_D \\
&\quad + k_{C+W\to D}c_Cc_W,
\end{aligned}
\tag{1.4}
$$

$$
\begin{aligned}
c_D^f &= c_D - k_{X\to 2A+D}c_X + k_{2A+D\to X}c_A^2c_D - k_{Y\to 2A+D}c_Y \\
&\quad + k_{2A+D\to Y}c_A^2c_D + k_{D\to C+W}c_D - k_{C+W\to D}c_Cc_W \\
&\quad + k_{B+D\to Z}c_Bc_D - k_{Z\to B+D}c_Z, \\
c_W^f &= c_W - k_{D\to C+W}c_D + k_{C+W\to D}c_Cc_W, \\
c_X^f &= c_X + k_{X\to 2A+D}c_X - k_{2A+D\to X}c_A^2c_D, \\
c_Y^f &= c_Y - k_{2A+D\to Y}c_A^2c_D + k_{Y\to 2A+D}c_Y, \\
c_Z^f &= c_Z - k_{B+D\to Z}c_Bc_D + k_{Z\to B+D}c_Z.
\end{aligned}
$$

Let us denote by k the vector formed by the parameters $k_{A+B\to C}$, $k_{C\to A+B}, \ldots,$ $k_{Z\to B+D}$. Now we denote by $p(c,k)$ the vector of right-hand sides of the system of polynomial equations (1.4), and we call it *the polynomial function associated to the reaction network* (1.1). We regard $p(c,k)$ as a vector-valued function of a (positive) composition vector c and depending on a (positive) vector of rate constants k.

We say that the reaction network (1.1) is an *injective reaction network* if the function $c \to p(c,k)$ is injective for all positive k.

The following simple fact is a key observation: *If a reaction network has the capacity for multiple positive equilibria, then there exists some choice of positive vector k_0 such that the function $c \to p(c,k_0)$ is not injective.* In particular, $p(c^*,k_0) = p(c^\#,k_0) = c^f$ for some feed composition c^f and some distinct compositions c^*, $c^\#$. In other words, an injective reaction network does not have the capacity for multiple positive equilibria; i.e., injectivity is a sufficient condition for the absence of multiple positive equilibria.

Remark 1.1. Injectivity is *not* a necessary condition for the absence of multiple positive equilibria. The reason is that, for a network to admit multiple positive equilibria, there must be a k_0 such that $p(\cdot,k_0)$ maps two distinct compositions not only into the same vector, but, in fact, also into a *nonnegative* feed composition c^f (see (1.4), (3.10)). Were it not for this nonnegativity condition, injectivity would be equivalent to uniqueness of equilibria.

Nevertheless, the class of injective reaction networks subsumes the largest class of reaction networks for which the answer was previously found in [20, 30, 31]. *The main purpose of this paper is to describe a method that allows us to decide whether a given reaction network is injective or not.*

Remark 1.2. In general, it is of course very difficult to check whether a given multidimensional polynomial function is injective or not. Moreover, the function $c \to p(c,k)$ involves several unknown parameters. Our method derives, first, from a theoretical observation about the function $p(\cdot,\cdot)$ and, second, from a rather remarkable empirical observation.

The theoretical observation, discussed in section 3, is that a reaction network is injective whenever its associated polynomial function has the property that $\frac{\partial p(c,k)}{\partial c}$ is nonsingular for all positive c and all positive k. (There is no claim here that any such assertion is true for polynomial functions in general; rather, the assertion is made specifically for polynomial functions that derive, in the manner indicated, from chemical reaction networks.)

To describe the empirical observation, we first note that the nonsingularity property is, of course, equivalent to the requirement that $\det(\frac{\partial p(c,k)}{\partial c})$ be nonzero for all positive c and all positive k. For moderately large networks, the calculation of $\det(\frac{\partial p(c,k)}{\partial c})$ will result in hundreds or thousands of terms, even after combining all similar monomials. Each resulting nonzero term will be a monomial in the (positive)

species concentrations and the (positive) rate constants, with each term containing an integer coefficient. Thus the sign of each term is carried by the sign of its integer coefficient. The empirical observation is this: *For very large and robust classes of networks it is the case that, despite the huge number of terms, the integer coefficient in every term is positive!* In this case, $\det(\frac{\partial p(c,k)}{\partial c})$ cannot vanish, and injectivity of the network is ensured (as is the impossibility of multiple positive equilibria). In fact, we will show that positivity of all nonzero coefficients is *both necessary and sufficient* for injectivity of the network.

In a subsequent article we intend to characterize, in graph-theoretical terms, large classes of networks for which all coefficients are positive. In the meantime, we observe that, for a given network of interest, checking for positivity of the coefficients is a matter that can be resolved by presently available computer algebra systems.

By way of example, we show in (1.5) the first few terms of the expansion of $\det(\frac{\partial p(c,k)}{\partial c})$ for network (1.1):

$$
\begin{aligned}
(1.5)\quad & \det\left(\frac{\partial p(c,k)}{\partial c}\right) \\
&= 10k_{C\to A+B}k_{D\to C+W}k_{2A+D\to X}c_Ac_D^2k_{W\to 0}k_{B+D\to Z}k_{X\to 0}k_{Y\to 0}k_{Z\to 0} \\
&+ 4k_{C\to A+B}k_{D\to 0}k_{2A+D\to X}c_Ac_D^2k_{W\to 0}k_{B+D\to Z}k_{X\to 0}k_{Y\to 2A+D}k_{Z\to 0} \\
&+ 4k_{C\to A+B}k_{D\to 0}k_{2A+D\to Y}c_Ac_Dk_{W\to 0}k_{B\to 0}k_{X\to 0}k_{Y\to 0}k_{Z\to 0} \\
&+ k_{C\to A+B}k_{2A+D\to X}c_A^2k_{A\to 0}k_{W\to 0}k_{B+D\to Z}c_Dk_{X\to 0}k_{Y\to 2A+D}k_{Z\to 0} \\
&+ 4k_{C\to A+B}k_{D\to 0}k_{2A+D\to Y}c_Ac_Dk_{W\to 0}k_{B\to 0}k_{X\to 2A+D}k_{Y\to 0}k_{Z\to 0} \\
&+ 6k_{C\to A+B}k_{D\to C+W}k_{2A+D\to Y}c_Ac_Dk_{W\to 0}k_{B\to 0}k_{X\to 2A+D}k_{Y\to 0}k_{Z\to B+D} \\
&+ 9k_{C\to 0}k_{2A+D\to Y}c_A^2c_Dk_{A+B\to C}k_{C+W\to D}c_Ck_{B+D\to Z}c_Bk_{Z\to 0}k_{X\to 0}k_{Y\to 0} \\
&+ 9k_{C\to 0}k_{2A+D\to Y}c_A^2c_Dk_{A+B\to C}k_{C+W\to D}c_Ck_{B+D\to Z}c_Bk_{Z\to 0}k_{X\to 2A+D}k_{Y\to 0} \\
&+ \cdots.
\end{aligned}
$$

In Table 1.2 we exhibit the (computer-generated) set of all coefficients that would have resulted had the expansion been completed. Note that all the entries are positive. Thus, we conclude that network (1.1) does not have the capacity for multiple positive equilibria in an isothermal CFSTR context.

Our claim that, across wide varieties of reaction networks, it is common for all coefficients to be positive is consistent with the paucity of experimental observations of multiple equilibria in isothermal homogeneous CFSTRs.

In section 3 we provide elaboration on the remarks made here.

Before we describe our results we would like to specify their place in the general landscape of chemical reaction network theory.

Stability results are discussed in [6, 7, 8, 11, 12, 13, 14, 15, 16, 18, 20, 24].

In [12, 13, 14, 15, 16, 17, 18, 19, 20, 25] reaction networks are classified by means of a nonnegative integer index called the *deficiency*. It is then shown how, for reaction networks of *small* deficiency, one can decide whether they have the capacity for multiple positive equilibria (see also the software package [21]).

On the other hand, it is also shown (see [27]) that the deficiency-oriented theory is not likely to give information for a large class of isothermal homogeneous CFSTRs. Work that is *complementary* to the deficiency-oriented theory, and aimed specifically at CFSTRs, was originated in [29] and then substantially broadened in [30, 31].

In [30, 31] Schlosser and Feinberg associate to any reaction network a graph called the *Species-Complex-Linkage (SCL) graph* of the reaction network. Then they describe

TABLE 1.2

The list of all nonzero coefficients in the expansion of the determinant of the Jacobian of the function $c \to p(c,k)$ for the reaction network (1.1). *Note that they are all positive.*

a criterion in terms of the SCL graph that implies that the CFSTR associated to the reaction network does not have the capacity for multiple positive equilibria. This SCL graph criterion of [30, 31] describes large classes of reaction networks that do not have the capacity for multiple positive equilibria. On the other hand, it is not conclusive for some reaction networks (including (1.1)), and it is not easy to implement as a computer algorithm.

In Theorems 3.1–3.3 we describe equivalent formulations of the injectivity criterion that allow us to decide whether a given reaction network is injective or not using a simple computer algorithm (recall that an injective reaction network cannot have the capacity for multiple positive equilibria). Moreover, the injectivity criterion is less restrictive than the SCL graph criterion in [30, 31]: if the SCL graph criterion can be applied, then our criterion can be applied as well, but sometimes the SCL graph criterion is not conclusive, while our criterion is conclusive.

Applications of chemical reaction network theory are very diverse. There has been a recent surge of interest in applications of dynamics arising from complex reaction networks in biology. A very interesting discussion of biological applications appears in [4]. Also, recent articles address the role of reaction networks in cellular biochemistry [1, 2, 5, 10], in genetics [22, 23, 33], in bioengineering [32], and immunology [34].

In section 2 we give a precise definition of a reaction network, and we discuss some associated ideas. In section 3 we prove equivalent formulations of injectivity for reaction networks (recall that injectivity implies the absence of multiple positive equilibria). We will see that some of these equivalent formulations of injectivity allow us to test whether a given reaction network is injective or not, using a very simple algorithm. In section 4 we describe a condition which implies that a reaction network *does* have the capacity for multiple positive equilibria. Section 5 contains concluding remarks.

2. Definitions and notation. We denote by $\mathbb{R}_+$ the set of strictly positive real numbers, and by $\bar{\mathbb{R}}_+$ the set of nonnegative real numbers. For an arbitrary finite set I we denote by $\mathbb{R}^I$ the real vector space of all formal sums $\sum_{i\in I}\alpha_i i$ for all $\alpha_i \in \mathbb{R}$. Note that I becomes a basis of $\mathbb{R}^I$. By $\mathbb{R}^I_+$ we mean the set of sums $\sum_{i\in I}\alpha_i i$ in which all α_i are strictly positive. By $\bar{\mathbb{R}}^I_+$ we mean the set of sums $\sum_{i\in I}\alpha_i i$ in which all α_i are nonnegative.

In the following definition the *complexes* of a reaction network are to be understood as the objects (such as $A + B$) at the heads and tails of the reaction arrows.

DEFINITION 2.1 (see [14, 18]). *A* chemical reaction network *consists of three finite sets:*

(i) *a set* $\mathscr{S}$ *of* species *of the network;*
(ii) *a set* $\mathscr{C} \subset \bar{\mathbb{R}}^{\mathscr{S}}_+$ *of* complexes *of the network;*
(iii) *a set* $\mathscr{R} \subset \mathscr{C} \times \mathscr{C}$ *of* reactions*, with the following properties:*
  (a) $(y, y) \notin \mathscr{R}$ *for any* $y \in \mathscr{C}$*;*
  (b) *for each* $y \in \mathscr{C}$ *there exists* $y' \in \mathscr{C}$ *such that* $(y, y') \in \mathscr{R}$ *or such that* $(y', y) \in \mathscr{R}$.

When $(y, y') \in \mathscr{R}$ we say that the complex y *reacts to* complex y'. When this is the case we will write $y \to y'$, since it is the usual notation in chemistry.

If we look at the differential equations in (1.3), it is clear that, for CFSTRs in general, there will be not only terms that derive from the occurrence of chemical reactions but also linear terms (such as $-(g/V)c_A$) that derive from the presence of the outflow stream, and constant terms (such as $(g/V)c^f_A$) that derive from the presence of the feed stream. So that all such terms can be brought into a common reaction network theory framework, it will be useful to regard such "flow" terms as having derived from formal chemical "reactions" such as $A \to 0$ (corresponding to the outflow of A) and $0 \to A$ (corresponding to the feed of A); see [12, 25]. Here we view "0" as the zero vector of $\mathbb{R}^{\mathscr{S}}$. If we imagine $A \to 0$ to be governed by mass-action kinetics with rate constant $k_{A\to 0} = g/V$, then the contribution to $\dot{c}_A$ in (1.3) will be precisely $-(g/V)c_A$. We adopt the convention that the mass-action rate of a reaction of the form $0 \to A$ is constant (and equal to the associated rate constant $k_{0\to A}$). Thus, if we choose $k_{0\to A} = (g/V)c^f_A$, then the contribution of the reaction $0 \to A$ to $\dot{c}_A$ is just $(g/V)c^f_A$. In this way, the formal "flow reactions" $A \to 0$ and $0 \to A$ account for the flow terms that appear in the equation for $\dot{c}_A$. More generally, there are advantages to viewing CFSTR mass-action differential equations as having derived from a mass-action system in which the set of "true" reactions is augmented with the set of "flow reactions," with appropriately chosen rate constants. (Recall that we have chosen units such that $g/V = 1$ so that, for us, $k_{s\to 0} = 1$ for all $s \in \mathscr{S}$.)

Hereafter, we shall regard the operative reaction network under discussion to be the augmented one. If, for example, all species are present in the feed stream, then we augment the set of reactions in (1.1) by adding the following flow reactions:

$$\begin{aligned} &0 \to A,\ 0 \to B,\ 0 \to C,\ 0 \to D,\ 0 \to W,\ 0 \to X,\ 0 \to Y,\ 0 \to Z,\\ &A \to 0,\ B \to 0,\ C \to 0,\ D \to 0,\ W \to 0,\ X \to 0,\ Y \to 0,\ Z \to 0. \end{aligned} \tag{2.1}$$

If a certain species, say W, is deemed absent from the feed stream (i.e., if $c^f_W = 0$), then the reaction $0 \to W$ would be omitted. (With respect to injectivity considerations, the presence or absence of certain species in the feed is of no consequence.) Flow reactions of type $0 \to A$ are called *feed reactions*, and flow reactions of type $A \to 0$ are called *outflow reactions*. As Figure 1.1 indicates, all species are deemed present

in the effluent stream, so there is an outflow reaction for each species. (In a future paper we will discuss the implications of relaxing this assumption.)

So, the augmented network corresponding to the reaction network (1.1) has the set of species $\mathscr{S} = \{A, B, C, D, W, X, Y, Z\}$ and the set of complexes $\mathscr{C} = \{A, B, C, D, W, X, Y, Z, 0, A + B, 2A + D, C + W, B + D\}$. It contains the ten true reactions in (1.1) and, when all species are deemed to be in the feed, the sixteen flow reactions in (2.1).

In general, we denote by $\mathscr{R}_t$ the set of true reactions, by $\mathscr{R}_f$ the set of feed reactions, and by $\mathscr{R}_o$ the set of outflow reactions.

DEFINITION 2.2. *A* mass-action system *is a reaction network* $(\mathscr{S}, \mathscr{C}, \mathscr{R})$ *taken together with an element* $k \in \mathbb{R}^{\mathscr{R}}_+$. *The number* $k_{y\to y'}$ *is the* rate constant *of the reaction* $y \to y' \in \mathscr{R}$.

For two vectors in $\bar{\mathbb{R}}^{\mathscr{S}}_+$, say $u = \sum_{s\in\mathscr{S}} u_s s$ and $v = \sum_{s\in\mathscr{S}} v_s s$, we denote $u^v = \prod_{s\in\mathscr{S}} (u_s)^{v_s}$. Here we use the convention that $0^0 = 1$.

We will now show how, by using the notation above, we can express the system of ODEs associated to a reaction network as a very compact formula. For example, note that the term $k_{A+B\to C} c_A c_B$ on the first line in (1.3) can be written as $k_{y\to y'} c^y$; here $y = A + B$ and $y' = C$ are regarded as vectors in $\mathbb{R}^{\mathscr{S}}$, where $\mathscr{S}$ is the set of species. Also, the term $-2k_{2A+D\to Y} c_A^2 c_D$ on the second line in (1.3) can be written as $-2k_{y\to y'} c^y$, where $y = 2A + D, y' = Y$.

If we look for *all* appearances of $k_{2A+D\to Y} c_A^2 c_D$ in (1.3), we notice that they take place in equations corresponding to species A, D, Y, i.e., exactly the species that appear in the complexes y, y'. Moreover, the coefficient of each species in the reaction $2A + D \to Y$ is equal (up to sign) to the coefficient of the monomial $k_{2A+D\to Y} c_A^2 c_D$ in the equation corresponding to that species. The sign is minus for species in y and plus for species in y'. Therefore the factor $k_{2A+D\to Y} c_A^2 c_D$ contributes to the right side of the (vector) ODE precisely as the term $k_{y\to y'} c^y (y' - y)$, where $y = 2A + D, y' = Y$.

Then we get the following two definitions (see [14, 19]).

DEFINITION 2.3. *The* species-formation-rate function *(or simply the* rate function*) for a mass-action system* $(\mathscr{S}, \mathscr{C}, \mathscr{R}, k)$ *is the function* $r(\cdot, k) : \bar{\mathbb{R}}^{\mathscr{S}}_+ \to \mathbb{R}^{\mathscr{S}}$, *defined by*

$$r(c, k) = \sum_{y\to y'\in\mathscr{R}} k_{y\to y'} c^y (y' - y).$$

DEFINITION 2.4. *The* system of differential equations associated to a mass-action system $(\mathscr{S}, \mathscr{C}, \mathscr{R}, k)$ *is given by*

$$\dot{c} = r(c, k).$$

We see here again that the reaction network $(\mathscr{S}, \mathscr{C}, \mathscr{R})$ and the vector k uniquely determine the system of differential equations associated to a mass-action system.

DEFINITION 2.5. *A* positive equilibrium *of a mass-action system* $(\mathscr{S}, \mathscr{C}, \mathscr{R}, k)$ *is an element* $c \in \mathbb{R}^{\mathscr{S}}_+$ *such that* $r(c, k) = 0$.

DEFINITION 2.6. *We say that a reaction network* $(\mathscr{S}, \mathscr{C}, \mathscr{R})$ has the capacity for multiple positive equilibria *if there exist* $k \in \mathbb{R}^{\mathscr{R}}_+$, $a \in \mathbb{R}^{\mathscr{S}}_+$, $b \in \mathbb{R}^{\mathscr{S}}_+$, $a \neq b$, *such that* $r(a, k) = r(b, k) = 0$.

To formulate the following definition recall that we have $\mathscr{R} = \mathscr{R}_f \cup \mathscr{R}_o \cup \mathscr{R}_t$, where $\mathscr{R}_f \cup \mathscr{R}_o$ is the set of flow reactions ($\mathscr{R}_f$ is the set of feed reactions, $\mathscr{R}_o$ is the set of outflow reactions), and $\mathscr{R}_t$ is the set of true reactions.

DEFINITION 2.7. *Given a chemical reaction network* $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$, *its* associated polynomial function $p_{\mathcal{N}}(\cdot,\cdot) : \mathbb{R}_+^{\mathscr{S}} \times \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o} \to \mathbb{R}^{\mathscr{S}}$ *is*

$$p_{\mathcal{N}}(c,k) = \sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} k_{y\to y'} c^y (y - y').$$

Note that

$$r(c,k) = -p_{\mathcal{N}}(c,k) + \sum_{y \to y' \in \mathscr{R}_f} k_{y\to y'} c^y (y' - y).$$

With $\mathscr{S}_f$ denoting the set of species in the feed stream, note also that

$$\sum_{y \to y' \in \mathscr{R}_f} k_{y\to y'} c^y (y' - y) = \sum_{s \in \mathscr{S}_f} k_{0\to s} s.$$

The last equation results from the fact that $\mathscr{R}_f = \{0 \to s : s \in \mathscr{S}_f\}$ and, for $y = 0$, $c^y = 1$. Finally, note that the equilibrium equation $r(c,k) = 0$ is equivalent to

$$p_{\mathcal{N}}(c,k) = \sum_{s \in \mathscr{S}_f} k_{0\to s} s, \tag{2.2}$$

and the sum on the right side of (2.2) is constant. Therefore, if the polynomial function $c \to p_{\mathcal{N}}(c,k)$ is injective for every value of the parameter $k \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$, then there cannot exist multiple positive equilibria.

DEFINITION 2.8. *We say that a chemical reaction network* $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$ *is* injective *if the polynomial function* $c \to p_{\mathcal{N}}(c,k)$ *is injective for all* $k \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$.

Remark 2.9. Our consideration of CFSTRs suggests that, for the outflow reactions (i.e., those of the form $s \to 0$), we should require the rate constants to be *identical* for all $s \in \mathscr{S}$. Recall that these rate constants were identified with g/V, which we set to 1. It would appear then that our requirement of injectivity of $p_{\mathcal{N}}(\cdot,k)$ for *all* $k \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ is stronger than it need be for the application we have in mind. However, it is not hard to show that if $p_{\mathcal{N}}(\cdot,k)$ is injective for all $k \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ satisfying the restriction $k_{s\to 0} = 1$ for every $s \in \mathscr{S}$, then $p_{\mathcal{N}}(\cdot,k)$ is injective for all $k \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$.

In fact, suppose that, for some $k^* \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$, there are distinct $a^* \in \mathbb{R}_+^{\mathscr{S}}$, $b^* \in \mathbb{R}_+^{\mathscr{S}}$ such that $p_{\mathcal{N}}(a^*,k^*) = p_{\mathcal{N}}(b^*,k^*)$. Now choose $k^\#$, $a^\#$, $b^\#$ as follows:

$$\begin{aligned} a_s^\# &= a_s^* k_{s\to 0}^* \quad \forall s \in \mathscr{S}, \\ b_s^\# &= b_s^* k_{s\to 0}^* \quad \forall s \in \mathscr{S}, \\ k_{y\to y'}^\# &= k_{y\to y'}^* / \prod_{s \in \mathscr{S}} {k_{s\to 0}^*}^{y_s} \quad \forall y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o. \end{aligned}$$

Then $k_{s\to 0}^\# = 1$ for all $s \in \mathscr{S}$, and $p_{\mathcal{N}}(a^\#,k^\#) = p_{\mathcal{N}}(b^\#,k^\#)$. This is to say that if $p_{\mathcal{N}}(\cdot,k^*)$ is not injective for some unrestricted k^*, then there is a restricted $k^\#$ such that $p_{\mathcal{N}}(\cdot,k^\#)$ also fails to be injective.

3. Characterizations of the injectivity property. In this section we prove some equivalent characterizations of the injectivity property that make it possible to check whether a given reaction network is injective by using standard computer algebra software.

Recall that for each reaction network $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$ we defined its associated polynomial function $p_{\mathcal{N}}(\cdot,\cdot) : \mathbb{R}^{\mathscr{S}}_+ \times \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+ \to \mathbb{R}^{\mathscr{S}}$.

THEOREM 3.1. *A reaction network $\mathcal{N}$ is injective if and only if we have*

$$\det\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right) \neq 0 \quad \forall c \in \mathbb{R}^{\mathscr{S}}_+ \text{ and } \forall k \in \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+. \tag{3.1}$$

Remark 3.1. Note that there is some similarity between this theorem and the Jacobian conjecture[2] over the field of real numbers, since we are concluding injectivity from the nonsingularity of the Jacobian of a polynomial function. Of course, there are also important differences, e.g., the fact that the domain of the function $p(\cdot,k)$ is restricted to $\mathbb{R}^{\mathscr{S}}_+$, and (3.1) holds for all positive values of the parameter k.

Proof. We will show a chain of equivalences from the negation of (3.1) to the noninjectivity of $p_{\mathcal{N}}(\cdot,k)$. The derivative of $p_{\mathcal{N}}(\cdot,k)$ at some point $c \in \mathbb{R}^{\mathscr{S}}_+$ is a linear transformation from $\mathbb{R}^{\mathscr{S}}$ to $\mathbb{R}^{\mathscr{S}}$. According to [18], the result of applying the derivative of $p_{\mathcal{N}}(\cdot,k)$ to an arbitrary vector $\gamma \in \mathbb{R}^{\mathscr{S}}$ can be written as

$$\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right)(\gamma) = \sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} k_{y\to y'} c^y (y * \gamma)(y - y'),$$

where "$*$" is a special scalar product in $\mathbb{R}^{\mathscr{S}}$, defined by

$$v * w = \sum_{s \in \mathscr{S}} (v_s w_s / c_s).$$

(Here we use the fact that all the components of c are strictly positive.) Note that to say that (3.1) is *not true* is equivalent to

$$\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right)(\gamma) = 0 \text{ for some } c \in \mathbb{R}^{\mathscr{S}}_+, k \in \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+, \gamma \in \mathbb{R}^{\mathscr{S}}, \gamma \neq 0, \tag{3.2}$$

which is also equivalent to

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} k_{y\to y'} c^y (y * \gamma)(y - y') = 0 \text{ for some } c \in \mathbb{R}^{\mathscr{S}}_+,\ k \in \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+ \text{ and some } \gamma \in \mathbb{R}^{\mathscr{S}},\ \gamma \neq 0. \tag{3.3}$$

Using the change of variables $\eta_{y\to y'} = k_{y\to y'} c^y$ and $\delta_s = \gamma_s / c_s$ we notice that condition (3.3) is equivalent to

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} \eta_{y\to y'} (y \cdot \delta)(y - y') = 0 \text{ for some } \eta \in \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+ \text{ and some } \delta \in \mathbb{R}^{\mathscr{S}},\ \delta \neq 0, \tag{3.4}$$

where "$\cdot$" is the usual scalar product in $\mathbb{R}^{\mathscr{S}}$. The condition (3.4) in turn is equivalent to

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} K_{y\to y'} (e^{y\cdot\delta} - 1)(y - y') = 0 \text{ for some } K \in \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+ \text{ and some } \delta \in \mathbb{R}^{\mathscr{S}},\ \delta \neq 0, \tag{3.5}$$

[2]The Jacobian conjecture over the field of real numbers says that if a polynomial function $f : \mathbb{R}^m \to \mathbb{R}^m$ has nonsingular Jacobian everywhere, then f is injective. This conjecture was proved to be false in [28].

since the signs of $y \cdot \delta$ and $e^{y\cdot\delta} - 1$ are the same, regardless of the value of $y \cdot \delta$. Then the condition (3.5) is equivalent to

$$\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} K_{y\to y'}\left(\frac{b^y}{a^y}-1\right)(y-y') = 0 \text{ for some } K \in \mathbb{R}_+^{\mathscr{R}_t\cup\mathscr{R}_o} \text{ and some } a \neq b \in \mathbb{R}_+^{\mathscr{S}} \tag{3.6}$$

via another change of variables, such that $\frac{b_s}{a_s} = e^{\delta_s}$ for all $s \in \mathscr{S}$. Note that $a \neq b$ if and only if $\delta \neq 0$. Condition (3.6) is equivalent to

$$\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \kappa_{y\to y'}(b^y - a^y)(y-y') = 0 \text{ for some } \kappa \in \mathbb{R}_+^{\mathscr{R}_t\cup\mathscr{R}_o} \text{ and some } a \neq b \in \mathbb{R}_+^{\mathscr{S}}, \tag{3.7}$$

where $\kappa_{y\to y'} = \frac{K_{y\to y'}}{a^y}$. Now, note that this is equivalent to saying that for some value of $\kappa \in \mathbb{R}_+^{\mathscr{R}_t\cup\mathscr{R}_o}$ the function $p_{\mathcal{N}}(\cdot,\kappa)$ is not injective on $\mathbb{R}_+^{\mathscr{S}}$. Therefore, we showed that the reaction network $\mathcal{N}$ is injective if and only if (3.1) is true. ∎

It is perhaps worthwhile to consider a small example, which is easily worked by hand. Consider network (3.8):

$$A + B \rightleftharpoons C, \quad A \to 2B. \tag{3.8}$$

The system of CFSTR differential equations associated to (3.8) is

$$\begin{aligned}
\dot{c}_A &= c_A^f - c_A - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C - k_{A\to 2B}c_A,\\
\dot{c}_B &= c_B^f - c_B - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C + 2k_{A\to 2B}c_A,\\
\dot{c}_C &= c_C^f - c_C + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C,
\end{aligned} \tag{3.9}$$

where we supposed that $g/V = 1$. If we now again look for equilibria and rearrange terms, we get

$$\begin{aligned}
c_A^f &= c_A + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C + k_{A\to 2B}c_A,\\
c_B^f &= c_B + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C - 2k_{A\to 2B}c_A,\\
c_C^f &= c_C - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C.
\end{aligned} \tag{3.10}$$

Therefore the associated polynomial function for the reaction network (3.8) is

$$\begin{aligned}
p(c,k) = (&c_A + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C + k_{A\to 2B}c_A,\\
&c_B + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C - 2k_{A\to 2B}c_A,\\
&c_C - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C).
\end{aligned} \tag{3.11}$$

Then, for the reaction network (3.8), we have

$$\begin{aligned}
&\det\left(\frac{\partial p}{\partial c}(c,k)\right)\\
&= \det\begin{bmatrix} 1 + k_{A+B\to C}c_B + k_{A\to 2B} & k_{A+B\to C}c_A & -k_{C\to A+B}\\ k_{A+B\to C}c_B - 2k_{A\to 2B} & 1 + k_{A+B\to C}c_A & -k_{C\to A+B}\\ -k_{A+B\to C}c_B & -k_{A+B\to C}c_A & 1 + k_{C\to A+B}\end{bmatrix}\\
&= 1 + k_{C\to A+B} + k_{A+B\to C}c_A + k_{A+B\to C}c_B\\
&\quad + 3k_{A\to 2B}k_{A+B\to C}c_A + k_{A\to 2B}k_{C\to A+B}.
\end{aligned} \tag{3.12}$$

Notice that in (3.12) all coefficients[3] of the monomials in the expansion of the determinant are 1, except the coefficient of $k_{A\to 2B}k_{A+B\to C}c_A$, which is 3. In particular, they are all positive numbers. Therefore, in this case, $\det(\frac{\partial f}{\partial c}(c,k)) > 0$ for all $c \in \mathbb{R}^n_+$ and for all $k \in \mathbb{R}^m_+$, so the reaction network (3.8) is injective as well.

Compare this to $\det(\frac{\partial p}{\partial c}(c,k))$ for the polynomial function associated to the reaction network (vii) in Table 1.1, which is

$$\det\left(\frac{\partial p}{\partial c}(c,k)\right) = 1 + k_{2A+B\to 3A}c_A^2 - 2k_{2A+B\to 3A}c_Ac_B + 3k_{3A\to 2A+B}c_A^2. \tag{3.13}$$

The reaction network (vii) in Table 1.1 does admit multiple positive equilibria, and, as we have seen above, the determinant of the Jacobian of its associated polynomial function has a monomial with a negative coefficient.

Now we are in a position to review and elaborate further on what was said in Remark 1.2. It is worth repeating here that $\det(\frac{\partial p}{\partial c}(c,k))$ can be calculated using currently available computer algebra software and that the result of such a computation will sometimes have hundreds or even thousands of terms, each a monomial in the (positive) species concentrations and the (positive) rate constants. It is remarkable that, more often than not, *all* such monomials will have positive coefficients, so that $\det(\frac{\partial p}{\partial c}(c,k))$ is positive for all positive c and all positive k (recall Table 1.2). Indeed, for large networks the positivity of the monomial coefficients can also be checked with computer algebra software. In this way, Theorem 3.1 provides a (surprisingly robust) way to ensure that a given network is injective and, therefore, incapable of multiple positive equilibria.

In fact, Theorem 3.1 provides the information that networks (ii) and (iv) in Table 1.1 cannot give rise to multiple positive equilibria. On the other hand, Theorem 3.1 by itself stands silent on the capacity for multiple positive equilibria of the very similar networks (i) and (iii). In section 4 we will discuss extensions of Theorem 3.1 that do give information about networks (i) and (iii).

For polynomials in general, it is not necessary that each coefficient be positive in order for the polynomial to take strictly positive values for all positive values of the variables. (The polynomial $x^2 - xy + y^2$ is, of course, an elementary counterexample.) On the other hand, we will show that, for the class of polynomials considered here, positivity of the numerical coefficients is also necessary if positive values of the polynomial are to result for all positive values of the variables (i.e., the species concentrations and rate constants). In turn, this will imply that positivity of all (nonzero) coefficients is not only sufficient but also necessary for a network's injectivity (see Theorem 3.3).

In the following theorem we draw a relationship between the underlying network of chemical reactions and the numerical coefficients in the expansion of $\det(\frac{\partial p}{\partial c}(c,k))$. This relationship will have some importance not only here but also in a subsequent paper, in which we describe large classes of networks for which all (nonzero) coefficients are positive.

THEOREM 3.2. *Consider some reaction network $\mathcal{N}$ with n species. Then for each coefficient in the expansion of* $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ *there is a set of n reactions $\{y_1 \to y_1', \ldots, y_n \to y_n'\}$ (taken from the true and outflow reactions) such that the coefficient is equal to*

$$\det([y_1, \ldots, y_n])\det([y_1 - y_1', \ldots, y_n - y_n']). \tag{3.14}$$

[3]We are looking at coefficients of monomials with respect to the coordinates of c and k.

Moreover, for each choice of n reactions such that (3.14) *is not zero, there is a corresponding coefficient in the expansion of* $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$.

Proof. Recall that, with the notation from the proof of Theorem 3.1, we have

$$\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right)(\gamma) = \sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y*\gamma)(y-y'),$$

where $\eta_{y\to y'} = k_{y\to y'}c^y$. With $\{e_1,\dots,e_n\}$ denoting the canonical basis of $\mathbb{R}^{\mathscr{S}}$, we have

$$\det\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right)$$
$$= \det\left[\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y*e_1)(y-y'),\dots,\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y*e_n)(y-y')\right],$$

and, according to the definition of "$*$", it follows that

$$\left(\prod_{i=1}^n c_i\right)\det\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right)$$
$$= \det\left[\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y\cdot e_1)(y-y'),\dots,\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y\cdot e_n)(y-y')\right].$$

Therefore the coefficients in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ are exactly the coefficients in the expansion of

$$\det\left[\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y\cdot e_1)(y-y'),\dots,\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} \eta_{y\to y'}(y\cdot e_n)(y-y')\right].$$

Note now that each term in the expansion of the determinant above is a scalar multiple of a product of the form $\prod_{i=1}^n \eta_{y_i\to y_i'}$, where $y_1\to y_1',\dots,y_n\to y_n'$ are some reactions in $\mathscr{R}_t\cup\mathscr{R}_o$.

Let us look at some fixed set $\{y_1\to y_1',\dots,y_n\to y_n'\}\subset\mathscr{R}_t\cup\mathscr{R}_o$. With S_n denoting the set of all permutations of $\{1,\dots,n\}$, the coefficient of $\prod_{i=1}^n \eta_{y_i\to y_i'}$ in the expansion of the determinant above is

$$\begin{aligned}
&\sum_{\sigma\in S_n} \det[(y_{\sigma(1)}\cdot e_1)(y_{\sigma(1)}-y'_{\sigma(1)}),\dots,(y_{\sigma(n)}\cdot e_n)(y_{\sigma(n)}-y'_{\sigma(n)})]\\
&= \sum_{\sigma\in S_n} \det[y^1_{\sigma(1)}(y_{\sigma(1)}-y'_{\sigma(1)}),\dots,y^n_{\sigma(n)}(y_{\sigma(n)}-y'_{\sigma(n)})]\\
&= \sum_{\sigma\in S_n} y^1_{\sigma(1)}y^2_{\sigma(2)}\dots y^n_{\sigma(n)}\det[(y_{\sigma(1)}-y'_{\sigma(1)}),\dots,(y_{\sigma(n)}-y'_{\sigma(n)})]\\
&= \sum_{\sigma\in S_n} y^1_{\sigma(1)}y^2_{\sigma(2)}\dots y^n_{\sigma(n)}\mathrm{sgn}(\sigma)\det[(y_1-y_1'),\dots,(y_n-y_n')]\\
&= \left(\sum_{\sigma\in S_n} y^1_{\sigma(1)}y^2_{\sigma(2)}\dots y^n_{\sigma(n)}\mathrm{sgn}(\sigma)\right)\det[(y_1-y_1'),\dots,(y_n-y_n')]\\
&= \det[y_1,\dots,y_n]\det[(y_1-y_1'),\dots,(y_n-y_n')].
\end{aligned}$$

Therefore all coefficients in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ are of the form

$$\det[y_1,\dots,y_n]\det[y_1-y_1',\dots,y_n-y_n']$$

for some set $\{y_1\to y_1',\dots,y_n\to y_n'\}\subset\mathscr{R}_t\cup\mathscr{R}_o$. ∎

Remark 3.2. In a future paper we will use the result of Theorem 3.2 to explain why, for large classes of reaction networks, all coefficients of the monomials in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ are nonnegative (i.e., our empirical observation).

Note that Theorem 3.2 gives us a way of computing the coefficients of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ one by one. In particular, it suggests a simple parallel computation algorithm for checking injectivity.

We prove now that the injectivity of a reaction network $\mathcal{N}$ is completely characterized by the signs of the coefficients of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$.

THEOREM 3.3. *A reaction network $\mathcal{N}$ is injective if and only if all the coefficients in the expansion of* $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ *are nonnegative.*

Proof. Suppose that all the coefficients in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ are nonnegative. We want to show that $\mathcal{N}$ is injective.

Consider the function $f:\mathbb{R}_+^{\mathscr{S}}\times\mathbb{R}_+^{\mathscr{R}_t\cup\mathscr{R}_o}\to\mathbb{R}$ defined by

$$f(c,k)=\left(\prod_{s\in\mathscr{S}}c_s\right)\det\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right).$$

Note that f vanishes if and only if $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ vanishes. As in the proof of Theorem 3.2, the terms in the expansion of $f(c,k)$ are of the form

$$\det[y_1,\dots,y_n]\det[y_1-y_1',\dots,y_n-y_n']\left(\prod_{i=1}^{n}\eta_{y_i\to y_i'}\right),\tag{3.15}$$

where $\eta_{y\to y'}=k_{y\to y'}c^y$, and with each term corresponding to some choice of n reactions from the set $\mathscr{R}_t\cup\mathscr{R}_o$. Note that $\prod_{s\in\mathscr{S}}c_s$ and $\prod_{i=1}^{n}\eta_{y_i\to y_i'}$ are strictly positive, since c and k are regarded to have strictly positive coordinates. Then, to show injectivity, it is enough to show that there exists some set $\{y_1\to y_1',\dots,y_n\to y_n'\}\subset\mathscr{R}_t\cup\mathscr{R}_o$ such that $\det[y_1,\dots,y_n]\det[y_1-y_1',\dots,y_n-y_n']\neq 0$. But if we just choose the set $\{y_1\to y_1',\dots,y_n\to y_n'\}$ to be $\mathscr{R}_o$, we have

$$\det[y_1,\dots,y_n]\det[y_1-y_1',\dots,y_n-y_n']=1,$$

because, up to a permutation, $y_i=e_i$ and $y_i'=0$ for $i=1,\dots,n$. Therefore (3.1) is true, and, according to Theorem 3.1, $\mathcal{N}$ is injective.

Suppose now that $\mathcal{N}$ is injective. We want to show that all the coefficients in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ are nonnegative. Of course, the coefficients in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$ are the same as the coefficients in the expansion of $f(c,k)$. We will show that all the coefficients in the expansion of $f(c,k)$ are nonnegative. Note that $f(c,k)$ equals a homogeneous polynomial of degree n of the coordinates of η. Note also that, since we can write the terms in the expansion of $f(c,k)$ as in (3.15), it follows that each monomial in this expansion contains a product $\prod_{i=1}^{n}\eta_{y_i\to y_i'}$ for some set of n *distinct* reactions $\{y_1\to y_1',\dots,y_n\to y_n'\}$, and there is no other monomial with the same set of n reactions. Suppose now that there is some monomial with a negative coefficient in the expansion of $f(c,k)$. Then, by choosing some $\eta\in\mathbb{R}_+^{\mathscr{R}_t\cup\mathscr{R}_o}$ such that the coordinates of η that appear in the negative monomial are very large, and

all other coordinates of η are very small (i.e., very close to zero), we conclude that f takes a negative value somewhere in its domain. Similarly, by using a monomial with a positive coefficient (for example, the monomial with the coefficient "1" that we mentioned above) we conclude that f takes a positive value somewhere in its domain. Since the domain of f is connected, it follows that f is zero somewhere in its domain. According to Theorem 3.1, this contradicts the hypothesis that $\mathcal{N}$ is injective. Therefore there cannot exist any monomial with a negative coefficient in the expansion of $f(c,k)$, so there cannot exist any monomial with a negative coefficient in the expansion of $\det(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k))$. □

Remark 3.3. Theorem 3.3 allows us to show that, although injectivity is *sufficient* to conclude that a reaction network does not admit multiple positive equilibria, *it is not a necessary condition*. One such example is the reaction network (vi) in Table 1.1. Indeed, that reaction network does not admit multiple positive equilibria but has

$$\det\left(\frac{\partial p}{\partial c}(c,k)\right) = 1 + k_{A+B\to 2A}c_A - k_{A+B\to 2A}c_B + 2k_{2A\to A+B}c_A,$$

which does have one negative coefficient, so the network is not injective.

Remark 3.4. Theorems 3.2 and 3.3 imply that, given a reaction network with n species and m reactions, it is only the structure of its subnetworks of exactly n reactions (some of which could be outflow reactions) that dictates whether the reaction network is injective or not. Also, given some reaction network that *does* admit multiple positive equilibria, Theorems 3.2 and 3.3 allow us to pinpoint the subnetwork or subnetworks that create the capacity for multiple positive equilibria as exactly the ones for which the product of determinants $\det[y_1,\dots,y_n]\det[y_1-y_1',\dots,y_n-y_n']$ is negative. Or, consider some finite family of reaction networks, each containing exactly n species. According to Theorem 3.2, we can enumerate all possible "bad" subnetworks in that family (i.e., subnetworks that have exactly n reactions, and for which the product of determinants above is negative). Then, in that family, only the reaction networks that contain a copy of some "bad" subnetwork can have the capacity for multiple positive equilibria.

Remark 3.5. Up to now we have considered only reaction networks where all species are in the outflow. If $\mathcal{N}$ is a reaction network such that not all species are in the outflow, but there are n reactions $\{y_1\to y_1',\dots,y_n\to y_n'\}$ in $\mathcal{N}$ (some of which could be outflow reactions) such that $\det[y_1,\dots,y_n]\det[y_1-y_1',\dots,y_n-y_n']>0$, then Theorem 3.3 remains valid.

4. Sufficient conditions for existence of multiple positive equilibria. Recall that, as we mentioned in section 1, the injectivity property is not a necessary condition for the absence of multiple positive equilibria (see also Remark 3.3). In other words, if a network $\mathcal{N}$ is not injective, this does not imply that $\mathcal{N}$ has the capacity for multiple positive equilibria. Theorems 4.1 and 4.2 below say that if $\mathcal{N}$ is not injective and satisfies an additional condition, then $\mathcal{N}$ does have the capacity for multiple positive equilibria. We begin with a lemma.

LEMMA 4.1. *Let $\mathcal{N}=(\mathscr{S},\mathscr{C},\mathscr{R})$ be some reaction network (augmented to include the flow reactions). Suppose that there is some $c\in\mathbb{R}_+^{\mathscr{S}}$ and some $k\in\mathbb{R}_+^{\mathscr{R}_t\cup\mathscr{R}_o}$ such that*

$$\det\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(c,k)\right)=0$$

and

$$\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o} k_{y\to y'}c^y(y-y')\in\mathbb{R}^{\mathscr{S}}_+.$$

Then $\mathcal{N}$ does have the capacity for multiple positive equilibria.

Proof. The reaction network $\mathcal{N}$ admits multiple positive equilibria if and only if there is some $\kappa\in\mathbb{R}^{\mathscr{R}_t\cup\mathscr{R}_o}_+$ and some $a\neq b\in\mathbb{R}^{\mathscr{S}}_+$ such that

$$\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\kappa_{y\to y'}a^y(y-y')=\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\kappa_{y\to y'}b^y(y-y')=c^f$$

for some $c^f\in\bar{\mathbb{R}}^{\mathscr{S}}_+$ (recall Remark 1.1). Consider $\eta\in\mathbb{R}^{\mathscr{R}_t\cup\mathscr{R}_o}_+$ such that $\eta_{y\to y'}=k_{y\to y'}c^y$ for each reaction $y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o$, where c and k are as in the theorem statement. Then, as in the proof of Theorem 3.1, there exists some $\delta\in\mathbb{R}^{\mathscr{S}},\ \delta\neq 0$, such that

$$\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\eta_{y\to y'}(y\cdot\delta)(y-y')=0.$$

Consider $a\in\mathbb{R}^{\mathscr{S}}_+$ given by $a_s=1$ for every $s\in\mathscr{S}$, and consider $b\in\mathbb{R}^{\mathscr{S}}_+$ given by $b_s=e^{\delta_s}$ for every $s\in\mathscr{S}$. Note that $\delta\neq 0$ implies $a\neq b$. Denote by $\kappa\in\mathbb{R}^{\mathscr{R}_t\cup\mathscr{R}_o}_+$ the vector given by $\kappa_{y\to y'}=\frac{y\cdot\delta}{e^{y\cdot\delta}-1}\eta_{y\to y'}$ for all $y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o$ with $y\cdot\delta\neq 0$, and $\kappa_{y\to y'}=\eta_{y\to y'}$ for all $y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o$ with $y\cdot\delta=0$.

Then we have

$$\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\kappa_{y\to y'}(b^y-a^y)(y-y')=\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\eta_{y\to y'}(y\cdot\delta)(y-y')=0.$$

Note that, without loss of generality, we can suppose that the norm of δ is very small. On the other hand we have

$$\begin{aligned}&\lim_{\delta\to 0}\left(\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\kappa_{y\to y'}a^y(y-y')\right)\\&=\lim_{\delta\to 0}\left(\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\kappa_{y\to y'}(y-y')\right)\\&=\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\eta_{y\to y'}(y-y')\\&=\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}k_{y\to y'}c^y(y-y')\ \in\ \mathbb{R}^{\mathscr{S}}_+.\end{aligned}$$

Then, for small enough δ, it follows that $\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\kappa_{y\to y'}a^y(y-y')\ \in\ \mathbb{R}^{\mathscr{S}}_+$. ∎

THEOREM 4.1. *Consider some reaction network $\mathcal{N}=(\mathscr{S},\mathscr{C},\mathscr{R})$ (augmented to include the flow reactions). For $\eta\in\mathbb{R}^{\mathscr{R}_t\cup\mathscr{R}_o}_+$ let $T_\eta:\mathbb{R}^{\mathscr{S}}\to\mathbb{R}^{\mathscr{S}}$ be defined by*

$$T_\eta(\delta)=\sum_{y\to y'\in\mathscr{R}_t\cup\mathscr{R}_o}\eta_{y\to y'}(y\cdot\delta)(y-y'),\tag{4.1}$$

and let

$$f(\eta)=\det(T_\eta).\tag{4.2}$$

Suppose that for some $\eta^* \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ *we have*

$$f(\eta^*) < 0, \tag{4.3}$$

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} \eta^*_{y \to y'}(y - y') \in \mathbb{R}_+^{\mathscr{S}}. \tag{4.4}$$

Then $\mathcal{N}$ *has the capacity for multiple positive equilibria.*

Proof. Consider some $\eta^\# \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ such that for all $y \to y' \in \mathscr{R}_o$ the number $\eta^\#_{y \to y'}$ is very large, and for all $y \to y' \in \mathscr{R}_t$ the number $\eta^\#_{y \to y'}$ is very small. Then condition (4.4) holds for $\eta^\#$, and, for reasons similar to those in the proof of Theorem 3.3, $f(\eta^\#) > 0$.

Suppose now that there is some $\eta^* \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ such that both (4.3) and (4.4) are true. Because the set of vectors η that satisfy (4.4) is convex, and because the function f is continuous, it follows that on the line segment that connects $\eta^\#$ and η^* there will be some $\tilde{\eta}$ such that condition (4.4) holds for $\tilde{\eta}$, and $f(\tilde{\eta}) = 0$.

Now, for some fixed $\tilde{c} \in \mathbb{R}_+^{\mathscr{S}}$, choose $\tilde{k} \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ such that $\tilde{\eta}_{y \to y'} = \tilde{k}_{y \to y'} \tilde{c}^y$ for all $y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o$. According to the chain of equivalences in the proof of Theorem 3.1 (from (3.1) to (3.4)) we have

$$\det\left(\frac{\partial p_{\mathcal{N}}}{\partial c}(\tilde{c}, \tilde{k})\right) = 0.$$

Also, note that

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} \tilde{k}_{y \to y'} \tilde{c}^y (y - y') \in \mathbb{R}_+^{\mathscr{S}}.$$

Then the hypothesis of Lemma 4.1 is satisfied, so its conclusion is also true. ∎

Remark 4.1. Note that if some vector $\eta^* \in \mathbb{R}_+^{\mathscr{R}_t \cup \mathscr{R}_o}$ satisfies (4.3) and (4.4), then $\lambda \eta^*$ also satisfies (4.3) and (4.4) for any positive number λ. Therefore, if there is some η^* that satisfies (4.3) and (4.4) and has all coordinates positive, then there is some η^{**} that satisfies (4.3) and (4.4) and has all coordinates positive *and of total sum* 1. Then Theorem 4.1 can be implemented by considering the polynomial optimization problem (4.5)–(4.8), with linear constraints on a compact domain:

$$\text{minimize} f(\eta) \tag{4.5}$$

subject to the constraints

$$\eta_{y \to y'} \geq \varepsilon \quad \forall y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o, \tag{4.6}$$

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} \eta_{y \to y'} = 1, \tag{4.7}$$

$$\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} \eta_{y \to y'}(y_s - y'_s) \geq \varepsilon \quad \forall s \in \mathscr{S}, \tag{4.8}$$

where ε is some very small positive number. Note that, from the point of view of applying Theorem 4.1, it is enough to find *some* vector η^* satisfying (4.6)–(4.8) and such that $f(\eta^*) < 0$ (i.e., we don't need to find the global minimum, as we are just interested in knowing if the minimum is negative).

THEOREM 4.2. *Consider some reaction network $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$ (augmented to include the flow reactions). Suppose that there is a set of n reactions $\{y_1 \to y_1', \ldots, y_n \to y_n'\}$ (where n is the number of species) such that*

$$\det(y_1, \ldots, y_n) \det(y_1 - y_1', \ldots, y_n - y_n') < 0 \tag{4.9}$$

and

$$\sum_{i=1}^{n} \eta_i (y_i - y_i') \in \mathbb{R}^{\mathscr{S}}_+ \text{ for some positive numbers } \eta_1, \ldots, \eta_n. \tag{4.10}$$

Then $\mathcal{N}$ does have the capacity for multiple positive equilibria.

Proof. Consider some $\eta^* \in \mathbb{R}^{\mathscr{R}_t \cup \mathscr{R}_o}_+$ such that for all $y \to y' \in \{y_1 \to y_1', \ldots, y_n \to y_n'\}$ the number $\eta^*_{y \to y'}$ is very large, and for all other $y \to y'$ the number $\eta^*_{y \to y'}$ is very small. Then, as in the proof of Theorem 3.3, it follows that $f(\eta^*) < 0$, because in the expansion of $\det(T_{\eta^*})$ the negative term corresponding to the subnetwork $\{y_1 \to y_1', \ldots, y_n \to y_n'\}$ dominates all other terms.

Suppose in particular that $\eta^*_{y_i \to y_i'} = \lambda \eta_i$ for some (very large) number λ. Then (4.4) holds for this η^*, since $\sum_{i=1}^n \eta_i (y_i - y_i') \in \mathbb{R}^{\mathscr{S}}_+$, and $\sum_{y \to y' \in \mathscr{R}_t \cup \mathscr{R}_o} \eta^*_{y \to y'} (y - y')$ is very close to $\lambda \sum_{i=1}^n \eta_i (y_i - y_i')$. Therefore we can apply Theorem 4.1. ∎

Remark 4.2. Note that if some numbers $\eta_1, \ldots, \eta_n$ satisfy $\sum_{i=1}^n \eta_i (y_i - y_i') \in \mathbb{R}^{\mathscr{S}}_+$, then the numbers $\lambda\eta_1, \ldots, \lambda\eta_n$ satisfy $\sum_{i=1}^n \lambda\eta_i (y_i - y_i') \in \mathbb{R}^{\mathscr{S}}_+$ for any positive number λ. Then, when implementing Theorem 4.2, we can replace condition (4.10) with the systems of inequalities

$$\eta_i \geq 1 \quad \text{for } i = 1, \ldots, n, \tag{4.11}$$

$$\sum_{i=1}^{n} \eta_i (y_{is} - y_{is}') \geq 1 \quad \forall s \in \mathscr{S}. \tag{4.12}$$

Remark 4.3. For networks (i), (iii), (v) in Table 1.1 the less powerful but easily applied Theorem 4.2 already affirms the capacity for multiple positive equilibria. For network (vii) Theorem 4.1 affirms the capacity for multiple positive equilibria, while Theorem 4.2 stands silent.

Remark 4.4. Suppose that we are given a reaction network $\mathcal{N}$ having n species, and we would like to know if $\mathcal{N}$ has the capacity for multiple positive equilibria (in the isothermal homogeneous CFSTR context). An algorithm that investigates this problem proceeds as follows: First, check[4] if there is any subnetwork of n reactions such that (4.9) holds. If (4.9) is false for all such subnetworks, then, according to Theorems 3.2 and 3.3, $\mathcal{N}$ does not have the capacity for multiple positive equilibria. If one or more subnetworks of $\mathcal{N}$ satisfy (4.9), then check[5] if Theorem 4.2 applies for any such subnetwork. If Theorem 4.2 remains indecisive, then try to apply the more computationally intensive method given by Theorem 4.1 and described in Remark 4.1.

[4]For example, this can be done by computing $\det(\frac{\partial p_{\mathcal{N}}(c,k)}{\partial c})$ in order to recover the coefficients for the various subnetworks (recall Theorem 3.2).

[5]This will be very easy, since we only have to check the feasibility of the system of linear inequalities (4.11) and (4.12).

5. Concluding remarks. We believe that the theorems presented here have broad utility in deciding the capacity of a complex mass-action system to engender multiple positive steady states in a homogeneous isothermal CFSTR context. That these techniques should be robust relies heavily on our assertion that, despite the presence of hundreds or even thousands of terms in the expansion of $\det(\frac{\partial p_{\mathcal{N}}(c,k)}{\partial c})$ for a complex reaction network, it will typically be the case that all (nonzero) coefficients are positive. (When there are negative coefficients for a given network, they will typically be very few in number.) Although we have given examples to support this assertion, we have not, in this paper, tried to explain why positivity of the coefficients is to be expected broadly. Nor have we tried to identify those aspects of reaction network structure that give rise to negative coefficients. We intend to take up these questions in a future paper. There we will show how certain representations of reaction networks in graph-theoretical terms give surprisingly rapid and incisive information.

AN ANALYSIS OF HIGHER ORDER BOUNDARY CONDITIONS FOR THE WAVE EQUATION*

JULIEN DIAZ† AND PATRICK JOLY†

Abstract. Thanks to the use of the Cagniard–De Hoop method, we derive an analytic solution in the time domain for the half-space problem associated with the wave equation with Engquist–Majda higher order boundary conditions. This permits us to derive new convergence results when the order of the boundary condition tends to $+\infty$, as well as error estimates. The theory is illustrated by numerical results.

Key words. Cagniard–De Hoop method, absorbing boundary conditions, wave equation, error estimates, convergence, Green's function

DOI. 10.1137/S0036139903436145

1. Introduction.

The design of accurate absorbing boundary conditions (ABCs) for the numerical calculation of waves in the time domain is already an old subject since the major work of Engquist and Majda [11], [12] in the late 1970s. Their main contribution was the construction and analysis of a hierarchy of local boundary conditions for the wave equation. Let us concentrate on the two-dimensional (2D) acoustic wave equation:

$$\frac{1}{c^2}\frac{\partial^2 u}{\partial t^2} - \Delta u = 0, \qquad x = (x_1, x_2) \in \mathbb{R}^2, \quad t > 0. \tag{1.1}$$

Assuming that the data (initial data) of the problem are supported in the upper half-space $\mathbb{R}^2_+ = \{x_2 > 0\}$, it is natural to try to reduce the effective numerical computations to this half-space by imposing adequate absorbing boundary conditions on the artificial boundary $\Gamma = \partial\mathbb{R}^2_+$. In [11], Engquist and Majda proposed the following condition (the integer N is a parameter meant to be large):

$$\mathcal{B}^N u = 0 \quad \text{on } \Gamma, \tag{1.2}$$

where the operators

$$\mathcal{B}^N = \mathcal{B}^N\left(\frac{\partial}{\partial t}, \frac{\partial}{\partial x_1}, \frac{\partial}{\partial x_2}\right), \quad N \geq 0,$$

are a family of homogeneous differential operators defined inductively by

$$\begin{cases} \mathcal{B}^0 = 2I, \quad \mathcal{B}^1 = \dfrac{\partial}{\partial t} - c\dfrac{\partial}{\partial x_2}, \\ \mathcal{B}^{N+1} = \dfrac{\partial}{\partial t}\mathcal{B}^N - \dfrac{c^2}{4}\dfrac{\partial^2}{\partial x_1^2}\mathcal{B}^{N-1}. \end{cases} \tag{1.3}$$

†INRIA Rocquencourt, Domaine de Voluceau, B. P. 105, 78153 Le Chesnay, France (julien.diaz@inria.fr, patrick.joly@inria.fr).

Note that $\mathcal{B}^N$ can be rewritten in the form

$$\mathcal{B}^N = S_{N-1}\left(\frac{\partial}{\partial t}, \frac{\partial}{\partial x_1}\right)\frac{\partial}{\partial x_2} - Q_N\left(\frac{\partial}{\partial t}, \frac{\partial}{\partial x_1}\right),$$

where Q_N and S_{N-1} are homogeneous polynomials of two variables of respective degrees N and $N-1$. In particular, $\mathcal{B}^N$ remains of first order with respect to x_2; the condition (1.2) can be seen as a Dirichlet-to-Neumann (or impedance) type boundary condition since it can be formally rewritten as

$$\frac{\partial u}{\partial x_2} - \frac{Q_N(\frac{\partial}{\partial t}, \frac{\partial}{\partial x_1})}{S_{N-1}(\frac{\partial}{\partial t}, \frac{\partial}{\partial x_1})}u = 0. \tag{1.4}$$

Remark 1.1. For smooth solutions (up to the boundary Γ) of the wave equation, the boundary condition (1.2) can be rewritten in terms of t and x_2 derivatives only. Indeed, $\mathcal{B}^N$ is obviously even with respect to the x_1 variable, and, thanks to the wave equation, the second order derivative with respect to x_1 can be replaced by t and x_2 derivatives:

$$\frac{\partial^2}{\partial x_1^2} \longrightarrow \frac{1}{c^2}\frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x_2^2}.$$

As a consequence, one can show that [21]

$$\mathcal{B}^N u = 0 \Longleftrightarrow \widetilde{\mathcal{B}}^N u = 0, \quad \widetilde{\mathcal{B}}^N = \left(\frac{\partial}{\partial t} - c\frac{\partial}{\partial x_2}\right)^N. \tag{1.5}$$

This remark will be useful in section 3.

Let us recall that the initial boundary value problems (IBVPs) for linear hyperbolic systems (1.2), or (1.4) or (1.5), are constructed as an approximation of an exact or transparent boundary condition

$$\mathcal{B}u = 0, \quad \mathcal{B} = \frac{\partial}{\partial x_2} - \mathcal{L}, \tag{1.6}$$

where $\mathcal{L}$ is a pseudodifferential operator in (x_1, t) whose symbol is known explicitly. More precisely, if one uses the Laplace–Fourier transform in the (t, x_1) plane (see (3.3) and (3.2)),

$$\varphi(x_1, t) \to \widetilde{\varphi}(k, s),$$

one has the formula

$$\widetilde{\mathcal{L}\varphi}(k, s) = \left(k^2 + \frac{s^2}{c^2}\right)^{\frac{1}{2}}\varphi(k, s), \qquad \mathcal{R}e\left(k^2 + \frac{s^2}{c^2}\right)^{\frac{1}{2}} \geq 0. \tag{1.7}$$

This comes from the fact that if u is a solution of the wave equation in the lower half-space $\mathbb{R}^2_- = \{x_2 < 0\}$ with zero initial data, its partial Laplace–Fourier transform in t and x_1, $\widetilde{u}(k, x_2, s)$, satisfies

$$\widetilde{u}(k, x_2, s) = \widetilde{u}(k, 0, s)e^{(k^2 + \frac{s^2}{c^2})^{\frac{1}{2}}x_2}, \quad x_2 \leq 0,$$

which yields in particular

$$\frac{d\widetilde{u}}{dx_2}(k,0,s) - \left(k^2 + \frac{s^2}{c^2}\right)^{\frac{1}{2}} \widetilde{u}(k,0,s) = 0.$$

The presence of the square root in the symbol of $\mathcal{L}$ makes the operator $\mathcal{L}$, and consequently the boundary condition (1.6), nonlocal in space and time, which is a priori very unpleasant from the numerical point of view. The approximate condition simply comes from a rational approximation of the symbol of $\mathcal{L}$ in such a way that the resulting boundary condition can be expressed in terms of differential operators, which is much more tractable from the numerical point of view. If one writes

$$\left(k^2 + \frac{s^2}{c^2}\right)^{\frac{1}{2}} = \frac{s}{c}\left(1 + \frac{c^2k^2}{s^2}\right)^{\frac{1}{2}},$$

the problem is reduced to the rational approximation of the function of one variable:

$$f(z) = (1+z^2)^{\frac{1}{2}}.$$

Noticing that $f(z)$ is a solution of the fixed point equation,

$$f(z) = 1 + \frac{z^2}{1+f(z)}, \tag{1.8}$$

one obtains a rational approximation (or continuous fraction expansion) of $f(z)$ with the following fixed point algorithm:

$$f_{n+1}(z) = 1 + \frac{z^2}{1+f_n(z)}, \quad f_1(z) = 1. \tag{1.9}$$

The condition (1.2) is obtained by replacing in (1.6) $\mathcal{L}$ by $\mathcal{L}_N$, whose symbol is $\frac{s}{c} f_N(\frac{ck}{s})$. It is then relatively easy to deduce the induction formula (1.3) from (1.9).

Remark 1.2. It is easy to show that the sequence $f_n(z)$ converges, for large n, to $f(z)$ only if $|z| < 1$. Moreover, the convergence is uniform and exponential in any compact of the unit circle. For $|z| > 1$, $f_n(z)$ converges to $-f(z)$, which is the other solution of (1.8). However, it is not a problem for the application to ABCs, as will be shown in this paper.

It is also well known that (1.9) provides the sequence of $\{n, n-1\}$ (for even n) and $\{n-1, n-1\}$ (for odd n) Padé approximants [3] of $f(z)$ at the neighborhood of the origin:

$$f_2(z) = 1 + \frac{z^2}{2}, \qquad f_3(z) = 1 + \frac{2z^2}{4+z^2}, \dots ;$$

and in particular one has

$$f_n(z) - f(z) = O((z^2)^N), \quad z \to 0. \tag{1.10}$$

That is why the boundary condition (1.2) is known as the Engquist–Majda condition of order $2m$. Equation (1.10) shows that the rational approximation of the symbol of $\mathcal{L}$ given by (1.9) is better for the small values of ck/s, which has a physical interpretation (see below).

During recent years, abundant research has been devoted to various improvements (including in particular "better" rational approximations) and extensions (including in

particular the application to other wave equations) of the Engquist–Majda conditions. It is not possible to give here an exhaustive bibliography, and we will refer the reader to recent review papers on the subject by Hagström [18], [19] and Givoli [13]. In the last decade, alternative solutions have been progressively developed and, especially, researchers have tried to promote again the use of exact nonlocal boundary either by using specific geometries for the absorbing boundaries, as in the works by Grote and Keller [14], [15], or by exploiting the recent progress in rapid algorithms (multipoles) and rational approximation, as in the work of Alpert, Greengard, and Hagström [2], [1]. Approximately during the same period, the introduction by Bérenger of the perfectly matched layers (PMLs) technique [6], [5] partly revolutionized the subject. The philosophy here is to replace the absorbing boundary with an absorbing layer (or sponge layer) which is such that any wave propagating in the computational domain is transmitted to the absorbing layer without being reflected. This method quickly attracted many researchers in different fields of application, in particular because of its good practical performances and its easy implementation.

All these methods (local higher order ABCs, nonlocal ABCs, and PMLs) have been successfully introduced in a number of different computational codes. Of course, for anybody who wants to use such codes, the natural question is, Which is the best method for the absorption of waves? Our feeling is that there is no universal answer to such a question and that a response should include some criteria: nature of the problem to be addressed, accuracy, speed of calculation, ease of implementation, long time behavior, etc. However, even with given criteria, the answer would be delicate, in particular because no complete and fair comparison has been done between the three classes of methods. The first reason, which is easy to understand, is that there is probably nobody in the world who has implemented the three methods with the same amount of care. The second reason is a lack of analysis, which is hard in particular if one is interested in getting convincing error estimates. The objective of the present paper is to fill partially this lack in the theory in the case of local ABCs.

Of course, there are a lot of available theoretical results about higher order ABCs. The first question that was raised by Engquist and Majda in their original papers was that of the well-posedness of the IBVP "wave equation—ABC." This is not a trivial question since it is known that polynomial approximations of degree greater than 2 of the function $f(z)$ (as, for instance, the successive Taylor approximations of f around 0) give rise to strongly ill-posed problems. However, thanks to the well-known Kreiss theory (the so-called normal mode analysis [26], [22]), the stability theory of higher order ABCs is more or less completely understood. In particular, necessary and sufficient conditions were given in [27] about the rational approximations of $f(z)$ in order to ensure the strong well-posedness of the corresponding IBVP (of course, the approximations f_n given by (1.9) fulfill these conditions, as already observed in [12]) and energy estimates (giving rise to stability results, i.e., a priori estimates independent of N) were obtained in [8].

Concerning the accuracy of ABCs, the simplest analysis consists in analyzing the reflection of plane waves, which amounts to studying particular solutions of the following form ($k \in \mathbb{R}$ and $\theta \in [-\frac{\pi}{2}, \frac{\pi}{2}]$ are parameters, K is the wave number, while θ represents the angle of incidence of the incident plane wave):

$$u_\theta(x,t) = \exp ik(x_1 \sin\theta - x_2 \cos\theta - ct) + \mathbf{R} \exp ik(x_1 \sin\theta + x_2 \cos\theta - ct), \tag{1.11}$$

where

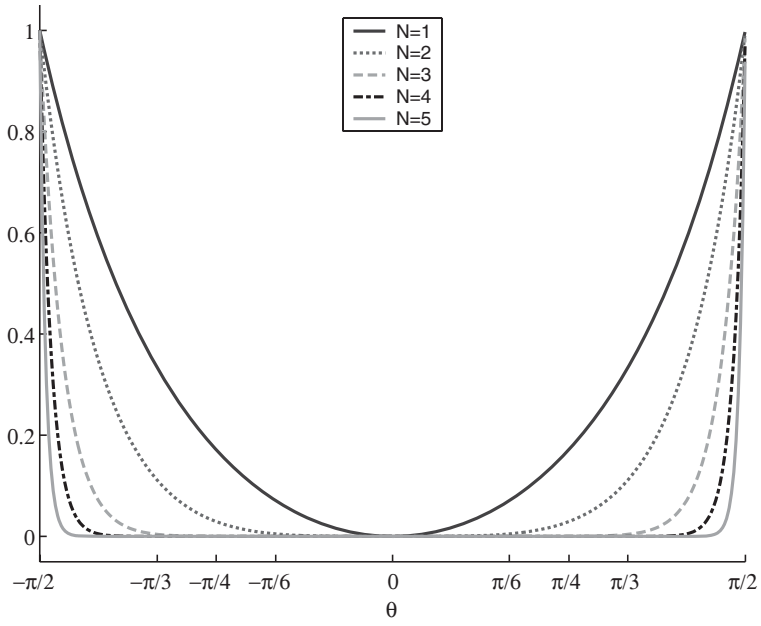

FIG. 1. *The reflection coefficient.*

(i) $\exp ik(x_1 \sin\theta - x_2 \cos\theta - ct)$ is the incident wave,

(ii) $\exp ik(x_1 \sin\theta + x_2 \cos\theta - ct)$ is the reflected wave, $\mathbf{R}$ being the reflection coefficient.

By construction, (1.11) is a solution of the wave equation (1.1). It remains to determine $\mathbf{R}$ in order to satisfy the boundary condition (1.2). The computations show that $\mathbf{R}$ depends only on the angle of incidence θ:

$$\mathbf{R} = \mathbf{R}_N(\theta) \equiv \frac{(f_N - f)(\sin\theta)}{(f_N + f)(\sin\theta)} = (-1)^N \left(\frac{1-\cos\theta}{1+\cos\theta}\right)^N . \tag{1.12}$$

In particular one sees that for any $\theta \in]-\frac{\pi}{2}, \frac{\pi}{2}[$, $\mathbf{R}_N(\theta)$ tends (exponentially fast) to 0 when $N \to +\infty$ while $|\mathbf{R}_N(\pm\frac{\pi}{2})| = 1$ (see also Figure 1). There are much fewer results about convergence and error estimates. In fact, there was no real progress since the initial result of Engquist and Majda, which we are recalling now. They were addressing the following 2D model problem:

$$\begin{cases} \text{Find } v : \mathbb{R}^2_- \times \mathbb{R} \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 v}{\partial t^2} - \Delta v = 0 & \text{in } \mathbb{R}^2_- \times \mathbb{R}^+, \\ v(x_1, 0, t) = g(x_1, t) & \text{on } x_2 = 0, \\ v(x,t) = 0 & \text{for } t < 0. \end{cases} \tag{1.13}$$

One wishes to get a good approximation of v in a domain $\Omega_b = \{x / -b < x_2 < 0\}$ for

given $b > 0$ by putting an ABC on the line $x_2 = -a$, with $a > b$:

$$\begin{cases} \text{Find } v^N : \Omega_a \times \mathbb{R} \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 v^N}{\partial t^2} - \Delta v^N = 0 & \text{in } \Omega_a \times \mathbb{R}^+, \\ v^N(x_1, 0, t) = g(x_1, t) & \text{on } x_2 = 0, \\ \mathcal{B}^N v^N = 0 & \text{on } x_2 = -a, \\ v^N(x, t) = 0 & \text{for } t < 0. \end{cases} \tag{1.14}$$

In (1.14) there are two important parameters: the order N of the boundary condition and the distance a from the source g to the interface. One assumes that the function g is square integrable in both space and time:

$$\int_0^{+\infty} \int_{\mathbb{R}} |g(x_1, t)|^2 \, dx_1 dt < +\infty. \tag{1.15}$$

THEOREM 1.3 (see [12]). *For any $\varepsilon > 0$ and any arbitrarily large integer M, there exist $N_0 = N_0(\varepsilon, M)$ and $a_0 = a_0(\varepsilon, M)$ such that, for any $N \geq N_0$ and $a \geq a_0$,*

$$\int_0^T \int_{\Omega_b} |(v - v^N)(x, t)|^2 \, dx \, dt < \varepsilon \quad \forall T \leq Ma. \tag{1.16}$$

(i) This result is only a convergence result and does not provide an error estimate. Thus it is not a guide for choosing in practice N and a.

(ii) The fact that the result is valid for any time interval of the form $[0, Ma]$ indicates that the result takes into account an arbitrary large number of reflections on the absorbing boundary.

(iii) What is not satisfactory with Theorem 1.3 is the fact that the estimate (1.16) requires a to be sufficiently large. In particular, this does not provide a convergence result when $N \to +\infty$ for fixed a.

(iv) Looking at the proof of the theorem enlightens the need for a sufficiently large. It is not our purpose to reproduce here the proof, but it seems useful to emphasize some points. The idea is to use the Fourier transform in space and time:

$$v(x_1, x_2, t) \to \widetilde{\mathbf{v}}(k, x_2, \omega) = \widetilde{v}(k, x_2, i\omega).$$

One can get an explicit solution for both $\widetilde{\mathbf{v}}$ and $\widetilde{\mathbf{v}}^N$. In particular, we have

$$\left| \begin{array}{l} \widetilde{\mathbf{v}}(k, x_2, \omega) = \widetilde{\mathbf{g}}(k, \omega) \exp(k^2 - \omega^2/c^2)^{\frac{1}{2}} \cdot x_2, \\ (k^2 - \omega^2/c^2)^{\frac{1}{2}} = \begin{cases} \sqrt{k^2 - \omega^2/c^2} & \text{if } k^2 \geq \omega^2/c^2, \\ i\sqrt{\omega^2/c^2 - k^2} & \text{if } k^2 \leq \omega^2/c^2. \end{cases} \end{array} \right.$$

In particular,

(i) if $k^2 < \omega^2/c^2$, the function $x_2 \to \widetilde{\mathbf{v}}(k, x_2, \omega)$ is oscillating: this is the region of propagative modes;

(ii) if $k^2 > \omega^2/c^2$, the function $x_2 \to \widetilde{\mathbf{v}}(k, x_2, \omega)$ is exponentially decaying when $x_2 \to -\infty$: this is the region of evanescent modes.

When one looks at the error $e^N = v^N - v$, its Fourier transform appears as a sum (the sum is a priori infinite but becomes finite if one is interested in times less than Ma) over $j \geq 1$ of terms of the form

$$\mathcal{R}_N \left(\frac{ck}{\omega} \right)^j \cdot \widetilde{\mathbf{g}}(k, \omega) \cdot \exp[(k^2 - \omega^2/c^2)^{\frac{1}{2}} (\pm x_2 + 2ja)],$$

where the *reflection coefficient* $\mathcal{R}_N$ is given by

$$\mathcal{R}_N(\nu) = \frac{(f_N - f)(\nu)}{(f_N + f)(\nu)} \tag{1.17}$$

and satisfies

$$\begin{cases} \mathcal{R}_N(\sigma) \leq 1 & \text{(stability result)}, \\ \mathcal{R}_N(\sigma) \to 0 & \text{for } |\sigma| < 1 \text{ (cf. Remark 1.2)}. \end{cases}$$

Up to technical details (this is in particular where the assumption (1.15) intervenes), the idea of the proof is the following:

(i) In the propagative region $k^2 < \omega^2/c^2$, $|\mathcal{R}_N(\sigma)|^j$ can be made arbitrarily small by choosing N large enough.

(ii) In the evanescent region $k^2 > \omega^2/c^2$, $|\exp[(k^2 - \omega^2/c^2)^{\frac{1}{2}} (\pm x_2 + 2ja)]|$ can be made arbitrarily small by choosing a large enough.

One then concludes with Plancherel's theorem.

Physically, the fact that $f_n(z)$ has nothing to do with $f(z)$ for $|z| > 1$ means that the evanescent modes are not correctly taken into account by the absorbing condition. This is why one needs to have a large enough in order to "kill" the amplitude of the evanescent modes at the boundary $x_2 = a$.

In 1988, Halpern and Rauch proposed a high-frequency analysis in [20]. More recently, an advance was achieved by Hagström (see [17] and [16], [18]), who derived an approximation theory for the approximation of (a class of) pseudodifferential operators, with the aim of applying it to ABCs, based on a new reinterpretation of (1.2) and standard quadrature theory. He obtained error estimates and convergence results only by making N go to $+\infty$ (i.e., without touching the position of the boundary). However, its results were nonuniform in time.

The history of the present work is the following. The Cagniard–De Hoop method is particularly well known in the physics and engineering communities for calculating analytical solutions of time-dependent wave propagation problems, especially in seismology (see [7], [25], [24]). This method permits one, moreover, to establish a link between time domain solutions and harmonic plane waves. Trying to learn something about this method (for a completely different problem), we immediately realized that it could easily be applied to the problem of ABCs and would probably help to get new error estimates. The computations are so simple that it is rather surprising to see that nobody did them before, to our knowledge. This article presents the results we have obtained with this method and may prove to be a useful tool in teaching this subject.

The outline of the paper is as follows. In section 2, we describe the model problem we are dealing with (the half-space problem with a point source) and state our two main results: Theorem 2.1, which provides an explicit solution of the corresponding fundamental solution, and Theorem 2.4, which provides error estimates in the case

of a general source function. These two results show that one can get a convergence result only by letting N go to $+\infty$. In some sense, this shows that the need for large a in Theorem 1.3 is due to the technique used in the proof but does not correspond to a necessity. However, our results in Theorems 2.1 and 2.4 show that increasing the distance from the source to the absorbing boundary helps to get better error estimates. We also pay attention to large time behavior of the error, which has already been the subject of previous research works (see [10], [9], [4]). Sections 3 and 4 are devoted to the proofs of Theorems 2.1 and 2.4. In section 5, we analyze our results in more detail and make the comparison between numerical results and (quasi-)analytical results.

2. Main results. The first result of this paper is an explicit expression of the fundamental solution of the 2D wave equation in the half-space $\mathbb{R}^+_2 = \{x_2 > 0\}$ with higher order ABCs on $\Gamma = \{x_2 = 0\} (= \partial\mathbb{R}^+_2)$. Since the problem is invariant under translations in the x_1-direction, we can restrict ourselves to the case where the source point is

$$x_S = (0, h) \quad \text{with } h > 0. \tag{2.1}$$

The problem we want to solve is

$$\begin{cases} \text{Find } u : \mathbb{R}^2_+ \times \mathbb{R} \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 u}{\partial t^2} - \Delta u = \delta(x - x_S) \times \delta(t) & \text{in } \mathbb{R}^2_+, \\ \mathcal{B}^N u = 0 & \text{on } \Gamma, \\ u(x,t) = 0 & \text{for } t < 0. \end{cases} \tag{2.2}$$

To state our result, it is useful to introduce some notation. Let us define the image source point x^*_S by

$$x^*_S = (0, -h) \tag{2.3}$$

and let us set (see Figure 2)

$$r(x) = |x - x_S|, \qquad r^*(x) = |x - x^*_S|. \tag{2.4}$$

We also define the function $\theta(x)$, $x \in \mathbb{R}^2_+$, by

$$\theta(x) \in \left]-\frac{\pi}{2}, \frac{\pi}{2}\right[, \quad x - x^*_S = (r^*(x)\sin\theta(x), r^*(x)\cos\theta(x))^t, \tag{2.5}$$

and finally the function $\Phi(x,t)$, $x \in \mathbb{R}^2_+$, $t > 0$, by

$$\Phi(x,t) = \frac{r^*(x)^2\sin^2\theta(x) - (c^2t^2 - r^*(x)^2)}{r^*(x)^2\sin^2\theta(x) + (c^2t^2 - r^*(x)^2)} = \frac{x_1^2 - (c^2t^2 - r^*(x)^2)}{x_1^2 + (c^2t^2 - r^*(x)^2)}. \tag{2.6}$$

We can notice that

$$ct > r^*(x) \Longrightarrow |\Phi(x,t)| < 1.$$

Finally, we recall that the Chebyshev polynomials $P_N(x)$, $N \geq 0$, are defined by

$$P_0(x) = 1, \qquad P_1(x) = x, \qquad P_{N+1}(x) - 2xP_N(x) + P_{N-1}(x) = 0 \tag{2.7}$$

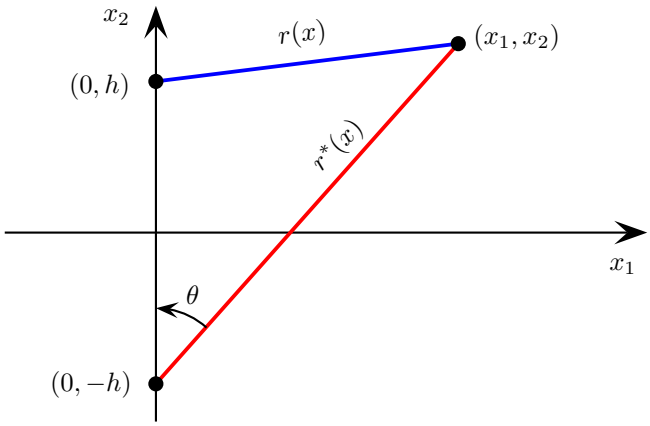

FIG. 2. *Illustration of the notation*

and satisfy

$$\forall x \in [-1,1], \quad P_N(x) = \cos(N \arccos(x)). \tag{2.8}$$

In particular, we see that

$$\forall x \in [-1,1], \quad |P_N(x)| \leq 1.$$

THEOREM 2.1. *The solution $u(x,t) = G^N(x,t)$ of problem (2.2) is given by*

$$G^N(x,t) = G_i(x,t) + G_r^N(x,t), \tag{2.9}$$

where, if H denotes the Heaviside function,

$$\left| \begin{array}{l} G_i(x,t) = \dfrac{1}{2\pi\sqrt{t^2 - \frac{r(x)^2}{c^2}}} H(ct - r(x)), \\ G_r^N(x,t) = -\dfrac{P_N\left(\Phi(x,t)\right)}{2\pi\sqrt{t^2 - \frac{r^*(x)^2}{c^2}}} \left[\dfrac{ct - (x_2+h)}{ct + (x_2+h)}\right]^N H(ct - r^*(x)). \end{array} \right. \tag{2.10}$$

Remark 2.2. The function $G_i(x,t)$, which does not depend on N, is nothing but the restriction to the half-space $\mathbb{R}^2_+$ of the fundamental solution of the 2D wave equation in the whole space. That is why it is called the incident field. Conversely, the field $G_r^N(x,t)$, due to the presence of the boundary Γ, is called the reflected field, which does depend on N.

Remark 2.3. The presence of the factor $H(ct - r^*(x))$ indicates that the reflected field $G_r^N(\cdot,t)$ is compactly supported in the set $\Omega(t) = \Omega_1(t) \cup \Omega_2(t)$ (see Definition 4.6).

Let us now consider the approximation in the upper half-space of the solution u of the 2D wave equation with a "smooth" point source:

$$\begin{cases} \text{Find } u : \mathbb{R}^2 \times \mathbb{R}^+ \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 u}{\partial t^2} - \Delta u = \delta(x - x_S) \times f(t) & \text{in } \mathbb{R}^2 \times \mathbb{R}^+, \\ u(x,0) = 0, \qquad \dfrac{\partial u}{\partial t}(x,0) = 0 & \text{in } \mathbb{R}^2, \end{cases} \tag{2.11}$$

where we assume that the source function $f(t)$ is bounded and has support $[0,T]$ (T can be equal to $+\infty$, which includes the case of a permanent source term) by the solution u^N of the boundary value problem

$$\begin{cases} \text{Find } u^N : \mathbb{R}^2 \times \mathbb{R}^+ \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 u^N}{\partial t^2} - \Delta u^N = \delta(x - x_S) \times f(t) & \text{in } \mathbb{R}^2 \times \mathbb{R}^+, \\ \mathcal{B}^N u^N = 0 & \text{on } \Gamma, \\ u(x,0) = 0, \qquad \dfrac{\partial u}{\partial t}(x,0) = 0 & \text{in } \mathbb{R}^2. \end{cases} \tag{2.12}$$

THEOREM 2.4. *At each point $x \in \mathbb{R}^2_+$, one has the following pointwise estimates:*

(i) *For $\frac{r^*(x)}{c} \le t \le \frac{r^*(x)}{c} + T$ ($\Leftrightarrow x \in \Omega_1(t)$—see (4.6)),*

$$\begin{aligned} &|u(x,t) - u^N(x,t)| \\ &\quad \le \frac{1}{2\pi}\left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N \mathrm{Log}\left(\frac{ct + \sqrt{c^2t^2 - r^*(x)^2}}{r^*(x)}\right) \|f\|_{L^\infty}. \end{aligned} \tag{2.13}$$

(ii) *For $t > \frac{r^*(x)}{c} + T$ ($\Leftrightarrow x \in \Omega_2(t)$—see (4.6)),*

$$\begin{aligned} &|u(x,t) - u^N(x,t)| \\ &\quad \le \frac{1}{2\pi}\left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N \mathrm{Log}\left(\frac{ct + \sqrt{c^2t^2 - r^*(x)^2}}{c(t-T) + \sqrt{c^2(t-T)^2 - r^*(x)^2}}\right) \|f\|_{L^\infty}. \end{aligned} \tag{2.14}$$

Moreover, one has the following uniform estimates:

(i) *For $\frac{h}{c} \le t \le \frac{h}{c} + T$,*

$$\|(u - u^N)(\cdot,t)\|_{L^\infty(\mathbb{R}^2_+)} \le \frac{1}{2\pi}\left(\frac{ct-h}{ct+h}\right)^N \mathrm{Log}\left(\frac{t + \sqrt{t^2 - (h/c)^2}}{(h/c)}\right) \|f\|_{L^\infty}. \tag{2.15}$$

(ii) *For $t > \frac{h}{c} + T$,*

$$\|(u - u^N)(\cdot,t)\|_{L^\infty(\mathbb{R}^2_+)} \le \frac{1}{2\pi}\left(\frac{ct-h}{ct+h}\right)^N \mathrm{Log}\left(\frac{t + \sqrt{t^2 - (t-T)^2}}{t - T}\right) \|f\|_{L^\infty}. \tag{2.16}$$

These results lead to the following comments:

(i) The error converges spectrally to 0 (in the uniform norm) when N goes to infinity.

(ii) For given t, the upper bounds in the estimates (2.15) and (2.16) diminish when the distance h from the source to the absorbing boundary increases. This is coherent with the physical intuition and numerical observations.

(iii) Concerning the behavior of the error for large t, if we assume that $T < +\infty$, we observe that the right-hand side in the estimate (2.16) behaves for large t as

$$\frac{1}{2\pi}\sqrt{\frac{2T}{t}},$$

which shows that, for all N and h, the error converges uniformly to 0 when t tends to $+\infty$. On the other hand, when $T = +\infty$, the right-hand side in the estimate (2.15) behaves as

$$\frac{1}{2\pi}\text{Log } t,$$

which a priori authorizes a logarithmic growth on the error when t tends to $+\infty$. This is what happens if $f(t)$ is, for instance, the Heaviside function.

Remark 2.5. We have chosen here to analyze the approximation of a problem associated to a point source. It would not be difficult to adapt Theorem 2.4 (or more precisely its proof) to treat the case of a distributed source term $f(x,t)$ or nonzero initial data u_0 and u_1. In the same way, we have chosen to present L^∞ estimates, which seemed to us more pertinent in practice. However, once again, it is easy to adapt the proof in order to get L^p or energy estimates.

3. Proof of Theorem 2.1. As we have already stated, the formula (2.9), (2.10) results directly from the application of the Cagniard–De Hoop method to problem (2.2). In order to make this paper easily understandable to a reader who is not familiar with this technique, we detail the proof (only some explicit calculations will be omitted). Let us decompose the solution u of (2.2) as

$$u = G_i + u^r,$$

where G_i, given by (2.10), is the fundamental solution of the 2D wave equation. By linearity, it is clear that u^r satisfies

$$\text{(3.1)}\qquad \begin{cases} \text{Find } u^r : \mathbb{R}^2_+ \times \mathbb{R} \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 u^r}{\partial t^2} - \Delta u^r = 0 & \text{in } \mathbb{R}^+_2, \\ \mathcal{B}^N u^r = -\mathcal{B}^N G_i & \text{on } \Gamma, \\ u(x,t) = 0 & \text{for } t < 0. \end{cases}$$

We apply the following successively to u^r:

(i) The Laplace transform in time (s is the dual variable of t):

$$\text{(3.2)}\qquad \widetilde{u}^r(x_1,x_2,s) = \int_0^{+\infty} u^r(x_1,x_2,t)e^{-st}\,dt.$$

(ii) The Fourier transform in the tangential space variable x_1 (k is the dual variable of x_1):

$$\text{(3.3)}\qquad \widehat{u}^r(k,x_2,s) = \int_{-\infty}^{+\infty} \widetilde{u}^r(x_1,x_2,s)e^{ikx_1}\,dx_1.$$

The algorithm for applying the Cagniard–De Hoop method is the following:

1. Compute explicitly $\widehat{u}^r(k,x_2,s)$.
2. Apply the inverse Fourier transform in x_1:

$$\text{(3.4)}\qquad \widetilde{u}^r(x_1,x_2,s) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \widehat{u}^r(k,x_2,s)e^{-ikx_1}\,dx_1.$$

3. Transform (by means of complex analysis methods) the integral (3.4) into an integral of the form

$$\widetilde{u}^r(x_1,x_2,s)=\int_0^{+\infty}F(x_1,x_2,t)e^{-st}\,dt. \tag{3.5}$$

Then, by surjectivity of the Laplace transform, we shall have identified the solution (compare (3.2) and (3.5))

$$u^r(x_1,x_2,t)\equiv F(x_1,x_2,t). \tag{3.6}$$

The first step is straightforward. From the wave equation, we deduce that the function $x_2\mapsto\widehat{u}^r(k,x_2,s)$ satisfies

$$-\frac{d^2\widehat{u}^r}{dx_2^2}+\left(k^2+\frac{s^2}{c^2}\right)\widehat{u}^r=0.$$

Retaining only the solutions that decay when $x_2\to+\infty$ for $\mathcal{R}e(s)\geq 0$, we deduce the existence of a complex-valued function $A(k,s)$ such that

$$\widehat{u}^r(k,x_2,s)=A(k,s)e^{-(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}x_2}, \tag{3.7}$$

where we have chosen to use the determination of the complex square root corresponding to

$$\forall z\in\mathbb{C},\quad \mathcal{R}e\ z^{\frac{1}{2}}\geq 0, \tag{3.8}$$

which corresponds to making the branch cut of $z^{\frac{1}{2}}$ coincide with the semireal axis $\mathcal{I}m\ z=0$, $\mathcal{R}e\ z<0$ (see Figure 3). Since u^r+G_i is smooth for $y<h$, we can use the fact that

$$\mathcal{B}^N(u^r+G_i)=0\Longleftrightarrow\left(\frac{1}{c}\frac{\partial}{\partial t}-\frac{\partial}{\partial x_2}\right)^N(u^r+G_i)=0\quad\text{for } x_2=0. \tag{3.9}$$

On the other hand, it is well known that the Laplace–Fourier transform of G_i is given by

$$\widehat{G}_i(k,x_2,s)=\frac{e^{-(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}|x_2-h|}}{2(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}}. \tag{3.10}$$

Taking into account the form (see (3.7) and (3.10)) of $\widehat{u}^r$ and $\widehat{G}_i$, the boundary condition (3.9) leads to

$$\left(\frac{s}{c}+\left(k^2+\frac{s^2}{c^2}\right)^{\frac{1}{2}}\right)^N A(k,s)+\frac{1}{2}\left(\frac{s}{c}-\left(k^2+\frac{s^2}{c^2}\right)^{\frac{1}{2}}\right)^N\frac{e^{-(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}h}}{(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}}=0.$$

This permits us to compute $A(k,s)$ and finally to get

$$\widehat{u}^r(k,x_2,s)=-R^N\left(k,\frac{s}{c}\right)\frac{e^{-(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}(x_2+h)}}{2(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}}, \tag{3.11}$$

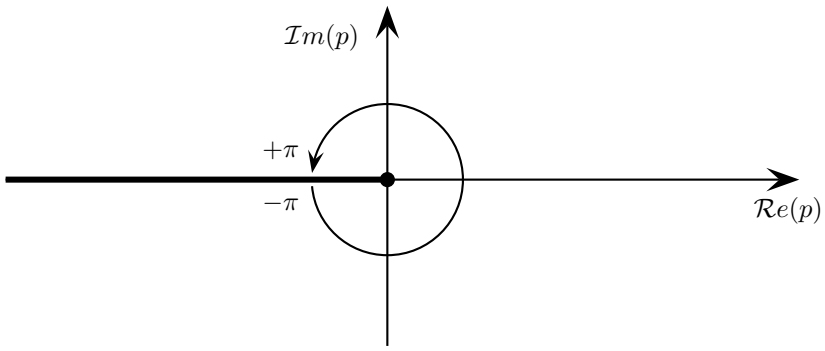

FIG. 3. *The branch cut for the determination of the complex square root.*

where we have set

$$R^N(k,\sigma) = \mathcal{R}_N\left(\frac{k}{\sigma}\right) = \left[\frac{\sigma - (k^2+\sigma^2)^{\frac{1}{2}}}{\sigma + (k^2+\sigma^2)^{\frac{1}{2}}}\right]^N. \tag{3.12}$$

Therefore (this is step 2) we have

$$\widetilde{u}^r(x_1,x_2,s) = -\frac{1}{4\pi}\int_{-\infty}^{+\infty} R^N\left(k,\frac{s}{c}\right)\frac{e^{-(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}(x_2+h)}}{(k^2+\frac{s^2}{c^2})^{\frac{1}{2}}}e^{-ikx_1}\,dk, \tag{3.13}$$

which we would like to transform into an integral of the form (3.5) (this is step 3). This is the part of the approach which is specific to the Cagniard–De Hoop method. We are helped by the following facts:

(i) The integrand in (3.13) is homogeneous in s and k.

(ii) The dependence with respect to x_2 of this integrand is exponential.

First, exploiting the homogeneity property, we apply the change of variable $k = ps/c$ and obtain

$$\begin{aligned}&\widetilde{u}^r(x_1,x_2,s)\\ &= -\frac{1}{4\pi}\int_{-\infty}^{+\infty} R^N(p,1)\frac{e^{-s[(1+p^2)^{\frac{1}{2}}(\frac{x_2+h}{c})+ip\frac{x_1}{c}]}}{(1+p^2)^{\frac{1}{2}}}dp, \quad \left(\equiv \int_{-\infty}^{+\infty}\Psi(p)dp\right).\end{aligned} \tag{3.14}$$

In what follows we fix $(x_1,x_2) \in \mathbb{R}^2_+$ with $x_1 > 0$ (which is not restrictive since the solution we are looking for is clearly even in x_1). We introduce $r^* = r^*(x)$ and $\theta = \theta(x)$ ($\in [0,\pi/2]$ since $x_1 \geq 0$) according to the definitions (2.4) and (2.5). We thus have

$$\begin{cases} x_1 = r^*\sin\theta, \\ x_2 + h = r^*\cos\theta. \end{cases} \tag{3.15}$$

Now the idea is to consider the variable p as a complex variable and to see the integral (3.14) as a contour integral, the contour coinciding with the real axis. If one is able, by a contour deformation, to transform this integral into a contour integral

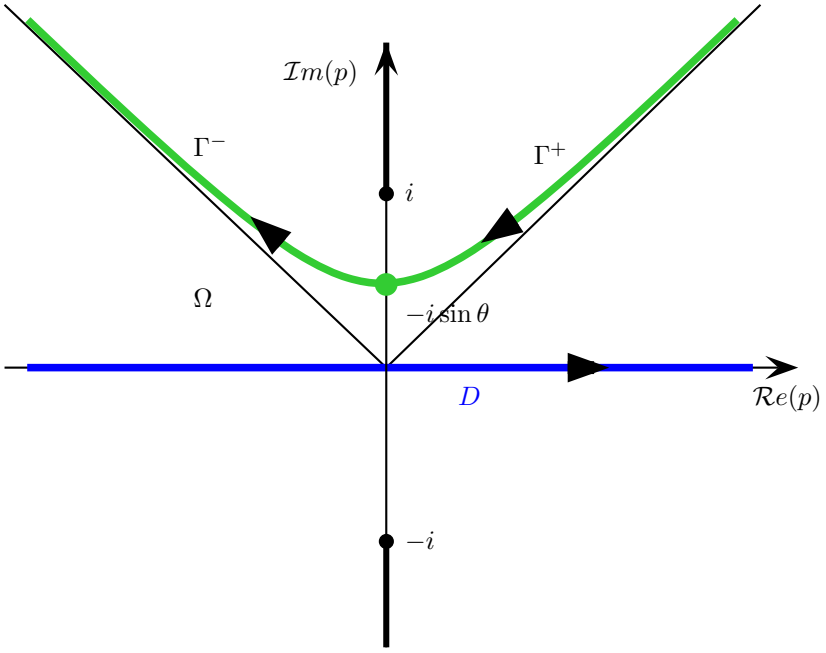

FIG. 4. *The contours* Γ *and* D.

on some curve Γ along which one can use a parametric representation of the form

$$(1+p^2)^{\frac{1}{2}}\left(\frac{x_2+h}{c}\right)+ip\frac{x_1}{c}=t \quad \text{for } t>0, \tag{3.16}$$

we shall have reached our goal. To achieve this, we first remark that the integrand $\Psi(p)$ in (3.14) is an analytic function of p if one excludes the two branch cuts constituted of the two half-lines of purely imaginary numbers whose modulus is greater than 1 (see Figure 4). Then we introduce the so-called Cagniard–De Hoop contour Γ, defined as

$$\begin{cases} \Gamma=\Gamma^+\cup\Gamma^-, \\ \Gamma^\pm=\left\{p=\gamma^\pm(t)\equiv -i\dfrac{ct}{r^*}\sin\theta\pm\cos\theta\sqrt{\dfrac{c^2t^2}{r^{*2}}-1},\ t\geq\dfrac{r^*}{c}\right\}. \end{cases} \tag{3.17}$$

It is clear that the two curves $\Gamma^\pm$ are symmetric with respect to the imaginary axis, and meet at point $-i\sin\theta$ (for $t=r^*/c$). More precisely, it is easy to check that Γ is nothing but the branch of the hyperbola of

$$\frac{Y^2}{\sin^2\theta}-\frac{X^2}{\cos^2\theta}=1 \quad (p=X+iY,\ (X,Y)\in\mathbb{R}^2),$$

which is located in the upper half-space $Y=\mathcal{I}m\ p>0$. Note that this hyperbola does not intersect the two branch cuts of Ψ. All this information is summarized in Figure 4.

In fact to understand where (3.17) comes from, it suffices to remark that $\gamma^\pm(t)$ are nothing but the two roots of (3.16), considered as an equation in p (the calculations are left to the reader).

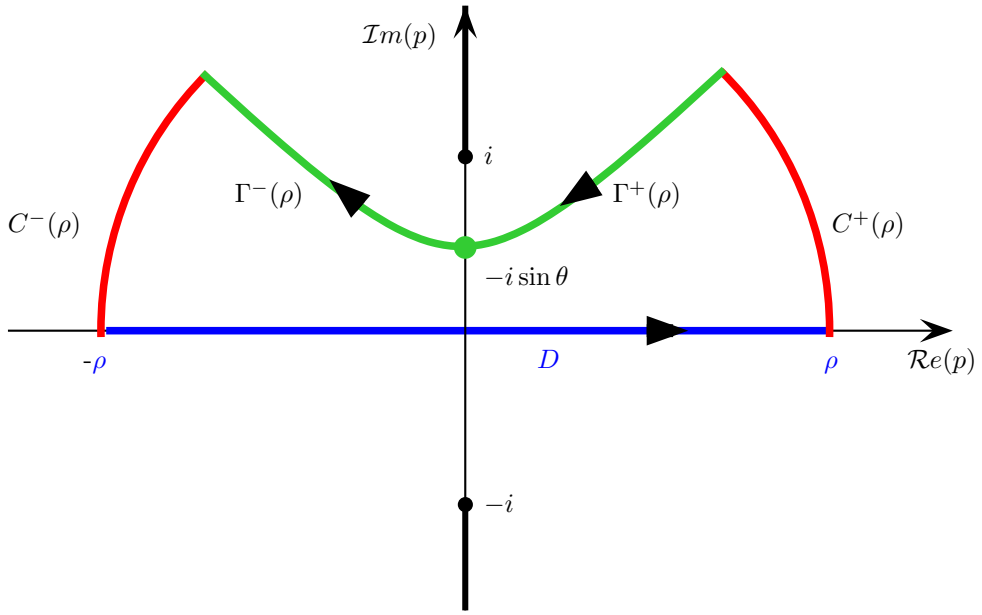

FIG. 5. *The closed contour* $D_\rho \cup C_\rho \cup \Gamma_\rho$.

Let us denote by D the real line and by Ω the connected part of the complex plane delimited by D and Γ. Let $\rho > 0$ be a parameter that is meant to tend to $+\infty$. We set

$$\left| \begin{array}{ll} D_\rho = \{p \in D / |p| \leq \rho\}, & \Gamma_\rho = \{p \in \Gamma / |p| \leq \rho\}, \\ C_\rho = \{p \in \Omega / |p| = \rho\}. & \end{array} \right.$$

Note that C_ρ is made of two arcs of the circle of center 0 and radius ρ that join D_ρ to Γ_ρ in such a way that $D_\rho \cup C_\rho \cup \Gamma_\rho$ is a closed curve. Since $\Psi(p)$ is analytic in Ω, the integral of Ψ along $D_\rho \cup C_\rho \cup \Gamma_\rho$ (we choose the orientation of this path such that the real segment is described in the sense of increasing values—see Figure 5) is identically 0:

$$\int_{D_\rho} \Psi(p)\, dp + \int_{C_\rho} \Psi(p)\, dp + \int_{\Gamma_\rho} \Psi(p)\, dp = 0.$$

Thanks to the choice of the square root, and since $x_2 + h > 0$, the function $\Psi(p)$ decays exponentially to 0 when $\mathcal{I}m\ p$ goes to $+\infty$. As a consequence, it is easy to show that (Jordan's lemma)

$$\lim_{\rho \to +\infty} \int_{C_\rho} \Psi(p)\, dp = 0.$$

Therefore, from (3.14), we deduce

$$\widetilde{u}^r(x_1, x_2, s) = -\frac{1}{4\pi} \int_\Gamma R^N(p, 1) \frac{e^{-s[(1+p^2)^{\frac{1}{2}}(\frac{x_2+h}{c}) + ip\frac{x_1}{c}]}}{(1+p^2)^{\frac{1}{2}}}\, dp.$$

We use the parametrizations $p = \gamma^+(t)$ and $p = \gamma^-(t)$ for $t \geq \frac{r^*(x)}{c}$, respectively, along Γ^+ and Γ^- and remark that

$$\left| \begin{array}{ll} \bullet\ (1+p^2)^{\frac{1}{2}} \left(\dfrac{x_2+h}{c} \right) + ip \dfrac{x_1}{c} = t & \text{(by construction)}, \\ \bullet\ \dfrac{dp}{(\frac{1}{c^2}+p^2)^{\frac{1}{2}}} = \pm \dfrac{dt}{(t^2 - \frac{r^{*2}}{c^2})^{\frac{1}{2}}} & \text{on } \Gamma^{\pm}. \end{array} \right.$$

Therefore, since t goes from $+\infty$ to $\frac{r^*}{c}$ on Γ^+ and from $\frac{r^*}{c}$ to $+\infty$ on Γ^-,

$$\widetilde{u}^r(x_1, x_2, s) = -\frac{1}{4\pi} \int_{\frac{r^*}{c}}^{+\infty} \left[R^N(\gamma^+(t), 1) + R^N(\gamma^-(t), 1) \right] \frac{e^{-st}}{(t^2 - \frac{r^{*2}}{c^2})^{\frac{1}{2}}}\, dt.$$

Finally, observing that $\gamma^-(t)^2 = \overline{\gamma^+(t)}^2$, and using the fact that $\sqrt{\overline{z}} = \overline{\sqrt{z}}$, we deduce that

$$R^N(\gamma^-(t), 1) = \overline{R^N(\gamma^+(t), 1)} \Longrightarrow R^N(\gamma^+(t), 1) + R^N(\gamma^-(t), 1) = 2\mathcal{R}e \left[R^N(\gamma^+(t), 1) \right],$$

which yields

$$\widetilde{u}^r(x_1, x_2, s) = -\frac{1}{2\pi} \int_{\frac{r^*}{c}}^{+\infty} \mathcal{R}e \left[R^N(\gamma^+(t), 1) \right] \frac{e^{-st}}{(t^2 - \frac{r^{*2}}{c^2})^{\frac{1}{2}}}\, dt. \tag{3.18}$$

Thanks to formula (3.12), one has

$$R^N(\gamma^+(t), 1) = \left[R^1(\gamma^+(t), 1) \right]^N, \tag{3.19}$$

while one easily computes that

$$R^1(\gamma^+(t), 1) = \frac{r^* - ct\cos\theta + i\sin\theta\sqrt{c^2t^2 - r^{*2}}}{r^* + ct\cos\theta - i\sin\theta\sqrt{c^2t^2 - r^{*2}}} = \rho_1(t) e^{i\alpha(t)}.$$

Setting $\Phi = \Phi(x, t)$ (cf. (2.6)), one finds that (the calculations—rather tedious but straightforward—are left to the reader)

$$\begin{cases} \rho_1(t) = \dfrac{ct - r^*\cos\theta}{ct + r^*\cos\theta} = \dfrac{ct - (x_2+h)}{ct + (x_2+h)}, \\ \cos\alpha(t) = \dfrac{r^{*2}\sin^2\theta - (c^2t^2 - r^{*2})}{r^{*2}\sin^2\theta + (c^2t^2 - r^{*2})} = \Phi. \end{cases}$$

Therefore, according to (3.19),

$$\mathcal{R}e \left[R^N(\gamma^+(t), 1) \right] = \rho_1(t)^N \cos(N\alpha(t)),$$

that is to say, since $\alpha(t) = \arccos\Phi$,

$$\mathcal{R}e \left[R^N(\gamma^+(t), 1) \right] = \left[\frac{ct - (x_2+h)}{ct + (x_2+h)} \right]^N P_N(\Phi). \tag{3.20}$$

It is then easy to conclude the proof of Theorem 2.1 from (3.18) and (3.20).

4. Proof of Theorem 2.4. Let u and u^N be the respective solutions of (2.11) and (2.12). We introduce the error (or reflected field) e^N defined as

$$e^N = u^N - u. \tag{4.1}$$

To get the pointwise estimates (2.13) and (2.14), we fix $x \in \mathbb{R}^2_+$ and set $r^* = r^*(x)$ and $\theta = \theta(x)$. Obviously $e^N(x,t) = 0$ for $t \le r^*/c$, while for $t > r^*/c$ we deduce from Theorem 2.1 that

$$e^N(x,t) = \int_{\max(\frac{r^*}{c}, t-T)}^{t} G_r^N(x,\tau) f(t-\tau)\, d\tau, \quad t \ge \frac{r^*}{c}, \tag{4.2}$$

using the fact that f is supported in $[0,T]$ and $G_r^N(x,\cdot)$ in $[0, \frac{r^*}{c}]$. We deduce that

$$\begin{cases} |e^N(x,t)| \le \|f\|_{L^\infty(0,t)} \cdot \|G_r^N(x,\cdot)\|_{L^1(\frac{r^*}{c},t)} & \text{if } \dfrac{r^*}{c} \le t \le \dfrac{r^*}{c} + T, \\ |e^N(x,t)| \le \|f\|_{L^\infty(0,T)} \cdot \|G_r^N(x,\cdot)\|_{L^1(t-T,t)} & \text{if } t > \dfrac{r^*}{c} + T. \end{cases} \tag{4.3}$$

We thus have to estimate the L^1-norm of the functions $t \mapsto G_r^N(\cdot,t)$. Using the fact that

$$|P_N(\Phi(x,t))| \le 1$$

(estimate which is quasi-optimal for a range of values of t) we get

$$|G_r^N(x,t)| \le \frac{1}{2\pi\sqrt{t^2 - \frac{r^{*2}}{c^2}}} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N.$$

We remark that, for $t \ge \frac{r^*}{c}$, the function $ct \mapsto (\frac{ct-(x_2+h)}{ct+(x_2+h)})$ is increasing. Therefore,

$$\begin{aligned} \|G_r^N(x,\cdot)\|_{L^1(\frac{r^*}{c},t)} &\le \frac{1}{2\pi} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N \int_{\frac{r^*}{c}}^{t} \frac{d\tau}{\sqrt{\tau^2 - \frac{r^{*2}}{c^2}}} \\ &= \frac{1}{2\pi} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N \operatorname{Log}\left(\frac{ct + \sqrt{c^2t^2 - r^{*2}}}{r^*}\right), \end{aligned} \tag{4.4}$$

while, as soon as $t > \frac{r^*}{c} + T$,

$$\begin{aligned} &\|G_r^N(x,\cdot)\|_{L^1(t-T,t)} \\ &\quad \le \frac{1}{2\pi} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N \int_{t-T}^{t} \frac{d\tau}{\sqrt{\tau^2 - \frac{r^{*2}}{c^2}}} \\ &\quad = \frac{1}{2\pi} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right)^N \operatorname{Log}\left(\frac{ct + \sqrt{c^2t^2 - r^{*2}}}{c(t-T) + \sqrt{c^2(t-T)^2 - r^{*2}}}\right). \end{aligned} \tag{4.5}$$

It is easy to deduce (2.13) and (2.14) from (4.3), (4.4), and (4.5).

We now move to the proof of the uniform estimates (2.15) and (2.16). Let us introduce the two disjoint sets

$$\begin{aligned} &\Omega_1(t) = \{x \in R^2_+ / c(t-T) < r^*(x) \le ct\}, \\ &\Omega_2(t) = \{x \in R^2_+ / r^*(x) \le c(t-T)\}. \end{aligned} \tag{4.6}$$

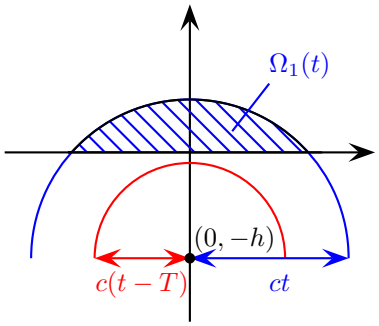

FIG. 6. *The set* $\Omega_1(t)$, $\frac{h}{c} \le t < \frac{h}{c} + T$.

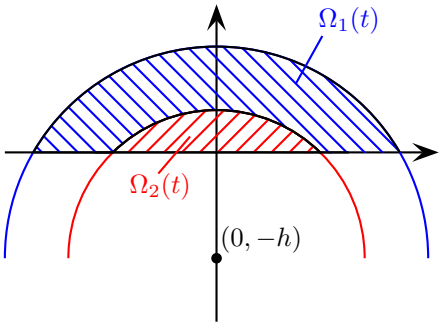

FIG. 7. $\Omega_1(t)$ *and* $\Omega_2(t)$, $t \ge \frac{h}{c} + T$.

These two sets are represented in Figures 6 and 7 for two values of t. Note that $\Omega_1(t)$ is not empty as soon as $t > \frac{h}{c}$, while $\Omega_2(t)$ is not empty as soon as $t > \frac{h}{c} + T$. According to (4.3), in order to derive an L^∞ estimate of $e^N(\cdot,t)$, we need an upper bound for the quantity

$$\sup_{x\in\Omega_1(t)} \|G_r^N(x,\cdot)\|_{L^1(\frac{r^*}{c},t)} \quad \text{when } t > \frac{h}{c}$$

and for the quantity

$$\sup_{x\in\Omega_2(t)} \|G_r^N(x,\cdot)\|_{L^1(t-T,t)} \quad \text{when } t > \frac{h}{c} + T.$$

We remark that for each $x \in \Omega(t) = \Omega_1(t) \cup \Omega_2(t)$, $h \le x_2 + h \le ct$. Therefore, noticing that the function

$$x \mapsto \frac{ct - x}{ct + x}, \quad x \in [0, ct],$$

is decreasing, we get

$$\sup_{x\in\Omega_1(t)} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right) = \sup_{x\in\Omega_2(t)} \left(\frac{ct - (x_2+h)}{ct + (x_2+h)}\right) = \frac{ct-h}{ct+h}. \tag{4.7}$$

On the other hand, using the fact that the two functions

$$\begin{cases} r \mapsto \dfrac{ct}{r} + \sqrt{\dfrac{c^2t^2}{r^2} - 1}, & r \in [0, ct], \\ r \mapsto \dfrac{ct + \sqrt{c^2t^2 - r^2}}{c(t-T) + \sqrt{c^2(t-T)^2 - r^2}}, & r \in [0, c(t-T)] \ (t > T), \end{cases}$$

are, respectively, decreasing and increasing, we deduce that

$$\left|\begin{array}{l} \displaystyle\sup_{x\in\Omega_1(t)} \operatorname{Log}\left|\frac{ct}{r^*}+\sqrt{\frac{c^2t^2}{r^{*2}}-1}\right| = \operatorname{Log}\left(\frac{t+\sqrt{t^2-(h/c)^2}}{(h/c)}\right) \quad \text{if } \frac{h}{c}<t<\frac{h}{c}+T, \\ \\ \displaystyle\sup_{x\in\Omega_1(t)} \operatorname{Log}\left|\frac{ct}{r^*}+\sqrt{\frac{c^2t^2}{r^{*2}}-1}\right| = \operatorname{Log}\left(\frac{t+\sqrt{t^2-(t-T)^2}}{t-T}\right) \quad \text{if } t>\frac{h}{c}+T, \end{array}\right.$$

$$\sup_{x\in\Omega_2(t)} \operatorname{Log}\left|\frac{ct+\sqrt{c^2t^2-r^{*2}}}{c(t-T)+\sqrt{c^2(t-T)^2-r^{*2}}}\right| = \operatorname{Log}\left(\frac{t+\sqrt{t^2-(t-T)^2}}{t-T}\right)$$

$$\text{if } t>\frac{h}{c}+T$$

These last three equalities, together with (4.3), (4.4), and (4.5), permit us to show the inequalities

$$\begin{aligned} &\sup_{x\in\Omega_1(t)} \left\|G_r^N(x,\cdot)\right\|_{L^1(\frac{r^*}{c},t)} \\ &\qquad \le \frac{1}{2\pi}\left(\frac{ct-h}{ct+h}\right)^N \operatorname{Log}\left(\frac{ct}{h}+\sqrt{\frac{c^2t^2}{h^2}-1}\right) \quad \left(t>\frac{h}{c}\right), \end{aligned} \tag{4.8}$$

$$\begin{aligned} &\sup_{x\in\Omega_2(t)} \left\|G_r^N(x,\cdot)\right\|_{L^1(t-T,t)} \\ &\qquad \le \frac{1}{2\pi}\left(\frac{ct-h}{ct+h}\right)^N \operatorname{Log}\left(\frac{t+\sqrt{t^2-(t-T)^2}}{t-T}\right) \quad \left(t>\frac{h}{c}+T\right). \end{aligned} \tag{4.9}$$

It is then easy to conclude the proof of Theorem 2.4 from (4.8), (4.9), and (4.3).

Remark 4.1. In formula (2.10), the function G_r^N naturally appears as the product of three terms. In the proof above, in order to estimate G_r^N we have estimated independently, for the sake of simplicity, each of these factors. In particular, our final estimates are not necessarily sharp.

5. Illustration and analysis of the results.

5.1. Analysis of the 2D fundamental solutions.

Relative error analysis. One of the difficulties in representing numerically the reflected field G_r^N given by (2.10) is the presence of the singularity of the circle $r^*(x) = ct$. To overcome this difficulty, the idea is to compare this reflected field to what it would be with the Dirichlet boundary condition (which corresponds to $N = 0$). That is why we introduce the relative error field defined as

$$\gamma_r^N(x,t) = \frac{G_r^N(x,t)}{G_r^0(x,t)} = P_N\left(\Phi(x,t)\right)\left[\frac{ct-(x_2+h)}{ct+(x_2+h)}\right]^N, \quad x\in\Omega(t). \tag{5.1}$$

(Note that $G_r^0(\cdot,t)$ does not vanish inside the disk $r^*(x) < ct$.) In the following experiments we choose $h = 1$ and $c = 1$. On Figures 8 to 12 we represent, at three different times—namely, $t = 3, 5$, and 7 from top to bottom—the level lines of $x \mapsto \gamma_r^N(x,t)$. Each figure corresponds to one value of N ($N = 1, 2, 5, 10, 20$).

We clearly observe the following:

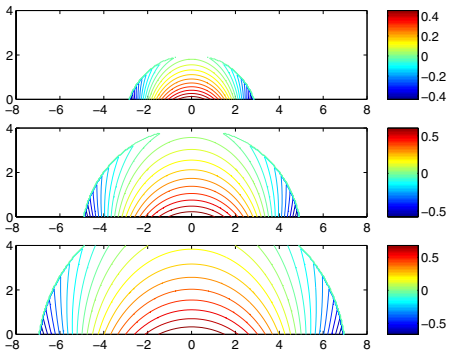

FIG. 8. $x \mapsto \gamma_r^1(x,t)$, $t = 3, 5,$ *and* 7.

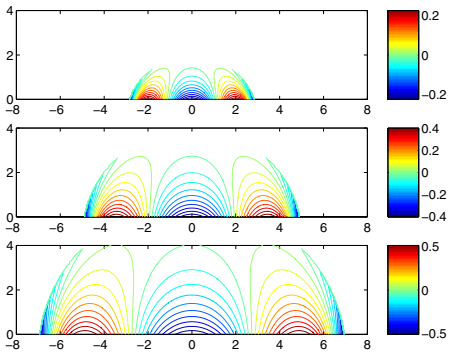

FIG. 9. $x \mapsto \gamma_r^2(x,t)$, $t = 3, 5,$ *and* 7.

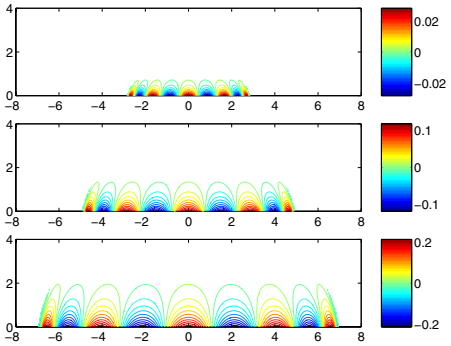

FIG. 10. $x \mapsto \gamma_r^5(x,t)$, $t = 3, 5,$ *and* 7.

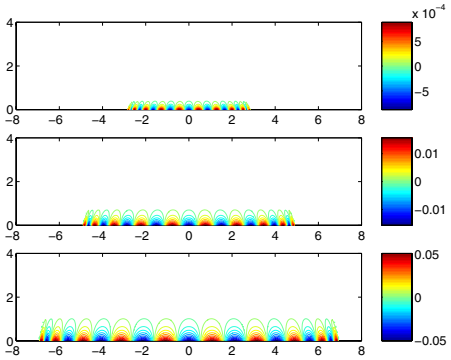

FIG. 11. $x \mapsto \gamma_r^{10}(x,t)$, $t = 5, 7,$ *and* 9.

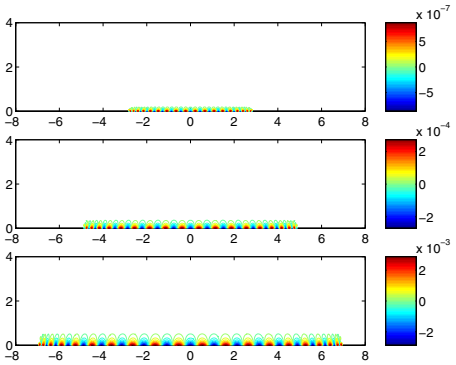

FIG. 12. $x \mapsto \gamma_r^{20}(x,t)$, $t = 3, 5,$ *and* 7.

(i) The amplitude of the error strongly decays with N (take care of the scales). For instance, at $t = 3$, the error level is 0.4 for $N = 1, 0.2$ for $N = 2, 0.02$ for $N = 5, 7.10^{-4}$ for $N = 10$, and 6.10^{-7} for $N = 20$.

(ii) As expected, the amplitude of the error also increases in time. By a homogeneity argument, it is obvious that looking at different t's for fixed h is equivalent to

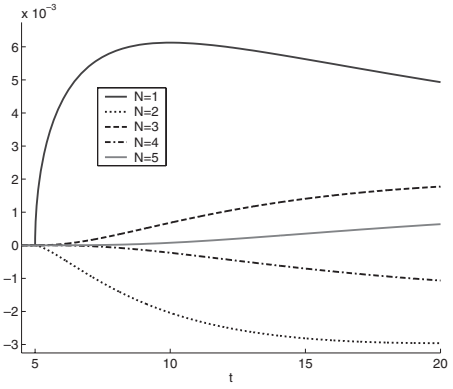

FIG. 13. $t \mapsto G_r^N(x,t)$, $r^* = 5$, $\theta = 0$.

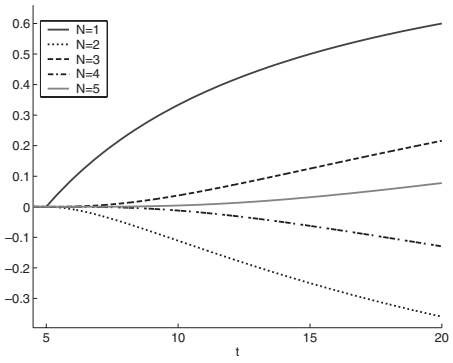

FIG. 14. $t \mapsto \gamma_r^N(x,t)$, $r^* = 5$, $\theta = 0$.

looking at different h's for fixed t. Therefore, our results also illustrate the influence of h on the reflected field.

(iii) When N increases, the relative error concentrates more and more on the neighborhood of the absorbing boundary. Moreover, its dependence with respect to the space variable is more and more complicated (this is the effect of the Chebyshev polynomials).

Study of the error as a function of time. Here we wish to study the evolution of the reflected field at a given point x as a function of time. All the points we observe are located on the circle $r^*(x) = 5$ so that the reflected field arrives at these points at time $t = 5$.

(i) *The case of the point* $\theta(x) = 0$. Contrary to what the plane wave analysis might suggest, the reflected field is not identically 0 for $\theta(x) = 0$, i.e., on the x_2 axis. However, the function $t \mapsto G_r^N(x,t)$ is not discontinuous (except for $N = 0$!) at time $t = \tau = \tau(x) = (x_2 + h)/c$, as shown by the formula

$$G_r^N(x,t) = \frac{(-1)^{N+1}}{2\pi} \frac{[ct - (x_2+h)]^{N-\frac{1}{2}}}{[ct + (x_2+h)]^{N+\frac{1}{2}}} \quad \text{for } t > \tau. \tag{5.2}$$

It becomes even less and less singular as N increases. Moreover, one sees that the function $t \mapsto G_r^N(x,t)$ is increasing from $t = \tau$ to $t = 2N\tau$, then decreasing for $t > 2N\tau$, and tends to 0 when $t \to +\infty$ as $1/2\pi ct$. The maximum of $t \mapsto G_r^N(x,t)$ is given by

$$\sup_{t \geq \tau} G_r^N(x,t) = \frac{1}{2N+1} \left(\frac{2N-1}{2N+1} \right)^{N-\frac{1}{2}} \sim \frac{1}{2Ne} \quad (N \to +\infty). \tag{5.3}$$

These properties are illustrated in Figures 13 and 14, where we represent (in Figure 13) the variations of $t \mapsto G_r^N(x,t)$, $t \in [0,20]$ for $N = 1$ to 5. Looking at the relative error, the formula

$$\gamma_r^N(x,t) = (-1)^N \frac{[ct - (x_2+h)]^{N-\frac{1}{2}}}{[ct + (x_2+h)]^{N+\frac{1}{2}}} \quad \text{for } t > \tau \tag{5.4}$$

shows that the function $t \mapsto \gamma_r^N(x,t)$, $t > \tau$, increases from 0 to 1. This is confirmed in Figure 14.

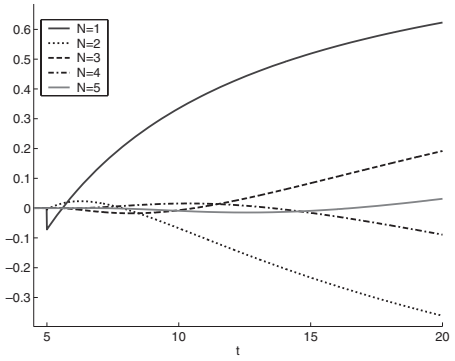

FIG. 15. $t \mapsto \gamma_r^N(x,t)$, $r^* = 5$, $\theta = \frac{\pi}{6}$.

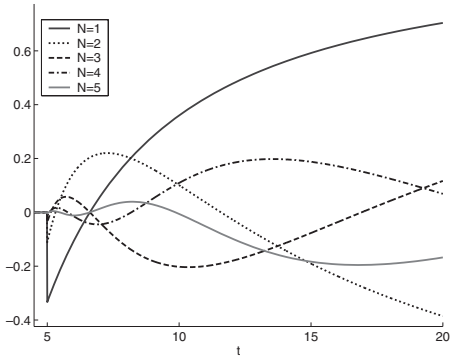

FIG. 16. $t \mapsto \gamma_r^N(x,t)$, $r^* = 5$, $\theta = \frac{\pi}{3}$.

(ii) *The case of points* $\theta(x) \neq 0$. In this case, the function $t \mapsto \gamma_r^N(x,t)$ is no longer continuous for $t = \tau$:

$$\lim_{t \to \tau} \gamma_r^N(x,t) = \mathbf{R}_N(\theta(x)) = (-1)^N \left(\frac{1 - \cos\theta}{1 + \cos\theta} \right)^N . \tag{5.5}$$

In Figures 15 and 16 we represent the variations of $t \mapsto \gamma_r^N(x,t)$ for $\theta = \pi/6$ and $\theta = \pi/3$. In each figure, one makes N vary from 1 to 5. Clearly, the higher N is, the more the function oscillates. Finally, for large times, one easily computes that

$$\lim_{t \to +\infty} \gamma_r^N(x,t) = (-1)^N \tag{5.6}$$

independently of the value of N.

Study of the error as a function of the distance to the image source. We consider here the spatial variation of the reflected field along a ray, namely, the part of a half-line starting from the image source point S^* included in the half-space $\mathbb{R}^2_+$. For a given direction $\theta \in]-\pi/2, \pi/2[$, this ray is also defined as

$$D_\theta = \left\{ x \in \mathbb{R}^2_+ / \theta(x) = \theta \right\} = \{ (r^* \sin\theta, r^* \cos\theta),\ r^* \geq h/\cos\theta \}.$$

In the following figures we represent the variations of the reflected field G_r^N, for fixed θ as a function of $r^* \geq h/\cos\theta$, for different values of t and N.

For $\theta = 0$, $r^* \leq h$. In Figures 17 to 19, we represent the variations of G_r^N along D_0 for three values of t, $t = 3, 5, 8$. Each figure corresponds to one value of N, and therefore the scale varies a lot from one picture to another. Once again, one observes that the reflected field is smoother and smoother as N increases.

For $\theta = \pi/6$, $r^* \leq 2h/\sqrt{3}$. In Figures 20 to 22, we represent the variations of G_r^N along $D_{\pi/6}$ for $t = 3, 5, 8$. This time, the functions are singular for $r^* = ct$. However, one observes that the region where G_r^N takes very large values becomes more and more confined close to the point $r^* = ct$ as N increases.

For $\theta = \pi/3$, $r^* \leq 2h$. In Figures 23 to 25, we represent the variations of G_r^N along $D_{\pi/3}$ for $t = 3, 5, 8$. The functions are still singular for $r^* = ct$. The shape of the reflected wave is more complicated than for $\theta = \pi/6$, especially for large N.

Angular variation of the reflected wave. Our previous results have already illustrated the dependence of the reflected field with respect to $\theta(x)$. Here, let us consider the relative error $\gamma_r^N(x,t)$ along the "reflected" wave front defined as

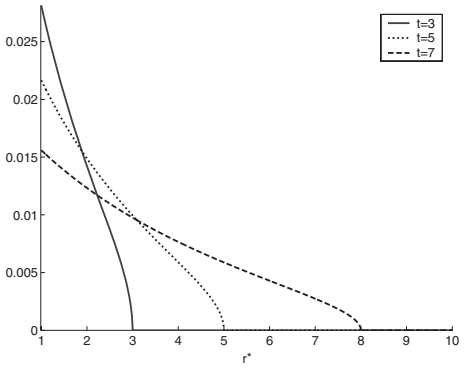

FIG. 17. $r^* \mapsto G_r^1(r^*, \theta = 0, t)$.

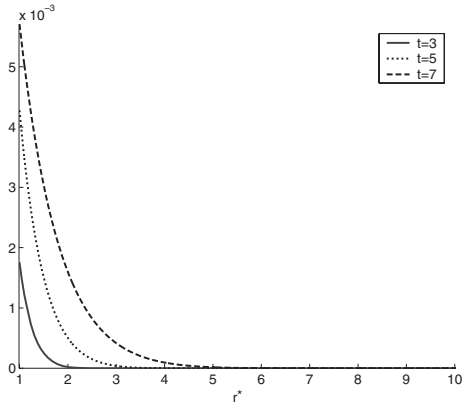

FIG. 18. $r^* \mapsto G_r^5(r^*, \theta = 0, t)$.

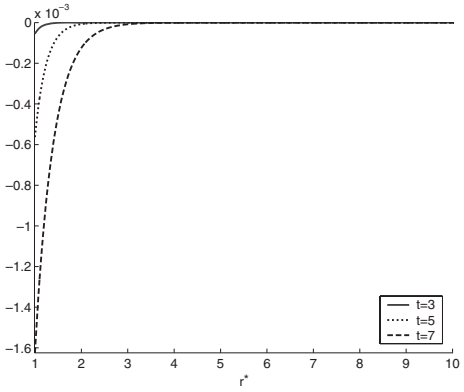

FIG. 19. $r^* \mapsto G_r^{10}(r^*, \theta = 0, t)$.

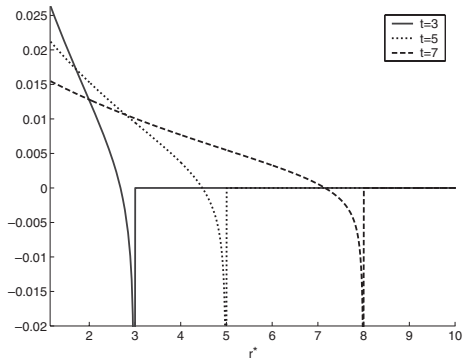

FIG. 20. $r^* \mapsto G_r^1(r^*, \theta = \pi/6, t)$.

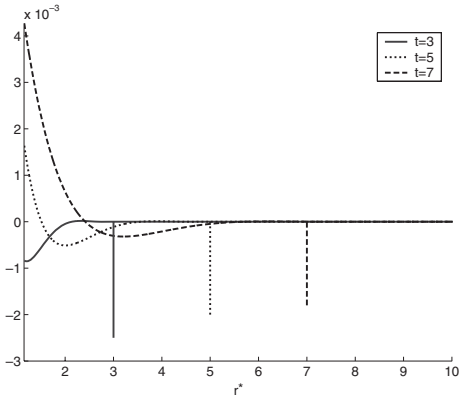

FIG. 21. $r^* \mapsto G_r^5(r^*, \theta = \pi/6, t)$.

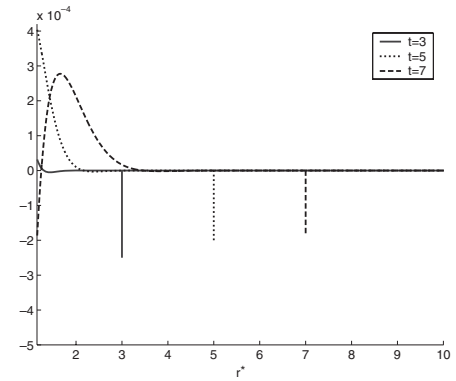

FIG. 22. $r^* \mapsto G_r^{10}(r^*, \theta = \pi/6, t)$.

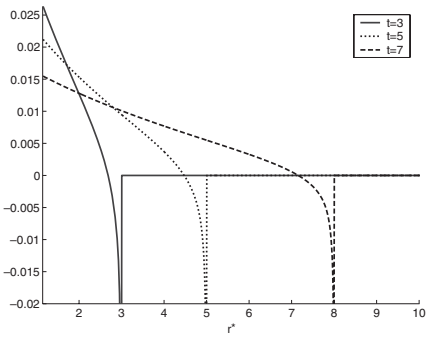

FIG. 23. $r^* \mapsto G_r^1(r^*, \theta = \pi/3, t)$.

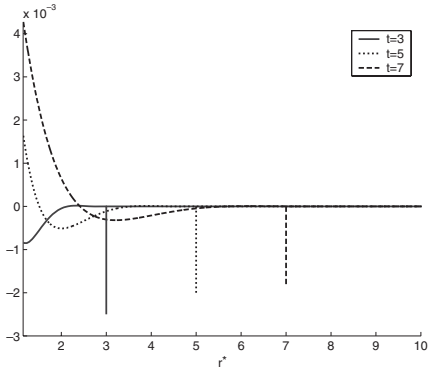

FIG. 24. $r^* \mapsto G_r^5(r^*, \theta = \pi/3, t)$.

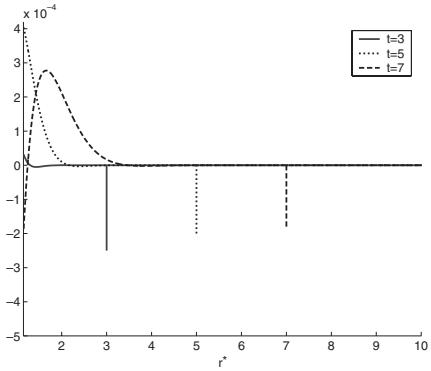

FIG. 25. $r^* \mapsto G_r^{10}(r^*, \theta = \pi/3, t)$.

$$WF_r(t) = \partial\Omega(t) = \{x \in \mathbb{R}^2_+ / r^*(x) = ct\} \quad \left(\neq \emptyset \text{ for } t > \frac{h}{c}\right).$$

Let $M_\theta(t) = (ct\sin\theta, ct\cos\theta) \in WF_r(t)$ (note that $M_\theta(t)$ describes $WF_r(t)$ when θ varies from $-\arccos\frac{h}{ct}$ to $+\arccos\frac{h}{ct}$); one easily deduces from (2.10) that

$$\lim_{x \to M_\theta(t),\ x \in \Omega(t)} \gamma_r^N(x,t) = \mathbf{R}_N(\theta) = (-1)^N \left(\frac{1-\cos\theta}{1-\cos\theta}\right)^N.$$

In other words, the curve representing, as a function of the direction θ, the variations of the relative error $\gamma_r^N(x,t)$ along the "reflected" wave front $WF_r(t)$ is nothing but the portion of the curve of Figure 1 that corresponds to $-\arccos\frac{h}{ct} \le \theta \le \arccos\frac{h}{ct}$.

5.2. The case of a source term.

Comparison with numerical experiments. We have implemented a MATLAB code for the computation of the convolution integral (4.2). To validate our "exact" solution(!), we have compared our results with those obtained with a finite difference code written by F. Collino. In our experiment, the source function is a truncated first derivative of a Gaussian:

$$f(t) = \frac{d}{dt}\{e^{-2\pi f_0 (t-t_0)^2}\} H(2t_0 - t), \quad f_0 = 10,\ t_0 = 1/f_0. \tag{5.7}$$

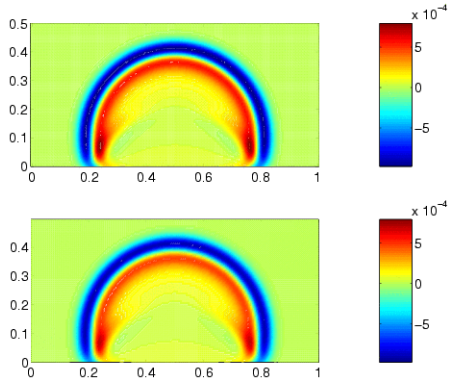

FIG. 26. *Total field.* $N = 1$.

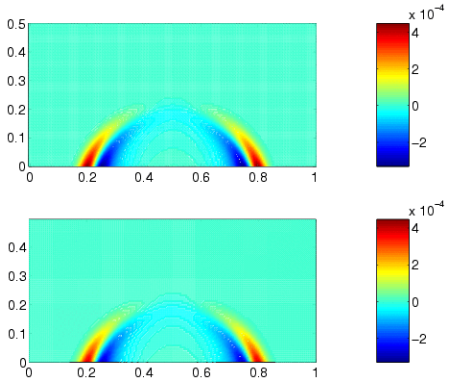

FIG. 27. *Reflected field.* $N = 1$.

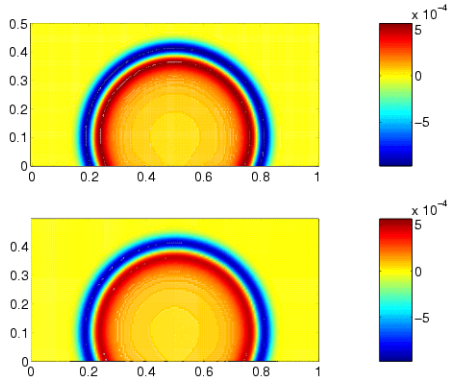

FIG. 28. *Total field.* $N = 5$.

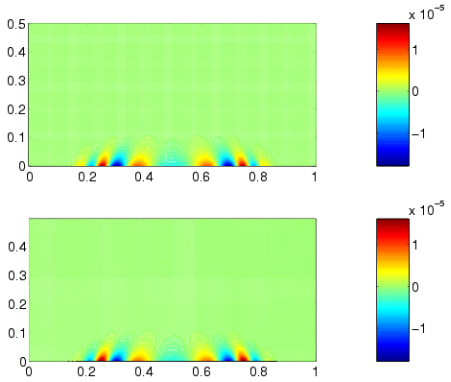

FIG. 29. *Reflected field.* $N = 5$.

In Figures 26 to 29 we have compared the "analytical" solution (top picture in each panel) to the numerical one (bottom picture in each panel) for two values of N: $N = 1$ and 5. In each picture we represent the level lines of the solution at time $t = 0.4$. The left pictures represent the total field while the right pictures represent the reflected field (the error). In each case, for the representation, the reflected field has been amplified by a factor which depends on N: 1.3 for $N = 1$ and 25 for $N = 5$. In each case, the results reveal a very good agreement between the two solutions. In Figures 30 to 33 we have compared both solutions at point $(0.9, 0.1)$ as functions of time. The solid curves represent the "analytical" solution and the dashed curves the numerical one for two values of N: $N = 1$ and 5. As before the left pictures represent the total field while the right pictures represent the reflected field.

L^∞ error estimates. In Figures 34 and 35 we have compared the L_∞-norm of the reflected field (the solid curves) to the uniform estimates (2.15) and (2.16) given by Theorem 2.4 (the dashed curves) for $N = 1, 2, 5, 10$. The source is a step function in time: $f(t) = 1$ if $0 \le t \le 2$ and $f(t) = 0$ otherwise. Our estimate appears to be very sharp for $N = 1$ and becomes less accurate (although quite acceptable) as N increases. Since we used the L^∞-norm of the source function to establish our error estimates, one could imagine that this estimate is not very sharp for more complicated source

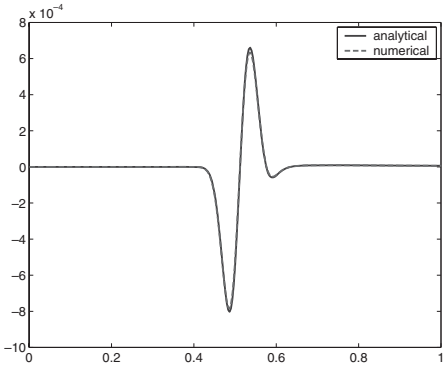

FIG. 30. *Total field.* $N = 1$.

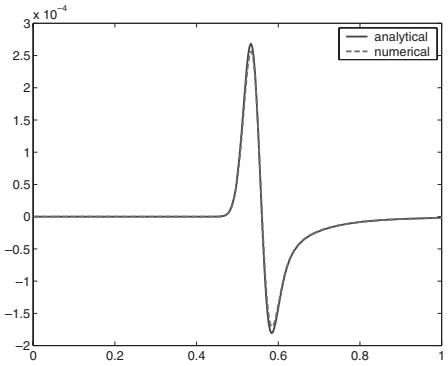

FIG. 31. *Reflected field.* $N = 1$.

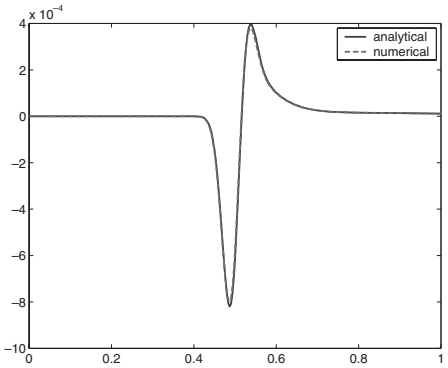

FIG. 32. *Total field.* $N = 5$.

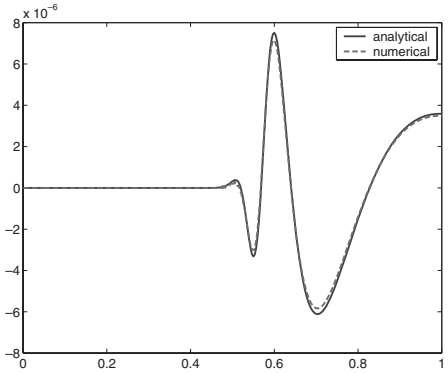

FIG. 33. *Reflected field.* $N = 5$.

functions. To check this, we have repeated the previous experiment when the source is still given by (5.7) with $f_0 = 1$. Figures 36 and 37 illustrate these experiments for $N = 1$ and 5. The estimate is obviously less accurate than in the case of the step source function but still gives a reasonable bound.

6. Conclusion and perspectives. The use of the Cagniard–De Hoop method has enabled us to obtain a quasi-analytical representation of the field reflected by Engquist–Majda higher order ABCs. This permits us to obtain new theoretical estimates for the time-dependent problem.

Of course, the method can be applied to other boundary conditions (we give in the appendix the example of Higdon's boundary conditions). It would also be interesting to treat other equations such as Maxwell's equations or elastodynamics equations. One also might think that the Cagniard–De Hoop method could be a new tool for analyzing the stability of boundary conditions.

In a forthcoming work, we wish to treat the case of the PMLs for ABCs. This should give some insights about the quantitative comparison between ABCs and PMLs.

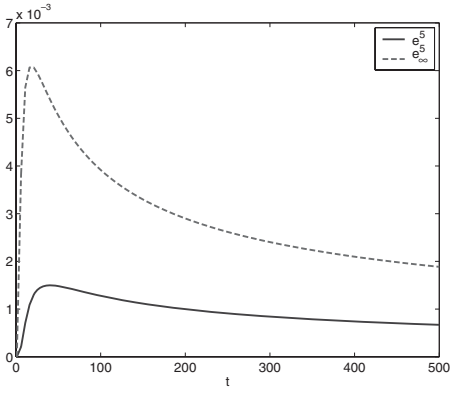

FIG. 37. *Error estimates.* $N = 5$.

Appendix. Extension to Higdon's boundary conditions. In 1986 Higdon [23], [21] proposed another approximation of the condition (1.2) of the form

$$B_{Hig}^N u = \prod_{j=1}^{N} \left(\cos\alpha_j \frac{\partial}{\partial t} - c\frac{\partial}{\partial x} \right) u = 0. \tag{A.1}$$

These conditions are a generalization of the condition (1.5) (obtained with $\alpha_j = 0$ for all j) and have the property to be exactly satisfied by any linear combination of plane waves whose angle of incidence is α_j.

Using the same method as in section 3, it can be shown that the solution of the problem

$$\begin{cases} \text{Find } u : \mathbb{R}^2_+ \times \mathbb{R} \mapsto \mathbb{R} & \text{such that} \\ \dfrac{1}{c^2}\dfrac{\partial^2 u}{\partial t^2} - \Delta u = \delta(x - x_S) \times \delta(t) & \text{in } \mathbb{R}^2_+, \\ \mathcal{B}_{Hig}^N u = 0 & \text{on } \Gamma, \\ u(x,t) = 0 & \text{for } t < 0 \end{cases} \tag{A.2}$$

is given by

$$u(x,t) = G^N_{Hig}(x,t) = G_i(x,t) + G^N_{Hig,r}(x,t), \tag{A.3}$$

where

$$\left| \begin{array}{l} G_i(x,t) = \dfrac{1}{2\pi\sqrt{t^2 - \frac{r(x)^2}{c^2}}} H(ct - r(x)), \\ G^N_{Hig,r}(x,t) = \dfrac{1}{2\pi\sqrt{t^2 - \frac{r^*}{c^2}}} \left[\prod_{j=1}^{n} \rho_j(x,t)\right] \cos\left[\sum_{j=1}^{n} \psi_i(x,t)\right] H(ct - r^*(x)), \end{array} \right. \tag{A.4}$$

where $\rho_j(x,t)$ and $\psi_i(x,t)$ are given by

$$\rho_j(x,t) = \sqrt{\frac{(ct-a_j)^2 - b_j^2}{(ct+a_j)^2 - b_j^2}} \tag{A.5}$$

and

$$\psi_j(x,t) = \arccos\left[\frac{r^*(x,t)^2 - c^2t^2 + r^*(x,t)^2\cos^2\alpha_j - r^*(x,t)^2\cos^2\theta}{\sqrt{((ct-a_j)^2 - b_j^2)((ct+a_j)^2 - b_j^2)}}\right], \tag{A.6}$$

$$\psi_j(x,t) = \arccos\left[\frac{r^*(x,t)^2 - c^2t^2 + r^*(x,t)^2\cos^2\alpha_j - (x_2+h)^2}{\sqrt{((ct-a_j)^2 - b_j^2)((ct+a_j)^2 - b_j^2)}}\right] \tag{A.7}$$

with

$$a_j = r^*(x)\cos\alpha_j\cos\theta = \cos\alpha_j(x_2+h)$$

and

$$b_j = r^*(x)\sin\theta\sin\alpha_j = x_1\sin\alpha_j.$$

Thanks to (A.5), one can see that the function $x \mapsto G^N_{Hig,r}(x,t)$ is singular on the circle $r^*(x) = ct$ except in the directions α_j.

STRUCTURAL BIFURCATION OF 2-D NONDIVERGENT FLOWS WITH DIRICHLET BOUNDARY CONDITIONS: APPLICATIONS TO BOUNDARY-LAYER SEPARATION*

MICHAEL GHIL†, TIAN MA‡, AND SHOUHONG WANG§

Abstract. This article addresses transitions in the topological structure of a family of divergence-free vector fields $u(\cdot, t)$ with Dirichlet boundary conditions. We show that structural bifurcation—i.e., change in topological-equivalence class—occurs at t_0 if $u(\cdot, t_0)$ has an isolated degenerate ∂-singular point $\bar{x} \in \partial M$ such that $\partial^2 u(\bar{x}, t_0)/\partial n \partial t \neq 0$. The main results are proved by classifying orbit structures of u near such a point $\bar{x} \in \partial M$ of $u(\cdot, t_0)$. The condition of $\bar{x}$ being a ∂-singular point is equivalent to the one originally postulated by Prandtl for boundary-layer separation. Our analysis and classification do contribute, in fact, to a rigorous characterization of boundary-layer separation in 2-D incompressible fluid flows.

Key words. structural bifurcation, boundary layer separation, 2-D incompressible flows

1. Introduction.

This article is part of a research program on the use of topological ideas to study the spatio-temporal structure of 2-D incompressible fluid flows in physical space, along with its stability and bifurcations. This program consists of research in two areas: (a) the study of the topological structure of divergence-free vector fields, and its evolution in time or with respect to an arbitrary parameter; and (b) the study of the structure and evolution of velocity fields for 2-D incompressible fluid flows governed by a class of equations that comprises the Navier–Stokes equations, the Euler equations, and the quasi-geostrophic equations of rotating flows.

Mathematically speaking, there are two general methods for describing a fluid flow: the Euler representation and the Lagrange representation; see [1, 2, 3, 6, 9, 13, 17]. In the Euler representation, the motion of a fluid is described by a set of partial differential equations (PDEs)—such as the Euler equations or the Navier–Stokes equations, supplemented with proper boundary conditions—that govern the velocity field at every point in the (2-D or 3-D) flow domain. The Lagrange representation of a fluid flow, on the other hand, amounts to studying the trajectories of fluid particles

as a function of initial position in the flow domain, subject to the ordinary differential equations (ODEs) that govern the change in position given the velocity. Of course the velocities of the particles satisfy the PDEs we just mentioned.

Our approach is to classify the topological structure of the *instantaneous* velocity field, treating the time variable as a parameter, and the changes in this structure with respect to time. The aforementioned two areas of our program draw inspiration from and are relevant to both the Eulerian and the Lagrangian approaches to fluid flows.

The study in area (a) is kinematic in nature, and the results and methods developed can naturally be applied to other problems of mathematical physics that involve divergence-free vector fields. These include, for instance, problems in electromagnetism in which the magnetic field is necessarily divergence-free. The main topics in this area include structural classification, structural stability, and structural bifurcation, as well as their applications to fluid dynamics in general and to geophysical fluid dynamics in particular. The study in area (b) involves specific connections between the solutions of the evolution equations—whether Navier–Stokes, Euler, or quasi-geostrophic—and the flow structure in the physical space.

The main objective of this paper is to contribute to a rigorous characterization of boundary-layer separation in 2-D incompressible fluid flows. This is a long-standing problem in fluid mechanics that goes back to the pioneering work of Prandtl [15] in 1904. Classical boundary-layer theory is presented in [2, 9, 16]. The Prandtl equation represents an approximation of the Navier–Stokes equations inside the boundary layer in the absence of separation; this equation is rigorously analyzed in a recent textbook [14] and several articles [4, 5, 18].

Basically, the boundary layer is a narrow region of sharp velocity gradients between a no-slip wall, where the velocity has to vanish, and the interior of the fluid. This layer of high shear can detach from the boundary, generating vortices and leading to more complicated turbulent behavior near the wall as well as in the interior of the flow domain [9]. It is important, therefore, to characterize, if at all possible, the conditions for separation. Experimentally one observes that the normal derivative of the velocity field vanishes at or near separation points. Chorin and Marsden [2] note that there is no known theorem that can be applied to determine the separation reliably. This article, along with [8, 10], is an attempt to derive a rigorous characterization of streamline detachment from the boundary for 2-D divergence-free vector fields. These results are applied in the companion papers [7, 12] to the actual problem of boundary-layer separation in solutions of the 2-D incompressible Navier–Stokes equations.

In the present article, we address structural transitions for a family of divergence-free vector fields $u(\cdot, t)$ with Dirichlet boundary conditions. We show that structural bifurcation—i.e., change in their topological-equivalence class—occurs at t_0 if $u(\cdot, t_0)$ has an isolated degenerate ∂-singular point $\bar{x} \in \partial M$, such that $\partial^2 u(\bar{x}, t_0)/\partial n \partial t \neq 0$. The condition that $\bar{x} \in \partial M$ is a ∂-singular point is related, as we shall see in section 3, to the Prandtl condition [15] for boundary-layer separation.

Our main results are based on a complete classification of orbit structures near an isolated degenerate ∂-singular point. These results extend over several papers and rely on a delicate analysis of the flow structure near the boundary for both free-slip and Dirichlet boundary conditions. The first step was to classify the flow structure and its transitions near the boundary for flows subject only to boundary conditions of zero normal flow, often called free-slip conditions in fluid dynamics [8]. Second, Ma and Wang [10] analyzed the case of Dirichlet boundary conditions for a 2-D divergence-free vector field; in fluid mechanics the Dirichlet condition on the velocity is often called

the no-slip condition.

Technically speaking, homogeneous Dirichlet boundary conditions for $u(\cdot, t_0)$ imply that all points on ∂M are singular points in the usual sense. Hence, to analyze and to classify the structure of u near the boundary, including the separation point, we need to use the concept of a ∂-singular point, introduced in [10], which corresponds to singular points of the normal derivative of u in the usual sense. Finally, in the present paper we make the connection between the structure of the original velocity fields and the structure of the normal derivative of the velocity field.

The paper is organized as follows. In section 2, we summarize our previous results, including a structural stability theorem, necessary conditions on structural bifurcation, and a singularity classification theory for 2-D divergence-free vector fields. Section 3 states the structural-bifurcation theorems near a flat boundary for such fields, which are proved in section 4. Section 5 addresses structural bifurcations near a curved boundary, and section 6 applies the theory to streamline detachment from the boundary. It is the results of section 6 that are applied in the companion papers [7, 12] to boundary-layer separation in the 2-D Navier–Stokes equations for incompressible flows.

2. Preliminaries. Let $M \subset \mathbb{R}^2$ be a closed and bounded domain with C^{r+1} $(r \geq 2)$ boundary ∂M, and let TM be the tangent bundle of M. Let $C_n^r(TM)$ be the space of all C^r vector fields on M that satisfy a boundary condition of no normal flow (or no penetration), let $D^r(TM)$ be the subspace of $C_n^r(TM)$ that is divergence-free, and let $B_0^r(TM)$ be the subspace of $D^r(TM)$ that satisfies a homogeneous Dirichlet boundary condition:

$$\begin{aligned} C_n^r(TM) &= \{u \in C^r(TM) \mid u_n|_{\partial M} = 0\}, \\ D^r(TM) &= \{u \in C^r(TM) \mid u_n|_{\partial M} = 0,\ \mathrm{div} u = 0\}, \\ B_0^r(TM) &= \{u \in D^r(TM) \mid u|_{\partial M} = 0\}. \end{aligned}$$

Here $u_n = u \cdot n$ and $u_\tau = u \cdot \tau$, while n and τ are the unit normal and tangent vector on ∂M, respectively. It is easy to see that

$$B_0^r(TM) \subset D^r(TM) \subset C_n^r(TM) \subset C^r(TM).$$

We start with some basic concepts. Let $X = D^r(TM)$ or $B_0^r(TM)$ in the following four definitions.

DEFINITION 2.1. *Two vector fields $u, v \in X$ are called topologically equivalent in X if there exists a homeomorphism of $\varphi : M \to M$, which takes the orbits of u to the orbits of v and preserves their orientation.*

DEFINITION 2.2. *Let $u \in C^1([0,T], X)$ be a one-parameter family of vector fields in X. The vector field $u_0 = u(\cdot, t_0)$ $(0 < t_0 < T)$ is called a bifurcation point of u at time t_0 if, for any $t^- < t_0$ and $t_0 < t^+$ with t^- and t^+ sufficiently close to t_0, the vector field $u(\cdot, t^-)$ is not topologically equivalent to $u(\cdot, t^+)$. In this case, we say that $u(x,t)$ has a bifurcation at t_0 in its global structure.*

DEFINITION 2.3. *Let $u \in C^1([0,T], X)$. We say that $u(x,t)$ has a bifurcation in its local structure in a neighborhood $U \subset M$ of x_0 at t_0 $(0 < t_0 < T)$ if, for any $t^- < t_0$ and $t_0 < t^+$ with t^- and t^+ sufficiently close to t_0, the vector fields $u(\cdot, t^-)$ and $u(\cdot, t^+)$ are not topologically equivalent locally in $U \subset M$.*

We remark here that bifurcation in the vector field's local structure does not imply bifurcation in its global structure. In fact, one can easily construct examples

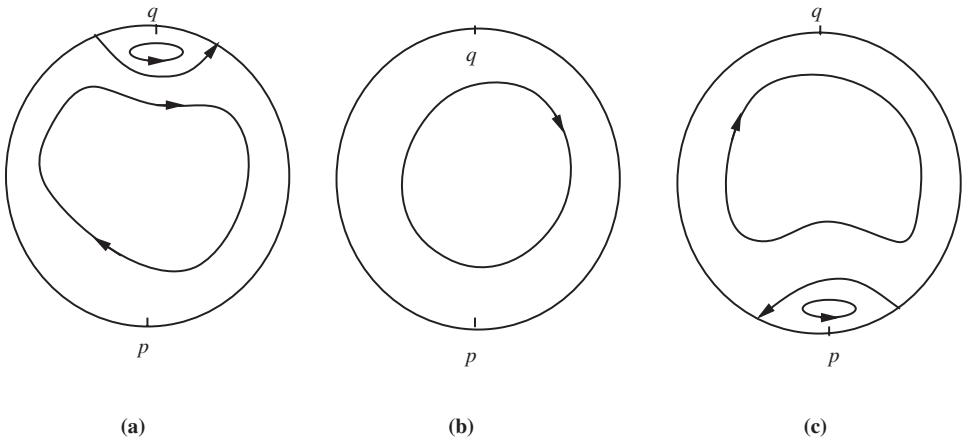

FIG. 2.1. *Flow structure* (a) *for* $t = t^- < t_0$, (b) *for* $t = t_0$, *and* (c) *for* $t = t^+ > t_0$. *Bifurcations in local structure occur at* $t = t_0$ *near both* p *and* q, *but there is no bifurcation in global structure when going from* (a) *to* (c).

showing that flow structure changes in some local area $U \subset M$, but not on the whole manifold M; see, for instance, the flow transitions shown in Figure 2.1.

DEFINITION 2.4. *A vector field* $v \in X$ *is called structurally stable in* X *if there exists a neighborhood* $\mathcal{O} \subset X$ *of* v *such that for any* $u \in \mathcal{O}$, u *and* v *are topologically equivalent.*

A point $p \in M$ is called a singular point of $u \in C_n^r(TM)$ if $u(p) = 0$; a singular point p of u is called nondegenerate if the Jacobian matrix $Du(p)$ is invertible; u is called regular if all singular points are nondegenerate.

By definition, in the case where homogeneous Dirichlet boundary conditions are satisfied, all points on the boundary are singular points. In order to classify the structure of the divergence-free vector fields near the boundary in this case, and infer the possible bifurcations in this structure, we need to distinguish between different types of singular points on the boundary. The concepts of ∂-regular and ∂-singular points introduced in [10] are crucial in order to study the topological structure of divergence-free vector fields with homogeneous Dirichlet boundary conditions.

Let $p \in \partial M$, and let U be a neighborhood of p. Then on $\partial M \cap U$ there exist unit tangent and normal vector fields τ and n. For U sufficiently small, we can extend these two vector fields to U so that the orbits of n in U are tangent to λn with n restricted to $\partial M \cap U$; here $0 \le \lambda \le 1$. Note that when U is sufficiently small, for any two points $x, y \in \partial M \cap U$, λn_x and λn_y do not intersect within U. The extension of τ in U is taken to be orthogonal to n.

DEFINITION 2.5. *Let* $u \in B_0^r(TM)$ $(r \ge 2)$.

(i) *A point* $p \in \partial M$ *is called a* ∂*-regular point of* u *if* $\partial u_\tau(p)/\partial n \ne 0$; *otherwise,* $p \in \partial M$ *is called a* ∂*-singular point of* u.

(ii) *A* ∂*-singular point* $p \in \partial M$ *of* u *is called nondegenerate if*

$$\det \begin{pmatrix} \dfrac{\partial^2 u_\tau(p)}{\partial \tau \partial n} & \dfrac{\partial^2 u_\tau(p)}{\partial n^2} \\ \dfrac{\partial^2 u_n(p)}{\partial \tau \partial n} & \dfrac{\partial^2 u_n(p)}{\partial n^2} \end{pmatrix} \ne 0.$$

A nondegenerate ∂-singular point of u is also called a ∂-saddle point of u.

DEFINITION 2.6. *$u \in B_0^r(TM)$ $(r \geq 2)$ is called D-regular if*

(i) *u is regular in $\overset{\circ}{M}$, the interior of M, and*

(ii) *all ∂-singular points of u on ∂M are nondegenerate.*

For a D-regular divergence-free vector field v on M, an interior nondegenerate singular point of v can be either a center or a saddle, and saddles of v must be connected to saddles. An interior saddle $p \in \overset{\circ}{M}$ is called *self-connected* if p is connected only to itself, i.e., p occurs in a graph whose topological form is that of the number 8.

The following structural stability theorem in the presence of homogeneous Dirichlet boundary conditions was proved in [10].

THEOREM 2.7 (Ma and Wang [10]). *Let $u \in B_0^r(TM)$ $(r \geq 2)$. Then u is structurally stable in $B_0^r(TM)$ if and only if*

1. *u is D-regular;*
2. *all interior saddle points of u are self-connected; and*
3. *each ∂-saddle point of u on ∂M is connected to a ∂-saddle point on the same connected component of ∂M.*

Moreover, the set of all structurally stable vector fields is open and dense in $B_0^r(TM)$.

Based on Theorem 2.7, the following theorem gives some necessary conditions for structural bifurcation.

THEOREM 2.8. *Let $u \in C^1([0,T], B_0^r(TM))$ $(r \geq 2)$.*

1. *If $u(x,t)$ has a bifurcation in its local structure in an arbitrarily small neighborhood $U \subset M$ of x_0 at t_0 $(0 < t_0 < T)$, then $x_0 \in \overset{\circ}{M}$ (respectively, $x_0 \in \partial M$) must be a degenerate singular point (respectively, degenerate ∂-singular point) of $u(x,t)$ at t_0.*
2. *If $u(x,t)$ has a bifurcation in its global structure at t_0 $(0 < t_0 < T)$, then $u(x,t_0)$ does not satisfy at least one of the conditions* (1)–(3) *in Theorem* 2.7.

To proceed, we need to recall the definition of indices of singular points of a vector field. Let $p \in M$ be an isolated singular point of $v \in C_n^r(TM)$; then

$$\operatorname{ind}(v,p) = \deg(v,p),$$

where $\deg(v,p)$ is the Brouwer degree of v at p.

Let $p \in \partial M$ be an isolated singular point of v, and let $\widetilde{M} \subset \mathbb{R}^2$ be an extension of M, i.e., $M \subset \widetilde{M}$ such that $p \in \widetilde{M}$ is an interior point of $\widetilde{M}$. In a neighborhood of p in $\widetilde{M}$, v can be extended by reflection to $\tilde{v}$ such that p is an interior singular point of $\tilde{v}$, thanks to the no normal flow condition, i.e., $v \cdot n|_{\partial M} = 0$. Then we define the index of v at $p \in \partial M$ by

$$\operatorname{ind}(v,p) = \frac{1}{2}\operatorname{ind}(\tilde{v},p).$$

Let $p \in M$ be an isolated singular point of $v \in C_n^r(TM)$. An orbit γ of v is said to be a stable orbit (respectively, an unstable orbit) connected to p if the limit set $\omega(x) = p$ (respectively, $\alpha(x) = p$) for any $x \in \gamma$.

We now introduce a singularity classification theorem for incompressible vector fields, which will be useful in our discussion of structural bifurcation.

THEOREM 2.9 (Ghil, Ma, and Wang [8]). *Let $p \in M$ be an isolated singular point of $v \in D^r(TM)$, $r \geq 1$. Then p is connected only to a finite number of orbits, and the stable and unstable orbits connected to p alternate when tracing a closed curve around p. Furthermore*

1. *when $p \in \mathring{M}$, p has $2n$ $(n \geq 0)$ orbits, n of which are stable, and the other n unstable, while the index of p is*
$$\mathrm{ind}(v, p) = 1 - n;$$
2. *when $p \in \partial M$, p has $n + 2$ $(n \geq 2)$ orbits, two of which are on the boundary ∂M, and the index of p is*
$$\mathrm{ind}(v, p) = -\frac{n}{2}.$$

No confusion should arise between the integer n, used for counting orbits, and the notation n for the normal direction to the boundary ∂M.

3. Structural bifurcations near a flat boundary. In this section, we assume that the boundary ∂M contains a flat part $\Gamma \subset \partial M$, and consider structural bifurcation near a ∂-singular point $\bar{x} \in \Gamma$. For simplicity, we take a coordinate system (x_1, x_2) with $\bar{x}$ at the origin and with Γ given by
$$\Gamma = \{(x_1, 0) \,\big|\, |x_1| \leq \delta\}$$
for some $\delta > 0$. Obviously, the tangent and normal vectors on Γ are the unit vectors in the x_1- and x_2-directions, respectively.

Let $u \in C^1([0, T], B_0^r(TM))$ $(r \geq 2)$ be a one-parameter family of divergence-free vector fields subject to homogeneous Dirichlet boundary conditions. In a neighborhood $U \subset M$ of $\bar{x} \in \Gamma$, $u(x, t)$ can be expressed near $x = 0$ by
$$u(x, t) = x_2 v(x, t). \tag{3.1}$$
It is easy to see that u and v have topologically equivalent streamlines in an interior neighborhood of $x = 0$. To proceed, we consider the Taylor expansions of both $u(x, t)$ and $v(x, t)$ at t_0 $(0 < t_0 < T)$:
$$\begin{cases} u(x,t) = u^0(x) + (t - t_0)u^1(x) + o(|t - t_0|^2), \\ u^0(x) = u(x, t_0), \\ u^1(x) = \dfrac{\partial u(x, t_0)}{\partial t}, \end{cases} \tag{3.2}$$
$$\begin{cases} v(x,t) = v^0(x) + (t - t_0)v^1(x) + o(|t - t_0|)^2, \\ v^0(x) = v(x, t_0), \\ v^1(x) = \dfrac{\partial v(x, t_0)}{\partial t}. \end{cases} \tag{3.3}$$

Let $u^i = (u_1^i, u_2^i)$, $v^i = (v_1^i, v_2^i)$, $i = 0, 1$. We start with the following conditions for structural bifurcation.

Assumption (H). Let $\bar{x} = 0 \in \Gamma$ be an isolated degenerate ∂-singular point of $u^0(x)$, $u^0 \in C^{k+1}$ near $\bar{x} \in \Gamma$ for some $k \geq 2$. Assume that
$$\frac{\partial u^0(0)}{\partial n} = 0, \tag{3.4}$$
$$\mathrm{ind}(v^0, 0) \neq -\frac{1}{2}, \tag{3.5}$$
$$\frac{\partial u^1(0)}{\partial n} \neq 0, \tag{3.6}$$
$$\frac{\partial^{k+1} u_1^0(0)}{\partial^k \tau \partial n} \neq 0. \tag{3.7}$$

Some remarks are now in order.

Remark 3.1. Condition (3.4) says that $\bar{x} = 0 \in \Gamma$ is a ∂-singular point of $u^0(x)$. In a 2-D incompressible flow governed by either the Euler or the Navier–Stokes equations, this condition is equivalent to the leading-order vorticity vanishing at $\bar{x}$. The latter is the so-called Prandtl condition, which Prandtl suggested might identify boundary-layer separation points in incompressible flows [15].

Remark 3.2. Condition (3.5) amounts to saying that there exist a number $n \neq 1$ of interior orbits of v^0 connected to $\bar{x} \in \Gamma$. Since $u^0 = x_2 v^0$, the number of interior orbits of u^0 connected to $\bar{x} \in \Gamma$ is exactly $n \neq 1$ as well. This shows that $\bar{x} \in \Gamma$ is a degenerate ∂-singular point of $u^0(x)$, which is necessary for structural bifurcation, according to our structural stability and bifurcation theorems; see Theorems 2.7 and 2.8 here, or [8, 10].

Remark 3.3. Condition (3.6) states that the first-order term u^1 of the Taylor expansion for the normal derivative of u is different from zero. This is just the simplest necessary condition of such a type; if it does not hold, we need to work on a higher-order Taylor expansion, and the corresponding results proved in this article will be true as well. In fluid-mechanics applications, condition (3.6) is equivalent to the vorticity associated with u^1 not vanishing at the boundary. In addition, it is easy to see that (3.6) is equivalent to

$$\frac{\partial u_1^1(0)}{\partial x_2} = \frac{\partial u_1^1(0)}{\partial n} \neq 0,$$

which shows that the acceleration of the fluid in the tangential direction near $\bar{x}$ is nonzero.

Remark 3.4. Condition (3.7) is a technical condition and amounts to saying that the tangential component u_1^0 of the leading-order term has a nontrivial Taylor expansion. Furthermore, let k be the smallest integer satisfying condition (3.7). It is easy to show that $k \geq 2$. In fact, $u^0(x)$ has the Taylor expansion at $x = 0$,

$$u^0(x) = \begin{cases} cx_2 + 2ax_1x_2 + bx_2^2 + x_2h_1(x), \\ \qquad\qquad -ax_2^2 + x_2h_2(x), \end{cases} \tag{3.8}$$

with $h_i(x) = o(|x|)$ $(i = 1, 2)$. Since $\bar{x} \in \Gamma$ is a degenerate ∂-singular point of $u^0(x)$, it follows that $c = 0$, $a = 0$, which implies that $k \geq 2$.

The structural bifurcation of $u(x, t)$ near a degenerate ∂-singular point on a flat boundary segment is described by the following theorems.

THEOREM 3.5. *Let $u \in C^1([0, T], B_0^r(TM))$ $(r \geq 2)$ satisfy Assumption* (H). *Then there exist a neighborhood*

$$\Gamma_0 = \{(x_1, 0) \,|\, |x_1| \leq \delta_0\} \subset \Gamma$$

of $\bar{x} = 0$ and an $\varepsilon_0 > 0$ such that all ∂-singular points of $u(\cdot, t_0 \pm \varepsilon)$ are nondegenerate for any $0 < \varepsilon \leq \varepsilon_0$. Moreover,

1. *if the index* $\mathrm{ind}(v^0, 0)$ *is an integer, then one of $u(x, t_0 \pm \varepsilon)$ has exactly two ∂-singular points on Γ_0, and the other has no ∂-singular points on Γ_0; and*
2. *if the index* $\mathrm{ind}(v^0, 0)$ *is not an integer, then each of $u(x, t_0 \pm \varepsilon)$ has exactly one ∂-singular point on Γ_0.*

THEOREM 3.6 (structural bifurcation theorem). *Let $u \in C^1([0, T], B_0^r(TM))$ $(r \geq 2)$ satisfy Assumption* (H). *Then*

1. *the vector field u has a bifurcation in its local structure at $(\bar{x}, t_0)$; and*

2. *if $\bar{x} \in \partial M$ is a unique ∂-singular point of u with the same index as* $\mathrm{ind}(v^0, 0)$ *on ∂M, then $u(x,t)$ has a bifurcation in its global structure at $t = t_0$.*

The proofs of these two theorems are based on analyzing the orbits of u to provide a complete classification of the local structure of u near $(\bar{x}, t_0)$. The bifurcation results follow immediately from the classification.

4. Proofs of the main theorems.

4.1. Proof of Theorem 3.5. The proof of the theorem is a direct consequence of the following three propositions.

PROPOSITION 4.1. *There exist a neighborhood $\Gamma_0 \subset \Gamma$ of $\bar{x} = 0$ and an $\varepsilon_0 > 0$ such that all ∂-singular points of $u(\cdot, t_0 \pm \varepsilon)$ are nondegenerate for any $0 < \varepsilon \le \varepsilon_0$.*

Proof. Let $x^* \in \Gamma$, $x^* = (x_1^*)$, and $0 < |x_1^*| \le \delta_0$ with $0 < \delta_0$ sufficiently small, to be chosen later. Then

$$\frac{\partial u}{\partial n}(x^*, t_0 \pm \varepsilon) = \frac{\partial u}{\partial x_2}(x^*, t_0 \pm \varepsilon) = 0. \tag{4.1}$$

By the Taylor expansion (3.2) and condition (3.6) it suffices to consider only the first-order approximation of (3.2). Hence,

$$\frac{\partial u_i^0(x_1^*, 0)}{\partial x_2} \pm \varepsilon \frac{\partial u_i^1(x_1^*, 0)}{\partial x_2} = 0 \qquad (i = 1, 2). \tag{4.2}$$

We need to show that

$$\det \begin{pmatrix} \dfrac{\partial^2 u_1^0}{\partial x_1 \partial x_2} \pm \varepsilon \dfrac{\partial^2 u_1^1}{\partial x_1 \partial x_2} & \dfrac{\partial^2 u_1^0}{\partial x_2^2} \pm \varepsilon \dfrac{\partial^2 u_1^1}{\partial x_2^2} \\ \dfrac{\partial^2 u_2^0}{\partial x_1 \partial x_2} \pm \varepsilon \dfrac{\partial^2 u_2^1}{\partial x_1 \partial x_2} & \dfrac{\partial^2 u_2^0}{\partial x_2^2} \pm \varepsilon \dfrac{\partial^2 u_2^1}{\partial x_2^2} \end{pmatrix}_{x=(x_1^*,0)} \neq 0. \tag{4.3}$$

For $u \in C^1([0,T], B_0^r(TM))$, $u(x_1, 0, t) = 0$ for all $(x_1, 0) \in \Gamma$ and $0 \le t \le T$. Thus we obtain

$$\frac{\partial u_1}{\partial x_1}(x_1, 0, t) = 0 \qquad \forall\, |x_1| \le \bar{\delta}.$$

Thanks to the fact that u is divergence-free, we have

$$\frac{\partial u_2}{\partial x_2}(x_1, 0, t) = -\frac{\partial u_1}{\partial x_1}(x, 0, t) = 0 \qquad \forall\, |x_1| \le \bar{\delta}.$$

Consequently

$$\frac{\partial u_2^0(x_1, 0)}{\partial x_2} \pm \varepsilon \frac{\partial u_2^1(x_1, 0)}{\partial x_2} = 0 \qquad \forall\, |x_1| \le \bar{\delta},$$

which yields

$$\frac{\partial^2 u_2^0(x_1^*, 0)}{\partial x_1 \partial x_2} \pm \varepsilon \frac{\partial^2 u_2^1(x_1^*, 0)}{\partial x_1 \partial x_2} = 0.$$

To verify (4.3), it suffices to prove that

$$\frac{\partial^2 u_1^0(x_1^*, 0)}{\partial x_1 \partial x_2} \pm \varepsilon \frac{\partial^2 u_1^1(x_1^*, 0)}{\partial x_1 \partial x_2} \neq 0,$$

since the sum of the diagonal terms in (4.3) is zero thanks to the fact that $\partial u/\partial x_2$ is divergence-free.

From conditions (3.7) and (3.6) we get

$$\begin{cases} \dfrac{\partial u_1^0(x_1,0)}{\partial x_2} = \alpha x_1^k + o(|x_1|^k), \quad \alpha \neq 0, \\ \dfrac{\partial u_1^1(x_1,0)}{\partial x_2} = \beta + o(|x_1|), \quad \beta \neq 0. \end{cases} \tag{4.4}$$

Therefore it follows from (4.2) that

$$\varepsilon = \pm \frac{\alpha}{\beta}\, x_1^{*^k} + o(|x_1^*|^k). \tag{4.5}$$

Thus from (4.4) and (4.5) we obtain that

$$\frac{\partial^2 u_1^0(x_1^*,0)}{\partial x_1 \partial x_2} \pm \varepsilon\, \frac{\partial^2 u_1^1(x_1^*,0)}{\partial x_1 \partial x_2} = \alpha k x_1^{*^{k-1}} + o\left(|x_1^*|^{k-1}\right),$$

which is different from zero for $0 < |x_1^*| \leq \delta_0$, provided that δ_0 is sufficiently small. Hence (4.3) follows, and the proof of the proposition is complete. □

PROPOSITION 4.2. *If* $\operatorname{ind}(v^0, 0) =$ *integer, then one of* $u(x, t_0 \pm \varepsilon)$ *has no* ∂*-singular points on* Γ_0*, and the other one has exactly two* ∂*-singular points on* Γ_0 *with one* ∂*-singular point on each side of* $\bar{x} = 0$*.*

Proof. From (3.1) it is easy to see that the zero points of $v(x,t)$ on Γ are equivalent to the ∂-singular points of $u(x,t)$. Hence we only have to prove the assertion for the vector field $v(x, t_0 \pm \varepsilon)$.

According to (3.8) we have, for the component v_2 that is normal to Γ,

$$v_2(x_1, 0, t) = 0 \quad \forall\, x_1 \in \Gamma,\ t \geq 0.$$

By (3.6) and (3.7) we infer from (3.1) that

$$\begin{cases} v_1^0(x_1,0) = \alpha x_1^k + o(|x_1|^k), & \alpha \neq 0, \\ v_1^1(x_1,0) = \beta + g(x_1), & \beta \neq 0,\ g(0) = 0. \end{cases} \tag{4.6}$$

On the other hand, if $\operatorname{ind}(v^0, 0)$ is an integer, then by Remark 3.2 the number n of interior orbits of v^0 connected to $\bar{x} = 0$ is even. Hence, one of the two boundary orbits of v^0 connected to $\bar{x} = 0$ is stable, and the other one is unstable. It follows that the exponent k in (4.6) is even, i.e., $k = 2m$ $(m \geq 1)$.

Consider the two equations

$$\begin{aligned} 0 &= v_1(x_1, 0, t_0 + \varepsilon) = v_1^0(x_1, 0) + \varepsilon v_1^1(x_1, 0) + o(|\varepsilon|) \\ &= \alpha x_1^{2m} + \varepsilon\beta + \varepsilon g(x_1) + o(|\varepsilon|, |x_1|^{2m}), \end{aligned} \tag{4.7}$$

$$\begin{aligned} 0 &= v_1(x_1, 0, t_0 - \varepsilon) = v_1^0(x_1, 0) - \varepsilon v_1^1(x_1, 0) + o(|\varepsilon|) \\ &= \alpha x_1^{2m} - \varepsilon\beta - \varepsilon g(x_1) + o(|\varepsilon|, |x_1|^{2m}), \end{aligned} \tag{4.8}$$

where $m \geq 1$. Without loss of generality, assume that $\alpha, \beta > 0$. Then there is a $\delta_0 > 0$ such that for any $\varepsilon > 0$ sufficiently small, (4.8) has only two solutions $x_1^{\pm}$ of opposite sign, $x_1^-(\varepsilon) < 0 < x_1^+(\varepsilon)$, in the interval $(-\delta_0, \delta_0)$, and (4.7) has no solutions in $(-\delta_0, \delta_0)$. The claim is verified. □

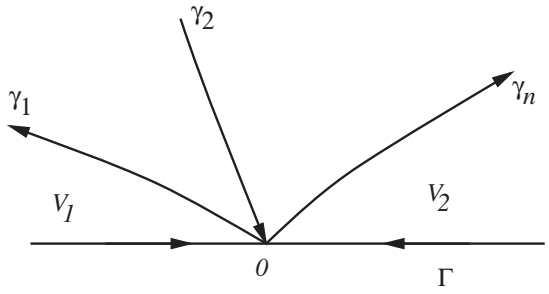

FIG. 4.1. *Case of n interior orbits connected to $\bar{x} = 0 \in \Gamma$, where $\Gamma \subset \partial M$ is flat, and $n \geq 3$ is odd.*

PROPOSITION 4.3. *If* $\operatorname{ind}(v^0, 0) =$ *noninteger, then for any* $\varepsilon > 0$ *sufficiently small each* $u(x, t_0 \pm \varepsilon)$ *has exactly one* ∂*-singular point on* Γ.

Proof. Indeed, when $\operatorname{ind}(v^0, 0) = -n/2$ is a fraction, then n is odd. Hence the exponent k in (4.6) is odd, i.e., $k = 2m + 1$ $(m \geq 1)$. Therefore each of the two equations

$$\alpha x_1^{2m+1} + \varepsilon\beta + \varepsilon g(x_1) + o\left(|\varepsilon|, |x_1|^{2m+1}\right) = 0,$$
$$\alpha x_1^{2m+1} - \varepsilon\beta - \varepsilon g(x_1) + o\left(|\varepsilon|, |x_1|^{2m+1}\right) = 0$$

has exactly one solution in $(-\delta_0, \delta_0)$. □

4.2. Proof of Theorem 3.6. As mentioned earlier, u and v have topologically equivalent streamlines in an interior neighborhood of $x = 0$; hence bifurcation in the local structure of u at $\bar{x} = 0$ is equivalent to that of v. As a result, we only have to consider the local bifurcation for the vector field v. We divide the proof into two steps.

Step 1. *The case where* $\operatorname{ind}(v^0, 0) =$ *integer.* By Theorem 3.5, the number of boundary saddle points of $v^0 + \varepsilon v^1$ in a small neighborhood $\Gamma_0 \subset \Gamma \subset \partial M$ of $\bar{x}$ is not the same as that for $v^0 - \varepsilon v^1$. Therefore, $v^0 + \varepsilon v^1$ and $v^0 - \varepsilon v^1$ are not topologically equivalent locally near $\bar{x} \in \Gamma \subset \partial M$.

Step 2. *The case where* $\operatorname{ind}(v^0, 0) =$ *fraction.* Without loss of generality, we assume that the two orbits connected to $\bar{x} = 0$ on $\Gamma_0 \subset \partial M$ are stable (i.e., $\alpha < 0$ in (4.6)), and $v_1^1(0) > 0$ (i.e., $\beta > 0$ in (4.6)). Let $x^+ = (x_1^+, 0)$ and $x^- = (x_1^-, 0) \in \Gamma_0 \subset \partial M$ be the singular points of $v^0 + \varepsilon v^1$ and $v^0 - \varepsilon v^1$, respectively. Hence, $x_1^- < 0 < x_1^+$ as in Theorem 3.5. The nondegeneracy of both x^- and x^+ implies that

$$\operatorname{ind}(v^0 \pm \varepsilon v^1, x^\pm) = -\frac{1}{2},$$

and there is exactly one orbit $\gamma^+(\varepsilon)$ of $v^0 + \varepsilon v^1$ in $\mathring{M}$ connected to x^+ (respectively, exactly only one orbit $\gamma^-(\varepsilon)$ of $v^0 - \varepsilon v^1$ in $\mathring{M}$ connected to x^-).

By (3.5) and Remark 3.2, there are n ($n \geq 3$ and odd) orbits γ_i $(1 \leq i \leq n)$ of v^0 in $\mathring{M}$ connected to $\bar{x} \in \Gamma$; see Figure 4.1. Let $V_1 \subset \mathring{M}$ (respectively, $V_2 \subset \mathring{M}$) be the domain near $\bar{x} = 0 \in \Gamma_0 \subset \partial M$ enclosed by ∂M and γ_1 (respectively, by ∂M and γ_n).

Since $v_1^1(0) > 0$, the flow of $v^0 + \varepsilon v^1$ crosses γ_n transversally and enters into V_2 (respectively, the flow of $u^0 - \varepsilon u^1$ crosses γ_1 transversally and enters into V_1).

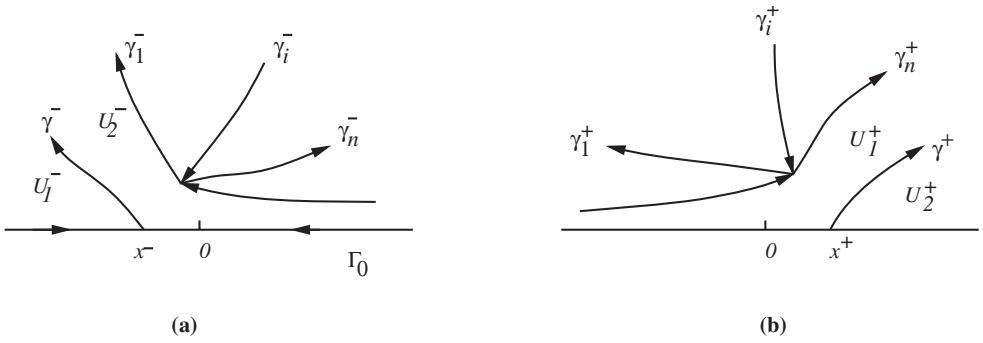

FIG. 4.2. *Sketch illustrating the proof of assertion* (1) *in Theorem* 3.6*:* (a) *orbits at* $t^- < t_0$*, and* (b) *orbits at* $t^+ > t_0$

Therefore, we have

$$\gamma^+(\varepsilon) \subset V_2, \quad \gamma^-(\varepsilon) \subset V_1. \tag{4.9}$$

Obviously,

$$\lim_{\varepsilon\to 0} \gamma^-(\varepsilon) = \gamma_1, \quad \lim_{\varepsilon\to 0} \gamma^+(\varepsilon) = \gamma_n.$$

Moreover, there are n orbits $\gamma_i^+ = \gamma_i^+(\varepsilon)$ of $v^0 + \varepsilon v^1$ in $V - V_1$ (respectively, n orbits $\gamma_i^- = \gamma_i^-(\varepsilon)$ of $v^0 - \varepsilon v^1$ in $V - V_2$), which are connected to singular points of $v^0 + \varepsilon v^1$ (respectively, $v^0 - \varepsilon v^1$) such that

$$\lim_{\varepsilon\to 0} \gamma_i^+(\varepsilon) = \gamma_i, \qquad \lim_{\varepsilon\to 0} \gamma_i^-(\varepsilon) = \gamma_i,$$

where $V \subset \mathring{M}$ is a neighborhood of $\bar{x} = 0$.

Let U_1^- (respectively, U_2^+) be the domain enclosed by ∂M and γ^- (respectively, by ∂M and γ^+), and $U_2^- = V - U_1^-$ (respectively, $U_1^+ = V - U_2^+$); see Figures 4.2(a) and 4.2(b), respectively. We infer from (4.9) that

$$\gamma_i^+ \subset U_1^+, \quad \gamma_i^- \subset U_2^- \quad (1 \le i \le n). \tag{4.10}$$

We know that, under topological equivalence, the orbits of $v^0 + \varepsilon v^1$ connected to a singular boundary point are mapped, preserving orientation, to the orbits of $v^0 - \varepsilon v^1$ connected to a singular boundary point. Since $v^0 + \varepsilon v^1$ and $v^0 - \varepsilon v^1$ are topologically equivalent locally at $\bar{x} \in \Gamma$, the restriction of $v^0 + \varepsilon v^1$ to U_1^+ would have to be topologically equivalent to $v^0 - \varepsilon v^1$ in U_1^-. This is in contradiction with (4.10). Thus, assertion (1) of Theorem 3.6 is proven.

Assertion (2) of Theorem 3.6 is a corollary of assertion (1). Indeed, if $\bar{x} \in \partial M$ is a unique singular point of u^0 which has the same index as $\mathrm{ind}(v^0, 0)$ on ∂M, then the structural bifurcation of $u(x,t)$ locally at $(\bar{x}, t_0)$ implies the structural bifurcation in its global structure.

The proof of Theorem 3.6 is thus complete.

5. Structural bifurcations near a curved boundary.

5.1. Main theorems. We now generalize in this section the main bifurcation theorems in section 3 for the flat boundary case to the curved boundary case.

Consider structural bifurcation near a ∂-singular point $\bar{x} \in \partial M$ of $u(x,t)$ on a general C^{r+1} boundary ∂M ($r \geq 2$). Let $\bar{x} \in \partial M$ and (x_1, x_2) be an orthogonal coordinate system with origin $\bar{x}$, which has its x_1-axis tangent to ∂M at $\bar{x}$, and its x_2-axis oriented in the inward normal direction.

Let $u \in C^1([0,T], B_0^r(TM))$ ($r \geq 2$) have the Taylor expansion at t_0 ($0 < t_0 < T$) as in (3.2). In particular, let

$$u^0 = (u_1^0, u_2^0) = u(x, t_0),$$
$$u^1 = (u_1^1, u_1^2) = \frac{\partial u(x, t_0)}{\partial t}.$$

In addition, let n be the number of interior orbits of $u^0(x)$ connected to $\bar{x}$. Then we can restate Assumption (H) as (H′) below, with condition (3.5) on the index there replaced by a geometrical condition $n \neq 1$, i.e., (5.2) below.

Assumption (H′). Let $\bar{x} \in \partial M$ be an isolated degenerate ∂-singular point of $u^0(x) = u(x, t_0)$, with $u^0 \in C^{k+1}$ near $\bar{x} \in \Gamma$ for some $k \geq 2$. Assume that

$$\frac{\partial u^0(\bar{x})}{\partial n} = 0, \tag{5.1}$$

$$n \neq 1, \tag{5.2}$$

$$\frac{\partial u_1^1(\bar{x})}{\partial n} \neq 0, \tag{5.3}$$

$$\frac{\partial^{k+1} u_1^0(\bar{x})}{\partial^k \tau \partial n} \neq 0. \tag{5.4}$$

We have then the following structural bifurcation theorems, as in section 3.

THEOREM 5.1. *Let $u \in C^1([0,T], B_0^r(TM))$ satisfy Assumption* (H′) *and let $r \geq 2$. Then in a neighborhood $\Gamma \subset \partial M$ of $\bar{x}$, the ∂-singular points of $u(x, t_0 \pm \varepsilon)$ are nondegenerate for any $\varepsilon > 0$ sufficiently small. Moreover,*

1. *if $n =$ even ($n \geq 0$), then one of $u(x, t_0 \pm \varepsilon)$ has two ∂-singular points on Γ, and the other one has no ∂-singular point on Γ; and*
2. *if $n =$ odd ($n \geq 3$), then each of $u(x, t_0 \pm \varepsilon)$ has only one ∂-singular point on Γ.*

THEOREM 5.2 (structural bifurcation theorem). *Let $u \in C^1([0,T], B_0^r(TM))$ be a one-parameter family of divergence-free vector fields satisfying Assumption* (H′) *and $r \geq 2$. Then the following assertions hold true:*

1. *$u(x,t)$ has a bifurcation in its local structure at $(\bar{x}, t_0)$; and*
2. *if $\bar{x} \in \partial M$ is a unique degenerate ∂-singular point of $u^0(x) = u(x, t_0)$ on ∂M, then $u(x,t)$ has a bifurcation in its global structure at t_0.*

5.2. Coordinate transformation. The main ideas that prove Theorems 5.1 and 5.2 are as follows. First, we introduce a local coordinate transformation, which preserves the divergence-free character of the vector field and maps a neighborhood $\Gamma \subset \partial M$ of $\bar{x}$ to a flat boundary. This allows us to show that Assumption (H′) is equivalent to Assumption (H) for the new transformed vector field. Then Theorems 5.1 and 5.2 follow immediately from Theorems 3.5 and 3.6.

In the coordinate system (x_1, x_2) introduced at the beginning of this section, the boundary ∂M can be expressed locally near $\bar{x} = 0 \in \partial M$ by

$$x_2 = f(x_1), \quad f(0) = 0, \quad f'(0) = 0. \tag{5.5}$$

We make the local coordinate transformation

$$\begin{cases} \tilde{x}_1 = x_1, \\ \tilde{x}_2 = x_2 - f(x_1). \end{cases} \tag{5.6}$$

Obviously, the transformation (5.6) takes a neighborhood $U \subset M$ of $\bar{x}$ to a domain $\tilde{U} \subset \mathbb{R}^2_+ = \{(\tilde{x}_1, \tilde{x}_2) \in \mathbb{R}^2 \mid \tilde{x}_2 \geq 0\}$ and maps the boundary part $U \cap \partial M$ to a neighborhood of $x = 0$ on the $\tilde{x}_1$-axis.

Let $\varphi : U \to \tilde{U}$ be the transformation (5.6), and $\varphi^* : C^r(TU) \to C^r(T\tilde{U})$ the isomorphism induced by φ. It is easy to see that

$$\varphi^* = D\varphi = \begin{pmatrix} 1 & 0 \\ -f'(\tilde{x}_1) & 1 \end{pmatrix},$$

and, for any $u \in C^r(TU)$,

$$\tilde{u} = \varphi^* \circ u = \begin{pmatrix} u_1 \\ u_2 - f'(\tilde{x}_1)u_1 \end{pmatrix}. \tag{5.7}$$

Then it is a direct calculation to derive the following lemma.

LEMMA 5.3. *If $u \in C^r(TU)$ is divergence-free, then $\tilde{u} = \varphi^* \circ u$ is also divergence-free. Moreover, as $u|_{\partial M \cap U} = 0$, then $\tilde{u}(\tilde{x}_1, 0) = 0$, and*

$$\begin{cases} \tilde{u}(\tilde{x}) = \tilde{x}_2 \tilde{v}(\tilde{x}), \\ \tilde{v}_2(\tilde{x}_1, 0) = 0. \end{cases} \tag{5.8}$$

5.3. Proof of Theorems 5.1 and 5.2. According to Theorems 3.5 and 3.6, the proof of these two theorems will be achieved in a few lemmas, as follows.

LEMMA 5.4. *Let $u \in C^1([0,T], B_0^r(TM))$ satisfy Assumption* (H′). *Then the vector field $\tilde{u} = \varphi^* \circ u = \tilde{x}_2 \tilde{v}(\tilde{x}, t)$ satisfies Assumption* (H).

Proof. Notice that φ maps $\bar{x} = 0$ to $\tilde{x} = 0$. Since u and $\tilde{u}$ are topologically equivalent locally near $x = 0$ and $\tilde{x} = 0$, (5.2) implies that the number n of interior orbits connected to $\tilde{x} = 0$ of $\tilde{v}(x, t_0)$ is different from 1. Hence

$$\operatorname{ind}(\tilde{v}(x, t_0), 0) = -\frac{n}{2} \neq -\frac{1}{2}.$$

By (5.7), $\tilde{u}_1 = u_1$, and φ^* takes the inward normal vector n at $x = 0$ to the normal vector $\tilde{n} = (0, 1)$ at $\tilde{x} = 0$. Therefore, we have

$$\frac{\partial u_1^1(0)}{\partial n} \neq 0 \Longrightarrow \frac{\partial \tilde{u}_1^1(0)}{\partial x_2} \neq 0,$$

where $u_1^1(x) = \partial u(x, t_0)/\partial t$.

By tensor analysis, we know that, under a coordinate transformation $\varphi : U \to \tilde{U}$, the directional derivative of a function $f(x)$ satisfies $\partial f/\partial r = \partial f/\partial \tilde{r}$, where r is a vector and $\tilde{r} = (D\varphi)r$.

By (5.7) we see that $u_1^0 = \tilde{u}_1^0$, and $\tilde{n} = (0,1)$ at $\tilde{x} = 0$. Hence we have

$$\frac{\partial^k}{\partial \tau^k}\frac{\partial u_1^0(0)}{\partial n} = \frac{\partial^k}{\partial \tilde{\tau}^k}\cdot\frac{\partial \tilde{u}_1^0(0)}{\partial \tilde{n}} = \frac{\partial^k}{\partial x_1^k}\frac{\partial \tilde{u}_1^0(0)}{\partial x_2},$$

and the proof of the lemma is complete. ∎

LEMMA 5.5. *A point $x \in \partial M \cap U$ is a ∂-regular point of $u \in B_0^r(TM)$ if and only if $\tilde{x} = \varphi(x) = (\tilde{x}_1, 0)$ is a ∂-regular point of $\tilde{u} = D\varphi \cdot u$.*

Proof. By Definition 2.5, it suffices to show that the two vector fields $\partial u/\partial n$ and $\partial \tilde{u}/\partial \tilde{x}_2$ have the same singular points on the boundary in the sense of homeomorphism; here

$$\frac{\partial u}{\partial n} = (N\cdot\nabla)u = n_1\frac{\partial u}{\partial x_1} + n_2\frac{\partial n}{\partial x_2}$$

and the vector field N is defined in U with the unit modulus $|N| = 1$ such that the orbits of N are the normal lines λn in U. Note that, when U is properly chosen, for any $x, y \in U \cap \partial M$, $x \neq y$, the normal lines λn_x and λn_y do not intersect within U.

Equivalently, we proceed to check the desired result for the two vector fields $\partial \tilde{u}/\partial \tilde{n}$ and $\partial \tilde{u}/\partial \tilde{x}_2$, where $\partial \tilde{u}/\partial \tilde{n}$ is the transformation of $\partial u/\partial n$ that is expressed by

$$\begin{cases} \dfrac{\partial \tilde{u}}{\partial \tilde{n}} = \left(\tilde{N}\cdot\tilde{\nabla}\right)\tilde{u} = \tilde{n}_1\dfrac{\partial \tilde{u}}{\partial \tilde{x}_1} + \tilde{n}_2\dfrac{\partial \tilde{u}}{\partial \tilde{x}_2}, \\ \tilde{N} = \begin{pmatrix}\tilde{n}_1\\ \tilde{n}_2\end{pmatrix} = D\varphi \circ N = \begin{pmatrix}1 & 0\\ -f' & 1\end{pmatrix}\begin{pmatrix}n_1\\ n_2\end{pmatrix} = \begin{pmatrix}n_1\\ n_2 - f'n_1\end{pmatrix}. \end{cases} \tag{5.9}$$

From (5.8) we see that

$$\tilde{u}(\tilde{x}_1, 0) = 0 \quad \forall\ \tilde{x}_1 \in \partial\mathbb{R}^2_+ \cap \tilde{U}. \tag{5.10}$$

By (5.9) and (5.10) we deduce that

$$\frac{\partial \tilde{u}}{\partial \tilde{n}} = (n_2 - f'(x_1)n_1)\frac{\partial \tilde{u}}{\partial \tilde{x}_2} \quad \text{on } \partial\mathbb{R}^2_+ \cap \tilde{U}. \tag{5.11}$$

From (5.5) and $n_2 \neq 0$ for $x \in \partial M$ near $\bar{x}$, the result follows and the proof of the lemma is complete. ∎

LEMMA 5.6. *A point $x \in \partial M \cap U$ is a ∂-saddle point of $u \in B_0^r(TM)$ if and only if $\tilde{x} = \varphi(x) \in \partial\mathbb{R}^2_+ \cap \tilde{U}$ is a ∂-saddle point of $\tilde{u} = D\varphi \cdot u$.*

Proof. It suffices to prove that $\partial \tilde{u}/\partial \tilde{n}$ and $\partial \tilde{u}/\partial \tilde{x}_2$ have the same nondegenerate singular points on the boundary $\Gamma = \partial\mathbb{R}^2_+ \cap \tilde{U} = \{(\tilde{x}_1, 0) \mid |\tilde{x}_1| < \delta\}$, i.e., both Jacobian determinants

$$\det\begin{pmatrix} \dfrac{\partial^2 \tilde{u}_1}{\partial \tilde{x}_1 \partial \tilde{n}} & \dfrac{\partial^2 \tilde{u}_1}{\partial \tilde{x}_2 \partial \tilde{n}} \\ \dfrac{\partial^2 \tilde{u}_2}{\partial \tilde{x}_1 \partial \tilde{n}} & \dfrac{\partial^2 \tilde{u}_2}{\partial \tilde{x}_2 \partial \tilde{n}} \end{pmatrix} \quad \text{and} \quad \det\begin{pmatrix} \dfrac{\partial^2 \tilde{u}_1}{\partial \tilde{x}_1 \partial \tilde{x}_2} & \dfrac{\partial^2 \tilde{u}_1}{\partial \tilde{x}_2^2} \\ \dfrac{\partial^2 \tilde{u}_2}{\partial \tilde{x}_1 \partial \tilde{x}_2} & \dfrac{\partial^2 \tilde{u}_2}{\partial \tilde{x}_2^2} \end{pmatrix}$$

have the same nonzero points on Γ.

From (5.8) we see that

$$\frac{\partial \tilde{u}_2(\tilde{x}_1,0)}{\partial x_2} = 0 \quad \forall\ |x_1| < \delta \tag{5.12}$$

for some $\delta > 0$. By (5.11) and (5.12) one deduces that

$$\frac{\partial^2 \tilde{u}_2(\tilde{x}_1,0)}{\partial \tilde{x}_1 \partial \tilde{n}} = 0, \quad \frac{\partial^2 \tilde{u}_2(\tilde{x}_1,0)}{\partial \tilde{x}_1 \partial \tilde{x}_2} = 0.$$

Hence we only need to prove that

$$\frac{\partial^2 \tilde{u}_1(\tilde{x}_1,0)}{\partial \tilde{x}_1 \partial \tilde{n}} \neq 0 \Longleftrightarrow \frac{\partial^2 \tilde{u}_1(\tilde{x}_1,0)}{\partial \tilde{x}_1 \partial \tilde{x}_2} \neq 0, \tag{5.13}$$

$$\frac{\partial^2 \tilde{u}_2(\tilde{x}_1,0)}{\partial \tilde{x}_2 \partial \tilde{n}} \neq 0 \Longleftrightarrow \frac{\partial^2 \tilde{u}_2(\tilde{x}_1,0)}{\partial \tilde{x}_2^2} \neq 0. \tag{5.14}$$

From (5.11) and (5.12) we immediately derive (5.14).

Thanks to (5.8), for any integer $k \geq 0$,

$$\frac{\partial^k \tilde{u}_1(\tilde{x}_1,0)}{\partial \tilde{x}_1 k} = 0. \tag{5.15}$$

By assumption, $(\tilde{x}_1, 0)$ is a singular point of $\partial\tilde{u}/\partial x_2$, i.e., a ∂-saddle point of $\tilde{u}$:

$$\frac{\partial \tilde{u}_1(\tilde{x}_1,0)}{\partial x_2} = 0. \tag{5.16}$$

From (5.15) and (5.16) it follows that

$$\begin{aligned}\frac{\partial^2 \tilde{u}_1(\tilde{x}_1,0)}{\partial \tilde{x}_1 \partial \tilde{n}} &= \frac{\partial}{\partial \tilde{x}_1}\left[\tilde{n}_1 \frac{\partial \tilde{u}_1}{\partial \tilde{x}_1} + \tilde{n}_2 \frac{\partial \tilde{u}_1}{\partial \tilde{x}_2}\right]\Bigg|_{\tilde{x}=(\tilde{x}_1,0)} \\ &= \tilde{n}_2 \frac{\partial \tilde{u}_1(\tilde{x}_1,0)}{\partial \tilde{x}_1 \partial \tilde{x}_2}\ .\end{aligned}$$

By (5.9), $\tilde{n}_2 = n_2 - f'(x_1)n_1 \neq 0$ for $x = (x_1, x_2) \in \partial M$ near $\bar{x} = 0$. Thus we derive (5.13), and the proof is complete. □

6. Applications to boundary-layer separation.

6.1. Two examples. In order to understand intuitively the connection between structural bifurcation and boundary-layer separation, we proceed by discussing two typical examples that illustrate how structural bifurcations occur in some fluid flows. For simplicity, we consider in this section only bifurcation near flat boundaries.

Let $u \in C^1([0,T], B_0^r(TM))$, $\bar{x} \in \Gamma \subset \partial M$ be an isolated ∂-singular point of $u^0(x) = u(x, t_0)$, $0 < t_0 < T$, where Γ is a flat part of ∂M. We take a coordinate system (x_1, x_2) with $\bar{x}$ at the origin and $\Gamma = \{x_1, 0) \,\big|\, |x_1| < \delta\}$. Thus $u(x,t)$ can be expressed in a neighborhood $U \subset M$ of $\bar{x}$ by

$$u(x,t) = x_2 v(x,t), \tag{6.1}$$

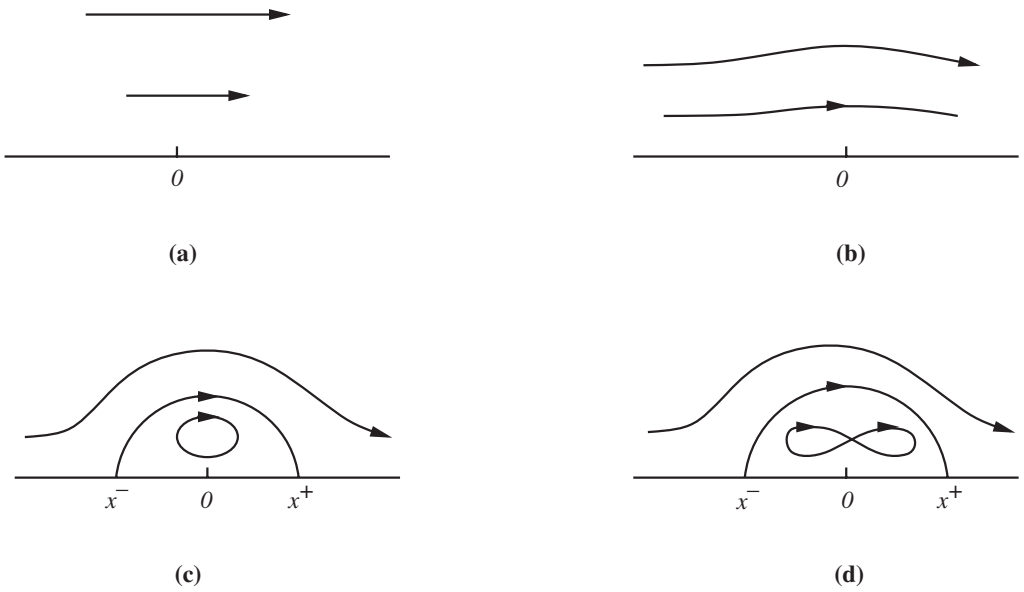

FIG. 6.1. *Boundary-layer separation and reattachment near a flat boundary.*

as in section 3. Let

$$v^0(x) = v(x, t_0) = (v_1^0(x), v_2^0(x)),$$
$$v^1(x) = \frac{\partial}{\partial t} v(x, t_0) = (v_1^1(x), v_2^1(x)).$$

Example 6.1. When the index of the vector field $v^0(x)$ at the singular point $\bar{x} = 0$ is zero, i.e., $\mathrm{ind}(v^0, 0) = 0$, structural bifurcation occurs, as shown in Figure 6.1. The figure corresponds to boundary-layer separation of an incompressible, initially parallel flow over a flat plate.

Figure 6.1(a) shows the flows structure of $u(x, t_0 - \varepsilon)$, a typical shear flow near the boundary. At the time instant $t_0 - \varepsilon$, with $\varepsilon > 0$ small, the flow exhibits no singular points near $\bar{x} = 0$. At the time instant t_0, the time at which structural bifurcation occurs, $u^0(x) = u(x, t_0)$ is given by Figure 6.1(b), which has an isolated ∂-singular point $\bar{x} = 0 \in \partial M$. At a later time, $u(x, t_0 + \varepsilon)$ is given by either Figure 6.1(c) or Figure 6.1(d). Even more complicated flow patterns are possible in the recirculation region, but in a real fluid the figure-eight streamline in Figure 6.1(d) will be affected by the viscosity and evolve into two separate, counterrotating vortices. On the boundary, there are exactly two ∂-saddle points on ∂M near $\bar{x} = 0$, denoted by x^- and x^+ in Figures 6.1(c) and 6.1(d). We shall prove hereafter that the pattern shown in Figure 6.1(c) is generic.

Example 6.2. When $\mathrm{ind}(v^0, 0) = -1$, global structural bifurcation of u may occur, due to a local transition near $\bar{x} \in \partial M$. An example of such a global bifurcation of an incompressible flow field is shown in Figure 6.2. The transition from Figure 6.2(a) through Figure 6.2(b) to Figure 6.2(c) is more idealized than in Figure 6.1 but is entirely consistent with our rigorous results, as well as physically plausible.

6.2. Boundary-layer separation. We now address the separation of streamlines and their reattachment in a 2-D divergence-free vector field, from the point of

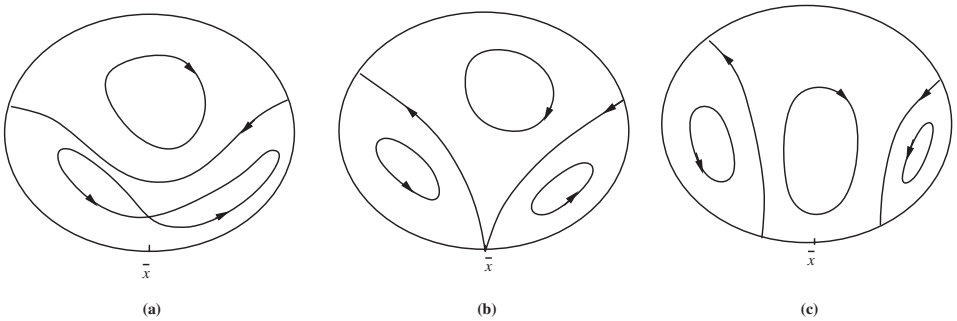

FIG. 6.2. *Global structural bifurcation of a 2-D incompressible flow in a compact domain.*

view of the rigorous results in sections 3 and 5. The connection to actual boundary-layer separation in an incompressible fluid governed by the Navier–Stokes equations is made in the companion papers [7, 12].

We start with Assumption (H) in the case where ind $(v^0, 0) = 0$, i.e., there are no interior orbits of u^0 connected to $\bar{x} = 0$. For convenience, we call it Assumption (H_0), and it reads as follows.

Assumption (H_0). Let $\bar{x} = 0 \in \Gamma$ be an isolated degenerate ∂-singular point of $u^0(x)$, $u^0 \in C^{k+1}$ near $\bar{x} \in \Gamma$ for some $k \geq 2$. Assume that

$$\frac{\partial u^0(0)}{\partial n} = 0, \tag{6.2}$$

$$\mathrm{ind}(v^0, 0) = 0, \tag{6.3}$$

$$\frac{\partial u^1(0)}{\partial n} \neq 0, \tag{6.4}$$

$$\frac{\partial^{k+1} u_1^0(0)}{\partial^k \tau \partial n} \neq 0. \tag{6.5}$$

THEOREM 6.3. *Let $u \in C^1([0,T], B_0^r(TM))$ be as given in* (6.1) *satisfying Assumption* (H_0). *Then the following conclusions hold:*

1. *There must be some closed orbits of u separated from $\bar{x} = 0 \in \partial M$, as shown schematically in either Figure* 6.1(c) *or Figure* 6.1(d).
2. *The flow structure after the separation enjoys the following properties:*
   (a) *there are exactly two ∂-saddle points x^- and x^+ of $u(\cdot, t)$ near $\bar{x} = 0$ with one on each side of $\bar{x}$, $x^- < \bar{x} < x^+$;*
   (b) *x^- and x^+ are connected by an extended interior orbit $\gamma(t)$ that consists of orbits of $u(\cdot, t)$; and*
   (c) *the closed orbits of conclusion* (1) *above are enclosed by the extended orbit $\gamma(t)$ and the portion of the boundary between x^- and x^+.*
3. *The whole extended orbit $\gamma(t)$ shrinks to $\bar{x}$ as $t \to t_0$.*

A few remarks are now in order.

Remark 6.4. The closed orbits in Figures 6.1(c), 6.1(d), and 6.2(a)–(c) correspond, in a real fluid, to isolated vortices or, in the case of figure-eight ones, to pairs of counterrotating vortices.

Remark 6.5. The separation occurs as t crosses the critical instant t_0 from either left to right or from right to left; this is dictated by the orientation of u^1 in comparison to that of u^0 in the expansion (3.2).

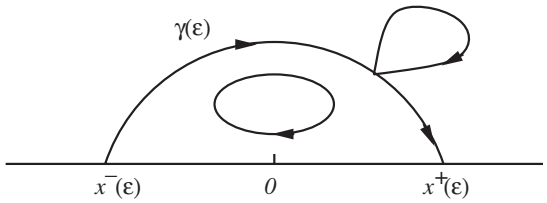

FIG. 6.3. *Convergence of an extended orbit* $\gamma(\varepsilon) \to \bar{x} = 0$.

Remark 6.6. The reattachment of a streamline $\gamma(t)$ to the boundary, as described in conclusion 2(b) above, differs from a particle's streakline (i.e., from its path in real time): as the vortex grows in time, particles are either trapped inside the vortex or pushed into the interior of the fluid, away from the vortex.

Proof of Theorem 6.3. By Theorem 3.5, without loss of generality, we assume that $u(x, t_0 + \varepsilon)$ has two ∂-saddle points $x^-(\varepsilon)$ and $x^+(\varepsilon)$, and $u(x, t_0 - \varepsilon)$ has none. Then both ∂-saddle points $x^-(\varepsilon)$ and $x^+(\varepsilon)$ of $u(x, t_0 + \varepsilon)$ tend to $x = 0$ as $\varepsilon \to 0$.

By assumption, the singular point $\bar{x} \in \partial M$ of $v^0(x)$ is isolated; therefore the stability lemma of extended orbits (Lemma 7.2) in the appendix ensures that both ∂-saddle points $x^-(\varepsilon)$ and $x^+(\varepsilon)$ must be connected by an extended orbit $\gamma(\varepsilon)$ with $\gamma(\varepsilon) \to \bar{x}$ as $\varepsilon \to 0$; see Figure 6.3. Because the sum of the indices of the singular points near $\bar{x} \in \partial M$ of $u(x, t_0 \pm \varepsilon)$ is zero, there exist centers of $v(x, t_0 + \varepsilon)$ near $\gamma(\varepsilon)$, which converge to $\bar{x} \in \partial M$ as $\varepsilon \to 0$. The other assertions are even easier to verify.

In the above theorem, there might be several centers that appear in the recirculation region. However, subject to an additional but generic assumption, the following theorem shows that there must be exactly one center that separates from the boundary near $\bar{x}$.

THEOREM 6.7. *Let* $u \in C^1([0, T], B_0^r(TM))$ *be as given in* (6.1)*; satisfy Assumption* (H_0) *with* $k = 2$*, and*

$$\frac{\partial^2 u_1^0(0)}{\partial x_2^2} \neq 0. \tag{6.6}$$

Then the center separated from $\bar{x} \in \partial M$ *is unique, as shown in Figure* 6.1(c).

Remark 6.8. Consider the Taylor expansion of the vorticity $\omega = -\partial u_2/\partial x_1 + \partial u_1/\partial x_2$ of the vector field u:

$$\begin{cases} \omega(x,t) = \omega^0(x) + \omega^1(x)(t - t_0) + o((t - t_0)^2), \\ \omega^0(x) = \omega(x, t_0), \qquad \omega^1(x) = \dfrac{\partial \omega}{\partial t}(x, t_0). \end{cases} \tag{6.7}$$

Conditions (6.2)–(6.4), and (6.6) are equivalent, respectively, to

$$\omega^0(0) = 0, \tag{6.8}$$

$$\frac{\partial^2 \omega^0(0)}{\partial x_1^2} \neq 0, \tag{6.9}$$

$$\omega^1(0) \neq 0, \tag{6.10}$$

$$\frac{\partial \omega^0(0)}{\partial n} \neq 0. \tag{6.11}$$

Proof of Theorem 6.7. First we observe that conditions (6.2), (6.4), and (6.5) are equivalent to the following conditions on v:

$$\frac{\partial^2 v_1^0(0)}{\partial x_1^2} \neq 0, \tag{6.12}$$

$$\frac{\partial v_1^0(0)}{\partial x_2} \neq 0, \tag{6.13}$$

$$v_1^1(0) \neq 0. \tag{6.14}$$

We only have to prove that the interior singular point of $v(x, t_0+\varepsilon)$ near $\bar{x} \in \partial M$ is unique. By the Taylor expansion, we have

$$\begin{cases} v_1(x, t_0+\varepsilon) = v_1^0(x) + \varepsilon v_1^1(x) + o(|\varepsilon|), \\ v_2(x, t_0, \varepsilon) = v_2^0(x) + \varepsilon v_2^1(x) + o(|\varepsilon|). \end{cases}$$

By the nondivergence of $u^0(x)$ and by (6.12) and (6.13), we derive

$$\begin{cases} v_1^0(x) = \lambda x_2 + \alpha x_1^2 + o(|x_1|^2, |x_2|), \quad \alpha \neq 0,\ \lambda \neq 0, \\ v_2^0(x) = -\alpha x_1 x_2 + x_2 \cdot o(|x|). \end{cases}$$

By (6.14) we have

$$\begin{cases} v_1^1(x) = \beta + O(|x|), \quad \beta < 0, \\ v_2^1(x) = x_2 \cdot O(|x|). \end{cases}$$

Hence the interior singular points $(\tilde{x}_1, \tilde{x}_2)$ of $v(x, t_0+\varepsilon)$ with $\tilde{x}_2 > 0$ satisfy the equations

$$\begin{cases} \alpha x_1^2 + \lambda x_2 + \varepsilon\beta + o(|\varepsilon|, |x_2|, |x_1|^2) = 0, \\ -\alpha x_1 + \varepsilon \cdot O(|x|) + o(|x|) = 0, \\ \alpha \neq 0,\ \lambda \neq 0,\ \beta < 0. \end{cases} \tag{6.15}$$

It follows from the implicit function theorem that a solution $(\tilde{x}_1, \tilde{x}_2)$ with $\tilde{x}_2 > 0$, if it exists, is unique for any $\varepsilon > 0$ sufficiently small. The existence of such a solution to (6.15) is derived by Theorem 6.3, and the proof is complete. □

Remark 6.9. The set of all vector fields u satisfying (6.12) and (6.13) is open and dense in the topological space

$$A = \left\{ u \in C^1([0,T], B_0^3(TM)) \,\middle|\, u \text{ satisfy Assumption } (\mathrm{H}_0) \right\}.$$

Hence, Theorem 6.3 shows that the separation from the boundary of a simple vortex is generic.

7. Appendix. Extended orbits and their stability. The purpose of this appendix is to recall a lemma on stability of extended orbits [11]. We start with a definition.

DEFINITION 7.1. *Let $v \in C^r(TM)$ be a vector field. A curve $\gamma \subset M$ is called an extended orbit of v if*

(i) *it is a union of curves*

$$\gamma = \bigcup_{i=1} \gamma_i;$$

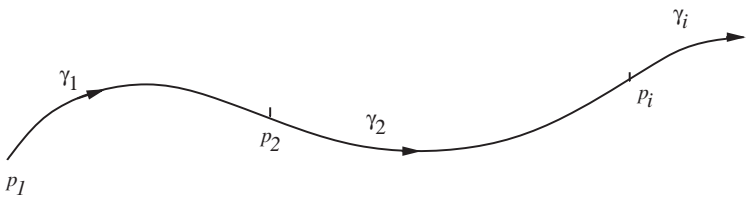

FIG. 7.1. *An extended orbit.*

(ii) *either γ_i is an orbit of v, or γ_i consists of both orbits and singular points of v; and*

(iii) *the ω-limit set of γ_i is the α-limit set of γ_{i+1},*

$$\omega(\gamma_i) = \alpha(\gamma_{i+1}),$$

whenever γ_i and γ_{i+1} are orbits of v; namely, the end points of γ_i are singular points of v, and the starting end point of γ_{i+1} is the finishing end point of γ_i; see Figure 7.1.

The point $p_1 = \alpha(\gamma_1)$ is called the starting point of the extended orbit γ.

The following stability lemma for extended orbits has been proved by Ma and Wang [11] in Step 2 of their proof of Lemma 4.5. We restate it here as a separate lemma since it is quite useful in analyzing the orbits of families of vector fields, and thus in solving some problems in 2-D incompressible fluid flows.

LEMMA 7.2 (stability of extended orbits [11]). *Let $v^n \in C^r(TM)$ be a sequence of 2-D vector fields with $\lim_{n\to\infty} v^n = v \in C^r(TM)$. Suppose that $\gamma^n \subset M$ is an extended orbit of v^n and the starting points p_1^n of γ^n converge to p_1. Then the extended orbits γ^n of v^n converge to an extended orbit γ of v with starting point p_1.*

AN AGE-STRUCTURED EPIDEMIC MODEL IN A PATCHY ENVIRONMENT*

WENDI WANG† AND XIAO-QIANG ZHAO‡

Abstract. A time-delayed epidemic model is proposed to describe the dynamics of disease spread among patches. An age structure is incorporated in order to simulate the phenomenon that some diseases only occur in the adult population. Sufficient conditions are established for global extinction and uniform persistence of the disease. One example shows that the disease could undergo persistence-extinction-persistence switches as the migration rate of juveniles increases, although juveniles are immune and cannot transmit the disease. The second example indicates that this switching phenomenon also happens when juveniles migrate with susceptible adults.

Key words. epidemic model, population dispersal, stage structure, persistence and extinction of disease

1. Introduction.

Population dispersal plays an important role in the dynamics of epidemic diseases. There has been much evidence that diseases spread from one region to other regions due to the immigration of infective individuals. For example, the arrival of new infectives has been demonstrated as being important in the outbreaks of measles observed in Iceland (see [5]); in the 19th century, cholera spread from its ancestral site in the Orient to other parts of the world, producing a pandemic in Europe; in the 14th century, Bubonic plague was transmitted to Europe and killed perhaps one third to one half of Europe's population, which was probably caused by trading ships moving from the East to Europe. Hence, it is important to use mathematical models to understand the effect of population dispersal on the spread of a disease.

Brauer and van den Driessche [4] proposed an epidemic model with population dispersal by adding an immigration term, where infective individuals enter the system at a constant rate. A constant immigration term has a stabilizing effect on the dynamics and tends to increase the minimum number of infective individuals in the models (see [3]).

In [19] we proposed an epidemic model for many patches where immigration rates and emigration rates of infective individuals depend on their numbers, and showed that population dispersal has a significant effect on a disease outbreak. Other researchers [1, 2] have studied multicity epidemic models and their basic reproduction numbers. For the models in [19, 1, 2], it is assumed that all the individuals in one patch have the same ability to transmit a disease and the same risk of being infected by a disease. For some diseases, such as sexual diseases, it is reasonable to consider

the disease transmission in adult population and neglect transmission in juveniles. In order to incorporate these points into epidemic models with population dispersal, we may divide a population into two stages: juvenile stage and adult stage (see, e.g., [6]). For simplicity, we assume that

(A1) disease transmission occurs only in adult individuals, and juvenile individuals are immune to the disease;

(A2) juvenile individuals do not have the ability to reproduce, and adults are responsible for the reproduction of the population.

In the case of population dispersal among n patches, which may simulate n cities or n countries, let J_i be the number of juvenile individuals in patch i and A_i be the number of adult individuals in patch i. When the patches are isolated, we assume that J_i satisfies the following equation:

$$\frac{dJ_i}{dt} = B_i(A_i)A_i - \mu_i J_i, \tag{1.1}$$

where $B_i(A_i)$ is the per capita birth rate of adult individuals in patch i and μ_i is the per capita death rate of juveniles in patch i. Following [6, 22], we assume that $B_i(A_i)$ satisfy the following basic assumptions:

(A3) $B_i(A_i) > 0$ for all $A_i > 0, i = 1, 2, \ldots, n$;

(A4) $B_i(A_i)$ is continuously differentiable for $A_i > 0$, and $B_i'(A_i) < 0$ for all $A_i > 0$, $i = 1, 2, \ldots, n$.

As mentioned in [6], the following three types of birth functions $B_i(A_i)$ can be found in the biological literature:

(B1) $B_i(A_i) = b_i e^{-a_i A_i}$ with $a_i > 0, b_i > 0$;

(B2) $B_i(A_i) = \frac{p_i}{q_i + A_i^m}$ with $p_i, q_i, m > 0$;

(B3) $B_i(A_i) = \frac{k_i}{A_i} + l_i$ with $k_i > 0, l_i > 0$.

We consider a disease transmission of SIS type. The adult population is divided into two classes: susceptible individuals and infective individuals. Susceptible individuals become infective after contact with infective individuals. Infective individuals return to the susceptible class when they are recovered. Gonorrhea and other sexually transmitted diseases or bacterial infections exhibit this phenomenon. We denote the number of susceptible individuals in patch i by S_i and the number of infective individuals in patch i by I_i. Therefore, $A_i = S_i + I_i$. When the patches are isolated, we assume that S_i and I_i obey the following system:

$$\begin{cases} \dfrac{dS_i}{dt} = R_i(t) - d_i S_i - \beta_i S_i I_i + \gamma_i I_i, \\ \dfrac{dI_i}{dt} = \beta_i S_i I_i - (d_i + \gamma_i) I_i, \end{cases} \tag{1.2}$$

where $R_i(t)$ is the transition rate of juvenile individuals from juvenile stage to adult stage in patch i, d_i is the death rate of adults in patch i, β_i is the contact rate of susceptible individuals with infectious individuals in patch i, and γ_i is the recovery rate of infectives in patch i.

When the patches are connected, we suppose that the immigration rate of susceptible individuals from the jth patch to the ith patch is a_{ij}, the immigration rate of infective individuals from the jth patch to the ith patch is b_{ij}, $-a_{ii} > 0$ is the emigration rate of susceptible individuals in the ith patch, $-b_{ii} > 0$ is the emigration rate of infective individuals in the ith patch, c_{ij} is the immigration rate of juvenile individuals from the jth patch to the ith patch, and $-c_{ii} > 0$ is the emigration rate

of juvenile individuals in the ith patch. Under the above assumptions, we have the following model:

$$\begin{cases} \dfrac{dJ_i}{dt} = B_i(A_i(t))A_i(t) - \mu_i J_i(t) - R_i(t) + \sum\limits_{j=1}^{n} c_{ij}J_j(t), \\ \dfrac{dS_i}{dt} = R_i(t) - d_i S_i - \beta_i S_i I_i + \gamma_i I_i + \sum\limits_{j=1}^{n} a_{ij}S_j, \\ \dfrac{dI_i}{dt} = \beta_i S_i I_i - (d_i + \gamma_i)I_i + \sum\limits_{j=1}^{n} b_{ij}I_j, \\ \quad i = 1, \ldots, n. \end{cases} \tag{1.3}$$

Here we have neglected the death rates and birth rates of individuals during the dispersal process. Thus, we have

$$\sum_{j=1}^{n} a_{ji} = 0, \quad \sum_{j=1}^{n} b_{ji} = 0, \quad \sum_{j=1}^{n} c_{ji} = 0, \quad i = 1, \ldots, n. \tag{1.4}$$

We further assume that all of a_{ij} and b_{ij}, $i \neq j$, are positive so that the $n \times n$ matrix (a_{ij}) and (b_{ij}) are irreducible. Note that system (1.3) indicates that the population can have different demographic structures and different infection forces among different patches.

We now derive a formula for $R_i(t)$ in terms of the parameters and the variables in the model. For simplicity, we define r as the age at which a juvenile in each patch becomes an adult host. Let $J(t,a) := (J_1(t,a), \ldots, J_n(t,a))^T$, where $J_i(t,a)$ is the number of juveniles in patch i at time t with age a. Clearly, $R(t) := (R_1(t), \ldots, R_n(t))^T = J(t,r)$. As in [13, 16], the age-space dynamics of the population is described by

$$\begin{aligned} (\partial_t + \partial_a)J_i(t,a) &= \sum_{j=1}^{n} c_{ij}J_j(t,a) - \left(\sum_{j=1}^{n} c_{ji} + \mu_i\right) J_i(t,a) \\ &= \sum_{j=1}^{n} c_{ij}J_j(t,a) - \mu_i J_i(t,a), \end{aligned} \tag{1.5}$$

with the birth law given by

$$J(t,0) = B(A(t)) := (B_1(A_1(t))A_1(t), \ldots, B_n(A_n(t))A_n(t))^T.$$

Define $V(t,a) := J(t,t-a)$ for all $t \geq a \geq 0$. Then $V(t,a)$ satisfies

$$\frac{\partial V(t,a)}{\partial t} = C_J V(t,a), \quad t \geq a, \tag{1.6}$$

where

$$C_J := \begin{bmatrix} -\mu_1 + c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & -\mu_2 + c_{22} & \cdots & c_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ c_{n1} & c_{n2} & \cdots & -\mu_n + c_{nn} \end{bmatrix}.$$

Integrating (1.6) from a to t, we have

$$V(t,a) = \exp(C_J(t-a))V(a,a) = \exp(C_J(t-a))B(A(a)) \quad \forall t \geq a,$$

and hence

$$J(t,s) = V(t,t-s) = \exp(C_J s)B(A(t-s)) \quad \forall t \geq s \geq 0.$$

It then follows that

$$R(t) = J(t,r) = \exp(C_J r)B(A(t-r)). \tag{1.7}$$

By arguments similar to those in [18], we can interpret the (i,j)-element of $\exp(C_J r)$ as the probability that a juvenile individual born in the jth patch will be found at age r in the ith patch.

Motivated by three types of birth functions (see (B1), (B2), and (B3)), we always assume that birth rate $G_i(A_i) := B_i(A_i)A_i$ satisfies $G_i \in C^1([0,\infty), R)$ for each i. Clearly, $G_i(A_i) \geq 0$ for all $A_i \geq 0$. Define $G(A) := (G_1(A_1), \ldots, G_n(A_n))$ for all $A = (A_1, \ldots, A_n) \in R^n_+$.

Note that $R(t)$ does not depend on the variables of juveniles. The S_i and I_i equations can be decoupled from the J_i equations in (1.3) to obtain the following reduced model:

$$\begin{cases} \dfrac{dS_i}{dt} = R_i(t) - d_i S_i - \beta_i S_i I_i + \gamma_i I_i + \displaystyle\sum_{j=1}^{n} a_{ij} S_j, \\ \dfrac{dI_i}{dt} = \beta_i S_i I_i - (d_i + \gamma_i) I_i + \displaystyle\sum_{j=1}^{n} b_{ij} I_j, \\ (R_1(t), \ldots, R_n(t))^T = \exp(C_J r) G(A(t-r)), \\ S(\theta) = \phi(\theta), I(\theta) = \psi(\theta), \ \forall\, \theta \in [-r, 0], \ (\phi, \psi) \in C^2_+, \ i = 1, \ldots, n, \end{cases} \tag{1.8}$$

where $C_+ := C([-r,0], R^n_+)$.

By [12, Theorem 5.2.1], it follows that for any $(\phi, \psi) \in C^2_+$ there is a unique solution $(S(t,\phi,\psi), I(t,\phi,\psi))$ of (1.8), and $S(t,\phi,\psi) \geq 0$, $I(t,\phi,\psi)) \geq 0$ for all $t \geq 0$ in its maximal interval of existence. The purpose of this paper is to study the long-term behavior of the model system (1.8) and the effects of population dispersal on the spread of the disease.

The remaining parts of this paper are organized as follows. Section 2 presents the discussion of the disease free equilibrium and reproduction number for model (1.8). In section 3, we establish sufficient conditions for the global extinction and persistence, respectively, of the disease. Section 4 contains the application of the general results to a special case of the model with two patches. A discussion section completes the paper.

2. Disease free equilibrium. In this section, we establish sufficient conditions for the existence and uniqueness of a disease free equilibrium so that we can define the reproduction number for the model (1.8). We start with the introduction of cooperative systems of delay differential equations.

For $x, y \in R^n$, we write $x \geq y$ if $x - y \in R^n_+$, $x > y$ if $x - y \in R^n_+ \setminus \{0\}$, $x \gg y$ if $x - y \in \text{int}(R^n_+)$. Let r be a nonnegative real number and $x(t)$ be a continuous function from $[-r, \sigma)$ to R^n $(\sigma > 0)$. For each $t \in [0, \sigma)$, we define $x_t \in C([-r,0], R^n)$ by $x_t(\theta) = x(t+\theta)$ for all $\theta \in [-r, 0]$. Consider an autonomous delay system

$$\frac{dx(t)}{dt} = f(x_t), \tag{2.1}$$

where $f : D \to R^n$ is Lipschitz continuous and D is an open subset of $C([-r,0], R^n)$. For any $\phi \in D$, let $x(t,\phi)$ be the unique solution of (2.1) satisfying $x(\theta,\phi) = \phi(\theta)$

for all $\theta \in [-r, 0]$. For $\phi, \psi \in C([-r, 0], R^n)$ we write $\phi \leq \psi$ if $\phi(\theta) \leq \psi(\theta)$ for all $\theta \in [-r, 0]$. System (2.1) is said to be cooperative if the following quasi-monotone condition holds:

(Q) Whenever $\phi \leq \psi$ and $\phi_i(0) = \psi_i(0)$ holds for some i, then $f_i(\phi) \leq f_i(\psi)$.

In particular, (2.1) with $r = 0$, an autonomous ordinary differential system, is cooperative if off-diagonal elements of the Jacobian matrix of f at any point in the domain are nonnegative. It is well known that the comparison principle holds for cooperative systems. For the basic theory of cooperative systems, we refer to [12].

Recall that the stability modulus of an $n \times n$ matrix M, denoted by $s(M)$, is defined by

$$s(M) := \max\{\mathrm{Re}\lambda : \ \lambda \text{ is an eigenvalue of } M\}.$$

If M has nonnegative off-diagonal elements and is irreducible, then $s(M)$ is a simple eigenvalue of M with a (componentwise) positive eigenvector (see, e.g., [14, Theorem A.5]).

Let $(S_1^*, \ldots, S_n^*, 0, \ldots, 0)$ be a disease free equilibrium of (1.8). Then it is easy to see that $(S_1^*, \ldots, S_n^*)$ is an equilibrium of the following ordinary differential system:

$$\frac{dS_i}{dt} = \overline{R}_i(S) - d_i S_i + \sum_{j=1}^{n} a_{ij} S_j, \quad i = 1, \ldots, n, \tag{2.2}$$

where $S = (S_1, \ldots, S_n) \in R_+^n$, $(\overline{R}_1(S), \ldots, \overline{R}_n(S))^T := \exp(C_J r) G(S)$. Set $\exp(C_J r) = (p_{ij})$. Since (1.6) is cooperative, it follows that $p_{ij} \geq 0$ for all $1 \leq i, j \leq n$. Further, we have

$$\overline{R}_i(S) = \sum_{j=1}^{n} p_{ij} G_j(S_j). \tag{2.3}$$

Define $H = (H_1, \ldots, H_n) : R_+^n \to R^n$ by

$$H_i(S) = \overline{R}_i(S) - d_i S_i + \sum_{j=1}^{n} a_{ij} S_j, \quad \forall S \in R_+^n, \ 1 \leq i \leq n.$$

Clearly, $H(0) \geq 0$. If $G_i'(A_i) \geq 0$ for all $A_i \geq 0$, $1 \leq i \leq n$, then $\frac{\partial H_i(S)}{\partial S_j} > 0$ for all $S \in R_+^n$, $1 \leq i \neq j \leq n$.

For any $\alpha \in (0, 1)$ and $S \gg 0$, by (2.3) and (A4), we have

$$\overline{R}_i(\alpha S) - d_i \alpha S_i + \sum_{j=1}^{n} a_{ij} \alpha S_j > \alpha \left[\overline{R}_i(S) - d_i S_i + \sum_{j=1}^{n} a_{ij} S_j \right]$$

for each $i = 1, 2, \ldots, n$, and hence $H(\alpha S) \gg \alpha H(S)$, which means that H is strongly sublinear on R_+^n (see, e.g., [21]).

For $S \gg 0$, let $M(S)$ denote the following matrix:

$$\begin{bmatrix} p_{11}B_1(S_1) - d_1 + a_{11} & a_{12} + p_{12}B_2(S_2) & \cdots & a_{1n} + p_{1n}B_n(S_n) \\ p_{21}B_1(S_1) + a_{21} & p_{22}B_2(S_2) - d_2 + a_{22} & \cdots & p_{2n}B_n(S_n) + a_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ p_{n1}B_1(S_1) + a_{n1} & p_{n2}B_2(S_2) + a_{n2} & \cdots & p_{nn}B_n(S_n) - d_n + a_{nn} \end{bmatrix}.$$

In what follows we use notation $K = (k, \ldots, k) \in R^n$ for each $k \in R$, and let $H'(S)$ be the Jacobian matrix of H at $S \in R_+^n$. Assume that the following hold:

(A5) $\frac{dG_i(A_i)}{dA_i} \geq 0$ for all $A_i \in (0,\infty)$, $i = 1,\dots,n$;
(A6) $s(M(\infty)) < 0$;
(A7) $s(H'(0)) > 0$ if $H(0) = 0$.

Biologically, (A5) means that the birth rate of juveniles in each patch increases as the number of adult individuals in the same patch increases. Roughly speaking, $M(\infty)$ is the per capita reproduction matrix for susceptible hosts in all patches when their numbers are sufficiently large in every patch. (A6) implies that the sizes of susceptible host populations decrease as long as they are large enough, which prevents unbounded susceptible populations. Similarly, (A7) implies that the sizes of susceptible host populations increase as long as they are small, which prevents the extinction of susceptible hosts. These can be seen from the proof of the following theorem.

THEOREM 2.1. *Let* (A1)–(A7) *hold. Then* (1.8) *has a unique disease free equilibrium* $E_0 = (S_1^*, S_2^*, \dots, S_n^*, 0, \dots, 0)$.

Proof. By (A6), we have $s(M(K)) < 0$ if k is large enough. Let $\bar{v} = (\bar{v}_1, \dots, \bar{v}_n)$ be a positive eigenvector associated with $s(M(K))$. Choose $l > 0$ large enough such that $l\bar{v}_i > k,\ i = 1, 2, \dots, n$. If we rewrite (2.2) as $\frac{dS}{dt} = H(S)$, by (A4) we have

$$0 > s(M(K))l\bar{v} = M(K)l\bar{v} > H(l\bar{v}), \qquad \forall t \geq 0. \tag{2.4}$$

Let $S(t, l\bar{v})$ be the solution of (2.2) satisfying $S(0, l\bar{v}) = l\bar{v}$. Since (2.2) is cooperative, it follows from (2.4) that $S(t, l\bar{v})$ is nonincreasing in $t \geq 0$ and converges to an equilibrium as t approaches infinity (see, e.g., [12, Corollary 5.2.2]). It follows that every solution $S(t, x)$ of (2.2) in R_+^n exists globally on $[0,\infty)$. Let $\Phi_0(t)$ be the solution semiflow of (2.2) on R_+^n, that is, $\Phi_0(t)x = S(t, x)$ for all $t \geq 0$, $x \in R_+^n$. Then $\Phi_0(t)$ is strongly monotone on R_+^n in the sense that $x > y$ implies $\Phi_0(t)x \gg \Phi_0(t)y$ for all $t > 0$. Note that H is strongly sublinear on R_+^n. By [21, Proposition 2.2] as applied to $\Phi_0(t)\,(t > 0)$, system (2.2) has at most one positive (componentwise) equilibrium. In the case where $H(0) > 0$, $S(t, 0)$ is nondecreasing in $t \geq 0$ and converges to an equilibrium $\bar{x} > 0$ as t approaches infinity, and hence $\bar{x} = \Phi_0(t)\bar{x} \gg \Phi_0(t)0 = S(t, 0) \geq 0$ for any $t > 0$. Thus, the standard comparison method implies that the positive equilibrium $\bar{x}$ is globally attractive, and hence asymptotically stable, for (2.2) in R_+^n. In the case where $H(0) = 0$, [21, Corollary 3.2] implies that (2.2) has a positive equilibrium $S^* = (S_1^*, S_2^*, \dots, S_n^*)$, which is globally asymptotically stable for $S \in R_+^n \setminus \{0\}$. Consequently, (1.8) has a unique disease free equilibrium. ∎

Now we are ready to consider a basic reproduction number for the system (1.8). The basic reproduction number, denoted by $\mathcal{R}_0$, is "the expected number of secondary cases produced, in a completely susceptible population, by a typical infective individual" (see [7]). For the case of a single infected compartment, $\mathcal{R}_0$ is simply the product of the infection rate and the mean duration of the infection. For the model (1.8) with several infected compartments, the basic reproduction number can be defined as the number of new infections produced by a typical infective individual in the population at the disease free equilibrium (see [18]). Following [18], we let $x_i = I_i$ for $i = 1, \dots, n$ and $x_{n+i} = S_i$ for $i = 1, \dots, n$. Then model (1.8) can be rewritten as

$$\frac{dx_i}{dt} = f_i(x) = \mathcal{F}_i(x) - \mathcal{V}_i(x), \quad i = 1, \dots, 2n,$$

where

$$\mathcal{F}_i(x) = \beta_i x_i x_{n+i}, \quad \mathcal{V}_i(x) = (d_i + \gamma_i)x_i - \sum_{j=1}^{n} b_{ij}x_j \quad \text{for} \quad i = 1, \dots, n.$$

Here we do not write the expressions for $\mathcal{F}_i(x), \mathcal{V}_i(x)$ for $i = n+1, \ldots, 2n$, since they are not important at this moment. Furthermore, the disease free equilibrium E_0 now becomes $(0, \ldots, 0, S_1^*, S_2^*, \ldots, S_n^*)$.

For $i = 1, \ldots, n, \mathcal{F}_i(x)$ is the rate of appearance of new infections in compartment i, and $\mathcal{V}_i(x)$ is the net decreasing rate of infectives in compartment i due to infective flows inside the system of infected compartments.

If $\mathcal{F} = (\mathcal{F}_1, \ldots, \mathcal{F}_{2n})$ and $\mathcal{V} = (\mathcal{V}_1, \ldots, \mathcal{V}_{2n})$, let us partition the derivatives $D\mathcal{F}(E_0)$ and $D\mathcal{V}(E_0)$ as

$$D\mathcal{F}(E_0) = \begin{bmatrix} F & 0 \\ 0 & 0 \end{bmatrix}, \quad D\mathcal{V}(E_0) = \begin{bmatrix} V & 0 \\ J_3 & J_4 \end{bmatrix},$$

where

$$F = \left[\frac{\partial \mathcal{F}_i}{\partial x_j}(E_0)\right]_{n\times n}, \quad V = \left[\frac{\partial \mathcal{V}_i}{\partial x_j}(E_0)\right]_{n\times n}.$$

Then it is easy to obtain

$$F = \begin{bmatrix} \beta_1 S_1^* & 0 & \cdots & 0 \\ 0 & \beta_2 S_2^* & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & \beta_n S_n^* \end{bmatrix}$$

and

$$V = \begin{bmatrix} d_1 + \gamma_1 - b_{11} & -b_{12} & \cdots & -b_{1n} \\ -b_{21} & d_2 + \gamma_2 - b_{22} & \cdots & -b_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ -b_{n1} & -b_{n2} & \cdots & d_n + \gamma_n - b_{nn} \end{bmatrix}.$$

According to [7, 18], the matrix FV^{-1} is called the next generation matrix, and its spectral radius is defined as the reproduction number for (1.8), that is,

$$\mathcal{R}_0 := \rho(FV^{-1}).$$

Let M_1 denote the matrix

$$\begin{bmatrix} \beta_1 S_1^* - d_1 - \gamma_1 + b_{11} & b_{12} & \cdots & b_{1n} \\ b_{21} & \beta_2 S_2^* - d_2 - \gamma_2 + b_{22} & \cdots & b_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ b_{n1} & b_{n2} & \cdots & \beta_n S_n^* - d_n - \gamma_n + b_{nn} \end{bmatrix}.$$

Clearly, M_1 is irreducible and has nonnegative off-diagonal elements. Then $s(M_1)$ is a simple eigenvalue of M_1 with a positive eigenvector. Furthermore, $M_1 = F - V$. Thus, the following observation is implied by the proof of [18, Theorem 2] with $J_1 = M_1$.

LEMMA 2.1. *There hold two equivalences:*

$$\mathcal{R}_0 > 1 \Leftrightarrow s(M_1) > 0, \qquad \mathcal{R}_0 < 1 \Leftrightarrow s(M_1) < 0. \tag{2.5}$$

By Lemma 2.1 and the proof of Theorem 2.1, it easily follows that $\mathcal{R}_0 < 1$ implies that E_0 is asymptotically stable, and that $\mathcal{R}_0 > 1$ implies that E_0 is unstable.

3. Global dynamics. The purpose of this section is to discuss the global extinction and persistence of the disease described by model (1.8).

Define $e_{ij} := \max\{a_{ij}, b_{ij}\}$, $i \neq j$, and $e_{ii} := \min\{a_{ii}, b_{ii}\}$. Let $\overline{M}(S)$ denote the matrix function

$$\begin{bmatrix} p_{11}B_1(S_1) - d_1 + e_{11} & e_{12} + p_{12}B_2(S_2) & \cdots & e_{1n} + p_{1n}B_n(S_n) \\ p_{21}B_1(S_1) + e_{21} & p_{22}B_2(S_2) - d_2 + e_{22} & \cdots & p_{2n}B_n(S_n) + e_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ p_{n1}B_1(S_1) + e_{n1} & p_{n2}B_2(S_2) + e_{n2} & \cdots & p_{nn}B_n(S_n) - d_n + e_{nn} \end{bmatrix}.$$

Consider a time-delayed cooperative system

$$\frac{dA_i}{dt} = \overline{R}_i(A(t-r)) - d_iA_i + \sum_{j=1}^{n} e_{ij}A_j, \qquad i = 1, \ldots, n. \tag{3.1}$$

Assume that (A1)–(A5) and (A7) hold and that $s(\overline{M}(\infty)) < 0$. By [21, Theorem 3.2] and an argument similar to the proof of Theorem 2.1, it easily follows that system (3.1) admits a unique positive equilibrium $\bar{A} = (\bar{A}_1, \ldots, \bar{A}_n)$, and $\bar{A}$ is globally stable in $C_+ \setminus \{0\}$. Let $\overline{M}_1$ denote the matrix

$$\begin{bmatrix} \beta_1\bar{A}_1 - d_1 - \gamma_1 + b_{11} & b_{12} & \cdots & b_{1n} \\ b_{21} & \beta_2\bar{A}_2 - d_2 - \gamma_2 + b_{22} & \cdots & b_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ b_{n1} & b_{n2} & \cdots & \beta_n\bar{A}_n - d_n - \gamma_n + b_{nn} \end{bmatrix}.$$

We then have the following result.

THEOREM 3.1. *Let* (A1)–(A5) *and* (A7) *hold. Assume that* $s(\overline{M}(\infty)) < 0$. *If* $s(\overline{M}_1) < 0$, *then* E_0 *is globally attractive for* (1.8) *in* $(C_+ \setminus \{0\}) \times C_+$.

Proof. Note that $A_i = S_i + I_i$ for all $1 \leq i \leq n$. By (1.8), we have

$$\frac{dA_i}{dt} = \overline{R}_i(A(t-r)) - d_iA_i + \sum_{j=1}^{n} a_{ij}S_j + \sum_{j=1}^{n} b_{ij}I_j, \qquad i = 1, \ldots, n. \tag{3.2}$$

Then we have

$$\frac{dA_i}{dt} \leq \overline{R}_i(A(t-r)) - d_iA_i + \sum_{j=1}^{n} e_{ij}A_j, \quad i = 1, \ldots, n. \tag{3.3}$$

Given $(\phi, \psi) \in (C_+ \setminus \{0\}) \times C_+$, let $(S(t), I(t))$ be the solution of (1.8). It then follows from the comparison principle that

$$\limsup_{t\to\infty} A_i(t) \leq \bar{A}_i, \quad i = 1, \ldots, n.$$

As a consequence, each positive solution of (1.8) satisfies

$$\limsup_{t\to\infty} S_i(t) \leq \bar{A}_i, \quad i = 1, \ldots, n.$$

Choose a sufficiently small positive number ϵ such that $s(\overline{M}_1 + \epsilon\beta) < 0$, where $\beta = \operatorname{diag}(\beta_1, \ldots, \beta_n)$. Then there exists a $t_0 > 0$ such that $S_i(t) \leq \bar{A}_i + \epsilon$ for all $t \geq t_0$, $i = 1, \ldots, n$. It follows that

$$\frac{dI_i}{dt} \leq (\beta_i(\bar{A}_i + \epsilon) - d_i - \gamma_i)I_i + \sum_{j=1}^{n} b_{ij}I_j, \quad \forall t \geq t_0,\ i = 1, \ldots, n. \tag{3.4}$$

Let us consider an auxiliary system

$$\frac{dI_i}{dt} = (\beta_i(\bar{A}_i + \epsilon) - d_i - \gamma_i)I_i + \sum_{j=1}^{n} b_{ij}I_j, \quad i = 1, \dots, n. \tag{3.5}$$

Since $s(\bar{M}_1 + \epsilon\beta) < 0$, it is easy to see that all the solutions of (3.5) tend to the origin as t tends to infinity. Since (3.5) is cooperative, it follows from the comparison principle that $I_i(t) \to 0$ as $t \to \infty, i = 1, \dots, n$.

Let $\Phi(t) : C_+^2 \to C_+^2$ be the solution semiflow of (1.8), that is,

$$\Phi(t)(\phi, \psi) = (S_t(\phi, \psi), I_t(\phi, \psi)),$$

where $S_t(\phi, \psi)(\theta) = S(t + \theta, \phi, \psi)$, $I_t(\phi, \psi)(\theta) = I(t + \theta, \phi, \psi)$ for all $\theta \in [-r, 0]$, and $(S(t, \phi, \psi), I(t, \phi, \psi))$ is the solution of (1.8) through (ϕ, ψ). For any $(\phi, \psi) \in (C_+ \setminus \{0\}) \times C_+$, it is easy to see that $S(t, \phi, \psi) > 0$ for $t > r$. Let $\omega = \omega(\phi, \psi)$ be the omega limit set of $\Phi(t)(\phi, \psi)$. Since $I(t, \phi, \psi) \to 0$ as $t \to \infty$, there holds $\omega = \bar{\omega} \times \{0\}$. We claim that $\bar{\omega} \neq \{0\}$. Assume that, by contradiction, $\bar{\omega} = \{0\}$. Then $\lim_{t\to\infty} (S(t, \phi, \psi), I(t, \phi, \psi)) = (0, 0)$. Consequently, for any sufficiently small $\xi > 0$ there is a $T^* > 0$ such that

$$S_i(t) < \xi, \quad I_i(t) < \xi, \qquad \forall\, i = 1, \dots, n, \quad t \geq T^*, \tag{3.6}$$

where the dependence of S_i and I_i on (ϕ, ψ) is suppressed. It follows from (1.8) that

$$\frac{dS_i}{dt} \geq \sum_{j=1}^{n} p_{ij}G_j(S_j(t - r)) - (d_i + \beta_i\xi)S_i + \sum_{j=1}^{n} a_{ij}S_j, \quad i = 1, \dots, n, \tag{3.7}$$

for $t \geq T^*$. Consider the cooperative system of delay differential equations

$$\frac{dS_i}{dt} = \sum_{j=1}^{n} p_{ij}G_j(S_j(t - r)) - (d_i + \beta_i\xi)S_i + \sum_{j=1}^{n} a_{ij}S_j, \quad i = 1, \dots, n. \tag{3.8}$$

In the case where $H(0) = 0$, since $s(H'(0)) > 0$, we can further restrict $\xi > 0$ such that $s(H'(0) - \xi\beta) > 0$, where $\beta = \mathrm{diag}(\beta_1, \dots, \beta_n)$. Let $x(t, \phi)$ be the solution of (3.8) satisfying $x_0(\phi) = \phi \in C_+$. By [21, Theorem 3.1], it follows that either $x(t, \phi)$ is unbounded for every $\phi \in C_+ \setminus \{0\}$ or there exists an equilibrium $x^* \gg 0$ of (3.8) such that $\liminf_{t\to\infty} x(t, \phi) \geq x^*$ for every $\phi \in C_+ \setminus \{0\}$. In the case where $H(0) > 0$, [12, Corollary 5.2.2]) implies that $x(t, 0)$ is nondecreasing in t. Moreover, if $x(t, 0)$ is bounded, then $x(t, 0)$ converges to an equilibrium $x^* > 0$. Since the ordinary differential system (3.8) with $r = 0$ is cooperative and irreducible, it follows that $x^* \gg 0$. Consequently, the comparison principle (see [12, Theorem 5.1.1]) implies that either $S(t)$ is unbounded or $\liminf_{t\to\infty} S(t) \geq x^*$, which contradicts $\lim_{t\to\infty} S_i(t) = 0$ for all $i = 1, \dots, n$.

It is easy to see that

$$\Phi(t) \mid_{\omega} (\phi, 0) = (\Phi_1(t)\phi, 0),$$

where $\Phi_1(t)$ is the solution semiflow of the following system:

$$\frac{dS_i}{dt} = \overline{R}_i(S(t - r)) - d_iS_i + \sum_{j=1}^{n} a_{ij}S_j, \quad i = 1, \dots, n. \tag{3.9}$$

By [9, Lemma 2.1′], ω is an internal chain transitive set for $\Phi(t)$, and hence $\bar{\omega}$ is an internal chain transitive set for $\Phi_1(t)$. By the proof of Theorem 2.1 and [21, Theorem 3.2], it follows that S^* is globally asymptotically stable for (3.9) in $C_+ \setminus \{0\}$. Since $\bar{\omega} \neq \{0\}$, we have $\bar{\omega} \cap W^s(S^*) \neq \emptyset$. By [9, Theorem 3.1 and Remark 4.6], we then get $\bar{\omega} = S^*$. This proves $\omega = \{(S^*, 0)\}$. Consequently, $(S(t,\phi,\psi), I(t,\phi,\psi)) \to (S^*, 0)$ as $t \to \infty$. □

REMARK 3.1. *Let* (A1)–(A5) *and* (A7) *hold. Assume that* $s(\overline{M}(\infty)) < 0$. *Note that* $\bar{A}_i$ *is near to* S_i^* *for* $i = 1, \ldots, n$, *provided that the dispersal coefficients* a_{ij} *and* b_{ij} *are small for* $i, j = 1, \ldots, n$. *Hence, it is one implication of Theorem* 3.1 *that the disease, which dies out in the absence of population dispersal, still dies out when population dispersal is weak.*

COROLLARY 3.1. *Let* (A1)–(A5) *and* (A7) *hold. Assume that* $s(\overline{M}(\infty)) < 0$. *If* $a_{ij} = b_{ij}$ *for* $i = 1, \ldots, n, j = 1, \ldots, n$, *and* $\mathcal{R}_0 < 1$, *then* E_0 *is globally attractive for* (1.8) *in* $(C_+ \setminus \{0\}) \times C_+$.

Proof. In this special case, $e_{ij} = a_{ij} = b_{ij}$ for all $1 \le i, j \le n$, and hence $\bar{A} = S^*$, $\bar{M} = M$, and $\bar{M}_1 = M_1$. By Lemma 2.1, $s(M_1) < 0$. Thus, the conclusion follows from Theorem 3.1. □

The subsequent result shows that the disease is uniformly persistent in the case where $\mathcal{R}_0 > 1$.

THEOREM 3.2. *Let* (A1)–(A7) *hold and* $\mathcal{R}_0 > 1$. *If* $s(\overline{M}(\infty)) < 0$, *then there is a positive constant* ϵ *such that every solution* $(S(t,\phi,\psi), I(t,\phi,\psi))$ *of* (1.8) *with* $(\phi,\psi) \in C_+^2$ *and* $\psi(0) > 0$ *satisfies*

$$\liminf_{t\to\infty} I_i(t,\phi,\psi) \ge \epsilon \qquad \forall 1 \le i \le n.$$

Furthermore, (1.8) *admits at least one (componentwise) positive equilibrium.*

Proof. Define

$$\begin{aligned} X &:= \{(\phi,\psi) \in C_+ \times C_+\}, \\ X_0 &:= \{(\phi,\psi) \in X : \psi(0) > 0\}, \\ \partial X_0 &:= X \setminus X_0. \end{aligned}$$

By the form of (1.8), it is easy to see that both X and X_0 are positively invariant. Clearly, ∂X_0 is relatively closed in X, and $\partial X_0 = \{(\phi,\psi) \in X : \psi(0) = 0\}$. Furthermore, system (1.8) is point dissipative in R_+^n since nonnegative solutions of (1.8) are ultimately bounded (see the proof of Theorem 3.1).

Let $(S(t,\phi,\psi), I(t,\phi,\psi))$ be the solution of (1.8) through (ϕ,ψ), and define

$$M_\partial := \{(\phi,\psi) \in X : (S_t(\phi,\psi), I_t(\phi,\psi)) \in \partial X_0 \ \forall\ t \ge 0\}.$$

Then we have the following claim.

CLAIM 1. $M_\partial = \{(\phi,\psi) \in \partial X_0 : I(t,\phi,\psi) = 0 \ \forall\ t \ge 0\}$.

Indeed, it suffices to prove that for each $(\phi,\psi) \in M_\partial$, $I(t,\phi,\psi) = 0$ for all $t \ge 0$. Suppose that this does not hold. Then there exist some $i_0, 1 \le i_0 \le n$, and $t_0 \ge 0$ such that $I_{i_0}(t_0,\phi,\psi) > 0$. We partition $\{1, 2, \ldots, n\}$ into two sets Q_1 and Q_2 such that

$$\begin{aligned} I_i(t_0,\phi,\psi) &= 0 \quad \forall i \in Q_1, \\ I_i(t_0,\phi,\psi) &> 0 \quad \forall i \in Q_2. \end{aligned}$$

By the definition of M_∂ we see that Q_1 is nonempty. Q_2 is also nonempty since $I_{i_0}(t_0, \phi, \psi) > 0$. For any $j \in Q_1$, we have

$$\left.\frac{dI_j(t,\phi,\psi)}{dt}\right|_{t=t_0} \geq b_{ji_0} I_{i_0}(t_0, \phi, \psi) > 0.$$

It follows that there is an $\epsilon_0 > 0$ such that $I_j(t, \phi, \psi) > 0, j \in Q_1$, for $t_0 < t < t_0 + \epsilon_0$. Clearly, we can restrict $\epsilon_0 > 0$ to be small enough such that $I_i(t, \phi, \psi) > 0, i \in Q_2$, for $t_0 < t < t_0 + \epsilon_0$. This means that $(S_t(\phi, \psi), I_t(\phi, \psi)) \notin \partial X_0$ for $t_0 < t < t_0 + \epsilon_0$, which contradicts the assumption that $(\phi, \psi) \in M_\partial$.

Define $M_3 := \operatorname{diag}(\beta_1, \ldots, \beta_n)$. Then we can choose $\eta > 0$ small enough such that $s(M_1 - \eta M_3) > 0$. Consider the following system:

$$\frac{dS_i}{dt} = \overline{R}_i(S(t-r)) - (d_i + \beta_i\epsilon_1)S_i + \sum_{j=1}^{n} a_{ij}S_j, \qquad i = 1, \ldots, n. \tag{3.10}$$

First, as in our previous analysis of system (2.2), we can restrict $\epsilon_1 > 0$ to be small enough such that (3.10) admits a unique positive equilibrium $S^*(\epsilon_1)$, which is globally asymptotically stable for (3.10) (see the proof of Theorem 2.1 and [21, Theorem 3.2]). By the implicit function theorem, it follows that $S^*(\epsilon_1)$ is continuous in ϵ_1. Thus, we can restrict ϵ_1 to be small enough such that $S^*(\epsilon_1) > S^* - \eta$. Let $S(t, \phi, \psi) = (S_1(t, \phi, \psi), \ldots, S_n(t, \phi, \psi))$ and $I(t, \phi, \psi) = (I_1(t, \phi, \psi), \ldots, I_n(t, \phi, \psi))$. Then we further have the following claim.

CLAIM 2. $\limsup_{t\to\infty} \max_i\{I_i(t, \phi, \psi)\} > \epsilon_1$ *for all* $(\phi, \psi) \in X_0$.

Suppose, for the sake of contradiction, that there is a $T > 0$ such that $0 < I_i(t) \leq \epsilon_1$, $i = 1, 2, \ldots, n$, for all $t \geq T$. Then for $t \geq T$ we have

$$\frac{dS_i}{dt} \geq \overline{R}_i(S(t-r)) - (d_i + \beta_i\epsilon_1)S_i + \sum_{j=1}^{n} a_{ij}S_j, \quad i = 1, \ldots, n. \tag{3.11}$$

Since the equilibrium $S^*(\epsilon_1)$ of (3.10) is globally asymptotically stable and $S^*(\epsilon_1) > S^* - \eta$, there is a $T_1 > 0$ such that $S(t) \geq S^* - \eta$ for $t \geq T + T_1$. As a consequence, for $t > T + T_1$, we have

$$\frac{dI_i}{dt} \geq \beta_i(S_i^* - \eta)I_i - (d_i + \gamma_i)I_i + \sum_{j=1}^{n} b_{ij}I_j, \qquad i = 1, \ldots, n. \tag{3.12}$$

Since the matrix $M_1 - \eta M_3$ has a positive eigenvalue $s(M_1 - \eta M_2)$ with a positive eigenvector, it is easy to see that $I_i(t) \to \infty$ as $t \to \infty$, $i = 1, 2, \ldots, n$, which leads to a contradiction.

Note that the delay differential system

$$\frac{dS_i}{dt} = \overline{R}_i(S(t-r)) - d_iS_i + \sum_{j=1}^{n} a_{ij}S_j, \qquad i = 1, \ldots, n, \tag{3.13}$$

admits a global asymptotic stable equilibrium S^* in $C([-r, 0], R_+^n) \setminus \{0\}$. In the case where $H(0) = 0$, there are exactly two equilibria $(0, 0)$ and $E_0 = (S^*, 0)$ in M_∂. By Claim 2, we see that $(0, 0)$ and E_0 are isolated invariant sets in X, $W^s((0, 0)) \cap X_0 = \emptyset$, and $W^s(E_0) \cap X_0 = \emptyset$. Clearly, every forward orbit in M_∂ converges to either $(0, 0)$ or E_0, and $(0, 0)$ and E_0 are acyclic in M_∂. By [17, Theorem 4.6], it follows that

the solution semiflow associated with (1.8) is uniformly persistent with respect to $(X_0, \partial X_0)$. In the case where $H(0) > 0$, there is only one equilibrium $E_0 = (S^*, 0)$ in M_∂, and every forward orbit in M_∂ converges to E_0. By a similar argument, we see that the solution semiflow is uniformly persistent with respect to $(X_0, \partial X_0)$. Consequently, [15, Theorem A.2] with $Z = C([-r, 0], R_+^{2n})$ and $e = (1, \dots, 1) \in R^{2n}$ implies the required uniform persistence of solutions of (1.8).

By applying [20, Theorem 2.4] to the autonomous semiflow generated by the ordinary differential system (1.8) with $A(t-r)$ replaced by $A(t)$, we conclude that system (1.8) has an equilibrium $(\bar{S}, \bar{I}) \in X_0$. Then $\bar{S} \in R_+^n$ and $\bar{I} \in \text{int}(R_+^n)$. We further claim that $\bar{S} \in R_+^n \setminus \{0\}$. Suppose that $\bar{S} = 0$. By the second equation in (1.4), we then get $0 = -\sum_{i=1}^n (\mu_i + \gamma_i)\bar{I}_i$, and hence $\bar{I}_i = 0,\ i = 1, 2, \dots, n$, a contradiction. By the first equation in (1.8) and the irreducibility of the cooperative matrix (a_{ij}), it follows that $\bar{S} = S(t, \bar{S}, \bar{I}) \in \text{int}(R_+^n)$ for all $t > 0$. Then $(\bar{S}, \bar{I})$ is a componentwise positive equilibrium of (1.8). □

4. A case study. In order to illustrate the results of the last section, we suppose that the birth rates are in the form of (B3) and that there are only two patches. Then model (1.8) becomes

$$
(4.1)\quad \begin{cases} \dfrac{dS_i}{dt} = R_i(t) - (d_i + a_i)S_i - \beta_i S_i I_i + \gamma_i I_i + a_j S_j, \quad i, j = 1, 2, i \neq j, \\ \dfrac{dI_i}{dt} = \beta_i S_i I_i - (d_i + \gamma_i + b_i)I_i + b_j I_j, \quad i, j = 1, 2, i \neq j, \\ (R_1(t), R_2(t))^T = \exp(C_J r)(k_1 + l_1 A_1(t-r), k_2 + l_2 A_2(t-r))^T, \end{cases}
$$

where a_i, b_i, and c_i are the migration rates of adult susceptibles, adult infectives, and juveniles, respectively, of patch i. Set $\exp(C_J r) = (p_{ij})$. Then we have

$$
\begin{aligned} R_1(t) &= p_{11}(k_1 + l_1 A_1(t-r)) + p_{12}(k_2 + l_2 A_2(t-r)), \\ R_2(t) &= p_{21}(k_1 + l_1 A_1(t-r)) + p_{22}(k_2 + l_2 A_2(t-r)). \end{aligned}
$$

Set

$$
M_4 := \begin{bmatrix} p_{11}l_1 - a_1 - d_1 & p_{12}l_2 + a_2 \\ p_{21}l_1 + a_1 & p_{22}l_2 - a_2 - d_2 \end{bmatrix}.
$$

Then it is easy to see that (A1)–(A7) are satisfied if $s(M_4) < 0$.

Let $E_0 = (S_1^*, S_2^*, 0, 0)$ be the disease free equilibrium of (4.1). Then S_1^* and S_2^* satisfy the following linear system:

$$
\begin{aligned} &p_{11}(k_1 + l_1 S_1^*) + p_{12}(k_2 + l_2 S_2^*) - (d_1 + a_1)S_1^* + a_2 S_2^* = 0, \\ &p_{21}(k_1 + l_1 S_1^*) + p_{22}(k_2 + l_2 S_2^*) - (d_2 + a_2)S_2^* + a_1 S_1^* = 0. \end{aligned}
$$

Set

$$
\begin{aligned} h_1 &= \beta_1 S_1^* + \beta_2 S_2^* - b_1 - b_2 - \gamma_1 - \gamma_2 - d_1 - d_2, \\ h_2 &= \beta_1 S_1^* \beta_2 S_2^* - b_1 b_2 - \beta_1 S_1^*(d_2 + \gamma_2 + b_2) \\ &\quad - \beta_2 S_2^*(d_1 + \gamma_1 + b_1) + (d_1 + \gamma_1 + b_1)(d_2 + \gamma_2 + b_2). \end{aligned} \tag{4.2}
$$

It is easy to see that

$$
s(M_1) = \frac{h_1 + \sqrt{h_1^2 - 4h_2}}{2}. \tag{4.3}
$$

Then $\mathcal{R}_0 > 1$ if and only if $h_1 \geq 0$ or

$$\begin{cases} h_1 < 0, \\ 1 + \dfrac{\beta_1 S_1^* \beta_2 S_2^* - b_1 b_2}{(d_1 + \gamma_1 + b_1)(d_2 + \gamma_2 + b_2)} < \dfrac{\beta_1 S_1^*}{d_1 + \gamma_1 + b_1} + \dfrac{\beta_2 S_2^*}{d_2 + \gamma_2 + b_2}. \end{cases} \tag{4.4}$$

Now, we illustrate that the dispersal of juvenile individuals has a significant effect on the spread of the disease, although they are immune to the disease and cannot transmit the disease.

Example 4.1. We fix $k_1 = k_2 = k, l_1 = l_2 = l, d_1 = d_2 = d, \mu_1 = \mu_2 = \mu, a_1 = a_2 = a, b_1 = b_2 = b, \gamma_1 = \gamma_2 = \gamma$. That is, we suppose that the population in the first patch has the same birth rate, death rate, dispersal rate for adults, and recovery rate as the population in the second patch. We let the contact rates β_i and the dispersal rates for juveniles vary in two patches. Let the migration rate of juveniles from the first patch to the second be c_1 and the rate from the second to the first be c_2. Thus we have

$$C_J = \begin{bmatrix} -\mu - c_1 & c_2 \\ c_1 & -\mu - c_2 \end{bmatrix}.$$

It is easy to obtain

$$\exp(C_J r) = \begin{bmatrix} \dfrac{c_2\, p + c_1\, q}{c_1 + c_2} & \dfrac{c_2\,(-q + p)}{c_1 + c_2} \\ \dfrac{c_1\,(-q + p)}{c_1 + c_2} & \dfrac{p\, c_1 + c_2\, q}{c_1 + c_2} \end{bmatrix},$$

with $p = e^{-\mu r}$ and $q = \exp(-r(\mu + c_1 + c_2))$. Note that

$$R_1(t) = \frac{k(c_1\, q + 2\, c_2\, p - c_2\, q) + l\,(c_1\, q + c_2\, p)A_1(t - r) + l\,(c_2\, p - c_2\, q)A_2(t - r)}{c_1 + c_2},$$
$$R_2(t) = \frac{k(2\, c_1\, p - c_1\, q + c_2\, q) - l\,(c_1\, q - c_1\, p)A_1(t - r) + l\,(c_2\, q + c_1\, p)A_2(t - r)}{c_1 + c_2}.$$

By direct calculations, we obtain

$$S_1^* = -\frac{(2\, c_1\, a\, p + 2\, a\, c_2\, p + c_1\, d\, q - c_1\, l\, p\, q + 2\, d\, c_2\, p - c_2\, l\, p\, q - c_2\, d\, q)\, k}{(c_1 + c_2)\,(p\, l - d)\,(-q\, l + 2\, a + d)},$$
$$S_2^* = -\frac{k\,(-c_1\, l\, p\, q + 2\, c_1\, a\, p - c_1\, d\, q + 2\, c_1\, d\, p - c_2\, l\, p\, q + 2\, a\, c_2\, p + c_2\, d\, q)}{(c_1 + c_2)\,(p\, l - d)\,(-q\, l + 2\, a + d)}.$$

Then we can use Theorem 3.1, Corollary 3.1, and Theorem 3.2 to discuss the effect of population dispersal. In order to be concise and clear, we further fix $a = b = 0.2$, $\mu = 2$, $r = 1$, $d = 0.5$, $l = 1$, $k = 1$, and $\gamma = 0$. Then, by the method of estimation, it is not hard to see that $s(M_4) < 0$. Hence (A1)–(A7) are satisfied. In this case, it is clear that $s(\overline{M}(K)) < 0$ for all large k.

Now, let us vary c_1, c_2, β_1, and β_2 to see the effect of the dispersal of juvenile members. First, we fix $\beta_1 = 1.4$ and $\beta_2 = 1$. If the dispersal of juvenile individuals is turned off, then

$$S_1^* = -\frac{p\, k}{p\, l - d} = 0.3711, \quad S_2^* = -\frac{p\, k}{p\, l - d} = 0.3711.$$

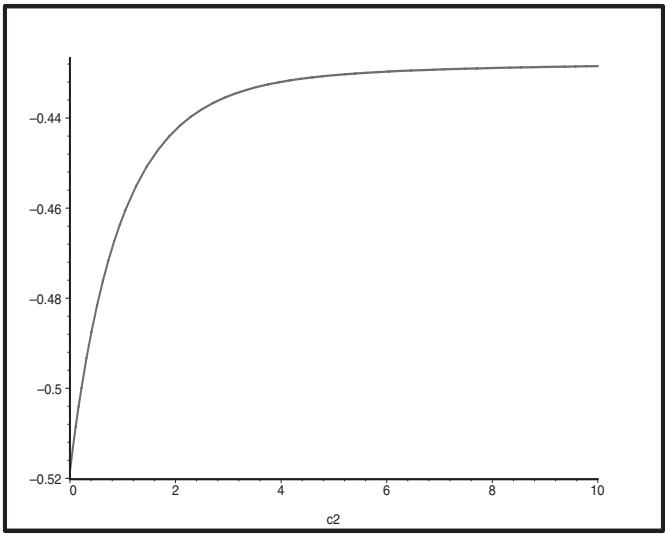

FIG. 1. *The graph of function* h_1 *when* $a = b = 0.2$, $\mu = 2$, $r = 1$, $d = 0.5$, $l = 1$, $k = 1$, $\beta_1 = 1.4$, $\beta_2 = 1$, $c_1 = 0.1$, *and* $\gamma = 0$.

