4.1. Motivation for the weak solution. Due to the boundary term, the lower semicontinuity of $\Phi_{\lambda,g}$ with respect to the L^2-norm is not clear. Therefore, the notion of solution using the theory of maximal monotone operators [12] cannot be directly applied. However, we can establish the existence and uniqueness of the solution in the following sense. Suppose that

$$v\in L^2(0,T;H^1(\Omega)) \tag{4.1}$$

and that u is a classical solution of (1.8)–(1.10). Multiplying (1.8) by $(v-u)$, integrating over Ω, and using the convexity of ϕ, we have that

$$\int_\Omega \dot{u}(v-u)dx + \Phi_{\lambda,g}(v) \geq \Phi_{\lambda,g}(u). \tag{4.2}$$

Integrating over $[0,s]$ for any $s \in [0,T]$ then yields

$$\int_0^s \int_\Omega \dot{u}(v-u)dxdt + \int_0^s \Phi_{\lambda,g}(v)dt \geq \int_0^s \Phi_{\lambda,g}(u)dt. \tag{4.3}$$

On the other hand, setting $v = u + \epsilon w$ in (4.3) with $w \in C_0^\infty(\Omega)$ makes it clear that

$$\int_0^s \int_\Omega \dot{u}(\epsilon w)dxdt + \int_0^s \Phi_{\lambda,g}(u+\epsilon w)dt$$

attains a minimum at $\epsilon = 0$. Therefore, if u satisfies (4.3) and $u \in L^2(0,T;BV \cap L^2(\Omega))$ with $\dot{u} \in L^2(\Omega^T)$, u is also a solution of (1.8)–(1.10) in the sense of distribution. This motivates the following definition.

DEFINITION 4.1. *We say that a function $u \in L^2(0,T;BV \cap L^2(\Omega))$ with $\dot{u} \in L^2(\Omega^T)$ is a pseudosolution of* (1.8)–(1.10) *if*

1. $u(x,0) = I(x)$ *on* Ω, *and*
2. u *satisfies* (4.3) *for all* $s \in [0,T]$ *and* $v \in L^2(0,T;BV \cap L^2(\Omega))$.

4.2. The approximate functional ϕ^ϵ. For $\epsilon > 0$, define

$$\phi^\epsilon(x,r) := \begin{cases} \frac{1}{q(x)}|r|^{q(x)}, & |r| \leq 1, \\ \frac{1}{1+\epsilon}|r|^{(1+\epsilon)} - \frac{q(x)-(1+\epsilon)}{(1+\epsilon)q(x)}, & |r| > 1. \end{cases} \tag{4.4}$$

Remark 4.2. We note the following properties, as they will be useful in later computations:

1. $\phi^\epsilon(x,r)$ is convex in r.
2. $\phi^\epsilon_r(x,r) \cdot r \geq 0$ for all $r \in \mathbb{R}^n$.
3. $\phi(x,r) \leq \phi^\epsilon(x,r)$ for all $r \in \mathbb{R}^n$.

To prove the existence and uniqueness of the pseudosolution of (1.8)–(1.10), we first study solutions of the approximate problem

$$\dot{u} - \epsilon\Delta u - \operatorname{div}(\phi^\epsilon_r(x,\nabla u)) + \lambda(u-I) = 0 \quad \text{in } \Omega \times [0,T], \tag{4.5}$$

$$u(x,t) = g(x) \quad \text{in } \partial\Omega \times [0,T], \tag{4.6}$$

$$u(x,0) = \tilde{I}(x) \quad \text{in } \Omega, \tag{4.7}$$

where $\tilde{I} \in H^1 \cap L^\infty(\Omega)$, $g \in L^\infty(\partial\Omega)$ with $g = TrG$ on $\partial\Omega$ for some $G \in H^1(\Omega)$, and $\tilde{I}|_{\partial\Omega} = g$.

LEMMA 4.3. *Suppose $\tilde{I} \in H^1(\Omega)$ with $\tilde{I}|_{\partial\Omega} = g$. Then problem* (4.5)–(4.7) *has a unique solution $u \in L^2(0,T;H^1(\Omega)) \cap C(0,T;L^2(\Omega))$ with $\dot{u} \in L^2(0,T;L^2(\Omega))$ such that*

$$\int_0^\infty \int_\Omega |\dot{u}|^2 dxdt + \sup_{t>0}\left[\int_\Omega \frac{\epsilon}{2}|\nabla u|^2 + \phi^\epsilon(x,\nabla u) + \frac{\lambda}{2}|u-\tilde{I}|^2\right] \leq \int_\Omega \frac{\epsilon}{2}|\nabla\tilde{I}|^2 + \phi^\epsilon(x,\nabla\tilde{I})dx. \tag{4.8}$$

Proof. Since (4.5) is uniformly parabolic, we can conclude this lemma by standard results for parabolic equations [24] and the corresponding energy estimate. ∎

4.3. Estimates for the solution of the approximate problem.

LEMMA 4.4. *If $\tilde{I} \in H^1 \cap L^\infty \cap BV(\Omega)$, $g \in L^\infty(\partial\Omega)$ with $\tilde{I}|_{\partial\Omega} = g$, and u is a solution of* (4.5)–(4.7)*, then*

$$\|u\|_{L^\infty(\Omega^T)} \le \max(\|\tilde{I}\|_{L^\infty(\Omega)}, \|g\|_{L^\infty(\partial\Omega)}). \tag{4.9}$$

Proof. Let $M := \max(\|\widetilde{I}\|_{L^\infty(\Omega)}, \|g\|_{L^\infty(\partial\Omega)})$. Multiply (4.5) by $(u-M)_+$, where

$$(u-M)_+ = \begin{cases} u-M & \text{if } u-M \ge 0, \\ 0 & \text{otherwise,} \end{cases}$$

and integrate over Ω to get

$$\int_\Omega \dot{u}(u-M)_+ dx + \epsilon \int_\Omega |\nabla u|^2 dx + \int_\Omega \phi_r^\epsilon(x,\nabla u)\cdot\nabla u dx + \lambda \int_\Omega (u-\tilde{I})(u-M)_+ dx = 0. \tag{4.10}$$

By property 2 of Remark 4.2, we have that $\int_\Omega \phi_r^\epsilon(x,\nabla u)\cdot\nabla u dx \ge 0$, and thus

$$\frac{1}{2}\int_\Omega \frac{d}{dt}(u-M)_+^2 dx \le 0.$$

Therefore, $\frac{1}{2}\int_\Omega (u-M)_+^2 dx$ is decreasing in t, and since

$$\frac{1}{2}\int_\Omega (u-M)_+^2 dx \ge 0 \quad \text{and} \quad \frac{1}{2}\int_\Omega (u-M)_+^2 dx|_{t=0} = 0,$$

we have that

$$\frac{1}{2}\int_\Omega (u-M)_+^2 dx = 0 \quad \text{for all t} \in [0, \mathrm{T}],$$

and thus

$$u(t) \le M = \max(\|\tilde{I}\|_{L^\infty(\Omega)}, \|g\|_{L^\infty(\partial\Omega)}) \ \mathcal{L}\text{-a.e. on } \Omega \text{ for all } t > 0.$$

Multiplying (4.5) by $(u+M)_+$, a similar argument yields that $u(t) \ge -M$ for all t. Equation (4.9) follows directly. ∎

LEMMA 4.5. *Let u be the solution of* (4.5)–(4.7)*. Then for all $v \in L^2(0,T;H^1(\Omega))$ with $v|_{\partial\Omega} = g$,*

$$\begin{aligned} \int_0^s \int_\Omega \dot{u}(v-u) + \frac{\epsilon}{2}|\nabla v|^2 + \phi^\epsilon(x,Dv) + \frac{\lambda}{2}|v-\tilde{I}|^2 dx dt \\ \ge \int_0^s \int_\Omega \frac{\epsilon}{2}|\nabla u|^2 + \phi^\epsilon(x,Du) + \frac{\lambda}{2}|u-\tilde{I}|^2 dx dt. \end{aligned} \tag{4.11}$$

Proof. Multiplying (4.5) by $v-u$, then integrating by parts and using the convexity of $\phi^\epsilon(x,r)$ in r, we see that (4.11) follows. ∎

Remark 4.6. Let u be the solution of (4.5)–(4.7). Then for any $0 < \epsilon < \alpha - 1$ (where $1 < \alpha \le q(x)$), we have the following estimate, which is a direct consequence of Lemma 4.3:

$$\int_0^\infty \int_\Omega |\dot{u}|^2 dx dt + \sup_{t>0}\left[\int_\Omega \frac{1}{1+\epsilon}|\nabla u|^{1+\epsilon} dx + \frac{\lambda}{2}\int_\Omega |u-\tilde{I}|^2 dx\right] \le C, \tag{4.12}$$

where $C > 0$ is a constant depending only on Ω and $\|\nabla\tilde{I}\|_{L^2(\Omega)}$.

4.4. Existence and uniqueness of (1.8)–(1.10). Suppose I is given as in Theorem 3.2. By Lemma 2.4 and Remark 2.5, there exists a sequence $\{I_\delta\}$ in $H^1 \cap L^\infty(\Omega)$ such that

$$TrI_\delta = TrI \quad \text{on } \partial\Omega, \tag{4.13}$$

$$\|I_\delta\|_{L^\infty(\Omega)} \le C\|I\|_{L^\infty(\Omega)}, \tag{4.14}$$

$$I_\delta \to I \quad \text{strongly in } L^2(\Omega) \quad \text{as } \delta \to 0, \tag{4.15}$$

and

$$\Phi_{\lambda,g}(I_\delta) \le \Phi_{\lambda,g}(I) + \delta. \tag{4.16}$$

THEOREM 4.7 (*existence and uniqueness*). *Suppose $I \in BV \cap L^\infty(\Omega)$, $g \in L^\infty(\partial\Omega)$, and $I|_{\partial\Omega} = g$ with $g = TrG$ for some function $G \in H^1(\Omega)$. Then there exists a unique pseudosolution u of* (1.8)–(1.10) *in the sense of Definition* 4.1.

Proof. Step 1. First, we fix $\delta > 0$ and pass to the limit $\epsilon \to 0$.

Let $\{u_\delta^\epsilon\}$ be the sequence of solutions to (4.5)–(4.7) with initial data $\tilde{I} = I_\delta$. By Lemma 4.4 and Remark 4.6, there exists a subsequence $\{u_\delta^{\epsilon_i}\}$ and a function $u_\delta \in L^\infty(\Omega^\infty)$ with $\dot{u}_\delta \in L^2(\Omega^\infty)$ such that as $\epsilon_i \to 0$,

$$u_\delta^{\epsilon_i} \rightharpoonup u_\delta \quad \text{weakly}^* \text{ in } L^\infty(\Omega^\infty), \tag{4.17}$$

$$\dot{u}_\delta^{\epsilon_i} \rightharpoonup w \quad \text{weakly in } L^2(\Omega^\infty). \tag{4.18}$$

The same argument used in the proof of Lemma 3.1 in [37] gives us that $\dot{u}_\delta = w$ and $u_\delta(0) = I_\delta$.

Moreover, for all $f \in L^2(\Omega)$,

$$\begin{aligned}\int_\Omega (u_\delta^{\epsilon_i}(\cdot,t) - I_\delta) f(x)dx &= \int_0^\infty \int_\Omega \dot{u}_\delta^{\epsilon_i}(x,s) 1_{[0,t]}(s) f(x)dxds \\ &\xrightarrow{\epsilon_i \to 0} \int_0^\infty \int_\Omega \dot{u}_\delta(x,s) 1_{[0,t]}(s) f(x)dxds \\ &= \int_\Omega (u_\delta(\cdot,t) - I_\delta) f(x)dx.\end{aligned}$$

Therefore, for each $t > 0$,

$$u_\delta^{\epsilon_i}(\cdot,t) \rightharpoonup u_\delta(\cdot,t) \quad \text{weakly in } L^2(\Omega). \tag{4.19}$$

From (4.12), for each $t > 0$, $\{u_\delta^{\epsilon_i}\}$ is a bounded sequence in $W^{1,1}(\Omega)$. Therefore, there exists a convergent subsequence $\{u_\delta^{\epsilon_{i_j}}\}$ of $\{u_\delta^{\epsilon_i}\}$ such that

$$u_\delta^{\epsilon_{i_j}}(\cdot,t) \to u_\delta(\cdot,t) \quad \text{strongly in } L^1(\Omega).$$

Note that every convergent subsequence of $\{u_\delta^{\epsilon_i}\}$ converges to the same limit $u_\delta(\cdot,t)$ due to (4.19). Then, for each $t > 0$,

$$u_\delta^{\epsilon_i}(\cdot,t) \to u_\delta(\cdot,t) \quad \text{strongly in } L^1(\Omega). \tag{4.20}$$

From (4.17) and (4.20), we have that for each $t > 0$,

$$u_\delta^{\epsilon_i}(\cdot,t) \to u_\delta(\cdot,t) \quad \text{strongly in } L^2(\Omega). \tag{4.21}$$

We also have from (4.12) and (4.20) that $u_\delta \in L^\infty(0,\infty, BV \cap L^\infty(\Omega))$ with $\dot{u}_\delta \in L^2(\Omega^\infty)$. Furthermore, by Lemma 4.5, for all $v \in L^2(0,T;H^1(\Omega))$ with $v|_{\partial\Omega} = g$,

$$\begin{aligned}(4.22)\qquad &\int_0^s \int_\Omega \dot{u}_\delta^{\epsilon_i}(v - u_\delta^{\epsilon_i}) + \frac{\epsilon_i}{2}|\nabla v|^2 + \phi^{\epsilon_i}(x,\nabla v) + \frac{\lambda}{2}|v - I_\delta|^2 dxdt \\ &\quad \geq \int_0^s \int_\Omega \frac{\epsilon_i}{2}|\nabla u_\delta^{\epsilon_i}|^2 + \phi^{\epsilon_i}(x, Du_\delta^{\epsilon_i}) + \frac{\lambda}{2}|u_\delta^{\epsilon_i} - I_\delta|^2 dxdt.\end{aligned}$$

Using (4.18) and (4.21), we can let $\epsilon_i \to 0$ in (4.22) to get

$$\begin{aligned}(4.23)\qquad &\int_0^s \int_\Omega \dot{u}_\delta(v - u_\delta) + \phi(x,\nabla v) + \frac{\lambda}{2}|v - I_\delta|^2 dxdt \\ &\quad \geq \lim_{\epsilon_i \to 0} \int_0^s \int_\Omega \phi^{\epsilon_i}(x, Du_\delta^{\epsilon_i}) dxdt + \frac{\lambda}{2}\int_0^s \int_\Omega |u_\delta - I_\delta|^2 dxdt.\end{aligned}$$

By Lemma 2.3, weak lower semicontinuity (w.l.s.c.), and property 3 of Remark 4.2,

$$(4.24)\qquad \lim_{\epsilon_i \to 0} \int_0^s \int_\Omega \phi^{\epsilon_i}(x, Du_\delta^{\epsilon_i}) dxdt \geq \int_0^s \int_\Omega \phi(x, Du_\delta) dxdt + \int_0^s \int_{\partial\Omega} |u_\delta - g| d\mathcal{H}^{n-1} dt.$$

The combination of (4.23) and (4.24) gives us

$$\begin{aligned}&\int_0^s \int_\Omega \dot{u}_\delta(v - u_\delta) + \phi(x,\nabla v) + \frac{\lambda}{2}|v - I_\delta|^2 dxdt + \int_0^s \int_{\partial\Omega} |v - g| d\mathcal{H}^{n-1} dt \\ (4.25)\qquad &\geq \int_0^s \int_\Omega \phi(x,\nabla u_\delta) + \frac{\lambda}{2}|u_\delta - I_\delta|^2 dxdt + \int_0^s \int_{\partial\Omega} |u_\delta - g| d\mathcal{H}^{n-1} dt\end{aligned}$$

for all $v \in L^2(0,\infty;H^1(\Omega))$ with $v = g$ on $\partial\Omega^\infty$. By approximation, (4.25) still holds for $v \in L^2(0,\infty;BV \cap L^\infty(\Omega))$ with $v = g$ on $\partial\Omega^\infty$. To see that (4.25) holds for all $v \in L^2(0,\infty;BV \cap L^\infty(\Omega))$ (in particular, without $v = g$ on $\partial\Omega^\infty$), replace v with $v_\beta = d_\beta v + (1 - d_\beta)G$ in (4.25) and (by Lemma 3.4) let $\beta \to 0$. By approximation, we can conclude that (4.25) holds for all $v \in L^2(0,\infty;BV \cap L^2(\Omega))$.

Step 2. Now it remains only to pass to the limit as $\delta \to 0$ in (4.25) to complete the proof. First note that (4.8) holds for $u_\delta^{\epsilon_i}$ with $\tilde{I} = I_\delta$. Fix $\delta > 0$. By w.l.s.c. and (4.20), the same argument used to deduce (4.24) also gives us that

$$\lim_{\epsilon_i \to 0} \int_\Omega \phi^{\epsilon_i}(x, Du_\delta^{\epsilon_i}) dx \geq \int_\Omega \phi(x, Du_\delta) dx + \int_{\partial\Omega} |u_\delta - g| d\mathcal{H}^{n-1}.$$

Therefore, we can pass to the limit as $\epsilon_i \to 0$ in (4.8) and get

$$\begin{aligned}(4.26)\qquad &\int_0^\infty \int_\Omega |\dot{u}_\delta|^2 dxdt + \sup_{t>0}\left[\int_\Omega \phi(x, Du_\delta) dxdt + \frac{\lambda}{2}|u_\delta - I_\delta|^2 + \int_{\partial\Omega} |u_\delta - g| d\mathcal{H}^{n-1} dt\right] \\ &\qquad \leq \int_\Omega \phi(x, \nabla I_\delta) dx.\end{aligned}$$

Then $\{u_\delta\}$ is uniformly bounded in $W^{1,1}(\Omega)$ for each $t > 0$. Note also that in Lemma 4.4 the bound is independent of both ϵ and δ. Therefore, $\{u_\delta\}$ is also uniformly bounded in $L^\infty(\Omega^\infty)$. From (4.26), we also have that $\{\dot{u}_\delta\}$ is uniformly bounded in $L^2(\Omega^\infty)$.

By the same argument used to obtain (4.17), (4.18), and (4.21), there exists a subsequence $\{u_{\delta_j}\}$ of $\{u_\delta\}$ and a function $u \in L^\infty(0,\infty, BV \cap L^\infty(\Omega))$ with $\dot{u} \in L^2(\Omega^\infty)$ such that as $\delta_j \to 0$,

$$u_{\delta_j} \rightharpoonup u \quad \text{weakly}^* \text{ in } L^\infty(\Omega^\infty), \tag{4.27}$$

$$\dot{u}_{\delta_j} \rightharpoonup \dot{u} \quad \text{weakly in } L^2(\Omega^\infty), \tag{4.28}$$

$$u_{\delta_j}(\cdot,t) \to u(\cdot,t) \quad \text{strongly in } L^2(\Omega) \text{ and uniformly in } t. \tag{4.29}$$

Let $\delta = \delta_j$ in (4.25). Using w.l.s.c. and (4.27)–(4.29), we can let $\delta_j \to 0$ in (4.25) to conclude that for all $v \in L^2(0,\infty, BV \cap L^2(\Omega))$,

$$\int_0^s \int_\Omega \dot{u}(v-u)dxdt + \int_0^s \Phi_{\lambda,g}(v)dt \geq \int_0^s \Phi_{\lambda,g}(u)dt.$$

Existence is proved.

Step 3 (*uniqueness*). Suppose that u_1, u_2 are both weak solutions of (1.8)–(1.10). As in [23, 37], we can obtain two inequalities: the first by setting $u = u_1$ and $v = u_2$ in (4.3) and the second by setting $u = u_2$ and $v = u_1$. Adding these two inequalities gives us that for all $s > 0$,

$$\int_0^s \int_\Omega \frac{1}{2}\frac{d}{dt}|u_1 - u_2|^2 dxdt \leq 0.$$

Therefore, $u_1 = u_2$ in Ω^∞. ∎

4.5. Behavior as $t \to \infty$.

THEOREM 4.8. *As $t \to \infty$, the weak solution, $u(x,t)$, of* (1.8)–(1.10) *converges strongly in $L^2(\Omega)$ to a minimizer $\tilde{u}$ of the function $\Phi_{\lambda,g}$, i.e., the pseudosolution, $\tilde{u}$, of* (3.1).

Proof. Since u satisfies (4.3), for any $s > 0$ we can substitute $v(x) \in BV \cap L^2(\Omega)$ into (4.3) as follows:

$$\begin{aligned}\int_\Omega (u(x,s) - I(x))v(x)dx - \frac{1}{2}\int_\Omega (u^2(x,s) - I^2(x))dx + s\int_\Omega \phi(x,\nabla v) \\ + s\frac{\lambda}{2}\int_\Omega |v-I|^2 dx + s\int_{\partial\Omega} |v-g| d\mathcal{H}^{n-1} \\ \geq \int_0^s \int_\Omega \phi(x,\nabla u)dt + \frac{\lambda}{2}\int_0^s \int_\Omega |u-I|^2 dxdt + \int_0^s \int_{\partial\Omega} |u-g| d\mathcal{H}^{n-1} dt.\end{aligned} \tag{4.30}$$

Proceeding as in [19], let

$$w(x,s) = \frac{1}{s}\int_0^s u(x,t)dt.$$

Since $u \in L^\infty(0,\infty; BV \cap L^\infty(\Omega))$, for each $s > 0$ we have that $w(\cdot,s) \in BV \cap L^\infty(\Omega)$ with $\{w(\cdot,s)\}$ uniformly bounded in $BV(\Omega)$ and $L^\infty(\Omega)$. Therefore, there exists a subsequence $\{w(\cdot,s_i)\}$ of $\{w(\cdot,s)\}$ which converges strongly in $L^1(\Omega)$ and weakly in $BV(\Omega)$ and $L^\infty(\Omega)$ to a function $\tilde{u} \in BV \cap L^\infty(\Omega)$ as $s_i \to \infty$. Since $\{w(\cdot,s)\}$ is uniformly bounded in $L^\infty(\Omega)$, $\{w(\cdot,s_i)\}$ also converges strongly in $L^2(\Omega)$ to $\tilde{u}$.

Dividing (4.30) by s and taking the limit along $s_i \to \infty$ gives us that

$$\int_\Omega \phi(x,\nabla v) + \frac{\lambda}{2}\int_\Omega |v-I|^2 dx + \int_{\partial\Omega} |v-g| d\mathcal{H}^{n-1} \geq \int_\Omega \phi(x,\nabla \tilde{u}) + \frac{\lambda}{2}\int_\Omega |\tilde{u}-I|^2 dx + \int_{\partial\Omega} |\tilde{u}-g| d\mathcal{H}^{n-1}$$

for all $v \in BV \cap L^2(\Omega)$; i.e., $\tilde{u}$ is a pseudosolution of (3.1). ∎

5. Numerical methods and experimental results. We solve the minimization problem (1.3) numerically using the flow of its associated Euler–Lagrange equation,

$$\frac{\partial u}{\partial t} - \operatorname{div}(\phi_r(x,Du)) + \lambda(u-I) = 0 \quad \text{in } \Omega\times[0,T], \tag{5.1}$$

$$\frac{\partial u}{\partial n}(x,t) = 0 \quad \text{on } \partial\Omega\times[0,T], \tag{5.2}$$

$$u(0) = I \quad \text{in } \Omega. \tag{5.3}$$

To approximate (5.1), we use an explicit finite difference scheme. The degenerate diffusion term,

$$\operatorname{div}(\phi_r(x,\nabla u)) = |\nabla u|^{p(x)-2}\left[(p(x)-1)\Delta u + (2-p(x))|\nabla u|\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) + \nabla p\cdot\nabla u \log|\nabla u|\right]$$

with

$$p(x) = \begin{cases} q(x) \equiv 1 + \frac{1}{1+k|\nabla G_\sigma * I(x)|^2}, & |\nabla u| < \beta, \\ 1, & |\nabla u| \geq \beta \end{cases} \tag{5.4}$$

for $k,\sigma > 0$, and G_σ the Gaussian filter, is approximated as follows:

- The coefficient, $|\nabla u|^{p(x)-2}$, is approximated using central differences;
- the isotropic diffusion term, Δu, is approximated using central differences;
- the curvature term, $|\nabla u|\operatorname{div}\big(\frac{\nabla u}{|\nabla u|}\big)$, is approximated using the minmod scheme for $\operatorname{div}\big(\frac{\nabla u}{|\nabla u|}\big)$ (see [31]) and central differences for $|\nabla u|$;
- if $|\nabla u| \neq 0$, the hyperbolic term $\nabla p\cdot\nabla u \log|\nabla u|$ is computed using an upwind scheme for $\nabla p\cdot\nabla u$ (see [29]) and central differences for $\log|\nabla u|$. Otherwise, the hyperbolic term is set to zero.

We found that the behavior of (1.3) is an innate behavior of the model, and variants on this numerical scheme also yield very good results.

We compared our model with the flow of the Euler–Lagrange equation associated with (1.2) (modified only by a fidelity term),

$$\frac{\partial u}{\partial t} = (p-1)\Delta u + (2-p)\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) - \lambda(u-I), \quad \text{where } p = \begin{cases} 2, & |\nabla u| < \beta, \\ 1, & |\nabla u| \geq \beta. \end{cases} \tag{5.5}$$

An explicit finite difference scheme was used, where central differences were used to implement Δu and the minmod scheme [31] was used to implement $\operatorname{div}(\frac{\nabla u}{|\nabla u|})$.

All of the images ranged in intensity from 0 to 255. The parameters $\lambda = .05$, $\sigma = .5$, $k = .0075$ and time step $= .05$ consistently yielded optimal results for all of the models we tested here. We compared various thresholds, β, to test the sensitivity of both models (1.2) and (1.3) to this parameter. All of the "edge maps" in the figures to follow were computed using the function

$$\textit{edge map of } u\text{:} \quad \frac{1}{1 + k|\nabla G_\sigma * u(x)|^2} \tag{5.6}$$

with $k = .0075$ (the same value of k is also used to compute the exponent $p(x)$ in (5.4)). We found that this value also gave the clearest edge map for each model. The number of iterations was chosen large enough so that the standard deviation between subsequent images was at most .005.

In Figure 5.1 we illustrate the proposed model's ability to reconstruct piecewise smooth functions while avoiding the staircasing effect. The first row from the top contains a piecewise smooth function plotted as both an image and a surface, and also contains its edge map (5.6). The surface is viewed from two different orientations: the first view displays the upper left corner of the image at the origin, and the second view displays the same surface rotated 180°. The second row contains the same series of images for the image degraded by Gaussian noise with mean zero. The third, fourth, and fifth rows contain reconstructions using isotropic diffusion only ($p \equiv 2$), TV-based diffusion only ($p \equiv 1$), and the proposed model, respectively. Isotropic diffusion reconstructs smooth regions, but edges are severely blurred. TV-based diffusion reconstructs sharp edges, but the staircasing effect is clearly present. This in turn creates false edges, which could lead to an incorrect segmentation of the image. The proposed model reconstructs sharp edges as effectively as TV-based diffusion *and* recovers smooth regions as effectively as pure isotropic diffusion (in particular, without staircasing).

Figure 5.2 contains a reconstruction of another piecewise smooth image with additive Gaussian noise. Our goal is to once again reconstruct the smooth regions while preserving their boundaries and without introducing false edges. Furthermore, we also wanted to compare the sensitivity of models (1.2) and (1.3) to the threshold, β. The top row shows the original and noisy images with their edge maps (5.6). The bottom three rows contain reconstructions using models (1.2) and (1.3). The first column from the left contains reconstructions using (1.2) with thresholds $\beta = 30, 50,$ and 70, respectively, and the second column contains their corresponding edge maps (5.6). The third column contains reconstructions using TV-based diffusion only ((1.2) or (1.3) with $\beta = 0$) and the proposed model (1.3) with thresholds $\beta = 30$ and 100, respectively. The last column contains their corresponding edge maps (5.6). TV-based diffusion only ($\beta = 0$) shows clear evidence of staircasing, while the proposed model is relatively insensitive to a broad range of thresholds, β. Although the exact behavior of the diffusion changes slightly at likely edges between $\beta = 30$ and $\beta = 100$, the effect on the resulting image is minimal. On the other hand, model (1.2) demonstrates a large change in behavior at both noise and edges across the range of thresholds $\beta = 30, 50,$ and 70. Similar experiments on the noisy radar images in Figures 5.3 and 5.4 yielded very similar results. Note that in Figure 5.3, even fine details, such as the lettering at the bottom of the image, are preserved using the proposed model. In Figure 5.4, the proposed model preserves the boundaries of the land mines as effectively as the TV model without enhancing the background noise.

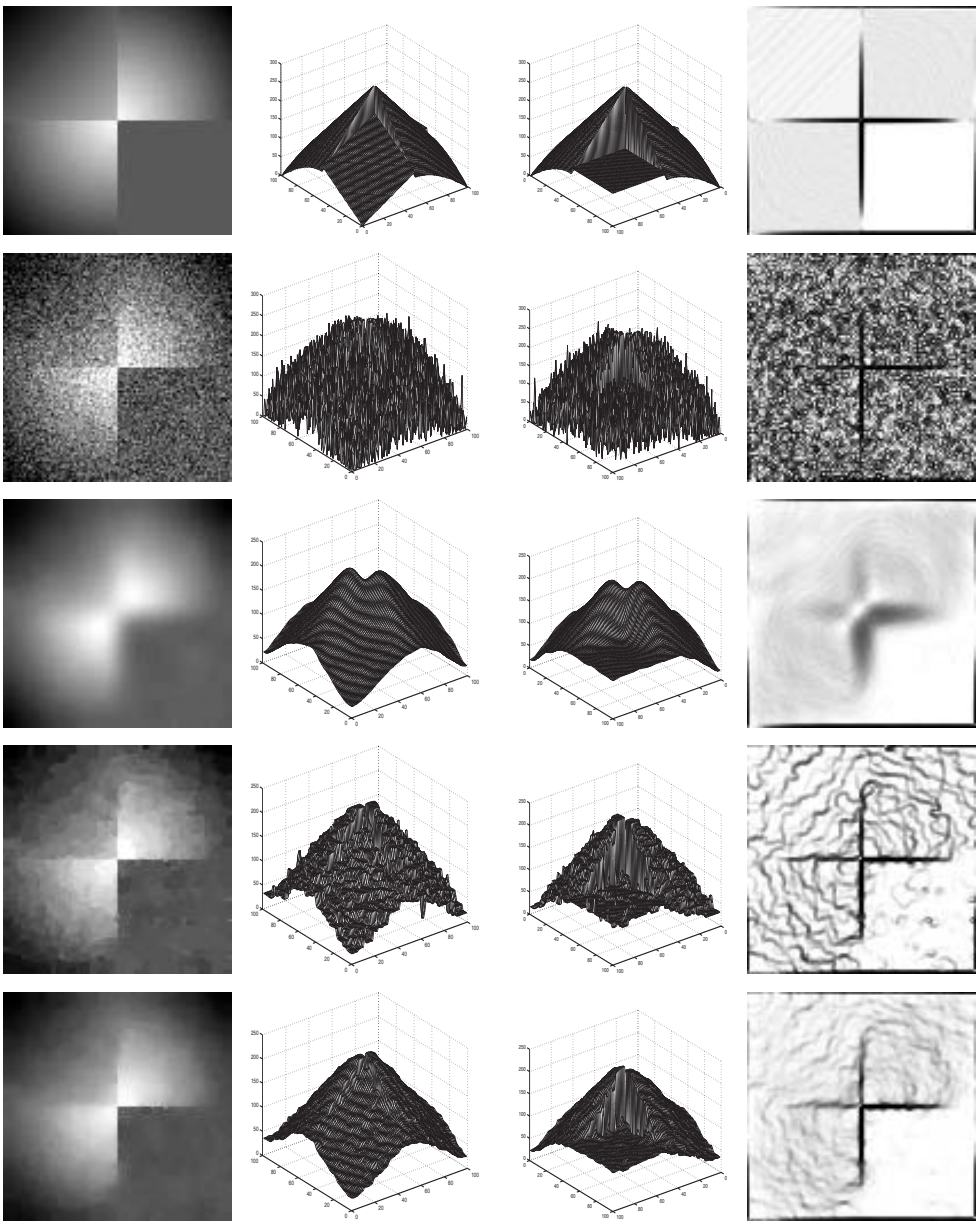

FIG. 5.1. *Top row*: *true image* (100×100), *surface plot of the image, surface rotated* $180°$, *edge map* (5.6). *Second row*: *image + noise. Third row*: *reconstruction using isotropic diffusion only* (200 *iterations*). *Fourth row*: *reconstruction using TV-based diffusion only* (2000 *iterations*). *Fifth row*: *reconstruction using the proposed model* (1000 *iterations*, $\beta = 30$, $k = .0075$).

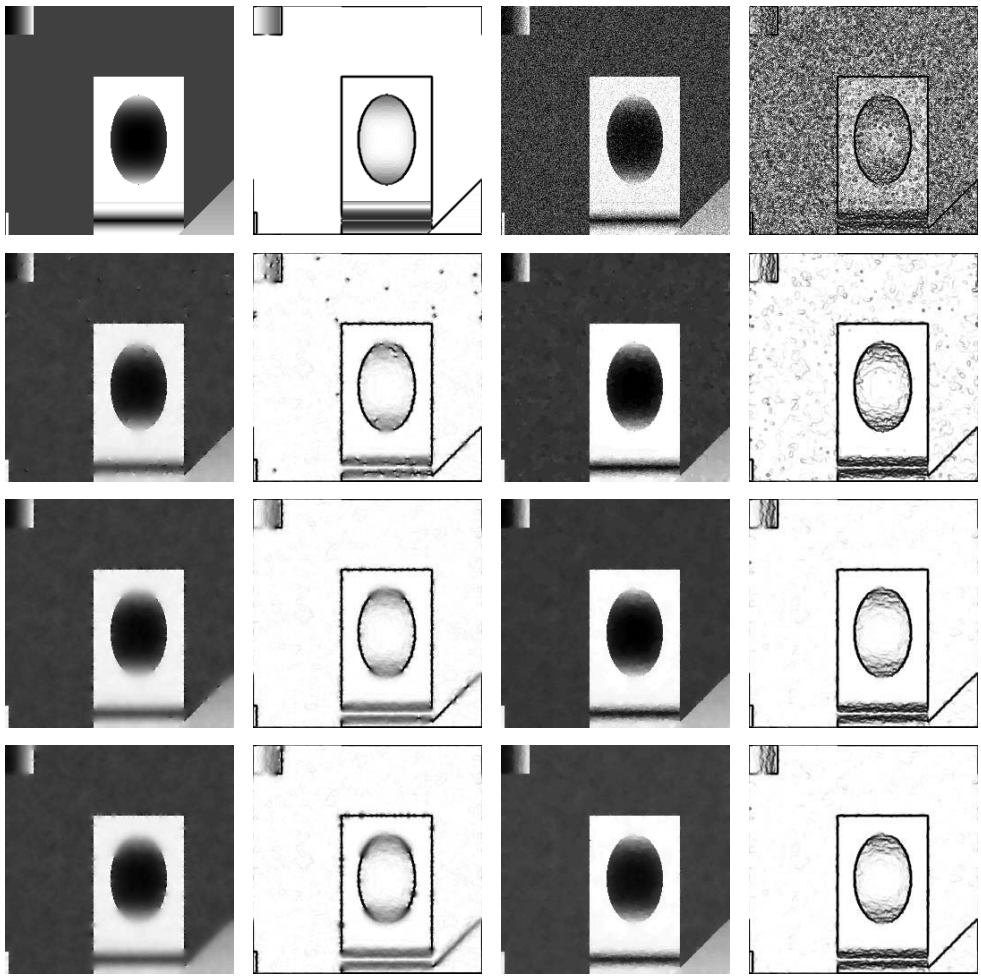

FIG. 5.2. *Top row*: *original piecewise smooth image* (256×256) *and edge map* (5.6)*, image + noise and edge map* (5.6)*. Bottom three rows*: *First column from left: reconstructions using* (1.2) *with thresholds* $\beta = 30, 50, 70$*, respectively* (1000 *iterations*)*. Second column*: *corresponding edge maps* (5.6)*. Third column*: *reconstruction using TV-based diffusion only* (2000 *iterations*) *and the proposed model with thresholds* $\beta = 30, 100$*, respectively* (1000 *iterations*)*. Fourth column*: *corresponding edge maps* (5.6) (*all images:* $k = .0075$*,* $\lambda = .05$*,* $\sigma = .5$*, time step* $= .05$).

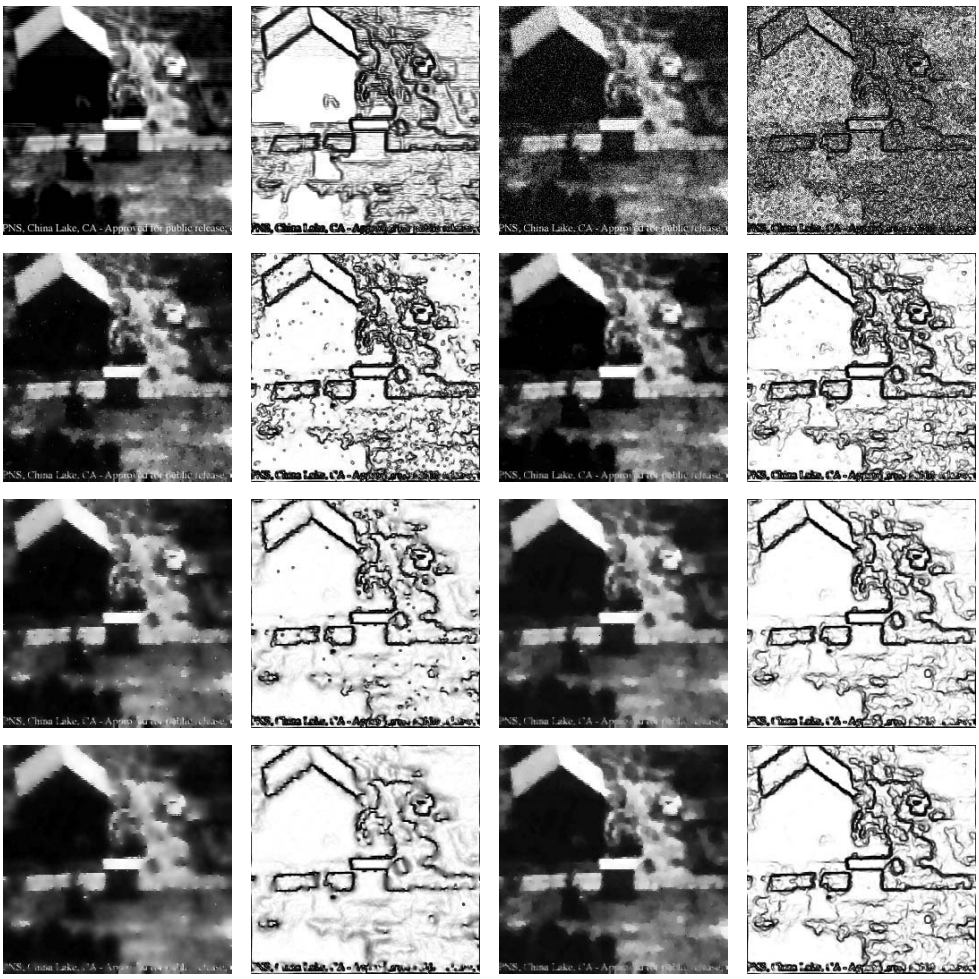

FIG. 5.3. *Top row*: *radar image* (256×256) *and edge map* (5.6); *radar image with Gaussian noise and edge map* (5.6) *with* $k = .0075$. *Bottom three rows*: *First column: reconstructions using* (1.2) *with thresholds* $\beta = 10, 20, 30$, *respectively* (1000 *iterations*). *Second column*: *corresponding edge maps* (5.6). *Third column*: *reconstruction using TV-based diffusion only* (4000 *iterations*) *and the proposed model with thresholds* $\beta = 30, 100$, *respectively* (1000 *iterations*). *Fourth column*: *corresponding edge maps* (5.6) (*all images:* $k = .0075$, $\lambda = .05$, $\sigma = .5$, *time step* $= .05$).

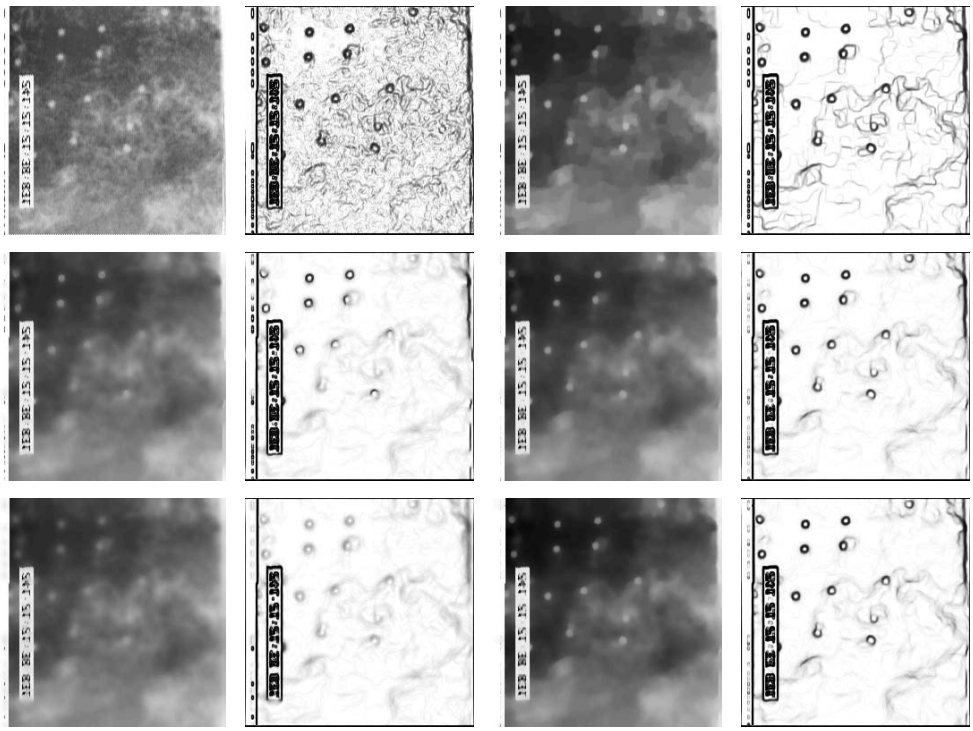

FIG. 5.4. *First column from left*: *radar image of land mines* (256×256); *reconstructions using* (1.2) *with thresholds* $\beta = 10, 20$, *respectively* (750 *iterations*). *Second column*: *corresponding edge maps* (5.6). *Third column*: *reconstruction using TV-based diffusion only* (1000 *iterations*); *reconstructions using the proposed model with thresholds* $\beta = 30, 100$, *respectively* (750 *iterations*). *Fourth column*: *corresponding edge maps* (5.6) (*all images:* $k = .0075$, $\lambda = .05$, $\sigma = .5$, *time step* $= .05$).

Figure 5.5 provides another successful reconstruction of a piecewise smooth image with additive Gaussian noise. TV-based diffusion alone creates false edges, while the proposed model preserved accurate object boundaries while minimizing the creation of false ones. Tests with $\beta = 30$ and 100 again demonstrate the proposed model's insensitivity to the threshold, β. Figure 5.6 displays a similar experiment with an MRI of a human heart. The original image is successfully denoised using the proposed model (top row). We then added more noise and, as in the previous experiments, found that TV alone created false edges, while the proposed model generated much fewer false artifacts.

Figure 5.7 contains several more examples in which the noise in each of the images was acquired directly through acquisition, storage, or transmission. The first row contains a diffusion tensor image (DTI) of a human brain; the second contains a magnetic resonance image (MRI) of a human chest cavity; the third contains a transmission electron microscope (TEM) image of aluminum. In all of these images, the goal is to detect "true" object boundaries without creating any false edges. The proposed model is successful in all of these cases.

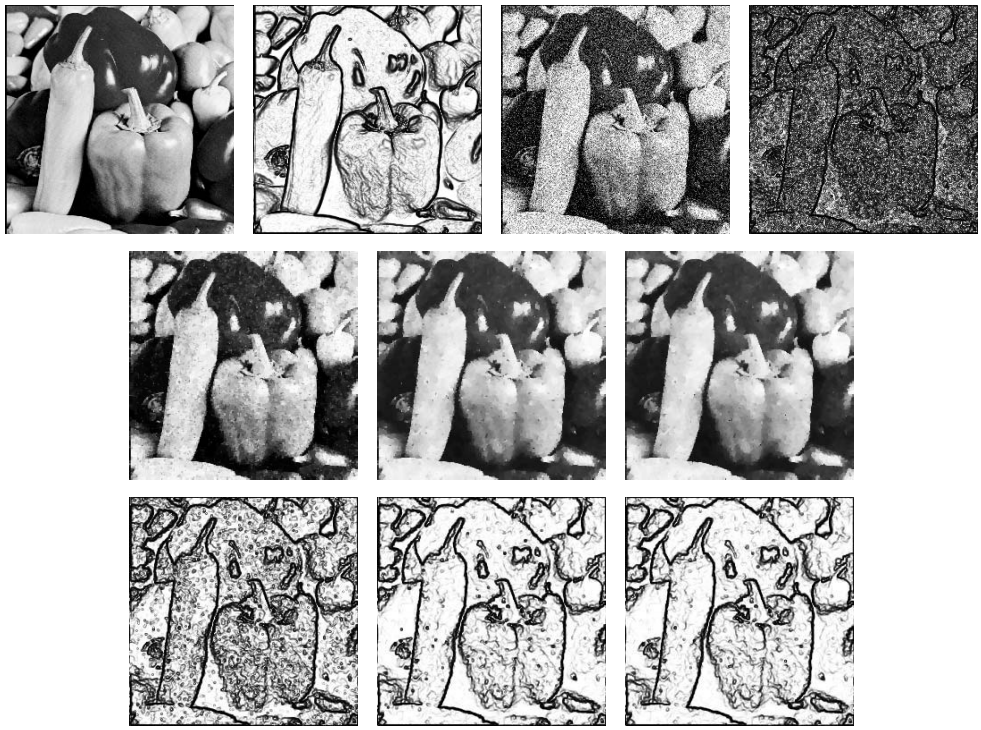

FIG. 5.5. *Top row*: *true image* (256×256) *and edge map* (5.6); *true image + noise and edge map* (5.6). *Second row*: *reconstructions using TV-based diffusion only* (2000 *iterations*) *and the proposed model with thresholds* $\beta = 30, 100$ (1000 *iterations,* $k = .0075$). *Third row*: *corresponding edge maps* (5.6) (*all images:* $k = .0075$, $\lambda = .05$, $\sigma = .5$, *time step* $= .05$).

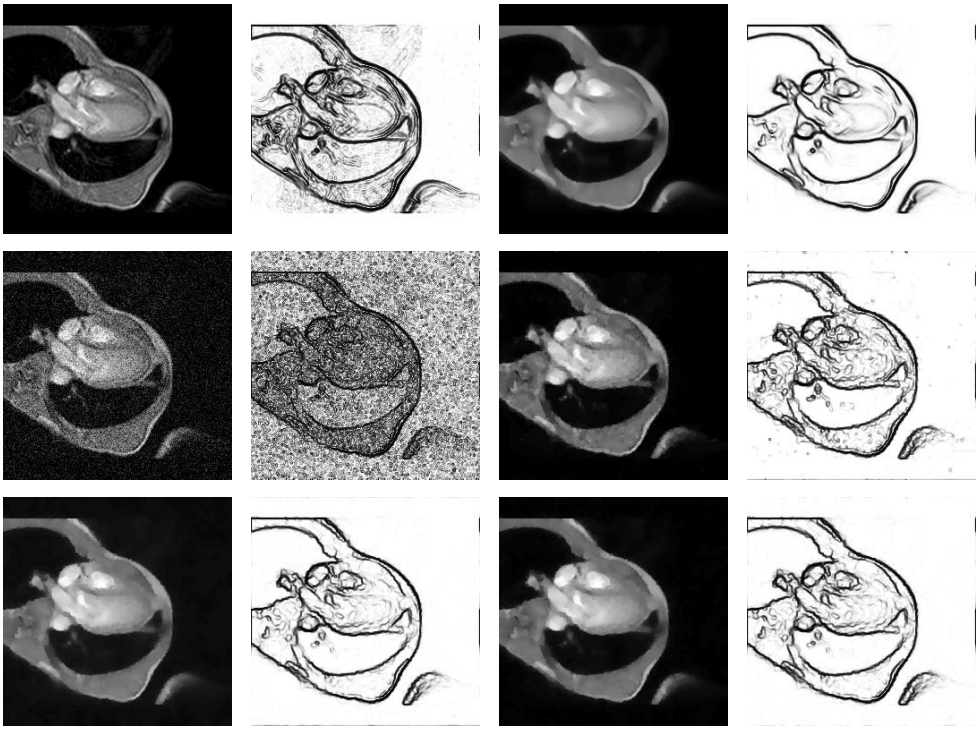

FIG. 5.6. *Top row*: *true image: human heart MRI* (256×256), *corresponding edge map* (5.6), *reconstruction using the proposed model* (*threshold* $\beta = 30$), *edge map* (5.6). *Second row: human heart MRI + noise, edge map* (5.6), *reconstruction using TV-based diffusion only, edge map* (5.6). *Third row*: *reconstruction using the proposed model* (*threshold* $\beta = 30$), *edge map* (5.6), *reconstruction using the proposed model* (*threshold* $\beta = 100$), *edge map* (5.6) (*all images*: $k = .0075$, $\lambda = .05$, $\sigma = .5$, *time step* $= .05$).

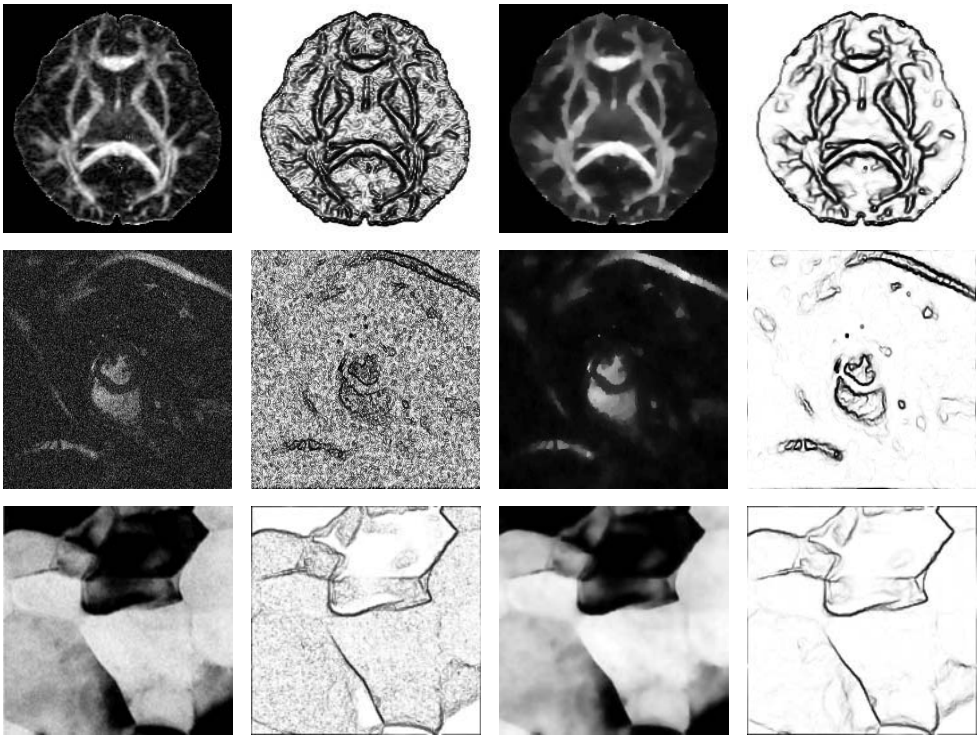

FIG. 5.7. *First column from left*: *true images*: *human brain DTI* (201 × 171), *human chest cavity MRI* (209 × 256), *TEM image of aluminum* (512 × 512). *Second column*: *corresponding edge maps* (5.6). *Third column*: *reconstructions using the proposed model* (420, 1000, 500 *iterations, respectively*). *Fourth column*: *corresponding edge maps* (5.6) *with* $k = .0075$ (*all images*: *threshold* = 30, $k = .0075$, $\lambda = .05$, $\sigma = .5$, *time step* = .05).

Acknowledgments. The authors would like to thank Bernard Mair for the radar images in Figures 5.3 and 5.4; Sebastien Barre for the MRI in Figure 5.6; and Yijun Liu for the DTI, Mark Griswold for the MRI, and Katayun Barmak for the TEM image in Figure 5.7. We would also like to thank the reviewers for their helpful comments.

THE IDENTIFICATION OF A TIME DEPENDENT SORPTION PARAMETER FROM SOIL COLUMN EXPERIMENTS*

K. RENEE FISTER†, MAEVE L. MCCARTHY†, AND SETH F. OPPENHEIMER‡

Abstract. Soil column studies are used frequently in seeking to understand the behavior of a particular contaminant in a saturated homogeneous soil of a given type. The concentration of the contaminant is modeled by a parabolic partial differential equation. We seek to identify the sorption partitioning coefficient as a function of time from limited boundary data. We discuss an output least squares formulation of the problem with Tikhonov regularization. We explicitly characterize a source condition that determines the rate of convergence of the method. Numerical examples are presented.

Key words. parameter identification, inverse problems, Tikhonov regularization, parabolic partial differential equation, sorption partitioning

1. Introduction.

The purpose of this paper is to develop theoretical and numerical approaches for approximating an unknown time dependent parameter in a parabolic partial differential equation, given limited boundary data. The equation we shall be working with is a model of a soil column study. These column studies are used frequently in seeking to understand the behavior of a particular contaminant in a saturated homogeneous soil of a given type. The parameter we are seeking to approximate is the sorption partitioning coefficient. This parameter is a measure of the proportion of contaminant that is bound to the soil. In isothermal situations when there are no other contaminants present, the partitioning coefficient is usually taken to be constant. However, if there is another contaminant, e.g., sea salt, or if the temperature is changing, the partitioning coefficient may change as well. Therefore, strictly speaking, the partitioning coefficient is a function of some physical factor other than time. However, if we understand the controlling physical factor as a function of time, we may treat the partitioning coefficient also as a function of time and deduce the true physical functional relationship after the partitioning coefficient has been found as a function of time.

This approach will allow us considerable savings in time and resources when determining how a partitioning coefficient varies with different physical factors. These savings will result from identifying the partitioning coefficient's dependence on the relevant physical factor by means of a single column experiment rather then a large number of separate batch tests.

Section 2 shall be devoted to a discussion of the model, the simplifying assumptions that are applicable, and various necessary facts about the forward problem.

Section 3 establishes identifiability of the sorption partitioning coefficient from the available experimental data and applies an output least squares method with Tikhonov regularization to the parameter identification problem. The method is tested in section 4.

2. Discussion of the model. The general approach to modeling convection-diffusion-sorption models may be found in the work of Leij and Dane [12] and Domenico and Schwartz [6]. Sorption of mixtures was treated by Oppenheimer [15]. A thorough treatment of the modeling of the sorption process may be found in Oppenheimer, Kingery, and Han [16]. Column studies are discussed in detail by Adrian, Ozkan, and Alshawabkeh [1].

We model the one dimensional flow of water with a dissolved contaminant through a soil column. The contaminant can be dissolved in the water or bound, that is sorbed, to the soil. We will assume cylindrical symmetry in the column to reduce the problem to one spatial dimension. The column will be assumed to have length L and is modeled as the interval $[0, L]$. The distance from the inflow end of the column will be given by z. The time since the start of the experiment will be given by τ. At spatial point z and time τ, the solution concentration (in mass of contaminant per unit volume of water) is denoted $c(z, \tau)$, and the sorbed concentration (in mass of contaminant per unit mass of soil) is denoted $q(z, \tau)$.

We will assume the equilibrium relationship $q = f(c)$. The function f is called the equilibrium isotherm.

We will assume the following physical values: $\rho_V(z)$ is the void density per unit volume at spatial coordinate z, $\rho_S(z)$ is the soil mass density per unit volume, A is the cross-sectional area of the column, v is the fluid velocity, and D is the diffusivity constant that appears in Fick's law for diffusion. Fick's law assumes that the rate of diffusion of the contaminant in the fluid is given by $-D\partial c/\partial z$.

Choosing z to be any interior point of the column, τ any positive time, and Δz and $\Delta\tau$ small positive numbers, the change in the amount of contaminant stored in the section of the column $[z, z + \Delta z]$ between τ and $\tau + \Delta\tau$ is given by

$$\int_z^{z+\Delta z} [A\rho_V(\eta)c(\eta, \tau + \Delta\tau) + A\rho_S(\eta)q(\eta, \tau + \Delta t) - (A\rho_V(\eta)c(\eta, \tau) + A\rho_S(\eta)q(\eta, \tau))]d\eta.$$

This will equal the total inward flux less the outward flux at z and $z + \Delta z$ over the time from τ to $\tau + \Delta\tau$,

$$\int_\tau^{\tau+\Delta\tau} \left[vA\rho_V(z)\, c(z, s) - DA\rho_V(z)\, \frac{\partial c}{\partial z}(z, s) - \left(vA\rho_V(z + \Delta z)\, c(z + \Delta z, s) - DA\rho_V(z + \Delta z)\, \frac{\partial c}{\partial z}(z + \Delta z, s) \right) \right] ds.$$

Setting the two expressions equal, dividing by $\Delta z\Delta\tau$, and letting Δz and $\Delta\tau$ tend to zero yields

$$A\left[\rho_V(z)c(z, \tau) + \rho_S(z)q(z, \tau)\right]_\tau = -vA\left[\rho_V(z)c(z, \tau)\right]_z + DA\left[\rho_V(z)c_z(z, \tau)\right]_z.$$

If we assume that the mass density $\rho_S = M/(LA)$ and the pore volume density $\rho_V = V/(LA)$ are constant, where M is the total mass of soil in the cylinder and V

is the total void space in the cylinder, we obtain

$$[Vc + Mq]_\tau = -vVc_z + DVc_{zz}. \tag{2.1}$$

We have already described the expected equilibrium relationship between the sorbed concentration, q, and the solution concentration, which is given by $q = f(c)$. Since the solution concentration is changing in time we must either assume that this equilibrium relationship holds even as c changes in time or we must specify how q changes as c changes. For completeness we will describe the nonequilibrium modeling approach before we make our final assumptions. The standard model [16, 12] for sorption when c is known at each time t is

$$\frac{\partial q}{\partial \tau} = rF(c, q), \tag{2.2}$$

where r is a sorption rate constant and F satisfies the following requirements: If $q < f(c)$, then F is positive; if $q = f(c)$, then $F = 0$; and if $q > f(c)$, then F is negative. Some typical examples of the isotherm f are the Henry or linear isotherm

$$f(c) = \xi c,$$

the Langmuir isotherm

$$f(c) = \frac{\xi c}{1 + \beta c},$$

and the Freundlich isotherm

$$f(c) = \xi c^\gamma.$$

An example of F is a simple reversible sink

$$F(c, q) = f(c) - q,$$

where the rates of sorption and desorption are the same and where, regardless of whether the process is sorbing or disorbing, the same fixed c value will yield the same equilibrium point. Another example of F is a simple irreversible sink

$$(f(c) - q)^+,$$

where there is hysteresis occurring, and while a contaminant can be sorbed, it cannot be desorbed. There are a wide variety of such models, and the reader is referred to [16].

When the local kinetics (2.2) are combined with the conservation-of-mass equation (2.1) previously derived, we obtain

$$\begin{aligned} V\frac{\partial c}{\partial \tau} + M\frac{\partial q}{\partial \tau} &= -vV\frac{\partial c}{\partial z} + DV\frac{\partial^2 c}{\partial z^2}, \\ \frac{\partial q}{\partial \tau} &= rF(c, q). \end{aligned} \tag{2.3}$$

The equilibrium partitioning assumption is that r is much larger than D and v. Dividing the second system by r and defining $\varepsilon = 1/r$, we may consider this a singular perturbation problem:

$$\begin{aligned} V\frac{\partial c}{\partial \tau} + M\frac{\partial q}{\partial \tau} &= -vV\frac{\partial c}{\partial z} + DV\frac{\partial^2 c}{\partial z^2}, \\ \varepsilon\frac{\partial q}{\partial \tau} &= F(c, q). \end{aligned} \tag{2.4}$$

Since we will consider only cases where we are close to equilibrium, we need consider only the outer solution to the unperturbed problem

$$F(c,q)=0 \qquad \text{or} \qquad q=f(c).$$

Thus, we can replace system (2.4) with

$$\frac{\partial}{\partial\tau}\left(Vc+Mf(c)\right)=-vV\frac{\partial c}{\partial z}+DV\frac{\partial^2 c}{\partial z^2}.$$

In this paper we will accept the equilibrium partitioning assumption and use a Henry isotherm. The linear partitioning assumption is usually valid when concentrations are low. The common set of boundary conditions that we will be using is

$$c(0,\tau)=0, \qquad \frac{\partial c}{\partial z}(L,\tau)=0.$$

The first boundary condition is used to model the case where the inflow of water contains no contaminant, and the second boundary condition models the fact that there is no diffusion across the end of the column, only convection.

We will perform the standard change of variables [12] with respect to time and length by introducing new variables

$$t=v\tau/L \qquad \text{and} \qquad x=z/L.$$

Using these new variables, we obtain the form of the model we wish to study:

$$\begin{aligned}\frac{\partial}{\partial t}(\beta c)&=-\frac{\partial c}{\partial x}+K\frac{\partial^2 c}{\partial x^2},\\ c(0,t)&=0,\\ \frac{\partial c}{\partial x}(1,t)&=0,\\ c(x,0)&=c_0(x),\end{aligned} \tag{2.5}$$

where

$$\beta=1+\frac{\xi M}{V} \tag{2.6}$$

and

$$K=\frac{D}{vL}$$

is the nondimensionalized diffusion coefficient. The pseudotime variable measures pore volumes; that is, $t=1$ is the time it takes the flow to move from the top of the column to the bottom of the column.

In column studies, measurements of the exit solution concentration are taken. Therefore, the extra information available is a sequence of N time measurements taken at the end of the column $x=1$,

$$c(1,t_1),\ldots,c(1,t_N).$$

It is worthwhile to briefly discuss how the forward model came to be. The same model, with constant β, was successfully used to model column studies of fresh water

sediments. However, the constant β model failed when dealing with salt water sediments, and it was hypothesized by Myers [13] that β was changing with the saline concentration. Since it was expected that the saline concentration would equalize much more quickly than the concentration of the contaminant being studied, we chose to approximate the salt concentration as being spatially uniform and, thus, β as spatially uniform. In the technical report on this approach [14], we used a decreasing exponential ansatz for the saline concentration, assuming that the concentration would be dominated by the decay in the first eigenfunction. This yielded model fits that were considered reasonable by the engineers on the project. Henceforth, we assume that ξ, and hence β, is changing with time.

The initial contaminant concentration is taken to be spatially constant, $c(x,0) = c_0 > 0$, because the samples have time to equilibrate before the experiment begins. It is worth noting that this initial contaminant concentration, while physically accurate, does not meet the boundary condition. Indeed, in the explicit solutions generated for the technical report [14], there is a Gibb's phenomenon. Fortunately the problem is governed by a parabolic evolution operator, and solutions satisfy the boundary conditions for all positive times.

2.1. Contaminant mass constraint. We will now compute the value $\beta(0)$, which is related to the equilibrium coefficient ξ; see (2.6). We will assume that we know the total mass of soil in the column M, the total volume of water in the column V, the cross-sectional area of the column A, the diffusivity constant D, and the fluid velocity v. We will also assume that we know that the initial solution concentration is a constant, c_0. The mass flow of contaminant out of the tube at time t will be given by

$$Ac\,(1,t)\,V/A.$$

Thus, if we let the process continue until almost all of the contaminant has been flushed from the column at time t_N, we have that the total mass of contaminant present in the column at time $t = 0$ will be approximately

$$\int_0^{t_N} c\,(1,t)\,V\,dt. \tag{2.7}$$

We also know that the total mass of contaminant at time $t = 0$ will be given by

$$\beta\,(0)\,c_0 V. \tag{2.8}$$

Equating the expressions in (2.7) and (2.8), we obtain

$$\beta\,(0) \approx \frac{1}{c_0}\int_0^{t_N} c\,(1,t)\,dt. \tag{2.9}$$

We need to add a caveat at this point. The physical system allows contaminant to leave the cylinder only through the boundary at $x = 1$. However, examining the original system and integrating with respect to x yields

$$\begin{aligned}\frac{\partial}{\partial t}\int_0^1 (\beta c)\,dx &= c\,(0,t) - c\,(1,t) + K\frac{\partial c}{\partial x}\,(1,t) - K\frac{\partial c}{\partial x}\,(0,t)\\ &= -c\,(1,t) - K\frac{\partial c}{\partial x}\,(0,t)\,.\end{aligned}$$

Integrating the previous equation with respect to t from 0 to t_N and assuming that the $c\,(x, t_N) \approx 0$ yields

$$\beta\,(0)\,c_0 \approx \int_0^{t_N} c\,(1,t)\,dt + \int_0^{t_N} K\frac{\partial c}{\partial x}\,(0,t)\,dt.$$

Finally, solving for $\beta\,(0)$, we have

$$\beta\,(0) = \frac{1}{c_0}\int_0^{t_N} c\,(1,t)\,dt + \frac{1}{c_0}\int_0^{t_N} K\frac{\partial c}{\partial x}\,(0,t)\,dt.$$

Thus, the model allows for contaminant to leave the cylinder at $x = 0$, which will give some discrepancy. We require that $D \ll v$, which implies that $K \approx 0$, in order to minimize this error.

3. Identification of the sorption coefficient. The forward problem is

$$\begin{aligned} (\beta c)_t &= -c_x + Kc_{xx}, && 0 < x < 1,\ 0 < t < T = t_N, \\ c(0,t) &= 0, \qquad c_x(1,t) = 0, && 0 < t < T, \\ c\,(x,0) &= c_0\,(x)\,, && 0 < x < 1. \end{aligned} \tag{3.1}$$

Our goal is to estimate the parameter β from noisy measurements of $c(1,t)$. Although identification problems for parabolic equations have been addressed both theoretically [11, 2, 3, 5, 18] and numerically [4, 10], the general framework is to consider the problem

$$\begin{aligned} u_t &= L(a)[u] && \text{in } \Omega \times [0,T], \\ u(x,0) &= u_0(x) && \text{on } \Omega, \\ G(a)[u] &= 0 && \text{on } \partial\Omega \times [0,T], \end{aligned} \tag{3.2}$$

subject to additional information $B[u] = 0$ on $\Omega \times [0,T]$ or $\partial\Omega \times [0,T]$. The spatial operators L, G, B may be linear or quasi-linear. The unknown coefficient a may be part of L or G and may depend on x, t, or u. The goal is to recover a from information about u, the solution of (3.2). Although our forward problem (3.1) can be transformed into the form (3.2) by setting $u = \beta c$, the boundary data available from our experiment is $c(1,t)$. Thus boundary data for the transformed problem $u(1,t)$ would require knowledge of β, the parameter we seek. Similar issues arise with other transformation approaches. As in [3], trace-type functionals can then be used to establish existence of a solution. This approach can also be implemented numerically [10]. However, the dependence of the operators on nonlocal information can lead to numerical instabilities. We wish to develop an algorithm that uses our available data directly and avoids the use of nonlocal information. We begin by establishing identifiability of the parameter β from the available data $c(1,t)$. We apply output least squares with Tikhonov regularization to this problem. We investigate the rate of convergence and determine an appropriate source condition.

3.1. Identifiability. Recall the contaminant mass constraint (2.9),

$$\beta\,(0) \approx \frac{1}{c_0}\int_0^{t_N} c\,(1,t)\,dt,$$

discussed in section 2.1. As a consequence of this and the fact that our data is $c(1,t)$, it is reasonable to assume that $\beta(0)$ is fixed and to let

$$\mathcal{B} = \left\{\beta \in H^1(0,T) \mid 0 < m < \beta(t) < \mathcal{M},\ \beta(0) = b\right\}.$$

Our existence result follows from the application of standard results; see [20, 9].

THEOREM 3.1. *If $\beta \in \mathcal{B}$, then $c_\beta \in W = L^2((0,T);H^1(0,1))$ and $c_\beta(1,\cdot) \in L^2(0,T)$.*

In order to establish the identifiability of β we must establish the injectivity of the parameter-to-output map

$$\beta \to \gamma c_\beta,$$

where γ denotes the trace operator

$$\gamma : L^2((0,T);H^1(0,1)) \to L^2(0,T), \qquad \gamma c = c(1,t).$$

THEOREM 3.2. *Let $c_1(x,t)$ and $c_2(x,t) \in W$ be solutions of the direct problem (3.1) corresponding to $\beta_1(t)$ and $\beta_2(t) \in \mathcal{B}$. If $\gamma c_1 = \gamma c_2$, then $\beta_1(t) = \beta_2(t)$ for all $t \in [0,T]$.*

Proof. Use β_1, c_1 and β_2, c_2 in (3.1) and subtract to find

$$(\beta_1 c_1 - \beta_2 c_2)_t = -(c_1 - c_2)_x + K(c_1 - c_2)_{xx}.$$

Let $\phi = \beta_1 c_1 - \beta_2 c_2$ and rearrange terms

$$\phi_t = -\frac{1}{\beta_1}\phi_x + \frac{K}{\beta_1}\phi_{xx} + \frac{(\beta_2 - \beta_1)}{\beta_1}(\mathcal{A}c_2),$$

where $\mathcal{A}c = -c_x + Kc_{xx}$. Multiply by ϕ and integrate with respect to x:

$$\begin{aligned}\int_0^1 \phi_t\phi\,dx &= -\frac{1}{\beta_1}\int_0^1 \phi_x\phi\,dx + \frac{K}{\beta_1}\int_0^1 \phi_{xx}\phi\,dx + \frac{(\beta_2-\beta_1)}{\beta_1}\int_0^1 (\mathcal{A}c_2)\,\phi\,dx \\ &= -\frac{1}{2\beta_1}\int_0^1 \left(\phi^2\right)_x dx - \frac{K}{\beta_1}\int_0^1 (\phi_x)^2\,dx + \frac{(\beta_2-\beta_1)}{\beta_1}\int_0^1 (\mathcal{A}c_2)\,\phi\,dx.\end{aligned}$$

Since $0 < m < \beta_i(t) < \mathcal{M}$, $i = 1,2$, and $\phi(0,t) = 0$, it follows that

$$\frac{1}{2}\frac{d}{dt}\left(\|\phi\|^2_{L^2(0,1)}\right) \le \frac{2\mathcal{M}}{m}\|\mathcal{A}c_2\|_{L^2(0,1)}\|\phi\|_{L^2(0,1)}.$$

By results in [14] or [17], there exists a constant C_1 such that

$$\|\mathcal{A}c_2\|_{L^2(0,1)} \le \frac{C_1\beta_2(0)}{t}\|c_0\|_{L^2(0,1)}.$$

Hence

$$\frac{d}{dt}\left(\|\phi\|_{L^2(0,1)}\right) \le \frac{2\mathcal{M}C_1\beta_2(0)}{mt}\|c_0\|_{L^2(0,1)}.$$

Integrating this over (t_1,t_2) yields

$$\begin{aligned}\|\phi\|_{L^2(0,1)}(t_2) &\le \|\phi\|_{L^2(0,1)}(t_1) + \left(2\mathcal{M}C_1\beta_2(0)\|c_0\|_{L^2(0,1)}/m\right)\ln|t_2/t_1| \\ &\le \|\phi\|_{L^2(0,1)}(t_1) + \left(2\mathcal{M}C_1\beta_2(0)\|c_0\|_{L^2(0,1)}/m\right)\ln|1+\varepsilon|,\end{aligned}$$

where $\varepsilon = (t_2 - t_1)/t_1$. Since t_2 can be chosen to be arbitrarily close to t_1, and since $\ln(1+z) < z$ for all $z > 0$, it follows that

$$\|\phi\|_{L^2(0,1)}(t_2) \le \|\phi\|_{L^2(0,1)}(t_1) + \left(2\mathcal{M}C_1\beta_2(0)\|c_0\|_{L^2(0,1)}/m\right)\varepsilon$$

for all $\varepsilon > 0$. Therefore $\|\phi\|_{L^2(0,1)}(t_2) \leq \|\phi\|_{L^2(0,1)}(t_1)$ or

$$\|\beta_1 c_1 - \beta_2 c_2\|_{L^2(0,1)}(t_2) \leq \|\beta_1 c_1 - \beta_2 c_2\|_{L^2(0,1)}(t_1).$$

Letting t_1 approach 0, we have

$$\|\beta_1 c_1 - \beta_2 c_2\|_{L^2(0,1)}(t) \leq \|\beta_1 c_1 - \beta_2 c_2\|_{L^2(0,1)}(0) = |\beta_1(0) - \beta_2(0)| \, \|c_0\|_{L^2(0,1)} = 0$$

for small t. This implies that $\beta_1(t)c_1(x,t) - \beta_2(t)c_2(x,t) = 0$ almost everywhere on $[0,1]$. It follows from $c_1(1,t) = c_2(1,t)$ that $\beta_1(t) = \beta_2(t)$ for small t. Repeated application of this argument extends the result to $[0,T]$. ∎

3.2. Output least squares and Tikhonov regularization. We define

$$G(\beta) \equiv \gamma c_\beta$$

with

$$G : \mathcal{B} \to L^2(0,T).$$

In the presence of perfect data z, we would solve the nonlinear ill-posed problem

$$G(\beta^0) = z, \tag{3.3}$$

where c_{β^0} is the solution of the direct problem with $\beta = \beta^0$. To do this using Tikhonov regularization would involve approximating the solution by minimizing

$$\min_{\beta \in \mathcal{B}} \|G(\beta) - z\|^2_{L^2(0,T)} + \alpha \|\beta - \hat{\beta}\|^2_{L^2(0,T)},$$

where $\alpha > 0$ is a small parameter and $\hat{\beta}$ is an a priori guess of the true solution β^0. In real applications, measurement errors mean that exact data is not available. Noisy data is assumed to have an error level δ,

$$\left\|z^\delta - z\right\|_{L^2(0,T)} \leq \delta.$$

We assume attainability of a true solution; i.e., if $z \in L^2(0,T)$, there exists $\beta^0 \in \mathcal{B}$ such that

$$G(\beta^0) = z. \tag{3.4}$$

We seek the minimizer $\beta^\delta_\alpha \in \mathcal{B}$ of

$$J_\alpha(\beta) = \left\|G(\beta) - z^\delta\right\|^2_{L^2(0,T)} + \alpha \|\beta - \hat{\beta}\|^2_{L^2(0,T)} \tag{3.5}$$

for appropriate choices of $\hat{\beta} \in \mathcal{B}$ and α. We begin by establishing the weak-closedness of the map $\beta \to \gamma c_\beta$. This will lead to the existence of a minimizer β^δ_α. Continuous dependence on the data z^δ for fixed α, and the convergence of β^δ_α toward the true parameter β^0 as the noise level δ and the regularization parameter α go to zero, also follow.

THEOREM 3.3. *If $\beta_n \rightharpoonup \beta_* \in \mathcal{B}$ in $H^1(0,T)$, then $c_{\beta_n} \rightharpoonup c_{\beta_*}$ in W and $\gamma c_{\beta^n} \rightharpoonup \gamma c^*_\beta$ in $L^2(0,T)$.*

Proof. Since we have existence of a unique solution to (3.1) from Theorem 3.1, we define $c_n = c(\beta_n)$. We make a change of variables, $w = e^{-\lambda t}c$, where λ is to be chosen. The state equation and initial and boundary conditions become

$$\begin{aligned}(\beta w)_t + \lambda\beta w - Kw_{xx} + w_x &= 0,\\ w(0,t) = 0, w_x(1,t) = 0, \quad t &\in [0,T],\\ w(x,0) &= c_0(x).\end{aligned}$$

Let $\langle\cdot,\cdot\rangle$ denote the duality between $(H^1(0,1))^*$ and $H^1(0,1)$. We use the weak definition of the transformed equation and integrate in time to obtain

(3.6)
$$0 = \int_0^t \langle(\beta_n w_n)_t, \beta_n w_n\rangle dt + \int_0^t\int_0^1 \left[\lambda(\beta_n w_n)^2 + K\beta_n(w_n)_x^2 + \beta_n(w_n)_x w_n\right] dxdt.$$

Upon simplification, use of $0 < m < \beta_n(t) < \mathcal{M}$, and Cauchy's inequality, we have

$$\begin{aligned}&\frac{m^2}{2}\int_0^1 [w_n(x,t)]^2\,dx + \lambda m^2\int_0^t\int_0^1 (w_n)^2 dxdt + Km\int_0^t\int_0^1 (w_n)_x^2 dxdt\\ &\le \frac{\mathcal{M}^2}{2}\int_0^1 [c_0(x)]^2 dx + \frac{\mathcal{M}^2}{2Km}\int_0^t\int_0^1 (w_n)^2 dxdt + \frac{Km}{2}\int_0^t\int_0^1 (w_n)_x^2 dxdt.\end{aligned}$$

After dividing by m^2, collecting terms, and choosing $\lambda > \frac{(2Km^3+1)\mathcal{M}^2}{2Km^3}$, we obtain

$$\begin{aligned}&\int_0^1 [w_n(x,t)]^2 dxdt + \frac{K}{m}\int_0^t\int_0^1 (w_n)_x^2 dxdt + 2\mathcal{M}^2\int_0^t\int_0^1 (w_n)^2 dxdt\\ &\le \frac{\mathcal{M}^2}{m^2}\int_0^1 [c_0(x)]^2 dx.\end{aligned} \tag{3.7}$$

We can conclude that $\|w_n\|_{L^2((0,T),H^1(0,1))}$, and hence $\|c_n\|$ is uniformly bounded independent of n. Using this bound and the state equation, we also have uniform bounds on $\|(\beta_n c_n)_t\|$. We can extract a subsequence such that

$$\begin{aligned}c_n &\rightharpoonup c_* \quad \text{in} \quad L^2((0,T);H^1(0,1)),\\ (c_n)_t &\rightharpoonup (c_*)_t \quad \text{in} \quad L^2((0,T);(H^1(0,1))^*),\\ \beta_n &\to \beta_* \quad \text{in} \quad L^2(0,T),\end{aligned}$$

where c_* and β_* are the relevant weak limits. In order to show that $c^* = c(\beta_*)$, we must establish that c_* is the state solution associated with β_*. We consider the weak form of the partial differential equation satisfied by c_n,

$$\int_0^T \langle(\beta^n c^n)_t, \phi\rangle dt + K\int_0^T\int_0^1 c_x^n\phi_x dxdt + \int_0^T\int_0^1 c_x^n\phi dxdt = 0, \tag{3.8}$$

where $\phi \in L^2((0,T);H^1(0,1))$.

Since $\beta_n \to \beta_*$ in $L^2(0,T)$ we know that $\beta_n \rightharpoonup \beta_*$ in $H^1(0,T)$. Therefore $(\beta_n)' \rightharpoonup (\beta_*)'$ in $L^2(0,T)$, where $'$ is used to indicate the derivative here because β is a function of one variable, t. We examine the first term in the weak definition of state solution,

$$\begin{aligned}&\int_0^T\int_0^1 \left[(\beta_n c_n)_t - (\beta_* c_*)_t\right]\phi dxdt\\ &= \int_0^T\int_0^1 \left[(\beta_n)'\left[c_n - c_*\right]\phi + (\beta_n - \beta_*)' c_*\phi\right.\\ &\qquad \left. + \beta_n((c_n)_t - (c_*)_t)\phi + (\beta_n - \beta_*)(c_*)_t\phi\right] dxdt.\end{aligned} \tag{3.9}$$

We note that, from a comparison result in [20], we have that $c_n \to c_*$ in $L^2((0,1)\times(0,T))$. By $(\beta_n)' \rightharpoonup (\beta_*)'$ in $L^2(0,T)$ and $c_n \to c_*$ in $L^2((0,1)\times(0,T))$, the first term of (3.9) converges to zero as $n \to \infty$. The second term converges to zero since $(\beta_n)' \rightharpoonup (\beta_*)'$ in $L^2(0,T)$. The third and fourth terms converge to zero because of the strong convergence of the β_n sequence. As we pass to the limit in the weak definition of the solution, we obtain that $c_* = c(\beta_*)$. ∎

Existence of a minimizer β_α^δ now follows from the lower semicontinuity of the $L^2(0,T)$ norm. Continuous dependence on the data z^δ for fixed α and the convergence of β_α^δ toward the true parameter β^0 follow from standard results [19].

COROLLARY 3.4. *For any data $z^\delta \in L^2(0,T)$, a minimizer β_α^δ of (3.5) exists.*

COROLLARY 3.5. *For fixed α, the minimizers depend continuously on the data z^δ. If $\alpha(\delta)$ satisfies*

$$\alpha(\delta) \to 0, \qquad \delta^2/\alpha(\delta) \to 0 \qquad \text{as } \delta \to 0,$$

then

$$\lim_{\delta\to 0} \left\|\beta_\alpha^\delta - \beta^0\right\|_{L^2(0,T)} = 0.$$

3.3. Convergence rates. Although we have established convergence of the minimizer β_α^δ to the true parameter β^0, the rate of convergence may be arbitrarily slow. We apply the theory of Engl, Hanke, and Neubauer [7] and Engl, Kunisch, and Neubauer [8] to determine a source condition that will guarantee a certain rate of convergence. Recall that we seek to solve the nonlinear problem (3.3), $G(\beta) = z$, where $G(\beta) \equiv \gamma c_\beta$. The true solution is β^0, and $\hat\beta$ is an a priori guess. Let $L(\beta)$ be the differential operator

$$L(\beta)u \equiv (\beta u)_t + u_x - K u_{xx}$$

on the domain $D(L) = \{u \in W \,|\, u(0,t) = u_x(1,t) = 0\}$. The soil problem (3.1) satisfies

$$L(\beta)c = 0, \qquad c(x,0) = c_0(x).$$

We establish next an estimate of the rate of convergence of our algorithm. Even when our regularization parameter α is comparable to our noise level δ, convergence requires assumptions involving $c(1,t)$ and $\beta^0 - \hat\beta$.

THEOREM 3.6. *Let $By \equiv -y'' + y$ with*

$$B : D(B) = \left\{y \in H^2(0,T) \mid y'(0) = y'(T) = 0\right\} \to L^2(0,T).$$

If

$$\frac{B\left(\beta^0(t) - \hat\beta(t)\right)}{c(1,t)} \in H^{-1}(0,T) \tag{3.10}$$

and if

$$\left\| \int_t^T \frac{B\left(\beta^0(t) - \hat\beta(t')\right)}{c(1,t')}\, dt' \right\|_{L^2(0,T)} \quad \text{is sufficiently small,} \tag{3.11}$$

then for the choice $\alpha \sim \delta$ *we obtain*

$$\left\|\beta_\alpha^\delta - \beta^0\right\|_{H^1(0,T)} = O(\sqrt{\delta}) \qquad \textit{and} \qquad \left\|G(\beta_\alpha^\delta) - z^\delta\right\|_{L^2(0,T)} = O(\delta).$$

Proof. We define

$$F(\beta) \equiv c(x,t).$$

If $\Psi_h(x,t) = F'(\beta)h(t)$ is the first Fréchet derivative in the direction h, then $\Psi_h \in D(L)$ and

$$L(\beta)\Psi_h = -(hc)_t, \qquad \Psi_h(x,0) = 0.$$

Similarly, if $\Phi_h(x,t) = F''(\beta)\left(h(t),h(t)\right)$ is the second Fréchet derivative in the direction h, then $\Phi_h \in D(L)$ and

$$L(\beta)\Phi_h = -2(h\Psi_h)_t, \qquad \Phi_h(x,0) = 0.$$

By continuity of the trace operator, we have

$$G'(\beta)h(t) = \Psi_h(1,t) = \gamma\Psi_h, \qquad G''(\beta)\left(h(t),h(t)\right) = \Phi_h(1,t) = \gamma\Phi_h.$$

Thus, G is twice Fréchet differentiable.

Define $p \in W$ to be the solution of

$$L(\beta)^* p = h, \qquad p(x,T) = 0,$$

where the adjoint L^* is taken with respect to $L^2(0,T)$. Notice that

$$\begin{aligned}
\langle g, G'(\beta)^* h\rangle_{H^1(0,T)} &= \langle G'(\beta)g, h\rangle_{L^2(0,T)} \\
&= \langle \gamma\Psi_g, h\rangle_{L^2(0,T)} = \gamma\langle \Psi_g, h\rangle_{L^2(0,T)} \\
&= \gamma\langle -L^{-1}(gc)_t, h\rangle_{L^2(0,T)} = -\gamma\langle (gc)_t, \left(L^{-1}\right)^* h\rangle_{L^2(0,T)} \\
&= -\gamma\langle (gc)_t, \left(L^*\right)^{-1} h\rangle_{L^2(0,T)} = -\gamma\langle (gc)_t, p\rangle_{L^2(0,T)} \\
&= \gamma\langle g, cp_t\rangle_{L^2(0,T)},
\end{aligned}$$

provided that $g(0) = 0$. Since

$$\langle g, v\rangle_{L^2(0,T)} = \left\langle \left(B^{-1}\right)^* g, v\right\rangle_{H^1(0,T)}$$

for every $v \in H^1(0,T)$, it follows that

$$\gamma\left\langle g, (cp_t)\right\rangle_{L^2(0,T)} = \gamma\left\langle \left(B^{-1}\right)^* g, cp_t\right\rangle_{H^1(0,T)} = \gamma\left\langle g, B^{-1}\left(cp_t\right)\right\rangle_{H^1(0,T)}.$$

This means that

$$G'(\beta)^* h = \gamma B^{-1}\left(cp_t\right)$$

with $L(\beta)^* p = h$, $p(x,T) = 0$. Since (3.10) holds, there exists $w \in L^2(0,T)$ such that

$$\beta^0 - \hat{\beta} = G'(\beta_0)^* w \tag{3.12}$$

or $B(\beta^0 - \hat{\beta}) = c(1,t)p_t(1,t)$ with

$$L(\beta^0)c = 0, c(x,0) = c_0(x), \qquad L(\beta^0)^* p = w(t), p(x,T) = 0.$$

Let $h := \beta_\alpha^\delta - \beta^0$ and $\beta^s := \beta^0 + sh$. Then

$$\begin{aligned}
&\left| 2\left\langle w, \int_0^1 G''(\beta^s)(h,h)(1-s)\,ds \right\rangle_{L^2(0,T)} \right| \\
&\quad = \left| 2\int_0^T w(t) \int_0^1 G''(\beta^s(t))(h(t),h(t))(1-s)\,ds\,dt \right| \\
&\quad \le \sup_{0\le s\le 1} \left| \langle w, G''(\beta^s)(h,h)\rangle_{L^2(0,T)} \right| \\
&\quad = \sup_{0\le s\le 1} \left| \left\langle \gamma L(\beta^0)^* p,\ , G''(\beta^s)(h,h)\right\rangle_{L^2(0,T)} \right| \\
&\quad = \|\gamma p\|_{L^2(0,T)} \left\| \gamma L(\beta^0)\Psi_h \right\|_{L^2(0,T)}.
\end{aligned}$$

As in [8], it can be shown that there exist constants C_1 and C_2 such that

$$\|\Phi_h\|_W \le C_1 \|h\|_{L^2(0,T)} \|\Psi_h\|_W, \qquad \|\Psi_h\|_W \le C_2 \|h\|_{L^2(0,T)} \|c\|_W.$$

By the trace theorem [9, p. 258] and boundedness of the operator $L(\beta^0)$, there exists C_3 such that

$$\left\| \gamma L(\beta^0)\Psi_h \right\|_{L^2(0,T)} \le C_3 \|h\|^2_{H^1(0,T)} \|c\|_W.$$

As the quantity appearing in (3.11) is $\|\gamma p\|_{L^2(0,T)}$, we deduce that

$$2\left\langle w, \int_0^1 G''(\beta^s)(h,h)(1-s)\,ds \right\rangle_{L^2(0,T)} \le \rho \|h\|^2_{H^1} \tag{3.13}$$

with $\rho < 1$. Since G is twice Fréchet differentiable and both (3.12) and (3.13) hold, application of the theory of Engl, Kunisch, and Neubauer [8, Theorem 2.4] yields the desired convergence result. ∎

Discussion of source condition. The condition (3.10) requires that the difference between the a priori guess $\hat{\beta}$ and the true solution β^0 must be in $D(B) \subset H^2(0,T)$. In practical applications, this regularity assumption is very restrictive.

It was established in Oppenheimer [14] for Hölder continuous β that there exist constants $C \ge 0$ and $\theta > 0$ such that

$$\|c(\cdot,t)\|_{L^2(0,1)} \le C\frac{\beta(0)}{\beta(t)} e^{-\theta t} \|c_0\|_{L^2(0,1)}.$$

Since $\beta \in \mathcal{B}$ is bounded, there exist constants $C \ge 0$ and $\theta > 0$ such that

$$\|c(\cdot,t)\|_{L^2(0,1)} \le Ce^{-\theta t} \|c_0\|_{L^2(0,1)}.$$

The requirement (3.11) means that the difference between our a priori guess $\hat{\beta}$ and the true parameter β^0 must be small and very smooth when our measurement $c(1,t)$ is small. This is both a local and global restriction. Since $c(\cdot,t)$ decays exponentially, this is possible only for sufficiently small T.

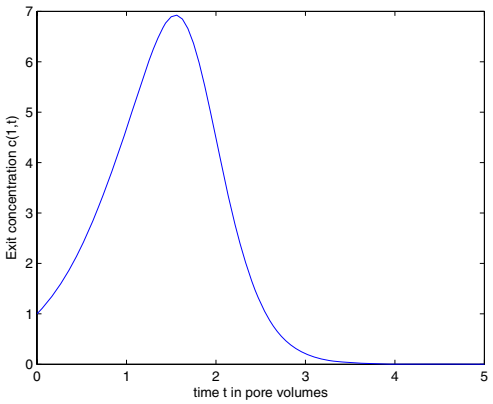

FIG. 4.1. *Exit concentration.*

4. Numerical results. In order to demonstrate the effectiveness of Tikhonov regularization for this application, we consider two examples. Recall that the solution of our forward problem (3.1) decays over time, i.e., $c(x,t) \to 0$ as $t \to \infty$. As a result, we do not expect to be able to use all of the available data or to recover $\beta(t)$ over the whole time interval.

All computations were carried out in MATLAB. The Tikhonov functional

$$J_\alpha(\beta) = \int_0^T \left(c(1,t) - z^\delta\right)^2 dt + \alpha \int_0^T \left(\beta(t) - \hat{\beta}(t)\right)^2 dt$$

was minimized using a Gauss–Newton method. Here z^δ and $\hat{\beta}$ represent noisy data and an a priori guess of the parameter. During the computation of $J_\alpha(\beta)$, exit concentrations $c(1,t)$ associated with a particular β were computed using an implicit finite-difference algorithm. The integrals were computed using a trapezoidal rule. Exit concentration data was generated using a method of lines algorithm with high accuracy. The a priori guess was chosen to be $\hat{\beta} = \beta(0)$, which was estimated using the approximation $\beta(0) \approx (\int_0^{t_N} c(1,t)\,dt)/c_0$. Strategies for the discussion of regularization parameters are discussed in [21]. For the purposes of this discussion, we will choose the regularization parameter to be $\alpha = 0$ in the absence of noise.

Example 1. Let $c_0(x) = 1$ and $K = 0.07$. Consider the sorption coefficient

$$\beta(t) = 1 + 10e^{-2t}.$$

The exit concentration $c(1,t)$ associated with this β is shown in Figure 4.1. Since the data decays over time, we restrict the recovery of β to the time interval $[0, 2.5]$. An initial guess of $\beta = 1$ was used. The parameter β and its recovery $\beta_{nonoise}$ from noiseless data are shown in Figure 4.2. Notice that quality of the recovery degrades after $t = 2$. This is due to the fact that the exit concentrations become very small and begin to amplify numerical error in the algorithm.

Example 2. Let $c_0(x) = 1$ and $K = 0.07$. Consider the sorption coefficient

$$\beta(t) = 2 + \cos(10t).$$

The exit concentration $c(1,t)$ associated with this β is shown in Figure 4.3. Once again the data decays over time, and we restrict the recovery of β to the time interval $[0, 2]$.

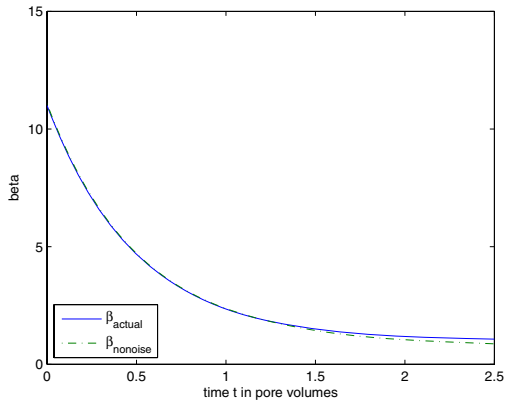

FIG. 4.2. *$\beta_{nonoise}$ recovered from exact data.*

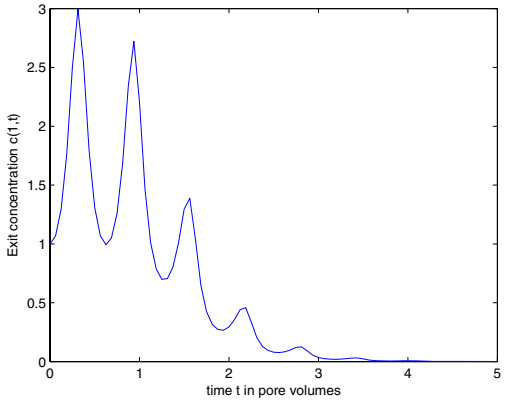

FIG. 4.3. *Exit concentration.*

An initial guess of $\beta = 2$ was used. The parameter β and its recovery $\beta_{nonoise}$ from noiseless data are shown in Figure 4.4. Notice that quality of the recovery degrades after $t = 1.25$.

Example 3*: Noisy data.* Since data for this problem is measured experimentally, it will contain a certain amount of noise. The nature of these experiments suggests that the noise level may be as much as 20%. Noise is introduced into the data from Example 1 via a normally distributed random number generator. Figure 4.5 shows the noisy exit concentration data.

In engineering applications, it is not practical to expect to have sufficient information about the unknown parameter β^0 in order to choose an a priori guess $\hat{\beta}$ so that $\beta^0 - \hat{\beta} \in D(B) \subset H^2(0,T)$. Hence Theorem 3.6 does not apply. Instead, a regularization parameter of $\alpha = 10^{-3}$ was chosen heuristically by an L-curve method, [21]. Figure 4.6 shows the recovery of β_{noise} with and without regularization. Clearly $\alpha = 10^{-3}$ produces better results than $\alpha = 0$, although the recovery is not as good as the noiseless case in Example 1.

5. Conclusions. In this paper, we have identified the sorption partitioning coefficient as a function of time from limited boundary data. A numerical approach for approximating this time dependent parameter in a parabolic partial differential equation has been analyzed. This work has brought insight into how a partitioning coefficient varies with different physical factors such as temperature fluctuations and contaminant introduction in the soil column. In the column studies, the boundary data is represented by the measurements of contaminant concentrations as the solution exits the soil column. The identifiability of the soil sorption parameter, β, is determined from these noisy exit concentration measurements. In order to establish the identifiability of the parameter β, we proved the injectivity of the parameter to the output map. We then discussed an output least squares formulation of the problem with Tikhonov regularization. Using this format, we found a minimizer to our approximate problem and were able to prove that this minimizer converges to the true parameter as the noise level and the regularization parameter approach zero. Although we proved convergence, the rate of convergence may be arbitrarily slow. Therefore, we established a source condition that guarantees a given rate of convergence. However, there is a trade-off here. The condition requires that the difference between our a priori guess and the true parameter must be small and relatively smooth when the boundary measurements are small. We found that this in possible only over a small time interval because the contaminant concentration decays over time. Within the numerical examples, this is seen after $t = 2$ in Example 1 and after $t = 1.6$ in Example 2. However, with the noisy data, the quality of the identification significantly improves with the inclusion of a regularization parameter. Consequently, the implementation of Tikhonov regularization provides a more tractable result.

INTRODUCING A POPULATION INTO A STEADY COMMUNITY: THE CRITICAL CASE, THE CENTER MANIFOLD, AND THE DIRECTION OF BIFURCATION*

BARBARA BOLDIN†

Abstract. In this paper we study deterministic, finite dimensional, continuous, as well as discrete time population invasion models. The ability of a newly introduced population, either a new species or a reproductively isolated subpopulation of one of the already present species, to settle in the community relies upon the basic reproduction ratio of the invader, $\mathcal{R}_0$. When $\mathcal{R}_0$ exceeds 1, the invading population meets with success, and when $\mathcal{R}_0$ is below 1, the invasion fails. The aim of this paper is to investigate the possible effects of an invasion when the parameters of a model are varied so that $\mathcal{R}_0$ of the invading population passes the value 1. We argue that population invasion models, regardless of the biology that underlies them, take a specific form that significantly simplifies the center manifold analysis. We make a uniform study of ecological, adaptive dynamics and disease transmission models and derive a simple formula for the direction of bifurcation from a steady state in which only the resident populations are present. Furthermore, we observe that among those bifurcation parameters that satisfy a certain condition, we acquire the same direction of bifurcation. The obtained mathematical results are used to gain insight into the biology of invasions. The theory is illustrated by several examples.

Key words. population model, physiologically structured population, *i*-state, *p*-state, reproductively isolated, population, species, center manifold, transcritical bifurcation, direction of bifurcation, basic reproduction ratio, finitely many states at birth, next generation matrix, invasibility

1. Introduction.

One of the basic questions of population biology is the following. Suppose that a population is introduced into a steady community in which it has not been present before. Under what conditions will this newly introduced population be able to settle in the community, and when will the dynamics lead to its extinction?

The literature that deals with this question is vast and diverse. We could roughly group the biological settings into the following categories:

1. In *ecology* one is studying an introduction of (i) a population of predators that forages on a resident prey community (i.e., the so-called predator-prey models; see [7], [11], [20], [26], [27], [30], [31], [32], [34] for some examples), or (ii) a population that competes for resources with the resident community (for examples of competition models, see [7], [20], [26], [31], [33]).

While it is common that the newly introduced population is also a new species, i.e., one that is not present in the resident community, there are also examples in which one is interested in the ability of what we shall call a reproductively isolated subpopulation of one species to be able to settle among individuals of another subpopulation of the same species. We shall define the precise meaning of the term *reproductive isolation* in Appendix B. The reader may at this point have in mind, for example, studying interactions (say, competition for shared resources) among different year classes of

semelparous species [2], [8], [9], [10] or different morphs in size-structured populations [3], [4].

2. In a branch of the theory of evolution called *adaptive dynamics* one is investigating the ability of a rare mutant phenotype to invade the environment set by the resident community (see [12], [21], [25] and the references therein).

3. *Epidemiology of infectious diseases* is concerned with introductions of infectious pathogens into susceptible populations (see, for example, [13], [18], [19], [22], [34], [35]).

When the resident community is at a stable equilibrium and we describe the process of invasion by a deterministic model we can, regardless of the biological background, answer the invasibility question in terms of the *basic reproduction ratio* [13], [15] of the invading population, $\mathcal{R}_0$, as follows: if $\mathcal{R}_0 < 1$, the invading population will go extinct, and if $\mathcal{R}_0 > 1$, it will settle in the community. The transition hence occurs when $\mathcal{R}_0 = 1$.

Now, what happens when $\mathcal{R}_0$ passes the value 1? The answer can be formulated mathematically or biologically. In mathematical terms one says that a *transcritical bifurcation* of a steady state and an *exchange of stability* take place [5], [6], [24], [36]. From a strictly mathematical point of view there is but one generic type of transcritical bifurcation. But when it comes to seeing the results from a biologist's point of view one must realize that a steady state is meaningful only when all its components are nonnegative, in particular those corresponding to the invading population. In many models the latter requirement is fulfilled only when $\mathcal{R}_0 > 1$. The bifurcation is then called *supercritical* or *forward* or, also, *soft* or *smooth*, since the size of the invading population remains small when $\mathcal{R}_0 - 1$ is positive but small. In some models, however, the positivity requirement is fulfilled only for $\mathcal{R}_0 < 1$, and one then speaks of a *subcritical* or *backward* bifurcation.

While in the case of a supercritical bifurcation the invasion fails when $\mathcal{R}_0$ of the invading population falls below 1, the invader can meet with success even if $\mathcal{R}_0 < 1$ (when introduced in sufficiently large quantities) when the bifurcation is backward. Moreover, even when the invader is introduced in small quantities, a small perturbation of $\mathcal{R}_0$ to a value greater than 1 can in a subcritical case lead to a rather large invader population size. This phenomenon is sometimes called *catastrophic transition* (see Figure 2.2).

Clearly then, it is important to be able to tell which of the two cases applies in any given situation, and in this paper we provide the reader with a simple criterion to distinguish between the two scenarios.

Of course, the invasibility question is equally meaningful when the resident community resides in a dynamic attractor. This situation is, however, outside the scope of this paper.

Throughout this paper we consider communities whose members differ in a finite number of characteristics. These characteristics are in the context of population models often called *i-states* [13], [15], with i standing for individual. Ideally, they should capture precisely the features that are relevant for the description of the process one is studying, and are hence to be considered for each problem separately.

In a general setting we assume that the community is divided into $m + n$ subpopulations, of which m subpopulations constitute the invading population and the remaining n make up the resident community. We denote by

$$\mathcal{Y} = \{(y_1, \dots, y_m) \ ; \ y_j \geq 0 \ \text{ for } j = 1, \dots, m\} = \mathbb{R}^m_+$$

the population state space (p-state space) of the invading population (i.e., for each $j \in \{1, \dots, m\}$ we denote by y_j the number (or density) of individuals in the jth subpopulation) and by

$$\mathcal{Z} = \{(z_1, \dots, z_n) \ ; \ z_j \geq 0 \ \text{ for } j = 1, \dots, n\} = \mathbb{R}^n_+$$

the community state space of the resident community. The c-state space of the joint community will be written as $\mathcal{Y} \times \mathcal{Z}$.

Now let $(y(t), z(t))$ denote the community state at time t, where time is measured from some conveniently chosen point. The dynamics of $(y(t), z(t))$ in time often depends not only on the present community state, but also on a number of parameters, such as per capita death rates, birth rates, etc., and, quite commonly, population models involve more than one parameter.

The aim of this paper is to study the ability of a newly introduced population to invade the existing community in the case when its basic reproduction ratio is near 1 and to derive a formula for the direction of bifurcation from a steady state in which the invading population is not present. We shall therefore concentrate on one distinguished parameter which we call the bifurcation parameter.

With this in mind we already at this point include only one (real) parameter μ and assume that the process we study is either a continuous time process described by a parametrized system of ordinary differential equations,

$$\begin{aligned} &\dot{y} = g(y, z, \mu), \\ &\dot{z} = h(y, z, \mu), \qquad\qquad y \in \mathcal{Y}, z \in \mathcal{Z}, \mu \in \mathbb{R}, \end{aligned} \tag{1.1a}$$

or a discrete time process described by a parametrized map,

$$\begin{aligned} &y \mapsto g(y, z, \mu), \\ &z \mapsto h(y, z, \mu), \qquad\qquad y \in \mathcal{Y}, z \in \mathcal{Z}, \mu \in \mathbb{R}. \end{aligned} \tag{1.1b}$$

If we consider a steady state of (1.1a) (or (1.1b)) in which the invading population is not present (these steady states lie on the boundary of the c-state space) and study the effect of perturbations corresponding to an introduction (in small quantities) of the missing population, we find that such an equilibrium is locally asymptotically stable when $\mathcal{R}_0$ of the invading population is below 1, and unstable when $\mathcal{R}_0$ exceeds 1. Moreover, stability can in these two cases be inferred from the linearization of (1.1) around the steady state.

The Perron–Frobenius theory of nonnegative matrices [1], [29], which applies for problems in population dynamics, leads us to the observation that the critical case, i.e., the case when $\mathcal{R}_0 = 1$, corresponds to the situation when

(i) the linearization of (1.1a) around the steady state yields a zero eigenvalue,
(ii) the linearization of (1.1b) around the steady state yields an eigenvalue 1.

In other words, when $\mathcal{R}_0 = 1$ we are dealing with nonhyperbolic steady states, and it is well known [24], [36] that the stability of nonhyperbolic equilibria cannot be determined by linearization alone.

Several papers (e.g., [11], [14], [18], [19], [22], [28], [30], [32], [35]) deal with this situation in the context of population models, most of them (with the exception of [14]) treating special cases or restricting their analysis to models describing the spread of infectious diseases.

In the present paper we study the critical case for general (not restricted to any particular biological background) finite dimensional population models. We will

argue that an introduction of either one new species or a reproductively isolated subpopulation of one of the existing species yields a property of (1.1) that significantly simplifies the center manifold analysis. More precisely, (1.1a) will be shown to be of the form

$$\begin{aligned} \dot{y} &= G(y,z,\mu)y, \\ \dot{z} &= h(y,z,\mu), \qquad y \in \mathcal{Y}, z \in \mathcal{Z}, \mu \in \mathbb{R}. \end{aligned} \tag{1.2}$$

A similar decomposition can be obtained for parametrized maps in (1.1b).

This will lead us to the observation that an introduction of a population whose basic reproduction ratio is close to 1 corresponds to a transcritical bifurcation of a steady state of (1.1) in which only the resident populations are present. In order to obtain the direction of bifurcation from such a steady state only the first derivatives of G and h are needed. This reduction of the order of the derivatives needed (in general, second order derivatives are needed) is, of course, most useful when one is dealing with large systems.

We will also see that among those bifurcation parameters for which

$$\begin{cases} \mu < 0 \iff \mathcal{R}_0 < 1, \\ \mu = 0 \iff \mathcal{R}_0 = 1 \end{cases}$$

holds on some neighborhood of $\mu = 0$ and the crossing of the point $\mathcal{R}_0 = 1$ occurs at a nonzero "speed," we obtain the same direction of bifurcation.

Moreover, we will show how G in (1.2) can be obtained by only considering the basic modeling ingredients, such as birth, growth, and survival rates—an approach that might be of interest to more biologically inclined readers.

The paper is structured as follows. In section 2 we study continuous time population invasion models described by (1.2). Section 3 is devoted to justifying the use of this particular form of models. We argue that this form is characteristic of population invasion models. It appears in all biological scenarios mentioned at the beginning of this Introduction and hence allows us to make a uniform study of ecological, adaptive dynamics and disease transmission models. We also show how G is obtained from basic modeling ingredients. Population models in discrete time are the theme of section 4. Section 5 provides some interpretation of the assumptions made in previous sections and draws attention to the link between continuous and discrete time population models. In section 6 we give some examples to illustrate the theory of the preceding sections. And lastly, in appendices at the end of the paper we collect some basic definitions and results regarding physiologically structured population models and put the notions of a *population, species,* and *reproductively isolated subpopulation* into a more mathematical setting.

2. Population invasion models in continuous time. We begin our study of continuous time population models by recalling the decomposition of the community state space

$$\mathcal{Y} \times \mathcal{Z} = \mathbb{R}_+^m \times \mathbb{R}_+^n,$$

where $\mathcal{Y} = \mathbb{R}_+^m$ denotes the population state space of the invading population and $\mathcal{Z} = \mathbb{R}_+^n$ the community state space of the resident community. The processes we study in this section are continuous time processes described by

$$\begin{aligned} \dot{y} &= G(y,z,\mu)y, \\ \dot{z} &= h(y,z,\mu), \qquad y \in \mathcal{Y}, z \in \mathcal{Z}, \mu \in \mathbb{R}, \end{aligned} \tag{2.1}$$

where we shall furthermore assume that $G \in M_{m\times m}(C^1(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}))$ and $h \in C^1(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}^n)$.

The form (2.1) is characteristic of continuous time population invasion models and one with which an experienced modeler may already be familiar. Those not familiar with it who feel perplexed at this point are referred to section 3, where we shall, in both mathematical and biological terms, explain why and how this form is obtained.

By writing

$$x = \begin{bmatrix} y \\ z \end{bmatrix}, \qquad f = \begin{bmatrix} Gy \\ h \end{bmatrix}, \tag{2.2}$$

we shall write (2.1) as $\dot{x} = f(x)$ and also use (1.1a) whenever this notation will be more convenient.

Consider now an equilibrium of (2.1) of the form $e = (0, z_0)$ for some $z_0 \in \mathcal{Z}$, i.e., a steady state in which only the resident populations are present. In general (2.1) can have more than one steady state of this form, and these steady states may also depend on μ. We therefore write $e(\mu) = (0, z_0(\mu))$ with $z_0(\mu) \in \mathcal{Z}$.

To study the linearized stability of $e(\mu)$ we write

$$Df\big((0, z_0(\mu), \mu)\big) = \begin{bmatrix} G(e(\mu), \mu) & 0 \\ h_y(e(\mu), \mu) & h_z(e(\mu), \mu) \end{bmatrix},$$

where

$$h_y(y, z, \mu) = \frac{\partial h(y, z, \mu)}{\partial y} \quad \text{and} \quad h_z(y, z, \mu) = \frac{\partial h(y, z, \mu)}{\partial z}. \tag{2.3}$$

Hence,

$$\sigma\big(Df(e(\mu), \mu)\big) = \sigma\big(G(e(\mu), \mu)\big) \cup \sigma\big(h_z(e(\mu), \mu)\big).$$

The next assumption that we shall make is that the equilibrium $e(\mu) = (0, z_0(\mu))$ is internally asymptotically stable; that is, it is asymptotically stable under perturbations within the invariant subspace $\{0\}^m \times \mathcal{Z}$. In other words, as long as no new population is introduced, the steady state of the resident community, $z_0(\mu)$, is locally asymptotically stable. We shall make the slightly stronger assumption that the stability can be inferred from the linearization. In mathematical terms this means that we assume

A_1. If $\lambda \in \sigma(h_z(e(\mu)))$, then $Re(\lambda) < 0$.

The spectrum of $G(e(\mu), \mu)$ thus completely determines the linearized stability of the steady state $e(\mu)$.

For the existence and uniqueness assertions that follow we need only "internal hyperbolicity," i.e., that $Re(\lambda) \neq 0$ for any $\lambda \in \sigma\big(h_z(e(\mu), \mu)\big)$. Assumption A_1 will allow us to make more detailed stability assertions, which are known as *the principle of the exchange of stability* [5], [6], [24].

Now we would like to know whether the invading population, after being introduced into the community, is able to settle in that community. As mentioned in the Introduction, the answer is *no* when the basic reproduction ratio of the newly introduced population is below 1 and *yes* when $\mathcal{R}_0$ of the invading population exceeds 1.

The basic reproduction ratio is, by definition, the spectral radius of the next generation matrix.[1] All the modeling ingredients needed to write down the next

[1] See Appendix A for more on the next generation matrix and $\mathcal{R}_0$.

generation matrix in the context of the model (see section 5) given by (2.1) are contained in G (remember that $\mathcal{R}_0$ of the invading population is the one we need), and it is known (see [13], [35] for the proof) that $\mathcal{R}_0$ of the invading population relates to the spectral bound of $G(e(\mu),\mu)$ in the following way:

$$s\big(G(e(\mu),\mu)\big) < 0 \iff \mathcal{R}_0 < 1,$$
$$s\big(G(e(\mu),\mu)\big) = 0 \iff \mathcal{R}_0 = 1,$$

where $s(.)$ denotes the spectral bound

$$s(A) = \max\{Re(\lambda); \lambda \in \sigma(A)\}.$$

Since the next generation matrix is a nonnegative matrix we can apply the Perron–Frobenius theory [1] to conclude that $\mathcal{R}_0$ is an eigenvalue with a corresponding nonnegative eigenvector. The dominant eigenvalue is often called the *transversal eigenvalue*, and if it exceeds 1 we say that the newly introduced population is able to *invade successfully*. If $\mathcal{R}_0$ is below 1, the invasion of the newly introduced population is doomed to fail.

The interesting situation to consider is hence the situation when the parameter μ is such that $s(G(e(\mu),\mu)) = 0$, the case where linearization around the steady state does not yet answer the question of invasibility.

In many models the computation of the basic reproduction ratio $\mathcal{R}_0$ and certainly the spectral bound $s(G(e(\mu),\mu))$ yields complicated functions of parameters that we may not be able to express explicitly. We therefore choose a bifurcation parameter μ with the following properties:

$$\mathrm{A}_2.\quad \begin{cases} \mu < 0 \iff s(G(e(\mu),\mu)) < 0 \iff \mathcal{R}_0 < 1, \\ \mu = 0 \iff s(G(e(\mu),\mu)) = 0 \iff \mathcal{R}_0 = 1, \\ \mu > 0 \iff s(G(e(\mu),\mu)) > 0 \iff \mathcal{R}_0 > 1. \end{cases}$$

The results that follow are based on local information only. It therefore suffices that A_2 holds on some neighborhood of $\mu = 0$.

Assumption A_2 means that the function $\mu \mapsto s(G(e(\mu),\mu))$ crosses the origin. We shall furthermore assume that this crossing occurs at a nonzero speed, i.e.,

A_3. $\frac{d}{d\mu} s(G(e(\mu),\mu))\big|_{\mu=0} > 0$.

We now denote by e an equilibrium that corresponds to $\mathcal{R}_0 = 1$, i.e., $e = e(0)$; denote $e' = e'(0)$; and also shorten the notation by defining

$$H_y = h_y(e,0), \quad H_z = h_z(e,0), \quad G_0 = G(e,0). \tag{2.4}$$

Denoting by E^c the center subspace of G_0, we shall furthermore assume the following.

A_4. $\dim E^c = 1$.

We have already given the interpretation behind the first three assumptions. We shall return to this last assumption in section 5 and explain in more detail which biological requirements are sufficient in order for A_4 to hold. Let us remark only that, in systems that arise from modeling population dynamics, the matrix G_0 will be a matrix with nonnegative off-diagonal entries, and hence the Perron–Frobenius theory guarantees that A_4 is satisfied when G_0 is irreducible.

Before stating the main result we make the following observation, which will be useful later on.

LEMMA 2.1. *Let $\mu \mapsto G(e(\mu),\mu) \in C^1(\mathbb{R},\mathbb{R}^{m\times m})$, assume* A_2 *and* A_4*, and let w and v denote, respectively, the left and the right eigenvector of G_0 corresponding to eigenvalue zero, normalized so that $v\cdot w = 1$. Then*

$$\frac{d}{d\mu} s(G(e(\mu),\mu))\Big|_{\mu=0} = w\cdot\Big(D_x G(e,0)e' + D_\mu G(e,0)\Big)v. \tag{2.5}$$

Proof. According to the implicit function theorem there exists a neighborhood of $\mu = 0$, say U, on which a branch of eigenvalues of $G(e(\mu),\mu)$ is defined. That is,

$$G(e(\mu),\mu)v(\mu) = \lambda(\mu)v(\mu) \tag{2.6}$$

for $\mu \in U$, and since $\mu \mapsto G(e(\mu),\mu) \in C^1(\mathbb{R},\mathbb{R}^{m\times m})$ we have $\mu \mapsto \lambda(\mu) \in C^1(U,\mathbb{R})$. Moreover, $\mu \mapsto v(\mu) \in C^1(U,\mathbb{R}^m)$. Differentiation of (2.6) with respect to μ yields

$$\left(\frac{\partial G}{\partial e}e'(\mu) + \frac{\partial G}{\partial \mu}\right)v(\mu) + Gv'(\mu) = \lambda'(\mu)v(\mu) + \lambda(\mu)v'(\mu). \tag{2.7}$$

Since zero is also the spectral bound of G_0 and since the spectral bound $s(G(e(\mu),\mu))$ is a continuous function of μ we have that $\lambda(\mu) = s(G(e(\mu),\mu))$ in some neighborhood of $\mu = 0$. By taking $\mu = 0$ in (2.7) and taking into account that $\lambda(0) = 0$, we obtain

$$\frac{d}{d\mu} s(G(e(\mu),\mu))\Big|_{\mu=0} v = \Big(D_x G(e,0)e' + D_\mu G(e,0)\Big)v,$$

which brings us, after premultiplication by w on both sides, to (2.5). ∎

We can now prove the following result.

THEOREM 2.2. *Consider a population model described by* (2.1)*, and let $e(\mu) = (0, z_0(\mu))$ be a steady state of* (2.1)*. Assume that* A_1*,* A_2*,* A_3*, and* A_4 *hold. Furthermore, assume that $\mu \mapsto e(\mu) \in C^1(\mathbb{R},\mathbb{R}^{n+m})$, and denote by e the steady state that corresponds to $\mathcal{R}_0 = 1$, i.e., $e = e(0)$ and by $e' = e'(0)$. Let G_0, H_y, and H_z be as in* (2.4)*, and let w and v denote, respectively, the left and the right eigenvector of G_0 corresponding to eigenvalue zero, normalized so that $v\cdot w = 1$. Let*

$$\begin{aligned} M = &\sum_{i,j,k=1,\dots,m} w_i\left(\frac{\partial G_{ij}(e,0)}{\partial y_k} + \frac{\partial G_{ik}(e,0)}{\partial y_j}\right)v_j v_k \\ &- 2\sum_{\substack{i,j=1,\dots,m\\ k=1,\dots,n}} w_i \frac{\partial G_{ij}(e,0)}{\partial z_k} v_j (H_z^{-1}H_y v)_k. \end{aligned} \tag{2.8}$$

There exists a $\delta > 0$ such that

(i) *if $M < 0$, there is a branch $\mu \mapsto (y(\mu), z(\mu))$, defined for $\mu \in (0,\delta)$, of positive, locally asymptotically stable steady states of* (2.1)*;*

(ii) *if $M > 0$, there is a branch $\mu \mapsto (y(\mu), z(\mu))$, defined for $\mu \in (-\delta, 0)$, of positive, unstable steady states of* (2.1)*.*

In other words, there exists, in a neighborhood of $\mu = 0$, a branch of nontrivial, positive (and hence biologically meaningful) steady states of (2.1)*, and M tells us about its initial slope. The former case, case* (i)*, is often referred to as a* supercritical *bifurcation and the latter, case* (ii)*, as a* subcritical *or* backward *bifurcation.*

At this point the following remarks regarding the terminology are in order.

Remark 1. As already mentioned in the Introduction, the resulting bifurcations are the so-called *transcritical bifurcations*. They correspond to an intersection of two

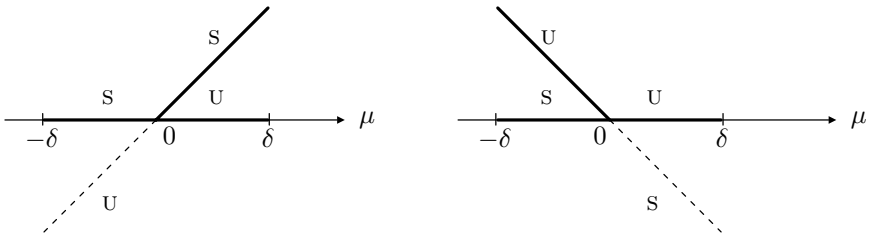

FIG. 2.1. *Supercritical (on the left) and subcritical (on the right) bifurcation. The branch of nonnegative steady states is denoted by a solid line. A dashed line represents steady states with negative components. Stability of equilibria is indicated by* **s** *(for stable) and* **u** *(for unstable).*

branches of equilibria, the trivial and the nontrivial, at $\mu = 0$, where the branches exchange stability (see Figure 2.1). In contrast with the purely mathematical point of view where these two transitions are qualitatively the same, we need to distinguish between the two in the biological context, since in that case only the nonnegative equilibria are of any relevance.

Remark 2. Note that only the first order derivatives of G and h are needed to determine the direction of bifurcation from e. Moreover, the expression M for the direction of bifurcation is independent of the bifurcation parameter except for the restrictions A_2 and A_3. In other words, provided that A_2 and A_3 are satisfied, we obtain the same direction of bifurcation for any choice of the bifurcation parameter.

The principle of the exchange of stability guarantees that the biologically meaningful, nontrivial bifurcating branch consists of stable equilibria in the supercritical case and of unstable equilibria in the subcritical case. The stable manifold of an unstable equilibrium then serves as a separatrix between the domains of attraction of the "residents only" steady state and some other attractor (frequently the same branch bent forward in a saddle node bifurcation).

Suppose now that an invader is introduced in small quantities into the resident community. In both the supercritical and the subcritical cases, this invasion will fail if the basic reproduction ratio of the invader is below 1.

In the supercritical case, the invader will be successful when its basic reproduction ratio exceeds 1, but its population size will be small when $\mathcal{R}_0 - 1$ is small. Because of this smooth transition, one sometimes calls this bifurcation *soft* or *smooth*.

In the subcritical case, on the other hand, a small introduction of the invading population for $\mathcal{R}_0 - 1$ small but positive leads to a large invader population size. Accordingly one also calls this bifurcation *hard* or *catastrophic*. Moreover, the invader can meet with success, despite $R_0 < 1$, if it is introduced in sufficiently large quantities. Catastrophic transition is illustrated in Figure 2.2, where unstable equilibria are denoted by a dashed line, stable by a solid line.

To restate Theorem 2.2 in biological terms we could say the following. When a new population, an invader, is successfully introduced into the community we observe one of the following:

(i) a smooth change to a positive but small invader population size or
(ii) a sudden, catastrophic transition to a rather large invader population size.

When all the assumptions of Theorem 2.2 are met, the sign of M in (2.8) determines which of the two scenarios we will observe in a concrete situation.

We now prove Theorem 2.2.

Proof. We have $G_0 v = 0, w^T G_0 = 0$, and $v \cdot w = 1$. By A_1, the matrix H_z is

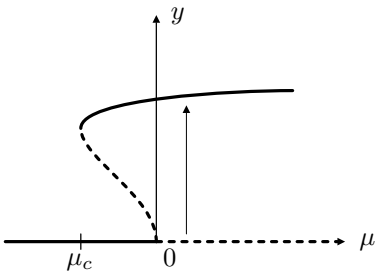

FIG. 2.2. *Catastrophic transition.*

invertible. The left and the right zero eigenvectors of $Df(e)$, denoted by W and V, are then of the form

$$W = \begin{bmatrix} w \\ 0 \end{bmatrix}, \qquad V = \begin{bmatrix} v \\ -H_z^{-1} H_y v \end{bmatrix}. \tag{2.9}$$

Moreover, $V \cdot W = 1$. By A_1 and A_4, the dimension of the center linear subspace equals 1, and the subspace is spanned by V.

We take the (generalized) right eigenvectors of $Df(e)$ for the basis of $\mathbb{R}^{m+n}$. It is known that the right (generalized) eigenvectors of $Df(e)$ that correspond to nonzero eigenvalues are orthogonal to W.

The center manifold theory [24], [36] states that the center manifold of the equilibrium e, denoted by $\mathcal{M}^c(e)$, can be (locally) parametrized by μ and a real variable u as

$$\mathcal{M}^c(e) = \{(x, \mu);\ x = e(\mu) + uV + \Phi(u, \mu)\},$$

where $\Phi(.)$ is defined on some neighborhood of the origin. Moreover, $\Phi(0,0) = D\Phi(0,0) = 0$ and $W \cdot \Phi(u, \mu) = 0$ for every u and μ.

The center manifold is also invariant under (2.1); that is,

$$\dot{x} = \dot{u}V + \dot{\Phi}(u, \mu) = f(x, \mu) = f(e(\mu) + uV + \Phi(u, \mu), \mu).$$

Since $W \cdot \frac{d}{dt}(\Phi(u, \mu)) = \frac{d}{dt}(W \cdot \Phi(u, \mu)) = 0$ and $V \cdot W = 1$ the inner product with W yields

$$\dot{u} = W \cdot f(e(\mu) + uV + \Phi(u, \mu), \mu) = w \cdot g(e(\mu) + uV + \Phi(u, \mu), \mu),$$

where we have used (2.9) in the last equality. Using the Taylor series expansion around $(e, 0)$, we can continue as follows:

$$\begin{aligned} \dot{u} \ = \ & w \cdot g(e,0) + w \cdot D_x g(e,0)(e(\mu) - e + uV + \Phi(u,\mu)) + w \cdot D_\mu g(e,0)\mu \\ & + \tfrac{1}{2} w \cdot D_{\mu\mu} g(e,0)\mu^2 + \tfrac{1}{2} w \cdot D_{xx} g(e,0)(e(\mu) - e + uV + \Phi(u,\mu))^2 \\ & + w \cdot D_{\mu x} g(e,0)(e(\mu) - e + uV + \Phi(u,\mu))\mu + \mathcal{O}(3), \end{aligned}$$

where $\mathcal{O}(3)$ contains the terms of third and higher order in u and μ.

Now, since e is an equilibrium of (2.1) the first term equals zero. So does the second because $w^T G_0 = 0$ and $D_z g(e, 0) = 0$. Since $g = Gy$ the third and the fourth terms also equal zero. Hence

$$\begin{aligned} \dot{u} = & \tfrac{1}{2} w \cdot D_{xx} g(e,0)(e(\mu) - e + uV + \Phi(u,\mu))^2 \\ & + w \cdot D_{\mu x} g(e,0)(e(\mu) - e + uV + \Phi(u,\mu))\mu + \mathcal{O}(3). \end{aligned}$$

By writing $e(\mu) = e + e'(0)\mu + \mathcal{O}(2)$ and taking into account that Φ has no constant and linear terms in u and μ, we can continue with

$$\begin{aligned}\dot{u} &= w \cdot \Big(\tfrac{1}{2} D_{xx} g(e,0) e'^2 + D_{\mu x} g(e,0) e'\Big)\mu^2 \\ &\quad + w \cdot \Big(D_{xx} g(e,0) e' V + D_{\mu x} g(e,0) V\Big)\mu u + \tfrac{1}{2} w \cdot D_{xx} g(e,0) u^2 V^2 + \mathcal{O}(3) \\ &= w \cdot \Big(D_{xx} g(e,0) e' V + D_{\mu x} g(e,0) V\Big)\mu u + \tfrac{1}{2} w \cdot D_{xx} g(e,0) u^2 V^2 + \mathcal{O}(3),\end{aligned}$$

where we have in the last equality taken into account that the first m components of $e(\mu)$ equal zero and the fact that $g = Gy$ implies $D_{zz} g(e,0) = D_{z\mu} g(e,0) = 0$. Moreover, this special form of g then gives us

$$\dot{u} = \mu u w \cdot \Big(D_x G(e,0) e' + D_\mu G(e,0)\Big) v + \tfrac{1}{2} w \cdot D_x G(e,0) u^2 V^2 + \mathcal{O}(3),$$

which, by denoting

$$N = w \cdot \Big(D_x G(e,0) e' + D_\mu G(e,0)\Big) v,$$

using (2.8), (2.9) and the fact that the first m components of e' equal zero, becomes

$$\dot{u} = \mu N u + \tfrac{1}{2} M u^2 + \mathcal{O}(3). \tag{2.10}$$

Note that, according to the Lemma 2.1, $N = \frac{d}{d\mu} s(G(e(\mu), \mu))\big|_{\mu=0}$, and so by assumption A_3, $N \neq 0$.

Now, the center manifold theory also states that the stability of the steady state under the initial system is determined by its stability under the restriction of the system to the center manifold. This restriction is now given in (2.10).

For u and μ close to zero we can neglect the higher order terms that are collected in $\mathcal{O}(3)$. The nontrivial steady state solutions of (2.10) that are near the origin are then close to the line $u = -2\mu N M^{-1}$, assuming, of course, that $M \neq 0$. By assumption, N is nonzero.

Our assumptions were that the steady state e is locally stable for $\mu < 0$ and unstable when $\mu > 0$. This steady state corresponds to $u = 0$. The local stability analysis shows that the nontrivial steady states are locally stable when $\mu > 0$ and unstable when $\mu < 0$. We shall see in the following section that we can choose the eigenvectors v and w so that all their components are nonnegative. Hence, the steady states of (2.1) that correspond to nontrivial equilibria of (2.10) can be biologically meaningful only when either $M < 0$ and $\mu > 0$ or $M > 0$ and $\mu < 0$.

Of course, when M is zero, higher order terms of the Taylor expansion need to be taken into account in order to obtain some information about the nontrivial equilibria of (2.10). □

The determination of the direction of bifurcation simplifies in a number of cases. For example, as mentioned before we can choose the eigenvectors v and w so that all their components are nonnegative. The sign of M can hence sometimes be determined without explicitly calculating the eigenvectors.

In the remarks that follow we describe a couple of situations in which further simplifications can be made.

Remark 3. One situation in which the expression for the direction of bifurcation can be further simplified is when (2.1) describes the spread of an infectious

disease. Introduction of an infectious agent to the community of hosts results in a redistribution of hosts to new compartments, such as, for example, latent or infectious individuals. A quite common assumption is that the population of hosts has reached an invariant attracting affine set (the reader can find two such examples in section 6), which means that we can eliminate one of the variables. In the case when the population of susceptible hosts is homogeneous (i.e., $n = 1$) we can, by choosing to eliminate the variable corresponding to the susceptible subpopulation (z), redefine G (which is now a function of y only and will be denoted by $\hat{G}$) and arrive at

$$M = \sum_{i,j,k=1,\dots,m} w_i \left(\frac{\partial \hat{G}_{ij}(e,0)}{\partial y_k} + \frac{\partial \hat{G}_{ik}(e,0)}{\partial y_j} \right) v_j v_k.$$

Remark 4. Another circumstance that allows for simplification of (2.8) is when the newly introduced population is homogeneous, i.e., $m = 1$. We can then choose $v = w = 1$, and the expression for the direction of bifurcation becomes

$$\tfrac{1}{2} M = \frac{\partial G(e,0)}{\partial y} - \sum_{k=1,\dots,n} \frac{\partial G(e,0)}{\partial z_k} (H_z^{-1} H_y)_k.$$

The reader can find two examples in this spirit in section 6.

3. On the characteristic form of population invasion models. The derivation of G. The purpose of this section in twofold. We first fulfill the promise made in section 6 and show that assuming that population invasion models in continuous time have the form (2.1) did not confine our study to a certain subclass of population invasion models. We will see that population invasion models, regardless of the biology that underlies them, indeed have a distinctive form of which the continuous time version is given in (2.1).

Once this part is established we shall provide the reader with a way of obtaining G by only considering the basic modeling ingredients, such as birth, survival, and reproduction rates.

So let us suppose that the process of invasion is described by the more general system (1.1) with $g \in C^2(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}^m)$ and $h \in C^1(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}^n)$.

Now, in ecology and adaptive dynamics we consider invasions of either one new species or a reproductively isolated subpopulation of one of the already present species, and we have by the very definition of reproductive isolation (see Appendix B for this definition) that $g(0, z, \mu) = 0$ for every $z \in \mathcal{Z}, \mu \in \mathbb{R}$ and also $h(y, 0, \mu) = 0$ for every $y \in \mathcal{Y}, \mu \in \mathbb{R}$.

On the other hand, when (1.1a) (or (1.1b)) describes the spread of an infectious disease into a population of susceptible hosts, a slight modification of terminology is needed. Namely, when an infectious agent is introduced into a population of susceptible hosts we indeed introduce another species, the pathogen. However, from that point on we are, on a population level, interested in how this agent spreads among the population of hosts. In this case, therefore, $\mathcal{Y}$ captures the subpopulations of hosts (i.e., members of the resident community) that carry the agent (i.e., the invading species). Since susceptible individuals don't have infected offspring we have that $g(0, z, \mu) = 0$ for every $z \in \mathcal{Z}, \mu \in \mathbb{R}$. But since infected individuals (that belong to $\mathcal{Y}$) may become susceptible again (i.e., enter $\mathcal{Z}$) once they get rid of the infection or they might have susceptible offspring, the subspace of the invading community, $\mathcal{Y} \times \{0\}^n$, may not be invariant under (1.1).

In any case we can say the following: since individuals in $\mathcal{Z}$ don't have offspring in $\mathcal{Y}$ the subspace of the resident community, $\{0\}^m \times \mathcal{Z}$, remains invariant under (1.1). In other words,

$$g(0, z, \mu) = 0 \quad \text{for every } z \in \mathcal{Z}, \mu \in \mathbb{R}. \tag{3.1}$$

Hence the following known result, due to Hadamard, can be used.

LEMMA 3.1. *Let $f = (f_1, \dots, f_k)^T \in C^r(\mathbb{R}^m \times \mathbb{R}^n, \mathbb{R}^k)$ for some $r \in \mathbb{N}$ be such that $f(0, y) = 0$ for every $y \in \mathbb{R}^n$. There exists $F \in C^{r-1}(\mathbb{R}^m \times \mathbb{R}^n, \mathbb{R}^{k \times m})$ such that*

$$f(x, y) = F(x, y)x, \qquad x = (x_1, \dots, x_m)^T.$$

The proof of this result can be found in [17].

The property (3.1) therefore yields a matrix $G \in M_{m \times m}(C^1(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}))$ such that g in (1.1) can be written as

$$g(y, z, \mu) = G(y, z, \mu)y, \qquad y = (y_1, \dots, y_m)^T. \tag{3.2}$$

Note that this decomposition is in general not unique, as the following simple example shows.

Example 1. Take $y = (y_1, y_2)$ and $g = y_1 y_2$. Then $G = [y_2, 0]$ and $G = [0, y_1]$ are two possible decompositions.

This nonuniqueness will, however, not affect our results—for our purposes, any correct decomposition will do. We shall nevertheless now point out one way, more interpretation motivated (and hence perhaps mainly of use to more biologically inclined readers), of obtaining G in (3.2).

The key to this decomposition is the so-called *environmental condition* [15], [16]. The defining property of an environmental condition is that individuals are independent of one another (and hence the equations are linear) when this condition is prescribed as a function of time. We then view (1.1) as a linear system together with feedback equations that tell us how, in turn, the environmental condition is influenced by the population size and composition. In general, the environment is set by all subpopulations involved. The environmental condition will hence be a function of $x = (y, z)$. Readers that are not familiar with the notion of an environmental condition and find this general definition a bit unclear are encouraged to take a look at Appendix A, where we explain the notion of an environmental condition by way of a simple example.

In order to arrive directly at the desired decomposition of g in (1.1) we first separate the reproduction in $\mathcal{Y}$ from all other processes.

Since individuals in $\mathcal{Z}$ don't have offspring in $\mathcal{Y}$ the invading population completely determines the reproduction in $\mathcal{Y}$. To describe it we define the following matrix:

$$P_{ij}(x) := \textit{the rate with which individuals with birth state } i \textit{ are born to an individual with state } j\textit{, given a constant environmental condition } x \in \mathcal{X}.$$

What remains is to describe other processes, namely maturation and survival.

We consider the dynamics of an individual's state after birth as a Markov process on the set of i-states, where the probabilities of changing a state are again determined by the environmental condition $x \in \mathcal{Y} \times \mathcal{Z}$. We define the matrix Q by

$$Q_{ij}(x) = \begin{cases} \textit{the rate of leaving state } j \textit{ to go to state } i, & i \neq j, \\ -(\textit{the rate of leaving state } j), & i = j, \end{cases}$$

given an environmental condition x.

Hence, the off-diagonal elements of Q describe the changes of states as long as the individual remains alive and does not move to $\mathcal{Z}$, and the diagonal elements denote the rate of leaving the state, either by leaving to another state in $\mathcal{Y}$, to $\mathcal{Z}$, or by death.

By taking into account all the processes, we can now write the matrix G as

$$G = P + Q. \tag{3.3}$$

This decomposition has, apart from offering biological interpretation, another advantage. Since the off-diagonal elements of G in (3.3) are nonnegative we can apply the theory of nonnegative matrices [1] to see that we can indeed choose the (left and right) eigenvector of G_0 in (2.4) corresponding to eigenvalue zero to be nonnegative.

If, for example, the off-diagonal elements of G_0 are strictly positive, the eigenvectors can be chosen to be strictly positive. In many cases this observation makes it a lot easier to determine the sign of M in (2.8).

Note that one could make a similar "per capita" description for the resident populations. However, for our purposes, this description is irrelevant since we are interested in only the c-states of the resident community that are not close to zero. It may help, though, when one wants to find $z_0(\mu)$ (see [14]).