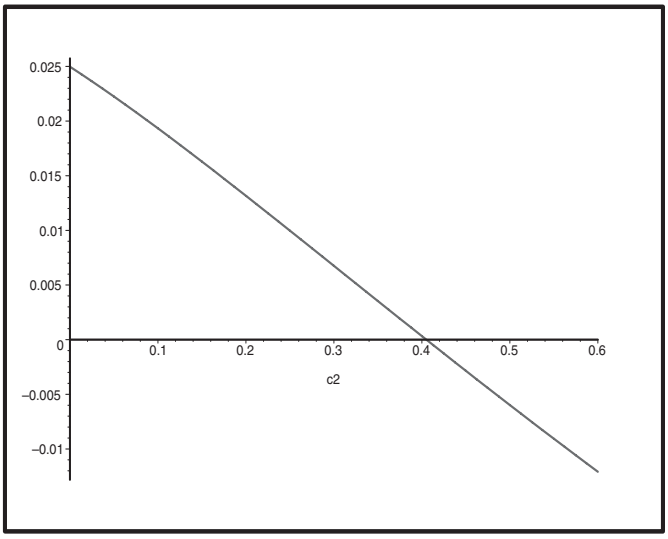

FIG. 2. *The graph of function* h_2 *when* $a = b = 0.2$, $\mu = 2$, $r = 1$, $d = 0.5$, $l = 1$, $k = 1$, $\beta_1 = 1.4$, $\beta_2 = 1$, $c_1 = 0.1$, *and* $\gamma = 0$.

As a consequence, $h_1 = -0.5093 < 0$, $h_2 = 0.0193 > 0$. Hence, the disease dies out in the patches if there is no dispersal for juvenile individuals. If we increase c_1 and c_2 from 0, by numerical calculations, we see that h_1 is always negative (see Figure 1). However, h_2 changes the sign as c_2 increases (see Figure 2). For the case in Figure 2, we see that the disease remains extinct in the two patches when the dispersal coefficient c_2 is weak, and breaks out in the two patches when c_2 is strong. In this case, the migration of juveniles from the second patch to the first patch could intensify the disease spread. Secondly, we fix $\beta_1 = 1.4, \beta_2 = 1.25$, and $c_1 = 0.6$. Then h_1 remains negative, and the graph of h_2 is given in Figure 3. From this figure and numerical calculations, we

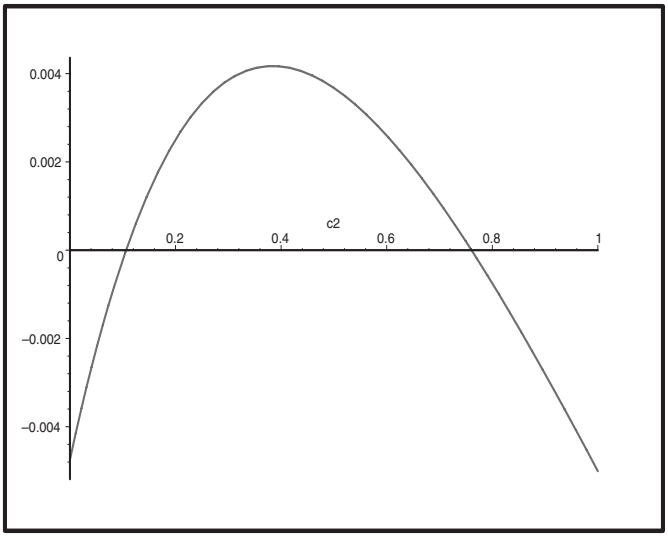

FIG. 3. *The graph of function* h_2 *when* $a = b = 0.2$, $\mu = 2$, $r = 1$, $d = 0.5$, $l = 1$, $k = 1$, $\beta_1 = 1.4$, $\beta_2 = 1.25$, $c_1 = 0.6$, *and* $\gamma = 0$.

see that the disease spreads in the two patches when $0 < c_2 < 0.1064$ or $0.7607 < c_2$, and dies out when $0.1064 < c_2 < 0.7607$. Thus, the disease undergoes a transition from uniform persistence to extinction and a second transition from extinction to uniform persistence; i.e., there exist persistence-extinction-persistence switches, as the dispersal rate c_2 increases from 0.

Let us now change the parameters to $a = b = 0.2$, $\mu = 2$, $r = 1$, $d = 0.5$, $l = 1$, $k = 1$, $\beta_1 = 2$, and $\beta_2 = 0.8$. In this case, if the dispersal of juvenile individuals is turned off, then $h_1 = -0.3609 < 0, h_2 = -0.0570 < 0$. Hence, Theorem 3.2 means that the disease spreads in two patches when there is no dispersal for juveniles. But if we take $c_2 = 0.01$, by means of Maple, we see that h_1 is always negative when c_1 varies. Further, the profile of h_2 is given in Figure 4. Numerical calculation shows that $h_2 = 0$ at $c_1 = 0.4484$. Hence, by Theorems 3.1 and 3.2, the disease spreads in two patches if $0 < c_1 < 0.4484$ and dies out in two patches if $c_1 > 0.4484$. This means that the dispersal of juveniles can also lower the risk of a disease outbreak.

Example 4.1 indicates the existence of the persistence-extinction-persistence switches where the migration rates of juveniles are independent of the migration rates of adults. However, the mobility of juveniles may be associated with that of their adults. To find functions that accurately describe patterns of juvenile movement and adult movement, a good way is to construct a submodel by considering factors such as behaviors of the population and resource differences among patches. For simplicity, we assume that juveniles and susceptible adults move together at the same migration rate. This is a very simple way to relate the movements of juveniles and adults. Our next example shows that persistence-extinction-persistence switches can also occur in this special case.

Example 4.2. We fix $\mu_1 = \mu_2 = 2$, $d_1 = d_2 = 0.5$, $l_1 = 1$, $l_2 = 0.5$, $r = 1$, $k_1 = 1$, $k_2 = 2$, $\beta_1 = 1.4$, $\beta_2 = 0.7$, $b_1 = 0.2$, $b_2 = 0.01$, $\gamma_1 = \gamma_2 = 0$, $a_1 = c_1 = 0.5$, and $a_2 = c_2$. Since $a_i = c_i$, $i = 1, 2$, we have assumed that juveniles and their susceptible adults in each patch move together. By arguments similar to those in Example 4.1, we see that $h_1 < 0$ if $0 \le a_2 \le 0.9$, $h_2 < 0$ if $0 \le a_2 < 0.1589$ or $0.4891 < a_2 \le 0.9$, and

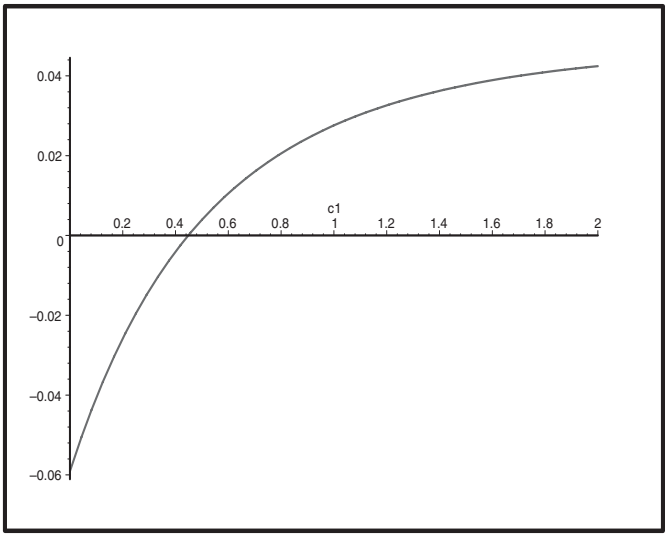

FIG. 4. *The graph of function* h_2 *when* $a = b = 0.2$, $\mu = 2$, $r = 1$, $d = 0.5$, $l = 1$, $k = 1$, $\beta_1 = 2$, $\beta_2 = 0.8$, $c_2 = 0.01$, *and* $\gamma = 0$.

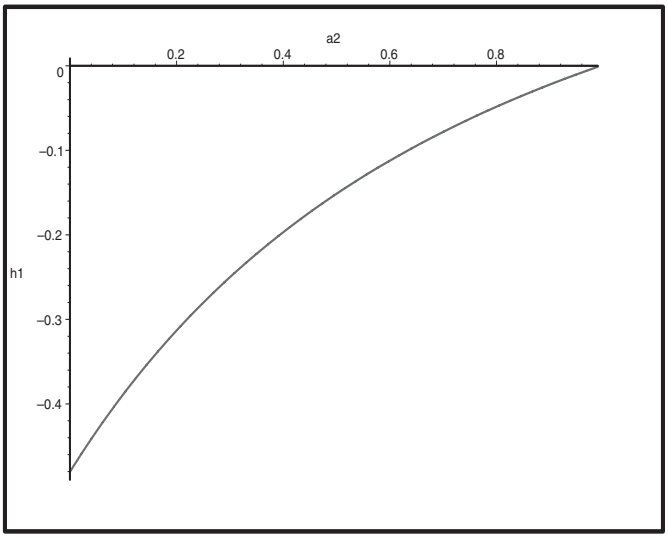

FIG. 5. h_1 *is negative as* a_2 *varies from* 0 *to* 0.9.

$h_2 > 0$ if $0.1589 < a_2 < 0.4891$ (see Figures 5 and 6). Hence, the disease is uniformly persistent in two patches when $0 \le a_2 < 0.1589$ or $0.4891 < a_2 \le 0.9$, and dies out when $0.1589 < a_2 < 0.4891$. This shows that the persistence-extinction-persistence switching phenomenon happens as the dispersal rate a_2 increases from 0.

5. Discussion. Spatial heterogeneity plays an important role in the persistence and dynamics of epidemics. Papers [4, 8, 10, 11] have discussed the effect of immigration of infectious individuals or age structure on the persistence of diseases from different point of views. In [19] we have shown that spatial heterogeneity can increase

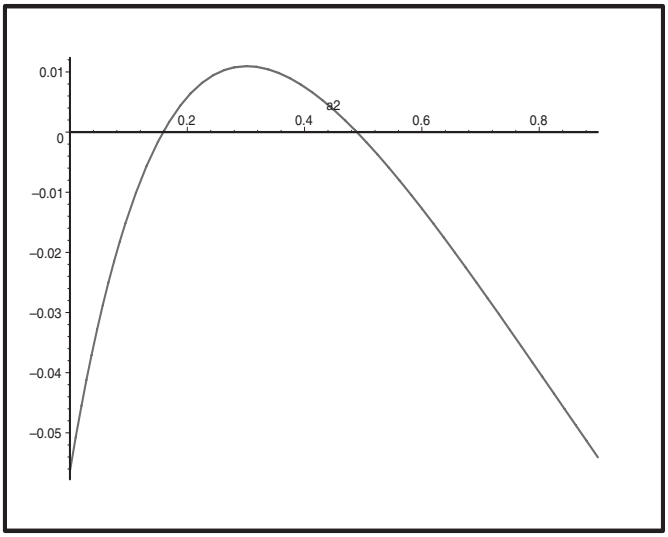

FIG. 6. *h_2 transits from negative value to positive value and then has a second transit from positive to negative as a_2 varies from* 0 *to* 0.9.

the persistence of a disease, and can also reduce the persistence of a disease in the presence of suitable parameters. In this paper, we have proposed an epidemic model with population dispersal among n patches, which may simulate n cities. This is clearly applicable to real situations because data for many diseases are available on a city-by-city scale. We have divided a population into two stages, juvenile stage and adult stage, and assumed that the disease spreads only in adult population. (Sexual diseases are typical examples for this.) The novelty of this paper is that we have incorporated the age structure into the model and studied the effect of the composition of spatial heterogeneity and age heterogeneity. In Theorem 2.1, we have obtained sufficient conditions under which the model admits a unique disease free equilibrium. Then we have defined the reproduction number of the model with many patches according to the ideas in [7, 18]. In Theorems 3.1 and 3.2, we have given sufficient conditions for global extinction and uniform persistence of the disease in terms of the reproduction number. Then we applied our general results to a case in which the birth rates are in the form of (B3) and there are only two patches. We have found that the dispersal of juveniles, although they are immune and cannot transmit the disease, has significant effect on the disease spread. Specifically, in Example 4.1 we have shown that the disease can spread to all patches by increasing the dispersal rate of juveniles in one patch, although the disease dies out in any patch in the absence of the dispersal of juveniles; we have also shown that the disease can die out in all patches by increasing the dispersal rate of juveniles in one patch, although the disease spreads in each patch in the absence of the dispersal of juveniles. Further, we have found the new phenomenon that the disease could undergo persistence-extinction-persistence switches in the sense that the disease admits a transition from uniform persistence to extinction and a second transition from extinction to uniform persistence as the dispersal rate c_2 increases. Example 4.2 shows that this switching phenomenon also happens when juveniles move together with susceptible adults.

The general behavior of the model with more than two patches or with birth rates of other forms is not clear at present. It should be more reasonable to consider

many stages or varying lengths of juvenile stages in different patches. We leave this as future work.

Acknowledgments. We are very grateful to two anonymous referees for careful reading and valuable comments which led to an improvement of our original manuscript.

A MAXIMUM PRINCIPLE FOR BELTRAMI COLOR FLOW*

LORINA DASCAL† AND NIR A. SOCHEN†

Abstract. We study, in this work, the maximum principle for the Beltrami color flow and the stability of the flow's numerical approximation by finite difference schemes. We discuss, in the continuous case, the theoretical properties of this system and prove the maximum principle in the strong and the weak formulations. In the discrete case, all the second order explicit schemes that are currently used violate, in general, the maximum principle. For these schemes we give a theoretical stability proof, accompanied by several numerical examples.

Key words. maximum principle, Beltrami framework, parabolic PDEs, finite difference schemes

1. Introduction.

The maximum principle in its various forms is a powerful and instrumental tool for establishing results concerning existence, uniqueness, and other qualitative properties of linear and nonlinear partial differential equations (PDEs). A complete overview of this subject through 1967 can be found in [14].

We are interested in the property of the maximum principle for Beltrami color flow in the context of scale-space theory. This theory claims that significant information exists in all levels of resolution/scale of the image. It is important to create a simplification process, called a "scale-space," from which the information can be extracted.

The notion of causality in the context of image processing and especially in scale-space and denoising arenas was put forward in the work of Koenderink [10]. In the one-dimensional case it is desirable that the simplification process of the signal not create new maxima. This demand, together with homogeneity, leads to filtering with a Gaussian kernel. The convolution of this kernel with the initial image is the solution of the linear diffusion equation with the initial image as initial condition. For higher-dimensional signals the noncreation of new maxima cannot be achieved. It is usually replaced by a new principle—the noncreation of new level sets. This new principle is called in the scale-space literature "the causality principle." It is directly related, in the scalar case, to the extremum principle as observed by Hummel [7]. The extremum principle is taken as the natural generalization of the causality principle to the vectorial case.

Moreover, the relevance of investigating the maximum principle for the Beltrami flow and other PDE-based models can be seen through the work of Alvarez et al. [1]. In this paper, the authors propose a rigorous connection between scale-space analysis and PDEs. They start from a very natural set of filtering axioms and show that the resulting filtered image must necessarily be the solution of a second order fully nonlinear parabolic PDE. The maximum principle is one of their axioms, which is imposed so that smoothing of the original image is made with no enhancement.

The problem of the discrete maximum principle was studied in many works. This issue is important as it ensures that intensity values in the evolving image are constrained by the initial image values and do not grow without bounds. Perona and Malik [12] proposed a numerical scheme which satisfies this property as proved in [22]. Also the PDE introduced by Catte et al. [3] was proved to satisfy the discrete maximum principle [22].

In this paper we treat the Beltrami flow for color images and study two aspects of the maximum principle (continuous and discrete). First we deal with the continuous formulation of the maximum principle and prove it for both the strong and the weak formulations. The motivation for considering these two formulations is threefold. First, the strong formulation is presented here in order to check the validity of the maximum principle for a smooth solution. Second, this property is generalized for a class of nonregular functions via a weak formulation of the maximum principle. In what concerns the weak formulation, we follow the duality approach of Florack [6] and later Mumford and Gidas [11]. In these works the image is conceived as a generalized function. The duality approach describes the sensor space (also called "device space") as a functional space. The data we usually process, which result from the interaction of the physical/optical data and the sensor, are modeled as an inner product of the sensor function and the "true image." In this context, the set of images is equivalent to the set of linear functionals on the sensor functional space. It is natural from this point of view to study the flow equations on the image space directly. We are able to do so by defining generalized (weak) solutions to our flow equations. Our third motivation lies in the fact that to achieve a proper analysis of images, we must consider functions with less regular structure than the smooth functions we dealt with in the strong formulation. This again leads to the study of weak solutions.

To the best of our knowledge, for highly nonlinear and strongly coupled systems like the one we describe here, no mathematical analysis has been performed even for smooth functions. In previous works [4, 2], well-posedness and the maximum principle were treated for scalar valued functions only and for initial data of Lipschitz type, which excludes discontinuous functions.

In the last part of the paper we study the discrete maximum principle for a certain explicit difference scheme by which the nonlinear differential equation is approximated. We show that to approximate the various derivatives to a given order is not enough to guarantee the maximum principle. This scheme can *violate* the maximum principle. We present, however, a proof of the stability of this scheme along with examples that clearly demonstrate stability while failing to obey the maximum principle.

The paper is organized as follows. In section 2 we review the Beltrami framework. In section 3 we deal with the continuous formulation of the maximum principle. We prove the extremum principle for the strong solution of the parabolic quasi-linear system that characterizes the Beltrami color flow. In section 4 we introduce a weak (generalized) solution for this system and prove the extremum principle in a weak formulation. In section 5 we discuss the properties of the second order central difference scheme, which in general violates the maximum principle. For this scheme we give a theoretical stability proof. In section 6 we present numerical results. We summarize and conclude in section 7.

2. The Beltrami framework. Let us briefly review the Beltrami framework for nonlinear diffusion in computer vision [8, 18, 19].

The space of interest in computer vision such as images, texture, disparity in

stereo-vision, optical flow, and distortion in registration is represented as a *fiber bundle*. The base manifold is the image domain. We consider in this work a flat and compact domain. A nonflat domain is treated, for example, in [17]. The feature space, be it gray-values, color, optical flow, texture, etc., is the fiber space. Any particular image or vector field is a *section* of this fiber bundle. We assume that the Riemannian structure can be defined for the base manifold and for the fiber bundle. Thus, we represent an image and other local features as an embedding map of a Riemannian manifold in a higher-dimensional space—the fiber bundle. The simplest example is a gray-level image which is represented as a two-dimensional surface embedded in $\mathbb{R}^3$. We denote the map by $X : \Sigma \to \mathbb{R}^3$, where Σ is a two-dimensional surface, and we denote the local coordinates on it by (σ^1, σ^2). The map U is given in general by $(U^1(\sigma^1, \sigma^2), U^2(\sigma^1, \sigma^2), U^3(\sigma^1, \sigma^2))$. In our example we represent the map U as follows: $(U^1 = \sigma^1, U^2 = \sigma^2, U^3 = I(\sigma^1, \sigma^2))$. We choose on this surface a Riemannian structure, namely a metric. The metric is a positive definite and symmetric 2-tensor that may be defined through the local distance measurements:

$$ds^2 = g_{11}(d\sigma^1)^2 + 2g_{12}d\sigma^1 d\sigma^2 + g_{22}(d\sigma^2)^2.$$

The canonical choice of coordinates in image processing is Cartesian. For such a choice, which we follow in the rest of the paper, we identify $\sigma^1 = x^1$ and $\sigma^2 = x^2$. We use below the Einstein summation convention in which a pair of upper and lower identical indices is summed over. With this convention, the above equation is written as $ds^2 = g_{ij}dx^i dx^j$. We denote the elements of the inverse of the metric by superscripts $g^{ij} = (g^{-1})_{ij}$, and the determinant by $g = \det(g_{ij})$.

Once the image is defined as an embedding mapping of Riemannian manifolds, it is natural to look for a measure on this space of embedding maps.

2.1. Polyakov action: A measure on the space of embedding maps. Denote by (Σ, g) the image manifold and its metric, and by (M, h) the space-feature manifold and its metric. Then the functional $S[U]$ attaches a real number to a map $U : \Sigma \to M$:

$$S[U^a, g_{ij}, h_{ab}] = \int dV ||dU||^2_{g,h},$$

where dV is a volume element that is expressed in a local coordinate system as $dV = \sqrt{g}dxdy$. The integrand $||dU||^2_{g,h}$ is the Riemannian Frobenius norm of the tangent map. It is expressed in a local coordinate system by $||dU||^2_{g,h} = (\partial_{x_i}U^a)g^{ij}(\partial_{x_j}U^b)h_{ab}$. This functional, for $m = 2$ and $h_{ab} = \delta_{ab}$, was first proposed by Polyakov [13] in the context of high energy physics, and the theory is known as *string theory*.

Let us formulate the Polyakov action in matrix form: (Σ, G) is the image manifold and its metric as before. Similarly, (M, H) is the spatial-feature manifold and its metric. Define

$$A^{ab} = (\vec{\nabla}U^a)^t G^{-1}\vec{\nabla}U^b.$$

The map $U : \Sigma \to M$ has a weight

$$S[U, G, H] = \int d^m\sigma\sqrt{g}\ \mathrm{Tr}(AH),$$

where m is the dimension of Σ and $g = \det(G)$.

Using standard methods in the calculus of variations, the Euler–Lagrange equations with respect to the embedding (assuming a Euclidean embedding space) are (see [18] for explicit derivation)

$$0 = -\frac{1}{2\sqrt{g}} h^{ab} \frac{\delta S}{\delta U^b} = \frac{1}{\sqrt{g}} \partial_{x_i} (\sqrt{g} g^{ij} \partial_{x_j} U^a), \tag{2.1}$$

or in matricial form,

$$0 = -\frac{1}{2\sqrt{g}} h^{ab} \frac{\delta S}{\delta U^b} = \underbrace{\frac{1}{\sqrt{g}} \operatorname{div} (D \nabla U^a)}_{\Delta_g U^a} \tag{2.2}$$

(where the matrix $D = (d^{ij})_{i,j=1,2} = \sqrt{g} G^{-1}$). The extension for non-Euclidean embedding space is treated in [9, 19, 20, 21]. The elements of the induced metric for color images with Cartesian color coordinates are

$$g_{ij} = \delta_{ij} + \beta^2 \sum_{a=1}^{3} U^a_{x_i} U^a_{x_j}, \tag{2.3}$$

where $\beta > 0$ is the ratio between the spatial and color distances, and the subscript of U denotes partial derivation. Note that this metric is different from the Di Zenzo matrix [24] (which is not a metric since it is not positive definite). A generalization of Di Zenzo's gradient for color images was investigated in [23] by constructing an anisotropic vector-valued diffusion model with a common tensor-valued structure descriptor.

The value of the parameter β, present in the elements of the metric g_{ij}, is very important and determines the nature of the flow. In the limit $\beta \to 0$, for example, the flow degenerates to the decoupled channel by channel linear diffusion flow. In the other limit $\beta \to \infty$ we get a new nonlinear flow. The gray-value analogue of this limit is the total variation (TV) flow of [15] (see details in [19]).

Since (g_{ij}) is positive definite, $g \equiv \det(g_{ij}) > 0$ for all σ^i. This factor is the simplest one that does not change the minimization solution while giving a reparameterization invariant expression. The operator that acts on U^a is the natural generalization of the Laplacian from flat spaces to manifolds and is called the Laplace–Beltrami operator, denoted by Δ_g.

The nonlinear diffusion or scale-space equation emerges via the gradient descent minimization:

$$U^a_t = \frac{\partial}{\partial t} U^a = -\frac{1}{2\sqrt{g}} h^{ab} \frac{\delta S}{\delta U^b} = \Delta_g U^a. \tag{2.4}$$

The mathematical properties of this system, together with the initial and boundary conditions which will be detailed below, are studied in the rest of the paper with an emphasis on the extremum principle.

3. The extremum principle in the strong formulation. Here we establish the maximum principle for the strong solution of the initial boundary-value problem which characterizes the Beltrami color flow. We refer to the term "strong solutions" when we talk about solutions which are functions with some smoothness criteria that we detail below. Let us first introduce some notation. We denote the image domain

by Ω. It is a bounded open domain in $\mathbb{R}^2$. We denote by $\partial\Omega$ the boundary of Ω. We define the space-time cylinder $Q_T = \Omega \times (0,T)$, and denote its lateral surface by $S_T = \{(x,t)|x \in \partial\Omega, t \in (0,T)\}$. We also define the parabolic boundary by the union of the bottom and the lateral boundaries of the cylinder $\Gamma_T = \Omega \bigcup S_T$.

The PDE is the gradient descent equation for the Polyakov action, as was described in the previous section. We rearrange the equation by explicitly carrying out the calculation of the derivation operator *div*. The result is the sum of two terms: The first term results from applying the *div* to $\sqrt{g}G^{-1}$, and the second from applying the *div* to the gradient's components $U^a_{x_i}$. Remember that the metric, and consequently its inverse and its determinant, depends on first order derivatives. Applying the *div* operator to it gives rise to second order derivatives of the different channels as well. Rearranging the right-hand side of (2.4) according to the second order derivatives, and the coefficients thereof, we arrive at the following coupled system of PDEs:

$$U^a_t = (F^a_{\ b})^{ij} U^b_{x_i x_j}, \quad (x,t) \in Q_T, \tag{3.1}$$

where $a,b = 1,2,3$ are indices in color space, $i,j = 1,2$ are spatial indices, and summation is applied to all repeated indices. Note that $(F^a_{\ b})$ are nine 2×2 matrices. Denote by $H^a = (U^a_{x_i x_j})_{ij=1}^2$ the Hessian of U^a. This system of PDEs can be written in terms of a trace in the spatial domain as

$$U^a_t = \text{Trace}\left(F^a_{\ b} H^b\right), \quad (x,t) \in Q_T, \tag{3.2}$$

where, as before, the repeated b index implies a summation over the color indices.

The system of PDEs for which we establish the extremum principle is

$$U^a_t = \Delta_g U^a = \frac{1}{\sqrt{g}} \text{div}(D \nabla U^a), \quad U^a = R,G,B, \tag{3.3}$$

where D is defined as before: $D = \sqrt{g}G^{-1}$.

The initial and boundary conditions are

$$U^a(x,0) = U^a_0(x), \quad x \in \Omega, \tag{3.4}$$

$$D\vec{\nabla}U^a \cdot \vec{n}\Big|_{S_T} = 0, \tag{3.5}$$

where $\vec{n}$ is the outer normal to $\partial\Omega$ and the dot product denotes, as usual, the Euclidean scalar product in $\mathbb{R}^2$.

LEMMA 3.1. *The nine* 2×2 *matrices* $(F^a_{\ b})$ *are symmetric, positive definite, and their elements* $(F^a_{\ b})^{ij}$ *are rational functions of the first derivatives of the different channels. These matrix elements are, moreover,* uniformly bounded functions *on* Q_T.

Proof. The proof is by direct calculation. One finds, for example,

$$\left(F^2_{\ 1}\right)^{11} = -R_x G_x \frac{g_{22}^2}{g^2} + (R_x G_y + R_y G_x)\frac{g_{12}g_{22}}{g^2} - \frac{R_y G_y}{g}\left(1 + \frac{g_{12}^2}{g}\right), \tag{3.6}$$

$$\left(F^2_{\ 1}\right)^{12} = \left(F^2_{\ 1}\right)^{21} = \frac{R_x G_y + R_y G_x}{g} - \frac{R_x G_y + R_y G_x}{g^2} g_{11} g_{22} \tag{3.7}$$

$$- \frac{R_x G_y + R_y G_x}{g^2} g_{12}^2 + 2\frac{R_x G_x g_{22} + R_y G_y g_{11}}{g^2} g_{12}^2, \tag{3.8}$$

$$\left(F^2_{\ 3}\right)^{22} = -R_y G_y \frac{g_{11}^2}{g^2} + (R_x G_y + R_y G_x)\frac{g_{11}g_{12}}{g^2} - \frac{R_x G_x}{g}\left(1 + \frac{g_{12}^2}{g}\right) \tag{3.9}$$

(here we have denoted by R, G, B the three components of the color vector $\overrightarrow{U}$).

These are rational functions of the first derivatives. The diagonal elements of (F^a_b) are strictly positive (by a direct check), and the negativity of the discriminant implies the positive definiteness of these matrices. One can verify directly that the coefficients are bounded functions of the first derivatives. These properties are verified along the same lines for all matrices. □

Next we state the maximum principle for the strong solutions of the coupled system of PDEs (3.3), with initial data (3.4) and boundary condition (3.5).

THEOREM 3.2. *Let $\overrightarrow{U_0} \in C^2(\Omega)$. Then a solution $\overrightarrow{U} \in C^{2,1}(\bar{Q}_T)$ satisfies the following maximum principle:*

$$(1) \quad \max_{\bar{Q}_T} \sum_{a=1}^{3} U^a = \max_{\Omega} \sum_{a=1}^{3} U_0^a, \tag{3.10}$$

$$(2) \quad \max_{\bar{Q}_T} U^a = \max_{\Omega} U_0^a. \tag{3.11}$$

Proof. Note that assertion (2) does not imply, in general, assertion (1). We start by proving assertion (1). Consider the following system of inequalities:

$$V_t^a < (F^a_b)^{ij} V^b_{x_i x_j}, \quad (x,t) \in Q_T, \tag{3.12}$$

where $F^a_b = F^a_b(\nabla \vec{V})$.

We now show that a smooth solution of this system of inequalities satisfies

$$\max_{\bar{Q}_T} \sum_{a=1}^{3} V^a = \max_{\Gamma_T} \sum_{a=1}^{3} V^a. \tag{3.13}$$

Let $\bar{V} = \sum_{a=1}^{3} V^a$, and suppose on the contrary that the maximum of $\bar{V}$ is attained at an interior point $(x_0, t_0) \in \bar{Q}_T \backslash \Gamma_T$. This assumption leads to a contradiction as follows: The maximality at the point (x_0, t_0) implies

$$\bar{V}_t|_{(x_0,t_0)} \geq 0 \quad (\bar{V}_t|_{(x_0,t_0)} = 0 \quad \text{if} \quad 0 \leq t_0 < T). \tag{3.14}$$

Based on (2.1), the system of inequalities (3.12) is equivalent to

$$V_t^a < \frac{1}{\sqrt{g}} \partial_{x_i} (g^{ij} \sqrt{g} \partial_{x_j} V^a), \quad (x,t) \in Q_T. \tag{3.15}$$

Since the Laplace–Beltrami operator that acts on the components depends only on the geometry, the sum of the components obeys the same inequality:

$$\bar{V}_t < \frac{1}{\sqrt{g}} \partial_{x_i} (g^{ij} \sqrt{g} \partial_{x_j} \bar{V}). \tag{3.16}$$

On the other hand, carrying out the *div* computation explicitly, we rewrite this inequality as

$$\frac{1}{\sqrt{g}} \partial_{x_i} (g^{ij} \sqrt{g} \partial_{x_j} \bar{V}) = g^{ij} \bar{V}_{x_i x_j} + \omega^j \bar{V}_{x_j}.$$

The functions ω^j depend on the first and second derivatives of each of the components of the color vector. They are bounded on Q_T by the smoothness of $\overrightarrow{V} \in C^{2,1}(\bar{Q}_T)$.

The positive definiteness of the matrix g^{ij} and the maximality at the point (x_0, t_0) imply

$$\frac{1}{\sqrt{g}}\partial_{x_i}(g^{ij}\sqrt{g}\partial_{x_j}\bar{V})|_{(x_0,t_0)} = g^{ij}\bar{V}_{x_ix_j}|_{(x_0,t_0)} < 0. \tag{3.17}$$

Clearly (3.14) and (3.17) contradict (3.16). We conclude that (3.13) holds for a solution of the system of inequalities (3.12).

Using the result for the solution of the system of inequalities, we prove the result concerning the solution $\vec{U}$ of our system (3.3). We define $W^a = U^a - \epsilon t$ and $\bar{W} = \sum_1^3 W^a$, $\bar{U} = \sum_1^3 U^a$. Then $\nabla W^a = \nabla U^a$, $g_{ij}(\vec{W}) = g_{ij}(\vec{U})$ and we obtain the following inequalities:

$$W_t^a - \frac{1}{\sqrt{g}}\partial_{x_i}(g^{ij}\sqrt{g}\partial_{x_j}W^a) = U_t^a - \frac{1}{\sqrt{g}}\partial_{x_i}(g^{ij}\sqrt{g}\partial_{x_j}U^a) - \epsilon < 0. \tag{3.18}$$

Since $\vec{W} = (W^a)_{a=1,2,3}$ satisfies (3.18), it follows that

$$\max_{\bar{Q}_T}\bar{W} = \max_{\Gamma_T}\bar{W}.$$

Letting $\epsilon \to 0$, we establish that

$$\max_{\bar{Q}_T}\bar{U} = \max_{\Gamma_T}\bar{U}.$$

Due to the boundary condition (3.5), the maximum cannot be attained on S_T (see [14, pp. 65–67]). Therefore assertion (1) is proved.

Next we prove assertion (2). Observe first that the off-diagonal matrices $F^a_{\ b}$ with $a \neq b$ can be written as $U^a_{x_i}$ times a bounded function. Taking, for example, $(a, b) = (1, 2)$, one finds by rearranging the terms in (3.1) that

$$(F_2^1)^{ij} = U^1_{x_1} \cdot f_1^{ij}(\nabla\overrightarrow{U}) + U^1_{x_2} \cdot f_2^{ij}(\nabla\overrightarrow{U}). \tag{3.19}$$

Thus if $i = 1, j = 1$, for example, then

$$f_1^{11} = -U^2_{x_1}\frac{g_{22}^2}{g^2} + U^2_{x_2}\frac{g_{12}g_{22}}{g^2}, \qquad f_2^{11} = U^2_{x_1}\frac{g_{12}g_{22}}{g^2} + U^2_{x_2}\left(\frac{g_{22}^2}{g^2} + \frac{1}{g}\right).$$

One can write the other off-diagonal matrices similarly. For the structure of the induced metric, we can easily see that

$$g \geq 1, \quad \frac{g_{ij}}{g} \leq 1 \quad \text{for all} \quad i, j = 1, 2. \tag{3.20}$$

Since the solution $\overrightarrow{U}$ is in $C^{2,1}(\bar{Q}_T)$, one can readily establish, using (3.20), that the functions f_1^{ij}, f_2^{ij} are bounded on Q_T. We can, therefore, write the first equation of the system (3.1), (3.4), (3.5) in the following form:

$$U_t^1 = (F_1^1)^{ij}U^1_{x_ix_j} + U^2_{x_ix_j}(U^1_{x_1}f_1^{ij} + U^1_{x_2}f_2^{ij}) + U^3_{x_ix_j}(U^1_{x_1}g_1^{ij} + U^1_{x_2}g_2^{ij}), \tag{3.21}$$

where g_1^{ij}, g_2^{ij} are, as above, bounded functions depending on the first derivatives of the vector solution $\overrightarrow{U}$. We rewrite this equation:

$$U_t^1 = (F_1^1)^{ij}U^1_{x_ix_j} + T^iU^1_{x_i},$$

where T^i are continuous functions on a compact domain and therefore bounded functions. Again using the maximality of the point (x_0, t_0), the positive definiteness of the matrix F_1^1, and reasoning similar to that in the proof of assertion (1), we can conclude that

$$\max_{\bar{Q}_T} U^1 = \max_{\Omega} U_0^1.$$

For the other two components the proof is the same, mutatis mutandis. Thus assertion (2) is proved. □

In the next section we define a weak solution for the Beltrami color flow and prove that it obeys the extremum principle if it exists.

4. Weak formulation of the extremum principle. In this section we define a weak solution of the system (3.3), (3.4), (3.5) under the smoothness assumptions that are detailed below. We further prove the extremum principle for this type of solution.

Let us introduce the following notations. Denote by $V(Q_T)$ the space of functions which belong to $L^2(Q_T)$ and have first weak derivatives satisfying $\nabla u \in L^\infty(Q_T)$, $u_t \in L^\infty(Q_T)$. The Sobolev space $W_r^{p,q}$ is the space of functions for which the L_r norm of their first generalized p spatial derivatives and q time derivatives is finite (below we omit the second superscript for functions on the spatial domain only).

First we define a weak solution as follows.

DEFINITION 4.1. *A weak solution of the system* (3.3)*, with initial and boundary conditions* (3.4), (3.5)*, is a vector function* $\vec{U} \in V(Q_T)$ *such that for any vector function* $\vec{\eta} \in V(Q_T)$ *(i.e., each of the components of the vector are in* $V(Q_T)$*) the following integral identities hold for almost all* $t \in [0, T]$:

$$\int_{Q_T} U_t^a \eta^a \sqrt{g}\, dxdt + \int_{Q_T} g^{ij} U_{x_i}^a \eta_{x_j}^a \sqrt{g}\, dxdt = 0. \tag{4.1}$$

Remark 4.1. The integral $\int_\Omega \sqrt{g}\, dx$ means the area of the two-dimensional manifold embedded in R^5.

Remark 4.2. Florack [6], in viewing an image as a tempered distribution (see [16]), adopted the space of the so-called slow growth functions (smooth functions of rapid decay) as the sensor space. In this paper we take $V(Q_T)$ as the sensor functional space, which we choose in accordance with the weak formulation of our problem.

Next we prove that if a weak solution exists and it satisfies $\nabla(\vec{U}_t) \in L^\infty(Q_T)$, the following weak extremum principle holds.

THEOREM 4.1. *Assume the initial data* $\vec{U_0} \in W_2^1(\Omega)$*. For a weak solution of the system* (3.3), (3.4), (3.5) *such that* $\nabla(\vec{U}_t) \in L^\infty(Q_T)$ *we have for almost all* $(x, t) \in Q_T$

$$\operatorname*{ess\,inf}_{\Omega} U_0^a \le U^a(x,t) \le \operatorname*{ess\,sup}_{\Omega} U_0^a. \tag{4.2}$$

Proof. We prove (4.2) for one of the components. We divide the cylinder Q_T into a finite number of cylinders of equal height $Q_{t_s} = \Omega \times (t_{s-1}, t_s)$, where $t_s = \frac{T}{N} s$ and $s = 1, 2, \ldots, N$. For the cylinder Q_{t_1} we define $k_a = \operatorname{ess\,sup}_\Omega U_0^a(x)$ and $(U^a)^{k_a} = \max\{0, U^a - k_a\}$ for $(x, t) \in \Omega \times (0, t_1)$.

Choose the test function $\eta^1 = R^{k_1}$. Note that by the hypothesis, $\vec{U} \in V(Q_T)$, and therefore the choice of such η is justified. Identity (4.1) for component R is now

$$\int_{Q_{t_1}} R_t R^{k_1} \sqrt{g} dxdt + \int_{Q_{t_1}} d^{ij} R_{x_i} R_{x_j}^{k_1}\, dx\, dt = 0. \tag{4.3}$$

Since the matrix D ($D = \sqrt{g}G^{-1}$) depends on the gradient $\nabla\vec{U}$ and $\nabla\vec{U} \in L^\infty(Q_{t_1})$, we have that D is a uniformly positive definite matrix, and thus there exists a constant $\nu > 0$ such that

$$d^{ij}(\nabla\bar{U})R_{x_i}R^{k_1}_{x_j} \geq \nu|\nabla R^{k_1}|^2 \quad \text{for almost every} \quad (x,t) \in Q_{t_1}.$$

Therefore, (4.3) for the component R becomes

$$\int_{Q_{t_1}} R_t R^{k_1}\sqrt{g}dxdt + \nu\int_{Q_{t_1}} |\nabla R|^2\,dx\,dt \leq 0. \tag{4.4}$$

Since for almost all $t \in (0,t_1)$

$$\int_\Omega R_t(x,t)R^{k_1}(x,t)\,dx = \frac{1}{2}\frac{d}{dt}\int_\Omega \left(R^{k_1}(x,t)\right)^2 dx,$$

we get

$$\int_{Q_{t_1}} R_t R^{k_1}\sqrt{g}\,dx\,dt = \frac{1}{2}\int_{Q_{t_1}} ((R^{k_1})^2)_t\sqrt{g}\,dx\,dt \tag{4.5}$$

$$= \frac{1}{2}\left(\int_\Omega (R^{k_1})^2\sqrt{g}\Big|_0^{t_1} dx - \int_{Q_{t_1}} (R^{k_1})^2(\sqrt{g})_t\,dx\,dt\right), \tag{4.6}$$

and using (4.4), we get

$$\frac{1}{2}\int_\Omega \left(R^{k_1}(x,t)\right)^2\Big|_{t=t_1} dx + \nu\int_{Q_{t_1}} |\nabla R^{k_1}|^2 dxdt \leq \frac{1}{2}\int_{Q_{t_1}} (R^{k_1})^2(\sqrt{g})_t\,dx\,dt + \frac{1}{2}\int_\Omega (R_0^{k_1})^2\sqrt{g_0}\,dx. \tag{4.7}$$

Since $\vec{U_0} \in W_2^1(\Omega)$ and $R^{k_1}(x,0) = R_0^{k_1} = 0$, then $\int_\Omega (R_0^{k_1})^2\sqrt{g_0}\,dx = 0$ and (4.7) becomes

$$\frac{1}{2}\int_\Omega \left(R^{k_1}(x,t)\right)^2 dx + \nu\int_{Q_{t_1}} |\nabla R^{k_1}|^2\,dx\,dt \leq \frac{1}{2}\int_{Q_{t_1}} (R^{k_1})^2(\sqrt{g})_t\,dx\,dt. \tag{4.8}$$

Denote by $||\cdot||_{V(Q_T)}$ the norm on the space $V(Q_T)$, where

$$||u||_{V(Q_T)} = \max_{0\leq t\leq T} ||u||_{L^2(\Omega)} + \sqrt{\int_{Q_T} |\nabla u|^2\,dx\,dt}.$$

By assumption, $\vec{U}_{tx} \in L^\infty(Q_T)$, and then there exists a positive constant C such that $C = \sup_{Q_T}(\sqrt{g})_t$.

The Cauchy–Schwarz inequality leads us to

$$\left|\int_{Q_{t_1}} (R^{k_1})^2(\sqrt{g})_t\,dx\,dt\right| \leq C\int_{Q_{t_1}} (R^{k_1})^2\,dx\,dt$$

$$\leq Ct_1\left(\max_{0\leq t\leq t_1} ||R^{k_1}||_{L^2(\Omega)}\right)^2 \leq Ct_1||R^{k_1}||^2_{V(Q_{t_1})}. \tag{4.9}$$

Therefore (4.8) becomes

$$\min\left\{\frac{1}{2},\nu\right\}||R^{k_1}||^2_{V(Q_{t_1})} \leq Ct_1||R^{k_1}||^2_{V(Q_{t_1})}.$$

Then for sufficiently small t_1 such that

$$Ct_1 < \min\left\{\frac{1}{2},\nu\right\}, \tag{4.10}$$

we obtain $||R^{k_1}||_{V(Q_{t_1})} = 0$, which implies that for almost every $(x,t) \in \Omega \times (0,t_1)$ we have

$$R(x,t) \leq \operatorname{ess\,sup}_{\Omega} R_0.$$

The same argument is valid for the cylinders $Q_{t_s} = \Omega \times (t_{s-1}, t_s)$, $2 \leq s \leq N$, as long as their height satisfies the requirement analogue of (4.10). Thus, after a finite number of steps we obtain for the component R the estimate (4.2), for almost every $(x,t) \in Q_T$. □

In a similar way we can proceed with the other components.

5. The discrete maximum principle and stability. In this section we show that the commonly used central difference second order explicit schemes in general violate the discrete maximum principle. Nevertheless, for these schemes, we give a theoretical proof of stability.

We work on a rectangular grid

$$x_i = i\Delta x, \quad y_j = j\Delta y, \quad t_m = m\Delta t,$$

$$i,j = 0,1,2,\ldots,M, \quad m = 0,1,2,\ldots,\left[\frac{T}{\Delta t}\right].$$

The spatial units are normalized such that $\Delta x = \Delta y = 1$. The approximate solution $(R^m_{ij}, G^m_{ij}, B^m_{ij})$ samples the functions

$$R^m_{ij} \equiv U^1(i\Delta x, j\Delta y, m\Delta t),$$

$$G^m_{ij} \equiv U^2(i\Delta x, j\Delta y, m\Delta t),$$

$$B^m_{ij} \equiv U^3(i\Delta x, j\Delta y, m\Delta t).$$

On the boundary we impose the Neumann boundary condition. This corresponds to a prolongation by reflection of the image across the boundary.

We replace the second spatial derivatives and the first time derivative by a central difference and forward difference, respectively. Based on (2.4), the first element R of the color vector satisfies the following equation:

$$R_t = \frac{1}{\sqrt{g}}\operatorname{div}(D\nabla R). \tag{5.1}$$

The diffusion matrix is written here as

$$D = \begin{pmatrix} a & b \\ b & c \end{pmatrix},$$

where the coefficients are given in terms of the image metric $a = g_{22}/\sqrt{g}$, $c = g_{11}/\sqrt{g}$, $b = -g_{12}/\sqrt{g}$. With this notation, (5.1) is written as

$$R_t = \frac{1}{\sqrt{g}}((aR_x + bR_y)_x + (bR_x + cR_y)_y). \tag{5.2}$$

We approximate (5.2) by the following central difference explicit scheme:

$$R_{ij}^{m+1} = R_{ij}^m + \beta \Delta t O_{ij}(R^m, G^m, B^m), \tag{5.3}$$

where $O_{ij}(R^m, G^m, B^m)$ is the discrete version of the right-hand side of (5.1) and is given explicitly, in the central difference framework, by

(5.4)

$$\begin{aligned} O_{ij} \;=\; & \frac{1}{\sqrt{g}_{i,j}^m}\Big[a_{i+\frac{1}{2},j}^m(R_{i+1,j}^m - R_{i,j}^m) - a_{i-\frac{1}{2},j}^m(R_{i,j}^m - R_{i-1,j}^m) \\ & + c_{i,j+\frac{1}{2}}^m(R_{i,j+1}^m - R_{i,j}^m) - c_{i,j-\frac{1}{2}}^m(R_{i,j}^m - R_{i,j-1}^m) \\ & + \frac{1}{4}b_{i,j+1}^m(R_{i+1,j+1}^m - R_{i-1,j+1}^m) - \frac{1}{4}b_{i,j-1}^m(R_{i+1,j-1}^m - R_{i-1,j-1}^m) \\ & + \frac{1}{4}b_{i+1,j}^m(R_{i+1,j+1}^m - R_{i+1,j-1}^m) - \frac{1}{4}b_{i-1,j}^m(R_{i-1,j+1}^m - R_{i-1,j-1}^m)\Big], \end{aligned}$$

where the half indices are obtained by linear interpolation. The equations for the two other color components are discretized in the same manner. This scheme is stable under CFL-like bound requirements of the time step. The stability, as well as the lack of extremum principle property, can be seen in the following theorem.

THEOREM 5.1. *If, for all* $m = 0, 1, 2, \ldots, [\frac{T}{\Delta t}]$, Δt *satisfies the condition*

$$\Delta t \le \frac{1}{8\beta \max\limits_{i,j}\left\{\frac{a_{i+\frac{1}{2},j}^m}{\sqrt{g_{i,j}^m}}, \frac{a_{i-\frac{1}{2},j}^m}{\sqrt{g_{i,j}^m}}, \frac{c_{i,j+\frac{1}{2}}^m}{\sqrt{g_{i,j}^m}}, \frac{c_{i,j-\frac{1}{2}}^m}{\sqrt{g_{i,j}^m}}\right\}}, \tag{5.5}$$

then the solution satisfies

$$\begin{aligned} |R_{i,j}^m| &\le e^{S\frac{\beta}{2}t_m} \max_{i,j}|R_{i,j}^0|, \\ |G_{i,j}^m| &\le e^{S\frac{\beta}{2}t_m} \max_{i,j}|G_{i,j}^0|, \\ |B_{i,j}^m| &\le e^{S\frac{\beta}{2}t_m} \max_{i,j}|B_{i,j}^0|, \end{aligned} \tag{5.6}$$

where

(5.7)

$$S = \max_{0\le p\le m} S_p \text{ and } S_p = \max_{i,j}\frac{|b_{i,j+1}^p|}{\sqrt{g_{ij}^p}} + \max_{i,j}\frac{|b_{i,j-1}^p|}{\sqrt{g_{ij}^p}} + \max_{i,j}\frac{|b_{i+1,j}^p|}{\sqrt{g_{ij}^p}} + \max_{i,j}\frac{|b_{i-1,j}^p|}{\sqrt{g_{ij}^p}}.$$

Proof. We give the proof for only one of the components, since the proof is the same for the other two. We introduce the following notation:

$$L_{ij}^m = a_{i+\frac{1}{2},j}^m (R_{i+1,j}^m - R_{i,j}^m) - a_{i-\frac{1}{2},j}^m (R_{i,j}^m - R_{i-1,j}^m), \tag{5.8}$$

$$M_{ij}^m = c_{i,j+\frac{1}{2}}^m (R_{i,j+1}^m - R_{i,j}^m) - c_{i,j-\frac{1}{2},j}^m (R_{i,j}^m - R_{i,j-1}^m), \tag{5.9}$$

$$N_{ij}^m = \frac{1}{4}\Big[b_{i,j+1}^m (R_{i+1,j+1}^m - R_{i-1,j+1}^m) - b_{i,j-1}^m (R_{i+1,j-1}^m - R_{i-1,j-1}^m)\Big], \tag{5.10}$$

$$P_{ij}^m = \frac{1}{4}\Big[b_{i+1,j}^m (R_{i+1,j+1}^m - R_{i+1,j-1}^m) - b_{i-1,j}^m (R_{i-1,j+1}^m - R_{i-1,j-1}^m)\Big]. \tag{5.11}$$

Therefore, using (5.3) and (5.5), we can write

$$\begin{aligned}\left|R_{ij}^{m+1}\right| \le \frac{1}{2}\left|R_{ij}^m\right| + \left|\frac{1}{4}R_{ij}^m + \beta\frac{\Delta t}{\sqrt{g_{ij}^m}}L_{ij}^m\right| + \left|\frac{1}{4}R_{ij}^m + \beta\frac{\Delta t}{\sqrt{g_{ij}^m}}M_{ij}^m\right| \\ + \left|\beta\frac{\Delta t}{\sqrt{g_{ij}^m}}N_{ij}^m\right| + \left|\beta\frac{\Delta t}{\sqrt{g_{ij}^m}}P_{ij}^m\right| .\end{aligned} \tag{5.12}$$

If

$$\Delta t \le \frac{1}{8\beta \max\limits_{i,j} \frac{a_{i+\frac{1}{2},j}^m}{\sqrt{g_{i,j}^m}}}$$

for all $m = 0, 1, 2, \ldots, [\frac{T}{\Delta t}]$, then

$$\begin{aligned}&\left|\frac{1}{8}R_{ij}^m + \beta\frac{\Delta t}{\sqrt{g_{ij}^m}}a_{i+\frac{1}{2},j}^m (R_{i+1,j}^m - R_{i,j}^m)\right| \\ &\qquad \le \max(|R_{i,j}^m|, |R_{i+1,j}^m|)\left(\frac{1}{8} - \frac{\beta\Delta t}{\sqrt{g_{ij}^m}}a_{i+\frac{1}{2},j}^m + \frac{\beta\Delta t}{\sqrt{g_{ij}^m}}a_{i+\frac{1}{2},j}^m\right),\end{aligned}$$

which implies

$$\left|\frac{1}{8}R_{ij}^m + \beta\frac{\Delta t}{\sqrt{g_{ij}^m}}a_{i+\frac{1}{2},j}^m (R_{i+1,j}^m - R_{i,j}^m)\right| \le \frac{1}{8}\max_{i,j}|R_{ij}^m| .$$

Thus we can get the estimate

$$\left|2\cdot\frac{1}{8}R_{ij}^m + \beta\frac{\Delta t}{\sqrt{g_{ij}^m}}L_{ij}^m\right| \le \frac{1}{4}\max_{ij}|R_{ij}^m| \quad \text{if} \quad \Delta t \le \frac{1}{8\beta\max\limits_{i,j}\left\{\frac{a_{i+\frac{1}{2},j}^m}{\sqrt{g_{i,j}^m}}, \frac{a_{i-\frac{1}{2},j}^m}{\sqrt{g_{i,j}^m}}\right\}} . \tag{5.13}$$

In the same way we obtain

$$\left|2\cdot\frac{1}{8}R_{ij}^m + \beta\frac{\Delta t}{\sqrt{g_{ij}^m}}M_{ij}^m\right| \le \frac{1}{4}\max_{ij}|R_{ij}^m| \quad \text{if} \quad \Delta t \le \frac{1}{8\beta\max\limits_{i,j}\left\{\frac{c_{i,j+\frac{1}{2}}^m}{\sqrt{g_{i,j}^m}}, \frac{c_{i,j-\frac{1}{2}}^m}{\sqrt{g_{i,j}^m}}\right\}} . \tag{5.14}$$

Let

$$N_{i,j}^{m,1} = \beta \frac{\Delta t}{4\sqrt{g_{ij}^m}} b_{i,j+1}^m (R_{i+1,j+1}^m - R_{i-1,j+1}^m)$$

and

$$N_{i,j}^{m,2} = \beta \frac{\Delta t}{4\sqrt{g_{ij}^m}} b_{i,j-1}^m (R_{i+1,j-1}^m - R_{i-1,j-1}^m).$$

Then we obtain for $N_{i,j}^{m,1}$

$$|N_{i,j}^{m,1}| \le 2 \cdot \beta \frac{\Delta t}{4\sqrt{g_{ij}^m}} |b_{i,j+1}^m| \max_{ij} |R_{i,j}^m|. \tag{5.15}$$

A similar inequality can be written for $|N_{i,j}^{m,2}|$ and for $|P_{i,j}^m|$. Thus we have

$$\begin{aligned} |N_{ij}^m| &\le \beta \frac{\Delta t}{2\sqrt{g_{ij}^m}} (|b_{i,j+1}^m| + |b_{i,j-1}^m|) \max_{ij} |R_{i,j}^m| \\ &\le \frac{\beta}{2} \Delta t \left(\max_{i,j} \frac{|b_{i,j+1}^m|}{\sqrt{g_{ij}^m}} + \max_{i,j} \frac{|b_{i,j-1}^m|}{\sqrt{g_{ij}^m}} \right) \max_{ij} |R_{i,j}^m| \end{aligned} \tag{5.16}$$

and

$$\begin{aligned} |P_{ij}^m| &\le \beta \frac{\Delta t}{2\sqrt{g_{ij}^m}} (|b_{i+1,j}^m| + |b_{i-1,j}^m|) \max_{ij} |R_{i,j}^m| \\ &\le \frac{\beta}{2} \Delta t \left(\max_{i,j} \frac{|b_{i+1,j}^m|}{\sqrt{g_{ij}^m}} + \max_{i,j} \frac{|b_{i-1,j}^m|}{\sqrt{g_{ij}^m}} \right) \max_{ij} |R_{i,j}^m|. \end{aligned} \tag{5.17}$$

From (5.13)–(5.17) it follows that

$$\begin{aligned} &|R_{ij}^{m+1}| \\ &\le \max_{i,j} |R_{ij}^m| \left(1 + \frac{\beta}{2} \Delta t \left(\max_{i,j} \frac{|b_{i,j+1}^m|}{\sqrt{g_{ij}^m}} + \max_{i,j} \frac{|b_{i,j-1}^m|}{\sqrt{g_{ij}^m}} + \max_{i,j} \frac{|b_{i+1,j}^m|}{\sqrt{g_{ij}^m}} + \max_{i,j} \frac{|b_{i-1,j}^m|}{\sqrt{g_{ij}^m}} \right) \right) \end{aligned} \tag{5.18}$$

if

$$\Delta t \le \frac{1}{8\beta \max\limits_{i,j} \left\{ \frac{a_{i+\frac{1}{2},j}^m}{\sqrt{g_{i,j}^m}}, \frac{a_{i-\frac{1}{2},j}^m}{\sqrt{g_{i,j}}}, \frac{c_{i,j+\frac{1}{2}}^m}{\sqrt{g_{i,j}^m}}, \frac{c_{i,j-\frac{1}{2}}^m}{\sqrt{g_{i,j}^m}} \right\}}. \tag{5.19}$$

Let

$$M_1^m = \max_{i,j} \frac{|b_{i,j+1}^m|}{\sqrt{g_{ij}^m}}, \qquad M_2^m = \max_{i,j} \frac{|b_{i,j-1}^m|}{\sqrt{g_{ij}^m}}$$

and

$$M_3^m = \max_{i,j} \frac{|b_{i+1,j}^m|}{\sqrt{g_{ij}^m}}, \qquad M_4^m = \max_{i,j} \frac{|b_{i-1,j}^m|}{\sqrt{g_{ij}^m}}.$$

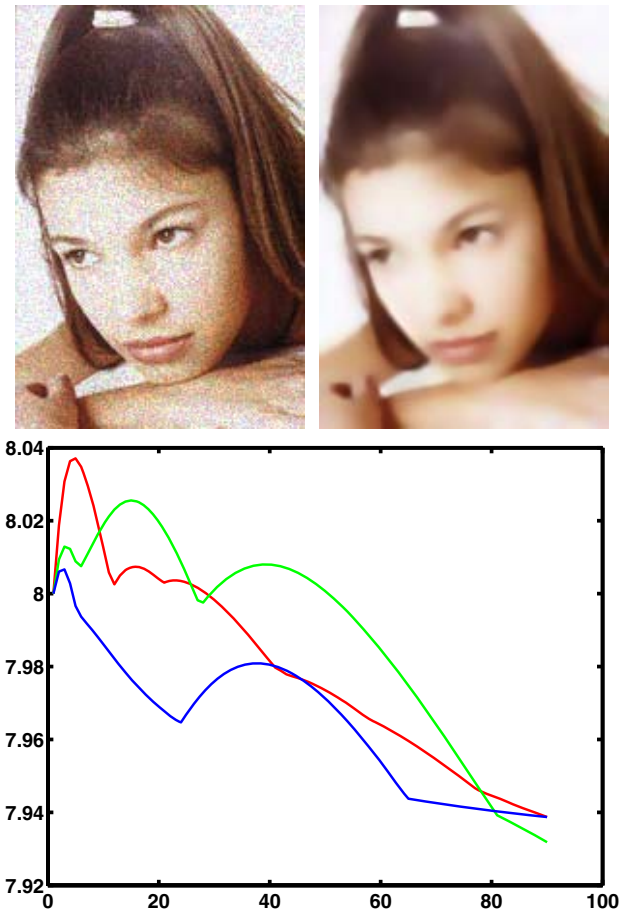

FIG. 5.1. *Top-left: noisy Camila image. Top-right: result of the Beltrami flow after* 90 *iteration. Bottom: plot of maximum of each of the channels versus number of iterations. Parameters:* $\beta^2 = 100$, $\Delta t = 0.0091$.

Next, applying (5.18) repeatedly, we find that if condition (5.19) is satisfied, then

$$\begin{aligned}|R_{ij}^m| &\le \left(1+\frac{\beta}{2}\Delta t S_{m-1}\right)\left(1+\frac{\beta}{2}\Delta t S_{m-2}\right)\cdots\left(1+\frac{\beta}{2}\Delta t S_0\right)\max_{i,j}|R_{i,j}^0| \\ &\le \left(1+\frac{\beta}{2}\Delta t S\right)^m \max_{i,j}|R_{i,j}^0| \le e^{\frac{\beta}{2}t_m S}\max_{i,j}|R_{i,j}^0|,\end{aligned}$$

where S is given in (5.7). □

The inequalities (5.6) clearly show that the maximum principle can be violated, but we still have stability. The inequalities in Theorem 5.1 show that the numerical solution is bounded in each iteration by the maximum value of the initial image multiplied by a factor. It guarantees that the flow does not blow up in finite time and ensures its stability. At the same time it is clear from the positivity of β that the maximum principle can be violated. One can actually see it in practice (see Figures 5.1, 5.2, and 5.3). We note that this does not indicate that the scheme is not accurate. This situation is not unprecedented. The Crank–Nicolson scheme for the

one-dimensional heat equation, for example, is also known not to obey the maximum principle while being a useful and accurate scheme.

The reason for this discrepancy between the continuous and the discrete setting is that this second order approximation is not a nonnegative one. Indeed, the mixed

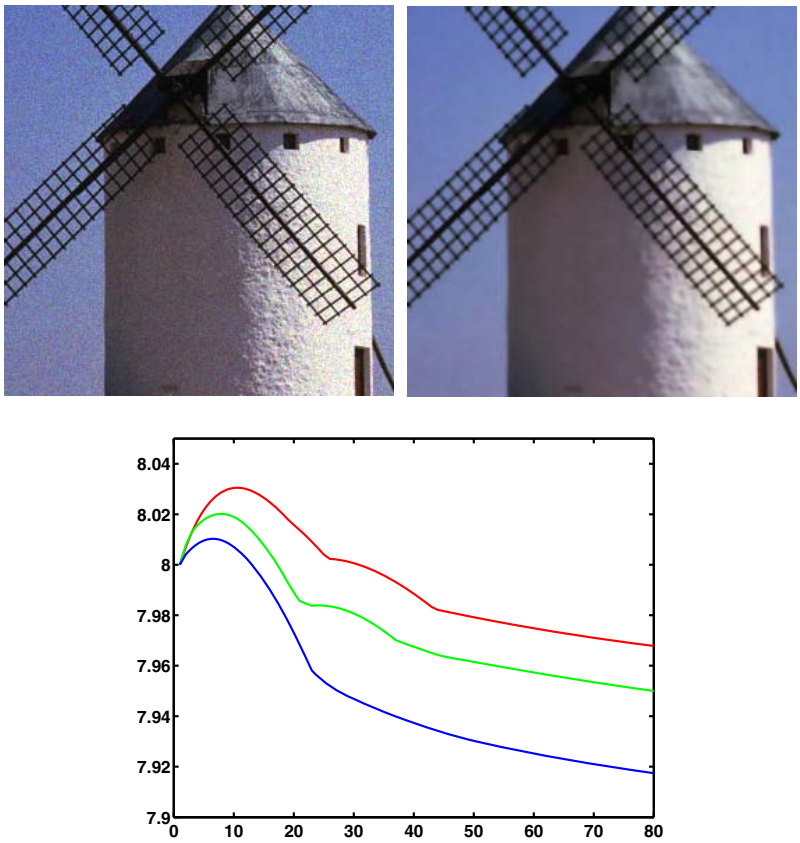

FIG. 5.3. *Top-left: noisy windmill. Top-right: denoised image by the Beltrami flow after* 80 *iterations. Bottom: plot of maximum of each of the channels versus number of iterations. Parameters:* β^2=3, $\Delta t = 0.0091$.

derivatives in (5.2) can create negative weights in certain pixels. One can easily show that a scheme which is based on a nonnegative discretization does satisfy the discrete maximum principle. Based on this result, the problem of proving the discrete maximum principle boils down to the problem of finding a nonnegative second order difference approximation. In [22], Weickert proposed a way to build a nonnegative scheme. The nonnegativity of his proposed scheme depends, however, on the condition number of the diffusion tensor D. Only in pixels where the condition number is smaller than $3 + 2\sqrt{2}$ are the weights nonnegative. This limits the application of the scheme, since in many images the condition number is higher than this limit in many pixels.

6. Details of the implementation and results. In this section we present results that represent the numerical behavior of the above described numerical scheme. The initial data are given in three channels r, g, and b in the range 0 to 255. We first transfer the images to the more perceptually adaptive coordinates $R = \log(1+r)$, $G = \log(1+g)$, $B = \log(1+b)$. The dynamic range of these variables is 0 to 8, and these adaptive coordinates do not limit the generality of our analysis. In the two examples presented below we corrupt the images with random noise and then denoise them using the scheme mentioned above. In the implementation, the parameters β and Δt were chosen to satisfy the stability condition (5.5).

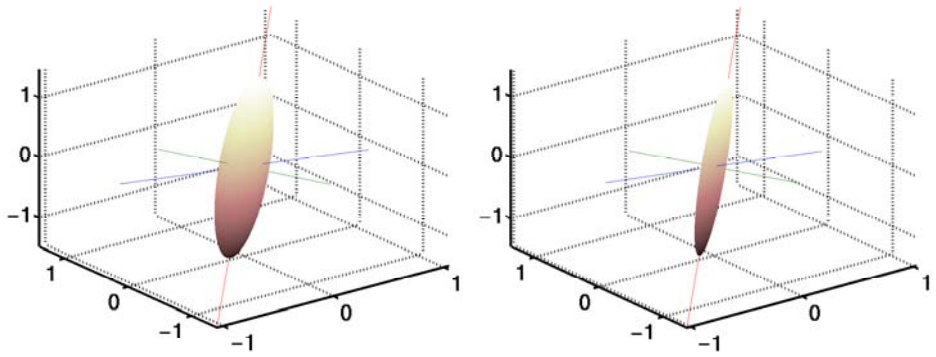

FIG. 6.1. *Camila image. Left: ellipsoid—initial noisy data. Right: ellipsoid—after applying Beltrami,* 90 *iterations,* $\beta = 10$.

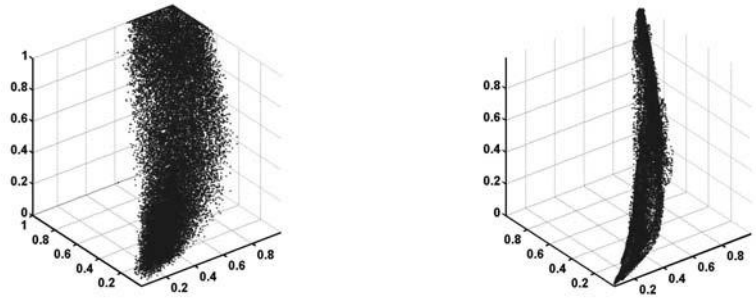

FIG. 6.2. *For Camila image* ($\beta = 10$). *Left: distribution of the initial noisy data. Right: distribution of the data after* 100 *iterations.*

Figures 5.1, 5.2, and 5.3 all demonstrate the stability of the process, on the one hand, and the violation of the maximum principle, on the other. In Figures 5.2 and 5.3, one notices that after a certain small number of iterations the maximum principle is satisfied. This is not the case in Figure 5.1, where the violation of the maximum principle is stable and is observable over the whole evolution. The stability can also be explained by the experiments presented in Figures 6.1 and 6.2.

Figure 6.2 depicts the distribution of colors in the Camila image before and after the Beltrami color flow. In Figure 6.1 the ellipsoids have as principle axes the eigenvectors of the covariance-matrix of the color image. The contracting form of the ellipsoid after applying the Beltrami flow indicates a stable denoising process.

7. Concluding remarks. In this paper, we studied the extremum principle property for the Beltrami color flow. We adapted the duality paradigm of Florack and considered "true images" as generalized functions. We therefore investigated, besides the strong solutions, also the generalized (weak) solutions. We proved the extremum principle in both the strong and the weak formulations.

We also addressed the problem of the discrete maximum principle and its close relationship with stability. In contrast to the continuous case, the discrete maximum principle cannot automatically be guaranteed. The central difference scheme does not necessarily satisfy the extremum principle. Though this property is violated, we

proved the stability of the scheme. Numerical examples show, nevertheless, that this scheme is a useful tool in denoising.

Questions of existence and uniqueness, as well as analysis of more elaborated numerical schemes, are currently being studied.

Acknowledgment. We thank Shoshana Kamin for interesting discussions.

PROBLEMS OF STATIONARY FLOW OF ELECTRORHEOLOGICAL FLUIDS IN A CYLINDRICAL COORDINATE SYSTEM*

R. H. W. HOPPE†‡, W. G. LITVINOV‡, AND T. RAHMAN§

Abstract. We consider the general problem on stationary flow of the electrorheological fluid with the constitutive equation developed in [R. H. W. Hoppe and W. G. Litvinov, *Comm. Pure. Appl. Anal.,* 3 (2004), pp. 809–848] in the cylindrical coordinate system. The problem is studied under mixed boundary conditions wherein velocities are specified on one part of the boundary and surface forces are given on the other part. The existence of a solution to this problem and the convergence of Galerkin approximations are established. Then, we consider the occasion where the flow is axially symmetric and study a problem on an electrorheological clutch. This problem is solved numerically, and the results of calculations of the electric field and velocities are presented.

Key words. electrorheological fluid, generalized solution, existence theorem, approximate solutions, electrorheological clutch

1. Introduction.

Electrorheological fluids are smart materials which are concentrated suspensions of polarizable particles in a nonconducting dielectric liquid. In moderately large electric fields, the particles form chains along the field lines, and these chains then aggregate to form columns [16]. These chainlike and columnar structures cause dramatic changes in the rheological properties of the suspensions. The fluids become anisotropic; the apparent viscosity (the resistance to flow) in the direction orthogonal to the direction of electric field abruptly increases, while the apparent viscosity in the direction of the electric field changes not so drastically.

The chainlike structures directed along the magnetic field lines are formed in magnetic suspensions whose behavior is similar to the behavior of electrorheological suspensions. It was shown experimentally that the apparent viscosity of the flow of magnetic suspensions in the direction orthogonal to the direction of the magnetic field is about three times greater than the apparent viscosity of the flow in the direction of the magnetic field; see [18, p. 85].

The chainlike and columnar structures are destroyed under the action of large stresses, and then the apparent viscosity of the fluid decreases and the fluid becomes less anisotropic.

The following constitutive equation of electrorheological fluids was developed in [8]:

(1.1)
$$\sigma_{ij}(p,u,E) = -p\delta_{ij} + 2\varphi(I(u),|E|,\mu(u,E))\varepsilon_{ij}(u), \quad i,j = 1,\dots,n, \quad n = 2 \text{ or } 3.$$

Here, $\sigma_{ij}(p,u,E)$ are the components of the stress tensor which depend on the pressure p, the velocity vector $u = (u_1,\dots,u_n)$, and the electric field strength $E = (E_1,\dots,E_n)$; δ_{ij} are the components of the unit tensor (the Kronecker delta); and $\varepsilon_{ij}(u)$ are the components of the rate of strain tensor

$$\varepsilon_{ij}(u) = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right), \tag{1.2}$$

where x_i are Cartesian coordinates of a point $x = (x_1,\dots,x_n)$.

Moreover, $I(u)$ is the second invariant of the rate-of-strain tensor

$$I(u) = \sum_{i,j=1}^{n} (\varepsilon_{ij}(u))^2, \tag{1.3}$$

and φ the viscosity function depending on $I(u)$, $|E|$, and $\mu(u,E)$.

The function μ is introduced into the constitutive equation (1.1) in order to take into account the anisotropy of the electrorheological fluid under which the viscosity of the fluid depends on the angle between the vector of the electric field and the vector of the velocity with respect to the charged electrode (the counter electrode is not charged usually). The electrode can move relative to the body of an electrorheological device, and hence we consider that the electrode can move relative to the reference frame under consideration.

Let $\breve{u}(x,t) = (\breve{u}_1(x,t), \breve{u}_2(x,t), \breve{u}_3(x,t))$ be a vector of transfer velocity; $\breve{u}(x,t)$ is the velocity of a point of the electrode which coincides with the point x of the frame at an instant t. It is assumed that $\breve{u}$ is a known function.

We define the function μ as the square of the cosine of the angle between the vector of the electric field and the vector of the velocity relative to the electrode, i.e.,

$$\mu(u,E) = \left(\frac{u-\breve{u}}{|u-\breve{u}|}, \frac{E}{|E|}\right)^2_{\mathbb{R}^3} = \frac{((u_i-\breve{u}_i)E_i)^2}{\left(\sum_{i=1}^3 (u_i-\breve{u}_i)^2\right)\left(\sum_{i=1}^3 E_i^2\right)}. \tag{1.4}$$

Here and below, the Einstein convention on summation over a repeated index is applied, and we denote by $(.,.)_{\mathbb{R}^3}$ the scalar product in $\mathbb{R}^3$.

If the electrode does not move relative to the reference frame, then $\breve{u} = 0$ and the function μ takes the form

$$\mu(u,E) = \left(\frac{u}{|u|}, \frac{E}{|E|}\right)^2_{\mathbb{R}^3}. \tag{1.5}$$

In the general case, the function $\breve{u}$ is defined as follows:

$$\breve{u}(x,t) = \mathring{u}(t) + w(x,t), \tag{1.6}$$

where $\mathring{u}(t) = (\mathring{u}_1(t), \mathring{u}_2(t), \mathring{u}_3(t))$ is a vector of the translation velocity and $w(x,t) = (w_1(x,t), w_2(x,t), w_3(x,t))$ is a vector of the rotational velocity.

The function $\mu(u,E)$ is an invariant which is independent of the choice of the reference frame and the motion of the frame with respect to the electrode.

The viscosity function φ is identified by approximation of flow curves (see [8]) and it was shown in [8] (see also the appendix) that it can be represented as follows:

$$\varphi(I(u),|E|,\mu(u,E)) = b(|E|,\mu(u,E))(\lambda + I(u))^{-\frac{1}{2}} + \psi(I(u),|E|,\mu(u,E)), \tag{1.7}$$

where λ is a small parameter, $\lambda \geq 0$.

The constitutive equation (1.1) with the viscosity function (1.7) allows one to describe the following main peculiarities of flow of electrorheological fluids:

(a) singular or almost singular viscosity function at zero value of the rate-of-strain tensor,
(b) an arbitrary nonlinear relationship between the shear rates and the shear stresses,
(c) an arbitrary dependence of the viscosity on the module of the vector of the electric field and on the angle between the vectors of the velocity and electric field (the anisotropy).

With some assumptions natural from a physical point of view, the constitutive equation (1.1) with the viscosity function (1.7) leads to well-posed mathematical problems (see sections 4 and 5 below and [8]).

The functions b and ψ in (1.7) can be identified so that a set of flow curves obtained for different electric fields E is approximated in an arbitrary range of the shear rates with an arbitrarily high degree of accuracy (for example, by splines).

The Bingham constitutive equation of electrorheological fluids, which is of considerable current use (see, e.g., [4], [16], [22]), gives no way to closely approximate a set of flow curves, especially at small shear rates (see Figure A-1 in the appendix). In addition, the Bingham constitutive equation takes no account of the anisotropy of electrorheological fluids.

We consider Maxwell's equations in the following form (see, e.g., [10]):

$$\begin{aligned} &\operatorname{curl} E + \frac{1}{c}\frac{\partial B}{\partial t} = 0, \qquad \operatorname{div} B = 0, \\ &\operatorname{curl} H - \frac{1}{c}\frac{\partial D}{\partial t} = 0, \qquad \operatorname{div} D = 0. \end{aligned} \tag{1.8}$$

Here E is the electric field, B the magnetic induction, D the electric displacement, H the magnetic field, and c the speed of light. One can assume that

$$D = \epsilon E, \qquad B = \mu H, \tag{1.9}$$

where ϵ is the dielectric permittivity and μ the magnetic permeability.

Since electrorheological fluids are dielectrics, the magnetic field H can be neglected. Then (1.8), (1.9) give the following relations:

$$\operatorname{curl} E = 0, \tag{1.10}$$

$$\operatorname{div}(\epsilon E) = 0. \tag{1.11}$$

It follows from (1.10) that there exists a function of potential θ such that

$$E = -\operatorname{grad}\theta, \tag{1.12}$$

and (1.11) implies

$$\operatorname{div}(\epsilon \operatorname{grad}\theta) = 0 \quad \text{in} \quad \Omega_1. \tag{1.13}$$

Here Ω_1 is the domain of the fluid flow in the Cartesian coordinate system.

The boundary conditions are the following:

$$\theta = U_i(t) \quad \text{on} \quad \Gamma_i, \quad i = 1, \dots, k, \tag{1.14}$$

$$\theta = 0 \quad \text{on} \quad \Gamma_{i0}, \tag{1.15}$$

$$\nu \cdot \epsilon \operatorname{grad}\theta = 0 \quad \text{on} \quad \Gamma \setminus \left(\bigcup_{i=1}^{k} \overline{(\Gamma_i \cup \Gamma_{i0})} \right). \tag{1.16}$$

Here Γ_i and Γ_{i0} are the surfaces of the ith control and null electrodes, respectively, and it is supposed that Γ_i, Γ_{i0} are open subsets of the boundary Γ of Ω_1.

Therefore, the equations for the functions E and (p, v) are separated. Because of this, we assume hereafter that the function of electric field E is known.

In the special case that the direction of the velocity relative to the electrode $u(x,t) - \check{u}(x,t)$ at each point (x,t) at which $E(x,t) \neq 0$ is known, the function $(x,t) \to \mu(u,E)(x,t)$ becomes well known, and the viscosity functions (1.7) takes the form

$$\varphi(I(u), |E|, x, t) = e(|E|, x, t)(\lambda + I(u))^{-\frac{1}{2}} + \psi_1(I(u), |E|, x, t), \tag{1.17}$$

where

$$\begin{aligned} e(|E|, x, t) &= b(|E|, \mu(u,E)(x,t)), \\ \psi_1(I(u), |E|, x, t) &= \psi(I(u), |E|, \mu(u,E)(x,t)). \end{aligned} \tag{1.18}$$

In many electrorheological devices the fluid flows in domains of which the boundaries are the surfaces of revolution. Problems on flow of electrorheological fluids in such domains are convenient to consider in cylindrical coordinates.

In section 2, we present governing equations. In section 3, we formulate a general boundary value problem on stationary flow of the electrorheological fluid in the cylindrical coordinate system and adduce some auxiliary results. Section 4 contains approximate solutions and existence theorems for the general boundary value problem. In section 5, we consider a problem on stationary axially symmetric flow. A problem on an electrorheological clutch is formulated and solved numerically in section 6.

2. Governing equations and assumptions. We consider the system of cylindrical coordinates r, α, z. An element of the length dl is defined in cylindrical coordinates as $dl = (dr^2 + r^2\, d\alpha^2 + dz^2)^{\frac{1}{2}}$. Denote the components of a vector v in the mobile orthonormal basis e_r, e_α, e_z by v_1, v_2, v_3; i.e., $v = (v_1, v_2, v_3)$.

Let $u = (u_1, u_2, u_3)$ be a velocity vector. The components of the rate-of-strain tensor have the following form in cylindrical coordinates,

$$\begin{aligned} &\epsilon_{11}(u) = \frac{\partial u_1}{\partial r}, \quad \epsilon_{22}(u) = \frac{1}{r}\frac{\partial u_2}{\partial \alpha} + \frac{u_1}{r}, \qquad \epsilon_{33}(u) = \frac{\partial u_3}{\partial z}, \\ &\epsilon_{12}(u) = \epsilon_{21}(u) = \frac{1}{2}\left(\frac{1}{r}\frac{\partial u_1}{\partial \alpha} + \frac{\partial u_2}{\partial r} - \frac{u_2}{r}\right), \\ &\epsilon_{23}(u) = \epsilon_{32}(u) = \frac{1}{2}\left(\frac{\partial u_2}{\partial z} + \frac{1}{r}\frac{\partial u_3}{\partial \alpha}\right), \\ &\epsilon_{13}(u) = \epsilon_{31}(u) = \frac{1}{2}\left(\frac{\partial u_1}{\partial z} + \frac{\partial u_3}{\partial r}\right), \end{aligned} \tag{2.1}$$

and the second invariant of the rate-of-strain tensor is defined by

$$I(u) = \sum_{i,j=1}^{3} (\epsilon_{ij}(u))^2. \tag{2.2}$$

We assume the following.

(A0) Ω_1 is a bounded domain in $\mathbb{R}^3$ with a Lipschitz continuous boundary Γ.

Let $\mathcal{P}$ be the operator of translation from cylindrical coordinates to Cartesian ones,

$$\mathcal{P} : (r, \alpha, z) \to \mathcal{P}(r, \alpha, z) = (x_1, x_2, x_3),$$
$$x_1 = r\cos\alpha, \quad x_2 = r\sin\alpha, \quad x_3 = z, \quad r \in \mathbb{R}_+, \quad \alpha \in [0, 2\pi), \quad z \in \mathbb{R}, \tag{2.3}$$

where $\mathbb{R}_+ = \{y \in \mathbb{R},\, y \geq 0\}$ and we identify the points $(0, \alpha, z)$ with the point $(0, 0, z)$, $\alpha \in [0, 2\pi)$. The inverse operator $\mathcal{P}^{-1}$ is defined by

$$\mathcal{P}^{-1} : \mathcal{P}^{-1}(x_1, x_2, x_3) = (r, \alpha, z),$$
$$r = (x_1^2 + x_2^2)^{\frac{1}{2}}, \qquad \alpha = \arctan\frac{x_2}{x_1}, \qquad z = x_3. \tag{2.4}$$

Here, we consider that the mapping $(x_1, x_2) \to \arctan\frac{x_2}{x_1}$ is a multifunction at the point $x_1 = x_2 = 0$, namely, $\arctan\frac{0}{0} = [0, 2\pi)$.

Let

$$\Omega = \mathcal{P}^{-1}(\Omega_1), \qquad S = \mathcal{P}^{-1}(\Gamma). \tag{2.5}$$

We consider a stationary flow problem under the Stokes approximation; i.e., we ignore inertial forces, which are assumed to be small as compared with the internal forces caused by the viscous stresses. Then the motion equations take the following form:

$$\frac{\partial p}{\partial r} - 2\frac{\partial}{\partial r}(\varphi\epsilon_{11}(u)) - \frac{2}{r}\frac{\partial}{\partial\alpha}(\varphi\epsilon_{12}(u)) - 2\frac{\partial}{\partial z}(\varphi\epsilon_{13}(u)) - \frac{2\varphi}{r}(\epsilon_{11}(u) - \epsilon_{22}(u)) = K_1 \quad \text{in } \Omega, \tag{2.6}$$

$$\frac{1}{r}\frac{\partial p}{\partial\alpha} - 2\frac{\partial}{\partial r}(\varphi\epsilon_{21}(u)) - \frac{2}{r}\frac{\partial}{\partial\alpha}(\varphi\epsilon_{22}(u)) - 2\frac{\partial}{\partial z}(\varphi\epsilon_{23}(u)) - \frac{4}{r}\varphi\epsilon_{12}(u) = K_2 \text{ in } \Omega, \tag{2.7}$$

$$\frac{\partial p}{\partial z} - 2\frac{\partial}{\partial r}(\varphi\epsilon_{31}(u)) - \frac{2}{r}\frac{\partial}{\partial\alpha}(\varphi\epsilon_{32}(u)) - 2\frac{\partial}{\partial z}(\varphi\epsilon_{33}(u)) - \frac{2}{r}\varphi\epsilon_{13}(u) = K_3 \text{ in } \Omega. \tag{2.8}$$

Here the viscosity function φ is defined either by (1.7) or by (1.17), and K_1, K_2, K_3 are the components of the volume force vector K.

The velocity function u meets the incompressibility condition

$$\operatorname{div}_c u = \frac{\partial u_1}{\partial r} + \frac{1}{r}\frac{\partial u_2}{\partial\alpha} + \frac{\partial u_3}{\partial z} + \frac{u_1}{r} = 0 \quad \text{in } \Omega. \tag{2.9}$$

Here and below, we denote by div_c the operator of divergence in cylindrical coordinates.

Suppose that S_1 and S_2 are open subsets of S such that S_1 is nonempty, $S_1 \cap S_2 = \emptyset$, and $\overline{S}_1 \cup \overline{S}_2 = S$. We consider mixed boundary conditions, wherein velocities are specified on S_1 and surface forces are given on S_2, i.e.,

$$u = \hat{u} \quad \text{on } S_1, \tag{2.10}$$

$$[-p\delta_{ij} + 2\varphi\epsilon_{ij}(u)]\nu_j = F_i \quad \text{on } S_2, \qquad i, j = 1, 2, 3. \tag{2.11}$$

Here, by ν_j and F_i we denote the components of the unit outward normal to S_2 and the components of the vector of surface force with respect to the basis vectors e_r, e_α, e_z.

Let

$$\tilde{S} = \{(r, \alpha, z) | r = 0, \quad \alpha \in [0, 2\pi), \quad z \in \mathbb{R}_+\}, \qquad S_0 = \Omega \cap \tilde{S}. \tag{2.12}$$

In particular, S_0 can be an empty set. It follows from (2.9) that

$$u_1 = 0 \quad \text{on} \quad S_0, \tag{2.13}$$

and therefore $\frac{\partial u_1}{\partial z} = 0$ on S_0, and since $\epsilon_{13}(u) = 0$ on S_0 (see (2.8)), we obtain

$$\frac{\partial u_3}{\partial r} = 0 \quad \text{on} \quad S_0. \tag{2.14}$$

It follows also from (2.6), (2.7), and (2.1) that

$$\begin{aligned} &\lim_{r \to 0} (\epsilon_{11}(u) - \epsilon_{22}(u))(r, \alpha, z) = 0, \\ &\lim_{r \to 0} (\epsilon_{12}(u))(r, \alpha, z) = 0, \qquad u_2 = 0 \quad \text{on } S_0. \end{aligned} \tag{2.15}$$

In the case when the viscosity function is defined by (1.7), we assume the following.

(A1) $b : y_1, y_2 \to b(y_1, y_2)$ is a function continuous in $\mathbb{R}_+ \times [0, 1]$, and, in addition,

$$0 \le b(y_1, y_2) \le a_0, \qquad (y_1, y_2) \in \mathbb{R}_+ \times [0, 1], \tag{2.16}$$

where a_0 is a positive constant.

(A2) $\psi : (y_1, y_2, y_3) \to \psi(y_1, y_2, y_3)$ is a function continuous in $\mathbb{R}^2_+ \times [0, 1]$, and for an arbitrarily fixed $(y_2, y_3) \in \mathbb{R}_+ \times [0, 1]$ the partial function $\psi(., y_2, y_3) : y_1 \to \psi(y_1, y_2, y_3)$ is continuously differentiable in $\mathbb{R}_+$, and the following inequalities hold:

$$a_2 \ge \psi(y_1, y_2, y_3) \ge a_1, \tag{2.17}$$

$$\psi(y_1, y_2, y_3) + 2 \frac{\partial \psi}{\partial y_1}(y_1, y_2, y_3) y_1 \ge a_3, \tag{2.18}$$

$$\left| \frac{\partial \psi}{\partial y_1}(y_1, y_2, y_3) \right| y_1 \le a_4, \tag{2.19}$$

where a_1–a_4 are positive constants.

In the case that the viscosity function is defined by (1.17), we suppose the following.

(A3) for an arbitrary fixed $(y_2, x, t) \in \mathbb{R}_+ \times \Omega_1 \times \mathbb{R}_+$, the partial function $\psi_1(., y_2, x, t) : y_1 \to \psi_1(y_1, y_2, x, t)$ is continuously differentiable in $\mathbb{R}_+$, and the following inequalities hold:

$$a_2 \ge \psi_1(y_1, y_2, x, t) \ge a_1, \tag{2.20}$$

$$\psi_1(y_1, y_2, x, t) + 2 \frac{\partial \psi_1}{\partial y_1}(y_1, y_2, x, t) y_1 \ge a_3, \tag{2.21}$$

$$\left| \frac{\partial \psi_1}{\partial y_1}(y_1, y_2, x, t) \right| y_1 \le a_4. \tag{2.22}$$

As for the function e, we assume

$$e \in L_\infty(\mathbb{R}_+ \times \Omega_1 \times \mathbb{R}_+), \quad 0 \le e(y, x, t) \le a_0, \qquad y \in \mathbb{R}_+, \quad x \in \Omega_1, \quad t \in \mathbb{R}_+. \tag{2.23}$$

At $\lambda = 0$ the viscosity function φ defined by (1.7) is singular at $I(u) = 0$, $\varphi(0, |E|, \mu(u, E)) = \infty$, and flow problems for such viscosity function reduce to the solution of variational inequalities.

The equation (1.7) with a small positive λ defines a fluid with a finite but possibly large viscosity at $I(u) = 0$. From a physical point of view a fluid with bounded viscosity is more reasonable than the fluid with singular unbounded viscosity (all is bounded in actuality). It is shown in [8] that the solutions of the problems with bounded viscosities converge to the solution of the problem with the singular viscosity as λ tends to zero. Because of this, we assume that

$$\lambda > 0 \quad \text{in (1.7) and (1.17).} \tag{2.24}$$

Let us dwell on the physical sense of the inequalities (2.16)–(2.23). The inequalities (2.16) and (2.17) indicate that the viscosity is bounded from below and from above by positive constants. The inequality (2.18) implies that for fixed values of $|E|$ and $\mu(u, E)$ the derivative of the function $I(u) \to G(u)$ is positive, where $G(u)$ is the second invariant of the stress deviator

$$G(u) = \sum_{i,j=1}^{n} (\sigma_{ij}(p, u, E) + p\delta_{ij})^2 = 4[\varphi(I(u), |E|, \ \mu(u, E))]^2 I(u).$$

This means that in case of simple shear flow the shear stress increases with increasing shear rate. (2.19) is a restriction on $\frac{\partial \varphi}{\partial y_1}$ for large values of y_1.

The inequalities (2.20)–(2.23) are analogous to the inequalities (2.16)–(2.19).

All inequalities (2.16)–(2.23) are natural from a physical point of view.

The viscosity function is identified by approximation of a set of flow curves which are obtained experimentally by viscometric testing for different electric fields. The inequalities (2.16)–(2.23) are consistent with the shapes of the flow curves and enable one to approximate a set of flow curves over a wide range of shear rates with a high degree of accuracy (see the appendix below and [3], [8], [19]).

3. Generalized solution of the problem. We define the following sets:

$$J_0 = \Bigg\{ v | v = (v_1, v_2, v_3) \in C^\infty(\overline{\Omega})^3, \ v_1\big|_{S_0} = 0, \ v_2\big|_{S_0} = 0,$$

$$\frac{\partial v^k}{\partial \alpha^k}\Big|_{\alpha=0} = \frac{\partial v^k}{\partial \alpha^k}\Big|_{\alpha=2\pi}, \ k = 0, 1, 2, \dots \Bigg\}, \tag{3.1}$$

$$J = \{v | v \in J_0, \ v\big|_{S_1} = 0\}, \tag{3.2}$$

$$J_1 = \{v | v \in J, \ \mathrm{div}_c \, v = 0\}. \tag{3.3}$$

Let H and H_1 be the closures of J and J_1 with respect to the norm

$$||v||_H = \left(\int_\Omega I(v) r \, dr \, d\alpha \, dz \right)^{\frac{1}{2}}, \tag{3.4}$$

and let H_0 be the closures of J_0 relative to the norm

$$||v||_{H_0} = \left(||v||_H^2 + \int_{S_1} |v|^2 \, ds \right)^{\frac{1}{2}}. \tag{3.5}$$

Let also Y be the space of scalar functions which are square integrable in Ω with respect to the measure $r\,dr\,d\alpha\,dz$. The norm in Y is defined by

$$||h||_Y = \left(\int_\Omega h^2\, r\, dr\, d\alpha\, dz \right)^{\frac{1}{2}}. \tag{3.6}$$

We define the operator G that maps H_0 into a set of vector valued functions determined in Ω_1 as follows:

$$\begin{aligned} v = (v_1, v_2, v_3) \in H_0, \qquad & G(v) = \{G(v)_i\}_{i=1}^3, \\ G(v)_1 = (v_1 \cos\alpha - v_2 \sin\alpha) \circ \mathcal{P}^{-1}, & \\ G(v)_2 = (v_1 \sin\alpha + v_2 \cos\alpha) \circ \mathcal{P}^{-1}, \quad & G(v)_3 = v_3 \circ \mathcal{P}^{-1}. \end{aligned} \tag{3.7}$$

We assign also the following norm in H_0:

$$||v||_1 = ||G(v)||_{H^1(\Omega_1)^3}, \tag{3.8}$$

where $||\,\cdot\,||_{H^1(\Omega_1)^3}$ is the norm of the product of three Sobolev spaces $H^1(\Omega_1)$.

LEMMA 3.1. *Suppose that the condition* (A0) *is satisfied. Then the expressions* (3.4) *and* (3.8) *define equivalent norms in* H*, and the expressions* (3.5) *and* (3.8) *are equivalent norms in* H_0*. The operator* G *is an isomorphism of* H_0 *onto* $H^1(\Omega_1)^3$*, and the following equality holds:*

$$||h||_Y = ||h \circ \mathcal{P}^{-1}||_{L_2(\Omega_1)}. \tag{3.9}$$

Proof. The equivalence of the norms (3.4) and (3.8) in H, and the norms (3.5) and (3.8) in H_0, follows from the fact that $I(v)$ is the invariant, i.e.,

$$\sum_{i,j=1}^3 [(\epsilon_{ij}(v))(r,\alpha,z)]^2 = \sum_{i,j=1}^3 [(\varepsilon_{ij}(G(v)))(\mathcal{P}(r,\alpha,z))]^2, \tag{3.10}$$

and from the Korn inequality.

Therefore, $G(H_0) \subset H^1(\Omega_1)^3$. Let $g = (g_1, g_2, g_3) \in H^1(\Omega_1)^3$. We have

$$\begin{aligned} \left(\frac{\partial}{\partial r}(g_i \circ \mathcal{P}) \right)(r,\alpha,z) &= \frac{\partial g_i}{\partial x_1}(\mathcal{P}(r,\alpha,z)) \cos\alpha + \frac{\partial g_i}{\partial x_2}(\mathcal{P}(r,\alpha,z)) \sin\alpha, \\ \left(\frac{\partial}{\partial \alpha}(g_i \circ \mathcal{P}) \right)(r,\alpha,z) &= -\frac{\partial g_i}{\partial x_1}(\mathcal{P}(r,\alpha,z)) r \sin\alpha + \frac{\partial g_i}{\partial x_2}(\mathcal{P}(r,\alpha,z)) r \cos\alpha, \\ \left(\frac{\partial}{\partial z}(g_i \circ \mathcal{P}) \right)(r,\alpha,z) &= \frac{\partial g_i}{\partial x_3}(\mathcal{P}(r,\alpha,z)), \qquad i = 1,2,3. \end{aligned} \tag{3.11}$$

We define a vector-function $v = (v_1, v_2, v_3)$ as follows:

$$\begin{aligned} v_1 &= (g_1 \circ \mathcal{P}) \cos\alpha + (g_2 \circ \mathcal{P}) \sin\alpha, \\ v_2 &= (g_2 \circ \mathcal{P}) \cos\alpha - (g_1 \circ \mathcal{P}) \sin\alpha, \quad v_3 = g \circ \mathcal{P}. \end{aligned} \tag{3.12}$$

It follows from (3.7), (3.11), and (3.12) that $v = G^{-1} g \in H_0$, where G^{-1} is the inverse of G. Therefore, $G(H_0) = H^1(\Omega_1)^3$.

The equalities (3.11) imply $G^{-1} \in \mathcal{L}(H^1(\Omega_1)^3, H_0)$, and by the Banach theorem on closed range the operator G is an isomorphism of H_0 onto $H^1(\Omega_1)^3$. ∎

Everywhere below, we use the following notations: if $\mathcal{H}$ is a normed space, we denote by $\mathcal{H}^*$ the dual of $\mathcal{H}$ and by (f,h) the duality between $\mathcal{H}^*$ and $\mathcal{H}$, where $f \in \mathcal{H}^*$, $h \in \mathcal{H}$. In particular, if $f \in Y$ or $f \in Y^n$, $n = 2$ or 3, then (f,h) is the scalar product in Y or in Y^n, respectively. That is, we identify the spaces Y and Y^n with their dual spaces Y^* and $(Y^n)^*$, respectively.

The sign $\rightharpoonup$ denotes weak convergence in a Banach space.

We suppose that $\hat{u}$ belongs to the space of traces on S_1 of the functions from H_0, i.e., $\hat{u} \circ \mathcal{P}^{-1} \in H^{\frac{1}{2}}(\mathcal{P}(S_1))$. Then, there exists a function $\tilde{u}$ such that

$$\tilde{u} \in H_0, \qquad \tilde{u}\big|_{S_1} = \hat{u}, \qquad \operatorname{div}_c \tilde{u} = 0. \tag{3.13}$$

We assume also that

$$K = (K_1, K_2, K_3) \in Y^3, \qquad F \circ \mathcal{P}^{-1} = (F_1, F_2, F_3) \circ \mathcal{P}^{-1} \in L_2(\mathcal{P}(S_2))^3. \tag{3.14}$$

We define operators $L : H \to H^*$ and $B \in \mathcal{L}(H, Y^*)$ as follows:

$$(L(v), h) = 2 \int_\Omega \varphi \epsilon_{ij}(\tilde{u} + v) \epsilon_{ij}(h) r \, dr \, d\alpha \, dz, \qquad v, h \in H, \tag{3.15}$$

$$(Bv, w) = \int_\Omega (\operatorname{div}_c v) w r \, dr \, d\alpha \, dz, \qquad v \in H, \ w \in Y. \tag{3.16}$$

In (3.15) the function φ is defined either by (1.7) or by (1.17).

We consider the problem: Find a pair of functions (v,p) satisfying

$$v \in H, \qquad p \in Y, \tag{3.17}$$

$$(L(v), h) - (B^* p, h) = (K + F, h), \qquad h \in H, \tag{3.18}$$

$$(Bv, w) = 0, \qquad w \in Y. \tag{3.19}$$

Here, B^* is the operator adjoint of B and

$$(K + F, h) = \int_\Omega K_i h_i \, r \, dr \, d\alpha \, dz + \int_{S_2} F_i h_i \, ds. \tag{3.20}$$

The pair $(u = v + \tilde{u}, p)$, where (v,p) is a solution of the problem (3.17)–(3.19), will be called the generalized solution of the problem (2.6)–(2.11), (2.13)–(2.15).

Indeed, by use of Green's formula, it can be seen that, if (v,p) is a solution of the problem (3.17)–(3.19), then the pair $(u = v + \tilde{u}, p)$ is a solution of the problem (2.6)–(2.11), (2.13)–(2.15) in the distributional sense. On the contrary, if (u,p) is a smooth solution of the problem (2.6)–(2.11), (2.13)–(2.15), then the pair $(v = u - \tilde{u}, p)$ is a solution of the problem (3.17)–(3.19).

LEMMA 3.2. *Suppose that the condition* (A0) *is satisfied. Then, the following inf-sup condition,*

$$\inf_{g \in Y} \sup_{w \in H} \frac{(Bw, g)}{||w||_H ||g||_Y} \geq \beta_1 > 0, \tag{3.21}$$

holds true. The operator B is an isomorphism from $H_1^\perp$ onto Y, where $H_1^\perp$ is the orthogonal complement of H_1 in H, and the operator B^* is an isomorphism from Y onto the polar set

$$H_1^\circ = \{q \in H^*, \quad (q, v) = 0, \quad v \in H_1\}. \tag{3.22}$$

Moreover

$$||B^{-1}||_{\mathcal{L}(Y,H_1^\perp)} \le \frac{1}{\beta_1}, \qquad ||(B^*)^{-1}||_{\mathcal{L}(H_1^\circ,Y)} \le \frac{1}{\beta_1}. \tag{3.23}$$

This lemma follows from the corresponding result in Cartesian coordinates (see [2], [8], [13]), since G is an isomorphism of H_0 onto $H^1(\Omega_1)^3$ and $I(v)$ is invariant (see (3.10)) and $\operatorname{div}_c v$ is an invariant also; i.e.,

$$(\operatorname{div}_c v)(r,\alpha,z) = (\operatorname{div} G(v))(\mathcal{P}(r,\alpha,z)). \tag{3.24}$$

4. Approximate solutions and existence theorems. Let $\{X_m\}_{m=1}^\infty$ and $\{N_m\}_{m=1}^\infty$ be sequences of finite-dimensional subspaces in H and Y, respectively, such that

$$\lim_{m\to\infty} \inf_{h\in X_m} ||w-h||_H = 0, \qquad w \in H, \tag{4.1}$$

$$\lim_{m\to\infty} \inf_{g\in N_m} ||f-g||_Y = 0, \qquad f \in Y, \tag{4.2}$$

$$\inf_{g\in N_m} \sup_{h\in X_m} \frac{(Bh,g)}{||h||_H||g||_Y} \ge \beta > 0, \tag{4.3}$$

$$X_m \subset X_{m+1}, \qquad N_m \subset N_{m+1}, \qquad m \in \mathbb{N}. \tag{4.4}$$

We seek an approximate solution of the problem (3.17)–(3.19) of the form

$$v_m \in X_m, \qquad p_m \in N_m, \tag{4.5}$$

$$(L(v_m),h) - (B^* p_m, h) = (K+F,h), \qquad h \in X_m, \tag{4.6}$$

$$(Bv_m, g) = 0, \qquad g \in N_m. \tag{4.7}$$

THEOREM 4.1. *Suppose that the function φ defining the operator L (see* (3.15)*) is given by* (1.7) *and that the conditions* (A0), (A1), (A2), (2.24) *are satisfied. Let also* (3.13), (3.14), (4.1)–(4.4) *hold. Then there exists a solution (v,p) of the problem* (3.17)–(3.19)*, and for an arbitrary $m \in \mathbb{N}$ there exists a solution of the problem* (4.5)–(4.7)*, and a subsequence $\{v_k, p_k\}$ can be extracted from the sequence $\{v_m, p_m\}$ such that*

$$v_k \to v \quad \text{in } H, \qquad p_k \to p \quad \text{in } Y. \tag{4.8}$$

Indeed, we replace cylindrical coordinates r, α, z by Cartesian coordinates x_1, x_2, x_3 in the problems (3.17)–(3.19) and (4.5)–(4.7). Then, we use Lemma 3.1 and Theorem 5.1 from [8] for these problems in Cartesian coordinates and pass back to cylindrical coordinates. As a result, we obtain that there exists a solution of the problem (3.17)–(3.19), and there exists a solution of the problem (4.5)–(4.7) for any $m \in \mathbb{N}$, and a subsequence $\{v_k, p_k\}$ can be extracted from the sequence $\{v_m, p_m\}$ such that

$$v_k \rightharpoonup v \quad \text{in } H, \qquad p_k \rightharpoonup p \quad \text{in } Y. \tag{4.9}$$

(4.8) is proved by using (4.9) and the arguments of Theorem 2.1 from [2].

The next theorem follows from the results of [2].

THEOREM 4.2. *Suppose that the function φ defining the operator L (see* (3.15)*) is given by* (1.17) *and that the conditions* (A0), (A3), (2.23), (2.24) *are satisfied. Let also* (3.13), (3.14), (4.1)–(4.4) *hold. Then there exists a unique solution (u,p) of the problem* (3.17)–(3.19)*, and for an arbitrary $m \in \mathbb{N}$ there exists a unique solution (v_m, p_m) of the problem* (4.5)–(4.7)*; moreover,*

$$v_m \to v \quad in \quad H, \qquad p_m \to p \quad in \quad Y.$$

5. Problem of axially symmetric flow.

5.1. Formulation of the problem. In the case of axially symmetric flow the components of a velocity vector u in the mobile orthonormal basis (e_r, e_α, e_z) of the cylindrical coordinate system depend on r, z only, i.e., $u(r,z) = (u_1(r,z), u_2(r,z), u_3(r,z))$; the components of the rate-of-strain tensor have the form

$$\epsilon_{11}(u) = \frac{\partial u_1}{\partial r}, \quad \epsilon_{22}(u) = \frac{u_1}{r}, \quad \epsilon_{33}(u) = \frac{\partial u_3}{\partial z},$$

$$\epsilon_{12}(u) = \epsilon_{21}(u) = \frac{1}{2}\left(\frac{\partial u_2}{\partial r} - \frac{u_2}{r}\right), \quad \epsilon_{23}(u) = \epsilon_{32}(u) = \frac{1}{2}\frac{\partial u_2}{\partial z},$$

$$\epsilon_{13}(u) = \epsilon_{31}(u) = \frac{1}{2}\left(\frac{\partial u_1}{\partial z} + \frac{\partial u_3}{\partial r}\right); \tag{5.1}$$

and the second invariant of the rate-of-strain tensor is defined by

$$I(u) = \left(\frac{\partial u_1}{\partial r}\right)^2 + \left(\frac{u_1}{r}\right)^2 + \left(\frac{\partial u_3}{\partial z}\right)^2 + \frac{1}{2}\left(\frac{\partial u_2}{\partial r} - \frac{u_2}{r}\right)^2$$

$$+ \frac{1}{2}\left(\frac{\partial u_2}{\partial z}\right)^2 + \frac{1}{2}\left(\frac{\partial u_1}{\partial z} + \frac{\partial u_3}{\partial r}\right)^2. \tag{5.2}$$

We assume that the domain of flow of the electrorheological fluid Ω_1 satisfies the condition (A0) and has the following form:

$$\Omega_1 = \{x | x = (x_1, x_2, x_3),\ x_3 \in (0,l),\ (x_1^2 + x_2^2)^{\frac{1}{2}} < R_2(x_3),$$

$$(x_1^2 + x_2^2)^{\frac{1}{2}} > R_1(x_3) \text{ if } R_1(x_3) > 0,\ (x_1^2 + x_2^2)^{\frac{1}{2}} \geq R_1(x_3) \text{ if } R_1(x_3) = 0\}, \tag{5.3}$$

where R_1 and R_2 are functions given in $(0,l)$. The function R_1 takes nonnegative values, R_2 takes positive values, and $R_2(x_3) > R_1(x_3)$ for all $x_3 \in (0,l)$.

The condition (A0) imposes restrictions on the functions R_1 and R_2. The functions R_1 and R_2 can be Lipschitz continuous as well as discontinuous with a finite number of points of discontinuity. But in the second case the functions R_1 and R_2 must be Lipschitz continuous in between the points of discontinuity.

Let $\Omega_2 = \mathcal{P}^{-1}(\Omega_1)$; the mapping $\mathcal{P}^{-1}$ is defined by (2.4). Since the flow of the fluid is assumed to be axially symmetric—i.e., the functions of velocity, pressure, and electric field are independent of α in cylindrical coordinate system—we consider our problem in the domain Ω_3, which consists of points (r,z) such that $(r,\alpha,z) \in \Omega_2$, $\alpha \in [0, 2\pi)$.

According to (5.3), the domain Ω_3 is defined by

$$\Omega_3 = \{(r,z) | 0 < z < l,\ R_1(z) < r \text{ if } R_1(z) > 0,$$

$$R_1(z) \leq r \text{ if } R_1(z) = 0, \quad r < R_2(z)\}. \tag{5.4}$$

We consider the stationary flow problem under the neglect of the inertial forces. Taking into account (2.6)–(2.8) and (5.1), we obtain the following motion equations:

(5.5)
$$\frac{\partial p}{\partial r} - 2\frac{\partial}{\partial r}\left(\varphi\frac{\partial u_1}{\partial r}\right) - \frac{\partial}{\partial z}\left(\varphi\left(\frac{\partial u_1}{\partial z} + \frac{\partial u_3}{\partial r}\right)\right) - \frac{2}{r}\varphi\left(\frac{\partial u_1}{\partial r} - \frac{u_1}{r}\right) = K_1 \quad \text{in } \Omega_3,$$

(5.6)
$$-\frac{\partial}{\partial r}\left(\varphi\left(\frac{\partial u_2}{\partial r} - \frac{u_2}{r}\right)\right) - \frac{\partial}{\partial z}\left(\varphi\frac{\partial u_2}{\partial z}\right) - \frac{2}{r}\varphi\left(\frac{\partial u_2}{\partial r} - \frac{u_2}{r}\right) = K_2 \quad \text{in } \Omega_3,$$

(5.7)
$$\frac{\partial p}{\partial z} - \frac{\partial}{\partial r}\left(\varphi\left(\frac{\partial u_1}{\partial z} + \frac{\partial u_3}{\partial r}\right)\right) - 2\frac{\partial}{\partial z}\left(\varphi\frac{\partial u_3}{\partial z}\right) - \frac{\varphi}{r}\left(\frac{\partial u_1}{\partial z} + \frac{\partial u_3}{\partial r}\right) = K_3 \quad \text{in } \Omega_3,$$

where the function φ is defined either by (1.7) or by (1.17).

The equation of incompressibility takes the form

$$\operatorname{div}_c u = \frac{\partial u_1}{\partial r} + \frac{\partial u_3}{\partial z} + \frac{u_1}{r} = 0 \quad \text{in } \Omega_3. \tag{5.8}$$

Let S be the boundary of Ω_3 and

$$\begin{aligned} &\mathcal{T} = \{z | z \in (0,l),\ R_1(z) = 0\}, \\ &S_0 = \{(r,z) | r = 0,\ z \in \mathcal{T}\}. \end{aligned} \tag{5.9}$$

In particular, S_0 can be an empty set.

Let also

$$S' = \{(r,\alpha,z) | (r,z) \in S\backslash S_0, \quad \alpha \in [0,2\pi)\}. \tag{5.10}$$

Then $\mathcal{P}(S') = \Gamma$, where Γ is the boundary of the domain Ω_1 defined by (5.3).

Suppose that S_1 and S_2 are open subsets of $S\backslash S_0$ such that S_1 is not empty, $S_1 \cap S_2 = \emptyset$, and $\overline{S}_1 \cup \overline{S}_2 = S\backslash S_0$. We consider mixed boundary conditions, wherein velocities are specified on S_1 and surface forces are given on S_2, i.e.,

$$u|_{S_1} = \check{u}, \tag{5.11}$$

$$[(-p + 2\varphi\epsilon_{11}(u))\nu_1 + 2\,\varphi\epsilon_{13}(u)\nu_3]|_{S_2} = F_1, \tag{5.12}$$

$$[2\varphi\epsilon_{21}(u)\nu_1 + 2\varphi\epsilon_{23}(u)\nu_3]|_{S_2} = F_2, \tag{5.13}$$

$$[(-p + 2\varphi\epsilon_{33}(u))\nu_3 + 2\varphi\epsilon_{31}(u)\nu_1]|_{S_2} = F_3, \tag{5.14}$$

where ν_1 and ν_3 are the components of the unit outward normal $\nu = (\nu_1, 0, \nu_3)$ to the boundary S'. By analogy with the above (see (2.13)–(2.15)), we obtain the following boundary conditions on S_0:

$$\begin{aligned} &u_1\big|_{S_0} = 0, \qquad u_2\big|_{S_0} = 0, \qquad \frac{\partial u_3}{\partial r}\Big|_{S_0} = 0, \\ &\lim_{r\to 0}\left(\frac{\partial u_1}{\partial r} - \frac{u_1}{r}\right)(r,z) = 0, \qquad z \in \mathcal{T}, \\ &\lim_{r\to 0}\left(\frac{\partial u_2}{\partial r} - \frac{u_2}{r}\right)(r,z) = 0, \qquad z \in \mathcal{T}. \end{aligned} \tag{5.15}$$

5.2. Functional spaces and two lemmas. We introduce the following sets:

$$\begin{aligned} &\mathcal{J}_0 = \{v | v = (v_1, v_2, v_3) \in C^\infty(\overline{\Omega}_3)^3,\ v_1\big|_{S_0} = 0,\ v_2\big|_{S_0} = 0\}, \\ &\mathcal{J} = \{v | v \in \mathcal{J}_0,\ v = 0 \quad \text{on } S_1\}, \\ &\mathcal{J}_1 = \{v | v \in \mathcal{J},\ \operatorname{div}_c v = 0\}, \end{aligned} \tag{5.16}$$

where the operator div_c is defined by (5.8).

We denote by $\mathcal{H}$ and $\mathcal{H}_1$ the closures of $\mathcal{J}$ and $\mathcal{J}_1$ with respect to the norm

$$||v||_{\mathcal{H}} = \left(\int_{\Omega_3} I(v) r \, dr \, dz \right)^{\frac{1}{2}}, \tag{5.17}$$

where $I(v)$ is given by (5.2).

Let $\mathcal{H}_0$ be the closure of $\mathcal{J}_0$ relative to the norm

$$||v||_{\mathcal{H}_0} = \left(||v||^2_{\mathcal{H}} + \int_{S_1} |v|^2 \, ds \right)^{\frac{1}{2}}, \tag{5.18}$$

where $ds = (dz^2 + dr^2)^{\frac{1}{2}}$.

Let also $\mathcal{Y}$ be the space of scalar functions which are square integrable in Ω_3 with respect to the measure $r \, dr \, dz$. The norm in $\mathcal{Y}$ is defined by

$$||h||_{\mathcal{Y}} = \left(\int_{\Omega_3} h^2 r \, dr \, dz \right)^{\frac{1}{2}}. \tag{5.19}$$

By analogy with the Lemma 3.1, we obtain the following result.

LEMMA 5.1. *Suppose that the domain Ω_1 defined by* (5.3) *satisfies the condition* (A0). *Then, the expressions* (5.17) *and* (3.8) *define equivalent norms $\mathcal{H}$, and the expressions* (5.18) *and* (3.8) *are equivalent norms in $\mathcal{H}_0$; moreover, the following equality holds:*

$$(2\pi)^{\frac{1}{2}} ||h||_{\mathcal{Y}} = ||\tilde{h} \circ \mathcal{P}^{-1}||_{L_2(\Omega_1)}, \tag{5.20}$$

with $\tilde{h}(r, \alpha, z) = h(r, z)$, $\alpha \in [0, 2\pi)$.

LEMMA 5.2. *Suppose that the domain Ω_1 defined by* (5.3) *satisfies the condition* (A0). *Denote by $\mathcal{B}$ the operator* div_c *acting in the space $\mathcal{H}$, i.e.,*

$$\mathcal{B}v = \frac{\partial v_1}{\partial r} + \frac{\partial v_3}{\partial z} + \frac{v_1}{r}. \tag{5.21}$$

Then, the following inf-sup condition,

$$\inf_{g \in \mathcal{Y}} \sup_{v \in \mathcal{H}} \frac{(\mathcal{B}v, g)}{||v||_{\mathcal{H}} ||g||_{\mathcal{Y}}} \geq \beta_2 > 0, \tag{5.22}$$

holds true.

The operator $\mathcal{B}$ is an isomorphism from $\mathcal{H}_1^{\perp}$ onto $\mathcal{Y}$, where $\mathcal{H}_1^{\perp}$ is the orthogonal complement of $\mathcal{H}_1$ in $\mathcal{H}$, and the operator $\mathcal{B}^*$ that is the adjoint of $\mathcal{B}$ is an isomorphism from $\mathcal{Y}$ onto the polar set

$$\mathcal{H}_1^{\circ} = \{ q \in \mathcal{H}^*, \quad (q, v) = 0, \quad v \in \mathcal{H}_1 \}. \tag{5.23}$$

Moreover,

$$||\mathcal{B}^{-1}||_{\mathcal{L}(\mathcal{Y}, \mathcal{H}_1^{\perp})} \leq \frac{1}{\beta_2}, \qquad ||(\mathcal{B}^*)^{-1}||_{\mathcal{L}(\mathcal{H}_1^{\circ}, \mathcal{Y})} \leq \frac{1}{\beta_2}. \tag{5.24}$$

Lemma 5.2 does not follow from Lemma 3.2. For the proof of Lemma 5.2, see [14].

5.3. Generalized solution. We suppose that the function $\breve{u}$ (see (5.11)) belongs to the traces on S_1 of the functions from $\mathcal{H}_0$. Then there exists a function $\overset{*}{u}$ such that

$$\overset{*}{u} \in \mathcal{H}_0, \qquad \overset{*}{u}\big|_{S_1} = \breve{u}, \qquad \mathrm{div}_c \overset{*}{u} = 0. \tag{5.25}$$

We assume also that

$$K = (K_1, K_2, K_3) \in \mathcal{Y}^3, \qquad F = (F_1, F_2, F_3) \in L_2(S_2)^3. \tag{5.26}$$

Define an operator $\mathcal{M} : \mathcal{H} \to \mathcal{H}^*$ as follows:

$$(\mathcal{M}(v), h) = 2 \int_{\Omega_3} \varphi \epsilon_{ij}(\overset{*}{u} + v)\epsilon_{ij}(h) r \, dr \, dz, \qquad v, h \in \mathcal{H}, \tag{5.27}$$

where the function φ is given either by (1.7) or by (1.17), and $\epsilon_{ij}(v)$ are defined by (5.1). We consider the problem: Find a pair of functions (v, p) satisfying

$$v \in \mathcal{H}, \qquad p \in \mathcal{Y}, \tag{5.28}$$

$$(\mathcal{M}(v), h) - (\mathcal{B}^* p, h) = (K + F, h), \qquad h \in \mathcal{H}, \tag{5.29}$$

$$(\mathcal{B}v, w) = 0, \qquad w \in \mathcal{Y}. \tag{5.30}$$

Here $\mathcal{B}^*$ is the operator adjoint of $\mathcal{B}$ and

$$(K + F, h) = \int_{\Omega_3} K_i h_i r \, dr \, dz + \int_{S_2} F_i h_i \, ds. \tag{5.31}$$

The pair $(u = \overset{*}{u} + v, p)$, where (v, p) is a solution of problem (5.28)–(5.30), will be called the generalized solution of the problem (5.5)–(5.8), (5.11)–(5.15).

Let $\{\mathcal{X}_m\}_{m=1}^{\infty}$ and $\{\mathcal{N}_m\}_{m=1}^{\infty}$ be sequences of finite-dimensional subspaces in $\mathcal{H}$ and $\mathcal{Y}$, respectively, such that

$$\lim_{m\to\infty} \inf_{h \in \mathcal{X}_m} ||w - h||_{\mathcal{H}} = 0, \qquad w \in \mathcal{H}, \tag{5.32}$$

$$\lim_{m\to\infty} \inf_{g \in \mathcal{N}_m} ||f - g||_{\mathcal{Y}} = 0, \qquad f \in \mathcal{Y}, \tag{5.33}$$

$$\inf_{g \in \mathcal{N}_m} \sup_{h \in \mathcal{X}_m} \frac{(\mathcal{B}h, g)}{||h||_{\mathcal{H}} ||g||_{\mathcal{Y}}} \geq \beta > 0, \tag{5.34}$$

$$\mathcal{X}_m \subset \mathcal{X}_{m+1}, \qquad \mathcal{N}_m \subset \mathcal{N}_{m+1}, \qquad m \in \mathbb{N}. \tag{5.35}$$

We seek an approximate solution of the problem (5.28)–(5.30) of the form

$$v_m \in \mathcal{X}_m, \qquad p_m \in \mathcal{N}_m, \tag{5.36}$$

$$(\mathcal{M}(v_m), h) - (\mathcal{B}^* p_m, h) = (K + F, h), \qquad h \in \mathcal{X}_m, \tag{5.37}$$

$$(\mathcal{B}\, v_m, g) = 0, \qquad g \in \mathcal{N}_m. \tag{5.38}$$

THEOREM 5.1. *Suppose that the function φ is given by* (1.7) *and that the conditions* (A1), (A2), (2.24) *are satisfied. Let the conditions* (A0), (5.3) *hold and Ω_3 be defined by* (5.4). *Assume also that* (5.25), (5.26), (5.32)–(5.35) *are fulfilled. Then there exists a solution v, p of the problem* (5.28)–(5.30), *and for an arbitrary $m \in \mathbb{N}$ there exists a solution of the problem* (5.36)–(5.38), *and a subsequence $\{v_k, p_k\}$ can be extracted from the sequence $\{v_m, p_m\}$ such that*

$$v_k \to v \quad \textit{in } \mathcal{H}, \qquad p_k \to p \quad \textit{in } \mathcal{Y}. \tag{5.39}$$

Indeed, by using the arguments of Theorem 5.1 from [8], we prove that there exists a solution of the problem (5.36)–(5.38) for any $m \in \mathbb{N}$, and a subsequence $\{v_k, p_k\}$ can be extracted from the sequence $\{v_m, p_m\}$ such that

$$v_k \rightharpoonup v \quad \text{in } \mathcal{H}, \qquad p_k \rightharpoonup p \quad \text{in } \mathcal{Y}. \tag{5.40}$$

(5.39) is proved by using (5.40) and the reasonings of the Theorem 2.1 from [2].

THEOREM 5.2. *Suppose that the function φ is given by* (1.17) *and that the conditions* (A0), (A3), (2.23), (2.24) *are satisfied. Let also* (5.25), (5.26), (5.32)–(5.35) *hold. Then, there exists a unique solution of the problem* (5.28)–(5.30), *and there exists a unique solution of the problem* (5.36)–(5.38) *for any $m \in \mathbb{N}$; in addition, $v_m \to v$ in $\mathcal{H}$, $p_m \to p$ in $\mathcal{Y}$.*

The proof of this theorem is analogous to the proof of Theorem 2.1 from [2].

6. Electrorheological clutch.

6.1. Problem on an electric field. Figure 1 (left) displays a scheme of an electrorheological clutch consisting of two coaxial cylinders. The gap between the cylinders is filled with an electrorheological fluid. The inner cylinder hosts a high voltage lead supplying the lateral surface, which serves as the electrode, whereas the lateral surface of the outer cylinder acts as the counter electrode.

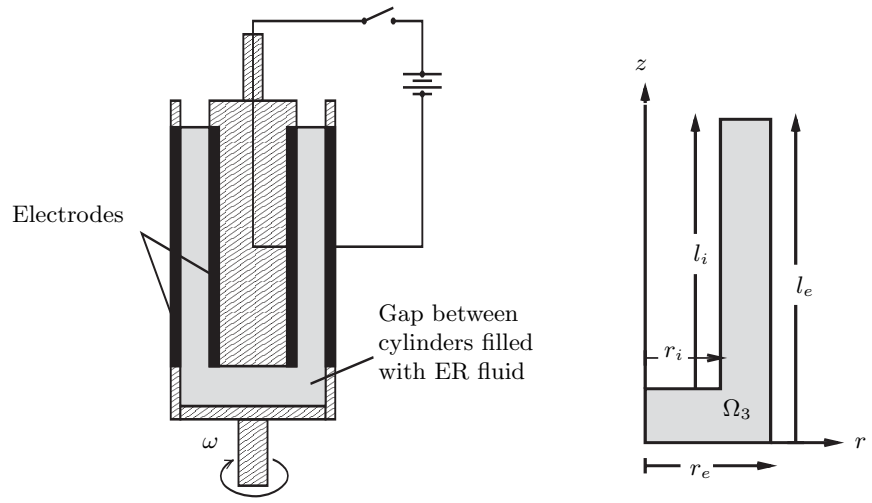

FIG. 1. *Simple model for an electrorheological fluid clutch (left) and the computational domain (right).*

By applying a voltage, one enhances the viscosity of the fluid. Under sufficiently large voltage the inner and external cylinders are almost rigidly bound and rotate practically at the same angular velocity. By varying the voltage, one obtains various slippage of the cylinders, i.e., various transmission ratio of the clutch.

The flow in the clutch is axially symmetric. According to Figure 1 (left) and (5.3), (5.4), the domain Ω_3 corresponding to the flow in the clutch has the form shown in Figure 1 (right).

The vector function of electric field E is defined as $E = -\operatorname{grad}\theta$, where θ is the function of the electric potential that meets the following equation:

$$\operatorname{div}(\chi \operatorname{grad}\theta) = 0, \tag{6.1}$$

where χ is the dielectric permittivity. In our case $\operatorname{grad}\theta = (\frac{\partial\theta}{\partial r}, \frac{\partial\theta}{\partial z})$, and (6.1) takes the form

$$\frac{\partial}{\partial r}\left(\chi\frac{\partial\theta}{\partial r}\right) + \frac{\chi}{r}\frac{\partial\theta}{\partial r} + \frac{\partial}{\partial z}\left(\chi\frac{\partial\theta}{\partial z}\right) = 0 \quad \text{in} \quad \Omega_3, \tag{6.2}$$

and θ satisfies the following boundary conditions:

$$\theta = U \quad \text{on } D_1, \qquad \theta = 0 \quad \text{on } D_2, \qquad \frac{\partial\theta}{\partial r} = 0 \quad \text{on } S_0,$$
$$\nu_1\chi\frac{\partial\theta}{\partial r} + \nu_3\chi\frac{\partial\theta}{\partial z} = 0 \quad \text{on } S\backslash(\overline{D}_1 \cup \overline{D}_2 \cup \overline{S}_0). \tag{6.3}$$

Here, $U = \text{constant} > 0$, S is the boundary of Ω_3, and

$$D_1 = \{(r,z)|\, r = r_i,\ z \in (l_e - l_i, l_e)\},$$
$$D_2 = \{(r,z)|\, r = r_e,\ z \in (l_e - l_i, l_e)\},$$
$$S_0 = \{(r,z)|\, r = 0,\ z \in (0, l_e - l_i)\}. \tag{6.4}$$

Let

$$\mathcal{Z} = \left\{w | w \in C^\infty(\overline{\Omega}_3),\ \frac{\partial w}{\partial r} = 0 \quad \text{on } S_0\right\}, \tag{6.5}$$

and let Z_0 be the closure of $\mathcal{Z}$ with respect to the norm

$$||w||_{Z_0} = \left(\int_{\Omega_3}\left[w^2 + \left(\frac{\partial w}{\partial r}\right)^2 + \left(\frac{\partial w}{\partial z}\right)^2\right] r\,dr\,dz\right)^{\frac{1}{2}}. \tag{6.6}$$

Again, we consider the following space:

$$Z = \{w | w \in Z_0,\ w = 0 \quad \text{on} \quad D_1 \cup D_2\}. \tag{6.7}$$

The expression

$$||w||_Z = \left(\int_{\Omega_3}\left[\left(\frac{\partial w}{\partial r}\right)^2 + \left(\frac{\partial w}{\partial z}\right)^2\right] r\,dr\,dz\right)^{\frac{1}{2}} \tag{6.8}$$

defines a norm in Z being equivalent to the norm of Z_0 determined by (6.6). Let θ_0 be a function such that

$$\theta_0 \in Z_0, \quad \theta_0 = U \quad \text{on } D_1, \qquad \theta_0 = 0 \quad \text{on } D_2. \tag{6.9}$$

We assume that χ is a function that is integrable in Ω_3 with respect to the measure $r\,dr\,dz$, and in addition,

$$b_1 \geq \chi \geq b_0 > 0 \quad \text{a.e. in} \quad \Omega, \tag{6.10}$$

where b_0 and b_1 are positive constants.

Define a bilinear form $a : Z_0 \times Z \to \mathbb{R}$ as follows:

$$a(q,h) = \int_{\Omega_3}\chi\left(\frac{\partial q}{\partial r}\frac{\partial h}{\partial r} + \frac{\partial q}{\partial z}\frac{\partial h}{\partial z}\right) r\,dr\,dz, \quad q \in Z_0, \quad h \in Z. \tag{6.11}$$

Consider the following problem: Find θ_1 satisfying

$$\theta_1 \in Z, \qquad a(\theta_1, h) = -a(\theta_0, h), \qquad h \in Z. \tag{6.12}$$

The function $\theta = \theta_0 + \theta_1$ is a generalized solution of the problem (6.2), (6.3).

The Riesz theorem implies the following result.

THEOREM 6.1. *Suppose that* (6.9) *and* (6.10) *are satisfied. Then there exists a unique solution of the problem* (6.12)*, and there exists a unique generalized solution* θ *of the problem* (6.2), (6.3)*. The function* θ *is represented in the form* $\theta = \theta_0 + \theta_1$*, where* θ_0 *is a function satisfying* (6.9) *and* θ_1 *is the solution of the problem* (6.12)*.*

6.2. Problem on the fluid flow. We assume that the velocity vector u and the pressure p depend only on r, z in the mobile orthonormal basis e_r, e_α, e_z of cylindrical coordinate system r, α, z and, in addition, $u(r, z) = (0, u_2(r, z), 0)$. We denote the function u_2 by u.

According to (2.1), we have

$$\epsilon_{12}(u) = \epsilon_{21}(u) = \frac{1}{2}\left(\frac{\partial u}{\partial r} - \frac{u}{r}\right), \qquad \epsilon_{23}(u) = \epsilon_{32}(u) = \frac{1}{2}\,\frac{\partial u}{\partial z},$$

$$\epsilon_{11}(u) = \epsilon_{22}(u) = \epsilon_{33}(u) = \epsilon_{13}(u) = \epsilon_{31}(u) = 0, \tag{6.13}$$

and

$$I(u) = \frac{1}{2}\left(\frac{\partial u}{\partial r} - \frac{u}{r}\right)^2 + \frac{1}{2}\left(\frac{\partial u}{\partial z}\right)^2. \tag{6.14}$$

In line with (5.5)–(5.7), the motion equations take the form

$$\frac{\partial p}{\partial r} = \frac{\partial p}{\partial z} = 0, \tag{6.15}$$

$$\frac{\partial}{\partial r}\left(\varphi\left(\frac{\partial u}{\partial r} - \frac{u}{r}\right)\right) + \frac{\partial}{\partial z}\left(\varphi\frac{\partial u}{\partial z}\right) + \frac{2}{r}\varphi\left(\frac{\partial u}{\partial r} - \frac{u}{r}\right) = 0, \tag{6.16}$$

where volume force vector is ignored.

In the case under consideration, the condition of incompressibility (2.9) is satisfied.

We prescribe velocities on the surfaces of the internal and external cylinders S_1 and specify surface forces on the top boundary of the electrorheological fluid S_2. In this case, we have (see Figure 1 (right))

$$S_1 = \bigcup_{i=1}^{4} S_{1i}, \tag{6.17}$$

where

$$S_{11} = \{(r, z) | z = 0,\ r \in (0, r_e)\}, \qquad S_{12} = \{(r, z) | r = r_e,\ z \in (0, l_e)\},$$

$$S_{13} = \{(r, z) | z = l_e - l_i,\ r \in (0, r_i)\}, \qquad S_{14} = \{(r, z) | r = r_i,\ z \in ((l_e - l_i), l_e)\}, \tag{6.18}$$

and

$$S_2 = \{(r, z) | z = l_e,\ r \in (r_i, r_e)\}. \tag{6.19}$$

In the case that the inner cylinder is leading, we deal with the following boundary conditions:

$$u(r,z) = \begin{cases} 0 & \text{on } S_{11} \cup S_{12} \cup S_0, \\ \omega r & \text{on } S_{13}, \\ \omega r_i & \text{on } S_{14}, \end{cases} \tag{6.20}$$

$$\varphi \frac{\partial u}{\partial z} = 0 \quad \text{on } S_2, \qquad p = \tilde{c} \quad \text{on } S_2. \tag{6.21}$$

Here ω is the angular velocity of the internal cylinder, and we assume that $F_1 = F_2 = 0$, $F_3 = -\tilde{c}$, $\tilde{c} = \text{constant} > 0$; see (5.12)–(5.14). S_0 is given in (6.4), and according to (5.15), we have

$$u\big|_{S_0} = 0, \qquad \lim_{r \to 0} \left(\frac{\partial u}{\partial r} - \frac{u}{r} \right)(r,z) = 0, \qquad z \in (0, l_e - l_i). \tag{6.22}$$

In the case that the external cylinder is leading, we consider the boundary conditions of this type:

$$u = \begin{cases} \omega r & \text{on } S_{11}, \\ \omega r_e & \text{on } S_{12}, \\ 0 & \text{on } S_{13} \cup S_{14} \cup S_0, \end{cases} \tag{6.23}$$

where ω is the angular velocity of the external cylinder, and, in addition, (6.21) and (6.22) hold.

In the case under consideration the set $\mathcal{J}_0$ has the form

$$\mathcal{J}_0 = \{v | v \in C^\infty(\overline{\Omega}_3), \quad v = 0 \quad \text{on } S_0\}, \tag{6.24}$$

and $\mathcal{H}_0$ is the closure of $\mathcal{J}_0$ relative to the norm (compare with (5.16)–(5.18), (6.14))

$$||v||_{\mathcal{H}_0} = \left(\int_{\Omega_3} \left[v^2 + \left(\frac{\partial v}{\partial r} - \frac{v}{r} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right] r \, dr \, dz \right)^{\frac{1}{2}}. \tag{6.25}$$

The space $\mathcal{H}$ appears as

$$\mathcal{H} = \{v | v \in \mathcal{H}_0, \, v = 0 \quad \text{on } S_1\}, \tag{6.26}$$

and the norm in $\mathcal{H}$ is given by

$$||v||_{\mathcal{H}} = \left(\int_{\Omega_3} \left[\left(\frac{\partial v}{\partial r} - \frac{v}{r} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right] r \, dr \, dz \right)^{\frac{1}{2}}. \tag{6.27}$$

It follows from Lemma 5.1 that the expressions (6.25) and (3.8) with $v_1 = 0$, $v_2 = v$, $v_3 = 0$ define equivalent norms in $\mathcal{H}_0$, whereas (6.27) and (3.8) are equivalent norms in $\mathcal{H}$.

Equation (6.15) implies $p = c = \text{constant}$, and (6.21) yields $c = \tilde{c}$.

Let $\overset{*}{u}$ be a function from $\mathcal{H}_0$ that satisfies either (6.20) or (6.23) according to which cylinder, inner or external, is leading.

The operator $\mathcal{M} : \mathcal{H} \to \mathcal{H}^*$ is defined as follows:

(6.28)
$$(\mathcal{M}(v), h) = \frac{1}{2} \int_{\Omega_3} \varphi \left[\left(\frac{\partial(\overset{*}{u} + v)}{\partial r} - \frac{\overset{*}{u} + v}{r} \right) \left(\frac{\partial h}{\partial r} - \frac{h}{r} \right) + \frac{\partial(\overset{*}{u} + v)}{\partial z} \frac{\partial h}{\partial z} \right] r \, dr \, dz.$$

In the case under consideration the velocity vector is orthogonal to the vector of the electric field at each point $(r, z) \in \overline{\Omega}_3$. Therefore, in (6.28) the function φ is defined by (see (1.7))

$$\varphi = b(|E|, 0)(\lambda + I(\overset{*}{u} + v))^{-\frac{1}{2}} + \psi(I(\overset{*}{u} + v), |E|, 0), \tag{6.29}$$

where the function I is given by (6.14).

We consider the following problem: Find a function v such that

$$v \in \mathcal{H}, \qquad (\mathcal{M}(v), h) = 0, \qquad h \in \mathcal{H}. \tag{6.30}$$

The pair $(u = \overset{*}{u} + v, p)$, where v is a solution of the problem (6.30) and $p = \tilde{c}$, is a generalized solution of the problem (6.15), (6.16), (6.21), (6.22), and (6.20) or (6.23).

Let $\{\mathcal{V}_m\}_{m=1}^{\infty}$ be a sequence of finite-dimensional subspaces in $\mathcal{H}$ such that

$$\lim_{m \to \infty} \inf_{h \in \mathcal{V}_m} ||w - h||_{\mathcal{H}} = 0, \qquad w \in \mathcal{H}, \tag{6.31}$$

$$\mathcal{V}_m \subset \mathcal{V}_{m+1}, \qquad m \in \mathbb{N}. \tag{6.32}$$

We define an approximate solution of the problem (6.30) of the form

$$v_m \in \mathcal{V}_m, \qquad (\mathcal{M}(v_m), h) = 0, \qquad h \in \mathcal{V}_m. \tag{6.33}$$

It follows from Theorem 5.2 that for the function φ defined by (6.29) there exists a unique solution of the problems (6.30) and (6.33); in addition, $v_m \to v$ in $\mathcal{H}$.

6.3. Simulation results. The nonlinear problem (6.30) is solved through solving a sequence of linear problems. Given $v^0 \in \mathcal{H}$, find $v^k \in \mathcal{H}$, $k = 1, 2, \ldots$, such that

$$d \in \mathcal{H}, \quad (\hat{\mathcal{M}}(v^{k-1})d, h) = -(\mathcal{M}(v^{k-1}), h) \quad \forall h \in \mathcal{H}, \tag{6.34}$$

$$v^k = v^{k-1} + \alpha \, d. \tag{6.35}$$

Here α is a relaxation parameter, and $\hat{\mathcal{M}}$ is the linearized version of the operator $\mathcal{M}$ (cf. [2]), defined as

$$\begin{aligned}(\hat{\mathcal{M}}(w)v, h) = \frac{1}{2} \int_{\Omega_3} & (b(|E|, 0)(\lambda + I(\overset{*}{u} + w))^{-\frac{1}{2}} + \psi(I(\overset{*}{u} + w), |E|, 0)) \\ & \times \left[\left(\frac{\partial(\overset{*}{u} + v)}{\partial r} - \frac{\overset{*}{u} + v}{r} \right) \left(\frac{\partial h}{\partial r} - \frac{h}{r} \right) + \frac{\partial(\overset{*}{u} + v)}{\partial z} \frac{\partial h}{\partial z} \right] r \, dr \, dz.\end{aligned} \tag{6.36}$$

Note that $(\hat{\mathcal{M}}(w)v, h) = (\mathcal{M}(v), h)$ whenever $w = v$. The algorithm can be termed the Birger–Kachanov method with relaxation; see [5] for the analysis of the original Birger–Kachanov method.

We consider the electrorheological fluid called the Rheobay TP AI 3656, a product of Bayer [1]. The experimentally obtained flow curves (relating the shear stress to the shear rate) of this product, corresponding to different electric field strengths

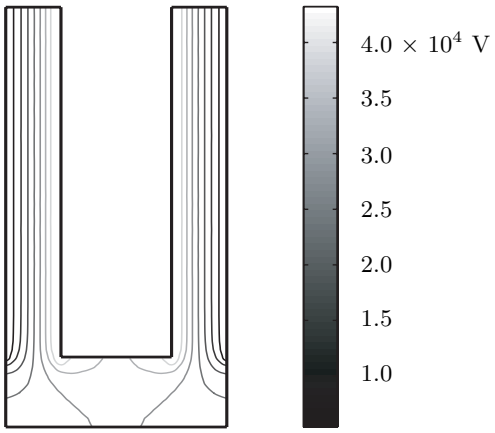

FIG. 2. *Contour plot of the electric potential: wide gap configuration.*

orthogonal to the velocities, have been approximated by cubic splines. The viscosity function φ is then calculated from these splines; see the appendix for details.

In order to understand the behavior of our electrorheological fluid in our model clutch, we study the flow in two different geometrical configurations of the clutch, the *wide*- and the *narrow* gap configurations. In the *wide* gap configuration, we take $r_i = 35$ mm, $r_e = 70$ mm, and $l_i = 250$ mm, $l_e = 300$ mm. During this test the cylinder (outer or inner, whichever is leading) rotates with an angular velocity of 125 rad sec^{-1}. For the *narrow* gap configuration, we take a much narrower gap between the cylinders by setting $r_i = 24$ mm and $r_e = 25$ mm. In this case $l_i = 25$ mm, $l_e = 30$ mm, and the angular velocity of the leading cylinder (outer or inner) is 5 rad sec^{-1}.

The function of the electric field potential θ was calculated approximately by using the Galerkin method with continuous and piecewise linear finite elements for the problem (6.12).

Figure 2 shows a contour plot of the electric potential calculated on the *wide* gap configuration for an applied voltage of 10 kV on the inner electrode. The distribution of this electric potential is linear along any cross-section inside the gap between the electrodes.

Angular velocity profiles for different applied voltages, calculated at one cross section of the gap, are shown in Figures 3 and 4.

From the calculations performed we arrive at the following conclusions:

1. The electric field $E = (E_r, E_z)$ in the gap between the cylinders is close to a constant vector $(U/(r_i - r_e), 0)$ for the narrow and wide gap configurations. At each point between the electrodes, with the exception of points in a very small zone by the ends of the electrodes, the electric field (E_r, E_z) tends to $(U/(r_i - r_e), 0)$ as $(r_e - r_i)/r_i$ tends to zero. The electric field decays sharply as the distance to the electrodes increases (see Figure 2).
2. In the case when the gap between the cylinders is wide and the outer cylinder is leading, a zone with a constant angular velocity is formed near the outer cylinder, and this zone increases with the increase of voltage (see Figure 3 left).
3. In the case when the gap between the cylinders is wide and the inner cylinder is leading, a zone with a constant angular velocity is formed near the outer

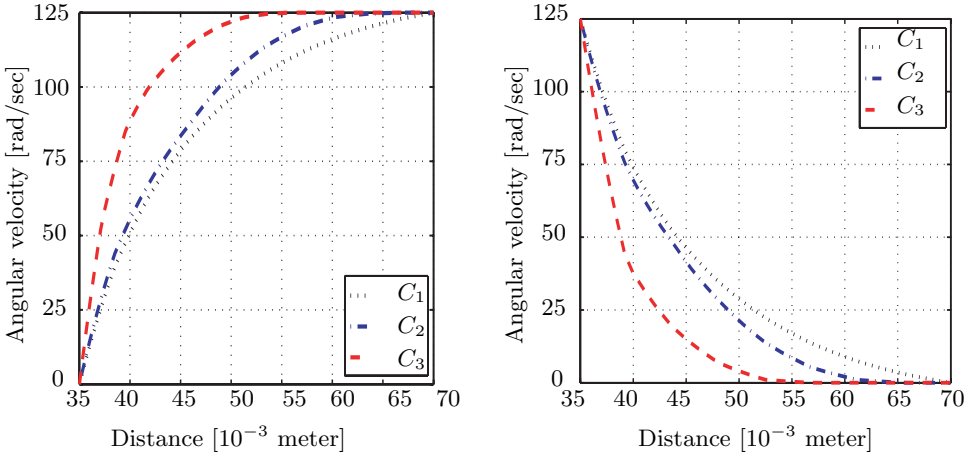

FIG. 3. *Angular velocity profile. Wide gap configuration with leading outer cylinder (left) and leading inner cylinder (right). The curves C_1, C_2, and C_3 correspond to $U = 0$ V, $U = 50$ kV, and $U = 100$ kV, respectively.*

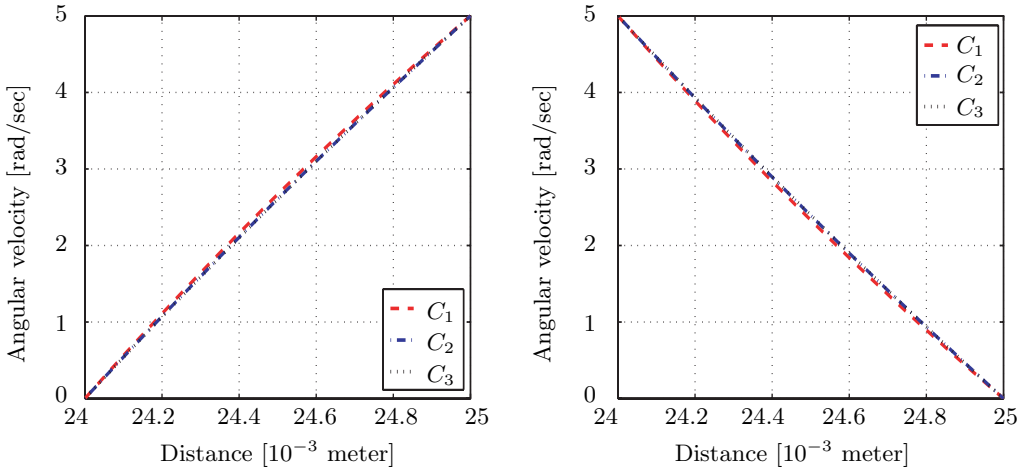

FIG. 4. *Angular velocity profile. Narrow gap configuration with leading outer cylinder (left) and leading inner cylinder (right). The curves C_1, C_2, and C_3 correspond to $U = 0$ V, $U = 2$ kV, and $U = 3$ kV, respectively.*

cylinder, as in the case when the outer cylinder is leading. This zone increases under the increase of voltage (see Figure 3 right).

4. In the case of a narrow gap between the cylinders, the zone with a constant angular velocity is not formed. The velocity profiles are almost linear at various voltages. No matter what cylinder is leading and what voltage is applied, the velocity profile tends to linear as $(r_e - r_i)/r_i$ tends to zero (see Figure 4). In this case essentially the velocity profile does not depend on the shape of a flow curve, and the shear rate is a constant.

We note that in the case of a wide gap between the cylinders, the zone with a constant angular velocity is also formed under the flow of the Bingham fluid. The proximity of the Bingham velocity profiles to the profiles presented in Figure 3

depends on the proximity of approximations of the flow curves by the affine functions $\tau_0+b_0\gamma$, where τ_0 and b_0 are the yield stress and the viscosity of the Bingham fluid and γ is the shear rate. (About the proximity of solutions for close flow curves, see [13, section 6.2].)

As may be seen from the appendix Figure A-1, one cannot obtain good approximations of the flow curves by affine functions, especially for small shear rates.

Appendix. Identification of the viscosity function. In the following, we present a set of cubic splines (flow splines) approximating a set of experimentally obtained flow curves and show how the viscosity function φ is calculated from these splines. These flow curves (splines) are for the electrorheological fluid called Rheobay TP AI 3656, a product of Bayer, based on a water-free dispersion of polymer particles in silicone oil (Baysilone Oil M); see [1] for specifications. The application of such a product can be found in various devices, such as shock absorbers, vibration dampers, clutches, and so on.

A.1. The flow splines. The set of cubic splines approximating experimentally obtained flow curves corresponding to a set of different electric field strengths, which are orthogonal to the velocity, are shown in Figure A-1. Complete information for the reconstruction of these splines, i.e., the sample points representing the shear rates γ, the data representing the shear stress τ, and the end slopes (derivatives), are provided in Table A-1.

Each flow curve has been approximated within the interval $[\gamma_0, \gamma_1]$ (in our case $\gamma_0 = 100\ \mathrm{sec}^{-2}$, $\gamma_1 = 2000\ \mathrm{sec}^{-2}$) by a cubic spline with the given end slopes. Outside of the interval $[\gamma_0, \gamma_1]$ the splines have been extended on $\mathbb{R}_+$ by straight lines (see the dotted lines in Figure A-1), so that the obtained function $\gamma \to \tau(\gamma)$ becomes continuously differentiable in $\mathbb{R}_+$.

A linear interpolation is used to calculate the function $\tau(\gamma)$ for values of $|E|$ intermediate between the values given in the Table A-1.

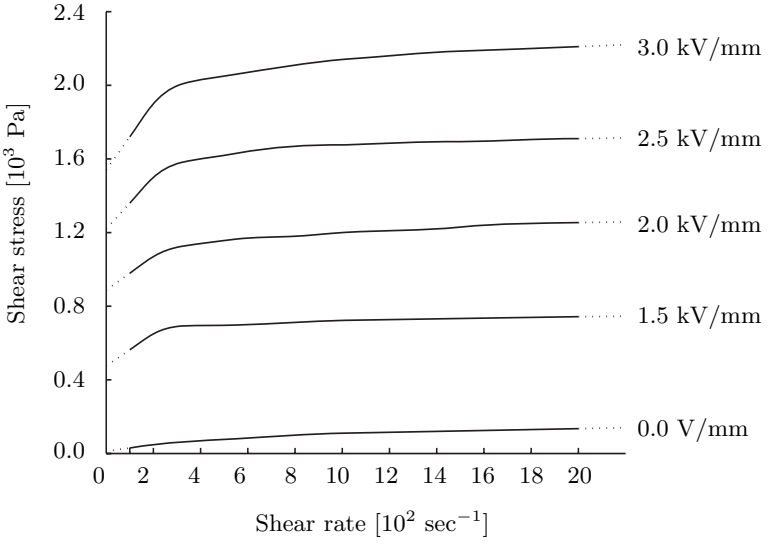

FIG. A-1. *Flow splines showing the effect of field strength (50Hz, AC) and shear rate γ on shear stress τ at 40°C. The cubic splines are constructed using the data provided in Table* A-1.

TABLE A-1

The table contains complete information for the reconstruction of the five cubic splines displayed in Figure A-1. *Each of the last five columns in the table corresponds to a spline approximating a flow curve, containing two end slopes and eleven data values corresponding to the eleven sample points in the first column of the table.*

	Shear stress (Pa)				
Shear rate γ [per sec]	0.0 V/mm	1.5 kV/mm	2.0 kV/mm	2.5 kV/mm	3.0 kV/mm

Slope at left end	0.180	0.870	0.910	1.400	1.800
Slope at right end	0.025	0.015	0.020	0.020	0.050

A.2. The viscosity function. We now show how the viscosity function φ is calculated from the function $\tau(\gamma)$. Let τ_0 be the point of intersection of a left dotted line with the shear stress axis. This dotted line is the continuation of the flow curve in the interval $[0, \gamma_0)$, and τ_0 is the yield stress.

The viscosity function, in the case of a simple shear flow, is determined as follows:

$$\varphi = \frac{1}{2}\frac{\tau}{\gamma}, \quad \text{where} \quad \gamma = \left(\frac{1}{2}I(u)\right)^{\frac{1}{2}}.$$

Generalizing it to an arbitrary flow, we get

$$b = \frac{\tau_0}{\sqrt{2}} \quad \text{and} \quad \psi = \frac{\tau - \tau_0}{2\gamma} = \frac{\tau - \tau_0}{(2I(u))^{\frac{1}{2}}}. \tag{A-1}$$

For a fixed value of $|E|$ and $I(u)$, we can thus find the value of φ using (A-1) and (6.29), i.e.,

$$\varphi = \frac{b}{(\lambda + I(u))^{\frac{1}{2}}} + \psi. \tag{A-2}$$

The parameter λ was chosen equal to $1.011e^{-11}$ sec^{-2}.

In the general case, when there are given flow curves for different values of $|E|$ and $\mu(u, E)$, one obtains expressions (A-2) for different values of $|E|$ and $\mu(u, E)$; see (1.7).

Acknowledgment. The authors are very thankful to the referees for useful comments.

DIFFUSION APPROXIMATION FOR LINEAR TRANSPORT WITH MULTIPLYING BOUNDARY CONDITIONS*

V. PROTOPOPESCU† AND L. THEVENOT‡

Abstract. We consider the diffusion limit of a suitably rescaled model transport equation in a slab with *multiplying boundary conditions*, as the scaling parameter ε tends to zero. We show that, for sufficiently smooth data, the solution converges in the L^2-norm for each $t > 0$ to the solution of a diffusion equation with *Robin boundary conditions* corresponding to an *incoming* flux. The derivation of the diffusive limit is based on an asymptotic expansion, which is rigorously justified.

Key words. diffusion approximation, transport equation, multiplying boundary condition, boundary layer, Milne problem, asymptotic expansion, spectral theory

1. Statement of the problem and main result. Traditionally, transport equations have been studied in media with either dissipative or conservative boundary conditions (BCs), while the possible multiplication of particles is confined to volume scattering effects (fission). Recently, multiplying BCs have attracted an interest on their own, first in connection with a model for cell population dynamics [R], and afterwards with the extension of general transport theory results [B1], [BE]. The cell population dynamics is described by an equation that shares strong formal similarities with the linear transport equation; in particular, multiplying BCs ensure the survivability of the cell population. For transport phenomena proper, multiplying BCs may occur in rarefied gas dynamics whereby, upon collision, molecules previously adsorbed at the boundaries may be liberated and reenter the medium. In heterogeneous reactors, with periodic structures of alternating slabs/rods/prisms of fissionable and moderating materials, one could model the effect of the fissionable material upon the moderating one as a multiplying boundary.

In general multidimensional geometries, multiplying BCs lead to difficulties, since the combined effect of geometry and net production of particles at the boundaries may result in the absence of overall control of the flux. In slab (one-dimensional) geometry, if the velocities are bounded, the growth effect can be controlled. This is also the case in general multidimensional geometries if the minimum travel time between two successive boundary collisions is bounded away from zero. Under these conditions, one can prove that the corresponding transport operator generates an exponentially bounded, positivity preserving evolution semigroup [BT], [MaT], [LaM], [B3].

In this paper, we consider the *diffusion limit* for the linear transport equation with *multiplying* BCs in slab geometry and provide the first proof of the existence

and precise meaning of such a limit. The derivation of diffusion (hydrodynamics) from transport with either dissipative or conservative BCs based on scaling arguments and/or asymptotic analysis has a rather long history. A more or less formal mathematical treatment can be found in [HM], [KL], [BLP], [Se], [Sa], [BSS], [DL2, Chap. XXI-5], [BM], [M1], [MPT], [MoT], and the references therein. However, when applied to *multiplying* BCs, the scaling method presents additional difficulties.

First, while conservative (dissipative) BCs for the transport equation result in Neumann (Dirichlet) BCs for the diffusion equation, without their own additional scaling, multiplying BCs have to be properly scaled: otherwise, in the limit of infinite time, they would lead to uncontrollable growth. To this end we introduce the scaled restitution coefficient at the surface $\alpha = 1 + \beta\varepsilon$ ($\beta > 0$), which means that we consider multiplying BCs which are almost conservative, and we prove that the corresponding transport semigroup is exponentially bounded in time, uniformly with respect to the scaling parameter ε. The time behavior is then controlled by adding an extra absorption term. We also study the spectral properties of the corresponding transport operator, which are related to the time asymptotic behavior of the transport semigroup. A direct estimate of the "leading eigenvalues," which could give a better understanding of the asymptotic behavior, is still missing.

The second difficulty is related to the boundary layer problem. Indeed, to carry out the analysis, we need to bound, uniformly in ε, the solution of the Milne problem with specularly reflecting BCs that arises from the boundary layer. The solvability condition of this Milne problem yields the BCs for the diffusion problem.

Finally, the proof of the convergence of the transport solution to the solution of the diffusive equation is based on rigorous estimates of the various terms in the asymptotic expansion. The interest of the asymptotic expansions is that the method permits one to solve the boundary layer problem. However, representing the solution of the transport equation as an expansion in the scaling parameter ε requires certain regularity of the solution of the diffusion equation and thereby of the data of the transport equation.

We state now the problem and the *main result*. Consider the linear transport equation

$$\text{Pb(1.1)} \quad \begin{cases} \dfrac{\partial f_\varepsilon}{\partial t}(x,\mu,t) = -\varepsilon^{-1}\mu\dfrac{\partial f_\varepsilon}{\partial x} - \varepsilon^{-2}Cf_\varepsilon - \gamma f_\varepsilon + S \quad \text{on } (-a,a)\times(-1,1)\times\mathbb{R}^+, \\ f_\varepsilon(-a,\mu,t) = (1+\beta\varepsilon)\ f_\varepsilon(-a,-\mu,t) + \varepsilon S^-(\mu), \quad \mu > 0, \\ f_\varepsilon(a,-\mu,t) = (1+\beta\varepsilon)\ f_\varepsilon(a,\mu,t) + \varepsilon S^+(\mu), \qquad \mu > 0, \\ f_\varepsilon(x,\mu,0) = f_0(x,\mu) \end{cases}$$

as an initial-boundary value problem in the space $L^2\big((-a,a)\times(-1,1)\big)$. Here γ and β are two positive constants, f_0 and S are in $L^2\big((-a,a)\times(-1,1)\big)$, and $S^+ \in L^2(0,1)$ and $S^- \in L^2(0,1)$. The collision operator C and the projection operator $\overline{P}$ are defined as

$$C\varphi(\mu) = \varphi(\mu) - P\varphi(\mu) = \varphi(\mu) - \frac{1}{2}\int_{-1}^{1}\varphi(\mu')\ d\mu', \quad \varphi \in L^2(-1,1),$$

$$\overline{P}\varphi = 2\int_0^1 \mu\varphi(\mu)d\mu, \quad \varphi \in L^2(0,1).$$

THEOREM 1. *Let γ be an absorption coefficient such that $\gamma > \frac{\beta}{2a} + \frac{\beta^2}{2}$. Let us assume that the data Pf_0 and PS are sufficiently smooth (for the precise conditions,*

see Lemma 3 *in section* 4*). Then the solution* f_ε *of the transport equation* Pb(1.1) *satisfies*

(1)
$$\|f_\varepsilon - f\|_{L^2((-a,a)\times(-1,1))} \le \varepsilon M e^{\delta T}, \quad \textit{uniformly on compact subsets of } \ t \in (0,T],$$

where $T > 0$*,* M *and* δ *are two positive constants independent of* T *and* ε*, and* f *is the solution of the related diffusion equation, considered as an initial-boundary value problem in* $H^1(-a,a)$*,*

$$\text{Pb(1.2)} \qquad \begin{cases} \dfrac{\partial f}{\partial t}(x,t) = \dfrac{1}{3}\dfrac{\partial^2 f}{\partial x^2} - \gamma f + PS \quad \textit{on } (-a,a)\times\mathbb{R}^+, \\ \dfrac{4}{3}\dfrac{\partial f}{\partial n} = \beta\ f + \overline{P}S^- \quad \textit{in } x = -a, \\ \dfrac{4}{3}\dfrac{\partial f}{\partial n} = \beta\ f + \overline{P}S^+ \quad \textit{in } x = a, \\ f(x,0) = Pf_0(x). \end{cases}$$

The additional absorption γ that appears in both the transport and diffusion problems is introduced in order to make the corresponding evolutions dissipative. Indeed, in the absence of net absorption, unscaled multiplying BCs lead to an unbounded semigroup, and even scaled multiplying BCs lead only to an exponentially bounded semigroup, with strictly positive type. On the other hand, introducing a suitable absorption, as described by the parameter γ, makes the semigroup a contraction, and as a result, the analysis is simplified. In this sense, the presence of γ may be viewed as a mathematical artifact. At the same time though, we note that γ estimates quite sharply the multiplicative effect of the boundaries. Besides and beyond the rigorous proof of the asymptotic equivalence between the transport and diffusive regimes as expressed by (1), this relationship between γ and β is an interesting result in itself, since it allows one to compare, within a specified geometry, the relative effects of the boundary multiplication and the volume absorption needed to counteract it.

The precise meaning and complete analysis of all the terms and operators appearing in the two problems above will be clarified in the next sections, as follows. In section 2 we study the properties of the transport operator with multiplying BCs in order to derive some exponential bound of the transport semigroup. In section 3 we investigate the Milne problem with specularly reflecting BCs that arises from the boundary layer. In section 4 we apply a scaling argument to prove the main result. Section 5 contains a short discussion.

2. Spectral properties of the transport operator. We define the space

$$\begin{aligned} W^2 &= W^2\big((-a,a)\times(-1,1)\big) \\ &= \left\{\varphi \in L^2\big((-a,a)\times(-1,1)\big);\ \mu\frac{\partial\varphi}{\partial x} \in L^2\big((-a,a)\times(-1,1)\big)\right\}, \end{aligned}$$

endowed with the norm $\|\varphi\|_{W^2} := (\|\varphi\|_{L^2}^2 + \|\mu\frac{\partial\varphi}{\partial x}\|_{L^2}^2)^{\frac{1}{2}}$, where L^2 denotes the usual $L^2\big((-a,a)\times(-1,1)\big)$-norm. It is known (see [DL2, Chap. XXI]) that functions of W^2 have traces on $\{a\}$ and on $\{-a\}$ in $L^2(-1,1)$.

We consider the transport operator

$$\text{(2)}\qquad \begin{cases} T_\varepsilon\varphi = -\dfrac{1}{\varepsilon}\ \mu\dfrac{\partial\varphi}{\partial x} - \dfrac{1}{\varepsilon^2}\ C\varphi, \\ D(T_\varepsilon) = \Big\{\varphi \in W^2,\ \varphi(-a,\mu) = \alpha\ \varphi(-a,-\mu) \text{ and } \varphi(a,-\mu) = \alpha\ \varphi(a,\mu) \text{ for } \mu > 0\Big\} \end{cases}$$

in a slab of width $2a$. The restitution coefficient at the surface, α, is strictly greater than 1, accounting for multiplying BCs. The collision operator C is a nonnegative self-adjoint operator on $L^2(-1,1)$. The spectrum of C is composed of two eigenvalues, namely, $\lambda = 0$ associated with the constant eigenvector and $\lambda = 1$ associated with the infinite-dimensional subspace of functions with zero mean. These two eigenspaces reduce the operator C. For convenience, we define the streaming operator [GMP]

$$A_\varepsilon\varphi = -\frac{1}{\varepsilon}\ \mu\frac{\partial\varphi}{\partial x} - \frac{1}{\varepsilon^2}\ \varphi, \qquad D(A_\varepsilon) = D(T_\varepsilon),$$

which generates a group (see [BT], [MaT], [LaM], and [B2]).

PROPOSITION 1. *The spectrum of A_ε, $\sigma(A_\varepsilon)$, is located in $\{\lambda \in \mathbb{C},\ -\frac{1}{\varepsilon^2} \le \operatorname{Re}\lambda \le -\frac{1}{\varepsilon^2} + \frac{\ln\alpha}{2a\varepsilon}\}$ and is composed of the line $\{\lambda \in \mathbb{C}, \operatorname{Re}\lambda = -\frac{1}{\varepsilon^2}\}$ and the segments*

$$\bigcup_{k\in\mathbb{Z}} \left\{ -\frac{1}{\varepsilon^2} + v\left(\frac{\ln\alpha}{2a\varepsilon} + i\ \frac{k\pi}{2a\varepsilon}\right),\ v \in [0,1]\right\}.$$

The spectrum of T_ε, $\sigma(T_\varepsilon)$, consists of the spectrum $\sigma(A_\varepsilon)$, plus possibly a denumerable set of isolated eigenvalues with finite algebraic multiplicities. Moreover, the semigroup generated by T_ε satisfies, for all $\varphi \in L^2\big((-a,a)\times(-1,1)\big)$, the estimate

$$\text{(3)}\qquad \left\| e^{tT_\varepsilon}\varphi\right\|_{L^2} \le \alpha\ e^{\omega(\alpha,\varepsilon)t}\ \|\varphi\|_{L^2}$$

with the exponential bound $\omega(\alpha,\varepsilon) = \frac{\ln\alpha}{2a\varepsilon} + \frac{1}{2\varepsilon^2}(\alpha + \frac{1}{\alpha} - 2)$.

Remark 1. With the scaled restitution coefficient $\alpha = 1 + \beta\varepsilon$ $(\beta > 0)$, the transport semigroup becomes exponentially bounded in time, uniformly in ε, since

$$w(1+\beta\varepsilon,\varepsilon) = \frac{\ln(1+\beta\varepsilon)}{2a\varepsilon} + \frac{1}{2\varepsilon^2}\left(1 + \beta\varepsilon + \frac{1}{1+\beta\varepsilon} - 2\right) \longrightarrow \frac{\beta}{2a} + \frac{\beta^2}{2}\ (\varepsilon \to 0).$$

Proof. First we study the spectrum of A_ε. Let us consider $\lambda = -\frac{1}{\varepsilon^2} + ib$, where $b \in \mathbb{R}$, and the sequence of functions $\varphi_n(x,\mu) = \sqrt{n}\ \mathrm{e}^{-i\frac{bx\varepsilon}{\mu} + \frac{1}{x^2-a^2}}\ f_n(\mu)$ $(n \in \mathbb{N})$, where $f_n(\mu) = n\mu\mathbb{1}_{[0,\frac{1}{n}]}(\mu) + (2-n\mu)\mathbb{1}_{[\frac{1}{n},\frac{2}{n}]}(\mu)$ and $\mathbb{1}_{[a,b]}(.)$ denotes the characteristic function of the interval $[a,b]$. We notice that φ_n is in the domain of A_ε and

$$(\lambda - A_\varepsilon)\ \varphi_n(x,\mu) = -\mu\ \frac{2x}{x^2-a^2}\ \varphi_n(x,\mu).$$

One verifies easily that there exists a constant $M > 0$ such that $\|\varphi_n\|_{L^2} \ge M$ and $\|(\lambda - A_\varepsilon)\varphi_n\|_{L^2}$ converges to zero as n tends to ∞. Therefore the line $\{\lambda \in \mathbb{C}, \operatorname{Re}\lambda = -\frac{1}{\varepsilon^2}\}$ belongs to the spectrum of A_ε.

Let us consider now $\lambda = -\frac{1}{\varepsilon^2} + v(\frac{\ln\alpha}{2a\varepsilon} + i\ \frac{k\pi}{2a\varepsilon})$, where $v \in (0,1)$ and $k \in \mathbb{Z}$, and the sequence of functions $\varphi_n(x,\mu) = \sqrt{n}\ \mathrm{e}^{-x\ \operatorname{sgn}(\mu)\ \left(\frac{\ln\alpha}{2a} + i\frac{k\pi}{2a}\right)}\ f_n(\mu)$ $(n \in \mathbb{N})$, where

$$\begin{aligned} f_n(\mu) = {} & (n(\mu+v)+1)\mathbb{1}_{[-v-\frac{1}{n},-v]}(\mu) + (-n(\mu+v)+1)\mathbb{1}_{[-v,-v+\frac{1}{n}]}(\mu) \\ & - (n(\mu-v)+1)\mathbb{1}_{[v-\frac{1}{n},v]}(\mu) - (-n(\mu-v)+1)\mathbb{1}_{[v,v+\frac{1}{n}]}(\mu). \end{aligned}$$

We notice that the functions φ_n are in the domain of A_ε and

$$(\lambda - A_\varepsilon)\ \varphi_n = \frac{\ln \alpha}{2a\varepsilon}\ (v - |\mu|)\ \varphi_n + \frac{k\pi i}{2a\varepsilon}\ (v - |\mu|)\ \varphi_n.$$

As before, one verifies that there exists a constant $M > 0$ such that $\|\varphi_n\|_{L^2} \geq M$ and $\|(\lambda - A_\varepsilon)\varphi_n\|_{L^2}$ converges to zero as n tends to ∞. Therefore the segment $\{-\frac{1}{\varepsilon^2} + v(\frac{\ln \alpha}{2a\varepsilon} + i\ \frac{k\pi}{2a\varepsilon}),\ v \in [0,1]\}$ belongs to the spectrum of A_ε.

The remainder of the complex plane is the resolvent set of the operator A_ε. This can be checked by writing down explicitly the expression of the evolution generated by A_ε, calculating the resolvent of A_ε via Laplace transform, and estimating its norm for complex numbers belonging to the complement of $\sigma(A_\varepsilon)$. A well-known compactness result (see [M2, Chap. 3]) ensures that the operators A_ε and T_ε have the same essential spectrum. Thus the spectrum of T_ε is composed of the spectrum of A_ε together with, possibly, isolated eigenvalues with finite algebraic multiplicities.

In order to prove the estimate (3), we consider the solution f_ε of the equation

$$\text{(4)}\qquad \begin{cases} \dfrac{\partial f_\varepsilon}{\partial t}(x,\mu,t) = -\dfrac{1}{\varepsilon}\mu\dfrac{\partial f_\varepsilon}{\partial x} - \dfrac{1}{\varepsilon^2}\ Cf_\varepsilon \quad \text{on } (-a,a)\times(-1,1)\times\mathbb{R}^+, \\ f_\varepsilon(-a,\mu,t) = \alpha\ f_\varepsilon(-a,-\mu,t), \quad \mu > 0, \\ f_\varepsilon(a,-\mu,t) = \alpha\ f_\varepsilon(a,\mu,t), \qquad \mu > 0, \\ f_\varepsilon(x,\mu,0) = \varphi(x,\mu), \end{cases}$$

where $\varphi \in L^2\big((-a,a)\times(-1,1)\big)$. We apply here the method of change of functions introduced in [LoM] in a related framework. Let $h_\varepsilon = \alpha^{\mathrm{sgn}(\mu)\frac{x}{2a}+\frac{1}{2}} f_\varepsilon$. The new function h_ε satisfies the following transport equation with (conservative) specularly reflecting BCs:

$$\text{(5)}\qquad \begin{cases} \dfrac{\partial h_\varepsilon}{\partial t}(x,\mu,t) = -\dfrac{1}{\varepsilon}\mu\dfrac{\partial h_\varepsilon}{\partial x} + \dfrac{1}{\varepsilon}|\mu|\dfrac{\ln\alpha}{2a}\ h_\varepsilon - \dfrac{1}{\varepsilon^2}\ h_\varepsilon \\ \quad + \dfrac{1}{2\varepsilon^2}\displaystyle\int_{-1}^{1} \alpha^{\frac{x}{2a}\ (\mathrm{sgn}(\mu)-\mathrm{sgn}(\mu'))}\ h_\varepsilon(x,\mu',t)\ d\mu' \quad \text{on } (-a,a)\times(-1,1)\times\mathbb{R}^+, \\ h_\varepsilon(-a,\mu,t) = h_\varepsilon(-a,-\mu,t), \quad \mu > 0, \\ h_\varepsilon(a,-\mu,t) = h_\varepsilon(a,\mu,t), \qquad \mu > 0, \\ h_\varepsilon(x,\mu,0) = \alpha^{\mathrm{sgn}(\mu)\frac{x}{2a}+\frac{1}{2}}\ \varphi(x,\mu). \end{cases}$$

Let us multiply the transport equation (5) by h_ε, integrate by parts on $(-a,a)\times(-1,1)\times(0,t)$ for $t > 0$, and use the specularly reflecting BCs; then

$$\frac{1}{2}\ \|h_\varepsilon(t)\|^2_{L^2} \leq \frac{1}{2}\ \|h_\varepsilon(0)\|^2_{L^2} + \left(\frac{\ln\alpha}{2a\varepsilon} - \frac{1}{\varepsilon^2}\right)\int_0^t \|h_\varepsilon(s)\|^2_{L^2}\ ds$$
$$+ \frac{1}{2\varepsilon^2}\int_0^t\int_{-a}^{a}\int_{-1}^{1}\int_{-1}^{1} \alpha^{\frac{x}{2a}\ (\mathrm{sgn}(\mu)-\mathrm{sgn}(\mu'))}\ h_\varepsilon(x,\mu',s)\ h_\varepsilon(x,\mu,s)\ d\mu' d\mu dx ds.$$

By noticing that the function $x \longmapsto \alpha^{\frac{x}{a}} + \alpha^{-\frac{x}{a}}$ attains its maximum on $[-a,a]$ in $-a$ and in a, it follows that

$$\int_{-a}^{a}\int_{-1}^{1}\int_{-1}^{1} \alpha^{\frac{x}{2a}\ (\mathrm{sgn}(\mu)-\mathrm{sgn}(\mu'))}\ h_\varepsilon(x,\mu')\ h_\varepsilon(x,\mu)\ d\mu' d\mu dx \leq \left(\alpha + \frac{1}{\alpha}\right)\ \|h_\varepsilon\|^2_{L^2},$$

yielding

$$\frac{1}{2}\ \|h_\varepsilon(t)\|^2_{L^2} \le \frac{1}{2}\ \alpha^2\|\varphi\|^2_{L^2} + \left(\frac{\ln\alpha}{2a\varepsilon} + \frac{1}{2\varepsilon^2}\left(\alpha + \frac{1}{\alpha} - 2\right)\right)\int_0^t \|h_\varepsilon(s)\|^2_{L^2}\ ds.$$

By Gronwall's lemma we have $\|h_\varepsilon(t)\|^2_{L^2} \le \alpha^2\ \mathrm{e}^{2\omega(\alpha,\varepsilon)t}\ \|\varphi\|^2_{L^2}$, which together with the inequality $\|f_\varepsilon(t)\|_{L^2} \le \|h_\varepsilon(t)\|_{L^2}$ concludes the proof. ∎

3. Milne problem with reflecting boundary conditions. The problem of the boundary layer is related to the conservative Milne problem with reflecting BCs in bounded and semi-infinite geometries. The difference in the nature of these geometries leads to somewhat different analyses. First, we introduce the functional spaces which we shall use in what follows. Let $H_T := L^2(((-1,1),|\mu|d\mu);L^\infty(0,\infty))$ and $L^2_\mu(0,1)$ denote the spaces of measurable functions for which the norms $\|\varphi\|^2_{H_T} := \int_{-1}^1 |\mu|\sup_{x\in(0,\infty)}|\varphi(x,\mu)|^2\,d\mu$, $\|\varphi\|^2_{L^2_\mu(0,1)} := \int_0^1 \mu|\varphi(\mu)|^2 d\mu$ are, respectively, bounded.

3.1. Bounded geometry.

LEMMA 1. *Let $e^{2a} > \alpha > 0$ (this condition is satisfied for $\alpha \in [0,1]$), and let f and g be in $L^2_\mu(0,1)$. Then there exists an extension ϕ of the functions f and g in W^2 which satisfies*

$$\text{(6)}\qquad \begin{cases} \mu\dfrac{\partial\phi}{\partial x} + \phi = 0 \quad \text{on } (-a,a)\times(-1,1), \\ \phi(-a,\mu) = \alpha\ \phi(-a,-\mu) + f(\mu), \quad \mu > 0, \\ \phi(a,-\mu) = \alpha\ \phi(a,\mu) + g(\mu), \quad \mu > 0. \end{cases}$$

Moreover, the extension application is continuous, i.e., there exists a constant M independent of α and a, such that

$$\|\phi\|_{W^2} \le M\alpha^2\big(\|f\|_{L^2_\mu(0,1)} + \|g\|_{L^2_\mu(0,1)}\big).$$

Proof. The solution of (6) is given, for $\mu > 0$, by

$$\phi(x,\mu) = \left(\mathrm{e}^{\frac{2a}{\mu}} - \alpha^2\mathrm{e}^{-\frac{2a}{\mu}}\right)^{-1}\left(\alpha g(\mu)\ \mathrm{e}^{-\frac{a+x}{\mu}} + f(\mu)\ \mathrm{e}^{-\frac{x-a}{\mu}}\right),$$

$$\phi(x,-\mu) = \left(\mathrm{e}^{\frac{2a}{\mu}} - \alpha^2\mathrm{e}^{-\frac{2a}{\mu}}\right)^{-1}\left(g(\mu)\ \mathrm{e}^{\frac{a+x}{\mu}} + \alpha f(\mu)\ \mathrm{e}^{\frac{x-a}{\mu}}\right).$$

If $\alpha > 1$, the condition $2a > \ln\alpha$ ensures $\mathrm{e}^{\frac{2a}{\mu}} - \alpha^2\mathrm{e}^{-\frac{2a}{\mu}} > 0$ for all $0 < \mu < 1$. ∎

LEMMA 2. *Let T_R be the transport operator with specularly reflecting BCs:*

$$\begin{cases} T_R\ \varphi = -\mu\dfrac{\partial\varphi}{\partial x} - C\varphi, \\ D(T_R) = \Big\{\varphi \in W^2,\ \varphi(-a,\mu) = \varphi(-a,-\mu)\ \textit{and}\ \varphi(a,-\mu) = \varphi(a,\mu)\ \textit{for}\ \mu > 0\Big\}. \end{cases}$$

The value 0 is an algebraically simple eigenvalue of T_R, associated with the constant eigenvector. The same result holds for the adjoint of T_R.

Proof. It is obvious that the constant functions are eigenfunctions of T_R associated with the eigenvalue 0. Let φ denote an eigenfunction associated with 0. Upon integrating by parts, we obtain $(T_R\varphi,\varphi) = (C\varphi,\varphi) = 0$, where the bracket denotes

the scalar product in $L^2\big((-a,a)\times(-1,1)\big)$. Then $C\varphi = 0$ and φ does not depend on μ. Thus φ is constant because $\frac{\partial\varphi}{\partial x} = 0$.

Now let us note that $(T_R\varphi, 1) = (-\mu\frac{\partial\varphi}{\partial x}, 1) - (C\varphi, 1) = -(\varphi, C1) = 0$. If φ is a generalized eigenfunction such that $T_R\varphi = 1$, then $(T_R\varphi, 1) = 4a$. Therefore T_R does not admit other generalized eigenfunctions beyond the constant functions. The same proof holds for the adjoint of T_R defined by $T_R^\star\,\varphi = \mu\frac{\partial\varphi}{\partial x} - C\varphi,\ D(T_R^\star) = D(T_R)$. ∎

From Lemma 2 and from the theory of isolated singularities of the resolvent (see [Y]), we deduce the Fredholm alternative for the operator T_R and the following proposition.

PROPOSITION 2. *Let f and g be in $L^2_\mu(0,1)$. The system*

$$\text{(7)}\qquad \begin{cases} \mu\dfrac{\partial\varphi}{\partial x} + C\varphi = 0 \quad \text{on } (-a,a)\times(-1,1), \\ \varphi(-a,\mu) = \varphi(-a,-\mu) + f(\mu), \quad \mu > 0, \\ \varphi(a,-\mu) = \varphi(a,\mu) + g(\mu), \quad \mu > 0, \end{cases}$$

admits a solution in W^2 if and only if

$$\text{(8)}\qquad \int_0^1 \mu\ \big(g(\mu) + f(\mu)\big)\ d\mu = 0.$$

Moreover, if they exist, the solutions are defined up to a constant, and there is a unique solution in $\ker(T_R)^\perp$ *which satisfies*

$$\text{(9)}\qquad \int_{-a}^{a}\int_{-1}^{1} \varphi(x,\mu)\ dxd\mu = 0.$$

Proof. According to Lemma 2, 0 is an algebraically simple eigenvalue of T_R and of its adjoint, $T_R{}^\star$, associated with the constant eigenvector. The associated spectral projection, P, is bounded and $\ker(P) = \overline{R(-T_R)}$ (see [Y]). Thus the range of T_R, $R(T_R)$, is a closed subspace and $R(T_R) = \overline{R(T_R)} = \ker(T_R{}^\star)^\perp = \ker(T_R)^\perp$.

Now let ϕ be the extension of f and g as in Lemma 1. Then φ satisfies (7) if and only if the function $\psi = \varphi - \phi$ satisfies the system

$$\text{(10)}\qquad \begin{cases} \mu\dfrac{\partial\psi}{\partial x} + C\psi = T_R\psi = -\mu\dfrac{\partial\phi}{\partial x} - C\phi \quad \text{on } (-a,a)\times(-1,1), \\ \psi(-a,\mu) = \psi(-a,-\mu), \quad \mu > 0, \\ \psi(a,-\mu) = \psi(a,\mu), \quad \mu > 0. \end{cases}$$

Since $R(T_R) = \ker(T_R)^\perp$, the system (10) admits a solution if and only if

$$\text{(11)}\qquad \int_{-a}^{a}\int_{-1}^{1}\Big(\mu\frac{\partial\phi}{\partial x}(x,\mu) + C\phi(x,\mu)\Big)dxd\mu = 0.$$

Moreover, the solution ψ is unique in $\ker(T_R)^\perp$, which implies

$$\int_{-a}^{a}\int_{-1}^{1} \varphi(x,\mu)\ dxd\mu = \int_{-a}^{a}\int_{-1}^{1} \phi(x,\mu)\ dxd\mu.$$

But $\phi = -\mu\frac{\partial\phi}{\partial x}$, and an integration by parts leads to (9). Likewise, we can see that condition (11) is equivalent to condition (8). ∎

3.2. Semi-infinite geometry. We note that, in contradistinction with the bounded geometry case, 0 belongs to the spectrum of the transport operator in semi-infinite geometry with reflecting BCs

$$\widetilde{T_R}\ \varphi = -\mu\frac{\partial\varphi}{\partial x} - C\varphi,\ D(\widetilde{T_R})$$
$$= \Big\{\varphi \in W^2\big((0,\infty)\times(-1,1)\big),\ \varphi(0,\mu) = \varphi(0,-\mu) \text{ for } \mu > 0\Big\}$$

but is *not* an isolated eigenvalue (see [P]).

PROPOSITION 3. *The systems*

$$\begin{cases} \pm\mu\dfrac{\partial\varphi}{\partial x} + C\varphi = 0 \quad \text{on } (0,\infty)\times(-1,1), \\ \varphi(0,\mu) = \varphi(0,-\mu) + f(\mu), \quad \mu > 0, \\ \lim\limits_{x\to\infty}\varphi(x,\mu) = 0 \end{cases} \tag{12}$$

admit a unique solution φ *in* $H_T \cap L^1((-1,1);\ L^\infty(0,\infty))$ *if* $f \in L^2_\mu(0,1)$, *in* $L^p((-1,1);\ L^\infty(0,\infty))$ *for all* $1 \le p < \infty$ *if* $f \in L^2(0,1)$, *and in* $L^\infty((0,\infty)\times(-1,1))$ *if* $f \in L^\infty(0,1)$ *if and only if*

$$\int_0^1 \mu f(\mu)d\mu = 0. \tag{13}$$

Moreover, there exists a positive constant M *such that*

$$\|\varphi\|_{H_T} \le M\|f\|_{L^2_\mu(0,1)}, \tag{14}$$

$$\|\varphi\|_{L^1((-1,1);\ L^\infty(0,\infty))} \le M\|f\|_{L^2_\mu(0,1)}, \tag{15}$$

$$\|\varphi\|_{L^p((-1,1);\ L^\infty(0,\infty))} \le M\|f\|_{L^2(0,1)}, \tag{16}$$

$$\|\varphi\|_{L^\infty} \le M\|f\|_{L^\infty(0,1)}, \tag{17}$$

$$\|\varphi(0,.)\|_{L^2(0,1)} \le M\|f\|_{L^2(0,1)}. \tag{18}$$

Proof. We consider the problem

$$\begin{cases} \mu\dfrac{\partial\varphi}{\partial x} + C\varphi = 0 \quad \text{on } (0,\infty)\times(-1,1), \\ \varphi(0,\mu) = \varphi(0,-\mu) + f(\mu), \quad \mu > 0, \\ \lim\limits_{x\to\infty}\varphi(x,\mu) = 0. \end{cases} \tag{19}$$

First we notice that, by integrating (19) with respect to x and μ, we get $\int_0^1 \mu f(\mu)d\mu = 0$. Now let $f \in L^2_\mu(0,1)$. Integration of (19) with respect to the spatial variable leads to

$$\begin{cases} \varphi(x,\mu) = -\dfrac{1}{\mu}\displaystyle\int_x^\infty \mathrm{e}^{\frac{s-x}{\mu}} P\varphi(s)ds, \quad \mu < 0, \\ \varphi(x,\mu) = \dfrac{1}{\mu}\displaystyle\int_0^x \mathrm{e}^{\frac{s-x}{\mu}} P\varphi(s)ds + \dfrac{1}{\mu}\int_0^\infty \mathrm{e}^{-\frac{s+x}{\mu}} P\varphi(s)ds + f(\mu)\mathrm{e}^{-\frac{x}{\mu}}, \quad \mu > 0. \end{cases} \tag{20}$$

By integrating (20) with respect to μ, we obtain that $P\varphi$ satisfies the integral equation

$$P\varphi(x) = \int_0^\infty H(x,s)P\varphi(s)ds + \frac{1}{2}\int_0^1 f(\mu)\mathrm{e}^{-\frac{x}{\mu}}d\mu,$$

where

$$H(x,s) = \frac{1}{2}\int_0^1 \frac{1}{\mu}\mathrm{e}^{-\frac{|x-s|}{\mu}}d\mu + \frac{1}{2}\int_0^1 \frac{1}{\mu}\mathrm{e}^{-\frac{|x+s|}{\mu}}d\mu = \frac{1}{2}\int_1^\infty \frac{1}{t}\mathrm{e}^{-t|x-s|}dt + \frac{1}{2}\int_1^\infty \frac{1}{t}\mathrm{e}^{-t|x+s|}dt.$$

Let H be the operator which acts on $L^2(0,\infty)$ as

$$Hg(x) = \int_0^\infty H(x,s)g(s)ds,$$

and let

$$F(x) = \frac{1}{2}\int_0^1 f(\mu)\mathrm{e}^{-\frac{x}{\mu}}d\mu.$$

We introduce the subspace $X = \{h \in L^2(0,\infty) \mid |||h||| < \infty\}$, endowed with the norm $|||h|||^2 = \|h\|_{L^2}^2 + \big(\int_0^\infty x^2|h(x)|dx\big)^2$. We check easily that $|||F||| \le C\|f\|_{L^2_\mu(0,1)}$. Then $P\varphi$ is a solution g of the equation $g - Hg = F$, with $F \in X$.

Now, let us consider the even extension of the functions g and F to $\mathbb{R}$. Since the kernel H is an even function in each variable, it follows that

$$Hg(x) = \int_{-\infty}^\infty \frac{1}{2}\int_1^\infty \frac{1}{t}\mathrm{e}^{-t|x-s|}dt\ g(s)ds.$$

Thus, we can take advantage of the Fourier analysis, as in [P]. The preceding equation is equivalent to

$$\hat{g}(\xi)\Big(1 - \frac{\arctan(\xi)}{\xi}\Big) = \hat{F}(\xi), \tag{21}$$

where $\hat{h}(\xi) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^\infty h(x)\ \mathrm{e}^{i\xi x}\ dx$ denotes the Fourier transform of a function h and $\xi \longmapsto \frac{\arctan(\xi)}{\xi}$ is the Fourier transform of the function $x \longmapsto \frac{1}{2}\int_1^\infty \frac{1}{t}\mathrm{e}^{-t|x|}dt$. Since F belongs to X, the Fourier transform of F, $\hat{F}$, belongs to $\mathcal{C}^2(\mathbb{R})$. Also, since the function $\xi \longmapsto (1 - \frac{\arctan(\xi)}{\xi})^{-1}$ has a quadratic singularity in $\xi = 0$, (21) admits a unique solution if and only if $\hat{F}(0) = 0$ and $\frac{d\hat{F}}{d\xi}(0) = 0$. While the condition

$$\frac{d\hat{F}}{d\xi}(0) = i\int_{-\infty}^\infty xF(x)dx = 0$$

is always satisfied due to the evenness of F, the condition

$$\hat{F}(0) = \int_{-\infty}^\infty F(x)dx = 2\int_0^\infty F(x)dx = 0$$

with $F(x) = \frac{1}{2}\int_0^1 f(\mu)\mathrm{e}^{-\frac{x}{\mu}}d\mu$ is implied by condition (13). We estimate now the $L^2(0,\infty)$-norm of the solution $g = P\varphi$ of (21). Let $\varepsilon > 0$; then according to Plancherel's formula, we get

$$\int_0^\infty |P\varphi(x)|^2dx = \int_0^\varepsilon \Big|\frac{\xi}{\xi - \arctan(\xi)}\ \hat{F}(\xi)\Big|^2 d\xi + \int_\varepsilon^\infty \Big|\frac{\xi}{\xi - \arctan(\xi)}\ \hat{F}(\xi)\Big|^2 d\xi.$$

On the one hand, by using the uniform boundedness on $\mathbb{R}^2$ of the function $(x,\xi)\in \mathbb{R}^2 \longmapsto \frac{e^{ix\xi}-1-ix\xi}{x^2\xi^2}$, we have

$$\begin{aligned}\int_0^\varepsilon \Big|\frac{\xi}{\xi-\arctan(\xi)}\ \hat F(\xi)\Big|^2 d\xi &\le C_2(\varepsilon)\int_0^\varepsilon \Big|\frac{\hat F(\xi)}{\xi^2}\Big|^2 d\xi\\ &= C_2(\varepsilon)\int_0^\varepsilon \Big|\frac{\hat F(\xi)-\hat F(0)-i\xi(\widehat{xF})(0)}{\xi^2}\Big|^2 d\xi\\ &= C_2(\varepsilon)\int_0^\varepsilon \Big|\int_0^\infty F(x)\ \frac{e^{ix\xi}-1-ix\xi}{\xi^2}\ dx\Big|^2 d\xi \le C_2(\varepsilon)\left(\int_0^\infty x^2|F(x)|\ dx\right)^2.\end{aligned}$$

On the other hand, it is easy to check that

$$\int_\varepsilon^\infty \Big|\frac{\xi}{\xi-\arctan(\xi)}\ \hat F(\xi)\Big|^2 d\xi \le C_1(\varepsilon)\int_\varepsilon^\infty \big|\hat F(\xi)\big|^2 d\xi \le C_1(\varepsilon)\|F\|_{L^2}^2.$$

Therefore, $\|P\varphi\|_{L^2(0,\infty)} \le |||F|||$ and $\|P\varphi\|_{L^2(0,\infty)} \le C\|f\|_{L^2_\mu(0,1)}$. Thus, we showed that $P\varphi$ is uniquely defined if condition (13) is satisfied, and (20) gives the solution of (19). To prove (14), we estimate each part of (20) as follows:

$$\int_0^1 \mu|f(\mu)|^2 \sup_{x\in(0,\infty)} |e^{-\frac{x}{\mu}}|^2 d\mu \ \le\ \|f\|^2_{L^2_\mu(0,1)},$$

$$\begin{aligned}\int_0^1 \frac{\mu}{\mu^2}\sup_{x\in(0,\infty)}\Big|\int_0^\infty e^{-\frac{s+x}{\mu}}P\varphi(s)ds\Big|^2 d\mu &= \int_0^1 \frac{d\mu}{\mu}\left(\sup_{x\in(0,\infty)} e^{-\frac{2x}{\mu}}\right)\Big|\int_0^\infty e^{-\frac{s}{\mu}}P\varphi(s)ds\Big|^2\\ &\le \int_0^1 \frac{d\mu}{\mu}\int_0^\infty e^{-\frac{2s}{\mu}}ds\int_0^\infty |P\varphi(s)|^2 ds \le M\|f\|^2_{L^2_\mu(0,1)},\end{aligned}$$

$$\begin{aligned}\int_0^1 \frac{\mu}{\mu^2}\sup_{x\in(0,\infty)}\Big|\int_0^x e^{\frac{s-x}{\mu}}P\varphi(s)ds\Big|^2 d\mu &\le \int_0^1 \frac{d\mu}{\mu}\sup_{x\in(0,\infty)}\int_0^x e^{2\frac{s-x}{\mu}}ds\int_0^x |P\varphi(s)|^2 ds\\ &\le \int_0^1 \frac{d\mu}{\mu}\ \frac{\mu}{2}\int_0^\infty |P\varphi(s)|^2 ds \le M\|f\|^2_{L^2_\mu(0,1)},\end{aligned}$$

$$\begin{aligned}\int_{-1}^0 \frac{|\mu|}{\mu^2}\sup_{x\in(0,\infty)}\Big|\int_x^\infty e^{\frac{s-x}{\mu}}P\varphi(s)ds\Big|^2 d\mu &\le \int_0^1 \frac{d\mu}{\mu}\sup_{x\in(0,\infty)}\int_x^\infty e^{2\frac{x-s}{\mu}}ds\int_x^\infty |P\varphi(s)|^2 ds\\ &\le \int_0^1 \frac{d\mu}{\mu}\ \frac{\mu}{2}\int_0^\infty |P\varphi(s)|^2 ds \le M\|f\|^2_{L^2_\mu(0,1)}.\end{aligned}$$

Inequality (15) is obtained using similar estimates.

We show now that $P\varphi$ is a bounded function if $f\in L^2(0,1)$; more precisely, there exists $M>0$ such that

$$\|P\varphi\|_{L^\infty(0,\infty)} \le M\|f\|_{L^2(0,1)}. \tag{22}$$

One first notices, by using the evenness of F, that

$$\hat{F}(\xi) = \frac{2}{\sqrt{2\pi}} \int_0^1 \frac{\mu f(\mu)}{1+\xi^2\mu^2}\, d\mu.$$

Then, as $P\varphi$ is the inverse Fourier transform of $\hat{g}$, it is sufficient to prove that $\hat{g}$ from (20) is bounded in $L^1(\mathbb{R})$. As before, we choose a sufficiently small $\varepsilon > 0$ and get

$$\int_0^\varepsilon \Big|\frac{\xi}{\xi - \arctan(\xi)}\, \hat{F}(\xi)\Big| d\xi = \int_0^\varepsilon \Big|\frac{\xi^3}{\xi - \arctan(\xi)}\, \frac{\hat{F}(\xi)}{\xi^2}\Big| d\xi \le C_2(\varepsilon) \left(\int_0^\varepsilon \Big|\frac{\hat{F}(\xi)}{\xi^2}\Big|^2 d\xi \right)^{1/2}$$
$$\le C_2(\varepsilon) \int_0^\infty x^2 |F(x)|\, dx \le C_2(\varepsilon)\, \|f\|_{L^2_\mu(0,1)} \;\le\; C_2(\varepsilon)\, \|f\|_{L^2(0,1)}.$$

On the other hand,

$$\int_\varepsilon^\infty \Big|\frac{\xi}{\xi - \arctan(\xi)}\, \hat{F}(\xi)\Big| d\xi \le C_1(\varepsilon) \int_\varepsilon^\infty |\hat{F}(\xi)| d\xi \le C_1(\varepsilon) \int_\varepsilon^\infty d\xi \int_0^1 \frac{\mu |f(\mu)|}{1+\xi^2\mu^2}\, d\mu$$
$$\le C_1(\varepsilon)\, \|f\|_{L^2(0,1)} \int_\varepsilon^\infty \left(\int_0^1 \frac{\mu^2}{\left(1+\xi^2\mu^2\right)^2}\, d\mu \right)^{1/2} d\xi \le C_1(\varepsilon)\, \|f\|_{L^2(0,1)}.$$

Thus estimate (22) is proven.

From (22) and (20), we easily obtain the estimates (16), (17), and (18). Finally, a similar result holds for the system

$$\begin{cases} -\mu \dfrac{\partial \varphi}{\partial x} + C\varphi = 0 \quad \text{on } (0,\infty)\times(-1,1), \\ \varphi(0,\mu) = \varphi(0,-\mu) + f(\mu), \quad \mu > 0, \\ \lim\limits_{x\to\infty} \varphi(x,\mu) = 0. \end{cases} \qquad \square$$

We consider now the Milne problem without the decay condition at infinity.

PROPOSITION 4. *Let $f \in L^2(0,1)$ and $1 \le p < \infty$. If $\int_0^1 \mu f(\mu) d\mu = 0$, then the systems*

$$\begin{cases} \pm\mu \dfrac{\partial \varphi}{\partial x} + C\varphi = 0 \quad \text{on } (0,\infty)\times(-1,1), \\ \varphi(0,\mu) = \varphi(0,-\mu) + f(\mu), \quad \mu > 0, \end{cases} \tag{23}$$

admit an infinity of solutions in $L^p((-1,1);\ L^\infty(0,\infty))$, or in $L^\infty((0,\infty)\times(-1,1))$ if $f \in L^\infty(0,1)$. These solutions are obtained by adding any constant to the unique solution of (12).

Proof. From the method introduced in [BSS], slightly modified in [DL2, Chap. XXI.3, Appendix, p. 335], we know (see the proof of [DL2, Thm. 3, p. 340]) that there exists a sequence $\{x_n\}_{n\in\mathbb{N}}$ such that $x_n \longrightarrow \infty$ and the solution φ of (23) satisfies

$$\int_0^{x_n} dx \int_{-1}^1 \big(\varphi(x,\mu) - P\varphi(x)\big)^2 d\mu \le \frac{1}{2} \int_{-1}^1 \mu \varphi^2(0,\mu) d\mu.$$

To prove the above estimate, the authors use only the fact that the solution is bounded in the space variable. Now if $f = 0$, we get

$$\int_{-1}^1 \mu\varphi^2(0,\mu) d\mu = \int_0^1 \mu\big(\varphi^2(0,\mu) - \varphi^2(0,-\mu)\big) d\mu = 0.$$

Therefore φ is independent of the velocity variable, and thus $\frac{\partial\varphi}{\partial x} = 0$ and φ is a constant. $\square$

4. Proof of the main result. In order to prove the existence of all the terms in the asymptotic expansion in the proof of Theorem 1, we need a few additional regularity results for the solution of the diffusion equation Pb(1.2). These results are warranted by the following lemma.

LEMMA 3. *If the data Pf_0 and PS are in $L^2(-a,a)$, then the problem* Pb(1.2) *admits a unique solution in $H^1(-a,a)$. Let h be a smooth extension function of the sources on the boundary $\overline{P}S^{\pm}$. Assuming that both functions Pf_0-h and $PS-\frac{1}{3}\frac{\partial^2 h}{\partial x^2}+\gamma h$ belong to $H^{10}(-a,a)$ and satisfy the BCs*

$$\frac{4}{3}\frac{\partial^{2i+1}}{\partial x^{2i+1}}\dot{}(\pm a)=\pm\beta\frac{\partial^{2i}}{\partial x^{2i}}\dot{}(\pm a),\quad i=0,\dots,4, \tag{24}$$

then the solution f of Pb(1.2) *is in $H^5(-a,a)$ and there exist two positive constants M and δ such that*

$$\left\|\frac{\partial^i f}{\partial x^i}(t)\right\|_{L^2(-a,a)}\le Me^{\delta t}\qquad \forall t\ge 0,\ i=1,\dots,5. \tag{25}$$

Remark 2. Notice that the exponential bound $\mathrm{e}^{\delta t}$ in estimate (25) is due to the fact that the Robin BCs are unstable. With the assumptions of Lemma 3, the solution f of the diffusion equation Pb(1.2) is in fact in $H^{10}(-a,a)$. The assumptions of Lemma 3 can probably be refined; here we focus only on the rigorous justification of the asymptotic expansion to prove the asymptotic equivalence as quantified by (1).

Proof. To simplify the proof we remove the constant 4/3 in the BCs. First, we use the superposition principle to eliminate the nonhomogeneous sources at the boundary, and define the (smooth) extension function

$$h(x)=\frac{\overline{P}S^+}{4a^2}(x+a)^2(x-a)+\frac{\overline{P}S^-}{4a^2}(x-a)^2(x+a).$$

Thus the function $g=f-h$ satisfies the following equation with homogeneous BCs:

$$\begin{cases}\dfrac{\partial g}{\partial t}(x,t)=\dfrac{1}{3}\dfrac{\partial^2 g}{\partial x^2}-\gamma g+\psi,\\ \dfrac{\partial g}{\partial n}=\beta\ g\quad \text{in } x=-a \text{ and } x=a,\\ g(x,0)=\varphi,\end{cases} \tag{26}$$

where $\varphi=Pf_0-h$ and $\psi=PS-\frac{1}{3}\frac{\partial^2 h}{\partial x^2}+\gamma h$.

We can now apply the variational theory (see, for example, [DL1, Chap. VII.2.3.2]) to deduce the existence of a solution in $H^1(-a,a)$ and that the operator

$$T_Df=\frac{1}{3}\frac{\partial^2 f}{\partial x^2}-\gamma f,\ D(T_D)=\left\{f\in H^2(-a,a),\ \frac{\partial f}{\partial x}(a)=\beta f(a),\ \frac{\partial f}{\partial x}(-a)=-\beta f(-a)\right\}$$

generates an analytic semigroup. Notice that the assumptions in Lemma 3 are equivalent to the fact that $\varphi\in D(T_D^5)$ and $\psi\in D(T_D^5)$. Then the semigroup theory (see [Pa]) implies that the solution g belongs to $D(T_D^5)$, namely, $g\in H^{10}(-a,a)$ and

$$\frac{\partial^{2i+1}g}{\partial x^{2i+1}}(\pm a)=\pm\beta\frac{\partial^{2i}g}{\partial x^{2i}}(\pm a),\quad i=0,\dots,4. \tag{27}$$

For sake of brevity, we omit here the rather technical proof of estimates (25); the interested reader can find them in [PT]. □

Proof of Theorem 1. We seek the solution f_ε in the form

$$f_\varepsilon = u_\varepsilon^0(x,\mu,t) + u_\varepsilon^i\left(x,\mu,\tau=\frac{t}{\varepsilon^2}\right) + u_\varepsilon^b\left(\xi=\frac{x}{\varepsilon},\mu,t\right) + w_\varepsilon(x,\mu,t),$$

where u_ε^0, u_ε^i, u_ε^b, and w_ε denote, respectively, the interior, initial layer, boundary layer, and remainder terms. Each one of these first three terms is assumed to satisfy exactly the transport equation and is written as an asymptotic expansion in ε, namely,

$$u_\varepsilon^0 = \sum_{n=0}^{\infty}\varepsilon^n u_n^0, \quad u_\varepsilon^i = \sum_{n=0}^{\infty}\varepsilon^n u_n^i, \quad u_\varepsilon^b = \sum_{n=0}^{\infty}\varepsilon^n u_n^b.$$

In what follows we expand u_ε^0 and u_ε^b to order 2 and u_ε^i to order 0 in ε. The initial layer term is assumed to satisfy

$$u_0^i(\tau) \longrightarrow 0 \ (\tau\to\infty). \tag{28}$$

The boundary layer terms are written as

$$u_j^b\left(\frac{x}{\varepsilon},\mu,t\right) = u_j^{b+}\left(\xi_+=\frac{a-x}{\varepsilon},\mu,t\right)\mathbb{1}_{(0,a)}(x) + u_j^{b-}\left(\xi_-=\frac{a+x}{\varepsilon},\mu,t\right)\mathbb{1}_{(-a,0)}(x)$$
$$(j=0,1,2).$$

Each term u_j^{b+} and u_j^{b-} $(j=0,1,2)$ are in fact defined on $\xi_\pm\in(0,\infty)$ and assumed to satisfy

$$u_j^{b\pm}(\xi_\pm) \longrightarrow 0 \ (\xi_\pm\to\infty) \quad (j=0,1,2). \tag{29}$$

In the initial and boundary layer terms we perform the change of variables $\tau = \frac{t}{\varepsilon^2}$ and $\xi = \frac{x}{\varepsilon}$, respectively. By replacing each term in Pb(1.1) and equating the coefficients of corresponding powers in ε, we get

$$Cu_0^0 = 0, \tag{30}$$

$$Cu_1^0 = -\mu\frac{\partial u_0^0}{\partial x}, \tag{31}$$

$$Cu_2^0 = -\Big(\frac{\partial u_0^0}{\partial t} + \mu\frac{\partial u_1^0}{\partial x} + \gamma u_0^0 - S\Big), \tag{32}$$

$$\frac{\partial u_0^i}{\partial\tau} = -Cu_0^i, \tag{33}$$

$$\mu\frac{\partial u_0^b}{\partial\xi} + Cu_0^b = 0, \tag{34}$$

$$\mu\frac{\partial u_1^b}{\partial\xi} + Cu_1^b = 0, \tag{35}$$

$$\mu\frac{\partial u_2^b}{\partial \xi} + Cu_2^b = -\gamma u_0^b - \frac{\partial u_0^b}{\partial t}. \tag{36}$$

The same procedure applied to the initial data and the BCs leads to

$$u_0^0(x,\mu,0) + u_0^i(x,\mu,0) = f_0(x,\mu), \tag{37}$$

and for $\mu > 0$

$$\begin{cases} u_0^0(-a,\mu) + u_0^b\left(-\frac{a}{\varepsilon},\mu\right) = u_0^0(-a,-\mu) + u_0^b\left(-\frac{a}{\varepsilon},-\mu\right), \\ u_0^0(a,-\mu) + u_0^b\left(\frac{a}{\varepsilon},-\mu\right) = u_0^0(a,\mu) + u_0^b\left(\frac{a}{\varepsilon},\mu\right), \end{cases} \tag{38}$$

(39)
$$\begin{cases} u_1^0(-a,\mu) + u_1^b\left(-\frac{a}{\varepsilon},\mu\right) = u_1^0(-a,-\mu) + u_1^b\left(-\frac{a}{\varepsilon},-\mu\right) \\ \qquad\qquad + \beta u_0^0(-a,-\mu) + \beta u_0^b\left(-\frac{a}{\varepsilon},-\mu\right) + S^-, \\ u_1^0(a,-\mu) + u_1^b\left(\frac{a}{\varepsilon},-\mu\right) = u_1^0(a,\mu) + u_1^b\left(\frac{a}{\varepsilon},\mu\right) + \beta u_0^0(a,\mu) + \beta u_0^b\left(\frac{a}{\varepsilon},\mu\right) + S^+, \end{cases}$$

(40)
$$\begin{cases} u_2^b\left(-\frac{a}{\varepsilon},\mu\right) + u_2^0(-a,\mu,t) = u_2^b\left(-\frac{a}{\varepsilon},-\mu\right) + \beta u_1^b\left(-\frac{a}{\varepsilon},-\mu\right) \\ \qquad\qquad + u_2^0(-a,-\mu,t) + \beta u_1^0(-a,-\mu,t), \\ u_2^b\left(\frac{a}{\varepsilon},-\mu\right) + u_2^0(a,-\mu,t) = u_2^b\left(\frac{a}{\varepsilon},\mu\right) + \beta u_1^b\left(\frac{a}{\varepsilon},\mu\right) + u_2^0(a,\mu,t) + \beta u_1^0(a,\mu,t). \end{cases}$$

Equations (30)–(33) are treated in a standard manner (see [Sa], [BSS], and [DL2, Chap. XXI-5]). Equation (30) implies that u_0^0 belongs to $\ker(C)$, i.e., $u_0^0(x,\mu,t) = u_0^0(x,t)$. We solve (31) and (32) using the solvability condition $R(C) = \ker(C)^\perp$, implied by the Fredholm alternative, since C is self-adjoint. Let us note that the solvability condition for (31) is trivially satisfied, and

$$u_1^0(x,\mu,t) = -\mu\frac{\partial u_0^0}{\partial x}(x,t) + c_1(x,t).$$

In what follows we shall take $c_1 = 0$. The solvability condition for (32),

$$\int_{-1}^{1}\Big(\frac{\partial u_0^0}{\partial t}(x,t) + \mu\frac{\partial u_1^0}{\partial x}(x,\mu,t) + \gamma u_0^0(x,t) - S\Big)\,d\mu = 0,$$

leads to the *diffusion equation* in Pb(1.2), namely,

$$\frac{\partial u_0^0}{\partial t} = \frac{1}{3}\frac{\partial^2 u_0^0}{\partial x^2} - \gamma u_0^0 + PS.$$

From (33), the initial layer term is given by

$$u_0^i\left(x,\mu,\frac{t}{\varepsilon^2}\right) = \frac{1}{2}\int_{-1}^{1} u_0^i(x,\mu',0)\,d\mu' \;+\; \mathrm{e}^{-\frac{t}{\varepsilon^2}}\;\left(u_0^i(x,\mu,0) - \frac{1}{2}\int_{-1}^{1} u_0^i(x,\mu',0)\,d\mu'\right).$$

Condition (28) yields $u_0^i(x,\mu,0) \in \ker(C)^\perp = \ker(Id - C)$, namely,

$$u_0^i(x,\mu,0) = f_0(x,\mu) - \frac{1}{2}\int_{-1}^{1} f_0(x,\mu')\ d\mu',$$

hence

$$u_0^i\left(x,\mu,\frac{t}{\varepsilon^2}\right) = \mathrm{e}^{-\frac{t}{\varepsilon^2}}\ \left(f_0(x,\mu) - \frac{1}{2}\int_{-1}^{1} f_0(x,\mu')\ d\mu'\right).$$

Consequently, (37) implies the *initial condition* for the diffusion equation in Pb(1.2):

$$u_0^0(x,0) = \frac{1}{2}\int_{-1}^{1} f_0(x,\mu')\ d\mu'.$$

To complete the analysis and show that u_0^0 is indeed the solution of Pb.(1.2), we treat now the boundary layer problem. Since u_0^0 does not depend on μ, and taking into account (34) and (39), the term u_0^b satisfies

$$\begin{cases} \mu\dfrac{\partial u_0^b}{\partial \xi} + Cu_0^b = 0 \quad \text{on } \left(-\dfrac{a}{\varepsilon},\dfrac{a}{\varepsilon}\right)\times(-1,1), \\ u_0^b\left(-\dfrac{a}{\varepsilon},\mu\right) = u_0^b\left(-\dfrac{a}{\varepsilon},-\mu\right), \quad \mu>0, \\ u_0^b\left(\dfrac{a}{\varepsilon},-\mu\right) = u_0^b\left(\dfrac{a}{\varepsilon},\mu\right), \quad \mu>0. \end{cases}$$

Then Lemma 2 implies that u_0^b is a constant, and condition (29) implies that $u_0^b = 0$. According to (35) and (38), the term u_1^b satisfies

(41)
$$\begin{cases} \mu\dfrac{\partial u_1^b}{\partial \xi} + Cu_1^b = 0 \quad \text{on } \left(-\dfrac{a}{\varepsilon},\dfrac{a}{\varepsilon}\right)\times(-1,1), \\ u_1^b\left(-\dfrac{a}{\varepsilon},\mu\right) = u_1^b\left(-\dfrac{a}{\varepsilon},-\mu\right) + 2\mu\dfrac{\partial u_0^0}{\partial x}(-a,t) + \beta u_0^0(-a,t) + S^-(\mu), \quad \mu>0, \\ u_1^b\left(\dfrac{a}{\varepsilon},-\mu\right) = u_1^b\left(\dfrac{a}{\varepsilon},\mu\right) - 2\mu\dfrac{\partial u_0^0}{\partial x}(a,t) + \beta u_0^0(a,t) + S^+(\mu), \quad \mu>0. \end{cases}$$

We note that u_1^b depends on the parameter t, which appears in the nonhomogeneous boundary terms. Let us define, for $\mu > 0$, the functions f and g as

$$f(\mu,t) = 2\mu\frac{\partial u_0^0}{\partial x}(-a,t) + \beta u_0^0(-a,t) + S^-(\mu), \quad g(\mu,t) = -2\mu\frac{\partial u_0^0}{\partial x}(a,t) + \beta u_0^0(a,t) + S^+(\mu).$$

According to Proposition 2, (41) admits some solutions u_1^b in $L^2\big((-a,a)\times(-1,1)\big)$ if and only if

$$\int_0^1 \mu\Big(f(\mu,t) + g(\mu,t)\Big)\ d\mu = 0. \tag{42}$$

Condition (42) is equivalent to

$$-\frac{2}{3}\frac{\partial u_0^0}{\partial x}(a,t) + \frac{\beta}{2}u_0^0(a,t) + \frac{2}{3}\frac{\partial u_0^0}{\partial x}(-a,t) + \frac{\beta}{2}u_0^0(-a,t) + \frac{1}{2}\overline{P}S^+ + \frac{1}{2}\overline{P}S^- = 0,$$

which leads to the *nonhomogeneous Robin BCs* in Pb(1.2). The boundedness of u_1^b in ε can be obtained from the solution of the Milne problem in semi-infinite geometry. The change of variables $\xi_\pm = \frac{a \mp x}{\varepsilon}$ implies

$$
\left\{
\begin{array}{l}
-\mu \dfrac{\partial u_1^{b+}}{\partial \xi_+} + C u_1^{b+} = 0 \quad \text{on } (0,\infty)\times(-1,1), \\
u_1^{b+}(0,-\mu) = u_1^{b+}(0,\mu) - 2\mu \dfrac{\partial u_0^0}{\partial x}(a,t) + \beta u_0^0(a,t) + S^+(\mu), \quad \mu > 0, \\
\lim\limits_{\xi_+ \to \infty} u_1^{b+}(\xi_+,\mu) = 0,
\end{array}
\right. \tag{43}
$$

$$
\left\{
\begin{array}{l}
\mu \dfrac{\partial u_1^{b-}}{\partial \xi_-} + C u_1^{b-} = 0 \quad \text{on } (0,\infty)\times(-1,1), \\
u_1^{b-}(0,\mu) = u_1^{b-}(0,-\mu) + 2\mu \dfrac{\partial u_0^0}{\partial x}(-a,t) + \beta u_0^0(-a,t) + S^-(\mu), \ \mu > 0, \\
\lim\limits_{\xi_- \to \infty} u_1^{b-}(\xi_-,\mu) = 0.
\end{array}
\right. \tag{44}
$$

Proposition 3 yields that (43) and (44) admit, respectively, a unique solution in $L^2((-1,1);L^\infty(0,\infty))$, and give separately the previous nonhomogeneous Robin BCs at a and $-a$. We deduce from

$$
\left\| u_1^b\left(\frac{x}{\varepsilon},\mu\right)\right\|^2_{L^2((-a,a)\times(-1,1))} \le a\Big(\|u_1^{b_+}\|^2_{L^2((-1,1);L^\infty(0,\infty))} + \|u_1^{b_-}\|^2_{L^2((-1,1);L^\infty(0,\infty))}\Big) \tag{45}
$$

that u_1^b is uniformly bounded in ε in $L^2((-a,a)\times(-1,1))$. Indeed

$$
\begin{aligned}
\int_{-1}^1 \int_0^a \left| u_1^{b+}\left(\frac{a-x}{\varepsilon},\mu\right)\right|^2 dx d\mu &= \int_{-1}^1 \varepsilon \int_0^{\frac{a}{\varepsilon}} \left|u_1^{b+}(\xi_+,\mu)\right|^2 d\xi_+ d\mu \\
&\le a \int_{-1}^1 \left(\sup_{\xi\in(0,\infty)} \left|u_1^{b+}(\xi,\mu)\right|\right)^2 d\mu.
\end{aligned}
$$

The same estimate holds for u_1^{b-}.

We notice that, according to Lemma 2 (see also Proposition 4), the term u_1^b is defined up to an arbitrary function of time that we denote $\sigma_\varepsilon(t)$. Then we have to replace in the asymptotic expansion the term u_1^b by $u_1^b + \sigma_\varepsilon(t)$, where u_1^b is uniquely defined with u_1^{b+} and u_1^{b-}. According to (36) and (40), the term u_2^b satisfies

$$
\left\{
\begin{array}{l}
\mu \dfrac{\partial u_2^b}{\partial \xi} + C u_2^b = 0 \quad \text{on } \left(-\dfrac{a}{\varepsilon},\dfrac{a}{\varepsilon}\right)\times(-1,1), \\
u_2^b\left(-\dfrac{a}{\varepsilon},\mu\right) = u_2^b\left(-\dfrac{a}{\varepsilon},-\mu\right) + \beta u_1^b\left(-\dfrac{a}{\varepsilon},-\mu\right) + \beta\sigma_\varepsilon + \beta\mu \dfrac{\partial u_0^0}{\partial x}(-a) \\
\qquad\qquad + u_2^0(-a,-\mu) - u_2^0(-a,\mu), \quad \mu > 0, \\
u_2^b\left(\dfrac{a}{\varepsilon},-\mu\right) = u_2^b\left(\dfrac{a}{\varepsilon},\mu\right) + \beta u_1^b\left(\dfrac{a}{\varepsilon},\mu\right) + \beta\sigma_\varepsilon - \beta\mu \dfrac{\partial u_0^0}{\partial x}(a) \\
\qquad\qquad + u_2^0(a,\mu) - u_2^0(a,-\mu), \quad \mu > 0.
\end{array}
\right. \tag{46}
$$

Of course, the nonhomogeneous boundary terms depend also on the time t. According to Proposition 2, (46) admits some solutions in $L^2\big((-a,a)\times(-1,1)\big)$ if and only if

$$\sigma_\varepsilon(t) = -\frac{1}{\beta}\int_0^1 \mu\left(\beta\mu\frac{\partial u_0^0}{\partial x}(-a,t) + \beta u_1^b\left(-\frac{a}{\varepsilon},-\mu,t\right) + u_2^0(-a,-\mu,t) - u_2^0(-a,\mu,t)\right.$$
$$\left. - \beta\mu\frac{\partial u_0^0}{\partial x}(a,t) + \beta u_1^b\left(\frac{a}{\varepsilon},\mu,t\right) + u_2^0(a,\mu,t) - u_2^0(a,-\mu,t)\right)\, d\mu.$$

As before, the boundedness of u_2^b in ε is related to the Milne problem in semi-infinite geometry. With $\sigma_\varepsilon = \sigma_\varepsilon^+ + \sigma_\varepsilon^-$, the terms u_2^{b+} and u_2^{b-} satisfy

$$\text{(47)}\qquad \begin{cases} -\mu\dfrac{\partial u_2^{b+}}{\partial \xi_+} + C u_2^{b+} = 0 \quad \text{on } (0,\infty)\times(-1,1), \\ u_2^{b+}(0,-\mu) = u_2^{b+}(0,\mu) + \beta u_1^b\left(\dfrac{a}{\varepsilon},\mu\right) + \beta\sigma_\varepsilon^+ - \beta\mu\dfrac{\partial u_0^0}{\partial x}(a) \\ \qquad\qquad + u_2^0(a,\mu) - u_2^0(a,-\mu), \quad \mu>0, \\ \lim\limits_{\xi_+\to\infty} u_2^{b+}(\xi_+,\mu) = 0, \end{cases}$$

$$\text{(48)}\qquad \begin{cases} \mu\dfrac{\partial u_2^{b-}}{\partial \xi_-} + C u_2^{b-} = 0 \quad \text{on } (0,\infty)\times(-1,1), \\ u_2^{b-}(0,\mu) = u_2^{b-}(0,-\mu) + \beta u_1^b\left(-\dfrac{a}{\varepsilon},-\mu\right) + \beta\sigma_\varepsilon^- + \beta\mu\dfrac{\partial u_0^0}{\partial x}(-a) \\ \qquad\qquad + u_2^0(-a,-\mu) - u_2^0(-a,\mu), \quad \mu>0, \\ \lim\limits_{\xi_-\to\infty} u_2^{b-}(\xi_-,\mu) = 0. \end{cases}$$

Proposition 3 yields that (47) and (48) admit, respectively, a unique solution in $L^2((-1,1);L^\infty(0,\infty))$ if and only if the two following conditions are satisfied:

$$\sigma_\varepsilon^+(t) = -\frac{1}{\beta}\int_0^1 \mu\left(-\beta\mu\frac{\partial u_0^0}{\partial x}(a,t) + \beta u_1^b\left(\frac{a}{\varepsilon},\mu,t\right) + u_2^0(a,\mu,t) - u_2^0(a,-\mu,t)\right)\, d\mu,$$
$$\sigma_\varepsilon^-(t) = -\frac{1}{\beta}\int_0^1 \mu\left(\beta\mu\frac{\partial u_0^0}{\partial x}(-a,t) + \beta u_1^b\left(-\frac{a}{\varepsilon},-\mu,t\right) + u_2^0(-a,-\mu,t) - u_2^0(-a,\mu,t)\right)\, d\mu.$$

As before, the estimate

$$\text{(49)}\qquad \left\| u_2^b\left(\frac{x}{\varepsilon},\mu\right)\right\|^2_{L^2((-a,a)\times(-1,1))} \le a\Big(\|u_2^{b+}\|^2_{L^2((-1,1);L^\infty(0,\infty))} + \|u_2^{b-}\|^2_{L^2((-1,1);L^\infty(0,\infty))}\Big)$$

yields that u_2^b is uniformly bounded in ε in $L^2((-a,a)\times(-1,1))$, where u_2^b is uniquely defined.

At this stage, all the functions which appear in the asymptotic expansion are well defined if u_0^0 is the solution of Pb(1.2). We estimate now the remainder w_ε, which satisfies the equation

$$\text{(50)}\qquad \begin{cases} \dfrac{\partial w_\varepsilon}{\partial t}(x,\mu,t) = -\varepsilon^{-1}\mu\dfrac{\partial w_\varepsilon}{\partial x} - \varepsilon^{-2}C w_\varepsilon - \gamma w_\varepsilon + \Psi_\varepsilon^0 \quad \text{on } (-a,a)\times(-1,1)\times\mathbb{R}^+, \\ w_\varepsilon(-a,\mu,t) = (1+\beta\varepsilon)\, w_\varepsilon(-a,-\mu,t) + \Psi_\varepsilon^{b-}(\mu,t), \quad \mu>0, \\ w_\varepsilon(a,-\mu,t) = (1+\beta\varepsilon)\, w_\varepsilon(a,\mu,t) + \Psi_\varepsilon^{b+}(\mu,t), \quad \mu>0, \\ w_\varepsilon(x,\mu,0) = \Psi_\varepsilon^i(x,\mu), \end{cases}$$

where

$$\Psi^0_\varepsilon(x,\mu,t) = -\varepsilon\left(\frac{\partial u_1^0}{\partial t} + \varepsilon\frac{\partial u_2^0}{\partial t} + \mu\frac{\partial u_2^0}{\partial x} + \gamma u_1^0 + \varepsilon\gamma u_2^0\right) - \gamma u_0^i\left(\frac{t}{\varepsilon^2}\right) - \frac{\mu}{\varepsilon}\frac{\partial u_0^i}{\partial x}\left(\frac{t}{\varepsilon^2}\right)$$
$$- \varepsilon\left(\frac{\partial u_1^b}{\partial t}\left(\frac{x}{\varepsilon}\right) + \gamma u_1^b\left(\frac{x}{\varepsilon}\right) + \frac{\partial \sigma_\varepsilon}{\partial t}(t) + \gamma\sigma_\varepsilon(t) + \varepsilon\frac{\partial u_2^b}{\partial t}\left(\frac{x}{\varepsilon}\right) + \varepsilon\gamma u_2^b\left(\frac{x}{\varepsilon}\right)\right),$$

$$\Psi^{b-}_\varepsilon(\mu,t) = \varepsilon^3\beta u_2^0(-a,-\mu,t) + \varepsilon^3\beta u_2^b\left(-\frac{a}{\varepsilon},-\mu,t\right),$$

$$\Psi^{b+}_\varepsilon(\mu,t) = \varepsilon^3\beta u_2^0(a,\mu,t) + \varepsilon^3\beta u_2^b\left(\frac{a}{\varepsilon},\mu,t\right),$$

$$\Psi^i_\varepsilon(x,\mu) = -\varepsilon\left(u_1^0(x,\mu,0) + \sigma_\varepsilon(0) + \varepsilon u_2^0(x,\mu,0) + u_1^b\left(\frac{x}{\varepsilon},\mu,0\right) + \varepsilon u_2^b\left(\frac{x}{\varepsilon},\mu,0\right)\right).$$

Let $\phi_\varepsilon(t)$ be an extension given by Lemma 1 of $\varepsilon^{-3}\Psi^{b-}_\varepsilon$ and $\varepsilon^{-3}\Psi^{b+}_\varepsilon$. We show in what follows that the extension ϕ_ε is uniformly bounded in ε in W^2. The function $W_\varepsilon = w_\varepsilon - \varepsilon^3\phi_\varepsilon$ satisfies

(51)
$$\begin{cases} \dfrac{\partial W_\varepsilon}{\partial t}(x,\mu,t) = -\varepsilon^{-1}\mu\dfrac{\partial W_\varepsilon}{\partial x} - \varepsilon^{-2}CW_\varepsilon - \gamma W_\varepsilon + \overline{\Psi}^0_\varepsilon \quad \text{on } (-a,a)\times(-1,1)\times\mathbb{R}^+, \\ W_\varepsilon(-a,\mu,t) = (1+\beta\varepsilon)\ W_\varepsilon(-a,-\mu,t), \quad \mu>0, \\ W_\varepsilon(a,-\mu,t) = (1+\beta\varepsilon)\ W_\varepsilon(a,\mu,t), \quad \mu>0, \\ W_\varepsilon(x,\mu,0) = \overline{\Psi}^i_\varepsilon(x,\mu), \end{cases}$$

where $\overline{\Psi}^i_\varepsilon(x,\mu) = \Psi^i_\varepsilon(x,\mu) - \varepsilon^3\phi_\varepsilon(x,\mu,0)$, and

$$\overline{\Psi}^0_\varepsilon = \Psi^0_\varepsilon - \varepsilon^3\frac{\partial\phi_\varepsilon}{\partial t} - \varepsilon^2\mu\frac{\partial\phi_\varepsilon}{\partial x} - \varepsilon C\phi_\varepsilon - \varepsilon^3\gamma\phi_\varepsilon = \Psi^0_\varepsilon - \varepsilon^3\frac{\partial\phi_\varepsilon}{\partial t} - \varepsilon C\phi_\varepsilon - \varepsilon^2\phi_\varepsilon\big(\varepsilon\gamma - 1\big).$$

We note that the semigroup generated by $T_\varepsilon - \gamma$, where T_ε is defined in (2), with a restitution coefficient $\alpha = 1+\beta\varepsilon$, is exponentially stable, due to the absorption γ. Indeed, in the limit $\varepsilon\to 0$, the exponential bound $w(1+\beta\varepsilon,\varepsilon)$ given in Proposition 1 is dominated by the absorption coefficient γ (see Remark 1). Finally, the estimate (3) and the Duhamel formula yield

$$\|W_\varepsilon\|_{L^2} \le (1+\beta)\|\overline{\Psi}^i_\varepsilon\|_{L^2} + (1+\beta)\int_0^t \|\overline{\Psi}^0_\varepsilon(s)\|_{L^2}ds.$$

Last, lengthy but straightforward calculations yield the estimates (see [PT])

$$\|\overline{\Psi}^i_\varepsilon\|_{L^2} \le \varepsilon M, \quad \|\overline{\Psi}^0_\varepsilon(t)\|_{L^2} \le \varepsilon M\mathrm{e}^{\delta t} \quad \forall t\ge 0,$$

which conclude the proof. ∎

5. Discussion. Theorem 1 remains true when the BCs are infinitesimally partially absorbing. In this case, $\beta<0$ and we can take $\gamma=0$ and obtain a diffusion equation with *stable* Robin BCs. While the proof is simpler, due to the fact that the transport operator (2) is now dissipative, the procedure to solve the boundary layer

problem is similar to the one presented here. In particular, we still need to expand the boundary layer term to the second order, because we are not able, due to the BCs, to obtain an estimate of the remainder directly from (50). This difficulty is overcome by using the superposition principle and considering an extension of the boundary sources. To control the quadratic singularity in ε the equation, we need the boundary sources to be of order three in ε, which can be obtained with an asymptotic expansion of the boundary layer term up to order two.

If the transport problem has finite (unscaled) partially absorbing BCs ($\alpha < 1$), the diffusion limit with Dirichlet BCs is obtained without any of the boundary layer complications.

Similar results can be proven for the transport problem set in $L^p((-a,a)\times(-1,1))$, $1 \le p < \infty$, by using the same scaling of the BCs. The case $p = 1$ is still open, but—at least formally—it appears that in order to prove the result for $p = 1$ one would need to resort to a different scaling of the BCs, namely, $\alpha = 1 + \beta\, \varepsilon^2$. This aspect of the problem is under investigation.

Finally, we remark on a specific feature of this problem within the P_1-approximation framework. In this approximation, which is widely used in neutron transport theory, the BCs are written as the difference between the (P_1-approximated values of the) incoming and outgoing currents at the boundaries. This leads to certain inconsistencies in the BCs for the diffusion limit, in which the notion of current is not well defined. To avoid these inconsistencies, one has to use the exact formulation and impose the (exact) BCs by using the distribution function itself or its integral (particle density), without resorting to the notion of (approximate) current. We are indebted to Profs. M. M. R. Williams and E. Larsen for independently raising the issue of this discrepancy between the exact and P_1-approximation results.

Acknowledgment. We thank M. Mokhtar-Kharroubi for helpful discussions.

REGULARIZATION BY KINETIC UNDERCOOLING OF BLOW-UP IN THE ILL-POSED STEFAN PROBLEM*

J. R. KING† AND J. D. EVANS‡

Abstract. It is well known that the one-dimensional supercooled Stefan problem possesses solutions that blow up in finite time. The asymptotics of such solutions have been analyzed by Herrero and Velazquez [*European J. Appl. Math.*, 7 (1996), pp. 119–150]. Here we consider the effect of kinetic undercooling as a regularizing mechanism to prevent the formation of such singularities and study the continuation of the solution through the "near blow-up" regime. The asymptotics of solutions and interfaces are described for small values of the kinetic undercooling parameter. It is shown that, in this limit, the interface jumps over an interval determined by the latent heat and by the initial data. Specifically, in dimensionless variables, if the temperature profile at blow-up is denoted by $u(x, t_c^-)$, where t_c is the finite blow-up time, then the interface jumps over the interval in which $u(x, t_c^-) < -\lambda$, where λ is the latent heat.

Key words. Stefan problem, kinetic undercooling, matched asymptotic expansions

1. Introduction.

The classical Stefan problem arises as an important model in conductive heat transfer problems that involve two phases separated by an unknown phase boundary. In its usual context, the governing equations for temperature are parabolic in both phases, and at the phase boundary the temperature is usually specified as being constant, with a release of latent heat on melting or an uptake on solidification; this latter condition is commonly referred to as the Stefan condition. Further, there is usually a sign requirement (relating to well-posedness) on the initial and/or boundary data that the temperature of the material in the solid phase be negative and that in the liquid phase be positive. Although the problem will be described in the notation and context of heat transfer, mathematically equivalent problems also arise in mass transfer applications. Accordingly, an appropriate generalization of the Stefan condition at the phase boundary will be considered in view of its relevance to such problems (see, for example, [2] or [27] and the references therein). In this context existence, uniqueness, and well-posedness, in both the classical and weak sense, are known (see, for example, Fasano and Primicerio [16], [17], [18] and Elliott and Ockendon [13]). However, as shown by Sherman [33] and characterized by Fasano, Primicerio, and Lacey [20], if the sign requirement on the temperature is violated, with the liquid being sufficiently supercooled (or the solid sufficiently superheated), then a solution may still exist locally in time, but now blow-up can occur in a finite time (i.e., the temperature develops an unbounded first derivative at the phase boundary (interface) or, equivalently, the speed of the interface becomes unbounded).

Several authors have considered the nature of the singularity which appears as blow-up occurs and the possible continuation of solutions after blow-up. In particular,

Herrero and Velazquez [25] have obtained asymptotic behaviors for the interface and blow-up profile, while Gurtin [24] and Götz and Zaltzman [23] argue that under certain conditions the interface jumps at the blow-up time. Regularization of the model is required in order for the phase change to be described to completion. Here we consider the one-phase, one-dimensional problem and hence consider kinetic undercooling as the regularizing mechanism (in higher space dimensions, surface energy effects could be included). An alternative (less physical) regularization approach is discussed in Fasano et al. [21], where a Baiocchi-type transformation is used to give the Crank–Gupta (oxygen diffusion-consumption) moving boundary problem; the constraint of solution nonnegativity for this problem provides the required regularizing mechanism.

The layout of the paper is as follows. In section 2, the statement of the one-phase problem is carefully derived as a limit case of the two-phase formulation. In section 3 the problem statement is given, together with integral statements and the conditions for blow-up. Section 4 derives the same blow-up asymptotics as those obtained by Herrero and Velazquez [25], albeit through the use of an alternative (in our case less rigorous but perhaps more transparent and comprehensive) approach. The regularization asymptotics are then described in section 5, with the main timescale for the interface jump described in section 5.2 and the consequent recovery of the classical Stefan problem in section 5.3. The case of zero segregation coefficient is discussed in section 6, where kinetic undercooling is shown not to prevent blow-up. Finally, in section 7, the asymptotics are compared to numerical solutions of the full problem.

2. Derivation of the one-phase Stefan problem. We first describe the derivation of the one-phase Stefan problem in multiple dimensions with kinetic undercooling and surface tension effects included. The governing equations for the two-phase multidimensional problem may be written as

$$\frac{\partial}{\partial t}(\rho c_i u_i) = \nabla.(K_i \nabla u_i), \quad \mathbf{x} \in D_i(t), \quad i = 1, 2, \quad D = D_1 \cup D_2,$$

where $i = 1$ denotes the liquid phase, $i = 2$ the solid phase, and $u_i(\mathbf{x}, t), K_i$, and c_i the temperature, conductivity, and specific heat, respectively, in the corresponding phase. The density ρ is taken to be the same in both phases. We present the problem in terms of heat transfer but, as indicated in (for instance) Evans and King [14], the same formulation arises in problems of mass transfer for which the one-phase limit discussed below is more often relevant.

The conditions on the moving phase boundary $F(\mathbf{x}, t) = 0$ are the Stefan condition

$$\left[K_i \frac{\partial u_i}{\partial n}\right]_{i=2}^{i=1} = -\rho v_n \left([c_i u_i]_{i=2}^{i=1} + L\right) \tag{2.1}$$

and temperature continuity (in view of the possibility of segregation in mass transfer applications, we allow greater generality by introducing a constant "partition coefficient" μ), together with kinetic undercooling and surface tension effects, i.e.,

$$u_1 = \frac{u_2}{\mu} = \alpha\kappa + \beta v_n. \tag{2.2}$$

Here $\mathbf{n}$ denotes the outward normal (from the liquid phase into the solid), v_n is the velocity of the phase boundary in that direction, $\partial/\partial n$ the outward normal derivative, α the surface tension coefficient, κ the mean curvature, β the kinetic undercooling coefficient, and L the latent heat per unit mass at the equilibrium temperature u_m

(cf. Charach, Zaltzman, and Götz [7], for example), and we choose units such that the equilibrium melting temperature is zero. We assume that appropriate initial conditions and boundary conditions on the fixed boundary ∂D are given to complete the problem statement.

We now introduce the dimensionless variables

$$\tilde{\mathbf{x}} = \frac{\mathbf{x}}{\ell}, \quad \tilde{t} = \frac{K_1}{\rho c_1 \ell^2} t, \quad \tilde{u}_i = \frac{u_i}{U} \quad \tilde{n} = \frac{n}{\ell}, \quad \tilde{\kappa} = \ell\kappa, \quad \tilde{v}_n = \frac{\rho c_1 \ell}{K_1} v_n,$$

where ℓ is a typical length scale and U is a representative temperature scale. We define the dimensionless parameters

$$\lambda = \frac{L}{c_1 U}, \quad \epsilon = \frac{\beta K_1}{\rho c_1 U \ell}, \quad \tilde{\alpha} = \frac{\alpha}{U\ell}, \quad c = \frac{c_2}{c_1}, \quad K = \frac{K_2}{K_1};$$

λ is commonly termed the Stefan number. For simplicity we have taken ρ, c_i, and K_i to be constant. Dropping the tildes then gives the dimensionless formulation

$$\frac{\partial u_1}{\partial t} = \nabla^2 u_1, \quad \mathbf{x} \in D_1(t), \quad \frac{\partial u_2}{\partial t} = \frac{K}{c}\nabla^2 u_2, \quad \mathbf{x} \in D_2(t), \tag{2.3}$$

$$\text{on} \quad F(\mathbf{x}, t) = 0 \qquad u_1 = \frac{u_2}{\mu} = \alpha\kappa + \epsilon v_n, \tag{2.4}$$

$$\frac{\partial u_1}{\partial n} - K\frac{\partial u_2}{\partial n} = -v_n\left((1 - \mu c)u_1 + \lambda\right) \tag{2.5}$$

subject to suitable nondimensionalized initial and fixed boundary conditions, in particular $u_2(\mathbf{x}, 0) = U_2(\mathbf{x})$. When $\epsilon \neq 0$, a truly one-phase problem is not possible in either the freezing or melting regime, since u_2 is nonzero on the moving boundary, leading to temperature variations in the solid. Moreover, even in the absence of kinetic undercooling and surface tension ($\epsilon = \alpha = 0$), only the melting regime $v_n > 0$ can be reduced to a bona fide one-phase problem, whereby $U_2 \equiv 0$ implies $u_2 \equiv 0$ and (2.10) below holds exactly. This contrasts with the freezing regime $v_n < 0$ when temperature variations in the solid result even when $U_2 \equiv 0$, as described below. Nevertheless, we can obtain a one-phase formulation asymptotically by considering the limit $K \to 0$, being careful to distinguish the cases of melting and freezing. To leading order in the solid, away from the moving interface, we then have, if $\mathbf{x}$ has not been visited by the interface, that

$$u_2 = U_2(\mathbf{x}), \tag{2.6}$$

where $U_2(\mathbf{x})$ is the initial temperature. However, there also exists an interior layer near the moving interface in which significant temperature changes occur in the solid. The scaling for this interior layer is

$$\mathbf{x} = \mathbf{x}_0(t) + \theta\hat{n}\mathbf{n},$$

where $F(\mathbf{x}_0, t) = 0$, so $\mathbf{x}_0$ lies on the moving boundary. At leading order within this layer in the solid we obtain from (2.3) that

$$\frac{\partial^2 u_2}{\partial \hat{n}^2} = -cv_n\frac{\partial u_2}{\partial \hat{n}} \tag{2.7}$$

subject to (in view of (2.4))

$$u_2 = \mu u_1(\mathbf{x}_0, t) \qquad \text{at } \hat{n} = 0,$$

which gives for $\hat{n} = O(1)$ that

$$u_2 \sim \begin{cases} (\mu u_1(\mathbf{x}_0, t) - U_2(\mathbf{x}_0))e^{-cv_n\hat{n}} + U_2(\mathbf{x}_0) & \text{if} \quad v_n > 0, \\ \mu u_1(\mathbf{x}_0, t) & \text{if} \quad v_n \leq 0, \end{cases} \tag{2.8}$$

where the sign in (2.7) implies that we can impose $u_2 \to U_2(\mathbf{x}_0)$ as $\hat{n} \to \infty$ (to match with (2.6)) in the former case but not in the latter (from which we have to exclude the possibility of exponential growth). This highlights the fact that the regimes $v_n > 0$ and $v_n < 0$ must be carefully distinguished. We do not consider cases in which the interface reverses direction; if it does, then the requirement of matching with (2.6) may need modification due to an earlier visit by the moving boundary. For $v_n < 0$, the leading-order equation in D_2, in the limit $K \to 0$ with $|\mathbf{x} - \mathbf{x}_0| = O(1)$, namely,

$$\frac{\partial u_2}{\partial t} = 0,$$

implies on matching with (2.8) that

$$u_2 = \mu u_1(\mathbf{x}, \omega(\mathbf{x})) \quad \text{for } \mathbf{x} \in D_2(t) \backslash D_2(0), \tag{2.9}$$

where we write $F(\mathbf{x}, t) = 0$ in the form $t = \omega(\mathbf{x})$ (of course, $D_2(t) \backslash D_2(0)$ being non-empty corresponds to $v_n < 0$). Since $\frac{\partial}{\partial \hat{n}} = K \frac{\partial}{\partial n}$, the leading-order Stefan condition (2.5) for the liquid becomes

$$\frac{\partial u_1}{\partial n} + v_n u_1 = v_n(cU_2 - \lambda) \quad \text{if} \quad v_n > 0 \tag{2.10}$$

and

$$\frac{\partial u_1}{\partial n} + v_n(1 - \mu c)u_1 = -\lambda v_n \quad \text{if} \quad v_n < 0. \tag{2.11}$$

In [14] we were concerned with the particular case $U_2 \equiv 0$ in the melting regime $v_n > 0$ (and it should be emphasized that the one-phase model derivation given there applies only when $v_n > 0$), in which the Stefan condition (2.10) simplifies to

$$\frac{\partial u_1}{\partial n} + v_n u_1 = -\lambda v_n. \tag{2.12}$$

Here we consider the freezing regime $v_n < 0$. For brevity we henceforth take $c = 1$, or equivalently redefine μ, so the Stefan condition (2.11) reads

$$\frac{\partial u_1}{\partial n} + v_n(1 - \mu)u_1 = -\lambda v_n. \tag{2.13}$$

In the case $\mu = 0$ (complete segregation into the fluid), this reduces to (2.12) and, as is to be expected, conservation of total heat within the fluid (sensible and latent) then follows, as discussed in [14]. For $\mu = 1$ (u_i continuous at the interface), however, the condition reduces to

$$\frac{\partial u_1}{\partial n} = -\lambda v_n. \tag{2.14}$$

It is the freezing (supercooled liquid) regime that has received the most atten-

tion in the literature, as it is this case which is ill-posed in the absence of kinetic undercooling and surface tension effects (as of course is the melting regime of a superheated solid). The effect of kinetic undercooling has been considered by numerous authors. Visintin [35] and Xie [36] established existence and uniqueness of the two-phase problem in one space dimension. Dewynne et al. [11] investigated the behavior of similarity (including traveling wave) solutions of the one-phase problem. Stability was investigated by Coriell and Parker [9] and Coriell and Sekerka [10]. Charach and Zaltzman [5], [6] and Charach, Zaltzman, and Götz [7] developed large-time asymptotic solutions.

The effects of surface tension have received even more attention. For example, Mullins and Sekerka [29] analyzed the stability of supersaturated solutes and supercooled melts in a spherical geometry. Chadam and Ortoleva [3] discussed the stability properties of planar melting and solidification (with and without surface tension). Zhu, Peirce, and Chadam [38] extended these linear stability results to earlier times. Chadam, Howison, and Ortoleva [4] considered the radially symmetric case and showed existence and uniqueness if the supersaturation is not too large, but nonexistence in finite time if the far-field supersaturation is sufficiently pronounced. Linear stability of a radially symmetric similarity solution is also examined. Existence and uniqueness results for small surface tension in the two-phase problem are discussed in Friedman and Reitich [22], while Scianna [32] showed global existence and determined the large-time asymptotics in the radially symmetric case.

The simultaneous effects of surface tension and kinetic undercooling have been considered by several authors. Schaefer and Glicksman [30] considered stability of the spherical supercooled case, while the two-dimensional case was considered by Umantsev and Davis [34]. Doole [12] examined the stability of similarity and traveling wave solutions for the two-dimensional, one-phase problem. Existence and uniqueness results were obtained by Chen and Reitich [8]. Yi [37] demonstrated existence of solutions for the Hele–Shaw problem (obtained from the Stefan problem in the limit of small specific heat) in the one-phase supercooled case. Surface tension is often incorporated through a Gibbs–Thomson term, as in (2.2). However, a term of the form $e^{\sigma\kappa}$, based on Nernst's law, was treated by Abergel, Hilhorst, and Issard-Roch [1] and Scheid [31]. Analogous considerations for nonlinear kinetic undercooling were discussed in Evans and King [15].

Of particular relevance to the work presented here is that of Gurtin [24], who postulates a jump in the position of the phase interface when blow-up occurs in the supercooled one-phase, one-dimensional case in the absence of kinetic undercooling. Götz and Zaltzman [23] studied the one-dimensional two-phase problem with kinetic undercooling and showed that as the kinetic modulus $\beta \to 0$ (in our notation), the limiting solution contains a jump exactly equal to the interval in which $u_1(x, t_c^-) < -\lambda$, where t_c is the blow-up time. It is the asymptotics of this situation that is of most interest to us here.

3. Problem formulation. The one-dimensional, one-phase supercooled Stefan problem with linear kinetic undercooling can be stated in dimensionless terms as follows:

$$\text{in } 0 < x < s(t) \qquad \frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}, \tag{3.1}$$

$$\text{on } x = s(t) \qquad u = \epsilon \dot{s}(t), \quad \frac{\partial u}{\partial x} + \dot{s}(t)(1-\mu)u = -\lambda \dot{s}(t), \tag{3.2}$$

$$\text{on } x = 0 \qquad \frac{\partial u}{\partial x} = 0, \tag{3.3}$$

$$\text{at } t = 0 \qquad s = 1, \quad u = u_{in}(x) \leq 0 \quad \text{for} \quad 0 \leq x \leq 1. \tag{3.4}$$

The suffix 1 on the temperature variable from the previous section has been dropped for brevity, and a Neumann condition has been taken on the fixed boundary $x = 0$. The length scale ℓ has been taken to be the width of the initial region occupied by the liquid, while a characteristic reference temperature U is provided by the initial temperature profile in the liquid.

The important dimensionless parameters are the kinetic undercooling parameter ϵ, the Stefan number λ, and the initial supercooling parameter Q, defined by

$$Q = \int_0^1 (u_{in}(x) + \lambda) dx. \tag{3.5}$$

In the absence of kinetic undercooling (i.e., for $\epsilon = 0$), $Q < 0$ is a necessary and sufficient condition for blow-up (see Sherman [33] and Fasano, Primicerio, and Lacey [20]). By this we mean that there exists a $t_c < \infty$ such that

$$\lim_{t \to t_c^-} s > 0 \quad \text{and} \quad \lim_{t \to t_c^-} \dot{s} = -\infty.$$

We are interested in describing the asymptotics of this case in the limit $\epsilon \to 0^+$, where kinetic undercooling has a regularizing effect.

The following integral statements hold:

$$\int_0^{s(t)} (u(x,t) + \lambda) dx = \mu\epsilon \int_0^t \dot{s}(\tau)^2 d\tau + Q \tag{3.6}$$

(the significance of positivity or otherwise of Q in the unregularized case $\epsilon = 0$ may be apparent from this expression) and

$$\int_0^{s(t)} x(u(x,t) + \lambda) dx = \int_0^1 x(u_{in}(x) + \lambda) dx + \int_0^t u(0,\tau) d\tau + \mu\epsilon \int_0^t s\dot{s}^2 d\tau - \epsilon(s-1). \tag{3.7}$$

It can be seen from (3.6) that in the case $\mu = 0$, kinetic undercooling will not prevent blow-up if $Q < 0$.

4. Blow-up of the unregularized problem. Results equivalent to those of Herrero and Velazquez [25] (and Herrero, Medina, and Velazquez [26], where the full asymptotic structure in the one-dimensional case is completed) are derived here through an alternative derivation using a Baiocchi-type transformation; they will be required subsequently for the analysis of the regularized case. Denoting the moving boundary by $t = \omega(x)$ (so that $\omega(s(t)) = t$) and setting $\epsilon = 0$, the transformation

$$w(x,t) = \int_{\omega(x)}^t u(x,t') dt' \tag{4.1}$$

gives the system

$$\text{in } 0 < x < s(t) \quad \frac{\partial w}{\partial t} = \frac{\partial^2 w}{\partial x^2} - \lambda, \tag{4.2}$$

$$\text{on } x = s(t) \qquad w = 0, \quad \frac{\partial w}{\partial x} = 0, \tag{4.3}$$

$$\text{on } x = 0 \qquad \frac{\partial w}{\partial x} = -Q, \tag{4.4}$$

$$\text{at } t = 0 \qquad s = 1, \quad w = \int_x^1 (x' - x)(u_{in}(x') + \lambda)dx' \quad \text{for} \quad 0 \le x \le 1. \tag{4.5}$$

Taking blow-up to occur at the location $x = x_c \in (0, 1)$ and the time $t = t_c < \infty$, the rescalings

$$y = \frac{(x - x_c)}{(t_c - t)^{\frac{1}{2}}}, \quad \tau = -\log(t_c - t), \quad L(\tau) = \frac{s(t) - x_c}{(t_c - t)^{\frac{1}{2}}} \tag{4.6}$$

(where L here is not to be confused with the latent heat which appeared earlier), with

$$w(x, t) = (t_c - t)\Phi(y, \tau), \tag{4.7}$$

transform (4.2)–(4.5) into the system

$$\text{in } -x_c e^{\tau/2} < y < L(\tau) \quad \frac{\partial \Phi}{\partial \tau} = \frac{\partial^2 \Phi}{\partial y^2} - \frac{y}{2}\frac{\partial \Phi}{\partial y} + \Phi - \lambda, \tag{4.8}$$

$$\text{on } y = L(\tau) \qquad \Phi = 0, \quad \frac{\partial \Phi}{\partial y} = 0, \tag{4.9}$$

$$\text{on } y = -x_c e^{\tau/2} \qquad \frac{\partial \Phi}{\partial y} = -Qe^{\tau/2}. \tag{4.10}$$

The asymptotic structure of this problem as $\tau \to \infty$ can be subdivided into two main regions, as follows. First, for $y = O(1)$ we introduce the expansion

$$\Phi \sim \lambda + A(\tau)\Phi_0(y) + \dot{A}(\tau)\Phi_1(y) \qquad \text{as } \tau \to \infty, \tag{4.11}$$

where $A(\tau) \equiv \Phi(0, \tau) - \lambda$ remains to be determined, with $\dot{A} \ll A \ll 1$ as $\tau \to \infty$. Thus

$$\frac{\partial^2 \Phi_0}{\partial y^2} - \frac{y}{2}\frac{\partial \Phi_0}{\partial y} + \Phi_0 = 0,$$

$$\frac{\partial^2 \Phi_1}{\partial y^2} - \frac{y}{2}\frac{\partial \Phi_1}{\partial y} + \Phi_1 = \Phi_0,$$

so that, without loss of generality (by excluding exponential growth as $y \to \infty$),

$$\Phi_0 = 1 - \frac{y^2}{2} \tag{4.12}$$

and

$$\frac{d}{dy}\left(e^{-y^2/4}\left(\Phi_0 \frac{d\Phi_1}{dy} - \Phi_1 \frac{d\Phi_0}{dy}\right)\right) = e^{-y^2/4}\Phi_0^2,$$

which implies

$$\Phi_0 \frac{d\Phi_1}{dy} - \Phi_1 \frac{d\Phi_0}{dy} = -\frac{1}{2}y^3 - y + 4e^{y^2/4}\int_{-\infty}^{y/2} e^{-\sigma^2} d\sigma,$$

and hence

$$\Phi_1 \sim -\frac{16\sqrt{\pi}}{y^3} e^{y^2/4} \qquad \text{as } y \to \infty. \tag{4.13}$$

Second, the scalings for the interior layer $z = O(1)$ at the moving boundary are

$$y = L + \frac{z}{L}, \qquad \Phi = \frac{1}{L^2}\Psi(z,\tau),$$

with $\Psi \sim \Psi_0(z)$ as $\tau \to \infty$ and

$$\frac{d^2\Psi_0}{dz^2} - \frac{1}{2}\frac{d\Psi_0}{dz} - \lambda = 0,$$

implying that

$$\Psi_0 = -2\lambda z - 4\lambda\left(1 - e^{z/2}\right). \tag{4.14}$$

Leading-order matching of (4.11)–(4.12) with (4.14) (in the limit $z \to -\infty$) yields

$$A \sim \frac{2\lambda}{L^2},$$

while matching of the exponential in (4.14) with (4.13) requires

$$\frac{16\sqrt{\pi}}{L^3} e^{L^2/4}\dot{A} \sim -\frac{4\lambda}{L^2},$$

so that

$$\frac{16\sqrt{\pi}}{L^4} e^{L^2/4}\dot{L} \sim 1. \tag{4.15}$$

This then gives

$$\frac{32\sqrt{\pi}}{L^5} e^{L^2/4} \sim \tau \qquad \text{as } \tau \to \infty$$

and thus

$$L \sim 2\left(\ln\tau\right)^{1/2}, \qquad A \sim \lambda/2\ln\tau \qquad \text{as } \tau \to \infty. \tag{4.16}$$

Since

$$u = \frac{\partial\Phi}{\partial\tau} + \frac{y}{2}\frac{\partial\Phi}{\partial y} - \Phi = \frac{\partial^2\Phi}{\partial y^2} - \lambda,$$

we have

$$u \sim -\lambda - A(\tau) \quad \text{for } y = O(1), \qquad u \sim -\lambda(1 - e^{z/2}) \quad \text{for } z = O(1). \tag{4.17}$$

Denoting the blow-up profile $u(x,t_c)$ by $u_c(x)$, it follows using (4.6) that

$$u_c(x) \sim -\lambda - \frac{\lambda}{2\ln\left(-\ln(x_c - x)\right)} \qquad \text{as } x \to x_c^-. \tag{4.18}$$

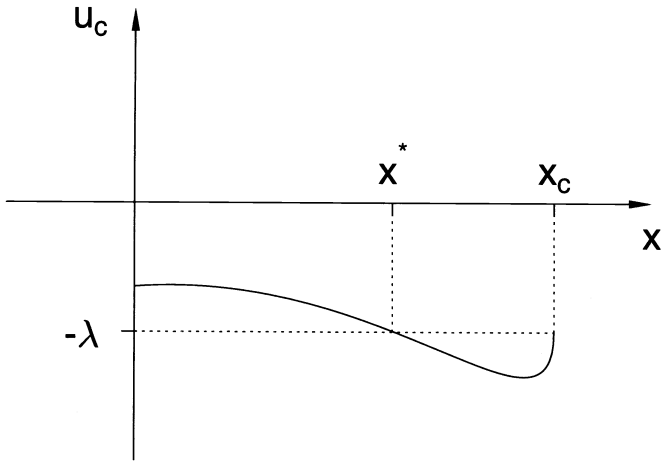

FIG. 1. *A schematic illustration of the generic blow-up profile* $u_c(x) = u(x, t_c)$ *which gives* $Q < 0$ *in* (4.19).

The profile is shown schematically in Figure 1. From (3.6), the blow-up profile satisfies

$$Q = \int_0^{x_c} (u_c(x) + \lambda)dx = \int_0^{x^*} (u_c(x) + \lambda)dx + Q_c, \tag{4.19}$$

where $u_c(x^*) = -\lambda$ (see Figure 1) and

$$Q_c = \int_{x^*}^{x_c} (u_c(x) + \lambda)dx.$$

As we shall see, $Q_c < 0$ represents the quantity of heat that the solid needs to absorb before the interface can be continued in the classical sense, the remainder, $Q - Q_c$, then being nonnegative (at least for profiles of the form shown in Figure 1). It is in effect the manner in which Q_c is removed from the liquid phase that is investigated in subsequent sections.

Nongeneric blow-up scenarios are also possible (see also [25]) and, since we shall need to exclude such a possibility in a particular situation in section 6 below, we record the first of these here. The analysis is in some respects simpler than that of the generic case above since there is no logarithmic dependence on τ. The expansion (4.11) is replaced by

$$\Phi \sim \lambda + e^{-\tau/2}\hat{\Phi}(y), \tag{4.20}$$

where

$$\hat{\Phi}(y) = A\left(y - \frac{y^3}{6}\right)$$

(the various modes can be identified as corresponding to solutions which are polynomials in y) and the value of the positive constant A depends on the initial data; the interior layer scalings then read

$$y = L + \frac{z}{L}, \qquad w = (t_c - t)^{4/3}\hat{\Psi}(z, \tau)$$

with

$$L \sim \left(\frac{6\lambda}{A}\right)^{1/3} e^{\tau/6}, \qquad \hat{\Psi} \sim \left(\frac{A}{6\lambda}\right)^{2/3} \hat{\Psi}_0$$

and

$$\frac{d^2\hat{\Psi}_0}{dz^2} - \frac{1}{3}\frac{d\hat{\Psi}_0}{dz} - \lambda = 0,$$

so that

$$\hat{\Psi}_0 = -3\lambda z - 9\lambda\left(1 - e^{z/3}\right).$$

It follows in particular that

$$u \sim -\lambda + A(x_c - x) \tag{4.21}$$

for $y = O(1)$, with (4.21) also furnishing the local behavior of $u_c(x)$ as $x \to x_c^-$, and that

$$s(t) \sim x_c + \left(\frac{6\lambda}{A}\right)^{1/3} (t_c - t)^{1/3} \qquad \text{as } t \to t_c^-. \tag{4.22}$$

5. The regularized problem with $\mu > 0$. The blow-up described in the previous section is moderated and then suppressed by the (small) kinetic undercooling term, as we now describe. There are three timescales of relevance, namely, the slow down timescale $t = t_c + O\left(\epsilon^2 \ln^3 \ln(1/\epsilon)\right)$, on which the blow-up rate in $\dot{s}$ is mitigated somewhat; the turnaround timescale $t = t_c + O(\epsilon)$, during which the interface speed goes through a minimum and the interface moves so as to release the required amount of latent heat (i.e., the interface moves quickly to the next location x^* at which $u_c(x) = -\lambda$); and, finally, the timescale $t = t_c + (\mu/3\nu)\epsilon \ln(1/\epsilon) + O(\epsilon)$ (where ν is a constant defined in section 5.2), at the end of which the classical Stefan problem is recovered.

5.1. The slow down timescale. This is the shortest of the timescales. As indicated by (4.17) the solution as blow-up is approached is almost of the self-similar form

$$u \sim U\left((x - x_c)/(t_c - t)^{\frac{1}{2}}\right),$$

so we first rescale via

$$t = t_c(\epsilon) + \epsilon^2 T, \qquad x = x_c(\epsilon) + \epsilon X, \qquad s = x_c(\epsilon) + \epsilon S(T)$$

to obtain in the first instance the full balance

$$\frac{\partial u}{\partial T} = \frac{\partial^2 u}{\partial X^2}, \tag{5.1}$$

$$\text{at } X = S(T) \qquad u = \dot{S}(T), \qquad \frac{\partial u}{\partial X} + (1 - \mu)\dot{S}u = -\lambda\dot{S}, \tag{5.2}$$

where $\dot{}$ denotes d/dT. However, as indicated by (4.17) (and indeed by (5.14) below, which implies "almost traveling-wave" behavior in matching as $T \to +\infty$), this

complete elimination of ϵ is in fact spurious; the scales appropriate to describing the transition are in fact

$$T = \delta^{-3}\hat{T}, \qquad S = \delta^{-2}\hat{S}, \qquad X = \delta^{-2}\hat{S} + \delta^{-1}\hat{Z},$$

where $\delta = 1/\ln\ln(1/\epsilon)$ (so that ϵ has to be minute for δ to be genuinely small in practice; fortunately this issue does not arise on the other timescales). The dependence on ϵ is thus remarkably weak.

Hence

$$\delta\frac{\partial u}{\partial \hat{T}} - \frac{d\hat{S}}{d\hat{T}}\frac{\partial u}{\partial \hat{Z}} = \frac{\partial^2 u}{\partial \hat{Z}^2}, \tag{5.3}$$

$$\text{on } \hat{Z} = 0 \qquad u = \delta\frac{d\hat{S}}{d\hat{T}}, \qquad \frac{\partial u}{\partial \hat{Z}} + (1-\mu)\frac{d\hat{S}}{d\hat{T}}u = -\lambda\frac{d\hat{S}}{d\hat{T}}, \tag{5.4}$$

so, writing

$$u \sim \hat{U}_0(\hat{Z},\hat{T}) + \delta\hat{U}_1(\hat{Z},\hat{T}), \qquad \hat{S} \sim \hat{S}_0(\hat{T}) + \delta\hat{S}_1(\hat{T}) \quad \text{as } \delta \to 0,$$

we find that

$$\hat{U}_0 = -\lambda\left(1 - \exp\left(-\frac{d\hat{S}_0}{d\hat{T}}\hat{Z}\right)\right), \tag{5.5}$$

$$\begin{aligned}\hat{U}_1 = \frac{\lambda\frac{d^2\hat{S}_0}{d\hat{T}^2}}{\left(\frac{d\hat{S}_0}{d\hat{T}}\right)^3}&\left(\left(\frac{1}{2}\left(\frac{d\hat{S}_0}{d\hat{T}}\right)^2\hat{Z}^2 + \frac{d\hat{S}_0}{d\hat{T}}\hat{Z} + 1\right)\exp\left(-\frac{d\hat{S}_0}{d\hat{T}}\hat{Z}\right) - 1\right)\\ &+ (1-\mu)\frac{d\hat{S}_0}{d\hat{T}}\exp\left(-\frac{d\hat{S}_0}{d\hat{T}}\hat{Z}\right) + \mu\frac{d\hat{S}_0}{d\hat{T}} - \lambda\frac{d\hat{S}_1}{d\hat{T}}\hat{Z}\exp\left(-\frac{d\hat{S}_0}{d\hat{T}}\hat{Z}\right).\end{aligned} \tag{5.6}$$

Since $d\hat{S}_0/d\hat{T} < 0$, we thus have to these orders that

$$u \sim -\lambda + \delta\left(\mu\frac{d\hat{S}_0}{d\hat{T}} - \frac{\lambda\frac{d^2\hat{S}_0}{d\hat{T}^2}}{\left(\frac{d\hat{S}_0}{d\hat{T}}\right)^3}\right) \qquad \text{as } \hat{Z} \to -\infty$$

as the condition required in matching with (4.18), so that

$$\mu\frac{d\hat{S}_0}{d\hat{T}} - \frac{\lambda\frac{d^2\hat{S}_0}{d\hat{T}^2}}{\left(\frac{d\hat{S}_0}{d\hat{T}}\right)^3} = -\frac{\lambda}{2}.$$

It follows (by suitable choice of $x_c(\epsilon)$ at $O(\epsilon\delta^{-2})$, i.e., up to a translation of $\hat{S}_0$) that we have

$$\mu\hat{S}_0 + \frac{\lambda}{2\left(\frac{d\hat{S}_0}{d\hat{T}}\right)^2} = -\frac{\lambda}{2}\hat{T}. \tag{5.7}$$

Finally, writing

$$\hat{S}_0 = -\frac{\lambda}{2\mu}\hat{T} - W^2 \tag{5.8}$$

yields

$$\frac{2W^2}{\left(\left(\frac{\lambda}{2\mu}\right)^{\frac{1}{2}} - \left(\frac{\lambda}{2\mu}\right)W\right)}\frac{dW}{d\hat{T}} = 1$$

so that, by suitable choice of $t_c(\epsilon)$ at $O(\epsilon^2\delta^{-3})$ (i.e., up to a translation of $\hat{T}$),

$$W^2 + 2\left(\frac{2\mu}{\lambda}\right)^{\frac{1}{2}} W + \frac{4\mu}{\lambda}\ln\left(W - \left(\frac{2\mu}{\lambda}\right)^{\frac{1}{2}}\right) = -\frac{\lambda}{2\mu}\hat{T}. \tag{5.9}$$

It follows from (5.9) that

$$W \sim \left(\frac{-\lambda\hat{T}}{2\mu}\right)^{1/2} - \left(\frac{2\mu}{\lambda}\right)^{1/2} \qquad \text{as } \hat{T} \to -\infty, \tag{5.10}$$

which gives the required behavior

$$\hat{S}_0 \sim 2\left(-\hat{T}\right)^{1/2} \qquad \text{as } \hat{T} \to -\infty \tag{5.11}$$

to match with (4.16) and also

$$W \sim \left(\frac{2\mu}{\lambda}\right)^{1/2} + e^{-\lambda^2\hat{T}/8\mu^2} \qquad \text{as } \hat{T} \to +\infty, \tag{5.12}$$

which gives the behavior

$$\hat{S}_0 \sim -\frac{\lambda}{2\mu}\hat{T} - \frac{2\mu}{\lambda} - 2\left(\frac{2\mu}{\lambda}\right)^{1/2} e^{-\lambda^2\hat{T}/8\mu^2} \qquad \text{as } \hat{T} \to +\infty, \tag{5.13}$$

furnishing a matching condition for the next timescale. The behaviors of $\hat{S}_0$ and $d\hat{S}_0/d\hat{T}$ are shown in Figure 2 using (5.7) and (5.11).

5.2. The turnaround timescale. Setting

$$t = t_c(\epsilon) + \epsilon\hat{t}, \qquad x = s(\hat{t};\epsilon) + \epsilon\hat{z}$$

in the interior layer located at the moving boundary, we have

$$\epsilon\frac{\partial u}{\partial \hat{t}} - \frac{ds}{d\hat{t}}\frac{\partial u}{\partial \hat{z}} = \frac{\partial^2 u}{\partial \hat{z}^2}, \tag{5.14}$$

$$\text{at } \hat{z} = 0 \qquad u = \frac{ds}{d\hat{t}}, \quad \frac{\partial u}{\partial \hat{z}} + (1-\mu)\frac{ds}{d\hat{t}}u = -\lambda\frac{ds}{d\hat{t}}, \tag{5.15}$$

while in the outer region $x = O(1)$

$$\frac{\partial u}{\partial \hat{t}} = \epsilon\frac{\partial^2 u}{\partial x^2},$$

so that

$$u \sim u_c(x), \tag{5.16}$$

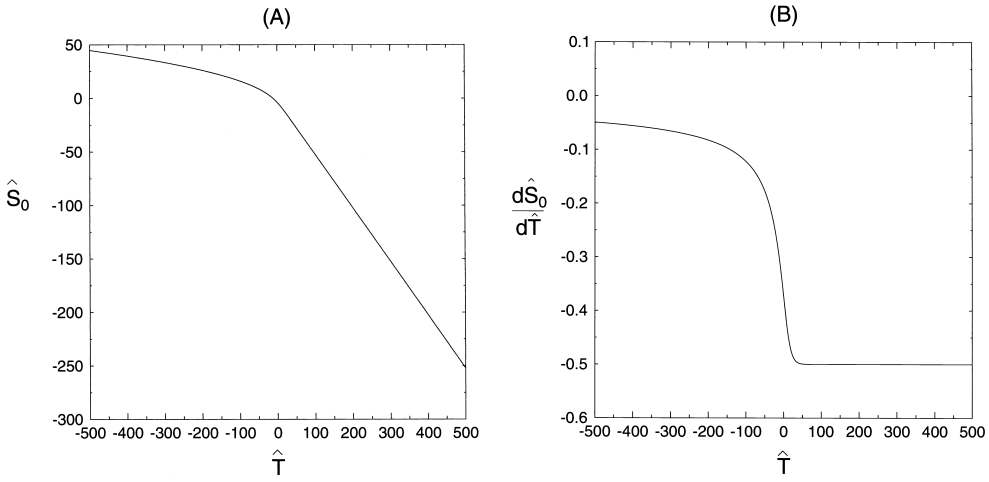

FIG. 2. *Illustration of the leading-order asymptotic solution showing* (A) $\hat{S}_0$ *and* (B) $d\hat{S}_0/d\hat{T}$ *using* (5.7)–(5.9) *with* $\lambda = \mu = 1$. *The far-field matching behaviors are clearly exhibited, particularly in* (B), *where* $d\hat{S}_0/d\hat{T} \sim -(-\hat{T})^{-1/2}$ *as* $\hat{T} \to -\infty$ *and* $d\hat{S}_0/d\hat{T} \sim -\lambda/2\mu$ *as* $\hat{T} \to +\infty$.

where, as before, $u_c(x) = u_0(x, t_c)$, u_0 being the solution to the classical ($\epsilon = 0$) Stefan problem, as discussed above. Expanding in (5.14)–(5.15) in the form

$$u \sim \hat{u}_0(\hat{z}, \hat{t}\,), \qquad s \sim \hat{s}_0(\hat{t}\,) \qquad \text{as } \epsilon \to 0$$

yields

$$\hat{u}_0 = -\lambda \left(1 - e^{-\dot{\hat{s}}_0 \hat{z}}\right) + \dot{\hat{s}}_0 \left(\mu + (1-\mu) e^{-\dot{\hat{s}}_0 \hat{z}}\right), \tag{5.17}$$

where $\dot{}$ now denotes $d/d\hat{t}$. Matching (5.17) as $\hat{z} \to -\infty$ with (5.16) requires that $\hat{s}_0$ be given by

$$\mu \dot{\hat{s}}_0 = u_c(\hat{s}_0) + \lambda \qquad \text{with } \hat{s}_0 = x_c \text{ at } \hat{t} = 0. \tag{5.18}$$

This first-order ordinary differential equation governs the dynamics of the interface motion over the current timescale.

In the one-phase limit, we have from (2.9) that

$$u_2 = \mu u_1(x, \omega(x)) = \epsilon \mu \frac{ds}{dt}\left(\omega(x)\right),$$

which implies that

$$u_2 \sim u_c(x) + \lambda$$

is, to leading order, independent of μ. Thus, as expected (cf. Gurtin [24]), the temperature left behind in the second phase during this rapid transition is given by that in the first phase modified by the latent heat λ in a manner which accounts correctly for the conservation of energy on change of phase.

It remains to discuss the behavior of the ordinary differential equation (5.18). First, it follows from (4.18) that the initial behavior is governed by

$$\mu \dot{\hat{s}}_0 \sim -\frac{\lambda}{2 \ln\left(-\ln(x_c - \hat{s}_0)\right)} \tag{5.19}$$

and hence

$$\hat{s}_0 \sim x_c - \frac{\lambda}{2\mu}\frac{\hat{t}}{\ln\left(-\ln\hat{t}\right)} \qquad \text{as } \hat{t} \to 0^+. \tag{5.20}$$

Since $\hat{t} = \epsilon\delta^{-3}\hat{T}$, this gives the matching condition

$$\hat{s}_0 \sim x_c - \frac{\lambda}{2\mu}\epsilon\delta^{-2}\hat{T},$$

consistent with (5.13).

Elsewhere, $u_c(x)$ depends on the initial data. The key observation regarding (5.18) is that the interface slows down as it approaches the point $x^* < x_c$ at which $u_c(x^*) = -\lambda$; we generically have

$$u_c \sim -\lambda - \nu(x - x^*) \tag{5.21}$$

as $x \to x^*$ for some positive constant ν and hence

$$\hat{s}_0 \sim x^* + e^{-\nu(\hat{t}-\hat{t}_c)/\mu} \qquad \text{as } \hat{t} \to +\infty \tag{5.22}$$

for some constant $\hat{t}_c$.