4. Population invasion models in discrete time. Sometimes the nature of the problem, the available data, or some other reason makes it more convenient to formulate a discrete time population model. Since the linearization theorem of Hartman and Grobman (see [24], [36]) and the center manifold theory apply for discrete time dynamical systems generated by maps as well as for flows generated by vector fields we can reformulate the problem and the results so that they hold for population invasion models in discrete time.

In the same way as before we decompose the population state space

$$\mathcal{Y} \times \mathcal{Z} = \mathbb{R}^m_+ \times \mathbb{R}^n_+$$

so that $\mathcal{Y}$ denotes the population state space of the newly introduced population and $\mathcal{Z}$ the community state space of the resident community.

We shall now study processes described by a parametrized map

$$\begin{aligned} &y \mapsto G(y,z,\mu)y, \\ &z \mapsto h(y,z,\mu), \qquad\qquad y \in \mathcal{Y}, z \in \mathcal{Z}, \mu \in \mathbb{R}, \end{aligned} \tag{4.1}$$

where we shall furthermore assume that $G \in M_{m\times m}(C^1(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}))$ and $h \in C^1(\mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}, \mathbb{R}^n)$.

We shall use the notation in (1.1b) or in (2.2) to write the map (4.1) as $x \mapsto f(x)$ whenever this notation will be more convenient.

Suppose that we have a steady state, that is, a fixed point of (4.1) of the form $e(\mu) = (0, z_0(\mu))$ for some $z_0(\mu) \in \mathcal{Z}$. The associated linear map is then given by

$$Df\big(e(\mu)\big) = \begin{bmatrix} G(e(\mu),\mu) & 0 \\ h_y(e(\mu),\mu) & h_z(e(\mu),\mu) \end{bmatrix}.$$

Hence

$$\sigma\big(Df(e(\mu),\mu)\big) = \sigma\big(G(e(\mu),\mu)\big) \cup \sigma\big(h_z(e(\mu),\mu)\big).$$

We shall again assume that the steady state $e(\mu)$ is internally asymptotically stable, i.e., that it is asymptotically stable under perturbations within the invariant subspace $\{0\}^m \times \mathcal{Z}$ and that this can be inferred from the linearization. In the discrete time setting this means that we assume

B_1. If $\lambda \in \sigma\big(h_z(e(\mu),\mu)\big)$, then $|\lambda| < 1$.

The spectrum of $G(e(\mu),\mu)$ hence determines the linearized stability of $e(\mu)$. Again, the theory of nonnegative matrices tells us that the spectral radius of G is an eigenvalue. The interesting case to consider is therefore when the parameter μ is such that $G(e(\mu),\mu)$ has an eigenvalue one, a situation where the linearization alone does not tell us whether the newly introduced population is able to settle in the community.

We now again take for a bifurcation parameter some μ such that the fixed points of (4.1) of the form $e(\mu) = (0, z_0(\mu))$ are linearly stable for $\mu < 0$ and unstable when $\mu > 0$. Thus,

$$B_2. \quad \begin{cases} \mu < 0 \iff r(G(e(\mu),\mu)) \iff \mathcal{R}_0 < 1, \\ \mu = 0 \iff r(G(e(\mu),\mu)) \iff \mathcal{R}_0 = 1, \\ \mu > 0 \iff r(G(e(\mu),\mu)) \iff \mathcal{R}_0 > 1, \end{cases}$$

where $r(.)$ denotes the spectral radius. Let us note that here $\mathcal{R}_0$ refers to the basic reproduction ratio in the context of the model, and we refer to [7], [29] for the justification of the equivalence between $r(.)$ and $\mathcal{R}_0$.

Since the results that follow rely upon local information only, it suffices that B_2 holds in some neighborhood of $\mu = 0$.

Assumption B_2 tells us that the function $\mu \mapsto r(G(e(\mu),\mu))$ crosses the point $(\mu, r(.)) = (0,1)$. We shall again assume that this crossing occurs at nonzero speed, i.e.,

$$B_3. \quad \frac{d}{d\mu} r(G(e(\mu),\mu))\Big|_{\mu=0} > 0.$$

Let e denote the equilibrium that corresponds to $\mathcal{R}_0 = 1$, i.e., $e = e(\mu = 0)$, and let $e' = e(0)$. We shall also use the notation introduced in (2.4). Denoting by E^c the center subspace of G_0, we shall furthermore assume that

$$B_4. \quad \dim E^c = 1$$

and refer the reader to the next section for the biological interpretation of this assumption.

We can now prove the discrete time analogue of Theorem 2.2.

THEOREM 4.1. *Consider a population model described by* (4.1)*, and let* $e(\mu) = (0, z_0(\mu))$ *be a steady state of* (4.1)*. Assume that* B_1*,* B_2*,* B_3*, and* B_4 *hold. Furthermore assume that* $\mu \mapsto e(\mu) \in C^1(\mathbb{R}, \mathbb{R}^{n+m})$*, and denote by* e *the steady state that corresponds to* $\mathcal{R}_0 = 1$*, i.e.,* $e = e(0)$ *and by* $e' = e'(0)$*. Let* G_0, H_y*, and* H_z *be as in* (2.4)*, and let* w *and* v *denote, respectively, the left and the right eigenvectors of* G_0 *corresponding to eigenvalue one, normalized so that* $v \cdot w = 1$*. Denote*

$$\begin{aligned} M = &\sum_{i,j,k=1,\dots,m} w_i \left(\frac{\partial G_{ij}(e,0)}{\partial y_k} + \frac{\partial G_{ik}(e,0)}{\partial y_j} \right) v_j v_k \\ &- 2 \sum_{\substack{i,j=1,\dots,m \\ k=1,\dots,n}} w_i \frac{\partial G_{ij}(e,0)}{\partial z_k} v_j ((I - H_z)^{-1} H_y v)_k. \end{aligned} \tag{4.2}$$

There exists a $\delta > 0$ *such that*

(i) *if $M < 0$, there is a branch $\mu \mapsto (y(\mu), z(\mu))$, defined for $\mu \in (0, \delta)$, of positive, locally asymptotically stable steady states of* (4.1). *In other words, the bifurcation is supercritical.*

(ii) *if $M > 0$, there is a branch $\mu \mapsto (y(\mu), z(\mu))$, defined for $\mu \in (-\delta, 0)$, of positive, unstable steady states of* (4.1). *That is, the bifurcation is subcritical.*

Remark 5. We again see that only the first order derivatives of G and h are needed to determine the direction of bifurcation from e. Moreover, the expression for the direction of bifurcation is independent of the bifurcation parameter except for the restrictions B_2 and B_3. In other words, provided that all the assumptions of Theorem 4.1 are satisfied, we obtain the same direction of bifurcation for any bifurcation parameter.

Remark 6. For some further remarks on the terminology and on the interpretation of the results of Theorem 4.1 in biological terms we refer the reader to the remarks made after Theorem 2.2.

Proof. We have $G_0 v = v, w^T G_0 = w^T$, and $w \cdot v = 1$. By B_1 the matrix $I - H_z$ is invertible. We can then calculate the left and the right eigenvectors of $Df(e)$ corresponding to eigenvalue one, denote them by W and V, and find that

$$W = \begin{bmatrix} w \\ 0 \end{bmatrix}, \qquad V = \begin{bmatrix} v \\ (I - H_z)^{-1} H_y v \end{bmatrix}. \tag{4.3}$$

Moreover, $W \cdot V = 1$.

By B_1 and B_4, the dimension of the center linear subspace equals 1, and the subspace is spanned by V. We take for the basis of $\mathbb{R}^{m+n}$ (generalized) eigenvectors of $Df(e)$. The eigenvectors of $Df(e)$ that correspond to eigenvalues different from 1 are orthogonal to W.

The center manifold theory states that there exists a center manifold of the equilibrium e, denoted by $\mathcal{M}^c(e)$, that can be locally parametrized by μ and a real variable u as

$$\mathcal{M}^c(e) = \{(x, \mu);\ x = e(\mu) + uV + \Phi(u, \mu)\},$$

where Φ is defined on some neighborhood of the origin.

Moreover, $\Phi(0,0) = D\Phi(0,0) = 0$ and $W \cdot \Phi(u, \mu) = 0$ for every u and μ. Since the center manifold is also invariant under (4.1) we have

$$\begin{aligned} x(k+1) &= e(\mu) + u(k+1)V + \Phi(u(k+1), \mu) \\ &= f(x(k), \mu) \\ &= f(e(\mu) + u(k)V + \Phi(u(k), \mu), \mu). \end{aligned}$$

We calculate the inner product with W, take into account that $W \cdot e(.) = 0$, $W \cdot V = 1$, and $W \cdot \Phi(.) = 0$, and obtain

$$u(k+1) = w \cdot g(e(\mu) + u(k)V + \Phi(u(k), \mu), \mu).$$

Written differently, the restriction of (4.1) to the center manifold is given by a map

$$u \mapsto w \cdot g(e(\mu) + uV + \Phi(u, \mu), \mu).$$

Using the Taylor series, we can now write

$$\begin{aligned} u \mapsto\ & w \cdot g(e,0) + w \cdot D_x g(e,0)(e(\mu) - e + uV + \Phi(u,\mu)) + w \cdot D_\mu g(e,0)\mu \\ &+ \tfrac{1}{2} w \cdot D_{\mu\mu} g(e,0)\mu^2 + \tfrac{1}{2} w \cdot D_{xx} g(e,0)(e(\mu) - e + uV + \Phi(u,\mu))^2 \\ &+ w \cdot D_{\mu x} g(e,0)(e(\mu) - e + uV + \Phi(u,\mu))\mu + \mathcal{O}(3), \end{aligned}$$

where $\mathcal{O}(3)$ denotes third and higher order terms in u and μ.

Now, the first term equals zero since e is a fixed point of f, and therefore $g(e,0) = 0$. The second term equals u since $w^T G_0 = w^T$, $W \cdot e(\mu) = W \cdot e = 0$, $W \cdot V = 1$, and $W \cdot \Phi(.) = 0$. Since $g = Gy$, the third and fourth terms are also equal to zero. Furthermore, by writing $e(\mu) = e(0) + e'(0)\mu + \mathcal{O}(2)$, taking into account that Φ has no constant and no linear terms in u and μ, and noting that $W^T = (w, 0)^T$, we are left with

$$\begin{aligned} u \mapsto u &+ w \cdot \Big(\tfrac{1}{2} D_{xx} g(e,0) e'^2 + D_{\mu x} g(e,0) e'\Big)\mu^2 \\ &+ w \cdot \Big(D_{xx} g(e,0) e' V + D_{\mu x} g(e,0) V\Big)\mu u \\ &+ \tfrac{1}{2} w \cdot D_{xx} g(e,0) u^2 V^2 + \mathcal{O}(3), \end{aligned}$$

which, by writing

$$N = w \cdot \Big(D_x G(e,0) e' + D_\mu G(e,0)\Big) v,$$

taking into account that $g = Gy$, (4.2), and the fact that the first m components of e equal zero, becomes

$$u \mapsto u + \tfrac{1}{2} M u^2 + \mu N u + \mathcal{O}(3). \tag{4.4}$$

Similar reasoning as in Lemma 2.1 establishes that assumptions B_2 and B_4 lead to

$$\frac{d}{d\mu} r(G(e(\mu), \mu))\big|_{\mu=0} = w \cdot \Big(D_x G(e,0) e' + D_\mu G(e,0)\Big) v, \tag{4.5}$$

and so by (4.5) and assumption B_4, $N \neq 0$.

Now, for u and μ close to zero we can neglect the higher order terms that are collected in $\mathcal{O}(3)$ and look for fixed points of $u \mapsto u + \frac{1}{2} M u^2 + \mu N u$. Nonzero fixed points are then near the line given by $u = -2\mu N M^{-1}$.

Our assumptions were that the steady state e is locally stable for $\mu < 0$ and unstable when $\mu > 0$. This steady state corresponds to $u = 0$. The local stability analysis yields that the nontrivial steady states are locally stable when $\mu > 0$ and unstable when $\mu < 0$. As we have seen in section 3, we can choose the eigenvectors v and w so that all their components are nonnegative. Hence, the steady states of (4.1) that correspond to nontrivial equilibria of (4.4) can be biologically meaningful only when either $M < 0$ and $\mu > 0$ or $M > 0$ and $\mu < 0$. If M is zero, then higher order terms of the Taylor expansion need to be taken into account in order to obtain some information about the nontrivial equilibria of (4.4). □

All the situations mentioned at the end of section 3 that lead to a simplified formula for the direction of bifurcation occur, of course, also in the discrete time setting. Modifying the obtained formulas for M to apply for discrete time models is a rather straightforward matter, and we therefore leave it to the reader.

5. On the basic reproduction ratio in the context of a model. The case $\mathcal{R}_0 = 1$. The aim of this section is to offer some interpretation of the assumptions made in previous sections. In order to do this we shall state some known results and refer the interested reader to the literature for their proofs. Two basic notions, one of the next generation matrix and the other of $\mathcal{R}_0$, are also defined in Appendix A.

The basic reproduction ratio $\mathcal{R}_0$ is defined as the expected number of offspring an "average" individual has in all of its life and is mathematically expressed as the spectral radius of the next generation operator (see [13], [15], [35]).

The key to the calculation of $\mathcal{R}_0$ of the newly introduced population in the context of the model is to decompose g in a way that separates reproduction in $\mathcal{Y}$ from other transitions (such as, for example, new infections from progressions of the disease to another stage), as was already done in section 3.

We then write

$$g(y,z) = \big(P(y,z) + Q(y,z)\big)y,$$

where P and Q are as in section 3.

Now, if we denote by $e = (0, z_0)$ a steady state of the system and define $\mathcal{P} = P(e)$ and $\mathcal{Q} = Q(e)$, then $\mathcal{P}$ is a nonnegative matrix and $\mathcal{Q}$ is a nonsingular M-matrix [1], [35]. Hence, $\mathcal{Q}$ is invertible and $-\mathcal{Q}^{-1}$ is nonnegative. Moreover, the elements of $\mathcal{Q}^{-1}$ have the following interpretation: the element $-\mathcal{Q}^{-1}_{jk}$ equals the time that an individual that was born with i-state k is expected to spend in state j [1], [13], [35]. In other words, the matrix $-\mathcal{Q}^{-1}$ describes an individual's i-state dynamics. The matrix $\mathcal{P}$ describes the reproduction, and so the matrix $-\mathcal{P}\mathcal{Q}^{-1}$ is the next generation matrix. By definition, $\mathcal{R}_0$ equals its spectral radius.

One can also prove [1], [13], [35] that the following holds:

$$\begin{aligned} \mathcal{R}_0 = r(-\mathcal{P}\mathcal{Q}^{-1}) < 1 &\iff s(\mathcal{P}+\mathcal{Q}) = s(G_0) < 0, \\ \mathcal{R}_0 = r(-\mathcal{P}\mathcal{Q}^{-1}) = 1 &\iff s(\mathcal{P}+\mathcal{Q}) = s(G_0) = 0, \end{aligned} \tag{5.1}$$

where r denotes the spectral radius and s the spectral bound.

It is reasonable to assume irreducibility of the next generation matrix. This guarantees that the spectral radius is an algebraically simple eigenvalue and that we can choose a strictly positive corresponding eigenvector [1]. In biological terms the assumption of irreducibility of the next generation matrix means that the populations are well mixed; that is, for every pair of i-states j and k, the individuals of the jth subpopulation will eventually have offspring in the kth subpopulation.

Under a more strict condition, namely the primitivity [1] of the next generation matrix, the modulus of the spectral radius is strictly greater than the modulus of all other eigenvalues of $-\mathcal{P}\mathcal{Q}^{-1}$. In biological terms the assumption of primitivity means that we require that, from some generation on, individuals with birth state j can have offspring with birth state k for any two conceivable i-states at birth, j and k.

We have assumed in sections 2 and 4 that the dimension of the center subspace of G_0 equals 1. Now, in the discrete time setting the matrix G_0 is a nonnegative matrix. Its primitivity therefore guarantees that the assumption B_4 is satisfied.

In contrast with the discrete time setting we know that G_0 in the continuous time case is a nonnegative off-diagonal matrix. The Perron–Frobenius theory then tells us that already the assumption of an irreducible G_0 guarantees that A_4 holds; i.e., a zero eigenvalue is an algebraically simple eigenvalue, and all other eigenvalues have strictly negative real parts. In biological terms an irreducible G_0 means that for every pair of i-states j and k ($j \neq k$) we will eventually observe an inflow of individuals of the jth subpopulation to the kth subpopulation.

The linearization theorem of Hartman and Grobman and the center manifold theory run for discrete time dynamical systems generated by maps parallel to the one for flows generated by vector fields, which allows us to formulate the results for both

settings. The basic reproduction ratio, $\mathcal{R}_0$, provides, due to relation (5.1), a further connection and links the continuous time results directly to corresponding discrete time results.

6. Examples. In this section we present four examples to illustrate the theory presented in previous sections.

In the first example we study a continuous time model describing the dynamics in a community in which the predator selectively forages on a stage structured prey. This example is motivated by the work of de Roos, Persson, and Thieme [11] and hopefully demonstrates how little effort is needed to study the occurrence of subcritical equilibria for a class of models, in this particular case models obtained by varying the preference of the predators.

The second example is a discrete time model describing the life cycle of biennials. This example is inspired by the work of Davydova and coworkers [9], [10] and demonstrates how the theory can also be applied to studying reproductively isolated subpopulations of the same species to see whether one missing year class is, after being introduced, able to settle among the existing year classes.

The last two examples are simple continuous time epidemic models related to the author's other work, namely, modeling the spread of infectious agents that can reside in several different parts of the host's body. Though very simple in the first place, they illustrate how the determination of the direction of bifurcation can be further simplified by assuming that the total population size has reached an equilibrium and the fact that the eigenvectors in question can be chosen to be nonnegative (see Remark 3).

After determining the direction of bifurcation from a "residents only" steady state, we shall in all of these examples write some interpretation of the results for the problem at hand. We have, however, already in the remarks after Theorem 2.2 described in biological terms what can in general be said about an invasion, given that we know the direction of bifurcation. We shall therefore not repeat these general facts in the examples and rather refer the reader to section 2.

Example 2. In this first example we study a continuous time model describing interactions in a community that consists of a stage structured prey population and a population of predators that preys exclusively on one of the prey stages.

Suppose that the prey is divided into three stages, juveniles, subadults, and adults, and let their densities be denoted, respectively, by J, S, and A. The density of the predators will be denoted by P. We describe the dynamics of the predator population that forages exclusively on the adult stages of prey by the following differential equation:

$$\frac{dP}{dt} = \big(\phi f(A) - \nu\big)P. \tag{6.1}$$

Here, ϕ indicates the conversion efficiency of prey biomass into newborn predators, ν denotes the per capita death rate of the predators, and $f(.)$ stands for the predator functional response (for example, Holling type 2 or Holling type 3 response). In what follows, the function f will not be specified; we shall assume only that it is an increasing function of the adult prey density.

We shall take a closer look at a situation in which the regulation of the prey population takes place within the subadult stage. We describe the dynamics of the

prey population by the following system of differential equations:

$$\begin{aligned} \frac{dJ}{dt} &= \beta A - \rho J - \mu_J J, \\ \frac{dS}{dt} &= \rho J - \pi(S)S - \mu_S(S)S, \\ \frac{dA}{dt} &= \pi(S)S - \mu_A A - f(A)P. \end{aligned} \tag{6.2}$$

Here, the parameters have the following meaning: β denotes the adult fecundity, ρ the maturation rate from the juvenile to the subadult stage, and μ_J the per capita death rate of the juveniles. Functions $\pi(S)$ and $\mu_S(S)$ denote, respectively, the (possibly density dependent) maturation rate of subadults into adults and the per capita death rate of the subadults. The per capita death rate of the adult prey in the absence of predators is denoted by μ_A.

Regulation of the subadult prey population through maturation and/or mortality can occur if the maturation rate $\pi(.)$ decreases and/or the mortality rate $\mu_S(.)$ increases with an increase in the density of subadults. We shall therefore assume that $\pi(.)$ is a nonincreasing and $\mu_S(.)$ a nondecreasing function of S, and we exclude the situation in which the derivatives of both vanish in some point, since the population is not regulated at all in that case.

We now first calculate the steady states of (6.2) in the absence of the predators. We obtain (the steady state values are denoted by *)

$$\begin{aligned} J^* &= \frac{\beta A^*}{\mu_J + \rho} = \frac{\beta \pi(S^*)S^*}{\mu_A(\mu_J + \rho)}, \\ A^* &= \frac{\pi(S^*)S^*}{\mu_A} \end{aligned}$$

as the steady state densities of the juvenile and adult prey, and the following equilibrium equation for the (nontrivial) steady state density of the subadult prey:

$$\frac{\rho\beta\pi(S^*)}{\mu_A(\mu_J + \rho)} = \pi(S^*) + \mu_S(S^*). \tag{6.3}$$

Now, in our previous notation we would have $y = P$ and $(z_1, z_2, z_3) = (J, S, A)$ and so $G = \phi f(A) - \nu$. Since the predator population is homogeneous, we can take $w = v = 1$. Furthermore, we consider the case when the basic reproduction ratio of the predators equals one, i.e.,

$$\mathcal{R}_0 = \frac{\phi f(A^*)}{\nu} = 1,$$

and so $f(A^*) = \frac{\nu}{\phi}$.

Now, since G is a function of A only we have

$$M = -2G'(A^*)(H_z^{-1}H_y)_3, \tag{6.4}$$

where

$$H_y = \begin{bmatrix} 0 \\ 0 \\ -f(A^*) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ -\frac{\nu}{\phi} \end{bmatrix}$$

and

$$H_z = \begin{bmatrix} -(\rho+\mu_J) & 0 & \beta \\ \rho & -\big(\pi(S)S+\mu_S(S)S\big)'\big|_{S=S^*} & 0 \\ 0 & \big(\pi(S)S\big)'\big|_{S=S^*} & -\mu_A \end{bmatrix}.$$

Now, since only the last component of H_y is nonzero and we need only the third component of $H_z^{-1}H_y$ it suffices to calculate $(H_z^{-1})_{33}$. We have

$$\big(H_z^{-1}\big)_{33} = \frac{1}{\det H_z}\,(\rho+\mu_J)\big(\pi(S)S+\mu_S(S)S\big)'\big|_{S=S^*},$$

and we can now rewrite (6.4) as

$$M = 2\nu(\rho+\mu_J)f'(A^*)\big(\det H_z\big)^{-1}\big(\pi(S)S+\mu_S(S)S\big)'\big|_{S=S^*}. \tag{6.5}$$

Now, ν and $(\rho+\mu_J)$ are positive. According to our assumptions, so is $f'(A^*)$. Using (6.3), we can furthermore see that

$$\det H_z = \frac{\beta\rho S^*\big(\pi'(S^*)\mu_S(S^*)-\pi(S^*)\mu_S'(S^*)\big)}{\pi(S^*)+\mu_S(S^*)},$$

which is, by our assumptions on $\pi(.)$ and $\mu_S(.)$, strictly negative. We have therefore arrived at the fact that

$$\text{sign } M = -\text{sign }\big(\pi(S)S+\mu_S(S)S\big)'\big|_{S=S^*},$$

as was also found in [11].

We have assumed that μ_S is a nondecreasing function of the subadult density. The function $\mu_S S$ is therefore an increasing function. In more biological terms we could therefore interpret the condition required for the subcritical bifurcation to occur (i.e., $M > 0$) in the following way: an emergent Allee effect (i.e., $M > 0$) is to occur in the predator population if and only if an overcompensation in the total maturation rate $\pi(S)S$ takes place, i.e., for certain values of S, an increase in the subadult density actually decreases the total maturation rate, and that this overcompensation is sufficiently strong.

In [11] the authors also studied the cases when the predator forages exclusively on either the juvenile or the subadult prey and found that the emergent Allee effect can occur (with a suitable overcompensation in the regulation) when the predators forage on one of the nonregulating stages of the prey population and can never occur when they forage on the regulating stage.

Hopefully, this example shows how little effort it would take, with the tools that we have developed in the previous sections, to consider these and also many other situations of interest.

Example 3. In this example we consider a community of strict biennials, that is, a community that consists of two age classes, with only the oldest class reproducing. Time will in this case be measured in years. We shall label the two classes by indices 0 and 1, the 0 denoting the subpopulation of individuals that have not reached age one and 1 the subpopulation of one-year-old individuals. If individuals survive till the end of their second year, they reproduce and die.

Survival and reproduction rates are described in terms of an environmental condition I, which will be taken to be the weighed sum of the two populations. More precisely, if $x_j(t)$ denotes the number (or the density) of j-year-old individuals ($j = 0, 1$) at time t, we take

$$I(t) = c_0 x_0(t) + c_1 x_1(t).$$

The weights c_0 and c_1 are also called the *impacts* of the corresponding age classes. Now let us denote by $F_0(I(t))$ the probability of surviving the first year and by $F_1(I(t))$ the reproduction rate of individuals that survive till the end of their second year. Since increasing the I means worsening the conditions for both classes, the functions F_0 and F_1 are decreasing functions. We shall also assume that they are differentiable at least once.

We can now formulate the following discrete time model:

$$\begin{aligned} x_0(t+1) &= F_1(I(t))x_1(t), \\ x_1(t+1) &= F_0(I(t))x_0(t). \end{aligned}$$

The functions F_i are also called *sensitivities to the environment*, and the index specifies how this sensitivity depends on age. Typical examples of sensitivity functions are the so-called

(i) *Ricker family*, where $F_i(I) = a_i e^{-b_i I}$;

(ii) *Beverton–Holt family*, where $F_i(I) = a_i\big(1 + b_i I\big)^{-1}$.

In order to illustrate the theory on this example we first compute the full life cycle map; that is, we apply the map

$$\begin{bmatrix} x_0(t) \\ x_1(t) \end{bmatrix} \mapsto \begin{bmatrix} 0 & F_1(I(t)) \\ F_0(I(t)) & 0 \end{bmatrix} \begin{bmatrix} x_0(t) \\ x_1(t) \end{bmatrix}$$

twice to obtain the community state after a two year time interval. We have

$$\begin{aligned} x_0(t+2) &= F_1(I(t+1))x_1(t+1) \\ &= F_1\Big(c_0 F_1(I(t))x_1(t) + c_1 F_0(I(t))x_0(t)\Big)F_0(I(t))x_0(t) \\ &= F_1(I_1(t))F_0(I(t))x_0(t), \end{aligned}$$

where

$$I_1(t) := c_0 F_1(I(t))x_1(t) + c_1 F_0(I(t))x_0(t)$$

denotes the environmental condition in the second year.

The full life cycle map is then given by

$$\begin{aligned} x_0(t+2) &= F_1(I_1(t))F_0(I(t))x_0(t), \\ x_1(t+2) &= F_0(I_1(t))F_1(I(t))x_1(t). \end{aligned}$$

Now let us assume that only the individuals with label zero are present in every second year and that the population is in a steady state, say x_0^*. This means that

$$F_1(c_1 F_0(c_0 x_0^*)x_0^*)F_0(c_0 x_0^*) = 1. \tag{6.6}$$

Furthermore, the assumption that the basic reproduction ratio of individuals with label 1 equals 1 translates into

$$F_0(c_1F_0(c_0x_0^*)x_0^*)F_1(c_0x_0^*) = 1. \tag{6.7}$$

Now, in our previous notation we have

$$\begin{aligned} G &= F_0(I_1(t))F_1(I(t)),\\ h &= F_1(I_1(t))F_0(I(t))x_0(t). \end{aligned}$$

Let us now compute the required derivatives for the case where both sensitivity functions belong to the Ricker family. We obtain

$$\begin{aligned} \frac{\partial G}{\partial x_1} &= F_0(I_1)F_1(I)\Big(b_0b_1c_0c_1F_1(I)x_1 + b_0^2c_1^2F_0(I)x_0 - b_0c_0F_1(I) - b_1c_1\Big),\\ \frac{\partial G}{\partial x_0} &= F_0(I_1)F_1(I)\Big(b_0b_1c_0^2F_1(I)x_1 + b_0^2c_0c_1F_0(I)x_0 - b_0c_1F_0(I) - b_1c_0\Big),\\ \frac{\partial h}{\partial x_1} &= F_0(I_1)F_1(I)x_0\Big(b_1^2c_0c_1F_1(I)x_1 + b_0b_1c_1^2F_0(I)x_0 - b_1c_0F_1(I) - b_0c_1\Big),\\ \frac{\partial h}{\partial x_0} &= F_0(I_1)F_1(I)\Big(x_0\big(b_1^2c_0^2F_1(I)x_1 + b_0b_1c_0c_1F_0(I)x_0 - b_1c_1F_0(I) - b_0c_0\big) + 1\Big). \end{aligned}$$

We evaluate these derivatives in $x_0 = x_0^*, x_1 = 0$; take (6.6) and (6.7) into account; and denote the results, respectively, by $\mathcal{G}_1, \mathcal{G}_0, \mathcal{H}_1$, and $\mathcal{H}_0$. We arrive at

$$\begin{aligned} \mathcal{G}_1 &= b_0^2c_1^2F_0(c_0x_0^*)x_0^* - b_0c_0F_1(c_0x_0^*) - b_1c_1,\\ \mathcal{G}_0 &= b_0^2c_0c_1F_0(c_0x_0^*)x_0^* - b_0c_1F_0(c_0x_0^*) - b_1c_0,\\ \mathcal{H}_1 &= x_0^*\Big(b_0b_1c_1^2F_0(c_0x_0^*)x_0^* - b_1c_0F_1(c_0x_0^*) - b_0c_1\Big),\\ \mathcal{H}_0 &= x_0^*\Big(b_0b_1c_0c_1F_0(c_0x_0^*)x_0^* - b_1c_1F_0(c_0x_0^*) - b_0c_0\Big) + 1. \end{aligned}$$

Now, equalities (6.6) and (6.7) in the Ricker case imply that

$$b_0 = b_1 \qquad \text{or} \qquad \left(F_0(c_0x_0^*) = \frac{c_0}{c_1} \quad \text{and} \quad F_1(c_0x_0^*) = \frac{c_1}{c_0}\right). \tag{6.8}$$

Moreover, we can take $v = w = 1$ in (4.2). The expression for the direction of bifurcation then translates into

$$M = 2\mathcal{G}_1 - 2\mathcal{G}_0\mathcal{H}_1\big(\mathcal{H}_0 - 1\big)^{-1},$$

and one can quickly see, by taking (6.8) into account, that the bifurcation is vertical (i.e., $M = 0$), as was also found in [9].

In [9], [10] it was actually shown that the bifurcation is vertical in the stronger sense that a family of period two points exists for exactly the critical parameter combination.

Example 4. Consider an infectious disease that spreads in a population of hosts that are susceptible to this infection, and assume that there are two parts of the body (the same two parts for all individuals) that can become infected. We shall assume that one of these two parts, part one, is necessarily the part where an individual's first infection occurs. Once infected at part one, the infection can spread by endogenous transmission to part two. We shall use the following notation and assumptions:

1. β_1 denotes the rate with which one individual that is infected at part one infects a susceptible individual, β_{12} the rate with which one individual that is infected at both parts infects a susceptible individual.

2. α denotes the rate of endogenous transmission of an individual's infection from part one to part two.

3. Infected individuals become infectious at the moment of infection.

4. Infected individuals retain their infection(s) until death.

5. The death rate is the same for all individuals and is denoted by μ.

6. The population birth rate is denoted by λ.

7. All newborns are susceptible.

Now let S denote the number of susceptible individuals, I_1 the number of those infected at part one, and I_{12} the number of individuals infected at both parts. If the sizes of all subpopulations are large, we can write the following system of differential equations to describe the dynamics:

$$\begin{aligned} \frac{dS}{dt} &= \lambda - \beta_1 I_1 S - \beta_{12} I_{12} S - \mu S, \\ \frac{dI_1}{dt} &= \beta_1 I_1 S + \beta_{12} I_{12} S - (\alpha + \mu) I_1, \\ \frac{dI_{12}}{dt} &= \alpha I_1 - \mu I_{12}. \end{aligned} \tag{6.9}$$

Put into our previous notation we have

$$y = (I_1, I_{12}) \in \mathbb{R}^2_+, \quad z = S \in \mathbb{R}_+,$$

and the disease-free steady state is $e = (0, 0, \frac{\lambda}{\mu})$.

Now we have only one i-state at birth in this case—all individuals are born (from an epidemiological point of view) by acquiring the infection at part one. Each individual that is infected at part one is expected to retain (only) this infection for time $1/(\mu + \alpha)$. In this time it is expected to infect $\beta_1 \lambda/\mu$ individuals. With probability $\alpha/(\alpha + \mu)$ an individual also becomes infected at part two. It is then expected to remain as such for time $1/\mu$ and in that time infects on average $\beta_{12}\lambda/\mu$ susceptibles. The basic reproduction ratio (i.e., the expected number of new infections caused by an infected individual that is introduced into a completely susceptible population, in all of its infectious period) hence equals

$$\mathcal{R}_0 = \frac{\lambda \beta_1}{\mu(\mu + \alpha)} + \frac{\lambda \alpha \beta_{12}}{\mu^2(\mu + \alpha)}.$$

The elaboration of the direction of the bifurcation can be further simplified in this case if we assume that the total population size has reached an equilibrium. The size of the whole population is then λ/μ, and we can eliminate one of the equations in (6.9). By choosing to eliminate the first and replacing S by $\lambda/\mu - I_1 - I_{12}$ in the other two equations, we see that we don't need to compute H_y and H_z in (2.8).

To compute the direction of bifurcation we write

$$G = \begin{bmatrix} \beta_1 S - \alpha - \mu & \beta_{12} S \\ \alpha & -\mu \end{bmatrix}$$

with $S = \frac{\lambda}{\mu} - I_1 - I_{12}$. Then

$$\frac{\partial G_{2i}}{\partial y_j} = 0 \quad \text{for } i, j = 1, 2$$

and

$$\frac{\partial G_{11}(e,0)}{\partial y_1} = -\beta_1, \qquad \frac{\partial G_{11}(e,0)}{\partial y_2} = -\beta_1,$$
$$\frac{\partial G_{12}(e,0)}{\partial y_1} = -\beta_{12}, \qquad \frac{\partial G_{12}(e,0)}{\partial y_2} = -\beta_{12}.$$

Hence

$$M = w_1\big(-2\beta_1 v_1^2 - 2(\beta_1+\beta_{12})v_1v_2 - 2\beta_{12}v_2^2\big).$$

Since the off-diagonal elements of G_0 are strictly positive we can choose w to be strictly positive. Since v can always be chosen to be nonnegative we see that M is negative and the bifurcation is supercritical. In other words, control measures with which we will decrease the value of $\mathcal{R}_0$ below 1 will allow us to eradicate the disease, while the infection will spread further as long as $\mathcal{R}_0$ stays above 1.

The attentive reader must have noticed that we have not specified the bifurcation parameter. As explained in section 2, we obtain the same direction of bifurcation for all bifurcation parameters, assuming that the assumptions of Theorem 2.2 are satisfied. That they indeed hold in this case can easily be verified, and we leave the details to the reader.

Example 5. Consider again an infectious agent that spreads in the population of susceptibles, and suppose again that there are two different parts of the body (the same for all individuals) at which a susceptible can become infected. These are the additional assumptions and the notation:

1. Susceptibility and infectivity of an individual have independent influences on the rate of transmission. Susceptibility to infection does not change if one is already infected at the other part of the body. That way we can write the rate with which someone, who is already infected at $\mathcal{J} \subseteq \{1,2\}$, infects someone at part j as $b_j B_{\mathcal{J}}$.
2. Once infected at one of the parts, individuals can obtain another infection only by another cross transmission.
3. Infected individuals become infectious at the moment of infection.
4. Infected individuals retain their infection(s) until death.
5. The death rate is the same for all individuals and is denoted by μ.
6. The population birth rate is denoted by λ.
7. All newborns are susceptible.

Let S denote the number of susceptibles and I_1, I_2, I_{12} the number of infected individuals that carry an infection at, respectively, the first, second, or both parts of the body.

If we assume that the sizes of all subpopulations are large, we can describe the dynamics by the following system of differential equations:

$$\frac{dS}{dt} = \lambda - \Big(\mu + (b_1+b_2)B_1I_1 + (b_1+b_2)B_2I_2 + (b_1+b_2)B_{12}I_{12}\Big)S,$$
$$\frac{dI_1}{dt} = b_1S(B_1I_1 + B_2I_2 + B_{12}I_{12}) - b_2I_1(B_1I_1 + B_2I_2 + B_{12}I_{12}) - \mu I_1,$$
$$\frac{dI_2}{dt} = b_2S(B_1I_1 + B_2I_2 + B_{12}I_{12}) - b_1I_2(B_1I_1 + B_2I_2 + B_{12}I_{12}) - \mu I_2,$$
$$\frac{dI_{12}}{dt} = (b_2I_1 + b_1I_2)(B_1I_1 + B_2I_2 + B_{12}I_{12}) - \mu I_{12}.$$

Put into our previous notation we have

$$y = (I_1, I_2, I_{12}), \qquad z = S,$$

and the disease-free equilibrium is $e = (0, 0, 0, \frac{\lambda}{\mu})$.

There are two i-states at birth in this case, i.e., becoming first infected at part one and becoming first infected at part two. We label these two birth states with 1 and 2, respectively. The next generation matrix is hence a 2×2 matrix, which, written for the case when an infected individual is introduced into a virgin environment, takes the form

$$R = \frac{\lambda}{\mu^2} \begin{bmatrix} b_1 B_1 & b_1 B_2 \\ b_2 B_1 & b_2 B_2 \end{bmatrix}.$$

The basic reproduction ratio $\mathcal{R}_0$ equals its dominant eigenvalue. Since R is a matrix of rank one, $\mathcal{R}_0$ equals its trace,

$$\mathcal{R}_0 = \frac{\lambda}{\mu^2}\Big(b_1 B_1 + b_2 B_2\Big).$$

We shall again assume that the total population has reached an equilibrium and eliminate S by taking $S = \lambda/\mu - I_1 - I_2 - I_{12}$.

To compute the direction of bifurcation we take

$$G = \begin{bmatrix} b_1 B_1 S - b_2 Y - \mu & b_1 B_2 S & b_1 B_{12} S \\ b_2 B_1 S & b_2 B_2 S - b_1 Y - \mu & b_2 B_{12} S \\ b_2 Y & b_1 Y & -\mu \end{bmatrix},$$

with $Y = B_1 I_1 + B_2 I_2 + B_{12} I_{12}$ and $S = \lambda/\mu - I_1 - I_2 - I_{12}$.

As was the case in the previous example, all bifurcation parameters yield the same direction of bifurcation from the disease-free steady state. However, we cannot determine the sign of M right away. We hence compute the left and the right zero eigenvectors of G_0 and obtain

$$w = \begin{bmatrix} B_1, & B_2, & B_{12} \end{bmatrix}^T, \qquad v = \begin{bmatrix} b_1, & b_2, & 0 \end{bmatrix}^T.$$

Then $M = M_1 + M_2 + M_3$, where

$$\begin{aligned} M_1 &= B_1\big(-2(b_2 + b_1)b_1^2 B_1 - 2(b_1 B_2 + b_2 B_2 + b_1 B_1)b_1 b_2 - 2b_1 b_2^2 B_2\big), \\ M_2 &= B_2\big(-2(b_2 + b_1)b_2^2 B_2 - 2(b_2 B_1 + b_2 B_2 + b_1 B_1)b_1 b_2 - 2b_2 b_1^2 B_1\big), \\ M_3 &= B_{12}\big(2b_1^2 b_2 B_1 + 2(b_1 B_1 + b_2 B_2)b_1 b_2 + 2b_1 b_2^2 B_2\big). \end{aligned}$$

In contrast with the previous example, bifurcation from a disease-free steady state may not always be supercritical. However, if we don't expect any "amplification" of individual's infectiousness by multiple infected parts, that is, if we assume that

$$B_{12} \le B_1 + B_2,$$

we expect a supercritical bifurcation, and indeed a simple computation (which we leave to the reader) shows that in such a case $M < 0$ and, as in the previous example, we are able to eradicate the disease by suppressing $\mathcal{R}_0$ below 1.

Appendix A. Some general considerations concerning physiologically structured population models. In this section we review some basic definitions and results that we have used in the main part of the paper.

A.1. Environmental condition. We begin with the notion of *environmental condition* [14], [15], [16]. The defining property of the environmental condition (we shall denote it by I) is that individuals are independent of one another when I is prescribed as a function of time.

The notion of the environmental condition can perhaps most easily be clarified by way of examples. We write the following ratio dependent predator-prey model and refer the reader to section 6 and [14], [15], [16] for more examples.

Example 6. Let us consider the following predator-prey model, the so-called Michaelis–Menten-type model:

$$\begin{aligned}\dot{x} &= rx\left(1-\frac{x}{K}\right)-\frac{cxy}{my+x},\\ \dot{y} &= \quad y\left(\frac{fx}{my+x}-D\right),\end{aligned}$$

where $x(t)$ and $y(t)$ denote, respectively, the prey and predator densities at time t. In the absence of the predators the prey grows with constant intrinsic growth rate r and constant carrying capacity K. The constants D, c, m, and f stand for the predators' per capita death rate, capturing rate, half saturation rate, and conversion rate, respectively.

In this case both the predator and prey densities influence the rates with which these two populations interact. Hence, by setting $I=(I_1,I_2)=(x,y)$, we can rewrite the equations so that all interactions are expressed in terms of the environmental variable I,

$$\begin{aligned}\dot{x} &= \left[r\left(1-\frac{I_1}{K}\right)-\frac{cI_2}{mI_2+I_1}\right]x,\\ \dot{y} &= \quad \left[\left(\frac{fI_1}{mI_2+I_1}-D\right)\right]y.\end{aligned}$$

Indeed, one sees that when I is prescribed as a function of time the individuals act independently of one another; i.e., equations are linear.

A.2. The next generation operator and the basic reproduction ratio $\mathcal{R}_0$. A population model is described by a collection of rules for reproduction, maturation, and survival of individuals in a given community. The traditional way to study a population model is to separate reproduction from all other processes. One of the modeler's first tasks is then to find the set of all conceivable i-states at birth and to construct the next generation operator [13], [15].

When the set of all conceivable i-states at birth is finite, the next generation operator is a matrix which we shall denote by R and which is defined as follows:

$R_{ij}(I) :=$ *the expected number of offspring with birth state i born to one individual that was born with state j, given a constant environmental condition I.*

The basic reproduction ratio, $\mathcal{R}_0(I)$, is by definition [13], [15] the spectral radius of $R(I)$.

Now, by its very definition, $R(I)$ is a nonnegative matrix. When it is irreducible (see [1] and Appendix B for the definition), its spectral radius, i.e., $\mathcal{R}_0(I)$, is a well-defined (dominant) eigenvalue, and the corresponding eigenvector can be chosen to be positive.

The literature where one can find special examples from population biology and where the next generation matrices are constructed in the context of models is vast. We refer the reader to [13], [34] and the references therein and also to section 6 for some concrete examples.

Appendix B. On the notions of species, population, and a reproductively isolated subpopulation. In the main part of the paper we have used terms such as *population* and *reproductively isolated subpopulation* in a vague, intuitive way.

The aim of this section is to describe these notions in mathematical terms (here we are inspired by an unpublished note of Gyllenberg [23]).

First, the following definition.

DEFINITION B.1. *A square matrix A is* reducible *if there exists a permutation matrix P such that*

$$P^{-1}AP = \begin{bmatrix} A_1 & 0 \\ B & A_2 \end{bmatrix}.$$

A matrix that is not reducible is irreducible.

Following [23], *we shall call a matrix A* decomposable *if the permutation matrix P can be chosen so that $B = 0$. A matrix that is not decomposable is* indecomposable.

Now, if an element of the next generation matrix, say $R_{ij}(I)$, is strictly positive for some environmental condition I, then, by definition, individuals with birth state j can have offspring with birth state i in this environment. Or, equivalently, the predecessors of individuals with birth state i may, in the environment I, be individuals with birth state j.

If $R(I)$ is indecomposable for some environmental condition I, then all the i-states at birth are in this environment related by either ancestry or descent and hence belong to one species. On the other hand, if the next generation matrix is decomposable for some environmental condition I, then the set of i-states at birth partitions into (at least) two disjoint sets of birth states that are not reproductively connected in I.

We shall speak of *reproductive isolation* of two sets of i-states at birth (and of reproductive isolation of the corresponding subpopulations) when these two sets are reproductively isolated in any conceivable environment. Two sets of i-states at birth (and the corresponding subpopulations) that are not reproductively isolated are *reproductively connected*.

A *population* is a collection of subpopulations that are reproductively connected and are at the same time the maximal connected collection in the sense that they are reproductively isolated from every subpopulation that is not included in the collection.

We now make these newly introduced terms more precise and make the following, almost mathematical definition (where "almost" refers to the unspecified "conceivable" below).

DEFINITION B.2. *Consider a finite set $\mathcal{J}$ of i-states at birth, and let $R(.)$ denote the corresponding next generation matrix. We say the following:*

1. *The set $\mathcal{J}$ of i-states at birth (and the corresponding community) is* reproductively connected *if there exists a conceivable environmental condition I in which the corresponding next generation matrix $R(I)$ is indecomposable.*

2. *If the set $\mathcal{J}$ of i-states at birth is not reproductively connected, it consists of (at least) two* reproductively isolated *subsets of i-states at birth. In other words, if $\mathcal{J}$ is not reproductively connected, the matrix $R(I)$ is decomposable for every conceivable environmental condition I. (Note, however, that in principle, different environmental conditions may yield a different number of blocks in the next generation matrix.)*

3. *Let $\mathcal{J}_1 \subseteq \mathcal{J}$. We say that individuals with i-states at birth in $\mathcal{J}_1$ form a* population *if*

(i) *$\mathcal{J}_1$ is reproductively connected and*

(ii) *if $\mathcal{J}_1 \subseteq \mathcal{J}_2 \subseteq \mathcal{J}$ and $\mathcal{J}_2$ is reproductively connected, then $\mathcal{J}_1 = \mathcal{J}_2$.*

Reproductive isolation is certainly a property that underlies the concept of species; i.e., two different species are reproductively isolated. Reproductive isolation alone, however, is not sufficient to deduce that we actually observe different species. Think of, for example, two groups of individuals that belong to the same species but live in areas that are not connected, say on two different continents.

Another display of this phenomenon would be the semelparous species, species that reproduce only once in their lives and die afterwards. Suppose that we observe a community whose individuals live for a fixed length of time, say l years. We could characterize individuals by the year of their birth. Instead of doing so, we split the whole community into year classes according to the year of birth (modulo l); for example, if $l = 2$, we divide the community into two year classes, one consisting of individuals that were born in odd numbered years, and the other of individuals born in even numbered years. Different year classes are reproductively isolated subpopulations of the same species that interact (for example, compete for food, etc.), and we can study whether a missing year class is, after being introduced into the community, able to settle among the existing year classes. The reader can find one example in this spirit in section 6.

Consider now a community, consisting of several species perhaps, whose individuals are characterized by finitely many i-states. We introduce one new population and assume that the set of conceivable i-states of this population is also finite. We find the set of all possible i-states at birth and write the next generation matrix of the combined community, which for every conceivable environmental condition I is of the form

$$R(I) = \begin{bmatrix} R(I)_{\text{new}} & 0 \\ 0 & R(I)_{\text{old}} \end{bmatrix}.$$

Since the resident community might consist of several populations, the matrix $R(I)_{\text{old}}$ may be decomposed further into indecomposable blocks. However, finding a way to deduce the number of reproductively isolated subpopulations from the next generation matrix and recognizing the set of i-states that constitute a population is not our aim here. We therefore refrain from these further decompositions.

Acknowledgment. I thank Odo Diekmann for suggesting this problem. I am very much indebted to him as well as to Hans Metz, Mats Gyllenberg, Mark Lewis, and two anonymous referees for various comments that helped to improve this paper in many ways.

AN EPIDEMIC MODEL WITH POPULATION DISPERSAL AND INFECTION PERIOD*

WENDI WANG† AND XIAO-QIANG ZHAO‡

Abstract. An epidemic model is proposed to incorporate population dispersals between patches and to include a constant infection period. A basic reproduction number of the model is established by means of a next generation matrix. It is found that a disease may spread when the population migrates in two patches, even though it dies out in each isolated patch. It is also found that the disease admits multiple exchanges between persistence and extinction for some types of migrations of individuals.

Key words. population dispersal, infection period, reproduction number, persistence, extinction

1. Introduction.

Population movements and the spatial structure of population communities can profoundly affect the dynamic process of an epidemic disease. This has been demonstrated by many communicable diseases. SARS was first reported in Guangdong Province of China in November of 2002. The emerging disease spread very quickly, due to the traveling of infectious persons by airplanes, trains, and buses, to some other regions in the mainland of China, as well as Hong Kong, Singapore, Vietnam, Canada, etc. By late June of 2003, it had spread to 32 countries and regions, causing about 800 deaths and more than 8000 infections (see, e.g., [21, 27]). For measles, Bartlett [5] discovered that population size was a crucial determinant of disease persistence. In large towns, measles was endemic with periodic eruptions. In cities below a population size threshold, measles displayed an epidemic pattern with complete disappearance of the disease between epidemics. These show that spatial structures and population movements, which give rise to spatio-temporal variations of population dynamics, may be of crucial importance for the prevalence of diseases. Thus, it is important to study how population movement, spatial structure, and disease transmission interact to determine the evolution of diseases. Of particular interest is the basic reproduction number of the disease under the influence of these components. The basic reproduction number is defined as the number of infections generated in a completely susceptible population by a single infected individual. In many cases, it serves as the threshold of disease transmissions, having profound implications for the control of diseases.

We choose our spatial scale so that we can represent space in a discretized way; i.e., the space is split into discrete patches. Here, one patch may represent one city or one village, and population movements in space are simulated by population dispersals among patches. The study of the effects of population dispersal on disease dynamics

in the setting of patchy space has been carried out in the context of SARS [21], influenza [22], measles [6], tuberculosis [13], and malaria [20]. These papers explore the influences of population dispersal by means of computer simulations or by analytic methods. In order to simulate the evolution of spatial epidemics and calculate their basic reproduction numbers, Arino and van den Driessche [2, 3] formulated epidemic models with population traveling among cities in which the residences of individuals are maintained. Wang and Zhao [29, 30] considered epidemic models of multipatches without any record of the residence of individuals. Brauer and van den Driessche [4], Castillo-Chavez and Yakubu [7], and Wang and Mulone [28] are among other studies of epidemic models of metapopulations. Based upon their calculations of basic reproduction numbers, these papers established the thresholds of spatial disease transmissions. The models capture the essence of SIR (susceptible→infected→recovered) epidemics or SIS (susceptible→infected→susceptible) epidemics. However, one common feature of the above works is that the duration of an infectious period is described by an exponential distribution. This mathematically convenient assumption is equivalent to assuming that the chance of recovery within a given time interval is constant, regardless of the time since infection. Epidemiologically, this is quite unrealistic, as is demonstrated by statistical studies of the transmission dynamics of many diseases [19]. In practice, the infectious periods for many diseases including myxomatosis appear to be distributed fairly closely around mean survival times [1]. As a first approximation, we can assume that infectious individuals remain infectious for the same amount of time. The purpose of the present paper is to incorporate a constant infectious period into an SIR epidemic model with the spatial structure of patches and study its evolutionary behavior in terms of the basic reproduction number.

The remaining parts of this paper are organized as follows. In the next section, we present the formulation of the model. Section 3 is devoted to the establishment of the basic reproduction number of the disease. Based upon this result, we provide three examples to illustrate the effect of the population dispersal on the spread of the disease, in section 4. Section 5 gives a brief discussion of the main results.

2. Model formulations. We consider an SIR type of disease transmission. The population is divided into three classes: susceptible individuals, infectious individuals, and recovered individuals. Susceptible individuals become infective after contact with infective individuals. Infectious individuals become recovered due to treatment or when an infection age passes the infection period. Measles, rubella, smallpox, and SARS are typical diseases of SIR type. For simplicity, we consider only two patches, which is the minimal case needed to investigate the influence of population mobility on spatial epidemic transmissions. We denote the density of susceptible individuals in patch i by S_i, the density of infective individuals in patch i by I_i, the density of recovered individuals in patch i by R_i, and the population size in patch i by N_i. Thus, $N_i = S_i + I_i + R_i$. In order to accommodate more epidemic diseases that have longer time scales, we consider the demography of populations and suppose that the demographic structure of the population in patch i is described by

$$\frac{dN_i}{dt} = B_i(N_i(t))N_i(t) - \mu_i N_i(t),$$

where B_i is the per capita birth rate and μ_i the per capita death rate. This type of demography has been adopted by [9, 12, 16]. If $B_i = \mu_i$, then the population size is a constant, which is suitable when the duration of an epidemic disease is much shorter than the lifespan of the individuals in a population. As mentioned in [9], three types of birth functions $B_i(N_i)$ can be found in the biological literature:

(C1) $B_i(N_i) = H_i e^{-A_i N_i}$ with $A_i > 0$, $H_i > 0$;
(C2) $B_i(N_i) = \frac{p_i}{q_i + N_i^{m_i}}$ with $p_i, q_i, m_i > 0$;
(C3) $B_i(N_i) = \frac{A_i}{N_i} + H_i$ with $A_i > 0$, $H_i > 0$.

We assume that the disease transmission in each patch obeys the mass action incidence. If there is no population dispersal between patches, i.e., the patches are isolated, with an exponentially distributed infectious period, the dynamics of disease transmission in the ith patch is governed by

$$\begin{aligned} \frac{dS_i}{dt} &= B_i(N_i(t))N_i(t) - \mu_i S_i(t) - k_i S_i(t) I_i(t), \\ \frac{dI_i}{dt} &= k_i S_i(t) I_i(t) - (\mu_i + \gamma_i) I_i(t), \\ \frac{dR_i}{dt} &= \gamma_i I_i(t) - \mu_i R_i(t), \end{aligned} \tag{2.1}$$

where k_i is the disease transmission coefficient and γ_i is the recovery rate of infected individuals.

When the patches are connected, the dynamics of disease transmission is described by

$$\begin{aligned} \frac{dS_1}{dt} &= B_1(N_1(t))N_1(t) - (\mu_1 + d_1)S_1(t) - k_1 S_1(t) I_1(t) + d_2 S_2(t), \\ \frac{dS_2}{dt} &= B_2(N_2(t))N_2(t) - (\mu_2 + d_2)S_2(t) - k_2 S_2(t) I_2(t) + d_1 S_1(t), \\ \frac{dI_1}{dt} &= k_1 S_1(t) I_1(t) - (\mu_1 + \gamma_1 + b_1) I_1(t) + b_2 I_2(t), \\ \frac{dI_2}{dt} &= k_2 S_2(t) I_2(t) - (\mu_2 + \gamma_2 + b_2) I_2(t) + b_1 I_1(t), \\ \frac{dR_1}{dt} &= \gamma_1 I_1(t) - (\mu_1 + c_1) R_1(t) + c_2 R_2(t), \\ \frac{dR_2}{dt} &= \gamma_2 I_2(t) - (\mu_2 + c_2) R_2(t) + c_1 R_1(t), \end{aligned} \tag{2.2}$$

where d_1 represents the rate at which susceptible individuals migrate from the first patch to the second patch, d_2 the rate at which susceptible individuals migrate from the second patch to the first patch, b_1 the rate at which infectious individuals migrate from the first patch to the second patch, b_2 the rate at which infected individuals migrate from the second patch to the first patch, c_1 the rate at which recovered individuals migrate from the first patch to the second patch, and c_2 the rate at which recovered individuals migrate from the second patch to the first patch. In this model, we neglect the death and birth processes of individuals when they are dispersing and neglect the time that individuals take to move between patches. Furthermore, for the convenience of mathematical analysis, it is assumed that $b_1 > 0$ and $b_2 > 0$.

We assume that all infectious individuals have a constant length of infection τ. This means that the duration of the infectious period is described by a step function, which is one of the conventional methods for representing infectious periods [8, 11, 16], and the biological motivations are presented in the introduction section. Let a be the infection age, i.e., the time since infection, and let $I_i(a,t)$ be the density of infected individuals at time t with respect to infection age a in the ith patch. We assume that the number of individuals recovered due to treatment per unit time is proportional to the total of infectious individuals. This means that we neglect the time delay for

treatment to take effect, which is reasonable when treatment takes effect in a short time. As a consequence, infected individuals in patch i are treated at a constant rate $r_i \geq 0$ up to infection-age τ, when any remaining infected individuals of infection-age τ immediately transfer to the recovered class. For simplicity, we assume that the death rates, the disease transmission coefficients, the treatment rates, and the migration rates are independent of infection ages. Then the force of infection in patch i at time t is $k_i \int_0^\tau I_i(a,t)da$. Thus, (2.2) can be modified as

$$
\begin{aligned}
&\frac{dS_1}{dt} = B_1(N_1(t))N_1(t) - (\mu_1 + d_1)S_1(t) - \lambda_1(t)S_1(t) + d_2S_2(t),\\
&\frac{dS_2}{dt} = B_2(N_2(t))N_2(t) - (\mu_2 + d_2)S_2(t) - \lambda_2(t)S_2(t) + d_1S_1(t),\\
&\frac{\partial I_1}{\partial t} + \frac{\partial I_1}{\partial a} = -(\mu_1 + r_1 + b_1)I_1(a,t) + b_2I_2(a,t), \quad 0 < a \leq \tau,\\
&\frac{\partial I_2}{\partial t} + \frac{\partial I_2}{\partial a} = -(\mu_2 + r_2 + b_2)I_2(a,t) + b_1I_1(a,t), \quad 0 < a \leq \tau,\\
&\frac{dR_1}{dt} = r_1\int_0^\tau I_1(a,t)da + I_1(\tau,t) - (\mu_1 + c_1)R_1(t) + c_2R_2(t),\\
&\frac{dR_2}{dt} = r_2\int_0^\tau I_2(a,t)da + I_2(\tau,t) - (\mu_2 + c_2)R_2(t) + c_1R_1(t),\\
&\lambda_i(t) = k_i\int_0^\tau I_i(a,t)da, \qquad N_i(t) = S_i(t) + R_i(t) + \int_0^\tau I_i(a,t)da,\\
&I_i(0,t) = \lambda_i(t)S_i(t), \quad i = 1,2,
\end{aligned}
\tag{2.3}
$$

with the initial conditions given by

$$
\begin{aligned}
&S_i(0) = S_i^0 > 0, \qquad R_i(0) = R_i^0 \geq 0, \quad i = 1,2,\\
&I_i(a,0) = f_i(a) \geq 0 \quad \text{for } 0 \leq a \leq \tau,\ i = 1,2.
\end{aligned}
\tag{2.4}
$$

Let $P_i(t) = \int_0^\tau I_i(a,t)da$ be the total density of infected members at time t in the ith patch. We derive the equations for $P_1(t)$ and $P_2(t)$ for $t \geq \tau$. Set $V_i(a,t) = I_i(t-a,t)$ for $0 \leq t-a \leq \tau$ and $\mathbf{V}(a,t) = (V_1(a,t), V_2(a,t))^T$, where T represents a transpose of a vector. Then $\mathbf{V}$ satisfies

$$
\frac{\partial \mathbf{V}(a,t)}{\partial t} = \mathbf{B}\mathbf{V}(a,t), \quad a \leq t \leq a + \tau,
\tag{2.5}
$$

where

$$
\mathbf{B} = \begin{bmatrix} -\mu_1 - r_1 - b_1 & b_2 \\ b_1 & -\mu_2 - r_2 - b_2 \end{bmatrix}.
$$

Integrating (2.5) from a to t, we have

$$
\mathbf{V}(a,t) = \exp(\mathbf{B}(t-a))(I_1(0,a), I_2(0,a))^T, \quad a \leq t \leq a + \tau,
$$

and hence

$$
\mathbf{I}(a,t) = \mathbf{V}(t-a,t) = \exp(\mathbf{B}a)(I_1(0,t-a), I_2(0,t-a))^T, \quad a \leq \tau.
\tag{2.6}
$$

Set

$$
(b_{ij}(a)) := \exp(\mathbf{B}a), \qquad Q_i(t) := k_iS_i(t)P_i(t).
$$

It then follows from (2.3) that

$$\begin{aligned} I_1(a,t) &= b_{11}(a)Q_1(t-a) + b_{12}(a)Q_2(t-a),\\ I_2(a,t) &= b_{21}(a)Q_1(t-a) + b_{22}(a)Q_2(t-a) \end{aligned} \tag{2.7}$$

for $t \geq \tau \geq a$.

Integrating (2.7) from 0 to τ, we have

$$\begin{aligned} P_1(t) &= \int_0^\tau b_{11}(a)Q_1(t-a)da + \int_0^\tau b_{12}(a)Q_2(t-a)da, \quad t \geq \tau,\\ P_2(t) &= \int_0^\tau b_{21}(a)Q_1(t-a)da + \int_0^\tau b_{22}(a)Q_2(t-a)da, \quad t \geq \tau, \end{aligned} \tag{2.8}$$

which is equivalent to

$$\mathbf{P}(t) = \int_0^\tau \exp(\mathbf{B}a)\mathbf{Q}(t-a)da = \int_{t-\tau}^t \exp(\mathbf{B}(t-s))\mathbf{Q}(s)ds, \quad t \geq \tau, \tag{2.9}$$

where $\mathbf{P}(t) = (P_1(t), P_2(t))^T$ and $\mathbf{Q}(t) = (Q_1(t), Q_2(t))^T$. It then follows that

$$\frac{d\mathbf{P}}{dt} = \mathbf{Q}(t) - \exp(\mathbf{B}\tau)\mathbf{Q}(t-\tau) + \mathbf{B}\mathbf{P}(t), \quad t \geq \tau. \tag{2.10}$$

Define

$$\gamma_i(t) := r_i P_i(t) + b_{i1}(\tau)Q_1(t-\tau) + b_{i2}(\tau)Q_2(t-\tau), \quad i = 1, 2. \tag{2.11}$$

Consequently, we obtain the following time-delayed model:

$$\begin{aligned} \frac{dS_1}{dt} &= B_1(N_1(t))N_1(t) - (\mu_1 + d_1)S_1(t) - Q_1(t) + d_2 S_2(t),\\ \frac{dS_2}{dt} &= B_2(N_2(t))N_2(t) - (\mu_2 + d_2)S_2(t) - Q_2(t) + d_1 S_1(t),\\ \frac{d\mathbf{P}}{dt} &= \mathbf{Q}(t) - \exp(\mathbf{B}\tau)\mathbf{Q}(t-\tau) + \mathbf{B}\mathbf{P}(t),\\ \frac{dR_1}{dt} &= \gamma_1(t) - (\mu_1 + c_1)R_1(t) + c_2 R_2(t),\\ \frac{dR_2}{dt} &= \gamma_2(t) - (\mu_2 + c_2)R_2(t) + c_1 R_1(t),\\ N_i(t) &= S_i(t) + R_i(t) + P_i(t), \quad i = 1, 2, \end{aligned} \tag{2.12}$$

for $t \geq \tau$. In view of (2.9), we need to impose the following condition on initial functions:

$$\mathbf{P}(\tau) = \int_0^\tau \exp(\mathbf{B}(\tau - s))\mathbf{Q}(s)ds. \tag{2.13}$$

It is easy to see that (2.12) is an autonomous functional differential system defined on $C([0,\tau], R_+^6)$. Without loss of generality, we will consider (2.12) on $C([-\tau, 0], R_+^6)$ (after a time translation) under the condition

$$\mathbf{P}(0) = \int_{-\tau}^0 \exp(-\mathbf{B}s)\mathbf{Q}(s)ds. \tag{2.14}$$

We finish this section with discussion of the well-posedness of system (2.12), with initial values subject to condition (2.14), and the positivity of its solutions. Assume that each $B_i(N_i)N_i$ extends to a continuously differentiable function $G_i(N_i)$ on $[0,\infty)$ with $G_i(0) \geq 0$. Let $\mathbf{u}(t) = (\mathbf{S}(t), \mathbf{P}(t), \mathbf{R}(t))$ be a continuous function from $[-\tau, \sigma)$ to R^6_+ for some $\sigma > 0$. For each $t \in [0, \sigma)$, we define $\mathbf{u}_t \in C([-\tau, 0], R^6_+)$ by $\mathbf{u}_t(s) = \mathbf{u}(t+s)$ for all $s \in [-\tau, 0]$. Set

$$X := \left\{ (\mathbf{S}, \mathbf{P}, \mathbf{R}) \in C([-\tau, 0], R^6_+) : \mathbf{P}(0) = \int_{-\tau}^{0} \exp(-\mathbf{B}s)\mathbf{Q}(s)ds \right\}.$$

By the standard theory of functional differential equations (see, e.g., [14, Theorems 2.1 and 2.3] or [18, Theorems 2.1 and 2.2]), it follows that for any $\boldsymbol{\phi} \in C([-\tau, 0], R^6_+)$ there exists a unique solution $\mathbf{u}(t, \boldsymbol{\phi})$ of system (2.12) satisfying $\mathbf{u}_0 = \boldsymbol{\phi}$, which is defined on its maximal interval of existence $[0, \sigma_{\boldsymbol{\phi}})$. We first show that X is positively invariant for solutions of system (2.12) in the sense that for any $\boldsymbol{\phi} \in X$ we have $\mathbf{u}_t(\boldsymbol{\phi}) \in X$ for all $t \in [0, \sigma_{\boldsymbol{\phi}})$. Let $\mathbf{u}(t, \boldsymbol{\phi}) = (\mathbf{S}(t), \mathbf{P}(t), \mathbf{R}(t))$, and define

$$\mathbf{W}(t) := \int_{t-\tau}^{t} \exp(\mathbf{B}(t-s))\mathbf{Q}(s)ds \quad \forall t \in [0, \sigma_{\boldsymbol{\phi}}).$$

It then follows that

$$\frac{d\mathbf{W}(t)}{dt} = \mathbf{Q}(t) - \exp(\mathbf{B}\tau)\mathbf{Q}(t-\tau) + \mathbf{B}\mathbf{W}(t) \quad \forall t \in [0, \sigma_{\boldsymbol{\phi}}).$$

Thus, we obtain

$$\frac{d(\mathbf{P}(t) - \mathbf{W}(t))}{dt} = \mathbf{B}(\mathbf{P}(t) - \mathbf{W}(t)) \quad \forall t \in [0, \sigma_{\boldsymbol{\phi}}).$$

Since $\boldsymbol{\phi} \in X$, we have $\mathbf{P}(0) = \mathbf{W}(0)$, and hence

$$\mathbf{P}(t) - \mathbf{W}(t) = \exp(\mathbf{B}t)(\mathbf{P}(0) - \mathbf{W}(0)) = \mathbf{0} \quad \forall t \in [0, \sigma_{\boldsymbol{\phi}}).$$

This means that

(2.15)
$$\mathbf{P}(t) = \int_{t-\tau}^{t} \exp(\mathbf{B}(t-s))\mathbf{Q}(s)ds = \int_{-\tau}^{0} \exp(\mathbf{B}(-s))\mathbf{Q}(t+s)ds \quad \forall t \in [0, \sigma_{\boldsymbol{\phi}}).$$

By (2.15) and the differential equations for $S_1(t)$, $S_2(t)$, $R_1(t)$, and $R_2(t)$, it then easily follows that for any $\boldsymbol{\phi} \in X$, $\mathbf{u}(t, \boldsymbol{\phi})$ is (componentwise) nonnegative on $[0, \sigma_{\boldsymbol{\phi}})$, and $\mathbf{u}_t(\boldsymbol{\phi}) \in X$ for all $t \in [0, \sigma_{\boldsymbol{\phi}})$.

3. Basic reproduction number. For simplicity, from this point on we always assume that two birth functions are of type (C3), that is, $B_i(N_i) = \frac{A_i}{N_i} + H_i$, $i = 1, 2$. Thus, the model (2.12) reduces to

(3.1)
$$\begin{aligned}
\frac{dS_1}{dt} &= A_1 + H_1 N_1(t) - (\mu_1 + d_1)S_1(t) - Q_1(t) + d_2 S_2(t),\\
\frac{dS_2}{dt} &= A_2 + H_2 N_2(t) - (\mu_2 + d_2)S_2(t) - Q_2(t) + d_1 S_1(t),\\
\frac{d\mathbf{P}}{dt} &= \mathbf{Q}(t) - \exp(\mathbf{B}\tau)\mathbf{Q}(t-\tau) + \mathbf{B}\mathbf{P}(t),
\end{aligned}$$

$$\frac{dR_1}{dt} = \gamma_1(t) - (\mu_1 + c_1)R_1(t) + c_2R_2(t),$$
$$\frac{dR_2}{dt} = \gamma_2(t) - (\mu_2 + c_2)R_2(t) + c_1R_1(t),$$
$$N_i(t) = S_i(t) + R_i(t) + P_i(t), \quad i = 1, 2,\ t \geq 0.$$

The objective of this section is to establish a basic reproduction number for model (3.1) and to show that it is a threshold for the disease invasion. Assume that we have the following:

(H) $A_i, H_i, \mu_i, k_i, b_i$, $i = 1, 2$, are positive constants with $H_i < \mu_i$; d_i and c_i are nonnegative constants for $i = 1, 2$.

Define

$$X_L := \left\{ \boldsymbol{\phi} = (\phi_1, \ldots, \phi_6) \in X : \sum_{i=1}^{6} \phi_i(0) \leq L \right\} \quad \forall L \geq 0$$

and

$$m := \min\{\mu_1 - H_1, \mu_2 - H_2\}, \qquad L^* := \frac{A_1 + A_2}{m}.$$

Then we have the following preliminary result.

LEMMA 3.1. *Let* (H) *hold. Then for any $L > L^*$, the set X_L is positively invariant for solutions of* (3.1)*, and every solution $\mathbf{u}(t, \boldsymbol{\phi})$ of* (3.1) *with $\boldsymbol{\phi} \in X$ eventually enters into $[0, L]^6$.*

Proof. By (3.1) and (2.11), we obtain

$$\begin{aligned} \frac{dN_1}{dt} &= A_1 - (\mu_1 - H_1)N_1 - d_1S_1 + d_2S_2 - b_1P_1 + b_2P_2 - c_1R_1 + c_2R_2, \\ \frac{dN_2}{dt} &= A_2 - (\mu_2 - H_2)N_2 - d_2S_2 + d_1S_1 - b_2P_2 + b_1P_1 - c_2R_2 + c_1R_1. \end{aligned} \tag{3.2}$$

Let $N = N_1 + N_2$. It then follows that

$$\frac{dN}{dt} \leq A_1 + A_2 - mN, \quad t \geq 0.$$

Now the standard comparison theorem [24] completes the proof. ∎

Let $\boldsymbol{\Phi}(t) : X \to X$ be the solution semiflow associated with (3.1); that is, $\boldsymbol{\Phi}(t)\boldsymbol{\phi} = \mathbf{u}_t(\boldsymbol{\phi})$, $\boldsymbol{\phi} \in X$, $t \geq 0$. By Lemma 3.1, solutions of (3.1) are uniformly bounded and ultimately bounded. Thus, the semiflow $\boldsymbol{\Phi}(t)$ is point dissipative on X, and $\boldsymbol{\Phi}(t) : X \to X$ is compact for each $t > \tau$. By [15, Theorem 3.4.8], it then follows that $\boldsymbol{\Phi}(t)$ admits a global attractor, which attracts every bounded set in X.

Under the assumption (H), it is easy to see that (3.1) has a unique disease-free equilibrium $E_0 = (S_1^*, S_2^*, 0, 0, 0, 0)$, where

$$S_1^* = -\frac{-H_2\,A_1 + \mu_2\,A_1 + d_2\,A_1 + d_2\,A_2}{-H_1\,H_2 + H_1\,\mu_2 + H_1\,d_2 + \mu_1\,H_2 - \mu_1\,\mu_2 - \mu_1\,d_2 + d_1\,H_2 - d_1\,\mu_2},$$
$$S_2^* = -\frac{d_1\,A_1 - H_1\,A_2 + \mu_1\,A_2 + d_1\,A_2}{-H_1\,H_2 + H_1\,\mu_2 + H_1\,d_2 + \mu_1\,H_2 - \mu_1\,\mu_2 - \mu_1\,d_2 + d_1\,H_2 - d_1\,\mu_2}.$$

To determine the basic reproduction number of (3.1), we assume that the population is at the disease-free equilibrium E_0. It then follows from (2.15) that

$$
\begin{aligned}
P_1(t) &= k_1 S_1^* \int_0^\tau b_{11}(a) P_1(t-a)da + k_2 S_2^* \int_0^\tau b_{12}(a) P_2(t-a)da,\\
P_2(t) &= k_1 S_1^* \int_0^\tau b_{21}(a) P_1(t-a)da + k_2 S_2^* \int_0^\tau b_{22}(a) P_2(t-a)da.
\end{aligned} \tag{3.3}
$$

Set

$$
\mathbf{U} = \begin{bmatrix} k_1 S_1^* \int_0^\tau b_{11}(a)da & k_2 S_2^* \int_0^\tau b_{12}(a)da \\ k_1 S_1^* \int_0^\tau b_{21}(a)da & k_2 S_2^* \int_0^\tau b_{22}(a)da \end{bmatrix}.
$$

Since $\mathbf{U}$ is a positive matrix, its spectral radius $\rho(\mathbf{U})$ is a simple eigenvalue with a positive eigenvector. Indeed, two eigenvalues of $\mathbf{U}$ are real, and $\rho(\mathbf{U})$ is the maximum of positive eigenvalues. Let $\boldsymbol{\psi}(a) = (\psi_1, \psi_2)^T$ be an initial distribution of infected members in the patches during the infection period, where ψ_1 and ψ_2 are constants. If we set

$$
\boldsymbol{\mathcal{F}} = \begin{bmatrix} k_1 S_1^* & 0 \\ 0 & k_2 S_2^* \end{bmatrix},
$$

then $\boldsymbol{\mathcal{F}}\boldsymbol{\psi}$ represents the emerging rate of new infectious individuals in the patches. From (2.6), we see that $b_{ij}(a)$ is the probability that an infective initially in patch j at infection age 0 is in patch i at infection age a. Then $\mathbf{U}\boldsymbol{\psi} = \int_0^\tau \exp(\mathbf{B}a)\boldsymbol{\mathcal{F}}\boldsymbol{\psi}da$ gives the members of infected individuals in the patches when the infection period ends. Motivated by [10, 26], we call $\mathbf{U}$ the next infection matrix and define $\rho(\mathbf{U})$ as the basic reproduction number R_0 of (3.1).

The following result shows that the disease is persistent if $R_0 > 1$.

THEOREM 3.2. *Let* (H) *hold. If $R_0 > 1$, then the disease is uniformly persistent in the sense that there is a positive number ϵ such that every solution $(\mathbf{S}(t), \mathbf{P}(t), \mathbf{R}(t))$ of* (3.1) *with $\mathbf{S}(0) \geq \mathbf{0}$, $\mathbf{P}(0) > \mathbf{0}$ (i.e., $\mathbf{P}(0) \geq \mathbf{0}$ and $\mathbf{P}(0) \neq \mathbf{0}$), and $\mathbf{R}(0) \geq \mathbf{0}$ satisfies $\liminf_{t\to\infty} P_i(t) \geq \epsilon$, $i = 1, 2$.*

Proof. As mentioned before, the solution semiflow $\boldsymbol{\Phi}(t)$ of (3.1) has a global attractor on X. In order to use persistence theory, we define

$$
X_0 := \{\boldsymbol{\phi} \in X : \phi_3(0) > 0, \phi_4(0) > 0\}, \qquad \partial X_0 := X \setminus X_0.
$$

In view of (2.15), it is easy to see that X_0 is positively invariant for $\boldsymbol{\Phi}(t)$. Clearly, ∂X_0 is relatively closed in X, and

$$
\partial X_0 = \{\boldsymbol{\phi} \in X : \phi_3(0) = 0 \text{ or } \phi_4(0) = 0\}.
$$

Let $L \in (L^*, \infty)$ be fixed. Then Lemma 3.1 implies that every solution of (3.1) enters $[0, L]^6$ ultimately. Define

$$
M_\partial := \{\boldsymbol{\phi} \in X : \boldsymbol{\Phi}(t)\boldsymbol{\phi} \in \partial X_0 \ \forall t \geq 0\}.
$$

Note that $b_1 > 0$ and $b_2 > 0$ imply that $\exp(\mathbf{B}a) > 0$ (see, e.g., [23]). Let $(\mathbf{S}(t, \boldsymbol{\phi}), \mathbf{P}(t, \boldsymbol{\phi}), \mathbf{R}(t, \boldsymbol{\phi}))$ be the solution of (3.1) satisfying $(\mathbf{S}_0(\boldsymbol{\phi}), \mathbf{P}_0(\boldsymbol{\phi}), \mathbf{R}_0(\boldsymbol{\phi})) = \boldsymbol{\phi}$. It then follows that

$$
M_\partial = \{\boldsymbol{\phi} \in \partial X_0 : \mathbf{P}(t, \boldsymbol{\phi}) = 0 \ \forall t \geq 0\}.
$$

Set

$$\mathbf{U}_\epsilon = \begin{bmatrix} k_1(S_1^*-\epsilon)\int_0^\tau b_{11}(a)da & k_2(S_2^*-\epsilon)\int_0^\tau b_{12}(a)da \\ k_1(S_1^*-\epsilon)\int_0^\tau b_{21}(a)da & k_2(S_2^*-\epsilon)\int_0^\tau b_{22}(a)da \end{bmatrix}.$$

Since the spectral radius of $\mathbf{U}_\epsilon$ is continuous in ϵ, we can restrict $\epsilon > 0$ small enough such that $\mathbf{U}_\epsilon$ is a positive matrix and $\rho(\mathbf{U}_\epsilon) > 1$. Let us consider the following linear system:

$$\begin{aligned} \frac{du_1(t)}{dt} &= A_1 - \xi + H_1 u_1(t) - (\mu_1 + d_1)u_1(t) + d_2 u_2(t), \\ \frac{du_2(t)}{dt} &= A_2 - \xi + H_2 u_2(t) - (\mu_2 + d_2)u_2(t) + d_1 u_1(t), \end{aligned} \tag{3.4}$$

where $\xi > 0$ is a small number. It is easy to see that (3.4) admits an equilibrium $(u_1^*(\xi), u_2^*(\xi))$, which is globally stable and satisfies $(u_1^*(\xi), u_2^*(\xi)) \to (S_1^*, S_2^*)$ as $\xi \to 0$. Thus, we can restrict $\xi > 0$ small enough such that every solution $(u_1(t), u_2(t))$ of (3.4) satisfies $u_i(t) > S_i^* - \epsilon$, $i = 1, 2$, for all large t.

Let $\delta = \min\{\frac{\xi}{k_1 L}, \frac{\xi}{k_2 L}\}$. We then have the following claim.

Claim. $\limsup_{t\to\infty} \max\{P_1(t, \boldsymbol{\phi}), P_2(t, \boldsymbol{\phi})\} \geq \delta$ for any $\boldsymbol{\phi} \in X_0$.

Assume, by contradiction, that the claim does not hold for some $\boldsymbol{\phi} \in X_0$. Then $P_i(t) := P_i(t, \boldsymbol{\phi}) < \delta$, $i = 1, 2$, for all large t. It follows that for all large t,

$$\begin{aligned} \frac{dS_1(t)}{dt} &> A_1 - \xi + H_1 S_1(t) - (\mu_1 + d_1)S_1(t) + d_2 S_2(t), \\ \frac{dS_2(t)}{dt} &> A_2 - \xi + H_2 S_2(t) - (\mu_2 + d_2)S_2(t) + d_1 S_1(t). \end{aligned} \tag{3.5}$$

By the comparison theorem of cooperative systems (see, e.g., [23, 24]), it follows that $S_i(t) > S_i^* - \epsilon$, $i = 1, 2$, for all large t. Thus, (2.8) implies that there is a $t_0 > 0$ such that for all $t \geq t_0$,

$$\begin{aligned} P_1(t) &> k_1(S_1^*-\epsilon)\int_0^\tau b_{11}(a)P_1(t-a)da + k_2(S_2^*-\epsilon)\int_0^\tau b_{12}(a)P_2(t-a)da, \\ P_2(t) &> k_1(S_1^*-\epsilon)\int_0^\tau b_{21}(a)P_1(t-a)da + k_2(S_2^*-\epsilon)\int_0^\tau b_{22}(a)P_2(t-a)da. \end{aligned} \tag{3.6}$$

Let $\mathbf{v} = (v_1, v_2)^T$ be a positive right eigenvector of $\mathbf{U}_\epsilon$ with respect to $\rho(\mathbf{U}_\epsilon)$. Choose $l > 0$ small enough such that $lv_i < \min\{P_i(t) : t_0 \leq t \leq t_0 + \tau\}$ for $i = 1, 2$. We further show that

$$lv_i < P_i(t), \quad i = 1, 2, \quad \forall t \geq t_0. \tag{3.7}$$

Otherwise, we set

$$t_1 = \inf\{t \in [t_0, \infty) : lv_1 = P_1(t) \text{ or } lv_2 = P_2(t)\}.$$

Clearly, $t_1 > t_0 + \tau$. It then follows that $lv_i < P_i(t)$, $i = 1, 2$, for $t_0 \leq t < t_1$, and $lv_1 = P_1(t_1)$ or $lv_2 = P_2(t_1)$. However, (3.6) implies that for all $t \in [t_0 + \tau, t_1]$,

$$\begin{aligned} P_1(t) &> k_1(S_1^*-\epsilon)lv_1\int_0^\tau b_{11}(a)da + k_2(S_2^*-\epsilon)lv_2\int_0^\tau b_{12}(a)da = \rho(\mathbf{U}_\epsilon)lv_1, \\ P_2(t) &> k_1(S_1^*-\epsilon)lv_1\int_0^\tau b_{21}(a)da + k_2(S_2^*-\epsilon)lv_2\int_0^\tau b_{22}(a)da = \rho(\mathbf{U}_\epsilon)lv_2, \end{aligned} \tag{3.8}$$

which contradicts $lv_1 = P_1(t_1)$ or $lv_2 = P_2(t_1)$. Thus, (3.7) holds.

Now suppose that for some $n \geq 1$,

$$\rho^{n-1}(\mathbf{U}_\epsilon)lv_i < P_i(t), \quad i = 1, 2, \quad \forall t \geq t_0 + (n-1)\tau. \tag{3.9}$$

We want to prove that

$$\rho^{n}(\mathbf{U}_\epsilon)lv_i < P_i(t), \quad i = 1, 2, \quad \forall t \geq t_0 + n\tau. \tag{3.10}$$

Note that (3.6) and (3.9) imply that $\rho^n(\mathbf{U}_\epsilon)lv_i < P_i(t_0 + n\tau)$, $i = 1, 2$. If (3.10) is not true, then there is a $t_2 > t_0 + n\tau$ such that $\rho^n(\mathbf{U}_\epsilon)lv_i < P_i(t)$, $i = 1, 2$, for $t_0 + n\tau \leq t < t_2$, and $\rho^n(\mathbf{U}_\epsilon)lv_1 = P_1(t_2)$ or $\rho^n(\mathbf{U}_\epsilon)lv_2 = P_2(t_2)$. By (3.6) and (3.9), it follows that for $t \in (t_0 + n\tau, t_2]$,

$$\begin{aligned}
P_1(t) &> k_1(S_1^* - \epsilon)\rho^{n-1}(\mathbf{U}_\epsilon)lv_1 \int_0^\tau b_{11}(a)da + k_2(S_2^* - \epsilon)\rho^{n-1}(\mathbf{U}_\epsilon)lv_2 \int_0^\tau b_{12}(a)da \\
&= \rho^n(\mathbf{U}_\epsilon)lv_1, \\
P_2(t) &> k_1(S_1^* - \epsilon)\rho^{n-1}(\mathbf{U}_\epsilon)lv_1 \int_0^\tau b_{21}(a)da + k_2(S_2^* - \epsilon)\rho^{n-1}(\mathbf{U}_\epsilon)lv_2 \int_0^\tau b_{22}(a)da \\
&= \rho^n(\mathbf{U}_\epsilon)lv_2,
\end{aligned}$$

which contradicts $\rho^n(\mathbf{U}_\epsilon)lv_1 = P_1(t_2)$ or $\rho^n(\mathbf{U}_\epsilon)lv_2 = P_2(t_2)$. By induction, we conclude that (3.10) holds for all $n \geq 0$. Since $\rho(\mathbf{U}_\epsilon) > 1$, we then obtain

$$\lim_{t\to\infty} P_i(t) \geq \lim_{n\to\infty} \rho^n(\mathbf{U}_\epsilon)lv_i = \infty,$$

a contradiction. This proves our claim.

Define $p : X \to R_+$ by

$$p(\boldsymbol{\phi}) = \min\{\phi_3(0), \phi_4(0)\} \quad \forall \boldsymbol{\phi} \in X.$$

Clearly, $X_0 = p^{-1}(0, \infty)$ and $\partial X_0 = p^{-1}(0)$. Note that p is a generalized distance function for the semiflow $\mathbf{\Phi}(t) : X \to X$ (see [25]). It is easy to see that any forward orbit of $\mathbf{\Phi}(t)$ in M_∂ converges to E_0. By the claim above, we see that E_0 is an isolated invariant set in X, and that $W^s(E_0) \cap X_0 = \emptyset$, where $W^s(E_0)$ is the stable manifold of E_0. By [25, Theorem 3.1], it then follows that there exists $\delta > 0$ such that $\min\{p(\boldsymbol{\psi}) : \boldsymbol{\psi} \in \omega(\boldsymbol{\phi})\} > \delta$ for any $\boldsymbol{\phi} \in X_0$. This implies our required uniform persistence of solutions of system (3.1). □

Next we show that a small invasion of the disease is unsuccessful if $R_0 < 1$.

THEOREM 3.3. *Let* (H) *hold. If* $R_0 < 1$*, then for every* $L \geq L^*$ *there exists a* $\zeta = \zeta(L) > 0$ *such that for any* $\boldsymbol{\phi} \in X_L$ *with* $(\phi_3(0), \phi_4(0)) \in [0, \zeta]^2$ *the solution* $(\mathbf{S}(t, \boldsymbol{\phi}), \mathbf{P}(t, \boldsymbol{\phi}), \mathbf{R}(t, \boldsymbol{\phi}))$ *of* (3.1) *converges to* E_0 *as* $t \to \infty$.

Proof. Let $L \geq L^*$ be given. By Lemma 3.1 and its proof, X_L is positively invariant for the solution semiflow of (3.1). We then have

$$(\mathbf{S}(t, \boldsymbol{\phi}), \mathbf{P}(t, \boldsymbol{\phi}), \mathbf{R}(t, \boldsymbol{\phi})) \in [0, L]^6 \quad \forall t \geq 0, \ \boldsymbol{\phi} \in X_L. \tag{3.11}$$

Set

$$\mathbf{V}_\epsilon = \begin{bmatrix} k_1(S_1^* + \epsilon)\int_0^\tau b_{11}(a)da & k_2(S_2^* + \epsilon)\int_0^\tau b_{12}(a)da \\ k_1(S_1^* + \epsilon)\int_0^\tau b_{21}(a)da & k_2(S_2^* + \epsilon)\int_0^\tau b_{22}(a)da \end{bmatrix}.$$

By the continuity of the spectral radius of $\mathbf{V}_\epsilon$ with respect to ϵ, we can restrict $\epsilon > 0$ small enough such that $\rho(\mathbf{V}_\epsilon) < 1$. Arguing as before, we can choose a small number $\xi_1 > 0$ and a large number $T_1 = T_1(L) > 0$ such that, for any solution $(u_1(t), u_2(t))$ of the system

$$\begin{aligned} \frac{du_1(t)}{dt} &= A_1 + \xi_1 + H_1 u_1(t) - (\mu_1 + d_1)u_1(t) + d_2 u_2(t), \\ \frac{du_2(t)}{dt} &= A_2 + \xi_1 + H_2 u_2(t) - (\mu_2 + d_2)u_2(t) + d_1 u_1(t) \end{aligned} \tag{3.12}$$

with $(u_1(0), u_2(0)) \in [0, L]^2$, we have $u_i(t) < S_i^* + \epsilon$, $i = 1, 2$, for all $t \geq T_1$. Similarly, we can select a small number $\xi_2 > 0$ and a large number $T_2 = T_2(L) > 0$ such that, for any solution $(w_1(t), w_2(t))$ of the system

$$\begin{aligned} \frac{dw_1(t)}{dt} &= \xi_2 - (\mu_1 + c_1)w_1(t) + c_2 w_2(t), \\ \frac{dw_2(t)}{dt} &= \xi_2 - (\mu_2 + c_2)w_2(t) + c_1 w_1(t) \end{aligned} \tag{3.13}$$

with $(w_1(0), w_1(0)) \in [0, L]^2$, we have $H_i w_i(t) < \xi_1/2$, $i = 1, 2$, for all $t \geq T_2$.

Let $\mathbf{v} = (v_1, v_2)^T$ be a positive right eigenvector of $\mathbf{V}_\epsilon$ associated with $\rho(\mathbf{V}_\epsilon)$. Choose $\xi_3 > 0$ small enough such that

$$\xi_3 \left(r_i v_i + b_{i1}(\tau)k_1 L v_1 + b_{i2}(\tau)k_2 L v_2\right) < \xi_2, \quad \xi_3 v_i H_i < \xi_1/2, \quad i = 1, 2. \tag{3.14}$$

Let $T_3 = T_3(L) := \max\{T_1, T_2\} + \tau$ and $\mathbf{W} := \operatorname{diag}(k_1 L, k_2 L)$. Then there exists $\zeta = \zeta(L) > 0$ such that for every solution $(P_1(t), P_2(t))$ of the linear system

$$\frac{d\mathbf{P}(t)}{dt} = (\mathbf{W} + \mathbf{B})\mathbf{P}(t), \quad t \geq 0, \tag{3.15}$$

with $(P_1(0), P_2(0)) \in [0, \zeta]^2$, we have $P_i(t) < \xi_3 v_i$, $i = 1, 2$, for all $t \in [0, 2T_3]$.

For a given $\boldsymbol{\phi} \in X_L$ with $(\phi_3(0), \phi_4(0)) \in [0, \zeta]^2$, we let $(\mathbf{S}(t), \mathbf{P}(t), \mathbf{R}(t)) = (\mathbf{S}(t, \boldsymbol{\phi}), \mathbf{P}(t, \boldsymbol{\phi}), \mathbf{R}(t, \boldsymbol{\phi}))$. By (3.1) and (3.11), we then have

$$\frac{d\mathbf{P}(t)}{dt} \leq (\mathbf{W} + \mathbf{B})\mathbf{P}(t) \quad \forall t \geq 0.$$

Since $\mathbf{P}(0) \in [0, \zeta]^2$, the comparison principle implies that

$$P_i(t) < \xi_3 v_i \quad \forall t \in [0, 2T_3], \quad i = 1, 2. \tag{3.16}$$

We further claim that (3.16) holds for all $t \geq 0$. If the claim is not true, then there exists a $T_4 = T_4(\boldsymbol{\phi}) > 2T_3$ such that $P_i(t) < \xi_3 v_i$ for $0 \leq t < T_4$, $i = 1, 2$, and $P_j(T_4) = \xi_3 v_j$ for $j = 1$ or $j = 2$. It follows from (3.1) and (3.14) that

$$\begin{aligned} \frac{dR_1(t)}{dt} &\leq \xi_2 - (\mu_1 + c_1)R_1(t) + c_2 R_2(t), \\ \frac{dR_2(t)}{dt} &\leq \xi_2 - (\mu_2 + c_2)R_2(t) + c_1 R_1(t) \end{aligned} \tag{3.17}$$

for $\tau \leq t \leq T_4$. By the comparison principle and the properties of system (3.13), we have $H_i R_i(t) < \xi_1/2$, $i = 1, 2$, for all $t \in [T_3, T_4]$. It follows from (3.1) that

$$\begin{aligned} \frac{dS_1(t)}{dt} &< A_1 + \xi_1 + H_1 S_1(t) - (\mu_1 + d_1)S_1(t) + d_2 S_2(t), \\ \frac{dS_2(t)}{dt} &< A_2 + \xi_1 + H_2 S_2(t) - (\mu_2 + d_2)S_2(t) + d_1 S_1(t) \end{aligned} \tag{3.18}$$

for all $t \in [T_3, T_4]$. By the comparison principle and the properties of system (3.12), we obtain

$$S_i(t) < S_i^* + \epsilon \quad \forall t \in [T_3 + T_1, T_4], \quad i = 1, 2.$$

Hence, (2.8) implies that for any $t \in [2T_3, T_4]$ we have

$$\begin{aligned} P_1(t) &< k_1(S_1^* + \epsilon) \int_0^\tau b_{11}(a) P_1(t-a)da + k_2(S_2^* + \epsilon) \int_0^\tau b_{12}(a) P_2(t-a)da, \\ P_2(t) &< k_1(S_1^* + \epsilon) \int_0^\tau b_{21}(a) P_1(t-a)da + k_2(S_2^* + \epsilon) \int_0^\tau b_{22}(a) P_2(t-a)da. \end{aligned} \tag{3.19}$$

It then follows that

$$\begin{aligned} P_1(t) &< k_1(S_1^* + \epsilon)\xi_3 v_1 \int_0^\tau b_{11}(a)da + k_2(S_2^* + \epsilon)\xi_3 v_2 \int_0^\tau b_{12}(a)da = \rho(\mathbf{V}_\epsilon)\xi_3 v_1, \\ P_2(t) &< k_1(S_1^* + \epsilon)\xi_3 v_1 \int_0^\tau b_{21}(a)da + k_2(S_2^* + \epsilon)\xi_3 v_2 \int_0^\tau b_{22}(a)da = \rho(\mathbf{V}_\epsilon)\xi_3 v_2 \end{aligned}$$

for all $t \in [2T_3, T_4]$. Since $\rho(\mathbf{V}_\epsilon) < 1$, we obtain $P_j(T_4) < \xi_3 v_j$ for $j = 1, 2$, which contradicts $P_j(T_4) = \xi_3 v_j$ for $j = 1$ or $j = 2$. This shows that $P_i(t) < \xi_3 v_i$, $i = 1, 2$, for all $t \geq 0$, and hence (3.19) holds for all $t \geq 2T_3$. By an induction argument similar to that in the proof of Theorem 3.2, it follows that

$$P_i(t) < \rho^n(\mathbf{V}_\epsilon)\xi_3 v_i \quad \forall t \geq 2T_3 + n\tau,\ n \geq 0,\ i = 1, 2,$$

which implies that $\lim_{t\to\infty} P_i(t) = 0$, $i = 1, 2$. By using the theory of chain transitive sets in [17] (see, e.g., the proof of [29, Theorem 2.2]), we further obtain that $(S_1(t), S_2(t), R_1(t), R_2(t)) \to (S_1^*, S_2^*, 0, 0)$ as $t \to \infty$. □

4. Examples. The objective of this section is to analyze the effect of population dispersal on the spread of the disease. Since $b_1 > 0$ and $b_2 > 0$ imply $\exp(\mathbf{B}a) > 0$, it follows that the matrix $\mathbf{U}$ is monotonically increasing with respect to τ. Thus, the basic reproduction number R_0, the spectral radius of the positive matrix $\mathbf{U}$, is an increasing function of the infection period τ. Therefore, the longer the infection period is, the more likely it is that the disease will spread, which is in accordance with our intuition.

In order to analyze the influences of the population dispersal, we begin with the case where two patches are isolated, i.e., $d_i = b_i = c_i = 0$, $i = 1, 2$. Then we have two decoupled subsystems:

$$\begin{aligned} &\frac{dS_1}{dt} = A_1 + H_1 N_1(t) - \mu_1 S_1(t) - Q_1(t), \\ &\frac{dP_1(t)}{dt} = Q_1(t) - e^{-(\mu_1 + r_1)\tau} Q_1(t-\tau) - (\mu_1 + r_1) P_1(t), \\ &\frac{dR_1}{dt} = r_1 P_1(t) + e^{-(\mu_1 + r_1)\tau} Q_1(t-\tau) - \mu_1 R_1(t), \\ &N_1(t) = S_1(t) + R_1(t) + P_1(t), \quad t \geq 0, \\ &P_1(0) = \int_{-\tau}^0 e^{(\mu_1 + r_1)s} Q_1(s)ds, \end{aligned} \tag{4.1}$$

and

$$
\begin{aligned}
&\frac{dS_2}{dt} = A_2 + H_2 N_2(t) - \mu_2 S_2(t) - Q_2(t),\\
&\frac{dP_2(t)}{dt} = Q_2(t) - e^{-(\mu_2+r_2)\tau} Q_2(t-\tau) - (\mu_2+r_2)P_2(t),\\
&\frac{dR_2}{dt} = r_2 P_2(t) + e^{-(\mu_2+r_2)\tau} Q_2(t-\tau) - \mu_2 R_2(t),\\
&N_2(t) = S_2(t) + R_2(t) + P_2(t), \quad t \geq 0,\\
&P_2(0) = \int_{-\tau}^{0} e^{(\mu_2+r_2)s} Q_2(s)ds.
\end{aligned} \tag{4.2}
$$

Note that system (4.1) has a disease-free equilibrium $E_{01} = (S_{01}^*, 0, 0)$ with $S_{01}^* = A_1/(\mu_1 - H_1)$, and that system (4.2) has a disease-free equilibrium $E_{02} = (S_{02}^*, 0, 0)$ with $S_{02}^* = A_2/(\mu_2 - H_2)$. Let R_{0i} be the basic reproduction number of the disease in patch i. By arguments similar to those for model (3.1), it follows that

$$R_{0i} = k_i S_{0i}^* \int_0^\tau e^{-(\mu_i+r_i)a} da = \frac{k_i A_i \left(1 - \exp(-(\mu_i + r_i)\tau)\right)}{(\mu_i - H_i)(\mu_i + r_i)},$$

and $R_{0i} > 1$ implies that the disease is uniformly persistent in the isolated patch i. The following result shows that the disease dies out in the isolated patch i if $R_{0i} < 1$.

PROPOSITION 4.1. *Let two patches be disconnected. Then the disease-free equilibrium E_{0i} is globally attractive if $R_{0i} < 1$.*

Proof. We consider only patch 1, since the proof for patch 2 is similar. As argued for general model (2.12), we have

$$P_1(t) = \int_{t-\tau}^{t} e^{-(\mu_1+r_1)(t-s)} Q_1(s)ds = \int_{-\tau}^{0} e^{(\mu_1+r_1)s} Q_1(t+s)ds \quad \forall t \geq 0. \tag{4.3}$$

It easily follows from (4.1) that

$$\frac{dN_1}{dt} = A_1 - (\mu_1 - H_1)N_1(t).$$

Thus,

$$N_1(t) \to A_1/(\mu_1 - H_1) = S_{01}^* \quad \text{as } t \to \infty. \tag{4.4}$$

Since $R_{01} < 1$, we can choose $\epsilon > 0$ small enough such that

$$R_{01}^\epsilon := \frac{k_1(S_{01}^* + \epsilon)\left(1 - \exp(-(\mu_1 + r_1)\tau)\right)}{\mu_1 + r_1} < 1. \tag{4.5}$$

By (4.4), we can choose $\bar{t} > 0$ large enough such that

$$S_1(t) < S_{01}^* + \epsilon \quad \text{for } t \geq \bar{t}. \tag{4.6}$$

It follows from (4.3) that

$$P_1(t) < k_1(S_{01}^* + \epsilon) \int_0^\tau e^{-(\mu_1+r_1)a} P_1(t-a)da \tag{4.7}$$

for $t \geq \bar{t} + \tau$. Fix a $\bar{v} > 0$ such that $P_1(t) < \bar{v}$ for $\bar{t} + \tau \leq t \leq \bar{t} + 2\tau$. By an induction argument similar to that in the proof of Theorem 3.2, it follows that

$$P_1(t) < (R_{01}^\epsilon)^n \bar{v} \quad \forall t \geq \bar{t} + (n+1)\tau,\ n \geq 0.$$

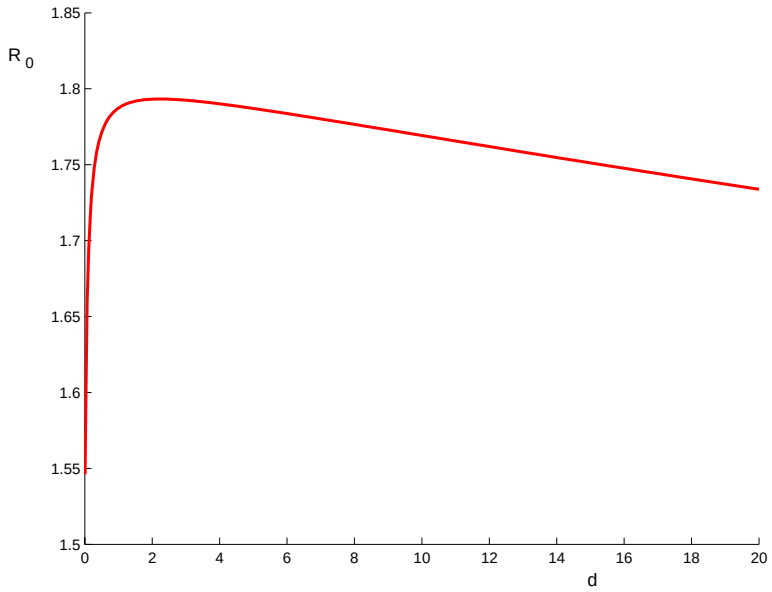

FIG. 1. *The graph of* R_0 *when* $\alpha = 0.5$.

Since $R_{01}^{\epsilon} < 1$, we have $P_1(t) \to 0$ as $t \to \infty$. By using the theory of chain transitive sets in [17] (see, e.g., the proof of [29, Theorem 2.2]), we further obtain that $(S_1(t), R_1(t)) \to (0, 0)$ as $t \to \infty$. □

When the patches are connected, we use numerical computations to find interesting dynamical behavior.

Example 4.1. We fix $A_1 = 1$, $A_2 = 0.6$, $\tau = 1$, $k_1 = 0.25$, $k_2 = 0.1$, $\mu_1 = \mu_2 = 0.2$, $H_1 = 0.05$, $H_2 = 0.1$, $r_1 = r_2 = 0$. Then we set $d_2 = d$ and take $d_1 = \alpha d$, $b_1 = 0.01\alpha d$, $b_2 = 0.01d$, where α represents the ratio of d_1 to d_2 and 0.01 means that 99 percent of infectious individuals in migration cannot pass through the borders of the two patches, due to control strategies, and only one percent can pass through, due to the failure of screening. Then $R_{01} = 1.5106$ and $R_{02} = 0.5438$. This means that if the two patches are isolated, the disease is persistent in the first patch and dies out in the second patch. If $\alpha = 0.5$, which means that individuals in the second patch have a higher migration rate than those in the first patch, from Figure 1 we see that $R_0 > \max\{R_{01}, R_{02}\}$. Thus, these kinds of mobilities facilitate disease propagation. When $\alpha = 1$, R_0 remains greater than 1 but has become a decreasing function of d. When $\alpha = 3$, from Figure 2 we see that the disease will die out when d is suitably large. Hence, the increase of mobility leads to the elimination of disease propagation. One interesting phenomenon occurs when α is larger. From Figure 3, which is typical for $\alpha \geq 4$, we see that R_0 goes through the stages of "above 1," "below 1," "above 1" as d increases, which means that the disease admits switches from persistence to extinction and then from extinction to persistence. These epidemiological changes result from the changes of population sizes in each patch under the influences of population dispersals. Indeed, if we regard S_i^* in the disease-free equilibrium as a function of d, we have $S_1^*(0) = 6.6667$ and $S_2^*(0) = 6$, which means that population sizes in the two patches are initially almost the same. For $\alpha < 0.9$, S_1^* is an increasing

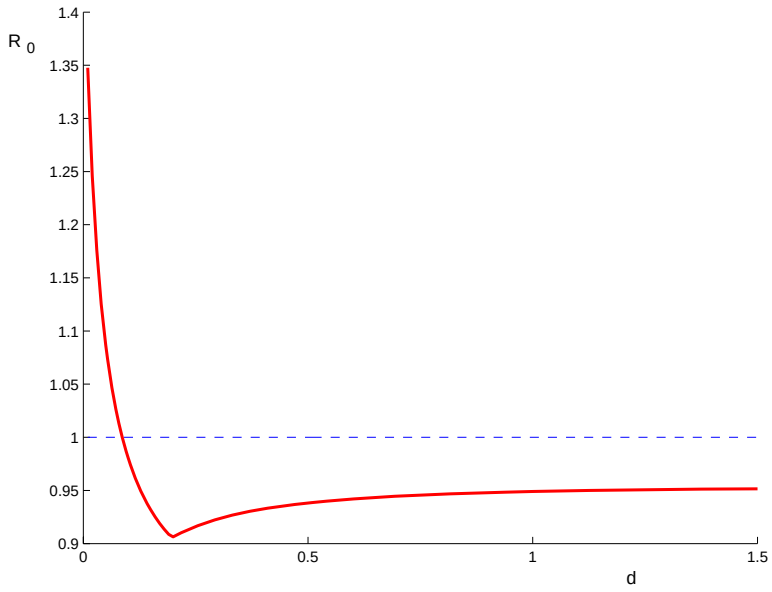

FIG. 2. *The graph of* R_0 *when* $\alpha = 3$.

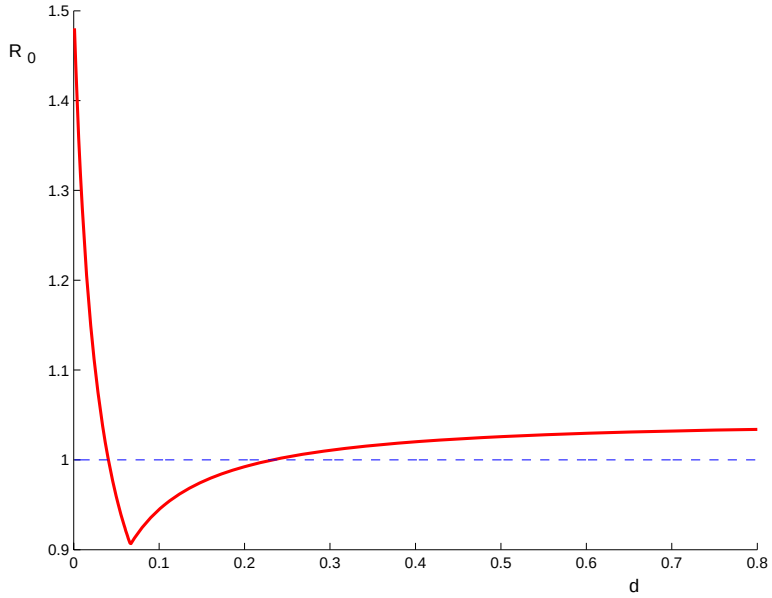

FIG. 3. *The graph of* R_0 *when* $\alpha = 4$.

function of d, and S_2^* is a decreasing function of d. For $\alpha > 0.9$, S_1^* is a decreasing function of d, and S_2^* is an increasing function of d. Thus, individuals aggregate towards the first patch when $\alpha < 0.9$ and aggregate towards the second patch when $\alpha > 0.9$. Note that $k_2 < k_1$ implies that the second patch is better than the first patch from the epidemiological perspective. Thus, it is easy to understand why the basic reproduction number for $d > 0$ is higher than that for $d = 0$ when $\alpha = 0.5$. For

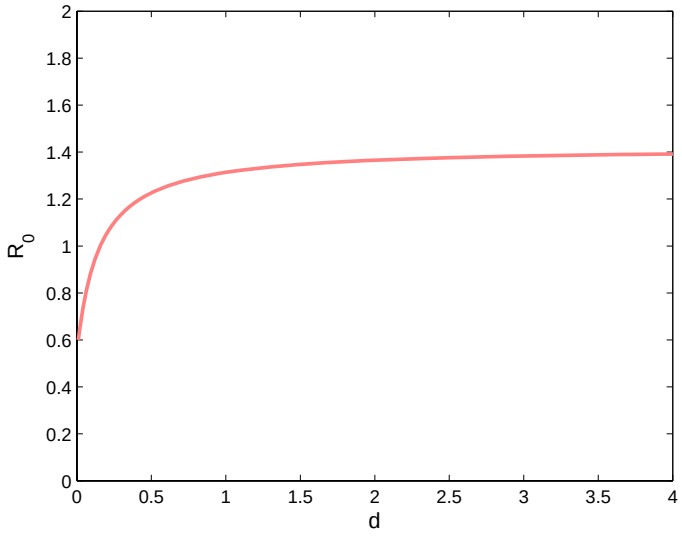

FIG. 4. $R_0 > 1$ *when* $d > 0.1574$.

the cases where $\alpha > 0.9$, the basic reproduction numbers tend to go down because the net spatial flow of population mobility is directed toward the better patch. Note that the basic reproduction number when $\alpha = 3$ is lower than 1 when the dispersal rate d is greater than a critical value. However, if $\alpha \geq 4$, the basic reproduction number fluctuates about the threshold value 1 for medium d. This cannot be interpreted in the manner above, and we should consider the collective effect of population sizes of two patches and the immigration of infectives. Hence, some unexpected effects of spatial disease transmission can be produced by population mobility.

It should be noted that there are distinctions in the demographies of the populations in two patches in the last example. However, we can find similar behavior even when the demographies of the populations in two patches are the same. Such an example can be obtained if we fix $A_1 = A_2 = 0.8$, $H_1 = H_2 = 0.9$, $\tau = 1$, $\mu_1 = \mu_2 = 0.2$, $r_1 = r_2 = 0$, $d_2 = d$ and $d_1 = \alpha d$, $b_1 = 0.01\alpha d$, $b_2 = 0.01d$.

Example 4.2. We fix $A_1 = 1$, $A_2 = 0.6$, $\tau = 1$, $k_1 = 0.1$, $k_2 = 0.1$, $\mu_1 = \mu_2 = 0.2$, $H_1 = 0.05$, $H_2 = 0.1$, $r_1 = 0$, $r_2 = 0$ and $b_1 = 0.01d$, $b_2 = 0.002d$, $d_1 = d$, $d_2 = 0.01d$. These values are different from those in the last example only in k_1 and migration rates. Now, $R_{01} = 0.6432$ and $R_{02} = 0.5438$. This means that if the two patches are isolated, the disease dies out in the two patches. When we have the migration rates, we see that the disease spreads in the two patches when $d > 0.1574$ (see Figure 4). Hence, the mobility of individuals in this case facilitates the spread of the disease. Note that the disease transmission coefficients of two patches are the same. We need to check the demography of two patches to reveal the mechanism of epidemiological changes. When the patches are disconnected, the condition for the prevalence of the disease in the ith patch is $S_i^* > 11.0333$. When $d > 0$, we see that S_1^* is a decreasing function of d, and S_2^* is an increasing function of d. Thus, when d increases, individuals aggregate towards the second patch, and S_2^* reaches 11.0333 at $d = 0.1573$. However, the basic reproduction number R_0 of the coupled system remains less than 1 for $0.1573 < d < 0.1574$. This seems to be related to the spatial heterogeneity. When

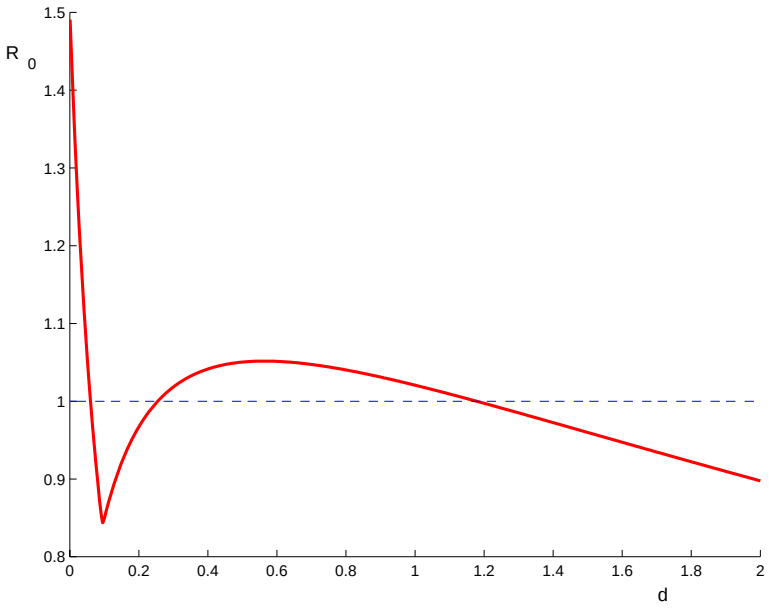

FIG. 5. *The graph of R_0 where there are multiple exchanges between persistence and extinction of the disease.*

$d > 0.1574$, we have $R_0 > 1$, which is a consequence of the aggregation of individuals in the second patch.

Example 4.3. We choose $A_1 = 1$, $A_2 = 0.6$, $\tau = 1$, $k_1 = 0.2$, $k_2 = 0.1$, $\mu_1 = \mu_2 = 0.21$, $H_1 = 0.09$, $H_2 = 0.1$ and $b_1 = 0.06d$, $b_2 = 0.4d$, $d_1 = d$, $d_2 = 0$. Numerical calculations show that R_0 crosses the critical value 1 three times at $d = 0.0601, 0.2546, 1.1784$ (see Figure 5). Hence, the disease admits three exchanges between persistence and extinction.

5. Discussions. In this paper, we have proposed an epidemic model to simulate the dynamics of disease transmission under the influence of a population dispersal among patches. The population dispersal among patches can be interpreted as the movements by which people travel or migrate from one city to another city or from one country to another country. We have incorporated a constant infection period into the model. Under the assumptions that the death rates, the disease transmission coefficients, the treatment rates, and the migration rates for infected individuals are constants, by using characteristic methods, we reduce the model to a time-delayed differential system. For this model, we have established a formula to compute the basic reproduction number, which extends the method in [26] of computing the basic reproduction number for multiple compartments governed by ordinary differential equations.

We have found that the longer the infection period is, the more likely it becomes that the disease will spread. We have shown that the disease cannot invade the population distributed in n patches if $R_0 < 1$ and invasion intensity is not strong, and the disease is uniformly persistent when $R_0 > 1$. If the disease spreads in the first isolated patch and dies out in the second isolated patch, by numerical calculations we have shown, in Example 4.1, that an increase of the ratio α between migration rates may lead to an increase of the basic reproduction number when α is small, lead

to the extinction of the disease in the two patches when α is larger, and lead to two switches between the persistence of the disease and extinction of the disease. Another example further shows that multiple switches between the persistence of the disease and extinction of the disease are possible. If the disease dies out in each isolated patch, we have shown that suitable migration rates may result in the outbreak of the disease in both patches.

We have assumed that the death rates, the infection force, the treatment rates, and the migration rates for infected individuals are independent of infection age. It is interesting to study the case where they are age-dependent. We leave this as future work.

Acknowledgments. We are very grateful to two anonymous referees for their careful reading and valuable comments which led to improvements of our manuscript.

TRAVELING FRONTS IN PRESSURE-DRIVEN COMBUSTION*

FATHI DKHIL† AND K. P. HADELER‡

Abstract. Brailovsky and Sivashinsky have proposed a model for pressure-driven combustion in the form of a degenerate parabolic system for temperature, concentration, and pressure. It is shown that the existence and uniqueness problem for traveling front solutions can be completely solved by exploiting the existing invariants and by phase plane methods. The approach yields exact propagation speeds which are noticeably larger than the approximations obtained so far.

Key words. combustion, deflagration, traveling front, reaction diffusion

1. Introduction. Brailovsky and Sivashinsky [2], [3] and Brailovsky, Frankel, and Sivashinsky [4] have proposed a model for pressure-driven subsonic combustion in a porous medium (deflagration as opposed to detonation). The model neglects inertia effects, and it does not produce shocks but traveling fronts; see Figure 1.1. This model and some modifications have been studied in a series of subsequent papers [5], [12], [13], [11], [7]; see also [6]. The analysis of the model is centered around the existence and uniqueness of traveling front solutions and their stability. Brézis, Kamin, and Sivashinsky [5] impose an additional condition derived from the behavior at the leading edge of the front and thus obtain a simplified system in the form of a degenerate diffusion system for temperature and pressure alone. Then they reduce the traveling

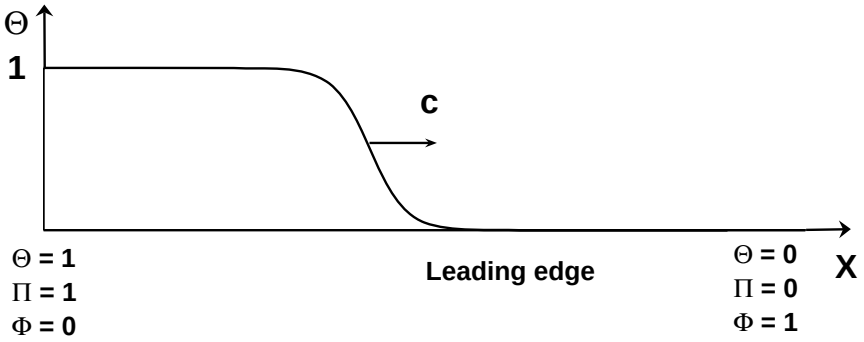

FIG. 1.1. *Deflagration front. Before the leading edge (right): temperature* $\Theta = 0$*, pressure* $\Pi = 0$*, and concentration* $\Phi = 1$*. Behind the front (left): temperature* $\Theta = 1$*, pressure* $\Pi = 1$*, concentration* $\Phi = 0$*. All quantities are given in nondimensionalized units.*

front problem to the discussion of a nonautonomous scalar differential equation. In the present paper we find a conservation law for the system of partial differential equations. In the four-dimensional system of ordinary differential equations for the shapes and speeds of traveling fronts we can use this conservation law and a second invariant to reduce the problem to a system in dimension two, which can be treated by phase plane methods.

In section 2 we define the full problem and the simplified problem and exhibit a conservation law. Section 3 consists of two parts, reduction of the four-dimensional traveling front problem to a two-dimensional problem (which works for general nonlinearities) and solution of the specific combustion problem. In section 4 we discuss the differences between the two models in quantitative terms (with proofs deferred to an appendix). In section 5 we present some results on a limiting case (gas near ignition temperature everywhere) without giving the proofs in detail. Finally, in a conclusion, section 6, we sketch the essentials of the analytic approach and mark the point from which one must use numerics.

2. The combustion problem. The original problem [2] reads

$$\begin{aligned} \gamma\Theta_t - (\gamma-1)\Pi_t &= \Omega(\Phi,\Theta), \\ \Phi_t &= -\Omega(\Phi,\Theta), \\ \Pi_t - \Theta_t &= \Delta\Pi, \end{aligned} \tag{2.1}$$

with

$$\Omega(\Phi,\Theta) = \Phi g(\Theta), \tag{2.2}$$

where $g(\Theta)$ is a nondecreasing function and $\gamma > 1$.

The variables Θ, Φ, and Π correspond, after suitable normalization, to the temperature $\Theta \in [0,1]$, the concentration of the deficient reactant $\Phi \in [0,1]$, and the pressure $\Pi \in [0,1]$. The function g describes the reaction rate as a function of temperature, and the constant γ is the specific heat ratio.

The function g is continuous and piecewise differentiable. There is some $\beta \in (0,1)$ such that $g(\Theta) = 0$ for $0 \le \Theta \le \beta$ and $g(\Theta) > 0$ for $\beta < \Theta \le 1$.

The number β is the ignition temperature. There are various stationary states of the gas with temperature below ignition and any pressure and concentration. In [2] it is assumed that prior to combustion (at the leading edge of the front; see Figure 1.1) the state is

$$\Theta = 0, \quad \Phi = 1, \quad \Pi = 0 \tag{2.3}$$

and that

$$\Theta = 1, \quad \Phi = 0, \quad \Pi = 1 \tag{2.4}$$

after the combustion process has been completed. As a deflagration front passes through, the state of the gas passes from (2.3) to (2.4). Hence a traveling front (traveling from left to right) is a wave solution of the system (2.1) which satisfies (2.3) at $x = +\infty$ and (2.4) at $x = -\infty$.

By linearly combining the equations, the system (2.1) can be written in the form of a standard dynamical system with only one time derivative in each equation:

$$\begin{aligned} \Pi_t &= \gamma\Delta\Pi + \Phi g(\Theta), \\ \Theta_t &= (\gamma-1)\Delta\Pi + \Phi g(\Theta), \\ \Phi_t &= -\Phi g(\Theta). \end{aligned} \tag{2.5}$$

Hence it is obvious that the model (2.1) is a degenerate parabolic system.

The approach in [5] is based on the following idea. If the explosion were homogeneous, then the spatial derivatives would vanish. Then, whatever the reaction term $\Omega(\Phi, \Theta)$ is, $\Theta + \Phi$ and $\Pi + \Phi$ are constants. Using the initial conditions (2.3), one finds

$$\Phi = 1 - \Theta. \tag{2.6}$$

If this equation is used to eliminate Φ from (2.5), then one arrives at

$$\begin{aligned} \Pi_t &= \gamma \Delta \Pi + (1 - \Theta) g(\Theta), \\ \Theta_t &= (\gamma - 1) \Delta \Pi + (1 - \Theta) g(\Theta). \end{aligned} \tag{2.7}$$

The authors of [5] discuss the problem of traveling fronts for the system (2.7), subject to the boundary condition $\Pi = \Theta = 0$ at the leading edge and $\Pi = \Theta = 1$ after the front has passed. But we observe that the system (2.5) has a conservation law, and hence we can improve on [5].

PROPOSITION 2.1. *For a given solution of the system* (2.5) *the function*

$$\Phi + \gamma \Theta - (\gamma - 1) \Pi \tag{2.8}$$

does not depend on the variable t.

Proof. In (2.5) check the equation $\Phi_t + \gamma \Theta_t - (\gamma - 1) \Pi_t \equiv 0$. □

The physical interpretation of (2.8) is evident. It says that, for a given solution, at a given space point, the expression (2.8) does not change in time, or, in other words, the pressure is determined by the remaining reactant and the temperature. Equation (2.8) could be used to eliminate the variable Φ from (2.5) and to obtain a system for the two variables Π and Θ which, however, has coefficients that explicitly depend on the space variable.

Of course (2.6) is based on a rather crude assumption since, away from the leading edge, the front is far from equilibrium. It is known that for certain diffusive traveling front problems (Fisher–KPP with concave nonlinearity) the speed is determined by the linearization at the leading edge (see [1], [8], [9], [10], [14]), but this is not so for combustion problems in general. For these reasons we treat the full problem here, whereby we can use (2.8).

3. Traveling fronts for the full problem. We look for traveling fronts of the problem (2.5) and for the simplified problem (2.7). We show the following result.

THEOREM 3.1. *If* $\gamma(1 - \beta) \leq 1$, *then there are no traveling fronts for the full system nor for the simplified system since the specific heat ratio is too small or the ignition temperature is too high. If* $\gamma(1 - \beta) > 1$, *then the full system has a traveling front solution with speed* $c(1)$, *and the simplified system has a traveling front solution with speed* $c(0)$. *In either case the front is unique up to translation. Furthermore,* $c(0) < c(1)$.

3.1. Reduction of the problem. For the proof we make a traveling wave ansatz in (2.5): $\Pi = \Pi(x - ct)$, $\Theta = \Theta(x - ct)$, $\Phi = \Phi(x - ct)$ with $c > 0$. We get a system of order four (counting the derivatives):

$$-c\Pi' = \gamma \Pi'' + \Phi g(\Theta), \tag{3.1}$$

$$-c\Theta' = (\gamma - 1)\Pi'' + \Phi g(\Theta), \tag{3.2}$$

$$-c\Phi' = -\Phi g(\Theta). \tag{3.3}$$

The $'$ denotes the derivative with respect to the traveling wave coordinate $x - ct$. We look for solutions of this system which satisfy the boundary conditions (2.3) at $+\infty$ and (2.4) at $-\infty$. We recover (2.8) as an invariant of motion and find another invariant.

PROPOSITION 3.2. *The system* (3.1), (3.2), *and* (3.3) *has one invariant of motion independent of the parameter c,*

$$\Phi + \gamma\Theta - (\gamma - 1)\Pi = \text{const}, \tag{3.4}$$

and another invariant of motion depending on the parameter c,

$$\Pi' + c(\Pi - \Theta) = \text{const}. \tag{3.5}$$

Proof. We subtract (3.2) from (3.1), get $-c\Pi' + c\Theta' = \Pi''$, integrate, and obtain (3.5). We add (3.1) and (3.3), get $-c\Pi' - c\Phi' = \gamma\Pi''$, integrate, and get

$$\gamma\Pi' + c\Pi + c\Phi = \text{const}. \tag{3.6}$$

Combining (3.5) and (3.6) yields (3.4). □

Using the condition (2.3) at the leading edge, we get from (3.4) and (3.5) for traveling fronts the equations

$$\Pi' = c\theta - c\Pi \tag{3.7}$$

and

$$\Phi = 1 - \Theta + (\gamma - 1)(\Pi - \Theta), \tag{3.8}$$

from which the difference from (2.6) is obvious. Now we use (3.7), (3.2), and (3.8) to get a system for the variables Π and Θ,

$$\begin{aligned} \Pi' &= c\Theta - c\Pi, \\ \Theta' &= c\frac{\gamma - 1}{\gamma}(\Theta - \Pi) - \frac{1 - \Theta + (\gamma - 1)(\Pi - \Theta)}{c\gamma} g(\Theta). \end{aligned} \tag{3.9}$$

We have used two invariants of motion, and hence this system is of order two only.

On the other hand, for front solutions of the simplified system (2.7) we get another (three-dimensional) system for the variables Π and Θ,

$$\begin{aligned} -c\Pi' &= \gamma\Pi'' + (1 - \Theta)g(\Theta), \\ -c\Theta' &= (\gamma - 1)\Pi'' + (1 - \Theta)g(\Theta). \end{aligned} \tag{3.10}$$

Integration as before (using only one invariant) leads to a two-dimensional system

$$\begin{aligned} \Phi' &= c\Theta - c\Pi, \\ \Theta' &= c\frac{\gamma - 1}{\gamma}(\Theta - \Pi) - \frac{1 - \Theta}{c\gamma} g(\Theta). \end{aligned} \tag{3.11}$$

Now we are ready to compare the systems (3.9) and (3.11). We scale the independent variable by a factor c, and we introduce a parameter $\epsilon \in [0, 1]$ such that we can write both systems in the same form

$$\begin{aligned} \Pi' &= \Theta - c\Pi, \\ \Theta' &= \frac{\gamma - 1}{\gamma}(\Theta - \Pi) - \frac{1 - \Theta + \epsilon(\gamma - 1)(\Pi - \Theta)}{c^2\gamma} g(\Theta), \end{aligned} \tag{3.12}$$

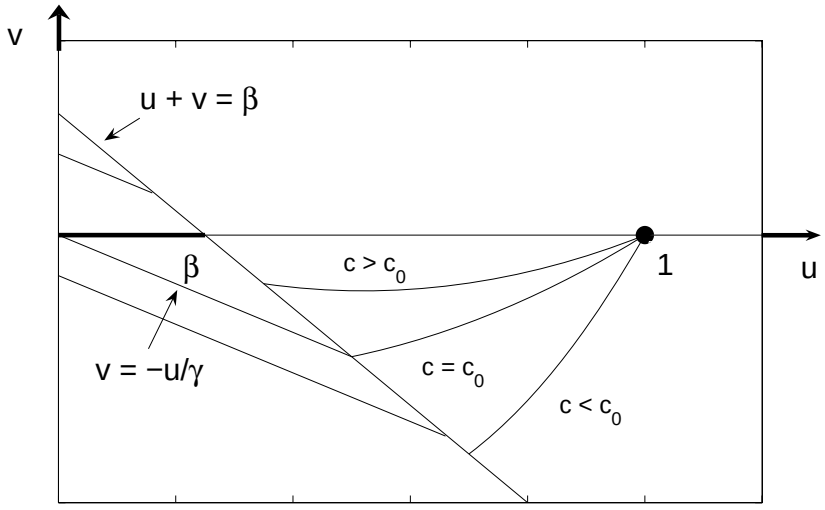

FIG. 3.1. *Schematic phase plane of the u, v-system for several values of c. There is an interval of stationary points between the origin and $(\beta, 0)$ and an isolated stationary point $(1, 0)$. For $c = c_0$ the unstable manifold of the saddle point $(1, 0)$ meets the straight line through the origin, which is the stable manifold of $(0, 0)$.*

with $\epsilon = 1$ for the full system (2.1) and $\epsilon = 0$ for the simplified system (2.7).

The system (3.12) can be further transformed by introducing new dependent variables (a similar substitution has been used in [5]):

$$u = \Pi, \qquad v = \Theta - \Pi. \tag{3.13}$$

The new system is

$$\begin{aligned} u' &= v, \\ v' &= -\frac{1}{\gamma} v - \frac{1}{c^2 \gamma}(1 - u - (1 + \epsilon(\gamma - 1))v) g(u + v). \end{aligned} \tag{3.14}$$

Now the boundary conditions read

$$\begin{aligned} u(+\infty) &= 0, \qquad v(+\infty) = 0, \\ u(-\infty) &= 1, \qquad v(-\infty) = 0. \end{aligned}$$

3.2. Qualitative analysis. We enter the qualitative analysis of the system (3.14). The phase plane is shown in Figure 3.1. There is an interval of stationary points $(u, 0)$ with $u \le \beta$ and an isolated stationary point $(1, 0)$, which is a saddle point. We are looking for a heteroclinic orbit, i.e., for a trajectory, for some value of c, which leaves the point $(1, 0)$ with the unstable manifold and ends at $(0, 0)$.

In the domain $u + v \le \beta$ the system is linear, $u' = v$, $v' = -v/\gamma$, and hence $-dv/du = 1/\gamma < 1$. Hence in this domain any trajectory follows a straight line which ends at one of the stationary points with $u \le \beta$. In particular, the trajectory ending at $(0, 0)$ lies on the straight line $v = -u/\gamma$. If we follow this line (backward in time), then it meets the line $u + v = \beta$ at the point

$$P_0 = (u_0, v_0) = (\beta\gamma/(\gamma - 1), -\beta/(\gamma - 1)). \tag{3.15}$$

The point $(1,0)$ is a saddle point. Consider the (negative part of the) unstable manifold of the saddle point. For any given $c>0$ it arrives at some point of the line $u+v=\beta$. Along the unstable manifold we have $(1-u-(1+\epsilon(\gamma-1))v)g(u+v)>0$ in view of $v<0$. Hence the factor of $-1/c^2\gamma$ in (3.14) is positive. Using this fact, one can show that the unstable manifolds for different c do not intersect (e.g., by the method of positively invariant sets; see [8]). Hence the unstable manifold depends on c in a monotone way. For very large c it arrives at the line $u+v=\beta$ at a point with v small. For very small positive c the unstable manifold arrives at that line near $u=1$, $v=-1/\gamma$. If $u_0\geq 1$, i.e., if $\gamma(1-\beta)\leq 1$, then there cannot be a heteroclinic connection. Next assume

$$\gamma(1-\beta)>1. \tag{3.16}$$

If c runs from 0 to $+\infty$, then there is exactly one value $c_0>0$ where the unstable manifold meets the point P_0 and thus forms a heteroclinic connection to $(0,0)$. Hence we have shown the following proposition.

PROPOSITION 3.3. *Suppose that* (3.16) *holds. For any choice of* $\epsilon\in[0,1]$ *there is exactly one value* $c=c(\epsilon)$ *such that the system* (3.14) *has a heteroclinic orbit connecting* $(1,0)$ *to* $(0,0)$.

If ϵ is increased from 0 to 1, then in (3.14), for given u, v, and c, the quantity v' is increasing, and hence the trajectory is moved upward; we have to increase c to move it down again to meet the point P_0. This argument shows that $c(\epsilon)$ is an increasing function. This argument can be worked out in detail using positively invariant sets. Hence Theorem 3.1 has been proved. □

4. Quantitative comparison. We have shown for the full system as well as for the simplified system the existence and uniqueness of the desired front solutions. The speeds $c(0)<c(1)$ are clearly different. The question arises whether the difference is small in some sense and whether $c(0)$ can be seen as a useful approximation. We just mention that in the limiting case $\beta=0$ (see below) the full problem and the simplified problem yield the same speed because that problem is linearly determined. However, for $\beta>0$ the two speeds are clearly different. To have something concrete at hand, we consider a caricature where at ignition temperature β the function $g(\Theta)$ jumps to some positive value κ and then stays constant,

$$g(\Theta)=\begin{cases}0, & 0\leq\Theta\leq\beta,\\ \kappa, & \beta<\Theta\leq 1.\end{cases} \tag{4.1}$$

Then the equations (3.14) become piecewise linear and can be solved explicitly. We get an explicit formula for $c(\epsilon)$,

$$c^2(\epsilon)=\kappa\frac{1+(1+\epsilon(\gamma-1))q}{q(1+\gamma q)},\quad \text{where}\quad q=\frac{\beta}{\gamma-1-\gamma\beta}. \tag{4.2}$$

Hence, as stated before, by choosing $\epsilon=0$ instead of $\epsilon=1$, the speed in underestimated. The effect becomes evident in the limit of large γ, where

$$c^2(\epsilon)\approx\kappa\gamma(1-\beta)\left(\frac{1-\beta}{\beta}+\epsilon\right). \tag{4.3}$$

5. The limiting case. The limiting case $\beta=0$ of the combustion problem can be interpreted as a situation of a traveling front moving into a gas which is at ignition

temperature but not yet burning. Then we have to be more specific about the shape of the nonlinearity. We assume

$$g(0) = 0, \quad g'(\Theta) > 0 \quad \text{for} \quad \Theta \geq 0. \tag{5.1}$$

Once the problem has been reduced to the system (3.14) for the variables u and v, the subsequent qualitative analysis, though complicated in the details, follows essentially the approach to the Fisher–KPP problem (see [8], [9]).

Linearization at the leading edge of the front yields two critical values for the speed c,

$$c_\pm = \sqrt{g'(0)}(\sqrt{\gamma} \pm \sqrt{\gamma - 1}). \tag{5.2}$$

PROPOSITION 5.1. *There is a number $c_0 \geq c_+$ such that for every $c \geq c_0$ the unstable manifold of $(1,0)$ connects to $(0,0)$ in such a way that the corresponding front is monotone. There are no monotone fronts for $c < c_0$.*

The speeds of monotone fronts form a half-line $[c_0, \infty)$. There are no such fronts for $c < c_+$, particularly not for $c < c_-$. Indeed, for $c \in (c_-, c_+)$ the point $(0,0)$ is a stable focus, and hence fronts (if they exist) are oscillating. For $c \in (0, c_-)$ the point $(0,0)$ is again a stable node. If the unstable manifold connects to $(0,0)$, then it first leaves the domain $u > 0$.

Now it remains to check whether the lower bound c_+ can be achieved. Here we use the subtangential condition (which in the Fisher case is sufficient for linear determinacy; see [9], [14]),

$$g(u) \leq g'(0)u. \tag{5.3}$$

The following proposition can be shown by comparison arguments.

PROPOSITION 5.2. *Assume that the function g satisfies the subtangential condition* (5.3). *Then $c_0 = c_+$.*

We remark that a unique traveling front can also be shown to exist for "bistable" nonlinearities such as $g(\Theta) = \Theta(\Theta - \alpha)$ with some $\alpha > 0$.

6. Conclusion. The combustion model of Brailovsky and Sivashinsky is, in mathematical terms, a degenerate parabolic system. Therefore one expects deflagration fronts traveling with asymptotically constant shape and speed. Shape and speed can be found from a nonlinear boundary value problem for a system of ordinary differential equations of order four with boundary conditions at infinity. In this paper we have found a new conservation law for the full system of partial differential equations, which yields an invariant of motion for the ordinary differential equations. The latter have a second invariant of motion independent of the first. With these two invariants and some invertible transformation we can reduce the four-dimensional problem to a two-dimensional problem, which can be treated by phase plane methods. These analytical steps work for the given system as well as for the simplified system which was studied by Brézis, Kamin, and Sivashinsky and further for a one-parameter family of problems connecting the full system and the simplified system. This approach yields the exact speed of propagation. A comparison property shows that it is always larger than the previously obtained estimates. Concrete examples show that discrepancy between the correct solution and these estimates can be very large.