It is worth remarking that the nongeneric behavior

$$u_c \sim -\lambda - \nu(x - x^*)^{2m+1} \tag{5.23}$$

as $x \to x^*$ for some positive constant ν and integer power $m > 0$ gives instead the algebraic decay behavior

$$\hat{s}_0 \sim x^* + \left(\frac{\mu}{2m\nu\hat{t}}\right)^{1/2m} \qquad \text{as } \hat{t} \to +\infty. \tag{5.24}$$

5.3. The timescale of recovery of the classical Stefan problem. The relevant timescale corresponds to $s = x_c + O(\epsilon^{1/3})$, so by (5.22) the scalings

$$\hat{t} = \frac{\mu}{3\nu}\ln(1/\epsilon) + \hat{t}_c + \bar{T}, \qquad s(\bar{T};\epsilon) = x^* + \epsilon^{1/3}\bar{S}, \qquad x = s(\bar{T};\epsilon) + \epsilon^{2/3}\frac{Z}{\dot{\bar{S}}}$$

pertain, where $\dot{}$ is now $d/d\bar{T}$. Thus in the interior layer $Z = O(1)$

$$\frac{\epsilon^{1/3}}{\dot{\bar{S}}^2}\frac{\partial u}{\partial \bar{T}} + \epsilon^{1/3}\frac{\ddot{\bar{S}}Z}{\dot{\bar{S}}^3}\frac{\partial u}{\partial Z} - \frac{\partial u}{\partial Z} = \frac{\partial^2 u}{\partial Z^2} \tag{5.25}$$

$$\text{at } Z = 0 \qquad u = \epsilon^{1/3}\dot{\bar{S}}, \quad \frac{\partial u}{\partial Z} + (1-\mu)u = -\lambda. \tag{5.26}$$

Expanding in the form

$$u \sim U_0(Z) + \epsilon^{1/3}U_1(Z,\bar{T}), \qquad \bar{S} \sim \bar{S}_0(\bar{T}) \qquad \text{as } \epsilon \to 0$$

yields

$$U_0 = -\lambda\left(1 - e^{-Z}\right)$$

and hence

$$-\lambda\frac{\ddot{\bar{S}}_0 Z}{\dot{\bar{S}}_0^3}e^{-Z}-\frac{\partial U_1}{\partial Z}=\frac{\partial^2 U_1}{\partial Z^2}, \tag{5.27}$$

$$\text{at } Z=0 \qquad U_1=\dot{\bar{S}}_0, \quad \frac{\partial U_1}{\partial Z}=-(1-\mu)\dot{\bar{S}}_0, \tag{5.28}$$

so that

$$U_1=\frac{\lambda\ddot{\bar{S}}_0}{\dot{\bar{S}}_0^3}\left(\left(\frac{1}{2}Z^2+Z+1\right)e^{-Z}-1\right)+(1-\mu)\dot{\bar{S}}_0 e^{-Z}+\mu\dot{\bar{S}}_0.$$

Since (5.16) still applies in $x<s$, matching as $Z\to+\infty$ (noting that $\dot{\bar{S}}<0$) with (5.22) requires that $\bar{S}_0$ be given by the ordinary differential equation

$$\mu\dot{\bar{S}}_0-\lambda\frac{\ddot{\bar{S}}_0}{\dot{\bar{S}}_0^3}=-\nu\bar{S}_0, \tag{5.29}$$

with

$$\bar{S}_0\sim e^{-\nu\bar{T}/\mu}-\frac{\lambda\mu}{3\nu^2}e^{2\nu\bar{T}/\mu} \qquad \text{as } \bar{T}\to-\infty. \tag{5.30}$$

As $\bar{T}\to+\infty$, the first term in (5.29) becomes negligible and we obtain

$$\bar{S}_0\sim-\left(\frac{6\lambda}{\nu}\right)^{1/3}\bar{T}^{1/3} \quad \text{as } \bar{T}\to+\infty; \tag{5.31}$$

the formulation (5.29) indicates how the interface s passes through x^*. A numerical solution of (5.29) as an initial value problem is shown in Figure 3, using the two-term behavior (5.30) at $\bar{T}=-\bar{T}_{\text{init}}$ (for suitably large $\bar{T}_{\text{init}}$) to start the scheme.

Finally, from (5.31) we can deduce that for $t=t_{c0}+O(1)$ we recover at leading order the classical Stefan problem

$$\begin{aligned}
&\text{in } 0<x<s_0(t) && \frac{\partial u_0}{\partial t}=\frac{\partial^2 u_0}{\partial x^2},\\
&\text{on } x=0 && \frac{\partial u_0}{\partial x}=0,\\
&\text{on } x=s_0(t) && u_0=0, \quad \frac{\partial u_0}{\partial x}=-\lambda\frac{ds_0}{dt},\\
&\text{at } t=t_{c0} && u_0=u_c(x), \quad s_0=x^*,
\end{aligned}$$

whose small $t-t_{c0}$ behavior can be shown (essentially as above) to take the form

$$s_0(t)\sim x^*-\left(\frac{6\lambda}{\nu}\right)^{1/3}(t-t_{c0})^{1/3} \qquad \text{as } t\to t_{c0}^+,$$

thereby matching with (5.31).

The discussion so far has assumed that the blow-up profile has only two roots for $u_c(x)+\lambda=0$ with $0\le x\le x_c$. The case in which there are more than two roots

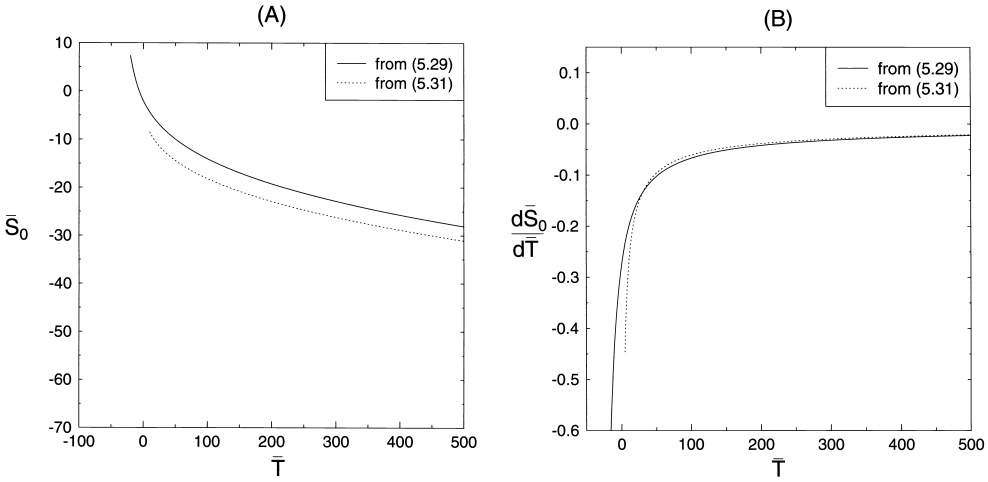

FIG. 3. (A) *and* (B) *show* $\bar{S}_0$ *and* $\dot{\bar{S}}_0$*, respectively, against* $\bar{T}$ *calculated from* (5.29)*. The values* $\nu = 0.1, \lambda = \mu = 1$ *were taken for illustrative purposes, and the scheme started from* $\bar{T} = -20$*. The asymptotic behavior* (5.31) *is also shown in both* (A) *and* (B)*.*

gives rise to the possibility of repeated blow-up in the unregularized problem. Such scenarios depend upon the blow-up profile satisfying

$$Q - Q_c = \int_0^{x^*} (u_c(x) + \lambda) dx < 0.$$

The case in which $u_c < -\lambda$ for all x is remarked upon in the next subsection.

5.4. Final behavior. In this section we address the possible ultimate outcomes of (3.1)–(3.4) for arbitrary ϵ. One possibility for any μ is that $s \to s_\infty$ as $t \to \infty$ for some positive constant s_∞ (which will depend on the initial data), with

$$\text{on } x = s_\infty \qquad \epsilon \frac{\partial u}{\partial x} \sim -\lambda u$$

giving the asymptotic boundary condition, implying that

$$u \sim -U_\infty e^{-\kappa^2 t} \cos(\kappa x) \qquad \text{as } t \to \infty \tag{5.32}$$

for some positive constant U_∞, where κ is (generically) the smallest root of

$$\epsilon \kappa \tan \kappa s_\infty = \lambda. \tag{5.33}$$

However, for $\mu < 1$ it is also possible that s drops to zero in finite time, a scenario which can be identified by assuming that the left-hand side of (3.1) is asymptotically negligible (the self-consistency of this assumption being readily checked a posteriori), implying that

$$u \sim U(t), \qquad \frac{\partial u}{\partial x} \sim \dot{U}(t) x$$

for some function $U(t)$. The moving boundary conditions then yield

$$U \sim \epsilon \dot{s}, \qquad \dot{U} s + \dot{s}(1 - \mu) U \sim -\lambda \dot{s},$$

so for $\mu \neq 1$ we obtain

$$\dot{s} \sim A s^{\mu-1} - \frac{\lambda}{\epsilon(1-\mu)} \tag{5.34}$$

for some constant A. If $A > 0$ and $\mu < 1$, then s tends to $s_\infty \sim (\lambda/\epsilon(1-\mu)A)^{1/(\mu-1)}$ as $t \to \infty$, and the behavior of (5.34) in this case can easily be seen to be consistent with the small s_∞ limit of (5.32)–(5.33). If $\mu > 1$, then A is necessarily less than zero (since $\dot{s} < 0$ must hold for $u < 0$) and the same conclusion applies (the equivalent result can easily be seen always to follow when $\mu = 1$ as well). However, for $\mu < 1$ with $A < 0$ we have that

$$s \sim ((2-\mu)(-A)(t_e - t))^{\frac{1}{2-\mu}}, \qquad U \sim \epsilon(-A)\left((2-\mu)(-A)(t_e-t)\right)^{-\frac{1-\mu}{2-\mu}} \qquad \text{as } t \to t_e^- \tag{5.35}$$

for some finite extinction time t_e which will depend on the initial data, with u becoming unbounded in this limit. Thus, interestingly, there are two possible generic outcomes for $\mu < 1$: first, $s \to s_\infty > 0$ with (5.32), and second, (5.35), the borderline between the two being given by the nongeneric case $A = 0$ in (5.34), whereby

$$s \sim \frac{\lambda}{\epsilon(1-\mu)}(t_e - t), \qquad U \sim -\frac{\lambda}{1-\mu}. \tag{5.36}$$

For small ϵ, when $u_c(\hat{s}_0) < -\lambda$ for all $\hat{s}_0$ the result (5.18) does not in general hold uniformly as $\hat{s}_0$ approaches zero. We shall not address the corresponding small ϵ asymptotics here, but it is plausible that for $\mu < 1$ the scenario (5.35) will typically ultimately apply, whereas for $\mu \geq 1$ we necessarily have $s_\infty > 0$, so the interface does not impinge upon the boundary, though as ϵ tends to zero s_∞ presumably also does so.

6. The special case $\mu = 0$. We stress that the parameter μ plays no role in the zero kinetic undercooling case, so it does not feature as a special case in the unregularized problem. It does, however, require separate treatment for $\epsilon > 0$ since, as already noted, even with kinetic undercooling bona fide blow-up can occur for $\mu = 0$. Here we treat the behavior close to the blow-up time $t = t_c$ for arbitrary $\epsilon > 0$. Two reformulations of (3.1)–(3.4) are helpful in this case (it is no coincidence that these reformulations are available only in the special case $\mu = 0$, which is also exceptional with regard to its blow-up properties); we first recall from (3.6) that

$$\int_0^{s(t)} (u(x,t) + \lambda)\,dx = Q \tag{6.1}$$

holds for all time when $\mu = 0$. Again introducing w as in (4.1), we obtain (4.2) subject to

$$\text{on } x = s(t) \qquad w = 0, \quad \frac{\partial w}{\partial x} = -\epsilon, \tag{6.2}$$

$$\text{on } x = 0 \qquad \frac{\partial w}{\partial x} = -Q - \epsilon, \tag{6.3}$$

$$\text{at } t = 0 \qquad s = 1, \quad w = \epsilon(1-x) + \int_x^1 (x' - x)(u_0(x') + \lambda)\,dx', \tag{6.4}$$

the conditions (6.3) and (6.4) following from (6.2) and

$$\text{at } t = 0 \qquad \frac{\partial^2 w}{\partial x^2} = u_0(x) + \lambda.$$

Second, introducing

$$v = -\int_x^{s(t)} (u(x',t) + \lambda)dx', \tag{6.5}$$

so that

$$v = \epsilon + \frac{\partial w}{\partial x}, \qquad u = \frac{\partial w}{\partial t} = \frac{\partial v}{\partial x} - \lambda, \tag{6.6}$$

leads to

$$\frac{\partial v}{\partial t} = \frac{\partial^2 v}{\partial x^2}, \tag{6.7}$$

$$\text{on } x = s(t) \qquad v = 0, \quad \frac{\partial v}{\partial x} = \lambda + \epsilon \dot{s}(t), \tag{6.8}$$

$$\text{on } x = 0 \qquad v = -Q, \tag{6.9}$$

$$\text{at } t = 0 \qquad s = 1, \quad v = -\int_x^1 (u_0(x') + \lambda)dx'. \tag{6.10}$$

If the λ terms are negligible, then (6.7)–(6.10) reduces to the classical Stefan problem with Stefan number ϵ. The boundary condition we have adopted on $x = 0$, (3.3), differs in form from (6.9), but provided $x_c > 0$ the analysis of section 4 carries over because it is local to $x = x_c$; thus identifying u with $-v$ and ϵ with λ, it follows from (4.17) that

$$v \sim \epsilon + A(\tau) \quad \text{for } y = O(1), \qquad v \sim \epsilon(1 - e^{z/2}) \quad \text{for } z = O(1), \tag{6.11}$$

immediately prior to blow-up, where (4.6) remains valid, as does $y = L + z/L$. The expressions (4.16) become

$$L \sim 2\,(\ln \tau)^{1/2}, \qquad A \sim \epsilon/2 \ln \tau \qquad \text{as } \tau \to \infty$$

in the current notation; since

$$\dot{s} \sim -\frac{1}{2} L(\tau)(t_c - t)^{-1/2} \qquad \text{as } t \to t_c^-$$

the λ term in (6.8) is indeed negligible, as required for self-consistency. From (6.6) and (4.18) (which now gives the local behavior of v) we have

$$u_c(x) \sim -\frac{\epsilon}{2\ln^2(-\ln(x_c - x))\,(-\ln(x_c - x))\,(x_c - x)} \quad \text{as } x \to x_c^-, \tag{6.12}$$

so (unlike (4.18)) u becomes unbounded as the blow-up time is approached.

For $u < 0$, we have from (6.6) that v is monotonic decreasing with x, and hence (6.11) is consistent with (6.9) only if $-Q > \epsilon$ (that this inequality should arise is perhaps not surprising in the light of (6.3)). A second, distinct, blow-up scenario thus necessarily pertains when this inequality is not satisfied; this has $x_c = 0$, so the form of the boundary condition on $x = 0$ is important in this case, and this form of blow-up can most conveniently be derived directly from the original formulation (3.1)–(3.4), with $\mu = 0$ and with the λ term again negligible in the limit $t \to t_c^-$. We thus seek self-similar behavior of the form

$$u \sim \frac{1}{(t_c - t)^{1/2}} f(\eta), \quad \eta = \frac{x}{(t_c - t)^{1/2}}, \quad s(t) \sim \sigma(t_c - t)^{1/2} \quad \text{as } t \to t_c^-, \tag{6.13}$$

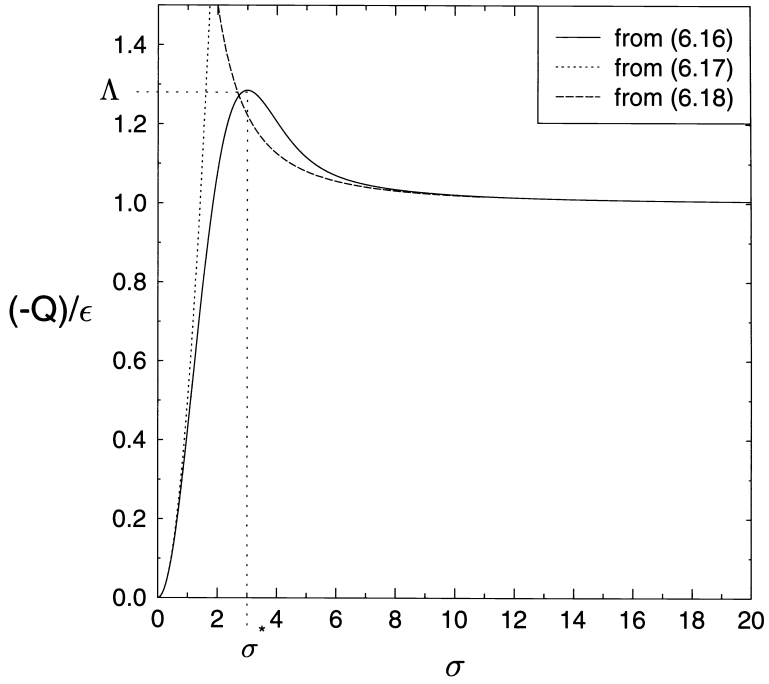

FIG. 4. *Plot of the solutions to the transcendental equation* (6.14) *together with the asymptotic behaviors* (6.16) *and* (6.17). *We have that* $\sigma^* \approx 3.0045$ *and* $\Lambda \approx 1.28475$.

implying

$$f = -Be^{\eta^2/4}$$

for some constant B, with σ given by the transcendental equation

$$\frac{1}{2}\sigma e^{-\sigma^2/4}\int_0^\sigma e^{\eta^2/4}d\eta = \frac{(-Q)}{\epsilon} \tag{6.14}$$

and with

$$B = \frac{\epsilon}{2}\sigma e^{-\sigma^2/4}; \tag{6.15}$$

these follow from (3.2) and (6.1). Thus as $(-Q)/\epsilon \to 0^+$ we have

$$\sigma \sim (2(-Q)/\epsilon)^{1/2}, \qquad B \sim ((-Q)\epsilon/2)^{1/2}, \tag{6.16}$$

and as $(-Q)/\epsilon \to 1^+$,

$$\sigma \sim (2/\left((-Q)/\epsilon - 1\right))^{1/2} \tag{6.17}$$

with B exponentially small.

We plot in Figure 4 the solutions to (6.14), the nonmonotonicity following from (6.16)–(6.17). There is thus a range of $(-Q)/\epsilon > 1$ (which we denote $1 < (-Q)/\epsilon < \Lambda$, as in Figure 4) for which two solutions are possible, and we speculate that those with

$\sigma \leq \sigma^*$ are stable (where $\sigma = \sigma^*$ corresponds to the maximum value of $(-Q)/\epsilon$ from (6.14)) and those beyond the fold, in $\sigma > \sigma^*$, are unstable. In the range of $1 < (-Q)/\epsilon < \Lambda$ there are thus two generic (stable) blow-up scenarios (one with $x_c = 0, \sigma < \sigma^*$ and another with $x_c > 0$ depending on the initial data, for which (6.12) applies), separated by a nongeneric (unstable) scenario of the form (6.13) with $\sigma > \sigma^*$. Finally, in the borderline case $(-Q)/\epsilon = 1$ it is in principle possible that a form of blow-up which would be nongeneric for arbitrary parameter values may occur generically, so it is worthwhile to confirm that the situation described at the end of section 4 cannot pertain with $x_c = 0$; thus, while in the current notation (4.21) becomes

$$v \sim \epsilon + Ax,$$

which satisfies (6.9), it also follows that v is increasing with x, contrary to the assumption that $u < 0$. Thus we conjecture that (6.13) provides the only generic form of blow-up for $(-Q)/\epsilon \leq 1$ and (6.17) for $(-Q)/\epsilon > 1$.

For completeness we also note that when $Q > 0$ (so that blow-up does not occur even without kinetic undercooling) we have $s \sim Q/\lambda$ as $t \to \infty$, with u decaying exponentially with t, as dictated by the relevant linear diffusion problem subject to

$$\text{on } x = Q/\lambda \qquad \epsilon \frac{\partial u}{\partial x} \sim -\lambda u.$$

Finally, for $Q = 0$ we have

$$u \sim -\lambda, \qquad s \sim \frac{\lambda}{\epsilon}(t_c - t) \qquad \text{as } t \to t_c^-,$$

which in fact furnishes the exact solution to (3.1)–(3.4) for $\mu = 0, u_0 \equiv -\lambda$. This exact solution generalizes to arbitrary $\mu < 1$ to

$$u = -\frac{\lambda}{1-\mu}, \qquad s = \frac{\lambda}{\epsilon(1-\mu)}(t_c - t), \tag{6.18}$$

a solution which is consistent with (5.18) and which has played a role above in (5.36); moreover, (6.18) generalizes further to

$$u = -\lambda - \epsilon\mu q + (\lambda - \epsilon(1-\mu)q)e^{qz}, \qquad s = q(t_c - t)$$

for arbitrary wavespeed q (cf. (5.17)).

For small ϵ, the relevant regime is of course that leading to (6.12). The transition to this from the blow-up behavior described in section 4 is rather complex, and we shall not give anything like full details; the initial stages can be described by naively incorporating the ϵ term in the boundary condition in $x = s$ into the interior layer analysis of section 4, in which case the ordinary differential equation (4.15) generalizes to

$$\frac{16\sqrt{\pi}}{L^4} e^{L^2/4} \dot{L} \sim 1 - \frac{\epsilon L}{2\lambda} e^{\tau/2},$$

which itself has a rather delicate asymptotic structure in the limit $\epsilon \to 0$ over the timescales on which the second term on the right-hand side comes to dominate the first. Subsequently, there is a phase in which the λ terms are asymptotically negligible (i.e., the evolution is governed by the zero latent heat problem), from which the blow-up behavior (6.12) ultimately emerges.

7. Numerical results. The method of lines may be used to solve the problem (3.1)–(3.4) numerically. The method adopted is described in detail in the appendix and follows Fasano, Meyer, and Primicerio [19], with the modification discussed in Meyer [28] used to accommodate the Neumann condition on the fixed boundary. The scheme may be used for both cases $\epsilon = 0$ and $\epsilon > 0$, with the minor modifications needed for the former case also described in the appendix.

For the numerical simulations, the initial profile adopted was the following piecewise linear function:

$$u_{in}(x) = \begin{cases} -a, & x < \hat{\alpha}, \\ -a + a\dfrac{(x-\hat{\alpha})(x-\hat{\beta})}{(1-\hat{\alpha})(1-\hat{\beta})}, & \hat{\alpha} < x \leq 1, \end{cases} \tag{7.1}$$

where $\hat{\alpha} = 0.2$ and $\hat{\beta} = 0.9$ were fixed in all of the following calculations.

Figure 5 shows the full numerical solution for the interface position and speed in the case with no kinetic undercooling, $\epsilon = 0$. Taking $a = 0.4, 0.5, 0.6, 0.8$ gives $Q = 0.33, 0.167, 1.3 \times 10^{-7}, -0.33$, respectively, from (3.5). The increase in the interface speed as Q decreases is clearly illustrated. Blow-up would be expected to occur in the case $Q = -0.33$. Not surprisingly, such behavior is not fully reproduced in the numerics, with truncation errors presumably serving to regularize the problem.

Figures 6 and 7 show the time development of the full numerical solution for the interface position and speed as the two key parameters, the segregation coefficient μ and the kinetic undercooling parameter ϵ, vary independently; the initial profile (7.1) with $a = 0.8$, corresponding to $Q = -0.33$, was adopted. Figure 6 shows the approach to blow-up behavior as $\mu \to 0^+$ for $\epsilon = 1$, while Figure 7 illustrates the corresponding behavior as $\epsilon \to 0^+$ for $\mu = 1$. As already noted, kinetic undercooling does not prevent blow-up when $\mu = 0$, with Figure 6 illustrating that this limit is approached relatively quickly as μ is decreased (the numerical scheme being particularly sensitive to the value of μ, as can be seen from the scalar equation (A.9) for determination of the position of the interface at the next time level). For comparison in Figure 7, the asymptotic blow-up behavior (4.16) of the unregularized problem

$$\dot{s} \sim -\left(\frac{1}{\ln(t_c - t)\sqrt{\ln(-\ln(t_c - t))}}\right)(t_c - t)^{-1/2} \quad \text{as } t \to t_c^- \tag{7.2}$$

is also plotted in Figure 7(B) (the estimate $t_c = 0.0096$ being used for the blow-up time, this being determined from the full numerical solution in the $\epsilon = 0$ case with the same initial profile). The value $\epsilon = 10^{-4}$ represents the smallest value accessible numerically with reasonable accuracy.

Figures 8 and 9 compare the full numerical solution (shown in both as (A) and (B)) with the asymptotics (shown in both as (C) and (D)) of sections 4 and 5 for the specific case $\epsilon = 10^{-3}, \mu = 1, Q = -0.33$. The same initial profile was used and the time variable $-\ln|t - t_c|$ was chosen to illustrate the timescales involved. The asymptotics require estimates of certain values from the blow-up profile which were obtained from the full numerical scheme in the $\epsilon = 0$ case with the same initial profile. This yielded the approximate values $x_c = 0.56, x^* = 0.15, t_c = 0.0096, \nu = 1.75$, with

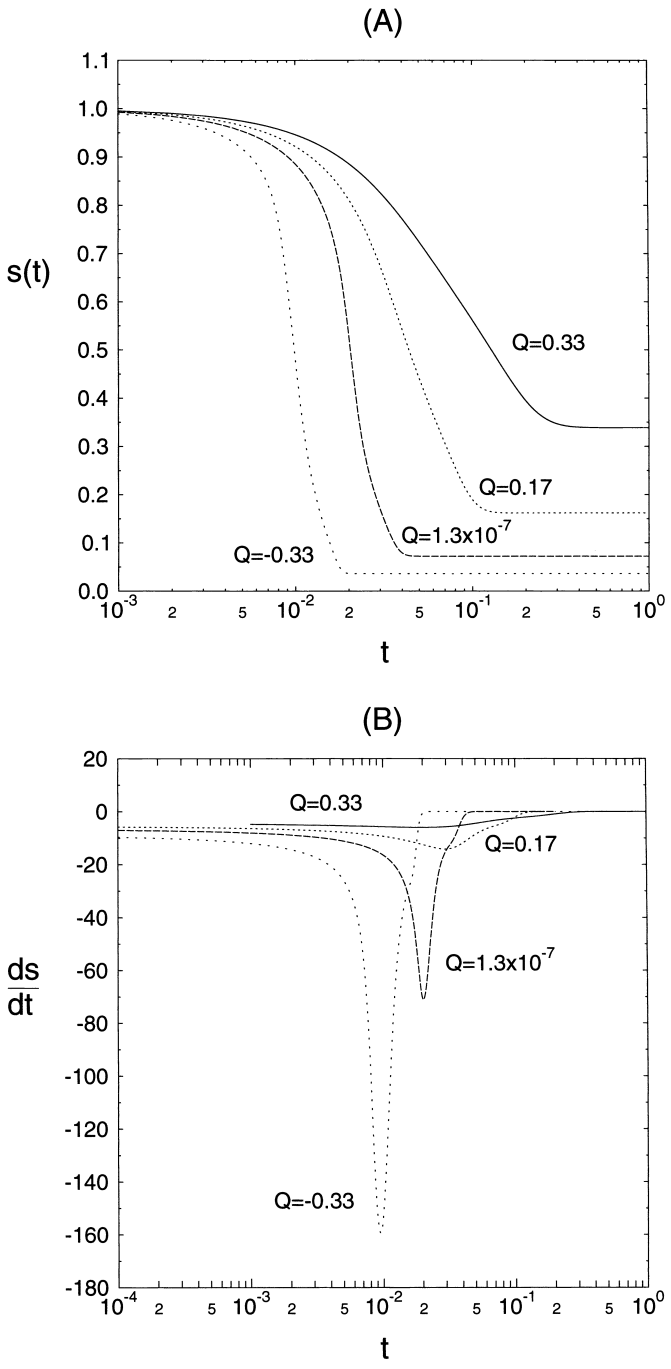

FIG. 5. *Results from the method of lines numerical scheme on* (3.1)–(3.4) *in the unregularized case* $\epsilon = 0$. *The initial profile* (7.1) *was taken with the parameter* a *varied to give the values of initial supercooling parameter* Q *shown. The interface location* s *is shown in* (A) *and its speed* $\dot{s}$ *in* (B).

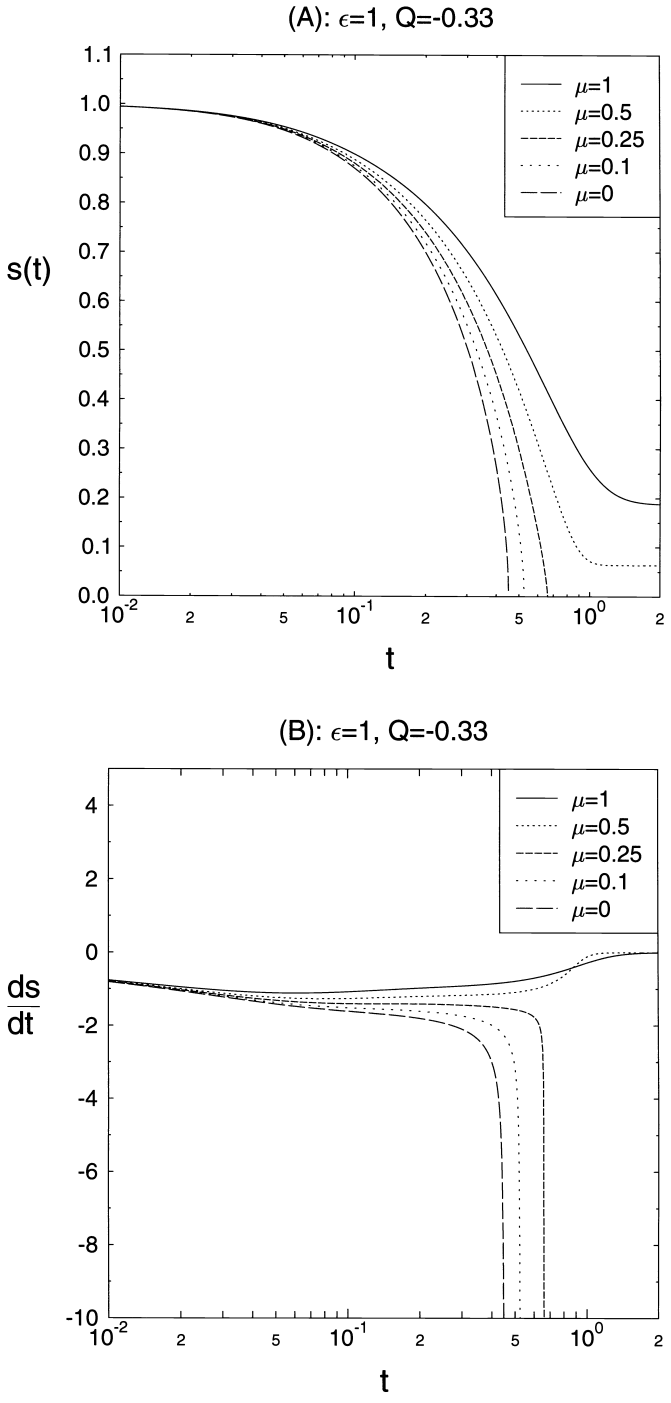

FIG. 6. *Results from the method of lines numerical scheme for* (3.1)–(3.4) *in the regularized case* $\epsilon = 1, Q = -0.33$ *for selected values of the segregation coefficient* μ*;* (A) *shows* s *and* (B) $\dot{s}$*. The initial profile* (7.1) *was taken with the parameter* $a = 0.8$*. Our analysis implies bona fide blow-up occurs for* $\mu = 0$*, and we observe that for* $\mu = 0.1$ *and* $\mu = 0.25$ *also the regularizing term seems insufficient to prevent the numerical scheme from breaking down in a manner akin to such blow-up.*

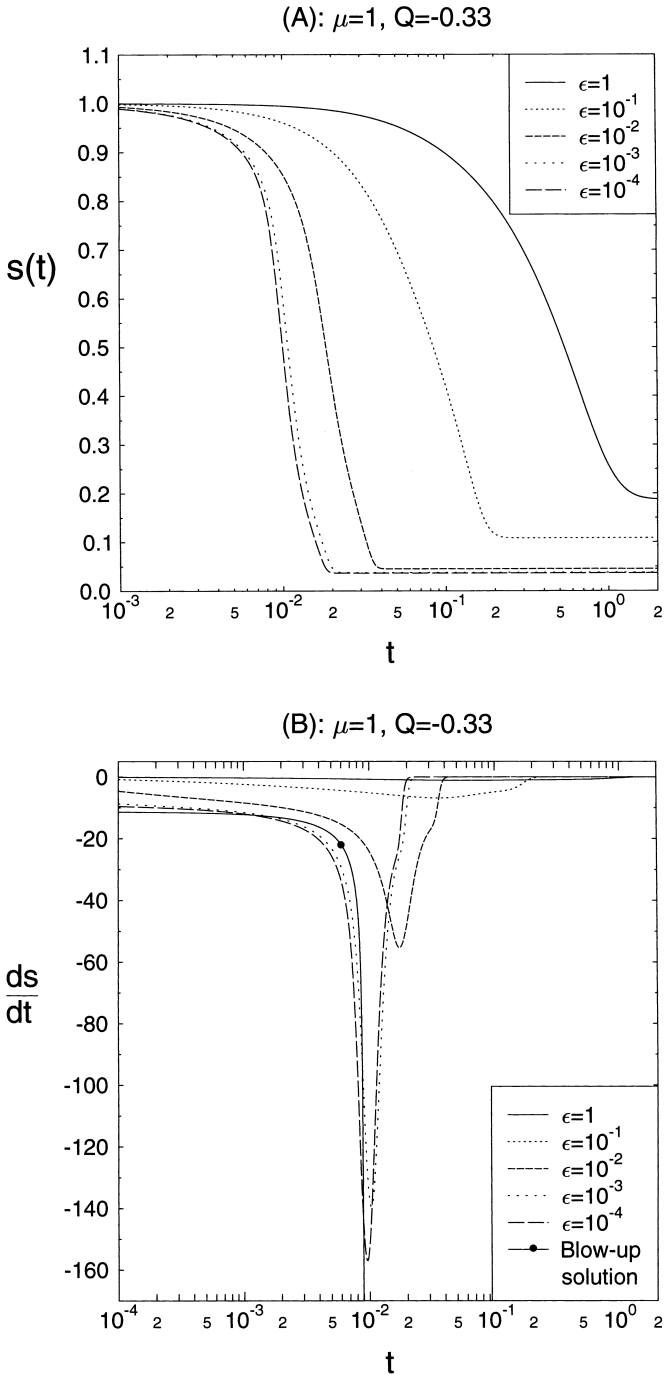

FIG. 7. *Results from the method of lines numerical scheme for* (3.1)–(3.4) *in the regularized case with* $\mu = 1, Q = -0.33$ *for selected values of the kinetic parameter* ϵ*;* (A) *shows* s *and* (B) $\dot{s}$*. The initial profile* (7.1) *was taken with the parameter* $a = 0.8$ *fixed. Also shown for comparison in* (B) *is the asymptotic blow-up behavior* (7.2).

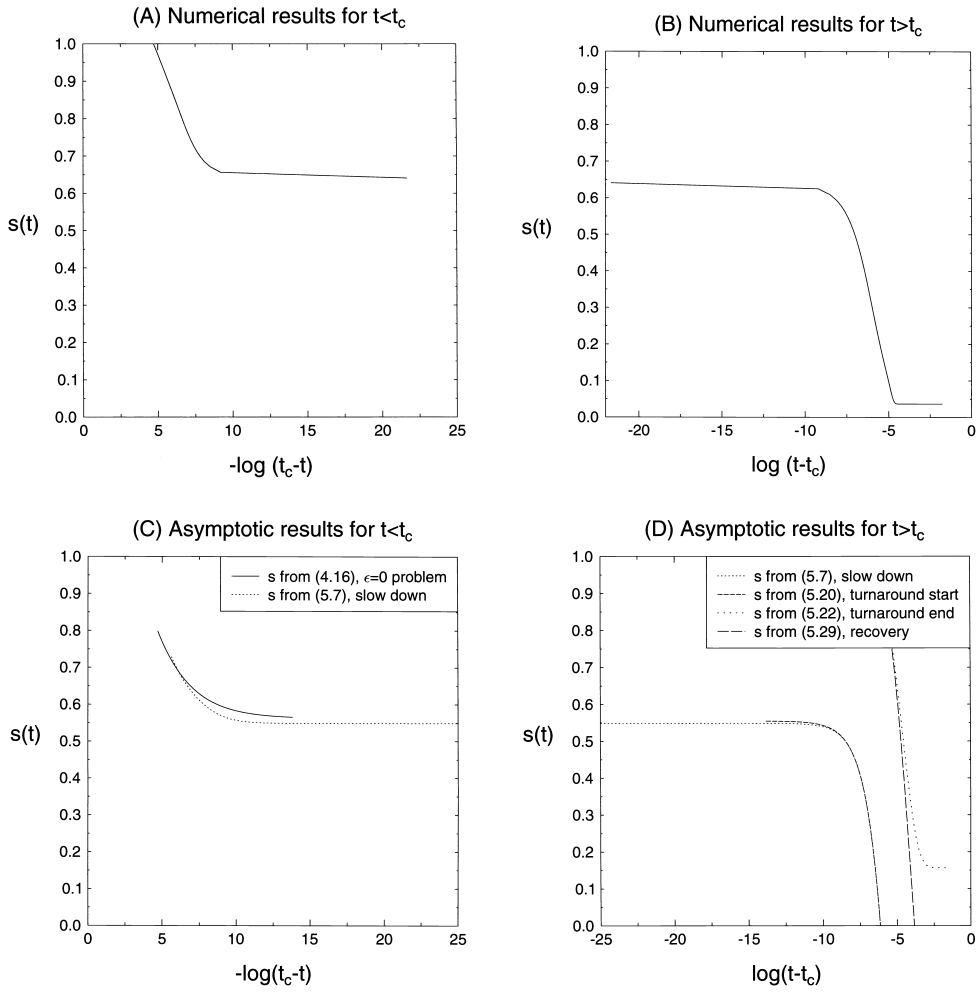

FIG. 8. *Comparison of numerical and asymptotic solutions for the interface* $s(t)$. *The parameter values taken were* $\epsilon = 10^{-3}, \mu = 1$. (A) *and* (B) *show* $s(t)$ *from the method of lines numerical scheme for* (3.1)–(3.4) *with* $a = 0.8$ *in the initial profile* (7.1), *so that* $Q = -0.33$. *The value* $t_c = 0.0096$ *was used in* (A) *and* (B) *for the transformed timescale, which was estimated using the numerical scheme on the same initial profile but with the parameter value* $\epsilon = 0$ *(this scheme also gave the estimates* $x_c = 0.56, x^* = 0.15$*). The upper curve gives* $s(t)$ *for* $t < t_c$ *and the lower gives* $s(t)$ *for* $t > t_c$. (C) *and* (D) *illustrate the asymptotic approximations derived for* $s(t)$ *in section* 5 *on the three main timescales. The parameter values for* ϵ *and* μ *are used to express these asymptotic approximations for* s *in terms of* $t - t_c$. *Since the asymptotics are for times relative to* t_c, *an approximation for* t_c *is not necessary, but the estimates* $x_c = 0.56, x^* = 0.15$ *from the numerical scheme with* $\epsilon = 0$ *were used. For comparison in* (C) *the blow-up asymptotic solution* (4.16) *is also shown. In* (D), *only the initial and final behaviors* (5.20) *and* (5.22) *on the turnaround timescale are shown since behavior over the whole of this timescale is controlled by* (5.18), *which requires the full profile* $u_c(x)$. *The interval over which the interface effectively "jumps" is represented in* (D) *by the vertical distance between horizontal asymptote at* $s \approx 0.56$ *and the end of the timescale that leads to the recovery of the classical Stefan problem at* $s \approx 0.15$.

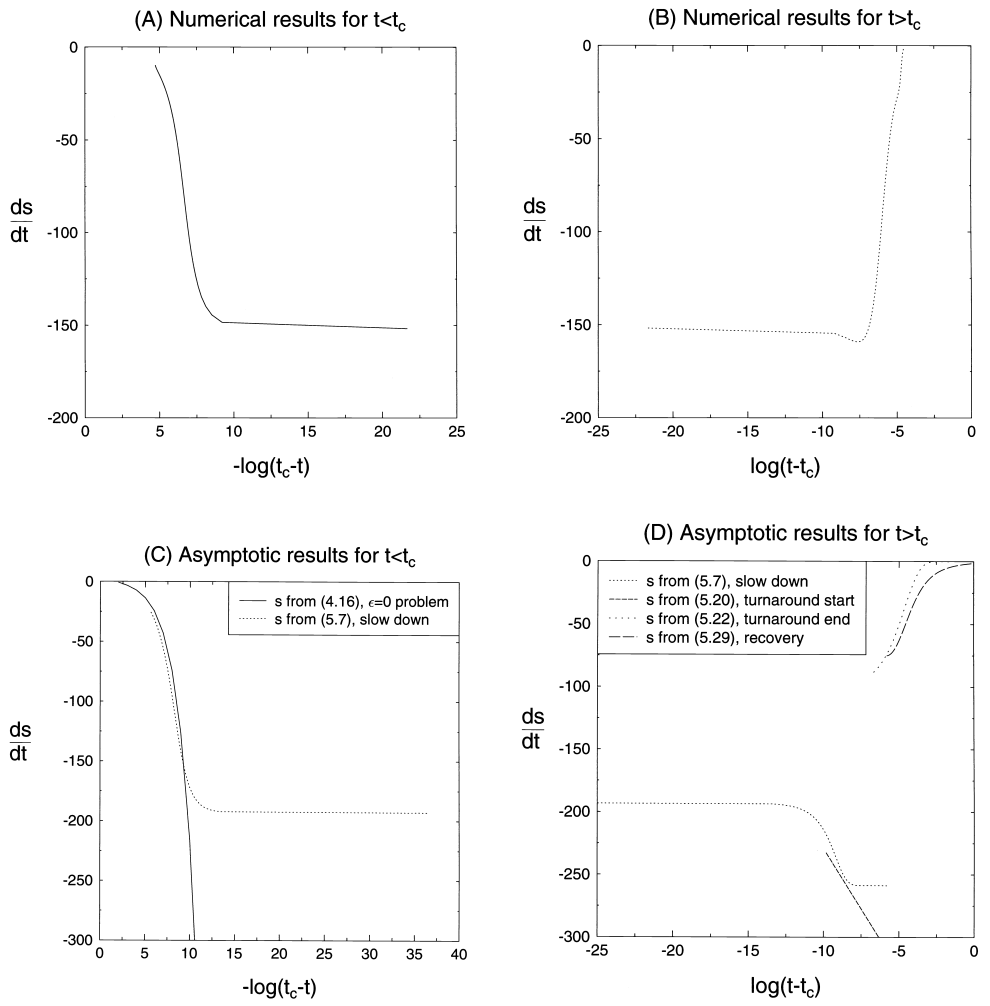

FIG. 9. *Comparison of numerical and asymptotic solutions for the interface speed ds/dt in the example described in Figure* 8. *Results analogous to those shown for s in Figure* 8 *are given here for ds/dt. Results from the method of lines numerical scheme are shown in* (A) *and* (B), *while the asymptotic approximations derived in section* 5 *are shown in* (C) *and* (D). *We note in* (D) *a gap in the asymptotic solution for the turnaround timescale where only the start and end behaviors are shown. The intermediate behavior requires the blow-up profile as dictated by* (5.18).

Figure 10 showing the initial profile $u_0(x)$ and an approximation to the blow-up profile $u_c(x)$. These values are very sensitive to the approximation to the blow-up profile chosen and are recorded here for illustrative purposes only. Even though $\epsilon = 10^{-3}$ is relatively large (as far as the asymptotics are concerned, since $\delta \approx 0.52$ is still not particularly small), only qualitative comparisons can be made. Although the initial behavior on the turnaround timescale of section 5.2 cannot really be observed for the ϵ chosen, the emergence of the predicted timescales is supported. On the turnaround timescale, the asymptotics suggest that ds/dt will decrease according to (5.13) before subsequently increasing to eventually give (5.22), with profiles of the form shown in Figure 1 indicating from (5.18) the existence of a local minimum for ds/dt.

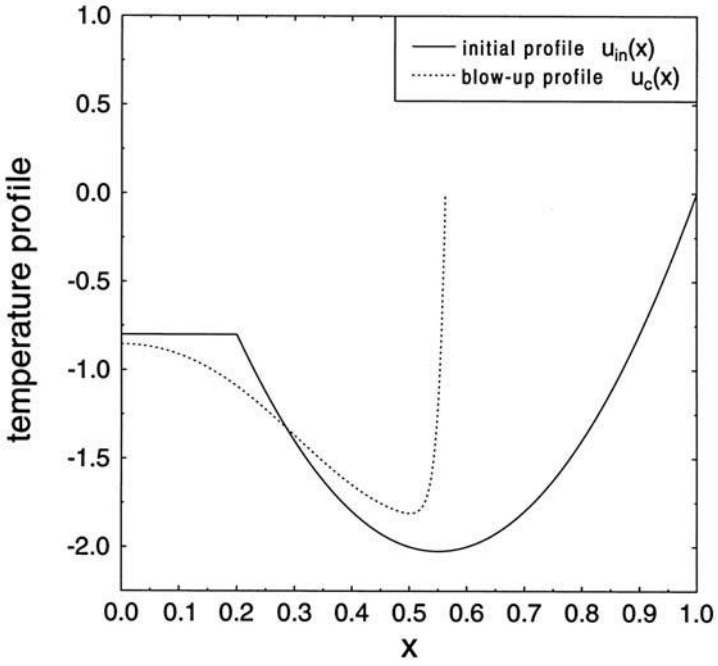

FIG. 10. *Illustration of the initial and blow-up profiles from the method of lines numerical scheme in the case* $\epsilon = 0, Q = -0.33$, *where* $a = 0.8$ *in the initial profile* (7.1). *The blow-up profile is of course approximate and has the value* $Q = -0.3$, *illustrating that approximately* 10% *of* Q *has been lost by the numerical scheme. This approximation to the blow-up profile was used to give the estimates* $x_c = 0.56, x^* = 0.15, \nu = 1.75$ *with* $t_c = 0.0096$. *These values are used in both the numerical scheme and asymptotic approximations shown in Figures* 8 *and* 9.

8. Discussion. The regularization of the supercooled Stefan problem by kinetic undercooling in the one-dimensional, one-phase case has been discussed both asymptotically and numerically. The derivation of the one-phase model from a two-phase formulation highlights the necessity to distinguish between the cases in which the interface advances and retreats. The asymptotics of the main transition timescales for regularization by kinetic undercooling support the proposal of Gurtin [24] that an appropriate $\epsilon = 0$ formulation which allows continuation through blow-up involves an instantaneous jump in the interface location (to a position which the $\epsilon \to 0^+$ asymptotics uniquely identifies, clarifying an issue raised in [24]) at the blow-up time. This abrupt jump becomes a smooth but rapid one in the regularized problem with $0 < \epsilon \ll 1$. For $\mu = 0$, the regularization becomes ineffective in preventing singularity formation (as follows from the conserved quantity (6.1)), and some intriguing blow-up behavior arises.

One way of characterizing concisely the asymptotic results is to note the power laws and so forth which describe the various intermediate asymptotic regimes. Here we note, in particular, the $(-\hat{T})^{1/2}$ behavior in (5.11), the near-linear nature of (5.20), the exponential decay in (5.22), and the $\bar{T}^{1/3}$ rate of decrease in (5.31). Other noteworthy features include the cases in which two distinct generic behaviors occur (so that which is realized depends on the initial data); these arise in section 5.4 for $0 < \mu < 1$ (related behavior for $\mu = 0$ is described at the end of section 6, but the conservation law (6.1) which pertains in this case means that the dependence on the initial conditions can be characterized explicitly through the value of $Q \geq -\epsilon$) and in section 6 for $\mu = 0$ with

$1 < (-Q)/\epsilon \leq \Lambda$, wherein the existence of multiple similarity solutions is particularly striking.

Obvious extensions of this work are to consider the analogous two-phase and higher-dimensional problems.

Appendix. Method of lines numerical scheme. The continuous time problem is discretized and solved at successive time levels as a sequence of free boundary problems for the ordinary differential equations which arise in this way.

At time level $t = t_n$ with $t_n - t_{n-1} = \Delta t$ the solution $\{u_n(x), s_n\}$ is computed as the solution of the discretized equations

$$\text{in } 0 < x < s_n \qquad u_n'' - \frac{1}{\Delta t}(u_n - u_{n-1}) = 0, \tag{A.1}$$

$$u_n'(0) = 0, \tag{A.2}$$

$$\frac{s_n - s_{n-1}}{\Delta t} = f(u_n(s_n)), \qquad s_0 = s(0) = 1, \tag{A.3}$$

$$u_n'(s_n) = -\frac{s_n - s_{n-1}}{\Delta t}\left(\lambda + (1-\mu)u_n(s_n)\right). \tag{A.4}$$

Here, we have allowed for a general kinetic condition of the form $\dot{s} = f(u)$, where $f(u)$ satisfies the conditions $f'(u) > 0$ and $f(0) = 0$. The power law form $f(u) = u^{1/n}/\epsilon$ is common, with $n = 1$ being the case considered in the main text. It is assumed that the function $u_{n-1}(x)$ (defined over $[0, s_{n-1}]$) and s_{n-1} are both known. The free boundary problem (A.1)–(A.4) may be solved by the method of invariant embedding (or the sweep method), as described in [28].

Writing (A.1)–(A.4) as a first-order system over $(0, s_n)$

$$u_n' = v_n, \qquad v_n' = \frac{1}{\Delta t}(u_n - u_{n-1}), \tag{A.5}$$

the Riccati transformation

$$v_n(x) = R(x)u_n(x) + W_n(x) \tag{A.6}$$

relates u_n and v_n, where

$$R' = \frac{1}{\Delta t} - R^2, \qquad R(0) = 0, \tag{A.7}$$

and

$$W_n' = -R(x)W_n - \frac{u_{n-1}(x)}{\Delta t}, \qquad W_n(0) = 0. \tag{A.8}$$

(A.3) and (A.6) show that s_n is a root of the scalar equation

$$\sigma_n(x) \equiv \frac{(x - s_{n-1})}{\Delta t} - f\left(\frac{-(W_n(x) + \lambda\frac{(x-s_{n-1})}{\Delta t})}{R(x) + (1-\mu)\left(\frac{x-s_{n-1}}{\Delta t}\right)}\right) = 0. \tag{A.9}$$

Given s_n, we have

$$u_n(s_n) = -\frac{\lambda\dot{s}_n + W_n(s_n)}{R(s_n) + (1-\mu)\dot{s}_n}, \tag{A.10}$$

where

$$\dot{s}_n = \frac{s_n - s_{n-1}}{\Delta t} = f(u_n(s_n)) \tag{A.11}$$

and

$$u_n'(s_n) = v_n(s_n) = -\dot{s}_n \left(\frac{\lambda R(s_n) - (1-\mu) W_n(s_n)}{R(s_n) + (1-\mu)\dot{s}_n} \right). \tag{A.12}$$

The triple $\{u_n(s_n), v_n(s_n), s_n\}$ is an exact solution of (A.3), (A.4), and (A.6).

Once s_n is determined, then v_n can be found by integrating backward over $[0, s_n)$ the reverse sweep equation

$$v_n' = \frac{1}{\Delta t} \left(R(x) v_n + W_n(x) - u_{n-1}(x) \right), \tag{A.13}$$

with $v_n(s_n)$ given in (A.12).

The above algorithm was implemented as follows. A time-independent mesh with grid points $\{x_i\}_{i=0}^N$ was imposed on the interval $[0,1]$, the grid being uniform with $x_i = i/N$. Nonuniform grids with clustering of grid points where the free boundary moves quickly may also be used. The time step Δt is variable. The Riccati equation (A.7) has the closed form solution

$$R(x, \Delta t) = \frac{1}{\sqrt{\Delta t}} \tanh\left(\frac{x}{\sqrt{\Delta t}} \right), \tag{A.14}$$

while the linear equation (A.8) is integrated to give

$$W_n(x) \cosh\left(\frac{x}{\sqrt{\Delta t}} \right) = -\int_0^x \frac{u_{n-1}(\tau)}{\Delta t} \cosh\left(\frac{\tau}{\sqrt{\Delta t}} \right) d\tau$$

and evaluated using a suitable quadrature rule (here the simple trapezoidal rule was used). The function $\sigma_n(x)$ is evaluated at successive mesh points of the grid before s_{n-1} until it changes sign between, say, x_ℓ and $x_{\ell-1}$. The free boundary s_n is now determined as the root of the quadratic interpolant through $\sigma(x_{\ell-1}), \sigma(x_\ell)$, and $\sigma(x_{\ell+1})$. Equation (A.6) is also integrated to give

$$u_n(x) = u_n(s_n) \frac{\cosh\left(\frac{x}{\sqrt{\Delta t}} \right)}{\cosh\left(\frac{s_n}{\sqrt{\Delta t}} \right)} + \cosh\left(\frac{x}{\sqrt{\Delta t}} \right) \int_{s_n}^x \frac{W_n(\tau)}{\cosh\left(\frac{\tau}{\sqrt{\Delta t}} \right)} d\tau$$

and evaluated by the trapezoidal rule, first from s_n to $x_{\ell-1}$ and then backward over the fixed mesh.

In the special case $\epsilon = 0$, (A.3) and (A.4) reduce to

$$u_n(s_n) = 0, \qquad s_0 = s(0) = 1, \tag{A.15}$$

$$u_n'(s_n) = -\lambda \frac{(s_n - s_{n-1})}{\Delta t}, \tag{A.16}$$

with (A.9) replaced with

$$\sigma_n(x) = W_n(x) + \lambda \frac{(x - s_{n-1})}{\Delta t} = 0 \tag{A.17}$$

and (A.10)–(A.12) modified to

$$u_n(s_n) = 0, \qquad \dot{s}_n = \frac{s_n - s_{n-1}}{\Delta t}, \qquad u_n'(s_n) = v_n(s_n) = W_n(s_n) = -\lambda \dot{s}_n.$$

The algorithm for this special case proceeds as before.

WEAKLY NONLINEAR AND NUMERICAL ANALYSES OF DYNAMICS IN A SOLID COMBUSTION MODEL*

L. K. GROSS† AND J. YU‡

Abstract. This paper contains qualitative and quantitative comparisons between a weakly nonlinear analysis and direct numerical simulations of a free-boundary problem. The former involves modulating the most linearly unstable mode, taking a small perturbation of the neutrally stable value ν_c of a parameter ν related to the activation energy. Analogously, we perform the direct numerical computations near the marginally unstable value, namely, $\nu = \nu_c - \epsilon^2$, where ϵ is rather small.

We delineate the role of a different parameter σ (related to the Arrhenius kinetics) in the combustion dynamics when $\nu = \nu_c - \epsilon^2$. In particular, the numerics show that varying σ produces a period-doubling scenario when ϵ lies approximately between 0.08 and 0.12. We describe the σ intervals within which complex dynamics occur for various values of ϵ and for ν fixed at $\nu_c - \epsilon^2$. When ϵ drops to approximately 0.06, the asymptotic and numerical solutions agree well for all physical values of σ.

Key words. free-boundary problems, condensed-phase combustion, weak instability, asymptotic expansions, Crank–Nicolson method, Fourier transforms

1. Introduction.

In this article, we study the nonuniform dynamics of front propagation in a free-boundary model of solid combustion, through both weakly nonlinear analysis and direct simulations. We do the first quantitative comparison of the two methods.

The asymptotic technique applies to the weakly unstable setting. In particular, we fix the bifurcation parameter ν related to the activation energy to within a rather small number ϵ^2 of the neutrally stable value ν_c. By solving numerically in the same regime, we closely investigate the role of a parameter σ associated with the Arrhenius kinetics. In particular, period-doubling and eventual chaos develop as the kinetics parameter σ decreases (and the bifurcation parameter ν remains at a deviation of ϵ^2 from its critical value).

Weakly nonlinear analysis involves modulating the most linearly unstable mode. Within quite a small neighborhood of the neutral stability boundary, Fourier spectra of the numerical quasi-steady-state solutions indicate a regime in which a single mode dominates, as well as complex regimes of front propagation.

As the bifurcation parameter ν approaches ever closer to the neutrally stable value, the range of the parameter σ for which period-doubling and other strongly nonlinear dynamics occur shrinks. Sufficiently near the stability threshold (ϵ approximately 0.06), numerical solutions for all values of σ agree closely with the weakly

nonlinear solutions. By varying ϵ, we quantify the domain of applicability of the weakly nonlinear analysis.

The problem under consideration models, for example, solid combustion, in which a chemical reaction converts a solid fuel directly into solid products with no intermediate gas phase formation. For instance, in self-propagating high-temperature synthesis (SHS), a flame wave advancing through powdered ingredients leaves high-quality ceramic materials or metallic alloys in its wake. (See, for instance, [15, 17, 20].)

The propagation results from the interplay between heat generation and heat diffusion in the medium. A balance exists between the two in some parametric regimes, producing a constant burning rate. In other cases, competition between the reaction and the diffusion results in a wide variety of nonuniform behaviors, some leading to chaos.

Shkadinsky, Khaikin, and Merzhanov [18] predicted the simplest oscillatory regimes through numerical simulation on reaction-diffusion partial differential equations (PDEs). The system contains Arrhenius-kinetics terms that account for chemical conversion throughout the spatial domain.

Various works have explored numerically the dynamics of models that employ approximations to the Arrhenius kinetics. For instance, in [1], Arrhenius kinetics with a cutoff was used to observe chaotic pulsations, following a number of period-doubling bifurcations.

Other approximations exploit the narrowness of the reaction zone. A point-source model has an exact traveling-wave solution and is more amenable to analysis than one with the full Arrhenius kinetics. Matkowsky and Sivashinsky [14] studied a concentrated-kinetics model in the case of large activation energy. The δ-function kinetics follow from an analysis similar to that of [19].

This free-interface problem has been studied numerically in [4]. For a sufficiently large activation energy, the work showed transitions to chaos via a period-doubling solution and highly irregular relaxational oscillations. The authors attributed a lack of sequential secondary bifurcations to the difference between the point-source and distributed-kinetics models (as in [1]). Later, however, in [9], the entire spectrum of behavior was observed for the free-interface model, as previously had been seen for distributed kinetics.

In [9], the authors performed numerical computations on a second model of solid combustion as well. They motivate it by noting that both the reaction-diffusion model as in [18] and the free-interface model in [14] assume a constant value of thermal diffusivity. However, some problems manifest a clear dependence of this parameter on degree of conversion. In fact, when the burnt product is a foam-like substance, heat diffusion in the product region is negligible. For such cases, they consider a model that includes the heat equation on a semi-infinite domain ahead of the reaction and a nonlinear kinetic condition imposed on the moving boundary. The present paper uses this free-boundary problem.

Note that both the free-interface (two-sided) model and the free-boundary (one-sided) model stem from reaction-diffusion PDEs with full Arrhenius kinetics. To emphasize, the one-sided model is not an adaptation of the two-sided model; rather each of them is a viable derivative of the reaction-diffusion model. The two-sided model assumes a single constant conductivity throughout the reactant and product zones. The one-sided model assumes zero conductivity in the burned region. In some cases the first approximation is more appropriate, in others the second.

Belyaev and Komkova discovered a pulsating regime in the burning of a chrome-

magnesium thermite in 1950 [2]. A planar front may have oscillated with a constant frequency in their experiments, but they did not observe the process in detail. Later Merzhanov, Filonenko, and Borovinskaya [16] observed experimentally both the periodic propagation of a flat front in SHS as well as spinning waves, showing a fuller understanding of the behaviors. All the models discussed in this literature review exhibit the same spectrum of dynamics as experiments. Specifically, we refer to computed solutions of (i) the reaction-diffusion system governed by the full Arrhenius kinetics (e.g., [5]), (ii) the reaction-diffusion system with Arrhenius kinetics with a cutoff (e.g., [1]), and models that use point-source kinetics like (iii) the free-interface ("two-sided") model with constant heat diffusivity (e.g., [9]), as well as (iv) the free-boundary ("one-sided") model, in which heat transfer behind the flame front (in the burned matter) is qualitatively unimportant (e.g., [9]).

Simulations on all these models show the same dynamical behaviors as one pushes the bifurcation parameters deeper into the instability regions. In particular, numerical simulations and analysis in [9] show that dynamics of the two-sided and one-sided problems agree extremely closely.

In the present work, we fix the bifurcation parameter ν within ϵ^2 of the neutrally stable value and vary the kinetics parameter σ, rather than exploring regimes more and more strongly unstable in ν. In addition, we vary ϵ, thereby also changing ν, and study the impact on the dynamics with respect to the kinetics parameter σ. We will point out the agreement with dynamical scenarios described in previous studies, which use a variety of models.

The stability thresholds for uniformly propagating fronts generally differ for all of the different kinetics mentioned, however. Distributed kinetics have only the numerical approximate bifurcation values. Intricate bifurcation analyses [13, 10] of instabilities for the point-source models have also classified the interactions of clockwise and counterclockwise spinning waves on the surface of a cylinder. Margolis's review paper [13] includes a thorough discussion of resonance phenomena, treating sample radii that yield close, as well as equal, eigenvalues. Also, Booty, Margolis, and Matkowsky [3] predicted cascades of bifurcations from a double eigenvalue of a linearized model of condensed-phase combustion in a long cylindrical sample. They show that the inclusion of melting in the model makes the neutral-stability threshold more accessible. A bifurcation parameter ν in the present work is restricted to a smaller neighborhood of the value corresponding to a single neutrally stable eigenvalue. A different parameter σ is varied to produce period-doubling behaviors numerically.

Combustion in two dimensions can be described by a one-dimensional model when the only unstable mode corresponds to the dynamics with no spatial variation in the transverse direction. For example, the linear stability analysis in [12] shows that for a free-boundary model, a flat front dominates the behavior for the case of a sufficiently narrow strip of material with insulated edges.

In particular, to satisfy the boundary conditions, the wave numbers are integer multiples of π/a, where a is the strip width [12]. If $a < \pi$, all modes are stable for $\nu > 1/3$. Exactly one mode (the zeroth mode) loses stability at $\nu_c = 1/3$. The zero mode corresponds to the dynamics with no spatial variation in the transverse direction (i.e., to the one-dimensional case). If, on the other hand, $\pi < a < 2\pi$, then, as we decrease ν, the first mode π/a loses stability prior to the flat mode, namely, at a value of $\nu > 1/3$. In both cases ($a < \pi$ and $\pi < a < 2\pi$) the weakly nonlinear analysis shows that the evolution is governed by a complex Landau–Stuart ordinary differential equation [11]. (See what follows for the narrow-strip analysis.)

At $a = \pi$, the flat mode and the first wavy mode both lose stability at $\nu_c = 1/3$, while the other modes remain stable. The nonlinear interaction of the flat and curvy modes is the subject of the weakly nonlinear analysis in [12], which culminates in the derivation of a system of two complex Landau–Stuart equations. (Notice that if the width a is infinite, a continuum of modes goes unstable, and the evolution is governed by Ginzburg–Landau PDEs.)

In the remainder of this section, we introduce the governing equations and, for convenience, summarize a linear stability analysis. Because we consider the case in which a zero-wavenumber mode is the most unstable, we present the model in one space dimension. In [21], we do a full linear stability study for the two-dimensional problem formulated as an initial-value problem.

Section 2 contains a weakly nonlinear analysis, and section 3 shows simulations in the marginally unstable regime. In computations, the dynamics unfold as the parameter σ associated with the Arrhenius kinetics decreases (while the bifurcation parameter ν remains fixed within ϵ^2 of its neutrally stable value).

Section 4 presents quantitative comparisons of the asymptotic solutions and computed solutions. Some qualitative comparisons for a similar problem—involving competing flat and wavy (two-dimensional) modes—appear in [6] (together with numerics that venture into more strongly unstable regimes than in the present paper). Here we investigate the numerical solutions for marginally unstable values of the activation energy, allowing a full range of kinetics-parameter values.

Specifically, we perform the computations with ν fixed near the marginally unstable value, namely, $\nu = \nu_c - \epsilon^2$, where ϵ is fairly small. For ϵ smaller than about 0.12, we see the smooth periodic solutions that the weakly nonlinear analysis predicts, provided σ has an appropriate value. In particular, Fourier transforms of the numerical data illustrate the ranges of σ in which the analysis accurately predicts the quantitative behavior of solutions.

The data simultaneously reveal the development of complex dynamics in various kinetics-parameter regimes (with the inverse activation energy ν held at ϵ^2 units below the stability threshold), when ϵ exceeds about 0.06. When ϵ drops below this value, the σ intervals of strongly nonlinear dynamics disappear.

In the model, we seek the temperature distribution $u(x,t)$ in one spatial dimension and the interface position $\Gamma(t) = \{x | x = f(t)\}$ that satisfy the appropriately nondimensionalized free-boundary problem

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}, \quad x > f(t), \quad t > 0, \tag{1.1}$$

$$V = G\left(u\big|_{\Gamma}\right), \quad t > 0, \tag{1.2}$$

$$\left.\frac{\partial u}{\partial x}\right|_{\Gamma} = -V, \quad t > 0. \tag{1.3}$$

Here V is the velocity of the rightward-traveling interface, i.e.,

$$V = \frac{df}{dt}.$$

In addition, the temperature satisfies the condition

$$u \to 0 \text{ as } x \to \infty; \tag{1.4}$$

that is, the ambient temperature is normalized to zero at infinity.

To model solid combustion, we take the Arrhenius function as the kinetics function G in the nonequilibrium interface condition (1.2) [4, 17]. Then, with appropriate nondimensionalization, the velocity of propagation relates to the interface temperature as

$$V = \exp\left[\left(\frac{1}{\nu}\right)\frac{u-1}{\sigma+(1-\sigma)u}\right] \tag{1.5}$$

at the interface Γ. Here ν is inversely proportional to the activation energy of the exothermic chemical reaction that occurs at the interface, and $0 < \sigma < 1$ is the ambient temperature nondimensionalized by the adiabatic temperature of combustion products. (See [8].)

Inverting the Arrhenius function (1.5), we reexpress the boundary condition (1.2) in the form

$$u|_\Gamma = 1 + \nu K(V;\sigma,\nu), \tag{1.6}$$

where

$$K(V;\sigma,\nu) = \frac{\ln(V)}{1-(1-\sigma)\nu\ln(V)}. \tag{1.7}$$

Note the function $K(V)$ has been introduced to have the convenient properties $K(1) = 0$, $K'(1) = 1$.

For ease of subsequent asymptotic and numerical analysis, we reformulate the problem in the front-attached coordinate frame:

$$\eta = x - f(t), \quad \tau = t.$$

Problem (1.1)–(1.6) then takes the form

$$\frac{\partial u}{\partial \tau} = \frac{\partial^2 u}{\partial^2 \eta} + V\frac{\partial u}{\partial \eta}, \quad \eta > 0,\ \tau > 0, \tag{1.8}$$

$$u|_\Gamma = u(0,\tau) = 1 + \nu K(V), \tag{1.9}$$

$$\left.\frac{\partial u}{\partial \eta}\right|_\Gamma = \left.\frac{\partial u}{\partial \eta}\right|_{(0,\tau)} = -V, \tag{1.10}$$

$$\lim_{\eta\to\infty} u = 0. \tag{1.11}$$

The free-boundary problem (1.8)–(1.11) admits a traveling-wave solution

$$u_0(\eta,\tau) = \exp(-\eta), \quad f_0(\tau) = \tau. \tag{1.12}$$

The problem linearized about the traveling wave has a normal-mode solution of the form

$$w = e^{\lambda\tau} g(\eta;\lambda), \quad \phi = e^{\lambda\tau}, \tag{1.13}$$

where w and ϕ represent the perturbations about u_0 and f_0, respectively. Substituting them into the linearized problem produces an eigenvalue problem in λ and $g(\eta;\lambda)$.

The discrete spectrum values are zero and

$$\lambda = \frac{1 - 3\nu \pm \sqrt{(3\nu-1)^2 - 4\nu^3}}{2\nu^2}. \tag{1.14}$$

The eigenfunction corresponding to the eigenvalue λ is

$$g(\eta;\lambda,\nu) = (1+\nu\lambda)\exp\left(-\left(1+\sqrt{1+4\lambda}\right)\frac{\eta}{2}\right) - \exp(-\eta). \tag{1.15}$$

Linearly unstable behavior occurs for this system only when $\Re\lambda$ is positive.

The basic solution (1.12) is neutrally stable under a small perturbation of the form (1.13) if $\Re\lambda = 0$. Setting $\Re\lambda = 0$ in (1.14) gives the critical value ν_c of ν, namely,

$$\nu_c = \frac{1}{3}. \tag{1.16}$$

The corresponding neutrally stable eigenvalues from (1.14) are $\pm i\omega$, where

$$\omega = \sqrt{3}. \tag{1.17}$$

If $\nu < 1/3$, then $\Re\lambda > 0$, and the basic solution is linearly unstable. (See, for example, [12, 21].)

2. Weakly nonlinear analysis. Let ϵ^2 be a small deviation from the neutrally stable value of ν, namely,

$$\epsilon^2 = \nu_c - \nu = \frac{1}{3} - \nu. \tag{2.1}$$

We consider the time scales

$$t_0 = \tau, \quad t_1 = \epsilon\tau, \quad t_2 = \epsilon^2\tau$$

as independent variables, so that $\partial/\partial\tau = \partial/\partial t_0 + \epsilon\,\partial/\partial t_1 + \epsilon^2\,\partial/\partial t_2$. We then seek a solution of the form

$$\begin{aligned} u(\eta,t_0,t_1,t_2) &= e^{-\eta} + \epsilon A(t_1,t_2)e^{i\sqrt{3}t_0} g\left(\eta; i\sqrt{3}, \frac{1}{3}\right) \\ &\quad + \epsilon^2 w_2(\eta,t_0,t_1,t_2) + \cdots + \text{CC}, \\ f(t_0,t_1,t_2) &= t_0 + \epsilon\left\{A(t_1,t_2)e^{i\sqrt{3}t_0} + \frac{1}{2}B(t_1,t_2)\right\} \\ &\quad + \epsilon^2\phi_2(t_0,t_1,t_2) + \cdots + \text{CC}, \end{aligned} \tag{2.2}$$

where $A(t_1,t_2)$ is complex, and "CC" stands for complex-conjugate terms. The real-valued function $B(t_1,t_2)$ modulates the constant-velocity solution to the linearized problem.

Notice that in $O(\epsilon)$, the weakly nonlinear solution (2.2) has only one Fourier term in t_0. We will show below in (2.19)–(2.20) that the $O(\epsilon^2)$ term contains the second harmonic. We refer to the expansion (2.2) as a "single-mode approximation" because the leading-order perturbation contains only one mode in fast time.

Making the substitutions (2.2) and equating like powers of ϵ results in subproblems for the terms in the perturbation expansions above, subject to solvability conditions on the amplitudes A and B. The $O(1)$ problem is satisfied identically because in (2.2) we took the temperature-interface pair (u, f) perturbed about $(e^{-\eta}, t_0)$, a solution to the nonlinear problem (1.8)–(1.11). The $O(\epsilon)$ problem is just the linearized problem with $\nu = \nu_c = 1/3$, which is satisfied identically by the $O(\epsilon)$ terms in the expansions (2.2).

The problems of order ϵ^j, $j = 2, 3$, are

$$\frac{\partial w_j}{\partial t_0} - \frac{\partial^2 w_j}{\partial \eta^2} - \frac{\partial w_j}{\partial \eta} + e^{-\eta}\frac{\partial \phi_j}{\partial t_0} = Q_j(\eta, \mathbf{t}), \tag{2.3}$$

$$w_j|_{\eta=0} - \frac{1}{3}\frac{\partial \phi_j}{\partial t_0} = \alpha_j(\mathbf{t}), \tag{2.4}$$

$$\left.\frac{\partial w_j}{\partial \eta}\right|_{\eta=0} + \frac{\partial \phi_j}{\partial t_0} = \beta_j(\mathbf{t}), \tag{2.5}$$

$$\lim_{\eta\to\infty} w_j = 0, \tag{2.6}$$

where $\mathbf{t} = (t_0, t_1, t_2)$. For brevity, we have named the right-hand sides above as Q_j, α_j, and β_j. The PDEs (2.3) can be represented as

$$\mathcal{L}_1 w_j + \mathcal{L}_2 \phi_j = \mathcal{P}(w_1, \phi_1, \ldots, w_{j-1}, \phi_{j-1}). \tag{2.7}$$

$\mathcal{L}_1$ and $\mathcal{L}_2$ are linear operators on bounded functions in $L^2(\Omega)$, where $\Omega = \{(\eta, \tau) | 0 \le \eta < \infty,\ 0 \le \tau < \infty\}$.

According to Fredholm's alternative, equation (2.7) has a nonsecular (bounded-in-time) solution if the right-hand side is orthogonal to the null space of the adjoint operator $\mathcal{L}^*$. That is,

$$(\mathcal{L}_1 w_j + \mathcal{L}_2 \phi_j,\ v) = 0 \tag{2.8}$$

for $v \in \ker \mathcal{L}^*$ and the inner product defined such that

$$(f_1, f_2) = \lim_{T\to\infty} \frac{1}{T} \int_0^T \int_0^\infty f_1(\eta, \tau)\overline{f_2(\eta, \tau)}\, d\eta\, d\tau. \tag{2.9}$$

The quantity v in (2.8) satisfies

$$\left(-\frac{\partial}{\partial t_0} - \frac{\partial^2}{\partial \eta^2} + \frac{\partial}{\partial \eta}\right) v = 0, \tag{2.10}$$

$$2i\frac{\sqrt{3}}{3}\ v|_{\eta=0} - \left(1 - i\frac{1}{3}\right)\left.\frac{\partial v}{\partial \eta}\right|_{\eta=0} = 0. \tag{2.11}$$

Nonzero solutions are

$$u_1(\eta, t_0; i\sqrt{3}) = \exp(i\sqrt{3}t_0)h(\eta; i\sqrt{3}) \ \text{ and } \ u_0(\eta, t_0; 0) = 1, \tag{2.12}$$

where

$$h(\eta; i\sqrt{3}) = \exp\left(\left(1 - \sqrt{1 - 4i\sqrt{3}}\right)\frac{\eta}{2}\right). \tag{2.13}$$

Substituting $v = u_1$ into the solvability condition (2.8) when $j = 2$ produces the differential equation

$$\frac{\partial A}{\partial t_1} = 0. \tag{2.14}$$

Substituting $v = u_0$ into the solvability condition (2.8) when $j = 2$ produces the differential equation

$$\frac{\partial B}{\partial t_1} = A\bar{A}r_0, \quad r_0 = -3(2 + K''(1)). \tag{2.15}$$

Substituting (2.14) and (2.15) into the $O(\epsilon^2)$ problem in (2.3)–(2.6) yields the problem

$$\frac{\partial w_2}{\partial t_0} - \frac{\partial^2 w_2}{\partial \eta^2} - \frac{\partial w_2}{\partial \eta} + e^{-\eta}\frac{\partial \phi_2}{\partial t_0} = A^2 e^{2i\sqrt{3}t_0}\mathcal{R}_2(\eta) + A\bar{A}\mathcal{R}_0(\eta) + \text{CC}, \tag{2.16}$$

$$w_2|_{\eta=0} - \frac{1}{3}\frac{\partial \phi_2}{\partial t_0} = A^2 e^{2i\sqrt{3}t_0}F_2 + A\bar{A}F_0 + \text{CC}, \tag{2.17}$$

$$\left.\frac{\partial w_2}{\partial \eta}\right|_{\eta=0} + \frac{\partial \phi_2}{\partial t_0} = A^2 e^{2i\sqrt{3}t_0}G_2 + A\bar{A}G_0 + \text{CC}. \tag{2.18}$$

The solution (w_2, ϕ_2) consists of a homogeneous and a particular solution. Because only the inhomogeneous terms will contribute to the solvability condition at the next order, we present the nonsecular solution as

$$w_2 = A^2 e^{2i\sqrt{3}t_0}g_2(\eta) + A\bar{A}g_0(\eta) + \text{CC}, \tag{2.19}$$

$$\phi_2 = A^2 e^{2i\sqrt{3}t_0}C_2 + A\bar{A} + \text{CC}, \tag{2.20}$$

where $g_j(\eta)$, $j = 0, 2$, satisfy the initial-value problems

$$g_j'' + g_j' - ji\sqrt{3}g_j = ji\sqrt{3}C_2 e^{-\eta} - \mathcal{R}_j(\eta), \tag{2.21}$$

$$g_j(0) = ji\frac{\sqrt{3}}{3}C_2 + F_j, \tag{2.22}$$

$$g_j'(0) = -ji\sqrt{3}C_2 + G_j, \tag{2.23}$$

$$g_2(\eta) \to 0 \text{ as } \eta \to \infty, \tag{2.24}$$

where

$$\mathcal{R}_j(\eta) = -(-1)^{j/2}g'(\eta)i\sqrt{3} - \frac{2-j}{4}r_0 e^{-\eta}, \tag{2.25}$$

$$F_j = \frac{1}{2}(-1)^{j/2}K''(1) + \frac{2-j}{12}r_0, \tag{2.26}$$

$$G_j = -\frac{2-j}{4}r_0. \tag{2.27}$$

Recall that r_0 is given in (2.15). Also, $g(\eta) = g(\eta; i\sqrt{3})$ is defined via (1.15).

Substituting $v = u_1$ into the solvability condition (2.8) when $j = 3$ produces the Landau–Stuart equation

$$\frac{dA}{dt_2} = \chi A + \beta A^2 \bar{A}, \tag{2.28}$$

where

$$\chi \equiv -\frac{\partial \lambda_0}{\partial \nu}\bigg|_{\nu=\nu_c} = \frac{3}{2}(9 + \sqrt{3}i). \tag{2.29}$$

The coefficient β is defined as

$$\beta = \frac{\int_0^\infty R(\eta)\bar{h}(\eta)\, d\eta + F\mathcal{U}}{\int_0^\infty (g(\eta) + e^{-\eta})\bar{h}(\eta)\, d\eta - \frac{1}{3}\mathcal{U} - 1}, \tag{2.30}$$

where

$$R(\eta) = r_0 g'(\eta) + i\sqrt{3}\,[2C_2\bar{g}'(\eta) - g_2'(\eta) + 2\mathrm{Re}\,(g_0'(\eta))]; \tag{2.31}$$

$$F = \frac{1}{3}(6C_2 + ir_0\sqrt{3})K''(1) + i\frac{\sqrt{3}}{2}K'''(1); \tag{2.32}$$

$$\mathcal{U} = -\frac{1}{2}(3 + i\sqrt{3}). \tag{2.33}$$

Once we solve the Landau–Stuart equation (2.28) subject to an initial condition, the full asymptotic expansion (2.2) is known with w_2 and ϕ_2 given in (2.19)–(2.20) and B given in (2.15). In what follows, we compare the asymptotic solution with a numerical solution over the range $0 < \sigma < 1$ with ν fixed at a small deviation ϵ^2 from the neutrally stable value $1/3$, as given in (2.1).

The amplitude equation (2.28) determines the dynamics of the unstable mode $A(t_2)e^{i\sqrt{3}t_0}$, subject to self-interaction. The dynamics of the mode depend on the relationships between the coefficients χ and β and are affected by the kinetics function $K(V)$, introduced in (1.7). Recall that the function $K(V)$ is normalized such that $K(1) = 0$ and $K'(1) = 1$. The form of the kinetics function comes into play via $K''(1)$ and $K'''(1)$, which appear explicitly in r_0, F_j, and F of (2.15), (2.26), and (2.32), respectively. Note from (2.17) that F_j, $j = 2, 0$, are the coefficients of $A^2e^{2i\sqrt{3}t_0}$ and $A\bar{A}$, respectively, on the right-hand side of an $O(\epsilon^2)$ boundary condition. Also, F is the coefficient of $A^2\bar{A}e^{i\sqrt{3}t_0}$ on the right-hand side $\alpha_3(\mathbf{t})$ of the $O(\epsilon^3)$ boundary condition (2.4). In particular, $\alpha_3(\mathbf{t})$ has the form

$$\alpha_3(\mathbf{t}) = \left\{ \left(\frac{\partial A}{\partial t_2} - \chi A\right)\frac{1}{3}e^{i\sqrt{3}t_0} + A^3e^{3i\sqrt{3}t_0}F_3 + A^2\bar{A}e^{i\sqrt{3}t_0}F + \mathrm{CC}\right\} + \frac{1}{3}\frac{\partial B}{\partial t_2}. \tag{2.34}$$

(F_3 does not pertain to this discussion.)

To examine the behavior of the front in the different parameter regimes, let us consider the real equation in $|A|$ corresponding to the complex equation (2.28), namely,

$$\frac{d|A|}{dt_2} = |A|(\mathrm{Re}(\chi) + |A|^2\mathrm{Re}(\beta)). \tag{2.35}$$

Perturbation amplitude $|A| = 0$ is a stationary solution for (2.35). Because $\mathrm{Re}(\chi) = 27/2$ is greater than zero, trajectories with an initial point near the origin in the complex A plane tend away from the origin. That is, in the absence of other equilibria, the amplitude blows up in (slow) time for ν slightly below the critical value $1/3$.

Equation (2.35) has a second equilibrium $|A| = \sqrt{-\mathrm{Re}(\chi)/\mathrm{Re}(\beta)}$ (a circle in the complex-A plane) if $\mathrm{Re}(\beta)$ is negative. A simple stability analysis of (2.35) shows that $d|A|/dt_2 < 0$ outside of the circle, and $d|A|/dt_2 > 0$ inside it. As a result, the limit cycle in the complex-A plane is asymptotically stable in this setting. A supercritical Hopf bifurcation occurs at $\nu = 1/3$. The nonlinear solution develops oscillations of magnitude $O(\epsilon)$ on the time scale $O(\epsilon^{-2})$. (See the expansion in (2.2).)

The quantity $\mathrm{Re}(\beta)$ is a quadratic function in σ with no roots at physical values of σ. For all $0 < \sigma < 1$, $\mathrm{Re}(\beta)$ is negative. The amplitude of the flat mode $A(t_2)e^{i\sqrt{3}t_0}$ approaches the limit cycle $|A| = \sqrt{-\mathrm{Re}(\chi)/\mathrm{Re}(\beta)}$. The nonlinear problem (1.8)–(1.11) develops oscillations, as detailed below.

3. Numerical method. We integrate numerically the exact problem as given by (1.8)–(1.11). In section 4, we compare the numerical solution with the asymptotics derived above. As was pointed out in [7], numerical solutions of (1.8)–(1.11) are very sensitive to the boundary condition (1.10). In order to obtain an alternative condition, we integrate (1.8) with respect to η from 0 to ∞. Subsequently applying conditions (1.9)–(1.11) results in the equation

$$\frac{d}{dt}\int_0^\infty u\,d\eta = -\nu f_t K(V). \tag{3.1}$$

We use (3.1) to replace (1.10) and adopt the Crank–Nicolson method for the numerical solution. The computation domain for η is $[0, 10]$ with $\delta t = \delta\eta = 0.025$. This produces a nonlinear system of m $(= 401)$ equations. In particular, in reference to (2.2), we introduce perturbation variables u^* and f^* defined by

$$u = e^{-\eta} + \epsilon u^*; \qquad f = t + \epsilon f^*. \tag{3.2}$$

Our discretization of condition (3.1) is

$$\begin{aligned}\Big(\int_0^\infty u^*\,d\eta\Big)\Big|_{t_k}^{t_{k+1}} = -\frac{\nu}{2\epsilon}[&(1+\epsilon f_t^*(t_{k+1}))K(1+\epsilon f_t^*(t_{k+1}))\\ &+(1+\epsilon f_t^*(t_k))K(1+\epsilon f_t^*(t_k))](t_{k+1}-t_k),\end{aligned} \tag{3.3}$$

where the integral on the left-hand side of (3.3) can be approximated by a composite trapezoidal rule.

We solve the nonlinear system of equations using Newton's method. The Jacobian matrix has the following sparse structure:

$$\begin{pmatrix} \# & \# & 0 & 0 & 0 & 0 & \dots & 0 \\ \# & \# & \# & \# & \# & \# & \dots & \# \\ \# & \# & \# & \# & 0 & 0 & \dots & 0 \\ \# & 0 & \# & \# & \# & 0 & \dots & 0 \\ \vdots & & & \ddots & \ddots & \ddots & & \vdots \\ \# & 0 & \dots & 0 & \# & \# & \# & 0 \\ \# & 0 & \dots & 0 & 0 & \# & \# & \# \\ \# & 0 & \dots & 0 & 0 & 0 & \# & \# \end{pmatrix}, \tag{3.4}$$

where # denotes a nonzero element. The matrix can be efficiently inverted by using Gaussian elimination with backward substitution.

The next section contains comparisons between numerical and asymptotic solutions. For the asymptotic solution, we integrate the ordinary differential equation (2.28) using a fourth-order Runge–Kutta method. As was pointed out in section 2, the Landau–Stuart equation (2.28) has circular limit cycles in the complex-A plane for all values of the kinetic parameter σ in the interval $0 < \sigma < 1$.

4. Comparison between asymptotics and numerics. To fix the idea, we first consider $\epsilon = 0.1$. The value of ν remains at the marginally unstable value $\nu_c - \epsilon^2$, as introduced in (2.1), so $\nu \approx 0.32\bar{3}$. We show in this section that this choice of ϵ corresponds to a mix of dynamics as σ varies. Subsequently, we both decrease and increase ϵ and discuss the impact on the front behavior. For the remainder of this paper, we take the initial condition $A(0) = 0.1$.

To start, take $\sigma = 0.48$ in the kinetic function (1.7). Figure 4.1 shows the numerical (solid line) and asymptotic (dashed line) values of front speed perturbation as a function of time t in the interval $0 \le t \le 60$. Specifically, for the numerical and asymptotic solutions we have graphed the quantities

$$v_n = f_t^* \quad \text{and} \quad v_a = A(t_2)e^{i\sqrt{3}t_0} + \frac{1}{2}B(t_1, t_2) + \epsilon\phi_2(t_0, t_1, t_2), \tag{4.1}$$

respectively, where f^* is defined in (3.2), and v_a contains the first three terms in the perturbation in (2.2).

Figure 4.1 shows that from $t = 0$ to about $t = 30$, the small front speed perturbation is linearly unstable, and its amplitude grows exponentially in time. As this amplitude becomes large, nonlinearity takes effect. At around $t = 30$, the front speed

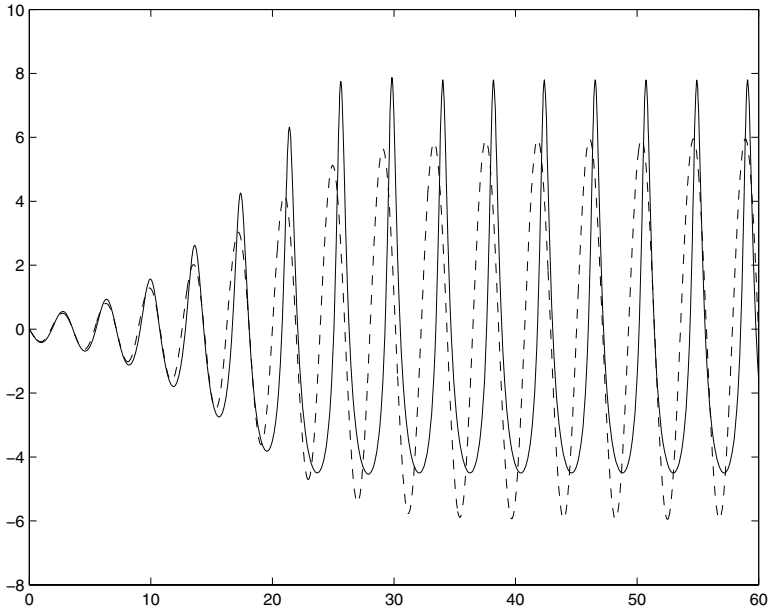

FIG. 4.1. *Velocity perturbation versus time: Comparison between numerical (solid line) and asymptotic (dashed line);* $\sigma = 0.48$, $\epsilon = 0.1$, $A(0) = 0.1$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.1)^2 = 0.32\bar{3}$*).*

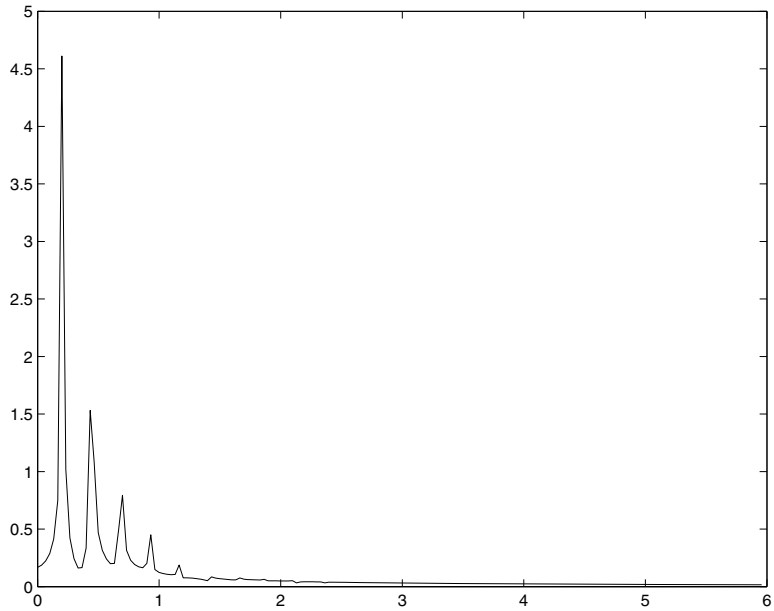

FIG. 4.2. *Fourier amplitude of the numerical steady-state velocity perturbation;* $\sigma = 0.48$, $\epsilon = 0.1$, $A(0) = 0.1$, $50 < t < 100$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.1)^2 = 0.32\bar{3}$*).*

perturbation has reached steady oscillation. The asymptotic solution accurately captures the period in both transient behavior for $t = 0$ to 30 and the long-time behavior after $t = 30$. The amplitude and phase differ somewhat.

The weakly nonlinear approach describes well, by definition, marginally unstable large-time behaviors when a single modulated temporal mode of frequency $\sqrt{3}$ captures the dynamics. (See (2.2).) We have illustrated such a case in Figure 4.1. We then numerically calculated the velocity perturbation data $\{f_t^*(t_i)\}$ on the time interval $50 < t < 100$, using the parameter values as in Figure 4.1. The discrete Fourier transform of the data reveals the dominance of one mode. (See Figure 4.2.)

However, the subsequent modes do contribute to the solution as well. The second spike in Figure 4.2 is about 3/5 the height of the first, and the third is fully 1/2 the height of the second. Contributions of higher-order modes may explain some quantitative discrepancies between the numerical and asymptotic solutions in Figure 4.1.

Figure 4.3 summarizes the Fourier transformed velocity data for all physical values of σ $(0 < \sigma < 1)$. For each σ value and each frequency, the color indicates the corresponding amplitude, with the red end of the spectrum standing for larger numbers than the violet end, as the legend to the right of the figure illustrates. For roughly $0.3 < \sigma < 0.6$, the figure shows the dominance of the lowest-order mode, suggesting the appropriateness of the weakly nonlinear analysis in this range.

Notice, however, that at least four additional modes appear significant as well. Nevertheless, for σ in the interval approximately $(0.3, 0.6)$, the weakly nonlinear solution captures the gross features of the oscillation. (See, for example, Figure 4.1.)

With our choice of $\epsilon = 0.1$, Figure 4.3 shows that for σ greater than approximately 0.6, a single mode cannot be expected to capture the full dynamics of the solution. For example, for $\sigma = 0.85$, the asymptotic solution certainly will not exhibit a velocity perturbation with the very sharp peaks seen in the numerical solution in Figure 4.4.

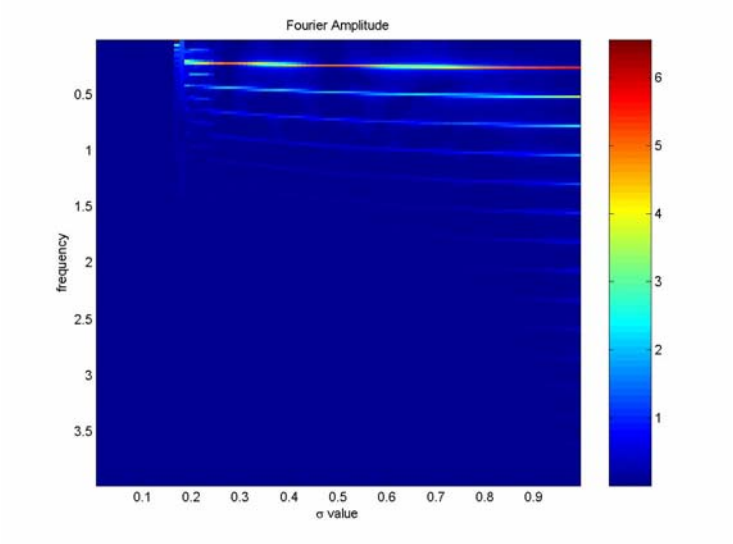

FIG. 4.3. *Amplitudes corresponding to each frequency of the Fourier transformed velocity perturbation data for the Arrhenius kinetics parameter* σ *in the interval* $(0,1)$*;* $\epsilon = 0.1$*,* $A(0) = 0.1$*,* $35 < t < 85$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.1)^2 = 0.32\bar{3}$*).*

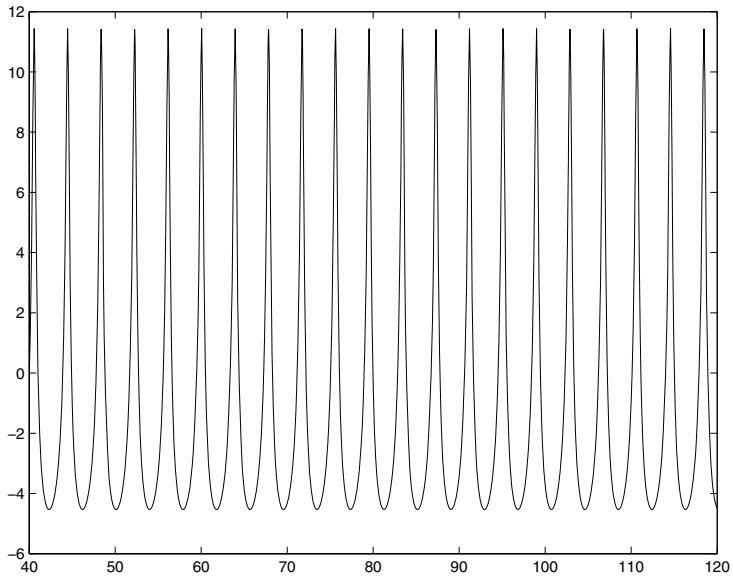

FIG. 4.4. *Velocity perturbation versus time: Numerical solution for* $\sigma = 0.85$*,* $\epsilon = 0.1$*,* $A(0) = 0.1$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.1)^2 = 0.32\bar{3}$*).*

Further, Figure 4.3 shows that the Fourier spectrum has a complicated character for σ sufficiently small, starting with the emergence of a period-doubling solution for $\sigma \approx 0.25$. Naturally, the asymptotic solution captures neither the period-doubling solution nor the period-quadrupling computed for $\sigma = 0.22$ and $\sigma = 0.21$, respectively. (Numerical solutions in Figures 4.5 and 4.6 illustrate the dynamics.) Figure 4.3 reflects the breakdown of the numerical solution for σ less than approximately 0.15.

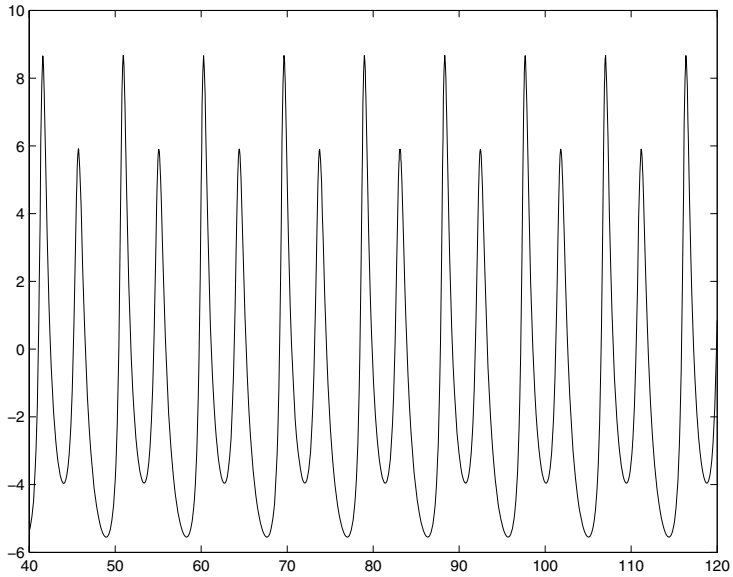

FIG. 4.5. *Velocity perturbation versus time: Period-doubling numerical solution for* $\sigma = 0.22$, $\epsilon = 0.1$, $A(0) = 0.1$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.1)^2 = 0.32\bar{3}$*).*

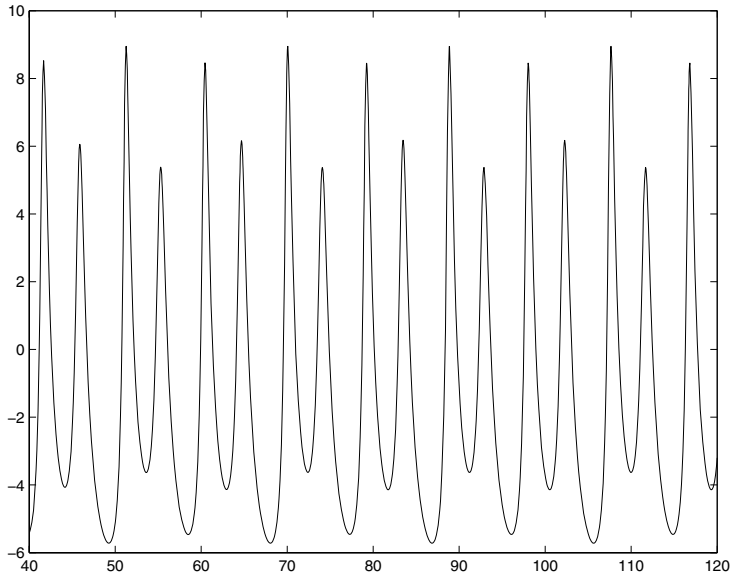

FIG. 4.6. *Velocity perturbation versus time: Period-quadrupling numerical solution for* $\sigma = 0.21$, $\epsilon = 0.1$, $A(0) = 0.1$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.1)^2 = 0.32\bar{3}$*).*

The weakly nonlinear analysis of section 2 predicts periodic single-mode-dominant solutions for all physical values of σ $(0 < \sigma < 1)$ when $\nu = 1/3 - \epsilon^2$ is sufficiently close to the neutrally stable value $\nu_c = 1/3$. From numerical simulation with $\epsilon = 0.1$, the interval in which a single mode dominates has been identified via Figure 4.3 as a subinterval of $(0, 1)$, namely, $(0.3, 0.6)$. The corresponding asymptotic solution

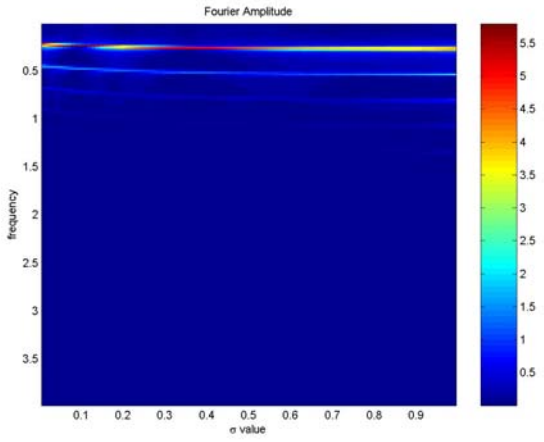

FIG. 4.7. *Amplitudes corresponding to each frequency of the Fourier transformed velocity perturbation data for the Arrhenius kinetics parameter σ in the interval $(0,1)$; $\epsilon = 0.06$, $A(0) = 0.1$, $35 < t < 85$ ($\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.06)^2$).*

captures the numerical solution accurately even for ϵ as large as 0.1 when the dynamics associated with varying the parameter σ are not too complex. In particular, the interval $0.3 < \sigma < 0.6$ corresponds to good agreement. In what follows, we discuss the effects of decreasing and increasing ϵ.

We have seen that the approximate interval of $\sigma \geq 0.6$ in Figure 4.3 corresponds to sharply spiking solutions with many Fourier modes contributing. This far right interval moves farther and farther to the right as ϵ decreases. When ϵ drops to 0.06, the interval of spiking solutions disappears.

As we decrease ϵ, graphs analogous to Figure 4.3 also show the period-doubling region pushed farther and farther to the left along the σ axis. Similarly, the far left code-failure region moves farther to the left. When ϵ drops to 0.07, the period-doubling interval essentially disappears, and solutions can be computed even for extremely small σ values.

Figure 4.7 shows that for $\epsilon = 0.06$, one mode dominates strongly throughout the entire interval $0 < \sigma < 1$. The asymptotic and numerical solutions are consistent for *all* physical values of σ when $\nu = 1/3 - \epsilon^2$ if ϵ lies in the relatively small interval $0 < \epsilon < 0.06$.

Figure 4.7 also shows that only three higher-order modes appear to make slight additional contributions, fewer than for any value of σ illustrated in Figure 4.3 for $\epsilon = 0.1$. Therefore, as expected, the weakly nonlinear and numerical solutions agree more closely with ϵ reduced from 0.1 to 0.06. Figure 4.8 ($\epsilon = 0.06$) shows good agreement in period—as does Figure 4.1 when $\epsilon = 0.1$. Also, the phase, amplitude, and centerline agreement has improved considerably in Figure 4.8 for the decreased ϵ. In Figure 4.8, the asymptotic solution oscillates between about -6 and 6, while the numerical extends from -5 to 7, and their difference at the quasi-steady-state peaks is about 1. In Figure 4.1 for $\epsilon = 0.1$, the asymptotic solution also lies between -6 and 6, but the numerical solution varies between -4.5 to 7.9. The difference at the peaks is about 2.

We have discussed the impact of reducing ϵ from the value 0.1 used in Figures 4.1–4.6, which all pertain to the dynamics when $\nu = 1/3 - (0.1)^2$. If ϵ *increases* beyond 0.1,

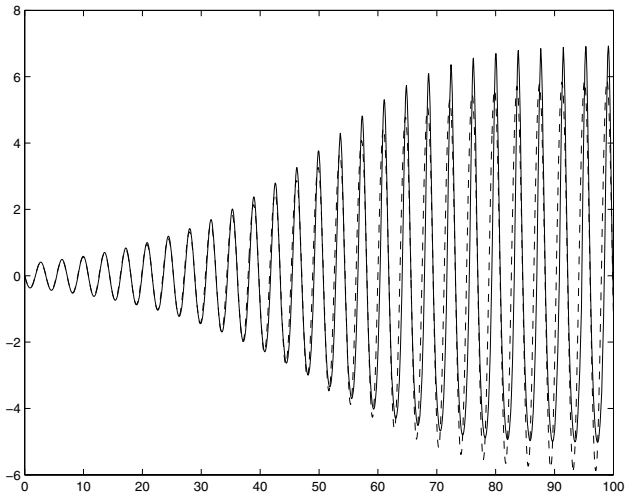

FIG. 4.8. *Velocity perturbation versus time: Comparison between numerical (solid line) and asymptotic (dashed line),* $\sigma = 0.48$, $\epsilon = 0.06$, $A(0) = 0.1$ *(*$\nu \approx \nu_c - \epsilon^2 = 1/3 - (0.06)^2 = 0.3297\overline{3}$*).*

then the far right σ interval in Figure 4.3, corresponding to sharply spiking solutions, has a left-hand endpoint that moves farther and farther to the *left*: The σ interval of solutions with sharp peaks expands.

Also, as we increase ϵ, graphs analogous to Figure 4.3 show the period-doubling region pushed farther and farther to the *right* along the σ axis, when compared with Figure 4.3. In addition, the far left code-failure region has a right-hand endpoint that moves farther and farther to the *right*: The σ interval on which the code breaks down expands.

When ϵ grows to 0.12, the σ zone in which one mode dominates strongly becomes extremely narrow. The asymptotic and numerical solutions agree well for σ in the approximate interval $(0.41, 0.42)$.

5. Conclusions and discussion. We have quantitatively compared a weakly nonlinear analysis and direct numerical integration for a solid combustion model. By definition, the weakly nonlinear approach is well suited to the study of marginally unstable large-time behaviors when the modulated most-unstable mode captures the dynamics.

For both the asymptotic and numerical methods, we examined nonuniform solutions corresponding to ν fixed within ϵ^2 of the stability boundary. When $\epsilon = 0.1$, for values of σ in the approximate interval $(0.3, 0.6)$, the weakly nonlinear analysis predicted accurately the transient and steady-state behaviors and particularly the period of oscillation. Beyond these special values of σ, the steady-state front propagation exhibited complicated nonlinear behaviors. We took the Fourier transforms of computational solutions to illustrate that higher-order modes play a significant role on σ intervals outside of $(0.3, 0.6)$ when $\epsilon = 0.1$.

For larger values of ϵ, the σ interval of applicability of the weakly nonlinear analysis shrinks. By contrast, when ϵ drops to approximately 0.06, the asymptotic and numerical solutions agree well for all physical values of σ.

Specifically, as ϵ increases from 0.06 (Figure 4.7) to $\epsilon = 0.1$ (Figure 4.3) and beyond, a period-doubling sequence develops in σ. As ϵ gets larger (thereby pushing

ν somewhat deeper into the instability region), the period-doubling bifurcation occurs at larger and larger values of σ, and the subsequent bifurcations occur as σ decreases. We note that this result, when viewed for a fixed value of σ, shows a period-doubling sequence in ν (as ϵ increases), which concurs with the dynamical scenarios described in the literature for experiments, as well as for simulations on reaction-diffusion and free-interface models.

In future work, we will suggest a hybrid expansion-perturbation technique for capturing more complex dynamics than those that have single-mode dominance. A more flexible general expansion as in [22] will assume that the temperature and interface position can be represented as a Fourier-like series that includes multiple temporal modes varying in fast time.

Acknowledgments. The authors would like to express their gratitude to the editor Stephen B. Margolis and to the referees for very insightful comments and suggestions. We also thank Yi Yang of the Institute of Applied Physics and Computational Mathematics in Beijing for helpful recommendations.

NÉEL WALLS IN LOW ANISOTROPY SYMMETRIC DOUBLE LAYERS*

CARLOS J. GARCIA-CERVERA†

Abstract. A new model for the study of one-dimensional walls in magnetic multilayers is presented. We obtain the optimal scaling of this energy functional for low anisotropy double layers with magnetic layers of equal thickness. We prove that the optimal scaling may be attained by opposing Néel walls. We obtain the core length of the Néel wall and a detailed description of its structure. We illustrate our findings numerically.

Key words. micromagnetics, Landau–Lifshitz, Γ-limit, Néel walls

1. Introduction. A magnetic multilayer consists of two or more magnetic films, separated by a layer of nonmagnetic material (see Figure 1). Each layer may be of a different thickness. Multilayers seem to have good permanent magnet properties, in particular a high coercive field and approximately rectangular hysteresis loop [17]. For that reason multilayers are an integral part of magnetic memories (MRAMs) and have been one of the most important applications of ferromagnetic thin films in the past few years.

The magnetization distribution in a ferromagnetic material is described by the micromagnetics model, introduced by Landau and Lifshitz [12]. In nondimensional variables, the Landau–Lifshitz energy functional for a sample occupying a volume V is

$$F[\mathbf{m}] = \frac{q}{2}\int_V \Phi(\mathbf{m})\,dx + \frac{1}{2}\int_V |\nabla \mathbf{m}|^2\,dx + \frac{1}{2}\int_{\mathbb{R}^3} |\nabla \eta|^2\,dx. \tag{1.1}$$

In (1.1), $|\mathbf{m}| = 1$ in V, and $\mathbf{m} = 0$ outside V. The three terms in (1.1) are anisotropy, exchange, and stray field energy, respectively. The parameter q is the quality factor, defined as $q = K_u/(\mu_0 M_s^2)$, where K_u is the crystalline anisotropy constant, M_s is the saturation magnetization, and μ_0 is the permeability of vacuum ($\mu_0 = 4\pi \times 10^{-7} N/A^2$). In (1.1), lengths are measured in units of the exchange length, $l = \sqrt{C_{ex}/(\mu_0 M_s^2)}$, where C_{ex} is the exchange constant. The energy is measured in units of $e = \sqrt{\mu_0 M_s^2 C_{ex}}$.

The stray field is $\mathbf{h}_s = -\nabla\eta$, where η is obtained by solving the equation

$$\text{div } (-\nabla\eta + \mathbf{m}) = 0 \quad \text{in } \mathbb{R}^3 \tag{1.2}$$

in the sense of distributions. The solution has the explicit form

$$\eta = \nabla N * \mathbf{m}, \tag{1.3}$$

where $N(\mathbf{x}) = -\frac{1}{4\pi}\frac{1}{|\mathbf{x}|}$ is the Newtonian potential.

For physical parameters typical of Permalloy ($C_{ex} = 1.3 \times 10^{-11} J/m$, $K_u = 5 \times 10^2 J/m^3$, $M_s = 8 \times 10^5 A/m$), the quality factor is $q \approx 6.21 \times 10^{-3}$. Thus it is physically relevant to consider the low anisotropy limit $q \to 0$, which is the situation considered in this article.

Functional (1.1) has been the focus of recent attention in the mathematical community, and the energy landscape for a single magnetic layer is now fairly well understood [9, 4, 5, 6, 8, 7, 18].

Due to the nonlocal nature of the magnetostatic interactions, the behavior of the magnetization distribution in double layers is very different from the single layer case. The magnetization patterns correspond to local minimizers of the Landau–Lifshitz energy. In a double layer, a pattern that would otherwise be energetically unfavorable for a single layer can be permitted by producing a pattern in the other layer which will cause the necessary field cancellations. With this compensating mechanism, new phenomena occur that are intrinsic to double layers.

The domain structure in magnetic films can be rather complicated [10, 6, 18]. In order to understand the structure in double films, we start by analyzing one-dimensional profiles, which will be the building blocks of more complicated structures. We are interested in both the structure and the energy of the minimizers. We are mainly interested in the scaling of the energy in terms of q as $q \to 0$, since all other parameters are kept fixed. To determine the energy of the minimizers, we consider an appropriate function in the admissible class, which provides us with an upper bound for the energy in terms of q. Subsequently we find a lower bound for the energy with the same scaling in q. The upper bound and the matching lower bound ensure that the energy is optimal, at least in terms of scaling.

In this article, we focus on the study of Néel walls in multilayers formed by two layers of equal thickness. Throughout this article we will refer to these multilayers as symmetric double layers. A description of the Néel wall in a single ferromagnetic layer was presented in [7], where the following energy functional, due originally to Aharoni [1], was analyzed:

$$\begin{aligned} F^A_{q,\delta}[\mathbf{m}] = {} & \frac{q}{2}\int_{\mathbb{R}} \left(m_1^2 + m_2^2\right) + \frac{1}{2}\int_{\mathbb{R}} |\mathbf{m}'|^2 + \frac{1}{2}\int_{\mathbb{R}} \left(m_1^2 - m_1\,(\Gamma_\delta * m_1)\right) \\ & + \frac{1}{2}\int_{\mathbb{R}} m_2\,(\Gamma_\delta * m_2). \end{aligned} \tag{1.4}$$

The set of admissible functions is

$$\mathcal{A} = \Big\{ \mathbf{m} = (m_1, m_2, m_3) | m_1, m_2 \in H^1(\mathbb{R}),\ m_3' \in L^2(\mathbb{R}),\ |\mathbf{m}| = 1 \text{ a.e.},\ \mathbf{m} \to \pm \mathbf{e}_3 \text{ as } x \to \pm\infty \Big\}. \tag{1.5}$$

In (1.4), δ represents the (rescaled) thickness of the sample, and

$$\Gamma_\delta(x) = \frac{1}{4\pi\delta} \log\left(1 + \frac{4\delta^2}{x^2}\right). \tag{1.6}$$

Functional (1.4) is derived directly from (1.1) by considering magnetization profiles that depend only on the x-variable. Functional (1.4) provides an accurate description of the minimizers for thin films ($\delta \ll 1$), since the dependence on the thickness variable becomes negligible as $\delta \to 0$ [9, 6, 8, 7, 18, 11, 3]. For thicker films, lower energy can be achieved with higher-dimensional structures [10, 18, 16].

For the study of Néel walls, we consider magnetization profiles such that $m_2 = 0$. The optimal energy scaling for a Néel wall in a single layer was obtained in [7]. In particular, it was proved that for a given $\delta > 0$ there exist positive constants c_0 and C_0 such that

$$\frac{c_0}{\log \frac{1}{q}} \le \inf_{\mathbf{m} \in \mathcal{A}, m_2 = 0} F^A_{q,\delta}[\mathbf{m}] \le \frac{C_0}{\log \frac{1}{q}} \tag{1.7}$$

as $q \to 0$. Moreover, it was shown that the Néel wall has a long logarithmic tail, which extends the stray field interactions to great distances.

In double layers the structure of Néel walls can be very different [14, 19, 20]. In this article we prove that in low anisotropy symmetric double layers, the logarithmic tail of the Néel wall disappears. The stray field becomes an exchange-type energy, and the wall becomes more localized and similar to the Landau–Lifshitz wall [12].

Considering a double layer as depicted in Figure 1, we have derived the following one-dimensional model for the study of magnetic walls in double layers:

$$\begin{aligned} G_{q,\alpha,\delta_1,\delta_2}[\mathbf{m}_1, \mathbf{m}_2] = {} & F_{q,\delta_1}[\mathbf{m}_1] + \frac{\delta_2}{\delta_1} F_{q,\delta_2}[\mathbf{m}_2] \\ & + \frac{\delta_2}{2} \int_{\mathbb{R}} u_1 \left(u_2 * \Theta_{\alpha,\delta_1,\delta_2}\right) - v_1 \left(v_2 * \Theta_{\alpha,\delta_1,\delta_2}\right) dx \\ & + \frac{\delta_2}{2} \int_{\mathbb{R}} v_1 \left(u_2 * \Psi_{\alpha,\delta_1,\delta_2}\right) - u_1 \left(v_2 * \Psi_{\alpha,\delta_1,\delta_2}\right) dx, \end{aligned} \tag{1.8}$$

where $\mathbf{m}_1 = (u_1, v_1, w_1)$ and $\mathbf{m}_2 = (u_2, v_2, w_2)$ represent the magnetization inside each layer, F_{q,δ_1} and F_{q,δ_2} are as in (1.4), and

$$\begin{aligned} \Theta_{\alpha,\delta_1,\delta_2}(x) &= \frac{1}{2\delta_1\delta_2\pi} \left(\log\left(\frac{x^2 + (2\alpha + \delta_1)^2}{x^2 + (2\alpha + \delta_1 + \delta_2)^2}\right) - \log\left(\frac{x^2 + 4\alpha^2}{x^2 + (2\alpha + \delta_2)^2}\right)\right), \\ \Psi_{\alpha,\delta_1,\delta_2}(x) &= \frac{1}{\delta_1\delta_2\pi} \Bigg(\arctan\left(\frac{2\alpha + \delta_1}{x - s}\right) - \arctan\left(\frac{2\alpha}{x - s}\right) \\ &\qquad - \arctan\left(\frac{2\alpha + \delta_1 + \delta_2}{x - s}\right) + \arctan\left(\frac{2\alpha + \delta_2}{x - s}\right)\Bigg). \end{aligned} \tag{1.9}$$

We have not been able to find this model in the literature, and therefore a complete derivation of this model is given in Appendix A. For the study of Néel walls, we assume $v_1 = v_2 = 0$. For a symmetric double layer, $\delta_1 = \delta_2 = \delta$.

This article is organized as follows. In section 2, we obtain the optimal energy scaling for Néel walls in symmetric double layers. In particular, we show that for fixed $\delta > 0$ and $\alpha > 0$ there exists a constant $C_0 > 0$ such that

$$4\sqrt{q} \le \inf_{\mathbf{m}\in\mathcal{A}} G_{q,\alpha,\delta,\delta}[\mathbf{m}] \le C_0\sqrt{q}. \tag{1.10}$$

The upper bound is obtained considering Néel walls in the double layer.

A more detailed analysis is carried out in section 3, where we prove that for a family of minimizers of the Néel wall functional (2.7), $\{\mathbf{m}_q\}_{\{q>0\}}$,

$$\lim_{q\to 0} \frac{1}{\sqrt{q}} G_{q,\alpha,\delta,\delta}[\mathbf{m}_q] = \min_{\mathbf{m}\in\mathcal{A}, m_2=0} \int_{\mathbb{R}} m_1^2\,dx + \frac{\delta\,(\delta+3\alpha)}{3}\int_{\mathbb{R}} (m_1')^2\,dx + \int_{\mathbb{R}} |\mathbf{m}'|^2\,dx. \tag{1.11}$$

We also prove that, given a family of minimizers $\{\mathbf{m}_q\}_{\{q>0\}}$, we can extract a sequence (not relabeled) such that the rescaled family $\{\mathbf{m}_q(x/\sqrt{q})\}_{\{q>0\}}$ converges strongly in $H^1(\mathbb{R})$. We interpret this in the Γ-limit sense of an appropriately scaled family of functionals. The limiting profile is studied in section 4 using a formal asymptotic expansion.

In section 5 we illustrate all of our findings numerically. To this end, we have implemented a modified Newton method for energy minimization. Finally, a detailed derivation of the model used in this article is presented in Appendix A.

2. Optimal scaling: Opposing Néel walls. Since the stray field energy is nonnegative, the Landau–Lifshitz wall profile always provides us with a lower bound for the energy:

$$G_{q,\alpha,\delta}[\mathbf{m}_1,\mathbf{m}_2] \ge \min_{\mathbf{m}_1,\mathbf{m}_2\in\mathcal{A}} \widetilde{F}_q[\mathbf{m}_1,\mathbf{m}_2], \tag{2.1}$$

where

$$\widetilde{F}_q[\mathbf{m}_1,\mathbf{m}_2] = \frac{1}{2}\sum_{j=1}^{2}\left(q\int_{\mathbb{R}}(u_j^2+v_j^2)\,dx + \int_{\mathbb{R}}|\mathbf{m}_j'|^2\,dx\right). \tag{2.2}$$

Since $\mathbf{m}_1$ and $\mathbf{m}_2$ are decoupled in (2.2), the minimum will be achieved for $\mathbf{m}_1 = \mathbf{m}_2 = (u,v,w)$. Moreover, we can assume that either $u = 0$ or $v = 0$. Otherwise, following Lemma 4 in [7], consider $\widetilde{\mathbf{m}} = (\sqrt{u^2+v^2}, 0, w)$. Then

$$\begin{aligned}\widetilde{F}_q[\widetilde{\mathbf{m}},\widetilde{\mathbf{m}}] &= q\int_{\mathbb{R}}(u^2+v^2) + \int_{\mathbb{R}}\left(\frac{(uu'+vv')^2}{u^2+v^2} + (w')^2\right)\\ &= q\int_{\mathbb{R}}(u^2+v^2) + \int_{\mathbb{R}}|\mathbf{m}'|^2 - \int_{\mathbb{R}}\frac{(uv'-vu')^2}{u^2+v^2} \le \widetilde{F}_q[\mathbf{m},\mathbf{m}].\end{aligned} \tag{2.3}$$

Therefore, a lower bound for (1.8) in a symmetric double layer is obtained by minimizing

$$\min_{\mathbf{m}\in\mathcal{A}, m_2=0} \widetilde{F}_q[\mathbf{m},\mathbf{m}]. \tag{2.4}$$

This is the minimization problem studied by Landau and Lifshitz in [12]. The minimizer is

$$\mathbf{m} = (\operatorname{sech}(\sqrt{q}x), 0, \tanh(\sqrt{q}x)), \tag{2.5}$$

and the minimum energy is

$$q\int_{\mathbb{R}} u^2\,dx + \int_{\mathbb{R}} |\mathbf{m}'|^2\,dx = 4\sqrt{q}. \tag{2.6}$$

In a single layer, this is not optimal for a Néel wall, as proved in [7]. However, we can prove that, due to stray field cancellations, this energy scaling is indeed optimal in a symmetric double layer.

To obtain a matching upper bound for the energy, we consider Néel walls in symmetric double layers and study the functional

$$\begin{aligned} G_{q,\alpha,\delta}[\mathbf{m}_1,\mathbf{m}_2] = {} & \frac{q}{2}\int_{\mathbb{R}} u_1^2 + \frac{1}{2}\int_{\mathbb{R}} |\mathbf{m}_1'|^2 + \frac{1}{2}\int_{\mathbb{R}} \left(u_1^2 - u_1\,(\Gamma_\delta * u_1)\right) + \frac{q}{2}\int_{\mathbb{R}} u_2^2 \\ & + \frac{1}{2}\int_{\mathbb{R}} |\mathbf{m}_2'|^2 + \frac{1}{2}\int_{\mathbb{R}} \left(u_2^2 - u_2\,(\Gamma_\delta * u_2)\right) + \frac{\delta}{2}\int_{\mathbb{R}} u_1\,(u_2 * \Theta_{\alpha,\delta}). \end{aligned} \tag{2.7}$$

In (2.13), we have renamed the energy functional $G_{q,\alpha,\delta} \equiv G_{q,\alpha,\delta,\delta}$, and the convolution kernel $\Theta_{\alpha,\delta} \equiv \Theta_{\alpha,\delta,\delta}$, in view of definitions (1.8) and (1.9), respectively. In Fourier space,

$$\begin{aligned} & G_{q,\alpha,\delta}[\mathbf{m}_1,\mathbf{m}_2] = \frac{q}{2}\int_{\mathbb{R}} |\widehat{u}_1|^2\,d\xi + \frac{1}{2}\int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{\mathbf{m}}_1|^2\,d\xi + \frac{1}{2}\int_{\mathbb{R}} |\widehat{u}_1|^2\left(1-\widehat{\Gamma}_\delta(\xi)\right)d\xi \\ & + \frac{q}{2}\int_{\mathbb{R}} |\widehat{u}_2|^2\,d\xi + \frac{1}{2}\int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{\mathbf{m}}_2|^2\,d\xi + \frac{1}{2}\int_{\mathbb{R}} |\widehat{u}_2|^2\left(1-\widehat{\Gamma}_\delta(\xi)\right)d\xi + \frac{\delta}{2}\Re\int_{\mathbb{R}} \widehat{u}_1\overline{\widehat{u}}_2\widehat{\Theta}_{a,\delta}(\xi)\,d\xi. \end{aligned} \tag{2.8}$$

In the following lemma, we prove that in a symmetric double layer the minimum of (2.7) is achieved by opposing Néel walls; i.e., $u_1 = -u_2$.

LEMMA 2.1. *Consider* $\mathbf{m}_1, \mathbf{m}_2 \in \mathcal{A}$, *where* $\mathbf{m}_1 = (u_1, 0, w_1)$ *and* $\mathbf{m}_2 = (u_2, 0, w_2)$. *Define* $\widetilde{\mathbf{m}}_1 = (-u_1, 0, w_1)$ *and* $\widetilde{\mathbf{m}}_2 = (-u_2, 0, w_2)$. *Then, either*

$$G_{q,\alpha,\delta}[\mathbf{m}_1, \widetilde{\mathbf{m}}_1] \le G_{q,\alpha,\delta}[\mathbf{m}_1, \mathbf{m}_2] \tag{2.9}$$

or

$$G_{q,\alpha,\delta}[\mathbf{m}_2, \widetilde{\mathbf{m}}_2] \le G_{q,\alpha,\delta}[\mathbf{m}_1, \mathbf{m}_2]. \tag{2.10}$$

Proof. We can rewrite the Fourier representation (2.8) as

$$\begin{aligned} G_{q,\alpha,\delta}[\mathbf{m}_1,\mathbf{m}_2] = {} & \frac{q}{2}\int_{\mathbb{R}} |\widehat{u}_1|^2\,d\xi + \frac{1}{2}\int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{\mathbf{m}}_1|^2\,d\xi \\ & + \frac{1}{2}\int_{\mathbb{R}} |\widehat{u}_1|^2\left(1-\widehat{\Gamma}_\delta(\xi) - \frac{\delta}{2}\widehat{\Theta}_{\alpha,\delta}(\xi)\right)d\xi + \frac{q}{2}\int_{\mathbb{R}} |\widehat{u}_2|^2\,d\xi + \frac{1}{2}\int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{\mathbf{m}}_2|^2\,d\xi \\ & + \frac{1}{2}\int_{\mathbb{R}} |\widehat{u}_2|^2\left(1-\widehat{\Gamma}_\delta(\xi) - \frac{\delta}{2}\widehat{\Theta}_{\alpha,\delta}(\xi)\right)d\xi + \frac{\delta}{4}\int_{\mathbb{R}} |\widehat{u}_1 + \widehat{u}_2|^2\widehat{\Theta}_{a,\delta}(\xi)\,d\xi. \end{aligned} \tag{2.11}$$

Note that

$$\int_{\mathbb{R}} |\widehat{u}_2|^2 \left(1 - \widehat{\Gamma}_\delta(\xi) - \frac{\delta}{2}\widehat{\Theta}_{\alpha,\delta}(\xi)\right) d\xi \tag{2.12}$$

is the stray field energy that corresponds to a symmetric double layer where $u_1 = -u_2$, and therefore it is nonnegative. Thus, given $(\mathbf{m}_1, \mathbf{m}_2)$, since all the terms in (2.11) are nonnegative, we can always lower the total energy by selecting $(\mathbf{m}_1, \widetilde{\mathbf{m}}_1)$ or $(\mathbf{m}_2, \widetilde{\mathbf{m}}_2)$. □

In view of this lemma, we need to consider only opposing Néel walls. Thus, we need to study functional

$$\begin{aligned}\widetilde{G}_{q,\alpha,\delta}[\mathbf{m}] = q\int_{\mathbb{R}} u^2\,dx + \int_{\mathbb{R}} |\mathbf{m}'|^2\,dx + \int_{\mathbb{R}} u^2\,dx - \int_{\mathbb{R}} u\,(\Gamma_\delta * u)\,dx \\ -\frac{\delta}{2}\int_{\mathbb{R}} u\,(u * \Theta_{\alpha,\delta})\,dx,\end{aligned} \tag{2.13}$$

which can be written in Fourier space as

$$\widetilde{G}_{q,\alpha,\delta}[\mathbf{m}] = q\int_{\mathbb{R}} |\widehat{u}|^2\,d\xi + \int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{\mathbf{m}}|^2\,d\xi + \int_{\mathbb{R}} |\widehat{u}|^2 \left(1 - \widehat{\Gamma}_\delta(\xi) - \frac{\delta}{2}\widehat{\Theta}_{\alpha,\delta}(\xi)\right) d\xi. \tag{2.14}$$

The lower semicontinuity and existence of minimizers of functional (2.13) follow from Lemmas 1, 2, and 3 in [7]. The main difficulty in establishing the existence of minimizers lies in the fact that functional (2.13) is translation invariant. This problem is resolved in [7] by considering a translation of $\mathbf{m}$ such that $\mathbf{m}(0) = (1, 0, 0)$. The result then follows from the Sobolev embedding and the Rellich compactness theorem [21].

As a consequence of Lemma 2.1,

$$\inf_{\mathbf{m}_1,\mathbf{m}_2\in\mathcal{A}} G_{q,\alpha,\delta}[\mathbf{m}_1, \mathbf{m}_2] = \inf_{\mathbf{m}\in\mathcal{A}} \widetilde{G}_{q,\alpha,\delta}[\mathbf{m}]. \tag{2.15}$$

Thus, the existence of minimizers for functional (2.7) is established. To simplify notation, in what follows we will drop the tilde from functional (2.13).

The matching upper bound that we need can be obtained by considering the test function $\mathbf{m} = (\operatorname{sech}(\sqrt{q}x), 0, \tanh(\sqrt{q}x))$, which is the Landau–Lifshitz wall. The Fourier transform of $u(x) = \operatorname{sech}(\sqrt{q}x)$ can be obtained by residues [2]:

$$\widehat{u}(\xi) = \frac{\pi}{\sqrt{q}}\operatorname{sech}\left(\frac{\pi^2\xi}{\sqrt{q}}\right). \tag{2.16}$$

The stray field energy of this profile is

$$\begin{aligned} E_s &= \int_{\mathbb{R}} \widehat{u}^2 \left(1 - \frac{1 - e^{-2\pi\delta|\xi|}}{2\pi\delta|\xi|} - \frac{1}{2}e^{-4\pi a|\xi|}\frac{(1 - e^{-2\pi\delta|\xi|})^2}{2\pi\delta|\xi|}\right) d\xi \\ &= \frac{\pi^2}{q}\int_{\mathbb{R}} \operatorname{sech}^2\left(\frac{\pi^2\xi}{\sqrt{q}}\right)\left(1 - \frac{1 - e^{-2\pi\delta|\xi|}}{2\pi\delta|\xi|} - \frac{1}{2}e^{-4\pi\alpha|\xi|}\frac{(1 - e^{-2\pi\delta|\xi|})^2}{2\pi\delta|\xi|}\right) d\xi \\ &= \frac{1}{\sqrt{q}}\int_{\mathbb{R}} \operatorname{sech}^2(\xi)\left(1 - \frac{1 - e^{-2\delta|\xi|\sqrt{q}/\pi}}{2\delta|\xi|\sqrt{q}/\pi} - \frac{1}{2}e^{-4\alpha|\xi|\sqrt{q}/\pi}\frac{(1 - e^{-2\delta|\xi|\sqrt{q}/\pi})^2}{2\delta|\xi|\sqrt{q}/\pi}\right) d\xi \\ &= \frac{4\delta\sqrt{q}}{\pi^2}\left(\frac{\delta}{3} + \alpha\right)\int_{\mathbb{R}} |\xi|^2\operatorname{sech}^2(\xi)\,d\xi + O(q) = \frac{2\delta\sqrt{q}}{3}\left(\frac{\delta}{3} + \alpha\right) + O(q). \end{aligned} \tag{2.17}$$

Therefore $\exists q_0 > 0$ such that

$$E_s \leq \frac{4\delta\sqrt{q}}{3}\left(\frac{\delta}{3}+\alpha\right) \quad \forall q \leq q_0. \tag{2.18}$$

The total energy is therefore

$$\widetilde{G}_{q,\alpha,\delta}[\mathbf{m}] = \left\{4+\frac{2\delta}{3}\left(\frac{\delta}{3}+\alpha\right)\right\}\sqrt{q}+O(q) \leq 4\left\{1+\frac{\delta}{3}\left(\frac{\delta}{3}+\alpha\right)\right\}\sqrt{q} \quad \forall q \leq q_0. \tag{2.19}$$

We collect all this in the following theorem.

THEOREM 2.2. *Consider the one-dimensional wall energy functional for a symmetric double layer* (1.8). *Given* $\alpha > 0$ *and* $\delta > 0$ *fixed,* $\exists\ q_0 > 0$ *such that*

$$4\sqrt{q} \leq \min_{\mathbf{m}_1,\mathbf{m}_2\in\mathcal{A}} G_{q,\alpha,\delta,\delta}[\mathbf{m}_1,\mathbf{m}_2] \leq 4\left\{1+\frac{\delta}{3}\left(\frac{\delta}{3}+\alpha\right)\right\}\sqrt{q} \quad \forall q \leq q_0. \tag{2.20}$$

An estimate of the value of q_0 is presented in Appendix B.

3. Néel walls: Limiting behavior. In this section we study the structure of Néel walls in symmetric double layers and obtain the limiting behavior of any sequence of minimizers of the Néel wall functional (2.13). This is the content of the following theorem.

THEOREM 3.1. *Given* $\alpha > 0$ *and* $\delta > 0$, *consider* $\{\mathbf{m}_q\}_{\{q>0\}} \subset \mathcal{A}_N = \{\mathbf{m} = (m_1, 0, m_3) \in \mathcal{A}\}$ *such that*

$$G_{q,\alpha,\delta}[\mathbf{m}_q] \leq C\sqrt{q}, \tag{3.1}$$

and define $\widetilde{\mathbf{m}}_q(x) = \mathbf{m}_q(\frac{x}{\sqrt{q}})$. *There exists a subsequence of* $\{\mathbf{m}_q\}_{\{q>0\}}$ *(not relabeled) such that the following two statements hold:*

(i)

$$\lim_{q\to 0}\frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{m}_q] = \min_{\mathbf{m}\in\mathcal{A}_N} F_{\alpha,\delta}[\mathbf{m}], \tag{3.2}$$

where

$$F_{\alpha,\delta}[\mathbf{m}] = \int_{\mathbb{R}} m_1^2\,dx + \left(1+\delta\left(\frac{1}{3}\delta+\alpha\right)\right)\int_{\mathbb{R}}(m_1')^2\,dx + \int_{\mathbb{R}}(m_3')^2\,dx. \tag{3.3}$$

(ii) *The subsequence converges strongly in* $\mathcal{A}_N$ *to* $\mathbf{n} \in \mathcal{A}_N$ *such that*

$$F_{\alpha,\delta}[\mathbf{n}] = \min_{\mathbf{m}\in\mathcal{A}_N} F_{\alpha,\delta}[\mathbf{m}]. \tag{3.4}$$

Proof. Given the sequence of minimizers, consider the new rescaled sequence $\widetilde{\mathbf{m}}_q(x) = \mathbf{m}_q(\frac{x}{\sqrt{q}})$. This sequence is bounded in the following sense:

$$\begin{aligned}\int_{\mathbb{R}}\widetilde{u}_q^2(x)\,dx + \int_{\mathbb{R}}|\widetilde{\mathbf{m}}_q'|^2\,dx &= \sqrt{q}\int_{\mathbb{R}}u_q^2(x)\,dx + \frac{1}{\sqrt{q}}\int_{\mathbb{R}}|\mathbf{m}_q'|^2\,dx \\ &\leq \frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{m}_q] \leq C.\end{aligned} \tag{3.5}$$

Thus there is a subsequence (not relabeled) that converges weakly in $\mathcal{A}_N$ to $\mathbf{n} \in \mathcal{A}_N$.

Consider now $\mathbf{n}_q(x) = \mathbf{n}(\sqrt{q}x)$. Then,

$$\widehat{\mathbf{n}}_q(\xi) = \frac{1}{\sqrt{q}}\widehat{\mathbf{n}}\left(\frac{\xi}{\sqrt{q}}\right) \tag{3.6}$$

and

$$\begin{aligned} G_{q,\alpha,\delta}[\mathbf{n}_q] &= \sqrt{q}\int_{\mathbb{R}} u^2(\xi)\,d\xi + \sqrt{q}\int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{\mathbf{n}}(\xi)|^2\,d\xi \\ &\quad + \frac{1}{\sqrt{q}}\int_{\mathbb{R}} \widehat{u}^2(\xi)\left(1 - \frac{1-e^{-2\pi\delta|\xi|\sqrt{q}}}{2\pi\delta|\xi|\sqrt{q}} - \frac{1}{2}e^{-4\pi a|\xi|\sqrt{q}}\frac{(1-e^{-2\pi\delta|\xi|\sqrt{q}})^2}{2\pi\delta|\xi|\sqrt{q}}\right)d\xi. \end{aligned} \tag{3.7}$$

We need to take the limit of the stray field energy. Since $\alpha\sqrt{q} \ll 1$ and $\delta\sqrt{q} \ll 1$,

$$\lim_{q\to 0}\frac{1}{q}\left(1 - \frac{1-e^{-2\pi\delta|\xi|\sqrt{q}}}{2\pi\delta|\xi|\sqrt{q}} - \frac{1}{2}e^{-4\pi a|\xi|\sqrt{q}}\frac{(1-e^{-2\pi\delta|\xi|\sqrt{q}})^2}{2\pi\delta|\xi|\sqrt{q}}\right) = \left(\frac{1}{3}\delta + a\right)4\pi^2|\xi|^2\delta. \tag{3.8}$$

The stray field energy can be written as

$$\frac{1}{\sqrt{q}}E_s = \delta\left(\frac{1}{3}\delta + a\right)\int_{\mathbb{R}} 4\pi^2\xi^2\widehat{u}^2(\xi)\widehat{\varphi}(\sqrt{q}\xi)\,d\xi, \tag{3.9}$$

where

$$\widehat{\varphi}(\xi) = \frac{1}{\left(\frac{1}{3}\delta + a\right)}\frac{1}{4\pi^2\xi^2}\left(1 - \frac{1-e^{-2\pi\delta|\xi|}}{2\pi\delta|\xi|} - \frac{1}{2}e^{-4\pi a|\xi|}\frac{(1-e^{-2\pi\delta|\xi|})^2}{2\pi\delta|\xi|}\right). \tag{3.10}$$

Note that $\widehat{\varphi}(0) = 1$ and $\widehat{\varphi} \in L^1(\mathbb{R}) \cap L^\infty(\mathbb{R})$, so $\varphi \in L^1(\mathbb{R}) \cap L^2(\mathbb{R})$. Therefore, the stray field can be written, in real space, as

$$\frac{1}{\sqrt{q}}E_s = \delta\left(\frac{1}{3}\delta + a\right)\int_{\mathbb{R}} u\left(u * \varphi_{\sqrt{q}}\right)dx, \tag{3.11}$$

where $\varphi_{\sqrt{q}}(x) = \frac{1}{\sqrt{q}}\phi(\frac{x}{\sqrt{q}})$, which is an approximation to the identity. Therefore we can take the limit in (3.7), and we obtain

$$\begin{aligned} \lim_{q\to 0}\frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{n}_q] &= \int_{\mathbb{R}}\widehat{u}^2(\xi)\,d\xi + \int_{\mathbb{R}} 4\pi^2\xi^2\left(1 + \delta\left(\frac{1}{3}\delta + a\right)\right)|\widehat{u}(\xi)|^2\,d\xi \\ + \frac{1}{2}\int_{\mathbb{R}} 4\pi^2\xi^2|\widehat{w}(\xi)|^2\,d\xi &= \int_{\mathbb{R}} u^2\,dx + \left(1 + \delta\left(\frac{1}{3}\delta + a\right)\right)\int_{\mathbb{R}}(u')^2\,dx + \int_{\mathbb{R}}(w')^2\,dx \\ &= F_{\alpha,\delta}[\mathbf{n}]. \end{aligned} \tag{3.12}$$

Since $\mathbf{m}_q$ was a minimizer,

$$\frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{m}_q] \le \frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{n}_q], \tag{3.13}$$

and thus

$$\limsup_{q\to 0}\frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{m}_q] \le \lim_{q\to 0}\frac{1}{\sqrt{q}}G_{q,\alpha,\delta}[\mathbf{n}_q] = F_{\alpha,\delta}[\mathbf{n}]. \tag{3.14}$$

Observe now that

$$\frac{1}{\sqrt{q}} G_{q,\alpha,\delta}[\mathbf{m}_q] = H_{q,\alpha,\delta}[\widetilde{\mathbf{m}}_q], \tag{3.15}$$

where

$$H_{q,\alpha,\delta}[\mathbf{m}] = \int_{\mathbb{R}} u^2\,dx + \int_{\mathbb{R}} |\mathbf{m}'|^2\,dx + \delta\left(\frac{1}{3}\delta + \alpha\right)\int_{\mathbb{R}} u\left(u * \varphi_{\sqrt{q}}\right)dx. \tag{3.16}$$

Since $\widetilde{\mathbf{m}}_q$ converges to $\mathbf{n}$ weakly in $\mathcal{A}_N$, by the lower semicontinuity of the functional,

$$F_{\alpha,\delta}[\mathbf{n}] \le \liminf_{q\to 0} \frac{1}{\sqrt{q}} G_{q,\alpha,\delta}[\mathbf{m}_q]. \tag{3.17}$$

Combining (3.14) and (3.17), we conclude that

$$\lim_{q\to 0} \frac{1}{\sqrt{q}} G_{q,\alpha,\delta}[\mathbf{m}_q] = F_{\alpha,\delta}[\mathbf{n}]. \tag{3.18}$$

It is easy to see that $\mathbf{n}$ must be a minimizer of $F_{\alpha,\delta}$: Given any $\mathbf{m}_0 \in \mathcal{A}$, consider $\widetilde{\mathbf{n}}_q(x) = \mathbf{m}_0\left(\sqrt{q}x\right)$. Then

$$F_{\alpha,\delta}[\mathbf{m}_0] = \lim_{q\to 0} \frac{1}{\sqrt{q}} G_{q,\alpha,\delta}[\widetilde{\mathbf{n}}_q] \ge \lim_{q\to 0} \frac{1}{\sqrt{q}} G_{q,\alpha,\delta}[\mathbf{m}_q] = F_{\alpha,\delta}[\mathbf{n}]. \tag{3.19}$$

This proves (i). Since the sequence $\mathbf{n}_q$ converges weakly to $\mathbf{n}$ and the energies converge, the limit is strong, which proves (ii). □

From the previous proof, it is easy to see that $H_{q,\alpha,\delta} \to F_{\alpha,\delta}$ in $\mathcal{A}_N$ as $q \to 0$, in the Γ-limit sense [13].

4. Asymptotic analysis of the limiting profile. We perform a formal asymptotic expansion of the minimizers of functional $F_{\alpha,\delta}$, defined in (3.3), for $\delta \ll 1$. Since $|\mathbf{m}| = 1$, it is customary to write $\mathbf{m} = (\cos\theta, 0, \sin\theta)$, where $\theta \to \pm\frac{\pi}{2}$ as $x \to \pm\infty$. We consider the functional

$$F_\beta[\mathbf{m}] = \int_{\mathbb{R}} m_1^2\,dx + (1+\beta)\int_{\mathbb{R}} (m_1')^2\,dx + \int_{\mathbb{R}} (m_3')^2\,dx, \tag{4.1}$$

where $\beta = \delta(3\alpha + \delta)/3 \ll 1$. We do the change of variables to θ, and get

$$F_\beta[\theta] = \int_{\mathbb{R}} \cos^2\theta\,dx + \int_{\mathbb{R}} (\theta')^2\,dx + \beta\int_{\mathbb{R}} (\theta')^2\sin^2\theta\,dx. \tag{4.2}$$

The Euler–Lagrange equation is

$$(1+\beta\sin^2\theta)\theta'' + (1+\beta(\theta')^2)\sin\theta\cos\theta = 0. \tag{4.3}$$

For $\beta = 0$, we get

$$\theta'' + \sin\theta\cos\theta = 0, \tag{4.4}$$

which has as solution $\cos\theta = \tanh x$. This is the Landau–Lifshitz profile [12]. The asymptotic analysis can be carried out more easily if we consider profiles of the form

$\mathbf{m} = (\operatorname{sech}\varphi, 0, \tanh\varphi)$ instead, and write the equation for φ. Since $\cos\theta = \operatorname{sech}\varphi$ and $\sin\theta = \tanh\varphi$, we get $\theta' = \varphi'\operatorname{sech}\varphi$ and

$$\theta'' = \operatorname{sech}\varphi\left(\varphi'' - (\varphi')^2\tanh\varphi\right). \tag{4.5}$$

The equation becomes then

$$\left(1+\beta\tanh^2\varphi\right)\left(\varphi'' - (\varphi')^2\tanh\varphi\right) + \left(1+\beta(\varphi')^2\operatorname{sech}^2\varphi\right)\tanh\varphi = 0. \tag{4.6}$$

Assume that $\varphi \sim \varphi_0 + \beta\varphi_1 + O(\beta^2)$. Then,

$$\begin{aligned}\left(1+\beta\tanh^2(\varphi_0+\beta\varphi_1)\right)&\left(\varphi_0'' + \beta\varphi_1'' - (\varphi_0'+\beta\varphi_1')^2\tanh(\varphi_0+\beta\varphi_1)\right)\\ &+\left(1+\beta(\varphi_0'+\beta\varphi_1')^2\operatorname{sech}^2(\varphi_0+\beta\varphi_1)\right)\tanh(\varphi_0+\beta\varphi_1) = 0.\end{aligned} \tag{4.7}$$

Collecting terms, we get

$$\varphi_0'' + (1-(\varphi_0')^2)\tanh\varphi_0 = 0. \tag{4.8}$$

The solution is $\varphi_0 = x$. The next term in (4.7) is

$$\begin{aligned}\varphi_1'' - 2\varphi_1'\varphi_0'\tanh\varphi_0 - (\varphi_0')^2\operatorname{sech}^2\varphi_0\varphi_1 + \tanh^2(\varphi_0)&\left(\varphi_0'' - (\varphi_0')^2\tanh\varphi_0\right)\\ +(\varphi_0')^2\operatorname{sech}^2\varphi_0\tanh\varphi_0 + \operatorname{sech}^2\varphi_0\varphi_1 &= 0.\end{aligned} \tag{4.9}$$

Since $\varphi_0 = x$ and $\varphi_0' = 1$, the equation simplifies to

$$\varphi_1'' - 2\varphi_1'\tanh x - \tanh^3 x + \operatorname{sech}^2 x\tanh x = 0. \tag{4.10}$$

Then

$$\left(\frac{\varphi_1'}{\cosh^2 x}\right)' = \frac{\varphi_1'' - 2\varphi_1'\tanh x}{\cosh^2 x} = \operatorname{sech}^2 x\tanh^3 x - \operatorname{sech}^4 x\tanh x. \tag{4.11}$$

We can integrate the right-hand side:

$$\begin{aligned}\int \operatorname{sech}^2 x\tanh^3 x\,dx &= \int \frac{\sinh x\left(\cosh^2 x - 1\right)}{\cosh^5 x}\,dx = \frac{1}{4}\frac{1}{\cosh^4 x} - \frac{1}{2}\frac{1}{\cosh^2 x},\\ \int \operatorname{sech}^4 x\tanh x\,dx &= \int \frac{\sinh x}{\cosh^5 x}\,dx = -\frac{1}{4}\frac{1}{\cosh^4 x}.\end{aligned} \tag{4.12}$$

Therefore,

$$\varphi_1' = C\cosh^2 x + \frac{1}{2}\frac{1}{\cosh^2 x} - \frac{1}{2} \tag{4.13}$$

and, integrating,

$$\varphi_1 = C\frac{\sinh 2x + 2x}{4} + \frac{1}{2}\tanh x - \frac{x}{2} + D. \tag{4.14}$$

We want φ to be odd, so $D = 0$. Unless $C = 0$, φ_1 will dominate over φ_0, so we take $C = 0$, and finally,

$$\varphi_1 = \frac{1}{2}\tanh x - \frac{x}{2}. \tag{4.15}$$

Therefore,

$$\mathbf{m} = \left(\operatorname{sech}\left(x + \frac{\beta}{2}\left(\tanh x - x\right)\right), 0, \tanh\left(x + \frac{\beta}{2}\left(\tanh x - x\right)\right)\right) + O(\beta^2). \tag{4.16}$$

5. Numerical experiments. We have implemented a truncated Newton method with an inexact line search for the minimization of

$$\begin{aligned} G_{q,\alpha,\delta}[\mathbf{m}_1,\mathbf{m}_2] &= \frac{1}{2}q\int_{\mathbb{R}} u_1^2\,dx + \frac{1}{2}\int_{\mathbb{R}} |\mathbf{m}_1'|^2\,dx + \frac{1}{2}\int_{\mathbb{R}} u_1^2\,dx - \frac{1}{2}\int_{\mathbb{R}} u_1\,(\Gamma_\delta * u_1)\,dx \\ &\quad + \frac{1}{2}q\int_{\mathbb{R}} u_2^2\,dx + \frac{1}{2}\int_{\mathbb{R}} |\mathbf{m}_2'|^2\,dx + \frac{1}{2}\int_{\mathbb{R}} u_2^2\,dx - \frac{1}{2}\int_{\mathbb{R}} u_2\,(\Gamma_\delta * u_2)\,dx \\ &\quad - \frac{\delta}{2}\int_{\mathbb{R}} u_1\,(u_2 * \Theta_{\alpha,\delta})\,dx. \end{aligned} \tag{5.1}$$

The method is well known, and the details can be found in the literature [15], so we will simply describe some of the details particular to our implementation.

We consider a finite interval $I = [-M, M]$, and restrict the functional to I. We have performed simulations in several intervals of increasing size until no change was found in the characteristics of the wall. For the results presented here we used $I = [-200, 200]$. We define the grid points $x_i = -M + i\Delta x$, for $i = 0, 1, \ldots, n+1$, where $\Delta x = \frac{2M}{n+1}$. The magnetization is approximated by a linear interpolant in the subinterval $I_i = [x_i, x_{i+1}]$, for $i = 0, 1, \ldots, n$. We impose the boundary conditions $u_0 = u_{n+1} = 0$. For the simulations presented here we fixed the parameters $\delta = 1$ and $a = 10^{-1}$. The parameter q varied in the range $q \in [10^{-3}, 1]$.

To evaluate the stray field, we need to approximate convolution integrals of the form

$$v(x_j) = \int_{-M}^{M} u(s)K(x_j - s)\,ds. \tag{5.2}$$

Substituting the piecewise linear interpolant,

$$v(x_j) \approx \sum_{i=0}^{n} \int_{x_i}^{x_{i+1}} \left(u_i + \frac{u_{i+1} - u_i}{\Delta x}(s - x_i)\right) K(x_j - s)\,ds. \tag{5.3}$$

Grouping terms,

$$v_j = \sum_{i=1}^{n} u_i \left[\int_{x_i}^{x_{i+1}} \left(1 - \frac{(s - x_i)}{\Delta x}\right) K(x_j - s)\,ds + \int_{x_{i-1}}^{x_i} \frac{(s - x_{i-1})}{\Delta x} K(x_j - s)\,ds\right]. \tag{5.4}$$

This can be written in the form

$$v_j = \sum_{i=1}^{n} K_{j-i} u_i, \tag{5.5}$$

where

$$K_\lambda = \Delta x \int_0^1 (1-t)\,K\left(\Delta x(\lambda - t)\right) + tK\left(\Delta x(\lambda + 1 - t)\right)\,dt. \tag{5.6}$$

The sum (5.5) has the shape of a discrete convolution, and it can therefore be efficiently evaluated using the fast Fourier transform (FFT) in $O(n \log n)$ operations.

The unit length constraint in the magnetization is taken into account by considering a line search on the function

$$h(\epsilon) = G_{q,\alpha,\delta}\left[\frac{\mathbf{m}_1 + \epsilon\mathbf{p}_1}{|\mathbf{m}_1 + \epsilon\mathbf{p}_1|}, \frac{\mathbf{m}_2 + \epsilon\mathbf{p}_2}{|\mathbf{m}_2 + \epsilon\mathbf{p}_2|}\right], \tag{5.7}$$

where $(\mathbf{p}_1, \mathbf{p}_2)$ is a descent direction, i.e., $h'(0) < 0$.

In Figure 2 we show the profiles of several minimizers as a function of q. All the numerically computed minimizers were opposed Néel walls, consistent with Lemma 2.1. These same profiles are presented in Figure 3, but this time the abscissa is rescaled by $\sqrt{q}$. As can be seen, all the plots collapse into one, illustrating that the core length is $1/\sqrt{q}$, as proved in section 4. This limiting profile is plotted in Figure 4, where it is compared to the profile of the minimizer of (5.1) computed numerically. The profiles are almost indistinguishable.

The computed values for the minimum energy as a function of q are presented in Table 1. From the results in the third column it is clear that the energy scales like $\sqrt{q}$. We plot the results in a logarithmic scale in Figure 5. The energy of the asymptotic approximation (4.16) was computed to machine precision using adaptive Gaussian quadrature. The computed energy coincides to a remarkable degree with the energy obtained using the asymptotic analysis described in the previous section.

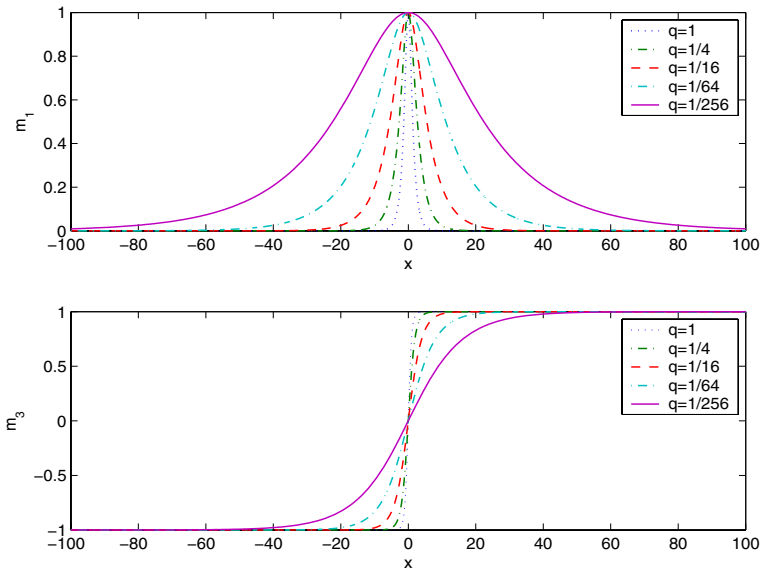

FIG. 2. *Néel wall profiles for several values of q.*

6. Conclusion. We have presented a new model for the analysis of one-dimensional walls in double layers. Using this new model, we have studied the structure of Néel walls and obtained the core length of the wall, the optimal energy scaling, and the structure of the minimizers. The main observation is that in a symmetric double layer the Néel wall no longer has a long logarithmic tail. The wall profile becomes local and similar to the classic Landau–Lifshitz wall. Thus, the range of nonlocal interactions is considerably reduced. We have implemented a truncated Newton method for energy minimization, and illustrated all the results numerically. In our simulations

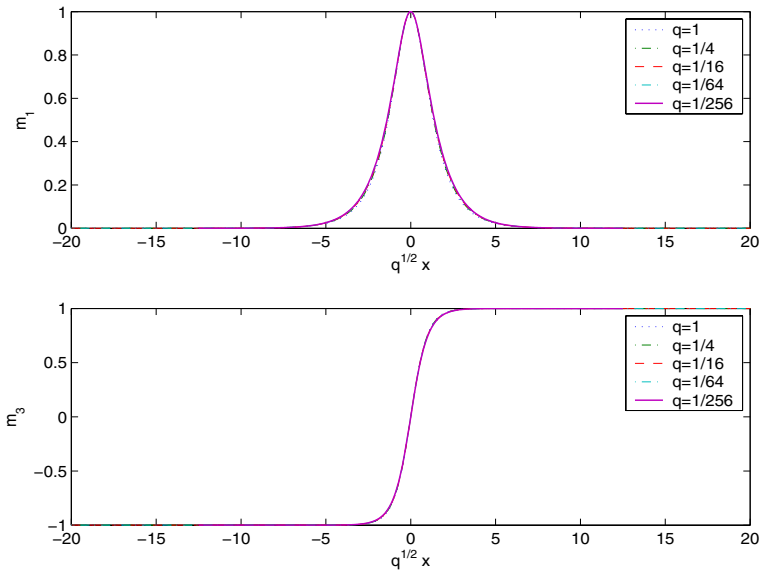

FIG. 3. *Néel wall profiles for several values of q. The abscissa has been rescaled to illustrate that the core length scales like $\sqrt{q}$.*

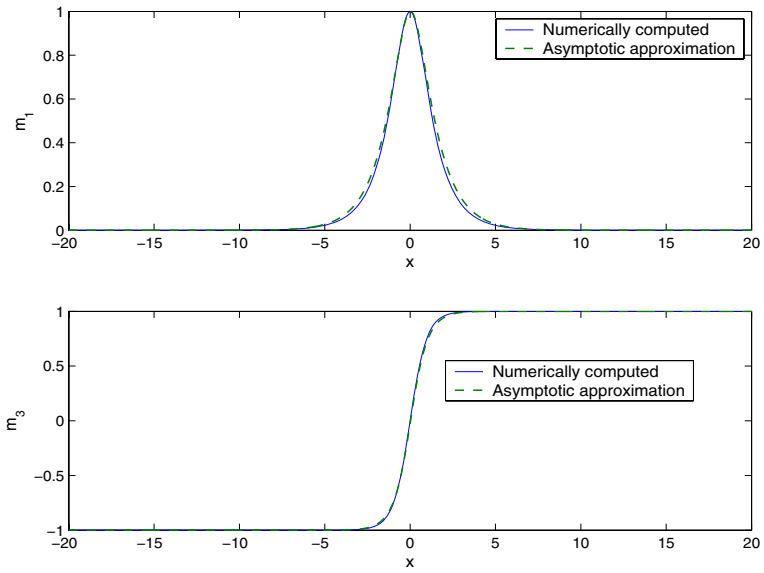

FIG. 4. *Comparison between the computed limiting profile and the asymptotic approximation obtained in section* 2.

we have managed to accurately capture the energy scaling, the core length, and the structure of the wall.

Appendix A. One-dimensional model for double layers. In this section we derive the model used in this article, starting from the Landau–Lifshitz energy functional.

TABLE 1

Minimum energy as a function of q. The energy is computed with the energy minimization algorithm described in section 5, and the energy scaling in q is obtained. We fixed the parameters $\delta = 1$ and $a = 10^{-1}$.

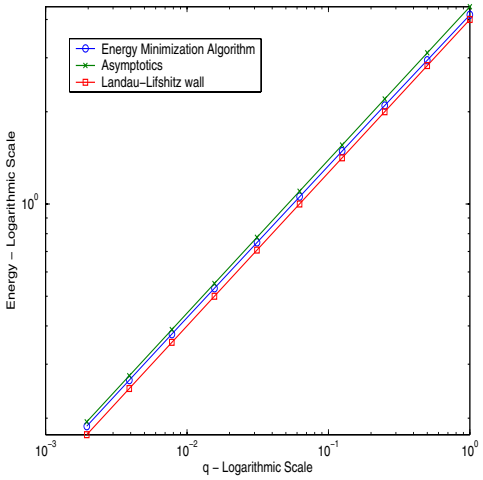

FIG. 5. *Comparison between the numerically computed energy, the optimal energy obtained in section 2, and the energy of the Landau–Lifshitz wall. The asymptotics give us an upper bound, while the Landau–Lifshitz wall provides us with a lower bound.*

We consider a double layer, infinite in both the x and y directions, and solve the magnetostatic equation in two dimensions. The stray field is $\mathbf{h}_s(x,z) = -\nabla\eta$, where

$$\eta = \nabla N * \mathbf{m} \tag{A.1}$$

is the magnetostatic potential, and $N(\mathbf{x}) = \frac{1}{2\pi}\log(|\mathbf{x}|)$, $\mathbf{x} = (x,z) \in \mathbb{R}^2$.

For the study on one-dimensional walls, we assume that $\mathbf{m}$ depends only on x. The double layer will be identified with the domain $\Omega = \mathbb{R}\times[-a-D_1,-a]\cup[a,a+D_2]$. In the bottom layer, we have $\mathbf{m} = (u_1, v_1, w_1)$, and in the top layer, $\mathbf{m} = (u_2, v_2, w_2)$.

Then,

$$\eta(x,z) = \int_\Omega \partial_x N(x-s,z-t)u(s)\,ds + \int_\Omega \partial_z N(x-s,z-t)v(s)\,ds \tag{A.2}$$
$$= \int_\Omega \partial_x N(x-s,z-t)u(s)\,ds + \int_{\mathbb{R}} \left(N(x-s,z+a+D_1) - N(x-s,z+a)\right) v_1(s)\,ds$$
$$+ \int_{\mathbb{R}} \left(N(x-s,z-a) - N(x-s,z-a-D_2)\right) v_2(s)\,ds.$$

The stray field energy is

$$\frac{2}{\mu_0 M_s^2} E = \int_\Omega \nabla\eta\cdot\mathbf{m}\,dx\,dz = \int_\Omega u\partial_x\eta + v\partial_z\eta\,dx\,dz \tag{A.3}$$
$$= \int_{\mathbb{R}} u_1(x) \int_{-a-D_1}^{-a} \partial_x\eta(x,z)\,dz\,dx + \int_{\mathbb{R}} u_2(x) \int_a^{a+D_2} \partial_x\eta(x,z)\,dz\,dx$$
$$+ \int_{\mathbb{R}} v_1(x)\left(\eta(x,-a) - \eta(x,-a-D_1)\right)dx + \int_{\mathbb{R}} v_2(x)\left(\eta(x,a+D_2) - \eta(x,a)\right)dx.$$

We can easily compute the derivative of η w.r.t. x:

$$\partial_x\eta(x,z) = \int_\Omega \partial_{xx} N(x-s,z-t)u(s)\,ds \tag{A.4}$$
$$+ \int_{\mathbb{R}} \left(\partial_x N(x-s,z+a+D_1) - \partial_x N(x-s,z+a)\right) v_1(s)\,ds$$
$$+ \int_{\mathbb{R}} \left(\partial_x N(x-s,z-a) - \partial_x N(x-s,z-a-D_2)\right) v_2(s)\,ds.$$

Since $\Delta N = \delta$, we get that $\partial_{xx}N(x-s,z-t) = \delta_{(x,z)} - \partial_{zz}N(x-s,z-t)$. Substituting this,

$$\partial_x\eta(x,z) = u(x) - \int_\Omega \partial_{zz} N(x-s,z-t)u(s)\,ds$$
$$+ \int_{\mathbb{R}} \left(\partial_x N(x-s,z+a+D_1) - \partial_x N(x-s,z+a)\right) v_1(s)\,ds \tag{A.5}$$
$$+ \int_{\mathbb{R}} \left(\partial_x N(x-s,z-a) - \partial_x N(x-s,z-a-D_2)\right) v_2(s)\,ds$$
$$= u(x) - \int_{\mathbb{R}} \left(\partial_z N(x-s,z+a+D_1) - \partial_z N(x-s,z+a)\right) u_1(s)\,ds$$
$$- \int_{\mathbb{R}} \left(\partial_z N(x-s,z-a) - \partial_z N(x-s,z-a-D_2)\right) u_2(s)\,ds$$
$$+ \int_{\mathbb{R}} \left(\partial_x N(x-s,z+a+D_1) - \partial_x N(x-s,z+a)\right) v_1(s)\,ds$$
$$+ \int_{\mathbb{R}} \left(\partial_x N(x-s,z-a) - \partial_x N(x-s,z-a-D_2)\right) v_2(s)\,ds.$$

Now we compute the energy step by step:

(A.6)
$$\int_{\mathbb{R}} u_1(x) \int_{-a-D_1}^{-a} \partial_x \eta(x,z)\,dz\,dx = D_1 \int_{\mathbb{R}} u_1^2(x)\,dx - \int_{\mathbb{R}} u_1(x) \int_{\mathbb{R}} u_1(s)(N(x-s,D_1)$$
$$-2N(x-s,0)+N(x-s,-D_1))ds\,dx$$
$$-\int_{\mathbb{R}} u_1(x) \int_{\mathbb{R}} u_2(s)\big(N(x-s,-2a)-N(x-s,-2a-D_1)$$
$$-N(x-s,-2a-D_2)+N(x-s,-2a-D_1-D_2)\big)ds\,dx$$
$$+\frac{1}{2\pi}\int_{\mathbb{R}} u_1(x) \int_{\mathbb{R}} v_2(s)\bigg(\arctan\left(\frac{2a+D_1}{x-s}\right)-\arctan\left(\frac{2a}{x-s}\right)$$
$$-\arctan\left(\frac{2a+D_1+D_2}{x-s}\right)+\arctan\left(\frac{2a+D_2}{x-s}\right)\bigg)ds\,dx$$
$$= D_1\int_{\mathbb{R}} u_1^2\,dx - D_1\int_{\mathbb{R}} u_1\,(u_1 * \Gamma_{D_1})\,dx + \frac{D_1D_2}{2}\int_{\mathbb{R}} u_1\,(u_2 * \Theta_{a,D_1,D_2})\,dx$$
$$+\frac{D_1D_2}{2}\int_{\mathbb{R}} u_1\,(v_2 * \Psi_{a,D_1,D_2})\,dx,$$

where we have defined

(A.7)
$$\Gamma_{D_i}(x) = \frac{1}{2\pi D_i}\log\left(1+\frac{D_i^2}{x^2}\right), \quad i=1,2,$$
$$\Theta_{a,D_1,D_2}(x) = \frac{1}{2D_1D_2\pi}\left(\log\left(\frac{x^2+(2a+D_1)^2}{x^2+(2a+D_1+D_2)^2}\right)-\log\left(\frac{x^2+4a^2}{x^2+(2a+D_2)^2}\right)\right),$$
$$\Psi_{a,D_1,D_2}(x) = \frac{1}{D_1D_2\pi}\bigg(\arctan\left(\frac{2a+D_1}{x-s}\right)-\arctan\left(\frac{2a}{x-s}\right)$$
(A.8)
$$-\arctan\left(\frac{2a+D_1+D_2}{x-s}\right)+\arctan\left(\frac{2a+D_2}{x-s}\right)\bigg),$$

(A.9)
$$\int_{\mathbb{R}} u_2(x) \int_a^{a+D_2} \partial_x \eta(x,z)\,dz\,dx = D_2\int_{\mathbb{R}} u_2^2\,dx - D_2\int_{\mathbb{R}} u_2\,(u_2 * \Gamma_{D_2})\,dx$$
$$+\frac{D_1D_2}{2}\int_{\mathbb{R}} u_2\,(u_1 * \Theta_{a,D_1,D_2})\,dx - \frac{D_1D_2}{2}\int_{\mathbb{R}} u_2\,(v_1 * \Psi_{a,D_1,D_2})\,dx.$$

Now

$$\begin{aligned}
&\eta(x,-a)-\eta(x,-a-D_1)\\
&\quad=\int_{\mathbb{R}} u_1(s)\int_{-a-D_1}^{-a}\left(\partial_x N(x-s,-a-t)-\partial_x N(x-s,-a-D_1-t)\right)dt\,ds\\
&\qquad+\int_{\mathbb{R}} u_2(s)\int_{a}^{a+D_2}\left(\partial_x N(x-s,-a-t)-\partial_x N(x-s,-a-D_1-t)\right)dt\,ds\\
&\qquad+\int_{\mathbb{R}}\left(N(x-s,D_1)-2N(x-s,0)+N(x-s,-D_1)\right)v_1(s)\,ds\\
&\qquad+\int_{\mathbb{R}}\big(N(x-s,-2a)-N(x-s,-2a-D_2)\\
&\qquad\qquad-N(x-s,-2a-D_1)+N(x-s,-2a-D_1-D_2)\big)v_2(s)\,ds\\
&\quad=\frac{D_1D_2}{2}u_2*\Psi_{a,D_1,D_2}+D_1v_1*\Gamma_{D_1}-\frac{D_1D_2}{2}v_2*\Theta_{a,D_1,D_2}
\end{aligned}\tag{A.10}$$

and

$$\begin{aligned}
&\eta(x,a+D_2)-\eta(x,a)\\
&\quad=\int_{\mathbb{R}} u_2(s)\int_{a}^{a+D_2}\left(\partial_x N(x-s,a+D_2-t)-\partial_x N(x-s,a-t)\right)dt\,ds\\
&\qquad+\int_{\mathbb{R}} u_1(s)\int_{-a-D_1}^{-a}\left(\partial_x N(x-s,a+D_2-t)-\partial_x N(x-s,a-t)\right)dt\,ds\\
&\qquad+\int_{\mathbb{R}}\big(N(x-s,2a+D_1+D_2)-N(x-s,2a+D_2)\\
&\qquad\qquad-N(x-s,2a+D_1)+N(x-s,2a)\big)v_1(s)\,ds\\
&\qquad+\int_{\mathbb{R}}\big(N(x-s,D_2)-2N(x-s,0)+N(x-s,-D_2)\big)v_2(s)\,ds\\
&\quad=-\frac{D_1D_2}{2}u_1*\Psi_{a,D_1,D_2}-\frac{D_1D_2}{2}v_1*\Theta_{a,D_1,D_2}+D_2v_2*\Gamma_{D_2}.
\end{aligned}\tag{A.11}$$

Assembling all this, we get the stray field energy:

$$\begin{aligned}
\frac{2}{\mu_0 M_s^2}E_s&=D_1\int_{\mathbb{R}}u_1^2\,dx-D_1\int_{\mathbb{R}}u_1\left(u_1*\Gamma_{D_1}\right)dx+D_1\int_{\mathbb{R}}v_1\left(v_1*\Gamma_{D_1}\right)dx\\
&\quad+D_2\int_{\mathbb{R}}u_2^2\,dx-D_2\int_{\mathbb{R}}u_2\left(u_2*\Gamma_{D_2}\right)dx+D_2\int_{\mathbb{R}}v_2\left(v_2*\Gamma_{D_2}\right)dx\\
&\quad+D_1D_2\int_{\mathbb{R}}u_1\left(u_2*\Theta_{a,D_1,D_2}\right)-v_1\left(v_2*\Theta_{a,D_1,D_2}\right)dx\\
&\quad+D_1D_2\int_{\mathbb{R}}u_1\left(v_2*\Psi_{a,D_1,D_2}\right)-v_1\left(u_2*\Psi_{a,D_1,D_2}\right)dx.
\end{aligned}\tag{A.12}$$

In order to write this in Fourier space, we need the Fourier transform of the convolution kernels. We start with the following:

$$\begin{aligned}\int_{\mathbb{R}} \log\left(\frac{x^2+\alpha^2}{x^2+\beta^2}\right) e^{-2\pi i\xi x}\,dx &= \int_{\mathbb{R}} \log\left(1+\frac{\alpha^2-\beta^2}{x^2+\beta^2}\right) e^{-2\pi i\xi x}\,dx \\ &= \frac{\beta^2-\alpha^2}{2\pi i\xi}\int_{\mathbb{R}} \frac{1}{1+\frac{\alpha^2-\beta^2}{x^2+\beta^2}}\frac{2x}{(x^2+\beta^2)^2} e^{-2\pi i\xi x}\,dx \\ &= \frac{\beta^2-\alpha^2}{2\pi i\xi}\int_{\mathbb{R}} \frac{2x}{(x^2+\alpha^2)(x^2+\beta^2)} e^{-2\pi i\xi x}\,dx.\end{aligned} \tag{A.13}$$

Using residue theory, we get that

$$\begin{aligned}\int_{\mathbb{R}} \frac{2x}{(x^2+\alpha^2)(x^2+\beta^2)} e^{-2\pi i\xi x}\,dx &= 2\pi i(\text{Res }(f,i\alpha)+\text{Res }(f,i\beta)) \\ &= 2\pi i\left(\frac{2i\beta}{2i\beta(\alpha^2-\beta^2)}e^{2\pi\beta\xi}+\frac{2i\alpha}{2i\alpha(\beta^2-\alpha^2)}e^{2\pi\alpha\xi}\right)\end{aligned} \tag{A.14}$$

for $\xi<0$. When we put it all together, we get

$$\int_{\mathbb{R}} \log\left(\frac{x^2+\alpha^2}{x^2+\beta^2}\right) e^{-2\pi i\xi x}\,dx = \frac{e^{-2\pi\beta|\xi|}-e^{-2\pi\alpha|\xi|}}{|\xi|}. \tag{A.15}$$

Therefore

$$\frac{1}{2\pi}\int_{\mathbb{R}} \log\left(1+\frac{D_j^2}{x^2}\right) e^{-2\pi i\xi x}\,dx = \frac{1-e^{-2\pi D_j|\xi|}}{2\pi|\xi|}, \quad j=1,2, \tag{A.16}$$

and

$$\begin{aligned}\frac{1}{2\pi}\int_{\mathbb{R}} \left(\log\left(\frac{x^2+4a^2}{x^2+(2a+D_2)^2}\right)-\log\left(\frac{x^2+(2a+D_1)^2}{x^2+(2a+D_1+D_2)^2}\right)\right) e^{-2\pi i\xi x}\,dx \\ = -e^{-4\pi a|\xi|}\frac{(1-e^{-2\pi D_1|\xi|})(1-e^{-2\pi D_2|\xi|})}{2\pi|\xi|}.\end{aligned} \tag{A.17}$$

Finally,

$$\begin{aligned}&\frac{1}{\pi}\int_{\mathbb{R}} e^{-2\pi i\xi x}\arctan\left(\frac{\alpha}{x}\right)dx = -\frac{2i}{\pi}\int_0^\infty \sin(2\pi\xi x)\arctan\left(\frac{\alpha}{x}\right)dx \\ &\quad = -\frac{2i}{\pi}\left(-\frac{1}{2\pi\xi}\cos(2\pi\xi x)\arctan\left(\frac{\alpha}{x}\right)\Big|_0^\infty - \frac{\alpha}{2\pi\xi}\int_0^\infty \cos(2\pi\xi x)\frac{1}{\alpha^2+x^2}\,dx\right) \\ &\quad = -i\frac{1-e^{-2\pi|\xi|\alpha}}{2\pi\xi}.\end{aligned} \tag{A.18}$$

Therefore

$$\begin{aligned}&\frac{1}{\pi}\int_{\mathbb{R}} e^{-2\pi i\xi x}\Big(\arctan\left(\frac{2a+D_1}{x}\right)-\arctan\left(\frac{2a}{x}\right) \\ &\qquad -\arctan\left(\frac{2a+D_1+D_2}{x}\right)+\arctan\left(\frac{2a+D_2}{x}\right)\Big)dx \\ &\quad = -ie^{-4\pi a|\xi|}\frac{(1-e^{-2\pi|\xi|D_1})(1-e^{-2\pi|\xi|D_2})}{2\pi\xi}.\end{aligned} \tag{A.19}$$

Thus, the stray field energy can be written in Fourier space as

(A.20)
$$\begin{aligned}\frac{2}{\mu_0 M_s^2}E_s &= D_1\int_{\mathbb{R}}\widehat{u_1}^2(\xi)\left(1-\frac{1-e^{-2\pi D_1|\xi|}}{2\pi D_1|\xi|}\right)d\xi + D_1\int_{\mathbb{R}}\widehat{v_1}^2(\xi)\frac{1-e^{-2\pi D_1|\xi|}}{2\pi D_1|\xi|}\,d\xi\\ &+ D_2\int_{\mathbb{R}}\widehat{u_2}^2(\xi)\left(1-\frac{1-e^{-2\pi D_2|\xi|}}{2\pi D_2|\xi|}\right)d\xi + D_2\int_{\mathbb{R}}\widehat{v_2}^2(\xi)\frac{1-e^{-2\pi D_2|\xi|}}{2\pi D_2|\xi|}\,d\xi\\ &+ \int_{\mathbb{R}}(\widehat{u_1}(\xi)\overline{\widehat{u_2}}(\xi)-\widehat{v_1}(\xi)\overline{\widehat{v_2}}(\xi))e^{-4\pi a|\xi|}\frac{(1-e^{-2\pi D_1|\xi|})(1-e^{-2\pi D_2|\xi|})}{2\pi|\xi|}\,d\xi\\ &- i\int_{\mathbb{R}}\Big(\widehat{v_1}(\xi)\overline{\widehat{u_2}}(\xi)-\widehat{u_1}(\xi)\overline{\widehat{v_2}}(\xi)\Big)e^{-4a\pi|\xi|}\frac{(1-e^{-2\pi D_1|\xi|})(1-e^{-2\pi D_2|\xi|})}{2\pi\xi}\,d\xi.\end{aligned}$$

Note that the interaction between the layers decays exponentially with the spacer distance.

In this one-dimensional setting, the Landau–Lifshitz energy for a double layer reduces to

(A.21)
$$\begin{aligned}F[\mathbf{m}_1,\mathbf{m}_2] &= \frac{K_u D_1}{2}\int_{\mathbb{R}}\left(u_1^2+v_1^2\right)dx + \frac{AD_1}{2}\int_{\mathbb{R}}|\mathbf{m}_1'|^2\,dx\\ &+ \frac{D_1\mu_0 M_s^2}{2}\int_{\mathbb{R}}u_1^2\,dx - \frac{D_1\mu_0 M_s^2}{2}\int_{\mathbb{R}}u_1\left(\Gamma_{D_1}*u_1\right)dx + \frac{D_1\mu_0 M_s^2}{2}\int_{\mathbb{R}}v_1\left(\Gamma_{D_1}*v_1\right)dx\\ &+ \frac{K_u D_2}{2}\int_{\mathbb{R}}\left(u_2^2+v_2^2\right)dx + \frac{AD_2}{2}\int_{\mathbb{R}}|\mathbf{m}_2'|^2\,dx\\ &+ \frac{D_2\mu_0 M_s^2}{2}\int_{\mathbb{R}}u_2^2\,dx - \frac{D_2\mu_0 M_s^2}{2}\int_{\mathbb{R}}u_2\left(\Gamma_{D_2}*u_2\right)dx + \frac{D_2\mu_0 M_s^2}{2}\int_{\mathbb{R}}v_2\left(\Gamma_{D_2}*v_2\right)dx\\ &+ \frac{D_1 D_2\mu_0 M_s^2}{2}\int_{\mathbb{R}}u_1\left(u_2*\Theta_{a,D_1,D_2}\right)-v_1\left(v_2*\Theta_{a,D_1,D_2}\right)dx\\ &+ \frac{D_1 D_2\mu_0 M_s^2}{2}\int_{\mathbb{R}}v_1\left(u_2*\Psi_{a,D_1,D_2}\right)-u_1\left(v_2*\Psi_{a,D_1,D_2}\right)dx,\end{aligned}$$

where

$$\Gamma_i(x) = \frac{1}{2\pi D_i}\log\left(1+\frac{D_i^2}{x^2}\right),\quad i=1,2,$$

$$\Theta_{a,D_1,D_2}(x) = \frac{1}{2D_1D_2\pi}\left(\log\left(\frac{x^2+(2a+D_1)^2}{x^2+(2a+D_1+D_2)^2}\right)-\log\left(\frac{x^2+4a^2}{x^2+(2a+D_2)^2}\right)\right),$$

$$\begin{aligned}\Psi_{a,D_1,D_2}(x) &= \frac{1}{D_1D_2\pi}\Bigg(\arctan\left(\frac{2a+D_1}{x-s}\right)-\arctan\left(\frac{2a}{x-s}\right)\\ &\qquad -\arctan\left(\frac{2a+D_1+D_2}{x-s}\right)+\arctan\left(\frac{2a+D_2}{x-s}\right)\Bigg)\end{aligned}\tag{A.22}$$

and in Fourier space

$$\widehat{\Gamma}_{D_j}(\xi) = \frac{1 - e^{-2\pi D_j|\xi|}}{2\pi D_j|\xi|}, \quad j = 1, 2,$$

$$\widehat{\Theta}_{a,D_1,D_2}(\xi) = e^{-4\pi a|\xi|}\frac{\left(1 - e^{-2\pi D_1|\xi|}\right)\left(1 - e^{-2\pi D_2|\xi|}\right)}{2\pi D_1 D_2|\xi|},$$

$$\widehat{\Psi}_{a,D_1,D_2}(\xi) = ie^{-4\pi a|\xi|}\frac{\left(1 - e^{-2\pi D_1|\xi|}\right)\left(1 - e^{-2\pi D_2|\xi|}\right)}{2\pi D_1 D_2\xi}. \tag{A.23}$$

To write the energy in dimensionless variables, we define $x = lx'$, $a = l\alpha$, $D_1 = l\delta_1$, and $D_2 = l\delta_2$, where $l = \sqrt{A/(\mu_0 M_s^2)}$. Define also $q = K_u/(\mu_0 M_s^2)$. Performing this change of variables and dropping the prime in x', we obtain

$$\begin{aligned}\frac{1}{D_1\sqrt{\mu_0 M_s^2 A}}F[\mathbf{m}_1, \mathbf{m}_2] = {} & \frac{q}{2}\int_{\mathbb{R}}\left(u_1^2 + v_1^2\right)dx + \frac{1}{2}\int_{\mathbb{R}}|\mathbf{m}_1'|^2\,dx \\ & + \frac{1}{2}\int_{\mathbb{R}}u_1^2\,dx - \frac{1}{2}\int_{\mathbb{R}}u_1\left(\Gamma_{\delta_1} * u_1\right)dx \\ & + \frac{1}{2}\int_{\mathbb{R}}v_1\left(\Gamma_{\delta_1} * v_1\right)dx + \frac{q\delta_2}{2\delta_1}\int_{\mathbb{R}}\left(u_2^2 + v_2^2\right)dx \\ & + \frac{\delta_2}{2\delta_1}\int_{\mathbb{R}}|\mathbf{m}_2'|^2\,dx + \frac{\delta_2}{2\delta_1}\int_{\mathbb{R}}u_2^2\,dx \\ & - \frac{\delta_2}{2\delta_1}\int_{\mathbb{R}}u_2\left(\Gamma_{\delta_2} * u_2\right)dx + \frac{\delta_2}{2\delta_1}\int_{\mathbb{R}}v_2\left(\Gamma_{\delta_2} * v_2\right)dx \\ & + \frac{\delta_2}{2}\int_{\mathbb{R}}u_1\left(u_2 * \Theta_{\alpha,\delta_1,\delta_2}\right) - v_1\left(v_2 * \Theta_{\alpha,\delta_1,\delta_2}\right)dx \\ & + \frac{\delta_2}{2}\int_{\mathbb{R}}v_1\left(u_2 * \Psi_{\alpha,\delta_1,\delta_2}\right) - u_1\left(v_2 * \Psi_{\alpha,\delta_1,\delta_2}\right)dx.\end{aligned} \tag{A.24}$$

Appendix B. Validity range for the upper bound. In order to estimate the value of q_0 in (2.18), we need to study the stray field (2.17). Define

$$\eta = \frac{2\delta|\xi|\sqrt{q}}{\pi} \tag{B.1}$$

and

$$\beta = \frac{\alpha}{\delta}. \tag{B.2}$$

We need to study the Taylor series of

$$\phi(\eta) = 1 - \frac{1 - e^{-\eta}}{\eta} - \frac{1}{2}e^{-2\beta\eta}\frac{(1 - e^{-\eta})^2}{\eta}. \tag{B.3}$$

Using the Taylor polynomials of $e^{-\eta}$ and $e^{-2\beta\eta}$, we obtain

$$\begin{aligned}\phi(\eta) = \left(\frac{1}{3} + \beta\right)\eta^2 + \eta^3\Bigg(\frac{e^{-\eta_1}}{4!} - \beta^2 e^{-2\beta\eta_3} - \beta e^{-2\beta\eta_4} \\ - \frac{e^{-2\beta\eta}}{2}\left(\frac{1}{4} + \frac{1}{3}e^{-\eta_2} - \frac{\eta}{3!}e^{-\eta_2} + \frac{\eta^2}{36}e^{-2\eta_2}\right)\Bigg),\end{aligned} \tag{B.4}$$

where $\eta_k \in [0,\eta]$ for $k = 1,2,3,4$. Using (B.4), (B.1), and (B.2) in (2.17), we obtain

$$E_s \le \frac{2\delta\sqrt{q}}{3}\left(\frac{\delta}{3}+\alpha\right)+\frac{8\delta^3 q}{\pi^3}\left(\frac{1}{3}+\frac{\alpha^2}{\delta^2}+\frac{\alpha}{\delta}\right)\int |\xi|^3\mathrm{sech}^2(\xi)\,d\xi + \frac{4\delta^4 q^{3/2}}{3\pi^4}\int |\xi|^4\mathrm{sech}^2(\xi)\,d\xi + \frac{4\delta^5 q^2}{9\pi^5}\int |\xi|^5\mathrm{sech}^2(\xi)\,d\xi. \tag{B.5}$$

Estimate (2.20) holds for

$$q_0 \le \min\left\{M, \frac{4}{9}\left(\frac{\delta}{3}+\alpha\right)^2\left[\frac{8}{\pi^3}\left(\frac{\delta^2}{3}+\alpha^2+\delta\alpha\right)\int |\xi|^3\mathrm{sech}^2(\xi)\,d\xi + \frac{4\delta^3 M^{1/2}}{3\pi^4}\int |\xi|^4\mathrm{sech}^2(\xi)\,d\xi + \frac{4\delta^4 M^{3/2}}{9\pi^5}\int |\xi|^5\mathrm{sech}^2(\xi)\,d\xi\right]^{-2}\right\}, \tag{B.6}$$

where $M > 0$ is arbitrary.

Note that as $\alpha \to \infty$, $q_0 \to 0$. This is consistent with the fact that as $\alpha \to \infty$, the layers are decoupled, and we recover the Néel wall energy for a single layer, for which the upper bound is not (2.20) but (1.7).

Acknowledgment. The author wishes to thank the anonymous reviewer. His/her comments helped improve considerably the presentation of the results in this article.

EFFECTS OF SOG ON DPP-RECEPTOR BINDING*

YUAN LOU†, QING NIE‡, AND FREDERIC Y. M. WAN†

Abstract. Concentration gradients of morphogens are known to be instrumental in cell signaling and tissue patterning. Of interest here is how the presence of a competitor of BMP ligands affects cell signaling. The effects of Sog on the binding of Dpp with cell receptors are analyzed for dorsal-ventral morphogen gradient formation in vertebrate and *Drosophila* embryos. This prototype system includes diffusing ligands, degradation of morphogens, and cleavage of Dpp-Sog complexes by Tolloid to free up Dpp. Simple and biologically meaningful necessary and sufficient conditions for the existence of a steady state gradient configuration are established, and existence theorems are proved. For high Sog production rates (relative to the Dpp production rate), it is found that the steady state configuration exhibits a more intense Dpp-receptor concentration near the dorsal midline. Numerical simulations of the evolution of the system show that, beyond some threshold Sog production rate, the transient Dpp-receptor concentration at the dorsal midline would become more intense than that of the steady state, before subsiding and approaching a nonuniform steady state of lower magnitude. The magnitude of the transient concentration has been found to increase by several fold with increasing Sog production rate. The highly intense Dpp activity at and around the dorsal midline is consistent with available experimental observations and other analytical studies.

1. Introduction.

The proper functioning of tissues and organs requires that each cell differentiate appropriately for its position. In many cases, the positional information that instructs cells about their prospective fate is conveyed by concentration gradients of morphogens bound to cell receptors. Morphogens are signaling molecules that, when bound to cell receptors, assign different cell fates at different concentrations [1], [2]. Morphogen action is of special importance in understanding development because it is a highly efficient way for a population of uncommitted cells in an embryo to create complex patterns of gene expression in space. This role of morphogens has been the prevailing thought in tissue patterning for over half a century, but only recently have there been sufficient experimental data and adequate analytical studies for us to begin to understand how various useful morphogen concentration gradients are formed [3], [4].

Dorsal-ventral (back-to-belly) patterning in vertebrate and *Drosophila* (fruit fly) embryos is now known to be regulated by bone morphogenetic proteins (BMP). The BMP activity is controlled mainly by several secreted factors including the antagonists *chordin* and *short gastrulation* (Sog). In *Drosophila*, seven zygotic genes have been proposed to regulate dorsal-ventral patterning. Among them, *decapentaplegic* (Dpp) encodes BMP homologues that promote dorsal cell fates such as *amnioserosa* and inhibits development of the ventral central nervous system. The chordin homologue

Sog is expressed ventrally and promotes central nervous system development. The phenotype of Sog loss-of-function mutants is intriguing; as expected for a Dpp antagonist, ventral structures are lost but, in addition, the amnioserosa is reduced. This result is paradoxical, as the amnioserosa is the dorsal-most tissue, and thus apparently a BMP antagonist is required for maximal BMP signaling [5], [6], [7], [8].

In principle, morphogen concentration gradients can be generated through the production of morphogens at particular sources, followed by their diffusion and degradation in appropriate regions [4], [9], [10], [11], [12]. In the above Dpp/Sog system, the production of Dpp is pretty much uniform in the dorsal region and absent in the ventral region, while the opposite is true for Sog. However, the Dpp activity has a sharp peak around the midline of the dorsal region in the presence of its "inhibitor" Sog. Mutation of Sog results in a reduction and a broadening of Dpp activity around the midline of the dorsal region. As the system contains many variables, the question of what leads to a sharp concentration peak is difficult to tackle by traditional experimental means.

Recently, Eldar et al. [13] studied a more complex morphogen system that includes the effects of Sog (and other morphogens) on Dpp activities. By performing massive computer calculations to search for molecular networks that support robustness, they found that the presence of the BMP inhibitor Sog stimulates intense Dpp activity at the dorsal midline resulting in highly nonuniform Dpp-receptor concentration in space for the the patterning process. They also showed that the Dpp concentration gradient itself is robust to changes in gene dosage. Two conditions were stipulated in their model to produce agreement with experimentally observed gradient formation. First, the steady state of the system is achieved by shutting off the production of Dpp through setting the production rate to zero 10 minutes after the initiation of the system [14], and there is no degradation of Dpp-receptor complex in the model. Second, the model requires immobility of free Dpp molecules; i.e., Dpp does not diffuse, but diffusion of the Dpp-Sog complexes and other ligands can occur.

For formation of morphogen gradients in a wing imaginal disc (a structure in the larva that will become the wing of the adult fly), Lander, Nie, and Wan [4] and Lou, Nie, and Wan [9] have demonstrated the important biological roles of diffusion for Dpp, and degradation for the Dpp-receptor complex. Without degradation, the steady state of the system is not achievable unless ligand production is shut off after a while, as in [14]. Eldar et al., in a recent paper [15], have also studied how degradation of ligand affects robustness of morphogen gradients. Most recently, the diffusion coefficient of Dpp has been measured *in vivo* using FCS (fluorescence correlation spectroscopy) techniques [16], and it was found that the magnitude of diffusion coefficient for Dpp is close to the magnitude of the diffusion coefficient for the Dpp-Sog complex used in [14] and hence not negligible.

Given the rather special restrictions on the Dpp/Sog system in [13] and [14], it is desirable to investigate the possibility of an alternative and simpler known biological mechanism for the generation of the intense Dpp activities around the dorsal midline. In this paper, we will extend the dynamic Dpp/Sog system formulated in [17] for morphogen activities in dorsal-ventral patterning by allowing for diffusion of ligands, degradation of the morphogens, and the cleavage of Dpp-Sog complexes by the enzyme Tolloid to free up a fraction τ of Dpp and to degrade part of Sog.

In this study, we will establish a biologically meaningful necessary and sufficient condition for the existence of a steady state. This condition requires a balance of the production of ligands, strength of degradation, and rate of cleavage of Dpp-Sog complex by Tolloid, with *no* restrictions on the diffusion coefficients of the ligands.

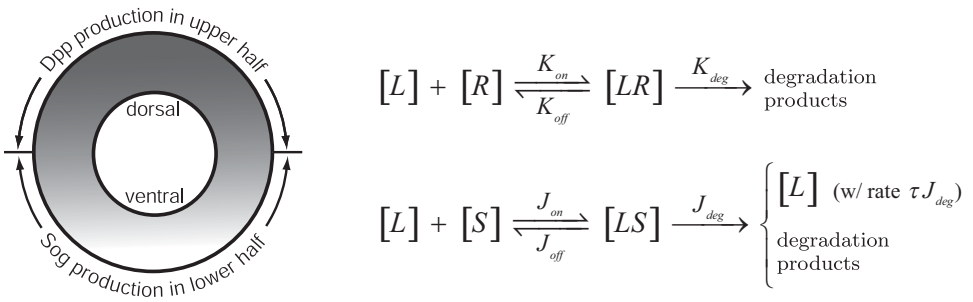

FIG. 1. *Cross section of a Drosophila embryo, and the reaction schemes with rate constants.*

To gain insight into the dependence of the morphogen activities on various biological parameters, we will obtain a perturbation solution of the steady state gradients with a biologically relevant assumption that the Sog production rate is high compared to that of Dpp [13], [14]. The solution indicates that the requirement for complete immobility of Dpp is not necessary for a biologically realistic Dpp-receptor gradient that is intense in Dpp activity at the dorsal midline. Finally, we will perform numerical simulations for the dynamics of the system. It is found that the cleavage of Sog-Dpp complex by Tolloid produces a transient peak of the Dpp-receptor concentration around the dorsal midline that is significantly stronger than the corresponding concentration at the steady state. The dependence of the peak on various biological parameters, including Sog production rate and diffusion coefficients, is also investigated. The overall features of the various concentrations of the model are consistent with experimental observations [5], [6], [7], [8]. A more complete model including more biological components and its comparison with new experiments on robustness of morphogen gradients will be presented in a separate paper [18].

2. Mathematical formulation. For an analytical and computational study of the biological phenomenon of interest, a system of partial differential equations and auxiliary conditions is formulated to capture the essential features of the dynamics of the two interacting morphogens. This approach was first applied to study the development of the *Drosophila* wing imaginal disc [19], [20], [4]. The three basic biological processes involving Dpp in the wing disc are diffusion for free Dpp molecules, their reversible binding with receptors, and degradation of the bound Dpp. The main purpose was to investigate the role of diffusion in the formation of a Dpp-receptor concentration gradient in the wing disc. That system was extended to include the effect of Sog on Dpp activities in a dorsal-ventral configuration [17] in an embryo, with the cleavage of Dpp-Sog complexes by Tolloid implicitly incorporated into the system through the complete recovery of Dpp after cleavage (while the Sog components degrade completely). The cleavage-recovery phenomenon has been suggested by previous experimental studies [21], [22]. Here we consider an even more general system than that in [17] by allowing fractional recovery through the fraction parameter τ, $0 \le \tau \le 1$, with $\tau = 1$ corresponding to complete recovery.

The setting for dorsal-ventral patterning in a *Drosophila* embryo during development is different and more complex than that considered in [4]. As shown in the sketch of the dorsal-ventral cross section of the embryo in Figure 1, Dpp is produced only in the dorsal region (with the rate $v_L(x)$), while Sog is produced only in the ventral region (with the rate $v_S(x)$). For a one-dimensional study of the dynamics of Sog and Dpp in the presence of cell receptors, we have idealized the dorsal-ventral an-

nular cross-section of the embryo as a ring and introduced an artificial cut of the ring at the ventral midline to map the cut ring onto the line segment $[-X_{\max}, X_{\max}]$, with $X = 0$ corresponding to the dorsal midline. Let [L], [S], [LS], [LR] denote the concentrations of Dpp, Sog, Dpp-Sog complexes, and Dpp bound to receptors, respectively. The first three diffuse with coefficients of diffusion D_L, D_S, and D_{LS}, respectively, while the concentration for the immobile and undegradable receptor is fixed at R_0 and uniformly distributed in $[-X_{\max}, X_{\max}]$. The system of equations governing the morphogen dynamics of such a system consists of the following four coupled second order differential equations, three of them being nonlinear partial differential equations (PDE) of the reaction-diffusion type:

$$\frac{\partial[\mathrm{L}]}{\partial T} = D_{\mathrm{L}}\frac{\partial^2[\mathrm{L}]}{\partial X^2} - K_{\mathrm{on}}[\mathrm{L}]\,(R_0 - [\mathrm{LR}]) - J_{\mathrm{on}}[\mathrm{L}][\mathrm{S}] + K_{\mathrm{off}}[\mathrm{LR}] + \big(J_{\mathrm{off}} + \tau J_{\mathrm{deg}}\big)[\mathrm{LS}] + v_L(X), \tag{1}$$

$$\frac{\partial[\mathrm{LR}]}{\partial T} = K_{\mathrm{on}}[\mathrm{L}]\,(R_0 - [\mathrm{LR}]) - \big(K_{\mathrm{off}} + K_{\mathrm{deg}}\big)[\mathrm{LR}], \tag{2}$$

$$\frac{\partial[\mathrm{LS}]}{\partial T} = D_{\mathrm{LS}}\frac{\partial^2[\mathrm{LS}]}{\partial X^2} + J_{\mathrm{on}}[\mathrm{L}][\mathrm{S}] - \big(J_{\mathrm{off}} + J_{\mathrm{deg}}\big)[\mathrm{LS}], \tag{3}$$

$$\frac{\partial[\mathrm{S}]}{\partial T} = D_{\mathrm{S}}\frac{\partial^2[\mathrm{S}]}{\partial X^2} - J_{\mathrm{on}}[\mathrm{L}][\mathrm{S}] + J_{\mathrm{off}}[\mathrm{LS}] + v_S(X) \tag{4}$$

for $-X_{\max} < X < X_{\max}$ and $T > 0$. The coefficients $\{K_{on}, J_{on}\}$, $\{K_{off}, J_{off}\}$, $\{K_{deg}, J_{deg}\}$ are the binding rate constants, the off rate constants, and the degradation rate constants of Dpp and Sog, respectively. With the morphogen activities symmetric about the ventral (as well as dorsal) midline, we must have the following symmetry (no flux) conditions at the two ends of the solution domain:

$$X = \pm X_{\max} : \frac{\partial[L]}{\partial X} = \frac{\partial[LS]}{\partial X} = \frac{\partial[S]}{\partial X} = 0.$$

The number of independent parameters may be reduced by suitable normalization. Let

$$x = \frac{X}{X_{max}}, \qquad t = \frac{D_0 T}{X_{max}^2}, \tag{5}$$

$$\{h_L, h_{LS}\} = \frac{X_{max}^2 R_0}{D_0}\{K_{on}, J_{on}\}, \tag{6}$$

$$\{f_L, f_{LS}, g_L, g_{LS}\} = \frac{X_{max}^2}{D_0}\{K_{off}, J_{off}, K_{deg}, J_{deg}\}, \tag{7}$$

$$\{V_L(x), V_S(x)\} = \frac{X_{max}^2}{R_0 D_0}\{v_L(X), v_S(X)\}, \tag{8}$$

$$\{\rho_L, \rho_S, \rho_{LS}\} = \left\{\frac{D_L}{D_0}, \frac{D_{LS}}{D_0}, \frac{D_S}{D_0}\right\}, \tag{9}$$

$$\{A, B, C, D\} = \left\{\frac{[\mathrm{L}]}{R_0}, \frac{[\mathrm{LR}]}{R_0}, \frac{[\mathrm{LS}]}{R_0}, \frac{[\mathrm{S}]}{R_0}\right\}. \tag{10}$$

In these relations, it would seem natural to choose the normalizing diffusion coefficient D_0 to be the maximum of the three diffusion coefficients. However, it turns out to be more appropriate to choose $D_0 = D_S$ to facilitate an appreciation of the implication of the solution. At this time, we will leave D_0 unspecified, but will see in section 4 why it is expeditious to specify it as D_S. In terms of these normalized quantities, (1)–(4) may be written as

$$A_{,t} = \rho_L A_{,xx} - h_L A(1-B) - h_{LS} AD + f_L B + (f_{LS} + \tau g_{LS})C + V_L(x), \tag{11}$$

$$B_{,t} = h_L A(1-B) - (f_L + g_L)B, \tag{12}$$

$$C_{,t} = \rho_{LS} C_{,xx} + h_{LS} AD - (f_{LS} + g_{LS})C, \tag{13}$$

$$D_{,t} = \rho_S D_{,xx} - h_{LS} AD + f_{LS} C + V_S(x) \tag{14}$$

for $-1 < x < 1$ and $t > 0$, with $(\ )_{,z} = \partial(\ )/\partial z$ for the temporal and spatial derivatives of the dependent variables A, B, C, D.

3. Existence of steady state solutions. In this section, we examine the existence of time-independent (or steady state) solutions of the system (11)–(14) subject to the no flux conditions at the two end points, which can now be written in terms of the normalized unknowns as

$$x = \pm 1: \quad A_{,x} = C_{,x} = D_{,x} = 0 \qquad (t > 0). \tag{15}$$

With the steady state solution independent of time, (12) becomes an algebraic equation and can be solved for B in terms of A:

$$B = \frac{A}{\alpha_L + A}, \qquad \alpha_L = \frac{g_L + f_L}{h_L}. \tag{16}$$

The expression for B is then used to eliminate it from (11), leaving the following three simultaneous equations for the three unknowns A, C, and D:

$$\rho_L A_{,xx} - \frac{g_L h_L A}{f_L + g_L + h_L A} - h_{LS} AD + (f_{LS} + \tau g_{LS})C + V_L = 0, \tag{17}$$

$$\rho_{LS} C_{,xx} + h_{LS} AD - (f_{LS} + g_{LS})C = 0, \tag{18}$$

$$\rho_S D_{,xx} - h_{LS} AD + f_{LS} C + V_S = 0 \tag{19}$$

for $-1 < x < 1$ subject to the boundary conditions (15).

Throughout this section we assume the following:

(A1) f_L, f_{LS}, g_L, g_{LS}, h_L, and h_{LS} are continuous positive functions in $[-1, 1]$; ρ_L, ρ_{LS}, and ρ_S are positive constants; V_S, V_L are nonnegative integrable functions that satisfy $\int_{-1}^{1} V_L > 0$ and $\int_{-1}^{1} V_S > 0$; and τ is a constant satisfying $0 \le \tau \le 1$.

If $V_L(x)$ and $V_S(x)$ are continuous, we seek a classical solution of (15)–(19); i.e., A, C, and D are twice continuously differentiable in $[-1, 1]$ that satisfy (15)–(19).

THEOREM 3.1. *Suppose that* (A1) *holds and* V_L, V_S *are continuous in* $[-1,1]$. *Then* (15)–(19) *has a positive classical solution if and only if both of the following inequalities hold:*

$$\int_{-1}^{1} V_L(x)dx > (1-\tau)\int_{-1}^{1} V_S(x)dx, \tag{20}$$

$$\int_{-1}^{1} V_L(x)dx < (1-\tau)\int_{-1}^{1} V_S(x)dx + \int_{-1}^{1} g_L(x)dx. \tag{21}$$

Since $\int_{-1}^{1} V_L(x) > 0$, the first condition is trivially satisfied for $\tau = 1$ (full recovery of Dpp), and the second is a distributed version of the necessary and sufficient condition for existence in [9], [10], [11], [12] (that the Dpp production rate must be slower than the degradation rate of the Dpp-receptor complexes). For $0 \le \tau < 1$, these two conditions may be combined to give a similar condition on a nonnegative "effective" Dpp production rate $[V_L - (1-\tau)V_S]$ (see section 5).

LEMMA 3.2. *If* (15)–(19) *has a positive classical solution, then* (20) *and* (21) *must hold.*

Proof. Adding up (17) and (18) and integrating over $[-1,1]$, we obtain with the help of (15)

$$\int_{-1}^{1} V_L = \int_{-1}^{1} \frac{g_L h_L A}{f_L + g_L + h_L A} + (1-\tau)\int_{-1}^{1} g_{LS}C. \tag{22}$$

Similarly, adding up (18) and (19) and integrating over $[-1,1]$, we get

$$\int_{-1}^{1} g_{LS}C = \int_{-1}^{1} V_S. \tag{23}$$

It follows from (22) and (23) that

$$\int_{-1}^{1} V_L = \int_{-1}^{1} \frac{g_L h_L A}{f_L + g_L + h_L A} + (1-\tau)\int_{-1}^{1} V_S. \tag{24}$$

For $A > 0$ in $[-1,1]$, we have

$$0 < \int_{-1}^{1} \frac{g_L h_L A}{f_L + g_L + h_L A} < \int_{-1}^{1} g_L, \tag{25}$$

which along with (24) implies (20)–(21). □

In view of Lemma 3.2, we'll assume that (20)–(21) holds for the rest of this subsection. Our goal is to show that if V_L and V_S are continuous, then the condition (20)–(21) implies that (15)–(19) has at least a positive classical solution. The idea is to introduce some parameter λ and consider the following system of equations:

$$\rho_L \tilde{A}_{,xx} + \lambda F_1(x, \tilde{A}, \tilde{C}, \tilde{D}) = 0, \quad -1 < x < 1, \tag{26}$$

$$\rho_{LS} \tilde{C}_{,xx} + \lambda F_2(x, \tilde{A}, \tilde{C}, \tilde{D}) = 0, \quad -1 < x < 1, \tag{27}$$

$$\rho_S \tilde{D}_{,xx} + \lambda F_3(x, \tilde{A}, \tilde{C}, \tilde{D}) = 0, \quad -1 < x < 1, \tag{28}$$

$$\tilde{A}_{,x} = \tilde{C}_{,x} = \tilde{D}_{,x} = 0 \quad \text{at } x = -1, 1, \tag{29}$$

where $\lambda \in (0, 1]$ and F_i $(i = 1, 2, 3)$ is given by

$$F_1(x, \tilde{A}, \tilde{C}, \tilde{D}) = -\frac{g_L h_L \tilde{A}}{f_L + g_L + h_L \tilde{A}} - h_{LS} \tilde{A} \tilde{D} + (f_{LS} + \tau g_{LS}) C + V_L, \tag{30}$$

$$F_2(x, \tilde{A}, \tilde{C}, \tilde{D}) = h_{LS} \tilde{A} \tilde{D} - (f_{LS} + g_{LS}) \tilde{C}, \tag{31}$$

$$F_3(x, \tilde{A}, \tilde{C}, \tilde{D}) = -h_{LS} \tilde{A} \tilde{D} + f_{LS} \tilde{C} + V_S. \tag{32}$$

We establish some a priori estimates for nonnegative classical solutions of (26)–(29).

LEMMA 3.3. *Let $(\tilde{A}, \tilde{C}, \tilde{D})$ be any nonnegative classical solution of* (26)–(29). *If $\lambda > 0$, then $\tilde{A}(x) > 0$, $\tilde{C}(x) > 0$, and $\tilde{D}(x) > 0$ for every $x \in [-1, 1]$.*

Proof. Similar to (23) we have $\int_{-1}^{1} g_{LS} \tilde{C} = \int_{-1}^{1} V_S$. Hence $\tilde{C} \geq 0$, $\tilde{C} \not\equiv 0$. By (27) and (31) we have

$$-\rho_{LS} \tilde{C}_{,xx} + \lambda (f_{LS} + g_{LS}) \tilde{C} = \lambda h_{LS} \tilde{A} \tilde{D} \geq 0, \quad -1 < x < 1. \tag{33}$$

This together with $\tilde{C}_{,x}(-1) = \tilde{C}_{,x}(1) = 0$, via the maximum principle [23], implies that $\tilde{C}(x) > 0$ for every $x \in [-1, 1]$. Since $V_L \not\equiv 0$ and $V_S \not\equiv 0$, similarly by (26)–(29) and the maximum principle we can show that $\tilde{A} > 0$ and $\tilde{D} > 0$ in $[-1, 1]$. ∎

LEMMA 3.4. *There exists some constant $M > 0$, independent of λ, such that for any $0 < \lambda \leq 1$ and any positive classical solution $(\tilde{A}, \tilde{C}, \tilde{D})$ of* (26)–(29) *we have*

$$\|\tilde{A}\|_{L^\infty} + \|\tilde{C}\|_{L^\infty} + \|\tilde{D}\|_{L^\infty} \leq M. \tag{34}$$

The proof of Lemma 3.4 is postponed to the appendix. Lemmas 3.3 and 3.4 enable us to define Leray–Schauder degree (see, e.g., [24]) for a certain operator whose fixed points correspond to positive solutions of (26)–(29).

Set $E = \{C[-1, 1]\}^3$ and $C_N^2[-1, 1] = \{u \in C^2[-1, 1] : u_{,x}(-1) = u_{,x}(1) = 0\}$. For any positive constant γ, let L_γ^{-1} denote the inverse of the operator $L_\gamma := -\gamma \frac{d^2}{dx^2} + I : C_N^2[-1, 1] \to C[-1, 1]$, where I denotes the identity map from $C[-1, 1]$ to itself.

For every $\lambda \in [0, 1]$, define operator $T(\lambda) : \quad E \to E$ by

$$T(\lambda)(\tilde{A}, \tilde{C}, \tilde{D}) = \begin{pmatrix} L_{\rho_L}^{-1}[\tilde{A} + \lambda F_1^+(x, \tilde{A}, \tilde{C}, \tilde{D})] \\ L_{\rho_{LS}}^{-1}[\tilde{C} + \lambda F_2(x, \tilde{A}, \tilde{C}, \tilde{D})] \\ L_{\rho_S}^{-1}[\tilde{D} + \lambda F_3(x, \tilde{A}, \tilde{C}, \tilde{D})] \end{pmatrix}, \tag{35}$$

where

$$F_1^+(x, \tilde{A}, \tilde{C}, \tilde{D}) = \frac{-g_L h_L A}{f_L + g_L + h_L A_+} - h_{LS} A D + (f_{LS} + \tau g_{LS}) C + V_L, \tag{36}$$

$A_+ = \max(A, 0)$. By standard regularity theory and the embedding theorem, we see that $T(\lambda)$ is well defined and continuous, and the operator $\tilde{T}$: $[-1, 1] \times E \to E$,

defined by $\tilde{T}(\lambda, \tilde{A}, \tilde{C}, \tilde{D}) = T(\lambda)(\tilde{A}, \tilde{C}, \tilde{D})$, is continuous and compact. For M given in (34), define

$$\Omega = \left\{ (\tilde{A}, \tilde{C}, \tilde{D}) \in E : \ 0 < \tilde{A}(x), \tilde{C}(x), \tilde{D}(x) < M + 1 \quad \forall x \in [-1, 1] \right\}.$$

Ω is an open and bounded subset of E. By Lemmas 3.3 and 3.4, we see that for any $\lambda \in (0, 1]$, $[I - T(\lambda)]^{-1} \{(0, 0, 0)\} \notin \partial\Omega$. Hence the Leray–Schauder degree, $\deg\big(I - T(\lambda), \Omega, (0, 0, 0)\big)$, is well defined for $0 < \lambda \leq 1$. Moreover, by the homotopy invariance of the Leray–Schauder degree [24], $\deg\left(I - T(\lambda), \Omega, (0, 0, 0)\right)$ is a constant function for $0 < \lambda \leq 1$. To complete the proof of Theorem 3.1, we need the following result.

PROPOSITION 3.5. *There exists* $\delta > 0$ *such that* $\deg\left(I - T(\lambda), \Omega, (0, 0, 0)\right) = 1$ *for* $\lambda \in (0, \delta)$.

The detail of the proof of this proposition is not particularly relevant to the proof of Theorem 3.1 and will be given in an appendix of this paper. Assuming Proposition 3.5, we can now complete the proof of Theorem 3.1.

Proof of Theorem 3.1. By Lemma 3.2, it suffices to establish the sufficiency part. By Proposition 3.5, for every $0 < \lambda \leq 1$, $\deg\left(I - T(\lambda), \Omega, (0, 0, 0)\right) = 1$. In particular, $\deg\left(I - T(1), \Omega, (0, 0, 0)\right) \neq 0$. This implies that there exists $(\tilde{A}, \tilde{C}, \tilde{D}) \in \Omega$ such that $(I - T(1))(\tilde{A}, \tilde{C}, \tilde{D}) = (0, 0, 0)$. By standard regularity theory we see that $\tilde{A}, \tilde{C}, \tilde{D} \in C^2[-1, 1]$ and is thus a positive classical solution of (15)–(19). ∎

Specific morphogen systems of interest include those with morphogen production rates that are discontinuous in the spatial variable (see section 4). When V_L and V_S are bounded and measurable, we will be seeking $C^{1,1}$ solutions of (15)–(19), i.e., functions A, C, D that are differentiable in $[-1, 1]$; have derivatives $A_{,x}, C_{,x}$, and $D_{,x}$ Lipschitz continuous in $[-1, 1]$; and satisfy (15) and for every $x \in [-1, 1]$

$$\rho_L A_{,x} + \int_{-1}^{x} F_1 = \rho_{LS} C_{,x} + \int_{-1}^{x} F_2 = \rho_S D_{,x} + \int_{-1}^{x} F_3 = 0. \tag{37}$$

THEOREM 3.6. *Suppose that* (A1) *holds and that* V_L *and* V_S *are bounded measurable. Then* (15)–(19) *has a positive* $C^{1,1}$ *solution if and only if* (20)–(21) *holds.*

Proof. Suppose that (15)–(19) has a positive $C^{1,1}$ solution. Setting $x = 1$ in (37) and applying the same argument as in the proof of Lemma 3.2, we see that (20)–(21) must hold. On the other hand, if (20)–(21) holds, we can choose a uniformly bounded sequence of continuous positive functions $V_L^n(x)$ and $V_S^n(x)$ such that $V_L^n(x) \to V_L$ and $V_S^n(x) \to V_S$ a.e., and $0 < \int_{-1}^{1} \left[V_L^n - (1 - \tau) V_S^n\right] < \int_{-1}^{1} g_L$. By Theorem 3.1 (17)–(19), with V_L and V_S being replaced by V_L^n and V_S^n, respectively, there is a sequence of positive classical solutions, denoted by A^n, C^n, and D^n. As for Lemma 3.4, we can show that there exists some positive constant M, independent of n, such that $\|A^n\|_{L^\infty} + \|C^n\|_{L^\infty} + \|D^n\|_{L^\infty} \leq M$. Furthermore, $\|A^n_{,xx}\|_{L^\infty}$, $\|C^n_{,xx}\|_{L^\infty}$, and $\|C^n_{,xx}\|_{L^\infty}$ are uniformly bounded. By passing to a subsequence if necessary, (A^n, C^n, D^n) converge to some functions (A, C, D) in C^1, and A, C, D satisfy (15) and are nonnegative solutions of (37). From (37) we see that $A_{,x}, C_{,x}, D_{,x}$ are Lipschitz continuous in $[-1, 1]$. By similar argument as in Lemma 3.3 (but instead using the maximum principle for weak solutions of (15)–(19)), we see that A, C, D are all positive in $[-1, 1]$. This completes the proof of Theorem 3.6. ∎

Remark 3.7. Note that $C \in C^2[-1, 1]$. If V_L and V_S are piecewise continuous, then A and D are also piecewise twice continuously differentiable in $[-1, 1]$.

4. Approximate steady state solutions for $V_L \ll V_S$. In previous studies [13], [14], the constant (in both space and time) Dpp production rate, $\bar{v}_L$, in the dorsal

region was estimated to be significantly smaller than the constant Sog production rate, $\bar{v}_S$, in the ventral region. In [14], the ratio of the two production rates, defined as $\epsilon \equiv \bar{v}_L/\bar{v}_S$, is 0.008 for its baseline study. The robustness of the solutions with respect to variations of $\bar{v}_S$ is studied for fixed $\bar{v}_L$ [13].

For $\bar{v}_L \ll \bar{v}_S$, so that $\epsilon \ll 1$, we obtain below a perturbation solution for the steady state of (15)–(19), with $\tau = 1$ for simplicity. For $\tau < 1$, perturbation solution procedure applies only if (20)–(21) hold. Similar to [14], we assume

$$V_L(x) = \bar{V}_L H\left(\frac{1}{2} - x\right), \qquad V_S(x) = \bar{V}_S H\left(x - \frac{1}{2}\right), \tag{38}$$

where $(\bar{V}_L, \bar{V}_S) = (\bar{v}_L, \bar{v}_S)X_{max}^2/(R_0 D_0)$ and $H(z)$ is the unit step function.

With $\bar{V}_L \ll \bar{V}_S$, we expect $D(x), C(x) = O(\bar{V}_S), O(\bar{V}_S)$, although the latter may be a smaller fraction of $\bar{V}_S$. On the other hand, we have $A(x) = O(\bar{V}_L)$ at most, in fact quite a bit smaller since free Dpp should eventually be bound to Sog or receptors, given that Sog is produced at a much higher rate. For these reasons, we set

$$A(x) = \frac{\overline{V}_L}{\mu_L^2} a(x), \quad C(x) = \frac{\overline{V}_S}{f_{LS} + g_{LS}} c(x), \quad D(x) = \overline{V}_S d(x), \tag{39}$$

where $\mu_L^2 = g_L/\alpha_L$ and $\alpha_L = (f_L + g_L)/h_L$. Then (17)–(19) become

$$\frac{\overline{V}_L}{\overline{V}_S}\left[\frac{\rho_L}{\mu_L^2} a'' - \frac{a}{1+\beta_L a} + H\left(\frac{1}{2} - x\right)\right] - \mu_D^2 ad + c = 0, \tag{40a}$$

$$\rho_{LS} c'' + (f_{LS} + g_{LS})[\mu_D^2 ad - c] = 0, \tag{40b}$$

$$\rho_S d'' - [\mu_D^2 ad - c] - (1 - \sigma_{LS})c + H\left(x - \frac{1}{2}\right) = 0, \tag{40c}$$

where $()' = d()/dx$, $\beta_L = \bar{V}_L/g_L$, $\sigma_{LS} = f_{LS}/(f_{LS}+g_{LS}) < 1$, and $\mu_D^2 = h_{LS}\alpha_L \bar{V}_L/g_L$. Using symmetry about $x = 0$, we need only to consider solutions for $0 < x < 1$ with the boundary conditions at $x = 0$ being again no flux for all three unknowns a, b, and c.

The form of (40a)–(40c) suggests that we seek a perturbation solution of $\{a, c, d\}$ in ε:

$$\{a(x;\epsilon), c(x;\epsilon), d(x;\epsilon)\} = \sum_{n=0}^{\infty} \{a_n(x), c_n(x), d_n(x)\}\, \epsilon^n. \tag{41}$$

For moderate values of $\bar{V}_L$ so that μ_D^2 is *not* small compared to unity, the three leading term coefficients are determined by

$$\mu_D^2 a_0 d_0 - c_0 = 0, \tag{42a}$$

$$\rho_{LS} c_0'' + (f_{LS} + g_{LS})[\mu_D^2 a_0 d_0 - c_0] = 0, \tag{42b}$$

$$\rho_S d_0'' - [\mu_D^2 a_0 d_0 - c_0] - (1 - \sigma_{LS})c_0 + H\left(x - \frac{1}{2}\right) = 0. \tag{42c}$$

The complementary case, $\mu_D^2 \ll 1$, can also be analyzed but is not relevant for our biological system.

Upon combining (42a) and (42b) we get

$$\rho_{LS} c_0'' = 0. \tag{43}$$

The no flux boundary conditions at $x = 0, 1$ require $c_0(x) \equiv \sigma_0$ for some constant σ_0. To determine σ_0, we note that (23) is still valid and requires

$$\frac{1}{2}\overline{V}_S = \int_0^1 V_s(x)dx = g_{LS}\int_0^1 C(x)dx = \overline{V}_S \frac{g_{LS}}{f_{LS}+g_{LS}}\int_0^1 c(x)dx \tag{44}$$

so that $\sigma_0 = 1/2(1-\sigma_{LS})$, i.e.,

$$(1-\sigma_{LS})c_0(x) = \frac{1}{2}, \qquad 0 \le x \le 1. \tag{45}$$

To determine $d_0(x)$, we use (42a) and (42c) to obtain

$$\rho_S d_0'' - (1-\sigma_{LS})c_0 + H\left(x-\frac{1}{2}\right) = 0. \tag{46}$$

Upon integration and application of boundary conditions at $x = 0, 1$, as well as the continuity condition at $x = 1/2$ for d_0, we obtain

$$\rho_S d_0(x) = \begin{cases} \delta_0 + \dfrac{x^2}{4} & \left(x \le \dfrac{1}{2}\right), \\ \delta_0 - \dfrac{1}{8} + \dfrac{1}{2}\left(x - \dfrac{x^2}{2}\right) & \left(x \ge \dfrac{1}{2}\right), \end{cases} \tag{47}$$

where δ_0 is an undetermined constant. By (42a) we have also

$$\frac{1-\sigma_{LS}}{\rho_S}\mu_D^2 a_0(x) = \frac{1-\sigma_{LS}}{\rho_S}\frac{c_0(x)}{d_0(x)} = \begin{cases} \dfrac{1}{2}\dfrac{1}{(\delta_0 + \frac{1}{4}x^2)} & \left(x < \dfrac{1}{2}\right), \\ \dfrac{1}{2}\dfrac{1}{[\delta_0 - \frac{1}{8} + \frac{1}{2}x - \frac{1}{4}x^2]} & \left(x > \dfrac{1}{2}\right). \end{cases} \tag{48}$$

It is rather fortuitous to have $a_0'(0) = a_0'(1) = 0$ because d_0 and c_0 satisfy no flux conditions at the two end points so that there are no boundary layers adjacent to the two ends.

It remains to determine δ_0. We note that (24) still holds, particularly when $\tau = 1$. In that case, (24) becomes

$$G(\delta_0) \equiv \int_0^1 \frac{a_0(x)}{1+\beta_L a_0(x)}dx = \frac{1}{2}. \tag{49}$$

It is easy to see that $G(\delta_0)$ is strictly monotone decreasing in δ_0 and that $G(\delta_0) \to 0$ as $\delta_0 \to \infty$. Hence $G(\delta_0) = \frac{1}{2}$ has at most one positive root, and it has one positive root if and only if $G(0) > \frac{1}{2}$. Note that $G(0)$ can be explicitly computed, and thus $G(\delta_0) = \frac{1}{2}$ determines δ_0.

Altogether, we have as the corresponding leading terms for the concentrations

$$A(x) \sim \frac{(1-\sigma_{LS})\mu_D^2 a_0(x)/\rho_S}{R_0 J_{on,eff}/(D_S/X_{\max}^2)}, \tag{50}$$

$$B(x) \sim \frac{\Gamma_{LS}(1-\sigma_{LS})\mu_D^2 a_0(x)/\rho_S}{1+\Gamma_{LS}(1-\sigma_{LS})\mu_D^2 a_0(x)/\rho_S}, \tag{51}$$

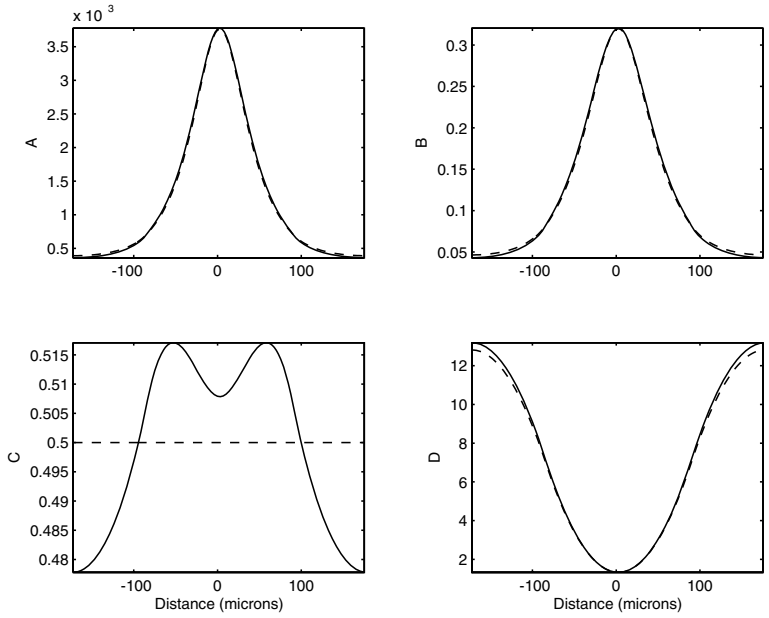

FIG. 2. *Comparisons between the numerical steady states (solid lines) and the perturbation solutions (dashed lines). The parameters are* $\bar{v}_L = 8 \times 10^{-4} s^{-1} \mu M$, $K_{on} = 0.4 s^{-1}$, $K_{off} = 4 \times 10^{-6} s^{-1}$, $K_{deg} = 3.2 \times 10^{-3} s^{-1}$, $\bar{v}_S = 6 \times 10^{-2} s^{-1} \mu M$, $J_{on} = 6 s^{-1} \mu M$, $J_{off} = 10^{-5} s^{-1}$, $J_{deg} = 6 \times 10^{-2} s^{-1}$, $\tau = 1$.

$$C(x) \sim \frac{1}{2} \frac{\bar{v}_S}{J_{deg} R_0}, \tag{52}$$

$$D(x) \sim \frac{\bar{v}_S / R_0}{D_S / X_{\max}^2} [\rho_S d_0(x)], \tag{53}$$

where

$$K_{on,eff} \equiv \frac{K_{deg} K_{on}}{K_{deg} + K_{off}}, \qquad J_{on,eff} \equiv \frac{J_{deg} J_{on}}{J_{deg} + J_{off}}, \qquad \Gamma_{LS} = \frac{K_{on,eff}}{J_{on,eff}} \frac{D_S}{K_{deg} X_{max}^2}. \tag{54}$$

In Figure 2, the perturbation solutions (50)–(53) are plotted against the numerical solutions obtained through temporal evolution (which will be discussed in the next section). The relative difference between the two solutions is 1.5% for A, 1.4% for B, 4.3% for C, and 2.9% for D for $\epsilon = \bar{v}_L / \bar{v}_S = 0.0133$ and $\mu_D^2 = 18.4$. This illustrates the approximation and accuracy of the perturbation solution for $\epsilon \ll 1$.

More interesting is the dependence of the leading term solutions (51)–(53) on the biological parameters. The simplest of the four is the uniformly distributed concentration of Dpp-Sog complexes in (53): it depends only on the production rate of Sog per receptor, which is uniform in the ventral region. Free Sog $D(x)$ is proportional to the quadratic function defined in (47) with a magnitude of $\bar{v}_S / R_0$ modified by the diffusion coefficient of Sog. That $D(x)$ is inversely proportional to D_S is not surprising, since faster diffusion of Sog would move more of it into the dorsal region for

binding with the available Dpp there. Note that $\rho_S d_0(x)$ is independent of the choice of normalizing diffusion coefficient D_0 and the effects of all biological parameters are felt by $\rho_S d_0(x)$ only implicitly through the parameter δ_0.

Less expected is the dependence of $A(x)$ and $B(x)$ on the biological parameters. From (51), we see that if $\Gamma_{LS} = O(1)$, the amplitude of $B(x)$ is determined mainly by Γ_{LS}. For $\Gamma_{LS} \gg 1$, we have $B(x) \sim 1$, except possibly for a region adjacent to the ventral midline $x = 1$. In either case, the amplitude of $B(x)$ does not depend explicitly on either of the two production rate parameters $\bar{v}_S/R_0$ or $\bar{v}_L/R_0$; the effects of these two parameters on $B(x)$ are felt only through δ_0.

The situation is similar for $A(x)$. It seems unreasonable that $A(x)$ does not tend to zero with $\bar{v}_L/R_0$ (with the same observation applied to $B(x)$ as well). However, we see from a closer examination of (40a) that $\mu_D^2 = h_{LS}\alpha_L \bar{V}_L/g_L$ tends to zero with $\bar{v}_L/R_0$. For sufficiently small $\bar{v}_L/R_0$, the first approximation relation (42a) would give $c_0(x) = 0$. In that case, $c(x)$ should be rescaled (by an additional factor μ_D^2) for a proper perturbation solution, while the solution of this section ceases to be applicable. In other words, to apply the perturbation solution $\{a_0(x), c_0(x), d_0(x)\}$ obtained above, we must have $\bar{v}_L/R_0$ sufficiently small so that $\bar{V}_L/\bar{V}_S = \bar{v}_L/\bar{v}_S \ll 1$ but not too small so that $\mu_D^2 = h_{LS}\alpha_L \bar{V}_L/g_L$ is *not* small compared to unity.

5. Numerical solutions for evolutions. The system (1)–(4) can be solved by finite difference schemes [25]. The diffusion terms are approximated by the second order central difference. The temporal evolution is approximated through the fourth order Adams–Moulton predictor-corrector method. The overall accuracy for the method is second order in space and fourth order in time.

For a typical calculation, the time step is chosen to be $\triangle t = 2 \times 10^{-4}$ seconds, and the number of points to discretize the entire dorsal and ventral region is $N = 64$. Smaller time step and larger number of points have been used to check the accuracy and convergence of the calculations.

Similar to [13], the span of both the dorsal region and the ventral region is chosen to be 175μm, i.e., $X_{max} = 175\mu$m. Unlike [13], the diffusion constants for Dpp, Sog, and Dpp-Sog are taken to be the same with $D_0 = D_L = D_{LS} = D_S = 20\mu\text{m}^2/\text{second}$ [4], so that $\rho_L = \rho_S = \rho_{LS} = 1$ (except for changes indicated in Figures 7 and 8). In this study, the synthesis rates for Dpp and Sog remain the same for all time. In particular, $v_L(X)$ is always chosen to be a nonzero constant, $\bar{v}_L$, in the dorsal region and zero in the ventral region, while $v_S(X)$ is the opposite, with $v_S(X) = \bar{v}_S$ in the ventral and zero in the dorsal region.

The dynamics of the system without Sog is very similar to that in [4], even though the ligand is produced from a localized source in [4] while the ligand is produced in the whole dorsal region for the system (1)–(4). For realistic ranges of the biological parameters of the problem, this system typically evolves quickly and monotonically to a steady state within a half hour, with the Dpp-receptor concentration almost uniform around the dorsal region. This behavior is consistent with the experimental observation of [8]. At $x = 0$ the steady state is approximately equal to $\bar{v}_L/(K_{deg}R_0)$.

Without Sog, the solution at any fixed x is found to be an increasing function of time. This feature is also observed for cases where Sog is synthesized at a slow rate or at a rate comparable to the Dpp production rate. The situation is different if the Sog production rate is significantly larger than the Dpp production rate, which is the most biologically relevant case [13]. In Figure 3, time evolution of a typical system for large $\bar{v}_S$ is plotted. It is observed that the spatial distributions of Dpp and the Dpp-receptor complex continue to have maximum concentrations at the middle of the

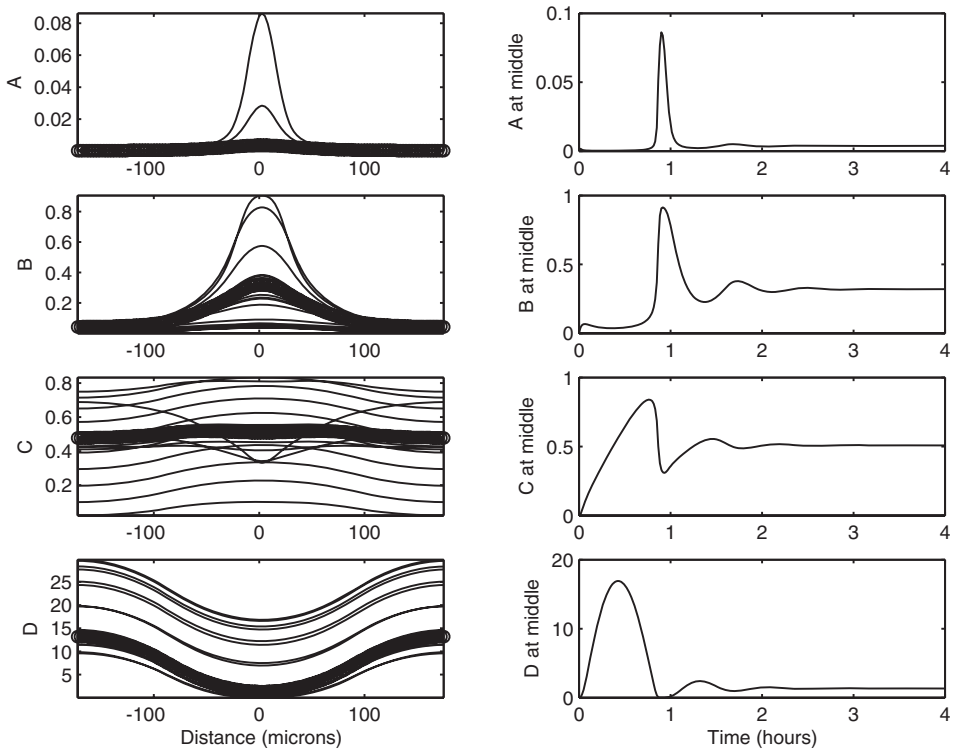

FIG. 3. *The dynamics of solutions with SOG at every* 5 *minutes; o in the left-hand panels marks the steady-state solutions. All parameters are the same as for Figure* 2.

dorsal region, $x = 0$, at any instance in time (see the left-hand panels). However, the various morphogen concentrations at $x = 0$ (the center of the dorsal region) peak at an early time, then oscillate, with the amplitude of oscillations decaying until the concentrations reach their steady state (see the right-hand panels). Therefore we record two interesting curves for Dpp-receptor concentration: the transient solution with the largest value at the dorsal midline and the steady state solution.

In Figure 4(a), the steady state for Dpp-receptor concentration of our system (from the same numerical simulations for Figure 3) are plotted. With Sog ($\bar{v}_S \neq 0$), the Dpp-receptor in the dorsal region generally has sharper gradient and larger concentration than those without Sog ($\bar{v}_S = 0$). For the transient solution at its maximal peak magnitude, the concentration with Sog is at least double that without Sog around the middle region. These are consistent with the experimental observation in [8].

In steady state, the system with or without Sog has the same total amount of Dpp-receptor complex for $\tau = 1$. This can be shown by simply adding the right-hand sides of (11)–(13) and (13)–(14), respectively, and then integrating them through the whole domain:

$$\int_{-1}^{1} g_L B dx = \int_{-1}^{1} \left(V_L(x) - (1-\tau)V_S(x)\right) dx. \tag{55}$$

This relationship is independent of the presence of Sog when $\tau = 1$. In other words, the effect of inhibitor on Dpp-receptor concentration in the steady state is a spatial

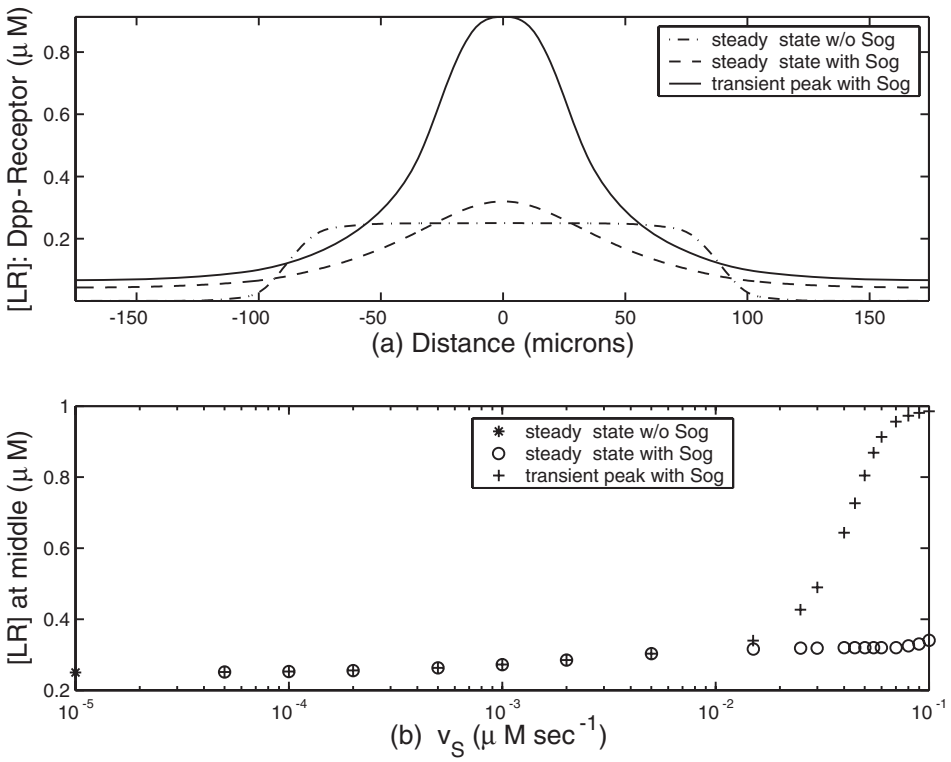

FIG. 4. *Effect of Sog on the transient and steady state solutions.* (a) $[LR]$ *as a function of space;* (b) $[LR]$ *at dorsal midline as a function of* $\bar{v}_S$. *Parameters are as in Figure* 3.

redistribution, not an increase or decrease in total concentration aggregated over the entire embryo if all degraded Dpp-Sog complexes, $[LS]$, are cleaved to free up Dpp and degrade only the Sog component.

For the transient solution, the presence of Sog clearly helps build up the Dpp-receptor complexes in terms of both gradient and concentration, as shown in Figure 3. In Figure 4(b), we study how the transient peak of Dpp-receptor and the steady state at the dorsal midline ($x = 0$) depend on $\bar{v}_S$. The steady state for B without Sog at $x = 0$ is 0.25, and its value is plotted at the y-axis in Figure 4(b). For a small amount of Sog, the transient peaks are not high, and the steady state has the largest value at $x = 0$, as shown for $\bar{v}_S/R_0 < 0.01$. Also, $B(x = 0)$ at steady state increases as $\bar{v}_S$ increases, and the transient peak begins to deviate from the steady state around $\bar{v}_S/R_0 = 0.01$. As $\bar{v}_S$ increases by one order of magnitude from 0.015 to 0.1, the transient peak increases from 0.34 to 0.99, while the steady state only from 0.32 to 0.34. Once $\bar{v}_S/R_0$ becomes large enough, the variation of the transient peak is more sensitively dependent on variation of $\bar{v}_S/R_0$ than that of the steady state at $x = 0$. The dependence of the transient peak on other parameters such as J_{on} and J_{deg} have been investigated previously in [17] for $\tau = 1$.

When $\tau < 1$, so that only a portion of the degraded Dpp-receptor complex is cleaved to free up Dpp, the dynamics of the system strongly depends on the size of τ when the steady state condition (20)–(21) holds. It is not surprising that for smaller τ, i.e., less free Dpp released from the degraded $[LS]$, the transient and steady

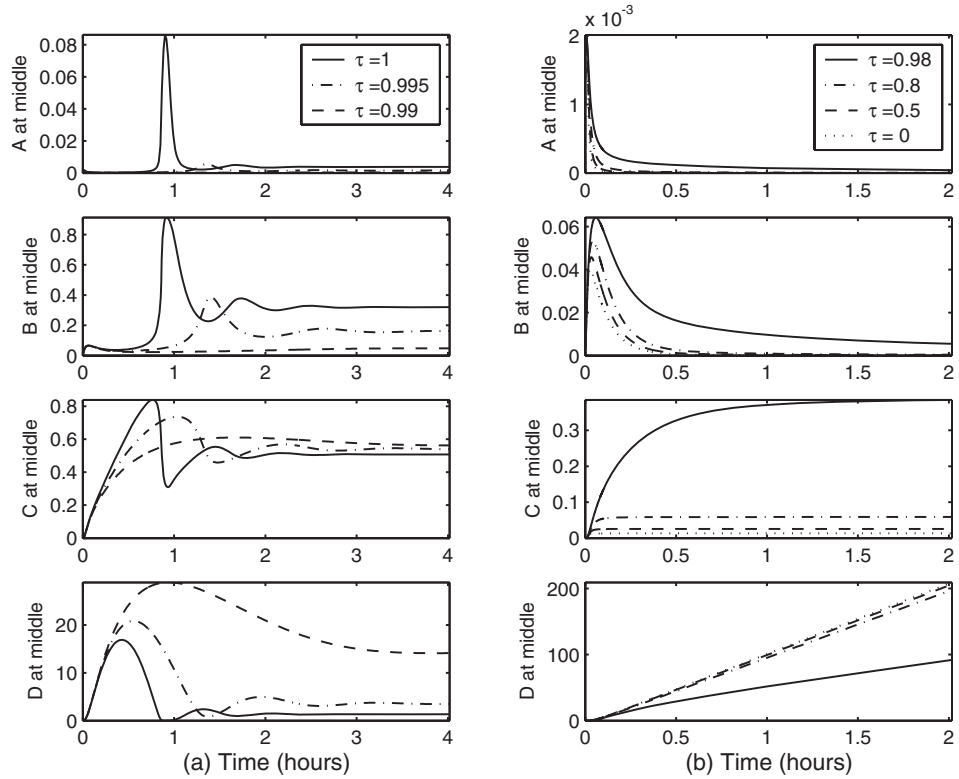

FIG. 5. *Effect of τ on the steady state solutions. Parameters are as in Figure* 3 *except for τ.* (a) *Cases with steady states;* (b) *cases without steady states.*

peaks of Dpp-receptor complex are lower, as shown in Figure 5(a) for $\tau = 0.995$ and 0.99. However, for $\tau = 0.99$, the concentration of Dpp-receptor complex around the dorsal region is much lower with Sog than without Sog, as shown in Figure 5(a). As demonstrated in (55), a small change of τ will result in a large change of $[LR]$ at steady state for a large $\bar{v}_S$, which is the case for Figure 5(a). In essence, $v_{eff} \equiv \bar{v}_L - (1-\tau)\bar{v}_S$ can be regarded as an effective production rate for Dpp.

When the effective production rate v_{eff} becomes negative, that is, the condition (20)–(21) does not hold, then the system can no longer sustain a steady state. For this situation, the concentrations of both free Dpp and the Dpp-receptor complex are typically very low, and the Dpp-receptor complex reaches the peak before Sog diffuses into the dorsal region from the ventral side and takes over the reaction with Dpp. With the availability of a large amount of Sog and its fast association rate with Dpp, Dpp-Sog reaction dominates. It is interesting to note in Figure 5(b) that as τ varies from 0.98 to 0, the time for Dpp and Dpp-receptor complex to reach their peaks barely changes. This critical time (to reach the peak) is mainly determined by the coefficient of diffusion D_S, which controls the speed of Sog movement into the dorsal zone.

In [14] (hence also in [13]), degradation for $[LR]$ is not allowed in the system ($K_{deg} = 0$); therefore the condition (20)–(21) does not hold for any $\bar{v}_L > 0$. In order to achieve steady state in [13], [14], the models there turned off production of Dpp after 10 minutes ($T^* = 10$ minutes). The effect of the choice of T^* and

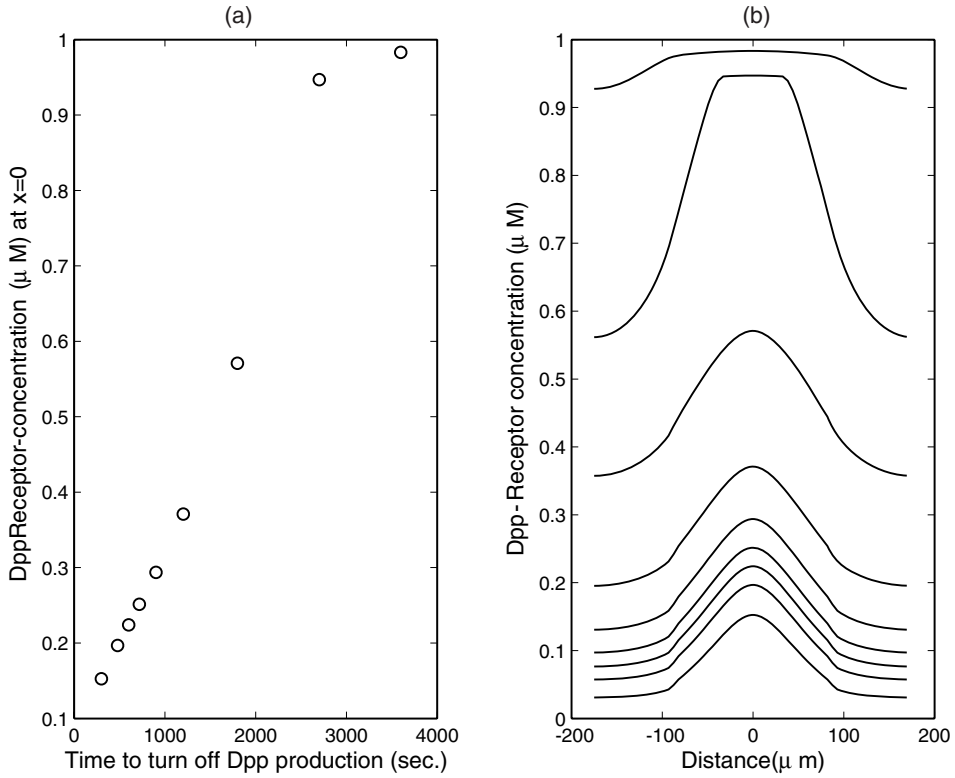

FIG. 6. *$\bar{v}_L$ is set to zero at different times.* (a) *$[LR]$ at the dorsal midline at steady state as a function of the time for turning off $\bar{v}_L$;* (b) *$[LR]$ at steady states as a function of space for different times of turning off $\bar{v}_L$, as shown in* (a). *Other parameters are as in Figure* 3 *except that $K_{deg} = 0$.*

the biological background for the choice $T^* = 10$ minutes were not discussed in [13] and [14]. In Figure 6, we study how our system reacts to the choice of T^* if $K_{deg} = 0$. It is found that the evolution of $[LR]$ at the dorsal midline becomes monotone, unlike the case in Figure 3, and as expected, the time to reach steady states strongly depends on the choice of T^*. In Figure 6, the steady states for $[LR]$ are shown for $T^* = 5, 8, 10, 12, 15, 20, 30, 45, 60$ minutes. The concentration of $[LR]$ varies almost linearly with respect to T^* until the receptors are close to being fully occupied when T^* is large.

Finally, we investigate the effect of diffusion. In Figure 7, Dpp-receptor complexes as functions of time and space are shown for five different choices of diffusion constants. Case (a) has all three diffusion constants the same as in Figure 3, cases (b)–(d) have one of the diffusion constants being 1% of the corresponding value in case (a), and the case (e) has two constants at 1% of the corresponding values in case (a). Similarly in Figure 8, some of the diffusion constants are 10-fold larger than others.

As shown in case (b) of both Figures 7 and 8, the magnitude of the diffusion coefficient for Dpp has very little effect on the broadness and intensity of Dpp activity at the dorsal midline. This is consistent with the behavior of the leading term perturbation solution. A larger diffusion for Dpp reduces the peak of transient Dpp-activity at the midline slightly and broadens it slightly. On the other hand, a decrease in diffusion constant for Dpp-Sog complexes, as in cases (d) and (e), significantly broad-

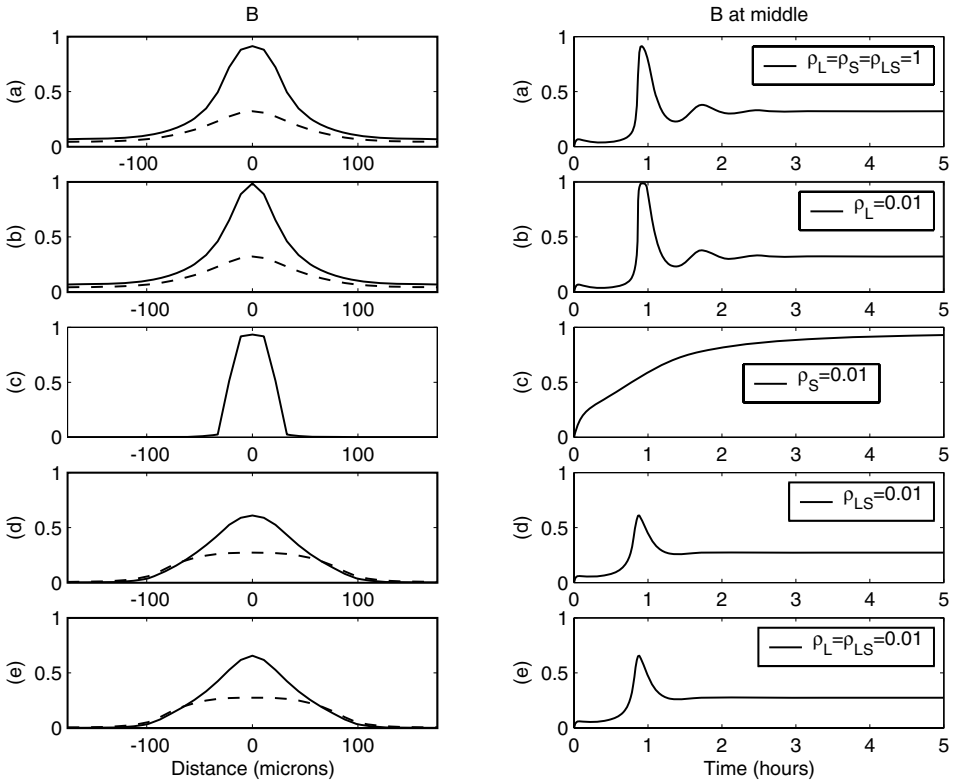

FIG. 7. *Effect of smaller diffusion constants on the transient peak and steady state. For the left-hand panels, solid line: transient peak; dotted line: steady state. Parameters are as in Figure* 3 *except for diffusion constants.*

ens the Dpp activity around the midline for both peak transient and steady state distributions, with the height of only the transient peak reduced significantly but with almost the same steady state at $x = 0$. The time to steady state and transient peaks seems to be insensitive to the change of the diffusion constants for Dpp or the Dpp-Sog complex.

As predicted by the perturbation solutions, varying the diffusion coefficient for Sog changes the Dpp activity around the dorsal midline significantly. As shown in Figure 7(c), a smaller diffusion of Sog relative to the diffusion of Dpp leads to more concentrated transient Dpp activity around the dorsal midline, but it takes much longer to reach the steady state, with a monotone increase of Dpp activity around the dorsal midline (i.e., there is no transient peak). On the other hand, larger diffusion of Sog relative to the diffusion of Dpp weakens and broadens the Dpp activity, as in Figure 8(c).

6. Conclusions. The dynamics of Dpp activities in the presence of the inhibitor Sog is analyzed herein to initiate a study of dorsal-ventral morphogen gradient formation in vertebrates and *Drosophila* embryos. Here we investigate a prototype morphogen system with typical ligand diffusion and degradation, but now with the additional feature of cleavage of Dpp-Sog complexes by Tolloid to free up Dpp.Among

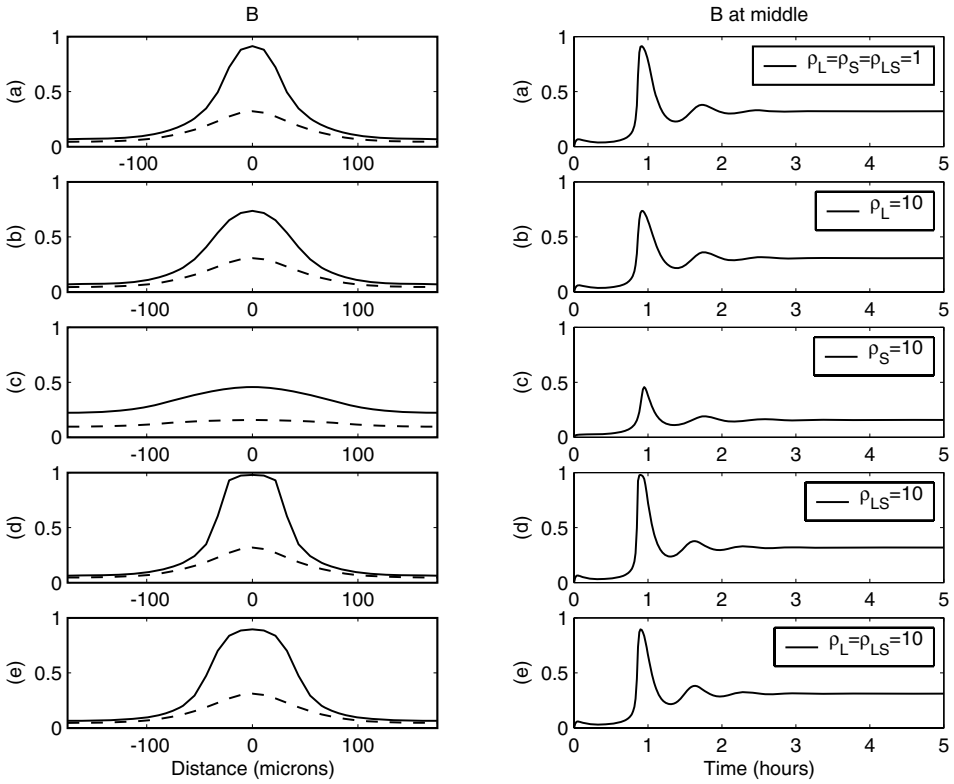

FIG. 8. *Effect of larger diffusion constants on the transient peak and steady state. For the left-hand panels, solid line: transient peak; dotted line: steady state. Parameters are as in Figure* 3 *except for diffusion constants.*

the principal results of our investigation is the establishment of a simple and biologically meaningful necessary and sufficient condition for the existence of a steady state gradient in the system. This condition requires a balance of the production rates of ligands, degradation rate of ligand-receptor complex, and rate of cleavage of ligand-inhibitor complex. For high Sog production rates (relative to the Dpp production rate), a perturbation solution has been obtained in terms of elementary functions. This solution exhibits an intense Dpp-receptor concentration near the dorsal midline. Numerical simulations of the *evolution* of the system confirmed these features of the steady state behavior. In addition, a transient peak of Dpp-receptor concentration at the dorsal midline was found to be even more intense prior to steady state, reaching more than twice the level of the steady state at its peak amount. This transient peak is more sensitively dependent on variation of the production of Sog than the steady state peak. The high Dpp-receptor concentration around the dorsal midline and other features of the system are consistent with experimental observations.

Appendix A.

Proof of Lemma 3.4. We show that there exists $M_1 > 0$ such that $\|\tilde{C}\|_{L^\infty} \leq M_1$. As in the proof of Lemma 3.3, $\|\tilde{C}\|_{L^1} \leq M_2$ for some constant $M_2 > 0$. Integrating

(27) in $(-1,1)$, we get

$$\int_{-1}^{1} h_{LS}\tilde{A}\tilde{D} = \int_{-1}^{1} (f_{LS}+g_{LS})\tilde{C}, \tag{56}$$

which implies that $\int_{-1}^{1}\tilde{A}\tilde{D} \le M_3\int_{-1}^{1}\tilde{C} \le M_2M_3$ for some $M_3>0$. Integrating (27) from -1 to x, we get

$$\rho_{LS}\tilde{C}_{,x} + \lambda\int_{-1}^{x}[h_{LS}\tilde{A}\tilde{D} - (f_{LS}+g_{LS})\tilde{C}] = 0, \quad -1<x<1. \tag{57}$$

Hence

$$\rho_{LS}\|\tilde{C}_{,x}\|_{L^\infty} \le \|h_{LS}\|_{L^\infty}\int_{-1}^{1}\tilde{A}\tilde{D} + \|f_{LS}+g_{LS}\|_{L^\infty}\int_{-1}^{1}\tilde{C} \le M_4 \tag{58}$$

for some constant $M_4>0$. This along with $\int_{-1}^{1}\tilde{C}\le M_2$ implies the L^∞ bound of $\tilde{C}$, which is independent of λ.

Next we show that there exists some constant $M_5>0$ such that $\|\tilde{A}\|_{L^\infty}\le M_5$. To this end, adding up (26) and (27) and integrating from -1 to x, we get

$$\rho_L\tilde{A}_{,x} + \rho_{LS}\tilde{C}_{,x} = \lambda\int_{-1}^{x}\left[\frac{g_Lh_L\tilde{A}}{f_L+g_L+h_L\tilde{A}} + (1-\tau)g_{LS}\tilde{C} - V_L\right], \tag{59}$$

which implies that

$$\|\tilde{A}_{,x}\|_{L^\infty} \le M_6\left(\|\tilde{C}_{,x}\|_{L^\infty} + \|g_L\|_{L^\infty} + \|\rho_{LS}\|_{L^\infty}\int_{-1}^{1}\tilde{C} + \|V_L\|_{L^\infty}\right) := M_7. \tag{60}$$

We claim that there exists some constant $M_8>0$ such that $\int_{-1}^{1}\tilde{A}\le M_8$. To establish this assertion, we argue by contradiction: if not, passing to a subsequence if necessary, we may assume that $\int_{-1}^{1}\tilde{A}\to+\infty$. This together with (60) implies that

$$\left|\frac{\tilde{A}(x)}{\int_{-1}^{1}\tilde{A}} - 1\right| \le \frac{\|\tilde{A}_{,x}\|_{L^\infty}}{\int_{-1}^{1}\tilde{A}} \le \frac{M_7}{\int_{-1}^{1}\tilde{A}} \to 0 \qquad \forall -1\le x\le 1. \tag{61}$$

Hence $\tilde{A}\to+\infty$ uniformly. Similar to (24) we have

$$\int_{-1}^{1} V_L = \int_{-1}^{1}\frac{g_Lh_L\tilde{A}}{f_L+g_L+h_L\tilde{A}} + (1-\tau)\int_{-1}^{1} V_S. \tag{62}$$

By (61) we have $\int_{-1}^{1}\frac{g_Lh_L\tilde{A}}{f_L+g_L+h_L\tilde{A}}\to\int_{-1}^{1}g_L$, which together with (62) implies that $\int_{-1}^{1}V_L = \int_{-1}^{1}g_L + (1-\tau)\int_{-1}^{1}V_S$. However, this contradicts (21). Therefore $\int_{-1}^{1}\tilde{A}$ is uniformly bounded for $\lambda\in(0,1]$. This together with (60) yields $\|\tilde{A}\|_{L^\infty}\le M_5$ for some $M_5>0$.

Finally we show that there exists some constant $M_9>0$ such that $\|\tilde{D}\|_{L^\infty}\le M_9$. We argue by contradiction: suppose not; passing to a subsequence if necessary, we may assume that $\|\tilde{D}\|_{L^\infty}\to\infty$ and $\lambda\to\hat{\lambda}\in[0,1]$. Set $\hat{D}(x) = \frac{\tilde{D}(x)}{\|\tilde{D}\|_{L^\infty}}$.Then $\hat{D}$

satisfies $\hat{D}_{,x}(-1) = \hat{D}_{,x}(1) = 0$, $\|\hat{D}\|_{L^\infty} = 1$, and

$$\rho_{LS}\hat{D}_{,xx} + \lambda\left[-h_{LS}\tilde{A}\hat{D} + \frac{f_{LS}\tilde{C} + V_S}{\|\hat{D}\|_{L^\infty}}\right] = 0, \quad -1 < x < 1. \tag{63}$$

Since $\|\tilde{A}\|_{L^\infty}$, $\|\tilde{A}_{,x}\|_{L^\infty}$ are uniformly bounded, we may assume that $\tilde{A}(x) \to A^*(x)$ uniformly in $[-1,1]$. From (62) and (20) we see $\int_{-1}^{1}\tilde{A} \geq M_{10} > 0$ for some constant M_{10}. Hence $A^* \not\equiv 0$ since $\int_{-1}^{1} A^* \geq M_{10} > 0$. By standard regularity theory we may assume that $\hat{D}(x) \to D^*(x)$ in $C^1[-1,1]$, and D^* is a weak solution of

$$\rho_{LS}D^*_{,xx} - \hat{\lambda}h_{LS}A^*D^* = 0, \quad -1 < x < 1, \quad D^*_{,x}(-1) = D^*_{,x}(1) = 0. \tag{64}$$

Moreover, $D^* \geq 0$ in $[-1,1]$ and $\|D^*\|_{L^\infty} = 1$. If $\hat{\lambda} > 0$, since $A^* \not\equiv 0$, $A^* \geq 0$, by the maximum principle we see that $D^* \equiv 0$, which contradicts $\|D^*\|_{L^\infty} = 1$; if $\hat{\lambda} = 0$, then it follows from (64) that $D^* \equiv 1$, i.e., $\hat{D}(x) \to 1$ uniformly. Dividing (56) by $\|\tilde{D}\|_{L^\infty}$, we have $\int_{-1}^{1} h_{LS}\tilde{A}\hat{D} = \int_{-1}^{1}(f_{LS} + g_{LS})\tilde{C}/\|\tilde{D}\|_{L^\infty}$. Then we obtain $\int_{-1}^{1} h_{LS}A^* = 0$, which implies that $A^* \equiv 0$. Contradiction! This completes the proof of (34). ∎

When $\lambda = 0$, $(\tilde{A}, \tilde{C}, \tilde{D})$ is a solution of (26)–(29) if and only if $\tilde{A}, \tilde{C}$, and $\tilde{D}$ are all constants. It turns out that a particular triple, denoted by $(\hat{A}, \hat{C}, \hat{D})$, is special, where $\hat{A}, \hat{C}, \hat{D}$ are defined as follows: by (20)–(21) it is easy to see that there is a unique positive constant, denoted by $\hat{A}$, such that

$$\int_{-1}^{1} \frac{g_L h_L \hat{A}}{f_L + g_L + h_L\hat{A}} = \int_{-1}^{1} V_L - (1-\tau)\int_{-1}^{1} V_S. \tag{65}$$

Set

$$\hat{D} = \frac{\int_{-1}^{1}(f_{LS} + g_{LS})\int_{-1}^{1} V_S}{\hat{A}\int_{-1}^{1} h_{LS}\int_{-1}^{1} g_{LS}}, \qquad \hat{C} = \frac{\int_{-1}^{1} V_S}{\int_{-1}^{1} g_{LS}}. \tag{66}$$

LEMMA A.1. *Suppose that* (20)–(21) *holds. Let* $(A_\lambda, C_\lambda, D_\lambda)$ *denote positive solutions of* (26)–(29). *Then as* $\lambda \to 0+$, $(A_\lambda, C_\lambda, D_\lambda) \to (\hat{A}, \hat{C}, \hat{D})$ *uniformly.*

Proof. By Lemma 3.4, $(A_\lambda, C_\lambda, D_\lambda)$ are uniformly bounded. By standard regularity theory and the embedding theorem, passing to a subsequence if necessary, we may assume that $(A_\lambda, C_\lambda, D_\lambda) \to (\overline{A}, \overline{C}, \overline{D})$ uniformly, where $\overline{A}$, $\overline{C}$, and $\overline{D}$ satisfy $\overline{A}_{xx} = \overline{C}_{xx} = \overline{D}_{xx} = 0$, and $\overline{A}_x = \overline{C}_x = \overline{D}_x = 0$ at $x = -1, 1$. Therefore $\overline{A}$, $\overline{C}$, $\overline{D}$ are all nonnegative constants. Passing to the limit in (62) (with $\tilde{A}$ being replaced by A_λ), we have $\overline{A} = \hat{A}$. Similarly we can show that $\hat{C} = \overline{C}$ and $\hat{D} = \overline{D}$. Since the limit $(\hat{A}, \hat{C}, \hat{D})$ is unique, the convergence $(A_\lambda, C_\lambda, D_\lambda) \to (\hat{A}, \hat{C}, \hat{D})$ is true for the whole sequence, and the limit is uniform in x. ∎

LEMMA A.2. *There exists some constant* $\delta_1 > 0$ *such that if* $0 < \lambda \leq \delta_1$, (26)–(29) *has a unique positive solution.*

Proof. Set $X = \{u \in C[-1,1] : \int_{-1}^{1} u(x)\,dx = 0\}$, $Z = \{u \in X : u_{,x}(-1) = u_{,x}(1) = 0\}$, and define the projection operator $P : C[-1,1] \to X$ by $Pu = u - \int_{-1}^{1} u(x)\,dx$. For $(\lambda, A_0, a_0, C_0, c_0, D_0, d_0) \in R^1 \times (Z \times R^1)^3$, define $F : R^1 \times (Z \times$

$R^1)^3 \to (X \times R^1)^3$ by

(67)
$$F(\lambda, A_0, a_0, C_0, c_0, D_0, d_0) = \begin{pmatrix} \rho_L A_{0,xx} + \lambda P F_1^+(x, A_0 + a_0, C_0 + c_0, D_0 + d_0) \\ \int_{-1}^1 F_1^+(x, A_0 + a_0, C_0 + c_0, D_0 + d_0)\, dx \\ \rho_{LS} C_{0,xx} + \lambda P F_2(x, A_0 + a_0, C_0 + c_0, D_0 + d_0) \\ \int_{-1}^1 F_2(x, A_0 + a_0, C_0 + c_0, D_0 + d_0)\, dx \\ \rho_S D_{0,xx} + \lambda P F_3(x, A_0 + a_0, C_0 + c_0, D_0 + d_0) \\ \int_{-1}^1 F_3(x, A_0 + a_0, C_0 + c_0, D_0 + d_0)\, dx \end{pmatrix}.$$

By the definition of $\hat{A}$, $\hat{C}$, $\hat{D}$, $F(0, \hat{A}, \hat{C}, \hat{D}, 0, 0, 0) = (0, 0, 0, 0, 0, 0)$. The Fréchet derivative of F with respect to $(A_0, a_0, C_0, c_0, D_0, d_0)$ at $(\lambda, A_0, a_0, C_0, c_0, D_0, d_0) = (0, \hat{A}, 0, \hat{C}, 0, \hat{D}, 0)$ is given by

(68)
$$D_{(A_0,a_0,C_0,c_0,D_0,d_0)} F\big|_{(0,\hat{A},0,\hat{C},0,\hat{D},0)} = \begin{pmatrix} \rho_L \frac{d^2}{dx^2} & 0 & 0 & 0 & 0 & 0 \\ 0 & \rho_{LS} \frac{d^2}{dx^2} & 0 & 0 & 0 & 0 \\ 0 & 0 & \rho_S \frac{d^2}{dx^2} & 0 & 0 & 0 \\ * & * & * & & & \\ * & * & * & M_{3\times 3} & & \\ * & * & * & & & \end{pmatrix},$$

where $M_{3\times 3}$ is the 3×3 matrix

(69)
$$\begin{pmatrix} \int_{-1}^1 \left[\frac{-g_L h_L (f_L + g_L)}{(f_L + g_L + h_L \hat{A})^2} - h_{LS} \hat{D} \right] & \int_{-1}^1 (f_{LS} + \tau g_{LS}) & -(\int_{-1}^1 h_{LS}) \hat{A} \\ (\int_{-1}^1 h_{LS}) \hat{D} & -\int_{-1}^1 (f_{LS} + g_{LS}) & (\int_{-1}^1 h_{LS}) \hat{A} \\ -(\int_{-1}^1 h_{LS}) \hat{D} & \int_{-1}^1 f_{LS} & -(\int_{-1}^1 h_{LS}) \hat{A} \end{pmatrix}.$$

Since the operator $\frac{d^2}{dx^2}$, subject to the no flux boundary condition, is an isomorphism from Z to X, we see that the operator $D_{(A_0,a_0,C_0,c_0,D_0,d_0)} F\big|_{(0,\hat{A},0,\hat{C},0,\hat{D},0)}$ is invertible from $(Z \times R^1)^3$ to $(X \times R^1)^3$ if and only if the matrix $M_{3\times 3}$ is invertible. It is straightforward to check that the determinant of $M_{3\times 3}$ is equal to

(70)
$$\left(\int_{-1}^1 h_{LS} \right) \hat{D} \cdot \int_{-1}^1 (f_{LS} + g_{LS}) \cdot \left(\int_{-1}^1 h_{LS} \right) \hat{A}\, (1 - \gamma_2)(-\gamma_1),$$

where γ_1, γ_2 are defined as

(71)
$$\gamma_1 = \frac{\int_{-1}^1 \frac{g_L h_L (f_L + g_L)}{(f_L + g_L + h_L \hat{A})^2}}{\left(\int_{-1}^1 h_{LS} \right) \hat{D}}, \qquad \gamma_2 = \frac{\int_{-1}^1 f_{LS}}{\int_{-1}^1 (f_{LS} + g_{LS})}.$$

Since $\gamma_1 > 0$ and $0 < \gamma_2 < 1$, $M_{3\times 3}$ is nondegenerate.

By the implicit function theorem, there exists $\delta_2 > 0$ such that if $0 < \lambda \le \delta_2$, there is a unique solution to $F = 0$, denoted by $(A_\lambda(x), a_\lambda(x), C_\lambda(x), c_\lambda(x), D_\lambda(x), d_\lambda(x))$, in some neighborhood of $(\hat{A}, 0, \hat{C}, 0, \hat{D}, 0)$. As $\lambda \to 0+$, $(A_\lambda, a_\lambda, C_\lambda, c_\lambda, D_\lambda, d_\lambda) \to (\hat{A}, 0, \hat{C}, 0, \hat{D}, 0)$ uniformly. In particular, for $0 < \lambda \le \delta_2$, $(A_\lambda + a_\lambda, C_\lambda + c_\lambda, D_\lambda + d_\lambda)$ is the unique positive solution of (26)–(29) in some neighborhood of $(\hat{A}, \hat{C}, \hat{D})$. This and Lemma A.1 imply that, for $0 < \lambda \ll 1$, (26)–(29) has a unique positive solution. ∎

LEMMA A.3. *Let (A^*, C^*, D^*) denote the unique positive solution of* (26)–(29) *for $0 < \lambda \ll 1$. Then for $0 < \lambda \ll 1$, the Fréchet derivative of $T(\lambda)$ with respect to $(\tilde{A}, \tilde{C}, \tilde{D})$ at (A^*, C^*, D^*), denoted by $D_{(\tilde{A},\tilde{C},\tilde{D})}T(\lambda)\big|_{(A^*,C^*,D^*)}$, has no eigenvalue greater than or equal to* 1.

Proof. By (35), $D_{(\tilde{A},\tilde{C},\tilde{D})}T(\lambda)\big|_{(A^*,C^*,D^*)}(\varphi_1, \varphi_2, \varphi_3)$ is given by

$$\begin{pmatrix} L_{\rho_L}^{-1}\Big\{\Big[1 + \lambda\frac{\partial F_1}{\partial \tilde{A}}(x, A^*, C^*, D^*)\Big]\varphi_1 + \lambda\frac{\partial F_1}{\partial \tilde{C}}\varphi_2 + \lambda\frac{\partial F_1}{\partial \tilde{D}}\varphi_3\Big\} \\ L_{\rho_{LS}}^{-1}\Big\{\lambda\frac{\partial F_2}{\partial \tilde{A}}\varphi_1 + \Big[1 + \lambda\frac{\partial F_2}{\partial \tilde{C}}\Big]\varphi_2 + \lambda\frac{\partial F_2}{\partial \tilde{D}}\varphi_3\Big\} \\ L_{\rho_S}^{-1}\Big\{\lambda\frac{\partial F_3}{\partial \tilde{A}}\varphi_1 + \lambda\frac{\partial F_3}{\partial \tilde{C}}\varphi_2 + \Big[\lambda\frac{\partial F_3}{\partial \tilde{D}} + 1\Big]\varphi_3\Big\} \end{pmatrix},$$

where $\frac{\partial F_i}{\partial \tilde{A}}$, $\frac{\partial F_i}{\partial \tilde{C}}$, $\frac{\partial F_i}{\partial \tilde{D}}$ $(i = 1, 2, 3)$ are evaluated at (x, A^*, C^*, D^*).

We argue by contradiction: suppose that Lemma A.3 fails. Passing to a subsequence if necessary, we may assume that for $0 < \lambda \ll 1$ the operator $D_{(\tilde{A},\tilde{C},\tilde{D})}T(\lambda)|_{(A^*,C^*,D^*)}$ has eigenvalue $\mu = \mu(\lambda) \ge 1$, with the corresponding eigenfunction $(\varphi_1, \varphi_2, \varphi_3)$ normalized by $\|\varphi_1\|_{L^\infty} + \|\varphi_2\|_{L^\infty} + \|\varphi_3\|_{L^\infty} = 1$. Then $(\varphi_1, \varphi_2, \varphi_3)$ satisfies

$$-\mu\rho_L\frac{d^2\varphi_1}{dx^2} + (\mu - 1)\varphi_1 = \lambda\left[\frac{\partial F_1}{\partial \tilde{A}}\varphi_1 + \frac{\partial F_1}{\partial \tilde{C}}\varphi_2 + \frac{\partial F_1}{\partial \tilde{D}}\varphi_3\right], \tag{72}$$

$$-\mu\rho_{LS}\frac{d^2\varphi_2}{dx^2} + (\mu - 1)\varphi_2 = \lambda\left[\frac{\partial F_2}{\partial \tilde{A}}\varphi_1 + \frac{\partial F_2}{\partial \tilde{C}}\varphi_2 + \frac{\partial F_2}{\partial \tilde{D}}\varphi_3\right], \tag{73}$$

$$-\mu\rho_S\frac{d^2\varphi_3}{dx^2} + (\mu - 1)\varphi_3 = \lambda\left[\frac{\partial F_3}{\partial \tilde{A}}\varphi_1 + \frac{\partial F_3}{\partial \tilde{C}}\varphi_2 + \frac{\partial F_3}{\partial \tilde{D}}\varphi_3\right], \tag{74}$$

$$(\varphi_1)_{,x} = (\varphi_2)_{,x} = (\varphi_3)_{,x} = 0 \quad \text{at } x = -1, 1, \tag{75}$$

where $\frac{\partial F_i}{\partial \tilde{A}}$, $\frac{\partial F_i}{\partial \tilde{C}}$, $\frac{\partial F_i}{\partial \tilde{D}}$ $(i = 1, 2, 3)$ in (72)–(74) are evaluated at $(\tilde{A}, \tilde{C}, \tilde{D}) = (A^*, C^*, D^*)$.

It is easy to see that $\mu(\lambda) \to 1$ as $\lambda \to 0+$, and the corresponding eigenfunctions $(\varphi_1, \varphi_2, \varphi_3) \to (\overline{\varphi}_1, \overline{\varphi}_2, \overline{\varphi}_3)$ uniformly, where $(\overline{\varphi}_1, \overline{\varphi}_2, \overline{\varphi}_3)$ are constants satisfying $|\overline{\varphi}_1| + |\overline{\varphi}_2| + |\overline{\varphi}_3| = 1$. Set $\mu(\lambda) = 1 + \lambda\mu_1(\lambda)$. Since $\mu(\lambda) \ge 1$, we have $\mu_1(\lambda) \ge 0$. Integrating (72)–(74), we get

$$\int_{-1}^{1}\left[\frac{\partial F_1}{\partial \tilde{A}} - \mu_1\right]\varphi_1 + \int_{-1}^{1}\frac{\partial F_1}{\partial \tilde{C}}\varphi_2 + \int_{-1}^{1}\frac{\partial F_1}{\partial \tilde{D}}\varphi_3 = 0, \tag{76}$$

$$\int_{-1}^{1} \frac{\partial F_2}{\partial \tilde{A}}\varphi_1 + \int_{-1}^{1} \left[\frac{\partial F_2}{\partial \tilde{C}} - \mu_1\right]\varphi_2 + \int_{-1}^{1} \frac{\partial F_2}{\partial \tilde{D}}\varphi_3 = 0, \tag{77}$$

$$\int_{-1}^{1} \frac{\partial F_3}{\partial \tilde{A}}\varphi_1 + \int_{-1}^{1} \frac{\partial F_3}{\partial \tilde{C}}\varphi_2 + \int_{-1}^{1} \left[\frac{\partial F_3}{\partial \tilde{D}} - \mu_1\right]\varphi_3 = 0. \tag{78}$$

We first prove that $\mu_1(\lambda)$ is uniformly bounded for all $0 < \lambda \ll 1$. If not, passing to a subsequence if necessary, we may assume that as $\lambda \to 0+$, $\mu_1(\lambda) \to +\infty$. Divide (76) by μ_1; passing to the limit, we find that $\overline{\varphi}_1 = 0$. Similarly, $\overline{\varphi}_2 = \overline{\varphi}_3 = 0$. However, this contradicts $|\overline{\varphi}_1| + |\varphi_2| + |\overline{\varphi}_3| = 1$. Therefore $\mu_1(\lambda)$ is nonnegative and uniformly bounded. Passing to a subsequence if necessary, we may assume that $\mu_1(\lambda) \to \overline{\mu}_1 \geq 0$ as $\lambda \to 0+$.

Passing to the limit in (76)–(78), by Lemma A.1, $(M_{3\times 3} - \overline{\mu}_1 I_{3\times 3})(\overline{\varphi}_1, \overline{\varphi}_2, \overline{\varphi}_3) = (0,0,0)$. Since $(\overline{\varphi}_1, \overline{\varphi}_2, \overline{\varphi}_3) \neq (0,0,0)$, $|M_{3\times 3} - \overline{\mu}_1 I_{3\times 3}| = 0$. However, direct calculation yields that $|M_{3\times 3} - \overline{\mu}_1 I_{3\times 3}|$ is equal to

$$\begin{aligned}
&- \left(\int_{-1}^{1} h_{LS}\right)\hat{D} \cdot \int_{0}^{1} (f_{LS} + g_{LS}) \cdot \left(\int_{-1}^{1} h_{LS}\right)\hat{A} \\
&\cdot \left\{ \left(\gamma_1 + \frac{\overline{\mu}_1}{(\int_{-1}^{1} h_{LS})\hat{D}}\right) \cdot \left(1 + \frac{\overline{\mu}_1}{\int_{-1}^{1}(f_{LS} + g_{LS})}\right) \cdot \frac{\overline{\mu}_1}{(\int_{-1}^{1} h_{LS})\hat{A}} \right. \\
&\quad + \left[(1-\tau)(1-\gamma_2) + \frac{\overline{\mu}_1}{\int_{-1}^{1}(f_{LS} + g_{LS})}\right] \cdot \frac{\overline{\mu}_1}{\int_{-1}^{1} h_{LS}\hat{A}} \\
&\quad \left. + \left(\gamma_1 + \frac{\overline{\mu}_1}{(\int_{-1}^{1} h_{LS})\hat{D}}\right) \cdot \left(1 - \gamma_2 + \frac{\overline{\mu}_1}{\int_{-1}^{1}(f_{LS} + g_{LS})}\right) \right\},
\end{aligned}$$

which is negative since $\overline{\mu}_1 \geq 0$, $\gamma_1 > 0$, $0 \leq \tau \leq 1$, and $\gamma_2 < 1$. Contradiction! This completes the proof of Lemma A.3. ∎

Proof of Proposition 3.5. By Lemma A.2, for $0 < \lambda \ll 1$, $T(\lambda)$ has a unique fixed point. By Lemma A.3, 1 is not an eigenvalue of $D_{(\tilde{A},\tilde{C},\tilde{D})}T(\lambda)|_{(A^*,C^*,D^*)}$. Hence $\deg\big(I - T(\lambda),\ \Omega,\ (0,0,0)\big) = (-1)^{\beta}$, where β is the number of eigenvalues (counting algebraic multiplicity) of $D_{(\tilde{A},\tilde{C},\tilde{D})}T(\lambda)|_{(A^*,C^*,D^*)}$, which is greater than 1. By Lemma A.3 we see that $\beta = 0$. Hence $\deg(I - T(\lambda), \Omega, (0,0,0)) = 1$ for $0 < \lambda \ll 1$. ∎

ASYMPTOTIC BEHAVIOR OF INTERNAL ROSSBY WAVES WITH A SHARP DENSITY INTERFACE*

A. OUAHSINE† AND P. A. BOIS‡

Abstract. An asymptotic analysis of a quasi-geostrophic model is presented to investigate the vertically propagating internal Rossby wave structure in the presence of a sharp density interface. For the case of a nonconstant density gradient, the pattern of the vertical structure is nontrivial and depends on the parameter of varying stratification, denoted by δ. As this parameter approaches a critical value from above (i.e., $\delta \approx \delta_{cri}$), the internal wave amplitudes increase continually until wave breaking occurs. When $\delta < \delta_{cri}$, two cases are considered. For the case without a turning-point, the requirement of appropriate interfacial conditions provides a general matching solution, available only for a certain range of δ. In the presence of a turning-point, which describes the solution transition from monotonic to oscillatory behavior or vice versa, three asymptotic forms of the solutions are derived, even for small values of δ.

Key words. asymptotic matching, internal waves, ocean waves, turning-points

1. Introduction.

Internal waves are long waves, with large amplitudes within several kilometers, which are generally produced in the upper layer of the sea surface by tidal fluctuations, differences of density, and atmospheric conditions. Internal waves increase the sea surface current and create a stormy current, which affects fishing grounds, en route vessels, rigs, etc. They may generate slowly varying local currents in open ocean or in fjords. Such induced currents are important factors to be considered when determining the dimensions of offshore platforms operating in deep water areas where internal waves might occur.

When there is a vertical density gradient with a thin density interface, the internal waves can be limited in their spectral density by sporadic local instabilities, and when the waves break, they produce turbulence (Fernando and Hunt [1] and Hannan, Fernando, and List [4]). This process produces a turbulent mixing between fluids of different densities, leading to the overturning of waves by static instability. In environmental fluid mechanics, an understanding of these mixing processes is essential in determining water quality and also the physical properties and concentrations of chemical and biological constituents in the well-mixed layers.

Thus, there is a general need for mathematical models of large-amplitude internal waves propagating along an arbitrary pycnocline or thermocline. In this paper we present an analytical study, to deal with this kind of wave when the density is a continuous function of depth in the presence of a very sharp gradient, taking viscous dissipation into account.

Several attempts have been made to investigate internal waves with respect to the interfacial thickness. Smith and Vallis [2] have presented work on using freely

decaying geostrophic turbulence to understand and explain the vertical and horizontal flow of energy through a stratified horizontally homogeneous geostrophic fluid. They found that the stratification profile, in particular the presence of a pycnocline, has significant qualitative effects on the efficiency and spectral pathways of energy flow. With uniform stratification, energy in high baroclinic modes transfers directly and almost completely to barotropic mode. In contrast, in the presence of ocean-like stratification, kinetic energy in high baroclinic modes transfers intermediately to the first baroclinic mode, whence it transfers inefficiently to the barotropic mode. The efficiency of transfer to the barotropic mode is reduced as the pycnocline is made increasingly thin.

In his theoretical study, Phillips [5] investigated the degradation of the first internal wave mode and considered the possible occurrence of a dynamic instability in the thermocline where the rate of shear U induced by internal waves reaches its maximum. He postulated the possibility of the occurrence of similar interfacial instabilities when the local gradient Richardson number $R_i = \Delta b L/U^2 < \frac{1}{4}$ for the case of the first internal wave mode at a sharp density interface, where Δb is the characteristic buoyancy jump and L is the characteristic length scale. He added that if the energy supply to the internal wave mode continues after the above limiting condition is reached, a local instability may develop. The possibility of such an instability occurring will be investigated in our study.

Thus, in this paper, in place of R_i we reorganize a critical value of the parameter of varying stratification, namely δ. With further decreases in δ, we deal with a sharp density interface, and hence with the generation of waves that grow until they break and overturn.

The possibility of exponential growth of internal wave amplitudes in horizontally inhomogeneous layers has been suggested by Navrotsky and Simonenko [16] and Navrotsky [17]. They have analyzed the propagation of weakly nonlinear internal waves with slowly varying amplitudes (compared to the wave period) in a layer with a horizontal gradient of buoyancy frequency $dN(z,x)/dx$. They showed that such waves could produce effective mixing within the thermocline. The horizontal variation of the vertical density gradient favorable for the amplification of high-frequency propagating waves can be developed through the deformation of the density field by long topographic or tidal internal waves.

In this analysis, we discuss a linear analysis for deriving the growth rate of the wave amplitude. The instability described here can be interpreted as a criterion in which the wave amplitude grows, according to the parameter δ (see Figure 3.2), to a level such that δ drops below a critical value; then the disturbances can grow exponentially, whence the primary wave amplitude exceeds a certain limiting value to such an extent that an effective discontinuity or front may develop (Basovich and Tsimring [3] and Badulin, Shrira, and Tsimring [6]).

The structure of this paper is as follows. In section 2 equations of motion with continuous density with variable gradient stratification are introduced. The mathematical problem with the asymptotic analysis is formulated, and the method of solving it is discussed. Section 3 considers the development of the solution as the characteristic scale of varying stratification decreases. Section 4 is devoted to the study of the three-layer discontinuous gradient model and to giving stable solutions in the case of the existence of turning-points. Section 5 extends this theory to seek stable solutions in the case of no turning-points. Observational evidence of large-amplitude internal waves and discussions are presented in section 6. Section 7 concludes the paper.

2. Equations of motion and formulation of the problem. The set of dimensionless equations of incompressible stratified fluid dynamics can be written in the Boussinesq approximation in a rotating flow (Ouahsine [8] and Bois [10]) as

$$\begin{aligned} \varrho\left(Ro\left(St\frac{\partial \mathbf{v}}{\partial t}+\mathbf{v}.\mathbf{D}\mathbf{v}+w\frac{\partial \mathbf{v}}{\partial z}\right)+(1+Ro\beta y)k\wedge\mathbf{v}\right)+\frac{Ro}{Fr^2}\mathbf{D}p &= E_v\frac{\partial^2\mathbf{v}}{\partial z^2}+E_h\mathbf{D}^2\mathbf{v},\\ \frac{\partial p}{\partial z}+Bo\varrho &= 0,\\ \mathbf{D}.\mathbf{v}+\frac{\partial w}{\partial z} &= 0,\\ St\frac{\partial \varrho}{\partial t}+\mathbf{v}.\mathbf{D}\varrho+\mathbf{w}\frac{\partial \rho}{\partial z} &= 0. \end{aligned} \tag{2.1}$$

These equations are valid for long wave motions, say $\gamma = H/L \ll 1$, where L and H are the horizontal and vertical characteristic scales, respectively, under the Boussinesq approximation (Pedlosky [12]) and the hydrostatic balance assumptions. Vectors $(\mathbf{i},\mathbf{j},\mathbf{k})$ are unit vectors eastwards, northwards, and locally upwards; $\mathbf{D} = (\partial/\partial x\,,\ \partial/\partial y)$ is the horizontal gradient; t is the time; p is the pressure; and $\beta = (L^2/U)\,(df_0/dy)_{y=0}$ is the beta-plane parameter, where $f_0 = 2\Omega\sin\lambda_0$ is the local Coriolis parameter, λ_0 is the latitude, $\Omega = 7.3\ 10^{-5}$ rad/s is the Earth's rotation, and a_0 is the Earth's radius. Additionally, $\mathbf{v}$ is the horizontal velocity vector (with eastward and northward components u and v), and w is the vertical velocity.

Let $T_0, U_0, \varrho_{00}, \Pi$ be the characteristic scales for time t, for the horizontal velocity (u,v), for the density ϱ, and for the pressure p, respectively. The nondimensional parameters appearing in these equations are the Rossby number $Ro = U_0/f_0L$, the Froude number $Fr = U_0/\sqrt{gH}$, the Strouhal number $St = L/U_0T_0$, the number $Bo = \varrho_{00}gH/\Pi$, and the Ekman numbers for vertical and horizontal kinematics viscosities, respectively $E_v = \nu/f_0H^2$ and $E_h = \nu/f_0L^2$.

The boundary conditions at the bottom (on $z=-1$) are $\mathbf{v}=\mathbf{0}$ and $w=0$, and the initial conditions (at $t=0$) are $\mathbf{v}=\mathbf{v}^0$ and $p=p^0$, where $\mathbf{v}^0$ and p^0 are known.

We assume that, at the sea surface (on $z=0$), the steady state motion is driven by the surface wind stress $[\tau]_w$. It follows that the stress continuity at the ocean-atmosphere interface may be given by (Gill [11])

$$[\tau]_i = [-p\mathbf{n}I_d + 2\mu\mathbf{n}D]_i \quad \text{and} \quad p = p_a, \tag{2.2}$$

where $\mathbf{n}$ is the unit normal vector to the interface, D is the symmetric part of the deformation rate tensor, μ is the eddy viscosity, I_d is the unit vector tensor, and p_a is the atmospheric pressure. The bracket $[u]_i$ denotes the jump of the function u across the interface i. This last condition leads to the following surface boundary condition:

$$\left[-p+2\mu\frac{U}{L}\frac{\partial w}{\partial z}\right]_i = 0, \qquad \left[\mu\frac{U}{L}\frac{\partial \mathbf{v}}{\partial z}\right]_i = 0. \tag{2.3}$$

As the parameters Ro, E_v, E_h, and Fr become too small, the initial condition strategy fails, giving rise to a singular perturbation problem. Eliminating this singularity requires the use of asymptotic analysis. To proceed further with this problem we introduce the following assumptions:

$$Ro = O(Fr), \quad \omega = \frac{Ro^2}{Fr^2}, \quad E_h = \hat{E}_hRo^2, \quad E_v = \hat{E}_vRo^2, \tag{2.4}$$

and we next assume that the parameters $(St,\ \omega, \hat{E}_h\,, \hat{E}_v)$ are fixed and are of $O(1)$. Thus, the asymptotic expansion of $\mathbf{v}, w, p, \rho$ with respect to Ro provides, at the zeroth order, expansions:

$$
\begin{aligned}
&p_0 = p_0(z), \quad \varrho_0 = \varrho_0(z), \quad \mathbf{D}p_0 = 0,\\
&\mathbf{v}_0 = \frac{\omega}{\varrho_0}\mathbf{k}\Lambda\mathbf{D}p_1, \quad \frac{dp_0}{dz} = -Bo\varrho_0.
\end{aligned}
\tag{2.5}
$$

The last two equations are the geostrophic and the hydrostatic assumptions, respectively.

Since the pressure fluctuation is the basic dynamical characteristic of the current, we assume that the wave motion may be specified in terms of the perturbation p_1 deduced, after some calculations from (2.1). Thus at the order R_0 we obtain the so-called quasi-geostrophic potential equation (Pedlosky [12]):

$$
\frac{d_h}{dt}\left[\mathbf{D}^2 p_1 + \frac{\omega}{B_0}\left\{\frac{\partial}{\partial z}\left\{-\frac{\varrho_0(z)}{\varrho_0'(z)}\frac{\partial p_1}{\partial z}\right\} + \frac{\partial p_1}{\partial z}\right\} + \varrho_0(z)\beta\omega y\right] = 0,
\tag{2.6}
$$

where $\frac{d_h}{dt} = St\frac{\partial}{\partial t} + \mathbf{v_0}.\mathbf{D}$ and $\mathbf{D} = \frac{\partial}{\partial x}\,\mathbf{i} + \frac{\partial}{\partial y}\,\mathbf{j}$.

The problem is now reduced to the study of the pressure perturbation p_1 governed by (2.6). The associate boundary conditions are determined supposing that there exist two Ekman boundaries at the ocean-atmosphere interface and at the bottom. To remain within the Ekman-layer thickness as E_v is small, the matching procedure between layers leads, after some calculation, to the following boundary conditions:

$$
\frac{d_h}{dt}\left(\frac{\partial p_1}{\partial z}\right) = \begin{cases} \Gamma(0)\varkappa(0)\,\varpi\,\mathbf{D}^2(\varrho_0^{-1}p_1)_{z=0},\\ \varkappa(-1)\,\varpi\,\mathbf{D}^2(\varrho_0^{-1}p_1)_{z=-1}, \end{cases}
\tag{2.7}
$$

where

$$
\begin{aligned}
&\varkappa(z) = \left(\frac{\hat{E}_v}{2}\right)^{\frac{1}{2}}\varrho_0'(z)\varrho_0(z)^{-\frac{1}{2}},\\
&\varpi = \frac{Bo}{\omega} = O(1),\\
&\Gamma(z) = -1 + \frac{\mu\,\varrho_0(z)^{\frac{1}{2}}}{\mu\,\varrho_0(z)^{\frac{1}{2}} + \mu^a\,\varrho_0^a(z)^{\frac{1}{2}}} < 0,
\end{aligned}
\tag{2.8}
$$

with μ the coefficient of the dynamic viscosity. The superscript "a" refers to the atmospheric terms and indicates the signature of the atmospheric effects in the matching procedure.

In order to analyze how the solution of (2.6) behaves in the presence of the density gradient, we consider only the vertical structure of the pressure perturbation. The study of the vertical structure of the upper ocean can be useful because pressure and bulk temperatures or salinities tend to vary more along a vertical distance of a hundred meters than along a horizontal distance of a thousand kilometers. This holds true over many parts of the world's oceans where it is the case that vertical exchange processes within the water column are likely to affect local conditions much more rapidly than horizontal advection and horizontal mixing. It follows that for our purposes we treat the upper ocean layers as being homogeneous along the horizontal; thus we consider the propagation of monochromatic waves in the form

$$
p_1(x, y, z, t) = P(z)\exp\left\{i(kx + ly - \sigma t)\right\},
\tag{2.9}
$$

where k and l are the characteristic wave numbers and σ is the frequency.

Substituting (2.9) into (2.6) and (2.7), we obtain

$$\frac{d}{dz}\left(\frac{1}{\rho_0'(z)}\frac{dP(z)}{dz}\right)+\frac{\lambda}{\rho_0(z)}P(z)=0, \tag{2.10}$$

where

$$\lambda = K_h^2+\frac{k\beta}{\sigma} \tag{2.11}$$

is a separation parameter to be determined in the analysis below. $K_h^2=k^2+l^2$ is the horizontal wave number, and k and l are the wave numbers in the x- and y-directions; σ is the frequency of the free harmonic waves.

This is an eigenvalue Sturm–Liouville problem for the vertical structure of the pressure perturbation $P(z)$, where λ, assumed to be function of the wave frequency σ from (2.11), is the problem eigenvalue. The associated boundary conditions are

$$\left(-\sigma St+\mathbf{v_0}.\nabla\right)\frac{dP(0)}{dz}-\alpha_2 P(0)=0,$$

$$\left(-\sigma St+\mathbf{v_0}.\nabla\right)\frac{dP(-1)}{dz}-\alpha_1 P(-1)=0, \tag{2.12}$$

where $\mathbf{v_0}$ is given by (2.5), $\nabla = k\mathbf{i}+l\mathbf{j}$, and α_1 and α_2 are given by

$$\begin{aligned}\alpha_2 &= iK_h^2\left(\frac{\hat{E}_v}{2}\right)^{1/2}\Gamma(0)\varrho_0'(0)\varrho_0^{-1/2}(0),\\ \alpha_1 &= iK_h^2\left(\frac{\hat{E}_v}{2}\right)^{1/2}\varrho_0'(-1)\varrho_0^{-1/2}(-1).\end{aligned} \tag{2.13}$$

We note that the horizontal velocity $\mathbf{v}_0$ depends on the pressure perturbation p_1 (2.5). Thus, its presence at the boundary conditions (2.12) is a nonlinear contribution to the eigenvalue problem.

3. Vertical structure of monochromatic internal Rossby waves with the stratification profile. In this section we deal with the set of equations (2.10) and (2.12). The first fact which we must notice is that the solution $P(z)$ depends on the boundary conditions. In other words, we deal with the Sturm–Liouville problem, which is essentially the problem of determining the dependence of the general behavior of the solution $P(z)$ on the parameter λ (or σ) and the dependence of the eigenvalues of λ (or σ) on the complexity of the boundary conditions imposed on $P(z)$. This complexity is due, first, to the presence of the frequency σ in the boundary conditions that render the set of eigenfunctions nonorthogonal. In order to overcome this difficulty, the assumption $St=\varepsilon \ll 1$ is made, where St is the Strouhal parameter. This assumption means that we consider a quasi-stationary flow.

3.1. Case of a variable gradient stratification profile. In the case of a nonuniform density distribution along the vertical, we consider a density distribution in tanh form, which may approximate a typical oceanic profile (see Figure 3.1):

$$\rho_0(z)=\rho_{00}\left[1-N_m^2\tanh\left(\frac{z+h}{\delta}\right)\right], \tag{3.1}$$

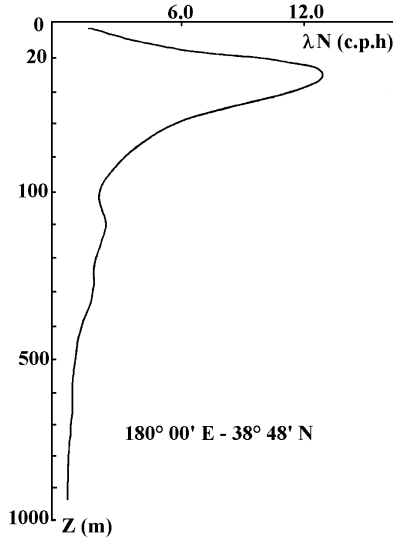

FIG. 3.1. *An example of a typical Brunt–Väisälä frequency profile (taken from* [6]*).*

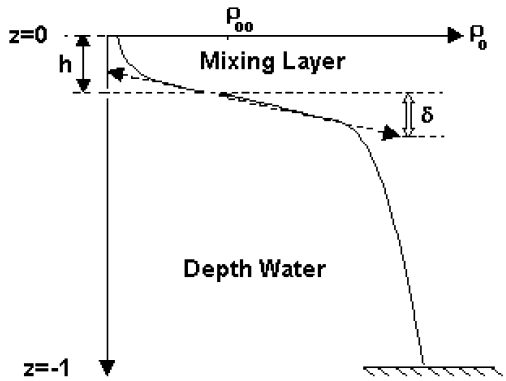

FIG. 3.2. *Schematic presentation of the density distribution in* tanh *form.*

where $N_m^2 \ll 1$ and ρ_{00} are constants. The parameter δ is the varying stratification parameter, which varies in the range $0 < \delta \leq 1$. It may roughly define the thickness of the layer along which $\rho_0(z)$ steeply varies (see Figure 3.2). An experimental study using a density distribution in a tanh profile was considered in Pawlak and Armi [9].

Following a classical procedure (see, for example, [13]), the wave equations (2.10) and (2.12) may be transformed into a suitable form by introducing in place of z a new variable ξ, defined as follows:

$$\xi = \frac{1}{J} \int_{-1}^{z} \left(-\frac{\rho_0(t)}{\rho_0'(t)} \right)^{1/2} dt, \tag{3.2}$$

with

$$J = \int_{-1}^{0} \left(-\frac{\rho_0(t)}{\rho_0'(t)} \right)^{1/2} dt. \tag{3.3}$$

With this form of J, the new variable ξ evolves in the range $[0,1]$ as z evolves in the range $[-1,0]$. Next, in place of the function $P(z)$ we introduce a new function:

$$X(\xi) = P(z) \sqrt[4]{\frac{-1}{\rho_0(z)\rho_0'(z)}}. \tag{3.4}$$

This yields the following modified Sturm–Liouville problem for $X(\xi)$:

$$\frac{d^2X(\xi)}{d\xi^2} - \left(\eta_1^2 + V(\xi,\delta)\right) X(\xi) = 0, \tag{3.5}$$

with

$$\frac{dX(1)}{d\xi} - aX(1) = 0 \quad \text{and} \quad \frac{dX(0)}{d\xi} - bX(0) = 0,$$

where $\eta_1^2 = \lambda.J^2$ (from (2.11) and (3.3)) and

$$V(\xi,\delta) = \left(-\rho_0(z)\rho_0'(z)\right)^{1/4} \frac{d^2}{d\xi^2}\left[\sqrt[4]{\frac{-1}{\rho_0(z)\rho_0'(z)}}\right],$$

$$\begin{aligned} a &= \frac{-\alpha_2 J}{\mathbf{v_0}.\nabla}\frac{\rho_0(0)}{\rho_0'(0)} - \frac{1}{4}(\rho_0\rho_0')\left[\frac{d}{d\xi}\left(\frac{-1}{\rho_0\rho_0'}\right)\right]_{\xi=1}, \\ b &= \frac{-\alpha_1 J}{\mathbf{v_0}.\nabla}\frac{\rho_0(-1)}{\rho_0'(-1)} - \frac{1}{4}(\rho_0\rho_0')\left[\frac{d}{d\xi}\left(\frac{-1}{\rho_0\rho_0'}\right)\right]_{\xi=0}, \end{aligned} \tag{3.6}$$

where $\mathbf{v_0}$ is given by (2.5) and $\nabla = k\mathbf{i} + l\mathbf{j}$. At this stage of analysis, we note that (2.10) and (2.12) correspond to the Sturm–Liouville eigenproblem, which is a problem of determining the dependence of the behavior of the solution $P(z)$ on the parameter λ (or σ). Thus, the presence of the frequency σ in the boundary conditions renders the set of eigenfunctions nonorthogonal. In order to overcome this difficulty, the assumption $St = \epsilon \ll 1$ is made, where St is the Strouhal parameter. This assumption means that we consider a quasi-stationary flow.

To proceed further with this problem, we have to find nontrivial solutions of the homogeneous set of equations (3.5), and we have to determine the values of the separation parameter λ (eigenvalues) for these nontrivial solutions (eigenfunctions). Thus, in the following analysis we consider only the case where η_1^2 is negative: $\eta_1^2 = -\mu_1^2$. Since η_1^2 is negative, we have

$$\lambda J^2 = k^2 + l^2 + \frac{k\beta}{\sigma_1} < 0. \tag{3.7}$$

Using a classical mathematical argument (see Ince [14]), the eigenfunctions $X(\xi)$ of the problem (3.5) can be given by

$$X(\xi) = c_1\cos(\mu_1\xi) + c_2\sin(\mu_1\xi) + \frac{1}{\mu_1}\int_{\varepsilon}^{\xi}\left[V(t,\delta)\sin\left(\mu_1(\xi-t)\right)X(t)\right]dt, \tag{3.8}$$

where $c_1$and c_2 are arbitrary and $0 \le \varepsilon \le 1$. Thus, from the first boundary condition at $\xi = 1$, we deduce that

$$c_2 = \frac{c_1 b}{\mu_1}, \tag{3.9}$$

and from the second condition at $\xi = 0$, we deduce the following eigenvalue equation:

$$\tan g(\mu_1) = \frac{c_1(b-a) + \int_0^1 |V(t,\delta)| \left[\cos(\mu_1 t) + \frac{a}{\mu_1}\sin(\mu_1 t)\right] X(t)dt}{c_1\left(\mu_1 + \frac{b}{\mu_1}\right) - \int_0^1 |V(t,\delta)| \left[\sin(\mu_1 t) - \frac{a}{\mu_1}\sin(\mu_1 t)\right] X(t)dt}. \tag{3.10}$$

The roots of this equation form a discrete spectrum ($\mu_{1k},\ k = 1, 2, \dots$). However, $X(\xi)$ is unknown; thus if μ_{1k} are sufficiently large and on using (3.9), a simple estimate of the solution (3.8) can satisfy an asymptotic form

$$X(\xi) = c_1 \cos(\mu_1 \xi) + \frac{g(\mu_1 \xi)}{\mu_1}, \tag{3.11}$$

where $g(\mu_1\xi)$ is a bounded function as $\mu_1 \longrightarrow \infty$. If we set this asymptotic form (3.11) in (3.10), we obtain

$$\tan(\mu_{1k}) \cong \frac{(b-a) + \frac{1}{2}\int_0^1 |V(t,\delta)|\, dt + O(\frac{1}{k})}{\mu_1 + O(\frac{1}{k})} \qquad (k = 1, 2, \dots). \tag{3.12}$$

By using the fixed point method, we can estimate the solution of the above equation. Thus, we obtain

$$\mu_{1k} \cong k\pi + \frac{(b-a) + \frac{1}{2}\int_0^1 |V(t,\delta)|\, dt}{k\pi} + O\left(\frac{1}{k^2}\right) \qquad (k = 1, 2, \dots). \tag{3.13}$$

The solution of (3.8) can be obtained by successive approximations in the form

$$X(\xi, \mu_1) = \sum_{k=0}^{\infty} x_k(\xi, \mu_1), \tag{3.14}$$

where

$$x_0(\xi, \mu_1) = c_1\left(\cos\mu_1\xi + \frac{b}{\mu_1}\sin\mu_1\xi\right), \tag{3.15}$$

$$x_{k+1}(\xi, \mu_1) = \frac{1}{\mu_1}\int_{\varepsilon}^{\xi} \sin\mu_1(\xi - t)V(t)x_k(t, \mu_1)dt. \tag{3.16}$$

If $|V(\xi)| \le A$, where A is an upper bound, we can prove by induction that

$$|x_{k+1}(\xi, t)| \le \frac{|c_1| + |c_1 b/\mu_1|}{k!}\frac{A^k\,|\xi - \varepsilon|^k}{\mu_1^k}, \qquad k = 1, 2, \dots . \tag{3.17}$$

The solution form, where $k = 0$, is given in (3.15).

We thus see from (3.17) that $x_{k+1}(\xi, t)$ is uniformly convergent in the interval $\xi \in [0, 1]$ as A is a bounded number, and that $x_{k+1}(\xi, t)$ is also an asymptotic expansion of $X(t, \xi)$ as $\mu_1 \to \infty$.

However, since the upper bound A becomes sufficiently large as δ diminishes, this leads to the increasing of $|x_{k+1}(\xi, t)|$ to a large wave amplitude. The same increasing feature may be derived from the Schwartz inequality. This establishes the existence

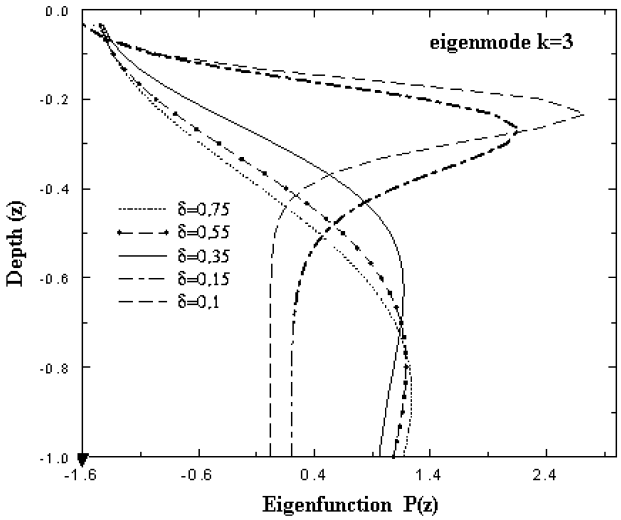

FIG. 3.3. *Variability in the structure eigenfunctions with the parameter δ for the eigenmode $k = 3$. The plots correspond to the numerical solution.*

of a fixed number such that $|x_{k+1}(\xi, t)| < M$. It remains to show from (3.16) that the solution amplitude verifies

$$|x_{k+1}(\xi,t)| \leq |c_1| \left(1 + \frac{b^2}{\mu_1^2}\right)^{1/2} + \frac{M}{\mu_1} \int_0^1 |V(t,\delta)|\, dt \tag{3.18}$$

and hence

$$M \leq |c_1| \sqrt{1 + \frac{b^2}{\mu_1^2}} \frac{1}{1 - \frac{1}{\mu_1} \int_0^1 |V(t,\delta)|\, dt}. \tag{3.19}$$

The validity of the last inequality depends on the behavior of the denominator. In this situation two problems arise. The first of these is that the upper bound must be positive; it follows that the expression in the denominator must be positive in turn. The second problem is the finding of a critical value δ_{cri} to ensure a bounded upper bound M. Then it will be necessary to impose restrictions on δ to prevent the denominator of (3.19) from vanishing. This consists of discarding the condition $\mu_1 = \int_0^1 |V(t,\delta)|\, dt$. This requirement involves the fact that the solution may hold in the interval $\delta_{cri} < \delta < 1$, while in the interval $0 < \delta \leq \delta_{cri}$ the upper bound M becomes sufficiently large so that the wave amplitude dominates the flow dynamics. Thus a significant increase of the energy is acquired as the wave approaches the layer of the maximum density gradient (Figure 3.3). The wave motion focuses at a certain depth $h\,(0 < h < 0.2)$. This depth is determined by the minimum of the characteristic scale of the varying stratification parameter δ (Figure 3.4). The growth of the solution amplitude is accompanied by the transformation of the vertical structure of internal wave modes and renders the vertical wave propagation unstable. The same features were also found in previous laboratory experiments (Stamp and Jacka [7] and Simpson and Linden [15]).

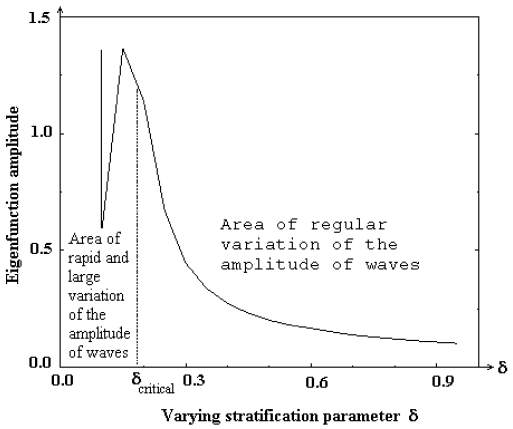

FIG. 3.4. *Growth rate of the eigenmodes as a function of the varying stratification parameter* δ.

The instability described here can be interpreted as a criterion in which the wave amplitudes grow, according to the parameter δ, to a level such that δ drops below a critical value δ_{cri}. Then the disturbances can grow exponentially, whence the primary wave amplitude exceeds a certain limiting value to such an extent that an effective discontinuity or front may develop (see Figures 3.3 and 3.4).

The exponential growth of internal wave amplitudes in horizontally inhomogeneous layers has been studied by Navrotsky and Simonenko [16] and Navrotsky [17]. They showed that such waves could produce effective mixing within the thermocline, and higher modes of internal waves can also play an important role in turbulence generation, especially in a multilayered stratification.

4. Finding the solutions for thin interface layers in the presence of turning-points. In this section we seek to obtain eigenvalues, as the stratification rate parameter δ is very small. For simplicity we proceed under the assumption that $\hat{E}_v \ll 1$ (Kraus [18]). Yet from the preceding section, the analysis of the vertical structure of the pressure perturbation explicitly exploits the thinness of these layers and does not reveal any particular problem due to the presence of the parameter $\hat{E}_v$ at the boundary conditions.

In the following we deal with the set of equations (3.5), which can be written as

$$\frac{d^2X(\xi)}{d\xi^2} + \lambda^2 q(\xi,\delta)X(\xi) = 0, \tag{4.1}$$

with the associated boundary conditions

$$\frac{dX(1)}{d\xi} - aX(1) = 0 \quad \text{and} \quad \frac{dX(0)}{d\xi} - bX(0) = 0, \tag{4.2}$$

where $\lambda^2 = 1/4\delta^4$ with $\delta \ll 1$, and the function $q(\xi,\delta)$ reads

$$q(\xi,\delta) = (\xi-\xi_1)(\xi-\xi_2)F(\xi_1,\xi_2), \tag{4.3}$$

with

$$F(\xi_1,\xi_2) = \frac{1}{\cosh^2\left(\frac{\xi_1-1+h}{\delta}\right)\cosh^2\left(\frac{\xi_2-1+h}{\delta}\right)},$$

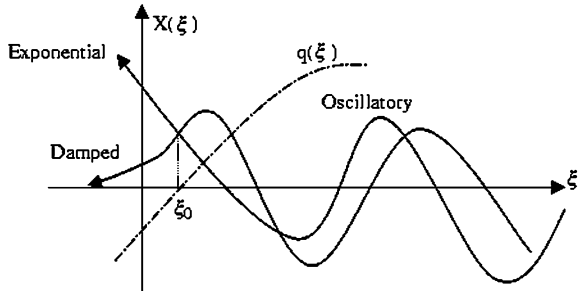

FIG. 4.1. *Schematic presentation of the solution behavior in presence of a turning-point* ξ_0.

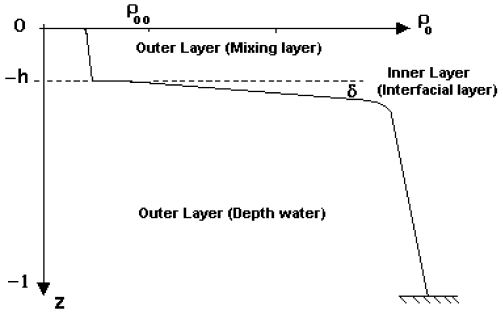

FIG. 4.2. *Three-layer schematic representation of the density, in the case when* $\delta \ll 1$.

$$\xi_1 = 1 - h - \delta \text{ argth } \sqrt{2 - 4\mu_1^2\delta^2}, \tag{4.4}$$

$$\xi_2 = 1 - h + \delta \text{ argth } \sqrt{2 - 4\mu_1^2\delta^2}. \tag{4.5}$$

The function $q(\xi, \delta)$ may vanish if the variable ξ is equal to ξ_1 or ξ_2, called turning-points. The core of the problem is to seek a stable solution, for a given fixed value of μ_1, when the stratification parameter δ is very small and when the function $q(\xi, \delta)$ changes the sign as ξ evolves from 0 to 1 on passing over the turning-points (see Figure 4.1). Elsewhere, as $\delta \to 0$, we deal with three cases (Figure 4.2):

(i) as $\xi > 1 - h$, $\frac{\xi - 1 + h}{\delta} \to +\infty$;
(ii) as $\xi > 1 - h$, $\frac{\xi - 1 + h}{\delta} \to +\infty$;
(iii) as $\xi = 1 - h$, $\frac{\xi - 1 + h}{\delta} = 0$.

Note that from (4.4) and (4.5), $q(\xi, \delta)$ may change the sign in the range

$$(\mu_1\delta) \in \left]\frac{-\sqrt{2}}{2}, \frac{-1}{2}\right[\cup \left]\frac{1}{2}, \frac{\sqrt{2}}{2}\right[. \tag{4.6}$$

To further proceed with this problem we use the WKB approximation. We seek solutions in the form

$$X(\xi) = \exp^{\pm i\phi(\xi)}. \tag{4.7}$$

Substituting the last equation into the wave equation (4.1), this yields the following

dispersion equation:

$$\frac{i\phi''(\xi)}{\phi'^2(\xi)} + \frac{q(\xi)}{\phi'^2(\xi)} - 1 = 0. \tag{4.8}$$

If we choose ϕ such that

$$\frac{\phi''(\xi)}{\phi'^2(\xi)} \ll 1 \quad \text{and} \quad \frac{q(\xi)}{\phi'^2(\xi)} - 1 = 0, \tag{4.9}$$

we deduce from the first condition the inequality

$$\frac{q'(\xi)}{2\sqrt{q(\xi)}} \ll q(\xi), \tag{4.10}$$

which remains verified as $\delta \to 0$. From (4.8) and the second condition in (4.9), ϕ may be approximated as

$$\phi(\xi) \cong \pm \int \sqrt{q(\xi)} + \frac{i}{4} \ln q(\xi); \tag{4.11}$$

then from (4.7), the approximate solution takes the form

$$X(\xi,\delta) \cong \frac{1}{\sqrt[4]{q(\xi)}} \left\{ \alpha \exp\left[i\lambda \int \sqrt{q(\xi)} d\xi \right] + \beta \exp\left[-i\lambda \int \sqrt{q(\xi)} d\xi \right] \right\}, \tag{4.12}$$

where α and β are arbitrary and $\lambda = 1/2\delta^2$.

The validity of this asymptotic form given in (4.12) depends on the sign of the function $q(\xi)$. It has an oscillatory character if $q(\xi)$ is positive and has a monotonic character if $q(\xi)$ is negative. Hence, there exists a point ξ_0 such that, at the vicinity of this point, the transition takes place from one type of behavior to the other (see Figure 4.1).

Thus, if $q(\xi) > 0$, the solution is oscillatory, and may read

$$X_{1(out)}(\xi,\delta) \cong \frac{1}{\sqrt[4]{q(\xi)}} a_1 \sin\left[\lambda \int \sqrt{q(\xi)} d\xi \right] + b_1 \cos\left[-\lambda \int \sqrt{q(\xi)} d\xi \right]. \tag{4.13}$$

If $q(\xi) < 0$, the solution is monotonic, and may read

$$X_{2(out)}(\xi,\delta) \cong \frac{1}{\sqrt[4]{-q(\xi)}} a_2 \exp\left[\lambda \int \sqrt{-q(\xi)} d\xi \right] + b_2 \exp\left[-\lambda \int \sqrt{-q(\xi)} d\xi \right]. \tag{4.14}$$

The solutions $X_{1(out)}(\xi,\delta)$ and $X_{2(out)}(\xi,\delta)$ are valid above and below the turning-points and are called *outer solutions*. In the vicinity of the turning-points ξ_1 and ξ_2, we use Langer's transformation (see Nayfeh [19]):

$$x = \varphi(\xi), \qquad \Phi = \psi(x) X. \tag{4.15}$$

The transformation (4.15) carries (4.1) into

$$\frac{d^2\Phi}{dx^2} + \frac{1}{\varphi'^2}\left(\varphi'' - 2\frac{\varphi'\psi'}{\psi} \right) \frac{d\Phi}{dx} + \frac{1}{\varphi'^2}\left(\lambda^2 q + \psi \left(\frac{\psi'}{\psi^2} \right)' \right) \Phi = 0. \tag{4.16}$$

We determine ψ and φ so that

$$\varphi'' - 2\frac{\varphi'\psi'}{\psi} = 0 \quad \Rightarrow \quad \psi = \sqrt{\varphi'} \tag{4.17}$$

and

$$\frac{-q}{\varphi'^2} = \varphi, \tag{4.18}$$

so that (4.16) becomes

$$\frac{d^2\Phi}{dx^2} - \lambda^2 x\Phi = v(x)\Phi, \tag{4.19}$$

where

$$v(x) = \frac{1}{2}\frac{\varphi'''}{\varphi'^3} - \frac{3}{4}\frac{\varphi''^2}{\varphi'^4}. \tag{4.20}$$

At the vicinity of the turning-point ξ_1 the solutions of (4.18) are

$$\frac{2}{3}(\varphi_1)^{3/2} = \int_{\xi_1}^{\xi} \sqrt{(t-\xi_1)(\xi_2-t)F(\xi_1,\xi_2)}dt \qquad \text{if } \xi > \xi_1, \tag{4.21}$$

$$\frac{2}{3}(-\varphi_1)^{3/2} = \int_{\xi}^{\xi_1} \sqrt{(\xi_1-t)(\xi_2-t)F(\xi_1,\xi_2)}dt \qquad \text{if } \xi < \xi_1. \tag{4.22}$$

In the same manner, at the vicinity of the turning-point ξ_2 the solutions of (4.18) read

$$\frac{2}{3}(-\varphi_2)^{3/2} = \int_{\xi}^{\xi_2} \sqrt{(t-\xi_1)(t-\xi_2)F(\xi_1,\xi_2)}dt \qquad \text{if } \xi > \xi_2, \tag{4.23}$$

$$\frac{2}{3}(\varphi_2)^{3/2} = \int_{\xi_2}^{\xi} \sqrt{(t-\xi_1)(\xi_2-t)F(\xi_1,\xi_2)}dt \qquad \text{if } \xi < \xi_2. \tag{4.24}$$

From (4.21) as $\xi \to \xi_1$, $\varphi_1 \to \sqrt[3]{(\xi_2-\xi_1)F(\xi_1,\xi_2)}.(\xi-\xi_1)$; hence from (4.20) the function $v = O(1)$. Thus as λ is large, this leads to the approximated equation

$$\frac{d^2\Phi}{dx^2} - \lambda^2 x\Phi = 0, \tag{4.25}$$

whose solution is

$$\Phi = c_1 Ai(\lambda^{2/3}x) + c_2 Bi(-\lambda^{2/3}x), \tag{4.26}$$

where c_1 and c_2 are constants of integration. Ai and Bi are the Airy functions of the first and second kind. Applying the previous results and (4.15), the asymptotic solution for $\xi > \xi_1$ reads

$$X_{1(in)}(\xi,\delta) \cong \frac{1}{\sqrt{\varphi_1'}}\left\{c_1^{(1)} Ai\left[\lambda^{2/3}\varphi_1(\xi)\right] + c_2^{(1)} Bi\left[-\lambda^{2/3}\varphi_1(\xi)\right]\right\}. \tag{4.27}$$

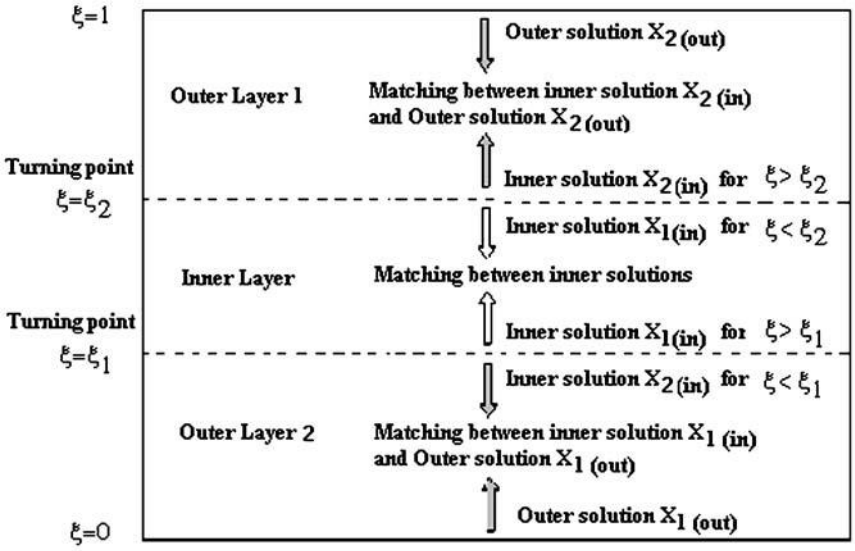

FIG. 4.3. *Sketch of the matching procedure in the presence of turning-points.*

Similarly, the asymptotic solution for $\xi < \xi_2$ reads

$$X_{2(in)}(\xi,\delta) \cong \frac{1}{\sqrt{\varphi_2'}}\left\{c_1^{(2)} Ai\left[\lambda^{2/3}\varphi_2(\xi)\right] + c_2^{(2)} Bi\left[-\lambda^{2/3}\varphi_2(\xi)\right]\right\}. \tag{4.28}$$

These solutions $X_{1(in)}$ and $X_{2(in)}$ (see Figure 4.3) are available for ξ in the range $\xi_1 + \varepsilon < \xi < \xi_2 - \varepsilon$ ($\varepsilon \ll 1$) and are called inner solutions. φ_1 and φ_2 are given by (4.21) and (4.24); $c_1^{(1)}, c_2^{(1)}, c_1^{(2)}, c_2^{(2)}$ are constants of integration.

The matching procedure (Figure 4.3) between the outer solutions given in (4.13) and (4.14) and the inner solutions given in (4.27) and (4.28) may lead to the relationship that exists between the constants $c_1^{(1)}, c_2^{(1)}, c_1^{(2)}, c_2^{(2)}$ and a_1, a_2, b_1, b_2.

4.1. Matching procedure between inner solutions. To match the solutions given in (4.27) and (4.28) we first use the asymptotic forms of large positive arguments of the Airy functions (Nayfeh [19]) given by

$$\begin{aligned} Ai(z) &= \frac{1}{2\sqrt{\pi}} z^{-1/4} \exp\left(-\frac{2}{3}z^{3/2}\right)\left[1 + O\left(\frac{2}{3}z^{3/2}\right)^{-1}\right], \\ Bi(z) &= \frac{1}{2\sqrt{\pi}} z^{-1/4} \exp\left(\frac{2}{3}z^{3/2}\right)\left[1 + O\left(\frac{2}{3}z^{3/2}\right)^{-1}\right]. \end{aligned} \tag{4.29}$$

These last assumptions transform (4.27) and (4.28) into

$$X_{1(in)}(\xi,\delta) \cong \frac{\lambda^{-1/6}}{\sqrt[4]{-q(\xi)}\sqrt{\pi}}\left\{\frac{c_1^{(1)}}{2}\exp\left(-\frac{2}{3}\lambda\varphi_1^{3/2}\right) + c_2^{(1)}\exp\left(\frac{2}{3}\lambda\varphi_1^{3/2}\right)\right\}, \tag{4.30}$$

$$X_{2(in)}(\xi,\delta) \cong \frac{\lambda^{-1/6}}{\sqrt[4]{-q(\xi)}\sqrt{\pi}}\left\{\frac{c_1^{(2)}}{2}\exp\left(-\frac{2}{3}\lambda\varphi_2^{3/2}\right) + c_2^{(2)}\exp\left(\frac{2}{3}\lambda\varphi_2^{3/2}\right)\right\}. \tag{4.31}$$

Equating (4.30) and (4.31) gives

(4.32)
$$\frac{c_1^{(1)}}{2}\exp\left(-\frac{2}{3}\lambda\varphi_1^{3/2}\right)+c_2^{(1)}\exp\left(\frac{2}{3}\lambda\varphi_1^{3/2}\right)=\frac{c_1^{(2)}}{2}\exp\left(-\frac{2}{3}\lambda\varphi_2^{3/2}\right)+c_2^{(2)}\exp\left(\frac{2}{3}\lambda\varphi_2^{3/2}\right).$$

If we introduce

$$\Delta=\frac{2}{3}\lambda(\varphi_1^{3/2}+\varphi_2^{3/2})=\int_{\xi_1}^{\xi_2}\sqrt{(t-\xi_1)(\xi_2-t)F(\xi_1,\xi_2)}dt, \tag{4.33}$$

we obtain from (4.32)

$$\begin{aligned}\frac{c_1^{(1)}}{2}+c_2^{(1)}&=\frac{c_1^{(2)}}{2}\exp(-\Delta)+c_2^{(2)}\exp(\Delta),\\ c_2^{(1)}-\frac{c_1^{(1)}}{2}&=\frac{c_1^{(2)}}{2}\exp(-\Delta)-c_2^{(2)}\exp(\Delta),\end{aligned} \tag{4.34}$$

so that

$$\begin{aligned}c_2^{(1)}&=c_1^{(2)}\exp(-\Delta),\\ c_2^{(2)}&=c_1^{(1)}\exp(-\Delta).\end{aligned} \tag{4.35}$$

Thus for (4.30) and (4.31) to have a bounded solution as λ is large, it is necessary that $c_2^{(1)}$ and $c_2^{(2)}$ vanish. It follows that Δ must be strictly positive.

Thus, on using the ξ_1 and ξ_2 expressions given by (4.4) and (4.5), the integration of (4.33) gives

$$\Delta=\frac{2}{3}\lambda(\varphi_1^{3/2}+\varphi_2^{3/2})=\frac{\pi}{2}\frac{\delta^2\mathrm{argth}^2\sqrt{2-4\mu_1^2\delta^2}}{\cosh(\frac{\xi_1-1+h}{\delta})\cosh(\frac{\xi_2-1+h}{\delta})} \tag{4.36}$$

and shows that Δ is positive for all values of $\delta>0$.

4.2. Matching procedure between inner and outer solutions. To match the outer solutions (4.13) and (4.14) with the inner solutions (4.27) and (4.28) (see Figure 4.3), we use a method similar to that employed in subsection 4.1, the asymptotic forms of large but negative arguments of the Airy functions given by

$$\begin{aligned}Ai(-z)&=\frac{1}{\sqrt{\pi}}z^{-1/4}\sin\left(\frac{2}{3}z^{3/2}+\frac{\pi}{4}\right),\\ Bi(-z)&=\frac{1}{\sqrt{\pi}}z^{-1/4}\cos\left(\frac{2}{3}z^{3/2}+\frac{\pi}{4}\right).\end{aligned} \tag{4.37}$$

These last assumptions transform (4.27) and (4.28) into

$$\begin{aligned}X_{1(in)}(\xi,\delta)\cong{}&\frac{\lambda^{-1/6}}{\sqrt[4]{-q(\xi)}\sqrt{2\pi}}(c_1^{(1)}-c_2^{(1)})\sin\left[\frac{2}{3}\lambda(-\varphi_1)^{2/3}\right]\\ &+(c_1^{(1)}+c_2^{(1)})\cos\left[\frac{2}{3}\lambda(-\varphi_1)^{2/3}\right],\end{aligned} \tag{4.38}$$

$$X_{2(in)}(\xi,\delta) \cong \frac{\lambda^{-1/6}}{\sqrt[4]{-q(\xi)}\sqrt{2\pi}} \left\{ (c_3^{(1)} - c_4^{(1)}) \sin\left[\frac{2}{3}\lambda(-\varphi_2)^{2/3}\right] + (c_3^{(1)} + c_4^{(1)}) \cos\left[\frac{2}{3}\lambda(-\varphi_2)^{2/3}\right] \right\}. \tag{4.39}$$

We shall now connect these last asymptotic representations with those obtained in the outer regions given by (4.13) and (4.14). We obtain the following relationships:

$$(a_1, b_1) = \frac{\lambda^{-1/6}}{\sqrt{2\pi}} \left\{ (c_1^{(1)} + c_2^{(1)}), (c_1^{(1)} - c_2^{(1)}) \right\}, \tag{4.40}$$

$$(a_2, b_2) = \frac{\lambda^{-1/6}}{\sqrt{2\pi}} \left\{ (c_1^{(2)} + c_2^{(2)}), (c_1^{(2)} - c_2^{(2)}) \right\}, \tag{4.41}$$

where $c_2^{(1)}$ and $c_2^{(2)}$ are given in (4.35)

5. Solving the solutions for thin interface without turning-points. From (3.5) and from the density profile given by (3.1), the wave equation reads

$$\frac{d^2X(\eta)}{d\eta^2} - \frac{1}{4}\left(\tanh^2\eta - [2 - 4\delta^2\mu_1^2]\right) X(\eta) = 0, \tag{5.1}$$

where $\eta = \frac{\xi - 1 + h}{\delta}$ and $\delta \ll 1$. The associated boundary condition with assumption $\hat{E}_v \ll 1$ reads

$$X(\eta) = 0 \quad \text{as} \quad \eta \to \pm\infty.$$

Note that, for a given fixed value of μ_1, the expression $\tanh^2\eta - (2 - 4\delta^2\mu_1^2)$ cannot change sign in the range

$$(\mu_1\delta) \in \left[\frac{-1}{2}, \frac{1}{2}\right]. \tag{5.2}$$

Using the transformation

$$X(\eta) = \frac{1}{\cosh^a\eta}\Phi(u), \tag{5.3}$$

where a is a factor to be determined in what follows and u is given by

$$u = \frac{1}{2}(1 + \tanh\eta), \tag{5.4}$$

the substitution of these transformations into (5.1) leads to the following hypergeometric differential equation for Φ:

$$u(u-1)\Phi''(u) + (1+a)(1-2u)\Phi'(u) - \left[\frac{1}{4} + a(a+1)\right]\Phi(u) = 0, \tag{5.5}$$

where $u = 0$ and $u = 1$ are singular points as $\eta \to \pm\infty$ and a verifies

$$a = \pm\frac{1}{4}\sqrt{1 - 4\mu_1^2\delta^2}. \tag{5.6}$$

In the following we will keep only the negative sign of the parameter a to ensure bounded solutions as u is equal to 0 or 1. Thus the analytical solution (Abramovitz and Stegun [20] and Bender and Orzag [21]), which is finite at $u = 0$ ($\eta \to -\infty$) satisfying the condition $\Phi(u = 0) = 0$, is given by

$$\Phi_0(u) = Au^{-a} F\left(\frac{1}{2}, \frac{1}{2}; 1 - a; u\right), \tag{5.7}$$

where F is the hypergeometric function given by Gauss series

$$F(\alpha, \beta; \gamma, z) = \sum_{n=0}^{N} \frac{(\alpha)_n (\beta)_n}{(\gamma)_n} \frac{z^n}{n!}. \tag{5.8}$$

The analytical solution, which is finite at $u = 1$ ($\eta \to +\infty$) satisfying the condition $\Phi(u = 1) = 0$, is given by

$$\Phi_1(u) = B(1 - u)^{-a} u^{-a} F\left(\frac{1}{2} + a, \frac{1}{2} + a; 1 - a; 1 - u\right), \tag{5.9}$$

where A and B are constants of integration. They may be determined using the normalization formula $\int_0^1 \Phi^2 du = 1$.

We note that the factor $(-a)$ present in (5.7) and (5.9) must be positive, in order that the solutions $\Phi_0(u)$ and $\Phi_1(u)$ be finite as u is equal to 0 or 1.

For the solution to be continuous at $u = 1$, we shall transform (5.7) in the neighborhood of $u = 1$ into two independent solutions, by using the linear transformation formulas given in [20, p. 559]. This step is necessary to transform (5.7) in power of $(1 - u)$ into a convenient form for matching (5.7) with (5.9). We obtain

$$\begin{aligned} \Phi_{01}(u) = \alpha_0^{(1)} &\left[Au^{-a} F\left(\frac{1}{2}, \frac{1}{2}; 1 + a; 1 - u\right)\right] \\ &+ \alpha_0^{(2)} \left[A(1 - u)^{-a} u^{-a} F\left(\frac{1}{2} - a, \frac{1}{2} - a; 1 - a; 1 - u\right)\right], \end{aligned} \tag{5.10}$$

with

$$\alpha_0^{(1)} = \frac{\Gamma(1 - a)\,\Gamma(-a)}{\Gamma(\frac{1}{2} - a)\Gamma(\frac{1}{2} - a)}, \tag{5.11}$$

$$\alpha_0^{(2)} = \frac{\Gamma(1 - a)\,\Gamma(a)}{\Gamma(\frac{1}{2})\Gamma(\frac{1}{2})}, \tag{5.12}$$

where Γ is the gamma function.

In order to determine a uniformly valid solution as u varies from 0 to 1, we must connect the solutions given in (5.9) and (5.10).

However, the matching will be valid only if the first term of (5.10) vanishes, i.e., $\alpha_0^{(1)} = 0$. It follows that, since the gamma function satisfies the property

$$\frac{1}{\Gamma(-n)} = 0 \qquad \text{for } n \geq 0, \tag{5.13}$$

then for n any positive integer ($n \geq 0$), the coefficient $\alpha_0^{(1)}$ (see 5.11) may vanish by setting

$$\frac{1}{2} - a = -n \qquad (n = 0, 1, \dots). \tag{5.14}$$

On using (5.6), this leads to the following relationship between the parameters δ and μ_1:

$$(\mu_1 \delta)_n = \pm\sqrt{n^2 + n + \frac{1}{4}} \qquad (n = 0, 1, 2, \dots). \tag{5.15}$$

As $n \geqslant 1$ the values of $(\mu_1\delta)_n$ become much larger than the lowest and highest limits of the interval given by (5.2). If this is the case, we have to deal with a turning-point problem. It turns out that the last analysis falls down.

Thus, the criterion of our analysis validity given in (5.2) will be satisfied only for the case $n = 0$. If this limiting requirement is met, then, from (5.15), the relationship between the eigenvalue μ_1 and the interface thickness δ takes the form $(\mu_1\delta)_0 = \pm\frac{1}{2}$. The associated solution $\Phi_{01}(u)$ reads

$$\Phi_{01}(u) = \alpha_0^{(2)} \left[A(1-u)^{-a} u^{-a} F\left(-n, -n; 1-a; 1-u\right)\right]. \tag{5.16}$$

6. Observational evidence and discussion. Several of the characteristics of large-amplitude internal waves in the presence of a strong stratification or of a thin interface, as discussed in the previous sections, can be observed in the real ocean.

In the Strait of Gibraltar, experiments were conducted in 1985–1986 to examine the structure of the interface layer between the inflowing Atlantic waters and the outflowing Mediterranean waters in this strait [26]. It was found that the interface is 60–100 m thick, with a strong vertical salinity gradient identified by fitting individual salinity profiles to a piecewise-linear, three-layer model. The interface is deeper, thicker, fresher, and colder on the west end of the strait than in the Narrows, where there is a minimum in thickness and a maximum in salinity gradient. Property variations in all three layers are also cast in terms of the three principal water types involved in the exchange. The complexity of interaction between the interface and the upper and lower layers argues against the use of two-layer models to characterize the exchange through the Strait of Gibraltar (see Bray, Ochoa, and Kinder [26] for more details).

In the Mozambique Channel, internal waves were observed in the narrowest passage between Mozambique and Madagascar [27]. By using the ADCP-observations and CTD-profiles,[1] a strong pycnocline has been found. Below the pycnocline, this is the cross-channel averaged value of $N(z)$. For the upper layer the cross-channel differences in pycnocline depth lead to smearing of the pycnocline when $N(z)$ is averaged. The pattern becomes particularly complicated due to beam scattering at the

[1] ADCP = acoustic Doppler current profiler; CTD = conductivity, temperature, and depth recorder.

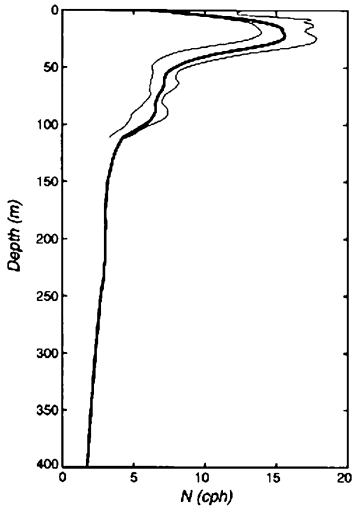

FIG. 6.1. *Measured mean buoyancy frequency profile N (cph) over the upper slope and shelf during summer PRIMER (taken from* [23]*; reproduced/modified by permission of American Geophysical Union). Also shown are the maximum and minimum N values at each depth from the horizontally averaged SeaSoar sections.*

pycnocline and the multiple reflections back into the basin. The authors argue that multiple reflections in a basin of sloping walls can in principle lead to the formation of internal-wave attractors, as was shown in Maas et al. [28].

In several places, for example, in the Andaman Sea (Osborne and Burch [29]), near a shelfbreak of the Sea of Japan (Navrotsky et al. [22]), in the Sulu Sea (Apel et al. [24]), and at the Mascarene Ridge (Konyaev, Sabinin, and Serebryany [30]), large-amplitude internal solitary waves are observed; that is, their amplitudes and the typical length scale of the vertical stratification are of the same order.

Experimental work has been presented by Colosi et al. [23] to describe the internal tide and high-frequency internal waves observed in the moored array data during the summer Shelfbreak Primer study. The summer Shelfbreak Primer study was conducted between July 26 and August 5, 1996. They found that in situ measurements and synthetic aperture radar (SAR) imagery show that packets of high-frequency nonlinear internal waves are generated near the shelfbreak during stratified conditions (late spring to early fall) and tend to propagate onshelf, while the SeaSoar data showed the presence of a shallow thermocline (pycnocline) over the shelf (see Figure 6.1), which allowed large-amplitude high-frequency internal waves of depression to form and propagate onshelf. The internal waves within the packets tend to become soliton-like, with large amplitudes, short wavelengths, and high frequencies near the local buoyancy frequency N.

Large-amplitude internal waves were also observed by Yessy and Masaki [31]. They used the monitoring result of internal wave detection in ERS-1/2 SAR and Topex/Poseidon (T/P) images over the southwest coast of Japan (see Figure 6.2). The left panel of Figure 6.2 shows two packets of internal waves at the south coast of Tsushima Island. In the right panel, the vertical transect of the internal wave clearly identifies eight crests of waves. The internal waves were propagated southeastward with lengths of wave crest around 17 km and length between crests from 375 m to 750 m.

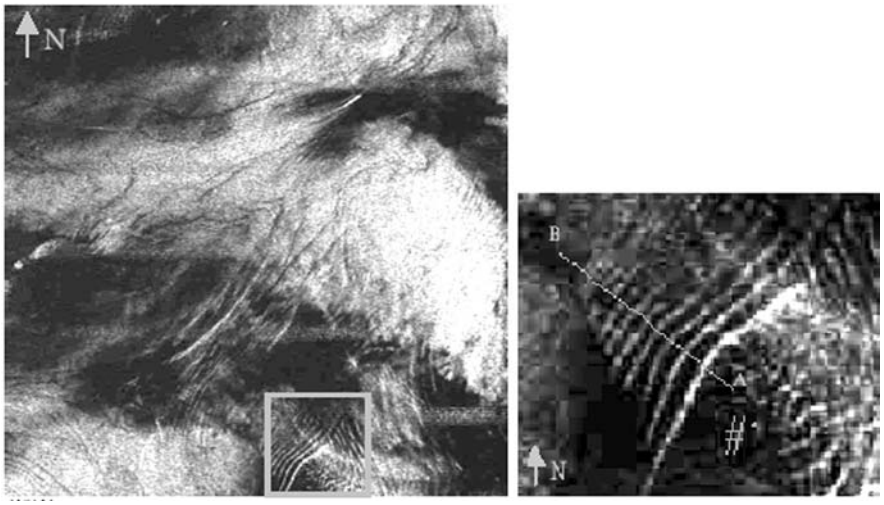

FIG. 6.2. *Internal waves around the southwest coast of Japan observed using ERS-*1/2 *SAR and T/P images (date: August,* 1993*). The right panel corresponds to the enlargement of rectangle area in the left panel (image from* [31] *by permission, and courtesy of the European Remote Sensing satellite).*

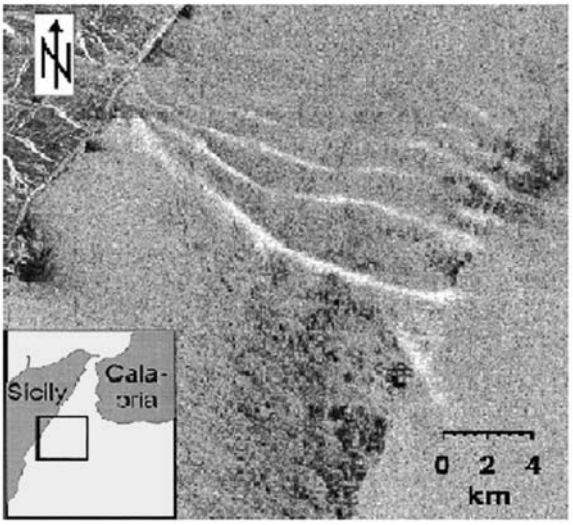

FIG. 6.3. *Radar image of a region south of the Strait of Messina, acquired by the SAR of the ERS-*2 *on August* 22, 1997*. The image shows sea surface manifestations of a train of southward propagating internal solitary waves (image taken from* [32] *and used by permission of the American Meteorological Society).*

Figure 6.3 presents a radar image showing sea surface manifestations of a train of southward propagating internal solitary waves south of the Strait of Messina in the Mediterranean Sea (see Vlasenko, Brandt, and Rubino [32] for details).

7. Conclusion. The primary purpose of this paper is to study the motion of long internal waves in a density-stratified fluid even for a very thin density interface. A theoretical model is then presented to establish stable solutions of these waves

in the presence or absence of turning-points at the interfacial layer. A prominent feature of our investigation is finding asymptotically stable and bounded solutions as the density gradient is very large. The results show that, in the case of variable stratification, a transformation of the vertical structure of internal wave occurs. This structure transformation is accompanied by the growth of the wave amplitude and steepness at the pycnocline. Here, there is a close similarity between this feature and the phenomenon of trapping internal waves by inhomogeneity of stratification discussed in [6]. Waves with the initial frequency σ_0 are trapped by a layer with the maximum effective Brunt-Väisälä frequency ($N_{ef} = N(z)/(1 - kU/\sigma_0)$) equal to σ_0. This trapping may concentrate the waves in a bandwidth in the vicinity of the pycnocline and give rise to a triple-layered area.

The presented model takes into account this layering feature, and permits us to obtain satisfactory results in the more complex situation even where turning-points exist. The model takes advantage of the analysis of internal waves filtered in quasi-geostrophic equations and based on Navier–Stokes equations under the Boussinesq and hydrostatic assumptions, with vertically varying stratification. Successive estimation of the velocity field and pressure leads to a single equation of the vertical structure of the pressure perturbation. An eigenvalue problem of Sturm–Liouville type is presented for the modal structures and frequencies of the eigenmode oscillations. The specification of these eigenmodes requires determination from boundary conditions that are complicated by the presence of the eigenvalues. This complication gives rise to the nonorthogonality of the boundary value problem verified by the pressure perturbation. Thus, to deal with this problem, an asymptotic analysis is used. The results show that a significant growth of the solution amplitude appears as the characteristic scale of a varying stratification parameter named δ approaches a critical value δ_{cri}, giving rise to the formation of an interfacial wave that dominates the flow. To deal with this interface, two cases are discussed of describing bounded internal solutions even for a very thin interface. In the first case it is assumed that the turning-points exist; thus we derive inner solutions at the vicinity of the turning-points and outer solutions above and below these points. A requirement of appropriate interfacial conditions provides a general stable matching solution, even for very small values of the parameter δ. In the second case no turning-points are allowed, and a two-layer discontinuous gradient system is examined. When matching solutions above and below the interface, a critical value of the parameter δ is required to obtain a uniform and valid solution in the entire domain.

BIFURCATION ANALYSIS OF AN SIRS EPIDEMIC MODEL WITH GENERALIZED INCIDENCE*

M. E. ALEXANDER† AND S. M. MOGHADAS†

Abstract. An SIRS epidemic model, with a generalized nonlinear incidence as a function of the number of infected individuals, is developed and analyzed. Extending previous work, it is assumed that the natural immunity acquired by infection is not permanent but wanes with time. The nonlinearity of the functional form of the incidence of infection, which is subject only to a few general conditions, is biologically justified. The stability analysis of the associated equilibria is carried out, and the threshold quantity ($\mathscr{R}_0$) that governs the disease dynamics is derived. It is shown that $\mathscr{R}_0$, called the basic reproductive number, is independent of the functional form of the incidence. Local bifurcation theory is applied to explore the rich variety of dynamical behavior of the model. Normal forms are derived for the different types of bifurcation that the model undergoes, including Hopf, saddle-node, and Bogdanov–Takens. The first Lyapunov coefficient is computed to determine various types of Hopf bifurcation, such as forward or backward, subcritical or supercritical. The existence of a saddle-node bifurcation, at the turning point of backward bifurcation, is established by applying Sotomayor's theorem. The Bogdanov–Takens normal form is used to formulate the local bifurcation curve for a family of homoclinic orbits arising when a Hopf and a saddle-node bifurcation merge. These theoretical results are detailed and numerically illustrated for two different kinds of incidence, corresponding to unbounded and saturated contact rates. The coexistence of two limit cycles, due to the occurrence of a backward subcritical Hopf bifurcation, is also demonstrated. These results lead to the determination of ranges for the periodicity behavior of the model based on two critical parameters: the basic reproductive number and the rate of loss of natural immunity.

Key words. epidemic models, nonlinear incidence, Hopf bifurcation, saddle-node bifurcation, Bogdanov–Takens bifurcation

1. Introduction.

In modeling of communicable diseases, there are several factors that substantially affect the dynamical behavior of the models. Recent studies have shown that the incidence rate is a major factor in producing the rich dynamics of epidemic models [1, 8, 13, 16, 23, 24, 25, 30, 31]. These studies have described interesting mathematical phenomena, such as bistability and periodicity, observed in data for some infectious diseases. In the bistability phenomenon (backward bifurcation), the model exhibits multiple endemic equilibria even when the classical requirement of the basic reproductive number being less than unity is satisfied. Disease eradication may then depend on other agents such as the initial conditions of the subpopulations. In the other scenario (periodicity), the model exhibits oscillatory behavior due to the existence of periodic solutions. This is an important dynamical feature of the model, as it shows periodically high level of incidence with a large number of infected individuals, which can be severely damaging to the population. Models with bistability or periodicity are numerous in the literature, and the reader may consult [1, 14, 15, 19, 21, 26, 30, 31].

In most classical models of epidemics, the incidence rate is taken to be mass

action incidence with bilinear interactions i.e., βIS, where β is the probability of transmission per contact and S and I represent the numbers of susceptible and infected individuals, respectively. These models typically do not admit bistability or periodicity, as they have at most one endemic equilibrium; the disease will be eradicated if the basic reproductive number is less than one, and will persist otherwise [3, 23]. Although these simple models lead to general conclusions for long-term disease dynamics, they may not provide sufficient details of complexity in the population behavior to contribute to a better understanding of epidemiological patterns and disease control. For instance, the nonlinearity in the incidence could lead to complex dynamics of epidemic models. In a previous study [1], we have shown that simple models with nonlinear incidence rates can exhibit periodic oscillations or backward bifurcations without time-dependent coefficients or being cyclic.

There are reasons for using nonlinear incidence rates in the process of disease modeling. Yorke and London [33] showed that the incidence rate $\beta(1 - cI)IS$ with positive c and time-dependent β is consistent with the results of the simulations for measles outbreaks. Capasso and Serio [6] used a saturated incidence rate $\beta IS/(1 + \beta\delta I)$, $\delta > 0$, to prevent the unboundedness of the contact rate. The effect of behavioral changes has been incorporated by Liu and colleagues [24, 25] through the use of a nonlinear incidence rate $\kappa I^l S/(1 + \alpha I^h)$ with $\kappa,\ l,\ \alpha,\ h > 0$. Recent studies have also pointed out several reasons for the nonlinearity of the incidence rates, including the change in the contact rate with increasing likelihood of infection from multiple exposures, severity and stage of the infection, and recruitment of infected individuals [13, 16, 30, 31].

This paper extends some previous studies [1, 30, 31] on the dynamics of simple SIR (Susceptible-Infected-Recovered) epidemic models by incorporating a generalized incidence rate in an SIRS (Susceptible-Infected-Recovered-Susceptible) model which satisfies some realistic assumptions. The transitions between subpopulations are mathematically expressed by the following differential equations:

$$\frac{dS}{dt} = \Pi - \beta[1 + f(I;\nu)]\frac{IS^p}{N} - \mu S + \delta R, \tag{1.1}$$

$$\frac{dI}{dt} = \beta[1 + f(I;\nu)]\frac{IS^p}{N} - (\mu + \alpha)I, \tag{1.2}$$

$$\frac{dR}{dt} = \alpha I - (\mu + \delta)R, \tag{1.3}$$

where $p > 0$; $N \equiv S + I + R$ is the total population size; Π is the rate of recruitment of individuals (including newborns and immigrants) into the susceptible class; μ is the natural death rate; β is the probability of infection per contact per unit time; α is the recovery rate; δ is the rate at which recovered individuals lose their immunity (acquired by infection); and $f(I;\nu) \in C^3(\mathbb{R})$ for $I,\ \nu \geq 0$, is a nonlinear function which satisfies the following assumptions:

(A1) $f(0;\nu) = f(I;0) = 0$,
(A2) $\partial f/(\partial\nu) > 0$ for $\nu > 0$,
(A3) $\partial f/(\partial I) > 0$ for $I > 0$,
(A4) $\partial^2 f/(\partial I^2) \leq 0$ for $I > 0$.

The term S^p in the infection rate $\beta[1 + f(I;\nu)]IS^p/N$ is a specific form of the general case $\psi(S)$ satisfying $\psi(0) = 0$ and $\psi'(S) \geq 0$ for $S \geq 0$ (see [27]). We note from (A1) that, for ν and I small, the term $\beta I/N$ (proportional mixing) in the infection rate dominates, while for large enough ν and I, the nonlinear term $f(I;\nu)I/N$ dominates. When $\nu = 0$, the incidence rate reduces to the case of proportional mixing, in which

case the model exhibits at most one endemic equilibrium; the disease dies out if the basic reproductive number is less than unity and invades otherwise. Therefore, ν may be considered as a parameter measuring departure from a proportional mixing rate of incidence (see [1]). Under the assumptions (A1)–(A4), the nonlinear function $f(I;\nu)$ covers both unbounded and bounded (saturated) cases that are frequently used. The nonlinearity may be due to several factors, such as crowding of infected individuals, multiple pathways to infection, stage of infection and its severity, or protective measures taken by susceptible individuals [1, 30, 31]. Some of the specific forms of $f(I;\nu)$ appearing in the literature and satisfying (A1)–(A4) are $f(I;\nu) = \nu I^q$; $f(I;\nu) = \nu I^q/(1+\nu I^q)$ with $0 < q \leq 1$, $\nu > 0$ [1, 31]; $f(I,\nu) = \nu I^q(1+\kappa I)^p/(1+\nu I^q)$ with $p+q=1,\ p,\kappa \geq 0$ [1, 31]; and $f(I;\nu) = 1 - e^{-\nu I}$ [17].

The model (1.1)–(1.3) is studied in [1] for the special case $p = 1$ and $\delta = 0$. It has been shown that this model not only exhibits backward bifurcation but also may undergo a Hopf bifurcation leading to the appearance of two concentric limit cycles. Similar models with nonlinear incidence rates have also been studied by a number of authors. Ruan and Wang [30] analyzed an SIRS model with the incidence rate $\kappa I^l S/(1+\alpha I^h)$ (introduced by Liu and colleagues [24, 25]), where $l = h = 2$, and showed that it undergoes a Bogdanov–Takens bifurcation. The case where $\alpha = 0$ was discussed by Hethcote and van den Driessche [16], Liu, Hethcote, and Levin [24], and Liu, Levin, and Iwasa [25]. Derrick and van den Driessche [8] discussed bifurcation behavior of an SIRS model with the incidence rate $\beta I^2 S/N^2$ [28]. Their study uses a modification of the Bogdanov–Takens–Carr procedure to blow up a Bogdanov point, and Melnikov's method to determine a locus of approximate values along which a homoclinic orbit can be perturbed. The uniqueness of periodic solutions for this model has been shown by Alwash [2].

This paper focuses on the detailed dynamics analysis of the model (1.1)–(1.3). We show that it may exhibit two endemic equilibria, giving rise to the phenomenon of bistability, for some ranges of parameter values. The local stability of these equilibria is investigated, which enables us to classify the types of model equilibria (e.g., attractor, saddle, or repeller). The different kinds of bifurcation the model undergoes for a general incidence rate f satisfying (A1)–(A4) are discussed. The normal form of the model is derived and used to determine the conditions for the existence of various types of Hopf bifurcation (sub- or supercritical, forward or backward). The existence of multiple limit cycles is also discussed. A saddle-node bifurcation is analyzed using Sotomayor's theorem at the turning point of backward bifurcation, in which two endemic equilibria merge. Finally, the existence of a homoclinic orbit is proven by using the Bogdanov–Takens normal form of the model which gives, among others, the local representation of a homoclinic bifurcation curve. The results of our analysis are applied in detail to two different examples of the function f: unbounded and bounded. Numerical simulations for these examples are presented to illustrate the theoretical results.

The paper is organized as follows. The existence of the model equilibria is discussed in section 2. The stability analysis of the equilibria is carried out in section 3 by reducing the model to a two dimensional system. Bifurcation behavior of the reduced model is analyzed in section 4. The results are detailed and numerically illustrated for two examples in section 5. The paper ends with a brief discussion of the results in section 6.

2. Model equilibria. In the absence of the disease ($I = 0$), the model has a unique disease-free equilibrium (DFE), given by $\mathscr{E}_0 = (\Pi/\mu, 0, 0)$. In order to find the

endemic equilibria in the presence of the disease ($I \neq 0$), we note that the equation for the total population is given by $dN/dt = \Pi - \mu N$. Since $N \to \Pi/\mu$ as $t \to \infty$, it follows that at any equilibrium $\mathscr{E}^* = (S^*, I^*, R^*)$, $N^* = S^* + I^* + R^* = \Pi/\mu$, and

$$\Omega = \left\{ (S, I, R) : \ S, I, R \geq 0, \ S + I + R = \frac{\Pi}{\mu} \right\}$$

is a positively invariant region for the model. Henceforth, we restrict our attention to the dynamics of the model in Ω.

Solving equations (1.2) and (1.3) for S and R in terms of I gives, at equilibrium,

$$S^p = \frac{\mu + \alpha}{\beta[1 + f(I;\nu)]} \frac{\Pi}{\mu}, \tag{2.1}$$

$$R = \frac{\alpha I}{\mu + \delta}. \tag{2.2}$$

Substituting (2.1) and (2.2) into (1.1) leads to the following equation for I at equilibrium:

$$\Pi - \frac{\mu(\mu + \alpha + \delta)}{\mu + \delta} I - \mu \left(\frac{\mu + \alpha}{\beta[1 + f(I;\nu)]} \frac{\Pi}{\mu} \right)^{\frac{1}{p}} = 0. \tag{2.3}$$

Defining

$$\mathscr{R}_0 = \frac{\beta}{\mu + \alpha} \left(\frac{\Pi}{\mu} \right)^{p-1}, \tag{2.4}$$

one can see that the roots of (2.3) are the fixed points of the equation:

$$\phi(I;\nu) \equiv \kappa \left(1 - \frac{1}{\mathscr{R}_0^{\frac{1}{p}} [1 + f(I;\nu)]^{\frac{1}{p}}} \right) = I, \tag{2.5}$$

where $\kappa = (\mu + \delta)\Pi/[\mu(\mu + \alpha + \delta)]$. In order to determine the number of endemic equilibria, we consider some properties of the function ϕ listed below:

(i) $\phi_0 \equiv \phi(0;\nu) = \kappa \left(1 - \dfrac{1}{\mathscr{R}_0^{\frac{1}{p}}} \right)$.

(ii) $\dfrac{\partial \phi}{\partial I} = \dfrac{\kappa f_I(I;\nu)}{p \mathscr{R}_0^{\frac{1}{p}} [1 + f(I;\nu)]^{1+\frac{1}{p}}} > 0.$

(iii) $\dfrac{\partial^2 \phi}{\partial I^2} = \kappa \dfrac{f_{II}(I;\nu)[1 + f(I;\nu)] - (1 + 1/p) f_I^2(I;\nu)}{p \mathscr{R}_0^{\frac{1}{p}} [1 + f(I;\nu)]^{2+\frac{1}{p}}} < 0.$

If $\mathscr{R}_0 > 1$, then $\phi_0 > 0$. It follows from (ii) that ϕ is an increasing function and hence $\lim_{I \to \infty} \phi(I;\nu) \equiv \phi_\infty$ is positive and finite. Since ϕ is concave down (by (iii)), there exists a unique $I^* > 0$ such that $\phi(I^*;\nu) = I^*$. If $\mathscr{R}_0 = 1$, then $\phi_0 = 0$ and $\partial\phi/(\partial I)(0) > 1 (\leq 1)$ if $f_I(0;\nu) > p/\kappa (\leq p/\kappa)$. Thus, $\phi(I;\nu) = I$ has a unique positive root if $f_I(0;\nu) > p/\kappa$, and no positive root otherwise. Finally, suppose $\mathscr{R}_0 < 1$, so that $\phi_0 < 0$. In this case, if $\lim_{I \to \infty} f(I;\nu) \equiv f_\infty(\nu) \leq 1/\mathscr{R}_0 - 1$, then $\phi_\infty < 0$, and

thus no positive roots of $\phi(I;\nu) = I$ exist. If $f_\infty(\nu) > 1/\mathscr{R}_0 - 1$, then depending on the functional form of ϕ, the equation $\phi(I;\nu) = I$ may have no, one, or two positive roots (see [1, Figure 1]). Therefore, we have the following theorem.

THEOREM 2.1. (a) *If $\mathscr{R}_0 > 1$, then the model* (1.1)–(1.3) *has a unique endemic equilibrium.*

(b) *If $\mathscr{R}_0 = 1$, then the model* (1.1)–(1.3) *has a unique endemic equilibrium if $f_I(0;\nu) > p/\kappa$ and no endemic equilibrium if $f_I(0;\nu) \le p/\kappa$.*

(c) *If $\mathscr{R}_0 < 1$, then*

(i) *the model* (1.1)–(1.3) *has no endemic equilibria whenever $f_\infty(\nu) \le 1/\mathscr{R}_0 - 1$;*

(ii) *the model* (1.1)–(1.3) *may have no, one, or two endemic equilibria if $f_\infty(\nu) > 1/\mathscr{R}_0 - 1$.*

We now determine the conditions under which the model exhibits two endemic equilibria when $\mathscr{R}_0 < 1$. Let $G(I;\nu) = \phi(I;\nu) - I$, and suppose that $f_I(0;\nu) > p/\kappa$, which implies $(\partial G/\partial I)|_{I=0} > 0$. Then $\lim_{I\to\infty} \partial G/\partial I = -1$ and $\partial^2 G/\partial I^2 = \partial^2\phi/\partial I^2 < 0$ for $I > 0$. Hence $\partial G/\partial I$ is a monotone decreasing function of I, and thus there exists a unique $I_0^* > 0$ such that $(\partial G/\partial I)|_{I=I_0^*} = 0$. This implies that G is an increasing function on $(0, I_0^*]$ and decreasing on (I_0^*, ∞) with maximum value at I_0^*. Since $G(0) < 0$ when $\mathscr{R}_0 < 1$, and $G(0) = 0$ when $\mathscr{R}_0 = 1$, by continuity, it follows that there exists $\mathscr{R}^*$ with $\mathscr{R}^* < 1$ for which $\partial G/\partial I$ has a unique root I_0^* with $(\partial G/\partial I)|_{I=I_0^*} = G(I_0^*) = 0$. Then for some values of $\mathscr{R}_0 \in (\mathscr{R}^*, 1)$, G has two roots I_1^* and I_2^* with $I_1^* < I_2^*$ (corresponding to two endemic equilibria of the model). Assuming $(\partial I/\partial \mathscr{R}_0)|_{I=I_1^*} > 0$ and taking into account that $(\partial\phi/\partial I)|_{I=I_1^*} > 1$, we have

$$\frac{\partial I}{\partial \mathscr{R}_0}\Big|_{I=I_1^*} > \frac{\partial I}{\partial \mathscr{R}_0}\Big|_{I=I_1^*} + \frac{\kappa}{p\mathscr{R}_0^{1+\frac{1}{p}}[1+f(I;\nu)]^{\frac{1}{p}}} > \frac{\partial I}{\partial \mathscr{R}_0}\Big|_{I=I_1^*},$$

which is a contradiction. This implies that $(\partial I/\partial \mathscr{R}_0)|_{I=I_1^*} < 0$, and thus the number of infected individuals at the low endemic equilibrium reduces when $\mathscr{R}_0$ increases. Similarly, it can be shown that $(\partial I/\partial \mathscr{R}_0)|_{I=I_2^*} > 0$, and hence the number of infected individuals at the high endemic equilibrium increases when $\mathscr{R}_0$ increases. Therefore, the quantity $\mathscr{R}^*$ for which $(\partial G/\partial I)|_{I=I_0^*} = G(I_0^*) = 0$ is unique and we have the following theorem.

THEOREM 2.2. *If $f_I(0;\nu) > p/\kappa$, then there exists a unique $\mathscr{R}^*$ with $\mathscr{R}^* < 1$ such that the model* (1.1)–(1.3) *has no endemic equilibrium if $\mathscr{R}_0 < \mathscr{R}^*$, a unique endemic equilibrium if $\mathscr{R}_0 = \mathscr{R}^*$, and two endemic equilibria if $\mathscr{R}^* < \mathscr{R}_0 < 1$.*

Remark 2.1. The case $f_I(0;\nu) > p/\kappa$ in Theorem 2.2 corresponds to backward (transcritical) bifurcation at E_0, which leads to the existence of multiple endemic equilibria for $\mathscr{R}_0 \in (\mathscr{R}^*, 1)$ (see Figure 4.1). There is also a forward transcritical bifurcation at E_0 (when $\mathscr{R}_0 = 1$) if $f_I(0;\nu) < p/\kappa$.

3. Reduced model and stability analysis. Since Ω is a positively invariant region for the model (1.1)–(1.3), assuming that the size of the population has reached its limiting value, i.e., $N \equiv \Pi/\mu = S + I + R$, and using $R = \Pi/\mu - S - I$ in (1.1), we can eliminate R from the equations. This gives the following reduced model:

$$\frac{dS}{dt} = \Pi - \left(\frac{\mu}{\Pi}\right)\beta[1+f(I;\nu)]IS^p - \mu S + \delta\left(\frac{\Pi}{\mu} - S - I\right), \tag{3.1}$$

$$\frac{dI}{dt} = \left(\frac{\mu}{\Pi}\right)\beta[1+f(I;\nu)]IS^p - (\mu+\alpha)I. \tag{3.2}$$

The equilibria of the reduced model correspond to those of the model (1.1)–(1.3). The DFE of (3.1)–(3.2), given by $E_0 = (\Pi/\mu, 0)$, has the corresponding Jacobian

$$J_0 = \begin{pmatrix} -(\mu+\delta) & -\beta\left(\frac{\Pi}{\mu}\right)^{p-1} - \delta \\ 0 & (\mu+\alpha)(\mathscr{R}_0 - 1) \end{pmatrix},$$

with the eigenvalues $\lambda_1 = -(\mu+\delta)$ and $\lambda_2 = (\mu+\alpha)(\mathscr{R}_0 - 1)$. Therefore, E_0 is locally asymptotically stable (LAS) if $\mathscr{R}_0 < 1$, and unstable if $\mathscr{R}_0 > 1$. The threshold quantity $\mathscr{R}_0$ is called the *basic reproductive number*. Biologically, this quantity is defined to be the average number of new infectious cases produced by one infected case introduced into a wholly susceptible population [3]. Mathematically, it determines the condition under which the DFE is LAS. In the following, we discuss how the critical threshold $\mathscr{R}_0$ governs disease dynamics.

Suppose $\mathscr{R}_0 < 1$. If the model has no endemic equilibrium, then (from the Poincaré–Bendixson theorem) no periodic orbits exist in Ω. Since Ω is a bounded positively invariant region and E_0 is the only equilibrium in Ω, the local stability of E_0 implies that every solution initiating in Ω approaches E_0.

THEOREM 3.1. *Suppose $\mathscr{R}_0 < 1$. If the model has no endemic equilibrium, then the DFE is globally asymptotically stable (GAS).*

This theorem implies that E_0 is GAS whenever $\mathscr{R}_0 < \mathscr{R}^*$. Note that if $f(I;\nu)$ is bounded and $\mathscr{R}_0 < 1/[1 + f_\infty(\nu)]$, then $\phi_\infty < 0$, and hence the model has no endemic equilibrium. Thus, the DFE is GAS.

Now suppose that $f_I(0;\nu) > p/\kappa$ and $\mathscr{R}^* < \mathscr{R}_0 < 1$ where the model exhibits two endemic equilibria. Then, we have the following result.

THEOREM 3.2. *If $\mathscr{R}^* < \mathscr{R}_0 < 1$, then one of the endemic equilibria is a saddle and the other is either an attractor or a repeller.*

Proof. Let $E_1^* = (S_1^*, I_1^*)$ and $E_2^* = (S_2^*, I_2^*)$ denote the equilibria of the reduced model with, respectively, low and high number of infected individuals when $\mathscr{R}^* < \mathscr{R}_0 < 1$. We shall show that E_1^* is always a saddle point. The corresponding Jacobian of the reduced model at a typical endemic equilibrium $E^* = (S^*, I^*)$ is given by

$$J^*(\nu) = \begin{pmatrix} -a - (\mu+\delta) & -b - \delta \\ a & b - (\mu+\alpha) \end{pmatrix},$$

where

$$a = p\left(\frac{\mu}{\Pi}\right)\beta[1 + f(I^*;\nu)]I^* S^{*p-1}, \tag{3.3}$$

$$b = \left(\frac{\mu}{\Pi}\right)\beta[1 + f(I^*;\nu) + I^* f_I(I^*;\nu)]S^{*p}. \tag{3.4}$$

The eigenvalues of $J^*(\nu)$ are the roots of the characteristic polynomial $P(\lambda) = \lambda^2 + B\lambda + C$, with

$$B = a - b + 2\mu + \alpha + \delta, \tag{3.5}$$

$$C = a(\mu + \alpha + \delta) - b(\mu + \delta) + (\mu + \alpha)(\mu + \delta). \tag{3.6}$$

Using (2.1) for S^*, the expression for C can be reduced to

$$C = a(\mu + \alpha + \delta)\left(1 - \frac{\partial\phi}{\partial I}\Big|_{I=I^*}\right). \tag{3.7}$$

Since $\partial\phi/(\partial I) > 1$ at E_1^*, it follows that $C|_{I=I_1^*} < 0$, and hence $P(\lambda)$ has two real roots with opposite signs. This implies that E_1^* is a saddle point. Noting that $\partial\phi/(\partial I) < 1$ at E_2^* (for any $\mathscr{R}_0 > \mathscr{R}^*$), it follows from (3.7) that $C|_{I=I_2^*} > 0$. This implies that E_2^* cannot be a saddle point. Therefore, the endemic equilibrium with high number of infected individuals is either an attractor or a repeller. ∎

4. Bifurcation analysis. In this section, different kinds of bifurcation will be discussed. We will undertake the stability analysis of the equilibria to obtain normal forms of the model for Hopf, saddle-node, and Bogdanov–Takens bifurcations.

4.1. Hopf bifurcation. Since $C|_{I=I_2^*} > 0$ at $E_2^* = (S_2^*, I_2^*)$, any exchange of stability of E_2^* corresponds to a Hopf bifurcation, which occurs when $B|_{I=I_2^*} = 0$ in (3.5). Suppose there exists ν^c such that $B(\nu^c) \equiv B|_{I=I_2^*(\nu^c)} = 0$ and $dB/(d\nu)|_{\nu^c} \neq 0$. Then, the model undergoes a Hopf bifurcation in which the roots of $P(\lambda)$ cross the imaginary axis as ν passes through ν^c such that $d(Re[\lambda(\nu)])/(d\nu) = -(1/2)(dB/d\nu) \neq 0$ at ν^c. The kind of Hopf bifurcation will be determined by the sign of the first Lyapunov coefficient of the normal form of the model. In the following, we will obtain this normal form for a neighborhood of E_2^*.

Consider the transformations $S = S^* + x$ and $I = I^* + y$ about a typical endemic equilibrium $E^* = (S^*, I^*)$ (where $C|_{I=I^*} > 0$), as the origin of coordinates (x, y). Using the expressions (2.1) and (2.5), the model (3.1)–(3.2) transforms to

$$\begin{pmatrix} \frac{dx}{dt} \\ \frac{dy}{dt} \end{pmatrix} = J^*(\nu) \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} -M(x,y,\nu) \\ M(x,y,\nu) \end{pmatrix}, \tag{4.1}$$

where

$$M(x,y;\nu) = \left(\frac{\mu}{\Pi}\right)\beta\Big\{[1+f(I^*;\nu)]I^* + p[1+f(I^*;\nu)+I^* f_I(I^*;\nu)]xyS^{*p-1} + [(I^*+y)f_2(y,I^*;\nu) + y^2 f_I(I^*;\nu)](S^{*p} + pxS^{*p-1})\Big\}\sum_{k=2}^{\infty}\begin{pmatrix} p \\ k \end{pmatrix} x^k S^{*p-k}$$

and $f_2(y, I^*; \nu)$ denotes second and higher order terms in y of the expression

$$f(I^*+y;\nu) = f(I^*;\nu) + yf_I(I^*;\nu) + f_2(y,I^*;\nu).$$

Note that $\text{trace}(J^*(\nu^c)) = -B(\nu^c) = 0$. Let $\mathbf{u}$ be an eigenvector of $J^*(\nu^c)$ corresponding to the eigenvalue $i\omega_c$, i.e., $J^*(\nu^c)\mathbf{u} = i\omega_c\mathbf{u}$, where $\mathbf{u} = (u^1, u^2)^T \in \mathbb{C}^2$ and $\omega_c = \sqrt{C(I^*(\nu^c))}$. A simple calculation gives $\mathbf{u} = (b+\delta, -b+\mu+\alpha-i\omega_c)^T$. Letting $\mathbf{u} = Re(\mathbf{u}) + i\text{Im}(\mathbf{u})$ and defining $Q = [\text{Re}(\mathbf{u}), \text{Im}(\mathbf{u})]$, it follows that

$$Q^{-1}J^*(\nu^c)Q = \begin{pmatrix} 0 & \omega_c \\ -\omega_c & 0 \end{pmatrix}.$$

Defining $(\xi, \eta)^T = Q^{-1}(x, y)^T$, the normal form of the system (4.1) is obtained as

$$\begin{pmatrix} \dot{\xi} \\ \dot{\eta} \end{pmatrix} = \begin{pmatrix} 0 & \omega_c \\ -\omega_c & 0 \end{pmatrix}\begin{pmatrix} \xi \\ \eta \end{pmatrix} - \frac{1}{b+\delta}\begin{pmatrix} 1 \\ \frac{\mu+\alpha+\delta}{\omega_c} \end{pmatrix}\tilde{M}(\xi,\eta;\nu), \tag{4.2}$$

where $\tilde{M}(\xi, \eta; \nu) = M((b+\delta)\xi, (-b+\mu+\alpha)\xi - \omega_c\eta; \nu)$. Since

$$\frac{d}{d\nu}\text{trace}(J^*(\nu))\Big|_{\nu=\nu^c} = -\frac{dB}{d\nu}\Big|_{\nu=\nu^c} \neq 0, \tag{4.3}$$

it follows that E^* is LAS for $\nu < \nu^c$ (respectively, $\nu > \nu^c$) and unstable for $\nu > \nu^c$ (respectively, $\nu < \nu^c$) if $dB/(d\nu)\big|_{\nu=\nu^c} < 0$ (respectively, $dB/(d\nu)\big|_{\nu=\nu^c} > 0$), and the model undergoes a Hopf bifurcation at $\nu = \nu_c$ [11, Theorem 8.6]. Evaluating the first Lyapunov coefficient (σ) [11, 22] of system (4.2) at $(0, 0, \nu^c)$ gives

$$16(b+\delta)^2\sigma = -(b+\delta)\left[\tilde{M}_{\xi\xi\xi} + \tilde{M}_{\xi\eta\eta} + \frac{\mu+\alpha+\delta}{\omega_c}(\tilde{M}_{\xi\xi\eta} + \tilde{M}_{\eta\eta\eta})\right]$$

$$- \frac{1}{\omega_c}\left\{\left[1 - \left(\frac{\mu+\alpha+\delta}{\omega_c}\right)^2\right]\tilde{M}_{\xi\eta}(\tilde{M}_{\xi\xi} + \tilde{M}_{\eta\eta}) - \frac{\mu+\alpha+\delta}{\omega_c}(\tilde{M}_{\xi\xi}^2 - \tilde{M}_{\eta\eta}^2)\right\}, \tag{4.4}$$

where

$$\tilde{M}_{\xi\xi\xi}(0,0,\nu^c) = \{Q_{11}^3 M_{xxx} + 3Q_{11}^2 Q_{21} M_{xxy} + 3Q_{11}Q_{21}^2 M_{xyy} + Q_{21}^3 M_{yyy}\}\big|_{(0,0,\nu^c)},$$

$$\tilde{M}_{\eta\eta\eta}(0,0;\nu^c) = Q_{22}^3 M_{yyy}\big|_{(0,0,\nu^c)}, \quad \tilde{M}_{\xi\eta}(0,0;\nu^c) = Q_{22}\{Q_{11}M_{xy} + Q_{21}M_{yy}\}\big|_{(0,0,\nu^c)},$$

$$\tilde{M}_{\xi\eta\eta}(0,0;\nu^c) = Q_{22}^2\{Q_{11}M_{xyy} + Q_{21}M_{yyy}\}\big|_{(0,0,\nu^c)}, \quad \tilde{M}_{\eta\eta}(0,0;\nu^c) = Q_{22}^2 M_{yy}\big|_{(0,0,\nu^c)},$$

$$\tilde{M}_{\xi\xi\eta}(0,0;\nu^c) = Q_{22}\{Q_{11}^2 M_{xxy} + 2Q_{11}Q_{21}M_{xyy} + Q_{21}^2 M_{yyy}\}\big|_{(0,0,\nu^c)},$$

$$\tilde{M}_{\xi\xi}(0,0;\nu^c) = \{Q_{11}^2 M_{xx} + 2Q_{11}Q_{21}M_{xy} + Q_{21}^2 M_{yy}\}\big|_{(0,0,\nu^c)},$$

with $Q_{11} = b + \delta$, $Q_{21} = -b + \mu + \alpha$, and $Q_{22} = -\omega_c$. Using these expressions in (4.4), we have the following theorem.

THEOREM 4.1. *If $\sigma \neq 0$, then a curve of periodic solutions bifurcates from the endemic equilibrium E^* such that*

(a) *for $\sigma < 0$, the model undergoes a supercritical Hopf bifurcation if $dB/(d\nu)|_{\nu=\nu^c} < 0$ and a backward supercritical Hopf bifurcation if $dB/(d\nu)|_{\nu=\nu^c} > 0$;*

(b) *for $\sigma > 0$, the model undergoes a subcritical Hopf bifurcation if $dB/(d\nu)|_{\nu=\nu^c} < 0$ and a backward subcritical Hopf bifurcation if $dB/(d\nu)|_{\nu=\nu^c} > 0$.*

A supercritical (backward supercritical) Hopf bifurcation in case (a) of Theorem 4.1 leads to the appearance (disappearance) of a stable limit cycle when ν passes through ν^c. In case (b), the model exhibits an unstable limit cycle around E^* when ν passes through ν^c. Thus, every solution starting inside the limit cycle approaches E^* (see [1, Figure 2]).

Remark 4.1. Note that E_0 is unstable whenever $\mathscr{R}_0 > 1$, and the unique endemic equilibrium is either stable or unstable. Since Ω is a bounded positively invariant set, if the model undergoes a subcritical Hopf bifurcation, then (from the Poincaré–Bendixson theorem) every solution initiating outside the limit cycle must approach a stable limit cycle. This shows that when $\mathscr{R}_0 > 1$, two concentric limit cycles can coexist: the inner one unstable and the outer one stable (see [1]). We shall discuss the existence of multiple limit cycles in section 5.2.

4.2. Saddle-node bifurcation. In order to show that the model may undergo a saddle-node bifurcation, we will take advantage of Sotomayor's theorem [12, Theorem 3.4.1]. Considering $\mathscr{R}_0$ as the bifurcation parameter, it follows from Theorem 2.2 that at $\mathscr{R}_0 = \mathscr{R}^*$, the model has a unique endemic equilibrium $E_0^* = (S_0^*, I_0^*)$ for which the Jacobian $J_{\mathscr{R}^*}^*(E_0^*)$ has a simple eigenvalue 0 and an eigenvalue $\lambda = -B_{\mathscr{R}^*}(E_0^*)$. Note that $\partial\phi/(\partial I)\big|_{I=I_0^*} = 1$, and hence $C_{\mathscr{R}^*}(E_0^*) = 0$ (see (3.7)). Let $\mathbf{V} = (v_1, v_2)^T$ and $\mathbf{W} = (w_1, w_2)$ be right and left eigenvectors of $J_{\mathscr{R}^*}^*(E_0^*)$, respectively, corresponding to the zero eigenvalue. Then, a simple calculation yields

$$\mathbf{V} = \big[b+\delta, -a-(\mu+\delta)\big]^T, \qquad \mathbf{W} = \big[a, a+\mu+\delta\big]. \tag{4.5}$$

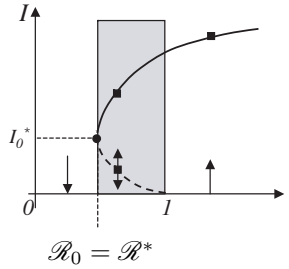

FIG. 4.1. *A backward bifurcation at $\mathscr{R}_0 = 1$ with a dashed curve for the location of the saddle point and solid curve for the location of the other endemic equilibrium. The saddle-node bifurcation occurs at $E_0^* = (S_0^*, I_0^*)$ when $\mathscr{R}_0$ passes through $\mathscr{R}^*$.*

Let $\mathscr{G} = (g_1, g_2)$, where g_1 and g_2 are, respectively, the right-hand sides of equations in (3.1)–(3.2). By considering β as a function of $\mathscr{R}_0$, we have

$$\mathscr{L}_1 \equiv \mathbf{W} \cdot \frac{\partial \mathscr{G}}{\partial \mathscr{R}_0}\Big|_{(E_0^*, \mathscr{R}^*)} = \frac{(\mu+\alpha)(\mu+\delta)I_0^*}{\mathscr{R}^*} > 0. \tag{4.6}$$

Using (2.1), it can be seen that

$$\begin{aligned}\mathscr{L}_2 \equiv \mathbf{W} \cdot [D^2_{(S,I)}\mathscr{G}(\mathbf{V},\mathbf{V})]\Big|_{(E_0^*, \mathscr{R}^*)} &= (w_1 - w_2)\left[\frac{\partial^2 g_1}{\partial S^2}v_1^2 + \frac{\partial^2 g_1}{\partial I^2}v_2^2 + 2\frac{\partial^2 g_1}{\partial S \partial I}v_1 v_2\right] \\ = -(\mu+\delta)\frac{\mu\beta}{\Pi}\Big\{ &- p(p-1)[1+f(I_0^*;\nu)]I_0^* S_0^{*p-2}(b+\delta)^2 \\ &- \big[2f_I(I_0^*;\nu) + I_0^* f_{II}(I_0^*;\nu)\big](a+\mu+\delta)^2 S_0^{*p} \\ &+ 2p\big[1+f(I_0^*;\nu) + I_0^* f_I(I_0^*;\nu)\big](b+\delta)(a+\mu+\delta)S_0^{*p-1}\Big\}.\end{aligned}$$

Then, since $C_{\mathscr{R}^*}(E_0^*) = 0$, after some manipulations, it follows from (A4) that

$$\begin{aligned}S_0^*\mathscr{L}_2 &= -(\mu+\delta)\left\{a(1+p)(b+\delta)^2 - \left(\frac{\mu\beta}{\Pi}\right)I_0^* S_0^{*p+1} f_{II}(I_0^*;\nu)(a+\mu+\delta)^2\right\} \\ &< -a(1+p)(\mu+\delta)(b+\delta)^2 < 0.\end{aligned} \tag{4.7}$$

Thus, from Sotomayor's theorem [12], there is a smooth curve of equilibria in $\mathbb{R}^2$ passing through E_0^*, tangent to the line $\mathscr{R}_0 = \mathscr{R}^*$ (see Figure 4.1). Since $\mathscr{L}_1 > 0$ and $\mathscr{L}_2 < 0$, there are no equilibria near E_0^* when $\mathscr{R}_0 < \mathscr{R}^*$ and two equilibria when $\mathscr{R}_0 > \mathscr{R}^*$. In fact, from (4.6) and (4.7), the local phase portraits of the model (3.1)–(3.2) are topologically equivalent to those of $\dot{v} = (\mathscr{R}_0 - \mathscr{R}^*) - (v - I_0^*)^2$. Therefore, we have the following theorem.

THEOREM 4.2. *If $f_I(0;\nu) > p/\kappa$, then the model undergoes a saddle-node bifurcation at E_0^* when $\mathscr{R}_0$ passes through the critical value $\mathscr{R}^*$.*

4.3. Homoclinic bifurcation. In this section, the Bogdanov–Takens bifurcations of the model (3.1)–(3.2) are discussed, from which the local representation of a homoclinic bifurcation curve is derived. Let $\mathscr{R}_{BT}$ and ν_{BT} denote the bifurcation parameters at which the model simultaneously undergoes a saddle-node bifurcation and a Hopf bifurcation. Here, we first consider the conditions for determining $\mathscr{R}_{BT}$

and ν_{BT}. Using (3.3) and (3.4), it can be seen that

$$\text{trace } J^*(\nu) = p(\mu+\alpha)(\mu+\delta)(u-1)\left(1-\frac{\partial\phi}{\partial I}\right), \tag{4.8}$$

$$\det J^*(\nu) = p(\mu+\alpha)(u-1)\frac{\partial\phi}{\partial I} - (\mu+\delta)\left(1+\frac{p(\mu+\alpha)(u-1)}{\mu+\alpha+\delta}\right), \tag{4.9}$$

where $u = \mathscr{R}_0^{1/p}[1+f(I;\nu)]^{1/p}$. A simple calculation yields that if trace $J^*(\nu) = \det J^*(\nu) = 0$, then

$$u = 1 + \frac{(\mu+\delta)(\mu+\alpha+\delta)}{p\alpha(\mu+\alpha)}. \tag{4.10}$$

Thus, it follows from (2.5) that $I_0^* = \kappa(1-1/u)$. Noting that $\partial\phi/\partial I = 1$ at the Bogdanov point (S_0^*, I_0^*), it can be seen that

$$I_0^* f_I(I_0^*;\nu_{BT}) = \frac{p(u-1)u^p}{\mathscr{R}_{BT}}. \tag{4.11}$$

Therefore, for given functional form of $f(I;\nu)$, equations (4.10) and (4.11) provide conditions for determining $\mathscr{R}_{BT}$ and ν_{BT}. These general equations will be applied to two specific forms of $f(I;\nu)$ in section 5, where closed form expressions for the Bogdanov point(s) are given.

We continue the analysis of the homoclinic bifurcation by deriving the normal form at the Bogdanov point. At this point, $B = C = 0$, and it follows from (3.5) and (3.6) that

$$\alpha a = (\mu+\delta)^2. \tag{4.12}$$

Using the transformations $S = S_0^* + \xi$ and $I = I_0^* + \eta$ (at $\mathscr{R}_0 = \mathscr{R}_{BT}$, $\nu = \nu_{BT}$), the model (3.1)–(3.2) becomes

$$\begin{pmatrix} \dot\xi \\ \dot\eta \end{pmatrix} = J(E_0^*)\begin{pmatrix} \xi \\ \eta \end{pmatrix} + \begin{pmatrix} -M(\xi,\eta;\nu_{BT}) \\ M(\xi,\eta;\nu_{BT}) \end{pmatrix}, \tag{4.13}$$

where, by (4.12),

$$J(E_0^*) = \frac{1}{\alpha}\begin{pmatrix} -(\mu+\delta)(\mu+\alpha+\delta) & -(\mu+\alpha+\delta)^2 \\ (\mu+\delta)^2 & (\mu+\delta)(\mu+\alpha+\delta) \end{pmatrix}.$$

Since $J(E_0^*) \neq 0$, there exist real linearly independent vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ such that $J(E_0^*)\mathbf{x}_1 = 0$ and $J(E_0^*)\mathbf{x}_2 = \mathbf{x}_1$. These vectors are given by

$$\mathbf{x}_1 = [-(\mu+\alpha+\delta), \mu+\delta]^T, \qquad \mathbf{x}_2 = [-1,1]^T.$$

Similarly, there exist vectors $\mathbf{y}_1$ and $\mathbf{y}_2$ such that $[J(E_0^*)]^T\mathbf{y}_1 = 0$ and $[J(E_0^*)]^T\mathbf{y}_2 = \mathbf{y}_1$, where $[J(E_0^*)]^T$ is the transposed matrix. These vectors may be expressed as

$$\mathbf{y}_1 = \left(\frac{1}{\alpha}\right)[\mu+\delta, \mu+\alpha+\delta]^T, \qquad \mathbf{y}_2 = \left(\frac{1}{\alpha}\right)[-1,-1]^T.$$

It is easy to verify that $\mathbf{x}_1\cdot\mathbf{y}_2 = \mathbf{x}_2\cdot\mathbf{y}_1 = 1$ and $\mathbf{x}_2\cdot\mathbf{y}_2 = \mathbf{x}_1\cdot\mathbf{y}_1 = 0$. By defining $\tilde{Q} = [\mathbf{x}_1, \mathbf{x}_2]$, any $(\xi,\eta)^T$ can be uniquely represented by $(\xi,\eta)^T = \tilde{Q}(\theta_1,\theta_2)^T$, for some real $\theta_1, \theta_2 \in \mathbb{R}$, from which the new coordinates (θ_1,θ_2) are obtained as

$$\theta_1 = -\frac{\xi+\eta}{\alpha}, \qquad \theta_2 = \frac{\mu+\delta}{\alpha}\xi + \frac{\mu+\alpha+\delta}{\alpha}\eta.$$

Considering (4.1) for all $\mathscr{R}_0$ and ν with $|\mathscr{R}_0 - \mathscr{R}_{BT}|$ and $|\nu - \nu_{BT}|$ small (recall that $B = C = 0$ at $\mathscr{R}_0 = \mathscr{R}_{BT}$, $\nu = \nu_{BT}$), and expanding its right-hand side as a Taylor series in (θ_1, θ_2) at $(0, 0)$ gives

$$\begin{aligned}
\frac{d\theta_1}{dt} &= \theta_2, \qquad (4.14)\\
\frac{d\theta_2}{dt} &= -C\theta_1 - B\theta_2\\
&\quad + \big[r^2 d_{11}(I^*, S^*) - rs d_{12}(I^*, S^*) + s^2 d_{22}(I^*, S^*)\big]\theta_1^2\\
&\quad + \big[d_{11}(I^*, S^*) - d_{12}(I^*, S^*) + d_{22}(I^*, S^*)\big]\theta_2^2\\
&\quad + \big[2r d_{11}(I^*, S^*) - (r+s) d_{12}(I^*, S^*) + 2s d_{22}(I^*, S^*)\big]\theta_1\theta_2\\
&\quad + O(\|(\theta_1, \theta_2)\|^3), \qquad (4.15)
\end{aligned}$$

where $r = \mu + \alpha + \delta$, $s = \mu + \delta$, and

$$\begin{aligned}
d_{11}(I^*, S^*) &= \frac{1}{2}\frac{\mu\beta}{\Pi} p(p-1)[1 + f(I^*; \nu)] I^* S^{*p-2},\\
d_{12}(I^*, S^*) &= \frac{\mu\beta}{\Pi} p[1 + f(I^*; \nu) + I^* f_I(I^*; \nu)] S^{*p-1},\\
d_{22}(I^*, S^*) &= \frac{1}{2}\frac{\mu\beta}{\Pi}[2 f_I(I^*; \nu) + I^* f_{II}(I^*; \nu)] S^{*p}.
\end{aligned}$$

For the sake of convenience, we define

$$\begin{aligned}
\mathscr{K}_{11} &= r^2 d_{11}(I^*, S^*) - rs d_{12}(I^*, S^*) + s^2 d_{22}(I^*, S^*),\\
\mathscr{K}_{12} &= 2r d_{11}(I^*, S^*) - (r+s) d_{12}(I^*, S^*) + 2s d_{22}(I^*, S^*),\\
\mathscr{K}_{22} &= d_{11}(I^*, S^*) - d_{12}(I^*, S^*) + d_{22}(I^*, S^*).
\end{aligned}$$

Assume that $\mathscr{K}_{12} \neq 0$ at the Bogdanov point. Then, there is a neighborhood of $(S_0^*, I_0^*; \mathscr{R}_{BT}, \nu_{BT})$ in which $\mathscr{K}_{12} \neq 0$. By setting $\Theta_1 = \theta_1 - \chi$, where $\chi = B/\mathscr{K}_{12}$, denoting Θ_1 as θ_1, and using a time reparametrization $dt = (1 - \mathscr{K}_{22}\theta_1)d\tau$, it is easy to check that (4.14) and (4.15) become

$$\begin{aligned}
\frac{d\theta_1}{d\tau} &= (1 - \mathscr{K}_{22}\theta_1)\theta_2, \qquad (4.16)\\
\frac{d\theta_2}{d\tau} &= (1 - \mathscr{K}_{22}\theta_1)\Big\{ -\chi(C - \mathscr{K}_{11}\chi) - (C - 2\mathscr{K}_{11}\chi)\theta_1\\
&\qquad + \mathscr{K}_{11}\theta_1^2 + \mathscr{K}_{22}\theta_2^2 + \mathscr{K}_{12}\theta_1\theta_2 + O(\|(\theta_1, \theta_2)\|^3)\Big\}. \qquad (4.17)
\end{aligned}$$

Introduce new variables $\Theta_1 = \theta_1$ and $\Theta_2 = (1 - \mathscr{K}_{22}\theta_1)\theta_2$ and rename Θ_1, Θ_2 as θ_1, θ_2, respectively. Then, (4.16) and (4.17) become

$$\begin{aligned}
\frac{d\theta_1}{d\tau} &= \theta_2, \qquad (4.18)\\
\frac{d\theta_2}{d\tau} &= -\chi(C - \mathscr{K}_{11}\chi) + \big[2\chi(C - \mathscr{K}_{11}\chi)\mathscr{K}_{22} - (C - 2\mathscr{K}_{11}\chi)\big]\theta_1 + \mathscr{K}_{12}\theta_1\theta_2\\
&\quad - \Big[\chi(C - \mathscr{K}_{11}\chi)\mathscr{K}_{22}^2 - 2(C - 2\mathscr{K}_{11}\chi)\mathscr{K}_{22} - \mathscr{K}_{11}\Big]\theta_1^2 + O(\|(\theta_1, \theta_2)\|^3). \qquad (4.19)
\end{aligned}$$

Let $\mathscr{J} = \chi(C - \mathscr{K}_{11}\chi)\mathscr{K}_{22}^2 - 2(C - 2\mathscr{K}_{11}\chi)\mathscr{K}_{22} - \mathscr{K}_{11}$. Since $\chi \to 0$, $C \to 0$ as $\mathscr{R}_0 \to \mathscr{R}_{BT}$ and $\nu \to \nu_{BT}$, it follows from (A4) that

$$\lim_{\substack{\mathscr{R}_0 \to \mathscr{R}_{BT} \\ \nu \to \nu_{BT}}} \mathscr{J} > \frac{1}{2S_0^*}(\mu + \alpha + \delta)\big[(\mu + \alpha + \delta)a + p(\mu + \delta)(a + \mu + \delta)\big] > 0.$$

Thus, since $\mathscr{K}_{12} \neq 0$, by making the change of variables $\Theta_1 = \mathscr{K}_{12}^2\theta_1/\mathscr{J}$, $\Theta_2 = \mathscr{K}_{12}^3\theta_2/\mathscr{J}^2$, and $t = \mathscr{J}\tau/\mathscr{K}_{12}$ in a small neighborhood of the origin and renaming Θ_1, Θ_2 as θ_1, θ_2, respectively, we have

(4.20)
$$\frac{d\theta_1}{dt} = \theta_2,$$
$$\frac{d\theta_2}{dt} = -\mathscr{K}_{12}^4\chi(C-\mathscr{K}_{11}\chi)/\mathscr{J}^3 + \mathscr{K}_{12}^2\big[2\chi(C-\mathscr{K}_{11}\chi)\mathscr{K}_{22} - (C-2\mathscr{K}_{11}\chi)\big]\theta_1/\mathscr{J}^2$$
(4.21)
$$-\theta_1^2 + \theta_1\theta_2 + O(\|(\theta_1,\theta_2)\|^3).$$

Therefore, from Theorem 8.4 and (8.52)–(8.54) in [22], the following theorem is established.

THEOREM 4.3. *Assume $\mathscr{K}_{12} \neq 0$ at the Bogdanov point. Then, the reduced model* (3.1)–(3.2) *has the following bifurcation behavior in a small neighborhood of E_0^*:*

(a) *there is a saddle-node bifurcation curve*

$$SN = \Big\{(\mathscr{R}_0,\nu):\ 4\chi(C-\mathscr{K}_{11}\chi)\mathscr{J} + \big[2\chi(C-\mathscr{K}_{11}\chi)\mathscr{K}_{22} - (C-2\mathscr{K}_{11}\chi)\big]^2 = 0\Big\};$$

(b) *there is a Hopf bifurcation curve*

$$H = \Big\{(\mathscr{R}_0,\nu):\ (\chi = 0 \Leftrightarrow B = 0),\ C > 0\Big\};$$

(c) *there is a homoclinic bifurcation curve*

$$P = \Big\{(\mathscr{R}_0,\nu):\ 2\chi(C-\mathscr{K}_{11}\chi)\mathscr{K}_{22} < C - 2\mathscr{K}_{11}\chi,$$
$$25\,\chi(C-\mathscr{K}_{11}\chi)\mathscr{J} - 6\big[2\chi(C-\mathscr{K}_{11}\chi)\mathscr{K}_{22} - (C-2\mathscr{K}_{11}\chi)\big]^2$$
$$= o(\|(\mathscr{R}_0 - \mathscr{R}_{BT}, \nu - \nu_{BT})\|^2)\Big\}.$$

Remark 4.2. The Bogdanov–Takens normal form in (4.21)–(4.21) is based on the assumption $\mathscr{K}_{12} \neq 0$ in a neighborhood of the Bogdanov point. It is worth noting that

$$\lim_{\substack{\mathscr{R}_0 \to \mathscr{R}_{BT} \\ \nu \to \nu_{BT}}} \mathscr{K}_{12} = \frac{1}{\alpha S_0^*}\Big\{-(\mu+\alpha+\delta)(\mu+\delta)^2 - p[(\mu+\alpha+\delta)^2(\mu+\delta) - \alpha^2(\mu+\alpha)]\Big\}$$
$$+ \left(\frac{\mu}{\Pi}\right)\beta(\mu+\delta)I_0^*S_0^{*p+1}f_{II}(I_0^*;\nu_{BT}).$$

Thus, for the parameter values for which

$$-(\mu+\alpha+\delta)(\mu+\delta)^2 - p[(\mu+\alpha+\delta)^2(\mu+\delta) - \alpha^2(\mu+\alpha)] < 0,$$

there is a neighborhood of $E_0^* = (S_0^*, I_0^*)$ in which $\mathscr{K}_{12} < 0$.

5. Examples. In this section, we shall detail the results of our analysis for two different forms of incidence rate. Numerical simulations are also presented to illustrate these results.

5.1. Unbounded case: $f(I;\nu) = \nu I^q$ ($\nu > 0$, $0 < q \leq 1$). In this case, if $p = 1$, then it can be seen from (3.5) that at a positive endemic equilibrium,

$$B = \frac{1}{(\mu+\alpha+\delta)(1+f)}\tilde{B}, \tag{5.1}$$

where

$$\tilde{B} = (\mu+\alpha)(\mu+\delta)\mathscr{R}_0 f^2 + \big\{(\mu+\delta)[2(\mu+\alpha)\mathscr{R}_0+\delta] - q(\mu+\alpha)(\mu+\alpha+\delta)\big\}f \\ +(\mu+\delta)[(\mu+\alpha)\mathscr{R}_0+\delta]. \tag{5.2}$$

Thus, $B(f) = 0$ if and only if $\tilde{B}(f) = 0$ and has two real roots for f (including the case of multiplicity 2) if and only if

$$\mathscr{R}_0 \leq \frac{(z_0-1)^2}{4z_1} \equiv \ell_0, \tag{5.3}$$

where

$$z_0 = \frac{\delta(\mu+\delta)}{q(\mu+\alpha)(\mu+\alpha+\delta)}, \qquad z_1 = \frac{\mu+\alpha}{\delta}z_0. \tag{5.4}$$

These roots are positive if and only if $z_0 < 1$, or equivalently,

$$q > \frac{\delta(\mu+\delta)}{(\mu+\alpha)(\mu+\alpha+\delta)}. \tag{5.5}$$

Suppose now that (5.3) and (5.5) hold. Then, there are positive ν_1, ν_2 such that $B(\nu_1) = B(\nu_2) = 0$. Differentiating B with respect to ν at ν_i and using (2.5) gives

$$\frac{dB}{d\nu}\Big|_{\nu=\nu_i} = \frac{1}{(\mu+\alpha+\delta)(1+f)}\frac{d\tilde{B}}{d\nu}\Big|_{\nu=\nu_i}, \qquad i = 1,2,$$

where, after some calculations, it can be seen that

$$\begin{aligned}\frac{d\tilde{B}}{d\nu}\Big|_{\nu=\nu_i} &= \big\{2(\mu+\alpha)(\mu+\delta)\mathscr{R}_0(1+f) - q(\mu+\alpha)(\mu+\alpha+\delta) + \delta(\mu+\delta)\big\}\frac{df}{d\nu}\Big|_{\nu=\nu_i} \\ &= \frac{2\delta(\mu+\delta)z_1^2\mathscr{R}_0}{z_0}\left\{f + 1 - \frac{1-z_0}{2z_1\mathscr{R}_0}\right\}\left(\frac{\mathscr{R}_0(1+f)^2 f I^*}{\kappa\nu\big[\mathscr{R}_0(1+f)^2 - (1+f) - qf\big]}\right)\Bigg|_{\nu=\nu_i}.\end{aligned}$$

Let $h_0 = (1-z_0)/(2z_1\mathscr{R}_0) - 1$ and $g = \mathscr{R}_0(1+f)^2 - (1+f) - qf$. If $\mathscr{R}_0 \geq 1$, then $g \geq f^2 + (1-q)f > 0$, and therefore,

$$\operatorname{sign}\left(\frac{dB}{d\nu}\Big|_{\nu=\nu_i}\right) = \operatorname{sign}(f-h_0)\big|_{\nu=\nu_i}, \qquad i = 1,2. \tag{5.6}$$

Let f_1 and f_2 (with $f_1 < f_2$) be positive roots of (5.1) when (5.3) and (5.5) hold. Then, if $\mathscr{R}_0 < \ell_0$, it follows that

$$\tilde{B}(h_0) = (\mu+\alpha)(\mu+\delta)\left[1 - \frac{(1-z_0)^2}{4z_1\mathscr{R}_0}\right] < (\mu+\alpha)(\mu+\delta)\left[1 - \frac{(1-z_0)^2}{4z_1\ell_0}\right] = 0,$$

and hence $f_1 < h_0 < f_2$. Therefore, from (5.6) it can be seen that $dB/(d\nu) < 0\,(> 0)$ at ν_1 (at ν_2). Thus, Theorem 4.1 implies that at E_2^* (where $C > 0$), the model undergoes a Hopf bifurcation which is forward at ν_1 and backward at ν_2.

THEOREM 5.1. *Suppose $1 \le \mathscr{R}_0 < \ell_0$ and $z_0 < 1$. Then the model undergoes a forward (backward) Hopf bifurcation at ν_1 (at ν_2). This bifurcation is supercritical if $\sigma < 0$ and subcritical if $\sigma > 0$.*

Suppose now $\mathscr{R}_0 < 1$. Thus, g has a unique positive root, namely f_0, such that $g < 0$ for $0 < f < f_0$ and $g > 0$ for $f > f_0$. Therefore, we have the following theorem.

THEOREM 5.2. *Suppose $\mathscr{R}^* < \mathscr{R}_0 < \min(\ell_0, 1)$ and $z_0 < 1$.*

(a) *If f_i lies in the interval between f_0 and h_0, then $dB/(d\nu) < 0$, and the model undergoes a forward supercritical (subcritical) Hopf bifurcation if $\sigma < 0$ (if $\sigma > 0$).*

(b) *If f_i lies outside the interval between f_0 and h_0, then $dB/(d\nu) > 0$, and the model undergoes a backward supercritical (subcritical) Hopf bifurcation if $\sigma < 0$ (if $\sigma > 0$).*

Remark 5.1. It can be seen, after some algebra, that for $p > 0$, $B = 0$ if and only if

$$1 - \frac{1}{w} = \tilde{z}_0 + \tilde{z}_1 u, \tag{5.7}$$

where $w = 1 + f$, $u = [\mathscr{R}_0(1 + f)]^{1/p}$, and

$$\tilde{z}_0 = \frac{(\mu + \delta)[\delta - (p-1)(\mu + \alpha)]}{q(\mu + \alpha)(\mu + \alpha + \delta)}, \qquad \tilde{z}_1 = \frac{p(\mu + \delta)}{q(\mu + \alpha + \delta)}. \tag{5.8}$$

Note that for the case $p = 1$, $\tilde{z}_0$ and $\tilde{z}_1$ reduce to z_0 and z_1, respectively, in (5.4). Equation (5.7) has a positive root of multiplicity 2 if and only if the tangency condition $\tilde{z}_1 u = p/w$ is satisfied. Then, it follows from (5.7) that there is a unique positive root u_* given by

$$u_* = \frac{p(1 - \tilde{z}_0)}{\tilde{z}_1(1 + p)}, \tag{5.9}$$

as long as $\tilde{z}_0 < 1$. This corresponds to a unique critical value of $\mathscr{R}_{crit} = \tilde{z}_1 u_*^{p+1}/p$ such that there is no Hopf bifurcation point if $\mathscr{R}_0 > \mathscr{R}_{crit}$, and two Hopf bifurcation points if $\mathscr{R}_0 < \mathscr{R}_{crit}$ and sufficiently close to $\mathscr{R}_{crit}$. These bifurcation points merge at the critical value $\mathscr{R}_{crit}$. Note that if $p = 1$, the threshold $\mathscr{R}_{crit}$ reduces to ℓ_0 in (5.3).

In the following, we consider the case where the model simultaneously undergoes a saddle-node and a Hopf bifurcation. It is easy to see that $If_I(I; \nu_{BT}) = qf(I; \nu_{BT})$, and hence from the definition of u and (4.11), we have

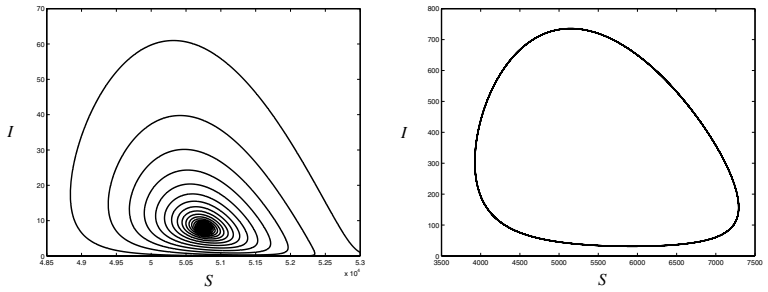
$$q\left(\frac{u^p}{\mathscr{R}_{BT}} - 1\right) = \frac{p}{\mathscr{R}_{BT}}(u - 1)u^p, \tag{5.10}$$

which implies that

$$\mathscr{R}_{BT} = \frac{u^p}{q}(p + q - pu). \tag{5.11}$$

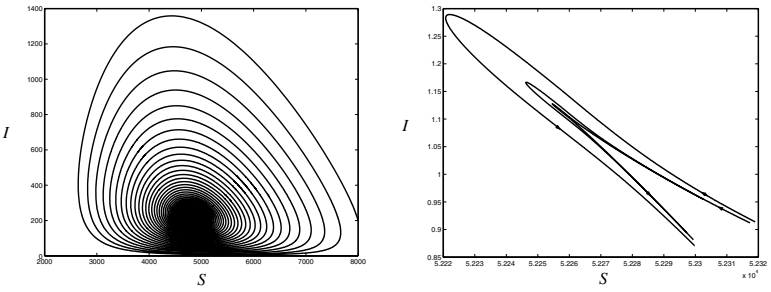
Thus, using the expression $I = \kappa(1 - 1/u)$ (see equation (2.5)), we find

$$\nu_{BT} = \frac{f(I; \nu)}{I^q} = \frac{1}{I^q}\left(\frac{u^p}{\mathscr{R}_{BT}} - 1\right). \tag{5.12}$$



(A) (B)

FIG. 5.1. (A) *Phase portrait for the stable endemic equilibrium in Example* 1 *with the parameter values* $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $q = 0.05$, $\delta = 0.1$, *and* $(\mathscr{R}_0, \nu) = (0.95, 0.08)$. (B) *Phase portrait for a stable periodic orbit in Example* 1 *with the parameter values:* $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $q = 0.05$, $\delta = 0.1$, *and* $(\mathscr{R}_0, \nu) = (0.95, 7)$.



(A) (B)

FIG. 5.2. (A) *Phase portrait for the stable endemic equilibrium in Example* 1 *with the parameter values* $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $q = 0.05$, $\delta = 0.1$, *and* $(\mathscr{R}_0, \nu) = (0.95, 8)$. (B) *Phase portrait at the Bogdanov point in Example* 1 *with the parameter values* $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $q = 0.05$, $\delta = 0.1$, *and* $(\mathscr{R}_{BT}, \nu_{BT}) = (0.9115413570, 0.1015835081)$.

It is worth noting that from (4.10), (5.11), and (5.12) it follows that the Bogdanov point for this example is unique.

To numerically illustrate the results of this bifurcation analysis, the model was simulated with parameter values estimated for a measles infection [1, 5]: $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $\delta = 0.1$, $q = 0.05$, and $p = 1$. With these values and $\mathscr{R}_0 = 0.95$, we have $\nu_1 = 9.49167 \times 10^{-2}$ and $\nu_2 = 7.14126$, corresponding to two Hopf bifurcation points. Numerical calculations show that $dB/d\nu < 0$, $\sigma < 0$ at ν_1, and $dB/d\nu > 0$, $\sigma < 0$ at ν_2, so that the Hopf bifurcation is supercritical at ν_1 and backward supercritical at ν_2. Figures 5.1(A)-(B) and 5.2(A) show phase portraits of the model for $\nu = 0.08 < \nu_1$ (with the stable endemic equilibrium), $\nu_1 < \nu = 7 < \nu_2$ (with the stable limit cycle), and $\nu = 8 > \nu_2$ (with a stable endemic equilibrium), respectively. The limit cycle created by the Hopf bifurcation at ν_1 shrinks and disappears when ν passes through ν_2 (see Figure 5.3(A)). Figure 5.2(B) shows the phase portrait at the Bogdanov point with $(\mathscr{R}_{BT}, \nu_{BT}) = (0.9115413570, 0.1015835081)$, which geometrically has cusp orbits. Homoclinic orbits exist as a codimension-1 family in every neighborhood of the Bogdanov point in parameter space.

In order to provide more intuition into the theoretical analysis of the model, bifurcation curves are displayed in Figure 5.4, with the same parameter values as used

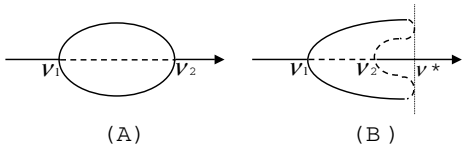


FIG. 5.3. *Bifurcation diagrams for* (A) *a supercritical Hopf bifurcation at* ν_1 *and a backward supercritical Hopf bifurcation at* ν_2*;* (B) *a supercritical Hopf bifurcation at* ν_1 *and a backward subcritical Hopf bifurcation at* ν_2*. above. This figure shows the $\mathscr{R}^*(\nu)$ and $\mathscr{R}_H(\nu)$ curves for a range of values of the bifurcation parameter ν, along which saddle-node and Hopf bifurcations, respectively, occur. Figure 5.4 also shows the saddle-node and Hopf bifurcation branches, locally described in parts (a) and (b) of Theorem 4.3, passing through the (unique) Bogdanov point.

5.2. Bounded case: $f(I;\nu) = \nu I^q/(1+\nu I^q)$ ($\nu > 0$, $0 < q \le 1$). With this function, if $p = 1$, then at a positive endemic equilibrium

$$B = \frac{1}{(\mu+\alpha+\delta)(1+h)(1+2h)}\tilde{\tilde{B}}, \tag{5.13}$$

where

$$\tilde{\tilde{B}} = (\mu+\delta)\big[(\mu+\alpha)\mathscr{R}_0+\delta\big] + \big\{(\mu+\delta)[4(\mu+\alpha)\mathscr{R}_0+3\delta] - q(\mu+\alpha)(\mu+\alpha+\delta)\big\}h$$
$$+2(\mu+\delta)\big[2(\mu+\alpha)\mathscr{R}_0+\delta\big]h^2, \tag{5.14}$$

and $h \equiv \nu I^q$. A simple calculation shows that $\tilde{\tilde{B}}(h) = 0$ has two real roots h (including the case of multiplicity 2) if and only if

$$\mathscr{R}_0 \le \frac{\big[(3-2\sqrt{2})z_0 - 1\big]\big[(3+2\sqrt{2})z_0 - 1\big]}{8z_1}, \tag{5.15}$$

where z_0 and z_1 are defined in (5.4). If (5.15) holds, then the roots of $\tilde{\tilde{B}}(h) = 0$ are positive if and only if $z_0 < 3 - 2\sqrt{2}$, or equivalently,

$$q > \frac{(3+2\sqrt{2})\delta(\mu+\delta)}{(\mu+\alpha)(\mu+\alpha+\delta)}. \tag{5.16}$$

Suppose (5.15) and (5.16) hold and ν_1 and ν_2 correspond, respectively, to the two positive roots of $\tilde{\tilde{B}}(h) = 0$, namely h_1 and h_2 (with $h_1 < h_2$). Then,

$$\frac{dB}{d\nu}\Big|_{\nu=\nu_i} = \frac{1}{(\mu+\alpha+\delta)(1+h)(1+2h)}\frac{d\tilde{\tilde{B}}}{d\nu}\Big|_{\nu=\nu_i},$$

where

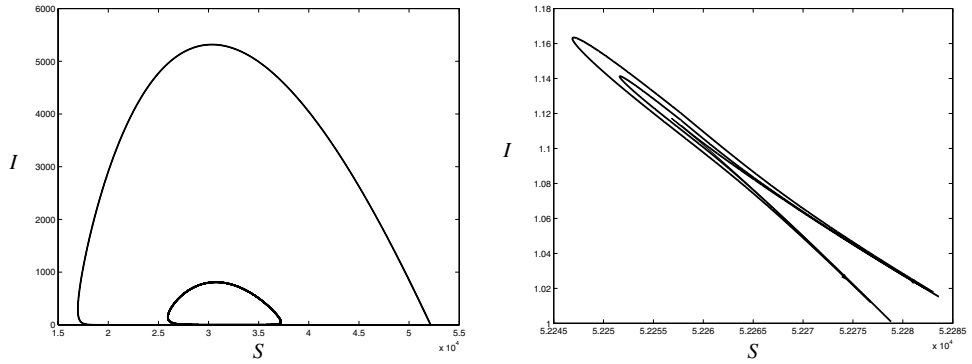
$$\frac{d\tilde{\tilde{B}}}{d\nu}\Big|_{\nu=\nu_i} = \delta(\mu+\delta)\left\{\left(\frac{8z_1\mathscr{R}_0}{z_0}+4\right)h + \frac{4z_1\mathscr{R}_0}{z_0} - \frac{1}{z_0} + 3\right\}$$
$$\times \frac{h(1+2h)}{\nu}\underbrace{\Big(\frac{(2\mathscr{R}_0-1)h + \mathscr{R}_0 - 1}{\mathscr{R}_0(1+2h)^2 - (1+h)(1+2h) - qh}\Big)\Big|_{\nu=\nu_i}}_{\Delta}.$$

Let $\tilde{h}_0 = (1-z_0)/[4(2z_1\mathscr{R}_0 + z_0)] - 1/2$. If $\mathscr{R}_0 \ge 1$, then $\Delta > 0$, and thus, $\text{sign}(dB/d\nu|_{\nu=\nu_i}) = \text{sign}(h-\tilde{h}_0)|_{\nu=\nu_i}, i = 1,2$. A simple calculation shows that $\tilde{\tilde{B}}(\tilde{h}_0) < 0$ and hence $h_1 < \tilde{h}_0 < h_2$. Therefore, $\text{sign}(dB/d\nu) = (-1)^i$ at $\nu_i, i = 1,2$. Consequently, the model undergoes a forward (backward) Hopf bifurcation at ν_1 (at ν_2). Whether these bifurcations are sub- or supercritical is determined by the sign of σ.

Suppose now $\mathscr{R}^* < \mathscr{R}_0 < 1$. From (2.5) and $\partial\phi/\partial I\big|_{I=I_0^*} = 1$, it is easy to see that $\mathscr{R}^* > 1/2$. Note that if $\mathscr{R}_0 \le 1/2$, then the model has no endemic equilibrium and the DFE is GAS. Let $L(h) = \mathscr{R}_0(1+2h)^2 - (1+h)(1+2h) - qh$. Then $L(h)$ has a unique positive root $\tilde{\tilde{h}}_0$ such that $L(h) < 0$ for $0 < h < \tilde{\tilde{h}}_0$ and $L(h) \ge 0$ for $h \ge \tilde{\tilde{h}}_0$. Defining $h_c = (1-\mathscr{R}_0)/(2\mathscr{R}_0 - 1)$, it can be shown that, regardless of whether h_c is less than or greater than $\tilde{\tilde{h}}_0$, $\Delta < 0$ in the interval between h_c and $\tilde{\tilde{h}}_0$, and $\Delta > 0$ outside this interval (see [1, Figure 9]). Therefore, $\text{sign}(dB/d\nu|_{\nu=\nu_i}) = \text{sign}(h-\tilde{h}_0)\ \text{sign}(\Delta)|_{\nu=\nu_i}, i = 1,2$.

Remark 5.2. It can be seen, after some manipulations, that for $p > 0$, $B = 0$ if and only if

$$-w + 3 - \frac{2}{w} = \tilde{z}_0 + \tilde{z}_1 u, \tag{5.17}$$



(A) (B)

FIG. 5.5. (A) *the coexistence of two limit cycles in Example* 2 *with the parameter values* $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $q = 0.05$, $\delta = 0.1$, $\mathscr{R}_0 = 1.05 > 1$, *and* $\nu = 1.2 > \nu_2$. *The limit cycle with large amplitude is stable, and the one with small amplitude is unstable, both surrounding the stable endemic equilibrium.* (B) *Phase portrait at the Bogdanov point in Example* 2 *with the parameter values* $\Pi = 1050$, $\mu = 0.02$, $\alpha = 26$, $q = 0.05$, $\delta = 0.1$, *and* $(\mathscr{R}_{BT}, \nu_{BT}) = (0.5612316061, 3.743081478)$.

where $w = 1 + f$, $u = [\mathscr{R}_0(1 + f)]^{1/p}$, and $\tilde{z}_0$ and $\tilde{z}_1$ are defined in (5.8). Equation (5.17) has a positive root of multiplicity 2 if and only if the tangency condition

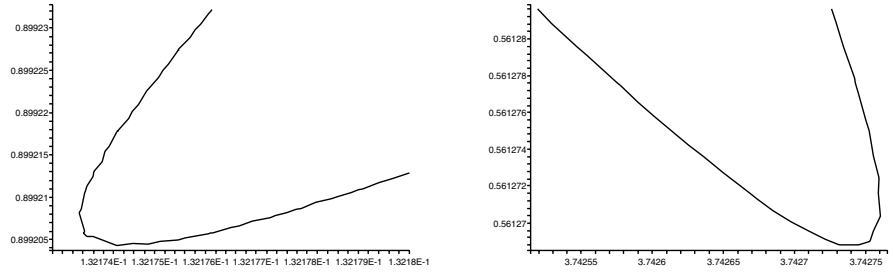
$$(p-1)w^2 + (3 - \tilde{z}_0)w - 2(p+1) = 0 \tag{5.18}$$

is satisfied. If $p < 1$, then (5.18) has two positive roots w_1, w_2 whenever $\tilde{z}_0 < 3 - 2\sqrt{2(1-p^2)}$, with $w_1 + w_2 = (3-\tilde{z}_0)/(1-p)$ and $w_1 w_2 = 2(1+p)/(1-p)$. Substituting these into (5.17) gives $u_1 + u_2 = -2p^2(3 - \tilde{z}_0)/[\tilde{z}_1(1-p^2)]$ and $\tilde{z}_1^2 u_1 u_2 = p^2[8 - (3 - \tilde{z}_0)^2]/(1-p^2)$. Therefore, if $\tilde{z}_0 \in (3 - 2\sqrt{2}, 3 - 2\sqrt{2(1-p^2)})$, then $u_1 u_2 > 0$, so that u_1 and u_2 are both negative even though $w_1, w_2 > 0$. If $0 < \tilde{z}_0 < 3 - 2\sqrt{2}$, then $u_1 u_2 < 0$, and thus there is a unique positive root u satisfying (5.17). In summary, from equations (5.17), (5.18), and the above discussion, we have

(i) for $p < 1$, there is a unique positive root u, provided $0 < \tilde{z}_0 < 3 - 2\sqrt{2}$;
(ii) for $p = 1$, there is a unique positive root u, provided $\tilde{z}_0 < 3$;
(iii) for $p > 1$, there is always a unique positive root u.

The conditions for the uniqueness of u provide a unique critical value of $\tilde{\mathscr{R}}_{crit} = u_*^p / w_*$ (where u_* and w_* are the unique solutions of (5.17) and (5.18)) such that there is no Hopf bifurcation point if $\mathscr{R}_0 > \tilde{\mathscr{R}}_{crit}$ and two Hopf bifurcation points if $\mathscr{R}_0 < \tilde{\mathscr{R}}_{crit}$ and sufficiently close to $\tilde{\mathscr{R}}_{crit}$. These bifurcation points merge at the critical value $\tilde{\mathscr{R}}_{crit}$.

The simulations were also run with the same parameter values as used in Example 1. With these values and $\mathscr{R}_0 = 1.05 > 1$, we have Hopf bifurcations at $\nu_1 = 0.147656$ and $\nu_2 = 1.12033$. Numerical calculations show that $dB/d\nu < 0\,(> 0)$, $\sigma < 0\,(> 0)$ at ν_1 (at ν_2), so that the Hopf bifurcation is supercritical at ν_1 and backward subcritical at ν_2 (Figure 5.3(B)). The bifurcation at ν_2 leads to the appearance of an unstable limit cycle in the presence of the stable limit cycle created by the Hopf bifurcation at ν_1 (see Remark 4.1). Figure 5.5(A) shows the phase portrait of the model for the coexistence of two limit cycles for $\nu = 1.2 > \nu_2$; the limit cycle with large amplitude is stable, and the one with small amplitude is unstable. Similar results were obtained for $\mathscr{R}_0 = 0.95 < 1$ with $\nu_1 = 0.127445$ ($\sigma < 0$) and $\nu_2 = 1.36961$ ($\sigma > 0$).



ν (A) ν (B)

FIG. 5.6. *Homoclinic branches ($\mathscr{R}_0$ vs ν) of the Bogdanov–Takens bifurcation for Example 2, as described in Theorem 4.3(c).*

We now consider the case where the model undergoes a Bogdanov–Takens bifurcation. It is easy to see that $If_I(I;\nu_{BT}) = qf(I;\nu_{BT})[1-f(I;\nu_{BT})]$, and hence from the definition of u and (4.11), we have

$$q\left(\frac{u^p}{\mathscr{R}_{BT}}-1\right)\left(2-\frac{u^p}{\mathscr{R}_{BT}}\right)=\frac{p}{\mathscr{R}_{BT}}(u-1)u^p, \tag{5.19}$$

which leads to the following quadratic equation:

$$q\wp^2+[p(u-1)-3q]\wp+2q=0, \tag{5.20}$$

where $\wp = u^p/\mathscr{R}_{BT}$. Let

$$\gamma \equiv p(u-1)=\frac{(\mu+\delta)(\mu+\alpha+\delta)}{\alpha(\mu+\alpha)}.$$

Then, $\Delta \equiv \gamma^2-6\gamma q+q^2=[\gamma-(3+2\sqrt{2})q][\gamma-(3-2\sqrt{2})q]>0$ if $\gamma>(3+2\sqrt{2})q$ or $\gamma<(3-2\sqrt{2})q$. Therefore, (5.20) has two positive roots if $\Delta>0$ and $\gamma<3q$, which reduce to the following condition:

$$\frac{(\mu+\delta)(\mu+\alpha+\delta)}{\alpha(\mu+\alpha)}<(3-2\sqrt{2})q. \tag{5.21}$$

The roots of (5.20) are given by

$$\wp_\pm=\frac{3q-\gamma\pm\sqrt{[(3+2\sqrt{2})q-\gamma][(3-2\sqrt{2})q-\gamma]}}{2q},$$

and thus $\mathscr{R}_{BT}^{\pm}=u^p/\wp_\pm$, where u is given by (4.10). Finally, using $I=\kappa(1-1/u)$ (see (2.5)), the expression for ν_{BT} is obtained:

$$\nu_{BT}^{\pm}=\frac{1}{I^q}\left(\frac{\wp_\pm-1}{2-\wp_\pm}\right).$$

A simple calculation yields that $\nu_{BT}^{\pm}>0$ for both positive roots of (5.20) given by $\wp_\pm$, provided that (5.21) is satisfied. This analysis shows that, in general, the values of the parameters in the parameter space $(\mathscr{R}_0,\nu)$ for which the model undergoes the Bogdanov–Takens bifurcation may not be unique. Figure 5.5(B) illustrates the phase portrait at the Bogdanov point with $(\mathscr{R}_{BT},\nu_{BT})=(0.5612316061, 3.743081478)$. Figure 5.6(A)–(B) representsbifurcation curves along which a homoclinic orbit exists in

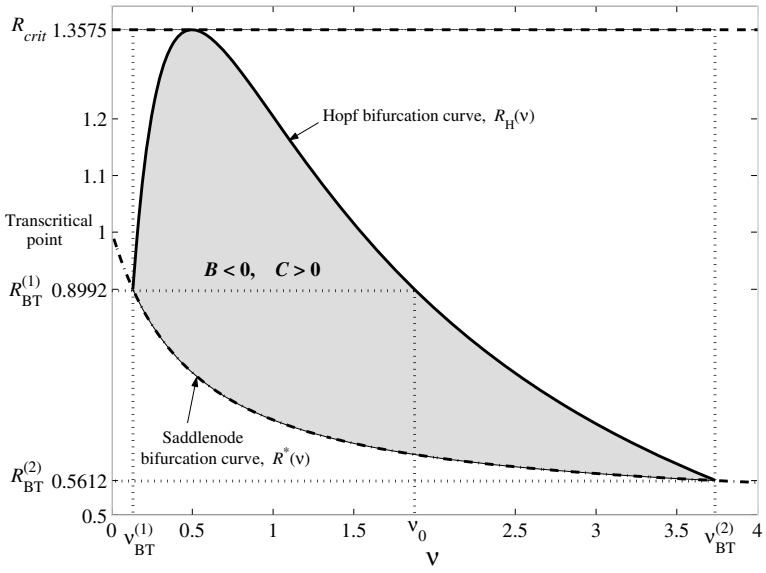


FIG. 5.7. *Bifurcation curves of the model for Example* 2*, with the parameter values* $\Pi = 1050$*,* $\mu = 0.02$*,* $\alpha = 26$*,* $q = 0.05$*,* $\delta = 0.1$*,* $p = 1$*, and* $0 \le \nu \le 4$*. neighborhoods of the two Bogdanov points $(\mathscr{R}_{BT}, \nu_{BT}) = (0.8991721941, 0.1321652741)$ and $(\mathscr{R}_{BT}, \nu_{BT}) = (0.5612316061, 3.743081478)$. As for Example 1, a diagram showing saddle-node and Hopf bifurcation curves for Example 2 is given in Figure 5.7. In this case, the two bifurcation curves merge at each of the Bogdanov points.

6. Discussion. In this paper, we focused on the bifurcation analysis of an SIRS epidemic model with generalized nonlinear incidence. This study extends our previous work on the Hopf bifurcation analysis of a similar model when $p = 1$ and $\delta = 0$ [1]. Stability analysis of the model equilibria enabled us to completely analyze their local bifurcation behavior, such as Hopf, saddle-node, and Bogdanov–Takens bifurcations. We computed the first Lyapunov coefficient to determine the various types of Hopf bifurcation the model undergoes. A saddle-node bifurcation at the threshold $\mathscr{R}^*$ of the bistability region was established by applying Sotomayor's theorem. Using the Bogdanov–Takens normal form in the parameter space $(\mathscr{R}_0, \nu)$, the local representation of a homoclinic bifurcation curve was also derived. Finally, we detailed and numerically illustrated our results with two examples (bounded and unbounded) of the nonlinear function $f(I; \nu)$. These results provide the conditions for the occurrence of Hopf bifurcations in terms of two major parameters: the basic reproductive number $(\mathscr{R}_0)$ and the rate of loss of immunity acquired by infection (δ).

The parameter δ is biologically important, as its inverse represents the mean period of natural immunity following recovery. Although this parameter may change due to several factors, such as age and the response of the immune systems of recovered individuals, in general it depends on the type of the disease being modeled. For example, natural measles infection induces life-long immunity [4, 32], while natural immunity following recovery from influenza is temporary and extremely variable among different age-categories in a population [7, 9]. Here, we would like to explore the effect of this factor in producing oscillatory behavior of the model. Let us first consider Example 1. From (5.5), it can be seen that there is a critical rate ($\delta_{\max}$) such that if $\delta > \delta_{\max}$, then no Hopf bifurcation occurs, and therefore the model exhibits no periodicity behavior. This critical rate is given by

$$\delta_{\max} = \frac{1}{2}\big(\alpha + \sqrt{\alpha^2 + 4(\mu+\alpha)^2}\big).$$

If $\delta > \delta_{\max}$, then no value of $q \in (0,1]$ satisfies (5.5). By making the assumption $\alpha \gg \mu$ (which is reasonable for most curable diseases), $\delta_{\max} \approx 1.618\alpha$. The corresponding maximum rate for Example 2 can be obtained from (5.16) as

$$\delta_{\max} = \frac{1}{2(3+2\sqrt{2})}\Big(\alpha - (2+2\sqrt{2})\mu + \sqrt{[\alpha - (2+2\sqrt{2})\mu]^2 + 4(3+2\sqrt{2})(\mu+\alpha)^2}\Big),$$

with $\delta_{\max} \approx 0.509\alpha$ for $\alpha \gg \mu$. As an immediate consequence of these approximations, it can be seen that not only does $\delta_{\max}$ depend on the type of the disease, but also it depends greatly on the factors affecting the magnitude of the incidence rate, and hence on the functional form of $f(I;\nu)$.

Our illustrations, based on the parameter values estimated for measles infection (see [1, 5] and the references therein), have been verified by many clinical studies. For instance, a clinical study of measles in Poland reports an epidemic outbreak between November, 1997, and July, 1998 (with 2255 cases), despite high vaccination coverage (95%) since the 1980s [18]. The results of this study confirm that reducing $\mathscr{R}_0$ to values less than unity may fail to control the spread of the disease, which is associated with the mathematical phenomenon of backward bifurcation. Furthermore, our model exhibits oscillatory behavior, which is consistent with what has been observed for some infectious diseases such as measles, whooping cough, and rubella [10, 20, 29]. This is due to the fact that the immunity acquired following recovery from these diseases is long-lasting ($\delta \approx 0$), so that $\delta < \delta_{\max}$. This prediction is confirmed by numerical experiments (using data from England) in [29], demonstrating periods of 2 and 2–3 years for measles and whooping cough dynamics, respectively.

This study has further epidemiological implications by providing a threshold quantity $\mathscr{R}^* < 1$ (where a saddle-node bifurcation occurs at $\mathscr{R}_0 = \mathscr{R}^*$) such that the disease dies out if $\mathscr{R}_0 < \mathscr{R}^*$. Unlike the basic reproductive number, the threshold $\mathscr{R}^*$ depends on the functional form of the incidence rate as well as other parameters. If $\mathscr{R}^* < \mathscr{R}_0 < 1$, then the model exhibits two endemic equilibria which may compete with the stable disease-free equilibrium. Therefore, the long-term disease dynamics may depend on the initial values of the subpopulations. In both Examples 1 and 2, we showed that for $\mathscr{R}_0 > \mathscr{R}^*$ there exists a unique threshold $\mathscr{R}_{crit}$ such that if $\mathscr{R}_0 > \mathscr{R}_{crit}$, no Hopf bifurcation occurs. Combining the above discussion for the rate of loss of immunity, the ranges for the feasibility of periodicity behavior of the model are obtained as $\delta < \delta_{\max}$ and $\mathscr{R}^* < \mathscr{R}_0 < \mathscr{R}_{crit}$.

Acknowledgments. The authors would like to thank the referees for their insightful comments which have improved the paper.

ASPECTS OF TOTAL VARIATION REGULARIZED L^1 FUNCTION APPROXIMATION*

TONY F. CHAN† AND SELIM ESEDOĞLU†

Abstract. The total variation–based image denoising model of Rudin, Osher, and Fatemi [*Phys. D*, 60, (1992), pp. 259–268] has been generalized and modified in many ways in the literature; one of these modifications is to use the L^1-norm as the fidelity term. We study the interesting consequences of this modification, especially from the point of view of geometric properties of its solutions. It turns out to have interesting new implications for data-driven scale selection and multiscale image decomposition.

Key words. total variation, denoising, scale space

1. Introduction.

Variational models for image reconstruction have had great success. One of the best known and influential examples is the total variation–based model of Rudin, Osher, and Fatemi (ROF) [22]. This model and its variants have been a very active research topic. The idea behind the model is to exhibit the reconstructed image as the minimizer of the following energy:

$$\int_D |\nabla u| + \lambda \int_D (f-u)^2 \, dx. \tag{1.1}$$

The functional is to be minimized over all $u \in L^2(D)$. Here D is a domain in $\mathbf{R}^N$, $N \geq 2$, with Lipschitz boundary; it represents, for example, the computer screen. In this paper, we will work with $D = \mathbf{R}^N$ for convenience. The function $f(x)$ represents the observed and possibly degraded image and is taken to be in $L^2(D)$. The second integral in the functional is the *fidelity* term; it encourages the solution $u(x)$ that is being sought to approximate the *observed image* $f(x)$. The first integral in the functional is the *regularization* term; it is the essential novelty of the ROF model, as it allows for the reconstruction of images with discontinuities across hypersurfaces. Nevertheless, it disfavors oscillations and is responsible for the elimination of noise in applications to noisy images.

The standard ROF model (1.1) is well known to have certain limitations. One important issue is the loss of contrast in solutions even for noise-free observed images. For example, Strong and Chan studied in [25] the case when the observed image $f(x)$ is a disk and showed that the solution to (1.1), for any given λ, is of the form $cf(x)$, where $c \in [0, 1)$ is a constant. We never get $c = 1$, no matter how large the constant λ is chosen. More generally, given any observed image $f(x)$ and $\lambda > (2\|f\|_*)^{-1}$, it can be shown [15] for the corresponding solution $u(x)$ that $\|f - u\|_* = \frac{1}{2\lambda}$. Here, $\|\cdot\|_*$ denotes the dual norm of total variation. (See [15] for definition of the dual norm and

†Mathematics Department, UCLA, Box 951555, Los Angeles, CA 90095 (TonyC@college.ucla.edu, esedoglu@math.ucla.edu).

proofs of the statements just mentioned.) It is in general desirable for image denoising algorithms to have a large class of "noise-free" images that they leave invariant. For the standard ROF model, as these results show, that class consists of only the trivial image $f(x) := 0$.

Recently, work of Meyer inspired research into understanding the role of the fidelity term better. It highlighted the fact that the choice of a suitable fidelity term can have far reaching consequences. For example, following up on Meyer's ideas, Vese and Osher [27] and then Osher, Sole, and Vese [21] came up with variants of the original model that replace the fidelity term with weaker norms. It is shown in these works that this modification allows for much better separation of the high frequency component of images, such as noise and texture, from the piecewise smooth or "cartoon" part.

In this paper, we ask related but rather different questions. We study a version of the ROF model that uses the L^1-norm as a measure of fidelity between the observed and denoised images. Given an observed image $f(x) \in L^1(\mathbf{R}^N)$, this model is based on the following variational problem:

$$\inf_{u(x)\in BV(\mathbf{R}^N)} \int_{\mathbf{R}^N} |\nabla u| + \lambda \int_{\mathbf{R}^N} |u(x) - f(x)|\, dx. \tag{1.2}$$

Our goal in this paper is to explore the consequences of this modest modification on the standard ROF model. In particular, we shall obtain some results that allow us to contrast the modified model (1.2) with the standard one (1.1). Also, the new understanding we develop about the nature of the scale space, lack of uniqueness of solutions, and lack of continuous dependence on data will suggest applications beyond mere removal of noise for the modified model: We will argue that some of these ordinarily undesirable characteristics can be real assets. Indeed, it turns out that the L^1 fidelity-based model has many desirable, and some unexpected, consequences in applications such as multiscale image decomposition and data-driven parameter selection.

Some distinctions between the modified model (1.2) and the standard ROF model (1.1) are immediate:

- The way the fidelity and regularization terms scale with respect to each other in the modified and standard models is different. In particular, unlike the standard model, the modified model is contrast invariant in the following sense: If $u(x)$ is a solution of the modified model for the observed image $f(x)$, then $cu(x)$ is a solution of the modified model for the observed image $cf(x)$.
- The original model is strictly convex, and therefore its solution (the minimizer of the functional) is unique. The modified model is not strictly convex, leading to nonuniqueness of minimizers. This makes the scale space generated by the modified model qualitatively very different—and, as explained in sections 6 and 7, for certain purposes more suitable—than that of the standard ROF model.

We concentrate especially on the scale space and geometric features of the decomposition technique derived from this model. The analytical and numerical results presented in this paper suggest the following major advantages of the L^1 fidelity-based model over the standard one:

- The regularization imposed on solutions by the L^1 model is more geometric. By "more geometric" we mean that the regularization process has less dependence on the contrast of image features than on their shapes. Indeed,

as some of our analytical results show, the L^1 model almost decouples the level sets of the given image from each other and treats them independently of their associated level (grayscale value).

- As distinct from the standard model, small features in the image maintain their contrast even as the fidelity parameter λ is lowered, maintaining good contrast until they suddenly disappear.
- An unexpected consequence of the modification is that it suggests a data-driven scale selection technique: It seems possible to identify certain critical values of the parameter λ at which features at the corresponding scale go through a discontinuous change.

Using the ROF model with L^1 fidelity is a natural idea, and was introduced and studied in the context of image denoising and deblurring by previous authors [1, 3, 4, 16, 17, 18, 8]. Among these, Alliney and Nikolova's works are relevant to ours. Alliney's previous work involves the variational model (1.2) in only one space dimension; moreover, his results are restricted to the discrete versions of the energy. Nevertheless, many of his observations are directly relevant to our results (see, for instance, Proposition 4.2 that we quote from his work), and some of our results (for instance part of Theorem 5.2) can be thought of as continuum analogues of his results in arbitrary dimensions. In [16] Nikolova shows that for certain types of noise the total variation regularization with L^1 fidelity outperforms the standard model. And [17] contains many impressive numerical results that clearly demonstrate the advantages of using the L^1 norm for a fidelity term in some applications. In fact, the analysis presented in [16] applies more generally to fidelity terms that are, like the L^1 fidelity term and unlike the L^2 fidelity term, nondifferentiable at the origin. The techniques of Nikolova also allow her to study certain typical properties of minimizers to the ROF model and its variants with different types of fidelity terms. For example, among the results is a characterization of the staircasing effect. Moreover, she calls attention to the fact that, with L^1-type fidelity terms, the solution reconstructs the given image exactly at some pixels; this relates to the contrast preserving property we touched on above. However, unlike the focus of this paper, results in [16, 17] mostly concern discrete versions of the denoising energies and depend on the discretization size; continuum analogues are not treated. Our focus in this paper is squarely on the continuum energies so that we can study geometric properties of their minimizers independently of the discretization.

We conclude the introduction with an outline of the remaining sections. Section 2 introduces the notation that is used throughout the paper. Section 3 works out the solution to minimization problems (1.1) and (1.2) in the simple case when the observed image $f(x)$ is the characteristic function of a disk in two dimensions. This illustrates some of the results obtained in subsequent sections for more general types of images. Section 4 consists of a collection of simple but useful facts that follow immediately from the definitions of section 2; these are used in the following sections of the paper. Section 5 deals with properties of minimizers of energy (1.2). In particular, it considers the case where the observed image is the characteristic function of a bounded set. It recalls the known results for the standard ROF model in this case and uses them for comparison. Section 6 elaborates on the differences between the scale spaces generated by the two models given by (1.1) and (1.2); it shows that the model based on L^1 fidelity makes it possible to determine special values of the parameter λ completely from the given observed image. Finally, section 7 presents numerical experiments and gives some implementation details. The numerical results corroborate the overall picture suggested by the analytical results of the previous sections.

2. Notation. In this section we introduce notation that will be used throughout the paper to compare the original ROF model (1.1) with the modified one (1.2) that uses an L^1 fidelity term. First, we recall the standard definitions of total variation of a function and the perimeter of a set [11, 12]. The total variation of a function $u(x) \in L^1_{loc}(\mathbf{R}^N)$ is defined to be

$$\int_{\mathbf{R}^N} |\nabla u(x)| := \sup_{\substack{\phi \in C_c^1(\mathbf{R}^N;\mathbf{R}^N) \\ |\phi(x)| \le 1 \forall x \in \mathbf{R}^N}} - \int_{\mathbf{R}^N} u(x) \operatorname{div} \phi(x)\, dx.$$

The perimeter of a set $\Sigma \subset \mathbf{R}^N$ is defined in terms of the above definition to be

$$\operatorname{Per}(\Sigma) := \int_{\mathbf{R}^N} |\nabla \mathbf{1}_\Sigma(x)|.$$

For a given possibly noisy image $f(x) \in L^1(\mathbf{R}^N)$, we will denote the energy of the total variation model with L^1 fidelity as $E_1(u, \lambda)$:

$$E_1(u, \lambda) := \int_{\mathbf{R}^N} |\nabla u| + \lambda \int_{\mathbf{R}^N} |f - u|\, dx.$$

It will be compared, for $f \in L^1(\mathbf{R}^N) \cap L^2(\mathbf{R}^N)$, with the energy of the standard ROF model, which we denote by $E_2(u, \lambda)$:

$$E_2(u, \lambda) := \int_{\mathbf{R}^N} |\nabla u| + \lambda \int_{\mathbf{R}^N} (f - u)^2\, dx.$$

Of particular interest are the minimum values of these energies as a function of the parameter λ:

$$\mathcal{E}_1(\lambda) := \min_{u \in L^1(\mathbf{R}^N)} E_1(u, \lambda),$$
$$\mathcal{E}_2(\lambda) := \min_{u \in L^2(\mathbf{R}^N)} E_2(u, \lambda).$$

Minimizers of the standard ROF energy $E_2(\cdot, \lambda)$ for a fixed λ are unique; this is a consequence of the energy's strict convexity. Minimizers of the modified energy $E_1(\cdot, \lambda)$ need not be unique in general. We therefore introduce the following notation to denote the set of minimizers of $E_1(\cdot, \lambda)$ at a given $\lambda \ge 0$:

$$M(\lambda) := \Big\{ u \in L^1(\mathbf{R}^N) : E_1(u, \lambda) = \mathcal{E}_1(\lambda) \Big\}.$$

For any given $f(x) \in L^1(\mathbf{R}^N)$ and $\lambda \ge 0$, the set $M(\lambda)$ is nonempty: A standard argument shows the existence of minimizers. Because of nonuniqueness, $M(\lambda)$ can have several elements. Different elements of $M(\lambda)$ can stand at different distances from the observed image $f(x)$. This motivates the following notation:

$$\mu^+(\lambda) := \sup \Big\{ \|f - u\|_{L^1(\mathbf{R}^N)} : u \in M(\lambda) \Big\},$$
$$\mu^-(\lambda) := \inf \Big\{ \|f - u\|_{L^1(\mathbf{R}^N)} : u \in M(\lambda) \Big\}.$$

The values of the parameter λ at which $M(\lambda)$ contains elements whose distances to the given image $f(x)$ are different turn out to be special. We therefore adopt the following notation to denote this set of special λ values:

$$S(f) := \Big\{ \lambda \in \mathbf{R}^+ : \mu^-(\lambda) \ne \mu^+(\lambda) \Big\}.$$

To emphasize the dependence of $E_i(\cdot,\lambda)$, $\mathcal{E}_i(\lambda)$,$M(\lambda)$, and $\mu^{\pm}(\lambda)$ on the observed image $f(x)$ in addition to λ, we will write $E_i(\cdot,\lambda,f),\mathcal{E}_i(\lambda,f)$, $M(\lambda,f)$, and $\mu^{\pm}(\lambda,f)$ whenever necessary.

3. An example. In this section we consider a very simple but illustrative example. Namely, we work out explicitly the solution to the problem of minimizing the two dimensional version of $E_1(\cdot,\lambda)$ in the case when the observed image $f(x)$ is given by the characteristic function $\mathbf{1}_{B_r(0)}(x)$ of a disk $B_r(0)$ that is centered at the origin and with radius r. It is important to compare the result with the one for the standard ROF model, which—as we noted in the introduction—was calculated in [25].

We start by recalling the calculation of [25]. For $\lambda \geq 0$ and the observed image given by $f(x) = \mathbf{1}_{B_r(0)}(x)$, the unique minimizer $u_\lambda(x)$ of $E_2(\cdot,\lambda)$ is given by

$$u_\lambda(x) \equiv \begin{cases} 0 & \text{if } 0 \leq \lambda \leq \dfrac{1}{r}, \\ \left(1 - \dfrac{1}{\lambda r}\right)\mathbf{1}_{B_r(0)}(x) & \text{if } \lambda > \dfrac{1}{r}. \end{cases}$$

Turning now to the case of $E_1(\cdot,\lambda)$, one can reason (for example with the help of some of the results presented in sections 5 and 6 of this paper) that for each $\lambda \geq 0$ every minimizer has to be of the form $c\mathbf{1}_{B_r(0)}(x)$ for some constant $c \in [0,1]$. We therefore need to minimize the function

$$E_1(c\mathbf{1}_{B_r(0)}(x),\lambda) = 2\pi r c + \lambda\pi r^2|1-c|$$

over $c \in [0,1]$. We get

$$M(\lambda) = \begin{cases} \{0\} & \text{if } 0 \leq \lambda < \dfrac{2}{r}, \\ \left\{c\mathbf{1}_{B_r(0)}(x) : c \in [0,1]\right\} & \text{if } \lambda = \dfrac{2}{r}, \\ \left\{\mathbf{1}_{B_r(0)}(x)\right\} & \text{if } \lambda \geq \dfrac{2}{r}. \end{cases}$$

Thus, we see that the solution is unique for all except one special value of the parameter λ. The special value is related to radius of the disk; for more general images we would expect such special values of the parameter λ to be related to the geometric scale of distinct objects contained in the scene.

The difference between scale spaces generated by the standard ROF model and the one with L^1 fidelity is made abundantly clear by this simple example. When L^1 fidelity is used, unlike in the standard ROF model, the scale space is mostly constant; it only makes a sudden transition at a special value of the scale parameter. This difference can also be manifested by plotting the "fidelity of minimizer" as a function of the parameter λ for each model and comparing the qualitative properties. Figure 1 shows the plots obtained based on the minimizers calculated above.

This example brings out another elementary aspect of using an L^1 fidelity term with total variation regularization. Fix a $\lambda > 0$. Then the unique minimizer of $E_1(\cdot,\lambda)$ with the observed image $f(x) = \mathbf{1}_{B_r(0)}(x)$ is identically 0 if $r < \frac{2}{\lambda}$, but $\mathbf{1}_{B_r(0)}(x)$ if $r > \frac{2}{\lambda}$. Thus the dependence of the solution to the L^1 model on the observed image is not continuous with respect to, say, the L^1-norm. This is clearly related to the lack of uniqueness in solutions to the model, and is a price to pay for having solutions in

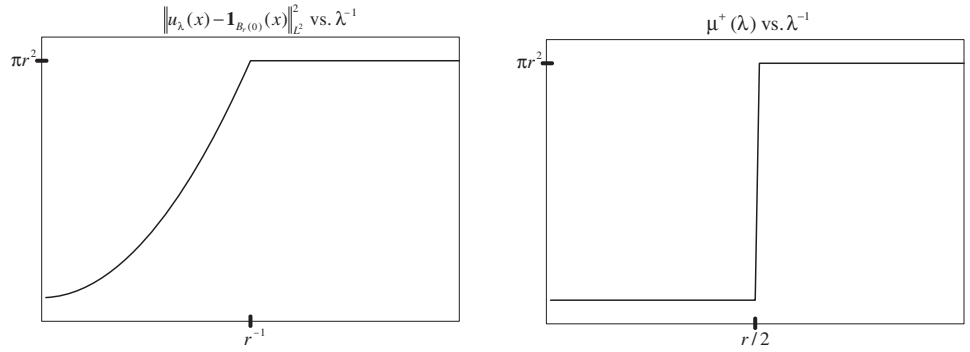

FIG. 1. *Left: Plot of* $\|u_\lambda(x) - f(x)\|_{L^2}^2$ *vs.* λ^{-1} *for the example of section* 3*, where* $u_\lambda(x)$ *denotes the unique minimizer of* $E_2(\cdot, \lambda)$*. which features of interest maintain good contrast until they are completely eliminated. However, sections 6 and 7 explain some applications for which such a discontinuity can actually be desirable, and Proposition 6.4 shows that certain important features of the *scale space* are continuous as a function of observed signal.

4. Basic facts. In this section, we collect a number of elementary facts that follow immediately from the definitions introduced in the previous section. These results will be useful in the subsequent sections.

The following claim shows that the minimum energies $\mathcal{E}_i(\lambda)$ are well-behaved functions of the parameter λ.

CLAIM 1. *For any given observed image* $f(x) \in L^1(\mathbf{R}^N)$ *the function* $\mathcal{E}_1(\lambda)$*, and for any given observed image* $f(x) \in L^2(\mathbf{R}^N)$ *the function* $\mathcal{E}_2(\lambda)$*, satisfy the following properties:*

1. $\mathcal{E}_i(\lambda)$ *for* $i = 1, 2$ *are increasing and concave.*
2. $\mathcal{E}_i(0) = 0$ *for* $i = 1, 2$*.*
3. $0 \le \mathcal{E}_1(\lambda) \le \|f\|_{L^1}\lambda$ *and* $0 \le \mathcal{E}_2(\lambda) \le \|f\|_{L^2}^2\lambda$ *for all* $\lambda \in [0, \infty)$*.*
4. $\mathcal{E}_i(\lambda)$ *are Lipschitz continuous for* $i = 1, 2$*.*

Proof. $\mathcal{E}_i(\lambda)$ are defined as pointwise infima of a collection of linear functions that are increasing in λ; this makes them increasing and concave. Statements 2 and 3 follow from the trivial fact that $\mathcal{E}_i(\lambda) \le E_i(0, \lambda)$ for $i = 1, 2$. Statement 4 now follows from the first three. □

CLAIM 2. *The set* $M(\lambda)$ *is closed and convex.*

Proof. This follows from convexity of the energy $E_{\mathbf{1}}$. □

The following claim, which must be a well-known fact, shows that the fidelity of the minimizer to the original ROF model varies continuously as a function of λ. This should be contrasted with the results for the L^1 model that are obtained in the subsequent sections. We include its proof for completeness.

CLAIM 3. *Given* $f(x) \in L^2(\mathbf{R}^N)$*, for each* $\lambda \ge 0$ *let* $u_\lambda(x)$ *denote the unique minimizer of* $E_2(\cdot, \lambda)$*. Then the function* $\lambda \to \|f - u_\lambda\|_{L^2}$ *is continuous.*

Proof. Fix $\lambda_* \ge 0$ and let $u_{\lambda_*}(x)$ be the unique minimizer of $E_2(\cdot, \lambda_*)$. Let $\{\lambda_j\}_j^\infty \subset \mathbf{R}^+$ converge to λ_*. Consider the sequence of corresponding minimizers: $\{u_{\lambda_j}\}$. The obvious relation $E_2(u_{\lambda_j}, \lambda_j) \le E_2(0, \lambda_j) = \lambda_j\|f\|_{L^2}^2$ implies that the sequence has uniformly bounded total variation and L^2-norm. It also implies that $\|u_\lambda - f\|_{L^2} \le \|f\|_{L^2}$ for every $\lambda \ge 0$. Applying the standard compactness prop-

erty (for functions with uniformly bounded total variation) on compact sets, we can find a subsequence, also denoted $\{u_{\lambda_j}\}$, such that $u_{\lambda_j}(x) \to v(x) \in L^1_{loc}(\mathbf{R}^N)$ in L^1 on any bounded set. We may then pass to another subsequence to make sure that $u_{\lambda_j}(x) \to v(x)$ pointwise a.e. as well. Fatou's lemma then shows that $\|v - f\|_{L^2} \leq \liminf_{j\to\infty} \|u_{\lambda_j} - f\|_{L^2}$, so that in fact $v \in L^2(\mathbf{R}^N)$. Also, the standard lower semicontinuity result for total variation implies that $\int |\nabla v| \leq \liminf_{j\to\infty} \int |\nabla u_{\lambda_j}|$. Hence we get that $E_2(v, \lambda_*) \leq \liminf_{j\to\infty} E_2(u_{\lambda_j}, \lambda_j)$.

On the other hand, $E_2(u_{\lambda_*}, \lambda_*) \geq \limsup_{j\to\infty} E_2(u_{\lambda_j}, \lambda_j)$. To see this, suppose not. Then there is $\varepsilon > 0$ and arbitrarily large j such that $E_2(u_{\lambda_*}, \lambda_*) \leq E_2(u_{\lambda_j}, \lambda_j) - \varepsilon$. But also, $\lim_{j\to\infty} E_2(u_{\lambda_*}, \lambda_j) = E_2(u_{\lambda_*}, \lambda_*)$. These two statements mean $E_2(u_{\lambda_*}, \lambda_j) < E_2(u_{\lambda_j}, \lambda_j)$ for some large j, which is a contradiction, since u_{λ_j} are supposed to be minimizers of $E_2(\cdot, \lambda_j)$. This, along with the remarks of the previous paragraph, adds up to the following conclusion:

$$\limsup_{j\to\infty} E_2(u_{\lambda_j}, \lambda_j) \leq E_2(u_{\lambda_*}, \lambda_*) \leq E_2(v, \lambda_*) \leq \liminf_{j\to\infty} E_2(u_{\lambda_j}, \lambda_j).$$

We thus see that v is a minimizer of $E_2(\cdot, \lambda_*)$; by uniqueness of minimizers of $E_2(\cdot, \lambda_*)$, we get that $v = u_{\lambda_*}$.

If $\lambda_* = 0$, then $u_{\lambda_*} = 0$ and so $\|u_{\lambda_*} - f\|_{L^2} = \|f\|_{L^2}$. Recalling from above that $\|u_\lambda - f\|_{L^2} \leq \|f\|_{L^2}$ for all λ, we see that in this case

$$\limsup_{j\to\infty} \|u_{\lambda_j} - f\|_{L^2} \leq \|u_{\lambda_*} - f\|_{L^2} \leq \liminf_{j\to\infty} \|u_{\lambda_j} - f\|_{L^2},$$

which establishes continuity of the map in question at $\lambda = 0$.

If $\lambda_* > 0$, we reason as follows: We must once again have $\limsup_{j\to\infty} \|u_{\lambda_j} - f\|_{L^2} \leq \|u_{\lambda_*} - f\|_{L^2}$, which immediately leads to the conclusion of the claim. To see this, we suppose that it is false and proceed as we did in the previous paragraphs. There is then arbitrarily large j and an $\varepsilon > 0$ such that $\|u_{\lambda_*} - f\|_{L^2} \leq \|u_{\lambda_j} - f\|_{L^2} - \varepsilon$. But then

$$E_2(u_{\lambda_*}, \lambda_*) \leq \liminf_{j\to\infty} E_2(u_{\lambda_j}, \lambda_j) - \varepsilon\lambda_j.$$

Also, $E_2(u_{\lambda_*}, \lambda_j) \to E_2(u_{\lambda_*}, \lambda_*)$ as $j \to \infty$. These last two statements lead as before to the contradictory statement that $E_2(u_{\lambda_*}, \lambda_j) < E_2(u_{\lambda_j}, \lambda_j)$. ∎

We will see whether the analogue of Claim 3 holds for E_1. In that regard, we first make the following basic observation.

CLAIM 4. *Let $\lambda_2 > \lambda_1 \geq 0$, and assume that u_{λ_1} and u_{λ_2} are any two minimizers of $E_1(\cdot, \lambda_1)$ and $E_1(\cdot, \lambda_2)$, respectively. Then*

$$\|u_{\lambda_1} - f\|_{L^1(\mathbf{R}^N)} \geq \|u_{\lambda_2} - f\|_{L^1(\mathbf{R}^N)}.$$

Proof. Suppose $\|u_{\lambda_2} - f\|_{L^1} > \|u_{\lambda_1} - f\|_{L^1}$. Then, since $u_{\lambda_1} \in M(\lambda_1)$, we have $E_1(u_{\lambda_1}, \lambda_1) \leq E_1(u_{\lambda_2}, \lambda_1)$. We then have

$$\begin{aligned} E_1(u_{\lambda_1}, \lambda_2) &= E_1(u_{\lambda_1}, \lambda_1) + (\lambda_2 - \lambda_1)\|u_{\lambda_1} - f\|_{L^1} \\ &\leq E_1(u_{\lambda_2}, \lambda_1) + (\lambda_2 - \lambda_1)\|u_{\lambda_1} - f\|_{L^1} \\ &< E_1(u_{\lambda_2}, \lambda_1) + (\lambda_2 - \lambda_1)\|u_{\lambda_2} - f\|_{L^1} \\ &= E_1(u_{\lambda_2}, \lambda_2), \end{aligned}$$

which is a contradiction, since $u_{\lambda_2} \in M(\lambda_2)$ by hypothesis. ∎

COROLLARY 4.1. *The functions $\mu^{\pm}(\lambda)$ are decreasing. In fact,*

$$\mu^-(\lambda_1) \le \mu^+(\lambda_1) \le \mu^-(\lambda_2) \le \mu^+(\lambda_2)$$

whenever $\lambda_1 > \lambda_2 \ge 0$.

The functions $\mu^{\pm}(\lambda)$ are the analogue for E_1 of $\|u_\lambda - f\|_{L^2}$ in Claim 3. These functions in general can be discontinuous; in fact, their set of discontinuity is precisely $S(f)$ according to our notation. The corollary above allows us to make the following simple statement about the discontinuities of these functions.

CLAIM 5. *For any given $f \in L^1(\mathbf{R}^N)$, the set $S(f)$ is at most countable.*

Proof. If $\lambda \in S(f)$, then $\mu^-(\lambda) < \mu^+(\lambda)$. By the corollary above, at such a λ both μ^- and μ^+ have a jump discontinuity. The set of discontinuities of a monotone function are at most countable. □

Finally, for completeness let us state the following rather obvious fact about the asymptotic value of the functions $\mu^{\pm}(\lambda)$ as $\lambda \to \infty$.

CLAIM 6. *Given $f(x) \in L^1(\mathbf{R}^N)$, we have $\lim_{\lambda\to\infty} \mu^{\pm}(\lambda) = 0$.*

Proof. Given $\varepsilon > 0$, we can find $f_\varepsilon(x) \in BV(\mathbf{R}^N)$ such that $\|f_\varepsilon - f\|_{L^1} \le \frac{\varepsilon}{2}$. If $u_\lambda(x) \in M(\lambda)$ with $\mu^+(\lambda) = \|u_\lambda - f\|_{L^1}$, then

$$\mu^-(\lambda) \le \mu^+(\lambda) \le \frac{1}{\lambda} E_1(u_\lambda, \lambda) \le \frac{1}{\lambda} E_1(f_\varepsilon, \lambda) \le \frac{1}{\lambda} \int |\nabla f_\varepsilon| + \frac{\varepsilon}{2}.$$

Hence, for all large enough λ we have $\mu^{\pm}(\lambda) \le \varepsilon$. □

The following fact is taken directly from [3]. It says that any image $u_*(x)$ which arises as the solution to model (1.2) for some observed image $f(x)$ is in fact also the solution to model (1.2) with observed image $f(x)$ taken to be $u_*(x)$ itself, provided that the parameter λ is taken large enough. We include it as a good way to emphasize the difference of model (1.2) from (1.1) in regard to the loss of contrast in solutions.

PROPOSITION 4.2. *Let $\lambda_* \ge 0$, $f(x) \in L^1(\mathbf{R}^N)$, and $u_*(x) \in M(\lambda_*, f)$. Then for every $\lambda \ge \lambda_*$ we have $u_*(x) \in M(\lambda, u_*)$.*

Proof. For the proof of this claim, see [3].

5. Minimizers of E_1. In this section, we study the behavior of the ROF model with L^1 fidelity on simple images. Our motivation is twofold. First, studying the behavior of image denoising models on simple images is a first step towards understanding the type of images they can successfully process. Second, this type of question allows us to compare different models. In fact, we will stress the difference of these results from the analogous ones obtained for the standard ROF model by previous authors. In particular, our results will bolster the intuitive observation that the L^1 fidelity term leads to more geometric regularizations.

The following proposition constitutes our starting point. It shows that the ROF model with L^1 fidelity term almost decouples the level sets of the given image from each other; it almost becomes a geometry problem for each level set, independent of the level. This idea of writing total variation–based optimization problems in terms of level sets appears previously in the works [23, 24] of Strang, and is used to show the existence of binary solutions, as we do in Theorem 5.2.

PROPOSITION 5.1. *The energy $E_1(u, \lambda)$ can be rewritten as follows:*

$$E_1(u,\lambda) = \int_{-\infty}^{\infty} \mathrm{Per}\big(\{x : u(x) > \gamma\}\big) + \lambda \big|\{x : u(x) > \gamma\} \triangle \{x : f(x) > \gamma\}\big|\, d\gamma. \tag{5.1}$$

Proof. Recall the coarea formula for functions of bounded variation (see [12] or [11]):

$$\int_{\mathbf{R}^N} |\nabla u| = \int_{-\infty}^{\infty} \mathrm{Per}\big(\{x : u(x) > \gamma\}\big)\, d\gamma. \tag{5.2}$$

Also, there is the following "layer cake" formula:

$$\begin{aligned}
\int_{\mathbf{R}^N} |u-f|\,dx &= \int_{\{u>f\}} |u-f|\,dx + \int_{\{f>u\}} |u-f|\,dx \\
&= \int_{\{u>f\}} \int_{f(x)}^{u(x)} d\gamma\,dx + \int_{\{f>u\}} \int_{u(x)}^{f(x)} d\gamma\,dx \\
&= \int_{\mathbf{R}^N} \int_{\mathbf{R}} \mathbf{1}_{\{u>f\}}(x)\mathbf{1}_{[f(x),u(x))}(\gamma) + \mathbf{1}_{\{f>u\}}(x)\mathbf{1}_{[u(x),f(x))}(\gamma)\,d\gamma\,dx \\
&= \int_{\mathbf{R}} \int_{\mathbf{R}^N} \mathbf{1}_{\{u>f\}}(x)\mathbf{1}_{[f(x),u(x))}(\gamma) + \mathbf{1}_{\{f>u\}}(x)\mathbf{1}_{[u(x),f(x))}(\gamma)\,dx\,d\gamma,
\end{aligned}$$

where we simply changed the order of integration in the last step. But now we have

$$\mathbf{1}_{\{u>f\}}(x)\mathbf{1}_{[f(x),u(x))}(\gamma) = 1 \quad \text{iff } x \in \{u > f\} \cap \{u > \gamma\} \cap \{f > \gamma\}^c$$

and 0 otherwise, and

$$\mathbf{1}_{\{f>u\}}(x)\mathbf{1}_{[u(x),f(x))}(\gamma) = 1 \quad \text{iff } x \in \{f > u\} \cap \{u > \gamma\}^c \cap \{f > \gamma\}$$

and 0 otherwise. That means

$$\mathbf{1}_{\{u>f\}}(x)\mathbf{1}_{[f(x),u(x))}(\gamma) + \mathbf{1}_{\{f>u\}}(x)\mathbf{1}_{[u(x),f(x))}(\gamma) = \mathbf{1}_{\{u>\gamma\}\triangle\{f>\gamma\}}(x).$$

Therefore

$$\int_{\mathbf{R}^N} |u-f|\,dx = \int_{-\infty}^{\infty} |\{x : u(x) > \gamma\} \triangle \{x : f(x) > \gamma\}|\,d\gamma.$$

Putting these formulas together gives the one in the statement of the claim. ∎

We now explore some consequences of Proposition 5.1. First, we consider what happens when the observed image is binary. In other words, we assume that $f(x)$ is the characteristic function of a domain. We assume that the domain is bounded, but for now make no assumptions about the boundary of the domain.

THEOREM 5.2. *If the observed image $f(x)$ is the characteristic function of a bounded domain $\Omega \subset \mathbf{R}^N$, then for any $\lambda \geq 0$ there is a minimizer of $E_1(\cdot,\lambda)$ that is also the characteristic function of a (possibly different) domain. In other words, when the observed image is binary, then for each $\lambda \geq 0$ there is at least one $u(x) \in M(\lambda)$ which is also binary.*

In fact, if $u_\lambda(x) \in M(\lambda)$ is any minimizer of $E_1(\cdot,\lambda)$, then for almost every $\gamma \in [0,1]$ we have that the binary function

$$\mathbf{1}_{\{x:u_\lambda>\gamma\}}(x)$$

is also a minimizer of $E_1(\cdot,\lambda)$.

Proof. Let $f(x) := \mathbf{1}_\Omega(x)$, where Ω is a bounded domain in $\mathbf{R}^N$. It can be easily seen that any minimizer $u(x)$ of E_1 satisfies $u(x) \in [0,1]$ for almost every $x \in \mathbf{R}^N$. Formula (5.1) of Proposition 5.1 above becomes, in this case,

$$E_1(u,\lambda) = \int_0^1 \mathrm{Per}\left(\{x : u(x) > \gamma\}\right) + \lambda \left| \{x : u(x) > \gamma\} \triangle \Omega \right| d\gamma.$$

This suggests that we consider for each level set of $u(x)$ the following geometry problem:

$$\min_{\Sigma \subset \mathbf{R}^N} \Big(\mathrm{Per}(\Sigma) + \lambda \big| \Sigma \triangle \Omega \big| \Big). \tag{5.3}$$

Standard compactness and lower semicontinuity facts show the existence of minimizers; let $\Sigma_* \subset \mathbf{R}^N$ be one of them. Let $u_\lambda(x)$ be any minimizer of $E_1(\cdot,\lambda)$, i.e., $u_\lambda(x) \in M(\lambda)$. Set

$$\Sigma(\gamma) := \big\{ x : u_\lambda(x) > \gamma \big\}.$$

Then

$$\mathrm{Per}\big(\Sigma(\gamma)\big) + \lambda \big| \Sigma(\gamma) \triangle \Omega \big| \geq \mathrm{Per}(\Sigma_*) + \lambda \big| \Sigma_* \triangle \Omega \big| \tag{5.4}$$

for almost every $\gamma \in [0,\infty)$. This now immediately implies that

$$E_1(u_\lambda(x),\lambda) \geq E_1(\mathbf{1}_{\Sigma_*}(x),\lambda),$$

which means that $\mathbf{1}_{\Sigma_*}(x)$ is also a minimizer of $E(\cdot,\lambda)$.

Furthermore, since $u_\lambda(x)$ is a minimizer, the inequality of (5.4) is in fact an equality for almost every $\gamma \in [0,1]$. Thus, $\Sigma(\gamma)$ is a minimizer of the geometry problem (5.3), and $1_{\Sigma(\gamma)}(x)$ is a minimizer of $E_1(\cdot,\lambda)$ for almost every γ. ∎

Remark. A version of the first statement of Theorem 5.2 was obtained for the discrete analogue of model (1.2) in one space dimension by Alliney in [4]. ∎

Remark. The claim leaves open the possibility that for a given $\lambda \geq 0$ there might be a $u \in M(\lambda)$ that takes more than two values.

Remark. The conclusion of Theorem 5.2 is interesting because it establishes the equivalence of a nonconvex problem (the geometry problem of minimizing over only binary images, which is encountered in many applications such as improving the appearance of fax documents) to a convex problem (minimizing over all images). Indeed, it follows from the corollary that to obtain a solution to (5.3), one can first minimize $E_1(\cdot,\lambda)$, taking $f(x) = 1_\Omega(x)$ as the observed image, and then look at a level set of the solution obtained. The resulting algorithm would be very different from the standard level set method of Osher and Sethian [19, 20]. Whether this observation can be turned into a useful computational tool needs to be explored, but this question will not be pursued any further here.

Theorem 5.2 highlights an important *qualitative difference* of the L^1 model from the standard ROF model. In contrast to the content of these claims, it is easy to show that for certain types of binary images (even with smooth edge sets) the minimizer of the standard ROF model takes more than two values for every large enough choice of the parameter λ.

We do not know whether the following comparison principle holds for the geometry problem (5.3): If $\Omega_1 \subset \Omega_2$ and Σ_1, Σ_2 are minimizers of (5.3) with $\Omega = \Omega_1$ and

$\Omega = \Omega_2$, respectively, then do we necessarily have $\Sigma_1 \subset \Sigma_2$? If true, this would imply, in particular, uniqueness for solutions of (5.3). In any case, we can make the following statement.

COROLLARY 5.3. *If the observed image $f(x)$ is the characteristic function of a bounded convex domain $\Omega \subset \mathbf{R}^N$, then for almost every $\lambda \geq 0$ the minimizer of $E_1(\cdot, \lambda)$ is unique and is the characteristic function of a set contained in Ω.*

Proof. Let $\lambda \in [0, \infty) \setminus S(f)$, and let $u_\lambda(x) \in M(\lambda)$. We recall from the proof of Theorem 5.2 that, using the same notation as in that proof, the set $\Sigma(\gamma)$ minimizes the geometry problem (5.3) for almost every $\gamma \in [0, 1]$. Let $1 \geq \gamma_1 > \gamma_2 \geq 0$, and assume that $\Sigma(\gamma_1) \neq \Sigma(\gamma_2)$ both minimize the geometry problem. By definition, we have $\Sigma(\gamma_1) \subset \Sigma(\gamma_2)$. Furthermore, convexity of Ω implies that

$$\mathrm{Per}(\Sigma(\gamma_i) \cap \Omega) \leq \mathrm{Per}(\Sigma(\gamma_i)) \text{ for } i = 1, 2.$$

Since $\mathbf{1}_{\Sigma(\gamma_1)}(x)$ and $\mathbf{1}_{\Sigma(\gamma_2)}(x)$ are minimizers, it follows that $\Sigma(\gamma_1) \subset \Sigma(\gamma_2) \subseteq \Omega$. Hence, $|\Sigma(\gamma_1) \triangle \Omega| \neq |\Sigma(\gamma_2) \triangle \Omega|$. But then $\lambda \in S(f)$, which is a contradiction. We have thus reached the conclusion that if $\lambda \in [0, \infty) \setminus S(f)$, then any minimizer of $E_1(\cdot, \lambda)$ is necessarily binary (i.e., the characteristic function of a set). Now suppose that $u_1(x)$ and $u_2(x)$ are two binary minimizers of $E_1(\cdot, \lambda)$. By convexity of $E_1(\cdot, \lambda)$, we then have that $\frac{1}{2}(u_1(x) + u_2(x))$ is also a minimizer, and thus binary. But the average of two binary functions is binary only if the two functions are identical.

Thus, whenever $\lambda \in [0, \infty) \setminus S(f)$, the minimizer of $E_1(\cdot, \lambda)$ is unique and is binary: It is of the form $\mathbf{1}_\Sigma(x)$ for some set Σ. The argument above shows that $\Sigma \subseteq \Omega$. And Claim 5 says that $S(f)$ is at most countable and thus negligible. That proves the claim. ∎

As an aside, we note the following result about problem (5.3) that follows immediately from the previous corollary (perhaps it can be obtained also in a less roundabout way).

COROLLARY 5.4. *Let Ω be a bounded convex domain in $\mathbf{R}^N$. Then, for almost every $\lambda \geq 0$, the solution of problem* (5.3) *is unique.*

Proof. If Σ_1 and Σ_2 are solutions to (5.3), then $\mathbf{1}_{\Sigma_1}(x)$ and $\mathbf{1}_{\Sigma_2}(x)$ are minimizers of $E_1(\cdot, \lambda)$ with the observed image given by $f(x) = \mathbf{1}_\Omega(x)$. Conditions on Ω imply that Corollary 5.3 applies so that $\Sigma_1 = \Sigma_2$. That proves the claim. ∎

We will next consider some simple images $f(x)$ for which the minimizer of $E_1(\cdot, \lambda)$ turns out to be precisely the image $f(x)$ itself for every large enough λ. In section 1, we recalled a result from Meyer's lecture notes [15] which says that for the standard ROF model given by $E_2(\cdot, \lambda)$ the only such image is $f(x) := 0$. For E_1, however, there are many such images, as shown by Proposition 4.2, which we quoted in section 4 from [3]. The following lemma will be instrumental in establishing whether certain simple observed images $f(x)$ have this property.

LEMMA 5.5. *Given an observed image $f(x) \in BV(\mathbf{R}^N)$, assume that there is a vector field $\phi(x)$ with the following properties:*

1. *$\phi(x) \in C_c^1(\mathbf{R}^N; \mathbf{R}^N)$,*
2. *$|\phi(x)| \leq 1$ for all $x \in \mathbf{R}^N$,*
3. *$\int_{\mathbf{R}^N} f(x) \operatorname{div} \phi(x)\, dx = \int_{\mathbf{R}^N} |\nabla f|$.*

Then there exists a threshold $\lambda_* \geq 0$ such that $M(\lambda) = \{f(x)\}$ for all $\lambda > \lambda_*$. In other words, the unique minimizer of $E_1(\cdot, \lambda)$ is given by the observed image $f(x)$.

Proof. Set $\lambda_* := \max_{x \in \mathbf{R}^N} |\operatorname{div} \phi(x)|$. Take any $\lambda > \lambda_*$. Then, given any

$u(x) \in BV(\mathbf{R}^N)$, we have

$$\begin{aligned} E_1(u,\lambda) &= \int |\nabla u| + \lambda \int |u-f|\,dx \\ &\geq \int u \operatorname{div}\phi\,dx + \lambda \int |u-f|\,dx \\ &= \int f \operatorname{div}\phi\,dx + \lambda \int |u-f|\,dx + \int (u-f)\operatorname{div}\phi\,dx \\ &\geq E_1(f,\lambda) + \Big(\lambda - \max_{x\in\mathbf{R}^N} |\operatorname{div}\phi(x)|\Big) \int |u-f|\,dx. \end{aligned}$$

Since $\lambda > \lambda_* := \max|\operatorname{div}\phi(x)|$, the last inequality shows that $E_1(u,\lambda) > E_1(f,\lambda)$ unless $u \equiv f$. Since u is a minimizer, it must in fact be the case that $u \equiv f$. □

Lemma 5.5 can now be applied, for example, to binary images to obtain an important class of exact solutions. This requires making some smoothness assumption about the interface between then two values of the binary function.

THEOREM 5.6. *Let $\Omega \subset \mathbf{R}^N$ be a bounded domain with C^2 boundary. Let the observed image $f(x)$ be given by $f(x) = \mathbf{1}_\Omega(x)$. Then there exists a threshold $\lambda_* \geq 0$ such that whenever $\lambda > \lambda_*$, the unique minimizer of $E_1(\cdot,\lambda)$ is the observed image $f(x) = \mathbf{1}_\Omega(x)$ itself.*

Proof. Since the boundary $\partial\Omega$ of the bounded domain Ω is assumed to be C^2, the outward unit normal vector field $n(x) : \partial\Omega \to \mathbf{S}^{N-1}$ of $\partial\Omega$ can be extended in a C^1 manner to a tubular neighborhood of $\partial\Omega$, so that one gets a vector field $\phi(x) \in C_c^1(\mathbf{R}^N;\mathbf{R}^N)$ such that $\phi(x)\big|_{x\in\partial\Omega} = n(x)$, and $|\phi(x)| \leq 1$ for all $x \in \mathbf{R}^N$. But then

$$\begin{aligned} \int_{\mathbf{R}^N} f \operatorname{div}\phi\,dx &= \int_\Omega \operatorname{div}\phi(x)\,dx = \int_{\partial\Omega} \phi(x)\cdot n(x)\,d\sigma \\ &= \operatorname{Per}(\partial\Omega) = \int_{\mathbf{R}^N} |\nabla f|\,dx. \end{aligned}$$

Hence, the vector field $\phi(x)$ satisfies all the requirements of Lemma 5.5, from which the conclusion of the present claim follows. □

At this point it is worth recalling the behavior of the standard ROF model on binary images of the form $f(x) = 1_\Omega(x)$. As we noted above, simple considerations show that the minimizer of the standard ROF model almost never turns out to be $u(x) = f(x) = 1_\Omega(x)$. A related question is whether the solution $u(x)$ has at least the correct "set of edges"; see [10]. In case Ω is a ball, one can calculate the minimizer explicitly [25]; it turns out to be $u(x) = c\mathbf{1}_\Omega(x)$, where $c = 1 - \frac{\operatorname{Per}(\Omega)}{2\lambda|\Omega|}$. In particular, $u(x)$ has the same set of edges as $f(x)$. The results of [5] generalize the results of [25] but also show that the class of binary images that have this weaker property (i.e., images for which the solution to the standard ROF model turns out to be a constant multiple of the observed image) is still rather limited; for example, there are smooth but nonconvex shapes that lack this property.

Remark. Theorem 5.6 can easily be extended to images of a more general form. Indeed, if the level sets $\{x : f(x) = \gamma\}$ of the given image $f(x)$ are smooth and vary smoothly with respect to γ, the same conclusion holds. We also see, among other things, that such an image $f(x)$ cannot have strict local extrema, for at a strict local extremum the level sets shrink to a point. Moreover, there are also binary images that lack this property (i.e., which are not exactly recovered for any $\lambda \geq 0$, no matter how

large). In fact, a repetition of some of the arguments of Meyer given in his lecture notes [15] on the standard ROF model show that the characteristic function of, say, a square cannot arise as the solution to the ROF model with L^1 fidelity either, no matter what the observed image $f(x) \in L^1$ is, and no matter how large the parameter λ is chosen.

Remark. A discrete version of Theorem 5.6 is proved in [17] for denoising models with nonsmooth (including L^1) fidelity terms and smooth regularization terms. In those results, unlike ours, the threshold value for the parameter λ necessarily involves the grid size.

The last few claims dealt with the behavior of the L^1 fidelity-based model for large values of the parameter λ. Next, we consider what happens when $\lambda \geq 0$ is small enough. The following claim is a very simple application of the isoperimetric inequality.

PROPOSITION 5.7. *Let $R > 0$. Then there exists a threshold $\lambda_* = \lambda_*(R, N)$ such that if $f \in L^1(\mathbf{R}^N)$ with $\operatorname{supp}(f) \subset B_R(0)$, then $M(\lambda) = \{0\}$ for any $\lambda < \lambda_*$. In other words, the unique minimizer of $E_1(\cdot, \lambda)$ is given by $u(x) \equiv 0$.*

Proof. Let $C = C(N)$ be the isoperimetric constant

$$\int_{\mathbf{R}^N} |\nabla u| \geq C(N) \|u\|_{L^{\frac{N}{N-1}}(\mathbf{R}^N)} \quad \text{for all } u \in BV(\mathbf{R}^N).$$

Then we set

$$\lambda_*(R, N) := \frac{C(N)}{R\omega_N^{\frac{1}{N}}},$$

where ω_N is the volume of the unit ball in $\mathbf{R}^N$. Take a $\lambda > \lambda_*$ and let $u(x) \in M(\lambda)$. Then $E_1(u, \lambda) \leq E_1(0, \lambda)$. By the isoperimetric inequality, that means

$$C(N)\|u\|_{L^{\frac{N}{N-1}}(\mathbf{R}^N)} + \lambda\|u - f\|_{L^1(\mathbf{R}^N)} \leq \lambda\|f\|_{L^1(\mathbf{R}^N)} = \lambda\|f\|_{L^1(B_R(0))}.$$

We apply Holder's inequality to the first term on the left-hand side after splitting it into integrations over $B_R(0)$ and $B_R^c(0)$. That gives

$$\frac{C(N)}{R\omega_N^{\frac{1}{N}}} \|u\|_{L^1(B_R(0))} + \lambda\|u - f\|_{L^1(B_R(0))} + C(N)\|u\|_{L^{\frac{N}{N-1}}(B_R^c(0))} \leq \lambda\|f\|_{L^1(B_R(0))},$$

which shows that if $\lambda < C(N)/R\omega_N^{\frac{1}{N}} = \lambda_*$, then

$$\|u\|_{L^1(B_R(0))} = \|u\|_{L^{\frac{N}{N-1}}(B_R^c(0))} = 0.$$

In other words, $u \equiv 0$. □

Remark. This behavior of the L^1 model is to be expected, based on its contrast invariance, as we have already noted in the introduction. It differs from the behavior at small λ values of the standard ROF model, which, according to [15], entails not just the support of a given compactly supported image $f(x)$ but its $\|\cdot\|_*$-norm.

6. Scale space and the set $S(f)$. The set $S(f)$ of discontinuities of the functions $\mu^{\pm}$ play a distinguished role in the scale space generated by varying the parameter λ in the L^1 model. As the value of λ is gradually decreased, minimizers of the image models become coarser as small scale objects in the image merge to form larger

scale structures. Intuitively, for the L^1 model we can expect the values of $\lambda \in S(f)$ to correspond to scales of distinct objects that make up the image. These are the values of λ at which the scale space makes a rapid and drastic transition.

We would first like to prove that the set $S(f)$ is nonempty for the kind of images we have been considering in the previous sections, namely images of the form $f(x) = \mathbf{1}_\Omega(x)$, where Ω is a bounded domain. Our arguments are based on verifying this claim for the special case where the given image is the characteristic function of a ball, and then generalizing the result to $f(x) = \mathbf{1}_\Omega(x)$ by comparing Ω with a ball that is contained in Ω.

LEMMA 6.1. *Let Ω be a bounded domain in $\mathbf{R}^2$, and assume that $B_R(p) \subset \Omega$. Consider the observed image given by $f(x) = \mathbf{1}_\Omega(x)$. Then for any $\lambda \geq 0$ and $r \in (0, R)$ we have*

$$E_1(\mathbf{1}_{B_r(p)}(x), \lambda) > \min\Big\{E_1(0, \lambda), E_1(\mathbf{1}_{B_R(p)}(x), \lambda)\Big\}.$$

Proof. Since $B_r(p) \subset B_R(p) \subset \Omega$ for each $r \in (0, R)$, we have

$$\|\mathbf{1}_\Omega(x) - \mathbf{1}_{B_r(p)}(x)\|_{L^1(\mathbf{R}^2)} = |\Omega| - \pi r^2.$$

That means

$$E_1(\mathbf{1}_{B_r(p)}(x), \lambda) = \lambda\big(|\Omega| - \pi r^2\big) + 2\pi r.$$

Considering $E_1(\mathbf{1}_{B_r(p)}(x), \lambda)$ as a function of r, we see that it achieves its minimum on $[0, R]$ strictly at the end points of the interval. ∎

In order to show that $\mu^{\pm}(\lambda)$ is a discontinuous function, we will show that its range omits a full interval of values but does include certain values on either side of that interval. The next claim exhibits such an omitted interval.

LEMMA 6.2. *Let Ω be a bounded domain in $\mathbf{R}^2$, and let $B_R(0) \subset \Omega$. Consider the observed image given by $f(x) = \mathbf{1}_\Omega(x)$. There is no $\lambda \in \mathbf{R}^+$ such that*

$$|\Omega| - \pi R^2 < \mu^+(\lambda) < |\Omega|.$$

Proof. Suppose there is a $\lambda \geq 0$ such that $|\Omega| - \pi R^2 < \mu^+(\lambda) < |\Omega|$. There exists $u(x)$ such that $u(x) \in M(\lambda)$ and $\|u - f\|_{L^1(\mathbf{R}^N)} = \mu^+(\lambda)$. As before, let $\Sigma(\gamma) := \{x : u(x) > \gamma\}$. By Proposition 5.1, we have $\mathbf{1}_{\Sigma(\gamma)}(x) \in M(\lambda)$ for almost every $\gamma \in (0, 1)$. Therefore, for almost every γ we have

$$\|\mathbf{1}_{\Sigma(\gamma)}(x) - f\|_{L^1(\mathbf{R}^2)} < |\Omega|$$

(otherwise $\mu^+(\lambda) \geq |\Omega|$). It also *cannot be the case* that $|\Sigma(\gamma) \triangle \Omega| \leq |\Omega| - \pi R^2$ for almost every $\gamma \in (0, 1)$ since we know that

$$\int_0^1 |\Sigma(\gamma) \triangle \Omega|\, d\gamma = \|u - f\|_{L^1(\mathbf{R}^2)} = \mu^+(\lambda) > |\Omega| - \pi R^2.$$

Thus, there exists $\gamma_* \in (0, 1)$ such that

$$\mathbf{1}_{\Sigma(\gamma_*)}(x) \in M(\lambda) \quad \text{and} \quad |\Omega| - \pi R^2 < \|\mathbf{1}_{\Sigma(\gamma_*)}(x) - f(x)\|_{L^1(\mathbf{R}^2)} < |\Omega|.$$

Case 1. $|\Sigma(\gamma_*)| \geq \pi R^2$. But then $\mathrm{Per}(B_R(0)) \leq \mathrm{Per}(\Sigma(\gamma_*))$, and

$$|\Omega \triangle B_R(0)| = |\Omega| - \pi R^2 < \|\mathbf{1}_{\Sigma(\gamma_*)}(x) - f(x)\|_{L^1}.$$

Hence, $E_1(\mathbf{1}_{B_R(0)}(x), \lambda) < E_1(\mathbf{1}_{\Sigma(\gamma_*)}(x), \lambda)$. This is a contradiction, since $\mathbf{1}_{\Sigma(\gamma)}(x)$ was supposed to be a minimizer.

Case 2. $|\Sigma(\gamma_*)| < \pi R^2$. In this case, take $r = \frac{1}{\sqrt{\pi}}|\Sigma(\gamma_*)|^{\frac{1}{2}}$. Since $r \in (0, R)$, we have that $B_r(0) \subset \Omega$. This implies

$$\|\mathbf{1}_{B_r(0)}(x) - f(x)\|_{L^1(\mathbf{R}^2)} \leq \|\mathbf{1}_{\Sigma(\gamma_*)}(x) - f(x)\|_{L^1(\mathbf{R}^2)}.$$

Moreover, as before, $\mathrm{Per}(B_R(0)) \leq \mathrm{Per}(\Sigma(\gamma_*))$. Therefore,

$$E_1(\mathbf{1}_{B_r(0)}(x), \lambda) \leq E_1(\mathbf{1}_{\Sigma(\gamma_*)}(x), \lambda) = E_1(u(x), \lambda).$$

On the other hand, by Lemma 6.1 we have

$$E_1(\mathbf{1}_{B_r(0)}(x), \lambda) > \min\Big\{E_1(0, \lambda), E_1(\mathbf{1}_{B_R(0)}(x), \lambda)\Big\}.$$

This is a contradiction, since $u(x) \in M(\lambda)$.

THEOREM 6.3. *Let Ω be a nonempty bounded domain in $\mathbf{R}^2$. Consider the observed image given by $f(x) = \mathbf{1}_\Omega(x)$. Then the functions $\mu^{\pm}(\lambda)$ are discontinuous.*

Proof. By Proposition 5.7, we have that $\mu^+(\lambda) = \|f\|_{L^1} = |\Omega|$ for all small enough λ. On the other hand, by Claim 6 we have that $\mu^{\pm}(\lambda) \to 0$ as $\lambda \to \infty$. However, by Lemma 6.2, there is a range of values near $|\Omega|$ that the function μ^+ cannot take. It therefore has to be discontinuous. Discontinuity of μ^- follows from that of μ^+ via Claim 4. ∎

Remark. This should be contrasted with the situation for the standard total variation model (with L^2 fidelity), which is explained in Claim 3.

We thus see that the scale spaces generated by the two models, the standard ROF model and the one with L^1 fidelity, are very different. With the standard ROF model, pronounced objects of distinct scale with sharp edges in the image gradually lose their contrast and merge with their neighbors as the parameter λ is lowered. With the L^1 model, such objects maintain their contrast with respect to their neighbors—however, their boundaries might be gradually smoothed out. This goes on until a critical value of λ is reached—one that belongs to the set $S(f)$, at which point the object suddenly merges with a neighboring one.

At this point, it is also worth comparing the scale space generated by the L^1 model with that generated by anisotropic diffusion via motion by mean curvature of level sets. The two are drastically different. This can be seen most easily in the case when $f(x)$ is the characteristic function of a disk. The scale space generated by motion by curvature consists of a family of concentric disks shrinking gradually to a point. Hence the same feature, i.e., the original disk, appears at many intermediate scales, albeit in different sizes. On the other hand, the scale space generated by the total variation model with L^1 fidelity term consists of either the original disk or the constant background at any given scale.

Finally, we return to the topic of continuous dependence on the observed signal for the L^1 model. Despite our remarks in section 3, we show in the next claim that the fidelity of minimizer versus λ graph depends on the observed image continuously.

PROPOSITION 6.4. *Let $\{f_j(x)\}_{j=1}^{\infty}$ be a sequence in $L^1(\mathbf{R}^N)$ that converges to $f(x)$ in the L^1-norm. Then, for almost all $\lambda \geq 0$, $\mu^{\pm}(\lambda, f_j)$ converges to $\mu^{\pm}(\lambda, f)$ as $j \to \infty$.*

Proof. Let $\mathcal{S} := S(f) \cup (\cup_{j=1}^{\infty} S(f_j))$. According to Claim 5, $S(f)$ and each $S(f_j)$ are countable. Therefore, $\mathcal{S}$ is countable and thus negligible. Fix $\lambda \in [0, \infty) \setminus \mathcal{S}$. For

each j, take $u_j \in M(\lambda, f_j)$. The sequence $\{u_j\}_{j=1}^{\infty}$ is bounded in total variation norm and hence is precompact in L^1 on compact sets. Passing to a subsequence if necessary, we may assume that $u_j \to u_\infty$ pointwise a.e. as $j \to \infty$.

We must have $u_\infty \in M(\lambda, f)$. To see this, assume otherwise. $M(\lambda, f)$ is nonempty, so take a $u \in M(\lambda, f)$. By lower semicontinuity we have

$$E_1(u, \lambda, f) < E_1(u_\infty, \lambda, f) \le \liminf_{j\to\infty} E_1(u_j, \lambda, f_j).$$

However, $E_1(u, \lambda, f_j) \to E_1(u, \lambda, f)$ as $j \to \infty$. Therefore, for large enough j, we get $E_1(u, \lambda, f_j) < E_1(u_j, \lambda, f_j)$. This gives a contradiction, since $u_j \in M(\lambda, f_j)$.

Now that we know $u_\infty \in M(\lambda, f)$, recall next that $\lambda \notin \mathcal{S}$. Therefore,

$$\mu^{\pm}(\lambda, f) = \|u_\infty - f\|_{L^1} = \lim_{j\to\infty} \|u_j - f_j\|_{L^1} = \lim_{j\to\infty} \mu^{\pm}(\lambda, f_j).$$

That proves the claim. ∎

7. Computation. In this section, we show numerical examples that bring out unique features of the total variation–based denoising model with L^1 fidelity term. We also give some details on the numerical schemes used to obtain these results.

Our computations are based on gradient descent schemes for decreasing the energies involved. The nondifferentiability of the terms involved in the energies calls for some sort of regularization. The regularized versions of energies $E_1(\cdot, \lambda)$ and $E_2(\cdot, \lambda)$ used in our numerical experiments are the following:

$$E_1^{\varepsilon,\delta}(u, \lambda) := \int_{\mathbf{R}^N} \sqrt{|\nabla u|^2 + \varepsilon} + \lambda \int_{\mathbf{R}^N} \sqrt{(f-u)^2 + \delta}\, dx,$$
$$E_2^{\varepsilon}(u, \lambda) := \int_{\mathbf{R}^N} \sqrt{|\nabla u|^2 + \varepsilon} + \lambda \int_{\mathbf{R}^N} (f-u)^2\, dx.$$

This type of approximation to total variation–based models is very standard. The discrete versions of these energies lead to the following equally standard explicit gradient descent schemes in two space dimensions:

$$\frac{u_{i,j}^{n+1} - u_{i,j}^n}{\delta t} = D_x^- \left(\frac{D_x^+ u_{i,j}^n}{\sqrt{(D_x^+ u_{i,j}^n)^2 + (D_y^+ u_{i,j}^n)^2 + \varepsilon}} \right) + D_y^- \left(\frac{D_y^+ u_{i,j}^n}{\sqrt{(D_x^+ u_{i,j}^n)^2 + (D_y^+ u_{i,j}^n)^2 + \varepsilon}} \right) + \lambda \frac{(f - u_{i,j}^n)}{\left((f - u_{i,j}^n)^2 + \delta\right)^{\alpha}},$$

where $\alpha = \frac{1}{2}$ for $E_1^{\varepsilon,\delta}$ and $\alpha = 0$ for E_2^{ε}. Here, D^+ and D^- denote forward and backward difference quotients, respectively, in the direction of their subscript.

We note that efficient numerical minimization of energies considered in this work is a topic unto itself; no doubt there are better ways to do it than the gradient descent approach taken and the specific choice of scheme made above. In particular, it is better to use algorithms that do not need to regularize the nondifferentiable terms appearing in the energy. Such an algorithm is presented by Alliney in [2] with applications to one dimensional signals in the context of an objective functional with mixed l^1,l^2 norms. Also, Chambolle recently developed an efficient algorithm for minimizing the standard ROF model for images without regularizing the total variation term

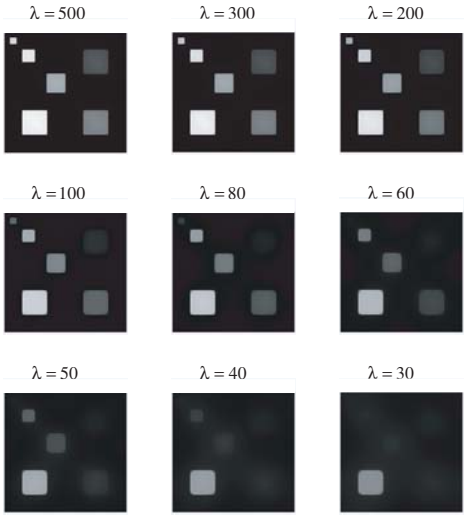

FIG. 2. *Example of scale space generated by the standard total variation model. Compare with the same example for the model with L^1 fidelity, shown in Figure* 3.

[7]. Further alternative numerical approaches to total variation–based models can be found in [6, 9]. Whether these algorithms can be adapted to our setting is a very interesting question that will be explored elsewhere.

An important point that we need to clarify is the following. Although, as we already noted several times, the energy $E_1(\cdot, \lambda)$ is not strictly convex and its minimizers in general lack uniqueness, for any given $\delta > 0$ the approximate energy $E_1^{\varepsilon,\delta}(\cdot, \lambda)$ *is* strictly convex so that its minimizers enjoy uniqueness. It is these minimizers that we have computed. Moreover, it is a very routine matter to verify that a sequence of minimizers of $E_1^{\varepsilon,\delta}(\cdot, \lambda)$ converges to the set of minimizers $M(\lambda)$ of $E_1(\cdot, \lambda)$ as $\varepsilon, \delta \to 0^+$. The analogous convergence statement is, of course, true also for a sequence of minimizers of $E_2^{\varepsilon}(\cdot, \lambda)$.

Figures 2 and 3 compare the scale spaces generated by the standard total variation model and the one with L^1 fidelity on a synthetic image. This experiment makes the more geometric nature of the L^1 model abundantly clear. The observed image consists of squares of various sizes and gray levels. In the scale space generated by the standard total variation model, the squares gradually lose their contrast (while at the same time their geometries get regularized) and gradually disappear. Moreover, some large squares with low contrast against the background—namely the square near the upper right corner—disappear before some smaller squares that have higher contrast against the background—namely the two intermediate sized squares along the diagonal. On the other hand, in the scale space generated by the model with L^1 fidelity, the squares get processed only in terms of their geometry: They preserve their contrast very well until all of a sudden they disappear. (They should, in fact, preserve their contrast perfectly, but because our numerical scheme regularizes the L^1 fidelity term to make it differentiable, in practice there is some loss of contrast.) In principle, the contrast of the squares plays no role in determining the order in which they are removed; that order is determined completely in terms of the geometry of the features.

Figure 4 shows the graph of the fidelity of the minimizer versus λ for the standard

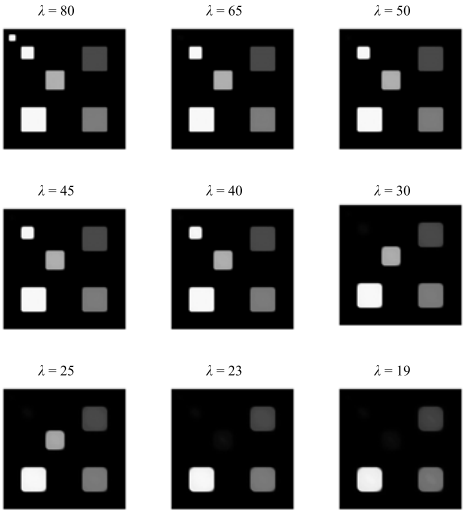

FIG. 3. *Example of scale space generated by the total variation model with L^1 fidelity. Compare with Figure 2.*

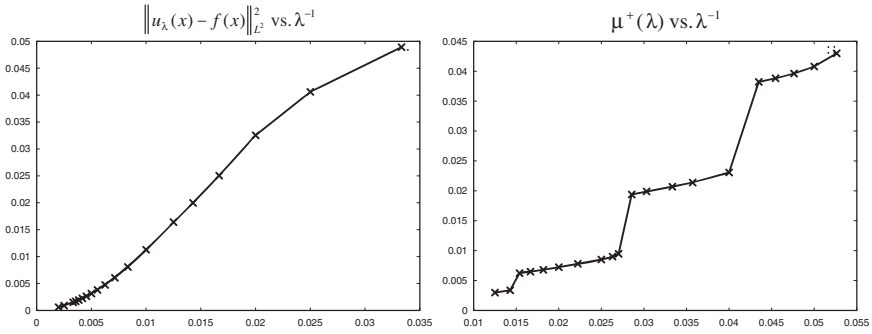

FIG. 4. *Plot of the fidelity of minimizer (i.e., $\|u_\lambda(x) - f(x)\|_{L^2}^2$) versus λ^{-1} for the standard ROF model (top graph) and of the fidelity of minimizer (i.e., $\|u_\lambda(x) - f(x)\|_{L^1}$) versus λ^{-1} for the ROF model with L^1 fidelity (bottom graph).*

total variation model and for the model with L^1 fidelity. An important ambiguity that we need to resolve is how the nonuniqueness of minimizers of $E_1(\cdot, \lambda)$ affects the fidelity-versus-λ plot for $E_1(\cdot, \lambda)$. To answer this question, recall that the fidelity of various minimizers of $E_1(\cdot, \lambda)$ differs from each other at only countably many values of λ. In particular, all ways of obtaining the second graph in Figure 4 yield plots that are identical up to a set of measure 0. Hence, there is no ambiguity in the results shown.

Discontinuities in the minimizer's fidelity-versus-λ graph for the L^1 model correspond to distinguished values of the parameter λ. As can be seen from the results, these are the values of λ at which a drastic change in the scale space takes place. Namely, at such values of λ one of the "features" (squares in this example) gets eliminated. There is no such distinguished value of λ in the plot for the standard ROF model at which the graph becomes discontinuous (as shown both by our theoretical results and by the numerical example shown). However, the graph in that case might have kinks, which are of course harder to detect than discontinuities. Thus, unlike

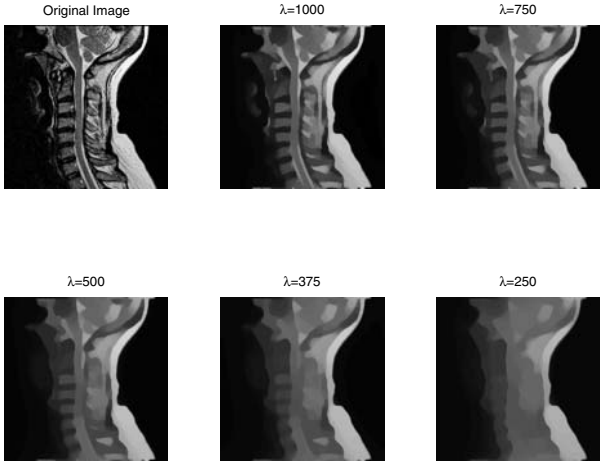

FIG. 5. *Scale space generated by the standard ROF model.*

the standard total variation model, the model with L^1 fidelity thus suggests a method for *data-driven parameter selection*.

For those familiar with the notion of an L-curve [13, 14] (which is a technique for choosing regularization parameters in ill-posed inverse problems), let us point out that from the point of view of this paper there is no apparent useful connection between the fidelity-versus-λ graph and the L-curve. According to the L-curve method, to determine a distinguished value of the regularization parameter λ, one should find the corner (point of maximum curvature) in the $\int |\nabla u_\lambda|$ versus $\|u_\lambda - f\|_{L^1}$ graph. However, for instance in the case of the example of section 3 (i.e., with $f(x) = \mathbf{1}_{B_r(0)}(x)$), the curvature of this graph is easily seen to be independent of the radius r; thus, the L-curve method does not yield any scale information.

The special values of parameter λ obtained from the fidelity-of-minimizer graph via the L^1 model can be used in many ways. For example, denoising models are sometimes used for generating multiscale decomposition of images, as in [26]. In such applications, it is necessary to select a *schedule* for the parameter λ a priori. In [26], this schedule is chosen in the form $\lambda = 2^j \lambda_0$, with $j = 1, 2, 3, \ldots$, and the initial value λ_0 is arbitrarily chosen by the user. The L^1 scale space suggests a more natural data-driven way to select these parameters using the discontinuities in the fidelity-of-minimizers graph. Moreover, even if one opts to use a λ-schedule of the form used in [26], the theoretical results and preliminary numerical examples of this paper suggest that one might obtain a much cleaner decomposition using the ROF model with L^1 fidelity in place of the standard ROF model. All these ideas pertaining to multiscale decomposition of images using the L^1 fidelity-based model will be explored elsewhere.

Finally, Figures 5 and 6 illustrate the differences between the standard ROF model and the one with L^1 fidelity on a real medical image. In this example also, one can see that the small scale features in the observed image, such as these indicated by the arrow on the lower-left-hand-side image of Figure 6, maintain their contrast much better in the L^1 fidelity model than in the standard ROF model, even as the parameter λ is gradually decreased to very low values.

8. Conclusion. We have considered the total variation–based image denoising model of Rudin, Osher, and Fatemi with the L^1-norm as the fidelity term. Our

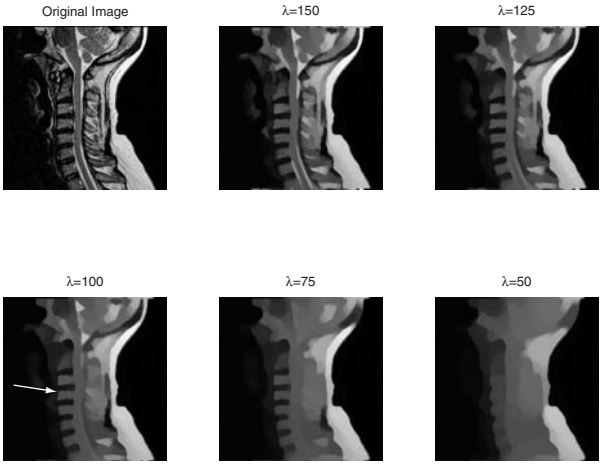

FIG. 6. *Scale space generated by the ROF model with L^1 fidelity term.*

results highlight that this modification leads to many interesting qualitative differences in the behavior of the modified model from the standard one. These differences have important consequences for image denoising. They also suggest interesting new research directions into applications to data-driven parameter selection and multiscale image decomposition.

Acknowledgments. The authors would like to thank Antonin Chambolle, Mila Nikolova, Stanley Osher, and Luminita Vese for helpful discussions.

CHANNEL FORMATION IN GELS*

N. G. COGAN† AND JAMES P. KEENER‡

Abstract. We derive and give an analysis of a model of gel dynamics based on a two-phase description of the gel, where one phase consists of networked polymer and the second phase is the fluid solvent. It is found that for the gel to maintain an edge in a poor solvent, the function describing the osmotic pressure must be of a particular form. The model is used to study the behavior of a gel forced by a pressure gradient to move between two flat plates. The distribution of the network phase under these conditions is found to be nonuniform and dependent on the pressure gradient. There is a range of pressure gradients for which the network has regions of high and low volume fraction separated by a sharp boundary, indicative of a channel. We provide the bifurcation analysis of how these novel, singularly perturbed, channeled solutions occur.

1. Introduction.

There are numerous biological and biotechnological examples where the structure and dynamics of polymer gels regulates the local environment. Biological examples include maintenance of structural integrity in biofilms [8], cellular cytoplasm [3], force generators in myxobacteria [14], and chemical diffusion and adsorption mediation in biofilm clusters [12]. Gel patches and ingestible pills used to regulate the diffusion and adsorption of drugs are examples of bioengineered gels. Quantifying the role of the polymer gel in such diverse systems requires understanding the effect of the physical and chemical structure of the polymers on the material properties of the system.

Gels are composed of a polymer network and a fluid solvent. This composition endows gels with properties different than those of viscous materials for two primary reasons. First, the polymeric structure induces viscoelastic behavior. Second, the chemical structure of the polymer induces force, causing gel swelling and deswelling. In this paper we first introduce a two-phase description of gel dynamics that emphasizes these two important differences between gels and Newtonian fluids. The behavior of a pressure driven gel between two flat plates is analyzed in a manner similar to the standard Poiseulle flow problem. Results from this analysis indicate that the steady-state network profile depends on the pressure gradient in a relatively complicated manner. There is an intermediate range of pressure gradients for which the majority of the network is compressed and located near the plates, creating a channeled region which is relatively free of polymer. This channeled solution arises via a novel bifurcation mechanism from a nearly uniform network distribution by forming a deep, narrow channel.

2. A model of gel dynamics.

Gels consist of two materials, networked polymer and fluid solvent, where the network encapsulates the solvent. The polymer

network can be formed by several different interactions between the polymers themselves including covalent bonding, coulombic bonding, hydrogen bonding, and physical entanglement.

In response to external conditions, gel networks absorb or expel solvent, causing swelling or contraction, respectively. Thus the structure of the gel depends on the temperature, solvent composition, pH, hydrostatic pressure, and ionic concentrations. The potential which is responsible for the swelling properties of the gel is referred to as osmotic or swelling pressure.

Forces due to osmotic pressure are not the only forces acting on the polymer network. Deformation of the gel induces forces due to the elastic nature of the polymer network. The elasticity is caused by both the elasticity of the polymers themselves and polymer interactions. That is, a single polymer acts as a spring for small deformations, while entanglement and cross-linking cause the network to resist deformations. The behavior is in general not well described by a simple linear relationship between displacement (strain) and stress primarily because the deformations are typically large.

Because the cross-links may be broken, a strain imposed on the gel and held induces a stress which dissipates, a process referred to as relaxation. Further, if a fixed stress is imposed on the gel, the gel will continue to displace, which is referred to as creep. The two behaviors of creep and relaxation indicate that gels are viscoelastic materials; therefore the constitutive relationship between stress and strain is typically more complicated than for viscous materials.

Here we assume that a gel is composed of two immiscible materials, polymer network and fluid solvent. The resulting model is similar to other models [3, 6, 9, 11, 13] that describe the gel as a two-phase material. The primary variation among models in the literature results from the treatment of the viscoelastic stress and the swelling pressure. In this study, we will neglect the relaxation of the network and assume that the gel is composed of an elastic solid (network) embedded in a viscous fluid (solvent). The swelling pressure is specified to ensure that physically reasonable swelling/deswelling is reflected in the deformation process.

In the following sections we describe a general model of gel dynamics and specify the forms of the viscoelastic stress and osmotic pressure used in this investigation. The resulting model is then used to study the distribution of the polymer network when the gel is forced to move between two flat plates by a pressure gradient.

2.1. Model derivation. We consider a region of space that contains networked polymer and solvent, where the volume fraction of network, θ_n, and the volume fraction of solvent, θ_s, sum to one. The network is assumed to act as a constant density viscoelastic material, while the solvent acts as a Newtonian fluid of much less viscosity than the networked material. The velocities of network and solvent are denoted $\vec{U}_n$ and $\vec{U}_s$, respectively.

The equation describing the momentum of the polymer network is given by the balance of four forces that act on the network. Surface forces are given by $\nabla \cdot (\theta_n \sigma_n)$, where σ_n is the network stress tensor. We assume that $\sigma_n = \sigma_v + \sigma_e$, where the viscous and elastic stresses are denoted σ_v and σ_e, respectively. The viscous stress tensor is proportional to the velocity gradient, $\sigma_v = \frac{\eta}{2}(\nabla \vec{U}_n + \nabla \vec{U}_n^T)$. The non-Newtonian stress tensor is given by constitutive relations which depend on the material and flow regimes [1]. Here we take the elastic stress to be proportional to the elastic strain, which is determined by the displacement gradient. We do not allow for creep or relaxation of stress. Thus, we are describing the deformation process of the moving gel. Since the displacements are not small, we use a finite strain tensor. The displacement of a fluid

particle relative to fixed Eulerian coordinates is determined by

$$\vec{x}' = \vec{x} + \vec{D}(\vec{x}, t),$$

where $\vec{x}'$ denotes the past position of the fluid particle and the components of the vector $\vec{D}$ are the displacements.

Following the development given in [1], the stress is related to the strain through

$$\sigma_e = \gamma \mathbf{C}, \tag{1}$$

where $\mathbf{C}$ is the relative Cauchy strain tensor

$$\mathbf{C}(\vec{x}, t)_{i,j} = \mathbf{F}_{ji}\mathbf{F}_{ij} - \delta_{ij},$$

with $\mathbf{F}_{ij} = \frac{\partial x_i'}{\partial x_j} = \frac{\partial D_i}{\partial x_j} + \delta_{ij}$ the deformation gradient tensor and $\delta_{ij} = 0$ if $i \neq j$, $\delta_{ii} = 1$.

We must also specify equations describing the change in displacements due to advection. The time derivative is measured in convected coordinates (i.e., relative to a fixed coordinate system). We assume that the gel is an elastic solid with rest position at which there is no network strain, while displacements from rest induce a strain on the network. Relaxation of the network has been ignored since we are primarily interested in coupling between elastic stress and network motion. Thus

$$\frac{\partial}{\partial t}\vec{D} + \nabla \cdot (\vec{D}\vec{U}_n) = \vec{U}_n. \tag{2}$$

The motion of the solvent influences the network through frictional drag, which we model by $h_f\theta_n\theta_s(\vec{U}_n - \vec{U}_s)$, where $\vec{U}_n$ and $\vec{U}_s$ are the network and solvent velocities and h_f is the constant coefficient of friction.

The third force is induced by the chemically active nature of the polymers within the gel. To model this force, we assume that there exists an osmotic pressure, $\Psi(\theta)$, gradients of which induce force on the polymers. Additional description of this term is provided below.

The final force that is included is due to hydrostatic pressure, P. Balancing all these forces yields

$$\begin{aligned}\nabla \cdot (\theta_n\sigma_n) - h_f\theta_n\theta_s(\vec{U}_n - \vec{U}_s) \\ - \nabla\Psi(\theta_n) - \theta_n\nabla P = 0.\end{aligned} \tag{3}$$

The equation governing the solvent momentum is derived in a similar manner. However, the fluid is chemically passive so there is no osmotic force on the solvent and the stress is Newtonian. Force balance yields

$$\nabla \cdot (\theta_s\sigma_s) + h_f\theta_n\theta_s(\vec{U}_n - \vec{U}_s) - \theta_s\nabla P = 0, \tag{4}$$

where $\sigma_s = \frac{\eta_s}{2}(\nabla\vec{U}_s + \nabla\vec{U}_s^T)$.

Notice that (3) and (4) are very similar to the Stokes equation for incompressible flows at zero Reynolds number. In particular, by neglecting the inertial terms, we are assuming that the system responds instantaneously to applied forces.

The redistribution of the polymer network is governed by the conservation equation

$$\frac{\partial}{\partial t}\theta_n + \nabla \cdot (\theta_n\vec{U}_n) = 0, \tag{5}$$

and a similar equation governs the conservation of solvent, namely,

$$\frac{\partial}{\partial t}\theta_s + \nabla \cdot (\theta_s \vec{U}_s) = 0. \tag{6}$$

Assuming that $\theta_n + \theta_s = 1$, we combine (5) and (6) to conclude that the divergence of the average flow, $\theta_n \vec{U}_n + \theta_s \vec{U}_s$, is zero; i.e.,

$$\nabla \cdot (\theta_n \vec{U}_n + \theta_s \vec{U}_s) = 0. \tag{7}$$

Equations (2), (3), (4), (5), and (7) govern the gel dynamics, subject to boundary conditions which depend on the specific problem. Throughout this paper, it will be useful to allow for diffusive smoothing of the network. This can be motivated physically by the fact that there is probably a small amount of polymeric diffusion within the gel. It is also useful from a mathematical perspective because it guarantees that solutions are smooth, even if there are sharp transitions. This modification yields the equation

$$\frac{\partial}{\partial t}\theta_n + \nabla \cdot (\theta_n \vec{U}_n) = \epsilon \nabla^2 \theta_n \tag{8}$$

for the redistribution of polymer network, and

$$\nabla \cdot (\theta_n \vec{U}_n + \theta_s \vec{U}_s) = \epsilon \nabla^2 \theta_n \tag{9}$$

for the incompressibility condition.

2.2. Osmotic pressure. Although there are many models of gel dynamics in the literature which include terms representing osmotic pressure [2, 3, 6, 7, 10, 11, 13], there is little agreement on either the definition or the derivation of this term. The treatment of this term varies from qualitative [3, 6] to quantitative [13]. In [7, 10, 11] a specific functional form of the osmotic pressure is not given. In fact, there has been little investigation of the dynamic behavior using different forms of the swelling pressure. Therefore our first task is to determine a model of swelling pressure which reflects some experimental results. Specifically, in many experiments a blob of gel is suspended in a solvent, causing the gel to swell. The amount of swelling is a measure of the effectiveness of the solvent. In general, the gel does not completely dissolve; instead, the blob swells a certain amount and then persists with a lower volume fraction, maintaining a distinct interface between the gel and the surrounding solvent.

We wish to determine what choice of Ψ, if any, allows for the existence of an edge between the gel and the surrounding solvent. To do so, we examine the solution of a simplified one-dimensional model of network redistribution due to swelling pressure alone. In the absence of elastic restoring force ($\sigma_e = 0$), network motion is governed by the balance of forces due to viscous stress, osmotic pressure, and hydrostatic pressure. Considering the steady-state problem implies that $\vec{U}_s = 0$ (from (5)). Using (4) to eliminate P from (3), the time independent one-dimensional equations governing network distribution are

$$\eta \frac{d}{dx}\left(\theta_n \frac{dV_n}{dx}\right) = h_f \theta_n V_n + \frac{d}{dx}\Psi(\theta_n), \tag{10}$$

$$\frac{d}{dx}(\theta_n V_n) = \epsilon \frac{d^2 \theta_n}{dx^2}, \tag{11}$$

where V_n is the x-component of $\vec{U}_n$. To be physically relevant, the solution should persist in the limit $\epsilon \to 0$.

The boundary conditions for this system are that $V_n = 0$ and there is no network flux $\epsilon \frac{d\theta_n}{dx} = \theta_n V_n$ at $x = 0$ and $x = L$, where L is the length of the one-dimensional spatial domain. This second condition allows us to integrate (11) and then substitute the result into (10), and also integrate this to find the second order system of equations

$$\eta \frac{dV_n}{dx} = \epsilon h_f + \frac{\Psi(\theta_n)}{\theta_n} + \frac{k}{\theta_n}, \tag{12}$$

$$\epsilon \frac{d\theta_n}{dx} = \theta_n V_n. \tag{13}$$

This is a singularly perturbed system. We want there to be solutions $\theta_n = 0$ and $\theta_n = \theta_{ref}$ which exist in the limit $\epsilon \to 0$ and which also can be connected by a transition layer. For $\theta_n = \theta_{ref}$ to be a solution, it must be that $k + \Psi(\theta_{ref}) = 0$, and for $\theta_n = 0$ to be a solution, it must be that

$$\lim_{\theta_n \to 0} \frac{\Psi(\theta_n)}{\theta_n} + \frac{k}{\theta_n} = 0. \tag{14}$$

It follows that

$$\Psi(\theta_n) = -k + \theta_n^2 f(\theta_n), \tag{15}$$

where $f(\theta_{ref}) = 0$. Of course, we can take $k = 0$, since only the gradient of Ψ appears in the governing equations.

Now we seek a transition layer that connects the two solutions $\theta_n = 0$ and $\theta_n = \theta_{ref}$. In this transition layer it must be that (ignoring the term ϵh_f)

$$\frac{\eta}{\epsilon} \frac{dV_n}{d\theta_n} = \frac{f(\theta_n)}{V_n}, \tag{16}$$

from which it follows that

$$\frac{\eta}{\epsilon} V_n^2 = -\int_{\theta_n}^{\theta_{ref}} f(\theta) d\theta, \tag{17}$$

implying that $f(\theta_n) < 0$ on the interval $0 \le \theta_n \le \theta_{ref}$. In the special case that $f(\theta_n) = \gamma_{os}(\theta_n - \theta_{ref})$, we find that

$$V_n = \pm \sqrt{\frac{\gamma_{os}\epsilon}{\eta}} (\theta_n - \theta_{ref}), \tag{18}$$

with transition layer trajectory satisfying

$$\frac{d\theta_n}{dx} = \pm \sqrt{\frac{\gamma_{os}}{\epsilon\eta}} \theta_n (\theta_n - \theta_{ref}), \tag{19}$$

a hyperbolic tangent solution with boundary layer width the order of $\sqrt{\epsilon}$.

It follows that, for a gel to hold an edge, Ψ must be of the form (up to an arbitrary additive constant) $\Psi(\theta_n) = \theta_n^2 f(\theta_n)$ with $f(\theta_{ref}) = 0$ and $f(\theta_n) \le 0$ for $0 < \theta_n < \theta_{ref}$. A specific example of such a function that we use throughout the rest of this paper is $\Psi(\theta_n) = \gamma_{os}\theta_n^2(\theta_n - \theta_{ref})$.

Having determined the form of the osmotic pressure that allows transition layers between $\theta_n = 0$ and $\theta_n = \theta_{ref}$, we now wish to determine the stability of steady solutions. Notice that any constant $\theta_n = \theta_0$ is a solution of (3), (4), (8), and (9) with $\vec{U}_n = \vec{U}_s = 0$ (provided $\sigma_e = 0$). To study its stability, we linearize the governing equations about this uniform solution (setting $\vec{U}_n = u$, $\vec{U}_s = v$, $\theta_n = \theta_0 + \phi$, $\theta_s = 1 - \theta_0 - \phi$.), to find

$$\frac{\partial \phi}{\partial t} + \nabla \cdot (u\theta_0) = \epsilon \nabla^2 \phi, \tag{20}$$

$$\nabla \cdot (u\theta_0 + v(1-\theta_0)) = \epsilon \nabla^2 \phi, \tag{21}$$

$$\frac{1}{2}\nabla \cdot (\theta_0 \eta(\nabla u + \nabla u^T)) - h_f \theta_0 (u - v) - \Psi'(\theta_0)\nabla\phi = 0. \tag{22}$$

To find the dispersion relation for this problem, we try a solution of the form $\phi = A(t)e^{i\omega\cdot x}$, $u = B(t)e^{i\omega\cdot x}$, $v = C(t)e^{i\omega\cdot x}$, and obtain equations for A, B, and C:

$$\frac{dA}{dt} + i\omega(B\theta_0) = -\omega^2 \epsilon A, \tag{23}$$

$$i\omega(B\theta_0 + C(1-\theta_0)) = -\omega^2 \epsilon A, \tag{24}$$

$$-\omega^2 \theta_0 \eta B - h_f \theta_0 (B - C) - \Psi'(\theta_0) i\omega A = 0. \tag{25}$$

We solve for B and C and substitute into (23) to find

$$C = \frac{i\omega\epsilon A - B\theta_0}{1-\theta_0}, \tag{26}$$

$$B = \frac{\epsilon h_f \theta_0 - (1-\theta_0)\Psi'(\theta_0)}{\omega^2 \theta_0 \eta (1-\theta_0) + h_f \theta_0} i\omega A, \tag{27}$$

$$\frac{dA}{dt} = \omega^2 \frac{\epsilon h_f \theta_0 - (1-\theta_0)\Psi'(\theta_0)}{\omega^2 \eta (1-\theta_0) + h_f} A - \omega^2 \epsilon A. \tag{28}$$

In the limit $\epsilon \to 0$ this is

$$\frac{dA}{dt} = -\omega^2 \frac{(1-\theta_0)\Psi'(\theta_0)}{\omega^2 \eta (1-\theta_0) + h_f} A. \tag{29}$$

Clearly, this is stable if $\psi'(\theta_0) > 0$ and unstable if $\psi'(\theta_0) < 0$.

Thus, for the function $\Psi(\theta_n) = \gamma_{os}\theta_n^2(\theta_n - \theta_{ref})$, a uniform gel with $\theta_n < \gamma_{os}\frac{2}{3}\theta_{ref}$ is unstable, while a uniform gel with $\theta_n > \gamma_{os}\frac{2}{3}\theta_{ref}$ is stable. Thus, very low density gels are not stable and will tend to form deswelled spatially localized aggregates.

3. Channeling behavior. We now turn to a simple problem illustrating one difference between gel dynamics and Newtonian fluid dynamics. We consider the deformation of the network component of a gel which is forced to move between two flat plates due to a constant imposed pressure drop. We make one further assumption that the viscosity of the system is dominated by the network viscosity ($\theta_n \eta \gg \theta_s \eta_s$), and thus, following [13], we neglect the solvent viscosity. Notice that although the solvent is inviscid, the frictional interaction between the solvent and the network still renders the entire system viscous.

The motion is assumed to be two-dimensional, where x, y and $\vec{U}_* = (V_*, W_*)$ denote the horizontal and vertical coordinates and velocities, respectively. For Newtonian fluids the steady-state x independent velocity profile is parabolic in y for all pressure drops. This is not the case for the gel-Poiseulle flow. Instead, the steady-state profile of the network volume fraction undergoes a large change as the magnitude of the pressure gradient varies.

To demonstrate this, we seek a solution of (3)–(7) that is the analogue of Poiseulle flow—the horizontally independent steady velocity profile for a fluid forced between two flat plates by a pressure drop.

Under the assumption that D_1 and D_2 are independent of x, the elements of the deformation gradient tensor $\mathbf{F}_{ij}$ are

$$\begin{aligned} \frac{\partial x'}{\partial x} &= 1, \\ \frac{\partial x'}{\partial y} &= \frac{\partial D_1}{\partial y}, \\ \frac{\partial y'}{\partial x} &= 0, \\ \frac{\partial y'}{\partial y} &= 1 + \frac{\partial D_2}{\partial y}, \end{aligned}$$

and the stress tensor becomes

$$\sigma_e = \gamma \begin{bmatrix} 0 & \frac{\partial D_1}{\partial y} \\ \frac{\partial D_1}{\partial y} & \left(\frac{\partial D_1}{\partial y}\right)^2 + 2\frac{\partial D_2}{\partial y} + \left(\frac{\partial D_2}{\partial y}\right)^2 \end{bmatrix}.$$

We change from vector to component notation here, so that the following simplifications are more apparent. In component form the steady-state equations for the gel-Poiseulle flow are

$$\eta \frac{\partial}{\partial y}\left(\theta_n \frac{\partial}{\partial y} V_n\right) - \frac{\partial P}{\partial x} + \gamma \frac{\partial}{\partial y}\left(\theta_n \frac{\partial}{\partial y} D_1\right) = 0, \tag{30}$$

$$\begin{aligned} \eta \frac{\partial}{\partial y}\left(\theta_n \frac{\partial}{\partial y} W_n\right) - \frac{\partial}{\partial y}\Psi(\theta_n) - \frac{\partial P}{\partial y} \\ + \gamma \frac{\partial}{\partial y}\left(\theta_n \left(\left(\frac{\partial D_1}{\partial y}\right)^2 + 2\frac{\partial D_2}{\partial y} + \left(\frac{\partial D_2}{\partial y}\right)^2\right)\right) = 0, \end{aligned} \tag{31}$$

$$h_f \theta_n (V_n - V_s) - \frac{\partial P}{\partial x} = 0, \tag{32}$$

$$h_f \theta_n (W_n - W_s) - \frac{\partial P}{\partial y} = 0, \tag{33}$$

$$\frac{\partial}{\partial y}(\theta_n W_n + (1 - \theta_n) W_s) = \epsilon \frac{\partial^2 \theta_n}{\partial y^2}, \tag{34}$$

$$\frac{\partial}{\partial y}(\theta_n W_n) = \epsilon \frac{\partial^2 \theta_n}{\partial y^2}, \tag{35}$$

$$\frac{\partial}{\partial y}(D_1 W_n) = V_n, \tag{36}$$

$$\frac{\partial}{\partial y}(D_2 W_n) = W_n. \tag{37}$$

Here we allow for network diffusion, with diffusion coefficient ϵ, but our goal is to solve the system in the limit $\epsilon \to 0$.

The distance between the two plates is taken to be L; hence the domain of the problem consists of an infinite strip $(-\infty < x < \infty) \times (0 < y < L)$. The boundary conditions are $D_1 = D_2 = 0$ and $\epsilon \frac{\partial \theta_n}{\partial y} = \theta_n W_n$ at $y = 0, L$, implying that there is neither network displacement nor network flux at the boundary.

We can simplify these equations substantially. Integrating (35) and solving for the vertical velocity of the network, we find

$$W_n = \epsilon \frac{\frac{\partial \theta_n}{\partial y} + c_1}{\theta_n}, \tag{38}$$

which, combined with (34), yields

$$(1 - \theta_n) W_s = c_2. \tag{39}$$

These can be used in (33) to solve for the $\frac{\partial P}{\partial y}$ as

$$\frac{\partial P}{\partial y} = h_f \theta_n \left(W_n - \frac{c_2}{1 - \theta_n} \right). \tag{40}$$

The boundary conditions imply that $c_1 = c_2 = 0$; hence $W_s = 0$ and $\frac{\partial P}{\partial y} = h_f \epsilon \frac{\partial \theta_n}{\partial y}$. Because $V_n = 0$ at steady state, and because the equations are independent of x, $\frac{\partial P}{\partial x}$ is independent of x. That is, (32) implies that $P = Gx + \hat{P}(y)$.

Integrating (30) and solving for $\frac{\partial D_1}{\partial y}$ yields

$$\frac{\partial D_1}{\partial y} = \frac{Gy + a}{\gamma \theta_n}. \tag{41}$$

We specify a by assuming that the steady-state profiles are symmetric about the center line, $y = \frac{1}{2}$. We also relate the vertical displacements to the network volume fraction using the Jacobian of the transformation

$$\hat{\theta}_n = \theta_n \left(1 + \frac{\partial D_2}{\partial y} \right),$$

where $\hat{\theta}_n$ is the original homogeneous unstressed distribution of the network.

Finally, (31) reduces to an ordinary differential equation (ODE) relating the volume fraction of the network to y and parameters G, γ, h_f, etc.:

$$\begin{aligned} &\epsilon \eta \frac{d}{dy} \left(\theta_n \frac{d}{dy} \left(\frac{\frac{d\theta_n}{dy}}{\theta_n} \right) \right) - \epsilon h_f \frac{d\theta_n}{dy} \\ &- \frac{d\Psi}{dy} + \gamma \frac{d}{dy} \left(\theta_n \left(\left(\frac{Gy - GL/2}{\gamma \theta_n} \right)^2 + \left(\frac{\hat{\theta}_n}{\theta_n} \right)^2 - 1 \right) \right) = 0. \end{aligned} \tag{42}$$

We nondimensionalize (42) by defining the nondimensional variable $y^* = \frac{y}{L}$ and the nondimensional parameters $\epsilon^* = \frac{\eta}{L^2\gamma}\epsilon$ and $h_f^* = \frac{L^2 h_f}{\eta}$, $G^* = \frac{L}{\gamma}G$; substituting these into (42); and dropping the $*$-notation. Integrating once yields

(43)
$$\epsilon\left(\theta_n \frac{d}{dy}\left(\frac{\frac{d\theta_n}{dy}}{\theta_n}\right)\right) - \epsilon h_f \theta_n - \frac{1}{\gamma}\Psi(\theta_n) + \left(\theta_n\left(G^2\left(\frac{y-1/2}{\theta_n}\right)^2 + \left(\frac{\hat{\theta}_n}{\theta_n}\right)^2 - 1\right)\right) = k,$$

which must be solved subject to the constraint that mass is conserved,

$$\int_0^1 \theta_n \, dy = \hat{\theta}_n. \tag{44}$$

Although simpler than the original system, there remains quite a lot of interesting structure in (43). In particular, (43) is a second order ODE which is singular in the limit $\epsilon \to 0$. In the following section, we describe the singular perturbation analysis of this problem, revealing the existence of channels, i.e., solutions with sharp interior transition layers.

3.1. The channeling bifurcation. In this section we analyze the bifurcation structure of channels by examining the solutions of (43) in the singular limit $\epsilon \to 0$. We assume that the initially uniform gel at $\hat{\theta}_n$ is stable so that $\Psi'(\hat{\theta}_n) > 0$.

The reduced equation ($\epsilon = 0$) is an algebraic equation relating the network volume fraction to the location between the plates. The steady state network profile is given by the solution of the algebraic equation

$$H(y, \theta_n) = G^2\left(y - \frac{1}{2}\right)^2 + h(\theta_n) = 0, \tag{45}$$

where

$$h(\theta_n) = -\theta_n\Psi(\theta_n) + \theta_n\Psi(\hat{\theta}_n) + \hat{\theta}_n^2 - \theta_n^2 - k\theta_n, \tag{46}$$

and

$$\Psi(\theta_n) = \kappa\theta_n^2(\theta_n - \theta_{ref}), \tag{47}$$

where $\kappa = \frac{\gamma_{os}}{\gamma}$ represents the strength of osmosis compared to the elastic modulus. Here k has been redefined so that $H(\hat{\theta}_n) = 0$ when $k = 0$. The solution profile $\theta_n(y)$ must also satisfy the integral constraint 44.

By virtue of the form of Ψ, the gel is capable of supporting an edge. In many hydrogels, the polymer network is of very low density and is highly charged [5]. This suggests that the strength of the osmotic pressure is large compared to the magnitude of the elastic modulus, so that κ is large.

This problem can be viewed as a nonlinear eigenvalue problem: "For each value of G determine the value(s) of k for which the solution of (45) satisfies the integral constraint (44)." However, it turns out that it is easier to view the problem as follows: "For each value of k find the value(s) of G for which the solution of (45) satisfies the integral constraint (44)." We explain below why this is the case.

First we make some observations about the function $h(\theta)$. Because $h(0) = \hat{\theta}_n^2 > 0$, and $h(\theta) < 0$ for large θ, $h(\theta)$ always has at least one positive and one negative root.

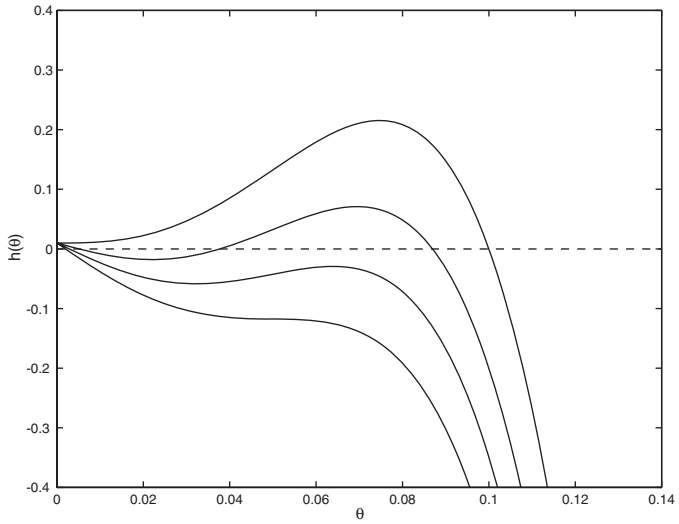

FIG. 1. *Plot of $h(\theta)$ as a function of θ for $k = 0, 2, 3.5, 5$. Other parameter values are $\kappa = 20{,}000$ and $\theta_{ref} = \hat{\theta}_n = 0.1$.*

Since $h(\theta)$ is a quartic polynomial in θ, there can be as many as three positive roots of $H(y, \theta_n) = 0$, depending on the value of k. To see this, in Figure 1 are shown four different plots of $h(\theta)$ for four values of $k = 0, 2, 3.5, 5$ (top to bottom). If $3\kappa\theta_{ref}^2 > 8$, the function $h(\theta)$ has two positive inflection points. Thus, if κ is sufficiently small, the function $h(\theta)$ is monotone for positive θ, whereas, if κ is sufficiently large, it is possible that $h(\theta)$ is nonmonotone.

We seek solutions of (45) that are of the form $\theta_n = \Theta_n(y)$. However, because $h(\theta)$ need not be monotone, such solutions do not always exist. However, it is always possible to write the solution implicitly for y as function of θ_n,

$$y = \frac{1}{2} \pm \frac{1}{G}\sqrt{-h(\theta_n)}. \tag{48}$$

Thus, one can visualize solutions by turning the plots in Figure 1 "on their side." If the resulting solution is single-valued, there is little more to do. If the resulting solution is multivalued, then one must determine which pieces of the multivalued function should be used to construct a single-valued function.

To construct admissible single-valued solutions from multivalued ones, we look for interior transition layers that connect different branches of the multivalued solution. Suppose that at $y = y_0$, $H(y_0, \theta_n) = 0$ has three positive roots, $\theta_- \le \theta_0 \le \theta_+$. We introduce an inner scaling of (43) defining $Y = \frac{y - y_0}{\epsilon^{1/2}}$. Substituting this into (43) and retaining the leading order terms in ϵ, we obtain

$$\frac{d}{dY}\left(\frac{\frac{d\theta_n}{dY}}{\theta_n}\right) + \frac{H(y_0, \theta_n)}{\theta_n^2} = 0. \tag{49}$$

With the change of variable $w = \ln(\theta_n)$, we can rewrite this as

$$\frac{d^2 w}{dY^2} + F(w, y_0) = 0, \tag{50}$$

where $F(w, y_0) = H(y_0, e^w)e^{-2w}$. Clearly, the function $F(w, y_0)$ has three roots, $w_\pm = \ln(\theta_\pm), w_0 = \ln(\theta_0)$. It is well known [4] that there is a solution to the inner-layer (50) that provides a transition between w_- and w_+ if

$$\int_{w_-}^{w_+} F(w, y_0)dw = 0. \tag{51}$$

Inverting the transformation yields an equivalent requirement in the variable θ_n. An interior layer providing a transition between θ_- and θ_+ can be fit at $y = y_0$ if

$$\int_{\theta_-}^{\theta_+} \frac{H(y_0, \theta_n)}{\theta_n^3} d\theta_n = 0. \tag{52}$$

There is another interior layer solution that can be used to construct solutions. If $y_0 = \frac{1}{2}$ and there are three positive roots of $H(\frac{1}{2}, \theta) = 0$, and if

$$\int_{\theta_-}^{\theta_+} \frac{H(\frac{1}{2}, \theta)}{\theta^3} d\theta < 0, \tag{53}$$

then there is a homoclinic orbit of (49) that approaches θ_+ asymptotically as $Y \to \pm\infty$ and has as its minimal value $\theta = \theta^*$, where $\theta_- < \theta^* < \theta_0$ and

$$\int_{\theta^*}^{\theta_+} \frac{H(\frac{1}{2}, \theta)}{\theta^3} d\theta = 0. \tag{54}$$

The first integral for this trajectory is

$$\frac{1}{2}\left(\frac{d\theta_n}{dY}\right)^2 - \theta_n^2 \int_{\theta_n}^{\theta_+} \frac{H(\frac{1}{2}, \theta)}{\theta^3} d\theta = 0. \tag{55}$$

Now we use this information to construct all the possible single-valued solutions. To do this we pick a value of k, determine the possible single-valued solutions, and then find the appropriate value of G (and y_0 if any) for this solution. There are three different types of solutions.

If $h(\theta) = 0$ has only one positive root and if and $h(\theta)$ is monotone decreasing for θ larger than this root, then the solution of $H(y, \theta_n) = 0$ is unique, for any value of G, as seen in Figure 1 for the curves with $k = 2$ and for $k = 5$. In Figure 2 the solution profiles $\theta_n(y)$ for $k = 5$ are shown for three different values of G.

Since G acts as a y-axis scale factor for these profiles, it is apparent that $\int_0^1 \theta_n(y)dy$ is a monotone decreasing function of G. Thus, there is a unique value of G for which $\int_0^1 \theta_n(y)dy = \hat{\theta}_n$. For the profiles shown in Figure 2, this unique value of G is 4.022.

Similarly, for small values of k, unique solutions can be obtained. For example, Figure 3 shows the solution profile for $k = 2$. Again, since the y-axis for this profile is scaled by G, the unique value of G for which $\int_0^1 \theta_n(y)dy = \hat{\theta}_n$ is easily determined. For the profile in Figure 3, this value is $G = 1.74$.

If the function $h(\theta_n)$ is not monotone decreasing, then there is the possibility of nonunique solutions of $H(y, \theta_n) = 0$. If a (positive) level x can be found so that

$$\int_{\theta_-}^{\theta_+} \frac{x + h(\theta_n)}{\theta_n^3} d\theta_n = 0, \tag{56}$$

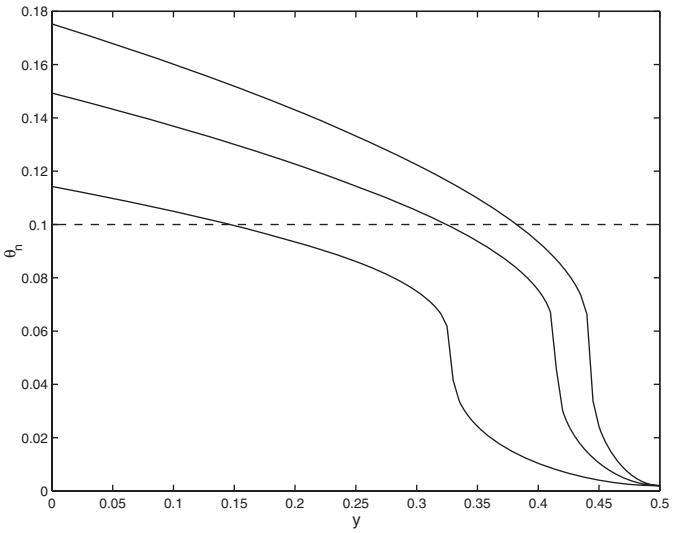

FIG. 2. *Plot of* $\theta_n(y)$ *for* $k = 5$ *and* $G = 2, 4.022, 6$. *Other parameter values are* $\kappa = 20{,}000$ *and* $\theta_{ref} = \hat{\theta}_n = 0.1$.

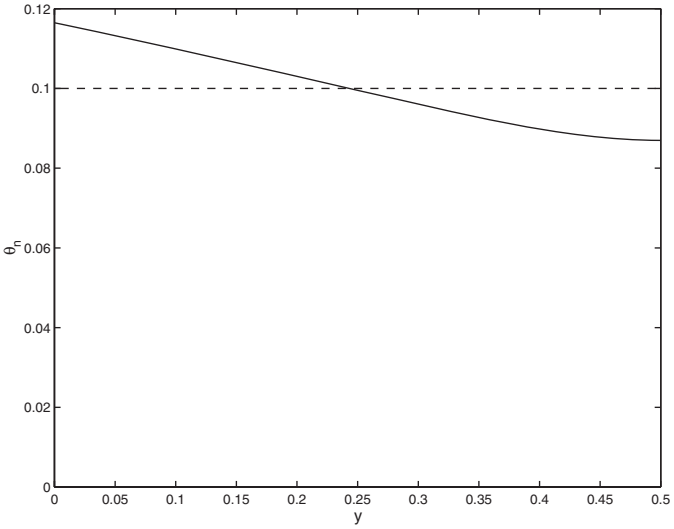

FIG. 3. *Plot of* $\theta_n(y)$ *for* $k = 2$ *and* $G = 1.74$. *Other parameter values are* $\kappa = 20{,}000$ *and* $\theta_{ref} = \hat{\theta}_n = 0.1$.

then a boundary layer can be inserted into the profile at $y_0 = \frac{1}{2} \pm \frac{\sqrt{x}}{G}$, and this boundary layer can be used to connect the largest solution of $H(y_0, \theta_n) = 0$ with the smallest. A plot of a profile that results is shown in Figure 4.

Notice that for this value of k (=2), there are three possible solution profiles, one with no interior layer (shown in Figure 3), one with a boundary layer (shown in Figure 4), and one with a symmetric boundary layer located at $y_0 = \frac{1}{2}$. In the limit that $\epsilon \to 0$, the third of these looks identical to the profile shown in Figure 3, with the exception that θ_n is discontinuous at $y = \frac{1}{2}$, with $\theta_n(\frac{1}{2}) = \theta^*$ defined in (54). The

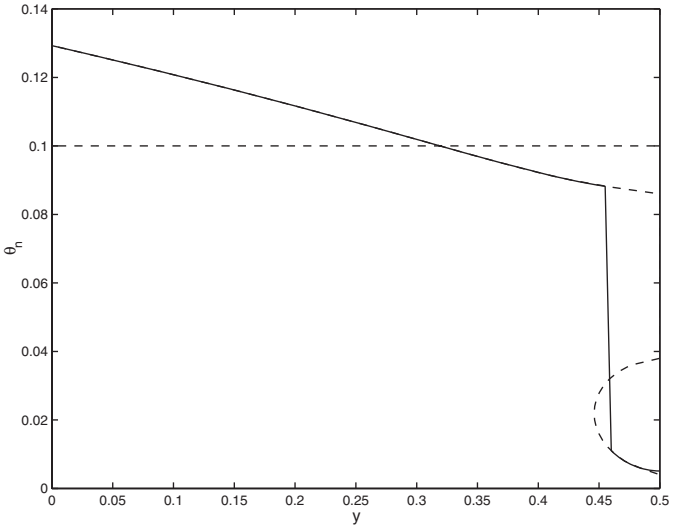

FIG. 4. *Plot of $\theta_n(y)$ for $k = 2$ and $G = 2.47$ with a boundary layer inserted at $y_0 = 0.46$. The dashed curves show all possible solutions of $H(y, \theta_n) = 0$. Other parameter values are $\kappa = 20{,}000$ and $\theta_{ref} = \hat{\theta}_n = 0.1$.*

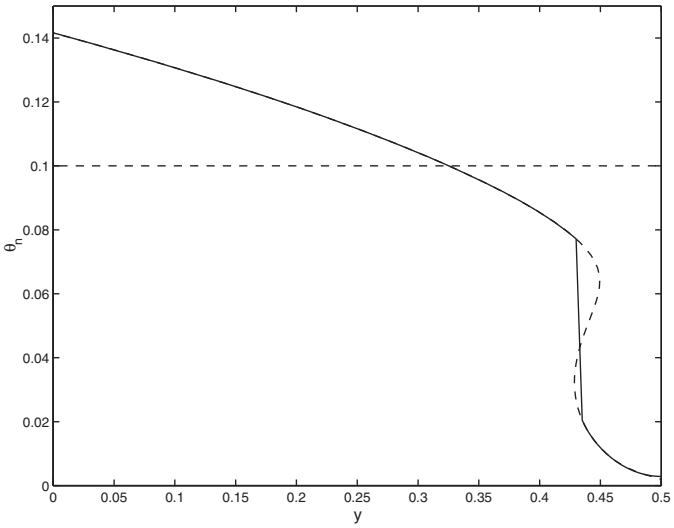

FIG. 5. *Plot of $\theta_n(y)$ for $k = 3.5$ and $G = 3.39$ with a boundary layer inserted at $y_0 = 0.43$. The dashed curves show all possible solutions of $H(y, \theta_n) = 0$. Other parameter values are $\kappa = 20{,}000$ and $\theta_{ref} = \hat{\theta}_n = 0.1$.*

value of G for the first and third solution profiles is the same, but it differs from the value of G for the second transition-layer profile. For some values of k, the boundary layer profile is the only possible solution. A profile of this type occurs for $k = 3.5$ and is shown in Figure 5.