In contrast to the traveling front problem for the Fisher equation where the well-known formula $c_0 = 2\sqrt{Df'(0)}$ holds under rather general concavity assumptions on the nonlinearity f, here in the combustion problem there is no explicit simple formula

(and cannot be); i.e., in concrete examples (other than in limiting cases as in the appendix) the two-dimensional boundary value problem (3.14) must be solved by a numerical method, e.g., by a shooting method starting at the unstable manifold of the stationary point behind the front $(1,0)$.

7. Appendix. Proof of formula (4.2). First observe that c^2 scales with κ, and hence we can choose $\kappa = 1$. In the domain $u + v > \beta$ we have

$$\begin{aligned} u' &= v, \\ v' &= -\frac{1}{c^2\gamma} + \frac{u}{c^2\gamma} - \frac{1}{c^2\gamma}(1 + \epsilon(\gamma - 1) - c^2)v. \end{aligned}$$

This is an inhomogeneous linear system. The stationary point $(1,0)^T$ yields a special constant solution. The homogeneous system has a 2×2 matrix with a positive and a negative eigenvalue (recall that $(1,0)$ is a saddle point). The positive eigenvalue λ_1 corresponds to the unstable manifold:

$$\lambda_1 = \frac{1 + \epsilon(\gamma - 1) - c^2}{2c^2\gamma} + \frac{1}{2c^2\gamma}\left[(1 + \epsilon(\gamma - 1) - c^2)^2 + 4c^2\gamma\right]^{1/2}.$$

The eigenvector is $(1, \lambda_1)^T$; hence the unstable manifold is given by

$$\begin{pmatrix} 1 \\ 0 \end{pmatrix} - \begin{pmatrix} 1 \\ \lambda_1 \end{pmatrix} e^{\lambda_1 t}. \tag{7.1}$$

This manifold is supposed to meet the point P_0 given in (3.15) for some value of t. This condition yields two equations,

$$1 - e^{\lambda_1 t} = \frac{\gamma}{\gamma - 1}\beta, \qquad -\lambda_1 e^{\lambda_1 t} = -\frac{1}{\gamma - 1}\beta. \tag{7.2}$$

We eliminate $e^{\lambda_1 t}$ and get

$$\lambda_1\left(1 - \frac{\gamma}{\gamma - 1}\beta\right) = \frac{1}{\gamma - 1}\beta. \tag{7.3}$$

Recall that λ_1 depends on c. In (7.3) we solve for c and get the explicit formula (4.2).

SMALL- AND WAITING-TIME BEHAVIOR OF A DARCY FLOW MODEL WITH A DYNAMIC PRESSURE SATURATION RELATION*

J. R. KING† AND C. M. CUESTA‡

Abstract. We address the small-time evolution of interfaces (fronts) for the pseudoparabolic generalization

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(u^\alpha \frac{\partial u}{\partial x} + u^\beta \frac{\partial^2 u}{\partial x \partial t}\right)$$

of the porous-medium equation, identifying regimes in which the local behavior remains fixed for some finite time and others in which it changes instantaneously. A number of phenomena beyond those exhibited by the porous-medium equation are elucidated, including retreating fronts and novel types of local behavior. Related results for the important limit case

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(u^\beta \frac{\partial^2 u}{\partial x \partial t}\right)$$

are also described.

Key words. degenerate pseudoparabolic equation, small-time behavior, waiting-time phenomena, time-reversibility

1. Introduction.

In this paper we consider the Cauchy problem for the degenerate pseudoparabolic equation

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(u^\alpha \frac{\partial u}{\partial x} + u^\beta \frac{\partial^2 u}{\partial x \partial t}\right), \tag{1.1}$$

where α and β are positive constants, with initial condition $u(x,0) = u_0(x)$ having $u_0(x) = 0$ for $x \geq a$ which, for definiteness, we take to satisfy

$$u_0(x) \sim A(a-x)_+^p \quad \text{as } x \to a \tag{1.2}$$

for some positive constants A and p. Since we are concerned here with the local behavior near the right-hand interface $x = a$, that near the left-hand one (if there is one) need not concern us. We shall need to defer detailed discussion of the boundary conditions which can hold at an interface $x = s(t)$ until we have analyzed the permissible local behavior of solutions. However, we shall throughout impose the conservation of mass condition

$$u^\alpha \frac{\partial u}{\partial x} + u^\beta \frac{\partial^2 u}{\partial x \partial t} = 0 \quad \text{at } x = s(t)\,. \tag{1.3}$$

Aspects of the physical background to (1.1) are given in [21] and [10]; see also [11]. We summarize these here. The model equation for unsaturated flow in porous media with a dynamic capillary pressure relation has the general form

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(K(u)\,\frac{\partial}{\partial x}\left(-p_c(u) + L\,\frac{\partial u}{\partial t}\right)\right). \tag{1.4}$$

The unknown is the water saturation u in a horizontally placed one-dimensional porous medium, $K(u)$ is the hydraulic conductivity, $p_c(u)$ is the capillary pressure function, and L can be regarded as a damping coefficient. Under the assumption that the water saturation u is small, adopting power laws for these nonlinear functions of u leads to (1.1). Typically $p_c(u)$ is a nonincreasing function, such that $p_c'(0^+) = \infty$, and $K(u)$ is increasing, with $K(0) = K'(0) = 0$. According to these criteria, when (1.1) provides a small u approximation to (1.4) the exponents necessarily satisfy $\alpha < \beta$; nevertheless we consider here all possible positive α and β for completeness and because of other possible applications. We note that (1.4) combines conservation of mass and Darcy's law with the pressure-saturation relation

$$p_c(u) = p_a - p_w + L\,\frac{\partial u}{\partial t} \quad (L > 0)\,, \tag{1.5}$$

where p_a and p_w denote the air and water pressures. This equation is the classical capillary-pressure relation extended by a relaxation term ($L > 0$), and models capillary forces, taking into account dynamic effects. This extension of the Darcy flow model is based on the approach introduced in [19], motivated by previous experimental work by Stauffer [32], among others; see [17] and [18] for an overview. Earlier related models can be found in [6], [4], and [3]. For derivations of (1.1) on the basis of homogenization and hysteresis ideas, see also [7] and [20], respectively. Third order mixed derivatives terms also appear as regularizations of forward-backward diffusion equations as in [30], and in the viscous Cahn–Hilliard equation [29]; other degenerate regularizations of forward-backward equations arise in the case of the viscous Cahn–Hilliard equation with degenerate mobility (see [14]) and as a model for poroviscous thin-film flows, which relates closely to (1.1); see [26]. Equation (1.1) can be obtained as a (somewhat ad hoc) model of thin-film flows of viscoelastic fluids, with $\alpha = \beta = 3$ (no slip) or $\alpha = \beta = 2$ (strong slip), if instead of surface tension (see [31]) gravity is considered as the driving force, the usual Reynolds equation being replaced for a "Maxwell" fluid by

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(u^\alpha\,\frac{\partial}{\partial x}\left(p + \tau\,\frac{\partial p}{\partial t}\right)\right)$$

(where u is the film thickness, p the pressure, and τ the relaxation time). Finally we mention the work by Düll [13], where (1.1) with $\alpha = \beta$ appears as a model of case II diffusion in polymers.

Observe that the classical capillary pressure relation ($L = 0$ in (1.5)) yields the familiar porous-medium equation (PME)

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(u^\alpha\,\frac{\partial u}{\partial x}\right). \tag{1.6}$$

This equation is very widely studied as a paradigm degenerate-diffusion equation; see [1]. An interesting property of the PME is the occurrence of fronts: interfaces

that, in terms of saturation, separate wet ($u > 0$) and dry ($u = 0$) regions. Many of the intriguing phenomena we shall discuss for (1.1) arise even in the absence of the diffusion term, i.e., for

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x}\left(u^{\beta}\frac{\partial^2 u}{\partial x \partial t}\right), \tag{1.7}$$

though in the case of (1.7) the evolution has to be forced somehow since the solution to the Cauchy problem is simply $u = u_0(x)$. Equation (1.7) with $\beta = 1$ governs (see [15] and the references therein) the thin-film limit of the Hele–Shaw problem with linear kinetic undercooling (similarly, (1.1) with $\alpha = \beta = 1$ arises when both gravity and kinetic undercooling are present) and, to the best of our knowledge, first arose [23] in the description of the growth of oxide layers during the fabrication of silicon integrated circuits. It is also a limit case of (1.1) for large α (for $u < 1$), and it is striking that, because only the time derivative of u appears inside the highest spatial derivative, it typically does not smooth nonanalyticities in the initial data. Equation (1.7) is formally time-reversible (i.e., invariant under $t \to -t$), but it is instructive to highlight straight away one of the noteworthy consequences that follow from the analysis later in the paper, namely, that this time-reversibility is in fact illusory. Thus we consider (1.7) with $\beta = 1$, say, subject to suitable compactly supported nonnegative initial data in $x > 0$ and to

$$u(t) = \int_0^t P(\tau)d\tau \quad \text{at } x = 0\,, \tag{1.8}$$

with the inlet pressure $P(t)$ prescribed. Were the problem time-reversible, then if, say, the sign of P changes at $t = t_1$ such that the right-hand side of (1.8) returns to zero at $t = t_2 > t_1$, then at $t = t_2$ we would simply recover the initial data for all x. If $P > 0$ for $0 < t < t_1$ and $P < 0$ for $t_1 < t < t_2$ (for brevity we consider only a single change in sign), this is indeed what transpires for the problem formulation described later in the paper, which implies here that u has zero slope at the interface throughout $0 < t < t_2$ (corresponding to the motion of a thin film of fluid in a Hele–Shaw cell over a flat substrate which it completely wets, in the sense of the contact angle at an advancing contact line being zero; advancing and retreating contact lines have distinct behaviors for reasons which are to some extent implicit in the analysis of [15] and are addressed in detail below). However, in the converse case the interface retreats for $0 < t < t_1$ (while P is negative; we assume it is not so negative that the interface reaches $x = 0$) with u in general having finite slope there, implying that this retraction is nonreversible: while the interface advances again for $t_1 < t < t_2$ (with $P > 0$), it does so with zero contact angle and the initial conditions are not recovered. The unregularized Hele–Shaw problem and the Hele–Shaw problem with linear kinetic undercooling share formal time-reversibility. In the former case the suction (negative-pressure) problem typically leads to finite-time singularities through which the solution cannot usually be meaningfully continued (see, for example, [12] and the references therein); in the latter case the kinetic-undercooling regularization ensures that, even if singularities form, the solution can be continued through them and the failure of time-reversibility has important implications for this and other such problems, some of which are explored briefly below. Thus the formulation (1.7) is an important problem in its own right, the theory for which is in its infancy compared to that of (1.6), and our results, notably those of the appendix, encompass this special case of (1.1).

In the context of occurrence of fronts, Hulshof and King [21] studied the behavior of solutions near fronts for (1.1). They show that for $2 \le \beta < 2\alpha$ the interface remains fixed (at $x = a$) for all time and the solution develops a discontinuity there with

$$u(a^-, t) = U(t),\ u(a^+, t) = 0\,. \tag{1.9}$$

We emphasize that the solution is then genuinely discontinuous, with $u = 0$ holding for all t throughout $x > a$. By contrast, in the other two ranges of (α, β) the front moves, and behaves locally as a traveling wave. In the range $\beta > 2\alpha$ the moving-front behavior is of PME type, whereas in the range $\beta < \min(2, 2\alpha)$ the second order term in (1.1) is irrelevant at the front, and the behavior of the moving front is "new." In the fixed-front cases (1.3) with $s(t) = a$ suffices to furnish a correctly specified problem, but in the moving-front cases additional conditions involving appropriate prescriptions of the local behavior are required; these are formulated in section 3 below.

It is well known for (1.6) that interfaces can either move immediately or remain fixed for a finite time (the waiting time) and then start to move; see, for instance, [8] and [2]. The purpose of this paper is to investigate such phenomena for (1.1). In some fixed-front cases we shall find that $U(t) > 0$ for all $t > 0$, while in the remainder (which we term "waiting-time" cases) we have

$$U(t) = 0 \quad \text{for} \quad 0 \le t \le t_w, \quad U(t) > 0 \quad \text{for} \quad t > t_w \tag{1.10}$$

for some waiting time $t_w > 0$. ($U(t)$ may in principle return to zero for some $t > t_w$, but we shall not investigate such cases here.) In other ranges of (α, β) the interfaces move, at least for sufficiently large t. In some of these cases we shall see that the right-hand interface, $x = s(t)$ with $s(0) = a$, satisfies $s(t) > a$ for all $t > 0$, while for the waiting-time regimes we have

$$s(t) = a \quad \text{for} \quad 0 \le t \le t_w\,. \tag{1.11}$$

We note that in some regimes both retreating and advancing fronts are possible so that, in contrast to (1.6), $s(t) > a$ need not hold for $t > t_w$. Waiting-time solutions should not be confused with fixed-front cases, even though (1.11) is satisfied by both; in view of the first expression in (1.10), fixed- and moving-front regimes are indistinguishable during the waiting period, but $U > 0$ ultimately applies in the former case, distinguishing waiting fronts (having $U = 0$) from fixed ones.

Our analysis here aims to clarify such matters by analyzing the local behavior close to $x = a$; moreover, we shall also identify retreating-front cases whereby $s(t) < a$ for sufficiently small positive t, say. The goal of this paper is thus to develop a comprehensive small-time classification of (1.1)–(1.2) comparable to that established for the PME in [16], [27] (see also [28]) and, in doing so, to identify new types of qualitative behavior which are of significance beyond the small-time regime; we shall see that the range of possibilities for (1.1) is significantly richer than that for (1.6).

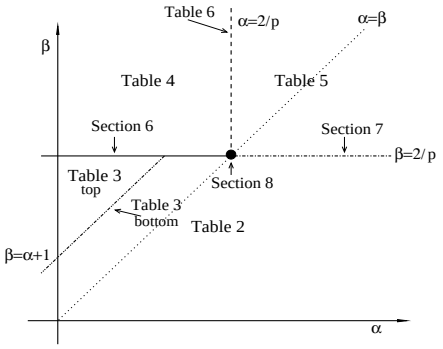
In the next two sections we give the necessary ingredients for our subsequent analysis. In section 3 we reexamine the local balances for (1.1) and identify regimes of α and β in which retreating fronts are possible. We then turn to the analysis of the different relevant small-time regimes. Most of these are for brevity summarized in tables (we refer the interested reader to [24], where the analysis of all cases is given explicitly). Section 5 examines cases in which (1.6) dominates the local behavior, a first case where there is no waiting-time, a case where there are "global" waiting-time scenarios (cf. [27] for (1.6)), and the "local" waiting-time case (cf. [28] for (1.6)).

TABLE 1

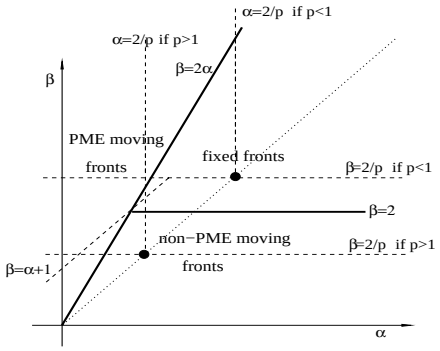
Each table or section listed below describes a distinct small-time regime. In the borderline cases we have fronts that move exponentially slowly with t. For a discussion of the distinction between "global" and "local" cases see the relevant sections below. "Immediate change" means the local solution instantaneously adjusts, but a waiting-time scenario may still ensue.

	$\beta < \alpha + 1$	$\beta = \alpha + 1$	$\beta > \alpha + 1$
$p < 2/\beta$ non-PME balance	Table 2[1]	Table 3 (bottom)	Table 3 (top)
	no waiting time		

	$p > 2/\alpha$	$p = 2/\alpha$	$p < 2/\alpha$
$p > 2/\beta$ PME balance	Table 5[1] "global" waiting time	Table 6 ($\beta > \alpha$) "local" waiting time	Table 4 ($\beta > \alpha$) no waiting time
$p = 2/\beta$ non-PME balance	Section 7 ($\beta < \alpha$) (I) immediate change (II) "global" waiting time (III) immediate change (borderline)	Section 8[1] ($\alpha = \beta$) (I) no waiting time (II) "local" waiting time (III) no waiting time (borderline)	Section 6 ($\beta > \alpha$) immediate change



(a) Regimes in the (α, β)-plane for fixed p.



(b) The regimes relevant to the small-time behavior and the moving-fixed-front cases.

FIG. 1. *The (α, β)-plane.*

Sections 5 and 6 discuss other non-waiting-time cases. Sections 7 and 8 discuss critical cases ($p = 2/\beta$ with $\beta < \alpha$ and $p = 2/\alpha$ with $\beta = \alpha$) in which the behavior is rather delicate (and novel) and we conclude in section 9 with a discussion.

Table 1 gives a summary of the results of small-time analysis. Figure 1 illustrates these regimes in the (α, β)-plane, together with the relevant moving/fixed front ranges. We observe that although in section 5 (i.e., for the case $p > 2/\beta$) the dominant balance is of PME type, the behavior may differ from PME, since this regime lies partially in the fixed-front ranges and partially in the non-PME moving-front range found in [21]; see Figure 1(b).

[1]Relevant regimes for the applications with $\alpha = \beta$; see the introduction.

2. Method/preliminaries. In order to identify the appropriate small-time behavior, we first introduce the small-time (outer) expansion

$$u \sim u_0(x) + u_1(x)t \qquad \text{as } t \to 0^+ \quad \text{with } a - x = O(1)\,, \tag{2.1}$$

which at leading order gives the equation

$$u_1 - \frac{d}{dx}\left(u_0^\beta \frac{du_1}{dx}\right) = \frac{d}{dx}\left(u_0^\alpha \frac{du_0}{dx}\right)\,. \tag{2.2}$$

The relevant boundary conditions on (2.2) will be noted as they arise. The expansion (2.1) may be nonuniform as $x \to a$, depending on the behavior of $u_0(x)$. If it is, then it is typically necessary to introduce a local similarity variable $\eta = (x-a)/t^\omega$, where ω needs to be identified, and consider the inner region $\eta = O(1)$ as $t \to 0^+$. It will be necessary to distinguish several regimes. Observe that in (2.2) the first term of the left-hand side dominates the second as $x \to a$ if $p > 2/\beta$, while the second dominates the first if $p < 2/\beta$. In the latter case, and in the borderline case $p = 2/\beta$, the sign of $\beta - (\alpha+1)$ dictates the dominant balance as $x \to a$. This leads us to distinguish regimes for which we will have different similarity (inner) behavior.

We now summarize some possible small-time balances in (1.1); these will provide the crucial ingredients in the analysis that follows. First, if we assume that the solution is of the form $u(x,t) \sim t^\gamma f(\eta)$ for small t, then by (1.1) possible small-time balances can be identified from

$$\gamma f - \omega\eta\frac{df}{d\eta} \sim t^{\alpha\gamma-2\omega+1}\frac{d}{d\eta}\left(f^\alpha\frac{df}{d\eta}\right) + t^{\beta\gamma-2\omega}\frac{d}{d\eta}\left(f^\beta\left((\gamma-\omega)\frac{df}{d\eta} - \omega\eta\frac{d^2f}{d\eta^2}\right)\right)\,. \tag{2.3}$$

This gives the following possibilities.

(i) If all the terms of (2.3) balance as $t \to 0^+$, then $\omega = \beta/2(\beta-\alpha)$, $\gamma = 1/(\beta-\alpha)$ and

$$u \sim t^{\frac{1}{(\beta-\alpha)}}\, f\left((x-a)/t^{\frac{\beta}{2(\beta-\alpha)}}\right) \quad \text{if } \beta \neq \alpha\,, \qquad u \sim (a-x)^{\frac{2}{\alpha}}\, f(t) \quad \text{if } \beta = \alpha\,, \tag{2.4}$$

which give exact similarity reductions of (1.1).

(ii) If the left-hand side and the first term on the right-hand side of (2.3) dominate as $t \to 0^+$, we get a one-parameter (γ) family of similarity solutions with $\omega = (1+\alpha\gamma)/2$, so

$$u \sim t^\gamma f\left((x-a)/t^{\frac{1}{2}(1+\alpha\gamma)}\right) \quad \text{as} \quad t \to 0^+\,. \tag{2.5}$$

This is a similarity reduction of the PME limit of (1.1), (1.6) and is consistent for (1.1) as $t \to 0^+$ (i.e., the omitted terms in (2.3) are indeed negligible) when $\gamma > 0$ if $\beta > \alpha$ with $\gamma > 1/(\beta-\alpha)$; the precise value of γ can readily be determined from that of p in (1.2) (see below).

(iii) If the left-hand side and the last term of the right-hand side in (1.1) balance and dominate as $t \to 0^+$, then the small-time behavior might be of the form

$$u \sim \Omega^{\frac{2}{\beta}}(t) f\left((x-a)/\Omega(t)\right)\,, \tag{2.6}$$

which is a similarity reduction of (1.7) for any $\Omega(t)$, and hence f satisfies the equation

$$f - \frac{\beta}{2}\eta\frac{df}{d\eta} = \frac{d}{d\eta}\left(f^\beta\frac{d}{d\eta}\left(f - \frac{\beta}{2}\eta\frac{df}{d\eta}\right)\right)\,. \tag{2.7}$$

We observe that the required solution to this equation, supplemented with appropriate boundary and initial conditions, can in a number of cases be written in closed form by noting that

$$u^\beta = \frac{\beta^2}{2(2-\beta)}(s(t)-x)^2 \tag{2.8}$$

is an exact solution of (1.7) for any $s(t)$. Writing $s(t) - a \sim \eta_0\Omega(t)$ we thus have the similarity solution

$$f^\beta(\eta) = \frac{\beta^2}{2(2-\beta)}(\eta_0-\eta)^2\,. \tag{2.9}$$

In many cases that follow it will suffice to restrict our attention to the special one-parameter (power-law) case (the parameter being again γ)

$$u \sim t^\gamma f\left((x-a)/t^{\frac{\beta\gamma}{2}}\right) \quad \text{as} \quad t \to 0^+\,, \tag{2.10}$$

whereby $\omega = \beta\gamma/2$, which, from (2.3), is consistent for (1.1) when $\gamma > 0$ if $\alpha < \beta$ with $\gamma < 1/(\beta-\alpha)$ or if $\alpha \geq \beta$.

(iv) If the two terms of the right-hand side balance and dominate as $t \to 0^+$, then $\gamma = 1/(\beta-\alpha)$ and the expected small-time behavior is of the one-parameter (namely, ω) form

$$u \sim t^{\frac{1}{(\beta-\alpha)}} h\left((x-a)/t^\omega\right) \quad \text{as} \quad t \to 0^+\,, \tag{2.11}$$

which gives a similarity reduction to

$$\frac{\partial}{\partial x}\left(u^\alpha \frac{\partial u}{\partial x}\right) \sim -\frac{\partial}{\partial x}\left(u^\beta \frac{\partial^2 u}{\partial x \partial t}\right) \tag{2.12}$$

and, from (2.3), is consistent for (1.1) if $\beta > \alpha$ with $\omega > \beta/2(\beta-\alpha)$. Requiring mass conservation, (1.3), and from the matching conditions which will subsequently follow, it follows that

$$\frac{1}{\alpha-\beta+1} u^{\alpha-\beta+1} \sim -\frac{\partial u}{\partial t} \tag{2.13}$$

for $\beta \neq \alpha + 1$. From this we obtain

$$u^{\beta-\alpha}(x,t) \sim \frac{\alpha-\beta}{\alpha-\beta+1} t + U_0^{\beta-\alpha}(x) \tag{2.14}$$

for some function $U_0(x)$ which we shall subsequently equate to the initial data $u_0(x)$; $U_0 = A(a-x)^{1/(\beta-\alpha)\omega}$ for constant A corresponds to the self-similar form (2.11).

(v) If the final term in (1.1) dominates, that is (in a slight abuse of notation),

$$\frac{\partial}{\partial x}\left(u^\beta \frac{\partial^2 u}{\partial x \partial t}\right) \sim 0\,, \tag{2.15}$$

then

$$u \sim t^\gamma h((x-a)/t^\omega) \quad \text{as } t \to 0^+ \tag{2.16}$$

provides a similarity reduction for any γ and ω, self-consistency demanding that $\beta\gamma < 2\omega$ and $(\beta-\alpha)\gamma < 1$. Imposing conservation of mass at $x = a$ implies from (2.15) that $\partial^2 u/\partial x \partial t \sim 0$ so for some constants A and B,

$$h(\eta) = A(-\eta)^{\frac{\gamma}{\omega}} + B\,. \tag{2.17}$$

(vi) Other possible small-time balances are of traveling-wave type, and will typically give inner-inner regions enabling the appropriate local behavior at the front to be attained. Setting $x = s(t) + \zeta$ gives

$$\frac{\partial u}{\partial t} - \dot{s}\frac{\partial u}{\partial \zeta} = \frac{\partial}{\partial \zeta}\left(u^\alpha \frac{\partial u}{\partial \zeta} - \dot{s}u^\beta \frac{\partial^2 u}{\partial \zeta^2} + u^\beta \frac{\partial^2 u}{\partial \zeta \partial t}\right), \tag{2.18}$$

so if the right-hand side is negligible, then the local solution scales according to

$$u \sim \dot{s}^{\frac{2}{2\alpha-\beta}}(t) G\left((x - s(t))/\dot{s}^{\frac{\beta}{2\alpha-\beta}}(t)\right), \tag{2.19}$$

the neglect of the right-hand side of (2.18) requiring that $\ddot{s} \ll \dot{s}^{\frac{(4\alpha-3\beta)}{(2\alpha-\beta)}}$; $G(Z)$ satisfies

$$\frac{d}{dZ}\left(G^\beta \frac{d^2 G}{dZ^2}\right) - \frac{d}{dZ}\left(G^\alpha \frac{dG}{dZ}\right) - \frac{dG}{dZ} = 0\,. \tag{2.20}$$

In particular, we may have for $\beta \neq 2\alpha$ that

$$u \sim t^{\frac{2(\nu-1)}{(2\alpha-\beta)}} g\left((x - \mu t^\nu)/t^{\frac{\beta(\nu-1)}{(2\alpha-\beta)}}\right) \quad \text{as} \quad t \to 0^+\,, \tag{2.21}$$

where $\nu > 0$, and if $\alpha < \beta < 2\alpha$, then $\nu > \beta/2(\beta-\alpha)$, or if $\beta > 2\alpha$, then $\nu < \beta/2(\beta-\alpha)$, in view of the condition $\ddot{s} \ll \dot{s}^{\frac{(4\alpha-3\beta)}{(2\alpha-\beta)}}$. Finally, a possible small-time balance of traveling-wave type for $\beta = 2\alpha$ is

$$u \sim t^\sigma g\left((x - \mu t)/t^{\alpha\sigma}\right) \quad \text{as} \quad t \to 0^+ \tag{2.22}$$

for $\sigma > 2/\beta$. Conserving mass at the interface $z = 0$, it follows from (2.21) that $g(z)$ satisfies

$$-\mu\nu g = g^\alpha \frac{dg}{dz} - \mu\nu g^\beta \frac{d^2 g}{dz^2}, \tag{2.23}$$

solutions to this traveling-wave ordinary differential equation (ODE) having been discussed in detail in [21]; for (2.22) we obtain (2.23) with $\nu = 1$.

When matching the similarity behavior into traveling-wave inner-inner regions, knowledge of the local behavior of fronts described in [21] will be valuable. It is convenient at this stage to summarize these results in the following form; however, we shall need to revisit this classification, which we do in section 3.

(a) Moving-front cases. The ranges in which the interfaces move, at least for sufficiently large times, and the corresponding local behaviors, are as follows:

$$u^\alpha \sim \alpha \dot{s}(t)(s(t) - x) \quad \text{as} \quad x \to s(t)^- \quad \text{if } \beta > 2\alpha\,, \tag{2.24}$$

requiring $\dot{s} \geq 0$ (here the β term in (1.1) is locally negligible);

$$u^\alpha \sim \frac{2\alpha\dot{s}(t)}{\left(1 + \sqrt{1 + 4(1-\alpha)\dot{s}(t)^2}\right)}\,(s(t) - x) \quad \text{as} \quad x \to s(t)^- \quad \text{if } \beta = 2\alpha\,, \tag{2.25}$$

requiring for all $\alpha > 0$ that $\dot{s} \geq 0$ and for $\alpha > 1$ that $\dot{s} \leq 1/2(\alpha - 1)^{\frac{1}{2}}$ (both terms on the right-hand side of (1.1) contribute to this local balance, except when $\alpha = 1$, $\beta = 2$, in which case (2.24) is recovered);

$$u^\beta \sim \frac{\beta^2}{2(2-\beta)}(s(t)-x)^2 \quad \text{as} \quad x \to s(t)^- \quad \text{if } \beta < \min(2, 2\alpha) \tag{2.26}$$

(cf. (2.8)), where $\dot{s}$ can in principle have either sign (in this case the α term from (1.1) is locally negligible).

(b) Fixed-front cases, $2 \leq \beta < 2\alpha$. As already noted (see (1.9) and (1.10)), the front remains fixed in the regime, and u satisfies the conservation of mass condition

$$u^\alpha \frac{\partial u}{\partial x} + u^\beta \frac{\partial^2 u}{\partial x \partial t} = 0 \quad \text{at} \quad x = a\,. \tag{2.27}$$

3. Classification of solution branches in moving-front regimes.

3.1. Local analysis. Equation (1.1) is of second order in x, so in fixed-front cases the no-flux condition (2.27) is sufficient to specify the solution uniquely. However, in the frame of reference of a moving front, we have (2.18), which is third order in ζ, so that the usual mass-conserving interface conditions

$$u \to 0, \quad u^\alpha \frac{\partial u}{\partial x} + u^\beta \frac{\partial^2 u}{\partial x \partial t} \to 0 \quad \text{as } x \to s^-(t) \tag{3.1}$$

may not suffice to completely specify the moving-boundary problem. Since (2.18) is third order, solutions to (1.1) can have up to three degrees of freedom in their local expansion about a moving front; we pursue below a classification of the local behavior which clarifies how the problem can be made correctly specified. We now describe the various possible solution branches and, in particular, identify new classes of retreating fronts; these did not arise in [21] because only advancing fronts were considered there. (It is worth remarking that for PME retreating fronts are not possible and such behavior thus represents a qualitatively distinct, and very important, effect of including the β term in (1.1); it can occur for $\beta < \min(2, \alpha + 1)$, which includes some of the cases of physical interest, e.g., $0 < \alpha = \beta < 2$.)

(A) $\beta > \max(\alpha+1, 2\alpha)$. Here the PME local form (2.24) is correctly specified, containing the single degree of freedom s. The balance

$$u^\alpha \frac{\partial u}{\partial \zeta} \sim \dot{s} u^\beta \frac{\partial^2 u}{\partial \zeta^2} \quad \text{as } \zeta \to 0^-$$

is also possible in (2.18), implying

$$\dot{s}\frac{\partial u}{\partial \zeta} \sim -\frac{u^{-(\beta-\alpha-1)}}{\beta-\alpha-1} + \Phi(t) \tag{3.2}$$

containing two degrees of freedom, s and Φ (other terms may intrude between the degrees of freedom, but we shall not keep track of such terms here), and having

$$u^{\beta-\alpha} \sim \frac{\beta-\alpha}{\beta-\alpha-1}\frac{s(t)-x}{\dot{s}(t)} \quad \text{as } x \to s^-(t)\,. \tag{3.3}$$

As might be expected from its having an additional degree of freedom, (3.3) is less smooth at $\zeta = 0$ than is (2.24); the signs imply that $\dot{s} > 0$ (advancing front) is required in both cases. The case $\beta = \alpha + 1$, in which (3.2) becomes

$$\dot{s}\frac{\partial u}{\partial \zeta} \sim \ln u + \Phi(t)$$

so that

$$u \sim \frac{1}{\dot{s}(t)}(s(t) - x) \ln\left(\frac{1}{s(t) - x}\right) \quad \text{as } x \to s^-(t)\,,$$

in consequence represents a new borderline regime for (1.1).

(B) $\boldsymbol{\beta < \min(2, 2\alpha)}$. Here the balance (2.26), for which the α term is locally negligible, contains one degree of freedom, s, and gives no constraints on the sign of $\dot{s}$ (so advancing and retreating fronts are both possible, at least in principle). From the local balance

$$u \sim u^\beta \frac{\partial^2 u}{\partial \zeta^2} \quad \text{as } \zeta \to 0^-$$

in (2.18) we also have

$$\frac{1}{2}\left(\frac{\partial u}{\partial \zeta}\right)^2 \sim \frac{u^{(2-\beta)}}{2 - \beta} + \frac{1}{2}\Lambda^2(t)\,, \tag{3.4}$$

which provides a two-degree-of-freedom (s and Λ) branch; when $\Lambda = 0$ we recover (2.26), while for $\Lambda > 0$ we have finite-slope local behavior,

$$u \sim \Lambda(t)(s(t) - x) \quad \text{as } x \to s^-(t), \tag{3.5}$$

and advancing and retreating fronts are again both possible. The local balance (3.5) is self-consistent only for $\beta < \min(2, \alpha + 1)$.

(C) $\boldsymbol{2\alpha < \beta < \alpha + 1}$. This is the most subtle regime. First, the two-degree-of-freedom branch (3.5) again represents a self-consistent balance, as does the one-degree-of-freedom (and zero-slope) branch (2.24), in which $\dot{s} > 0$ necessarily holds. However, the one-degree-of-freedom branch (3.3), in which we now require $\dot{s} < 0$, is also possible. For (3.3) to hold with $\beta < \alpha + 1$ we require $\Phi = 0$ in (3.2) (setting $\Phi \equiv -\dot{s}\Lambda \neq 0$ leads in the current regime to (3.5) rather than (3.2)).

3.2. Classification of advancing and retreating fronts. We focus exclusively here (and in the rest of the paper) on the smoothest (and, in consequence, correctly specified) solution branches, namely, in the case of advancing fronts, the one-degree-of-freedom branches (2.24) for (A) (in this case a distinct one-degree-of-freedom branch arises by enforcing $\Phi = 0$ in (3.2)) and for (C), and (2.26) for (B); see [21] and [10] for a discussion (in terms of a lifting regularization) of why these solution branches may be expected on physical grounds typically to be the relevant ones. However, there is an important distinction between advancing and retreating fronts which is perhaps most easily seen by rewriting (1.1) in the form

$$\frac{\partial}{\partial x}\left(u^\beta \frac{\partial w}{\partial x} + u^\alpha \frac{\partial u}{\partial x}\right) = w\,, \quad w = \frac{\partial u}{\partial t}\,. \tag{3.6}$$

The first of these represents an elliptic two-point boundary value problem for w (treating u as known) which is to be solved subject to (1.3) (with an appropriate second boundary condition elsewhere; in the case of the Cauchy problem this will of course take the form (1.3) at the left-hand interface). In fixed and contracting domain cases the ODE for u (now treating w as known) requires no further boundary condition (with the evolution of $s(t)$ then being determined according to where u reaches zero); by contrast, for advancing fronts initial data on u is not available to the right of the current front location (i.e., in $x > s$), which is why a further boundary condition (such as zero slope) is needed there. Indeed, in order to specify the moving-boundary problem correctly (3.1) should be supplemented by

$$u^{\alpha-1}\frac{\partial u}{\partial x} \to -\dot{s}(t) \quad \text{as } x \to s^-(t)$$

in cases (A) and (C), and by

$$\frac{\partial u}{\partial x} \to 0 \quad \text{as } x \to s^-(t)$$

in case (B). Thus the results of section 3.1 need a different interpretation when $\dot{s} < 0$; retreating fronts are not possible in regime (A), but in regimes (B) and (C) they are and we need the two-degree-of-freedom branch (3.5) when $\dot{s} < 0$, in which (by the above argument) s and Λ are determined as part of the solution, i.e., (3.5) is a correctly specified branch when $\dot{s} < 0$ and (3.1) on its own specifies the moving-boundary problem correctly when the interface is retreating. In regime (C), the one-degree-of-freedom branch (3.3) has the status of a nongeneric (overspecified) branch which separates advancing fronts (2.24) from retreating ones (3.5). Since (1.1) is of second order in x, it is worth clarifying further why three boundary conditions are needed at an advancing front (this is associated with the convected version of (2.18) being of third order in ζ; this issue of the order of the highest spatial derivative that appears depending on the frame of reference is common for equations with mixed derivatives and has here important implications). The key point is that the nonanalyticity at $x = a$ of the initial data is not instantaneously smoothed. We have continuity conditions

$$[u]^+_- = \left[u^\alpha \frac{\partial u}{\partial x} + u^\beta \frac{\partial^2 u}{\partial x \partial t}\right]^+_- = 0 \quad \text{at } x = a \tag{3.7}$$

and, defining $u(a,t) = u_a(t)$ (which is positive for an advancing front), we have that the degrees of freedom in the local expansion are (assuming for brevity that $du_0/dx = 0$ at $x = a^-$) the functions $u_a(t)$, $\lambda_a(t)$, and $\Phi_\pm(x)$ in

$$u \sim u_a(t) + \lambda_a(t)(x-a) + \Phi_\pm(x) e^{-\int_0^t u_a^{\alpha-\beta}(t')\,dt'} \quad \text{as } x \to \pm a, \tag{3.8}$$

where the continuity of the u_a and λ_a terms corresponds precisely to the conditions (3.7) and $\Phi_-(x)$ can be thought of as being determined by the initial data, in which case it is the determination of the arbitrary function $\Phi_+(x)$ as part of the solution that requires a third boundary condition to hold at $x = s(t)$, the latter in effect serving to provide the initial data in the expanding domain $a < x < s(t)$. We remark that for (1.7), the explicit solution (2.8) implies that in this special case $\Phi_+(x) \equiv 0$; this will not be the case in general, however. Since for retreating fronts we have $u = 0$ for $x > s(t)$, where $s(t) < a$, the nonanalyticity at $x = a$ *is* lost in the case; this important distinction is implicit in some of the discussion that follows.

We now expand upon such matters for the limit case (1.7), in which the α term is absent, with $\beta < 2$. The initial value problem for (1.7) of course has the solution $u = u_0(x)$ for all t so we need to force the solution to evolve by, for example, imposing

$$u = u_b(t) \quad \text{at } x = 0 \tag{3.9}$$

for some prescribed $u_b(t)$. As noted in [23], if $s(t) > a$, then the solution in $x > a$ is given exactly by (2.8) (being the required one-degree-of-freedom (s) solution), with $s(t)$ to be determined. In $0 < x < a$ we are thus required to solve (1.7) subject to continuity of u and of flux, i.e., to

$$u = \left(\frac{\beta^2 s(t)^2}{2(2-\beta)}\right)^{\frac{1}{\beta}}, \quad u^\beta \frac{\partial^2 u}{\partial x \partial t} = -\left(\frac{\beta^2 s(t)^2}{2(2-\beta)}\right)^{\frac{1}{\beta}} \dot{s}(t) \quad \text{at } x = a^- ; \tag{3.10}$$

in other words, we have a fixed domain ($0 < x < a$) problem for (1.7), subject to (3.9) and (by elimination of s from (3.10))

$$u^{\frac{\beta}{2}} \frac{\partial^2 u}{\partial x \partial t} = -\sqrt{\frac{2-\beta}{2}} \frac{\partial u}{\partial t} \quad \text{at } x = a^- , \tag{3.11}$$

which also determines s via (3.10). (Because (1.7) does not smooth nonanalyticities in the initial data, (2.8) need not, and does not in general, apply at $x < a$.)

However, the above formulation applies only if $u_a(t) \geq 0$, and it can easily be seen that this need not apply. Thus, if picking $u_b(t) = \phi(t)$ leads to $\dot{u}_a > 0$ initially, then (in view of the apparent time-reversibility of (1.7)) taking $u_b(t) = \phi(-t)$ would lead to $\dot{u}_a < 0$ for small time, and a contracting front of finite slope will instead result, as in (3.5). This confirms that the moving-boundary problem for (1.7) is not in fact time-reversible, since if a front switches from retreating (which it will generically do with nonzero slope) to advancing, then the slope becomes zero instantaneously on reversal of direction. An exception to this is that for initial data of the extremely special form (2.8) at $t = 0$, for which contraction with zero slope occurs, reversibility is possible; zero-slope retraction will of course occur while $s(t) > a$ for u_a decreasing if u_a first increases, so that (2.8) holds in $a < x < s$, and then decreases again—as already indicated, such behavior is time-reversible, in contrast to cases in which u_a decreases and then increases again.

We now turn to the description of the small-time behavior, distinguishing several parameter regimes. We shall only analyse in any detail the retreating front cases, and advancing and fixed front cases where the behavior of the front or discontinuity cannot be directly inferred from the small-time similarity balances listed in section 2. All other cases are summarized in tables, in which we note the inner balances and the associated front behavior. The expansion (2.1) holds in the outer region. One of the self-similar forms (i)–(v) of section 2 provides the inner solution and in some cases yet narrower inner-inner and possibly inner-inner-inner regions are required to match the corresponding front behavior, i.e., (2.24), (2.25), or (2.26) for advancing front cases and (3.5) for retreating ones. In most cases in the narrowest region a traveling-wave balance (section 2 (vi)) provides the solution. In some cases there are multiple inner structures, whereby an inner region generates a new local exponent $p' \neq p$ and one then needs to consult the table appropriate to that new value to obtain the full asymptotic structure. The tables should be read from left to right and the last column in blocks from top to bottom (starting at cases where the (widest) inner region matches the front behavior). Thus the solution appearing at the top/right (specified by writing (inner)) also holds in the inner region of the subsequent cases in the same block of the table, and so on down the column.

TABLE 2

The non-PME balance $p < 2/\beta$, $\beta < \alpha + 1$, in which the β-term in (1.1) dominates the small-time behavior of the front. An immediate change occurs with, in the moving-front regime, the interface advancing (retreating) if $B > 0$ ($B < 0$).

4. The case $p < 2/\beta$. In this case (2.2) is to be solved subject to the mass conservation condition

$$u_0^\alpha \frac{du_0}{dx} + u_0^\beta \frac{du_1}{dx} \to 0 \quad \text{as } x \to \pm a\,. \tag{4.1}$$

The regimes $p < \alpha + 1$, $p > \alpha + 1$, and $p = \alpha + 1$ are summarized in Tables 2 and 3. We first consider the regime $\beta < \alpha + 1$, $p < 2/\beta$. Here the second term of the left-hand side of (2.2) dominates as $x \to a^-$, so that $u_1(x) \sim B$ as $x \to a$, where the constant B, which may take either sign, is determined by solving (2.2) subject to (4.1). The expansion (2.1), which becomes

$$u \sim A(a-x)^p + Bt \quad \text{as } t \to 0^+\,, \tag{4.2}$$

is nonuniform as $x \to a$. For $B > 0$, in $x < a$ the local expansion (4.2) is of the similarity form (2.16) with $\gamma = 1$, $\omega = 1/p$, simply giving (2.17). In the fixed-front cases $2 \le \beta < \alpha + 1$ this completes the small-time structure. For the moving-front cases, however, this structure is clearly incomplete since (2.17) does not become zero, and a further inner-inner region is needed; see Table 2.

We now turn to the case $B < 0$, starting with the moving-front regimes. Since $\beta < \alpha + 1$, we lie in class (B) or (C) of section 3, so in either case a contracting front occurs, whereby

$$s(t) - a \sim -\left(\frac{-B}{A}\right)^{\frac{1}{p}} t^{\frac{1}{p}} \quad \text{as } t \to 0^+\,, \tag{4.3}$$

with the local expansion (4.2) holding right up to the front, so that

$$\Lambda(t) \sim pA\left(\frac{-B}{A}\right)^{\frac{p-1}{p}} t^{\frac{p-1}{p}} \quad \text{as } t \to 0^+ \tag{4.4}$$

TABLE 3

The non-PME balance $p < 2/\beta$, $\beta \geq \alpha + 1$. The α and β terms in (1.1) dominate the left-hand side of the front. An immediate change occurs, with the interface advancing in the moving-front cases.

$\beta > \alpha + 1$	$\alpha + 1 < \beta < 2\alpha$ (fixed fronts)	$U(t) \sim h(0) t^{\frac{1}{(\beta-\alpha)}}$ as $t \to 0^+$
		$(h(0) = ((\beta-\alpha)/(\beta-\alpha-1))^{1/(\beta-\alpha)})$
No waiting time	Similarity form (2.16) with $\omega = 1/(\beta-\alpha)p$ (inner)	
	$\beta > 2\alpha$ (moving fronts)	$s(t) - a \sim \eta_0\, t^{\frac{\beta}{2(\beta-2)}}$ as $t \to 0^+$
	Similarity form (2.4) (inner-inner)	
$\beta = \alpha + 1$	$\alpha > 1$ (fixed fronts)	$U(t) \sim t \ln(1/t)$ as $t \to 0^+$
	Similarity form $u \sim t \ln(1/t) h\big((x-a)/t^{\frac{1}{p}} \ln^{\frac{1}{p}}(1/t)\big)$, see (2.16) (inner)	
No waiting time	$\alpha = 1$, $\beta = 2$ (moving fronts)	$s(t) - a \sim t \ln^{\frac{1}{2}}(1/t)$ as $t \to 0^+$
	Similarity form $u \sim t \ln(1/t) f\big((x-a)/t \ln^{\frac{1}{2}}(1/t)\big)$ (inner-inner)	
	$\alpha < 1$ (moving fronts)	$G^\alpha(Z) \sim \alpha(-Z)$ as $Z \to 0^-$ (inner-inner-inner)
	Traveling-wave form (2.19) with $s(t) - a = \eta_0 t^{\frac{\beta}{2}} \ln^{\frac{\beta}{2}}(1/t)$	

holds in (3.5). In the fixed-front regime $\beta > 2$ (for which $p < 2/\beta$ evidently implies $p < 1$), the situation is very different. Here (4.2) holds in $x < \sigma(t)$, where we introduce $\sigma(t)$ such that

$$\sigma(t) - a \sim -\left(\frac{-B}{A}\right)^{\frac{1}{p}} t^{\frac{1}{p}} \quad \text{as } t \to 0^+, \tag{4.5}$$

as in (4.3), and setting $\zeta = x - \sigma(t)$ leads to the "traveling-wave" balance

$$u - u_\infty(t) \sim u^\beta \frac{\partial^2 u}{\partial \zeta^2}, \quad \begin{matrix} u \to u_\infty(t) & \text{as } \zeta \to +\infty, \\ u \sim \Lambda(t)(-\zeta) & \text{as } \zeta \to -\infty, \end{matrix} \tag{4.6}$$

where $\Lambda(t)$ in the second matching condition is again given by (4.4) and $u_\infty(t)$ is to be determined as part of the solution of (4.6) (from (4.4), it follows that the relevant scalings in (4.6) are $\zeta \propto t^{\frac{\beta(1-p)}{(\beta-2)p}}$, $u, u_\infty \propto t^{\frac{2(1-p)}{(\beta-2)p}}$). In $\sigma < x < a$ we have $\partial u/\partial t = 0$ at leading order, subject (by (4.4)) to

$$u = \left(\frac{(\beta-1)(\beta-2)p^2A^2}{2}\right)^{-\frac{1}{\beta-2}} \left(\frac{-B}{A}\right)^{\frac{2(1-p)}{(\beta-2)p}} t^{\frac{2(1-p)}{(\beta-2)p}} \quad \text{at } x = \sigma$$

and hence, by (4.5),

$$u \sim \left(\frac{(\beta-1)(\beta-2)p^2A^2}{2}\right)^{-\frac{1}{\beta-2}} (a-x)^{\frac{2(1-p)}{(\beta-2)}} \quad \text{as } t \to 0 \text{ for } \sigma < x < a, \tag{4.7}$$

with $a - x = O(t^{\frac{1}{p}})$. A front thus attempts to retreat, leaving behind a power-law profile (4.7) with $p' = 2(1-p)/(\beta-2)$; since $p' > 2/\beta$ for $p < 2/\beta$, the small-time response at $x = a$ generated by (4.7) is as described in section 5 by substituting p' for p, with $p' = 2/\alpha$ corresponding to $\beta = (1-p)\alpha + 2$. Note that for $p = 2/\beta$ we have

TABLE 4

The PME balance $2/\beta < p < 2/\alpha$, $\beta < \alpha$, the α term being dominant in (1.1) in the left-hand side of the front. There is no waiting-time behavior, as for PME.

$\beta < \alpha$, $p < 2/\alpha$	$\beta/2 < \alpha < \beta$, $\beta \geq 2$ (fixed fronts)	$U(t) \sim f(0)t^{p/(2-\alpha p)}$ as $t \to 0^+$
	Similarity form (2.5) with $\gamma = p/(2-\alpha p)$ (inner)	
	$\alpha \leq \beta/2$ (moving fronts)	$s(t) - a \sim \eta_0 t^{1/(2-\alpha p)}$ as $t \to 0^+$
	Similarity form (2.5) with $\gamma = p/(2-\alpha p)$ (inner)	
No waiting time	$\alpha < 1$ (moving fronts)	$g^\beta(z) \sim \frac{\beta^2}{2(2-\beta)}(-z)^2$ as $z \to 0^-$
	Traveling-wave form (2.21) with $\nu = 1/(2-\alpha p)$, $\mu = \eta_0$ (inner-inner)	

TABLE 5

The PME balance $p > \max(2/\alpha, 2/\beta)$. "Global" waiting-time behavior occurs for $0 < t < t_w$, and the local form (1.2) persists for $0 < t \leq t_w$. In the fixed front cases ($2 \leq \beta < 2\alpha$) a discontinuity at $x = a$ will emerge at t_w, while in the remaining (moving-front) regimes the interfaces can be expected to move on arrival of a "shock" (essentially as in [27] for PME; see also [22]).

$p > \max(2/\beta, 2/\alpha)$	$2 \leq \beta < 2\alpha$ (fixed fronts)	(1.10) holds
"Global" waiting time	$\alpha \leq \beta/2$ (moving fronts)	arrival of a "shock" at $t = t_w$

TABLE 6

The PME balance $p = 2/\alpha$, $\beta > \alpha$. A local waiting-time solution is available as for PME. This case differs from the PME in that fixed-front cases arise (for $\alpha > 1$ with $2 \leq \beta < 2\alpha$; see Figure 1).

$p = 2/\alpha$ "Local" waiting time	Fixed and moving fronts	$t_w \leq \frac{\alpha}{2(\alpha+2)A^\alpha}$
	Separable form $u \sim (a-x)^{\frac{2}{\alpha}} f(t)$ of (1.6) as $x \to a^-$ (inner)	

formally that $p' = 2/\beta$; the corresponding regime is that described in section A.5 of the appendix.

We shall not discuss here either of the borderline cases, $\beta = 2$ (in which we expect a profile that is exponentially small in $a - x$ to be left behind; cf. (4.7)) and $B = 0$ (which, in the moving-front regimes, separates advancing and retreating fronts and is particularly awkward since it requires the investigation of $u_2(x)$, the $O(t^2)$ correction term in the small-t expansion (2.1); this may lead to further subcases (and a further refined borderline), depending on the sign of u_2 at $x = a$). In case (C) of section 3 the nongeneric local solution (3.3) corresponds to the borderline behavior when $B = 0$.

5. The case $p > 2/\beta$. The second term on the left-hand side of (2.2) is negligible in this limit, thus giving the local expansion

$$u(x,t) \sim A(a-x)_+^p + p\Big((\alpha+1)p - 1\Big)A^{\alpha+1}(a-x)_+^{(\alpha+1)p-2}t \quad \text{as } x \to a\,.$$

The sign of $p - 2/\alpha$ can therefore be expected to determine whether there is a waiting time or not. The results in this regime are summarized in the Tables 4–6.

6. The critical case $p = 2/\beta$, $\alpha < \beta$. In this borderline case for the exponent p the first and second terms on the left-hand side of (2.2) are the same size as $x \to a^-$,

giving as the dominant balance the equation

$$u_1 + 2A^\beta(a-x)\frac{du_1}{dx} - A^\beta(a-x)^2\frac{d^2u_1}{dx^2} \sim A^{\alpha+1}\frac{2(2(\alpha+1)-\beta)}{\beta^2}(a-x)^{\frac{2(\alpha+1-\beta)}{\beta}} \quad \text{as } x \to a^-\,. \tag{6.1}$$

This is a nonhomogeneous Euler equation, with complementary functions of the form $(a-x)^m$, where m satisfies the quadratic equation $1 - A^\beta(m^2+m) = 0$. We specify the solution to (2.2) uniquely by excluding the negative root for m (required for the no-flux condition (4.1) to hold), leaving the acceptable root

$$m = \frac{1}{2}\left((1+4A^{-\beta})^{\frac{1}{2}} - 1\right)\,. \tag{6.2}$$

Defining $q = \frac{2(\alpha+1-\beta)}{\beta}$, then, provided $q \neq m$, a particular integral to (6.1) satisfies

$$u_1(x) \sim \frac{2A^{\alpha+1}(2\alpha+2-\beta)}{\beta^2(1-A^\beta(q^2+q))}(a-x)^q\,; \tag{6.3}$$

the dominant term in the local expansion for u_1 is thus given by (6.3) if $q < m$ and by $u_1 \sim B(a-x)^m$ for some constant B if $q > m$, with m given by (6.2). Since $q < p$, the outer expansion is nonuniform in this regime ($m < q < p$), and it follows that waiting-time behavior does not occur.

In the forthcoming analysis we let $A_1 \equiv \left(\beta^2/2(2\alpha+2-\beta)\,(\alpha+1-\beta)\right)^{\frac{1}{\beta}}$, so that q satisfies $1 - A_1^\beta(q^2+q) = 0$. There are various possibilities depending on the sign of $m-q$, and these are expressed in terms of A and A_1 when $\beta < \alpha+1$. We have the following cases.

(I) $A > A_1$ for $\alpha < \beta < \alpha+1$ ($0 < m < q$). Here the term on the right-hand side of (6.1) is locally negligible. Hence

$$u_1(x) \sim B(a-x)^m \quad \text{as } x \to a^-, \tag{6.4}$$

where m is given by (6.2) and B is a constant which may take either sign and which can be found by solving (2.2) (subject to the appropriate boundary conditions). In this case the solution in the inner region close to $x = a$ is of the similarity form (2.10) with $\gamma = 2/(2-\beta m)$ and with

$$f(\eta) \sim A(-\eta)^{\frac{2}{\beta}} + B(-\eta)^m \quad \text{as } \eta \to -\infty, \tag{6.5}$$

both terms here being needed to specify $f(\eta)$, as is to be expected since some time-dependent forcing (namely, the B term) is needed if the solution to (1.7) is not to be simply $u \sim u_0(x)$; note that $f(\eta) = A(-\eta)^{2/\beta}$ is an exact solution of (2.7), and this implies the presence of a borderline corresponding to the special case $B = 0$. Such similarity reductions of (1.7) are the subject of the appendix. We start by discussing the case $B > 0$. In the moving-front regime $\beta < 2$, $f(\eta)$ satisfies (2.7), with (2.9) holding for $0 < \eta < \eta_0$ and in $\eta < 0$ we thus have conditions

$$f^{\frac{\beta}{2}}\frac{d}{d\eta}\left(f - \frac{\beta}{2}\eta\frac{df}{d\eta}\right) = -\sqrt{\frac{2-\beta}{2}}\left(f - \frac{\beta}{2}\eta\frac{df}{d\eta}\right) \quad \text{at } \eta = 0^- \tag{6.6}$$

TABLE 7

The parameter regime $p = 2/\beta$, $\alpha < \beta$, with $A > A_1$ for $\beta < \alpha + 1$ and with $B > 0$ in (6.5). In the moving-front cases the interface immediately advances.

$A > A_1$ for $\alpha < \beta < \alpha + 1$, $B > 0$	$\beta \geq 2$ (fixed fronts)	$U(t) \sim f(0) t^{\frac{2}{(2-\beta m)}}$ as $t \to 0^+$
	Similarity form (2.10) with $\gamma = 2/(2-\beta m)$ (inner)	
	$\beta < \min(2, 2\alpha)$ (moving fronts)	$s(t) - a \sim \eta_0 \, t^{\frac{\beta}{2(\beta-2)}}$ as $t \to 0^+$
	Similarity form (2.10) with $\gamma = 2/(2-\beta m)$ (inner)	
No waiting time	$2\alpha \leq \beta < 2$ (moving fronts)	$g^\alpha(z) \sim \eta_0 \frac{\alpha\beta}{(2-\beta m)}(-z)$, as $z \to 0^-$
	Traveling-wave form (2.21) with $\nu = \beta/(2-\beta m)$ $\mu = \eta_0$ (inner-inner)	

(see (3.11)) and (6.5). Thus as $\eta \to -\infty$ we have in effect two boundary conditions (both A and B are specified in (6.5), leaving a single eigenmode, $(-\eta)^{-(m+1)}$), while at the origin the eigenmodes are $(-\eta)^0$, $(-\eta)^1$, and $(-\eta)^{2/\beta}$; a relation between the first two of these is furnished by (6.6), while the third gives a nonanalyticity whereby u at $t = 0^+$ has a term $C_0(a-x)^{2/\beta}$ as $x \to a^-$ (C_0 being the coefficient of the $(-\eta)^{2/\beta}$ eigenmode, determined by the solution $f(\eta)$ of (2.7) and not in general equal to A), but no comparable term in $x > a$. Assuming that for $t > 0$ we have $u_a > 0$, then, by balancing the terms on the right-hand side, (1.1) implies that u contains a term $C(t)(a-x)^{2/\beta}$ as $x \to a^-$, with this nonanalyticity decaying according to (cf. (3.8))

$$\frac{dC}{dt} = -u_a^{\alpha-\beta} C \,, \; C = C_0 \quad \text{at } t = 0 \,; \tag{6.7}$$

we have

$$u_a(t) \sim f(0) t^{\frac{2}{(2-\beta m)}} \quad \text{as } t \to 0^+ \tag{6.8}$$

and, since $m < 2/\beta < q$, it follows that $-1 < 2(\alpha - \beta)/(2 - \beta m) < 0$ and hence that (6.7) behaves in an appropriate fashion as $t \to 0^+$. It is worth repeating the more general point that (unlike (1.6) with $u > 0$) equation (1.1) does not instantaneously smooth nonanalyticities in u. We note that in the special case $A = A^* \equiv (\beta^2/2(2-\beta))^{1/\beta}$ (for this value of A to lie in the current regime we require $\beta < 2\alpha$) the relevant similarity solution can be constructed explicitly; we have $m = (2-\beta)/\beta$ and the solution (2.9) applies for all η, with

$$\eta_0 = \frac{\beta B}{2A^*}, \quad C_0 = A^* \tag{6.9}$$

(see (A.11)). Table 7 summarizes the front behavior. The analysis of the case $B < 0$ follows from that of the appendix, and can be summarized as follows. In the moving-front regime $\beta < 2$ the self-similarity form (2.7) applies and for $A > A^* \equiv (\beta^2/2(2-\beta))^{\frac{1}{\beta}}$ we have a contracting front with local behavior of the form (A.3) (with $\eta_0 < 0$), while for $A_1 < A < A^*$ we have a switch in the structure of the inner solution whereby (A.4) provides its local behavior (note that, in the notation of the appendix, $A_1 > A_2 \equiv (\beta^2/2(\beta+2))^{\frac{1}{\beta}}$ holds in this regime, whatever the sign of $2-\beta$). In the fixed-front regime $\beta \leq 2$ with $B < 0$ we recover the local behavior (A.4) for any $A > A_1$; see the analysis of section A.5. Since in (A.4) we have $\hat{A} < A_2 < A_1$, this is not the end of the story in these final two cases, however; $\hat{A}$ lies in the regime

TABLE 8

The parameter regime $p = 2/\beta$, $\alpha < \beta$, for $\alpha + 1 \le \beta$ or $A < A_1$ with $\alpha < \beta < \alpha + 1$. There is no waiting-time behavior, and, in particular, the interface immediately advances in the moving-front cases.

$\alpha + 1 \le \beta$ or $A < A_1$ with $\alpha < \beta < \alpha + 1$	No waiting time	$\alpha < \beta < 2\alpha$, $\beta \ge 2$ (fixed fronts)	$U(t) \sim f(0) t^{\frac{1}{(\beta-\alpha)}}$ as $t \to 0^+$
		Similarity form (2.4)	(inner)
		$\alpha < \beta \le 2\alpha$, $\beta > 2$ (moving fronts)	$s(t) - a \sim \eta_0\, t^{\frac{\beta}{2(\beta-2)}}$ as $t \to 0^+$
		Similarity form (2.4)	(inner)

TABLE 9

The parameter regime $p = 2/\beta$, $\alpha < \beta$, for $A = A_1$ with $\alpha < \beta < \alpha + 1$. There is no waiting-time behavior as in case (II) *above.*

$A = A_1$ for $\alpha < \beta < \alpha + 1$	$\beta \ge 2$ (fixed fronts)	$U(t) \sim f(0) t^{\frac{1}{(\beta-\alpha)}} \ln^{\frac{1}{\beta-\alpha}}(1/t)$ as $t \to 0^+$ with $f(0) > 0$	
	Similarity form (2.6) with $\Omega(t) = t^{\frac{\beta}{2(\beta-\alpha)}} \ln^{\frac{\beta}{2(\beta-\alpha)}}(1/t)$		(inner)
No waiting time	$\beta < 2$, $\beta \le 2\alpha$ (moving fronts)	$s(t) - a \sim \eta_0 t^{\frac{\beta}{2(\beta-\alpha)}} \ln^{\frac{\beta}{2(\beta-\alpha)}}(1/t)$ as $t \to 0^+$	
	Similarity form (2.6) with $\Omega(t) = t^{\frac{\beta}{2(\beta-\alpha)}} \ln^{\frac{\beta}{2(\beta-\alpha)}}(1/t)$		(inner)
	$2\alpha < \beta < 2$ (moving fronts)	$G^\alpha(Z) \sim \alpha(-Z)$ as $Z \to 0^-$	(inner-inner)
	Traveling-wave form (2.19) with $s(t) - a = \eta_0 t^{\frac{\beta}{2(\beta-\alpha)}} \ln^{\frac{\beta}{2(\beta-\alpha)}}(1/t)$		

governed by (II) below, so there is in the small-time behavior a further (inner-inner) region described by the similarity solution (2.4) (in the inner region (2.10) holds with $\beta\gamma/2 = \beta/(2-\beta m) < \beta/2(\beta-\alpha)$ because $m < q$ here, so (as required) the inner-inner region is much narrower than the inner one for $t \ll 1$).

(II) $\alpha + 1 \le \beta$ or $A < A_1$ with $\alpha < \beta < \alpha + 1$ ($q < m$). See Table 8.

(III) $A = A_1$ for $\alpha < \beta < \alpha + 1$ ($q = m$). See Table 9.

7. The critical case $p = 2/\beta$, $\beta < \alpha$. The dominant local balance within this section is (1.7), and the dominant balance in (2.2) is the homogeneous version of (6.1). Hence u_1 is of the form

$$u_1(x) \sim B(a - x)^m \quad \text{as } x \to a^-, \tag{7.1}$$

where m is given by (6.2), and the constant B is determined by the boundary value problem for (2.2) implied by (7.1) with (6.2). Whether (7.1) is locally negligible compared to (1.2) depends on whether m is greater or less than p ($= 2/\beta$), and the critical value of A is therefore given by A_2. We accordingly distinguish three cases.

(I) $A > A_2$. Here $m < 2/\beta$, so (2.1) is nonuniform and the small-time behavior is as outlined in case (II) of section 6 except that, since $\hat{A} < A_2$ holds in (A.4), in the relevant cases the local behavior switches into the regime (II) below, corresponding to waiting-time behavior; see also the appendix. The advancing-front cases can here lie only in the range given in (2.26), so the front behaves as

$$s(t) - a \sim \eta_0 t^{\frac{\beta}{(2-\beta m)}} \quad \text{as } t \to 0^+,$$

and a further "traveling-wave" region (i.e., (vi) of section 2) is not present.

(II) $A < A_2$. Here $m > 2/\beta$, and (1.2) is valid as $x \to a^-$ for $t > t_w$, so that "global" waiting-time behavior occurs.

(III) $A = A_2$. In this borderline case we have $m = 2/\beta$ and the appropriate matching condition thus takes the form

$$u \sim (a-x)^{\frac{2}{\beta}} (A_2 + Bt)\,. \tag{7.2}$$

There is no relevant separable solution of the balance (1.7), but adopting the "near-separable" form

$$u = (a-x)^{\frac{2}{\beta}}\, \Phi(\xi, t), \qquad \xi = -\ln(a-x)\,, \tag{7.3}$$

it can be inferred that $\Phi(\xi, t) \sim A_2 + \Psi(\xi, t)$ as $t \to 0^+$ with

$$\Psi = \frac{Bt}{1 - \frac{B(\beta+2)}{A_2(\beta+4)}\xi t}\,, \tag{7.4}$$

which for $B > 0$ blows up as $\xi t \to \frac{A_2(\beta+4)^-}{B(\beta+2)}$. Equations (7.3) and (7.4) furnish the matching condition

$$u \sim (a-x)^{\frac{2}{\beta}} \left(A_2 + \frac{A_2(\beta+4)}{(\beta+2)} \frac{1}{\frac{A_2(\beta+4)}{B(\beta+2)t} + \ln(a-x)} \right) \quad \text{as } x \to a^-\,,\ t \to 0^+ \tag{7.5}$$

for the final (inner-inner) region for $B > 0$ in which $x - a$ is exponentially small, with the asymptotic solution essentially taking the form

$$u \sim e^{-\frac{2A_2(\beta+4)}{B\beta(\beta+2)t}} f((x-a)e^{\frac{A_2(\beta+4)}{B(\beta+2)t}}), \tag{7.6}$$

where $f(\eta)$ is a similarity solution of (1.7) with, in view of (7.5),

$$f(\eta) \sim A_2(-\eta)^{\frac{2}{\beta}} + \frac{A_2(\beta+4)}{(\beta+2)} \frac{(-\eta)^{\frac{2}{\beta}}}{\ln(-\eta)} \quad \text{as } \eta \to -\infty \tag{7.7}$$

(cf. section A.3 of the appendix, in particular (A.16)). We note that, as is typical in such borderline regimes, the relevant similarity reduction could in fact include multiplicative terms which are algebraic in t, as well as the exponentials in (7.6); calculation of these terms requires higher-order matching which we shall not pursue here ((7.6) nevertheless embodies the dominant time dependence of the relevant exponentially small region).

When $B < 0$, no blow-up occurs in (7.4), the inner-inner region is absent, and waiting-time behavior ensues. The local behavior is summarized in Table 10.

This borderline regime $A = A_2$ could be refined further by an analysis of the case $B = 0$. We note that we are assuming throughout that the correction terms to (1.2) are at least algebraically smaller in $(x - a)$ and so do not influence the logarithmic correction terms in (7.5), for example.

8. The critical case $p = 2/\beta$, $\beta = \alpha$. This is the most delicate case of all, lying at the intersection of other borderlines (see Figure 1), and is therefore worth recording in detail. We also observe that, as in section 7, the only moving fronts

TABLE 10

The critical regime $p = 2/\beta$, $\beta < \alpha$ with $A = A_2$. This borderline case is noteworthy in that in the moving-front regime the interface immediately advances (though exponentially slowly) for $B > 0$, while for $B < 0$ no change in the leading-order local behavior occurs, though a logarithmic correction term immediately enters; as such this represents a natural borderline with the "switch" in local behavior which occurs for $A > A_2$.

</table>

which are possible are of the form (2.26), when $p > 1$ ($\beta < 2$); otherwise, this regime lies in the fixed-front domain.

The dominant balance in (2.2) is again given by (6.1), i.e.,

$$u_1 + 2A^\beta(a-x)\frac{du_1}{dx} - A^\beta(a-x)^2\frac{d^2u_1}{dx^2} \sim A^{\beta+1}\frac{2(\beta+2)}{\beta^2}(a-x)^{\frac{2}{\beta}} \quad \text{as } x \to a^- . \tag{8.1}$$

As before we let m denote the positive solution of the quadratic equation $1 - A^\beta(m^2 + m) = 0$. In this case q from section 6 is $2/\beta$, and the critical value of A is given by A_2, which in this case coincides with A_1. The following three subcases arise.

(I) $A > A_2$. Here $m < 2/\beta$, and $u_1(x) \sim B(a-x)^m$ as $x \to a^-$. The behavior is identical to that given in case (I) of section 7; in the cases in which (A.4) applies, the local solution subsequently evolves as in subcase (II) below with $\hat{A}$ replacing A.

(II) $A < A_2$. Here $m > 2/\beta$ and (6.3) holds with $q = 2/\beta$, and the matching condition

$$u \sim A(a-x)^{\frac{2}{\alpha}} \left(1 + \frac{A^{\alpha+1}}{A_2^\alpha - A^\alpha} t\right) \quad \text{as } x \to a^-$$

thus applies. Aiming to extend this analysis beyond the small t regime, we seek a separable solution to (1.1) with $\beta = \alpha$ of the form (2.4), finding that

$$\left(A_2 f^{-(\alpha+1)} - f^{-1}\right)\frac{df}{dt} = 1 \tag{8.2}$$

so that

$$\frac{1}{\alpha}(f/A_2)^{-\alpha} + \ln f = -t + \frac{1}{\alpha}(A/A_2)^{-\alpha} + \ln A \tag{8.3}$$

for $t \leq T$, where T is given by $f(T) = A_2$, i.e.,

$$T = \ln(A/A_2) + \left((A/A_2)^{-\alpha} - 1\right)/\alpha . \tag{8.4}$$

Thus the coefficient f of the local solution automatically increases towards the borderline A_2 between waiting-time ($f < A_2$) and non-waiting-time ($f > A_2$) scenarios, and the solution to (8.2) ceasing to exist at $t = T$, with

$$f \sim A_2(1 - (2(T-t)/\alpha)^{\frac{1}{2}}) \quad \text{as } t \to T^- . \tag{8.5}$$

This again represents a local waiting-time solution with $t_w \leq T$; unlike (7.4), however, the solution (8.3) does not blow up as the local waiting time $t = T$ is reached, and a further set of scalings needs to be considered for $t - T$ small if we are to describe the "local" waiting-time scenario in which $t_w = T$.

Again we write

$$u = (a-x)^{\frac{2}{\alpha}}\Phi(\xi,t), \quad \xi = -\ln(a-x) . \tag{8.6}$$

In view of the behavior (8.5) near $t = T$ we now seek a "backward" self-similar solution of the form

$$\Phi \sim A_2 + \Psi(\xi,t), \ \Psi(\xi,t) = (T-t)^{\frac{1}{2}}F_-(\xi(T-t)^{\frac{1}{2}}) \quad \text{as } t \to T^- \tag{8.7}$$

to give (after some manipulations and again assuming the initial data does not contain correction terms to (1.2) which are only logarithmically smaller in $(a-x)$)

$$\frac{dF_-}{d\zeta} = \frac{(\alpha+2)}{(\alpha+4)A_2}\left(F_-^2 - \frac{2A_2^2}{\alpha}\right) . \tag{8.8}$$

Matching to (8.5) requires $F_- \to -\sqrt{2/\alpha}A_2$ as $\zeta \to +\infty$, while we require F_- to behave as $1/\zeta$ as $\zeta \to 0^+$ in order that (8.7) have suitable behavior at $t = T$; this finally gives $F_- = -A_2\sqrt{2/\alpha}\coth((\alpha+2)/(\alpha+4)\sqrt{2/\alpha}\zeta)$ so that at $t = T$

$$\Phi \sim A_2\left(1 + \frac{(\alpha+4)}{(\alpha+2)\ln(a-x)}\right) \quad \text{as } x \to a^- \tag{8.9}$$

as in section 7 (III) for $B < 0$; see Table 10. In view of (8.9), we can now continue the local solution into $t > T$ by seeking a "forward" self-similar solution Ψ of the form

$$\Psi(\xi,t) = (t-T)^{\frac{1}{2}}F_+(\xi(t-T))^{\frac{1}{2}} \quad \text{as } t \to T^+, \tag{8.10}$$

so that $F_+(\zeta)$ satisfies

$$\frac{dF_+}{d\zeta} = \frac{(\alpha+2)}{(\alpha+4)A_2}\left(F_+^2 + \frac{2A_2^2}{\alpha}\right),$$

and matching with (8.9) requires that

$$F_+(\zeta) = -\sqrt{\frac{2}{\alpha}}A_2\cot\left(\frac{(\alpha+2)}{(\alpha+4)}\sqrt{\frac{2}{\alpha}}\zeta\right) . \tag{8.11}$$

Hence $F_+ \to +\infty$ as $\zeta \to \pi\sqrt{\alpha/2}\,(\alpha+4)/(\alpha+2)$ and one more region is needed with scalings essentially of the form

$$u \sim e^{-\pi\sqrt{\frac{2}{\alpha}}\frac{(\alpha+4)}{(\alpha+2)}\frac{1}{(t-T)^{1/2}}}\phi\left((x-a)e^{\pi\sqrt{\frac{\alpha}{2}}\frac{(\alpha+4)}{(\alpha+2)}\frac{1}{(t-T)^{1/2}}}\right)$$

TABLE 11

The critical regime $p = 2/\beta$, $\alpha = \beta$ with $A < A_2$, in the local waiting-time case $t_w = T$ is available, for which (unlike the PME) the evolution past the waiting time can be tracked asymptotically.

$A < A_2$ Local waiting time	$\beta \geq 2$ (fixed fronts)	$U(t) \sim \phi(0) e^{-\pi \sqrt{\frac{2}{\alpha}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{(t-t_w)^{1/2}}}$ as $t \to t_w^+$
	Similarity form (2.6) with $\Omega(t) = e^{-\pi \sqrt{\frac{\alpha}{2}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{(t-t_w)^{1/2}}}$ (inner-inner)	
Separable form (2.4)	$\beta < 2$ (moving fronts)	$x - a \sim \eta_0 e^{-\pi \sqrt{\frac{\alpha}{2}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{(t-t_w)^{1/2}}}$ as $t \to t_w^+$
(inner)	Similarity form (2.6) with $\Omega(t) = e^{-\pi \sqrt{\frac{\alpha}{2}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{(t-t_w)^{1/2}}}$ (inner-inner)	

TABLE 12

The critical regime $p = 2/\beta$, $\alpha = \beta$ with $A = A_2$. No waiting time occurs, with the interface immediately advancing in the moving-front regime albeit exponentially slowly.

$A = A_2$ No waiting time	$\beta \geq 2$ ($p \leq 1$) (fixed fronts)	$U(t) \sim \phi(0) e^{-\frac{\pi}{2} \sqrt{\frac{2}{\alpha}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{t^{1/2}}}$ as $t \to 0^+$
	Similarity form (2.6) with $\Omega(t) = e^{\frac{\pi}{2} \sqrt{\frac{\alpha}{2}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{t^{1/2}}}$ (inner-inner)	
Near-separable form (8.6)	$\beta < 2$ ($p > 1$) (moving fronts)	$s(t) - a \sim \eta_0 e^{-\frac{\pi}{2} \sqrt{\frac{\alpha}{2}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{t^{1/2}}}$ as $t \to 0^+$
(inner)	Similarity form (2.6) with $\Omega(t) = e^{\frac{\pi}{2} \sqrt{\frac{\alpha}{2}} \frac{(\alpha+4)}{(\alpha+2)} \frac{1}{t^{1/2}}}$ (inner-inner)	

(again, both here and in Table 12 there may be additional algebraic terms), giving a similarity solution of the form (2.6) to (1.7), with $\alpha = \beta$ and

$$\phi(\eta) \sim A_2 \left(1 + \frac{(\alpha+4)}{(\alpha+2)\ln(-\eta)}\right)(-\eta)^{\frac{2}{\alpha}} \quad \text{as } \eta \to -\infty. \tag{8.12}$$

A striking feature of this analysis is that, unlike existing analyses of the PME (but more like Hele–Shaw corners [25]), it is possible here to follow explicitly the local analysis through the waiting-time in the "local" case $t_w = T$, the behavior being summarized in Table 11.

(III) $A = A_2$ ($m = q = 2/\beta$). See Table 12.

9. Discussion. Our small-time results serve in particular to identify, and to provide concrete illustrations of, certain phenomena not shared by PME. Specifically, for (1.1) with $\beta < \min(2, \alpha + 1)$ we have the possibility (when $B < 0$) of (finite-slope) retreating fronts or of interfaces which instantaneously switch the coefficient in their local behavior. Those local solutions which switch necessarily have $p = 2/\beta$ in (1.2) with $A \in (A_2, A^*)$ and, when they are applicable, represent a (slightly diffuse) borderline between retreating fronts and solutions in which the local behavior remains unchanged for some finite time. It is worth remarking that, by choosing initial data which exhibit different power laws over different orders of magnitude of $a - x$, it is possible to construct in the relevant (α, β) regimes solutions in which, for example, the interface advances, retreats, and then advances again. We leave the behavior at the end of a waiting time (for example, whether the interface can then begin to retreat rather than advance) as an open problem.

It is worth highlighting that we have in a number of places alluded to the formal time-reversibility of (1.7) being violated by differences between advancing and retreating fronts in terms of the nature of the local singularity at the interface. Thus despite

its apparent time-reversibility, (1.7) does exhibit a clear arrow of time in the sense of there being a marked distinction between the two directions of interface motion; a specific example of this is given in section 1 (taking $t_2 = 2t_1$, $P(t_2 - t) = -P(t)$, one could distinguish a film of fluid-thickness profile being run forward from $t = 0$ from one being run backwards from $t = t_2$ when P is negative, but not when P is positive, for $0 < t < t_1$). Such phenomena are of relevance to other formally time-reversible evolution equations; see [5] for a discussion of certain related issues. Our final remark in this regard is that, as described in section 3, the finite-slope branch (3.5), say, can also be admissible for advancing fronts, but is then underspecified. This implies that an extra physical constraint is needed to specify the solution, perhaps relating the slope Λ to the interface speed $\dot{s}$ (as may occur in other contexts, such as capillary-driven spreading). It would be worthwhile to explore the circumstances under which such solutions may be pertinent to (1.1).

Appendix. The similarity solution (2.7).

A.1. Formulation. Here we discuss relevant boundary value problems for (2.7), the results being of independent interest in view of their direct applicability to (1.7). We impose the far-field condition (6.5) with $A > 0$ and B prescribed and with m given by (6.2). We defer the fixed-front case $\beta > 2$ to section A.5, first describing the various regimes for $\beta < 2$. The requirement that m be less than $2/\beta$ implies that $A > A_2$ must hold, where $A_2 \equiv (\beta^2/2(\beta+2))^{\frac{1}{\beta}}$. The expression (6.5) then represents two boundary conditions, and imposing (6.6), with (2.9) holding in $\eta > 0$, thus yields a correctly specified system provided a solution exists in which $f(0) > 0$; the free-boundary location, $\eta_0 > 0$, in (2.9) is then given by

$$\eta_0 = \frac{(2(2-\beta)f^\beta(0))^{\frac{1}{2}}}{\beta}\,. \tag{A.1}$$

However, it is also possible for $f(\eta)$ to attain zero at $\eta = \eta_0 < 0$ with

$$f \to 0, \quad f^\beta \frac{d^2 f}{d\eta^2} \to 0 \quad \text{as } \eta \to \eta_0^- \tag{A.2}$$

leading to a correctly specified free-boundary problem, the solution of which has the local form

$$f(\eta) \sim \lambda(\eta_0 - \eta) \quad \text{as } \eta \to \eta_0^-, \eta_0 < 0\,, \tag{A.3}$$

for some constant $\lambda > 0$, corresponding to (3.5) and containing the necessary two-degree-of-freedom λ and η_0. Finally, there is a third possibility with the required two degrees of freedom, namely, that f attains zero at $\eta_0 = 0$ (so that this case represents a waiting-time scenario) with

$$f \sim \hat{A}(-\eta)^{\frac{2}{\beta}} + \hat{B}(-\eta)^{\hat{m}} \quad \text{as } \eta \to 0^-, \tag{A.4}$$

where $0 < \hat{A} < A_2$, so that

$$\hat{m} = \frac{1}{2}\left((1 + 4\hat{A}^{-\beta})^{\frac{1}{2}} - 1\right) \tag{A.5}$$

satisfies $\hat{m} > 2/\beta$. The constants $\hat{A}$ and $\hat{B}$ provide the two degrees of freedom in (A.4), with the calculation of the dependence of $\hat{A}$ upon A requiring the solution

of the boundary value problem for $f(\eta)$. We emphasize that, while the interface waits in this case, the local behavior (A.3) differs from that of the initial data, with $\hat{A} < A_2 < A$.

Since it may seem mysterious that retreating fronts, whereby (A.3) holds, satisfy one less boundary condition than advancing ones (for which $df/d\eta = 0$ at $\eta = \eta_0$) it is worth also giving an explanation for this in the similarity ODE context (noting that the ODE (2.7) is of third order in η, whereas (1.1) is second order in x). The expression (6.5) represents two boundary conditions and (A.2) two more which, given that η_0 is unknown, gives a correctly specified problem for $\eta_0 < 0$. For $\eta_0 > 0$, however, the continuity conditions

$$[f]_-^+ = \left[\frac{2}{\beta}\frac{df}{d\eta} - \eta\frac{d^2f}{d\eta^2}\right]_-^+ = 0 \quad \text{at } \eta = 0 \tag{A.6}$$

lead to the degrees of freedom f_0, f_1, $C_\pm$ in

$$f \sim f_0 + f_1\eta + C_\pm|\eta|^{\frac{2}{\beta}} \quad \text{as } \eta \to 0^\pm\,.$$

From (2.9) it happens that $C_+ = 0$; it is the need also to determine C_- that requires the third condition at $\eta = \eta_0$.

A.2. Exact results. When $B = 0$ we have the exact (borderline, steady-state) solution

$$f(\eta) = A(-\eta)^{\frac{2}{\beta}}, \quad \eta_0 = 0\,, \tag{A.7}$$

which can play the role of separating advancing and retreating fronts. When $B \neq 0$, the rescaling

$$f(\eta) = |B|^{\frac{2}{2-\beta m}}\hat{f}(\hat{\eta})\,,\ \hat{\eta} = \eta/|B|^{\frac{\beta}{2-\beta m}} \tag{A.8}$$

enables us to set $B = \pm 1$ without loss of generality, with corresponding solutions $\hat{f}_\pm(\hat{\eta})$, where we might anticipate that

$$\hat{f}_+(0) > 0,\ \eta_0 = (2(2-\beta)\hat{f}_+^\beta(0)^{\frac{1}{2}})B^{\frac{\beta}{2-\beta m}}/\beta\,, \tag{A.9}$$

and

$$\hat{f}_-(\hat{\eta}_0) = 0,\ \eta_0 = |B|^{\frac{\beta}{2-\beta m}}\hat{\eta}_0 \tag{A.10}$$

for some $\hat{\eta}_0 < 0$, so that $B > 0$ gives an advancing front and $B < 0$ a retreating one; in view of the alternative scenario (A.4) this is far from clear a priori, a point to which we shall return in section A.4.

When $A = A^* \equiv \left(\beta^2/2(2-\beta)\right)^{\frac{1}{\beta}}$ we have $m = 2/\beta - 1$ and

$$f^\beta(\eta) = \frac{\beta^2}{2(2-\beta)}(\eta_0 - \eta)^2\,,\ \eta_0 = \frac{\beta B}{2A^*} \tag{A.11}$$

holds exactly, both for $B > 0$ (giving $\eta_0 > 0$) and for $B < 0$ (with $\eta_0 < 0$); in this special case we thus have $\lambda = 0$ in (A.3). Other cases may also be analytically tractable; for example, for $\beta = 1$, $m = 1/2$ (so that $A = 4/3$) we have $f(\eta) = \frac{4}{3}(-\eta)^2 + B(-\eta)^{\frac{1}{2}}$ for $B < 0$, so that $\eta_0 = -(3|B|/4)^{\frac{2}{3}}$.

A.3. Asymptotics. The two regimes $A \to \infty$ and $A \to A_2^+$ are amenable to asymptotic investigation. In the former case we have $m \to 0$ and the right-hand side of (2.7) dominates; the boundary conditions then imply that the leading-order solution is simply

$$f(\eta) \sim A(-\eta)^{\frac{2}{\beta}} + B\,, \tag{A.12}$$

the relevant η scaling being $-\eta = O((|B|/A)^{\frac{\beta}{2}})$. Hence for $B > 0$ we have $\eta_0 > 0$, given by (A.1) with $f(0) \sim B$, while for $B < 0$ a retreated front occurs with

$$\eta_0 \sim -\left(\frac{|B|}{A}\right)^{\frac{\beta}{2}}, \quad \lambda \sim \frac{2}{\beta}\left(\frac{A}{|B|}\right)^{\frac{\beta}{2}} |B|\,. \tag{A.13}$$

Now setting $A = A_2 + \varepsilon$, with $0 < \varepsilon \ll 1$, we have

$$m \sim \frac{2}{\beta} - \varepsilon\mu,$$

where $\mu = \beta^2/A_2^{\beta+1}(4+\beta)$, and for algebraic convenience it is helpful to use the rescaling invariance to set, without loss of generality, $|B| = 2\varepsilon$. Under the change of variables

$$f = (-\eta)^{\frac{2}{\beta}}(A_2 + \varepsilon G(\zeta)), \quad \zeta = -\varepsilon\ln(-\eta)\,,$$

appropriate to the outer region $\zeta = O(1)$, we find at leading order that

$$0 = \frac{\beta}{A_2} G_0 \frac{dG_0}{d\zeta} - \frac{4+\beta}{\beta} A_2^{\beta} \frac{d^2 G_0}{d\zeta^2}\,.$$

Requiring $G_0(\zeta) \sim 1 + 2\frac{B}{|B|}e^{\mu\zeta}$ as $\zeta \to -\infty$ yields

$$\frac{dG_0}{d\zeta} = \frac{\mu}{2}(G_0^2 - 1)$$

and then

$$G_0(\zeta) = \coth\left(\frac{\mu}{2}(-\zeta)\right) \quad \text{if } B > 0\,, \tag{A.14}$$

$$G_0(\zeta) = \tanh\left(\frac{\mu}{2}(-\zeta)\right) \quad \text{if } B < 0\,. \tag{A.15}$$

For $B > 0$ (i.e., $B = 2\varepsilon$), the inner scaling is $\eta = O(1)$ (i.e., $\zeta = O(\varepsilon)$) and at leading order we obtain the full problem, except that the far-field condition (6.5) is replaced by

$$f_0(\eta) \sim (-\eta)^{\frac{2}{\beta}}\left(A_2 + \frac{2}{\mu\ln(-\eta)}\right) \quad \text{as } \eta \to -\infty \tag{A.16}$$

in order to match with (A.14); we conjecture that this condition leads to a solution with $\eta_0 > 0$. Finally, for $B < 0$ (i.e., $B = -2\varepsilon$) the outer expansion does not break down (unlike (A.14), the expression (A.15) does not become singular), and by taking the limit $\zeta \to +\infty$ ($\eta \to 0^-$) we obtain

$$f(\eta) \sim (A_2 - \varepsilon)(-\eta)^{\frac{2}{\beta}}\,, \tag{A.17}$$

consistent with our third scenario (A.4) with $\hat{A} \sim A_2 - \varepsilon$; we have $\hat{m} \sim \frac{2}{\beta} + \varepsilon\mu$ and, by (A.17), $\hat{B} \sim 2\varepsilon$.

A.4. Parameter regimes. The above results enable us to piece together as the likely picture the following scenario. The problem evidently warrants further study, not least by rigorous techniques, in order to confirm the behavior is indeed as outlined here. Further corroborating evidence for what follows can be obtained by an analysis of the limit $A \to A^*$; one then finds in particular that, setting $A = A^* - \varepsilon$ with $0 < \varepsilon \ll 1$, one has for $B < 0$

$$\hat{A} \sim \varepsilon h_\infty \quad \text{for } 0 < \beta < 1\,, \quad \hat{A} \sim \varepsilon^{\frac{1}{2-\beta}} h_\infty \quad \text{for } 1 < \beta < 2\,, \tag{A.18}$$

for some positive constant $h_\infty(\beta)$. The reasons for the transition in (A.18) at $\beta = 1$ can be identified from noting that the leading-order inner solution satisfies for $\beta \neq 1$ the traveling-wave balance

$$\frac{1}{2-\beta} h^{2-\beta} - \frac{1}{1-\beta} h_\infty h^{1-\beta} + \frac{1}{(2-\beta)(1-\beta)} h_\infty^{2-\beta} = \frac{1}{2}\left(\frac{dh}{d\zeta}\right)^2 . \tag{A.19}$$

In the outer region $\eta_0^* < \eta < 0$, where $\eta_0^* = \beta B/2A^*$ is the location of the interface for the $A = A^*$ problem (see (A.11)), we have from (2.7) that

$$h - \frac{\beta}{2}\eta \frac{dh}{d\eta} = 0$$

holds to leading order (where $f = \varepsilon h$ for $0 < \beta < 1$, $f = \varepsilon^{1/(2-\beta)} h$ for $1 < \beta < 2$), so that

$$f \sim \varepsilon h_\infty (-\eta/\eta_0^*)^{\frac{2}{\beta}} \quad \text{for } 0 < \beta < 1, \quad f \sim \varepsilon^{\frac{1}{2-\beta}} h_\infty (-\eta/\eta_0^*)^{\frac{2}{\beta}} \quad \text{for } 1 < \beta < 2$$

for $\eta_0^* < \eta < 0$, whereby $\hat{A} \to 0$, $\hat{m} \to \infty$ in (A.4) as $\varepsilon \to 0^+$. Thus the apparently abrupt transition in η_0 from $\eta_0^* < 0$ at $A = A^*$ to zero for $A < A^*$ with $A^* - A$ arbitrarily small is effected by f tending to zero in $\eta_0^* < \eta < 0$ as $\varepsilon \to 0^+$.

The main purpose of the subdivision which follows is to distinguish for $B < 0$ the ranges of A in which (A.3) holds from those in which (A.4) holds.

(1) $A > A^*$. Here we have (as illustrated by the large A solution (A.11)) $\eta_0 > 0$ for $B > 0$ and $\eta_0 < 0$ for $B < 0$ (so (A.3) applies for $B < 0$), with the borderline case $B = 0$ being given by (A.7).

(2) $A = A^*$. For $B < 0$, this case furnishes the borderline between the regime $A > A^*$ in which solutions satisfy (A.3) with $\eta_0 < 0$ and $A_2 < A < A^*$ in which (A.4) applies. It is characterized by the solution (A.10) having zero slope (and thus representing the exceptional case $\lambda = 0$ in (A.3)).

(3) $A_2 < A < A^*$. For $B > 0$ we conjecture that $\eta_0 > 0$ remains valid (with (A.9) here applying whenever $A > A_2$ for $B > 0$), while for $B < 0$ we have (A.4), as illustrated by (A.17) and (A.18) (determining the full dependence of $\hat{A}$ on A for given β would require the boundary value problem to be solved numerically), and $\eta_0 = 0$ thus holds in this regime for all $B \leq 0$.

A.5. The fixed-front regime $\beta \leq 2$. As $\beta \to 2^-$ we have $A^* \to +\infty$ and much of the behavior in the fixed-front cases $\beta \geq 2$ is naturally different from that described above. The borderline $A = A_2$ still applies, however, but for $B < 0$ we now have that (A.4) applies for all $A > A_2$ for the relevant solutions, implying that $U(t)$ remains zero for some finite time. The analysis of section A.3 for $A = A_2 + \varepsilon$ still applies, as does that for $A \to \infty$ with $B > 0$, so for $B > 0$ we have

$$U(t) \sim \Omega^{\frac{2}{\beta}}(t) f(0) \quad \text{as } t \to 0$$

with $f(0) \sim B$ as $A \to \infty$ and with the leading-order expression for $f(0)$ as $A \to A_2$ being determined by the boundary value problem in which the far-field condition is given by (A.16) (we conjecture that this leads to a solution with $f(0) > 0$). To complete the picture it remains only to analyze the limit $A \to \infty$ with $B < 0$, for which the structure is somewhat similar to that described at the end of section 4. The scalings in the first of the two outer regions, namely, $\xi = O(1)$ with $\xi < -1$, are

$$\eta = (|B|/A)^{\frac{\beta}{2}}\xi\,, \quad f = |B|g,$$

whereby to leading order as $A \to \infty$ we have

$$0 = \frac{d}{d\xi}\left(g^\beta \frac{d}{d\xi}\left(g - \frac{\beta}{2}\xi\frac{dg}{d\xi}\right)\right),$$

from which the leading-order solution

$$g = (-\xi)^{\frac{2}{\beta}} - 1$$

follows. The inner scalings are

$$\xi = \xi_0(\varepsilon) + A^{-\frac{\beta}{\beta-2}}\zeta, \quad g = A^{-\frac{\beta}{\beta-2}}h\,,$$

with $\xi_0(0) = -1$ and where, for brevity, we shall not address the borderline case $\beta = 2$ in which the relevant scalings are exponentially small. This again gives the traveling-wave balance

$$h - h_\infty \sim h^\beta \frac{d^2h}{d\zeta^2}\,, \quad \begin{array}{l} h \sim \dfrac{2}{\beta}(-\zeta) \quad \text{as } \zeta \to -\infty\,, \\ h \to h_\infty \quad \text{as } \zeta \to +\infty\,, \end{array} \tag{A.20}$$

at leading order, where the positive constant h_∞ is determined as part of the solution; since the first integral (A.19) is available, we have that

$$h_\infty = (2(\beta-2)(\beta-1)/\beta^2)^{-\frac{1}{\beta-2}}\,.$$

Finally, in the second outer region $-1 < \xi < 0$ we have

$$h - \frac{\beta}{2}\xi\frac{dh}{d\xi} = 0$$

to leading order, so matching into the interior layer $\zeta = O(1)$ we obtain $h \sim h_\infty(-\xi)^{\frac{2}{\beta}}$, and hence in (A.4) we have

$$\hat{A} \sim A^{-\frac{2}{\beta-2}}h_\infty \quad \text{as } A \to \infty\,.$$

A.6. The special case $\beta = 1$. The implications of the above results for this special case (in which $A_2 = 1/6$, $A^* = 1/2$) are worth spelling out because it also represents the thin-film limit of the Hele–Shaw problem with kinetic undercooling (see [23], [9]; the formulation applies when the problem is symmetric about the x-axis, though the results can readily be generalized). The current analysis pertains locally when the initial fluid region contains an outward-pointing cusp of the form

$$u_0(x) \sim A(a-x)_+^2 \quad \text{as } x \to a^-\,. \tag{A.21}$$

In this context $y = u(x,t)$ denotes the upper fluid interface and the thin-film problem can be written in the form

$$p = \frac{\partial}{\partial x}\left(u\frac{\partial p}{\partial x}\right), \quad p = \frac{\partial u}{\partial t},$$

where p corresponds to the fluid pressure. Thus at $t = 0$ we typically have

$$p \sim B(a-x)^m \quad \text{as } x \to a^-$$

for some constant B (so that $\Omega(t) = t^{1/(2-m)}$ applies in the small-time local solution (2.6)), where m is given by (6.2) with $\beta = 1$. For $A < 1/6$ we have $m > 2$, so a waiting-time phenomenon ensues in which (A.21) remains valid locally for some finite time. In the injection case (corresponding to $B > 0$), for $A > 1/6$ the interface immediately propagates forward, though (for reasons discussed more generally in [15]) not according to the above thin-film prescription; rather we should impose on (2.7) the (fixed-front) condition

$$f\frac{d}{d\eta}\left(f - \frac{1}{2}\eta\frac{df}{d\eta}\right) = 0 \quad \text{at } \eta = 0^-,$$

with u in $x > a$ then being asymptotically given for small t by a quarter circle of radius $t^{2/(2-m)}f(0)$ (which is not of course of large aspect ratio, so does not fall within the remit of the thin-film evolution equation).

For the suction case ($B < 0$), however, we have for $1/6 < A < 1/2$ that the local behavior flips to (A.4) and then waits for some finite time. This class of suction phenomena is strikingly similar to that exhibited by the unregularized (and hence ill-posed) Hele–Shaw problem in which the interface initially contains a corner [25]; if the corner angle is less than $\pi/2$, the local behavior is then preserved for some finite time (as it is here for $A < 1/6$), while for angles between $\pi/2$ and π the corner angle instantaneously decreases to a value less than $\pi/2$ (which depends only on the initial angle) and then waits for some finite time (akin to the instantaneous decrease described above in the relevant coefficient from A to $\hat{A}$ ($< 1/6$), where $\hat{A}$ depends only on A for given β). However, for angles greater than π, the unregularized problem has no solution for $t > 0$, whereas in the current case the interface retracts in the equivalent regime $A > 1/2$, forming a corner of small but increasing angle (as in (A.3)). This continued existence of the solution is a desirable feature of the regularization; moreover, while the Hele–Shaw problem with kinetic undercooling exhibits (not just in its thin-film limit) formal time-reversal symmetry between the suction and injection cases, this symmetry is again broken by singularity formation (whereby if a corner forms and propagates under suction, it is immediately smoothed by injection in a non-time-reversible fashion; cf. the discussion of cusps in the zero-surface-tension Stokes flow problem in [12]).

PERMEABILITY HYSTERESIS IN GRAVITY COUNTERFLOW SEGREGATION*

C. E. SCHAERER†, M. SARKIS‡, D. MARCHESIN†, AND P. BEDRIKOVETSKY§

Abstract. Hysteresis effects in two-phase flow in porous media are important in applications such as waterflooding or gas storage in sand aquifers. In this paper, we develop a numerical scheme for such a flow where the permeability hysteresis is modeled by a family of reversible scanning curves enclosed by irreversible imbibition and drainage permeability curves. The scheme is based on associated local Riemann solutions and can be viewed as a modification of the classical Godunov method. The Riemann solutions necessary for the scheme are presented, as well as the criteria that guarantee the well-posedness of the Riemann problem with respect to perturbations of left and right states. The numerical and analytical results show strong influence of the permeability hysteresis on the flow. In addition, the numerical scheme accurately reproduces the available experimental data once hysteresis is taken into account in the model.

Key words. relative permeability, hysteresis, Riemann problem, conservation laws, two-phase flow in porous media, Godunov method

1. Introduction.

Capillary hysteresis strongly affects two-phase flow in porous media during sequential increase and decrease of wetting phase saturation (i.e., during the so-called imbibition and drainage, respectively) [6, 8]. The alternation of imbibition and drainage occurs in several oil recovery processes. It occurs in waterflooding with displacement direction change due to redistribution of injection and production rates in a system of wells, WAG (water-alternate-gas) injection of sequences of water and gas slugs, and sequential injection and production in the same well [4]. Annual injection and production of natural gas in aquifers or in depleted petroleum reservoirs for storage purposes also result in significant hysteretic phenomena. A similar flow regime change phenomenon, from imbibition to drainage and vice versa, occurs in secondary migration of hydrocarbons during the formation of petroleum accumulations [1], in irrigation, and in soil contamination by gasoline.

Capillary hysteresis at a macroscopic scale is caused by several pore scale phenomena. The contact angle on menisci between wetting and nonwetting phases suffers hysteresis during flow changes in a single pore. Creation of new interfacial surfaces resulting in energy losses occurs during imbibition; on the contrary, energy is released during drainage due to oil droplet joining. All these phenomena result in different scenarios of porous space filling by wetting and nonwetting phases.

Models for multiphase flow in porous media are based on conservation of mass and Darcy's law. The associated equations contain quantities describing the rock and fluid properties, in particular relative phase permeabilities. The latter describe the capability of each phase to flow in the porous medium [2, 9]. Relative permeability of the nonwetting phase exhibits hysteresis or memory effects [10], i.e., according to the saturation tendency, the relative permeability is different [18].

The model for hysteretic relative permeability of the nonwetting phase [2, 12] follows experimental observations of drainage, imbibition, and scanning behavior of relative permeability [6, 7, 8, 13, 19]. Changes in the direction of the flow in drainage and imbibition are irreversible [6, 18]; flow in the region between drainage and imbibition curves is in general almost reversible [8, 19, 17]; however, we will make the approximation that it is exactly reversible [6, 13].

Observations and explanations of permeability hysteresis in laboratory experiments for horizontal one-dimensional flow were presented in several works [17, 6, 8]. However, mathematical understanding is insufficient, hindering the inclusion of hysteresis in numerical simulation of reservoir flow. Formulae for drainage, imbibition, and scanning relative permeabilities curves were developed in [2, 12], among others. In [15], only the imbibition and drainage curves were considered. A model that we will call the scanning hysteresis model (SHM) for the history dependence of the relative permeabilities was presented in [10] and in [18].

In the current work, we concentrate on hysteretic gravity segregation. This phenomenon occurs after waterflooding or after gas injection in thick oil formations. It also occurs in in-situ gas storage in thick formations between injection and production cycles. Estimation of the gravity separation time is necessary for planning of tertiary recovery from reformed formations.

Our goal is to develop a numerical tool for the gravitational counterflow segregation problem with a hysteretic relative permeability. Because Riemann solutions with hysteresis in the relative permeability are not unique, we introduce criteria to obtain well-posedness with respect to left and right states. In the large scale approximation formulation, we do not include the capillarity pressure and its hysteresis [4].

The paper is organized as follows: In section 2, we present the model for two-phase gravity counterflow segregation. In addition, we extend the SHM for the nonwetting relative permeability [18] to include gravity. This model associates a hysteretic parameter π in order to "remember" the value of the saturation at the last time when the saturation tendency was reversed. In the equations used to model the segregation, the capillary forces and its hysteresis affect both the transport part and the diffusive part. We concentrate on the hysteresis in relative permeability. In section 3, the Riemann solutions for the hysteretic conservation law are discussed. Criteria to select a unique well-posed solution are developed. In section 4, we propose a corrected Godunov scheme that updates both the saturation and the hysteretic states. This scheme conserves mass locally. Finally, in section 5, we show that the numerical solution of the Riemann problem converges to the exact solution. Comparisons of the numerical solution (with and without hysteresis) with laboratory data are presented. They show that hysteresis must be taken into account to obtain correct predictions of segregation. Additionally, it is demonstrated that the proposed numerical method captures adequately the experimental profiles, and the main hysteresis effects can be modeled through the relative permeability curves.

2. The two-phase model for gravity counterflow segregation. We consider a sand-packed vertical tube with a given initial saturation profile of two incom-

pressible immiscible fluids. Redistribution of the fluids with different densities occurs due to gravitational forces. The total flow along the tube is zero as the tube is closed at the top and bottom. Neglecting diffusive terms due to capillarity relative to gravitational forces, the two-phase flow model equation expressing mass conservation and Darcy's law in dimensionless variables (z,t), $\{0 \le z \le 1, t \ge 0\}$ is [4]

$$\partial_t s + \partial_z F(s,\pi) = 0, \tag{2.1}$$

where the flow function $F(s,\pi)$ is

$$F(s,\pi) := \frac{k_{rw}k_{ro}}{k_{ro} + (\mu_o/\mu_w)k_{rw}}. \tag{2.2}$$

We use the indices w and o to refer to the wetting and nonwetting phases, respectively. The quantities k_{rw} (k_{ro}) and μ_w (μ_o) are the relative permeability and the viscosity of the wetting phase w (nonwetting o), respectively. In the absence of hysteresis, k_{rw} (k_{ro}) are functions of the effective wetting phase saturation s defined as

$$s := \frac{s_w - s_{wi}}{s_{ro} - s_{wi}}, \tag{2.3}$$

where s_{wi} is the irreducible wetting saturation and s_{ro} is the residual nonwetting saturation.

2.1. The SHM: Mathematical description. To model the hysteresis phenomenon observed experimentally in the relative permeabilities [6], we extend the SHM presented in [10, 18] to include gravity. For simplicity, the nonwetting phase exhibits hysteresis, while the wetting phase does not. In order to describe the behavior due to hysteresis, a parameter π is introduced. Concretely, we generalize the permeability functions presented in [18] and use the following special permeability functions of the effective saturation s [3].

The wetting relative permeability is defined as (Figure 2.1(a))

$$k_{rw}(s) := \gamma s^{\beta},\ \beta > 1, \tag{2.4}$$

where γ is a parameter to adjust the curve (2.4) to the relative permeability curve obtained experimentally, so that $k_{rw}(1) = \gamma$, as the nonwetting permeability is normalized as 1 for $s = 0$.

The nonwetting drainage and imbibition relative permeabilities functions (expressed by k^d_{ro} and k^i_{ro}) are defined as (Figure 2.1(a)) [3]

$$\begin{aligned} k^d_{ro}(s) &= (1-s)^{\eta} \quad \text{for } 0 \le s \le 1 \quad \text{and when } \frac{\partial s}{\partial t} < 0, \\ k^i_{ro}(s) &= (1-s)^{\theta} \quad \text{for } 0 \le s \le 1 \quad \text{and when } \frac{\partial s}{\partial t} > 0, \end{aligned} \tag{2.5}$$

where $1 < \theta < \eta$. In this paper, we use $\beta = 2$, $\eta = 3$, and $\theta = 2$; therefore $k^d_{ro} \le k^i_{ro}$.

The scanning region corresponds to the region between the nonwetting drainage and imbibition relative permeabilities curves. In such a region the nonwetting permeability k_{ro} is chosen as

$$k_{ro}(s,\pi) := \frac{(1-\pi)^{\xi}}{(1-\alpha\pi)^{\zeta}}(1-\alpha s)^{\zeta}, \tag{2.6}$$

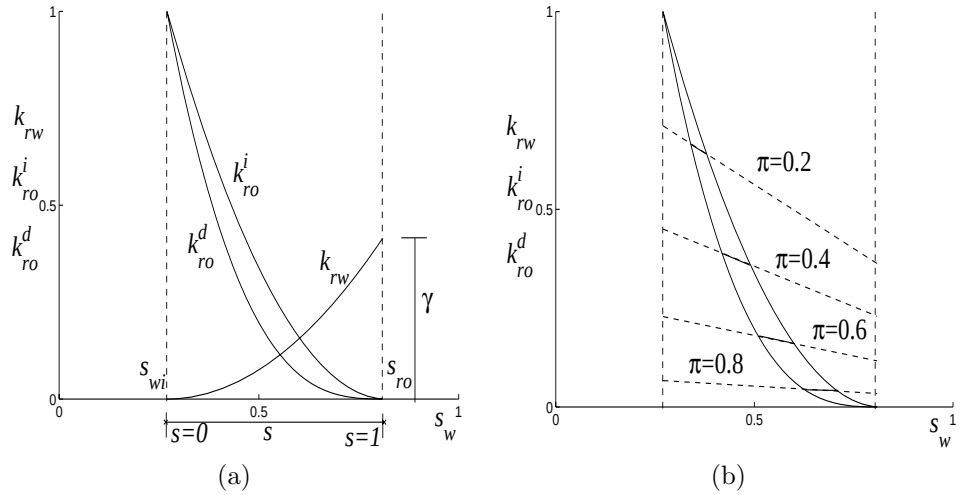

FIG. 2.1. (a) *Nonwetting imbibition and drainage permeabilities functions, and wetting permeability, and* (b) *scanning curves (as a function of the saturation of the wetting phase s_w and the hysteresis parameter π); inspired by Braun and Holland* [6].

where the parameter π ($0 \le \pi \le 1$) discriminates each scanning curve. We use $\xi = 2$ and $\zeta = 1$; therefore, k_{ro} defined above is linear in s for each fixed π; see Figure 2.1(b). Notice that the dashed lines meet at the point $(1/\alpha, 0)$, where α is another parameter used to adjust the slopes of the scanning curves to the experimental ones. We use $\alpha = 0.5$. In the SHM, the scanning curve associated to π is defined in the saturation range $s^i(\pi) < s < s^d(\pi)$. The functions $s^i(\pi)$ and $s^d(\pi)$ are defined implicitly by

$$k^d_{ro}(s^d(\pi)) = k_{ro}(s^d(\pi), \pi) \quad \text{and} \quad k^i_{ro}(s^i(\pi)) = k_{ro}(s^i(\pi), \pi). \tag{2.7}$$

On the drainage and imbibition permeability curves, expressions for the parameter π as a function of the saturation s, and vice versa, can be obtained. Thus we define from (2.7) the functions $\pi^d(s)$ and $\pi^i(s)$. Plots of these functions are shown in Figure 2.2(a).

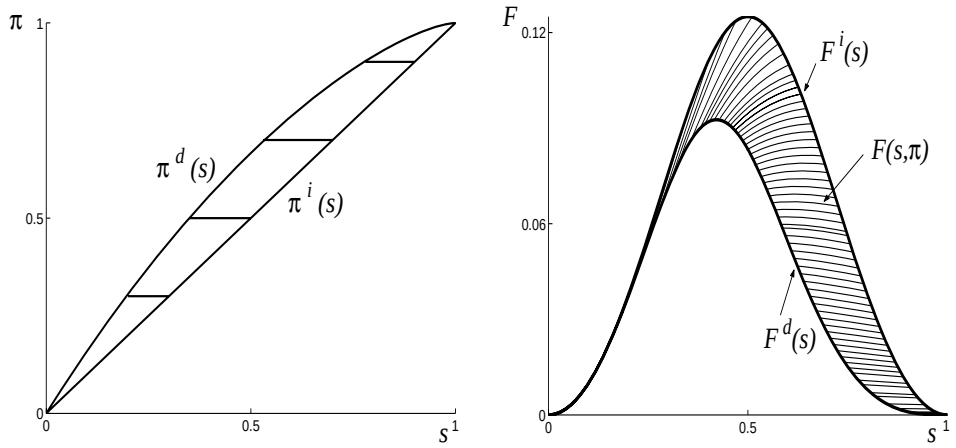
The flux (2.2) depends on the history (expressed by the parameter π) and the type of the flow (expressed through the sign of $\partial_t s$). Using the relative permeabilities k_{ro} in (2.6) and (2.5), and using k_{rw} in (2.4), the flux function (2.2) takes the form

$$F(s, \pi) \text{ in the scanning region, where } \partial_t \pi = 0, \tag{2.8}$$

$$F^d(s) := F(s, \pi^d(s)) \text{ on the drainage curve, where } \partial_t s < 0, \tag{2.9}$$

$$F^i(s) := F(s, \pi^i(s)) \text{ on the imbibition curve, where } \partial_t s > 0. \tag{2.10}$$

The fluxes $F(s, \pi)$, $F^d(s)$, and $F^i(s)$ (given by (2.2), (2.9), and (2.10), respectively) are shown in Figure 2.2(b). Notice that the drainage and imbibition curves $F^d(s)$ and $F^i(s)$ bound the admissible scanning region Ω on the plane (s, F), defined as $\Omega = \{(s, F) \in \Re^2 : F^d(s) \le F \le F^i(s)\}$. We define the drainage and imbibition curves as $dr := \{(s, F) \in \Re^2 : F = F^d(s)\}$ and $im := \{(s, F) \in \Re^2 : F = F^i(s)\}$, respectively. The permeability functions (2.4) and (2.5) lead to the following necessary properties of the fractional flow function in the scanning, drainage, and imbibition



(a) (b)

FIG. 2.2. (a) *State space.* (b) *Fractional flow curves (imbibition, drainage, and scanning).*

flows in the SHM:

$$F^d(0) = 0, \quad F^d(1) = 0, \quad F^i(0) = 0, \quad F^i(1) = 0, \tag{2.11}$$

$$\partial_s F^d(s) \le \partial_s F(s, \pi^d(s)), \quad \partial_s F^i(s) \le \partial_s F(s, \pi^i(s)); \tag{2.12}$$

of course other permeability functions satisfying (2.11) and (2.12) can be chosen. These properties ensure that the intersection of the scanning curves with the drainage (or imbibition) curve varies smoothly with π. In addition, as we will see in the next section, property (2.12) guarantees the existence of solution at the intersections of the scanning with the drainage and imbibition curves.

3. The Riemann problem. For imbibition and drainage flows the pair (s, π) lies on the imbibition and drainage curves; therefore the value of π is given by $\pi = \pi^i(s)$ and $\pi = \pi^d(s)$. In these cases, scalar conservation laws are satisfied:

$$\partial_t s + \partial_z F^j(s) = 0, \ j := i, d. \tag{3.1}$$

For scanning flow the conservation law (3.1) is extended to include the independent variable π. Hence the conservation law becomes

$$\partial_t s + \partial_z F(s, \pi) = 0, \tag{3.2}$$

$$\partial_t \pi = 0, \tag{3.3}$$

and can be written in quasi-linear form $\partial_t u + A^s \partial_z u = 0$ with Jacobian

$$A^s = \begin{bmatrix} \partial_s F(s,\pi) & \partial_\pi F(s,\pi) \\ 0 & 0 \end{bmatrix} \text{ and } u := [s, \pi]^T.$$

For scanning flow, the eigenvalues of A^s (or characteristics speeds) are zero and $\partial_s F(s, \pi)$, with corresponding eigenvectors $[\partial_\pi F(s,\pi), \ -\partial_s F(s,\pi)]^T$ and $[1, \ 0]^T$.

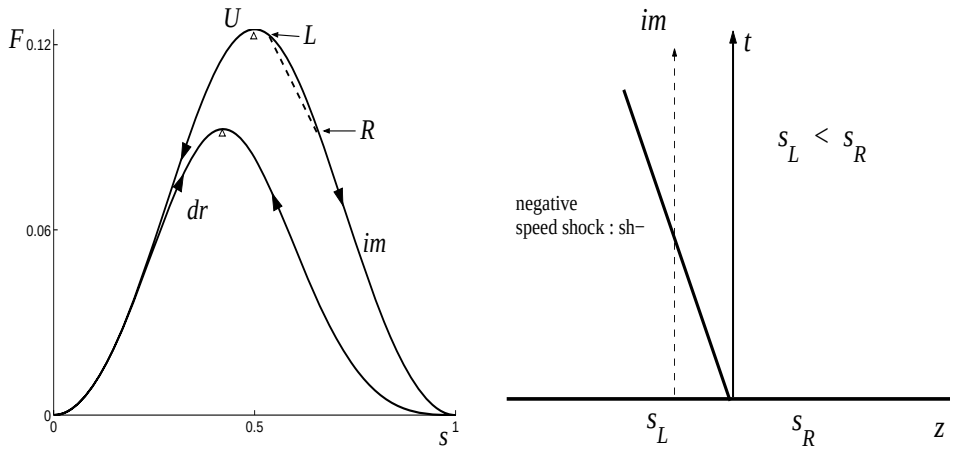


FIG. 3.1. *Flow direction in drainage and imbibition curves. dr: drainage, im: imbibition;* s_U*: saturation associated to the state* $U = \big(s_U, F^i(s_U)\big)$.

3.1. Wave families. For each flow we describe the solution of the Riemann problem:

$$(s,\pi)|_{t=0} = \begin{cases} (s_L,\pi_L) & \text{for } z < z_o, \\ (s_R,\pi_R) & \text{for } z > z_o. \end{cases} \tag{3.4}$$

Hereafter, we will use the following notation. A state L is defined as $L := (s, F) \in \Omega$, where s_L and F_L are the saturation and the flux associated to the state L. Additionally, π_L is the associated parameter π to the state L. In the scanning region, $F_L = F(s_L, \pi_L)$, and on the curve dr (im) $F_L = F^d(s_L)$ $(F_L = F^i(s_L))$.

3.1.1. Imbibition or drainage flow. Since in imbibition (drainage) flow the saturation increases (decreases) in time, i.e., $\partial_t s > 0$ $(\partial_t s < 0)$, a rarefaction wave is characterized by a continuous and monotonically increasing speed $\lambda = \partial_s F^j(s)$ from s_L to s_R. Additionally, a shock wave with speed σ satisfies the Rankine–Hugoniot (RH) condition:

$$\sigma = \frac{F^j(s_R) - F^j(s_L)}{s_R - s_L},\ j = i, d; \tag{3.5}$$

furthermore, the shock is required to satisfy the Oleinik entropy condition for scalar equations. Therefore, admissible sequences of shock and rarefaction waves can be constructed graphically using the concave and convex hull of the fractional flow curves, following [16]. We still have to impose the imbibition and drainage flow orientation. Let s_U be the saturation that maximizes $F^i(s)$ $(U := \{(s_U, F^i(s_U) : F_U = \max(F^i(s)) \text{ for } 0 \le s \le 1\})$. To select the imbibition (drainage) flow orientation the conditions $s_U \le s_L \le s_R$ or $s_R \le s_L \le s_U$ $(s_U \le s_R \le s_L$ or $s_L \le s_R \le s_U)$ must hold. For instance, a shock satisfying these conditions is shown in Figure 3.1(a), and we see that $\partial_t s > 0$ in Figure 3.1(b). For other cases, such as $s_U \le s_R \le s_L$, $s_L \le s_R \le s_U$ $(s_U \le s_L \le s_R$, $s_R \le s_L \le s_U$ for drainage), $s_L \le s_U \le s_R$, and $s_R \le s_U \le s_L$, the Riemann solution must contain scanning waves; otherwise $\partial_t s$ would be negative and therefore the solution could not be on the imbibition curve.

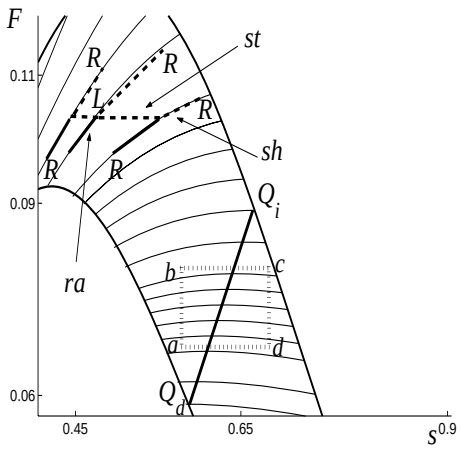

FIG. 3.2. *Scanning cases. Stationary shock, st; shock, sh; rarefaction, ra.*

3.1.2. Scanning flow. The RH condition is

$$F(s_R, \pi_R) - F(s_L, \pi_L) = \sigma(s_R - s_L), \tag{3.6}$$

$$0 - 0 = \sigma(\pi_R - \pi_L). \tag{3.7}$$

Equations (3.6) and (3.7) are satisfied by two kinds of discontinuities; see Figure 3.2. The first one is a shock with speed σ:

$$F(s_R, \pi) - F(s_L, \pi) = \sigma\left(s_R - s_L\right), \tag{3.8}$$

where π is constant, i.e., $\pi = \pi_L = \pi_R$. This corresponds to the Riemann solution of the single scalar conservation law (3.2) (see Figure 3.2). The second kind of discontinuities satisfying the RH condition (3.6)–(3.7) are stationary discontinuities with speed $\sigma = 0$ and constant fractional flow function; generically they satisfy $\pi_R \neq \pi_L$ and $s_L \neq s_R$.

Summarizing, the scanning curve and the horizontal line through state L divide the scanning region in R-regions where the solution consists of a combination of a stationary wave and scanning waves that are either rarefaction or shocks. Some simple cases are presented in Figure 3.2. A more complex Riemann solution exists when scanning curves have a maximum in Ω and there is no interaction with the imbibition and drainage curves. This RP presents multiplicity of solutions; therefore, we have to make choices to have appropriate solutions. To classify the chosen Riemann solutions, we analyze the *abcd* region in Figure 3.2. This region is sketched in Figures 3.3(a) and (b). The curve Q_dQ_i is the set of states $Q = (s, F(s, \pi))$ in Ω where the saturation s maximizes $F(s, \pi)$ for each π (see Figure 3.2).

In Figures 3.3(a) and (b), we show the regions and their associated Riemann solutions for left states L_1 and L_2 lying on opposite sides of the curve Q_dQ_i. A summary of the solutions is given in Table 3.1; the waves are ordered from lower to higher speeds. For example, the solution $L_1I_1R_1$ consists of a stationary shock L_1I_1 connecting states L_1 and I_1 (denoted by $L_1 \xrightarrow{st} I_1$), and a positive speed shock I_1R_1 connecting states I_1 and R_1 (denoted by $I_1 \xrightarrow{sh+} R_1$).

3.1.3. Intermediate flow. Denoting by I the intersection state between the π_L-scanning and the drainage (imbibition) curves, the solution between a scanning state

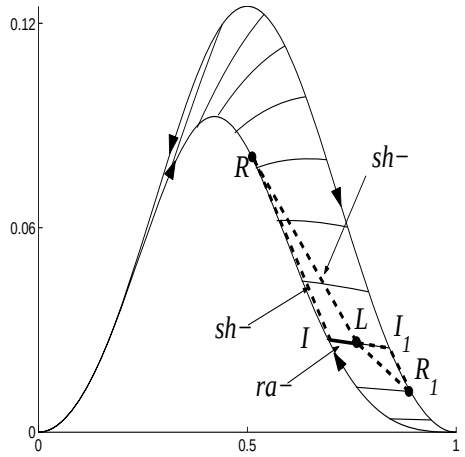
L and a drainage (imbibition) state R is constructed using a concave (convex) hull curve on the effective flux function LIR (see Figure 3.4). Therefore, the interaction of the two waves LI and IR yields a shock LR with speed

$$\sigma = \frac{F^d(s_R) - F(s_L, \pi_L)}{s_R - s_L}, \tag{3.9}$$

since the shock IR has a smaller speed than the rarefaction LI, i.e., $(F^d(s_R) - F^d(s^d(\pi_L)))/(s_R - s^d(\pi_L)) \le \partial_s F(s^d(\pi_L), \pi_L)$, and at I the drainage and scanning curves satisfy inequalities (2.12).

3.2. Riemann solutions. The construction of the Riemann solutions is simplified by describing state space in terms of (s, F) instead of (s, π). We subdivide Ω into four subregions (L-regions) defined as follows (see Figure 3.5):

$$\begin{aligned}
A &= \{(s,F) \in \Omega : s_{Q_d} \le s \le 1 \text{ and } F \le F(s, \pi_{Q_d})\},\\
B &= \{(s,F) \in \Omega : s_M \le s \le s_P \text{ and } F(s, \pi_{Q_d}) \le F \le F^d(s_M)\},\\
C &= \{(s,F) \in \Omega : 0 \le s \le 1 \text{ and } F^d(s_M) \le F\},\\
D &= \{(s,F) \in \Omega : 0 \le s \le s_M \text{ and } F \le F^d(s_M)\},
\end{aligned}$$



(a)

FIG. 3.4. *Transition from a scanning curve to a drainage or imbibition curve.*

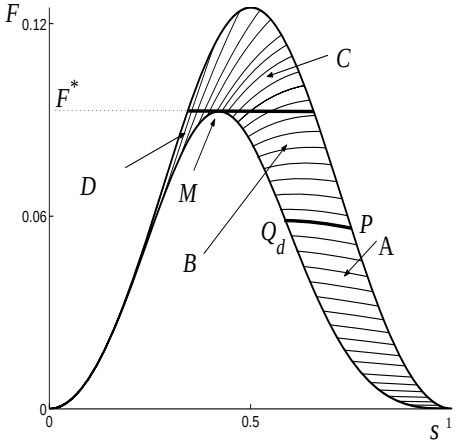


FIG. 3.5. *L-regions of* Ω.

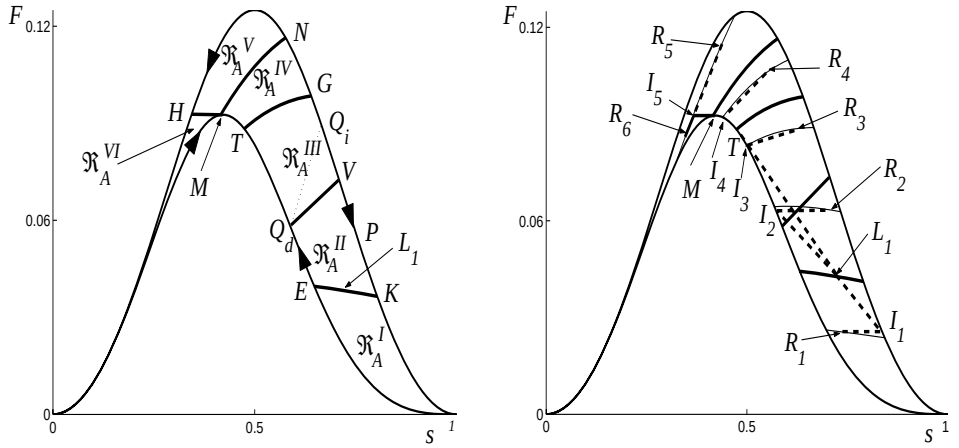
where the imbibition state P is defined as the intersection point of the imbibition curve with the scanning curve through the states Q_d, while M is the state where s_M maximizes $F^d(s_M)$. Next we construct the solutions for L in each of the L-regions.

Case A: $L_1 = (s_L, F(s_L, \pi_L)) \in A$. In this case, there are the following six R-regions (see Figure 3.6(a)):

$$\begin{aligned}
\Re_A^I &= \{(s,F) \in \Omega : s_E \le s \text{ and } F \le F(s,\pi_L)\},\\
\Re_A^{II} &= \{(s,F) \in \text{region enclosed by } EKVQ_d\},\\
\Re_A^{III} &= \{(s,F) \in \text{region enclosed by } Q_dVGT\},\\
\Re_A^{IV} &= \{(s,F) \in \Omega : s_M \le s \le s_G \text{ and } F(s,\pi_T) \le F \le F(s,\pi_M)\},\\
\Re_A^{V} &= \{(s,F) \in \Omega : s_H \le s \le s_N \text{ and } F(s,\pi_M) \le F \text{ and } F^d(s_M) \le F\},\\
\Re_A^{VI} &= \{(s,F) \in \Omega : s \le s_M \text{ and } F \le F^d(s_M)\},
\end{aligned}$$



(a) (b)

FIG. 3.6. *Figure* (a) *(Case A): R-regions for L_1 in L-region A. Figure* (b) *(Case A): solutions for L_1 in L-region A and R in R-regions: $R_1 \in \Re_A^I$, $R_2 \in \Re_A^{II}$, $R_3 \in \Re_A^{III}$, $R_4 \in \Re_A^{IV}$, $R_5 \in \Re_A^V$, and $R_6 \in \Re_A^{VI}$.*

where the states E and K are the intersection of drainage and imbibition curves with the scanning curve through L_1. We define the state $V \in im$ and the curve Q_dV by $Q_dV := \{W = (s_W, F_W) \in \Omega : (s_W, F_W) = (s_I + 2(s_Q - s_I), F_I)\ \forall I \in dr\}$. States N and H are the intersections of the imbibition curve with the scanning and the horizontal line through M, respectively. We define the drainage state T through $\partial_s F^d(s_T) = (F^d(s_T) - F_L)/(s_T - s_L)$, and the state G as the intersection of the imbibition curve with the scanning curve though T. Notice that T and G depend on L_1. Assuming that $\partial_{ss}F(s,\pi) < 0$, the Riemann solution associated to each R-region as shown in Figure 3.6(a) is presented in Figure 3.6(b) and described below:

A.1. For $R_1 \in \Re_A^I$, the solution is $L_1 \xrightarrow{sh-} I_1 \xrightarrow{st} R_1$.

A.2. For $R_2 \in \Re_A^{II}$, the solution is $L_1 \xrightarrow{sh-} I_2 \xrightarrow{st} R_2$.

A.3. For $R_3 \in \Re_A^{III}$, the solution is $L_1 \xrightarrow{sh-} I_3 \xrightarrow{sh+} R_3$, where state I_3 is determined by the intersection of the drainage curve with the scanning curve through R_3.

A.4. For $R_4 \in \Re_A^{IV}$, the solution is $L_1 \xrightarrow{sh-} T \xrightarrow{ra-} I_4 \xrightarrow{sh+} R_4$, where I_4 is determined by the intersection of the drainage curve with the scanning curve through R_4.

A.5. For $R_5 \in \Re_A^V$, the solution is $L_1 \xrightarrow{sh-} T \xrightarrow{ra-} M \xrightarrow{st} I_5 \xrightarrow{sh+} R_5$, where state I_5 is the intersection of the horizontal line through M and the scanning curve through R_5.

A.6. For $R_6 \in \Re_A^{VI}$, the solution is $L_1 \xrightarrow{sh-} T \xrightarrow{ra-} M \xrightarrow{st} I_5 \xrightarrow{ra+} R_6$. When I_5 is on the imbibition curve, the solution will be shown in Case *C*, Figure 3.9(a)

Case B: $L_2 = (s_L, F(s_L, \pi_L)) \in B$. The R-regions are shown in Figure 3.7(a). The Riemann solutions for the R-regions $\Re_B^V$, $\Re_B^{VI}$, and $\Re_B^{VII}$ are analogous to those of solutions for the R-regions $\Re_A^{IV}$, $\Re_A^V$, and $\Re_A^{VI}$, respectively. The solutions for R-regions $\Re_B^I$, $\Re_B^{II}$, $\Re_B^{III}$, and $\Re_B^{IV}$ are shown in Figure 3.7(b) and described below:

B.1. For $R_1 \in \Re_B^I$, the solution is $L_2 \xrightarrow{sh-} I_1 \xrightarrow{st} R_1$.

B.2. For $R_2 \in \Re_B^{II}$, the solutions is $L_2 \xrightarrow{sh-} I_2 \xrightarrow{st} Q \xrightarrow{ra+} R_2$.

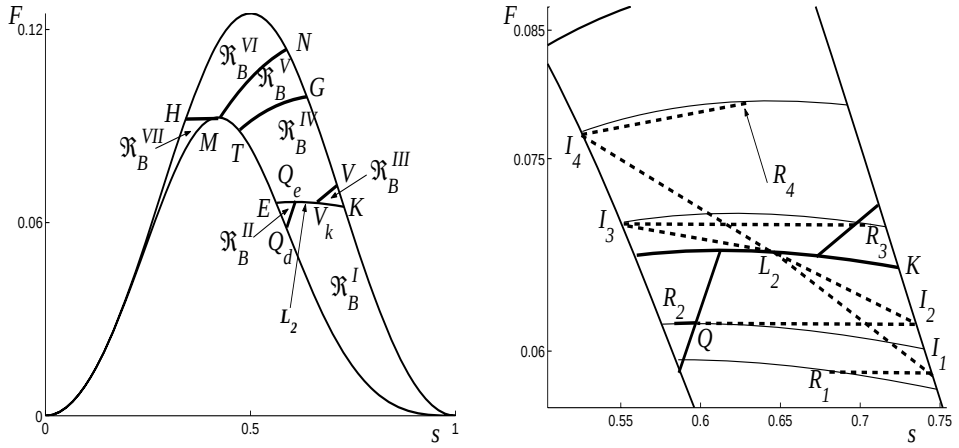


FIG. 3.7. *Figure* (a) *(Case B): R-regions for L_2 in the L-region B. Figure* (b) *(Case B): L_2 in L-region B and $R_1 \in \Re_B^I$, $R_2 \in \Re_B^{II}$, $R_2 \in \Re_B^{III}$, and $R_4 \in \Re_B^{IV}$.*

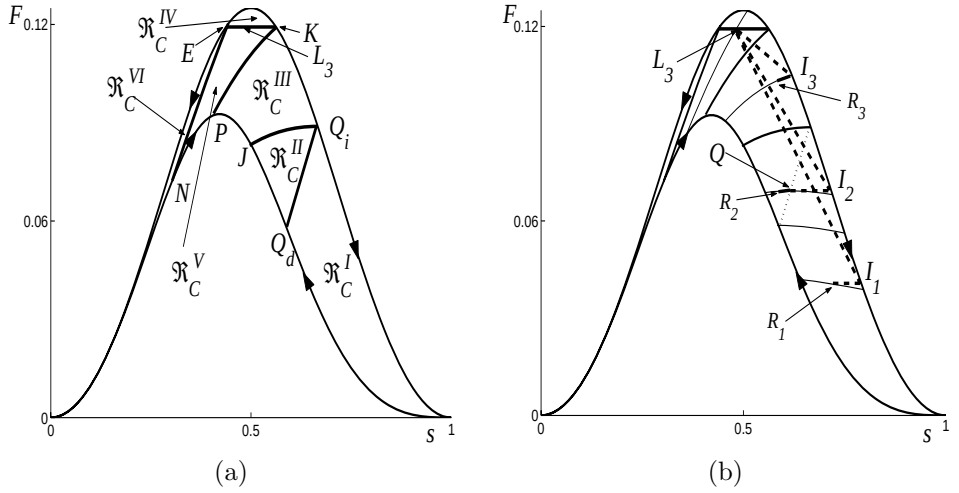

FIG. 3.8. *Figure* (a) *(Case C): R-regions for L_3 in L-region C. Figure* (b) *(Case C): solutions for L_3 in L-region C and R in R-regions: $R_1 \in \Re_C^I$, $R_2 \in \Re_C^{II}$, and $R_3 \in \Re_C^{III}$.*

B.3. For $R_3 \in \Re_B^{III}$, the solution is $L_2 \xrightarrow{sh-} I_3 \xrightarrow{st} R_3$.

B.4. For $R_4 \in \Re_B^{IV}$, the solution is $L_2 \xrightarrow{sh-} I_4 \xrightarrow{sh+} R_4$.

Case C: $L_3 = (s_L, F(s_L, \pi_L)) \in C$. The R-regions are shown in Figure 3.8(a). The Riemann solution belongs to one of the following cases:

C.1. For $R_1 \in \Re_C^I$ (Figure 3.8(b)), the solution is $L_3 \xrightarrow{sh-} I_1 \xrightarrow{st} R_1$.

C.2. For $R_2 \in \Re_C^{II}$, the solution is analogous to that of Case B (subcase B.2). In the solution shown, I_2 cannot be connected to R_2 only by a stationary shock because the stationary shock intersects the scanning curve with π_R. Therefore, the solution is $L_3 \xrightarrow{sh-} I_2 \xrightarrow{st} Q \xrightarrow{ra+} R_2$.

C.3. For $R_3 \in \Re_C^{III}$, the solution is $L_3 \xrightarrow{sh-} I_3 \xrightarrow{ra+} R_3$.

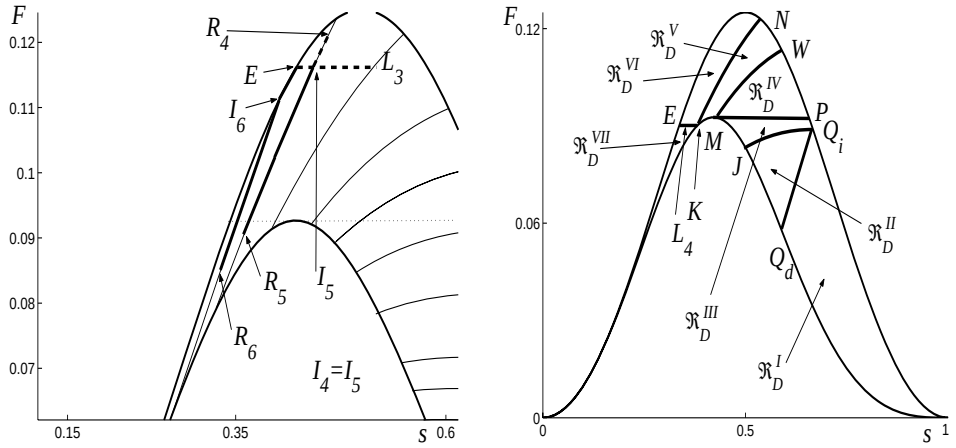

FIG. 3.9. *Figure* (a) *(Case C): solutions for* $L_3 \in C$ *and* R *in* R*-regions:* $R_5 \in \Re_C^V$ *and* $R_6 \in \Re_C^{VI}$. *Figure* (b) *(Case D): R-regions for* $L_4 \in D$.

C.4. For $R_4 \in \Re_C^{IV}$ (Figure 3.9(a)), the solution is $L_3 \xrightarrow{st} I_5 \xrightarrow{sh+} R_4$.

C.4. For $R_5 \in \Re_C^V$, the solution is $L_3 \xrightarrow{st} I_5 \xrightarrow{ra+} R_5$.

C.5. For $R_6 \in \Re_C^{VI}$, L_3 cannot be connected to the scanning curve through R_6 only by a stationary shock, because the latter intersects the imbibition curve (state E). For L_3 and R_6 the solution is $L_3 \xrightarrow{st} E \xrightarrow{ra+} I_6 \xrightarrow{ra+} R_6$.

Case D: $L_4 = (s_L, F(s_L, \pi_L)) \in D$. The R-regions are shown in Figure 3.9(b). The Riemann solutions belong to one of the following cases:

D.1. For $R_1 \in \Re_D^I$ (Figure 3.10(a)), the solution is $L_4 \xrightarrow{st} K \xrightarrow{sh-} I_2 \xrightarrow{st} R_1$.

D.2. For $R_2 \in \Re_D^{II}$, the solution is $L_4 \xrightarrow{st} K \xrightarrow{sh-} I_1 \xrightarrow{st} Q \xrightarrow{ra} R_2$.