In this way, for each value of k we determine all possible solutions and their corresponding values of G. A plot of the relationship between k and G is shown in Figure 6. Here we see two curves. The lower curve that extends from $k = 0$ to

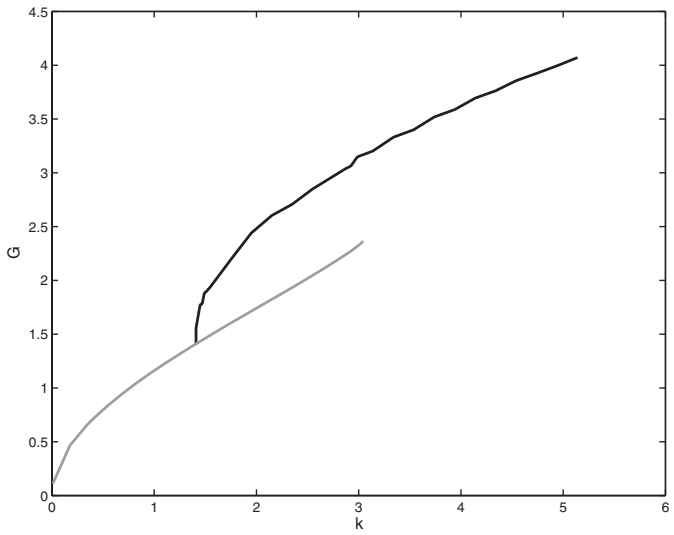

FIG. 6. *Plot of G versus k for the solutions of the gel-flow problem. For this plot, $\kappa = 20{,}000$ and $\theta_{ref} = \hat{\theta}_n = 0.1$.*

$k = 2.9$ corresponds to solutions like those shown in Figure 3 , with no boundary layer. The upper curve that extends from the lower curve at about $k = 1.4$ (with $y_0 = \frac{1}{2}$) corresponds to channeled solutions, with a boundary layer as shown in Figures 4 and 5 for $k < 5$. These solutions merge smoothly into non–boundary layer solutions, such as those shown in Figure 2, as k increases.

The nature of the bifurcation structure of these solutions is not apparent from Figure 6. This is because, for values of k larger than the merger point, the lower branch corresponds to two different solutions. The easier way to visualize this difference is seen in Figure 7, where $\theta_n(\frac{1}{2})$ is plotted as a function of G. Here, the upper solution branch corresponds to those solutions with no boundary layers, the lower solution branch corresponds to those with interior transition layers, and the middle branch (shown dashed) gives the solutions with a symmetric boundary layer at $y = \frac{1}{2}$. In the limit $\epsilon \to 0$, this boundary layer has no thickness and so has no influence on the integral of θ_n. Here we see that the solution is an S-shaped curve, and the bifurcations are via limit points.

The physically significant feature of these curves is that for some values of G there are two physically realizable solutions, a boundary layer, or channeled, solution and a nonchanneled solution. The solution with a boundary layer at $y = \frac{1}{2}$ is transitional between the two and is interesting for mathematical reasons but is unstable and hence not physically realized. Thus, the solution of the gel-flow problem is not unique and exhibits hysteretic behavior, with a hysteresis loop between channeled and nonchanneled solutions, governed by the pressure gradient G.

The behavior of the fluid flow through these two different solution types is understandably different, as the channeled solution permits a higher flux for the same cost. This is illustrated by Figure 8, where the flux of solvent,

$$J = \int_0^1 V_s dy = \frac{1}{h_f} \int_0^1 \frac{1 - \theta_n}{\theta_n} dy, \tag{57}$$

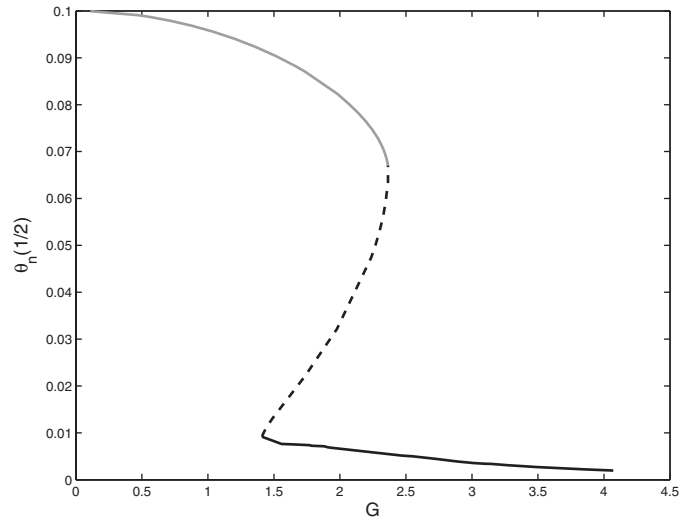

FIG. 7. *Plot of* $\theta_n(\frac{1}{2})$ *versus* G *for the solutions of the gel-flow problem. For this plot,* $\kappa = 20{,}000$ *and* $\theta_{ref} = \hat{\theta}_n = 0.1$.

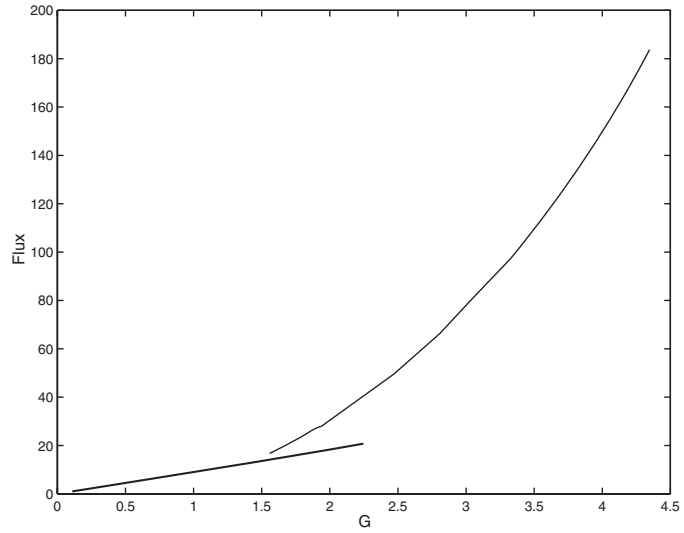

FIG. 8. *Plot of solvent flux as a function of* G. *For this plot,* $\kappa = 20{,}000$ *and* $\theta_{ref} = \hat{\theta}_n = 0.1$.

is plotted as a function of G for the two different solution types. Not surprisingly, if two solutions are possible for the same value of G, the boundary layer solution permits a larger solvent flux than the non–boundary layer solution.

4. Discussion. From this analysis we can deduce the physical mechanism that underlies the formation of channels in a gel. If the osmotic force is sufficiently strong compared to the elastic restoring force, then under a sufficiently high pressure gradient, it is energetically favorable to compress the gel near the wall and swell the gel in the interior, thereby forming a low-resistance channel.

This same conclusion is correct for all gels for which there are two stable gel

concentrations. That is, if $\Psi(\theta_n)$ is such that $\Psi'(\theta_n) < 0$ for $0 \leq \theta_* < \theta_n < \theta^* < 1$ and is positive elsewhere, then if the uniform gel distribution has $\hat{\theta}_n > \theta^*$ and if the osmotic force is sufficiently strong compared to the elastic force, channels will form under sufficiently high pressure gradient flows. This follows from the analysis of the previous section, which relied entirely upon the generic "cubic" shape of the function $\Psi(\theta_n)$ and not on its details. Any function $\Psi(\theta_n)$ with similar structure will lead to the same bifurcation channeling behavior.

FORCE DENSITY FUNCTION RELATIONSHIPS IN 2-D GRANULAR MEDIA*

ROBERT C. YOUNGQUIST†, PHILIP T. METZGER†, AND KELLY N. KILTS†

Abstract. An integral transform relationship is developed to convert between two important probability density functions (distributions) used in the study of contact forces in granular physics. Developing this transform has now made it possible to compare and relate various theoretical approaches with one another and with the experimental data, despite the fact that one may predict the Cartesian probability density and another the force magnitude probability density. Also, the transforms identify which functional forms are relevant to describing the probability density observed in nature, and so the modified Bessel function of the second kind has been identified as the relevant form for the Cartesian probability density corresponding to exponential forms in the force magnitude distribution. Furthermore, it is shown that this transform pair supplies a mathematical framework sufficient for describing the evolution of the force magnitude distribution under shearing. Apart from the choice of several coefficients, whose evolution of values must be explained in the physics, this framework successfully reproduces the features of the distribution that are taken to be an indicator of jamming and unjamming in a granular packing.

1. Introduction.

A central topic within modern granular physics research is the study of intergranular force probability densities [1, 2, 3, 4, 5, 6]. The goal being to develop theory—from simplest assumptions—predicting the force density functions seen in simulations and experimental measurements. However, this goal is complicated by the differing forms for the force density functions presented in the literature, two of which are often treated as fundamental.

The first of these force density functions is dependent upon the magnitude and angle of the contact forces between grains. It predicts force chains, the onset of granular jamming [7], strain hardening [1], and fracture of the individual grains. It has several odd and unexplained features, such as a finite, but nonzero, probability at zero force, followed by a probability increasing to a peak near the average value of the force. It has attracted scientific attention because its exponential tail at high forces and power law at weak forces are reminiscent of the Maxwell–Boltzman distribution of velocities from statistical mechanics. However, its overall form is unlike any of the known statistical mechanics distributions, and there have been numerous attempts to derive it [8, 9, 10, 11, 12, 13].

The second type of distribution that has been treated as fundamental in the physics literature is a force density function dependent upon the Cartesian components of the contact force vectors. This type of distribution is appealing because it relates to

the following conservation law: If external forces are ignored and if the arrangement of grains is static, then the total Cartesian force perpendicular to a plane cutting through the medium is conserved for any translation of the plane. Consequently, granular thermodynamic theories have been developed based on this conservation of the total Cartesian forces [14, 15].

The problem addressed by this paper is to clearly define these two types of force density functions and then to establish relationships between them. At first glance this seems straightforward, and it would be if in the literature these densities were handled as functions of two dimensions for two-dimensional media and three dimensions for three-dimensional media, but this is usually not the case. Probability force distributions are typically expressed using one of the following variables: the force magnitude, the force angle, or a selected Cartesian component. Because of this contraction to a single variable, pertinent information is not available, and converting between the two types of densities is not possible. Yet this conversion is important. Analytical theories usually favor one distribution or the other, and empirical investigations typically collect only one type of distribution. Without a well established conversion it is not possible to compare the competing theories and their data against one another.

The paper is organized as follows. Random variables are chosen such that the two two-dimensional probability force densities can be defined and the probability theory relations between them shown. In particular, an integral relation is developed whereby the two-dimensional polar force probability density can be converted to a Cartesian force density. From probability theory alone this relationship cannot be inverted, but the integral relation can be recast as a set of Fourier transforms. Doing this allows an inverse relation to be found such that if the one-dimensional Cartesian force density function is known for all rotations of the axes, then the two-dimensional polar force probability function can be found. This inversion allows, for the isotropic case, the two force distributions to be treated as a transform pair. The properties of this transform relationship are discussed and significant solutions provided. An example is provided along with data generated from a Monte Carlo process. Then, an example of a pair of force density functions for the anisotropic case is given and compared with published results.

2. Two-dimensional force probability density functions. Suppose that a large number of grains are placed randomly into a two-dimensional container and that the edges of the container push the grains against each other. These grains are not idealized and may be compressible, have arbitrary shape, be attracted or repulsed by each other, or have frictional contacts. The only restrictions on the grains are that they be static and that at each grain-to-grain contact a force vector be identifiable. Thus, the development presented here is applicable to a wide range of granular media and could be extended to other discrete, static media such as intertwined fibers, foams, glass, and emulsions. Also, the contact forces between the grains and walls may be included in the density functions provided below, as long as identifiable force vectors exist and both force vectors, the grain on the wall and the wall on the grain, are counted in the statistics.

At each grain-to-grain or grain-to-wall contact there are two force vectors, of equal magnitude and opposite direction, according to Newton's third law, as shown in Figure 2.1. Assign the random variable F, where $0 \leq F < \infty$, to the magnitude of these force vectors and the angle θ, where $0 \leq \theta < 2\pi$, to the angle between them and the x-axis. A two-dimensional "polar" force probability density can then be defined in terms of the random variables, F and θ, and expressed as $P_{F,\theta}(F, \theta)$, describing

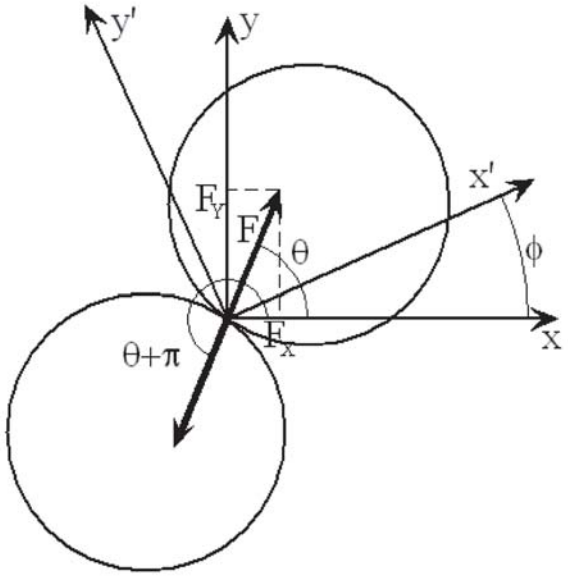

FIG. 2.1. *A sketch showing intergrain forces and the associated random variables.*

the probability of finding a granular contact force with magnitude F and angle θ. An immediate attribute of this function is that

$$P_{F,\theta}(F,\theta) = P_{F,\theta}(F,\theta+\pi), \tag{2.1}$$

a result of there being equal and opposite forces at each granular contact. (It is implied in the definition of $P_{F,\theta}(F,\theta)$ that the angle θ is modulo 2π.)

A one-dimensional force magnitude probability density function, $P_F(F)$, can be defined by integrating over all values of θ, as shown in (2.2) below. This equation also shows that the symmetry relation given by (2.1) allows the θ integration to occur over any contiguous arc of length π radians:

$$P_F(F) \equiv \int_0^{2\pi} P_{F,\theta}(F,\theta)d\theta = 2\int_0^{\pi} P_{F,\theta}(F,\theta)d\theta = 2\int_{\phi-\pi/2}^{\phi+\pi/2} P_{F,\theta}(F,\theta)\,\mathrm{d}\theta. \tag{2.2}$$

By integrating over all values of the force magnitude variable, a one-dimensional force angle probability density function, $P_\theta(\theta)$, is defined by

$$P_\theta(\theta) \equiv \int_0^{\infty} P_{F,\theta}(F,\theta)\,\mathrm{d}F. \tag{2.3}$$

From (2.1) and (2.3) the equal and opposite force result, i.e., $P_\theta(\theta) = P_\theta(\theta+\pi)$, can be shown. For frictionless grains (often studied in the physics literature) the direction of the force vector is normal to the contacting surfaces of the grains. In that special case the density function of (2.3) is identical to the distribution of contact angles, referred to in the literature as the fabric of the granular material [16].

Not unexpectedly, there exists an alternative pair of random variables, $F_x = F\cos(\theta)$ and $F_y = F\sin(\theta)$, that can be used to describe a Cartesian force probability density function, $P_{F_x,F_y}(F_x,F_y)$, which describes the probability of finding a granular

contact force with Cartesian components F_x and F_y, where $0 \leq F_x,\ F_y < \infty$. The polar and Cartesian force probability densities are related through their corresponding Jacobians, yielding

$$P_{F,\theta}(F,\theta) = P_{F_x,F_y}(F\cos(\theta), F\sin(\theta))F \tag{2.4}$$

and

$$P_{F_x,F_y}(F_x,F_y) = \frac{P_{F,\theta}((F_x^2+F_y^2)^{1/2}, \arctan(F_y/F_x))}{(F_x^2+F_y^2)^{1/2}}. \tag{2.5}$$

In (2.5), care should be taken to ensure that the arctangent returns an angle in the proper quadrant. Using (2.1) and (2.4), a Cartesian force density analogue for the existence of equal and opposite forces is found,

$$P_{F_x,F_y}(F_x,F_y) = P_{F_x,F_y}(-F_x,-F_y). \tag{2.6}$$

Also, by integrating over either of the two Cartesian random variables, a one-dimensional Cartesian force density can be defined. Without loss of generality, integrating over F_y yields $P_{F_x}(F_x)$, which, as shown in (2.7) below, can also be found by integrating the polar two-dimensional density function expression from (2.5),

$$\begin{aligned} P_{F_x}(F_x) &= \int_{-\infty}^{\infty} P_{F_x,F_y}(F_x,F_y)\,\mathrm{d}F_y \\ &= \int_{-\infty}^{\infty} \frac{P_{F,\theta}((F_x^2+F_y^2)^{1/2}, \arctan(F_y/F_x))}{(F_x^2+F_y^2)^{1/2}}\,\mathrm{d}F_y. \end{aligned} \tag{2.7}$$

Changing variables from F_y to θ via $\tan\theta = F_y/F_x$ yields the following integral relationship between the polar force density function and the one-dimensional Cartesian force density:

$$\begin{aligned} P_{F_x}(F_x) &= \left(\int_0^{\pi/2} + \int_{3\pi/2}^{2\pi}\right) P_{F,\theta}(F_x\sec\theta,\theta)\sec\theta\,\mathrm{d}\theta \qquad \text{if } F_x \geq 0, \\ P_{F_x}(F_x) &= \int_{\pi/2}^{3\pi/2} P_{F,\theta}(F_x\sec\theta,\theta)\sec\theta\,\mathrm{d}\theta \qquad \text{if } F_x \leq 0. \end{aligned} \tag{2.8}$$

Equations (2.6) and (2.7) imply that only one of the integrals in (2.8) needs to be calculated.

A more general form for the Cartesian density function can be defined that will prove useful in the analysis that follows. Figure 2.1 shows a coordinate system rotated by angle ϕ, yielding new random variables $F_{x'}$ and $F_{y'}$. Recalling that rotation does not stretch space, the Jacobian of the transformation between the random variables $F_{x'}, F_{y'}$ and F_x, F_y is unity, so their respective probability density functions are equal; i.e., $P_{F_{x'},F_{y'}}(F_{x'},F_{y'}) = P_{F_x,F_y}(F_x(F_{x'},F_{y'}), F_y(F_{x'},F_{y'}))$. Using this result, a one-dimensional Cartesian force density along the x'-axis, $P_{F_{x'}}(F_{x'})$, can be defined as

$$\begin{aligned} P_{F_{x'}}(F_{x'}) &= \int_{-\infty}^{\infty} P_{F_{x'},F_{y'}}(F_{x'},F_{y'})\,\mathrm{d}F_{y'} \\ &= \int_{-\infty}^{\infty} \frac{P_{F,\theta}((F_{x'}^2+F_{y'}^2)^{1/2}, \arctan(F_{y'}/F_{x'})+\phi)}{(F_{x'}^2+F_{y'}^2)^{1/2}}\,\mathrm{d}F_{y'}, \end{aligned} \tag{2.9}$$

similar to the result in (2.7). Now, changing variables from $F_{y'}$ to θ via $\arctan(F_{y'}/F_{x'})+\phi=\theta$ yields a result similar to that shown in (2.8) except that the additional ϕ angle appears in the integrand and in the limits of integration. The variable transformation yields

$$P_{F_{x'}}(F_{x'}) = \left(\int_{\phi}^{\phi+\pi/2} + \int_{\phi+3\pi/2}^{\phi+2\pi}\right) P_{F,\theta}(F_{x'}\sec(\theta-\phi),\theta)\sec(\theta-\phi)\,\mathrm{d}\theta \quad (\text{if } F_{x'}\geq 0)$$

$$= \int_{\phi+\pi/2}^{\phi+3\pi/2} P_{F,\theta}(F_{x'}\sec(\theta-\phi),\theta)\sec(\theta-\phi)\,\mathrm{d}\theta \qquad (\text{if } F_{x'}\leq 0). \tag{2.10}$$

Even though the density function $P_{F_{x'}}(F_{x'})$ is well defined by the above equations, it suffers from two shortcomings. First, it is an explicit function of the angle ϕ, and this should be reflected in the notation chosen. Second, if the angle ϕ is allowed to range from zero to 2π radians, there is an ambiguity in the choice of how to represent the domain of this function. Specifically, choosing a rotation angle ϕ and a random variable $F_{x'}$ is identical to rotating by $\phi+\pi$ radians and choosing a value for the random variable of $-F_{x'}$. We choose to resolve the second issue by allowing the angle ϕ to range from zero to 2π radians and defining a new random variable F_ϕ, which is equal to $F_{x'}$ but is always positive, i.e., $0\leq F_\phi<\infty$. The first issue above can then be resolved by adopting the notation $P_{F_\phi}(F_\phi,\phi)$ for the density function associated with this new random variable. The single variable subscript indicates that this is a one-dimensional density function, but the two-dimensional domain shows that it is an explicit function of the two variables F_ϕ and ϕ. Thus the function $P_{F_\phi}(F_\phi,\phi)$ has the same "polar" domain as the density function $P_{F,\theta}(F,\theta)$. It can be explicitly expressed using the first integral expression above—where $F_{x'}>0$—and merging the integrals by using the 2π periodic nature of the variable θ:

$$P_{F_\phi}(F_\phi,\phi) = 2\int_{\phi-\pi/2}^{\phi+\pi/2} P_{F,\theta}(F_\phi\sec(\theta-\phi),\theta)\sec(\theta-\phi)\,\mathrm{d}\theta, \tag{2.11}$$

where a factor of 2 has been added for normalization. Also, note that the function $P_{F_\phi}(F_\phi,\phi)$, in order to be a density function, must be normalized at each angle ϕ. In other words, the total number of forces does not change with the choice of ϕ, so the integral of $P_{F_\phi}(F_\phi,\phi)$ over all F_ϕ must always equal 1.

Equation (2.11) is a general integral relation allowing integration of the "polar" two-dimensional probability force density function to yield any desired Cartesian projection density function. This is a useful relationship within granular physics research in that it allows the calculation of a Cartesian density function from a force magnitude density function, but it is not a surprising result. Once the proper definitions are made, the derivation is straightforward. The more difficult result is to perform the inverse operation, namely, to find the polar form from the Cartesian form, but this is not possible within the realm of probability theory because the function $P_{F_\phi}(F_\phi,\phi)$ is not a two-dimensional probability density function. Even so, the inverse operation can be performed as demonstrated in the next section.

Finally, by using the variable transformation $\theta'=\theta+\pi$, it can be shown that

$$P_{F_\phi}(F_\phi,\phi+\pi) = P_{F_\phi}(F_\phi,\phi). \tag{2.12}$$

3. Fourier transform representation of force density integrals. In this section it will be shown that (2.11) above can be represented as a set of Fourier

transforms. Accomplishing this allows (2.11) to be inverted by utilizing the Fourier transform inversion properties. This approach is similar to the mathematics used in tomography [17], but the development presented here is distinct for two reasons. First, the symmetry relations of (2.1) and (2.3) provide simplification that does not occur in tomography. Second, the emphasis in tomography is on generating three-dimensional functions from a set of two-dimensional images, while in the present development the goal is to obtain two- or, in a future work, three-dimensional representations of the force density functions from one-dimensional Cartesian projections.

As a result of the symmetries obtained above in (2.1) and (2.12), we will require only restricted forms of the Fourier transforms. For example, we require only the Fourier cosine transform instead of the full exponential form. The Fourier cosine transform of a function $f(x)$ is expressed as

$$\mathcal{F}_c[f(x);u] = \sqrt{\frac{2}{\pi}} \int_0^\infty f(x)\cos(ux)\ \mathrm{d}x,$$

which has the same form as the inverse cosine transform [18]. The Fourier transform representations are written out in detail in order to resolve notational and normalization variations that appear in the literature. In addition to this one-dimensional transform, we will require a two-dimensional Fourier transform. In Cartesian form this is written as

$$\mathcal{F}_{2D}[f(x,y);(u,v)] = \frac{1}{2\pi} \int_{-\infty}^\infty \int_{-\infty}^\infty f(x,y)\exp\left(i(ux+vy)\right)\ \mathrm{d}x\ \mathrm{d}y, \tag{3.1}$$

but since the density functions are in polar form, this transform will need to be expressed in polar form also. Using the change of variables $x = F\cos(\theta)$, $y = F\sin(\theta)$, $u = G\cos(\phi)$, $v = G\sin(\phi)$, the following form for the two-dimensional, polar, Fourier transform is found,

$$\begin{aligned}
&\mathcal{F}_{2D}[f(F,\theta);(G,\phi)] \\
&= \frac{1}{2\pi} \int_0^\infty \int_0^{2\pi} f(F,\theta)\exp\left(iFG(\cos(\theta)\cos(\phi)+\sin(\theta)\sin(\phi))\right)F\ \mathrm{d}F\ \mathrm{d}\theta \\
&= \frac{1}{2\pi} \int_0^\infty \int_0^{2\pi} f(F,\theta)\exp\left(iFG\cos(\theta-\phi)\right)F\ \mathrm{d}F\ \mathrm{d}\theta,
\end{aligned}$$

but we will only be transforming functions where $f(F,\theta) = f(F,\theta+\pi)$. Using this symmetry simplifies this to a two-dimensional form of the Fourier cosine transform,

$$\mathcal{F}_{2D,c}[f(F,\theta);(G,\phi)] = \frac{1}{2\pi} \int_0^\infty \int_0^{2\pi} f(F,\theta)\cos(FG\cos(\theta-\phi))F\ \mathrm{d}F\ \mathrm{d}\theta. \tag{3.2}$$

Having established the above notation, now consider the following lemma which is the key result of this paper.

LEMMA 1. *The projected force density function is given by*

$$P_{F_\phi}(F_\phi,\phi) = 2\sqrt{2\pi}\mathcal{F}_c\left[\mathcal{F}_{2D,c}\left[\frac{P_{F,\theta}(F,\theta)}{F};(G,\phi)\right];F_\phi\right]. \tag{3.3}$$

Proof. Note that

$$
\begin{aligned}
&2\sqrt{2\pi}\mathcal{F}_c\left[\mathcal{F}_{2D,c}\left[\frac{P_{F,\theta}(F,\theta)}{F};(G,\phi)\right];F_\phi\right]\\
&\quad=2\sqrt{2\pi}\sqrt{\frac{2}{\pi}}\int_0^\infty\left[\frac{1}{2\pi}\int_0^\infty\int_0^{2\pi}P_{F,\theta}(F,\theta)\cos(FG\cos(\theta-\phi))\,\mathrm{d}F\,\mathrm{d}\theta\right]\cos(GF_\phi)\,\mathrm{d}G\\
&\quad=\frac{2}{\pi}\int_0^{2\pi}\int_0^\infty P_{F,\theta}(F,\theta)\left(\int_0^\infty\cos(FG\cos(\theta-\phi))\cos(GF_\phi)\,\mathrm{d}G\right)\,\mathrm{d}F\mathrm{d}\theta\\
&\quad=\int_0^{2\pi}\int_0^\infty P_{F,\theta}(F,\theta)\left(\delta(F\cos(\theta-\phi)-F_\phi)\right)\mathrm{d}F\mathrm{d}\theta.
\end{aligned}
$$

Changing the argument of the Dirac delta function, $\delta(x)$, is done using

$$\delta(F\cos(\theta-\phi)-F_\phi)=\frac{\delta(F-F_\phi\sec(\theta-\phi))}{|\cos(\theta-\phi)|}.$$

Thus integration with respect to F is well defined. The limits of integration with respect to θ can be compacted and shifted so that $\cos(\theta-\phi)$ is always positive, removing the need for the absolute value and introducing a factor of two. Then

$$
\begin{aligned}
&2\sqrt{2\pi}\mathcal{F}_c\left[\mathcal{F}_{2D,c}\left[\frac{P_{F,\theta}(F,\theta)}{F};(G,\phi)\right];F_\phi\right]\\
&=2\int_{\phi-\pi/2}^{\phi+\pi/2}P_{F,\theta}(F_\phi\sec(\theta-\phi),\theta)\sec(\theta-\phi)\,\mathrm{d}\theta\\
&=P_{F_\phi}(F_\phi,\phi).\qquad\square
\end{aligned}
$$

The benefit of this form is that (3.3) can be immediately inverted because each of the Fourier transforms is its own inverse, yielding the second key result of this paper, as follows.

LEMMA 2. *The two-dimensional polar probability force density may be expressed as a function of the projected Cartesian force density by*

$$P_{F,\theta}(F,\theta)=\frac{F}{2\sqrt{2\pi}}\,\mathcal{F}_{2D,c}[\mathcal{F}_c[P_{F_\phi}(F_\phi,\phi);(G,\phi)];(F,\theta)].\tag{3.4}$$

Equivalently,

$$
\begin{aligned}
&P_{F,\theta}(F,\theta)\\
&=\frac{F}{(2\pi)^2}\int_0^\infty\int_0^{2\pi}\int_0^\infty P_{F_\phi}(F_\phi,\phi)\cos(F_\phi G)\cos(FG\cos(\phi-\theta))G\,\mathrm{d}G\,\mathrm{d}\phi\,\mathrm{d}F_\phi.
\end{aligned}\tag{3.5}
$$

This integral can be integrated immediately with respect to the variable G, but this leads to an awkward functional form that is not amenable to solution using the standard look-up tables. Instead, we choose to leave it in this form, allowing the order of integration to be carried out on a case-by-case basis. This integral can be further integrated with respect to either F or θ to yield the single variable force density functions, demonstrating that knowledge of the projected Cartesian force density function can yield an explicit form for the force magnitude density.

Furthermore, for a frictionless packing, in which the force angles are the same as the contact angles, as discussed above, one may integrate out F from (3.5) according

to (2.3) to obtain the fabric of the packing. This result is striking because it begins with a knowledge of only $P_{F_\phi}(F_\phi, \phi)$, which is a set of contact force distributions that on the surface appear to have no contact angle information. This is the first time that force distributions, alone, have been directly related to the fabric of a packing, and this may be important to developing a theory of granular rheology in which changes in the fabric and the forces are coupled. Also, if the empirical studies can determine a simple ϕ-dependence for $P_{F_\phi}(F_\phi, \phi)$, then it may be possible to discern the fabric of a frictionless packing simply by sampling P_{F_ϕ} at only a few orientations of ϕ, or maybe only along the principle stress axes.

4. Force density integrals for isotropic material. In this section the two integral equations derived above, (2.11) and (3.5), are simplified for the isotropic case, yielding a pair of integral transform equations. Some of the properties of this transform pair are presented, and a list of useful solutions is shown. We start with the following definition.

DEFINITION 3. *An isotropic medium is one in which* $P_{F,\theta}(F, \theta) = P_F(F)/(2\pi)$.

Thus, an isotropic medium implies a force density with no angular dependence. As an immediate consequence of this definition, (2.11) can be simplified to show that an isotropic material also has no ϕ-dependence on its Cartesian projected force density,

$$P_{F_\phi}(F_\phi, \phi) = \frac{1}{\pi} \int_{-\pi/2}^{\pi/2} P_F(F_\phi \sec(\theta)) \sec(\theta)\, \mathrm{d}\theta. \tag{4.1}$$

Thus, for the rest of this section we will use the notation $P_{F_\phi}(F_\phi)$ for the Cartesian projected force density, since the function is no longer dependent upon the angle ϕ.

Equation (4.1) can be put into a more useful form by changing variables from the angle θ back to the force magnitude using $F = F_\phi \sec(\theta)$. This yields the integral equation

$$P_{F_\phi}(F_\phi) = \frac{2}{\pi} \int_{F_\phi}^{\infty} \frac{P_F(F)}{(F^2 - F_\phi^2)^{1/2}}\, \mathrm{d}F. \tag{4.2}$$

Equation (3.5) can be simplified as well. Since neither of the density functions has angular dependence, the ϕ integration on the right-hand side can be performed, yielding the result

$$P_F(F) = F \int_0^{\infty} \int_0^{\infty} P_{F_\phi}(F_\phi) \cos(F_\phi G) J_0(FG) G\, \mathrm{d}F_\phi\, \mathrm{d}G, \tag{4.3}$$

where J_0 is the zero-order Bessel function [18, eqn. 3.715.18], where we choose to perform the integration with respect to F_ϕ before G.

Equations (4.2) and (4.3) are inverse transform relations relating the force magnitude probability density, $P_F(F)$, to the projected Cartesian force probability density, $P_{F_\phi}(F_\phi)$, for isotropic two-dimensional granular materials. Such materials are of current theoretical and experimental interest, and these equations apply to any such material as long as an identifiable force can be assigned to the grain-to-grain, and, if included, grain-to-wall contacts. Consequently, a wide variety of force distributions are expected to result from current research, making it beneficial to discuss some of the properties of this transform pair as well as to present some of the more significant solution pairs. In the discussion below we will use the symbol $\leftrightarrow$ to link transform pairs, and we will not always normalize the pairs.

Equations (4.2) and (4.3) are clearly linear in that if $P_{F_\phi}(F_\phi) \leftrightarrow P_F(F)$ and $R_{F_\phi}(F_\phi) \leftrightarrow R_F(F)$ are two sets of solutions, then

$$aP_{F_\phi}(F_\phi) + bR_{F_\phi}(F_\phi) \leftrightarrow aP_F(F) + bR_F(F) \tag{4.4}$$

is a solution pair, where a and b are arbitrary constants. Another method for generating new solutions is to note that if $P_{F_\phi}(F_\phi) \leftrightarrow P_F(F)$ is a solution pair, then

$$F_\phi \frac{\partial P_{F_\phi}(F_\phi)}{\partial F_\phi} \leftrightarrow F \frac{\partial P_F(F)}{\partial F} \tag{4.5}$$

is also a solution pair, as a result of properties of the transform. By combining this result with the linearity result, it can be shown that

$$F_\phi^2 \frac{\partial^2 P_{F_\phi}(F_\phi)}{\partial F_\phi^2} \leftrightarrow F^2 \frac{\partial^2 P_F(F)}{\partial F^2} \tag{4.6}$$

is also a solution pair and more generally that

$$F_\phi^n \frac{\partial^n P_{F_\phi}(F_\phi)}{\partial F_\phi^n} \leftrightarrow F^n \frac{\partial^n P_F(F)}{\partial F^n} \tag{4.7}$$

is a solution pair. This result is very useful for obtaining sets of similar solutions when trying to fit experimental or simulation data.

A set of Bessel function integral equations [18, eqns. 6.592.10, 6.592.12–15], provides a method for obtaining useful solution pairs. Let Z_ν represent any of the Bessel functions, first kind J_ν, second kind Y_ν, third kind H_ν, or modified second kind K_ν. Then after appropriate changes of variable the referenced integral equations can be put into the form of (4.2), yielding the following transform pair:

$$\sqrt{\frac{2}{\pi\alpha}} \frac{Z_{\nu-1/2}(\alpha F_\phi)}{F_\phi^{\nu-1/2}} \leftrightarrow \frac{Z_\nu(\alpha F)}{F^{\nu-1}}. \tag{4.8}$$

Using this result and the differential generation result of (4.7), the solution pairs listed in Table 4.1 can be found. Not unexpectedly, since the transforms derived above are between polar and Cartesian representations, the solution pairs are often a Cartesian function (i.e., a sine, cosine, or exponential) and a polar function (i.e., a Bessel function). Probability densities are positive functions with finite total integrals, so the exponential and modified Bessel function pairs are especially useful. Since the transform relationships are linear, it is worthwhile to show the cosine and sine solutions (both as $P_F(F)$ and $P_{F_\phi}(F_\phi)$) so that, if desired, the Fourier components of a solution can be considered.

Other solution pairs to (4.2) and (4.3) exist and can be found in the standard integral tables, but many of them cannot be normalized. Table 4.2 shows five normalized solution pairs involving modified Bessel functions and Gaussians, which may be useful in granular physics applications.

To close this section a normalized pair of solutions is shown that has been fit to the results of a discrete element model (DEM) of a granular packing. DEM is a well-established technique which solves Newton's laws numerically grain-by-grain. It was implemented in the commercially available software package "Particle Flow Code in Two Dimensions" (PFC2D) by HCItasca (http://www.hcitasca.com/pfc.html). In

this case, the grains are round, hard, frictionless disks with a linear spring contact law implemented at the disk contacts. The disk diameters were distributed uniformly over the range 1.0 to 1.5 length units and were deposited randomly into a rectangular cell with flat, rigid, frictionless walls. Their diameters were then increased by rescaling until the disks jammed together across the span of the container. At each step of the incremental rescaling the grains were allowed to push each other around within the cell until every grain obtained static equilibrium. This incrementally dynamic

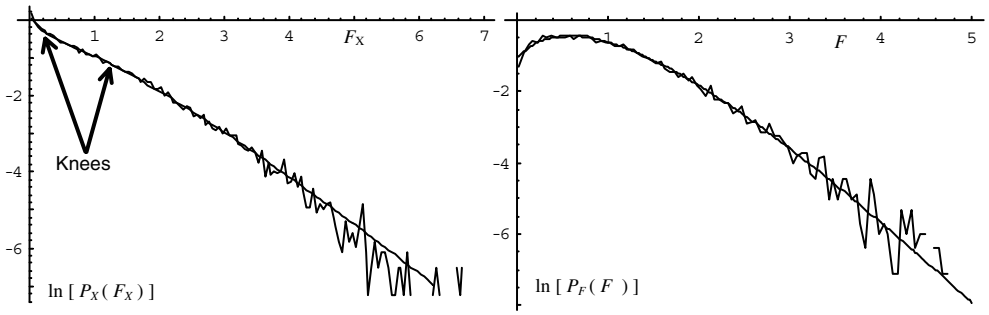

FIG. 4.1. *(Left) Graph of the Cartesian distribution from a DEM with an analytical fit. (Right) Graph of the force magnitude distribution from a DEM with an analytical fit.*

rescaling method naturally produces a disordered but statistically homogeneous and isotropic fabric within the bulk of the packing. Over 55,000 grain forces in the bulk of the packing were calculated, and the Cartesian force density function and the force magnitude density function were found. Grains within four grain diameters of the walls were excluded from these statistics. A fit to the Cartesian force density function was then found using a three-term modified Bessel function summation, as shown below. The solution pairs given above were then used to determine the force magnitude density function. The expansion coefficients can be chosen so that both distributions provide a good fit to the empirical data, as seen in Figure 4.1, thus demonstrating the success of the transformation developed in this paper. The plotted density functions are

$$P_{F_\phi}(F_\phi) = C\ \left[11F_\phi^2 K_2\left(\frac{\pi}{2}F_\phi\right) - 2F_\phi K_1\left(\frac{\pi}{2}F_\phi\right) + 3K_0\left(\frac{\pi}{2}F_\phi\right)\right] \tag{4.9}$$

and

$$P_F(F) = C\ \left[\left(\frac{11\pi}{2}\right)F^2 + (11-\pi)F + \frac{3\pi}{2}\right]\exp\left(-\frac{\pi}{2}F\right), \tag{4.10}$$

where the normalization constant $C = \pi^2/(132 - 4\pi + 3\pi^2)$.

It should be helpful to the field of granular research that the modified Bessel function of the second kind has been identified as the naturally occurring form for the Cartesian distribution, corresponding to the exponential forms of the polar distributions. The two "knees" in the curve that are visible in the Cartesian distribution of Figure 4.1 seem to be indicated in the Cartesian distributions of Bagi [14], as well, although this identification has not been previously made.

5. An example of an anisotropic solution pair. In most real world cases, granular media are subjected to greater total compressional force along one axis than the other, for example, in a gravity-dominated situation. Consequently, the anisotropic case is of interest, although it is significantly more complicated. Furthermore, the physics of jamming and unjamming have emerged as possibly the key concepts in granular media. The anisotropic case is relevant to this because shear stress (an aspect of anisotropy in the stress state) is one of the three ways to unjam granular media, as represented by the jamming phase diagram [19]. It has been proposed that the evolution of $P_F(F)$—from having a peak, as shown in Figure 4.1, to being monotonically decreasing—serves as an indicator of unjamming [7]. Numerical

simulations have indeed shown that this evolution occurs when the material is unjammed through stress anisotropy [1]. Therefore, an explanation for the evolution of $P_F(F)$ is central to the aims of granular physics. In this section a reasonable form is selected for the density function $P_{F_\phi}(F_\phi, \phi)$ for a sample anisotropic case and then the integrals evaluated to yield $P_F(F)$. This solution is discussed and compared against published data [1]. The purpose is to demonstrate that this mathematical framework is a *sufficient* framework to include the evolution of $P_F(F)$.

The reason we start with $P_{F_\phi}(F_\phi, \phi)$ instead of $P_{F,\theta}(F, \theta)$ in this demonstration is because the Cartesian distribution is the one associated with the force conservation law, and it is through that conservation law that the anisotropy is injected into the problem. It is well known that the normal components (diagonal elements) in the stress tensor scale according to $\sigma_{xx} = a + b\cos(2\phi)$ as the coordinate system is rotated through angle ϕ. Hence, the quantity of conserved force normal to the layers of a granular material will also scale according to this form when the layer is oriented at angle ϕ. The values of a and b are determined by the forces applied along the principal stress axes of the system. Based on the successful fits presented at the end of the previous section, we choose to let $P_{F_\phi}(F_\phi, \phi)$ be represented as a sum of the first three modified Bessel functions, but where this explicit angular dependence is added.

$$P_{F_\phi}(F_\phi, \phi) = \sum_{n=0}^{2} a_n \left(\frac{a-b}{a+b}\right)^{n-1} (a+b\cos(2\phi))^{n+1} F_\phi^n K_n((a+b\cos(2\phi))F_\phi). \tag{5.1}$$

The parameter b determines the amount of variation in force with angle, equaling zero for the isotropic case and approaching a for extreme anisotropy. Thus the force density is shifted towards higher forces along the y-axis with b nonzero. The $(a+b\cos(2\phi))^{n+1}$ factor has been included to normalize the distribution at every particular value of ϕ, as required from the discussion above. The $(a+b)/(a-b)$ factor is conjectural but it, or something similar to it, is necessary. Without this weighting, the resultant force density functions change only minimally with increasing anisotropy and do not agree with published literature. Including it yields results that correspond to dynamic simulations [1], as seen in Figure 5.1, but whose basis is unclear. The point is that the framework developed above allows choices to be made for the Cartesian form of the force density functions, which can then be converted to force magnitude or force angle density functions (i.e., fabric) and compared to published data.

The force magnitude density function is found by using this form for $P_{F_\phi}(F_\phi, \phi)$ in (3.5) and integrating with respect to θ (see (2.2)), yielding

$$\begin{aligned} P_F(F) = \frac{F}{(2\pi)^2} \sum_{n=0}^{2} a_n \left(\frac{a-b}{a+b}\right)^{n-1} \int_0^{2\pi}\int_0^{2\pi}\int_0^{\infty}\int_0^{\infty} (a+b\cos(2\phi))^{n+1} F_\phi^n \\ \cdot K_n((a+b\cos(2\phi))F_\phi) \cos(F_\phi G)\cos(FG\cos(\phi-\theta)) G \,\mathrm{d}G\,\mathrm{d}F_\phi\,\mathrm{d}\phi\,\mathrm{d}\theta. \end{aligned}$$

The integration with respect to θ can be performed immediately, yielding $2\pi J_0(FG)$, and the integration with respect to F_ϕ can be performed via [18, eqn. 6.699.12]. Then the integration with respect to G can be performed via [18, eqn. 6.565.4], yielding the partial result

$$\begin{aligned} P_F(F) = \sum_{n=0}^{2} \frac{a_n F^{n+1/2}}{4} \sqrt{\frac{2}{\pi}} \left(\frac{a-b}{a+b}\right)^{n-1} \\ \cdot \int_0^{2\pi} (a+b\cos(2\phi))^{n+3/2} K_{n-1/2}(F(a+b\cos(2\phi)))\,\mathrm{d}\phi. \end{aligned}$$

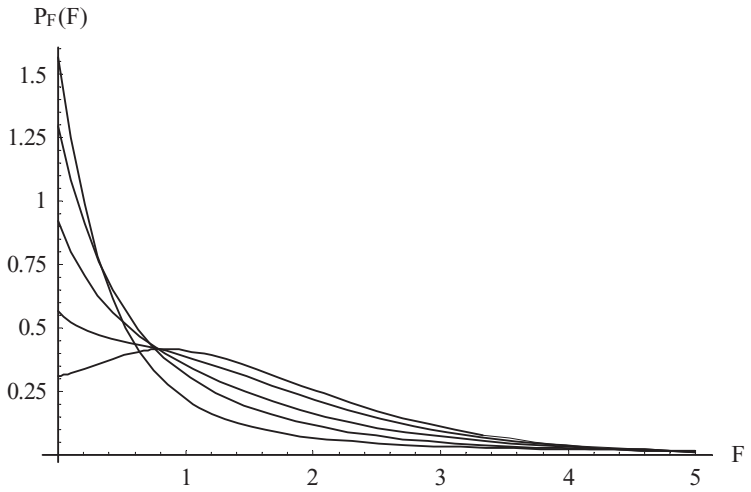

FIG. 5.1. *Evolution of force magnitude distribution with increasing anisotropy. The curve with the lowest probability density for $F = 0$ is the $b = 0$ isotropic case. The other curves, in order, correspond to $b = 0.3, 0.6, 0.9,$ and 1.57.*

Using the identities for the half-order modified Bessel functions, the integrations with respect to ϕ can be made, yielding the result

$$\begin{aligned} P_F(F) = \frac{\pi}{2}\ \exp(-aF)\Bigg(& a_0\left(\frac{a+b}{a-b}\right)(aI_0(bF) - bI_1(bF)) \\ &+ a_1((a^2+b^2)FI_0(bF) - (b+2abF)I_1(bF)) \\ &+ a_2\left(\frac{a-b}{a+b}\right)(F(a^2+2b^2+a^3F+3ab^2F)I_0(bF) \\ &- (3b+5abF+3a^2bF^2+b^3F^2)I_1(bF))\Bigg), \end{aligned} \tag{5.2}$$

where the exponential dependence on the force is expected from the isotropic case, but the Bessel function dependence on the parameter b is novel. ($I(x)$ is the modified Bessel function of the first kind.) Using the values $a_0 = 3\pi^2/4$, $a_1 = -\pi$, $a_2 = 11$, and $a = \pi/2$, Figure 5.1 shows a plot of (5.2) for various degrees of anisotropy (these plots have been normalized).

For $b = 0$, the isotropic case, the plot is identical to that shown in Figure 4.1, and (5.2) reduces (with the addition of a normalization term) to (4.10), but as b increases, the shape of the curve changes, slowly moving towards a pure exponential. This is in agreement with published simulation data, where the force magnitude density function evolves in a similar fashion with increasing anisotropy [1]. This demonstrates that the mathematical framework can produce this evolution naturally; nothing more exotic than the relative weighting of the Bessel terms need be invoked to produce it.

6. Summary and conclusions. It is possible within the straightforward techniques of probability theory to convert from $P_{F,\theta}(F,\theta)$ to $P_{F_\phi}(F_\phi,\phi)$. Unfortunately, those techniques cannot provide a conversion in the opposite direction. However, we may recognize that the conversion in the forward direction is equivalent to the composition of Fourier cosine transforms of the function. Since these transforms have their

own well-defined inverses, the conversion from $P_{F_\phi}(F_\phi, \phi)$ to $P_{F,\theta}(F, \theta)$ can likewise be expressed.

This inverse conversion is interesting for several reasons. First, it allows theoretical models that only predict Cartesian force distributions (such as the q model [15]) to be directly compared against the force magnitude distributions, which have been more important to granular physics. Second, the inverse conversion indicates a previously unrecognized relationship between the Cartesian force component distributions $P_{F_\phi}(F_\phi, \phi)$ and the fabric of the granular packing, which may be important in future theoretical developments. Third, for the special case of isotropic granular packings in which the ϕ and θ dependencies may be eliminated, the transform pair reduces to a simple form that can be solved for a wide range of functions. This indicates which functional forms for the Cartesian components correspond to particular functional forms for the force magnitudes. Since it is well known that the distribution of the latter has an exponential tail, the corresponding form for $P_{F_X}(F_X)$ ought to be modified Bessel functions of the second kind. Expansions in a series of such functions (of increasing order) display two characteristic "knees" when graphed, and indeed it turns out that such knees are observed in the empirical Cartesian distributions. Thus, the natural form for $P_{F_X}(F_X)$ appears to have been identified, and this should provide insight into the physical mechanisms that produce the distributions. Fourth, treating these modified Bessel functions with increasing anisotropic stress naturally produces an evolution of $P_F(F)$ that depends upon the choice of coefficients in the series expansion. Prior research has associated this evolution with the occurrence of jamming and unjamming in granular packings, and so the inverse transform indicates that jamming may be described as an increase in weighting of the zeroth-order modified Bessel function. This insight should be helpful to explain the physics of jamming and unjamming, which are important concepts in granular physics. Because this inverse conversion identifies these relationships and natural functional forms for granular force distributions, its derivation should be a helpful contribution in future research into the physics of granular jamming and unjamming.

A SCHOOL-ORIENTED, AGE-STRUCTURED EPIDEMIC MODEL*

VIGGO ANDREASEN† AND THOMAS FROMMELT†

Abstract. A model of childhood epidemics focusing on the impact of the school-year is presented. At the onset of the epidemic season, a new cohort of susceptible students enter the school, all other age-classes advance one year, while the oldest age-group leaves the mixing pool. If the susceptible pool is sufficiently large at the onset of the season, an epidemic will arise and run to its conclusion prior to the end of the school-year. The system is expressed in terms of a discrete dynamical system giving the changes in the age-dependent immunity structure on a year-to-year basis. If disease transmission is independent of age, the system settles at epidemics of constant size in each season. If disease transmission is age-dependent, more complicated dynamics may occur, including multiple stable states and chaos.

Key words. epidemic model, seasonal forcing, discrete map, closed epidemic, age-structure

1. Introduction.

Disease transmission in schools played a central role in maintaining the regularly recurring epidemics of childhood diseases during the prevaccination era. In particular the summer break with low transmission, the annual infusion of a new cohort of (susceptible) first-year students, and the progression of students through the school system contributed substantially to the external forcing and the well-known two-year cycle in measles epidemics [42, 18, 38, 3]. The aim of this paper is to include this pulsed forcing in a mathematically tractable, age-structured epidemic model.

From an analytical viewpoint, the discontinuous nature of student admission and class-progression makes it rather awkward to incorporate the phenomenon into an epidemic model describing disease transmission dynamics in terms of the flow of hosts from the susceptible through the infected to the recovered class (SIR-model). Consequently the previous models of childhood epidemics with annual updates of the host structure have not been amenable to analytic methods. However, these "realistic age-structured" models (RAS-models) reflect quite accurately the prevaccination measles epidemics in England [42, 10, 23, 28], although recent results suggest that a detailed description of the seasonal variation in contact rates—rather than age-structure—is essential for matching the observed pattern of childhood diseases in England [16, 8, 18, 29, 41]. To simplify the analysis most mathematical studies of seasonally driven childhood epidemics have assumed that transmission strength varies sinusoidally with a period of one year, neglecting the details of the school-year [13, 31, 7, 33, 37]. Recently Billings and Schwartz [9] have provided a detailed description of the Poincaré return map associated with a forced SIR-model and showed how noise may lead to stochastic chaotic dynamics in such models.

In Schenzle's original model [42] as well as in other RAS-models, the host population is divided into cohorts, where new susceptible hosts are recruited continuously into the youngest age-class, age-classes in the school-age are updated annually, and hosts in adult age-classes continuously move through a fixed number of classes (one class in Schenzle's final formulation) and all mortality is concentrated in the adult age-classes. Thus the demographic structure is a discretization of the "von Forester model," which is often used in conjunction with epidemic models (see [26]). However, the original partial differential equation model as well as the age-group formulation of Tudor [44] describe a continuous flow through the age-classes, in contrast to the discrete annual progression through the school-system. See [25] for a recent review.

In this paper we will take an approach that allows us to account for the summer break and the annual infusion of new susceptible hosts into the mixing pool. In order to obtain an analytically tractable model, we will neglect the fine-scale variation in the school-year, assuming that the year can be divided into a (long) period of high disease transmission and a period where no transmission takes place. The basic idea is to completely separate the time scale of the epidemic from that of the school demographics by assuming that the duration of an epidemic is short compared to the length of the school-year. Thus each school-year starts with the introduction of a new cohort of susceptible hosts, one-year progression of all cohorts, and removal of the oldest age-class. We will assume that if the susceptible pool at the beginning of the school-year is large enough to support an epidemic, then an epidemic will occur that year, and this epidemic will run to its conclusion before the end of the school-year. This allows us to describe the epidemics only in terms of their size, i.e., the fraction of susceptible hosts that get infected during the season in question. Once the size of the epidemic is known, we can update the age-dependent immunity structure at the end of the school year, and we are ready to start the next season.

Clearly the model will not account for pathogen persistence over the summer period with low disease activity. Therefore the model cannot describe the exact inoculum at the onset of the subsequent season, and consequently the timing of the epidemic within the season cannot be determined. We shall return to these issues in the discussion.

Models of annual epidemics combined with interseasonal updating of the host population was first used by Gillespie [20] in his description of disease-induced natural selection in an (annual) insect population, and by May [32] and Dwyer et al. [15], who described disease-induced regulation of an insect population. Recently Andreasen and coworkers [6, 11] used the same modeling approach to describe the transmission dynamics of influenza under drift.

In the next section we derive a map connecting the age-distribution of susceptible hosts at the onset of one epidemic season to the age-distribution at the onset of the subsequent season. The dynamics of the season-to-season map can be quite complicated, and only a partial analysis is presented. In section 3 we show that the season-to-season model has a unique equilibrium. The case of age-independent susceptibility is studied in section 4, and in particular we shall show that when disease transmission is completely age-independent, the endemic equilibrium is locally asymptotically stable. In section 5 we give examples where the size of the annual epidemic changes in an irregular manner, with some years totally lacking an epidemic, indicating that the dynamics of the model may in fact be quite complicated.

2. The model. The separation of time scales naturally breaks the dynamics into two steps. The first step describes the demographic and school class dynamics

of the population, which is updated once a year at the beginning of the school-year, while the second step will describe disease transmission during a school-year in the closed population.

Reflecting the structure of school-classes, the population is divided into m cohorts, one for each year from introduction into the mixing-pool until removal from the pool, and we denote by N_k^T the number of hosts who are in the kth cohort during season T. At the onset of an epidemic season, M new (susceptible) hosts are introduced into the first cohort: $N_1^{T+1}(\textit{season-start}) = M$; cohorts $k = 1, \ldots, m-1$ move one age-class up: $N_k^T(\textit{season-end}) \to N_{k+1}^{T+1}(\textit{season-start})$, while the oldest cohort is removed. We will assume that the population is closed in the sense that all new hosts enter through the first cohort at the onset of a season and that hosts leave only by the removal of the oldest cohort at end of the season. Thus, provided that the population is at demographic equilibrium, all cohorts are of the same size throughout the epidemic season. This corresponds to an extreme case of type I mortality [34, 2]. Since the population size remains constant, it turns out to be convenient to describe the population structure in terms of n_k^T, the fraction of the host population that is in cohort k during season T. We note that $n_k = 1/m$ for all k.

To determine disease transmission dynamics during the season, we assume that the epidemic can be described by an SIR-epidemic model. Thus we subdivide the kth cohort of the host population into susceptible, infectious, and immune hosts and denote by s_k, i_k, and r_k the fraction of the total population in age-class k that is currently susceptible, infected, and recovered, respectively. During the season the dynamics become

$$\frac{ds_k}{dt} = -\sigma_k \Lambda s_k, \tag{2.1}$$

$$\frac{di_k}{dt} = \sigma_k \Lambda s_k - \nu i_k, \tag{2.2}$$

$$\frac{dr_k}{dt} = \nu i_k, \tag{2.3}$$

where $\Lambda = c \sum \tau_j i_j$ gives the force of infection that would be experienced by a totally susceptible host; ν denotes the rate of recovery, while c is the contact rate. To account for age-dependence in disease transmission, each age-class is assigned two factors: σ_k and τ_k, denoting, respectively, the susceptibility and infectivity of hosts in age-class k relative to the maximal values. Thus by definition we have $0 \le \sigma_k, \tau_k \le 1$. This description of age-dependent transmission corresponds to the "proportionate mixing" assumption in the continuous age-structured epidemic model [14]. Although it is straightforward to include more complicated mixing patterns in (2.1)–(2.3), such mixing patterns are not easily amenable to the analysis we shall apply below.

Initial conditions for the seasonal dynamics are determined by the demographic model, so that at the onset of the season, $s_k(0)$ and $r_k(0)$ are known. Since the epidemic from the previous season has run to its conclusion, we have $s_k(0) + r_k(0) = n_k = 1/m$ and $i_k(0) \ll 1$. At the beginning of the epidemic season a few infectious individuals are introduced into the population, so that $0 < \Lambda(0) \ll 1$. As we shall see it suffices to assume that $\Lambda(0) > 0$ rather than specifying the age-distribution of the initial infectious cases.

The description of the seasonal epidemic model can be simplified substantially. Since immune hosts play no role in the transmission dynamics, the r_k-equations are redundant and may be omitted. Furthermore by introducing the force of infection

as a dynamic variable, we can eliminate direct reference to the infectious classes i_k. Summing over all age-classes, one finds that Λ follows the equation

$$\frac{d\Lambda}{dt} = \left(c \sum \sigma_k \tau_k s_k - \nu\right) \Lambda. \tag{2.4}$$

The transmission dynamics during the epidemic season is therefore captured by (2.1) and (2.4).

These equations can be solved explicitly by Gart's modification to the analysis of the single epidemic [30]. We first introduce a reference age-class s_f, namely an age-class for which $\sigma_f = 1$. Eliminating time, we find that $ds_k/ds_f = \sigma_k s_k/s_f$, so that

$$s_k(t) = s_k(0) \left(\frac{s_f(t)}{s_f(0)}\right)^{\sigma_k}. \tag{2.5}$$

By substituting these values for s_k into (2.4), we obtain

$$\frac{d\Lambda}{ds_f} = \frac{c\Lambda \sum \sigma_k \tau_k s_k - \nu\Lambda}{-\Lambda s_f} = -c \sum \sigma_k \tau_k \left(\frac{s_f}{s_f(0)}\right)^{\sigma_k - 1} \frac{s_k(0)}{s_f(0)} + \frac{\nu}{s_f},$$

which may be solved to yield

$$\Lambda(t) - \Lambda(0) = -c \sum \tau_k \left(\frac{s_f(t)}{s_f(0)}\right)^{\sigma_k} s_k(0) + \nu \log(s_f(t)) + c \sum \tau_k s_k(0) - \nu \log(s_f(0)).$$

We are now ready to apply our separation of time scales, in that we express the final size of the epidemic in terms of $\theta = s_f(\infty)/s_f(0)$.

Provided that the threshold condition

$$\frac{d\Lambda}{dt}_{|t=0} = c \left(\sum \tau_k \sigma_k s_k(0) - \nu\right) \Lambda > 0 \tag{2.6}$$

is satisfied, an epidemic will occur. Since the epidemic will eventually die out, we have that $\Lambda(t) \to 0$ for $t \to \infty$. By assumption, $\Lambda(0) \ll 1$, so we find that if the threshold condition (2.6) holds, then θ satisfies the equation

$$G(\theta) = \Lambda(\infty) - \Lambda(0) = \log\theta + \gamma \sum \tau_k s_k(0)(1 - \theta^{\sigma_k}) = 0,$$

where $\gamma = c/\nu$.

It is straightforward to show that if $G'(1) < 0$, this equation has exactly one solution in the interval $(0, 1)$, and none if $G'(1) > 0$; for details see [6]. Clearly the condition on $G'(1)$ is identical to the threshold condition (2.6). If the threshold condition does not hold, no epidemic can occur, and consequently we set $\theta = 1$.

These observations lead to the following statement.

DEFINITION OF θ. *If the threshold condition*

$$\gamma \sum \tau_k \sigma_k s_k > 1 \tag{2.7}$$

holds, then $0 < \theta < 1$ *is the unique solution to*

$$\log\theta + \gamma \sum \tau_k s_k (1 - \theta^{\sigma_k}) = 0; \tag{2.8}$$

if the threshold condition is not satisfied, then

$$\theta = 1.$$

Notice that, by (2.5), θ now determines the changes in all susceptible classes, since we have

$$s_k(\infty) = \theta^{\sigma_k} s_k(0). \tag{2.9}$$

Thus the entire outcome of the epidemic season is captured in a single (implicit) function θ of the initial conditions.

Since we no longer will be concerned with the dynamics within a season, we use the notation $s_k = s_k(0)$ here and for the remainder of this paper. The definition of θ generalizes the concept of the final size of an epidemic in a closed population (cf. [12, p. 10]) to a closed structured population.

The quantity $\gamma \sum \tau_k \sigma_k s_k$ gives the number of secondary infections per primary infection at the onset of the epidemic, and it may therefore be thought of as the *effective replacement number*, R_e, at the onset of the epidemic.

We are now ready to describe the complete dynamics over a full year, from the beginning of one epidemic season to the beginning of the next season. Since $s_k + r_k = n_k = 1/m$, it suffices to specify the age-distribution of susceptible hosts $(s_1, s_2, \ldots, s_m)$, and the process taking the susceptible population from the onset of one school-year to the onset of the next year is described by the following two steps:

$$\begin{aligned}
\text{Start of year:} &\quad (s_1, s_2, \ldots, s_m) \\
\text{Epidemic season:} &\quad \downarrow \\
\text{End of year:} &\quad (\theta^{\sigma_1} s_1, \theta^{\sigma_2} s_2, \ldots, \theta^{\sigma_m} s_m) \\
\text{Change of school class:} &\quad \downarrow \\
\text{Start of next year:} &\quad (1/m, \theta^{\sigma_1} s_1, \theta^{\sigma_2} s_2, \ldots, \theta^{\sigma_{m-1}} s_{m-1}),
\end{aligned}$$

where the first step is given by (2.9) and the second step by the cohortwise age-progression. The long-term behavior of the epidemics is now determined by this map connecting the age-distribution of susceptible hosts from one year to the next. To facilitate the analysis of the system we introduce the following notation. Since at the beginning of each season $s_1 = 1/m$, the population structure is characterized by the $m - 1$ values of $S = (s_2, \ldots, s_m)$. The size of a susceptible cohort can only decrease, so we have $0 \le s_k \le 1/m$ for all k. Thus the state space for the system is $B = [0, 1/m]^{m-1}$. With this notation the season-to-season map $F : B \to B$ can be written in the form

$$F : \begin{pmatrix} s_2 \\ \vdots \\ s_m \end{pmatrix} \mapsto \begin{pmatrix} \theta^{\sigma_1}/m \\ \vdots \\ \theta^{\sigma_{m-1}} s_{m-1} \end{pmatrix}, \tag{2.10}$$

where the value of θ is defined above with the understanding that $s_1 = 1/m$.

The definition makes θ a continuous function $\theta : B \to [0, 1]$, which is nondifferentiable on the hyperplane where the threshold quantity equals unity. To get an impression of the function θ, let us for a moment set $\sigma_k = 1$ and define w as the weighted sum of all susceptibles $w = \sum \tau_k s_k$. We can now consider θ as a composite

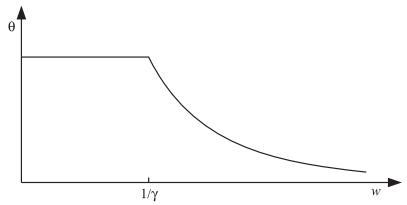

FIG. 2.1. *The function $\theta(w)$. The function is continuous but not differentiable at $w = 1/\gamma$ and has no inverse.*

function $S \mapsto w \mapsto \theta$, where θ is determined as function of w by

$$\theta(w) = \begin{cases} \text{the solution to} \\ 0 = \log\theta + \gamma w(1-\theta) & \text{if } \gamma w > 1; \\ 1 & \text{otherwise.} \end{cases}$$

Figure 2.1 shows the graph of $\theta(w)$ and its two unusual features. The function $\theta(w)$ is continuous but not differentiable at $w = \gamma$—in fact, we have $\theta'(1/\gamma^-) = 0$ and $\theta'(1/\gamma^+) = -2\gamma$. Furthermore, for $w \le 1/\gamma$ the function is a constant, so no inverse map exists. The constant section of $\theta(w)$ introduces a "folding" where a whole line-segment is mapped into the same point; this folding turns out to play a major role in the long-term dynamics of the system for some parameter values. The nondifferentiability of $\theta(w)$ leads to some technical (but less significant) complications in the mathematical analysis.

3. Repeated epidemics. The map (2.10) describes how the age-structure of susceptible hosts changes from the beginning of one school-year to the next, and we now turn our attention to the dynamics on the slow season-to-season time scale.

We first determine equilibria $\hat{S} \in B$ of the system in terms of $\vartheta = \theta(\hat{S})$, noting that an equilibrium $F(\hat{S}) = \hat{S}$ with $\vartheta < 1$ corresponds to a situation where an epidemic of the same size occurs in all seasons.

If $F(\hat{S}) = \hat{S}$ and $\vartheta = \theta(\hat{S})$, it follows that

$$\hat{s}_k = \vartheta^{\sigma_{k-1}}\hat{s}_{k-1} = \frac{\vartheta^{u_{k-1}}}{m}, \qquad k = 2, \dots, m,$$

where $u_k = \sum_{j=1}^{k} \sigma_j$ and $u_0 = 0$. Equilibria of the model are therefore characterized by those $\vartheta \in (0, 1]$ that solve the equation

$$H(\vartheta) = \log\vartheta + \frac{\gamma}{m}\sum \tau_k \vartheta^{u_{k-1}}(1 - \vartheta^{\sigma_k}) = 0. \tag{3.1}$$

Using the method in [6, Proposition 1], we have that the following properties hold for H and $\sigma^* = \min\{\, \sigma_k \,|\, \sigma_k > 0 \,\}$:

(1) $H(0^+) = -\infty$.
(2) $H(1) = 0$.
(3) $H'(1) = 1 - \frac{\gamma}{m}\sum \tau_k\sigma_k$.
(4) The function $H(\vartheta)/(1 - \vartheta^{\sigma^*})$ is increasing on the interval $(0, 1)$.

Property (2) ensures that H is positive to the left of $\vartheta = 1$ if $H'(1) < 0$, and in combination with property (1), this shows that $H(\vartheta)$ has a zero on the interval $(0, 1)$, while property (4) shows that this zero is unique. If $H'(1) > 0$, the function must

have an even number to zeroes on $(0,1)$, and from property (4) we conclude that no zeroes exist in $(0,1)$.

Since $H(1)=0$, $\vartheta=1$ will always satisfy (3.1). However, because of our assumption that an epidemic occurs if the threshold condition (2.7) is satisfied, θ evaluated at the disease-free state $S_0=(1,\dots,1)/m$ equals unity only if condition (2.7) does not hold at S_0. Therefore the disease-free state is an equilibrium only when the effective replacement number at S_0 is below 1.

We summarize our observations in the following claim.

PROPOSITION 3.1. *The model* (2.10) *has exactly one equilibrium. If the threshold condition*

$$R_0=\frac{\gamma}{m}\sum_{k=1}^{m}\tau_k\sigma_k>1 \tag{3.2}$$

holds, then the equilibrium is endemic, corresponding to an annual epidemic. If the threshold condition does not hold, then the equilibrium is disease-free, i.e., $s_k=1/m$, $k=1,\dots,m$.

The quantity R_0 gives the *basic replacement number*, i.e., the number of secondary infections per primary infection in a totally susceptible population, and Proposition 3.1 therefore shows that the model has an endemic equilibrium exactly when R_0 exceeds unity, as one expects in epidemic models [12]. However, in contrast to most epidemic models, there is no (unstable) disease-free equilibrium when condition (3.2) holds. This is due to our basic assumption that an infection from an external source will cause an epidemic in every season where it is possible.

The present model can exhibit quite complicated dynamics, including multiple steady states, chaos, and cycles where epidemics occur only in some seasons. We cannot provide a complete analysis of the model, but in the following section we analyze the stability of the endemic equilibrium for a particularly simple mixing structure, and in the subsequent section we provide some numerical examples of the complicated dynamics that can arise.

4. Local stability. From the previous section we know that for $R_0>1$ there exists a unique endemic equilibrium. In this section we will determine the local stability of this equilibrium for the case where disease susceptibility is independent of age, $\sigma_k=1, k=1,\dots,m$. This structure is chosen for its mathematical convenience rather than for its epidemiological interest, but it suffices when demonstrating the possibility of destabilization of the endemic equilibrium through variation in infection rates. Assuming constant susceptibility $\sigma_k=1$ (but age-dependent infectivity τ_k) simplifies the analysis considerably, especially because $\theta(S)$, the size of the epidemic, can be treated as a composite map consisting of a linear map followed by a (complicated) one-dimensional (1-D) map, as discussed in section 2.

The endemic equilibrium now takes the form

$$\hat{S}=(\hat{s}_2,\hat{s}_3,\dots,\hat{s}_m)=\frac{1}{m}(\vartheta,\vartheta^2,\dots,\vartheta^m),$$

where ϑ is the fraction of hosts that get infected during a season at equilibrium. It turns out that it is more convenient to use ϑ, rather than $\gamma=c/\nu$ as a (bifurcation) parameter. To see that this is possible we start by proving that the equilibrium condition expressed in terms of ϑ can be used to define a one-to-one map between γ and ϑ.

LEMMA 4.1. *For fixed age-specific infectivity* $(\tau_1, \dots, \tau_m)$ *the implicit equation*

$$\log \vartheta + \frac{\gamma}{m} \sum_{k=1}^{m} \tau_k \vartheta^{k-1}(1-\vartheta) = 0$$

defines a one-to-one map $\gamma \mapsto \vartheta$ *from* $(m/\sum \tau_k, +\infty)$ *onto* $(0,1)$.

Proof. According to Proposition 3.1, the map is well defined, and the inverse map $\vartheta \mapsto \gamma$ is given explicitly as

$$\gamma = \frac{-m \log \hat{\vartheta}}{\sum_{k=1}^{m} \tau_k \vartheta^{k-1}(1-\vartheta)}, \tag{4.1}$$

showing that the map is one-to-one. Clearly $\gamma(\vartheta)$ is positive on $(0,1)$ and $\gamma(0^+) = +\infty$, while $\gamma(1^-) = m/\sum \tau_k$.

The stability of the equilibrium $\hat{S}$ is determined by the Jacobian of F, given by (2.10) evaluated at $\hat{S}$. A straightforward computation yields

$$DF = \begin{pmatrix} 0 & 0 & \dots & 0 & 0 \\ \vartheta & 0 & \dots & 0 & 0 \\ 0 & \vartheta & & 0 & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & \vartheta & 0 \end{pmatrix} + \begin{pmatrix} \hat{s}_1 \\ \hat{s}_2 \\ \hat{s}_3 \\ \vdots \\ \hat{s}_{m-1} \end{pmatrix} \begin{pmatrix} \theta_2' & \theta_3' & \dots & \theta_m' \end{pmatrix},$$

where

$$\theta_k' = \frac{\partial \theta}{\partial s_k \,|\hat{s}} = \frac{\gamma \tau_k (1-\vartheta)}{\gamma \sum_1^m \tau_j \hat{s}_j - \vartheta^{-1}} = -\frac{\gamma \tau_k (1-\vartheta)}{\frac{\log \vartheta}{1-\vartheta} + \frac{1}{\vartheta}} = \frac{\tau_k m}{\sum_1^m \tau_j \vartheta^{j-1}} \psi(\vartheta) < 0$$

denotes the partial derivative of θ after s_k evaluated at the equilibrium. The third equality is obtained by using the equilibrium condition

$$\log \vartheta + \gamma \sum \tau_k \hat{s}_k (1-\vartheta) = 0,$$

while the subsequent equality follows from (4.1).

The elementary function

$$\psi(\vartheta) = \frac{\log \vartheta}{\frac{\log \vartheta}{1-\vartheta} + \frac{1}{\vartheta}}$$

will play a central role in the analysis, and we note the following claim.

LEMMA 4.2. *The function* ψ *satisfies the inequality*

$$0 > \vartheta + \psi(\vartheta) > -1$$

on the interval $(0,1)$, *and* $\psi(0^+) = 0$, *while* $\psi(1^-) = -2$.

Proof. We find

$$\begin{aligned} 1 + \vartheta + \psi(\vartheta) &= 1 + \vartheta + \frac{\log \vartheta}{\frac{1}{\vartheta} + \frac{\log \vartheta}{1-\vartheta}} \\ &= 1 - \frac{\vartheta - 1 - \log \vartheta}{\vartheta^{-1} - 1 - \log \vartheta^{-1}} \qquad (4.2) \\ &= \frac{\vartheta^{-1} - \vartheta + 2 \log \vartheta}{\vartheta^{-1} - 1 - \log \vartheta^{-1}}. \qquad (4.3) \end{aligned}$$

By applying the elementary inequality $y - 1 - \log y > 0$ to the numerator and the denominator in expression (4.2), we observe that $\vartheta + \psi(\vartheta) < 0$. To see that $\vartheta + \psi(\vartheta) + 1 > 0$, apply the same inequality to the denominator of (4.3) and observe that $t(\vartheta) = \vartheta^{-1} - \vartheta + 2\log\vartheta > 0$ since $t(1) = 0$ and $t'(\vartheta) = -(1 - \vartheta^{-1})^2$.

In principle, the characteristic polynomial can be determined by a straightforward computation of the determinant of $DF - zE$. However, the following two lemmas considerably simplify the computation.

LEMMA 4.3. *For an $n \times n$-matrix M and (column) vectors c_1, c_2, and d we have*

$$\det(M + d(c_1 + c_2)^T) = \det(M + dc_1^T) + \det(M + dc_2^T) - \det M.$$

Proof. The proof follows from Theorem 8.4.3 in [22].

LEMMA 4.4. *Let $P_{nj}(a)$ denote the determinant of the $n \times n$ matrix*

$$L = \begin{pmatrix} -z & 0 & \dots & 0 & 0 \\ u & -z & \dots & 0 & 0 \\ 0 & u & & 0 & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & u & -z \end{pmatrix} + a \begin{pmatrix} 1 \\ u \\ u^2 \\ \vdots \\ u^{n-1} \end{pmatrix} e_j^T,$$

where e_j denotes the jth unit vector; then

$$P_{nj}(a) = \det L = (-1)^n \left(z^n - au^{j-1}(z^{n-1} + \ldots + z^{n-j})\right).$$

Proof. Expansion of the determinant after the first row of L gives the recursion formula

$$P_{nj}(a) = -zP_{n-1\,j-1}(au) + (-1)^{j+1}u^{j-1}(-z)^{n-j},$$

and the result follows by induction.

Combining the two lemmas, we find that the characteristic polynomial of $DF(\hat{S})$ is

$$\begin{aligned} p(z) &= (-1)^{m-1}\left(z^{m-1} - \frac{1}{m}\sum_{k=2}^{m}\theta_k'\vartheta^{k-2}(z^{m-2} + \cdots + z^{m-k})\right) \\ &= (-1)^{m-1}\left(z^{m-1} - \frac{1}{m}\sum_{k=2}^{m}\theta_k'\vartheta^{k-2}z^{m-k}\frac{z^{k-1} - 1}{z - 1}\right). \end{aligned} \tag{4.4}$$

Here the reader should bear in mind that since the first age-class is omitted, DF is in fact an $(m-1) \times (m-1)$-matrix, where θ_j' appears in the $(j-1)$th column. Since $\theta_k' < 0$, the penultimate expression is a polynomial where all coefficients are nonnegative, showing that the polynomial cannot have positive real zeroes. Therefore the last expression may be used to determine the eigenvalues of DF.

The polynomial (4.4) is too complex to allow for a general analysis, and we will study only a—somewhat artificial—situation where infected hosts in age-class $j, j \geq 2$, can infect with full strength $\tau_j = 1$, while hosts in other age-classes infect with reduced strength $\tau_k = \tau \leq 1$, for $k \neq j$. In particular, for $\tau = 1$ we obtain as a special case the homogeneous model where all hosts infect equally well, and we shall analyze this case in some detail below.

Since $\theta'_k = \tau\theta'_j$, $k \neq j$, we set $\theta'_j = \theta'$ and find that

$$\theta' = \frac{\psi(\vartheta)}{\tau\frac{\vartheta^m-1}{\vartheta-1} + (1-\tau)\vartheta^{j-1}}.$$

The characteristic polynomial takes the form

$$\begin{aligned} p(z) &= (-1)^{m-1}\left(z^{m-1} - \frac{1-\tau}{m}\theta'\vartheta^{j-2}z^{m-j}\frac{z^{j-1}-1}{z-1} - \frac{\tau}{m}\sum_{k=2}^{m}\theta'\vartheta^{k-2}z^{m-k}\frac{z^{k-1}-1}{z-1}\right) \\ &= \frac{(-z)^{m-1}}{z-1}\Bigg((z-1) - \frac{(1-\tau)\theta'}{m}\vartheta^{j-2}(1-z^{-j+1}) \\ &\qquad\qquad - \frac{\tau\theta'}{m}\left(\frac{\vartheta^{m-1}-1}{\vartheta-1} - z\frac{\left(\frac{\vartheta}{z}\right)^{m-1}-1}{\frac{\vartheta}{z}-1}\right)\Bigg). \end{aligned}$$

Thus eigenvalues of DF will satisfy the equation

$$0 = p(z) = \frac{z^{m+1} + az^m + bz^{m-1} - (c + dz^{m-j} + fz^{m-j+1})}{(z-1)(\vartheta - z)}, \tag{4.5}$$

where

$$\begin{aligned} a &= -\left(1 + \vartheta + \tau\frac{\theta'}{m}\frac{\vartheta^{m-1}-1}{\vartheta-1} + (1-\tau)\frac{\theta'}{m}\vartheta^{j-2}\right), \\ c &= \tau\frac{\theta'}{m}\vartheta^{m-1}, \\ d &= (1-\tau)\frac{\theta'}{m}\vartheta^{j-1}, \\ f &= -(1-\tau)\frac{\theta'}{m}\vartheta^{j-2}, \\ b &= -1 - a + c + d + f = \vartheta + \psi(\vartheta). \end{aligned}$$

From Lemma 4.2 we have that $0 > b > -1$.

We now describe the eigenvalues of DF by analyzing the roots of

$$h(z) = p(z)(z-1)(\vartheta - z) = z^{m+1} + az^m + bz^{m-1} - (c + dz^{m-j} + fz^{m-j+1}),$$

noticing that we have introduced artificial roots at $z = \vartheta, 1$, which do not correspond to eigenvalues of DF. Since DF cannot have positive real eigenvalues, double roots at these two values of z cannot occur.

The equation $h(z) = 0$ is not amenable to analytic solution, and we first study the two extreme cases $\tau = 1$, corresponding to homogeneous disease spread, and $\tau = 0$, corresponding to the situation where only age-class j can spread the disease.

4.1. Homogeneous disease transmission. For homogeneous disease transmission, $\sigma_k = \tau_k = 1$, the reproduction ratio simplifies to $R_0 = \gamma$, and from Proposition 3.1, we know that an internal (endemic) equilibrium exists exactly when $R_0 > 1$, while a disease-free equilibrium exists only when $R_0 < 1$. The picture is clear in that we can prove the following result.

PROPOSITION 4.5. *When disease spread is age-independent and $\gamma > 1$, the endemic equilibrium is always locally stable.*

The proof naturally breaks into two lemmas.

LEMMA 4.6. *If disease transmission is independent of age $\sigma_k = \tau_k = 1$, then the eigenvalues of the Jacobian DF cannot lie on the unit circle.*

Proof. When $\tau = 1$, the coefficients d and f vanish, and the equation $h(z) = 0$ simplifies to

$$z + a + bz^{-1} = cz^{-m}, \tag{4.6}$$

where the coefficients a and c are

$$a = -\left(1 + \vartheta + \psi(\vartheta)\frac{\vartheta^{m-1} - 1}{\vartheta^m - 1}\right),$$
$$c = \psi(\vartheta)\frac{\vartheta^m - \vartheta^{m-1}}{\vartheta^m - 1}.$$

Taking the absolute value of both sides of the equation, we find that roots of unit length $z = e^{i\omega}$ must satisfy the equation

$$((1 + b)\cos\omega + a)^2 + (1 - b)^2 \sin^2\omega = c^2.$$

Using the fact that $a + b + 1 = c$, the equation simplifies to

$$(\cos\omega - 1)[2a(1 + b) + 4b(1 + \cos\omega)] = 0.$$

Clearly $z = 1$ solves (4.6). However, (4.6) was obtained by multiplying the characteristic equation by $(z - 1)$ to simplify the expression. We have already observed that DF has no positive real eigenvalues, excluding the possibility of an eigenvalue at $z = 1$. Characteristic roots of unit length $z = e^{i\omega}$ are therefore possible only if

$$\cos\omega = -1 - \frac{a(b + 1)}{2b},$$

and thus it suffices to show that

$$\frac{a(b + 1)}{2b} > 0.$$

Since we know that $0 > b > -1$, we need only show that $a < 0$.

To see that $a < 0$, observe that

$$-a = 1 + \vartheta + \psi(\vartheta)\frac{1 - \vartheta^{m-1}}{1 - \vartheta^m}$$
$$> 1 + \vartheta + \psi(\vartheta) > 0.$$

We conclude that roots of the characteristic polynomial cannot cross the unit circle in the case of homogeneous mixing, completing the proof of Lemma 4.6.

LEMMA 4.7. *If disease transmission is independent of age $\tau_k = \sigma_k = 1$, then for large epidemics ($\vartheta \ll 1$) all eigenvalues of DF lie within the unit circle.*

Proof. At $\vartheta = 0$, the characteristic polynomial (and, in fact, the entire model!) is singular in the sense that 0 is a root of multiplicity m, and we apply a singular perturbation analysis to the characteristic equation. For ϑ small, $\psi(\vartheta) \approx \vartheta \log\vartheta$, so that (4.6) may be written in the form

$$z^{m+1} - (1 - \vartheta\log\vartheta)z^m + \vartheta\log\vartheta z^{m-1} - \vartheta^{m-1}\log\vartheta = 0, \tag{4.7}$$

where we have retained only the terms of leading order. By inspection, it is clear that the equation has the following $m+1$ approximate solutions: $z=1$, $z=\vartheta\log\vartheta$, and $z=w_k\vartheta, k=1,\dots,m-1$, where w_k denotes the $m-1$ roots of unity solving the equation $w^{m-1}=1$. Since (4.7) must have exactly $m+1$ complex solutions, our list is exhaustive. During our simplification of the characteristic polynomial we introduced additional roots at $z=1$ and $z=\vartheta$, and we conclude that the remaining $m-1$ solutions are in fact the eigenvalues of DF, all of which lie well within the unit circle.

Since, by the implicit function theorem, solutions of the characteristic equation are continuous in ϑ, Lemmas 4.6 and 4.7 immediately give us Proposition 4.5.

4.2. Age-dependent transmissibility. We now return to the situation where age-class j, $j\geq 2$, can infect at full strength $\tau_j=1$, while all other age-classes infect with reduced strength $\tau_k=\tau$, $k\neq j$. We first study the extreme case of $\tau=0$ and show the following result.

PROPOSITION 4.8. *If only age-class j, $j\geq 2$, can infect, then the endemic equilibrium is always unstable.*

From an intuitive viewpoint the proposition is quite simple. Since all hosts are equally susceptible, an epidemic will reduce the susceptible population in all age-classes by the same amount, and since the infective age-class j can no longer support an epidemic, neither can younger age-classes. Thus a new epidemic cannot arise before a new cohort has been born and has lived for j seasons, bringing it into the age-class where it is capable of infecting others. We now offer a formal proof.

Proof of Proposition 4.8. The proof follows the same method as that of Proposition 4.5, and we first show that roots of the characteristic polynomial cannot cross the unitcircle. For $\tau=0$, the equation $h(z)=0$ simplifies to

$$z+a+bz^{-1}=z^{-j}(d+zf),$$

where $a=-\left(1+\vartheta+\psi(\vartheta)/\vartheta\right)$, $b=\vartheta+\psi(\vartheta)$, $d=\psi(\vartheta)$, and $f=-\psi(\vartheta)/\vartheta$. Since age-classes $j+1,\dots,m$ do not contribute to disease transmission, the corresponding variables span an $(m-j)$-dimensional generalized nullspace, so that we need to identify only $j-1$ eigenvalues (plus the two roots at $z=1,\vartheta$). As in Lemma 4.6, we can derive a necessary condition for the existence of roots of unit length $z=e^{i\omega}$ and find that ω must satisfy the equation

$$\begin{aligned}\cos\omega &= -1-\frac{a(b+1)-df}{2b}\\ &= -1+\frac{\left(1+\vartheta+\frac{\psi(\vartheta)}{\vartheta}\right)\left(1+\vartheta+\psi(\vartheta)\right)-\frac{\psi(\vartheta)^2}{\vartheta}}{2(\vartheta+\psi(\vartheta))}\\ &= -1+\frac{\frac{(1+\vartheta)^2}{\vartheta}}{2}>1,\end{aligned}$$

excluding the existence of such roots.

It remains to see that there exists one value of ϑ for which the equation has solutions outside the unit circle. This may be done by studying small ϑ, as in Lemma 4.7. One finds that the leading terms of the $j+1$ nonzero roots of $h(z)$ are ϑ, $\log\vartheta$, and the $j-1$ roots of unity solving $w^{j-1}=1$. Clearly the root near $\log\vartheta$ lies outside the unit circle.

For fixed ϑ, the endemic equilibrium is stable for $\tau=1$ and unstable for $\tau=0$, so by the continuity of the characteristic roots, destabilization occurs for an intermediate value of $\tau=\tau_B$. Our analysis cannot exclude the possibility of multiple stability

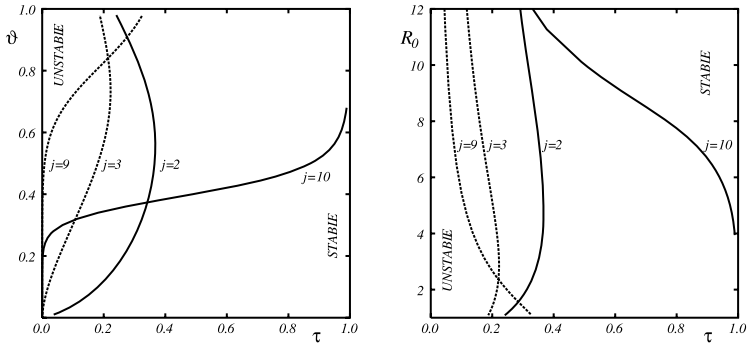

FIG. 4.1. *The location of the critical value $\tau = \tau_B$ for which the endemic equilibrium loses its stability. The parameter τ gives the strength of disease transmission from all age-classes except the highly infective age-class j. The value of τ_B is determined by numerically solving the modified characteristic equation $h(z) = 0$ using Laguere's method* [36]*, excluding the artificial solutions at $z = 1$ and applying a bisection method (in τ-space) to locate the value for which the largest solution is of unit length. The number of age-classes is fixed at $m = 10$. The left-hand panel shows the diagram in (τ, ϑ)-space, which is used in the analysis. The right-hand panel shows the diagram in (τ, R_0)-space, which is more natural for biological interpretation.*

switches, but numerical investigations of the equation $h(z) = 0$ indicate that such switches do not occur. Figure 4.1 shows τ_B for various j and $m = 10$. Clearly odd and even j lead to qualitatively different stability regions; furthermore, for odd j the bifurcation seems to be always a Hopf-type bifurcation through a pair of complex eigenvalues, while the bifurcation for even j is a flip bifurcation through an eigenvalue of -1. Since the age-structure of disease transmission is chosen for its mathematical convenience rather than for biological reasons, the phenomenon probably has no biological significance.

5. Nonequilibrium dynamics. In addition to the endemic equilibrium, more complicated dynamics may occur, and we finish our discussion of the school model with some examples of these complications.

For $m = 3$, i.e., three age-classes, the underlying dynamics is 2-D. Using the methods of [6], we have studied in some detail the case of age-independent susceptibility for $\tau_3 = 1$ and $\gamma = 5$. The analysis is quite similar to that of [6], so we only sketch the results; details of the analysis and the exact location of the bifurcations may be found in [19].

Figure 5.1 shows the main features of the bifurcations for $\tau_1 = 0.1$. The structure is most easily explained by starting at high values of τ_2, i.e., with the lower right-hand panel of Figure 5.1. For $\tau_2 = 0.60$ the endemic equilibrium is stable. When τ_2 is decreased, the equilibrium undergoes a Hopf bifurcation, giving rise to a stable limit-cycle, e.g., for $\tau_2 = 0.53$. As τ_2 decreases further, the limit-cycle degenerates, in that a segment of the limit-cycle meets the region of state space where no epidemic occurs, and three "arms" are created, $\tau_2 = 0.32$. Numerical simulations suggest that the dynamics on this attractor is chaotic, in that the trajectories of neighboring points diverge. In addition, the third iterate of F undergoes a saddle-node bifurcation, creating a stable and an unstable 3-cycle. As τ_2 decreases even more, the unstable 3-cycle meets the three "arms" on the chaotic attractor; a segment of the "arms" now lies in the basin of attraction for the stable triennial-annual cycle, and the chaotic attractor loses its stability.

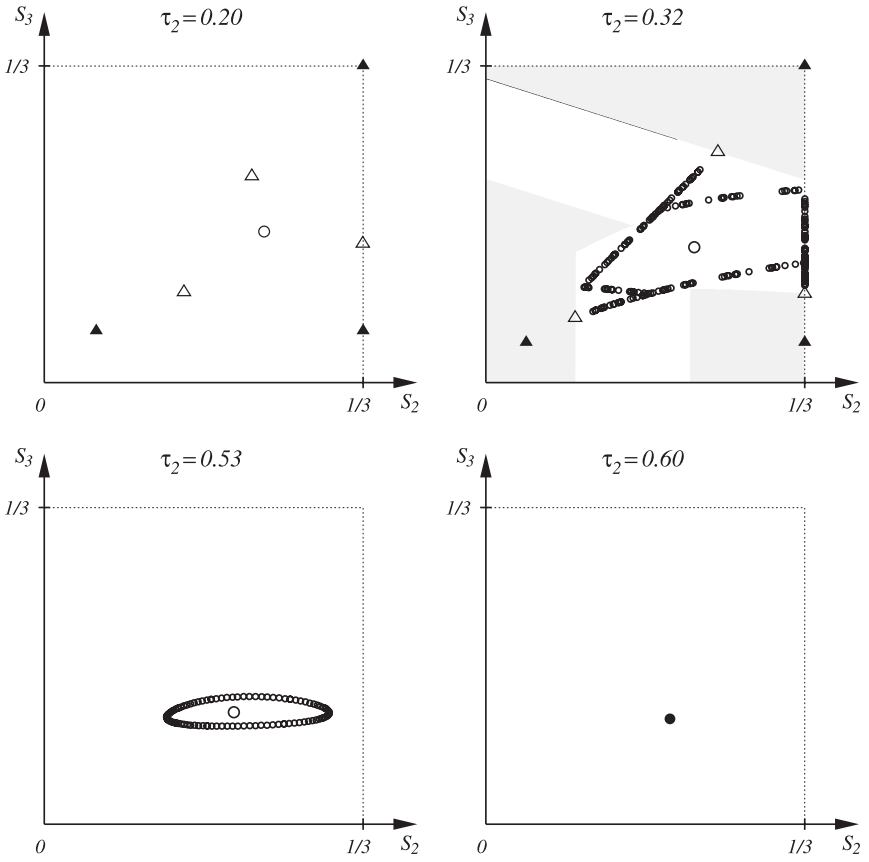

FIG. 5.1. *Trajectories and equilibria for the map F, showing the bifurcations that give rise to the complicated dynamics for $m = 3$. In all panels $\gamma = 5$, $\tau_1 = 0.1$, and $\tau_3 = 1$. For $\tau_2 = 0.60$ the endemic equilibrium is stable. For $\tau = 0.53$ the endemic equilibrium is unstable, and a stable periodic (or quasi-periodic) cycle is created through a Hopf bifurcation. For $\tau_2 = 0.32$ the limit cycle has met the boundary, and "arms" appear on the cycle. In addition, a stable and an unstable 3-cycle have appeared through a saddle-node bifurcation of the third iterate F^3. Notice that the "arms" of the attractor almost touch the unstable 3-cycle. The stable attractor will disappear in a global bifurcation for slightly smaller τ_2, and for $\tau_2 = 0.20$ the stable 3-cycle is globally stable. Other symbols: ○ endemic equilibrium; △ three-cycle. Filled marks indicate that the point is stable; open marks indicate that the point is unstable. For $\tau_2 = 0.32$ the shaded area indicates the basin of attraction for the stable 3-cycle.*

The dynamics of the model appears to be similar—but not identical—to those of the "realistic age-structured models" based on Schenzle's approach where the transfer of infection from season to season is accounted for explicitly [42, 10]. Figure 5.2 shows the bifurcation diagrams for model (2.10) and for a modified version of Schenzle's model. Schenzle's original model does not assume proportionate mixing in disease transmission, so it is not directly comparable to the present model. In addition, Schenzle assumes that births and deaths are distributed evenly over the year, and he accounts in detail for changes in disease transmission in response to school closure during weekends and breaks. In the modified model we neglect the seasonal variation in transmission and set the transmission coefficient from cohort j to cohort k to

$$\beta_{jk} = R_0 b_j b_k N \nu,$$

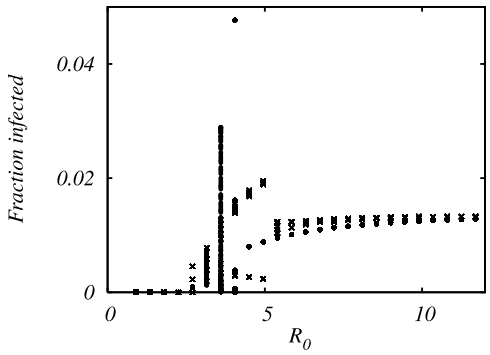

FIG. 5.2. *Bifurcation diagram showing the fraction of the host population that is infected in a season as a function of the basic reproduction number R_0. Crosses: model* (2.10)*; dots: a modified version of Schenzle's "realistic age-structured model," where the size of the infection is carried over between seasons; for details see the text.*

where

$$b_k = \begin{cases} \sqrt{0.5} & \text{for } 1 \le k \le 6, \\ 1 & \text{for } 7 \le k \le 10, \\ \sqrt{3.5/9.0} & \text{for } 11 \le k \le 20, \\ \sqrt{1/3} & \text{for } k = 21. \end{cases}$$

Here $k = 21$ is Schenzle's adult age-class. The strange values of b_k are chosen to ensure that the values of $\beta_{kk} = b_k^2$ are identical to those used by Schenzle. Following Schenzle, we assume that new individuals are born susceptible and at a constant rate during the year, while deaths occur only in the adult class and at a constant rate corresponding to a mean residence time of 55 years. To compare this "Schenzle" model to model (2.10), we have set $\tau_k = \sigma_k = b_k$ and included a total of $m = 75$ cohorts. Clearly the carry-over of infection from one season to the next has significant impact on the dynamics for small values of R_0, suggesting that stochastic effects during the summer break may play a role in this situation.

6. Discussion. The school model gives a somewhat different picture of disease transmission dynamics than that of the well-known SIR-model [24, 3]. In the present model the disease appears after the introduction of a new susceptible cohort, it produces an epidemic, and disappears, quite similarly to our everyday experience of epidemic diseases such as measles and influenza. The role of the school-year, class-progression, and admission of new students is quite explicit. The emphasis is on the dynamics of the age-specific herd immunity rather than on the virus population as such. Consequently the model does not address the question of disease persistence during periods of low disease transmission. In fact, we are assuming that the virus population will survive between epidemics in some unspecified reservoir. The model, for example, could describe transmission dynamics in a medium-sized town or island that is fairly well connected to a large city. This suggests a way to separate the non-linear transmission dynamics during periods of high transmission from the persistence problem where the stochastic effects due to the finite population size may play a significant role [21]. In the case of isolated island populations it will allow us to separate the (stochastic) arrival of an index case from the subsequent transmission dynamics during the epidemic; we are currently exploring this issue.

Since the endemic equilibrium appears to be stable unless the age-dependent variation in transmissibility is unrealistically pronounced, our findings do not corroborate Schenzle's [42] suggestion that the remarkably stable two-year cycle of measles epidemics in many urban areas is caused by the uptake of new susceptible hosts immediately after the summer break. Still we have not explored the entire parameter space, and in particular we have not studied the effect of age-dependent susceptibility in any detail, so a final conclusion awaits further investigations.

In the model, focus is on the slow year-to-year time scale, neglecting the details within the epidemic season, and the model does not give information about the precise onset of the epidemic. In some way this may be an advantage, since the exact timing of the epidemics may depend on specific geographic details of the meta-population in question [17]. However, measles epidemics tend to last several months, and it has been suggested that the exact timing of school breaks may in fact influence the dynamics of childhood diseases [41]. The present model, of course, is not designed to capture such subtleties.

Similarly to other epidemic models, we identified a basic reproduction number R_0 giving the number of secondary infections per primary infection in a susceptible population and showed that when $R_0 > 1$ there exists an endemic equilibrium. When disease transmission is independent of age, this equilibrium is always stable, but when infectivity is concentrated in just one age-class, the equilibrium is unstable. These results parallel those for the SIR-model with continuous aging of the host population, where the endemic equilibrium is stable for homogeneous disease transmission and short duration of infection [4] but may lose stability when disease transmission is age-dependent [5, 43, 27]. It is remarkable that the stability results are considerably easier to obtain for the present model than they were for the PDE model with continuous age-progression.

In the unstable region of parameter-space, the dynamics can be quite complicated, with multiple stable states, complicated attractors, and an unusual global bifurcation. These features are due to the model formulation in which the dynamics are governed by a differential equation for a period followed by a discrete map. Such hybrid models have become increasingly common in biology and epidemiology [35, 39, 40], and also general results on "time scale calculus" are available [1]. Usually the models do not exhibit as complicated behavior as the present model. However, in time scale calculus—as in most specific applications—one assumes that the dynamics follows the differential equation model for a *finite time*, ensuring that the composite map is in fact smooth. In contrast, for our epidemic model the fast time scale in effect runs over the entire time interval $(-\infty, +\infty)$. Smoothness of the map is no longer guaranteed, and in fact our map is continuous but nondifferentiable along the hyperplane defining the epidemic threshold. In addition, our map is constant below the threshold, allowing for a "folding" that seems to be responsible for the observed chaotic dynamics. It is unclear how one might extend time scale calculus to include such dynamics.

WAVELET MIE REPRESENTATIONS FOR SOLENOIDAL VECTOR FIELDS WITH APPLICATIONS TO IONOSPHERIC GEOMAGNETIC DATA*

THORSTEN MAIER†

Abstract. A wavelet technique, the wavelet Mie representation, is introduced for the analysis and modeling of the earth's magnetic field and corresponding electric current distributions from geomagnetic data obtained within the ionosphere. The considerations are essentially based on two well-known geomathematical keystones, (i) the Helmholtz decomposition of spherical vector fields and (ii) the Mie representation of solenoidal vector fields in terms of poloidal and toroidal parts. The wavelet Mie representation is shown to provide an adequate tool for geomagnetic modeling in the case of ionospheric magnetic contributions and currents which exhibit spatially localized features. An important example is ionospheric currents flowing radially onto or away from the earth. To demonstrate the functionality of the approach, such radial currents are calculated from vectorial data of the MAGSAT and CHAMP satellite missions.

1. Introduction.

Macroscopic electrodynamics is the theoretical basis for dealing with the subject of satellite magnetometry in geomagnetism. The fundamental equations governing that branch are Maxwell's equations for polarizable media. Since typical time-scales in satellite magnetometry are on the order of days and typical length-scales are on the order of the earth's radius, the typical system velocities are much smaller than the speed of light, and therefore the quasi-static (or stationary) approximations of Maxwell's equations (i.e., the pre-Maxwell equations) can be used (cf., e.g., [2]). As far as the magnetic field is concerned, these equations read

$$\nabla \cdot b = 0,$$
$$\nabla \wedge b = \mu_0 j,$$

where b (in classical geophysical notation usually denoted by $\vec{B}$) is the magnetic induction, i.e., the magnetic field; j is the electric current density; and μ_0 is the vacuum permeability, $\mu_0 = 4\pi \cdot 10^{-7}\mathrm{VsA}^{-1}\mathrm{m}^{-1}$. Note that, in this approximation, the electric current density j is also of zero divergence, i.e.,

$$\nabla \cdot j = 0.$$

Many concepts in geomagnetic modeling assume that the geomagnetic data are solely collected within a spherical shell $\Omega_{(R_1,R_2)}$ around the origin—with inner radius R_1 and outer radius R_2—between the earth's surface and the ionosphere, so that the current density j can be neglected. This results in $\nabla \wedge b = 0$, $\nabla \cdot b = 0$, which implies

that there exists a scalar potential U in $\Omega_{(R_1,R_2)}$ such that $b = -\nabla U$ and $\Delta U = 0$ in $\Omega_{(R_1,R_2)}$. In order to model the magnetic field b the potential is expanded into a Fourier series of (scalar) spherical harmonics and the expansion coefficients are chosen such that the gradient of the potential fits—in the sense of a least-square metric—the given vectorial data as well as possible. This method, which is known as Gauss representation, has been used and constantly improved for more than 150 years now, so that profound numerical and theoretical techniques exist (see, e.g., [23]).

Satellite missions (like MAGSAT, Oersted, and CHAMP) collect their data *within* the ionosphere. Due to the intense solar radiation on the earth's dayside (i.e., the hemisphere directed to the sun), the electric conductivity of the ionosphere is increased, and tidal forces, due to solar heating as well as solar and lunar attraction, can drive large electric current systems. Among the most important ionospheric current systems are the so-called equatorial electro jet (EEJ) and the polar electro jets (PEJ), as well as the so-called field aligned currents that are flowing radially towards and away from the geomagnetic poles. In connection with polarization effects in the ionospheric plasma, the geomagnetic field produces an enhanced Hall conductivity (Cowling effect) in the vicinity of the geomagnetic equator. This increased conductivity results in an amplified current system—the EEJ—flowing roughly along the magnetic equator. With regard to our later considerations, it is worth mentioning that the EEJ, though mainly tangential, also provides a notable radial current density, which is known as the radial contribution of the meridional current system of the EEJ. The PEJ is mainly due to an increased conductivity and large horizontal electric field contributions in the polar ionosphere. Currents flowing along the geomagnetic field lines—the field aligned currents—are caused by magnetospheric and ionospheric coupling or imbalances of Sq-current systems (see, e.g., [29] and the references therein). In the polar regions field aligned currents flow onto or away from the earth's body, thus contributing large radial current densities confined to these areas. The radial currents and the resulting magnetic effects, as well as the corresponding modeling approaches, are increasingly the focus of research (see, for example, in chronological order, [30], [34], [9], [23], [29], [11], [4], [27], [31], and [35]). The numerical examples presented in this article also deal with the determination of such radial ionospheric currents from geomagnetic vectorial satellite data.

Due to the electric currents, the magnetic field measured by satellites in the ionosphere is no longer a gradient-field. In fact, it now contains magnetic contributions from current densities on the satellite's track. But this means that new vectorial methods, not based on the existence of a scalar potential, must be derived in close orientation on a (quasi-static) formulation of Maxwell's equations. The authors of [1], [2], [18], [34] suggest the resolution of the magnetic field by means of the Mie representation as an adequate replacement of the Gauss approach. The Mie representation, i.e., splitting the magnetic field into poloidal and toroidal parts, has the advantage that it can equally be applied in regions of vanishing as well as nonvanishing electric current densities. The poloidal fields are due to toroidal current densities below and above the satellite's track, whereas the toroidal fields are created by the radial currents which are crossing the satellite's orbit. It is this characteristic that makes the Mie approach a powerful tool for dealing with geomagnetic source problems, i.e., the problems of calculating magnetic effects due to given electric currents (direct source problem) and, conversely, determining those current distributions that produce a predefined magnetic field (inverse source problem).

There remains the question of how to computationally obtain, in terms of suitable trial functions, the Mie representation from a given set of vectorial data. Most

of the considerations in [1], [2] and all the results in [11], [25], [29] are based on a spherical harmonic parametrization; i.e., the starting points of the considerations are expansions of the poloidal and toroidal scalars in terms of spherical harmonics. On the one hand, this approach is advantageous since it admits the possibility of incorporating radial dependencies of magnetic fields and electric currents in a natural way. On the other hand, the global support of the spherical harmonics limits the practicability of this technique since it cannot cope with electric currents (and corresponding magnetic effects) that vary rapidly with latitude or longitude or that are confined to certain regions. In fact, Backus [1] states that it might be advantageous to find a field parametrization in terms of functions that take efficient account of the specific concentration of the current densities in space. The uncertainty principle (see the scalar theory by Freeden and Windheuser [17] and their generalization to the vector case by Beth [5]) provides an adequate tool for the classification of (spherical restrictions of) poloidal and toroidal vector fields by determining a trade-off between two "spreads," one for the position (space) and the other for the momentum (frequency). The main statement is that sharp localizations in space and in frequency are mutually exclusive. The varieties of space/frequency localization can be illustrated by considering different poloidal and toroidal trial fields on the sphere as suitable for constructive approximation. Vector (spherical) harmonics show an ideal frequency localization but no space localization. The spectrum of (band-limited and non–band-limited) kernel functions known from harmonic and vectorial spline theory (cf. [12], [33], [14], [15]) shows all intermediate cases of space/frequency localization. But in view of the amount of space/frequency localization, it is also worth distinguishing band-limited from non–band-limited kernels. As a matter of fact, it turns out that non–band-limited kernels show a much stronger space localization than their comparable band-limited counterparts. Roughly speaking, this is due to the fact that band-limited kernels can be represented as finite sums of polynomials and therefore—though strongly smoothed compared to polynomial functions—tend to oscillate. In contrast, non–band-limited kernels cannot be displayed as finite sums of polynomials and hence yield a stronger space localization. Finally, the Dirac kernels show ideal space localization but no frequency localization. Thus they provide the final stage in the spatial resolution of the magnetic field by trial functions. In conclusion, vector harmonics and Dirac kernels are "extreme trial functions" for purposes of geomathematical modeling. These facts help us to find a suitable characterization and categorization of the trial functions for modeling and approximation: Fourier methods (in terms of scalar/vector spherical harmonics, for example) are the canonical starting point for obtaining an approximation of low frequency contributions (global modeling), while band-limited kernel functions can be used for the intermediate cases between long and short wavelengths (global to regional modeling). Due to their extreme space localization, non–band-limited kernels can be utilized to deal with short wavelength phenomena (local modeling). Most data show correlation in space as well as in frequency, and the kernel functions with their simultaneous space and frequency localization allow for the efficient detection and approximation of essential features in the data by using only a fraction of the original information (decorrelation). Using kernels at different scales (*multiscale modeling*), the corresponding approximation techniques can be constructed so as to be suitable for the particular data situation.

In this article we are concerned with *wavelet techniques* for the parametrization of the Mie representation, i.e., methods based on certain classes of kernel functions, the *scaling functions and wavelets*. Suitably constructed wavelets admit a basis property in certain function spaces, the elements of which—the data functions—admit a series

representation in terms of a structured sequence of kernels at different positions and at different scales (*multiscale approximation*). It is thus possible to break up complicated functions like the geomagnetic field, electric current densities, or geopotentials into different pieces and to study these pieces separately. Consequently, the efficiency of wavelets lies in the fact that only a few wavelet coefficients are needed in areas where the data are smooth, and in regions where the data exhibit more complicated features, higher resolution approximations can be derived by "zooming-in" with more and more wavelets of higher scales and consequential stronger space localization.

The outline of the paper is as follows. In section 2 the fundamentals, such as necessary notation and representation theorems for vector fields (the Helmholtz decomposition theorem for spherical and the Mie representation theorem for solenoidal vector fields) are presented. In section 3 we recapitulate how the Mie representation can be applied in satellite magnetometry in order to interpret different source terms and their geomagnetic effects. In section 4 scalar and vectorial scaling functions and wavelets for the analysis of square-integrable scalar and vectorial spherical functions are introduced. In section 5 the Helmholtz decomposition theorem is utilized to combine the wavelet techniques and the Mie representation of the geomagnetic field into what is called the *wavelet Mie representation*. The resulting method of data analysis is illustrated in section 6, where the wavelet Mie representation is used to calculate radial ionospheric current distributions from the toroidal geomagnetic contributions extracted from MAGSAT and CHAMP vectorial data sets.

2. Fundamentals.

2.1. Notation and preliminaries. In order to avoid notational complications we will, unless stated otherwise, use the following scheme: Scalar fields will be denoted by capital roman letters (F, G, etc.), while vector fields are symbolized by lower-case roman letters (f, g, etc.).

A sphere of radius R centered in the origin, i.e., the set $\{x \in \mathbb{R}^3 : |x| = R\}$, will be denoted by Ω_R. In particular, $\Omega(= \Omega_1)$ is the unit sphere in $\mathbb{R}^3$. A spherical shell with inner radius R_1 and outer radius R_2, $R_2 > R_1 > 0$, is given by $\Omega_{(R_1,R_2)} = \{x \in \mathbb{R}^3 : R_1 \le |x| \le R_2\}$. Any element $x \in \mathbb{R}^3$ with $|x| \neq 0$ may be written in the form $x = r\xi$, where $r = |x|$ and $\xi = \frac{x}{r} \in \Omega$, $\xi = (\xi_1, \xi_2, \xi_3)^T$, is the uniquely determined directional unit vector of x. Using this separation, the gradient ∇ in $\mathbb{R}^3$ reads

$$\nabla_x = \xi \frac{\partial}{\partial r} + \frac{1}{r} \nabla^*_\xi,$$

where the horizontal part ∇^* is the *surface gradient* on the unit sphere Ω. Moreover, the Laplace operator $\Delta = \nabla \cdot \nabla$ in $\mathbb{R}^3$ has the representation

$$\Delta_x = \left(\frac{\partial}{\partial r} \right)^2 + \frac{2}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \Delta^*_\xi,$$

where Δ^* is the *Beltrami operator* on the unit sphere Ω. The *surface curl gradient* L^* on Ω can be calculated from ∇^* by the relation $L^*_\xi = \xi \wedge \nabla^*_\xi$, $\xi \in \Omega$ (where "$\wedge$" denotes the usual cross product).

A function is said to be of class $\mathcal{C}^{(k)}(\Omega_R)$, $0 \le k < \infty$, if it possesses k continuous derivatives on Ω_R. The set $c^{(k)}(\Omega_R)$, $0 \le k < \infty$, denotes the space of k-times continuously differentiable vector fields on Ω_R. The Hilbert spaces of measurable square-integrable scalar and vector fields on the sphere Ω_R are denoted by $\mathcal{L}^2(\Omega_R)$

and $l^2(\Omega_R)$, respectively. Let $H_n : \mathbb{R}^3 \to \mathbb{R}$ be a homogeneous harmonic polynomial of degree n; then the restriction $Y_n = H_n|_\Omega$ is called a (scalar) spherical harmonic of degree n. The space of all spherical harmonics of degree n is of dimension $2n+1$. Spherical harmonics of different degrees are orthogonal in the sense of the $\mathcal{L}^2(\Omega)$-inner product

$$(Y_n, Y_m)_{\mathcal{L}^2(\Omega)} = \int_\Omega Y_n(\xi) Y_m(\xi) d\omega(\xi) = 0, \quad n \neq m.$$

Throughout the remainder of this work, we denote by $\{Y_{n,k}\}$, $n = 0, 1, \ldots$, $k = 1, \ldots, 2n+1$, a complete orthonormal system in the Hilbert space $\mathcal{L}^2(\Omega)$. It is obvious that $\{Y^{R_1}_{n,k}\}$, $n = 0, 1, \ldots$, $k = 1, \ldots, 2n+1$, with $Y^{R_1}_{n,k} = \frac{1}{R_1} Y_{n,k}$ denotes an $\mathcal{L}^2(\Omega_{R_1})$-orthonormal system. Let $F \in \mathcal{C}^{(0_i)}(\Omega)$; then the operators $o^{(i)}_\xi : \mathcal{C}^{(0_i)}(\Omega) \to c(\Omega)$ are given by

$$\begin{aligned} o^{(1)}_\xi F(\xi) &= \xi F(\xi), \qquad \xi \in \Omega, \\ o^{(2)}_\xi F(\xi) &= \nabla^*_\xi F(\xi), \quad \xi \in \Omega, \\ o^{(3)}_\xi F(\xi) &= L^*_\xi F(\xi), \quad \xi \in \Omega, \end{aligned}$$

where 0_i is an abbreviation given by $0_1 = 0$ and $0_i = 1$ for $i \in \{2, 3\}$. Clearly, $o^{(1)}_\xi F(\xi)$ is a radial field. From the definitions of the operators ∇^* and L^* it is easy to see that $o^{(2)}_\xi F(\xi)$ and $o^{(3)}_\xi F(\xi)$ are purely tangential. Furthermore, $o^{(2)}_\xi F(\xi)$ is curl-free, whereas $o^{(3)}_\xi F(\xi)$ is divergence-free, which is clear from $\nabla^*_\xi F(\xi)$ being a gradient- and $L^*_\xi F(\xi)$ being a curl-field. Additionally, it is not difficult to see that

$$o^{(i)}_\xi F(\xi) \cdot o^{(j)}_\xi F(\xi) = 0 \quad \text{for all } i \neq j, \quad i, j \in \{1, 2, 3\}.$$

Using a complete system of scalar spherical harmonics, we are able to introduce a complete orthonormal set $\{y^{(i)}_{n,k}\}$ of vector spherical harmonics in $l^2(\Omega)$ (e.g., see [15]):

$$y^{(i)}_{n,k} = (\mu^{(i)}_n)^{-1/2} o^{(i)} Y_{n,k}, \tag{2.1}$$

$i = 1, 2, 3$, $n \in \mathbb{N}_{0_i}$, $k = 1, \ldots, 2n+1$. The normalization factor is chosen to be

$$\mu^{(i)}_n = \begin{cases} 1 & \text{if} \quad i = 1, \\ n(n+1) & \text{if} \quad i = 2, 3. \end{cases}$$

2.2. Helmholtz decomposition and Mie representation. The wavelet Mie representations are based on two main results for the decomposition of vector fields: the Helmholtz decomposition of spherical vector fields and the Mie representation of solenoidal vector fields. We start with the *Helmholtz decomposition theorem* (cf. [15]), as follows.

THEOREM 2.1. *Let $f \in c^{(1)}(\Omega)$. Then there exist uniquely determined scalar functions $F_1 \in \mathcal{C}^{(1)}(\Omega)$ and $F_2, F_3 \in \mathcal{C}^{(2)}(\Omega)$ satisfying*

$$\int_\Omega F_i(\xi) d\omega(\xi) = 0, \quad i = 2, 3,$$

such that

$$f = \sum_{i=1}^{3} o^{(i)} F_i.$$

It should be mentioned that F_1 is just the radial projection of f, while representations for the Helmholtz scalars F_2 and F_3 are available in terms of the Green function with respect to the Beltrami operator (cf. [15]). Note that the above theorem is also valid for vector fields on Ω_R, since they are isomorphic to those on Ω.

In addition to the Helmholtz representation presented above, we will make use of the so-called Mie representation for solenoidal vector fields. A vector field f on an open subset $\mathcal{U} \subset \mathbb{R}^3$ is called solenoidal if and only if the integral $\int_S f(x) \cdot \nu(x) d\omega(x)$ vanishes for every closed surface S lying entirely in U (ν denotes the outward normal of S). Every such solenoidal vector field admits a representation in terms of two uniquely defined scalar functions by means of the *Mie representation theorem* (e.g., [1, 2, 18, 32]), which follows.

THEOREM 2.2. *Let $0 < R_1 < R_2$, and let $f : \Omega_{(R_1,R_2)} \to \mathbb{R}^3$ be a solenoidal vector field in the spherical shell $\Omega_{(R_1,R_2)}$. Then there exist unique scalar functions $P_f, Q_f : \Omega_{(R_1,R_2)} \to \mathbb{R}$ such that*

(1) $\int_{\Omega_r} P_f(x) d\omega_r(x) = \int_{\Omega_r} Q_f(x) d\omega_r(x) = 0$,

(2) $f = \nabla \wedge LP_f + LQ_f$

for all $r \in (R_1, R_2)$ with the operator L given by $L_x = x \wedge \nabla_x$.

Vector fields of the form $\nabla \wedge LP_f$ are called poloidal, while vector fields of the form LQ_f are denoted toroidal. For the sake of completeness we present the following theorem (cf. [2]).

THEOREM 2.3. *Let $0 < R_1 < R_2$, and let $f : \Omega_{(R_1,R_2)} \to \mathbb{R}^3$ be a solenoidal vector field in the spherical shell $\Omega_{(R_1,R_2)}$. Then there exist a unique poloidal field p as well as a unique toroidal field t such that*

$$f = p + t$$

in $\Omega_{(R_1,R_2)}$.

For our further considerations it is important that, for each $x = r\xi$ with $R_1 < r < R_2$ and $\xi \in \Omega$, the Mie representation $f = \nabla \wedge LP_f + LQ_f$ can be rewritten as

$$f(r\xi) = \xi \frac{\Delta_\xi^* P_f(r\xi)}{r} - \nabla_\xi^* \frac{\partial_r r P_f(r\xi)}{r} + L_\xi^* Q_f(r\xi) \tag{2.2}$$

(cf., e.g., [1, 2, 25, 29]), where we have used the abbreviation $\partial_r = \partial/\partial r$. (Actually, with regard to the second term, it is mathematically correct to write

$$\left(\frac{\partial}{\partial \tilde{r}} \tilde{r} P_f(\tilde{r}\xi) \right) \Big|_{\tilde{r}=r}.$$

We avoid this awkward notation, however, and stick to the easy nomenclature.) Note that (2.2) is the Helmholtz decomposition of the Mie representation of f and links the previously defined vector spherical harmonics to the Mie representation of vector fields.

Finally, we mention the following last result, which is concerned with the curl of a Mie representation.

COROLLARY 2.4. *Let $f, g : \Omega_{(R_1,R_2)} \to \mathbb{R}^3$ be two solenoidal vector fields with representations*

$$f = \nabla \wedge LP_f + LQ_f,$$
$$g = \nabla \wedge LP_g + LQ_g,$$

and which are connected via $\nabla \wedge f = \lambda g$, $\lambda \in \mathbb{R} \setminus \{0\}$. *Then the Mie scalars are related via*

$$P_g = \frac{1}{\lambda} Q_f,$$
$$Q_g = -\frac{1}{\lambda} \Delta P_f.$$

This shows us that the curl of a poloidal field is a toroidal field, and vice versa.

3. The (geo)magnetic field in Mie representation. If we assume the typical length- and time-scales of the magnetic field b and the electric current densities j to be such that retarding effects (and displacement currents) are negligible, then we can consider the quasi-static approximation of Maxwell's equations, the pre-Maxwell equations, to be valid:

$$\nabla \cdot b = 0,$$
$$\nabla \wedge b = \mu_0 j,$$

where μ_0 is the vacuum permeability. Since the magnetic field is divergence-free everywhere, it can be split up into a poloidal and a toroidal part (see Theorem 2.2):

$$b = b_{pol} + b_{tor} = \nabla \wedge L P_b + L Q_b. \tag{3.1}$$

The quasi-static approximation being true is equivalent to the current densities being divergence-free everywhere. Consequently the electric currents also admit a Mie representation:

$$j = j_{pol} + j_{tor} = \nabla \wedge L P_j + L Q_j. \tag{3.2}$$

According to Corollary 2.4 the Mie scalars of the magnetic field and the electric currents are related via

$$P_j = \frac{1}{\mu_0} Q_b, \tag{3.3}$$

$$Q_j = -\frac{1}{\mu_0} \Delta P_b. \tag{3.4}$$

Using (2.2), we can, for each $x = r\xi$ with $r \neq 0$ and $\xi \in \Omega$, rewrite (3.1) and (3.2) as

$$b = \xi \frac{\Delta_\xi^* P_b}{r} - \nabla_\xi^* \frac{\partial_r r P_b}{r} + L_\xi^* Q_b \tag{3.5}$$

and

$$j = \xi \frac{\Delta_\xi^* P_j}{r} - \nabla_\xi^* \frac{\partial_r r P_j}{r} + L_\xi^* Q_j. \tag{3.6}$$

The first two terms in (3.5) and (3.6) can be interpreted as the restriction of the poloidal magnetic field b_{pol} and the poloidal currents j_{pol}, respectively, to the sphere Ω_r. The last terms represent the toroidal field b_{tor} and currents j_{tor} on Ω_r. These equations will serve as a starting point for the wavelet Mie representations in section 5.

Following Backus [1], Engels and Olsen [11], and Maus [25], we assume either the geomagnetic field b or the electric current distributions j to be sampled within

a spherical shell $\Omega_{(R_1,R_2)}$, $0 < R_1 < R_2 < \infty$. This assumption takes into account elliptical satellite orbits as well as the decrease in altitude with the lifetime of the satellite. The geomagnetic field within the shell $\Omega_{(R_1,R_2)}$ consists of four different parts (cf. [29]), i.e.,

$$b = b_{pol}^{int} + b_{pol}^{ext} + b_{pol}^{sh} + b_{tor}.$$

b_{pol}^{int} denotes the poloidal magnetic field due to internal toroidal currents in the region with $r < R_1$. b_{pol}^{ext} is the poloidal part caused by external toroidal current densities in the region with $r > R_2$, and b_{pol}^{sh} is the poloidal magnetic field due to the toroidal electric currents within $\Omega_{(R_1,R_2)}$. Finally, b_{tor} is the toroidal part of b generated by poloidal currents in $\Omega_{(R_1,R_2)}$. If there are no currents in the shell $\Omega_{(R_1,R_2)}$, then $b_{pol}^{sh} = b_{tor} = 0$, and b can be represented as the gradient-field of a scalar harmonic potential or by means of the Mie representation equivalently. If only the toroidal currents vanish within the shell, then $b_{pol}^{sh} = 0$, and the magnetic field within the shell can be represented by

$$b = b_{pol}^{int} + b_{pol}^{ext} + b_{tor}. \tag{3.7}$$

The situation changes if the toroidal currents within the shell $\Omega_{(R_1,R_2)}$ do not vanish. Let us suppose that the radii of the shell satisfy

$$R_2 - R_1 \ll \frac{R_2 + R_1}{2},$$

i.e., the thickness of the shell is small compared to the mean radius. Such a shell is called a *thin shell*. As pointed out by Backus [1] and Olsen [29], even for non-vanishing (toroidal) current densities in the shell, the magnetic field within a thin shell can (approximately) be represented by (3.7), i.e., the poloidal field b_{pol}^{sh} tends to zero in thin shells, while the toroidal part b_{tor} remains finite. Actually, for thin shells, it holds that $b_{pol}^{sh} \to 0$ as $(R_2 - R_1)/H \to 0$, where H is a reference length characterizing the vertical scale of the current density (e.g., [1], [29]). In more detail, if in a thin shell,

$$R_2 - R_1 \ll H \simeq \frac{R_2 + R_1}{2},$$

i.e., the current density changes significantly on vertical scales that can be compared to the mean radius and that are much larger than the thickness of the shell, then the thin shell approximation (3.7) is surely valid. If, in a thin shell,

$$R_2 - R_1 \simeq H \ll \frac{R_2 + R_1}{2},$$

i.e., the currents change significantly on vertical length scales that are small compared to the mean radius but that can be compared to the thickness of the shell, then the thin shell approximation can fail as well. For more details the interested reader is directed to [1]. In what follows we assume the thin shell approximation to be valid (which is a reasonable assumption for the examples presented in section 6; see, e.g., [29] and [25]).

At this point, there remains the question of how to numerically obtain—in terms of suitable trial functions—the Mie representation of a given set of vectorial data.

As we have already mentioned, the global support of the spherical harmonics limits the practicability of spherical harmonic parametrizations since most of the relevant ionospheric currents vary rapidly with latitude and longitude and/or are confined to certain regions. Consequently, it seems reasonable to find a field parametrization in terms of functions that take efficient account of the specific concentration of the current densities in space. In [4] we have already presented first methods to deal with the Mie representation in terms of space-localizing trial functions, so-called spherical vectorial wavelets, which are able to reflect various levels of space localization (see also [3]). The techniques developed in section 5 are generalizations and enhancements of this approach. For a complete and comprehensive description, the interested reader is directed to the thesis [24].

4. Scaling functions and wavelets in $\mathcal{L}^2(\Omega)$ and $l^2(\Omega)$. As far as this article is concerned, it suffices to introduce scaling functions and wavelets for the spaces of square-integrable scalar and vector fields on the unit sphere, i.e., $\mathcal{L}^2(\Omega)$ and $l^2(\Omega)$. This theory is well known since, starting from classical wavelet theory (see, e.g., [7] and [6] for an overview), the concept of multiresolution has been adapted to spherical geometries for scalar fields by, e.g., Freeden and Windheuser [16], [17] and, for vector fields, by Bayer, Beth, and Freeden [3] and Freeden, Gervens, and Schreiner [15], for example. We therefore just repeat some results which are useful for our further considerations as follows.

DEFINITION 4.1. *A real sequence $\{(\Phi_J)^\wedge(n)\}$, $J \in \mathbb{Z}$, $n \in \mathbb{N}_0$, is called a generator (or symbol) of an $\mathcal{L}^2(\Omega)$-scaling function if it satisfies*

(i) $\sum_{n=0}^{\infty} \left((\Phi_J)^\wedge(n)\right)^2 < \infty$,
(ii) $\sum_{n=0}^{\infty} \left((\Phi_J)^\wedge(n) Y_{n,k}(\xi)\right)^2 < \infty$ *for all* $\xi \in \Omega$,
(iii) $\lim_{J\to\infty} \left((\Phi_J)^\wedge(n)\right)^2 = 1$, $n \in \mathbb{N}$,
(iv) $\left((\Phi_J)^\wedge(n)\right)^2 \geq \left((\Phi_{J-1})^\wedge(n)\right)^2$,
(v) $\lim_{J\to-\infty} \left((\Phi_J)^\wedge(n)\right)^2 = 0$,
(vi) $\left((\Phi_J)^\wedge(0)\right)^2 = 1$, $J \in \mathbb{Z}$.

The corresponding family $\{\Phi_J\}$ of kernels given by

$$\Phi_J(\xi,\eta) = \sum_{n=0}^{\infty} \sum_{k=1}^{2n+1} (\Phi_J)^\wedge(n) Y_{n,k}(\xi) Y_{n,k}(\eta), \qquad \xi,\eta \in \Omega,$$

is called $\mathcal{L}^2(\Omega)$-scaling function.

Wavelets come into play via the refinement equation, as in the following.

DEFINITION 4.2. *The real sequence $\{(\Psi_J)^\wedge(n)\}$, $J \in \mathbb{Z}$, $n \in \mathbb{N}_0$, defined via the refinement equation*

$$(\Psi_J)^\wedge(n) = \left(\left((\Phi_{J+1})^\wedge(n)\right)^2 - \left((\Phi_J)^\wedge(n)\right)^2\right)^{\frac{1}{2}},$$

is called the generator (or symbol) of the $\mathcal{L}^2(\Omega)$-wavelet $\{\Psi_J\}$ given as

$$\Psi_J(\xi,\eta) = \sum_{n=0}^{\infty} \sum_{k=1}^{2n+1} (\Psi_J)^\wedge(n) Y_{n,k}(\xi) Y_{n,k}(\eta), \qquad \xi,\eta \in \Omega.$$

The concept of scaling functions and wavelets can also be carried over to the vectorial case as in the following.

DEFINITION 4.3. *Let, for $i \in \{1,2,3\}$, the real sequence $\{(\varphi_J^{(i)})^\wedge(n)\}$, $J \in \mathbb{Z}$, $n \in \mathbb{N}_{0_i}$, be generators of $\mathcal{L}^2(\Omega)$-scaling functions; then the vectorial kernels*

$$\varphi_J^{(i)}(\xi,\eta) = \sum_{n=0_i}^{\infty} \sum_{k=1}^{2n+1} (\varphi_J^{(i)})^\wedge(n) Y_{n,k}(\xi) y_{n,k}^{(i)}(\eta) \tag{4.1}$$

are called $l^2(\Omega)$-scaling functions of type i. The $l^2(\Omega)$-wavelets of type i are given by

$$\psi_J^{(i)}(\xi,\eta) = \sum_{n=0_i}^{\infty} \sum_{k=1}^{2n+1} (\psi_J^{(i)})^\wedge(n) Y_{n,k}(\xi) y_{n,k}^{(i)}(\eta), \tag{4.2}$$

with generators $\{(\psi_J^{(i)})^\wedge(n)\}$ satisfying the refinement equation

$$(\psi_J^{(i)})^\wedge(n) = \left(\left((\varphi_{J+1}^{(i)})^\wedge(n) \right)^2 - \left((\varphi_J^{(i)})^\wedge(n) \right)^2 \right)^{\frac{1}{2}}.$$

With these definitions at hand, we can find approximations of $\mathcal{L}^2(\Omega)$ and $l^2(\Omega)$ functions in terms of the respective scaling functions and wavelets (e.g., [16]).

THEOREM 4.4. *Let the families $\{\Phi_J\}$, $\{\Psi_J\}$ be $\mathcal{L}^2$-scaling functions and wavelets. For any $F \in \mathcal{L}^2(\Omega)$ it holds that*

$$F = \Phi_{J'} * \Phi_{J'} * F + \sum_{J=J'}^{\infty} \Psi_J * \Psi_J * F \tag{4.3}$$

$$= \Phi_0 * \Phi_0 * F + \sum_{J=0}^{\infty} \Psi_J * \Psi_J * F, \tag{4.4}$$

where the convolution operator "$*$" for scalar kernels and functions is defined by

$$K * F = \int_\Omega K(\cdot,\eta) F(\eta)\, d\omega(\eta).$$

In the case of vector fields $f \in l^2(\Omega)$ it is possible to show the following (cf. [3]).

THEOREM 4.5. *Let the families $\{\varphi_J^{(i)}\}$, $\{\psi_J^{(i)}\}$ be vectorial scaling functions and wavelets. Then, for $f \in l^2(\Omega)$,*

$$f = \sum_{i=1}^{3} \varphi_{J'}^{(i)} \star \varphi_{J'}^{(i)} * f + \sum_{J=J'}^{\infty} \sum_{i=1}^{3} \psi_J^{(i)} \star \psi_J^{(i)} * f \tag{4.5}$$

$$= \sum_{i=1}^{3} \varphi_0^{(i)} \star \varphi_0^{(i)} * f + \sum_{J=0}^{\infty} \sum_{i=1}^{3} \psi_J^{(i)} \star \psi_J^{(i)} * f, \tag{4.6}$$

where the convolution "$*$" of a vectorial kernel against a vector field is given as

$$k * f = \int_\Omega k(\cdot,\eta) \cdot f(\eta)\, d\omega(\eta),$$

and the convolution "$\star$" of a vectorial kernel against a scalar field is

$$k \star F = \int_\Omega k(\eta,\cdot) F(\eta)\, d\omega(\eta).$$

The representations of square-integrable scalar and vectorial functions in terms of scaling functions and wavelets build one of the fundamentals for our considerations in the next section. It is noteworthy that the vectorial wavelets are defined in correspondence to the vector spherical harmonics in section 2.1 and can therefore be linked to the Mie representation via (2.2), (3.5), and (3.6), which is the task of the next section.

It should be remarked that, in the case of F being one of the Mie-scalars, the first term in (4.4) vanishes, since the Mie-scalars have vanishing zeroth order moment. A similar argument holds true for the case of f being the magnetic field or the electric current density; i.e., since both are of zero divergence, the first term in (4.6) vanishes.

Before we go on, we mention some properties of the above kernel functions (scaling functions and wavelets) which are important from a numerical point of view. Let K and $k^{(i)}$ be either scalar scaling functions or wavelets, or vectorial scaling functions or wavelets, respectively. Using the addition theorem for spherical harmonics, each scalar kernel K admits the following representation:

$$\begin{aligned} K(\xi,\eta) &= \sum_{n=0}^{\infty}\sum_{k=1}^{2n+1} (K)^\wedge(n) Y_{n,k}(\xi) Y_{n,k}(\eta) \\ &= \sum_{n=0}^{\infty} (K)^\wedge(n) \frac{2n+1}{4\pi} P_n(\xi\cdot\eta), \end{aligned}$$

where P_n is the Legendre polynomial of degree n. For the evaluation of such series of Legendre polynomials there exist fast and stable recursive algorithms (e.g., [8]).

In the case of vectorial kernels, the situation is only slightly more complicated. From the definition of the vector spherical harmonics and the vectorial kernel functions (see (2.1), (4.1), and (4.2)) we see that

$$k^{(i)}(\xi,\eta) = \sum_{n=0_i}^{\infty}\sum_{k=1}^{2n+1} (k^{(i)})^\wedge(n)\, Y_{n,k}(\eta)\, (\mu_n^{(i)})^{-\frac{1}{2}}\, o_\xi^{(i)} Y_{n,k}(\xi) \tag{4.7}$$

$$= o_\xi^{(i)} \sum_{n=0_i}^{\infty}\sum_{k=1}^{2n+1} (k^{(i)})^\wedge(n)\, Y_{n,k}(\eta)\, (\mu_n^{(i)})^{-\frac{1}{2}}\, Y_{n,k}(\xi) \tag{4.8}$$

$$= o_\xi^{(i)} \sum_{n=0_i}^{\infty} \frac{2n+1}{4\pi}\, (k^{(i)})^\wedge(n)\, (\mu_n^{(i)})^{-\frac{1}{2}}\, P_n(\xi\cdot\eta). \tag{4.9}$$

For $\eta\in\Omega$ fixed, the Legendre polynomials are isotropic functions on the unit sphere and the $o^{(i)}$ can be applied. This results in

$$o_\xi^{(1)} P_n(\xi\cdot\eta) = \xi P_n(\xi\cdot\eta), \tag{4.10}$$

$$o_\xi^{(2)} P_n(\xi\cdot\eta) = (\eta - (\xi\cdot\eta)\,\xi)\; P_n'(\xi\cdot\eta), \tag{4.11}$$

$$o_\xi^{(3)} P_n(\xi\cdot\eta) = (\xi\wedge\eta)\, P_n'(\xi\cdot\eta)\,. \tag{4.12}$$

Using this, the kernels in (4.9) admit the representation

$$k^{(1)}(\xi,\eta) = \xi \sum_{n=0}^{\infty} \frac{2n+1}{4\pi}\, (k^{(i)})^\wedge(n)\, (\mu_n^{(i)})^{-\frac{1}{2}}\, P_n(\xi\cdot\eta), \tag{4.13}$$

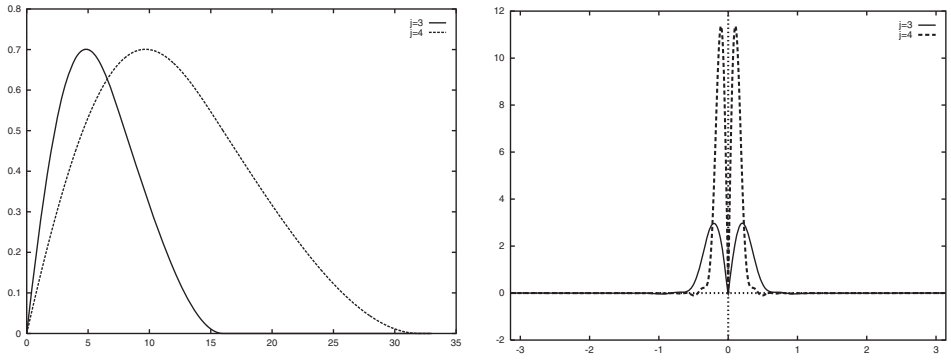

FIG. 1. *Left: Generators of CuP wavelets of scales* 3 *and* 4. *Right: Cross section through the corresponding CuP wavelets of scales* 3 *and* 4. *Note that an increasing scale leads to a decreasing localization in the Fourier domain (generator) but to an increasing localization in the space domain.*

$$k^{(2)}(\xi,\eta) = (\eta - (\xi\cdot\eta)\,\xi)\sum_{n=1}^{\infty}\frac{2n+1}{4\pi}\,(k^{(i)})^{\wedge}(n)\,(\mu_n^{(i)})^{-\frac{1}{2}}\,P_n'(\xi\cdot\eta), \tag{4.14}$$

$$k^{(3)}(\xi,\eta) = (\xi\wedge\eta)\sum_{n=1}^{\infty}\frac{2n+1}{4\pi}\,(k^{(i)})^{\wedge}(n)\,(\mu_n^{(i)})^{-\frac{1}{2}}\,P_n'(\xi\cdot\eta) \tag{4.15}$$

such that the fast and stable one-dimensional recursive algorithms can also be used for calculating the vectorial kernels. It should be noted that, if the kernel functions are non–band-limited (nondegenerate), the sums in the above equations need to be truncated if no analytic representations for the kernels are known.

For later use we present, as a certain choice of possible kernels, the vectorial cubic polynomial (CuP) wavelets, which can be derived by using a generator of the form

$$\varphi_0^{(i)}(x) = \begin{cases} (1-x)^2(1+2x), & x\in[0,1),\\ 0, & x\in[1,\infty). \end{cases}$$

The left-hand side of Figure 1 shows generators of CuP wavelets of scales 3 and 4, while the right-hand side presents cross sections of the corresponding CuP wavelets. It is obvious that—with increasing scale—the localization in the Fourier domain (generators) decreases, while the localization in the space domain (wavelets) increases. Figure 2 provides illustrations of tangential CuP vectorial wavelets in the longitude-latitude plane. Note again that the significant support of the wavelets decreases with increasing scale, a feature typical for wavelets. It is this property that, via the wavelet Mie representation, allows for the analysis and modeling of spatially confined structures in the geomagnetic field and the corresponding current distributions.

5. Wavelet Mie parametrizations. In what follows we restrict ourselves to the wavelet parametrization of toroidal magnetic fields and the corresponding poloidal electric current densities in the spherical shell $\Omega_{(R_1,R_2)}$. This case is sufficient for the applications presented in section 6. For details on the wavelet parametrization of poloidal magnetic fields, the reader may consult our treatise in [24]. This approach, however, requires the introduction of inner and outer harmonic wavelets (e.g., [13]), which is beyond the scope of this article.

The starting point for our considerations is a separation of variables for the

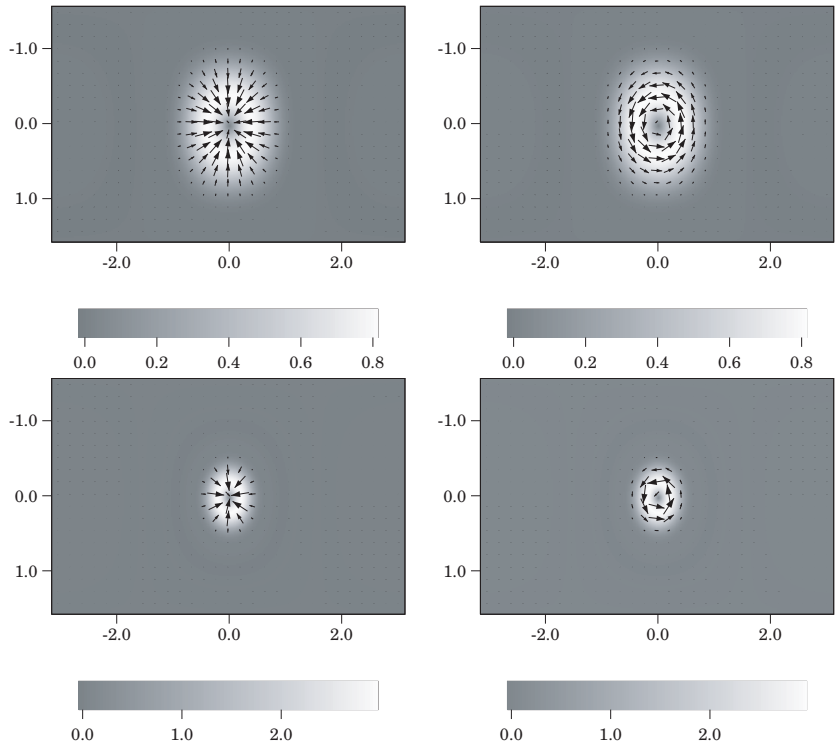

FIG. 2. *CuP wavelets in the longitude-latitude plane. Arrows indicate direction and shading indicates magnitude. Top: Curl-free ($i = 2$, left) and divergence-free ($i = 3$, right) CuP wavelets at scale $j = 2$. Bottom: Curl-free ($i = 2$, left) and divergence-free ($i = 3$, right) CuP wavelets at scale $j = 3$. Note how the increasing scale leads to a sharper localization in the space domain.*

toroidal field scalar Q_b; i.e., we assume that

$$Q_b(r\xi) = Q_{b,1}(r)Q_{b,2}(\xi) \quad \text{in } \Omega_{(R_1,R_2)}. \tag{5.1}$$

Relation (3.3) suggests proceeding likewise in the case of the scalar P_j for the poloidal currents, and hence we suppose that

$$\begin{aligned} P_j(r\xi) &= P_{j,1}(r)P_{j,2}(\xi) \\ &= \frac{1}{\mu_0} Q_{b,1}(r)Q_{b,2}(\xi) \quad \text{in } \Omega_{(R_1,R_2)}. \end{aligned}$$

The results of section 4 yield that the angular parts $Q_{b,2}$ and $P_{j,2}$ can be expanded in terms of scalar spherical $\mathcal{L}^2(\Omega)$-wavelets $\{\Psi_J\}$; i.e.,

$$Q_{b,2} = \sum_{J=0}^{\infty} \Psi_J * \Psi_J * Q_{b,2}, \tag{5.2}$$

$$P_{j,2} = \sum_{J=0}^{\infty} \Psi_J * \Psi_J * P_{j,2}. \tag{5.3}$$

Combining this with (3.1)–(3.2) and (3.5)–(3.6), we can come up with the following representations for the toroidal magnetic field and the corresponding poloidal current density.

THEOREM 5.1. *Let, for $J \in \mathbb{Z}$, $\{\Psi_J\}$ be an $\mathcal{L}^2(\Omega)$-wavelet. Under the assumptions above, the toroidal magnetic field in $\Omega_{(R_1,R_2)}$ can be represented via*

$$b_{tor}(r\cdot) = Q_{b,1}(r)\left(\bar{\varphi}^{(3)}_{J'} \star \Phi_{J'} * Q_{b,2} + \sum_{J=J'}^{\infty} \bar{\psi}^{(3)}_J \star \Psi_J * Q_{b,2}\right) \tag{5.4}$$

$$= Q_{b,1}(r)\left(\bar{\varphi}^{(3)}_0 \star \Phi_0 * Q_{b,2} + \sum_{J=0}^{\infty} \bar{\psi}^{(3)}_J \star \Psi_J * Q_{b,2}\right) \tag{5.5}$$

$$= Q_{b,1}(r) \sum_{J=0}^{\infty} \bar{\psi}^{(3)}_J \star \Psi_J * Q_{b,2}, \tag{5.6}$$

where the vectorial kernels $\bar{\varphi}^{(3)}_J$ and $\bar{\psi}^{(3)}_J$ are given via $\bar{\varphi}^{(3)}_J(\xi,\eta) = L^*_\xi \Phi_J(\xi,\eta)$ and $\bar{\psi}^{(3)}_J(\xi,\eta) = L^*_\xi \Psi_J(\xi,\eta)$. The corresponding poloidal current density in $\Omega_{(R_1,R_2)}$ is given by

$$\mu_0 j_{pol}(r\cdot) = \frac{1}{r} Q_{b,1}(r)\left(\tilde{\varphi}^{(1)}_{J'} \star \Phi_{J'} * Q_{b,2} + \sum_{J=J'}^{\infty} \tilde{\psi}^{(1)}_J \star \Psi_J * Q_{b,2}\right) \tag{5.7}$$

$$+ \left(\partial_r + \frac{1}{r}\right) Q_{b,1}(r)\left(\hat{\varphi}^{(2)}_{J'} \star \Phi_{J'} * Q_{b,2} + \sum_{J=J'}^{\infty} \hat{\psi}^{(2)}_J \star \Psi_J * Q_{b,2}\right) \tag{5.8}$$

$$= \frac{1}{r} Q_{b,1}(r)\left(\tilde{\varphi}^{(1)}_0 \star \Phi_0 * Q_{b,2} + \sum_{J=0}^{\infty} \tilde{\psi}^{(1)}_J \star \Psi_J * Q_{b,2}\right) \tag{5.9}$$

$$+ \left(\partial_r + \frac{1}{r}\right) Q_{b,1}(r)\left(\hat{\varphi}^{(2)}_0 \star \Phi_0 * Q_{b,2} + \sum_{J=0}^{\infty} \hat{\psi}^{(2)}_J \star \Psi_J * Q_{b,2}\right) \tag{5.10}$$

$$= \frac{1}{r} Q_{b,1}(r) \sum_{J=0}^{\infty} \tilde{\psi}^{(1)}_J \star \Psi_J * Q_{b,2} \tag{5.11}$$

$$+ \left(\partial_r Q_{b,1}(r) + \frac{1}{r} Q_{b,1}(r)\right) \sum_{J=0}^{\infty} \hat{\psi}^{(2)}_J \star \Psi_J * Q_{b,2}, \tag{5.12}$$

where the kernel functions $\tilde{\varphi}^{(1)}_J$ and $\hat{\varphi}^{(2)}_J$ as well as $\tilde{\psi}^{(1)}_J$ and $\hat{\psi}^{(2)}_J$ are defined to be $\tilde{\varphi}^{(1)}_J(\xi,\eta) = \xi \Delta^*_\xi \Phi_J(\xi,\eta)$ and $\hat{\varphi}^{(2)}_J(\xi,\eta) = -\nabla^*_\xi \Phi_J(\xi,\eta)$, as well as $\tilde{\psi}^{(1)}_J(\xi,\eta) = \xi \Delta^*_\xi \Psi_J(\xi,\eta)$ and $\hat{\psi}^{(2)}_J(\xi,\eta) = -\nabla^*_\xi \Psi_J(\xi,\eta)$.

Proof. Equation (5.4) follows from (3.1), (3.5), and (5.2). Theorems 4.4 and 4.5 lead to (5.5). The fact that the magnetic field is of zero divergence everywhere implies—via the Gauss theorem—that the magnetic field has vanishing zeroth order moment (i.e., the magnetic field is solenoidal), which means that

$$Q_{b,1}(r)\left(\bar{\varphi}^{(3)}_0 \star \Phi_0 * Q_{b,2}\right) = 0.$$

Equations (5.7) and (5.8) follow from (3.2), (3.6), and (5.3) in combination with (3.4). Theorems 4.4 and 4.5 then imply (5.9) and (5.10). Since in the pre-Maxwell approximation the current density is solenoidal, too, it follows that

$$\frac{1}{r} Q_{b,1}(r)\left(\tilde{\varphi}^{(1)}_0 \star \Phi_0 * Q_{b,2}\right) = 0$$

and

$$\left(\partial_r + \frac{1}{r}\right) Q_{b,1}(r) \left(\hat{\varphi}_0^{(2)} \star \Phi_0 * Q_{b,2}\right) = 0. \qquad \square$$

Note that all of the kernel functions that appear in Theorem 5.1 can be calculated using the rules and results of (4.10)–(4.15), as well as the fact that scalar spherical harmonics of degree n are eigenfunctions of the Beltrami operator with respect to eigenvalues $-n(n+1)$.

Theorem 5.1 presents the wavelet Mie representation of the toroidal magnetic field and the corresponding poloidal electric currents in the spherical shell $\Omega_{(R_1,R_2)}$. Due to the space localization of the ansatz functions, this representation yields the possibility of using or deriving different models of Q_b in different regions, depending on the underlying physical effects and, of course, the data situation.

The ansatz (5.1) is quite simple and might fail if the radial dependency is very complex (see also the considerations in [25]). Nevertheless, assumption (5.1) is reasonable as long as the data situation is such that the radial behavior of the field is difficult to extract. This is arguably the case when using data from single satellite missions. (See also the comments in [1], [29], and [25] concerning time-variations and single satellite missions.) Nevertheless, if the data situation allows for determination of higher order radial dependencies (e.g., if data from multisatellite missions are used, or if measurements from satellites are combined with terrestrial observations), we might expand our ansatz by adding further toroidal scalars with different radial behavior (cf. [24]).

The product ansatz for the toroidal field scalar Q_b is reflected in the corresponding toroidal magnetic field as well as in the representation of the corresponding poloidal current density. As regards the poloidal current, both its radial and its tangential parts admit a product representation, too. In more detail, let j_{rad} and j_{∇^*} be the radial and the tangential parts, respectively, of j_{pol}. Then (5.11) and (5.12) of Theorem 5.1 show that j_{rad} and j_{∇^*} can be represented as

$$j_{rad}(r\xi) = J_{rad,1}(r) j_{rad,2}(\xi)$$

and

$$j_{\nabla^*}(r\xi) = J_{\nabla^*,1}(r) j_{\nabla^*,2}(\xi),$$

where the scalar functions $J_{rad,1}(r)$ and $J_{\nabla^*,1}(r)$ are given via

$$\begin{aligned} \mu_0 J_{rad,1}(r) &= \frac{1}{r} Q_{b,1}(r), \\ \mu_0 J_{\nabla^*,1}(r) &= \left(\partial_r Q_{b,1}(r) + \frac{1}{r} Q_{b,1}(r)\right) \end{aligned}$$

and the vectorial parts are

$$\begin{aligned} \mu_0 j_{rad,2} &= \sum_{J=0}^{\infty} \tilde{\psi}_J^{(1)} \star \Psi_J * Q_{b,2}, \\ \mu_0 j_{\nabla^*,2} &= \sum_{J=0}^{\infty} \hat{\psi}_J^{(2)} \star \Psi_J * Q_{b,2}. \end{aligned}$$

Using the ansatz (5.1) together with (3.6) immediately leads us to the same results for $J_{rad,1}$ and $J_{\nabla^*,1}$ but, with regard to $j_{rad,2}$ and $j_{\nabla^*,2}$, we end up with

$$\mu_0 j_{rad,2}(\xi) = \xi \Delta_\xi^* Q_{b,2}(\xi),$$

$$\mu_0 j_{\nabla^*,2}(\xi) = -\nabla_\xi^* Q_{b,2}(\xi),$$

which is independent from any parametrization of Q_b. Nevertheless, we know from section 4 that we can expand the radial vector field $\mu_0 j_{rad,2}$ and the tangential vector field $\mu_0 j_{\nabla^*,2}$ using vectorial $l^2(\Omega)$-wavelets $\{\psi_J^{(i)}\}$ of type $i = 1$ and $i = 2$, respectively. Consequently we are led to the following alternative representation in terms of $l^2(\Omega)$-wavelets.

COROLLARY 5.2. *Let the families $\{\varphi_J^{(i)}\}$, $\{\psi_J^{(i)}\}$, $i = 1, 2$, be vectorial scaling functions and wavelets. The radial part j_{rad} and tangential part j_{∇^*} of the poloidal current density can be represented via*

$$j_{rad}(r\cdot) = \varphi_{J'}^{(1)} \star \left(\varphi_{J'}^{(1)} * j_{rad}\right)(r) + \sum_{J=J'}^{\infty} \psi_J^{(1)} \star \left(\psi_J^{(1)} * j_{rad}\right)(r) \tag{5.13}$$

$$= \varphi_0^{(1)} \star \left(\varphi_0^{(1)} * j_{rad}\right)(r) + \sum_{J=0}^{\infty} \psi_J^{(1)} \star \left(\psi_J^{(1)} * j_{rad}\right)(r) \tag{5.14}$$

$$= \sum_{J=0}^{\infty} \psi_J^{(1)} \star \left(\psi_J^{(1)} * j_{rad}\right)(r) \tag{5.15}$$

$$= \frac{1}{r} Q_{b,1}(r) \sum_{J=0}^{\infty} \psi_J^{(1)} \star \psi_J^{(1)} * j_{rad,2} \tag{5.16}$$

$$= \sum_{J=0}^{\infty} \psi_J^{(1)} \star \left(\psi_J^{(1)} * j\right)(r) \tag{5.17}$$

and

$$j_{\nabla^*}(r\cdot) = \varphi_{J'}^{(2)} \star \left(\varphi_{J'}^{(2)} * j_{rad}\right)(r) + \sum_{J=J'}^{\infty} \psi_J^{(2)} \star \left(\psi_J^{(2)} * j_{rad}\right)(r) \tag{5.18}$$

$$= \varphi_0^{(2)} \star \left(\varphi_0^{(2)} * j_{rad}\right)(r) + \sum_{J=0}^{\infty} \psi_J^{(2)} \star \left(\psi_J^{(2)} * j_{rad}\right)(r) \tag{5.19}$$

$$= \sum_{J=0}^{\infty} \psi_J^{(2)} \star \left(\psi_J^{(2)} * j_{\nabla^*}\right)(r) \tag{5.20}$$

$$= \left(\partial_r + \frac{1}{r}\right) Q_{b,1}(r) \sum_{J=0}^{\infty} \psi_J^{(2)} \star \psi_J^{(2)} * j_{\nabla^*,2} \tag{5.21}$$

$$= \sum_{J=0}^{\infty} \psi_J^{(2)} \star \left(\psi_J^{(2)} * j\right)(r). \tag{5.22}$$

Note that (5.17) and (5.22) are true since only the poloidal current density contains a radial or ∇^*-contribution (see (3.6)). In other words, on each Ω_r with $R_1 < r < R_2$, the radial current density can be derived from expanding the total current density in terms of spherical vectorial wavelets of type $i = 1$, while the tangential

part of the poloidal current density can be calculated via spherical vectorial wavelets of type $i = 2$. Equations (5.15)–(5.22) can therefore be used to determine the toroidal field scalar or, of course, the corresponding toroidal magnetic field.

A similar approach can be applied in order to determine the poloidal current density j_{pol} in $\Omega_{(R_1,R_2)}$ from the corresponding toroidal field b_{tor}. Assuming the product ansatz for Q_b and applying (3.5), we see that the toroidal magnetic field admits a product representation as well, i.e.,

$$b_{tor}(r\xi) = B_{tor,1}(r)b_{tor,2}(\xi),$$

where $b_{tor,2} = L^*Q_{b,2}$ can be expressed in terms of spherical vectorial $l^2(\Omega)$-wavelets $\{\psi_J^{(3)}\}$ of type $i = 3$ as follows:

$$b_{tor,2} = \sum_{J=0}^{\infty} \psi_J^{(3)} \star \psi_J^{(3)} * b_{tor,2}.$$

From our previous results we know that the scalar $B_{tor,1}$ is just given by

$$B_{tor,1}(r) = Q_{b,1}(r).$$

Since the toroidal magnetic field b_{tor} is the only part of b that contributes an L^*-portion, it is clear that

$$\begin{aligned} b_{tor}(r\cdot) &= \sum_{J=0}^{\infty} \psi_J^{(3)} \star \left(\psi_J^{(3)} * b_{tor}\right)(r) \\ &= \sum_{J=0}^{\infty} \psi_J^{(3)} \star \left(\psi_J^{(3)} * b\right)(r) \end{aligned}$$

on any sphere Ω_r with $R_1 < r < R_2$. Summarizing the above considerations, we are led to the following claim.

COROLLARY 5.3. *Let the families $\{\varphi_J^{(3)}\}$ and $\{\psi_J^{(3)}\}$ be vectorial scaling functions and wavelets of type* 3. *The toroidal magnetic field b_{tor} can be represented via*

$$b_{tor}(r\cdot) = Q_{b,1}(r)\left(\varphi_{J'}^{(3)} \star \varphi_{J'}^{(3)} * b_{tor,2} + \sum_{J=J'}^{\infty} \psi_J^{(3)} \star \psi_J^{(3)} * b_{tor,2}\right) \tag{5.23}$$

$$= Q_{b,1}(r)\left(\varphi_0^{(3)} \star \varphi_0^{(3)} * b_{tor,2} + \sum_{J=0}^{\infty} \psi_J^{(3)} \star \psi_J^{(3)} * b_{tor,2}\right) \tag{5.24}$$

$$= Q_{b,1}(r) \sum_{J=0}^{\infty} \psi_J^{(3)} \star \psi_J^{(3)} * b_{tor,2} \tag{5.25}$$

$$= \sum_{J=0}^{\infty} \psi_J^{(3)} \star \left(\psi_J^{(3)} * b\right)(r) \tag{5.26}$$

on any sphere Ω_r with $R_1 < r < R_2$.

This yields one possible way of determining the poloidal field scalar (and consequently the corresponding poloidal electric current density) from magnetic measurements in $\Omega_{(R_1,R_2)}$.

Assuming that the data are given only at constant altitude (or with negligible radial dependencies), the previous approach can be easily applied to calculate radial

current densities on a sphere Ω_r, with $R_1 < r < R_2$, from measurements of the magnetic field on that very sphere. We assume that the magnetic field b is sampled on a dense grid on the sphere Ω_r. We make use of the fact that, with a suitably chosen maximum scale J_{max}, we can approximate the toroidal part b_{tor} on Ω_r via a series expansion in terms of $l^2(\Omega)$-wavelets (see Corollary 5.3):

$$b_{tor}(r\xi) \simeq \left(\sum_{J=0}^{J_{max}} \psi_J^{(3)} \star \left(\psi_J^{(3)} * b \right)(r) \right)(\xi).$$

Using the fact that $b_{tor}(r,\cdot) = L^* Q_b$, we immediately get an approximation for the toroidal scalar, i.e.,

$$Q_b(r\xi) \simeq \left(\sum_{J=0}^{J_{max}} \tilde{\Psi}_J * \left(\psi_J^{(3)} * b \right)(r) \right)(\xi), \tag{5.27}$$

where the kernel $\tilde{\Psi}_J$ is given such that the relation $\psi_J^{(3)}(\eta,\xi) = L_\xi^* \tilde{\Psi}_J(\eta,\xi)$ holds true. Using (5.27) together with (3.6), we arrive at an approximation of the radial current density on Ω_r corresponding to the toroidal magnetic field there:

$$\begin{aligned} \mu_0 j_{rad}(r\xi) &= \frac{1}{r} \xi \Delta_\xi^* Q_b(r\xi) \\ &\simeq \frac{1}{r} \left(\sum_{J=0}^{J_{max}} \tilde{\psi}_J^{(1)} \star \left(\psi_J^{(3)} * b \right)(r) \right)(\xi), \end{aligned} \tag{5.28}$$

with $\tilde{\psi}_J^{(1)}(\eta,\xi) = \xi \Delta_\xi^* \tilde{\Psi}_J(\eta,\xi)$. Note that this equation is just a different expression of a well known fact; i.e., the toroidal magnetic field at a certain altitude is solely due to the radial current distributions at that very height. Equation (5.28) is the starting point of the examples in the next section. It is noteworthy that, from a practical point of view, (5.28) can successfully be applied if the geomagnetic measurements available are sampled within a comparatively short period of time; i.e., the time-scale under consideration is such that the variations in the satellite's altitude can be neglected to some extent (cf. [27] and [24] for first applications). If the radial variations start to play a role, one can still neglect these variations if the data are appropriately preprocessed, i.e., if suitable geomagnetic field models are subtracted prior to the numerical applications (see, e.g., [28]).

6. Applications to geomagnetic satellite data. As examples of the wavelet Mie representation of the magnetic field, electric current distributions at satellite altitudes are determined from data sets of vectorial MAGSAT and CHAMP data. The method is based on our considerations in section 5, especially (5.28). The current distributions under consideration are due to ionospheric F region currents, which are extensively treated in the literature (see [29] and the references therein).

The data sets used in the first example are similar to those used by Olsen [29] for a spherical harmonic approach to the Mie representation and have kindly been made available by him. MAGSAT was orbiting the earth in a sun-synchronous orbit, thus acquiring data only at dawn and dusk local times. Neglecting the variations in altitude of the MAGSAT satellite, one month of MAGSAT data (centered at March 21, 1980) is transformed to geomagnetic components and is averaged onto the equiangular longitude-latitude grid (90×90 grid points) proposed in [10], which is then used to

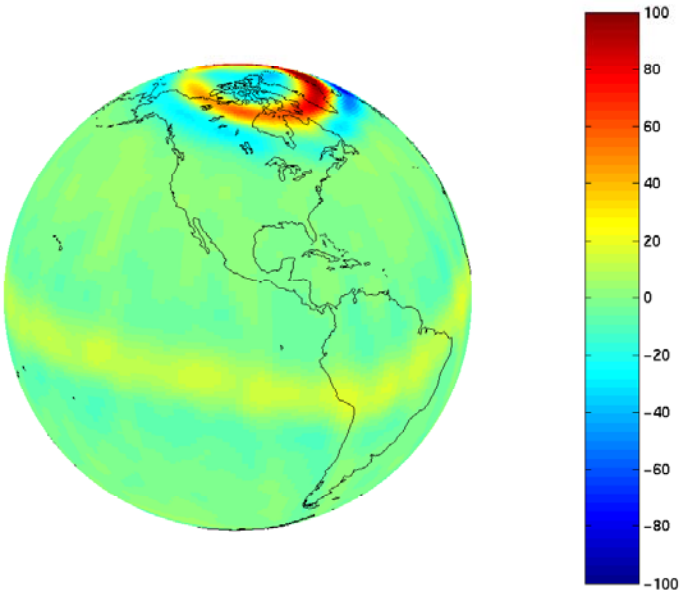

FIG. 3. *Radial current density during evening local time obtained from a wavelet Mie representation of MAGSAT data with vectorial CuP wavelets up to scale* 5. *[nA/m^2]*

discretize the convolution integrals. This averaging process is performed using a robust Tuckeys biweight method (cf. [19]). The dusk and dawn data are treated separately such that two separate data sets are obtained. Prior to the averaging process, a geomagnetic field model (GSFC(12/83) up to degree and order 12) due to [21] is subtracted from the measurements in order to avoid spurious effects due to the neglected altitude variations (cf. [29]).

According to (5.28), the radial current distribution at a fixed height can be calculated from the wavelet coefficients of the toroidal field at that altitude, i.e., $(\psi_J^{(3)} * b)(r)$. With regard to the present example, we calculate these coefficients by means of spherical vectorial CuP wavelets up to scale 5 from the evening data set. Then, in a second step, these coefficients are utilized to calculate the corresponding radial current distribution. Figure 3 shows the reconstruction of the radial current density $J_{rad} = (\xi \cdot j_{rad}(\xi))$. (Note that, for enhancing the visible features, the color scale has been driven in saturation; i.e., although there are currents with absolute values larger than 100 nano-Amperes per square meter (nA/m^2), we use a color bar ranging from -100 to 100 nA/m^2.)

The largest radial current densities ($|J_{rad}| \lesssim 150$ nA/m^2) are present in the polar regions. In agreement with the results in [29], the main current flow in the polar cap is directed into the ionosphere ($J_{rad} > 0$) during evening. At the poleward boundary of the polar oval the currents flow out of the ionosphere, while the main current direction is into the ionosphere at the equatorward boundary. At the magnetic dip equator one realizes comparatively weak upward currents ($|J_{rad}| \lesssim 25$ nA/m^2) accompanied by even weaker downward currents at low latitudes. These current distributions are the radial components of the so-called meridional current system of the EEJ. Figure 4 presents the same results as Figure 3 but in a different projection, thus enabling a better view of the meridional currents. As can be expected from theoretical considerations, the corresponding signatures follow the geomagnetic dip equator.

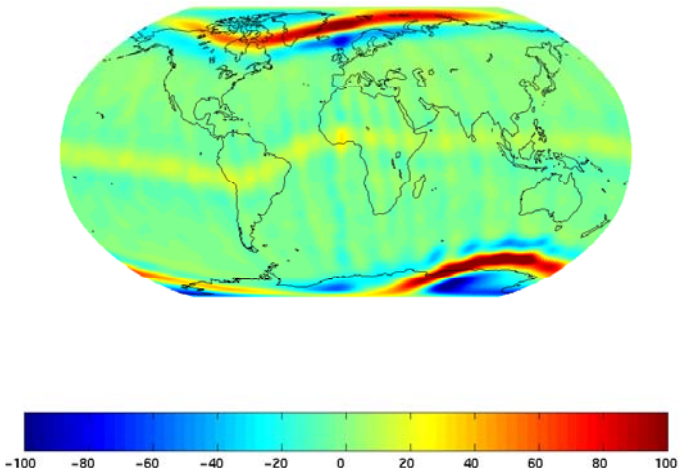

FIG. 4. *Radial current density during evening local time obtained from a wavelet Mie representation of MAGSAT data with vectorial CuP wavelets up to scale* 5. *[nA/m²]*

With regard to the convergence of our approach, there remains the question of how to find a suitable maximum scale J_{max} where the calculations should be stopped. Thus far, we have not investigated this matter in mathematical detail; nevertheless, our numerical results hint at a reasonably good convergence rate (see [16] for a first theoretical discussion). In this study, we use a heuristic way of determining a suitable maximum scale: Wavelet-approximations of the poloidal and toroidal parts of the magnetic field are calculated, added up, and then compared to the input magnetic field. As long as increasing the wavelet-scale reduces the residual, we have not yet reached the suitable maximum scale and, consequently, the corresponding toroidal coefficients should be used to calculate the associated details of the current distribution. In our numerical example this leads to a maximum wavelet-scale $J_{max} = 5$. If a wavelet-scale higher than 5 is chosen, one immediately realizes numerical artifacts in the detail information; e.g., the magnetic field and the electric currents reach unreasonably high peak values all along the satellite's tracks, and the detail information is dominated by spiky features. Though this method of determining the maximum scale is quite heuristic, we can also estimate a reasonable maximum scale using the Shannon sampling theorem. The Shannon sampling theorem tells us that the resolution of the features detectable in the data is limited, depending on the sampling rate of the data set. In the example above, we have used a 90×90 point equiangular grid. This corresponds to a resolvable horizontal wavelength of approximately 898 kilometers. In terms of spherical harmonics, this yields a maximum of approximately 43. Since our wavelets are constructed as linear combinations of spherical harmonics, the maximum scale of the wavelets is determined by this maximum degree. In the present example this estimated maximum wavelet-scale turns out to be 5, which is in accordance with our numerical results. Figures 5 and 6 show a multiresolution of the radial currents and illustrate the convergence of the approximation process up to wavelet-scale 5. The upper rows show the scale information of consecutive scales ($J = 0, 1, 2, 3$ in Figure 5, $J = 4, 5, 6$ in Figure 6), while the lower rows present the respective detail information. Note that adding the scale information and the details of corresponding scales leads to the scale information of the next higher scale, and so on. Though the typical structures of the polar field aligned currents and the EEJ

gradually start to become visible in the detail information of scale 3, it is obvious from the magnitude of the respective currents that the contributions of scales 4 and 5 are predominant.

In order to demonstrate the possibility of regional calculations, Figure 7 presents a reconstruction of the radial current systems during dusk local times over the polar region. These results are obtained using vectorial CuP wavelets of scales 4 and 5 (recall the predominance of these scales in Figures 5 and 6) and a data window centered at the geographic north pole with a half angle of 60° as well as an integration window with the same center but a half angle of 55° (the white border approximately illustrates the extent of the calculation region). The visualization window is a little smaller than the calculation window in order to suppress Gibbs phenomena. Comparing Figure 7 with Figure 3 shows that the structures of the radial currents are clearly visible

though slightly weaker in magnitude. This slight difference is due to the fact that we have omitted the contributions of wavelet-scales up to 3, i.e., features of coarse spatial resolution. The signatures seen in our results are the effects of higher wavelet-scales (4 and 5) and consequently are of more or less confined spatial extent. As might be expected from the physical point of view, these are clearly the main radial current contributions in the polar region. The effects of lower scales can be neglected. This, however, demonstrates the regional character of the radial current distributions and suggests the use of space-adaptive methods like the one presented here.

The results of the previous example illustrate the geometry of the ionospheric currents at a fixed (magnetic) local time, i.e., the Earth-satellite-Sun geometry was fixed during the process of data accumulation. The reader should be aware of the fact that the current distributions presented in Figures 3–7 do not illustrate the global distribution of the radial currents but show a small strip of the currents moving over the earth (along longitude) during the course of the day. This is because ionospheric current systems are not properly described in earth-fixed coordinate systems like geographic longitude and latitude. Since the conductance of the ionosphere is varying with the influence of the sun, the magnetic field induced by ionospheric currents is linked to the position of the sun and the distance of the observing satellite to the geomagnetic equator. Consequently, a sun-fixed reference frame should rather be used to parameterize ionospheric currents. Very advantageous, in that sense, is the coordinate system of magnetic local time $MLT \in [0, 24]$ (instead of longitude) and quasi-dipole latitude $QDlat \in [-90, 90]$. The magnetic local time thereby denotes the relative position of the satellite with respect to the magnetic field and the sun, while the quasi-dipole latitude gives the relative position of the satellite with respect to the geomagnetic equator. For more information on these coordinate systems, the reader might consult [22] and the references therein. In order to use MLT and QDlat as a parametrization, one needs to utilize geomagnetic data from satellites with polar but not sun-synchronous orbits thus covering the whole span of magnetic local times

(i.e., from 0 h to 24 h). The German geoscientific satellite CHAMP, operated by the GeoForschungsZentrum in Potsdam, Germany, is such a satellite. Among other instruments, the CHAMP satellite is equipped with high precision vector and scalar magnetometers and, in contrast to MAGSAT, covers all magnetic local times within four months. In what follows we present a result calculated by Mayer [26] analyzing a CHAMP data set via a wavelet Mie representation parameterized in QDlat and MLT. Three days of CHAMP vector data (September 10, 16, and 17, 2001) are used. In polar regions these data suffice to cover the whole span of magnetic local times (see [26]). The polar data are transformed to the QDlat-MLT coordinate system and then averaged to an equiangular integration grid using a robust method. A wavelet Mie representation is performed over the geomagnetic north pole, and the radial current distributions are calculated via (5.28) from the toroidal magnetic field contribution. Figure 8 shows the resulting radial currents in the northern polar region, which are in accordance with the physical models presented in [20] and [11]. This result can now be interpreted as the evolution of the currents' morphology in magnetic local time; for example, it is clearly visible how the currents' polarity changes at the noon-midnight plane.

7. Summary and outlook. The Mie representation for the geomagnetic field has the advantage that it can equally be applied in regions of vanishing as well as nonvanishing electric current densities. The standard method of deriving the Mie representation is given by a spherical harmonic parametrization, i.e., by expanding the corresponding Mie scalars in terms of spherical harmonics. Considering the measurements (magnetic field or currents) to be given in a spherical shell, we have presented a wavelet parametrization of the magnetic field and the corresponding electric current densities in Mie representation, i.e., a wavelet Mie representation. The use of wavelets as trial functions for field parametrization enables us to cope with electric currents

(and corresponding magnetic effects) that vary rapidly with latitude or longitude, or that are confined to certain regions. Consequently, we are able to reflect the various levels of space localization in the form of a vectorial multiresolution analysis and can thus take efficient account of the specific concentration of the current densities in space. Using our approach, the direct as well as the inverse geomagnetic source problem now admit a treatment within a vectorial multiscale framework.

Neglecting variations in altitude, we have provided numerical examples that illustrate the multiscale approximation of radial current distributions from sets of vectorial geomagnetic field data from the MAGSAT as well as the CHAMP satellite. Global as well as regional reconstructions of the radial current densities are calculated and demonstrate the functionality of the approach. With regard to future studies, the next reasonable step is to incorporate the variations in altitude of the satellite—at least to some extent—since this would allow for the determination of horizontal current distributions, too. Additionally—in studies using synthetic data, based on satellite data sampled over large time intervals, or using data from multisatellite missions—a simultaneous wavelet parametrization of the poloidal and toroidal magnetic fields from the corresponding electric currents (or vice versa) should be derived in future works.

Acknowledgments. The author thanks Prof. Dr. W. Freeden (TU Kaiserslautern), Dr. C. Mayer (TU Kaiserslautern), and Dr. N. Olsen (Danish Space Research Institute, Copenhagen) for their support, their comments, and many fruitful discussions. The detailed and helpful comments of the referees are also gratefully acknowledged.

RETRIEVING TOPOLOGICAL INFORMATION FOR PHASE FIELD MODELS*

QIANG DU†, CHUN LIU†, AND XIAOQIANG WANG†

Abstract. The phase field approach has become a popular tool in modeling interface motion, microstructure evolution, and more recently the shape transformation of vesicle membranes under elastic bending energy. While it is advantageous to employ phase field models in numerical simulations to automatically handle topological changes to the microstructures or the configurations of vesicle membranes, detecting topological events may also become important for many applications such as those in the simulation of blood cells. Motivated by such considerations, a new quantity is formulated to retrieve some topological information based on the phase field formulation and to capture the occurrence of topological events. It can also be used as a control method to avoid unphysical changes of topology due to the numerical methods, should it become necessary for particular practical applications. Through numerical experiments, we demonstrate the effectiveness and the robustness of the new quantity in detecting the topology of fluid bubbles and vesicle membranes.

Key words. phase field, elastic bending energy, Gauss–Bonnet formula

DOI. 10.1137/040606417

1. Introduction.

Phase field modeling of mezoscopic morphology and microstructure evolution has become popular in recent years (see [6, 7, 8, 9, 12, 13, 21, 22, 24, 34, 35, 38, 39] and the references therein). These phase field approaches are usually combined with energetic variational formulations that lead to a diffuse interface modeled by a mixing energy. This allows topological changes of the interface to take place naturally [28, 31, 37]. Such a feature gives such approaches many advantages in numerical simulation of the interface variation and the interfacial motion (cf. [11]). More recently, we have given another successful application of the phase field model for computing the equilibrium configurations of vesicle membranes that minimize the bending elastic energy [19, 18]. The methods developed in [19] can be very useful in morphological studies of vesicle membranes under elastic bending energy, which has many interesting applications.

In this paper, we continue the study of the phase field model but from a different, and perhaps also very novel, point of view. We are motivated by the fact that in many engineering and biological applications, such as the modeling of blood cells in vascular systems, topological information about the vesicle membranes is of critical value. Thus, how to detect and control the topological change of the interface in the phase field modeling and numerical simulation becomes an important issue. Partly due to the nature of the phase field method (and all other level set methods) in their standard formulation, there is no mechanism preventing the topological change of the membranes or other interfaces. In fact, some of the topological changes are due purely to the formulations, instead of the underlying physics. To our knowledge, there has not

†Department of Mathematics, Pennsylvania State University, University Park, PA 16802 (qdu@math.psu.edu, liu@math.psu.edu, wang@math.psu.edu).

been any discussion in the literature on how to recover relevant topological information from the phase field simulations, nor to address further control mechanisms.

The general phase field model is based on the introduction of a phase function (or order parameter) $\phi = \phi(x)$, defined on the physical (computational) domain Ω that encloses Γ. The function ϕ is used to label the inside and the outside of the vesicle Γ: the level set $\{x : \phi(x) = 0\}$ gives the membrane, while $\{x : \phi(x) > 0\}$ represents the interior of the membrane and $\{x : \phi(x) < 0\}$ the exterior. A *transition thickness* parameter is also chosen to characterize the typical length scale of the transition layer (or the thickness of the *regularized* diffuse interface). For time dependent problems, it is natural to allow $\phi = \phi(x, t)$. The objective of our study here is to propose some robust and efficient methods for retrieving or recovering interesting topological information within the phase field framework. In particular, we will develop some robust formulae for computing the Euler number for the modeled interface based on order parameter ϕ.

We expect that our study here has the potential of opening up a host of exciting new applications of phase field modeling, including the use of the topological quantities in a control setting. Our numerical simulation indicates that the generalized Euler number ($\frac{\chi}{2}$ in three dimensions and χ in two dimensions) not only is a better indicator of topological changes than the energy functional we had been using in our previous paper [19], but in fact, gives a quantized jump upon a completion of the topological change (a direct consequence of the Gauss–Bonnet formula) for regular surfaces. Moreover, when the computed surface passes singularity, the new formula for χ based on the phase field formulation gives a fractional interpolation of the usual Euler number.

The study of the Euler number in terms of χ, or the Euler–Poincaré index number η, may provide guidance for the study of other topological quantities within the phase field framework. The ideas proposed in this paper may be equally applicable to other simulation methods for free boundary and interface problems such as the level set methods. Our work here is also likely to shed light on the study of many geometrical modeling problems, where providing topological information or controlling topological changes may be highly desirable.

The rest of the paper is organized as follows. In section 2, we briefly recall the phase field model, and we discuss a formulation of the Euler number (in terms of χ) within the phase field framework that can be used to recover some topological information. We present a set of formulae in various three-dimensional (3-D) and two-dimensional (2-D) cases. We also discuss the Euler–Poincaré index number η when the surfaces involve singularities. In section 4, we illustrate the method of computing the quantity χ in two applications and demonstrate the effectiveness and the robustness of the our formulation. Finally, some concluding remarks are given in section 5.

2. The Euler number. Given an oriented (regular) compact (i.e., without boundary) surface Γ, the well-known Gauss–Bonnet formula states that

$$\int_{\Gamma} K \, ds = 2\pi\chi, \tag{2.1}$$

where $K = k_1 k_2$ is the Gaussian curvature of the surface in R^3, ds is the area element, and $\frac{\chi}{2}$ in three dimensions (χ in two dimensions) is the Euler number [16]. The number χ is a commonly used topological quantity. For some frequently encountered surfaces, we have $\chi = 2$ for a sphere, $\chi = 0$ for a torus, and $\chi = -2$ for a torus with two holes.

For 2-D curves, K is the curvature and $\chi = 1$ for a circle. For convenience, in this paper we call $\frac{\chi}{2}$ the Euler number in 3-D cases and χ in 2-D cases.

In this section, it is our goal to find a suitable expression of the Euler number when the surface is implicitly defined by a phase field formulation. We first give the general formula of the Euler number under a general phase field definition for both 2-D and 3-D spaces. Then we give some simplified formulae under some specific ansatz assumptions corresponding to our applications. For simplicity, we focus on only the static case when deriving the formulae. In the time dependent case, since we are mostly interested in the topological information of a spatially distributed interface at a fixed time stance, the generalizations to time dependent problems are obvious.

We note that many of our derivations are through formal asymptotics, though more detailed and more rigorous justifications will be provided in our subsequent work [17].

2.1. The 3-D case. Let Γ be a smooth oriented compact surface in a domain Ω in $\mathbf{R}^3$; we note that Γ is allowed to have multiple disconnected pieces. Let p be a monotone increasing function defined from $\mathbf{R}$ to $\mathbf{R}$ with $p(0) = 0$. For each function p, we take a phase field function $\phi = \phi(x)$ of Ω as $\phi(x) = p(d(x, \Gamma))$ where the *signed* distance function $d = d(x, \Gamma)$ is defined to be positive inside Ω and negative outside Ω. The level sets of ϕ are denoted by $\Gamma_\mu = \{x \in \Omega | \phi(x) = \mu\}$. In particular, we have $\Gamma = \Gamma_0$. We also define $\Omega(a, b) = \{x \in \Omega \,|\, b < \phi(x) < a\}$, which forms a banded (layered) neighborhood around the surface for $b < 0 < a$.

Define $\Lambda(M) = \mathrm{Tr}(\mathrm{Adj}(M))$ for a matrix M. Clearly, $\Lambda(M)$ is the coefficient of the linear term of the characteristic polynomial of M. In particular, for the singular matrix $M = \nabla^2 d$ we have $\Lambda(M) = \lambda_1(M)\lambda_2(M)$, with λ_1 and λ_2 being the two nonzero eigenvalues of M.

THEOREM 2.1. *Using the notation above, for any monotone increasing function p there exists $b < 0 < a$ such that the matrix M, defined by*

$$M(x)_{ij} = \frac{1}{2\sqrt{\pi(a-b)|\nabla\phi|}} \left(\nabla_i \nabla_j \phi - \frac{\nabla |\nabla\phi|^2 \cdot \nabla\phi}{2|\nabla\phi|^4} \nabla_i \phi \nabla_j \phi \right), \tag{2.2}$$

is a singular matrix for any $x \in \Omega(a, b)$ and the Euler number of Γ is given by

$$\frac{\chi}{2} = \int_{\Omega(a,b)} \Lambda(M(x))\, dx. \tag{2.3}$$

Proof. Since ϕ depends only on the distance d, and p is monotone increasing, there exist real numbers a and b, with $b < 0 < a$, sufficiently close to 0 such that Γ_μ are close to the parallel translations of Γ in the normal direction for all $b \le \mu \le a$, and all Γ_μ have the same topology as Γ.

Direct computation shows

$$\nabla_i \nabla_j d = \frac{\nabla^2 \phi}{p'} - \frac{p''}{p'} \nabla_i d \nabla_j d = \frac{1}{p'} [\nabla_i \nabla_j \phi - p'' \nabla_i d \nabla_j d].$$

The matrix $\nabla^2 d$, with $d = d(x, \Gamma)$ being the signed distance from x to the surface Γ, always has a zero eigenvalue with ∇d as the eigenvector. This is due to the fact that $\nabla^2 d$ is symmetric and $|\nabla d| = 1$. On the surface Γ, the two other eigenvalues are actually the two principle curvatures of Γ (k_1 and k_2 in this case). The Gaussian curvature K is of course the product of these two eigenvalues, while the mean curvature H is

given by the mean of the two eigenvalues. Both quantities can in fact be defined and computed on all the level sets in $\Omega(a,b)$. For instance, the Gaussian curvature K can be conveniently computed from $\mathrm{Tr}(\mathrm{Adj}(\nabla^2 d))$ (the sum of the three principal 2×2 minors of $\nabla^2 d$; see section 2.6 for an example in the cylindrically symmetric case).

Assuming that $k_1$and k_2 remain constant along the normal directions in Ω', we have

$$\begin{aligned}
\frac{\chi}{2} &= \frac{1}{4\pi}\int_\Gamma k_1(x)k_2(x)\,ds \\
&= \frac{1}{4\pi(a-b)}\int_{p^{-1}(b)}^{p^{-1}(a)} p'(\tau)d\tau \int_\Gamma k_1(x)k_2(x)\,ds \\
&= \frac{1}{4\pi(a-b)}\int_{\Omega(a,b)} p'(d(x,\Gamma))k_1(x)k_2(x)\,dx \qquad (2.4)\\
&= \frac{1}{4\pi(a-b)}\int_{\Omega(a,b)} p'(d(x,\Gamma))\Lambda(\nabla^2 d(x,\Gamma))\,dx \\
&= \frac{1}{4\pi(a-b)}\int_{\Omega(a,b)} \frac{1}{p'(d(x,\Gamma))}\Lambda(\nabla^2\phi - p''\nabla_i d\nabla_j d)\,dx. \qquad (2.5)
\end{aligned}$$

Now, since p is monotone increasing, we have $p'(d(x,\Gamma)) = |\nabla\phi(x)|$ and

$$p''(d(x,\Gamma)) = \nabla|\nabla\phi|\cdot\frac{\nabla\phi}{|\nabla\phi|}(x) = \frac{\nabla|\nabla\phi|^2\cdot\nabla\phi}{2|\nabla\phi|^2}(x).$$

Hence we get the general formula for the Euler number in three dimensions:

$$\begin{aligned}
\frac{\chi}{2} &= \frac{1}{4\pi(a-b)}\int_{\Omega(a,b)}\frac{1}{|\nabla\phi|}\Lambda\left(\nabla_i\nabla_j\phi - \frac{\nabla|\nabla\phi|^2\cdot\nabla\phi}{2|\nabla\phi|^4}\nabla_i\phi\nabla_j\phi\right)dx \qquad (2.6)\\
&= \frac{1}{4\pi(a-b)}\int_{\Omega(a,b)}\frac{1}{|\nabla\phi|}\Lambda(M(x))\,dx.
\end{aligned}$$

From the definitions of M and $\Lambda(M)$, we know that $M(x)$ is singular for any $x\in\Omega(a,b)$ in the sense that it always has a zero eigenvalue, and (2.3) holds. ∎

The formula (2.3) forms the basis for our efforts to recover topological information, in particular the Euler number.

2.2. The 2-D case.

THEOREM 2.2. *If $\Omega\in\boldsymbol{R}^2$, with the same notation as in Theorem* 2.1*, for any monotone increasing function p there exists $b<0<a$ such that*

$$\chi = \frac{1}{2\pi(a-b)}\int_{\Omega(a,b)}\left(-\triangle\phi + \frac{\nabla|\nabla\phi|^2\cdot\nabla\phi}{2|\nabla\phi|^2}\right)dx. \qquad (2.7)$$

Proof. Using the same argument as above, this can be derived as follows:

$$\begin{aligned}
\chi &= \frac{1}{2\pi}\int_\Gamma K(x)\,ds \\
&= \frac{1}{2\pi(a-b)}\int_{\Omega(a,b)} p'(d(x,\Gamma))K(x)\,dx \\
&= \frac{1}{2\pi(a-b)}\int_{\Omega(a,b)} (-\triangle\phi + p''(d(x,\Gamma)))\,dx \\
&= \frac{1}{2\pi(a-b)}\int_{\Omega(a,b)}\left(-\triangle\phi + \frac{\nabla|\nabla\phi|^2\cdot\nabla\phi}{2|\nabla\phi|^2}\right)dx. \qquad (2.8)
\end{aligned}$$

∎

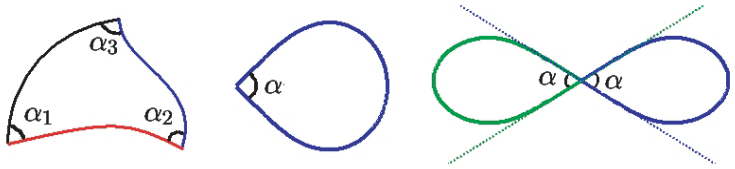

FIG. 2.1. *Singular 2-D cases.*

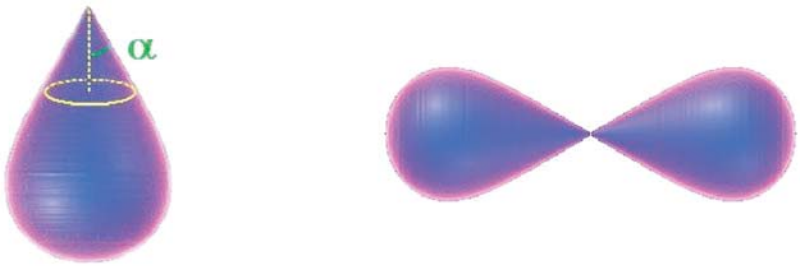

FIG. 2.2. *Singular 3-D cases.*

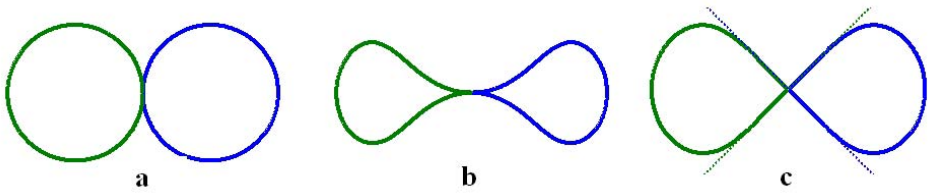

FIG. 2.3. *Singular 2-D cases. The inner intersect angles are* π, 0, $\pi/2$ *for cases a, b, and c, respectively.*

2.3. Cases involving singularities on the interfaces. Both Theorems 2.1 and 2.2 require that Γ be a smooth oriented compact surface. However, in realistic physical applications, we always encounter the singular cases where either the curves or the surfaces intersect or have some sharp angles or cones. Figure 2.1 illustrates several simple singular cases in two dimensions, while Figure 2.2 shows two singular shapes in three dimensions.

With the possible occurrence of the singularities, we will employ the general Gauss–Bonnet formula. In the 2-D case, suppose that the curves are piecewise smooth with n vertices (sharp corners) and that the inner angles for each vertices are $\{\alpha_i, i = 1, \ldots, n\}$. The Gauss–Bonnet formula reads as

$$2\pi\eta = \int_\Gamma K\, ds + \sum_{i=1}^{n}(\pi - \alpha_i) \; = 2\pi\chi + \sum_{i=1}^{n}(\pi - \alpha_i),$$

where η, the Euler–Poincaré index number, is the topological integer, the genus of the surface [16].

We give illustrations, in Figures 2.1 and 2.3, of the values of χ defined by $2\pi\chi = \int_\Gamma K\, ds$ in the singular cases. For configurations such as the third image in Figure

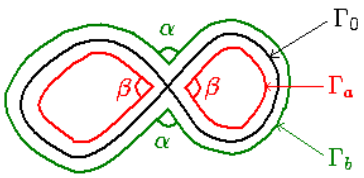

FIG. 2.4. Γ_0, Γ_a, *and* Γ_b *have different topologies but the same Euler number.*

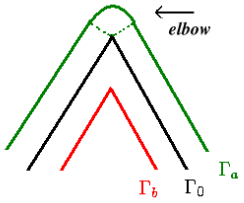

FIG. 2.5. *By getting rid of the singular complement,* Γ_0, Γ_a, *and* Γ_b *have the same Euler number.*

2.1, $2\pi\eta = \int_\Gamma K\,ds + 2(\pi - \alpha)$. In particular, for the cases in Figure 2.3, $\alpha = \pi, 0, \frac{\pi}{2}$ for the cases a, b, and c, respectively. In all of these cases, the Euler–Poincaré index number η is always 2, representing the number of bubbles.

On the other hand, the value of χ can be used to detect the change of topology even with the presence of the singular cases. Again, using the example in Figure 2.3, the Euler numbers χ are 2, 1, and 1.5, respectively, with the singularity being signaled by the fractional value. We want to point out that in the first case, the Euler number χ is still equal to the Euler–Poincaré index number η, even with the singularity.

When we consider the definition of χ for the 3-D singular cases, we may also get a fractional Euler number when singularity appears. For example, for the configuration in the first picture of Figure 2.2, suppose that the angle of the tangent cone is α; the Euler number can be derived from the following explicit analytic formula by calculating the ratio between the spherical cap cut by the α-cone and the total area of the sphere:

$$\frac{\chi}{2} = \frac{1}{4\pi}\int_\Gamma K\,ds = 1 - \frac{1}{4\pi}(2\pi(1-\sin\alpha)) = \frac{1}{2} + \frac{1}{2}\sin\alpha. \tag{2.9}$$

Finally, we discuss the validity of formulae (2.3) and (2.7) in singular cases. Figure 2.4 shows that Γ_μ seem to have (visual) topology different from that of Γ for some $b < \mu < a$.

However, in reference to Figure 2.4, because each Γ_μ has a singular vertex with angle either α or $\beta = \pi - \alpha$, the Euler number ξ for every Γ_μ is the same as that of Γ_0. Thus Theorems 2.1 and 2.2 still hold for this singular case where the Euler number is a fractional number.

One will encounter the issue of a *singular complement* in the numerical simulations of the interfaces involving singularities. This is crucial in calculating the fractional Euler number correctly. To clarify this phenomenon, let us examine Figure 2.5.

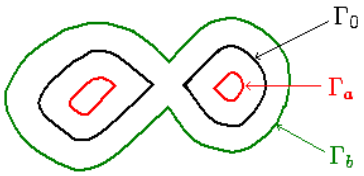

FIG. 2.6. *An illustration of the choice of a and b. Γ_0, Γ_a, and Γ_b have the same Euler number.*

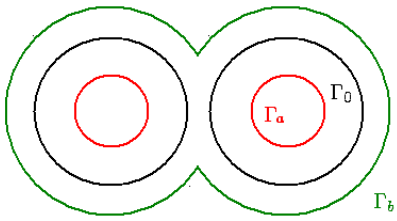

FIG. 2.7. *Γ_0, Γ_b have different Euler numbers.*

Because of the *elbow* shape associated with Γ_a, Γ_a has a different Euler number from Γ_0. This phenomenon, hereafter referred to as the *singularity compensation*, occurs in all numerical experiments involving interfacial singularities due to the numerical smoothing of the surfaces. This appears to introduce difficulties into the application of Theorems 2.1 and 2.2. However, noticing that the elbow has very large curvature, if a method can be designed to filter out such an elbow, the Euler number calculated for the remaining Γ_a would remain the same as that of Γ_0. Such a technique will be introduced and developed later in section 3.

2.4. Stability and autoselection of parameters. Although the proofs of Theorems 2.1 and 2.2 are given under the condition that for every $b < \mu < a$, Γ_μ has the same topology as Γ_0, to correctly identify the Euler number, one can relax such a condition to requiring that the Euler number of Γ_μ be the same as that of Γ_0. By the analysis of section 2.3, it is desirable that the parameters a and b are chosen to be quite different from 0. Figure 2.6 gives an illustration of such a case.

The advantage of choosing a and b some distance away from 0 is to ensure that $\Omega(a, b)$ contains plenty of grid points, which in turn makes the integration for the Euler number more accurate and stable.

However, in general, it is not true that all the neighboring curves or surfaces always share the same Euler number. In Figure 2.7, Γ_0 and Γ_b clearly have different Euler numbers. The largest b can be selected only where the two circles of Γ_b are tangent to each other. How to choose the value of b in such situations becomes a very relevant issue in our computation of the Euler numbers.

On the other hand, in Figure 2.7, we may notice that Γ_a always has the same Euler number as Γ_0, and a can be very different from 0. Thus the selection of a and b may be problem dependent. In some cases, we can select the integration area to be either $\Omega(0, a)$ or $\Omega(b, 0)$ in order to get the correct Euler number.

Denote the Euler number as $E(b,a)$, corresponding to the integration region $\Omega(a,b)$; in order to see the impact of a and b, we employ the following algorithm in our numerical simulations.

ALGORITHM: PARAMETER AUTOSELECTION FOR a. Given a phase field function ϕ defined on region Ω, select a relatively far away from 0 (for instance, $a=1$). Select a tolerance number ν (for instance, $\nu=0.1$) and a small step h (we can use, as an example, $h=a/50$).

- Step 1. If $|E(0,a)-E(0,a/2)|<\nu$, exit; else set $a=a-h$.
- Step 2. If $a<h$, exit with $a=0$; else loop back to Step 1.

The above algorithm is used to select the best a. A similar algorithm can be used to select the best b. A bisection method can be adopted to make the autoselection more efficient. The resulting a and b are used to compute the correct Euler numbers. As verified in the earlier theorems, the above algorithm is assured to terminate with suitable a and b if the step size h and the tolerance ν are chosen to be reasonably small.

2.5. Formula simplification. The formulae given in the above discussion of the Euler number are computable numerically, but for many practical situations they can be further simplified if some appropriate ansatz can be taken. We now discuss some of these simplifications.

First let us take the ansatz

$$\phi=\tanh\left(\frac{d}{\sqrt{2}\epsilon}\right)=p\left(\frac{d}{\sqrt{2}\epsilon}\right), \tag{2.10}$$

which is actually an accurate description of the phase field function in many models such as the basic Allen–Cahn (Ginzburg–Landau) equations, which are popular prototype phase field models for interface and microstructure evolution. Such an ansatz also captures well the phase field function in our energetic phase field model of the vesicle membranes under bending elastic energy.

With such an ansatz, we have the following theorem.

THEOREM 2.3. *As in Theorem* 2.1, *if* $\phi=\tanh(\frac{d}{\sqrt{2}\epsilon})=p(\frac{d}{\sqrt{2}\epsilon})$, *we have the following:*

3-*d case: Let*

$$M_{ij}=\sqrt{\frac{3\epsilon}{8\sqrt{2}\pi}}\left(\nabla^2_{ij}\phi+\frac{2\phi}{1-\phi^2}\nabla_i\phi\nabla_j\phi\right) \tag{2.11}$$

and $\Lambda(M)$ *be defined as before. The Euler number of* Γ *is given by*

$$\frac{\chi}{2}=\lim_{\epsilon\to 0}\int_\Omega \Lambda(M(x))\,dx. \tag{2.12}$$

2-*d case: The Euler number of* Γ *is given by*

$$\chi=\lim_{\epsilon\to 0}\frac{1}{4\pi}\int_\Omega\left(-\triangle\phi+\frac{1}{\varepsilon^2}(\phi^2-1)\phi\right)\,dx. \tag{2.13}$$

Remark 2.4. Based on the ansatz (2.10), we have that

$$p'=1-p,\quad p''=(p-1)p. \tag{2.14}$$

Hence each term in the matrix M is in fact nonsingular.

Proof. A direct calculation shows that

$$\nabla\phi = p'\frac{1}{\sqrt{2}\epsilon}\nabla d, \quad \nabla^2_{ij}\phi = p''\frac{1}{2\epsilon^2}\nabla_i d\nabla_j d + p'\frac{1}{\sqrt{2}\epsilon}\nabla^2 d,$$

and

$$\nabla^2 d = \frac{\sqrt{2}\epsilon\nabla^2\phi}{p'} - \frac{p''}{\sqrt{2}\epsilon p'}\nabla_i d\nabla_j d.$$

Several elementary facts are in order:

$$p'(x) = \tanh'(x) = 1 - \tanh^2(x) = 1 - p^2(x), \qquad p'' = -2p(1-p^2), \quad p'' = -2pp'.$$

Since $\nabla d = \sqrt{2}\epsilon\nabla\phi/p'$, we have

$$\begin{aligned}\nabla^2 d &= \frac{\sqrt{2}\epsilon\nabla^2\phi}{p'} - \frac{p''}{\sqrt{2}\epsilon p'}\nabla_i d\nabla_j d = \sqrt{2}\epsilon\frac{\nabla^2\phi}{p'} + \sqrt{2}\epsilon\frac{2p}{(1-p^2)^2}\nabla_i\phi\nabla_j\phi \\ &= \frac{\sqrt{2}\epsilon}{1-p^2}\left(\nabla^2\phi + \frac{2p}{1-p^2}\nabla_i\phi\nabla_j\phi\right) = \frac{\sqrt{2}\epsilon}{1-\phi^2}\left(\nabla^2\phi + \frac{2\phi}{1-\phi^2}\nabla_i\phi\nabla_j\phi\right).\end{aligned}$$

Simple calculation yields that

$$\int_{-\infty}^{+\infty}(1-\phi^2)^2 dx = \sqrt{2}\epsilon\int_{-\infty}^{+\infty}(1-\tanh^2(x))^2 dx = \frac{4\sqrt{2}\epsilon}{3}.$$

With sufficiently small ϵ, the function ϕ goes to 1 or -1 very quickly (exponentially) away from Γ. Thus, we can just take $a = -b = 1$ with $\epsilon \to 0$, and the matrix in the formula (2.2) becomes

$$M = \sqrt{\frac{3\epsilon}{8\sqrt{2}\pi}}\left(\nabla^2\phi + \frac{2\phi}{1-\phi^2}\nabla_i\phi\nabla_j\phi\right),$$

and (2.12) holds.

For the 2-D cases, by taking a similar ansatz and putting

$$|\nabla\phi|^2 = \frac{1}{2\varepsilon^2}(1-\phi^2)^2$$

into formula (2.7), we finally have (2.13). ∎

More simplifications can be made for problems where periodic boundary conditions are used, since $\int_\Omega \triangle\phi = 0$; the above formula can be further simplified to

$$\chi \approx \frac{1}{4\pi\varepsilon^2}\int_\Omega(\phi^2-1)\phi\, dx. \tag{2.15}$$

The above formula can be compared with the formula (2.7) (with $a = -b = 1$) applied to the periodic boundary condition case:

$$\begin{aligned}\chi &= \frac{1}{4\pi}\int_\Omega \frac{\nabla|\nabla\phi|^2\cdot\nabla\phi}{2|\nabla\phi|^2}\, dx = \frac{1}{8\pi}\int_\Omega \nabla\ln|\nabla\phi|^2\cdot\nabla\phi\, dx \\ &= -\frac{1}{8\pi}\int_\Omega \triangle\phi\ln|\nabla\phi|^2\, dx, \end{aligned} \tag{2.16}$$

where we need only p being monotone from -1 to 1 in Ω instead of being a strictly tanh function.

The previous formula (2.15) has no derivative terms, while the latter one in (2.16) involves no bulk part.

We note that the approximations in (2.12), (2.13), and (2.15) are of spectral accuracy with $\epsilon \to 0$.

Remark 2.5. We note that it is possible to get simplified formulae of other types with the ansatz (2.10). For instance, in the 3-D case, let

$$\tilde{M}_{ij}(\phi) = \sqrt{\frac{35\epsilon}{64\sqrt{2}\pi}} \left((1-\phi^2)\nabla^2\phi + 2\phi\nabla_i\phi\nabla_j\phi\right). \tag{2.17}$$

Then, the Euler number of the surface Γ in the phase field formulation can also be given by

$$\frac{\chi}{2} = \lim_{\epsilon\to 0}\int_\Omega \Lambda(\tilde{M}(\phi))\,dx. \tag{2.18}$$

Note that the change of the constant factors in front of the matrices in (2.11) and (2.17) are due to the use of different weight functions $(1-\tanh^2(x))^2$ and $(1-\tanh^2(x))^4$ in the derivation.

2.6. Formulae for cylindrically symmetric membranes. In [19], we have used the energetic phase field models to compute 3-D vesicle membranes minimizing the bending elastic energy. The numerical examples are for cylindrically symmetric membranes with various different topologies. We now present the Euler number computation in such situations.

In the numerical simulations given in [19], where $\phi(x) \to \tanh(\frac{d(x,\Gamma)}{\sqrt{2}\epsilon})$ as $\epsilon \to 0$, the conventional cylindrical coordinates (r,θ,z) are used. Suppose that the membrane is rotationally invariant with respect to the z-axis, i.e., $\phi = \phi(z,r,\theta) = \phi(z,r)$; then

$$\nabla\phi = \begin{pmatrix} \partial_z\phi \\ \partial_r\phi \\ 0 \end{pmatrix}, \quad \nabla_i\phi\nabla_j\phi = \begin{pmatrix} (\partial_z\phi)^2 & \partial_z\phi\partial_r\phi & 0 \\ \partial_z\phi\partial_r\phi & (\partial_r\phi)^2 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \tag{2.19}$$

and

$$\nabla^2\phi = \begin{pmatrix} \partial^2_{zz}\phi & \partial^2_{zr}\phi & 0 \\ \partial^2_{zr}\phi & \partial^2_{rr}\phi & 0 \\ 0 & 0 & \frac{1}{r}\partial_r\phi \end{pmatrix}. \tag{2.20}$$

If we substitute (2.19) and (2.20) into (2.11), we have that

$$M = \sqrt{\frac{3\epsilon}{8\sqrt{2}\pi}} \begin{pmatrix} \partial^2_{zz}\phi + \frac{2\phi}{1-\phi^2}(\partial_z\phi)^2 & \partial^2_{zr}\phi + \frac{2\phi}{1-\phi^2}\partial_z\phi\partial_r\phi & 0 \\ \partial^2_{zr}\phi + \frac{2\phi}{1-\phi^2}\partial_z\phi\partial_r\phi & \partial^2_{rr}\phi + \frac{2\phi}{1-\phi^2}(\partial_r\phi)^2 & 0 \\ 0 & 0 & \frac{1}{r}\partial_r\phi \end{pmatrix}.$$

Hence F, the sum of the determinants of all principal 2×2 minors, is equal to

$$F(r,z) = \frac{3\epsilon}{8\sqrt{2}\pi r}\partial_r\phi\left\{\partial^2_{zz}\phi + \partial^2_{rr}\phi + \frac{2\phi}{1-\phi^2}[(\partial_z\phi)^2 + (\partial_r\phi)^2]\right\}, \tag{2.21}$$

and

$$\begin{aligned}\frac{\chi}{2} &\approx \int\int 2\pi r F(r,z)\, drdz \\ &\approx \frac{3\epsilon}{4\sqrt{2}} \int\int \partial_r\phi \left\{ \partial^2_{zz}\phi + \partial^2_{rr}\phi + \frac{2\phi}{1-\phi^2}[(\partial_z\phi)^2 + (\partial_r\phi)^2] \right\} drdz \\ &\approx \frac{3\epsilon}{4\sqrt{2}} \int\int \partial_r\phi \left\{ \triangle\phi + \frac{2\phi}{1-\phi^2}|\nabla\phi|^2 \right\} drdz, \end{aligned} \tag{2.22}$$

where the operators ∇ and $\triangle$ are taken in the r-z plane.

If we do not take the ansatz $\phi = \tanh(\frac{d}{\sqrt{2}\epsilon})$, but simply take (2.19) and (2.20) into the formula (2.2), we get a similar formula in the more general case:

$$\frac{\chi}{2} = \frac{1}{4\pi(a-b)} \int_{\Omega(a,b)} \frac{1}{r} \frac{1}{|\nabla\phi|} \partial_r\phi \left\{ \partial^2_{zz}\phi + \partial^2_{rr}\phi - \frac{\nabla|\nabla\phi|^2 \cdot \nabla\phi}{2|\nabla\phi|^4}[(\partial_z\phi)^2 + (\partial_r\phi)^2] \right\} dx,$$

or

$$\frac{\chi}{2} = \frac{1}{2(a-b)} \int\int_{\Omega(a,b)} \frac{1}{|\nabla\phi|} \partial_r\phi \left\{ \triangle\phi - \frac{\nabla|\nabla\phi|^2 \cdot \nabla\phi}{2|\nabla\phi|^2} \right\} drdz. \tag{2.23}$$

We remark here that in the 3-D cylindrically symmetric case, the two curvatures can be calculated by

$$k_1 = \triangle\phi - \frac{\nabla|\nabla\phi|^2 \cdot \nabla\phi}{2|\nabla\phi|^2}, \tag{2.24}$$

$$k_2 = \frac{\partial_r\phi}{r|\nabla\phi|}, \tag{2.25}$$

respectively. One can also use them to derive the formula for the Euler number directly.

Using the partial derivatives, (2.23) can be written as

$$\frac{\chi}{2} = \int\int_{\Omega(a,b)} \frac{\partial_r\phi \left(\partial^2_{rr}\phi(\partial_z\phi)^2 + \partial^2_{zz}\phi(\partial_r\phi)^2 - 2\partial_r\phi\partial_z\phi\partial^2_{rz}\phi \right)}{2(a-b)((\partial_r\phi)^2 + (\partial_z\phi)^2)^{\frac{3}{2}}}\, drdz. \tag{2.26}$$

Using the difference approximation as described in [19], the above integrals can be readily evaluated numerically on a spatial grid.

3. Numerical realizations. In section 2, various formulae were presented for calculating the Euler number in two and three dimensions under different kinds of conditions. In general, we can apply finite difference or spectral methods directly to those formulae to calculate the Euler number. However, as discussed in section 2.3, the singular cases often happen in the process with topology changes, such as surface entanglement. When we apply the Euler number formulae to those singular cases, the numerical values at the singular vertices are always very large, which make the final results inaccurate.

Figure 3.1 illustrates a 3-D singular case. The right-most panel shows the function $F(r,z)$ in formula (2.21) with the r and z coordinates. From the right-most graph, we see the numerical value may even go up to $10,000$. If the Euler number is calculated directly by formula (2.23), although the theoretical value for this shape is 0.7500, we get 1.0671 which is close to the value 1, the Euler number of a sphere.

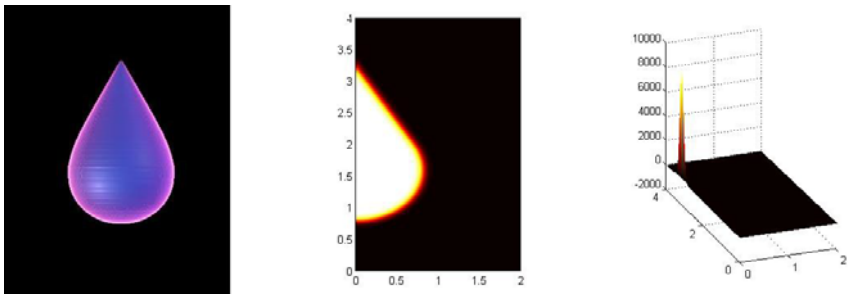

FIG. 3.1. *Singular values at the singular vertex. From left to right: the 3-D picture, the 2-D axis symmetrical r-z planar section, and the singular value around the singular vertex.*

This phenomenon is due to the so-called *singularity compensation* discussed earlier. Because of the finite discrete grid adopted in the numerical scheme, the curvature value at a singular vertex is always regularized from ∞ to a finite number. And in our case, such a change to the finite number provides certain *compensation* to the total Euler number, which can be viewed as putting a small elbow with a large curvature to complement the shape so that the singular shape changes to a regular shape.

A simple but effective way for getting rid of this singularity compensation is to avoid integrating over those singular vertices which are easy to detect, because the numerical values of the integrand at those locations are very big relative to other points. From the formula (2.4), we know that

$$\Lambda(M(x)) = \frac{1}{4\pi(a-b)} p'(d(x,\Gamma))K(x),$$

where $K(x)$ is the Gaussian curvature at a point x. If $p(x) = \tanh(x/(\sqrt{2}\epsilon))$, $p'(d(x,\Gamma)) = (1-p^2(d(x,\Gamma)))/(\sqrt{2}\epsilon)$, then

$$|\Lambda(M(x))| \le \frac{1}{4\sqrt{2}\pi\epsilon(a-b)} K(x).$$

In most cases, it is easy to estimate the possible largest Gaussian curvature value. In the phase field models, the radius of the smallest ball should be at least larger than the band width ϵ. Thus it is natural to choose $K < 1/\epsilon^2$ for the regular points and regard the singular points as those satisfying the condition $\Lambda(M(x)) > 1/(4\epsilon^3\sqrt{2}\pi(a-b))$.

We verify the above argument using the examples shown in Figure 3.2, which represent the same cylindrically symmetric membrane with a singularity at the upper tip whose Euler number can be calculated by formula (2.26). By excluding the singular points with $\Lambda(M(x)) > 200$, based on a 100×200 grid with $h = 0.01$, $\epsilon = 2h = 0.02$, and $\alpha = \frac{\pi}{6}$, the computed Euler number we get is 0.7498, which is a very good approximation of the theoretical value 0.7500 obtained from formula (2.9). For $\alpha = \frac{\pi}{4}$, the computed Euler number 0.8534 is again an accurate approximation of the theoretical value 0.8536.

In the following section, we apply this technique to all our experiments.

4. Applications to some phase field models. In this section, we present two applications of the Euler number developed in the earlier sections for general phase field models. The special examples include the deformation of vesicle membrane configurations minimizing the bending elastic energy and the coarsening of two

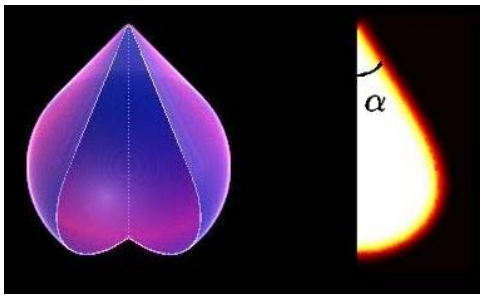

FIG. 3.2. *A special cylindrically symmetric membrane with a singular point.*

Newtonian bubbles in another Newtonian fluid. We expect that our formula can be equally applied to other more complicated and physical examples involving the phase field models as well.

4.1. The model for membranes minimizing the bending elastic energy. We now consider the problem of minimizing the bending elastic energy:

$$E_{\text{elastic}} = \int_\Gamma \frac{k}{2} H^2 \, ds, \tag{4.1}$$

with area and volume constraints. Here, $H = (k_1 + k_2)/2$ is the mean curvature of the membrane surface, with k_1 and k_2 as the principal curvatures. k is the bending rigidity, which can depend on the local heterogeneous concentration of the species (such as protein molecules on the blood cells).

The energetic phase field model studied in [19] is given by the solution of the following modified elastic energy:

$$W(\phi) = \int_\Omega \frac{k\epsilon}{2} \left| \Delta\phi - \frac{1}{\epsilon^2}(\phi^2 - 1)\phi \right|^2 dx. \tag{4.2}$$

As ϵ is taken asymptotically to zero, the minimum of the energy W approaches the original energy (4.1). Moreover, at least when the membrane Γ, viewed as a surface in Ω, is regular enough, we have

$$\phi(x) \tilde{=} \tanh\left(\frac{d(x,\Gamma)}{\sqrt{2}\epsilon}\right) + O(\epsilon^2) \tag{4.3}$$

approximately satisfied for all $x \in \Omega$. Here, $d = d(x,\Gamma)$ is the distance of the point $x \in \Omega$ to the surface Γ. Furthermore, the functional

$$A = \int_\Omega \phi(x) \, dx \tag{4.4}$$

goes to the difference of interior volume and exterior volume, and the function

$$B = \int_\Omega \left[\frac{\epsilon}{2} |\nabla\phi|^2 + \frac{1}{4\epsilon}(\phi^2 - 1)^2 \right] dx \tag{4.5}$$

approaches $2\sqrt{2}\,\text{area}(\Gamma)/3$, or about 0.94 times the area of Γ. We note that for energy minimizing functions,

$$\int_\Omega \frac{\epsilon}{2} |\nabla\phi|^2 dx \approx \int_\Omega \frac{1}{4\epsilon}(\phi^2 - 1)^2 \, dx.$$

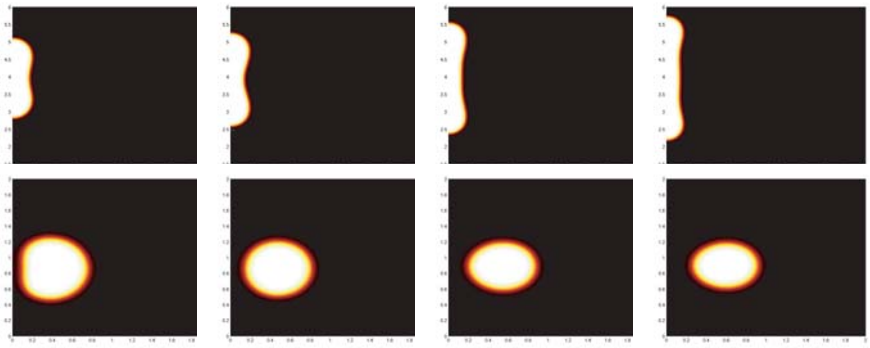

FIG. 4.1. *Deformation of a gourd (top) and a torus (bottom) with areas at* 5.834, 6.258, 6.682, *and* 7.000. *Pictures are displayed in different scales for best view.*

Thus, it is also convenient to take

$$B = \int_\Omega \epsilon |\nabla \phi|^2 dx$$

as the constraint for numerical purposes. For a more detailed asymptotic analysis and a more rigorous convergence analysis, including the convergence of the Euler Lagrange equation, we refer to our subsequent work [17].

It has come to our attention recently that the unconstrained variational approach of using (4.2) to approximate the 2-D Willmore functional (4.1) was also previously used, by the name of a relaxed formulation, in the application of image inpainting (see [23, 10, 32] and the references cited therein). This relaxed formulation was motivated by the Γ-convergence framework of De Giorgi [14] (see also [32]) for general variational problems, although the convergence of such a formulation remains to be rigorously justified.

The numerical simulations in [19] were aimed at the study of the minimizers of the elastic energy $W(\phi)$ under given surface area and volume. By scaling invariance, the volume can be fixed to be a constant, while the area is changed continuously to probe the energy landscape. A set of bubble shapes was discovered, and topological changes were observed along the way only when the configurations were visualized. Our objective here is to show that the Euler number formula (2.26) can be used as an effective tool to automatically detect the topological changes.

The detailed numerical algorithms and numerical simulations of the branches of membrane shape deformations have been presented in [19].

Figure 4.1 shows the deformation of a gourd (the first row, computed with a 40×375 grid and $\epsilon = 1.5h = 0.03$) and a torus (the second row, 100×100 grid, $\epsilon = 1.5h = 0.03$) with increasing surface areas, with volumes fixed at 1.1000. The gourd becomes thinner, and the torus moves further away from its axis. It is obvious that there is no topological change for both the gourd and the torus. This can be seen from the graph of the Euler numbers (Figure 4.2) with the value being kept at 1 for the gourd and 0 for the torus. On the other hand, in the same figure, the graphs of their energy are two intersecting curves, which illustrates the existence of two shapes with totally different topologies but the same energy.

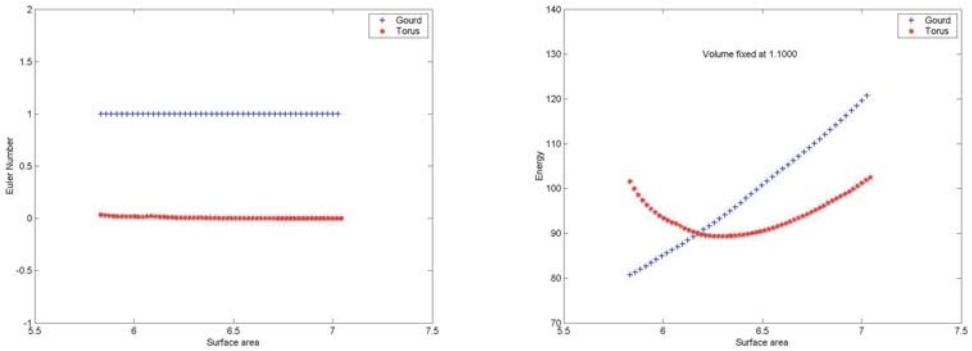

FIG. 4.2. *The energy (left) and the computed Euler number (right) of gourd and torus shapes.*

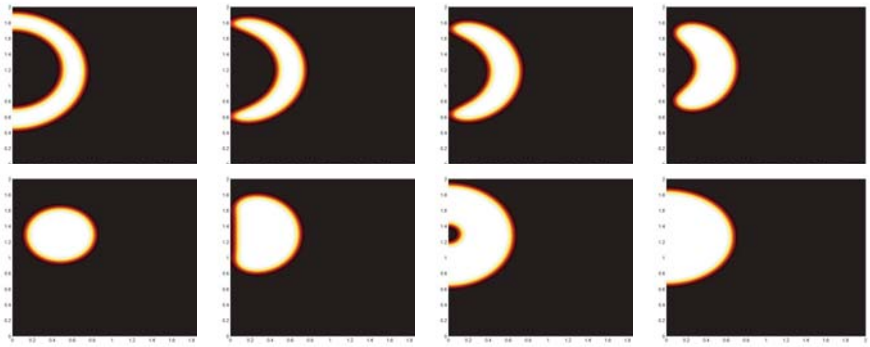

FIG. 4.3. *Deformation of a shell to a pitomba, a bangle, a torus, a longan and finally a ball (cross section view) with areas valued at* 9.811, 9.546, 8.485, 6.894, 6.364, 5.515, 5.303, *and* 5.091.

In the next set of numerical simulations, a rectangular domain with a 100×200 Cartesian grid, with $h = 0.01$, is used and $\epsilon = 2h = 0.02$. Figure 4.3 shows the shape deformations with a decreasing area from 11.2960 to 5.0912 while fixing the volume at 1.1000. The left picture in Figure 4.4 shows the corresponding change of the bending energy with different surface areas. Good resolutions of the interfaces based on the above choices of the computational grid and the parameter values have been demonstrated in [19] for such a solution branch.

In the whole energy minimizing process, the shape always jumps from one branch to another, which results in a discontinuous energy curve. Here the shape of the vesicle changes from a shell to a bangle (with no obvious energy jump), then to a torus (with a noticeable energy jump at the surface area $\beta = 6.6822$), then a longan (with an energy jump at around $\beta = 5.3563$), and finally to a spherical ball (an energy jump at around $\beta = 5.1442$). There are three topological changes during the shape deformation: (1) from shell to a bangle, (2) from torus to a longan, and (3) from longan to a spherical ball. The energy can hardly detect the change from shell to bangle, despite the occurrence of the topology change.

The right picture in Figure 4.4 shows the change of the computed Euler numbers. The graph has exactly three jumps corresponding to the three topological changes. We can see the corresponding Euler numbers 2, 0, 2, and 1 for shell, torus, longan,

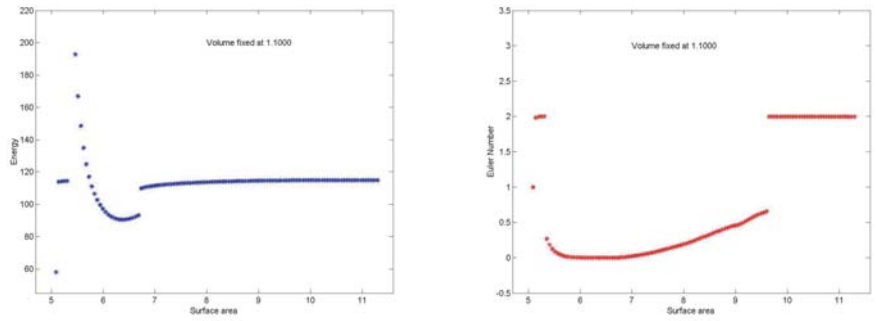

FIG. 4.4. *The energy (left) and the computed Euler number (right) for the deformation of a shell shape with decreasing area.*

and ball shapes, respectively.

The calculation of the Euler numbers used the autoselection algorithm for the best parameters a and b. Observing the second, third, and sixth graphs of Figure 4.3 carefully, it is not hard to understand why we need such an algorithm here, based on the theory stated in section 2.4. As different shapes have different best values of a and b, we thus have different integration areas for the Euler numbers. It may be noticeable that some values are not exactly 0 when the vesicle surface area belongs to the interval $[5.3, 9.8]$. Such small errors are mainly due to the approximation errors of the finite difference scheme and the integration scheme. Fortunately, those errors are always sufficiently small (less than 0.1 in this case) to be distinguishable from the Euler number jumps, which are at least 1. This makes our method very stable and sensitive in detecting the topology changes.

In summary, the above experiments demonstrate that our formula for the Euler number can be successfully used to retrieve topological information and to capture topological events. Of course, the Euler number alone does not completely determine the topology of the interface.

4.2. The phase field model of fluid bubble motion. In the study of the coarsening of the Newtonian bubbles in another Newtonian fluid, the following 2-D simple problem has been considered:

$$
\begin{cases}
\dfrac{\partial u}{\partial t} + (u \cdot \nabla)u - \nu \nabla \cdot D(u) + \nabla p + \lambda \nabla \cdot (\nabla \phi \odot \nabla \phi) = 0, & (x,t) \in Q_T, \\
\nabla \cdot u = 0, & (x,t) \in Q_T, \\
\dfrac{\partial \phi}{\partial t} + (u \cdot \nabla)\phi - \gamma \Delta(\Delta \phi + f(\phi)) = 0, & (x,t) \in Q_T,
\end{cases} \tag{4.6}
$$

with the initial values $u(x,0) = u_0(x), d(x,0) = d_0(x)$ and periodic boundary conditions. Here $f(\phi) = (1-\phi^2)\phi/\epsilon^2$, $D(u) = (\nabla u + (\nabla u)^T)/2$, $\nabla \phi \odot \nabla \phi$ is the induced elastic tensor, with the (j,k)th entry being $\partial_{x_j}\phi \partial_{x_k}\phi$. The above equations have been used in [28] to analyze the motion of bubbles in a Newtonian fluid. These phase field models are also very similar to the liquid crystal model studied in [20, 27, 29].

The above simple system was used to study the free interface motion under the surface tension in the mixture of two Newtonian fluids with the same density and viscosity constants [1, 2, 3, 4, 5, 15, 21, 25, 26, 28, 30, 31, 33, 36, 40]. The system

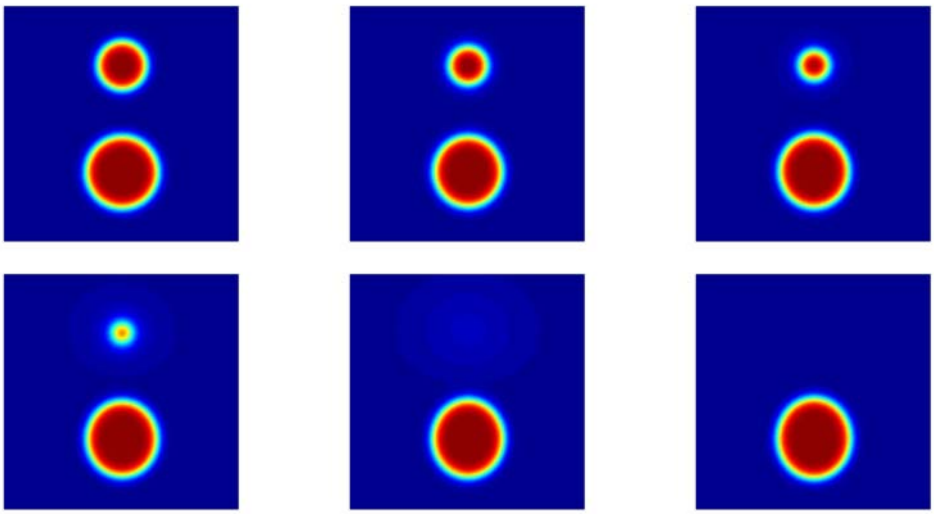

FIG. 4.5. *Deformation of two bubbles in a Newtonian fluid with the time valued at* 0.00, 0.10, 0.18, 0.22, 0.24, 0.28.

satisfies the following energy law:

(4.7)
$$\frac{d}{dt}\int_\Omega \left\{\frac{1}{2}|u|^2 + \frac{\lambda}{2}|\nabla\phi|^2 + \lambda F(\phi)\right\} dx = -\int_\Omega \{\nu|\nabla u|^2 + \gamma\lambda|\nabla(\Delta\phi - f(\phi))|^2\}\, dx.$$

Moreover, the whole system can be viewed as the approximation of the classical sharp interface model with the kinematic and traction-free boundary condition on the free interface [28]. As the transition width ϵ approaches zero, the induced bulk elastic stress term converges to the corresponding surface tension.

To test our formula for computing the Euler number, we solve the above system in two space dimensions via a spectral spatial discretization coupled with a second order semi-implicit-in-time scheme for ϕ and a semi-implicit projection scheme for the Navier–Stokes equations, such as those in [20, 28].

Figure 4.5 shows a special example of the deformation of two Newtonian bubbles in another Newtonian fluid. In this experiment, we take the 128×128 grid, period boundary condition on area $[0, 2\pi] \times [0, 2\pi]$, and $\epsilon = 2.5h = 0.1227$, $\lambda = 10.0$, $\gamma = 3.0$, $\nu = 1.0$. In the simulation, the larger bubble grows at the expense of the shrinkage of the smaller one. In fact, the smaller bubble dissolves into the fluid, while the bigger bubble absorbs from the fluid, similar to the well-known Oswald ripening effects (due to the Cahn–Hillard effect of the phase equation in (4.6)). The total volume of these two bubbles remains constant in time.

The topology change in this simulation can be characterized by the Euler number of the whole configuration. At the beginning, the Euler number of the configuration with the two bubbles is 2. And finally, after the smaller bubble is totally absorbed by the larger bubble, the Euler number of the bubble configuration becomes 1. Figure 4.6 shows the sharp change in the Euler number in this procedure using the formula (2.16).

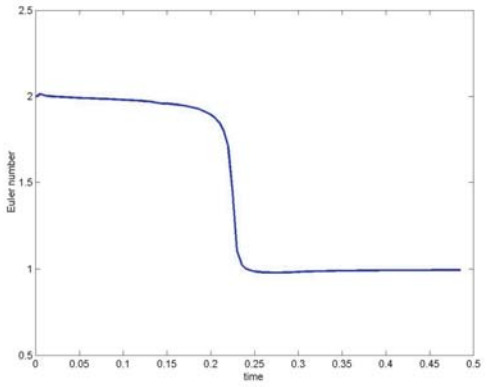

FIG. 4.6. *A plot of the Euler number in time with the annihilation of the small bubble.*

5. Conclusion. While an important advantage of phase field modeling of the interface variation and the interfacial motion is its ability to handle the change of interface topologies in natural and physically meaningful ways, it has also come to our attention that in many practical problems, useful topological information may be needed, and the effective control of the topological transformations may be important. In this paper, mechanisms to retrieve relevant topological information based on the phase field formulations are discussed. In particular, some robust formulae for computing a generalized Euler number of the interface are proposed based on the phase field order parameter ϕ. Using a special ansatz, we also get further simplified formulae. For smooth interfaces, our formulae give desired quantized characterization of the interface genus. When passing through singularities, they give fractional values that generalize the notion of the genus.

As a demonstration, numerical experiments are performed for the cases of a static deformation of a 3-D axial symmetric membrane as well as a time dependent annihilation of fluid bubbles in 2-D space. The experimental results show that the proposed methods for computing the Euler number are very effective and robust in detecting the topological changes. The ideas presented in this paper are very natural and easy to implement for other phase field models and may also be equally applicable to other simulation methods for free boundary and interface problems including the standard level set methods. Rigorous analysis of the formulae derived here based on formal asymptotic analysis are currently underway [17]. We are also working on the problem of taking the Euler number as a constraint within the phase field framework to study and analyze mechanisms in a physical system for controlling and preventing topological changes, should they become desirable.

THE FOCUS-CENTER-LIMIT CYCLE BIFURCATION IN SYMMETRIC 3D PIECEWISE LINEAR SYSTEMS*

EMILIO FREIRE†, ENRIQUE PONCE†, AND JAVIER ROS†

Abstract. The birth of limit cycles in 3D (three-dimensional) piecewise linear systems for the relevant case of symmetrical oscillators is considered. A technique already used by the authors in planar systems is extended to cope with 3D systems, where a greater complexity is involved.

Under some given nondegeneracy conditions, the corresponding theorem characterizing the bifurcation is stated. In terms of the deviation from the critical value of the bifurcation parameter, expressions in the form of power series for the period, amplitude, and the characteristic multipliers of the bifurcating limit cycle are also obtained.

The results are applied to accurately predict the birth of symmetrical periodic oscillations in a 3D electronic circuit genealogically related to the classical Van der Pol oscillator.

Key words. piecewise linear systems, bifurcation theory, limit cycles

AMS subject classifications. 37G15, 34C15

DOI. 10.1137/040606107

1. Introduction and main results. Piecewise linear modeling of nonlinear dynamical systems is especially successful in some engineering problems, such as the analysis and design of electronic oscillators or control systems (see, e.g., [CFPT02]). However, in the framework of piecewise linear systems, there are no general bifurcation results explaining the appearance or disappearance of self-sustained oscillations, as is the case for the Hopf bifurcation theorem in the context of differentiable systems. Thus, the authors gave in [FPR99] a complete characterization of the focus-center-limit cycle bifurcation for symmetric planar piecewise linear systems. Now we show how the corresponding result can be extended to the 3D case.

We consider a common situation in applications, namely, dynamical systems defined by piecewise continuous vector fields with three linear zones and two parallel frontiers. Furthermore, it is assumed that such systems show symmetry with respect to the origin; that is, if we put them in the form $d\mathbf{x}/d\tau = f(\mathbf{x})$ with $\mathbf{x} \in \mathbb{R}^3$, they satisfy $f(-\mathbf{x}) = -f(\mathbf{x})$. In particular, $f(0) = 0$, and so the origin is an equilibrium point for all values of the parameters. By means of a linear change of variables, it is always possible to suppose that the frontiers are the planes $\Sigma_1 = \{\mathbf{x} \in \mathbb{R}^3 : x_1 = 1\}$ and $\Sigma_{-1} = \{\mathbf{x} \in \mathbb{R}^3 : x_1 = -1\}$. We denote by L (left), C (central), and R (right) the regions of $\mathbb{R}^3$ at which $x_1 < -1$, $|x_1| \leq 1$, and $x_1 > 1$, respectively, hold.

To be more precise, we consider systems expressed as follows:

$$\dot{\mathbf{x}} = \begin{cases} A_L\mathbf{x} - \mathbf{b} & \text{if } x_1 < -1, \\ A_C\mathbf{x} & \text{if } |x_1| \leq 1, \\ A_L\mathbf{x} + \mathbf{b} & \text{if } x_1 > 1, \end{cases} \tag{1.1}$$

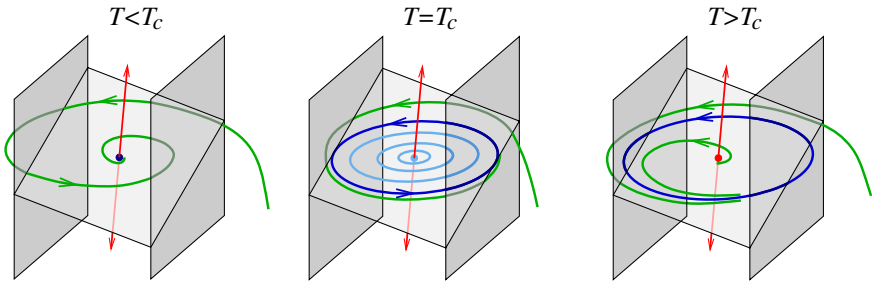

FIG. 1. *The focus-center-limit cycle bifurcation in the case $D > 0$, $\gamma > 0$. The focal plane and the complementary one-dimensional invariant manifold at the origin are shown, along with the two parallel planes which separate the three linear regions. In the situation sketched, as deduced from Theorem* 1.1*, the bifurcating limit cycle is of saddle type.*

where we have taken advantage of the continuity and symmetry of the vector field involved; in particular, the matrices A_L and A_C differ only in their first columns.

From Proposition 16 of [CFPT02], under the generic condition of observability, every system (1.1) can be written in the generalized Liénard form

$$\frac{d}{d\tau}\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} t & -1 & 0 \\ m & 0 & -1 \\ d & 0 & 0 \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} T-t \\ M-m \\ D-d \end{bmatrix}\operatorname{sat}(x_1), \tag{1.2}$$

where $\operatorname{sat}(x_1)$ is the *normalized saturation*

$$\operatorname{sat}(x_1) = \begin{cases} -1, & x_1 \le -1, \\ x_1, & |x_1| < 1, \\ 1, & x_1 \ge 1, \end{cases}$$

so that, regarding system (1.1), we have

$$A_L = \begin{bmatrix} t & -1 & 0 \\ m & 0 & -1 \\ d & 0 & 0 \end{bmatrix}, \qquad A_C = \begin{bmatrix} T & -1 & 0 \\ M & 0 & -1 \\ D & 0 & 0 \end{bmatrix}, \qquad \mathbf{b} = \begin{bmatrix} T-t \\ M-m \\ D-d \end{bmatrix}.$$

Note that system (1.2) is a particular instance of the more general Lur'e form

$$\frac{d\mathbf{x}}{d\tau} = A\mathbf{x} + \mathbf{b}\operatorname{sat}(\mathbf{c}^T\mathbf{x})$$

for the case $A = A_L$ and $\mathbf{c} = \mathbf{e_1}$, where $\mathbf{e}_1$ stands for the first vector of the canonical basis.

Clearly, the parameters t, m, d and T, M, D stand for the trace, the sum of principal minors of order two, and the determinant of each matrix, and they completely determine the dynamics of the system.

Choosing T as the bifurcation parameter, for the critical value $T_c = D/M$ with $M > 0$, system (1.2) has a linear center in the zone C (see Figure 1); that is, the matrix A_C has a pair of pure imaginary eigenvalues. We want to analyze whether a limit cycle bifurcates from this configuration as the bifurcation parameter T varies. Note the similarities with the classical Hopf bifurcation scenario.

It will be useful, in order to know the stability of such a limit cycle, to estimate the characteristic multipliers of the limit cycle, that is, the eigenvalues of the derivative of a Poincaré return map defined in an adequate section of the phase space. We will denote the logarithms of these characteristic multipliers by μ_r and μ_a, from radial and axial, respectively. Our main result is the following.

THEOREM 1.1. *Let us consider system* (1.2) *with* $M > 0$, $T_c = D/M$, *and* $\gamma = DM - Dm + dM - tM^2 \neq 0$. *For* $T = T_c$ *the system undergoes a focus-center-limit cycle bifurcation; that is, from the lineal center configuration in the central zone, which exists for* $T = T_c$, *one limit cycle appears for* $\gamma(T - T_c) > 0$ *and* $T - T_c$ *sufficiently small.*

The amplitude "a" (measured as the maximum of $|x_1|$*), the period* P_{er}, *and the logarithms of characteristic multipliers* μ_r *and* μ_a *of the periodic orbit are analytic functions at* 0, *in the variable* $(T - T_c)^{1/3}$; *namely,*

$$
\begin{aligned}
a &= 1 + \frac{(6\pi)^{2/3} M^{4/3}}{8\gamma^{2/3}} (T - T_c)^{2/3} + \frac{(6\pi^4)^{1/3} a_4}{960 M^{1/3} \gamma^{7/3}} (T - T_c)^{4/3} + O\left(T - T_c\right)^{5/3}, \\
P_{er} &= \frac{2\pi}{\sqrt{M}} + \frac{\pi(M - m)\sqrt{M}}{\gamma} (T - T_c) - \frac{6^{2/3} \pi^{5/3} M^{5/6} P_5}{20\gamma^{8/3}} (T - T_c)^{5/3} + O\left(T - T_c\right)^2, \\
\mu_r &= -\frac{(48\pi)^{1/3} M^{7/6} \gamma^{2/3}}{D^2 + M^3} (T - T_c)^{1/3} + O\left(T - T_c\right)^{2/3}, \\
\mu_a &= \frac{2\pi D}{M^{3/2}} + \frac{(48\pi)^{1/3}}{M^{5/6}} \left(\frac{Mt - D}{\gamma^{1/3}} + \frac{M^2 \gamma^{2/3}}{D^2 + M^3} \right) (T - T_c)^{1/3} + O\left(T - T_c\right)^{2/3},
\end{aligned}
$$

where

$$
\begin{aligned}
a_4 &= -120 t M^5 + \left(120D + 2t^3 + 21mt + 72d\right) M^4 \\
&\quad + \left[-\left(93m + 27t^2\right) D + \left(27m - 2t^2\right) d \right] M^3 + \left(2t^2 m + 25dt - 27m^2\right) DM^2 \\
&\quad + \left[25D^3 + 23\left(mt - d\right) D^2\right] M - 25mD^3, \\
P_5 &= \left[M\left(M - m\right)^2 + \left(Mt - d\right)^2\right] \left(Mt - D\right).
\end{aligned}
$$

In particular, if $\gamma > 0$ *and* $D < 0$, *then the limit cycle bifurcates for* $T > T_c$ *and is orbitally asymptotically stable.*

This theorem describes a codimension-one bifurcation, similar to the Hopf bifurcation of differentiable dynamics (see [CH82]), but some differences should be noted. In particular, the expressions characterizing the bifurcation are in terms of the parameter to the one third power instead of the one half power, and, more important, the limit cycle amplitude's leading order is $O(1)$. Thus, the stability change of the origin is accompanied by the abrupt appearance of a limit cycle of significant size. This comment also applies to the planar case, as appeared in [Kr87] and [FPR99].

When the coefficient γ is not equal to zero, it allows a complete characterization of the bifurcation criticality. Its role is analogous to the coefficient of the cubic term in the Poincaré–Andronov–Hopf normal form. When $\gamma = 0$, the bifurcation is of higher codimension, requiring a specific treatment that will appear elsewhere.

We want to remark that it is possible, with the same techniques, to obtain similar bifurcation results for the asymmetric case of single-sided saturation. Thus, the proposed methodology is able to cope with a wider class of piecewise linear systems.

The rest of the paper is structured as follows. In section 2, we show how the above result can be useful for accurately predicting the birth of symmetrical periodic

oscillations in a tridimensional electronic circuit, which can be built by taking a Van der Pol oscillator as starting point. The proof of Theorem 1.1 is given in section 3.

2. Predicting the onset of symmetrical periodic oscillations in a 3D electronic circuit. In this section, we consider the electronic circuit of Figure 2(a), genealogically related with the classical Van der Pol oscillator, in order to show the applicability of our results. Regarding this circuit, the nonlinear conductance NL is its active element, implemented by means of an operational amplifier with the feedback structure of Figure 2(b), and the current-voltage characteristic is shown in Figure 2(c). Note that we are dealing with a nonlinearity characteristic qualitatively similar to the cubic one appearing in the classical Rayleigh–Van der Pol oscillator. In fact, if we eliminate the capacitor C_2 and make $R = R_0 = 0$, then the resulting planar circuit could be thought of as a modern electronic realization of such classical oscillators; see [Kr87] and [FPR99].

Thus, the 3D circuit of Figure 2 can be built by adding the capacitance C_2 to a bidimensional oscillator circuit. In the context of chaotic circuits, such topology was originally proposed in [SYM81], and was studied afterwards in [FGA84] and [FRGP93] in the case $R_0 = 0$ and assuming a nonlinear positive conductance for the resistor R. With slight modifications, this circuit has been extensively studied in the last two decades; see [GK92] or [HBCJM91]. Taking $R_0 = 0$ and substituting the nonlinear element by the so-called Chua diode, many papers have also been written; see [CWHZ93], [Ma93], and references therein. Anyway, the onset of symmetrical periodic oscillations was never accurately predicted, since in most cases the circuit was analyzed by taking polynomial approximations. Thus, the rapid bifurcation for the limit cycle observed in practice was never justified.

It should be remarked that the characteristic of Chua's diode is qualitatively similar to the one presented in Figure 2(c) but the zone of negative slope is made up by three pieces with two different slopes. For that, at least two subcircuits with operational amplifiers like those shown in Figure 2(b) are needed. Thus, the Chua circuit characteristic has five linear segments instead of only three, as in our case. However, in modeling Chua's circuit, usually only the three innermost pieces are represented, since the two outermost pieces of positive slope are not physically used; see [Ke93].

As stated in [Kr87] and [FPR99], there exists an excellent agreement between the actual response of the nonlinear device NL in the circuit and its symmetric piecewise

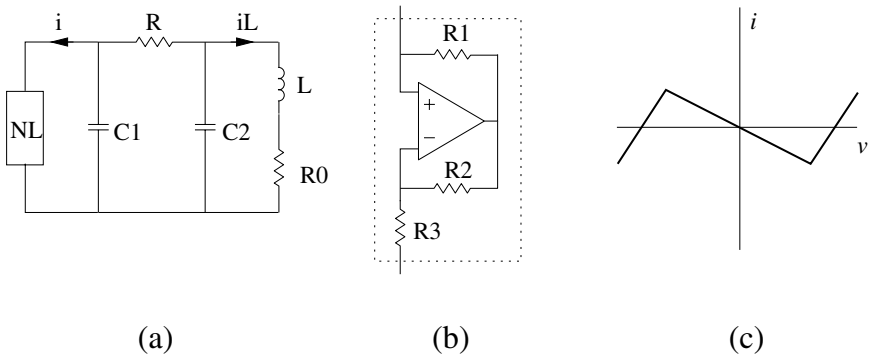

FIG. 2. (a) *The 3D electronic circuit.* (b) *Implementation of the nonlinear conductance NL.* (c) *Piecewise linear current-voltage characteristic of NL.*

linear mathematical model. Therefore, we are led to consider the piecewise linear dynamical system

$$\begin{aligned} C_1\frac{dv_1}{d\tau} &= \frac{v_2-v_1}{R}-i(v_1),\\ C_2\frac{dv_2}{d\tau} &= \frac{v_1-v_2}{R}-i_L,\\ L\frac{di_L}{d\tau} &= v_2-R_0i_L, \end{aligned} \tag{2.1}$$

where v_1 and v_2 are the voltages across the capacitors C_1 and C_2, respectively, while i_L is the current through the inductance. The nonlinear current-voltage characteristic is

$$i(v_1)=\frac{v_1-f(v_1)}{R_1} \quad \text{with} \quad f(v_1)=\begin{cases} E\,\text{sign}(v_1), & |v_1|>E/\sigma,\\ \sigma v_1, & |v_1|\le E/\sigma, \end{cases}$$

where

$$\sigma=1+\frac{R_2}{R_3}$$

is the gain of the operational amplifier configured (using feedback) as a noninverting amplifier and E is its saturation voltage.

With the following linear change of variables and time rescaling,

$$v_1=\frac{E}{\sigma}y_1, \quad v_2=\frac{E}{\sigma}y_2, \quad i_L=\frac{E}{\sigma}\sqrt{\frac{C_2}{L}}y_3, \quad \tau=RC_1\bar{\tau}, \tag{2.2}$$

and defining the following five nonnegative dimensionless parameters,

$$r=\frac{R}{R_1}, \quad c=\frac{C_1}{C_2}, \quad \mu=(\sigma-1)\frac{R}{R_1}=\frac{RR_2}{R_1R_3}, \quad \rho=\frac{R^2C_1^2}{LC_2}, \quad \kappa=\frac{RR_0C_1}{L}, \tag{2.3}$$

we can express system (2.1) as follows:

$$\frac{d}{d\bar{\tau}}\begin{bmatrix} y_1\\ y_2\\ y_3 \end{bmatrix}=\begin{bmatrix} -r-1 & 1 & 0\\ c & -c & -\sqrt{\rho}\\ 0 & \sqrt{\rho} & -\kappa \end{bmatrix}\begin{bmatrix} y_1\\ y_2\\ y_3 \end{bmatrix}+\begin{bmatrix} \mu+r\\ 0\\ 0 \end{bmatrix}\text{sat}(y_1). \tag{2.4}$$

For the subsequent analysis, we will choose μ and ρ as the main bifurcation parameters. In practice, to detect the bifurcation in a experimental way, it is better to tune the parameter μ by means of a variable resistor R_2, which is equivalent to varying the gain σ.

The observability matrix for system (2.1) is

$$\mathcal{O}=\begin{bmatrix} \mathbf{e}_1^T\\ \mathbf{e}_1^TA\\ \mathbf{e}_1^TA^2 \end{bmatrix}=\begin{bmatrix} 1 & 0 & 0\\ -r-1 & 1 & 0\\ (r+1)^2+c & -c-r-1 & -\sqrt{\rho} \end{bmatrix},$$

which has full rank for all the values of components of the circuit. From Proposition 16 of [CFPT02], system (2.1) can be expressed in Liénard's generalized form (1.2) with the following values:

$$\begin{aligned} &T=\mu-c-\kappa-1, && t=-r-c-\kappa-1<0,\\ &M=(c+1)\kappa-(c+\kappa)\mu+\rho, && m=(c+1)\kappa+(c+\kappa)r+\rho>0,\\ &D=(c\kappa+\rho)\mu-\rho, && d=-(c\kappa+\rho)r-\rho<0. \end{aligned} \tag{2.5}$$

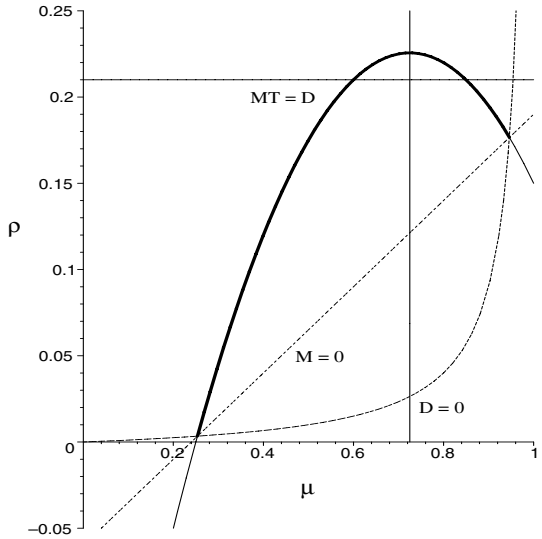

FIG. 3. *The parabolic arc (thick line) in the plane (μ, ρ) corresponding to the bifurcation locus of Proposition* 2.1 *for $c = 0.2$ and $\kappa = 0.05$. The horizontal line indicates the path followed as μ varies for a fixed value of ρ. The dashed line represents points with $D = 0$, so that above it we have $D < 0$. At the dotted straight line we have $M = 0$, and above this line we have $M > 0$. The vertical line corresponds to $\mu = \mu_*$.*

Note that these coefficients are the linear invariants of the two matrices involved, so that their computation is straightforward, and that it is not necessary to explicitly compute the linear change of variables required to get the Liénard form for applying Theorem 1.1.

The equation $MT - D = 0$ leads to

$$(c+\kappa)\mu^2 - \left[(c+\kappa)^2 + c + 2\kappa\right]\mu + \rho(c+\kappa) + \kappa\,(c+1)\,(c+\kappa+1) = 0, \tag{2.6}$$

which can be rewritten as $(\mu - \mu_*)^2 + \rho - \rho_* = 0$, where

$$\begin{aligned} \mu_* &= 1 + \frac{(c+\kappa)^2 - c}{2(c+\kappa)}, \\ \rho_* &= {\mu_*}^2 - \kappa(c+1)\left(1 + \frac{1}{c+\kappa}\right) \end{aligned} \tag{2.7}$$

represent the coordinates in the (μ, ρ)-plane of the vertex of the quadratic (2.6); see Figure 3. Now the application of Theorem 1.1 allows us to state the following result.

PROPOSITION 2.1. *Let us consider system* (2.4) *and assume that $c > 0$ and the parameter κ satisfies*

$$0 < \kappa < \kappa_{\max}(c) = \frac{\sqrt{c^2 + c} - c}{2}. \tag{2.8}$$

Then the system undergoes the focus-center-limit cycle bifurcation described in Theorem 1.1 *at the points of the (μ, ρ)-plane belonging to the parabolic arc defined by the quadratic equation*

$$(\mu - \mu_*)^2 + \rho - \rho_* = 0 \tag{2.9}$$

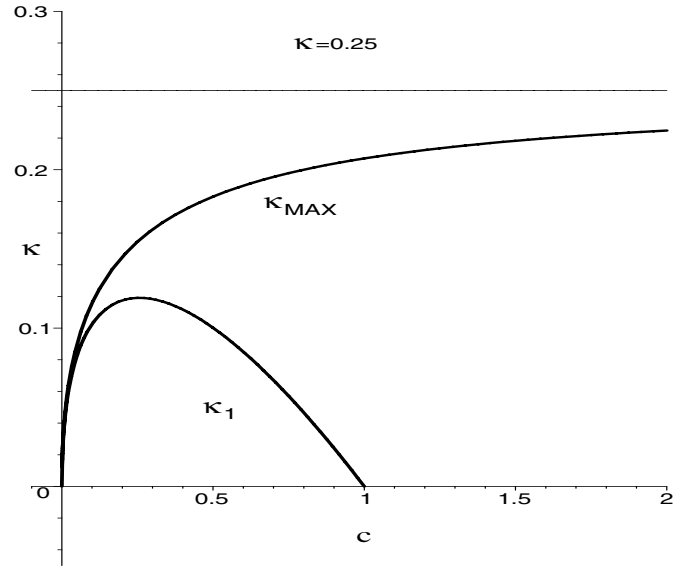

FIG. 4. *The graphs of the functions* $\kappa_{\max}(c)$ *and* $\kappa_1(c)$*, which determine different regions in the plane* (c,κ) *as described in statements* (a) *and* (b) *of Proposition* 2.1. *Note the horizontal asymptote at* $\kappa = 1/4$.

and satisfying

$$\rho > (c+\kappa)\mu - (c+1)\kappa. \tag{2.10}$$

The endpoints of the above parabolic arc are

$$(\mu_1,\rho_1) = \left(1 - \frac{c+\underline{c}}{2(c+\kappa)}, \frac{c(1-2\kappa)-\underline{c}}{2}\right), \quad (\mu_2,\rho_2) = \left(1 - \frac{c-\underline{c}}{2(c+\kappa)}, \frac{c(1-2\kappa)+\underline{c}}{2}\right),$$

where

$$\underline{c} = \sqrt{c^2(1-2\kappa)^2 - 4c(c+1)\kappa^2}.$$

In the points of the above parabolic arc, the inequality $D < 0$ *holds, and the following cases arise:*

(a) *If* $0 < c < 1$ *and* $0 < \kappa < \kappa_1$*, where* $\kappa_1 = \kappa_1(c)$ *is the only positive root of the quartic*

$$(c+\kappa)^4 + 4c\kappa(c+\kappa) - c^2 = 0, \tag{2.11}$$

then $\mu_1 < \mu_* < \mu_2$ *and two subcases appear; see Figure* 4.

(a.1) *If* $\mu_1 < \mu < \mu_*$*, then at the bifurcation points of the parabolic arc given by* (2.9)–(2.10) *one has* $\gamma > 0$*. Consequently, when* ρ *varies, the bifurcation is supercritical and the limit cycle is orbitally asymptotically stable.*

(a.2) *If* $\mu_* < \mu < \mu_2$*, then* $\gamma < 0$ *at the bifurcation points of the parabolic arc. Here, when* ρ *varies, the bifurcation is subcritical and the limit cycle is unstable.*

(b) *If* $0 < c < 1$ *and* $\kappa \geq \kappa_1$*, or* $c \geq 1$*, then all the bifurcation points of the parabolic arc* (2.9)–(2.10) *satisfy* $\gamma > 0$*. Therefore, the bifurcation is supercritical and the bifurcating limit cycle is orbitally asymptotically stable.*

TABLE 2.1
List of components for the circuit.

$C = C_1 = C_2$	100 nF
L	220 mH
R_1	10 kΩ
R_3	2200 Ω
R	1 kΩ
R_0	220 Ω

Proof. Conditions $T = T_c$ and $M > 0$ of Theorem 1.1 lead to $MT - D = 0$, which is equivalent to (2.9), and to (2.10). After some manipulations, we get the inequality

$$(c+\kappa)\mu^2 - (c+2\kappa)\mu + (c+1)\kappa < 0,$$

whose discriminant, namely $c^2 - 4c^2\kappa - 4c\kappa^2$, is positive due to (2.8). In fact, this expression coincides with $\underline{c}^2$. The endpoints of the parabolic arc can be obtained by solving the equation $M = 0$ and (2.9).

To show that $D < 0$ at the bifurcation values, as we are working at points where $MT - D = 0$ along with $M > 0$, it suffices to show that $T < 0$, which is a trivial task.

To prove statements (a) and (b), it is enough to study the sign of the coefficient γ in Theorem 1. Using the condition $MT - D = 0$, we have

$$\gamma = MT(M-m) + M(d - tM) = M[T(M-m) + d - tM],$$

and with $M > 0$ we get $\operatorname{sign}(\gamma) = \operatorname{sign}[T(M-m) + d - tM]$. Thus, using (2.5), (2.6), and canceling a factor $r + \mu > 0$, we conclude that

$$\operatorname{sign}(\gamma) = \operatorname{sign}\left[(c+\kappa)^2 + c + 2\kappa - 2(c+\kappa)\mu\right] = \operatorname{sign}(\mu_* - \mu). \tag{2.12}$$

Assume now that $0 < c < 1$ and $0 < \kappa < \kappa_1$. Thus, the left-hand side of (2.11) is negative, which implies $(c+\kappa)^2 < \underline{c}$. Then $\mu_1 < \mu_* < \mu_2$, and statement (a) follows.

When $c \le 1$ and $\kappa \ge \kappa_1$, we have $(c+\kappa)^2 \ge \underline{c}$. If $c > 1$, then we have $(c+\kappa)^2 > c > \underline{c}$. In both cases, we conclude that $\mu_* \ge \mu_2$, and statement (b) follows. ∎

For the sake of completeness, if we define, for $0 < c < 1$, the constants

$$q_1 = \sqrt[3]{27c + 26 + 3\sqrt{81c^2 + 156c + 75}} > 0, \qquad q_2 = q_1 + \frac{1}{q_1} - 4 > 0,$$

we obtain

$$\kappa_1(c) = \sqrt{\frac{c}{6}q_2} + \sqrt{c\sqrt{\frac{6c}{q_2}} - \frac{cq_2}{6} - 2c} - c,$$

which is represented for $0 < c < 1$ in Figure 4.

The above proposition enables us to design the electronic oscillator by choosing adequately the component values of the circuit. In particular, in order to minimize the signal distortion from the sinusoidal wave form, one must select parameters not far from the bifurcation curve where the onset of periodic oscillations has been predicted.

To assess the accuracy of piecewise linear modeling for this circuit, a SPICE implementation of the circuit was made; see [QNPS93]. The values chosen for the components are in Table 2.1, while the operational amplifier used was an LM324,

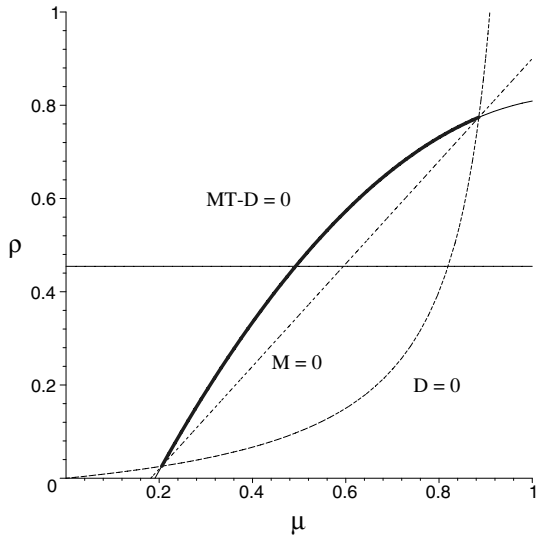

FIG. 5. *The parabolic arc (thick line) in plane* (μ, ρ) *predicted by Proposition* 2.1 *for* $\kappa = 0.1$. *The horizontal line indicates the path followed as* μ *varies for the fixed value of* ρ *used in the simulations. The dashed line represents points with* $D = 0$, *so that above it we have* $D < 0$. *The dotted straight line indicates points with* $M = 0$, *and above it we have* $M > 0$.

with a supply voltage of 9V and a measured saturation voltage of 8.5V (with slight variations around).

For these values, we have

$$c = \frac{C_1}{C_2} = 1, \quad \kappa = \frac{RR_0C}{L} = 0.1 < \frac{\sqrt{2}-1}{2} \approx 0.2071,$$

so that we can apply Proposition 2.1 and, in particular, its statement (b). Note that

$$\mu = \frac{RR_2}{R_1R_3} \approx \frac{R_2}{22000}, \quad \rho = \frac{R^2C}{L} \approx 0.4545,$$

so that by varying R_2 we move μ, describing a horizontal path that crosses the curve corresponding to the locus of bifurcation points, as shown in Figure 5. For the above value of ρ, the bifurcation takes place for the value $\bar{\mu} \approx 0.4924$, in accordance with (2.6), that corresponds with the value $R_2 \approx 10833\Omega$, and oscillations will appear by increasing R_2 above this critical value.

In Figures 6 and 7, we show the comparison between some experimental results taken from a SPICE simulation, once put into dimensionless form, and the predictions of Theorem 1.1 for the amplitude and the period of the bifurcating limit cycle. The excellent agreement achieved validates the piecewise linear model assumed for the operational amplifier nonlinear characteristic.

3. Proof of Theorem 1.1. In this section we provide the results necessary to prove Theorem 1.1.

For the critical value of the bifurcation parameter $T_c = D/M$, the matrix A_C has a pair of imaginary eigenvalues, so that for T in a neighborhood of T_c the eigenvalues of A_C will be $\alpha \pm i\beta$ and $\delta \in \mathbb{R}$. The characteristic polynomial of A_C is

$$p(\lambda) = \det(A_C - \lambda I) = -\lambda^3 + T\lambda^2 - M\lambda + D,$$

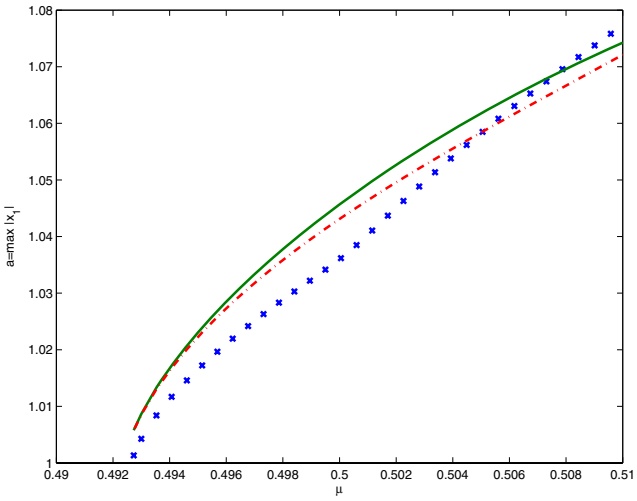

FIG. 6. *Comparison for amplitude between SPICE simulation data (× × ×), the expression corresponding to the two first non-null terms of Theorem* 1.1 *(—), and three non-null terms (-·-).*

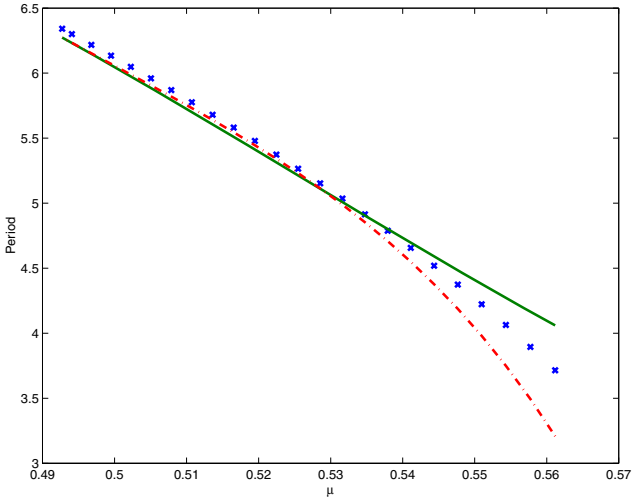

FIG. 7. *Comparison for period between SPICE simulation data (× × ×), the expression corresponding to the two first non-null terms of Theorem* 1.1 *(—), and three non-null terms (-·-).*

and thus

$$\begin{aligned} T &= \delta + 2\alpha, \\ M &= 2\alpha\delta + \alpha^2 + \beta^2, \\ D &= \delta(\alpha^2 + \beta^2). \end{aligned} \tag{3.1}$$

When $\alpha = 0$ and $\beta > 0$, or equivalently $D = MT$ and $M > 0$, system (1.2) has a linear center contained in an invariant plane given by $\delta^2 x_1 - \delta x_2 + x_3 = 0$. Additionally, the outermost periodic orbit of the center is tangent to the planes Σ_1 and Σ_{-1} at the points $[1, \delta, 0]^T$ and $[-1, -\delta, 0]^T$, respectively. Consequently, the time

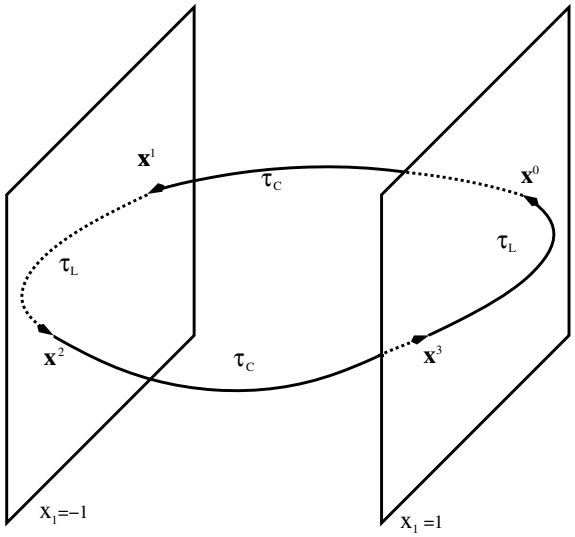

FIG. 8. *Sketch of a symmetrical periodic orbit which uses the three linear zones of system* (1.2).

spent by this orbit in going from $\mathbf{x}^0$ to $\mathbf{x}^1$ is $\tau_C = \pi/\beta$ in the zone C, and obviously $\tau_L = 0$ in the zone L.

We want to analyze the possible bifurcation of a limit cycle from the linear center in the zone C. (Obviously, it should be born from the outermost periodic orbit of the center.) As system (1.2) is linear in every zone, it is possible to obtain its solutions explicitly, and to identify symmetrical periodic solutions of the system living in the three zones with the solutions of the equations

$$\begin{aligned} e^{A_C\tau_C}\mathbf{x}^0 - \mathbf{x}^1 &= \mathbf{0}, \\ e^{A_L\tau_L}\mathbf{x}^1 - \int_0^{\tau_L} e^{A_L(\tau_L - s)}\mathbf{b}\, ds + \mathbf{x}^0 &= \mathbf{0}, \end{aligned} \tag{3.2}$$

where τ_C and τ_L are the times spent by the semiorbit in each zone, and

$$\mathbf{x}^0 = \begin{bmatrix} 1 \\ x_2^0 \\ x_3^0 \end{bmatrix}, \quad \mathbf{x}^1 = \begin{bmatrix} -1 \\ x_2^1 \\ x_3^1 \end{bmatrix},$$

are two intersection points of the orbit with the planes Σ_1 and Σ_{-1}, respectively (from the symmetry, there will be two more, $\mathbf{x}^2 = -\mathbf{x}^0$ and $\mathbf{x}^3 = -\mathbf{x}^1$); see Figure 8. We will refer to the system formed by (3.2) as the *closing equations*. The use of these equations goes back to Andronov and coworkers [AVK66], and it was exploited by Kriegsmann [Kr87] in the context of limit cycle bifurcations. This author studied the *rapid* bifurcation in the Wien bridge oscillator, later revisited in [FPR99].

Starting from the critical value $T = T_c$ and considering the outermost periodic orbit of the corresponding center configuration, we want to use the closing equations to analyze what happens with such periodic orbit as T varies, keeping M and D constant and always assuming $M > 0$. To achieve this goal, it is more convenient to vary the eigenvalues of A_C in a neighborhood of $(\alpha, \beta, \delta) = (0, \sqrt{M}, D/M)$, adding to the closing equations (3.2) the last two equations of (3.1), to impose that M and D are fixed.

The sorted set formed by (3.2) and the last two equations of (3.1) will be denoted by

$$\mathbf{F}(\mathbf{z}) = \mathbf{0}, \tag{3.3}$$

where $\mathbf{z} = (\alpha, \beta, \delta, \tau_C, \tau_L, x_2^0, x_3^0, x_2^1, x_3^1)$, which constitutes a nonlinear system of eight equations and nine unknowns, to be studied in a neighborhood of the point

$$\bar{\mathbf{z}} = \left(0, \sqrt{M}, \frac{D}{M}, \frac{\pi}{\sqrt{M}}, 0, \frac{D}{M}, 0, -\frac{D}{M}, 0\right).$$

Obviously, we are interested in a branch of solutions of (3.3) passing through $\bar{\mathbf{z}}$, and leading to positive values of τ_L. It turns out that system (3.3) has a trivial branch of solutions that passes through $\bar{\mathbf{z}}$ and can be parameterized as

$$\mathbf{z}(\mu) = \left(0, \sqrt{M}, \frac{D}{M}, \frac{\pi}{\sqrt{M}}, 0, \frac{D}{M} + \mu, \mu\frac{D}{M}, -\frac{D}{M} - \mu, -\mu\frac{D}{M}\right) \tag{3.4}$$

for every real μ. This trivial branch will be called the *spurious branch* because, for $\mu \neq 0$, these solutions do not correspond to periodic orbits of the system (1.2). The Jacobian matrix of $\mathbf{F}$ in $\bar{\mathbf{z}}$ does not have full rank; in fact, as the following result shows, the point $\bar{\mathbf{z}}$ is a branch point where two branches intersect each other. Moreover, we obtain a new set of equations for which $\bar{\mathbf{z}}$ is nonsingular.

LEMMA 3.1. *For the closing equations* (3.3) *with* $M > 0$*, the following statements hold:*

(a) *The fourth equation of* (3.3)*, namely*

$$F_4(\mathbf{z}) = 0,$$

is satisfied for every $\mathbf{z}$ *with* $\tau_L = 0$.

(b) *The function* $\widetilde{F}_4(\mathbf{z})$ *such that* $F_4(\mathbf{z}) = \tau_L \widetilde{F}_4(\mathbf{z})$ *is an analytic function in a neighborhood of* $\bar{\mathbf{z}}$.

(c) *If we define the modified closing equations*

$$\mathbf{G}(\mathbf{z}) = \mathbf{0}, \tag{3.5}$$

where $G_4 = \widetilde{F}_4$ *and* $G_i = F_i$ *for* $i \neq 4$*, then the solution set of* (3.5) *in a neighborhood of* $\bar{z}$ *is the solution set of* (3.3) *excepting the spurious branch* (3.4).