D.3. For $R_3 \in \Re_D^{III}$, the solution is $L_4 \xrightarrow{st} K \xrightarrow{sh+} I_3 \xrightarrow{ra+} R_3$. Notice that segment KI_3 is tangent to the *dr* curve at I_3 to the scanning curve through R_3.

D.4. For $R_4 \in \Re_D^{IV}$, the solution is $L_4 \xrightarrow{st} K \xrightarrow{sh+} I_4 \xrightarrow{sh+} R_4$.

D.5. For $R_5 \in \Re_D^{IV}$ (Figure 3.10(b)), the solution is $L_4 \xrightarrow{st} K \xrightarrow{sh+} I_5 \xrightarrow{sh+} R_5$.

D.6. For $R_6 \in \Re_D^{VI}$, the solution is $L_4 \xrightarrow{st} I_6 \xrightarrow{sh+} R_6$.

D.7. For $R_7 \in \Re_D^{VII}$, the solution is $L_4 \xrightarrow{st} I_7 \xrightarrow{ra+} R_7$. If the stationary shock intersects the *im* curve, the solution is analogous to that of Case C (subcase C.5).

3.3. Uniqueness criteria. Without appropriate restrictions for given L and R states, the Riemann problem might have multiple solutions. We are interested in solutions satisfying (1) the Oleinik condition in Ω and (2) the orientation of the drainage and imbibition curves. However, these conditions are insufficient to guarantee uniqueness of solution. A solution can be obtained if we further require that (3) the solution must be $\mathcal{L}_1^{loc}$ continuous with respect to changes in L and R. A Riemann solution is well posed if it satisfies conditions (1), (2), and (3) mentioned above. The choices presented in section 3.2 give rise to well-posed global solutions; however, some of them are not evident; so we discuss these cases here.

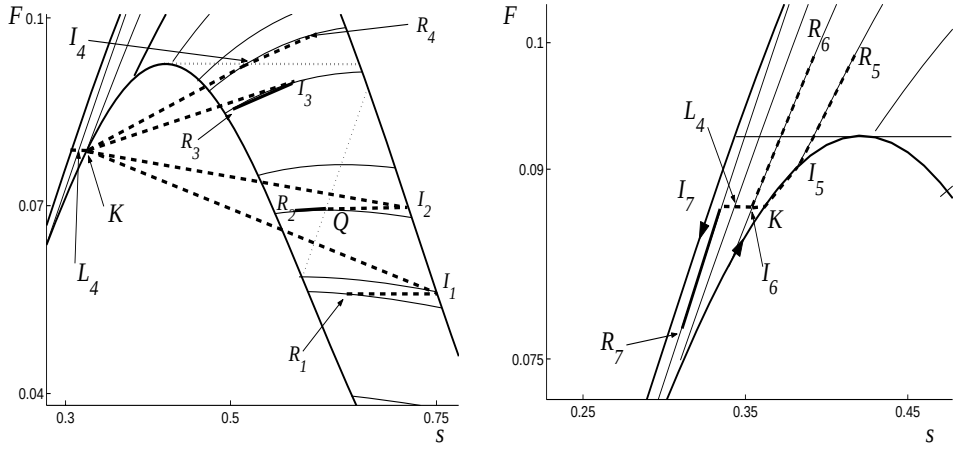

FIG. 3.10. *Figure* (a) *(Case D): L_4 in L-region D and R in R-regions $R_3 \in \Re^{III}$, $R_4 \in \Re^{IV}$, $R_5 \in \Re^{V}$, and $R_6 \in \Re^{VI}$. Figure* (b) *(Case D): $L_4 \in D$ and R in R-regions $R_1 \in \Re^{I}$ and $R_2 \in \Re^{II}$.*

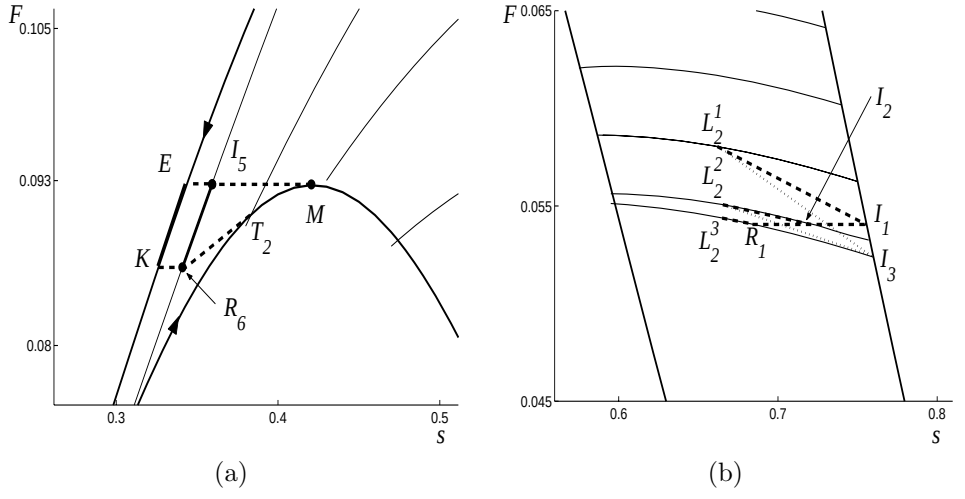

FIG. 3.11. *Figure* (a) *(Case A): $R_6 \in \Re_A^{VI}$. Figure* (b) *(Case B): $L_2^1 \in B$ and $R_1 \in \Re_B^I$.*

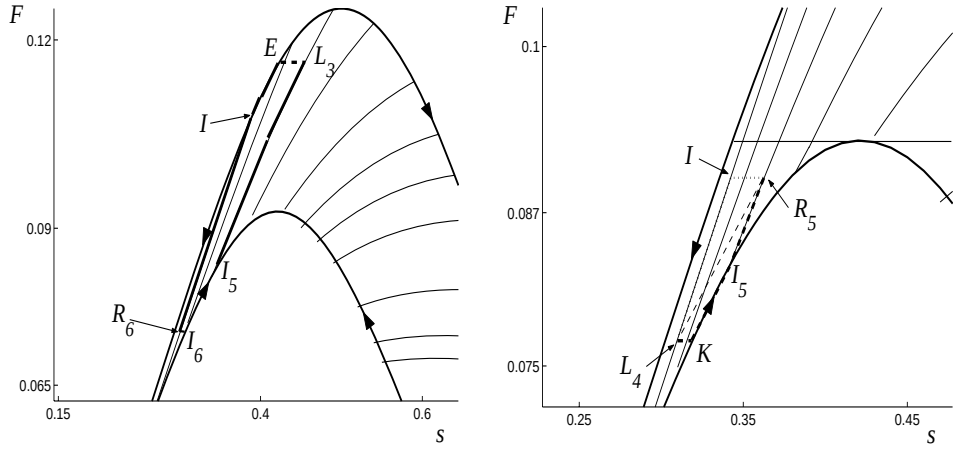
Case A: $L_1 \in A$ and $R_6 \in \Re_A^{VI}$. As mentioned in section 3.2, the solution for this case is represented by the segment $L_1TMI_5R_6$ as shown in Figure 3.6(b). We show that other tentative solutions are impossible. In Figure 3.11(a) we analyze the connection between states M and R_6. Consider the curve MT_2R_6: the rarefaction MT_2 and shock T_2R_6. This solution is inadmissible because the rarefaction MT_2 violates the physical orientation of the drainage curve. Another tentative solution such as $MEKR_6$ is also inadmissible because the interaction of the waves EK and KR_6 yields the shock ER_6, which violates the scanning region RH condition (3.6), (3.7). Therefore, between states M and R_6, the sequence $LTMIR_6$ is the only admissible solution that we were able to find.

Case B: $L_2^1 \in B$ and $R_1 \in \Re_B^I$ (see Figure 3.7(b)). We choose the Riemann solution $L_2^1I_1R_1$. We can also consider $L_2^1I_3R_1$ as another solution (see Figure 3.11(b)).



(a) (b)

FIG. 3.12. *Figure* (a) *(Case C): $L_3 \in C$ and $R_6 \in \Re_C^{VI}$. Figure* (b) *(Case D): $L_4 \in D$ and $R_5 \in \Re_D^V$.*

In principle $L_2^1 I_1 R_1$ and $L_2^1 I_3 R_1$ seem possible. However, only the solution $L_2^1 I_1 R_1$ depends continuously on changes of the left and right states. To analyze these solutions we change the state L_2^1. In this case the solution $L_2^1 I_3 R_1$ generates a sequence of solutions

$$L_2^1 I_3 R_1 \to L_2^2 I_3 R_1 \to L_2^3 I_3 R_1, \tag{3.10}$$

which converges to the wrong solution $L_2^3 I_3 R_1$. Notice that when $L_2^1 = L_2^3$ the correct solution is a shock $L_2^3 R_1$. Additionally, the solution $L_2^1 I_1 R_1$ generates a sequence of solutions

$$L_2^1 I_1 R_1 \to L_2^2 I_2 R_1 \to L_2^3 R_1 \tag{3.11}$$

converging to the correct solution $L_2^3 R_1$ without producing $\mathcal{L}_1^{loc}$ discontinuities in the Riemann solution. Therefore, solutions other than $L_2^1 I_1 R_1$ do not ensure the continuity of the solution when the states L and R are perturbed.

Case C: $L_3 \in C$ and $R_6 \in \Re_C^{VI}$. In this case the orientation of the drainage and imbibition curves ensures the uniqueness and $\mathcal{L}_1^{loc}$ continuity of the Riemann solution. For example, in Figure 3.12(a), the solution for left and right states L_3 and R_6 is $L_3 E I R_6$; notice that another tentative solution such as $L_3 I_5 I_6 R_6$ is inadmissible because the rarefaction $I_5 I_6$ violates the drainage curve orientation.

Case D: $L_4 \in D$ and $R_5 \in \Re_D^V$. From Figure 3.12(b), the solution chosen is $L_4 K I_5 R_5$. A tentative solution such as $L_4 I R_5$ is not possible because its yields a shock $L_4 R_5$ which violates the scanning region Oleinik condition.

4. The corrected Godunov method. We discretize the z-t plane by choosing a mesh width $h := \Delta z = 1/N_z$ and a time step $k = \Delta t$, and we define the discrete grid points (z_j, t_n) by

$$z_j = jh + h/2,\ z_{j\pm 1/2} = z_j \pm h/2,\ \ j = 0, 1, 2, \ldots, N_z - 1, \tag{4.1}$$

$$t_n = nk,\ \ n = 0, 1, 2, \ldots . \tag{4.2}$$

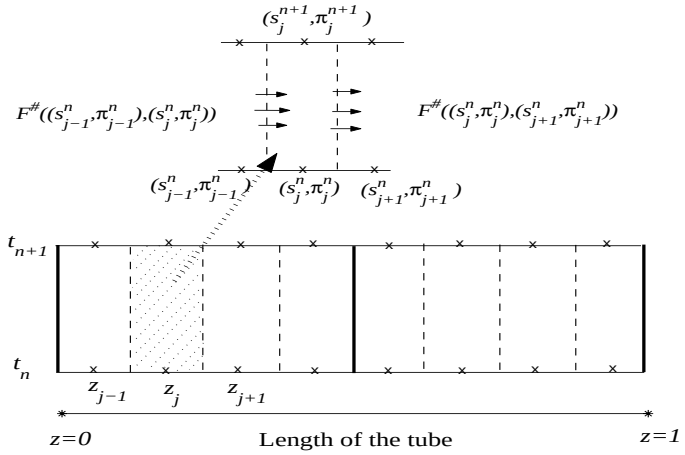


FIG. 4.1. *Numerical fluxes using local Riemann solution.*

Each time step of the numerical method consists of two stages. In the first stage (*predictor*) equations (3.1) and (3.2) are solved numerically by the Godunov method [11]. The second stage (*corrector*) is the correction of the parameter π, which is necessary when the predicted state lies outside the admissible region Ω. In such a case, the corrected state is obtained from the predicted state by a projection (with fixed s) on $\partial\Omega$ of the predictor state. The saturation is maintained constant in order to preserve conservation of mass, which is guaranteed in the prediction step because it uses Godunov method.

Predictor. Denoting the cell state at (z_j, t_n) by (s_j^n, π_j^n), we then have that the conservative Godunov method on a cell $[z_{j-1/2}, z_{j+1/2}] \times [t_n, t_{n+1}]$ for the saturation value is expressed as

$$s_j^{n+1} = s_j^n - \frac{k}{h}[F^{\#}((s_j^n,\pi_j^n),(s_{j+1}^n,\pi_{j+1}^n)) - F^{\#}((s_{j-1}^n,\pi_{j-1}^n),(s_j^n,\pi_j^n))], \tag{4.3}$$

where $F^{\#}((s_j^n,\pi_j^n),(s_{j+1}^n,\pi_{j+1}^n))$ and $F^{\#}((s_{j-1}^n,\pi_{j-1}^n),(s_j^n,\pi_j^n))$ are the numerical fluxes at the right and left boundaries of the cell $[z_{j-1/2}, z_{j+1/2}] \times [t_n, t_{n+1}]$, respectively. We impose zero numerical flux boundary conditions at $z = 0$ and $z = 1$; see Figure 4.1.

Notice that the left and right numerical fluxes of each cell are constant along the left and right boundaries, respectively. This is so because these boundaries coincide with zero speed characteristics at $z_{j-1/2}$ and $z_{j+1/2}$, respectively. Consequently, for each pair of states (s, π), the numerical fluxes can be determined directly from the Riemann solution presented in section 3.2.

For example, consider the left state $L = (s_L, F_L)$ and right state $R = (s_R, F_R)$ at time t_n (see Figure 4.1), with the Riemann solution represented in Figure 5.1(b). Then the numerical flux $F^{\#}((s_L^n,\pi_L^n),(s_R^n,\pi_R^n))$ is exactly the flux F_M^d specified by the state M or I; notice that either choice produces the same numerical flux as shown in Figure 5.1(b). As another example, consider the left state L and right state R, and suppose that the Riemann solution consists of a positive speed shock represented in Figure 3.10(b) by $L_4KI_5R_5$. Consequently, the numerical flux $F^{\#}((s_L^n,\pi_L^n),(s_R^n,\pi_R^n))$ is $F(s_L, \pi_L)$ at state L_4. In this way, the numerical flux for each pair of left and right states is chosen by using the solutions presented in section 3.2.

Corrector. Once (4.3) for the saturation is satisfied, we update π_j^n. We de-

fine the external imbibition and drainage regions as $\Omega^i := \{(s,F) \in \Re^2 : 0 \le s \le 1 \text{ and } F^i(s) \le F\}$ and $\Omega^d := \{(s,F) \in \Re^2 : 0 \le s \le 1 \text{ and } F \le F^d(s)\}$, respectively. To obtain π_j^{n+1}, we choose $\pi_j^{n+1} = \pi_j^n$ if (s_j^{n+1}, π_j^n) lies in the scanning region Ω, and $\pi_j^{n+1} = \pi^i(s_j^{n+1})$ or $\pi_j^{n+1} = \pi^d(s_j^{n+1})$ if $(s_j^{n+1}, F(s_j^{n+1}, \pi_j^n))$ lies on the external imbibition or drainage region, respectively. This strategy for updating π was proposed in [18] and guarantees mass conservation of each phase. For the computational results presented in section 5, we adopt the global CFL condition as $|\frac{k}{h} v_{\max}| \le 1$, where

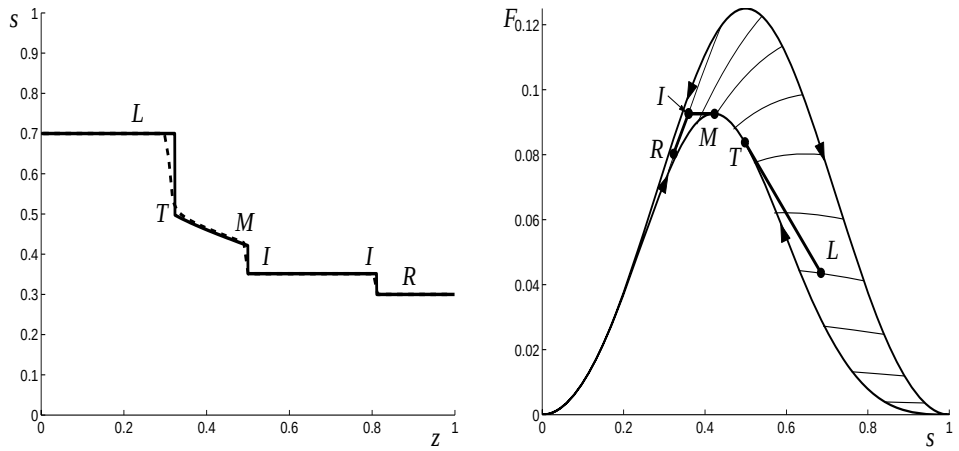
$$v_{\max} = \max\left(\max_{(s,\pi)\in\Omega} \mid \partial_s F(s,\pi) \mid, \max_{(s,F)\in j} \mid \partial_s F^j(s) \mid\right), \; j = i, d. \tag{4.4}$$

We note, however, that a sharper time-dependent CFL condition can be derived as the maximum velocity of all local Riemann solutions in each time step.

5. Computational results.

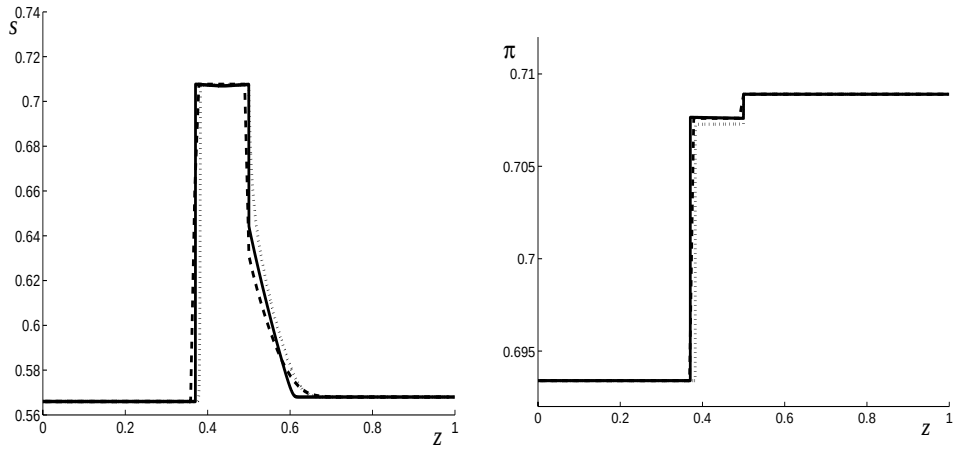
Example 1: Comparison between the numerical and the analytical solutions. The aim of this comparison is to demonstrate that the numerical method can capture accurately all the features of the analytical solution. We consider the numerical and analytical dimensionless solutions associated to the Riemann problem with initial discontinuity at $z = 0.50$ separating states $(s_l, \pi_l) = (0.7, 0.8)$ and $(s_r, \pi_r) = (0.3, 0.4)$. Both states lie inside the scanning region. The following parameters were used in the simulations $\mu_w = 1\ cp$, $\mu_o = 0.9\ cp$, and for this case the global CFL condition is 0.3849. The dimensionless simulated time was $t = 2.4\ 10^3$. The analytical solution (represented in Figure 5.1(b)) is shown as a solid line in Figure 5.1(a), and the numerical solution obtained with the proposed scheme using $N_z = 100$ as a dashed line in the same figure.

The numerical and analytical profiles at dimensionless time are presented in Figure 5.1. The saturation profile consists from left to right of a scanning to drainage shock wave LT, followed by a rarefaction wave TM, a stationary wave MI, and a rarefaction wave IR. The small discrepancy around the shock LT in Figure 5.1(a) is due to the correction scheme for π. However, the discrepancy potentially occurs at only one mesh point.



(a) (b)

FIG. 5.1. *Comparison between the analytical and the numerical method. Dashed line corresponds to the numerical solution, and solid corresponds to analytical solution.*



(a) (b)

FIG. 5.2. *The solid curve corresponds to the analytical solution, the dashed curve to the corrected Godunov method with* $N_z = 50$, *and the dotted curve to the corrected Lax–Friedrichs scheme with* $N_z = 4000$. (a) *Saturation values and* (b) π *values.*

Example 2: Comparison between corrected Godunov and corrected Lax–Friedrichs schemes. We consider the Riemann problem with initial discontinuity at $z = 0.50$ separating states $(s_l, \pi_l) = (0.57, 0.69)$ and $(s_r, \pi_r) = (0.57, 0.71)$. Figure 5.2(a) and (b) show a comparison among the proposed corrected Godunov scheme with $N_z = 40$, the corrected Lax–Friedrichs with $N_z = 4000$, and the analytical solution. The global CFL restriction is followed. To obtain an accurate approximation for the analytical solution, the corrected Godunov scheme requires a mesh size $N_z = 40$, while the corrected Lax–Friedrichs requires $N_z = 4000$. Hence, to satisfy the global CFL condition (4.4), the corrected Godunov scheme requires substantially fewer time steps than the corrected Lax–Friedrichs, so that the simulation using the Godunov scheme takes 500 times less CPU time than using the Lax–Friedrichs scheme.

The classical Godunov and Lax–Friedrichs schemes do not work without the corrector step. We note also that the design of numerical schemes for the problems considered here is not trivial. Because of hysteresis, there are stationary waves, the orientation of the curves (imbibition and drainage) has to be taken into account, and the restriction on the admissibility scanning region Ω must be followed.

Example 3: Comparison between solutions with and without hysteresis. The strong influence of the hysteresis effect in the saturation profiles can be seen by comparing the profiles obtained numerically with and without hysteretic relative permeabilities. We choose the drainage curve opposite the imbibition curve as the nonhysteretic relative permeability curve since the corresponding nonhysteretic solution agrees most with the hysteretic solution.

We introduce in the simulation the top and bottom boundaries of the tube. We perform the simulation with $N_z = 50$, $\mu_w = 1$ *cp*, and $\mu_o = 0.9$ *cp*. The density of the wetting phase is $\rho_w = 1$ g/cm^3 and the density of the nonwetting phase is taken as $\rho_o = 0.844$ g/cm^3. We consider the porous media having a permeability of 11.84 Darcys and porosity of 0.389. The tube length is 86 cm. Additionally, $s_L = 0.9$ and $s_R = 0.1$.

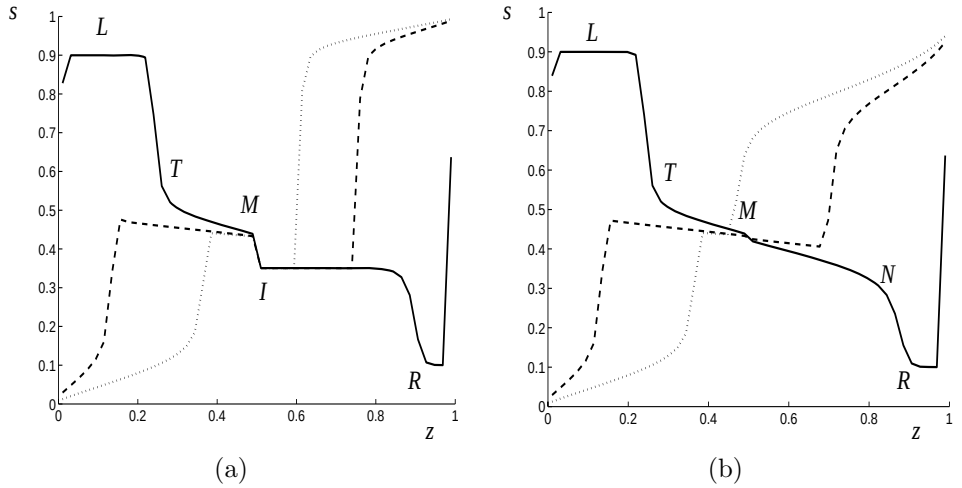


FIG. 5.3. *Profile $s(z)$ at several times:* (a) *hysteretic solution,* (b) *nonhysteretic solution. Saturations are represented as a solid curve at* 5.87 h*, as a dashed curve at* 14.59 h*, and as a dotted curve at* 19.38 h*. Compare with Figure* 5.4.

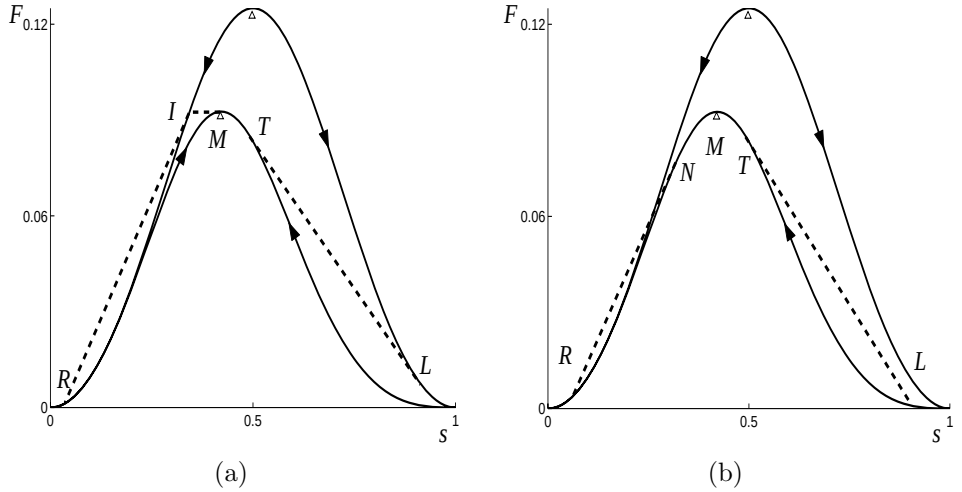

FIG. 5.4. *Solutions in (s, F) space* (a) *with hysteresis,* (b) *without hysteresis at imbibition and drainage curves.*

The hysteretic and nonhysteretic simulation results differ significantly; see Figure 5.3. Observing Figure 5.3(a), three sections are clearly identified. We can see that in the top zone (around $z = 0$), wetting phase saturation decreases with time, i.e., a drainage process. At the bottom zone (around $z = 1$), the saturation increases with time, i.e., an imbibition process. The most relevant discrepancy between hysteretic and nonhysteretic solutions occurs at the middle zone ($z \in [0.3, 0.7]$), where both drainage and imbibition take place. In this zone the hysteretic profiles have a sharper decline MI, which is not captured in Figure 5.3(b) without hysteresis.

The discrepancy between the hysteretic and nonhysteretic solutions can be under-

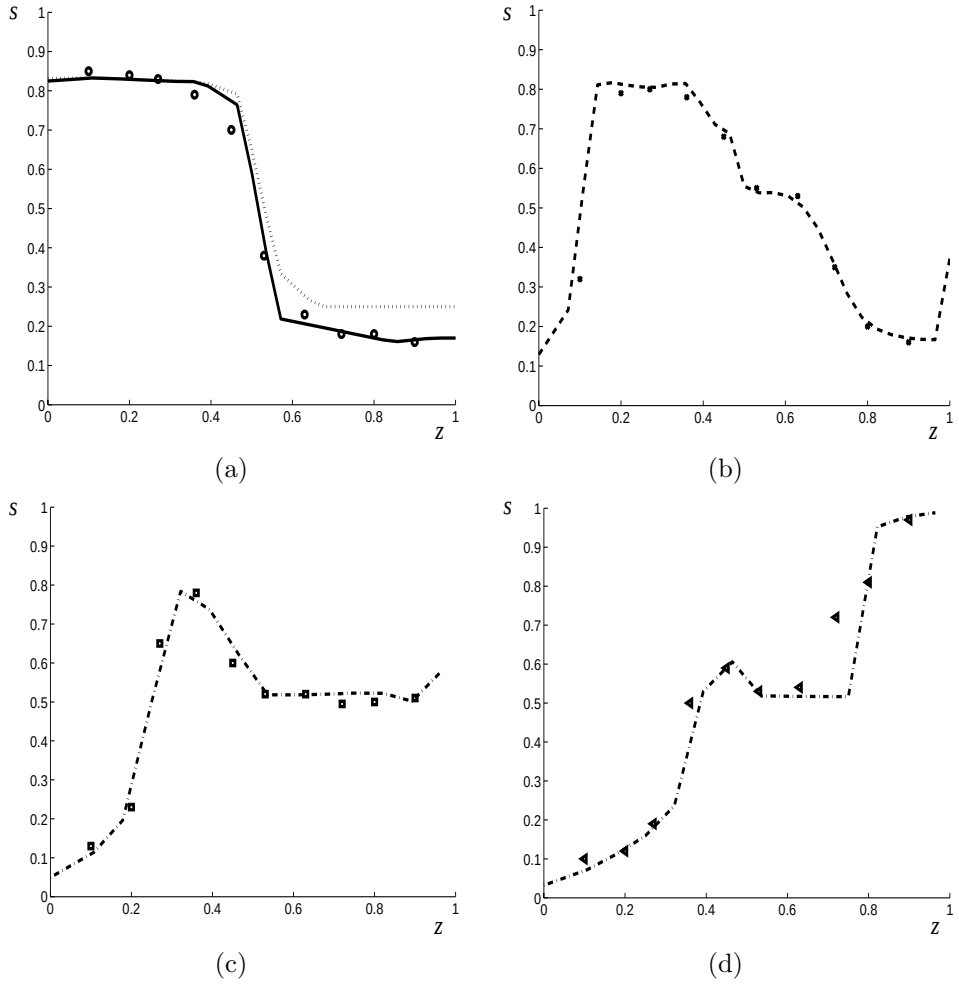

FIG. 5.5. *Comparison between saturation profiles obtained by the numerical simulation and the laboratory data (marked points) several times (*(a) 0 *min.,* (b) 19 *min.,* (c) 60 *min.,* (d) 38.6 *hours). In* (a)*, the dotted line is the initial value of* π *used for the simulation.*

stood by comparing the Riemann solution for hysteretic and nonhysteretic fractional flow functions. With hysteresis (Figure 5.4(a)), the solution combining imbibition and drainage necessarily goes through the scanning region. For instance, consider the case when $s_L > s_R$. Due to the imbibition and drainage curve orientation, the solution is $LTMIR$, a negative speed shock LT, a drainage rarefaction TM, a stationary shock wave MI connecting the drainage and the imbibition curves, and a positive speed imbibition shock IR. On the other hand, without hysteresis (Figure 5.4(b)), the solution is $LTNR$, a negative speed shock LT, a rarefaction wave TN, and a positive speed shock NR.

Example 4: Comparison with experimental work data. To validate the proposed model we compare the numerical gas-water saturation profile with saturation profiles found in [7] and [20]. Following [7], we consider a sand pack with a permeability of 11.84 Darcys and porosity of 0.389. The tube length is 86 cm. Additionally,

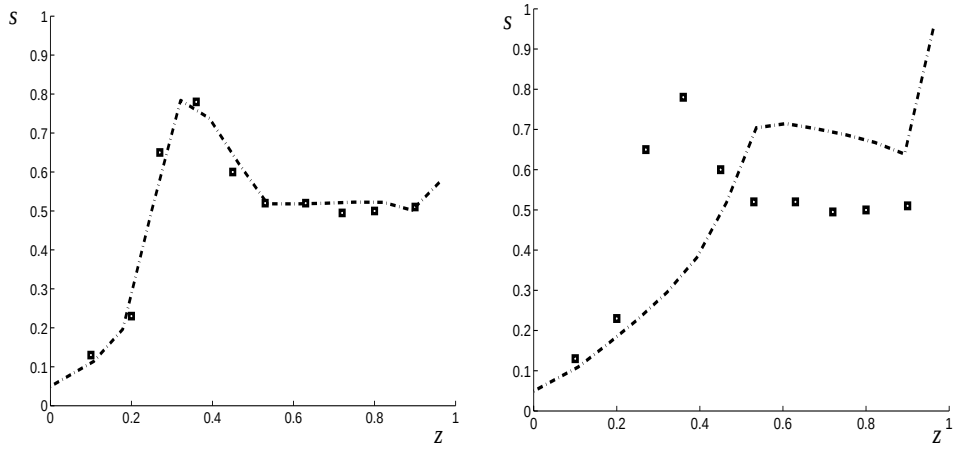

FIG. 5.6. *Comparison between saturation profiles with hysteresis* (a) *and without hysteresis* (b) *obtained by the numerical simulation and the laboratory data (marked points) for* 60 *min.*

we use the following values for the parameters: $\alpha = 0.5$, $\gamma = 0.5$, $\mu_w = 0.8550$ *cp*, and $\mu_o = 0.0185$ *cp*. The density of the wetting phase (water) is $\rho_w = 1$ g/cm^3 and the density of the nonwetting phase (air) is considered negligible compared to ρ_w. These values were taken from [7].

The procedure consists in injecting a measured amount of radioactive water into the tube containing air in its pores, closing it off at both ends, and allowing the two phases to reach the equilibrium distribution. This saturation distribution is measured, providing the initial distribution in the simulation. This distribution is a spatial transition between air in the presence of residual water to water in the presence of residual air. This water saturation distribution results from the balance between pressure gradient and the buoyancy force.

Usage of the correct initial distribution of π is crucial to reproducing the results presented in [7]. To obtain this initial distribution from the procedure described in [7], we consider the injection of a certain quantity of water from the top of an air-saturated tube. Consequently, the lower half of the tube corresponds to an imbibition process and the upper half corresponds to a drainage process. The values of π are chosen accordingly. This choice of initial values for π are shown by the dotted line in Figure 5.5(a).

The tube is then inverted and measurements of water saturation are made during the segregation process at ten different locations along the tube. Figures 5.5(a)–(d) confirm the excellent agreement between the laboratory data and the simulated saturation profiles at different times, while Figures 5.6(a) and (b) show the importance of including the hysteresis effects in the model. There is agreement in Figure 5.6(a) with hysteresis and disagreement in Figure 5.6(b) without hysteresis.

6. Concluding remarks. We present Riemann solutions for each left and right state for a hysteretic counterflow segregation problem as well as criteria to guarantee well-posedness to the solution. Based on the Riemann solutions, we propose a corrected Godunov scheme that updates both the saturation and the hysteretic parameter. This scheme conserves mass locally. Numerically, we show that the solution

obtained by the proposed method agrees with the analytical solution. We also validate the numerical scheme by comparing simulations with laboratory experimental data. We show numerically that the inclusion of hysteresis effects in the relative permeability suffices for simulations for accurate simulations.

A SEMIANALYTICAL THERMAL STRESS MODEL FOR THE CZOCHRALSKI GROWTH OF TYPE III-V COMPOUNDS*

C. SEAN BOHUN†, IAN FRIGAARD‡, HUAXIONG HUANG§, AND SHUQING LIANG§

Abstract. In this paper we describe a semianalytical approach to computing the temperature and thermal stress inside a III-V compound grown with the Czochralski technique. An analysis of the growing conditions indicates that the crystal growth occurs on the conductive time scale. A perturbation method for the temperature field is developed for an arbitrary crystal profile using the Biot number as a (small) expansion parameter. The zeroth order solution is one-dimensional in the axial direction. Explicit solutions are obtained for a cylindrical and a conical crystal. Under typical growth conditions, a parabolic temperature profile in the radial direction is shown to arise naturally as the first order correction. As a result, the thermal stress is obtained explicitly and its magnitude is shown to depend on the zeroth order temperature and Biot number. Both the axial temperature gradient and crystal profile are shown to be important for controlling thermal stress and defect density. Some issues relevant to growth conditions are also discussed.

Key words. crystal growth, asymptotic expansion, moving interface, thermal stress, dislocation density, finite difference method, Czochralski technique

1. Introduction.

Directional solidification methods are widely used for growing large industrial sized crystals. Among them, the Czochralski (Cz) method is the most popular technique for growing crystals used by the semiconductor and related industries. By dipping a small seed crystal into a pool of molten material in the crucible and carefully controlling the heat balance inside the grower, a large crystal can be grown by pulling the crystal away from the melt in a slow and steady fashion. The pulling rod and the crucible are normally rotated in opposite directions during the growth period. Delicate control is often needed to maintain the crystal quality, and a slight change of the growth conditions may result in defect formation inside the crystal. With care, a single crystal with low defect density can be obtained routinely when the size of the crystal does not exceed a critical value. For a more detailed account of the Cz and other techniques, we refer the readers to the extremely informative handbooks by Hurle [16, 17].

Due to the complex nature of the thermal, structural, and dynamic coupling of the molten material, the crystal, the crucible, the gas chamber, and other parts of the grower, considerable efforts have been devoted to laboratory experiments and to modeling and simulation of the growth environment over the past several decades. As a result, there exists an extensive literature, mostly in engineering fields. These studies

cover a wide spectrum of areas, from decoupled one- or two-dimensional simulations to fully coupled three-dimensional computations; see, e.g., [4, 5, 16, 17, 18, 26, 27, 29]. Most of the studies rely heavily on computer simulation since the fully coupled system cannot be solved otherwise. These investigations have generated useful information including temperature distribution, crystal-melt interface shape, and melt flow patterns inside the crucible. By comparison, much less attention has been paid to the coupling of defect modeling and field variables even though significant progress has been made in identifying main factors that determine the formation of defects [31].

In this paper, we present a semianalytical approach for studying the temperature field inside the crystal and the related thermal stress. It is believed that defect formation can be related to an excessive thermal stress above some critical value; see, e.g., [1, 11, 13, 19, 29, 33, 34] and the references therein. Therefore, analysis of the growth factors that determine the stress level will be extremely useful for crystal growers. The stress analysis requires that a particular crystal structure be specified, and we have chosen the ZnS structure shared by the type III-V binary semiconductors. Even though the basic mathematical structure remains the same for any III-V compound, we will focus on indium antimonide (InSb) for the rest of the paper. InSb has the narrowest bandgap and highest temperature mobility of the III-V binary compound semiconductors. Because of these properties, InSb is widely used in both magnetic field detectors and infrared sensors. A review of these properties can be found in Micklethwaite and Johnson [24].

The primary reason for focusing on InSb is that it is exceedingly difficult to grow with the Cz technique mainly because of its small critically resolved shear stress (CRSS). It is known experimentally that attempting to grow InSb in a cylindrical profile with the Cz technique produces crystals with an unacceptable defect density, contrary to the growth of more common crystals such as silicon, where low defect density crystals can be grown in a cylindrical shape. Thus it is often an art to find the most suitable profile of the solidifying crystal by carefully varying the furnace temperature and the rate that the crystal is extracted [23]. To determine the influence of various resulting crystal profiles (i.e., axial variations of the lateral surface or crystal shapes) on the stress experienced within the crystal, we assume that the profile of the crystal is an arbitrary function of the axial displacement while allowing the solid-liquid interface to be driven by a Stefan condition and a compatibility condition at the solid-liquid-gas triple point.

By examining the physical process and parameter values of the growth environment closely, we are able to identify the main features associated with InSb crystals. In particular, if the heat flux from the melt is uniform across the crystal-melt interface, the temperature field will be dominated by the lateral flux through the crystal-gas surface, characterized by a nondimensional Biot number. The value of the Biot number is small under the growth conditions for InSb crystals, suggesting an asymptotic expansion of the solution in terms of this parameter. Much of the asymptotic framework discussed in this paper has appeared elsewhere in the literature [3, 14, 20, 35, 36, 37, 38, 39]. For example, Kuiken and Roksnoer [20] assumed a pseudosteady solid-liquid interface to obtain an accurate temperature distribution of a Si crystal grown with the floating-zone technique. Their solution takes the form of an expansion in terms of the Peclet and Nusselt numbers of the crystal, giving a solution valid for slender crystals grown in conductive heat transfer environments. By specifying an externally defined solid-liquid interface shape these authors avoided using a Stefan condition to evolve the interface. An asymptotic analysis that con-

sidered the melt was undertaken by Brattkus and Davis [3], where the geometry allowed an expansion in terms of the aspect ratio of the solidification cell. Young and Chait [36] considered a system driven by surface tension and more recently Young and Heminger [37, 38] have utilized a small aspect ratio to study the growth of single crystal fibers.

This paper blends the asymptotic expansion with the plane strain approximation to examine thermal stress inside the crystals. It contrasts significantly with the above references by assuming a radially independent heat flux from the melt that avoids a boundary layer analysis around the solidification front, greatly simplifying the asymptotics. Any angular dependence is minimized by the rotation of the seed and crucible, and the experimental evidence of an almost flat interface for Cz grown InSb crystals [23] suggests that the flux from the melt is likely to be largely independent of the radius. This is also supported in the literature [8, 9]. On the other hand, if the heat flux is radially dependent then the same asymptotic framework applies, but there will be a boundary layer solution similar to that in [3, 36] or [20] on the crystal side to match the asymptotic solutions.

While the details of the motion of the melt are ignored, the crystal-melt and crucible-melt heat transfer coefficients are estimated from the Ekman layer and natural convection submodel, respectively. As the crystal grows two situations are investigated. In the first, the flux is constant so that the model is more accurately a description of the solid in a directional solidification technique. In the second, the flux is calculated through an essentially zero-dimensional model for the melt. This enables the heat flux from the melt to be influenced by some of the crucible and operating parameters of the Cz process.

In the fully unsteady case, the asymptotic expansion results in a system of one-dimensional equations and the thermal stress can be obtained explicitly in an analytical form, under the plane strain assumption. In the pseudosteady limit this reduces to the classical result that the stress is proportional to the concavity of the temperature field [22, 34]. This also extends the work of [19], where stress was obtained for a cylindrical crystal with a flat crystal-melt interface. The pseudosteady solutions are contrasted with the unsteady solutions for cylindrical and conical crystals justifying the pseudosteady approximation for the growth parameters of InSb used in this paper. A detailed description of the pseudosteady approximation with respect to Cz growth can be found in the paper by Derby and Brown [10]. Other examples of the use of the pseudosteady approximation can be found elsewhere [14, 35].

Compared to most of the previous work using asymptotic or numerical methods, this study moves a step further by coupling stress calculation with the asymptotic field temperature solution and deriving an explicit form for the stress. Furthermore, formulated in a nondimensional form, the dependence of the stress level on the Biot number is useful for crystal growers when larger crystals are grown. Since the Biot number is proportional to the product of the heat transfer coefficient and the mean crystal radius, it is obvious that one should try to reduce the heat flux via the lateral surface when a crystal of larger radius is grown. In addition, the explicit nature of the stress solution enables us to identify the effect of crystal profile (shape) as well as the crystal size (radius) on the stress. More importantly, obtaining an explicit formulation for the stress allows us to apply other techniques such as optimal control methodologies to efficiently search for better growth conditions. A simplified model for the heat exchange between the gas flow and the crystal is used to clarify the presentation. However, the asymptotic solution developed here is still valid if a more

realistic model for the gas is incorporated. More detailed discussion related to the growth conditions for InSb will be given in sections 2 and 5.

The rest of the paper is organized as follows. In section 2, we will present the mathematical model and dimensional analysis. Asymptotic solutions are given in section 3. Thermal stress is discussed in section 4. In section 5, results are presented for both pseudosteady and unsteady cases. We conclude the paper with a brief summary and discussion on future directions in section 6.

2. Mathematical model and dimensional analysis. The basic assumptions made in this study are (1) the crystal is axis-symmetric; (2) the heat exchange between the crystal and gas along the lateral surface of the crystal is a constant; (3) the heat exchange between the crystal and melt along the crystal-melt interface is uniform; (4) the mean crystal radius is small compared to its length; (5) thermal stress is elastic and computed under a plane strain assumption. Some of the assumptions are made to simplify the derivation, and others are made based on previous study of similar problems or observations made by us and engineers we have been collaborating with. We will revisit some of the assumptions in section 6.

Figure 1 illustrates the geometry of a typical crystal. The coordinate system is fixed to the top of the growing crystal at $z = 0$, the final length of the crystal is denoted Z, and the crystal radius is denoted $R(z)$. The growth starts with a seed crystal with radius of order $R_0 = 0.5$ cm and length $Z_0 = 3$ cm. The crystal grows outward in a slowly developing cone, eventually reaching a radius $R(Z) \simeq 5$ cm after a length $Z \simeq 30$ cm. A crystal can take 10–20 hours to grow. Thus, at the outset we make two observations. First, the crystal growth is characterized by a large aspect ratio. Second, it is evident that any transients in the system, unless caused by rapidly changing boundary conditions, are very slow. These two features will be used to derive our eventual model.

Within the crystal Ω, the temperature $T(\mathbf{x}, t)$ satisfies the heat equation

$$\rho_s c_s \frac{\partial T}{\partial t} = k_s \sum_j \frac{\partial^2 T}{\partial x_j^2}, \qquad \mathbf{x} \in \Omega,\ t > 0, \tag{1}$$

where ρ_s, c_s, and k_s, respectively, are the density, specific heat, and thermal conductivity of the crystal solid phase. The lateral surface of the crystal is denoted Γ_g and is subjected to cooling from the circulating chamber gases and from radiative heat losses. Although radiation is not insignificant, for simplicity we model both effects through a simple Newtonian cooling law

$$-k_s \frac{\partial T}{\partial \mathbf{n}} = h_{gs}(T - T_g), \qquad \mathbf{x} \in \Gamma_g. \tag{2}$$

Here we assume that the heat transfer coefficient h_{gs} incorporates both convective and radiative heat transfer (the latter via linearization). The top of the crystal is fixed at $z = 0$, where we also invoke a Newtonian cooling law

$$k_s \frac{\partial T}{\partial z} = h_{ch}(T - T_{ch}), \tag{3}$$

in the case that the radius at $z = 0$ is assumed to be nonzero. Here h_{ch} represents the heat transfer coefficient for the seed-chuck connection and T_{ch} is the chuck temperature.

The crystal-melt interface is denoted Γ_S and is where $T = T_m$, the melting temperature. The interface of the phase transition is thus implicitly defined from the temperature field. Explicitly we denote the melting isotherm by

$$z - S(\mathbf{x}, t) = 0, \qquad \mathbf{x} \in \Gamma_S. \tag{4}$$

The motion of the interface of the phase transition is governed by the Stefan condition

$$\rho_s L\, |\vec{v}_n| = k_s \left.\frac{\partial T}{\partial \mathbf{n}}\right|_{z \to S^-} - q_{l,n}, \tag{5}$$

where $|\vec{v}_n|$ is the speed at which the interface moves in the direction of the outward unit normal $\mathbf{n}$, L is the latent heat, and $q_{l,n}$ is the heat flux from the melt normal to the interface.

Figure 2 illustrates the triple point (TP) where the solid, liquid, and gas come into contact and the solid-liquid interface moves at a velocity $\vec{v}_n = v_n \mathbf{n}$. If $\partial S/\partial t$ denotes the speed of the interface in the $\mathbf{k}$ direction, then

$$|\vec{v}_n| = v_n = \frac{\partial S}{\partial t} \mathbf{k} \circ \mathbf{n}. \tag{6}$$

Still referring to Figure 2, the profile (shape) of the crystal $R(z)$ is determined by the motion of the TP given by

$$\left.\frac{\partial R}{\partial t}\right|_{z=S} = \tan(\theta - \theta_c) \left.\frac{\partial S}{\partial t}\right|_{r=R}, \tag{7}$$

where θ_c is the contact angle formed by the wetting fluid (melt) and the crystal and θ is the angle formed by the meniscus with the vertical z-axis. This expression simply

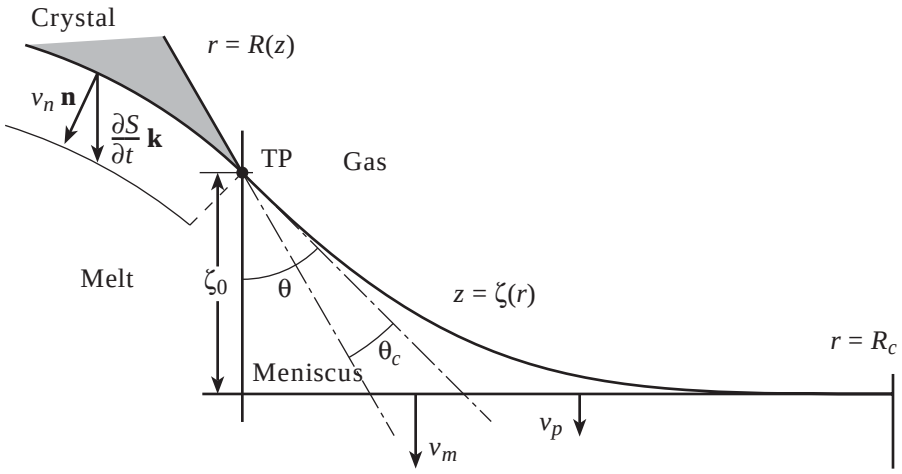

FIG. 2. *Schematic diagram of the meniscus $z = \zeta(r)$ with capillary height ζ_0, defined on $R(S) \le r \le R_c$, where $R(S)$ is the radius of the crystal at the interface, θ_c is the contact angle, and R_c is the radius of the crucible. The motion of the TP is determined by the advancing interface S, the speed at which the melt falls v_m, and the pull rate applied to the crucible v_p.*

states that the crystal prefers to grow in the direction defined by the contact angle. The motion of the advancing interface S, the advancement due to the pulling rate, and the motion due to the loss of melt determine the vertical position of the triple junction ζ_0 via

$$\frac{d\zeta_0}{dt} = v_p + v_m - \frac{\partial S}{\partial t}, \tag{8}$$

where v_m is the rate at which the melt-gas surface drops given by

$$v_m = \frac{\rho_s R^2}{\rho_l R_c^2} \frac{\partial S}{\partial t} \tag{9}$$

from the law of mass conservation and v_p is the pulling rate at which the crucible is dropped to ensure that the crystal-melt interface remains at the surface of the liquid.

We note that properly it is necessary to close the model by relating growth in S to that in R, i.e., solving (7). To do this we must model the crystal withdrawal from the crucible, the formation of the meniscus, and the coupling of S and R. It has been shown in [32] that the growth angle is related to the capillary height ζ_0 for large Bond number growth. In principle, crystals with desirable shapes can be grown by adjusting the pulling rate, which determines the meniscus angle θ in (7). Therefore, if we are not interested in the dynamics, we can impose a geometry $R(z)$ on the model. This approach has the advantage of allowing us to investigate the thermal fields and associated stresses that develop for a particular observed shape.

Note that for cylindrical crystals the capillary height does not change throughout the growth cycle. Therefore (8) can be simplified as

$$v_p = \frac{\partial S}{\partial t} - v_m. \tag{10}$$

TABLE 1
A summary of the thermophysical and typical growth parameters of InSb.

Data	Symbol	Value
Growing properties		
Mean crystal radius	$\overline{R}$	0.03 m
Final crystal length	Z	0.30 m
Characteristic growth rate	$\overline{v}$	6.9×10^{-6} m/s
Ambient gas temperature	T_g	600 K
Solid properties at $T = T_m$		
Melting temperature	T_m	798.4 K
Density	ρ_s	5.64×10^3 kg/m^3
Thermal conductivity	k_s	4.57 W/m K
Heat capacity	$\rho_s c_s$	1.5×10^6 J/m^3 K
Latent heat of fusion	L	2.3×10^5 J/kg
Heat transfer coefficients		
Crystal-gas	h_{gs}	$1 - 4$ W/m^2 K

2.1. Typical scales in InSb crystal growth. Although it is possible to treat the three-dimensional case above, it is somewhat unwieldy, and hence we instead attempt to simplify the model first. Table 1 specifies a typical set of thermophysical and process data. Consider a time t, after any initial growth transient, when the crystal has length S onto which a thin layer of crystal of radius $\overline{R}$ has just solidified. Utilizing (1) and the characteristic values in Table 1, the conduction of heat across a crystal cross-section and the time taken to grow a length $\overline{R}$ of crystal have the following time scales:

$$t_{\text{cond}} \simeq \frac{\overline{R}^2 \rho_s c_s}{k_s} = 3.0 \times 10^2 \text{ s}, \qquad t_{\text{grow}} \simeq \frac{\overline{R}}{\overline{v}} = 1.7 \times 10^4 \text{ s}.$$

Thus, the conductive time scale is typically much shorter than that for growth (i.e., over similar length scales). The growth time scale for the entire crystal is still longer and given by $t \simeq Z/\overline{v}$. It is over this latter growth time scale that significant changes in either the radius or area occur related to significant changes in the cooling capacity and heat capacity, respectively.

Therefore, apart from imposed rapid changes in the growth (e.g., at the start of the process and at the end as the crystal is withdrawn from the melt), all other thermal changes are slow and occur on the growth time scale. Since there is no process change that occurs on the conductive time scale, the process is likely to be pseudosteady on the growth related time scale.

Turning now to the thermal gradients, the magnitude of the radial variation in the temperature is maximized at the lateral surface where the crystal comes into contact with the surrounding gas. From (2) and Table 1,

$$\left|\frac{\partial T}{\partial n}\right|_{\Gamma_g} \leq \frac{h_{gs}}{k_s}(T_m - T_g) \simeq 175 \text{ K/m}.$$

The magnitude of the axial temperature gradient is maximal at the interface of the phase transition where the Stefan condition (5)–(6) is satisfied. Assuming a nearly flat interface, which will be justified later, an estimate for $T_z|_{S^-}$ is obtained by neglecting the heat flux in the liquid phase

$$\left|\frac{\partial T}{\partial z}\right|_{S^-} \simeq \frac{\rho_s L \overline{v}}{k_s} = 850 \text{ K/m}.$$

The sides of the crystal are predominantly vertical and the crystal-melt interface predominantly horizontal. Thus, we see that the vertical gradients dominate, at least in some neighborhood of the crystal-melt interface. However, we must note that the vertical gradients arise mostly due to heat loss to the cooling gases, which occurs in the radial direction. Since the cooling influences are weak, this implies that a long crystal is needed to get a significant temperature drop along the crystal length and suggests we will need to scale the axial and radial directions differently.

2.2. Nondimensionalization. The above discussion motivates our scaling below. For simplicity, we start by assuming an axisymmetric model, although the crystal cross-section is not in fact circular. The other assumptions that we make here, for simplicity only, are that the heat transfer coefficient h_{gs} and the gas temperature T_g are constant. In reality there will be local variations along the crystal surface, but in any case these require a more detailed analysis of the gas flows in order to be properly evaluated.

We define the Biot number by

$$\epsilon = \frac{h_{gs}\overline{R}}{k_s}, \tag{11}$$

and using the parameter values in Table 1, we find $\epsilon \lesssim 0.026 \ll 1$. We seek an asymptotic expansion in terms of ϵ. With this in mind we adopt the following scalings:

$$r = \overline{R}\hat{r}, \qquad R(z) = \overline{R}\hat{R}(\hat{z}), \quad \epsilon^{1/2}z = \overline{R}\hat{z}, \qquad \epsilon^{1/2}S(r,t) = \overline{R}\hat{S}(\hat{r},\hat{t}),$$

$$\Delta T = T_m - T_g, \qquad \mathrm{St} = \frac{L}{c_s\Delta T}, \qquad T = T_g + \Delta T\Theta, \qquad t = \frac{\mathrm{St}\,\overline{R}^2\rho_s c_s}{k_s\epsilon}\hat{t}.$$

Here variables with hats ($\hat{}$) are the nondimensional ones. In terms of these variables the heat equation in the crystal (1) becomes

$$\frac{\epsilon}{\mathrm{St}}\Theta_t = \frac{1}{r}(r\Theta_r)_r + \epsilon\Theta_{zz}, \qquad \mathbf{x}\in\Omega,\ t>0, \tag{12a}$$

with boundary conditions (2)–(4) becoming

$$-\Theta_r + \epsilon\Theta_z R'(z) = \epsilon\left[1+\epsilon(R'(z))^2\right]^{1/2}\Theta, \qquad \mathbf{x}\in\Gamma_g, \tag{12b}$$

$$\Theta_z(0,t) = \delta(\Theta(0,t) - \Theta_{ch}), \tag{12c}$$

$$\Theta = 1, \qquad \mathbf{x}\in\Gamma_S, \tag{12d}$$

where $\delta = \epsilon^{1/2}h_{ch}/h_{gs}$. The hats have been dropped for brevity. The crystal-melt interface advances according to the Stefan condition (5)–(6) which in nondimensional coordinates becomes

$$\Theta_z - \frac{1}{\epsilon}S_r\Theta_r = (\gamma + S_t), \qquad \gamma = \frac{q_l\overline{R}}{\epsilon^{1/2}k_s\Delta T}, \tag{12e}$$

where q_l and γ are the dimensional and nondimensional heat fluxes in the liquid across the crystal-melt interface in the axial direction. Note that we have chosen the rate of solidification to define the characteristic time scale. The Stefan number St gives the ratio of this characteristic solidification time scale to the time scale associated with conductive heat loss through the crystal side surface. Based on the parameter values in Table 1, we have $\mathrm{St} \simeq 4.3$, suggesting that the conductive scale is small and the temperature inside the crystal is steady on the growth time scale.

2.3. Growth conditions. Under general growth conditions the process may be pseudosteady. However, near the end of the process, transient influences may become important. To investigate both possibilities two situations are considered.

1. The growth of the crystal is characterized by an externally chosen value of q_l (or the nondimensional flux γ), constant for the duration of the simulation.
2. Using the temperature of the crucible Θ_c as a control parameter, q_l is determined implicitly by an effective heat transfer coefficient of the crucible to the crystal through the melt.

In the second scenario a simple model is used to couple the heat fluxes inside the grower based on the fact that the system is almost at thermal equilibrium. The nondimensional liquid temperature satisfies

(13a)
$$\frac{\phi}{\lambda\,\mathrm{St}}\frac{d}{dt}\left[\left(\frac{T_g}{\Delta T}+\Theta_l\right)V_l\right]=-\mu\lambda^2\frac{h_{sl}}{h_{gs}}A(\Theta_l-1)-\mu\frac{h_{gl}}{h_{gs}}(A_c-\lambda^2A)\Theta_l+\frac{h_{cl}}{h_{gs}}A_l(\Theta_c-\Theta_l)$$

with $\Theta_l(0)=1$ and $\Theta_c(0)$ chosen so that $\Theta_l'(0)=0$. The detailed derivation is given in the appendix, and from expression (47c) the γ in (12e) becomes

(13b)
$$\gamma=\epsilon^{1/2}\frac{h_{sl}}{h_{gs}}(\Theta_l-1).$$

3. Perturbation solution. We now seek to approximate the scaled model in section 2.2 via a straightforward perturbation expansion. In turn, this perturbation model will form the basis for a numerical solution. Since St is O(1) under the current growth conditions it is retained as a parameter. Equations (12a) and (12b) strongly suggest that the temperature Θ is independent of r to leading order. If true, then the crystal-melt interface S is also independent of r to leading order, and we see that this is consistent in (12e) with the growth being driven primarily by the vertical gradients. These observations motivate the following approximations:

(14)
$$\begin{aligned}\Theta&\sim\Theta_0(z,t)+\epsilon\Theta_1(r,z,t)+\epsilon^2\Theta_2(r,z,t)+\cdots,\\ S&\sim S_0(t)+\epsilon S_1(r,t)+\epsilon^2S_2(r,t)+\cdots.\end{aligned}$$

We substitute them into the scaled model, expand in powers of ϵ, simplify, and collect terms. The resulting field equations to first order are

(15a)
$$\frac{1}{\mathrm{St}}\Theta_{0,t}-\Theta_{0,zz}=\frac{1}{r}\frac{\partial}{\partial r}(r\Theta_{1,r}),\qquad \mathbf{x}\in\Omega,\ t>0,$$

(15b)
$$\frac{1}{\mathrm{St}}\Theta_{1,t}-\Theta_{1,zz}=\frac{1}{r}\frac{\partial}{\partial r}(r\Theta_{2,r}),\qquad \mathbf{x}\in\Omega,\ t>0,$$

where the boundary condition on the lateral surface becomes

(16a)
$$(\Theta_{1,r}-R'\Theta_{0,z}+\Theta_0)(R(z),z,t)=0,$$

(16b)
$$\left(\Theta_{2,r}-R'\Theta_{1,z}+\frac{1}{2}R'^2\Theta_0+\Theta_1\right)(R(z),z,t)=0.$$

Continuing this procedure for the remaining conditions, at the top of the crystal one has

$$\begin{aligned}\Theta_{0,z}(0,t)&=\delta(\Theta_0(0,t)-\Theta_{ch}),\\ \Theta_{1,z}(r,0,t)&=\delta\Theta_1(r,0,t),\end{aligned}$$

and at the solid-liquid interface

$$\Theta_0(S_0(t),t) = 1, \tag{17a}$$

$$(S_1\Theta_{0,z} + \Theta_1)(r, S_0(t), t) = 0. \tag{17b}$$

Finally, the evolution of the interface is governed by

$$S_0'(t) = \Theta_{0,z}(S_0(t),t) - \gamma, \qquad S_0(0) = Z_0, \tag{18a}$$

$$S_{1,t}(r,t) = \left(\Theta_{1,z} + S_1\Theta_{0,zz} + \frac{\Theta_{1,r}^2}{\Theta_{0,z}}\right)(r, S_0(t), t), \qquad S_1(r,0) = 0, \tag{18b}$$

where we have used (17b) to eliminate the $S_{1,r}$ term. We note that by expanding the solid-liquid interface into the same asymptotic series and deriving the above equations, we have implied that the interface will adjust its shape to avoid a temperature singularity at the solid-liquid-gas triple point. We also note that Z_0 is the nondimensional length of the seed. In addition there will be symmetry conditions at $r = 0$ for Θ_k, S_k, $k = 0, 1$.

3.1. Resolution of the zeroth order model. Integrating (15a) once and imposing the symmetry condition $\Theta_{1,r} = 0$ at $r = 0$, we have

$$\frac{r}{2}\left(\frac{1}{\mathrm{St}}\Theta_{0,t} - \Theta_{0,zz}\right) = \Theta_{1,r}.$$

Applying (16a) at $r = R$ gives the zeroth order problem

$$\frac{1}{\mathrm{St}}\Theta_{0,t} - \Theta_{0,zz} = \frac{2}{R}\left(R'\Theta_{0,z} - \Theta_0\right), \qquad 0 < z < S_0(t),\ t > 0, \tag{19a}$$

$$\Theta_{0,z}(0,t) = \delta(\Theta_0(0,t) - \Theta_{ch}), \qquad t \geq 0, \tag{19b}$$

$$\Theta_0(S_0(t),t) = 1, \qquad t \geq 0, \tag{19c}$$

$$S_0'(t) = \Theta_{0,z}(S_0(t),t) - \gamma, \qquad S_0(0) = Z_0,\ t > 0, \tag{19d}$$

with an initial condition $\Theta_0(z,0) = f(z) \leq 1$ compatible with the boundary conditions. Provided that $R \in C^1([0, S_0])$, the Stefan problem will have a unique solution. For details see Friedman [12].

Equation (19a) is parabolic and involves only the heat fluxes along the length of the crystal. With the chosen expansion we see that at zeroth order the temperature field has no radial dependence. In addition, we can see that the thermal gradients, as discussed previously, are caused by cooling effects at the surface. In section 5.1 we solve the time dependent system (19) on $0 < z < S_0(t)$ for a suitable set of initial conditions. Also notice expression (19d) illustrates that the chosen time scale balances the growth. The appearance of $\mathrm{St} > 1$ in (19a) suggests that thermal transients in the bulk of the crystal are not as important as the growth transient. This is explored further in section 5.1. The limit as $\mathrm{St} \to \infty$ leads naturally to a pseudosteady leading order model in which time dependency enters the thermal model only through the growth; i.e., we also solve as the pseudosteady limit

$$\Theta_{0,zz} + \frac{2}{R}\left(R'\Theta_{0,z} - \Theta_0\right) = 0, \qquad 0 < z < S_0(t),\ t > 0, \tag{20}$$

with (19b)–(19d). Expression (20) together with (19b)–(19d) is analogous to a Hele–Shaw problem, and it is well known that in one dimension solutions of the Stefan

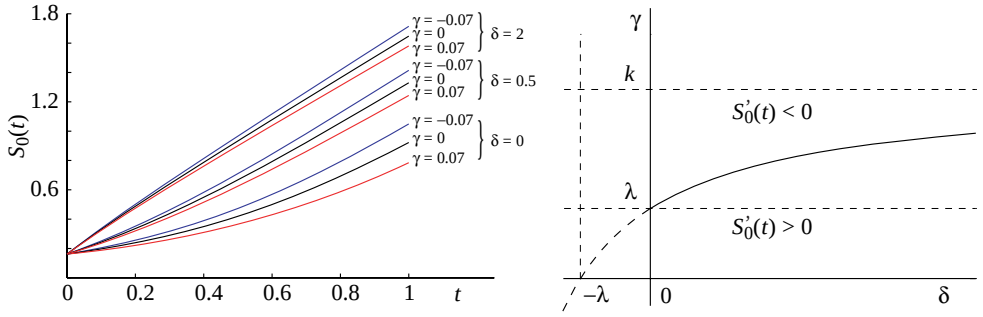

FIG. 3. *To the left is the evolution of the length of a cylindrical crystal grown using the pseudosteady approximation according to* (22). *For the simulations,* $\Theta_{ch} = 0$, $R_0 = 1$, $Z_0 = 0.162$ *(3 cm), and* $\epsilon = 0.026$ *(*$h_{gs} = 4\,W/m^2K$*). The position* $S_0 = 1.8$ *at* $t = 1$ *corresponds to a crystal length of 33 cm grown in 13.6 hours, typical for Cz grown InSb* [24]. *The curve on the right is* $S_0'(t) = 0$, *which characterizes the balance of the heat flux from the melt with the loss of heat at the chuck. The quantity* $\lambda = k \tanh kS_0$ *increases with* S_0.

problem (19) converge to solutions of Hele–Shaw as St $\to \infty$. However, the convergence is not uniform and the intermediate asymptotic behaviors are different [30].

We start by exploring two special cases for which an analytic solution may be computed to the pseudosteady model.

3.1.1. Constant radius crystals. In this case we take $R(z) = R_0$, and (20) becomes simply

$$\Theta_{0,zz} - \frac{2}{R_0}\Theta_0 = 0, \qquad 0 < z < S_0(t),\ t > 0,$$

with boundary conditions (19b) and (19c). Solving for Θ_0 gives

$$\Theta_0(z,t) = \frac{k\cosh kz + \delta \sinh kz + \delta\Theta_{ch}\sinh k(S_0 - z)}{k\cosh kS_0 + \delta \sinh kS_0}, \quad k^2 = \frac{2}{R_0}. \tag{21}$$

The crystal grows at a rate governed by the Stefan condition (19d)

$$S_0'(t) = k\frac{k\sinh kS_0 + \delta\cosh kS_0 - \delta\Theta_{ch}}{k\cosh kS_0 + \delta\sinh kS_0} - \gamma, \quad S_0(0) = Z_0. \tag{22}$$

The left-hand side of Figure 3 shows the time dependence of the position of the interface and therefore the length of the crystal as a function of time for various combinations of δ and γ. The right-hand side details the balance between these two parameters. The initial position of the curve is determined by the length of the seed Z_0. If the γ, δ pair is chosen above the curve $S_0'(t) = 0$ $\big(\gamma > \gamma_{\max}(\delta) = k^2(\lambda_0 + \delta)/(k^2 + \delta\lambda_0), \lambda_0 = k\tanh kZ_0, \Theta_{ch} = 0\big)$, the seed melts back. If we are below the curve, then $S_0(t)$ increases without bound and the curve asymptotically approaches $\gamma = k$. For small S_0, (22) gives $S_0' = k^2S_0 - \gamma + \delta(1-\Theta_{ch})(1-\delta S_0) + \mathcal{O}(S_0^2)$ and for large S_0, the growth rate is asymptotically $S_0' = k - \gamma$.

3.1.2. Conical crystals. One source of ambiguity in the constant radius model above is the need to specify the chuck temperature and heat transfer coefficient. In the case of a conical crystal, which is closer to reality, this ambiguity is less prominent. We assume $R(z) = R_0 + \alpha z$, where $\arctan\alpha \simeq \mathcal{O}(1)$ is one-half the opening angle of

the crystal when using nondimensional units. This assumption is predicated on the condition that the dimensional version of $\alpha \simeq \mathcal{O}(\sqrt{\epsilon})$, and it is easily verified using the data in Table 1. Substituting for $R(z)$ we solve

$$\Theta_{0,\eta\eta} + \frac{2}{\eta}(\Theta_{0,\eta} - \Theta_0) = 0, \qquad R_0 < \alpha^2\eta < R_0 + \alpha S_0,\ t > 0, \tag{23a}$$

$$\Theta_{0,\eta} = \alpha\delta(\Theta_0 - \Theta_{ch}), \qquad \alpha^2\eta = R_0,\ t \geq 0, \tag{23b}$$

$$\Theta_0 = 1, \qquad \alpha^2\eta = R_0 + \alpha S_0,\ t \geq 0, \tag{23c}$$

where $\alpha^2\eta(z) = R_0 + \alpha z$. The resulting solution takes the form of linear combinations of modified Bessel functions

$$\Theta_0(\eta, t) = \frac{W_{fg}(\eta, \eta(0)) - \alpha\delta\left[V_{fg}(\eta, \eta(0)) - \Theta_{ch}V_{fg}(\eta, \eta(S_0))\right]}{W_{fg}(\eta(S_0), \eta(0)) - \alpha\delta V_{fg}(\eta(S_0), \eta(0))}, \tag{24}$$

where

$$W_{fg}(x,y) = \begin{vmatrix} f(x) & g(x) \\ f'(y) & g'(y) \end{vmatrix}, \quad V_{fg}(x,y) = \begin{vmatrix} f(x) & g(x) \\ f(y) & g(y) \end{vmatrix},$$
$$f(\eta) = \frac{I_1(\sqrt{8\eta})}{\sqrt{\eta}}, \qquad g(\eta) = \frac{K_1(\sqrt{8\eta})}{\sqrt{\eta}}.$$

The corresponding expression for the growth rate is

$$S_0'(t) = \frac{1}{\alpha}\frac{V_{f'g'}(\eta(S_0), \eta(0)) + \alpha\delta\left[W_{fg}(\eta, \eta(0)) - \Theta_{ch}W_{fg}(\eta, \eta(S_0))\right]}{W_{fg}(\eta(0), \eta(S_0)) - \alpha\delta W_{fg}(\eta(S_0), \eta(S_0))} - \gamma, \quad S_0(0) = Z_0.$$

Two limiting cases are considered. To compare with the cylindrical case one sets $R_0 = 1$ and expands (24) in a power series of α yielding

$$\Theta_0(z,t) = \frac{\cosh\sqrt{2}z}{\cosh\sqrt{2}S_0}\left\{1 - \frac{\alpha}{8}\left[6(z - S_0) + \sqrt{8}(z^2 - U)\tanh\sqrt{2}z \right.\right.$$
$$\left.\left. - \sqrt{8}(S_0^2 - U)\tanh\sqrt{2}S_0\right]\right\} + \mathcal{O}(\alpha^2) \tag{25a}$$

with

$$U = \frac{3}{2} + 2\delta\left(1 - \Theta_{ch}\cosh\sqrt{2}S_0\right). \tag{25b}$$

Expressions (25) should be compared to (21). Since for a cone $R_0 \ll 1$, a simple form of (24) can be obtained by expanding the solution in R_0 as

$$\Theta_0(z,t) = \sqrt{\frac{S_0}{z}}\frac{I_1(\sqrt{8z/\alpha})}{I_1(\sqrt{8S_0/\alpha})}\left[1 + \frac{R_0}{\alpha}\left(\sqrt{\frac{2}{\alpha z}}\frac{I_0(\sqrt{8z/\alpha})}{I_1(\sqrt{8z/\alpha})}\right.\right.$$
$$\left.\left. - \sqrt{\frac{2}{\alpha S_0}}\frac{I_0(\sqrt{8S_0/\alpha})}{I_1(\sqrt{8S_0/\alpha})} - \frac{1}{z} + \frac{1}{S_0}\right)\right] + \mathcal{O}(R_0^2). \tag{26}$$

The solution for conical crystals is more complicated, and we will defer the discussion to section 5.

3.1.3. Comments. This model for a one-dimensional temperature variation in the axial direction is not new. For example, it has been used in [32] but without formal justifications. What we have done here, by deriving it using asymptotic expansion, is to allow the reader to realize the applicability and restrictions of the model.

3.2. Radial variations: Resolution of the first order model. Having solved the zeroth order model, to give Θ_0 and S_0, we can resolve the radial variations in temperature, which occur at first order in Θ_1, and also consider the shape of the crystal-melt interface as it evolves, through S_1. From resolution of the zeroth order model we have

$$\Theta_{1,r} = \frac{r}{2}\left(\frac{1}{\mathrm{St}}\Theta_{0,t} - \Theta_{0,zz}\right),$$

and integrating with respect to r we have

$$\Theta_1(r,z,t) = \Theta_1(0,z,t) + \frac{r^2}{4}\left(\frac{1}{\mathrm{St}}\Theta_{0,t} - \Theta_{0,zz}\right),$$

or

$$\Theta_1(r,z,t) = \Theta_1^0(z,t) + r^2\Theta_1^1(z,t), \tag{27}$$

where $\Theta_1^0(z,t) = \Theta_1(0,z,t)$ and using (19a)

$$\Theta_1^1(z,t) = \frac{1}{2R}(R'\Theta_{0,z} - \Theta_0). \tag{28}$$

The function $\Theta_1^1(z,t)$ is known from the data and the zeroth order solution. By adopting the same procedure as for the zeroth order model we can find $\Theta_1^0(z,t)$, i.e., integrating (15b) with respect to r and using the boundary condition at $r = R$ to eliminate $\Theta_{2,r}$. We derive

$$\frac{1}{\mathrm{St}}\Theta_{1,t}^0 - \Theta_{1,zz}^0 = \frac{2}{R}(R'\Theta_{1,z}^0 - \Theta_1^0) + F_1, \qquad 0 < z < S_0(t),\ t > 0, \tag{29a}$$

$$\Theta_{1,z}^0(0,t) = \delta\Theta_1^0(0,t), \qquad t \geq 0, \tag{29b}$$

$$\Theta_1^0(S_0(t),t) = -S_1(0,t)\Theta_{0,z}(S_0(t),t), \qquad t \geq 0, \tag{29c}$$

$$S_1'(r,t) = \left(\Theta_{1,z}^0 + S_1\Theta_{0,zz} + r^2F_2\right)(S_0(t),t), \qquad S_1(r,0) = 0,\ t > 0, \tag{29d}$$

where

(29e)

$$F_1 = -\frac{R^2}{2}\left(\frac{1}{\mathrm{St}}\Theta_{1,t}^1 - \Theta_{1,zz}^1\right) + 2R(R'\Theta_{1,z}^1 - \Theta_1^1) - \frac{R'^2\Theta_0}{R}, \quad F_2 = \Theta_{1,z}^1 + \frac{4(\Theta_1^1)^2}{\Theta_{0,z}},$$

and r appears as a parameter in (29d).

This first order problem (29) has the same structure as the zeroth order problem (19) but is inhomogeneous; i.e., the zeroth order solution provides the forcing (or heating). A further key difference is in the coupling with the crystal-melt interface position S_1. Equation (29c) provides the lower boundary condition for Θ_1 and S_1 advances through (29d), which is consequently a first order quasi-linear partial differential equation.

In general, the coupled system (29) must be solved numerically. For the pseudosteady case, the formula can be simplified as follows. From the definition of Θ_1^1 and using the pseudosteady condition $\Theta_{0,zz} = -4\Theta_1^1$, expressions (29a) and (29d) reduce to

(30)
$$\Theta^0_{1,zz} + \frac{2}{R}(R'\Theta^0_{1,z} - \Theta^0_1) = \frac{1}{4}(2R' + 5R'R'' - RR''')\Theta_{0,z} - \frac{1}{4R}(2R - 4R'^2 + 5RR'')\Theta_0$$

and

(31)
$$S_1'(r,t) = \Theta^0_{1,z} + \frac{2}{R}(1 - R'\Theta_{0,z})S_1 + \frac{r^2}{2R^2}\left(-3R' + (RR'' + R'^2 + R)\Theta_{0,z} + \frac{2}{\Theta_{0,z}}\right),$$

where the right-hand side of (31) is evaluated at $z = S_0(t)$ and r appears as a parameter.

3.2.1. Constant radius crystals. Since $R(z) = R_0$, expression (30) reduces to $\Theta^0_{1,zz} - k^2\Theta^0_1 = -\Theta_0/2$ with $k^2 = 2/R_0$. Solving for Θ^0_1 and using (27)–(28) one finds

$$\Theta_1(r,z,t) = \frac{\cosh kz}{\cosh kS_0}\left[-\Gamma(S_0) - S_1^0\Theta_{0,z}(S_0)\right] + \Gamma(z) - \frac{1}{4}k^2r^2\Theta_0(z)$$

with $S_1^0 = S_1(0,z)$ and

$$\Gamma(z) = \frac{1}{2k}\int_0^z \Theta_0(\xi)\sinh k(\xi - z)\,d\xi.$$

When $\delta = 0$, $\Gamma(z) = -z\sinh kz/4k\cosh kS_0$ yields

$$\Theta_1(r,z,t) = \frac{1}{4k}\frac{\cosh kz}{\cosh kS_0}\left(S_0\tanh kS_0 - z\tanh kz - 4k^2S_1^0\tanh kS_0 - k^3r^2\right).$$

S_1 can be obtained by (29d).

3.2.2. Conical crystals. Since $R(z) = R_0 + \alpha z$, and from (20) $\Theta_1^1 = (\alpha\Theta_{0,z} - \Theta_0)/2R = -\Theta_{0,zz}$, we find

$$\Theta^1_{1,z} = -\left(\frac{3\alpha^2}{2R^2} + \frac{1}{2R}\right)\Theta_{0,z} + \frac{3\alpha}{2R^2}\Theta_0, \quad \Theta^1_{1,zz} = \left(\frac{6\alpha^3}{R^3} + \frac{3\alpha}{R^2}\right)\Theta_{0,z} - \left(\frac{6\alpha^2}{R^3} + \frac{1}{R^2}\right)\Theta_0.$$

Consequently, (30) reduces to

$$\Theta^0_{1,zz} + \frac{2\alpha}{R}\Theta^0_{1,z} - \frac{2}{R}\Theta^0_1 = \frac{\alpha}{2}\Theta_{0,z} + \frac{1}{2R}(2\alpha^2 - R)\Theta_0, \tag{32}$$

and we see that even for the pseudosteady cone, numerical methods will have to be used in general.

Further discussion is deferred to section 5. In the following we turn our discussion to thermal stress inside the crystal.

4. Thermal stress. The thermal stress experienced by the crystal during its growth leads to the generation of structural defects in the crystal [31]. If we want to eliminate these undesirable defects, then one must control the thermal stress. We begin with a brief introduction to the case of an isotropic body. Although InSb is

anisotropic with respect to its elasticity, this will be dealt with in a subsequent section. Fundamentals can be found elsewhere [21, 28].

From the elements of the stress tensor the characteristic amount of stress at a particular position can be described by the von Mises stress σ_{VM} with the relationship

$$2\sigma_{\mathrm{VM}}^2 = (\sigma_1 - \sigma_2)^2 + (\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2, \tag{33}$$

where σ_1, σ_2, σ_3 are the eigenvalues of the stress tensor. Being a function of the eigenvalues, the von Mises stress is invariant under coordinate transformations.

For a given temperature field, the resulting set of thermoelastic equations for the displacement vector are coupled, and a numerical method will be needed to solve the displacements before thermal stress can be computed. It is instructive to consider the special case where the displacement occurs in one of the three directions, due to the nature of temperature variation. In the following, we will address the thermal stress that arises from temperature variation in the radial direction, as this is the dominant contribution.

4.1. Thermal stress due to radial temperature variation. We assume the displacement vector is of the form $\vec{u} = \langle u(r), 0, 0\rangle$ and converting to nondimensional units u satisfies

$$\frac{\partial}{\partial r}\left[\frac{1}{r}\frac{\partial}{\partial r}(ru)\right] = \epsilon\frac{(1+\nu)}{(1-\nu)}\frac{\partial\Theta_1}{\partial r}, \qquad u(0) < \infty, \quad \sigma_{rr}(R) = 0,$$

where ν is the Poisson ratio. The condition $u(0) < \infty$ is due to the axisymmetry, and since the crystal surface is unstressed, $\sigma_{rr}(R) = 0$. The stress has been nondimensionalized by $\alpha_0\Delta TE/(1-\nu)$, E is the Young's modulus, and α_0 is the coefficient of thermal expansion. We have assumed here that $\Theta_z \simeq 0$ since we want to focus on the sole effect of any radial temperature variations. The solution satisfying the boundary conditions is

$$u(r) = \epsilon\frac{(1+\nu)}{(1-\nu)}\left[\frac{1}{r}\int_0^r \Theta_1(s)s\,ds + (1-2\nu)\frac{r}{R^2}\int_0^R \Theta_1(s)s\,ds\right],$$

and using (27), the corresponding nontrivial stresses are

$$\sigma_{rr} = \epsilon\left[\frac{1}{R^2}\int_0^R \Theta_1(s)s\,ds - \frac{1}{r^2}\int_0^r \Theta_1(s)s\,ds\right] = \frac{1}{4}\epsilon\Theta_1^1\left(R^2 - r^2\right), \tag{34a}$$

$$\sigma_{\theta\theta} = \epsilon\left[\frac{1}{R^2}\int_0^R \Theta_1(s)s\,ds + \frac{1}{r^2}\int_0^r \Theta_1(s)s\,ds - \Theta_1(r)\right] = \frac{1}{4}\epsilon\Theta_1^1\left(R^2 - 3r^2\right), \tag{34b}$$

$$\sigma_{zz} = \epsilon\left[\frac{2}{R^2}\int_0^R \Theta_1(s)s\,ds - \Theta_1(r)\right] = \frac{1}{2}\epsilon\Theta_1^1\left(R^2 - 2r^2\right) \tag{34c}$$

with σ_{zz} modified using St. Venant's principle.

Using (33) to compute the von Mises stress gives

$$\sigma_{\mathrm{VM}}(r,z,t) = \frac{1}{4}\epsilon\left|\Theta_1^1\right| R^2\left[1 - 4\left(\frac{r}{R}\right)^2 + 7\left(\frac{r}{R}\right)^4\right]^{1/2}. \tag{35}$$

The object in the square brackets is a shape factor, and it ranges from a value of

$\sqrt{3/7}$ at a radius of $r = \sqrt{2/7}R(z)$ to a maximum value of two at the outer edge of the crystal. For $\sqrt{4/7}R(z) < r \leq R(z)$ this factor is greater than one.

Remark 1. From (19a) and (28), $\Theta_1^1 = (\Theta_{0,t}/\,\mathrm{St} - \Theta_{0,zz})/4$, which reduces to $|\Theta_1^1| = |\Theta_{0,zz}|/4$ in the pseudosteady limit. This generalizes the classical result that the stress level is a characteristic of the concavity of the temperature in the axial direction [22, 34]. The stress is also linearly proportional to the Biot number ϵ indicating that an increase in the crystal radius will also increase the stress level, other conditions being equal. It also indicates that the increase of radius can be offset by reducing the heat transfer coefficient h_{gs}, suggesting that a possible way to reduce the stress is by changing the local heat flux from the crystal lateral surface.

Remark 2. Also from (28), it is clear that there are two components in the expression for Θ_1^1. Therefore both the temperature gradient and the crystal profile are important for stress reduction. Since circular cylindrical shape is normally adopted for the growth of more common crystals such as silicon, the shape effect has not been discussed much in the literature. However, for crystals such as InSb with relatively low resistance to thermal stress, finding the right shape is often part of an important strategy for growing defect-free crystals. We will address this issue again in later sections.

Remark 3. As other stresses, such as the total resolved stress, are often considered more relevant for causing defects, it is important to point out that the same characteristics remain for different representations of the thermal stress or for crystals being pulled in different directions. These issues will be the topic of the following two subsections.

4.2. Resolved stress. InSb crystallizes in a zincblende or $\bar{4}$3m structure. The structure description is two interpenetrating face-centered cubic (f.c.c.) sublattices of In and Sb separated by the displacement vector $a\langle 1,1,1\rangle/4$. Each In (Sb) atom is tetrahedrally coordinated with an Sb (In) atom. An alternative description of the structure is a f.c.c. sublattice of Sb atoms with one-half of the tetrahedral sites filled with In atoms. The nearest neighbor distance is $\sqrt{3}a/4$ and the lattice parameter is $a = 0.6476$ nm.

The preferred method of dislocation generation in InSb, as in all III-V semiconductors, is through the generation of slip defects, in particular the $\{111\}$, $\langle 1\bar{1}0\rangle$ slip system [19]. This system consists of four glide planes within which atoms can slip in one of three directions. For example, in the (111) plane the slip directions are $[10\bar{1}]$, $[\bar{1}10]$, and $[0\bar{1}1]$. Figure 4 looks down the z-axis of the tetrahedral structure of the crystal and shows each of the 12 permissible glide directions classified into five different categories.

The amount of stress in a particular slip direction $\vec{g}$ within a given glide plane with normal $\vec{n}$ is known as the resolved stress, σ_{RS}. If one assumes the crystallographic axes coincide with the coordinate axes, then σ_{RS} is computed by finding

$$\sigma_{\mathrm{RS}} = \vec{g}^T Q \sigma Q^T \vec{n}, \tag{36}$$

where Q is the coordinate transformation matrix that takes $(r,\theta,z) \to (x,y,z)$ and σ is the stress tensor in the (r,θ,z) coordinates. In summary, the five categories

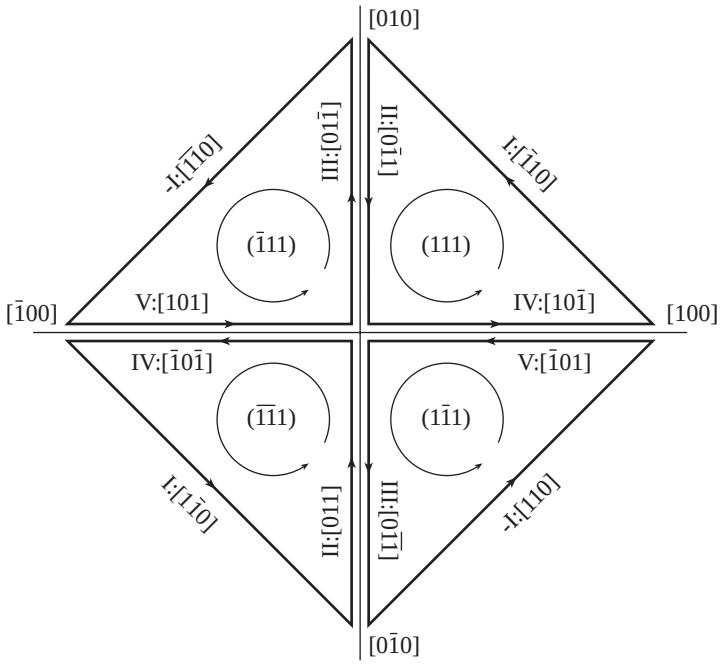

FIG. 4. *Illustrated are each of the* 12 *slip directions in the* $\{111\}$, $\langle 1\bar{1}0\rangle$ *slip system. The roman numerals refer to the functional form of the stress in the direction of the appropriate slip plane.*

illustrated in Figure 4 yield[1]

$$\sigma_{\mathrm{RS}}^{\mathrm{I}} = -\frac{1}{\sqrt{6}}(\sigma_{rr} - \sigma_{\theta\theta})\cos 2\theta, \tag{37a}$$

$$\sigma_{\mathrm{RS}}^{\mathrm{II}} = \frac{1}{\sqrt{6}}[(\sigma_{zz} - \sigma_{\theta\theta}) - (\sigma_{rr} - \sigma_{\theta\theta})(\sin^2\theta + \sin\theta\cos\theta)], \tag{37b}$$

$$\sigma_{\mathrm{RS}}^{\mathrm{III}} = -\frac{1}{\sqrt{6}}[(\sigma_{zz} - \sigma_{\theta\theta}) - (\sigma_{rr} - \sigma_{\theta\theta})(\sin^2\theta - \sin\theta\cos\theta)], \tag{37c}$$

$$\sigma_{\mathrm{RS}}^{\mathrm{IV}} = -\frac{1}{\sqrt{6}}[(\sigma_{zz} - \sigma_{\theta\theta}) - (\sigma_{rr} - \sigma_{\theta\theta})(\cos^2\theta + \sin\theta\cos\theta)], \tag{37d}$$

$$\sigma_{\mathrm{RS}}^{\mathrm{V}} = \frac{1}{\sqrt{6}}[(\sigma_{zz} - \sigma_{\theta\theta}) - (\sigma_{rr} - \sigma_{\theta\theta})(\cos^2\theta - \sin\theta\cos\theta)]. \tag{37e}$$

Plastic deformation of the crystal occurs if the stress in any of the 12 slip directions exceeds the critical resolved shear stress, σ_{crss}. To leading order, the actual density of dislocations suffered by the crystal is proportional to the total excess stress at any given point within the crystal. In this sense, an estimation of where dislocations are likely to occur is given by the distribution of the total absolute stress:

$$|\sigma_{\mathrm{tot}}| = 4\left|\sigma_{\mathrm{RS}}^{\mathrm{I}}\right| + 2\left(\left|\sigma_{\mathrm{RS}}^{\mathrm{II}}\right| + \left|\sigma_{\mathrm{RS}}^{\mathrm{III}}\right| + \left|\sigma_{\mathrm{RS}}^{\mathrm{IV}}\right| + \left|\sigma_{\mathrm{RS}}^{\mathrm{V}}\right|\right). \tag{38}$$

An additional complication is that, in general, the elastic constants depend on the solidification direction since the thermal and crystallographic axes are not aligned. However, for crystals that belong to the cubic classes this does not play a role [2].

[1]Note: $\theta = -\varphi$, where φ is the angular coordinate used by Jordan, Caruso, and von Neida [19].

4.3. Crystal extraction in an arbitrary direction. The previous subsection supposes the crystal is extracted from the melt in a direction coincident with the crystallographic axes. If there is a misalignment between the frame defined by the crystallographic axes of the unit cell and the frame with its z-axis coincident with the solidification direction, then a coordinate transformation is required to align $\vec{n}$ and $\vec{g}$. These directions must change because they are with respect to the crystallographic axes and not the the temperature field that determines the stress tensor. Let U_{v_p} denote a coordinate transformation, depending on the pulling direction, that takes vectors in the crystallographic frame to the solidification frame. The total resolved stress of the $\{111\}$, $\langle 1\bar{1}0\rangle$ slip system becomes

$$|\sigma_{\text{tot}}| = \sum_{i=1}^{12} \left| \vec{g}_i^T U_{v_p}^T Q \sigma Q^T U_{v_p} \vec{n}_i \right|, \tag{39}$$

where the symmetry in expression (38) has been broken.

5. Numerical results and discussion. We first discuss the temperature solutions for the decoupled growth; i.e., the heat flux from the melt to the crystal is assumed a known (constant) value. In particular, we compare the pseudosteady $\big((19), (29)$ with $\Theta_{0,t} = \Theta_{1,t}^0 = \Theta_{1,t}^1 = 0\big)$ and the unsteady solution (12). Even though the Stefan number is not much bigger than unity, the results show that the pseudosteady solutions are in good agreement with the unsteady calculation. This indicates that the thermal stress can be reasonably estimated using the pseudosteady solution, which greatly simplifies the calculation. The case for coupled growth is also investigated, and we show the transient influence of the melt is only important towards the end of the growth. During the growth, the heat flux from the melt to the crystal changes slowly, suggesting that the temperature solutions for the decoupled case are good approximations. The thermal stress is computed based on the pseudosteady solution using the decoupled growth condition for simplicity.

Table 2 displays the various quantities used in the simulation and not found in the previous table.[2]

5.1. Temperature solutions.

5.1.1. Decoupled growth. In this section we attempt to justify the pseudosteady approximation. To begin, we assume $\gamma = \delta = 0$, decoupling the crystal from the melt in the crucible. Figure 5 compares the time dependence of the position of the crystal-melt interface $S(r,t)$ using (12) (the unsteady case) with its zeroth order approximation $S_0(t)$ using (20), (19b)–(19d) (the pseudosteady case). To determine the influence of both the crystal profile and the amount of heat transfer, a cylindrical and conical profile were assumed and, for each profile, two values of ϵ ($\epsilon_1 = 0.0066$, $\epsilon_2 = 0.026$) were considered. Using only the zeroth order approximation, the interface position is uniformly overestimated with the pseudosteady approximation, and the amount of overestimate is proportional to ϵ. The largest relative difference is about 10% and occurs at the end of the growth for a cylindrical crystal with the largest value of ϵ.

The radial dependence of the interface can be estimated with the first order perturbation, $S_0(t) + \epsilon S_1(r,t)$. Figure 6 compares this approximation with the radial de-

[2] h_{sl} and h_{cl} are based on estimated boundary layer thicknesses of 2.5 mm and 1.8 mm, respectively. The former is due to an Ekman layer (rotations of crucible and the crystal at 5 rpm) and the latter is due to natural convection ($\Delta T = 1$ K, $\nu = 3.3 \times 10^{-7}$ m^2/s, Grashof number $\simeq 6.0 \times 10^6$).

TABLE 2
Remaining liquid and growth parameters used in the simulations.

Data	Symbol	Value
Growing properties		
Ambient temperature	T_a	600 K
Seed radius	R_0	0.005 m
Seed length	Z_0	0.03 m
Crucible depth	$\tilde{Z}_c$	0.0875 m
Crucible radius	$\tilde{R}_c$	0.0875 m
Thermal expansion	α_0	5.5×10^{-6} /K
Liquid properties at $T = T_m$		
Density	ρ_l	6.47×10^3 kg/m^3
Thermal conductivity	k_l	9.23 W/m K
Heat capacity	$\rho_l c_l$	1.7×10^6 J/m^3 K
Heat transfer coefficients		
Solid-liquid	h_{sl}	3700 W/m^2 K
Gas-liquid	h_{gl}	2 W/m^2 K
Crucible-liquid	h_{cl}	5230 W/m^2 K

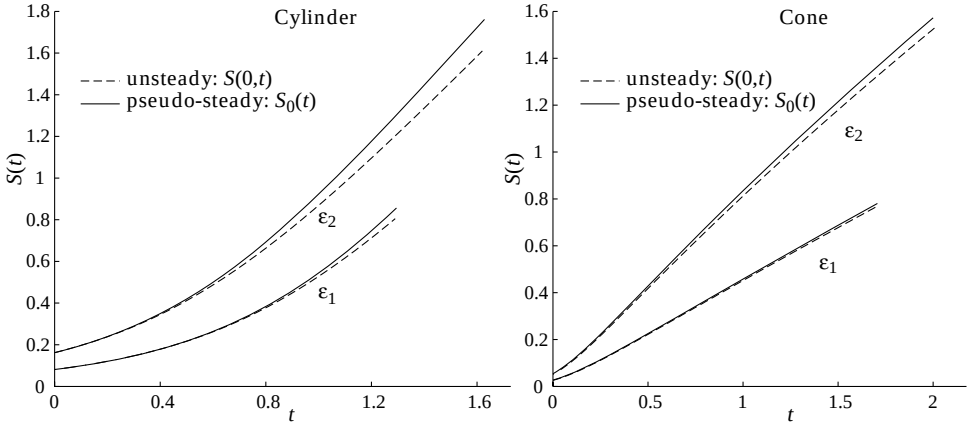

FIG. 5. *Time evolution of $S_0(t)$ for the pseudosteady approximation compared with $S(0,t)$. For both values of ϵ and both crystal profiles $S_0(t)$ closely approximates $S(0,t)$.*

pendence obtained by solving the unsteady equations at the end of the crystal growth, $t = t_f$. In both the case of a cylindrical and a conical crystal the growth interface is convex (viewed from inside the crystal). For the conical crystal the interface is flatter even though the curvature grows with time for both cases. The pseudosteady results closely track the unsteady solution with a maximum relative difference less than 5%.

As a final comparison, Figures 7 and 8 display the predicted thermal profile for the cylindrical and conical crystals, respectively. The crystals are displayed in the physically correct aspect ratio and with their respective solid-liquid interface. It can be seen that the pseudosteady and unsteady solutions are in close agreement.

From the previous results it is clear that without any coupling from the melt, the pseudosteady solution approximates the solution of the fully time dependent Stefan problem. When one considers coupling the melt in the crucible with the crystal, the pseudosteady approximation will remain valid if the predicted heat flux from the melt does not change appreciably over the growth of the crystal. In this case the temperature and flux of the melt are determined by (13).

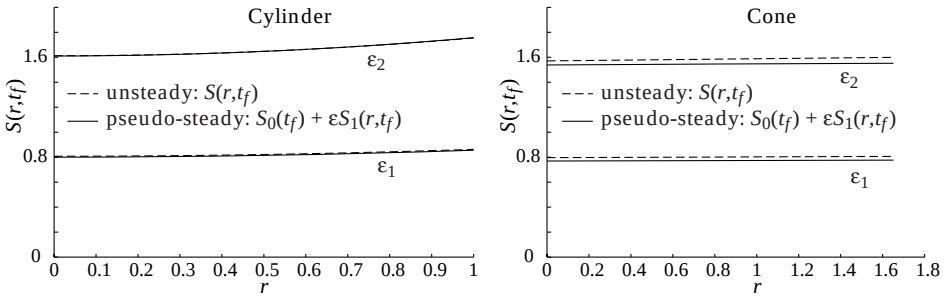

FIG. 6. *Comparison of the radial dependence of interface at the end of growth for the unsteady* $\left(S(r,t_f)\right)$ *and the first order approximation pseudosteady* $\left(S_0(r,t_f)+\epsilon S_1(r,t_f)\right)$ *cases.*

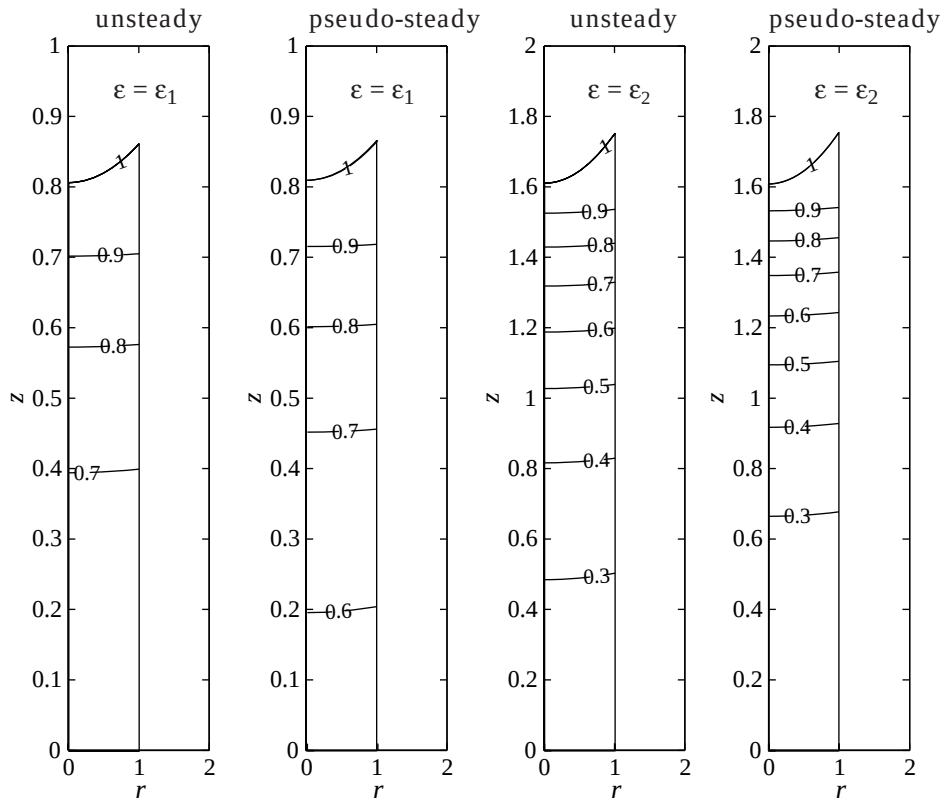

FIG. 7. *Nondimensional temperature contours for the cylinder at the end of the growth illustrated at the correct aspect ratio.*

5.1.2. Coupled growth with melt in the crucible. In this simulation we solve (19) with a cylindrical seed where $\gamma = \gamma(t)$ as determined by (13). In addition, $h_{gs} = 4$, $\delta = 0$, and the remaining heat transfer coefficients are listed in Table 2. Results for a cylindrical and conical crystal pulled from a parabolic crucible $\left(z = \tilde{Z}_c(r/\tilde{R}_c)^2\right)$ are displayed in Figure 9. In both cases the temperature of the crucible was initially $T_c(0) = T_m + 0.046$ K (dimensional) and reduced at a constant rate of

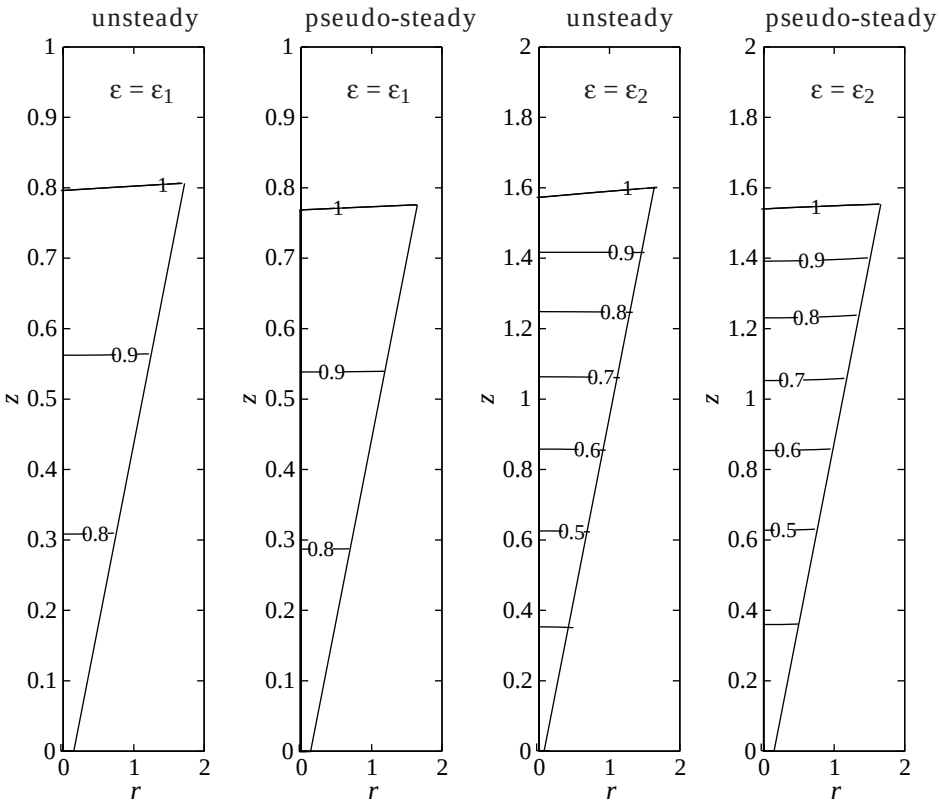

FIG. 8. *Nondimensional temperature contours for the cone at the end of the growth illustrated at the correct aspect ratio.*

0.2 K/hr.

On the far left of Figure 9 the grown crystal is illustrated at the physically correct aspect ratio with the initial and final melt levels. The initial level is chosen so that 25% of the melt remains in the crucible once the crystal achieves its final length. Growth times for each crystal are indicated on the far right.

The center two images display the time evolution of the crystal temperature with the pseudosteady position (St $\to \infty$) of the interface indicated with crosses. For the cylindrical case the initial rapid increase in the radius imprints an echo of the seed into the thermal field which will increase the stress in the shoulder of the crystal. Such an effect has recently been described elsewhere [22]. The dashed lines show the solution if $\gamma = 0$. By setting γ constant the growth rate of the crystal becomes essentially constant rather than accelerating as seen in the coupled case.

The far right shows the growth rate of the interface $S_0'(t)$, the corresponding pull rate $v_p(t)$, and the rate at which the melt drops $\lambda^2 v_m(t)$. For the cylindrical crystal, the growth rate rapidly decreases as the crystal shoulder is formed from the initial seed. This effect is decreased for the conical crystal, leading to a more uniform pull rate with this profile. As the crucible empties, the melt falls more rapidly, causing the pulling speed to reduce near the end of the growth. For the cone this is emphasized as the cross-sectional area increases with time.

Figure 10 illustrates both $\gamma(t)$ and the components of expression (13) during the

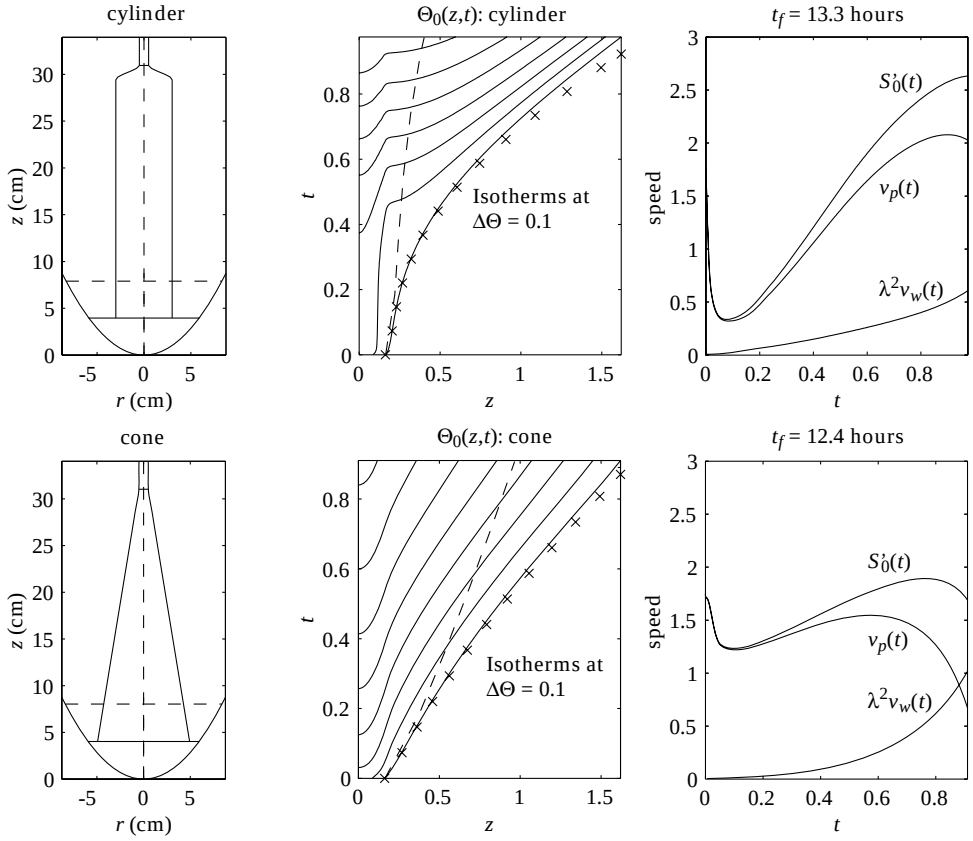

FIG. 9. *Final configuration of the crystal-melt system, thermal fields, and interface speeds for the coupled system* (13) *and* (19). *On the left is the final crystal position in the furnace. The temperature field is detailed in the center and the interfacial velocities are displayed to the right. Cylindrical and conical growth are on the top and bottom rows, respectively.*

growth cycle for the cylindrical and conical crystal profiles. The flux from the melt $\gamma(t)$ is shown to the left of the figure. Changes in the flux are driven primarily by the chosen rate of change of the crucible temperature and is relatively insensitive to the crystal profile. In both cases the magnitude of undercooling was $\simeq 2$ K. A more sophisticated model that considers the dynamics of the melt is clearly required to quantitatively estimate any undercooling effects. This research is currently underway.

Even with our very simple model for the melt, two separate growth regimes are clearly identified. By considering the source of the various heat fluxes acting on the melt one observes that in the initial states of growth, the heat loss to the ambient gas $Q_{gl} = h_{gl}(A_c - A)(T_l - T_g)$ and the heat gain from the crucible $Q_{cl} = h_{cl}A_l(T_c - T_l)$ are the dominant terms in (13). Once the crucible is cool enough, it becomes the dominant channel for heat loss, whereas the melt is heated by the solid-liquid interface at T_m and the decreased heat capacity through volume loss of the melt. The profile of the crystal changes $Q_{sl} = h_{sl}A(T_l - T_m)$ and Q_{gl}, while the shape of the crucible governs the behavior of Q_{cl}. $Q_{vl} = -\rho_l c_l T_l V_l'$ is dictated by the rate of growth. The nondimensional quantities in Figure 10 are found by dividing the Q_i by the dimensional factor $\tilde{R}_c{}^2 \tilde{Z}_c h_{gs} \Delta T / \overline{R}$.

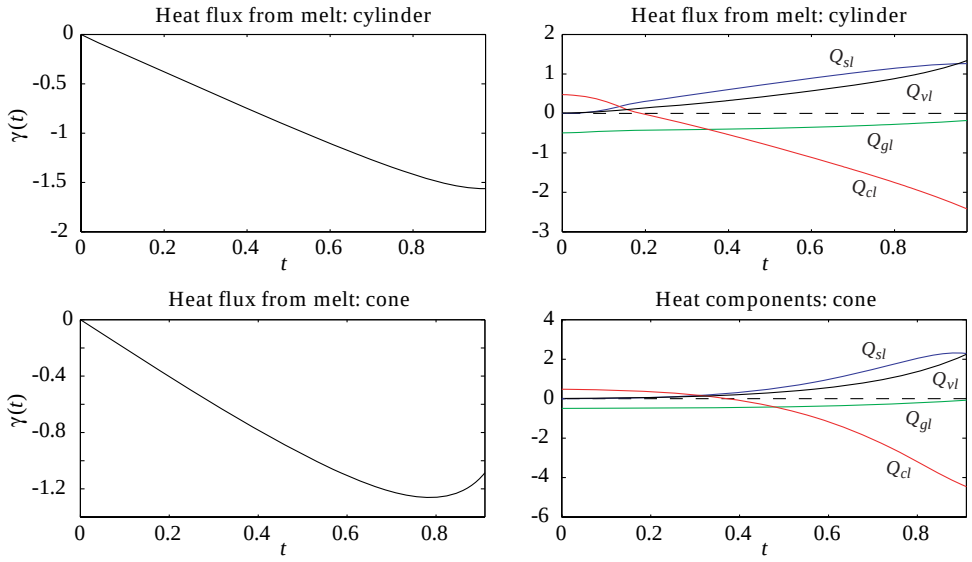

FIG. 10. *The nondimensional flux and the heat flux components of expression* (13) *through the growth cycle. The various components detailed to the right are discussed in section* 5.1.2.

5.2. Thermal stress. For an anisotropic crystal, Young's modulus E and Poisson's ratio ν depend on the specific orientation of the crystal. However, these values are invariant within the {111} planes [2]. For InSb one has

$$E_{\{111\}} = \frac{4(C_{11}+2C_{12})(C_{11}-C_{12})C_{44}}{(C_{11}+2C_{12})(C_{11}-C_{12})+2C_{11}C_{44}} = 6.18\times 10^4 \text{ MPa},$$
$$\nu_{\{111\}} = \frac{1}{3}\frac{(C_{11}+2C_{12})(C_{11}-C_{12})-2C_{44}(C_{11}-4C_{12})}{(C_{11}+2C_{12})(C_{11}-C_{12})+2C_{11}C_{44}} = 0.364,$$

where $C_{11} = 6.70\times 10^4$, $C_{12} = 3.65\times 10^4$, $C_{44} = 3.02\times 10^4$ are crystal stiffness constants[3] in MPa and, consequently, the dimensional constant for the stress calculations is $\alpha_0 \Delta T E/(1-\nu) \simeq 107$ MPa.

Figure 11 shows the stress contours of the von Mises stress for the cylinder and the cone at the end of the growth corresponding to the pseudosteady results in Figures 7 and 8. For a fixed value of ϵ the stress in the conical case is about one-half that of the cylindrical case. Also, increasing ϵ increases the stress level dramatically. By growing a conical crystal the stress can be reduced significantly. For a given temperature the amount of stress at which crystal deformation begins to occur is known as the critical resolved shear stress, σ_{crss}. In the case of InSb, σ_{crss} varies from 0.245 MPa [25] to 4.90 MPa [6] as the temperature varies from $T_m = 798.4$ K to 491 K, respectively, indicating that the conical crystal remains below this critical stress level.

An additional method of reducing the stress level in the crystal is to use the anisotropic nature of the crystal to our advantage by changing the direction in which the crystal is solidified. From expression (39) one can see that for a fixed vertical position in the crystal the total absolute resolved stress is a complicated function of

[3]The corresponding compliances are $S_{11} = 2.42\times 10^{-5}$ MPa^{-1}, $S_{12} = -8.55\times 10^{-6}$ MPa^{-1}, $S_{44} = 3.31\times 10^{-5}$ MPa^{-1}.

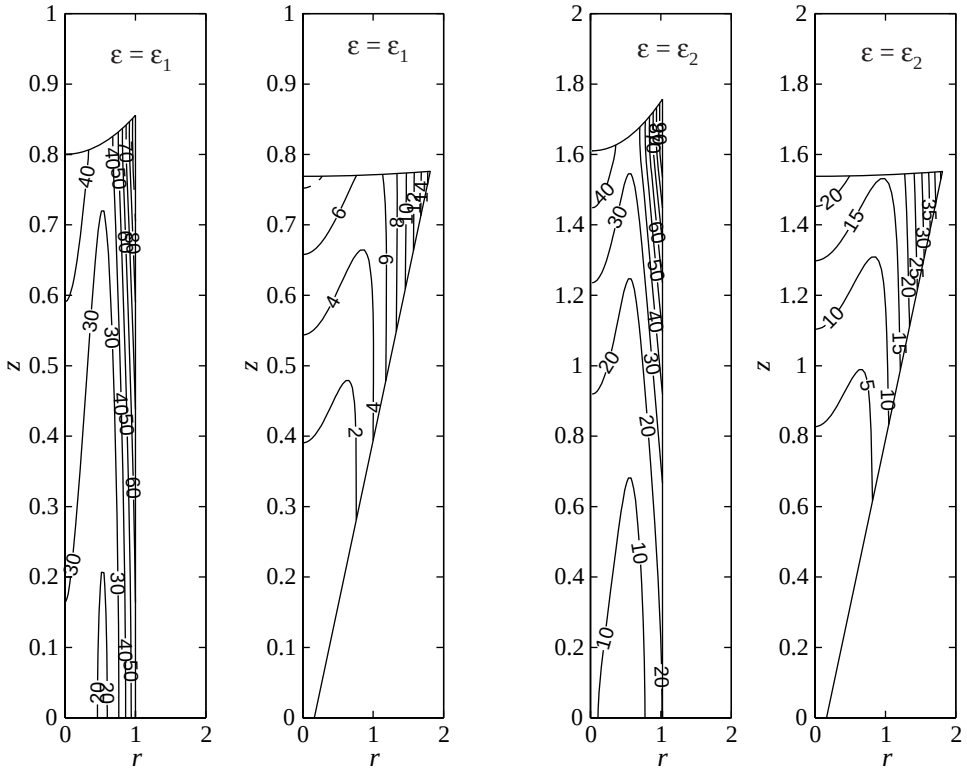

FIG. 11. *von Mises stress for the pseudosteady cylindrical and conical crystal cases. Isostress contours are labeled as a percent of the maximum stress (*0.176 *MPa for* ϵ_1 *and* 0.706 *MPa for* ϵ_2*).*

the angular coordinate. Figure 12 shows the stress pattern for a cylindrical crystal just inside the crystal-melt interface when the crystal is pulled in the directions [001], [111], $[10\bar{1}]$, and $[\bar{1}2\bar{1}]$ respectively. The temperature field corresponds to values of $h_{gs} = 4$, $\gamma = 0$, and $\delta = 0$ grown with the pseudosteady approximation. The $\langle 211 \rangle$ directions are preferred growth directions [23]. The other directions are for comparative purposes. Notice that the isostress contours are square for the [001] direction and hexagonal for the [111] direction, while the $[\bar{1}2\bar{1}]$ direction generates distorted rectangular isostress curves. If one assumes that the crystal will solidify in a manner consistent with minimizing the surface stress, then these curves should somewhat approximate the actual cross-sectional shape of the crystal as it is pulled from the melt. Clearly the crystal orientation can significantly reduce the stress. However, not all growth directions are amenable to crystal growth [23]. Because of these other issues, changes in the growth orientation are more effective at redistributing the stress within a particular cross-section than reducing the overall magnitude of stress. The issue of optimizing the growth conditions will be addressed in a subsequent paper.

6. Conclusion. In this study, we present a semianalytical approach for the temperature and thermal stress inside an InSb crystal. The purpose of the paper is twofold. By identifying the main physical features and using suitable mathematical models, we have gained useful insights into this complex manufacturing process. In particular, we have determined the dependence of the crystal stress on the evolving

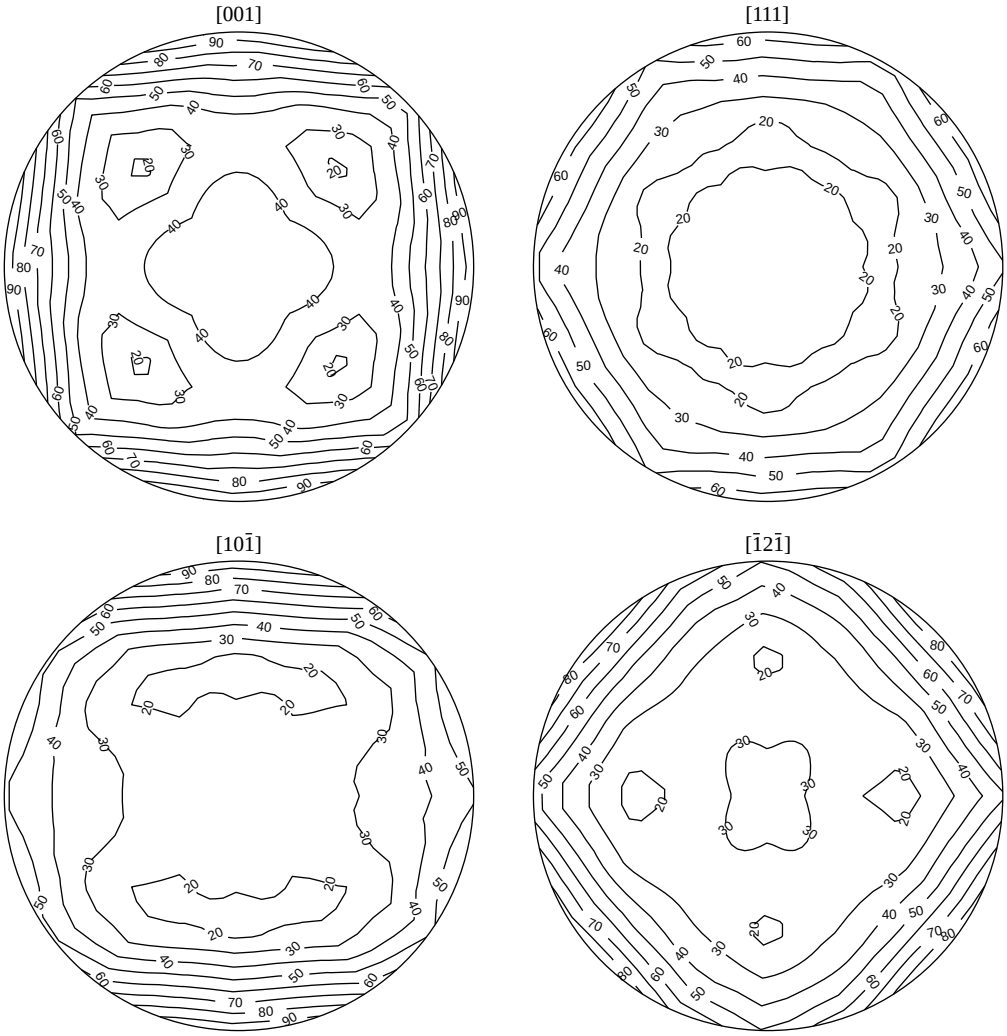

FIG. 12. *Total resolved stress distribution, computed using* (39)*, for a cylindrical crystal, at the indicated orientation, just inside the crystal-melt interface at the end of the growth. All reported stress values are expressed in percent with* 100% *occurring at the outer edge of a crystal grown in the* [001] *direction.*

crystal profile. By deriving semianalytical solutions, we have also provided a base that can be used to search for suitable growth conditions to improve the manufacturing procedure for all III-V compounds.

An important feature of our approach is that it allows us to derive explicit relationships between the thermal stress and relevant physical and geometrical parameters. This is achieved by using an asymptotic expansion of the solution in terms of the Biot number, characterizing the lateral heat flux. The asymptotic solution is obtained by solving essentially one-dimensional problems. The results show that the stress induced by radial temperature variation is related to the size (radius) and the profile (variation of the radius) of the crystal and heat flux through the side surface. On the other hand, the influence of the crystal radius on the stress induced by the

axial temperature variation is much weaker. The heat flux through the side surface is an important factor for reducing the overall thermal stress inside the crystal. The explicit nature of the thermal stress allows for a more efficient optimal control approach for finding better growth conditions, as shown in [15].

The other advantage of our semianalytical approach is that it can be extended to cases with more complicated models for the melt and gas flows. For example, the effect of the gas flow on the lateral heat flux between the crystal surface and the gas can be modeled by a nonconstant heat exchange coefficient h_{gs}. The motion of the melt can also be modeled by a similar approach, using a boundary layer argument [8, 9] or by solving the Navier–Stokes equations and temperature equation numerically. These will be the subject of a subsequent paper.

As pointed out earlier, we have assumed that the pulling rate can be adjusted to grow a crystal with a desirable shape. In practice, we may need to consider the dynamics and stability of the radial motion of the three-phase triple point. Models and computations have been carried out to capture the motion of the three-phase contact point [7, 32] and can be incorporated with the current model in a straightforward fashion. This work is currently underway.

Finally, we note that our study has its limitations and there is room for improvements and future investigations. For example, a nonuniform heat flux from the melt will introduce radial variation in the zeroth order temperature solution. As a result, the thermal stress will be determined not only by the axial gradient of the zeroth order solution but its radial variation as well. However, this radial variation is likely to be small, from our own observations and others, and an asymptotic solution can also be obtained, as indicated in [20]. Furthermore, we have not discussed the validity of the plane strain assumption. We believe that an asymptotic argument similar to that used for the temperature can be employed to derive the plane strain solution as part of the asymptotic series. We plan to address this issue also in a future study. Finally, the crystal grown in practice is not axisymmetric. It would be of practical interest to investigate the effect of anisotropy. Study is currently underway for a weakly anisotropic crystal.

Appendix: A simple model for the melt temperature. Starting with dimensional variables, we consider crystal growth in an axisymmetric setting where the rate of growth is small. We assume that the melt (liquid) in the crucible is well mixed and the temperature of the melt, $T_l(t)$, is uniform in space except in the thin layers near the crystal-melt and melt-ambient gas interfaces. We also assume that the ambient gas is well mixed and the temperature of the gas is a constant T_g. Furthermore, we will neglect the shape of the meniscus and assume that the crystal-melt and melt-gas interfaces are flat.[4] Therefore by adjusting the pulling speed v_p, the positions of the crystal-melt and melt-gas interfaces can be described by a single function $z = S(t)$.[5] Finally, we assume that the crystal radius $R(z)$ varies slowly in the z direction, $|R_z| \ll 1$. The coordinate system is fixed to the top of the growing crystal at $z = 0$, as described previously.

Figure 13 shows the three surfaces through which the melt can transfer heat

[4]For InSb crystals under consideration here, the typical length scale is $\overline{R} = 0.03$ m, the surface tension coefficient between the melt and gas is $\sigma_{gl} = 0.434$ N/m, and the melt density is $\rho_l = 6.47 \times 10^3$ kg/m^3. The Bond number is Bo $= \rho_l g \overline{R}^2/\sigma_{gl} \simeq 132 \gg 1$. Thus the meniscus is dominated by the gravity effect and the meniscus changes shape only near the three-phase contact point with a small capillary rise.

[5]The flat interface assumption allows one to drop the explicit r dependence of $S(t)$.

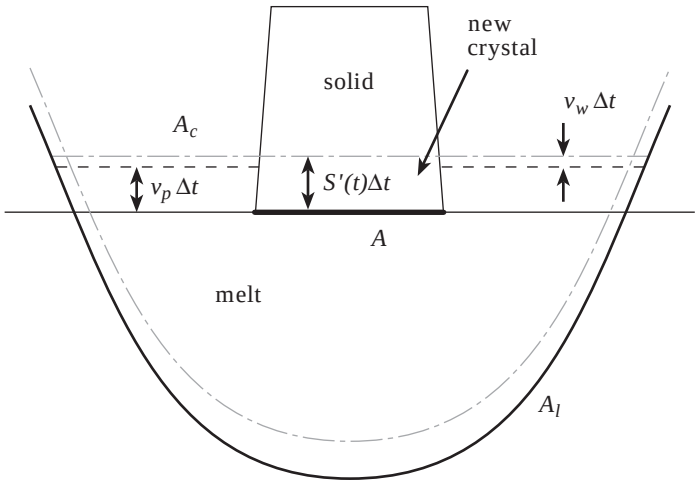

FIG. 13. *For a small time interval Δt the new crystal extends a distance $S'(t)\Delta t$ beyond the original interface location (dashed-dotted line). The corresponding drop in the melt is $v_m\Delta t$ (dashed line), and to realign the melt-gas interface and the crystal-melt the crystal must be extracted an additional distance of $v_p\Delta t$ (solid line).*

energy. These are denoted as $A = \pi R^2$, the area of the crystal-melt interface; $A_c = \pi R_c^2$, the cross-sectional area of the crucible ($A_c - A$ is the area of the melt-gas interface); and A_l, the surface area of the crucible in contact with the melt. Continuing to refer to the figure, conservation of mass implies that the rate at which the melt-gas interface drops due to the change in density upon solidification is

$$v_m(t) = \frac{\rho_s A}{\rho_l A_c} S'(t). \tag{40}$$

To ensure that the crystal-melt interface remains at the surface of the liquid the crucible is dropped at an optimal pull rate

$$v_p(t) = (S' - v_m)(t) = \frac{\rho_l A_c - \rho_s A}{\rho_l A_c} S'(t). \tag{41}$$

If the actual pull rate of the crystal exceeds v_p by a moderate amount, then the surface tension of the melt will cause the radius of the crystal to decrease. Similarly, pulling at a rate slower than v_p will cause the radius to increase.

Using these velocities, the position of the crystal-melt interface is $S = Z_0 + u_w + u_p$, where

$$u_w(t) = \int_0^t v_m(\tau)\, d\tau, \qquad u_p(t) = \int_0^t v_p(\tau)\, d\tau \tag{42}$$

are the displacements due to the loss of melt during the solidification and the growth of the crystal, respectively. The top of the crystal is fixed at $z = 0$.

During the growth period we assume that the heat flux from the melt to the crystal is given by

$$q_l = h_{sl}(T_l - T_m). \tag{43}$$

As a result the heat balance inside the melt yields

$$\frac{d}{dt}\left(\rho_l c_l T_l V_l\right) = -q_l A - h_{gl}(A_c - A)(T_l - T_g) + h_{cl} A_l (T_c - T_l), \tag{44}$$

where V_l is the time dependent volume of the melt, and T_c is the temperature of the crucible. The last term in (44) is the heat flux from the crucible to the liquid and is assumed to be a control parameter with T_c acting as the control.

For simulations in section 5.1.2 the crucible was assumed to be parabolic and filled to the extent that once the crystal reaches its final mass $\rho_s V_{\text{xtal}}$ and growth stops, there is a given proportion, p, of melt mass left in the crucible. As a result, $R_c(\xi) = \tilde{R}_c(\xi/\tilde{Z}_c)^{1/2}$, $0 \le \xi \le \tilde{Z}_c$, and the initial depth of the melt Z_{c0} is determined with the condition

$$\frac{\rho_s}{\rho_l} V_{\text{xtal}} = (1-p)\int_0^{Z_{c0}} \pi R_c^2(\xi)\, d\xi. \tag{45}$$

Since the shape of the crucible is known, A_l and V_l can be obtained as

$$A_l(t) = \int_0^{Z_{c0}-u_w(t)} 2\pi R_c(\xi)\sqrt{1+R_c'^2(\xi)}\, d\xi, \quad V_l(t) = \int_0^{Z_{c0}-u_w(t)} \pi R_c^2(\xi)\, d\xi \tag{46}$$

computed with respect to a local coordinate system fixed to the bottom of the crucible.

A nondimensionalized version of (44) is obtained by substituting the characteristic radius $\tilde{R}_c$ and depth $\tilde{Z}_c$ for the crucible so that

$$R_c = \tilde{R}_c \hat{R}_c, \qquad A = \overline{R}^2 \hat{A}, \qquad A_c = \tilde{R}_c^2 \hat{A}_c, \qquad A_l = \tilde{R}_c \tilde{Z}_c \hat{A}_l, \qquad V_l = \tilde{R}_c^2 \tilde{Z}_c \hat{V}_l.$$

Letting $T_l = T_g + \Delta T \Theta_l$ and $T_c = T_g + \Delta T \Theta_c$ and defining $\lambda = \overline{R}/\tilde{R}_c, \mu = \tilde{R}_c/\tilde{Z}_c, \phi = \rho_l c_l/\rho_s c_s$ one obtains

$$\frac{\phi}{\lambda\,\mathrm{St}}\frac{d}{d\hat{t}}\left[\left(\frac{T_g}{\Delta T}+\Theta_l\right)\hat{V}_l\right] = -\mu\lambda^2\hat{A}\frac{h_{sl}}{h_{gs}}(\Theta_l - 1) - \mu\frac{h_{gl}}{h_{gs}}(\hat{A}_c - \lambda^2\hat{A})\Theta_l + \frac{h_{cl}}{h_{gs}}\hat{A}_l(\Theta_c - \Theta_l) \tag{47a}$$

with $\Theta_l(0) = 1$ and a nondimensional heat flux given by

$$\gamma = \frac{q_{l,n}\overline{R}}{\epsilon^{1/2} k_s \Delta T} = \epsilon^{1/2}\frac{h_{sl}}{h_{gs}}(\Theta_l - 1). \tag{47b}$$

When commencing, the growth of the seed is slowly dropped until it contacts the melt surface and a meniscus is supported. Once the meniscus stabilizes and the seed reaches a thermal equilibrium with the melt and the crystal, the seed is extracted and the furnace temperature is slowly decreased [23]. Assuming a cylindrical seed of length Z_0 and radius R_0 and using expression (22) one finds an initial interface speed of

$$S_0'(0) = k\frac{k\sinh(kZ_0) + \delta\cosh(kZ_0) - \delta\Theta_{ch}}{k\cosh(kZ_0) + \delta\sinh(kZ_0)} \tag{47c}$$

with $k^2 = 2/R_0$. The initial crucible temperature is chosen so that $\Theta_l'(0) = 0$ and from (47a) one has

$$\Theta_c(0) = \left[1 + \mu\frac{h_{gl}}{h_{cl}}\left(\frac{\hat{A}_c - \lambda^2\hat{A}}{\hat{A}_l}\right) + \frac{\phi}{\lambda\,\mathrm{St}}\frac{h_{gs}}{h_{cl}}\frac{1}{\hat{A}_l}\frac{d\hat{V}_l}{d\hat{t}}\left(\frac{T_g}{\Delta T}+1\right)\right](0). \tag{47d}$$

To simulate the cooling of the furnace the crucible temperature was dropped at a constant rate of 0.2 K/hr for all simulations.

Nondimensional versions of the interface speeds (40)–(41), displacements (42), initial depth condition (45), and geometrical factors (46) are derived using the substitutions

$$Z_{c0} = \tilde{Z}_c \hat{Z}_{c0}, \qquad \epsilon^{1/2} u_p = \overline{R} \hat{u}_p, \qquad \epsilon^{1/2} u_w = \lambda^3 \tilde{R}_c \hat{u}_w.$$

DISCRETE-TIME SIS EPIDEMIC MODEL IN A SEASONAL ENVIRONMENT*

JOHN E. FRANKE† AND ABDUL-AZIZ YAKUBU‡

Abstract. We study the combined effects of seasonal trends and diseases on the extinction and persistence of discretely reproducing populations. We introduce the epidemic threshold parameter, $\mathcal{R}_0$, for predicting disease dynamics in periodic environments. Typically, in periodic environments, $\mathcal{R}_0 > 1$ implies disease persistence on a cyclic attractor, while $\mathcal{R}_0 < 1$ implies disease extinction. We also explore the relationship between the demographic equation and the epidemic process. In particular, we show that in periodic environments, it is possible for the infective population to be on a chaotic attractor while the demographic dynamics is nonchaotic.

Key words. epidemics, infectives, periodic environments, susceptibles

1. Introduction.

The complexities of a periodic environment can significantly affect the regulation of species [26]. In periodic environments, population sizes are often either enhanced via *resonance* or diminished via *attenuance* [5, 10, 11, 13, 14, 15, 16, 17, 18, 19, 20, 23, 24, 25, 30, 31, 32, 33, 34, 35, 37, 38, 45, 48, 50]. However, most epidemic models in the literature (with a few exceptions) neglect seasonal factors [3, 4, 12]. For example, Allen and Burgin [1], Allen [2], and Castillo-Chavez and Yakubu [7, 8, 9] studied disease invasions in discretely reproducing populations that live on attractors in constant (nonperiodic) environments. Cushing and Henson [14], Elaydi and Sacker [17, 18, 19, 20], Franke and Yakubu [23, 24], Kocic [35], Kocic and Ladas [36], Kon [37, 38], and others have studied the effects of periodic environments on ecological models without explicit disease dynamics [46].

In this paper, we focus on the impact of seasonal factors on a discrete-time SIS (susceptible-infected-susceptible) epidemic model. The model reduces to the SIS epidemic model of Castillo-Chavez and Yakubu when the environment is constant (nonperiodic) [7, 8, 9]. To understand the impact of seasonality and disease on life-history outcomes, we study the long-term dynamics of our model under specific functional forms for the periodic recruitment function. The periodic Beverton–Holt [6], the periodic constant, and the periodic Malthus (geometric growth) models are the periodic recruitment functions for this study [7, 8, 9].

We assume that a disease invades and subdivides the target population into two classes: susceptibles (noninfectives) and infectives. Prior to the time of disease invasion, the population is assumed to be governed by a periodically forced demographic equation with a periodic recruitment function. Hence, the population is assumed to be either at a demographic "steady state" (an attracting cycle) or growing at a periodic

geometric rate. The transition from susceptible to infective is a function of the contact rate α (between individuals) and the proportion of infectives (prevalence) in the population. We derive the epidemic threshold parameter, $\mathcal{R}_0$, for predicting disease persistence or extinction in periodic environments. We also explore the relationship between the demographic equation and the epidemic process. Castillo-Chavez and Yakubu, in [7, 8, 9], show that in constant environments the demographic equation drives the disease dynamics. In stark contrast, we use numerical simulations to show that in periodic environments the demographic equation does not always drive the disease dynamics. We show that, in periodic environments, it is possible for the infective population to be on a chaotic attractor while the demographic dynamics is nonchaotic.

The paper is organized as follows. In section 2, we introduce the periodically forced demographic equation for the study. The equation, a nonautonomous nonlinear difference equation with periodic recruitment function, describes the dynamics of the (total) population before disease invasion. We review, in section 2, the results of Franke and Yakubu on periodically forced recruitment functions. The main model, a periodically forced discrete-time SIS epidemic model, is constructed in section 3. When the recruitment function is either a periodic constant or the periodic Beverton–Holt model, then the total population is persistent and lives on a globally attracting cycle. Autonomous discrete-time models do not support (nontrivial) globally stable cycles [21]. In section 4, the basic reproductive number $\mathcal{R}_0$ is introduced and used to predict the (uniform) persistence or extinction of the infective population, where the recruitment function is either a periodic constant or the periodic Beverton–Holt model. Section 5 covers the SIS epidemic model under asymptotically cyclic demographic dynamics, while sections 6 and 7 describe the epidemic model under geometric demographic dynamics. As in section 4, in section 6, $\mathcal{R}_0$ is used to predict the (uniform) persistence or extinction of the proportion of infectives in the total population. Conditions for disease persistence on cyclic attractors are introduced in section 7.

Periodically forced population models support multiple attractors, and we use numerical simulations to show, in section 8, that our periodic epidemic model supports multiple attractors. Section 9 is on period-doubling bifurcations in the epidemic model where the demographic dynamics is simple and nonchaotic. The implications of our results are discussed in section 10.