(d) *For system* (3.5) *the point* $\bar{z}$ *is a nonsingular point. Moreover, the solutions of* (3.5) *are analytic functions of* τ_L *at* 0*, and their corresponding Taylor series are*

$$\alpha = \frac{M^{5/2}\gamma}{12\pi(D^2 + M^3)}\tau_L^3 + \frac{M^{1/2}\xi_1}{720\ pi(D^2 + M^3)}\tau_L^5 + O\left(\tau_L^6\right), \tag{3.6}$$

$$\beta = \sqrt{M} - \frac{DM\gamma}{12\pi(D^2 + M^3)}\tau_L^3 - \frac{D\xi_1}{720\pi M(D^2 + M^3)}\tau_L^5 + O\left(\tau_L^6\right), \tag{3.7}$$

$$\delta = \frac{D}{M} + \frac{D^2\gamma}{6\pi M^{1/2}(D^2 + M^3)}\tau_L^3 + \frac{D^2\xi_1}{360\pi M^{5/2}(D^2 + M^3)}\tau_L^5 + O\left(\tau_L^6\right), \tag{3.8}$$

$$\tau_C = \frac{\pi}{\sqrt{M}} - \tau_L + \frac{M - m}{12}\tau_L^3 + \frac{\xi_2}{720\pi M^2}\tau_L^5 + O\left(\tau_L^6\right), \tag{3.9}$$

$$x_2^0 = \frac{D}{M} + \frac{M}{2}\tau_L + \frac{Mt-D}{12}\tau_L^2 + \frac{4M\gamma + \pi\sqrt{M}\xi_3}{24\pi M^{3/2}}\tau_L^3 - \frac{\xi_4}{720M^2}\tau_L^4$$
$$+ \left[\frac{D\xi_3 - M^3 d}{24M^2\left(e^{\pi D/M^{3/2}}+1\right)} - \frac{DM^{3/2}\gamma}{12\pi(D^2+M^3)}\right]\tau_L^4 + O\left(\tau_L^5\right), \tag{3.10}$$

$$x_2^1 = -\frac{D}{M} + \frac{M}{2}\tau_L - \frac{Mt-D}{12}\tau_L^2 - \frac{4M\gamma - \pi\sqrt{M}\xi_3}{24\pi M^{3/2}}\tau_L^3 + \frac{\xi_4}{720M^2}\tau_L^4$$
$$- \left[\frac{e^{\pi D/M^{3/2}}(D\xi_3 - M^3 d)}{24M^2\left(e^{\pi D/M^{3/2}}+1\right)} + \frac{DM^{3/2}\gamma}{12\pi(D^2+M^3)}\right]\tau_L^4 + O\left(\tau_L^5\right), \tag{3.11}$$

$$x_3^0 = \frac{D}{2}\tau_L + \frac{(Mt-D)\,D}{12M}\tau_L^2 + \left[\frac{DM^{3/2}\gamma}{6\pi(D^2+M^3)} + \frac{D\xi_3}{24M^2}\right]\tau_L^3$$
$$- \frac{D\xi_3 - M^3 d}{12M^2\left(e^{\pi D/M^{3/2}}+1\right)}\tau_L^3 - \frac{D\xi_4}{720M^3}\tau_L^4 + O\left(\tau_L^5\right), \tag{3.12}$$

$$x_3^1 = \frac{D}{2}\tau_L - \frac{(Mt-D)\,D}{12M}\tau_L^2 - \left[\frac{DM^{3/2}\gamma}{6\pi(D^2+M^3)} + \frac{D\xi_3}{24M^2}\right]\tau_L^3$$
$$+ \frac{D\xi_3 + e^{\pi D/M^{3/2}}M^3 d}{12M^2\left(e^{\pi D/M^{3/2}}+1\right)}\tau_L^3 + \frac{D\xi_4}{720M^3}\tau_L^4 + O\left(\tau_L^5\right), \tag{3.13}$$

where

$$\begin{aligned}
\gamma &= DM - Dm + dM - tM^2,\\
\xi_1 &= 5D^3M - 5D^3m - 15D^2M^2t + 11D^2Md + 4D^2Mmt - 15DM^4\\
&\quad + 21DM^3m + 9DM^3t^2 - 10DM^2dt - 6DM^2m^2 + DM^2mt^2 + 15M^5t\\
&\quad - 9M^4d - 12M^4mt + M^4t^3 + 6M^3dm - M^3dt^2,\\
\xi_2 &= 5D^2M - 5D^2m - 10DM^2t + 6DMd + 4DMmt - 9M^4\\
&\quad + 15M^3m + 5M^3t^2 - 6M^2dt - 6M^2m^2 + M^2mt^2,\\
\xi_3 &= D\,(D - Mt) + M^2m,\\
\xi_4 &= 15D^3 - 20D^2Mt + 16DM^2m + 4DM^2t^2 - 9M^3d - 7M^3mt + M^3t^3.
\end{aligned} \tag{3.14}$$

Proof. Statements (a) and (b) come from a direct inspection of (3.3).

Recalling (3.2), from statement (b) and (3.3) we conclude that

$$\widetilde{F}_4(\mathbf{z})\Big|_{\tau_L=0} = \lim_{\tau_L\to 0}\frac{1}{\tau_L}F_4(\mathbf{z}) = \mathbf{e}_1^T A_L \begin{bmatrix} -1 \\ x_2^1 \\ x_3^1 \end{bmatrix} + \mathbf{e}_1^T \begin{bmatrix} t-2\alpha-\delta \\ m-M \\ d-D \end{bmatrix} = -x_2^1 - 2\alpha - \delta.$$

The above computation shows that $\widetilde{F}_4(\mathbf{z}(\mu)) = \mu$, so that the spurious branch (3.4) does not belong to the solution set of $\widetilde{F}_4(\mathbf{z}) = 0$. Besides, every solution $\mathbf{z}$ of (3.3) with $\tau_L \neq 0$ is a solution of (3.5), and statement (c) is proven.

For the computation of the Jacobian matrix $\partial\mathbf{G}/\partial\mathbf{z}\big|_{\mathbf{z}=\bar{\mathbf{z}}}$ and the series (3.6)–(3.13), we have used the following approach. For the first three rows of the closing equations, we work with the equivalent expression

$$\mu_0 e^{\delta\tau_C}\mathbf{v} + e^{\alpha\tau_C}\cos(\beta\tau_C)\,\widehat{\mathbf{v}} + e^{\alpha\tau_C}\frac{\sin(\beta\tau_C)}{\beta}\,(A_C - \alpha I)\,\widehat{\mathbf{v}} - \mathbf{x}^1 = \mathbf{0},$$

where $\mathbf{v} = \left[1, 2\alpha, \alpha^2 + \beta^2\right]^T$ is a right eigenvector of A_C associated with the real eigenvalue δ, and

$$\widehat{\mathbf{v}} = \mathbf{x}^0 - \mu_0 \mathbf{v}$$

is the projection (following the direction of $\mathbf{v}$) of the vector $\mathbf{x}^0$ onto the invariant plane associated with the complex eigenvalues of A_C. Consequently, the coefficient μ_0 is

$$\mu_0 = \frac{\mathbf{w}^T \mathbf{x}^0}{\mathbf{w}^T \mathbf{v}} = \frac{\delta^2 - \delta x_2^0 + x_3^0}{(\delta - \alpha)^2 + \beta^2},$$

where $\mathbf{w}^T = \left[\delta^2, -\delta, 1\right]$ is a left eigenvector of A_C associated with the eigenvalue δ.

Regarding the next three rows of the closing equations, it is useful to write the matrix exponentials in series of τ_L. Then, in computing partial derivatives with respect to the variables other from τ_L, one only needs to consider the terms of degree zero in τ_L. This comment is also useful for obtaining $\widetilde{F}_4$ from F_4.

Thus, the Jacobian matrix $\partial \mathbf{G}/\partial \mathbf{z}\big|_{\mathbf{z}=\overline{\mathbf{z}}}$ is

$$\begin{bmatrix}
-\frac{\pi}{\sqrt{M}} & 0 & DMK & 0 & 0 & -DMK & M^2K & 0 & 0 \\
-\frac{\pi D}{M^{3/2}} & -\pi & 0 & -M & 0 & -1 & 0 & -1 & 0 \\
0 & -\frac{\pi D}{M} & DM^2K & -D & 0 & -DM^2K & M^3K - 1 & 0 & -1 \\
-2 & 0 & -1 & 0 & \frac{M}{2} & 0 & 0 & -1 & 0 \\
0 & 0 & 0 & 0 & -M & 1 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & -D & 0 & 1 & 0 & 1 \\
\frac{2D}{M} & 2\sqrt{M} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & \frac{2D}{\sqrt{M}} & M & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix},$$

where

$$K = \frac{e^{\pi D/M^{3/2}} + 1}{D^2 + M^3}. \tag{3.15}$$

If we remove the fifth column (corresponding to τ_L), the determinant of the resulting matrix is equal to

$$-2\pi M^2 \left(e^{\pi D/M^{3/2}} + 1\right) \neq 0,$$

and hence the matrix has full rank. From the implicit function theorem for analytic functions (see [CH82]) we obtain statement (d). All the computations of the above series expansions have been checked with the symbolic manipulator Maple; see [MGHLVM03]. □

In what follows, we give an auxiliary result to analyze the stability of the bifurcating limit cycle. First, we must study the behavior of the return map near a periodic orbit of three zones. Due to the symmetry, we need to use only the semiorbit that starts from $\mathbf{x}^0 \in \Sigma_1$, crosses Σ_{-1} at the point $\mathbf{x}^1$, and returns to this section at the point $\mathbf{x}^2 = -\mathbf{x}^0 \in \Sigma_{-1}$. We denote by $\mathbf{p}_0$, $\mathbf{p}_1 \in \mathbb{R}^2$, the coordinates of $\mathbf{x}^0$ and $\mathbf{x}^1$ restricted to their respective sections. From the transition maps associated with the flow, locally defined at the points $\mathbf{x}^0$ and $\mathbf{x}^1$, it is possible in adequate neighborhoods at the sections to define the functions providing the corresponding restricted coordinates. Let us denote by π_C, π_L such functions, satisfying $\pi_C(\mathbf{p}_0)$=$\mathbf{p}_1$, $\pi_L(\mathbf{p}_1) = -\mathbf{p}_0$,

and let $\pi_{LC} = \pi_L \circ \pi_C$. We will let $\tau_C(\mathbf{p}_0)$ and $\tau_L(\mathbf{p}_1)$ denote the times spent by the semiorbit in passing from $\mathbf{x}^0$ to $\mathbf{x}^1$ and from $\mathbf{x}^1$ to $\mathbf{x}^2$, respectively, and write $D_{\mathbf{p}}(\cdot)$ to indicate the derivative with respect to the restricted coordinates. The next result shows how to compute the derivative $D_{\mathbf{p}}\pi_{LC}$, intimately related to the monodromy matrix associated with the periodic orbit.

PROPOSITION 3.2. *Consider a symmetrical periodic orbit of system* (1.2) *that uses the three zones, starting from* $\mathbf{x}^0 \in \Sigma_1$ *with coordinates* $\mathbf{p}_0 \in \mathbb{R}^2$*, passing through* $\mathbf{x}^1 \in \Sigma_{-1}$ *with coordinates* $\mathbf{p}_1 \in \mathbb{R}^2$*, and transversal to both sections. Then, the product of the two matrices*

$$\begin{bmatrix} 1 & D_{\mathbf{p}}\tau_L(\mathbf{p}_1) \\ \mathbf{0} & D_{\mathbf{p}}\pi_L(\mathbf{p}_1) \end{bmatrix} \begin{bmatrix} -1 & D_{\mathbf{p}}\tau_C(\mathbf{p}_0) \\ \mathbf{0} & D_{\mathbf{p}}\pi_C(\mathbf{p}_0) \end{bmatrix} = \begin{bmatrix} -1 & D_{\mathbf{p}}\tau_C(\mathbf{p}_0) + D_{\mathbf{p}}\tau_L(\mathbf{p}_1)D_{\mathbf{p}}\pi_C(\mathbf{p}_0) \\ \mathbf{0} & D_{\mathbf{p}}\pi_{LC}(\mathbf{p}_0) \end{bmatrix}$$

is similar to

$$e^{A_L\tau_L(\mathbf{p}_1)}e^{A_C\tau_C(\mathbf{p}_0)}. \tag{3.16}$$

Proof. It is enough to use the explicit expressions of the solutions of system (1.2) at every zone and the continuity of the vector field; see [Ro03] for more details. ∎

The following lemma deals with a technical result that allows us to invert certain power series; see [FPR99] for a proof.

LEMMA 3.3. *Let be* $\eta = \xi^n\rho(\xi)$ *with* n *odd, where* ρ *is a real function analytic at* 0 *and such that* $\rho(0) = \rho_0 \neq 0$*. Then there exists a real function* χ *analytic at* 0*, with* $\chi(0) \neq 0$ *and such that* $\xi = \eta^{\frac{1}{n}}\chi(\eta^{\frac{1}{n}})$.

If we select only the solutions of the closing equations with $\tau_L > 0$ but sufficiently small, and $0 < \tau_C < \pi/\sqrt{M}$ but sufficiently close to $\pi/\sqrt{M}$, then we can assure that such solutions correspond to symmetrical and transversal periodic orbits; see [Ro03] for more details. Reciprocally, if we take a symmetrical periodic orbit that uses the three zones and is sufficiently close to the outermost periodic orbit of the center that exists for the critical values of parameters, then its corresponding values $\tau_C > 0$, $\tau_L > 0$, $\mathbf{x}^0$, $\mathbf{x}^1$, and remaining parameters determine a point $\mathbf{z}$ satisfying the closing equations. Therefore, we can establish with the above restrictions a correspondence between solutions $\mathbf{z}$ of closing equations and symmetrical periodic orbits. This correspondence, along with the uniqueness of the solution obtained in Lemma 3.1, ensures that the corresponding bifurcating periodic is an isolated periodic orbit, that is, a limit cycle.

Coming back to the statements of Theorem 1.1, we begin by using statement (d) of Lemma 3.1. We can compute $T(\tau_L)$ using that $T = 2\alpha + \delta$ and the corresponding expansions (3.6) and (3.8) for α and δ, obtaining

$$T = \frac{D}{M} + \frac{\gamma}{6\pi M^{1/2}}\tau_L^3 + \frac{\xi_1}{360\pi M^{5/2}}\tau_L^5 + O\left(\tau_L^6\right), \tag{3.17}$$

where γ and ξ_1 are given in the statement of Lemma 3.1. From (3.17) and taking into consideration that τ_L must be positive, it is obvious that $MT - D$ and γ have the same sign, and so the condition $\gamma(MT - D) > 0$ holds.

Now, if we apply Lemma 3.3 to (3.17), taking $n = 3$, $\eta = MT - D$, and $\xi = \tau_L$, we conclude that τ_L is an analytic function at the origin in the variable $(MT - D)^{1/3}$. A standard computation leads to the expansion

$$\tau_L = \frac{(6\pi)^{1/3}(MT - D)^{1/3}}{M^{1/6}\gamma^{1/3}} + \frac{\pi\xi_1}{30M^{5/2}\gamma^2}(MT - D) + O(MT - D)^{4/3}. \tag{3.18}$$

Due to the symmetry of the orbit, its period is equal to $2(\tau_C + \tau_L)$. Substituting expansion (3.18) into (3.9), and computing the above expression for the period, we get the expansion given for P_{er}.

We will now determine the amplitude of the periodic orbit. By using the variation of parameters formula, the solution of system (1.2) in zone R is

$$\mathbf{x}(\tau) = e^{A_L \tau} \mathbf{x}^3(\tau_L) + \int_0^\tau e^{A_L(\tau - s)} \mathbf{b}(\tau_L)\, ds, \tag{3.19}$$

so that its first component is

$$x_1(\tau) = \mathbf{e}_1^T \left\{ e^{A_L \tau} \begin{bmatrix} 1 \\ -x_2^1(\tau_L) \\ -x_3^1(\tau_L) \end{bmatrix} + \left(\sum_{i=0}^{\infty} A_L^i \frac{\tau^{i+1}}{(i+1)!} \right) \mathbf{b}(\tau_L) \right\}. \tag{3.20}$$

Let τ^* be the time when $|x_1|$ attains its maximum value in zone R. Taking derivatives with respect to τ in (3.20), and imposing that it must vanish at τ^*, we get

$$G(\tau_L, \tau^*) = \left. \frac{dx_1(\tau)}{d\tau} \right|_{\tau = \tau^*} = \mathbf{e}_1^T e^{A_L \tau^*} \begin{bmatrix} x_2^1(\tau_L) + T(\tau_L) \\ x_3^1(\tau_L) + M \\ D \end{bmatrix} = 0. \tag{3.21}$$

Now using expressions (3.11) and (3.13) and computing the power series of G in (τ_L, τ^*) at $(0,0)$, we obtain

$$G(\tau_L, \tau^*) = \frac{M}{2}\tau_L - M\tau^* + \frac{D - Mt}{12}\tau_L^2 + \frac{Mt - D}{2}\tau_L \tau^* + \frac{D - Mt}{2}\tau^{*2} + O(\tau_L, \tau^*)^3.$$

Hence, (3.21) defines implicitly in a neighborhood of $(0,0)$ a function $\tau^* = \psi(\tau_L)$ such that $G(\tau_L, \psi(\tau_L)) = 0$, namely,

$$\tau^* = \frac{1}{2}\tau_L + \frac{Mt - D}{24M}\tau_L^2 + O(\tau_L^4).$$

Substituting the above expansion together with (3.11), (3.13), and (3.17) into the expression (3.20), we get

$$a = x_1(\tau^*) = 1 + \frac{M}{8}\tau_L^2 + \frac{1}{1152M}(13D^2 - 11DMt + 15M^2 m - 2M^2 t^2)\tau_L^4 + O(\tau_L^5).$$

Using expression (3.18) for τ_L, we obtain the final expression for the amplitude a.

Let us now compute the characteristic multipliers of the bifurcating limit cycle. Due to the similarity relationship established in Proposition 3.2, we conclude that the product $\exp(A_L \tau_L) \cdot \exp(A_C \tau_C)$ corresponding to a solution of (3.5) has an eigenvalue equal to -1. We will denote by λ_r and λ_a the other two eigenvalues that correspond to the eigenvalues of the derivative $D_{\mathbf{p}} \pi_{LC}(\mathbf{p}_0)$ of the transition map associated with the semiorbit. The product of the three eigenvalues is then equal to

$$-\lambda_r \lambda_a = \det\left(e^{A_L \tau_L}\right) \det\left(e^{A_C \tau_C}\right).$$

Using that $\det(e^{A\tau}) = \exp(\tau \operatorname{trace}(A))$, we get

$$-\lambda_r \lambda_a = e^{\tau_L t + \tau_C T}. \tag{3.22}$$

The expansion of the product of exponentials in (3.16) leads to an expression of the form

$$e^{A_L\tau_L}e^{A_C(\tau_L)\tau_C(\tau_L)} = H_0 + \tau_L H_1 + \tau_L^2 H_2 + \cdots . \tag{3.23}$$

To compute the above matrices H_i, we write

$$\left(I + A_L\tau_L + A_L^2\frac{\tau_L^2}{2!} + \cdots\right) \times \left(e^{A_C(0)\tau_C(0)} + \tau_L \left.\frac{d}{d\tau_L}e^{A_C(\tau_L)\tau_C(\tau_L)}\right|_{\tau_L=0} + \frac{\tau_L^2}{2!}\left.\frac{d^2}{d\tau_L^2}e^{A_C(\tau_L)\tau_C(\tau_L)}\right|_{\tau_L=0} + \cdots\right).$$

From expansions (3.6)–(3.13), we obtain $\tau_C(0) = \pi/M^{1/2}$, $\tau_C'(0) = -1$, $\tau_C''(0) = 0$, $A_C'(0) = A_C''(0) = \mathbf{0}$, and using these values in the above expression, we finally get

$$H_0 = e^{A_C(0)\tau_C(0)} = \begin{bmatrix} D^2K - 1 & -DMK & M^2K \\ 0 & -1 & 0 \\ D^2MK & -DM^2K & M^3K - 1 \end{bmatrix},$$

$$H_1 = \begin{bmatrix} t - D/M \\ m - M \\ d - D \end{bmatrix} \begin{bmatrix} D^2K - 1 & -DMK & M^2K \end{bmatrix}$$

and

$$H_2 = \frac{Mt - D}{2M}H_1,$$

where K has been defined in (3.15), and it is emphasized that H_1 and H_2 are rank-one matrices.

The matrix H_0 has eigenvalues -1 (double) and $\lambda_0 = \exp(\pi D/M^{3/2})$. For the single eigenvalue λ_0, we select a right eigenvector $\mathbf{v}_0 = [1, 0, M]^T$ and a left eigenvector $\mathbf{w}_0^T = [D^2/M^2, -D/M, 1]$. We will denote by λ_a the eigenvalue of $D\pi_{LC}(\mathbf{p}_0)$ that for $\tau_L = 0$ is equal to λ_0. Since the eigenvalue λ_0 of H_0 is simple, we can apply perturbation theory (see section 2.8 of [Wi65]) to assure that the equality

$$\left(H_0 + \tau_L H_1 + \tau_L^2 H_2 + \cdots\right)\left(\mathbf{v}_0 + \tau_L\mathbf{v}_1 + \tau_L^2\mathbf{v}_2 + \cdots\right)$$

$$= \left(\lambda_0 + \tau_L\lambda_1 + \tau_L^2\lambda_2 + \cdots\right)\left(\mathbf{v}_0 + \tau_L\mathbf{v}_1 + \tau_L^2\mathbf{v}_2 + \cdots\right)$$

holds for certain vectors $\mathbf{v}_1$, $\mathbf{v}_2 \ldots$. As a consequence of Proposition 3.2 and (3.23), we get

$$\lambda_a = \lambda_0 + \tau_L\lambda_1 + \tau_L^2\lambda_2 + \cdots .$$

After some computations, we arrive at

$$\lambda_1 = \frac{\mathbf{w}_0^T H_1\mathbf{v}_0}{\mathbf{w}_0^T\mathbf{v}_0} = \left(\frac{Mt - D}{M} + \frac{\gamma M}{D^2 + M^3}\right)\lambda_0,$$

$$\lambda_2 = \frac{\mathbf{w}_0^T\left(H_2\mathbf{v}_0 + (H_1 - \lambda_1 I)\,\mathbf{v}_1\right)}{\mathbf{w}_0^T\mathbf{v}_0} = \frac{(Mt - D)\left(D^2 + M^3\right) + \gamma}{2M^2\left(D^2 + M^3\right)^2(\lambda_0 + 1)} \times \left[(Mt - D)\left[\left(D^2 + M^3\right)\lambda_0 + D^2 - M^3\right] + 2M^2(dM - Dm)\right]\lambda_0.$$

The logarithms μ_r and μ_a of characteristic multipliers of the complete periodic orbit must satisfy

$$e^{\mu_r} = \lambda_r^2, \qquad e^{\mu_a} = \lambda_a^2, \tag{3.24}$$

while from (3.22) we get the relationship

$$\mu_r + \mu_a = 2t\tau_L + 2T\tau_C. \tag{3.25}$$

From (3.24) and using the computed simple eigenvalue λ_a, we obtain

$$\mu_a = 2\log\left[\lambda_0 + \lambda_1\tau_L + \lambda_2\tau_L^2 + O(\tau_L^3)\right] = 2\log\lambda_0 + 2\log\left[1 + \frac{\lambda_1}{\lambda_0}\tau_L + \frac{\lambda_2}{\lambda_0}\tau_L^2 + O(\tau_L^3)\right]$$
$$= 2\lambda_0 + 2\frac{\lambda_1}{\lambda_0}\tau_L + \left[2\frac{\lambda_2}{\lambda_0} - \frac{\lambda_1^2}{\lambda_0^2}\right]\tau_L^2 + O(\tau_L^3).$$

Substituting here λ_1 and λ_2, and using expansion (3.18) of τ_L, we finally get the expression for μ_a that appears in Theorem 1.1. Using in (3.25) the expansions (3.9) for τ_C and (3.18) for τ_L, we compute μ_r.

Since the last assertion of Theorem 1.1 is a direct consequence of previous statements, its proof is now completed.

Acknowledgments. The authors sincerely appreciate the careful reading of the anonymous referees and their interesting suggestions that have notably improved the paper. They also want to acknowledge Jorge Galán for his invaluable suggestions and comments on a preliminary version of the manuscript, Manuel Román for his help with SPICE simulation of the circuit, and Fernando Fernández for helping with figures.

ON A MATHEMATICAL MODEL OF THE PRODUCTIVITY INDEX OF A WELL FROM RESERVOIR ENGINEERING*

AKIF IBRAGIMOV†, DINARA KHALMANOVA‡, PETER P. VALKO§, AND JAY R. WALTON‡

Abstract. Motivated by the reservoir engineering concept of the productivity index of a producing oil well in an isolated reservoir, we analyze a time dependent functional, diffusive capacity, on the solutions to initial boundary value problems for a parabolic equation. Sufficient conditions providing for time independent diffusive capacity are given for different boundary conditions. The dependence of the constant diffusive capacity on the type of the boundary condition (Dirichlet, Neumann, or third boundary condition) is investigated using a known variational principle and confirmed numerically for various geometrical settings. An important comparison between two principal constant values of a diffusive capacity is made, leading to the establishment of criteria when the so-called pseudo-steady-state and boundary-dominated productivity indices of a well significantly differ from each other. The third boundary condition is shown to model the thin skin effect for the constant wellbore pressure production regime for a damaged well. The questions of stabilization and uniqueness of the time independent values of the diffusive capacity are addressed. The derived formulas are used in numerical study of evaluating the productivity index of a well in a general three-dimensional reservoir for a variety of well configurations.

Key words. parabolic equation, productivity index, diffusive capacity, time-invariant, skin

1. Introduction.

In many applied problems, where the modeled processes are, in general, transient, it is important to define such functionals on the solutions, which are, in a sense, time invariant. Existence of such property is important from both practical and theoretical points of view. An important such example to petroleum reservoir engineering, the productivity index (PI), is studied here.

It was long ago observed by petroleum engineers that if a bounded reservoir is depleted by a well, then the ratio of the flow rate to the pressure drawdown (the pressure drop between the reservoir and the wellbore) stabilizes to a constant value. This constant value seems to depend only on the geometrical and hydrodynamical characteristics of the reservoir. In particular, it appears to be independent of the pressure drawdown in the reservoir or the flow rate from the well [23].

The first concise description of this fact was formulated in the classical book by Muskat [23]. The ratio of the rate of flow from the well to the difference between the average pressure on the wellbore and the average pressure in the reservoir is called the productivity index of the well [23]. There are two idealized production regimes considered most frequently for the purpose of analysis in engineering practice: the well can be produced either with a constant flow rate or with a constant wellbore

pressure. In a bounded reservoir depleted in either of the two regimes, the PI of a well stabilizes and remains constant in a long time asymptote.

To analyze the productivity of the well we consider three initial boundary value problems (IBVPs) that correspond to current engineering practice. However, while two of the formulated problems corresponding to the constant pressure production regime are well-posed, the problem modeling the regime with a constant rate of production is ill-posed in the sense of nonuniqueness of solution.

Field operations often reduce the permeability of the region adjacent to the wellbore—the so-called skin zone. Disregarding the skin effect leads to overestimation of the PI of the damaged well [30, 15]. One of the IBVPs considered in this article models the skin effect in the constant pressure production regime.

The objective for this paper is to build a rigorous mathematical frame for studying the PI. In this respect, it proves useful to introduce the concept of *diffusive capacity* for a well-reservoir system. The diffusive capacity is an integral type characteristic of the solution of an IVBP. To address the issue of nonuniqueness of solution of the ill-posed IBVP, we impose restrictions defining a class of solutions in which the diffusive capacity is unique. The inflicted restrictions are motivated by physical considerations as well as traditional engineering practice.

An important property of the PI to stabilize with time regardless of the production regime is then analyzed in terms of the diffusive capacity. Sufficient conditions for the diffusive capacity to be time independent are given for different boundary conditions; through a variational approach to studying the diffusive capacities, its dependence on different boundary conditions is revealed. The obtained theoretical results are then illustrated by numerical computations of the constant diffusive capacities for processes with different boundary conditions in various geometrical settings.

1.1. PI of a well in a bounded reservoir. Reservoir engineering approach: Shape factors. Consider a bounded hydrocarbon reservoir with a flowing fluid (oil) and a well produced with either constant wellbore pressure or constant production rate. The PI of a well is defined as [26]

$$PI(t) = \frac{q(t)}{p_w(t) - p_a(t)}, \tag{1}$$

where $q(t)$ is the rate of flow from the well, $p_w(t)$ is the flowing bottomhole pressure, and $p_a(t)$ is the average pressure of the fluid in the reservoir. When the well is produced with a constant wellbore pressure, its value is taken as $p_w(t)$ in (1). The concept of the PI of a well facilitates reservoir engineering methods of estimation of the available reserves and, consequently, helps to optimize the recovery efficiency.

About a century ago it was empirically observed that under either of the two recovery regimes, the PI of a well stabilizes and remains almost constant in a long time asymptote [26]. When the PI of a well is constant, the production regimes have traditionally accepted names: the production regime with the constant rate and constant PI is called a pseudo-steady-state (PSS), and the production regime with the constant wellbore pressure and the constant PI is called a boundary-dominated (BD) state.

The first analytical formula for representation of the PI of a well for a PSS regime was obtained by Muskat [23] for an isolated cylindrical reservoir and a given constant production rate on the fully penetrated vertical well. The IBVPs with the constant rate well boundary condition for a number of typical drainage shapes were first solved

by Matthews, Brons, and Hazebroek in [21] in connection to the analysis of the build-up wellbore pressure after well shut-in. Using the result of Matthews, Brons, and Hazebroek, an approximate formula for a PSS PI (with skin s) can be written as

$$J_{Dietz} = \frac{1}{\frac{1}{2}\ln\frac{4V}{\gamma C_A r_w^2} + s}, \tag{2}$$

where V is the area of the two-dimensional reservoir (a three-dimensional reservoir with a uniform thickness), r_w is the radius of the circular well, and γ is Euler's constant. Equation (2) uses the solution for the dimensionless PSS wellbore pressure first derived by Ramey and Cobb in [27]. The values of the so-called shape factor C_A were first presented in [6] and are usually referred to as Dietz's shape factors in the petroleum engineering literature. Positive skin captures the damage to the skin zone, while the negative skin was shown to model a stimulated well [12, 15, 4, 8, 14, 19].

The approximate formula (2) is also used to estimate the productivity of a well produced with a constant bottomhole pressure. However, it is known that the BD state PI of a well is, in general, different from the PSS PI. In particular, the empirical evidence is that the PSS PI is always greater than or equal to the BD PI.

In 1998 Wattenbarger and Helmy derived an algorithm and computed the values of shape factors in (2) for the typical shapes of the drainage area for BD state, using a method of images, Laplace transform, and a fundamental relationship between the images in Laplace space of the cumulative production and the production rate. The applicability of (2) is contingent on the method of images—a drainage area to which the method of images can be applied must be of a shape, which, when translated infinitely many times in all directions, can cover the entire two-dimensional plane.

Most solutions for evaluating the PI in three-dimensional reservoirs, i.e., for directionally drilled wells, follow the same principle as the two-dimensional methods in that they are based on a semianalytical solution for a particular case, from which one finds a convenient approximate formula which is then applied to similar reservoir/well configurations. The semianalytical solution is often based on the superposition of analytical solutions for a transient problem in an unbounded reservoir. For the solution of the problem to be unique, additional assumptions must be made. Usually the restrictions are imposed on the distribution of the pressure on the wellbore. Under one such restriction, the wellbore is assumed to have infinite conductivity, i.e., the wellbore pressure is assumed to be constant on the wellbore at each moment of time. Under another restriction the pressure flux through the wellbore surface is constant at all times.

The solution in a bounded reservoir is then expressed in terms of an infinite time dependent series, similar to the technique used in [21, 16]. Then a comprehensive computing procedure is applied to determine the stabilized values of the time dependent series in the obtained solution [20, 25, 29, 17, 3, 28].

In most cases the methods for computing the PI of a deviated or horizontal well in a three-dimensional reservoir are aimed at obtaining an appropriate value of a shape factor C_A and skin factor s in (2). The effects associated with the deviation of the well from a fully penetrated vertical one are included in the skin s. A vertical well is called fully penetrated if its penetration length is equal to the thickness of the reservoir. A vertical fully penetrated well corresponds to $s = 0$. The effects of the geometry of the external boundaries of the reservoir are included in the shape factor C_A [20, 7].

As seen from this brief review, the existing methods and techniques of evaluation of the PI impose serious restrictions on the geometry of the reservoir. In particular,

the vertical dimension of the reservoir has to be small in comparison to its lateral dimensions to allow one to neglect the flow in the vertical direction or include its effect in the geometrical skin, s_g. Another restriction is due to the use of the method of images, which requires the drainage area shape to be convex and suitable for covering the whole plane when translated infinitely many times.

One should also note that very little attention has been paid to methods for evaluating a BD PI. For instance, all works mentioned above are concerned only with evaluating the PSS PI in three-dimensional reservoirs. In practice, the BD PI values are taken to be equal to the PSS PI, although it has been shown that the difference between these two values of PI can be up to 10% even for horizontal flow in simple drainage shapes [13, 16].

2. Statement of the problem. Let a point in $\mathbb{R}^n$ be denoted by $x = (x_1, \dots, x_n)$, $n = 2, 3$. Let Ω be an open domain in $\mathbb{R}^n$ which is bounded by the two disjoint piecewise smooth surfaces Γ_w and Γ_e. Let $u(x,t)$, $t \in \mathbb{R}$, be a solution of the equation

$$\frac{\partial u}{\partial t} = Lu, \tag{3}$$

where $L = \nabla \cdot (A(x)\nabla)$, A is a symmetric positive definite matrix with smooth components and $\nabla = (\frac{\partial}{\partial x_1}, \dots, \frac{\partial}{\partial x_n})$ is the usual gradient operator.

Let $u(x,t)$ be subject to the homogeneous Neumann boundary condition on Γ_e:

$$\frac{\partial u}{\partial \vec{\nu}} = (A(x)\nabla u) \cdot \vec{n} = 0, \tag{4}$$

where $\vec{n}$ is the outward normal to Γ_e. On the remaining part of the boundary, Γ_w, three types of boundary conditions will be considered:

(a) constant total flux $\int_{\Gamma_w} \frac{\partial u}{\partial \vec{\nu}} dS = -q$, q being a real positive constant;
(b) constant Dirichlet condition $u|_{\Gamma_w} = u_{w2}$, u_{w2} being a real positive constant;
(c) mixed boundary condition $\left((u - u_{w3})|_{\Gamma_w} + \alpha \frac{\partial u}{\partial \vec{\nu}}\right)|_{\Gamma_w} = 0$, where α and u_{w3} are real constants, $u_{w3} > 0$.

For simplicity, we assume that the components of the coefficient matrix A and the domain boundary are smooth, so solutions of the IBVPs I, II, and III (stated below) are understood in a classical sense. In (b), $u_{w2} > 0$ is a given constant; in (c), $u_{w3} > 0$ and α are given constants.

This leads to three IBVPs:

Problem I.

$$Lu = \frac{\partial u}{\partial t}, \quad x \in \Omega, \quad t > 0,$$
$$\frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_e} = 0,$$
$$\int_{\Gamma_w} \frac{\partial u}{\partial \vec{\nu}} dS = -q,$$
$$u(x,0) = f_1(x).$$

Remark 1. As mentioned in the introduction, Problem I is ill-posed: there are infinitely many solutions. The PI will be modeled as an integral characteristic of a solution and hence will be lacking uniqueness of definition. Therefore, we will

consider two classes of solutions in each of which the solution is unique up to an additive constant. These two classes will be described in detail in sections 3 and 4. Each class has a clear physical meaning. The integral characteristic modeling the PI will be shown to be unique in each class.

Problem II.

$$\begin{aligned} Lu = \frac{\partial u}{\partial t}, \quad x \in \Omega, \quad t > 0, \\ \frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \\ u|_{\Gamma_w} = u_{w2}, \\ u(x,0) = f_2(x). \end{aligned}$$

Problem III.

$$\begin{aligned} Lu = \frac{\partial u}{\partial t}, \quad x \in \Omega, \quad t > 0, \\ \frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \\ \left(\alpha \frac{\partial u}{\partial \vec{\nu}} + (u - u_{w3})\right)|_{\Gamma_w} = 0, \\ u(x,0) = f_3(x). \end{aligned}$$

Remark 2. Physically, $u(x,t)$ is interpreted as the fluid pressure in the reservoir, and hence, we will restrict our attention only to positive solutions of Problems I, II, and III. Moreover, a solution to Problem I is not necessarily positive on Ω for all $t > 0$, even if the initial function $f_1(x)$ is positive on Ω. It will be shown that for positive q, there exists a solution to Problem I which is positive on Ω for $t \in (0, T)$ for some positive T.

Remark 3. The maximum principle for a parabolic equation implies that the solution of Problem II is unique and positive if the initial condition f_2 is positive on Ω [10]. The uniqueness, existence, and regularity of the solutions of Problem III with respect to the sign of the coefficient α in the boundary condition on Γ_w are discussed, for example, in [10]. Formally, Problem III is a generalization of Problem II. However, we consider Problem II separately in light of its importance for applications in the reservoir engineering.

Remark 4. The obtained results can be extended to a generalized Wiener solution of an IBVP in a locally smooth domain [18]. We will not present it in this work to preserve the original engineering statement of the problem.

2.1. Definition of diffusive capacity. Let us introduce the following notation. If v is a function defined on Ω, then let $\bar{v}_w$ and $\bar{v}_\Omega$ denote the average of v on Γ_w and Ω, respectively, defined by

$$\bar{v}_w = \frac{1}{W} \int_{\Gamma_w} v dS$$

and

$$\bar{v}_\Omega = \frac{1}{V} \int_{\Omega} v dx,$$

where $V = mes_n \Omega$, $W = mes_{n-1} \Gamma_w$.

DEFINITION 1. *Let $u(x,t)$ be a classical solution* [10] *of the parabolic equation $Lu = \frac{\partial u}{\partial t}$ in $\Omega \times (0,\infty)$ with boundary condition $\frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_e} = 0$ and* (a), (b), *or* (c) *on Γ_w. Let $T > 0$ be such that $u(x,t) > 0$ for all $x \in \Omega$ and $t \in (0,T)$. The diffusive capacity of Γ_w with respect to Γ_e (or simply diffusive capacity) corresponding to the solution $u(x,t)$ is the ratio*

$$J(u,t) = \frac{\int_{\Gamma_w} \frac{\partial u}{\partial \vec{\nu}} dS}{\bar{u}_w - \bar{u}_\Omega}, \tag{5}$$

where $t \in (0,T)$.

Remark 5. For fixed boundary and initial conditions in Problem II (III), the diffusive capacity $J(u,t)$ corresponding to the solution u of Problem II (III) is a function of time only. However, for fixed boundary and initial conditions in Problem I, the diffusive capacity $J(u,t)$ is a time dependent functional on the set of solutions $\{u\}$ to Problem I.

Remark 6. The corresponding diffusive capacity corresponding to a solution of Problem III is defined as

$$J(u,t) = \frac{\int_{\Gamma_w} \frac{\partial u}{\partial \vec{\nu}} dS}{u_{w3} - \bar{u}_\Omega}. \tag{6}$$

Such correction to the general definition is based on the physical assumption that u_{w3} is an average wellbore pressure, measured inside the wellbore.

In our intended application, Ω represents a hydrocarbon reservoir with a flowing fluid (oil) with the outer boundary Γ_e and a well with boundary Γ_w. The outer boundary of the reservoir is assumed impermeable to the flowing fluid. It is assumed that the fluid is slightly compressible and its flow in the reservoir is governed by Darcy's law relating the gradient of pressure in the reservoir to the filtration velocity [23, 26]. Then $u(x,t)$ corresponds to the pressure in the reservoir and the three types of boundary conditions specified on the well Γ_w correspond to different recovery regimes. Boundary condition (a) models the recovery regime with constant production rate, (b) models the recovery regime with constant wellbore pressure, and (c) models the constant wellbore pressure regime of production from a well with nonzero skin [26]. The initial conditions f_1, f_2, and f_3 take on a meaning of the pressure distribution in the reservoir Ω; hence, we will require that $f_i \geq 0$ on Ω, $i = 1,2,3$. IBVP III will be discussed in greater detail in section 5. The diffusive capacity $J(u,t)$ takes on the meaning of the PI of the well.

3. Time independent diffusive capacity. In this section we show that for each of the IBVP (I, II, and III) there exist initial distributions $f_1(x)$, $f_2(x)$, and $f_3(x)$, respectively, such that the diffusive capacity with respect to the corresponding problem is constant [16]. For Problem I, we describe the class of solutions to IBVP I on which the diffusive capacity takes a unique value. In the last subsection, the time independent values of the diffusive capacity for Problems I, II, and III are compared to each other.

3.1. IBVP I. All solutions of Problem I, for which the diffusive capacity is independent of time, possess the following property.

Remark 7. If $u(x,t)$ is a solution of Problem I and $J(u,t) = J(u)$ is constant for all $t > 0$, then there exist real constants C and B such that

$$\bar{u}_w = \frac{1}{W} \int_{\Gamma_w} u dS = C + Bt. \tag{7}$$

This can be seen from the following argument. From the definition of the diffusive capacity (5), it follows that $\bar{u}_w = -\frac{q}{J(u)} + \bar{u}_\Omega$. Hence, $\frac{\partial \bar{u}_w}{\partial t} = \frac{\partial \bar{u}_\Omega}{\partial t}$. The divergence theorem implies that

$$\frac{\partial \bar{u}_\Omega}{\partial t} = \frac{1}{V}\int_\Omega Ludx = \frac{1}{V}\int_{\Gamma_w} \frac{\partial u}{\partial \vec{\nu}} dS. \tag{8}$$

Consequently,

$$\frac{\partial \bar{u}_w}{\partial t} = -\frac{q}{V}, \tag{9}$$

from which (7) easily follows.

The "infinite conductivity of the well" assumption asserts that at each instant of time, the pressure on the wellbore is constant. Together with the latter remark, this motivated us to study the diffusive capacity on the class of solutions of Problem I, defined by $\Upsilon = \{\, u \mid \exists C$ and B are constants, such that $u(x,t) = C + Bt$ for $x \in \Gamma_w$ and for $t \geq 0\,\}$.

PROPOSITION 1. *Problem* I *has a unique solution in class* Υ.

Proof. Assume that $u \in \Upsilon$ and $v \in \Upsilon$ are solutions of Problem I. Let C_1, B_1, C_2, and B_2 be such that for $t > 0$,

$$u(x,t)|_{\Gamma_w} = C_1 + B_1 t$$

and

$$v(x,t)|_{\Gamma_w} = C_2 + B_2 t.$$

Then the difference $g(x,t) = u(x,t) - v(x,t)$ is the solution of the following IBVP:

$$Lg = \frac{\partial g}{\partial t}, \quad x \in \Omega, \quad t > 0, \tag{10}$$

$$\frac{\partial g}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{11}$$

$$g|_{\Gamma_w} = (C_1 - C_2) + (B_1 - B_2)t, \tag{12}$$

$$g(x,0) = 0. \tag{13}$$

In addition,

$$\int_{\Gamma_w} \frac{\partial g}{\partial \vec{\nu}} = 0. \tag{14}$$

Condition (13) immediately implies that $C_1 = C_2$.

The function $h = \frac{\partial g}{\partial t}$ is a solution of the following problem:

$$Lh = \frac{\partial h}{\partial t}, \quad x \in \Omega, \quad t > 0, \tag{15}$$

$$\frac{\partial h}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{16}$$

$$h|_{\Gamma_w} = B_1 - B_2, \tag{17}$$

$$h(x,0) = \frac{\partial g}{\partial t}(x,0). \tag{18}$$

In addition, from the boundary condition on Γ_w of Problem I and the divergence theorem it follows that for $t > 0$,

$$\int_\Omega h dx = \frac{\partial}{\partial t}\int_\Omega g dx = \int_\Omega L g dx \equiv 0. \tag{19}$$

As a solution of the parabolic equation (15) with the Dirichlet condition (17) on one part of the boundary $\partial\Omega$ and Neumann condition (16) on the remaining part of $\partial\Omega$, h will converge to a constant $B_1 - B_2$ on Ω as $t \to \infty$ [18]. Together with condition (19) this implies that

$$(B_1 - B_2)V = \lim_{t\to\infty}\int_\Omega h(x,t)dx = 0. \tag{20}$$

Thus, $u = v$. □

For purposes that will become clear from Proposition 2, let us introduce the following auxiliary steady-state boundary value problem. Let $u_1(x)$ be such that

$$Lu_1 = -\frac{1}{V}, \tag{21}$$

$$u_1|_{\Gamma_w} = 0, \tag{22}$$

$$\frac{\partial u_1}{\partial \vec{\nu}}|_{\Gamma_e} = 0. \tag{23}$$

Then the following proposition gives a sufficient condition providing for time independent unique diffusive capacity $J(u,t) = J(u)$.

PROPOSITION 2. *If the initial condition in Problem* I *is given by* $f_1(x) = qu_1(x) + C$ *where* u_1 *is the solution of* (21)–(23) *and* C *is an arbitrary constant such that* $f_1(x) > 0$ *for all* $x \in \Omega$, *then the diffusive capacity corresponding to a solution* $u \in \Upsilon$ *of Problem* I *is independent of time and determined by*

$$J_I := J(u,t) = \frac{V}{\int_\Omega u_1(x)dx}. \tag{24}$$

Proof. Let the initial condition in Problem I be $f_1(x) = qu_1(x)$ and

$$u(x,t) = qu_1(x) - \frac{q}{V}t. \tag{25}$$

By virtue of the divergence theorem,

$$\int_{\Gamma_w}\frac{\partial u}{\partial \vec{\nu}}dS = -q.$$

Consequently, u is a solution of IBVP I with the initial distribution $f_1(x) = qu_1(x)$.

Note that u, defined by (25), belongs to class Υ. In addition, it is clear that the diffusive capacity $J(u,t)$ on $u(x,t)$ is constant and is given by

$$J(u,t) = \frac{V}{\int_\Omega u_1(x)dx} = J_{\mathrm{I}}. \qquad \square$$

Remark 8. Function u, defined by (25), is positive on Ω only for $t \in (0,T)$, where

$$T = \frac{\min_{x\in\Omega} u_1(x)}{V}. \tag{26}$$

Solutions of Problem I represent the pressure distribution in the reservoir at time t; hence, we are interested in the positive on Ω solutions only. Therefore, the diffusive capacity (as a model of a PSS PI) $J(u,t) = J_{\mathrm{I}}$ is defined only for $t \in (0,T)$, where T is given by (26).

The necessary condition for the time independent diffusive capacity on the solutions of Problem I in class Υ is given by the following proposition.

PROPOSITION 3. *If the diffusive capacity $J(u,t)$, corresponding to a solution $u \in \Upsilon$ of Problem* I, *is constant for all $t > 0$, then*

$$\int_\Omega (u(x,0) - qu_1(x))dx + C^* = 0, \tag{27}$$

where constant C^* is independent of q and u_1 is the solution of the problem (21)–(23).

Proof. Let $u \in \Upsilon$ be a solution of Problem I such that $J(u,t) = J(u)$ is constant for all $t > 0$. Let

$$g(x,t) = u(x,t) - \left(qu_1(x) - \frac{q}{V}t\right). \tag{28}$$

There exist constants C and B such that $u|_{\Gamma_w} = C + Bt$. Moreover, by (9), $B = -\frac{q}{V}$. Hence, g is a solution of the problem

$$Lg = \frac{\partial g}{\partial t}, \quad x \in \Omega, \quad t > 0, \tag{29}$$

$$\frac{\partial g}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{30}$$

$$g|_{\Gamma_w} = C, \tag{31}$$

$$g(x,0) = u(x,0) - qu_1(x). \tag{32}$$

In addition, g is subject to the following condition:

$$\int_{\Gamma_w} \frac{\partial g}{\partial \vec{\nu}} dS = 0. \tag{33}$$

As a solution of the parabolic equation (29) with the boundary conditions (30) and (31), $g(x,t) \to C$ as $t \to \infty$. Together with (33), the latter implies that $\bar{g}_\Omega = C$ for all $t > 0$. Therefore, $\int_\Omega g(x,0)dx = \int_\Omega (u(x,0) - qu_1(x))dx = CV = C^*$. $\square$

Remark 9. By Proposition 3, the initial distribution providing for the time independent diffusive capacity is unique up to an additive function of zero average on Ω and an additive constant independent of the geometry of the domain or boundary conditions.

Remark 10. The integral of the solution of Problem I at $t = 0$ represents the initial reserves in the reservoir [9, 2]. The main physical consequence of Proposition 3 is that the diffusive capacity as a model of the PI uniquely determines the average initial amount of the reserves in the reservoir.

3.2. IBVP II. Let

$$\frac{\partial u_2}{\partial t} = Lu_2, \tag{34}$$

$$\frac{\partial u_2}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{35}$$

$$u_2|_{\Gamma_w} = 0, \tag{36}$$

$$u_2(x,0) = f_2(x) - u_{w2}. \tag{37}$$

Obviously, $u(x,t) = u_2(x,t) + u_{w2}$ solves Problem II. Then the diffusive capacity for Problem II can be expressed in terms of $u_2(x,t)$, namely,

$$J(u,t) := J(u_2,t) = \frac{\int_{\Gamma_w} \frac{\partial u_2}{\partial \vec{\nu}} dS}{-\frac{1}{V}\int_\Omega u_2(x,t)dx}. \tag{38}$$

Consider the related Sturm–Liouville problem for the elliptic operator L and the first eigenpair of the latter; i.e., let λ_0 and $\phi_0(x)$ be the first eigenvalue and first eigenfunction, respectively, of the problem

$$L\phi_0 = -\lambda_0\phi_0, \tag{39}$$

$$\phi_0|_{\Gamma_w} = 0, \tag{40}$$

$$\frac{\partial \phi_0}{\partial \vec{\nu}}|_{\Gamma_e} = 0. \tag{41}$$

Let $u_2(x,t)$ be a solution of the IBVP (34)–(37) with the initial distribution $u_2(x,0)$ equal to $\phi_0(x)$. Then $u_2(x,t) = \phi_0(x)e^{-\lambda_0 t}$ is a solution of the IBVP (34)–(37). The diffusive capacity is constant and is equal to

$$J_{\mathrm{II}} := J(u_2,t) = \frac{\lambda_0 \int_\Omega \phi_0(x)dx e^{-\lambda_0 t}}{\frac{1}{V}\int_\Omega \phi_0(x)dx e^{\lambda_0 t}} = \lambda_0 V. \tag{42}$$

This leads to the next proposition.

PROPOSITION 4. *If the initial condition of Problem* II *is given by* $f_2(x) = \phi_0(x) + u_{w2}$*, where* ϕ_0 *is the eigenfunction of problem* (39)–(41) *corresponding to the minimal eigenvalue* λ_0*, then the diffusive capacity on the solution* u *of Problem* II *is constant and is given by*

$$J(u,t) = J_{\mathrm{II}} = \lambda_0 V.$$

In fact, the diffusive capacity is constant provided that the initial distribution $u_2(x,0)$ is equal to any eigenfunction $\phi_i(x)$, $i = 1, 2 \ldots$. However, only the eigenfunction corresponding to the minimal eigenvalue does not change sign on Ω; therefore, in terms of the pressure distribution in the hydrocarbon reservoir, $\phi_0(x)$ is the only physically realistic initial distribution.

3.3. IBVP III. Let $u_3(x,t) = u(x,t) - u_{w3}$, where u solves (III) and u_{w3} is the given average value of u on Γ_w (see Remark 6). Then $u_3(x,t)$ is a solution of the reduced problem

$$Lu_3 = \frac{\partial u_3}{\partial t}, \tag{43}$$

$$\frac{\partial u_3}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{44}$$

$$\left(\alpha \frac{\partial u_3}{\partial \vec{\nu}} + u_3\right)|_{\Gamma_w} = 0, \tag{45}$$

$$u_3(x,0) = f_3(x) - u_{w3}. \tag{46}$$

Diffusive capacity $J(u,t)$ corresponding to Problem III is expressed in terms of $J(u_3,t)$ in the following way:

$$J(u,t) = J(u_3,t) = \frac{\int_{\Gamma_w} \frac{\partial u_3}{\partial \vec{\nu}} dS}{-\frac{1}{V}\int_\Omega u dx}. \tag{47}$$

Physically, the Robin boundary condition on Γ_w in Problem III corresponds to production from a well with a thin-skin zone with constant wellbore pressure (constant $\bar{u}_3|_{\Gamma_w}$) [26]. A sufficient condition for the diffusive capacity to be constant is similar to that for Problem II.

In particular, consider the related Sturm–Liouville problem. Let λ_k^α and $\phi_k^\alpha(x)$ be an eigenpair of the problem

$$L\phi_k^\alpha = -\lambda_k^\alpha \phi_k^\alpha, \tag{48}$$

$$\frac{\partial \phi_k^\alpha}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{49}$$

$$\phi_k^\alpha + \alpha \frac{\partial \phi_k^\alpha}{\partial \vec{\nu}}|_{\Gamma_w} = 0. \tag{50}$$

Here, the superscript α is intended to emphasize that the solution and, hence, the diffusive capacity of Problem III depend on the value of parameter α. This dependence will be analyzed in subsequent sections. Let $u_3(x,t)$ be a solution of the IBVP (43)–(46) with the initial distribution $u_3(x,0) = \phi_k^\alpha(x)$. Then $u_3(x,t) = \phi_k^\alpha(x) e^{-\lambda_k^\alpha t}$ solves (43)–(46) and the diffusive capacity is time independent.

When parameter α in Problem III is positive, then the minimal eigenvalue λ_0^α is positive and the corresponding eigenfunction $\phi_0^\alpha(x)$ does not change sign on Ω.

In section 5 we will show that the boundary condition on Γ_w of Problem III models skin effect for a damaged well produced with a constant wellbore pressure. As mentioned in section 1, the production from a stimulated well is modeled by a negative skin factor s; therefore, we will analyze the behavior of the diffusive capacity on the solutions of Problem III for negative values of parameter α. The latter case will be discussed in more detail in section 5. For the purposes of this section, it is

sufficient to note that when $\alpha < 0$, the minimal eigenvalue and hence the constant diffusive capacity may be negative. Negative PI is an indication of injection into the well; therefore, to avoid the contradiction, our attention will be restricted to positive eigenvalues only. The analysis of the first eigenfunction will be given in section 5.

Regardless of the sign of α, let λ_0^α be the first nonnegative eigenvalue. If the initial distribution in (43)–(46) is equal to the corresponding eigenfunction, the constant diffusive capacity is given by

$$J_{\mathrm{III}}(\alpha) := J(u_3, t) = \lambda_0^\alpha V. \tag{51}$$

Therefore, we have shown the following proposition.

PROPOSITION 5. *If the initial condition of Problem* III *is given by* $f_3(x) = \phi_0^\alpha(x) + u_{w3}$, *where* ϕ_0^α *is the eigenfunction of problem* (48)–(50) *corresponding to the minimal positive eigenvalue* λ_0^α, *then the diffusive capacity on the solution* u *of Problem* III *is constant and is given by*

$$J(u,t) = J_{\mathrm{III}}(\alpha) = \lambda_0^\alpha V.$$

3.4. Comparison of the time independent diffusive capacities for Problems I, II, and III. The steady-state auxiliary problem (21)–(23) introduced earlier has a convenient variational formulation which facilitates deriving an important relation between the time independent diffusive capacities of Γ_w with respect to Γ_e in Ω.

Assume that solutions of Problems I, II, and III satisfy the conditions in Propositions 2, 4, and 5, respectively. Then the diffusive capacities for Problems I, II, and III (J_{I}, J_{II}, and $J_{\mathrm{III}}(\alpha)$) are time independent and their values are given by (24), (42), and (51), respectively.

Let $H^{1,2}(\Omega)$ be the Sobolev space [1]. Denote by $\overset{\circ}{H}{}^{1,2}(\Omega, \Gamma_w)$ the closure in the $H^{1,2}(\Omega)$ norm of smooth functions that vanish on Γ_w, and denote by $\overset{\circ}{H}{}^{1,2}(\Omega, \Gamma_w, \alpha)$ the closure in the $H^{1,2}(\Omega)$ norm of smooth functions such that $(u + \alpha \frac{\partial u}{\partial \vec{\nu}})|_{\Gamma_w} = 0$ [1].

The following are well-known variational principles yielding the first eigenvalues λ_0 and λ_0^α of the problems (39)–(41) and (48)–(50), respectively (see [5]):

$$\lambda_0 = \inf_{u \in \overset{\circ}{H}{}^{1,2}(\Omega, \Gamma_e)} \frac{\int_\Omega A \nabla u \cdot \nabla u dx}{\int_\Omega u^2 dx}, \tag{52}$$

$$\lambda_0^\alpha = \inf_{u \in \overset{\circ}{H}{}^{1,2}(\Omega, \Gamma_w \alpha)} \frac{\int_\Omega A \nabla u \cdot \nabla u dx + \frac{1}{\alpha} \int_{\Gamma_w} u^2 dS}{\int_\Omega u^2 dx}. \tag{53}$$

These two principles imply that for any positive α_1 and α_2 such that (see [5]) $\alpha_1 > \alpha_2$, $\lambda_0^{\alpha_1} < \lambda_0^{\alpha_2}$. Moreover, $\lambda_0^\alpha \nearrow \lambda_0$ as $\alpha \searrow 0$. This leads to the next proposition.

PROPOSITION 6. *If the initial conditions in Problems* II *and* III *are such that* J_{II} *and* $J_{\mathrm{III}}(\alpha)$ *are time independent and* $\alpha \searrow 0$, *then* $J_{\mathrm{III}}(\alpha) \nearrow J_{\mathrm{II}}$.

Another important comparison can be made between the time independent capacities for Problems I and II.

THEOREM 1. *If the initial conditions in Problems* I *and* II *are such that the diffusive capacities* J_{I} *and* J_{II} *are time independent, then*

$$J_{\mathrm{II}} \le J_{\mathrm{I}} \le C_\Omega J_{\mathrm{II}}, \tag{54}$$

where $C_\Omega = \frac{\max_\Omega \phi_0}{\bar{\phi}_0}$.

Proof. Let $u_1 \in \overset{\circ}{H}{}_2^1(\Omega, \Gamma_w)$ be a solution of the problem (21)–(23). We need to show that

$$\frac{1}{\int_\Omega u_1(x)dx} \geq \lambda_0.$$

From (52) it follows that

$$\lambda_0 \leq \frac{\int_\Omega (\nabla u_1)\cdot(A\nabla u_1)dx}{\int_\Omega u_1^2 dx}. \tag{55}$$

Using the identity

$$\nabla\cdot(u_1 A\nabla u_1) = (\nabla u_1)\cdot(A\nabla u_1) - u_1\nabla\cdot(A\nabla u_1),$$

applying the divergence theorem to the numerator, and making use of (21)–(23), we obtain

$$\lambda_0 \leq \frac{1}{V}\frac{\int_\Omega u_1 dx}{\int_\Omega u_1^2 dx}. \tag{56}$$

The last inequality can be rewritten as

$$\lambda_0 \leq \frac{1}{V}\frac{\left(\int_\Omega u_1 dx\right)^2}{\int_\Omega u_1^2 dx}\frac{1}{\int_\Omega u_1 dx}. \tag{57}$$

The first part of (54) now follows from Hölder's inequality.

Let $u_1(x)$ be a solution of (21)–(23) and ϕ_0 of (39)–(41). After multiplication of both sides of (21) by ϕ_0, using the symmetry of A in the identity

$$(\nabla\cdot(A\nabla u_1))\phi_0 = \nabla\cdot(\phi_0 A\nabla u_1) - \nabla\cdot(u_1 A\nabla\phi_0) + \nabla\cdot(A\nabla\phi_0)u_1, \tag{58}$$

followed by integration over Ω, from the divergence theorem one concludes that

$$\lambda_0 \max_\Omega \phi_0 \int_\Omega u_1 dV \geq \lambda_0 \int_\Omega u_1\phi_0 dV = \frac{1}{V}\int_\Omega \phi_0 dV = \bar{\phi}_0. \tag{59}$$

The latter can be recast as the second part of (54), using the positivity of u_1 and ϕ_0. ∎

Remark 11. The constant C_Ω is a peak-to-average ratio and has a clear physical meaning [24].

4. Transient diffusive capacity. In section 3 it was shown that the PI of a well in a reservoir is constant for all $t > 0$ provided that the pressure distribution at $t = 0$ satisfies certain conditions. The PI is known to stabilize in a long time asymptote regardless of the initial pressure distribution. In this chapter we will consider a transient diffusive capacity and investigate questions related to its stabilization. Thus, we will analyze Problems I and II with arbitrary initial conditions. The only restriction that is imposed on the initial conditions f_1 and f_2 of Problems I and II, respectively, is motivated by physical considerations: we require that f_1 and f_2 be positive smooth functions on Ω.

4.1. IBVP I: Constant production rate regime. In section 1 it was mentioned that the constant rate regime is usually modeled with one of two assumptions: at each time $t > 0$ either the pressure or the pressure flux is assumed to be constant on the wellbore. Proposition 2 shows that the condition of a constant wellbore pressure at each time $t > 0$ (infinite conductivity condition) is equivalent to the conditions of the PSS, i.e., the PI of a well is time independent. In this section we will show that the diffusive capacity on the class Υ of solutions of Problem I (defined in section 3) is stable with respect to small perturbations of boundary conditions. Recall that Υ is the class of solutions u of Problem I such that at each time $t > 0$, u is constant on Γ_w. Then the stability of J is established by the following proposition.

PROPOSITION 7. *Let $v(x,t)$ be a solution of Problem* I *such that $v(x,t) = Bt + C$ for all $x \in \Gamma_w$. Let $u(x,t)$ be a solution of Problem* I *such that $u(x,t) = Bt + C + h(x,t)$ for all $x \in \Gamma_w$, where $h(x,t)$ is a smooth, bounded function. For any $\epsilon > 0$, there exists $\delta > 0$ such that if for all $t > 0$, $|h(x,t)| \le \delta$ for all $x \in \Gamma_w$, then $|J(u,t) - J(v,t)| \le \epsilon$ for all $t > 0$.*

Proof. Function $\tilde{v}(x,t) = u(x,t) - v(x,t)$ is a solution of the following problem:

$$L\tilde{v} = \frac{\partial \tilde{v}}{\partial t}, \quad x \in \Omega, \quad t > 0, \tag{60}$$

$$\frac{\partial \tilde{v}}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{61}$$

$$\tilde{v}|_{\Gamma_w} = h(x,t), \tag{62}$$

$$\tilde{v}(x,0) = 0. \tag{63}$$

The maximum principle for parabolic equation (60) implies that $|\tilde{v}(x,t)| \le \delta$ for all $x \in \Omega$ and $t \ge 0$. Since $\int_{\Gamma_w} \frac{\partial u}{\partial \nu} dS = \int_{\Gamma_w} \frac{\partial u}{\partial \nu} dS = -q$ for $t \ge 0$,

$$\left| \frac{1}{J(v,t)} - \frac{1}{J(u,t)} \right| \le \frac{1}{q} \left| \frac{1}{W} \int_{\Gamma_w} (u - v) dS + \frac{1}{V} \int_{\Omega} (u - v) dx \right|.$$

Hence, $|\frac{1}{J(v,t)} - \frac{1}{J(u,t)}| \le \delta$. ∎

One should note that J_{I} is shown to be a PSS PI of a well only for solutions of Problem I that belong to class Υ. The extent to which the assumption of the infinite conductivity of the well is realistic for various reservoir-well configurations will be discussed in more detail in section 7. Below we investigate the question of the uniqueness of the PSS PI. Recall that the PSS PI is a constant value of the diffusive capacity on the solutions to Problem I.

Remark 12. J_{I} is not necessarily a unique constant value of the diffusive capacity on the solutions to Problem I.

This is established by the following argument. Consider solutions to Problem I with a constant flux on Γ_w; i.e., let $u(x,t)$ be a solution of the following problem:

$$Lu = \frac{\partial u}{\partial t}, \quad x \in \Omega, \quad t > 0, \tag{64}$$

$$\frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{65}$$

$$\frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_w} = -\frac{q}{W}, \tag{66}$$

$$u(x,0) = f_1(x). \tag{67}$$

The solution to (64)–(67) is given (up to an additive constant) by $u(x,t) = qv - \frac{q}{V}t + h(x,t)$, where $v(x)$ is a solution of the steady-state problem

$$Lv = -\frac{1}{V}, \quad x \in \Omega, \tag{68}$$

$$\frac{\partial v}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{69}$$

$$\frac{\partial v}{\partial \vec{\nu}}|_{\Gamma_w} = -\frac{1}{W}, \tag{70}$$

and $h(x,t)$ is a solution of the corresponding problem with homogeneous boundary conditions:

$$Lh = \frac{\partial h}{\partial t}, \quad x \in \Omega, \quad t > 0, \tag{71}$$

$$\frac{\partial h}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{72}$$

$$\frac{\partial h}{\partial \vec{\nu}}|_{\Gamma_w} = 0, \tag{73}$$

$$h(x,0) = f_1(x) - qv(x). \tag{74}$$

The solution to (71)–(74) is given by $h(x,t) = \sum_{n=0}^{\infty} c_n \phi_n(x) e^{-\lambda_n t}$, where $\phi_n(x)$ and λ_n are solutions of the related Sturm–Liouville problem and c_n are the coefficients of the Fourier expansion of $h(x,0)$ in terms of ϕ_n. The diffusive capacity $J(u,t)$ is given by

$$J(u,t) = \frac{-q}{\bar{v}_w - \bar{v}_\Omega + \bar{h}_w - \bar{h}_\Omega}. \tag{75}$$

Note that $\bar{v}_w$ and $\bar{v}_\Omega$ are constant, while $\bar{h}_w$ and $\bar{h}_\Omega$ are functions of time. Clearly, the difference $\bar{h}_w - \bar{h}_\Omega = \sum_{n=0}^{\infty} c_n(\bar{\phi}_{nw} - \bar{\phi}_{n\Omega}) e^{-\lambda_n t}$ converges to a constant as $t \to \infty$. Therefore, $J(u,t)$ converges to a constant value $\hat{J}$ as $t \to \infty$. However, $\hat{J}$ is not necessarily equal to J_{I}.

Henceforth, we do not address the uniqueness of the constant diffusive capacity on the solutions of Problem I and, consequently, of the PSS PI. In the subsequent sections we will refer to J_{I} as the value of the PSS PI, thus implicitly assuming that the wellbore has an infinite conductivity.

4.2. IBVP II: Constant wellbore pressure regime. For simplicity, consider the following problem for a parabolic equation. Let $u(x,t)$ be a solution of

$$Lu = \frac{\partial u}{\partial t}, \quad x \in \Omega, \quad t \geq 0, \tag{76}$$

$$\frac{\partial u}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{77}$$

$$u|_{\Gamma_w} = 0, \tag{78}$$

$$u(x,0) = u_0(x), \tag{79}$$

where $u_0(x) > 0$. Then the diffusive capacity is simply

$$J(u,t) = V \frac{\int_{\Gamma_w} \frac{\partial u}{\partial \vec{\nu}} dS}{\int_\Omega u dx}. \tag{80}$$

Along with (76)–(79), consider the related Sturm–Liouville problem for the operator L,

$$L\phi_k = -\lambda_k \phi_k, \qquad x \in \Omega, \quad t \geq 0, \tag{81}$$

$$\frac{\partial \phi_k}{\partial \vec{\nu}}|_{\Gamma_e} = 0, \tag{82}$$

$$\phi_k|_{\Gamma_w} = 0. \tag{83}$$

Let $\{\phi_k(x)\}_{k=0}^\infty$ be an orthonormal family of solutions of (81)–(83) with respect to the usual inner product in $L^2(\Omega)$. Define $d_k = \int_\Omega \phi_k(x)dx$ and $c_k = \int_\Omega u_0(x)\phi_k(x)dx$. Then the diffusive capacity can be written as

$$J(u,t) = V \frac{\sum_{k=0}^\infty c_k \lambda_k d_k e^{-\lambda_k t}}{\sum_{k=0}^\infty c_k d_k e^{-\lambda_k t}}.$$

The latter can be recast into

$$J(u,t) = V\lambda_0 \left[1 + \frac{\sum_{k=1}^\infty \frac{c_k}{c_0}\frac{d_k}{d_0}\left(\frac{\lambda_k}{\lambda_0} - 1\right) e^{-(\lambda_k - \lambda_0)t}}{1 + \sum_{k=1}^\infty \frac{c_k}{c_0}\frac{d_k}{d_0} e^{-(\lambda_k - \lambda_0)t}} \right]. \tag{84}$$

Since $\lambda_0 < \lambda_1 < \lambda_3 < \cdots$, as $t \to \infty$, $J(u,t) \to \lambda_0 V$. This proves the following.

PROPOSITION 8. *If u is a solution of IBVP* II, *then the diffusive capacity $J(u,t)$ converges to the constant value J_{II} as $t \to \infty$ for any initial condition f_2.*

In terms of the PI, Proposition 8 can be rephrased in the following way: if a well is produced with a constant wellbore pressure, the PI stabilizes to constant value J_{II} as $t \to \infty$ regardless of the initial pressure distribution.

Note that since the initial condition $u_0(x)$ is positive on Ω, $c_0 > 0$ and $d_0 > 0$. From the maximum principle for parabolic equation (76) it follows that $u(x,t) \geq 0$

for all $t > 0$. Consequently, the denominator in (84), equal to $\int_\Omega u(x,t)dx/c_0d_0e^{-\lambda_0 t}$, is positive for all $t > 0$. Therefore, from (84) follows the next remark.

Remark 13. If in (84) $c_kd_k > 0$ for any k, then $J(u,t) \searrow \lambda_0 V$.

The last observation allows one to analyze several physically important examples of the transient PI in terms of the diffusive capacity on the solutions of the IBVP for a parabolic equation.

Example 1. Suppose that a well is produced with constant rate, the PI is constant, and the well has infinite conductivity. Then the pressure in the reservoir $u(x,t)$ is determined (up to an additive constant) by $u(x,t) = qu_1(x) - \frac{q}{V}t$ (see Proposition 2), where $u_1(x)$ is a solution of the auxiliary steady-state problem

$$Lu_1(x) = -\frac{1}{V}, \quad x \in \Omega,$$

$$\frac{\partial u_1}{\partial \vec{\nu}}|_{\Gamma_e} = 0,$$

$$u_1|_{\Gamma_w} = 0.$$

Suppose that at some time $t_0 > 0$, the production regime was changed to a constant wellbore pressure production. Then the pressure in the reservoir $u(x,t)$ for $t > t_0$ is defined by $u(x,t) = v(x,t-t_0) - \frac{q}{V}(t-t_0)$, where $v(x,t)$ is a solution of the problem

$$Lv(x) = -\frac{\partial v}{\partial t}, \quad x \in \Omega, \quad t > 0,$$

$$\frac{\partial v}{\partial \vec{\nu}}|_{\Gamma_e} = 0,$$

$$v|_{\Gamma_w} = 0,$$

$$v(x,0) = qu_1(x).$$

The diffusive capacity $J(u,t) = J(v,t)$, where $v(x,t)$ is defined by

$$v(x,t) = \sum_{n=0}^{\infty} c_k\phi_k(x)e^{-\lambda_k t},$$

where $c_k = q\int_\Omega u_1(x)\phi_k dx$. Using integration by parts, we obtain

$$\int_\Omega Lu_1\phi_k = \int_\Omega u_1 L\phi_k.$$

Hence,

$$\frac{1}{V}\int_\Omega \phi_k = \lambda_k \int_\Omega u_1\phi_k.$$

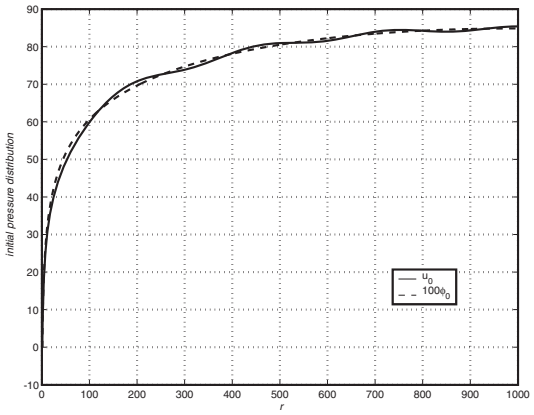

FIG. 1. *Radial profile of an initial distribution yielding small diffusive capacity.*

Thus, for any $k = 1, 2 \dots$, $d_k c_k > 0$ and (84) implies that $J(u,t) \searrow J_{\text{II}}$. In other words, when the regime of production changes from PSS, i.e., constant flow rate, to constant wellbore pressure, the PI monotonically decreases to the BD PI.

Example 2. For the purpose of analysis it is frequently assumed that at $t = 0$ the pressure in the reservoir is distributed uniformly, i.e., $u_0(x) = u_i$, where u_i is a positive constant. Then $c_k = u_i d_k$ and the PI is monotonically decreasing to the BD PI.

Finally, consider an example of the initial pressure distribution yielding the PI which is less than the BD PI.

Example 3. Let $u_0(x) = 100\phi_0(x) - 3\phi_1(x)$. Then the diffusive capacity $J(u,t) < \lambda_0 V$.

An example of such initial distribution for an ideal cylindrical reservoir with vertical fully penetrated well is given in Figure 1, where the radial profile of $u_0(r)$ is given. The dimensionless radius of the reservoir is equal to $R_D = 1000$. Physically this example may be interpreted as follows. Assume that the reservoir has been depleted by a set of wells. Suppose that the old wells are shut down and a new well is drilled and produced. Then the PI of the new well will monotonically increase to the BD PI value.

5. Model of the skin effect. Stabilized production with constant rate is characterized by the PSS PI. When the well is damaged, the value of the PI is less than what is predicted by the model. As described in section 1, such effect is called thin-skin effect. To take into account the skin effect, the PSS PI is corrected according to the equation

$$PI_{PSS,skin} = \frac{1}{\frac{1}{PI_{PSS}} + s}, \tag{85}$$

where s is the so-called *skin factor* or simply *skin*. The skin factor concept was originally introduced to describe the behavior of damaged wells. Others have extended the idea to stimulated wells which have a higher PI than the PSS PI of an ideal well. In [15] it was shown that a negative skin s corresponds to a stimulated well.

All existing results on modeling the skin effect pertain to the constant rate production regime. In this section it will be shown that for the constant wellbore pressure

production regime, the skin effect can be modeled by a third boundary condition specified on the well boundary.

5.1. Diffusive capacity for IBVP III in an annulus. Let $u(r,t)$ be a solution of the problem

$$\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right)=\frac{\partial u}{\partial t},\quad 1<r<R_D,\quad t>0, \tag{86}$$

$$\frac{\partial u}{\partial r}|_{r=R_D}=0, \tag{87}$$

$$\left(u+\alpha\frac{\partial u}{\partial r}\right)|_{r=1}=0, \tag{88}$$

$$u(r,0)=u_0(r). \tag{89}$$

Problem (86)–(89) models the axisymmetric flow of oil in an ideal isolated circular reservoir with a perfect circular well situated in the center. Here, $u(r,t)$ is the dimensionless pressure in the reservoir, the dimensionless formation permeability is 1, and the dimensionless outer radius is equal to R_D. The dimensionless wellbore radius is equal to 1. Constant wellbore pressure production is assumed. The thin skin zone adjacent to the well has a permeability below than that of the formation.

We will call a production regime for a well with a thin skin zone characterized by a constant PI a *generalized BD state*. When $\alpha=0$ (no damaged zone around the well), it is a BD regime.

Along with problem (86)–(89), consider a related Sturm–Liouville problem:

$$\frac{\partial}{\partial r}\left(r\frac{\partial \phi_k^\alpha}{\partial r}\right)=-\lambda_k^\alpha \partial\phi_k^\alpha,\quad 1<r<R_D,\quad t>0, \tag{90}$$

$$\frac{\partial \phi_k^\alpha}{\partial r}|_{r=R_D}=0, \tag{91}$$

$$\left(\phi_k^\alpha+\alpha\frac{\partial \phi_k^\alpha}{\partial r}\right)|_{r=1}=0. \tag{92}$$

Let λ_0^α be the minimal nonnegative eigenvalue of the problem (90)–(92). If the initial condition $u_0(r)=\phi_0^\alpha$ is the eigenfunction corresponding to λ_0^α, then by Propositions 5 and 6 the generalized BD PI is determined by $J_{\mathrm{III}}(\alpha)=\lambda_0^\alpha V$ and $J_{\mathrm{III}}(0)=J_{\mathrm{II}}$.

In analogy to (85), we define the skin factor s by

$$s=s(\alpha):=\frac{1}{J_{\mathrm{III}}(\alpha)}-\frac{1}{J_{\mathrm{II}}}=\frac{1}{J_{\mathrm{III}}(\alpha)}-\frac{1}{J_{\mathrm{III}}(0)}. \tag{93}$$

Positive skin defined by (93) is evidence of a damaged well. By analogy, the generalized BD index of a stimulated well should be greater than the BD index, yielding negative skin s.

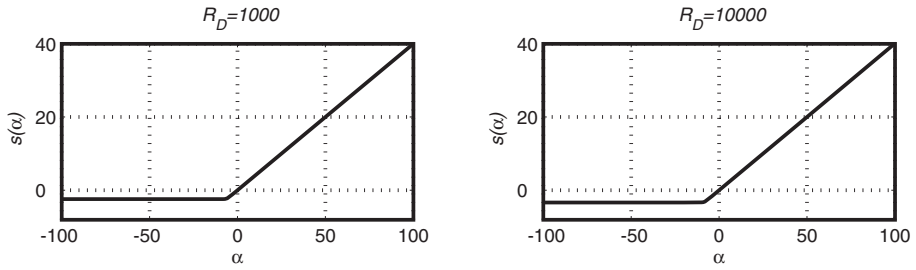

FIG. 2. *Graph of $s(\alpha)$ for $R_D = 1000$ (left panel) and for $R_D = 10,000$ (right panel).*

When $\alpha < 0$, λ_0^α is the first positive eigenvalue. The eigenpair solves known equations involving Bessel functions of the first and the second kind. Using known facts from the theory of Bessel functions, it is not hard to show the following.

PROPOSITION 9. *As $\alpha \to \infty$, $\lambda_0^\alpha \to 0$. As $\alpha \to -\infty$, $\lambda_0^\alpha \to \lambda_0^{(N)}$, where $\lambda_0^{(N)}$ is the minimal nontrivial eigenvalue of the following problem:*

$$\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right) = \frac{\partial u}{\partial t}, \quad 1 < r < R_D, \quad t > 0, \tag{94}$$

$$\frac{\partial u}{\partial r}|_{r=R_D} = 0, \tag{95}$$

$$\frac{\partial u}{\partial r} = 0, \tag{96}$$

$$u(r,0) = u_0(r). \tag{97}$$

This implies, in particular, that $s(\alpha)$, defined by (93), is bounded from below, since $\lambda_0^{(N)}$ is bounded from above. The relation between s and α for $R_D = 1000$ and $R_D = 1000$ is shown in Figure 2 for a range of values of α. Figure 2 illustrates that when $\alpha > 0$, skin $s = \alpha$, i.e., the positive skin can be successfully modeled by the third boundary condition, in perfect agreement with the constant rate case. To analyze the case of $\alpha < 0$, additional considerations are necessary.

Eigenfunctions ϕ_0^α corresponding to the minimal positive eigenvalue λ_0^α of the problem (90)–(92) for two sample positive and negative values of α are pictured in Figure 3. As seen in Figure 3, for negative α the corresponding eigenfunction ϕ_0^α changes sign on the interval $1 < r < R_D$. Recall that the initial condition of the problem (86)–(89) u_0 is equal to ϕ_0^α. Consequently, the sufficient condition for the generalized BD state is such that the initial pressure distribution in the reservoir is not everywhere positive. Thus, a negative value of the skin factor s creates a physical contradiction, and problem (86)–(89) with $\alpha < 0$ cannot serve as an appropriate model for a stimulated well.

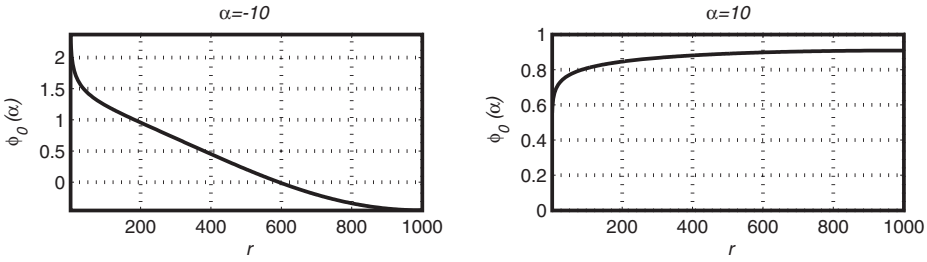

FIG. 3. *Eigenfunctions for negative α (left panel) and positive α (right panel).* $R_D = 1000$.

6. PI in a two-dimensional reservoir. In this chapter we present a numerical study of the diffusive capacity/PI in two-dimensional domains. We will restrict our attention to PSS and BD productivity indices only, that is, we will consider only IBVPs I and II.

If the thickness of the reservoir is uniform, then for a fully penetrated vertical well the three-dimensional problem reduces to a two-dimensional one. Since the radius of wellbore is small compared to the dimensions of the reservoir, we can assume that the pressure is uniformly distributed on the wellbore. Therefore, for a two-dimensional problem, the PSS PI is equal to J_{I} given by (24).

Under the assumption that the reservoir is ideal and the well is perfectly circular, vertical, and fully penetrated, the IBVPs I and II can be formulated in terms of dimensionless variables as follows. Let $\Omega \in \mathbb{R}^2$ be the horizontal cross-section of such a reservoir. Let $\{r, \theta\}$ be a polar coordinate system specified on Ω along with the Cartesian coordinate system $\{x, y\}$. The origins of both coordinate systems are located at the center of the well, which is represented by a circle with equation $r = 1$. Let R_D be the radius of the circle of the same area as Ω. Then the dimensionless area V of Ω is equal to $(R_D^2 - 1)/2$. As before, let Γ_e denote the exterior boundary of Ω. The auxiliary steady-state problem (21)–(23) and the Sturm–Liouville problem (39)–(41) can be written as

$$\frac{\partial^2 u_1}{\partial x^2} + \frac{\partial^2 u_1}{\partial y^2} = -\frac{1}{V}, \tag{98}$$

$$u_1|_{r=1} = 0, \tag{99}$$

$$\frac{\partial u_1}{\partial \vec{n}}|_{\Gamma_e} = 0, \tag{100}$$

and

$$\frac{\partial^2 \phi_0}{\partial x^2} + \frac{\partial^2 \phi_0}{\partial y^2} = -\lambda_0 \phi_0, \tag{101}$$

$$\phi_0|_{r=1} = 0, \tag{102}$$

$$\frac{\partial \phi_0}{\partial \vec{n}}|_{\Gamma_e} = 0, \tag{103}$$

respectively. By Propositions 2 and 4, the values of the PSS and BD PIs are given by the following equations, respectively:

$$J_{\mathrm{I}} = \frac{V}{\int_\Omega u_1 dx} \tag{104}$$

and

$$J_{\mathrm{II}} = \lambda_0 V. \tag{105}$$

As the first stage, J_{I} and J_{II} values were compared to the values obtained by Dietz's equation (2) for domains in which (2) can be applied, that is, for domains with polygonal exterior boundaries: rectangle, triangle, circle, romb, and hexagon. Value J_{I} was compared to the value of the PSS PI J_{PSS} computed by (2) with the shape factors C_A taken from [6] for every considered shape. The constant diffusive capacity J_{II}, given by (105), was compared to the PI J_{BD} computed by (2) with the BD shape factors C_A provided in [13]. The results were obtained for two values of the dimensionless radius R_D of the drainage area, $R_D = 1000$ and $R_D = 10,000$.

The obtained results are not presented here due to limited space, but (104) and (105) closely agree to the corresponding existing formulas. The largest difference between the corresponding values is the one between J_{I} and J_{II} in the drainage areas where the well is located far from the center of symmetry of the domain.

As noted, one of the disadvantages of (2) is that it cannot be applied to the drainage area shapes that do not satisfy the requirements of the method of images. On the other hand, (104) and (105) are valid for all drainage area shapes and can be applied to a general reservoir without the usual assumptions of the homogeneity and isotropy of the media. Below we exploit these useful features of the new formulas for PI to analyze its behavior in more complex geometries and for anisotropic media. Then, using the new method we will evaluate the diffusive capacity in domains with more complex geometry, revealing some geometric characteristics of the domain that lead to the nonnegligible difference between J_{I} and J_{II}.

6.1. PI in domains violating isoperimetric inequality. Theorem 1 of section 3 gives the means to investigate more deeply the effects on the difference between J_{I} and J_{II} of the shape of the exterior boundary of the domain. The difference between J_{I} and J_{II} is expected to be greater when the constant C_Ω on the right-hand side of inequality (54) is much greater than 1. The constant C_Ω is, in its turn, determined by the minimal eigenvalue λ_0 and the behavior of the corresponding eigenfunction ϕ_0 of the elliptic problem (101)–(103).

The first eigenpair of the problem is directly related to the geometry of the domain, namely, to the symmetry and curvature of the exterior boundary and the shape of the well boundary. To illustrate the effect of the curvature and the symmetry of the exterior boundary, consider domains in Figure 4 (A) and (B). If the domain does not satisfy the classical isoperimetric inequality, the first eigenvalue of the problem (101)–(103) can be small enough in comparison to C_Ω to make the difference between J_{I} and J_{II} significant [22]. It is not hard to show that for $0 < \epsilon < 1$, both domains pictured in Figure 4 violate the classical isoperimetric inequality [22]. For either shape, the domain parameters b and ϵ change so that the ratio of the area of the domain to the radius of the well is held constant and corresponds to $R = 1000$. The circular well is located in the center of the area. The results of the numerical investigation for domains violating the classical isoperimetric inequality [22] are collected in Table 1.

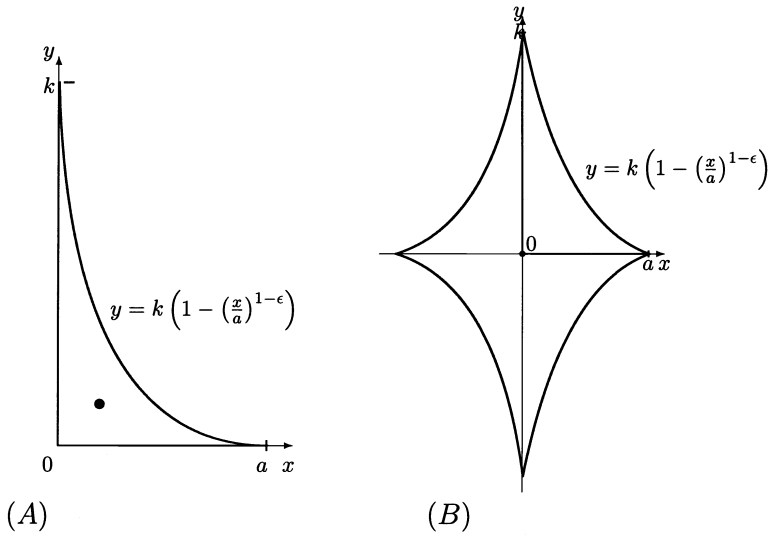

FIG. 4. *Domains violating isoperimetric inequality.*

TABLE 1
The difference between J_{I} and J_{II} in domains violating the isoperimetric inequality.

Shape	ϵ	J_{I}	J_{II}	$\left\lvert\frac{J_{\mathrm{I}}-J_{\mathrm{II}}}{J_{\mathrm{II}}}\right\rvert$, percent
	0.0	0.1227	0.1065	4.69
	0.4	0.0539	0.4370	23.34
	0.6	0.0137	0.0100	37.00
see Figure 4 (A)	0.8	0.0071	0.005	39.22
	0.8	0.0990	0.1222	19.00
see Figure 4 (B)	0.95	0.0056	0.0311	82.00

The symmetrical domain is presented to illustrate the importance of symmetry: the difference between J_{I} and J_{II} for a symmetrical domain is significantly less than for a nonsymmetrical domain with the same curvature of the exterior boundary.

7. PI in a three-dimensional reservoir. As described in the introduction, the existing methods for evaluating the PI have two major drawbacks. First, the evaluation of a PI requires solving a transient problem in a period long enough for the pressure to reach a PSS. When the well is not fully penetrated or directionally drilled (deviated or horizontal), the period necessary for the pressure to stabilize may become excessively long, creating difficulties for computational procedures. To address the problem of excessively long computations, some simplifying assumptions are made. Most of the methods are based on the assumption that the thickness of the reservoir is small enough to make the flow in the vertical direction negligible or so insignificant that its impact on the distribution of pressure can be included in a skin factor [20, 11]. With the restriction on the reservoir thickness, the problem reduces to a two-dimensional one. Then the techniques for two-dimensional reservoirs can be applied. The majority of such techniques utilize the method of images, creating the second drawback—restrictions on the geometry of the domain.

With this in mind, a number of numerical experiments were conducted for various

well configurations in three-dimensional domains. Here we illustrate the behavior of the PIs in a general homogeneous three-dimensional reservoir/well system. Equations (24) and (42) are convenient to use in such settings, since they require only solution of steady-state three-dimensional problems. Note that the use of (24) implies that in a constant rate of production regime, the pressure is uniformly distributed on the wellbore at each $t > 0$. One can argue that this assumption is physically realistic for horizontal wells of any length, if we assume that the wellbore has infinite conductivity so that the pressure of the fluid entering the wellbore instantly equalizes at every point of the wellbore. For vertical or slanted wells, the assumption of uniform pressure distribution on the wellbore at each $t > 0$ implies that we neglect gravity effects. Certainly, for long vertical or slanted wells, this assumption is not physically realistic.

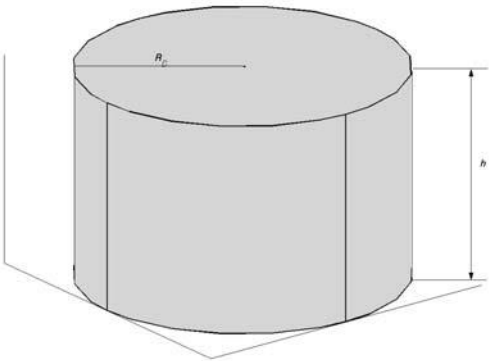

FIG. 5. *Schematic representation of domain* D_1.

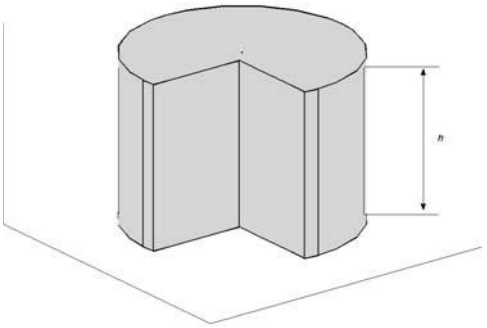

FIG. 6. *Schematic representation of domain* D_2.

Two domains modeling three-dimensional reservoirs that were considered for the numerical study are depicted in Figures 5, 6, and 7. Domain D_1 is a cylindrical reservoir of uniform thickness h and the dimensionless radius R_D. Analogously to the two-dimensional definition, R_D is defined as the ratio of the radius of the horizontal cross-section (in this case, circle) to the well radius. The value of R_D is set to 1000 for all settings. For consistency of comparisons made below, the radius of the circle

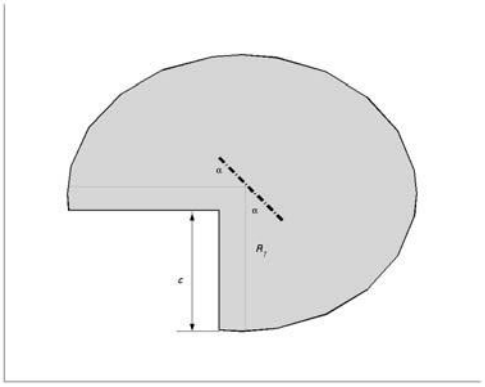

FIG. 7. *Schematic representation of horizontal projection of domain* D_2.

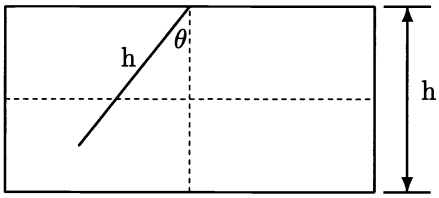

FIG. 8. *Schematic representation of the vertical cross-section for well configuration* (C).

of the cross-section of the domain D_2 is chosen so that the remaining area is equal to the area of the cross-section of domain D_1; i.e., the dimensionless radius associated with the horizontal cross-section of D_2 is $R_D = 1000$.

Two well configurations were considered for both reservoir models. For domain D_2, the direction of any considered well was such that its projection on the top of the reservoir corresponded to the schematic configuration shown in Figure 7. A well is modeled by a circular cylinder with the dimensionless radius $r_w = 1$. Then for both domains D_1 and D_2, the cross-section by the plane containing the well is a rectangle. Figures 8 and 9 show such cross-sections for every well configuration considered in the computational experiments. In configuration (E), the center of symmetry of the well coincides with the center of symmetry of the cross-section. In configuration (C), the well is drilled from the middle of the top side of the reservoir cross-section.

7.1. Directionally drilled wells. Effect of vertical flow. Productivity indices for well configuration (C) for domains D_2 and D_1 are given in Tables 2 and 3, respectively. In all cases, the penetration length of the well is equal to h so that for $\theta = 0$, the vertical well fully penetrates the reservoir. The graphs of J_{I} and J_{II} as functions of the angle θ of the well direction, shown in Figures 10 and 11, reveal that the optimal direction of a well of the fixed penetration length is not the vertical one. It is a clear indication of the effect of the vertical flow of fluid from the bottom of the reservoir toward the slanted well. This effect cannot be quantified by a reduced two-dimensional problem for a fully penetrated vertical well.

7.2. Horizontal well. Methods presented in [20, 11] rely heavily on the assumption that the vertical dimension of the reservoir is small compared to the penetration

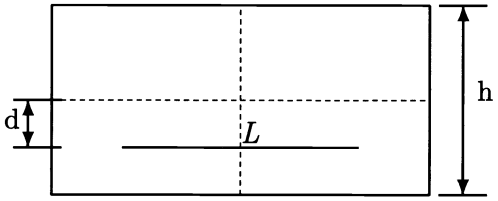

FIG. 9. *Schematic representation of the vertical cross-section for well configuration* (E).

length of the well. Moreover, as noted in [20], the precision of the evaluation of the PI for horizontal wells decreases drastically as the distance from the well to vertical boundaries of the reservoir becomes comparable to the distance to the top and/or the bottom of the reservoir, if the reduction to the two-dimensional problem is used. This section presents computational results for such settings when the assumption of the small reservoir thickness and the well being clearly inside the drainage area are relaxed.

The setting considered is a horizontal well with configuration (E), located at distance d below the plane of symmetry of domain D_1. The graphs of the computed PSS PI J_{I} as a function of distance d from the center of the reservoir for various penetration lengths L are shown in Figure 12.

For all practical purposes, one can conclude that the optimal location of a horizontal well in a cylindrical reservoir D_1 is in the horizontal plane of symmetry of the reservoir. Note that for long wells, however, the PSS PI slightly increases for small values of d. This may be an indication of an interesting feature of the diffusive capacity as a geometrical characteristic defined through the first eigenvalue λ_0. The latter is sensitive to the location of the well relative to the planes and lines of symmetry of the domain, as it is comprehensively illustrated in section 6. In three-dimensional

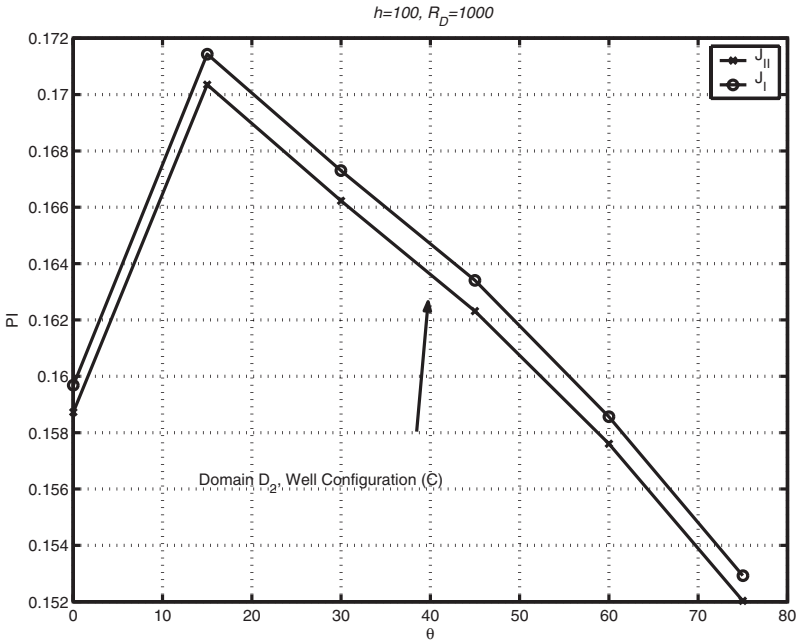

FIG. 10. *PIs for domain D_2, well configuration* (C).

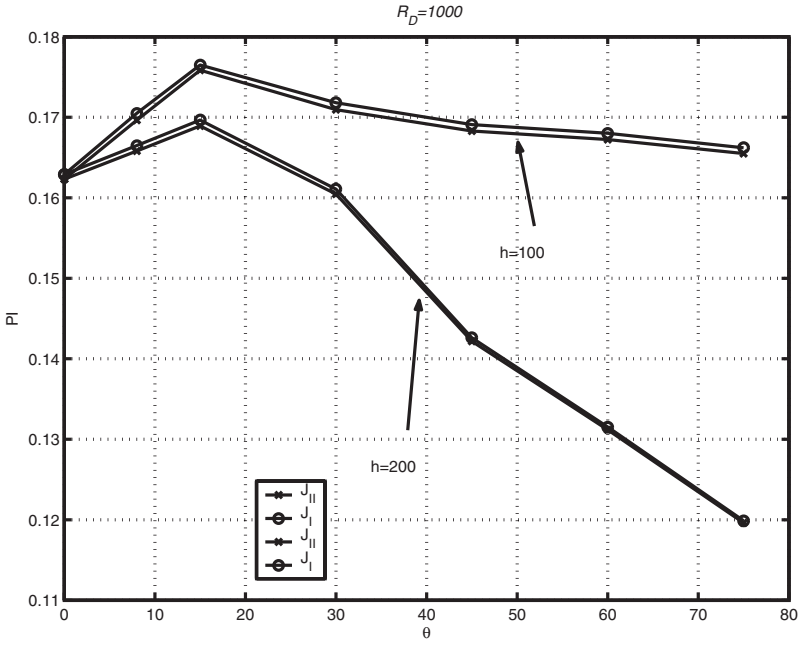

FIG. 11. *PIs for domain D_1, well configuration* (C).

domains, there are more such planes and lines of symmetry and, therefore, there may be several well configurations yielding maximal PI.

WEBSTER'S HORN EQUATION REVISITED*

SJOERD W. RIENSTRA†

Abstract. The problem of low-frequency sound propagation in slowly varying ducts is systematically analyzed as a perturbation problem of slow variation. Webster's horn equation and variants in bent ducts, in ducts with nonuniform soundspeed, and in ducts with irrotational mean flow, with and without lining, are derived, and the entrance/exit plane boundary layer is given. It is shown why a varying lined duct in general does not have an (acoustic) solution.

Key words. Webster's horn equation, duct acoustics, sound propagation in lined ducts with mean flow, perturbation methods, method of slow variation

1. Introduction.

Sound of long wavelength, propagating in ducts of varying diameter like horns, is suitably described by an approximate equation, known as Webster's horn equation or just Webster's equation. This is an ordinary differential equation in the axial coordinate, and therefore forms a significant simplification of the problem [1, 2, 3].

The usual derivation is based on the assumption of a crosswise uniform acoustic pressure field, such that, by averaging over a duct cross section, the spatial dimensions of the problem are reduced from three to one.

Although it shows a remarkable evidence of ingenuity and physical insight, this derivation is mathematically unsatisfying. It is not clear (i) what exactly is the small parameter underlying the approximation, (ii) why the pressure may be assumed to be uniform, (iii) what the error is of the approximation, (iv) what the conditions are on the duct geometry and on the frequency of the field, (v) how to generalize to similar problems, (vi) how to generate higher order corrections, and (vii) what happens near the source or duct entrance or exit plane.

An asymptotically systematic derivation of the three-dimensional (3D) classic problem was given by Lesser and Crighton [4], extending the derivation of Lesser and Lewis in [5, 6]. They also showed for a number of 2D configurations how abrupt changes of the geometry (open end, slit in the wall) can be incorporated as boundary layer regions in a setting of matched asymptotic expansion. Their approach, based on introducing different longitudinal and lateral scales, is a special case of the method of slow variation put forward by Van Dyke [7]. Although only an asymptotically sound derivation is able to indicate the range of validity and the order of the error of the approximation, we found in the literature no variants of this problem (e.g., with mean flow [8, 9, 10, 11, 12]) that strictly follow that approach.

Particularly interesting would be an investigation of the related problems of lined ducts without and with flow, as this would form a natural long wavelength closure of the multiple scales theory of sound propagation in slowly varying ducts [13, 14, 15, 16].

Another problem of practical interest that is directly related to a systematic set-up is the entrance problem for a 3D duct of arbitrary cross section. The structure of the boundary layer was indicated by Lesser and Crighton [4], but they gave explicit examples only for 2D geometries.

All in all, while the problem of long wave sound propagation in slowly varying ducts, in various generalizations, is practically important, it still has a lot of open ends.

We will consider various cases in detail. First, we show how a systematic approach, known as the method of slow variation coupled with ideas of matched asymptotic expansions, leads to the classic Webster equation for hard-walled ducts with the entrance boundary layer. The small parameter ε is equal to the Helmholtz number, the ratio between a typical wavelength and the duct diameter, while a typical length scale of duct variation is of the same order of magnitude as the wavelength. Using similar results for the related problem of heat conduction [17], this entrance problem will be solved explicitly. It leads via matching conditions to conclusions about the way that the $\mathcal{O}(1)$ duct field error ($\mathcal{O}(\varepsilon)$ or $\mathcal{O}(\varepsilon^2)$) depends on the source.

Then we will show that our problem is not essentially different in other coordinate systems (like spherical coordinates), although special coordinates may be helpful in obtaining a more efficient approximation. Curved ducts, with a curvature radius of no more than the typical length scale of diameter variation, are shown to still produce the same equation.

The same type of analysis can be applied to ducts with lined walls of, say, impedance Z. It is found that for $Z = \mathcal{O}(1)$ only the trivial solution exists, while for $Z = \mathcal{O}(\varepsilon)$ there are only nontrivial solutions possible for certain geometry-dependent values of the wall impedance. As these impedance values vary along the duct, there are in general no solutions possible for the full duct. A subtle functional analytic result is used, due to Professor Jan de Graaf (TU Eindhoven), which is not available in the literature; therefore, Prof. de Graaf was kind enough to attach his derivation as an appendix to this paper.

We continue with more general analyses of the problem in a stagnant medium with slowly varying sound speed, and of sound in an irrotational isentropic mean flow, leading to generalized forms of Webster's horn equation.

We finish with the same problem with mean flow but now extended to ducts with lined walls. Using a recent result obtained for the related problem for high-frequency sound propagation in lined flow ducts [16], we are able to show for $Z = \mathcal{O}(1)$ that also here only a special hydrodynamic (nonacoustic) wave is possible.

2. The physical models.

2.1. The equations. In the acoustic realm of a perfect gas that we will consider, we have for pressure $\tilde{p}$, velocity $\tilde{\boldsymbol{v}}$, density $\tilde{\rho}$, entropy $\tilde{s}$, and soundspeed $\tilde{c}$

$$\begin{aligned} &\frac{\mathrm{d}\tilde{\rho}}{\mathrm{d}t} = -\tilde{\rho}\nabla\cdot\tilde{\boldsymbol{v}}, \quad \tilde{\rho}\frac{\mathrm{d}\tilde{\boldsymbol{v}}}{\mathrm{d}t} = -\nabla\tilde{p}, \quad \frac{\mathrm{d}\tilde{s}}{\mathrm{d}t} = 0, \\ &\mathrm{d}\tilde{s} = C_V\frac{\mathrm{d}\tilde{p}}{\tilde{p}} - C_P\frac{\mathrm{d}\tilde{\rho}}{\tilde{\rho}}, \quad \tilde{c}^2 = \frac{\gamma\tilde{p}}{\tilde{\rho}}, \quad \gamma = \frac{C_P}{C_V}, \end{aligned} \tag{1}$$

where γ, C_P, and C_V are gas constants. When the flow originates from a thermodynamically uniform state and consists of a stationary mean flow, with unsteady

time-harmonic perturbations of frequency ω given, in the usual complex notation, by

$$\tilde{\boldsymbol{v}} = \boldsymbol{V} + \mathrm{Re}(\boldsymbol{v}\,\mathrm{e}^{\mathrm{i}\omega t}), \quad \tilde{p} = P + \mathrm{Re}(p\,\mathrm{e}^{\mathrm{i}\omega t}), \quad \tilde{\rho} = D + \mathrm{Re}(\rho\,\mathrm{e}^{\mathrm{i}\omega t}), \quad \tilde{s} = S + \mathrm{Re}(s\,\mathrm{e}^{\mathrm{i}\omega t}) \tag{2}$$

($\omega > 0$), we obtain for the mean flow, upon linearization for small amplitude,

$$\begin{gathered} \nabla\cdot(D\boldsymbol{V}) = 0, \quad D(\boldsymbol{V}\cdot\nabla)\boldsymbol{V} = -\nabla P, \\ (\boldsymbol{V}\cdot\nabla)S = 0, \quad S = C_V \log P - C_P \log D, \quad C^2 = \frac{\gamma P}{D}, \end{gathered} \tag{3}$$

and for the perturbations

$$\mathrm{i}\omega\rho + \nabla\cdot(\boldsymbol{V}\rho + \boldsymbol{v}D) = 0, \tag{4a}$$

$$D\big(\mathrm{i}\omega + \boldsymbol{V}\cdot\nabla\big)\boldsymbol{v} + D\big(\boldsymbol{v}\cdot\nabla\big)\boldsymbol{V} + \rho(\boldsymbol{V}\cdot\nabla)\boldsymbol{V} = -\nabla p, \tag{4b}$$

$$(\mathrm{i}\omega + \boldsymbol{V}\cdot\nabla)s + \boldsymbol{v}\cdot\nabla S = 0, \tag{4c}$$

while

$$s = \frac{C_V}{P}p - \frac{C_P}{D}\rho = \frac{C_V}{P}\big(p - C^2\rho\big). \tag{4d}$$

Without mean flow, such that $\boldsymbol{V} = \nabla P = 0$, the equations may be reduced to (see section 8)

$$\nabla\cdot\big(C^2\nabla p\big) + \omega^2 p = 0. \tag{5}$$

If, in addition, the ambient medium is uniform, with a constant soundspeed C and density D, the acoustic field becomes isentropic and irrotational, and we may introduce a potential $\boldsymbol{v} = \nabla\phi$. Furthermore, (5) reduces to the Helmholtz equation. After introducing the free field wave number $k = \omega/C$, we have (see sections 3, 4, 6, 7)

$$\nabla^2\phi + k^2\phi = 0. \tag{6}$$

If the original flow field $\tilde{\boldsymbol{v}}$ is irrotational and isentropic everywhere (homentropic), we can introduce a potential for the velocity, where $\tilde{\boldsymbol{v}} = \nabla\tilde{\phi}$, and express $\tilde{p}$ as a function of $\tilde{\rho}$ only, such that we can integrate the momentum equation (Bernoulli's law, with constant E) to obtain for the mean flow

$$\tfrac{1}{2}V^2 + \frac{C^2}{\gamma - 1} = E, \quad \nabla\cdot(D\boldsymbol{V}) = 0, \quad \frac{P}{D^\gamma} = \text{constant}, \tag{7}$$

and for the acoustic perturbations

$$\big(\mathrm{i}\omega + \boldsymbol{V}\cdot\nabla\big)\rho + \rho\nabla\cdot\boldsymbol{V} + \nabla\cdot\big(D\nabla\phi\big) = 0, \quad D\big(\mathrm{i}\omega + \boldsymbol{V}\cdot\nabla\big)\phi + p = 0, \quad p = C^2\rho. \tag{8}$$

These last equations are further simplified (eliminate p and ρ and use the fact that $\nabla\cdot(D\boldsymbol{V}) = 0$) to the rather general convected wave equation (see section 9)

$$D^{-1}\nabla\cdot\big(D\nabla\phi\big) - \big(\mathrm{i}\omega + \boldsymbol{V}\cdot\nabla\big)\Big[C^{-2}\big(\mathrm{i}\omega + \boldsymbol{V}\cdot\nabla\big)\phi\Big] = 0. \tag{9}$$

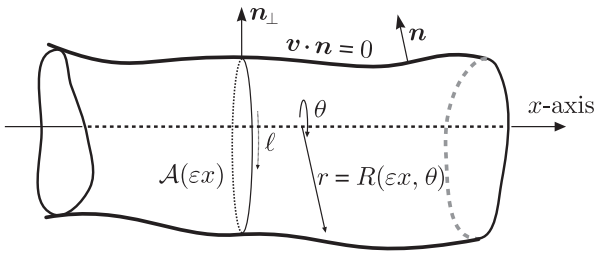

FIG. 1. *Sketch of geometry.*

2.2. Nondimensionalization. Without further change of notation, we will assume throughout this paper that the problem is made dimensionless: lengths on a typical duct radius, time on typical sound speed / typical duct radius, etc.

2.3. The geometry. The domain of interest consists of a duct $\mathcal{V}$ of arbitrary cross section, slowly varying in axial direction (see Figure 1). For definiteness, it is given by the function Σ in cylindrical coordinates, as follows:

$$\Sigma(X,r,\theta)=r-R(X,\theta)\leq 0, \tag{10}$$

where $X=\varepsilon x\geqslant 0$ is a so-called slow variable, while ε is small. A cross section $\mathcal{A}(X)$ at axial position X has surface area $A(X)$. Whenever relevant,[1] we assume lengths made dimensionless such that

$$A(0)=1.$$

At the duct surface $\Sigma=0$, the gradient $\nabla\Sigma$ is a vector normal to the surface (i.e., $\nabla\Sigma\propto\boldsymbol{n}$), while the transverse gradient $\nabla_\perp\Sigma$,

$$\nabla_\perp=\boldsymbol{e}_r\frac{\partial}{\partial r}+\boldsymbol{e}_\theta\frac{1}{r}\frac{\partial}{\partial\theta},\quad\text{with}\quad\nabla_\perp\Sigma=\boldsymbol{e}_r-\boldsymbol{e}_\theta\frac{1}{r}R_\theta, \tag{11}$$

(where R_θ denotes the partial derivative of R to θ) is directed in the plane of a cross section $\mathcal{A}(X)$ and normal to the duct circumference $\partial\mathcal{A}$. Thus if $\boldsymbol{n}_\perp$ is the component of the surface normal vector $\boldsymbol{n}$ in the plane of a cross section, we have $\nabla_\perp\Sigma\propto\boldsymbol{n}_\perp$.

2.4. Frequency. The frequencies considered are low, such that the corresponding typical wave number is of the same order of magnitude as the length scale of the duct variations, i.e., dimensionless $\mathcal{O}(\varepsilon^{-1})$. In order to quantify this, we will rescale $k=\varepsilon\kappa$ and $\omega=\varepsilon\Omega$.

3. The classical problem.

3.1. Equations and boundary conditions. The duct is semi-infinite and hard-walled. The solution is determined by a source at entrance plane $x=0$, and radiation conditions for $x\to\infty$. Other conditions, like a reflecting impedance plane at some exit plane $x=L$ (e.g., modeling a radiating open end [5] or a slit in the wall [4]), are also possible, but they do not essentially alter the present analysis.

Inside $\mathcal{V}$ we have for acoustic potential ϕ (see (6))

$$\nabla^2\phi+\varepsilon^2\kappa^2\phi=0\ \text{ if }\ \boldsymbol{x}\in\mathcal{V},\quad\text{with}\quad\nabla\phi\cdot\boldsymbol{n}=0\ \text{ at }\ \boldsymbol{x}\in\partial\mathcal{V}. \tag{12}$$

[1] In particular, in section 4.

At the entrance interface $x = 0$ we have a suitable boundary condition, say,

$$\phi(0, r, \theta) = F(r, \theta). \tag{13}$$

The boundary condition of hard walls at $r = R(X, \theta)$ may be given by

$$\nabla_\perp \phi \cdot \nabla_\perp \Sigma = \phi_r - \frac{R_\theta}{R^2}\phi_\theta = \varepsilon R_X \phi_x. \tag{14}$$

Except for the immediate neighborhood of the entrance plane, the typical axial variations of the acoustic field scale on the slow variable X, so we rewrite the equations and boundary conditions as

$$\begin{gathered} \varepsilon^2 \phi_{XX} + \nabla_\perp^2 \phi + \varepsilon^2 \kappa^2 \phi = 0, \\ \text{with} \quad \nabla\phi \cdot \nabla\Sigma = -\varepsilon^2 \phi_X R_X + \nabla_\perp \phi \cdot \nabla_\perp \Sigma = 0 \quad \text{at} \quad r = R. \end{gathered} \tag{15}$$

This rewriting in a slow variable is known as the method of slow variation [7]. Note that this equation has a small parameter multiplied by the highest derivative in the X-direction, suggesting a singular perturbation problem [4, 18, 19, 20] with boundary layers in X.

3.2. Asymptotic analysis: Outer solution. The following outer solution analysis will largely follow Lesser and Crighton [4], but we will give it in some detail for two reasons. First, we will have to define the solution for the inner solution at the entrance boundary layer to be discussed later. Second, it explicates the method of integration along a cross section that will be used in the various other configurations later.

Based on the observation that ε^2 is the only small parameter that occurs, we might be tempted to expand the solution in a Poincaré asymptotic power series in ε^2. However, we will see that this is not exactly true. Depending on the behavior of the solution near the entrance, the correction term should in general be $\mathcal{O}(\varepsilon)$ for matching. Nevertheless, the leading and first order equations will be equivalent. With the assumed Poincaré expansion of ϕ, expressed in X,

$$\phi(X, r, \theta; \varepsilon) = \phi_0(X, r, \theta) + \varepsilon\phi_1(X, r, \theta) + \varepsilon^2\phi_2(X, r, \theta) + \cdots, \tag{16}$$

we obtain to leading order

$$\nabla_\perp^2 \phi_0 = 0, \quad \text{with} \quad \nabla_\perp \phi_0 \cdot \boldsymbol{n}_\perp = 0 \quad \text{at} \quad r = R, \tag{17}$$

with a solution $\phi_0 = 0$. As the solution of a Neumann problem is unique up to a constant, $\phi_0 = \phi_0(X)$, a function to be determined. To first order we have

$$\nabla_\perp^2 \phi_1 = 0, \quad \text{with} \quad \nabla_\perp \phi_1 \cdot \boldsymbol{n}_\perp = 0 \quad \text{at} \quad r = R, \tag{18}$$

also with a constant solution, and so $\phi_1 = \phi_1(X)$, a function to be determined. To second order we now have

$$\nabla_\perp^2 \phi_2 + \phi_{0,XX} + \kappa^2 \phi_0 = 0, \qquad \text{with} \quad \nabla_\perp \phi_2 \cdot \boldsymbol{n}_\perp = \phi_{0,X} \frac{R R_X}{\sqrt{R^2 + R_\theta^2}} \quad \text{at} \quad r = R. \tag{19}$$

The assumption (16) that there exists a Poincaré expansion for ϕ, expressed in this slow variable X, is not trivial. (Poincaré expansions are critically dependent on the

variables chosen!) It requires certain solvability conditions for, e.g., ϕ_2, yielding an equation for ϕ_0. To obtain this, we integrate along a cross section $\mathcal{A}(X)$ and apply Gauss' theorem

$$\iint_{\mathcal{A}} \nabla_\perp^2 \phi_2 \,\mathrm{d}\sigma = \int_{\partial\mathcal{A}} \nabla_\perp \phi_2 \cdot \boldsymbol{n}_\perp \,\mathrm{d}\ell = \int_{\partial\mathcal{A}} \phi_{0,X} \frac{RR_X}{\sqrt{R^2+R_\theta^2}} \,\mathrm{d}\ell = \cdots .$$

Then we parametrize $\partial\mathcal{A}$ with θ such that $\mathrm{d}\ell = \sqrt{R^2+R_\theta^2}\,\mathrm{d}\theta$, and we continue

$$= \int_0^{2\pi} \phi_{0,X} RR_X \,\mathrm{d}\theta = \phi_{0,X} \int_0^{2\pi} RR_X \,\mathrm{d}\theta = \phi_{0,X} A_X. \tag{20}$$

On the other hand, we also have

$$\iint_{\mathcal{A}} \big[\phi_{0,XX} + \kappa^2\phi_0\big] \,\mathrm{d}\sigma = A\big(\phi_{0,XX} + \kappa^2\phi_0\big). \tag{21}$$

Altogether we have for ϕ_0 the equation

$$A^{-1}\big(A\phi_{0,X}\big)_X + \kappa^2\phi_0 = 0, \tag{22}$$

which is indeed Webster's horn equation [1, 2] in properly scaled coordinates.

Evidently, the first order solution follows the same pattern and also satisfies

$$A^{-1}\big(A\phi_{1,X}\big)_X + \kappa^2\phi_1 = 0. \tag{23}$$

For completeness we note from [21, 22, 23, 24, 3] that Webster's equation can be recast into a more transparent form by the transformation

$$A(X) = d(X)^2, \quad \phi = d^{-1}\psi, \tag{24}$$

leading to

$$\psi'' + \Big(\kappa^2 - \frac{d''}{d}\Big)\psi = 0. \tag{25}$$

Depending on the sign of $\kappa^2 - d''/d$, the solutions behave like propagating or exponentially decaying waves. Elementary solutions are readily found for geometries with $d''/d = m^2$, a constant, yielding Salmon's family of exponential and conical horns [21, 22].

3.3. Boundary conditions in X. The above equation for ϕ_0 and ϕ_1 is of second order, and therefore two boundary conditions are required to determine the solution. For $X \to \infty$ we have the condition of radiation. At $X = 0$ (Figure 2), ϕ_0 and ϕ_1 cannot satisfy the (r,θ)-dependent boundary condition (13). Indeed, as anticipated before, near $x = 0$ there is a boundary layer of $X = \mathcal{O}(\varepsilon)$, i.e., $x = \mathcal{O}(1)$, which determines the (outer) solutions ϕ_0 and ϕ_1 via conditions of matching. This will be considered in the next section.

4. Entrance boundary layer. Near the entrance, for $X = \mathcal{O}(\varepsilon)$, i.e., $x = \mathcal{O}(1)$, we have of course equation (12)

$$\nabla^2\phi + \varepsilon^2\kappa^2\phi = 0 \ \text{ if } \ \boldsymbol{x} \in \mathcal{V}, \qquad \text{with } \ \nabla_\perp\phi \cdot \boldsymbol{n} = 0 \ \text{ at } \ \boldsymbol{x} \in \partial\mathcal{V}. \tag{12}$$

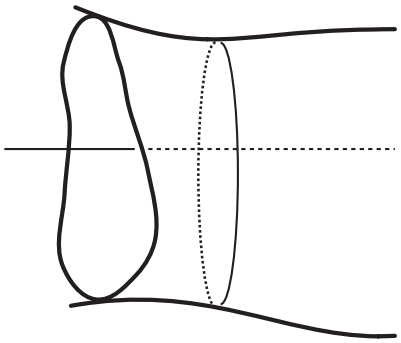

FIG. 2. *The entrance.*

Up to $\mathcal{O}(\varepsilon^2)$, this Helmholtz equation is equivalent to the Laplace equation. Therefore, the boundary layer analysis is essentially similar to that for the heat equation, discussed in Chandra [17]. Expand

$$\phi(X, r, \theta; \varepsilon) = \Phi_0(x, r, \theta) + \varepsilon\Phi_1(x, r, \theta) + \mathcal{O}(\varepsilon^2) \tag{26}$$

so that we have inside $\mathcal{V}$ to leading and first order,

$$\mathcal{O}(1): \quad \nabla^2\Phi_0 = 0, \tag{27a}$$

$$\mathcal{O}(\varepsilon): \quad \nabla^2\Phi_1 = 0. \tag{27b}$$

At $x = 0$ we have from (13) the initial conditions

$$\Phi_0(0, r, \theta) = F(r, \theta), \quad \Phi_1(0, r, \theta) = 0. \tag{28}$$

For $x \to \infty$ conditions of matching with the outer solution $\phi_0 + \varepsilon\phi_1$ apply. For the boundary condition at $r = R$ we have to expand $R(\varepsilon x, \theta)$. Note that for any function f

$$f(R(\varepsilon x); \varepsilon) = f(R + \varepsilon x R_X + \mathcal{O}(\varepsilon^2); \varepsilon) = f_0(R) + \varepsilon\big(f_1(R) + x f_{0,r}(R) R_X\big) + \mathcal{O}(\varepsilon^2), \tag{29}$$

where R without any argument denotes the value at $X = 0$. Furthermore, we have

$$\frac{R_\theta(X, \theta)}{R^2(X, \theta)} = \frac{R_\theta}{R^2} + \varepsilon x\Big(\frac{R_X}{R^2}\Big)_\theta + \mathcal{O}(\varepsilon^2). \tag{30}$$

Thus at the boundary

$$\begin{aligned}\nabla_\perp\phi \cdot \nabla_\perp\Sigma &= \phi_r - \frac{R_\theta}{R^2}\phi_\theta \\ &= \Phi_{0,r} - \frac{R_\theta}{R^2}\Phi_{0,\theta} + \varepsilon\left[\Phi_{1,r} - \frac{R_\theta}{R^2}\Phi_{1,\theta} + x\Phi_{0,rr}R_X - x\frac{R_\theta}{R^2}R_X\Phi_{0,r\theta} - x\Big(\frac{R_X}{R^2}\Big)_\theta\Phi_{0,\theta}\right] \\ &= \varepsilon R_X\Phi_{0,x},\end{aligned} \tag{31}$$

which means that at $r = R(0,\theta)$ for the leading and first order,

$$\nabla_\perp \Phi_0 \cdot \nabla_\perp \Sigma_0 = \Phi_{0,r} - \frac{R_\theta}{R^2}\Phi_{0,\theta} = 0, \tag{32a}$$

$$\begin{aligned}\nabla_\perp \Phi_1 \cdot \nabla_\perp \Sigma_0 &= \Phi_{1,r} - \frac{R_\theta}{R^2}\Phi_{1,\theta} \\ &= R_X\Phi_{0,x} - x\Phi_{0,rr}R_X + x\frac{R_\theta}{R^2}R_X\Phi_{0,r\theta} + x\Big(\frac{R_X}{R^2}\Big)_\theta\Phi_{0,\theta},\end{aligned} \tag{32b}$$

where $\Sigma_0 = \Sigma(0,r,\theta)$.

It is important for the subsequent matching to note that the solutions of (27) with (32) are defined only up to a linear term Kx. For Φ_0, however, this would result in terms of $\mathcal{O}(\varepsilon^{-1})$ if $x = \mathcal{O}(\varepsilon^{-1})$, which do not match with an outer solution $\phi_0 = \mathcal{O}(1)$. Therefore, we will not include this extra term. For Φ_1, on the other hand, we will have to retain the possibility, and in the end a linear term $K_1 x$ will be added, where K_1 must be determined by the matching.

From the identity at $r = R$,

$$\frac{\mathrm{d}}{\mathrm{d}\theta}\Phi_{0,\theta} = \Phi_{0,r\theta}R_\theta + \Phi_{0,\theta\theta}, \tag{33}$$

and with the defining equation applied at $r = R$ while using relation (32a),

$$-\Phi_{0,rr} = \frac{1}{R}\Phi_{0,r} + \frac{1}{R^2}\Phi_{0,\theta\theta} + \Phi_{0,xx} = \frac{R_\theta}{R^3}\Phi_{0,\theta} + \frac{1}{R^2}\Phi_{0,\theta\theta} + \Phi_{0,xx}, \tag{34}$$

it follows that (32b) is equivalent to

$$\begin{aligned}\nabla_\perp \Phi_1 \cdot \nabla_\perp \Sigma_0 &= \mathcal{Q}_0(x,\theta) \\ &\overset{\text{def}}{=\!=} R_X\Phi_{0,x}\big|_{r=R} + \frac{x}{R}\left\{RR_X\Phi_{0,xx}\big|_{r=R} + \frac{\mathrm{d}}{\mathrm{d}\theta}\Big(\frac{R_X}{R}\Phi_{0,\theta}\big|_{r=R}\Big)\right\}.\end{aligned} \tag{35}$$

4.1. Leading order. The right-running solution Φ_0 (only nonincreasing exponentials are allowed for matching) may be expressed by the eigenfunction expansion

$$\Phi_0(\boldsymbol{x}) = \sum_{n=0}^{\infty} F_n\psi_n(r,\theta)\,\mathrm{e}^{-\lambda_n x}, \tag{36}$$

where

$$\nabla_\perp^2\psi_n + \lambda_n^2\psi_n = 0, \quad \nabla_\perp\psi_n \cdot \nabla_\perp\Sigma_0 = 0, \tag{37}$$

with $\lambda_0 = 0$, ψ_0 a constant (normalized to 1), the other eigenvalues[2] λ_n real positive, and the eigenfunctions ψ_n real, orthogonal, and assumed normalized. In general these eigenfunctions are to be determined numerically. However, if the duct is cylindrical (i.e., R is independent of θ), we have

$$\psi_n(r,\theta) := \psi_{\nu\mu}(r,\theta) = \begin{cases} \dfrac{J_\nu\big(j'_{\nu\mu}r/R\big)}{\sqrt{\frac{\pi}{2}\Big(1-\frac{\nu^2}{{j'_{\nu\mu}}^2}\Big)}RJ_\nu(j'_{\nu\mu})}\begin{Bmatrix}\cos\nu\theta\\ \sin\nu\theta\end{Bmatrix} & \text{for } \nu \neq 0, \\ \dfrac{J_0\big(j'_{0\mu}r/R\big)}{\sqrt{\pi}RJ_0(j'_{0\mu})} & \text{for } \nu = 0, \end{cases} \tag{38}$$

[2]Strictly speaking, the numbers $-\lambda_n^2$ are the eigenvalues of operator $\nabla_\perp^2$.

where the index n is more practically changed into the double index $(\nu\mu)$. J_ν is the νth order ordinary Bessel function of the first kind [25], and $j'_{\nu\mu}$ is the μth (real-valued, positive) zero of J'_ν. The corresponding eigenvalue is thus $\lambda_n := j'_{\nu\mu}/R$.

The amplitudes are determined from the entrance interface $x = 0$ as follows:

$$F_n = \iint_{\mathcal{A}(0)} F(r,\theta)\psi_n(r,\theta)\,\mathrm{d}\sigma. \tag{39}$$

Note that, as ψ_n are orthonormal, the axial flux is, to leading order, proportional to the imaginary part of

$$\int_0^{2\pi}\int_0^R \Phi_0\Phi^*_{0,x} r\,\mathrm{d}r\mathrm{d}\theta = -\sum_{n=1}^{\infty}\lambda_n|F_n|^2\,\mathrm{e}^{-2\lambda_n x}\,. \tag{40}$$

As this expression is real, its imaginary part is zero, and thus the axial flux vanishes to leading order. Indeed, the outer solution is a slowly varying function of X, and therefore the flux, proportional to the axial derivative, is $\mathcal{O}(\varepsilon)$.

For $x \to \infty$, the exponential terms in $\Phi_0(\boldsymbol{x})$ vanish and we have

$$\Phi_0(\boldsymbol{x}) \simeq F_0. \tag{41}$$

4.2. First order. With the found expression for Φ_0, the right-hand side of (35), $\mathcal{Q}_0$, may be written as

$$\begin{aligned}\mathcal{Q}_0(x,\theta) &= \sum_{n=1}^{\infty} F_n\,\mathrm{e}^{-\lambda_n x}\left[-R_X\lambda_n\psi_n\big|_{r=R} + xR_X\lambda_n^2\psi_n\big|_{r=R} + \frac{x}{R}\frac{\mathrm{d}}{\mathrm{d}\theta}\Big(\frac{R_X}{R}\psi_{n,\theta}\big|_{r=R}\Big)\right]\\ &= R^{-1}\sum_{n=1}^{\infty} F_n\left[-\lambda_n RR_X\big(x\,\mathrm{e}^{-\lambda_n x}\big)_x\psi_n\big|_{r=R} + x\,\mathrm{e}^{-\lambda_n x}\,\frac{\mathrm{d}}{\mathrm{d}\theta}\Big(\frac{R_X}{R}\psi_{n,\theta}\big|_{r=R}\Big)\right].\end{aligned} \tag{42}$$

To solve the problem for Φ_1, we introduce a Green's function $G(\boldsymbol{x};\boldsymbol{\xi})$ with $\boldsymbol{x} = (x, r, \theta)$ and $\boldsymbol{\xi} = (\xi, \rho, \eta)$ satisfying

$$\begin{gathered}\nabla_\perp^2 G + \frac{\partial^2}{\partial x^2}G = -\delta(\boldsymbol{x}-\boldsymbol{\xi}), \quad \frac{\partial}{\partial n}G = 0 \ \text{ at } \ r = R(0,\theta), \quad G(\boldsymbol{x};\boldsymbol{\xi}) = 0 \ \text{ at } \ x = 0,\\ G(\boldsymbol{x};\boldsymbol{\xi}) \to \text{a constant} \ \text{ for } \ x\to\infty, \qquad x\frac{\partial}{\partial x}G(\boldsymbol{x};\boldsymbol{\xi}) \to\ 0 \ \text{ for } \ x\to\infty.\end{gathered} \tag{43}$$

We determine the Green's function by applying the Fourier sine transform[3] with respect to x $(x \to \alpha)$ to (43), to obtain

$$\nabla_\perp^2\hat{G} - \alpha^2\hat{G} = -\sqrt{\frac{2}{\pi}}\sin(\alpha\xi)\delta(\boldsymbol{x}_\perp - \boldsymbol{\xi}_\perp), \tag{44}$$

where $\boldsymbol{x}_\perp$ denotes the transverse component of $\boldsymbol{x}$, i.e., $\boldsymbol{x}_\perp = (r,\theta)$ (similarly for $\boldsymbol{\xi}_\perp$). We assume that the Green's function can be expanded by the same basis function as has been used for Φ_0,

$$\hat{G}(\alpha, r, \theta; \boldsymbol{\xi}) = \sum_{m=0}^{\infty} a_m(\alpha,\boldsymbol{\xi})\psi_m(r,\theta).$$

[3]Here $\hat{f}(\alpha) = \sqrt{\frac{2}{\pi}}\int_0^\infty \sin(\alpha x)f(x)\,\mathrm{d}x$, $f(x) = \sqrt{\frac{2}{\pi}}\int_0^\infty \sin(\alpha x)\hat{f}(\alpha)\,\mathrm{d}\alpha$.

Therefore

$$\nabla^2\hat{G} = -\sum_{m=0}^{\infty} a_m\lambda_m^2\psi_m(r,\theta).$$

Substituting this into (44) yields

$$\sum_{m=0}^{\infty} a_m\psi_m(\lambda_m^2+\alpha^2) = \sqrt{\frac{2}{\pi}}\sin(\alpha\xi)\delta(\boldsymbol{x}_\perp-\boldsymbol{\xi}_\perp). \tag{45}$$

Next, we multiply (45) with ψ_n and integrate over the cross section $\mathcal{A}(0)$ to obtain

$$\iint\limits_{\mathcal{A}(0)}\sum_{m=0}^{\infty} a_m\psi_n\psi_m(\lambda_m^2+\alpha^2)\,\mathrm{d}\sigma = \sqrt{\frac{2}{\pi}}\iint\limits_{\mathcal{A}(0)}\psi_n(r,\theta)\sin(\alpha\xi)\delta(\boldsymbol{x}_\perp-\boldsymbol{\xi}_\perp)\,\mathrm{d}\sigma. \tag{46}$$

Orthonormality of the basis functions yields

$$a_m = \sqrt{\frac{2}{\pi}}\left(\frac{\sin(\alpha\xi)}{\lambda_m^2+\alpha^2}\right)\psi_m(\rho,\eta). \tag{47}$$

Therefore,

$$\hat{G}(\alpha,r,\theta;\xi,\rho,\eta) = \sqrt{\frac{2}{\pi}}\sum_{m=0}^{\infty}\frac{\sin(\alpha\xi)}{\lambda_m^2+\alpha^2}\psi_m(\rho,\eta)\psi_m(r,\theta). \tag{48}$$

The inverse Fourier sine transform yields

$$G(\boldsymbol{x};\boldsymbol{\xi}) = \frac{2}{\pi}\sum_{m=0}^{\infty}\psi_m(\rho,\eta)\psi_m(r,\theta)\int_0^{\infty}\frac{\sin(\alpha x)\sin(\alpha\xi)}{\lambda_m^2+\alpha^2}\,\mathrm{d}\alpha, \tag{49}$$

where [25] for $\lambda_0 = 0$,

$$\int_0^{\infty}\frac{\sin(\alpha x)\sin(\alpha\xi)}{\alpha^2}\,\mathrm{d}\alpha = \frac{1}{2}\pi\min(x,\xi), \tag{50}$$

and for $\lambda_m > 0$,

$$\int_0^{\infty}\frac{\sin(\alpha x)\sin(\alpha\xi)}{\lambda_m^2+\alpha^2}\,\mathrm{d}\alpha = \frac{1}{2}\pi\,\mathrm{e}^{-\lambda_m\max(x,\xi)}\,\frac{1}{\lambda_m}\sinh(\lambda_m\min(x,\xi)). \tag{51}$$

Therefore, the $m=0$ term can be taken apart, and the Green's function becomes

$$G(\boldsymbol{x};\boldsymbol{\xi}) = x + \sum_{m=1}^{\infty}\psi_m(\rho,\eta)\psi_m(r,\theta)\,\mathrm{e}^{-\lambda_m\xi}\,\frac{\sinh(\lambda_m x)}{\lambda_m} \qquad \text{if } 0\le x\le\xi \tag{52a}$$

$$= \xi + \sum_{m=1}^{\infty}\psi_m(\rho,\eta)\psi_m(r,\theta)\,\mathrm{e}^{-\lambda_m x}\,\frac{\sinh(\lambda_m\xi)}{\lambda_m} \qquad \text{if } 0\le\xi\le x. \tag{52b}$$

Note that as $x\to\infty$, G tends to ξ and $\frac{\partial G}{\partial x}$ tends to zero exponentially.

Using this Green's function, we obtain for Φ_1 the following relation, to be integrated over domain $\mathcal{V}$:

$$\Phi_1\delta(\boldsymbol{x}-\boldsymbol{\xi}) = G\nabla^2\Phi_1 - \Phi_1\nabla^2 G. \tag{53}$$

However, since $\Phi_1 \sim K_1\xi$ for large ξ (see the remark below (32)), this yields a divergent integral as the domain here is a semi-infinite duct. Therefore, we consider a region $\mathcal{V}'$ with a finite length $0 \le x \le x_0$, where x_0 is small compared to ε^{-1} but large enough for all exponential terms to practically vanish. Integrate (53) along domain $\mathcal{V}'$ and by using Green's second identity we get

$$\Phi_1(\boldsymbol{\xi}) = \iiint_{\mathcal{V}'} \left(G\nabla^2\Phi_1 - \Phi_1\nabla^2 G\right) \mathrm{d}\boldsymbol{x} = \iint_{x=0} \left(-G\frac{\partial\Phi_1}{\partial x} + \Phi_1\frac{\partial G}{\partial x}\right) \mathrm{d}\sigma + \iint_{r=R(0,\eta)} \left(G\nabla_\perp\Phi_1 - \Phi_1\nabla_\perp G\right)\cdot\boldsymbol{n}_\perp \,\mathrm{d}\sigma + \iint_{x=x_0} \left(G\frac{\partial\Phi_1}{\partial x} - \Phi_1\frac{\partial G}{\partial x}\right) \mathrm{d}\sigma$$

$$= \iint_{r=R(0,\eta)} \frac{G\mathcal{Q}_0(x,\theta)}{|\nabla_\perp\Sigma|}\,\mathrm{d}\ell\mathrm{d}\xi + K_1\xi. \tag{54}$$

Since $|\nabla_\perp\Sigma| = \frac{1}{R}\sqrt{R^2+R_\theta^2}$ and $\mathrm{d}\ell = \sqrt{R^2+R_\theta^2}\,\mathrm{d}\theta$, we obtain

$$\Phi_1(\boldsymbol{\xi}) = \int_0^{2\pi}\int_0^\infty \mathcal{Q}_0(x,\theta)G(\boldsymbol{x};\boldsymbol{\xi})|_{r=R} R\,\mathrm{d}x\mathrm{d}\theta + K_1\xi. \tag{55}$$

As we have $\mathcal{Q}_0$ in the form of a series expansion, we can write

$$\Phi_1(\boldsymbol{\xi}) = K_1\xi + \sum_{n=1}^\infty F_n \int_0^{2\pi}\Bigg[-RR_X\lambda_n\psi_n\big|_{r=R}\int_0^\infty \mathrm{e}^{-\lambda_n x}\,G(\boldsymbol{x};\boldsymbol{\xi})\big|_{r=R}\,\mathrm{d}x + \left\{RR_X\lambda_n^2\psi_n\big|_{r=R} + \frac{\mathrm{d}}{\mathrm{d}\theta}\Big(\frac{R_X}{R}\psi_{n,\theta}\big|_{r=R}\Big)\right\}\int_0^\infty x\,\mathrm{e}^{-\lambda_n x}\,G(\boldsymbol{x};\boldsymbol{\xi})\big|_{r=R}\,\mathrm{d}x\Bigg]\mathrm{d}\theta. \tag{56}$$

As the series for $\mathcal{Q}_0$ converges uniformly for $x > 0$, we may exchange summation and integration. On the other hand, the fact that all basis functions have vanishing normal derivatives at the wall, i.e., $\nabla_\perp\psi_n\cdot\boldsymbol{n}_\perp = 0$, whereas $\nabla_\perp\Phi_1\cdot\boldsymbol{n}_\perp \neq 0$, suggests that this series does not converge uniformly near the wall.

The expression for Φ_1 is further specified by removing the x-integration:

$$\int_0^\infty \mathrm{e}^{-\lambda_n x}\,G(\boldsymbol{x};\boldsymbol{\xi})\Big|_{r=R}\,\mathrm{d}x = \frac{1-\mathrm{e}^{-\lambda_n\xi}}{\lambda_n^2} - \sum_{m=1}^\infty \psi_m(R,\theta)\psi_m(\rho,\eta)\frac{\mathrm{e}^{-\lambda_n\xi}-\mathrm{e}^{-\lambda_m\xi}}{\lambda_n^2-\lambda_m^2}, \tag{57}$$

$$\int_0^\infty x\,\mathrm{e}^{-\lambda_n x}\,G(\boldsymbol{x};\boldsymbol{\xi})\Big|_{r=R}\,\mathrm{d}x = \frac{2-(2+\lambda_n\xi)\,\mathrm{e}^{-\lambda_n\xi}}{\lambda_n^3} - \sum_{m=1}^\infty \psi_m(R,\theta)\psi_m(\rho,\eta)\frac{2\lambda_n(\mathrm{e}^{-\lambda_n\xi}-\mathrm{e}^{-\lambda_m\xi}) + \xi(\lambda_n^2-\lambda_m^2)\,\mathrm{e}^{-\lambda_n\xi}}{(\lambda_n^2-\lambda_m^2)^2}. \tag{58}$$

If $m = n$, the limit $\lambda_m \to \lambda_n$ should be taken. Now we are better able to recognize the nature of the nonuniform convergence. The dominating term is (we ignore for the moment the θ-integration)

$$\Phi_1(\boldsymbol{\xi}) \sim \sum_{m=1}^\infty \frac{\psi_m(R,\theta)\psi_m(\rho,\eta)}{\lambda_m^2}.$$

For a circular duct this may be compared, near $\rho = R$, to the prototype series

$$\sim \sum_{m=1}^{\infty} \frac{\cos(2\pi m\rho/R)}{m^2}.$$

The normal derivative yields the well-known saw-tooth function that vanishes (pointwise) at $\rho = R$ but converges to a finite nonzero value for any $\rho \neq R$.

For $x \to \infty$, the exponential terms in $\Phi_1(\boldsymbol{x})$ vanish and we have (we exchange the variables $\boldsymbol{x}$ and $\boldsymbol{\xi}$)

$$\Phi_1(\boldsymbol{x}) \simeq K_1 x + \sum_{n=1}^{\infty} F_n \int_0^{2\pi} \left[RR_X \lambda_n^{-1} \psi_n\big|_{\rho=R} + \frac{2}{\lambda_n} \frac{\mathrm{d}}{\mathrm{d}\eta} \Big(\frac{R_X}{R} \psi_{n,\eta}\big|_{\rho=R} \Big) \right] \mathrm{d}\eta.$$

By using the periodicity of ψ_n in its circumferential argument η, we have finally

$$\Phi_1(\boldsymbol{x}) \simeq K_1 x + \sum_{n=1}^{\infty} \frac{F_n}{\lambda_n} \int_0^{2\pi} RR_X \psi_n\big|_{\rho=R} \mathrm{d}\eta \qquad \text{for } \ x \to \infty. \tag{59}$$

4.3. Matching. Both the initial conditions for ϕ_0 and ϕ_1 and the constant K_1 are determined from matching with the outer solution. From (41) and (59) we have

$$\phi_0(0) + X\phi_{0,X}(0) + \varepsilon\phi_1(0) \sim F_0 + \varepsilon K_1 x + \varepsilon \sum_{n=1}^{\infty} \frac{F_n}{\lambda_n} \int_0^{2\pi} RR_X \psi_n\big|_{\rho=R} \mathrm{d}\eta, \tag{60}$$

and so we find

$$\begin{cases} \phi_0(0) = F_0, \\ \quad K_1 = \phi_{0,X}(0), \\ \phi_1(0) = \displaystyle\sum_{n=1}^{\infty} \frac{F_n}{\lambda_n} \int_0^{2\pi} RR_X \psi_n\big|_{\rho=R} \mathrm{d}\eta. \end{cases} \tag{61}$$

This determines the outer solution $\phi_0 + \varepsilon\phi_1$ (together with the radiation condition). It wouldn't be too difficult to guess that ϕ_0 depends on the average source excitation F_0, but the initial value for ϕ_1 is really subtle. The constant term in (59) is therefore probably the most important result of this tour de force to determine Φ_1.

An interesting question is then when ϕ_1 is present at all in the outer solution (or put in another way: what the error is if we only consider ϕ_0). For example, ϕ_1 is zero when the source consists of a simple piston with just $F(r,\theta) = F_0$, or when the duct entrance starts smoothly with $R_X = 0$, or when $RR_X\psi_n$ for all $n > 0$ are periodic along the circumference.

Although this last condition is not very likely to be possible, for a cylindrical duct at least the nonsymmetric modes vanish. In this case the eigenfunctions are given by (38). The integrals in (59) vanish for all $\nu \neq 0$. As a result we have

$$\phi_1(0) = 2\sqrt{\pi} RR_X \sum_{\mu=2}^{\infty} \frac{F_{0\mu}}{j'_{0\mu}}. \tag{62}$$

In other words, the first constant mode determines ϕ_0, while only the nonconstant symmetric modes determine ϕ_1. For example, a piston tilting along a diagonal like $F \sim r\sin\theta$ would produce a field vanishing to $\mathcal{O}(\varepsilon^2)$, while a "piston" that is symmetrically folded like $F \sim r^2$ would produce both $\mathcal{O}(1)$ and $\mathcal{O}(\varepsilon)$ terms.

5. Other coordinate systems. It was shown by Agullo, Barjau, and Keefe [26] that if the shape of the hard-walled duct is described in an orthogonal coordinate system (u, v, w) by the surface $\Sigma(v, w) = 0$, while the Helmholtz equation allows separable solutions of the form $\phi(u, v, w) = F(u)G(v, w)$, then there exist unidimensional (i.e., self-similar) waves in u of the type $\phi(u, v, w) = F(u)$. In this way it is possible to produce exact solutions of certain horn shapes, like the straight and exponential cone and others.

Although these solutions are interesting on their own, they have little to do with the present low k asymptotic problem, where the duct wall is never outside the lateral near field of the wave. Without this, there is no built-in mechanism that enforces the self-similarity, so any defect of symmetry in source or surface will produce deviations in the wave field that propagate without attenuation in other directions. Also the generalizations that will be discussed below are not possible at all or only in very limited form.

On the other hand, if the duct shape considered is close to one that allows such an exact solution, it may be advantageous, in terms of practical accuracy of the final result, to reformulate the problem in the other set of coordinates. The essence of the asymptotic problem remains the same.

We will illustrate this for spherical coordinates (r, θ, φ), where we temporarily redefine $x = r\cos\varphi$, $y = r\sin\varphi\cos\theta$, $z = r\sin\varphi\sin\theta$. (Note that we will use these coordinates *only in this section.*) A circular cone around the positive x-axis is given by $\varphi =$ constant, and a general cone of constant cross section by $\varphi = f(\theta)$.

In order to maintain the slender shape, necessary for the asymptotics, the duct will be long in r, compensated by a small opening angle in φ. We therefore introduce the scaled variables

$$\tau = \frac{2\sin\frac{1}{2}\varphi}{\varepsilon}, \qquad R = \varepsilon r \tag{63}$$

and write the general duct geometry as

$$\tilde{\Sigma}(R, \tau, \theta) = \tau - T(R, \theta) = 0, \tag{64}$$

where T is, by assumption, independent of ε. By this choice the surface area, $\tilde{A}(R)$ of any spherical cross section $R =$ constant is now exactly (i.e., independent of ε) equal to

$$\begin{aligned}\tilde{A}(R) &= \int_0^{2\pi}\int_0^{\varphi(R,\theta)} r^2\sin\varphi\,\mathrm{d}\varphi\mathrm{d}\theta = \int_0^{2\pi}\int_0^{T} r^2\varepsilon^2\tau\,\mathrm{d}\tau\mathrm{d}\theta \\ &= \frac{1}{2}R^2\int_0^{2\pi} T^2(R,\theta)\,\mathrm{d}\theta. \end{aligned} \tag{65}$$

Other choices for describing the duct shape are not essentially different, other than T, and therefore $\tilde{A}$, becoming dependent on ε. This gives complications in the form of extra asymptotic terms in the higher orders, which are irrelevant now.

The Helmholtz equation is given by

$$\frac{\varepsilon^2}{R^2}\frac{\partial}{\partial R}\Big(R^2\frac{\partial\phi}{\partial R}\Big) + \frac{1}{R^2\tau}\frac{\partial}{\partial\tau}\left(\tau\left(1-\frac{1}{4}\varepsilon^2\tau^2\right)\frac{\partial\phi}{\partial\tau}\right) + \frac{1}{R^2\tau^2(1-\frac{1}{4}\varepsilon^2\tau^2)}\frac{\partial^2\phi}{\partial\theta^2} + \varepsilon^2\kappa^2\phi = 0, \tag{66}$$

while the hard-wall boundary condition becomes

$$\nabla\phi\cdot\nabla\tilde{\Sigma} = \frac{1-\frac{1}{4}\varepsilon^2T^2}{R^2}\frac{\partial\phi}{\partial\tau} - \varepsilon^2\frac{\partial T}{\partial R}\frac{\partial\phi}{\partial R} - \frac{1}{R^2T^2(1-\frac{1}{4}\varepsilon^2T^2)}\frac{\partial T}{\partial\theta}\frac{\partial\phi}{\partial\theta} = 0. \tag{67}$$

We expand, as before,

$$\phi(R,\tau,\theta;\varepsilon) = \phi_0(R,\tau,\theta) + \varepsilon^2\phi_2(R,\tau,\theta) + \cdots$$

(skipping for now the $\mathcal{O}(\varepsilon)$-term) to obtain to leading order

$$\phi_{0,\tau\tau} + \frac{1}{\tau}\phi_{0,\tau} + \frac{1}{\tau^2}\phi_{0,\theta\theta} = 0, \quad \text{with} \quad \phi_{0,\tau} - \frac{T_\theta}{T^2}\phi_{0,\theta} = 0 \quad \text{at} \quad \tau = T. \tag{68}$$

If τ and θ are read as polar coordinates, this problem is qua form the same as (17), and thus we have the solution $\phi_0 = \phi_0(R)$ to be determined at the next order. We have

$$\phi_{2,\tau\tau} + \frac{1}{\tau}\phi_{2,\tau} + \frac{1}{\tau^2}\phi_{2,\theta\theta} + \big(R^2\phi_{0,R}\big)_R + R^2\kappa^2\phi_0 = 0,$$
$$\text{with} \quad \phi_{2,\tau} - \frac{T_\theta}{T^2}\phi_{2,\theta} = R^2T_R\phi_{0,R} \quad \text{at} \quad \tau = T.$$

This can be written as

$$\tilde{\nabla}^2\phi_2 + \big(R^2\phi_{0,R}\big)_R + R^2\kappa^2\phi_0 = 0, \quad \text{with} \quad \tilde{\nabla}\phi_2\cdot\tilde{\boldsymbol{n}} = R^2\phi_{0,R}\frac{TT_R}{\sqrt{T^2+T_\theta^2}}, \tag{69}$$

where $\tilde{\nabla}$ and $\tilde{\boldsymbol{n}}$ denote gradient and normal, respectively, in the (τ,θ)-plane. As a result we have virtually the same equation as (19), and after integration along a spherical surface $\tilde{A}(R)$ in (τ,θ) and using (65), we obtain

$$-\frac{\tilde{A}}{R^2}\Big(R^2\phi_{0,R}\Big)_R - \tilde{A}\kappa^2\phi_0 = \frac{1}{2}R^2\phi_{0,R}\frac{\mathrm{d}}{\mathrm{d}R}\int_0^{2\pi}T^2(R,\theta)\,\mathrm{d}\theta = R^2\phi_{0,R}\Big(\frac{\tilde{A}}{R^2}\Big)_R$$

or

$$\tilde{A}^{-1}\big(\tilde{A}\phi_{0,R}\big)_R + \kappa^2\phi_0 = 0. \tag{70}$$

We see that changing from the axial coordinate X to R and from the transverse cross section A to the spherical cross section $\tilde{A}$ leaves the final equation for ϕ_0 unchanged. Indeed, to the order considered, X and R and A and $\tilde{A}$ are the same.

6. Curved ducts. The present results remain valid for the slightly more general problem of curved ducts (like certain musical instruments) if the curvature of the duct axis (and its derivative) is $\mathcal{O}(\varepsilon)$. Together with the assumed slow variation in the axial coordinate, the associated orthogonal coordinate system (based on the tangent and, possibly, the normal and binormal of the curve that describes the duct axis) leave the Laplacian unchanged up to $\mathcal{O}(\varepsilon^3)$.

A simple example is the inside of a perturbed torus, described by a fixed torus radius ε^{-1} and slowly varying tube radius R. With local (polar-type) coordinates ξ, r, φ, we define

$$x = \varepsilon^{-1}(1+\varepsilon r\cos\theta)\cos(\varepsilon\xi), \quad y = \varepsilon^{-1}(1+\varepsilon r\cos\theta)\sin(\varepsilon\xi), \quad z = r\sin\theta, \tag{71}$$

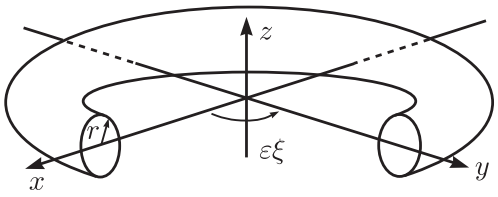

FIG. 3. *The torus coordinates.*

where $0 \le r \le R(\varepsilon\xi,\theta)$, $0 \le \theta < 2\pi$, $0 \le \varepsilon\xi < 2\pi$ (see Figure 3). If we write $X = \varepsilon\xi$, we get (cf. (6))

$$\nabla^2\phi + \varepsilon^2\kappa^2\phi$$
$$= \nabla_\perp^2\phi + \varepsilon^2\big(1+\varepsilon r\cos\theta\big)^{-2}\frac{\partial^2}{\partial X^2}\phi + \varepsilon\big(1+\varepsilon r\cos\theta\big)^{-1}\left[\cos\theta\frac{\partial}{\partial r}\phi - \frac{1}{r}\frac{\partial}{\partial\theta}\phi\right] + \varepsilon^2\kappa^2\phi = 0. \tag{72}$$

Boundary conditions at $\Sigma = r - R(X,\theta) = 0$ are

$$\nabla_\perp\phi\cdot\nabla_\perp\Sigma - \frac{\varepsilon^2 R_X\phi_X}{(1+\varepsilon r\cos\theta)^2} = 0. \tag{73}$$

If we expand $\phi = \phi_0 + \varepsilon\phi_1 + \varepsilon^2\phi_2 + \cdots$, we get to leading order

$$\nabla_\perp^2\phi_0 = 0, \qquad \text{with } \nabla_\perp\phi_0\cdot\boldsymbol{n}_\perp = 0, \tag{74}$$

and so $\phi_0 = \phi_0(X)$. Then $\frac{\partial}{\partial r}\phi_0 = \frac{\partial}{\partial\theta}\phi_0 = 0$, and we also have

$$\nabla_\perp^2\phi_1 = 0, \qquad \text{with } \nabla_\perp\phi_1\cdot\boldsymbol{n}_\perp = 0, \tag{75}$$

leading to $\phi_1 = \phi_1(X)$. Thus again $\frac{\partial}{\partial r}\phi_1 = \frac{\partial}{\partial\theta}\phi_1 = 0$, and we again obtain

$$\nabla_\perp^2\phi_2 + \phi_{0,XX} + \kappa^2\phi_0 = 0, \qquad \text{with } \nabla_\perp\phi_2\cdot\nabla_\perp\Sigma = \phi_{0,X}R_X,$$

yielding thus, after a similar argument as before, Webster's horn equation.

7. Impedance walls. If the duct walls is equipped with an impedance-type acoustic lining of complex impedance Z, we will in general (at least if $\mathrm{Re}(Z) > 0$) expect solutions that decay exponentially in the axial direction. Therefore, in the compressed variable X, only trivial (i.e., zero) solutions will exist. We will see that this is by and large the case, not only for dissipative walls with $\mathrm{Re}(Z) > 0$, but for any $|Z| < \infty$. Only for a purely imaginary impedance in a *straight* duct are there exceptions.

The impedance-wall boundary condition at $r = R$ is given by

$$\nabla\phi\cdot\boldsymbol{n} = -\frac{\mathrm{i}\varepsilon\kappa}{Z}\phi = \zeta\phi \tag{76}$$

with specific impedance Z. As before, we assume the Poincaré expansion $\phi = \phi_0 + \varepsilon\phi_1 + \varepsilon^2\phi_2 + \cdots$. First we note that it is easily verified that if $Z = 0$, only the trivial solutions $\phi_0 = \phi_1 = 0$ occur. Then we consider two possibilities: $Z = \mathcal{O}(1)$ and $Z = \mathcal{O}(\varepsilon)$.

7.1. $Z = \mathcal{O}(1)$. As $\zeta = \mathcal{O}(\varepsilon)$, we write $\zeta = \varepsilon\zeta_1$. In this case we have only trivial solutions. Expand equations and boundary conditions as before, to get to leading order

$$\nabla_\perp^2\phi_0 = 0, \quad \text{with} \quad \nabla_\perp\phi_0 \cdot \boldsymbol{n}_\perp = 0, \tag{77}$$

with solution $\phi_0 = \phi_0(X)$, a function to be determined. To first order we have

$$\nabla_\perp^2\phi_1 = 0, \quad \text{with} \quad \nabla_\perp\phi_1 \cdot \boldsymbol{n}_\perp = \zeta_1\phi_0. \tag{78}$$

Since

$$\iint_{\mathcal{A}} \nabla_\perp^2\phi_1 \,\mathrm{d}\sigma = \zeta_1\phi_0 \int_{\partial\mathcal{A}} \mathrm{d}\ell = 0, \tag{79}$$

we must have $\phi_0 = 0$, and so $\phi_1 = \phi_1(X)$. Nothing changes when we continue, and so all terms of the expansion vanish. Note that this is true for any Z.

7.2. $Z = \mathcal{O}(\varepsilon)$. Now we have $\zeta = \mathcal{O}(1)$, which changes the boundary condition expansion. To leading order we have

$$\nabla_\perp^2\phi_0 = 0 \ \text{ in } \ \mathcal{A}, \quad \text{with} \quad \nabla\phi_0 \cdot \boldsymbol{n}_\perp = \zeta\phi_0 \ \text{ at } \ \partial\mathcal{A}. \tag{80}$$

We would be tempted to assume that this problem has a solution or solutions for any given Z, but this is not true. Nontrivial solutions exist only for certain ζ. From Green's second identity applied to ϕ_0 and its complex conjugate, it can be deduced that any possible ζ is real. Furthermore, from Green's first identity applied to ϕ_0, it follows that any possible ζ is positive, and Z is thus negative imaginary.

But even with ζ real positive, there are only certain discrete values that allow a solution. This is best seen as follows. The problem described in (80) is an eigenvalue problem for the Dirichlet-to-Neumann operator Ξ: $f \mapsto g$, which maps a given Dirichlet boundary value f to the normal derivative g of f's harmonic extension into $\mathcal{A}$ (see [17]). In other words, $\Xi(f) = \frac{\partial}{\partial n}\psi\big|_{\partial\mathcal{A}}$, where ψ is the solution of

$$\nabla^2\psi = 0 \ \text{ in } \ \mathcal{A}, \quad \text{with} \quad \psi = f \ \text{ at } \ \partial\mathcal{A}. \tag{81}$$

As we are looking for $\Xi(\phi_0) = \zeta\phi_0$, equation (80) corresponds to the eigenvalue problem of Ξ. For the present discussion it is most relevant to know that this spectrum of eigenvalues of Ξ is discrete. As this result, due to Prof. Jan de Graaf, appears not to be available in the literature, it is considered concisely, but in great depth, in the appendix.

An example that illustrates this behavior explicitly is the circular duct $r = R(X)$, where

$$\phi_0 = f(X)\Big(\frac{r}{R(X)}\Big)^m \begin{Bmatrix}\cos m\theta\\ \sin m\theta\end{Bmatrix}, \quad \text{with} \quad \zeta = \frac{m}{R(X)}, \tag{82}$$

and m is a nonnegative integer. As the shape of the cross section $\mathcal{A}(X)$ changes with X, the discreteness of the spectrum of Ξ implies that the values of ζ that allow a solution also change with X, and in general there are no (nonzero) solutions possible along a varying duct for a fixed given ζ.

This is of course not true for a duct of constant cross section, $r = R(\theta)$, although now the asymptotics for small ε loses its meaning because there is no axial length

scale for the acoustic wave to be compared with. The problem simplifies further for the circular duct $r = R$, where (without approximation)

$$\phi(x, r, \theta) = J_m(\alpha r)\, \mathrm{e}^{-\mathrm{i}m\theta - \mathrm{i}\gamma x}, \quad \alpha^2 + \gamma^2 = k^2 \tag{83}$$

and the boundary condition requires

$$\frac{\alpha R J'_m(\alpha R)}{J_m(\alpha R)} = m - \frac{\alpha R J_{m+1}(\alpha R)}{J_m(\alpha R)} = \zeta R. \tag{84}$$

This equation has infinitely many solutions, but the wave is guaranteed unattenuated (γ real) if α is imaginary, say $\alpha = \mathrm{i}\tau$. Such solutions exist for real $\zeta \geq m/R$, because

$$\zeta R = m - \frac{\mathrm{i}\tau R J_{m+1}(\mathrm{i}\tau R)}{J_m(\mathrm{i}\tau R)} = m + \frac{\tau R I_{m+1}(\tau R)}{I_m(\tau R)} \geq m \tag{85}$$

(see [27]). Note that for small k, γ, α solutions we recover (82)

$$\zeta = \frac{m}{R} - \frac{\alpha^2 R}{2m+2} + \mathcal{O}(\alpha^4). \tag{86}$$

In other words, only solutions of this type exist near special values of ζ.

8. Variable mean soundspeed and density. If soundspeed $C = C(X, r, \theta)$ and mean density $D = D(X, r, \theta)$ are not uniformly constant, but vary in r, θ, and slowly in x, we have the reduced wave equation (5), rewritten in slowly varying coordinates as

$$\varepsilon^2 \frac{\partial}{\partial X}\big(C^2 p_X\big) + \nabla_\perp \cdot \big(C^2 \nabla_\perp p\big) + \varepsilon^2 \Omega^2 p = 0, \tag{87}$$

where the dimensionless frequency $\omega = \varepsilon\Omega$ is small. The hard-wall boundary condition is the same as (14). When we expand $p = p_0 + \varepsilon p_1 + \varepsilon^2 p_2 + \cdots$, we get to leading order

$$\nabla_\perp \cdot \big(C^2 \nabla_\perp p_0\big) = 0, \quad \text{with} \quad \nabla_\perp p_0 \cdot \boldsymbol{n}_\perp = 0, \tag{88}$$

which has a constant as the solution, so $p_0 = p_0(X)$, a function to be determined. We can derive the same equation for p_1, to get the same result $p_1 = p_1(X)$. For the second order we have

$$\nabla_\perp \cdot \big(C^2 \nabla_\perp p_2\big) + \frac{\partial}{\partial X}\big(C^2 p_{0,X}\big) + \Omega^2 p_0 = 0, \quad \text{with} \quad \nabla_\perp p_2 \cdot \boldsymbol{n}_\perp = p_{0,X} \frac{R R_X}{\sqrt{R^2 + R_\theta^2}}. \tag{89}$$

We go on to find a solvability condition for p_2 by integrating this equation along a cross section $\mathcal{A}$. Utilizing the following identity for any differentiable function f,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}X} \iint_{\mathcal{A}} f(\boldsymbol{X})\, \mathrm{d}\sigma &= \frac{\mathrm{d}}{\mathrm{d}X} \int_0^{2\pi}\!\!\int_0^R f(X, r, \theta) r\, \mathrm{d}r\theta \\ &= \int_0^{2\pi}\!\!\int_0^R f_X r\, \mathrm{d}r\mathrm{d}\theta + \int_0^{2\pi} f(X, R, \theta) R R_X\, \mathrm{d}\theta, \end{aligned} \tag{90}$$

we have

$$\iint_{\mathcal{A}} \nabla_\perp \cdot (C^2 \nabla_\perp p_2)\,\mathrm{d}\sigma = p_{0,X} \int_0^{2\pi} C^2 R R_X \mathrm{d}\theta$$

$$= p_{0,X}\left[\frac{\mathrm{d}}{\mathrm{d}X}\iint_{\mathcal{A}} C^2\,\mathrm{d}\sigma - \iint_{\mathcal{A}} \frac{\partial}{\partial X} C^2\,\mathrm{d}\sigma\right]. \tag{91a}$$

Furthermore, we have

$$\iint_{\mathcal{A}} \frac{\partial}{\partial X}\left(C^2 p_{0,X}\right)\mathrm{d}\sigma = p_{0,X}\iint_{\mathcal{A}} \frac{\partial}{\partial X} C^2\,\mathrm{d}\sigma + p_{0,XX}\iint_{\mathcal{A}} C^2\,\mathrm{d}\sigma,$$

$$\text{and} \quad \iint_{\mathcal{A}} \Omega^2 p_0\,\mathrm{d}\sigma = \Omega^2 p_0 A. \tag{91b}$$

Then, after introducing the cross-sectional averaged squared soundspeed

$$\overline{C^2} = \frac{1}{A}\iint_{\mathcal{A}} C^2\,\mathrm{d}\sigma, \tag{92}$$

a generalization of Webster's horn equation is obtained:

$$A^{-1}\left(A\overline{C^2}p_{0,X}\right)_X + \Omega^2 p_0 = 0. \tag{93}$$

This may be further simplified by the transformation

$$A(X)\overline{C^2}(X) = d(X)^2, \quad p_0 = d^{-1}\psi \tag{94}$$

into

$$\psi'' + \left(\frac{\Omega^2}{\overline{C^2}} - \frac{d''}{d}\right)\psi = 0. \tag{95}$$

9. Irrotational and isentropic mean flow. To analyze asymptotically low-frequency acoustic perturbations in a slowly varying duct with an irrotational isentropic mean flow, as described by (7) and (9), we need to approximate both mean flow and acoustic field to the same order of accuracy.

We start here with the mean flow. In the dimensionless variables used, we have $C^2 = D^{\gamma-1}$, so equations (7) simplify to

$$\tfrac{1}{2}V^2 + \frac{D^{\gamma-1}}{\gamma-1} = E, \qquad \nabla\cdot(D\boldsymbol{V}) = 0. \tag{96}$$

The mass flux at any cross section A is given by

$$\iint_{\mathcal{A}} DU\,\mathrm{d}\sigma = \mathcal{F}. \tag{97}$$

Due to the nondimensionalization, U, D, A, $\mathcal{F}$, and E are $\mathcal{O}(1)$. Introduce the slow variable $X = \varepsilon x$, and assume that $\boldsymbol{V}$ and D depend essentially on X, rather than x. We write the velocity as

$$\boldsymbol{V} = U\boldsymbol{e}_x + \boldsymbol{V}_\perp \tag{98}$$

to distinguish between axial and crosswise components. If flux $\mathcal{F}$ and thermodynamical constant E are given and independent of ε, we can expand $U = U_0 + \mathcal{O}(\varepsilon^2)$ and $D = D_0 + \mathcal{O}(\varepsilon^2)$. As the flow is a potential flow, we can derive, in the same way as in Rienstra [14, 16], that $D_0 = D_0(X)$, $U_0 = U_0(X)$, and $\boldsymbol{V}_\perp = \varepsilon \widetilde{\boldsymbol{V}}_{\perp 0} + \mathcal{O}(\varepsilon^3)$, satisfying the equations (to be solved numerically)

$$D_0 U_0 A = \mathcal{F}, \qquad \frac{\mathcal{F}^2}{2D_0^2 A^2} + \frac{D_0^{\gamma-1}}{\gamma - 1} = E. \tag{99}$$

9.1. Mean flow and hard walls. Next we consider the acoustic field. Using the above results for the mean flow, (9) becomes to leading order

$$\begin{aligned}&\nabla_\perp^2 \phi + \varepsilon^2 D_0^{-1} \big(D_0 \phi_X\big)_X \\ &\qquad = \varepsilon^2 \left(\mathrm{i}\Omega + U_0 \frac{\partial}{\partial X} + \widetilde{\boldsymbol{V}}_{\perp 0} \boldsymbol{\cdot} \nabla_\perp\right) \left[C_0^{-2} \left(\mathrm{i}\Omega + U_0 \frac{\partial}{\partial X} + \widetilde{\boldsymbol{V}}_{\perp 0} \boldsymbol{\cdot} \nabla_\perp\right) \phi\right],\end{aligned}$$

with hard wall boundary condition

$$\nabla \phi \boldsymbol{\cdot} \boldsymbol{n} = 0 \quad \text{at} \quad r = R.$$

We expand $\phi = \phi_0 + \varepsilon \phi_1 + \varepsilon^2 \phi_2 + \cdots$. To leading order we have

$$\nabla_\perp^2 \phi_0 = 0, \quad \nabla_\perp \phi_0 \boldsymbol{\cdot} \boldsymbol{n}_\perp = 0, \tag{100}$$

yielding the constant solution, i.e., $\phi_0 = \phi_0(X)$.

To first order we have the same equation. To second order we have

$$\begin{aligned}&\nabla_\perp^2 \phi_2 + D_0^{-1} \big(D_0 \phi_{0,X}\big)_X \\ &\qquad = \left(\mathrm{i}\Omega + U_0 \frac{\partial}{\partial X} + \widetilde{\boldsymbol{V}}_{\perp 0} \boldsymbol{\cdot} \nabla_\perp\right) \left[C_0^{-2} \left(\mathrm{i}\Omega + U_0 \frac{\partial}{\partial X} + \widetilde{\boldsymbol{V}}_{\perp 0} \boldsymbol{\cdot} \nabla_\perp\right) \phi_0\right],\end{aligned}$$

with boundary conditions given by (19). After integration across a cross section $\mathcal{A}(X)$, we obtain, similar to before, Webster's horn equation generalized for irrotational isentropic mean flow:

$$(D_0 A)^{-1} (D_0 A \phi_{0,X})_X = \left(\mathrm{i}\Omega + U_0 \frac{\partial}{\partial X}\right) \left[C_0^{-2} \left(\mathrm{i}\Omega + U_0 \frac{\partial}{\partial X}\right) \phi_0\right]. \tag{101}$$

This result seems to be equivalent to equations given by [8, 9, 10, 11, 12] and (apart from a factor $\frac{1}{2}$) [3, p. 422].

9.2. Mean flow and impedance walls. The problem with mean flow and an impedance wall is more intricate. Instead of the duct wall boundary condition given in (76), we have Myers' condition [28], rewritten (see [29, 30]) as follows:

$$\mathrm{i}\omega D\big(\boldsymbol{v} \boldsymbol{\cdot} \boldsymbol{n}\big) = \frac{\mathrm{i}\omega D p}{Z} + \mathcal{M}\Big(\frac{D \boldsymbol{V} p}{Z}\Big), \tag{102}$$

where impedance $Z = Z(X, \theta)$ may be function of position, and operator $\mathcal{M}$ is defined by

$$\mathcal{M}(\boldsymbol{F}) = \nabla \boldsymbol{\cdot} \boldsymbol{F} - \boldsymbol{n} \boldsymbol{\cdot} (\boldsymbol{n} \boldsymbol{\cdot} \nabla \boldsymbol{F}). \tag{103}$$

Since $\mathcal{M}(\frac{D\boldsymbol{V}p}{Z}) = \mathcal{O}(\varepsilon)$, we write $\mathcal{M}(\frac{D\boldsymbol{V}p}{Z}) = \varepsilon\widetilde{\mathcal{M}}(\frac{D\boldsymbol{V}p}{Z})$. After expanding $\phi = \phi_0 + \varepsilon\phi_1 + \cdots$ and $p = \varepsilon p_0 + \cdots$ with

$$p_0 = -D_0\left(\mathrm{i}\Omega + U_0\frac{\partial}{\partial X} + \widetilde{\boldsymbol{V}}_{\perp 0}\cdot\nabla_\perp\right)\phi_0, \tag{104}$$

we get

$$\mathrm{i}\Omega D_0\big(\nabla_\perp\phi_0\cdot\boldsymbol{n}_\perp\big) + \mathrm{i}\varepsilon\Omega D_0\big(\nabla_\perp\phi_1\cdot\boldsymbol{n}_\perp\big) = \varepsilon\frac{\mathrm{i}\Omega D_0 p_0}{Z} + \varepsilon\widetilde{\mathcal{M}}\Big(\frac{D_0\boldsymbol{V}_0 p_0}{Z}\Big) + \mathcal{O}(\varepsilon^2), \tag{105}$$

where $\boldsymbol{V}_0 = U_0\boldsymbol{e}_x + \varepsilon\widetilde{\boldsymbol{V}}_{\perp 0}$.

9.2.1. $Z = \mathcal{O}(1)$. As before, we get to leading order

$$\nabla_\perp^2\phi_0 = 0, \quad \text{with} \quad \nabla_\perp\phi_0\cdot\boldsymbol{n}_\perp = 0,$$

so $\phi_0 = \phi_0(X)$ and therefore $p_0 = p_0(X)$. To first order we have the same equation $\nabla_\perp^2\phi_1 = 0$ for ϕ_1, but the boundary condition is now

$$\mathrm{i}\Omega D_0\big(\nabla_\perp\phi_1\cdot\boldsymbol{n}_\perp\big) = \frac{\mathrm{i}\Omega D_0 p_0}{Z} + \widetilde{\mathcal{M}}\Big(\frac{D_0\boldsymbol{V}_0 p_0}{Z}\Big). \tag{106}$$

In order to continue, we need from [16] the following property of the operator $\mathcal{M}$.

For any sufficiently smooth vectorfield with $\boldsymbol{f}\cdot\boldsymbol{n} = 0$ at $r = R$, we have

$$\int_{\partial\mathcal{A}}\Big[\nabla\cdot\boldsymbol{f} - \boldsymbol{n}\cdot\big(\boldsymbol{n}\cdot\nabla\boldsymbol{f}\big)\Big]\left\|\frac{\partial\boldsymbol{r}}{\partial x}\times\frac{\partial\boldsymbol{r}}{\partial\ell}\right\|\mathrm{d}\ell = \frac{\mathrm{d}}{\mathrm{d}x}\int_{\partial\mathcal{A}}\big(\boldsymbol{f}\times\boldsymbol{n}\big)\cdot\mathrm{d}\boldsymbol{\ell},$$

where $(x,\ell)\mapsto\boldsymbol{r}(x,\ell)$ is a parameterization of the surface.

Since

$$\left\|\frac{\partial\boldsymbol{r}}{\partial x}\times\frac{\partial\boldsymbol{r}}{\partial\ell}\right\| = \sqrt{1+\varepsilon^2\frac{R^2R_X^2}{R^2+R_\theta^2}} = 1+\mathcal{O}(\varepsilon^2),$$

we have as a result

$$\int_{\partial\mathcal{A}}\widetilde{\mathcal{M}}\Big(\frac{D_0\boldsymbol{V}_0 p_0}{Z}\Big)\mathrm{d}\ell = \frac{\mathrm{d}}{\mathrm{d}X}\int_{\partial\mathcal{A}}\frac{D_0U_0p_0}{Z}\mathrm{d}\ell + \mathcal{O}(\varepsilon).$$

We apply this to the equation for ϕ_1, in order to obtain an equation for ϕ_0. From

$$\iint_{\mathcal{A}}\nabla_\perp^2\phi_1\,\mathrm{d}\sigma = \int_{\partial\mathcal{A}}\nabla_\perp\phi_1\cdot\boldsymbol{n}_\perp\,\mathrm{d}\ell = 0,$$

together with (106) and noting that most functions depend on X only, it follows that

$$\mathrm{i}\Omega D_0p_0\mathcal{L} + \frac{\mathrm{d}}{\mathrm{d}X}\big(U_0D_0p_0\mathcal{L}\big) = 0, \quad \text{where} \quad \mathcal{L}(X) = \int_{\partial\mathcal{A}}\frac{1}{Z}\,\mathrm{d}\ell$$

($\mathcal{L}$ may be interpreted as the "total admittance" at X), with solution

$$p_0 = \text{constant}\,\frac{1}{U_0D_0\mathcal{L}}\exp\left(-\mathrm{i}\int^X\frac{\Omega}{U_0(\xi)}\,\mathrm{d}\xi\right).$$

Here ϕ_0 follows from (104) but is more difficult to obtain in explicit form. Note that this pressure field is not an acoustic wave, but it is of hydrodynamic nature. It does not propagate with the soundspeed, but with the mean flow velocity.

9.2.2. $Z = \mathcal{O}(\varepsilon)$. When $Z = \varepsilon Z_0$, we get for ϕ_0 the apparently difficult boundary condition

$$\mathrm{i}\Omega D_0\big(\nabla_\perp \phi_0 \cdot \boldsymbol{n}_\perp\big) = \frac{\mathrm{i}\Omega D_0 p_0}{Z_0} + \widetilde{\mathcal{M}}\Big(\frac{D_0 \boldsymbol{V}_0 p_0}{Z_0}\Big),$$

which is, analogous to the no-flow case, likely to be an eigenvalue problem with discrete eigenvalues Z_0 (apart from the trivial solutions $p_0 = 0$, $\phi_0 = \phi_0(X) \propto \exp(-\mathrm{i}\Omega \int^X U_0(\xi)^{-1}\mathrm{d}\xi)$, i.e., hydrodynamically convected pressureless perturbations). If this conjecture is true, the possible eigenvalues vary with the geometry, and no other than the trivial solution is possible in a varying duct.

10. Conclusions. Generalizations of Webster's classic horn equation for nonuniform media, lined walls, and mean flow have been derived systematically, as an asymptotic perturbation problem for low Helmholtz number and slowly varying duct diameter. The conditions on frequency, acoustic medium, and duct geometry are explicitly indicated in terms of small parameter ε, the ratio between a typical length of duct variation and the duct diameter. The error and higher order corrections are also explicitly stated.

The presence of lining in a varying duct is shown to allow in general only trivial or merely hydrodynamic solutions. A curved duct is shown to produce the same equation if the radius of curvature is not smaller than the typical wavelength or duct length scale.

The approximation is nonuniform near a source or entrance. The prevailing boundary layer solution for an arbitrary duct cross section is given, together with the $\mathcal{O}(1)$ and $\mathcal{O}(\varepsilon)$ matching conditions to the outer ("Webster") region. From these expressions conditions are derived for which the $\mathcal{O}(\varepsilon)$-outer field is absent.

Appendix. On the spectrum of the Dirichlet-to-Neumann operator Ξ on smooth bounded domains in $\mathbb{R}^2$. We will show that the Dirichlet-to-Neumann operator Ξ, introduced in section 7 (see (80)), has a discrete spectrum of finite multiplicity. The basic idea is to relate the problem for the general simply connected open domain $\Omega \subset \mathbb{R}^2$ (which has apparently no explicit solution), via conformal mapping, to the corresponding problem for the unit disk D, which does have a simple explicit solution.

Note that the related result for an annular domain is entirely analogous.

Step 1. Consider the open unit-disk $D \subset \mathbb{R}^2$. Its boundary ∂D, the unit circle, is parametrized by the angle θ, with $0 \le \theta < 2\pi$. The set of functions

$$\mathrm{e}_n : \quad \theta \mapsto \mathrm{e}_n(\theta) = \frac{1}{\sqrt{2\pi}}\,\mathrm{e}^{\mathrm{i}n\theta}, \quad n \in \mathbb{Z}, \tag{A.1}$$

establishes an orthonormal basis in $L_2(\partial D; \mathrm{d}\theta)$.[4] We introduce for real a the linear operator $\mathcal{N}_a$ in $L_2(\partial D, \mathrm{d}\theta)$, defined via the way it acts on the basis $\{\mathrm{e}_n\}$,

$$\mathcal{N}_a : \quad \mathrm{e}_n \mapsto \mathcal{N}_a \mathrm{e}_n, \quad \text{with} \quad \mathcal{N}_a \mathrm{e}_n(\theta) = (|n| + a)\mathrm{e}_n(\theta), \tag{A.2}$$

followed by linear extension and closure.

[4] $L_2(U; w(x)\mathrm{d}x)$ denotes the space of square integrable functions, defined on U, with inner product $\int_U \overline{f(x)} g(x) w(x)\,\mathrm{d}x$.

Let $u : \partial D \to \mathbb{C}$ be a sufficiently smooth function. Let $u_\mathcal{H}$, the harmonic extension of u, denote the (unique) solution of the Dirichlet problem

$$\nabla^2 u_\mathcal{H}(\boldsymbol{x}) = 0 \quad \text{for} \quad \boldsymbol{x} \in D, \quad \text{while} \quad u_\mathcal{H}(\boldsymbol{x}) = u \quad \text{for} \quad \boldsymbol{x} \in \partial D. \tag{A.3}$$

The normal derivative at the boundary ∂D produces a function

$$\frac{\partial}{\partial n} u_\mathcal{H} : \quad \partial D \to \mathbb{C}. \tag{A.4}$$

Altogether this defines the linear mapping $u \mapsto \frac{\partial}{\partial n} u_\mathcal{H}$, which is called the *Dirichlet-to-Neumann operator* in $L_2(\partial D; \mathrm{d}\theta)$. By noting that $\mathrm{e}_{n\mathcal{H}}(\boldsymbol{x}) = (x \pm \mathrm{i}y)^{|n|} = r^{|n|}\,\mathrm{e}^{\pm \mathrm{i}|n|\theta}$, and hence $\frac{\partial}{\partial n}\mathrm{e}_{n\mathcal{H}} = |n|\mathrm{e}_n$ at ∂D, it is easily verified that this operator is just equal to $\mathcal{N}_0$.

Step 2. Consider the bounded open domain $\Omega \subset \mathbb{R}^2$ with piecewise smooth boundary $\partial\Omega$. Let $v : \partial\Omega \to \mathbb{C}$ be a sufficiently smooth function. As in the previous section (just replace D by Ω), we introduce

$$\Xi : \quad v \mapsto \Xi v = \frac{\partial}{\partial n} v_\mathcal{H}, \tag{A.5}$$

the Dirichlet-to-Neumann operator in $L_2(\partial\Omega; \mathrm{d}\theta)$. Thus $\Xi = \mathcal{N}_0$ if $\Omega = D$. We want to show that Ξ is nonnegative self-adjoint with a pure point spectrum of finite multiplicity. In the previous paragraph we showed this to be true in $L_2(\partial D; \mathrm{d}\theta)$.

The self-adjointness and nonnegativity follows, formally, from Green's first and second identities (see section 7). In order to achieve some spectral results, we invoke the Riemann mapping theorem and consider a conformal mapping $\beta : D \to \Omega$. The supposed smoothness of $\partial\Omega$ implies that the parametrization $\theta \mapsto \beta(\mathrm{e}^{\mathrm{i}\theta})$ for $\partial\Omega$ is such that both $|\beta'(\mathrm{e}^{\mathrm{i}\theta})|$ and its reciprocal are bounded.

Standard results from conformal mapping theory and harmonic functions on $\mathbb{R}^2$ lead to

$$\Xi v\big(\beta(\mathrm{e}^{\mathrm{i}\theta})\big) = \left(\frac{\partial}{\partial n} v_\mathcal{H}\right)\big(\beta(\mathrm{e}^{\mathrm{i}\theta})\big) = \big|\beta'(\mathrm{e}^{\mathrm{i}\theta})\big|^{-1} \frac{\partial}{\partial n}(v \circ \beta)_\mathcal{H}(\mathrm{e}^{\mathrm{i}\theta}). \tag{A.6}$$

This means that, instead of the original problem, we could study the eigenvalue problem

$$\mathcal{B}\mathcal{N}_0 u = \lambda u \tag{A.7}$$

in $L_2(\partial D, \mathrm{d}\theta)$, with $\mathcal{B}$ the multiplication operator defined by

$$(\mathcal{B}w)(\theta) = B(\theta)w(\theta) = \big|\beta'(\mathrm{e}^{\mathrm{i}\theta})\big|^{-1} w(\theta). \tag{A.8}$$

(Although the inverse $\mathcal{B}^{-1}$ involves no more than division by the function $B(\theta)$, we retain for clarity the operator symbolism.)

Step 3. In order to turn the operator $\mathcal{B}\mathcal{N}_0$ into a self-adjoint one, we consider the eigenvalue problem in $L_2(\partial D; B^{-1}(\theta)\mathrm{d}\theta)$, which is topologically equivalent to $L_2(\partial D; \mathrm{d}\theta)$. Note that

$$\big\{\theta \mapsto u(\theta)\big\} \mapsto \big\{\theta \mapsto B^{-\frac{1}{2}}(\theta) u(\theta)\big\} \tag{A.9}$$

furnishes a unitary transformation from $L_2(\partial D; B^{-1}(\theta)\mathrm{d}\theta)$ to $L_2(\partial D; \mathrm{d}\theta)$, because

$$\int_0^{2\pi} \overline{u(\theta)} v(\theta) B^{-1}(\theta)\,\mathrm{d}\theta = \int_0^{2\pi} \overline{\left(B^{-\frac{1}{2}}(\theta)u(\theta)\right)}\left(B^{-\frac{1}{2}}(\theta)v(\theta)\right)\mathrm{d}\theta. \tag{A.10}$$

At the same time this implies that the eigenvalue problem (A.7) is unitary equivalent to the eigenvalue problem

$$\mathcal{B}^{\frac{1}{2}}\mathcal{N}_0\mathcal{B}^{\frac{1}{2}}\varphi = \lambda\varphi, \tag{A.11}$$

with $\varphi = \mathcal{B}^{-\frac{1}{2}}u$.

Step 4. If we can show that $(\mathcal{I}+\mathcal{B}^{\frac{1}{2}}\mathcal{N}_0\mathcal{B}^{\frac{1}{2}})^{-1}$ (where $\mathcal{I}$ is the identity) is a compact self-adjoint operator, we are ready. In that case it has a discrete spectrum with finite multiplicity [31], and the same holds, a fortiori, for $\mathcal{B}^{\frac{1}{2}}\mathcal{N}_0\mathcal{B}^{\frac{1}{2}}$.

Take a positive and sufficiently small such that $\theta \mapsto B^{-1}(\theta) - a$ is still positive and uniformly bounded away from zero. By noting that $\mathcal{N}_a = \mathcal{N}_0 + a\mathcal{I}$, we can rewrite

$$\mathcal{I} + \mathcal{B}^{\frac{1}{2}}\mathcal{N}_0\mathcal{B}^{\frac{1}{2}} = \mathcal{B}^{\frac{1}{2}}\mathcal{N}_a^{\frac{1}{2}}\left\{\mathcal{N}_a^{-\frac{1}{2}}(\mathcal{B}^{-1} - a\mathcal{I})\mathcal{N}_a^{-\frac{1}{2}} + \mathcal{I}\right\}\mathcal{N}_a^{\frac{1}{2}}\mathcal{B}^{\frac{1}{2}}. \tag{A.12}$$

The operator between brackets, { }, is bounded, positive, and self-adjoint and has an inverse with the same properties. We thus find

$$\left(\mathcal{I} + \mathcal{B}^{\frac{1}{2}}\mathcal{N}_0\mathcal{B}^{\frac{1}{2}}\right)^{-1} = \mathcal{B}^{-\frac{1}{2}}\mathcal{N}_a^{-\frac{1}{2}}\left\{\mathcal{N}_a^{-\frac{1}{2}}(\mathcal{B}^{-1} - a\mathcal{I})\mathcal{N}_a^{-\frac{1}{2}} + \mathcal{I}\right\}^{-1}\mathcal{N}_a^{-\frac{1}{2}}\mathcal{B}^{-\frac{1}{2}}, \tag{A.13}$$

which is a composition of operators. Since the factor $\mathcal{N}_a^{-\frac{1}{2}}$ is compact, also $(\mathcal{I} + \mathcal{B}^{\frac{1}{2}}\mathcal{N}_0\mathcal{B}^{\frac{1}{2}})^{-1}$ is a compact operator.

REVEALING PAIRWISE COUPLING IN LINEAR-NONLINEAR NETWORKS*

DUANE Q. NYKAMP†

Abstract. Through an asymptotic analysis of a simple network, we derive an estimate of the coupling between a pair of units when all other units are unobservable. The analysis is based on a model where the response of each unit is a linear-nonlinear function of a white noise stimulus. The results accurately determine the coupling when all unmeasured units respond to the stimulus differently than the measured pair. To account for the possibility of unmeasured units similar to the measured pair, we cast our results in the framework of "subpopulations," which are defined as a group of units who respond to the stimulus similarly. We demonstrate that we can determine when correlations between two units are caused by a connection between their subpopulations, although the precise identity of the units involved in the connection may remain ambiguous. The result is rigorously valid only when the coupling is sufficiently weak to justify a second-order approximation in the coupling strength. We demonstrate through simulations that the results are still valid even with stronger coupling and in the presence of some deviations from the linear-nonlinear model. The analysis is presented in terms of neuronal networks, although the general framework is more widely applicable.

1. Introduction.

This analysis of coupling within networks is motivated by neuroscience, and we use the vocabulary of neuroscience throughout. The measured response properties of a neuron arise from the structure of the neural network in which the neuron is embedded. To understand the relationship between these response properties and the neural network structure, one would like to simultaneously measure the response of neurons and estimate their connectivity. However, it has proven difficult to estimate the connectivity from measurements of neural activity because only a small subset of neurons can be monitored simultaneously.

In particular, a direct connection between two measured neurons is difficult to distinguish from a connection onto both neurons that originates from a third, unmeasured neuron. We refer to the latter configuration as the common input configuration. We address the case where one simultaneously measures two neurons in a network and attempts to distinguish the direct connection configuration from the common input configuration.

This distinction is especially difficult because when studying a network, one typically does not directly measure the internal state of neurons, but records only their discrete output events, called spikes. From simultaneous recordings of two neurons' spike times, one can analyze the joint statistics of the two spike trains in hopes of detecting a direct connection. Two widely used tools are the joint peristimulus time histogram (JPSTH) and its integral, the shuffle-corrected correlogram [14, 1, 13]. Unfortunately, inferences from the JPSTH or correlogram about the connections between

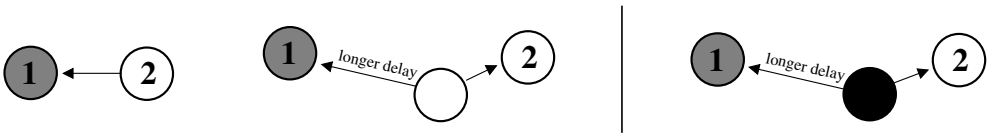

FIG. 1. *To determine "subpopulation connectivity," one needs to distinguish a direct connection from only certain kinds of common input. Three sample network configuration are shown, where neurons one and two are measured and the unlabeled neuron is not measured. The subpopulation of each neuron, which is defined within the context of a model, is indicated by the shading (white, gray, or black.) To determine subpopulation connectivity, as we have defined it, one must be able to distinguish the right configuration from the left two configurations. In both of the left configurations (but not in the right configuration), there is a connection from a neuron within neuron two's subpopulation (white) onto a neuron within neuron one's subpopulation (gray). Hence, we do not need to distinguish the left two configurations from each other in order to determine subpopulation connectivity.*

the two measured neurons are ambiguous because these measures cannot distinguish a direct connection from common input.

The joint statistics of the two spike trains alone may be insufficient to distinguish a direct connection from common input. If one could measure the neurons inducing the common input effects, then the joint statistics of all the measured spike trains would be sufficient, and one could use analysis tools such as partial coherence [15] to distinguish a direct connection from common input. However, when one cannot measure all possible sources of common input, one cannot rule out common input through partial coherence.

Our approach is to analyze the joint statistics, not just of the measured spike trains, but also of an experimentally controlled stimulus. The idea motivating this approach is that the joint stimulus-spike statistics may be sufficient to distinguish the direct connection configuration from the common input configuration even if the neurons inducing the common input are unmeasured.

It turns out that we cannot distinguish a direct connection from all possible cases of common input. Instead, we can characterize connectivity only in terms of certain *subpopulations* of neurons, defined so that each neuron in a subpopulation responds to the stimulus in a similar manner (the definition of responding "similarly" is made in the context of a model). The concept of subpopulation connectivity is illustrated in Figure 1. Imagine that the spikes of neuron one are correlated with a delayed version of the spikes of neuron two, consistent with a direct connection from neuron two onto neuron one. Our central result is that we can distinguish between (A) a direct connection from neuron two onto neuron one and (B) common input that does not originate from neuron two's subpopulation. On the other hand, if the common input does originate from neuron two's subpopulation, the common input may not be distinguishable from a direct connection. However, in this latter case, the common input does contain a connection from neuron two's subpopulation onto neuron one. Consequently, the identification of a direct connection from neuron two onto neuron one must be interpreted as the identification of a connection from neuron two's subpopulation onto neuron one. The precise identity of the neuron originating the connection remains ambiguous (it could be neuron two or another neuron in neuron two's subpopulation). To summarize this ambiguity, we say we can determine connectivity only at the level of subpopulations (and not at the level of individual neurons).

Our analysis is fundamentally model-driven. The structure imposed by an explicit

model gives the framework necessary for making the subtle distinction between a direct connection and most cases of common input. In this paper, we analyze a network modeled as interacting linear-nonlinear systems responding to a white noise stimulus. Clearly, this choice limits the applicability of this implementation to networks that can be approximated by this simple model. Our motivation for using this model is the ability to compute analytic expressions for necessary stimulus-spike statistics. We mention possible generalizations in the Discussion.

In section 2, we describe the model network and the assumptions required for the analysis. In section 3, we derive analytic expressions for measurable stimulus-spike statistics and solve the resulting system of equations for the coupling strength. We test our findings via simulations in section 4, and discuss the results in section 5.

2. The model.

2.1. The model network. We base our analysis on a model network of linear-nonlinear neurons that builds on the models we have presented previously [12, 10, 11, 9]. Let n be the (presumably unknown) number of neurons in the network. Let the random vector[1] $\mathbf{X}$ denote the stimulus. The components of $\mathbf{X}$ represent the spatio-temporal sequence of stimulus values, such as the pixel values for each refresh of a computer monitor.

The response of neuron $q = 1, 2, \ldots, n$ will depend on the convolution of the stimulus with a spatio-temporal kernel[2] $\bar{\mathbf{h}}_q$, normalized so that $\|\bar{\mathbf{h}}_q\| = 1$. To make later notation simpler, we view the kernel $\mathbf{h}_q$ as sliding along the stimulus with time, and denote by $\bar{\mathbf{h}}_q^i$ the kernel shifted for the discrete time point i. We implicitly view the temporal index of the stimulus as going backward in time, and write the convolution of the kernel with the stimulus as the dot product $\bar{\mathbf{h}}_q^i \cdot \mathbf{X}$.

Let the binary vector $\mathbf{R}$ represent the spike times of neurons in the network. A component $R_q^i = 1$ indicates that neuron q spiked at time i; otherwise, $R_q^i = 0$. When neuron p spikes, the probability that neuron q spikes j time steps later is modified by the connectivity factor $\bar{W}_{pq}^j$. The quantity $\bar{W}_{pq}^j$ is simply added to the convolution $\bar{\mathbf{h}}_q^i \cdot \mathbf{X}$.

The only nonlinear part of the linear-nonlinear model is that the above linear sum is composed with a static monotonically increasing nonlinearity $\bar{g}_q(\cdot)$. This output nonlinearity represents, for example, the neuron's spike generating mechanism and ensures that spiking probabilities stay between zero and one. The resulting linear-nonlinear network model is the following expression for the probability of a spike of neuron q at time i, conditioned on the stimulus and previous spikes (denoted $\mathbf{R}^{<i}$):

$$\Pr\left(R_q^i = 1 \middle| \mathbf{X} = \mathbf{x}, \mathbf{R}^{<i} = \mathbf{r}^{<i}\right) = \bar{g}_q\left(\bar{\mathbf{h}}_q^i \cdot \mathbf{x} + \sum_{p=1}^{n} \sum_{j>0} \bar{W}_{pq}^j r_p^{i-j}\right). \tag{2.1}$$

We let the recent stimulus $\mathbf{X}$ be a discrete approximation to temporal or spatio-temporal Gaussian white noise. For the analysis, we need to estimate stimulus-spike statistics conditioned on the stimulus. The estimation of these statistics implicitly assumes that we repeat each realization of the white noise stimulus multiple times.

[1] With the exceptions of $\bar{W}$, we will use capital variables to denote random quantities.

[2] We use overbars (e.g., $\bar{\mathbf{h}}$) to indicate original model parameters, and will remove the bars (e.g., $\mathbf{h}$) to indicate their estimates from data. In addition, we use subscripts to denote neuron index, and superscripts to denote temporal indices.

2.2. The weak coupling assumption. To facilitate our analysis, we make a weak coupling assumption, which asserts that the coupling $\bar{W}_{pq}^j$ is sufficiently small to justify a second-order approximation in $\bar{W}$. This assumption is really an assumption on how $\bar{W}$ scales with the number of neurons n. As one expands equations such as (2.1) in powers of $\bar{W}$, one obtains terms that are kth-order in $\bar{W}$ summed over the population k times. Hence, one obtains terms of the magnitude $(n\langle\bar{W}\rangle)^k$, where $\langle\bar{W}\rangle$ is an average of n values of $\bar{W}$. To truncate this series at finite k, one at minimum needs $n\langle\bar{W}\rangle < 1$. For a densely coupled large network, the coupling strength must, on average, scale at most like $1/n$. (Individual connections could be stronger, as long as the average scales like $1/n$.) We compute an approximation of order $k = 2$, and we ignore all terms that are third-order or higher in $\bar{W}$.

In our analysis, we go one step further. We ignore all second-order terms that are not summed over the population. Since, in this case, we are not summing over the population, it is no longer a scaling argument. This approximation simply asserts than any one connection cannot be too large. We will use $\approx$ to indicate equality within this modified second-order approximation in $\bar{W}$.

We use this approximation out of necessity, not because we believe it is justified by the biology. However, we demonstrate with simulations that the results often still hold even for larger coupling than needed for the analytic results.

2.3. Effective uncoupled neuron model. Our first step is to fit the spikes of each neuron separately to an uncoupled linear-nonlinear model of the form[3]

$$\Pr\big(R_q^i = 1\big|\mathbf{X} = \mathbf{x}\big) = g_q\big(\mathbf{h}_q^i \cdot \mathbf{x}\big), \tag{2.2}$$

where $\|\mathbf{h}_q^i\| = 1$. For the purpose of subpopulation definitions, below, we imagine we can do this for all neurons. In practice, of course, we can fit uncoupled models only to the two measured neurons. Fitting the uncoupled model (2.2) when the spikes were actually generated by the network model (2.1) defines the effective nonlinearities $g_q(\cdot)$ and kernels $\mathbf{h}_q^i$.

We derive expressions for the effective parameters in terms of the original parameters plus coupling effects. We simply need to calculate $\Pr(R_q^i = 1\big|\mathbf{X} = \mathbf{x})$ from the network model (2.1). Because we assume a second-order approximation in coupling strength $\bar{W}$, it turns out that a first-order approximation in $\bar{W}$ is sufficient for the effective single-neuron parameters.[4]

From a trivial generalization of the calculation in Appendix A.1 of [11], we can average the network model (2.1) over all spikes before time i to conclude that the probability of a spike at time i is

$$\Pr\big(R_q^i = 1\big|\mathbf{X} = \mathbf{x}\big) = \bar{g}_q(\bar{\mathbf{h}}_1^i \cdot \mathbf{x}) + \sum_{p=1}^{n}\sum_{j>0} \bar{W}_{pq}^j \bar{g}_q'(\bar{\mathbf{h}}_1^i \cdot \mathbf{x})\bar{g}_p(\bar{\mathbf{h}}_p^{i-j} \cdot \mathbf{x}) + O(\bar{W}^2). \tag{2.3}$$

Combining this expression with the uncoupled model (2.2), we obtain the following relationship between the effective kernels $\mathbf{h}_q^i$ and nonlinearities $g_q(\cdot)$, on one hand,

[3]Note the absence of bars to indicate effective parameters that can be estimated from data (at least for the measured neurons).

[4]We will show that all terms for the spike-pair statistics will be first- or second-order in $\bar{W}$ (all zero-order terms cancel out), and thus approximating the single-neuron parameters to first order is sufficient to retain a second-order approximation for the spike-pair statistics.

and the original model kernels $\bar{\mathbf{h}}_q^i$ and nonlinearities $\bar{g}_q(\cdot)$, on the other hand:

$$g_q(\mathbf{h}_q^i \cdot \mathbf{x}) = \bar{g}_q(\bar{\mathbf{h}}_q^i \cdot \mathbf{x}) + \sum_{p=1}^{n} \sum_{j>0} \bar{W}_{pq}^j \bar{g}_q'(\bar{\mathbf{h}}_q^i \cdot \mathbf{x}) \bar{g}_p(\bar{\mathbf{h}}_p^{i-j} \cdot \mathbf{x}) + O(\bar{W}^2). \tag{2.4}$$

Since $g_q(\mathbf{h}_q^i \cdot \mathbf{x})$ and $\bar{g}_q(\bar{\mathbf{h}}_a^i \cdot \mathbf{x})$ differ by only a first-order correction, and we are computing only to first order, we can simply erase the bars from $\bar{g}$ and $\bar{\mathbf{h}}$ in the $\bar{W}_{pq}^j$ term (creating a second-order error) to obtain

$$\bar{g}_q(\bar{\mathbf{h}}_q^i \cdot \mathbf{x}) = g_q(\mathbf{h}_q^i \cdot \mathbf{x}) - \sum_{p=1}^{n} \sum_{j>0} \bar{W}_{pq}^j g_q'(\mathbf{h}_q^i \cdot \mathbf{x}) g_p(\mathbf{h}_p^{i-j} \cdot \mathbf{x}) + O(\bar{W}^2). \tag{2.5}$$

This effective parameter relationship will be used in the following analysis to express all equations in terms of the effective parameters.

2.4. Subpopulation definition. A subpopulation is a group of neurons that respond to the stimulus in a similar manner. The effective kernel $\mathbf{h}$ derived from fitting a neuron's spikes to the uncoupled model (2.2) describes the relationship of neuronal spikes to the stimulus. (In some contexts, this kernel would be referred to as the neuron's *receptive field*.) We base our subpopulation definitions on this effective kernel. We define the similarity between two neurons based on the correlation coefficient between the linear components from the uncoupled model (2.2):

$$cc_{pq}^k = \mathrm{cor}(\mathbf{h}_p^i \cdot \mathbf{X}, \mathbf{h}_q^{i-k} \cdot \mathbf{X}), \tag{2.6}$$

where

$$\mathrm{cor}(A, B) = \frac{\mathrm{cov}(A, B)}{\sqrt{\mathrm{var}(A)\,\mathrm{var}(B)}}.$$

Note that $-1 \le cc_{pq}^k \le 1$. In fact, since each component of $\mathbf{X}$ is a unit normal random variable, the correlation coefficient is simply the cosine of the angle between the kernels:

$$cc_{pq}^k = \frac{\mathbf{h}_p^i \cdot \mathbf{h}_q^{i-k}}{\|\mathbf{h}_p^i\| \|\mathbf{h}_q^{i-k}\|} = \mathbf{h}_p^i \cdot \mathbf{h}_q^{i-k}. \tag{2.7}$$

(The last equality results because the kernels are normalized to be unit vectors.)

Define the maximum correlation coefficient as

$$cc_{pq}^{\max} = \max_k cc_{pq}^k. \tag{2.8}$$

If $cc_{pq}^{\max}$ is large, then neurons p and q respond to the stimulus similarly, and we consider the neurons as part of the same subpopulation. On the other hand, if $cc_{pq}^{\max}$ is small, then we consider the neurons as parts of different subpopulations. For the analysis, when we assume that neurons p and q are from different subpopulations, we will effectively assume that each cc_{pq}^k is $O(\bar{W})$. We show via simulations that, in practice, we can relax this condition somewhat.

3. The analysis.

3.1. Overview of the analysis. We assume we have access to only the spikes of neuron one and two (R_1^i and R_2^i) as well as the discrete white noise stimulus $\mathbf{X}$. Given the stimulus, the probability of spikes from the network is specified by the network model (2.1). We initially assume that all unmeasured neurons (with index $p > 2$) are from different subpopulations than those of neurons one or two (in particular, that cc_{p1}^k and cc_{p2}^k for all k are $O(\bar{W})$). Using this assumption, we can solve for the direct connection ($\bar{W}_{21}^j$ and $\bar{W}_{12}^j$) in terms of the joint statistics of the random variables R_1^i, R_2^i, and $\mathbf{X}$.

When we allow unmeasured neurons from the same subpopulations as the measured neurons, we do not change the algorithm to determine a direct connection. We demonstrate that, with this algorithm, common input from neuron one's subpopulation may be identified as a direct connection from neuron one onto neuron two. Similarly, common input from neuron two's subpopulation may be identified as a direct connection from neuron two onto neuron one. Although this results in a misidentification at the level of individual neurons, it still accurately identifies connectivity at the level of subpopulations (since, for example, common input from neuron two's subpopulation does contain a connection from neuron two's subpopulation onto neuron one's subpopulation).

For this analysis, we assume that we have an infinite dataset, so we can estimate the expected values of functions of the random variables. Since in practice, we will have much smaller datasets, we must reduce the bias in estimations from finite datasets using a procedure such as that outlined in [12, 11, 8]. We do not address such bias reduction here.

We give a brief overview of the analysis here and give more details of each step in the following sections. In the first step, we analyze the spikes of neuron one and neuron two separately. From their stimulus-spike statistics, we fit uncoupled linear-nonlinear models (2.2) as if we were using standard white noise analysis methods such as those outlined in [12]. This calculation is based on the mean spike rates[5] ($E\{R_1^i\}$ and $E\{R_2^i\}$) and the stimulus-spike correlations ($E\{\mathbf{X}R_1^i\}$ and $E\{\mathbf{X}R_2^i\}$). Since the spike times are really given by the network model (2.1), the effective kernels ($\mathbf{h}_q^i$ and $\mathbf{h}_2^i$) and nonlinearities ($g_1(\cdot)$ and $g_2(\cdot)$) are functions of network model parameters (including coupling and parameters from other neurons), as given by (2.4).

Next, we calculate the spike rates conditioned on a particular realization of the stimulus[6] ($E\{R_1^i|\mathbf{X}\}$ and $E\{R_2^i|\mathbf{X}\}$). These statistics are equivalent to the peristimulus time histogram (PSTH) commonly used in the neuroscience literature.

We look at spike pairs, where neuron two spikes k units of time before neuron one (note that k could be positive or negative). We subtract off the product of the PSTHs from the rate of spike pairs conditioned on the stimulus, forming

$$E\{R_1^i R_2^{i-k}|\mathbf{X}\} - E\{R_1^i|\mathbf{X}\}E\{R_2^{i-k}|\mathbf{X}\}.$$

The result is the JPSTH cast into the notation of the model.

If we take the expected value of the JPSTH over all realizations of the stimulus,

[5] Note that, due to the stationarity of the stimulus and model, many stimulus-spike statistics do not depend on time, despite the notation. The mean rates $E\{R_q^i\}$, for example, do not depend on the time point i.

[6] Here we assume that each realization of the stimulus is repeated multiple times.

we obtain the shuffle-corrected correlogram or covariogram

$$C_{21}^k = E\{R_1^i R_2^{i-k}\} - E\big\{E\{R_1^i|\mathbf{X}\}E\{R_2^{i-k}|\mathbf{X}\}\big\}. \tag{3.1}$$

Here we have used the fact that $E\{E\{R_1^i R_2^{i-k}|\mathbf{X}\}\} = E\{R_1^i R_2^{i-k}\}$. For a given value of k, C_{21}^k is effectively a sum over the diagonal of the JPSTH corresponding to the delay k. From analysis of the network model (2.1), we derive an equation for C_{21}^k in terms of model parameters.

As we argued in the introduction, the covariogram alone is insufficient to distinguish common input from a direct connection. In terms of the model parameters, there are too many unknowns to solve for $\bar{W}_{21}^k$ (or $\bar{W}_{12}^{-k}$ if $k < 0$). To obtain more equations, we combine white noise analysis methods with the JPSTH.

The key of the approach is to calculate the correlation[7] of the JPSTH with the stimulus:

$$D_{21}^{ki} = E\{\mathbf{X}R_1^i R_2^{i-k}\} - E\big\{\mathbf{X}E\{R_1^i|\mathbf{X}\}E\{R_2^{i-k}|\mathbf{X}\}\big\}. \tag{3.2}$$

Note that the stimulus-spike correlations (e.g., $E\{\mathbf{X}R_1^i\}$) were calculated by correlating the stimulus with a binary vector (e.g., the R_1^i). The above statistic D_{21}^{ki} is a correlation of the stimulus not with a spike vector, but with the vector composed of values from the diagonal of the JPSTH corresponding to delay k. This vector is, of course, not binary, but the correlation can be computed nearly identically. For a fixed k, the result D_{21}^{ki} will be a vector of the same dimension as the correlations $E\{\mathbf{X}R_1^i\}$ and $E\{\mathbf{X}R_2^{i-k}\}$ and hence the same dimension as the kernels $\mathbf{h}_1^i$ and $\mathbf{h}_2^{i-k}$.

Consequently, for a given k, we can decompose D_{21}^{ki} into components parallel to the kernels $\mathbf{h}_1^i$ and $\mathbf{h}_2^{i-k}$, calculating the coefficients A_1^k and A_2^k for which

$$D_{21}^{ki} = A_1^k \mathbf{h}_1^i + A_2^k \mathbf{h}_2^{i-k} + \mathbf{O}^{ki}, \tag{3.3}$$

where $\mathbf{O}^{ki}$ is perpendicular to $\mathbf{h}_1^i$ and $\mathbf{h}_2^{i-k}$. By analyzing the network model (2.1), we calculate expressions for A_1^k and A_2^k in terms of model parameters. From C_{21}^k, A_1^k, and A_2^k, we have three equations for each delay k.

If one compares the number of unknown parameters with the number of equations, the situation still looks hopeless. Assume that we calculate the statistics for the delays $k = \pm 1, \pm 2, \ldots, \pm M$, so that we have $2M \times 3 = 6M$ equations.[8] Assume also that the coupling is zero for delays longer than M time units. Then the coupling parameters are $\bar{W}_{pq}^j$ for $j \in \{1, 2, \ldots, M\}$ and $p, q \in \{1, 2, \ldots, n\}$, where n is the (presumably unknown) number of neurons, for a total of Mn^2 parameters.

If the number of neurons is more than two, the system appears vastly underdetermined. This limitation make sense. If we were sufficiently audacious as to claim that we could reconstruct the coupling of the entire network based on measures of just two neurons, our absurdity would be exposed by this reality check. Our goal is simply to estimate the direct connection $\bar{W}_{21}^j$ and $\bar{W}_{12}^j$ between the two measured neurons.

As demonstrated below, if we assume that unmeasured neurons are from different subpopulations than the measured neurons, all the coupling terms involving unmeasured neurons appear in the same combination[9] in all three sets of equations. We denote this combination by $\hat{U}^k$, and refer to $\hat{U}^k$ as the common input contribution[10]

[7] We use the term "correlation" loosely.

[8] We ignore the single-neuron statistics and single-neuron parameters for this rough calculation.

[9] For this overview, we ignore the presence of indirect connections (see section 3.3).

[10] It turns out that $\hat{U}^k$ contains only combinations of coupling terms that correspond to common input.

to delay k. This notation makes it clear there are really only two unknowns per delay k ($\hat{U}^k$ and either $\bar{W}_{21}^k$ or $\bar{W}_{12}^{-k}$, depending on whether k is positive or negative, respectively). We have a total of $2M \times 2 = 4M$ parameters for $6M$ equations.[11] The system is actually overdetermined. Moreover, due to the weak coupling assumption of section 2.2, the system is linear in $\hat{U}^k$, $\bar{W}_{21}^k$, and $\bar{W}_{12}^{-k}$. We can easily solve it via least squares and estimate the direct connection between neurons one and two as well as the effective common input.

This estimate is, of course, valid only when unmeasured neurons are from different subpopulations than the measured neurons. We address the case of unmeasured neurons from the same subpopulations as the measured neurons in section 3.4. There we argue that our estimate of $\bar{W}_{21}^k$ or $\bar{W}_{12}^{-k}$ accurately reconstructs connectivity between the subpopulations of neuron one and neuron two.

3.2. Single-neuron statistics. In the following sections, we present more details of the analysis outlined above. As many of the calculations are long, we present only the key details, referring where possible to similar calculations from previous papers.

For each of the measured neurons $q = 1, 2$, we analyze its spikes R_q^i and the stimulus $\mathbf{X}$ as though the uncoupled model (2.2) held. We view the parameters from the uncoupled model (2.2) as effective parameters that can be estimated from the stimulus-spike statistics. We have already calculated the effective parameter relationship (2.5) that relates effective parameters to the original model parameters.

In terms of the effective parameters, the stimulus-spike correlation is

$$\begin{aligned} E\{\mathbf{X}R_q^i\} &= E\{\mathbf{X}\Pr(R_q^i = 1 \big| \mathbf{X})\} \\ &= E\{\mathbf{X}g_q(\mathbf{h}_q^i \cdot \mathbf{X})\} \\ &= E\{g_q'(\mathbf{h}_q^i \cdot \mathbf{X})\}\mathbf{h}_q^i, \end{aligned} \tag{3.4}$$

and the mean rate is

$$\begin{aligned} E\{R_q^i\} &= E\{\Pr(R_q^i = 1 \big| \mathbf{X})\} \\ &= E\{g_q(\mathbf{h}_q^i \cdot \mathbf{X})\}, \end{aligned} \tag{3.5}$$

where we used the integration-by-parts formula (A.3) to obtain the final expression for $E\{\mathbf{X}R_q^i\}$.

Given (3.4) and the normalization $\|\mathbf{h}_q^i\| = 1$, the effective kernel can be calculated from the stimulus-spike correlation as

$$\mathbf{h}_q^i = \frac{E\{\mathbf{X}R_q^i\}}{\|E\{\mathbf{X}R_q^i\}\|}. \tag{3.6}$$

If we assume a two-parameter family of nonlinear functions for $g_q(\cdot)$, we can calculate those parameters from $E\{R_q^i\}$ and $\|E\{\mathbf{X}R_q^i\}\|$ (see [12]).

3.3. Neuron pair statistics. We repeat the calculations of Appendices A and B of [11], computing terms only up to the modified second-order approximation in $\bar{W}$, described above in section 2.2. To simplify the notation, we define $\bar{W}_{pq}^k = 0$ for $k \leq 0$.

[11] Although we could, in principle, look for higher-order corrections by retaining higher-order terms in $\bar{W}$, the system would not collapse to $4M$ parameters, and we would have to look for more equations.

After long, tedious calculations and use of the effective parameter relationship (2.5), most of the terms cancel out, and we are left with

$$
\begin{aligned}
&\Pr\bigl(R_1^i = 1 \,\&\, R_2^{i-k} = 1 \bigm| \mathbf{X} = \mathbf{x}\bigr) - \Pr(R_1^i = 1 | \mathbf{X} = \mathbf{x}) \Pr(R_2^{i-k} = 1 | \mathbf{X} = \mathbf{x}) \\
&\quad \approx \left[\bar{W}_{21}^k + \sum_{p=3}^{n} \sum_{j>0} \bar{W}_{2p}^{k-j} \bar{W}_{p1}^j g_p'(\mathbf{h}_p^{i-j} \cdot \mathbf{x}) \right] g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) [1 - g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x})] \\
&\qquad + \left[\bar{W}_{12}^{-k} + \sum_{p=3}^{n} \sum_{j>0} \bar{W}_{1p}^j \bar{W}_{p2}^{-k-j} g_p'(\mathbf{h}_p^{i+j} \cdot \mathbf{x}) \right] g_1(\mathbf{h}_1^i \cdot \mathbf{x}) [1 - g_1(\mathbf{h}_1^i \cdot \mathbf{x})] g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) \\
&\qquad + \sum_{p=3}^{n} \sum_{j > \max(0,k)} \bar{W}_{p1}^j \bar{W}_{p2}^{j-k} g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) g_p(\mathbf{h}_p^{i-j} \cdot \mathbf{x}) [1 - g_p(\mathbf{h}_p^{i-j} \cdot \mathbf{x})],
\end{aligned}
\tag{3.7}
$$

where $\approx$ indicates equality within our modified second-order approximation in $\bar{W}$. Note that if $k \leq 0$, then $\bar{W}_{21}^k = 0$ and $\bar{W}_{2p}^{k-j} = 0$, and the first expression in square brackets is zero. On the other hand, if $k \geq 0$, then $\bar{W}_{12}^{-k} = 0$ and $\bar{W}_{p2}^{-k-j} = 0$, and the second expression in square brackets is zero. Consequently, either the first or the second term is zero for any given k.

This expression is the expected value of the JPSTH, given that the stimulus $\mathbf{X} = \mathbf{x}$. Note that the first term is a direct connection with delay k from neuron two to neuron one, combined with an indirect connection through neuron p of total delay k. The second term is a direct connection, combined with an indirect connection, from neuron one to neuron two (of total delay $-k$, which is positive when this term is nonzero). The last term is due to common input from neuron p onto both neuron one and neuron two. (The expression $\bar{W}_{p1}^j \bar{W}_{p2}^{j-k}$ is nonzero only if neuron p is connected to both neuron one and neuron two.)

The covariogram (3.1) is the expected value of the JPSTH (3.7), and the statistic D (3.2) is the expected value of the JPSTH (3.7) times the stimulus $\mathbf{X}$. Without further assumptions on the unmeasured neurons, we cannot dissociate the contribution of unmeasured neurons from the contribution of measured neurons. In order to solve the equations, we assume that we can factor each expected value into (A) the expected value of an expression involving unmeasured neuron parameters multiplied by (B) the expected value of an expression involving measured neuron parameters. Note that unmeasured neuron parameters appear only in those terms that are second-order in $\bar{W}$. Given our second-order approximation in $\bar{W}$, this step assumes that, to zeroth order in $\bar{W}$, the $g_p(\mathbf{h}_p^{i-j} \cdot \mathbf{X})$ are independent of $g_1(\mathbf{h}_1^i \cdot \mathbf{X})$ and $g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})$ (i.e., the effective uncoupled models (2.2) for unmeasured neurons are independent of the effective uncoupled models for measured neurons). In particular, we are assuming that cc_{p1}^j and cc_{p2}^{j-k} are $O(\bar{W})$, which means that the unmeasured neurons are from different subpopulations than the measured neurons (as defined in section 2.4).

Under this assumption the covariogram (3.1) (i.e., the expected value of the JPSTH (3.7)) becomes[12]

$$
\begin{aligned}
C_{21}^k \approx\ & \hat{W}_{21}^k E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X}) [1 - g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\} \\
& + \hat{W}_{12}^{-k} E\{g_1(\mathbf{h}_1^i \cdot \mathbf{X}) [1 - g_1(\mathbf{h}_1^i \cdot \mathbf{X})] g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})\} \\
& + \hat{U}_{21}^k E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})\},
\end{aligned}
\tag{3.8}
$$

[12]Recall that stationarity of the stimulus and model imply that the statistics in the equation for C_{21}^k (as well as A_1^k and A_2^k) do not depend on time point i, despite the notation.

where $\approx$ indicates equality within our modified second-order approximation in $\bar{W}$ and

$$\begin{aligned}
\hat{W}_{21}^{k} &= \bar{W}_{21}^{k} + \sum_{p=3}^{n} \sum_{j>0} \bar{W}_{2p}^{k-j} \bar{W}_{p1}^{j} E\{g_p'(\mathbf{h}_p^{i-j} \cdot \mathbf{X})\}, \\
\hat{W}_{12}^{-k} &= \bar{W}_{12}^{-k} + \sum_{p=3}^{n} \sum_{j>0} \bar{W}_{1p}^{j} \bar{W}_{p2}^{-k-j} E\{g_p'(\mathbf{h}_p^{i+j} \cdot \mathbf{X})\}, \\
\hat{U}_{21}^{k} &= \sum_{p=3}^{n} \sum_{j>\max(0,k)} \bar{W}_{p1}^{j} \bar{W}_{p2}^{j-k} E\{g_p(\mathbf{h}_p^{i-j} \cdot \mathbf{X})[1 - g_p(\mathbf{h}_p^{i-j} \cdot \mathbf{X})]\}. \qquad (3.9)
\end{aligned}$$

The new parameters $\hat{W}_{21}^{k}$ and $\hat{W}_{12}^{-k}$ are the effective direct connections between neurons one and two. (By definition, $\hat{W}_{21}^{k} = 0$ for $k \leq 0$ and $\hat{W}_{12}^{-k} = 0$ for $k \geq 0$.) Note that this effective direct connection factor $\hat{W}$ is a combination of both the direct connections and the indirect connections through any unmeasured neuron p. This fact indicates that we cannot distinguish between direct connections and indirect connections through unmeasured neurons. Our goal is to distinguish these effective direct connections $\hat{W}$ from the effective common input $\hat{U}$, which is the sum total effect from all unmeasured neurons p that project to both neuron one and neuron two.

We multiply the JPSTH (3.7) by $\mathbf{X}$, take the expected value, and use the integration-by-parts formula (A.3) to obtain an expression for D_{21}^{ki} (given by (3.2))

$$D_{21}^{ki} \approx A_1^k \mathbf{h}_1^i + A_2^k \mathbf{h}_2^{i-k} + \mathbf{O}^{ki}, \qquad (3.10)$$

where $\mathbf{O}^{ki}$ is an expression that is $O(\bar{W}^2)$ and involves the kernels of the unmeasured neurons. Since we are assuming that the unmeasured neurons are from different subpopulations than the measured neurons, $\mathbf{O}^{ki}$ can be viewed as orthogonal to[13] $\mathbf{h}_1^i$ and $\mathbf{h}_2^{i-k}$. The components of D_{21}^{ki} parallel to $\mathbf{h}_1^i$ and $\mathbf{h}_2^{i-k}$ are

$$\begin{aligned}
A_1^k &= \hat{W}_{21}^{k} E\{g_1''(\mathbf{h}_1^i \cdot \mathbf{X}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\} \\
&\quad + \hat{W}_{12}^{-k} E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X})[1 - 2g_1(\mathbf{h}_1^i \cdot \mathbf{X})] g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})\} \\
&\quad + \hat{U}_{21}^{k} E\{g_1''(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})\}, \\
A_2^k &= \hat{W}_{21}^{k} E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - 2g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\} \\
&\quad + \hat{W}_{12}^{-k} E\{g_1(\mathbf{h}_1^i \cdot \mathbf{X})[1 - g_1(\mathbf{h}_1^i \cdot \mathbf{X})] g_2''(\mathbf{h}_2^{i-k} \cdot \mathbf{X})\} \\
&\quad + \hat{U}_{21}^{k} E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2''(\mathbf{h}_2^{i-k} \cdot \mathbf{X})\}. \qquad (3.11)
\end{aligned}$$

From measuring the spikes of neuron one and two (R_1^i and R_2^i) in response to the stimulus $\mathbf{X}$, we can calculate the effective uncoupled model parameters ($g_1(\cdot)$, $g_2(\cdot)$, $\mathbf{h}_1^i$, and $\mathbf{h}_2^{i-k}$), the covariogram C_{21}^k (via (3.1)), the statistic D_{21}^{ki} (via (3.2)), and consequently its components A_1^k and A_2^k. The nine expected values in (3.8) and (3.11) are simply Gaussian integrals of known functions that can be calculated. The only unknown quantities are the $\hat{W}_{12}^{-k}$, $\hat{W}_{21}^{k}$, and $\hat{U}_{21}^{k}$.

To emphasize that the direct connection is simply one variable per delay, we define

[13] Since, for any $p > 2$ and any j, the correlation coefficients cc_{p1}^{j} and cc_{p2}^{j-k} are assumed to be $O(\bar{W})$, the component of $\mathbf{h}_p^{i-j}$ parallel to $\mathbf{h}_1^i$ or $\mathbf{h}_2^{i-k}$ is $O(\bar{W})$. Hence, the component of $\mathbf{O}^{ki}$ parallel to these kernels must be $O(\bar{W}^3)$, which we can ignore.

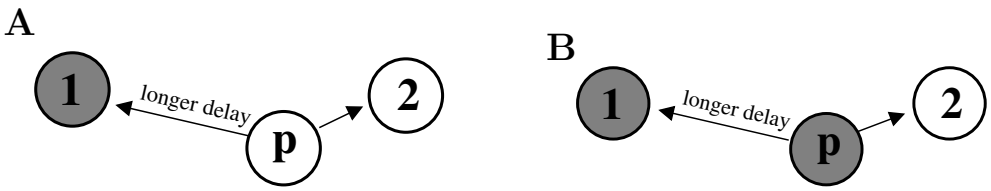

FIG. 2. *Schematic of common input from unmeasured neuron p onto measured neurons one and two. The gray shading indicates which neurons are from the same subpopulation. The connection from neuron p to neuron one is delayed, so the common input introduces a correlation between the spikes of neuron one and two that is similar to the correlation induced by a connection from neuron two to neuron one.* (A) *Neuron p is within neuron two's subpopulation. In this case, the common input may appear as a direct connection from neuron two onto neuron one.* (B) *Neuron p is within neuron one's subpopulation. In this case, the common input will not be confused with a direct connection.*

a new direct connection variable

$$\hat{W}^k = \begin{cases} \hat{W}_{12}^{-k} & \text{for } k < 0, \\ 0 & \text{for } k = 0, \\ \hat{W}_{21}^{k} & \text{for } k > 0. \end{cases} \tag{3.12}$$

Note that the equations for different delays k are uncoupled. For each $k \neq 0$, equations (3.8) and (3.11) are three linear equations for the two unknowns $\hat{U}_{21}^k$ and $\hat{W}^k$. This system is easily solved for the two unknowns using linear least squares. For $k = 0$, the only unknown is $\hat{U}_{21}^0$, for which we solve using (3.8).

3.4. Common input from the measured neurons' subpopulations. To complete the above analysis, we assumed that the unmeasured neurons were from different subpopulations than the measured neurons. In particular, we assumed that the correlation coefficients between the measured neurons and the unmeasured neurons (cc_{p1}^k and cc_{p2}^k for $p > 2$ and all k) were small.

In the brain, one typically finds groups of neurons that respond to a stimulus in a similar way and hence would be from the same subpopulation, as we defined them in section 2.4. Consequently, one would anticipate the presence of unmeasured neurons from the subpopulations of both neuron one and neuron two. Since such measured neurons could be the source of common input, we must address the case of common input from the neurons within the measured neurons' subpopulations. (With the exception of common input and indirect connection effects, all effects of unmeasured neurons had already been canceled in the analysis leading to the JPSTH (3.7), before we made any assumptions about subpopulations.)

We examine networks with a common input configuration where an unmeasured neuron p has a connection onto neuron two, and, with a longer delay, a connection onto neuron one, as schematized in Figure 2. To implement this, we let the connection onto neuron one have a delay of j time steps ($\bar{W}_{p1}^j \neq 0$) and the connection onto neuron two have a delay of $j - k$ time steps ($\bar{W}_{p2}^{j-k} \neq 0$), with $j > k > 0$. With this set of delays, the common input will introduce correlations between the measured neurons that mimic a direct connection from neuron two onto neuron one with a delay of k time steps.

We first show how common input from neuron two's subpopulation (Figure 2(A)) can be misidentified as a direct connection from neuron two onto neuron one. (Note

that this results in a correct identification of a connection from neuron two's subpopulation onto neuron one's subpopulation.) Since the connection from neuron p onto neuron two is due to the term $\bar{W}_{p2}^{j-k} \neq 0$, the correlation coefficient cc_{p2}^{j-k} will determine whether the neuron p acts as a member of neuron two's subpopulation (this inference comes from inspection of the last term in the JPSTH (3.7)). If cc_{p2}^{j-k} is large, neuron p will act as a member of neuron two's subpopulation.

We examine the extreme case where neuron p responds to nearly the same stimulus features as neuron two does $j-k$ time steps later; i.e., $\mathbf{h}_p^{i-j} = \mathbf{h}_2^{i-k} + O(\bar{W})$. Consequently, $cc_{p2}^{j-k} = 1+O(\bar{W})$. Then, the contribution of this neuron to the JPSTH (3.7) is

$$\bar{W}_{p1}^{j}\bar{W}_{p2}^{j-k} g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{x})[1 - g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{x})].$$

The contribution of neuron p to the covariogram is

$$C_{21}^k = \bar{W}_{p1}^{j}\bar{W}_{p2}^{j-k} E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X}) g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\}. \tag{3.13}$$

Since the kernel $\mathbf{h}_p^{i-j}$ is identical to $\mathbf{h}_2^{i-k}$, an additional term will appear in A_2^k after the integration by parts, so that the contribution of neuron p to A_1^k and A_2^k is

$$\begin{aligned} A_1^k &= \bar{W}_{p1}^{j}\bar{W}_{p2}^{j-k} E\{g_1''(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X}) g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\}, \\ A_2^k &= \bar{W}_{p1}^{j}\bar{W}_{p2}^{j-k} E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2''(\mathbf{h}_2^{i-k} \cdot \mathbf{X}) g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\} \\ &\quad + \bar{W}_{p1}^{j}\bar{W}_{p2}^{j-k} E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X}) g_p'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - 2g_p(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\}. \end{aligned} \tag{3.14}$$

Compare this contribution to the effect of a direct connection from neuron two to neuron one at a delay of k units of time (the $\bar{W}_{21}^k$ terms from (3.8) and (3.11)):

$$\begin{aligned} C_{21}^k &= \hat{W}_{21}^k E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\}, \\ A_1^k &= \hat{W}_{21}^k E\{g_1''(\mathbf{h}_1^i \cdot \mathbf{X}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\}, \\ A_2^k &= \hat{W}_{21}^k E\{g_1'(\mathbf{h}_1^i \cdot \mathbf{X}) g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})[1 - 2g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{X})]\}. \end{aligned} \tag{3.15}$$

Ignoring the first term of A_2^k in (3.14), we observe that the relationship among C_{21}^k, A_1^k, and A_2^k in (3.13) and (3.14) is nearly identical to their relationship in (3.15). For the case $g_p = g_2$, the only difference is the additional common factor of $g_2'(\mathbf{h}_2^{i-k} \cdot \mathbf{X})$ in the expected value.

If the second term of A_2^k in (3.14) does dominate the first term, then the common input from neuron two's subpopulation leads to a relationship among the statistics C_{21}^k, A_1^k, and A_2^k that mimics a direct connection from neuron two to neuron one. Consequently, we would expect that applying the results of section 3.3 would indicate the presence of a direct connection. Simulations confirm that the second term of A_2^k in (3.14) does indeed dominate, as network configurations such as Figure 2(A) are categorized as direct connection configurations.

We next consider the case where neuron p is from neuron one's subpopulation (Figure 2(B)). If neuron p responds to the stimulus almost exactly as neuron one does, j time steps later, the analysis does not give a clear answer. If we assume $\mathbf{h}_p^{i-j} = \mathbf{h}_1^i + O(\bar{W})$ so that $cc_{p1}^j = 1 + O(\bar{W})$, we do not obtain a relationship among C_{21}^k, A_1^k, and A_2^k that mimics their relationship in (3.15). In this case, simulations indicate that this configuration appears as common input. (Of course, if the connection from

neuron p to neuron two had the longer delay, the network would be equivalent to Figure 2(A) with the roles of neuron one and two reversed. In this case, the network would mimic a direct connection from neuron one to neuron two.)

We conclude that we cannot distinguish between a direct connection from neuron two onto neuron one and common input from neuron two's subpopulation. (An equivalent statement holds with the roles of neuron one and neuron two reversed.) Since common input from neuron two's subpopulation does contain a connection from neuron two's subpopulation onto neuron one, we conclude that the connectivity is correctly identified at the level of subpopulations. In applications where the distinction among particular neurons within a subpopulation is unimportant, the ambiguity in the precise identification of the connection is not problematic. See the Discussion for more details.

4. Tests via simulation.

4.1. Simulations of small linear-nonlinear networks. We tested our analytic results with simulations of networks of linear-nonlinear neurons given by (2.1). We used kernels $\bar{\mathbf{h}}_q^i$ that capture some features of the responses of neurons in visual cortex [6]. For spatial grid point $\mathbf{j} = (j_1, j_2)$ and time t, the kernels were of the form

$$\bar{h}_q(\mathbf{j}, t) = (t - b_q) \exp\left(-\frac{t - b_q}{\tau_h} - \frac{|\mathbf{j}|^2}{10}\right) \sin((j_1 \cos\psi_q + j_2 \sin\psi_q) f_q + \phi_q) \tag{4.1}$$

for $t > b_q$ and $\bar{h}_q(\mathbf{j}, t) = 0$ otherwise. We sampled $\bar{h}_q(\mathbf{j}, t)$ on a $10 \times 10 \times 10$ grid and normalized it to the unit vector $\bar{\mathbf{h}}_q^i$. For the analysis, the only important geometry is the inner product between the kernels, $\bar{\mathbf{h}}_q^i \cdot \bar{\mathbf{h}}_p^{i-j}$, which is the correlation between normal random variables $\bar{\mathbf{h}}_p^{i-j} \cdot \mathbf{X}$ and $\bar{\mathbf{h}}_q^i \cdot \mathbf{X}$.

For each example, we simulated the network response to 500,000 units of time, adjusting the nonlinearities $\bar{g}_q(\cdot)$ to obtain between 10,000 and 15,000 spikes from each neuron. Each simulation was composed of 100 trials, each lasting 5,000 units of time. For ten trials, the stimulus was independent realizations of the Gaussian white noise. We repeated each realization ten times to form the 100 trials. The repetitions allowed estimation of the spiking probabilities $\Pr(R_1^i | \mathbf{X} = \mathbf{x})$ and $\Pr(R_2^{i-k} | \mathbf{X} = \mathbf{x})$ needed for the JPSTH (3.7) by averaging over the ten repetitions (equivalent to a shuffle correction).

The analysis was based on expected values of stimulus-spike statistics. Naive estimates of products of these statistics, including the shuffle correction, from finite datasets can be highly biased. We reduced these biases using techniques described elsewhere [12, 11, 8]. From the independent trials, we estimated confidence intervals as described in Appendix C.

To compute the Gaussian integrals in (3.8) and (3.11), we needed to choose a form for the nonlinear functions $g_q(y)$. To allow us to compute the integrals analytically, we assume that the nonlinear functions are error functions of the form

$$\bar{g}_q(y) = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{y - \bar{y}_q}{\bar{\epsilon}_q \sqrt{2}}\right)\right], \tag{4.2}$$

where $\bar{y}_q$ is the threshold, $\bar{\epsilon}_q$ defines the steepness of the nonlinearity, and the error function is $\operatorname{erf}(y) = \frac{2}{\sqrt{\pi}} \int_0^y e^{-t^2} dt$. Note that $\lim_{y \to \infty} g_q(y) = 1$ and $\lim_{y \to -\infty} g_q(y) = 0$. The expressions for C_{21}^k, A_1^i, and A_2^{i-k} for the case of an error function nonlinearity are given in Appendix B. We demonstrate below that the results are not sensitive to

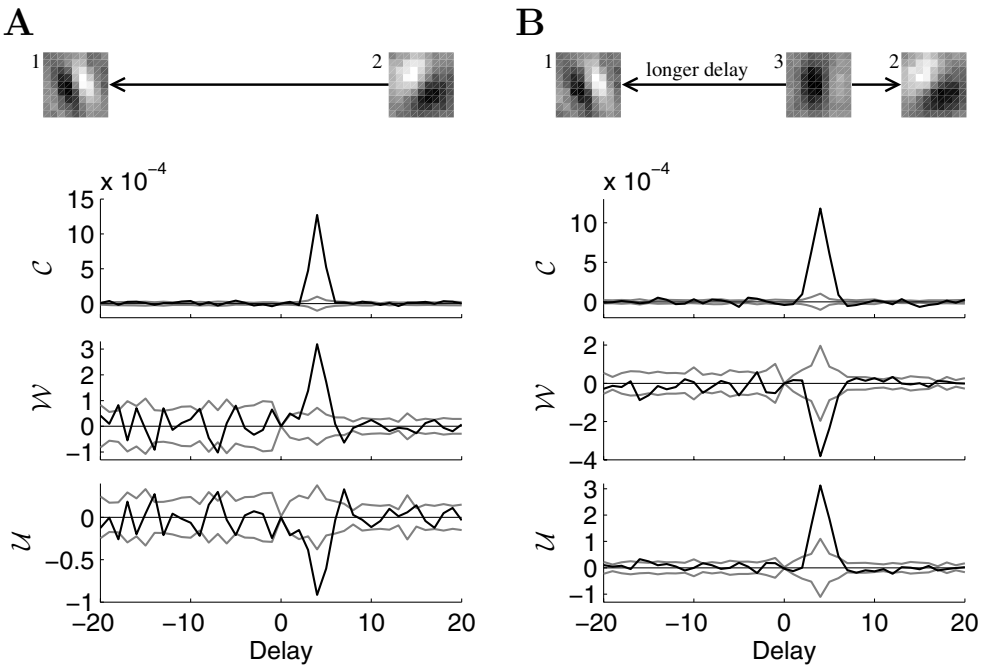

FIG. 3. *Results from sample simulations showing successful distinction between* (A) *the direct connection configuration and* (B) *the common input configuration, using only the spike times from neurons one and two. The top panels are schematics of the network architecture, with grayscale plots of the time slice in which each kernel (*$\mathbf{h}_1$*,* $\mathbf{h}_2$*, or* $\mathbf{h}_3$*, labeled by neuron number) reached its maximal value. (The spikes of neuron three were used to calculate* $\mathbf{h}_3$ *for this illustration. The remaining analysis used only the spikes of neuron one and two.) The bottom three panels plot with black lines the covariogram* $\mathcal{C}$*, direct connection measure* $\mathcal{W}$*, and common input measure* $\mathcal{U}$*. The gray lines estimate confidence intervals of one standard error. Delay is the spike time of neuron one minus the spike time of neuron two.* (A) *The direct connection from neuron two onto neuron one creates a positive covariogram* $\mathcal{C}$ *around a delay of four units of time. The significantly positive direct connection measure* $\mathcal{W}$ *at that delay indicates that the correlation was due to a direct connection. The negative common input measure* $\mathcal{U}$*, though indicating departure from the weak coupling assumption, does not confuse the direct connection interpretation. The direct connection was given by* $\bar{W}^4_{21} = 0.8$*,* $\bar{W}^3_{21} = \bar{W}^5_{21} = 0.4$*. (All other* $\bar{W}$ *were zero.) Parameters used:* $\tau_h = 2$*,* $\psi_1 = \pi/8$*,* $\psi_2 = -\pi/4$*,* $\phi_1 = 0$*,* $\phi_2 = \pi$*,* $f_1 = 1.0$*,* $f_2 = 0.3$*,* $b_1 = b_2 = 0$*,* $\bar{T}_1 = 2.3$*,* $\bar{T}_2 = 2.8$*,* $\bar{\epsilon}_1 = 0.5$*,* $\bar{\epsilon}_2 = 1.0$*.* (B) *For the network with common input from unmeasured neuron three, the covariogram* $\mathcal{C}$ *is nearly identical to the direct connection case from panel* A*. The fact that the correlation was due to common input is revealed by the positive* $\mathcal{U}$ *(and negative* $\mathcal{W}$*). The common input to neuron one was delayed four more units of time compared with that to neuron two:* $\bar{W}^6_{31} = \bar{W}^2_{32} = 1.8$*,* $\bar{W}^5_{31} = \bar{W}^7_{31} = \bar{W}^1_{32} = \bar{W}^3_{32} = 0.8$*. Parameters as in* (A) *except* $\psi_3 = 0$*,* $\phi_3 = -\pi/3$*,* $f_3 = 0.6$*,* $b_3 = 0$*,* $\bar{T}_1 = 2.6$*,* $\bar{T}_2 = 3.0$*,* $\bar{T}_3 = 2.4$*,* $\bar{\epsilon}_3 = 0.7$*.*

this particular choice of nonlinear function. One could perform a similar analysis for other nonlinear functions, although then one would presumably need to compute the integrals numerically.

We denote by $\mathcal{C}^k$ the covariogram C^k_{21} (3.1) estimated from a dataset. Similarly, we denote by $\mathcal{W}^k$ and $\mathcal{U}^k$ estimates of the direct connection $\hat{W}^k$ (3.12) and common input $\hat{U}^k_{21}$ (3.9), respectively.

To illustrate the method, we looked at minimal networks containing two or three neurons. First, we simulated a pair of neurons, where neuron two has a direct connection onto neuron one. The results are shown in Figure 3(A). The covariogram $\mathcal{C}$ shows

a peak at the delay corresponding to the connection. However, the covariogram does not indicate whether this spike correlation is due to a direct connection or common input from an unmeasured neuron.

This ambiguity is resolved by the measures $\mathcal{W}$ and $\mathcal{U}$. The direct connection measure $\mathcal{W}$ is significantly positive at the delay corresponding to the connection. On the other hand, the common input measure $\mathcal{U}$ is negative at that delay. Hence, $\mathcal{W}$ and $\mathcal{U}$ indicate that the spike correlation was caused by a direct connection rather than by a common input.

Note that the noise in $\mathcal{W}$ and $\mathcal{U}$ is dramatically greater than in the covariogram $\mathcal{C}$. This increase is presumably due to the subtlety of the distinction we are attempting to make. For this reason, we required long simulations with up to 15,000 spikes to obtain good results.

The reciprocal behavior observed between $\mathcal{W}$ and $\mathcal{U}$ is not predicted by the analysis. According to the analysis, $\mathcal{U}$ should be flat in the presence of a direct connection. The fact that $\mathcal{U}$ is negative is surprising. Simulations indicate that this behavior is a result of a breakdown in the weak coupling assumption. For a weaker direct connection (and much longer simulation to compensate for noise), the reflection in $\mathcal{U}$ disappears (not shown). The combination of a positive $\mathcal{W}$ and a negative $\mathcal{U}$ could theoretically be caused by either a positive direct connection or a negative common input. The ambiguity is removed by the positive $\mathcal{C}$, indicating that we indeed have a positive direct connection.

We next simulated three neurons, where the unmeasured neuron three was a source of common input to neurons one and two. In this example, neuron three was from a different subpopulation than neuron one or two, as defined in section 2.4. Figure 3(B) shows the results obtained from analyzing the spikes of neurons one and two. The covariogram $\mathcal{C}$ is essentially identical to the direct connection case in Figure 3(A). The covariogram cannot be used to distinguish this common input configuration from the direct connection configuration. This distinction can be made from the measures $\mathcal{W}$ and $\mathcal{U}$. In this case, the common input measure $\mathcal{U}$ is significantly positive, while the direct connection measure $\mathcal{W}$ is negative. Since $\mathcal{C}$ is positive, this combination correctly indicates the common input configuration.

We demonstrate in Figure 4 two simulations to confirm our analysis, with common input from neurons within the subpopulation of neuron one or neuron two (section 3.4). We retain the same common input configuration of Figure 3(B), but change the kernel of the unmeasured neuron three to match the kernel of either neuron two or neuron one.

For the case when the unmeasured neuron three was in neuron two's subpopulation (Figure 4(A)), the common input appears as a direct connection from neuron two onto neuron one, because $\mathcal{W}$ is significantly positive. The results fail to correctly identify that neuron two does not have a direct connection onto neuron one. If one cares about the distinction between neuron two and neuron three, then this result is unacceptable. If, on the other hand, the precise of identity of neurons within a subpopulation is unimportant, the results are adequate, as they correctly indicate that a neuron from neuron two's subpopulation has a direct connection onto neuron one.

For the case when the unmeasured neuron three was in neuron one's subpopulation (Figure 4(B)), the results correctly indicate the common input configuration. In this network, there was no direct connection from neuron two's subpopulation onto neuron one's subpopulation. Fortunately, the similarity between neuron three and neuron one does not affect the results.

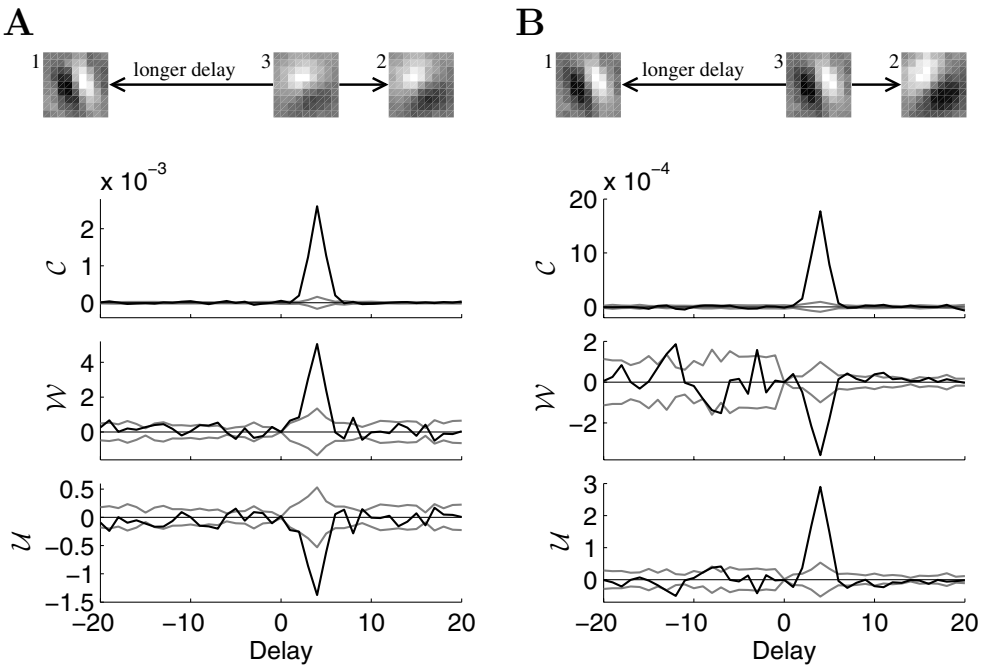

FIG. 4. *Tests of the effect of common input from an unmeasured neuron within the subpopulation of neuron one or neuron two. Panels as in Figure* 3. (A) *The network configuration is identical to the common input of Figure* 3(B) *except that the kernel of neuron three is similar to that of neuron two* ($cc_{32}^{\max} > 0.9$*; see* (2.8)*), so that neuron three is in neuron two's subpopulation. In this case, the common input is misidentified as a direct connection* ($\mathcal{W}$ *is positive).* $\mathcal{W}$ *can be interpreted as indicating a direct connection from a neuron within neuron two's subpopulation onto neuron one. The connectivity* $\bar{W}$ *and the parameters are identical to those of Figure* 3(B) *except* $b_2 = 2$, $\psi_3 = -3\pi/8$, $\phi_3 = 7\pi/8$, $f_3 = 0.4$, $\bar{T}_2 = 3.4$. (B) *When the kernel of neuron three is similar to that of neuron one* ($cc_{31}^{\max} > 0.9$*) so that neuron three is in neuron one's subpopulation, the common input is correctly identified* ($\mathcal{U}$ *is positive). In this case, there is no connection from neuron two's subpopulation to neuron one. The connectivity* $\bar{W}$ *and the parameters are identical to those of Figure* 3(B) *except* $b_1 = 6$, $\psi_3 = \pi/8$, $\phi_3 = 0.0$, $f_3 = 0.8$, $\bar{T}_1 = 3.0$.

As indicated by the analysis, our approach cannot distinguish a direct connection from an indirect connection via a third intermediate neuron. An example of an indirect connection is shown in Figure 5(A). Since the direct connection measure $\mathcal{W}$ is positive, the indirect connection is classified as a direct connection.

Although the analysis was based on an error function nonlinearity (4.2), the results are not sensitive to small changes in nonlinearity shape. In Figure 5, we demonstrate a simulation with a (truncated) power law nonlinearity: $\bar{g}_q(y) = \min\{A_q y^{\beta_q}, 1\}$ for $y > 0$, and $\bar{g}_q(y) = 0$ otherwise. This example includes both a direct connection from neuron one onto neuron two (we use the sign convention where this is a negative delay) and common input from an unmeasured neuron three (with a positive net delay, so that it mimics a connection from neuron two onto neuron one). We analyzed the spike responses from neurons one and two (R_1^i and R_2^i) and the stimulus $\mathbf{X}$ just as we did in the previous examples; i.e., we used the results of Appendix B, in which the nonlinearities $\bar{g}_q(\cdot)$ are assumed to be error functions.

The covariogram contains two similar peaks at a positive and negative delay and therefore cannot distinguish the two type of connections. The measures $\mathcal{W}$ and $\mathcal{U}$

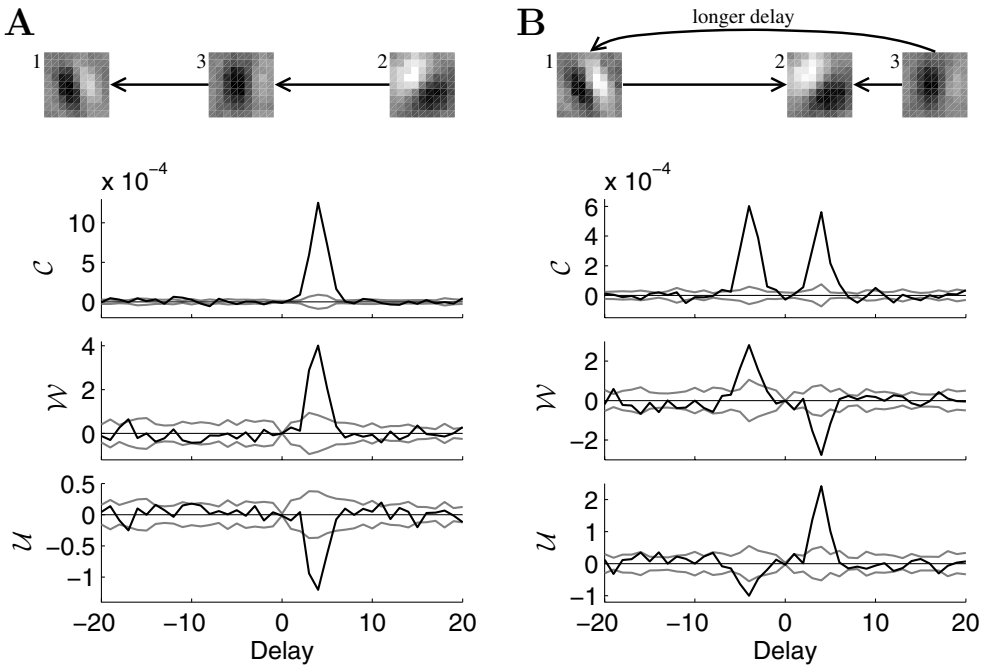

FIG. 5. *Further demonstrations of the approach. Panels as in Figure* 3. (A) *An indirect connection from neuron two onto neuron one through an unmeasured neuron three. This connection appears as a direct connection ($\mathcal{W}$ is positive). As shown by the analysis, we cannot distinguish such an indirect connection from a direct connection. The indirect connection is given by* $\bar{W}^2_{23} = \bar{W}^2_{31} = 1.6$, $\bar{W}^1_{23} = \bar{W}^3_{23} = \bar{W}^1_{31} = \bar{W}^3_{31} = 0.8$. *Parameters are identical to Figure* 3(B) *except* $\bar{T}_1 = 2.5$, $\bar{T}_2 = 2.8$, $\bar{T}_3 = 2.6$. (B) *A simulation with nonlinear functions* $\bar{g}_q(\cdot)$ *given by power laws. In this case, the network contains a direct connection from neuron one onto neuron two (corresponding to a negative delay) and common input from unmeasured neuron three onto neurons one and two (with a longer delay to neuron one to give a positive delay). The spikes of neuron one and two were analyzed as though the nonlinearities were error functions. Although the covariogram contains two virtually identical peaks, the measures $\mathcal{W}$ and $\mathcal{U}$ successfully identify the direct connection at negative delay and the common input at positive delay. The connections were given by* $\bar{W}^4_{12} = 0.6$, $\bar{W}^3_{12} = \bar{W}^5_{12} = 0.4$, $\bar{W}^6_{31} = \bar{W}^2_{32} = 1.8$, $\bar{W}^5_{31} = \bar{W}^7_{31} = \bar{W}^1_{32} = \bar{W}^3_{32} = 0.8$. *Kernel parameters are as in Figure* 3(B). *Power law parameters:* $A_1 = 0.02$, $A_2 = 0.035$, $A_3 = 0.05$, $\beta_1 = 2.6$, $\beta_2 = 2.0$, $\beta_3 = 2.3$.

differentiate between the origins of these peaks. Since $\mathcal{W}$ is positive at a negative delay, it indicates a direct connection from neuron one onto neuron two. On the other hand, since $\mathcal{U}$ is positive at a positive delay, it indicates a common input from a third neuron rather than any direct connection from neuron two onto neuron one. The method correctly identifies the circuitry of the model network even with a power law nonlinearity.

4.2. Simulation of integrate-and-fire networks. To test the robustness of the method to deviations from the linear-nonlinear model, we simulated a system of integrate-and-fire neurons. In this case, we viewed each time step as corresponding to a millisecond. The evolution of the voltage of neuron q in response to input $G_q(t)$ is given by $\tau_m \frac{\mathrm{d}V_q}{\mathrm{d}t} + V_q + G_q(t)(V_q - \mathcal{E}_s) = 0$. The spike times T_q^j of neuron q are those times when $V_q(T_q^j)$ reaches 1. After each spike, the voltage was reset to 0 and held there for an absolute refractory period of length τ_{ref}. Each neuron was driven by the

input conductance $G_q(t)$, which we specified by

$$G_q(t) = 0.05 \sum_{j>0} f(t - T_q^{\text{ext},j}) + \sum_{p=1}^{n} \sum_{j>0} W_{pq} f(t - T_p^j - d_{pq}),$$

where the first term is the response to external input events at times $T_p^{\text{ext},j}$ and the second term is due to internal coupling. The function $f(t) = \frac{e^2}{4}\left(\frac{t}{\tau_s}\right)^2 e^{-t/\tau_s}$ for $t > 0$, and $f(t) = 0$ otherwise. Here, W_{pq} specifies the strength of coupling from neuron p onto neuron q, and d_{pq} is the delay of that connection.

We set the external input to be a linear-nonlinear function of the stimulus. Accordingly, the $T_q^{\text{ext},j}$ were drawn from a modulated Poisson process with rate given by $\alpha_q\left[\mathbf{h}_q^i \cdot \mathbf{X}\right]_+$, where $[x]_+ = x$ if $x > 0$ and is zero otherwise.

We first simulated a network of three neurons that contained both a direct connection from neuron one onto neuron two and common input from neuron three onto neurons one and two (just as in Figure 5(B)). We used the same linear kernels (4.1) as before, sampling them on an $80 \times 10 \times 10$ grid in time and space. For realism, we sampled the white noise stimulus every ten units of time (i.e., every 10 ms). We simulated the network to 5,000 simulated seconds (nearly 1.4 simulated hours), recording 30,000 to 40,000 spikes per neuron. We needed such long simulations to obtain good results.

Figure 6(A) demonstrates that our analysis can distinguish common input from a direct connection even with integrate-and-fire neurons. The results are equivalent to Figure 5(B). The covariogram $\mathcal{C}$ show peaks corresponding to the direct connection and the common input. The source of these correlations is distinguished by the measures $\mathcal{W}$ and $\mathcal{U}$. The correlation at a negative delay is identified as a direct connection from neuron one onto neuron two; the correlation at a positive delay is identified as common input from a third neuron.

Since the integrate-and-fire neurons are driven by the stimulus in a fairly linear fashion, the basic relationship of neural response to the stimulus is similar to that assumed in the linear-nonlinear model (2.1). However, unlike model (2.1), the probability of a spike does depend strongly on previous spike times. The presence of a refractory period prevents the neuron from firing a spike immediately after spiking. Even after the refractory period, the voltage must integrate up to threshold, further increasing dependence among spike times. Figure 6(A) demonstrates that our approach can still work in the presence of these deviations from model assumptions.

As a final test of our approach, we simulated a slightly larger network of 20 integrate-and-fire neurons. The network included a direct connection from neuron one onto neuron two. In addition, four of the unmeasured neurons (neurons 3–20) were randomly selected to give common input onto both neurons one and two, where the connection onto neuron one had a delay that was 30 ms longer than the delay to neuron two. In this case, the measured spike trains had a correlation at a negative delay due to the direct connection and a correlation at a positive delay due to the common input, just as in the previous example. We randomly added additional connections to the network so that any given neuron had a 10% chance of connecting onto any given unmeasured neuron.

We simulated this network to 5,000 simulated seconds (nearly 1.4 simulated hours), measuring approximately 10,000–40,000 spikes per neuron. We discarded the spikes of all neurons except neurons one and two. The results from analyzing just these spikes are shown in Figure 6(B). In this case, the direct connection and

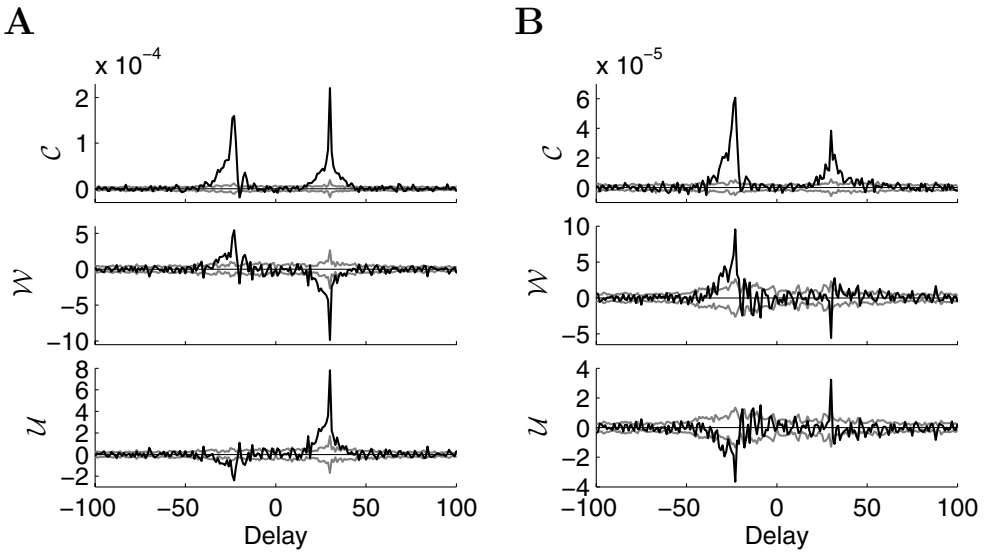

FIG. 6. *Demonstration of the results applied to networks of integrate-and fire neurons. Panels as in the bottom panels of Figure* 3. (A) *Results from a simulation of three neurons with network architecture identical to that pictured at the top of Figure* 5(B). *(The network contained both a direct connection at negative delay and common input at positive delay.) The direct connection measure* $\mathcal{W}$ *correctly identifies the direct connection from neuron one onto neuron two (appearing with negative delay). The common input measure* $\mathcal{U}$ *correctly identifies the common input at positive delay. Parameters:* $W_{12} = 0.1$, $W_{31} = W_{32} = 0.15$ *(all other* $W_{pq} = 0$*),* $d_{12} = 20$ *ms,* $d_{31} = 40$ *ms,* $d_{32} = 10$ *ms,* $\alpha_1 = \alpha_2 = 0.25$ ms^{-1}, $\alpha_3 = 0.3$ ms^{-1}, $\tau_m = 5$ *ms,* $\mathcal{E}_s = 6.5$, $\tau_s = 2$ *ms,* $\tau_{ref} = 2$ *ms. Parameters for* $\bar{\mathbf{h}}$ *are the same as those in Figure* 3(B) *except that* $\tau_h = 20$ *ms.* (B) *Results from a simulation of a random network of twenty neurons. The measure* $\mathcal{W}$ *correctly identified the direct connection from neuron one onto neuron two at negative delay (established by setting* $W_{12} = 0.12$, $d_{12} = 20$ *ms). The measure* $\mathcal{U}$ *correctly identified the common input at positive delay. Four neurons with index* $p > 2$ *were randomly selected to give this common input. For these p, the connection strength was randomly selected from* $W_{p1} \in (0.05, 0.15)$*, and* $W_{p2} = W_{p1}$*. For these four neurons, the delays were coordinated so that the delay to neuron one was* 30 *ms longer:* $d_{p2} = 2$ *ms,* $d_{p1} = 32$ *ms. The remaining connections were randomly generated as follows. For any* $p > 0$ *and* $q > 2$, $W_{pq} = 0$ *with* 90% *probability; otherwise the parameters* W_{pq} *and* d_{pq} *were randomly generated with* $W_{pq} \in (0.05, 0.15)$ *and* $d_{pq} \in (1, 40)$ *ms. Parameters for* $\bar{\mathbf{h}}_1$ *and* $\bar{\mathbf{h}}_2$ *are as in Figure* 3(A)*, except that* $\tau_h = 20$ *ms and* $b_2 = 2$ *ms. The remaining kernels with* $p > 2$ *were randomly generated with* $\psi_p \in (0, 2\pi)$, $\phi_p \in (0, 2\pi)$*, and* $f_p \in (0.2, 1.0)$*. We set* $\alpha_1 = \alpha_2 = 0.25$ ms^{-1} *and, for* $p > 2$*, randomly generated* $\alpha_p \in (0.15, 0.3)$ ms^{-1}*. We set* $\tau_m = 5$ *ms,* $\mathcal{E}_s = 6.5$, $\tau_s = 2$ *ms, and* $\tau_{ref} = 2$ *ms.*

common input are correctly identified by the measures $\mathcal{W}$ and $\mathcal{U}$, respectively. We did not constrain the unmeasured neurons to be from different subpopulations than the measured neurons. For the four common input neurons p, the maximal correlation coefficient $cc_{p2}^{\max}$ (see (2.8)) between neuron p and neuron two ranged from 0.0 to 0.7. Since the common input correlations mimicked a connection from neuron two to neuron one, these $cc_{p2}^{\max}$ were the critical measures for determining whether the common input would be identified as a direct connection. The simulation indicates that the common input neurons (at least on average) were considered to be from subpopulations different from that of neuron two.

5. Discussion. The results demonstrate that we can correctly identify subpopulation connectivity when neural response can be captured by the linear-nonlinear model (2.1), the coupling is not too strong, and we have a lot of data. Before we focus

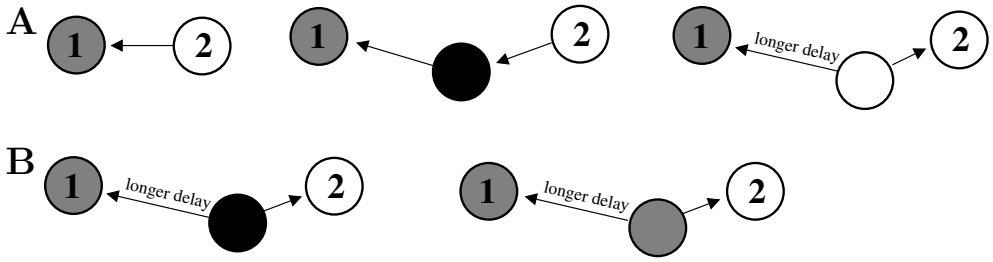

FIG. 7. *Schematic summary of the determination of subpopulation connectivity that we are able to achieve. Each pictured network configuration leads to a correlation between the spikes of neuron one and a delayed version of the spikes of neuron two. If one analyzed the joint statistics of the spikes of neurons one and two (e.g., with a covariogram), each example would appear to involve a direct connection from neuron two onto neuron one. (The unlabeled neuron is not measured.) Our result is that we can distinguish* (A) *network configurations in the top row from* (B) *network configurations in the bottom row using our analysis of the joint statistics of the stimulus and the spikes of neurons one and two. The subpopulation of each neuron is indicated by the shading (white, gray, or black).* (A) *We consider the network configurations in the top row to belong to the "direct connection class," as each configuration will be identified as a direct connection by our analysis. We cannot distinguish among the configurations in the direct connection class. Nonetheless, since each configuration contains a causal connection from neuron two's subpopulation (white) onto neuron one's subpopulation (gray), our analysis can still accurately determine connectivity at the level of subpopulations. From left to right, the configurations are a direct connection from neuron two onto neuron one, an indirect connection through an unmeasured neuron, and common input from neuron two's subpopulation.* (B) *We consider network configurations in the bottom row to belong to the "common input class," as each configuration will be identified as common input by our analysis. Since these configurations have no causal connection from neuron two's subpopulation (white) onto neuron one's subpopulation (gray), it is important that our analysis can distinguish them from the direct connection configurations* (A)*. From left to right, the configurations are common input from a different subpopulation (black) and common input from neuron one's subpopulation (gray).*

on the limitations caused by these conditions, we discuss the significance of subpopulation connectivity and the relationship between this approach and other works.

5.1. Identification of subpopulation connectivity. Recall that two neurons are in the same subpopulations if their effective kernels $\mathbf{h}_q$ (defined by fitting the uncoupled model (2.2)) are similar. In some contexts, neuroscientists would refer to these kernels as the neurons' *receptive fields*; in this case, a subpopulation would be a group of neurons with similar receptive fields.

We have shown that common input originating from within one neuron's subpopulation could appear like a direct connection from that neuron onto the other measured neuron. Hence, when we identify a direct connection between neurons, we can only conclude that there is a connection between those neurons' subpopulations.

We summarize our conclusions in Figure 7. The direct connection measure $\mathcal{W}$ and the common input measure $\mathcal{U}$ effectively divide network configurations into two classes; we will call these a direct connection class and a common input class. The top row (A) shows network configurations that would be classified as having a direct connection from neuron two onto neuron one. Besides the actual direct connection, this direct connection class contains an indirect connection through an unmeasured neuron and common input from neuron two's subpopulation. All three network configurations contain a causal connection from neuron two's subpopulation (white) onto neuron one's subpopulation (gray).

The bottom row (B) shows network configurations that would be classified as having common input. When the delay onto neuron one is longer (so that the correlations

mimic a direct connection from neuron two onto neuron one), the common input class contains networks with common input from different subpopulations and networks with common input from neuron one's subpopulation. In neither of these cases is there a connection from neuron two's subpopulation onto neuron one. Consequently, in order to accurately identify subpopulation connectivity, these configurations must be distinguished from the direct connection class of the first row. We have shown that, subject to the limitations mentioned above, we can make this distinction.

We argue that, in some experimental contexts, determining subpopulation connectivity is as informative as determining the actual connectivity between two measured neurons. In many experiments, electrodes are "blindly" inserted into the brain, and the precise identity of measured neurons remains unknown. In this situation, neurons are simply characterized by their response properties (e.g., their receptive fields), such as those captured by the effective kernels $\mathbf{h}_q^i$.

Since the precise identify of measured neurons is unknown, the best conclusion one can make about connectivity is that a neuron with response properties "A" is connected to a neuron with response properties "B." In other words, the best one can say is that a neuron from the subpopulation characterized by response properties "A" is connected to a neuron from the subpopulation characterized by response properties "B." This is the best possible conclusion even if we didn't have to worry about ambiguity introduced by connections from unmeasured neurons. Our central result is that we have developed an approach to achieve this best possible conclusion even in the presence of common input from unmeasured neurons.

5.2. Precise identity of subpopulations. The above discussion assumes the presence of discrete subpopulations. If this were the case, the statement that two neurons are from the same subpopulation would be unambiguous. Of course, in general, this is not the case. The response properties of neurons across a large population may be better modeled as a continuum, where the correlation coefficients $cc_{pq}^{\max}$ of (2.8) could be any value between 0 and 1. (Since cc_{pq}^{k} tends to zero for large $|k|$, the maximum is always nonnegative.) In order to make our subpopulation definition precise, we would like to have some cutoff value of $cc_{pq}^{\max}$, above which we could say that neurons p and q are from the same population and below which we could say they are from different subpopulations.

To explore this issue, we simulated the common input network of Figures 3(B) and 4 and the integrate-and-fire network of Figure 6(A), varying the model parameters to change[14] $cc_{32}^{\max}$. Although there was no clean cutoff, the cutoff value was around $cc_{32}^{\max} = 0.6$. If $cc_{32}^{\max}$ was near 0.6, the results were mixed, and the subpopulation of neuron three seemed to depend on model parameters. But for larger $cc_{32}^{\max}$, neuron three acted like a member of neuron two's subpopulation because the common input appeared as a direct connection in measure $\mathcal{W}$ (as in Figure 4(A)). Similarly, for $cc_{32}^{\max}$ much smaller than 0.6, neuron three acted like a member of a different subpopulation because the common input was correctly identified as common input (as in Figures 3(B) and 4(B)). Hence, at least for these coupling strengths and roughly equivalent firing rates, neurons p and q were effectively in the same subpopulation when $cc_{pq}^{\max}$ was well above 0.6. (See section 5.5 for examples of how strong coupling and disparity in firing rates can further complicate the picture.)

[14]To keep the discussion as simple as possible, we ensured that the maximum of cc_{32}^{k} occurred at the delay $k = 2$, since $\bar{W}_{32}^{j}$ was maximal at $j = 2$. Section 3.4 shows why cc_{32}^{2} is the important correlation coefficient for this case.

5.3. Heuristic explanation for results. To provide some intuition into how our approach successfully determines subpopulation connectivity, we give a heuristic explanation of why one should be able to distinguish subpopulation connectivity by analyzing the joint statistics of the measured spikes and the stimulus. We claim that one should expect that the relationship between the measured neurons' spikes and the stimulus will differ between the direct connection class of Figure 7(A) and the common input class of Figure 7(B).

For example, when the stimulus sequence happens to be optimal for neuron two and subsequently optimal for neuron one, the effectiveness of a connection from neuron two's subpopulation onto neuron one's subpopulation will be enhanced. (In this case, a spike from neuron two's subpopulation is likely to reach the neuron from neuron one's subpopulation when it is ready to fire.) Since in each network configuration in the direct connection class (Figure 7(A)) the correlation between neuron one and neuron two depends on a connection from neuron two's subpopulation onto neuron one, we expect the correlation to be especially strong for this particular stimulus sequence.

On the other hand, we would not expect the correlations in the common input class (Figure 7(B)) to be especially strong when the stimulus happens to be optimal for neuron two and subsequently optimal for neuron one. None of the connections leading to the correlation will be enhanced for this stimulus sequence, since no connection exists from neuron two's subpopulation onto neuron one's subpopulation. This example of an extreme stimulus sequence illustrates one case where the joint stimulus spike statistics will differ depending on subpopulation connectively. One might expect the differences to be evident even with other stimuli. Our results show that, at least for a simple model, one can exploit this difference to determine subpopulation connectivity.