2. Demographic equations with seasonality. In constant environments, theoretical discrete-time epidemic models are usually formulated under the assumption that the dynamics of the total population size in generation t, denoted by $N(t)$, is governed by equations of the form

$$N(t+1) = f(N(t)) + \gamma N(t), \tag{1}$$

where $\gamma \in (0,1)$ is the constant "probability" of surviving per generation and $f : \mathbb{R}_+ \to \mathbb{R}_+$ models the birth or recruitment process [7, 9].

Seasonality can be introduced into (1) by writing the recruitment function as a p-periodically forced function. This is modeled with the *p-periodic demographic equation*

$$N(t+1) = f(t, N(t)) + \gamma N(t), \tag{2}$$

where $\exists\ p \in \mathbb{N}$ such that

$$f(t, N(t)) = f(t+p, N(t)) \quad \forall t \in \mathbb{Z}_+.$$

We assume throughout that $f(t,N) \in C^2(\mathbb{Z}_+ \times \mathbb{R}_+, \mathbb{R}_+)$ and $\gamma \in (0,1)$ [25].

Franke and Yakubu, in [25], studied model (2) with the periodic constant recruitment function

$$f(t,N(t)) = k_t(1-\gamma)$$

and with the periodic Beverton–Holt recruitment function

$$f(t,N(t)) = \frac{(1-\gamma)\mu k_t N(t)}{(1-\gamma)k_t + (\mu - 1 + \gamma)N(t)},$$

where the carrying capacity k_t is *p-periodic*, $k_{t+p} = k_t$ for all $t \in \mathbb{Z}_+$ [14, 25]. Franke and Yakubu proved that the periodically forced recruitment functions generate globally attracting cycles in model (2) [25]. We summarize their results in the following two theorems.

THEOREM 1. *Model* (2) *with* $f(t,N(t)) = k_t(1-\gamma)$ *has a globally attracting positive s-periodic cycle that starts at*

$$\overline{x}_0 = \frac{(1-\gamma)\left(k_{p-1} + k_{p-2}\gamma + \cdots + k_0\gamma^{p-1}\right)}{1-\gamma^p},$$

where s divides p.

THEOREM 2. *Model* (2) *with* $f(t,N(t)) = \frac{(1-\gamma)\mu k_t N(t)}{(1-\gamma)k_t + (\mu-1+\gamma)N(t)}$ *and* $\mu > 1$ *has a globally attracting positive s-cycle, where s divides p.*

Theorems 1 and 2 imply that the total population is asymptotically periodic (bounded) and lives on a cyclic attractor when the recruitment function is either a periodic constant or the Beverton–Holt model. Denote this cycle by $\{\overline{N}_0, \overline{N}_1, \ldots, \overline{N}_{s-1}\}$. When new recruits arrive at the periodic positive per-capita growth rate λ_t, then

$$f(t,N(t)) = \lambda_t N(t),$$

where $\lambda_{t+p} = \lambda_t$ for all $t \in \mathbb{Z}_+$. The solution to the demographic equation is

$$N(t) = \left(\prod_{J=0}^{t-1} (\lambda_J + \gamma)\right) N(0),$$

and the demographic basic reproductive number is

$$\mathcal{R}_d = \frac{\prod_{J=0}^{p-1} (\lambda_J + \gamma) - \gamma^p}{1-\gamma^p}. \tag{3}$$

$\mathcal{R}_d$ gives the average number of descendants produced by a typically small initial population over a *p-cycle*. If $\mathcal{R}_d < 1$, the total population goes extinct at a geometric rate, and if $\mathcal{R}_d > 1$, the total population explodes at a geometric rate. In constant environments, $p = 1$, $\lambda_J = \lambda$, and $\mathcal{R}_d$ reduces to

$$\mathcal{R}_d = \frac{\lambda}{1-\gamma}.$$

In [7, 8, 9], Castillo-Chavez and Yakubu used $\mathcal{R}_d = \frac{\lambda}{1-\gamma}$ to study the long-term behavior of geometrically growing populations in constant environments.

3. SIS epidemic model in periodic environments. In this section, we introduce the main model, an SIS epidemic model with periodic forcing. To do this, we assume that a nonfatal infectious disease has invaded a population living in a seasonal environment. The population is governed by (2). To model the disease, we build a simple SIS epidemic process on "top" of the periodic demographic equation. We let $S(t)$ denote the population of susceptibles; $I(t)$ denotes the population of the infected, assumed infectious; $N(t) \equiv S(t) + I(t)$ denotes the total population size at generation t, N_∞ denotes the demographic steady state or attracting population, and $\overline{N}_0$ the initial point on a globally attracting cycle, when they exist. We assume that individuals survive with constant probability γ each generation, and infected individuals recover with constant probability $(1-\sigma)$.

Let $\phi : [0,\infty) \to [0,1]$ be a monotone concave probability function with $\phi(0) = 1$, $\phi'(x) < 0$, and $\phi''(x) \geq 0$ for all $x \in [0,\infty)$. We assume that the susceptible individuals become infected with nonlinear probability $\left(1 - \phi\left(\alpha \frac{I}{N}\right)\right)$ per generation, where the transmission constant $\alpha > 0$. When infections are modeled as Poisson processes, then $\phi\left(\alpha \frac{I}{N}\right) = e^{-\alpha \frac{I}{N}}$ [7, 8, 9].

Our assumptions and notation lead to the following SIS epidemic model in period p environments:

$$\left.\begin{aligned} S(t+1) &= f(t, N(t)) + \gamma\phi\left(\alpha \tfrac{I(t)}{N(t)}\right) S(t) + \gamma(1-\sigma) I(t), \\ I(t+1) &= \gamma\left(1 - \phi\left(\alpha \tfrac{I(t)}{N(t)}\right)\right) S(t) + \gamma\sigma I(t), \end{aligned}\right\} \tag{4}$$

where $0 < \gamma, \sigma < 1$ and $N(t) > 0$. When the environment is constant, $f(t, N(t)) = f(N(t))$ and model (4) reduces to the model of Castillo-Chavez and Yakubu [7, 8, 9]. The total population in generation $t+1$, $S(t+1) + I(t+1)$, the sum of the two equations of model (4), is the demographic equation (2). Using the substitution $S(t) = N(t) - I(t)$, the I-equation in model (4) becomes

$$I(t+1) = \gamma\left(1 - \phi\left(\alpha \frac{I(t)}{N(t)}\right)\right)(N(t) - I(t)) + \gamma\sigma I(t).$$

Let

$$F_N(I) = \gamma\left(1 - \phi\left(\alpha \frac{I}{N}\right)\right)(N - I) + \gamma\sigma I.$$

When F_N has a unique positive fixed point and critical point, we denote them by I_N and C_N, respectively.

$$I(t+1) = F_{N(t)}(I(t)),$$

and the set of iterates of the nonautonomous map $F_{N(t)}$ is the set of density sequences generated by the infective equation. In the next section, we use the map F_N to study disease dynamics in the periodic SIS epidemic model, model (4).

4. Disease extinction versus disease persistence. The classical theory of disease epidemics usually involves computation of an epidemic threshold parameter, the basic reproductive number $\mathcal{R}_0$ [3]. Here, we introduce $\mathcal{R}_0$ and use it to predict the successful invasion or extinction of the disease modeled in (4). In constant environments $f(t, N(t)) = f(N(t))$, and

$$\mathcal{R}_0 = \frac{-\gamma\alpha\phi'(0)}{1 - \gamma\sigma}. \tag{5}$$

$\mathcal{R}_0$ is the average number of secondary infections generated by an initial population of infected (assumed infectious) individuals over their lifetimes [7, 8, 9].

In our periodic model, we use the same $\mathcal{R}_0$ to prove that $\mathcal{R}_0 < 1$ implies disease extinction and $\mathcal{R}_0 > 1$ implies disease persistence. To prove this result we need the following definition [49].

DEFINITION 3. *The total population in model* (2) *is persistent if*

$$\lim_{t\to\infty} \inf N(t) > 0$$

whenever $N(0) > 0$. *The total population is uniformly persistent if there exists a positive constant* η *such that*

$$\lim_{t\to\infty} \inf N(t) \geq \eta$$

whenever $N(0) > 0$.

By this definition, when the recruitment function is either a periodic constant or the Beverton–Holt model, the total population is uniformly persistent. Also, when new recruits arrive at the periodic positive per-capita growth rate λ_t and $\mathcal{R}_d > 1$, the total population is uniformly persistent. However, the population goes extinct when $\mathcal{R}_d < 1$.

The following auxiliary lemmas will be used to prove our results.

LEMMA 4. *If* $0 < I(t) \leq N(t)$ *in model* (4), *then* $I(t+1) < \min\{N(t), N(t+1)\}$.

Proof. In model (4),

$$I(t+1) = \gamma\left(1 - \phi\left(\alpha\frac{I(t)}{N(t)}\right)\right)S(t) + \gamma\sigma I(t)$$

and

$$N(t+1) = S(t+1) + I(t+1) = f(t, N(t)) + \gamma N(t).$$

Therefore,

$$\begin{aligned} I(t+1) &= \gamma\left(1 - \phi\left(\alpha\frac{I(t)}{N(t)}\right)\right)(N(t) - I(t)) + \gamma\sigma I(t) \\ &< \gamma(N(t) - I(t)) + \gamma I(t) = \gamma N(t) \\ &= N(t+1) - f(t, N(t)) \leq N(t+1). \end{aligned}$$

Hence,

$$I(t+1) < \min\{N(t), N(t+1)\}. \qquad \square$$

LEMMA 5. *If* $I(0) > 0$ *in model* (4), *then* $I(t) > 0$ *for all* $t \in \mathbb{Z}_+$.

Proof. $I(t+1) = \gamma\left(1 - \phi\left(\alpha\frac{I(t)}{N(t)}\right)\right)(N(t) - I(t)) + \gamma\sigma I(t)$. By Lemma 4, $N(t) - I(t) \geq 0$ for all $t \in \mathbb{Z}_+$. Therefore, $\gamma\left(1 - \phi\left(\alpha\frac{I(t)}{N(t)}\right)\right)(N(t) - I(t)) \geq 0$. $I(0) > 0$ implies $\gamma\sigma I(0) > 0$, and hence $I(1) > 0$. By induction, $I(t) > 0$ and $\gamma\sigma I(t) > 0$. Hence, $I(t+1) > 0$. $\square$

LEMMA 6.

$$F_N(I) = \gamma\left(1 - \phi\left(\alpha\frac{I}{N}\right)\right)(N - I) + \gamma\sigma I$$

satisfies the following conditions:

(a) $F_N'(0) = -\alpha\gamma\phi'(0) + \gamma\sigma$ *and* $F_N'(N) > -1$.
(b) $F_N(I)$ *is concave down on* $[0, N]$.
(c) $F_N(I) \le F_N'(0)I$ *on* $[0, N]$.
(d) *If* $F_N'(0) > 1$, *then* F_N *has a unique positive fixed point* I_N *in* $[0, N]$.
(e) *Let* $\Psi_N(I) = \frac{I}{N}$. *Then* $F_1(\Psi_N(I)) = \Psi_N(F_N(I))$. *That is,* Ψ_N *is a topological conjugacy between* F_1 *and* F_N.
(f) *If* $N_0 < N_1$ *and* $(-\alpha\gamma\phi'(0) + \gamma\sigma) > 1$, *then* $I_{N_0} < I_{N_1}$ *where* I_{N_i} *is the positive fixed point of* F_{N_i} *in* $[0, N_i]$.
(g) *If* C_1 *exists, then* $C_N = NC_1$.
(h) *If* $N_0 < N_1$, *then* $F_{N_0}(I) < F_{N_1}(I)$ *for all* $I \in (0, N_0]$.

Proof. (a)

$$F_N'(I) = -\frac{\alpha\gamma}{N}\phi'\left(\alpha\frac{I}{N}\right)(N - I) - \gamma\left(1 - \phi\left(\alpha\frac{I}{N}\right)\right) + \gamma\sigma,$$

$$\begin{aligned} F_N'(0) &= -\frac{\alpha\gamma}{N}\phi'(0)(N - 0) - \gamma(1 - \phi(0)) + \gamma\sigma \\ &= -\alpha\gamma\phi'(0) + \gamma\sigma, \end{aligned}$$

$$\begin{aligned} F_N'(N) &= -\frac{\alpha\gamma}{N}\phi'\left(\alpha\frac{N}{N}\right)(N - N) - \gamma\left(1 - \phi\left(\alpha\frac{N}{N}\right)\right) + \gamma\sigma \\ &= -\gamma(1 - \phi(\alpha)) + \gamma\sigma > -\gamma > -1. \end{aligned}$$

(b)

$$F_N''(I) = -\left(\frac{\alpha}{N}\right)^2\gamma\phi''\left(\alpha\frac{I}{N}\right)(N - I) + 2\frac{\alpha\gamma}{N}\phi'\left(\alpha\frac{I}{N}\right).$$

Since $\phi' < 0$ and $\phi'' \ge 0$ on $[0, \infty)$, we have

$$F_N''(I) < 0 \quad \text{on } [0, N].$$

(c) $F_N(0) = 0$ implies that $y = F_N'(0)I$ is the tangent line to the graph of $F_N(I)$ at 0. Since F_N is concave down on $[0, N]$, its graph is below the tangent line at the origin on $[0, N]$. Hence,

$$F_N(I) \le F_N'(0)I \quad \text{on } [0, N].$$

(d) $F_N(N) = \gamma\sigma N < N$. Since $F_N'(0) > 1$, the graph of $F_N(I)$ starts out higher than the diagonal and must cross it before $I = N$. The concavity property of $F_N(I)$ (see (b)) implies that there is a unique positive fixed point.

(e) $F_1(I) = \gamma(1 - \phi(\alpha I))(1 - I) + \gamma\sigma I$. Thus,

$$F_1(\Psi_N(I)) = \gamma\left(1 - \phi\left(\alpha\frac{I}{N}\right)\right)\left(1 - \frac{I}{N}\right) + \gamma\sigma\frac{I}{N} = \frac{1}{N}F_N(I) = \Psi_N(F_N(I)).$$

(f) Since $F_{N_0}'(0) = (-\alpha\gamma\phi'(0) + \gamma\sigma) > 1$, I_{N_0} exists with $F_{N_0}(I_{N_0}) = I_{N_0}$. Thus $\Psi_{N_0}(F_{N_0}(I_{N_0})) = \Psi_{N_0}(I_{N_0}) = F_1(\Psi_{N_0}(I_{N_0}))$. That is $\Psi_{N_0}(I_{N_0}) = I_1$, the unique positive fixed point of F_1, and $I_{N_0} = N_0 I_1$. Similarly, $I_{N_1} = N_1 I_1$. Hence, $N_0 < N_1$ implies $I_{N_0} < I_{N_1}$.

(g) Topological conjugacy preserves critical points. The result follows from (e).

(h) Let $N_0 < N_1$ and $I \in (0, N_0]$. The topological conjugacy in part (e) shows that $F_{N_0}(I) = N_0 F_1(\frac{I}{N_0})$ and $F_{N_1}(I) = N_1 F_1(\frac{I}{N_1})$. Note that $\frac{I}{N_1} < \frac{I}{N_0}$. Since the graph of F_1 goes through the origin with positive slope and is concave down, the ray through the origin and $\big(\frac{I}{N_1}, F_1(\frac{I}{N_1})\big)$ has a larger slope than the ray through the origin and $\big(\frac{I}{N_0}, F_1(\frac{I}{N_0})\big)$. The first ray contains the point $\big(I, N_1 F_1(\frac{I}{N_1})\big)$, while the second ray contains $\big(I, N_0 F_1(\frac{I}{N_0})\big)$. Hence, $F_{N_1}(I) = N_1 F_1(\frac{I}{N_1}) < N_0 F_1(\frac{I}{N_0}) = F_{N_0}(I)$. □

THEOREM 7. *Let the total population in model* (2) *be uniformly persistent.*

(a) *If* $\mathcal{R}_0 < 1$, *then in model* (4), $\lim_{t\to\infty} I(t) = 0$ *whenever* $I(0) \le N(0)$. *That is, the disease goes extinct.*

(b) *If* $\mathcal{R}_0 > 1$, *then in model* (4), $\exists\ \eta > 0$ *such that* $\lim_{t\to\infty} \inf I(t) \ge \eta$ *whenever* $N(0) \ge I(0) > 0$. *That is, the disease persists uniformly.*

Proof. Since $I(0) \le N(0)$, Lemma 4 implies that $I(t) \le N(t)$ for all $t \in \mathbb{Z}_+$.

(a) $\mathcal{R}_0 = \frac{-\gamma\alpha\phi'(0)}{1-\gamma\sigma} < 1$ is equivalent to $-\alpha\gamma\phi'(0) + \gamma\sigma < 1$. Lemma 6 gives $F'_N(0) = F'_{N(t)}(0) = -\alpha\gamma\phi'(0) + \gamma\sigma < 1$ and $I(t+1) = F_{N(t)}(I(t)) \le F'_{N(t)}(0) I(t)$. Thus, the sequence $\{I(t)\}$ is dominated by the geometrically decreasing sequence $\{(-\alpha\gamma\phi'(0) + \gamma\sigma)^t I(0)\}$, and hence

$$\lim_{t\to\infty} I(t) = 0.$$

(b) Lemma 5 implies that $I(t) > 0$ for all $t \in \mathbb{Z}_+$. Lemma 6 gives $F'_N(0) = F'_{N(t)}(0) = -\alpha\gamma\phi'(0) + \gamma\sigma > 1$. Since $I(t+1) = F_{N(t)}(I(t))$, $I(t+1) > I(t)$ on the open interval $\big(0, I_{N(t)}\big)$. If $I(t) \in (I_{N(t)}, N(t))$, $I(t+1) \ge \min\{I_{N(t)} = N(t)I_1, F_{N(t)}(N(t)) = \gamma\sigma N(t)\}$. Since the total population is uniformly persistent, $\exists\ \widehat{\eta} > 0$ satisfying $\lim_{t\to\infty} \inf N(t) \ge \widehat{\eta}$ whenever $N(0) > 0$. This implies that $\exists\ \eta > 0$ such that

$$\lim_{t\to\infty} \inf\left(\min\{N(t)I_1, \gamma\sigma N(t)\}\right) \ge \eta > 0.$$

Thus, the orbit $\{I(t)\}$ increases when it is small and eventually gets larger and remains larger than a fixed positive number. Hence, $\exists\ \eta > 0$ satisfying

$$\lim_{t\to\infty} \inf I(t) \ge \eta. \qquad \square$$

A slight modification of the proof of Theorem 7 reveals that uniform persistence can be replaced with persistence in the hypothesis and conclusion. That is, if the total population persists, then the disease persists whenever $\mathcal{R}_0 > 1$.

When the recruitment function is either a periodic constant or the periodic Beverton–Holt model, then the (total) population is uniformly persistent. If, in addition, $\mathcal{R}_0 < 1$, then in model (4), $\lim_{t\to\infty} I(t) = 0$, and the disease goes extinct. However, if $\mathcal{R}_0 > 1$, then in model (4), $\lim_{t\to\infty} \inf I(t) \ge \eta > 0$, and the disease persists uniformly (Theorem 7).

In constant environments, when the total population lives on a globally attracting positive fixed point, $\mathcal{R}_0 > 1$ implies uniform persistence of the infectives on a globally attracting positive fixed point [7, 8, 9]. With the advent of periodicity, when the total population lives on an attracting cycle, $\mathcal{R}_0 > 1$ implies uniform persistence of the infectives on a globally attracting cycle (section 5), multiple cyclic attractors (section 8), or a chaotic attractor (section 9). We summarize these results in the following corollary.

COROLLARY 8. *If the demographic equation, model* (2)*, has a globally attracting p-cycle* ($p > 1$) *and* $\mathcal{R}_0 > 1$*, then the uniform persistent infective population in model* (4) *is not on a fixed point attractor.*

Proof. By Theorem 7, the infective population in model (4) is uniformly persistent when $\mathcal{R}_0 > 1$. To establish this result, we use a contradiction proof to show that the infective population in model (4) has no positive fixed point when the demographic equation, model (2), has a globally attracting p-cycle ($p > 1$).

Assume that $(N(0), I(0))$ is an initial condition where $\{I(t)\}$ is constantly fixed at $I(0) > 0$. Now $I(t+1) = F_{N(t)}(I(t)) = I(0)$. Lemma 6 gives the fixed point of $F_{N(t)} = N(t)I_1 = I(0)$. Hence, $\{N(t)\}$ is constantly fixed at $N(0)$. Since all initial total populations are attracted to a nontrivial cycle, we have a contraction. Hence, the uniformly persistent infective population in model (4) is not on a fixed point attractor. □

5. Asymptotically cyclic epidemics. We now study the long-term disease dynamics for a population living in a seasonal environment, where the p-periodic demographic equation has a globally attracting positive cycle $\{\overline{N}_0, \overline{N}_1, \ldots, \overline{N}_{p-1}\}$. For example, when the recruitment function is either periodically constant or periodic Beverton–Holt, the demographic equation is asymptotically cyclic (Theorems 1 and 2). If in addition $\mathcal{R}_0 > 1$, we show that it is possible for the uniformly persistent epidemic to live on a globally attracting cycle. That is, the demographic dynamics drives the disease dynamics. To predict this long-term dynamics of the epidemic process, we use the very general "limiting systems" theory of Franke and Yakubu [23].

The general theory of Franke and Yakubu uses the following periodic hierarchical system:

$$\left.\begin{array}{rcll} x(t+1) & = & g(t,x(t)), & x(0) = x \in R_+^n, \\ y(t+1) & = & h(t,x(t),y(t)), & (x(0),y(0)) = (x,y) \in V \subseteq R_+^{n+m}, \end{array}\right\} \tag{6}$$

where $g : Z_+ \times R_+^n \to R_+^n$ and $h : Z_+ \times V \to R_+^m$ are smooth functions and where there exist smallest positive integers T_1 and T_2 satisfying $g(t+T_1, x(t)) = g(t, x(t))$ and $h(t+T_2, x(t), y(t)) = h(t, x(t), y(t))$, respectively.

Let

$$V = \{(N, I) : I \leq N\}.$$

Then V is a connected set, and for each $N \in \mathbb{R}_+$

$$\{I \in \mathbb{R}_+ : (N, I) \in V\}$$

is a connected set. Lemma 4 shows that the (N, I) system,

$$\left.\begin{array}{l} N(t+1) = f(t, N(t)) + \gamma N(t), \\ I(t+1) = \gamma \left(1 - \phi\left(\alpha \frac{I(t)}{N(t)}\right)\right)(N(t) - I(t)) + \gamma\sigma I(t), \end{array}\right\} \tag{7}$$

is an example of model (6).

System (6) is the sequence of maps $\{G_i\}$, where for each $i \in \mathbb{Z}_+$, $G_i : V \to V$ is defined by

$$G_i(x, y) = (g(i \bmod(T_1), x), h(i \bmod(T_2), x, y)) \equiv (g_i(x), h_i(x, y)).$$

G_i has period $T = \operatorname{lcm}(T_1, T_2)$.

To define a limiting system for system (6), we assume that $\{x_0, x_1, \dots, x_{k-1}\}$ is a *k-cycle* for the T_1*-periodic* dynamical system $\{g_0, g_1, \dots, g_{T_1-1}\}$. For each $i \in \mathbb{Z}_+$, define the sets $V_i = \{y \in \mathbb{R}_+^m : (x_{i \bmod(k)}, y) \in V\}$. Also, define the periodically forced (nonautonomous) maps

$$\widehat{G}_i : \mathbb{R}_+^n \times V_i \to \mathbb{R}_+^n \times V_{i+1} \quad \text{by} \quad \widehat{G}_i(x,y) = (g_i(x), h_i(x_{i \bmod(k)}, y)),$$

and

$$\widehat{H}_i : V_i \to V_{i+1} \quad \text{by} \quad \widehat{H}_i(y) = h_i(x_{i \bmod(k)}, y).$$

Note that

$$\widehat{H}_{kT_2-1} \circ \cdots \circ \widehat{H}_1 \circ \widehat{H}_o : V_0 \to V_0.$$

The periodic system $\{\widehat{G}_0, \widehat{G}_1, \dots, \widehat{G}_{q-1}, \dots\}$ is a limiting system of model (6) when the *k-cycle* is attracting.

Inserting cycle $\{\overline{N}_0, \overline{N}_1, \dots, \overline{N}_{p-1}\}$ into model (7) produces the limiting system

$$\left.\begin{aligned} N(t+1) &= f(t, N(t)) + \gamma N(t), \\ I(t+1) &= \gamma \left(1 - \phi\left(\alpha \tfrac{I(t)}{\overline{N}_t}\right)\right)(\overline{N}_t - I(t)) + \gamma\sigma I(t). \end{aligned}\right\} \tag{8}$$

The second equation of system (8) is $F_{\overline{N}_t}(I(t))$.

The following straightforward generalization of a theorem of Franke and Yakubu gives conditions under which the long-term qualitative dynamics of the nonautonomous system (6) is equivalent to that of the limiting system.

THEOREM 9 (see [23]). *Assume that all orbits of system* (6) *are bounded, V is a connected set, and for each* $x \in \mathbb{R}_+^n$

$$\{y \in \mathbb{R}_+^m : (x,y) \in V\}$$

is a connected set. Then system (6) *has*

$$\{(x_0, y_0), (x_1, y_1), \dots, (x_{l-1}, y_{l-1}), \dots\}$$

as a globally attracting cycle if and only if

$$\{x_0, x_1, \dots, x_{k-1}, \dots\}$$

is a globally attracting k-cycle of the T_1-periodic *dynamical system* $\{g_0, g_1, \dots, g_{T_1-1}\}$ *and* y_0 *is a globally attracting fixed point of the composition* $\widehat{H}_{kT_2-1} \circ \cdots \circ \widehat{H}_1 \circ \widehat{H}_o$.

To apply Theorem 9, we need the following result.

COROLLARY 10. *Assume that all orbits of system* (7) *are bounded. Then system* (7) *has*

$$\{(\overline{N}_0, \overline{I}_0), (\overline{N}_1, \overline{I}_1), \dots, (\overline{N}_{p-1}, \overline{I}_{p-1}), \dots\}$$

as a globally attracting cycle if and only if $\{\overline{N}_0, \overline{N}_1, \dots, \overline{N}_{p-1}, \dots\}$ *is a globally attracting cycle for the p-*periodic *dynamical system* $\{g_0, g_1, \dots, g_{p-1}\}$, *where*

$$g_i(N) = f(i, N) + \gamma N,$$

and $\overline{I}_0$ *is a globally attracting fixed point of the composition* $\widehat{H}_{p-1} \circ \cdots \circ \widehat{H}_1 \circ \widehat{H}_o$, *where*

$$\widehat{H}_i(I) = F_{\overline{N}_i}(I) = \gamma \left(1 - \phi\left(\alpha \frac{I}{\overline{N}_i}\right)\right)\left(\overline{N}_i - I\right) + \gamma\sigma I.$$

Now we derive conditions for disease persistence on a globally attracting cycle in periodic environments. In the following result, we prove that the disease lives on a globally attracting cycle when F_1 is a monotone map with no critical points.

THEOREM 11. *If* F_1 *has no critical points in* $[0,1]$ *and* $\mathcal{R}_0 > 1$, *then the composition map*

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point $\overline{I}_0$, *and the uniformly persistent epidemic lives on a globally attracting cycle.*

Proof. By Lemma 6, each $F_{\overline{N}_i}$ is increasing, concave down, and has no critical point on $[0, \overline{N}_i]$. $\mathcal{R}_0 > 1$ is equivalent to $F'_{\overline{N}_i}(0) > 1$. $F_{\overline{N}_i}(0) = 0$ and $F_{\overline{N}_i}(\overline{N}_i) = \gamma\sigma\overline{N}_i < \overline{N}_i$. Thus, each positive initial condition converges under $F_{\overline{N}_i}$ iterations monotonically to the positive fixed point. That is, $F_{\overline{N}_i}$ has a globally attracting positive fixed point on $[0, \overline{N}_i]$.

By Lemma 4,

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0} : [0, \overline{N}_0] \to [0, \overline{N}_0).$$

Using the chain rule on the composition map $F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$ shows that it is increasing, concave down, and has derivative at the origin larger than 1. So, as in the previous paragraph, $F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$ has a unique globally attracting positive fixed point, $\overline{I}_0$. By Corollary 10, the uniformly persistent epidemic lives on a globally attracting cycle. □

To give a specific example of disease persistence on a globally attracting cycle as predicted by Theorem 11, we assume that infections are modeled as Poisson processes [7, 8, 9]. Then $\phi\left(\alpha \frac{I}{N}\right) = e^{-\alpha \frac{I}{N}}$ and

$$F_{\overline{N}_i}(I) = \gamma \left(1 - e^{-\alpha \frac{I}{\overline{N}_i}}\right)\left(\overline{N}_i - I\right) + \gamma\sigma I. \tag{9}$$

EXAMPLE 12. *In* (9), *set the following parameter values:*

$$\alpha = 2, \quad \gamma = 0.9, \quad \sigma = .9.$$

From the graph of F_1 (see Figure 1) it is clear that F_1 has no critical points in $[0,1]$ and $\mathcal{R}_0 > 1$.

Hence, with these parameters, the composition map

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point, $\overline{I}_0$, and the uniformly persistent epidemic lives on a globally attracting cycle (Theorem 11). Numerical experiments show that this result is also true when $\alpha \in [1, 2.1]$, $\gamma = [0.88, 1)$, and $\sigma = [0.88, 1)$; as well as on other intervals.

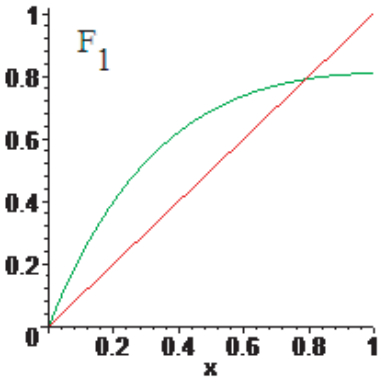

FIG. 1. *Graph of F_1 satisfies the hypotheses of Theorem* 11.

If in Example 12 the recruitment function is the periodic Beverton–Holt model

$$f(t,N(t)) = \frac{(1-\gamma)\mu k_t N(t)}{(1-\gamma)k_t + (\mu - 1 + \gamma)N(t)}$$

with

$$\mu = 2, \quad \gamma = 0.9, \quad \alpha = 2, \quad \sigma = 0.9, \quad p = 2, \quad k_0 = 2, \quad k_1 = 8,$$

then, as predicted by Theorem 11, the total population, susceptible population, and infective population live on the globally attracting 2-cycle

$$\{(8.087, 1.903, 6.184), (7.788, 1.437, 6.351)\}.$$

In the following result, we prove that the disease lives on a globally attracting cycle when F_1 has a critical point with an image (under F_1 iteration) smaller than the critical point.

THEOREM 13. *Let F_1 have a critical point, C_1, in $(0,1)$. If*

$$C_1 > F_1(C_1), \qquad F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) < C_{\min\{\overline{N}_i\}},$$

and $\mathcal{R}_0 > 1$, then the composition map

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point $\overline{I}_0$, and the uniformly persistent epidemic lives on a globally attracting cycle.

Proof. By Lemma 6 and our hypothesis, each $F_{\overline{N}_i}$ is increasing, concave down, and has no critical point on $[0, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$. Since $C_1 > F_1(C_1)$, $I_1 < C_1$ and F_1 is increasing on $[I_1, C_1]$. Consequently, $I_1 < F_1(C_1)$, and by topological conjugacy and Lemma 6, $I_{\overline{N}_i} < F_{\overline{N}_i}(C_{\overline{N}_i}) \le F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) < C_{\min\{\overline{N}_i\}}$. Further, $\mathcal{R}_0 > 1$ is equivalent to $F'_{\overline{N}_i}(0) > 1$. Thus, each positive initial condition converges under $F_{\overline{N}_i}$ iterations monotonically to the positive fixed point. That is, $F_{\overline{N}_i}$ has a globally attracting positive fixed point on $[0, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$.

By the preceding arguments,

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0} : [0, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})] \to [0, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})).$$

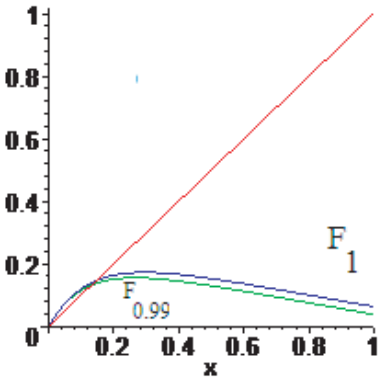

FIG. 2. *Graphs of F_1 and $F_{0.99}$ satisfy the hypotheses of Theorem* 13.

Using the chain rule on the composition map $F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$ shows that it is increasing, concave down, and has derivative at the origin larger than 1. So, as in the previous paragraph, $F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$ has a unique globally attracting positive fixed point on $[0, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$. Since $F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})$ is the maximum value of all the $F_{\overline{N}_i}$, every point immediately gets into $[0, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$, and the composition map

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point, $\overline{I}_0$. By Corollary 10, the uniformly persistent epidemic lives on a globally attracting cycle. □

Next we demonstrate, via a specific example, disease persistence on a globally attracting cycle, as predicted by Theorem 13.

EXAMPLE 14. *In* (9)*, set the following parameter values:*

$$\alpha = 7, \quad \gamma = 0.25, \quad \sigma = 0.25, \quad \max\{\overline{N}_i\} = 1, \quad \min\{\overline{N}_i\} = .99.$$

From the graphs of $F_{\max\{\overline{N}_i\}}$ and $F_{\min\{\overline{N}_i\}}$ (see Figure 2*) it is clear that $C_1 > F_1(C_1)$,*

$$F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) < C_{\min\{\overline{N}_i\}},$$

and $\mathcal{R}_0 > 1$.

Hence, with these parameters, the composition map

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point $\overline{I}_0$, and the uniformly persistent epidemic lives on a globally attracting cycle. Numerical experiments show that this result is also true when $\alpha \in [7, 10]$, $\gamma = [0.15, 0.25]$, $\sigma = [0.15, 0.25]$, and $\overline{N}_J \in [0.9, 1]$; as well as on other intervals.

If in Example 14 the recruitment function is the periodic Beverton–Holt model

$$f(t, N(t)) = \frac{(1-\gamma)\mu k_t N(t)}{(1-\gamma)k_t + (\mu - 1 + \gamma)N(t)}$$

with

$$\mu = 2, \quad \gamma = 0.25, \quad \alpha = 7, \quad \sigma = 0.25, \quad p = 2, \quad k_0 = 0.665, \quad k_1 = 0.965,$$

then

$$\max\{\overline{N}_i\} = 0.995, \qquad \min\{\overline{N}_i\} = 0.905,$$

and, as predicted by Theorem 13, the total population, susceptible population, and infective population live on the globally attracting 2-cycle

$$\{(0.995, 0.860, 0.135), (0.905, 0.765, 0.140)\}.$$

Next, we prove that the disease lives on a globally attracting cycle when F_1 has a critical point with an image (under F_1 iteration) bigger than the critical point.

THEOREM 15. *Let F_1 have a critical point, C_1, in $(0,1)$. If*

$$C_1 < F_1(C_1), \qquad F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) < \min\{\overline{N}_i\},$$

$$C_{\max\{\overline{N}_i\}} < F_{\min\{\overline{N}_i\}} \circ F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}),$$

and $\mathcal{R}_0 > 1$, then the composition map

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point $\overline{I}_0$, and the uniformly persistent epidemic lives on a globally attracting cycle.

Proof. By Lemma 6 and our hypothesis, each $F_{\overline{N}_i}$ is decreasing on $[C_{\overline{N}_i}, \overline{N}_i] \supseteq [C_{\max\{\overline{N}_i\}}, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$ and $F_{\overline{N}_i}(C_{\max\{\overline{N}_i\}}) \le F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})$. By our hypothesis, $C_{\max\{\overline{N}_i\}} < F_{\min\{\overline{N}_i\}} \circ F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) \le F_{\overline{N}_i} \circ F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})$. Thus, each $F_{\overline{N}_i}$ is decreasing on $[C_{\max\{\overline{N}_i\}}, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$ and sends this interval into itself. Consequently, each $F_{\overline{N}_i}$ has a fixed point $I_{\overline{N}_i}$ in this interval. Since $F'_{\overline{N}_i}(I) \in (-1, 0]$ for all $I \in [C_{\max\{\overline{N}_i\}}, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$ and $\overline{N}_i \in \{\overline{N}_0, \overline{N}_1, \ldots, \overline{N}_{p-1}\}$ (Lemma 6), each $F_{\overline{N}_i}$ is a contraction on this interval. This implies that $F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$ is a contraction with a unique fixed point, which is $\overline{I}_0$.

By Lemma 6 and our hypothesis, $F_{\overline{N}_i}(I) < F_{\overline{N}_i}(C_{\overline{N}_i}) \le F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) < \min\{\overline{N}_i\}$ for all $I \in [0, \overline{N}_i]$ and $\overline{N}_i \in \{\overline{N}_0, \overline{N}_1, \ldots, \overline{N}_{p-1}\}$. $F_{\overline{N}_i}(I) > I$ for all $I \in (0, I_{\overline{N}_i})$. Thus, all positive points below $C_{\max\{\overline{N}_i\}}$ increase until they are in $[C_{\max\{\overline{N}_i\}}, F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}})]$. Consequently, $F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$ has a globally attracting positive fixed point, $\overline{I}_0$, and by Corollary 10, the uniformly persistent epidemic lives on a globally attracting cycle. ∎

Now we demonstrate, via a specific example, disease persistence on a globally attracting cycle, as predicted by Theorem 15.

EXAMPLE 16. *In (9) set the following parameter values:*

$$\alpha = 20, \quad \gamma = 0.5, \quad \sigma = .5, \quad \max\{\overline{N}_i\} = 1, \quad \min\{\overline{N}_i\} = .7.$$

From the graphs of $F_{\max\{\overline{N}_i\}}$ and $F_{\min\{\overline{N}_i\}}$ (see Figure 3) it is clear that

$$C_1 < F_1(C_1), \qquad F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}) < \min\{\overline{N}_i\},$$

$$C_{\max\{\overline{N}_i\}} < F_{\min\{\overline{N}_i\}} \circ F_{\max\{\overline{N}_i\}}(C_{\max\{\overline{N}_i\}}),$$

and $\mathcal{R}_0 > 1$.

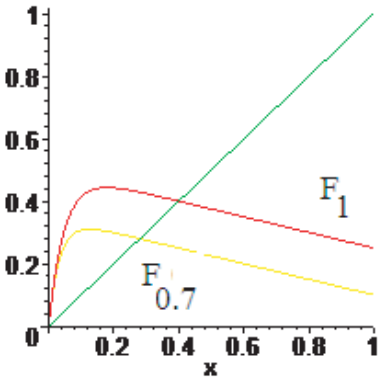

FIG. 3. *Graphs of F_1 and $F_{0.7}$ satisfy the hypotheses of Theorem* 15.

Hence, with these parameters, the composition map

$$F_{\overline{N}_{p-1}} \circ \cdots \circ F_{\overline{N}_1} \circ F_{\overline{N}_0}$$

has a globally attracting positive fixed point $\overline{I}_0$, and the uniformly persistent epidemic lives on a globally attracting cycle. Numerical experiments show that this result is also true when $\alpha \in [15, 25]$, $\gamma = [0.45, 0.6)$, $\sigma = [0.45, 0.6)$, and $\overline{N}_J \in [0.7, 1]$; as well as on other intervals.

If in Example 16 the recruitment function is the periodic Beverton–Holt model

$$f(t, N(t)) = \frac{(1-\gamma)\mu k_t N(t)}{(1-\gamma)k_t + (\mu - 1 + \gamma)N(t)}$$

with

$$\mu = 2, \quad \alpha = 20, \quad \gamma = 0.5, \quad \sigma = .5, \quad p = 2, \quad k_0 = 0.1, \quad k_1 = 0.9,$$

then

$$\max\{\overline{N}_i\} = 0.917, \qquad \min\{\overline{N}_i\} = 0.741,$$

and, as predicted by Theorem 15, the total population, susceptible population, and infective population live on the globally attracting 2-cycle

$$\{(0.917, 0.644, 0.273), (0.741, 0.352, 0.389)\}.$$

In all the above examples, we use the periodic Beverton–Holt model as the recruitment function to highlight uniform persistence via attracting cycles. Similar examples can be obtained using the periodic constant recruitment function.

6. Uniform persistence and geometric demographics. When new recruits arrive at the periodic positive per-capita growth rate λ_t, the demographic long-term dynamics is determined by the demographic basic reproductive number $\mathcal{R}_d$ (see (3)). In this case, we use proportions to study the epidemic process. We introduce the new variables

$$s(t) = \frac{S(t)}{N(t)}$$

and

$$i(t) = \frac{I(t)}{N(t)}.$$

In the new variables, when $f(t, N) = \lambda_t N$, then

$$N(t+1) = (\lambda_t + \gamma)\, N(t),$$

and model (4) becomes

$$\left.\begin{aligned} s(t+1) &= \tfrac{\lambda_t}{\lambda_t+\gamma} + \tfrac{\gamma\phi(\alpha i(t))}{\lambda_t+\gamma} s(t) + \tfrac{\gamma(1-\sigma)}{\lambda_t+\gamma} i(t), \\ i(t+1) &= \tfrac{\gamma(1-\phi(\alpha i(t)))}{\lambda_t+\gamma} s(t) + \tfrac{\gamma\sigma}{\lambda_t+\gamma} i(t). \end{aligned}\right\} \tag{10}$$

Since $i(t)+s(t) = 1$ for all t, the substitution $s(t) = 1-i(t)$ reduces the i-equation of the system to the one-dimensional nonautonomous equation

$$i(t+1) = \frac{\gamma\,(1-\phi\,(\alpha i(t)))}{\lambda_t+\gamma}\,(1-i(t)) + \frac{\gamma\sigma}{\lambda_t+\gamma} i(t).$$

Let

$$\widetilde{F}_\lambda(i) = \frac{\gamma\,(1-\phi\,(\alpha i))}{\lambda+\gamma}\,(1-i) + \frac{\gamma\sigma}{\lambda+\gamma} i.$$

Since $i \le 1$,

$$\widetilde{F}_\lambda(i) < 1 \quad \text{and} \quad \widetilde{F}_\lambda(i) = \frac{1}{\lambda+\gamma} F_1(i).$$

By Lemma 6,

$$\widetilde{F}'_\lambda(0) = \frac{-\alpha\gamma\phi'\,(0) + \gamma\sigma}{\lambda+\gamma}$$

and

$$\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) = \frac{(-\alpha\gamma\phi'\,(0) + \gamma\sigma)^p}{\prod_{t=0}^{p-1}(\lambda_t+\gamma)}.$$

Let

$$\mathcal{R}_0 = \frac{-\alpha\gamma\phi'\,(0)}{(\mathcal{R}_d(1-\gamma^p)+\gamma^p)^{\frac{1}{p}} - \gamma\sigma}.$$

If $\mathcal{R}_d = 1$, the total population is bounded and uniformly persistent, and $\mathcal{R}_0$ reduces to $\frac{-\alpha\gamma\phi'(0)}{1-\gamma\sigma}$, which is (5). We will prove that $\mathcal{R}_0 > 1$ implies that $i(t)$ persists, and $\mathcal{R}_0 < 1$ implies $\lim_{t\to\infty} i(t) = 0$. First, we obtain local stability results when $\mathcal{R}_0 \neq 1$.

LEMMA 17. *$\mathcal{R}_0 > 1$ is equivalent to $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) > 1$, and $\mathcal{R}_0 < 1$ is equivalent to $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) < 1$.*

Proof. Assume $\mathcal{R}_0 > 1$; then

$$\frac{-\alpha\gamma\phi'\,(0)}{(\mathcal{R}_d(1-\gamma^p)+\gamma^p)^{\frac{1}{p}} - \gamma\sigma} > 1.$$

Since $-\alpha\gamma\phi'(0) > 0$, $(\mathcal{R}_d(1-\gamma^p)+\gamma^p)^{\frac{1}{p}} - \gamma\sigma > 0$ and $-\alpha\gamma\phi'(0) > (\mathcal{R}_d(1-\gamma^p)+\gamma^p)^{\frac{1}{p}} - \gamma\sigma$. This implies that

$$(-\alpha\gamma\phi'(0)+\gamma\sigma)^p > \mathcal{R}_d(1-\gamma^p)+\gamma^p = \frac{\prod_{J=0}^{p-1}(\lambda_J+\gamma)-\gamma^p}{1-\gamma^p}(1-\gamma^p)+\gamma^p$$
$$= \prod_{J=0}^{p-1}(\lambda_J+\gamma).$$

Hence,

$$\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) = \frac{(-\alpha\gamma\phi'(0)+\gamma\sigma)^p}{\prod_{J=0}^{p-1}(\lambda_J+\gamma)} > 1.$$

Since all the steps are reversible, $\mathcal{R}_0 > 1$ is equivalent to $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) > 1$.

To prove the other inequality, note that $(\mathcal{R}_d(1-\gamma^p)+\gamma^p)^{\frac{1}{p}} - \gamma\sigma > (\gamma^p)^{\frac{1}{p}} - \gamma\sigma > 0$, and proceed as in the proof of the last inequality. □

THEOREM 18. *Let*

$$f(t,N) = \lambda_t N$$

in model (2)*, where* $\lambda_{t+p} = \lambda_t$.

(a) *If* $\mathcal{R}_0 < 1$*, then in model* (10)*,* $\lim_{t\to\infty} i(t) = 0$*. That is, the proportion of infectives in the total population goes extinct.*

(b) *If* $\mathcal{R}_0 > 1$*, then in model* (10)*,* $\exists\ \eta > 0$ *satisfying* $\lim_{t\to\infty} \inf i(t) \geq \eta$*. That is, the proportion of infectives in the total population uniformly persists.*

Proof. (a) Lemma 17 shows that $\mathcal{R}_0 < 1$ implies

$$\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) = \frac{(-\alpha\gamma\phi'(0)+\gamma\sigma)^p}{\prod_{J=0}^{p-1}(\lambda_J+\gamma)} < 1.$$

Let $i > 0$; then $\widetilde{F}_\lambda(i) = \frac{1}{\lambda+\gamma}F_1(i) < \frac{1}{\lambda+\gamma}F_1'(0)i = \frac{-\alpha\gamma\phi'(0)+\gamma\sigma}{\lambda+\gamma}i$, by Lemma 6. Using this p times gives

$$i(p) = \left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)(i(0)) < \frac{(-\alpha\gamma\phi'(0)+\gamma\sigma)^p}{\prod_{J=0}^{p-1}(\lambda_J+\gamma)} i(0) < i(0).$$

Thus, the sequence $\{i(tp)\}$ is dominated by the geometrically decreasing sequence

$$\left\{\left(\frac{(-\alpha\gamma\phi'(0)+\gamma\sigma)^p}{\prod_{J=0}^{p-1}(\lambda_J+\gamma)}\right)^t i(0)\right\}$$

and hence, by continuity of the system,

$$\lim_{t\to\infty} i(t) = 0.$$

(b) Lemma 17 shows that $\mathcal{R}_0 > 1$ implies

$$\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) > 1.$$

Since $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)(0) = 0$, the graph of $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ starts out above the diagonal. Since for each λ_J and each $i \in [0,1]$, $\widetilde{F}_{\lambda_J}(i) < 1$, $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)(1) < 1$. Thus $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has at least one positive fixed point. Let i^* be the minimum of these positive fixed points; then $i((t+1)p) > i(tp)$ when $i(tp)$ is in the open interval $(0, i^*)$.

Let

$$m = \min\left\{\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)(i) : i \in [i^*, 1]\right\}.$$

Note that $m > 0$. If $i(tp) \in (0, m)$, then $i((t+1)p) > i(tp)$, and the sequence $\{i(tp)\}$ continues to increase until the value is at least m. But then the sequence can never jump lower than m. Hence,

$$\lim_{t\to\infty} \inf i(tp) \geq m.$$

Now each of the maps $\widetilde{F}_{\lambda_0}, \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}, \ldots, \widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has positive minima on $[m, 1]$, and $\lim_{t\to\infty} \inf i(t)$ is at least the minimum of these minima. Hence, $\exists\ \eta > 0$ satisfying

$$\lim_{t\to\infty} \inf i(t) > \eta. \qquad \square$$

7. Cyclic attractors and geometric demographics. We assume that the total population is growing geometrically. That is, the recruitment function in the p-periodic demographic equation is $f(t, N(t)) = \lambda_t N(t)$. If, in addition,

$$\mathcal{R}_0 = \frac{-\alpha\gamma\phi'(0)}{(\mathcal{R}_d(1-\gamma^p) + \gamma^p)^{\frac{1}{p}} - \gamma\sigma} > 1,$$

we show that it is possible for the persistent i-population to live on a globally attracting cycle. This implies that both the *i-dynamics* under periodic geometric recruitment function and the *I-dynamics* under either periodic constant or periodic Beverton–Holt recruitment functions are capable of living on globally attracting cycles.

Next, we prove that the proportion of infectives live on a globally attracting cycle when $\widetilde{F}_{\lambda_t}$ is a monotone map with no critical points.

THEOREM 19. *If each $\widetilde{F}_{\lambda_t}$ has no critical points in $[0,1]$ and $\mathcal{R}_0 > 1$, then the composition map*

$$\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$$

has a globally attracting positive fixed point $\bar{i}_0$, and the uniformly persistent proportion of infectives in the total population lives on a globally attracting cycle.

Proof. By Lemma 6 each $\widetilde{F}_{\lambda_t}(i) = \frac{1}{\lambda_t+\gamma} F_1(i)$ is increasing, concave down, and has no critical point on $[0,1]$. Hence, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ is also increasing, concave down, and has no critical point on $[0,1]$. $\mathcal{R}_0 > 1$ is equivalent to $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) > 1$. Since

$$\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)(0) = 0,$$

$\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has a fixed point in $(0,1)$. Thus, each positive initial condition converges monotonically under iteration of $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ to the positive fixed

point. That is, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has a globally attracting positive fixed point on $[0,1]$, and the uniformly persistent proportion of infectives in the total population lives on a globally attracting cycle. □

To give a specific example of disease persistence on a globally attracting cycle as predicted by Theorem 19, following Example 12, we assume that infections are modeled as Poisson processes [7, 8, 9]. Then $\phi(\alpha i) = e^{-\alpha i}$, $\phi'(0) = -1$, and

$$\widetilde{F}_\lambda(i) = \frac{\gamma\left(1 - e^{-\alpha i}\right)}{\lambda + \gamma}(1 - i) + \frac{\gamma\sigma}{\lambda + \gamma} i. \tag{11}$$

EXAMPLE 20. *In* (11)*, set the following parameters:*

$$\alpha = 2, \quad \gamma = 0.9, \quad \sigma = 0.9, \quad \lambda_0, \lambda_1 \in [0.1, 0.75].$$

As in Example 12, $\widetilde{F}_\lambda$ has no critical point in $[0,1]$. For the special case $\alpha = 2$, $\gamma = 0.9$, $\sigma = 0.9$, $\lambda_0 = 0.5$, and $\lambda_1 = 0.6$ the proportion of infectives in the total population lives on the stable period 2 orbit $\{0.447, 0.469\}$ (see Theorem 19).

Now, we prove that the disease lives on a globally attracting cycle when F_1 has a critical point with an image (under $\widetilde{F}_{\max\{\lambda_t\}}$ iteration) smaller than the critical point.

THEOREM 21. *Let each F_λ have a critical point, C_1, in $(0,1)$. If*

$$\widetilde{F}_{\min\{\lambda_t\}}(C_1) < C_1$$

and $\mathcal{R}_0 > 1$, then the composition map

$$\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$$

has a globally attracting positive fixed point $\bar{i}_0$, and the uniformly persistent proportion of infectives in the total population lives on a globally attracting cycle.

Proof. By Lemma 6 and our hypothesis, each $\widetilde{F}_{\lambda_t}(i) = \frac{1}{\lambda_t + \gamma} F_1(i)$ has C_1 as its only critical point on $[0,1]$, is increasing on $[0, C_1]$, and concave down on $[0,1]$. We also have

$$\widetilde{F}_{\max\{\lambda_t\}}(i) \le \widetilde{F}_{\lambda_t}(i) \le \widetilde{F}_{\min\{\lambda_t\}}(i).$$

Since $\widetilde{F}_{\min\{\lambda_t\}}(C_1) < C_1$, the image of each $\widetilde{F}_{\lambda_t}$ is in $[0, C_1)$. Thus, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has C_1 as its only critical point, and its image is in $[0, C_1)$. Hence, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ is increasing and concave down on $[0, C_1]$.

$\mathcal{R}_0 > 1$ is equivalent to $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) > 1$. Since $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)(0) = 0$, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has a fixed point in $(0, C_1)$. Thus, each positive initial condition gets into $[0, C_1]$ and converges monotonically under iteration of $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ to the positive fixed point. That is, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has a globally attracting positive fixed point on $(0,1]$, and the uniformly persistent proportion of infectives in the total population lives on a globally attracting cycle. □

To give a specific example of disease persistence on a globally attracting cycle as predicted by Theorem 21, following Example 14, we assume that infections are modeled as Poisson processes [7, 8, 9].

EXAMPLE 22. *In* (11)*, set the following parameter values:*

$$\alpha \in [7, 10], \quad \gamma \in [0.15, 0.25], \quad \sigma \in [0.15, 0.25], \quad \lambda_0, \lambda_1 \in [0.85, 1.0].$$

As in Example 14, all the conditions of Theorem 21 are satisfied. For the special case $\alpha = 7$, $\gamma = 0.25$, $\sigma = 0.25$, $\lambda_0 = 0.85$, and $\lambda_1 = 0.95$ the proportion of infectives in the total population lives on the stable period 2 orbit $\{0.107, 0.113\}$ (see Theorem 21).

Next, we prove that the disease lives on a globally attracting cycle when F_1 has a critical point with an image (under $\widetilde{F}_{\max\{\lambda_t\}}$ iteration) bigger than the critical point.

THEOREM 23. *Let F_1 have a critical point, C_1, in $(0,1)$. If*

$$C_1 < \widetilde{F}_{\max\{\lambda_t\}} \circ \widetilde{F}_{\min\{\lambda_t\}}(C_1),$$

then $\mathcal{R}_0 > 1$, and the composition map

$$\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$$

has a globally attracting positive fixed point $\bar{i}_0$, and the uniformly persistent proportion of infectives in the total population lives on a globally attracting cycle.

Proof. By Lemma 6 and our hypothesis, each $\widetilde{F}_{\lambda_t}(i) = \frac{1}{\lambda_t+\gamma}F_1(i)$ has C_1 as its only critical point on $[0,1]$, is increasing on $[0, C_1]$, and concave down on $[0,1]$. We also have

$$\widetilde{F}_{\max\{\lambda_t\}}(i) \le \widetilde{F}_{\lambda_t}(i) \le \widetilde{F}_{\min\{\lambda_t\}}(i).$$

Since $C_1 < \widetilde{F}_{\max\{\lambda_t\}} \circ \widetilde{F}_{\min\{\lambda_t\}}(C_1) < \widetilde{F}_{\max\{\lambda_t\}}(C_1) \le \widetilde{F}_{\lambda_t}(C_1)$ and $\widetilde{F}_{\lambda_t}(0) = 0$, each $\widetilde{F}'_{\lambda_t}(0) > 1$. Hence, $\left(\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}\right)'(0) > 1$ and, by Lemma 17, $\mathcal{R}_0 > 1$.

By our hypothesis, $C_1 < \widetilde{F}_{\max\{\lambda_t\}} \circ \widetilde{F}_{\min\{\lambda_t\}}(C_1) \le \widetilde{F}_{\lambda_t} \circ \widetilde{F}_{\min\{\lambda_t\}}(C_1)$ and $\widetilde{F}_{\lambda_t}(C_1) \le \widetilde{F}_{\min\{\lambda_t\}}(C_1)$ for each λ_t. Thus, each $\widetilde{F}_{\lambda_t}$ is decreasing on $[C_1, \widetilde{F}_{\min\{\lambda_t\}}(C_1)]$ and sends this interval into itself. Consequently, each $\widetilde{F}_{\lambda_t}$ has a fixed point $\bar{i}_{\lambda_t}$ in this interval:

$$\begin{aligned}\widetilde{F}'_{\lambda_i}(i) &= \frac{1}{\lambda_i+\gamma}F'_1(i) = \frac{1}{\lambda_i+\gamma}\left(-\alpha\gamma\phi'(\alpha i)(1-i) - \gamma(1-\phi(\alpha i)) + \gamma\sigma\right)\\ &> \frac{-\gamma}{\lambda_i+\gamma} > -1.\end{aligned}$$

Hence, $\widetilde{F}'_{\lambda_i}(i) \in (-1, 0]$ for all $i \in [C_1, \widetilde{F}_{\min\{\lambda_t\}}(C_1)]$ and all λ_i. Each $\widetilde{F}_{\lambda_i}$ is a contraction on this interval. This implies that $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ is a contraction with a unique fixed point in $[C_1, \widetilde{F}_{\min\{\lambda_t\}}(C_1)]$. Thus, all positive points below C_1 increase until they are in $[C_1, \widetilde{F}_{\min\{\lambda_t\}}(C_1)]$. Consequently, $\widetilde{F}_{\lambda_{p-1}} \circ \cdots \circ \widetilde{F}_{\lambda_1} \circ \widetilde{F}_{\lambda_0}$ has a globally attracting positive fixed point on $(0,1]$, and the uniformly persistent proportion of infectives in the total population lives on a globally attracting cycle. □

To give a specific example of disease persistence on a globally attracting cycle as predicted by Theorem 23, following Example 16, we assume that infections are modeled as Poisson processes [7, 8, 9].

EXAMPLE 24. *In (11), set the following parameter values:*

$$\alpha \in [15, 25], \quad \gamma \in [0.45, 0.6], \quad \sigma \in [0.45, 0.6], \quad \lambda_0, \lambda_1 \in [0.7, 1.0].$$

As in Example 16, all the conditions of Theorem 23 are satisfied. For the special case $\alpha = 20$, $\gamma = 0.5$, $\sigma = 0.5$, $\lambda_0 = 0.8$, and $\lambda_1 = 0.9$ the proportion of infectives in the total population lives on the stable period 2 orbit $\{0.289, 0.327\}$ (see Theorem 23).

FIG. 4. *Two attracting 4-cycles (multiple attractors). Red and black attractors.*

8. Multiple attractors. In constant environments, single patch discrete-time epidemic models typically support only one attractor [7, 8, 9]. Henson and coworkers [30, 31, 32, 33], Franke and Selgrade [22], and Franke and Yakubu [24] found multiple attractors in periodically forced models, where the corresponding models in constant environments have no multiple attractors. These multiple attractors are a result of periodic perturbations of the corresponding models in constant environments. In this section, we illustrate that our periodically forced discrete-time single patch epidemic model can generate multiple (coexisting) attractors. In this situation, the long-term disease dynamics depends on initial conditions.

Periodicity is not the only mechanism for generating multiple attractors. Migration and age-structure are known to induce multiple attractors in population models [5, 7, 9, 28, 29, 48, 50]. Also, epidemic models with "backward" bifurcations support multiple attractors [27, 47].

EXAMPLE 25. *Consider model* (7) *with 4-periodic constant recruitment function*

$$f(t,N) = k_t(1-\gamma)$$

and

$$\phi\left(\frac{\alpha I}{N}\right) = e^{-\frac{\alpha I}{N}},$$

where

$$\alpha = 250, \quad \gamma = 0.4, \quad \sigma = 0.02, \quad k_0 = 1, \quad k_1 = 200, \quad k_2 = 1, \quad k_3 = 210.$$

Example 25 has two coexisting 4-cycle attractors, a "red" attractor at

$$\{(60.32, 52.44), (144.13, 3.57), (58.25, 56.14), (149.30, 1.29)\}$$

and a "black" attractor at

$$\{(60.32, 58.19), (144.13, 1.32), (58.25, 51.32), (149.30, 3.18)\}.$$

In this example, the total population is on a globally attracting 4-cycle, while the infective population is on multiple 4-cycle attractors. That is, the disease dynamics has multiple outcomes, while the total population has a single long-term dynamics. Figure 4 displays the two attracting 4-cycles.

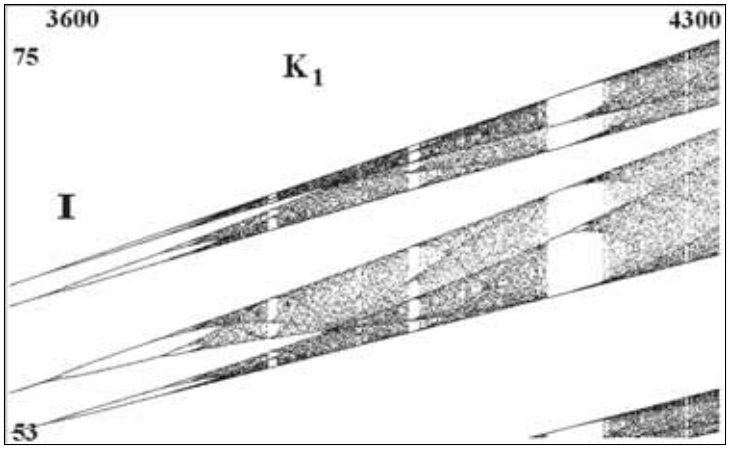

FIG. 5. *As k_1 varies between* 3600 *and* 4300*, the infective population in Example* 26 *undergoes period-doubling bifurcations route to chaos.*

9. Nonchaotic demographic dynamics generates chaotic disease dynamics. In constant environments, the demographic dynamics is capable of driving the disease dynamics [1, 2, 7, 8, 9]. That is, when the total population (in the absence of the disease) is on a cycle of period k, the population of infectives (in the presence of the disease) is also on a cycle of the same period k, albeit the amplitude of the total population is much larger than that of the infected population.

Our demographic equation with periodic constant or periodic Beverton–Holt or periodic geometric recruitment function can have either asymptotically bounded growth via globally attracting cycles (constant or Beverton–Holt models) or geometric growth (geometric model). In this section, we use numerical simulations to illustrate that the periodic epidemic model (4) can generate chaotic attractors where the periodic recruitment function is periodic constant or the periodic Beverton–Holt or periodic geometric function [39, 40, 41, 42, 43, 44, 45]. That is, in periodic environments, the demographic dynamics does not always drive the disease dynamics. We illustrate these cases in the following three examples.

EXAMPLE 26. *Consider model* (7) *with* 2*-periodic constant recruitment function*

$$f(t,N) = k_t(1-\gamma),$$
$$\phi\left(\frac{\alpha I}{N}\right) = e^{-\frac{\alpha I}{N}},$$

and

$$\alpha = 250, \quad \gamma = 0.44, \quad \sigma = 0.002, \quad k_0 = 1, \quad 3600 \le k_1 \le 4300.$$

Figure 5 shows parameter regimes of chaotic dynamics in the infective population of Example 26, where the total population is on a cyclic (nonchaotic) attractor. In this example, the recruitment function is a 2-periodic constant function. Next, we use numerical simulations to illustrate chaotic dynamics in the infective population where the recruitment function is the periodic Beverton–Holt model.

EXAMPLE 27. *Consider model* (7) *with* 2*-periodic geometric growth model*

$$f(t,N) = \frac{(1-\gamma)\mu k_t N(t)}{(1-\gamma)k_t + (\mu - 1 + \gamma)N(t)},$$

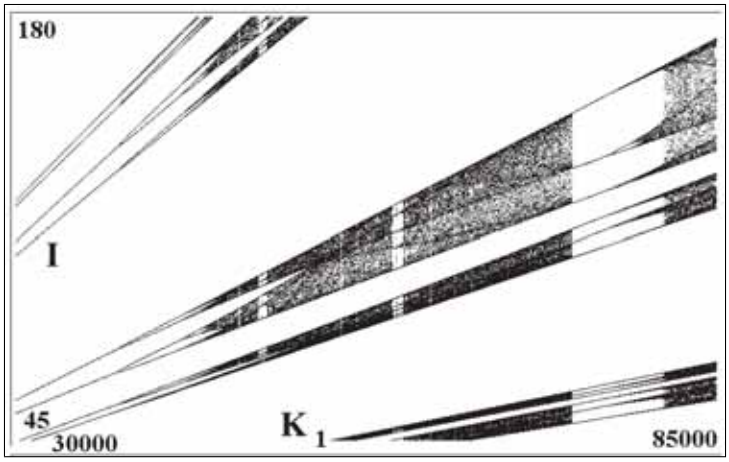

FIG. 6. *As k_1 varies between* 30000 *and* 85000*, the infective population in Example* 27 *undergoes period-doubling bifurcations route to chaos.*

$$\phi\left(\frac{\alpha I}{N}\right) = e^{-\frac{\alpha I}{N}},$$

and

$$\alpha = 250, \quad \gamma = 0.44, \quad \sigma = 0.002, \quad \mu = 2, \quad k_0 = 1, \quad 30000 \leq k_1 \leq 85000.$$

As we vary k_1 between 30000 and 85000, Figure 6 shows the infective population undergoing period-doubling bifurcations route to chaos. As in Figure 5, Figure 6 shows parameter regimes of chaotic dynamics in the infective population of Example 27, where the total population is governed by the 2-periodic Beverton–Holt model (nonchaotic dynamics). Next, we use numerical simulations to illustrate chaotic dynamics in the infective population where the recruitment function is the periodic geometric growth model.

EXAMPLE 28. *Consider model* (7) *with* 2*-periodic geometric growth model*

$$f(t, N) = \lambda_t N$$

and

$$\phi\left(\frac{\alpha I}{N}\right) = e^{-\frac{\alpha I}{N}},$$

where

$$\alpha = 250, \quad \gamma = 0.44, \quad \sigma = 0.002, \quad \lambda_0 = 0.0004, \quad 0.3 \leq \lambda_1 \leq 1.5.$$

As λ_1 varies between 0.3 and 1.5, the infective population in Example 28 undergoes period-doubling bifurcations route to chaos. As in Figures 5 and 6, Figure 7 shows parameter regimes of chaotic dynamics in the infective population of Example 28, where the total population is under geometric (nonchaotic) growth.

In periodic environments, Examples 26, 27, and 28 show that demographics dynamics does not always drive disease dynamics. In particular, they illustrate chaotic disease dynamics in the absence of chaotic dynamics in the demographic equation. These examples have only highlighted some of the complex interactions between disease and demographics dynamics in periodic environments.

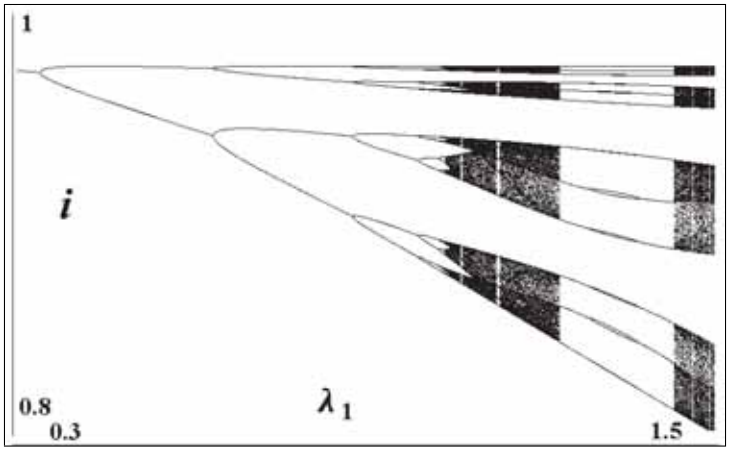

FIG. 7. *As* λ_1 *varies between* 0.3 *and* 1.5*, the infective population in Example* 28 *undergoes period-doubling bifurcations route to chaos.*

10. Conclusion. The study of the combined effects of seasonal trends and diseases on the extinction and persistence of discretely reproducing populations has received little attention. The focus has been on the impact of diseases on populations in constant (nonseasonal) environments [1, 2, 3, 7, 8, 9]. Most species live in seasonal environments, and the neglect of seasonal factors is apt to lead to a misunderstanding of how the population is interacting with its environment [26]. In this paper, we focus on the joint impact of periodic environments and disease epidemics on life-history outcomes of discretely reproducing populations. We formulated and analyzed a periodically forced discrete-time SIS epidemic model via the epidemic threshold parameter $\mathcal{R}_0$. We also investigated the relationship between the predisease invasion population dynamics and the diseases dynamics.

Fixed point (nonoscillatory) dynamics are rare in periodic environments. We use the periodic Beverton–Holt, the periodic constant, and the periodic Malthus (geometric growth) models as recruitment functions to highlight disease (uniform) persistence on globally attracting cycles whenever $\mathcal{R}_0 > 1$. The disease persists on fixed point attractors in the corresponding autonomous epidemic models [7, 8, 9].

In constant environments, Castillo-Chavez and Yakubu, in an earlier work, showed that the SIS discrete-time epidemic model supports only one attractor [7, 8, 9]. That is, the long-term epidemic dynamics is independent of initial population sizes. It is known that periodically forced (nonautonomous) population models without explicit disease dynamics are capable of generating multiple attractors via cusp bifurcations, where the corresponding autonomous models do not have multiple attractors [24]. In periodic environments, we use numerical simulations to show that the SIS model supports multiple attractors. That is, in periodic environments, the ultimate disease dynamics depends on initial population sizes. Seasonality is not the only mechanism for generating multiple attractors. Dispersal and age-structure are other factors that lead to the creation of multiple attractors in constant environments.

Castillo-Chavez and Yakubu, in [7, 8, 9], used the autonomous SIS discrete-time epidemic model to answer the following questions. Will the infective population survive? And if it does, will it settle on a particular attractor? What is the relationship between the population and epidemic attractors? Castillo-Chavez and Yakubu showed that in constant environments, infectives can survive on cyclic attractors. The period

of the (predisease invasion) population attractor is the same as the period of the infective population. In this paper, we show that it is possible for the disease dynamics to be chaotic, where the (predisease invasion) population is cyclic and nonchaotic. That is, with the advent of seasonality the demographic dynamics does not always drive the disease dynamics.

Acknowledgment. We thank the referees for useful comments and suggestions.

THE MOTION OF A THIN LIQUID FILM DRIVEN BY SURFACTANT AND GRAVITY*

R. LEVY† AND M. SHEARER‡

Abstract. We investigate wave solutions of a lubrication model for surfactant-driven flow of a thin liquid film down an inclined plane. We model the flow in one space dimension with a system of nonlinear PDEs of mixed hyperbolic-parabolic type in which the effects of capillarity and surface diffusion are neglected. Numerical solutions reveal distinct patterns of waves that are described analytically by combinations of traveling waves, some with jumps in height and surfactant concentration gradient. The various waves and combinations are strikingly different from what is observed in the case of flow on a horizontal plane. Jump conditions admit new shock waves sustained by a linear surfactant wave traveling upstream. The stability of these waves is investigated analytically and numerically. For initial value problems, a critical ratio of upstream to downstream height separates two distinct long-time wave patterns. Below the critical ratio, there is also an exact solution in which the height is piecewise constant and the surfactant concentration is piecewise linear and has compact support.

Key words. PDE, surfactants, hyperbolic-parabolic system

1. Introduction.

Spatial variations in surface tension on the free surface of a fluid induce a surface force, known as a Marangoni force [8]. Such variations can occur through temperature changes [2, 4] or by introducing surfactants. In thin film flow, surfactants have been studied in the context of industrial coating processes [9, 16] and as a component in the treatment of premature babies, whose lungs are in danger of collapse due to insufficient natural surfactant [3, 11]. Both applications have motivated extensive recent research on thin films driven by surfactant [12, 13, 17, 18].

In much of the research into surfactant spreading, the effect of gravity in driving the flow has been assumed to be negligible [10]. In this paper, we consider flow on an inclined plane, building on the work of Edmonstone, Craster, and Matar [6, 7] that explores the effect of adding gravity to the driving force. Our results demonstrate that gravity has a profound effect and probably should not be neglected in simulations of surfactant spreading.

For constant Marangoni force, as in studies of thermally driven thin films [2, 4, 8], the equations of motion are reasonably represented by a scalar fourth order PDE, known as the thin film equation. In the presence of surfactant, however, the Marangoni force is not constant; the density and motion of the surfactant molecules are modeled by an additional equation. The full model, derived using lubrication theory in [3], consists of a system of two nonlinear coupled PDEs for the film height and the surfactant concentration.

The PDE system exhibits a complicated combination of wave-like structures in the solution of initial value and boundary value problems [6, 7]. The complexity comes

about in part because the underlying equation for the transport of surfactant is a degenerate *parabolic* equation resembling the porous medium equation, the degeneracy occurring at zero surfactant concentration. In contrast with the scalar thin film equation [15], we cannot appeal to the theory of hyperbolic equations to predict the long-time behavior of solutions, and indeed we find that it is different from the combination of shocks and rarefaction waves of the hyperbolic theory. Nonetheless, we explore the point of view that long-time behavior of the underlying equations should be predictable from basic information in the initial and boundary conditions, and it should be given by combinations of similarity solutions of the equations.

The underlying equations we study are derived from the full lubrication system (in section 2) by omitting terms related to surface diffusion and capillarity, i.e., taking the Péclet number to be infinite and the capillary number to be zero. We also neglect a second order diffusive term that is small for steep inclines. This enables us to focus on the underlying structure of solutions by analogy with the connection between hyperbolic systems and their parabolic regularization.

Numerical simulations of the reduced system, described in section 3, contain discontinuities in film height and surfactant concentration gradient. These solutions have a recognizable structure, and the goal of much of the rest of the paper is to explain the structure analytically. There is extensive numerical evidence [6] that the omitted regularizing terms primarily smooth the discontinuities without changing their structure or speeds, provided the coefficients are small.

The analysis of traveling waves in section 4 and jump conditions in section 5 reveals a surprisingly rich variety of individual waves. In section 6, we show how these waves can be combined to explain the wave patterns in the numerical simulations. However, the combination is possible only below a critical value of the ratio h_R/h_L of downstream height h_R to upstream height h_L. This analysis is used in section 7 to generate special exact solutions that are piecewise constant in h and piecewise linear in Γ, with Γ having compact support.

Above the critical value a different wave pattern emerges, described through numerical experiments in section 7. A notable feature of these new patterns is a hyperbolic precursor wave propagating ahead of the surfactant front. Also in this section we probe the critical value in PDE simulations and investigate the stability of individual waves predicted by jump conditions. In section 8 we summarize the catalogue of new individual waves and discuss the results in the context of ongoing research into the role of gravity in surfactant spreading.

2. The model. Consider a flat solid substrate, inclined as shown in Figure 1, in which $z = \tilde{h}(x, y, t)$ is the height of a thin film flowing down the slope. On the surface of the film is a layer of surfactant with concentration $\tilde{\Gamma}(x, y, t)$, which measures the density of surfactant molecules on the free surface. The surfactant is assumed to be immiscible and does not add to the height of the film.[1]

The full multidimensional model consists of a system of two nonlinear PDEs derived from the Navier–Stokes equations and the well-known lubrication approximation [1, 6, 13, 19]:

$$h_t + \nabla \cdot \left[\mathbf{C} \frac{h^3}{3} \nabla \nabla^2 h - \mathbf{G} \cos\theta \frac{h^3}{3} \nabla h - \frac{h^2}{2} \nabla \Gamma \right] + \left[\mathbf{G} \sin\theta \frac{h^3}{3} \right]_x = 0, \tag{2.1}$$

[1] The amount of surfactant is also assumed to be below the critical micelle concentration [5].

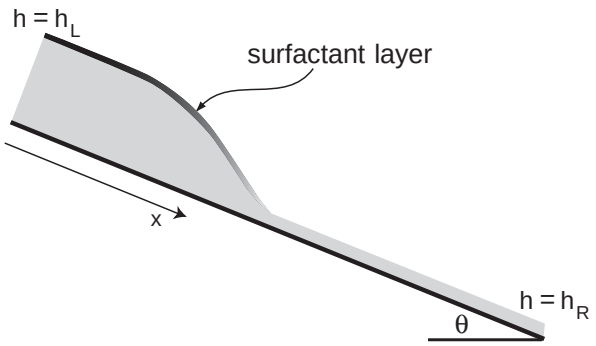

FIG. 1. *A thin film on an inclined substrate with partial coating by surfactant of varying concentration and negligible height.*

(2.2)
$$\Gamma_t + \nabla \cdot \left[\mathbf{C} \frac{h^2}{2} \Gamma \nabla \nabla^2 h - \mathbf{G} \cos\theta \frac{h^2}{2} \Gamma \nabla h - h \Gamma \nabla \Gamma \right] + \left[\mathbf{G} \sin\theta \frac{h^2}{2} \Gamma \right]_x - \mathbf{D} \nabla^2 \Gamma = 0.$$

Here h, Γ are dimensionless variables: $h = \tilde{h}/H$, $\Gamma = \tilde{\Gamma}/\Gamma_m$, where H is a characteristic length scale for the film thickness, and Γ_m is a typical surfactant concentration. The system contains nondimensional parameters associated with gravity, $\mathbf{G} = \frac{\rho g H L}{\Pi}$, surface diffusion $\mathbf{D} = \frac{1}{\mathbf{Pe}} = \frac{\mu D_s}{\Pi H}$ (where $\mathbf{Pe}$ is the Péclet number), and capillarity $\mathbf{C} = \frac{\epsilon^2 \sigma_m}{\Pi}$. These parameters depend on density ρ, gravity g, viscosity μ, and surface diffusivity D_s of the surfactant, all taken to be constant. They also depend on a characteristic length L of the film and on the small parameter $\epsilon = \frac{H}{L}$. The spreading pressure Π is given by $\Pi = \sigma_0 - \sigma_m$, where σ_0 is the surface tension in the absence of surfactant, and σ_m is a typical reduced surface tension in the presence of a typical concentration of surfactant. The spreading pressure Π is related to the Marangoni number, which after nondimensionalization is effectively set to 1. Note that in (2.1), (2.2) we have used a linear relation $\sigma = 1 - \Gamma$ (in nondimensional form) between surface tension and surfactant concentration. We refer the reader to [6] for typical values of the parameters.

In this paper, we consider a reduced model in which the variables are considered to be independent of the transverse variable y, and the regularizing effects of capillarity and surface diffusion are neglected by taking $\mathbf{C} = 0$ and $\mathbf{D} = 0$. Letting $\alpha = \mathbf{G} \sin\theta$, the reduced equations are

$$h_t - \frac{1}{2} \left(h^2 \Gamma_x \right)_x + \frac{\alpha}{3} \left(h^3 \right)_x = 0, \tag{2.3}$$

$$\Gamma_t - (h \Gamma \Gamma_x)_x + \frac{\alpha}{2} \left(h^2 \Gamma \right)_x = 0. \tag{2.4}$$

In this system we have also neglected the gravity terms with coefficient $\mathbf{G} \cos\theta$. This coefficient is small for θ near $\frac{\pi}{2}$, where it has a minor smoothing effect on solutions [6]. It is well known that fourth order diffusion gives rise to a capillary ridge [20], which is not captured in the reduced system. Neither capillarity nor surface diffusion affects wave speeds significantly, at least for small values of $\mathbf{C}$ and $\mathbf{D}$, as verified numerically in [6].

It is perhaps helpful to compare this system to familiar PDEs. For a given function $\Gamma(x,t)$, (2.3) would be a scalar conservation law

$$h_t + f(h)_x = 0,$$

with $f(h) = -\frac{1}{2}h^2\Gamma_x + \frac{\alpha}{3}h^3$. Similarly, for a given $h(x,t)$, (2.4) resembles a porous medium equation. Specifically, if h is constant, and $\alpha = 0$, then (2.4) is

$$\Gamma_t = \frac{1}{2}h\left(\Gamma^2\right)_{xx}.$$

Consequently, we may expect discontinuities in h and Γ_x, while Γ itself remains continuous; this would be typical in a quasi-linear conservation law for h and a porous medium equation for Γ.

As this discussion suggests, the system of equations is of parabolic-hyperbolic type. In a series of papers [17, 18], Renardy examined analytical issues such as local existence, propagation speed, and formation of shocks in the case $\alpha = 0$. While some of these results may generalize to the case $\alpha > 0$, we do not pursue this line of analysis in this paper.

3. Numerical experiments I. The numerical algorithm used to compute solutions of the system of PDEs (2.3), (2.4) is a first order composite finite difference scheme that couples a fully implicit time step and central spatial differences for second order derivatives with an upwind scheme for the more hyperbolic first order terms (with coefficient α in (2.3), (2.4)).

We define a spatial finite difference operator acting on $u_j^n = u(x_j, t_n)$ as

$$(\delta_x u)^n_{j+\frac{1}{2}} \equiv \frac{u^n_{j+1} - u^n_j}{\Delta x}. \tag{3.1}$$

We also use standard notation for spatial averages:

$$(\bar{u})^n_{j+\frac{1}{2}} \equiv \frac{u^n_{j+1} + u^n_j}{2}, \tag{3.2}$$

and let $\lambda \equiv \frac{\Delta t}{\Delta x}$. The finite difference scheme is then defined as

$$h_j^{n+1} = h_j^n + \lambda\left(\frac{1}{2}\left(\bar{h}^2\delta_x\Gamma\right)^{n+1}_{j+\frac{1}{2}} - \frac{1}{2}\left(\bar{h}^2\delta_x\Gamma\right)^{n+1}_{j-\frac{1}{2}} - \frac{\alpha}{3}\left((h^3)^n_j - (h^3)^n_{j-1}\right)\right), \tag{3.3}$$

$$\Gamma_j^{n+1} = \Gamma_j^n + \lambda\left(\left(\bar{h}\bar{\Gamma}\delta_x\Gamma\right)^{n+1}_{j+\frac{1}{2}} - \left(\bar{h}\bar{\Gamma}\delta_x\Gamma\right)^{n+1}_{j-\frac{1}{2}} - \frac{\alpha}{2}\left((h^2\Gamma)^n_j - (h^2\Gamma)^n_{j-1}\right)\right). \tag{3.4}$$

The resulting nonlinear system is solved with Newton's method; the composite scheme is formally first order in both time and space.

The goal of our analysis is to understand the structure of long-time solutions as a function only of boundary data. In order to simulate initial value problems with initial data in which h and Γ are constant outside an interval, and $\Gamma = 0$ downstream, we impose simple boundary conditions at the end points of the computational domain $[0, x_{max}]$:

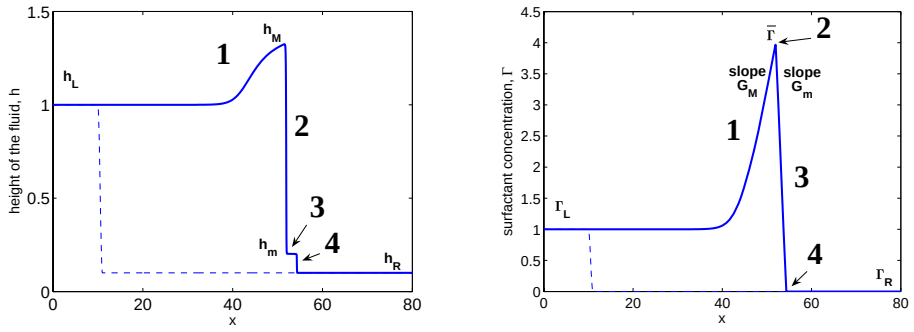

FIG. 2. *Typical solution profiles* $h(x,60)$ *(left) and* $\Gamma(x,60)$ *(right) with* $h_R = 0.1$. *Initial data* $h(x,0)$ *and* $\Gamma(x,0)$ *are represented by dashed lines. Numbered labels:* (1) *nonlinear traveling wave;* (2) *jump in* h, Γ_x*;* (3) *linear traveling wave with* Γ *linear and* h *constant;* (4) *jump in* h, Γ_x.

$$h(0,t) = h_L, \quad \Gamma(0,t) = \Gamma_L; \quad h(x_{max},t) = h_R, \quad \Gamma(x_{max},t) = 0.$$

In the PDE simulations, we exploit the following scalings in the equations. Let $h = H(x,t)$, $\Gamma = g(x,t)$ satisfy (2.3), (2.4) with $H(0,t) = 1$, $g(0,t) = 1$, and $\alpha = 1$. Then h, Γ given by

$$h(x,t) = h_L\, H\left(\frac{\alpha h_L}{\Gamma_L}x, \frac{\alpha^2 h_L^3}{\Gamma_L}t\right) \quad \text{and} \quad \Gamma = \Gamma_L\, g\left(\frac{\alpha h_L}{\Gamma_L}x, \frac{\alpha^2 h_L^3}{\Gamma_L}t\right) \tag{3.5}$$

satisfy (2.3), (2.4) with $h(0,t) = h_L$, $\Gamma(0,t) = \Gamma_L$, provided $\Gamma_L > 0$. Thus, to explore variation in wave structures, we can fix $\alpha = h_L = \Gamma_L = 1$ and vary h_R (note that $\Gamma_R = 0$). We employ this simplification in numerical simulations. In the analysis, we retain all the parameters so that their effect can be seen explicitly.

Figure 2 contains graphs of numerical simulations of (2.3), (2.4) at time $t = 60$. The initial data (indicated by dashed lines) contain a single (smoothed) jump in h from $h_L = 1.0$ to $h_R = 0.1$ and in Γ from $\Gamma_L = 1.0$ to $\Gamma_R = 0$. The same structure emerges from the same upstream and downstream heights for more general smooth height data (including oscillatory data) after transients have died away. The figure is annotated to show the broad wave structure of the solution. In the graph of h, note that at (1) the height increases monotonically from the fixed boundary value h_L to a maximum height h_M; at (2) there is a jump from h_M to the height h_m of the horizontal "step" at (3). Finally, the step contains a second jump at (4) from h_m to the precursor layer of fixed height h_R.

The graph of the surfactant concentration Γ has jumps at the same locations as those of the height, but the jumps are in the slope Γ_x (henceforth denoted by G, as in the figure), while Γ is continuous. The surfactant concentration increases monotonically (1) to a maximum concentration Γ_0 at the corner (2), where there is a jump in Γ_x from $G_M > 0$ to $G_m < 0$. In (3), Γ appears to be linear, extending down to $\Gamma = 0$, where there is a second jump (4) in Γ_x from $G_m < 0$ to zero.

As the spatial grid is refined, the discontinuities are better resolved, and no additional data points appear in the discontinuities. We demonstrate this for the jump in height in Figure 3, in which the number of grid points is doubled from 2500 ($\Delta x = 0.012$) to 5000 ($\Delta x = 0.006$).

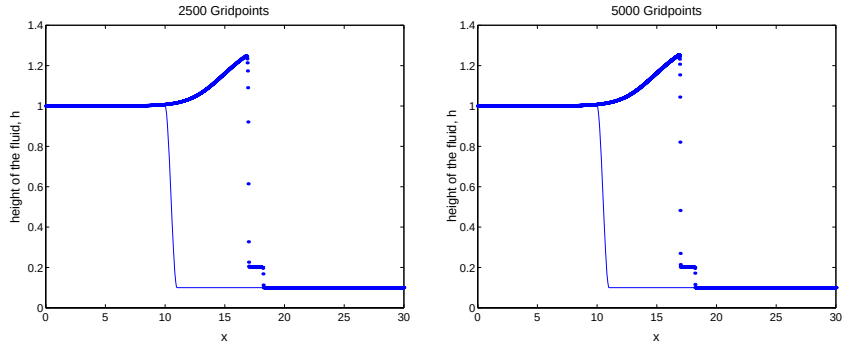

FIG. 3. *Grid refinement to distinguish the discontinuity in height from a steep gradient. The coarse grid on the left has* 2500 *points; the fine grid on the right has* 5000 *points. The number of points in the shock is approximately the same in both cases.*

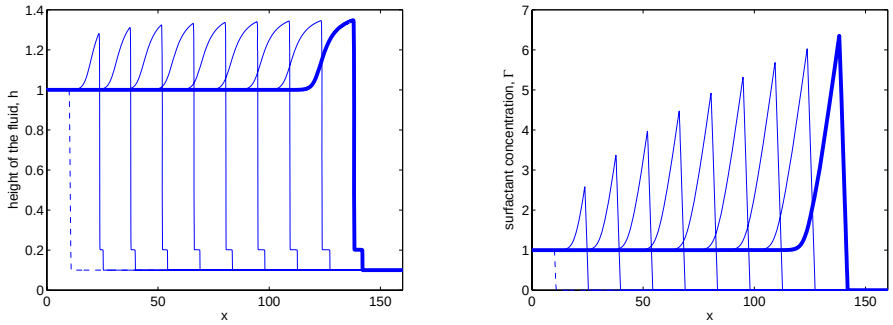

FIG. 4. *Numerical solutions showing the evolution of* h *and* Γ *for* $h_R = 0.1$. *The profiles are separated by* 40 *time steps, and the final profiles at* $t = 180$ *are in bold. The computational time step is* $\Delta t = 0.001$, *and the grid is fairly coarse with* $\Delta x = 0.04$.

Figure 4 illustrates the evolution of the solution, with a dashed line indicating the initial profile. After a rapid initial transient between the first two plots, the maximum height h slowly asymptotes to a constant value, whereas the maximum surfactant concentration Γ increases without bound. (Note that surfactant is supplied from the left boundary.) The step height h_m develops at a very early time and remains constant, although the width of the step increases slowly.

To visualize the data from Figure 4 in a different way, in Figure 5 we plot the curves $(h(x,t), \Gamma(x,t))$, $0 < x < x_{max}$, for various values of $t > 0$. Starting from $(h_L, \Gamma_L) = (1,1)$, there is a sequence of curves on the right that appears to be converging. A jump in h occurs at the maximum value of Γ, which is increasing in time. On the left of the figure, Γ decreases to zero at a height h which is constant in space and time. The final step occurs on the h-axis.

4. Traveling waves. In this section we explore analytical solutions of the PDE (2.3), (2.4) that capture some of the features observed in the numerical simulations. The traveling waves we consider are smooth solutions $h = \hat{h}(x - ct)$, $\Gamma = \hat{\Gamma}(x - ct)$ that move with constant speed c. Substituting into system (2.3), (2.4) and integrating

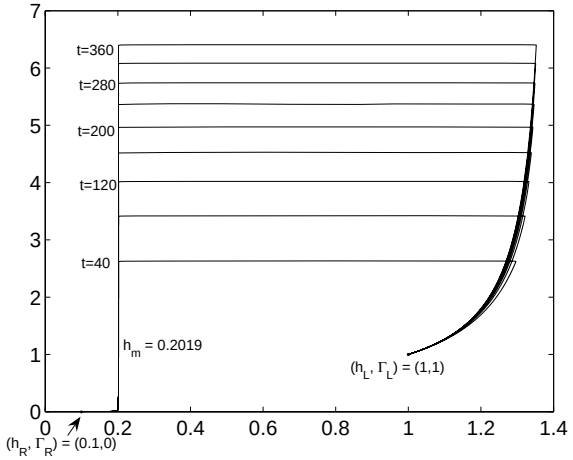

FIG. 5. *Phase portrait of numerical PDE solutions* (h, Γ) *with* $h_R = 0.1$.

once, we obtain the ODE system (dropping the hats)

$$-ch - \frac{1}{2}h^2\Gamma' + \frac{\alpha}{3}h^3 = K_1, \tag{4.1}$$

$$-c\Gamma - h\Gamma\Gamma' + \frac{\alpha}{2}h^2\Gamma = K_2 \tag{4.2}$$

in which $\Gamma' = \frac{d\Gamma}{d\xi}$, $\xi = x - ct$. First, we observe that there are traveling waves in which h is constant and Γ is linear. We refer to these traveling waves as *simple traveling waves*. Note that simple traveling waves should be considered to be defined only for values of $x - ct$ where Γ is nonnegative.

THEOREM 4.1. *Let* $h > 0$ *be constant, and let* $\Gamma = \Gamma_0 + G\xi$, *with* $G = \Gamma' =$ *constant. Then* (4.1) *is satisfied identically with* $K_1 = -ch - \frac{1}{2}h^2G + \frac{\alpha}{3}h^3$, *and* (4.2) *is satisfied if and only if* $K_2 = 0$ *and*

$$c = -hG + \frac{\alpha}{2}h^2. \tag{4.3}$$

Proof. The only complication is in the Γ equation, where the left-hand side has a constant term and a term linear in ξ. The restrictions on K_2 and c come from equating coefficients. ∎

Interestingly, the speed in (4.3) is the transport velocity in (2.4); it is neither the transport velocity $-\frac{1}{2}hG + \frac{\alpha}{3}h^2$ nor the characteristic speed $-hG + \alpha h^2$ for the conservation law (2.3) with $\Gamma_x = G$ constant. This is not a contradiction, since h is constant.

There are also *nonlinear traveling waves* corresponding to solutions of system (4.1), (4.2) in which h is not constant and Γ is not linear. Consider a solution $h(\xi)$, $\Gamma(\xi)$ with boundary conditions at $\xi = -\infty$:

$$h(-\infty) = h_L, \quad \Gamma(-\infty) = \Gamma_L, \quad \Gamma'(-\infty) = 0. \tag{4.4}$$

These conditions serve to determine the constants K_1, K_2, so that (4.1), (4.2) become

$$-ch - \frac{1}{2}h^2\Gamma' + \frac{\alpha}{3}h^3 = -ch_L + \alpha\frac{h_L^3}{3}, \tag{4.5}$$

$$-c\Gamma - h\Gamma\Gamma' + \frac{\alpha}{2}h^2\Gamma = -c\Gamma_L + \frac{\alpha}{2}h_L^2\Gamma_L. \tag{4.6}$$

Eliminating Γ', we obtain an invariant curve through (h_L, Γ_L) in the (h, Γ)-plane:

$$\Gamma(h) = \frac{h\Gamma_L\left(c - \frac{\alpha}{2}h_L^2\right)}{c(2h_L - h) + \alpha\left(\frac{1}{6}h^3 - \frac{2}{3}h_L^3\right)}. \tag{4.7}$$

On the curve $\Gamma(h)$, the flow is given by solving (4.1) for Γ' and using the chain rule $\frac{d\Gamma}{d\xi} = \frac{d\Gamma}{dh}\frac{dh}{d\xi}$ to obtain an expression for h'. Differentiating (4.7), we obtain

$$\frac{d\Gamma}{dh} = \frac{6\Gamma_L(2c - \alpha h_L^2)(6ch_L - \alpha h^3 - 2\alpha h_L^3)}{(12ch_L - 6ch + \alpha h^3 - 4\alpha h_L^3)^2}. \tag{4.8}$$

Therefore, after some processing, we find

$$\frac{d\Gamma}{d\xi} = \frac{\frac{2}{3}(h_L - h)(3c - \alpha(h^2 + hh_L + h_L^2))}{h^2}, \tag{4.9}$$

$$\frac{dh}{d\xi} = \frac{-\frac{1}{9}(h - h_L)(3c - \alpha(h^2 + hh_L + h_L^2))(12ch_L - 6ch + \alpha h^3 - 4\alpha h_L^3)^2}{h^2\Gamma_L(2c - \alpha h_L^2)(6ch_L - \alpha h^3 - 2\alpha h_L^3)}. \tag{4.10}$$

In particular, the point (h_L, Γ_L) is an equilibrium; whether it is stable or unstable depends on the signs of the various factors in (4.9), (4.10). It is unstable for the traveling waves we seek.

As suggested by the numerical results of the previous section, the traveling waves of most interest to us in this paper have h and Γ increasing, with h approaching finite limits at $\pm\infty$, and Γ unbounded at $+\infty$. The following result establishes the existence of such waves.

THEOREM 4.2. *For each $h_M \in (h_L, 2^{\frac{2}{3}}h_L)$, there is a traveling wave solution $h(\xi)$, $\Gamma(\xi)$, $\xi = x - ct$ satisfying*

(i) *$h'(\xi) > 0$; $\Gamma'(\xi) > 0$;*

(ii) *$h(-\infty) = h_L$, $\Gamma(-\infty) = \Gamma_L$, $h(\infty) = h_M$, $\Gamma(\infty) = \infty$, $\Gamma'(\infty) = G_M$*

with speed

$$c = -h_M G_M + \frac{\alpha}{2}h_M^2, \tag{4.11}$$

where

$$G_M = \frac{\alpha}{3}\frac{(h_L - h_M)}{h_M(2h_L - h_M)}(h_M^2 - 2h_Lh_M - 2h_L^2). \tag{4.12}$$

Proof. Let

$$d(h; c, h_L) = c(2h_L - h) + \frac{\alpha}{6}(h^3 - 4h_L^3),$$

the denominator in the expression (4.7) for $\Gamma = \Gamma(h)$. Solving $d(h; c, h_L) = 0$, we find

$$c = c(h) = \frac{\alpha}{6}\left(\frac{h^3 - 4h_L^3}{h - 2h_L}\right). \tag{4.13}$$

By considering the graph of this rational function of h, we find c has a positive local maximum at $h = h_L$, a zero at $h = 2^{\frac{2}{3}}h_L < 2h_L$, and $c(0) = \frac{\alpha}{3}h_L^2$. Consequently, for h_M in the range of the theorem, there is a single zero of d, parameterized by either $h = h_M$ or by $c \in (0, \frac{\alpha}{2}h_L^2)$. For $\frac{\alpha}{3}h_L^2 < c < \frac{\alpha}{2}h_L^2$, there is a second positive root $h_0 < h_L$, which crosses $h = 0$ at $c = \frac{\alpha}{3}h_L^2$.

In summary, the zero of d that we seek is given by (4.13) with $h = h_M$:

$$c = c(h_M) = \frac{\alpha}{6}\left(\frac{h_M^3 - 4h_L^3}{h_M - 2h_L}\right), \quad h_L < h_M < 2^{\frac{2}{3}}h_L. \tag{4.14}$$

Then $\Gamma(h)$ has a vertical asymptote at $h = h_M$ and, moreover, Γ stays positive: $\Gamma(h) \to \infty$ as $h \nearrow h_M$. Examining the flow (4.9), (4.10), we find that (h_L, Γ_L) is an unstable equilibrium. Let $(h(\xi), \Gamma(\xi))$ be the corresponding trajectory satisfying (4.5), (4.6) with $(h(-\infty), \Gamma(-\infty)) = (h_L, \Gamma_L)$, $h' > 0$, $\Gamma' > 0$. Then $h(\infty) = h_M$ and $\Gamma(\infty) = \infty$.

The final step is to set $h = h_M$ in (4.9), from which we find (after substitution for c from (4.14)) $\Gamma'(\xi) \to G_M$, as given in (4.12). Formula (4.11) is then easily checked. □

Remarks. 1. Formula (4.11) suggests that the traveling wave approaches a simple traveling wave as $\xi \to \infty$. Indeed, $h(\xi) \to h_M$, a constant, and $\Gamma'(\xi) \to G_M$, as $\xi \to \infty$.

2. Equations (4.11), (4.12) link the asymptotic behavior as $\xi \to \infty$ to the equilibrium (h_L, Γ_L) without needing to integrate the ODEs. The formulae are independent of Γ_L, reflecting the scale invariance of the equations. Moreover, these formulae persist as $\Gamma_L \to 0$. In this limit, the traveling wave approaches a simple nonsmooth wave (see Corollary 5.5 below).

3. From (4.14), we observe that $c(h_M) \in \left(\frac{\alpha}{3}h_L^2, \frac{\alpha}{2}h_L^2\right)$, an interval that collapses onto zero as $\alpha \to 0$. Consequently, the nonlinear traveling waves of the theorem do not appear in the case $\alpha = 0$ of the horizontal substrate.

5. Jump conditions. As discussed above, and as observed in numerical simulations, solutions of system (2.3), (2.4) typically contain discontinuities in h and Γ_x. In this section, we begin a systematic study of the Rankine–Hugoniot jump conditions for the system.

Consider the Cauchy problem for system (2.3), (2.4) with initial data

$$h(x,0) = h_0(x), \quad \Gamma(x,0) = \Gamma_0(x), \quad -\infty < x < \infty. \tag{5.1}$$

By a *weak solution* of the Cauchy problem, we mean a function $(h, \Gamma) : \mathbb{R} \times \mathbb{R}_+ \to \mathbb{R}_+^2$ with $h, \Gamma, \Gamma_x \in L^\infty \cap L^1_{loc}$ such that for every test function $\phi \in C_c^\infty(\mathbb{R} \times \mathbb{R}_+)$,

$$\begin{aligned} \int_0^\infty \int_{-\infty}^\infty \left\{h\phi_t - (\tfrac{1}{2}h^2\Gamma_x - \tfrac{\alpha}{3}h^3)\phi_x\right\} dx\, dt &= \int_{-\infty}^\infty h_0\phi(x,0)dx, \\ \int_0^\infty \int_{-\infty}^\infty \left\{\Gamma\phi_t - (h\Gamma\Gamma_x - \tfrac{\alpha}{2}h^2\Gamma)\phi_x\right\} dx\, dt &= \int_{-\infty}^\infty \Gamma_0\phi(x,0)dx. \end{aligned} \tag{5.2}$$

Note that in this definition of weak solutions, $\Gamma(x,t)$ is continuous with respect to x for each time t.

In analyzing jump conditions, we will always assume that h is C^1 and Γ is C^2, apart from a finite number of curves $x = \gamma(t)$ across which h and Γ_x can have jump discontinuities. We refer to such solutions as *piecewise-smooth*. We shall be

particularly interested in solutions in which surfactant spreads into a region with initially uniform film height. Let (h, Γ) be a piecewise-smooth weak solution, and suppose the leading edge of the surfactant is located on a curve $x = \gamma_\ell(t)$:

$$\Gamma(x,t) = 0, \quad x \geq \gamma_\ell(t). \tag{5.3}$$

The following theorem determines the speed at the leading edge of the surfactant.

THEOREM 5.1. *Let h, Γ be a piecewise-smooth weak solution of* (2.3), (2.4) *satisfying* (5.3). *If $G_- \equiv \Gamma_x(\gamma_\ell(t)-, t) < 0$, then*

$$\gamma_\ell'(t) = -h_- G_- + \frac{\alpha}{2} h_-^2, \tag{5.4}$$

where $h_- = h(\gamma_\ell(t)-, t)$.

Proof. Differentiating $\Gamma(\gamma_\ell(t)-, t) = 0$, we have

$$\Gamma_x \gamma_\ell'(t) + \Gamma_t = 0.$$

But from (2.4), $\Gamma_t = (h\Gamma\Gamma_x)_x - \frac{\alpha}{2}\left(h^2\Gamma\right)_x = h_- G_-^2 - \frac{\alpha}{2} h_-^2 G_-$, since $\Gamma = 0$ at the leading edge $x = \gamma_\ell(t)$. The formula (5.4) now follows, since $\Gamma_x = G_- \neq 0$. ∎

Now we derive a set of equations from the Rankine–Hugoniot conditions for the discontinuities in h and Γ_x and an equation enforcing the continuity of Γ at the discontinuities. Consider a solution (h, Γ) that is smooth away from a differentiable curve $C = \{x = \gamma(t)\}$ such that Γ is continuous across C, and h, Γ_x have well-defined one-sided limits at C. Let $[u]$ denote the jump in a function u across C, and let $c = \gamma'(t)$. It is also convenient to use the notation

$$G = \Gamma_x, \quad \overline{\Gamma} = \Gamma(\gamma(t), t).$$

Then the jump conditions are as follows. From (2.3) we obtain

$$-c[h] + \left[-\frac{1}{2} h^2 G + \frac{\alpha}{3} h^3\right] = 0, \tag{5.5}$$

while (since Γ is continuous) (2.4) yields

$$\overline{\Gamma}\left[-hG + \frac{\alpha}{2} h^2\right] = 0. \tag{5.6}$$

The continuity of Γ provides an additional equation matching the left and right limits of Γ at $x = \gamma(t)$:

$$\Gamma(\gamma(t)-, t) = \Gamma(\gamma(t)+, t). \tag{5.7}$$

We refer to weak solutions that consist of a simple traveling wave (see section 4) on either side of a jump in h, Γ_x as a *simple jump*. In a simple jump, both h and G are constant, so that the jump condition (5.5) implies the speed is constant also. By translation invariance, we may without loss of generality take the simple jump to lie along the line $x = ct$:

(5.8)

$$h(x,t) = \begin{cases} h_- & \text{if } x < ct, \\ h_+ & \text{if } x > ct, \end{cases} \qquad \Gamma(x,t) = \begin{cases} \Gamma_0 + G_-(x - c_- t) & \text{if } x < ct, \\ \Gamma_0 + G_+(x - c_+ t) & \text{if } x > ct. \end{cases}$$

In this solution, we are leaving open the possibility that the simple traveling waves on either side of the jump travel with different speeds. In this case, continuity of Γ (5.7) requires

$$G_-(c-c_-) = G_+(c-c_+). \tag{5.9}$$

The jump conditions (5.5), (5.6) for a simple jump (5.8) become

$$-c(h_+ - h_-) - \frac{1}{2}(h_+^2 G_+ - h_-^2 G_-) + \frac{\alpha}{3}(h_+^3 - h_-^3) = 0, \tag{5.10}$$

$$(\Gamma_0 + G_-(c-c_-)t)\left(-h_+G_+ + h_-G_- + \frac{\alpha}{2}(h_+^2 - h_-^2)\right) = 0. \tag{5.11}$$

Equating coefficients in the second equation, we have a pair of conditions:

$$\begin{aligned} \Gamma_0\left(-h_+G_+ + h_-G_- + \tfrac{\alpha}{2}(h_+^2 - h_-^2)\right) &= 0, \\ G_-(c-c_-)\left(-h_+G_+ + h_-G_- + \tfrac{\alpha}{2}(h_+^2 - h_-^2)\right) &= 0. \end{aligned} \tag{5.12}$$

The analysis of the jump conditions is organized as follows. First, we show that for $\alpha = 0$, and $\overline{\Gamma} = 0$, there is a simple jump in h; the height doubles across the jump, and the speed is determined by the height and surfactant concentration gradient on one side of the jump. However, when $\overline{\Gamma} > 0$, there are no simple jumps when $\alpha = 0$. For $\alpha > 0$, there are two simple jumps: one at the leading edge, but with the jump in height coupled to the surfactant concentration gradient, and another in the bulk, where the jump conditions can be solved explicitly.

The horizontal substrate: $\alpha = 0$. First, we investigate the structure of the leading edge of the surfactant when $\alpha = 0$. The speed $c = \gamma_\ell'(t)$ of the leading edge $x = \gamma_\ell(t)$ was characterized in Theorem 5.1.

THEOREM 5.2.[2] *Let h, Γ be a piecewise-smooth weak solution of* (2.3), (2.4) *with $\alpha = 0$ satisfying* (5.3). *If $G_- = \Gamma_x(\gamma_\ell(t)-, t) < 0$, then*

$$h_- = 2h_+, \tag{5.13}$$

where $h_\pm = h(\gamma_\ell(t)\pm, t)$.

Proof. The result follows immediately by substituting the expression for the speed at the jump (5.4) into the height jump condition (5.5). Specifically, (5.5) with $\alpha = 0$ becomes

$$-c(h_+ - h_-) + \frac{1}{2}h_-^2 G_- = 0, \tag{5.14}$$

since $G_+ = \Gamma_x(\gamma_\ell(t)+, t) = 0$. But from (5.4), $c = -h_-G_-$. Substitution into (5.14) leads to the result, since $G_- \neq 0$. ∎

Next, we show there are no simple jumps with $\overline{\Gamma} > 0$.

THEOREM 5.3. *Let $\alpha = 0$, $\overline{\Gamma} > 0$. There are no simple jumps with $c \neq 0$. For $c = 0$, there is a nonphysical solution with a stationary jump in h and no jump in Γ_x.*

Proof. Set $\alpha = 0$ in the jump conditions (5.10), (5.12) to get

$$-c(h_+ - h_-) - \frac{1}{2}h_+^2 G_+ + \frac{1}{2}h_-^2 G_- = 0 \tag{5.15}$$

[2] These jumps were first characterized by Borgas and Grotberg [3].

and

$$\begin{aligned} \Gamma_0\,(-h_+G_+ + h_-G_-) &= 0, \\ G_-(c-c_-)\,(-h_+G_+ + h_-G_-) &= 0. \end{aligned} \tag{5.16}$$

Since $\Gamma_0 > 0$, we see that

$$h_-G_- = h_+G_+. \tag{5.17}$$

Consequently, the speeds c_-, c_+ of the simple traveling waves on each side of the simple jump are equal (see Theorem 4.1 with $\alpha = 0$):

$$c_- = -h_-G_- = c_+ = -h_+G_+. \tag{5.18}$$

Substituting (5.17) into (5.15), we conclude that either $h_+ = h_-$, in which case $G_+ = G_-$ and there is no jump, or $h_+ \neq h_-$ and a jump in h and G would have speed

$$c = -\frac{1}{2}h_-G_-. \tag{5.19}$$

But then (5.9), (5.18) imply that either $c = c_- = c_+ = 0$, so that $G_- = G_+ = 0$, or $G_- = G_+ \neq 0$. In the former case, we regard the solution with an arbitrary stationary jump in h as unphysical, since the fluid discontinuity would collapse in the presence of additional smoothing terms such as capillarity or second order diffusion. In the latter case, (5.17) implies $h_- = h_+$, and we are back to the simple traveling wave of the previous section with no jump in h or Γ_x. ∎

The inclined substrate: $\alpha > 0$. When we consider a film flowing down an inclined substrate in which $\alpha > 0$, we find solutions of the jump conditions that are strikingly different from the $\alpha = 0$ case. We explore the wave structures analytically here and numerically in section 7. As with $\alpha = 0$, we treat the leading edge of surfactant separately.

THEOREM 5.4. *Let h, Γ be a piecewise-smooth weak solution of* (2.3), (2.4) *with $\alpha > 0$ satisfying* (5.3). *Let $h_\pm = h(\gamma_\ell(t)\pm, t)$, and suppose $G_- = \Gamma_x(\gamma_\ell(t)-, t) < 0$. Then*

$$\text{(a)}\quad h_- < h_+ \quad \textit{or} \quad \text{(b)}\quad 2h_+ < h_- < (1+\sqrt{3})h_+; \tag{5.20}$$

in both cases

$$G_- = \frac{\alpha}{3}\frac{(h_- - h_+)(h_-^2 - 2h_-h_+ - 2h_+^2)}{h_-(h_- - 2h_+)}, \qquad \gamma_\ell'(t) = -h_-G_- + \frac{\alpha h_-^2}{2}. \tag{5.21}$$

Proof. The speed in (5.21) is given by Theorem 5.1 (see (5.4)). Substituting $c = \gamma_\ell'(t)$ and $G_+ = 0$ into the jump condition (5.10) gives the formula for G_- in (5.21). The inequalities (5.20) are equivalent to $G_- < 0$. (The inequality $G_- \leq 0$ is needed to ensure $\Gamma > 0$ behind the leading edge of the surfactant.) ∎

Remarks. 1. For $\alpha > 0$, the jump in h and the surfactant concentration gradient are linked, in contrast to the $\alpha = 0$ case, in which the jump in h is determined, and G_- is a free parameter that influences only the speed.

2. Conditions (5.21) correspond to the limit $\Gamma_L \to 0$ of the nonlinear traveling wave in Theorem 4.2.

3. The case $h_- < h_+$ appears to be unphysical; both gravity and the surfactant concentration gradient act downwards and cannot sustain such a jump in the height.

We conjecture that this jump is unstable, as suggested by the numerical evidence in Figure 8. Further explanation for the instability of the wave is suggested by the observation that the speed of the discontinuity in (5.21) is smaller than the characteristic speed αh_+^2 in the surfactant-free region ahead of the discontinuity.

The following corollary parallels the result of Theorem 5.4, except that it concerns the trailing edge of the surfactant, so the roles of h_+, h_- are exchanged. However, the cases are not symmetric, since gravity and the Marangoni force are now opposed. In particular, $h_+ > h_-$.

COROLLARY 5.5. *Let h, Γ be a piecewise-smooth weak solution of* (2.3), (2.4) *with $\alpha > 0$ satisfying $\Gamma(x,t) = 0$, $x \le \gamma_T(t)$. Let $h_\pm = h(\gamma_T(t)\pm, t)$, and suppose $G_+ = \Gamma_x(\gamma_T(t)+, t) > 0$. Then*

$$\text{(a)} \quad h_+ > (1+\sqrt{3})h_- \quad \textit{or} \quad \text{(b)} \quad h_- < h_+ < 2h_-; \tag{5.22}$$

in both cases

$$G_+ = \frac{\alpha}{3}\frac{(h_+ - h_-)(h_+^2 - 2h_-h_+ - 2h_-^2)}{h_+(h_+ - 2h_-)}, \qquad \gamma_T'(t) = -h_+G_+ + \frac{\alpha h_+^2}{2}. \tag{5.23}$$

Proof. The proof parallels that of Theorem 5.4 with h_-, h_+ switched; the bounds on $h_\pm$ ensure $G_+ > 0$. ∎

THEOREM 5.6. *For $\alpha > 0$, let h, Γ be a piecewise-smooth weak solution of* (2.3), (2.4) *with a simple jump across the line $x = ct$, where $\Gamma = \Gamma_0 > 0$. Then either*
(a) $\Gamma = \Gamma_0 + G(x - st)$ *is linear, in which case*

$$G = \frac{\alpha}{2}(h_+ + h_-); \quad s = -\frac{\alpha}{2}h_+h_-; \quad c = \frac{\alpha}{12}(h_+ - h_-)^2, \tag{5.24}$$

or (b) Γ_x *has a jump with*

$$\begin{gathered} G_- = -\frac{\alpha}{6h_-}(h_+ - h_-)(h_+ + 2h_-); \quad G_+ = \frac{\alpha}{6h_+}(h_+ - h_-)(2h_+ + h_-); \\ c = \frac{\alpha}{6}(h_+^2 + h_+h_- + h_-^2). \end{gathered} \tag{5.25}$$

Proof. In case (a), we substitute $\Gamma = \Gamma_0 + G(x - st)$, $h = h_\pm$ into (2.4) to find

$$s = -h_+G + \frac{\alpha}{2}h_+^2 = -h_-G + \frac{\alpha}{2}h_-^2.$$

(That is, $(h_\pm, \Gamma)$ is a simple traveling wave with the same speed s and surfactant gradient G on each side of $x = ct$ but with a jump in h.) The second equality gives the formula for G (consistent with (5.6)) from which the expression for s follows. The speed of the jump in h comes from the jump condition (5.10) in which $G_\pm = G$.

In case (b), since $\Gamma > 0$, the jump condition (5.11) together with Theorem 4.1 for simple traveling waves implies

$$c_+ = -h_+G_+ + \frac{\alpha}{2}h_+^2 = -h_-G_- + \frac{\alpha}{2}h_-^2 = c_-.$$

But now continuity of Γ (see (5.9)) and $G_+ \ne G_-$ imply $c = c_+ = c_-$. Substituting into the jump condition (5.10) leads to the result (noting that $h_+ = h_-$ implies $G_+ = G_-$). ∎

Remark. The motion of the film in this case is somewhat surprising, since the linear wave with slope $G = \frac{\alpha}{2}(h_+ + h_-)$ moves to the left with speed $s = -\frac{\alpha}{2}h_+h_-$, while simultaneously the jump in height moves to the right with speed $c = \frac{\alpha}{12}(h_+ - h_-)^2$.

6. Combining waves when $\alpha > 0$. The numerical experiments of section 3 suggest that as time increases, the solution approaches a combination of traveling waves and simple jumps. We can now interpret this structure in terms of the traveling waves of section 4 and the jumps of section 5. Each of the four numbered features in the figure is associated with formulae relating the parameters labeled in the figure to each other and to the wave speeds. In processing the equations, we observe that the jump condition (5.6) effectively equates wave speeds of simple traveling waves on either side of a jump. Consequently, the four wave speeds are all equal to a single speed c. We combine the following:

(1) A traveling wave with speed c connecting h_L to h_M (see Theorem 4.2):

$$c = \frac{\alpha\left(\frac{1}{6}h_M^3 - \frac{2}{3}h_L^3\right)}{h_M - 2h_L}, \tag{6.1}$$

$$G_M = \frac{\alpha}{3}\frac{(h_L - h_M)(h_M^2 - 2h_L h_M - 2h_L^2)}{h_M(2h_L - h_M)}. \tag{6.2}$$

(2) A simple jump in h, Γ_x (see Theorem 5.6):

$$G_M = -\frac{\alpha}{6h_M}(h_m - h_M)(h_m + 2h_M), \tag{6.3}$$

$$G_m = \frac{\alpha}{6h_m}(h_m - h_M)(2h_m + h_M). \tag{6.4}$$

(3) A simple traveling wave with Γ descending to zero and (4) a simple jump in h (see Theorems 4.1 and 5.4):

$$G_m = \frac{\alpha}{3}\frac{(h_m - h_R)(h_m^2 - 2h_m h_R - 2h_R^2)}{h_m(h_m - 2h_R)}. \tag{6.5}$$

Noting the symmetry in the expressions for G_m and G_M, we solve the equations by treating h_L and h_R as parameters. We can then simplify the equations by equating G_M in (6.2), (6.3) and equating G_m in (6.4), (6.5), giving two simultaneous equations for h_M, h_m:

$$2h_L(h_m^2 + h_M^2 - 2h_L^2) - h_M h_m(h_M + h_m - 2h_L) = 0, \tag{6.6}$$

$$2h_R(h_m^2 + h_M^2 - 2h_R^2) - h_M h_m(h_M + h_m - 2h_R) = 0. \tag{6.7}$$

THEOREM 6.1. *The polynomial equations* (6.6), (6.7) *have two positive solutions for* $0 < h_R/h_L < r^*$, *where* $r^* = \frac{1}{2}(\sqrt{3} - 1)$, *and no solution for* $r^* < h_R/h_L < 1$. *The only relevant solution has* $h_m < h_M$.

Proof. It is perhaps easier to see the structure if we rewrite the variables in (6.6), (6.7):

$$x = h_M, \quad y = h_m, \quad u = h_L, \quad v = h_R.$$

Then the system becomes

$$\begin{aligned} 2u(x^2 + y^2 - 2u^2) - xy(x + y - 2u) &= 0, \qquad \text{(a)} \\ 2v(x^2 + y^2 - 2v^2) - xy(x + y - 2v) &= 0. \qquad \text{(b)} \end{aligned} \tag{6.8}$$

Since $u \neq v$, taking $v(\mathrm{a}) - u(\mathrm{b})$ leads to

$$xy(x+y) = 4uv(u+v). \tag{6.9}$$

Substituting back into (6.8(a)), we get

$$x^2 + y^2 + xy = 2(u^2 + uv + v^2). \tag{6.10}$$

We can eliminate x, since $xy(x+y) = y(x^2+xy)$. Thus, $x^2 + xy = 4uv(u+v)/y$. Substituting into (6.10),

$$y^2 + 4uv(u+v)/y = 2(u^2 + uv + v^2),$$

leaving a cubic in y:

$$y^3 - ay + b = 0, \tag{6.11}$$

where $a = 2(u^2 + uv + v^2)$, $b = 4uv(u+v)$. Consequently, the equation has one negative root and zero, one, or two positive roots, since $u > 0$, $v > 0$. The number of solutions of (6.11) changes from one to three precisely on the curve

$$27b^2 = 4a^3.$$

In terms of u, v this equation is

$$27u^2v^2(u+v)^2 = 2(u^2 + uv + v^2)^3. \tag{6.12}$$

The polynomial $27u^2v^2(u+v)^2 - 2(u^2+uv+v^2)^3$ has three quadratic factors:

$$\begin{aligned} &27u^2v^2(u+v)^2 - 2(u^2+uv+v^2)^3 \\ &\quad = \left(v^2 + 4\,uv + u^2\right)\left(v^2 - 2\,uv - 2\,u^2\right)\left(u^2 - 2\,uv - 2\,v^2\right). \end{aligned}$$

The first factor is positive in the first quadrant, and the other factors have conjugate roots stemming from

$$\frac{v}{u} = \frac{1}{2}\left(\sqrt{3} - 1\right) \equiv r^*,$$

the threshold beyond which we can no longer obtain solutions consistent with (6.1) through (6.5). □

To understand better how the various parameters relate to each other, first we note that $x = h_m$ and $y = h_M$ are interchangeable in (6.8). Without loss of generality, we take $u = h_L = 1$ and rewrite (6.11) as a quadratic equation for v in terms of $y = h_m$ (or h_M):

$$v^2 + v + \frac{y(y^2-2)}{2(2-y)} = 0. \tag{6.13}$$

For $0 < y < \sqrt{2}$, the product of the two roots is negative, so they are real and of opposite sign. In Figure 6, we plot $v = h_R$ on the horizontal axis to clarify that for each choice of h_R, $0 < h_R < r^*$, there are two values of y corresponding to h_m, h_M. From this graph or from (6.13), we see that, as the precursor height $h_R = v \to 0$, we have $h_m \to 0$ and $h_M \to \sqrt{2}$. From (6.3), we find that $G_m \to -\infty$, $G_M \to \frac{\sqrt{2}}{3}$.

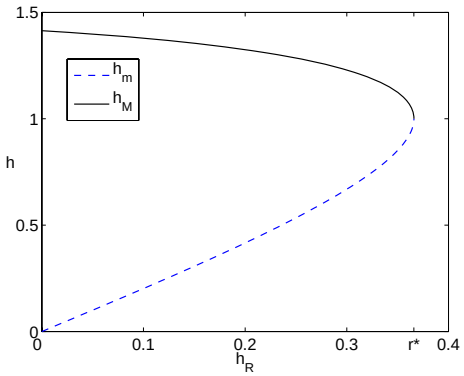

FIG. 6. *Plot of* h_R *versus* h_m, h_M *from* (6.13).

Correspondingly, the speed $c \to \frac{1}{3}$, a value that appears in the proof of Theorem 4.2. That is, if h_M is restricted to lie in the interval $(h_L, \sqrt{2}h_L)$ in Theorem 4.2, then the traveling wave speed is in the interval $\left(\frac{\alpha}{3}h_L^2, \frac{\alpha}{2}h_L^2\right)$. In Figure 6 we observe that h_m, h_M both approach $h = 1$ as $v = h_R$ approaches the threshold $r^* = \frac{1}{2}(\sqrt{3} - 1)$ of Theorem 6.1.

For a film propagating onto a prewetted surface (i.e., with a small precursor height h_R), it might seem reasonable from Figure 6, relating the values of h_M and h_m to h_R, to approximate the height of the step to be twice that of the precursor height. However, for larger precursors this is not a good approximation. The step is always greater than twice the precursor height; in fact, for a given h_R, as h_m approaches $2h_R$, G_M approaches ∞ and the speed of the wave goes to ∞. Moreover, $h_m \to 1$ as $h_R \to r^*$.

In the next section, numerical simulations illustrate the wave structures introduced in the analysis of sections 5 and 6.

7. Numerical simulations II. PDE simulations of (2.3), (2.4) for the inclined substrate illustrate a number of issues presented in the above analysis. First, we explore a combination of linear waves and simple jumps using the analysis of section 6 to choose appropriate initial film profiles. Then we test the stability of linear waves and simple jumps, presented in Theorems 5.4 and 5.6. Next, we explore simulations near the critical threshold r^*. Finally, we vary h_R to observe changes in the wave structures that occur above the threshold.

PDE simulations for linear waves and simple jumps. Equations (6.1)–(6.5) were derived to explain the numerical simulations shown in Figure 4. However, the same equations apply to a combination of linear waves and simple jumps with $\Gamma_L = 0 = \Gamma_R$, all traveling with speed c given by (6.1). The connection between the two structures stems from the limit $\Gamma_L \to 0$ in the nonlinear traveling wave, which does not affect the formulae in (6.1), (6.2).

In the PDE simulations of Figure 7, we choose initial data in which h is piecewise constant and Γ is piecewise linear, consistent with (6.1)–(6.5). The intermediate parameters h_m, h_M, G_m, and G_M annotated in Figure 2 are calculated from (6.6), (6.7), (6.3), and (6.4) for the most common boundary conditions in the simulations,

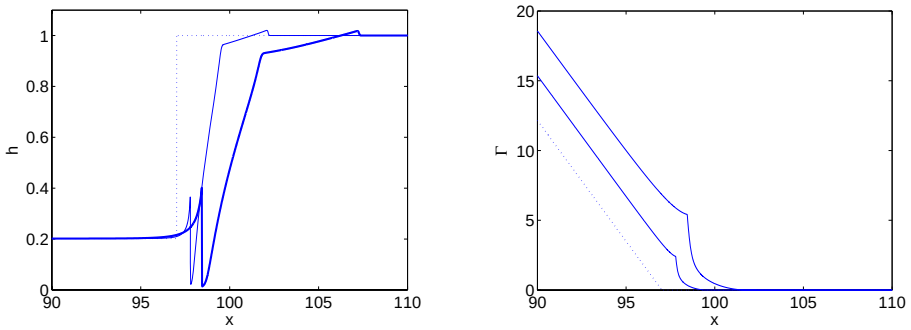

FIG. 8. *Numerical evidence that the linear wave and jump combination of* (5.20) *with* $h_- = 0.2$, $h_+ = 1.0$ *is unstable as in Theorem* 5.4. *Initial data are dotted, and final profiles in bold are at time* $t = 10$.

$h_L = 1.0$, $h_R = 0.1$:

$$h_M = 1.3787; \quad h_m = 0.2019; \quad G_M = 0.4210; \quad G_m = -1.7316. \tag{7.1}$$

The initial data have jumps at $x = 10$, $x = 20$; the initial location of the leading edge of the surfactant is then determined by the data.

In Figure 7, the entire structure moves to the right with speed 0.37 predicted by Theorem 5.4. Note that the maximum value of Γ remains constant, as expected.

Figure 8 provides numerical evidence that the waves conjectured to be unstable in Theorem 5.4 are indeed so. In these plots notice that for the wave emerging from h_L, it appears that $h_x \to \infty$, followed by a jump in the height corresponding to a corner in Γ_x. To the right of the discontinuity, there is a smooth wave preceded by a hydrodynamic wave where there is no surfactant present.

The numerical experiments shown in Figures 9 and 10 explore the wave structure introduced in Theorem 5.6(a). In this case, the positive surfactant gradient creates a linear profile for Γ that travels up the incline and maintains the jump in film height, which can have either sign. The depth-averaged velocity $-\frac{1}{2}hG + \frac{\alpha}{3}h^2$ changes sign across the jump, but the surface velocity $s = -\frac{\alpha}{2}h_+h_-$ is negative, while the jump speed $c = \frac{\alpha}{12}(h_+ - h_-)^2$ is positive. Since $G = \Gamma_x$ is constant, the jump in h is a shock wave solution of (2.3). In general, a jump down satisfies the Lax entropy condition

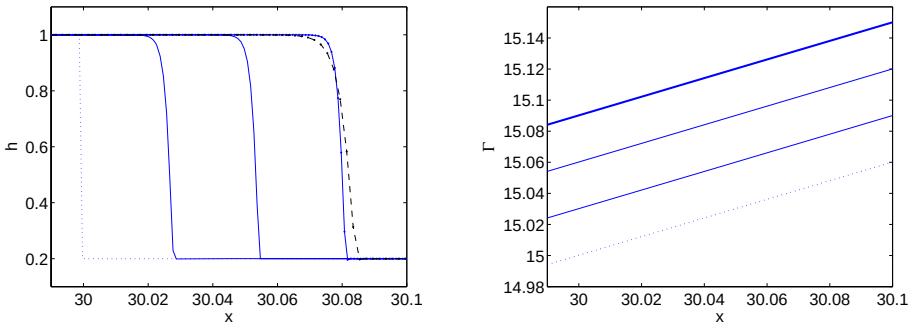

FIG. 9. *PDE simulation of linear wave in* Γ *moving to the left as jump in* h *moves to the right. The initial condition is dotted, and the final profile at time* $t = 1.5$ *is in bold* ($\Delta x = .00025$). *For the height plot, the dashed profile at* $t = 1.5$ *has a more coarse grid* ($\Delta x = .001$); *the consistent location of grid points in the final profile at both mesh sizes and steepening with mesh refinement indicate the presence of a shock.*

and is stable, as in Figure 9, while a jump up is unstable, as shown in Figure 10. In the latter case, it is tempting to think of the spreading solution as a rarefaction, with Γ_x constant, but, in fact, the rarefaction solution fails to satisfy the surfactant equation (2.4).

PDE simulations varying h_R. Figure 11 contains the results of numerical simulation of the PDE with $h_L = 1$ and with h_R just above and just below the threshold of the theorem. For $h_R = 0.365$, below the threshold, the step in h is clearly emerging, but for $h_R = 0.367$, above the threshold, the step fails to emerge. To quantify this observation, in Figure 12 we plot the difference in height Δh between the local maximum near the leading shock and the local minimum immediately behind. Plotted as a function of time in the figure, we observe that Δh approaches zero for $h_R = 0.365$, whereas Δh appears to be converging to a positive value for $h_R = 0.367$.

Numerical PDE simulations with $h_L = 1$, $\Gamma_L = 1$, and $\alpha = 1$ and varying values of h_R below the critical threshold $h_R = \frac{\sqrt{3}-1}{2}$ of Theorem 6.1 reproduce the same pattern of waves shown in Figure 4. In Figure 13 we show the results of PDE simulations for selected values of h_R *above* the critical threshold. These wave structures have not been observed previously, since h_R is generally taken to be the thickness of a precursor

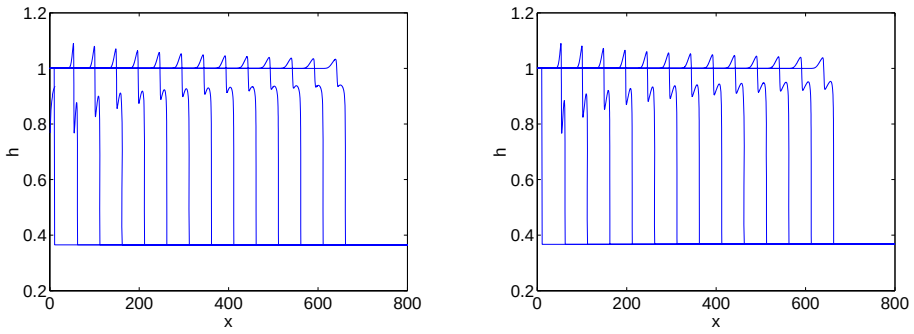

FIG. 11. *Solutions near the transition between solution types.* $h_L = 1$, $h_R = 0.365$ *(left);* $h_L = 1$, $h_R = 0.367$ *(right). Plots are separated by* 100 *time units.*

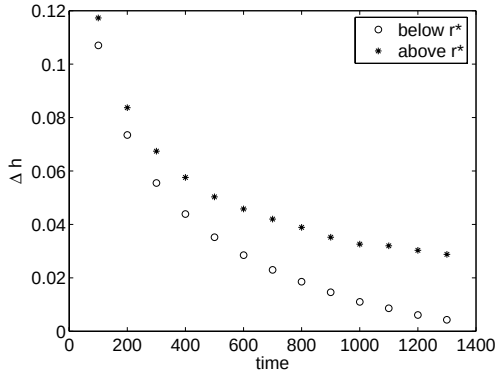

FIG. 12. *Comparison of step heights for the plots in Figure* 11. *As the step forms for the solution below the critical threshold* ($h_R < r^*$)*, the difference* Δh *in maximum and minimum heights within the step goes to zero. layer, and therefore much smaller than h_L. In all of the height plots, a distinctive jog in the height develops, which on the incline resembles a Z-shaped wave. We call this new wave a *Z-wave*, in which a shock is between two smooth waves. By comparison, an N-wave of hyperbolic conservation laws consists of a rarefaction bounded by two shocks. The middle height to the right of the Z is the same as h_L, instead of the step height h_m observed below the threshold.

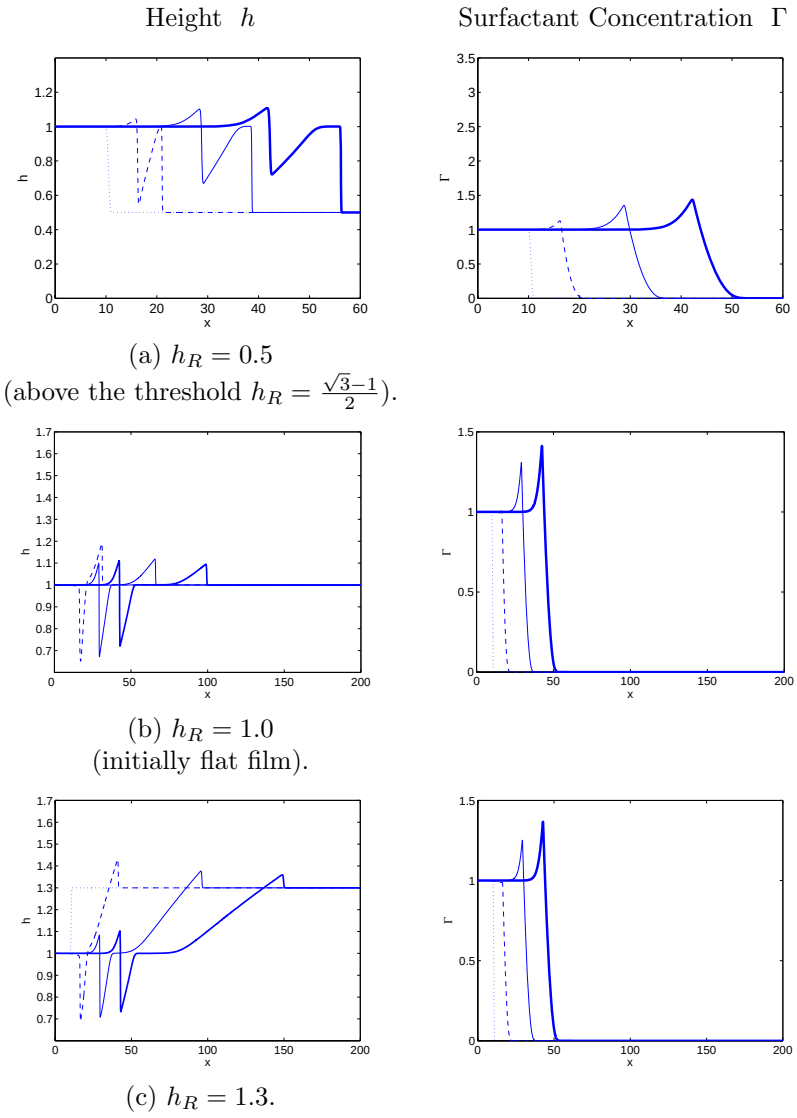
In Figure 13(a), we observe a leading shock (i.e., a jump in h) ahead of the leading edge of surfactant. The shock is a solution of the conservation law

$$h_t + \frac{1}{3}(h^3)_x = 0, \tag{7.2}$$

i.e., (2.3) with $\alpha = 1$ and $\Gamma = 0$. Similarly, in Figure 13(b), the fluid surface is initially flat. The surface tension gradient and gravity force a volume of fluid out ahead of the surfactant, forming a rarefaction wave interacting with a shock, both solutions of (7.2) and decaying in time. For larger values of h_R, as in Figure 13(c), there is also a leading shock being eroded by the rarefaction wave behind it, once again ahead of the surfactant.



(a) $h_R = 0.5$
(above the threshold $h_R = \frac{\sqrt{3}-1}{2}$).

(b) $h_R = 1.0$
(initially flat film).

(c) $h_R = 1.3$.

FIG. 13. *Variation in wave structure for fixed upstream height* $h_L = 1$ *and various downstream heights* h_R. *Each plot has graphs for* $t = 0$ *(dotted line),* $t = 15$ *(dashed line),* $t = 45$ *(thin line), and* $t = 75$ *(bold line).*

The structure of the surfactant profiles is remarkably unchanged over the entire range of h_R. However, Γ appears to reach $\Gamma = 0$ smoothly without the corner observed in simulations with h_R below the critical value.

8. Discussion. The mixed hyperbolic-parabolic system of this paper is derived from the lubrication approximation for the influence of surfactant on flow of a thin liquid film on an inclined plane, neglecting smoothing terms of capillarity and surface diffusion. The analysis of traveling waves and jump conditions leads to the identification of a variety of individual waves.

There are traveling waves in which h and Γ are smooth and nonlinear (Theo-

rem 4.2), and there are three cases in which h is piecewise constant and Γ is piecewise linear:

Neither h nor Γ_x jumps (Theorem 4.1). h is constant and Γ is linear.

Only h jumps (Theorem 5.6(a)). In numerical simulations, we find that jumps down are stable and jumps up are unstable. The stable waves are counterpropagating in that the thin film and surfactant flow up the inclined plane but the jump propagates downwards.

Both h and Γ_x jump (Theorems 5.4 and 5.6). Jumps at $\Gamma = 0$, the leading edge of the surfactant, are related to the step in film height discovered by Borgas and Grotberg [3] for horizontal substrates.

We have constructed an exact solution of the PDE with three jumps that is piecewise constant in h and piecewise linear in Γ and propagates with constant speed. However, this construction is possible only for the ratio of downstream to upstream height below a critical value r^*. This ratio also limits the construction of wave combinations that mimic numerical simulations of initial value problems in which surfactant is supplied from upstream. The supply of surfactant from the boundary has the effect of allowing the maximum surfactant concentration to grow without bound, as shown in Figure 4. This effect is not explained by the analysis, but Taylor series expansions can be used to capture the increase locally in space and time [14].

Above the critical ratio, solutions approach a different structure that we plan to analyze in a future paper. These solutions have a distinctive Z-wave pattern, together with precursor waves propagating into the undisturbed film with no surfactant. As the Z-wave pattern forms, the film height has large dips, which might lead to dewetting. This is a concern in surfactant replacement therapy [13], in which a coating of surfactant is required for healthy lung function. This risk of dewetting does not occur for boundary height ratios below the critical ratio.

While we have discussed stability of waves numerically and to some extent analytically, much remains to be done. It would be interesting to analyze stability of the individual waves for $C > 0$ and $D > 0$. In a future paper, we plan to analyze the constant volume case in which a thin liquid drop on an inclined substrate is spread by the influence of surfactant and gravity.

Acknowledgments. We would like to thank Barry Edmonstone, Richard Craster, and Omar Matar, who introduced us to the problem presented in this paper and who generously shared preliminary versions of their papers. We also thank Andrea Bertozzi and Tom Witelski for helpful suggestions regarding numerics.

INTERACTION OF ADVANCING FRONTS AND MENISCUS PROFILES FORMED BY SURFACE-TENSION-GRADIENT-DRIVEN LIQUID FILMS*

P. L. EVANS† AND ANDREAS MÜNCH‡

Abstract. On a tilted heated substrate, surface tension gradients can draw liquid up out of a reservoir. The resulting film thickness profile is controlled by two parameters, which depend on the tilt of the substrate, the imposed temperature gradient, and the thickness of a postulated thin precursor layer. The evolution of this film in time is studied using a lubrication model. A number of distinct behaviors are possible as the substrate tilt angle and other parameters are varied. Recent results for the multiple stationary profiles possible near the meniscus are used, and the interaction of these profiles with the advancing front is examined. We demonstrate how to systematically determine the evolution of the entire film profile from the meniscus to the apparent contact line. This allows a categorization of the range of behaviors for a transversely uniform profile in a two-dimensional parameter space. In addition to capillary fronts and double shock structures, new combinations that arise for certain ranges of large substrate tilt and precursor thickness are described. These include profiles involving rarefaction fans, connecting to either an undercompressive or a classical wave at the advancing front.

Key words. lubrication theory, Marangoni shear stress, capillarity, traveling waves

1. Introduction.

In this paper we consider the time-dependent behavior of a thin liquid film on a tilted heated substrate. Such a film is produced when a temperature difference is imposed along a substrate with one end immersed into a reservoir containing a liquid such as silicone oil, giving rise to a surface tension gradient. The resulting surface shear stress drags liquid up from the reservoir, while gravitational forces act to return liquid to the reservoir. This may give rise to a film of liquid which climbs up the substrate. The evolution of the film above the reservoir has received considerable attention in recent years [11, 12, 16]. An understanding of thin-film flows driven by surface tension gradients is of importance, for instance, in "Marangoni drying" [9] and controlling flows in microfluidic applications [6].

Experiments (e.g., by Schneemilch and Cazabat [14, 15]) reveal that the film tends to advance with a steep front at a contact line, where the liquid-air interface meets the substrate. Previous studies have considered the film behavior in the vicinity of the meniscus and at the advancing front independently of each other. The advancing front can be a simple compressive one or an undercompressive shock as part of a double wave structure [2, 11]. Furthermore, it is known that at the meniscus, multiple film profiles are possible. For a fixed combination of substrate inclination and shear stress, the meniscus can settle into either of basically two different profiles [13]. In

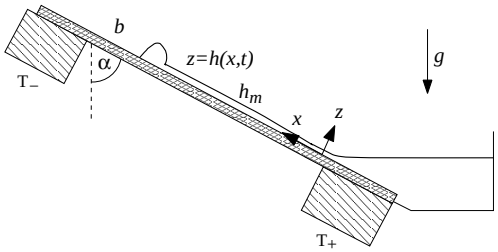

FIG. 1.1. *The thin film on a heated tilted substrate rises from a meniscus. Two heaters hold the temperature at the ends of the substrate at temperatures $T_+ > T_-$. The resulting Marangoni shear stress drives a thin liquid film of thickness $h(x,t)$ up the substrate. At the front, the film advances over a thin precursor layer of thickness b (not shown).*

this paper we determine which meniscus profiles are linked with which traveling wave profiles, and how this link occurs, i.e., which are selected. In the sense that this is a composite description, this work is in the spirit of earlier work by Hocking [7] on the connection between a moving contact line and the meniscus during withdrawal of a moving substrate, which is closely related to the present work. The picture that emerges here for the Marangoni-driven film is, however, more complicated, since we have to include the additional possibility arising from structures involving nonclassical waves in our investigation.

As in our earlier work [13], we consider the arrangement shown in Figure 1.1. The substrate is held at an angle α measured from the vertical, and it is heated so as to impose a uniform temperature gradient $(\mathrm{d}T/\mathrm{d}x) = \gamma < 0$ along the substrate. The film surface tension is σ at some reference temperature, and $\sigma_T = (\mathrm{d}\sigma/\mathrm{d}T) < 0$ is the sensitivity of the surface tension to temperature changes. The shear stress is then $\tau = \gamma\sigma_T$. The film density is ρ, and g is the acceleration due to gravity. We begin section 2 with a statement of the equations governing the film evolution. We then review the evolution of the film at the meniscus and advancing front, considered individually. The former area has been the subject of extensive investigations by us [11, 13] and others, and the latter by Münch, Bertozzi, and others [2, 10].

The dimensionless parameter D was introduced by Bertozzi, Münch, and Shearer [2]. It is a measure of both the substrate angle α and the strength of the surface shear stress driving the flow. Thus

$$D = \left(\frac{3\delta}{\cos^2\alpha}\right)^{2/3} \sin\alpha, \quad \text{where } \delta = \frac{\tau}{2\sqrt{\sigma\rho g}}. \tag{1.1}$$

Bertozzi, Münch, and Shearer [2] define their substrate angle as the complement of α, but their definition of D is equivalent to (1.1). For large inclinations from the vertical (and fixed shear stress) the parameter D is relatively large, and in this case the normal component of gravity is important. A distinct separation between the meniscus and a structure at the advancing front occurs in most circumstances. We build on earlier work, including our preliminary investigation [13], by systematically considering the possible interactions between these structures, and we describe what structures can arise, and the connections between them, in section 3. The combined picture we present is confirmed by dynamical simulations. We also extend previous work by considering the large D limit in section 4. In this case we find that the film can no longer be thought of as separate meniscus and front structures; instead the

film smoothly varies from one to the other without a flat region. The result of our investigations in sections 3 and 4 is a coherent picture of the film behavior as D and the thickness of a presumed precursor layer are varied, which we present in section 5. Finally section 6 summarizes our work.

2. Preliminaries.

2.1. Formulation. We denote the time-dependent film thickness profile by $h(x,t)$, where x measures distance up the substrate and t is time. Using ideas from singular perturbation theory, an evolution equation governing $h(x,t)$ may be obtained [11]. This governing equation is

$$h_t + \Omega_x (h^2)_x - (h^3)_x = -(h^3 \kappa_x)_x + D(h^3 h_x)_x, \tag{2.1}$$

where $\kappa = h_{xx}(1+\epsilon^2 h_x)^{-3/2}$ is the nonlinear expression for the curvature of the free surface. Here $\epsilon = H/L$ (where H and L are given below) is a small parameter, and so $\epsilon \ll 1$. In (2.1), Ω is a dimensionless temperature profile for which $\Omega_x = 1$ except near the heaters, where Ω becomes constant, cutting off surface tension gradients there. Equation (2.1) is obtained by scaling h, x, and t by

$$H = \frac{3\tau}{2\rho g \cos\alpha}, \quad L = \left(\frac{3\sigma\tau}{2\rho^2 g^2 \cos^2\alpha}\right)^{1/3}, \quad T_0 = 2\mu\left(\frac{4\sigma\rho g\cos\alpha}{9\tau^5}\right)^{1/3},$$

respectively. The terms in h^2 and h^3 on the left-hand side of (2.1) account for the competing effects of the imposed shear stress and drainage due to the component of gravity parallel to the substrate. The first term on the right-hand side is due to surface tension, which is supposed to not differ appreciably from its reference value, except inasmuch as it provides the driving shear stress. The second arises from the leveling effect of the component of gravity normal to the substrate. It is useful to define the flux function, $f(h) = h^2 - h^3$, which represents the flux of liquid up the substrate in the absence of the second- and fourth-order smoothing terms in (2.1).

As explained in our earlier work [13], when $\epsilon = H/L = (9\delta^2/\cos\alpha)^{1/3} \ll 1$, it is appropriate to replace κ by the approximate expression h_{xx} in the thin film region away from the reservoir. In addition, when $\epsilon \ll D$ it follows that $\epsilon|h_x| \ll 1$ in the vicinity of the reservoir, and approximating κ by h_{xx} is also appropriate there. We set $\Omega_x \equiv 1$, requiring that as α is increased the position of the heater is moved further into the reservoir, i.e., towards large negative x values. In this way a uniform temperature gradient, and hence uniform shear stress, is imposed. Equation (2.1) then reduces to

$$h_t + (h^2 - h^3)_x = -(h^3 h_{xxx})_x + D(h^3 h_x)_x. \tag{2.2}$$

An appropriate boundary condition at the meniscus is that the film profile flattens out to meet the undisturbed reservoir, so $\partial h^*/\partial x^* \sim -\cot\alpha$ in dimensional units. After rescaling, this yields

$$h \sim -x/D \qquad \text{as } x \to -\infty. \tag{2.3}$$

To avoid the singularity associated with a moving contact line, we adopt a precursor model so

$$h \to b \qquad \text{as } x \to \infty \tag{2.4}$$

and define the apparent contact line to be the point where the film thickness first becomes approximately b.

We are concerned with the behavior of solutions of (2.2) subject to (2.3) and (2.4). Solutions of (2.2)–(2.4) are potentially influenced by just two parameters, D defined by (1.1) above and the precursor layer thickness, b. A particular combination of these parameters determines the structure of the climbing film, including the meniscus. In the following sections, we enumerate and describe the possible film structures.

Solutions of (2.2) typically have two distinct parts, a meniscus and a wave structure consisting of one or two advancing waves. Near the reservoir the meniscus part settles into an equilibrium solution with thickness approaching some value h_m. Immediately behind the moving apparent contact line, where the film abruptly decreases to the precursor, is a traveling wave, which we refer to as the "advancing front." Behind it may be additional waves that, together with the advancing front, make up the moving wave structure.

A good guide to the possible behavior of the complete film comes from considering what happens in the two parts independently. In the remainder of this section, we first describe the waves near the contact line. Here the resulting wave structure is determined by a left thickness h_w, together with D and b. We then (in section 2.3) summarize what limiting meniscus thicknesses h_m are possible for a given D. We assume that the precursor thickness b is the smallest thickness scale that appears in the film profile, and so we consider only cases where $h_w > b$.

2.2. Advancing front behavior. The wave dynamics that arise at and behind the rising contact line have been investigated in detail in recent years [1, 2, 10] by considering solutions of (2.2) with initial data that connect flat left and right states where the film profile thicknesses are h_w and b, respectively. To capture the large scale structure of the emerging waves, we rescale $x = x^*/\lambda$ and $t = t^*/\lambda$ in (2.2) and let $\lambda \to 0$. We find that (2.2) is a nonlinear perturbation of the scalar conservation law (dropping the asterisks),

$$h_t + [f(h)]_x = 0, \qquad f(h) \equiv h^2 - h^3. \tag{2.5}$$

We first discuss the situation when (2.5) is considered as the limit of the problem with exclusively nonlinear second-order diffusion, i.e., of the equation

$$h_t + [f(h)]_x = (h^3 h_x)_x. \tag{2.6}$$

One quickly finds that traveling wave solutions of (2.6) with left and right far-field conditions $h_w > b$ and b, respectively, exist precisely if $h_w \le h_{\rm int} \equiv (1-b)/2$. In the limit of vanishing second-order diffusion, these traveling waves correspond to shock solutions of (2.5), i.e., jump discontinuities

$$h(x,t) = \begin{cases} h_w & \text{if } x < st, \\ b & \text{if } x > st, \end{cases} \tag{2.7}$$

that move according to the Rankine–Hugoniot condition,

$$s = s(h_w, b) = (f(h_w) - f(b))/(h_w - b). \tag{2.8}$$

If, however, $h_w > h_{\rm int}$, a double wave structure forms, which corresponds to a rarefaction-shock solution of (2.5),

$$h(x,t) = \begin{cases} h_w & \text{if } x \le f'(h_w)t, \\ f'^{-1}(x/t) & \text{if } f'(h_w)t \le x \le f'(h_{\rm int})t, \\ b & \text{if } x \ge st, \end{cases} \tag{2.9}$$

where the speed $s = s(h_{\rm int}, b)$ of the shock between the intermediate height $h_{\rm int}$ and b also satisfies $s = f'(h_{\rm int})$.

This solution structure is consistent with the classical theory of conservation laws, which admits only Lax (also called compressive) shocks in solutions of (2.5), i.e., shocks that satisfy the Lax entropy condition

$$f'(b) < s < f'(h_w), \tag{2.10}$$

which stipulates that characteristics from both states must cross the shock trajectory, or at most the limits of Lax shocks, sometimes called *generalized Lax* shocks, where one of the inequalities is replaced by an equality. The shock in (2.9) is an example of a generalized Lax shock.

Returning to the situation where (2.5) is considered to be the limit problem of (2.2), we find that new combinations of waves that include nonclassical undercompressive shocks which violate (2.10) arise for $D = 0$, i.e., pure fourth-order diffusion, and for a range of $D > 0$. These waves have been studied in detail for $D = 0$ by Bertozzi, Münch, and Shearer [2] and for general D by Münch [10]. This investigation was carried out via numerical simulations of (2.2) and by systematic determination of the traveling wave solutions $h(x,t) = h(\xi)$, $\xi = x - st$ with far-field states h_- as $\xi \to -\infty$ and b as $\xi \to \infty$. Inserting this ansatz into (2.2), we obtain, after integrating once and using the far-field condition, the third-order ODE

$$h''' = -Dh' + f(h) - f(b) - s(h - b), \qquad ' \equiv {\rm d}/{\rm d}\xi, \tag{2.11}$$

with the wave speed $s = s(h_-, b)$ given by (2.8). This ODE was systematically investigated via phase space methods [2, 3, 10]. Traveling wave profiles appear as heteroclinic connections between the equilibria of (2.11), formed by the intersections of invariant manifolds. These can be computed numerically by following individual trajectories on the manifolds, and the intersections of invariant manifolds can be tracked (as b is varied) in Poincaré sections.

We now summarize the results of these studies on the solution of (2.2) connecting h_w and b. For $D = 0$ and a fixed value for $b < 1/3$, four different situations arise as $h_w > b$ is increased. For $b < h_w < h_{ii}(b)$, with a b-dependent upper bound, a compressive wave arises. In contrast to the case of second-order diffusion, which smooths the shock to a monotonic profile, the fourth-order diffusion induces a capillary ridge (see Figure 2.1, lower left corner). Furthermore, in a thin region $h_i(b) < h_w < h_{ii}(b)$, multiple traveling wave solutions of (2.2) exist that correspond to the same compressive shock. These waves differ by the width of their capillary ridge. Furthermore, for $1 - h_{\rm uc} - b < h_w < h_{ii}(b)$, double shocks composed of a Lax and an undercompressive shock are also possible; $h_{\rm uc}$ and undercompressive shocks are explained below. However, for $h_w < h_{ii}(b)$, monotonic initial data for (2.2) typically gives rise to the compressive wave with the smallest capillary ridge. For $h_{ii}(b) < h_w < h_{\rm uc}(b)$ a double shock results,

$$h(x,t) = \begin{cases} h_w & \text{if } x \le s(h_w, h_{\rm uc})t, \\ h_{\rm uc} & \text{if } s(h_w, h_{\rm uc})t \le x \le s(h_{\rm uc}, b)t, \\ b & \text{if } x \ge s(h_{\rm uc}, b)t, \end{cases} \tag{2.12}$$

where the trailing shock that connects the states h_w and $h_{\rm uc}$ is a Lax shock, and the leading shock from $h_{\rm uc}$ to b is undercompressive; i.e., it violates the Lax entropy condition (2.10) in that characteristics only enter from the right. The undercompressive

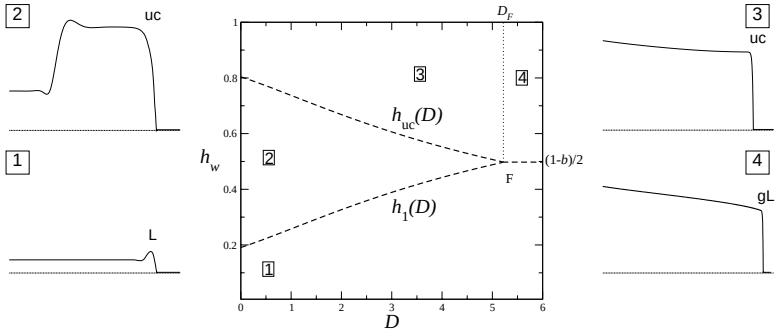

FIG. 2.1. *The front wedge diagram for $b = 0.005$ showing the four possible types of advancing front behavior, depending on D and the left state value h_w. Surrounding subfigures show qualitatively the behavior observed in each of regions 1 to 4: region 1—compressive front; 2—double shock structure (compressive and undercompressive waves); 3—rarefaction fan and undercompressive front; 4—rarefaction fan and generalized Lax shock. These regions are described further in the text. Labels indicate the type of front: L—Lax shock; uc—undercompressive shock; gL—generalized Lax shock.*

wave arises as a codimension one intersection of invariant manifolds for (2.11) and for a given b (and D) appears only for a specific value of the left state, $h_{\rm uc}$. (In contrast, compressive waves arise as codimension zero intersections.) In practice, a shooting method allows easy computation of $h_{\rm uc}(D, b)$ and hence the shape of the wedge. The trailing wave moves at a slower speed, so that the width of the plateau separating the two waves grows in time. The profile of a numerical solution of (2.2) corresponding to such a double shock is shown in the upper left corner of Figure 2.1. The emergence of nonclassical undercompressive shocks as one passes a certain threshold for h_w has been interpreted as "nucleation" [8].

For $h_w > h_{\rm uc}$, we get a rarefaction-undercompressive shock wave combination,

$$h(x,t) = \begin{cases} h_w & \text{if } x \le f'(h_w)t, \\ f'^{-1}(x/t) & \text{if } f'(h_w)t \le x \le f'(h_{\rm uc})t, \\ h_{\rm uc} & \text{if } f'(h_{\rm uc})t \le x \le s(h_{\rm uc}, b)t, \\ b & \text{if } x \ge s(h_{\rm uc}, b)t. \end{cases} \tag{2.13}$$

Note that since the shock is undercompressive, i.e., $f'(h_{\rm uc}) < s(h_{\rm uc}, b)$, it separates from the leading edge of the trailing rarefaction wave. The upper right corner of Figure 2.1 shows the corresponding solution of the full PDE (2.2).

The results for general values of D as described by Münch [10] may be summarized in a two-dimensional diagram that displays, for each D, the values of left states h_w where the different types of wave or waves connecting this state to the precursor right state b exist. In the (D, h_w) plane, the boundaries between these different ranges essentially form a wedge-like shape, shown in Figure 2.1 for the precursor thickness $b = 0.005$. This shape is defined by the graphs of $h_{\rm uc}(D, b)$ (at the upper edge) and $h_1(D, b) = 1 - h_{\rm uc} - b$ (lower edge). We refer to this shape as the "front wedge."

Because $h_{\rm uc}$ depends on b, the shape and position of the front wedge on a (D, h_w) diagram also depends on b. The apex of the wedge (shown as F in Figure 2.1) is located at $(D_F, (1-b)/2))$, where D_F is itself a monotonically decreasing function of b. The significance of this will become apparent in section 3. The two sides of the wedge, together with the extension of the wedge's apex $\{(D, h) : D > D_F,\ h = (1-b)/2\}$ and the line $\{(D, h) : D = D_F,\ h > (1-b)/2\}$ divide the plane into four regions,

labeled 1–4 in the figure. Which wave structure results from a particular (D, h_w) pair is indicated by the region in which the pair belongs, as follows:

1. For relatively small values of h_w, corresponding to region 1, a simple compressive wave arises. This wave has a capillary ridge that diminishes as D increases.
2. Within the wedge (region 2), one obtains the compressive-undercompressive double shock structure described above.
3. For large values of h_w, one obtains double wave structures involving a rarefaction fan; these are either a rarefaction-undercompressive wave when $D < D_F$ and $h_w > h_{\rm uc}$ (region 3), or
4. a rarefaction-shock wave (with a leading generalized Lax shock), for larger D (region 4).

The sketches for regions 3 and 4 in Figure 2.1 differ in the profile behind the leading undercompressive wave. In the former, the rarefaction wave separates from the leading shock, giving rise to a convex portion behind the front, while the latter profile is concave right up to the shock. In region 3, the rarefaction wave separates from the leading shock, but not in region 4. To the right of the apex ($D > D_F$) there are no structures involving undercompressive waves: above $(1 - b)/2$ there is a rarefaction-shock wave combination, while below this line a simple compressive wave occurs. Existence of undercompressive shock solutions for D less than some finite upper bound, and nonexistence for sufficiently large D, was proved by Bertozzi and Shearer [3].

We have limited the above discussion to values of $h_w > b$. In this study, the initial film profiles used have thickness $h \geq b$ everywhere, and so the thickness at later times is never much smaller than b.

In addition, we have simplified matters by neglecting the presence of a thin region of thicknesses h_w located around the lower side of the wedge. This exists for a range of D close to zero, where multiple wave structures that connect h_w to b are possible, either one of a number of compressive waves or the double shock structure. This range ends towards the right at a value D (say D_1) below two [10]. Which wave structure is selected in a numerical simulation depends on the initial profile; for monotonic initial data connecting h_w and b, a single compressive wave with the smallest capillary ridge typically arises [1, 2]. Hence for such initial data and $D < D_1$, the range of h_w for which we get a single compressive front is slightly increased above the lower edge of the wedge.

2.3. Meniscus structures. At the meniscus, the profile should become stationary after the contact line has moved away, up the inclined substrate. Hence, of primary interest here are the stationary solutions of (2.2) with far-field condition (2.3) as $x \to -\infty$ and a flat right state $h \to h_m$ for $x \to \infty$. Letting $h_t = 0$ and integrating once yields the ODE

$$h_{xxx} = Dh_x - (f(h) - f(h_m))/h^3. \tag{2.14}$$

Note that the constant of integration $Q = f(h_m)$ represents the total flux through the flat film. In earlier work [13] we investigated this boundary value problem by numerically exploring the relevant invariant manifolds in the three-dimensional phase space associated with (2.14). Solutions satisfying the far-field conditions as $x \to -\infty$ form a two-dimensional invariant manifold, while those that tend to a constant film thickness h_m as $x \to \infty$ form either a one- or a two-dimensional (stable) invariant manifold

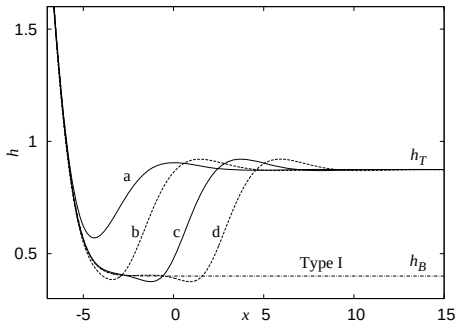

FIG. 2.2. *The first two stable and first two unstable Type* II *steady meniscus profiles, for* $D = 0.322$. *The profiles labeled a and c are stable, while b and d are unstable. Here* $h_m = h_T(0.322) = 0.8744$, *so there are an infinite number of these profiles. Also shown is the Type* I *meniscus profile for this value of D; it has* $h_m = h_B(0.322) = 0.4002$.

when either $h_m < 2/3$ or $h_m > 2/3$, respectively. Hence the stationary meniscus profiles correspond to either codimension one or codimension zero intersections of the invariant manifolds, respectively, and we call these Type I meniscus solutions in the former, and Type II meniscus solutions in the latter, case. While Type I solutions monotonically decrease in thickness as they approach h_B, Type II solutions typically have a characteristic depression or dimple in the meniscus region, particularly for sufficiently small values of D, followed by damped oscillations as $x \to \infty$ (Figure 2.2). The dimple and the oscillations can be suppressed by the normal component of gravity, i.e., for larger values of D.

The Type I solutions are structurally unstable and, for given D, exist only for discrete values of h_m. In fact, for a range of values $D < D_M = 0.8008$, numerical exploration of the phase space [13] shows that a unique Type I solution exists for a single thickness $h_m = h_B(D)$, while there are none at all for $D > D_M$. In the range $D > D_M$, Type II meniscus profiles exist for all $h_m > 2/3$, while for $D < D_M$, the situation is more complicated. We define $h_T(D)$ to be the larger positive root h of the cubic equation $f(h) = f(h_B)$, so that $h_T > 2/3$. Then Type II solutions can always be found for $h_m \geq h_T(D)$. In addition, for $D < D_B = 0.7142$, Type II solutions exist for a range of thicknesses h_m slightly below $h_T(D)$, down to a value $h_*(D)$. Moreover, when h_m is near $h_T(D)$, in the range $h_*(D) < h_m < h_{**}(D)$, with a D-dependent value $h_{**}(D) > h_T(D)$, multiple Type II solutions appear with the same thickness h_m; their profiles differ by the depth and width of the dimple, as shown in Figure 2.2. The profiles of four of the multiple Type II menisci are shown in Figure 2.2 for $D = 0.322$ and $h_m = h_T(0.322) \approx 0.8744$. (The corresponding Type I profile for this value of D is also shown.) The question of which, if any, of the Type II menisci are stable to in-plane disturbances then arises. Numerical simulations of the time-dependent PDE (2.2) revealed that these meniscus solutions are alternately stable and unstable. These simulations were initialized using the Type II profiles computed by a shooting method [13]. The unstable solutions to the ODE do not occur as solutions of the PDE at long times; instead, initial conditions which are close to these evolve toward the stable solutions. In Figure 2.2 the stable and unstable solutions are shown as solid and dashed lines, respectively.

Figure 2.3 summarizes the solution structure, showing the thicknesses $h_B(D)$ and $h_T(D)$ controlling Type I and Type II solutions in the (D, h) plane. These values

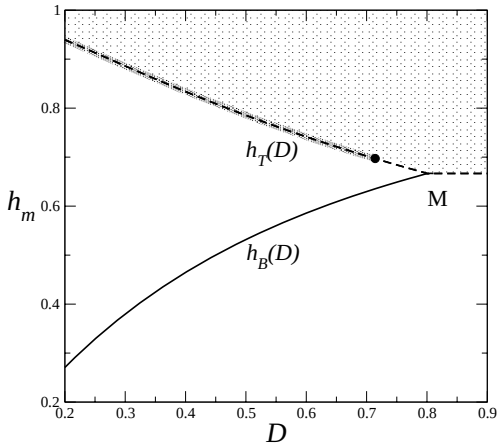

FIG. 2.3. *The meniscus wedge diagram. Lines show the allowable values for the right state of the meniscus, h_m. For $D < D_M$, the meniscus may approach a thickness h_m, where either $h_m = h_B(D)$ is given by the lower branch (a Type* I *solution) or h_m lies above the upper branch, i.e., $h_m > h_T(D)$ (a Type* II *solution). The dark shaded line indicates where multiple Type* II *menisci are possible for a range of values h_m above and below $h_T(D)$. For $D > D_M$, Type* I *solutions are not possible, but Type* II *solutions exist for all h_m above* 2/3. *The light shaded region shows where one or more Type* II *menisci are available.*

merge with $h = h_T = h_B = 2/3$ when D approaches D_M, at the point labeled M in the figure. We call the structure formed by the graphs of $h_T(D)$ and $h_B(D)$ the "meniscus wedge." Note that it does not depend on b. One or more Type II solutions exist at points in the light shaded region. The range of thicknesses with multiple Type II solutions is not precisely shown in Figure 2.3, but is indicated there by the dark shaded line along $h_T(D)$, ending in a solid dot in the figure at $D = D_B$.

3. Interaction of meniscus and front dynamics. The information summarized in section 2.2 and encapsulated in the front wedge diagram gives a fairly complete picture of which wave, or combination of waves, arises near the contact line if, for given b and D, the leftmost value of the film thickness is set at some specific value, h_w. The question of how this value is selected then arises; it is evident that the meniscus plays an important role here. If at long times, when the contact line has traveled far from the reservoir, the meniscus profile approaches a steady state, then the value of h_w must be equal to an h_m for which either a Type I or Type II solution exists. This information is found in the "meniscus wedge" diagram in section 2.3. An overview of the possible combinations of the different types of meniscus and wave structures can be obtained by superimposing the two wedge diagrams. In many cases, this suggests more than one possible outcome for a given D and b. For example, if $D < D_M$, wave structures can be found to connect either to a Type I meniscus or to a whole range of Type II menisci. However, the only situations which can arise dynamically are those for which the wave part next to the meniscus has a nonnegative speed. (If its speed were negative, such a wave part could never emerge from the meniscus.) Rarefaction waves, or parts of rarefaction waves, move with a wave speed given by characteristics, namely $f'(h)$, where the film thickness is h. For shock profiles, with left and right states h_- and h_+ the wave speed s is given by the Rankine–Hugoniot condition, $s = (f(h_+) - f(h_-))/(h_+ - h_-)$.

In this section we use such considerations to determine which meniscus and film

profile eventually evolves from monotonic initial data representing a thin precursor layer on a substrate which is partially immersed into the reservoir. The approach outlined above nearly always allows us to single out one possible scenario. The exceptions will be pointed out further below. We then verify our predictions using time-dependent simulations of (2.2). To obtain numerical solutions we use finite difference schemes on a finite spatial domain, $[0, L]$. At the left-hand boundary, we specify $h = H_0$ to be a large constant (typically 20–50) and impose $h_{xxx} = 0$. At the right-hand boundary, $h_x = h_{xxx} = 0$. Solutions are advanced in time using an implicit Euler scheme. The time step is controlled using a step-doubling approach.

Simulations began from an initial profile $h(x, 0) = h_0(x)$. The form used for h_0 was generally

$$h_0(x) = \begin{cases} D^{-3/2}\left(\exp(D^{1/2}x) - D^{1/2}x - 1\right) + b & \text{for } x \le 0, \\ b & \text{for } x > 0. \end{cases} \tag{3.1}$$

This represents the static meniscus which arises through the balance of mean surface tension and gravity for $x < 0$, and joins smoothly to the precursor layer at $x = 0$. Other initial profiles, including the function

$$h_0(x) = \frac{\log(2\cosh(ay)) - ay}{2a} + b, \tag{3.2}$$

where $y = x/D - 20$ and $a = 0.4$, were also used. This has slope -1 for $x \to -\infty$, and has $h_0 \to b$ as $x \to \infty$. We also used

$$h_0(x) = \max\left(-x/D, b\right).$$

The particular choice did not alter the qualitative behavior of the film.

As explained in section 2.2, the apex of the front wedge at $D = D_F$ moves towards smaller values of D as b is increased. Following Bertozzi, Münch, and Shearer [2], b is restricted to be less than $1/3$. Depending on b, the front wedge and meniscus wedge can therefore overlap in four characteristic arrangements, leading to four different cases. In increasing order of b, these are as follows:

A. The most important case is for small b, i.e., a very thin precursor layer. In this case D_F is large, and $h = (1-b)/2$ is close to its maximum value of $1/2$. The upper part of the front wedge $h_{\rm uc}(D)$ makes intersections with both $h_T(D)$ and $h = 2/3$. This is the arrangement which results when $b = 0.005$; it is shown in Figure 3.1(a). Here a line marked with circles indicates the left state of the advancing front h_f, while the right state of the meniscus $h_m = h_w$ is shown by crosses, for each value of D. It continues until $h_{\rm uc}(D_M, b) = 2/3$; this happens for $b = 0.0202$ (to four decimal places).

B. For larger b, the line $h_{\rm uc}(D)$ makes only one intersection with the meniscus wedge, and this is now along the lower branch $h_B(D)$. Figure 3.1(b) shows the situation for $b = 0.05$. At $b = 0.1484$, the apex of the meniscus wedge and that of the front wedge are at the same value of D, i.e., $D_F = D_M$.

C. In the third case (for $0.1484 < b < 0.2338$ to four decimal places), $D_F < D_M$, but $h_B(D_F) > (1-b)/2$, so the graph of $h_{\rm uc}(D)$ still intersects $h_B(D)$. The significance of this is explained below. Figure 3.1(c) shows this case when $b = 0.16$.

D. For the largest b ($b > 0.2338$ to four decimal places) D_F is small enough that the merger at $D = D_F$ happens with $h = (1-b)/2 > h_B(D)$, i.e., above and to the left of the line $h_B(D)$ (see Figure 3.1(d) for $b = 0.25$).

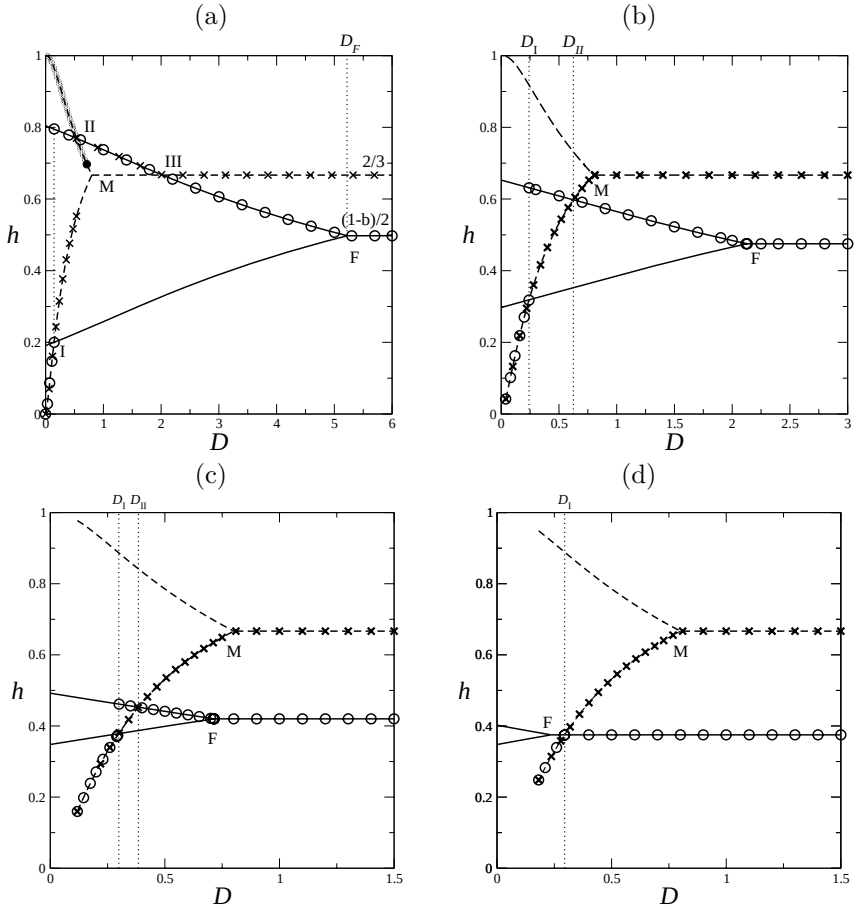

FIG. 3.1. *The (D, h) diagrams, showing the front wedge (solid lines) and meniscus wedge (dashed lines). A line marked with circles indicates the left state, h_f, of the advancing front. A line with crosses indicates the right state of the meniscus, h_m. When these lines coincide, there is a flat film region directly connecting the meniscus to the advancing front.* (a) *Case A, when $b = 0.005$;* (b) *Case B for $b = 0.05$. In* (b)*, a new profile featuring a Type* I *meniscus connected to a rarefaction fan becomes possible for D between $D_{\rm II}$ and D_M.* (c) *Case C, $b = 0.16$;* (d) *Case D, $b = 0.25$. In Case C, $D_F < D_M$, requiring a connection between h_B and $(1 - b)/2$ for $D_F < D < D_M$. In Case D, D_F is so small that the front wedge does not intersect h_B at all.*

3.1. Case A: Thin precursor layer. We first define $D_{\rm I}(b)$ to be the solutions of

$$h_B(D) = h_1(D, b) = 1 - b - h_{\rm uc}(D,\, b);$$

thus, for a given value of b, $(D_{\rm I}, h_B(D_{\rm I}))$ is the point in the (D, h) diagram where the lower sides of the two wedges intersect. We also define $D_{\rm II}(b)$ and $D_{\rm III}(b)$, denoting the solutions of

$$h_T(D) = h_{\rm uc}(D,\, b) \quad \text{and} \quad h_{\rm uc}(D, b) = \frac{2}{3},$$

respectively. These define the intersection of the upper side of the front wedge with the upper side of the meniscus wedge or the line $h = 2/3$, respectively, and are

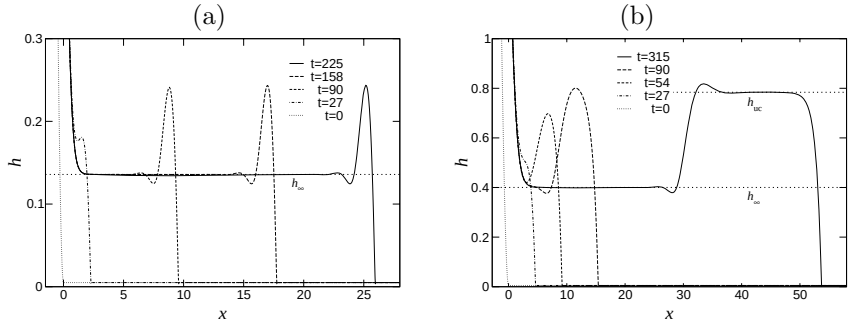

FIG. 3.2. *Numerical solutions of* (2.2) *when* (a) $D = 0.1021$ *and* (b) $D = 0.322$. *Film profiles are shown at dimensionless times given in the legends. In* (a) *there is a single compressive wave, while in* (b) *an undercompressive-Lax double shock develops and travels up the substrate. There is a thin precursor film of thickness* $b = 0.005$ *in both cases.*

shown as points II and III on Figure 3.1(a). When $b = 0.005$, the numerical value for $D_{\rm I} = 0.1461$. The other special values of D given in this section are also for $b = 0.005$.

We begin with the smallest D (but sufficiently large that $h_B > b$) and argue that the meniscus must be of Type I there. First, consider values of $D < D_{\rm I}$. Suppose that the meniscus is of Type II, with a right state thickness $h_m \geq h_T$. In this range of D, h_T in turn is larger than $h_{\rm uc}$. A connection from h_m to the precursor would involve a rarefaction fan followed by an undercompressive wave joining to b. However, the left part of the rarefaction fan would have negative speed, and therefore would fall back into the meniscus. Hence such a solution cannot persist.

On the other hand, if the meniscus is of Type I, then $h_m = h_B < h_1$, and a simple compressive connection to the precursor is possible. This is connected by a flat film to a steadily advancing front. The left state of the advancing front and the right state of the meniscus are identical in this case, since the two are directly connected. Our dynamical simulations for $D = 0.1021 < D_{\rm I}$ and $b = 0.005$ (Example 1 in [13], also shown in Figure 3.2(a)) confirm that this combination of Type I meniscus and a simple compressive wave occurs. The flat region thickness in this case is controlled by the meniscus.

When D is increased above $D_{\rm I}$, the graph of $h_B(D)$ enters the undercompressive region of the front wedge. In place of a simple compressive connection, a Type I meniscus must now connect to a double shock structure. A Type II meniscus is still not possible, for the same reason as in the previous case, namely that $h_T > h_{\rm uc}$ while $D < D_{\rm II}$. Now the left state of the advancing front is the undercompressive wave height $h_{\rm uc}$. The flat region ahead of the meniscus, with thickness h_B, is connected to $h_{\rm uc}$ by the trailing compressive part of the double wave structure. This trailing shock moves upwards, but somewhat slower than the advancing front. In the (D, h) diagram, Figure 3.1(a), the line marked by circles jumps to $h_{\rm uc}$ at $D = D_{\rm I}$, separating from the line portion emphasized by crosses.

In section 2.2 it was noted that when D is small, compressive waves exist for $h_w < h_{ii}$, where h_{ii} is slightly larger than h_1. For $h_1 < h_w < h_{ii}$, the meniscus can be connected to either a double shock structure or to one of several compressive waves. These all have positive wave speeds, and which one is selected depends on the initial data. Due to the experience with monotonic (jump) initial data, we expect that the simplest compressive wave is selected if $h_B < h_{ii}$. The net effect of this is that, for the initial profiles considered in this paper, the transition from a compressive front to

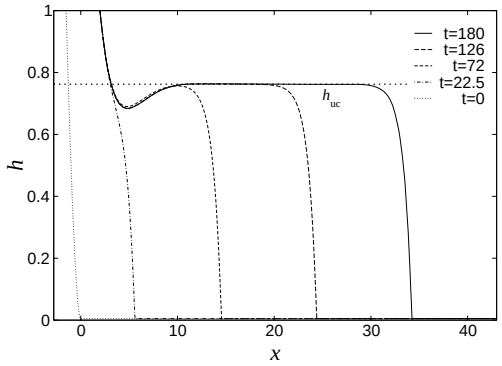

FIG. 3.3. *Evolution of* (2.2) *for* $D = 0.6424$ *at dimensionless times given in the legends. Only the undercompressive shock propagates away from the meniscus, which evolves into a Type* II *meniscus. Again the precursor layer thickness is* $b = 0.005$.

a double shock is delayed and occurs for a value D_I' slightly larger than D_I. Indeed, for $b = 0.005$ we find that this transition occurs for D between 0.16 and 0.18, instead of precisely at $D_{\mathrm{I}} = 0.1461$.

This behavior continues until $D = D_{\mathrm{II}}$, the value of D at which $h_{\mathrm{uc}} = h_T$ and the upper sides of the two wedges cross. For $b = 0.005$, D_{II} equals 0.535. A double shock structure moving up the substrate is shown for $D = 0.322$ in Example 2 of [13], and also in Figure 3.2(b) just as we described it here.

For $D_{\mathrm{II}} < D < D_{\mathrm{III}}$, h_{uc} is larger than h_T, and so it is in the region where Type II meniscus solutions are possible. Hence a direct undercompressive shock connection from a Type II meniscus to the precursor is possible. (The existence of multiple Type II solutions for h near h_T means that a Type II solution is available for matching to h_{uc} via a direct connection at values of D slightly below D_{II}.) These continue until $D = D_{\mathrm{III}}$; for $b = 0.005$, $D_{\mathrm{III}} = 2.025$. For $D < D_{\mathrm{III}}$, h_{uc} is larger than 2/3. Thus we can rule out connections involving intermediate waves as follows. Only shocks can connect to h_{uc} from below (since characteristics for the left and right state would cross, ruling out a rarefaction fan), and these would have a negative speed. Similarly, any wave connection from above must be a rarefaction fan, all parts of which would also have a negative speed.

As a result, the only structure possible is a Type II meniscus connecting directly to a flat state with thickness h_{uc}. This flat state is the left state of an undercompressive shock connection to the precursor. The right state of the meniscus and the left state of the advancing front are again identical, and in Figure 3.1(a) the lines marked by crosses and circles coincide. It is notable that in this range of D the thickness of the flat region, h_{uc}, is determined by the precursor thickness, not by the meniscus. We therefore refer to these structures as "front controlled." This situation in this range is exactly what is observed for Example 3 from [13] and in Figure 3.3, where $D = 0.6424$.

Once again, this description has to be slightly amended. The reason is that, for $D < D_B = 0.7142$, Type II menisci exist even for h_m below h_T (down to the value h_* introduced in section 2.3). Hence, in principle, they can arise and connect directly to an advancing front for values slightly smaller than D_{II}, as an alternative to a double shock structure rising from a Type I meniscus. Furthermore, in the range from h_* to $h_{**} > h_T$, mentioned in section 2.3, different Type II meniscus solutions sharing the

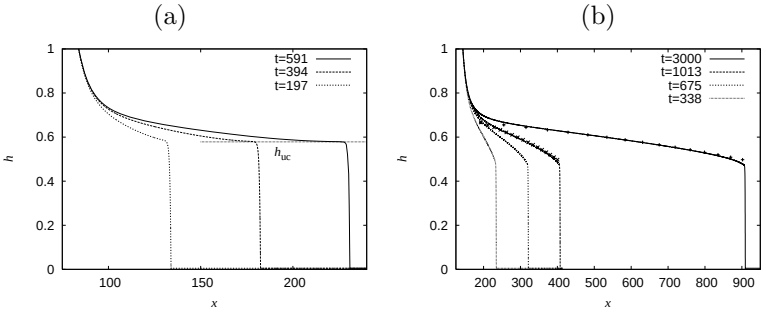

FIG. 3.4. (a) *Evolution of* (2.2) *when* $D = 3.5$ *and* $b = 0.005$*, so* $D < D_F$*. The front is undercompressive. A small flat region of thickness* $h_{\rm uc}$ *(indicated by a dotted line) gradually develops behind the front.* (b) *With* D *increased to* 6*, larger than* D_F*, the front is a generalized Lax shock. The rarefaction fan is also shown at* $t = 3000$ (+ *symbols*) *and* $t = 1013$ (×)*; it was obtained by solving the scalar hyperbolic conservation law as described in detail in section* 4.

same value for h_m exist. Hence, in the thin range of values of D for which $h_{\rm uc}(D, b)$ lies between the graphs of $h_*(D)$ and $h_{**}(D)$, the combination of the wedge diagrams and the criterion for the wave speeds is not sufficient to predict the film behavior. Instead behavior can be determined by, e.g., numerical simulations. We will not elaborate further on this subtlety.

For the small values of D considered so far, there is in fact a distinct flat region between the meniscus and the wave structure. For larger D, this is not so. As D increases beyond $D_{\rm III}$, the height of the left state for an undercompressive front $h_{\rm uc}$ drops below $h = 2/3$. Now there can be no direct connection between meniscus and front. All available meniscus profiles have h_m larger than $h_{\rm uc}$, so an intermediate wave is needed to span the gap of thicknesses. From the front wedge part in Figure 2.1, we see that the resulting wave structure must be a rarefaction-undercompressive wave combination.

No flat film can emerge between the meniscus and the rarefaction wave of thickness $h_m = h_w$ strictly larger than $2/3$, since the portions of the rarefaction wave larger than $2/3$ would have a negative characteristic speed. Instead, the meniscus evolves into a shape that is the limiting profile of all the Type II menisci, while the portions of the film between $2/3$ and $h_{\rm uc}$ tend to the profile of a rarefaction wave with left state $2/3$. Since the characteristic speed at $h = 2/3$ is exactly zero, the rarefaction wave never completely separates from the meniscus, but as it gets increasingly stretched, the film thickness at any fixed position x in front of the meniscus eventually tends to $2/3$. We call the emerging limiting meniscus profile with thickness $h_m = 2/3$ a *generalized Type II meniscus*, in analogy to the terminology for Lax shocks, to reflect the fact that $f'(2/3) = 0$.

This situation is indicated in Figure 3.1(a), where for $D > D_{\rm III}$ the crossed and circled lines part again. The former lies at the boundary of the Type II regime, while the latter follows the upper edge of the front wedge. Dynamical simulations with $D = 3.5$ confirm our picture. In Figure 3.4(a) we show the evolution of the film from the initial condition (3.2), for $D = 3.5$. At long times, the film left of the advancing front forms a flat plateau with thickness equal to $h_{\rm uc} = 0.5783$ (the value was obtained by solving the traveling wave ODE as in [2, 10]). At an increasing distance from the advancing front, the film profile slightly steepens to a rarefaction wave, which blends over into the meniscus.

When D increases further, $h_{\rm uc}$ decreases, and the difference between the speed of the undercompressive wave and the left characteristic speed of this wave also decreases. They become equal when $D = D_F$ and $h_{\rm uc} = (1-b)/2$ at the apex of the front wedge. For $b = 0.005$, D_F is 5.227. For the largest D, in excess of D_F, the possible wave structures are those that are permitted according to classical shock theory.

Again, the meniscus profile tends to a generalized Type II meniscus, and it must connect to a rarefaction fan with left state 2/3. The rarefaction wave now connects directly to the advancing front, which connects in turn to b. The characteristic speed of the thickness $(1-b)/2$ where the two structures connect is identical to the shock speed. The leading shock is therefore a generalized Lax shock, which is not undercompressive, and there is neither the flat region of thickness $h_{\rm uc}$ nor the steep shock front which were visible when $D = 3.5$. This is seen in a dynamical simulation for $D = 6$ in Figure 3.4(b). Instead, the rarefaction fan expands over time, always stretching from the meniscus to the advancing front. The front is a generalized Lax shock and connects to the rarefaction fan via a rounded corner at thickness $h = (1-b)/2 = 0.4975$.

3.2. Case B: Thicker precursor layer, $0.0202 < b < 0.1484$. For larger precursor thicknesses, the expected film configuration is generally similar to the small b case described above. However, some new configurations do appear for a range of D values, while the front controlled profiles with a Type II meniscus and flat region thicker than 2/3 no longer occur.

The intersections occurring at $D = D_{\rm II}$ and $D = D_{\rm III}$ both happen at $D = D_M$ when $b = 0.0202$. For larger b, the upper branch $h_{\rm uc}$ of the front wedge intersects only the lower branch of the meniscus wedge. We call the value of D for the remaining intersection $D_{\rm II}$, and so

$$h_B(D_{\rm II}) = h_{\rm uc}(D_{\rm II}, b)$$

for this range of b. The two wedges are shown for $b = 0.05$ in Figure 3.1(b). We describe below the profiles which result as D is increased.

For $D < D_{\rm II}$, the film behaves as for the first two cases in Case A (section 3.1). For the smallest D, profiles continue to be controlled by the meniscus, with a Type I meniscus, a flat region of thickness h_B, and simple compressive front, with a capillary ridge connecting the flat region to the precursor layer. When $D_{\rm I} < D < D_{\rm II}$, there are again a Type I meniscus and flat region with thickness h_B, but at the advancing front there is a double shock structure. Both these behaviors have been seen in our dynamic simulations with $b = 0.05$.

Because $h_{\rm uc}(D)$ is smaller than in Case A for the larger values of b considered here, it never exceeds h_T, the threshold for a Type II meniscus. (See Figure 3.1(b).) Thus for this range of b there are no front controlled profiles. Instead, for $D_{\rm II} < D < D_M$, a new configuration is possible. Now both h_B and h_T are greater than $h_{\rm uc}$, so any connection from the meniscus must be via a rarefaction fan. This cannot connect to a Type II meniscus, since $h_T > 2/3$, and so the left part of the rarefaction would have negative speed. Thus here there is a Type I meniscus, connected via a rarefaction fan to a flat region of height $h_{\rm uc}$ where the film is thinner. This in turn is connected via an undercompressive shock to b. All parts of the rarefaction wave have positive speed, so it must gradually move away from the meniscus, leaving a flat region of thickness h_B behind it. Furthermore, the leading edge of the rarefaction fan is slower than the undercompressive wave, so the length of the flat region between the rarefaction fan leading edge and the advancing front, with thickness $h_{\rm uc}$, will increase with time. Dynamical simulations with $D = 0.7$ and $b = 0.05$, shown in Figure 3.5(a), confirm

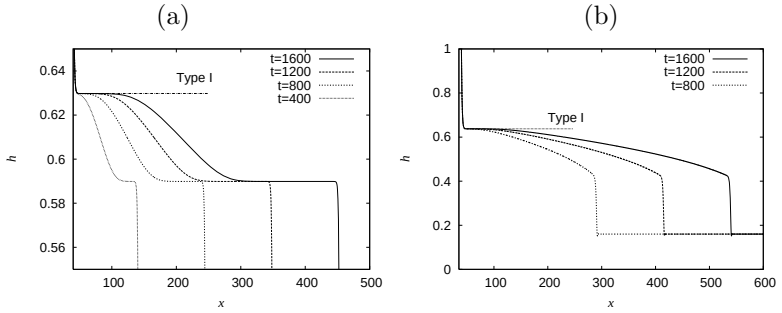

FIG. 3.5. (a) *Evolution of the film when* $D = 0.7$ *and* $b = 0.05$ *(so* $D_{\rm II} < D < D_M$*). A Type* I *meniscus, which tends towards* $h_B = 0.6298$*, is connected via a rarefaction fan to a flat region of height* $h_{\rm uc}$*, which connects to the precursor thickness* b *via an undercompressive shock. This configuration is possible only when* $b > 0.0202$*.* (b) *Evolution of the film when* $D = 0.72$*. Here* $b = 0.16$*. The front is now a generalized Lax shock, unlike that seen in the left figure. The meniscus is still Type* I*, approaching a value* $h_B = 0.6376 < 2/3$*. A knee develops close to* $h = (1-b)/2 = 0.42$*.*

that two flat regions develop. The first has thickness close to $h_B = 0.6298$, as expected for a Type I meniscus solution for this value of D, and extends up to the rarefaction fan. A second develops between the rarefaction fan and the advancing front, with a thickness close to the expected undercompressive region height $h_{\rm uc} = 0.5907$.

For $D > D_M$, the behavior is similar to that for $D > D_{\rm III}$ for small b (section 3.1). There is a rarefaction fan extending from a generalized Type II meniscus at $h = 2/3$ to $h_{\rm uc}$. Provided that $D < D_F$, a flat region of thickness $h_{\rm uc}$ exists before an undercompressive shock, while for $D > D_F$ there is no flat region, and the connection to the precursor is a generalized Lax shock.

3.3. Case C: Even thicker precursor layer, $0.1484 < b < 0.2338$. As b is further increased, D_F reduces, so that when it reaches the critical value $b = 0.1484$, D_F and D_M are equal. For somewhat larger b (so that $D_F < D_M$, but is not too small) the apex of the front wedge still lies outside the meniscus wedge. This arrangement of the wedges is shown in Figure 3.1(c) when $b = 0.16$.

With this arrangement, the film behaves as for Cases A and B while $D < D_{\rm II}$, forming a Type I meniscus with a compressive shock for $D < D_{\rm I}$, and then a double shock for $D_{\rm I} < D < D_{\rm II}$. For $D > D_{\rm II}$ but less than D_F, the Type I meniscus still exists and connects to the precursor via a flat region of thickness h_B, then a rarefaction fan and undercompressive shock, as in Case B. In dynamic simulations the flat $h_{\rm uc}$ region takes a long time to develop.

For $D_F < D < D_M$ another new behavior occurs. Type I menisci are still possible, but they must connect to the precursor by a rarefaction fan with right state $(1-b)/2$, followed by a classical generalized Lax shock, since undercompressive connections do not exist for $D > D_F$. Such behavior is seen in Figure 3.5(b), for $D = 0.72$ and $b = 0.16$. (Note that $D_F = 0.7153$ for $b = 0.16$.) Here $h_B = 0.6376$, and it is apparent that in the meniscus region the film approaches this thickness before entering the rarefaction fan region and dropping to $(1-b)/2 = 0.42$. Since h_B is quite close to $2/3$ here, characteristics have a slow speed, and the left edge of the rarefaction fan takes a long time to move away from the meniscus. Finally, for $D > D_M$, behavior is again as for the largest D values in Cases A and B: a generalized Type II meniscus connects to a rarefaction fan and from there to a generalized Lax shock, as in Figure 3.4(b).

3.4. Case D: Thickest precursor layers: $b > 0.2338$. With this arrangement of the wedges, $D_F < D_{\mathrm{I}}$, and the front wedge lies entirely within the meniscus wedge. Figure 3.1(d) shows the case $b = 0.25$. Three types of behavior are possible; these are similar to those of Case C.

For small $D < D_{\mathrm{I}}$ (but sufficiently large that $h_B > b$), the film continues to display meniscus-controlled behavior. There is a Type I meniscus, followed by a flat region with thickness $h_B(D)$, which is connected to the precursor layer by a compressive advancing front. This is the case, regardless of whether D is larger or smaller than D_F.

When $D > D_{\mathrm{I}}$, the connection to the precursor must be via a classical structure (since $D_{\mathrm{I}} > D_F$). Since the preferred right state of the meniscus exceeds $(1 - b)/2$, there is a rarefaction fan, connecting to a classical generalized Lax shock. The two behaviors possible for $D > D_{\mathrm{I}}$ differ near the meniscus: for $D_{\mathrm{I}} < D < D_M$, it is a Type I meniscus, which connects to the rarefaction fan as in section 3.3. Once D exceeds D_M, there is a generalized Type II meniscus that joins to the rarefaction fan, as for the largest D values in the previous cases.

4. Nearly horizontal substrate: Large D. For a substrate which is nearly horizontal, the leveling effects of the normal component of gravity become important. Here we consider steady state profiles in the limit $D \to \infty$. For studying this regime, we adopt a scaling in which surface tension is neglected but both components of gravity are retained. Smoothing of discontinuities in the film is now provided by the normal component of gravity instead of predominantly by surface tension. Rescaling by defining $\tilde{x}$ and $\tilde{t}$ by

$$D\tilde{x} = x, \qquad D\tilde{t} = t, \tag{4.1}$$

and letting $D \to \infty$ causes the governing PDE (2.2) to reduce from fourth to second order:

$$h_{\tilde{t}} + \left(h^2 - h^3\right)_{\tilde{x}} = \left(h^3 h_{\tilde{x}}\right)_{\tilde{x}}. \tag{4.2}$$

Steady state solutions of (4.2), which represent feasible meniscus profiles, must satisfy boundary conditions far upstream and downstream. The film must match onto the reservoir, so

$$\frac{\mathrm{d}h}{\mathrm{d}\tilde{x}} \to -1 \qquad \text{as } \tilde{x} \to -\infty$$

(which is simply the rescaled form of (2.3)), and its thickness must approach a constant value h_m far downstream:

$$h \to h_m \qquad \text{as } \tilde{x} \to \infty.$$

Setting $h_{\tilde{t}}$ to zero, (4.2) can be integrated with respect to $\tilde{x}$ to yield a first-order (nonlinear) ODE:

$$h_{\tilde{x}} = \frac{h^2 - h^3 - c}{h^3}. \tag{4.3}$$

For large h, equation (4.3) has $h_{\tilde{x}} \to -1$, and by setting the constant of integration $c = (h_m^2 - h_m^3)$, both boundary conditions are satisfied. Note that c is the total flux of liquid flowing through the flat film in front of the meniscus; physically meaningful

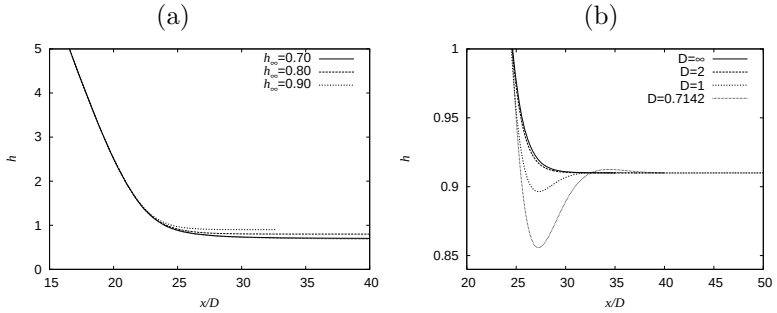

FIG. 4.1. (a) *Solutions of* (4.3) *in a parameter regime where surface tension is unimportant. Shown are* $h_m = 0.7, 0.8, 0.9$. *On this scale, the solution with* $h_m = 0.7$ *is barely distinguishable from the solution of* (4.5) *with* $h_m = 2/3$, *shown as a dotted line.* (b) *Steady solutions of* (2.2), *which have* $h_m = 0.91$, *rescaled according to* (4.1). *As* D *is increased, these approach the large* D *limit, shown as a solid line. The dip which is a feature of Type* II *solutions for small* D *is gone for* $D = 2$.

values for climbing films are $0 < c \leq 4/27$. A one-parameter family of solutions is generated by varying h_m, or alternatively, c. For $c < 4/27$, the positive-valued fixed points of (4.3) are $h = h_B < 2/3$ and $h = h_T > 2/3$, the same as those of the steady form of (2.2).

When h_B and h_T are distinct, (4.3) shows that $h_{\tilde{x}}$ is negative for $h > h_T$ and $h < h_B$, and positive for $h_B < h < h_T$; h_T is therefore a stable fixed point, while h_B is unstable. Any solution which becomes infinite as $\tilde{x} \to -\infty$ must be monotonic, decreasing, and have $h > h_T > 2/3$ everywhere, with $h \to h_T$ as $\tilde{x} \to \infty$. In other words, the meniscus profiles for $c < 4/27$ connect to a thickness $h_m > 2/3$, and so are Type II profiles. The exact solution to (4.3), up to translation in $\tilde{x}$, is given implicitly by

$$\tilde{x} = -h + \sum_{i=1}^{3} \frac{h_i^3}{(h_i - h_j)(h_k - h_i)} \log|h - h_i|, \qquad j \neq i,\ k \neq i, j, \tag{4.4}$$

where the summation is over the three distinct roots h_B, h_T, and $(1 - h_B - h_T)$ of the cubic equation $h^2 - h^3 - c = 0$. Solutions of the form of (4.4) are shown in Figure 4.1(a) for three values of $h_m > 2/3$. The solution with $h_m = 0.91$ is compared to meniscus profiles with finite D in Figure 4.1(b). As the influence of surface tension diminishes, the dip disappears, and the meniscus profiles become monotonic, even though they are of Type II.

As h_m approaches $2/3$, the fixed points h_B and h_T also approach $2/3$. When $h_m = 2/3$, $c = 4/27$, and there is a repeated root of $h^2 - h^3 - c = 0$. The solution to (4.3) is then given by

$$\tilde{x} = -h + \frac{8}{27}\frac{1}{h - 2/3} - \frac{28}{27}\log\left|h - \frac{2}{3}\right| + \frac{1}{27}\log\left|h + \frac{1}{3}\right|. \tag{4.5}$$

The $(h - 2/3)^{-1}$ term rapidly blows up, indicating that the film requires a very long distance to reach its limiting value h_m. The solution for $h_m = 2/3$ is shown in Figure 4.1(a) as a dotted line.

At this point, we have established essentially the same picture for the possible meniscus structure as for the large (but finite) D case discussed in section 3. On

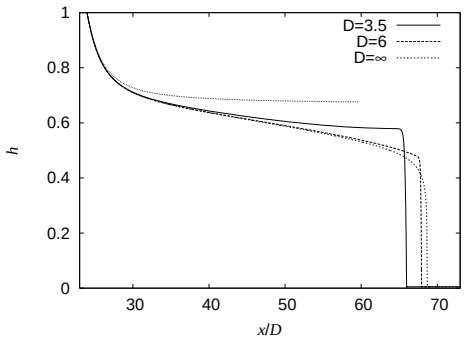

FIG. 4.2. *Advancing fronts with $b = 0.005$ and different D, shown at the same scaled time $\tilde{t} = 169$. Also shown is the long-time solution for $h_m = 2/3$ and $D = \infty$ (dotted line), which is approached by the solutions for large D, and when the front has moved far from the meniscus.*

the other hand, since (4.2) is a second-order equation, the classical theory of shocks only allows a rarefaction fan and generalized Lax shock combination for connecting a thickness larger than $(1-b)/2$ with a precursor of thickness b. Therefore in numerical simulations of (4.2) a generalized Type II meniscus profile should emerge connected to such a combination, and indeed, this is seen in the results of the previous section for sufficiently large D.

We compared the profiles obtained from our dynamic model including the surface tension terms (2.2) for two moderately large values of D with those of the time-dependent model (4.2) valid when $D \to \infty$. Simulations were performed with $b = 0.005$, for which $D_F \approx 5.227$. The same initial condition (3.2) was used for each case.

As described in section 2.2, when D is larger than D_F, the presence of the surface tension terms is expected to give rise to a classical front, with a rarefaction fan connected to a compressive shock. Numerical simulations with $D = 6$ confirm this. This is shown in Figure 3.4(b), where the front advances with a rounded corner, typical of a generalized Lax shock. In contrast, when $D = 3.5 < D_F$ the advancing front is undercompressive (Figure 3.4(a)). It separates from the rarefaction wave and has a markedly higher left state. At the same rescaled time $\tilde{t} = 169$, the rescaled profiles for the meniscus region and much of the film are very similar to the large D result, i.e., using (4.2), for both finite D values. This is shown in Figure 4.2. However, at the advancing front, the difference between the undercompressive and generalized Lax fronts is evident, while the transition from generalized Lax shock to the precursor is slightly more rounded for $D = 6$ than for $D = \infty$.

Finally, we demonstrate that the portion behind the advancing front seen in Figure 3.4(b) (and also Figure 3.5(b)) is indeed a rarefaction fan, by comparing it directly to solutions of the first-order equation resulting from neglecting all second- and fourth-order smoothing terms in (2.2). Rarefaction wave solutions of $h_t + f(h)_x = 0$ may be found, subject to appropriate initial data, using the method of characteristics. Thus within the rarefaction fan delimited by left and right states h_- and h_+,

$$h(x,t) = h_R(\xi) = (f')^{-1}(\xi), \quad \text{where } \xi = \frac{x - x_0}{t - t_0} \tag{4.6}$$

for some x_0 and t_0. The function $h_R(\xi)$ is given implicitly by $\xi = f'(h) = 2h - 3h^2$. The unknowns x_0 and t_0 may be estimated as follows. For the situation shown in Figure 3.4(b), we take h_+ to be $(1-b)/2 = 0.4975$. At a given time, t_2 say, we observe

where $h(x, t_2) = h_+$, at $x = x_+$ say, and estimate a value for t_0. We then compute

$$x_0 = x_+ + (t_2 - t_0)\xi_+,$$

where $\xi_+ = f'(h_+)$. The shape of the rarefaction fan may be constructed at any time t using

$$x = (t - t_0)\xi(h) + x_0 \quad \text{for } h_+ < h < 2/3. \tag{4.7}$$

We vary t_0 until (4.7) provides a good fit for $h(x, t_2)$ within the rarefaction fan.

We demonstrate this by computing the rarefaction fan constants x_0 and t_0 using our result at $t = 3000$ (shown using "+" symbols in Figure 3.4(b)) and then confirming these by comparison with (4.7) at $t = 1013$ ("×" symbols in Figure 3.4(b)). The agreement is satisfactory in the interior of the rarefaction fan. At the ends, the higher-order terms in (2.2) are important and smooth the profile.

5. Summary of behavior: A catalog. The previous sections' observations can be summarized by considering regions of (D, b) parameter space in which distinct behaviors arise. These are shown in Figure 5.1. The graphs of $D_i(b)$ $(i = \mathrm{I}, \mathrm{II}, \mathrm{III})$ and $D_F(b)$ divide the parameter space into several regions. These regions are indicated by the labels in the figure. The descriptions given for Cases A to D in section 3 correspond to moving along horizontal lines (constant b) in this figure.

A number of features are apparent. For small D (though with $D \gg \epsilon$), a Type I meniscus (labeled "T1+L") results for all choices of b. At the other extreme, for the largest $D > \max(D_F, D_M)$, the advancing front is a generalized Lax shock, and the connection to the meniscus is via a rarefaction fan (labeled "2/3+rf+gL"). States in

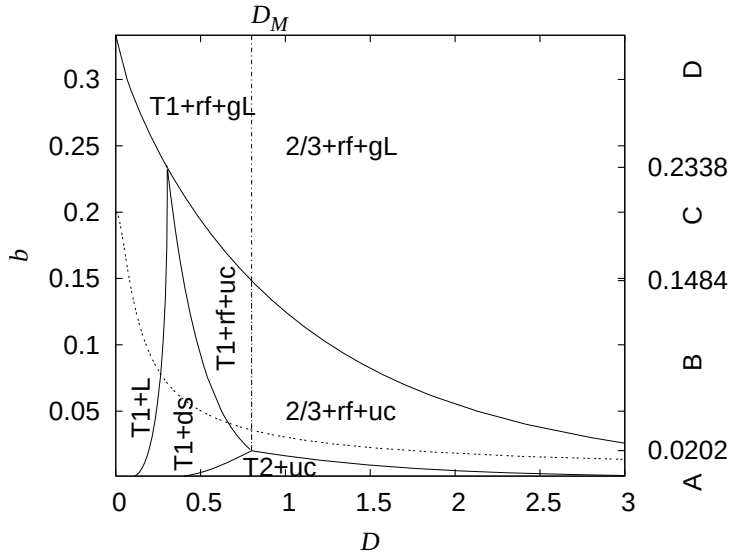

FIG. 5.1. *Behavior of a thin surface-tension-gradient-driven film emerging from a meniscus. The thickness b of a thin precursor layer and an inclination parameter D control the behavior. The following abbreviations are used, and explained in the text: T1, T2, and 2/3 denote Type* I, *Type* II, *and 2/3 (generalized Type* II*) menisci, respectively; the other labels are: L—(compressive) Lax shock, ds—double shock, gL—generalized Lax shock, rf—rarefaction fan, uc—undercompressive shock. The dotted line indicates points which differ only in tilt angle* α.

which there is only a flat region between the meniscus and front—the Type I meniscus with a Lax front or with a double shock structure, and the Type II meniscus with an undercompressive front—exist in the lower left part of the diagram, shown by labels "T1+L," "T1+ds," and "T2+uc." These are states are familiar from previous work, e.g., [13]. For a fixed value of D, one of these three configurations can arise only when a sufficiently thin precursor is present. As the precursor layer is thickened these give way to film profiles with rarefaction fans, shown by "rf" in the figure labels. These new kinds of behavior were described in section 3. In particular, the combination of a Type I meniscus and rarefaction fan seen in Figure 3.5(a) occurs only for $b > 0.0202$, while a Type II meniscus with an extended flat region and undercompressive front occurs only for b smaller than this value. In the upper right part of the diagram lie structures with rarefaction fans, for which there is no clear separation between the meniscus and the front.

It should be noted that in a set of experiments, the dimensional precursor thickness b^* (or equivalently the wetting behavior) is likely to be fixed. If the substrate angle α is varied while other parameters including b^* are fixed, then this corresponds to moving along a curved path in Figure 5.1, given parametrically by $((3\delta)^{2/3} \sin\alpha/\cos^{4/3}\alpha,\, b_0 \cos\alpha)$, where b_0 is the dimensionless precursor thickness for $\alpha = 0$. One such curve is shown in the figure for $\delta = 0.00782$, corresponding to experiments by Schneemilch and Cazabat [14], and $b_0 = 0.2$, as a dotted line. This value is likely to be larger than in their experiments, but demonstrates how the film changes from a Type I meniscus and compressive front to more complex behavior as α is increased. For this value of δ, values of $b_0 > 0.11$ result in not entering the "T2+uc" region for any α.

6. Concluding remarks. In this paper, understanding of the film on a heated tilted substrate near a meniscus and at an advancing front has been combined to generate an understanding of the possible behavior for the entire film. This is graphically summarized by Figure 5.1. This analysis is based on approximating the curvature, which is appropriate for relatively tilted substrates, for which $\tan\alpha \gg 1$. This is equivalent to requiring that $D \gg \epsilon$.

When D is of order ϵ or smaller, the curvature can no longer be approximated by h_{xx} everywhere. In this limit h_B approaches a finite nonzero value [4, 5, 11, 13]. For practical values of the shear stress, the most significant effect is to move the bottom edge of the meniscus wedge so that the graph of $1 - b - h_{\rm uc}$ no longer intersects $h_B(D)$. This situation occurs more easily for smaller values of b. In that case, instead of a Type I meniscus with a compressive front for the smallest values of D, either a double shock profile or a Type II meniscus with undercompressive front may occur. In principle, this means that undercompressive advancing fronts are possible for nearly vertical substrates, provided that the precursor layer is sufficiently thin. Retaining full curvature would modify the results shown in Figure 5.1 for D near 0.

Our results indicate that when the control parameter D is sufficiently large there is no extended flat region, but rather a rarefaction fan links the meniscus to the advancing front. An interesting observation is that when a Type II meniscus arises, its flat region thickness is not controlled by conditions at the meniscus, as for the Type I meniscus. Rather, it is the precursor thickness which determines $h_{\rm uc}$ and so the thickness of the flat region.

Similarly the interesting question of what would happen if the film were to advance over a substrate for which wetting is imperfect, i.e., for which there is a nonzero contact angle, has not been addressed. For the drag-out problem, there is a minimum

withdrawal speed required to draw out a film, if the contact angle is prescribed [7].

Despite these limitations, we expect that the guide presented here will be a useful tool for experimentalists. We look forward to experimental confirmation of these results.

ALGORITHMS FOR FINDING GLOBAL MINIMIZERS OF IMAGE SEGMENTATION AND DENOISING MODELS*

TONY F. CHAN†, SELIM ESEDOĞLU‡, AND MILA NIKOLOVA§

Abstract. We show how certain nonconvex optimization problems that arise in image processing and computer vision can be restated as convex minimization problems. This allows, in particular, the finding of global minimizers via standard convex minimization schemes.

Key words. denoising, segmentation

AMS subject classifications. 94A08, 65K10

DOI. 10.1137/040615286

1. Introduction.

Image denoising and segmentation are two related, fundamental problems of computer vision. The goal of denoising is to remove noise and/or spurious details from a given, possibly corrupted, digital picture while maintaining essential features such as edges. The goal of segmentation is to divide the image into regions that belong to distinct objects in the depicted scene.

Approaches to denoising and segmentation based on the calculus of variations and partial differential equations (PDEs) have had great success. One important reason for their success is that these models are particularly well suited to imposing geometric constraints (such as regularity) on the solutions sought. Among the best known and most influential examples are the Rudin–Osher–Fatemi (ROF) total variation–based image denoising model [22] and the Mumford–Shah image segmentation model [17].

Denoising models such as the ROF model can be easily adapted to different situations. An interesting scenario is the denoising of shapes: Here, the given image is binary (representing the characteristic function of the given shape), and the noise is in the geometry of the shape: Its boundary might be very rough, and the user might be interested in smoothing out its boundary, and perhaps removing small, unnecessary connected components of the shape. This task is a common first step in many object detection and recognition algorithms.

A common difficulty with many variational image processing models is that the energy functional to be minimized has local minima (which are not global minima). This is a much more serious drawback than nonuniqueness of global minimizers (which is also a common phenomenon) because local minima of segmentation and denoising models often have completely wrong levels of detail and scale: whereas global minimizers of a given model are usually all reasonable solutions, the local minima tend to be blatantly false. Many solution techniques for variational models are based on gradient descent, and are therefore prone to getting stuck in such local minima. This

makes the initial guess for gradient descent–based algorithms sometimes critically important for obtaining satisfactory results.

In this paper we propose algorithms which are guaranteed to find global minimizers of certain denoising and segmentation models that are known to have local minima. As a common feature, the models we consider involve minimizing functionals over characteristic functions of sets, which is a nonconvex collection; this feature is responsible for the presence of local minima. Our approach, which is based on observations of Strang in [23, 24], is to extend the functionals and their minimization to all functions in such a way that the minimizers of the extended functionals can be subsequently transformed into minimizers for the original models by simple thresholding. This allows, among other things, computing global minimizers for the original nonconvex variational models by carrying out standard convex minimization schemes.

Our first example is binary image denoising, which we briefly discuss as a precursor to and a motivation for the more general segmentation problem that we subsequently consider. Here the given noisy image for the ROF model is taken to be binary, and the solution is also sought among binary images. This problem has many applications where smoothing of geometric shapes is relevant. Some examples are the denoising of fax documents, and the fairing of surfaces in computer graphics. Because the space of binary functions is nonconvex, the minimization problem involved is actually harder than minimizing the original ROF model. In section 2, we recall results from [6] that show how this model can be written as a convex optimization problem, and we exhibit its use as a numerical algorithm. In this section, we also analytically verify that the energy concerned possesses local minimizers that are not global minimizers, which can trap standard minimization procedures.

In section 3, we extend some of the results of [6] to the more important problem of *image segmentation*. In particular, we consider the two-phase, piecewise constant Mumford–Shah segmentation functional proposed by Chan and Vese in [7] and show that part of the minimization involved can be given a convex formulation. This model has become a very popular tool in segmentation and related image processing tasks (also see [26] for its multiphase version). The convex formulation we obtain turns out to be closely related to the algorithm of Chan and Vese presented in [7]. Our observations indicate why this algorithm is successful in finding interior contours and other hard-to-get features in images.

2. Previous work. The results and the approach of this paper follow very closely the observations of Strang in [23, 24]. In those papers, optimization problems of the following form, among others, are studied:

$$\inf_{\{u:\int f u\,dx=1\}} \int |\nabla u|, \tag{1}$$

where $f(x)$ is a given function. It is shown in particular that the minimizers of (1) turn out to be characteristic functions of sets. The main idea involved is to express the functional to be minimized and the constraint in terms of the super level sets of the functions $u(x)$ and $f(x)$. The coarea formula of Fleming, Rishel, and Rishel [11] is the primary tool.

In this paper, the idea of expressing functionals in terms of level sets is applied to some simple image processing models. For instance, in section 4, where we study the piecewise constant Mumford–Shah energy, we show that the relevant energy, which is originally formulated in terms of *sets*, can be reformulated as an optimization problem over *functions* in such a way that the resulting *convex* energy turns out to be almost

the same as (1). After this reformulation, following Strang's work, we are also able to express the resulting convex variational problem in terms of super level sets of the unknown functions. That in turn allows us to extract a minimizer of the original nonconvex model from a minimizer of the convex functional by simple thresholding.

We should point out that our emphasis in this paper is in some sense opposite that of [23, 24]. Indeed, in those works the main point is that some energies of interest that need to be minimized over all functions turn out to have minimizers that take only two values. In our case, we start with a variational problem that is to be minimized over only functions that take two values (i.e., characteristic functions of sets) but show that we may instead minimize over all functions (that are allowed to take intermediate vales), i.e., we may ignore the nonconvex constraint. This allows us to end up with a convex formulation of the original nonconvex problem.

3. The ROF model. Rudin, Osher, and Fatemi's total variation image denoising model [22] is one of the best known and successful of PDE-based image denoising models. Indeed, being convex it is one of the simplest denoising techniques that has the all-important edge preserving property.

Let $D \subset \mathbf{R}^N$ denote the image domain. In practice, D is simply a rectangle, modeling the computer screen. Therefore, mathematically, it is natural to assume that D is a bounded domain with Lipschitz boundary. However, for the convenience of not dealing with boundaries, in this section we will take D to be the entire space $\mathbf{R}^N$. This simplifying assumption has no bearing on the essential ideas discussed below.

Let $f(x) : \mathbf{R}^N \to [0,1]$ denote the given (grayscale) possibly corrupted (noisy) image. The energy to be minimized in the standard ROF model is then given by

$$E_2(u,\lambda) = \int_{\mathbf{R}^N} |\nabla u| + \lambda \int_{\mathbf{R}^N} \Big(u(x) - f(x)\Big)^2 \, dx. \tag{2}$$

The appropriate value of the parameter $\lambda > 0$ in the model (2) can be determined if the noise level is known; an algorithm for doing so is given in [22]. If information about noise level is not available, then λ needs to be chosen by the user. This choice can be facilitated by the observation that λ acts as a scale parameter [25]: Its value determines in some sense the smallest image feature that will be maintained in the reconstructed image. Energy (2) is often minimized via gradient descent; however, see [5, 9] for an alternative approach in the $\lambda = 0$ case.

An interesting application of the ROF model described above is to *binary* image denoising. This situation arises when the given image $f(x)$ is binary (i.e., $f(x) \in \{0,1\}$ for all $x \in \mathbf{R}^N$) and is known to be the corrupted version of another binary image $u : \mathbf{R}^N \to \{0,1\}$ that needs to be estimated. Naturally, $f(x)$ can then be expressed as

$$f(x) = \mathbf{1}_\Omega(x),$$

where Ω is an arbitrary bounded measurable subset of $\mathbf{R}^N$. In this case, the noise is in the *geometry*; for example, the boundary $\partial\Omega$ of Ω might have spurious oscillations, or Ω might have small connected components (due to presence of noise) that need to be eliminated. The ROF model (2) can easily be specialized to this scenario by restricting the unknown $u(x)$ to have the form $u(x) = \mathbf{1}_\Sigma(x)$, where Σ is a subset of

$\mathbf{R}^N$. One then obtains the following optimization problem:

$$\min_{\substack{\Sigma\subset\mathbf{R}^N\\ u(x)=\mathbf{1}_\Sigma(x)}} \int_{\mathbf{R}^N} |\nabla u| + \lambda \int_{\mathbf{R}^N} \Big(u(x) - \mathbf{1}_\Omega(x)\Big)^2\, dx. \tag{3}$$

Problem (3) is nonconvex because the minimization is carried out over a nonconvex set of functions. Recalling that the total variation of the characteristic function of a set is its perimeter (see, e.g., [10, 12] for such basic facts), and noticing that the fidelity term in this case simplifies, we write (3) as the following geometry problem:

$$\min_{\Sigma\subset\mathbf{R}^N} \mathrm{Per}(\Sigma) + \lambda|\Sigma \triangle \Omega|, \tag{4}$$

where $\mathrm{Per}(\cdot)$ denotes the perimeter, $|\cdot|$ is the N-dimensional Lebesgue measure, and $S_1 \triangle S_2$ denotes the symmetric difference between the two sets S_1 and S_2.

Usual techniques for approximating the solution. A very successful method of solving problems of the type (4) has been via some *curve evolution* process, sometimes referred to as *active contours*. Indeed, the unknown set Σ can be described by its boundary $\partial\Sigma$. The boundary $\partial\Sigma$ is then updated iteratively, usually according to gradient flow for the energy involved.

Numerically, there are several ways of representing $\partial\Sigma$. For the applications mentioned above, explicit curve representations as in Kass, Witkin, and Terzopoulos [15] are not appropriate, since such methods do not allow changes in curve topology (and have a number of other drawbacks). Instead, the most successful algorithms are those based on either the level set method of Osher and Sethian [21, 20] or on the variational approximation approach known as Gamma convergence theory [8].

In the level set formulation, the unknown boundary $\partial\Sigma$ is represented as the 0-level set of a (Lipschitz) function $\phi : \mathbf{R}^N \to \mathbf{R}$:

$$\Sigma = \big\{x \in \mathbf{R}^N : \phi(x) > 0\big\},$$

so that $\partial\Sigma = \{x \in \mathbf{R}^N : \phi(x) = 0\}$. The functional to be minimized in (3), which we called $E_2(\cdot, \lambda)$, can then be expressed in terms of the function $\phi(x)$ as follows:

$$\int_{\mathbf{R}^N} |\nabla H(\phi(x))|\, dx + \lambda \int_{\mathbf{R}^N} \Big(H(\phi(x)) - \mathbf{1}_\Omega(x)\Big)^2\, dx. \tag{5}$$

Here, the function $H(x) : \mathbf{R} \to \mathbf{R}$ is the Heaviside function:

$$H(\xi) = \begin{cases} 0 & \text{if } x < 0,\\ 1 & \text{if } x \geq 0. \end{cases}$$

In practice, one takes a smooth (or at least Lipschitz) approximation to $H(x)$, which we shall call $H_\varepsilon(\xi)$, where $H_\varepsilon(\xi) \to H(\xi)$ in some manner as $\varepsilon \to 0$.

The Euler–Lagrange equation for (5) is easy to obtain. It leads to the following gradient flow:

$$\phi_t(x,t) = H'_\varepsilon(\phi)\left\{\mathrm{div}\left(\frac{\nabla\phi}{|\nabla\phi|}\right) + 2\lambda\Big(\mathbf{1}_\Omega(x) - H_\varepsilon(\phi)\Big)\right\}. \tag{6}$$

When (6) is simulated using reinitialization for the level set function $\phi(x)$ and a compactly supported approximation $H_\varepsilon(x)$ to $H(x)$, it is observed to define a continuous

evolution (with respect to, say, the L^1-norm) for the unknown function $u(x) = \mathbf{1}_\Sigma(x)$ and decreases the objective energy (3) through binary images. It is analogous to the gradient descent equation in [7], which is natural since (3) is the restriction to binary images of also the energy considered in that work, namely, the two-phase, piecewise constant Mumford–Shah segmentation energy. In section 4, we will consider this energy for general (not necessarily binary) images.

Another representation technique for the unknown set Σ in (4) is, as we mentioned, based on the Gamma convergence ideas. Here, the given energy is replaced by a sequence of approximate energies with a small parameter $\varepsilon > 0$ in them. The sequence converges to the original energy as $\varepsilon \to 0$. The approximations have the form

$$E_\varepsilon(u, \lambda) = \int_{\mathbf{R}^N} \varepsilon|\nabla u|^2 + \frac{1}{\varepsilon}W(u) + \lambda\Big\{u^2\big(c_1 - f\big)^2 + (1-u)^2\big(c_2 - f\big)^2\Big\}\, dx.$$

In this energy, $W(\xi)$ is a double-well potential with equidepth wells at 0 and 1; for instance, a simple choice is $W(\xi) = \xi^2(1-\xi)^2$. The term $\frac{1}{\varepsilon}W(u)$ can be thought of as a penalty term that forces the function u to look like the characteristic function of a set: u is forced to be approximately 0 or 1 on most of $\mathbf{R}^N$. The term $\varepsilon|\nabla u|^2$, on the other hand, puts a penalty on the transitions of u between 0 and 1. Taken together, it turns out that these terms both impose the constraint that u should be a characteristic function and approximate its total variation. Precise versions of these statements have been proved in [16]. The remaining terms in E_ε are simply the fidelity term written in terms of u. This approach was extended to the full Mumford–Shah functional in [4].

We now argue, with the help of a very simple example, that these techniques will get stuck in local minima in general, possibly leading to resultant images with the wrong level of detail. This fact is already quite familiar to researchers working with these techniques from practical numerical experience.

Example. Consider the two-dimensional case, where the observed binary image $f(x)$ to be denoised is the characteristic function of a ball $B_R(0)$ of radius R, which is centered at the origin. In other words, we take $\Omega = B_R(0)$. Implementing the gradient descent algorithm defined by (6) requires the choice of an initial guess for the interface $\phi(x)$ (or, equivalently, an initial guess for the set Σ that is represented by $\phi(x)$). A common choice in practical applications is to take the observed image itself as the initial guess. In our case, that means initially we set $\Sigma = B_R(0)$.

Now, one can see without much trouble that the evolution defined by (6) will maintain radial symmetry of $\phi(x)$. That means, at any given time $t \geq 0$, the set (i.e., the candidate for minimization) represented by $\phi(x)$ is of the form

$$\Big\{x \in \mathbf{R}^2 : \phi(x) > 0\Big\} = B_r(0)$$

for some choice of the radius $r \geq 0$. We can write the energy of $u(x) = \mathbf{1}_{B_r(0)}(x)$ in terms of r, as follows:

$$E(r) := E_2(\mathbf{1}_{B_r(0)}(x), \lambda) = 2\pi r + \lambda\pi|R^2 - r^2|.$$

A simple calculation shows that if $\lambda < \frac{2}{R}$, then the minimum of this function is at $r = 0$. Hence, if we fix $\lambda > 0$, then the denoising model prefers to remove disks of radius smaller than the critical value $\frac{2}{R}$.

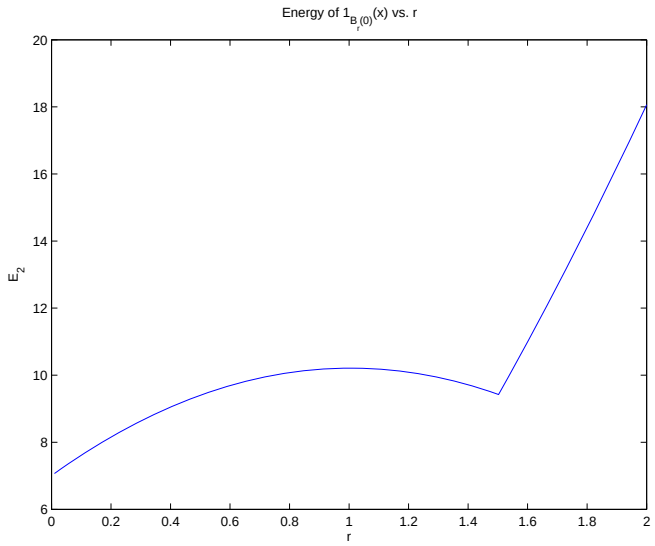

FIG. 1. *Energy* (3) *of* $u(x) = \mathbf{1}_{B_r(0)}(x)$ *as a function of* $r \in [0, 2]$ *when the observed image is given by* $f(x) = \mathbf{1}_{B_R(0)}(x)$. *Here,* $R = \frac{3}{2}$ *and the parameter* λ *was chosen to be* $\lambda = 1$. *There is clearly a local minimum, corresponding to* $r = R = \frac{3}{2}$.

But now, once again an easy calculation shows that if $R > \frac{1}{\lambda}$, then $E(r)$ has a local maximum at $r_{max}(\lambda) = \frac{1}{\lambda}$. See Figure 1 for the plot of $E(r)$ in such a case. Thus the energy minimization procedure described by (6) cannot shrink disks of radius $R \in (\frac{1}{\lambda}, \frac{2}{\lambda})$ to a point, even though the global minimum of the energy for an original image given by such a disk is at $u(x) \equiv 0$.

We can easily say a bit more: There exists $\delta > 0$ such that if $\Sigma \subset \mathbf{R}^N$ satisfies $|\Sigma \triangle B_R(0)| < \delta$, then $E_2(\mathbf{1}_\Sigma(x), \lambda) > E_2(\mathbf{1}_{B_R(0)}(x), \lambda)$. In other words, all binary images close to, but not identical with, the observed image $\mathbf{1}_{B_R(0)}(x)$ have strictly higher energy. This can be seen simply by noting that the energy of any region that is *not* a disk is strictly larger than the energy of the disk having the same area as the given region and its center at the origin.

To summarize: If $f(x) = \mathbf{1}_{B_R(0)}(x)$ with $R \in (\frac{1}{\lambda}, \frac{2}{\lambda})$, and if the initial guess for the continuous curve evolution–based minimization procedure (6) is taken to be the observed image $f(x)$ itself, then the procedure gets stuck in the local minimizer $u(x) = f(x)$. The unique global minimizer is actually $u(x) \equiv 0$.

Our example highlights the following caveat of using continuous curve evolution–based gradient descent algorithms in practice: There are many situations in which the user should be able to choose the value of λ that appears in the model in such a way that all image features smaller than the one implied by this choice of parameter are eliminated from the final result. (Such a need might arise, for instance, in the denoising of printed text, where the noise can consist of small ink blots.) With continuous curve evolution techniques, whether this goal will be achieved depends on the initial guess (our example above exhibits an unfortunate initial guess). It is clearly of interest to find an algorithm that does not have this dependence on initial conditions.

Proposed method for finding the global minimum. We now turn to an alternative way of carrying out the constrained, nonconvex minimization problem (3) that is guaranteed to yield a global minimum.

The crux of our approach is to consider minimization of the following convex energy, defined for any given observed image $f(x) \in L^1(\mathbf{R}^N)$ and $\lambda \geq 0$:

$$E_1(u(x), \lambda) := \int_{\mathbf{R}^N} |\nabla u| + \lambda \int_{\mathbf{R}^N} |u(x) - f(x)|\, dx. \tag{7}$$

This energy differs from the standard ROF model only in the fidelity term: The L^2-norm square of the original model is replaced by the L^1-norm as a measure of fidelity. It was previously introduced and studied in signal and image processing applications in [1, 2, 3, 18, 19, 6]. This variant of the ROF model has many interesting properties and uses; the point we'd like to make in this section is that it also turns out to solve our geometry denoising problem (4).

First, let us state the obvious fact that energies (2) and (7) agree on binary images (i.e., when both u and f are characteristic functions of sets). On the other hand, energy (7) is convex, but unlike energy (2), it is not strictly so. Accordingly, its global minimizers are not unique in general. Nevertheless, being convex, it does not have any local minima that are not global minima, unlike the constrained minimization (3). We therefore adopt the following notation: For any $\lambda \geq 0$, we let $M(\lambda)$ denote the set of all minimizers of $E_1(\cdot, \lambda)$. It is easy to show that for each $\lambda \geq 0$ the set $M(\lambda)$ is nonempty, closed, and convex.

The relevance of energy (7) for our purposes is established in Theorem 5.2 of [6], where additional geometric properties of it are noted. The proof is based on the following proposition, taken from [6], that expresses energy (7) in terms of the super level sets of u and f.

PROPOSITION 1. *The energy $E_1(u, \lambda)$ can be rewritten as follows:*

$$E_1(u, \lambda) = \int_{-\infty}^{\infty} \mathrm{Per}\big(\{x : u(x) > \mu\}\big) + \lambda \Big| \{x : u(x) > \mu\} \triangle \{x : f(x) > \mu\} \Big|\, d\mu. \tag{8}$$

Proof. The proof can be found in [6] (Proposition 5.1). □

We now recall also Theorem 5.2 of [6].

THEOREM 1. *If the observed image $f(x)$ is the characteristic function of a bounded domain $\Omega \subset \mathbf{R}^N$, then for any $\lambda \geq 0$ there is a minimizer of $E_1(\cdot, \lambda)$ that is also the characteristic function of a (possibly different) domain. In other words, when the observed image is binary, then for each $\lambda \geq 0$ there is at least one $u(x) \in M(\lambda)$ which is also binary.*

In fact, if $u_\lambda(x) \in M(\lambda)$ is any minimizer of $E_1(\cdot, \lambda)$, then for almost every $\gamma \in [0, 1]$ we have that the binary function

$$\mathbf{1}_{\{x : u_\lambda > \gamma\}}(x)$$

is also a minimizer of $E_1(\cdot, \lambda)$.

Proof. The proof can be found in [6] (Theorem 5.2). □

The proposition and its consequence, the theorem cited above from [6] (which are related to observations in [23, 24]), lead to a guaranteed algorithm for solving the binary image denoising problem (3), which we now state.

ALGORITHM 1. *To find a solution (i.e., a global minimizer) $u(x)$ of the nonconvex variational problem (3), it is sufficient to carry out the following three steps:*

1. *Find any minimizer of the* **convex** *energy (7); call it $v(x)$.*
2. *Let $\Sigma = \{x \in \mathbf{R}^N : v(x) > \mu\}$ for some $\mu \in (0, 1)$.*
3. *Set $u(x) = \mathbf{1}_\Sigma(x)$.*

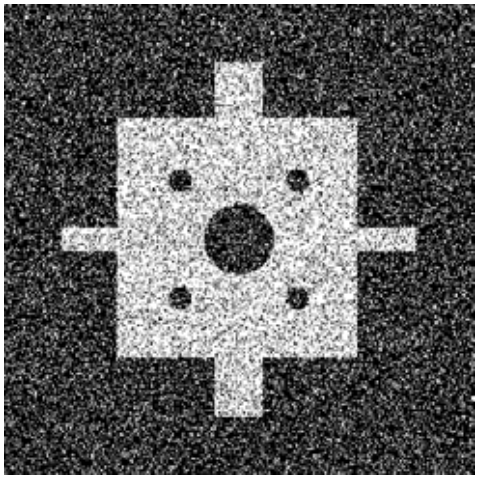

FIG. 2. *Original noisy binary image used in the numerical experiment of section* 3.

Then $u(x)$ *is a global minimizer of* (3) *for almost every choice of* μ.

Algorithm 1 reduces the *shape optimization* problem (4) to the *image denoising* problem (7). In section 4, we will obtain the analogue of Proposition 1 for the piecewise constant Mumford–Shah segmentation model of Chan and Vese, which will lead to a guaranteed algorithm for finding global minimizers of the more general shape optimization problem involved in that model, just like Algorithm 1 did for model (3); this is the content of Theorem 2 in that section. Our convex formulation will once again reduce the Chan–Vese shape optimization to a variant of the image denoising model (7).

The most involved step in the solution procedure described in Algorithm 1 is finding a minimizer of (7). One can approach this problem in many ways; for instance, one possibility is to simply carry out gradient descent.

Numerical example. The synthetic image of Figure 2 represents the given binary image $f(x)$, which is a simple geometric shape covered with random (binary) noise. The initial guess was an image composed of all 1's (an all white image). In the computation, the parameter λ was chosen to be quite moderate, so that in particular the small circular holes in the shape should be removed while the larger one should be kept. The result of the minimization is shown in Figure 3; in this case the minimizer is automatically very close to being binary, and hence the thresholding step of Algorithm 1 is almost unnecessary.

Figure 4 shows the histograms of intermediate steps during the gradient descent based minimization. As can be seen, the intermediate steps themselves are very far from being binary. The histogram in the lower right-hand corner belongs to the final result shown in Figure 3. Thus the gradient flow goes through nonbinary images, but in the end reaches another binary one. Although this is not implied by Proposition 1, Theorem 1, or Algorithm 1, it seems to hold in practice.

4. Piecewise constant segmentation. In this section, we extend the discussion of section 3 to the two-phase, piecewise constant Mumford–Shah segmentation model [17] of Chan and Vese [7]. Unlike in the previous section, this time we let the corrupted image $f(x)$ be nonbinary: it is merely assumed to be some measurable

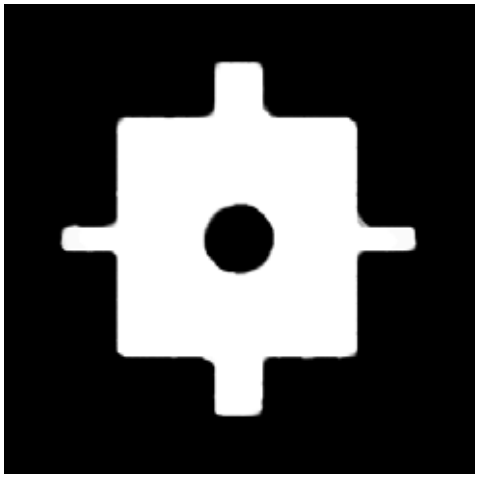

FIG. 3. *Final result found using the algorithm proposed in section* 3*, by minimizing* (7)*. Algorithm* 1 *says that global minimizers of the binary image denoising problem can be obtained by simply thresholding this result. In this case, the minimizer of energy* (7) *turns out to be very close to being binary itself, so there is no need to threshold. In the experiment, the value of* λ *was chosen small enough so that small holes in the original shape should get filled in, but also large enough so that the large hole in the middle should be maintained.*

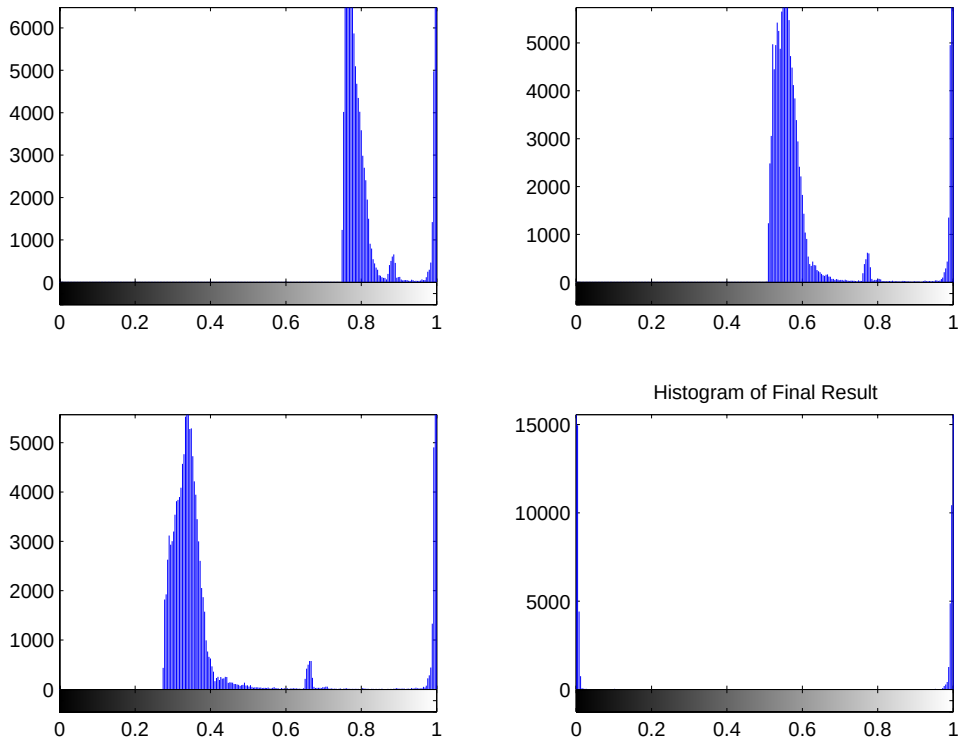

FIG. 4. *Histograms for intermediate images as the gradient descent proceeds. As can be seen, the intermediate images themselves are not binary; however, by the time the evolution reaches steady state, we are back to a binary image.*

function that takes its values in the unit interval. Thus, the discussion of this section supersedes that of the previous. Also, from now on we will assume that the image domain D is a bounded subset of $\mathbf{R}^N$ with Lipschitz boundary. The segmentation energy, which we will call MS, can then be written as

$$MS(\Sigma, c_1, c_2) := \mathrm{Per}(\Sigma; D) + \lambda \int_{\Sigma} (c_1 - f(x))^2 \, dx + \lambda \int_{D \setminus \Sigma} (c_2 - f(x))^2 \, dx. \tag{9}$$

The model says we should solve

$$\min_{\substack{c_1, c_2 \in \mathbf{R} \\ \Sigma \subset D}} MS(\Sigma, c_1, c_2). \tag{10}$$

This optimization problem can be interpreted to be looking for the best approximation in the L^2 sense to the given image $f(x)$ among all functions that take only two values. These values, denoted c_1, c_2, and where each is taken, namely, Σ and $D \setminus \Sigma$, are unknowns of the problem. As before, there is a penalty on the geometric complexity of the interface $\partial\Sigma$ that separates the regions where the two values c_1 and c_2 are taken. Functional (9) is nonconvex and can have more than one minimizer. Existence of at least one minimizer follows easily from standard arguments. Notice that if Σ is fixed, the values of c_1 and c_2 that minimize $MS(\Sigma, \cdot, \cdot)$ read

$$c_1 = \frac{1}{|\Sigma|} \int_{\Sigma} f(x) \, dx \quad \text{and} \quad c_2 = \frac{1}{|D \setminus \Sigma|} \int_{D \setminus \Sigma} f(x) \, dx. \tag{11}$$

A natural way to approximate the solution is a two-step scheme where in the first step one computes c_1 and c_2 according to these formulae, and in the second step updates the shape Σ. Even the minimization of $MS(\cdot, c_1, c_2)$ is a difficult problem since this functional is nonconvex. In what follows we focus on the minimization of $MS(\cdot, c_1, c_2)$.

We point out that if the two constants c_1 and c_2 are fixed to be 1 and 0, respectively, and if the given image $f(x)$ in (9) is taken to be the characteristic function $\mathbf{1}_{\Omega}(x)$ of a set Ω, then the minimization problem (10) reduces to the geometry problem (4); it is in this sense that this section's problem is a generalization of the previous section's.

Chan–Vese algorithm. In [7] Chan and Vese proposed a level set–based algorithm for solving the optimization problem (10). The idea is to represent the boundary $\partial\Sigma$ with the 0-level set of the function $\phi : D \to \mathbf{R}^N$. Energy (9) can then be written in terms of the level set function ϕ; it turns out to be

$$\begin{aligned} CV(\phi, c_1, c_2) = &\int_D |\nabla H_\varepsilon(\phi)| \\ &+ \lambda \int_D H_\varepsilon(\phi)(c_1 - f(x))^2 + (1 - H_\varepsilon(\phi))(c_2 - f(x))^2 \, dx. \end{aligned} \tag{12}$$

The function H_ε is, as before, a regularization of the Heaviside function. *The precise choice of the regularization H_ε of H is a crucial ingredient of the Chan–Vese algorithm.* We will return to this topic.

Variations of energy (12) with respect to the level set function ϕ lead to the following gradient descent scheme:

$$\phi_t = H'_\varepsilon(\phi) \left\{ \mathrm{div} \left(\frac{\nabla \phi}{|\nabla \phi|} \right) - \lambda \left((c_1 - f(x))^2 - (c_2 - f(x))^2 \right) \right\}.$$

The optimal choice for the constants c_1, c_2 is easily determined in terms of the function ϕ.

The proposed algorithm. The Chan–Vese algorithm chooses a noncompactly supported, smooth approximation H_ε for H. As a result, the gradient descent equation given above and the following one have the same stationary solutions:

$$\phi_t = \operatorname{div}\left(\frac{\nabla\phi}{|\nabla\phi|}\right) - \lambda\left((c_1 - f(x))^2 - (c_2 - f(x))^2\right),$$

where we simply omitted the approximate Heaviside function altogether. This equation, in turn, is gradient descent for the following energy:

$$\int_D |\nabla\phi| + \lambda \int_D \left((c_1 - f(x))^2 - (c_2 - f(x))^2\right)\phi\, dx. \tag{13}$$

This energy is homogeneous of degree 1 in ϕ. As a result, it does not have a minimizer in general. In other words, the gradient descent written above does not have a stationary state: If the evolution is carried out for a long time, the level set function ϕ would tend to $+\infty$ wherever it is positive, and to $-\infty$ wherever it is negative. This issue is related to the nonuniqueness of representation with level sets and is easy to fix: one can simply restrict minimization to ϕ such that $0 \le \phi(x) \le 1$ for all $x \in D$. With this fix, and following [23, 24], we arrive at the statement below.

THEOREM 2. *For any given fixed $c_1, c_2 \in \mathbf{R}$, a global minimizer for $MS(\cdot, c_1, c_2)$ can be found by carrying out the following convex minimization:*

$$\min_{0\le u\le 1} \underbrace{\int_D |\nabla u| + \lambda \int_D \left\{(c_1 - f(x))^2 - (c_2 - f(x))^2\right\} u(x)\, dx}_{:=\tilde{E}(u,c_1,c_2)}$$

and then setting $\Sigma = \{x : u(x) \ge \mu\}$ for a.e. $\mu \in [0,1]$.

Proof. We once again rely on the coarea formula; since u takes its values in $[0,1]$, we have

$$\int_D |\nabla u| = \int_0^1 \operatorname{Per}(\{x : u(x) > \mu\}; D)\, d\mu.$$

For the other terms that constitute the fidelity term, we proceed as follows:

$$\begin{aligned}\int_D (c_1 - f(x))^2 u(x)\, dx &= \int_D (c_1 - f(x))^2 \int_0^1 \mathbf{1}_{[0,u(x)]}(\mu)\, d\mu\, dx \\ &= \int_0^1 \int_D (c_1 - f(x))^2 \mathbf{1}_{[0,u(x)]}(\mu)\, dx\, d\mu \\ &= \int_0^1 \int_{D\cap\{x:u(x)>\mu\}} (c_1 - f(x))^2\, dx\, d\mu.\end{aligned}$$

Also, we have

$$\begin{aligned}\int_D (c_2 - f(x))^2 u(x)\, dx &= \int_0^1 \int_{D\cap\{x:u(x)>\mu\}} (c_2 - f(x))^2\, dx\, d\mu \\ &= C - \int_0^1 \int_{D\cap\{x:u(x)>\mu\}^c} (c_2 - f(x))^2\, dx\, d\mu,\end{aligned}$$

where $C = \int_D (c_2 - f)^2\,dx$ is independent of u. Putting it all together, and setting $\Sigma(\mu) := \{x : u(x) > \mu\}$, we get the following formula that is valid for any $u(x) \in L^2(D)$ such that $0 \le u(x) \le 1$ for a.e. $x \in D$:

$$\begin{aligned}\tilde{E}(u, c_1, c_2) &= \int_0^1 \left\{ \mathrm{Per}(\Sigma(\mu); D) + \lambda \int_{\Sigma(\mu)} (c_1 - f(x))^2\,dx \right. \\ &\qquad \left. + \lambda \int_{D\setminus\Sigma(\mu)} (c_2 - f(x))^2\,dx \right\} d\mu - C \\ &= \int_0^1 MS\big(\Sigma(\mu), c_1, c_2\big)\,d\mu - C.\end{aligned}$$

It follows that if $u(x)$ is a minimizer of the convex problem, then for a.e. $\mu \in [0, 1]$ the set $\Sigma(\mu)$ has to be a minimizer of the original functional $MS(\cdot, c_1, c_2)$. ∎

Remark. The optimization problem that forms the content of Theorem 2 can be interpreted as follows: The level set formulation of the two-phase model depends on the level set function ϕ only through the term $H(\phi)$. The term $H(\phi)$ represents a parametrization of binary functions (since, for any given function ϕ, the function $H(\phi)$ is binary). So the minimization of (12) is thus a minimization over binary functions. Minimization of (13), on the other hand, corresponds to removing the nonconvex constraint of being binary; instead we minimize over functions that are allowed to take intermediate values. The content of the theorem above is that the minimizers (essentially) automatically satisfy the more stringent constraint.

We now turn to the question of how to minimize the convex problem stated in the theorem. In that connection, we have the following claim.

Claim 1. *Let $s(x) \in L^\infty(D)$. Then the convex, constrained minimization problem*

$$\min_{0\le u\le 1} \int_D |\nabla u| + \lambda \int_D s(x)u\,dx$$

has the same set of minimizers as the following convex, unconstrained *minimization problem:*

$$\min_u \int_D |\nabla u| + \int_D \alpha\nu(u) + \lambda s(x)u\,dx,$$

where $\nu(\xi) := \max\{0, 2|\xi - \frac{1}{2}| - 1\}$, provided that $\alpha > \frac{\lambda}{2}\|s(x)\|_{L^\infty(D)}$.

Proof. The term $\alpha\nu(u)$ that appears in the second, unconstrained minimization problem given in the claim is an *exact penalty* term [13, 14]; see Figure 5 for a plot of its graph. Indeed, the two energies agree for $\{u \in L^\infty(D) : 0 \le u(x) \le 1\ \forall x\}$. So we only need to show that any minimizer of the unconstrained problem automatically satisfies the constraint $0 \le u \le 1$. This is immediate: If $\alpha > \frac{\lambda}{2}\|s(x)\|_{L^\infty}$, then

$$|\lambda s(x)| \max\{|u(x)|, |u(x) - 1|\} < \alpha\nu(u(x)) \text{ whenever } u(x) \in [0, 1]^c,$$

which means that the transformation $u \to \min\{\max\{0, u\}, 1\}$ always decreases the energy of the unconstrained problem (strictly if $u(x) \in [0, 1]^c$ on a set of positive measure). That leads to the desired conclusion. ∎

Numerical examples. Here we detail how we obtained the numerical results pertaining to the two-phase piecewise constant segmentation models that are presented in this paper. Given c_1, c_2, the "exact penalty" formulation of the equivalent

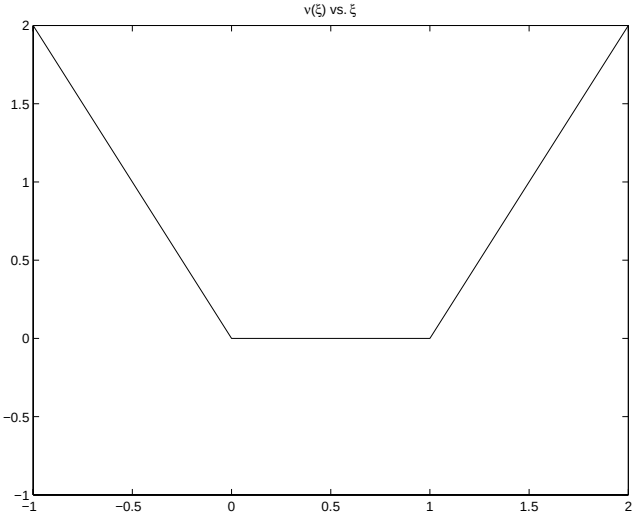

FIG. 5. *The function $\nu(\xi)$ is used for exact penalization as a method to impose the constraint $0 \le u \le 1$ in the minimization of Claim* 1.

minimization problem described above leads to the following Euler–Lagrange equation:

$$\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) - \lambda s(x) - \alpha \nu'(u) = 0,$$

where $s(x) = (c_1 - f(x))^2 - (c_2 - f(x))^2$. The following explicit gradient descent scheme was used to solve the last equation:

$$\frac{u^{n+1} - u^n}{\delta t} = D_x^- \left(\frac{D_x^+ u^n}{\sqrt{(D_x^+ u^n)^2 + (D_y^+ u^n)^2 + \varepsilon_1}} \right) + D_y^- \left(\frac{D_y^+ u^n}{\sqrt{(D_x^+ u^n)^2 + (D_y^+ u^n)^2 + \varepsilon_1}} \right) - \lambda s(x) - \alpha \nu'_{\varepsilon_2}(u^n), \tag{14}$$

where $\varepsilon_1, \varepsilon_2 > 0$ are small constants, and $\nu_{\varepsilon_2}(\xi)$ is a regularized version of $\nu(\xi)$ that smooths the latter's kinks at 0 and 1.

The image shown in the Figure 6 is not piecewise constant with two regions; in fact it is not very well approximated by any image that takes only two values. This makes it a challenging test case for the two-phase segmentation problem (images that are already approximately two-valued are easily and very quickly segmented by these algorithms, and thus are easier examples).

Figure 7 shows the result found (i.e., the function u) using (14) to update the unknown function $u(x)$ that represents the two phases, when the given image $f(x)$ is the one shown in Figure 6. The two constants c_1 and c_2 were initially chosen to be 1 and 0, and updated occasionally according to (11); they eventually converged to 0.4666 and 0.0605, respectively. Although the considerations above (in particular, Theorem 2) do not imply that the minimizers of the objective functional turn out to be binary themselves (which would make the thresholding step in the algorithm

FIG. 6. *The given image $f(x)$ used in the two-phase segmentation numerical results discussed in section* 4.

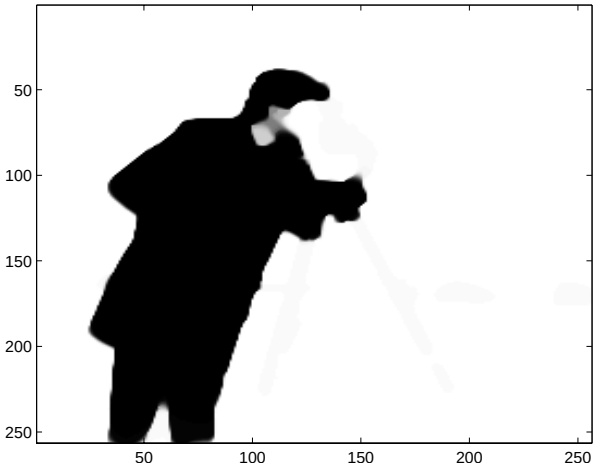

FIG. 7. *The solution $u(x)$ obtained by the numerical scheme of section* 4. *Although our claims do not imply the solution itself turns out to be binary, this seems to be always the case in practice. As can be seen, the computed solution is very close to being binary.*

of Theorem 2 unnecessary), in practice they seem to. Indeed, the image of Figure 7 is very close to being binary. Furthermore, it gets even closer to being binary if the computation is repeated using smaller values of the regularization parameters ε_1 and ε_2 that appear in scheme (14). On the other hand, it might be possible to cook up special given images f and special values λ for which there are nonbinary minimizers; for instance, in the case of the convex formulation (7) of the related geometry problem (4), the simple example of a disk as the given shape leads to nonbinary solutions for a specific choice of the parameter λ, as shown in [6].

Figure 8 displays the histograms of $u(x)$ at intermediate stages of the gradient descent computation. During the evolution, the function u certainly takes a continuum of values; however, as the steady state approaches, the values that u can take accumulate at the extreme ends of its allowed range. In this case, the extreme values

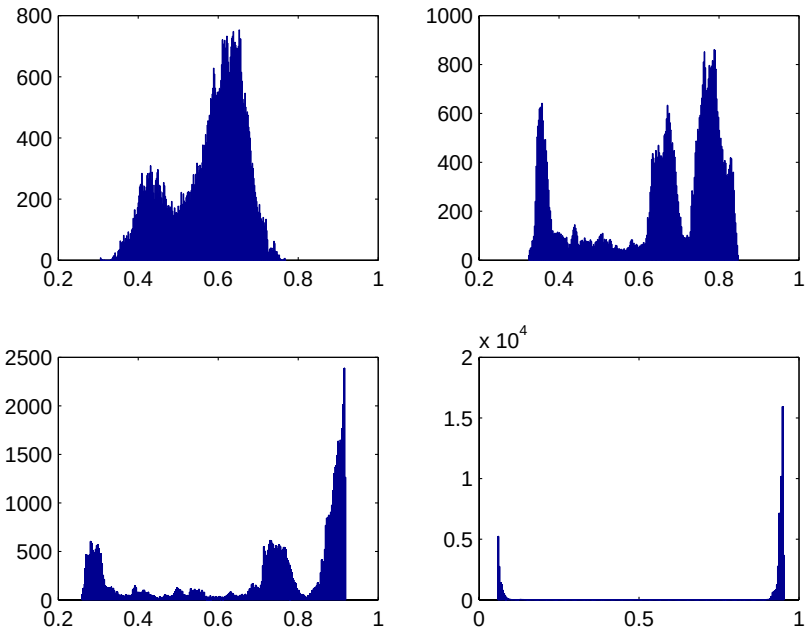

FIG. 8. *Histograms of intermediate solutions* $u^n(x)$ *of the flow in* (14)*, for the example of Figures* 6 *and* 7.

seem to be about 0.04 at the low end and 0.97 at the high end. They are not 0 and 1 because the exact penalty function ν that appears in (14) is regularized.

The theory above says that for fixed c_1 and c_2, all level sets of the function $u(x)$ are minimizers. The table below shows the value of energy (9) computed by taking $\Sigma = \{x : u(x) = \mu\}$ for several different values of μ, where $u(x)$ is the numerical example of Figures 6, 7, and 8, and the constants c_1 and c_2 have the values quoted above.

μ	Energy
0.2	17.7055
0.4	17.6458
0.5	17.6696
0.6	17.6655
0.8	17.6740

For comparison, we note that the energy of a disk centered at the middle of the image with radius a quarter of a side of the image domain has energy of about 112. Thus, even though there is some minor variation among different level sets of the function $u(x)$ (see Figure 9 for a plot of several level contours) and their corresponding energies (due to some of the approximations, such as in the penalty function μ, that were made to get a practical numerical algorithm), the difference in energy between them is quite small; they are all almost minimizers.

Acknowledgment. The authors would like to thank Prof. Robert V. Kohn, from whom they learned the observations of Strang in [23, 24].

MULTIPLE SCATTERING BY MULTIPLE SPHERES: A NEW PROOF OF THE LLOYD–BERRY FORMULA FOR THE EFFECTIVE WAVENUMBER*

C. M. LINTON† AND P. A. MARTIN‡

Abstract. We provide the first classical derivation of the Lloyd–Berry formula for the effective wavenumber of an acoustic medium filled with a sparse random array of identical small scatterers. Our approach clarifies the assumptions under which the Lloyd–Berry formula is valid. More precisely, we derive an expression for the effective wavenumber which assumes the validity of Lax's quasi-crystalline approximation but makes no further assumptions about scatterer size, and then we show that the Lloyd–Berry formula is obtained in the limit as the scatterer size tends to zero.

Key words. multiple scattering, effective wavenumber, random media, acoustics

1. Introduction.

Suppose that we are interested in the scattering of sound by many small scatterers; for example, we might be interested in using ultrasound to determine the quality of certain composites [15], fresh mortar [2], or food products such as mayonnaise [24]. If we knew the shape, size, and location of every scatterer, we could solve the multiple-scattering problem by solving a boundary integral equation, for example [22]. However, usually we do not have this information. Thus, it is common to regard the volume containing the scatterers as a random medium, with certain average (homogenized) properties. Here, we are concerned with finding an *effective wavenumber*, K, that can be used for modeling wave propagation through the scattering volume. This is a classical topic with a large literature: we cite well-known papers by Foldy [7], Lax [18, 19], Waterman and Truell [28], Twersky [26], and Fikioris and Waterman [6], and we refer to the book by Tsang et al. [25] for more information.

A typical problem is the following. The region $z < 0$ is filled with a homogeneous compressible fluid of density ρ and sound-speed c. The region $z > 0$ contains the same fluid and many scatterers; to fix ideas, suppose that the scatterers are identical spheres. Then, a time-harmonic plane wave with wavenumber $k = \omega/c$ (ω is the angular frequency) is incident on the scatterers. The scattered field may be computed exactly for any given configuration (ensemble) of N spheres, but the cost increases as N increases. If the computation can be done, it may be repeated for other configurations, and then the average reflected field could be computed (this is the Monte Carlo approach). Instead of doing this, we shall do some ensemble averaging in order to calculate the average (coherent) field. One result of this is a formula for K.

Foldy [7] considered isotropic point scatterers; this is an appropriate model for

small sound-soft scatterers. He obtained the formula

$$K^2 = k^2 - 4\pi \mathrm{i} g n_0/k, \tag{1.1}$$

where n_0 is the number of spheres per unit volume and g is the scattering coefficient for an isolated scatterer. The formula (1.1) assumes that the scatterers are independent and that n_0 is small. We are interested in calculating the correction to (1.1) (a term proportional to n_0^2), and this will require saying more about the distribution of the scatterers; specifically, we shall use pair correlations. Thus, our goal is a formula of the form

$$K^2 = k^2 + \delta_1 n_0 + \delta_2 n_0^2, \tag{1.2}$$

with computable expressions for δ_1 and δ_2. Moreover, we do not want to restrict our formula only to sound-soft scatterers.

There is some controversy over the proper value for δ_2. In order to state one such formula, we introduce the *far-field pattern* f. For scattering by one sphere, we have $u_{\mathrm{in}} = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r})$ for the incident plane wave, where $\boldsymbol{k} = k\hat{\boldsymbol{k}}$, $\boldsymbol{r} = r\hat{\boldsymbol{r}}$, $k = |\boldsymbol{k}|$, and $r = |\boldsymbol{r}|$; the angle of incidence, θ_{in}, is defined by $\cos\theta_{\mathrm{in}} = \hat{\boldsymbol{k}}\cdot\hat{\mathbf{z}}$, where $\hat{\mathbf{z}} = (0,0,1)$ is a unit vector in the z-direction. Then the scattered waves satisfy

$$u_{\mathrm{sc}} \sim (\mathrm{i}kr)^{-1}\mathrm{e}^{\mathrm{i}kr} f(\Theta) \quad \text{as } kr \to \infty, \tag{1.3}$$

where $\cos\Theta = \hat{\boldsymbol{r}}\cdot\hat{\boldsymbol{k}}$. Then, Twersky [26] has obtained (1.2) with

$$\delta_1 = -(4\pi\mathrm{i}/k) f(0) \quad \text{and} \quad \delta_2 = (4\pi^2/k^4)\sec^2\theta_{\mathrm{in}} \left\{ [f(\pi - 2\theta_{\mathrm{in}})]^2 - [f(0)]^2 \right\}. \tag{1.4}$$

The formula for δ_2 involves θ_{in}, so that it gives a different effective wavenumber for different incident fields. The same formulas but with $\theta_{\mathrm{in}} = 0$ (normal incidence) were given by Urick and Ament [27] and by Waterman and Truell [28]:

$$\delta_1 = -(4\pi\mathrm{i}/k) f(0) \quad \text{and} \quad \delta_2 = (4\pi^2/k^4) \left\{ [f(\pi)]^2 - [f(0)]^2 \right\}. \tag{1.5}$$

Other formulas were obtained more recently [14, 30].

In 1967, Lloyd and Berry [21] showed that the formula for δ_2 should be

$$\delta_2 = \frac{4\pi^2}{k^4} \left\{ -[f(\pi)]^2 + [f(0)]^2 + \int_0^\pi \frac{1}{\sin(\theta/2)} \frac{\mathrm{d}}{\mathrm{d}\theta} [f(\theta)]^2 \, \mathrm{d}\theta \right\}, \tag{1.6}$$

with no dependence on θ_{in}. They used methods and language coming from nuclear physics. Thus, in their approach, which they

> call the "resummation method," a point source of waves is considered to be situated in an infinite medium. The scattering series is then written out completely, giving what Lax has called the "expanded" representation. In this expanded representation the ensemble average may be taken exactly [but then] the coherent wave does not exist; the series must be resummed in order to obtain any result at all.

The main purpose of the present paper is to demonstrate that a proper analysis of the semi-infinite model problem (with arbitrary angle of incidence) leads to the Lloyd–Berry formula. Our analysis does not involve "resumming" series or divergent integrals. It builds on a conventional approach, in the spirit of the paper by Fikioris and Waterman [6].

There are two good reasons for giving a new derivation of the Lloyd–Berry formula. First, our analysis clarifies the assumptions that lead to (1.6). Second, erroneous formulas (such as (1.4) or (1.5)) continue to be used widely, perhaps because they are simpler than (1.6) or perhaps because the original derivation in [21] seems suspect. For some representative applications, see [15, 2, 23] and [24, Chapter 4].

The paper begins with a brief summary of some elementary probability theory. The pair-correlation function is introduced, including the notion of "hole correction," which ensures that spheres do not overlap during the averaging process. In section 3, we consider isotropic scatterers and derive the integral equations of Foldy (independent scatterers, no hole correction) and of Lax (hole correction included). Foldy's equation is solved exactly. A method is developed in section 3.2 for obtaining an expression for K which does not require an exact solution of the integral equation, merely an assumption that an effective wavenumber can be used at some distance from the "interface" at $z = 0$ between the homogeneous region ($z < 0$) and the region occupied by many small scatterers ($z > 0$). The virtue of this method is that it succeeds when the governing integral equation cannot be solved exactly. Thus, in section 3.3, we obtain an expression for K from Lax's integral equation; Foldy's approximation is recovered when the hole correction is removed. The same method is used in section 4 but without the restriction to isotropic scatterers. We start with an exact, deterministic theory for acoustic scattering by N spheres; the spheres can be soft, hard, or penetrable. We combine multipole solutions in spherical polar coordinates with an appropriate addition theorem. This method is well known; for some recent applications, see [17, 10, 12]. The exact system of equations is then subjected to ensemble averaging in section 4.3; Lax's "quasi-crystalline approximation" [19] is invoked. This leads to a homogeneous infinite system of linear algebraic equations; the existence of a nontrivial solution determines K. We solve the system for small n_0 and recover the Lloyd–Berry formula.

An analogous theory can be developed in two dimensions and leads to a result that is reminiscent of the Lloyd–Berry formula [20]. However, the three-dimensional calculations described below are much more complicated, as they involve addition theorems for spherical wavefunctions and properties of spherical harmonics. Nevertheless, the final results are rather simple.

2. Some probability theory. In this section, we give a very brief summary of the probability theory needed. For more information, see [7], [18], or Chapter 14 of [13].

Suppose that we have N scatterers located at the points $\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N$; denote the configuration of points by $\Lambda_N = \{\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N\}$. Then, the ensemble (or configurational) average of any quantity $F(\boldsymbol{r}|\Lambda_N)$ is defined by

$$\langle F(\boldsymbol{r})\rangle = \int\cdots\int p(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N)\, F(\boldsymbol{r}|\Lambda_N)\, \mathrm{d}V_1 \cdots \mathrm{d}V_N, \tag{2.1}$$

where the integration is over N copies of the volume B_N containing N scatterers. Here, $p(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N)\, \mathrm{d}V_1\, \mathrm{d}V_2 \cdots \mathrm{d}V_N$ is the probability of finding the scatterers in a configuration in which the first scatterer is in the volume element $\mathrm{d}V_1$ about $\boldsymbol{r}_1$, the second scatterer is in the volume element $\mathrm{d}V_2$ about $\boldsymbol{r}_2$, and so on, up to $\boldsymbol{r}_N$. The joint probability distribution $p(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N)$ is normalized so that $\langle 1\rangle = 1$. Similarly, the average of $F(\boldsymbol{r}|\Lambda_N)$ over all configurations for which the first scatterer is fixed

at $\boldsymbol{r}_1$ is given by

$$\langle F(\boldsymbol{r})\rangle_1 = \int\cdots\int p(\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N|\boldsymbol{r}_1)\,F(\boldsymbol{r}|\Lambda_N)\,\mathrm{d}V_2\cdots\mathrm{d}V_N, \tag{2.2}$$

where the conditional probability $p(\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N|\boldsymbol{r}_1)$ is defined by $p(\boldsymbol{r}_1,\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N) = p(\boldsymbol{r}_1)\,p(\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N|\boldsymbol{r}_1)$. If two scatterers are fixed, say the first and the second, we can define

$$\langle F(\boldsymbol{r})\rangle_{12} = \int\cdots\int p(\boldsymbol{r}_3,\ldots,\boldsymbol{r}_N|\boldsymbol{r}_1,\boldsymbol{r}_2)\,F(\boldsymbol{r}|\Lambda_N)\,\mathrm{d}V_3\cdots\mathrm{d}V_N, \tag{2.3}$$

where $p(\boldsymbol{r}_2,\ldots,\boldsymbol{r}_N|\boldsymbol{r}_1) = p(\boldsymbol{r}_2|\boldsymbol{r}_1)\,p(\boldsymbol{r}_3,\ldots,\boldsymbol{r}_N|\boldsymbol{r}_1,\boldsymbol{r}_2)$.

As each of the N scatterers is equally likely to occupy $\mathrm{d}V_1$, the density of scatterers at $\boldsymbol{r}_1$ is $Np(\boldsymbol{r}_1) = n_0$, the (constant) number of scatterers per unit volume. Thus

$$p(\boldsymbol{r}) = n_0/N = |B_N|^{-1}, \tag{2.4}$$

where $|B_N|$ is the volume of B_N. For spheres of radius a, the simplest sensible choice for the pair-correlation function is

$$p(\boldsymbol{r}_2|\boldsymbol{r}_1) = (n_0/N)H(R_{12}-b), \quad \text{where } R_{12} = |\boldsymbol{r}_1-\boldsymbol{r}_2| \tag{2.5}$$

and H is the Heaviside unit function: $H(x) = 1$ for $x > 0$, and $H(x) = 0$ for $x < 0$. The parameter b (the "hole radius") satisfies $b \geq 2a$ so that spheres are not allowed to overlap.

3. Foldy–Lax theory: Isotropic scatterers. Foldy's theory [7] begins with a simplified deterministic model for scattering by N identical scatterers, each of which is supposed to scatter isotropically. Thus, the total field is assumed to be given by the incident field plus a point source at each scattering center, $\boldsymbol{r}_j$:

$$u(\boldsymbol{r}|\Lambda_N) = u_{\mathrm{in}}(\boldsymbol{r}) + g\sum_{j=1}^{N} u_{\mathrm{ex}}(\boldsymbol{r}_j;\boldsymbol{r}_j|\Lambda_N)\,h_0(k|\boldsymbol{r}-\boldsymbol{r}_j|). \tag{3.1}$$

Here, $h_n(w) \equiv h_n^{(1)}(w)$ is a spherical Hankel function, g is the (assumed known) scattering coefficient, and the exciting field u_{ex} is given by

$$u_{\mathrm{ex}}(\boldsymbol{r};\boldsymbol{r}_n|\Lambda_N) = u_{\mathrm{in}}(\boldsymbol{r}) + g\sum_{\substack{j=1\\ j\neq n}}^{N} u_{\mathrm{ex}}(\boldsymbol{r}_j;\boldsymbol{r}_j|\Lambda_N)\,h_0(k|\boldsymbol{r}-\boldsymbol{r}_j|); \tag{3.2}$$

the N numbers $u_{\mathrm{ex}}(\boldsymbol{r}_j;\boldsymbol{r}_j|\Lambda_N)$ $(j = 1,2,\ldots,N)$ required in (3.1) are to be determined by solving the linear system obtained by evaluating (3.2) at $\boldsymbol{r} = \boldsymbol{r}_n$.

If we try to compute the ensemble average of u, using (3.1) and (2.1), we obtain

$$\langle u(\boldsymbol{r})\rangle = u_{\mathrm{in}}(\boldsymbol{r}) + gn_0\int_{B_N}\langle u_{\mathrm{ex}}(\boldsymbol{r}_1)\rangle_1\,h_0(k|\boldsymbol{r}-\boldsymbol{r}_1|)\,\mathrm{d}V_1, \tag{3.3}$$

where we have used (2.2), (2.4), and the indistinguishability of the scatterers. For $\langle u_{\mathrm{ex}}(\boldsymbol{r}_1)\rangle_1$, we obtain

$$\langle u_{\mathrm{ex}}(\boldsymbol{r})\rangle_1 = u_{\mathrm{in}}(\boldsymbol{r}) + g(N-1)\int_{B_N} p(\boldsymbol{r}_2|\boldsymbol{r}_1)\,\langle u_{\mathrm{ex}}(\boldsymbol{r}_2)\rangle_{12}\,h_0(k|\boldsymbol{r}-\boldsymbol{r}_2|)\,\mathrm{d}V_2, \tag{3.4}$$

where we have used (2.3) and (3.2). Equations (3.3) and (3.4) are the first two in a hierarchy, involving more and more complicated information on the statistics of the scatterer distribution. In practice, the hierarchy is broken using an additional assumption. At the lowest level, we have Foldy's assumption,

$$\langle u_{\rm ex}(\boldsymbol{r})\rangle_1 \simeq \langle u(\boldsymbol{r})\rangle, \tag{3.5}$$

at least in the neighborhood of $\boldsymbol{r}_1$. When this is used in (3.3), we obtain

$$\langle u(\boldsymbol{r})\rangle = u_{\rm in}(\boldsymbol{r}) + gn_0 \int_{B_N} \langle u(\boldsymbol{r}_1)\rangle\, h_0(k|\boldsymbol{r}-\boldsymbol{r}_1|)\,{\rm d}V_1, \quad \boldsymbol{r}\in B_N. \tag{3.6}$$

We call this *Foldy's integral equation* for $\langle u\rangle$. The integral on the right-hand side is an acoustic volume potential. Hence, an application of (∇^2+k^2) to (3.6) eliminates the incident field and shows that $(\nabla^2+K^2)\langle u\rangle = 0$ in B_N, where K^2 is given by Foldy's formula, (1.1).

At the next level, we have Lax's quasi-crystalline assumption (QCA) [19],

$$\langle u_{\rm ex}(\boldsymbol{r})\rangle_{12} \simeq \langle u_{\rm ex}(\boldsymbol{r})\rangle_2. \tag{3.7}$$

When this is used in (3.4) evaluated at $\boldsymbol{r}=\boldsymbol{r}_1$, we obtain

$$v(\boldsymbol{r}) = u_{\rm in}(\boldsymbol{r}) + g(N-1)\int_{B_N} p(\boldsymbol{r}_1|\boldsymbol{r})\, v(\boldsymbol{r}_1)\, h_0(k|\boldsymbol{r}-\boldsymbol{r}_1|)\,{\rm d}V_1, \quad \boldsymbol{r}\in B_N, \tag{3.8}$$

where $v(\boldsymbol{r}) = \langle u_{\rm ex}(\boldsymbol{r})\rangle_1$. We call this *Lax's integral equation*.

In what follows, we let $N\to\infty$ so that $B_N\to B_\infty$, a semi-infinite region, $z>0$.

3.1. Foldy's integral equation: Exact treatment. Consider a plane wave at oblique incidence, so that

$$u_{\rm in} = \exp({\rm i}\boldsymbol{k}\cdot\boldsymbol{r}) = {\rm e}^{{\rm i}\alpha z}\exp({\rm i}\boldsymbol{k}_T\cdot\boldsymbol{q}), \tag{3.9}$$

where $\boldsymbol{r}=(x,y,z)$, $\boldsymbol{q}=(x,y,0)$, $\boldsymbol{k}=\boldsymbol{k}_T+\alpha\hat{\mathbf{z}}$, $\hat{\mathbf{z}}=(0,0,1)$, the wavenumber vector $\boldsymbol{k}$ is given in spherical polar coordinates by

$$\boldsymbol{k} = k\hat{\boldsymbol{k}} \quad \text{with} \quad \hat{\boldsymbol{k}} = (\sin\theta_{\rm in}\,\cos\phi_{\rm in},\ \sin\theta_{\rm in}\,\sin\phi_{\rm in},\ \cos\theta_{\rm in}), \quad 0\le\theta_{\rm in}<\pi/2,$$

$\alpha = k\cos\theta_{\rm in}$, and $\boldsymbol{k}_T$ is the transverse wavenumber vector, satisfying $\boldsymbol{k}_T\cdot\hat{\mathbf{z}}=0$.