5.4. Comparison to other approaches. Our approach succeeds in reconstructing subpopulation connectivity by combining spike correlation analysis [14, 1, 13] with white noise analysis [7, 5, 4]. It builds on previous work [10, 11] that did not address the presence of unmeasured neurons. We have previously reported [9] on our early attempts to address the unmeasured neurons where, since we did not require stimulus repeats, we had to assume that all unmeasured neurons had dissimilar kernels (effectively, that every unmeasured neuron was in its own subpopulation).

Our approach differs from the partial coherence of Rosenberg et al. [15] because it does not require measurement of the neuron producing the common input. In cases where one monitors multiple neurons simultaneously, partial coherence can rule out common input from the other measured neurons without appealing to the model assumptions underlying our analysis. Although there is a large literature in which researchers have developed methods to reconstruct the connectivity among measured neurons, we are unaware of others that explicitly account for unmeasured neurons. Without accounting for unmeasured neurons, common input from unmeasured neurons would be erroneously identified as a direct connection.

5.5. The weak coupling assumption. The analysis underlying the measures $\mathcal{W}$ and $\mathcal{U}$ relied on the assumption that the coupling $\bar{W}$ was small. The simulations demonstrate that one can obtain correct results even when the coupling is not weak. We used values of $\bar{W}^j_{pq}$ as large as 1.8 and values of $\sum_j \bar{W}^j_{pq}$ as large as 3.4. For this parameter range, the weak coupling assumption is not justified, yet the results successfully determined subpopulation connectivity.

At this point, we lack an analysis of the effects of strong coupling. We have discovered through simulations that violations of the weak coupling assumption can cause invalid results when the firing rates of the two measured neurons are greatly different. For example, if $E\{R_1^i\} \gg E\{R_2^i\}$, strong coupling can cause a direct connection from neuron one to neuron two to appear as common input. The same situation can also cause common input to appear as a direct connection from neuron two to neuron one. In other words, there is a bias for a faster neuron appearing to have a connection from a slower neuron and a bias against a slower neuron appearing to have a connection from a faster neuron. The strength of coupling at which the misidentification occurs depends on the degree of inequality between the firing rates.

For example, we analyzed a sequence of simulations of the direct connection of Figure 3(A) where we increased the disparity between the firing rate of neurons one and two. By the time neuron two fired ten times faster than neuron one, the direct connection was misidentified as common input, and we failed to reconstruct the subpopulation connectivity. On the other hand, when we halved the strength of the direct connection (and ran very long simulations), a direct connection was still accurately identified even when neuron two fired more than fifty times faster than neuron one.

We also analyzed a similar sequence of simulations of the common input configuration of Figure 3(B). The common input appeared as a direct connection from neuron two onto neuron one when neuron one fired over 20 times faster than neuron two. Because neuron three was not in neuron two's subpopulation ($c_{32}^{\max} < 0.2$), this misidentification is a failure in reconstructing subpopulation connectivity. When we increased the connection strengths by 50% (adjusting kernel parameters to keep $c_{32}^{\max} < 0.2$), the misidentification began when neuron one fired only eight times faster than neuron two. (As one might infer from the observations of section 5.2, when we changed the kernels to increase $cc_{32}^{\max}$, the common input was identified as a direct connection with lower disparities in firing rate.)

5.6. Improving statistical efficiency. Our reconstruction is based on an analysis of just a few stimulus-spike moments. We employed this moment-based approach because our intuition on such moments' behavior could guide development of this initial implementation of our subpopulation connectivity approach. One important demerit of this choice was made clear in our simulations, where we needed long simulations to obtain good results. To apply this approach to realistic neuroscience data, we will presumably need more statistically efficient techniques, such as maximum likelihood estimators, which will yield reliable estimates of subpopulation connectivity with less data.

5.7. Validations. Clearly, the assumptions of the analysis are idealizations that will never be satisfied by biological neuronal networks. The approach is viable only because accurate results can be obtained outside the strict assumptions (as demonstrated throughout section 4). However, section 5.5 demonstrated some violations of the assumptions that do lead to inaccurate results. Another possible source of inaccuracies is covariation in latency or excitability, as discussed by Brody [2]. Since such covariation is not addressed by the network model (2.1), this covariation could invalidate our results. To address possible sources of error, we must develop validation methods that can identify critical violations of assumptions that may skew the results. Such validations will allow one to trust that the results are accurate.

Ideally, one would like to test the accuracy of these results with *in vitro* experiments, where the actual connectivity can be determined by other means (such as with electrodes that enter neurons). Unfortunately, our approach depends on having

an experimentally controlled stimulus $\mathbf{X}$, where the relationship between the firing probabilities is given by (2.1). Given that *in vitro* preparations are typically severed from sensory receptors, this requirement may be difficult to achieve. A more promising testbed may be a lower organism, where the connectivity is known and neurons can be driven by a stimulus.

5.8. Extensions to other models. The model (2.1) was made as simple as possible to facilitate the analysis. It assumes, for example, that the response is an approximately linear function of the stimulus, that the network is in an asynchronous state, and that the internal dynamics of the neuron can be neglected. The results are valid only when the network is stimulated by white noise. An extension to more general elliptically symmetric stimuli should be possible. Since in this case, a linear-nonlinear model can be reconstructed (see, for example, [3]), the results should be attainable if one replaces the integration-by-parts formula (A.3) with a more general version.

We view the implementation presented in this paper simply as an example of a new framework of network analysis. The principle of analyzing joint input-output statistics may be generalized to reveal pairwise coupling in other network models. The current version should have only limited applicability to neuroscience experiments because the relationship of neural response to a stimulus will in most cases be more fundamentally nonlinear than the linear-nonlinear model (2.1). Extension of the results to more complicated models and stimuli will increase the range of applicability, allowing the approach to evolve into a useful tool for analyzing neuronal networks and other stimulus-driven networks.

Appendix A. Integration-by-parts formula. In our notation, we do not explicitly distinguish spatial versus temporal components of the stimulus, but rather let time be represented only by the temporal index of the kernels $\bar{\mathbf{h}}_q^i$ and the spikes R_q^i. We let each of the m components of $\mathbf{X}$ be independent standard normal variables, so that the probability density function of $\mathbf{X}$ is

$$\rho_{\mathbf{X}}(\mathbf{x}) = \frac{1}{(2\pi)^{m/2}} e^{-\frac{\|\mathbf{x}\|^2}{2}}. \tag{A.1}$$

To assist the reader, we derive an integration-by-parts formula (A.3), although such a formula is not new. Let $\mathbf{h}_k$ for $k = 1, 2, \ldots, K$ be linearly independent unit vectors corresponding to K kernels. We wish to compute

$$E\{\mathbf{X}F(\mathbf{h}_1 \cdot \mathbf{X}, \ldots, \mathbf{h}_K \cdot \mathbf{X})\},$$

where F is some smooth function with K arguments. Given the probability density function (A.1) for $\mathbf{X}$, this expected value is

$$\frac{1}{(2\pi)^{m/2}} \int \mathbf{x} F(\mathbf{h}_1 \cdot \mathbf{x}, \ldots, \mathbf{h}_K \cdot \mathbf{x}) e^{-\frac{\|\mathbf{x}\|^2}{2}} d\mathbf{x}.$$

Denote the standard unit vectors by $\mathbf{e}_j$, so that we can write the kernel $\mathbf{h}_k$ and the dot product $\mathbf{h}_k \cdot \mathbf{x}$ in component form as

$$\mathbf{h}_k = \sum_j h_{kj} \mathbf{e}_j \quad \text{and} \quad \mathbf{h}_k \cdot \mathbf{x} = \sum_j h_{kj} x_j,$$

where h_{kj} is the jth component of $\mathbf{h}_k$.

We calculate the components of $E\{\mathbf{X}F(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\}$. Through integration by parts with respect to x_j, the jth component is

$$\begin{aligned}
&E\{X_jF(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\}\\
&\quad=\frac{1}{(2\pi)^{m/2}}\int x_jF\left(\sum_k h_{1k}x_k,\dots,\sum_k h_{Kk}x_k\right)e^{-\frac{\|\mathbf{x}\|^2}{2}}d\mathbf{x}\\
&\quad=\frac{1}{(2\pi)^{m/2}}\sum_i h_{ij}\int F_i\left(\sum_k h_{1k}x_k,\dots,\sum_k h_{Kk}x_k\right)e^{-\frac{\|\mathbf{x}\|^2}{2}}d\mathbf{x}\\
&\quad=\sum_i h_{ij}E\{F_i(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\},
\end{aligned}$$

where F_i indicates the partial derivative of F with respect to the ith variable.

Putting the components together, we conclude that

$$\begin{aligned}
E\{\mathbf{X}F(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\}&=\sum_j E\{x_jF(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\}\mathbf{e}_j\\
&=\sum_i E\{F_i(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\}\left(\sum_j h_{ij}\mathbf{e}_j\right)\\
&=\sum_i E\{F_i(\mathbf{h}_1\cdot\mathbf{X},\dots,\mathbf{h}_K\cdot\mathbf{X})\}\mathbf{h}_i. \qquad \text{(A.2)}
\end{aligned}$$

The special case we need for our derivation is

$$\begin{aligned}
&E\{\mathbf{X}g_p(\mathbf{h}_p^i\cdot\mathbf{X})g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X})g_r(\mathbf{h}_r^{i-k}\cdot\mathbf{X})\}\\
&\quad=E\{g_p'(\mathbf{h}_p^i\cdot\mathbf{X})g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X})g_r(\mathbf{h}_r^{i-k}\cdot\mathbf{X})\}\mathbf{h}_p^i\\
&\qquad+E\{g_p(\mathbf{h}_p^i\cdot\mathbf{X})g_q'(\mathbf{h}_q^{i-j}\cdot\mathbf{X})g_r(\mathbf{h}_r^{i-k}\cdot\mathbf{X})\}\mathbf{h}_q^{i-j}\\
&\qquad+E\{g_p(\mathbf{h}_p^i\cdot\mathbf{X})g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X})g_r'(\mathbf{h}_r^{i-k}\cdot\mathbf{X})\}\mathbf{h}_r^{i-k} \qquad \text{(A.3)}
\end{aligned}$$

and the equivalent for fewer factors.

Appendix B. Equations for error function nonlinearity. The analysis for error function $\bar{g}_q(\cdot)$ (see (4.2)) mirrors the derivations outlined in [11]. In this appendix, we summarize the intermediate steps and then give the error function result for (3.8) and (3.11).

We define the effective error function parameters (ϵ_q, y_q) from the spikes of each neuron q by fitting to these spikes the uncoupled model (2.2) with nonlinearity,

$$g_q(y)=\frac{1}{2}\left[1+\operatorname{erf}\left(\frac{y-y_q}{\epsilon_q\sqrt{2}}\right)\right].$$

Denote the inner product between kernels by $\cos\theta_{pq}^j=\mathbf{h}_p^i\cdot\mathbf{h}_q^{i-j}$. (Note that for Gaussian white noise $\cos\theta_{pq}^j=cc_{pq}^j$; see (2.7).) Define the following expressions as

functions of the parameters ϵ_q, y_q, and $\cos\theta_{pq}^j$:

$$\delta_q = \frac{1}{\sqrt{1+\epsilon_q^2}},$$

$$\lambda_{qp}^j = \frac{\delta_q y_q - \delta_p^2 \delta_q y_p \cos\theta_{qp}^j}{\sqrt{2(1-\delta_p^2\delta_q^2\cos^2\theta_{qp}^j)}},$$

$$\mu_{qp}^j = \frac{\delta_p\delta_q}{2\pi\sqrt{1-\delta_p^2\delta_q^2\cos^2\theta_{qp}^j}} \exp\left(-\frac{\delta_p^2 y_p^2 - 2\delta_p^2\delta_q^2 y_p y_q \cos\theta_{qp}^j + \delta_q^2 y_q^2}{2(1-\delta_p^2\delta_q^2\cos^2\theta_{qp}^j)}\right),$$

$$\xi_{qp}^j = \frac{\delta_q^2(1-\delta_p^2\cos^2\theta_{qp}^j)}{1-\delta_p^2\delta_q^2\cos^2\theta_{qp}^j}.$$

Define a double complementary error function

$$\operatorname{derfc}(a,b,c) = \frac{4}{\pi}\int_a^\infty dy\, e^{-y^2} \int_{\frac{b-cy}{\sqrt{1-c^2}}}^\infty dz\, e^{-z^2}. \tag{B.1}$$

The function derfc is a two-dimensional analogue of the complementary error function (see [10]).

Using the fact that $\mathbf{h}_p^i \cdot \mathbf{X}$ and $\mathbf{h}_q^{i-j} \cdot \mathbf{X}$ are joint unit normal random variables with correlation $\cos\theta_{qp}^j$, we compute the following expected values:

$$E\{g_p'(\mathbf{h}_p^i\cdot\mathbf{X})g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X})\} = \frac{\delta_p}{2\sqrt{2\pi}}\exp\left(-\frac{\delta_p^2y_p^2}{2}\right)\operatorname{erfc}(\lambda_{qp}^j),$$

$$E\{g_p'(\mathbf{h}_p^i\cdot\mathbf{X})(g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X}))^2\} = \frac{\delta_p}{4\sqrt{2\pi}}\exp\left(-\frac{\delta_p^2y_p^2}{2}\right)\operatorname{derfc}(\lambda_{qp}^j,\lambda_{qp}^j,\xi_{qp}^j),$$

$$E\{g_p'(\mathbf{h}_p^i\cdot\mathbf{X})g_q'(\mathbf{h}_q^{i-j}\cdot\mathbf{X})\} = \mu_{qp}^j,$$

$$E\{g_p'(\mathbf{h}_p^i\cdot\mathbf{X})g_q'(\mathbf{h}_q^{i-j}\cdot\mathbf{X})g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X})\} = \frac{\mu_{qp}^j}{2}\operatorname{erfc}\left(\frac{\lambda_{qp}^j(1-\xi_{qp}^j)}{\sqrt{1-(\xi_{qp}^j)^2}}\right),$$

$$E\{g_p''(\mathbf{h}_p^i\cdot\mathbf{X})g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X})\} = \frac{\delta_p^3y_p}{2\sqrt{2\pi}}\exp\left(-\frac{\delta_p^2y_p^2}{2}\right)\operatorname{erfc}(\lambda_{qp}^j) - \delta_p^2\cos\theta_{qp}^j\mu_{qp}^j,$$

$$E\{g_p''(\mathbf{h}_p^i\cdot\mathbf{X})(g_q(\mathbf{h}_q^{i-j}\cdot\mathbf{X}))^2\} = \frac{\delta_p^3y_p}{4\sqrt{2\pi}}\exp\left(-\frac{\delta_p^2y_p^2}{2}\right)\operatorname{derfc}(\lambda_{qp}^j,\lambda_{qp}^j,\xi_{qp}^j) - \delta_p^2\cos\theta_{qp}^j\mu_{qp}^j\operatorname{erfc}\left(\frac{\lambda_{qp}^j(1-\xi_{qp}^j)}{\sqrt{1-(\xi_{qp}^j)^2}}\right),$$

$$E\{g_p''(\mathbf{h}_p^i\cdot\mathbf{X})g_q'(\mathbf{h}_q^{i-j}\cdot\mathbf{X})\} = \frac{\delta_p^2[y_p-\delta_q^2y_q\cos\theta_{qp}^j]\mu_{qp}^j}{(1-\delta_p^2\delta_q^2\cos^2\theta_{qp}^j)}.$$

We rewrite (3.8) and (3.11) in terms of the above quantities:

$$\begin{aligned} C_{21}^k = {} & \hat{W}_{21}^k\frac{\delta_1}{2\sqrt{2\pi}}\exp\left(-\frac{\delta_1^2y_1^2}{2}\right)\left[\operatorname{erfc}(\lambda_{21}^k) - \frac{1}{2}\operatorname{derfc}(\lambda_{21}^k,\lambda_{21}^k,\xi_{21}^k)\right] \\ & + \hat{W}_{12}^{-k}\frac{\delta_2}{2\sqrt{2\pi}}\exp\left(-\frac{\delta_2^2y_2^2}{2}\right)\left[\operatorname{erfc}(\lambda_{12}^{-k}) - \frac{1}{2}\operatorname{derfc}(\lambda_{12}^{-k},\lambda_{12}^{-k},\xi_{12}^{-k})\right] \\ & + \hat{U}_{21}^k\mu_{21}^k, \end{aligned} \tag{B.2}$$

$$
\begin{aligned}
A_1^k = \hat{W}_{21}^k \Bigg\{ & \frac{\delta_1^3 y_1}{2\sqrt{2\pi}} \exp\left(-\frac{\delta_1^2 y_1^2}{2}\right) \left[\operatorname{erfc}(\lambda_{21}^k) - \frac{1}{2}\operatorname{derfc}(\lambda_{21}^k, \lambda_{21}^k, \xi_{21}^k)\right] \\
& - \delta_1^2 \cos\theta_{21}^k \mu_{21}^k \left[1 - \operatorname{erfc}\left(\frac{\lambda_{21}^k(1-\xi_{21}^k)}{\sqrt{1-(\xi_{21}^k)^2}}\right)\right] \Bigg\} \\
& + \hat{W}_{12}^{-k} \mu_{12}^{-k} \left[1 - \operatorname{erfc}\left(\frac{\lambda_{12}^{-k}(1-\xi_{12}^{-k})}{\sqrt{1-(\xi_{12}^{-k})^2}}\right)\right] \\
& + \hat{U}_{21}^k \frac{\delta_1^2[y_1 - \delta_2^2 y_2 \cos\theta_{21}^k]\mu_{21}^k}{(1-\delta_1^2\delta_2^2\cos^2\theta_{21}^k)},
\end{aligned} \tag{B.3}
$$

$$
\begin{aligned}
A_2^k = & \hat{W}_{21}^k \mu_{21}^k \left[1 - \operatorname{erfc}\left(\frac{\lambda_{21}^k(1-\xi_{21}^k)}{\sqrt{1-(\xi_{21}^k)^2}}\right)\right] \\
& + \hat{W}_{12}^{-k} \Bigg\{ \frac{\delta_2^3 y_2}{2\sqrt{2\pi}} \exp\left(-\frac{\delta_2^2 y_2^2}{2}\right) \left[\operatorname{erfc}(\lambda_{12}^{-k}) - \frac{1}{2}\operatorname{derfc}(\lambda_{12}^{-k}, \lambda_{12}^{-k}, \xi_{12}^{-k})\right] \\
& - \delta_2^2 \cos\theta_{12}^{-k} \mu_{12}^{-k} \left[1 - \operatorname{erfc}\left(\frac{\lambda_{12}^{-k}(1-\xi_{12}^{-k})}{\sqrt{1-(\xi_{12}^{-k})^2}}\right)\right] \Bigg\} \\
& + \hat{U}_{21}^k \frac{\delta_2^2[y_2 - \delta_1^2 y_1 \cos\theta_{12}^{-k}]\mu_{12}^{-k}}{(1-\delta_2^2\delta_1^2\cos^2\theta_{12}^{-k})}.
\end{aligned} \tag{B.4}
$$

The key point of these long formulas is that, with the exception of $\hat{W}_{21}^k$, $\hat{W}_{12}^{-k}$, and $\hat{U}_{21}^k$, all expressions are functions of the error function parameters of the measured neurons (ϵ_1, ϵ_2, y_1, and y_2) and $\cos\theta_{21}^k = \cos\theta_{12}^{-k}$. The kernels (and hence $\cos\theta_{21}^k$) are computed from (3.6). The parameters ϵ_q and y_q, for $q = 1, 2$, can be calculated from (3.4) and (3.5) with the use of the formulas

$$
\begin{aligned}
E\{g_q(\mathbf{h}_q^i \cdot \mathbf{X})\} &= \frac{1}{2}\operatorname{erfc}\left(\frac{\delta_q y_q}{\sqrt{2}}\right), \\
E\{g_q'(\mathbf{h}_q^i \cdot \mathbf{X})\} &= \frac{\delta_q}{\sqrt{2\pi}} \exp\left(-\frac{\delta_q^2 y_q^2}{2}\right).
\end{aligned}
$$

Appendix C. Estimating confidence intervals. We estimate the confidence interval of our measures using essentially the procedure outlined in Appendix B of [10]. Besides changing the base variables to those needed for the current analysis, we make the following two minor changes. First, we calculate the covariances of inner products accurately using the covariances among all the factors in the product. Second, since the statistics from different delays are uncoupled in our equations, we ignore covariances among statistics from different delays.

Acknowledgment. The author thanks Dario Ringach for numerous helpful discussions throughout the development of this research.

MATHEMATICAL ANALYSIS OF THE GENERALIZED NATURAL MODES OF AN INHOMOGENEOUS OPTICAL FIBER*

E. M. KARTCHEVSKI†, A. I. NOSICH‡, AND G. W. HANSON§

Abstract. The eigenvalue problem for generalized natural modes of an inhomogeneous optical fiber without a sharp boundary is formulated as a problem for the set of time-harmonic Maxwell equations with the Reichardt condition at infinity in the cross-sectional plane. The generalized eigenvalues (including, as subsets, the well-known guided and leaky modes) of this problem are the complex propagation constants on a logarithmic Riemann surface. A theorem on spectrum localization is proved, and then the original problem is reduced to a nonlinear spectral problem with a compact integral operator. It is proved that the set of all eigenvalues of the original problem can only be a set of isolated points on the Riemann surface, and it is also proved that each eigenvalue depends continuously on the frequency and refraction index and can appear and disappear only at the boundary of the Riemann surface.

Key words. electromagnetic theory, optical fiber, waveguides, eigenvalue problem, guided modes

1. Introduction.

Optical fibers are dielectric waveguides (DWs), i.e., regular dielectric rods, having various cross sectional shapes, and where generally the refractive index of the dielectric may vary in the waveguide's cross section. Although existing technologies often result in a refractive index that is anisotropic, frequently it is possible to assume that the fiber is isotropic, which is the case investigated in this work. The study of the source-free electromagnetic fields, called *natural modes*, that can propagate on DWs necessitates that longitudinally the rod extend to infinity. Since often DWs are not shielded, the medium surrounding the waveguide transversely forms an unbounded domain, typically taken to be free space. This fact plays an extremely important role in the mathematical analysis of natural waveguide modes, and brings into consideration a variety of possible formulations. Each different formulation can be cast as an eigenvalue problem for the set of time-harmonic Maxwell equations, but they differ in the form of the condition imposed at infinity in the cross-sectional plane, and hence in the functional class of the natural-mode field. As we discuss below, this also restricts the localization of the eigenvalues in the complex plane of the eigenparameter.

Historically, the first DWs to be studied were step-index waveguides having circular cross section; interior to the waveguide, the refractive index was either homo-

geneous or coaxial-layered. In these cases, by using separation of variables, modal eigenvalue problems are easily reduced to families of transcendental dispersion equations associated with the azimuthal indices (see, e.g., [1], [2]). All questions concerning discreteness and existence of the natural-mode spectrum are settled "automatically" due to general results from the theory of complex variables and the analytic properties of cylindrical functions with integer indices and complex arguments.

For these circular cross section DWs the first class of natural modes to be studied were *purely guided modes*, which have real-valued wavenumbers. The fields of the guided modes are confined near to the waveguide, decaying exponentially transversely away from the waveguide, so that they belong to the space L_2 in the whole cross-sectional plane. Corresponding eigenvalue problems are self-adjoint. Later it was discovered that the guided modes of a circular DW can turn into (i.e., be analytically continued as) so-called *leaky-wave modes*, existing on the "improper" sheet of a square-root Riemann surface, with the wavenumbers migrating off the real axis of the "proper" sheet onto the "improper" sheet as some parameters of the structure vary [3]. It was noticed that leaky modes can be studied as solutions of a more general eigenvalue problem, without cross-sectional field confinement, due to some relaxed, although never explicitly formulated, condition at infinity.

Although leaky waves exist on an "improper" Riemann sheet, they have considerable physical importance in wave excitation and fiber discontinuity problems. In particular, it is known that the electromagnetic fields existing on a dielectric waveguide can be represented as a discrete sum of bound modes (which are the mentioned guided modes generated by the eigenvalues of the propagation constant on the real axis of the "proper" sheet) and a continuous sum (i.e., integral) of so-called *radiation modes* (whose physical sense still causes discussions) [1], [2], [4]. It has been shown that, although leaky waves are not themselves a part of a "proper" spectral field representation, in many cases the continuum of the radiation modes may be approximated by a discrete sum of leaky modes [5], representing the near field of a source-excited fiber. Often the leaky-wave sum can be reduced to a single term, providing a concise analytical form for the near-zone radiation field. Furthermore, various features in the far-field radiation pattern of a real, finite-length, source-driven fiber can be interpreted in terms of leaky-wave excitation. In addition to source-driven waveguides, leaky modes on longitudinally invariant fibers are important in the analysis of radiation and mode-conversion effects associated with waveguide discontinuities such as fiber splices [6], radiation from waveguide bends [7], and radiation from anisotropic fibers [8], [9]. Some properties of leaky modes on dielectric waveguides, and, in particular, dielectric fibers, are presented in [2], [3], [5], [6], [7], [8], [9], [10], [11], [12].

In addition to leaky modes, it was discovered that on the "proper" sheet, but off its real axis, one can also find other generalized eigenvalues (modal wavenumbers) [13] known as *complex modes*. Analogous results were obtained numerically for gradient-index DWs of arbitrary cross section [14]. These complex modes are often important in near-field fiber discontinuity problems and mode-matching analysis. It is important to note that all of these known types of natural modes can transform (be continued) one into another, following variation of some geometrical or material parameter or frequency. Due to the presence of the two-dimensional unbounded domain and the resulting Green's functions represented as Hankel functions, it is easy to see that the dispersion equations contain logarithmic as well as square-root–type branch points.

If the cross section is not circular, the study of the natural modes encounters both methodological and numerical problems. In [15] an elliptic DW was studied by using expansions in terms of Mathieu functions. However, in that work as well as in other studies of waveguides having complicated cross sections, or of multirod waveguides, the modal problems are reduced not to transcendental equations but to infinite matrix equations or integral equations (IEs). Hence, it is necessary to base the analysis on the theory of operator-functions depending on parameters. Once again, by restricting the desired field behavior in the cross-sectional plane, one arrives at different formulations of the eigenvalue problem in terms of the transverse condition at infinity; eigenvalue localization and the function class of the natural mode field are tied up with this condition.

In recent years, research on the natural modes of arbitrarily shaped DWs has been focused on the development of efficient and reliable computational methods. For instance, in [16] the eigenvalue problem for the natural modes of arbitrary DWs was studied by splitting the differential operator into self-adjoint and perturbation parts and using a discretization in terms of the eigenfunctions of the self-adjoint operator. This enabled the authors to develop a very efficient numerical technique, although its convergence was not proven.

In the papers on numerical methods for DWs, the mathematical grounding of the methods was frequently neglected; however, useful insight into the encountered difficulties and modal behavior has been discussed (e.g., see [17], [18]). The most rigorous efforts were connected with IE formulations. Within this class the domain IE method has the attractive advantage of being applicable to cross-sectionally inhomogeneous (and, in fact, anisotropic) DWs [19], [20]. A problem with domain IEs is that they are strongly singular, which previously prevented their use in a mathematical study of the spectrum of the eigenvalues, with the exception of [21] for the purely guided modes of an inhomogeneous DW. For real-valued propagation constants it was proven in [21] that the operator of the domain IE is semi-Fredholm.

A rigorous mathematical study of an arbitrary-shaped DW was performed in [22] within the guided (proper) mode formulation. This enabled the authors to make extensive use of the theory of unbounded self-adjoint operators. For example, by using the min-max principle, they proved the existence of guided modes, the number of which is finite and depends on frequency. However, generalized natural modes having complex valued propagation constants cannot be studied by this approach.

The above considerations give a new thrust to the idea of elaborating a generalized formulation of the modal eigenproblem in order to bring together all the possible natural-mode solutions. All of the known natural-mode solutions (i.e., guided modes, leaky modes, complex modes) satisfy the Reichardt condition [23] at infinity. The wavenumbers may be generally considered on the appropriate logarithmic Riemann surface. The Reichardt condition in this problem is connected with the fact that the wavenumber may be complex. For real wavenumbers on the principal ("proper") sheet of this Riemann surface, one can reduce the Reichardt condition to either the Sommerfeld radiation condition or to the condition of exponential decay. The Reichardt condition may be considered as a generalization of the Sommerfeld radiation condition and can be applied for complex wavenumbers. This condition may also be considered as the continuation of the Sommerfeld radiation condition from a part of the real axis of the complex parameter (wavenumber) to the appropriate logarithmic Riemann surface.

During recent years the Reichardt condition has been widely used for statements of various wave propagation problems [24], [25], [26]. By using the Reichardt condition, the problems on generalized modes of microstrip and slot lines on a cylindrical substrate were investigated in [27], [28], [29]. Tensor Green's functions of generic open waveguides with compact cross sections were analyzed in [30] by using Fourier transforms and IE techniques in the transform domain. It was shown that the complex-valued poles of analytic continuations of the Green's functions satisfy a certain eigenvalue problem. Their residues can be interpreted as the generalized natural modes. In this case, the eigenvalue problem should be formulated with the Reichardt condition at infinity. Reducing Maxwell's equations to an IE and converting the latter to a Fredholm second kind equation enabled the proof of some important properties of the spectrum of the generalized modes. Furthermore, in [31], [32] a similar formulation was applied to study generalized guided modes in DWs, and a numerical algorithm was developed based on a Galerkin discretization in terms of a trigonometric basis.

In this paper we extend the approach of [30], [31], [32] to the analysis of generalized natural modes of arbitrary-cross-section DWs having inhomogeneous (although continuous) refractive index. Here, we use the model of DW without a sharp boundary, as was proposed in [33]. Such an approach enables one to reduce the original problem to a nonlinear spectral problem with a compact integral operator, and was originally introduced in [34] and used in [35]. We present a unified and rigorous theory of generalized natural modes in terms of the Reichardt condition at infinity.

The rest of this paper is organized as follows. Physical assumptions, basic equations, and notation are presented in section 2. In section 3 we formulate the modal eigenvalue problem as a problem for the set of time-harmonic Maxwell equations with the Reichardt condition at infinity in the cross-sectional plane. The eigenvalues of this problem are the complex propagation constants of the natural modes, and we introduce a classification of modal eigenvalues in terms of their location on the logarithmic Riemann surface. In section 4 we prove a theorem on localization of eigenvalues, where it is established that there exists a domain free of eigenvalues on this surface. In section 5 we investigate the eigenvalues as functions of frequency and refractive index, and we reduce the original problem to a nonlinear spectral problem with a compact integral operator. Using general results from the spectral theory of operator-valued functions [36], we prove that the set of all eigenvalues of the original problem can only be a set of isolated points on the logarithmic Riemann surface, and also we prove that each eigenvalue depends continuously on frequency and refractive index, and can appear and disappear only at the boundary of the logarithmic Riemann surface.

2. Basic relations. We consider the generalized natural modes of the regular DW shown in Figure 1. Let the three-dimensional space $\{(x_1, x_2, x_3) : -\infty < x_1, x_2, x_3 < \infty\}$ be occupied by an isotropic source-free medium, and let the refractive index be prescribed as a positive real-valued function $n = n(x_1, x_2)$ independent of the longitudinal coordinate x_3 and equal to a constant n_∞ outside a cylinder. The axis of the cylinder is parallel to the x_3-axis, and its cross section is a bounded domain Ω with a Lipschitz boundary on the plane $\mathbb{R}^2 = \{(x_1, x_2) : -\infty < x_1, x_2 < \infty\}$. Denote by Ω_∞ the unbounded domain $\Omega_\infty = \mathbb{R}^2 \setminus \overline{\Omega}$, and denote by n_+ the maximum of the function n in the domain Ω, where $n_+ > n_\infty$. Let the function n belong to the space of real-valued twice continuously differentiable functions in $\mathbb{R}^2$.

The modal problem can be formulated as a vector eigenvalue problem for the set of harmonic Maxwell equations, assuming that electric and magnetic field vectors

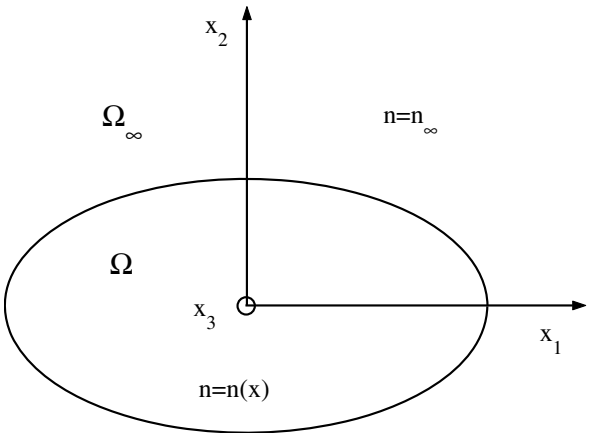

FIG. 1. *Geometry of a dielectric waveguide.*

have the form

$$\mathcal{E}(x, x_3, t) = \mathrm{Re}\left(\mathrm{E}(x)\exp\left(i\beta x_3 - i\omega t\right)\right), \tag{1}$$

$$\mathcal{H}(x, x_3, t) = \mathrm{Re}\left(\mathrm{H}(x)\exp\left(i\beta x_3 - i\omega t\right)\right). \tag{2}$$

Here $x = (x_1, x_2)$, $\omega > 0$ is the radian frequency, β is the complex-valued modal wavenumber (or propagation constant), and E and H are complex amplitudes of $\mathcal{E}$ and $\mathcal{H}$. For the sake of clarity, we note that, unlike in [22], we consider the propagation constant β as an unknown complex parameter and $\omega > 0$ as a given parameter. Such a choice seems to be commonly adopted in the fiber optics and microwave research communities due to the easy control of frequency.

For the fields of the form (1), (2), the set of Maxwell equations becomes

$$\mathrm{Rot}_\beta \mathrm{E} = i\omega\mu_0 \mathrm{H}, \quad x \in \mathbb{R}^2, \tag{3}$$

$$\mathrm{Rot}_\beta \mathrm{H} = -i\omega\varepsilon_0 n^2 \mathrm{E}, \quad x \in \mathbb{R}^2. \tag{4}$$

Here ε_0, μ_0 are the free-space dielectric and magnetic constants, respectively, and

$$\mathrm{Rot}_\beta \mathrm{E} = \begin{bmatrix} \partial E_3/\partial x_2 - i\beta E_2 \\ i\beta E_1 - \partial E_3/\partial x_1 \\ \partial E_2/\partial x_1 - \partial E_1/\partial x_2 \end{bmatrix}. \tag{5}$$

By $C^2(\mathbb{R}^2)$ denote the space of twice continuously differentiable in $\mathbb{R}^2$ complex-valued functions. We shall be seeking nonzero solutions $[\mathrm{E}, \mathrm{H}]$ of set (3), (4) in the space $(C^2(\mathbb{R}^2))^6$.

Let F be a three-dimensional vector-function,

$$\mathrm{F} = \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix} \in \left(C^2(\mathbb{R}^2)\right)^3,$$

and let $u \in C^2(\mathbb{R}^2)$ be a scalar function. By definition, set

$$\mathrm{Div}_\beta \mathrm{F} = \frac{\partial F_1}{\partial x_1} + \frac{\partial F_2}{\partial x_2} + i\beta F_3, \tag{6}$$

$$\Delta u = \frac{\partial^2 u}{\partial x_1^2} + \frac{\partial^2 u}{\partial x_2^2}, \tag{7}$$

$$\mathrm{Grad}_\beta u = \begin{bmatrix} \partial u/\partial x_1 \\ \partial u/\partial x_2 \\ i\beta u \end{bmatrix}, \quad \mathrm{grad} u = \begin{bmatrix} \partial u/\partial x_1 \\ \partial u/\partial x_2 \\ 0 \end{bmatrix}, \tag{8}$$

$$\mathrm{grad}_2 u = \begin{bmatrix} \partial u/\partial x_1 \\ \partial u/\partial x_2 \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} F_1 \\ F_2 \end{bmatrix}. \tag{9}$$

By direct calculation it is easy to obtain the following equations:

$$\mathrm{Div}_\beta \left(\mathrm{Grad}_\beta u\right) = \Delta u - \beta^2 u, \tag{10}$$

$$\mathrm{Div}_\beta \left(\mathrm{Rot}_\beta \mathrm{F}\right) = 0, \tag{11}$$

$$\mathrm{Div}_\beta \left(u\mathrm{F}\right) = u\mathrm{Div}_\beta \mathrm{F} + \left(\mathrm{F}, \mathrm{grad} u\right), \tag{12}$$

$$\mathrm{Rot}_\beta \left(\mathrm{Grad}_\beta u\right) = 0, \tag{13}$$

$$\mathrm{Rot}_\beta \left(\mathrm{Rot}_\beta \mathrm{F}\right) = -\Delta \mathrm{F} + \beta^2 \mathrm{F} + \mathrm{Grad}_\beta \left(\mathrm{Div}_\beta \mathrm{F}\right), \tag{14}$$

where

$$(\mathrm{F}, \mathrm{L}) = \sum_{i=1}^{3} F_i L_i. \tag{15}$$

LEMMA 2.1. *If* $[\mathrm{E}, \mathrm{H}]$ *is a solution of the set* (2.3), (2.4), *then for* $x \in \mathbb{R}^2$

$$\mathrm{Rot}_\beta \left(\mathrm{Rot}_\beta \mathrm{E}\right) = k^2 n^2 \mathrm{E}, \tag{16}$$

$$\mathrm{Rot}_\beta \left(n^{-2} \mathrm{Rot}_\beta \mathrm{H}\right) = k^2 \mathrm{H}, \tag{17}$$

$$\mathrm{Div}_\beta \left(n^2 \mathrm{E}\right) = 0, \tag{18}$$

$$\mathrm{Div}_\beta \left(\mathrm{H}\right) = 0, \tag{19}$$

where $k^2 = \varepsilon_0 \mu_0 \omega^2$.

Proof. Applying the Rot_β operator to both sides of (3) and (4), we obtain (16), (17). Applying the Div_β operator to both sides of (3) and (4) and using (11), we obtain (18), (19). ∎

LEMMA 2.2. *If* $[\mathrm{E}, \mathrm{H}]$ *is a solution of the set* (2.3), (2.4), *then*

$$\mathrm{Div}_\beta \left(\left(n^2 - n_\infty^2\right) \mathrm{E}\right) = n_\infty^2 (\mathrm{E}, n^{-2} \mathrm{grad} n^2), \quad x \in \mathbb{R}^2. \tag{20}$$

Proof. Using (12) leads to

$$\mathrm{Div}_\beta \left(\left(n^2 - n_\infty^2\right) \mathrm{E}\right) = \left(n^2 - n_\infty^2\right) \mathrm{Div}_\beta \mathrm{E} + \left(\mathrm{E}, \mathrm{grad}\left(n^2 - n_\infty^2\right)\right), \quad x \in \mathbb{R}^2. \tag{21}$$

Taking into account (18) and (12), we arrive at

$$-\mathrm{Div}_\beta \mathrm{E} = (\mathrm{E}, n^{-2} \mathrm{grad} n^2), \quad x \in \mathbb{R}^2. \tag{22}$$

Combining (21) and (22), we obtain (20). ∎

LEMMA 2.3. *If* $[\mathrm{E},\mathrm{H}]$ *is a solution of the set* (2.3), (2.4), *then*

$$\left[\Delta + \left(k^2 n_\infty^2 - \beta^2\right)\right] \begin{bmatrix} \mathrm{E} \\ \mathrm{H} \end{bmatrix} = 0, \quad x \in \Omega_\infty. \tag{23}$$

Proof. The function n is equal to a constant n_∞ in the domain Ω_∞. Therefore we obtain (23) from (16)–(19) and (14). □

3. Reichardt condition. Because the domain Ω_∞ is unbounded, to have the problem formulation complete we have to specify the behavior of E and H at infinity. This can be done in various ways; for the problem under consideration the most general condition is the Reichardt condition [23], as discussed below. Denote by Ω_R a circle $\Omega_R = \left\{x \in \mathbb{R}^2 : |x| \le R\right\}$, and by Γ_R the boundary of Ω_R.

DEFINITION 3.1. *Let* R_0 *be a large positive constant such that* $\Omega \subset \Omega_{R_0}$. *We say that functions* E *and* H *satisfy the Reichardt condition if the functions* E *and* H *can be represented for all* $x \in \mathbb{R}^2 \setminus \Omega_{R_0}$ *as*

$$\begin{bmatrix} \mathrm{E} \\ \mathrm{H} \end{bmatrix} = \sum_{l=-\infty}^{\infty} \begin{bmatrix} \mathrm{A}_l \\ \mathrm{B}_l \end{bmatrix} H_l^{(1)}(\chi r) \exp(il\varphi), \tag{24}$$

where $H_l^{(1)}$ *is the Hankel function of the first kind and index* l *(see, e.g.,* [37]*),* (r,φ) *are the polar coordinates of the point* x, *and* $\chi = \sqrt{k^2 n_\infty^2 - \beta^2}$. *The series in* (3.1) *should converge uniformly and absolutely.*

DEFINITION 3.2. *By* Λ *denote the Riemann surface of the function* $\ln \chi(\beta)$. *A nonzero vector* $[\mathrm{E},\mathrm{H}] \in (C^2(\mathbb{R}^2))^6$ *is referred to as a* generalized eigenvector *(or eigenmode) of the problem* (2.3), (2.4), *and* (3.1) *corresponding to an eigenvalue* $\beta \in \Lambda$ *if the relations of problem* (2.3), (2.4), *and* (3.1) *are valid.*

In order to discuss the Reichardt condition in more detail, we need to analyze the Riemann surface Λ and consider the different types of modes that are possible.

3.1. Riemann surface Λ. The Hankel functions $H_l^{(1)}(\chi(\beta)r)$ are many-valued functions of the variable β. If we want to consider these functions as holomorphic functions, it is seen that β should be considered on the set Λ, which is the Riemann surface of the function $\ln \chi(\beta)$. This is due to the fact that Hankel functions can be represented as

$$H_l^{(1)}(\chi r) = c_l^{(1)}(\chi r) \ln(\chi r) + R_l^{(1)}(\chi r), \tag{25}$$

where $c_l^{(1)}(\chi r)$ and $R_l^{(1)}(\chi r)$ are holomorphic single-valued functions (see, e.g., [37]). The Riemann surface Λ is infinitely sheeted, with each sheet having two branch points, $\beta = \pm k n_\infty$. More precisely, due to the branching of $\chi(\beta)$ itself, we consider an infinite number of logarithmic branches Λ_m, $m = 0, \pm 1, \ldots$, each consisting of two square-root sheets of the complex variable β: $\Lambda_m^{(1)}$ and $\Lambda_m^{(2)}$. By $\Lambda_0^{(1)}$ denote the principal ("proper") sheet of Λ, which is specified by the conditions

$$-\pi/2 < \arg \chi(\beta) < \frac{3\pi}{2}, \quad \mathrm{Im}(\chi(\beta)) \ge 0, \quad \beta \in \Lambda_0^{(1)}. \tag{26}$$

The "improper" sheet $\Lambda_0^{(2)}$ is specified by the conditions

$$-\pi 2 < \arg \chi(\beta) < \frac{3\pi}{2}, \quad \mathrm{Im}(\chi(\beta)) < 0, \quad \beta \in \Lambda_0^{(2)}. \tag{27}$$

Denote also the whole real axis of $\Lambda_0^{(1)}$ as $R_0^{(1)}$, and that of $\Lambda_0^{(2)}$ as $R_0^{(2)}$. All the other pairs of sheets $\Lambda_{m\neq 0}^{(1),(2)}$ differ from $\Lambda_0^{(1),(2)}$ by a shift in $\arg\chi(\beta)$ equal to $2\pi m$, and satisfy the conditions

$$
\begin{aligned}
&-\pi/2+2\pi m<\arg\chi(\beta)<\frac{3\pi}{2}+2\pi m, \quad \operatorname{Im}(\chi(\beta))\geq 0, \quad \beta\in\Lambda_m^{(1)},\\
&-\pi/2+2\pi m<\arg\chi(\beta)<\frac{3\pi}{2}+2\pi m, \quad \operatorname{Im}(\chi(\beta))< 0, \quad \beta\in\Lambda_m^{(2)}.
\end{aligned}
\tag{28}
$$

Hence, on $\Lambda_0^{(1)}$ there is only a pair of branch-cuts dividing it from $\Lambda_0^{(2)}$; they run along the real axis at $|\beta|<kn_\infty$ and along the imaginary axis. On $\Lambda_0^{(2)}$, additionally, there is a pair of branch-cuts dividing it from $\Lambda_{\pm 1}^{(2)}$; they run along the real axis at $|\beta|>kn_\infty$.

3.2. Purely guided, complex, and leaky-wave modes. Denote a set of points on the real axis $R_0^{(1)}$ of the sheet $\Lambda_0^{(1)}$ by G, that is, the union of two intervals:

$$
G=\{\beta\in R_0^{(1)}: kn_\infty<|\beta|<kn_+\}. \tag{29}
$$

By $C_0^{(1)}$ denote the set

$$
C_0^{(1)}=\{\beta\in\Lambda_0^{(1)}:\operatorname{Re}\beta\neq 0\}\setminus R_0^{(1)}. \tag{30}
$$

Propagation constants β of purely guided modes, complex modes, and leaky-wave modes belong to sets $G\subset\Lambda_0^{(1)}$, $C_0^{(1)}\subset\Lambda_0^{(1)}$, and $\Lambda_0^{(2)}\setminus R_0^{(2)}$, respectively.

If $-\pi/2<\arg\chi<3\pi/2$, then the large-argument asymptotic forms of the Hankel functions of the first kind are known (see, e.g., [37]) to be

$$
H_l^{(1)}(\chi r)=\sqrt{\frac{2}{\pi\chi r}}\exp\left[i\left(\chi r-\frac{l\pi}{2}-\frac{\pi}{4}\right)\right]\left[1+O\left(\frac{1}{\chi r}\right)\right], \quad r\to\infty. \tag{31}
$$

Hence, if $-\pi/2<\arg\chi<3\pi/2$, $\operatorname{Im}(\chi)\neq 0$, and a function $[\mathrm{E},\mathrm{H}]$ satisfies the Reichardt condition, then this function satisfies the following condition at infinity:

$$
\begin{bmatrix}\mathrm{E}\\ \mathrm{H}\end{bmatrix}=\exp(i\chi r)\,O\left(\frac{1}{\sqrt{r}}\right), \quad r\to\infty. \tag{32}
$$

It is easy to see that for purely guided and complex modes, $\operatorname{Im}(\chi)>0$. Therefore corresponding eigenmodes $[\mathrm{E},\mathrm{H}]$ decay at infinity as $\exp(-\operatorname{Im}(\chi)r)r^{-1/2}$. Eigenvectors $[\mathrm{E},\mathrm{H}]$ of leaky-wave modes grow at infinity as $\exp(-\operatorname{Im}(\chi)r)r^{-1/2}$ because $\operatorname{Im}(\chi)<0$ for them.

3.3. Radiation modes. By D denote the set

$$
D=\{\beta\in\Lambda_0^{(1)}:\operatorname{Re}\beta=0\}\bigcup\{\beta\in R_0^{(1)}:|\beta|<kn_\infty\}. \tag{33}
$$

The continuous spectrum of radiation modes belongs to domain D, and each radiation mode can be expressed as (see [1])

$$
\begin{bmatrix}\mathrm{E}\\ \mathrm{H}\end{bmatrix}=\sum_{l=-\infty}^{\infty}\begin{bmatrix}\mathrm{A}_l\\ \mathrm{B}_l\end{bmatrix}H_l^{(1)}(\chi r)\exp(il\varphi)+\sum_{l=-\infty}^{\infty}\begin{bmatrix}\mathrm{C}_l\\ \mathrm{D}_l\end{bmatrix}H_l^{(2)}(\chi r)\exp(il\varphi), \tag{34}
$$

where $x \in \mathbb{R}^2 \setminus \Omega_{R_0}$ and $H_l^{(2)}$ is the Hankel function of the second kind and index l (see, e.g., [37]).

If $-\pi/2 < \arg\chi < 3\pi/2$, then the large-argument asymptotic forms of the Hankel functions of the second kind are known (see, e.g., [37]) to be

$$H_l^{(2)}(\chi r) = \sqrt{\frac{2}{\pi\chi r}} \exp\left[-i\left(\chi r - \frac{l\pi}{2} - \frac{\pi}{4}\right)\right]\left[1 + O\left(\frac{1}{\chi r}\right)\right], \quad r \to \infty. \tag{35}$$

It is easy to see that for radiation modes $\mathrm{Im}(\chi) = 0$, and that the radiation modes satisfy the following condition at infinity:

$$\begin{bmatrix} \mathrm{E} \\ \mathrm{H} \end{bmatrix} = O\left(\frac{1}{\sqrt{r}}\right), \quad r \to \infty. \tag{36}$$

The Reichardt condition (24) for all functions which satisfy (23) and all $\beta \in D$ is equivalent to the Sommerfeld condition

$$\left(\frac{\partial}{\partial r} - i\chi\right)\begin{bmatrix} \mathrm{E} \\ \mathrm{H} \end{bmatrix} = o\left(\frac{1}{\sqrt{r}}\right), \quad r \to \infty, \tag{37}$$

a fact which was proven in [38]. Therefore, radiation modes do not satisfy the Reichardt condition (24). In section 4 we will prove that the set D is free of the eigenvalues of problem (3), (4), and (24). In section 5, using the Reichardt condition (24), we will reduce problem (3), (4), and (24) to a problem with a purely point spectrum. Therefore, in this work we will not investigate the continuous spectrum of radiation modes.

3.4. Mode notation. The eigenvectors corresponding to the eigenvalues $\beta \in R_0^{(1)}$ such that $|\beta| < kn_\infty$ and satisfying the Sommerfeld condition (37) do not exist in a "passive" DW (i.e., when $\mathrm{Im}n^2 = 0$), which we investigate in this paper. However, if the waveguide is "active," i.e., if $\mathrm{Im}n^2 < 0$, then such modes, radiating to $r \to \infty$ (i.e., satisfying the Sommerfeld condition (37)) and propagating along x_3 without attenuation, may exist. In contrast, the eigenvectors corresponding to the eigenvalues $\beta \in G \subset R_0^{(1)}$ satisfy the condition of exponential decay at infinity. We suggest calling all natural modes generated by the real-axis eigenvalues *eigenmodes*, and, to distinguish between them, calling the first ones *radiating eigenmodes* and the second *guided-wave eigenmodes*. Note, however, that our radiating eigenmodes should not be confused with the "radiation modes" discussed in the previous section. Note that the condition (24) leads to a non–self-adjoint problem in general, which becomes self-adjoint if $\beta \in G$, i.e., for the guided-wave eigenmodes.

If $\beta \in \Lambda_0^{(1),(2)}$ but off $R_0^{(1)}$, then the corresponding modes will be called *quasi eigenmodes*: they consist of the exponentially decaying *"proper" complex quasi eigenmodes* if $\beta \in C_0^{(1)}$, the exponentially growing *leaky-wave quasi eigenmodes* if $\beta \in \Lambda_0^{(2)} \setminus R_0^{(2)}$, and the exponentially growing *"anti-guided" quasi eigenmodes* if $\beta \in R_0^{(2)}$ such that $|\beta| > kn_\infty$.

For all $m \neq 0$, $l = 0, \pm1, \pm2, \ldots$, and $\beta \in \bigcup_{m\neq0}(\Lambda_m^{(1)} \bigcup \Lambda_m^{(2)})$ we have

$$H_l^{(1)}(\chi \exp(i2\pi m)r) = \alpha_l^{(m)} H_l^{(1)}(\chi r) + \gamma_l^{(m)} H_l^{(2)}(\chi r), \qquad \alpha_l^{(m)}, \gamma_l^{(m)} \neq 0. \tag{38}$$

All of the modes whose wavenumbers are located on the higher-order pairs of sheets $\Lambda_{m\neq0}^{(1),(2)}$ will be collectively called *pseudoeigenmodes* because, according to (31), (35),

and (38), they are composed of a sum of incoming and outgoing cylindrical waves. Another justification of this terminology is that all of the possible eigenmodes in a "passive" DW are solutions of a self-adjoint problem, whereas quasi eigenmodes and pseudoeigenmodes satisfy non–self-adjoint problems.

The eigenvalues β on Λ possess a symmetry which is a consequence of equivalency between positive and negative directions along the longitudinal axis x_3 and time t (see [33]). Namely, if β is an eigenvalue and $[\mathrm{E},\mathrm{H}]$ is a corresponding generalized eigenvector, then $-\beta$ is also an eigenvalue, with the generalized eigenvector given by $[-\mathrm{E},\mathrm{H}]$. Further, because $\operatorname{Im}\omega = 0$ and $\operatorname{Im} n = 0$, the complex-conjugate numbers $\pm\overline{\beta}$ are eigenvalues as well, with the eigenvectors given by $\left[\mp\overline{\mathrm{E}}, -\overline{\mathrm{H}}\right]$. All these facts can be easily verified by direct substitution into (3), (4), and (24). We shall call the above-mentioned modes *forward*, *backward*, *conjugate*, and *backward-conjugate* modes, respectively.

4. Localization of the eigenvalues.

THEOREM 4.1. *The sets* $B = \{\beta \in R_0^{(1)} : |\beta| \geq kn_+\}$ *and* D *are free of the eigenvalues of problem* (2.3), (2.4), *and* (3.1).

Proof. Suppose that conditions (3), (4), and (24) are satisfied for some $[\mathrm{E},\mathrm{H}] \in (C^2(\mathbb{R}^2))^6$ and $\beta \in B$. Multiplying both sides of (17) by $\overline{\mathrm{H}}$, integrating over $\mathbb{R}^2$, and using (31), we obtain

$$
\begin{aligned}
k^2 \int_{\mathbb{R}^2} |\mathrm{H}|^2 dx &= \int_{\mathbb{R}^2} \left(\mathrm{Rot}_\beta \left(\frac{1}{n^2} \mathrm{Rot}_\beta \mathrm{H} \right), \overline{\mathrm{H}} \right) dx \\
&= \int_{\mathbb{R}^2} \left(\frac{1}{n^2} \mathrm{Rot}_\beta \mathrm{H}, \overline{\mathrm{Rot}_\beta \mathrm{H}} \right) dx \\
&\geq \frac{1}{n_+^2} \int_{\mathbb{R}^2} \left(\mathrm{Rot}_\beta \mathrm{H}, \overline{\mathrm{Rot}_\beta \mathrm{H}} \right) dx \\
&= \frac{1}{n_+^2} \int_{\mathbb{R}^2} \left(\mathrm{Rot}_\beta \left(\mathrm{Rot}_\beta \mathrm{H} \right), \overline{\mathrm{H}} \right) dx.
\end{aligned} \tag{39}
$$

Combining this with (19) and (14), we obtain

$$
\begin{aligned}
k^2 \int_{\mathbb{R}^2} |\mathrm{H}|^2 dx &\geq \frac{1}{n_+^2} \int_{\mathbb{R}^2} \left(-\Delta \mathrm{H} + \beta^2 \mathrm{H}, \overline{\mathrm{H}} \right) dx \\
&= \frac{1}{n_+^2} \int_{\mathbb{R}^2} |\operatorname{grad} \mathrm{H}|^2 dx + \frac{\beta^2}{n_+^2} \int_{\mathbb{R}^2} |\mathrm{H}|^2 dx.
\end{aligned} \tag{40}
$$

Therefore, we have

$$
\left(\beta^2 - k^2 n_+^2 \right) \int_{\mathbb{R}^2} |\mathrm{H}|^2 dx + \int_{\mathbb{R}^2} |\operatorname{grad} \mathrm{H}|^2 dx \leq 0. \tag{41}
$$

Hence, if $\beta \in B$ and $|\beta| > kn_+$, then $\mathrm{H} = 0$ for $x \in \mathbb{R}^2$, and

$$
\mathrm{E} = \frac{-1}{(i\omega\varepsilon_0 n^2)} \mathrm{Rot}_\beta \mathrm{H} = 0 \tag{42}
$$

for $x \in \mathbb{R}^2$. If $\beta \in B$ and $|\beta| = kn_+$, then the function H is equivalent to a constant in $\mathbb{R}^2$, but if H satisfies (24), then it must vanish at infinity for all $\beta \in B$. Therefore,

if $\beta \in B$ and $|\beta| = kn_+$, then $\mathrm{H} = 0$ for $x \in \mathbb{R}^2$, and $\mathrm{E} = 0$ for $x \in \mathbb{R}^2$. Therefore the vector $[\mathrm{E}, \mathrm{H}]$ is not an eigenvector of problem (3), (4), and (24) if $\beta \in B$.

Now suppose that conditions (3), (4), and (24) are satisfied for some $[\mathrm{E}, \mathrm{H}] \in (C^2(\mathbb{R}^2))^6$ and $\beta \in D$. Multiplying both sides of (16) by $\overline{\mathrm{E}}$, integrating over Ω_R where $R \geq R_0$, and using (14) and (18), we obtain

$$
\begin{aligned}
(43) \quad k^2 \int_{\Omega_R} n^2 \left|\mathrm{E}\right|^2 dx &= \int_{\Omega_R} \left(\mathrm{Rot}_\beta \left(\mathrm{Rot}_\beta \mathrm{E}\right), \overline{\mathrm{E}}\right) dx \\
&= \int_{\Omega_R} \left(-\Delta \mathrm{E} + \beta^2 \mathrm{E} + \mathrm{Grad}_\beta \left(\mathrm{Div}_\beta \mathrm{E}\right), \overline{\mathrm{E}}\right) dx \\
&= \int_{\Omega_R} \left|\mathrm{grad}\, \mathrm{E}\right|^2 dx - \int_{\Gamma_R} \left(\frac{\partial \mathrm{E}}{\partial \left|x\right|}, \overline{\mathrm{E}}\right) dx + \beta^2 \int_{\Omega_R} \left|\mathrm{E}\right|^2 dx \\
&\quad - \int_{\Omega_R} \left|\mathrm{Div}_\beta \mathrm{E}\right|^2 dx.
\end{aligned}
$$

For all $\beta \in D$ the number β^2 is real, and therefore we have

$$
(44) \qquad \mathrm{Im} \int_{\Gamma_R} \left(\frac{\partial \mathrm{E}}{\partial \left|x\right|}, \overline{\mathrm{E}}\right) dx = 0, \quad R \geq R_0.
$$

If we combine this with (24), we obtain

$$
(45) \qquad 2\pi\chi R \sum_{l=-\infty}^{\infty} \mathrm{Im} \left[H_l^{(2)} \left(\chi R\right) H_l^{(1)'} \left(\chi R\right)\right] \left|\mathrm{A}_l\right|^2 = 0, \quad R \geq R_0.
$$

We also have

$$
(46) \qquad \mathrm{Im} \left[H_l^{(2)} \left(\chi R\right) H_l^{(1)'} \left(\chi R\right)\right] = \frac{2}{\pi \chi R}, \quad l = 0, \pm 1, \pm 2, \ldots,
$$

which leads to $A_l = 0$ for all l and any $R \geq R_0$. Hence $\mathrm{E} = 0$ for $r \geq R_0$. Under the assumption of the smoothness of the function n, we have $\mathrm{E} = 0$ for $x \in \Omega_{R_0}$ (see [39, p. 190]) and

$$
(47) \qquad \mathrm{H} = \frac{1}{(i\omega\mu_0)} \mathrm{Rot}_\beta \mathrm{E} = 0
$$

for $x \in \mathbb{R}^2$. Therefore the vector $[\mathrm{E}, \mathrm{H}]$ is not an eigenvector of problem (3), (4), and (24) if $\beta \in D$. The proof of the theorem is complete. □

5. Discreteness and dependence of the eigenvalues on parameters. Now we shall prove that the set of all eigenvalues of problem (3), (4), and (24) can be only a set of isolated points on Λ. We shall also investigate the behavior of eigenvalues β of the problem (3), (4), and (24) as functions of parameters $n_\infty \in \mathbb{R}_+$ and $\omega \in \mathbb{R}_+$, where $\mathbb{R}_+$ is the set of all positive numbers, $\mathbb{R}_+ = \{x > 0\}$. We will use general results of the theory of operator-valued functions [36]. The results in [36] were obtained for operators of the form $I + \mathcal{B}(\beta)$, where I is the identity operator and the operator $\mathcal{B}(\beta)$ is compact for all β. Therefore we shall reduce the problem (3), (4), and (24) to a nonlinear spectral problem with a compact integral operator.

LEMMA 5.1. *Suppose that* $[\mathrm{E},\mathrm{H}]$ *is an eigenvector of the problem* (2.3), (2.4), *and* (3.1) *corresponding to an eigenvalue* $\beta \in \Lambda$. *Then*

$$\mathrm{E}(x) = \left(\mathcal{B}(\beta)\mathrm{E}\right)(x), \quad x \in \mathbb{R}^2, \tag{48}$$

where

$$\begin{aligned}\left(\mathcal{B}(\beta)\mathrm{E}\right)(x) = k^2 \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y)\mathrm{E}(y)dy \\ + \mathrm{Grad}_\beta \int_\Omega (\mathrm{E}, n^{-2}\mathrm{grad}n^2)(y)\Phi(\beta; x, y)dy,\end{aligned} \tag{49}$$

$$\Phi\left(\beta; x, y\right) = \frac{i}{4} H_0^{(1)}\left(\chi(\beta)\left|x - y\right|\right). \tag{50}$$

Proof. For all $\beta \in \Lambda$ and $x \in \mathbb{R}^2$ we have

$$\mathrm{E}(x) = \left(k^2 n_\infty^2 + \mathrm{Grad}_\beta \mathrm{Div}_\beta\right) \frac{1}{n_\infty^2} \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y)\mathrm{E}(y)dy. \tag{51}$$

This result is well known for $\beta \in G$ (see, e.g., [40]). The desired assertion for all $\beta \in \Lambda$ is obtained by applying the method of Green functions to the vector Helmholtz equation for the electric field with the use of the relation

$$\int_{\Gamma_R} \left(\frac{\partial \mathrm{E}(y)}{\partial |y|} \Phi(\beta; x, y) - \frac{\partial \Phi(\beta; x, y)}{\partial |y|} \mathrm{E}(y)dy \right) = 0, \quad R \geq R_0, \tag{52}$$

which is valid for any $\beta \in \Lambda$ and an arbitrary function E satisfying the Reichardt condition (24). The validity of relation (52) was proved in [38], [23].

By the supposition of the lemma, $\mathrm{E} \in (C^2(\mathbb{R}^2))^3$. The function n is twice continuously differentiable in $\mathbb{R}^2$ too. Therefore, the following divergence relation is valid:

$$\begin{aligned}\mathrm{Div}_\beta \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y)\mathrm{E}(y)dy \\ = \int_\Omega \mathrm{Div}_\beta \left[\left(n^2(y) - n_\infty^2\right) \mathrm{E}(y)\right] \Phi(\beta; x, y)dy, \quad x \in \mathbb{R}^2.\end{aligned} \tag{53}$$

Taking into account (53) and (20), we obtain the assertion of the lemma. □

For all $\beta \in \Lambda$ the operator $\mathcal{B}(\beta)$ determined by (49) will be considered as an operator in the space of complex-valued functions $[L_2(\Omega)]^3$. By definition, set

$$\mathcal{A}(\beta) = I - \mathcal{B}(\beta),$$

where I is the identity operator in $[L_2(\Omega)]^3$. The kernel of the integral operator $\mathcal{B}(\beta)$ is weakly singular for all $\beta \in \Lambda$, and the domain Ω has a Lipschitz boundary. Therefore, the operator $\mathcal{B}(\beta)$ is compact for all $\beta \in \Lambda$ (see, e.g., [41]).

DEFINITION 5.2. *A nonzero vector* $\mathrm{F} \in [L_2(\Omega)]^3$ *is called an eigenvector of an operator-valued function* $\mathcal{A}(\beta)$ *corresponding to an eigenvalue* $\beta \in \Lambda$ *if the relation*

$$\mathcal{A}(\beta)\mathrm{F} = 0 \tag{54}$$

is valid. The set of all $\beta \in \Lambda$ *for which the operator* $\mathcal{A}(\beta)$ *does not have the bounded inverse operator in* $[L_2(\Omega)]^3$ *is called the spectrum of problem* (5.7)

Next we shall prove a theorem on the spectral equivalence of the problem (3), (4), and (24) and the problem (54), but before doing this we consider the following.

DEFINITION 5.3. *A nonzero vector* $u \in C^2(\mathbb{R}^2)$ *is called a* generalized eigenvector *of the problem*

$$\left[\Delta + \left(k^2 n^2 - \beta^2\right)\right] u = 0, \quad x \in \mathbb{R}^2, \tag{55}$$

$$u = \sum_{l=-\infty}^{\infty} a_l H_l^{(1)}(\chi r) \exp(il\varphi) \quad \text{for all } r \geq R_0 \tag{56}$$

(where the series is supposed to converge uniformly and absolutely), corresponding to an eigenvalue $\beta \in \Lambda$ *if the relations* (5.8) *and* (5.9) *are valid.*

LEMMA 5.4. *The set of all eigenvalues of problem* (5.8) *and* (5.9) *can only be a set of isolated points on* Λ. *The sheet* $\Lambda_0^{(1)}$, *except for the set* G, *is free of the eigenvalues of the problem* (5.8) *and* (5.9).

The proof is found in [42]. Note that the solutions of problem (55) and (56) represent the solutions of the weak-guidance approximation of the original problem (3), (4), and (24).

THEOREM 5.5. *Suppose that* $[\mathrm{E}, \mathrm{H}] \in (C^2(\mathbb{R}^2))^6$ *is an eigenvector of the problem* (2.3), (2.4), *and* (3.1) *corresponding to an eigenvalue* $\beta_0 \in \Lambda$. *Then* $\mathrm{F} = \mathrm{E} \in [L_2(\Omega)]^3$ *is an eigenvector of the operator-valued function* $\mathcal{A}(\beta)$ *corresponding to the same eigenvalue* β_0. *Suppose that* $\mathrm{F} \in [L_2(\Omega)]^3$ *is an eigenvector of the operator-valued function* $\mathcal{A}(\beta)$ *corresponding to an eigenvalue* $\beta_0 \in \Lambda$, *and also suppose that the same number* β_0 *is not an eigenvalue of the problem* (5.8) *and* (5.9). *Let* $\mathrm{E} = \mathcal{B}(\beta_0)\mathrm{F}$ *and* $\mathrm{H} = (i\omega\mu_0)^{-1}\mathrm{Rot}_{\beta_0}\mathrm{E}$ *for* $x \in \mathbb{R}^2$. *Then* $[\mathrm{E}, \mathrm{H}] \in (C^2(\mathbb{R}^2))^6$, *and* $[\mathrm{E}, \mathrm{H}]$ *is an eigenvector of the problem* (2.3), (2.4), *and* (3.1) *corresponding to the same eigenvalue* β_0.

Proof. From Lemma 5.1 we obtain the first assertion of the theorem. Now we shall prove the second assertion of the theorem. Suppose that $\mathrm{F} \in [L_2(\Omega)]^3$ is an eigenvector of the operator-valued function $\mathcal{A}(\beta)$ corresponding to an eigenvalue $\beta \in \Lambda$. Assume $\mathrm{E} = \mathcal{B}(\beta)\mathrm{F}$ for $x \in \mathbb{R}^2$. The kernel of the integral operator $\mathcal{B}(\beta)$ is weakly singular for any $\beta \in \Lambda$. By virtue of the well-known property of the integral operator with weakly singular kernel on the domain with a Lipschitz boundary (see, e.g., [41]), we have $\mathrm{E} \in [\mathrm{C}(\overline{\Omega})]^3$. The function n belongs to the space of twice continuously differentiable functions in $\mathbb{R}^2$. By virtue of the well-known properties of the area potential (see, e.g., [41]), we have $\mathrm{E} \in [\mathrm{C}^2(\mathbb{R}^2)]^3$.

Applying the operator Div_β to both sides of (48), and using (10) and (53), we obtain

$$\begin{aligned} \mathrm{Div}_\beta \mathrm{E}(x) = k^2 \int_\Omega \mathrm{Div}_\beta \left[\left(n^2(y) - n_\infty^2\right) \mathrm{E}(y)\right] \Phi(\beta; x, y) dy \\ + \left(\Delta - \beta^2\right) \int_\Omega (\mathrm{E}, n^{-2}\mathrm{grad} n^2)(y) \Phi(\beta; x, y) dy \end{aligned} \tag{57}$$

for all $x \in \mathrm{R}^2$. If we combine this with Poisson's formula

$$\left(\Delta + k^2 n_\infty^2 - \beta^2\right) \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) \mathrm{E}(y) dy = -\left(n^2(x) - n_\infty^2\right) \mathrm{E}(x), \tag{58}$$

we get

$$\mathrm{Div}_\beta \mathrm{E}(x) = k^2 \int_\Omega \mathrm{Div}_\beta \left[\left(n^2(y) - n_\infty^2\right) \mathrm{E}(y)\right] \Phi(\beta; x, y) dy - k^2 n_\infty^2 \int_\Omega (\mathrm{E}, n^{-2}\mathrm{grad} n^2)(y) \Phi(\beta; x, y) dy - (E, n^{-2}\mathrm{grad} n^2)(x) \tag{59}$$

for all $x \in \mathrm{R}^2$. Using (12), we have

$$\mathrm{Div}_\beta \left[\left(n^2 - n_\infty^2\right) \mathrm{E}\right] = \mathrm{Div}_\beta \left(n^2 \mathrm{E}\right) - n_\infty^2 \mathrm{Div}_\beta \mathrm{E}, \tag{60}$$

$$(\mathrm{E}, n^{-2}\mathrm{grad} n^2) = n^{-2}\mathrm{Div}_\beta \left(n^2 \mathrm{E}\right) - \mathrm{Div}_\beta \mathrm{E}. \tag{61}$$

If we combine this with (59), we see that the function $u = n^{-2}\mathrm{Div}_\beta \left(n^2 \mathrm{E}\right)$ satisfies

$$u = \int_\Omega k^2 \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) u(y) dy, \quad x \in \mathbb{R}^2.$$

If the number β is not an eigenvalue of the problem (55) and (56), then this equation has only the trivial solution (see [42]). Therefore, we have

$$\mathrm{Div}_\beta \left(n^2 \mathrm{E}\right) = 0, \quad x \in \mathbb{R}^2. \tag{62}$$

Using this, (48), and (61), for $x \in \mathbb{R}^2$, we obtain

$$\mathrm{E}(x) = k^2 \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) \mathrm{E}(y) dy - \mathrm{Grad}_\beta \int_\Omega \Phi(\beta; x, y) \mathrm{Div}_\beta \mathrm{E}(y) dy. \tag{63}$$

Assume $\mathrm{H} = (i\omega\mu_0)^{-1}\mathrm{Rot}_\beta \mathrm{E}$, $x \in \mathbb{R}^2$; i.e., $[\mathrm{E}, \mathrm{H}]$ satisfies (3). Combining (63) and (13), we have

$$\mathrm{H}(x) = -i\omega\varepsilon_0 \mathrm{Rot}_\beta \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) \mathrm{E}(y) dy, \quad x \in \mathbb{R}^2. \tag{64}$$

Therefore, if $\mathrm{E} \in [\mathrm{C}^2(\mathbb{R}^2)]^3$, then $\mathrm{H} \in [\mathrm{C}^2(\mathbb{R}^2)]^3$.

Now we shall prove that $[\mathrm{E}, \mathrm{H}]$ satisfies (4). Multiplying both sides of (63) by $i\omega\varepsilon_0 n_\infty^2$, applying the operator Rot_β to both sides of (64), and combining the results, we obtain

$$\mathrm{Rot}_\beta \mathrm{H} + i\omega\varepsilon_0 n_\infty^2 \mathrm{E} = -i\omega\varepsilon_0 \mathrm{Rot}_\beta \mathrm{Rot}_\beta \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) \mathrm{E}(y) dy + i\omega\varepsilon_0 n_\infty^2 k^2 \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) \mathrm{E}(y) dy - i\omega\varepsilon_0 n_\infty^2 \mathrm{Grad}_\beta \int_\Omega \Phi(\beta; x, y) \mathrm{Div}_\beta \mathrm{E}(y) dy \tag{65}$$

for all $x \in \mathbb{R}^2$. If we combine this with (14) and (53), we obtain

$$\mathrm{Rot}_\beta \mathrm{H} + i\omega\varepsilon_0 n_\infty^2 \mathrm{E} = i\omega\varepsilon_0 \left[\Delta + (k^2 n_\infty^2 - \beta^2)\right] \int_\Omega \left(n^2(y) - n_\infty^2\right) \Phi(\beta; x, y) \mathrm{E}(y) dy - i\omega\varepsilon_0 \mathrm{Grad}_\beta \int_\Omega \mathrm{Div}_\beta \left[\left(n^2(y) - n_\infty^2\right) \mathrm{E}(y)\right] \Phi(\beta; x, y) dy - i\omega\varepsilon_0 n_\infty^2 \mathrm{Grad}_\beta \int_\Omega \Phi(\beta; x, y) \mathrm{Div}_\beta \mathrm{E}(y) dy$$

for all $x \in \mathbb{R}^2$. Using this, (62), and (58), we have

$$\mathrm{Rot}_\beta \mathrm{H} + i\omega\varepsilon_0 n_\infty^2 \mathrm{E} = -i\omega\varepsilon_0 \left(n^2 - n_\infty^2\right) \mathrm{E}, \quad x \in \mathbb{R}^2. \tag{66}$$

Therefore $[\mathrm{E}, \mathrm{H}]$ satisfies (4).

Using the Bessel function addition theorem (see, e.g., [37]), we can readily prove that the number β and the vector $[\mathrm{E}, \mathrm{H}]$ satisfy condition (24). The proof of the theorem is complete. □

THEOREM 5.6. *The set of all eigenvalues of the problem* (2.3), (2.4), *and* (3.1) *can be only a set of isolated points on* Λ. *Each eigenvalue* β *of the problem* (2.3), (2.4), *and* (3.1) *depends continuously on* $(\omega, n_\infty) \in \mathbb{R}^2_+$ *and can appear and disappear only at the boundary of* Λ, *i.e., at* $\beta = \pm k n_\infty$ *and at infinity on* Λ.

Proof. For any $(x, y) \in \Omega^2$ and any $(\omega, n_\infty) \in \mathbb{R}^2_+$ the kernel of the operator $\mathcal{A}(\beta)$ is analytic in $\beta \in \Lambda$. Hence, the operator-valued function $\mathcal{A}(\beta)$ is holomorphic in $\beta \in \Lambda$ for any $(\omega, n_\infty) \in \mathbb{R}^2_+$. The operator-valued function $\mathcal{A}(\beta; \omega, n_\infty)$ is jointly continuous in $(\beta; \omega, n_\infty) \in \Lambda \times \mathbb{R}^2_+$. For all $(\beta; \omega, n_\infty) \in \Lambda \times \mathbb{R}^2_+$ the operator $\mathcal{B}(\beta; \omega, n_\infty)$ is compact. Therefore, using Theorems 4.1 and 5.5 and Lemma 5.4, we see that the operator $\mathcal{A}(\beta; \omega, n_\infty)$ has a bounded inverse operator in $[L_2(\Omega)]^3$ for all $\beta \in B \bigcup D$ and $(\omega, n_\infty) \in \mathbb{R}^2_+$. Hence, for each $(\omega, n_\infty) \in \mathbb{R}^2_+$ the spectrum of problem (54) can be only a set of isolated points on Λ, which are the eigenvalues of the operator-valued function $\mathcal{A}(\beta)$; each eigenvalue β of the operator-valued function $\mathcal{A}(\beta)$ depends continuously on $(\omega, n_\infty) \in \mathbb{R}^2_+$ and can appear and disappear only at the boundary of Λ, i.e., at $\beta = \pm k n_\infty$ and at infinity on Λ (see [36]). Using Theorem 5.5, we obtain the assertion of the current theorem, which is now complete. □

INVERSE MEDIUM SCATTERING PROBLEMS FOR ELECTROMAGNETIC WAVES*

GANG BAO† AND PEIJUN LI†

Abstract. Consider a time-harmonic electromagnetic plane wave incident on a medium enclosed by a bounded domain in $\mathbb{R}^3$. In this paper, existence and uniqueness of the variational problem for forward scattering are established. An energy estimate for the scattered field with a uniform bound with respect to the wavenumber is obtained in the case of low frequency on which the Born approximation is based. A continuation method for the inverse medium scattering problem, which reconstructs the scatterer of an inhomogeneous medium from boundary measurements of the scattered wave, is developed. The algorithm requires multifrequency scattering data. Using an initial guess from the Born approximation, each update is obtained via recursive linearization on the wavenumber k by solving one forward problem and one adjoint problem of Maxwell's equations.

Key words. inverse medium scattering, Maxwell's equations, recursive linearization

1. Introduction.

Consider the systems of time-harmonic Maxwell's equations in three dimensions

$$\nabla \times E^t = \mathrm{i}\omega\mu^* H^t, \tag{1.1}$$

$$\nabla \times H^t = -\mathrm{i}\omega\varepsilon^* E^t, \tag{1.2}$$

where E^t and H^t are the total electric field and magnetic field, respectively; $\omega > 0$ is the frequency; and ε^* and μ^* are the electric permittivity and the magnetic permeability, respectively. Denote by $\varepsilon_0 > 0$, $\mu_0 > 0$ the permittivity and permeability of the vacuum. The fields are further assumed to be nonmagnetic; i.e., $\mu^* = \mu_0$. Rewriting $\varepsilon^* = \varepsilon_0\varepsilon$, $\varepsilon = 1 + q(x)$ is the relative permittivity, where $q(x)$ is the scatterer, which is assumed to have a compact support, and $\Re(q(x)) > -1$.

Taking the curl of (1.1) and eliminating the magnetic field H^t, we obtain the uncoupled equation for the electric field E^t:

$$\nabla \times (\nabla \times E^t) - k^2\varepsilon E^t = 0, \tag{1.3}$$

where $k = \omega\sqrt{\varepsilon_0\mu_0}$ is called the wavenumber, satisfying $0 < k_{\min} \le k \le k_{\max} < \infty$. The total electric field E^t consists of the incident field E^i and the scattered field E:

$$E^t = E^i + E.$$

Assume that the incident field is a plane wave of the normalized form [5]

$$E^i = \mathrm{i}k\vec{p}\,e^{\mathrm{i}kx\cdot\vec{n}}, \tag{1.4}$$

†Department of Mathematics, Michigan State University, East Lansing, MI 48824-1027 (bao@math.msu.edu, lipeijun@math.msu.edu).

where $\vec{n} \in \mathbb{S}^2$ is the propagation direction and $\vec{p} \in \mathbb{S}^2$ is the polarization satisfying $\vec{p} \cdot \vec{n} = 0$. Evidently, such an incident wave satisfies the homogeneous equation

$$\nabla \times (\nabla \times E^i) - k^2 E^i = 0. \tag{1.5}$$

It follows from (1.3) and (1.5) that the scattered field satisfies

$$\nabla \times (\nabla \times E) - k^2 \varepsilon E = k^2 q(x) E^i. \tag{1.6}$$

In addition, the scattered field is required to satisfy the following Silver–Müller radiation condition:

$$\lim_{r \to \infty} r \left[\nabla \times E \times \frac{x}{r} - \mathrm{i}kE \right] = 0,$$

where $r = |x|$. In practice, it is convenient to reduce the problem to a bounded domain by introducing an artificial surface. Let Ω be the compact support of the scatterer $q(x)$. Assume that $R > 0$ is a constant such that the support of the scatterer, Ω, is included in the ball $B = \{x \in \mathbb{R}^3 : |x| < R\}$. Let S be the sphere of the ball, i.e., $S = \{x \in \mathbb{R}^3 : |x| = R\}$. Denote by ν the outward unit normal to S. A suitable boundary condition then has to be imposed on S. For simplicity, we employ the first order absorbing boundary condition (impedance boundary condition) [12] as

$$\nu \times (\nabla \times E) + \mathrm{i}k\nu \times (\nu \times E) = 0 \quad \text{on } S. \tag{1.7}$$

Given the incident field E^i, the forward problem is to determine the scattered field E for the known scatterer $q(x)$, which is assumed further to be in $L^\infty(B)$. Based on the Helmholtz decomposition and a compact imbedding result, the forward problem is shown to have a unique solution for all but possibly a discrete set of wavenumbers. Furthermore, an energy estimate for the scattered field, with a uniform bound with respect to the wavenumber, is given in the low frequency case. The estimate provides a theoretical basis for our linearization algorithm. For numerical solution of the forward scattering problem in an open domain, the reader is referred to [14, 15, 16, 21] and references therein. The inverse medium scattering problem is to determine the scatterer $q(x)$ from the measurements of near field current densities, the tangential trace of the scattered field $\nu \times E|_S$, given the incident field. Although this is a classical problem in inverse scattering theory, little is known on reconstruction methods, especially in the three dimensional case, due to the nonlinearity, ill-posedness, and large scale computation associated with the inverse scattering problem. We refer the reader to [1, 6, 10, 11, 23] for related results on the inverse medium problem. See [5] for an account of recent progress on the general inverse scattering problem.

The goal of this work is to present a recursive linearization method that solves the inverse medium scattering problem of Maxwell's equations in three dimensions. The reader is referred to [2, 4] for recursive linearization approaches for solving the inverse medium scattering problems in two dimensions. Our algorithm requires multi-frequency scattering data, and the recursive linearization is obtained by a continuation method on the wavenumber. It first solves a linear equation (Born approximation) at the lowest wavenumber, which may be done by using the fast Fourier transform (FFT). Updates are subsequently obtained by using higher and higher wavenumbers. Following the idea of the Kaczmarz method [6, 18, 19], we use partial data to perform the nonlinear Landweber iteration at each wavenumber. For each iteration, one forward and one adjoint state of Maxwell's equations are solved, which may be implemented by using the symmetric second order edge (Nédélec) elements.

The plan of this paper is as follows. Analysis of the variational problem for forward scattering is presented in section 2. Based on the Helmholtz decomposition, a compact imbedding result, and the Lax–Milgram lemma, the well-posedness of the forward scattering is proved. An important energy estimate is given. Section 3 is devoted to the numerical study of inverse medium scattering. Using the initial guess of the reconstruction derived from the Born approximation, a regularized iterative linearization algorithm is proposed. Numerical examples are presented in section 4. The paper is concluded with some remarks and future directions in section 5.

2. Analysis of the variational problem for forward scattering. In this section, the variational formulation for the forward scattering problem is discussed. The analysis provides a criterion for weak scattering, which plays an important role in the inversion algorithm.

To state our boundary value problem, following [17], we first introduce the standard Sobolev spaces:

$$
\begin{aligned}
&L_t^2(S) = \{u \in (L^2(S))^3 : \nu \cdot u = 0 \ \text{ on } S\},\\
&H_0^1(B) = \{u \in H^1(B) : u = 0 \ \text{ on } S\},\\
&H(\mathrm{curl}, B) = \{u \in (L^2(B))^3 : \nabla \times u \in (L^2(B))^3\},\\
&H_{\mathrm{imp}}(\mathrm{curl}, B) = \{u \in H(\mathrm{curl}, B) : \nu \times u \in L_t^2(S)\},
\end{aligned}
$$

where $H_{\mathrm{imp}}(\mathrm{curl}, B)$ is an appropriate subspace of $H(\mathrm{curl}, B)$ for solving problems involving the impedance boundary condition. Correspondingly, these spaces are equipped with the norms

$$
\begin{aligned}
&\| u \|_{L_t^2(S)} = \| u \|_{(L^2(S))^3},\\
&\| u \|_{H^1(B)}^2 = \| u \|_{L^2(B)}^2 + \| \nabla u \|_{(L^2(B))^3}^2,\\
&\| u \|_{H(\mathrm{curl},B)}^2 = \| u \|_{(L^2(B))^3}^2 + \| \nabla \times u \|_{(L^2(B))^3}^2,\\
&\| u \|_{H_{\mathrm{imp}}(\mathrm{curl},B)}^2 = \| u \|_{H(\mathrm{curl},B)}^2 + \| \nu \times u \|_{L_t^2(S)}^2.
\end{aligned}
$$

For convenience, denote the $(L^2(B))^3$ and $(L^2(S))^3$ inner products by

$$
(u, v) = \int_B u \cdot \overline{v} dx \quad \text{and} \quad \langle u, v \rangle = \int_S u \cdot \overline{v} ds,
$$

respectively, where the overline denotes the complex conjugate. Introduce the bilinear form $a : H_{\mathrm{imp}}(\mathrm{curl}, B) \times H_{\mathrm{imp}}(\mathrm{curl}, B) \to \mathbb{C}$,

$$
a(E, \phi) = (\nabla \times E, \nabla \times \phi) - k^2(\varepsilon E, \phi) + \mathrm{i}k\langle \nu \times E, \nu \times \phi \rangle,
$$

and the linear functional on $H_{\mathrm{imp}}(\mathrm{curl}, B)$,

$$
b(\phi) = k^2(qE^i, \phi).
$$

Then we have the weak form of the boundary value problem (1.6) and (1.7): find $E \in H_{\mathrm{imp}}(\mathrm{curl}, B)$ such that

$$
a(E, \phi) = b(\phi) \quad \forall\, \phi \in H_{\mathrm{imp}}(\mathrm{curl}, B). \tag{2.1}
$$

Throughout the paper, C stands for a positive generic constant, whose value may change step by step but should always be clear from the context.

Before presenting the main result for the variational problem, we state several useful lemmas. The reader is referred to [17] for detailed discussions and proofs.

LEMMA 2.1 (Helmholtz decomposition). *The spaces X and Y are closed subspaces of $H_{\rm imp}(\mathrm{curl}, B)$, which is the direct sum of the spaces X and Y; i.e.,*

$$H_{\rm imp}(\mathrm{curl}, B) = X \oplus Y.$$

Here

$$X = \{u \in H_{\rm imp}(\mathrm{curl}, B) : \mathrm{div}(\varepsilon u) = 0 \quad \text{in } B\}$$

and

$$Y = \{\nabla \xi : \xi \in H_0^1(B)\}.$$

LEMMA 2.2 (compact imbedding). *The space X is compactly imbedded into the space $(L^2(B))^3$.*

LEMMA 2.3 (Friedrichs inequality). *There exists a positive constant C, independent of the wavenumber, such that for all $u \in X$*

$$\| u \|_{(L^2(B))^3} \leq C \left(\| \nabla \times u \|_{(L^2(B))^3} + \| \nu \times u \|_{(L^2(S))^3} \right).$$

Next we prove the well-posedness of the variational problem (2.1) and obtain an energy estimate for the scattered field with a uniform bound with respect to the wavenumber in the case of low frequency.

THEOREM 2.1. *If the wavenumber is sufficiently small, the variational problem* (2.1) *admits a unique weak solution in $H_{\mathrm{imp}(\mathrm{curl}, B)}$ given by $E = u + \nabla p$, while $u \in X, p \in H_0^1(B)$. Furthermore, we have the estimate*

$$\| E \|_{H_{\mathrm{imp}(\mathrm{curl}, B)}} \leq Ck|\Omega|^{1/2} \| q \|_{L^\infty(B)}, \tag{2.2}$$

where the constant C is independent of k and Ω is the compact support of the scatterer.

Proof. Using the Helmholtz decomposition, we take $E = u + \nabla p$ and $\phi = v + \nabla \xi$, for any $v \in X, \xi \in H_0^1(B)$. Observe that $a(u, \nabla \xi) = 0$, for any $\xi \in H_0^1(B)$, by the definition of X. Therefore, we decompose the variational equation (2.1) into the form

$$a(u, v) + a(\nabla p, v) + a(\nabla p, \nabla \xi) = b(v) + b(\nabla \xi) \quad \forall\, v \in X,\ \xi \in H_0^1(B). \tag{2.3}$$

First, we determine $p \in H_0^1(B)$ by the solution of

$$a(\nabla p, \nabla \xi) = b(\nabla \xi) \quad \forall\, \xi \in H_0^1(B),$$

which gives explicitly

$$-(\varepsilon \nabla p, \nabla \xi) = (qE^i, \nabla \xi) \quad \forall\, \xi \in H_0^1(B).$$

The existence and uniqueness of the solution p in $H_0^1(B)$ may be proved by a direct application of the Lax–Milgram lemma with the estimate

$$\| \nabla p \|_{(L^2(B))^3} \leq Ck|\Omega|^{1/2} \| q \|_{L^\infty(B)}. \tag{2.4}$$

Rewrite (2.3) as

$$a(u, v) = b(v) - a(\nabla p, v) \quad \forall\, v \in X, \tag{2.5}$$

and decompose the bilinear form a into $a = a_1 + k^2 a_2$, where

$$a_1(u,v) = (\nabla \times u, \nabla \times v) + \mathrm{i}k\langle \nu \times u, \nu \times v\rangle,$$
$$a_2(u,v) = -(\varepsilon u, v).$$

Using the inequality of arithmetic and geometric means, we conclude from Lemma 2.3 that a_1 is coercive:

$$|a_1(u,u)| \geq Ck(\| \nabla \times u \|^2_{(L^2(B))^3} + \| \nu \times u \|^2_{(L^2(S))^3}) \geq Ck \| u \|^2_{H_{\mathrm{imp}}(\mathrm{curl},B)} \quad \forall\, u \in X.$$

The continuity of the bilinear form a_1 follows from the Cauchy–Schwarz inequality.

Next we prove the compactness of a_2. Define an operator $\mathcal{A} : (L^2(B))^3 \to X$ by

$$a_1(\mathcal{A}u, v) = a_2(u,v) \quad \forall\, v \in X,$$

which gives

$$(\nabla \times \mathcal{A}u, \nabla \times v) + \mathrm{i}k\langle \nu \times \mathcal{A}u, \nu \times v\rangle = -(\varepsilon u, v) \quad \forall\, v \in X.$$

Using the Lax–Milgram lemma again, it follows that

$$\| \mathcal{A}u \|_{H_{\mathrm{imp}}(\mathrm{curl},B)} \leq \frac{C}{k} \| u \|_{(L^2(B))^3}, \tag{2.6}$$

where the constant C is independent of k. Thus $\mathcal{A}$ is bounded from $(L^2(B))^3$ to X, and X is compactly imbedded into $(L^2(B))^3$. Hence $\mathcal{A} : (L^2(B))^3 \to (L^2(B))^3$ is a compact operator.

Define a function $w \in (L^2(B))^3$ by requiring $w \in X$ and satisfying

$$a_1(w,v) = b(v) - a(\nabla p, v) \quad \forall\, v \in X.$$

More specifically, we have by using the Stokes formula that

$$a_1(w,v) = k^2(qE^i, v) + k^2(\varepsilon \nabla p, v) \quad \forall\, v \in X.$$

It follows from the Lax–Milgram lemma that

$$\| w \|_{H_{\mathrm{imp}}(\mathrm{curl},B)} \leq C(k^2|\Omega|^{1/2} \| q \|_{L^\infty(B)} + k \| \nabla p \|_{(L^2(B))^3}).$$

An application of (2.4) yields

$$\| w \|_{H_{\mathrm{imp}}(\mathrm{curl},B)} \leq Ck^2|\Omega|^{1/2} \| q \|_{L^\infty(B)}. \tag{2.7}$$

Using the operator $\mathcal{A}$, we can see that the problem (2.5) is equivalent to finding $u \in (L^2(B))^3$ such that

$$(\mathcal{I} + k^2\mathcal{A})u = w. \tag{2.8}$$

When the wavenumber k is small enough, the operator $\mathcal{I} + k^2\mathcal{A}$ has a uniformly bounded inverse. We then have the estimate

$$\| u \|_{(L^2(B))^3} \leq C \| w \|_{(L^2(B))^3}, \tag{2.9}$$

where the constant C is independent of k. However, rearranging (2.8), we have $u = w - k^2\mathcal{A}u$, so $u \in X$ and, by the estimate (2.6) for the operator $\mathcal{A}$, we have

$$\| u \|_{H_{\rm imp}({\rm curl},B)} \le \| w \|_{H_{\rm imp}({\rm curl},B)} + Ck \| u \|_{(L^2(B))^3}.$$

Combining the estimates (2.9) and (2.7) leads to

$$\| u \|_{H_{\rm imp}({\rm curl},B)} \le Ck^2|\Omega|^{1/2} \| q \|_{L^\infty(B)}. \tag{2.10}$$

Finally, it follows from the definition of the norm in $H_{\rm imp}({\rm curl}, B)$ that

$$\| E \|_{H_{\rm imp}({\rm curl},B)} \le \| u \|_{H_{\rm imp}({\rm curl},B)} + \| \nabla p \|_{(L^2(B))^3}.$$

The proof is complete by noting the estimates (2.10) and (2.4) for sufficiently small wavenumbers. □

Remark 2.1. The energy estimate of the scattered field (2.2) provides a criterion for weak scattering. From this estimate, it is easily seen that, fixing any two of the three quantities, i.e., the wavenumber, the compact support of the scatterer Ω, and the $L^\infty(B)$ norm of the scatterer, the scattering is weak when the third one is small. Especially for the given scatterer $q(x)$, i.e., the norm and the compact support are fixed, the scattering is weak when the wavenumber is small.

Remark 2.2. For a general wavenumber, from (2.8) the uniqueness and existence follow from the Fredholm alternative. If the scatterer $q(x)$ is more regular, say of $C_0^2(B)$ [8], unique continuation may be used to prove the uniqueness and thus the existence of the forward scattering problem (1.6), (1.7) for all $k > 0$. Otherwise, if k^2 is not the eigenvalue for Maxwell's equations in the domain B, then the operator $\mathcal{I} + k^2\mathcal{A}$ has a bounded inverse. However, the bound depends on the wavenumber. Therefore, the constant C in the estimate (2.2) depends on the wavenumber.

From the above discussion, we have the following theorem on the well-posedness of the variational problem (2.1).

THEOREM 2.2. *Given the scatterer $q \in L^\infty(B)$, for all but possibly a discrete set of wavenumbers, the variational problem* (2.1) *admits a unique weak solution in $H_{\rm imp}({\rm curl}, B)$, given by $E = u + \nabla p$, while $u \in X$, $p \in H_0^1(B)$.*

3. Inverse medium scattering. In this section, a regularized recursive linearization method for solving the inverse medium scattering problem of Maxwell's equations in three dimensions is proposed. The algorithm, obtained by a continuation method on the wavenumber, requires multifrequency scattering data. At each wavenumber, the algorithm determines a forward model which produces the prescribed scattering data. At a low wavenumber, the scattered field is weak. Consequently, the nonlinear equation becomes essentially linear, known as the Born approximation. The algorithm first solves this nearly linear equation at the lowest wavenumber to obtain low-frequency modes of the true scatterer. The approximation is then used to linearize the nonlinear equation at the next higher wavenumber to produce a better approximation which contains more modes of the true scatterer. This process is continued until a sufficiently high wavenumber, where the dominant modes of the scatterer are essentially recovered.

3.1. Low-frequency modes of the scatterer. Rewrite (1.6) as

$$\nabla \times (\nabla \times E) - k^2 E = k^2 q(x)(E^i + E), \tag{3.1}$$

where the incident wave is taken as $E^i = \mathrm{i}k\vec{p}_1 e^{\mathrm{i}kx\cdot\vec{n}_1}$. Consider a test function $F = \mathrm{i}k\vec{p}_2 e^{\mathrm{i}kx\cdot\vec{n}_2}$, where $\vec{p}_2, \vec{n}_2 \in \mathbb{S}^2$ satisfy $\vec{p}_2 \cdot \vec{n}_2 = 0$. Hence F satisfies (1.5).

Multiplying (3.1) by F and integrating over B on both sides, we have

$$\int_B F \cdot [\nabla \times (\nabla \times E)]dx - k^2 \int_B F \cdot E dx = k^2 \int_B q(x) F \cdot E^i dx + k^2 \int_B q(x) F \cdot E dx.$$

Integration by parts yields

$$\int_B E \cdot [\nabla \times (\nabla \times F)]dx + \int_S \big[E \times (\nabla \times F) - F \times (\nabla \times E)\big] \cdot \nu ds - k^2 \int_B F \cdot E dx = k^2 \int_B q(x) F \cdot E^i dx + k^2 \int_B q(x) F \cdot E dx.$$

We have, by noting (1.5),

$$\int_S \big[E \times (\nabla \times F) - F \times (\nabla \times E)\big] \cdot \nu ds = k^2 \int_B q(x) F \cdot E^i dx + k^2 \int_B q(x) F \cdot E dx.$$

Using the boundary condition (1.7) of the scattered field and the special form of the incident wave E^i and F, we get

$$-\int_S (\nu \times E) \cdot (\vec{n}_2 \times \vec{p}_2) e^{\mathrm{i}kx\cdot\vec{n}_2} ds + \int_S \big[\nu \times (\nu \times E)\big] \cdot \vec{p}_2 e^{\mathrm{i}kx\cdot\vec{n}_2} ds = \int_B q(x) F \cdot E^i dx + \int_B q(x) F \cdot E dx.$$

A simple calculation yields

$$\int_B q(x) e^{\mathrm{i}kx\cdot(\vec{n}_1+\vec{n}_2)} dx = \frac{1}{(\vec{p}_1 \cdot \vec{p}_2)k^2} \int_S (\nu \times E) \cdot (\vec{n}_2 \times \vec{p}_2 + \nu \times \vec{p}_2) e^{\mathrm{i}kx\cdot\vec{n}_2} ds + \frac{\mathrm{i}}{(\vec{p}_1 \cdot \vec{p}_2)k} \int_B q(x) \vec{p}_2 \cdot E e^{\mathrm{i}kx\cdot\vec{n}_2} dx. \tag{3.2}$$

From Theorem 2.1 and Remark 2.1, for a small wavenumber, the scattered field is weak and the inverse scattering problem becomes essentially linear. Dropping the nonlinear (second) term of (3.2), we obtain the linearized integral equation

$$\int_B q_0(x) e^{\mathrm{i}kx\cdot(\vec{n}_1+\vec{n}_2)} dx = \frac{1}{(\vec{p}_1 \cdot \vec{p}_2)k^2} \int_S (\nu \times E) \cdot (\vec{n}_2 \times \vec{p}_2 + \nu \times \vec{p}_2) e^{\mathrm{i}kx\cdot\vec{n}_2} ds, \tag{3.3}$$

which is the Born approximation. The function $q_0(x)$ will be used as the starting point for our recursive linearization algorithm.

Since the scatterer $q_0(x)$ has a compact support, we use the notation

$$\hat{q}_0(\xi) = \int_B q_0(x) e^{\mathrm{i}kx\cdot(\vec{n}_1+\vec{n}_2)} dx,$$

where $\hat{q}_0(\xi)$ is the Fourier transform of $q_0(x)$ with $\xi = k(\vec{n}_1 + \vec{n}_2)$. Choose

$$\vec{n}_j = (\sin\theta_j \cos\phi_j, \sin\theta_j \sin\phi_j, \cos\theta_j), \quad j = 1, 2,$$

where θ_j, ϕ_j are the latitudinal and longitudinal angles, respectively. It is obvious that the domain $[0,\pi]\times[0,2\pi]$ of (θ_j,ϕ_j), $j=1,2$, corresponds to the ball $\{\xi\in\mathbb{R}^3 : |\xi|\le 2k\}$. Thus, the Fourier modes of $\hat{q}_0(\xi)$ in the ball $\{\xi : |\xi|\le 2k\}$ can be determined. The scattering data with the higher wavenumber must be used in order to recover more modes of the true scatterer.

Define the data

$$G(\zeta)=\begin{cases} \frac{1}{(\vec{p}_1\cdot\vec{p}_2)k^2}\int_S(\nu\times E)\cdot(\vec{n}_2\times\vec{p}_2+\nu\times\vec{p}_2)e^{\mathrm{i}kx\cdot\vec{n}_2}ds & \text{for } |\zeta|\le 2k,\\ 0, & \text{otherwise,}\end{cases}$$

where $\zeta=\zeta(k,\theta_1,\phi_1,\theta_2,\phi_2)\in\mathbb{R}^3$. The linear integral equation (3.3) can then be formally reformulated as

$$\int_{\mathbb{R}^3} q_0(x)e^{\mathrm{i}x\cdot\zeta}dx = G(\zeta). \tag{3.4}$$

Taking the inverse Fourier transform of (3.4) leads to

$$\frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{-\mathrm{i}x\cdot\zeta}\left[\int_{\mathbb{R}^3} q_0(y)e^{\mathrm{i}y\cdot\zeta}dy\right]d\zeta = \frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{-\mathrm{i}x\cdot\zeta}G(\zeta)d\zeta.$$

By the Fubini theorem, we have

$$\frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} q_0(y)\left[\int_{\mathbb{R}^3} e^{\mathrm{i}(y-x)\cdot\zeta}d\zeta\right]dy = \frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{-\mathrm{i}x\cdot\zeta}G(\zeta)d\zeta.$$

Using the inverse Fourier transform of the Dirac delta function

$$\frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{\mathrm{i}(y-x)\cdot\zeta}d\zeta = \delta(y-x),$$

we deduce

$$\int_{\mathbb{R}^3} q_0(y)\delta(y-x)dy = \frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{-\mathrm{i}x\cdot\xi}G(\xi)d\xi,$$

which gives

$$q_0(x) = \frac{1}{(2\pi)^3}\int_{\mathbb{R}^3} e^{-\mathrm{i}x\cdot\zeta}G(\zeta)d\zeta. \tag{3.5}$$

In practice, the integral equation (3.5) is implemented by using the FFT.

3.2. Recursive linearization. As discussed in the previous section, when the wavenumber is small, the Born approximation allows a reconstruction of those Fourier modes less than or equal to $2k$ for the function $q(x)$. We now describe a procedure that recursively determines q_k at $k=k_j$ for $j=1,2,\ldots$ with increasing wavenumbers. Suppose now that the scatterer $q_{\tilde{k}}$ has been recovered at some wavenumber $\tilde{k}$, and that the wavenumber k is slightly larger than $\tilde{k}$. We wish to determine q_k, or equivalently, to determine the perturbation

$$\delta q = q_k - q_{\tilde{k}}.$$

For the reconstructed scatterer $q_{\tilde{k}}$, we solve at the wavenumber k the forward scattering problem

$$\nabla \times (\nabla \times \tilde{E}) - k^2(1 + q_{\tilde{k}})\tilde{E} = k^2 q_{\tilde{k}} E^i, \quad x \in B, \tag{3.6}$$

$$\nu \times (\nabla \times \tilde{E}) + \mathrm{i}k\nu \times (\nu \times \tilde{E}) = 0 \quad \text{on } S. \tag{3.7}$$

For the scatterer q_k, we have

$$\nabla \times (\nabla \times E) - k^2(1 + q_k)E = k^2 q_k E^i, \quad x \in B, \tag{3.8}$$

$$\nu \times (\nabla \times E) + \mathrm{i}k\nu \times (\nu \times E) = 0 \quad \text{on } S. \tag{3.9}$$

Subtracting (3.6), (3.7) from (3.8), (3.9) and omitting the second order smallness in δq and in $\delta E = E - \tilde{E}$, we obtain

$$\nabla \times (\nabla \times \delta E) - k^2(1 + q_{\tilde{k}})\delta E = k^2 \delta q (E^i + \tilde{E}), \quad x \in B, \tag{3.10}$$

$$\nu \times (\nabla \times \delta E) + \mathrm{i}k\nu \times (\nu \times \delta E) = 0 \quad \text{on } S. \tag{3.11}$$

For the scatterer q_k and the incident wave E^i, we define the map $S(q_k, E^i)$ by

$$S(q_k, E^i) = E,$$

where E is the scattered field at the wavenumber k. Let γ be the trace operator to the boundary S of the ball B. Define the scattering map

$$M(q_k, E^i) = \gamma S(q_k, E^i).$$

It is easily seen that the scattering map $M(q_k, E^i)$ is linear with respect to E^i but is nonlinear with respect to q_k. For simplicity, denote $M(q_k, E^i)$ by $M(q_k)$. By the definition of the trace operator, we have

$$M(q_k) = \nu \times E|_S.$$

We refer to [1] for the Fréchet differentiability of the scattering map. Let $DM(q_{\tilde{k}})$ be the Fréchet derivative of $M(q_k)$, and denote the residual operator

$$R(q_{\tilde{k}}) = \nu \times \delta E|_S.$$

It follows from [1] that

$$DM(q_{\tilde{k}})\delta q = R(q_{\tilde{k}}). \tag{3.12}$$

The regularized least-squares solution of (3.12) is

$$\delta q = [\alpha I + DM^*(q_{\tilde{k}})DM(q_{\tilde{k}})]^{-1} DM^*(q_{\tilde{k}})R(q_{\tilde{k}}),$$

where $DM^*(q_{\tilde{k}})$ is the adjoint operator of $DM(q_{\tilde{k}})$, I is the identity operator, and α is some suitable positive number. In practice, the main difficulty is the enormous computational cost of solving linear systems with huge full matrix. Here, we consider an alternative way of solving (3.12) which is much less computationally demanding.

To state the approach, we first examine the boundary data $\nu \times E(x; \theta, \phi; k)$. Here, the variable x is the observation point, which has two degrees of freedom since it is on the sphere S. The terms θ, ϕ are latitudinal and longitudinal angles, respectively, of the incident wave E^i. At each frequency, we have four degrees of freedom, and thus

data redundancy, which may be addressed by fixing one of the incident angles, say θ. Define $\phi_j = (j-1) * \frac{2\pi}{m}, j = 1, \ldots, m$, and the residual operator

$$R_j(q_{\tilde{k}}) = \nu \times E(x; \theta, \phi_j; k)|_S - \nu \times \tilde{E}(x; \theta, \phi_j; k)|_S,$$

where m is the total number of the incident waves or sweeps, and $\tilde{E}(x; \theta, \phi_j; k)$ is the solution of (3.6), (3.7) with the incident wave of longitudinal angle ϕ_j and the scatterer $q_{\tilde{k}}$. Instead of solving (3.12) for all incident waves simultaneously, we may solve it for one incident wave at a time while updating the residual operator after each determination of the incremental correction δq. Thus, for each incident wave with incident angle ϕ_j, we consider the equation

$$M_j(q_k) = \nu \times E(x; \theta, \phi_j; k)|_S, \tag{3.13}$$

where $M_j(q_k)$ is the scattering map corresponding to the incident wave with longitudinal angle ϕ_j. It follows from [1] that

$$DM_j(q_{\tilde{k}})\delta q_j = R_j(q_{\tilde{k}}), \tag{3.14}$$

where $DM_j(q_{\tilde{k}})$ is the Fréchet derivative of the scattering map $M_j(q_k)$. The nonlinear Landweber iteration for (3.13) yields

$$\delta q_j = \beta_k DM_j^*(q_{\tilde{k}}) R_j(q_{\tilde{k}}), \tag{3.15}$$

where $DM_j^*(q_{\tilde{k}})$ is the adjoint operator of $DM_j(q_{\tilde{k}})$, and β_k is some relaxation parameter [7].

Remark 3.1. For a fixed wavenumber, the stopping index of nonlinear Landweber iteration (3.15) could be determined from the discrepancy principle. However, in practice, it is not necessary to do many iterations. Our numerical results indicate that the iterative process for different incident angles $\phi_j, j = 1, \ldots, m$, is sufficient to obtain reasonable accuracy.

Next, we discuss the role of the relaxation parameter β_k in the iteration (3.15), which may be understood more clearly by considering the iteration from a different point of view.

Consider the optimization problem of (3.13),

$$\min_{q_k} \parallel M_j(q_k) - \nu \times E(x; \theta, \phi_j; k) \parallel^2_{(L^2(S))^3}. \tag{3.16}$$

The first order optimality condition for the problem (3.16) is given by

$$DM_j^*(q_{\tilde{k}}) \left(M_j(q_k) - \nu \times E(x; \theta, \phi_j; k)\right)|_S = 0. \tag{3.17}$$

To solve the optimality equation (3.17), the time marching scheme proposed in [22] consists of finding the steady state of the following parabolic equation:

$$\frac{dq_k}{dt} = DM_j^*(q_{\tilde{k}}) \left(\nu \times E(x; \theta, \phi_j; k) - M_j(q_k)\right)|_S.$$

The numerical solution could be computed from the explicit method

$$\delta q_j = \tau DM_j^*(q_{\tilde{k}}) R_j(q_{\tilde{k}}),$$

where τ is the discretized time step. Thus, the relaxation parameter β_k is essentially the step size of time marching, whose length is restricted by the stability of the explicit method.

In order to compute the correction δq_j, we need some efficient way to compute $DM_j^*(q_{\tilde{k}})R_j(q_{\tilde{k}})$, which is given by the following theorem.

THEOREM 3.1. *Given the residual $R_j(q_{\tilde{k}})$, there exits a function F_j satisfying the adjoint equations*

$$\nabla \times (\nabla \times F_j) - k^2(1 + \overline{q_{\tilde{k}}})F_j = 0, \quad x \in B, \tag{3.18}$$

$$\nabla \times F_j - \mathrm{i}k\nu \times F_j = R_j(q_{\tilde{k}}) \quad \text{on } S, \tag{3.19}$$

such that the adjoint Fréchet derivative $DM_j^*(q_{\tilde{k}})$ satisfies

$$\big[DM_j^*(q_{\tilde{k}})R_j(q_{\tilde{k}})\big](x) = k^2(\overline{E_j^i}(x) + \overline{\tilde{E}_j}(x)) \cdot F_j(x), \tag{3.20}$$

where E_j^i is the incident wave with the longitudinal angle ϕ_j and $\tilde{E}_j$ is the solution of (3.6), (3.7) *with the incident wave E_j^i.*

Proof. Let $\tilde{E}_j$ be the solution of (3.6), (3.7) with the incident wave E_j^i. Consider the equations as follows,

$$\nabla \times (\nabla \times \delta E) - k^2(1 + q_{\tilde{k}})\delta E = k^2 \delta q(E_j^i + \tilde{E}_j), \quad x \in B, \tag{3.21}$$

$$\nu \times (\nabla \times \delta E) + \mathrm{i}k\nu \times (\nu \times \delta E) = 0 \quad \text{on } S, \tag{3.22}$$

and the adjoint equations (3.18) and (3.19), which take the variational form

$$(\nabla \times F_j, \nabla \times \phi) - k^2((1 + \overline{q_{\tilde{k}}})F_j, \phi) - \mathrm{i}k\langle \nu \times F_j, \nu \times \phi\rangle = \langle R_j(q_{\tilde{k}}), \nu \times \phi\rangle \quad \forall \phi \in H_{\mathrm{imp}}(\mathrm{curl}, B).$$

The existence and uniqueness of the weak solution for the adjoint equations may be proved in the same way as for the scattered field. The proof is omitted.

Multiplying (3.21) with the complex conjugate of F_j and integrating over B on both sides, we obtain

$$\int_B \overline{F}_j \cdot \big[\nabla \times (\nabla \times \delta E)\big]dx - k^2 \int_B (1 + q_{\tilde{k}})\overline{F}_j \cdot \delta E dx = k^2 \int_B \delta q(E_j^i + \tilde{E}_j) \cdot \overline{F}_j dx.$$

Integration by parts yields

$$\int_S \big[\delta E \times (\overline{\nabla \times F_j}) - \overline{F}_j \times (\nabla \times \delta E)\big] \cdot \nu ds = k^2 \int_B \delta q(E_j^i + \tilde{E}_j) \cdot \overline{F}_j dx.$$

Using the boundary condition (3.22), we deduce

$$\int_S (\nu \times \delta E) \cdot (\overline{\nabla \times F_j + \mathrm{i}k\nu \times F_j})ds = k^2 \int_B \delta q(E_j^i + \tilde{E}) \cdot \overline{F}_j dx.$$

It follows from (3.14) and the boundary condition (3.19) that

$$\int_S [DM_j(q_{\tilde{k}})\delta q] \cdot \overline{R_j(q_{\tilde{k}})}ds = k^2 \int_B \delta q(E_j^i + \tilde{E}_j) \cdot \overline{F}_j dx.$$

We know from the adjoint operator $DM_j^*(q_{\tilde{k}})$ that

$$\int_B \delta q\, \overline{DM_j^*(q_{\tilde{k}})R_j(q_{\tilde{k}})}dx = k^2 \int_B \delta q(E_j^i + \tilde{E}_j) \cdot \overline{F}_j dx.$$

TABLE 1
Recursive linearization reconstruction algorithm for inverse medium scattering.

Initialization:
  $k = k_{\min}$ smallest $k_{\min}$
  q_0 Born approximation
Reconstruction loop:
  FOR $k = k_{\min} : k_{\max}$ march along wavenumbers
    FOR $j = 1 : m$ perform m sweeps over incident angles
      solve (3.6)–(3.7) for $\tilde{E}_j$ one forward problem
      solve (3.18)–(3.19) for F_j one adjoint problem
      $\delta q_k^j = \beta_k k^2 (\overline{E_j^i} + \overline{\tilde{E}_j}) \cdot F_j$
      $q_k^j := q_k^j + \delta q_k^j$
    END
    $q_k := q_k^m$
  END
  $q := q_{k_{\max}}$ final reconstruction

Since this holds for any δq, we have

$$\overline{DM_j^*(q_{\tilde{k}}) R_j(q_{\tilde{k}})} = k^2 (E_j^i + \tilde{E}_j) \cdot \overline{F}_j.$$

Taking the complex conjugate of the above equation yields the result. □

Using this theorem, we can rewrite (3.15) as

$$\delta q_j = \beta_k k^2 (\overline{E_j^i}(x) + \overline{\tilde{E}_j}(x)) \cdot F_j(x). \tag{3.23}$$

Thus, for each incident wave with a longitudinal angle ϕ_j, we solve one forward problem (3.6), (3.7) and one adjoint problem (3.18), (3.19). Since the adjoint problem has a variational form similar to that of the forward problem, we need to compute essentially two forward problems at each sweep. Once δq_j is determined, $q_{\tilde{k}}$ is updated by $q_{\tilde{k}} + \delta q_j$. After completing the mth sweep, we get the reconstructed scatterer q_k at the wavenumber k.

The recursive linearization for inverse medium scattering of Maxwell's equations can be summarized in Table 1.

4. Numerical experiments. In this section, we discuss the numerical solution of the forward scattering problem and the computational issues of the recursive linearization algorithm.

As for the forward solver, we adopt the edge elements which were developed originally for the finite element solution of Maxwell's equations [20, 12] in the early 1980s. From the mathematical point of view, these are natural approximation spaces for the Hilbert space $H(\mathrm{curl}, B)$, which is the adequate functional space for the variational formulation of Maxwell's equations. Vector fields in such finite element (FE) spaces have continuous tangential traces, which is consistent with the physics. Therefore, the natural degrees of freedom for these elements are related to tangential traces along edges or faces. Here, we take the symmetric second order edge elements for tetrahedral edge elements [13]. When the unknowns are ordered according to the reverse Cuthill–McKee (RCM) ordering [9], the profile of FE matrix is highly banded, which improves the condition number of the FE coefficient matrix. The sparse large scale linear system can be most efficiently solved if the zero elements of the coefficient matrix are not stored. We use the commonly used compressed row storage (CRS)

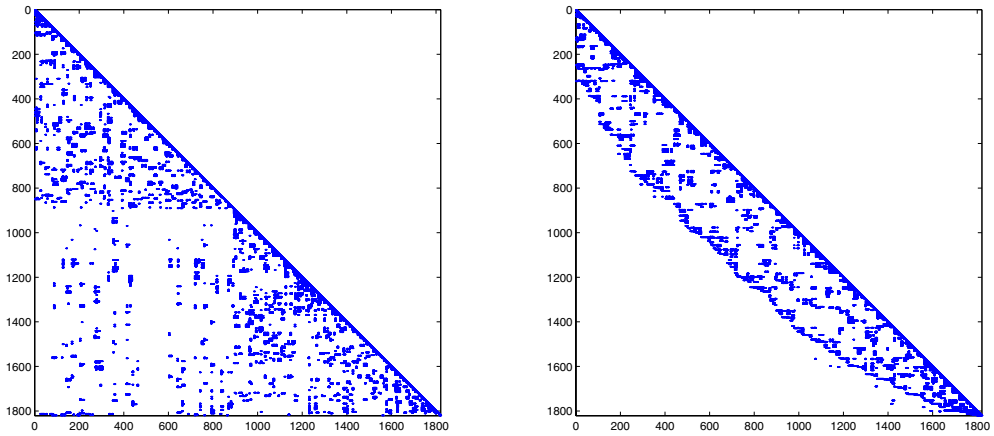

FIG. 1. *Sparsity pattern of an FE matrix with* 1820 *unknowns:* (a) *original ordering,* (b) *RCM ordering.*

format, which makes no assumptions about the sparsity structure of the matrix and does not store any unnecessary elements. In fact, from the variational formula of our direct problem (2.1), the coefficient matrix is complex symmetric. Hence, only the lower triangular portion of the matrix needs to be stored. Figure 1 shows a typical sparsity pattern of an FE matrix with 1820 unknowns from the symmetric second order edge element. Regarding the linear solver, either biconjugate gradient (BiCG) or quasi-minimal residual (QMR) algorithms with diagonal preconditioning may be employed to solve the sparse, symmetric, and complex system of the equations. It appears for our experiments that the QMR is more efficient.

In the following, we present two numerical examples where the number of the incident wave $m = 20$, the incident latitudinal angle $\theta = 0$, and the incident longitudinal angle $\phi_j = (j-1) * \frac{2\pi}{m}, j = 1, \ldots, m$. The relaxation parameter β_k is taken to be $0.1/k$ for the tested examples. For stability analysis, some relative random noise is added to the data; i.e., the tangential trace of the electric field takes the form

$$\nu \times E|_S := (1 + \sigma \,\mathrm{rand}) \cdot (\nu \times E|_S).$$

Here, rand gives uniformly distributed random numbers in $[-1, 1]$, and σ is a noise level parameter taken to be 0.02 in our numerical experiments. Define the relative error by

$$e_2 = \frac{\left(\sum_{i,j,k} |q_{ijk} - \bar{q}_{ijk}|^2\right)^{\frac{1}{2}}}{\left(\sum_{i,j,k} |q_{ijk}|^2\right)^{\frac{1}{2}}},$$

where $\bar{q}$ is the reconstructed scatter and q is the true scatterer.

Example 4.1. Reconstruct a scatterer defined by

$$q(x, y, z) = \begin{cases} 1 - \sqrt{\frac{x^2}{1^2} + \frac{y^2}{0.8^2} + \frac{z^2}{0.5^2}} & \text{for } \frac{x^2}{1^2} + \frac{y^2}{0.8^2} + \frac{z^2}{0.5^2} \le 1, \\ 0, & \text{otherwise.} \end{cases}$$

The compact support of this scatterer is an ellipsoid contained in the unit ball. For simplicity, we take $\vec{n}_1 = \vec{n}_2$ and $\vec{p}_1 = \vec{p}_2$ to test the forward solver. The numerical

results are shown in Figure 2. In Figure 2(a), for the fixed incident latitudinal angle $\theta = \frac{\pi}{3}$ and the longitudinal angle $\phi = \frac{\pi}{3}$, the forward problem is solved at different wavenumbers. In Figure 2(b) and 2(c), for the fixed wavenumber $k = 2$, the numerical results are shown with different latitudinal angles $\theta \in [0, \pi]$ (fix $\phi = \frac{\pi}{3}$) and $\phi \in [0, 2\pi]$ (fix $\theta = \frac{\pi}{3}$), respectively. It is easily seen from Figure 2(a) that the first term of the right-hand side of the integral equation (3.2) is dominant compared with the second (nonlinear) term when the wavenumber is small, which validates the Born approximation. Figure 3 shows the slices of the true scatterer, and Figure 4 gives the reconstruction at the wavenumber $k = 6$. The relative errors are shown in Table 2 at different wavenumbers.

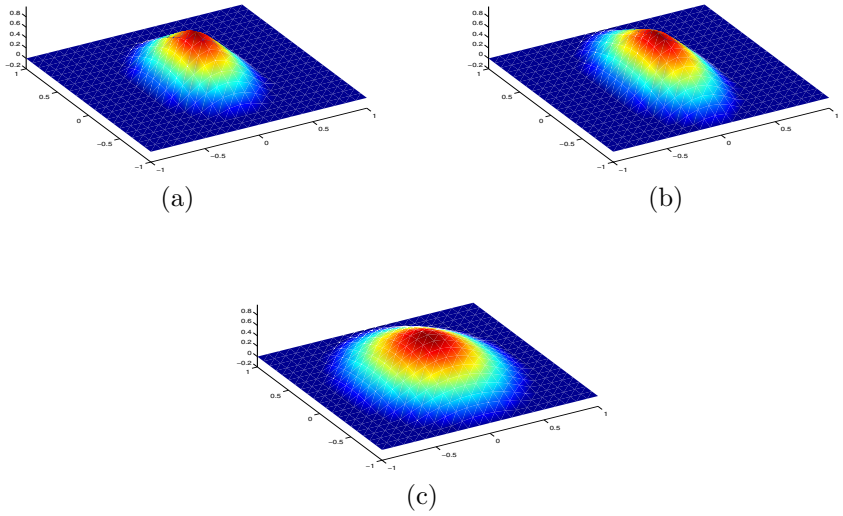

FIG. 3. *True scatterer of Example* 4.1: (a) *the slice* $x = 0$*;* (b) *the slice* $y = 0$*;* (c) *the slice* $z = 0$.

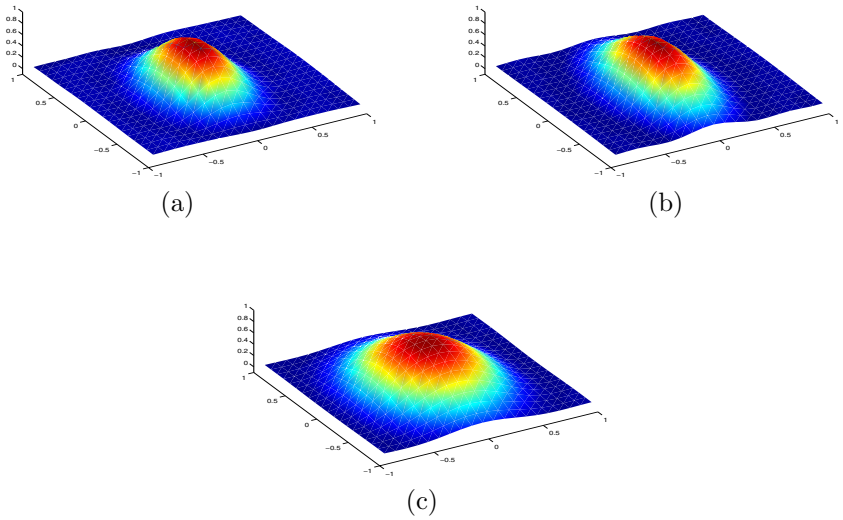

FIG. 4. *Reconstruction of Example* 4.1: (a) *the slice* $x = 0$*;* (b) *the slice* $y = 0$*;* (c) *the slice* $z = 0$.

Example 4.2. Reconstruct a scatterer defined by

$$q(x,y,z)=\begin{cases}\sin(\frac{4\pi}{25})-\sin\big((x^2+(y+0.5)^2+z^2)\pi\big) & \text{for } x^2+(y+0.5)^2+z^2\le 0.4^2,\\ \sin(\frac{4\pi}{25})-\sin\big((x^2+(y-0.5)^2+z^2)\pi\big) & \text{for } x^2+(y-0.5)^2+z^2\le 0.4^2,\\ 0, & \text{otherwise.}\end{cases}$$

The compact support of this scatterer is two isolated balls with the same radius of 0.4 and the centers at $(0,-0.5,0)$ and $(0,0.5,0)$. For simplicity, we take $\vec{n}_1 = \vec{n}_2$

and $\vec{p}_1 = \vec{p}_2$ in the test of the forward solver. The numerical results are given in Figure 5. In Figure 5(a), for the fixed incident latitudinal angle $\theta = \frac{\pi}{3}$ and the longitudinal angle $\phi = \frac{\pi}{3}$, the forward problem is solved at different wavenumbers. In Figure 5(b) and 5(c), for the fixed wavenumber $k = 3$, the numerical results are shown with different latitudinal angles $\theta \in [0, \pi]$ (fix $\phi = \frac{\pi}{3}$) and $\phi \in [0, 2\pi]$ (fix $\theta = \frac{\pi}{3}$), respectively. It is easily seen from Figure 5(a) that the first term of the right-hand side of the integral equation (3.2) is dominant compared with the second (nonlinear) term when the wavenumber k is small, which once again validates the Born approximation. Figure 6 shows the slices of the true scatterer and Figure 7 gives the reconstruction at the wavenumber $k = 7$. The relative errors are shown in Table 3 at different wavenumbers.

5. Concluding remarks. The proposed recursive linearization algorithm is stable and efficient for solving the inverse medium scattering problem with multiple

frequency scattering data in three dimensions. Theoretically, scattering data with even higher wavenumbers could be used to recover more complicated scatterers which contain higher-frequency features, i.e., more Fourier modes. However, the difficulty lies in the fact that the forward model becomes difficult to solve due to the highly oscillatory nature of the solution. For a larger k, the mesh size has to be smaller, which makes numerical solution more expensive. Finally, we point out two important future directions of this research. The first concerns the convergence analysis of the

recursive linearization algorithm, which is currently in progress and will be reported elsewhere. Another challenging project is to develop an efficient algorithm for the inverse medium scattering with fixed frequency scattering data.

STIMULUS-LOCKED TRAVELING WAVES AND BREATHERS IN AN EXCITATORY NEURAL NETWORK*

STEFANOS E. FOLIAS† AND PAUL C. BRESSLOFF*

Abstract. We analyze the existence and stability of stimulus-locked traveling waves in a one-dimensional synaptically coupled excitatory neural network. The network is modeled in terms of a nonlocal integro-differential equation, in which the integral kernel represents the spatial distribution of synaptic weights, and the output firing rate of a neuron is taken to be a Heaviside function of activity. Given an inhomogeneous moving input of amplitude I_0 and velocity v, we derive conditions for the existence of stimulus-locked waves by working in the moving frame of the input. We use this to construct existence tongues in (v, I_0)-parameter space whose tips at $I_0 = 0$ correspond to the intrinsic waves of the homogeneous network. We then determine the linear stability of stimulus-locked waves within the tongues by constructing the associated Evans function and numerically calculating its zeros as a function of network parameters. We show that, as the input amplitude is reduced, a stimulus-locked wave within the tongue of an unstable intrinsic wave can undergo a Hopf bifurcation, leading to the emergence of either a traveling breather or a traveling pulse emitter.

Key words. traveling waves, traveling breathers, inhomogeneous neural media

1. Introduction.

Understanding the conditions under which traveling waves of activity can propagate in cortical neural tissue is becoming an increasingly active area of research. Experimentally, these waves can be induced by a brief electrical stimulation of a disinhibited in vitro cortical slice [7, 14, 39, 29, 30]. The underlying mechanism for the propagation of such waves appears to be synaptic in origin rather than diffusive, with action potentials traveling along the axons of individual neurons. Axonal waves are modeled in terms of reaction diffusion equations based on either the four-variable Hodgkin–Huxley equations [20] or the reduced two-variable FitzHugh–Nagumo equations [12]. On the other hand, synaptic waves are typically modeled in terms of nonlocal integro-differential equations of the form [27]

$$\begin{aligned} \tau \frac{\partial u(x,t)}{\partial t} &= -u(x,t) + \int_{-\infty}^{\infty} w(x|x') f(u(x',t)) dx' - \beta q(x,t) + I(x,t), \\ \frac{1}{\epsilon} \frac{\partial q(x,t)}{\partial t} &= -q(x,t) + u(x,t), \end{aligned} \tag{1.1}$$

where τ is a membrane or synaptic time constant, $u(x,t)$ is a neural field that represents the local activity of a population of excitatory neurons at position $x \in \mathbb{R}$, $I(x,t)$ is an external input current, $f(u)$ denotes the output firing rate function, and $w(x|x')$ is the strength of connections from neurons at x' to neurons at x. The neural field $q(x,t)$ represents some form of local negative feedback mechanism such as spike frequency adaptation or synaptic depression, with β, ε determining the relative strength and rate of feedback. This form of inhibitory feedback is distinct from nonlocal synaptic inhibition, which tends to favor the formation of stationary bumps of

activity rather than traveling waves [38, 1, 28]. The nonlinear function f is typically taken to be a sigmoid function $f(u) = 1/(1 + \mathrm{e}^{-\gamma(u-\kappa)})$ with gain γ and threshold κ. Since there is strong vertical coupling between cortical layers, it is possible to treat a thin vertical cortical slice as an effective one-dimensional medium. Analysis of the model provides valuable information regarding how the speed of a traveling wave, which is relatively straightforward to measure experimentally, depends on various features of the underlying neural tissue [27]. Indeed, one prediction of the model, concerning how the speed of the wave depends on the firing threshold of the neurons, has recently been confirmed experimentally in disinhibited rat cortical slices [32]. External electric fields are used to modulate the threshold and thus control wave propagation.

One of the common assumptions in the analysis of traveling wave solutions of (1.1) is that the system is spatially homogeneous, that is, that the external input $I(x,t)$ is independent of both x and t and the synaptic weights depend only on the distance between presynaptic and postsynaptic cells, $w(x|x') = w(x - x')$. The existence of traveling waves can then be established for a class of positive, bounded weight distributions $w(x)$ that includes the exponential function $(2d)^{-1}\mathrm{e}^{-x/d}$, where d determines the range of synaptic coupling. For appropriate choices of network parameters, one finds that a single right- or left-moving traveling front exists in the absence of any feedback [4, 9, 21], whereas a pair of right- or left-moving traveling pulses exists when there is significant feedback [27]; numerically it is found that the faster pulse is stable, whereas the slower pulse is unstable. Following the original work of Amari [1], exact traveling wave solutions can be constructed by taking the high gain limit $\gamma \to \infty$, for which $f(u) = H(u - \kappa)$, where H is the Heaviside step function; that is, $H(u) = 1$ if $u \geq 0$ and $H(u) = 0$ if $u < 0$. The stability of traveling wave solutions of (1.1) in the case of a Heaviside firing rate function has recently been analyzed by Zhang [42, 43] using an Evans function approach. This is a technique for analyzing wave stability in unbounded domains that was originally developed within the context of reaction diffusion equations describing the axonal propagation of action potentials [10, 11, 22]. The basic idea is to linearize the full nonlinear equations about the traveling wave solution and to construct a complex analytic function known as the Evans function, whose zeros correspond to the point spectrum of the associated linear operator. Having established that the essential spectrum lies in the left-half complex plane, the wave is linearly stable if no eigenvalues have a positive real part and the zero eigenvalue is simple; the existence of the latter reflects the translation invariance of the system. Evans functions have now been applied to a variety of dissipative and Hamiltonian PDE systems [35], as well as a number of nonlocal integrodifferential equations [42, 43, 23, 34]. In the case of traveling wave solutions of (1.1), Zhang [42] derived an analytical expression for the Evans function using a variation of the parameters method to solve the inhomogeneous ordinary differential equation arising from linearization about the traveling wave solution. In the scalar case (zero feedback), the eigenvalues can be calculated explicitly and the associated front shown to be stable. On the other hand, for the full vector equation (1.1), it has been possible to prove stability of the fast traveling pulse only in the singular limit of slow feedback (small ε). However, one can still numerically evaluate the zeros of the Evans function outside this regime. This has been implemented by Coombes and Owen [8], who have extended the Evans function approach of Zhang [42] to a more general class of network models that incorporates discrete axonal delays and dendritic processing.

We have recently been interested in the effects of stationary inhomogeneous inputs on wave propagation and its failure in excitatory networks described by (1.1). As one

might expect intuitively, a sufficiently large variation in input blocks wave propagation (in one dimension) by spatially pinning the activity of the network. In particular, a step input or ramp results in a stationary front, whereas a local Gaussian input induces a stationary pulse. We have analyzed the stability of these stationary solutions for a Heaviside firing rate function, and shown how reducing the amplitude of the input can induce a Hopf bifurcation leading to the formation of a stable, spatially localized oscillatory solution, or *breather* [5, 13]. In the case of fronts, we have further shown that there is a critical level of negative feedback at which the homogeneous system undergoes a symmetry-breaking front bifurcation, whereby a stationary front loses stability and bifurcates into a pair of stable counterpropagating fronts. The front bifurcation acts as an organizing center for the formation of a breather in the presence of a weak input inhomogeneity [13]. Analogous results have been found for fronts [36, 18, 19, 2, 31] and pulses [33] in reaction diffusion systems. One of the potential difficulties in experimentally testing our predictions regarding input-induced coherent oscillations in cortical slices is that persistent currents tend to destroy the neurons. Although it might be possible to circumvent this problem using other forms of stimulation such as external electric fields [32], an alternative strategy is to consider the effects of moving stimuli. This is also more realistic from the perspective of the intact cortex, which is constantly being bombarded by nonstationary sensory inputs.

In this paper we extend the Evans function approach of Zhang [42] and our own previous work on stationary inhomogeneous inputs, in order to analyze the existence and stability of traveling waves locked to a moving input of constant speed v. In order to construct exact traveling wave solutions, we follow previous treatments [1, 27, 42] by considering a Heaviside firing rate function and a homogeneous weight distribution, for which (1.1) becomes

$$\tau \frac{\partial u(x,t)}{\partial t} = -u(x,t) - \beta q(x,t) + \int_{-\infty}^{\infty} w(x-x')H(u(x',t)-\kappa)dx' + I(x-vt),$$

$$\frac{1}{\epsilon}\frac{\partial q(x,t)}{\partial t} = -q(x,t) + u(x,t). \tag{1.2}$$

We assume throughout that $w(x)$ is a positive symmetric function that is monotonically decreasing on $[0,\infty)$ and satisfies the normalization condition $\int_{-\infty}^{\infty} w(x)dx < \infty$. The input is written as $I(x-vt) = I_0\,\chi(x-vt)$, with χ a fixed spatial profile that is either a bounded monotonically decreasing function in the case of fronts, or a unimodal Gaussian-like function in the case of pulses. The input amplitude I_0 and velocity v are treated as bifurcation parameters. Working in the moving frame of the input, we derive threshold-crossing conditions for the existence of a stimulus-locked wave, and use this to construct existence tongues in (v, I_0)-parameter space whose tips at $I_0 = 0$ correspond to the intrinsic waves of the homogeneous network, assuming that the latter exist. In the particular case of an exponential weight distribution, we show that there are two tongues in the positive v domain, corresponding to an unstable/stable pair of right-moving intrinsic waves. We determine the stability of the waves within these existence tongues by first constructing the Evans function for a general weight distribution w satisfying the properties listed below (1.2) and then numerically calculating the zeros of the Evans function for the exponential weight distribution. We show that as the input is reduced, a stimulus-locked wave within the tongue of the unstable intrinsic wave can undergo a Hopf bifurcation leading to the emergence of a traveling oscillatory wave. The latter takes the form of a breather or a pulse emitter in the moving frame of the stimulus. In the limit $v \to 0$ our results reduce to those previously obtained for stationary inputs [6, 13].

Note that analogous wave instabilities have been found in a scalar network with asymmetric lateral inhibition [40]. Such a network consists of a Mexican hat weight function $w_\circ$ that models short-range excitation and long-range inhibition, which is shifted asymmetrically from the center such that $w(x|x') = w_\circ(x - x' - s)$ for some fixed displacement s. This displacement introduces a form of directional selectivity, in which the network responds preferentially to stimuli moving in a particular direction, and has thus been suggested as a possible recurrent mechanism for the directional selectivity of neurons in visual cortex [37, 25]. Xie and Giese [40] have analyzed the existence and stability of stimulus-locked pulses in an asymmetric lateral inhibition network. They effectively construct the associated Evans function, although they do not identify it as such, and show how the pulse can destabilize when the stimulus velocity differs significantly from the natural velocity of unidirectional intrinsic waves; this instability generates a transition to a so-called lurching wave. Yet another neural system in which a traveling pulse can undergo a Hopf bifurcation leading to the formation of lurching waves is a synaptically coupled integrate-and-fire network with discrete axonal delays [15, 16]. Here a pulse consists of a single propagating spike, and the instability is due to fluctuations in the sequence of neuronal firing times, which start to grow at a critical value of the delay [3]. This example applies to intrinsic waves in a homogeneous network.

The structure of the paper is as follows. In order to illustrate the general approach, we begin by considering the simpler case of zero negative feedback ($\beta = 0$), for which (1.1) reduces to a scalar equation in u (section 2). The corresponding existence tongues for stimulus-locked fronts and their stability can be completely determined analytically. We next consider the existence of stimulus-locked pulses in the full vector system (1.1), numerically solving a set of nonlinear functional equations in order to construct the associated tongues (section 3). We then develop the linear stability analysis of stimulus-locked pulses in order to determine the stability of solutions within the tongues (section 4). Finally, we present numerical simulations illustrating the formation of traveling breathers and pulse emitters. Although we focus on traveling pulses rather than fronts in the case of the full system (1.1), it is straightforward to carry over our results to the case of stimulus-locked fronts, as briefly reported elsewhere [6]. Throughout the paper we work with dimensionless units. The fundamental time scale is taken to be the membrane time constant τ, which is assumed to be of the order 10 msec. The fundamental length scale is taken to be in the range d of synaptic coupling, which can vary from a few hundred micrometers to a few millimeters.

2. Stimulus-locked traveling fronts in a scalar equation. In this section we carry out a complete analysis of the existence and stability of stimulus-locked fronts in a scalar version of (1.2). As an illustrative example, we construct tongue diagrams for an exponential weight distribution, showing how the existence regions of fronts in the (v, I_0)-plane deform as the threshold κ is varied. We also establish that the fronts within the existence tongues are always stable.

2.1. Existence of stimulus-locked fronts. Consider

$$\frac{\partial u(x,t)}{\partial t} = -u(x,t) + \int_{-\infty}^{\infty} w(x-y)H(u(y,t)-\kappa)dy + I(x-vt), \tag{2.1}$$

where the input is taken to be a positive bounded monotonic function. We seek traveling front solutions of the form $u(x,t) = U(\xi)$, where $\xi = x - vt$ and

$$U(\xi) > \kappa, \quad \xi < \xi_0; \qquad U(\xi_0) = \kappa; \qquad U(\xi) < \kappa, \quad \xi > \xi_0,$$

for some $\xi_0 \in \mathbb{R}$. The wave of excitation is assumed to travel at the same velocity as the input, though the relative positions of the active region (above threshold) and the input may vary with respect to the velocity and the input strength. Thus, the active region is locked to the input but may precede or succeed the input in position. We take $U \in \mathcal{C}^1(\mathbb{R},\mathbb{R})$, where $\mathcal{C}^n(\mathbb{R},\mathbb{R})$ denotes the set of all n-times continuously differentiable functions $f : \mathbb{R} \longrightarrow \mathbb{R}$ that are bounded with respect to the sup norm. If $I_0 = 0$, then the system is translationally invariant and ξ_0 becomes a free parameter. In this case we refer to traveling waves as intrinsic or *natural* waves. The profile of the front is determined according to

$$-v\frac{dU(\xi)}{d\xi} = -U(\xi) + \int_{-\infty}^{\xi_0} w(\xi-\eta)d\eta + I(\xi). \tag{2.2}$$

Setting

$$W(\xi) = \int_{-\infty}^{\xi} w(\eta)d\eta,$$

we can integrate (2.2) over $[\xi,\infty)$ for $v > 0$ to obtain

$$U(\xi) = \frac{1}{v}\int_{\xi}^{\infty} e^{(\xi-\eta)/v} N_e(\eta;\xi_0)d\eta,$$

where

$$N_e(\xi;\xi_0) = 1 - W(\xi-\xi_0) + I(\xi).$$

We are assuming that w is normalized such that $\int_{-\infty}^{\infty} w(\eta)d\eta = 1$. Similarly, for $v < 0$ we integrate over $(-\infty,\xi]$ to find

$$U(\xi) = -\frac{1}{v}\int_{-\infty}^{\xi} e^{(\xi-\eta)/v} N_e(\eta;\xi_0)d\eta.$$

The threshold condition for the existence of a stimulus-locked front is $\kappa = U(\xi_0)$.

As a specific example, we consider a Heaviside input $I(\zeta) = I_0 H(-\zeta)$ and an exponential weight function

$$w(x) = \frac{1}{2d}e^{-|x|/d}, \tag{2.3}$$

with the length scale fixed by setting $d = 1$. The resulting threshold condition is

$$\kappa = \begin{cases} \dfrac{1}{2(1+v)} + \begin{cases} 0, & \xi_0 \geq 0, \\ I_0(1-e^{\xi_0/v}), & \xi_0 < 0, \end{cases} & v > 0, \\ \dfrac{1+2|v|}{2(1+|v|)} + \begin{cases} I_0 e^{\xi_0/v}, & \xi_0 > 0, \\ I_0, & \xi_0 \leq 0, \end{cases} & v < 0. \end{cases} \tag{2.4}$$

In the absence of an input ($I_0 = 0$), the threshold condition reduces to

$$\kappa = \begin{cases} \dfrac{1}{2(1+v_\circ)}, & v \geq 0, \\ \dfrac{1+2|v_\circ|}{2(1+|v_\circ|)}, & v < 0, \end{cases}$$

where $v_\circ$ is the natural speed of the wave. Solving for $v_\circ$ in terms of κ, we find that $v_\circ$ is a sigmoidal function of κ:

$$v_\circ(\kappa) = \begin{cases} \dfrac{\frac{1}{2}-\kappa}{\kappa}, & 0 < \kappa \leq \frac{1}{2}, \\ \dfrac{\frac{1}{2}-\kappa}{(\kappa-1)}, & \frac{1}{2} < \kappa < 1. \end{cases}$$

The homogeneous network supports a stationary natural front ($v_\circ = 0$) when $\kappa = \frac{1}{2}$, a front moving to the right for $0 < \kappa < \frac{1}{2}$, and front moving to the left for $\frac{1}{2} < \kappa < 1$. Moreover, $v_\circ \to \infty$ as $\kappa \to 0$ and $v_\circ \to -\infty$ as $\kappa \to 1$. It does not support a natural front when $\kappa > 1$, as any heteroclinic orbit joining the equilibrium $\{0, 1\}$ at infinity does not satisfy the threshold behavior used to define a traveling front solution. This recovers a result from [9].

We now analyze (2.4) for $I_0 > 0$ in order to determine the regions of the (v, I_0)-parameter subspace for which stimulus-locked waves exist. We first consider the case $v > 0$. For $\xi_0 \geq 0$ we have the threshold condition

$$\kappa = \frac{1}{2(1+v)},$$

and hence there are infinitely many waves parameterized by $\xi_0 \in [0, \infty)$, all of which travel with the natural speed $v = \frac{1-2\kappa}{2\kappa}$ for $0 < \kappa < \frac{1}{2}$. This degeneracy is a consequence of using the Heaviside input and would not occur if a continuous strictly monotonic input were used; however, the analysis is considerably more involved. For $\xi_0 < 0$ we have instead

$$\kappa = \frac{1}{2(1+v)} + I_0(1 - e^{\xi_0/v}).$$

As the right-hand side is monotonic in ξ_0, we can solve for ξ_0 as a function of v to obtain

$$\xi_0(v) = v \ln \left[1 - \frac{1}{I_0} \left(\kappa - \frac{1}{2(1+v)} \right) \right].$$

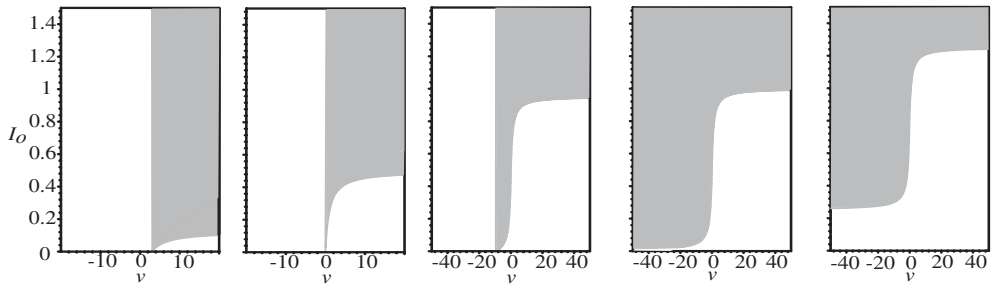
Since $\xi_0 < 0$ and $v > 0$, we see that solutions exist only if

$$0 < 1 - \frac{1}{I_0} \left(\kappa - \frac{1}{2(1+v)} \right) \leq 1$$

or, equivalently,

$$2(\kappa - I_0) \ < \ \frac{1}{1+v} \ \leq \ 2\kappa. \tag{2.5}$$

The right inequality of (2.5) implies that, if $\kappa < \frac{1}{2}$, then $v > v_\circ(\kappa)$, where $v_\circ$ is the corresponding natural velocity. Similarly, the left inequality implies that, if $I_0 < \kappa$, then $0 < v < v_1(\kappa - I_0)$, with $v_1(s) = \frac{1}{2s} - 1$. Hence, for $0 < \kappa \leq \frac{1}{2}$ we obtain the existence regions in the (v, I_0)-plane shown in Figure 2.1(a)–(b). The left boundary is given by $v = v_\circ(\kappa)$ and the right boundary by $v = v_1(\kappa - I_0)$. The two boundaries form a tongue that emerges from the natural speed $v_\circ(\kappa)$ at $I_0 = 0$.



(a) $0 < \kappa < 1/2$ (b) $\kappa = 1/2$ (c) $1/2 < \kappa < 1$ (d) $\kappa = 1$ (e) $\kappa > 1$

FIG. 2.1. *Deformation of existence regions (gray) for stimulus-locked traveling fronts as* κ *varies in the scalar equation. Particular values of* κ *are as follows:* (a) $\kappa = 0.125$, (c) $\kappa = 0.95$, (e) $\kappa = 1.25$.

Now consider $v < 0$. For $\xi_0 < 0$ we have the threshold condition

$$\kappa = \frac{1 + 2|v|}{2(1 + |v|)} + I_0,$$

which implies

$$|v| = \frac{1 - 2(\kappa - I_0)}{2(\kappa - I_0 - 1)} \equiv v_2(\kappa - I_0).$$

Again we have an infinite family of waves corresponding to a single speed. Since $|v| \geq 0$, such solutions exist only for

$$\kappa - 1 \ < \ I_0 \ < \ \kappa - \frac{1}{2}.$$

On the other hand, for $\xi_0 \geq 0$ we have the threshold condition

$$\kappa = \frac{1 + 2|v|}{2(1 + |v|)} + I_0 e^{\xi_0/v}.$$

Monotonicity of the right-hand side again allows us to solve for $\xi_0(v)$ to find

$$\xi_0(v) = v \ln \left[\frac{1}{I_0} \left(\kappa - \frac{1 + 2|v|}{2(1 + |v|)} \right) \right],$$

and, since $v < 0$ and $\xi_0 \geq 0$, it follows that waves exist only for v satisfying

$$\kappa - I_0 \leq \frac{1 + 2|v|}{2(1 + |v|)} < \kappa. \tag{2.6}$$

The right inequality of (2.6) implies that if $\frac{1}{2} < \kappa < 1$, then $v_\circ(\kappa) < v < 0$. Thus, for $\frac{1}{2} < \kappa < 1$ we obtain the existence region shown in Figure 2.1(c); the left boundary is given by $v = v_0(\kappa)$ and the right boundary by $v = v_2(\kappa - I_0)$ for $v < 0$ and $v = v_1(\kappa - I_0)$ for $v > 0$. Again there is a tongue with tip at the natural speed. For $\kappa > 1$ the left boundary disappears, and one finds stimulus-locked waves only when $I_0 > \kappa - 1$, i.e., when there no longer exist natural waves. The left inequality of (2.6) implies that if $\frac{1}{2} < \kappa - I_0 < 1$, then $v < v_2(\kappa - I_0) < 0$, whereas if $\kappa - I_0 > 1$, then no solution exists. For all $\kappa > 1$ the region of existence is identical to that for $\kappa = 1$, though it is shifted vertically by $\kappa - 1$, as shown in Figure 2.1(d)–(e).

2.2. Stability of stimulus-locked fronts. Consider the evolution of small smooth perturbations $\bar{\varphi}$ of the stimulus-locked front solution U. Linearizing (2.1) about the wave, the perturbations evolve according to

$$\frac{\partial \bar{\varphi}}{\partial t} - v\frac{\partial \bar{\varphi}}{\partial \xi} + \bar{\varphi} = \int_{\mathbb{R}} w(\xi-\eta)H'(U(\eta)-\kappa)\bar{\varphi}(\eta)d\eta. \tag{2.7}$$

Separating variables, $\bar{\varphi}(\xi,t) = \varphi(\xi)e^{\lambda t}$, we find that $\varphi \in \mathcal{C}^1(\mathbb{R},\mathbb{C})$ satisfies the eigenvalue problem

$$(\mathcal{L}+\mathcal{N}_s)\,\varphi = \lambda\,\varphi, \tag{2.8}$$

where

$$\mathcal{L}\varphi = v\frac{\partial \varphi}{\partial \xi} - \varphi, \qquad \mathcal{N}_s\varphi\,(\xi) = \frac{w(\xi-\xi_0)}{|U'(\xi_0)|}\,\varphi(\xi_0). \tag{2.9}$$

We need to characterize the spectrum of the linear operator $\mathcal{L}+\mathcal{N}_s : \mathcal{C}^1(\mathbb{R},\mathbb{C}) \longrightarrow \mathcal{C}^0(\mathbb{R},\mathbb{C})$ in order to determine the linear stability of the traveling pulse. The following definitions concern linear operators $\mathcal{T} : \mathcal{D}(\mathcal{T}) \longrightarrow \mathcal{B}$, where $\mathcal{B}$ is a Banach space and the domain $\mathcal{D}(\mathcal{T})$ of $\mathcal{T}$ is dense in $\mathcal{B}$ [41]. In our case $\mathcal{D}(\mathcal{L}+\mathcal{N}_s) = \mathcal{C}^1(\mathbb{R},\mathbb{C})$, which is dense in $\mathcal{C}^0(\mathbb{R},\mathbb{C})$. λ is in the resolvent set ρ if $\lambda \in \mathbb{C}$ is such that $\mathcal{T}-\lambda$ has a range dense in $\mathcal{B}$ and a continuous inverse $(\mathcal{T}-\lambda)^{-1}$; otherwise λ is in the spectrum σ. We decompose the spectrum into the following disjoint sets: λ is an element of the point spectrum σ_p if $\mathcal{T}-\lambda$ is not invertible; λ is an element of the continuous spectrum σ_c if $\mathcal{T}-\lambda$ has an unbounded inverse with domain dense in $\mathcal{B}$; λ is an element of the residual spectrum σ_r if $\mathcal{T}-\lambda$ has an inverse (bounded or not) whose domain is not dense in $\mathcal{B}$. We refer to elements of the point spectrum as eigenvalues and the union of the continuous and residual spectra as the essential spectrum.

Regarding the essential spectrum, we mention that $\mathcal{N}_s$ is a compact linear operator. The consequence is that, since $\mathcal{N}_s$ is compact, the operators $\mathcal{L}+\mathcal{N}_s$ and $\mathcal{L}$ have the same essential spectra [24, 23]. To see that the operator is compact, we define $\mathcal{N}_s$ by the composition $\mathcal{TS}$, where

$$\mathcal{S}\,\varphi = \varphi(\xi_0), \qquad (\mathcal{T}\,z)(\xi) = \frac{w(\xi-\xi_0)}{|U'(\xi_0)|}z.$$

Since $\mathcal{S} : \mathcal{C}^1(\mathbb{R},\mathbb{C}) \longrightarrow \mathbb{C}$ has a finite-dimensional range, it is a compact linear operator. Moreover, since $\mathcal{T} : \mathbb{C} \longrightarrow \mathcal{C}^0(\mathbb{R},\mathbb{C})$ is a bounded linear operator, it follows that the composition $\mathcal{TS}$ is a compact linear operator.

Resolvent and the point spectrum. We seek to construct a bounded inverse by solving the inhomogeneous equation

$$(\mathcal{L}+\mathcal{N}_s-\lambda)\varphi = -f, \tag{2.10}$$

where $f \in \mathcal{C}^0(\mathbb{R},\mathbb{C})$, using a variation of parameters approach along the lines of Zhang [42]. We write (2.10) as

$$\frac{\partial}{\partial \xi}\Big(e^{-\left(\frac{1+\lambda}{v}\right)\xi}\,\varphi(\xi)\Big) = -\frac{1}{v}\,e^{-\left(\frac{1+\lambda}{v}\right)\xi}\,\Big(\mathcal{N}_s\varphi(\xi)+f(\xi)\Big). \tag{2.11}$$

For $\frac{\mathcal{R}e(\lambda)+1}{v} > 0$, integrating (2.11) over $[\xi,\infty)$ yields

$$\varphi(\xi) - \Lambda_+(\lambda;\xi)\,\varphi(\xi_0) \;=\; \mathcal{H}_f(\xi), \tag{2.12}$$

where

$$\Lambda_+(\lambda;\xi) = \frac{1}{v|U'(\xi_0)|}\int_\xi^\infty w(\eta-\xi_0)e^{\left(\frac{1+\lambda}{v}\right)(\xi-\eta)}d\eta,$$

$$\mathcal{H}_f(\xi) = \frac{1}{v}\int_\xi^\infty e^{\left(\frac{1+\lambda}{v}\right)(\xi-\eta)}f(\eta)d\eta.$$

Using the Hölder inequality, it can be shown that both $\Lambda_+(\lambda;\xi)$ and $\mathcal{H}_f(\xi)$ are bounded for all $\xi \in \mathbb{R}$ and $f \in \mathcal{C}^0(\mathbb{R},\mathbb{C})$. It is then seen from (2.12) that $\varphi(\xi)$ is determined by its restriction $\varphi(\xi_0)$, in which case we obtain

$$\left(1-\Lambda_+(\lambda;\xi_0)\right)\varphi(\xi_0) = \frac{1}{v}\int_{\xi_0}^\infty e^{\left(\frac{1+\lambda}{v}\right)(\xi-\eta)}f(\eta)d\eta.$$

This can be solved for $\varphi(\xi_0)$ and hence for $\varphi(\xi)$ if and only if

$$1-\Lambda_+(\lambda;\xi_0) \neq 0.$$

This results in a bounded inverse which is defined on all of $\mathcal{C}^0(\mathbb{R},\mathbb{C})$, and therefore all corresponding λ are in the resolvent set. On the other hand, we cannot invert the operator for λ such that

$$1-\Lambda_+(\lambda;\xi_0) = 0.$$

In this case

$$(\mathcal{L}+\mathcal{N}_s-\lambda)\varphi = 0 \tag{2.13}$$

has nontrivial solutions, indicating that λ is in the point spectrum. Moreover, if we define the function

$$\mathcal{E}_+(\lambda;\xi_0) = 1-\Lambda_+(\lambda;\xi_0), \qquad \frac{\mathcal{R}e(\lambda)+1}{v} > 0,$$

we see that eigenvalues form the zero set. Similarly for $\frac{\mathcal{R}e(\lambda)+1}{v} < 0$, integrating (2.11) over $(-\infty,\xi_0]$ yields a similar condition for the existence of eigenfunctions

$$1 = \Lambda_-(\lambda,\xi_0), \qquad \frac{\mathcal{R}e(\lambda)+1}{v} < 0,$$

where

$$\Lambda_-(\lambda;\xi) = -\frac{1}{v|U'(\xi_0)|}\int_{-\infty}^\xi w(\eta-\xi_0)e^{\left(\frac{1+\lambda}{v}\right)(\xi-\eta)}d\eta. \tag{2.14}$$

The Evans function is then defined as

$$\mathcal{E}(\lambda;\xi_0) = 1-\Lambda_\pm(\lambda;\xi_0), \qquad \frac{\mathcal{R}e(\lambda)+1}{v} \gtrless 0.$$

Essential spectrum. Since $\mathcal{N}_s$ does not contribute to the essential spectrum of $\mathcal{L}+\mathcal{N}_s$, we need only calculate the essential spectrum of the linear operator $\mathcal{L}$. The essential spectrum is the set of $\lambda = -1 + iv\rho$, where $\rho \in \mathbb{R}$. Since this has negative real part, the essential spectrum does not contribute to any wave instabilities. We demonstrate that, for these values of λ, there exist bounded functions for which the inverse operator $(\mathcal{L}-\lambda)^{-1}$ becomes unbounded, indicating that λ is a member of the continuous spectrum.

Suppose that $\lambda = -1 + iv\rho$, and consider the sequence of bounded functions [43]

$$\varphi_m(\xi) = (1 - e^{-\xi^2/2m^2})e^{i\rho\xi}, \qquad m \in \mathbb{N},$$

for which

$$\|\varphi_m\|_\infty = 1 \qquad \forall \ \ m \in \mathbb{N},\ \rho \in \mathbb{R}.$$

However,

$$(\mathcal{L}-\lambda)\varphi_m(\xi) = \frac{v}{m^2}\ \xi e^{-\xi^2/2m^2}\ e^{i\rho\xi},$$

which implies that

$$\left\|(\mathcal{L}-\lambda)\varphi_m\right\|_\infty = \frac{v}{m^2}\left\|\xi e^{-\xi^2/2m^2}\right\|_\infty \longrightarrow 0 \quad \text{as} \quad m \longrightarrow \infty.$$

Hence, $(\mathcal{L}-\lambda)^{-1}$ is unbounded, and the set of $\lambda = -1 + iv\rho$, where $\rho \in \mathbb{R}$, form the essential spectrum. The residual spectrum in this case is empty, though we shall see that the vector system does, in fact, have a nonempty residual spectrum.

Evans function for an exponential weight distribution. We now explicitly calculate the zeros of the Evans functions for a Heaviside input and exponential weight distribution. The region in the complex plane $\mathbf{D} = \{z \ : \ \mathcal{R}e(z) > -1\}$ is the domain of the Evans function $\mathcal{E}_+$, and we need only consider this region to determine the stability of the wave. For $v > 0$ and $\lambda \in \mathbf{D}$,

$$\begin{aligned}\mathcal{E}_+(\lambda,\xi_0) &= 1 - \frac{1}{v|U'(\xi_0)|}\int_{\xi_0}^{\infty} w(\eta-\xi_0)e^{\left(\frac{1+\lambda}{v}\right)(\xi_0-\eta)}d\eta \\ &= 1 - \frac{1}{2(1+\lambda+v)}\frac{1}{|U'(\xi_0)|},\end{aligned}$$

and similarly for $v < 0$ and $\lambda \in \mathbf{D}$,

$$\begin{aligned}\mathcal{E}_-(\lambda,\xi_0) &= 1 + \frac{1}{v|U'(\xi_0)|}\int_{-\infty}^{\xi_0} w(\eta-\xi_0)e^{\left(\frac{1+\lambda}{v}\right)(\xi_0-\eta)}d\eta \\ &= 1 + \frac{1}{2(1+\lambda+v)}\frac{1}{|U'(\xi_0)|}.\end{aligned}$$

Note that this recovers the Evans function obtained by Zhang [42] in the case of a homogeneous input. From this we can directly solve $\mathcal{E}_\pm(\lambda;\xi_0) = 0$ for λ:

$$\lambda = -(1+|v|) + \frac{1}{2|U'(\xi_0)|}, \qquad v \in \mathbb{R}, \tag{2.15}$$

with $U'(\xi_0)$ determined from (2.2),

$$U'(\xi_0) = \frac{1}{v}\left(U(\xi_0) - \int_{-\infty}^{\xi_0} w(\xi_0 - \eta)d\eta - I(\xi_0)\right)$$
$$= \frac{1}{v}\left(\kappa - \frac{1}{2} - I(\xi_0)\right)$$

and κ satisfying the self-consistency conditions (2.4).

In the case $I_0 = 0$ the eigenvalues are given by

$$\lambda = -(1 + |v|) + \frac{|v|}{2\left|\kappa - \frac{1}{2}\right|}, \qquad v \in \mathbb{R}, \tag{2.16}$$

where v is the natural wave speed. Substituting (2.4) into (2.16), we find that the only eigenvalue in $\mathbf{D}$ is the zero eigenvalue $\lambda = 0$. Moreover, it can be shown that the eigenvalue is simple [42] and hence that the natural front is linearly stable, modulo uniform translations.

In the case of an inhomogeneous input ($I_0 > 0$), we have to deal with each of the separate subdomains of the threshold conditions (2.4). First, for $v > 0,\ \xi_0 > 0$ we notice that $I(\xi_0) = 0$ and κ is identical to the case of a natural wave; hence, $\lambda = 0$ is the only eigenvalue in $\mathbf{D}$. If $v > 0,\ \xi_0 < 0$, substituting (2.4) for κ into (2.15) yields the eigenvalue

$$\lambda = -1 - v + \frac{v}{2|\kappa - \frac{1}{2} - I_0|}$$
$$= (1 + v)\left[-1 + \frac{v}{\left|v + 2(1 + v)I_0(1 - e^{\xi_0/v})\right|}\right].$$

Since $I_0(1 - e^{\xi_0/v}) > 0$ for all $v > 0,\ \xi_0 < 0,\ I_0 > 0$, it follows that $\lambda < 0$ and the corresponding front is always stable. On the other hand, if $v < 0$ and $\xi_0 < 0$, we find $\lambda = 0$, again indicating stability with respect to the degenerate family of waves corresponding to the boundary of the tongue. For $\xi_0 > 0$ we similarly calculate

$$\lambda = (1 + |v|)\left[-1 + \frac{|v|}{\left||v| + 2(1 + |v|)I_0 e^{\xi_0/v}\right|}\right].$$

Since $2(1 + |v|)I_0 e^{\xi_0/v} > 0$ for $v < 0,\ \xi_0 > 0,\ I_0 > 0$, it again follows that $\lambda < 0$ and the corresponding front is always stable.

3. Stimulus-locked traveling pulses in the vector system. In this section we construct stimulus-locked traveling pulse solutions of (1.2) in the case of a unimodal input moving with constant velocity v. We first derive the formal solution for a general weight distribution w, and then use this to construct existence tongues in the (v, I_0)-plane for an exponential weight distribution and a Gaussian input of amplitude I_0.

3.1. Existence of stimulus-locked pulses. Consider a traveling pulse that is generated by, and locked to, an inhomogeneous input I traveling with constant speed v. Such a wave has permanent or *stationary* form; i.e., it translates as a rigid structure. Define the traveling wave coordinates (ξ, t), where $\xi = x - vt$ and v is

the velocity associated with the input. A *stimulus-locked traveling pulse* is a pair of functions (U,Q), with $U,Q \in \mathcal{C}^1(\mathbb{R},\mathbb{R})$, which in traveling wave coordinates satisfy the conditions

$$\begin{aligned} &U(\xi_i)=\kappa, \qquad i=1,2; && U(\xi)\longrightarrow 0 \qquad \text{as } \xi\longrightarrow\pm\infty;\\ &U(\xi)>\kappa, \qquad \xi_1<\xi<\xi_2; && U(\xi) < \kappa, \qquad \text{otherwise,}\end{aligned}$$

with ξ_1,ξ_2 defining the points at which the activity U crosses threshold. Taking $u(x,t)=U(x-vt)$ and $q(x,t)=Q(x-vt)$, the profile of the pulse is governed by

$$\begin{aligned} -v\,U_\xi &= -U-\beta Q+\int_{\xi_1}^{\xi_2} w(\xi-\eta)d\eta + I(\xi),\\ -\frac{v}{\epsilon}\,Q_\xi &= -Q \;+\; U.\end{aligned}$$

In general, we take the excitatory weight function $w(x)$ to be nonnegative, continuous, symmetric in x, and monotonically decreasing in $|x|$. Let $\mathbf{s}=(U,Q)^T$ and W denote an antiderivative of w; we can rewrite the system more compactly as

$$\mathcal{L}\mathbf{s} \equiv \begin{pmatrix} vU_\xi - U - \beta Q \\ vQ_\xi + \epsilon U - \epsilon Q\end{pmatrix} = -\begin{pmatrix} N_e \\ 0\end{pmatrix}, \tag{3.1}$$

where

$$N_e(\xi) = W(\xi-\xi_1) - W(\xi-\xi_2) + I(\xi). \tag{3.2}$$

We use variation of parameters to solve this linear equation. The homogeneous problem $\mathcal{L}\mathbf{s}=\mathbf{0}$ has the two linearly independent solutions,

$$\mathbf{S}_+(\xi) = \begin{pmatrix} \beta \\ m_+ - 1\end{pmatrix}\exp(\mu_+\xi), \qquad \mathbf{S}_-(\xi) = \begin{pmatrix} \beta \\ m_- - 1\end{pmatrix}\exp(\mu_-\xi),$$

where

$$\mu_\pm = \frac{m_\pm}{v}, \qquad m_\pm = \frac{1}{2}\Big(1+\epsilon \pm \sqrt{(1-\epsilon)^2-4\epsilon\beta}\Big).$$

We set

$$\mathbf{s}(\xi) = \Big[\mathbf{S}_+\big|\mathbf{S}_-\Big]\begin{pmatrix} a(\xi)\\ b(\xi)\end{pmatrix},$$

where $a,b\in\mathcal{C}^1(\mathbb{R},\mathbb{R})$ and $[A|B]$ denotes the matrix whose first column is defined by the vector A and whose second column is defined by the vector B. Since $\mathcal{L}\mathbf{S}_\pm = 0$, (3.1) becomes

$$\Big[\mathbf{S}_+\big|\mathbf{S}_-\Big]\,\frac{\partial}{\partial\xi}\begin{pmatrix} a(\xi)\\ b(\xi)\end{pmatrix} = -\frac{1}{v}\begin{pmatrix} N_e(\xi)\\ 0\end{pmatrix}. \tag{3.3}$$

Since $[\mathbf{S}_+|\mathbf{S}_-]$ is invertible, we find

$$\frac{\partial}{\partial\xi}\begin{pmatrix} a(\xi)\\ b(\xi)\end{pmatrix} = -\frac{1}{v\beta(m_+-m_-)}\Big[\mathbf{Z}_+\big|\mathbf{Z}_-\Big]^T\begin{pmatrix} N_e(\xi)\\ 0\end{pmatrix},$$

where

$$\mathbf{Z}_+(\xi) = \begin{pmatrix} 1-m_- \\ \beta \end{pmatrix} \exp(-\mu_+\xi), \qquad \mathbf{Z}_-(\xi) = -\begin{pmatrix} 1-m_+ \\ \beta \end{pmatrix} \exp(-\mu_-\xi).$$

For $v > 0$, we integrate over $[\xi, \infty)$ to obtain

$$\begin{pmatrix} a(\xi) \\ b(\xi) \end{pmatrix} = \begin{pmatrix} a_\infty \\ b_\infty \end{pmatrix} + \frac{1}{v\beta(m_+ - m_-)} \int_\xi^\infty \Big[\mathbf{Z}_+ \big| \mathbf{Z}_-\Big]^T \begin{pmatrix} N_e(\eta) \\ 0 \end{pmatrix} d\eta,$$

where a_∞, b_∞ denote the values of $a(\xi), b(\xi)$ as $\xi \longrightarrow \infty$. Thus

(3.4)
$$\mathbf{s}(\xi) = \Big[\mathbf{S}_+ \big| \mathbf{S}_-\Big] \begin{pmatrix} a_\infty \\ b_\infty \end{pmatrix} + \frac{1}{v\beta(m_+ - m_-)} \Big[\mathbf{S}_+ \big| \mathbf{S}_-\Big] \int_\xi^\infty \Big[\mathbf{Z}_+ \big| \mathbf{Z}_-\Big]^T \begin{pmatrix} N_e(\eta) \\ 0 \end{pmatrix} d\eta.$$

Using the Hölder inequality and that $N_e \in \mathcal{C}^0(\mathbb{R}, \mathbb{R})$, it is straightforward to show that the integral term in (3.4) is bounded for all $\xi \in \mathbb{R}$; hence, a bounded solution $\mathbf{s}$ exists only if $a_\infty = b_\infty = 0$. The general stimulus-locked pulse is given by

$$\mathbf{s}(\xi) = \frac{1}{v\beta(m_+ - m_-)} \Big[\mathbf{S}_+ \big| \mathbf{S}_-\Big] \int_\xi^\infty \Big[\mathbf{Z}_+ \big| \mathbf{Z}_-\Big]^T \begin{pmatrix} N_e(\eta) \\ 0 \end{pmatrix} d\eta.$$

Furthermore, if we define the functions

$$\mathcal{M}_\pm(\xi) = \frac{1}{v(m_+ - m_-)} \int_\xi^\infty e^{\mu_\pm(\xi-\eta)} N_e(\eta) d\eta,$$

we can express the solution (U, Q) as follows:

$$U(\xi) = (1-m_-)\mathcal{M}_+(\xi) - (1-m_+)\mathcal{M}_-(\xi), \tag{3.5}$$

$$Q(\xi) = \beta^{-1}(m_+ - 1)(1-m_-)\big[\mathcal{M}_+(\xi) - \mathcal{M}_-(\xi)\big]. \tag{3.6}$$

Since $N_e(\xi)$ is dependent upon ξ_1, ξ_2, the threshold conditions $U(\xi_i) = \kappa$, where $i = 1, 2$ and $\xi_1 < \xi_2$, determine the relationship between the input strength I_0 and the position of the pulse relative to the input I. This provides the following consistency conditions for the existence of a stimulus-locked traveling pulse, which, we note, reduce to the case of natural waves for $I_0 = 0$:

$$\kappa = (1-m_-)\mathcal{M}_+(\xi_1) - (1-m_+)\mathcal{M}_-(\xi_1), \tag{3.7}$$

$$\kappa = (1-m_-)\mathcal{M}_+(\xi_2) - (1-m_+)\mathcal{M}_-(\xi_2). \tag{3.8}$$

3.2. Pulses for an exponential weight distribution. Consider, in particular, an exponential weight distribution given by (2.3) with $d = 1$ and a Gaussian input

$$I(x) = I_0\, e^{-(x/\sigma)^2}. \tag{3.9}$$

Existence conditions determined from (3.7) and (3.8) yield the following system of nonlinear equations that determines the relationship between the input parameters (v, I_0) and the threshold points (ξ_1, ξ_2):

$$\kappa = K(\xi_1 - \xi_2) + T_+(\xi_1) - T_-(\xi_1), \tag{3.10}$$

$$\kappa = J(\xi_1 - \xi_2) + T_+(\xi_2) - T_-(\xi_2), \tag{3.11}$$

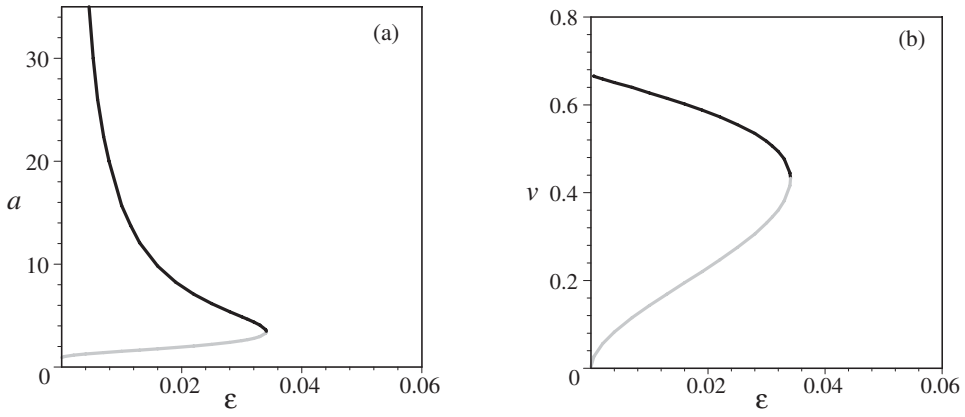


FIG. 3.1. *Bifurcation curves for the existence of natural traveling pulses ($I_0 = 0$) for the vector system* (1.2) *in* (a) *the (ϵ, a)-plane and* (b) *the (ϵ, v)-plane, illustrating that natural waves exist only for small ϵ. Here $a = \xi_2 - \xi_1$ denotes the width of a pulse. The stable branch (black), characterized by wide (large a), fast pulses, and the unstable branch (gray), characterized by narrow, slow pulses, annihilate in a saddle-node bifurcation at a critical value ϵ_c. In this case $\kappa = 0.3$, $\beta = 2.5$, and $\epsilon_c \approx 0.341$.*

where

$$K(\zeta) = K_0 + K_1 e^{\zeta} - K_+ e^{\mu_+ \zeta} + K_- e^{\mu_- \zeta}, \qquad J(\zeta) = \frac{v+\epsilon}{2(v+m_+)(v+m_-)}\Big(1 - e^{\zeta}\Big),$$

$$K_1 = \frac{1}{2}\frac{v-\epsilon}{(v-m_+)(v-m_-)}, \qquad K_\pm = \frac{v^2(1-m_\mp)}{m_\pm(v^2 - {m_\pm}^2)(m_+ - m_-)},$$

$$K_0 = \left(\frac{(1-m_-)(2v+m_+)}{2m_+(v+m_+)(m_+-m_-)}\right) - \left(\frac{(1-m_+)(2v+m_-)}{2m_-(v+m_-)(m_+-m_-)}\right),$$

$$T_\pm(\zeta) = \frac{\sqrt{\pi}\ \sigma I_0}{2\ v}\ \left(\frac{1-m_\mp}{m_+ - m_-}\right) \exp\left(\frac{(\mu_\pm \sigma)^2}{4} + \mu_\pm \zeta\right) \mathbf{erfc}\left(\frac{\zeta}{\sigma} + \frac{\mu_\pm \sigma}{2}\right),$$

and $\mathbf{erfc}(z)$ denotes the complementary Error function.

Natural traveling pulses ($I_0 = 0$). Numerically solving (3.10) and (3.11) for $I_0 = 0$, we find that for sufficiently small ϵ there exists a pair of traveling pulses arising from a saddle-node bifurcation. Numerical simulations suggest that the larger and faster pulse is stable while the smaller slower pulse is unstable and acts as a separatrix between the fast pulse and the rest state [27]. Zhang's analysis has shown the fast pulse to be stable in the singular limit $\epsilon \longrightarrow 0$ [42]. In Figure 3.1 we present bifurcation diagrams using ϵ as a bifurcation parameter to demonstrate the existence and stability of natural waves; stability is determined by numerically solving for the zero set of the Evans function, constructed in section 4.2. It is found that the larger, faster wave is stable (black), while the smaller, slower wave is unstable (gray).

Stimulus-locked traveling pulses. Numerically solving (3.10) and (3.11) for $I_0 > 0$, we can determine the regions in the (v, I_0)-plane where one or more stimulus-locked waves exist. First, performing a continuation from the pair of natural waves, we generate a corresponding pair of existence tongues with tips at $I_0 = 0$. These are illustrated in Figure 3.2 with the left-hand (right-hand) tongue emerging from the unstable (stable) natural wave. We then note that the left-hand tongue includes

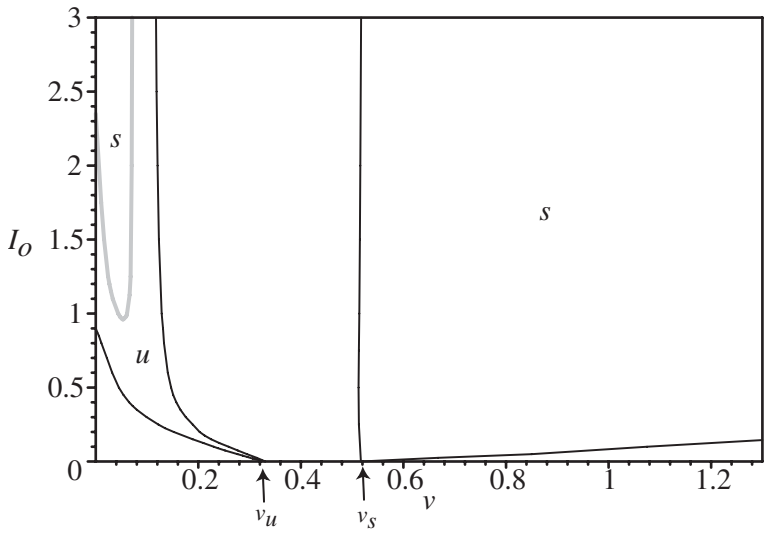

FIG. 3.2. *Regions of existence of the stimulus-locked traveling pulses in the* (v, I_0)*-plane for* $\sigma = 1.0$*,* $\kappa = 0.3$*,* $\epsilon = 0.03$*, and* $\beta = 2.5$*. The left and right regions form tongues that issue from the unstable* v_u *and stable* v_s *natural traveling pulses, respectively. The Hopf curve within the left-hand tongue is shown in gray. Stationary pulses correspond to the intersection of the tongue and the line* $v = 0$*.*

stationary pulses at $v = 0$. In previous work we have shown how a stationary unimodal input can generate a stable stationary pulse that bifurcates to a stable breather via a Hopf bifurcation as the input amplitude is reduced [5, 13]. In section 4 we construct the associated Evans function for traveling pulses within the tongue regions and use this to determine the stability of stimulus-locked pulses. We find that there is a Hopf curve within the left-hand tongue that is a continuation of the Hopf bifurcation point for stationary pulses ($v = 0$); this is shown in Figure 3.2 by the gray curve. Above the Hopf curve the pulse is stable, while it is unstable below. On the other hand the pulse within the right-hand tongue is always stable. Finally, note that there also exist additional stimulus-locked pulse solutions in certain subregions inside as well as outside of the tongues; however, these are found to be always unstable.

4. Stability of the stimulus-locked traveling pulse. We begin by analyzing the resolvent and the spectrum of the operator associated with the linearization of the vector system (1.2) about the general stimulus-locked traveling pulse constructed in section 3.1. This analysis indicates that potential instabilities arise only due to the behavior of eigenvalues, which can be determined by calculation of the zero set of the Evans function. We then present the explicit construction of the Evans function for the stimulus-locked traveling pulse in the particular case of the exponential weight distribution, and calculate the zero sets of this Evans function for the pulse existence tongues shown in Figure 3.2, thereby determining their stability.

4.1. Spectral analysis of the linearized operator. Consider the evolution of small smooth perturbations of the stimulus-locked traveling pulse with stationary form (U, Q),

$$u = U + \bar{\varphi},$$
$$q = Q + \bar{\psi}.$$

Substituting into the system expressed in traveling wave coordinates and linearizing, we find that the perturbations, to first order, satisfy

$$\frac{\partial \bar{\varphi}}{\partial t} - v\frac{\partial \bar{\varphi}}{\partial \xi} + \bar{\varphi} + \beta\bar{\psi} = \int_{\mathbb{R}} w(\xi-\eta)H'(U(\eta)-\kappa)\bar{\varphi}(\eta)d\eta, \tag{4.1}$$

$$\frac{\partial \bar{\psi}}{\partial t} - v\frac{\partial \bar{\psi}}{\partial \xi} - \epsilon\bar{\varphi} + \epsilon\bar{\psi} = 0. \tag{4.2}$$

Separating variables,

$$\begin{pmatrix} \bar{\varphi}(\xi,t) \\ \bar{\psi}(\xi,t) \end{pmatrix} = \begin{pmatrix} \varphi(\xi) \\ \psi(\xi) \end{pmatrix} e^{\lambda t}, \tag{4.3}$$

the spatial components $\varphi, \psi \in \mathcal{C}^1(\mathbb{R},\mathbb{C})$ satisfy the spectral problem

$$(\mathcal{L}+\mathcal{N}_s)\begin{pmatrix} \varphi \\ \psi \end{pmatrix} = \lambda\begin{pmatrix} \varphi \\ \psi \end{pmatrix}, \tag{4.4}$$

where

$$\mathcal{L} = v\frac{\partial}{\partial \xi} - \mathcal{A}, \qquad \mathcal{A} = \begin{bmatrix} 1 & \beta \\ -\epsilon & \epsilon \end{bmatrix}, \tag{4.5}$$

$$\mathcal{N}_s\begin{pmatrix} \varphi \\ \psi \end{pmatrix} = \begin{pmatrix} \frac{w(\xi-\xi_1)}{|U'(\xi_1)|}\,\varphi(\xi_1) + \frac{w(\xi-\xi_2)}{|U'(\xi_2)|}\,\varphi(\xi_2) \\ 0 \end{pmatrix}. \tag{4.6}$$

Resolvent and the point spectrum. Letting $\mathbf{z} = (\varphi,\psi)^T$, we seek to construct a bounded inverse by solving

$$(\mathcal{L}+\mathcal{N}_s-\lambda)\mathbf{z} = -\mathbf{f},$$

where $\mathbf{f} = (f_1,f_2)^T$ and $f_1, f_2 \in \mathcal{C}^0(\mathbb{R},\mathbb{C})$. Following the variation of parameters approach of Zhang [42], we find that the linearly independent solutions of the homogeneous problem $(\mathcal{L}-\lambda)\phi = 0$ are

$$\Phi_+(\xi,\lambda) = \begin{pmatrix} \beta \\ m_+ - 1 \end{pmatrix} e^{\left(\frac{\lambda+m_+}{v}\right)\xi},$$

$$\Phi_-(\xi,\lambda) = \begin{pmatrix} \beta \\ m_- - 1 \end{pmatrix} e^{\left(\frac{\lambda+m_-}{v}\right)\xi},$$

in which case we set

$$\mathbf{z}(\xi) = \Big[\Phi_+\Big|\Phi_-\Big]\begin{pmatrix} \bar{a}(\xi) \\ \bar{b}(\xi) \end{pmatrix}.$$

Subsequently, the coefficient functions are determined according to

$$\Big[\Phi_+\Big|\Phi_-\Big]\frac{\partial}{\partial \xi}\begin{pmatrix} \bar{a} \\ \bar{b} \end{pmatrix} = -\frac{1}{v}\Big(\mathcal{N}_s\mathbf{z}+\mathbf{f}\Big). \tag{4.7}$$

Inversion of $[\Phi_+|\Phi_-]$ leads to

$$\frac{\partial}{\partial \xi}\begin{pmatrix} \bar{a} \\ \bar{b} \end{pmatrix} = -\frac{1}{v\beta(m_+-m_-)}\Big[\Psi_+\Big|\Psi_-\Big]^T\Big(\mathcal{N}_s\mathbf{z}+\mathbf{f}\Big), \tag{4.8}$$

where

$$\Psi_+(\xi,\lambda) = \begin{pmatrix} 1-m_- \\ \beta \end{pmatrix} e^{-\left(\frac{\lambda+m_+}{v}\right)\xi},$$
$$\Psi_-(\xi,\lambda) = -\begin{pmatrix} 1-m_+ \\ \beta \end{pmatrix} e^{-\left(\frac{\lambda+m_-}{v}\right)\xi}.$$

For $\mathcal{R}e(\lambda) > -m_-$, we integrate over $[\xi,\infty)$ to obtain

$$\begin{pmatrix} \bar{a}(\xi) \\ \bar{b}(\xi) \end{pmatrix} = \begin{pmatrix} \bar{a}_\infty \\ \bar{b}_\infty \end{pmatrix} + \frac{1}{v\beta(m_+ - m_-)} \int_\xi^\infty \Big[\Psi_+\big|\Psi_-\Big]^T \big(\mathcal{N}_s\mathbf{z} + \mathbf{f}\big) d\eta,$$

where $\bar{a}_\infty, \bar{b}_\infty$ denote the values of $a(\xi), b(\xi)$ as $\xi \longrightarrow \infty$. Thus

$$\mathbf{z}(\xi) = \Big[\Phi_+\big|\Phi_-\Big] \begin{pmatrix} \bar{a}_\infty \\ \bar{b}_\infty \end{pmatrix} + \frac{1}{v\beta(m_+ - m_-)} \Big[\Phi_+\big|\Phi_-\Big] \int_\xi^\infty \Big[\Psi_+\big|\Psi_-\Big]^T \big(\mathcal{N}_s\mathbf{z} + \mathbf{f}\big) d\eta.$$

As we shall discuss, the integral term is bounded for all ξ, and, consequently, for a bounded solution to exist, we must require that $\bar{a}_\infty = \bar{b}_\infty = 0$. Thus

$$\mathbf{z}(\xi) = \frac{1}{v\beta(m_+ - m_-)} \Big[\Phi_+\big|\Phi_-\Big] \int_\xi^\infty \Big[\Psi_+\big|\Psi_-\Big]^T \big(\mathcal{N}_s\mathbf{z} + \mathbf{f}\big) d\eta,$$

which can be rewritten as

$$\begin{pmatrix} \varphi(\xi) \\ \psi(\xi) \end{pmatrix} - \Lambda_1(\lambda,\xi) \begin{pmatrix} \varphi(\xi_1) \\ 0 \end{pmatrix} - \Lambda_2(\lambda,\xi) \begin{pmatrix} \varphi(\xi_2) \\ 0 \end{pmatrix} = \mathcal{H}(\xi), \tag{4.9}$$

where

$$\Lambda_i(\lambda,\xi) = \frac{1}{v\beta(m_+ - m_-)} \Big[\Phi_+\big|\Phi_-\Big] \int_\xi^\infty \Big[\Psi_+\big|\Psi_-\Big]^T \frac{w(\eta-\xi_i)}{|U'(\xi_i)|}\, d\eta,$$
$$\mathcal{H}(\xi) = \frac{1}{v\beta(m_+ - m_-)} \Big[\Phi_+\big|\Phi_-\Big] \int_\xi^\infty \Big[\Psi_+\big|\Psi_-\Big]^T \mathbf{f}(\eta)\, d\eta.$$

Elements of Λ_i and $\mathcal{H}$ are finite sums of terms of the forms

$$\int_\xi^\infty e^{\left(\frac{\lambda+m_\pm}{v}\right)(\xi-\eta)} w(\eta-\xi_i) d\eta, \qquad \int_\xi^\infty e^{\left(\frac{\lambda+m_\pm}{v}\right)(\xi-\eta)} f_i(\eta) d\eta.$$

Using the Hölder inequality, it is straightforward to show that these terms, and hence Λ_i and $\mathcal{H}$, are bounded for all $\xi \in \mathbb{R}$ and for all $f_i \in \mathcal{C}^0(\mathbb{R},\mathbb{C})$. Now we must determine the conditions under which (4.9) has a unique solution. Since the solution $\mathbf{z}(\xi)$ is determined completely by the restrictions $\mathbf{z}(\xi_1)$ and $\mathbf{z}(\xi_2)$, we obtain the following finite-dimensional system by substituting $\xi = \xi_1, \xi_2$ into (4.9):

$$\Big(\mathbf{I} - \Delta(\lambda)\Big) \begin{pmatrix} \varphi(\xi_1) \\ \varphi(\xi_2) \end{pmatrix} = \begin{pmatrix} \mathcal{H}_1(\xi_1) \\ \mathcal{H}_1(\xi_2) \end{pmatrix},$$

where $\mathcal{H} = (\mathcal{H}_1, \mathcal{H}_2)^T$, $\bar{\Lambda}_i(\lambda,\xi) = (\,1\ 0\,)\ \Lambda_i(\lambda,\xi)\ (\,1\ 0\,)^T$, and

$$\Delta(\lambda,\xi_1,\xi_2) = \begin{pmatrix} \bar{\Lambda}_1(\lambda,\xi_1) & \bar{\Lambda}_2(\lambda,\xi_1) \\ \bar{\Lambda}_1(\lambda,\xi_2) & \bar{\Lambda}_2(\lambda,\xi_2) \end{pmatrix}.$$

This system has a unique solution if and only if $\mathbf{det}(\mathbf{I}-\Delta(\lambda))\neq 0$, resulting in a bounded inverse defined on all of $\mathcal{C}^0(\mathbb{R},\mathbb{C})\times\mathcal{C}^0(\mathbb{R},\mathbb{C})$. All such λ are elements of the resolvent set. Conversely, we cannot invert the operator for λ such that

$$\mathbf{det}\big(\mathbf{I}-\Delta(\lambda,\xi_1,\xi_2)\big)=0,$$

in which case

$$(\mathcal{L}+\mathcal{N}_s-\lambda)\mathbf{z}=0$$

has nontrivial solutions and λ is an element of the point spectrum. As in the scalar front case, the function

$$\mathcal{E}(\lambda,\xi_1,\xi_2)=\mathbf{det}\big(\mathbf{I}-\Delta(\lambda,\xi_1,\xi_2)\big),\qquad \mathcal{R}e(\lambda)>-m_- \tag{4.10}$$

identifies eigenvalues with its zero set, indicating that $\mathcal{E}$ is an Evans function for the set for which $\mathcal{R}e(\lambda)>-m_-$. In a similar fashion, a resolvent and an Evans function can be defined on the set for which $\mathcal{R}e(\lambda)<-m_+$; however, we do not pursue the explicit construction, as it does not reflect an instability of the stimulus-locked wave.

Continuous spectrum. Using arguments similar to those of the case of the scalar equation, it can be shown that the operator $\mathcal{N}_s:\mathcal{C}^1(\mathbb{R},\mathbb{C})\times\mathcal{C}^1(\mathbb{R},\mathbb{C})\longrightarrow\mathcal{C}^0(\mathbb{R},\mathbb{C})\times\mathcal{C}^0(\mathbb{R},\mathbb{C})$ is compact. Again this implies that the essential spectrum of $\mathcal{L}+\mathcal{N}_s$ is identical to that of $\mathcal{L}$. In the case of the vector operator $\mathcal{L}$, the continuous spectrum is the union of the disjoint sets of $\lambda=-m_\pm+iv\rho$, where $\rho\in\mathbb{R}$. To see this, assume such λ and consider the sequence of functions $\phi_n^\pm\in\mathcal{C}^1(\mathbb{R},\mathbb{C})\times\mathcal{C}^1(\mathbb{R},\mathbb{C})$, where n is a positive integer; $\mathcal{Y}_\pm$ are the eigenvectors of the matrix $\mathcal{A}$ defined in (4.5), corresponding to the eigenvalues $m_\pm$; and

$$\phi_n^\pm(\xi)=e^{i\rho\xi}\big(1-e^{-\xi^2/2n^2}\big)\mathcal{Y}_\pm.$$

If $\mathcal{Y}_\pm$ are normalized to unity, then $\big\|\phi_n^\pm\big\|_\infty=1$ for all n; however,

$$\Big\|\mathcal{L}\phi_n^\pm\Big\|=\frac{v}{n^2}\Big\|\xi e^{-\frac{\xi^2}{2n^2}}\Big\|\longrightarrow 0\qquad\text{as}\quad n\longrightarrow\infty.$$

Hence, $(\mathcal{L}-\lambda)^{-1}$ is unbounded, and λ is a member of the continuous spectrum of $\mathcal{L}+\mathcal{N}_s$.

Residual spectrum. To complete the characterization of the spectrum, we demonstrate that the set $\{\lambda\in\mathbb{C}:\mathcal{R}e(\lambda)\in(-m_+,-m_-)\}$ defines the residual spectrum of $\mathcal{L}+\mathcal{N}_s$. We must show that for such λ there exists a bounded inverse whose domain is not dense in $\mathcal{C}^0(\mathbb{R},\mathbb{C})\times\mathcal{C}^0(\mathbb{R},\mathbb{C})$. Consider our previous construction of the inverse operator $(\mathcal{L}+\mathcal{N}_s-\lambda)^{-1}$. Since we need calculate only the residual spectrum of $\mathcal{L}$, we integrate (4.8) over $[c,d]$, neglecting $\mathcal{N}_s$, to obtain

$$\begin{pmatrix}\bar a(d)\\ \bar b(d)\end{pmatrix}-\begin{pmatrix}\bar a(c)\\ \bar b(c)\end{pmatrix}=-\frac{1}{v\beta(m_+-m_-)}\int_c^d\Big[\Psi_+\big|\Psi_-\Big]^T f(\eta)d\eta.$$

There are only two cases to consider. First, taking $c=\xi$ and $d=\infty$, we examine the integral term of $\mathbf{z}(\xi)$, components of which have the form

$$\int_\xi^\infty e^{\left(\frac{\lambda+m_\pm}{v}\right)(\xi-\eta)}\Big[(1-m_\mp)f_1(\eta)+\beta f_2(\eta)\Big]d\eta.$$

Since $\lambda + m_- < 0$ and $v > 0$, all components are bounded, and hence $\mathcal{L} + \mathcal{N}_s - \lambda$ is bounded only if f either decays sufficiently fast such that

$$\int_\xi^\infty e^{\left(\frac{\lambda+m_+}{v}\right)(\xi-\eta)}\Big[(1-m_-)f_1(\eta)+\beta f_2(\eta)\Big]d\eta < \infty, \qquad \xi \in \mathbb{R},$$

or satisfies $(1-m_-)f_1(\eta)+\beta f_2(\eta) = 0$ for all η. Similarly, for $c = -\infty$ and $d = \xi$, we must require that

$$\int_{-\infty}^\xi e^{\left(\frac{\lambda+m_-}{v}\right)(\xi-\eta)}\Big[(1-m_+)f_1(\eta)+\beta f_2(\eta)\Big]d\eta < \infty, \qquad \xi \in \mathbb{R},$$

or $(1-m_+)f_1(\eta)+\beta f_2(\eta) = 0$ for all η. Since the union of all such f is not dense in $\mathcal{C}^0(\mathbb{R},\mathbb{C}) \times \mathcal{C}^0(\mathbb{R},\mathbb{C})$, we conclude that λ lies in the residual spectrum.

4.2. Evans function for stimulus-locked traveling pulses. The following gives the explicit construction of the Evans function for stimulus-locked waves in the case of a Gaussian input, Heaviside firing rate function, and exponential weight distribution. Note that this includes natural waves where $I_0 = 0$. After a lengthy calculation,

$$\begin{aligned}\mathcal{E}(\lambda,\xi_1,\xi_2) &= \mathbf{det}\big(\mathbf{I}-\Delta(\lambda,\xi_1,\xi_2)\big) \qquad\qquad \Re e(\lambda) > -m_-\\ &= \left(1-\frac{\Theta_+(\lambda)}{\big|U'(\xi_1)\big|}\right)\left(1-\frac{\Theta_+(\lambda)}{\big|U'(\xi_2)\big|}\right) - \frac{\Theta_+(\lambda)\Gamma(\lambda)}{\big|U'(\xi_1)U'(\xi_2)\big|}e^{(\xi_1-\xi_2)},\end{aligned} \tag{4.11}$$

where

$$\begin{aligned}\Gamma_\pm(\lambda) &= \frac{(1-m_\mp)v}{(m_+-m_-)(v^2-(\lambda+m_\pm)^2)},\\ \Theta_\pm(\lambda) &= \frac{1}{2(m_+-m_-)}\left(\frac{1-m_-}{\lambda+m_+\pm v}-\frac{1-m_+}{\lambda+m_-\pm v}\right),\\ \Gamma(\lambda) &= \Theta_-(\lambda)e^{(\xi_1-\xi_2)}+\Gamma_+(\lambda)e^{\left(\frac{\lambda+m_+}{v}\right)(\xi_1-\xi_2)}-\Gamma_-(\lambda)e^{\left(\frac{\lambda+m_-}{v}\right)(\xi_1-\xi_2)}.\end{aligned} \tag{4.12}$$

Since the zero set of the Evans function (4.11) comprises solutions of a transcendental equation, we solve for the eigenvalues numerically by finding the intersection points of the zero sets of the real and complex parts of the Evans function. This leads to the stability results shown in Figure 3.2, namely, that pulses within the right-hand tongue are stable whereas pulses within the left-hand tongue are stable only if they lie inside the region enclosed by the Hopf curve. An example of a zero set construction is shown in Figure 4.1 for fixed I_0 and various values of v.

Linear stability of the traveling pulse solution is characterized by all eigenvalues of the linearization having negative real part, with the possible exception that $\lambda = 0$ is a simple eigenvalue. Moreover, Hopf bifurcations may be identified by a pair of complex eigenvalues crossing the imaginary axis from the left-half plane. It has been found in many infinite-dimensional dynamical systems, such as semilinear parabolic equations, that the criterion for a Hopf bifurcation carries over from ordinary differential equations. Although smoothness properties of the flow are required for its proof using invariant manifold theory, the result is *essentially* based on the behavior of eigenvalues of the linearized operator [26]. We shall assume this and use numerical

simulations, as discussed in the following section, to explore the behavior of the model near these bifurcation points. Note, for $I_0 > 0$, $\lambda = 0$ is not an eigenvalue and does not complicate the eigenvalue criteria of the standard Hopf bifurcation theorem, as would be the case with natural waves.

4.3. Numerical simulations. In this section we explore the behavior of the vector system (1.2) in all regions of the (v, I_0)-plane shown in Figure 3.2. In particular, we describe the various types of solutions that emerge beyond the Hopf bifurcation curve, as well as beyond the existence tongues.

For parameter values supporting natural traveling waves, and in the absence of an input ($I_0 = 0$), an initial sufficiently large local displacement of the activity u from rest induces a locally excited region of activity, which rapidly develops into a pair of diverging natural traveling pulses, as in the reaction diffusion analogue. Similarly, for parameter values supporting stable stimulus-locked waves in the presence of an input ($I_0 > 0$), an initial displacement of u near the input (or no initial displacement in the case of sufficiently large input strength I_0) rapidly approaches the stable traveling pulse. For certain speeds v the initial transient can generate an additional single or pair of traveling waves that propagate away from the input. As expected, the speed and width of the stimulus-locked traveling pulse closely match those of the theory.

Interestingly, for the parameter values in Figure 3.2, numerical simulations suggest that the left-hand branch of the Hopf curve (gray) corresponds to a supercritical bifurcation, while the right-hand branch is subcritical without a sharp transition to a breathing pulse. We first characterize the nature of solutions obtained by crossing the subcritical branch of the Hopf curve. We find a region of activity moving with the input whose right boundary oscillates with increasing amplitude. After a critical point, the system emits a natural traveling pulse, whose speed is faster than that of the input, as shown in Figure 4.2. The region between the one excited by the

FIG. 4.2. *Instability of the stimulus-locked traveling pulse in the presence of two complex conjugate eigenvalues with positive real part for* $I_0 = 1.0$, $v = 0.07$, $\sigma = 1$, $\kappa = 0.3$, $\epsilon = 0.03$, *and* $\beta = 2.5$. *In this case the bifurcation appears subcritical with the absence of a sharp jump to a stable breathing pulse. Instead, instability manifests itself as a periodic cycling of an initial phase of periodically modulated growth of the active region, followed ultimately by the shedding of a natural traveling pulse.* (a) *Space-time plot showing one cycle of the instability, where the vertical axis represents time and the horizontal axis represents space.* (b) *Graph of the corresponding zero set of the Evans function. The periodic process of shedding or emitting natural traveling pulses becomes more rapid as the real part of the eigenvalue increases.*

input and the new natural wave recovers, and the process repeats periodically. Such solutions we refer to as *pulse-emitters*. The smaller the real part of the eigenvalue, the slower the instability grows and the more time is required for the wave to be emitted. As v is increased, the real part of the eigenvalue grows and the number of oscillations occurring before the shedding of natural waves decreases, until the eigenvalues become real, as illustrated in the figure sequence 4.1(b)–(d), and the pulse rapidly emits natural pulses. This behavior continues until v is increased to the boundary of the right-hand tongue where there is a smooth transition to a stable stimulus-locked pulse.

When the left-hand supercritical branch of the Hopf curve is crossed by reducing I_0 or v, we find a smooth transition to a stimulus-locked traveling breather. In the special case of a stationary stimulus ($v = 0$), reducing I_0 generates a stationary breather, as we have shown previously [5, 13]. The breathing solutions continue to persist in a subregion of the (v, I_0)-plane bounded to the right by the left (supercritical) branch of the Hopf curve in 3.2. As one moves in this subregion away from the left Hopf branch, the amplitude of the oscillations grows. After some point, the breathing solution disappears, and a new type of temporally periodic solution appears, each cycle of which is characterized by one or more breathing pulse oscillations followed by the emission of a pair of natural waves, possibly intermixed with interludes of subthreshold behavior. An example of such a transition is illustrated in Figure 4.3. This type of pulse-emitting solution appears to be part of a family of related responses of the system to a localized input, which also includes the pulse-emitting behavior associated with the region between the subcritical Hopf curve and the stable right

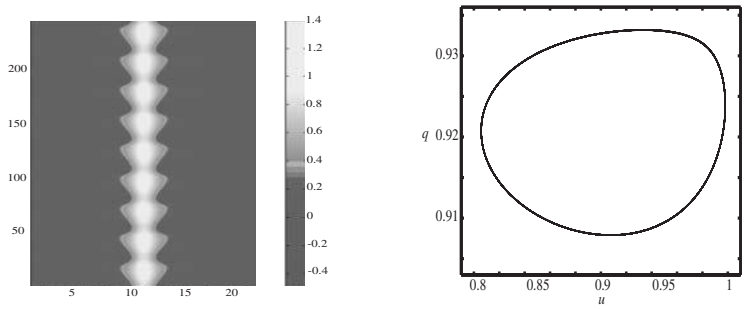
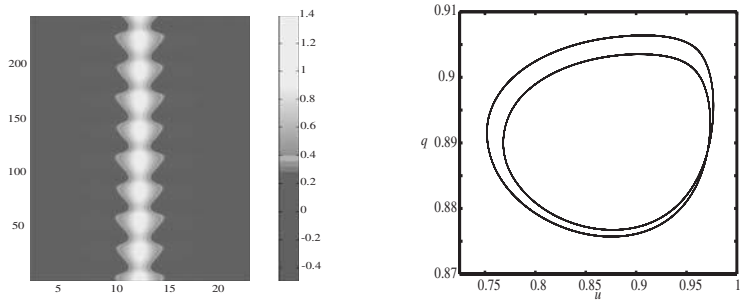
tongue shown in Figure 3.2. Furthermore, there is a smooth transition of behaviors joining the two regions, as shown in Figure 4.4.

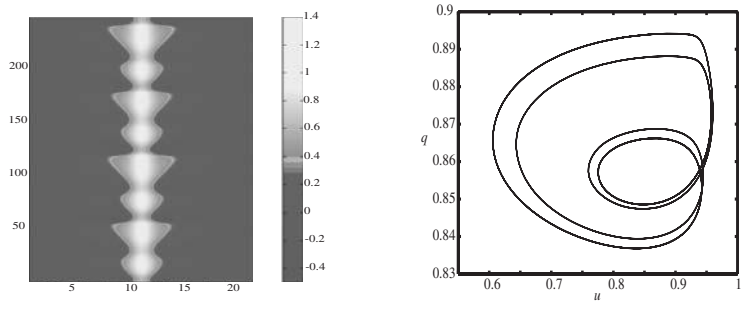
Although the above account applies to the case $\sigma = 1$, most features are valid for more general σ. One main point of difference lends insight into the disappearance of the breather. If we consider stationary pulses for $\sigma = \sqrt{2}$ and explore the evolution of the breathing pulse as we further decrease I_0 beyond the bifurcation point, we find that a secondary bifurcation occurs, giving rise to two modes of breathing rather than



(a) $I_0 = 2.4$



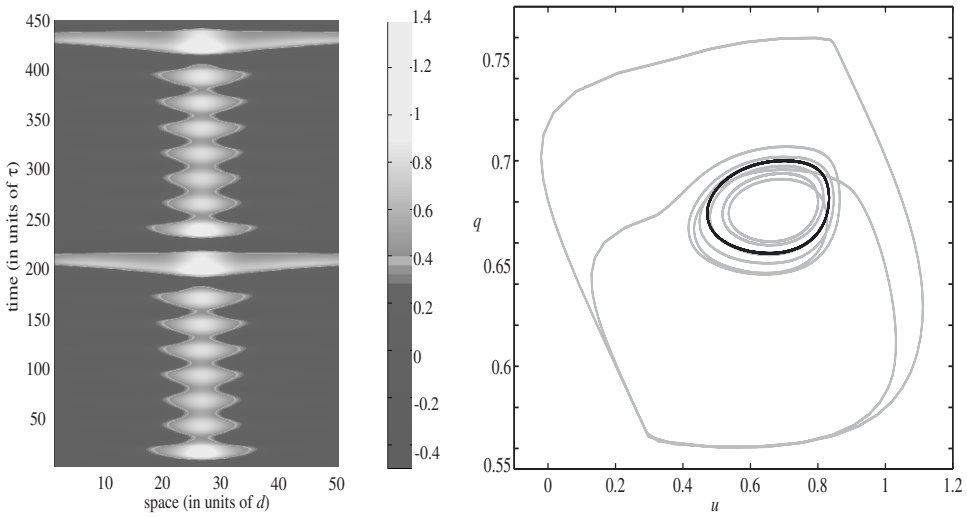
(b) $I_0 = 2.3$



(c) $I_0 = 2.2$

FIG. 4.5. *Sequence of period-doubling bifurcations of a breathing pulse for* $\sigma = \sqrt{2}$. *The left-hand column shows space-time plots for different values of current amplitude beyond the initial Hopf bifurcation point, with an orbit corresponding to the center spatial point plotted in the* (u, q)*-phase plane in the right-hand column; other spatial points are qualitatively similar. Other parameter values are* $\kappa = 0.3$, $\beta = 2.5$, $\epsilon = 0.03$, $v = 0$. *(Note that at higher resolution each loop in* (c) *is actually a pair of closely spaced loops, indicating that it corresponds to the third doubling in the sequence.)*

one. By graphing, in the (u, q)-phase plane, the orbit corresponding to a spatial point at the center of the input, we find that the evolution of the orbit, as I_0 is decreased, strongly resembles that of a period-doubling bifurcation, as shown in Figure 4.5(a)–(b). Decreasing I_0 leads to additional period doublings, as illustrated in Figure 4.5(c). Ultimately, decreasing I_0 leads to behavior similar to that found for $\sigma = 1$. This suggests that for $\sigma = 1$ the first period-doubling bifurcation may be subcritical, and the orbit instead weaves its way around the unstable limit cycle giving rise to the sequence of breathing pulses and emission, as shown in Figure 4.6.



(a) (b)

FIG. 4.6. (a) *Space-time plot of a stationary ($v = 0$) pulse-emitter for $\sigma = 1$, $I_0 = 1.35$, $\kappa = 0.3$, $\beta = 2.5$ and $\epsilon = 0.03$.* (b) *Corresponding phase portrait showing the orbit (gray trajectory) of the center spatial point plotted in the (u, q)-phase plane. Also shown is the corresponding orbit (black trajectory) of the stable breather that exists when $I_0 = 1.4$.*

5. Discussion. In this paper we have shown how to extend the analysis of the existence and stability of pulses arising from a stationary stimulus input to that of a input moving with constant speed. We described the continuation from the unstable/stable pair of natural waves by constructing a corresponding pair of existence tongues emerging from the natural waves at $I_0 = 0$, with the left-hand tongue including stationary pulses at $v = 0$, for a particular choice of parameter values supporting natural waves. We have extended Zhang's analysis of stability of natural waves to that of stimulus-locked waves and numerically evaluated the Evans function to determine eigenvalues away from the singular limit $\epsilon \to 0$. This allowed us to analyze the stability of the existence tongues in the (v, I_0)-plane and show the continuation of the Hopf bifurcation found for stationary pulses. Numerically this Hopf curve was found to have a supercritical branch, from which breathing pulses emerge and a subcritical branch from which no breathing pulse emerges. In general for parameter values that do not support either stimulus-locked pulses or breathers, the system generates more complicated behavior, including the emission of natural traveling waves when such waves exist.

It would be interesting to contrast the type of local inhibition analyzed in this paper, which is primarily due to intrinsic neuronal properties, with that of nonlocal inhibition, arising from the ubiquitous inhibitory populations of neurons found in cortex. From previous work [1, 28], we know that the two-population, excitatory-inhibitory system supports stable stationary pulses which, moreover, can undergo a subcritical Hopf bifurcation. In this case no breathing pulse emerges; however, it is possible that the presence of a localized input is capable of stabilizing such a breathing pulse solution. In addition, it would be interesting to provide a more thorough analysis

of the scalar model considered by Xie and Giese [40], by constructing tongue diagrams and Hopf bifurcation curves and, furthermore, considering the effect of varying the degree of nonlocal inhibition.

From a more general perspective, the analysis presented here and in related work [6, 13] has established that the combined effect of local inhomogeneities and recurrent synaptic interactions can result in nontrivial forms of coherent oscillations and waves. Although we have focused on rather abstract neural field equations, we expect our results to carry over (at least qualitatively) to more biophysically realistic conductance-based models. Indeed, elsewhere we have confirmed the existence of stationary breathers and pulse emitters in the case of a modified Traub model [13]. One of the advantages of studying simplified models is that it can generate predictions regarding how dynamical properties such as wave speed depend on characteristic features of neural tissue. One striking demonstration of this is the recent study of wave propagation in disinhibited cortical slices, where the speed of the wave was controlled by external electric fields, confirming predictions based on homogeneous neural field equations [32]. Our own work predicts that coherent oscillations can be induced by local inhomogeneities. Such inhomogeneities could arise from external stimuli or reflect changes in the excitability of local populations of neurons. The former suggests a network mechanism for stimulus-induced oscillations, which may play an important role in visual processing [17], whereas the latter suggests a network mechanism for generating epileptiform activity.

ENERGY MAXIMIZERS, NEGATIVE TEMPERATURES, AND ROBUST SYMMETRY BREAKING IN VORTEX DYNAMICS ON A NONROTATING SPHERE*

CHJAN C. LIM†

Dedicated to Bro. Felix Donohue, La Sallian, with friendship and respect.

Abstract. This paper relates the existence and uniqueness of constrained energy maximizers to the occurrence of negative temperatures in a recent statistical mechanics model of the energy-enstrophy theory. We construct examples of steady state solutions of the vorticity equation which break $SO(3)$ symmetry from the negative temperature vorticity distributions in the spherical model. These vortex states correspond to solid-body rotation flows at rotation rates Θ, which depend only on the fixed value of enstrophy Γ, that is, $\Theta = \sqrt{\Gamma/(4\int_{S^2}\cos^2\theta\, dx)}$. They are robust in the sense that they constitute most probable states in a spherical model of the statistical energy-enstrophy theory at negative temperatures, and have exponentially large Gibbs probability relative to any other macrostates. The existence and uniqueness of energy maximizers in a variational formulation of the new energy-enstrophy theory also give a necessary condition for the spherical model energy-enstrophy theory to be well defined at all temperatures.

Key words. energy maximizers, energy-enstrophy model on a sphere, spherical model, negative temperature

DOI. 10.1137/040605916

1. Introduction. Negative temperatures exist in many physical systems including lasers. The work of Onsager [3], Montgomery and Joyce [2], and Eyink and Spohn [4] shows that negative temperatures arise in two-dimensional (2d) point vortex statistics. We have extended this to vortex statistics on the nonrotating sphere by constructing a convergent family of lattice spin models H_N. In each member of the family parametrized by the number N of lattice nodes placed on the sphere S^2, we construct a well-defined equilibrium statistic, using a new version of the energy-enstrophy theory known as the spherical model:

$$Z_N = \int (\Pi ds_j)\delta\left(N\Gamma - \sum s_j^2\right)\exp\left[-\beta H_N\right]. \tag{1.1}$$

One can regard the spin state $\vec{s}(N) = (s_1, \ldots, s_N)$ as a macrostate or coarse-grained vorticity distribution for which there are many equivalent microstates, each of which can be viewed as a rearrangement of distinguishable vorticity parcels of similar strength between lattice cells/sites. A spin state $\vec{s}$ tends in the continuum/thermodynamic limit to a vorticity function $w(\theta, \phi) \in L_2(S^2)$, where $L_2(S^2)$ denotes the Hilbert space of square-integrable measurable functions on the sphere S^2 with coordinates given by co-latitude θ and longitude ϕ. We sketch one derivation of the spherical model in this paper.

This new version was done for two specific reasons: the classical energy-enstrophy theory based on a Gibbs canonical ensemble in the energy and enstrophy [8] is equivalent to the Gaussian model [13], [12], [1] and has a vanishingly small temperature range of validity in the continuum limit (only for $\beta = 0$); changing the canonical constraint on the enstrophy to a microcanonical constrain converted the resulting statistics into that of Kac's spherical model, which is exactly solvable in the continuum limit of N tending to infinity and, more importantly, it is valid for all values of inverse temperature β, including negative ones. The exact solution in the continuum/thermodynamic limit of the spherical model for energy-enstrophy theory has been discussed in Lim [13], [12] and simulated in Lim and Nebus [29]. One of the main conclusions from this work is that for large values of kinetic energy H relative to the enstrophy Γ, when $\beta < 0$, there is only one most probable vorticity distribution, namely, the solid-body rotation state [13], [12], [29]. This macrostate is directly related to the spherical harmonic Y_{10} corresponding to the smallest positive eigenvalue of the Laplace–Beltrami operator $-\Delta$ on the sphere S^2.

In this paper, we go deeper into the relationship between negative temperature states in the spherical model for energy-enstrophy theory and the existence of unique maximal energy states in a variational formulation of the constrained enstrophy problem. The main results of the paper are the existence and uniqueness of these maximal energy states modulo a symmetry group in a variational formulation of the problem on the surface of the sphere, and two applications. First, we discuss an important application to statistical physics in the following subsection, concerning a necessary condition for a statistical mechanics energy-enstrophy theory to be well defined, namely, bounds on the energy. The second application concerns the existence and robustness of symmetry-breaking steady-states of the Euler equations and the ergodicity of inviscid vortex dynamics on a nonrotating sphere. This application is motivated by Shepherd's discovery that on a rapidly rotating sphere, inviscid single layer vortex dynamics is highly anisotropic and nonergodic. His proof of nonergodicity does not extend to the nonrotating sphere. We have implicitly assumed that inviscid vortex dynamics on the nonrotating sphere are ergodic when formulating the spherical model energy-enstrophy theory.

1.1. Unboundedness in the classical energy-enstrophy theory. What then is the main advantage of the spherical model over the older Kraichnan energy-enstrophy theory? The results in this paper establish a necessary condition for the spherical model to be well defined for all temperatures; that is, the energy $H[w]$ has a finite upper bound for fixed enstrophy $\Gamma[w]$. This is not the case in the Kraichnan energy-enstrophy theory where, because enstrophy is constrained in a canonical manner, the augmented energy has the form

$$E[w] = H[w] + \frac{\mu}{\beta}\Gamma[w].$$

We have recently shown in [25] that $E[w]$ has no upper bound for $\frac{\mu}{\beta} < 0$ when

$$-2\frac{\mu}{\beta} < \|G\|,$$

where G is the integral operator whose kernel is the Green's function of the Laplace–Beltrami operator on the sphere S^2 when $\int_{S^2} w\,dx = 0$. A more serious difficulty arises for the classical energy-enstrophy theory for inviscid flows on a nonrotating

sphere when the temperature is positive. Namely, for $\beta > 0$ and $\mu > 0$, the unique global minimizer w_m of $E[w]$ is the trivial vorticity $w_m = 0$ [25]; that is

$$E[w_m] = \min_{\int_{S^2} w dx = 0} E[w] = 0.$$

This positive temperature difficulty is not as serious in Kraichnan's original energy-enstrophy theory for inviscid flows on the plane as it is for the sphere S^2, because $\int w dx$ need not be zero for planar flows.

General dissatisfaction with the classical energy-enstrophy theory has led to several new directions for research. Works criticizing the classical energy-enstrophy theory include the Miller–Robert theory [19], [18], which invokes an infinite number of vorticity constraints; the Turkington–Majda model [21], [22], which is based on information theoretic Bayesian statistics; and the spherical model of energy-enstrophy-circulation theory [13], [12], [14], which is based on a microcanonical constraint on enstrophy rather than the canonical one in Kraichnan's theory [8]. Like the Miller–Robert [19], [18] and Turkington–Majda [21], [22] theories, the spherical model has predicted much the same results obtained by the older energy-enstrophy theories. They are all capable of supporting negative temperatures and the inverse energy cascade, which are ubiquitous in 2d flows, when the effective rotation rates are small enough or zero. The advantages of the spherical model over the other recent theories lie in its relative simplicity of constraining only energy and enstrophy—which follows from the deep relationships between them and has important consequences further discussed below—and the fact that there is an exact analytical solution for its partition function [14].

1.2. Ergodicity and robust symmetry breaking. This paper also examines the phenomena of symmetry breaking in inviscid vortex dynamics on a nonrotating sphere in relation to its ergodicity. We will discuss the following questions: (a) Do inviscid 2d flows on a nonrotating sphere exhibit anisotropy strong enough to imply nonergodicity? (b) Is this symmetry breaking robust in some other suitable sense? The answer to the first question is yes, there is symmetry breaking or anisotropy, but there is no evidence of nonergodicity of 2d inviscid flows on a nonrotating sphere. The answer to the second question is also yes, the symmetry breaking that we discover for vortex dynamics on the nonrotating sphere is robust in the sense of having exponentially high probability in a Gibbs canonical ensemble.

Invoking statistical mechanics to prove the robustness of the symmetry breaking basic states on the nonrotating sphere is more than just a convenient and physically valid tool. There is no known Lyapunov stability result for the zonally symmetric basic states in this problem, unlike the case of a strongly rotating sphere [6]. Moreover, rigorous arguments prove that in most high dimensional Hamiltonian systems, some trajectories near these steady states must escape along a chain of whiskered tori [28]. Without recourse to results on dynamical stability, the tools of equilibrium statistical mechanics are indispensable. Provided we are satisfied that the problem is ergodic, only the issue of which statistical mechanics model to use matters, and is one of the main topics of discussion in this paper.

An elegant paper by Shepherd [6] argued convincingly that inviscid 2d flows on the beta plane and rotating sphere are nonergodic for sufficiently large beta and rotation rates. His arguments are based on a version of Arnold's stability theorems for zonally symmetric basic solutions. This method requires the beta or rotation rate to be not only nonzero but large. Numerical experiments confirm this anisotropy in unforced

flows on the sphere [15], [16] and forced flows [20]. The anisotropy discovered by Shepherd [6] and the resulting nonergodic property of the (large beta) beta plane and strongly rotating sphere models put into question whether equilibrium statistical mechanics is valid for these models.

On the other hand, there is no known proof that vortex dynamics on the nonrotating sphere is nonergodic. But like many other parts of physics, there is no proof of ergodicity either. In light of this situation, we have the usual physicist's justifications to use equilibrium statistical mechanics to demonstrate the robustness of symmetry breaking.

There are two special relationships between energy and enstrophy which make them natural constraints in any statistical mechanics theory for inviscid flows. First and foremost is the fact that the enstrophy is just the L_2 norm of the vorticity w, and the kinetic energy is the quadratic form whose kernel is the Green's function of the Laplace–Beltrami operator in the problem. Poincaré's inequality then implies that the Dirichlet quotient of enstrophy over energy is bounded below by the spectrum of the Laplace–Beltrami operator in the domain. This yields a very natural variational framework which is further exploited in this paper.

Next is the powerful theory called the principle of selective decay [7] or minimum enstrophy, which tells us that the Dirichlet quotient tends to a nontrivial and fixed minimum in the unforced periodic 2d Navier–Stokes equations, even as the energy and the enstrophy separately tend to zero under the effect of viscosity. This principle, which provides a valuable link between inviscid models and the long time dynamics of damped 2d flows, is again based only on the two quadratic forms of energy and enstrophy.

As far as we know, there are no equally compelling results for higher vorticity moments as there are for the energy and enstrophy. Several important issues for inviscid vortex dynamics have been discussed in relation to the number of vorticity constraints to keep in any physically relevant statistical theories of 2d flows. Kraichnan [8], Leith [9], Chorin [10], [11], and Majda and Holen [17] have all argued for the sufficiency of the first two in equilibrium statistical mechanics, namely total circulation and enstrophy, in addition to energy. Nonetheless, there are subtle issues concerning the role of higher order vorticity moments in the variational theory of the Barotropic vorticity equation, which are discussed in a recent work [30].

Our third and most important reason for using a statistical mechanics model with only the energy and enstrophy constraints is the simple fact that we are interested in the robustness of truly global energy maximizers which break $SO(3)$ symmetry. Adding more constraints to the canonical probability measure will increase the number of terms and Lagrange multipliers in the corresponding enthalpy functional. Likewise, adding more microcanonical constraints is equivalent to the more constrained variational problem of finding energy extrema on the intersection of more than one manifold in phase space, which must necessarily yield suboptimal extrema instead of the global energy maximizer we are looking at.

1.3. Summary of content. We discuss the relationships between energy, enstrophy and total circulation of inviscid vortex dynamics on a nonrotating sphere in a deterministic variational setting to show that unique energy maximizers are related to negative temperatures in a family of lattice spin models for energy-enstrophy theory on a sphere. To show that symmetry breaking solutions are robust in a physically meaningful sense, we use this equilibrium statistical mechanics energy-enstrophy model to prove that the energy maximizers are in fact most probable macrostates

in a Gibbs ensemble. For this argument to work, negative temperatures must be supported in this model. The rigorous proof of negative temperatures in the spherical model for energy-enstrophy theory is given in exact solutions of the spherical model [13], [12], [14]. The main results on which these applications are based are the existence and uniqueness of constrained energy maximizers on the intersection of iso-enstrophy and iso-circulation manifolds. Finally, we end with a discussion of the relationship between the constrained energy maximizer (shown to exist in this paper) and the maximizer of the free energy.

2. Inviscid vortex dynamics on a nonrotating sphere. Without loss of generality we will discuss only the case of flows on the unit sphere S^2. Inviscid flows on the nonrotating sphere are governed by the equation

$$\frac{D}{Dt}w = 0, \tag{2.1}$$

where w is the absolute vorticity, which further satisfies the zero total circulation condition

$$K[w] = \int_{S^2} w dx = 0.$$

The Casimir symmetries of (2.1) imply that in addition to the kinetic energy of flow (from time invariance)

$$H[w] = \frac{1}{4}\int_{S^2} dx w(x) \int_{S^2} dx' w(x') \ln \frac{1}{|x - x'|} \tag{2.2}$$

and the usual momenta (from $SO(3)$ symmetry), the inviscid vortex dynamics governed by (2.1) conserves an infinite number of vorticity moments [10]. The first two of these moments are total circulation $K[w]$ and enstrophy

$$\Gamma[w] = \int_{S^2} w^2 dx.$$

We recall that any spherical harmonic Y_{lm} (that is, any eigenfunction of the Laplace–Beltrami operator on the unit sphere) is a steady solution of the equation of motion. Thus, any zonally symmetric harmonic such as $Y_{10} = k\cos\theta$, where θ is the co-latitude, is a steady solution of (2.1). These are symmetry breaking solutions. In other words, instead of the full $SO(3)$ symmetry of (2.1), the zonal harmonics Y_{l0} are only $SO(2)$ symmetric.

Recall that for any given zonal basic solution in Shepherd's proof, there is a small enough rotation rate Ω of the sphere which results in the vanishing of the meridional gradient of the total vorticity $Q_{(\cos\theta)}$ somewhere on the sphere. This spoils the upper bound in the Lyapunov stability theorem, which so effectively controlled the growth of the enstrophy of the disturbance vorticity q in the problem of the strongly rotating sphere [6]. Thus Shepherd's proof does not work here since the rate of rotation $\Omega = 0$.

Without results as strong as those in [6], a generic stability analysis of these zonal basic states within the framework of high-dimensional Hamiltonian dynamics reveals that there are nearby solutions that escape to infinity via the well-known phenomena of Arnold's whiskered tori and Nekhoroshev's theory [28]. There is, as far as we know, no proof of nonergodicity in the case of the nonrotating sphere. That is not to say that there is a known proof of ergodicity, which is a notoriously difficult result to

obtain. Thus, without any definite evidence to the contrary, we bow to the wisdom of physicists and assume that inviscid vortex dynamics on the surface of the nonrotating sphere is ergodic [10]. We will construct an equilibrium statistical mechanics theory for this problem. But before we do that, we will formulate a pair of optimization problems related to the definition of the statistical theory and to symmetry breaking in vortex dynamics on a sphere.

3. Variational analysis. We will show that kinetic energy, enstrophy, and total circulation conservation yield a dual pair of related optimization problems for inviscid vortex flows on the nonrotating sphere. The first problem is to maximize the energy H for fixed enstrophy Γ; i.e.,

$$\max H[w] = H_{\max}(\Gamma) < \infty,$$
$$w \in W(\Gamma), \quad K[w] = \int_{S^2} w dx = 0,$$

where $W(\Gamma)$ consists of all vorticity distributions w in $L^2(S^2)$, which has fixed L^2 norm or enstrophy. The dual problem is to minimize the enstrophy for fixed energy. Existence of a unique energy maximizer $w_0(\Gamma)$ such that $H[w_0] = H_{\max}(\Gamma) < \infty$ is an important result with subsequent applications in constructing a well-defined statistical mechanics theory.

3.1. Upper bound and energy maximizers. The kinetic energy $H[w_0]$ of a purely solid-body rotation vorticity distribution

$$w_0 = k(\Theta)\cos\theta$$

(at spin rate Θ, with θ denoting the co-latitude and assuming unit fluid density on the unit sphere S^2) is given by

$$H[w_0] = 4\Theta^2 \int_{S^2} \sin^2\theta \, dx. \tag{3.1}$$

The enstrophy of the same vorticity distribution w_0 is

$$\Gamma = 4\Theta^2 \int_{S^2} \cos^2\theta \, dx. \tag{3.2}$$

Rayleigh's (or Poincaré's) variational inequality [26] implies that

$$\frac{H[w]}{\Gamma[w]} = \frac{\frac{1}{2}\langle w, G(w)\rangle}{\langle w, w\rangle} \le D^{-1},$$

where

$$G(w)(x) = \frac{1}{2}\int_{S^2} w(x') \ln \frac{1}{|x - x'|} dx' \tag{3.3}$$

is the integral operator inverse to $-\Delta$ on S^2 with $K[w] = 0$ and D is the smallest positive eigenvalue of $-\Delta$ on S^2. The Dirichlet quotient is thus bounded below by

$$Q[w] = \frac{\Gamma[w]}{H[w]} = \frac{\int_{S^2} w^2 dx}{\frac{1}{2}\langle w, G(w)\rangle} \ge D.$$

Since the ratio

$$\Gamma/H(w_0(\Gamma)) = \frac{\int_{S^2} \cos^2\theta \, dx}{\int_{S^2} \sin^2\theta \, dx} = D$$

is a universal constant that does not depend on Γ, $w_0(\Gamma)$ is an energy maximizer for any finite enstrophy Γ; that is,

$$H[w_0] = H_{\max}(\Gamma).$$

The maximum value of the kinetic energy $H_{\max}(\Gamma)$ is therefore given by the above simple calculation to be

$$H_{\max}(\Gamma) = D\Gamma.$$

3.2. Concavity and uniqueness. Next we show that $w_0(\Gamma)$ is the unique zonally symmetric energy maximizer modulo the group $SO(3)$. That is, if $H[w'] = H_{\max}(\Gamma) = D\Gamma$, $w' \in W(\Gamma)$, $K[w'] = 0$, and w' is $SO(2)$ symmetric, then $w' = \gamma w_0$ for some $\gamma \in SO(3)$. Uniqueness of this type can be obtained from the observations that any $w \in L^2(S^2)$ can be decomposed into a linear combination of spherical harmonics Y_{lm}; the value $1/D = l(l+1) = 2$ (with $l = 1$) is the smallest positive eigenvalue of the Laplace–Beltrami operator on S^2; and the eigenspace associated with $1/D$ has dimension $2l + 1 = 3$ (with $l = 1$) modulo $SO(3)$, that is, any eigenfunction in this subspace is equal to γw_0, γw_1, or γw_{-1} for some $\gamma \in SO(3)$. Here w_0, w_1, and w_{-1} correspond to the spherical harmonics Y_{10}, Y_{11}, and $Y_{1,-1}$, respectively. Only w_0 is zonally or $SO(2)$ symmetric.

We will prove a stronger result from which uniqueness follows, namely, the strict concavity of the augmented energy functional

$$H'[w(x)] = H[w(x)] - D\Gamma[w] \tag{3.4}$$

on a convex subset; that is,

$$H'[\lambda p + (1-\lambda)q] > \lambda H'[p] + (1-\lambda)H'[q] \tag{3.5}$$

for any $\lambda \in (0,1)$ and for p and q in $M(\Gamma)$ such that

$$\begin{gathered} (1)\ K[p] = K[q] = 0, \\ (2)\ p - q \text{ is not identically zero, and} \\ (3) \text{ only one of } p \text{ or } q \text{ is in the } SO(3) \text{ orbit of } \operatorname{span}(Y_{10}, Y_{11}, Y_{1,-1}). \end{gathered} \tag{3.6}$$

It is well known (from Ekeland and Temam [27]) that the maximizer set

$$M(\Gamma) = \{w \in W(\Gamma) \mid K(w) = 0 \text{ and } H[w] = H_{\max}(\Gamma)\}$$

of the first optimization problem is a convex set if it is nonempty. The existence of the maximizer $w_0(\Gamma)$ means that this set $M(\Gamma)$ is nonempty and, thus, a convex set for any enstrophy $\Gamma < \infty$. The convexity of $M(\Gamma)$ allows the argument in the next paragraph to be carried out. The convexity of the set $W(\Gamma)$ is needed in the usual calculus of variations framework to prove the existence of energy maximizers. Fortunately for us, the existence of this maximizer was derived above by other means. The set $W(\Gamma)$ is in fact not convex.

Let w' be a different energy maximizer than w_0 that has zero total circulation and the same enstrophy Γ as w_0 and satisfies the third condition in (3.6) in the sense that w' is not in the $SO(3)$ orbit of $\mathrm{span}(w_0, w_1, w_{-1})$. Let

$$w^* = \lambda w' + (1-\lambda)w_0$$

for $\lambda \in (0,1)$. Then $H'[w^*] < 0$ because w^* is neither identically zero for any $\lambda \in (0,1)$ nor in the eigenspace containing Y_{10}. This contradicts the strict concavity theorem (3.5) which states that

$$H'[w^*] > \lambda H'[w'] + (1-\lambda)H'[w_0] = 0,$$

where the equality comes from the fact that both w_0 and w' are energy maximizers in $M(\Gamma)$, i.e.,

$$H'[w_0] = H'[w'] = 0.$$

Thus we have proven the uniqueness result.

3.3. Proof of the strict concavity of $H'[w]$. From the definition of $H'[w]$ it follows that

$$\begin{aligned}
H'[\lambda p + (1-\lambda)q] &= \frac{1}{2}\int_{S^2} d\vec{x} \int_{S^2} d\vec{x'} \\
&\quad \times [\lambda^2 p(\vec{x})p(\vec{x'}) + \lambda(1-\lambda)p(\vec{x})q(\vec{x'}) \\
&\qquad + \lambda(1-\lambda)q(\vec{x})p(\vec{x'}) + (1-\lambda)^2 q(\vec{x})q(\vec{x'})] \ln \frac{1}{|\vec{x}-\vec{x'}|} \\
&\quad - 2D\Gamma[\lambda p + (1-\lambda)q] \\
&= \frac{1}{2}\lambda^2 \int_{S^2} d\vec{x} \int_{S^2} d\vec{x'} p(\vec{x})p(\vec{x'}) \ln \frac{1}{|\vec{x}-\vec{x'}|} \\
&\quad + \frac{1}{2}(1-\lambda)^2 \int_{S^2} d\vec{x} \int_{S^2} d\vec{x'} q(\vec{x})q(\vec{x'}) \ln \frac{1}{|\vec{x}-\vec{x'}|} \\
&\quad + \lambda(1-\lambda) \int_{S^2} d\vec{x} \int_{S^2} d\vec{x'} q(\vec{x'})p(\vec{x}) \ln \frac{1}{|\vec{x}-\vec{x'}|} \\
&\quad - 2D \int_{S^2} (\lambda^2 p^2(\vec{x}) + 2\lambda(1-\lambda)q(\vec{x})p(\vec{x}) + (1-\lambda)^2 q^2(\vec{x}))d\vec{x}.
\end{aligned}$$

Defining

$$\begin{aligned}
G[p,q] &= \lambda(1-\lambda) \int_{S^2} d\vec{x} \int_{S^2} d\vec{x'} q(\vec{x'})p(\vec{x}) \ln \frac{1}{|\vec{x}-\vec{x'}|} \\
&\quad - 4D\lambda(1-\lambda) \int_{S^2} q(\vec{x})p(\vec{x})d\vec{x},
\end{aligned}$$

as in another paper by Lim and Zhu [25], we will prove

$$\lambda^2 H'[p] + (1-\lambda)^2 H'[q] + G[p,q] > \lambda H'[p] + (1-\lambda)H'[q], \tag{3.7}$$

which is equivalent to

$$\begin{aligned}
H'[p] + H'[q] &< \int_{S^2} d\vec{x} \int_{S^2} d\vec{x'} q(\vec{x'})p(\vec{x}) \ln \frac{1}{|\vec{x}-\vec{x'}|} \\
&\quad - 4D \int_{S^2} q(\vec{x})p(\vec{x})d\vec{x}.
\end{aligned}$$

By splitting the term on the right into two equal pieces, we see that we will need to prove

$$\begin{aligned}
&\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}p(\vec{x})p(\vec{x'})\ln\frac{1}{|\vec{x}-\vec{x'}|} - 2D\int_{S^2} p^2(\vec{x})d\vec{x}\\
&\quad+\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}q(\vec{x})q(\vec{x'})\ln\frac{1}{|\vec{x}-\vec{x'}|} - 2D\int_{S^2} q^2(\vec{x})d\vec{x}\\
&\quad-\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}q(\vec{x'})p(\vec{x})\ln\frac{1}{|\vec{x}-\vec{x'}|} + 2D\int_{S^2} q(\vec{x})p(\vec{x})d\vec{x}\\
&\quad-\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}q(\vec{x'})p(\vec{x})\ln\frac{1}{|\vec{x}-\vec{x'}|} + 2D\int_{S^2} q(\vec{x})p(\vec{x})d\vec{x}\\
&< 0.
\end{aligned}$$

The left side of the inequality is just $H'[p-q]$, as seen in the following rearrangement:

$$\begin{aligned}
&\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}p(\vec{x'})(p(\vec{x})-q(\vec{x}))\ln\frac{1}{|\vec{x}-\vec{x'}|}\\
&\quad+\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}q(\vec{x'})(q(\vec{x})-p(\vec{x}))\ln\frac{1}{|\vec{x}-\vec{x'}|}\\
&\quad-2D\int_{S^2} d\vec{x}p(\vec{x})(p(\vec{x})-q(\vec{x})) + 2D\int_{S^2} d\vec{x}q(\vec{x})(p(\vec{x})-q(\vec{x}))\\
&=\frac{1}{2}\int_{S^2} d\vec{x}\int_{S^2} d\vec{x'}(p(\vec{x})-q(\vec{x}))(p(\vec{x'})-q(\vec{x'}))\ln\frac{1}{|\vec{x}-\vec{x'}|}\\
&\quad-2D\int_{S^2} d\vec{x}(p(\vec{x})-q(\vec{x}))^2\\
&=H'[p-q].
\end{aligned}$$

In the existence of the upper bound $H_{\max}[\Gamma] = D\Gamma$, we have shown that $H'[w] \le 0$ for any nonzero $w \in W(\Gamma)$ such that $K[w] = 0$. Thus $H'[p-q] \le 0$. But for p and q satisfying the conditions in (3.6), we have

$$H'[p-q] < 0$$

because $p-q$ is not identically zero and is not in the eigenspace containing Y_{10}. The proof of the strict concavity of $H'[w]$ is now complete. The weaker statement of concavity follows from the existence of the upper bound $H'[p-q] \le 0$.

This completes the proof that for a fixed finite enstrophy, the kinetic energy $H(w)$ is bounded above by a finite positive value, i.e.,

$$H(w) \le H_{\max}(\Gamma) = D\Gamma < \infty.$$

Moreover the energy maximum is achieved by a unique zonal vorticity distribution w_0 modulo the group of rotations $SO(3)$.

4. Statistical mechanical proof of robust symmetry breaking. Next, we show that the solid-body rotation state w_0 that maximizes the energy $H[w]$ (along with the remaining spherical harmonics w_1 and w_{-1} in the first eigenspace) is robust in the sense that the most probable macrostate in an equilibrium statistical mechanics theory has overwhelming probability relative to other allowed macrostates. For this

we need a physically meaningful statistical mechanics energy-enstrophy theory of 2d inviscid flows on the nonrotating sphere, in which the solid rotating state w_0 arises naturally as its most probable macrostate.

The discussion on the relative merits of the spherical model in the introduction to this paper centers on the minimum required conditions in a statistical model for demonstrating the robustness of truly global energy maximizers such as the zonally symmetric states. A further necessary condition for any equilibrium statistical mechanics theory to be able to support such a most probable state w_0, which is, moreover, an energy maximizer for fixed enstrophy, is that negative inverse temperatures are allowed in this theory. This is because the Gibbs probability measure has the form

$$P(w) = \frac{e^{-\beta H[w]}\delta(\Gamma[w] - \Gamma')}{Z(\beta, \Gamma)}$$

for $w \in W(\Gamma)$, where β denotes the inverse temperature.

The spherical model energy-enstrophy theory with zero total circulation [13] is such a theory. It predicts that for negative inverse temperatures $\beta < 0$, there is a unique most probable macrostate (solid-body rotation)

$$w_0 = k \cos\theta = cY_{10} \tag{4.1}$$

which maximizes the kinetic energy $H[w] = H_{\max}(\Gamma)$ under the microcanonical constraint of fixed total enstrophy $\Gamma[w] = \Gamma > 0$. This can be seen by solving for the explicit form of its partition function. The somewhat lengthy derivation of the closed-form partition function from the expression

$$Z(\beta, \Gamma) = \int_{W(\Gamma)} e^{-\beta H[w]}\delta(\Gamma - \Gamma^*)dw \tag{4.2}$$

can be found in [13], [12], [14] and will not be repeated here. The value of $k = k(\Gamma)$ in (4.1) depends on the fixed value of the enstrophy Γ, which means that the rate of rotation $\Theta(w_0)$ of the solid-body rotation flow w_0 depends on the enstrophy Γ, i.e.,

$$\Theta^2(w_0) = \frac{\Gamma}{4\int_{S^2} \cos^2\theta \, dx}.$$

4.1. Derivation of the spherical model. The name spherical model comes from the fact that in a lattice approximation, the conservation of enstrophy takes the form of a hyperspherical constraint in vorticity phase space (4.3), as shown next. Using a uniform mesh M of N points $\{x_1, \ldots, x_N\}$ on S^2 and the Voronoi cells based on this mesh, approximate the vorticity by

$$w(x) \simeq \sum_{j=1}^{N} s_j H_j(x),$$

where $s_j = w(x_j)$ and H_j is the indicator function on the Voronoi cell D_j centered at x_j [29]. The truncated kinetic energy of flow in (2.2) now takes the standard form of a spin lattice model Hamiltonian,

$$H_N = -\frac{1}{2}\sum_{j=1}^{N}\sum_{k=1}^{N} J_{jk} s_j s_k,$$

where

$$J_{jk} = \int_{S^2} dx H_j(x) \int_{S^2} dx' \ln|1 - x \cdot x'| H_k(x')$$
$$\simeq \frac{16\pi^2}{N^2} \ln|1 - x_j \cdot x_k| \quad \text{for } N \gg 1.$$

The truncated relative enstrophy is likewise given by

$$\Gamma_N = \int_{S^2} dx w^2 = \int_{S^2} dx \left(\sum_{j=1}^{N} s_j H_j(x) \right)^2 = \frac{4\pi}{N} \sum_{j=1}^{N} s_j^2. \tag{4.3}$$

Last, the truncated total circulation is given by

$$TC_N = \int_{S^2} dx w = \int_{S^2} dx \sum_{j=1}^{N} s_j H_j(x) = \frac{4\pi}{N} \sum_{j=1}^{N} s_j.$$

Thus, the microcanonical constraint $\delta(\Gamma - \Gamma^*)$ in (4.2) is approximated in this lattice formulation by a hyperspherical constraint,

$$\sum_{j=1}^{N} s_j^2 = \frac{N}{4\pi} \Gamma^*.$$

The canonical constraint on kinetic energy $H[w]$ should be taken to mean that in a numerical simulation of its equilibrium statistics, one sets the value of the inverse temperature of an infinite energy reservoir and allows the energy to flow between the vortex system and this reservoir and, thence, towards equilibrium. On the other hand, the microcanonical constraint on the enstrophy implies that in the same simulation, the value of the enstrophy is held fixed while the energy flows between the vortex system and the energy reservoir. Total circulation is held fixed at zero throughout such simulations (cf. Lim and Nebus [29]). As the simulation proceeds, the value of the energy changes and finally fluctuates around its equilibrium value $\langle H \rangle(\beta, \Gamma^*)$. Similarly, all other conserved quantities of the Euler equations on a sphere that are not explicitly built into this model, including the angular momentum of the fluid, will in general fluctuate as the simulation runs.

Indeed our experience shows Monte Carlo simulations of the spherical model have the following robust behavior: the angular momentum which is often set to zero initially changes significantly and then settles on a nonzero value given by

$$\Lambda[u] = \int_{S^2} u(\theta) \sin^2\theta d\theta d\phi,$$

where $u(\theta)$ is the zonal velocity of the solid-body rotation vorticity state $w_0(\Gamma^*)$ and θ is the co-latitude on the unit sphere S^2. Clearly, the angular momentum (per unit density) $\Lambda[u] = f(\Gamma^*)$ depends on the enstrophy Γ^* or equivalently the energy $H = 2D\Gamma^*$. From the point of view of globally maximizing the kinetic energy, the addition of a fixed angular momentum constraint into the statistical mechanics formulation must lead to undesired local energy maximizers.

This completes our demonstration that symmetry breaking of the $SO(3)$ symmetry by global energy maximizers in the problem of nonrotating spheres is robust

in a statistical sense. The same arguments can be used to prove the robustness of other symmetry breaking spherical harmonic vortex states Y_{lm} on the nonrotating sphere. The principle of selective decay then implies that the asymptotic vorticity of decaying 2d Navier–Stokes flows on S^2 is the ground state Y_{10} found, thus providing an important connection between the results on ideal flows and more realistic flows with nonzero viscosity.

5. Statistical thermodynamics of ideal flows on a sphere. We end with a discussion of the relationship between the constrained energy maximizer and the maximizer of the free energy. Since the work of Planck, it is well known that the most probable state in the statistics of the partition function (1.1) represents a minimum of the free energy $F = E - TS$, where E is the internal energy, $T = \beta^{-1}$ is the temperature, and S is the entropy. Dynamic equilibria of the underlying dynamical system, on the other hand, are related to the extremals of the energy functional E. In recent work [24], [23] on the Onsager vortex gas problem on the unbounded plane, we have asked the question, under what conditions are the minima of F well approximated by the energy extremals of E? It turns out that for low positive temperatures, this approximation is excellent, even for relatively small numbers M of point vortices, and for order one temperatures.

We first use the exact solution of the spherical model for energy-enstrophy theory to confirm the validity of this approximation in situations with negative temperatures and in systems that are based, not on a particle method like the Onsager problem, but on a lattice or spatial discretization like the family of spherical models in this paper. From the expression $F = E - TS$, one should expect from general principles that if

$$T < 0, \qquad |T| \to 0, \tag{5.1}$$

and

$$\begin{aligned} &\langle E \rangle \text{ is not small compared to } S \text{ when both are} \\ &\text{evaluated at the most probable state } w_0(T), \end{aligned} \tag{5.2}$$

then a similar approximation is again valid:

(1) The maximizers w_0 of F are the most probable states for $T < 0$;

(2) These maximizers are close to the maximizers w_0' of E.

We show that for the spherical model of ideal fluid flows on a nonrotating sphere, this approximation is actually valid for all negative temperatures, but for reasons that are different than (5.1) and (5.2). The exact solution of the spherical model for energy-enstrophy theory has the important consequence that for any negative T, large or small in numerical value, the expected value $\langle E \rangle$ of the energy has a maximal ratio to the given value of the enstrophy Γ. This ratio is given by the reciprocal of the smallest positive eigenvalue of the Laplace–Beltrami operator on the sphere S^2. This is known as Rayleigh's inequality and is related to Poincaré's inequality, and the corresponding eigenfunction is the spherical harmonic $Y_{10} = d\cos\theta$ with θ equal to the co-latitude on S^2. Thus, for all $T < 0$, E is maximally related to the enstrophy Γ.

Furthermore, the entropy

$$S(\vec{s}(N)) = k \log R(\vec{s}(N)),$$

where $R(\vec{s}(N))$ is the number of rearrangements of vorticity parcels between lattice sites corresponding to a particular spin state $\vec{s}(N) = (s_1, \ldots, s_N)$. Since, in the

continuum limit,

$$\vec{s}(N) \to w(\theta, \phi) \in L_2(S^2),$$

the family of spin states $\{\vec{s}_0(N)\}_1^\infty$ which has minimal entropy $S_N = S(\vec{s}_0(N))$ for each N, corresponds to a most probable vorticity distribution $w_0(\theta, \phi) \in L_2(S^2)$. Under generic conditions, the most probable state w_0 corresponds to the uniform function which is the spherical harmonic ψ_{00} on the sphere (cf. Lieb and Loss [5]). But in this particular problem, under the additional condition $\int_{S^2} w_0 dx = 0$ of zero total circulation which comes from Stokes's theorem, the most probable vorticity is not $d\psi_{00}$, and it may not be possible to use the method of rearrangement in [5] to find the most probable vorticity w_0. Nonetheless, the exact solution of the spherical model's partition functions Z_N implies that the most probable spin states

$$\vec{s}_0(N) \to w_0(\theta, \phi) = d\psi_{10} \in L_2(S^2)$$

for all $T < 0$. Thus, in the continuum limit, the unique most probable vorticity function $w_0 = d\psi_{10}$ is the solid-body rotation state for all negative temperatures.

Therefore, the same vorticity function $d\psi_{10}$ simultaneously maximizes the energy E and minimizes the entropy S for all $T < 0$. This certainly proves that the maximizer $w_0(T)$ of F for $T < 0$ is exactly equal to the maximizer $w_o'(T)$ of the energy E, but we had to use the exact solution of the spherical model to establish the validity of the approximation.

In problems where the validity of this approximation can be established by a priori means (that is, without solving the full partition function), one can in principle compute the most probable state $w_0(T)$, that is, maximizers of the free energy F, at $T < 0$ by performing the easier task of computing the maximizer $w_0'(T)$ of the energy E. The natural question to ask at this point is whether one can establish the validity of this approximation without using the exact solution of the partition function (1.1). It is not clear this can be done.

Future work will include further attempts to give a priori derivations of the above approximation, and the extension of the results in this paper to the barotropic vorticity equation on a rotating sphere, where the variational theory is richer and exhibits interesting bifurcations when the rate of rotation of the sphere changes relative to the total enstrophy.

Acknowledgments. The presentation of this paper benefited from the comments of two anonymous reviewers. The author would also like the acknowledge the scientific support of Dr. Gary Johnson and Dr. Robert Launer.

RECONSTRUCTION OF A SMALL INCLUSION IN A TWO-DIMENSIONAL OPEN WAVEGUIDE*

HABIB AMMARI†, EKATERINA IAKOVLEVA†, AND HYEONBAE KANG‡

Abstract. We consider wave propagation in a perturbed open waveguide. We provide a new asymptotic expansion for the scattered wave when the inclusion is of small diameter. We design a MUSIC (multiple signal classification) type of algorithm for locating the inclusion and illustrate its viability in numerical examples.

Key words. open waveguide, electromagnetic inclusion, reconstruction, MUSIC algorithm

1. Introduction.

Optical waveguides are the basis of the optoelectronics and telecommunications industry. It is important in engineering design of optical communication devices not only to find out whether a defect is present or absent in a device, but also to precisely locate it and accurately characterize its size.

In this paper we discuss wave propagation in a perturbed optical waveguide. The perturbation in the electromagnetic characteristics of the waveguide is caused by a small electromagnetic inclusion. The waveguide we consider is half space ($y > 0$) with the Dirichlet boundary condition on $y = 0$. The region $0 < y < h$ is considered the core of the fiber, while the remainder is considered the cladding. The electromagnetic characteristics of the waveguide are constant in each part. The electric permittivity and the magnetic permeability are then given by

$$\varepsilon(y) = \begin{cases} \varepsilon_1 & \text{in }]0,h[, \\ \varepsilon_2 & \text{in }]h,+\infty[\end{cases}$$

and

$$\mu(y) = \begin{cases} \mu_1 & \text{in }]0,h[, \\ \mu_2 & \text{in }]h,+\infty[, \end{cases}$$

where $\varepsilon_1\mu_1 \geq \varepsilon_2\mu_2$ and $\mu_1 \neq \mu_2$.

We suppose that there is an electromagnetic inclusion D in the core of the waveguide, of the form $D = Z + \alpha B$, where $B \subset \mathbb{R}^2$ is a bounded, smooth ($\mathcal{C}^\infty$) domain containing the origin. The point $Z = (z_x, z_y) \in \mathbb{R}\times]0,h[$, which determines the location of the inclusion, is assumed to satisfy $h - d_0 \geq z_y \geq d_0 > 0$. The value of α is the order of magnitude of the diameter of the inclusion. Let μ_* and ε_* denote the magnetic permeability and the electric permittivity of the inclusion D; we shall

assume that these are positive constants. Using these notations, we introduce the piecewise constant magnetic permeability

$$\mu_\alpha(x,y) := \begin{cases} \mu_* & \text{in } D, \\ \mu_1 & \text{in } \mathbb{R}\times]0,h[\setminus \bar{D}, \\ \mu_2 & \text{in } \mathbb{R}\times]h,+\infty[\,. \end{cases}$$

If we allow the degenerate case $\alpha = 0$, then

$$\mu_0(x,y) := \begin{cases} \mu_1 & \text{in } \mathbb{R}\times]0,h[, \\ \mu_2 & \text{in } \mathbb{R}\times]h,+\infty[\,. \end{cases}$$

The piecewise constant electric permittivity $\varepsilon_\alpha(x,y)$ is defined analogously.

An incident wave u_0, in the form of a guided mode, is sent along the perturbed waveguide. It encounters the inclusion D in the core region of the waveguide and is scattered. Our first goal in this work is to provide an asymptotic formula for the scattered wave when α goes to zero. Our second goal is to use this expansion for efficiently determining the location and the shape of the inclusion D.

To set the problem mathematically, let u_α satisfy the Helmholtz equation

$$\left(\nabla\cdot\frac{1}{\mu_\alpha}\nabla+\omega^2\varepsilon_\alpha\right)u_\alpha = 0 \quad \text{in } \mathbb{R}\times]0,+\infty[\,, \tag{1}$$

and $u_\alpha - u_0$ satisfy some form of radiation condition. Unfortunately, not much is known about the exact form of this condition due to the fact that the waveguide extends from $-\infty$ to $+\infty$. We avoid this issue by first obtaining a representation of the Green's function of the homogeneous waveguide. The Green's function we give is based on the requirement that waves be outgoing and remain bounded. Using the obtained Green's function, we derive an asymptotic expansion of the solution u_α of the inhomogeneous waveguide problem. We shall mention the work by Zhang and Chandler-Wilde [23], which discusses the issue of radiation conditions for the scattering by an infinite layer. However, these conditions do not rule out the guided waves localized in the layer.

Let us emphasize here that the use of the formal equivalence between electromagnetics and linear acoustics, by term-to-term replacing permittivity and permeability by compressibility and volume density of mass, and the scalar electric field by the scalar acoustic pressure characteristic of compressional waves inside fluid media, opens up the investigation of this paper to many other applications, such as ocean-acoustics, even though the type of materials and of geometrical configurations investigated and the range of values that are allowed to be taken by the two sets of parameters in the two disciplines may differ considerably in practice. The configuration considered in this paper has also been used as a model of underwater acoustics. The area of applications is the identification of mines, submarines, or submerged obstacles in harbors and other shallow bodies of water.

The paper is organized as follows. In section 2, we construct the Green's function corresponding to the unperturbed waveguide. The main ingredient for doing this is an inverse transform formula from [5]. A similar formula was first derived by Magnanini and Santosa [12], [13]. Section 3 is devoted to the derivation of the leading-order term in the asymptotic expansion of the scattered wave. In section 4 we exploit this formula for recovering the location and the shape of the inclusion. A MUSIC (multiple signal classification) type of algorithm is developed for locating the inclusion. Numerical examples are given in section 5. A discussion section ends the paper.

Finally, we shall mention, in connection with our asymptotic expansion for the scattered wave, the nice work by Vogelius and Volkov [20].

2. Green's function for the unperturbed waveguide. This section is devoted to the derivation of an expression of the Green's function. We will separate the Green's function into three components: the guided component, the radiated component, and the evanescent component. We will also provide asymptotic results that show how the nonguided part of the Green's function decays along the core of the waveguide. Our approach for constructing the Green's function follows [12]. We note that one can also employ complex analysis for deriving an explicit representation of the Green's function, starting with the assumption of its separability in the variables x and y, and a representation in terms of a contour integral in the separation parameter; see [9].

For a function f, continuous of compact support, let u satisfy the Helmholtz equation

$$\left(\nabla \cdot \frac{1}{\mu_0}\nabla + \omega^2 \varepsilon_0\right) u = f \quad \text{in } \mathbb{R}^2_+ := \mathbb{R} \times]0, +\infty[\,, \tag{2}$$

with the boundary condition $u = 0$ on $y = 0$.

We introduce the following notation:

$$q(y) = \omega^2(\varepsilon_1\mu_1 - \varepsilon(y)\mu(y)),$$
$$d^2(\omega) = \omega^2(\varepsilon_1\mu_1 - \varepsilon_2\mu_2) \geq 0.$$

Let $g(y, \lambda)$ be defined by

$$\begin{cases} \partial_{yy} g(y,\lambda) + (\lambda - q(y)) g(y,\lambda) = 0 \quad \text{in }]0,h[\cup]h,+\infty[, \\ [g(.,\lambda)] = 0 \quad \text{on } y = h, \\ \left[\dfrac{1}{\mu}\partial_y g(.,\lambda)\right] = 0 \quad \text{on } y = h, \\ g(0,\lambda) = 0 \quad \text{and} \quad \partial_y g(0,\lambda) = \sqrt{\lambda}. \end{cases} \tag{3}$$

Setting $\phi(y, \lambda) = \sin(\sqrt{\lambda}y)$, we then write

$$g(y,\lambda) = \begin{cases} \phi(y,\lambda) \quad \text{if } y \in]0,h[, \\ \phi(h,\lambda)\cos\left[\sqrt{\lambda - d^2}(y-h)\right] + \dfrac{\mu_2}{\mu_1}\dfrac{\partial_y\phi(h,\lambda)}{\sqrt{\lambda - d^2}}\sin\left[\sqrt{\lambda - d^2}(y-h)\right] \\ \text{if } y \in]h,+\infty[. \end{cases}$$

For $\lambda \geq d^2$, $g(y, \lambda)$ is bounded. For $\lambda < d^2$, in view of the above expression of g, we impose the dispersion relation

$$\phi(h,\lambda) + \frac{\mu_2}{\mu_1}\frac{\partial_y\phi(h,\lambda)}{\sqrt{d^2 - \lambda}} = 0,$$

or equivalently,

$$\sqrt{d^2 - \lambda}\tan\sqrt{\lambda}h + \frac{\mu_2}{\mu_1}\sqrt{\lambda} = 0, \tag{4}$$

to make $g(y,\lambda)$ bounded in $\mathbb{R}^+$. It is straightforward to see that there are a finite number of roots $\lambda_l(\omega)$ of (4) with associated solutions: $g(y,\lambda_l)$ for $l=1,2,\dots,m$. Moreover, the set of eigenfunctions $g(y,\lambda), \lambda \in]0,+\infty[$ is complete in $L^2(\mathbb{R}_+)$. When the magnetic permeabilities μ_1 and μ_2 are equal ($\mu_1=\mu_2$), the completeness of the associated eigenvalue problem has been proved and an inverse transform formula has been rigorously derived in [12]. See also [21], [22], where the spectrum of the Pekeris operator is investigated. Here the following more general inverse transform formula from [5] will be needed. Let $f \in L^2(\mathbb{R}_+, \frac{dy}{\mu(y)})$. We have the inverse transform formula

$$
\begin{aligned}
f(x) = &\sum_{l=1}^{m} \frac{2\mu_1\sqrt{d^2-\lambda_l}\int_0^{+\infty} g(y,\lambda_l)f(y)\frac{dy}{\mu(y)}}{\frac{\mu_1}{\mu_2}\phi(h,\lambda_l)^2 + 2\sqrt{d^2-\lambda_l}\int_0^h \phi(y,\lambda_l)^2 dy} g(x,\lambda_l) \\
&+ \frac{1}{\pi}\int_{d^2}^{+\infty} \frac{\mu_2\sqrt{\lambda-d^2}\int_0^{+\infty} g(y,\lambda)f(y)\frac{dy}{\mu(y)}}{(\lambda-d^2)\phi(h,\lambda)^2 + (\frac{\mu_2}{\mu_1})^2\partial_y\phi(h,\lambda)^2} g(x,\lambda)d\lambda
\end{aligned} \tag{5}
$$

almost everywhere.

We now return to the Helmholtz equation (2). Let

$$
U(x,\lambda) = \int_0^{+\infty} u(x,y)g(y,\lambda)\,\frac{dy}{\mu(y)}.
$$

Multiplying (2) by $\frac{1}{\mu(y)}g(y,\lambda)$ and integrating with respect to the variable y over the interval $]0,+\infty[$, after some straightforward manipulations for $x \in \mathbb{R}$ we obtain

$$
\partial_{xx}U(x,\lambda) + (\omega^2\varepsilon_1\mu_1 - \lambda)U(x,\lambda) = \int_0^{+\infty} f(x,\eta)g(\eta,\lambda)\,\frac{d\eta}{\mu(\eta)}. \tag{6}
$$

The solution of (6), which is outgoing for $0 \le \lambda < \omega^2\varepsilon_1\mu_1$ and decays exponentially for $\lambda > \omega^2\varepsilon_1\mu_1$ as $|x| \to +\infty$, is readily given for $x \in \mathbb{R}$ by the following expression:

$$
U(x,\lambda) = \int_{-\infty}^{\infty} \frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}}{2i\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}} \int_0^{+\infty} f(\zeta,\eta)g(\eta,\lambda)\,\frac{d\eta}{\mu(\eta)}d\zeta. \tag{7}
$$

By the inversion formula (5), we have

$$
\begin{aligned}
u(x,y) = &\sum_{l=1}^{m} \frac{2\mu_1\sqrt{d^2-\lambda_l}U(x,\lambda_l)}{\frac{\mu_1}{\mu_2}\phi(h,\lambda_l)^2 + 2\sqrt{d^2-\lambda_l}\int_0^h \phi(y,\lambda_l)^2 dy} g(y,\lambda_l) \\
&+ \frac{1}{\pi}\int_{d^2}^{+\infty} \frac{\mu_2\sqrt{\lambda-d^2}U(x,\lambda)}{(\lambda-d^2)\phi(h,\lambda)^2 + (\frac{\mu_2}{\mu_1})^2\partial_y\phi(h,\lambda)^2} g(y,\lambda)d\lambda \quad \forall\,(x,y) \in \mathbb{R}^2_+;
\end{aligned}
$$

hence, by (7) and by interchanging the order of integration, we obtain that the solution u of (2) corresponding to the case where no energy is radiated from the far field ($x^2+y^2 \to +\infty, y>0$) can be represented by

$$
u(x,y) = \int_{\mathbb{R}^2_+} G(x,y,\zeta,\eta)f(\zeta,\eta)\,d\zeta d\eta,
$$

where the Green's function G is given by

$$
\begin{aligned}
&G(x,y,\zeta,\eta)\\
&:=\sum_{l=1}^{m}\frac{2\mu_1\sqrt{d^2-\lambda_l}}{\frac{\mu_1}{\mu_2}\phi(h,\lambda_l)^2+2\sqrt{d^2-\lambda_l}\int_0^h\phi(y,\lambda_l)^2dy}\left(\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1\mu_1-\lambda_l}}}{2i\sqrt{\omega^2\varepsilon_1\mu_1-\lambda_l}}\right)g(y,\lambda_l)g(\eta,\lambda_l)\\
&+\frac{1}{\pi}\int_{d^2}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}}{(\lambda-d^2)\phi(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi(h,\lambda)^2}\left(\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}}{2i\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}\right)g(y,\lambda)g(\eta,\lambda)d\lambda.
\end{aligned}
$$

Note that the Green's function G has been constructed so that all the waves are outgoing.

Following [12], we now separate the Green's function G into three components $G=G^g+G^r+G^e$. The guided component

$$
\begin{aligned}
&G^g(x,y,\zeta,\eta)\\
&:=\sum_{l=1}^{m}\frac{2\mu_1\sqrt{d^2-\lambda_l}}{\frac{\mu_1}{\mu_2}\phi(h,\lambda_l)^2+2\sqrt{d^2-\lambda_l}\int_0^h\phi(y,\lambda_l)^2dy}\left(\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1\mu_1-\lambda_l}}}{2i\sqrt{\omega^2\varepsilon_1\mu_1-\lambda_l}}\right)g(y,\lambda_l)g(\eta,\lambda_l)
\end{aligned}
$$

corresponds to the solution that is concentrated near the core. The radiated component

$$
\begin{aligned}
&G^r(x,y,\zeta,\eta)\\
&:=\frac{1}{\pi}\int_{d^2}^{\omega^2\varepsilon_1\mu_1}\frac{\mu_2\sqrt{\lambda-d^2}}{(\lambda-d^2)\phi(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi(h,\lambda)^2}\left(\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}}{2i\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}\right)g(y,\lambda)g(\eta,\lambda)d\lambda
\end{aligned}
$$

and the evanescent component

$$
\begin{aligned}
&G^e(x,y,\zeta,\eta)\\
&:=\frac{1}{\pi}\int_{\omega^2\varepsilon_1\mu_1}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}}{(\lambda-d^2)\phi(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi(h,\lambda)^2}\left(\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}}{2i\sqrt{\omega^2\varepsilon_1\mu_1-\lambda}}\right)g(y,\lambda)g(\eta,\lambda)d\lambda
\end{aligned}
$$

are radiated away from the source at (ζ,η).

We will need to estimate G^r and G^e for fixed y and η. Following [12] once again, we can apply Laplace's method [6], and obtain for $|x-\zeta|\to+\infty$ that

$$
G^e(x,y,\zeta,\eta)=O\left(\frac{1}{\omega|x-\zeta|}\right). \tag{8}
$$

Moreover, making use of the method of steepest descent [6], we can show that

$$
G^r(x,y,\zeta,\eta)=O\left(\frac{1}{\omega|x-\zeta|}\right)\quad\text{as } |x-\zeta|\to+\infty. \tag{9}
$$

We can therefore conclude that for a fixed y, as one looks down the core of the waveguide, the nonguided components of the waves die off like $O(1/\omega|x|)$.

Let $X=(x,y)$ and $Y=(\zeta,\eta)$. Observe that the Green's function for the problem,

$$
\begin{cases}
\nabla_X\cdot\dfrac{1}{\mu_0}\nabla_X G_0(X,Y)=\delta_Y \quad \text{in } \mathbb{R}\times]0,h[\cup\mathbb{R}\times]h,+\infty[,\\
G_0\big|_+=G_0\big|_-,\quad \dfrac{1}{\mu_2}\dfrac{\partial G_0}{\partial y}\bigg|_+=\dfrac{1}{\mu_1}\dfrac{\partial G_0}{\partial y}\bigg|_- \quad \text{on } y=h,\\
G_0=0 \quad \text{on } y=0,
\end{cases}
$$

is given by the following explicit formula. If $0 < \eta < h$, then

(10)

$$G_0(X,Y) = \mu_1 \begin{cases} \dfrac{2\mu_2}{\mu_1+\mu_2}\big[\Gamma(X-Y)-\Gamma(\overline{X}-Y)\big], & y > h, \\ \big[\Gamma(X-Y)-\Gamma(\overline{X}-Y)\big] + \dfrac{\mu_2-\mu_1}{\mu_1+\mu_2}\big[\Gamma(\overline{X}-Y+(0,2h))-\Gamma(X-Y-(0,2h))\big], \\ \qquad 0 < y < h. \end{cases}$$

Here $\Gamma(X) = (1/(2\pi)) \log|X|$ is the fundamental solution for the Laplacian and $\overline{X} = (x,-y)$. If $\eta > h$, the formula takes the form

(11)

$$G_0(X,Y) = \mu_2 \times \begin{cases} \big[\Gamma(X-Y)-\Gamma(\overline{X}-Y)\big] + \dfrac{\mu_1-\mu_2}{\mu_1+\mu_2}\big[\Gamma(\overline{X}-Y+(0,2h))-\Gamma(X-Y-(0,2h))\big], \\ \qquad y > h, \\ \dfrac{2\mu_1}{\mu_1+\mu_2}\big[\Gamma(X-Y)-\Gamma(\overline{X}-Y)\big], \quad 0 < y < h. \end{cases}$$

We will need the following lemma.

LEMMA 2.1. *For each M and a fixed but arbitrary (ζ,η) with $0 < \eta < h$,*

$$R(x,y,\zeta,\eta) := G(x,y,\zeta,\eta) - G_0(x,y,\zeta,\eta) \tag{12}$$

is $\mathcal{C}^1$ in (x,y) for $|x-\zeta| \le M$ and $0 \le y \le h$, and its $\mathcal{C}^1$-norm is bounded independently of (ζ,η).

Proof. Fix (ζ,η) and let $v(x,y) := G(x,y,\zeta,\eta)$ and $w(x,y) := G_0(x,y,\zeta,\eta)$. Choose $M > 0$ so that on the domain $\Omega_M :=]\zeta - M, \zeta + M[\times]0,h[$ the problem

$$\begin{cases} \left(\nabla \cdot \dfrac{1}{\mu_0}\nabla + \omega^2\varepsilon_0\right) u = 0 & \text{in } \Omega_M, \\ u = f & \text{on } \partial\Omega_M \end{cases}$$

is well posed. Since $(\nabla \cdot \frac{1}{\mu_0}\nabla + \omega^2\varepsilon_0)v = \delta_{(\zeta,\eta)}$ and $\nabla \cdot \frac{1}{\mu_0}\nabla w = \delta_{(\zeta,\eta)}$, the function R given by (12) satisfies

$$\left(\nabla \cdot \frac{1}{\mu_0}\nabla + \omega^2\varepsilon_0\right) R = -\omega^2\varepsilon_0 w \quad \text{in } \Omega_M.$$

Moreover, $R|_{\partial\Omega_M}$ is a piecewise $\mathcal{C}^1$-function, and $R(x,y) = 0$ if $y = 0$. Define

$$W(x,y) := -\omega^2\varepsilon_0 \int_{\Omega_M} G_0(x,y,\zeta,\eta) w(\zeta,\eta) dA.$$

Then one can easily see from the explicit forms (10) and (11) of G_0 that W is $\mathcal{C}^1$ on Ω_M and $\|W\|_{\mathcal{C}^1(\Omega_M)} \le C$ uniformly in (ζ,η). Observe that $R - W$ satisfies

$$\left(\nabla \cdot \frac{1}{\mu_0}\nabla + \omega^2\varepsilon_0\right)(R - W) = -\omega^2\varepsilon_0 W \quad \text{in } \Omega_M,$$

and hence by the standard regularity theorem for the elliptic equations we get

$$\|R - W\|_{\mathcal{C}^1(\Omega_{M/2})} \leq C$$

for some C uniformly in (ζ, η). This completes the proof. □

3. Asymptotic expansion of the scattered wave. In this section we derive an asymptotic formula for the perturbation $u_\alpha - u_0$ due to the presence of the inclusion $D = Z + \alpha B$ as α tends to 0.

For $k > 0$, let the fundamental solution Γ_k be defined by

$$\Gamma_k(X) = -\left(\frac{i}{4}\right) H_0^{(1)}(k|X|) \quad \text{for } X \neq 0,$$

where $H_0^{(1)}$ is the Hankel function of the first kind of order 0. For a bounded smooth domain D in $\mathbb{R}^2$, let $\mathcal{S}_D^k$ be the single layer potential defined by Γ_k; that is, for $\phi \in L^2(\partial D)$,

$$\mathcal{S}_D^k \phi(X) = \int_{\partial D} \Gamma_k(X - Y)\phi(Y) d\sigma(Y), \quad X \in \mathbb{R}^2.$$

Let $\widetilde{\mathcal{S}}_D$ be the single layer potential defined by G; that is, for $\psi \in L^2(\partial D)$,

$$\widetilde{\mathcal{S}}_D \psi(X) = \frac{1}{\mu_1} \int_{\partial D} G(X, Y)\psi(Y) d\sigma(Y), \quad X \in \mathbb{R}^2.$$

Suppose that the following assumption (H1) holds: the trivial solution is the unique solution to the Helmholtz equation

$$\left(\nabla \cdot \frac{1}{\mu_\alpha} \nabla + \omega^2 \varepsilon_\alpha\right) u = 0 \quad \text{in } \mathbb{R}^2_+,$$

with the boundary condition $u = 0$ on $y = 0$ and the decay estimates

$$\left| u_l(x) \mp i\beta_l \frac{du_l}{dx}(x) \right| = O\left(\frac{1}{|x|}\right) \quad \text{as } x \to \pm\infty,$$

for $l = 1, \ldots, m$, where $u_l(x) = \int_0^{+\infty} u(x, y) g(y, \lambda_l)\, dy$.

Following [2], an integral representation formula for the outgoing solution u_α of (1) can be proved.