For a semi-infinite domain B_∞ ($z>0$), Foldy's integral equation (3.6) becomes

$$\langle u(x,y,z)\rangle = u_{\rm in}(x,y,z) + gn_0\int_0^\infty\int_{-\infty}^\infty\int_{-\infty}^\infty \langle u(x+X,y+Y,z_1)\rangle\, h_0(k\varrho_1)\,{\rm d}X\,{\rm d}Y\,{\rm d}z_1,$$

for $0\le|x|<\infty$, $0\le|y|<\infty$, and $z>0$, where $\varrho_1=\sqrt{X^2+Y^2+(z-z_1)^2}$. This equation can be solved exactly. Thus, writing

$$\langle u(x,y,z)\rangle = U(z)\,\exp({\rm i}\boldsymbol{k}_T\cdot\boldsymbol{q}), \quad 0\le|\boldsymbol{q}|<\infty, \quad z>0, \tag{3.10}$$

we obtain

$$U(z) = {\rm e}^{{\rm i}\alpha z} + gn_0\int_0^\infty\int_{-\infty}^\infty\int_{-\infty}^\infty U(z_1)\,h_0(k\varrho_1)\,\exp({\rm i}\boldsymbol{k}_T\cdot\mathbf{Q})\,{\rm d}X\,{\rm d}Y\,{\rm d}z_1 \tag{3.11}$$

for $z > 0$, where $\mathbf{Q} = (X, Y, 0)$.

In Appendix B, it is shown that

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h_0(k\varrho_1)\,\exp\left(\mathrm{i}\boldsymbol{k}_T\cdot\mathbf{Q}\right)\mathrm{d}X\,\mathrm{d}Y = \frac{2\pi}{k\alpha}\,\mathrm{e}^{\mathrm{i}\alpha|z-z_1|}. \tag{3.12}$$

Thus, we see that U solves

$$U(z) = \mathrm{e}^{\mathrm{i}\alpha z} + \frac{2\pi g n_0}{k\alpha}\int_0^{\infty} U(z_1)\,\mathrm{e}^{\mathrm{i}\alpha|z-z_1|}\,\mathrm{d}z_1, \quad z > 0. \tag{3.13}$$

Now, set $U(z) = U_0\,\mathrm{e}^{\mathrm{i}\lambda z}$, so that (3.13) gives

$$U_0\,\mathrm{e}^{\mathrm{i}\lambda z} - \mathrm{e}^{\mathrm{i}\alpha z} = \frac{2\pi g n_0}{\mathrm{i}k\alpha}U_0\left(\frac{2\alpha\mathrm{e}^{\mathrm{i}\lambda z}}{\lambda^2-\alpha^2} - \frac{\mathrm{e}^{\mathrm{i}\alpha z}}{\lambda-\alpha}\right),$$

where we have assumed that $\operatorname{Im}\lambda > 0$. If we compare the coefficients of $\mathrm{e}^{\mathrm{i}\lambda z}$, we see that U_0 cancels, leaving

$$\lambda^2 - \alpha^2 = -4\pi\mathrm{i}g n_0/k, \tag{3.14}$$

which determines λ. Then, the coefficients of $\mathrm{e}^{\mathrm{i}\alpha z}$ give $U_0 = 2\alpha/(\lambda+\alpha)$. A similar method can be used to find $\langle u\rangle$ when B_∞ is a slab of finite thickness, $0 < z < h$.

It is natural to define an effective wavenumber vector by

$$\begin{aligned}\mathbf{K} &= K(\sin\vartheta\cos\varphi,\ \sin\vartheta\sin\varphi,\ \cos\vartheta) = K\hat{\mathbf{K}}\\ &= (k\sin\theta_{\mathrm{in}}\cos\phi_{\mathrm{in}},\ k\sin\theta_{\mathrm{in}}\sin\phi_{\mathrm{in}},\ \lambda),\end{aligned} \tag{3.15}$$

whence

$$\lambda = K\cos\vartheta \quad\text{and}\quad K\sin\vartheta = k\sin\theta_{\mathrm{in}}. \tag{3.16}$$

The last equality is recognized as Snell's law, even though K and ϑ are complex, with $\operatorname{Im}K > 0$. Hence, we see that

$$\lambda^2 - \alpha^2 = K^2 - k^2, \tag{3.17}$$

whence (3.14) reduces to Foldy's formula (1.1).

3.2. Foldy's integral equation: Alternative treatment. We have seen that Foldy's integral equation can be solved exactly, and that the solution process has two parts: first find λ (and hence the effective wavenumber) and then find U_0. In fact, λ can be found without finding the complete solution; the reason for pursuing this is that we cannot usually find exact solutions. Thus, consider (3.13), and suppose that

$$U(z) = U_0\mathrm{e}^{\mathrm{i}\lambda z} \quad \text{for } z > \ell,$$

where U_0, λ, and ℓ are unknown. To proceed, we need say nothing about the solution U in the "boundary layer" $0 < z < \ell$. Now, evaluate the integral equation for $z > \ell$; we find that

$$\begin{aligned}U_0\,\mathrm{e}^{\mathrm{i}\lambda z} - \mathrm{e}^{\mathrm{i}\alpha z} &= \frac{2\pi g n_0}{k\alpha}\,\mathrm{e}^{\mathrm{i}\alpha z}\int_0^{\ell} U(t)\,\mathrm{e}^{-\mathrm{i}\alpha t}\,\mathrm{d}t + \frac{2\pi g n_0}{k\alpha}\int_{\ell}^{\infty} U(t)\,\mathrm{e}^{\mathrm{i}\alpha|z-t|}\,\mathrm{d}t\\ &= \mathcal{A}\,\mathrm{e}^{\mathrm{i}\lambda z} + \mathcal{B}\,\mathrm{e}^{\mathrm{i}\alpha z} \quad \text{for } z > \ell,\end{aligned}$$

where $\mathcal{A} = -4\pi \mathrm{i} g n_0 U_0/[k(\lambda^2 - \alpha^2)]$ and

$$\mathcal{B} = \frac{2\pi g n_0}{k\alpha} \int_0^\ell U(t)\, \mathrm{e}^{-\mathrm{i}\alpha t}\, \mathrm{d}t + \frac{2\pi \mathrm{i} g n_0 U_0}{k\alpha(\lambda - \alpha)}\, \mathrm{e}^{\mathrm{i}(\lambda-\alpha)\ell}.$$

Then, setting $U_0 = \mathcal{A}$ gives (3.14) again, without knowing the solution U everywhere. This basic method will be used again below.

3.3. Lax's integral equation. Using (2.5) for $p(\boldsymbol{r}_1|\boldsymbol{r})$ in (3.8) gives

$$v(\boldsymbol{r}) = u_{\mathrm{in}}(\boldsymbol{r}) + g n_0 \frac{N-1}{N} \int_{B_N^b} v(\boldsymbol{r}_1)\, h_0(kR_1)\, \mathrm{d}\boldsymbol{r}_1, \quad \boldsymbol{r} \in B_N, \tag{3.18}$$

where $B_N^b(\boldsymbol{r}) = \{\boldsymbol{r}_1 \in B_N : R_1 = |\boldsymbol{r} - \boldsymbol{r}_1| > b\}$, which is B_N with a (possibly incomplete) ball excluded.

Let $N \to \infty$ and take an incident plane wave, (3.9), giving

$$v(x,y,z) = \mathrm{e}^{\mathrm{i}\alpha z} \exp(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}) + g n_0 \int_{z_1>0,\ \varrho_1>b} v(x+X, y+Y, z_1)\, h_0(k\varrho_1)\, \mathrm{d}X\, \mathrm{d}Y\, \mathrm{d}z_1,$$

for $0 \le |\boldsymbol{q}| < \infty$ and $z > 0$. As in section 3.1, we write

$$v(x,y,z) = V(z)\, \exp(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}), \quad 0 \le |\boldsymbol{q}| < \infty, \quad z > 0, \tag{3.19}$$

giving

$$V(z) = \mathrm{e}^{\mathrm{i}\alpha z} + g n_0 \int_{z_1>0,\ \varrho_1>b} V(z_1)\, h_0(k\varrho_1)\, \exp(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q})\, \mathrm{d}X\, \mathrm{d}Y\, \mathrm{d}z_1 \tag{3.20}$$

for $0 \le |\boldsymbol{q}| < \infty$ and $z > 0$, where $\mathbf{Q} = (X, Y, 0)$. Then, using (3.12), we see that V solves

$$V(z) = \mathrm{e}^{\mathrm{i}\alpha z} + g n_0 \int_0^\infty V(z_1)\, \mathcal{L}(z - z_1)\, \mathrm{d}z_1, \quad z > 0, \tag{3.21}$$

where the kernel, $\mathcal{L}(z - z_1)$, is given by

$$\begin{aligned} \mathcal{L}(Z) &= \frac{2\pi}{k\alpha} \mathrm{e}^{\mathrm{i}\alpha|Z|} - \int_0^{c(Z)} \int_0^{2\pi} h_0(k\sqrt{Q^2+Z^2}) \mathrm{e}^{\mathrm{i}kQ \sin\theta_{\mathrm{in}} \cos(\Phi - \phi_{\mathrm{in}})} Q\, \mathrm{d}\Phi\, \mathrm{d}Q \\ &= \frac{2\pi}{k\alpha}\, \mathrm{e}^{\mathrm{i}\alpha|Z|} - 2\pi \int_0^{c(Z)} h_0(k\sqrt{Q^2+Z^2})\, J_0(kQ\sin\theta_{\mathrm{in}})\, Q\, \mathrm{d}Q \end{aligned} \tag{3.22}$$

with $c(Z) = \sqrt{b^2 - Z^2}\, H(b - |Z|)$; here, J_n is a Bessel function, and we have written the double integral over X and Y in (3.20) as an integral over all X and Y minus an integral through the cross section of the ball at z, if necessary.

We have been unable to solve (3.21) exactly. However, the alternative method described in section 3.2 can be used. Thus, let us suppose that

$$V(z) = V_0\, \mathrm{e}^{\mathrm{i}\lambda z} \quad \text{for } z > \ell, \tag{3.23}$$

where V_0, λ, and ℓ are unknown. Then, consider (3.21) for $z > \ell + b$, so that the interval $|z - z_1| < b$ is entirely within the range $z_1 > \ell$. Using (3.22), (3.21) gives

$$\begin{aligned} \frac{V_0\, \mathrm{e}^{\mathrm{i}\lambda z} - \mathrm{e}^{\mathrm{i}\alpha z}}{g n_0} &= \frac{2\pi}{k\alpha}\, \mathrm{e}^{\mathrm{i}\alpha z} \int_0^\ell V(t)\, \mathrm{e}^{-\mathrm{i}\alpha t}\, \mathrm{d}t + \frac{2\pi}{k\alpha} \int_\ell^\infty V(t)\, \mathrm{e}^{\mathrm{i}\alpha|z-t|}\, \mathrm{d}t \\ &\quad - 2\pi \int_{z-b}^{z+b} V(t) \int_0^{c(z-t)} h_0(k\sqrt{Q^2 + (z-t)^2})\, J_0(kQ\sin\theta_{\mathrm{in}})\, Q\, \mathrm{d}Q\, \mathrm{d}t \end{aligned} \tag{3.24}$$

for $z > \ell + b$. Equation (3.23) can be used in the second and third integrals. The second integral is elementary, and has the value

$$\frac{2\pi \mathrm{i} V_0}{k\alpha}\left\{\frac{\mathrm{e}^{\mathrm{i}(\lambda-\alpha)\ell}}{\lambda-\alpha}\,\mathrm{e}^{\mathrm{i}\alpha z} - \frac{2\alpha}{\lambda^2-\alpha^2}\,\mathrm{e}^{\mathrm{i}\lambda z}\right\}.$$

Denote the third integral in (3.24) by I_3; we have

$$\begin{aligned} I_3 &= -2\pi V_0 \int_{-b}^{b} \mathrm{e}^{\mathrm{i}\lambda(z+\xi)} \int_0^{\sqrt{b^2-\xi^2}} h_0(k\sqrt{Q^2+\xi^2})\, J_0(kQ\sin\theta_{\mathrm{in}})\, Q\,\mathrm{d}Q\,\mathrm{d}\xi \\ &= -2\pi V_0\,\mathrm{e}^{\mathrm{i}\lambda z} \int_0^{\pi}\int_0^{b} \mathrm{e}^{\mathrm{i}\lambda r\cos\theta}\, h_0(kr)\, J_0(kr\sin\theta\sin\theta_{\mathrm{in}})\, r^2\sin\theta\,\mathrm{d}r\,\mathrm{d}\theta \\ &= -V_0\,\mathrm{e}^{\mathrm{i}\lambda z} \int_0^{2\pi}\int_0^{\pi}\int_0^{b} \mathrm{e}^{\mathrm{i}r[\lambda\cos\theta + k\sin\theta\sin\theta_{\mathrm{in}}\cos(\phi-\phi_{\mathrm{in}})]}\, h_0(kr)\, r^2\sin\theta\,\mathrm{d}r\,\mathrm{d}\theta\,\mathrm{d}\phi. \end{aligned}$$

Using (3.16), the exponent simplifies to $\mathbf{K}\cdot\boldsymbol{r}$, whence

$$\begin{aligned} I_3 &= -V_0\,\mathrm{e}^{\mathrm{i}\lambda z} \int_{r<b} \exp(\mathrm{i}\mathbf{K}\cdot\boldsymbol{r}) h_0(k|\boldsymbol{r}|)\,\mathrm{d}V(\boldsymbol{r}) \\ &= -2\pi V_0\,\mathrm{e}^{\mathrm{i}\lambda z} \int_0^{b}\int_0^{\pi} \frac{\mathrm{e}^{\mathrm{i}kr}}{\mathrm{i}kr}\,\mathrm{e}^{\mathrm{i}Kr\cos\theta}\, r^2\sin\theta\,\mathrm{d}\theta\,\mathrm{d}r \\ &= \frac{2\pi V_0}{kK}\,\mathrm{e}^{\mathrm{i}\lambda z}\int_0^{b}\mathrm{e}^{\mathrm{i}kr}\left(\mathrm{e}^{\mathrm{i}Kr}-\mathrm{e}^{-\mathrm{i}Kr}\right)\mathrm{d}r = \frac{4\pi\mathrm{i}V_0}{k(K^2-k^2)}\,\mathrm{e}^{\mathrm{i}\lambda z}\{1-\mathcal{N}_0(Kb)\}, \end{aligned}$$

where $\mathcal{N}_0(x) = \mathrm{e}^{\mathrm{i}kb}\{\cos x - \mathrm{i}(kb/x)\sin x\}$. Using these results in (3.24) and noting (3.17), we obtain

$$V_0\,\mathrm{e}^{\mathrm{i}\lambda z} - \mathrm{e}^{\mathrm{i}\alpha z} = \mathcal{A}\,\mathrm{e}^{\mathrm{i}\lambda z} + \mathcal{B}\,\mathrm{e}^{\mathrm{i}\alpha z} \quad \text{for } z > \ell + b,$$

where

$$\mathcal{A} = \frac{4\pi\mathrm{i}gn_0V_0}{k(k^2-K^2)}\,\mathcal{N}_0(Kb), \qquad \mathcal{B} = \frac{2\pi g n_0}{k\alpha}\int_0^{\ell} V(t)\,\mathrm{e}^{-\mathrm{i}\alpha t}\,\mathrm{d}t + \frac{2\pi\mathrm{i}gn_0V_0}{k\alpha(\lambda-\alpha)}\,\mathrm{e}^{\mathrm{i}(\lambda-\alpha)\ell}.$$

For a solution, we must have $\mathcal{A} = V_0$, whence

$$K^2 = k^2 - 4\pi\mathrm{i}g(n_0/k)\,\mathcal{N}_0(Kb), \tag{3.25}$$

which is a nonlinear equation for K. Notice that this equation does not depend on the angle of incidence, θ_{in}.

We have $\mathcal{N}_0(Kb) \to 1$ as $Kb \to 0$ so that, in this limit, we recover Foldy's formula for the effective wavenumber, (1.1).

Let us solve (3.25) for small n_0. (We could use the dimensionless volume fraction $\frac{4}{3}\pi a^3 n_0$, but it is customary to use n_0.) Begin by writing

$$K^2 = k^2 + \delta_1 n_0 + \delta_2 n_0^2 + \cdots, \tag{3.26}$$

where δ_1 and δ_2 are to be found; for δ_1, we expect to obtain the result given by (1.1). It follows that $K = k + \frac{1}{2}\delta_1 n_0/k + O(n_0^2)$ and then

$$\begin{aligned} \mathcal{N}_0(Kb) &= \mathcal{N}_0(kb) + (Kb-kb)\mathcal{N}_0'(kb) + \cdots \\ &= 1 - \tfrac{1}{2}\mathrm{i}b(n_0/k)\delta_1 d_0(kb) + O(n_0^2), \end{aligned}$$

where $d_0(x) = 1 - x^{-1}\mathrm{e}^{\mathrm{i}x}\sin x$. When this approximation for $\mathcal{N}_0(Kb)$ is used in (3.25), we obtain

$$K^2 = k^2 - 4\pi\mathrm{i}gn_0/k - 2\pi bg(n_0/k)^2\delta_1 d_0(kb).$$

Comparison of this formula with (3.26) gives $\delta_1 = -4\pi\mathrm{i}g/k$ (as expected) and $\delta_2 = 8\pi^2\mathrm{i}g^2bk^{-3}d_0(kb)$, so that we obtain the approximation

$$K^2 = k^2 - \frac{4\pi\mathrm{i}g}{k}n_0 + \frac{8\mathrm{i}b(\pi g n_0)^2}{k^3}\left(1 - \mathrm{e}^{\mathrm{i}kb}\frac{\sin kb}{kb}\right). \tag{3.27}$$

(Recall that a common choice for the hole radius is $b = 2a$.) As far as we know, the formula (3.27) is new. Note that the second-order term in (3.27) vanishes in the limit $kb \to 0$.

4. A finite array of identical spheres: Exact theory. Let O be the origin of three-dimensional Cartesian coordinates, so that a typical point has position vector $\boldsymbol{r} = (x, y, z)$ with respect to O. Define spherical polar coordinates (r, θ, ϕ) at O, so that $\boldsymbol{r} = r\hat{\boldsymbol{r}} = r(\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta)$. We consider N identical spheres, S_j, $j = 1, 2, \ldots, N$. The sphere S_j has radius a and center O_j at $\boldsymbol{r} = \boldsymbol{r}_j$. We define spherical polar coordinates $(\rho_j, \theta_j, \phi_j)$ at O_j, so that $\boldsymbol{r} = \boldsymbol{\rho}_j + \boldsymbol{r}_j$ with

$$\boldsymbol{\rho}_j = \rho_j\hat{\boldsymbol{\rho}}_j = \rho_j(\sin\theta_j\cos\phi_j,\ \sin\theta_j\sin\phi_j,\ \cos\theta_j).$$

We assume that $\theta_j = 0$ is in the z-direction ($\theta = 0$).

Exterior to the spheres the pressure field is u, where

$$\nabla^2 u + k^2 u = 0. \tag{4.1}$$

Inside S_j, the field is u_j, where

$$\nabla^2 u_j + \kappa^2 u_j = 0, \tag{4.2}$$

$\kappa = \omega/\tilde{c}$, and $\tilde{c}$ is the sound speed inside the spheres. The transmission conditions on the spheres are

$$u = u_j, \qquad \frac{1}{\rho}\frac{\partial u}{\partial \rho_j} = \frac{1}{\tilde{\rho}}\frac{\partial u_j}{\partial \rho_j} \quad \text{on} \quad \rho_j = a, \quad j = 1, \ldots, N, \tag{4.3}$$

where $\tilde{\rho}$ is the fluid density inside the spheres.

A plane wave, given by (3.9), is incident on the spheres. The problem is to calculate the scattered field outside the spheres, defined as $u_{\mathrm{sc}} = u - u_{\mathrm{in}}$. We start with just one sphere, in order to fix our notation.

4.1. Scattering by one sphere. For the incident plane wave, we have

$$u_{\mathrm{in}}(\boldsymbol{r}) = \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}) = 4\pi\sum_{n,m}\mathrm{i}^n\hat{\psi}_n^m(\boldsymbol{r})\,\overline{Y_n^m(\hat{\boldsymbol{k}})}, \tag{4.4}$$

where $\hat{\psi}_n^m(\boldsymbol{r}) = j_n(kr)Y_n^m(\hat{\boldsymbol{r}})$, $j_n(w)$ is a spherical Bessel function, $Y_n^m(\hat{\boldsymbol{r}}) = Y_n^m(\theta, \phi)$ is a spherical harmonic (see Appendix A), the overbar denotes complex conjugation, and we have used the shorthand notation

$$\sum_{n,m} \equiv \sum_{n=0}^{\infty}\sum_{m=-n}^{n}.$$

With our choice of normalization, the spherical harmonics are orthonormal; see (A.1).

For the scattered and interior fields, we can write

$$u_{\rm sc}(\boldsymbol{r}) = 4\pi \sum_{n,m} \mathrm{i}^n A_n^m Z_n \psi_n^m(\boldsymbol{r}) \quad \text{and} \quad u_{\rm int}(\boldsymbol{r}) = 4\pi \sum_{n,m} \mathrm{i}^n B_n^m j_n(\kappa r)\, Y_n^m(\hat{\boldsymbol{r}}),$$

respectively, where $\psi_n^m(\boldsymbol{r}) = h_n(kr)\, Y_n^m(\hat{\boldsymbol{r}})$, the coefficients A_n^m and B_n^m are to be found, and the factor

$$Z_n = \frac{q j_n'(ka) j_n(\kappa a) - j_n(ka) j_n'(\kappa a)}{q h_n'(ka) j_n(\kappa a) - h_n(ka) j_n'(\kappa a)}, \tag{4.5}$$

with $q = \tilde{\rho}\tilde{c}/(\rho c)$, has been introduced for later convenience. Then, the transmission conditions on $r = a$ yield A_n^m and B_n^m; in particular, we obtain $A_n^m = -\overline{Y_n^m(\hat{\boldsymbol{k}})}$. Also, the far-field pattern, defined by (1.3), is given by

$$f(\Theta) = 4\pi \sum_{n,m} Z_n A_n^m\, Y_n^m(\hat{\boldsymbol{r}}) = -\sum_{n=0}^{\infty} (2n+1) Z_n P_n(\cos\Theta), \tag{4.6}$$

where $\cos\Theta = \hat{\boldsymbol{r}} \cdot \hat{\boldsymbol{k}}$ and we have used (A.3) in order to evaluate the sum over m. Note that we recover the sound-soft results in the limit $q \to 0$, whereas the limit $q \to \infty$ gives the sound-hard results.

4.2. Scattering by N spheres. A phase factor for each sphere is defined by $I_j = \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r}_j)$, and then we can write

$$u_{\rm in} = I_j \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{\rho}_j) = 4\pi I_j \sum_{n,m} \mathrm{i}^n \hat{\psi}_n^m(\boldsymbol{\rho}_j)\, \overline{Y_n^m(\hat{\boldsymbol{k}})}. \tag{4.7}$$

We seek a solution to (4.1) and (4.2) in the form

$$u = u_{\rm in} + 4\pi \sum_{j=1}^{N} \sum_{n,m} \mathrm{i}^n A_{nj}^m Z_n \psi_n^m(\boldsymbol{\rho}_j), \qquad u_j = 4\pi \sum_{n,m} \mathrm{i}^n B_{nj}^m\, j_n(\kappa\rho_j)\, Y_n^m(\hat{\boldsymbol{\rho}}_j),$$

for some set of unknown complex coefficients A_{nj}^m and B_{nj}^m.

Now, in order to apply the transmission conditions on each sphere, we shall need an *addition theorem*. Thus, given vectors $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c} = \boldsymbol{a} + \boldsymbol{b}$, we have

$$\psi_n^m(\boldsymbol{c}) = \sum_{\nu,\mu} S_{n\nu}^{m\mu}(\boldsymbol{b})\, \hat{\psi}_\nu^\mu(\boldsymbol{a}) \quad \text{for } |\boldsymbol{a}| < |\boldsymbol{b}|, \tag{4.8}$$

where the separation matrix $S_{\nu n}^{\mu m}$ is given by

$$S_{\nu n}^{\mu m}(\mathbf{R}) = 4\pi \mathrm{i}^{n-\nu} (-1)^m \sum_q \mathrm{i}^q \psi_q^{\mu - m}(\mathbf{R})\, \mathcal{G}(n, m; \nu, -\mu; q). \tag{4.9}$$

In this formula, $\mathcal{G}$ is a Gaunt coefficient (defined by (A.5)), and the sum has a finite number of terms; in fact, q runs from $|n - \nu|$ to $(n + \nu)$ in steps of 2, so that

$$(q + n + \nu) \text{ is even.} \tag{4.10}$$

For more information on the addition theorem, see [3, 10, 11] and references therein.

Let $\mathbf{R}_{sj} = \boldsymbol{r}_s - \boldsymbol{r}_j = \boldsymbol{\rho}_j - \boldsymbol{\rho}_s$ be the position vector of O_s with respect to O_j. Then, provided that $\rho_s < R_{sj} = |\mathbf{R}_{sj}|$ for all j, we can write the field exterior to the sphere S_s as

$$u = 4\pi \sum_{n,m} \mathrm{i}^n \left\{ I_s \hat{\psi}_n^m(\boldsymbol{\rho}_s)\, \overline{Y_n^m(\hat{\boldsymbol{k}})} + A_{ns}^m Z_n \psi_n^m(\boldsymbol{\rho}_s) \right\} + 4\pi \sum_{n,m} \hat{\psi}_n^m(\boldsymbol{\rho}_s) \sum_{\substack{j=1 \\ j\neq s}}^{N} \sum_{\nu,\mu} \mathrm{i}^\nu A_{\nu j}^\mu Z_\nu S_{\nu n}^{\mu m}(\mathbf{R}_{sj}). \tag{4.11}$$

The geometrical restriction implies that this expression is valid near the surface of S_s, and so (4.11) can be used to apply the transmission conditions on $\rho_s = a$. Thus, after using the orthogonality of the functions $Y_n^m(\hat{\boldsymbol{\rho}}_s)$, (A.1), and then eliminating the coefficients B_{nj}^m, we obtain

$$A_{ns}^m + \sum_{\substack{j=1 \\ j\neq s}}^{N} \sum_{\nu,\mu} \mathrm{i}^{\nu-n} A_{\nu j}^\mu Z_\nu S_{\nu n}^{\mu m}(\mathbf{R}_{sj}) = -I_s \overline{Y_n^m(\hat{\boldsymbol{k}})}, \qquad \begin{array}{l} s = 1, 2, \ldots, N, \\ n = 0, 1, 2, \ldots, \\ m = -n, \ldots, n, \end{array} \tag{4.12}$$

an infinite linear system of equations for A_{nj}^m. Note that the quantities q, κ, and a enter the equations only through the terms Z_ν.

4.3. Arrays of spheres: Averaged equations. The above analysis applies to a specific configuration of scatterers. Now we take ensemble averages. Specifically, setting $s = 1$ in (4.12) and then taking the conditional average, using (2.5), we obtain

$$\langle A_{n1}^m \rangle_1 + n_0 \frac{N-1}{N} \sum_{\nu,\mu} \mathrm{i}^{\nu-n} Z_\nu \int_{B_N:\, R_{12}>b} S_{\nu n}^{\mu m}(\mathbf{R}_{12})\, \langle A_{\nu 2}^\mu \rangle_{12}\, \mathrm{d}V_2 = -I_1 \overline{Y_n^m(\hat{\boldsymbol{k}})}, \tag{4.13}$$

for $n = 0, 1, 2, \ldots$ and $m = -n, \ldots, n$. Then, we let $N \to \infty$ so that B_N becomes the half-space $z > 0$, and invoke Lax's QCA, (3.7). This implies that $\langle A_{n2}^m \rangle_{12} = \langle A_{n2}^m \rangle_2$. Hence, (4.13) reduces to

$$\langle A_{n1}^m \rangle_1 + n_0 \sum_{\nu,\mu} \mathrm{i}^{\nu-n} Z_\nu \int_{z_2>0,\, R_{12}>b} S_{\nu n}^{\mu m}(\mathbf{R}_{12})\, \langle A_{\nu 2}^\mu \rangle_2\, \mathrm{d}V_2 = -I_1 \overline{Y_n^m(\hat{\boldsymbol{k}})}, \tag{4.14}$$

for $n = 0, 1, 2, \ldots$ and $m = -n, \ldots, n$. As $I_1 = \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r}_1) = \mathrm{e}^{\mathrm{i}\alpha z_1} \exp(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}_1)$ with $\alpha = k \cos\theta_{\mathrm{in}}$ and $\boldsymbol{q}_s = (x_s, y_s, 0)$, we seek a solution to (4.14) in the form

$$\langle A_{ns}^m \rangle_s = \Phi_n^m(z_s)\, \exp(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}_s) \tag{4.15}$$

so that

$$\Phi_n^m(z_1) + n_0 \sum_{\nu,\mu} \mathrm{i}^{\nu-n} Z_\nu \int_{z_2>0,\, R_{12}>b} S_{\nu n}^{\mu m}(\mathbf{R}_{12})\, \exp(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}_{21})\, \Phi_\nu^\mu(z_2)\, \mathrm{d}V_2 = -\mathrm{e}^{\mathrm{i}\alpha z_1} \overline{Y_n^m(\hat{\boldsymbol{k}})} \tag{4.16}$$

for $n = 0, 1, 2, \ldots$ and $m = -n, \ldots, n$, where $\boldsymbol{q}_{sj} = \boldsymbol{q}_s - \boldsymbol{q}_j$.

Proceeding as before, suppose that for sufficiently large z (say, $z > \ell$) we can write

$$\Phi_n^m(z) = F_n^m \mathrm{e}^{\mathrm{i}\lambda z}. \tag{4.17}$$

Then if $z_1 > \ell + b$, (4.16) becomes

(4.18)

$$F_n^m \mathrm{e}^{\mathrm{i}\lambda z_1} + n_0 \sum_{\nu,\mu} (-\mathrm{i})^{\nu-n} Z_\nu \left\{ \int_0^\ell \Phi_\nu^\mu(z_2) \mathcal{L}_{\nu n}^{\mu m}(z_{21})\, \mathrm{d}z_2 + F_\nu^\mu \mathrm{e}^{\mathrm{i}\lambda z_1} \mathcal{M}_{\nu n}^{\mu m} \right\} = -\mathrm{e}^{\mathrm{i}\alpha z_1} \overline{Y_n^m(\hat{\boldsymbol{k}})}$$

for $n = 0, 1, 2, \ldots$ and $m = -n, \ldots, n$, where $z_{21} = z_2 - z_1$,

$$\mathcal{L}_{\nu n}^{\mu m}(z_{21}) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} S_{\nu n}^{\mu m}(\mathbf{R}_{21}) \, \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}_{21}\right) \mathrm{d}x_2 \, \mathrm{d}y_2,$$

$$\mathcal{M}_{\nu n}^{\mu m} = \int_{z_2 > \ell,\, R_{21} > b} S_{\nu n}^{\mu m}(\mathbf{R}_{21}) \, \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}_{21}\right) \mathrm{e}^{\mathrm{i}\lambda z_{21}} \, \mathrm{d}V_2,$$

and we have used $S_{\nu n}^{\mu m}(-\boldsymbol{r}) = (-1)^{n+\nu} S_{\nu n}^{\mu m}(\boldsymbol{r})$, a relation that follows from (4.9). Indeed, because of (4.9), it is sufficient to consider

$$L_n^m(z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \psi_n^m(\mathbf{R}) \, \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q}\right) \mathrm{d}X \, \mathrm{d}Y$$

for $z < 0$ and

$$M_n^m = \int_{z_2 > \ell,\, R_{21} > b} \psi_n^m(\mathbf{R}_{21}) \, \Psi(\mathbf{R}_{21}) \, \mathrm{d}V_2,$$

where $\Psi(\mathbf{R}) = \mathrm{e}^{\mathrm{i}\lambda z} \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q}\right) = \exp\left(\mathrm{i}\mathbf{K} \cdot \mathbf{R}\right)$ and $\mathbf{K} = K\hat{\mathbf{K}}$ is defined by (3.15).

From (B.5), we have

$$L_n^m(z_{21}) = \frac{2\pi \mathrm{i}^n}{k\alpha} Y_n^m(\hat{\boldsymbol{k}}) \, \mathrm{e}^{\mathrm{i}\alpha(z_1 - z_2)} \quad \text{for } z_1 > z_2.$$

Hence, $\mathcal{L}_{\nu n}^{\mu m}$ is proportional to $\mathrm{e}^{\mathrm{i}\alpha(z_1 - z_2)}$, and so the integral term in (4.18) is proportional to $\mathrm{e}^{\mathrm{i}\alpha z_1}$.

The volume integral M_n^m can be evaluated readily using Green's theorem. We have $\psi_n^m \nabla^2 \Psi - \Psi \nabla^2 \psi_n^m = (k^2 - K^2) \psi_n^m \Psi$. It follows that

$$M_n^m = \frac{1}{k^2 - K^2} \int_{\partial B} \left[\psi_n^m \frac{\partial \Psi}{\partial n} - \Psi \frac{\partial \psi_n^m}{\partial n} \right] \mathrm{d}S_2,$$

where ∂B consists of two parts, the plane $z_2 = \ell$ and the sphere $R_{12} = b$. Now, on $z_2 = \ell$, $\partial/\partial n = -\partial/\partial z_2$, and so we have

$$-\int_{z_2 = \ell} \left[\psi_n^m \frac{\partial \Psi}{\partial z_2} - \Psi \frac{\partial \psi_n^m}{\partial z_2} \right] \mathrm{d}x_2 \, \mathrm{d}y_2 = \frac{2\pi}{k\alpha} \mathrm{e}^{\mathrm{i}(\alpha - \lambda)(z_1 - \ell)} \, \mathrm{i}^{n-1} (\lambda + \alpha) \, Y_n^m(\hat{\boldsymbol{k}}),$$

using (B.8). Thus, the plane part of ∂B contributes a term to $\mathcal{M}_{\nu n}^{\mu m}$ proportional to $\mathrm{e}^{\mathrm{i}(\alpha - \lambda) z_1}$, which in turn gives a contribution to (4.18) proportional to $\mathrm{e}^{\mathrm{i}\alpha z_1}$.

Next, from (4.4), we have

$$\Psi = \exp\left(\mathrm{i}\mathbf{K} \cdot \mathbf{R}\right) = 4\pi \sum_{\nu,\mu} \mathrm{i}^\nu j_\nu(KR) \, \overline{Y_\nu^\mu(\hat{\mathbf{R}})} \, Y_\nu^\mu(\hat{\mathbf{K}}).$$

Then, the contribution from the sphere $R_{12} = b$ is

$$\begin{aligned} &-\int_\Omega \left[\psi_n^m \frac{\partial \Psi}{\partial R} - \Psi \frac{\partial \psi_n^m}{\partial R} \right]_{R=b} b^2 \, \mathrm{d}\Omega \\ &\quad = 4\pi b^2 \sum_{\nu,\mu} \mathrm{i}^\nu Y_\nu^\mu(\hat{\mathbf{K}}) \{ k j_\nu(Kb) \, h_n'(kb) - K j_\nu'(Kb) \, h_n(kb) \} \int_\Omega Y_n^m \overline{Y_\nu^\mu} \, \mathrm{d}\Omega \\ &\quad = 4\pi b^2 \mathrm{i}^n Y_n^m(\hat{\mathbf{K}}) \{ k j_n(Kb) \, h_n'(kb) - K j_n'(Kb) \, h_n(kb) \}, \end{aligned}$$

which is independent of z_1; here, Ω is the unit sphere and we have used (A.1).

Collecting up our results, we find that (4.18) can be written as

$$\mathcal{A}_n^m \,\mathrm{e}^{\mathrm{i}\lambda z_1} + \mathcal{B}_n^m \,\mathrm{e}^{\mathrm{i}\alpha z_1} = -\mathrm{e}^{\mathrm{i}\alpha z_1}\,\overline{Y_n^m(\hat{\boldsymbol{k}})}, \tag{4.19}$$

for $n = 0, 1, 2, \ldots, m = -n, \ldots, n$, and $z_1 > \ell + b$, where

$$\mathcal{A}_n^m = F_n^m + \frac{(4\pi)^2 \mathrm{i} n_0 (-1)^m}{k(k^2 - K^2)} \sum_{\nu,\mu} Z_\nu F_\nu^\mu \sum_q Y_q^{\mu-m}(\hat{\mathbf{K}})\, \mathcal{N}_q(Kb)\, \mathcal{G}(n, m; \nu, -\mu; q), \tag{4.20}$$

$$\mathcal{N}_n(x) = \mathrm{i}kb\{x\, j_n'(x)\, h_n(kb) - kb\, j_n(x)\, h_n'(kb)\}, \tag{4.21}$$

and we have used (4.10) to remove a factor of $(-1)^{q+n+\nu}$. In particular, we note that $\mathcal{N}_0$ appeared in section 3.3 during our analysis of Lax's integral equation.

From (4.19), we immediately obtain $\mathcal{A}_n^m = 0$ for $n = 0, 1, 2, \ldots$, $m = -n, \ldots, n$. These equations yield an infinite homogeneous system of linear algebraic equations for F_n^m. The existence of a nontrivial solution to this system determines K.

It is worth noting that even though the solution of the system $\mathcal{A}_n^m = 0$ can depend on θ_{in} via $\hat{\mathbf{K}}$ (see (3.15)), the effective wavenumber itself, K, should not depend on θ_{in}.

4.4. Approximate determination of K for small n_0. The only approximation made in the derivation of the system $\mathcal{A}_n^m = 0$ is the QCA, which is expected to be valid for small values of the scatterer concentration ($n_0 a^3 \ll 1$). We now assume (as in section 3.3) that $n_0 b/k^2$ is also small and write $K^2 = k^2 + \delta_1 n_0 + \delta_2 n_0^2 + \cdots$. Then

$$\mathcal{N}_n(Kb) = 1 - \frac{\mathrm{i}bn_0}{2k}\delta_1 d_n(kb) + O(n_0^2), \tag{4.22}$$

where

$$d_n(x) = x j_n'(x)[x h_n'(x) + h_n(x)] + [x^2 - n(n+1)] j_n(x)\, h_n(x), \tag{4.23}$$

and so

$$\frac{\mathcal{N}_n(Kb)}{k^2 - K^2} = -\frac{1}{\delta_1 n_0} + \frac{\mathrm{i}b d_n(kb)}{2k} + \frac{\delta_2}{\delta_1^2} + O(n_0). \tag{4.24}$$

If (4.24) is substituted into $\mathcal{A}_n^m = 0$, with $\mathcal{A}_n^m$ defined by (4.20) and $O(n_0^2)$ terms neglected, we obtain

$$F_n^m = \frac{(4\pi)^2 \mathrm{i}}{k\delta_1}(-1)^m \left(1 - \frac{n_0\delta_2}{\delta_1}\right) \sum_{\nu,\mu} Z_\nu F_\nu^\mu W_{n\nu}^{m\mu} + \frac{(4\pi)^2 b n_0}{2k^2}(-1)^m \sum_{\nu,\mu} Z_\nu F_\nu^\mu X_{n\nu}^{m\mu}, \tag{4.25}$$

where

$$W_{n\nu}^{m\mu} = \sum_q Y_q^{\mu-m}(\hat{\mathbf{K}})\, \mathcal{G}(n, m; \nu, -\mu; q), \tag{4.26}$$

$$X_{n\nu}^{m\mu} = \sum_q Y_q^{\mu-m}(\hat{\mathbf{K}})\, \mathcal{G}(n, m; \nu, -\mu; q)\, d_q(kb). \tag{4.27}$$

The Gaunt coefficients appear in the linearization formula for spherical harmonics, (A.4). Replacing μ by $-\mu$ and $\hat{\boldsymbol{r}}$ by $\hat{\mathbf{K}}$ in the complex conjugate of (A.4), we obtain

$$W_{n\nu}^{m\mu} = Y_n^{-m}(\hat{\mathbf{K}})\, Y_\nu^\mu(\hat{\mathbf{K}}).$$

Thus, at leading order, (4.25) gives

$$F_n^m = \frac{(4\pi)^2\mathrm{i}}{k\delta_1}\overline{Y_n^m(\hat{\mathbf{K}})}\sum_{\nu,\mu} Z_\nu F_\nu^\mu Y_\nu^\mu(\hat{\mathbf{K}})$$

for $n = 0, 1, 2, \ldots$ and $m = -n, \ldots, n$. Set $F_n^m = \overline{Y_n^m(\hat{\mathbf{K}})}\,\widetilde{F}_n^m$, whence

$$\widetilde{F}_n^m = \frac{(4\pi)^2\mathrm{i}}{k\delta_1}\sum_{\nu,\mu} Z_\nu \widetilde{F}_\nu^\mu Y_\nu^\mu(\hat{\mathbf{K}})\,\overline{Y_\nu^\mu(\hat{\mathbf{K}})}$$

for $n = 0, 1, 2, \ldots$ and $m = -n, \ldots, n$. However, the right-hand side of this equation does not depend on n or m, so that $\widetilde{F}_n^m = \widetilde{F}$, say. Hence

$$\delta_1 = \frac{(4\pi)^2\mathrm{i}}{k}\sum_{\nu=0}^{\infty} Z_\nu \sum_{\mu=-\nu}^{\nu} Y_\nu^\mu(\hat{\mathbf{K}})\,\overline{Y_\nu^\mu(\hat{\mathbf{K}})}. \tag{4.28}$$

The sum over μ can be evaluated using Legendre's addition theorem, (A.3). Setting $\hat{\boldsymbol{r}}_1 = \hat{\boldsymbol{r}}_2 = \hat{\mathbf{K}}$ in (A.3) and noting that $P_n(1) = 1$, we obtain

$$\delta_1 = \frac{4\pi\mathrm{i}}{k}\sum_{\nu=0}^{\infty}(2\nu+1)Z_\nu = -\frac{4\pi\mathrm{i}}{k}f(0), \tag{4.29}$$

where f is the far-field pattern given by (4.6).

Returning to (4.25), we now set

$$F_n^m = \overline{Y_n^m(\hat{\mathbf{K}})}\,\widetilde{F} + n_0 G_n^m,$$

and then the $O(n_0)$ terms give

$$G_n^m = \overline{Y_n^m(\hat{\mathbf{K}})}\,V + \frac{(4\pi)^2 b}{2k^2}(-1)^m\widetilde{F}\sum_{\nu,\mu} Z_\nu\,\overline{Y_\nu^\mu(\hat{\mathbf{K}})}\,X_{n\nu}^{m\mu}, \tag{4.30}$$

where

$$V = \frac{(4\pi)^2\mathrm{i}}{k\delta_1}\sum_{\nu,\mu} Z_\nu G_\nu^\mu Y_\nu^\mu(\hat{\mathbf{K}}) - \frac{\delta_2}{\delta_1}\widetilde{F}. \tag{4.31}$$

Note that V does not depend on n or m. Substituting for G_ν^μ from (4.30) in (4.31), making use of (4.28), gives a formula for δ_2:

$$\delta_2 = \frac{(4\pi)^4\mathrm{i}b}{2k^3}\sum_{n,m}\sum_{\nu,\mu}(-1)^m Z_n Z_\nu Y_n^m(\hat{\mathbf{K}})\,\overline{Y_\nu^\mu(\hat{\mathbf{K}})}\,X_{n\nu}^{m\mu}. \tag{4.32}$$

So far we have not made any assumptions about the size of ka or kb (though clearly $kb \geq 2ka$). Now we will assume that kb is small. In the limit $x \to 0$, we have $d_n(x) \sim \mathrm{i}n/x$. Using this approximation simplifies $X_{n\nu}^{m\mu}$, defined by (4.27). Hence,

$$\delta_2 \sim -\frac{1}{2}(4\pi/k)^4\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty} Z_n Z_\nu\, K_{n\nu}(\hat{\mathbf{K}}) \quad \text{as } kb \to 0, \tag{4.33}$$

where

$$K_{n\nu}(\hat{\mathbf{K}}) = \sum_{m=-n}^{n} \sum_{\mu=-\nu}^{\nu} (-1)^m Y_n^m(\hat{\mathbf{K}})\, \overline{Y_\nu^\mu(\hat{\mathbf{K}})} \sum_q q\, Y_q^{\mu-m}(\hat{\mathbf{K}})\, \mathcal{G}(n,m;\nu,-\mu;q). \tag{4.34}$$

From (A.5) and $\int_0^{2\pi} \mathrm{e}^{\mathrm{i}m\phi}\,\mathrm{d}\phi = 2\pi\delta_{0m}$, we have

$$\begin{aligned} Y_q^{\mu-m}(\hat{\mathbf{K}})\, \mathcal{G}(n,m;\nu,-\mu;q) &= (-1)^m \sum_M Y_q^M(\hat{\mathbf{K}}) \int_\Omega \overline{Y_n^m} Y_\nu^\mu \overline{Y_q^M}\,\mathrm{d}\Omega \\ &= (-1)^m \frac{2q+1}{4\pi} \int_\Omega \overline{Y_n^m}(\hat{\boldsymbol{r}})\, Y_\nu^\mu(\hat{\boldsymbol{r}})\, P_q(\hat{\boldsymbol{r}}\cdot\hat{\mathbf{K}})\,\mathrm{d}\Omega(\hat{\boldsymbol{r}}), \end{aligned}$$

using (A.3). Hence, using (A.3) two more times, we obtain

$$\begin{aligned} K_{n\nu}(\hat{\mathbf{K}}) &= \frac{(2n+1)(2\nu+1)}{(4\pi)^3} \sum_q q(2q+1) \int_\Omega P_n(\hat{\boldsymbol{r}}\cdot\hat{\mathbf{K}})\, P_\nu(\hat{\boldsymbol{r}}\cdot\hat{\mathbf{K}})\, P_q(\hat{\boldsymbol{r}}\cdot\hat{\mathbf{K}})\,\mathrm{d}\Omega(\hat{\boldsymbol{r}}) \\ &= \frac{\sqrt{(2n+1)(2\nu+1)}}{(4\pi)^{3/2}} \sum_q q\sqrt{2q+1}\, \mathcal{G}(n,0;\nu,0;q), \end{aligned}$$

where we have used $Y_n^0 = \sqrt{(2n+1)/(4\pi)}\, P_n$ and (A.5). When this formula for $K_{n\nu}$ is substituted into (4.33), we obtain complete agreement with the formula of Lloyd and Berry [21]; see Appendix C.

In conclusion, we note that if we were to replace (2.5) with the (clearly unreasonable)

$$p(\boldsymbol{r}_2|\boldsymbol{r}_1) = (n_0/N)H(|z_2 - z_1| - a),$$

an analysis similar to that given above yields Twersky's erroneous expression for δ_2, as given in (1.4). We omit the details of this calculation, but see [21] for a related discussion and [20] for analogous calculations in two dimensions.

It is perhaps worth summarizing the various approximations that are needed to arrive at the Lloyd–Berry formula. The system $\mathcal{A}_n^m = 0$ (with $\mathcal{A}_n^m$ defined by (4.20)) serves to determine the effective wavenumber, subject only to the QCA. The QCA is certainly appropriate only for low volume fractions, but it is very difficult to make a precise quantitative assessment of its range of validity. Some numerical estimates of the accuracy of the QCA can be found in, for example, [16] and [9]. If we assume that the concentration of scatterers is small, in the sense that $n_0 a^3 \ll 1$ (which is consistent with the QCA) and also that $n_0 b/k^2 \ll 1$, then the effective wavenumber, up to second order in concentration, follows from (4.29) and (4.32). If we finally let $kb \to 0$, we obtain the Lloyd–Berry formula in the form of (4.29) and (4.33).

Appendix A. Spherical harmonics. We define spherical harmonics Y_n^m by

$$Y_n^m(\hat{\boldsymbol{r}}) = Y_n^m(\theta,\phi) = (-1)^m \sqrt{\frac{2n+1}{4\pi}} \sqrt{\frac{(n-m)!}{(n+m)!}} P_n^m(\cos\theta)\, \mathrm{e}^{\mathrm{i}m\phi},$$

where P_n^m is an associated Legendre function. We have orthonormality,

$$\int_\Omega Y_n^m\, \overline{Y_\nu^\mu}\,\mathrm{d}\Omega = \delta_{n\nu}\delta_{m\mu}, \tag{A.1}$$

where Ω is the unit sphere. Also, $Y_n^{-m} = (-1)^m \overline{Y_n^m}$.

For $0 \le m \le n$, we have the expansion

$$\frac{P_n^m(t)}{(1-t^2)^{m/2}} = \frac{1}{2^n\, n!}\frac{\mathrm{d}^{m+n}}{\mathrm{d}t^{m+n}}(t^2-1)^n = \sum_{l=0}^{[(n-m)/2]} B_l^{n,m} t^{n-m-2l}, \tag{A.2}$$

where $[n]$ denotes the integer part of n. The coefficients $B_l^{n,m}$ are known explicitly, but we shall not need them.

We shall make use of Legendre's addition theorem, namely,

$$P_n(\hat{\boldsymbol{r}}_1 \cdot \hat{\boldsymbol{r}}_2) = \frac{4\pi}{2n+1} \sum_{m=-n}^{n} Y_n^m(\hat{\boldsymbol{r}}_1)\, \overline{Y_n^m(\hat{\boldsymbol{r}}_2)}, \tag{A.3}$$

where $P_n(t)$ is a Legendre polynomial.

The linearization formula for spherical harmonics is

$$Y_n^m(\hat{\boldsymbol{r}})\, Y_\nu^\mu(\hat{\boldsymbol{r}}) = \sum_q Y_q^{m+\mu}(\hat{\boldsymbol{r}})\, \mathcal{G}(n,m;\nu,\mu;q), \tag{A.4}$$

where $\mathcal{G}$ is a Gaunt coefficient. Note that $\mathcal{G}$ is real. Making use of (A.1), we obtain

$$\mathcal{G}(n,m;\nu,-\mu;q) = (-1)^m \int_\Omega \overline{Y_n^m} Y_\nu^\mu \overline{Y_q^{\mu-m}}\, \mathrm{d}\Omega. \tag{A.5}$$

Appendix B. Some integrals. Consider the integral

$$L(z) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h_0(kR)\, \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q}\right) \mathrm{d}X\, \mathrm{d}Y,$$

where $R = |\mathbf{R}|$, $\mathbf{R} = (X, Y, z)$, and $\mathbf{Q} = (X, Y, 0)$. Set $\mathbf{Q} = Q(\cos\Phi,\ \sin\Phi,\ 0)$ so that $\boldsymbol{k}_T \cdot \mathbf{Q} = kQ\sin\theta_{\mathrm{in}}\, \cos(\Phi - \phi_{\mathrm{in}})$. Hence, as $\mathrm{d}X\, \mathrm{d}Y = Q\, \mathrm{d}Q\, \mathrm{d}\Phi$, we can integrate over Φ, giving

$$L(z) = 2\pi \int_0^\infty h_0(k\sqrt{Q^2+z^2})\, J_0(kQ\sin\theta_{\mathrm{in}})\, Q\, \mathrm{d}Q.$$

We have

$$Qh_0(k\sqrt{Q^2+z^2}) = \frac{Q\, \mathrm{e}^{\mathrm{i}k\sqrt{Q^2+z^2}}}{\mathrm{i}k\sqrt{Q^2+z^2}} = \frac{1}{(\mathrm{i}k)^2}\frac{\mathrm{d}}{\mathrm{d}Q}\mathrm{e}^{\mathrm{i}k\sqrt{Q^2+z^2}},$$

so that an integration by parts (using $J_0' = -J_1$) gives

$$L(z) = 2\pi k^{-2}\{\mathrm{e}^{\mathrm{i}k|z|} - \hat{L}(z)\}, \tag{B.1}$$

where

$$\hat{L}(z) = k\sin\theta_{\mathrm{in}} \int_0^\infty J_1(kQ\sin\theta_{\mathrm{in}})\, \mathrm{e}^{\mathrm{i}k\sqrt{Q^2+z^2}}\, \mathrm{d}Q.$$

Now, from [8, equation 6.637(1)] (with $\nu = 1$ therein), we have

$$\int_0^\infty \frac{\mathrm{e}^{-a\sqrt{x^2+\beta^2}}}{\sqrt{x^2+\beta^2}}\, J_1(\gamma x)\, \mathrm{d}x = I_{1/2}(X_-)\, K_{1/2}(X_+), \tag{B.2}$$

where $X_\pm = \frac{1}{2}\beta\{\sqrt{a^2+\gamma^2} \pm a\}$, $\operatorname{Re} a > 0$, $\operatorname{Re}\beta > 0$, and $\operatorname{Re}\gamma > 0$. From [1, 10.2.13 and 10.2.17], the modified Bessel functions are given by

$$I_{1/2}(w) = \{2/(\pi w)\}^{1/2} \sinh w \quad \text{and} \quad K_{1/2}(w) = \{\pi/(2w)\}^{1/2} \mathrm{e}^{-w},$$

so that

$$I_{1/2}(X_-)\, K_{1/2}(X_+) = (\beta\gamma)^{-1} \left\{ \mathrm{e}^{-a\beta} - \mathrm{e}^{-\beta\sqrt{a^2+\gamma^2}} \right\}.$$

Then, differentiating (B.2) with respect to a gives

$$\gamma \int_0^\infty J_1(\gamma x)\, \mathrm{e}^{-a\sqrt{x^2+\beta^2}}\, \mathrm{d}x = \mathrm{e}^{-a\beta} - \frac{a}{\sqrt{a^2+\gamma^2}} \mathrm{e}^{-\beta\sqrt{a^2+\gamma^2}}. \tag{B.3}$$

The calculations leading to (B.3) are certainly valid for $\operatorname{Re} a > 0$, $\operatorname{Re}\beta > 0$, and $\operatorname{Re}\gamma > 0$. We want to use (B.3) for $\beta = z$; as the left-hand side of (B.3) is an even function of β, we can replace β by $|\beta|$ on the right-hand side. We also want to substitute $a = -\mathrm{i}k$ and $\gamma = k\sin\theta_{\mathrm{in}}$, so that $\sqrt{a^2+\gamma^2} = \pm \mathrm{i}k\cos\theta_{\mathrm{in}}$. To determine the sign, we note that (from [8, equations 6.671(1) and 6.671(2)])

$$\gamma \int_0^\infty J_1(\gamma x)\, \mathrm{e}^{\mathrm{i}kx}\, \mathrm{d}x = 1 - \frac{k}{\sqrt{k^2-\gamma^2}} \quad \text{for } k > \gamma,$$

implying that we should take $\sqrt{a^2+\gamma^2} = -\mathrm{i}k\cos\theta_{\mathrm{in}}$. (Alternatively, we note that the right-hand side of (B.3) is an analytic function of a in a cut plane; we can take the cut between $a = \mathrm{i}\gamma$ and $a = -\mathrm{i}\gamma$ (γ real and positive), and we choose the branch so that the right-hand side of (B.3) is real when a is real and positive. This leads to $\sqrt{a^2+\gamma^2} = -\mathrm{i}\sqrt{k^2-\gamma^2}$ when $a = -\mathrm{i}k$ with $k > \gamma > 0$.) Hence,

$$\hat{L}(z) = \mathrm{e}^{\mathrm{i}k|z|} - \mathrm{e}^{\mathrm{i}k|z|\cos\theta_{\mathrm{in}}} \sec\theta_{\mathrm{in}},$$

and so (B.1) gives

$$L(z) = \int_{-\infty}^\infty \int_{-\infty}^\infty h_0(kR)\, \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q}\right) \mathrm{d}X\, \mathrm{d}Y = \frac{2\pi}{k^2\cos\theta_{\mathrm{in}}}\, \mathrm{e}^{\mathrm{i}k|z|\cos\theta_{\mathrm{in}}}. \tag{B.4}$$

This formula generalizes. Thus, let

$$L_n^m(z) = \int_{-\infty}^\infty \int_{-\infty}^\infty \psi_n^m(\mathbf{R})\, \exp\left(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q}\right) \mathrm{d}X\, \mathrm{d}Y,$$

with $\psi_n^m(\boldsymbol{r}) = h_n(kr) Y_n^m(\hat{\boldsymbol{r}})$. Then,

$$L_n^m(z) = \frac{2\pi\,\mathrm{i}^n}{k^2\cos\theta_{\mathrm{in}}}\, Y_n^m(\hat{\boldsymbol{k}})\, \mathrm{e}^{-\mathrm{i}kz\cos\theta_{\mathrm{in}}} \quad \text{for } z < 0, \tag{B.5}$$

with a similar formula for $z > 0$ (which we shall not need). When both $m = 0$ and $\theta_{\mathrm{in}} = 0$, (B.5) reduces to a result obtained in [27].

To prove (B.5), begin by assuming that $0 \le m \le n$. Let

$$\Omega_n^m(\boldsymbol{r}) = h_n(kr)\, P_n^m(\cos\theta)\, \mathrm{e}^{\mathrm{i}m\phi}. \tag{B.6}$$

($\psi_n^m(\boldsymbol{r})$ is a normalized form of $\Omega_n^m(\boldsymbol{r})$.) Then, we have [5, 29, 4]

$$\Omega_n^m(\boldsymbol{r}) = \mathcal{Y}_n^m h_0(kr),$$

where the Erdélyi operator $\mathcal{Y}_n^m$ is defined by

$$\mathcal{Y}_n^m = (\mathcal{D}_{xy})^m \sum_{l=0}^{[(n-m)/2]} (-1)^l B_l^{n,m} (\mathcal{D}_z)^{n-m-2l}, \qquad \mathcal{D}_{xy} = -\frac{1}{k}\left(\frac{\partial}{\partial x} + \mathrm{i}\frac{\partial}{\partial y}\right),$$

and $\mathcal{D}_z = -k^{-1}\partial/\partial z$; the coefficients $B_l^{n,m}$ appear in the expansion (A.2). Hence,

$$O_n^m(z) \equiv \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \Omega_n^m(\mathbf{R}) \exp(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q})\, \mathrm{d}X\, \mathrm{d}Y = \sum_l (-1)^l B_l^{n,m} (\mathcal{D}_z)^{n-m-2l} \mathcal{I}_m(z),$$

where the sum is from $l = 0$ to the integer part of $(n-m)/2$, and

$$\begin{aligned}\mathcal{I}_m(z) &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \exp(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q})\, (\mathcal{D}_{XY})^m h_0(kR)\, \mathrm{d}X\, \mathrm{d}Y \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h_0(kR)\, (-\mathcal{D}_{XY})^m \exp(\mathrm{i}\boldsymbol{k}_T \cdot \mathbf{Q})\, \mathrm{d}X\, \mathrm{d}Y = \mathrm{i}^m \sin^m\theta_{\mathrm{in}}\, \mathrm{e}^{\mathrm{i}m\phi_{\mathrm{in}}} L(z).\end{aligned}$$

Hence, substituting for $L(z)$ from (B.4) and carrying out the differentiations with respect to z, we obtain

$$O_n^m(z) = \frac{2\pi\,\mathrm{i}^n}{k^2\cos\theta_{\mathrm{in}}}\, P_n^m(\cos\theta_{\mathrm{in}})\, \mathrm{e}^{\mathrm{i}m\phi_{\mathrm{in}}}\, \mathrm{e}^{-\mathrm{i}kz\cos\theta_{\mathrm{in}}} \tag{B.7}$$

for $z < 0$. The result (B.5) follows after multiplication by the appropriate normalization constant. It can be shown that the same result is also true for $-n \le m \le 0$.

Next, we consider an integral required in section 4.3. We have

$$\begin{aligned}-\int_{z_2=\ell} &\left[\Omega_n^m \frac{\partial\Psi}{\partial z_2} - \Psi\frac{\partial\Omega_n^m}{\partial z_2}\right] \mathrm{d}x_2\, \mathrm{d}y_2 \\ &= \mathrm{e}^{\mathrm{i}\lambda(\ell - z_1)} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \exp(\mathrm{i}\boldsymbol{k}_T \cdot \boldsymbol{q}_{21}) \left[-\mathrm{i}\lambda\Omega_n^m + \frac{\partial\Omega_n^m}{\partial z_2}\right]_{z_2=\ell} \mathrm{d}x_2\, \mathrm{d}y_2,\end{aligned}$$

where $\Psi = \exp(\mathrm{i}\mathbf{K}\cdot\mathbf{R}_{21})$. Using

$$\mathcal{D}_z\Omega_n^m = (2n+1)^{-1}\{(n-m+1)\Omega_{n+1}^m - (n+m)\Omega_{n-1}^m\}$$

and (B.7) thrice gives the integral's value as

$$\frac{2\pi}{k\alpha}\mathrm{e}^{\mathrm{i}(\alpha-\lambda)(z_1-\ell)}\, \mathrm{i}^{n-1}(\lambda+\alpha)\, P_n^m(\cos\theta_{\mathrm{in}})\, \mathrm{e}^{\mathrm{i}m\phi_{\mathrm{in}}}, \tag{B.8}$$

where we have also used $(2n+1)tP_n^m(t) = (n-m+1)P_{n+1}^m(t) + (n+m)P_{n-1}^m(t)$.

Appendix C. The Lloyd–Berry formula. Recall the formula (1.6). From (4.6) and $Y_n^0(\hat{\boldsymbol{r}}) = \sqrt{(2n+1)/(4\pi)}P_n(\cos\theta)$, we obtain

$$f(\theta) = -\sqrt{4\pi}\sum_{n=0}^{\infty}\sqrt{2n+1}\, Z_n Y_n^0.$$

Then, the linearization formula (A.4) gives

$$[f(\theta)]^2 = \sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}\sum_q T(n,\nu;q)\, P_q(\cos\theta), \tag{C.1}$$

where

$$T(n,\nu;q) = \sqrt{4\pi(2n+1)(2\nu+1)(2q+1)}\, Z_n Z_\nu\, \mathcal{G}(n,0;\nu,0;q).$$

Hence,

$$-[f(\pi)]^2 + [f(0)]^2 = \sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}\sum_{q} T(n,\nu;q)\,\{1-(-1)^q\}. \tag{C.2}$$

For the integral term in (1.6), we use (C.1) and

$$\int_0^\pi \frac{1}{\sin(\theta/2)}\frac{\mathrm{d}}{\mathrm{d}\theta}P_q(\cos\theta)\,\mathrm{d}\theta = -\int_{-1}^{1}\sqrt{\frac{2}{1-x}}\,P_q'(x)\,\mathrm{d}x = (-1)^q - 1 - 2q. \tag{C.3}$$

(The last equality was obtained as follows. From [8, equation 7.225(1)], we have

$$\begin{aligned}\frac{2}{2n+1}\frac{1}{\sqrt{1+x}}\{T_n(x)+T_{n+1}(x)\} &= \int_{-1}^{x}\frac{1}{\sqrt{x-t}}\,P_n(t)\,\mathrm{d}t \\ &= 2(-1)^n\sqrt{1+x} + 2\int_{-1}^{x}\sqrt{x-t}\,P_n'(t)\,\mathrm{d}t,\end{aligned}$$

after an integration by parts, where $T_n(\cos\theta) = \cos n\theta$ is a Chebyshev polynomial, and we have used $P_n(-1) = (-1)^n$. Now, differentiate this formula with respect to x and then let $x \to 1$, using $T_n(1) = 1$ and $T_n'(1) = n^2$.) Substituting (C.1), (C.2), and (C.3) into (1.6) gives

$$\delta_2 = -\frac{8\pi^2}{k^4}\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}\sum_{q} q\,T(n,\nu;q), \tag{C.4}$$

which is the same as (4.33).

NON-LORENTZIAN SPECTRAL LINESHAPES NEAR A HOPF BIFURCATION*

J. P. GLEESON† AND F. O'DOHERTY†

Abstract. The effects of additive white noise upon the dynamics of a system described by its Hopf normal form are investigated, with particular reference to the well-known model of a detuned single-mode laser. The power spectrum corresponding to the laser amplitude is determined by finite-difference solution of a partial differential equation, and analytical formulas are determined in the asymptotic limits of large parameters. The effect of the amplitude-phase coupling parameter in generating non-Lorentzian lineshapes is highlighted, and the regions of parameter space where accurate first-eigenvalue approximations of the Fokker–Planck equation exist are indicated.

Key words. white noise, stochastic differential equations, Hopf normal form, Fokker–Planck equation, semiconductor lasers, oscillators

1. Introduction.

In this paper we consider the effects of white noise upon the dynamics of a system near a Hopf bifurcation point. The well-known deterministic (noise-free) Hopf normal form is [1]

$$\frac{dE}{dt} = i\Omega E + (1 + i\delta)\left(a - |E|^2\right) E, \tag{1}$$

where $E(t)$ is a complex-valued function of time representing, for example, the electric field of a single-mode laser in a semiclassical approximation [2] with fundamental frequency Ω. The parameters a and δ are real-valued and dimensionless; see the Appendix for details of their derivation from the standard normal form parameters. This equation can be written in amplitude-phase coordinates using $E = r\exp(i\theta)$, with the dynamics of the polar coordinates $r(t)$ and $\theta(t)$ being governed by the pair of equations

$$\begin{aligned} \frac{dr}{dt} &= \left(a - r^2\right) r, \\ \frac{d\theta}{dt} &= \Omega + \delta\left(a - r^2\right). \end{aligned} \tag{2}$$

As discussed in Chapter 12 of [2], noise effects may be incorporated into the deterministic system by the addition of a complex Langevin fluctuation term

$$\Gamma(t) = \xi_x(t) + i\,\xi_y(t) \tag{3}$$

to the right-hand side of (1). The zero-mean, real-valued white noise processes $\xi_x(t)$ and $\xi_y(t)$ are described by their delta-function autocorrelation functions [2]:

$$\langle \xi_x(t)\xi_x(t')\rangle = \langle \xi_y(t)\xi_y(t')\rangle = 2\delta(t - t'), \qquad \langle \xi_x(t)\xi_y(t')\rangle = 0. \tag{4}$$

Note that the noise intensity is set to unity by our choice of length and time units (see the Appendix for details). Angle brackets are used throughout this paper to denote averaging over an ensemble, i.e., taking an expectation value. Our goal is to describe the effects of the noise terms upon the dynamics of the system (2).

Any system undergoing a Hopf bifurcation may be written in the Hopf normal form (1). The deterministic dynamics of the Hopf bifurcation are well understood. When the bifurcation parameter a is negative, the origin $r = 0$ is an attracting point for all trajectories of the system (2) in the absence of noise. As the bifurcation parameter passes through zero and becomes positive, the origin becomes unstable and trajectories are attracted to the stable limit cycle at $r = \sqrt{a}$. The flow on the limit cycle is purely circular, with angular speed Ω. The parameter δ does not affect these steady-state results, but it has important consequences when the system is subject to fluctuations. For example, in the stable limit cycle case $a > 0$, trajectories which are kicked off the limit cycle eventually flow back onto it, moving at an angular speed which varies with their amplitude when $\delta \neq 0$ and being equal to the steady-state speed Ω only when on the limit cycle. Because δ quantifies this effect of amplitude fluctuations upon the phase angle θ, it is sometimes referred to as the *amplitude-phase coupling parameter*. When $a < 0$ the flow into the attracting origin has a spiral structure. Nonzero δ alters the angular speed of the spiral motion and induces a differential rotation effect; i.e., trajectories further from the origin spiral inwards at rates different from those closer to $r = 0$.

In this paper we study the effect of noise on the dynamics of (2), with particular reference to the *correlation function* of E,[1]

$$R(\tau) = \langle E(t)E^*(t+\tau)\rangle\,, \tag{5}$$

or to its *power spectrum*, which is found by Fourier transforming $R(\tau)$. The deterministic limit cycle solution described above in the case $a > 0$ is periodic, and so the power spectrum of E exhibits a delta-function spike at the frequency Ω. The effect of small random fluctuations modeled by the noise terms ξ_x and ξ_y in (3) is to broaden the peak in the power spectrum, and so generate a finite linewidth. For $a < 0$ the stable solution is $r = 0$, but "precursor" peaks in the power spectrum of E can be seen: these grow in intensity as the bifurcation parameter a is increased towards the bifurcation point [3, 4, 5]. The stable oscillation generated when $a > 0$ is generic and has been studied in many fields, including electric and electronic engineering, chemical physics, and laser physics. As the system (2) has been extensively studied in the laser literature (at least for the case $\delta = 0$), for convenience we will adopt the nomenclature and notation specific to that field. However, our results are applicable to any system of the form (2) in the presence of additive white noise. Recent examples where nonzero values of the parameter δ are important arise in applications to electronic oscillator circuits [5, 6, 7] and to chemical reaction systems [8]. For instance, Coram [7], as a test case for various recently proposed methods [5, 9] for predicting the spectral lineshape of noisy electronic oscillator circuits, proposes a model which (in the limit of small noise) is essentially equivalent to (2). The important new effects due to the amplitude-phase coupling parameter δ demonstrated in this paper are thus also immediately applicable to electronic oscillator models such as Coram's.

In the laser literature the parameter a is commonly referred to as the *pump parameter*, with the regime $a < 0$ termed *below (lasing) threshold*, and $a > 0$ *above*

[1] In the laser physics literature the function $R(\tau)$ is known as the amplitude correlation function; here star denotes complex conjugation.

threshold. The parameter δ has received comparatively little attention in the literature, owing to its relative insignificance in the most commonly studied laser systems. Depending on the physical causes of the effect, the parameter has variously been named the *detuning parameter* [2], the *linewidth enhancement factor* [10], or as noted above, the *amplitude-phase coupling parameter*. The effect of δ is known to be non-negligible in semiconductor lasers, and so we believe this study of its effects is timely. As mentioned above, the Hopf normal form (2) is frequently used as the simplest model of a noisy, self-sustained oscillator in many other fields, e.g., electronic circuit design [7] and chemical reaction dynamics [8], and so a complete description of the power spectrum beyond the well-studied $\delta = 0$ case is of some importance.

The dynamics of Hopf bifurcations with additive noise, but with $\delta = 0$, have been studied by several authors. For instance, Baras, Mansour, and Van den Broek [11] discuss in detail the stationary probability density near a Hopf bifurcation point in the weak noise limit. In the review paper [12] the more general stationary distribution problem for a noisy Hopf bifurcation with a noncircular limit cycle is discussed. The effects of multiplicative [13, 14] or colored noises [15, 16] near a Hopf bifurcation have also been considered, as well as noisy bifurcations in delay-differential equations [17]. Our work concentrates on the simplest additive white noise case, and is new in two respects: first, it describes the spectral lineshape (not just the stationary probability density) of the dynamical system near the bifurcation point, and, second, to our knowledge, this is the first comprehensive study of the important effects of the amplitude-phase coupling parameter δ—most previous studies assume δ to be zero or negligibly small. While we use standard results for the stationary probability density near the bifurcation point (e.g., see (8) below), the focus of our work is on the dynamical effect of δ, as evidenced by the shape of the power spectrum. The distinction is crucial—the stationary probability density is independent of δ, while the spectral lineshape is very sensitive to nonzero δ values.

The most complete study of the δ-effect to date appears to be that of Seybold and Risken [18], referred to hereafter as SR. They approach the Fokker–Planck equation corresponding to (2) using the same methods that were successful in the $\delta = 0$ case [2], i.e., an eigenfunction expansion of the transition probability density. The resulting correlation function is then an infinite sum of exponentials, yielding a power spectrum composed of a sum of Lorentzians. Although the calculation of eigenvalues must be done numerically, a crucial result of SR is that for $\delta < 1.2$ the first term in the infinite series is dominant, and so only this first eigenvalue term need be used to find the spectrum to a high order of accuracy. As shown in Figure 1, this single-Lorentzian expression for the spectrum is accurate to power levels many orders of magnitude below the peak. The divergence between the exact spectrum and the SR approximation seen at high frequencies in Figure 2 can be traced to the inaccuracies in the small-time expansion of the correlation function, as noted in SR. However, near the peak of the spectrum (within, say, three orders of magnitude in power level) the SR Lorentzian form of the spectrum is very accurate for $\delta \lesssim 1$. Thus the description of the spectral lineshape (and linewidth) is reduced to finding the appropriate eigenvalue of the Fokker–Planck equation. We note in passing that this first-eigenvalue approach is also used in recent papers attempting to predict the spectral lineshape arising from noise in electronic oscillator circuits [5, 6] and limit cycles modeling chemical clocks [8].

The SR paper covers only the case $\delta < 1.2$, which encompassed the values of the parameter δ of interest to the laser community at the time. However, more recent research in the field of semiconductor lasers indicates that the values of δ

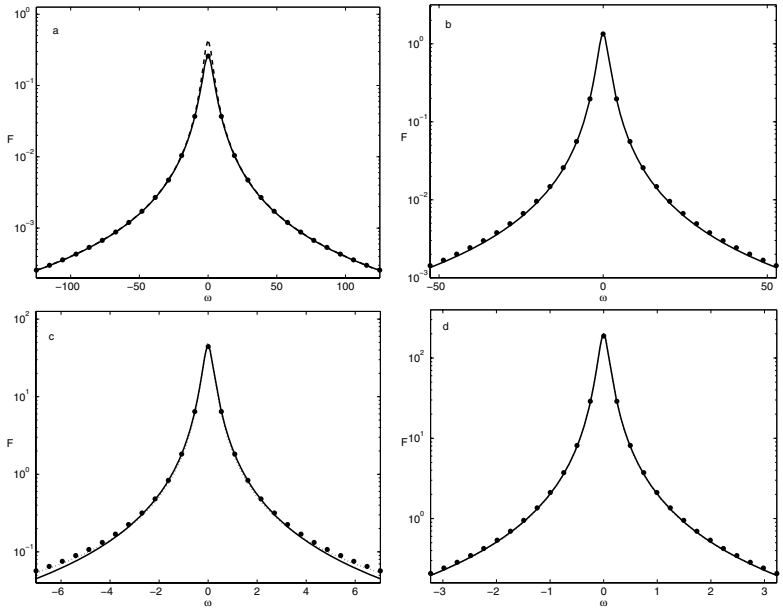

FIG. 1. *Spectrum $F(\omega)$ for $\delta = 0$ and various values of a:* (a) $a = -3$, (b) $a = 0$, (c) $a = 5$, (d) $a = 10$. *Results from the numerical solution* (25) *are shown as symbols; the solid line is the Lorentzian lineshape* (31)*; the dashed (for $a < 0$) and dotted (for $a > 0$) lines show the asymptotic results of section* 4.

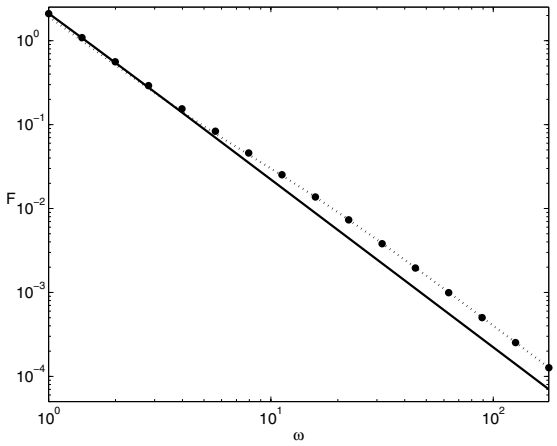

FIG. 2. *Log-log plot of the spectrum $F(\omega)$ for large frequencies, with parameters $a = 5$ and $\delta = 0$ (cf. Figure* 1(c)*). Line types are as in Figure* 1.

appropriate to the model (2) are on the order of 5 to 7. The most obvious effect of this larger δ is a significant widening of the spectral line—hence the title of *linewidth enhancement factor* (or simply *α-factor*) which is sometimes applied to δ. Implicit in most discussions of the linewidth of semiconductor lasers is the belief that the lineshape is intrinsically Lorentzian. Indeed some workers have followed the methods of SR to calculate the first eigenvalue in the case $\delta \geq 5$, and to compare the resulting linewidth to experimental calculations [19]. However, our results, using numerical

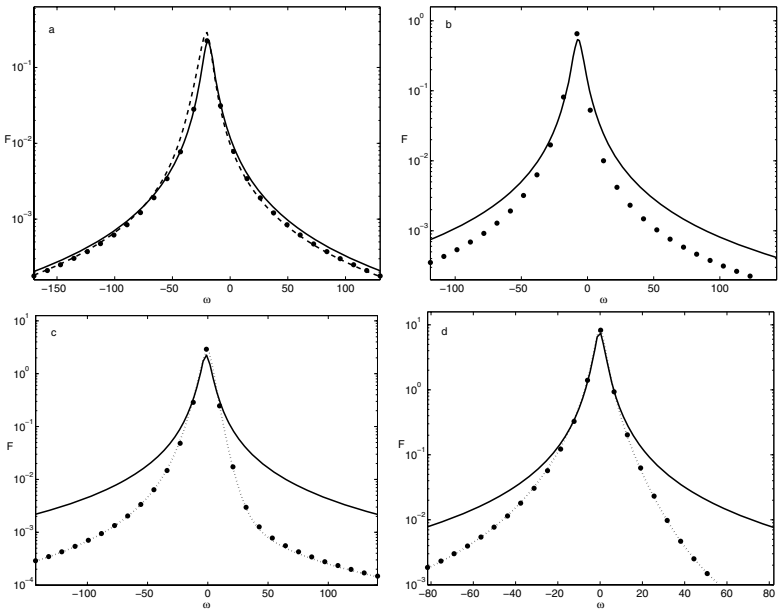

FIG. 3. *Spectrum $F(\omega)$ for $\delta = 5$ and various values of a:* (a) $a = -3$, (b) $a = 0$, (c) $a = 5$, (d) $a = 10$. *See Figure* 1 *for description of line types.*

solutions and asymptotic analysis of the Fokker–Planck equation (see Figures 3 and 4), indicate that the lineshape is markedly non-Lorentzian at $\delta = 5$ (at least for certain values of the pump parameter a). It is therefore useful to experimentalists working with δ levels higher than those examined in SR to have numerical methods and closed form asymptotic solutions which are valid for arbitrarily large values of the parameter δ.

The main results of this paper are presented in caricature form in Figure 5, showing the (a, δ) parameter plane. Since the spectrum for negative δ can be found from the corresponding positive δ result by changing the sign of frequencies ($\omega \to -\omega$, $\Omega \to -\Omega$), we consider only $\delta \geq 0$. The hatched region is where the SR first-eigenvalue Lorentzian lineshape fits reasonably well[2] to the exact spectrum, which we determine by a finite-difference numerical solution of (23) below. As originally shown in SR, the Lorentzian lineshape fits well for all values of the pumping parameter a, provided that δ is less than approximately unity. When δ is significantly greater than one, SR remains accurate very far from the threshold at $a = 0$, but the required magnitude of the pumping increases as δ increases. For instance, we show that for $a < 0$ the SR solution is accurate when the ratio $\delta/a^2 \ll 1$; the corresponding requirement for positive pumping parameter is that $\delta/a \ll 1$. These constraints on the SR solution give the borders of the hatched region above $\delta = 1$. These limits on the single-Lorentzian form of the spectrum are derived using new asymptotic solutions, valid for $|a| \gg 1$ and for all δ values. Our new asymptotic solutions are found to be accurate outside of the region of the (a, δ) plane enclosed by the dashed lines at $a = -5$ and $a = 3$, and show that non-Lorentzian lineshapes are increasingly

[2]The precise meaning of "reasonably well" of course depends on the level of accuracy desired; Figure 5 is intended to indicate only the estimated (order of magnitude) borders where various approximations hold.

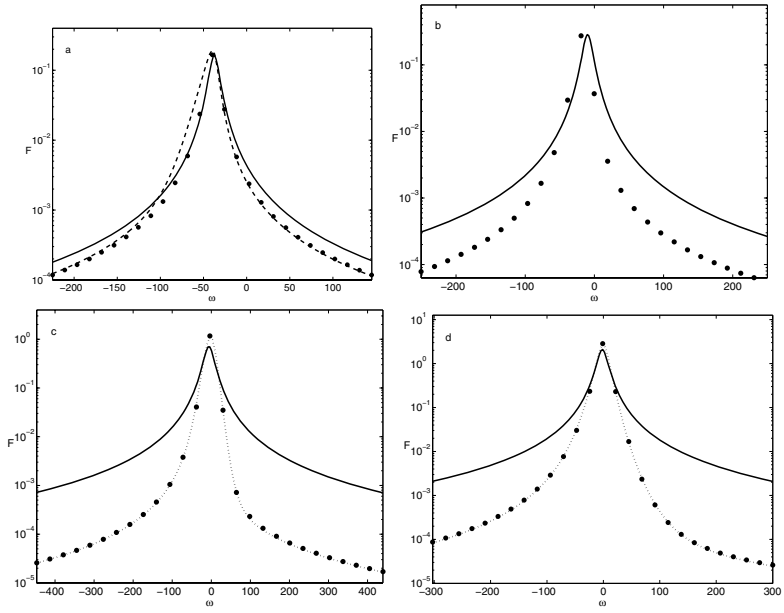

FIG. 4. *Spectrum $F(\omega)$ for $\delta = 10$ and various values of a:* (a) $a = -3$, (b) $a = 0$, (c) $a = 5$, (d) $a = 10$. *See Figure* 1 *for description of line types.*

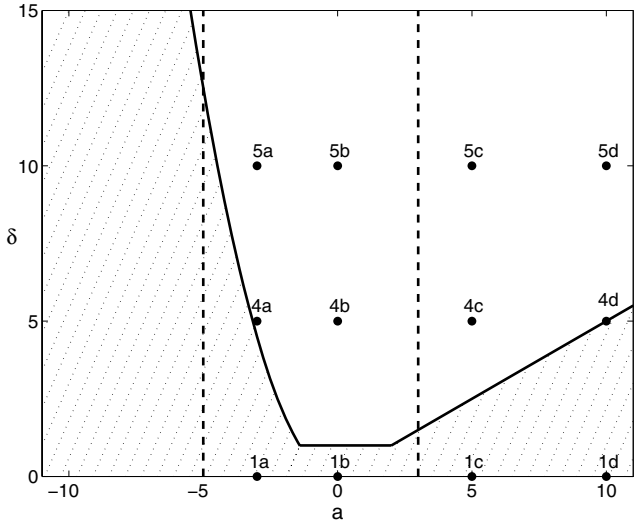

FIG. 5. *The (a, δ) parameter plane. The shaded region shows where the single-Lorentzian spectrum of SR matches the exact result reasonably well; the boundaries are taken to be $\delta/a^2 = 1/2$ for $a < 0$, and $\delta/a = 1/2$ for $a > 0$. The new asymptotic results derived in section* 4 *match the exact results well when $a \ll -5$ or $a \gg 3$. These limits are shown as dashed lines in the figure—note the considerable regions of the parameter plane (e.g., for $a \gg 3$ and $\delta \gg a/2$) where our asymptotic results match the exact values, but those of SR do not. The labeled dots mark the parameter values where spectra are plotted in the corresponding figures.*

important as δ increases. The analytical expressions are likely to be useful not only to experimentalists characterizing lineshapes with $\delta > 1$, but also in providing a novel test case for schemes attempting to characterize spectral lineshapes in self-sustained oscillators of arbitrary dimension in various applications [5, 20].

2. Fokker–Planck equation. The dynamics of the system (1) in the presence of the noise term (3) is fully described by the solution of the Fokker–Planck equation [2], which gives the transition probability density $P(\mathbf{x}, \tau|\mathbf{x}', 0)$ of the two-dimensional stochastic process $\mathbf{x}(t)$, written in polar coordinates as $\mathbf{x}(t) = (r(t)\cos\theta(t), r(t)\sin\theta(t))$ using (2). The transition probability density is the probability that a trajectory of the system passes through the point $\mathbf{x}$ at time $t = \tau$, given that it passed through $\mathbf{x}'$ at time $t = 0$. The Fokker–Planck equation is a partial differential equation for P:

(6)
$$\frac{\partial P}{\partial \tau} + \frac{1}{r}\frac{\partial}{\partial r}\left[\left(a - r^2\right) r^2 P\right] + \frac{\partial}{\partial \theta}\left[\left(\Omega + \delta\left(a - r^2\right)\right) P\right] - \frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\partial P}{\partial r}\right] - \frac{1}{r^2}\frac{\partial^2 P}{\partial \theta^2} = 0,$$

with initial condition

$$P(\mathbf{x}, 0|\mathbf{x}', 0) = \delta(\mathbf{x} - \mathbf{x}'), \tag{7}$$

where here $\delta(\mathbf{x})$ is the Dirac delta-function (not to be confused with the parameter δ, as should be clear from the context). Equation (6) has a stationary ($\tau \to \infty$) solution which depends only on r (and is independent of δ), as shown in [11, 2]:

$$P_\infty(r) = C\exp\left(\frac{ar^2}{2} - \frac{r^4}{4}\right). \tag{8}$$

The normalization constant C is given in terms of the error function as

$$C = \frac{\exp\left(-\frac{a^2}{4}\right)}{\pi^{\frac{3}{2}}\left[1 + \operatorname{erf}\left(\frac{a}{2}\right)\right]}, \tag{9}$$

in order to ensure unit probability over the two-dimensional space

$$\int_0^{2\pi}\int_0^{\infty} P_\infty(r) r\, dr\, d\theta = 1. \tag{10}$$

Note that stationary moments may be calculated from $P_\infty(r)$, for example [2]:

$$\left\langle r^2 \right\rangle = a + 2\pi C. \tag{11}$$

The transition probability density may be used to calculate the correlation between arbitrary functionals $f(\mathbf{x})$ and $g(\mathbf{x})$ of the dynamical system trajectories at times separated by τ [2, 21]:

$$\langle f\left(\mathbf{x}(t)\right) g\left(\mathbf{x}(t+\tau)\right)\rangle = \int d\mathbf{x}'\, P_\infty(\mathbf{x}') f\left(\mathbf{x}'\right) \int d\mathbf{x}\, P(\mathbf{x}, \tau|\mathbf{x}', 0) g\left(\mathbf{x}\right), \tag{12}$$

where each of the integrals above is over the two-dimensional trajectory space. The correlation function may be directly related to the Fokker–Planck equation by defining an auxiliary function $Q(\mathbf{x}, \tau)$ as

$$Q(\mathbf{x}, \tau) = \int P_\infty\left(\mathbf{x}'\right) f\left(\mathbf{x}'\right) P(\mathbf{x}, \tau|\mathbf{x}', 0)\, d\mathbf{x}'. \tag{13}$$

Note that this auxiliary function is a solution of the Fokker–Planck differential equation (6):

(14)
$$\frac{\partial Q}{\partial \tau} + \frac{1}{r}\frac{\partial}{\partial r}\left[\left(a - r^2\right) r^2 Q\right] + \frac{\partial}{\partial \theta}\left[\left(\Omega + \delta\left(a - r^2\right)\right) Q\right] - \frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\partial Q}{\partial r}\right] - \frac{1}{r^2}\frac{\partial^2 Q}{\partial \theta^2} = 0,$$

but with an initial condition that differs from (7):

$$Q(\mathbf{x}, 0) = f(\mathbf{x})\, P_\infty(\mathbf{x}). \tag{15}$$

Assuming that the auxiliary function has been determined, the correlation function is then obtained by integration:

$$\langle f(\mathbf{x}(t))\, g(\mathbf{x}(t+\tau))\rangle = \int g(\mathbf{x}) Q(\mathbf{x}, \tau)\, d\mathbf{x}. \tag{16}$$

The correlation function of the complex quantity E defined in (5) may be calculated by applying this general method, using the functionals

$$f(\mathbf{x}) = r\exp(i\theta) \quad \text{and} \quad g(\mathbf{x}) = r\exp(-i\theta) \tag{17}$$

and the stationary probability density given by (8) and (9). In this case, the auxiliary function is defined as the solution of (14) with initial condition

$$Q(r, \theta, 0) = re^{i\theta} P_\infty(r), \tag{18}$$

and the desired correlation function is found from Q by integration:

$$R(\tau) = \langle E(t) E^*(t+\tau)\rangle = \int_0^{2\pi}\int_0^\infty r^2 e^{-i\theta} Q(r, \theta, \tau)\, dr\, d\theta. \tag{19}$$

The power spectrum of E is defined using the Fourier transform of the correlation function, following the convention of SR:

$$F(\omega) \equiv 2\,\mathrm{Re}\left[\int_0^\infty e^{i\omega\tau} R(\tau)\, d\tau\right]. \tag{20}$$

This formulation of the problem in terms of the auxiliary function Q proves extremely useful for both numerical calculations and asymptotic analysis, and thus forms the theoretical basis for the remainder of the paper. While the formulation (12) for correlation functions is common [2, 21], the reduction to a partial differential equation (pde) for an auxiliary function Q is a nonstandard approach. This idea is potentially very useful for the calculation of correlation functions and spectra in low-dimensional systems, where standard numerical methods for pdes may be applied, as in (23) below.

3. Numerical calculations. In this section we compare two methods for numerical calculation of the spectrum. The auxiliary function approach presented in section 3.1 provides the high-accuracy solutions used throughout the paper; the single-eigenvalue spectrum used by Seybold and Risken is also reviewed in section 3.2.

3.1. Auxiliary function approach. The solution of the pde (14) for the auxiliary function is facilitated by noting that the initial condition (18) permits a separable form:

$$Q(r,\theta,\tau) = e^{i\theta} q(r,\tau). \tag{21}$$

Moreover, the power spectrum $F(\omega)$ may be calculated without first finding the correlation function. To see this, multiply (14) by $\exp(i\omega\tau)$ and integrate over τ. The resulting equation for the quantity $\hat{q}(r,\omega)$, defined as

$$\begin{aligned} \hat{q}(r,\omega) &\equiv \int_0^\infty e^{i\omega\tau} q(r,\tau)\, d\tau \\ &= \int_0^\infty e^{i\omega\tau} e^{-i\theta} Q(r,\theta,\tau)\, d\tau, \end{aligned} \tag{22}$$

is an ordinary differential equation, parameterized by the frequency ω:

$$-i\omega\hat{q} - rP_\infty(r) + \frac{1}{r}\frac{d}{dr}\left[\left(a - r^2\right) r^2 \hat{q}\right] + i\Omega\hat{q} + i\delta\left(a - r^2\right)\hat{q} - \frac{1}{r}\frac{d}{dr}\left[r\frac{d\hat{q}}{dr}\right] + \frac{1}{r^2}\hat{q} = 0. \tag{23}$$

The boundary conditions on $\hat{q}$ are

$$\begin{aligned} \hat{q} &\to 0 \quad \text{as } r \to 0, \\ \hat{q} &\to 0 \quad \text{as } r \to \infty. \end{aligned} \tag{24}$$

Equation (23) is solved numerically for each frequency ω using a standard finite-difference algorithm. The boundary condition for $r \to \infty$ is implemented by truncating the finite-difference grid at a large value of r and setting a Dirichlet condition at the truncation point. We check that this truncation point is sufficiently large to have negligible effect on all spectra shown. Finally, the spectrum $F(\omega)$ is calculated directly from $\hat{q}$ by numerical integration:

$$F(\omega) = 4\pi\,\mathrm{Re}\left[\int_0^\infty r^2 \hat{q}(r,\omega)\, dr\right]. \tag{25}$$

The accuracy of the finite-difference solution depends only on the number of grid points and on the truncation point, and so effectively gives an exact solution for the spectrum. The values found from this numerical method are plotted as symbols in the figures and enable us to compare various analytical approximations for the spectrum.

3.2. Eigenfunction expansion. The formulation given in SR (see also [2]) uses (12) to calculate the correlation function, but instead of defining the auxiliary function and solving (14), the Fokker–Planck equation (6) for the transition probability density $P(\mathbf{x},\tau|\mathbf{x}',0)$ is solved directly. The solution may be found by an eigenfunction expansion [18] or by expansion into a complete set as in [2], i.e., writing P as

$$P(r,\theta,\tau|r',\theta',0) = \frac{1}{2\pi} e^{-r^2/\alpha} \sum_{n=0}^{\infty} \sum_{\nu=-\infty}^{\infty} c_n^{(\nu)} \left(\frac{r'^2}{\alpha}, \tau\right) r^{|\nu|} \alpha^{-|\nu|/2} L_n^{(|\nu|)}\left(\frac{r^2}{\alpha}\right) e^{i\nu(\theta-\theta')}. \tag{26}$$

Here $L_n^{(|\nu|)}$ denotes the generalized Laguerre function, and α is a scaling parameter which can be varied to improve the accuracy of a truncated series approximation

to (26). The coefficients $c_n^{(\nu)}$ satisfy ordinary differential equations, which may be written as

$$\frac{dc_n^{(\nu)}}{d\tau} = \sum_{m=0}^{\infty} A_{nm}^{(\nu)} c_m^{(\nu)}, \tag{27}$$

with initial conditions derived from (7); see [2] for details. To solve numerically, we truncate the sums over n and m in (26) and (27) at a large integer N, and for each ν solve for $c_n^{(\nu)}$ using the matrix exponential of the $(N+1) \times (N+1)$ complex-valued matrix $\mathbf{A}^{(\nu)}\tau$. The final result for the correlation function (19) is then of the form

$$R_{SR}(\tau) = \langle r^2 \rangle \sum_{n=0}^{N} V_n \, e^{\Lambda_n \tau}, \tag{28}$$

where Λ_n are the eigenvalues of the matrix $\mathbf{A}^{(1)}$, and the V_n depend upon the eigenvectors and the initial conditions. The value of $\langle r^2 \rangle$ is given in (11). All Λ_n have negative real parts, so the dominant term when the separation time τ is large gives

$$R_{SR}(\tau) \sim \langle r^2 \rangle \, V_0 \, e^{\Lambda_0 \tau} \quad \text{as } \tau \to \infty, \tag{29}$$

where Λ_0 is the eigenvalue of $\mathbf{A}^{(1)}$ with largest real part. The corresponding spectrum is

$$F_{SR}(\omega) = 2 \langle r^2 \rangle \, \mathrm{Re}\left[\frac{V_0}{-\Lambda_0 - i\omega} \right]. \tag{30}$$

Seybold and Risken [18] take $V_0 \equiv 1$ (with error of less than 3% when $\delta \leq 1.2$), and we therefore compare our numerical results to the SR first-eigenvalue spectrum

$$F_{SR} = 2 \langle r^2 \rangle \, \frac{|\Lambda_{0r}|}{{\Lambda_{0r}}^2 + (\Lambda_{0i} + \omega)^2}, \tag{31}$$

with Λ_{0r} and Λ_{0i} being the real and imaginary parts of Λ_0. This Lorentzian spectrum is peaked at frequency $\omega = \omega_p = -\Lambda_{0i}$ and reaches half of its peak power at frequencies $\omega = \omega_p \pm \Delta\omega$, where $\Delta\omega = |\Lambda_{0r}|$. The frequency difference $\Delta\omega$ gives the half-width of the Lorentzian spectrum at half of the peak value, and when normalized by $\langle r^2 \rangle$ it is referred to as the half-width-at-half-maximum (HWHM), or simply *linewidth*, of the laser spectral line. The spectrum (31) is plotted as a solid line in the figures for comparison with numerical values calculated using the auxiliary function method (symbols), and with asymptotic approximations. The linewidth is examined further in Figures 6 and 7, see section 4.1.

4. Asymptotic solutions. To simplify our notation and conform with the usual conventions in the laser physics literature [18], we set the fundamental frequency Ω to zero in (2). Note that this can formally be accomplished by moving to a rotating reference frame, i.e., changing the angular variable from θ to $\theta - \Omega t$. This change of frame shifts the spectrum so that the peak at $\omega = \Omega$ in the original frame is moved to $\omega = 0$. All results reported here are thus at frequencies ω relative to the fundamental frequency Ω.

4.1. Above threshold: $a \gg 1$. The deterministic dynamics of (2) for positive values of the pump parameter a lead to limit cycles of radius $\sqrt{a}$, as discussed in section 1. When a is sufficiently large, the effects of the (order one) noise terms on the amplitude are small compared to $\sqrt{a}$. The behavior of the dynamics close to the deterministic limit cycle may be examined by making the change of variables

$$r = \sqrt{a} + \frac{\rho}{\sqrt{2a}} \tag{32}$$

in (14). This scaling focuses close to the limit cycle at $r = \sqrt{a}$, with (as shown below) the new variable ρ being of order one in the region of interest. The variable ρ is interpreted as a linear variable, with range $(-\infty, \infty)$ in the $a \to \infty$ limit. The two-dimensional area integral is modified as follows:

$$\int_0^{2\pi} \int_0^{\infty} r\, dr\, d\theta \longrightarrow \frac{1}{\sqrt{2}} \int_0^{2\pi} \int_{-\infty}^{\infty} d\rho\, d\theta, \tag{33}$$

and the stationary probability density becomes

$$P_\infty(\rho) = \frac{1}{2\pi^{3/2}} \exp\left(-\frac{\rho^2}{2}\right). \tag{34}$$

Using (32) in (14) leads to the linearized equation

$$\frac{\partial Q}{\partial \tau} - 2a \frac{\partial}{\partial \rho}(\rho Q) - \sqrt{2}\delta\rho \frac{\partial Q}{\partial \theta} - 2a \frac{\partial^2 Q}{\partial \rho^2} - \frac{1}{a} \frac{\partial^2 Q}{\partial \theta^2} = 0, \tag{35}$$

where the first term of an asymptotic expansion for $a \to \infty$ replaces each term in (14). The initial condition (18) is expanded to

$$Q(\tau = 0) = \sqrt{a} \left(1 + \frac{\rho}{\sqrt{2a}}\right) e^{i\theta} P_\infty(\rho). \tag{36}$$

Equation (35) with initial condition (36) may be solved exactly by Fourier transforming in ρ and using the method of characteristics [2]. Separating variables as in (21) and defining the spatial Fourier transform as

$$\tilde{q}(k, \tau) = \int_{-\infty}^{\infty} e^{i\rho k} q(\rho, \tau)\, d\rho, \tag{37}$$

we obtain the hyperbolic equation

$$\frac{\partial \tilde{q}}{\partial \tau} + \left(2ak - \sqrt{2}\delta\right) \frac{\partial \tilde{q}}{\partial k} = -\left(2ak^2 + \frac{1}{a}\right) \tilde{q} \tag{38}$$

with initial condition

$$\tilde{q}(k, 0) = \frac{1}{\pi} \sqrt{\frac{a}{2}} \left(1 + i \frac{k}{\sqrt{2a}}\right) e^{-\frac{1}{2}k^2}. \tag{39}$$

Solving (38) by the method of characteristics leads to the solution

$$\tilde{q}(k, \tau) = \frac{1}{\pi} \sqrt{\frac{a}{2}} \left[f_1(\tau) + f_2(\tau) k\right] \exp\left[-\frac{1}{2}k^2 + f_3(\tau) k - D(\tau)\right], \tag{40}$$

where

$$f_1(\tau) = 1 + i\frac{\delta}{2a^2}\left(1 - e^{-2a\tau}\right),$$
$$f_2(\tau) = i\frac{1}{\sqrt{2}a}e^{-2a\tau},$$
$$f_3(\tau) = \frac{\delta}{\sqrt{2}a}\left(e^{-2a\tau} - 1\right),$$
$$D(\tau) = \frac{1}{a}\tau + \frac{\delta^2}{2a^2}\left(2a\tau + e^{-2a\tau} - 1\right). \tag{41}$$

The correlation function (19) can be related directly to the Fourier transform of Q via

$$R(\tau) = \sqrt{2a}\pi\left[\tilde{q} - i\frac{1}{\sqrt{2}a}\frac{\partial\tilde{q}}{\partial k}\right]\Bigg|_{k=0}, \tag{42}$$

and the final result may be written as

$$R(\tau) = a\left(a_0 + a_1 e^{-2a\tau} + a_2 e^{-4a\tau}\right)e^{-D(\tau)}, \tag{43}$$

where the coefficients a_n depend upon the parameters as follows:

$$a_0 = \left(1 + \frac{\delta}{2a^2}i\right)^2,$$
$$a_1 = \frac{1}{2a^2}\left(1 + \frac{\delta^2}{a^2} - 2\delta i\right),$$
$$a_2 = -\frac{\delta^2}{4a^4}. \tag{44}$$

Note that for convenience we have assumed $\tau > 0$ in the above; the symmetry of R implies that for negative arguments τ should be replaced by $|\tau|$.

Analytical expressions may be found for the Fourier transform of (43). For instance, a series expansion of the $\exp(D(\tau))$ term allows the autocorrelation to be written as

$$R(\tau) = a\exp\left(\frac{\delta^2}{2a^2}\right)\sum_{n=0}^{\infty} b_n e^{-\lambda_n\tau}, \tag{45}$$

with $\lambda_n = 2an + \frac{1}{a}\left(\delta^2 + 1\right)$, and

$$b_0 = \left(1 + \frac{\delta^2}{2a^2}i\right)^2, \tag{46}$$

$$b_1 = \frac{1}{2a^2}\left(1 + \frac{\delta^2}{2a^2} - i\delta\right)^2, \tag{47}$$

$$b_n = \frac{(-1)^{n+1}}{n!}\frac{\delta^{2n-2}}{2^n a^{2n}}\left[n + \frac{\delta^2}{2a^2} - i\delta\right]^2 \quad \text{for } n \geq 2. \tag{48}$$

The corresponding spectrum is then an infinite sum of Lorentzians,

$$F(\omega) = 2a\exp\left(\frac{\delta^2}{2a^2}\right)\mathrm{Re}\left[\sum_{n=0}^{\infty}\frac{b_n}{\lambda_n - iw}\right]. \tag{49}$$

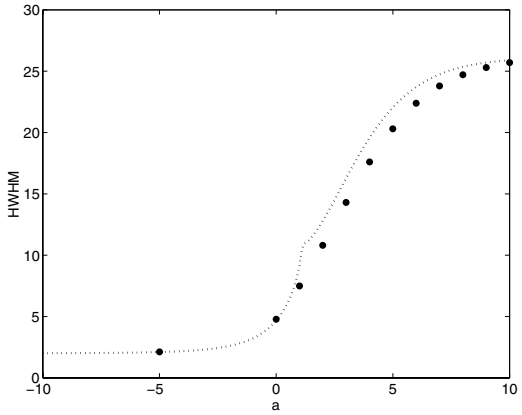

FIG. 6. *The normalized linewidth (HWHM) $\langle r^2 \rangle \Delta\omega$ of the spectra as a function of a for $\delta = 5$. Numerical results are shown by symbols; the dotted line is the SR first-eigenvalue result.*

Note that this sum converges very slowly when $|\delta| \gg 1$, so that many terms are required to give the spectrum accurately. Also, the leading-order dependence on δ is of the form δ/a; this implies that non-Lorentzian lineshapes arise when δ is a nonnegligible fraction of a, and leads us to sketch the estimated border $\delta = a/2$ for positive a in Figure 5.

An alternative expression for the spectrum may be given in terms of a finite sum, but involving the generalized incomplete gamma function [22, 23], defined as

$$\gamma(y, z) = \int_0^z t^{y-1} e^{-t} dt. \tag{50}$$

In terms of this function, the spectrum is

$$F(\omega) = \exp\left(\frac{\delta^2}{2a^2}\right) \operatorname{Re}\left[\sum_{n=0}^{2} a_n \left(\frac{2a^2}{\delta^2}\right)^{\frac{\lambda_n - i\omega}{2a}} \gamma\left(\frac{\lambda_n - i\omega}{2a}, \frac{\delta^2}{2a^2}\right)\right], \tag{51}$$

with the coefficients a_n as defined in (44). The spectrum (51) is plotted with a dotted line in parts (c) and (d) of Figures 1, 3, and 4, and matches the numerical spectrum (symbols) very well, even for values of a as low as 5. The SR Lorentzian spectrum (solid line) fits poorly when $\delta > 0$. Close to the peak of the spectrum the fit of the SR approximation can be quantified by the HWHM of the lineshape, as defined in section 3.2. The fit of the numerical linewidth to the SR prediction is reasonably good at $\delta = 5$ (Figure 6), indicating that the non-Lorentzian effects have most impact away from the peak; however, the SR linewidth estimation decays in accuracy as δ increases; see the $\delta = 10$ case in Figure 7.

4.1.1. Large-frequency spectrum. A small-τ expansion of $R(\tau)$ from (43) yields

$$R(\tau) \sim a - 2(1 - i\delta)|\tau| + O\left(\tau^2, a^{-1}\right) \quad \text{as } \tau \to 0,\ a \to \infty, \tag{52}$$

and the corresponding large-frequency asymptotic form of the spectrum $F(\omega)$ from (20) is

$$F(\omega) \sim \frac{4}{\omega^2} + O\left(\omega^{-3}\right) \quad \text{as } \omega \to \infty. \tag{53}$$

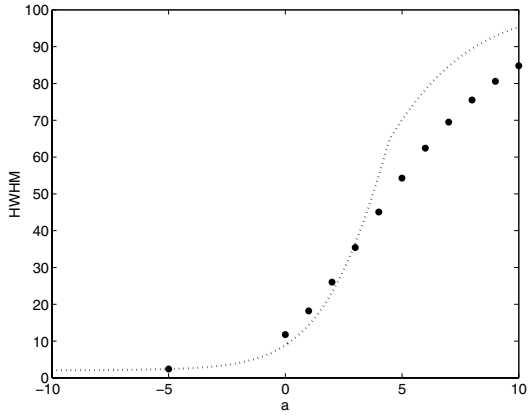

FIG. 7. *The normalized linewidth (HWHM)* $\langle r^2 \rangle \Delta\omega$ *of the spectra as a function of* a *for* $\delta = 10$. *Line types are as in Figure* 6.

Note that this leading order behavior of the spectrum can be derived directly from a small-τ expansion in (14) and (19), and is independent of the values of the parameters a and δ.

In the $a \gg 1$ asymptotic limit, the single-Lorentzian form of the spectrum used in SR corresponds to the correlation function

$$R_{\mathrm{SR}}(\tau) = a \exp\left[-\frac{1}{a}\left(1+\delta^2\right)|\tau|\right]. \tag{54}$$

The large-frequency asymptote of the SR spectrum is then [18]

$$F_{\mathrm{SR}} \sim \frac{2\left(1+\delta^2\right)}{\omega^2} + O\left(\omega^{-3}\right) \qquad \text{as } \omega \to \infty \tag{55}$$

and clearly does not match the exact result (53) for general δ. The mismatch of the exact spectrum and the SR approximation far from the peak can be clearly seen in Figure 2. As noted by SR, this effect occurs even when $\delta = 0$. We show in the following sections that the correct large-frequency asymptote depends upon the consistent inclusion of random fluctuations in the amplitude r of the oscillations.

4.1.2. Comparison with other approximations. The above-threshold laser regime has been the subject of many theoretical and experimental investigations. Here we compare our results for $|a| \gg 1$ with other approximation schemes yielding non-Lorentzian lineshapes.

The Langevin equations arising from (2) and (3) may be linearized near the deterministic orbit by the change of variables (32) to give (with $\Omega = 0$)

$$\frac{d\rho}{dt} = -2a\rho + \sqrt{2a}\xi_r, \tag{56}$$

$$\frac{d\theta}{dt} = -\sqrt{2}\delta\rho + \frac{1}{\sqrt{a}}\xi_\theta. \tag{57}$$

Here $\xi_r(t)$ and $\xi_\theta(t)$ are independent, unit intensity white noise terms; cf. the Fokker–Planck equation (35). Equation (56) is linear in ρ with a white-noise forcing, and so

generates an Ornstein–Uhlenbeck colored-noise process $\rho(t)$. Equation (57) describes the stochastic process of the phase angle $\theta(t)$, which is forced by the colored-noise process $\rho(t)$ and the white noise ξ_θ.

In the full description of the correlation function (5), fluctuations in both the phase $\theta(t)$ and the amplitude $r(t)$ of the oscillation have important effects. The linearized Langevin equations, however, suggest the use of a *phase oscillator* approximation [24], wherein the effects of the colored noise ρ are incorporated into the evolution of the phase angle θ, but all other influence of the amplitude fluctuations are neglected. Under this approximation, the correlation function (5) is simply

$$R_{\mathrm{P}O}(\tau) = a\,\langle \exp\left[i\,\theta(t) - i\,\theta(t+\tau)\right]\rangle \tag{58}$$

and can be calculated directly from the linearized Langevin equation for θ. The result is [22]

$$R_{\mathrm{P}O}(\tau) = a\,e^{-D(\tau)}, \tag{59}$$

where $D(\tau)$ is given in (41). Note that this corresponds to setting $a_0 = 1$ and $a_1 = a_2 = 0$ in the asymptotic result (43).

The spectrum of (59) is non-Lorentzian for $\delta > 0$, but the large-frequency asymptote is

$$F_{\mathrm{P}O} \sim \frac{2}{\omega^2} + O\left(\omega^{-3}\right) \qquad \text{as } \omega \to \infty, \tag{60}$$

i.e., a factor of 2 lower than the correct form (53). This discrepancy is due to the neglect of the direct effect of amplitude fluctuations upon the spectrum of E within the phase oscillator approximation; the correct values of a_0, a_1, and a_2 from (44) are required for the full description of the spectrum.

The *Voigt lineshape*, obtained by convoluting a Lorentzian and a Gaussian in frequency space, is sometimes fitted to experimental oscillation data [25, 26]. We note that in the phase-oscillator approximation the correlation function (59) is the exponential of the function $D(\tau)$; if this function is assumed to be replaced by the first two terms of its Taylor series about $\tau = 0$, the resulting correlation function

$$R_{\mathrm{V}}(\tau) = a\,e^{-\frac{1}{a}|\tau| - \delta^2\tau^2} \tag{61}$$

corresponds to a Voigt spectral lineshape. This result can also be derived directly from the linearized phase equation (57) if the amplitude deviation ρ is assumed to be a (frozen) random variable chosen from the Gaussian distribution (34). This approximation completely ignores the temporal variation of $\rho(t)$ as given in (56), and is valid only in the limit $\delta \to \infty$.

4.2. Below threshold: $a \ll -1$. When the pumping parameter a is negative, the origin $r = 0$ is the attracting steady solution of the deterministic system (2). In order to find asymptotic solutions valid for $a \ll -1$, we therefore rescale lengths to closely examine the neighborhood of the origin:

$$r = \frac{1}{\sqrt{|a|}}\rho, \tag{62}$$

where ρ is of order one and is restricted to the interval $[0, \infty)$. The two-dimensional area integral transforms as

$$\int_0^{2\pi}\int_0^{\infty} r\,dr\,d\theta \longrightarrow \frac{1}{|a|}\int_0^{2\pi}\int_0^{\infty} \rho\,d\rho\,d\theta, \tag{63}$$

and the stationary probability density is

$$P_\infty(\rho) = \frac{|a|}{2\pi} \exp\left(-\frac{\rho^2}{2}\right). \tag{64}$$

Retaining the most significant terms (and all δ-dependent terms) in (14) as $|a| \to \infty$ yields the asymptotic equation

$$\frac{\partial Q}{\partial \tau} + \frac{a}{\rho}\frac{\partial}{\partial \rho}\left(\rho^2 Q\right) + \left(a\delta + \frac{1}{a}\delta\rho^2\right)\frac{\partial Q}{\partial \theta} + \frac{a}{\rho}\frac{\partial}{\partial \rho}\left(\rho\frac{\partial Q}{\partial \rho}\right) + \frac{a}{\rho^2}\frac{\partial^2 Q}{\partial \theta^2} = 0, \tag{65}$$

with initial condition

$$Q(\tau = 0) = \frac{\sqrt{|a|}}{2\pi} e^{i\theta} \rho\, e^{-\frac{1}{2}\rho^2}. \tag{66}$$

Motivated by work in the mixing of scalar fields in vortex fluid flows [27, 28], we seek a solution of (65) in the form

$$Q = \frac{\sqrt{|a|}}{2\pi} e^{i\theta} \rho \exp\left[-g(\tau)\rho^2 + h(\tau)\right]. \tag{67}$$

This is an *exact* solution of the equation if g and h satisfy the ordinary differential equations

$$\begin{aligned} \frac{1}{|a|}\frac{dg}{d\tau} &= 2g - 4g^2 - i\frac{\delta}{a^2}, \\ \frac{1}{|a|}\frac{dh}{d\tau} &= -8g + 3 + i\delta, \end{aligned} \tag{68}$$

with initial conditions $g(0) = 1/2$, $h(0) = 0$. The solutions of this system may be obtained in closed form, and the correlation function resulting from the integration (19) is

(69)

$$\begin{aligned} R(\tau) &= \frac{1}{|a|}\int_0^\infty \rho^3 \exp\left[-g(\tau)\rho^2 + h(\tau)\right]\, d\rho \\ &= \frac{1}{2|a|g^2(\tau)} \exp\left[h(\tau)\right] \\ &= \frac{2\left(1-4\mu\right)^2}{|a|\left(1-2\mu\right)^4} \exp\left[\left(-1 + i\delta + 8\mu\right)|a\tau|\right] \left\{1 - \frac{4\mu^2}{(1-2\mu)^2}\exp\left[\left(-2+8\mu\right)|a\tau|\right]\right\}^{-2}, \end{aligned}$$

where $\mu = \left(1 - \sqrt{1 - 4i\delta/a^2}\right)/4$.

In contrast to the above-threshold case in section 4.1, an analytical formula for the spectrum corresponding to this correlation function has not been found. However, numerical integration of (20) using (69) can be used to find the asymptotic spectrum for $a \ll -1$, valid for arbitrarily large values of δ. This spectrum is plotted for $a = -3$ as a dashed line in part (a) of Figures 1, 3, and 4. The requirement $a \ll -1$ for validity of the asymptotics does not really hold at the chosen value of a, and the fit to the numerical spectrum is poor near the peak, though better than the SR lineshape away from the peak. However, for $a = -10$, Figure 8 shows an excellent match between the asymptotic spectrum and the numerics—here we have taken $\delta = 200$ (so that $\delta/a^2 = 2$) in order to highlight the non-Lorentzian lineshape. Note that the non-Lorentzian effects in (69) depend on the parameter combination δ/a^2; this leads us to define the border $\delta/a^2 = 1/2$ for negative a in Figure 5.

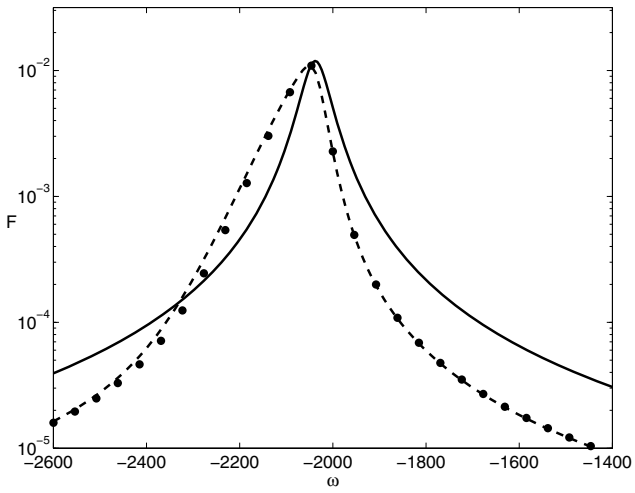

FIG. 8. *Spectrum $F(\omega)$ for $a = -10$ and $\delta = 200$. See Figure 1 for description of line types.*

5. Conclusions. We have studied the effects of additive white noise on the spectral lineshape of a dynamical system described by the Hopf normal form (1). Particular emphasis is laid on the role of the amplitude-phase coupling (detuning) parameter δ. Non-Lorentzian lineshapes occur when δ is nonnegligible, in contrast to the heretofore most studied case of $\delta = 0$.

We use asymptotic methods to find closed form solutions for the laser amplitude correlation function, valid for any δ value, when the pump parameter a is both above (equation (43)) and below (equation (69)) threshold. In the former case an analytic formula for the spectrum is also given. The asymptotics are formally valid for $|a| \gg 1$, but we find they match the numerical solution well even when the magnitude of a is as small as 5. In contrast to previous work on this problem, no assumption on the size of δ is made, so that the formulas are valid for arbitrarily large δ values. The spectrum becomes non-Lorentzian as δ increases, and we indicate (Figure 5) the parameter regions where single-eigenvalue methods fail to accurately describe the lineshape. We look at existing approximation methods (section 4.1.2) and show that they are special limiting cases of our results.

Both asymptotic and numerical solutions are based on the auxiliary function approach developed in section 2. It should be stressed that (despite the use of convenient nomenclature from the laser physics literature) the results presented are quite general and apply to any noisy dynamical system near a Hopf bifurcation point. We anticipate that the results and methods presented here will be of interest both for their applicability to high-δ lasers, and as test cases for single-eigenvalue methods developed to predict spectra in high-dimensional oscillators for electronic and chemical applications [5, 8, 20]. It would also be interesting to apply the asymptotic methods used here to more detailed models of lasers which supplement (1) with equations for the laser gain and carrier density, leading to relaxation oscillation sidebands in the spectrum [29].

Appendix. The Hopf normal form equations (2) contain only three parameters: a, Ω, and δ. In this appendix we describe in detail the derivation of (2), beginning

with the standard deterministic Hopf normal form presented in [1]:

$$\begin{aligned} \frac{d\tilde{r}}{d\tilde{t}} &= \left(d\mu + \tilde{a}\tilde{r}^2\right)\tilde{r}, \\ \frac{d\theta}{d\tilde{t}} &= \omega + c\mu + b\tilde{r}^2. \end{aligned} \tag{70}$$

(Here we use tildes to distinguish between certain parameters and dimensionless versions of the same name.) The parameters $\tilde{a}$, b, c, and d are all typically of order unity, with $\tilde{a} < 0$, and can in theory be found from the properties of the dynamical system at the bifurcation point $\mu = 0$. The bifurcation parameter is μ, and for analysis "near" the bifurcation point, the magnitude of μ is assumed to be small: $|\mu| \ll 1$. The differential equation for the evolution of the complex quantity $\tilde{E} = \tilde{r}\exp(i\theta)$ follows from (70); the effect of random fluctuations is modeled by adding a white noise term $\tilde{\Gamma}$:

$$\frac{d\tilde{E}}{d\tilde{t}} = i\left(\omega + c\mu\right)\tilde{E} + \left(d\mu + (\tilde{a} + ib)\left|\tilde{E}\right|^2\right)\tilde{E} + \tilde{\Gamma}, \tag{71}$$

with

$$\tilde{\Gamma} = \tilde{\xi}_x(t) + i\tilde{\xi}_y(t) \tag{72}$$

being a complex noise of intensity κ:

$$\left\langle \tilde{\xi}_x(t)\tilde{\xi}_x(t')\right\rangle = \left\langle \tilde{\xi}_y(t)\tilde{\xi}_y(t')\right\rangle = 2\kappa\delta(t-t'), \qquad \left\langle \tilde{\xi}_x(t)\tilde{\xi}_y(t')\right\rangle = 0. \tag{73}$$

As further discussed below, the balance between the noise intensity κ and the (small-magnitude) bifurcation parameter μ is crucial to understanding the effects of noise upon the dynamics.

To nondimensionalize the system, we write the Fokker–Planck equation for (71) in the polar coordinates $\tilde{r}$ and θ:

$$\frac{\partial P}{\partial \tilde{\tau}} + \frac{1}{\tilde{r}}\frac{\partial}{\partial \tilde{r}}\left[\left(d\mu + \tilde{a}\tilde{r}^2\right)\tilde{r}^2 P\right] + \frac{\partial}{\partial\theta}\left[\left(\omega + c\mu + b\tilde{r}^2\right)P\right] - \frac{\kappa}{\tilde{r}}\frac{\partial}{\partial\tilde{r}}\left[\tilde{r}\frac{\partial P}{\partial\tilde{r}}\right] - \frac{\kappa}{\tilde{r}^2}\frac{\partial^2 P}{\partial\theta^2} = 0. \tag{74}$$

Choosing a length scale L and a time scale T as references, $\tilde{r}$ and $\tilde{\tau}$ may be written in terms of the dimensionless variables r and τ used in (2):

$$\tilde{r} = Lr, \qquad \tilde{\tau} = T\tau. \tag{75}$$

The Fokker–Planck equation (74) then becomes

$$\begin{aligned} &\frac{\partial P}{\partial \tau} + \frac{1}{r}\frac{\partial}{\partial r}\left[\left(Td\mu + TL^2\tilde{a}r^2\right)r^2 P\right] + \frac{\partial}{\partial\theta}\left[\left(T\omega + Tc\mu + TL^2 br^2\right)P\right] - \frac{\kappa T}{L^2}\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\partial P}{\partial r}\right] \\ &\quad - \frac{\kappa T}{L^2}\frac{1}{r^2}\frac{\partial^2 P}{\partial\theta^2} = 0. \end{aligned} \tag{76}$$

We can now choose the length and time scales L and T in order to reduce the number of dimensionless parameters. The conventional choice in the laser literature (see, e.g.,

Chapter 12 of [2]) is to set the diffusion coefficients $\kappa T/L^2$ to unity, and the parameter combination $TL^2\tilde{a}$ to -1 (recall that $\tilde{a}$ is negative). These choices determine T and L in terms of the parameter $\tilde{a}$ and the noise intensity κ, and yield the nondimensional Fokker–Planck equation:

(77)
$$\frac{\partial P}{\partial \tau} + \frac{1}{r}\frac{\partial}{\partial r}\left[\left(a - r^2\right) r^2 P\right] + \frac{\partial}{\partial \theta}\left[\left(\Omega + \delta\left(a - r^2\right)\right) P\right] - \frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\partial P}{\partial r}\right] - \frac{1}{r^2}\frac{\partial^2 P}{\partial \theta^2} = 0,$$

as used in (6). The parameters a, Ω, and δ appearing here are thus given in terms of the original system parameters as

(78)
$$a = d\mu\sqrt{\frac{-1}{\kappa\tilde{a}}}, \quad \Omega = \sqrt{\frac{-1}{\kappa\tilde{a}}}\left(\omega + c\mu - \frac{bd\mu}{\tilde{a}}\right), \quad \delta = \frac{b}{\tilde{a}}.$$

Note the appearance of the bifurcation parameter μ and the noise intensity κ in the definition of the parameter a. As stated above, the magnitude of μ must be small, $|\mu| \ll 1$, for analysis near the Hopf bifurcation point. However, the noise intensity κ may also be very small, and the resulting parameter a may therefore have arbitrarily large magnitude even for small $|\mu|$ if the noise intensity κ goes to zero. Note also that the amplitude-phase coupling parameter δ is independent of μ and depends only on the properties of the dynamical system at the bifurcation point (as determined by the parameters b and $\tilde{a}$ in the normal form (70)).

The derivation of the normal form equations at a bifurcation point relies on the transformation of the dependent and/or independent variables in the original system. The assumption made above that the noise terms enter additively into (71) is therefore somewhat simplistic—when the noise in the original dynamical system is subject to the normal form transformation, it may very well appear in (71) as, for example, multiplicative noise [13], or with unequal intensities in the real and imaginary directions. Nevertheless, the generality of the normal form is such that the study of the simplest case, i.e., additive isotropic white noise, is still instructive. Moreover, additive isotropic noise is often adopted as a phenomenological model when the details of the noise sources or the underlying dynamical system are not known; this is the case for the semiclassical laser equations as derived in Chapter 12 of [2], for example. It is hoped that the new results of this paper (especially on the importance of the amplitude-phase coupling parameter δ) for additive isotropic noise will stimulate further work on the combined effects on spectral lineshapes with nonzero δ and multiplicative and/or nonisotropic noise.

PHASE TRANSITIONS AND CHANGE OF TYPE IN LOW-TEMPERATURE HEAT PROPAGATION*

KATARZYNA SAXTON† AND RALPH SAXTON‡

Abstract. Classical heat pulse experiments have shown heat to propagate in waves through crystalline materials at temperatures close to absolute zero. With increasing temperature, these waves slow down and finally disappear, to be replaced by diffusive heat propagation. Several features surrounding this phenomenon are examined in this work. The model used switches between an internal parameter (or extended thermodynamics) description and a classical (linear or nonlinear) Fourier law setting. This leads to a hyperbolic-parabolic change of type, which allows wavelike features to appear beneath the transition temperature and diffusion above. We examine the region around and immediately below the transition temperature, where dissipative effects are insignificant.

Key words. phase transition, hyperbolic-parabolic, change of type

1. Introduction. The analysis in this paper is based on a low-temperature heat propagation model described in [9] and [10]. The model is based on experimental results of [3], [2], [5], and [6], which provide evidence of second sound, i.e., hyperbolic, or wavelike, thermal effects where Fourier's law fails, in very pure crystals of sodium fluoride and bismuth.

Significantly, these features appear only at certain temperatures below which the materials reach their peak thermal conductivities (at approximately 18.5 K and 4.5 K for NaF and Bi, respectively). No wavelike behavior is found in NaF and Bi at higher temperatures, where only diffusive heat propagation is observed. Further, the speed, U_E, at which small amplitude thermal waves propagate is a decreasing function of temperature in the region where the waves can be detected, after which the diffusion process dominates. This hyperbolic region appears separated from the diffusive region by a "critical" temperature, ϑ_λ, at which $U_E = 0$ [1]. The aim of this paper is to understand the dynamics of regular solutions having temperatures close to that of the phase transition. We begin, in section 2, by describing a phenomenological one-dimensional model which uses an internal variable behaving as an order parameter. In section 3, we will examine properties of the phase transition, and in section 4, we obtain conditions under which this class of solutions remain smooth. Some explicit cases are, finally, examined in section 5.

2. Preliminaries. We briefly describe our model and refer to [10] (see also [9]) for further details concerning the thermodynamics of materials with internal parameters. In the present context, two forms of heat transmission—diffusive propagation at high temperatures and wavelike propagation at low temperatures—are separated by a phase transition at a critical temperature, $\vartheta_\lambda > 0$. At temperatures above ϑ_λ, we

employ the equations for heat flow through a one-dimensional rigid solid, consisting of balance of energy and Fourier's law,

$$\varepsilon(\vartheta)_t + q_x = 0, \tag{2.1}$$

$$q = -k(\vartheta)\vartheta_x, \tag{2.2}$$

where $\varepsilon(\vartheta)$ represents internal energy, $\varepsilon'(\vartheta) = c_v(\vartheta)$ is the specific heat at constant volume, q denotes heat flux, and $k(\vartheta)$ is the heat conductivity.

At temperatures between $\vartheta = 0$ (absolute) and $\vartheta = \vartheta_\lambda$, experimental results indicate that the constitutive description of q given by (2.2) is inadequate [2]. This then requires the use of an extended form of thermodynamics, in which we employ an internal parameter, p, to appropriately model observations. The internal parameter satisfies a particular form of evolution equation (see [10], [9]), and heat flow is described below ϑ_λ by the equations

$$\varepsilon(\vartheta)_t + q_x = 0, \tag{2.3}$$

$$p_t = g_1(\vartheta)\vartheta_x + g_2(\vartheta)p, \tag{2.4}$$

$$q = -\alpha(\vartheta)p, \tag{2.5}$$

where $g_1(\vartheta) \geq 0 \geq g_2(\vartheta)$ and $\alpha(\vartheta) \geq 0$ are material functions. The second law of thermodynamics imposes the restriction that $\alpha(\vartheta) = \psi_{20}\vartheta^2 g_1(\vartheta)$, where the constant $\psi_{20} > 0$ comes from the Helmholtz free energy, ψ, which has the form $\psi = \psi_1(\vartheta) + \frac{1}{2}\psi_{20}\vartheta p^2$. While satisfying the second law of thermodynamics, the model has internal energy depending only on temperature [9]. In effect, (2.3)–(2.5) permit q to depend on the history of the temperature gradient.

The following constitutive relations will be used for g_1 and g_2 (see [10]):

$$g_1(\vartheta) = g_{10}(\vartheta)(\vartheta_\lambda - \vartheta)^r, \qquad g_{10}(\vartheta) > 0, \tag{2.6}$$

$$g_2(\vartheta) = g_{20}(\vartheta)(\vartheta_\lambda - \vartheta)^{2r}, \qquad g_{20}(\vartheta) < 0, \tag{2.7}$$

where $0 \leq \vartheta \leq \vartheta_\lambda$. Here $g_{10}, g_{20} \in C[0, \vartheta_\lambda]$ and $r \in (0, 1)$. The form of these functions can be derived from experimental data on the wave speed, $U_E(\vartheta)$, the heat conductivity, $K(\vartheta)$, and the specific heat, $c_v(\vartheta)$, as we now describe.

The characteristic equation for (2.3)–(2.5) is given by

$$c_v(\vartheta)\lambda^2 + \lambda\alpha'(\vartheta)p - \alpha(\vartheta)g_1(\vartheta) = 0. \tag{2.8}$$

If one considers waves propagating into an undisturbed state $\vartheta =$ constant, $p = 0$ ($q = 0$), this provides an expression for U_E,

$$\lambda^2 = U_E^2 \equiv \frac{\alpha(\vartheta)g_1(\vartheta)}{c_v(\vartheta)} = \psi_{20}\vartheta^2\frac{g_1^2(\vartheta)}{c_v(\vartheta)}. \tag{2.9}$$

Given experimental measurements of $U_E(\vartheta)$ and $c_v(\vartheta)$, this specifies $g_1(\vartheta)$. It is observed that second sound is a decreasing function of temperature, which we allow to reach zero [1] at $\vartheta = \vartheta_\lambda$ (cf. (2.6)).

In order to find $g_2(\vartheta)$, we use measurements of heat conductivity made in near-stationary states, for which fast processes are considered to be minor, $p_t \approx 0$.[1] In this case, the difference between solutions to (2.3)–(2.5) and the diffusion equation

$$\varepsilon(\vartheta)_t - (K(\vartheta)\vartheta_x)_x = 0, \tag{2.10}$$

where $K(\vartheta) = -\frac{\alpha(\vartheta)g_1(\vartheta)}{g_2(\vartheta)} = -\frac{U_E^2(\vartheta)c_v(\vartheta)}{g_2(\vartheta)} > 0$, becomes small. Requiring $K(\vartheta)$ to remain finite as $\vartheta \to \vartheta_\lambda -$ then leads to the form of $g_2(\vartheta)$ in (2.7).

The behavior of the specific heats of Bi and NaF is typically considered to be continuous in temperature, and we will assume this here, with

$$c_v(\vartheta) \sim c_\lambda, \qquad |\vartheta_\lambda - \vartheta| \ll 1, \qquad c_\lambda > 0, \tag{2.11}$$

where "$\sim$" denotes leading order behavior. Otherwise c_v is considered to be described by a continuous function which obeys Debye's law, $c_v(\vartheta) \sim \vartheta^3$, as $\vartheta \to 0$.

Particular forms of (2.6) and (2.7) chosen to fit available data for crystals of high purity NaF and Bi can be found in [10]. Together with (2.11), these result in U_E having the general form

$$U_E^2(\vartheta) \sim U_0^2(\vartheta)(\vartheta_\lambda - \vartheta)^{2r} \tag{2.12}$$

for $\vartheta \le \vartheta_\lambda$, with U_0, a continuous function of ϑ, found experimentally.

For convenience, we introduce the following change of variables:

$$e = \varepsilon(\vartheta) - \varepsilon(\vartheta_\lambda), \quad \vartheta = \varepsilon^{-1}(e + \varepsilon_\lambda), \quad \text{and } \varepsilon_\lambda = \varepsilon(\vartheta_\lambda). \tag{2.13}$$

We may rewrite (2.1), (2.2) in terms of $e > 0$ and q as

$$e_t + q_x = 0, \tag{2.14}$$

$$q = -d(e)e_x, \tag{2.15}$$

where $d(e) = k(\vartheta)/c_v(\vartheta),\ k(\vartheta) > 0$. When $e < 0$, equations (2.3), (2.4) become

$$e_t + q_x = 0, \tag{2.16}$$

$$q_t + \frac{h'(e)}{h(e)} q q_x = f(e)\{q + D(e)e_x\}, \tag{2.17}$$

where[2]

$$f(e) = g_2(\vartheta), \quad h(e) = \alpha(\vartheta), \quad D(e) = \frac{K(\vartheta)}{c_v(\vartheta)}. \tag{2.18}$$

[1] In this limit, however, thermal waves do not necessarily propagate at the speed dictated by the qualitatively approximate parabolic equation (2.10), but still at a characteristic velocity, λ, given by (2.9). We also distinguish $p_t \approx 0$ (for which $g_1(\vartheta), g_2(\vartheta) \neq 0$) from $p_t = 0$ (where $g_1(\vartheta) = g_2(\vartheta) = 0$). The former is an assumption concerning the dynamics, such as the time asymptotic behavior which may arise due to damping (for instance, as seen in [4], and which still preserves hyperbolic features such as finite speed of propagation) in the original system. In the latter case, ϑ is assumed to have reached the transition temperature, $\vartheta = \vartheta_\lambda$.

[2] For physical reasons [2], we will here assume that $k(\vartheta_\lambda) = K(\vartheta_\lambda)$ (where $q = -K(\vartheta)\vartheta_x = -D(e)e_x$), which occurs in the limit $p_t \approx 0$ leading to (2.10). $K(\vartheta)$ is sometimes known as the *quasistatic* heat conductivity.

Continuous initial data, $e_0(x)$ or $\vartheta_0(x)$, will be defined such that

$$e(\vartheta(x,0)) = e_0(x), \qquad e_0(0) = 0, \tag{2.19}$$

with

$$xe_0(x) > 0 \quad \text{for } x \neq 0, \tag{2.20}$$

where

$$\vartheta(x,0) = \vartheta_0(x), \qquad \vartheta_0(0) = \vartheta_\lambda. \tag{2.21}$$

Given the observed sharp decay in the speed of heat pulse propagation, nonlinear effects are involved. Since the system (2.16), (2.17) is quasilinear and hyperbolic (cf. (2.3)–(2.5)), it is possible to account for this decay, but it also becomes possible for shocks to form in finite times [7], [8], [10] in temperatures below ϑ_λ. The present analysis examines the situation under which solutions taking values at temperatures on both sides of ϑ_λ should remain smooth. As such, it can be regarded as a first step in analyzing experiments using large amplitude temperature pulses crossing into phases that involve dissipation.

3. Properties of phase transitions. Let Γ denote a curve $x = \varphi(t),\ t \geq 0$, such that $e(\varphi(t),t) = 0$ ($\vartheta(\varphi(t),t) = \vartheta_\lambda$) and let $V \subset \mathbb{R}^2_+ = \{(x,t) \in \mathbb{R}^2, t \geq 0\}$ be a neighborhood of Γ. Set $V = U_- \cup \Gamma \cup U_+$, where the regions U_- and U_+ correspond to $e < 0$ and $e > 0$, respectively. Heat propagation is then governed by (2.14), (2.15) in U_- and by (2.16), (2.17) in U_+.

We denote limits of a function u from the left and right of Γ, as $x \to \varphi(t)$, by $u^-(t) = u(\varphi(t)-,t)$ and $u^+(t) = u(\varphi(t)+,t)$, respectively, and denote the jump of u across Γ by $[u](t) = u^+(t) - u^-(t)$. Let $PC^1(Q)$ denote the class of piecewise differentiable functions on $Q \subset \mathbb{R}^2$. By assuming $\vartheta \in PC^1(\mathbb{R}^2_+)$, e becomes continuous across Γ.

Let $s = \dot{\varphi}$. Using (2.14) and (2.16) together with the jump condition across Γ,

$$-s[e] + [q] = 0, \tag{3.1}$$

demonstrates that q is continuous across Γ. This allows us to define

$$q_\flat(t) \equiv q(\varphi(t),t) = -\lim_{x \to \varphi(t)+} (d(e)e_x) = -k(\vartheta_\lambda)\vartheta_x^+(t). \tag{3.2}$$

In the following, where we wish to categorize s and to obtain a relationship between $\vartheta_x^+(t)$ and $\vartheta_x^-(t)$, ϑ and q are considered to be smooth in $V\backslash\Gamma$ (at least locally). For convenience, we next set $\psi_{20} = 1$.