LEMMA 3.1. *Suppose that $\omega\sqrt{\varepsilon_1 \mu_1}$ is not a Dirichlet eigenvalue of $-\Delta$ on D, and let $k_* := \omega\sqrt{\varepsilon_* \mu_*}$. The solution u_α of (1) can be represented by*

$$u_\alpha(X) = \begin{cases} u_0(X) + \widetilde{\mathcal{S}}_D \psi(X), & X \in \mathbb{R}^2_+ \setminus \overline{D}, \\ \mathcal{S}_D^{k_*} \phi(X), & X \in D, \end{cases} \tag{13}$$

where the pair $(\phi, \psi) \in L^2(\partial D) \times L^2(\partial D)$ is the unique solution to the system of integral equations

$$\begin{cases} \mathcal{S}_D^{k_*} \phi - \widetilde{\mathcal{S}}_D \psi = u_0 \quad \text{on } \partial D, \\ \dfrac{1}{\mu_*} \dfrac{\partial \mathcal{S}_D^{k_*} \phi}{\partial \nu}\bigg|_- - \dfrac{1}{\mu_1} \dfrac{\partial \widetilde{\mathcal{S}}_D \psi}{\partial \nu}\bigg|_+ = \dfrac{1}{\mu_1} \dfrac{\partial u_0}{\partial \nu} \quad \text{on } \partial D. \end{cases} \tag{14}$$

Here ν denotes the outward unit normal to ∂D; subscripts $+$ and $-$ indicate the limiting values as we approach ∂D from outside D and from inside D.

Proof. Define the operator $T : L^2(\partial D) \times L^2(\partial D) \to L^2(\partial D) \times L^2(\partial D)$ by

$$T(\phi,\psi) = \left(\mathcal{S}_D^{k_*}\phi - \widetilde{\mathcal{S}}_D\psi,\ \frac{1}{\mu_*}\frac{\partial \mathcal{S}_D^{k_*}\phi}{\partial \nu}\bigg|_- - \frac{1}{\mu_1}\frac{\partial \widetilde{\mathcal{S}}_D\psi}{\partial \nu}\bigg|_+ \right).$$

By (12), T is a Fredholm type of operator. Thus, in order to prove the existence and uniqueness of a solution to (14), it is enough to show that T is injective. Let the pair $(\phi,\psi) \in L^2(\partial D) \times L^2(\partial D)$ be a solution to the following homogeneous system of integral equations:

$$\begin{cases} \mathcal{S}_D^{k_*}\phi - \widetilde{\mathcal{S}}_D\psi = 0 \quad \text{on } \partial D, \\ \dfrac{1}{\mu_*}\dfrac{\partial \mathcal{S}_D^{k_*}\phi}{\partial \nu}\bigg|_- - \dfrac{1}{\mu_1}\dfrac{\partial \widetilde{\mathcal{S}}_D\psi}{\partial \nu}\bigg|_+ = 0 \quad \text{on } \partial D. \end{cases}$$

Introduce

$$v(X) = \begin{cases} \widetilde{\mathcal{S}}_D\psi(X), & X \in \mathbb{R}^2_+ \setminus \overline{D}, \\ \mathcal{S}_D^{k_*}\phi(X), & X \in D. \end{cases}$$

It is easy to see that v satisfies the equation $(\nabla \cdot (1/\mu_\alpha)\nabla + \omega^2\varepsilon_\alpha)\, v = 0$ in $\mathbb{R}^2_+$, with the boundary condition $v = 0$ on $y = 0$ together with the decay estimates

$$\left| v_l(x) \mp i\beta_l \frac{dv_l}{dx}(x) \right| = O\left(\frac{1}{|x|}\right) \quad \text{as } x \to \pm\infty,$$

for $l = 1, \dots, m$, where

$$v_l(x) = \int_0^{+\infty} v(x,y) g(y,\lambda_l)\, dy,$$

which hold because of the form of the Green's function G. Then, it immediately follows from (H1) that $v = 0$ in $\mathbb{R}^2_+$. Next, the unique continuation for the operator $(\Delta + \omega^2\varepsilon_*\mu_*)$ yields $\mathcal{S}_D^{k_*}\phi = 0$ in D. Since $(\Delta + \omega^2\varepsilon_1\mu_1)\widetilde{\mathcal{S}}_D\psi = 0$ in D and $\omega\sqrt{\varepsilon_1\mu_1}$ is not a Dirichlet eigenvalue of $-\Delta$ on D, then $\widetilde{\mathcal{S}}_D\psi = 0$ in $\mathbb{R}], \times]0, h[$, which leads to a contradiction because of the jump of the normal derivative of $\widetilde{\mathcal{S}}_D\psi$ on ∂D. ∎

The derivation of the asymptotic formula for $u_\alpha - u_0$ relies on the representation formula (13) and is parallel to that in [2]. However, there are some technical differences, and so we include the main steps for its derivation.

Let us introduce two more layer potentials. Define

$$\mathcal{S}_D\phi(X) = \int_{\partial D} \Gamma(X - Y)\phi(Y) d\sigma(Y), \quad X \in \mathbb{R}^2,$$

where $\Gamma(X)$ is the fundamental solution for the Laplacian Δ. We also define

$$\mathcal{S}_D^0\phi(X) = \frac{1}{\mu_1}\int_{\partial D} G_0(X,Y)\psi(Y) d\sigma(Y), \quad X \in \mathbb{R}^2.$$

Let

$$\widehat{\phi}(Y) := \phi(Z + \alpha Y), \quad \widehat{\psi}(Y) := \psi(Z + \alpha Y), \quad Y \in \partial B. \tag{15}$$

Because of (12), we have

$$\begin{aligned} G(Z+\alpha X, Z+\alpha Y) &= G_0(Z+\alpha X, Z+\alpha Y) + C + O(\alpha|X-Y|) \\ &= G_0(X,Y) + C + O(\alpha|X-Y|), \quad X,\ Y \in \partial B, \end{aligned}$$

for some constant C. Therefore,

$$\widetilde{\mathcal{S}}_D\phi(Z+\alpha X) = \alpha \mathcal{S}_B^0 \widehat{\phi}(X) + C + O(\alpha^2), \quad X \in \partial B,$$

where $O(\alpha^2) \leq C\alpha^2 \|\widehat{\phi}\|_{L^2(\partial B)}$. Here and in what follows, C denotes a constant which may be different at each occurrence. Since $\Gamma_{k_*}(X) - \Gamma(X)$ is $\mathcal{C}^1(\mathbb{R}^2)$, we also have

$$\mathcal{S}_D^{k_*}\phi(Z+\alpha X) = \alpha \mathcal{S}_B \widehat{\phi}(X) + C + O(\alpha^2), \quad X \in \partial B.$$

Since $u_0(Z+\alpha Y) = u_0(Z) + \alpha \nabla u_0(Z)\cdot Y + o(\alpha)$, the integral equation (14) takes the form

$$\begin{cases} \mathcal{S}_B\widehat{\phi} - \mathcal{S}_B^0\widehat{\psi} = C + \nabla u_0(Z)\cdot Y + O(\alpha) \quad \text{on } \partial B, \\ \dfrac{1}{\mu_*}\dfrac{\partial \mathcal{S}_B\widehat{\phi}}{\partial \nu}\bigg|_- - \dfrac{1}{\mu_1}\dfrac{\partial \mathcal{S}_B^0\widehat{\psi}}{\partial \nu}\bigg|_+ = \dfrac{1}{\mu_1}\nabla u_0(Z)\cdot\dfrac{\partial Y}{\partial \nu} + O(\alpha) \quad \text{on } \partial B. \end{cases} \tag{16}$$

Let (f,g) be the solution to

$$\begin{cases} \mathcal{S}_B f - \mathcal{S}_B^0 g = C + \nabla u_0(Z)\cdot Y \quad \text{on } \partial B, \\ \dfrac{1}{\mu_*}\dfrac{\partial \mathcal{S}_B f}{\partial \nu}\bigg|_- - \dfrac{1}{\mu_1}\dfrac{\partial \mathcal{S}_B^0 g}{\partial \nu}\bigg|_+ = \dfrac{1}{\mu_1}\nabla u_0(Z)\cdot\dfrac{\partial Y}{\partial \nu} \quad \text{on } \partial B. \end{cases} \tag{17}$$

Then

$$\widehat{\psi} = g + O(\alpha) \quad \text{on } \partial B. \tag{18}$$

Since $C + \nabla u_0(Z)\cdot Y$ is harmonic in B, the first equation in (17) yields

$$\mathcal{S}_B f(Y) - \mathcal{S}_B^0 g(Y) = C + \nabla u_0(Z)\cdot Y, \quad Y \in B,$$

and hence

$$\frac{\partial \mathcal{S}_B f}{\partial \nu}\bigg|_- - \frac{\partial \mathcal{S}_B^0 g}{\partial \nu}\bigg|_- = \nabla u_0(Z)\cdot\frac{\partial Y}{\partial \nu} \quad \text{on } \partial B.$$

Combining this with the second equation in (17), we get

$$\frac{\partial \mathcal{S}_B^0 g}{\partial \nu}\bigg|_+ - \frac{\mu_1}{\mu_*}\frac{\partial \mathcal{S}_B^0 g}{\partial \nu}\bigg|_- = \left(\frac{\mu_1}{\mu_*} - 1\right)\nabla u_0(Z)\cdot\frac{\partial Y}{\partial \nu} \quad \text{on } \partial B. \tag{19}$$

Observe that for each $h \in L^2(\partial B)$ with $\int_{\partial B} h\,d\sigma = 0$ there exists a unique solution $g \in L^2(\partial B)$ with $\int_{\partial B} g\,d\sigma = 0$ to the equation

$$\frac{\partial \mathcal{S}_B^0 g}{\partial \nu}\bigg|_+ - \frac{\mu_1}{\mu_*}\frac{\partial \mathcal{S}_B^0 g}{\partial \nu}\bigg|_- = h \quad \text{on } \partial B.$$

This fact can be proved using the method in Chapter 1 of [1], and so we omit its proof.

Let $Y = (y_1, y_2)$ and ψ_j, $j = 1, 2$, be the solution to

$$\left.\frac{\partial \mathcal{S}_B^0 \psi_j}{\partial \nu}\right|_+ - \frac{\mu_1}{\mu_*}\left.\frac{\partial \mathcal{S}_B^0 \psi_j}{\partial \nu}\right|_- = \left(\frac{\mu_1}{\mu_*} - 1\right)\frac{\partial y_j}{\partial \nu} \quad \text{on } \partial B. \tag{20}$$

It then follows from (18) and (19) that

$$\widehat{\psi} = \sum_{j=1}^{2} \frac{\partial u_0}{\partial x_j}(Z)\psi_j + O(\alpha) \quad \text{on } \partial B. \tag{21}$$

We are now ready to derive an asymptotic formula for $u_\alpha - u_0$. According to (13),

$$u_\alpha(X) = u_0(X) + \int_{\partial D} G(X, \Xi)\psi(\Xi)d\sigma(\Xi).$$

Making the change of variables $\Xi \to Z + \alpha Y$, $Y \in \partial B$, we get

$$u_\alpha(X) = u_0(X) + \alpha \int_{\partial B} G(X, Z + \alpha Y)\widehat{\psi}(Y)d\sigma(Y),$$

where

$$\widehat{\psi}(Y) := \psi(Z + \alpha Y), \quad Y \in \partial B.$$

Since

$$G(X, Z + \alpha Y) = G(X, Z) + \alpha \nabla_Y G(X, Z) \cdot Y + o(\alpha)$$

for X away from D, we get

$$u_\alpha(X) = u_0(X) + \alpha G(X, Z) \int_{\partial B} \widehat{\psi} d\sigma + \alpha^2 \nabla_Y G(X, Z) \cdot \int_{\partial B} Y\widehat{\psi}(Y)d\sigma(Y) + o(\alpha^2) \tag{22}$$

for X away from D.

By (14) we have

$$\psi = \frac{\mu_1}{\mu_*}\left.\frac{\partial \mathcal{S}_D^{k_*}\phi}{\partial \nu}\right|_- - \frac{\partial u_0}{\partial \nu} - \left.\frac{\partial \widetilde{\mathcal{S}}_D \psi}{\partial \nu}\right|_-,$$

and hence it follows that

$$\begin{aligned}
\alpha \int_{\partial B} \widehat{\psi} d\sigma &= \int_{\partial D} \psi d\sigma \\
&= \frac{\mu_1}{\mu_*} \int_D \Delta \mathcal{S}_D^{k_*}\phi - \int_D \Delta u_0 - \int_D \Delta \widetilde{\mathcal{S}}_D \psi \\
&= \frac{\mu_1}{\mu_*}\omega^2 \varepsilon_* \mu_* \int_D \mathcal{S}_D^{k_*}\phi - \omega^2 \varepsilon_1 \mu_1 \int_D u_0 - \omega^2 \varepsilon_1 \mu_1 \int_D \widetilde{\mathcal{S}}_D \psi \\
&= \omega^2 \mu_1 (\varepsilon_* - \varepsilon_1) \left[\int_D u_0 + \int_D \widetilde{\mathcal{S}}_D \psi\right],
\end{aligned}$$

where the last equality follows from (14). Note that

$$\int_D u_0 = \alpha^2 u_0(Z)|B| + O(\alpha^3).$$

We also have

$$\int_D \widetilde{\mathcal{S}}_D \psi = O(\alpha^3). \tag{23}$$

In fact, since $\int_{\partial B} \psi_j d\sigma = 0$, equation (21) yields $\int_{\partial B} \widehat{\psi} d\sigma = O(\alpha)$, and hence

$$\widetilde{\mathcal{S}}_D \psi(Z + \alpha X) = \alpha \mathcal{S}_B^0 \widehat{\psi} + O(\alpha) O(\alpha).$$

Thus we have (23). Therefore, we obtain

$$\alpha \int_{\partial B} \widehat{\psi} d\sigma = \alpha^2 \omega^2 \mu_1 (\varepsilon_* - \varepsilon_1) u_0(Z)|B| + O(\alpha^3). \tag{24}$$

On the other hand, it follows from (21) that

$$\int_{\partial B} Y \widehat{\psi}(Y) d\sigma(Y) = M \nabla u_0(Z) + O(\alpha), \tag{25}$$

where $M = (M_{ij})$ and

$$M_{ij} = \int_{\partial B} y_j \psi_i(Y) d\sigma(Y), \quad i, j = 1, 2. \tag{26}$$

By (22), (24), and (25), we finally arrive at the following theorem.

THEOREM 3.2. *Let u_α be the solution of* (1)*, and let M be the polarization tensor defined by* (26)*. Then, for $X = (x, y)$ bounded away from D, we have the pointwise expansion*

$$\begin{aligned} u_\alpha(X) = u_0(X) + \alpha^2 \Bigg[& \nabla_Y G(X, Z) \cdot M \nabla u_0(Z) \\ & + \omega^2 \mu_1 \varepsilon_1 \left(\frac{\varepsilon_*}{\varepsilon_1} - 1 \right) |B| G(X, Z) u_0(Z) \Bigg] + o(\alpha^2). \end{aligned} \tag{27}$$

A few words are in order on the matrix M defined by (26). It follows from the jump relation of the single layer potential and (20) that

$$\begin{aligned} \int_{\partial B} y_j \psi_i d\sigma &= \int_{\partial B} y_j \left[\frac{\partial \mathcal{S}_B^0 \psi_j}{\partial \nu} \bigg|_+ - \frac{\partial \mathcal{S}_B^0 \psi_j}{\partial \nu} \bigg|_- \right] d\sigma \\ &= \left(\frac{\mu_1}{\mu_*} - 1 \right) \int_{\partial B} y_j \frac{\partial \Phi_i}{\partial \nu} \bigg|_- d\sigma, \end{aligned}$$

where

$$\Phi_i(Y) = y_i + \mathcal{S}_B^0 \psi_i(Y), \quad Y \in \mathbb{R}^2.$$

Note that $\Phi_i(Y)$ for $Y = (y_1, y_2)$ is the solution to

$$\begin{cases} \Delta\Phi_i = 0 \quad \text{in } B \cup \left(\mathbb{R} \times \right]-\frac{z_y}{\alpha}, \frac{(h-z_y)}{\alpha}\left[\setminus \overline{B}\right) \cup \mathbb{R} \times \left]\frac{(h-z_y)}{\alpha}, +\infty\right[, \\ \Phi_i \text{ is continuous across } \partial B \text{ and } y_2 = \dfrac{(h-z_y)}{\alpha}, \\ \left.\dfrac{\partial \Phi_i}{\partial \nu}\right|_+ - \dfrac{\mu_1}{\mu_*}\left.\dfrac{\partial \Phi_i}{\partial \nu}\right|_- = 0 \quad \text{on} \quad \partial B, \\ \left.\dfrac{\partial \Phi_i}{\partial y}\right|_+ - \dfrac{\mu_2}{\mu_1}\left.\dfrac{\partial \Phi_i}{\partial y}\right|_- = 0 \quad \text{on} \quad y_2 = \dfrac{(h-z_y)}{\alpha}, \\ \Phi_i(Y) - y_i \to 0 \quad \text{as } |Y| \to \infty, \\ \Phi_i(Y) = 0 \quad \text{on } y_2 = -\dfrac{z_y}{\alpha}. \end{cases}$$

In its appearance M_{ij} may seem to be dependent on α. However, $M_{ij} = \text{constant} + O(\alpha)$. To see this, let us investigate three typical cases: (i) when $D = Z + \alpha B$ is away from the interface $y_2 = h$ and the boundary $y_2 = 0$, (ii) when D is close to the interface, (iii) when D is close to the boundary.

(i) Suppose that D is away from the interface and the boundary. In this case, after scaling, the distance from B to the interface $y_2 = (h - z_y)/\alpha$ and the boundary is of order $1/\alpha$. Thus one can see from (10) that

$$G_0(X, Y) = \mu_1 \Gamma(X - Y) + O(\alpha), \quad X, Y \in \partial B,$$

and hence (20) can written as

$$\left.\frac{\partial \mathcal{S}_B \psi_j}{\partial \nu}\right|_+ - \frac{\mu_1}{\mu_*}\left.\frac{\partial \mathcal{S}_B \psi_j}{\partial \nu}\right|_- = \left(\frac{\mu_1}{\mu_*} - 1\right)\frac{\partial y_j}{\partial \nu} + O(\alpha) \quad \text{on } \partial B. \tag{28}$$

Let g_j be the solution of (28) without $O(\alpha)$-term on the right-hand side. Then, $M(\frac{\mu_1}{\mu_*})$ defined by

$$M_{ij}\left(\frac{\mu_1}{\mu_*}\right) := \int_{\partial B} y_j g_i d\sigma$$

is the Pólya–Szegö polarization tensor whose properties were extensively studied in [1]. We get from (28) that

$$M = M\left(\frac{\mu_1}{\mu_*}\right) + O(\alpha),$$

and hence, in this case, the formula (27) holds with M replaced with $M(\frac{\mu_1}{\mu_*})$. Recall that if the inclusion B is a disk, then its polarization tensor $M(\frac{\mu_1}{\mu_*})$ takes the following explicit form:

$$M = \frac{2(\mu_1 - \mu_*)}{\mu_1 + \mu_*}|B|\, I_2, \tag{29}$$

where I_2 is the 2×2 identity matrix.

(ii) Suppose that D is close to the interface and that the distance between them is of order α. In this case, one can see from (10) that

$$G_0(X,Y) = \mu_1\left(\Gamma(X-Y) - \frac{\mu_2-\mu_1}{\mu_1+\mu_2}\Gamma(X-Y-(0,2h))\right) + O(\alpha), \quad X,Y \in \partial B.$$

By a similar argument one can show that

$$M_{ij} = \left(\frac{\mu_1}{\mu_*} - 1\right)\int_{\partial B_*} y_j \frac{\partial \widehat{\Phi}_i}{\partial \nu}\bigg|_- d\sigma + O(\alpha) := P_{ij}\left(\frac{\mu_*}{\mu_1}, \frac{\mu_1}{\mu_2}\right) + O(\alpha),$$

where $B_* = B - (0, (h-z_y)/\alpha)$ and $\widehat{\Phi}_i, i = 1,2$, is the solution to

$$\begin{cases} \Delta\widehat{\Phi}_i = 0 \quad \text{in } B_* \text{ and in } (\mathbb{R}\times\,]-\infty,0[\,\setminus\overline{B_*}) \cup \mathbb{R}\times\,]0,+\infty[, \\ \widehat{\Phi}_i \text{ is continuous across } \partial B_* \text{ and } y_2 = 0, \\ \dfrac{\partial\widehat{\Phi}_i}{\partial\nu}\bigg|_+ - \dfrac{\mu_1}{\mu_*}\dfrac{\partial\widehat{\Phi}_i}{\partial\nu}\bigg|_- = 0 \quad \text{on} \quad \partial B_*, \\ \dfrac{\partial\widehat{\Phi}_i}{\partial y}\bigg|_+ - \dfrac{\mu_2}{\mu_1}\dfrac{\partial\widehat{\Phi}_i}{\partial y}\bigg|_- = 0 \quad \text{on} \quad y_2 = 0, \\ \widehat{\Phi}_i(Y) - \widehat{Y}_i \to 0 \quad \text{as } |Y| \to \infty. \end{cases}$$

Here

$$\widehat{Y} = (\widehat{Y}_1, \widehat{Y}_2) = \begin{cases} (y_1, y_2) & \text{for } y_2 > 0, \\ \left(y_1, \dfrac{\mu_1}{\mu_2}y_2 + 1\right) & \text{for } y_2 < 0. \end{cases}$$

Thus in this case, we obtain that for $X = (x,y), 0 < y < h$, bounded away from D, the following pointwise expansion holds:

$$u_\alpha(X) = u_0(X) + \alpha^2\Bigg[\nabla_Y G(X,Z)\cdot P\left(\frac{\mu_*}{\mu_1}, \frac{\mu_1}{\mu_2}\right)\nabla u_0(Z) + \omega^2\mu_1\varepsilon_1\left(\frac{\varepsilon_*}{\varepsilon_1} - 1\right)|B|G(X,Z)u_0(Z)\Bigg] + o(\alpha^2).$$

The feature of the above formula is that it is expressed in terms of the new polarization tensor $P = (P_{ij})$.

The case when D is close to the boundary can be treated in a similar way, which we omit.

4. Reconstruction of the inclusion. In this section we develop a MUSIC type of algorithm for recovering the inclusion D from measurements of propagated modes excited by incident waves. MUSIC is generally used in signal processing problems as a method for estimating the individual frequencies of multiple-harmonic signals [19]. The MUSIC algorithm makes use of the eigenvalue structure of the so-called response matrix. A more detailed description of this algorithm can be found in [10], [7], and [3]; see also [17], [11], [14], and [15] for further background on closely related time-reversal methodologies and on MUSIC in this specific context.

Let $\beta_l = \sqrt{\omega^2\varepsilon_1\mu_1 - \lambda_l}$, and let

$$c_l = -i\frac{\mu_1\sqrt{d^2-\lambda_l}}{\frac{\mu_1}{\mu_2}\phi(h,\lambda_l)^2 + 2\sqrt{d^2-\lambda_l}\int_0^h \phi(y,\lambda_l)^2 dy}$$

for $1 \le l \le m$.

When the incident wave is a guided mode (of the unperturbed waveguide), then

$$u_0(x,y) = g(y,\lambda_{l_0})e^{-i\beta_{l_0}x}$$

for some $1 \le l_0 \le m$. Recall that $X = (x,y)$ and $Z = (z_x, z_y)$.

We compute

$$\nabla u_0(Z) = \begin{pmatrix} i\beta_{l_0} g(z_y,\lambda_{l_0}) \\ g'(z_y,\lambda_{l_0}) \end{pmatrix} e^{-i\beta_{l_0}z_x},$$

and, by making use of (8) and (9), we obtain that

$$\nabla G(X,Z) \approx \sum_{l=1}^m \frac{c_l}{\beta_l} e^{i\beta_l x} e^{-iz_x(\beta_{l_0}+\beta_l)} \begin{pmatrix} -i\beta_l g(z_y,\lambda_l) \\ g'(z_y,\lambda_l) \end{pmatrix} g(y,\lambda_l)$$

as $x \to +\infty$.

Suppose for the sake of simplicity that B is a disk; then, using (29), it follows that

$$\begin{aligned}(u_\alpha - u_0)(X) \approx |D| \sum_{l=1}^m \frac{c_l}{\beta_l} e^{i\beta_l x} g(y,\lambda_l) e^{-iz_x(\beta_{l_0}+\beta_l)} \\ \times \left[\frac{2(\mu_* - \mu_1)}{\mu_* + \mu_1} \big(\beta_{l_0}\beta_l g(z_y,\lambda_l) g(z_y,\lambda_{l_0}) + g'(z_y,\lambda_l) g'(z_y,\lambda_{l_0})\big) \right. \\ \left. + \omega^2 \mu_1 \varepsilon_1 \left(\frac{\varepsilon_*}{\varepsilon_1} - 1\right) g(z_y,\lambda_l) g(z_y,\lambda_{l_0}) \right]\end{aligned}$$

as $x \to +\infty$.

The coefficients of the scattered modes C_{ll_0}, which are excited by the incident wave u_0, are then approximated by

$$\begin{aligned}C_{ll_0} \approx |D| e^{-iz_x(\beta_{l_0}+\beta_l)} \left[\frac{2(\mu_* - \mu_1)}{\mu_* + \mu_1} \big(\beta_{l_0}\beta_l g(z_y,\lambda_l) g(z_y,\lambda_{l_0}) + g'(z_y,\lambda_l) g'(z_y,\lambda_{l_0})\big) \right. \\ \left. + \omega^2 \mu_1 \varepsilon_1 \left(\frac{\varepsilon_*}{\varepsilon_1} - 1\right) g(z_y,\lambda_l) g(z_y,\lambda_{l_0}) \right].\end{aligned}$$

Define the (response) matrix $C = (C_{ll_0})_{l,l_0=1,\dots,m}$. We now show how to apply the MUSIC algorithm for recovering the location Z and the volume $|D|$ of the inclusion from the above approximate formula for the matrix $C \in \mathbb{C}^{m\times m}$. We consider separately three cases in stating the following lemma.

LEMMA 4.1.

(a) *Suppose $\mu_* = \mu_1$. For $X = (x,y)$ in the core of the waveguide, define the vector $\mathbf{g}_{x,y} \in \mathbb{C}^m$ by*

$$\mathbf{g}_{x,y} = \big(g(y,\lambda_1)e^{-ix\beta_1}, \dots, g(y,\lambda_m)e^{-ix\beta_m}\big)^T,$$

where T denotes the transpose. Then

$$\mathbf{g}_{x,y} \in \mathrm{Range}(C) \quad \text{iff } x = z_x \text{ and } y = z_y. \tag{30}$$

(b) *Suppose* $\varepsilon_* = \varepsilon_1$. *For* $X = (x, y)$ *in the core of the waveguide, define the vector* $\mathbf{g}_{x,y} \in \mathbb{C}^{2m}$ *by*

(31)
$$\mathbf{g}_{x,y} = \big((\beta_1 g(y,\lambda_1), g'(y,\lambda_1))^T e^{-ix\beta_1}, \ldots, (\beta_m g(y,\lambda_m), g'(y,\lambda_m))^T e^{-ix\beta_m}\big)^T.$$

Then

$$\mathbf{g}_{x,y} \in \text{Range}(C) \quad \textit{iff } x = z_x \textit{ and } y = z_y.$$

(c) *Suppose* $\mu_* \neq \mu_1$ *and* $\varepsilon_* \neq \varepsilon_1$. *For* $X = (x, y)$ *in the core of the waveguide, define the vector* $\mathbf{g}_{x,y} \in \mathbb{C}^{3m}$ *by*

$$\mathbf{g}_{x,y} = \big((\beta_1 g(y,\lambda_1), g'(y,\lambda_1), g(y,\lambda_1))^T e^{-ix\beta_1}, \ldots, (\beta_m g(y,\lambda_m), g'(y,\lambda_m), g(y,\lambda_m)^T e^{-ix\beta_m}\big)^T.$$

Then

$$\mathbf{g}_{x,y} \in \text{Range}(C) \quad \textit{iff } x = z_x \textit{ and } y = z_y.$$

Proof. The idea of the proof of the characterization of the location of the inclusion in terms of the range of the matrix C is the same for the three cases above. Let us then for the sake of simplicity consider only the first case. For $X = (x, y)$ suppose that $\mathbf{g}_{x,y} \in \text{Range}(C)$ and $X \neq Z$. Then

(32) $\mathbf{g}_{x,y}$ is proportional to the vector $\big(g(z_y,\lambda_1)e^{-i\beta_1 z_x}, \ldots, g(z_y,\lambda_m)e^{-i\beta_m z_x}\big)^T$.

Consider now the Green's functions $G(\cdot, X)$ and $G(\cdot, Z)$. Identity (32) yields that the guided components of these Green's functions are proportional. This implies that the Green's functions $G(Y, X)$ and $G(Y, Z)$ are proportional for any Y in the core, $Y \notin \{X, Z\}$. The singularity of $G(\cdot, X)$ at the source X (see Lemma 2.1) then leads to a contradiction. ∎

The MUSIC algorithm is as follows. Denote by P the orthogonal projection onto the left null space (noise space) of C, which can be computed via a singular value decomposition (SVD) of the matrix C. We can form an image of the location Z by plotting, at each point $X = (x, y)$, the quantity

(a) $W := \|\mathbf{g}_{x,y}\|/\|P\mathbf{g}_{x,y}\|$ if $\mu_* = \mu_1$.
(b) $W_b := \|b \cdot \mathbf{g}_{x,y}\|/\|P(b \cdot \mathbf{g}_{x,y})\|$ for $b \in \mathbb{R}^2 \setminus \{0\}$ if $\varepsilon_* = \varepsilon_1$.
(c) $W_c := \|c \cdot \mathbf{g}_{x,y}\|/\|P(c \cdot \mathbf{g}_{x,y})\|$ for $c \in \mathbb{R}^3 \setminus \{0\}$ if $\mu_* \neq \mu$ and $\varepsilon_* \neq \varepsilon_1$.

In the case (a) (resp., (b), (c)), the matrix C has 1 (resp., 2, 3) significant singular values. The image space of C is of dimension 1 (resp., 2, 3).

This MUSIC type of algorithm can be used to recover the location of n well-separated electromagnetic inclusions, provided that $m > n$ (case (a)), $m > 2n$ (case(b)), and $m > 3n$ (case (c)).

5. Numerical results. Consider the function $f(\lambda)$ defined by

$$f(\lambda) = \sqrt{d^2 - \lambda}\tan\sqrt{\lambda}h + \frac{\mu_2}{\mu_1}\sqrt{\lambda}, \quad \lambda \in]0, d^2[. \tag{33}$$

From (4), the isolated eigenvalues λ_l, $l = 1, \ldots, m$, are defined by

$$f(\lambda_l) := \sqrt{\lambda_l - d^2}\ \text{tg}\ \sqrt{\lambda_l}h + \frac{\mu_2}{\mu_1}\sqrt{\lambda_l} = 0, \quad l = 1, \ldots, m.$$

We set $\mu_1 = 2, \varepsilon_1 = 2$ and $\mu_2 = 1, \varepsilon_2 = 1$, $\omega = 4$, and $h = 4$. For this set of parameters, the function $f(\lambda)$ has 8 zeros, $\lambda_l, l = 1, \ldots, 8$.

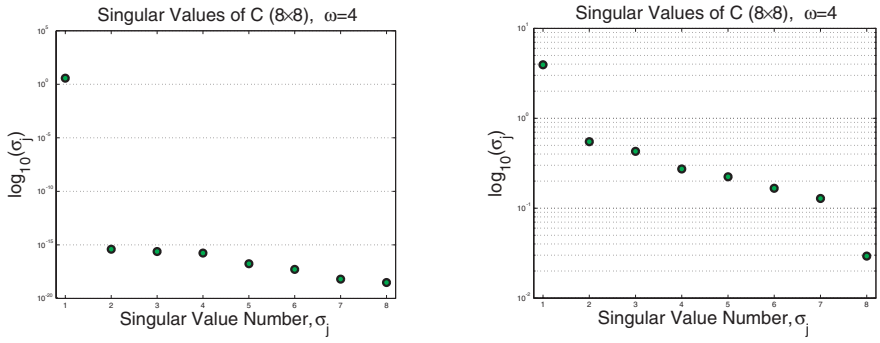

FIG. 1. *Case* (a) *(dielectric contrast only): distribution of the singular values of C (left) and in the case of noisy data* (12 *dB) (right).*

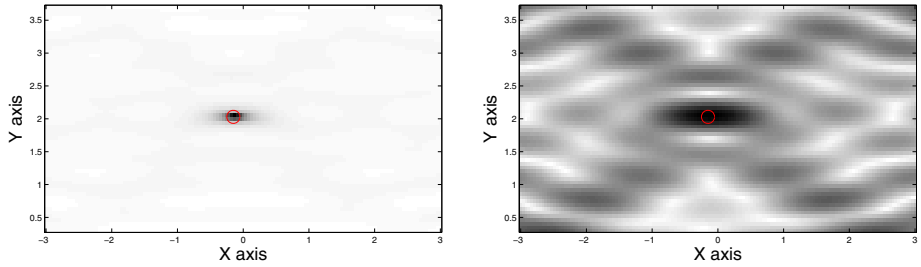

FIG. 2. *Case* (a) *(dielectric contrast only): gray-level (or color) maps of the amplitudes of W (left) and* $\mathcal{D}^{diel}$ *(right).*

5.1. Reconstruction of one inclusion. We consider a small homogeneous circular disk D of diameter $\alpha = 0.1$, centered at $Z = (-0.45, 2.03)$ within a rectangle search box prescribed as $\Omega = [-3, 3] \times [\delta, h - \delta] \subset \mathbb{R}^2$, where $\delta = 0.3$. The parameters of the inclusion are set to $\varepsilon_* = 5$ and/or $\mu_* = 5$. We need one more notation:

$$\mathbf{g}^1_{x,y} = \left(\beta_1 g(y, \lambda_1) e^{-ix\beta_1}, \ldots, \beta_m g(y, \lambda_m) e^{-ix\beta_m}\right)^T,$$

$$\mathbf{g}^2_{x,y} = \left(g'(y, \lambda_1) e^{-ix\beta_1}, \ldots, g'(y, \lambda_m) e^{-ix\beta_m}\right)^T,$$

$$\tau_1 = |D| \frac{2(\mu_* - \mu_1)}{\mu_* + \mu_1} \quad \text{and} \quad \tau_2 = |D| \omega^2 \varepsilon_1 \mu_1 \left(\frac{\varepsilon_*}{\varepsilon_1} - 1\right).$$

Using this notation, the vector $\mathbf{g}_{x,y}$, defined by (31), can be written as $\mathbf{g}_{x,y} = [\mathbf{g}^1_{x,y} \mathbf{g}^2_{x,y}]$.

5.1.1. Dielectric inclusion. We set $\varepsilon_* = 5$ and $\mu_* = \mu_1 = 2$. The singular values of the matrix $C \in \mathbb{C}^{8\times 8}$ and those in the case of noisy data (white Gaussian noise for both the amplitude and the phase of the scattered modes) with 12 dB signal-to-noise ratio are displayed in Figure 1. The maps of the amplitudes of W and the product $\mathcal{D}^{\text{diel}} = (v_1 v_1^*)\, \mathbf{g}_{x,y}$ in the case of noisy data are shown in Figure 2. Here v_1 denotes the first singular vector of the matrix C (i.e., the first eigenvector of the matrix CC^*).

The numerical results obtained here are easy to interpret. One singular value emerges from the seven others in the noise subspace. As for the singular vector,

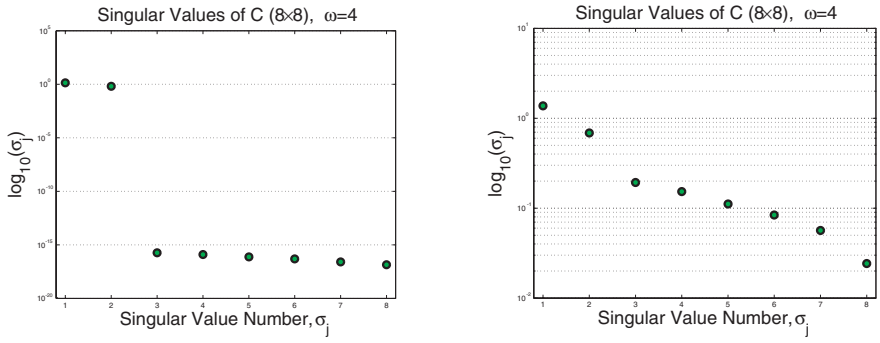

FIG. 3. *Case* (b) *(permeable contrast only): distribution of the singular values of C (left) and in the case of noisy data* (12 *dB) (right).*

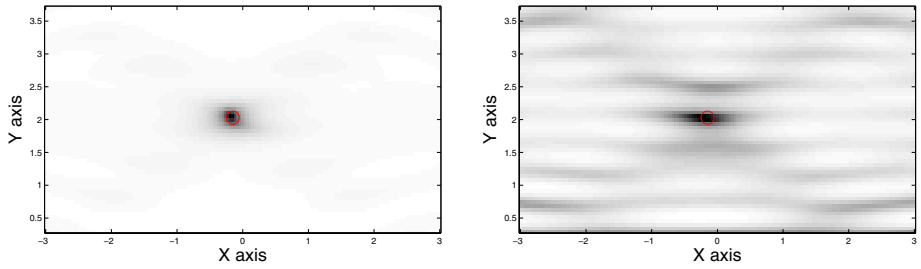

FIG. 4. *Case* (b) *(permeable contrast only): gray-level maps of the amplitudes of* W_b, $b = (1,0),(0,1)$ *(ordered from left to right).*

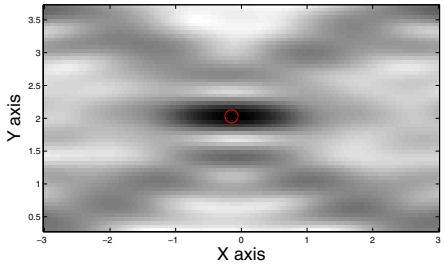

FIG. 5. *Case* (b) *(permeable contrast only): gray-level map of the amplitude of* $\mathcal{D}^{perm}$.

once operated upon by $\mathbf{g}_{x,y}$, it focuses onto the inclusion as expected. Note that, in this simple case, $v_1 = \mathbf{g}_{z_x,z_y}/\|\mathbf{g}_{z_x,z_y}\|$, with corresponding singular value $\sigma_1 = \|\mathbf{g}_{z_x,z_y}\|^2|D|\omega^2\varepsilon_1\mu_1(\varepsilon_*/\varepsilon_1 - 1)$.

5.1.2. Permeable inclusion. In this case we set $\mu_* = 5$ and $\varepsilon_* = \varepsilon_1 = 2$. The singular values of C and those in the case of noisy data with 12 dB signal-to-noise ratio are shown in Figure 3. The maps of the amplitudes of W_b, $b = (1,0)$ or $(0,1)$, in the case of noisy data are depicted in Figure 4. Here, the numerical results show that the first singular vector v_1 corresponds to $\mathbf{g}^1_{x,y}$. The map of the amplitude of the product $\mathcal{D}^{\text{perm}} = (v_1 v_1^*)\,\mathbf{g}^1_{x,y} + (v_2 v_2^*)\,\mathbf{g}^2_{x,y}$ is shown in Figure 5. The vectors v_1 and v_2 denote the first two eigenvectors of the matrix CC^*.

As previously, the results obtained in this case are easy to interpret. Only two

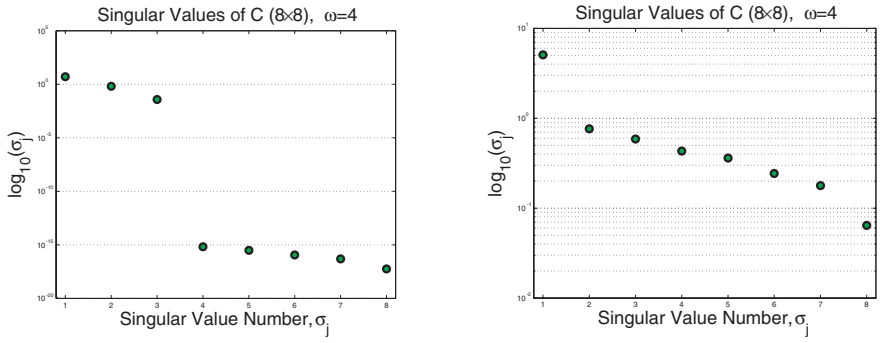

FIG. 6. *Case* (c) *(dielectric and permeable contrasts): distribution of the singular values of* C *(left) and in the case of noisy data (*12 *dB) (right).*

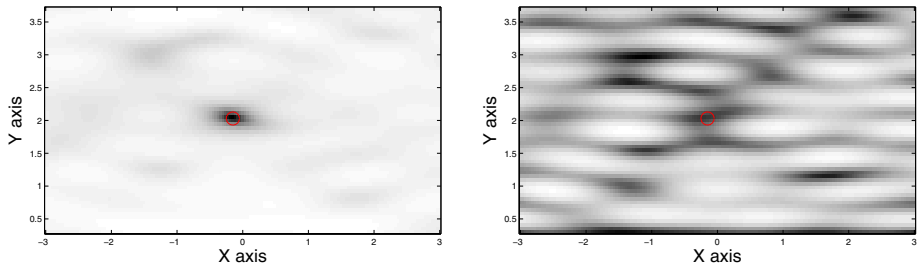

FIG. 7. *Case* (c) *(dielectric and permeable contrasts): gray-level maps of the amplitudes of* W_c, $c = (1, 0, 0)$ *(left),* $c = (0, 1, 0)$ *(right).*

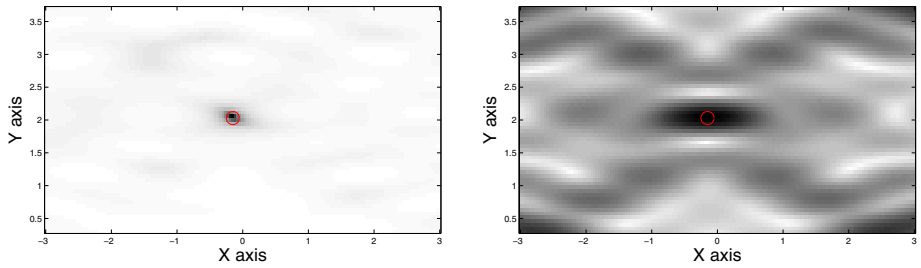

FIG. 8. *Case* (c) *(dielectric and permeable contrasts): gray-level maps of the amplitudes of* W_c, $c = (0, 0, 1)$ *(left), and* $\mathcal{D}$ *(right).*

singular values emerge from noise. The inclusion is clearly discriminated from the background, the visual aspect depending upon the choice of b. The focusing of the singular vectors is rather good.

5.1.3. Dielectric and permeable inclusion. We set $\mu_* = 5$ and $\varepsilon_* = 5$. The singular values of C and those in the case of noisy data with 12 dB signal-to-noise ratio are shown in Figure 6. The maps of the amplitudes of W_c, $c = (1, 0, 0), (0, 1, 0)$, in the case of noisy data are shown in Figure 7. The map of the amplitude of W_c, $c = (0, 0, 1)$, for noisy data is shown in Figure 8 (left). In this case, the numerical results show that all information about the location of the inclusion is contained in the first singular vector v_1. The map of the amplitude of the product $\mathcal{D} = (v_1 v_1^*)\, \mathbf{g}^1_{x,y} + (v_1 v_1^*)\, \mathbf{g}_{x,y}$ in

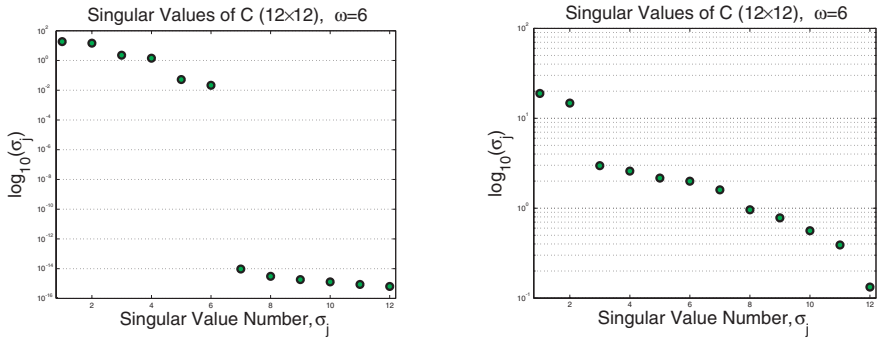

FIG. 9. *Case* (c) *(dielectric and permeable contrasts): distribution of the singular values of* C *(left) and those in the case of noisy data* (12 *dB) (right).*

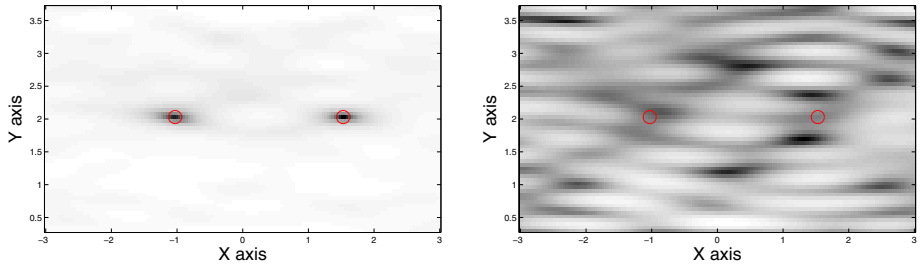

FIG. 10. *Case* (c) *(dielectric and permeable contrasts): gray-level maps of the amplitudes of* W_c, $c = (1, 0, 0)$ *(left),* $c = (0, 1, 0)$ *(right).*

the case of noisy data is shown in Figure 8 (right).

The results obtained in this case are less easy to interpret than before due to the more complicated character of the inclusion. However, the singular values of the signal subspace still emerge from the noise. The inclusion is clearly discriminated from the background (except for $c = (0, 1, 0)$), the visual aspect depending upon the choice of c.

5.2. Reconstruction of multiple inclusions. We set, as in the case of one inclusion, $\mu_1 = 2, \varepsilon_1 = 2$, $\mu_2 = 1, \varepsilon_2 = 1$, and $h = 4$, but now we take $\omega = 6$. For these parameters the function $f(\lambda)$, which is defined by (33), has more than twelve zeros.

We consider two small homogeneous circular disks D_1 and D_2 of diameter $\alpha = 0.1$, centered at $z_1 = (1.53, 2.03)$ and $z_2 = (-1.03, 2.03)$, within the rectangle search box $\Omega = [-3, 3] \times [\delta, h - \delta] \subset \mathbb{R}^2$, $\delta = 0.3$. The parameters of the inclusions are set to $\varepsilon_{*,1} = \varepsilon_{*,2} = 5$ and $\mu_{*,1} = \mu_{*,2} = 5$.

The singular values of C and those in the case of noisy data with 12 dB signal-to-noise ratio are shown in Figure 9. The maps of the amplitudes of W_c, $c = (1, 0, 0), (0, 1, 0)$, in the case of noisy data are shown in Figures 10 and 11 for $c = (0, 0, 1)$.

6. Conclusion. In this paper we have derived a new asymptotic formula for the scattered wave in an open waveguide in the presence of an inclusion of small

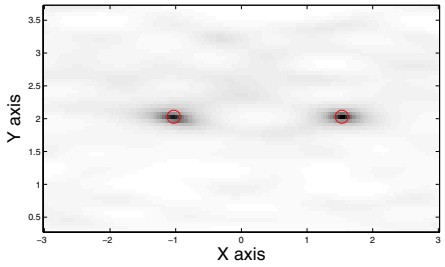

FIG. 11. *Case* (c) *(dielectric and permeable contrasts): gray-level maps of the amplitudes of* W_c, $c = (0, 0, 1)$.

diameter. We then successfully used this formula for the purpose of locating the inclusion from measurements of the propagated modes excited by incident waves, in the form of guided modes of the reference structure. In the case of multiple inclusions, improvements may include the use of a recursive procedure in which the function $W_\cdot(z)$ is changed after each inclusion is found; i.e., a new function $W_\cdot(z)$ is adjusted recursively by projecting the signal space away from the subspace spanned by the inclusions found [16]. Indeed, using more singular vectors than theoretically needed in the presence of noisy data seems to be useful [18].

A mathematical study of the properties of the eigenstructure of the response matrix C can be made following the arguments given in [4]. However, the analysis becomes more complicated because of the form of the Green's function G of the unperturbed waveguide.

TRANSPORT OF NUTRIENTS IN BONES*

GUILLERMO H. GOLDSZTEIN†

Abstract. Lacunar-canalicular systems are networks of pores (lacunae) interconnected by thin channels (canaliculi) that are embedded in bones. The efficient transport of nutrients within lacunar-canalicular systems is necessary to keep bones healthy. Several theories have been proposed to identify the physical phenomena responsible for this efficient transport. In this paper, we develop and study a mathematical model motivated by one of those theories.

Key words. bones, porous media, nutrient transport, solute transport, effective diffusion, mathematical modeling

1. Introduction. As illustrated in Figure 1.1, we consider long bones of our extremities such as the femur. Bones are porous media with complex microgeometry. The particular components of bones that we discuss here are osteons. These are cylindrical structures of about 120 μm radii that extend along the long axis of the bone (see Figure 1.1). An osteonal canal is located at the center of osteons. This canal contains blood vessels, a nerve, and bone fluid (see Figure 1.1). Pores, called lacunae, are distributed within the osteon. Thin channels, called canaliculi, and the lacunae form a connected system known as the lacunar-canalicular system, which is filled with fluid and is connected to the osteonal canal. A cartoon of the osteon microgeometry is given in Figure 1.1. More details on the structure of bones are given in [4, 12, 13, 2, 14] among numerous other articles.

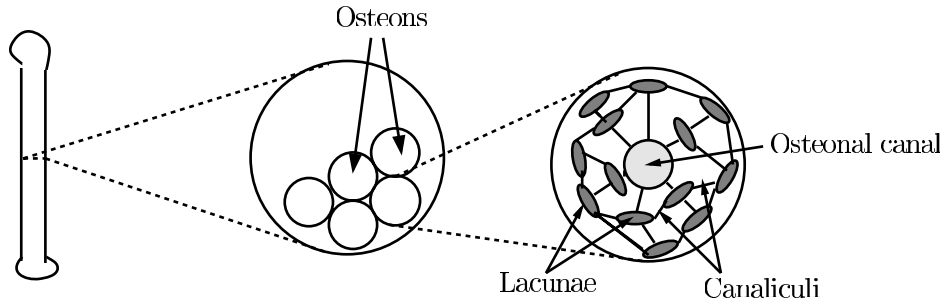

FIG. 1.1. *At left is the cartoon of a bone. A horizontal cross section (view from the top) is shown in the middle figure. The right-most image is a cartoon of the microgeometry of a section of an osteon (also viewed from the top); the white region is the solid part of the bone.*

Bones consume nutrients and produce waste products. It is believed that nutrients are transported from the osteonal canal into the rest of the osteon through the lacunar-canalicular system (see [17] and references therein). Waste products, on the other hand, are produced within the osteon and need to be transported to the osteonal

canal so that they can be disposed of. Thus, efficient transport within the lacunar-canalicular system is necessary to maintain a healthy bone.

The solid part of the bone is an elastic material. Thus, activities that apply and remove loads to bones, such as walking, produce small deformations of the bone. As a consequence, the incompressible fluid that fills the lacunar-canalicular system is squeezed, producing fluid flow. This is illustrated in Figure 1.2. As shown in the left-hand image, when a bone is subjected to a load, fluid is squeezed out of the lacunar-canalicular system and into the osteonal canal. Once the load is removed, an equal volume of fluid flows back from the osteonal canal into the lacunar-canalicular system (see the right-hand image in Figure 1.2). After each cycle of a periodic load, there is no net volume of fluid transported from the osteonal canal into the lacunar-canalicular system simply because the volume of the bone does not change after each cycle.

In this paper we study the ideal one-dimensional lacunar-canalicular system illustrated in Figure 1.3. The length of each canaliculus is $L - \ell$, and the diameter of each lacuna is of the order ℓ (recall that the diameter of a set Ω is $\sup_{x,y\in\Omega} \|x - y\|$, where $\|x - y\|$ is the distance from x to y). As suggested by Figure 1.3, we assume that $L \gg \ell$.

We assume that there is a periodic exchange of fluid between the osteonal canal and the lacunar-canalicular system and denote that period by t_0. Motivated by the above discussion on flows in lacunar-canalicular systems induced by periodic applied loads, we assume that there is no net transport of any volume of fluid between the osteonal canal and the lacunar-canalicular system after each period. More precisely, we assume that there is $t^\star < t_0$ such that a volume V_F of fluid flows from the osteonal canal into the lacunar-canalicular system during the time interval $(0, t^\star)$ and the same volume of fluid flows back into the osteonal canal during the time interval $(t^\star, t_0)$.

We denote by V_ℓ the volume of each lacuna. Let D be the coefficient of diffusion of nutrients in the host liquid. Due to diffusion, the mixing of nutrients with the host

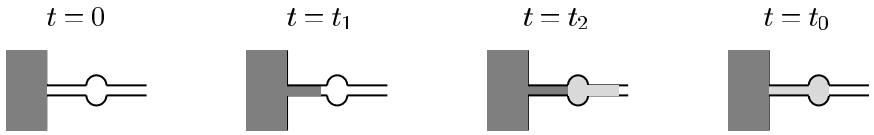

FIG. 1.4. *Nutrient concentration within the lacunar-canalicular system at four different times. The shades represent the concentration of nutrients. The darker the region, the higher the concentration of nutrients.*

fluid within each lacuna occurs in times of order ℓ^2/D. The time that an element of fluid stays in a lacuna is of the order $V_\ell t_0/V_F$. We restrict our attention to the parameter regime

$$\ell^2/D \ll \min\left\{1, \frac{V_\ell}{V_F}\right\} t_0. \tag{1.1}$$

Thus, since we are interested in events that occur in the time scale of t_0, we can and do assume that mixing is instantaneous within each lacuna.

Within the canaliculi, nutrients are transported along the direction of the x-axis by convection and an effect known as Taylor dispersion (that is the result of fluid motion and diffusion); see [16, 1]. Note that velocities within the canaliculi are of the order $V_F/(at_0)$, where a is the cross-sectional area of each canaliculus. Thus, in a period of time of the order t_0, the distances traveled by nutrients due to Taylor dispersion are of the order $\sqrt{(D + V_F^2/(48at_0^2D))t_0}$; see [16, 1]. We will assume that

$$\sqrt{Dt_0 + \frac{V_F^2}{48at_0D}} \ll L. \tag{1.2}$$

Since, as we will see later in the paper, we are interested in the parameter regime where fluid is convected from one end of a canaliculus to the other in times smaller than t_0, we can and do neglect diffusion and Taylor dispersion within the canaliculi in the direction of the x-axis.

The osteonal canal acts as a reservoir of nutrients, and thus the concentration of nutrients within the osteonal canal remains constant in time. Assume that the lacunar-canalicular system does not contain any nutrients initially. If $V_F < V_c$, where V_c is the volume of a canaliculus, the nutrients that enter the lacunar-canalicular system in the time interval $(0, t^\star)$ do not reach the first lacuna. Since there is no dispersion within the canaliculi and there is no net transport of volume of fluid between the osteonal canal and the lacunar-canalicular system after each period, all the nutrients that enter the system flow back to the osteonal canal during the time interval $(t^\star, t_0)$. Therefore, there is no transport of nutrients at the end of a cycle.

Assume now that $V_F > V_c$. In Figure 1.4 we show the osteonal canal and part of the lacunar-canalicular system (that includes only one lacuna) at four different times. The shades represent the concentration of nutrients: the darker the region, the higher the concentration of nutrients. At $t = 0$, the lacunar-canalicular system does not contain any nutrients. The times t_1 and t_2 satisfy $0 < t_1 < t_2 < t^\star$. The volume of fluid that enters the system in the time interval $(0, t_1)$ is smaller than V_c. As soon as some nutrient from the osteonal canal reaches the first lacuna, there is instantaneous mixing (of the nutrients with the host fluid) in that lacuna, and the fluid that flows from that lacuna into the second canaliculus carries nutrients (at some

lower concentration). This is illustrated in Figure 1.4; at $t = t_2$, the fluid that entered the system had reached the first lacuna. After a complete period, i.e., $t = t_0$, nutrient that was initially in the osteonal canal will be left in the lacunar-canalicular system (see Figure 1.4). In fact, if n is a positive integer such that $nV_c < V_F$, after a complete cycle there will be nutrients left in the first n lacunae and n canaliculi. Hence, there is a net transport of nutrients after each period. Moreover, in this paper we show that, in the parameter regime $V_c \ll V_F$, the system exhibits a diffusion-like macroscopic behavior with effective diffusion coefficient

$$D_{\text{eff}} = \left(\frac{V_\ell}{V_c + V_\ell}\right)^2 \left(\frac{V_F}{V_c + V_\ell}\right) \left(\frac{L^2}{t_0}\right). \tag{1.3}$$

This paper is motivated by the work in [17], where the authors make the key assumptions of instantaneous mixing within lacunae and negligible Taylor dispersion within canaliculi. They argue that these assumption are valid by showing that (1.1) and (1.2) are satisfied for typical parameter values (see also [18]). They consider a one-dimensional lacunar-canalicular system with five lacunae, where neighboring lacunae are connected by ten canaliculi. They propose a numerical algorithm and explore the system numerically. Our work is based on the same key physical assumptions. Our new contribution is a detailed mathematical analysis, from which a more explicit description of the behavior of the system is achieved; in particular, we obtain (1.3).

Identifying the phenomena responsible for nutrient transport in bones has been a subject of study for several years. It was first proposed in [15] that convection in the lacunar-canalicular system induced by loading and unloading the bone increases the transport of nutrients (see also [11]). This phenomenon was studied experimentally in [5]. However, this is a partial picture of the relevant phenomena, and there is no agreement among the scientific community on the complete set of physical mechanisms responsible for the transport of nutrients in bones. See [17, 3, 6, 7, 8, 11, 9, 10, 18] for some of the proposed theories and related experiments.

The content of the rest of this paper is the following. In section 2 we derive the governing equations. In section 3 and the appendix we obtain the asymptotic approximation to the governing equations in the limit of a thin canaliculus. In section 4 we consider some examples. The paper ends with conclusions in section 5.

2. Governing equations. The lacunar-canalicular system we consider, displayed in Figure 1.3, extends to infinity in one direction. The right wall of the osteonal canal is the origin of the coordinate system, $x = 0$; the location of the ith canaliculus is the segment $[(i-1)L, iL-\ell]$; and the location of the ith lacuna is $[iL-\ell, iL]$. The cross-sectional area of a canaliculus is a. We denote by $V_c = (L-\ell)a$ and V_ℓ the volumes of the canaliculus and lacuna, respectively. We assume a, V_c, and V_ℓ to be constants. An incompressible fluid, of constant density both in space and time, fills the lacunar-canalicular system. The concentration of nutrients in the osteonal canal remains at the constant value c_0 at all times t.

We denote by $c_i(t)$ the concentration of nutrients at time t in the ith lacuna, and thus $\rho_f c_i(t)$ is the density of nutrients at time t in the ith lacuna, where ρ_f is the fluid density. For x in the canaliculi, we denote by $c(x,t)$ the concentration of nutrients at x and time t. Since Taylor dispersion is neglected within the canaliculi, nutrients flow with the same velocity as the fluid $v = v(x,t)$ within the canaliculi (more precisely, $v(x,t)$ is the average fluid velocity in the cross-section of the canaliculi at x). Fluid incompressibility and mass conservation imply that v is independent of x;

i.e., $v = v(t)$. Thus, conservation of nutrients within the canaliculi reduces to

$$\frac{\partial c}{\partial t} + v\frac{\partial c}{\partial x} = 0 \tag{2.1}$$

for all x in canaliculi.

Whenever the velocity is positive, nutrients flow from the ith canaliculus into the ith lacuna at a rate $a\rho_f v(t)c(iL-\ell,t)$. Nutrients also flow out of that same lacuna into the $(i+1)$th canaliculus at a rate $a\rho_f v(t)c_i(t)$. Analogously, when the velocity is negative, nutrients flow from the $(i+1)$th canaliculus into the ith lacuna at a rate $-a\rho_f v(t)c(iL,t)$ and flow out of that same lacuna into the ith canaliculus at a rate $-a\rho_f v(t)c_i(t)$. This implies

$$V_\ell \frac{\mathrm{d}c_i}{\mathrm{d}t} = \begin{cases} av\,(c(iL-\ell,t) - c_i(t)) & \text{when } v(t) > 0, \\ av\,(c_i(t) - c(iL,t)) & \text{when } v(t) < 0 \end{cases} \tag{2.2}$$

for all positive integers i.

Whenever the velocity is positive, there is flow from each lacuna into the canaliculus located at its right, and thus the concentration of nutrients in the left end of a canaliculus is equal to the concentration of nutrients in the adjacent lacuna. Analogously, whenever the velocity is negative, the concentration of nutrients in the right end of a canaliculus is equal to the concentration of nutrients in the lacuna located at the right end of the canaliculus. Thus,

$$\begin{aligned} &c((i-1)L,t) = c_{i-1}(t) && \text{if } v(t) > 0, \\ &c((i+1)L-\ell,t) = c_{i+1}(t) && \text{if } v(t) < 0, \end{aligned} \tag{2.3}$$

the first of the above equations being valid for all integers $i \geq 2$ and the second for all integers $i \geq 0$. Similarly, whenever the velocity is positive, there is flow from the osteonal canal into the first canaliculus, and thus the concentration of nutrients in the left end of the first canaliculus is equal to c_0, the concentration of nutrients in the osteonal canal,

$$c(0,t) = c_0 \quad \text{if } v(t) > 0. \tag{2.4}$$

Consistent with our discussion in the introduction, we assume that the flow velocity in the canaliculi v is a known periodic function with period t_0 and zero time average

$$\int_0^{t_0} v(t)\,\mathrm{d}t = 0. \tag{2.5}$$

To simplify our analysis we assume that there exist $0 < t^\star < t_0$ such that $v(t) > 0$ if $t \in (0, t^\star)$ and $v(t) < 0$ if $t \in (t^\star, t_0)$. Thus, the volume of fluid that flows from the osteonal canal into the lacunar-canalicular system in the time interval $(0, t^\star)$ is

$$V_F = a\int_0^{t^\star} v(t)\mathrm{d}t. \tag{2.6}$$

Equations (2.1)–(2.4) can be solved once initial conditions and boundary conditions at ∞ are provided.

3. Solution to the governing equations in the thin canaliculus limit. Assume that the initial conditions on the concentration of nutrients is regular enough that there exists a smooth function $\rho_{\text{in}} = \rho_{\text{in}}(z)$ (except probably in isolated points) defined for all $z \geq 0$ such that

$$\rho_{\text{in}}(iL) = c_i(0) \quad \text{for all positive integers } i, \tag{3.1}$$

and the limit

$$c_\infty = \lim_{i\to\infty} c_i(0) \tag{3.2}$$

exists. (More precisely, we need that $\rho'_{\text{in}} = O(V_c/(V_F L))$ except in isolated points.)

Let $\rho = \rho(z,t)$ be the solution

$$\frac{\partial \rho}{\partial t} = D_{\text{eff}} \frac{\partial^2 \rho}{\partial z^2} \qquad \text{for } \ t > 0 \ \text{ and } \ z > 0, \tag{3.3}$$

where D_{eff} was defined in (1.3), subject to the initial conditions

$$\rho(z,0) = \rho_{\text{in}}(z) \quad \text{for } \ z > 0 \tag{3.4}$$

and boundary conditions

$$\rho(0,t) = c_0 \ \text{ and } \ \lim_{z\to+\infty} \rho(z,t) = c_\infty \ \text{ for } \ t \geq 0. \tag{3.5}$$

We extend the definition of ρ to $z < 0$ as follows,

$$\rho(z,t) = c_0 \ \text{ if } \ z \leq 0, \tag{3.6}$$

and let $z_i = z_i(t)$ be defined as

$$z_i(t) = iL - \frac{aL}{V_\ell + V_c} \int_0^t v(s)\,\mathrm{d}s. \tag{3.7}$$

In the appendix we show that ρ gives the asymptotic approximation of the concentrations; more precisely,

$$c_i(t) \simeq \rho\,(z_i(t), t) \quad \text{if } \ V_F \gg V_c. \tag{3.8}$$

From (3.3) and (1.3) and the fact that distance between z_i and z_{i+1} remains equal to L for all i and all t, it follows that D_{eff} given in (1.3) is the effective diffusion coefficient of nutrients in the lacunar-canalicular system.

4. Examples. As an example, we now assume that there are no nutrients within the lacunar-canalicular system initially. This corresponds to the initial condition

$$\rho(z,0) = \rho_{\text{in}}(z) = 0 \ \text{ for all } z > 0, \tag{4.1}$$

and the condition at ∞

$$\lim_{z\to+\infty} \rho(z,t) = 0 \ \text{ for } \ t \geq 0. \tag{4.2}$$

Given these conditions, ρ can be obtained explicitly; more precisely,

$$\rho(z,t) = c_0 - c_0 \frac{2}{\sqrt{\pi}} \int_0^{z/(2\sqrt{D_{\text{eff}}t})} \mathrm{e}^{-s^2}\,\mathrm{d}s. \tag{4.3}$$

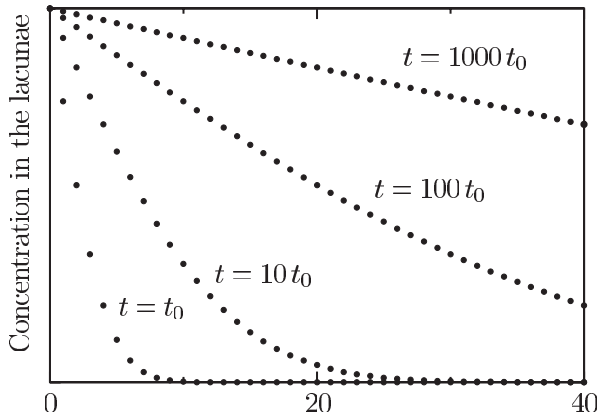

FIG. 4.1. *Plot of the concentration of nutrients in the lacunae* $c_i(t) \simeq \rho(z_i(t), t)$ *versus* i *for different fixed values of* t.

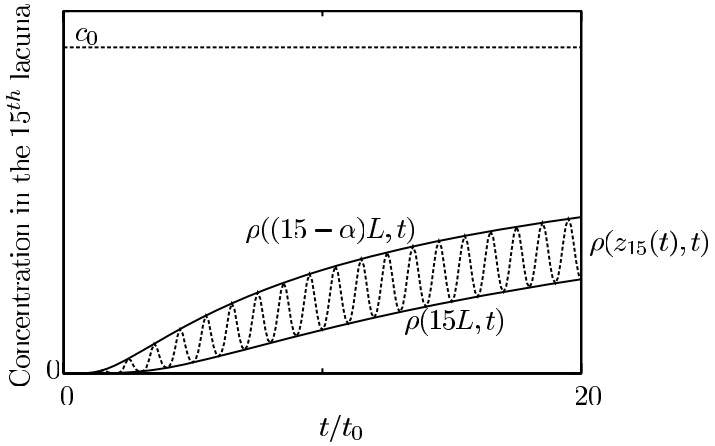

FIG. 4.2. *Plot of concentration of nutrients in the* 15*th lacuna,* $c_{15}(t) \simeq \rho(z_{15}(t), t)$ *(dashed line), and the envelopes* $\rho(15L, t)$ *(lower solid line) and* $\rho((15-\alpha)L, t)$ *(upper solid line) versus normalized time* t/t_0.

In the example presented in this section, we select the velocity

$$v(t) = \frac{\pi V_F}{a t_0} \sin\left(\frac{2\pi t}{t_0}\right), \tag{4.4}$$

and the parameters V_F, V_c, and V_ℓ satisfy $V_c = 0.01 V_\ell$ and $V_\ell = 0.2 V_F$.

In Figure 4.1, we show a plot of the concentration of nutrients in the lacunae, using the approximation $c_i(t) \simeq \rho(z_i(t), t)$, versus i for different fixed values of t.

We define the parameter α as follows:

$$\alpha = \frac{V_F}{V_c + V_\ell}. \tag{4.5}$$

Figure 4.2 shows the evolution of concentration in the fifteenth lacuna $c_{15}(t) \simeq \rho(z_{15}(t), t)$ plotted against normalized time t/t_0. The oscillations in concentration reflect the evolution in concentration in each cycle of the periodic velocity field v. We

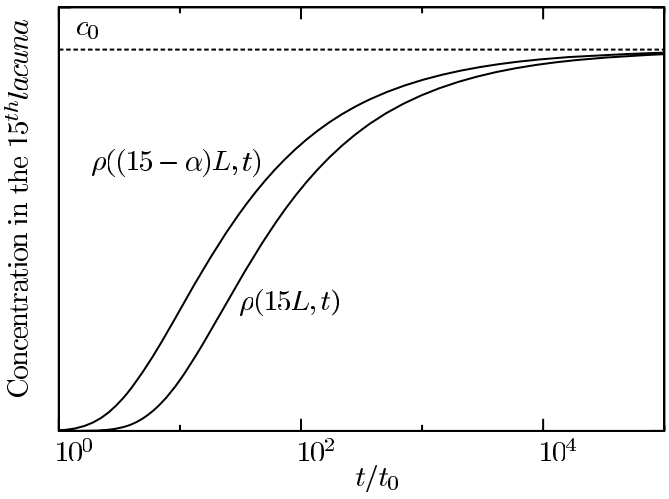

FIG. 4.3. *Plot of the envelopes of the concentration of nutrients in the* 15*th lacuna,* $\rho(15L,t)$ *and* $\rho((15-\alpha)L,t)$*, versus normalized time* t/t_0 *in log scale.*

have also plotted the envelopes that are $\rho(15L,t)$ (lower envelope) and $\rho((15-\alpha)L,t)$ (upper envelope) versus normalized time t/t_0. Figure 4.3 also shows the envelopes $\rho(15L,t)$ and $\rho((15-\alpha)L,t)$ in a longer time scale to illustrate the convergence to c_0 of the concentration in the fifteenth lacuna after a large number of cycles.

5. Conclusions. In this paper we studied the transport of nutrients in a one-dimensional model lacunar-canalicular system. Our motivation was a recently proposed explanation of how nutrients are transported within bones [17]. We have shown that the system exhibits a diffusion-like macroscopic behavior with effective diffusion coefficient, given in (1.3). Note that the effective diffusion coefficient is explicitly given in terms of the geometry of the system and the applied velocity field. Our analysis is the simplest possible that keeps the relevant physics. Nevertheless, our analysis can be extended to include effects neglected here, such as considering a finite and elastic system instead of a rigid and infinite one (as we do in this work). More experimental and theoretical studies are required for a better and more clear understanding of the processes responsible for the transport of nutrients in bones. We hope our work will prove to be an important step toward that goal.

Appendix. Asymptotic analysis of the thin canaliculus limit. Our analysis is valid for thin canaliculus; more precisely, we assume that V_c, the volume of each canaliculus, is much smaller than V_F, the volume of fluid that enters the lacunar-canalicular system during the part of the period where $v > 0$; i.e.,

$$\varepsilon = \frac{V_c}{V_F} \ll 1. \tag{A.1}$$

We first write the velocity v in the form

$$v(t) = \frac{V_F}{at_0} f\left(\frac{t}{t_0}\right). \tag{A.2}$$

Note that $f = f(s)$ is a periodic function of s with period 1 and that

$$\int_0^1 |f(s)|\, \mathrm{d}s = 2. \tag{A.3}$$

We define

$$\beta = t_0\varepsilon \left(\frac{1}{|f(t/t_0)|} + \varepsilon \frac{f'(t/t_0)}{2f^3(t/t_0)} + O(\varepsilon^2) \right). \tag{A.4}$$

In the subsection A.1 we show that

$$\begin{array}{ll} c(iL-\ell,t) = c_{i-1}(t-\beta) & \text{if } v(t) > 0, \\ c(iL,t) = c_{i+1}(t-\beta) & \text{if } v(t) < 0. \end{array} \tag{A.5}$$

We use (A.5) to transform (2.2) into

$$V_\ell \frac{\mathrm{d}c_i}{\mathrm{d}t} = \begin{cases} av\,(c_{i-1}(t-\beta) - c_i(t)) & \text{when } v(t) > 0, \\ av\,(c_i(t) - c_{i+1}(t-\beta)) & \text{when } v(t) < 0 \end{cases} \tag{A.6}$$

for all positive integers i, where β is again given by (A.4).

We now propose the ansatz

$$c_i(t) \simeq \rho\left(y = \varepsilon i, \tau = \frac{t}{t_0} \right), \tag{A.7}$$

where $\rho(y,\tau)$ is a smooth function. We define the parameter

$$\lambda = \frac{V_c}{V_\ell + V_c}. \tag{A.8}$$

In subsection A.2 we show that, given the ansatz (A.7), equations (A.6) reduce to the single PDE

$$\frac{\partial \rho}{\partial \tau} + \lambda f \frac{\partial \rho}{\partial y} \simeq \varepsilon \frac{\lambda |f|}{2} \left(\frac{\partial^2 \rho}{\partial y^2} + \frac{2}{f} \frac{\partial^2 \rho}{\partial y \partial \tau} + \frac{1}{f^2} \frac{\partial^2 \rho}{\partial \tau^2} - \frac{f'}{f^3} \frac{\partial \rho}{\partial \tau} \right), \tag{A.9}$$

where ρ and its derivatives are evaluated in (y,τ) and f and f' are evaluated in τ (terms of higher order in ε are neglected).

Our next step, which we carry out in subsection A.3, is to show that, neglecting corrections of order ε^2, equation (A.9) reduces to

$$\frac{\partial \rho}{\partial \tau} + \lambda f \frac{\partial \rho}{\partial y} \simeq \varepsilon \frac{\lambda |f|}{2} (1-\lambda)^2 \frac{\partial^2 \rho}{\partial y^2}. \tag{A.10}$$

Finally, the asymptotic approximation of section 3 results from the two-time-scale analysis of subsection A.4.

A.1. Derivation of (A.4) and (A.5). Let $X(s)$ be the solution of

$$X'(s) = v(s) \quad \text{and} \quad X(t) = iL - \ell, \tag{A.11}$$

where X' is the derivative of X. Fix t and let $\beta > 0$. If $(i-1)L \le X(s) \le iL - \ell$ for all $s \in [t-\beta, t]$, then (2.1) implies that c is constant along the characteristic paths;

i.e., $c(X(s),s)$ is independent of s for $s \in [t-\beta, t]$. Assume that $v(s)$ is positive for all $s \in [t-\beta, t]$ and β is implicitly given by the equation

$$X(t-\beta) = (i-1)L. \tag{A.12}$$

We have that $c(iL-\ell, t) = c(X(t), t) = c(X(t-\beta), t-\beta) = c((i-1)L, t-\beta)$. On the other hand, since $v(t-\beta) > 0$, equation (2.3) implies that $c((i-1)L, t-\beta) = c_{i-1}(t-\beta)$. Thus,

$$c(iL-\ell, t) = c_{i-1}(t-\beta). \tag{A.13}$$

To compute β, we first use the expression for v given in (A.2) and expand v in powers of $(s-t)$ to get

$$v(s) \simeq \frac{V_F}{at_0} f\left(\frac{t}{t_0}\right) + \frac{V_F}{at_0^2} f'\left(\frac{t}{t_0}\right)(s-t). \tag{A.14}$$

We then integrate this approximation of v and use the condition $X(t) = iL - \ell$ to get

$$X(s) \simeq iL - \ell + \frac{V_F}{at_0} f\left(\frac{t}{t_0}\right)(s-t) + \frac{V_F}{2at_0^2} f'\left(\frac{t}{t_0}\right)(s-t)^2. \tag{A.15}$$

Next use this approximation of $X(s)$ in (A.12) to get

$$(i-1)L \simeq iL - \ell - \frac{V_F}{at_0} f\left(\frac{t}{t_0}\right)\beta + \frac{V_F}{2at_0^2} f'\left(\frac{t}{t_0}\right)\beta^2. \tag{A.16}$$

We subtract $(i-1)L$ on both sides of the above equation, then multiply by a/V_F, note that $a(L-\ell) = V_c$, and recall that $\varepsilon = V_c/V_F$ to get

$$0 \simeq \varepsilon - f\left(\frac{t}{t_0}\right)\frac{\beta}{t_0} + \frac{1}{2} f'\left(\frac{t}{t_0}\right)\left(\frac{\beta}{t_0}\right)^2. \tag{A.17}$$

Once we note that we are considering the case $v(t) > 0$, and thus $f(t/t_0) > 0$, equation (A.17) and elementary calculations show the validity of (A.4) for t such that $v(t) > 0$. The case $v(t) < 0$ results from a similar analysis.

A.2. Derivation of (A.8). Use the ansatz (A.7) and the expression (A.2) for the velocity in (A.6), multiply that equation by t_0/V_F, recall that $\varepsilon = V_c/V_F$, make the change of variables $\tau = t/t_0$, and define $b = \beta/t_0$ to get

$$\frac{V_\ell}{V_F}\frac{\partial \rho}{\partial \tau}(i\varepsilon, \tau) = \begin{cases} f(\tau)\left(\rho((i-1)\varepsilon, \tau - b) - \rho(i\varepsilon, \tau)\right) & \text{if } f(\tau) > 0, \\ f(\tau)\left(\rho(i\varepsilon, \tau) - \rho((i+1)\varepsilon, \tau - b)\right) & \text{if } f(\tau) < 0, \end{cases} \tag{A.18}$$

where

$$b = \varepsilon \frac{1}{|f(\tau)|} + \varepsilon^2 \frac{f'(\tau)}{2f^3(\tau)} + O(\varepsilon^3). \tag{A.19}$$

Expanding in powers of ε, we have that, when $f(\tau) > 0$,

$$\rho((i-1)\varepsilon, \tau - b) \simeq \rho - \varepsilon\left(\frac{\partial \rho}{\partial y} + \frac{1}{f}\frac{\partial \rho}{\partial \tau}\right) + \frac{\varepsilon^2}{2}\left(\frac{\partial^2 \rho}{\partial y^2} + \frac{2}{f}\frac{\partial^2 \rho}{\partial y \partial \tau} + \frac{1}{f^2}\frac{\partial^2 \rho}{\partial \tau^2} - \frac{f'}{f^3}\frac{\partial \rho}{\partial \tau}\right).$$

Analogously, when $f(\tau) < 0$, we have

$$\rho((i+1)\varepsilon, \tau - b) \simeq \rho + \varepsilon\left(\frac{\partial \rho}{\partial y} + \frac{1}{f}\frac{\partial \rho}{\partial \tau}\right) + \frac{\varepsilon^2}{2}\left(\frac{\partial^2 \rho}{\partial y^2} + \frac{2}{f}\frac{\partial^2 \rho}{\partial y \partial \tau} + \frac{1}{f^2}\frac{\partial^2 \rho}{\partial \tau^2} - \frac{f'}{f^3}\frac{\partial \rho}{\partial \tau}\right).$$

In the last two equations ρ and its derivatives are evaluated in $(\varepsilon i, \tau)$, and f and f' are evaluated in τ. Once we plug these expressions into (A.18) and perform simple algebraic manipulations, we obtain (A.9).

A.3. Derivation of (A.10). From (A.9) we infer that

$$\frac{\partial \rho}{\partial \tau} = -\lambda f \frac{\partial \rho}{\partial y} + O(\varepsilon). \tag{A.20}$$

Taking derivatives with respect to y in (A.20), we get

$$\frac{\partial^2 \rho}{\partial y \partial \tau} = -\lambda f \frac{\partial^2 \rho}{\partial y^2} + O(\varepsilon). \tag{A.21}$$

On the other hand, taking derivatives with respect to τ in (A.20) and using (A.21), we have

$$\frac{\partial^2 \rho}{\partial \tau^2} = -\lambda f \frac{\partial^2 \rho}{\partial y \partial \tau} - \lambda f' \frac{\partial \rho}{\partial y} + O(\varepsilon) = \lambda^2 f^2 \frac{\partial^2 \rho}{\partial y^2} - \lambda f' \frac{\partial \rho}{\partial y} + O(\varepsilon). \tag{A.22}$$

Once we replace $\partial \rho / \partial \tau$, $\partial^2 \rho / \partial y \partial \tau$, and $\partial^2 \rho / \partial \tau^2$ in the right-hand side of (A.9) by the expressions obtained in the last three equations and neglect terms of order ε^2, we obtain (A.10).

A.4. Two-time-scale analysis on (A.10). We now follow the standard procedures in two-time-scale asymptotics. We introduce a second time scale

$$\theta = \varepsilon \lambda (1-\lambda)^2 \tau. \tag{A.23}$$

We need to replace $\partial \rho / \partial \tau$ by $\varepsilon \lambda (1-\lambda)^2 \partial \rho / \partial \theta + \partial \rho / \partial \tau$ in (A.10), treat τ and θ as independent variables, and assume that ρ depends on the three variables y, τ, and θ; i.e., $\rho = \rho(y, \tau, \theta)$. Equation (A.10) becomes

$$\varepsilon \lambda (1-\lambda)^2 \frac{\partial \rho}{\partial \theta} + \frac{\partial \rho}{\partial \tau} + \lambda f \frac{\partial \rho}{\partial y} = \varepsilon \frac{\lambda |f|}{2} (1-\lambda)^2 \frac{\partial^2 \rho}{\partial y^2}. \tag{A.24}$$

Next we expand ρ in powers of ε,

$$\rho = \rho_0 + \varepsilon \rho_1 + \varepsilon^2 \rho_2 + \cdots, \tag{A.25}$$

and require that $\rho_1 = \rho_1(y, \tau, \theta)$ be periodic (with period 1) in τ (this requirement makes the asymptotic approximation valid for long values of τ). We then plug this ansatz into (A.24) and collect powers of ε. At order 1 we get

$$\frac{\partial \rho_0}{\partial \tau} + \lambda f \frac{\partial \rho_0}{\partial y} = 0, \tag{A.26}$$

and at order ε

$$\lambda (1-\lambda)^2 \frac{\partial \rho_0}{\partial \theta} + \frac{\partial \rho_1}{\partial \tau} + \lambda f \frac{\partial \rho_1}{\partial y} = \frac{\lambda |f|}{2} (1-\lambda)^2 \frac{\partial^2 \rho_0}{\partial y^2}. \tag{A.27}$$

From (A.26), we obtain that the dependence of ρ_0 on y and τ is through the variable η defined as

$$\eta = y - \lambda \int_0^\tau f(s)\, \mathrm{d}s. \tag{A.28}$$

Thus, if we change independent variables from (y, τ, θ) to (η, τ, θ), we have

$$\rho = \rho(\eta, \theta) \quad \text{and} \quad \rho_1 = \rho_1(\eta, \tau, \theta). \tag{A.29}$$

In the new independent variables, (A.27) becomes

$$\lambda(1-\lambda)^2\frac{\partial \rho_0}{\partial \theta}+\frac{\partial \rho_1}{\partial \tau}=\frac{\lambda|f|}{2}(1-\lambda)^2\frac{\partial^2 \rho_0}{\partial \eta^2}. \tag{A.30}$$

Finally we take the average of the above equation with respect to τ, keeping η and θ fixed. Since ρ_1 is periodic in τ, we have

$$\int_0^1 \frac{\partial \rho_1}{\partial \tau}\,\mathrm{d}\tau = 0. \tag{A.31}$$

Recalling the definition of f and its properties (see (A.2) and (A.3)), we have $\int_0^1 |f|\,\mathrm{d}\tau = 2$. Thus, given that ρ_0 is independent of τ, we have that, after averaging with respect to τ, (A.30) becomes

$$\frac{\partial \rho_0}{\partial \theta}=\frac{\partial^2 \rho_0}{\partial \eta^2}. \tag{A.32}$$

We define the spatial variable

$$z=\frac{L}{\varepsilon}y-\frac{aL}{V_\ell+V_c}\int_0^t v(s)\,\mathrm{d}s. \tag{A.33}$$

From the different changes of variables made, it follows that

$$\eta=\frac{V_c}{V_F L}z \quad \text{and} \quad \theta=\frac{V_c^2 V_\ell^2}{V_F(V_\ell+V_c)^3}\frac{t}{t_0}. \tag{A.34}$$

The last three equations imply that ρ_0 satisfies (3.3). Thus, dropping the subindex 0 and observing the appropriate boundary and initial conditions, we obtain the asymptotic approximation of section 3.

Acknowledgments. The author thanks Professor Santamarina for introducing the author to this area of research and for stimulating discussions. This work was motivated by the work in [17].

FIELD-INDUCED MOTION OF NEMATIC DISCLINATIONS*

PAOLO BISCARI† AND TIMOTHY J. SLUCKIN‡

Abstract. An individual defect in a nematic liquid crystal moves not only in response to its interaction with other defects but also in response to external fields. We analyze the motion of a wedge disclination in the presence of an applied field of strength H. We neglect backflow and seek steadily traveling patterns. The stationary picture yields a semi-infinite wall of strength π, bounded by the defect line. We find that the disclination advances into the region containing the wall at velocity $v(H)$, where v scales as $H/|\log H|$ as long as the magnetic coherence length is greater than the core radius. When the external field is applied in the presence of a pair of disclinations, their dynamics is strongly influenced. We compute the expected relative velocity of the disclinations as a function of distance and field. The natural tendency for the disclinations to annihilate each other can be overcome by a sufficiently strong field suitably directed.

1. Introduction.

Singularities in liquid crystals, or *defects*, have played a fundamental role not only in the development of the understanding of the physics of liquid crystals but also in the later development of the topological theory of defects in condensed matter. In nematic liquid crystals, point, line, and wall defects can be found. Line defects were first classified by Sir Charles Frank, who noted that line defects came in classes with an integer or half-integer charge [1]. Later workers, using the topological theory of defects, realized that nematic liquid crystals sustain a topologically unique line defect [2, 3, 4]. However, Frank's naïve classification, which effectively supposes that the nematic order parameter is restricted to a plane, remains important in providing guidance and intuition for the physics of defects in nematic liquid crystals.

The topological total charge of a system is conserved during its evolution. Under many circumstances this remains true for Frank's definition of charge; this is a stronger condition. For instance, defects of opposite charges may annihilate, and defects of higher topological charges may decay to a bunch of defects of smaller topological charges. Topological dipoles may even be nucleated from a smooth field [5].

In this paper we focus on nematic disclinations, i.e., line defects. According to Frank's definition, the topological charge of a line defect is defined as the number of turns the director performs along a closed path surrounding the defect. This number may be half-integer because of the head-and-tail symmetry of nematic liquid crystal molecules. When the final director is rotated by an angle π with respect to the initial director, the physical state they describe does not exhibit any discontinuity.

The physical manifestation of the topological theory of defects in nematic liquid crystals concerns *escape into the third dimension*. Nematic disclinations of integer

charge are not topologically stable. A suitable continuous transformation, involving the third previously neglected dimension, dissolves the singularity and leaves behind a regular field [6]. In a similar manner, all half-integral disclinations can be distorted into each other. However, free energy criteria often impede this process, and the Frank classification remains useful. In particular, annihilation of opposite-charge half-integral defects is favored, but of same-charge defects is hindered.

Defect dynamics has been widely studied either in the classical Oseen–Zocher–Frank (OZF) theory [7, 8, 1], or within the extended de Gennes–Ericksen theory [9, 10]. However, there are fundamental dilemmas in treating defect motion. The OZF theory is not a dynamical theory, and defect cores are regions in which, strictly speaking, the OZF theory does not apply. The theory can be extended to deal with moving defects, but only by introducing a phenomenological dissipation function using director rate of change. This minimal extension is incorrect; the full extension involves hydrodynamic terms which depend on the local director [11]. But the local director is not defined in the defect region, and so this extension is also inadequate to describe defect motion. The alternative de Gennes–Ericksen approach (now usually called the **Q**-tensor theory) is in principle up to the task, but now the defect regions are no longer special. In addition, it is now necessary to consider a whole set of new degrees of freedom. In fact, however, these new degrees of freedom are important only inside the core region.

Despite these problems, some theoretical progress has been made, in part because some authors have detected analogous topological structures in liquid crystals and cosmological models. A single disclination may move through an otherwise smooth field [12, 13], but then the problem is why the defect is moving in the first place. An implicit response to this question is to devote more attention to the interaction between two or more defects. In such cases the defects move, slowly, to reduce their elastic energy. For example, attraction between two point defects of opposite charges has been studied in both planar [14, 15, 16] and cylindrical [17, 18, 19] geometries. The attraction between two oppositely charged smectic disclinations has been studied in [20].

More precise quantitative descriptions of the defect evolution must necessarily take into account backflow effects [21, 22, 23], i.e., the interactions between director rotation and macroscopic molecular motion. The first analytical attempt to introduce backflow effects was performed in [24], where the macroscopic velocity field was coupled to the degree of orientation, though not to the director field. A series of recent numerical simulations [25, 26, 27, 28, 29] have determined the main effects of backflow coupling. The dynamical director patterns turn out to be strongly influenced in the final part of the annihilation process, but some effects may be noted even during all the defect evolution. In particular, the disclination speeds may be different [25], and recent numerical simulations suggest that positively charged disclinations can move almost twice as fast as those with negative charge [28].

In this paper we investigate the effect of an applied external field on the defect dynamics. We consider a simple geometry: a single $+\frac{1}{2}$, or a dipole of $\pm\frac{1}{2}$ disclinations, in planar symmetry. We compute the defect speed with the aid of the Leslie's dissipation balance [11]. It turns out that the external field exerts a profound effect on the defect dynamics and the defect interaction. By suitably adjusting the external field strength and direction, it is possible to drive a single disclination through the sample, as has been experimentally observed [30, 31]. More interestingly, the effect of the external field may go beyond a simple acceleration or deceleration of the annihilation process. The field can also stop the defects, or even reverse their veloc-

ities, thus transforming an attractive into a repulsive interaction. Depending on the external field direction, a critical defect distance may arise, which characterizes the defect interaction. They annihilate each other if they come closer than that distance; otherwise, they repel.

Throughout our presentation we will introduce and discuss some assumptions that simplify our analytical calculations. The 1-constant approximation in the elastic free energy, and a parabolic approximation in the magnetic energy, linearize the free energy derivatives. We remark that the parabolic approximation would have to be abandoned if we were to generalize the present study to highly charged defects. We also neglect backflow. This approximation allows us to derive an analytical condition which determines the defect velocity, and in particular the critical distance that reverses the defect interaction. A numerical analysis would correct these computed values, even if the described phenomena will certainly remain.

The plan of the paper is as follows. In section 2 we analyze the motion of a single disclination in an external field. Section 3 describes the defect interaction, and how it can be reversed with the aid of the applied field. In section 4 we summarize our results and compare them with the observed experimental data.

2. Single defect motion. We consider a $+\frac{1}{2}$ disclination embedded in an external magnetic field. This field will favor the director orientation of one side of the defect with respect to the other side. This asymmetry is sufficient, as we shall see, for energy considerations alone to determine that the defect will move and to determine the direction of its motion. Our task is to determine the magnitude of the velocity as a function of the field intensity. We adopt the 1-constant approximation and neglect backflow. This latter approximation implies that our estimated velocity will certainly be smaller than the actual velocity. In fact, backflow effects reduce the total dissipation, thus allowing faster director dynamics.

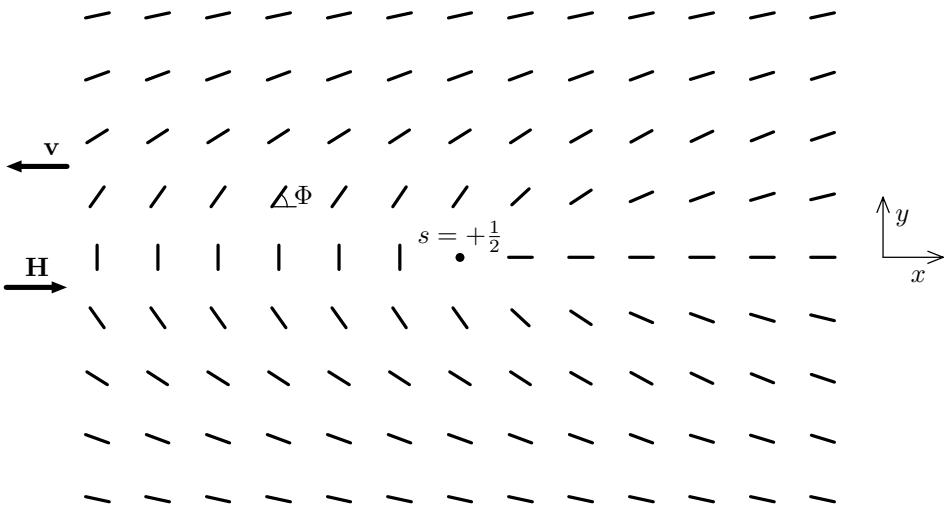

FIG. 1. *Geometric setting for the analysis of the single defect motion. The defect occupies the origin of the comoving reference frame and moves towards the π-wall. The angle Φ is determined by the director and the motion direction (parallel to the external field).*

Let us consider the reference frame illustrated in Figure 1. It moves with the disclination, which sits at the origin **O**. The x-axis is parallel to the external field.

Given any point **P** in the plane, let ϑ be the polar angle between the radial direction **OP** and the x-axis. Disclinations of half-integer charge do not benefit from escaping into the third dimension. Thus, we restrict our interest to the situation in which the director **n** is confined to the plane, and let $\Phi(\mathbf{P})$ be the angle between the nematic director at **P** and the x-axis.

In the absence of a field, the 1-constant approximation implies that the director angle varies linearly with the polar angle: $\Phi = \frac{1}{2}\,\vartheta$. In the presence of the field, the same linear dependence holds, roughly speaking, on length scales smaller than the magnetic coherence length ξ. So long as we confine ourselves to these length scales, the elastic energy overwhelms the external field. However, far from the defect, the magnetic energy forces the system toward its preferred value $\Phi = 0$. On the other hand, over a closed path around the defect, no matter how far that path may be from the defect, topology *forces* the angle Φ to rotate through π. This creates a dilemma, for the system must rotate through an angle π and yet remain at $\Phi = 0$.

These two constraints are reconciled by restricting the region over which Φ rotates. This region is a topologically irreducible *wall* between regions of space whose director is oppositely oriented. Associated with the wall is a well-defined surface free energy analogous to the surface tensions of fluid mechanics. This is a π-wall, since the director concentrates its π-rotation in it. In the presence of the field, the previously isolated defect line has been transformed into the trailing edge of a wall defect. The disclination then moves into the wall in order to reduce the wall area and consequently the free energy of the system.

2.1. Dissipation principle. We determine both the director field and the value of the disclination velocity by imposing the energy balance between the free-energy loss-rate and the dissipation [11]:

$$\dot{\mathcal{F}} + \mathcal{D} = 0. \tag{2.1}$$

In the 1-constant approximation, the free-energy functional is given by

$$\mathcal{F}[\Phi] = \int_{\mathbb{R}^2} \left(K \left| \nabla \Phi \right|^2 + \chi_{\mathrm{a}} H^2 \sin^2 \Phi \right) da, \tag{2.2}$$

where K is an average elastic constant, χ_{a} is the magnetic anisotropy, and H is the strength of an external magnetic field.

It is well known that a $+\frac{1}{2}$ disclination possesses an infinite core energy. The elastic free-energy density diverges at the defect, and the singularity is not integrable. There are two ways to avoid this divergence. The first consists of excluding from our integration region a small disk centered in the defect, the *core region* $\mathcal{B}_\circ$. The radius of the excised disk, the *core radius* $r_\circ$, is usually much smaller than all other characteristic lengths entering the problem, so that many studies have been performed in the limit of vanishing $r_\circ$ [32]. A more precise physical description of the defect requires an extension of the classical OZF theory, and the replacement of the nematic director with the nematic order tensor [33]. We will choose the first option and perform all the integrations in the pierced domain, which excludes $\mathcal{B}_\circ$. We further assume that the core radius is fixed. The basic physics of the phenomenon is well described using these approximations. However, in order to deal with external fields of any intensity, it would be interesting to apply the techniques of [34] to determine how and when the magnetic coherent length influences the core radius.

A second, though less worrying, free-energy divergence comes from the supposedly infinite size of the domain. The domain may extend indefinitely in the y-direction

without inducing any singularity, since both the elastic and the magnetic energy densities vanish away from the x-axis. On the other hand, there will be few cases in which a large-x cut will be needed to keep energies finite. In those cases we will assume that our domain is bounded by $|x| \leq L$. Whenever possible, we will perform the $L \to +\infty$ limit, and we will notice that the large scale length L will not finally enter in the defect velocity.

Our final approximation concerns the magnetic free energy. We will perform the *parabolic approximation* $\sin^2 \Phi \simeq \Phi^2$. This approximation allows us to obtain linear field equations in Φ. It can be used in the whole domain, provided that we define $\Phi \in [-\frac{\pi}{2}, \frac{\pi}{2}]$, since in that case all the values attained by the director angle belong to the potential well of the equilibrium configuration $\Phi = 0$. We remark that this approximation would not be valid if we were interested in analyzing the equilibrium configurations of more complex defects.

When we neglect backflow, the dissipation assumes the simple expression

$$\mathcal{D} = \gamma_1 \int_{\mathcal{B}_\circ} \dot{\Phi}^2 \, dx \, dy, \tag{2.3}$$

where the pierced integration domain $\mathcal{B}_\circ$ comes into play since the dissipation density also diverges in the core region.

Let us perform an infinitesimal displacement $\delta\Phi$ of the director field. If we make use of the divergence theorem, the dissipation principle (2.1) requires

$$\int_{\partial\mathcal{B}_\circ} \delta\Phi \, \left(2K \, \nabla\Phi\right) \cdot \nu \, d\ell + \int_{\mathcal{B}_\circ} \delta\Phi \, \left[\gamma_1 \, \dot{\Phi} - 2K\Delta\Phi + 2\chi_{\mathrm{a}} H^2 \Phi\right] da = 0 \quad \forall \, \delta\Phi, \tag{2.4}$$

where ν is the outer normal along $\partial\mathcal{B}_\circ$. The arbitrariness of $\delta\Phi$ requires that the quantity in square brackets in the second integral must vanish identically:

$$\gamma_1 \, \dot{\Phi} = 2K\Delta\Phi - 2\chi_{\mathrm{a}} H^2 \, \Phi. \tag{2.5}$$

Equation (2.5) is the well-known time-dependent Ginzburg–Landau evolution equation of the system. It will supply us the director field. However, the Ginzburg–Landau equation alone is not able to guarantee the dissipation principle. We must check that the first integral in (2.4) also vanishes. The boundary $\partial\mathcal{B}_\circ$ is made of two parts: a small circle around the defect and a large boundary at infinity. The integral around the latter vanishes, since at infinity $\nabla\Phi$ fades everywhere except along the π-wall, where it is orthogonal to the outward normal. We are then left with the first integral in (2.4), performed along the boundary of the core region. This quantity has a simple physical meaning [35]: it is the power supplied by the core region to the rest of the domain. Thus, to require that all the free-energy loss be dissipated within the system is equivalent to requiring that no energy be supplied to it, either from the outside or from the core region.

2.2. Steadily moving defects. We will look for stationary solutions of equation (2.5). They aim at representing a defect moving at a constant speed v towards the π-wall. We will find that, for any positive value of v, it is possible to find a solution of (2.5) which satisfies the boundary conditions. However, there is just one value of the velocity which also cancels the first integral in (2.4) (or, equivalently, that satisfies the global dissipation condition). It is the only velocity at which the defect is able to move without any external boost.

In a steadily moving reference frame, traveling with the defect itself, the relative stationary differential equation follows by replacing the time derivative in (2.5) with $v\,\partial_x$. We thus obtain

$$\Delta\Phi - \frac{\lambda}{\xi}\,\frac{\partial\Phi}{\partial x} - \frac{\Phi}{\xi^2} = 0, \tag{2.6}$$

where $\xi := \sqrt{\frac{K}{\chi_a H^2}}$ is the magnetic coherence length, and $\lambda := \frac{\gamma_1}{2\sqrt{K\chi_a}}\,\frac{v}{|H|}$ is a dimensionless quantity. We look for solutions of the eigenvalue problem (2.6) that satisfy the symmetry requirement $\Phi(x,-y) = -\Phi(x,y)$ for all $y \neq 0$, and the boundary conditions

$$\Phi(x,0^+) = \begin{cases} 0 & \text{if } x > 0, \\ \dfrac{\pi}{2} & \text{if } x < 0, \end{cases} \qquad \text{and} \qquad \lim_{y\to\infty} \Phi(x,y) = 0 \quad \forall\, x \in \mathbb{R}, \tag{2.7}$$

where the latter condition is determined by the presence of the magnetic field. The boundary conditions (2.7) are singular only at the origin, where a disclination of topological charge $+\frac{1}{2}$ stands. Indeed, the discontinuity that the angle Φ suffers along the negative x-axis does not induce any physical singularity, since $\Phi = \pi/2$ and $\Phi = -\pi/2$ describe the same director orientation.

Among the solutions of the eigenvalue problem (2.6)–(2.7), the dissipation principle (2.1) will single out the only physical one.

2.3. Director field. We solve the linear partial differential equation (2.6) with a Fourier transform. To this end, it is useful to write the first of the boundary conditions (2.7) as

$$\Phi(x,0^+) = \frac{\pi}{4} - \frac{1}{4\mathrm{i}}\ \mathrm{PV}\!\int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx}}{q}\,dq \qquad \forall\, x \neq 0, \tag{2.8}$$

where PV denotes the Cauchy principal value of an integral. We then look for solutions of (2.6) of the form

$$\Phi(x,y) = \frac{\pi}{4}\,g_1(y) - \frac{1}{4\mathrm{i}}\ \mathrm{PV}\!\int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx}}{q}\,g_2(q,y)\,dq, \tag{2.9}$$

with

$$g_1(0) = g_2(q,0) = 1 \quad \text{and} \quad \lim_{y\to\infty} g_1(y) = \lim_{y\to\infty} g_2(q,y) = 0 \quad \forall\, q \in \mathbb{R}. \tag{2.10}$$

If we insert (2.9) into (2.6), we obtain

$$\frac{\pi}{4}\left(g_1'' - \frac{1}{\xi^2}\,g_1\right) - \frac{1}{4\mathrm{i}}\ \mathrm{PV}\!\int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx}}{q}\left[\frac{\partial^2 g_2}{\partial y^2} - k^2(q)\,g_2\right] dq = 0, \tag{2.11}$$

where $k(q)$ will henceforth denote the positive-real-part square root of $k^2(q) = q^2 + \frac{\mathrm{i}q\lambda}{\xi} + \frac{1}{\xi^2}$. The solution of (2.11) and (2.10) in the upper half-plane $\{y \geq 0\}$ is

$$\Phi(x,y) = \frac{\pi}{4}\,\mathrm{e}^{-\frac{y}{\xi}} - \frac{1}{4\mathrm{i}}\ \mathrm{PV}\!\int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx - k(q)y}}{q}\,dq, \tag{2.12}$$

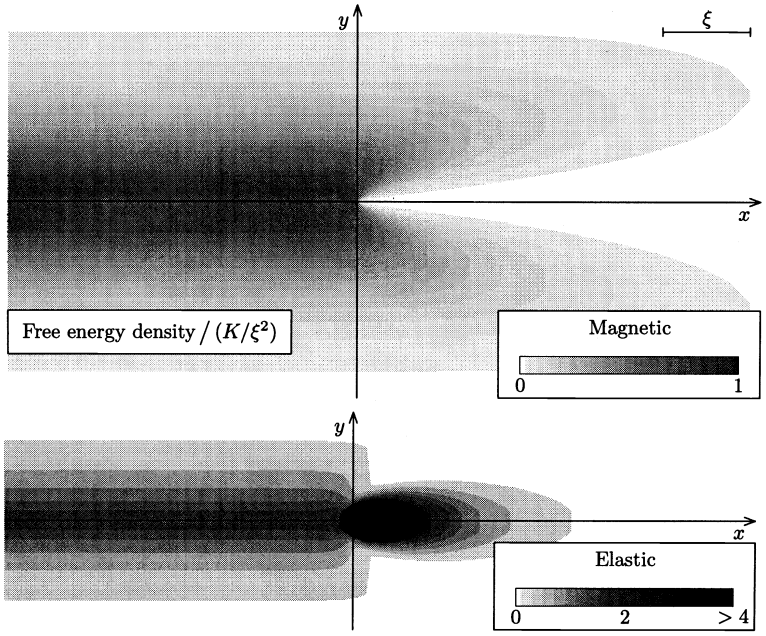

FIG. 2. *Density plots of the magnetic (upper graph) and elastic (lower graph) parts of the free-energy density, computed from the analytical solution* (2.13). *The elastic energy is localized close to the defect. In contrast, the magnetic energy is mostly packed around the π-wall. The defect core is not symmetric with respect to the defect position; it is slightly shifted behind it with respect to the direction of motion.*

whereas, by symmetry, the solution in the whole plane is given by

$$\Phi(x,y) = \varepsilon(y)\left[\frac{\pi}{4}\,\mathrm{e}^{-\frac{|y|}{\xi}} - \frac{1}{4\mathrm{i}}\ \mathrm{PV}\!\int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx-k(q)|y|}}{q}\,dq\right], \tag{2.13}$$

with

$$\varepsilon(y) := \begin{cases} 1 & \text{if } y \geq 0, \\ -1 & \text{if } y < 0. \end{cases} \tag{2.14}$$

Figure 2 illustrates the solution (2.13). More precisely, in the upper plot it is possible to observe how the magnetic free-energy density is concentrated on the π-wall, whereas the lower plot shows that the elastic free-energy density is mostly localized on the defect. In both cases, it is possible to notice that the decay pattern from $\Phi = \pm\frac{\pi}{2}$ on the left x-axis to the equilibrium value $\Phi = 0$ becomes constant when we move some magnetic coherence lengths away from the defect.

We notice that no use of the core region has been made for the time being. In fact, the differential problem (2.6)–(2.7) admits a solution in $\mathbb{R}^2 \setminus (0,0)$, without any need to excise a finite region around the defect. We will see below that this will not be the case when we have to deal with the derivatives of the field, and in particular with the dissipation (2.3).

2.4. Disclination velocity. We have succeeded in finding a solution of the stationary Ginzburg–Landau equation for any value of v. We will now complete the

eigenvalue analysis and determine the correct disclination velocity by imposing the global dissipation condition (2.1).

We have already noticed that, in the moving reference frame, time derivatives transform into spatial derivatives. Thus,

(2.15)
$$\dot{\mathcal{F}} = v \int_{\mathcal{B}_\circ} \frac{\partial}{\partial x} \left(K \left| \nabla \Phi \right|^2 + \chi_{\mathrm{a}} H^2 \Phi^2 \right) dx\, dy = v \left[\int_{\mathbb{R}} \left(K \left| \nabla \Phi \right|^2 + \chi_{\mathrm{a}} H^2 \Phi^2 \right) dy \right]_{x=-\infty}^{x=+\infty} .$$

When $|x|$ is very large, the principal value of the q-integral in (2.13) is dominated by the low q values:

$$\lim_{x \to \pm\infty} \frac{1}{4\mathrm{i}} \ \mathrm{PV} \int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx - k(q)y}}{q}\, dq = \frac{1}{4\mathrm{i}} \lim_{x \to \pm\infty} \ \mathrm{PV} \int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}qx - \frac{y}{\xi}}}{q}\, dq = \pm \frac{\pi}{4}\, \mathrm{e}^{-\frac{y}{\xi}} . \tag{2.16}$$

Thus,

$$\dot{\mathcal{F}} = -\frac{\pi^2 K v}{\xi^2} \int_0^{+\infty} \mathrm{e}^{-\frac{2y}{\xi}}\, dy = -\frac{\pi^2 K v}{2\xi} . \tag{2.17}$$

The result (2.17) admits a simple physical interpretation, which already exhibits in (2.15). The quantity within square brackets in (2.15) is the free energy contained in an infinite vertical strip of unit width, centered at x. When $x \to +\infty$, both the elastic and magnetic energy densities relax to 0, as Figure 2 shows. As a consequence, the total energy stored in the right-side strip is negligible. The picture completely changes in the $x \to -\infty$ limit. A unit-width strip crossing the π-wall stores a finite amount of free energy, measured in (2.17). In fact, it is precisely the difference between the energies stored in those strips that keeps the defect moving. In unit time, the defect motion replaces a left-side strip of width v, with free energy given in (2.17), with a right-side strip of equal width, with no free energy.

While the free-energy variation depends only on the asymptotic structure of the director field, dissipation takes place in the whole domain. Indeed, it is so strong close to the moving defect that we will be forced to exclude the core region in order to avoid an infinite dissipation. We have

$$\begin{aligned}
\mathcal{D} &= \gamma_1 \int_{\mathbb{R}^2} \dot{\Phi}^2\, dx\, dy = \gamma_1 v^2 \int_{\mathbb{R}^2} \left(\frac{\partial \Phi}{\partial x} \right)^2 dx\, dy \\
&= \frac{\gamma_1 v^2}{16} \int_{\mathbb{R}^2} dx dy \ \mathrm{PV} \int_{\mathbb{R}} dq \ \mathrm{PV} \int_{\mathbb{R}} dq' \mathrm{e}^{\mathrm{i}(q+q')x - (k(q)+k(q'))|y|} \\
&= \frac{\gamma_1 v^2}{8} \ \mathrm{PV} \int_{\mathbb{R}} dq \ \mathrm{PV} \int_{\mathbb{R}} dq' \, \frac{2\pi \delta\big(q+q'\big)}{k(q)+k(q')} \\
&= \frac{\pi \gamma_1 v^2}{2} \int_0^{\frac{q_{\mathrm{M}}}{2\pi}} \frac{dq}{\sqrt{q^2 + \mathrm{i}q\lambda/\xi + 1/\xi^2} + \sqrt{q^2 - \mathrm{i}q\lambda/\xi + 1/\xi^2}} \\
&= -\frac{\mathrm{i}\pi K v}{2\xi} \int_0^{\frac{\xi}{r_\circ}} \left(\sqrt{1 + \frac{\mathrm{i}\lambda}{s} + \frac{1}{s^2}} - \sqrt{1 - \frac{\mathrm{i}\lambda}{s} + \frac{1}{s^2}} \right) ds,
\end{aligned} \tag{2.18}$$

where δ denotes the Dirac delta function. The high-q cutoff is needed in order to avoid the logarithmic divergence which the disclination induces both in the free energy (but

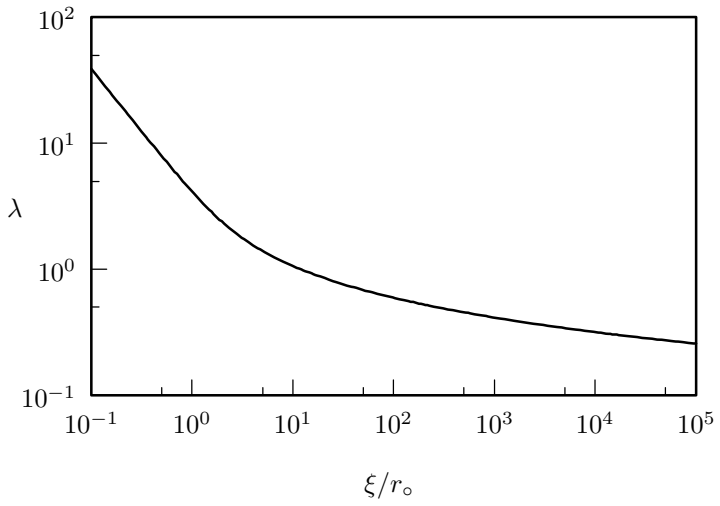

FIG. 3. *Disclination velocity as a function of the external applied field.*

not in its time-derivative) and in the dissipation. This is related to the inverse of the core radius: $q_{\mathrm{M}} = 2\pi/r_\circ$.

When we substitute (2.15) and (2.18) into the dissipation principle (2.1), we obtain the self-consistency equation that determines λ (i.e., v), as a function of the ratio $\xi/r_\circ$:

$$\int_0^{\frac{\xi}{r_\circ}} \left(\sqrt{1 + \frac{\mathrm{i}\lambda}{s} + \frac{1}{s^2}} - \sqrt{1 - \frac{\mathrm{i}\lambda}{s} + \frac{1}{s^2}} \right) ds = \mathrm{i}\pi. \tag{2.19}$$

The most interesting region in physical applications is $\xi \gg r_\circ$. The integral on the left-hand side is dominated by its logarithmic high-s divergence, and we obtain

$$\mathrm{i}\lambda \log \frac{\xi}{r_\circ} = \mathrm{i}\pi \quad \Longrightarrow \quad v = \frac{2\pi\sqrt{K\chi_{\mathrm{a}}}}{\gamma_1 \log\left(\xi/r_\circ\right)} \, |H| \qquad \text{when} \quad \xi \gg r_\circ. \tag{2.20}$$

However, it is interesting to push the analysis of (2.19) into the opposite regime, $\xi \ll r_\circ$. The low-s terms dominate the integral on the left-hand side, and we find

$$\mathrm{i}\lambda \, \frac{\xi}{r_\circ} = \mathrm{i}\pi \quad \Longrightarrow \quad v = \frac{2\pi\chi_{\mathrm{a}} r_\circ}{\gamma_1} \, H^2 \qquad \text{when} \quad \xi \ll r_\circ. \tag{2.21}$$

The quite intriguing quadratic behavior predicted by (2.21) must be handled carefully. When the external field becomes so intense that ξ becomes of the order of $r_\circ$, we have to question our assumption that $r_\circ$ is independent from ξ. A more complete theory, which can be derived following the steps of [34], would yield an $r_\circ(\xi)$, and thus a disclination velocity depending only on the strength of the applied field.

Figure 3 shows the numerical solution of (2.19). The plot highlights that the transition between the two asymptotic regimes derived above occurs for $\xi \gtrsim r_\circ$. Even though this is the limit up to which we can seriously trust our analytical result, Figure 3 suggests that the nonlinear effects increase the disclination velocity.

3. Defect interaction. Let us now consider two nematic defects of opposite topological charges $s = \pm\frac{1}{2}$ placed on the x-axis at a distance $\Delta = 2d$, but in the absence of any external field. After a certain period of time these defects amalgamate and thus annihilate each other. The two cores disappear at once, with a large and rapid reduction in free energy [14, 16, 28]. Imagine, however, that we apply a magnetic field that favors the director orientation of the molecules that lie within the defects. The defect speed will certainly be reduced. In this section we show that it can even be reversed. There exists a critical distance such that the defect interaction is attractive only if their mutual distance is smaller than the critical one. Otherwise, they repel.

Throughout this section, we will work out in detail the geometry illustrated in Figure 4. The applied field lies parallel both to the line connecting the defects and to the director orientation between them. In this geometry, the defects may only approach or separate, thus avoiding even more complicated motions such as mutual rotations.

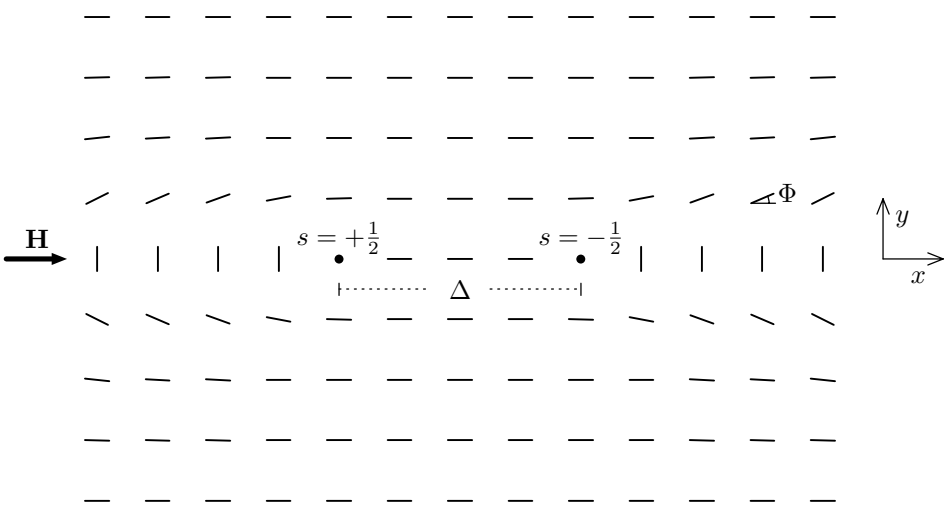

FIG. 4. *Two attracting defects placed at a distance Δ along the x-axis. The external field is parallel both to the line connecting the defects and to the director orientation between them.*

We compute the speed of two stationarily moving defects. We will show below that the stationarity assumption holds approximately even when the defect distance becomes of the order of, or smaller than, the magnetic coherence length. It must certainly be abandoned when one wants to describe the complete annihilation process, and in particular when the defect distance becomes of the order of the core radius.

In the final subsection we will briefly analyze the case when the external field determines a generic angle α with respect to the defect line. In this case the motion may be much more complicated. However, we are able to estimate how the nature of the defect interaction depends on α. More precisely, we will determine for which values of α the defect interaction may become repulsive, and how the critical distance depends on the external field direction.

The time-dependent Ginzburg–Landau equation (2.6) is linear, due to the parabolic approximation we used for the magnetic energy. We can thus obtain a solution describing two stationarily approaching (or separating) defects by simply superposing two functions of the type (2.13). More precisely, we add a solution describing a defect

placed at $x = +d$, traveling with velocity $-v$, and a solution describing a defect placed at $x = -d$, traveling with velocity $+v$. The velocity $v(d)$ will be determined later, again using the dissipation principle. The director field is given by

$$\Phi(x,y) = \varepsilon(y)\left[\frac{\pi}{2}\,\mathrm{e}^{-\frac{|y|}{\xi}} + \frac{1}{4\mathrm{i}}\ \mathrm{PV}\int_{\mathbb{R}} \frac{\mathrm{e}^{\mathrm{i}q(x-d)-k(q)|y|} - \mathrm{e}^{\mathrm{i}q(x+d)-k(-q)|y|}}{q}\,dq\right]$$

$$= \varepsilon(y)\left[\frac{\pi}{2}\,\mathrm{e}^{-\frac{|y|}{\xi}} - \int_0^{+\infty} \cos qx\ \sin\left(qd + \operatorname{Im} k(q)\,|y|\right)\,\mathrm{e}^{-\operatorname{Re} k(q)\,|y|}\,\frac{dq}{q}\right]. \tag{3.1}$$

Figure 5 illustrates the countervailing tendencies of the elastic and magnetic energies: the elastic contribution aims at annihilating the defects in order to relax the infinite core energy. In contrast, the magnetic field tries to broaden the intermediate region, where all the molecules are already correctly aligned.

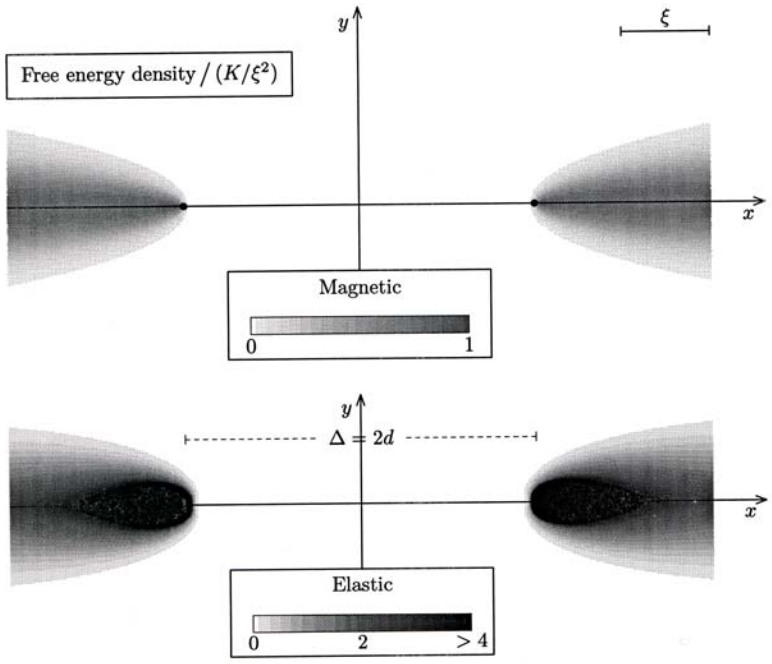

FIG. 5. *Density plot of the magnetic free-energy density (upper graph) and the elastic free-energy density (lower graph), computed from the analytical solution* (3.1). *For these particular values of the distance and the magnetic coherence length, it will turn out that the defects are separating (that is,* $v < 0$*). Both the magnetic and the elastic free-energy densities are mainly concentrated on the defect walls. Between the defects, the free-energy density is negligible.*

The free energy associated with the traveling configuration (3.1) is given by

$$\mathcal{F}(\Delta,\lambda) = K\pi\left[\frac{\pi L}{\xi} + \operatorname{arcsinh}\frac{\xi}{r_\circ} - K_0\left(\frac{\Delta}{\xi}\right) - \frac{\pi\Delta}{\xi} + 2\int_0^{\infty} \frac{\sin^2\frac{\Delta s}{2\xi}}{s^2\sqrt{1+s^2}}\,ds\right.$$

$$\left. + F_1(\Delta,\lambda) + F_2(\lambda)\right]. \tag{3.2}$$

The first term in (3.2) diverges in the $L \to +\infty$ limit. (L is the horizontal scale of the system: $x \in [-L, L]$.) This term corresponds to the energy of the two walls.

The second term is related to the infinite elastic energy stored in the defects. ($r_\circ$ is the core radius as in the preceding section.) The next three terms depend only on the defect distance, and are independent of their velocity. In particular, the term containing the modified Bessel function of the second kind K_0 is able to cancel the free-energy divergence when $\Delta \simeq r_\circ$. Finally, both F_1 and F_2 are velocity corrections, which vanish if λ (i.e., v) vanishes:

$$F_1(\Delta,\lambda) := \frac{1}{2}\int_0^\infty \mathrm{Re}\left[\left(\mu(\lambda,s)-\mu(0,s)+\frac{1}{\mu(\lambda,s)}-\frac{1}{\mu(0,s)}\right)\left(1-\mathrm{e}^{-\mathrm{i}s\Delta/\xi}\right)\right]\frac{ds}{s^2}$$
$$-\frac{1}{2}\int_0^\infty \mathrm{Re}\left[\left(\frac{1}{\mu(\lambda,s)}-\frac{1}{\mu(0,s)}\right)\mathrm{e}^{-\mathrm{i}s\Delta/\xi}\right]ds, \tag{3.3}$$

$$F_2(\lambda) := \int_0^\infty \left(\frac{1}{\mu(\lambda,s)+\mu(-\lambda,s)}-\frac{1}{2\mu(0,s)}\right)ds$$
$$-\frac{1}{4}\int_0^\infty \frac{\left(\mu(\lambda,s)-\mu(-\lambda,s)\right)^2}{\mu(\lambda,s)+\mu(-\lambda,s)}\left(1+\frac{1}{\mu(\lambda,s)\mu(-\lambda,s)}\right)\frac{ds}{s^2}, \tag{3.4}$$

where $\mu(\lambda,s)$ is the positive-real-part square root of $\mu^2(\lambda,s) = 1+\mathrm{i}s\lambda+s^2$, and $\lambda = \frac{\gamma_1}{2\sqrt{K\chi_\mathrm{a}}}\frac{v}{|H|}$, as in the preceding section.

In the absence of backflow, the dissipation stems only from the director rotation. When computing $\dot\Phi$, we assume that only the defect position d depends on time. In our stationary approximation, we thus neglect the time derivative of the velocity v. However, we remark that when we want to determine the nonstationary effects depending on $\dot v$, we are no longer allowed to use the solution (3.1). The dissipation function is given by

$$\mathcal{D} = \gamma_1\int_{\mathbb{R}^2}\dot\Phi^2\,dx\,dy = \frac{\pi\dot d^2}{2}\left[\mathrm{arcsinh}\,\frac{\xi}{r_\circ}+K_0\left(\frac{\Delta}{\xi}\right)+G_1(\Delta,\lambda)+G_2(\lambda)\right], \tag{3.5}$$

with

$$G_1(\Delta,\lambda) := \int_0^\infty \mathrm{Re}\left[\left(\frac{1}{\mu(\lambda,s)}-\frac{1}{\mu(0,s)}\right)\mathrm{e}^{-\mathrm{i}s\Delta/\xi}\right]ds \qquad \text{and} \tag{3.6}$$

$$G_2(\lambda) := 2\int_0^\infty \left(\frac{1}{\mu(\lambda,s)+\mu(-\lambda,s)}-\frac{1}{2\mu(0,s)}\right)ds. \tag{3.7}$$

The functions G_1 and G_2 vanish in the low-velocity limit $v\to 0$. The dissipation principle delivers the self-consistency equation that determines the defect velocity $v=-\dot d$:

$$\frac{\partial\mathcal{F}}{\partial d}\,\dot d+\mathcal{D}=0 \qquad \Longleftrightarrow$$
$$K_1\left(\frac{\Delta}{\xi}\right)+\frac{\Delta}{\xi}\int_0^\infty \frac{\sin s\;ds}{s\sqrt{\frac{\Delta^2}{\xi^2}+s^2}}+\xi\,\frac{\partial F_1}{\partial\Delta}$$
$$-\frac{\lambda}{2}\left[\mathrm{arcsinh}\,\frac{\xi}{r_\circ}+K_0\left(\frac{\Delta}{\xi}\right)+G_1(\Delta,\lambda)+G_2(\lambda)\right]=\pi. \tag{3.8}$$

Before analyzing the solutions $\lambda(\Delta)$ of (3.8), we want to stress the importance of the first two terms on its left-hand side. In fact, if we define

$$f(x) := K_1(x)+x\int_0^\infty \frac{\sin s}{s\sqrt{x^2+s^2}}\,ds, \tag{3.9}$$

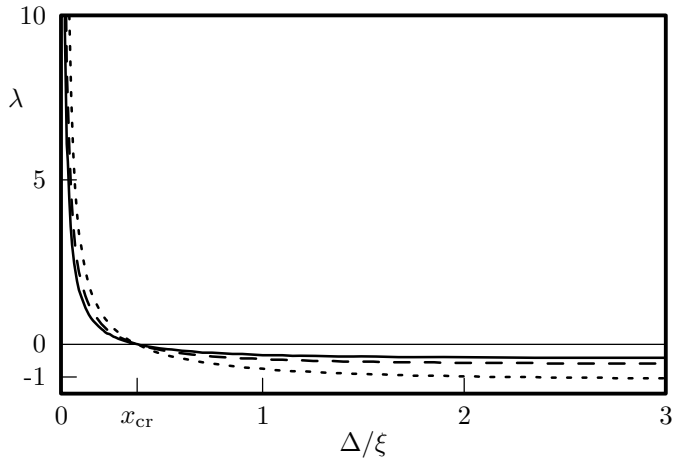

FIG. 6. *Defect velocity as a function of the external field for different values of the core radius* $r_\circ$: $\xi/r_\circ = 10$ *(dotted line),* 100 *(dashed),* 1000 *(full). For any value of the core radius, the defects attract only if their distance is smaller than* $\Delta_{\rm cr}$.

we have

$$\left.\frac{\partial \mathcal{F}}{\partial \Delta}\right|_{v=0} = \frac{K\pi}{\xi}\left[f\left(\frac{\Delta}{\xi}\right) - \pi\right]. \tag{3.10}$$

Thus, in general, the defects will approach or separate, depending on whether $f(\Delta/\xi)$ exceeds π or not. We postpone the analysis of the properties of f to the next subsection, when we will generalize (3.10) to the case of tilted applied fields. For now, we only remark that $f(x) = \pi$ when $x = x_{\rm cr} \doteq 0.377388$. The function f is greater than π (thus inducing defect attraction) when $\Delta < x_{\rm cr}\,\xi$. Defect repulsion is induced at distances greater than $x_{\rm cr}\,\xi$.

Figure 6 illustrates the numerical solutions of (3.8) for three different values of the ratio between the magnetic coherence length and the core radius. They exhibit the following properties:

- In the large distance limit, all Bessel functions decay exponentially with Δ/ξ. The functions G_1, G_2, and the derivative of F_1 vanish too. Furthermore,

$$\lim_{x\to\infty} x\int_0^\infty \frac{\sin s}{s\sqrt{x^2+s^2}}\,ds = \int_0^\infty \frac{\sin s}{s}\,ds = \frac{\pi}{2}\,. \tag{3.11}$$

  Thus, the large-distance limit of λ is given by

$$\lim_{\Delta\to\infty} \lambda(\Delta) = -\frac{\pi}{\operatorname{arcsinh}(\xi/r_\circ)} \quad\Longrightarrow\quad v \simeq -\frac{2\pi\sqrt{K\chi_{\rm a}}\,|H|}{\gamma_1\,\operatorname{arcsinh}(\xi/r_\circ)} \quad \text{when } \Delta \gg \xi. \tag{3.12}$$

  The defects repel and move at a constant speed. In fact, if we compare (3.12) with (2.20), we notice that in the large-distance limit the defects behave independently, each moving at the velocity computed in the 1-defect case, since $\operatorname{arcsinh}(\xi/r_\circ) \simeq \log(\xi/r_\circ)$ when $\xi \gg r_\circ$.
- The critical distance at which the defect interaction changes sign does not depend on the core radius $r_\circ$; all plots in Figure 6 cross the x-axis at $\Delta = x_{\rm cr}\,\xi$.
- In the small-distance limit, the stationary approximation we have used is not well justified. In this limit, the velocity diverges, and all terms depending

on $\dot{v}$ must be taken into account in the equation of motion. In any case, we remark that the Bessel function K_1 induces a divergence in the derivative of the free-energy that scales as the inverse of the defect distance. Figure 6 suggests that the fully nonlinear regime is limited to distances much smaller than the magnetic coherence length.

3.1. Tilted external fields. Let us now imagine that the external field is rotated by an angle α with respect to the direction of Figure 4. In this case, the nematic director is forced to relax to the external field direction everywhere but on the topologically irreducible π-wall. The motion will be much more complex—the defects will rotate, and the π-wall will not necessarily be straight at all times. However, it is possible to ascertain whether the defect interaction will lead to attraction or repulsion. To this end, we pin the defects at a distance Δ, and we look for the stationary director field in the presence of a tilted external field. Then, we compute the free energy of the stationary solution, and we check the sign of its derivative with respect to the distance. We stress that it is not possible to use this derivative in a dissipation principle to obtain a defect velocity. However, its sign will determine whether or not the defects, whatever their complex motion, will approach each other.

The stationary director field can be simply derived by running through the above steps again. In the presence of two defects placed at $x = \pm d$, and an external field tilted at an angle α with respect to the x-axis, the stationary configuration is given by

$$\Phi(x,y) = \varepsilon(y)\left[\alpha + \left(\frac{\pi}{2} - \alpha\right) \mathrm{e}^{-\frac{|y|}{\xi}} - \int_0^{+\infty} \cos qx \, \sin qd \, \mathrm{e}^{-k_0(q)\,|y|} \, \frac{dq}{q}\right], \tag{3.13}$$

where $k_0(q)$ coincides with the zero-velocity limit of $k(q)$ above: $k_0(q) := \sqrt{q^2 + 1/\xi^2}$.

If we compute the free energy associated with (3.13), and differentiate it with respect to Δ, we obtain the generalization of (3.10):

$$\left.\frac{\partial \mathcal{F}}{\partial \Delta}\right|_{v=0} = \frac{K\pi}{\xi}\left[f\left(\frac{\Delta}{\xi}\right) - \big(\pi - 2\alpha\big)\right], \tag{3.14}$$

with the same f defined in (3.9). The left panel of Figure 7 shows the plot of f. It enjoys the following properties:

- $f'(x) = \frac{1}{2}\big(K_0(x) - K_2(x)\big) < 0$ for all $x > 0$. Thus, the critical distance at which the defect interaction becomes repulsive increases when the external field is tilted. Furthermore, the free energy is a concave function of the distance between the defects.
- $\lim_{x\to 0} f(x) = +\infty$ and $\lim_{x\to\infty} f(x) = \frac{\pi}{2}$. More precisely,

$$\begin{aligned} f(x) &= \frac{1}{x} - \frac{x}{2}\log x + O(x) \text{ as } x \to 0^+ \quad \text{and} \\ f(x) &= \frac{\pi}{2} + o\left(\mathrm{e}^{-x}\right) \text{ as } x \to +\infty. \end{aligned} \tag{3.15}$$

Thus, the equation

$$\frac{\partial \mathcal{F}}{\partial \Delta} = 0 \quad \Longleftrightarrow \quad f(x) = \pi - 2\alpha, \tag{3.16}$$

which determines the equilibrium distances, possesses exactly one solution if and only if $\alpha < \frac{\pi}{4}$. This limiting value for the tilting angle could be predicted

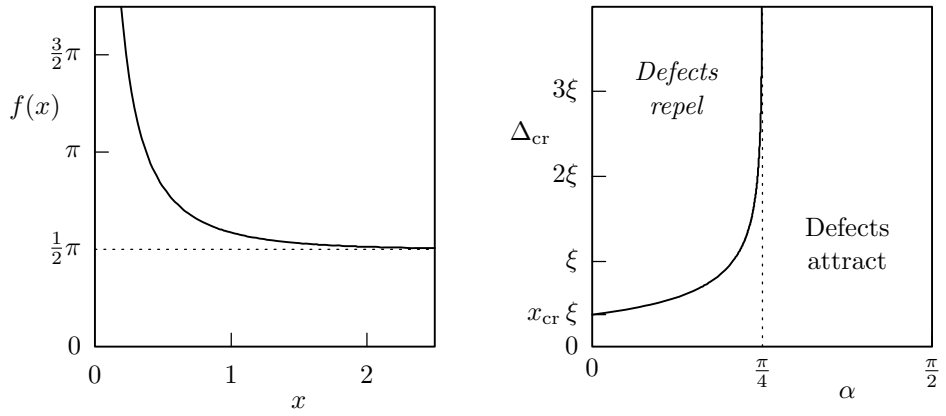

FIG. 7. *Left: Plot of the function f defined in the text. Right: Critical value of the defect distance as a function of the tilt angle α.*

easily. In fact, if the external field determines an angle greater than $\frac{\pi}{4}$ with the defect line, the director orientation between the defects costs *more* magnetic energy than the director orientation outside the defects. Thus, in this case, the external field strengthens the defect attraction at any distance.

In summary, we have the following:

- When $\alpha = 0$, the defects attract if $\Delta < \Delta_{\rm cr}\left(\frac{\pi}{2}\right) = 0.3774\xi$; they repel when $\Delta > \Delta_{\rm cr}\left(\frac{\pi}{2}\right)$.
- When $\alpha > 0$, the critical distance $\Delta_{\rm cr}(\beta)$ increases. It diverges when $\alpha \to \frac{\pi}{4}^{-}$.
- When $\alpha \geq \frac{\pi}{4}$, there is no critical distance: the defects always attract (the external field enhances the attraction).

4. Discussion. We have studied the motion of a single disclination, and a disclination dipole in an external field. Our results show that it is possible to drive the disclinations by suitably adjusting the external field direction and strength.

In the case of a single disclination, we have shown that the disclination velocity depends almost linearly on the field strength, since the coefficient depends on the logarithm of (2.20). Figure 3 shows that the linear scaling is abandoned when $\xi \simeq r_{\circ}$. Equation (2.21) shows that below this regime the disclination velocity is expected to scale as the square of the applied strength. However, this last prediction should be tested carefully, since it is surely influenced by our assumption that the core radius does not depend on the field strength.

A comparison between our analytical results and the experimental observations confirms our predictions and gives an estimate of the quantitative corrections that backflow effects require. If we again let v be the defect speed and H the external field intensity, the pioneering work of Geurst, Spruijt, and Gerritsma [30] reported a quadratic scaling $v \sim H^2$. However, their geometry is completely different from ours, since in this work the defect was confined in a very thin cell. Indeed, those authors observed that their measured velocity was consistent with the assumption that the presence of the external field did not influence the director field at all. The nematic cell was wider in the measurements reported by Cladis, van Saarloos, and Kortan [31], whose data fitted almost perfectly a linear relation similar to (2.20). This latter group realized that the defect speed is determined by a balance between the free energy gained by reducing the wall area and the dissipation stemming from the defect

core. Their estimate of the free energy gain coincides with ours (see (2.17)), but again they neglected the electric field effects when (over)estimating the dissipation. If we insert their numerical values into (2.20), we obtain a much closer value for the slope of their linear fit: their estimated defect speed was 0.43 times the actual measured speed, while, if we replace in (2.20) the same values for the same material parameters, the derived defect speed turns out to be 0.73 times the observed velocity.

We have also computed the velocity of two opposite disclinations in the presence of a field that promotes the director orientation between them. The velocity depends on the defect distance Δ, but, whatever the value of the ratio $\xi/r_\circ$, the defects approach if Δ is smaller than a critical distance $\Delta_{\rm cr}$; otherwise, they repel. We have finally generalized our calculations in order to deal with rotated external fields. Figure 7 (right) shows how the $\Delta_{\rm cr}$ depends on the angle α, which the external field determines, with the lie, which connects the defects.

The introduction of backflow may change the picture we have developed, in both the one- and two-disclination cases. In the one-disclination case the dissipation may sometimes be significantly reduced. The system can match the disclination motion with a flow that almost cancels the dissipation in the crucial core region. Whether this occurs seems likely to depend on the charge of the central disclination. We note that central physical and mathematical issues associated with backflow in nematic liquid crystal problems remain open even over a quarter of a century after its essential role was first realized [21].

Likewise in the two-disclination problem, our computed defect velocity is symmetrical in both disclinations. This is also an effect of the no-backflow simplification. A generalization of the present study should allow one to compute the different approaching or separating velocities. It could even happen that one defect moves towards the other, but that the other retreats faster still, allowing the defects eventually to separate. However, the existence of a critical distance that reverses the defect interaction cannot be erased by backflow effects. The critical distance stems from the balance between the elastic and magnetic free-energy gains. The magnetic gain does not depend on the defect distance, while the elastic gain vanishes when the defects move apart. Thus, at some intermediate distance one overwhelms the other.

SLOW PASSAGE THROUGH RESONANCE FOR A WEAKLY NONLINEAR DISPERSIVE WAVE*

SERGEI GLEBOV†, OLEG KISELEV‡, AND VLADIMIR LAZAREV†

Abstract. A solution of the nonlinear Klein–Gordon equation perturbed by a small external force is investigated. The frequency of the perturbation varies slowly and passes through a resonance. The resonance generates solitary packets of waves. The full asymptotic description of this process is presented.

Key words. nonlinear optics, resonance, solitons, nonlinear waves

Introduction. This work is devoted to the problem of generation of a nearly monochromatic weakly nonlinear dispersive wave with small amplitude in a strong nonlinear media. It is well known that packets of nearly monochromatic waves propagate without changing their shape when the envelope function of the packet is a soliton of the nonlinear Schrödinger equation (NLSE). The solitary packets of waves would be more suitable for communication in optical fibers over a large distance if one could control the parameters of the envelope function for such packets. The wave packets have a soliton-like shape form for sufficiently large range of initial data. But the parameters of such self-generated solitons are difficult to predict in practice. This is explained by an instability of the parameters for solitons with respect to the initial data.

Here we propose a new approach for the generation of solitary packets of waves with given parameters. In our approach the wave packets appear due to a slow passage of the external driving force through the resonance. After the resonance, the envelope function of the wave packet is determined by the NLSE. In the most important cases the envelope function is a sequence of solitary waves which are called solitons. The wave packets, with the solitons as the envelope function, are propagated without dissipation. The parameters of the solitons are obviously defined by the value of the driving force on a resonance curve. We demonstrate this phenomenon for the perturbed nonlinear Klein–Gordon equation.

Here we give the mathematical basis for the proposed approach. This basis allows us to derive explicit formulas that define parameters for the solitary packets of waves with respect to the external driving force. Generation of the solitary packets of waves by the small driving force is described in detail. The formulas for the asymptotic solution before, after, and in the neighborhood of the resonant curve are obtained.

The proposed approach is based on a local resonance phenomenon. The local resonance in linear ordinary differential equations was investigated in papers [1, 2]. Later this phenomenon was studied in partial differential equations in the linear case

[3] and in the weak nonlinear case [4, 5]. In these papers it was shown that the amplitude of the wave increases linearly when the wave passes through the local resonance. The increase of the amplitude is proportional to the width of the local resonance layer.

After the resonance a special proportion between the order of the solution and scales of independent variables appears. This magic proportion gives the NLSE for the envelope function. The deriving of the NLSE in such a case is a well-known result [6, 7, 8]. This result is justified in [9].

An important kind of solution of the NLSE is the soliton. The phenomenon of the generation of solitary waves for some nonlinear equations due to modulation instability is a well-known result [10]. For example, the detailed analytical description of the disappearance (generation) of the soliton due to modulation instability in the case of the Kadomtsev–Petviashvili equation was done in [11]. Some results about an appearance of solitons in the nonlinear Schrödinger equation due to instability were presented in [12]. The structural instability of the solitons for the Davey–Stewartson equation was shown in [13]. Such perturbations do not allow us to obtain solitons with the given parameters.

The generation of solitary waves by a small external resonant force was found by numerical simulation [14]. This simulation shows the possibility of generation of solitons by the external driving force. But it does not allow us to relate the parameters of the solitons and the perturbation. Therefore the problem about the generation of the soliton with the given parameters was still open.

The goal of this paper is to show that the process of generation of the solitary waves due to the local resonance is universal. This process allows us to control the parameters of the generated waves. This phenomenon previously was asymptotically investigated in the case of the nonlinear Schrödinger equation in [15]. In our work we consider the similar phenomenon in the nonlinear Klein–Gordon equation. Our approach demonstrates that solitary waves with the given parameters can be obtained for nonlinear systems.

This paper has the following structure. Section 1 contains the main result and an example of numerical simulations. Section 2 contains the asymptotic construction in the preresonant domain. In section 3 we construct the asymptotic solution in the neighborhood of the resonant curve. Section 4 is devoted to the construction of the postresonant asymptotics. All asymptotic approximations are matched. In the Summary (section 5) we outline the results and open problems.

1. Statement of the problem and result.

1.1. Statement of the problem. Let us consider the Klein–Gordon equation with a cubic nonlinearity

$$\partial_t^2 U - \partial_x^2 U + U + \gamma U^3 = \varepsilon^2 f(\varepsilon x) \exp\left\{ i \frac{S(\varepsilon^2 t, \varepsilon^2 x)}{\varepsilon^2} \right\} + \text{c.c.}, \quad 0 < \varepsilon \ll 1. \tag{1}$$

Here $\gamma =$ constant and c.c. stands for complex conjugate; $f(y)$ is smooth and rapidly vanishes as $y \to \pm\infty$. The phase function $S(y, z)$ of the driving force and all derivatives with respect to y, z are bounded. Here and below we use the following notation:

$$x_j = \varepsilon^j x, \quad t_j = \varepsilon^j t, \quad j = 1, 2;$$

$$l(t_2, x_2) \equiv (\partial_{t_2} S)^2 - (\partial_{x_2} S)^2 - 1.$$

We will construct a special asymptotic solution of (1) in a strip of finite width with respect to x_2, t_2. This domain covers the resonant curve $l = 0$. This asymptotic solution corresponds the forced oscillations as $l < 0$,

$$U \sim -\varepsilon^2 \frac{f}{l} \exp\left(\frac{iS(t_2, x_2)}{\varepsilon^2}\right) + c.c. \tag{2}$$

1.2. Main result. Let us formulate the main result of the work. If the solution of (1) has the form (2) when $l < 0$, then in the domain $l > 0$ this asymptotic solution is

$$U(x, t, \varepsilon) \sim \varepsilon \Psi(x_1, t_1, t_2) \exp\left\{\frac{i\varphi(x_2, t_2)}{\varepsilon^2}\right\} + c.c. \tag{3}$$

The phase function φ satisfies the eikonal equation

$$(\partial_{t_2}\varphi)^2 - (\partial_{x_2}\varphi)^2 - 1 = 0$$

with conditions

$$\varphi|_{l=0} = S|_{l=0}, \quad \partial_{t_2}\varphi|_{l=0} = \partial_{t_2} S|_{l=0}.$$

The envelope function of the leading-order term is a solution of the NLSE

$$2i\partial_{t_2}\varphi\partial_{t_2}\Psi + \partial_\xi^2\Psi + i[\partial_{t_2}^2\varphi - \partial_{x_2}^2\varphi]\Psi + \gamma|\Psi|^2\Psi = 0,$$

where the ξ is defined by

$$\frac{dx_1}{d\xi} = \partial_{t_2}\varphi, \quad \frac{dt_1}{d\xi} = \partial_{x_2}\varphi.$$

The initial condition for Ψ is

$$\Psi|_{l=0} = \int_{-\infty}^{\infty} d\sigma f(x_1) \exp\left(i\int_0^\sigma d\mu\lambda(x_1, t_1, \varepsilon)\right). \tag{4}$$

The integration in this integral is done in the characteristic direction related with (24), (25).

1.3. Higher-order terms and matching. The structure of the constructed asymptotic solution when $l < 0$ and $l > 0$ is sufficiently obvious. We concentrate on the description of the changing of the solution from the preresonant to postresonant form. This transition takes place in the thin layer near the curve $l = 0$. In this transition layer the amplitude of the solution increases due to the resonant pumping. The value of the amplitude is defined by the width of the resonant layer. We found the width of the layer by construction and analysis of the higher-order terms of the asymptotic solution in all domains. This analysis looks very complicated, but it is necessary to match the asymptotics of the solution in different domains and obtain formula (4). This formula defines the leading-order term of the solution after the slow passage through the resonance.

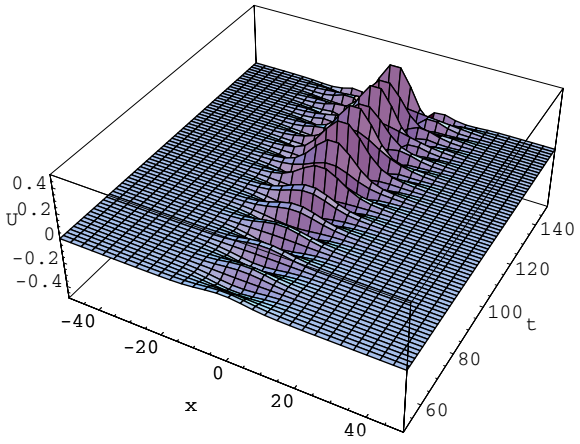

FIG. 1. *This picture shows the generation of the solitary packet of waves for* (1) *with special right-hand side* (5) *and at* $\varepsilon = 0.1$. *Initial conditions are* $U|_{t=0} = -\varepsilon^2 f \exp(iS/\varepsilon^2)|_{t=0}$, $\partial_t U|_{t=0} = -\varepsilon^2 \partial_t (f \exp(iS/\varepsilon^2))|_{t=0}$. *The resonant curve is* $t = 100$.

1.4. Numeric simulations. To illustrate the obtained result we consider (1) with $\gamma = 2$ and the simplest driving force, where

$$S = \frac{t_2^2}{2}, \quad f = \frac{2\sqrt{2}}{\sqrt{\pi}\cosh(2x_1)}. \tag{5}$$

In this case the curve of the local resonance is the line $t_2 = 1$. The preresonant solution has the form

$$U \sim \frac{-\varepsilon^2}{(t_2 - 1)} \frac{2\sqrt{2}}{\sqrt{\pi}\cosh(2x_1)} \cos\left(\frac{it_2^2}{\varepsilon^2}\right), \quad 0 < t_2 < 1.$$

In the domain $t_2 > 1$ the solution has the form

$$U \sim \varepsilon \exp\{i\varphi\left\{\frac{(x_2, t_2)}{\varepsilon^2}\right\} \Psi(x_1, t_1, t_2) + c.c.$$

Here $\varphi = t_2 - 1/2$. The function $\Psi(x_1, t_1, t_2)$ is the solution of the Cauchy problem for the NLSE:

$$2i\partial_{t_2}\Psi + \partial^2_{x_1 x_1}\Psi + 2|\Psi|^2\Psi = 0,$$

$$\Psi|_{t_2=1} = \frac{\sqrt{2}(1+i)}{\cosh(2x_1)}.$$

The solution of this Cauchy problem is the pure soliton. This soliton is the envelope function of the fast oscillating carrier in the postresonant solution of (1). The carrier with the soliton as the envelope function is the single solitary packet of waves. This packet is propagated in the nonlinear media without dispersion.

The numerical simulation at $\varepsilon = 0.1$ is given in Figure 1. The profile of the generation process for the solitary packet of waves can be seen in Figure 2.

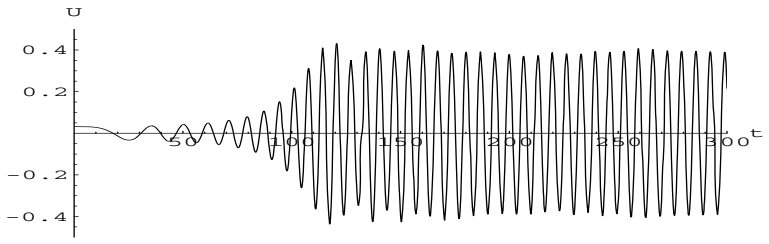

FIG. 2. *This picture shows a profile* $(U(x,t)|_{x=0})$ *of the generation process for the solitary packet of waves.*

1.5. Qualitative analysis. Here we explain the behavior of the solution for (1). All domains where we construct the solution are separated on three pairwise joint domains. The preresonant domain corresponds to the forced oscillations with amplitude of order ε^2. This oscillations down when the driving force becomes resonant.

The resonant layer is a thin domain near the resonant curve $l(x_2,t_2)=0$. In this layer the amplitude of the oscillations increases up to the order ε:

$$U(x,t,\varepsilon)\sim \varepsilon W_{1,1}(x_1,t_1,x_2,t_2)\exp\left\{\frac{iS}{\varepsilon^2}\right\}+c.c..$$

The coefficient $W_{1,1}(x_1,t_1,x_2,t_2)$ is defined by nonautonomous first-order partial differential equation

$$2i\partial_{t_2}S\partial_{t_1}W_{1,1}-2i\partial_{x_2}S\partial_{x_1}W_{1,1}-\lambda W_{1,1}=f,$$

with a given asymptotic behavior:

$$W_{1,1}\sim\frac{-f}{\lambda},\quad \lambda\to-\infty.$$

Here $\lambda=l/\varepsilon$.

The asymptotic behavior of $W_{1,1}$ as $\lambda\to\infty$ allows us to relate formulas (2) and (3).

The equation for $W_{1,1}$ may be written in the form of a first-order ordinary differential equation along the characteristic direction

$$\frac{d}{d\sigma}W_{1,1}+\lambda W_{1,1}=f.$$

Such an ordinary equation appears under studying of slow passage through resonance for a one-dimensional oscillator with slowly varying frequency [1]. The solution of equations of such type is defined by Fresnel integrals.

After the passage through this thin layer, the driving force becomes nonresonant. In this postresonant domain the amplitude of the solution has the order ε. In Figure 3 one can see the schematic position of the domains mentioned above.

Remark on WKB asymptotics. In this work we describe the special asymptotic solution of (1). This solution is defined by the driving force in the domain $l<0$. One can add any solution of WKB type [16] of the order ε^2 to this constructed solution, leading to an asymptotic solution for (1) in the form

$$\tilde{U}=U(t,x,\varepsilon)+\sum_{n\geq 2}^{N}\varepsilon^n\mathbf{U}_n(t,x,\varepsilon).$$

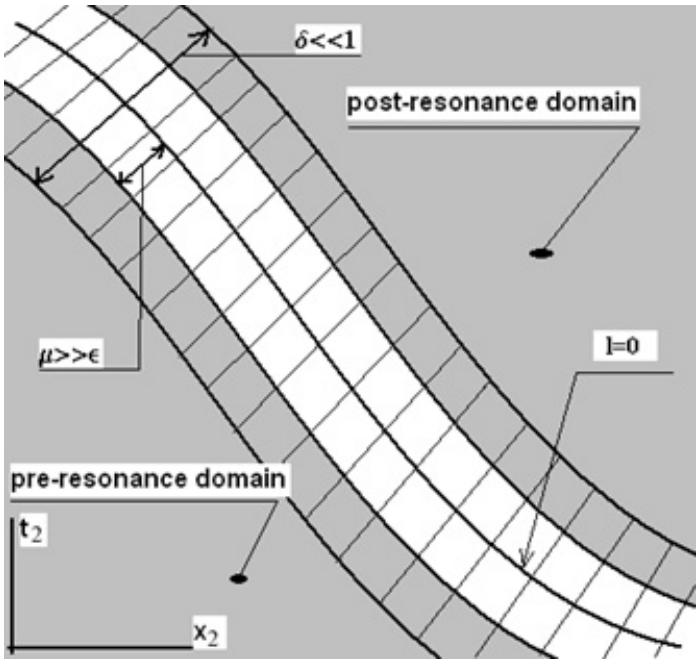

FIG. 3. *Schematic position of domains.*

The coefficients $\mathbf{U}_n(t,x,\varepsilon)$ of the asymptotics are calculated by standard methods of WKB-theory. This additional term leads to ponderous formulas and does not change the leading-order term of the postresonant asymptotics.

2. Preresonance expansion. In this section the formal asymptotic solution is constructed in the domain before the resonance. This domain is defined by the condition $l < 0$. The asymptotic expansion has a WKB-type form. The leading-order term of the asymptotics has the order of the driving force and oscillates with the frequency of the perturbation. The constructed asymptotics is valid when $-l \gg \varepsilon$. The result of this section is formulated below.

THEOREM 1. *In the domain $-l \gg \varepsilon$ the formal asymptotic solution of* (1) *modulo $O(\varepsilon^{N+1})$ has the form*

$$U = \sum_{n\geq 2}^{N} \varepsilon^n U_n(t,x,\varepsilon), \tag{6}$$

where

$$U_n = \sum_{k\in\Omega_n} U_{n,k}(t_2,x_2,\varepsilon x)\exp\left\{ik\frac{S(t_2,x_2)}{\varepsilon^2}\right\}.$$

The set Ω_n for the higher-order term is described by the formula

$$\Omega_n = \begin{cases} \{\pm 1\}, & n \leq 5, \\ \{\pm 1, \pm 3, \ldots, \pm(2l+3)\}, & l = \big[(n-6)/4\big], \quad n \geq 6. \end{cases}$$

The functions $U_{n,k}$ and $U_{n,-k}$ are complex conjugated.

The coefficients of the asymptotics $U_{n,k}$ are defined out of algebraic equations (7), (8), (9), *and* (11).

The proof of the theorem contains two steps. In the first step (subsection 2.1) we construct the coefficients of (6), and in the second step (subsection 2.2) we determine the domain of validity for (6).

2.1. Construction of preresonant asymptotics. Let us substitute (6) into (1) and collect the terms of the same order of ε. As a result we obtain a recurrent sequence of algebraic equations,

$$U_{2,1} = -\frac{f}{l}, \tag{7}$$

$$U_{3,1} = 2i\frac{\partial_{x_1} f \partial_{x_2} S}{l^2}, \tag{8}$$

$$U_{4,1} = \frac{2if[\partial_{t_2} S \partial_{t_2} l - \partial_{x_2} S \partial_{x_2} l] - 4(\partial_{x_2} S)^2 \partial_{x_1}^2 f}{l^3} - \frac{2i\partial_{t_2} f \partial_{t_2} S + \partial_{x_1}^2 f + i\partial_{t_2}^2 Sf}{l^2}, \tag{9}$$

where

$$l = (\partial_{t_2} S)^2 - (\partial_{x_2} S)^2 - 1.$$

The curve where the phase function S satisfies the eikonal equation is called the resonant curve,

$$l[S] = (\partial_{t_2} S)^2 - (\partial_{x_2} S)^2 - 1 = 0. \tag{10}$$

The amplitude $U_{n,1}$ has a singularity on this curve.

The formula for the nth-order term has the form

$$U_{n,k} = \frac{1}{l}\Bigg[\partial_{t_2 t_2}^2 U_{n-4,k} + 2ik\partial_{t_2} S \partial_{t_2} U_{n-2,k} + ikS_{t_2 t_2} U_{n-2,k} - 2ik\partial_{x_2} S \partial_{x_2} U_{n-2,k} - ik\partial_{x_2}^2 S U_{n-2,k} - \partial_{x_1 x_1}^2 U_{n-2,k} - 2\partial_{x_1 x_2}^2 U_{n-3,k} - \partial_{x_2 x_2}^2 U_{n-4,k} - 2ik\partial_{x_2} S \partial_{x_1} U_{n-1,k} + \gamma \sum_{\substack{n_1+n_2+n_3=n,\\ k_1+k_2+k_3=k \\ k\in\Omega_n}} U_{n_1,k_1} U_{n_2,k_2} U_{n_3,k_3}\Bigg]. \tag{11}$$

The first step of the proof of Theorem 1 is completed.

2.2. The asymptotic behavior of the coefficients. To realize the second step of the proof for Theorem 1 we need to determine the behavior of the coefficients of (6) as $l \to -0$.

LEMMA 1. *The coefficient $U_{n,k}$ has the following behavior:*

$$U_{n,k} = O(l^{-(n-k)}), \quad k > 0, l \to -0. \tag{12}$$

Proof. Let us prove this formula at $k = 1$. The validity of formula (12) for $n = 2, 3, 4$ obtains from (7), (8), (9). Now suppose that this formula is valid for the term $U_{n-1,1}$. The increase of the order of the singularity when $l \to 0$ occurs due to differentiation with respect to x_2, t_2 and the nonlinear term in formula (11). Differentiation of the terms in formula (11) leads to formula (12).

Let us consider $U_{n,k}$ for $k > 1$. The validity of formula (12) for small values of n and k obtains by direct calculations. Consider the nth-order term. It contains the terms with different values of k. The higher-order terms with $k = 3$ have the greatest order of singularity,

$$U_{n,3} = O(l^{-(n-3)}), \quad l \to -0. \tag{13}$$

It takes place because the right-hand side of (11) contains the term $U_{n-4,\pm1}U_{2,\pm1} \cdot U_{2,\pm1}$. The calculation of the order of singularity for this term leads to formula (13). The terms of the type of $U_{n_3,\pm3}U_{n_1,\mp k_1}U_{n_2,\pm k_1}$, $n_1 + n_2 + n_3 = n$, lead to weak singularities; for example, for $k_1 = 3$ we obtain that the order of singularity is equal to $n - 9$.

Consider the nonlinear term $U_{n_1,k_1}U_{n_2,k_2}U_{n_3,k_3}$ from right-hand side of (11) when the number of the higher-order term is equal to n. Calculate the order of the singularity for this term using the $(n-1)$th step of the induction. The indexes of the amplitudes are related by formulas

$$n_1 + n_2 + n_3 = n, \quad k_1 + k_2 + k_3 = k.$$

Using (12) for $n_1, n_2, n_3 < n$, we obtain, that the order of the singularity for this term is equal to $(n - k)$.

The right-hand side of (11) contains derivatives of previous terms with respect to x_2, t_2. It leads to the increase of the order of the singularity, but the leading order nevertheless we obtain from nonlinear terms. The lemma is proved. □

Domain of validity. The domain of validity as $l \to -0$ for the formal asymptotic solution in form (6) is defined by

$$\varepsilon \max_{x_2,t_2} |U_{n+1}| = o\left(\max_{x_2,t_2} |U_n|\right), \quad l < 0, \quad \varepsilon \to 0.$$

Using Lemma 1, we obtain

$$-l \gg \varepsilon.$$

Theorem 1 is proved. □

Remark. The constructed asymptotic solution (6) is also valid in the domain $l \gg \varepsilon$. However, we use the asymptotics for the preresonant domain (when $l < 0$) only.

Lemma 1 gives the asymptotic representation for (6), as $l \to -0$ has the form

$$U = \sum_{n=2}^{N} \varepsilon^n \sum_{k \in \Omega_n} \exp\left\{\frac{ikS}{\varepsilon^2}\right\} \sum_{j=-(n-k)}^{\infty} U_{n,k}^j \, l^j, \quad l \to -0. \tag{14}$$

3. Internal asymptotics. This part of the paper contains the asymptotic construction of the solution for (1) in the neighborhood of the curve $l = 0$. The domain of validity of this asymptotics intersects with the domain of validity of expansion (6). These expansions are matched.

THEOREM 2. *In the domain $|l| \ll 1$ the formal asymptotic solution for* (1) *modulo* $O(\varepsilon^{N+1})$ *has the form*

$$U = \sum_{n\geq 1}^{N} \varepsilon^n W_n(t_1, x_1, t_2, x_2, \varepsilon), \tag{15}$$

where

$$W_n = \sum_{k\in\Omega_n} W_{n,k}(x_2, t_2, x_1, t_1) \exp\left\{ ik\frac{S(t_2, x_2)}{\varepsilon^2}\right\}. \tag{16}$$

The function $W_{n,1}$ is a solution of the problem for (21), (23) *with zero condition as $\lambda \to -\infty$. When $k \neq 1$, $W_{n,k}$ is the solution of algebraic equation* (23). *The functions $W_{n,k}$ and $W_{n,-k}$ are complex conjugated.*

There is an essential difference between asymptotics (15) and external preresonance asymptotics (6). In the first place the leading-order term in (15) has order ε, while the leading order term in (6) has order ε^2. In the second place the coefficients of asymptotics (15) depend on fast variables $x_1 = x_2/\varepsilon$ and $t_1 = t_2/\varepsilon$.

The proof of theorem 2 consists of three steps. In the first step (subsection3.1) we derive equations for coefficients of the asymptotics. In the second step (subsection3.2) we solve the problems for the asymptotic coefficients. In the third step (subsection3.3) we determine the domain of the validity for expansion (15).

3.1. The equations for coefficients. Let us construct the internal asymptotic expansion in the domain $|l| \ll 1$. Define

$$\lambda(x_1, t_1, \varepsilon) = \frac{1}{\varepsilon} l(\varepsilon x_1, \varepsilon t_1). \tag{17}$$

In the domain $1 \ll -\lambda \ll \varepsilon^{-1}$ both asymptotics (6) and (15) are valid. This fact allows us to obtain the asymptotic representation for coefficients of the internal asymptotics. Substituting $l = \varepsilon\lambda$ into formula (14) and expanding the obtained expression in powers of ε, we find that

$$W_{n,k} = \sum_{j=(n-k+1)}^{\infty} \lambda^{-j} U^j_{n+1,k}(x_2, t_2, x_1), \quad k \in \Omega_n, \quad \lambda \to -\infty. \tag{18}$$

Let us obtain the differential equations for the coefficients of asymptotics (15). Substituting (15), (16) into (1) and collecting the terms with equal powers of small parameter and exponents, we find the equations for coefficients $W_{n,k}$. In particular, the terms of order ε^2 give us the equations for the leading-order terms of the asymptotics,

$$2i\partial_{t_2} S \partial_{t_1} W_{1,1} - 2i\partial_{x_2} S \partial_{x_1} W_{1,1} - \lambda W_{1,1} = f, \tag{19}$$

and the complex conjugated equation for $W_{1,-1}$.

The relation of order ε^3 in (1) gives us four equations. Two of them are complex conjugate differential equations for $W_{2,1}$ and $W_{2,-1}$:

$$\begin{aligned} &2i\partial_{t_2} S \partial_{t_1} W_{2,1} - 2i\partial_{x_2} S \partial_{x_1} W_{2,1} - \lambda W_{2,1} = \partial^2_{x_1} W_{1,1} - \partial^2_{t_1} W_{1,1} \\ &- i[\partial^2_{t_2} S - \partial^2_{x_2} S] W_{1,1} - 2i\partial_{t_2} S \partial_{t_2} W_{1,1} + 2i\partial_{x_2} S \partial_{x_2} W_{1,1} - 3\gamma |W_{1,1}|^2 W_{1,1}. \end{aligned} \tag{20}$$

Two another equations are algebraic. These last equations allow us to determine the function $W_{3,3}$

$$W_{3,3} = \frac{\gamma}{8}(W_{1,1})^3.$$

The higher-order terms are calculated in the same way. In particular, the term $W_{n,1}$ is determined by the differential equation

$$2i\partial_{t_2}S\partial_{t_1}W_{n,1} - 2i\partial_{x_2}S\partial_{x_1}W_{n,1} - \lambda W_{n,1} = F_{n,1}. \tag{21}$$

The right-hand side of (21) has the form

$$\begin{aligned} F_{n,1} = {} & -2i\partial_{t_2}S\partial_{t_2}W_{n-1,1} + 2i\partial_{x_2}S\partial_{x_2}W_{n-1,1} + (\partial_{t_2}S)^2W_{n-1,1} - (\partial_{x_2}S)^2W_{n-1,1} \\ & - \partial_{t_1}^2W_{n-1,1} + \partial_{x_1}^2W_{n-1,1} - \partial_{t_2}\partial_{t_1}W_{n-2,1} + \partial_{x_2}\partial_{x_1}W_{n-2,1} \\ & - \partial_{t_2}^2W_{n-3,1} + \partial_{x_2}^2W_{n-3,1} - \gamma \sum_{\substack{n_1+n_2+n_3=n+1,\\ k_1+k_2+k_3=1,\\ k_j\in\Omega_{n_j},\ j=1,2,3}} W_{n_1,k_1}W_{n_2,k_2}W_{n_3,k_3}. \end{aligned} \tag{22}$$

The term $W_{n,k}$, $k \neq 1$ is determined by algebraic equation

$$\begin{aligned} W_{n,k} = \frac{\gamma}{k^2-1}\Bigg(& -2i\partial_{t_2}S\partial_{t_2}W_{n-2,k} + 2i\partial_{x_2}S\partial_{x_2}W_{n-2,k} \\ & + (\partial_{t_2}S)^2W_{n-2,k} - (\partial_{x_2}S)^2W_{n-2,k} \\ & - \partial_{t_1}^2W_{n-2,k} + \partial_{x_1}^2W_{n-2,k} - \partial_{t_2}\partial_{t_1}W_{n-3,k} + \partial_{x_2}\partial_{x_1}W_{n-3,k} \\ & - \partial_{t_2}^2W_{n-4,k} + \partial_{x_2}^2W_{n-4,k} - \sum_{\substack{n_1+n_2+n_3=n+1,\\ k_1+k_2+k_3=k,\\ k_j\in\Omega_{n_j},\ j=1,2,3}} W_{n_1,k_1}W_{n_2,k_2}W_{n_3,k_3}\Bigg). \end{aligned} \tag{23}$$

Thus we complete step 1 of the proof for Theorem 2.

3.2. Solvability of equations for higher-order terms. In this subsection we present the explicit form for higher-order term $W_{n,1}$ and investigate the asymptotic behavior as $\lambda \to \pm\infty$.

3.2.1. Characteristic variables. The function $W_{n,1}$ satisfies (21). The solution is constructed by the method of characteristics. Define the characteristic variables σ, ξ. We choose a point (x_1^0, t_1^0) such that $\partial_{x_2}l|_{(x_1^0,t_1^0)} \neq 0$ is an origin, and denote by σ the variable along the characteristics for (21). We suppose $\sigma = 0$ on the curve $\lambda = 0$. The variable ξ measures the distance along the curve $\lambda = 0$ from the point (x_1^0, t_1^0). This point (x_1^0, t_1^0) corresponds to $\xi = 0$. The positive direction for parameter ξ coincides with the positive direction of x_2 in the neighborhood of (x_1^0, t_1^0).

The characteristic equations for (21) have a form

$$\frac{dt_1}{d\sigma} = 2\partial_{t_2}S(\varepsilon x_1, \varepsilon t_1), \quad \frac{dx_1}{d\sigma} = -2\partial_{x_2}S(\varepsilon x_1, \varepsilon t_1). \tag{24}$$

The initial conditions for the equations are

$$x_1|_{\sigma=0} = x_1^0, \quad t_1|_{\sigma=0} = t_1^0. \tag{25}$$

LEMMA 2. *The Cauchy problem for characteristics has a solution when* $|\sigma| < c_1\varepsilon^{-1}, c_1 = const. > 0$.

Proof. The Cauchy problem (24), (25) is equivalent to the system of integral equations

$$t_1 = t_1^0 + 2\int_0^\sigma \partial_{t_2} S(\varepsilon x_1, \varepsilon t_1)d\zeta, \qquad x_1 = x_1^0 - 2\int_0^\sigma \partial_{x_2} S(\varepsilon x_1, \varepsilon t_1)d\zeta. \tag{26}$$

Substituting $\tilde{t}_2 = (t_1 - t_1^0)\varepsilon,\ \tilde{x}_2 = (x_1 - x_1^0)\varepsilon$, we obtain

$$\tilde{t}_2 = 2\int_0^{\varepsilon\sigma} \partial_{t_2} S(\tilde{x}_2 - \varepsilon x_1^0, \tilde{t}_2 - \varepsilon t_1^0)d\zeta, \qquad \tilde{x}_2 = -2\int_0^{\varepsilon\sigma} \partial_{x_2} S(\tilde{x}_2 - \varepsilon x_1^0, \tilde{t}_2 - \varepsilon t_1^0)d\zeta.$$

The integrands are smooth and bounded functions on the plane x_2, t_2. There exists the constant $c_1 = \text{const.} > 0$ such that the integral operator is a contraction operator when $\varepsilon|\sigma| < c_1$. Lemma 2 is proved. □

It is convenient to use the following asymptotic formulas for the change of variables $(x_1, t_1) \to (\sigma, \xi)$.

LEMMA 3. *In the domain* $|\sigma| \ll \varepsilon^{-1}$ *the asymptotics as* $\varepsilon \to 0$ *of the solutions for Cauchy problem* (24), (25) *have the form*

$$x_1(\sigma, \xi, \varepsilon) - x_1^0(\xi) = -2\sigma\partial_{x_2} S + 2\sum_{n=1}^{N} \varepsilon^n \sigma^{n+1} g_n(\varepsilon x_1, \varepsilon t_1) + O(\varepsilon^{N+1}\sigma^{N+2}), \tag{27}$$

$$t_1(\sigma, \xi, \varepsilon) - t_1^0(\xi) = 2\sigma\partial_{t_2} S + 2\sum_{n=1}^{N} \varepsilon^n \sigma^{n+1} h_n(\varepsilon x_1, \varepsilon t_1) + O(\varepsilon^{N+1}\sigma^{N+2}), \tag{28}$$

where

$$g_n = -\frac{d^n}{d\sigma^n}(\partial_{x_2} S)\Big|_{\sigma=0}, \quad h_n = \frac{d^n}{d\sigma^n}(\partial_{t_2} S)\Big|_{\sigma=0}.$$

The lemma can be proved by integration by parts of (26). □

The next claim gives us the asymptotic formula which relates the variables σ and λ as $\sigma, \lambda \to \pm\infty$.

LEMMA 4. *Let be* $\sigma \ll \varepsilon^{-1}$*; then*

$$\lambda = \varphi(\xi)\sigma + O(\varepsilon\sigma^2), \qquad \varphi(\xi) = \frac{d\lambda}{d\sigma}\Big|_{\sigma=0} \qquad \text{as } \sigma \to \infty.$$

Proof. From formula (17) we obtain the representation

$$\lambda = \sum_{j=1}^{\infty} \lambda_j(x_1, t_1, \varepsilon)\sigma^j \varepsilon^{j-1},$$

where

$$\lambda_j(x_1, t_1, \varepsilon) = \frac{1}{j!}\frac{d^j}{d\sigma^j}\lambda(x_1, t_1, \varepsilon)|_{\sigma=0}.$$

It yields

$$\lambda = \frac{d\lambda}{d\sigma}\Big|_{\sigma=0}\sigma + O\left(\varepsilon\sigma^2 \frac{d^2\lambda}{d\sigma^2}\right).$$

Let

$$\left|\frac{d^2 l}{d\sigma^2}\right| \geq \text{const.} \qquad \xi \in R.$$

The function $d\lambda/d\sigma$ is not equal to zero:

$$\frac{d\lambda}{d\sigma} = \frac{1}{2}\left(-\partial_{x_2}\lambda\partial_{x_2}S + \partial_{t_2}\lambda\partial_{t_2}S\right) \neq 0.$$

Let us suppose $d\lambda/d\sigma > 0$. It yields

$$\lambda = \varphi(\xi)\sigma + O(\varepsilon\sigma^2), \qquad \varphi(\xi) = \left.\frac{d\lambda}{d\sigma}\right|_{\sigma=0}.$$

The lemma is proved. □

3.2.2. Solutions of the equations for higher-order terms. The higher-order terms $W_{n,\pm 1}$ are solutions of (21) with the given asymptotic behavior $\lambda \to -\infty$. Equation (21) can be written in characteristic variables as

$$i\frac{d}{d\sigma}W_{n,1} - \lambda W_{n,1} = F_{n,1}. \tag{29}$$

LEMMA 5. *The solution of* (21) *with the asymptotic behavior* (18) *as* $\lambda \to -\infty$ *has the form*

(30)
$$W_{n,1} = \exp\left(-i\int_0^\sigma d\zeta\lambda(x_1,t_1,\varepsilon)\right)\int_{-\infty}^{\sigma} d\zeta F_{n,1}(x_1,t_1,\varepsilon)\exp\left(-i\int_0^\zeta d\chi\lambda(x_1,t_1,\varepsilon)\right).$$

Proof. By direct substitution we see that expression (30) is the solution of (29). The asymptotics of this solution as $\lambda \to -\infty$ can be obtained by integration by parts and substitution:

$$\frac{d}{d\sigma} = 2\partial_{t_2}S\partial_{t_1} - 2\partial_{x_2}S\partial_{x_1}.$$

This yields

$$W_{n,1} = \sum_{j=0}^{\infty}\left(\frac{2\partial_{t_2}S\partial_{t_1} - 2\partial_{x_2}S\partial_{x_1}}{i\lambda}\right)^j\left[\frac{F_{n,1}}{i\lambda}\right], \quad \lambda \to -\infty. \tag{31}$$

From formula (22) we obtain that formulas (31) and (18) are equivalent. The lemma is proved. □

Thus we complete step 2 of the proof for Theorem 2.

3.3. Asymptotics as $\lambda \to \infty$ and domain of validity of the internal asymptotics. The domain of validity of the internal expansion is determined by the asymptotic behavior of higher-order terms. In this section we show that the nth-order term of the asymptotic solution increases as λ^{n-1} when $\lambda \to \infty$. This increase of higher-order terms allows us to determine the domain of validity for internal asymptotics (15) as $\lambda \to \infty$.

3.3.1. Asymptotics of higher-order terms. This section contains two propositions concerning asymptotic behavior as $\lambda \to \infty$ for higher-order terms in (15). The first lemma describes the asymptotic behavior of higher-order terms as $\lambda \to \infty$, and the second one contains a result about asymptotics of the phase function.

LEMMA 6. *The asymptotic behavior of $W_{n,1}$ when $1 \ll \lambda \ll \varepsilon^{-1}$ has the form*

$$W_{n,1} = \sum_{j=0}^{n-1}\sum_{k=0}^{j-1}\left(\lambda^j \ln^k|\lambda| W_{n,1}^{(j,k)}(\xi)\right)\exp\left(-i\int_0^\sigma d\zeta\lambda(x_1,t_1,\varepsilon)\right) + \sum_{j=0}^{\infty}\left(\frac{2\partial_{t_2}S\partial_{t_1} - 2\partial_{x_2}S\partial_{x_1}}{i\lambda}\right)^j\left[\frac{F_{n,1}}{i\lambda}\right]. \tag{32}$$

Proof. The asymptotic behavior of the coefficients $W_{n,1}$ is calculated recurrently. Let us calculate the asymptotic behavior of the leading-order term

$$\begin{aligned} W_{1,1} &= \exp\left(-i\int_0^\sigma d\zeta\lambda(x_1,t_1,\varepsilon)\right)\int_{-\infty}^{\zeta} d\zeta f(x_1)\exp\left(i\int_0^\sigma d\chi\lambda(x_1,t_1,\varepsilon)\right) \\ &= \exp\left(-i\int_0^\sigma d\zeta\lambda(x_1,t_1,\varepsilon)\right)\int_{-\infty}^{\infty} d\zeta f(x_1)\exp\left(i\int_0^\zeta d\chi\lambda(x_1,t_1,\varepsilon\right) \\ &\quad - \exp\left(-i\int_0^\sigma d\zeta\lambda(x_1,t_1,\varepsilon)\right)\int_{-\sigma}^{\infty} d\zeta f(x_1)\exp\left(i\int_0^\zeta d\chi\lambda(x_1,t_1,\varepsilon)\right). \end{aligned}$$

Further, by integration by parts of the last term, we obtain formula (32) at $n = 1$, where

$$W_{1,1}^{(0,0)}(\xi) = \int_{-\infty}^{\infty} d\sigma f(x_1)\exp\left(i\int_0^\sigma d\chi\lambda(x_1,t_1,\varepsilon)\right),$$
$$F_{1,1} = f(x_1).$$

To calculate the asymptotics of $W_{n,1}$ in formula (30) we use the asymptotics with respect to σ of the previous correction terms. In this case the integral (30) contains the increasing terms with respect to σ. We eliminate this growing part from the integral explicitly. The residual integral converges as $\sigma \to \infty$. It can be calculated in the same manner as it was calculated for $W_{1,1}$ and yields formulas (32) for any n,

$$W_{n,1}^{(k,0)}(\xi) = \frac{1}{k}W_{n-1,1}^{(k-1,0)}(\xi) + \frac{\gamma}{k}\sum W_{m_1,\chi_1}^{(\kappa_1,0)}(\xi)W_{m_2,\chi_2}^{(\kappa_2,0)}(\xi)W_{m_3,\chi_3}^{(\kappa_3,0)}(\xi),$$

where $m_1+m_2+m_3 = n+1,\ \kappa_1+\kappa_2+\kappa_3 = k-1,\ \chi_1+\chi_2+\chi_3 = 1$, and

$$W_{n,1}^{(j,k)}(\xi) = \frac{1}{j}W_{n-1,1}^{(j-1,k)}(\xi) + \frac{1}{k}W_{n-1,1}^{(j-1,k-1)}(\xi) + \Sigma_1 + \Sigma_2.$$

We define

$$\Sigma_1 = \frac{\gamma}{j}\sum W_{m_1,\chi_1}^{(\kappa_1,\nu_1)}(\xi)W_{m_2,\chi_2}^{(\kappa_2,\nu_2)}(\xi)W_{m_3,\chi_3}^{(\kappa_3,\nu_3)}(\xi),$$

where $m_1+m_2+m_3 = n-1,\ \kappa_1+\kappa_2+\kappa_3 = j-1,\ \chi_1+\chi_2+\chi_3 = 1, \nu_1+\nu_2+\nu_3 = k$, and

$$\Sigma_2 = \frac{\gamma}{k}\sum W_{m_1,\chi_1}^{(\kappa_1,\nu_1)}(\xi)W_{m_2,\chi_2}^{(\kappa_2,\nu_2)}(\xi)W_{m_3,\chi_3}^{(\kappa_3,\nu_3)}(\xi),$$

where $m_1+m_2+m_3 = n-1,\ \kappa_1+\kappa_2+\kappa_3 = j-1,\ \chi_1+\chi_2+\chi_3 = 1, \nu_1+\nu_2+\nu_3 = k-1$.

The lemma is proved. □

To complete the proof of Theorem 2 we need to obtain the domain of validity of asymptotics (15). The formal series (15) is asymptotic when

$$\varepsilon \max_{x_1,x_2,t_1,t_2} |W_{n+1}| = o\left(\max_{x_1,x_2,t_1,t_2} |W_n|\right), \quad \varepsilon \to 0.$$

Lemma 6 gives $\lambda \ll \varepsilon^{-1}$. After substitution $\lambda = \varepsilon l$, we obtain $l \ll 1$. Theorem 2 is proved. □

3.4. Asymptotics of the phase function as $\lambda \to \infty$. To obtain the asymptotics as $\lambda \to \infty$ we need to derive the asymptotics of the phase function in formula (32).

LEMMA 7. *As* $\lambda \to \infty$,

$$\int_0^\sigma d\xi\lambda = \frac{S}{\varepsilon^2} + \frac{1}{\varepsilon}(\partial_{x_2} S(x_1 - x_1^0) + \partial_{t_2} S(t_1 - t_1^0)) + O(\varepsilon\lambda^3). \tag{33}$$

Proof. Substitute the asymptotics of λ from Lemma 6. Calculate the asymptotics of the integral in formula (33)

$$\int_0^\sigma d\zeta\lambda(x_1, t_1, \varepsilon) = \int_0^\sigma \frac{d\zeta}{2}\left[(-\partial_{x_2} l\partial_{x_2} S + \partial_{t_2} l\partial_{t_2} S)\zeta + O(\varepsilon\zeta^2)\right]$$
$$= (-\partial_{x_2} l\partial_{x_2} S + \partial_{t_2} l\partial_{t_2} S)\frac{\sigma^2}{4} + O(\varepsilon\sigma^3).$$

The asymptotics of the phase function $S(x_2, t_2)$ in the neighborhood of the curve $l = 0$ is represented by a segment of the Taylor series. It yields

$$\frac{S}{\varepsilon^2} = \frac{1}{\varepsilon}(\partial_{x_2} S(x_1 - x_1^0) + \partial_{t_2} S(t_1 - t_1^0))$$
$$+ \frac{1}{2}(S_{x_2x_2}(x_1 - x_1^0)^2 + 2S_{x_2t_2}(x_1 - x_1^0)(t_1 - t_1^0) + S_{t_2t_2}(t_1 - t_1^0)^2)$$
$$+ O(\varepsilon(|t_1 - t_1^0| + |t_1 - t_1^0|)^3).$$

Substitute instead of $(x_1 - x_1^0)$ and $(t_1 - t_1^0)$ their asymptotic behavior with respect to ε from Lemma 3. This substitution and the result of Lemma 4 complete the proof of Lemma 7. □

The asymptotics as $\lambda \to -\infty$ contains fast oscillating terms with phase functions $kS, k \in Z$. The leading-order term of the asymptotics as $\lambda \to \infty$ contains the oscillations with an additional phase function. We obtain this result from Lemma 6. Denote this new phase function by $\varphi(x_2, t_2)/\varepsilon^2$. The asymptotics of this function is obtained in Lemma 7. The nonlinearity and additional phase function lead to more complicated structure of the phase set for higher-order terms of the asymptotics as $\lambda \to \infty$.

LEMMA 8. *The phase set K_n for the nth-order term of the asymptotics as $\lambda \to \infty$ is determined by formula*

$$K_1 = \pm\varphi, \quad K_2 = \pm\varphi, \pm S, \quad K_n = \cup_{j_1+j_2+j_3=n}\chi_{j_1} + \chi_{j_2} + \chi_{j_3}, \ \chi_{j_k} \in K_{j_k}.$$

Proof. The proof of this lemma follows from the asymptotic formula for the nth-order term. Representation (15), formula (32), and Lemma 6 allow us to construct

the asymptotics as $\lambda \to \infty$ of the internal expansion in an explicit form:

$$U = \sum_{n=1}^{N} \varepsilon^n \left(\sum_{j=0}^{n-1} \sum_{k=0}^{n-2} \lambda^j \ln^k |\lambda| W_{n,1}^{(j,k)}(\xi) \right)$$
$$\times \exp\left[-i\left(\frac{1}{\varepsilon}(\partial_{x_2} S(x_1 - x_1^0) + \partial_{t_2} S(t_1 - t_1^0)) + O(\varepsilon\lambda^3) \right) \right]$$
$$+ \sum_{n=1}^{N} \varepsilon^n \left(\sum_{j=0}^{\infty} \left(\frac{2\partial_{t_2} S \partial_{t_1} - 2\partial_{x_2} S \partial_{x_1}}{i\lambda} \right)^j \left[\frac{F_{n,1}}{i\lambda} \right] \right) \exp\left\{ i \frac{S(t_2, x_2)}{\varepsilon^2} \right\}$$
$$+ \sum_{n=2}^{N} \varepsilon^n \left(\sum_{k \in \Omega, k \neq \pm 1} W_{n,k} \exp\left\{ ik \frac{S(t_2, x_2)}{\varepsilon^2} \right\} \right) + \text{ c.c.} \tag{34}$$

This representation and formula (23) complete the proof of the lemma. □

4. Postresonant expansion. This section contains the construction of the asymptotics of the solution for (1) after the passage through the resonance. The constructed solution has the order ε and oscillates. The envelope function of these oscillations satisfies the nonlinear Schrödinger equation. This section consists of two parts. The first part contains the construction of the formal asymptotic solution. We obtain the equations for the higher-order terms of the asymptotics. The asymptotic behavior for the higher-order terms as $l \to +0$ follows from section 3.4. In the second part of this section we determine the domain of validity for this external asymptotics near the resonant curve $l(x_2, t_2) = 0$. The matching method gives us the initial conditions for higher-order terms of the asymptotics.

The main result of this section is formulated in the following theorem.

THEOREM 3. *In the domain $l \gg \varepsilon$ the formal asymptotic solution of* (1) *modulo $O(\varepsilon^{N+1})$ has the form*

$$U(x,t,\varepsilon) = \sum_{1}^{N} \varepsilon^n \sum_{k=0}^{n-2} \ln^k(\varepsilon) \left(\sum_{\pm\varphi} \exp\left\{ \pm \frac{i\varphi(x_2,t_2)}{\varepsilon^2} \right\} \Psi_{n,k,\pm\varphi}(x_1,t_1,t_2) \right.$$
$$\left. + \sum_{\chi \in K'_{n,k}} \exp\left\{ \frac{i\chi(x_2,t_2)}{\varepsilon^2} \right\} \Psi_{n,k,\chi}(x_1,t_1,t_2) \right). \tag{35}$$

Here the function $\varphi(x_2, t_2)$ satisfies the eikonal equation

$$(\partial_{t_2}\varphi)^2 - (\partial_{x_2}\varphi)^2 - 1 = 0 \tag{36}$$

and initial condition on the curve $l = 0$:

$$\varphi|_{l=0} = S|_{l=0}, \quad \partial_{t_2}\varphi_{l=0} = \partial_{t_2} S|_{l=0}.$$

The leading-order term of the asymptotics is a solution of the Cauchy problem for the nonlinear Schrödinger equation

$$2i\partial_{t_2}\varphi\partial_{t_2}\Psi_{1,0,\varphi} + \partial_\xi^2 \Psi_{1,0,\varphi} + i[\partial_{t_2}^2\varphi - \partial_{x_2}^2\varphi]\Psi_{1,0,\varphi} + \gamma|\Psi_{1,0,\varphi}|^2\Psi_{1,0,\varphi} = 0,$$

$$\Psi_{1,0,\varphi}|_{l=0} = \int_{-\infty}^{\infty} d\sigma f(x_1) \exp\left(i \int_0^{\sigma} d\chi \lambda(x_1, t_1, \varepsilon) \right),$$

where ξ is defined by

$$\frac{dx_1}{d\xi} = \partial_{t_2}\varphi, \quad \frac{dt_1}{d\xi} = \partial_{x_2}\varphi.$$

The coefficients $\Psi_{n,k,\pm\varphi}$ are determined from Cauchy problems for linearized Schrödinger equation (42). *The coefficients $\Psi_{n,k,\chi}$, $\chi \in K'_{n,k}$, are determined from algebraic equations* (43). *The set $K'_{n,k} = K_{n,k}\backslash\{\pm\varphi\}$.*

The proof of this theorem contains two steps. In the first step (subsection 4.1) we derive the recurrent system of the problems for the coefficients of the expansion (35). In the second step (subsection 4.1) we define the domain of validity for (35).

4.1. Structure of the second external asymptotics. Let us construct the formal asymptotic solution from Theorem 3.

LEMMA 9. *The coefficients of formal asymptotic solution* (35) *satisfy recurrent system of equations* (36), (41), (42), *and* (43).

Proof. Substitute (35) into (1) and collect the terms of the same order with respect to ε. This yields $N+1$ equations and a residual of the order ε^{N+1}. After collecting the terms with the same phase functions, we obtain the recurrent system of the equations for the coefficients of (35).

The terms with the phase function φ/ε^2 and of the order ε^1 give us (36) for the phase function of eigenoscillations. The initial data is determined by the matching condition and represented by the value of the driven phase S on the resonance curve $l = 0$,

$$\varphi|_{l=0} = S|_{l=0}, \quad \partial_{t_2}\varphi|_{l=0} = \partial_{t_2}S|_{l=0}.$$

The terms of the order ε^2,

$$2i\left(\partial_{t_2}\varphi\partial_{t_1}\Psi_{1,0,\varphi} - \partial_{x_2}\varphi\partial_{x_1}\Psi_{1,0,\varphi}\right) = 0,$$

give us the homogeneous transport equation

$$\partial_{t_2}\varphi\partial_{t_1}\Psi_{1,0,\varphi} - \partial_{x_2}\varphi\partial_{x_1}\Psi_{1,0,\varphi} = 0. \tag{37}$$

This equation allows us to determine the dependence with respect to the characteristic variable ζ of the leading-order term. Equation (37) along the characteristics

$$\frac{dx_1}{d\zeta} = -\partial_{x_2}\varphi, \quad \frac{dt_1}{d\zeta} = \partial_{t_2}\varphi \tag{38}$$

can be written in the form of an ordinary differential equation:

$$\frac{d\Psi_{1,0,\varphi}}{d\zeta} = 0. \tag{39}$$

This gives us that $\Psi_{1,0,\varphi}$ depends on ξ. The variable ξ is defined by

$$\frac{dx_1}{d\xi} = \partial_{t_2}\varphi, \quad \frac{dt_1}{d\xi} = \partial_{x_2}\varphi.$$

The terms of the order ε^3 which oscillate as $\exp(i\varphi/\varepsilon^2)$ are

$$\begin{aligned} &2i\left(\partial_{t_2}\varphi\partial_{t_1}\Psi_{2,0,\varphi} - \partial_{x_2}\varphi\partial_{x_1}\Psi_{2,0,\varphi}\right) \\ &+ 2i\partial_{t_2}\varphi\partial_{t_2}\Psi_{1,0,\varphi} + [(\partial_{t_1}\xi)^2 - (\partial_{x_1}\xi)^2]\partial^2_{\xi\xi}\Psi_{1,0,\varphi} \\ &+ i[\partial^2_{t_2}\varphi - \partial^2_{x_2}\varphi]\Psi_{1,0,\varphi} + \gamma|\Psi_{1,0,\varphi}|^2\Psi_{1,0,\varphi} = 0. \end{aligned}$$

It is convenient to write this equation in the form of an ordinary differential equation in terms of the characteristic variables:

$$\frac{d\Psi_{2,0,\varphi}}{d\zeta} = -2i\partial_{t_2}\varphi\partial_{t_2}\Psi_{1,0,\varphi} - [(\partial_{t_1}\xi)^2 - (\partial_{x_1}\xi)^2]\partial^2_{\xi\xi}\Psi_{1,0,\varphi}$$
$$- i[\partial^2_{t_2}\varphi - \partial^2_{x_2}\varphi]\Psi_{1,0,\varphi} - \gamma|\Psi_{1,0,\varphi}|^2\Psi_{1,0,\varphi}. \tag{40}$$

Equation (39) shows that the right-hand-side of (40) does not depend on ζ. To avoid the secular terms in the asymptotics we demand that the right-hand side of the equation be equal to zero. This allows us to determine the dependence of the leading-order term on the slow variable t_2,

$$2i\partial_{t_2}\varphi\partial_{t_2}\Psi_{1,0,\varphi} + [(\partial_{t_1}\xi)^2 - (\partial_{x_1}\xi)^2]\partial^2_{\xi\xi}\Psi_{1,0,\varphi}$$
$$+ i[\partial^2_{t_2}\varphi - \partial^2_{x_2}\varphi]\Psi_{1,0,\varphi} + \gamma|\Psi_{1,0,\varphi}|^2\Psi_{1,0,\varphi} = 0. \tag{41}$$

The equations for the higher-order terms are obtained in the same manner,

$$2i\left(\partial_{t_2}\varphi\partial_{t_1}\Psi_{n+1,k,\varphi} - \partial_{x_2}\varphi\partial_{x_1}\Psi_{n+1,k,\varphi}\right) = 2i\partial_{t_2}\varphi\partial_{t_2}\Psi_{n,k,\varphi} - \partial^2_{\xi\xi}\Psi_{n,k,\varphi}$$
$$- i[\partial^2_{t_2}\varphi - \partial^2_{x_2}\varphi]\Psi_{n,k,\varphi} + \partial_{t_1}\xi\partial^2_{\xi t_2}\Psi_{n-1,k,\varphi}$$
$$- \gamma \sum_{k_1,k_2,l_1,l_2,m_1,m_2,\alpha,\beta,\delta} \Psi_{k_1,k_2,\alpha}\Psi_{l_1,l_2,\beta}\Psi_{m_1,m_2,\delta},$$

where $k_1 + l_1 + m_1 = n + 2,\ k_2 + l_2 + m_2 = k,\ \alpha + \beta + \delta = \varphi,\ \alpha \in K_{k_1,k_2},\ \beta \in K_{l_1,l_2},\ \delta \in K_{m_1,m_2}$.

To construct the uniform asymptotic expansion with respect to ζ we obtain the linearized Schrödinger equation for higher-order term

$$2i\partial_{t_2}\varphi\partial_{t_2}\Psi_{n,k,\varphi} + \partial^2_{\xi\xi}\Psi_{n,k,\varphi} + i[\partial^2_{t_2}\varphi - \partial^2_{x_2}\varphi]\Psi_{n,k,\varphi}$$
$$= -\partial_{t_1}\xi\partial^2_{\xi t_2}\Psi_{n-1,k,\varphi} - \gamma \sum_{k_1,k_2,l_1,l_2,m_1,m_2,\alpha,\beta,\delta} \Psi_{k_1,k_2,\alpha}\Psi_{l_1,l_2,\beta}\Psi_{m_1,m_2,\delta}, \tag{42}$$

where $k_1 + l_1 + m_1 = n + 2,\ k_2 + l_2 + m_2 = k,\ \alpha + \beta + \delta = \varphi,\ \alpha \in K_{k_1,k_2},\ \beta \in K_{l_1,l_2},\ \delta \in K_{m_1,m_2}$.

The amplitudes $\Psi_{n,\chi}$ at $\chi \neq \pm\varphi$ are determined by the algebraic equations

$$\left[-(\partial_{t_2}\chi)^2 + (\partial_{x_2}\chi)^2 + 1\right]\Psi_{n,k,\chi} = F_{n,k,\chi}, \quad \chi \neq \pm\varphi. \tag{43}$$

Here the right hand-side of the equation depends on the previous terms and their derivatives

$$F_{n,k,\chi} = -2i\chi_{t_2}\partial_{t_1}\Psi_{n-1,k,\chi} + 2i\chi_{x_2}\partial_{x_1}\Psi_{n-1,k,\chi} - 2i\chi_{t_2}\partial_{t_2}\Psi_{n-2,k,\chi}$$
$$- i\left[\chi_{t_2t_2} - \chi_{x_2x_2}\right]\Psi_{n-2,k,\chi} - \partial^2_{t_1t_2}\Psi_{n-3,k,\chi} - \partial^2_{t_2t_2}\Psi_{n-4,k,\chi}$$
$$- \gamma \sum_{k_1,k_2,l_1,l_2,m_1,m_2,\alpha,\beta,\delta} \Psi_{k_1,k_2,\alpha}\Psi_{l_1,l_2,\beta}\Psi_{m_1,m_2,\delta},$$

where $k_1 + l_1 + m_1 = n - 4,\ k_2 + l_2 + m_2 = k,\ \alpha + \beta + \delta = \chi,\ \alpha \in K_{k_1,k_2},\ \beta \in K_{l_1,l_2},\ \delta \in K_{m_1,m_2}$.

These equations are similar to the equations for the amplitudes from the pre-resonance section. Lemma 9 is proved. □

The right-hand side of (42) has a singularity as $l \to 0$. The singularity appears due to $\Psi_{n,k,\chi}$ at $\chi \neq \pm\varphi$. The analysis of the right-hand side of the equation allows us to calculate the order of singularity as $l \to 0$. It is equal to $O(l^{-(n-1)})$. Below we prove the solvability of (42) with the given asymptotics as $l \to 0$.

LEMMA 10. *The asymptotics as $l \to 0$ of the solution of* (42) *has the form*

$$\Psi_{n,k,\varphi}(x_1,t_1,t_2) = \sum_{j=-(n-2)}^{1} \sum_{m=0}^{j-1} \Psi^{j,m}_{n,k,\varphi}(x_1,t_1)\; l^j (\ln l)^m + O(1), \quad l \to 0. \tag{44}$$

Proof. Determine the order of the singularity of the right-hand side of the equation as $l \to 0$. Consider (42) for $n = 3, k = 0$. The solution of this equation gives us the coefficient $\Psi_{3,0,\varphi}$. The nonlinearity contains the term $|\Psi_{2,0,S}|^2\Psi_{1,0,\varphi}$. The function $\Psi_{2,0,S}$ has the singularity of the order l^{-1} as $l \to 0$. It determines the order of the singularity for the right-hand side l^{-2}. We construct the asymptotics of $\Psi_{3,0,\chi}$ in the form

$$\Psi_{3,0,\varphi} = \Psi^{-1,0}_{3,0,\varphi} l^{-1} + \Psi^{0,1}_{3,0,\varphi} \ln(l) + \Psi^{1,1}_{3,0,\varphi} l \ln(l) + \widehat{\Psi}_{3,0,\varphi}. \tag{45}$$

Substitute (45) into (42) for $n = 3$. It leads to a recurrent system of equations for coefficients $\Psi^{(j,k)}_{3,0,\varphi}$:

$$-2i\partial_{t_2}\varphi\partial_{t_2} l\Psi^{(-1,0)}_{3,0,\varphi} = -\Psi_{1,0,\varphi}|\Psi_{2,0,S}|^2 l^2,$$

$$2i\partial_{t_2}\varphi\partial_{t_2} l\Psi^{(0,1)}_{3,0,\varphi} = L[\Psi^{(-1,0)}_{3,0,\varphi}],$$

$$2i\partial_{t_2}\varphi\partial_{t_2} l\Psi^{(1,1)}_{3,0,\varphi} = L[\Psi^{(0,1)}_{3,0,\varphi}].$$

Here we denote the linear operator by

$$L[\Psi] = 2i\partial_{t_2}\varphi\partial_{t_2}\Psi + \partial^2_\xi\Psi + i[\partial^2_{t_2}\varphi - \partial^2_{x_2}\varphi]\Psi + \gamma\big(2|\Psi_{1,0,\varphi}|^2\Psi + (\Psi_{1,0,\varphi})^2\Psi^*\big).$$

The regular part $\widehat{\Psi}_{3,0,\varphi}$ of the asymptotics satisfies the nonhomogeneous linear Schrödinger equation. The right-hand side of the equation is smooth,

$$L[\widehat{\Psi}_{3,0,\varphi}] = -l\ln|l| L[\Psi^{(1,1)}_{3,0,\varphi}] - 2i\partial_{t_2}\varphi\partial_{t_2} l\Psi^{(1,1)}_{3,0,\varphi}.$$

The initial condition for the regular part of the asymptotics is determined below by matching with the internal asymptotic expansion.

The structure of the terms $\Psi_{n,k,\pm\varphi}$ for $n > 3$ has a similar form. The right-hand side of (42) depends on junior terms. These singularities can be eliminated:

$$F_{n,k,\varphi} = \sum_{j=0}^{-(n-2)} \sum_{m=0}^{-j+1} l^j \ln^m|l| f^{(j,m)}_{n,k,\varphi} + \widehat{F}_{n,k,\varphi}.$$

The coefficients $f^{(j,m)}_{n,k,\varphi}$ do not contain singularities as $l \to 0$. These coefficients are easy calculated.

The direct substituting of (44) into (42) and collecting the terms with the same order of l completes the proof of Lemma 10. □

Thus we complete step 1 of the proof of Theorem 3.

4.2. The domain of validity of the second external asymptotics and matching procedure. The domain of validity of the second external asymptotics is determined by

$$\varepsilon \max_{\xi,t_2,x_2} |V_{n+1}| = o\left(\max_{\xi,t_2,x_2} |V_n| \right), \quad \varepsilon \to 0.$$

Formulas (35) and (44) give the condition

$$l \ll \varepsilon.$$

The domain $|l| \ll 1$ of validity of the internal asymptotics and domain of validity of the second external asymptotics intersect. This fact allows us to complete the construction of the second external asymptotics by a matching method [17]. The structure of singular parts of the internal asymptotics as $\lambda \to +\infty$ and external asymptotics as $l \to 0$ are equivalent. The coefficients are coincident due to our construction. The matching of regular parts of these asymptotics takes place due to

$$\Psi_{n,0,\varphi}|_{l=0} = W_n^{(0,0)}(\xi).$$

The function $W_n^{(0,0)}(\xi)$ is determined in Lemma 6.

In particular, the initial condition for the leading-order term has the form

$$\Psi_{1,0,\varphi}|_{l=0} = \int_{-\infty}^{\infty} d\sigma f(x_1) \exp\left(i \int_0^{\sigma} d\chi \lambda(x_1, t_1, \varepsilon) \right).$$

The soliton theory for the nonlinear Schrödinger equation leads us to the fact that the function $\Psi_{1,0,\varphi}$ contains the solitary waves when $f(x_1)$ is sufficiently large.

Theorem 3 is now proved. □

5. Summary. In this work we found the formula connecting the form of the resonant pumping and the shape of the solution after the slow passage through the resonance. In particular, it gives the mathematical basis for a solution of the important problem of nonlinear optics about the generation of the solitary packets of nearly monochromatic weakly nonlinear dispersive waves. We present the obvious form for the perturbation which generates such packets with a soliton as an envelope function.

The proposed approach opens ways for solving similar problems in pure and applied mathematics. The pure mathematical problem is a justification of the constructed asymptotic formulas obtained in this work. The applied problems are the generation of the solitary packet of waves with few carrier frequencies. One more applied problem is a pumping of the amplitudes of nonlinear waves up to the order of 1. Such resonant pumping would be useful for magnetics, Josephson junctions, and other applications in physics.

Acknowledgments. We are grateful to I. V. Barashenkov, L. A. Kalyakin, and B. I. Suleimanov for helpful comments and for help in improving the mathematical presentation of the results.

INSTABILITY OF THE IONOSPHERIC PLASMA: MODELING AND ANALYSIS*

CHRISTOPHE BESSE†, JEAN CLAUDEL‡, PIERRE DEGOND†, FABRICE DELUZET†, GÉRARD GALLICE‡, AND CHRISTIAN TESSIERAS‡

Abstract. This paper is concerned with the theory and modeling of plasma instabilities in the ionosphere. We first consider the so-called striation model, which consists of balance equations for the density and momenta of the plasma species, coupled with an elliptic equation for the potential. The linearized instability of this model is analyzed in the framework of Fourier theory, both for smooth and discontinuous steady states. Then, we show that the dissipation mechanisms at work in the more refined "dynamo model" allow us to stabilize high wave-number perturbations. We also analyze turbulence as a possible source of additional dissipation (in a similar way as in fluid mechanics). To this aim, we use the statistical approach to turbulence and derive a so-called turbulent striation model, of which we analyze the stability properties. Numerical experiments are used to support our investigations.

Key words. Euler–Maxwell system, dynamo model, striation model, ionospheric plasma, striations, turbulence, statistical approach, linearized stability analysis

1. Introduction.

This paper is concerned with the modeling and analysis of plasma instabilities in the ionosphere, at altitudes ranging between a few hundred and a thousand kilometers (the F region). The plasma may be created, either by the natural ionization of the atmosphere or by possible artificial causes (such as, e.g., thermonuclear explosions [31], [43], [19]). The ionospheric plasma is strongly structured by the earth's magnetic field. Indeed, the mobility of the ionized species (i.e., their velocity in response to an external electric field) is strongly anisotropic: while field-aligned mobilities (i.e., mobilities in the direction of the magnetic field) are large, transverse mobilities (also called Pedersen mobilities) are quite small. Additionally, a component of the plasma velocity orthogonal to both the electric and magnetic fields appears as a result of the Hall effect. This component is the major actor in the so-called $E \times B$ drift instability, which we are going to discuss in the present paper.

At lower altitudes, the density of the neutral atmosphere is large, and the plasma is dragged by the motion of the neutral molecules (or neutral wind). As a result, a net electrical current flows across the magnetic field lines and generates an induced electric field. This is the so-called ionospheric dynamo effect [1]. The reader can refer to [37], [21], [9], and [2] for reviews about ionospheric physics. In the presence of a gradient in the plasma density, the neutral wind can trigger the $E \times B$ drift instability,

which bears strong similarities to the Rayleigh–Taylor instability in fluid mechanics [10]. This instability produces strong inhomogeneities (the ionospheric striations), which soon propagate over hundreds of kilometers along the magnetic field lines. The generation of plasma irregularities is reviewed in [13], [14], [36].

Our goal is to discuss some aspects of the mathematical and numerical modeling of this instability. Striations as well as related instability phenomena of the ionospheric plasma have been the subject of a wide literature (see, e.g., discussions of the "Spread F" in [44], [26], [34]; of the equatorial electrojet in [8], [41], [38], [39]; and of Barium releases experiments in [12]). The well-accepted mathematical model for these phenomena is the "dynamo" model [44], [12], which consists of mass and momentum balance equations for the plasma species. A simpler model, the "striation" model, is obtained when the field-aligned mobilities are supposed infinite. The derivation of these models and their interrelations are reviewed in [3] and will be briefly recalled in section 2.

The $E\times B$ drift instability is well described in the framework of the striation model (see section 3). A linear stability analysis indeed shows that exponential density profiles are unstable (see the review in [14] and section 3.2). Exponential density profiles are the only nonconstant smooth stationary states which allow analytical computations (via Fourier analysis). However, they are quite unrealistic, and a better theory should consider discontinuous density profiles. We consider this problem in section 3.3 and show that the striation model is also unstable in this case for certain configurations of the neutral wind. In a companion work [6], we show that smooth density profiles which are linearly unstable are nonlinearly unstable. However, the proof of [6] does not extend to discontinuous solutions. Similarly, we do not know, even for smooth density profiles, whether linear stability implies nonlinear stability.

In practice, the instability saturates and cascades towards smaller scales by nonlinearity [13], [39], [41], [25], [33], until it is ultimately damped by dissipation. In the striation model, however, all dissipation mechanisms have been removed. In section 4, we reintroduce dissipation effects by considering the dynamo model, where both finite temperature and finite conductivity effects are retained. A linearized stability analysis shows that high-wave-number perturbations are damped. However, in practice, the magnitude of the dissipation is too small, and we must consider other sources of dissipation.

In this paper, we investigate the possible influence of fluid turbulence. In fluid mechanics, it is a well-known fact that turbulence may enhance dissipation (see [32] and references therein). The statistical approach to fluid turbulence considers averages of the Navier–Stokes equations over various approximate realizations of the same solution. The chains of resulting statistical equations are closed by various types of phenomenological assumptions, which are still mathematically unjustified except in very simple cases, such as that considered in [27]. The models obtained (such as the K-ϵ model) involve additional terms compared with the standard Navier–Stokes equations, which describe the enhancement of diffusion by turbulence.

In section 5, we develop a similar statistical framework to model turbulence within the striation model (see also [28] for an application to MHD theory). We first derive an averaged striation model, for which we propose a closure ansatz inspired by [27]. This leads to a diffusive version of the striation model, the "turbulent striation model." To find the value of the turbulent diffusion constant, a stability analysis of the model is performed. It allows us to relate the threshold wave-number for instability (i.e., the typical size of the finest persisting structures in the plasma, which can be

experimentally observed) with the value of this constant.

Section 6 is devoted to two-dimensional numerical simulations. Their goal is to provide numerical and quantitative evidence of the features predicted in section 5, namely to show that the turbulent striation model produces persisting structures whose typical sizes are related to the magnitude of the diffusion. Three-dimensional simulations of the striation model are shown in [4]. A review collecting material from [3], [4], [6] as well as from the present paper is presented in [5].

Turbulence modeling in ionospheric plasmas has been widely investigated in the literature. Most of the approaches rely on nonlinear Fourier analysis [39], [22], [23] and bear similarities with the spectral approach to turbulence in fluid mechanics [29] (see also [15] for applications of these ideas to other plasma physics contexts). In using the statistical approach, we have chosen a slightly different route.

2. The "dynamo" and "striation" models of the ionospheric plasma. We consider two different species of particles: electrons and one-ion species. They are assumed so dilute that they have no influence on the dynamics of the neutrals, the velocity of which $u_n(x,t)$ (also called the neutral wind) is supposed known. In [3], a hierarchy of models for the ionospheric plasma has been derived. Of particular interest in the present study are the "dynamo" and "striation" models. The dynamo model is written as follows:

$$\partial_t n + \nabla \cdot (n u_i) = 0, \tag{2.1}$$

$$-\nabla\phi + u_{e,i} \times B = \kappa q_{e,i} \left[\nu_{e,i}(u_{e,i} - u_n) + \eta \nabla \log n \right], \tag{2.2}$$

$$\nabla \cdot j = 0, \quad \kappa j = n(u_i - u_e), \tag{2.3}$$

where we denote by $n(x,t)$ the density of the plasma; $u_e(x,t)$, $u_i(x,t)$ the electron and ion velocities; $j(x,t)$ the plasma current; $\phi(x,t)$ the electric potential; $B(x)$ the earth magnetic field; and $\nu_e(x)$, $\nu_i(x)$ the electron-neutral and ion-neutral collision frequencies, respectively. These quantities depend on the three-dimensional position coordinate x and on the time $t \geq 0$. The parameters η and κ are dimensionless and defined below. Equation (2.2) actually consists of two equations, one for the electrons (with the index "e" chosen everywhere) and one for the ions (with the index "i"). We let $q_i = 1$, $q_e = -1$. We suppose that the geomagnetic field $B(x)$ is unperturbed by the presence of the plasma and is known. Similarly, the collision frequencies $\nu_e(x)$, $\nu_i(x)$, which primarily depend on the neutral density, are supposed known. The plasma is supposed quasi-neutral; i.e., the electron and ion densities coincide with n. Despite the quasi-neutrality, the electron and ion velocities can be different, giving rise to a nonzero plasma current j. We have supposed that the electron and ion gases are isothermal with the same uniform temperature, which seems a valid physical hypothesis for the earth ionosphere [7]. The ionization-recombination terms which should appear on the right-hand side (r.h.s.) of (2.1) have been omitted as well. Typical ionization-recombination times are of the order of several hours, which is about the typical growth time of the instability. Therefore, these terms would make only a small correction to the analysis below and have been omitted for the sake of simplicity.

System (2.1)–(2.3) is written in dimensionless units. The scaling units and their typical values in the situations of interest are summarized in Table 2.1 below. The parameters η and κ are given by

$$\eta = \frac{k_B \bar{T}}{m_i \bar{u}^2} \frac{1}{\bar{\nu}_i \bar{t}} \qquad \kappa = \frac{m_e \bar{\nu}_e}{e\bar{B}} = \frac{m_i \bar{\nu}_i}{e\bar{B}}$$

TABLE 2.1
Scaling units.

Quantity	Scaling unit	Value
Time	$\bar{t}$	10^3 s
Length	$\bar{x}$	10^5 m
Velocity	$\bar{u} = \bar{x}/\bar{t}$	10^2 ms^{-1}
Density	$\bar{n}$	10^{12} m^{-3}
Temperature	$\bar{T}$	10^3 K
Magnetic field	$\bar{B}$	10^{-5} T
Electric potential	$\bar{\phi} = \bar{u}\bar{B}\bar{x}$	10^2 V
e-n collision frequency	$\bar{\nu}_e$	10^2 s^{-1}
i-n collision frequency	$\bar{\nu}_i = \frac{m_e}{m_i}\bar{\nu}_e$	10^{-2} s^{-1}

(where k_B is the Boltzmann constant) and respectively measure the ratio of the thermal energy to the ion drift energy and the typical number of electron-neutral or ion-neutral collisions per rotation period in the geomagnetic field. These two parameters have typical values (according to Table 2.1) $\eta \sim 10^1$, $\kappa \sim 10^{-4}$. Since κ is small, it is meaningful to investigate the limit of the dynamo model when $\kappa \to 0$. This leads to the so-called striation model that we give in more detail below.

Before doing so, we rewrite the dynamo model in a more appropriate form. In a local reference frame in which the last basis vector is aligned with the magnetic field, the ion and electron mobility matrices $\mathbb{M}_e$ and $\mathbb{M}_i$ are given by

$$\mathbb{M}_e = \begin{pmatrix} \mu_e^P & -\mu_e^H & 0 \\ \mu_e^H & \mu_e^P & 0 \\ 0 & 0 & \mu_e^\parallel \end{pmatrix}, \quad \mathbb{M}_i = \begin{pmatrix} \mu_i^P & \mu_i^H & 0 \\ -\mu_i^H & \mu_i^P & 0 \\ 0 & 0 & \mu_i^\parallel \end{pmatrix},$$

where the electron and ion Pedersen, Hall, and field-aligned mobilities are respectively defined by

$$\mu_{e,i}^P = \frac{\kappa\nu_{e,i}}{(\kappa\nu_{e,i})^2 + |B|^2}, \quad \mu_{e,i}^H = \frac{|B|}{(\kappa\nu_{e,i})^2 + |B|^2}, \quad \mu_{e,i}^\parallel = \frac{1}{\kappa\nu_{e,i}}.$$

In the situation $\kappa \to 0$, the electron or ion field-aligned mobilities tend to infinity.

Thanks to the mobility matrices, (2.2) and (2.3) may be rewritten as

$$u_{e,i} = \mathbb{M}_{e,i}\left(-q_{e,i}\nabla\phi + \kappa(\nu_{e,i}u_n - \eta\nabla\log n)\right), \tag{2.4}$$

$$-\nabla\cdot(n(\mathbb{M}_i + \mathbb{M}_e)\nabla\phi) = -\kappa\nabla\cdot(n[\mathbb{M}_i(\nu_i u_n - \eta\nabla\log n) - \mathbb{M}_e(\nu_e u_n - \eta\nabla\log n)]). \tag{2.5}$$

It is clear that the conductivity matrix $n(\mathbb{M}_i + \mathbb{M}_e)$ is positive definite (provided that ν_i or ν_e is positive and finite). Therefore, (2.5) is a three-dimensional elliptic equation for ϕ.

Now, we assume that the magnetic field is constant and uniform (see Figure 2.1). An extension to the nonuniform B case is given in [3] and [4]. Let us denote by $(\hat{x}_1, \hat{x}_2, \hat{x}_3)$ the orthonormal coordinate basis, with $\hat{x}_3$ aligned with B. We can choose the scaling units such that $|B| = 1$, so that $B = \hat{x}_3$. We denote by $\underline{x} = (x_1, x_2)$ the position vector in the two-dimensional plane orthogonal to B and by $\underline{\nabla} = (\partial_{x_1}, \partial_{x_2})$ the two-dimensional gradient. For any three-dimensional vector $a = (a_1, a_2, a_3)$, we define $\underline{a} = (a_1, a_2)$ as its projection onto this plane.

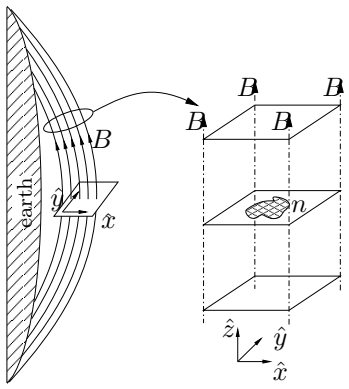

FIG. 2.1. *Geometry of the earth environment and reduction to a Cartesian geometry.*

When $\kappa \to 0$, the dynamo model reduces to the so-called striation model [3]:

$$\partial_t n + \nabla \cdot (nu) = 0, \tag{2.6}$$

$$u = -\underline{\nabla}\phi \times B + ((u_n - \eta\nu^{-1}\nabla \log n) \cdot B)B, \tag{2.7}$$

$$\underline{\nabla} \cdot (-\sigma(\underline{x})\underline{\nabla}\phi + (U_n - 2\eta\underline{\nabla}N) \times B) = 0, \tag{2.8}$$

with $\phi = \phi(\underline{x})$, $\sigma(\underline{x}) = \int n\nu dx_3$, $U_n = \int n\nu u_n dx_3$, $N = \int n dx_3$, $\nu = \nu_i + \nu_e$, and $u_i = u_e = u$. The striation model couples a three-dimensional convection-diffusion equation (2.6), (2.7) for the density n with a two-dimensional elliptic equation (2.8) for the electric potential ϕ. The coefficients of the elliptic equation (2.8) involve integrals of n over x_3, i.e., along the magnetic field lines. The infinite conductivity of the plasma along the magnetic field lines constrains the electric potential to be constant along these lines, i.e., to depend only on the two-dimensional coordinate $\underline{x}$.

If we additionally suppose that u_n is orthogonal to B and that all data and unknowns are independent of x_3, the striation model reduces to the following monolayer striation model:

$$\partial_t n + \nabla \cdot (nu) = 0, \quad u = -\nabla\phi \times B, \tag{2.9}$$

$$\nabla \cdot (nh) = 0, \quad h = \nu\left(-\nabla\phi + (u_n - 2\eta\nu^{-1}\nabla \log n) \times B\right), \tag{2.10}$$

where now all variables and vectors are two-dimensional (except $B = \hat{x}_3$) and 2-dimensional vectors are now left without being underlined. The quantity h represents the electron-ion relative velocity. We remark that $\nabla \cdot u = 0$. Therefore, we can write relation (2.9) as

$$\partial_t n + (u \cdot \nabla)n = 0. \tag{2.11}$$

As we will next see, the pressure term $\nabla \log n$ does not change the linearized stability properties of the striation model. When $\eta = 0$, (2.10) becomes

$$\nabla \cdot (nh) = 0, \qquad h = \nu\left(-\nabla\phi + u_n \times B\right). \tag{2.12}$$

In the next section, we analyze the linearized stability of this model.

3. Stability analysis of the striation model.

3.1. Introduction and phenomenology. The striation model exhibits an instability, the gradient-drift or $E \times B$ drift instability [13], [14]. In a recent work [6], local-in-time existence and uniqueness of solutions for this model have been proven and, following the methodology of [18], [20], [11], [24], smooth stationary density profiles which are linearly unstable have been shown to be nonlinearly unstable. However, it is still open whether the converse is true. In [6], a variational formulation for the instability growth rate is given. In the present work, we are aiming at a more quantitative result for certain specific classes of stationary profiles.

We restrict ourselves to two particular kinds of steady-state profiles. The first ones are smooth with an exponentially increasing density in one direction; they have already been investigated [13], [14], and we shall only summarize the results. The second ones are discontinuous density profiles; their analysis is, to the best of our knowledge, new. In passing, we shall have to show that it is meaningful to consider discontinuous solutions of the striation model.

We first give a phenomenological view of the instability of the striation model. We consider a steady state consisting of a discontinuous density $n(x) = \underline{n}$ for $x_2 < 0$ and $n = \overline{n} > \underline{n}$ for $x_2 > 0$, with $\nabla\phi = 0$ and $u_n = (0, U)$. We slightly perturb the interface, which is now represented by the graph of the function $x_2 = \varepsilon \sin(\xi x_1)$, where ε represents the magnitude of the perturbation ($\varepsilon \ll 1$) and ξ is its spatial frequency.

The term $u_n \times B$ in (2.12) creates a charge modulation along the interface which is alternately positive and negative. A nonzero electric field $-\nabla\phi$ parallel to the interface with a similar sign modulation is generated according to (2.12). Then, by (2.9), a nonzero component of the velocity u in the direction normal to the interface is created with again an alternating sign. According to the sign of u_n, this component of the velocity tends to either damp the modulation of the interface or increase it. The former case is a stable one, while the latter is an unstable one. The precise geometric configuration is depicted in Figures 3.1 and 3.2.

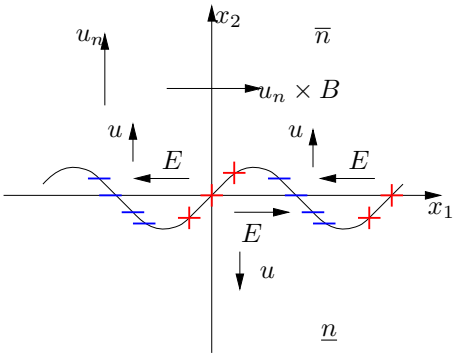

FIG. 3.1. *Stable configuration.*

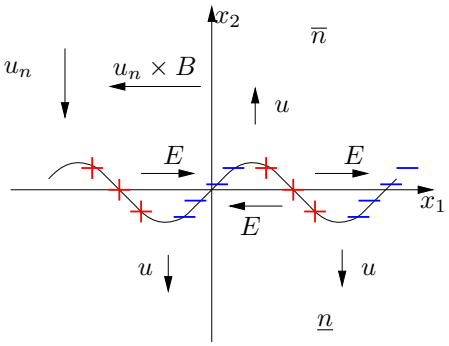

FIG. 3.2. *Unstable configuration.*

This behavior can be recovered by the linear stability analysis. We first turn to the analysis of the exponential density profile. In the remainder of this section, we assume that ν is a uniform constant and, by a convenient choice of the scaling units, we let $\nu = 1$.

3.2. Linear stability analysis: The exponential density profile. Let us denote by (n^0, u^0, h^0, ϕ^0) the unperturbed state, i.e., a time-independent solution

of the striation system (2.9), (2.12). We consider an exponential density profile in the x_2-direction, i.e., $n^0 = N\exp(x_2/\lambda)$, where $\lambda > 0$ is the gradient length, while $(u^0, h^0, \nabla\phi^0)$ are uniform constants. We suppose that the neutral wind is uniform as well and has components $u_n = (V, U)$. In this configuration, a necessary and sufficient condition for (n^0, u^0, h^0, ϕ^0) to form a steady state is that $u^0 = (V, 0)$, $h^0 = (\nu U, 0)$, $-\nabla\phi^0 = (0, V)$. In this analysis, we suppose that $\eta = 0$ unless otherwise specified.

Then, we introduce the perturbation $n = n^0(1+\varepsilon n^1 + O(\varepsilon^2))$, $(u, h, \phi) = (u^0, h^0, \phi^0) + \varepsilon(u^1, h^1, \phi^1) + O(\varepsilon^2)$, with $\varepsilon \ll 1$ in the striation model, and neglect the terms of order higher than ε. The neutral wind, being a datum, remains unperturbed. We note that $\nabla n^0 = (0, n^0/\lambda)$. An easy computation gives the linearized system governing the first order perturbation:

$$\partial_t n^1 + \lambda^{-1}\partial_{x_1}\phi^1 + V\partial_{x_1} n^1 = 0, \tag{3.1}$$

$$-\lambda^{-1}\partial_{x_2}\phi^1 - \Delta\phi^1 + U\partial_{x_1} n^1 = 0. \tag{3.2}$$

Remark 3.1. If the pressure gradient terms are retained in the model (i.e., if $\eta \neq 0$), the steady state is modified only through the expression of h^0, which should be taken as $h^0 = (U - 2\eta\lambda^{-1}, 0)$. However, the first order perturbation equations are the same as (3.1), (3.2). The details are left to the reader.

We develop the solution of (3.1), (3.2) into plane waves, i.e., (dropping the superscripts "1" for clarity) $(n, \phi) = (\bar{n}, \bar{\phi}\lambda|U|)\exp(i\lambda^{-1}(\xi_1 x_1 + \xi_2 x_2 - \omega t|U|))$, where $\xi = (\xi_1, \xi_2)$ is the (normalized) wave-vector of the perturbation and ω its frequency. Introducing this ansatz into (3.1), (3.2), we get

$$-\omega\bar{n} + \xi_1\bar{\phi} = 0, \quad i\sigma\xi_1\bar{n} + (\xi_1^2 + \xi_2^2 - i\xi_2)\bar{\phi} = 0, \tag{3.3}$$

with $\sigma = \mathrm{sign}(U) \in \{-1, 1\}$. This system has a nontrivial solution iff its determinant is nonvanishing. This condition yields the dispersion relation

$$\omega = \frac{-i\sigma\xi_1^2}{(\xi_1^2 + \xi_2^2)^2 + \xi_2^2}(\xi_1^2 + \xi_2^2 + i\xi_2). \tag{3.4}$$

We now recall the following standard definition.

DEFINITION 3.2. *The perturbation is stable if n and ϕ stay bounded for all times $t \geq 0$ and unstable in the converse situation. Therefore, a perturbation is stable iff $\Im m(\omega) \leq 0$ and unstable iff $\Im m(\omega) > 0$. A stationary state is called stable if all its perturbations are stable for all wave vectors ξ. It is unstable as soon as there exists a wave vector ξ giving rise to an unstable perturbation.*

Thanks to (3.4), we have $\mathrm{sign}(\Im m(\omega)) = -\sigma$. We then conclude the following result.

PROPOSITION 3.3. *The steady-state configuration with an exponential density profile is stable iff $U \geq 0$, i.e., if the x_2-component of the neutral wind points in the same direction as the density gradient. Furthermore, in the case $U < 0$, all wave vectors $\xi \neq 0$ are unstable, and for $\xi_2 = 0$ the growth rate is independent of ξ_1.*

As seen above, exponential density profiles allow explicit computations. However, they are fairly unrealistic, as the density tends to infinity on one side and degenerates to zero (and the elliptic problem (2.12) as well) on the other side. In order to study a more realistic situation, we extend our analysis to the case of discontinuous density profiles in the next section.

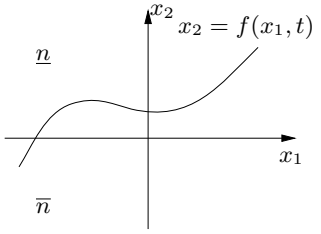

FIG. 3.3. *Discontinuity curve of n.*

3.3. Linear stability analysis: Discontinuous density profiles. We consider a density profile which is piecewise constant and discontinuous across a parametrized curve $C(t)$ given by the equation $x_2 = f(x_1, t)$, where $f \in C^1(\mathbb{R} \times [0, +\infty[)$, i.e., (see Figure 3.3)

$$n(x,t) = \begin{cases} \underline{n} & \text{for} \quad x_2 < f(x_1,t)\,, \\ \overline{n} & \text{for} \quad x_2 > f(x_1,t)\,. \end{cases} \tag{3.5}$$

First, we must give a meaning to discontinuous solutions of this kind. Toward this aim, we use the notion of a weak solution of (2.11).

DEFINITION 3.4. *Let $u \in C^1(\mathbb{R}^2 \times [0,\infty[)$. A function $n \in L^\infty_{loc}(\mathbb{R}^2 \times [0,\infty))$ is a weak solution of* (2.11) *with initial data n_0 iff n verifies*

$$\int_{\mathbb{R}^2 \times [0,\infty)} n \left(\frac{\partial \varphi}{\partial t} + \nabla \cdot (u\varphi) \right) dx\, dt + \int_{\mathbb{R}^2} n_0\, \varphi(x,0)\, dx = 0 \tag{3.6}$$

for all functions $\varphi(x,y,t) \in C^1_c(\mathbb{R}^2 \times [0,\infty))$, where C^1_c defines the space of functions of class C^1 with compact support.

The solution of (3.6) can be obtained through the method of characteristics. In particular, it satisfies the maximum principle. Therefore, if there exist two constants n_*, n^* such that $0 < n_* < n_0(x) < n^*$, this inequality is satisfied at all times: $0 < n_* < n(x,t) < n^*$.

This notion has to be extended to the case of discontinuous velocities. Suppose that $u = (u_1, u_2)$ is taken in the space $L^1_{\text{loc}}([0,\infty), H_{\text{div}})$, with $H_{\text{div}}(\mathbb{R}^2) = \{u \in L^2(\mathbb{R}^2)$, s.t. $\nabla \cdot u \in L^2(\mathbb{R}^2)\}$. Then, $\nabla \cdot (u\varphi) \in L^1_{\text{loc}}(\mathbb{R}^2 \times [0,\infty))$ for all test functions φ, and the expression (3.6)} still has a meaning. Now, in the striation model, u is a given by $u = -\nabla\phi \times B$, where ϕ is a solution of (2.12). To solve (2.12), we use the following (classical) proposition.

PROPOSITION 3.5. *Let $u_n \in L^2(\mathbb{R}^2)$ and n be such that there exist two constants n_*, n^* with $0 < n_* < n(x,t) < n^*$. Then,* (2.12)*, which can be written*

$$\nabla \cdot (n \nabla \phi) = \nabla \cdot (n u_n \times B),$$

has a solution in the space $L^1_{loc}([0,\infty), H)$, with $H = \{\phi \in \mathcal{D}'(\mathbb{R}^2),\ \nabla\phi \in L^2(\mathbb{R}^2)\}$, unique up to an additive constant.

Since u satisfies $\nabla \cdot u = 0$, this proposition guarantees that u belongs to $L^1_{\text{loc}}([0,\infty), H_{\text{div}}(\mathbb{R}^2))$. For such velocities, this allows us to define n as a weak solution of (2.11) in the sense of (3.6). Therefore, it is meaningful to look for solutions with discontinuous densities. Of course, we have not shown the actual existence of such solutions, which will be the subject of future work. Now, we recall the following classical trace property (see [16]).

LEMMA 3.6. *Let C be a regular orientable curve of $\mathbb{R}^2$. Then the mapping $\gamma_N : v \to (v \cdot N)|_C$ (with N the unit normal vector to C) defined on $\mathcal{D}(\mathbb{R}^2)$ can be extended by continuity to a linear and continuous mapping, still denoted by γ_N, from $H_{div}(\mathbb{R}^2)$ into $H^{-1/2}(C)$.*

We are now ready to determine the conditions that f must fulfill for n to be a weak solution. We have the following.

PROPOSITION 3.7. *Let u belong to $L^1_{loc}([0,\infty), H_{div}(\mathbb{R}^2))$. A function n defined by (3.5) is a weak solution to (2.11) iff f is a smooth solution to the equation*

$$\partial_t f = (u \cdot N)\left(1 + (\partial_{x_1} f)^2\right)^{1/2}, \quad (x_1, t) \in \mathbb{R} \times [0,\infty), \tag{3.7}$$

where N is the unit normal vector to the curve of discontinuity $C(t)$ (pointing towards $x_2 > 0$) and $(u \cdot N)$ is the trace along $C(t)$ as defined by Lemma 3.6. We can write $(u \cdot N)(1 + (\partial_{x_1} f)^2)^{1/2} = [u_2 - u_1 \partial_{x_1} f]\,|_C$, where the index C indicates that this quantity is the common limit of the bracket as $x_2 \to f(x_1, t)$ from above and below.

Proof. We insert the expression for n into (3.6). We get

$$0 = \underline{n} \int_{x_2 < f,\, t \geq 0} (\partial_t \varphi + \nabla \cdot (u\varphi))\, dx\, dt + \overline{n} \int_{x_2 > f,\, t \geq 0} (\partial_t \varphi + \nabla \cdot (u\varphi))\, dx\, dt\,.$$

Since φ is compactly supported, we have $\int_{\mathbb{R}^2 \times [0,\infty)} (\partial_t \varphi + \nabla \cdot (u\varphi))\, dx\, dt = 0$. We regard φ as compactly supported in $\mathbb{R}^2 \times (0,\infty)$ since the treatment of the initial condition at $t = 0$ is standard. We deduce that

$$0 = (\underline{n} - \overline{n}) \int_{x_2 < f,\, t \geq 0} (\partial_t \varphi + \nabla \cdot (u\varphi))\, dx\, dt\,. \tag{3.8}$$

In order to apply the Green formula, we use Lemma 3.6. We define the surface $\Sigma = \{(x,t) \in \mathbb{R}^2 \times [0,\infty),\, x \in C(t)\}$ and the open sets $\mathcal{O}(t) = \{x \in \mathbb{R}^2,\, x_2 < f(x_1, t)\}$ and $\Omega = \{(x,t) \in \mathbb{R}^2 \times [0,\infty),\, x \in \mathcal{O}(t)\}$. Let $\tilde{N} = (\tilde{N}_1, \tilde{N}_2, \tilde{N}_t)$ be the outgoing unit normal to Ω at (x,t) of Σ and $\tilde{N}_x = (\tilde{N}_1, \tilde{N}_2)$. Thanks to Lemma 3.6, we can apply the Green formula and get

$$\int_\Omega (\partial_t \varphi + \nabla \cdot (u\varphi))\, dx\, dt = \int_\Sigma \varphi \left(\tilde{N}_t + u \cdot \tilde{N}_x\right) d\Sigma(x,t)\,,$$

where the integrals on Σ should be understood as the duality $L^\infty([0,\infty), H^{1/2}(C(t)))$ against $L^1([0,\infty), H^{-1/2}(C(t)))$. Now, we have $\tilde{N} d\Sigma(x,t) = (-\partial_{x_1} f,\, 1,\, -\partial_t f)\, dx_1\, dt$, which implies $\tilde{N}_x d\Sigma(x,t) = (1 + (\partial_{x_1} f)^2)^{1/2} N\, dx_1\, dt$. Assuming that $\underline{n} \neq \overline{n}$, (3.8) gives

$$\int_{\mathbb{R} \times [0,\infty)} \varphi \left((u \cdot N)\left(1 + (\partial_{x_1} f)^2\right)^{1/2} - \partial_t f\right) dx_1\, dt = 0. \tag{3.9}$$

Since (3.9) has to be verified for all test functions φ, we deduce (3.7). ∎

Then, the striation model (2.9), (2.12) for weak solutions can be written

$$\partial_t f = [\partial_{x_2} \phi\, \partial_{x_1} f + \partial_{x_1} \phi]\,|_{C(t)}\,, \tag{3.10}$$

$$-\nabla \cdot ((\underline{n} \chi_f + \overline{n}(1 - \chi_f))(\nabla \phi - u_n \times B)) = 0, \tag{3.11}$$

with $\chi_f = 1$ if $x_2 < f(x_1, t)$ and $\chi_f = 0$ otherwise.

We now turn to the stability analysis of the striation model with discontinuous initial density. A steady state of this model is given by $f^0 = 0$, $\nabla\phi^0 = (0, -V)$, $u_n = (V, U)$. We define the small perturbations of order ε as $f = \varepsilon f^1$, $\phi = \phi^0 + \varepsilon\phi^1$, with $\varepsilon \ll 1$. We introduce this ansatz in (3.10), (3.11) and keep only the terms of order ε. We get

$$\left(\partial_t f^1 + V\partial_{x_1} f^1 - \partial_{x_1}\phi^1\right)|_{(x_1,0,t)} = 0, \tag{3.12}$$

$$-\nabla\cdot(n^0\nabla\phi^1) = -U\lim_{\varepsilon\to 0}\varepsilon^{-1}\partial_{x_1}(\underline{n}\chi_{(\varepsilon f^1)} + \overline{n}(1-\chi_{(\varepsilon f^1)})), \tag{3.13}$$

where $n^0 = \underline{n}\chi_0 + \overline{n}(1-\chi_0)$ is the unperturbed density profile. A simple computation leads to $\partial_{x_1}\chi_{(\varepsilon f)} = \varepsilon(\partial_{x_1} f)\delta_{x_2=0} + O(\varepsilon^2)$, where the distribution $g(x_1)\delta_{x_2=0}$ is defined through the relation $\langle g(x_1)\delta_{x_2=0}, \varphi\rangle = \int_{\mathbb{R}}\varphi(x_1,0)g(x_1)\,dx_1$ with $\varphi(x) \in C_c^\infty$. Then (3.13) reads

$$-\nabla\cdot(n^0\nabla\phi^1) = U(\overline{n}-\underline{n})\partial_{x_1} f^1\,\delta_{x_2=0}\,. \tag{3.14}$$

Like in the exponential density profile case, we develop the solution as a plane wave in the x_1 direction: $(f^1, \phi^1) = (\bar f, \bar\phi(x_2))\exp i(\xi x_1 - \omega t)$, where $\bar f$ and $\bar\phi(x_2)$ must be determined.

We introduce the plane-wave ansatz in (3.12), (3.14), and we get

$$-i\omega\bar f + iV\xi\bar f = i\xi\bar\phi(0)\,, \tag{3.15}$$

$$-\left(\partial_{x_2}\left(n^0\partial_{x_2}\bar\phi\right) - \xi^2 n^0\bar\phi\right) = U(\overline{n}-\underline{n})i\xi\bar f\delta_{x_2=0}\,. \tag{3.16}$$

If we solve (3.16) away from the point $x_2 = 0$ and look for a bounded solution when $|x_2| \to \infty$, we find $\bar\phi(x_2) = \bar\phi(0)e^{-|\xi||x_2|}$. Then, in the distributional sense on $\mathbb{R}$, we have

$$-\left(\partial_{x_2}\left(n^0\partial_{x_2}\bar\phi\right) - \xi^2 n^0\bar\phi\right) = -(\underline{n}+\overline{n})|\xi|\bar\phi(0)\delta_{x_2=0}\,. \tag{3.17}$$

We introduce (3.17) in (3.16) and find

$$i\xi\bar f\delta_{x_2=0} - \frac{\overline{n}+\underline{n}}{\overline{n}-\underline{n}}\frac{|\xi|}{U}\bar\phi(0)\delta_{x_2=0} = 0\,. \tag{3.18}$$

Solving for $\bar f$ thanks to (3.15) and inserting it into (3.18) allows us to find the dispersion relation

$$\omega = -V\xi - i\,U\frac{\overline{n}-\underline{n}}{\overline{n}+\underline{n}}\,\xi. \tag{3.19}$$

We can easily deduce the following stability result.

PROPOSITION 3.8. *Let us assume that $\overline{n} > \underline{n}$. Steady states defined by* (3.5) *with $f = 0$ are stable iff $U \geq 0$. Furthermore, if $U < 0$, all wave-vectors ξ are unstable. The growth rate of the instability is given by*

$$|\Im m(\omega)| = \frac{\overline{n}-\underline{n}}{\overline{n}+\underline{n}}\,U\,|\xi|. \tag{3.20}$$

This theorem makes the formal analysis of section 3.1 more quantitative. We note that the growth rate increases linearly as a function of ξ, while it was a constant in the exponential density case (section 3.2). This feature prevents us from extending the nonlinear instability theorem of [6] to the discontinuous case.

3.4. Conclusion of the stability analysis. The instability contributes to the development of smaller and smaller structures in the plasma. Quickly, the plasma becomes chaotic (see section 6). In practice, the instability saturates after reaching some level by the effects of physical dissipation mechanisms, which are not accounted for so far in the model. We can think of three sources of physical dissipation: (i) finite temperature effects, (ii) finite conductivity effects, (iii) turbulence effects. By Remark 3.1, we have seen that finite temperature effects alone do not change the results of the stability analysis. Therefore, we must simultaneously introduce finite temperature and finite conductivity effects; i.e., we must go back to the full dynamo model (2.1)–(2.3). In section 4, we perform the stability analysis of the dynamo model and show that large wave-vector perturbations are stable. However, the level of dissipation, i.e., the threshold wave-number for stability, is too large to match practical observations. Therefore, in section 5, we investigate the effects of fluid turbulence.

4. Stability analysis of the dynamo model (2.1)–(2.3). This analysis can be found, in parts, in [13], [14]. We consider steady states with exponential density profiles. Due to diffusion, discontinuous density profiles are not steady states of the dynamo model any longer, and there is no point in trying to analyze their stability. To simplify the analysis and to make it as close as possible to that of the striation model in section 3.2, we still consider a uniform magnetic field pointing in the x_3-direction, and we suppose that u_n is orthogonal to B. All unknowns are independent of x_3, and vectors are contained in the plane (x_1, x_2). We assume that ν_e and ν_i are constants and such that $\nu = \nu_e + \nu_i = 1$.

The steady state is given by

$$
\begin{aligned}
&n^0 = N \exp\left(\frac{x_2}{\lambda}\right), \quad u_n = (V, U), \quad h^0 = \left(U - 2\eta\lambda^{-1}\right)\hat{x}_1,\\
&u_i^0 = \left\{\kappa\nu_e(U - 2\eta\lambda^{-1}) + V\right\}\hat{x}_1, \quad u_e^0 = \left\{-\kappa\nu_i(U - 2\eta\lambda^{-1}) + V\right\}\hat{x}_1,\\
&\nabla\phi^0 = (-\kappa^2\nu_i\nu_e(U - 2\eta\lambda^{-1}), -\kappa(\nu_e - \nu_i)(U - \eta\lambda^{-1}) - V).
\end{aligned}
$$

We proceed to the linear stability analysis as in section 3.2. We introduce the perturbation $n = n^0(1 + \varepsilon n^1 + O(\varepsilon^2))$, $u_{i,e} = u_{i,e}^0 + \varepsilon u_{i,e}^1 + O(\varepsilon^2)$, and $\phi = \phi^0 + \varepsilon\phi^1 + O(\varepsilon^2)$ in the dynamo model (2.1)–(2.3). We keep only order ε terms and develop the solution as a plane wave according to the same ansatz as in section 3.2. Let us define

$$
\begin{aligned}
&\mu_-^H = \mu_i^H - \mu_e^H, \quad \mu_+^H = \mu_i^H + \mu_e^H, \quad \mu_-^P = \mu_i^P - \mu_e^P, \quad \mu_+^P = \mu_i^P + \mu_e^P,\\
&X = \xi_1\mu_i^H - \xi_2\mu_i^P, \quad Y = \xi_1\mu_-^H - \xi_2\mu_+^P, \quad Z = \xi_1\mu_+^H - \xi_2\mu_-^P,\\
&A_X = \mu_i^P|\xi|^2 + iX, \quad A_Y = \mu_+^P|\xi|^2 + iY, \quad A_Z = \mu_-^P|\xi|^2 + iZ.
\end{aligned}
$$

Then, we get the dispersion relation

$$
\omega = \frac{A_Y^*}{|U||A_Y|^2}\left(\xi_1 u_{ix}^0 A_Y - i\frac{\kappa\eta}{\lambda}A_X A_Y - \xi_1 h_x^0 A_X + i\frac{\kappa\eta}{\lambda}A_X A_Z\right), \tag{4.1}
$$

where $h = u_i - u_e$ and the star denotes the complex conjugate. The expression of $\Im m(\omega)$ may be simplified as follows:

$$
\Im m(\omega) = \frac{2\kappa\eta}{\lambda|U||A_Y|^2}\mu_i^P\mu_e^P\mu_+^P|\xi|^2 P(\xi), \qquad P(\xi) = -|\xi|^4 + (a+1)\xi_1^2 + 2c\xi_1\xi_2 - \xi_2^2, \tag{4.2}
$$

with $a = -U\lambda\,(\,2\kappa\eta\nu_e\nu_i\mu_+^P\,)^{-1}$, $c = \mu_-^H(\mu_+^P)^{-1}$.

If $\kappa \to 0$, the dynamo model reduces to the striation model with nonzero temperature, which has the same dispersion relation (3.4) as the striation model with zero temperature (see Remark 3.1). We can verify this property on the dispersion relation (4.2). Indeed, as $\kappa \to 0$, we have $a \sim -U\lambda\,(\,2\eta\nu_e\nu_i\,)^{-1}\kappa^{-2}$, $c \sim \kappa(\nu_e - \nu_i)$. Therefore, $P(\xi) \sim -U\lambda\,(\,2\eta\nu_e\nu_i\,)^{-1}\xi_1^2\kappa^{-2}$, and we have $P(\xi) < 0$ if $U > 0$ (resp., $P(\xi) > 0$ if $U < 0$). Thus, we recover the results of section 3.2 for the striation model.

On the other hand, if we let the temperature go to zero (i.e., $\eta \to 0$) in (4.2) while keeping κ finite, we find $a = O(\eta^{-1})$ while $c = O(1)$. Therefore, $P(\xi) \sim -U\lambda(2\kappa\nu_i\nu_e\mu_P^+\eta)^{-1}$, and again the stability conditions for this model are the same as those of the striation model; i.e., the model is unstable for all wave-vectors if $U < 0$ and stable otherwise. Therefore, for the model to exhibit a stable range of wave-vectors, we need at the same time a finite conductivity and a finite temperature. We now show that this is indeed the case.

PROPOSITION 4.1. *Suppose that $\eta > 0$ and $\kappa > 0$. Then,*

(i) *the dynamo model* (2.1)–(2.3)*, linearized about the above-defined steady states, is stable iff $U\lambda > 2\eta\kappa^2\nu_e\nu_i$;*

(ii) *if $U\lambda < 2\eta\kappa^2\nu_e\nu_i$, there exists $R_0(\eta,\kappa) > 0$ such that if ξ is an unstable wave-vector, then $|\xi| < R_0$. Furthermore, $R_0 = O((\sqrt{\eta}\kappa)^{-1})$ as $\sqrt{\eta}\kappa \to 0$.*

We note that the stability criterion for the dynamo model is more restrictive than that of the striation model. The quantity $U\lambda$ needs to be not only positive, but also large enough. However, in the unstable case, when $U\lambda$ is not large enough, the instability region is a bounded domain in wave-vector space (by contrast with the case of the striation model, in which the instability domain is unbounded). The instability region grows as η or κ decreases to 0, and ultimately fills the entire wave-vector space in the limit.

Proof. We introduce polar coordinates $\xi_1 = r\cos\theta$ and $\xi_2 = r\sin\theta$. We can write $P = -r^2Q$ with $Q = r^2 - F(\theta)$ with

$$F(\theta) = (a+1)\cos^2\theta + 2c\cos\theta\sin\theta - \sin^2\theta = \delta\cos(2\theta - \alpha) + \left(\frac{a}{2}\right)$$

and $\delta = (((a/2)+1)^2+c^2)^{1/2}$, $\alpha = \tan^{-1}(a/(a+2))$. Therefore, $Q = 0$ iff $\cos(2\theta-\alpha) = \delta^{-1}(r^2 - (a/2))$. For this equation to have roots, we need that $-1 \le \delta^{-1}(r^2 - (a/2)) \le 1$. Therefore, if $-a/(2\delta) > 1$, this equation cannot have any root, for any value of $r > 0$. Conversely, if $-a/(2\delta) \le 1$, this equation has roots as long as $(a/2) - \delta \le r^2 \le (a/2) + \delta$. Therefore, the case $-(a/(2\delta)) > 1$ characterizes the stable cases. This condition is equivalent to $a + 1 + c^2 < 0$, or, after some easy computations, to $U\lambda > 2\eta\kappa^2\nu_e\nu_i$. In the unstable case, the instability domain, i.e., the set of wave-vectors ξ leading to unstable modes, is contained in the ball centered at 0 and of radius R_0 with $R_0^2 = (a/2) + \delta$. As κ or η tend to 0, we notice that $R_0^2 \sim |U\lambda|(2\nu_e\nu_i)^{-1}(\eta\kappa^2)^{-1}$, which ends the proof of Proposition 4.1. ∎

The fact that the model is stable apart from a bounded region of wave-vectors can be seen as a favorable feature. Indeed, in such a case, small wave-vector (i.e., long wave-length) perturbations first grow exponentially due to the instability, but also undergo a mode cascade towards higher wave-numbers due to nonlinearity. Once the wave-vectors are large enough to reach the stability region, they are damped by the dissipation. We therefore expect that only structures of typical size R_0^{-1} will remain for long times.

However, the values of the physical parameters in the dynamo model are too small to ensure a viable stabilization process. Indeed, we see that $R_0 = O((\kappa^2\eta)^{-1/2})$

when κ or $\eta \to 0$. This is too large compared with the observations (see, e.g., [13], [14]). Therefore, another dissipation mechanism must be present. In this paper, we postulate that the turbulence of the plasma induced by the instability modifies the dissipation constants in a way similar to what happens in fluid mechanics (see, e.g., [32] and references therein). To make this assumption more quantitative, in the next section we develop a statistical approach to turbulence adapted to the striation model.

5. A "turbulent" striation model.

5.1. Derivation of the "turbulent" striation model. To produce this new model, we follow the statistical approach to turbulence [32] (see also [28] for an application to MHD). We suppose that the unknowns (n, u, ϕ, h) in the striation model (2.9), (2.12) are random variables representing the possible realizations of the flow. Any of these quantities a can be decomposed according to $a = \bar{a} + a'$, where $\bar{a}$ is its mean value and a' is a random fluctuation about this average. Since the randomness concerns the realization of the flow, the mean value operator commutes with the space and time derivatives. Therefore, we have $\overline{(\bar{a})} = \bar{a}$, $\overline{a'} = 0$, $\nabla a = \nabla \bar{a} + \nabla a'$, $\partial_t a = \partial_t \bar{a} + \partial_t a'$. If b is a nonfluctuating quantity, we have $\overline{ba} = b\bar{a}$, and for two random quantities a and b, $\overline{ab} \neq \bar{a}\bar{b}$ unless they are statistically independent. However, we note that $\overline{a\bar{b}} = \bar{a}\bar{b}$.

We assume that u_n and ν are nonfluctuating quantities. Under this assumption, by averaging the striation model (2.9)–(2.12), we obtain

$$\partial_t \bar{n} + \nabla \cdot (\overline{nu}) = 0, \quad \bar{u} = -\nabla \bar{\phi}, \tag{5.1}$$

$$\nabla \cdot (\overline{nh}) = 0, \quad \bar{h} = -\nu(\bar{u} - u_n) \times B. \tag{5.2}$$

We can write $\overline{nu} = \bar{n}\bar{u} + \overline{n'u'}$ with $\overline{n'u'} \neq 0$, since n' and u' are in general not independent random variables. In a same way, we have $\overline{nh} = -\nu(\bar{n}\bar{u} + \overline{n'u'} - \bar{n}u_n) \times B \neq \bar{n}\bar{h}$.

To close the model, we need a prescription for the correlation $\overline{n'u'}$ as a function of the mean quantities. As in fluid turbulence (see, e.g., [32]), we model this correlation by means of a diffusion term acting on the density, i.e., $\overline{n'u'} = -D\nabla\bar{n}$, where $D > 0$ is a diffusion coefficient. The use of this ansatz can be formally justified by invoking Kesten–Papanicolaou's theorem [27] (see also [32] for a review and [35] for a related result). For simplicity, we assume that D is a constant. Under this assumption, and noting that $\nabla \cdot (\overline{n'u'} \times B) = -D\nabla \cdot (\nabla n \times B) = 0$, system (5.1)–(5.2) reduces to the following (turbulent striation) model (dropping the bars):

$$\partial_t n + \nabla \cdot (nu) - \nabla \cdot (D\nabla n) = 0, \quad u = -\nabla\phi \times B, \tag{5.3}$$

$$\nabla \cdot (nh) = 0, \quad h = \nu\left(-\nabla\phi + u_n \times B\right). \tag{5.4}$$

The difficulty is now to find the correct value for the diffusion coefficient D. For this purpose, we again proceed to a stability analysis, in a similar fashion as what was done in sections 3.2 and 4.

5.2. Stability analysis of the turbulent striation model. We again choose a steady state characterized by an exponential density profile and uniform neutral wind $u_n = (V, U)$ and electric field. The unperturbed state is defined by $n_0 = Ne^{x_2/\lambda}$, $u_0 = (V, 1/\lambda) = (-\partial_{x_2}\phi_0, \partial_{x_1}\phi_0)$. We introduce $\bar{D}$ such that $D = |U|\lambda\bar{D}$. We proceed as in sections 3.2 and 4 and we get the following imaginary part of the dispersion

relation (with $\sigma = \text{sign}(U)$):

$$\Im m(\omega) = \frac{\mathcal{N}}{\mathcal{D}}, \quad \mathcal{N} = -\bar{D}|\xi|^2(|\xi|^4 + \xi_2^2) - (\sigma - \bar{D})\xi_1^2|\xi|^2, \quad \mathcal{D} = |\xi|^4 + \xi_2^2. \tag{5.5}$$

Since $\mathcal{D} \geq 0$, we just have to discuss the sign of $\mathcal{N}$. We introduce the polar coordinates $\xi_1 = r\cos\theta$ and $\xi_2 = r\sin\theta$. Then, $\mathcal{N} = -\bar{D}r^4(r^2 + \sin^2\theta - (1 - \sigma\bar{D}^{-1})\cos^2\theta)$. The domain $\mathcal{I}$ defined in polar coordinates by $r \leq r(\theta) := \{(1 - \sigma\bar{D}^{-1})\cos^2\theta - \sin^2\theta\}^{1/2}$ (for all θ such that the expression inside the square root is positive) characterizes the (bounded) instability domain. We can summarize the results in the following.

PROPOSITION 5.1. (i) *If $\sigma = 1$ (stable case for the original striation model) and $\bar{D} < 1$, the turbulent striation model* (5.3), (5.4) *linearized about the above-defined stationary states is stable.*

(ii) *If ($\sigma = 1$ and $\bar{D} > 1$) or $\sigma = -1$, the turbulent striation model is unstable for wave-vectors lying in the instability domain $\mathcal{I}$. $\mathcal{I}$ is bounded and contained in the ball centered at the origin and of radius $(1 - \sigma\bar{D}^{-1})^{1/2}$.*

We note this strange feature that adding too large a diffusion can destabilize the striation model in the case where the unperturbed striation model is stable (case $\sigma = 1$ and $\bar{D} > 1$).

Thanks to this stability result, we can return to the problem of finding the value for D. Suppose that we know (from experimental observations, for instance) that no structures finer than a certain scale ℓ can persist. This means that all perturbations with a wavelength less than ℓ are stable (i.e., are damped by dissipation), or equivalently, that all wave-vectors ξ larger than $1/\ell$ lie in the stability domain. To ensure this property, it is enough to have $1/\ell > (1 + \bar{D}^{-1})^{1/2}$. (We take $\sigma = -1$ because, in practice, there are always regions where the density gradient and the neutral wind have configurations which trigger the instability; see, e.g., the numerical results in section 6.) This condition translates into $\bar{D} \geq \ell^2(1 - \ell^2)^{-1}$. In practice, it is legitimate to assume that $\ell \ll 1$ (because the typical size of the ultimate permanent structures is far smaller than the typical size of the observation domain). Going back to the unscaled value of the diffusion constant D, we get

$$D \gtrapprox \ell^2\lambda|U|\,. \tag{5.6}$$

In the next section, we present numerical simulations which display the relation between the typical size of the persisting structures triggered by the instability and the value of this diffusion coefficient.

6. Numerical experiments. In this section, we present some numerical simulations of the striation model (2.9), (2.12) and of the turbulent striation model (5.3), (5.4). The elliptic equation (2.12) or (5.4) is discretized by a conservative finite difference method. The plasma velocity is computed by means of finite differences applied to the second equation of (2.9) or (5.3) on staggered grids. The transport equation (first equation of (2.9) or (5.3)) is discretized thanks to a classical TVD-scheme [17], [42], [30]. In order to deal with steep density gradients, the diffusion operator in (5.3) is implicitly discretized, and we make use of a Strang splitting for the overall time discretization of this equation. A preconditioned gradient method [40] is applied to solve the linear systems resulting from the discretization of the elliptic equation (2.12) or (5.4) and from the implicit discretization of the diffusion equation (5.3).

Our first test problem is intended to mimic that of [44]. The initial density is a random perturbation of a uniform density in the x_1-direction with a Gaussian profile

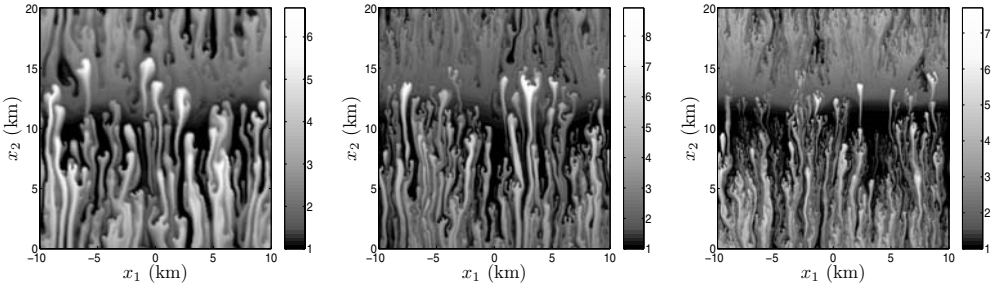
FIG. 6.2. *Plasma density at various times given by the striation model discretized on mesh* 1.

in the x_2-direction (cf. Figure 6.1). The neutral wind u_n is directed along the x_2-axis and has a value of 45 ms^{-1}. Different mesh sizes listed in Table 6.1 are considered. When the turbulent striation model is considered, the diffusion length ℓ (which sets the value of the diffusion coefficient through (5.6)) is equal to 0.1×10^3 m (a scale resolved by all mesh steps). In practice, its value should be prescribed by comparing with experimental measurements (see, for instance, [8]). However, our purpose here is towards qualitative rather than quantitative results.

We first consider the original striation model (2.9), (2.12). Figure 6.2 displays the time evolution of the plasma density as a function of the two-dimensional coordinate x. Periodic boundary conditions are used. We see that the upper side (with respect to the orientation of the figure) of the density gradient is unstable, while the lower side is stable. The instability produces finger-like structures which rise in the positive x_2-direction and eventually (by periodicity) appear as originating from the lower boundary. In Figure 6.3 we represent the plasma density computed on the different meshes (see Table 6.1) at time $t = 804$ s. The mesh-size is divided by a factor 2 from panel (a) to panel (b) and from panel (b) to panel (c). One can notice that the



(a) Mesh 1 (200 × 200). (b) Mesh 2 (400 × 400). (c) Mesh 3 (800 × 800).

FIG. 6.3. *Plasma density at $t = 804$ s given by the striation model discretized on the three different meshes of Table* 6.1.

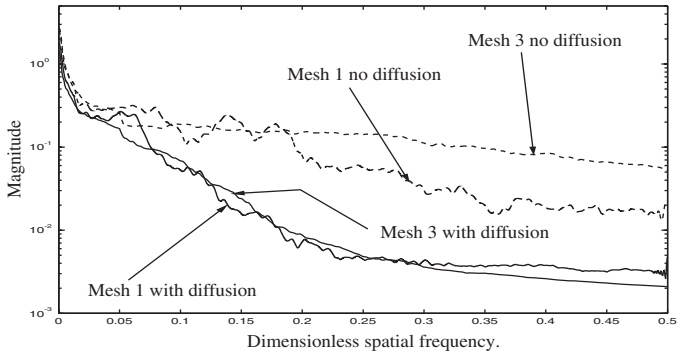


FIG. 6.4. *Spectral density of the plasma density n computed on the coarsest and the finest meshes of Table* 6.1 *(mode magnitude versus dimensionless spatial frequency). The spatial frequency scale is set to ℓ^{-1}, where ℓ, given by* (5.6)*, is equal to* $0.1\,10^3$ *m.*

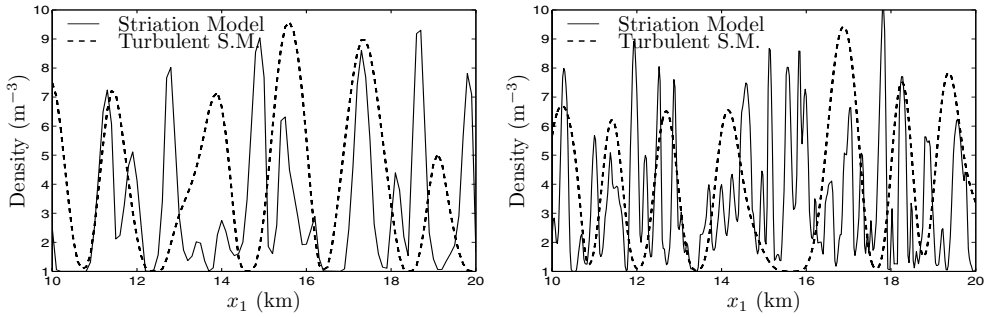
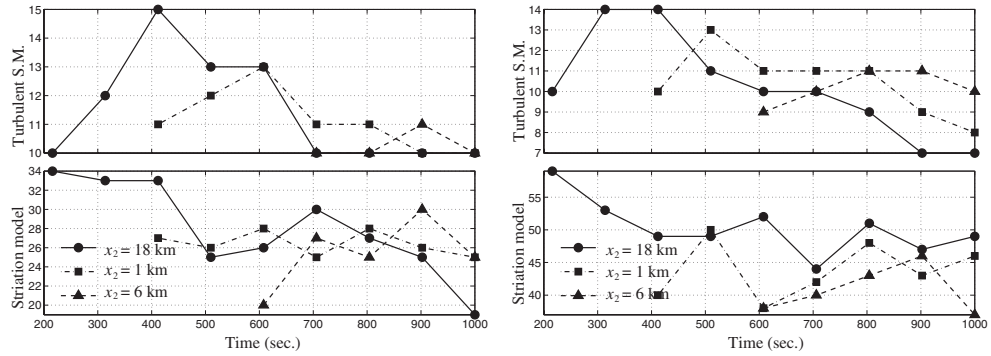
number of persisting structures grows with the number of cells, while their typical size decreases with the mesh-size. This remark can be made more quantitative as in Figure 6.4, where the spectral density (i.e., the modulus of the Fourier transform) of the plasma density is displayed for the coarsest and finest meshes (dashed curves). We can see that high frequency modes (corresponding to space scales ranging from 2 to 5 times the value of ℓ) have a significantly larger contribution when the finest mesh is used. Correspondingly, in Figure 6.3, we notice that the structures are all the tinier as the mesh becomes finer.

This behavior can be related to the instability of the model. Indeed, numerical diffusion is the only damping mechanism, and the numerical diffusivity is proportional to the mesh size [17], [42], [30]. According to the stability analysis in section 5.2, the diffusive striation model becomes stable for wave-vectors of the order of $1/\sqrt{D}$, which is proportional to $1/\sqrt{\Delta x}$. Therefore, the size of the typical persisting structures must be divided by a factor $\sqrt{2}$ each time the mesh-size is divided by 2. This is, roughly speaking, what we observe in Figure 6.5, where cuts of the density along lines $x_2 =$ constant are plotted. The calculation carried out on the coarsest mesh (solid line of Figure 6.5(a)) exhibits five to six main structures (areas where the density varies significantly) in the last quarter of the x_1 range. In the same interval approximately

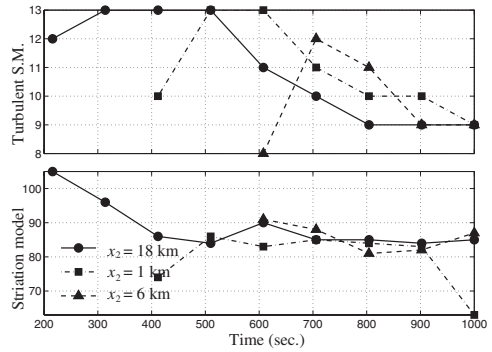


(a) Mesh 1 (second half of the x_1 range). (b) Mesh 3 (second half of the x_1 range).

FIG. 6.5. *Plasma density profiles along the line $x_2 = 2$ km at time $t = 392$ s.*



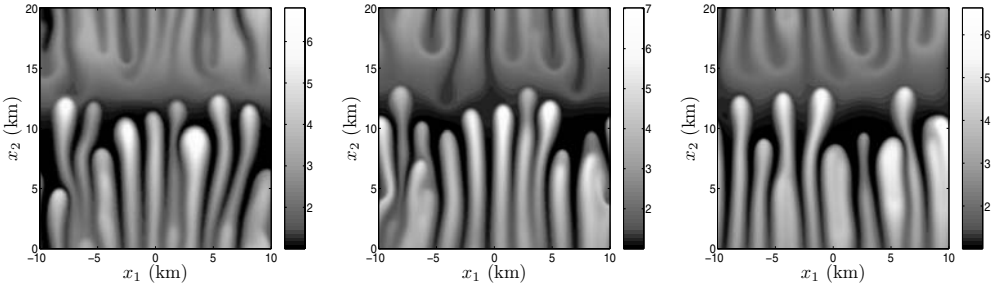
(a) Mesh 1 (200 × 200). (b) Mesh 2 (400 × 400).



(c) Mesh 3 (800 × 800).

FIG. 6.6. *Number of local maxima along the lines $x_2 = 18, 1, 6$ km (circles, squares, and triangles, respectively) as a function of time for the turbulent striation model* (a), (b) *and the classical one* (c) *computed on the three meshes of Table* 6.1. *The number of local maxima is computed as half the number of sign changes in the density derivative.*

14 main structures are counted for the density profile computed with the finest grid (solid line of Figure 6.5(b)). Note that small patterns can exist in addition to the persisting structures. Indeed there are seven and more than twenty local maxima for meshes 1 and 3, respectively. The same ratio is observed in Figure 6.6, where the



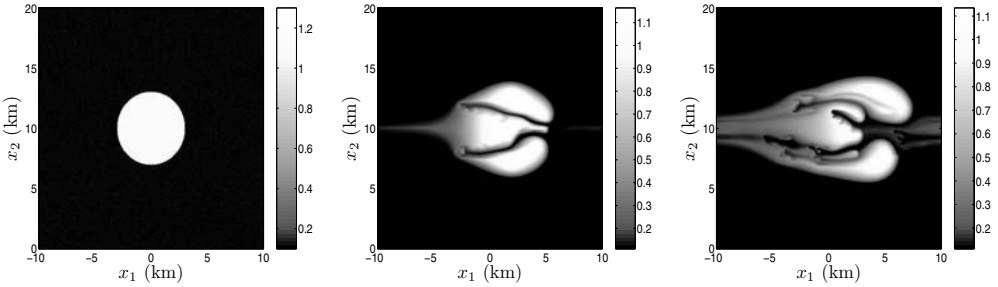
(a) Mesh 1 (200 × 200). (b) Mesh 2 (400 × 400). (c) Mesh 3 (800 × 800).

FIG. 6.7. *Plasma density at* $t = 804$ *s, given by the turbulent striation model discretized on the three different meshes of Table* 6.1.

time evolution of the number of local maxima is displayed. For long time evolution (greater than 600 (s.)) the number of local maxima can be estimated as 25 for the coarsest mesh and 85 for the finest one. These results confirm the mesh-dependence of the simulations.

We next consider the turbulent striation model (5.3), (5.4). Figure 6.7 demonstrates the stability brought by the diffusion: the number and size of the structures remain almost the same when the mesh resolution increases. The dashed curves of Figure 6.5 display cuts of the density on a line $x_2 =$ constant for the coarsest and finest meshes, respectively. The small patterns which could be observed on the results computed with the classical striation model (solid curves) have disappeared. Moreover, the number of local maxima (six for the coarsest mesh, seven for the finest one) observed in Figure 6.5 are now quite independent of the grid resolution. This invariance of the number of local maxima with respect to the grid resolution can be observed in the course of the time evolution (see Figure 6.6). Indeed, this number remains almost constant in time, and equal to 9 when the mesh-size varies. These results therefore show a significant difference between the turbulent striation model and the original one. The spectral densities computed with the turbulent striation model are displayed in Figure 6.4. The diffusion damps out the high frequency modes, and the curves computed with the two different mesh-sizes are very similar, whatever space scales are considered, in contrast with the behavior of the original striation model. Note that the characteristic size of the striations observed in Figures 6.7 and 6.5 amounts to a few kilometers, which fits well with experimental observations.

The second simulation is aimed at illustrating the results of the stability analysis developed in the discontinuous density profile framework (see section 3.3). To this purpose, we consider a set of simulation parameters similar to those above, except for the initial density and the neutral wind. The initial density consists of a plasma bubble (density equal to one) in a quasi-vacuum medium (very small density). This initial data is perturbed by a random noise. The neutral wind is oriented along the x_1-axis; its speed is set to 100 $\mathrm{m} \cdot \mathrm{s}^{-1}$. Simulations performed on mesh 2 (Table 6.1) with the classical striation model are displayed in Figure 6.8(a), 6.8(b), and 6.8(c), respectively, at time t = 0, 281.4, and 562.8 seconds. The plasma bubble is set into motion by the neutral wind, and since periodic boundary conditions are used, the bubble seems to go out of the domain through the right boundary of the frame and to re-enter the computational box through the left boundary. The instability develops



(a) Initial density. (b) t = 281.4 s. (c) t = 562.8 s.

FIG. 6.9. *Plasma density at* $t = 562.8$ *s given by the classical striation model on mesh* 1 (a)*, the turbulent striation model with a moderate diffusion on mesh* 2 (b)*, and the turbulent striation model with a large diffusion on mesh* 2 (c)*, with the discontinuous initial density of Figure* 6.8(a)*.*

along the right edge of the bubble, the other edge being unaffected.

The same simulation run on mesh 1 produces the result displayed on Figure 6.9(a) and shows the sensitivity of the instability pattern with respect to the grid resolution. The last two panels of the figure, (b) and (c) show calculations performed with the turbulent striation model on mesh 2. The diffusion parameter used in Figure 6.9(c) is four times as big as the one considered for 6.9(b). When comparing Figures 6.8(c) (without any diffusion) and 6.9(b), we get the same conclusion as before: diffusion brings stability for small space scales, since the tiniest patterns have disappeared from Figure 6.9(b). More diffusion can also bring stability for all space scales and prevent the growth of the instability, as demonstrated by the results of Figure 6.9(c).

7. Conclusion. In this paper, we have been concerned with the modeling of ionospheric plasma instabilities. The first main point of this work was to remark that the "striation model" allows for discontinuous solutions, and that discontinuous steady states may be unstable in a similar way as are smooth ones. The second point was to propose that the turbulence induced by the instability may actually produce diffusion, in a way similar to what occurs in fluid mechanics, and that this diffusion may actually contribute to stabilizing large wave-number perturbations. Following the statistical

approach to turbulence, we have derived and analyzed a "turbulent striation model." Numerical simulations have been produced in support of our analysis.