LEMMA 3.1. *Let $\vartheta_x^+ > 0$. Then $s\vartheta_x^- = 0$, and $q \in C^1(V)$ if $s = 0$.*

Proof. Let us write (2.17) in the form

$$qq_x = \frac{h(e)}{h'(e)}(f(e)\{q + D(e)e_x\} - q_t). \tag{3.3}$$

Using (2.6)–(2.13), (2.18) in U_- for $e \sim 0$ ($\vartheta \sim \vartheta_\lambda$) gives

$$c_\upsilon(\vartheta) \sim c_\lambda, \tag{3.4}$$

$$h(e) \sim \vartheta_\lambda^2 g_{10}(\vartheta_\lambda)\left(\frac{1}{c_\lambda}|e|\right)^r, \tag{3.5}$$

$$f(e) \sim g_{20}(\vartheta_\lambda)\left(\frac{1}{c_\lambda}|e|\right)^{2r}, \tag{3.6}$$

and

$$D(e) \sim -\frac{(\vartheta_\lambda g_{10}(\vartheta_\lambda))^2}{c_\lambda g_{20}(\vartheta_\lambda)}. \tag{3.7}$$

Thus, since $D(e)e_x = D(e)c_v(\vartheta)\vartheta_x$, (3.3) implies

$$qq_x \sim -\frac{1}{r}eq_t \to 0 \quad \text{as } e \to 0^-. \tag{3.8}$$

Using (3.2) for $\vartheta_x^+ > 0$ implies that $q_x^- = 0$ and consequently $e_t^- = 0$, by (2.16). The definition of Γ implies that $e_t^- + se_x^- = 0$, and so $se_x^- = 0$, whence $s\vartheta_x^- = 0$.

Finally, if $s = 0$, the definition of Γ also implies that $e_t^+ = 0$, in which case (2.14) implies $q_x^+ = 0$.

Assuming that solutions depend continuously on the initial data (2.21) locally in time in V, we now obtain the following.

COROLLARY 3.2. *Let $\vartheta_0'^{\pm} = \lim_{x\to 0\pm}\vartheta_0'(x) > 0$. Then there exists $\tau > 0$ such that $s = 0$ for $t \in (0,\tau)$.*

Proof. This follows immediately from the lemma, since $\vartheta_x^-(t), \vartheta_x^+(t) > 0$, through continuous dependence, over some interval $t \in (0,\tau)$.

Remark. Since $\varphi(0) = 0$ from (2.19), in this case $\varphi(t) \equiv 0$ for all $t \in (0,\tau)$.

The next results provide a connection between the left and right states of Γ and show that the condition $s = 0$ is controlled only by initial data corresponding to these states and by the solution to the diffusion equation, (2.14), (2.15), and (2.19).

LEMMA 3.3. *Let $\vartheta_0'^-, \vartheta_0'^+ > 0$ and $s = 0$. Then $\vartheta_x^+(t) > 0 \Rightarrow \vartheta_x^-(t) > 0$, $t \in (0,\tau)$.*

Proof. Let $\gamma_\alpha \subset U_-$ denote the line segment $x = \alpha < 0$, $t \in (0,\tau)$, which lies parallel to Γ. For α sufficiently small, $q|_{\gamma_\alpha}$ can be bounded above, strictly, by 0. This can be seen by defining a curve $\gamma_\beta \in U_- \cup \Gamma$ as follows,

$$\gamma_\beta = \left\{(x,t(x)), x \le 0 : \frac{dt}{dx} = \frac{h(e)}{h'(e)q},\ t(0) = \beta \ge 0\right\}, \tag{3.9}$$

and by writing (2.17) in the form

$$\frac{1}{2}\frac{dq^2}{dx}\bigg|_{\gamma_\beta} = \frac{h(e)}{h'(e)}f(e)\{q + D(e)e_x\} \equiv \frac{h}{h'}\mathcal{M}. \tag{3.10}$$

Using (2.7), (2.18), and (3.5), we find that

$$\frac{h(e)}{h'(e)}|_{\gamma_\alpha} \sim \frac{e}{r} \tag{3.11}$$

for $\alpha \sim 0$.

Also, $D(e)e_x = K(\vartheta)\vartheta_x|_{\gamma_\alpha} \to k(\vartheta_\lambda)\vartheta_x^-$ and $q_{|_{\gamma_\alpha}} \to q_\flat = -k(\vartheta_\lambda)\vartheta_x^+$ as $\alpha \to 0$. Since $e_{|_{\gamma_\alpha}} \to 0$ as $\alpha \to 0$, and through (3.6), it follows that as $\alpha \to 0$,

$$\mathcal{M}_{|_{\gamma_\alpha}} \sim g_{20}(\vartheta_\lambda)k(\vartheta_\lambda)\left(\frac{1}{c_\lambda}\right)^{2r}(\vartheta_x^- - \vartheta_x^+)(|e|^{2r})_{|_{\gamma_\alpha}} \sim 0. \tag{3.12}$$

As a result, by (3.10),

$$q(x,t)_{|_{\gamma_\beta}} \sim q_\flat(\beta), \tag{3.13}$$

where

$$\frac{dt}{dx}{}_{|_{\gamma_\beta}} \sim \frac{e}{rq}\,. \tag{3.14}$$

Next, the use of (2.16), (2.17), and (3.12) shows that

$$\left(q_t - \frac{r}{e} q e_t\right)\Big|_{\gamma_\alpha} \sim 0, \tag{3.15}$$

from which a rearrangement and integration give

$$q(\alpha,t) \sim q(\alpha,0)\left(\frac{e(\alpha,t)}{e_0(\alpha)}\right)^r. \tag{3.16}$$

Since $\vartheta_0'^+ > 0$ and $e_0(\alpha) < 0$, we have, locally for $x < 0$ and $t > 0$, that $e < 0$ and $q \sim q_\flat \sim -k(\vartheta_\lambda)\vartheta_x^+ < 0$. Consequently $\frac{dt}{dx}{}_{|_{\gamma_\beta}} > 0$ by (3.14), and hence there exists some $\beta > 0$ such that $q(\alpha,0) \sim q_\flat(\beta)$, with $\beta \to 0+$ as $\alpha \to 0-$. Therefore (3.16) implies

$$q_\flat(t) = q_\flat(0) \lim_{\alpha\to 0}\left(\frac{e(\alpha,t)}{e_0(\alpha)}\right)^r. \tag{3.17}$$

Given $\varepsilon'(\vartheta) = c_v(\vartheta)$ and (2.11), (2.13), and (3.4), we have

$$\lim_{\alpha\to 0}\frac{e(\alpha,t)}{e_0(\alpha)} = \lim_{\alpha\to 0}\frac{\vartheta_\lambda - \vartheta(\alpha,t)}{\vartheta_\lambda - \vartheta_0(\alpha)} = \frac{\vartheta_x^-(t)}{\vartheta_0'^-}. \tag{3.18}$$

Finally, since $q_\flat(t)/q_\flat(0) = \vartheta_x^+(t)/\vartheta_0'^+$, this implies

$$\frac{\vartheta_x^-(t)}{\vartheta_0'^-} = \left(\frac{\vartheta_x^+(t)}{\vartheta_0'^+}\right)^{1/r}, \tag{3.19}$$

which leads to the desired conclusion.

THEOREM 3.4. *Let* $\vartheta_0'^-, \vartheta_0'^+ > 0$, *and* $\vartheta_x^+(t) > 0$ *for* $t \in (0,T)$, *where* $T > 0$. *Then* $s = 0$ *for* $t \in (0,T)$.

Proof. Suppose that $t^\sharp < T$ denotes the first time for which $\vartheta_x^-(t) = 0$, so that $t^\sharp > 0$ by Corollary 3.1. Using Lemma 3.1 and continuity in t implies $s(t^\sharp) = 0$, and thus Lemma 3.2 holds for $t \in (0,t^\sharp)$. Using continuity once again then implies that $\vartheta_x^+(t^\sharp) = 0$, which violates the hypothesis $\vartheta_x^+(t) > 0$ for $t \in (0,T)$. The result follows through contradiction.

4. Smooth solutions in the transcritical region. Next we set up the problem of phase transition in the region $U_- \cup \Gamma \cup U_+$, where we now extend U_+ to all of $\mathbb{R}^2_{++} = \{(x,t) \in \mathbb{R}^2, t \geq 0,\, x > \varphi(t)\}$ and restrict U_- to temperatures close to ϑ_λ. Assuming $\vartheta_0'^+, \vartheta_0'^- > 0$ means that we may set $\varphi(t) = 0$ for $t > 0$, given $\varphi(0) = 0$, from the results of the previous section.

The transcritical phase transition problem reduces to solving

$$e_t - (d(e)e_x)_x = 0 \tag{4.1}$$

in U_+, by (2.14) (2.15). In U_-, equations (2.16), (2.17) become

$$e_t + q_x = 0, \tag{4.2}$$

$$q_t + \frac{rq}{e} q_x = 0, \tag{4.3}$$

where we have used (3.11) to obtain (4.3). We recall that across Γ, where now

$$e(0,t) = 0, \quad t > 0, \tag{4.4}$$

both e and q are continuous. Initial data for (4.1)–(4.3) are given by

$$e(x,0) = e_0(x), \quad \text{with } xe_0(x) > 0 \text{ for } x \neq 0, \qquad \text{and } e_0(0) = 0. \tag{4.5}$$

In U_+, $e(x,t)$ is a solution to (4.1) satisfying the Dirichlet boundary condition (4.4), together with (4.5). This solution determines $q_\flat(t)$,

$$q_\flat(t) = q(0,t) = -\lim_{x \to 0+} (d(e(x,t))e_x(x,t)) = -k(\vartheta_\lambda)\vartheta_x^+(t), \tag{4.6}$$

as a function of the initial data $e_0(x)$, for $x > 0$.

In U_-, the pair $(e(x,t), q(x,t))$ is a solution to (4.2), (4.3) satisfying (4.4), (4.5), and (4.6).

Eigenvalues of the system (4.2), (4.3) are given by $\lambda_\alpha = 0 < \lambda_\beta = \frac{rq}{e}$. Due to the fact that q does not possess initial data, characteristic curves $\gamma_\alpha, \gamma_\beta$ are parametrized by t and x, respectively (see (3.9), (3.14)):

$$\left.\frac{dx}{dt}\right|_{\gamma_\alpha} = 0, \qquad \left. x(t;\alpha)\right|_{\gamma_\alpha} = \left. x(0;\alpha)\right|_{\gamma_\alpha} = \alpha < 0, \tag{4.7}$$

and

$$\left.\frac{dt}{dx}\right|_{\gamma_\beta} = \frac{e}{rq}, \qquad \left. t(x;\beta)\right|_{\gamma_\beta} > 0, \ \left. t(0;\beta)\right|_{\gamma_\beta} = \beta > 0. \tag{4.8}$$

This system has Riemann invariants, $|e|^r/q$ and q, which satisfy

$$\left.\frac{|e|^r}{q}\right|_{\gamma_\alpha} = \text{ constant} \tag{4.9}$$

and

$$q_{|\gamma_\beta} = \text{ constant}. \tag{4.10}$$

In order to examine when solutions in U_- remain smooth, we use the following results.

LEMMA 4.1. *Let $(e,q) \in C^1(U_-)$, and suppose that there are constants $\delta > 0, \alpha_0 < 0$ such that $e_0(\alpha) < -\delta$ for $\alpha < \alpha_0$ and $q_\flat(\beta) > -1/\delta$ for $\beta > 0$. Then for each β small enough, there is a unique characteristic, γ_β, connecting Γ with $\mathbb{R}_- = \{(x,t) : x < 0, t = 0\}$.*

Proof. Consider a region $\mathcal{W} \subset U_-$ bounded to the left and right by the line $x = \alpha < 0$ and by Γ, and to the top and bottom by the characteristic γ_β and by $\mathbb{R}_-$.

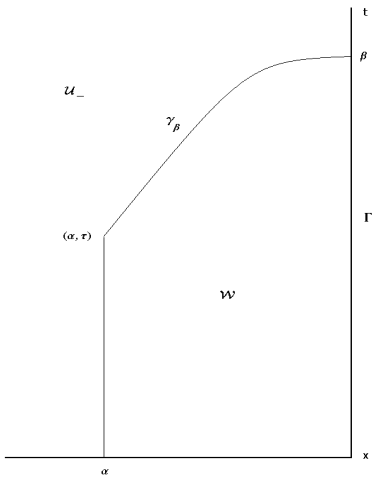

FIG. 4.1.

Let γ_β meet the line $x = \alpha$ at $(x,t) = (\alpha,\tau)$, where $\tau = \tau(\alpha,\beta) \le \beta$ by (4.8) (see Figure 4.1). We assume in the following that γ_β is entirely contained inside U_-.

Applying the divergence theorem to (4.2) on $\mathcal{W}$, and using (4.10), provides the relation

$$\int_\alpha^0 e_0(x)dx = \int_0^\beta q_\flat(t)dt - (1-r)\beta q_\flat(\beta) + \tau(1-r)q_\flat(\beta) - \int_0^\tau q(t,\alpha)dt. \tag{4.11}$$

Fixing β in (4.11) and differentiating with respect to α then gives

$$\begin{aligned} -e_0(\alpha) &= ((1-r)q_\flat(\beta) - q(\tau,\alpha))\frac{\partial\tau}{\partial\alpha} \\ &= -rq_\flat(\beta)\frac{\partial\tau}{\partial\alpha}. \end{aligned} \tag{4.12}$$

So $\frac{\partial\tau}{\partial\alpha} = \frac{e_0(\alpha)}{rq_\flat(\beta)} > \delta^2/r$ for $\alpha < \alpha_0$, which means that $\tau(\alpha,\beta)$ is bounded below, for fixed β, by a uniformly increasing function of α. Since $\tau(0,\beta) = \beta > 0$, it follows that τ must reduce to zero as α decreases from $\alpha = 0$, at which point γ_β meets $\mathbb{R}_-$.

We note that if γ_β connects Γ to $\mathbb{R}_-$, then (4.11) reduces to

$$\int_\alpha^0 e_0(x)dx = \int_0^\beta q_\flat(t)dt - (1-r)\beta q_\flat(\beta), \tag{4.13}$$

which gives a functional relation between α and β. In particular, differentiating with respect to α,

$$-e_0(\alpha)\frac{d\alpha}{d\beta} = rq_\flat(\beta) - (1-r)\beta q_\flat'(\beta) \tag{4.14}$$

shows that $\frac{d\alpha}{d\beta} < 0$ if $rq_\flat(\beta) - (1-r)\beta q_\flat'(\beta) < 0$. Thus, at least for small $\beta > 0$, one finds that $\frac{d\alpha}{d\beta} < 0$, since $q_\flat(0) < 0$ due to our assumption $\vartheta_0'^{+} > 0$.

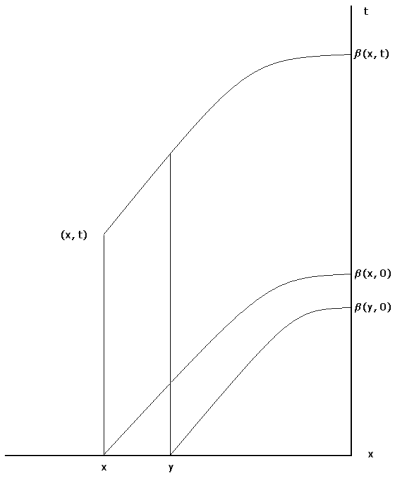

FIG. 4.2.

We will use the notation $\beta = \beta(\alpha, \tau)$ to denote the time of intersection of the characteristic curve going through $(x,t) = (\alpha, \tau)$, with Γ, i.e., $\beta = \beta(\alpha, \tau(\alpha, \beta)), \alpha < 0$. The inversion is possible whenever $\frac{\partial \tau}{\partial \beta} > 0$, which is a subject of the following results.

LEMMA 4.2. *Let* $(e,q) \in C^1(U_-)$, $q_\flat(\beta) < 0$, *and* $q_\flat'(\beta) \neq 0$. *Then* $\frac{\partial t}{\partial \beta}(x,\beta) > 0$, *and if* $\frac{\partial t}{\partial \beta} \to 0$ *as* $x \to x^* < 0$, *then* $|q_t(x, t(x,\beta))| \to \infty$.

Proof. By (4.10), we have that

$$q(x, t(x,\beta)) = q_\flat(\beta) \tag{4.15}$$

along γ_β, and so $q_{|_{\gamma_\beta}} < 0$. Differentiating relation (4.15) in β gives

$$(q_t t_\beta)_{|_{\gamma_\beta}} = q_t(0, t(0,\beta)) = q_\flat'(\beta) \tag{4.16}$$

since $t(0,\beta) = \beta$. Thus $\frac{\partial t}{\partial \beta} \to 0 \Leftrightarrow |q_t|_{|_{\gamma_\beta}} \to \infty$.

In the following we take, for simplicity, U_- to be the vertical strip $\{(x,t) \in \mathbb{R}^2_+ : x^* < x < 0\}$ for some $x^* < 0$. With regard to the theorem, we remark that the two crystalline materials, bismuth and sodium fluoride, have values of the material constant, r, lying between zero and one-half [10].

THEOREM 4.3. *Let* $\beta_1 \neq \beta_2$. *Then* γ_{β_1} *and* γ_{β_2} *do not intersect in* U_-, *provided that one of the following holds:*

Case 1. $r \in (0,1)$, *and either*

(i) $q_\flat'(\beta) > 0$

or

(ii) $q_\flat'(\beta) < 0$ *and* $r q_\flat(\beta) - (1-r)\beta q_\flat'(\beta) < 0$.

Case 2. $r > 1$, *and either*

(i) $q_\flat'(\beta) < 0$

or

(ii) $q_\flat'(\beta) > 0$ *and* $r q_\flat(\beta) - (1-r)\beta q_\flat'(\beta) < 0$.

Case 3. $r = 1$.

Proof. Recalling (4.9) and (4.10), for $(x,t) \in U_-$,

$$\frac{|e(x,t)|^r}{q_\flat(\beta(x,t))} = \frac{|e(x,t)|^r}{q(x,t)} = \frac{|e_0(x)|^r}{q(x,0)} = \frac{|e_0(x)|^r}{q_\flat(\beta(x,0))}, \tag{4.17}$$

which gives

$$|e(x,t)|^r = \frac{q_\flat(\beta(x,t))}{q_\flat(\beta(x,0))}|e_0(x)|^r. \tag{4.18}$$

As a result, (4.8) can be written as

$$\frac{dt}{dx}|_{\gamma_\beta} = -|q_\flat(\beta(x,t))|^{(1-r)/r}\frac{e_0(x)}{r|q_\flat(\beta(x,0))|^{1/r}}\,. \tag{4.19}$$

Integrating (4.19) along γ_β and using (4.10) again,

$$t = t(x,\beta) = \beta - |q_\flat(\beta)|^{(1-r)/r}\int_0^x \frac{e_0(y)}{r|q_\flat(\beta(y,0))|^{1/r}}dy \tag{4.20}$$

with $x* < x < 0$ and $0 < t < \beta$. Thus, differentiating with respect to $\beta = \beta(x,t)$,

$$\frac{\partial t}{\partial \beta} = 1 - \frac{1-r}{r}|q_\flat(\beta)|^{1/r-3}q_\flat(\beta)q_\flat'(\beta)\int_0^x \frac{e_0(y)}{r|q_\flat(\beta(y,0))|^{1/r}}dy. \tag{4.21}$$

Case 1(i) of the proof follows since $e_0 < 0, q_\flat < 0$, and characteristics spread with decreasing x, $\frac{\partial t}{\partial \beta} > 1$.

In order to establish Case 1(ii), let us first suppose that $(x^*,t^*) \in \partial U_-$ for $x^* < 0$, and that $t^* > 0$ is the least time at which solutions may fail to be in C^1. Next, assume that $\beta_1 < \beta_2$ are such that γ_{β_1} and γ_{β_2} intersect at (x^*,t^*), where $\gamma_{\beta_i} = \{(x,t) : t = t(x,\beta_i)\}$, $i = 1,2$. So (4.20) holds for $i = 1$, $i = 2$ at (x^*,t^*),

$$t^*(x^*,\beta_i) = \beta_i - |q_\flat(\beta_i)|^{(1-r)/r}\int_0^{x^*} \frac{e_0(y)}{r|q_\flat(\beta_i(y,0))|^{1/r}}dy, \quad i = 1,2, \tag{4.22}$$

where we note that the integral terms are identical for $i = 1,2$. Eliminating this term leads to the relation

$$t^* - \beta_2 = (t^* - \beta_1)\left(\frac{q_\flat(\beta_2)}{q_\flat(\beta_1)}\right)^{(1-r)/r}, \tag{4.23}$$

where $Q \equiv \frac{q_\flat(\beta_2)}{q_\flat(\beta_1)})^{(1-r)/r} > 1$ since $q_\flat' < 0$, by our hypothesis. However, it is easily shown that conditions (ii) imply

$$1 < \mathcal{Q} < \frac{\beta_2}{\beta_1}\,. \tag{4.24}$$

Thus $t^* > 0$ cannot exist since (4.23), (4.24) imply

$$t^* = \beta_1\frac{\beta_2/\beta_1 - Q}{1-Q} < 0. \tag{4.25}$$

Cases 2(i) and (ii) can be established as above, and Case 3 follows since (4.20) then implies $t_\beta \equiv 1$.

Remark. In addition to q_t, the terms e_t, q_x, and e_x naturally blow up where $\frac{\partial t}{\partial \beta} \to 0$, under the conditions of Theorem 4.3. This results from q remaining constant on γ_β and e remaining bounded away from zero on γ_α by (4.10) and (4.9). Equation (4.3) then implies $|q_x| \to \infty$ as $|q_t| \to \infty$, and therefore $|e_t| \to \infty$ by (4.2). On differentiating (4.9) in α, the same result follows for $|e_x|$.

Let us finally state some relationships more concisely. For any point $(x,t) \in U_-$, the solution $(e(x,t), q(x,t))$ to (4.2), (4.3) subject to (4.4), (4.5), and (4.6) takes the form

$$q(x,t) = q_\flat(\beta(x,t)), \tag{4.26}$$

$$e(x,t) = \left(\frac{q_\flat(\beta(x,t))}{q_\flat(\beta(x,0))}\right)^{1/r} e_0(x), \tag{4.27}$$

with

$$t = \beta(x,t) - \left(\frac{q_\flat(\beta(x,t))}{q_\flat(\beta(x,0))}\right)^{(1-r)/r} \beta(x,0), \tag{4.28}$$

where $\beta(x,0)$ is derived from (4.13) (with $\alpha = x$) and (4.28) comes from repeated use of (4.20) with $t > 0$ and $t = 0$ to eliminate the integral term. Using Theorem 4.3, we may invert (4.28) for fixed x in order to obtain $\beta(x,t)$ used in (4.26) and (4.27). Similarly, by using (4.20) in (4.21), one can find $\frac{\partial t}{\partial \beta}$ in terms of $\beta(x,t)$ in the useful form

$$\frac{\partial t}{\partial \beta} = 1 - \frac{1-r}{r}\frac{q_\flat'(\beta)}{q_\flat(\beta)}(\beta - t). \tag{4.29}$$

5. Some explicit smooth solutions. Having observed the role that heat flux continuity across Γ plays in solving (4.2)–(4.3), we now examine the effect on U_- of having a stationary or self-similar solution to (4.1) in U_+. The solutions are defined for U_- lying in the transcritical region.

In the case that the U_+ component of the solution is stationary, i.e., $e_t = q_x = 0$ with $q = -d(e)e_x < 0$, this implies that $q_\flat(\beta) = q_\flat(0)$ for all $\beta > 0$. Since $q|_{\gamma_\beta}$ remains constant, this means in turn that $q = q_\flat(0)$ in U_-. Consequently, since $(|e|^r/q)|_{\gamma_\alpha}$ is also constant, it follows that $e(x,t) = e_0(x)$ for arbitrary initial temperature distributions, $e_0(x)$, in U_-. As a result, the solution is everywhere stationary.

In the next case, we choose U_+ to be governed by the linear heat equation $d(e) = 1$ (assuming $c_\lambda = 1$), in which we can use, for example, any explicit solution formula for the semi-infinite interval. We set up the following example by means of a self-similar solution, in U_+, of the form $e(x,t) = e(x/\sqrt{t+1})$ and let this extend to U_- through Γ. The solution in U_+ is then represented by

$$e(x,t) = A\sqrt{\pi}\, erf\left(\frac{x}{2\sqrt{t+1}}\right), \quad A > 0, \tag{5.1}$$

giving heat flux as

$$q(x,t) = -\frac{A}{\sqrt{t+1}} e^{-x^2/4(t+1)} \quad \text{with } q_\flat(t) = -\frac{A}{\sqrt{t+1}}. \tag{5.2}$$

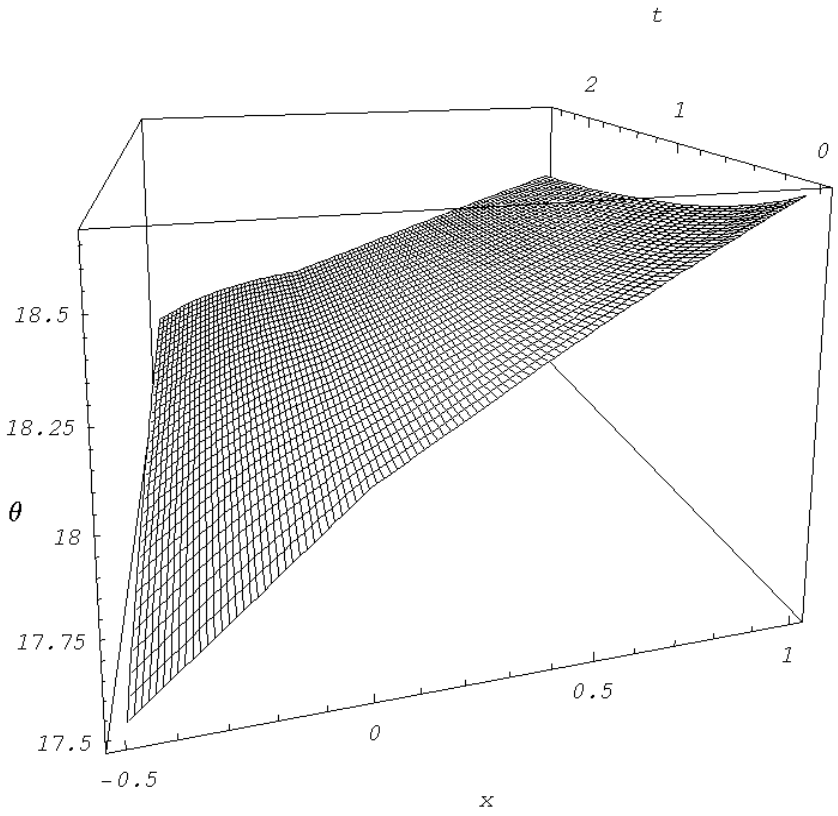

FIG. 5.1. *Temperature evolution with* $\vartheta_\lambda = 18K$, *for* $0 \le t \le 2.5\,\mu sec.$ *and* $-.5 \le x \le 1\,cm.$

Since $q_b'(t) > 0$, Theorem 4.1 guarantees that the characteristics in U_- do not intersect. We choose as initial data for e in U_-,

$$e_0(x) = x, \quad x < 0, \tag{5.3}$$

which is equivalent to $\vartheta_0(x) = x + \vartheta_\lambda$. The following connection can now be made from (4.13) (with $\alpha = x$),

$$\beta(x,0) = \left(\frac{B(x) + \sqrt{B(x)^2 - (1-r^2)}}{1+r} \right)^2 - 1, \tag{5.4}$$

where

$$B(x) = \frac{1}{4A}x^2 + 1. \tag{5.5}$$

Equation (4.28) then leads to a relation for $\beta = \beta(x,t)$,

$$t = \beta - (\beta+1)^{-(1-r)/2r}(\beta(x,0)+1)^{(1-r)/2r}\beta(x,0). \tag{5.6}$$

Taking, as a special case, $r = 1/3$ in (5.6) gives

$$\beta(x,t) = \frac{t - 1 + \sqrt{(1+t)^2 + 4H(x;1/3)}}{2}, \tag{5.7}$$

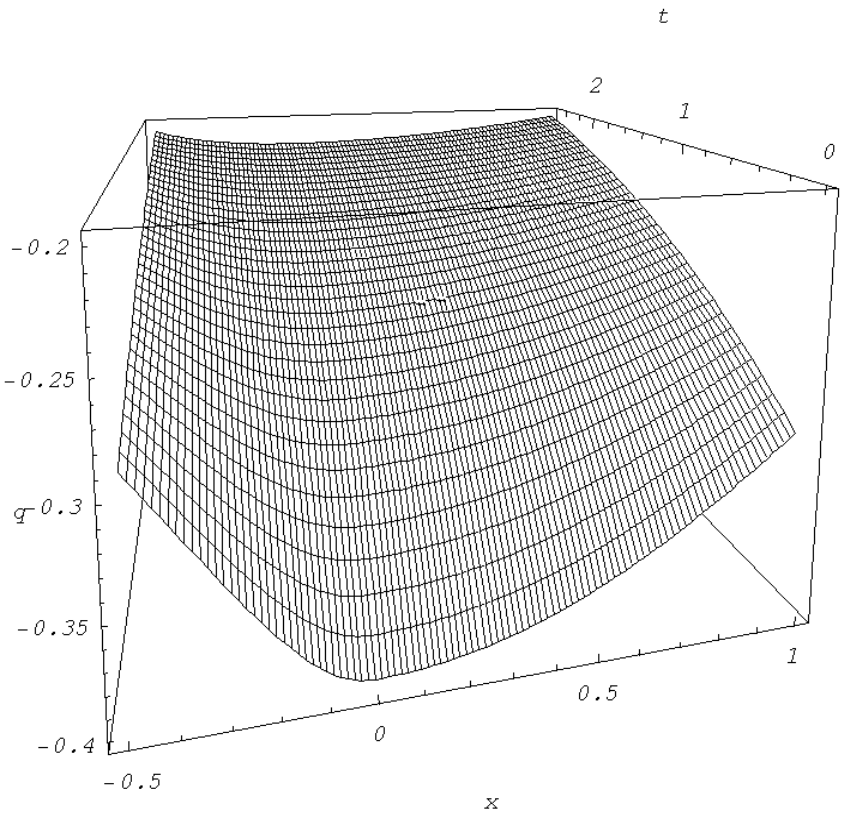

FIG. 5.2. *Heat flux evolution with* $\vartheta_\lambda = 18K$, *for* $0 \le t \le 2.5\,\mu sec.$, $-.5 \le x \le 1$ *cm, with* $-0.4 \le q < 0\,W/cm^2$.

where we have set

$$H(x;r) = (\beta(x,0)+1)^{(1-r)/2r}\beta(x,0). \tag{5.8}$$

Using (4.26), (4.27) together with (5.2), (5.3), (5.4), and (5.7) finally gives a solution for (e,q) in U_-,

$$e(x,t) = \left(\frac{3\sqrt{2}}{4}\right)^3 \left(\frac{B(x)+\sqrt{B(x)^2-8/9}}{\sqrt{t+1+\sqrt{(1+t)^2+4H(x;1/3)}}}\right)^3 e_0(x), \tag{5.9}$$

$$q(x,t) = -\sqrt{2}\frac{A}{\sqrt{t+1+\sqrt{(1+t)^2+4H(x;1/3)}}}, \tag{5.10}$$

where, from (2.11), (2.13) and the definition $\varepsilon'(\vartheta) = c_v(\vartheta)$,

$$\vartheta(x,t) = \vartheta_\lambda + e(x,t). \tag{5.11}$$

Figures 5.1 and 5.2 illustrate the behavior of $\vartheta(x,t)$ and $q(x,t)$ in $U_- \cup \Gamma \cup U_+$, using (5.1), (5.2), and (5.9)–(5.11) with $A = 2/5$.

One can see in Figure 5.2 that, despite the temperature gradient being initially larger to the left of the phase transition at $x = 0$ than to the right (see Figure 5.1), q is nevertheless greater there than at the transition itself. This illustrates distinctly "non-Fourier" behavior in U_-. It is also possible to observe in Figure 5.1 the derivative discontinuity in ϑ at $x = 0$ changing from "concave down" to "concave up" as time progresses. From (3.19), with $r = 1/3$, this change occurs when $\vartheta_x^+(t) = (\vartheta_0'^+)^3/(\vartheta_0'^-)^{1/2}$, or at about $t = 1$. With $q_\flat'(\beta) > 0$ and $r < 1$, as in the present case, it is easy to check that such a concavity change can occur only if $0 < \vartheta_0'^{\,+} < \vartheta_0'^{\,-}$.

FIBER DYNAMICS IN TURBULENT FLOWS: GENERAL MODELING FRAMEWORK*

NICOLE MARHEINEKE† AND RAIMUND WEGENER†

Abstract. The paper at hand deals with the modeling of turbulence effects on the dynamics of a long slender elastic fiber. Independent of the choice of the drag model, a general aerodynamic force concept is derived on the basis of the velocity field for the randomly fluctuating component of the flow. Its construction as a centered differentiable Gaussian field complies thereby with the requirements of the stochastic k-ϵ turbulence model and Kolmogorov's universal equilibrium theory on local isotropy.

Key words. fiber-fluid interaction, Cosserat rod, turbulence modeling, Kolmogorov's energy spectrum, double-velocity correlations, differentiable Gaussian fields

1. Introduction.

The understanding of fiber-fluid interactions is of great interest for research, development, and production in textiles manufacturing. In the melt-spinning process of nonwoven materials, hundreds of individual endless fibers obtained by continuous extrusion of a melted polymer are stretched and entangled by highly turbulent air flows to finally form a web. The quality of this web and the resulting nonwoven material depends essentially on the dynamics of the fibers.

Fiber-turbulence interaction is a complex phenomenon that is governed by many factors, including the nature of the flow field, turbulent length scales, concentration, and size of fibers [13], [14]. Thin fibers decrease the turbulent intensity by increasing the apparent viscosity, whereas fibers whose thickness induces Reynolds numbers greater than some critical one intensify the turbulence due to vortex shedding [5]. Both mechanisms are strongly affected by the concentration. In the application considered here, however, the turbulence is not significantly influenced by the fibers. Hence, the turbulent flow is determined under neglect of suspended fibers, and its effect is theoretically studied on a single long slender fiber using a general drag model.

The fiber dynamics is described in section 2 by the Kirchhoff–Love equations for the motion of a Cosserat rod capable of large bending deformations. In terms of these the fiber slenderness allows the formulation of a wavelike system of nonlinear PDEs of fourth order with the algebraic constraint of inextensibility. The behavior of this system relies on the model for the external force imposed on the fiber by the turbulent flow, particularly on the choice of the air drag coefficients. The modeling of a generally valid aerodynamic force in section 4 is based on the splitting of the flow velocity into mean and fluctuation parts in the Reynolds-averaged Navier–Stokes equations. Thus, a centered differentiable Gaussian field for the randomly fluctuating component of the flow velocity is derived under the Global-from-Local Assumption of underlying locally isotropic and homogeneous turbulence, given in section 3. The

construction of the initial condition for the respective local double-velocity correlation tensors satisfies thereby Kolmogorov's universal equilibrium theory as well as the local distribution of kinetic energy k and dissipation ϵ provided by the stochastic k-ϵ turbulence model. The dynamic behavior of the local correlation tensors is described by an advection equation, whose solution coincides with Taylor's hypothesis of frozen turbulence patterns. The temporal change of the global coherences is included by the averaging procedure. In section 4 the developed local velocity fluctuation fields hand their properties to the corresponding correlated local stochastic forces along the fiber. Gluing them together yields the global aerodynamic force that represents the turbulence effects on the fiber motion. Considering a wide class of feasible air drag models, the stated Global-from-Local Force Concept in combination with a linearization ansatz enables a good $\mathcal{L}^2$- and $\mathcal{L}^\infty$-approximation of the correlated force by Gaussian white noise with flow-dependent amplitude in case of a macroscopic description of the fiber.

2. Fiber dynamics. In the actual spinning process the fiber is endless, and its deposition plays a crucial role for the generation of the nonwoven material. However, as this paper focuses exclusively on the description of its dynamics due to the turbulent flow, the following considerations are restricted on a long slender elastic polymer fiber that is fixed at one end, suspended in a highly turbulent air stream. Let l denote its length and d its diameter with slenderness ratio $\delta = d/l \ll 1$. To describe its motion a one-dimensional model is derived on the dynamical Kirchhoff–Love theory for a Cosserat rod capable of large geometrically nonlinear deformations [2].

2.1. Equations of motion. Treat the fiber in the reference configuration as a body $\mathcal{B}$ given within a fixed Cartesian frame $\mathbf{e_1}, \mathbf{e_2}, \mathbf{e_3}$. Define $\mathbf{p}(\mathbf{z}, t)$ to be the position of the material point $\mathbf{z} \in \mathcal{B}$ at time t; then $\mathbf{p}(., t)$ states the actual configuration of the closure $\mathrm{cl}\mathcal{B}$ of $\mathcal{B}$ at time t. Introduce the curvilinear coordinates $\mathbf{x} := (x_1, x_2, s) \in \mathbb{R} \times \mathbb{R} \times [0, l]$ on $\mathcal{B}$ with s denoting the arc length. Then define $\tilde{\mathbf{p}}(\mathbf{x}, t) := \mathbf{p}(\tilde{\mathbf{z}}(\mathbf{x}), t)$, where $\tilde{\mathbf{z}}$ assigns $\mathbf{z} \in \mathrm{cl}\,\mathcal{B}$ to each $\mathbf{x}$. In particular, $\tilde{\mathbf{p}}(., ., s, t)$ describes the actual configuration of the cross section $\mathcal{B}(s)$ at time t.

The fiber model is now developed under the assumption that the position field $\tilde{\mathbf{p}}$ is determined by three vector-valued functions $\mathbf{r}(s, t)$, $\mathbf{d_1}(s, t)$, and $\mathbf{d_2}(s, t)$, i.e.,

$$\tilde{\mathbf{p}}(\mathbf{x}, t) = \mathbf{r}(s, t) + \mathbf{j}(\mathbf{r}(s, t), \mathbf{d_1}(s, t), \mathbf{d_2}(s, t), \mathbf{x}, t), \tag{1}$$

where the fiber line $\mathbf{r}(s, t)$ might be interpreted as the actual configuration of the center line at time t and the orthonormal directors $\mathbf{d_1}(s, t)$ and $\mathbf{d_2}(s, t)$ state the orientation of the actual configuration of $\mathcal{B}(s)$ at time t. Additionally, let $\mathbf{d_3}(s, t) = \mathbf{d_1}(s, t) \times \mathbf{d_2}(s, t)$. In terms of these functions, the feasible deformations of the fiber, e.g., flexure κ_1, κ_2, torsion τ, shear w_1, w_2, and dilatation w_3, are then expressed using the relations $\partial_s \mathbf{d_i} = \mathbf{b} \times \mathbf{d_i}$, $\mathbf{b} = \kappa_1 \mathbf{d_1} + \kappa_2 \mathbf{d_2} + \tau \mathbf{d_3}$, and $\partial_s \mathbf{r} = \sum_{i=1}^{3} w_i \mathbf{d_i}$. Thus,

$$\kappa_1 = -\mathbf{d_2} \cdot \partial_s \mathbf{d_3}, \quad \kappa_2 = -\mathbf{d_3} \cdot \partial_s \mathbf{d_1}, \quad \tau = -\mathbf{d_1} \cdot \partial_s \mathbf{d_2},$$
$$w_i = \partial_s \mathbf{r} \cdot \mathbf{d_i}.$$

According to Bernoulli's hypothesis that cross sections never experience warping as a consequence of deformation, the function $\mathbf{j}$ of (1) can moreover be prescribed by $\mathbf{j}(\mathbf{r}, \mathbf{d_1}, \mathbf{d_2}, \mathbf{x}, t) = x_1 \mathbf{d_1} + x_2 \mathbf{d_2}$. Assuming the reference configuration $\mathcal{B}$ to be a homogeneous (with respect to the density distribution) cylindrical body with circular cross sections of constant radius, the linear and angular impulse-momentum laws for

$\mathcal{B}$ read [2]

$$\partial_s \mathbf{q} + \mathbf{f} = \rho A \partial_{tt} \mathbf{r}, \tag{2}$$

$$\partial_s \mathbf{m} + \partial_s \mathbf{r} \times \mathbf{q} + \mathbf{l} = \rho I \sum_{i=1}^{2} (\partial_{tt} \mathbf{d_i} \times \mathbf{d_i}). \tag{3}$$

Here, ρ denotes density, $A = \pi d^2/4$ cross-sectional area, and $I = \pi d^4/64$ the moment of inertia. Closing the system by means of constitutive laws for inner force $\mathbf{q}$ and moment $\mathbf{m}$ as well as given outer line force $\mathbf{f}$ and moment $\mathbf{l}$, the Kirchhoff–Love equations (2) and (3) yield the description for fiber line and directors $\mathbf{r}$, $\mathbf{d_1}$, $\mathbf{d_2}$. The orthonormality of $\mathbf{d_1}$ and $\mathbf{d_2}$ thus reduces the number of unknowns to six. As no outer moment is acting on the fiber, $\mathbf{l} = \mathbf{0}$.

Constitutive laws for elastic materials look in general like

$$\mathbf{m} = \mathbf{M}(\kappa_1, \kappa_2, \tau, w_1, w_2, w_3, s), \qquad \mathbf{q} = \mathbf{Q}(\kappa_1, \kappa_2, \tau, w_1, w_2, w_3, s).$$

We apply here, in particular, Bernoulli–Euler beam theory that the inner moment $\mathbf{m}$ arises due to bending and torsion,

$$\mathbf{m} = EI(\kappa_1 \mathbf{d_1} + \kappa_2 \mathbf{d_2}) + GJ\tau \mathbf{d_3}, \tag{4}$$

with Young's modulus E, shear modulus G, and polar moment of inertia $J = \pi d^4/32$. Moreover, we interpret $\mathbf{q}$ as a vectorial Lagrangian multiplier and impose instead of a material law for $\mathbf{q}$ the following constraints on $\mathbf{d_3}$ and $\partial_s \mathbf{r}$:

$$\mathbf{d_3} = \frac{\partial_s \mathbf{r}}{\|\partial_s \mathbf{r}\|_2}, \qquad \|\partial_s \mathbf{r}\|_2 = 1. \tag{5}$$

This excludes shear and extensional deformation from the model. The restrictions are reasonable for a long slender fiber because shear and elongation are negligibly small in comparison to bending.

Apart from this, the slenderness enables a further simplification of system (2), (3). Nondimensionalizing (3) yields $\partial_s \mathbf{m} + \partial_s \mathbf{r} \times \mathbf{q} = \delta^2 D \sum_{i=1}^{2} (\partial_{tt}^2 \mathbf{d_i} \times \mathbf{d_i})$ with negligibly small right-hand side as the slenderness ratio δ satisfies $\delta \ll 1$ and $D = \mathcal{O}(1)$. Setting the right-hand side to zero, i.e.,

$$\partial_s \mathbf{m} + \partial_s \mathbf{r} \times \mathbf{q} = \mathbf{0}, \tag{6}$$

and using (5), we obtain $\partial_s \tau = 0$. Consequently, the torsion over the whole fiber equals the introduced torsion at the ends, $\tau = \tau_0$. Rewriting (4) thus gives $\mathbf{m} = EI(\mathbf{d_3} \times \partial_s \mathbf{d_3}) + GJ\tau_0 \mathbf{d_3}$, where $\partial_s \mathbf{d_3}$ represents the curvature vector $\partial_{ss} \mathbf{r} = \kappa \mathbf{n}$ with $\kappa = \sqrt{\kappa_1^2 + \kappa_2^2}$ and $\mathbf{n}$ a normal vector. Splitting the inner force $\mathbf{q}$ into tangential and normal parts with respect to the fiber position yields

$$\begin{aligned} \mathbf{q} &= (\mathbf{q} \cdot \mathbf{d_3})\, \mathbf{d_3} + \mathbf{d_3} \times (\mathbf{q} \times \mathbf{d_3}) \\ &\overset{(6)}{=} (\mathbf{q} \cdot \mathbf{d_3} + EI\,(\partial_{ss} \mathbf{d_3} \cdot \mathbf{d_3}))\, \mathbf{d_3} - EI\,(\mathbf{d_3} \cdot \mathbf{d_3})\, \partial_{ss} \mathbf{d_3} + GJ\tau_0\, \mathbf{d_3} \times \partial_s \mathbf{d_3}. \end{aligned}$$

Defining

$$\begin{aligned} T :=\ & \mathbf{q} \cdot \mathbf{d_3} + EI\,(\partial_{ss} \mathbf{d_3} \cdot \mathbf{d_3}) \\ \overset{(5)}{=}\ & \underbrace{\mathbf{q} \cdot \partial_s \mathbf{r}}_{\text{tension}} - \underbrace{EI\,\|\partial_{ss} \mathbf{r}\|_2^2}_{\text{curvature due to bending}} \end{aligned}$$

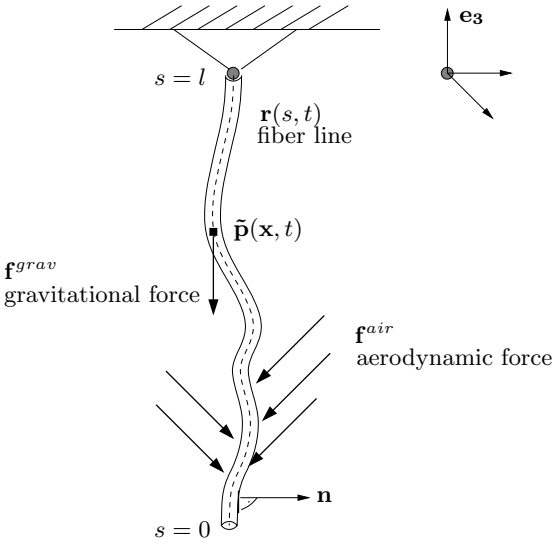

FIG. 1. *Fiber dynamics caused by external forces.*

as a modified tractive force, $\mathbf{q}$ depends exclusively on fiber line $\mathbf{r}$ and scalar Lagrangian multiplier T, and thus two more degrees of freedom vanish, which is consistent with the removing of the unknown directors $\mathbf{d_i}$. Plugging

$$\partial_s \mathbf{q} \overset{(5)}{=} \partial_s(T\,\partial_s \mathbf{r}) - EI\;\partial_{ssss}\mathbf{r} + GJ\tau_0\,\partial_s\mathbf{r} \times \partial_{sss}\mathbf{r}$$

into (2), the dynamics of a freely swinging fiber that is fixed at one end (cf. Figure 1) is described by

$$\begin{aligned} \rho A\,\partial_{tt}\mathbf{r}(s,t) &= \partial_s[T(s,t)\,\partial_s\mathbf{r}(s,t)] - EI\,\partial_{ssss}\mathbf{r}(s,t) + GJ\tau_0\,\partial_s\mathbf{r}(s,t) \times \partial_{sss}\mathbf{r}(s,t) \\ &\quad + \mathbf{f}^{grav} + \mathbf{f}^{air}(\mathbf{r}(.),s,t), \qquad (7) \\ \|\partial_s\mathbf{r}(s,t)\|_2 &= 1, \qquad (8) \end{aligned}$$

for $(s,t) \in (0,l) \times \mathbb{R}^+$ with Dirichlet conditions at the fixed end ($s = l$) and Neumann at the free end ($s = 0$),

$$\begin{aligned} \mathbf{r}(l,t) &= \mathbf{0}, & \partial_{ss}\mathbf{r}(0,t) &= \mathbf{0}, \\ \partial_s\mathbf{r}(l,t) &= \mathbf{e_3}, & \partial_{sss}\mathbf{r}(0,t) &= \mathbf{0}, \\ & & T(0,t) &= 0, \end{aligned}$$

as well as appropriate initial conditions ($t = 0$), e. g.,

$$\mathbf{r}(s,0) = (s-l)\,\mathbf{e_3}, \qquad \partial_t\mathbf{r}(s,0) = \mathbf{0}.$$

The Neumann conditions might be interpreted as natural boundary conditions, and the ending $s = 0$ is free of stress. Thus, neither outer moment nor force are acting on it. Moreover, $T(0,t)$ viewed as a tractive force vanishes. The Lagrangian multiplier $T(s,t)$ is thereby related to the algebraic constraint (8) of conservation of length. The behavior of our fiber system (7), (8)—but definitely also of the original one

(2), (3)—is strongly affected by the external line forces that arise due to gravitational ($\mathbf{f}^{grav} = \rho A\,\mathbf{g}$) and aerodynamic ($\mathbf{f}^{air}$) forces. We prescribe the aerodynamic force as a function depending on arc length s, time t, and additionally on the fiber line $\mathbf{r} : [0, l] \times \mathbb{R}_0^+ \to \mathbb{R}^3$ in a functional sense.

In this work, we initially introduce no twisting at the fiber ends, $\tau_0 = 0$, such that (7) simplifies to a wavelike system of nonlinear PDEs of fourth order, if the feasible functional dependence of the aerodynamic force is localized on the fiber point, e.g., $\mathbf{f}^{air}(\mathbf{r}(.), s, t) = \mathbf{f}^{air}(\mathbf{r}(s,t), \partial_s\mathbf{r}(s,t), \partial_t\mathbf{r}(s,t), s, t)$.

2.2. Air drag. The description of the fiber dynamics in a turbulent flow relies essentially on the model for the aerodynamic force $\mathbf{f}^{air}$ that is imposed on the fiber by the fluid. Neglecting the fiber influence on the flow, a dimensionless air drag coefficient c^{drag} based on Reynolds (Re), Mach, and Froude numbers can be associated with $\mathbf{f}^{air}$ [16]. If just frictional and inertial forces occur in the flow around the fiber, c^{drag} is particularly determined by

$$c^{drag} = \frac{\|\mathbf{f}^{air}\|_2}{0.5\,\rho^{air}\,d\,\|\mathbf{v}\|_2^2},$$

with air density ρ^{air}, fiber diameter d, and relative velocity between fluid flow and fiber $\mathbf{v} = \mathbf{u} - \partial_t\mathbf{r}$. Thus, the magnitude of the line force is proportional to Bernoulli's dynamic pressure $p = 0.5\rho^{air}\|\mathbf{v}\|_2^2$ acting along d. In general, we characterize a feasible air drag model by a function $\mathbf{f} : \mathbb{R}^3 \times \mathbb{R}^2 \to \mathbb{R}^3$, depending on a given velocity and a normalized direction. In this context, the aerodynamic force of (7) reads as

$$\mathbf{f}^{air}(\mathbf{r}(.), s, t) = \mathbf{f}(\mathbf{u}(\mathbf{r}(s,t), t) - \partial_t\mathbf{r}(s,t), \partial_s\mathbf{r}(s,t)), \tag{9}$$

where the flow velocity $\mathbf{u} : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^3$ acts as outer input parameter to the fiber problem. However, as this instantaneous flow velocity is not available from a stochastic description of a turbulent flow, we derive a concept for a random Gaussian aerodynamic force in this work. Note that this concept utilizes exclusively the functional relation $\mathbf{f}$ and is hence generally applicable to a wide class of air drag models.

3. Model for a velocity fluctuation field. Consider the flow to be subsonic, highly turbulent, with small pressure gradients and Mach number Ma $< 1/3$. Then it can be modeled as an incompressible Newtonian fluid using the incompressible Navier–Stokes equations (NSE). Solving NSE by means of direct numerical simulation (DNS) gives the exact velocity field needed for the determination of the force of (9). However, DNS presupposes the resolution of all vortices ranging from the large energy-bearing ones of length l_T to the smallest, viscously determined Kolmogorov vortices of size η with $l_\mathrm{T}/\eta = \mathrm{Re}^{3/4}$ [18]. Therefore, the number of grid points that are required for the refinement of a three-dimensional domain is proportional to $\mathrm{Re}^{9/4}$. Despite the existence of recent high speed computers, DNS is thus still restricted to simple, small Reynolds number flow. Large eddy simulation (LES) as a combination of DNS and stochastic turbulence models offers an alternative. Applying a low-pass filter on NSE, only the vortices of large scales are resolved directly, whereas the small vortices are taken into account by a stochastic approximation of their effect on the larger ones [15]. However, for the relevant flow regime under consideration, LES also requires enormous computational capacity, due to very long run time and high memory demands. Because of neglect of the fiber influence on the flow, which

leads to the decoupling of fiber and flow computation, the Reynolds number is here specified by the machine geometry and not by the fiber diameter. For the resulting high Reynolds number flow, the stochastic turbulence models represent a reasonable compromise between accuracy and computational efficiency [6]. They are based on the Reynolds-averaged NSE (RANS), where the instantaneous velocity $\mathbf{u} : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^3$ is expressed as the sum of a mean $\bar{\mathbf{u}}$ and a fluctuating part $\mathbf{u}'$:

$$\mathbf{u}(\mathbf{x}, t) = \bar{\mathbf{u}}(\mathbf{x}, t) + \mathbf{u}'(\mathbf{x}, t).$$

Applying in particular the standard k-ϵ model [12] yields a deterministic description of mean velocity $\bar{\mathbf{u}} : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^3$, turbulent kinetic energy $k : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^+$, and dissipation rate $\epsilon : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^+$. Hereby, the variables k and ϵ might be interpreted as parameters of an $\mathbb{R}^3$-valued differentiable random field representing the fluctuations $(\mathbf{u}'_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}_0^+)$:

$$k(\mathbf{x}, t) = \frac{1}{2}\, \mathbb{E}[\mathbf{u}'(\mathbf{x}, t) \cdot \mathbf{u}'(\mathbf{x}, t)], \tag{10}$$

$$\epsilon(\mathbf{x}, t) = \nu\, \mathbb{E}[\nabla \mathbf{u}'(\mathbf{x}, t) : \nabla \mathbf{u}'(\mathbf{x}, t)]. \tag{11}$$

To conform to the notation of probability theory and turbulence literature, note that the mean $\mathbb{E}[\mathbf{u}']$ equals the averaged quantity $\overline{\mathbf{u}'}$. Constructing a suitable fluctuation field requires the analysis of the turbulent behavior of the flow, which is characterized by means of statistical quantities, i.e., double-velocity correlations revealing spatial and temporal relations within a domain.

DEFINITION 1 (velocity fluctuation field). *Let* $(\Omega, \mathcal{A}, \mathrm{P})$ *be a probability space. The* velocity fluctuation field *of a turbulent flow is said to be a centered* $\mathbb{R}^3$*-valued random field* $(\mathbf{\Phi}_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}_0^+)$ *with* $\mathbf{\Phi}_{\mathbf{x},t} \in \mathcal{L}^2(\Omega, \mathcal{A}, \mathrm{P})$*. Its correlation tensor reads*

$$\mathbf{\Gamma}(\mathbf{x}, t, \mathbf{y}, \tau) = \mathbb{E}[\mathbf{\Phi}(\mathbf{x}, t) \otimes \mathbf{\Phi}(\mathbf{y}, \tau)].$$

Classifying turbulence, we face shear turbulence in practice. Although it can be simulated via RANS models, this kind of flow is hardly understood. Physical interpreting and mathematical handling of the statistical quantities is extremely difficult. Therefore, it is helpful to consider approximations like homogeneous and/or isotropic turbulent flows. Isotropy obviously has a hypothetical character, but knowledge of its characteristics forms a fundamental basis for the study of actual, anisotropic turbulent flows. Certain theoretical considerations concerning the energy transfer through the eddy-size spectrum from the larger to the smaller eddies (i.e., forward-scatter) lead to the conclusion that the fine structure of anisotropic turbulent flows is almost isotropic (Kolmogorov's local isotropy hypothesis [8]). Thus, many features of isotropic turbulence apply to phenomena in actual turbulence that are mainly determined by the fine-scale structure. Even if we consider the anisotropic large-scale structure of an actual turbulence, it is possible to treat such a turbulence, for purposes of a first approximation, as isotropic. The differences are mostly sufficiently small [10]. However, effects like back-scatter are not included. As velocity fluctuations in an isotropic flow are Gaussian [7], we restrict ourselves to Gaussian flows that are uniquely determined by their correlation tensor. This motivates the following assumption.

GLOBAL-FROM-LOCAL ASSUMPTION. *Let* $(\Omega, \mathcal{A}, \mathrm{P})$ *be a probability space. Let* $\{(\mathbf{w}^{\mathbf{y},\tau}_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}_0^+),\ (\mathbf{y}, \tau) \in \mathbb{R}^3 \times \mathbb{R}_0^+\}$ *be a family of local velocity fluctuation fields that correspond to spatially and temporally homogeneous, isotropic, and incompressible Gaussian flows with respect to the points* $(\mathbf{y}, \tau)$*. Let* $\tilde{\boldsymbol{\gamma}}^{\mathbf{y},\tau} : (\mathbb{R}^3 \times \mathbb{R}_0^+)^2 \to$

$\mathbb{R}^{3\times 3}$ *denote their respective correlation tensors. For each local field the quantities* $k = k(\mathbf{y},\tau)$, $\epsilon = \epsilon(\mathbf{y},\tau)$, *and* $\bar{\mathbf{u}} = \bar{\mathbf{u}}(\mathbf{y},\tau)$ *are taken as constant. Then we assume that our actual global fluctuation field* $\mathbf{u}'$ *can be constructed as*

$$\mathbf{u}'(\mathbf{x},t) = \langle \mathbf{w}^{\mathbf{y},\tau}(\mathbf{x},t)\rangle_{M(\mathbf{x},t)}, \tag{12}$$

with $M(\mathbf{x},t) = \{(\mathbf{y},\tau) \in \mathbb{R}^3 \times \mathbb{R}_0^+ \mid \|\mathbf{x}-\mathbf{y}-\bar{\mathbf{u}}(\mathbf{x},t)(t-\tau)\|_2 \le l_{\mathrm{T}} \wedge |t-\tau| \le t_{\mathrm{T}}\}$, $|M(\mathbf{x},t)| = \int_{M(\mathbf{x},t)} d\mathbf{y}\, d\tau$, *and turbulent large-scale length* l_{T} *and time* t_{T}. *The brackets* $\langle\cdot\rangle$ *represent the Gaussian average that is uniquely prescribed by expectation and covariance (resp.) correlations according to*

$$\begin{aligned}
\mathbb{E}[\mathbf{u}'(\mathbf{x},t)] &= \frac{1}{|M(\mathbf{x},t)|}\int_{M(\mathbf{x},t)} \mathbb{E}[\mathbf{w}^{\mathbf{y},\tau}(\mathbf{x},t)]\; d\mathbf{y}\, d\tau = \mathbf{0},\\
\mathrm{Cov}(\mathbf{u}'(\mathbf{x_1},t_1),\mathbf{u}'(\mathbf{x_2},t_2)) &= \frac{1}{\sqrt{|M(\mathbf{x_1},t_1)||M(\mathbf{x_2},t_2)|}}\int_{M(\mathbf{x_1},t_1)\cap M(\mathbf{x_2},t_2)} \tilde{\boldsymbol{\gamma}}^{\mathbf{y},\tau}(\mathbf{x_1},t_1,\mathbf{x_2},t_2)\; d\mathbf{y}\, d\tau\\
&= \boldsymbol{\Gamma}'(\mathbf{x_1},t_1,\mathbf{x_2},t_2).
\end{aligned}$$

Note that the terminology used will be explained in the course of this section. The construction rule (12) enables the realization of a globally inhomogeneous and anisotropic turbulent flow on the basis of a very limited number of data stemming from general turbulence theory and specific, case-dependent k-ϵ simulations. So far, it is not clear at all whether such a differentiable turbulent field exists. The underlying local fluctuation fields $\mathbf{w}^{\mathbf{y},\tau}$, which can be interpreted as fine-scale structure of the turbulence, satisfy Kolmogorov's local isotropy hypothesis as well as the local kinetic energy k and dissipation ϵ distribution of the k-ϵ model. Averaging their statistical parameters over a region M where the local stochastic quantities differ only slightly glues them together to the global fluctuation field $\mathbf{u}'$, the anisotropic large-scale structure. The respective global quantities $k_{\mathbf{u}'}$ and $\epsilon_{\mathbf{u}'}$ are thus prescribed as averages of the hardly varying local ones. This is indicated by using the turbulent large-scale length l_{T} and time t_{T}. Presuming global homogeneity, the global and local quantities coincide and obey (10), (11), as desired.

In the following, we deal with the generation of the centered local fluctuation fields by modeling their correlation tensors. Therefore we skip the superscripts denoting the respective points. To determine the temporal behavior of the correlations, we first construct an initial condition for the correlation tensor satisfying the assumptions of homogeneity and isotropy as well as the requirements of the k-ϵ model and Kolmogorov's energy spectrum (sections 3.1–3.4). This initial condition meets the smoothness demands and guarantees the differentiability of the actual global field. Then we formulate an advection equation for the dynamics, whose solution coincides with Taylor's hypothesis of frozen turbulence (section 3.5). In section 3.6 we finally formulate the global fluctuation field as Ito-integral over the local fields, which yields the positive definite correlation tensor proposed in the Global-from-Local Assumption.

3.1. Locally homogeneous isotropic turbulence.

Definition 2 (homogeneous turbulence). *Let* $(\Omega,\mathcal{A},\mathrm{P})$ *be a probability space. Let* $(\boldsymbol{\Phi}_{\mathbf{x},t},(\mathbf{x},t) \in \mathbb{R}^3\times\mathbb{R}_0^+)$ *be a velocity fluctuation field with correlation tensor* $\boldsymbol{\Gamma}$. *A turbulent flow is said to be* spatially homogeneous *if* $\boldsymbol{\Gamma}$ *is invariant regarding spatial translations, i.e.,*

$$\boldsymbol{\Gamma}(\mathbf{x},t,\mathbf{y},\tau) = \boldsymbol{\Gamma}(\mathbf{x}-\mathbf{a},t,\mathbf{y}-\mathbf{a},\tau) \quad \forall\, \mathbf{a}\in\mathbb{R}^3.$$

A turbulent flow is said to be temporally homogeneous *if* $\mathbf{\Gamma}$ *is invariant regarding time shifts, i.e.,*

$$\mathbf{\Gamma}(\mathbf{x},t,\mathbf{y},\tau)=\mathbf{\Gamma}(\mathbf{x},t-a,\mathbf{y},\tau-a)\quad\forall\, a\in\mathbb{R}.$$

Definition 3 (isotropic turbulence). *Let* $(\Omega,\mathcal{A},\mathrm{P})$ *be a probability space. Let* $(\mathbf{\Phi}_{\mathbf{x},t},(\mathbf{x},t)\in\mathbb{R}^3\times\mathbb{R}_0^+)$ *be a velocity fluctuation field with correlation tensor* $\mathbf{\Gamma}$*. A turbulent flow is said to be* isotropic *if* $\mathbf{\Gamma}$ *is invariant regarding rotations and reflections, i.e.,*

$$\mathbf{\Gamma}(\mathbf{x},t,\mathbf{y},t)=\mathbf{S}\;\mathbf{\Gamma}(\mathbf{S}^{-1}\mathbf{x},t,\mathbf{S}^{-1}\mathbf{y},t)\;\mathbf{S}^t\quad\forall\,\mathbf{S}\in\mathcal{O}(3). \tag{13}$$

The correlation tensor $\tilde{\boldsymbol{\gamma}}$ corresponding to a local fluctuation field $\mathbf{w}$, $\tilde{\boldsymbol{\gamma}}(\mathbf{x},t,\mathbf{y},\tau)=\mathbb{E}[\mathbf{w}(\mathbf{x},t)\otimes\mathbf{w}(\mathbf{y},\tau)]$, depends only on the spatial and temporal difference of its arguments due to homogeneity. Thus, we define

$$\boldsymbol{\gamma}(\mathbf{z},\varsigma)=\tilde{\boldsymbol{\gamma}}(\mathbf{x}+\mathbf{z},t+\varsigma,\mathbf{x},t). \tag{14}$$

To derive the structure of the initial correlation tensor in the following, we focus now on

$$\boldsymbol{\gamma}_0(\mathbf{z})=\boldsymbol{\gamma}(\mathbf{z},0)\quad\text{ or }\quad\tilde{\boldsymbol{\gamma}}_0(\mathbf{x},\mathbf{y})=\tilde{\boldsymbol{\gamma}}(\mathbf{x},t,\mathbf{y},t).$$

Properties of the Initial Correlation Tensor. *The correlation tensor corresponding to a homogeneous isotropic turbulent flow has the following properties:*

$$\boldsymbol{\gamma}_0(\mathbf{z})=\boldsymbol{\gamma}_0(-\mathbf{z}), \tag{15}$$

$$\boldsymbol{\gamma}_0(\mathbf{z})\quad\textit{is symmetric}, \tag{16}$$

$$\boldsymbol{\gamma}_0(\mathbf{0})=c\mathbf{I},\quad c\neq 0, \tag{17}$$

$$\boldsymbol{\gamma}_0(\mathbf{z})\quad\textit{has two different eigenvalues:}\quad c_1(z)\ \textit{in}\ \tfrac{\mathbf{z}}{z}\ \textit{and}\ c_2(z)\ \textit{in the respective normal plane,} \tag{18}$$

$$\boldsymbol{\gamma}_0(\mathbf{z})=\frac{c_1(z)-c_2(z)}{z^2}\mathbf{z}\otimes\mathbf{z}+c_2(z)\mathbf{I},\quad z=\|\mathbf{z}\|_2. \tag{19}$$

Hereby, the symmetry of $\boldsymbol{\gamma}_0$, (16), results directly from its definition and the permutability of the arguments (15) that is concluded from the translation and reflection invariance. Applying additionally rotation invariance yields (17) and (18). The general form (19) is deduced from the spectral theorem using the eigenvalues of (18).

The one-dimensional functions c_1 and $c_2\in\mathcal{C}^\infty(\mathbb{R}_0^+)$ can be interpreted as longitudinal and lateral correlations [10]. In general $c_1\neq c_2$, but for $z\to 0$ we have $c_2(z)\to c_1(z)\to c$, with c given in (17).

As a turbulent flow contains a continuous spectrum of scales, it is convenient to introduce the spectral density $\mathbf{M}$ depending on the wave vector $\boldsymbol{\kappa}$. Assuming absolute Lebesgue-continuity of the spectrum of the underlying fluctuation velocity field [4], the spectral density $\mathbf{M}$ is the Fourier transform of the correlation tensor $\boldsymbol{\gamma}_0$,

$$\mathbf{M}(\boldsymbol{\kappa})=\frac{1}{(2\pi)^3}\int_{\mathbb{R}^3}e^{-i\mathbf{z}\cdot\boldsymbol{\kappa}}\boldsymbol{\gamma}_0(\mathbf{z})\,d\mathbf{z}. \tag{20}$$

Then, the spectral energy distribution (energy spectrum) E is defined by

$$E(\kappa)=\frac{1}{2}\kappa^2\int_{S^2}\mathrm{tr}(\mathbf{M}(\kappa\mathbf{e}))\,d\mathbf{e}, \tag{21}$$

with $\kappa = \|\boldsymbol{\kappa}\|_2$, unit sphere S^2, and unit vector $\mathbf{e} \in S^2$.

PROPERTIES OF THE SPECTRAL DENSITY. *The spectral density corresponding to a homogeneous isotropic turbulent flow has the following properties:*

$$\mathbf{M}(\boldsymbol{\kappa}) = \frac{e_1(\kappa) - e_2(\kappa)}{\kappa^2} \boldsymbol{\kappa} \otimes \boldsymbol{\kappa} + e_2(\kappa)\mathbf{I}, \tag{22}$$

$$\mathrm{tr}\mathbf{M}(\kappa) = \frac{1}{2\pi} \frac{E(\kappa)}{\kappa^2}. \tag{23}$$

Due to the Fourier relation (20), $\mathbf{M}$ inherits the isotropic property (13) from $\boldsymbol{\gamma}_0$ and therefore has an analogous representation with the one-dimensional spectral functions $e_1,\ e_2 \in \mathcal{C}^\infty(\mathbb{R}_0^+)$. The connection (23) between trace $\mathrm{tr}\mathbf{M}$ and energy spectrum E can be concluded from (21). Because of isotropy the sphere integral becomes $\int_{S^2} \mathrm{tr}(\mathbf{M}(\kappa\mathbf{e}))d\mathbf{e} = 4\pi\,\mathrm{tr}\mathbf{M}(\kappa)$.

In our case of an incompressible local flow field $\mathbf{w}$, the presented characteristics and dependencies of correlation and spectral functions can be simplified, which halves the number of unknowns and results in a well-structured Sine–Fourier relation between c_1 and E.

INFLUENCE OF INCOMPRESSIBILITY ON CORRELATIONS AND SPECTRAL DENSITY. *Assuming incompressibility, the following relation for the correlation functions c_1 and $c_2 : \mathbb{R}_0^+ \to \mathbb{R}$ is valid:*

$$c_1(z) + \frac{z}{2}\partial_z c_1(z) = c_2(z). \tag{24}$$

Moreover, the spectral functions e_1 and $e_2 : \mathbb{R}_0^+ \to \mathbb{R}$ are given by

$$e_1(\kappa) = 0, \qquad e_2(\kappa) = \frac{1}{4\pi} \frac{E(\kappa)}{\kappa^2}. \tag{25}$$

Relation (24) is concluded from the incompressibility using

$$\mathbf{0} = \mathbb{E}[(\nabla_{\mathbf{x}} \cdot \mathbf{w}(\mathbf{x},t))\,\mathbf{w}(\mathbf{y},t)] = \nabla_{\mathbf{x}} \cdot \tilde{\boldsymbol{\gamma}}_0(\mathbf{x},\mathbf{y}) \overset{\mathbf{z}:=\mathbf{x}-\mathbf{y}}{=} \nabla_{\mathbf{z}} \cdot \boldsymbol{\gamma}_0(\mathbf{z})$$

and substituting (19). Analogously to the correlation functions, the number of unknown spectral functions can be reduced to one. In particular, (25) is deduced by combining $\mathbf{0} = \nabla_{\mathbf{z}} \cdot \boldsymbol{\gamma}_0(\mathbf{z}) = i \int_{\mathbb{R}^3} e^{i\boldsymbol{\kappa}\cdot\mathbf{z}}\,\mathbf{M}(\boldsymbol{\kappa})\boldsymbol{\kappa}\,d\boldsymbol{\kappa}$ and thus $\mathbf{M}(\boldsymbol{\kappa})\boldsymbol{\kappa} = \mathbf{0}$ for all $\boldsymbol{\kappa} \in \mathbb{R}^3$ with (23).

For an incompressible isotropic and homogeneous turbulent flow, the correlation tensor $\boldsymbol{\gamma}_0$ of second order can thus be expressed by the single one-dimensional correlation function c_1. In particular,

$$\mathrm{tr}\boldsymbol{\gamma}_0(z) = 3c_1(z) + z\,\partial_z c_1(z) = \frac{1}{z^2}\,\partial_z\,(z^3\,c_1(z)). \tag{26}$$

Consequently, the whole local fluctuation velocity field is uniquely determined by c_1, whose relation to E will be useful for the further realization of the initial correlations.

RELATION BETWEEN CORRELATION FUNCTION AND ENERGY SPECTRUM. *Let c_1 be the correlation function, and E the energy spectrum corresponding to an homogeneous, isotropic, and incompressible turbulent flow. This implies their finiteness over the whole definition range. Then the following relations are valid:*

$$c_1(z) = \frac{2}{z^3} \int_0^\infty \frac{1}{\kappa}\,\partial_\kappa \left(\frac{E(\kappa)}{\kappa}\right) \sin(\kappa z)\,d\kappa, \tag{27}$$

$$E(\kappa) = \frac{\kappa}{\pi} \int_0^\infty \frac{1}{z}\,\partial_z\,(z^3\,c_1(z))\,\sin(\kappa z)\,dz. \tag{28}$$

The Sine–Fourier relations follow from the respective connections of c_1 and E to the Fourier transforms γ_0 and $\mathbf{M}$. Plugging (26) and (23) into

$$\mathrm{tr}\boldsymbol{\gamma}_0(z) = \int_0^\infty \int_0^{2\pi} \int_{-1}^{1} e^{i\kappa z q}\kappa^2 \,\mathrm{tr}\mathbf{M}(\kappa)\, dq\, d\phi\, d\kappa = \frac{4\pi}{z}\int_0^\infty \kappa\,\mathrm{tr}\mathbf{M}(\kappa)\sin(\kappa z)\, d\kappa$$

gives $\partial_z(z^3\, c_1(z)) = 2z\int_0^\infty E(\kappa)/\kappa\, \sin(\kappa z)\, d\kappa$ and consequently, after some algebraic manipulations, (27).

Further Decisive Coherences. *Further relevant relations between longitudinal correlation function c_1 and energy spectrum E are formulated as*

$$c_1(0) = \frac{2}{3}\int_0^\infty E(\kappa) d\kappa, \tag{29}$$

$$\partial_{zz} c_1(0) = -\frac{2}{15}\int_0^\infty E(\kappa)\kappa^2 d\kappa. \tag{30}$$

By means of partial integration, (27) can be rewritten as

$$c_1(z) = 2\int_0^\infty E(\kappa)\frac{\sin(\kappa z) - \kappa z\cos(\kappa z)}{k^3 z^3}\, d\kappa,$$

from which L'Hospital directly yields (29) and (30).

Finally, the differentiability of a homogeneous Gaussian flow can be concluded from

$$\int_{\mathbb{R}^3} (\ln(1+\kappa))^\alpha\ \kappa^{2p}\,\mathbf{M}(\boldsymbol{\kappa}) d\boldsymbol{\kappa} < \boldsymbol{\infty} \quad \text{for } \alpha > 3. \tag{31}$$

According to [11], equation (31) ensures the existence of an almost surely p-times sample differentiable modification, which we equate to the considered flow for purposes of an intuitive notation. As for our isotropic incompressible local flow field, the differentiability can thus be formulated as a requirement on the decay of the energy spectrum E by rewriting the volume integral of (31) with the help of (22) and (25) as

$$\int_0^\infty \int_{S^2} (\ln(1+\kappa))^\alpha\, \kappa^{2p}\, \frac{E(\kappa)}{4\pi}\, (\mathbf{I} - \mathbf{e}\otimes\mathbf{e})\, d\mathbf{e}\, d\kappa = \int_0^\infty \frac{2}{3}\,(\ln(1+\kappa))^\alpha\, \kappa^{2p}\, E(\kappa) d\kappa\ \mathbf{I}. \tag{32}$$

3.2. Parameters from the k-ϵ model. The kinetic turbulent energy k and the dissipation rate ϵ stemming from the k-ϵ turbulence model act as parameters for the differentiable local fluctuation fields. Presupposing an isotropic, homogeneous, and incompressible Gaussian flow, they can be expressed in terms of the correlation c_1 (resp., the energy function E).

With $\mathbb{E}[\mathbf{w}(\mathbf{x},t)\cdot\mathbf{w}(\mathbf{x},t)] = \mathrm{tr}\boldsymbol{\gamma}_0(0) \overset{(26)}{=} 3\, c_1(0)$, we obtain

$$k = \frac{1}{2}\mathbb{E}[\mathbf{w}(\mathbf{x},t)\cdot\mathbf{w}(\mathbf{x},t)] = \frac{3}{2}c_1(0) \overset{(29)}{=} \int_0^\infty E(\kappa) d\kappa. \tag{33}$$

As for ϵ, we consider $\mathbb{E}[\nabla\mathbf{w}(\mathbf{x},t)\otimes\nabla\mathbf{w}(\mathbf{y},t)] = \nabla_{\mathbf{x}}\nabla_{\mathbf{y}}\tilde{\boldsymbol{\gamma}}_0(\mathbf{x},\mathbf{y}) = -\nabla_{\mathbf{z}}\nabla_{\mathbf{z}}\boldsymbol{\gamma}_0(\mathbf{z})$ with $\mathbf{z} = \mathbf{x} - \mathbf{y}$. Thus, the dissipation reads as

$$\epsilon = \nu\,\mathbb{E}[\nabla\mathbf{w}(\mathbf{x},t) : \nabla\mathbf{w}(\mathbf{x},t)] = -\nu\,\nabla_{\mathbf{z}}\cdot\nabla_{\mathbf{z}}\mathrm{tr}(\boldsymbol{\gamma}_0(\mathbf{z}))|_{\mathbf{z}=\mathbf{0}} = -3\nu\,\partial_{zz}\mathrm{tr}\boldsymbol{\gamma}_0(z)|_{z=0},$$

and with (26) and the differentiability of c_1,

$$\epsilon = -15\nu\,\partial_{zz}c_1(0) \overset{(30)}{=} 2\nu\int_0^\infty E(\kappa)\kappa^2 d\kappa. \tag{34}$$

The even extension $c_1(z) = c_1(-z)$ for $z \le 0$ in combination with the Fourier relation (27) results in a global differentiability of c_1 on $\mathbb{R}$ such that its odd derivatives vanish at $z = 0$. Therefore, the parameters k and ϵ describe the behavior of c_1 for small z by a Taylor expansion up to fourth order,

$$c_1(z) = \frac{2}{3}k - \frac{1}{30}\frac{\epsilon}{\nu}z^2 + \mathcal{O}(z^4).$$

3.3. Kolmogorov's energy spectrum. For the construction of the complete correlation function c_1 we need additional physical information about the flow, which can be gained from the energy spectrum E. The energy spectrum of isotropic turbulence was a well-studied topic of research during the last century (see references in [8, 10]). In particular, Kolmogorov's work (1941) was trendsetting. Based on dimensional analysis, he derived not only the characteristic ranges but also the typical run of the spectrum which agree with later physical concepts and experiments [1]. In the following, we briefly state Kolmogorov's 5/3-law and his hypothesis of local isotropy.

By (21), the energy spectrum depends on the wave number κ. Moreover, observing that turbulence is strongly driven by the large eddies, E can certainly be expected to be a function of the length l_T of the larger energy-containing eddies and the mean strain rate feeding the turbulence through direct interaction between mean flow and large eddies. Since turbulence is dissipative in the mean, it should additionally depend on ν and ϵ. Assuming a wide separation of energy (κ_e) and dissipation (κ_d) scales, Kolmogorov formulated the following.

Universal equilibrium theory (see [8]).

1. *If $\kappa_e < \kappa_d$, there exists a range for wave numbers $\kappa > \kappa_e$ in which the turbulence is in a statistical equilibrium and exclusively determined by dissipation ϵ and kinematic viscosity ν. This equilibrium state is universal; i.e., it occurs in isotropic as well as anisotropic turbulence. (This is the local isotropy hypothesis.)*
2. *If $\kappa_e \ll \kappa_d$, there exists an inertial subrange for wave numbers $\kappa_e < \kappa < \kappa_d$ in which the energy spectrum is just a function of dissipation ϵ and wave number κ.*

By means of dimensional analysis the first hypothesis leads to the Kolmogorov scales for length η, time t_K, and velocity v_K:

$$\eta = \left(\frac{\nu^3}{\epsilon}\right)^{1/4}, \qquad t_\mathrm{K} = \left(\frac{\nu}{\epsilon}\right)^{1/2}, \qquad v_\mathrm{K} = (\nu\,\epsilon)^{1/4},$$

with characteristic wave number $\kappa_\mathrm{K} = \eta^{-1} \approx \kappa_d$. The Kolmogorov length η is the smallest characteristic turbulence length. The second hypothesis yields Kolmogorov's 5/3-law,

$$E(\kappa) = C_\mathrm{K}\,\epsilon^{2/3}\kappa^{-5/3}, \qquad \kappa_e < \kappa < \kappa_d, \tag{35}$$

with Kolmogorov constant C_K. Here, $C_\mathrm{K} = 0.5$ is supposed to be an appropriate estimate according to the experiments of Yeung and Zhou [19].

The form of the energy spectrum sketched in Figure 2 is also designed by Batchelor and Proudman [3]. They derived that $E(\kappa) \sim \kappa^4$ for $\kappa \to 0$, whereas Heisenberg [9] deduced $E(\kappa) \sim \kappa^{-7}$ for $\kappa \to \infty$.

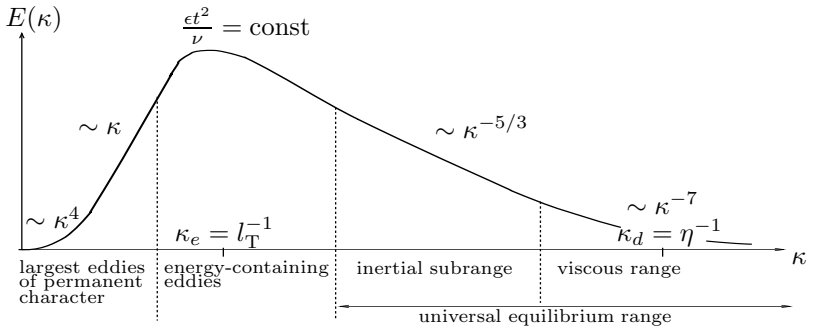

FIG. 2. *Sketch of energy spectrum for isotropic turbulence.*

3.4. Initial local correlations. Having provided the mathematical and physical fundamental ideas, we now model the initial correlation tensor of a local, homogeneous, $\mathcal{L}^2$-continuous, and differentiable Gaussian fluctuation field that satisfies the k-ϵ model and Kolmogorov's 5/3-law. For this purpose, we introduce an admissible underlying spectral energy distribution function.

MODEL FOR THE INITIAL LOCAL CORRELATION TENSOR. *Let $(\Omega, \mathcal{A}, \mathrm{P})$ be a probability space. Let $(\mathbf{w}_{\mathbf{x},t}, (\mathbf{x},t) \in \mathbb{R}^3 \times \mathbb{R}_0^+)$ be the Gaussian velocity fluctuation field of an isotropic, homogeneous, and incompressible turbulent flow with $\mathbf{w}_{\mathbf{x},t} \in \mathcal{L}^2(\Omega, \mathcal{A}, \mathcal{P})$. Let kinetic energy k and dissipation rate ϵ be constant. Construct the initial correlation function $c_1 \in \mathcal{C}^\infty(\mathbb{R}_0^+)$,*

$$c_1(z) = \frac{2}{z^3} \int_0^\infty \frac{1}{\kappa}\, \partial_\kappa \left(\frac{E(\kappa)}{\kappa} \right) \sin(\kappa z)\, d\kappa,$$

by choosing $E \in \mathcal{C}^2(\mathbb{R}_0^+)$ as

$$E(\kappa) = \begin{cases} K\kappa_1^{-5/3} \sum_{j=4}^{6} a_j \, (\frac{\kappa}{\kappa_1})^j, & \kappa < \kappa_1, \\ K\kappa^{-5/3}, & \kappa_1 \le \kappa \le \kappa_2, \\ K\kappa_2^{-5/3} \sum_{j=7}^{9} b_j \, (\frac{\kappa}{\kappa_2})^{-j}, & \kappa > \kappa_2, \end{cases} \tag{36}$$

where κ_1 and κ_2 are implicitly given by

$$\int_0^\infty E(\kappa)\, d\kappa = k \quad \text{and} \quad \int_0^\infty E(\kappa)\kappa^2\, d\kappa = \frac{\epsilon}{2\nu}. \tag{37}$$

The parameters are fixed as $a_4 = 230/9$, $a_5 = -391/9$, $a_6 = 170/9$, $b_7 = 209/9$, $b_8 = -352/9$, $b_9 = 152/9$, $K = C_{\mathrm{K}}\, \epsilon^{2/3}$, $C_{\mathrm{K}} = 0.5$, and viscosity ν.

Then, $(\mathbf{w}_{\mathbf{x},t}, (\mathbf{x},t) \in \mathbb{R}^3 \times \mathbb{R}_0^+)$ is differentiable and fulfills the requirements of the Kolmogorov's 5/3-law as well as these of the k-ϵ model,

$$k = \frac{1}{2}\, \mathbb{E}[\mathbf{w}(\mathbf{x},t) \cdot \mathbf{w}(\mathbf{x},t)], \qquad \epsilon = \nu\, \mathbb{E}[\nabla \mathbf{w}(\mathbf{x},t) : \nabla \mathbf{w}(\mathbf{x},t)].$$

According to (27), the presented nonnegative function E satisfies the requirements on a spectral energy distribution function. Furthermore, it coincides with the run of Kolmogorov's energy spectrum (35). The differentiability of the local flow field, i.e., $(\ln(1+\kappa))^\alpha\, \kappa^2\, E(\kappa) \in \mathcal{L}^1(\mathbb{R}_0^+)$ for $\alpha > 3$ (cf. (32)), is ensured by the constructed

decay of $E(\kappa) \sim \kappa^{-7}$ for $\kappa \to \infty$. The information coming from the k-ϵ model is finally included in the defined moments of E on the basis of (33) and (34).

Alternatively, smoother variants of the piecewise composed energy spectrum are also imaginable for adapted regularity parameters a_i and b_j. However, E given by (36), (37) turns out to successfully satisfy our demands.

Summing up, the high Reynolds number flow under consideration is characterized by the flow quantities k, ϵ, ν in combination with the model for the energy spectrum, equations (36), (37). The flow quantities particularly determine the size of the characteristic energy ranges (energy bearing, inertial, and viscous) in Figure 2 by specifying κ_1 and κ_2 for fixed regularity parameters a_i and b_j. Note that, outside of the flow regime, the use of the k-ϵ turbulence model with the stated energy spectrum is questionable. However, the derivation of the initial local correlation tensor and the following general force concept require just the description of an appropriate spectral energy distribution that could alternatively be obtained by another turbulence model, e.g., LES.

3.5. Dynamics of local correlations. The dynamics of a local correlation tensor $\boldsymbol{\gamma}$ might be described by an advection equation according to the observation that the decay of the mean properties is rather slow with respect to the time scale of the fluctuating fine-scale structures

$$\partial_\varsigma \boldsymbol{\gamma}(\mathbf{z}, \varsigma) + \bar{\mathbf{u}} \cdot \nabla_{\mathbf{z}} \boldsymbol{\gamma}(\mathbf{z}, \varsigma) = 0.$$

Its solution,

$$\boldsymbol{\gamma}(\mathbf{z}, \varsigma) = \boldsymbol{\gamma}_0(\mathbf{z} - \bar{\mathbf{u}}\varsigma), \tag{38}$$

coincides with Taylor's hypothesis of frozen turbulence [17]; i.e., fluctuations arise due to so-called frozen turbulence patterns that are transported by the mean flow without changing their structure.

Equation (38) completes the construction of the local correlation tensor $\boldsymbol{\gamma}$. Consequently, we deal here locally with homogeneous, isotropic, incompressible turbulence moving with the mean flow velocity $\bar{\mathbf{u}}$, whose spectral energy distribution E fulfills the demands of the k-ϵ model as well as of Kolmogorov's universal equilibrium theory.

3.6. Construction of global turbulence. The Global-from-Local Assumption (12) prescribes the actual global fluctuation field $(\mathbf{u}'_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}^+_0)$ on the basis of the family of underlying parameterized local fields $\{(\mathbf{w}^{\mathbf{y},\tau}_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}^+_0), (\mathbf{y}, \tau) \in \mathbb{R}^3 \times \mathbb{R}^+_0\}$. However, so far the positive definiteness of its proposed correlation tensor $\boldsymbol{\Gamma}'$ is not proved, but it might be concluded from an explicit formulation of $\mathbf{u}'$.

Explicit Formulation of the Global Fluctuation Field. *Let the global fluctuation field* $(\mathbf{u}'_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}^+_0)$ *be given as an Ito-integral over the family of the local fields* $\{(\mathbf{w}^{\mathbf{y},\tau}_{\mathbf{x},t}, (\mathbf{x}, t) \in \mathbb{R}^3 \times \mathbb{R}^+_0), (\mathbf{y}, \tau) \in \mathbb{R}^3 \times \mathbb{R}^+_0\}$:

$$\mathbf{u}'(\mathbf{x}, t) = \frac{1}{\sqrt{|M(\mathbf{x}, t)|}} \int_{M(\mathbf{x},t)} \mathbf{w}^{\mathbf{y},\tau}(\mathbf{x}, t)\, d\mathcal{W}_{\mathbf{y},\tau}, \tag{39}$$

$$M(\mathbf{x}, t) = \{(\mathbf{y}, \tau) \in \mathbb{R}^3 \times \mathbb{R}^+_0 \mid \|\mathbf{x} - \mathbf{y} - \bar{\mathbf{u}}(\mathbf{x}, t)(t - \tau)\|_2 \le l_{\mathrm{T}} \wedge |t - \tau| \le t_{\mathrm{T}}\},$$

where $(\mathcal{W}_{\mathbf{y},\tau}, (\mathbf{y}, t) \in \mathbb{R}^3 \times \mathbb{R}^+_0)$ *represents a Wiener process (Brownian motion). Then the field of* (39) *satisfies the probability distribution, expectation, and covariance structure of the averaging procedure* $\langle\cdot\rangle$ *in the Global-from-Local Assumption.*

The global field results from linear superpositions of joint Gaussians and is thus also Gaussian. Due to the permutability of expectation and integration with respect to space and time following from Fubini's theorem, it inherits the centered property from the local fields, so that the constructed $(\mathbf{u}'_{\mathbf{x},t}, (\mathbf{x},t) \in \mathbb{R}^3 \times \mathbb{R}_0^+)$ satisfies the definition of a turbulent Gaussian flow. Additionally, it is differentiable. Its correlation tensor reads

$$\begin{aligned}\boldsymbol{\Gamma}'(\mathbf{x_1},t_1,\mathbf{x_2},t_2) &= \frac{1}{\sqrt{|M(\mathbf{x_1},t_1)|\,|M(\mathbf{x_2},t_2)|}} \\ &\quad \cdot \mathbb{E}\left[\int_{M(\mathbf{x_1},t_1)} \mathbf{w}^{\mathbf{y_1},\tau_1}(\mathbf{x_1},t_1)\,d\mathcal{W}_{\mathbf{y_1},\tau_1} \otimes \int_{M(\mathbf{x_2},t_2)} \mathbf{w}^{\mathbf{y_2},\tau_2}(\mathbf{x_2},t_2)\,d\mathcal{W}_{\mathbf{y_2},\tau_2}\right]. \end{aligned} \tag{40}$$

By means of the Ito-calculus, the expectation of the dyadic product of the integrals can be expressed by

$$\begin{aligned}&\mathbb{E}\left[\int_{M(\mathbf{x_1},t_1)} \mathbf{w}^{\mathbf{y_1},\tau_1}(\mathbf{x_1},t_1)\,d\mathcal{W}_{\mathbf{y_1},\tau_1} \otimes \int_{M(\mathbf{x_2},t_2)} \mathbf{w}^{\mathbf{y_2},\tau_2}(\mathbf{x_2},t_2)\,d\mathcal{W}_{\mathbf{y_2},\tau_2}\right] \\ &\qquad = \mathbb{E}\left[\int_{M(\mathbf{x_1},t_1)\cap M(\mathbf{x_2},t_2)} \mathbf{w}^{\mathbf{y},\tau}(\mathbf{x_1},t_1) \otimes \mathbf{w}^{\mathbf{y},\tau}(\mathbf{x_2},t_2)\,d\mathbf{y}\,d\tau\right].\end{aligned}$$

Plugging this relation into (40), we obtain the proposed covariance of the Global-from-Local Assumption for the in general inhomogeneous, anisotropic global flow

$$\boldsymbol{\Gamma}'(\mathbf{x_1},t_1,\mathbf{x_2},t_2) = \frac{1}{\sqrt{|M(\mathbf{x_1},t_1)|\,|M(\mathbf{x_2},t_2)|}} \int_{M(\mathbf{x_1},t_1)\cap M(\mathbf{x_2},t_2)} \tilde{\boldsymbol{\gamma}}^{\mathbf{y},\tau}(\mathbf{x_1},t_1,\mathbf{x_2},t_2)\;d\mathbf{y}\;d\tau.$$

Due to its derivation from the random field of (39), $\boldsymbol{\Gamma}'$ is undoubtedly a positive definite function, which is necessary for the numerical realization of $\mathbf{u}'$.

The global quantities for kinetic energy $k_{\mathbf{u}'}$ and dissipation rate $\epsilon_{\mathbf{u}'}$ are the averages over a region M where the local, RANS-based quantities k and ϵ differ only slightly. This region is determined by means of the turbulent large-scale length l_T and time t_T and under regard of the advective influence of the mean flow in (38):

$$\begin{aligned}k_{\mathbf{u}'}(\mathbf{x},t) &= \frac{1}{|M(\mathbf{x},t)|}\int_{M(\mathbf{x},t)} k(\mathbf{y},\tau)\;d\mathbf{y}\;d\tau, \\ \epsilon_{\mathbf{u}'}(\mathbf{x},t) &= \frac{1}{|M(\mathbf{x},t)|}\int_{M(\mathbf{x},t)} \epsilon(\mathbf{y},\tau)\;d\mathbf{y}\;d\tau.\end{aligned}$$

In case of global homogeneity we achieve, in particular, the conformity of the global and local statistic quantities.

Despite weakening the conditions on the global turbulent flow, $\boldsymbol{\Gamma}'$ still keeps the correlation structure of the local fields. Let λ_T be the turbulent fine-scale length; then $\boldsymbol{\gamma}_0^{\mathbf{y},\tau}(\mathbf{x_1}-\mathbf{x_2}-\bar{\mathbf{u}}(\mathbf{y},\tau)(t_1-t_2)) \approx \mathbf{0}$ for $\|\mathbf{x_1}-\mathbf{x_2}-\bar{\mathbf{u}}(\mathbf{y},\tau)(t_1-t_2)\|_2 > \lambda_\mathrm{T}$, $(\mathbf{y},\tau) \in \mathbb{R}^3 \times \mathbb{R}_0^+$. Gluing the local correlations together yields $\boldsymbol{\Gamma}'(\mathbf{x_1},t_1,\mathbf{x_2},t_2) \approx \mathbf{0}$, even if $M(\mathbf{x_1},t_1) \cap M(\mathbf{x_2},t_2) \neq \emptyset$ as $\lambda_\mathrm{T} \ll l_\mathrm{T}$. Thus, $\boldsymbol{\Gamma}'$ states no wrong, absurd correlations.

4. General aerodynamic force concept. In the course of this section, the aerodynamic force that is acting on the fiber is modeled on top of the RANS-based

description for the turbulent flow. Thus, we introduce the mean relative velocity $\bar{\mathbf{v}}(s,t) = \bar{\mathbf{u}}(\mathbf{r}(s,t),t) - \partial_t \mathbf{r}(s,t)$. Then,

$$\tilde{\mathbf{f}}^{air}(s,t) = \mathbf{f}(\bar{\mathbf{v}}(s,t) + \mathbf{u}'(\mathbf{r}(s,t),t), \partial_s \mathbf{r}(s,t)) \tag{41}$$

prescribes a stochastic force $(\tilde{\mathbf{f}}^{air}_{s,t}, (s,t) \in [0,l]\times\mathbb{R}^+_0)$ as a (generally nonlinear) function on the derived global fluctuation field $\mathbf{u}'$. However, the efficient numerical handling of this inhomogeneous construct (41) seems to be hopeless because of its complexity. Thus, we follow the Global-from-Local ansatz once more.

Global-from-Local Force Concept. *Let $\mathbf{f} : \mathbb{R}^3 \times \mathbb{R}^2 \to \mathbb{R}^3$ be an arbitrarily chosen air drag model. Let $\{(\mathbf{g}^{\sigma,\tau}_{s,t}, (s,t) \in [0,l]\times\mathbb{R}^+_0), (\sigma,\tau) \in [0,l]\times\mathbb{R}^+_0\}$ be a family of homogeneous local aerodynamic forces that are imposed by local Gaussian velocity fluctuation fields on the locally linear fiber around the respective fiber points (σ,τ). Then, the global aerodynamic force is constructed as a Gaussian,*

$$\mathbf{f}^{air}(\mathbf{r}(.),s,t) = \langle \mathbf{g}^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)}, \tag{42}$$

with

$$\begin{aligned} N(\mathbf{r}(.),s,t) = \{&(\sigma,\tau) \in [0,l]\times\mathbb{R}^+_0 \,| \\ &\|\mathbf{r}(s,t) - \mathbf{r}(\sigma,\tau) - \bar{\mathbf{u}}(\mathbf{r}(s,t),t)(t-\tau)\|_2 \le l_{\mathrm{T}} \wedge |t-\tau| \le t_{\mathrm{T}}\}, \end{aligned} \tag{43}$$

and mean flow velocity $\bar{\mathbf{u}}$, turbulent large-scale length l_{T}, and time t_{T} as well as averaging brackets $\langle\cdot\rangle$ defined analogously to (12).

In analogy to the velocity fluctuations in section 3, this concept (42) realizes a Gaussian global aerodynamic force along the fiber on the basis of a family of homogeneous local random forces. Focusing on the construction of these forces, correlated local forces are deduced from the restriction of our derived Gaussian local velocity fields on the fiber in section 4.1. The proposed linearization approach of section 4.2 enables their approximation by Gaussian white noise with flow-dependent amplitude for a macroscopic description of the fiber. Therefore, $\mathcal{L}^2$- and $\mathcal{L}^\infty$-similarity estimates are stated in section 4.3. In section 4.4 we finally present the corresponding correlated global aerodynamic force and its uncorrelated asymptotic limit.

4.1. Correlated local force. Define the family $\{(\mathbf{g}^{\sigma,\tau}_{s,t}, (s,t) \in [0,l]\times\mathbb{R}^+_0), (\sigma,\tau) \in [0,l]\times\mathbb{R}^+_0\}$ of local aerodynamic forces by

$$\mathbf{g}^{\sigma,\tau}(s,t) = \mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau) + \mathbf{w}^{\sigma,\tau}_f(s,t), \partial_s \mathbf{r}(\sigma,\tau)), \tag{44}$$

$$\mathbf{w}^{\sigma,\tau}_f(s,t) = \mathbf{w}^{\mathbf{r}(\sigma,\tau),\tau}(\mathbf{r}(\sigma,\tau) + (s-\sigma)\partial_s \mathbf{r}(\sigma,\tau) + (t-\tau)\partial_t \mathbf{r}(\sigma,\tau), t). \tag{45}$$

Presupposing a linear fiber around the point (σ,τ), the centered local Gaussian velocity fluctuation fields of section 3 keep their homogeneous correlation structure for their respective restrictions on the fiber in (45):

$$\begin{aligned} \mathbb{E}[\mathbf{w}^{\sigma,\tau}_f(s_1,t_1) \otimes \mathbf{w}^{\sigma,\tau}_f(s_2,t_2)] &= \boldsymbol{\gamma}^{\mathbf{r}(\sigma,\tau),\tau}_0((s_1-s_2)\partial_s \mathbf{r}(\sigma,\tau) - (t_1-t_2)\bar{\mathbf{v}}(\sigma,\tau)) \\ &= \boldsymbol{\gamma}^{\sigma,\tau}_f(s_1-s_2, t_1-t_2). \end{aligned} \tag{46}$$

Locally, for small spatial and temporal differences, the assumption of fiber linearity is reasonable, whereas for large ones, $\boldsymbol{\gamma}^{\sigma,\tau}_f \approx \mathbf{0}$ anyway due to the decay of the correlations. By means of the transformation theorem of random variables, the homogeneous property is handed on $\mathbf{g}^{\sigma,\tau}$ for all feasible drag models $\mathbf{f}$ in (44). Indeed, the chosen

drag model determines the probability distributions of $\mathbf{g}^{\sigma,\tau}$ that are in general not Gaussian. Averaging over the prescribed homogeneous local forces along the fiber in (42) results in a correlated global aerodynamic force that represents the turbulence effects on the fiber motion in (7). Be aware that the stated Global-from-Local Force Concept generates here a functional dependence between $\mathbf{f}^{air}$ and $\mathbf{r}$, so that the fiber dynamics is not modeled by a system of PDEs as in the deterministic flow case of (9).

4.2. Linearization approach. The numerical realization of the correlated Gaussian global aerodynamic force $\mathbf{f}^{air}$ depends crucially on the determination of the probability distributions of $\mathbf{g}^{\sigma,\tau}$, particularly on the computation of the integrals for expectation and covariance according to the definition of the averaging brackets $\langle\cdot\rangle$; cf. (12). The degree of difficulty is thereby mainly determined by the air drag model. For practical reasons, we hence propose a linearization ansatz for $\mathbf{g}^{\sigma,\tau}$ that yields Gaussian local forces

$$\begin{aligned}\mathbf{g}^{\sigma,\tau}(s,t) &= \mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau)+\mathbf{w}_f^{\sigma,\tau}(s,t),\partial_s\mathbf{r}(\sigma,\tau))\\ &\approx \mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau),\partial_s\mathbf{r}(\sigma,\tau))+\mathbf{L}^{\mathbf{f}}(\sigma,\tau)\ \mathbf{w}_f^{\sigma,\tau}(s,t)\\ &= \mathbf{g}_{cc}^{\sigma,\tau}(s,t),\end{aligned}\tag{47}$$

where the linear operator $\mathbf{L}^{\mathbf{f}}$ is induced by the air drag model $\mathbf{f}$. The finite-dimensional distributions of $\mathbf{g}_{cc}^{\sigma,\tau}$ are uniquely given by expectation and covariance,

$$\begin{aligned}\mathbb{E}[\mathbf{g}_{cc}^{\sigma,\tau}(s,t)] &= \mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau),\partial_s\mathbf{r}(\sigma,\tau)) = \boldsymbol{\mu}^{\sigma,\tau},\\ \mathrm{Cov}(\mathbf{g}_{cc}^{\sigma,\tau}(s_1,t_1),\mathbf{g}_{cc}^{\sigma,\tau}(s_2,t_2)) &= \mathbf{L}^{\mathbf{f}}(\sigma,\tau)\ \boldsymbol{\gamma}_f^{\sigma,\tau}(s_1-s_2,t_1-t_2)\ (\mathbf{L}^{\mathbf{f}}(\sigma,\tau))^t\\ &= \boldsymbol{\Gamma}_{\mathbf{g},cc}^{\sigma,\tau}(s_1-s_2,t_1-t_2),\end{aligned}\tag{48}$$

whose evaluation is directly deduced from the centered, homogeneous Gaussian $\mathbf{w}_f^{\sigma,\tau}$; see (46).

4.3. Limit to uncorrelated local force. The correlated Gaussian local forces $\mathbf{g}_{cc}^{\sigma,\tau}$ contain all turbulent coherences explicitly in their covariance function $\boldsymbol{\Gamma}_{\mathbf{g},cc}^{\sigma,\tau}$: $[0,l]\times\mathbb{R}_0^+\to\mathbb{R}^{3\times3}$ of (48). Alternatively, uncorrelated generalized Gaussian local forces $\mathbf{g}_{uc}^{\sigma,\tau}$ might be introduced whose flow-dependent amplitude represents the mean turbulent coherences. Their covariance functions read

$$\boldsymbol{\Gamma}_{\mathbf{g},uc}^{\sigma,\tau}(s,t)=\int_{\mathbb{R}^2}\boldsymbol{\Gamma}_{\mathbf{g},cc}^{\sigma,\tau}(\xi,\varsigma)\ d\xi\,d\varsigma\ \ \delta_0(s)\,\delta_0(t),\tag{49}$$

with the real one-dimensional Dirac function δ_0. If their effects, i.e., their correlations, are compared on a macroscopic fiber scale that includes the whole covariance structure of $\mathbf{g}_{cc}^{\sigma,\tau}$, the family of the uncorrelated forces $\mathbf{g}_{uc}^{\sigma,\tau}$ is a good approximation for that of the correlated $\mathbf{g}_{cc}^{\sigma,\tau}$. In the following, $\mathcal{L}^2$- and $\mathcal{L}^\infty$-estimates for their similarity take center stage.

Define the family $\{((\mathbf{g}_{uc}^{\sigma,\tau})_{s,t},(s,t)\in[0,l]\times\mathbb{R}_0^+),(\sigma,\tau)\in[0,l]\times\mathbb{R}_0^+\}$ of local uncorrelated aerodynamic forces by

$$\mathbf{g}_{uc}^{\sigma,\tau}(s,t)=\mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau),\partial_s\mathbf{r}(\sigma,\tau))+\mathbf{L}^{\mathbf{f}}(\sigma,\tau)\ \mathbf{z}^{\sigma,\tau}(s,t),\tag{50}$$

$$\mathbf{z}^{\sigma,\tau}(s,t)=\mathbf{D}^{\sigma,\tau}\,\mathbf{p}^{\sigma,\tau}(s,t).\tag{51}$$

The centered uncorrelated local velocity fluctuation fields $(\mathbf{z}_{s,t}^{\sigma,\tau},(s,t)\in[0,l]\times\mathbb{R}_0^+)$ along the fiber are particularly given by Gaussian white noise $(\mathbf{p}_{s,t}^{\sigma,\tau},(s,t)\in[0,l]\times\mathbb{R}_0^+)$

with flow-dependent amplitude

$$\mathbf{D}^{\sigma,\tau} = \sqrt{\int_{\mathbb{R}^2} \boldsymbol{\gamma}_f^{\sigma,\tau}(\xi,\varsigma)\ d\xi\, d\varsigma} \tag{52}$$

that contains the integral correlations of $\mathbf{w}_f^{\sigma,\tau}$. The existence of $\mathbf{D}^{\sigma,\tau}$ presupposes the linear independence of the fiber tangent $\partial_s\mathbf{r}(\sigma,\tau)$ and the relative velocity $\bar{\mathbf{v}}(\sigma,\tau)$, as can be concluded from the definition of $\boldsymbol{\gamma}_f^{\sigma,\tau}$ in (46). The velocity correlations are then described by

$$\begin{aligned}\mathbb{E}[\mathbf{z}^{\sigma,\tau}(s_1,t_1)\otimes\mathbf{z}^{\sigma,\tau}(s_2,t_2)] &= (\mathbf{D}^{\sigma,\tau})^2\,\delta_0(s_1-s_2)\,\delta_0(t_1-t_2)\\ &= \boldsymbol{\delta}_f^{\sigma,\varsigma}(s_1-s_2,t_1-t_2),\end{aligned} \tag{53}$$

with the real one-dimensional Dirac function δ_0. In this sense, $\boldsymbol{\delta}_f^{\sigma,\tau}$ is the uncorrelated analogue to $\boldsymbol{\gamma}_f^{\sigma,\tau}$ and induces the desired integral dependence (49) between $\boldsymbol{\Gamma}_{\mathbf{g},uc}^{\sigma,\tau}$ and $\boldsymbol{\Gamma}_{\mathbf{g},cc}^{\sigma,\tau}$ due to the linear construction in (50) and (47).

Focusing on an arbitrarily chosen fiber point (σ,τ), we skip the superscripts of the quantities in the following and deduce a formulation for the force amplitude $\mathbf{D}$ in terms of the manageable energy spectrum E of (21). Therefore, we presume the linear independence of fiber tangent $\mathbf{t} = \partial_s\mathbf{r}$ and mean relative velocity $\bar{\mathbf{v}}$, so that they induce the intuitive choice of a right-hand orthonormal basis, i.e., $\mathbf{t}$, $\mathbf{n} = (\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t})/\|\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t}\|_2$, $\mathbf{b} = \mathbf{t}\times\mathbf{n}$.

Relation between Local Fiber Correlations and Spectral Quantities. *Assume* $\mathbf{t}$ *and* $\bar{\mathbf{v}}$ *to be linearly independent. Let* $\boldsymbol{\gamma}_f(\xi,\varsigma) = \boldsymbol{\gamma}_0(\xi\mathbf{t} - \varsigma\bar{\mathbf{v}})$, $(\xi,\varsigma)\in\mathbb{R}^2$, *be the local velocity correlation tensor along the fiber. Then, its negative Fourier transform* $\mathbf{m} = \mathcal{F}_{\boldsymbol{\gamma}_f}$ *is expressed by the spectral density* $\mathbf{M}$ *of* (20)*:*

$$\mathbf{m}(\lambda_1,\lambda_2) = \int_{\mathbb{R}^3} \mathbf{M}(\boldsymbol{\kappa})\ \delta_0(\lambda_1 - \mathbf{t}\cdot\boldsymbol{\kappa})\ \delta_0(\lambda_2 + \bar{\mathbf{v}}\cdot\boldsymbol{\kappa})\ d\boldsymbol{\kappa}. \tag{54}$$

The integral correlations are prescribed by $\mathbf{m}(0,0) = (2\pi)^{-2}\int\boldsymbol{\gamma}_f(\xi,\varsigma)\,d\xi\,d\varsigma = \mathcal{F}_{\boldsymbol{\delta}_f}$. *In particular,*

$$\mathbf{m}(0,0) = \frac{1}{2\pi\bar{v}_\mathrm{n}}\int_0^\infty \frac{E(\kappa)}{\kappa^2}d\kappa\ \mathbf{P}_{\mathbf{t},\mathbf{n}}, \tag{55}$$

where $\mathbf{P}_{\mathbf{t},\mathbf{n}} := \mathbf{t}\otimes\mathbf{t} + \mathbf{n}\otimes\mathbf{n}$ *denotes the projector onto the plane spanned by* $\mathbf{t}$ *and* $\mathbf{n}$*, and* $\bar{v}_\mathrm{n} := \bar{\mathbf{v}}\cdot\mathbf{n}$.

Inserting the Fourier relation (20) for $\boldsymbol{\gamma}_0$ and $\mathbf{M}$ into the definition of $\mathbf{m}$ and evaluating the two-dimensional integral over the exponential function yields relation (54). Using isotropy and incompressibility of $\mathbf{M}$, (22) and (25), the dependence on the energy spectrum follows:

$$\mathbf{m}(\lambda_1,\lambda_2) = \frac{1}{4\pi}\int_{\mathbb{R}^3}\frac{E(\kappa)}{\kappa^2}\left(\mathbf{I} - \frac{1}{\kappa^2}\boldsymbol{\kappa}\otimes\boldsymbol{\kappa}\right)\ \delta_0(\lambda_1 - \mathbf{t}\cdot\boldsymbol{\kappa})\ \delta_0(\lambda_2 + \bar{\mathbf{v}}\cdot\boldsymbol{\kappa})\ d\boldsymbol{\kappa}, \tag{56}$$

with $\kappa = \|\boldsymbol{\kappa}\|_2$. Consider the matrix $\mathbf{m}^{\mathbf{t},\mathbf{n},\mathbf{b}}$ that represents the tensor $\mathbf{m}$ in the $(\mathbf{t},\bar{\mathbf{v}})$-induced basis, and substitute $\mathbf{t}\cdot\boldsymbol{\kappa} = \kappa_\mathrm{t}$, $\mathbf{n}\cdot\boldsymbol{\kappa} = \kappa_\mathrm{n}$, and $\mathbf{b}\cdot\boldsymbol{\kappa} = \kappa_\mathrm{b}$. Integration over κ_t and κ_n then gives $\mathbf{m}^{\mathbf{t},\mathbf{n},\mathbf{b}}(0,0) = \int_0^\infty E(\kappa)/\kappa^2 d\kappa/(2\pi\bar{v}_\mathrm{n})\ \mathrm{diag}(1,1,0)$ and, with the spectral theorem on the eigenvalues, the invariant form (55) of the tensor.

RELATION BETWEEN FORCE AMPLITUDE AND ENERGY SPECTRUM. *Let* $\mathbf{D}$ *be the force amplitude and* E *the energy spectrum corresponding to a homogeneous, isotropic, and incompressible local velocity fluctuation field. Then the following relation holds:*

$$\mathbf{D} = \sqrt{\frac{2\pi}{\bar{v}_{\mathrm{n}}} \int_0^\infty \frac{E(\kappa)}{\kappa^2} d\kappa}\ \mathbf{P}_{\mathbf{t},\mathbf{n}}. \tag{57}$$

Relation (57) results directly from (52) and (55). It allows the interesting observation that the uncorrelated local velocity fluctuation field $\mathbf{z}$ of (51) has no component in the binormal direction $\mathbf{b}$ of the fiber. The reason for this behavior is the incompressibility of the underlying flow field, since

$$\mathbf{P_b} \int_{\mathbb{R}^2} \boldsymbol{\gamma}_f(\xi,\varsigma)\ d\xi\, d\varsigma = \mathbf{P_b} \int_0^\infty z c_2(z)\, dz = \mathbf{P_b} \int_0^\infty e_1(\kappa)\, d\kappa = \mathbf{0}, \qquad \mathbf{P_b} = \mathbf{b} \otimes \mathbf{b},$$

due to (25) or, respectively, to (24) and partial integration.

Proceeding with the general similarity estimates for the correlated and an uncorrelated local force, it is sufficient to study the effects of the centered local velocity fluctuation fields on a macroscopic fiber scale because of their linear relation, (47), (50). For this purpose, we consider the respective macroscopic velocity fields that are gained from spatially and temporally smoothing along the fiber, and compare their correlation tensors.

Let $\mathbf{w}_f$ and $\mathbf{z}$ be a correlated and an uncorrelated local velocity fluctuation field. The introduction of the normalized spatial and temporal smoothing functions $G_{\boldsymbol{\alpha}} : \mathbb{R}^2 \to \mathbb{R}$, $\boldsymbol{\alpha} = (\alpha_s, \alpha_t) \in (\mathbb{R}_0^+)^2$, enables then the definition of two families of macroscopic velocity fields along the fiber:

$$\mathbf{W}_{\boldsymbol{\alpha}}(s,t) = \int G_{\boldsymbol{\alpha}}(s-\phi, t-\psi)\ \mathbf{w}_f(\phi,\psi)\ d\psi\ d\phi, \tag{58}$$

$$\mathbf{Z}_{\boldsymbol{\alpha}}(s,t) = \int G_{\boldsymbol{\alpha}}(s-\phi, t-\psi)\ \ \mathbf{z}(\phi,\psi)\ \ d\psi\ d\phi, \tag{59}$$

with their correlation tensors

$$\boldsymbol{\Gamma}_{\mathbf{W}_{\boldsymbol{\alpha}}}(\xi,\varsigma) = \int H_{\boldsymbol{\alpha}}(\xi-\phi, \varsigma-\psi)\ \boldsymbol{\gamma}_f(\phi,\psi)\ d\psi\, d\phi, \tag{60}$$

$$\boldsymbol{\Gamma}_{\mathbf{Z}_{\boldsymbol{\alpha}}}(\xi,\varsigma) = \int H_{\boldsymbol{\alpha}}(\xi-\phi, \varsigma-\psi)\ \boldsymbol{\delta}_f(\phi,\psi)\ d\psi\, d\phi, \tag{61}$$

where $H_{\boldsymbol{\alpha}}(\xi,\varsigma) = \int G_{\boldsymbol{\alpha}}(\xi-\phi, \varsigma-\psi)\ G_{\boldsymbol{\alpha}}(\phi,\psi)\ d\psi\, d\phi$ are also normalized smoothing functions. Taking the convolution keeps the properties of the local fields so that $\mathbf{W}_{\boldsymbol{\alpha}}$ and $\mathbf{Z}_{\boldsymbol{\alpha}}$ are Gaussian, centered, and homogeneous for all smoothing parameters $\boldsymbol{\alpha} \in (\mathbb{R}_0^+)^2$. The Gaussian property follows thereby directly from the linear superposition of joint Gaussians. The centered and homogeneous properties are deduced by using the permutability of expectation and integration according to Fubini's theorem.

CHOICE OF SMOOTHING OPERATORS. *Let the smoothing functions* $G_{\boldsymbol{\alpha}} : \mathbb{R}^2 \to \mathbb{R}$, $\boldsymbol{\alpha} = (\alpha_s, \alpha_t) \in (\mathbb{R}_0^+)^2$, *be defined as products of spatial and temporal characteristic functions*

$$G_{\boldsymbol{\alpha}}(\xi,\varsigma) = \alpha_s \alpha_t\ \chi_{[\frac{-1}{2\alpha_s}, \frac{1}{2\alpha_s}]}(\xi)\, \chi_{[\frac{-1}{2\alpha_t}, \frac{1}{2\alpha_t}]}(\varsigma). \tag{62}$$

Then, $H_{\boldsymbol{\alpha}} : \mathbb{R}^2 \to \mathbb{R}$ are given by the products of the hat functions, and their respective negative Fourier transforms are

$$H_{\boldsymbol{\alpha}}(\xi,\varsigma) = \alpha_s\,\alpha_t\ (1-|\alpha_s\,\xi|)\,(1-|\alpha_t\,\varsigma|)\ \chi_{[\frac{-1}{\alpha_s},\frac{1}{\alpha_s}]}(\xi)\,\chi_{[\frac{-1}{\alpha_t},\frac{1}{\alpha_t}]}(\varsigma),$$

$$\mathcal{F}_{H_{\boldsymbol{\alpha}}}(\kappa_1,\kappa_2) = \mathcal{F}_{H_{\mathbf{1}}}\left(\frac{\kappa_1}{\alpha_s},\frac{\kappa_2}{\alpha_t}\right) = \frac{1}{\pi^2}\ \frac{1-\cos(\kappa_1/\alpha_s)}{(\kappa_1/\alpha_s)^2}\ \frac{1-\cos(\kappa_2/\alpha_t)}{(\kappa_2/\alpha_t)^2}. \tag{63}$$

The relation between $\mathcal{F}_{H_{\boldsymbol{\alpha}}}$ and $\mathcal{F}_{H_{\mathbf{1}}}$ results directly from their definition by using $H_{\boldsymbol{\alpha}}(\xi,\varsigma) = \alpha_s\,\alpha_t\,H_{\mathbf{1}}(\alpha_s\,\xi,\alpha_t\,\varsigma)$.

The derivation of the similarity estimates depends decisively on the behavior of the symmetric, nonnegative, differentiable function $\mathcal{E} : \mathbb{R}^2 \to \mathbb{R}_0^+$ that is defined by means of the energy spectrum E,

$$\mathcal{E}(\kappa_1,\kappa_2) := \int_{\mathbb{R}} \frac{E(\|(\kappa_1,\kappa_2,l)\|_2)}{(\kappa_1,\kappa_2,l)^2}\ dl. \tag{64}$$

It is radially decaying with maximum in the origin, i.e., $\max_{\boldsymbol{\kappa}} \mathcal{E}(\kappa_1,\kappa_2) = \mathcal{E}(0,0)$ and $g(\kappa) := \mathcal{E}(\kappa,a\kappa), \kappa \in \mathbb{R}_0^+$, strictly monotonically decreasing for $a \in \mathbb{R}$.

Similarity Estimates. *Choose the smoothing functions $G_{\boldsymbol{\alpha}} : \mathbb{R}^2 \to \mathbb{R}$, $\boldsymbol{\alpha} = (\alpha_s,\alpha_t) \in (\mathbb{R}_0^+)^2$, of* (62) *for the definition of the families of macroscopic velocity fields according to* (58) *and* (59)*. Then the following estimates hold:*

$\mathcal{L}^2$-similarity:

$$\begin{aligned}\mathcal{I}_{\mathcal{L}^2} &:= \|\boldsymbol{\Gamma}_{\mathbf{W}_{\boldsymbol{\alpha}}} - \boldsymbol{\Gamma}_{\mathbf{Z}_{\boldsymbol{\alpha}}}\|_{\mathcal{L}^2(l^2(\mathbb{R}^2))} \\ &\le \frac{\sqrt{\alpha_s\,\alpha_t}}{\sqrt{6}\,\pi\,\bar{v}_{\mathrm{n}}}\sqrt{\mathcal{S}^2\left(\alpha_s^2\left(1+\frac{\bar{v}_{\mathrm{t}}^2}{\bar{v}_{\mathrm{n}}^2}\right)+\frac{\alpha_t^2}{\bar{v}_{\mathrm{n}}^2}\right)+\frac{8\mathcal{E}_0^2}{3\pi}\left(\alpha_s^3+\frac{\alpha_t^3}{(\bar{v}_{\mathrm{n}}+|\bar{v}_{\mathrm{t}}|)^3}\right)}.\end{aligned} \tag{65}$$

$\mathcal{L}^\infty$-similarity:

$$\begin{aligned}\mathcal{I}_{\mathcal{L}^\infty} &:= \|\boldsymbol{\Gamma}_{\mathbf{W}_{\boldsymbol{\alpha}}} - \boldsymbol{\Gamma}_{\mathbf{Z}_{\boldsymbol{\alpha}}}\|_{\mathcal{L}^\infty(l^2(\mathbb{R}^2))} \\ &\le \frac{\sqrt{2}\,\alpha_s\,\alpha_t}{\pi^2\,\bar{v}_{\mathrm{n}}}\left[\mathcal{S}\left(\alpha_s\left(1+\frac{\bar{v}_{\mathrm{t}}}{\bar{v}_{\mathrm{n}}}\right)\left(\frac{c}{2}+\ln\left(\frac{1}{\alpha_s}\right)\right)+\frac{\alpha_t}{\bar{v}_{\mathrm{n}}}\left(\frac{c}{2}+\ln\left(\frac{\bar{v}_{\mathrm{n}}+|\bar{v}_{\mathrm{t}}|}{\alpha_t}\right)\right)\right)\right. \\ &\qquad \left.+\mathcal{E}_0\left(\alpha_s+\frac{\alpha_t}{\bar{v}_{\mathrm{n}}+|\bar{v}_{\mathrm{t}}|}\right)\right],\end{aligned} \tag{66}$$

where

$$\|\boldsymbol{\Gamma}\|_{\mathcal{L}^2(l^2(\mathbb{R}^2))} := \left(\int_{\mathbb{R}^2} \boldsymbol{\Gamma}(\xi,\varsigma) : \boldsymbol{\Gamma}(\xi,\varsigma)\ d\xi\,d\varsigma\right)^{1/2},$$

$$\|\boldsymbol{\Gamma}\|_{\mathcal{L}^\infty(l^2(\mathbb{R}^2))} := \sup_{(\xi,\varsigma)\in\mathbb{R}^2}(\boldsymbol{\Gamma}(\xi,\varsigma) : \boldsymbol{\Gamma}(\xi,\varsigma))^{1/2}.$$

The quantities $\mathcal{E}_0 = \mathcal{E}(0,0)$ and $\mathcal{S} = \sup_{\boldsymbol{\kappa}\in[0,1]^2}\|\nabla_{\boldsymbol{\kappa}}\mathcal{E}(\kappa_1,\kappa_2)\|_2$ are defined by the energy moment of (64)*. Moreover, $\bar{v}_{\mathrm{t}} = \bar{\mathbf{v}}\cdot\mathbf{t}$, $\bar{v}_{\mathrm{n}} = \bar{\mathbf{v}}\cdot\mathbf{n}$, and $c = \int_0^1(1-\cos\iota)/\iota\,d\iota$.*

Proof. (1) $\mathcal{L}^2$-similarity. The norm in $\mathcal{L}^2(l^2(\mathbb{R}^2))$ is conserved under the Fourier transformation according to the Plancherel theorem as the operator : induces a scalar product in the l^2-space. Using the fact that the Fourier transform of a convolution equals the product of the respective Fourier transforms then gives

$$\begin{aligned}\|\boldsymbol{\Gamma}_{\mathbf{W}_{\boldsymbol{\alpha}}} - \boldsymbol{\Gamma}_{\mathbf{Z}_{\boldsymbol{\alpha}}}\|^2_{\mathcal{L}^2(l^2(\mathbb{R}^2))} &= (2\pi)^2\,\|(\mathcal{F}_{\boldsymbol{\gamma}_f} - \mathcal{F}_{\boldsymbol{\delta}_f})\,\mathcal{F}_{H_{\boldsymbol{\alpha}}}\|^2_{\mathcal{L}^2(l^2(\mathbb{R}^2))} \\ &= (2\pi)^2\int_{\mathbb{R}^2}\|\mathbf{m}(\lambda_1,\lambda_2)-\mathbf{m}(0,0)\|^2_{l^2}\,\mathcal{F}^2_{H_{\boldsymbol{\alpha}}}(\lambda_1,\lambda_2)\ d\lambda_1 d\lambda_2.\end{aligned} \tag{67}$$

With (56) and

$$\left(\mathbf{I}-\frac{1}{\boldsymbol{\kappa}^2}\boldsymbol{\kappa}\otimes\boldsymbol{\kappa}\right):\left(\mathbf{I}-\frac{1}{\boldsymbol{\iota}^2}\boldsymbol{\iota}\otimes\boldsymbol{\iota}\right)=1+\frac{(\boldsymbol{\kappa}\cdot\boldsymbol{\iota})^2}{\boldsymbol{\kappa}^2\boldsymbol{\iota}^2}\leq 2, \tag{68}$$

we obtain

$$\begin{aligned}\|\mathbf{m}(\lambda_1,\lambda_2)-\mathbf{m}(0,0)\|_{l^2}^2=&\frac{1}{(4\pi)^2}\int_{\mathbb{R}^3}\int_{\mathbb{R}^3}\frac{E(\|\boldsymbol{\kappa}\|_2)}{\boldsymbol{\kappa}^2}\frac{E(\|\boldsymbol{\iota}\|_2)}{\boldsymbol{\iota}^2}\left(1+\frac{(\boldsymbol{\kappa}\cdot\boldsymbol{\iota})^2}{\boldsymbol{\kappa}^2\boldsymbol{\iota}^2}\right)\\&\cdot(\delta_0(\lambda_1-\mathbf{t}\cdot\boldsymbol{\kappa})\delta_0(\lambda_2+\bar{\mathbf{v}}\cdot\boldsymbol{\kappa})-\delta_0(\mathbf{t}\cdot\boldsymbol{\kappa})\delta_0(\bar{\mathbf{v}}\cdot\boldsymbol{\kappa}))\\&\cdot(\delta_0(\lambda_1-\mathbf{t}\cdot\boldsymbol{\iota})\delta_0(\lambda_2+\bar{\mathbf{v}}\cdot\boldsymbol{\iota})-\delta_0(\mathbf{t}\cdot\boldsymbol{\iota})\delta_0(\bar{\mathbf{v}}\cdot\boldsymbol{\iota}))\;d\boldsymbol{\kappa}\,d\boldsymbol{\iota}.\end{aligned}$$

Inserting this relation into (67) and integrating over λ_1 and λ_2 cancels two Dirac functions. The other two vanish after choosing the $(\mathbf{t},\bar{\mathbf{v}})$-induced basis. Applying (64) and (68) yields, with $\bar{v}_\mathrm{t}=\bar{\mathbf{v}}\cdot\mathbf{t}$ and $\bar{v}_\mathrm{n}=\bar{\mathbf{v}}\cdot\mathbf{n}=\|\bar{\mathbf{v}}-(\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t}\|_2>0$,

$$\begin{aligned}\mathcal{I}_{\mathcal{L}^2}^2\leq&\frac{1}{2\bar{v}_\mathrm{n}}\left[\int_{\mathbb{R}^2}\left(\mathcal{E}^2(\kappa_1,\kappa_2)-2\mathcal{E}(\kappa_1,\kappa_2)\mathcal{E}(0,0)\right)\;\mathcal{F}_{H_{\boldsymbol{\alpha}}}^2(\kappa_1,-(\bar{v}_\mathrm{t}\kappa_1+\bar{v}_\mathrm{n}\kappa_2))\;d\kappa_1\,d\kappa_2\right.\\&\left.+\int_{\mathbb{R}^2}\frac{1}{\bar{v}_\mathrm{n}}\mathcal{E}^2(0,0)\;\mathcal{F}_{H_{\boldsymbol{\alpha}}}^2(\lambda_1,\lambda_2)\,d\lambda_1\,d\lambda_2\right]\\=&\frac{\alpha_s\alpha_t}{2\bar{v}_\mathrm{n}^2}\int_{\mathbb{R}^2}\left(\mathcal{E}\left(\alpha_s\iota_1,\frac{1}{\bar{v}_\mathrm{n}}(\alpha_t\iota_2-\alpha_s\bar{v}_\mathrm{t}\iota_1)\right)-\mathcal{E}(0,0)\right)^2\mathcal{F}_{H_1}^2(\iota_1,\iota_2)\,d\iota_1\,d\iota_2.\end{aligned} \tag{69}$$

The latter calculation is based on the substitution $\kappa_1=\alpha_s\iota_1$, $\bar{v}_\mathrm{t}\kappa_1+\bar{v}_\mathrm{n}\kappa_2=\alpha_t\iota_2$, $\lambda_1=\alpha_s\iota_1$, $\lambda_2=\alpha_t\iota_2$ and on the properties of the even smoothing functions (63). Positivity and radial decay of $\mathcal{E}$ induce the splitting of the integral in (69),

$$\mathcal{I}_{\mathcal{L}^2}^2\leq\frac{\alpha_s\alpha_t}{2\bar{v}_\mathrm{n}^2}\;(J_U+J_{\mathbb{R}^2\setminus U}), \tag{70}$$

with regard to the domain decomposition $\mathbb{R}^2=U\cup(\mathbb{R}^2\setminus U)$, where

$$U:=\{(\iota_1,\iota_2)\;|\;\iota_1\in[-\alpha_s^{-1},\alpha_s^{-1}]\;\wedge\;\iota_2\in[-\alpha_t^{-1}(\bar{v}_\mathrm{n}+|\bar{v}_\mathrm{t}|),\alpha_t^{-1}(\bar{v}_\mathrm{n}+|\bar{v}_\mathrm{t}|)]\}.$$

The energy difference in J_U can be estimated by means of its differentiability, for $(\mathcal{E}(\alpha_s\iota_1,\bar{v}_\mathrm{n}^{-1}(\alpha_t\iota_2-\alpha_s\bar{v}_\mathrm{t}\iota_1))-\mathcal{E}(0,0))^2\leq S^2\,\|(\alpha_s\iota_1,\bar{v}_\mathrm{n}^{-1}(\alpha_t\iota_2-\alpha_s\bar{v}_\mathrm{t}\iota_1))\|_2^2$. Thus,

$$J_U\leq\mathcal{S}^2\int_U\left(\alpha_s^2\left(1+\frac{\bar{v}_\mathrm{t}^2}{\bar{v}_\mathrm{n}^2}\right)\iota_1^2+\frac{\alpha_t^2}{\bar{v}_\mathrm{n}^2}\iota_2^2-2\alpha_s\alpha_t\frac{\bar{v}_\mathrm{t}}{\bar{v}_\mathrm{n}^2}\iota_1\iota_2\right)\;\mathcal{F}_{H_1}^2(\iota_1,\iota_2)\;d\iota_1\,d\iota_2.$$

The odd term vanishes by the integration. Using the equivalence of the integrand in the four quadrants, we obtain with (63)

$$\begin{aligned}J_U\leq&\,4\mathcal{S}^2\int_0^{\alpha_t^{-1}(\bar{v}_\mathrm{n}+|\bar{v}_\mathrm{t}|)}\int_0^{\alpha_s^{-1}}\left(\alpha_s^2\left(1+\frac{\bar{v}_\mathrm{t}^2}{\bar{v}_\mathrm{n}^2}\right)\iota_1^2+\frac{\alpha_t^2}{\bar{v}_\mathrm{n}^2}\iota_2^2\right)\;\mathcal{F}_{H_1}^2(\iota_1,\iota_2)\;d\iota_1\,d\iota_2\\\leq&\,\frac{\mathcal{S}^2}{3\pi^2}\left(\alpha_s^2\left(1+\frac{\bar{v}_\mathrm{t}^2}{\bar{v}_\mathrm{n}^2}\right)+\frac{\alpha_t^2}{\bar{v}_\mathrm{n}^2}\right),\end{aligned} \tag{71}$$

where the compact integration domain is replaced by $(\mathbb{R}_0^+)^2$. On the other hand, the energy difference in $J_{\mathbb{R}^2\setminus U}$ can be estimated by its maximum $\mathcal{E}_0$ due to the strict decay

of $\mathcal{E}$. The equivalence of the integrand in the quadrants leads then to

$$J_{\mathbb{R}^2\setminus U} \le 4\mathcal{E}_0^2 \left(\int_0^\infty \int_{\alpha_s^{-1}}^\infty \mathcal{F}_{H_1}^2(\iota_1,\iota_2)\, d\iota_1\, d\iota_2 + \int_{\alpha_t^{-1}(\bar v_{\mathrm{n}}+|\bar v_{\mathrm{t}}|)}^\infty \int_0^{\alpha_s^{-1}} \mathcal{F}_{H_1}^2(\iota_1,\iota_2)\, d\iota_1\, d\iota_2 \right)$$

(72)

$$\le \frac{8\mathcal{E}_0^2}{9\pi^3} \left(\alpha_s^3 + \frac{\alpha_t^3}{(\bar v_{\mathrm{n}}+|\bar v_{\mathrm{t}}|)^3} \right),$$

where the integration interval of ι_1 in the second summand is replaced by $\mathbb{R}_0^+$. Inserting (71) and (72) into (70) yields the $\mathcal{L}^2$-estimate.

(2) $\mathcal{L}^\infty$-similarity. The $\mathcal{L}^\infty$-estimate is derived in analogy to the $\mathcal{L}^2$-estimate. Consider therefore

$$\begin{aligned}
\|(\mathbf{\Gamma}_{\mathbf{W}_{\boldsymbol\alpha}} - \mathbf{\Gamma}_{\mathbf{Z}_{\boldsymbol\alpha}})(\boldsymbol\sigma)\|_{l^2}^2 &= \left\| \int_{\mathbb{R}^2} e^{i\boldsymbol\lambda\cdot\boldsymbol\sigma} \left(\mathbf{m}(\boldsymbol\lambda) - \mathbf{m}(\mathbf{0})\right) \mathcal{F}_{H_{\boldsymbol\alpha}}(\boldsymbol\lambda)\, d\boldsymbol\lambda \right\|_{l^2}^2 \\
&= \frac{1}{(4\pi)^2} \int_{\mathbb{R}^2}\int_{\mathbb{R}^2}\int_{\mathbb{R}^3}\int_{\mathbb{R}^3} e^{i(\boldsymbol\lambda+\boldsymbol\mu)\cdot\boldsymbol\sigma}\, \mathcal{F}_{H_{\boldsymbol\alpha}}(\boldsymbol\lambda)\, \mathcal{F}_{H_{\boldsymbol\alpha}}(\boldsymbol\mu) \frac{E(\|\boldsymbol\kappa\|_2)}{\boldsymbol\kappa^2} \frac{E(\|\boldsymbol\iota\|_2)}{\boldsymbol\iota^2} \left(1 + \frac{(\boldsymbol\kappa\cdot\boldsymbol\iota)^2}{\boldsymbol\kappa^2\boldsymbol\iota^2}\right) \\
&\qquad \cdot \left(\delta_0(\lambda_1 - \mathbf{t}\cdot\boldsymbol\kappa)\delta_0(\lambda_2 + \bar{\mathbf{v}}\cdot\boldsymbol\kappa) - \delta_0(\mathbf{t}\cdot\boldsymbol\kappa)\delta_0(\bar{\mathbf{v}}\cdot\boldsymbol\kappa)\right) \\
&\qquad \cdot \left(\delta_0(\mu_1 - \mathbf{t}\cdot\boldsymbol\iota)\delta_0(\mu_2 + \bar{\mathbf{v}}\cdot\boldsymbol\iota) - \delta_0(\mathbf{t}\cdot\boldsymbol\iota)\delta_0(\bar{\mathbf{v}}\cdot\boldsymbol\iota)\right) d\boldsymbol\kappa\, d\boldsymbol\iota\, d\boldsymbol\lambda\, d\boldsymbol\mu,
\end{aligned}$$

according to (56) and (68). Following the calculations of the $\mathcal{L}^2$-estimate gives

$$\begin{aligned}
&\|(\mathbf{\Gamma}_{\mathbf{W}_{\boldsymbol\alpha}} - \mathbf{\Gamma}_{\mathbf{Z}_{\boldsymbol\alpha}})(\boldsymbol\sigma)\|_{l^2}^2 \\
&\le \frac{\alpha_s^2\,\alpha_t^2}{8\pi^2\,\bar v_{\mathrm{n}}^2} \left(\int_{\mathbb{R}^2} e^{i(\alpha_s\iota_1, -\alpha_t\iota_2)\cdot\boldsymbol\sigma} \left(\mathcal{E}\left(\alpha_s\iota_1, \frac{1}{\bar v_{\mathrm{n}}}(\alpha_t\iota_2 - \alpha_s\bar v_{\mathrm{t}}\iota_1)\right) - \mathcal{E}(0,0)\right) \mathcal{F}_{H_1}(\boldsymbol\iota) d\boldsymbol\iota \right)^2 \\
&\le \frac{\alpha_s^2\,\alpha_t^2}{8\pi^2\,\bar v_{\mathrm{n}}^2} \left(\int_{\mathbb{R}^2} \left| \mathcal{E}\left(\alpha_s\iota_1, \frac{1}{\bar v_{\mathrm{n}}}(\alpha_t\iota_2 - \alpha_s\bar v_{\mathrm{t}}\iota_1)\right) - \mathcal{E}(0,0)\right| \mathcal{F}_{H_1}(\boldsymbol\iota)\, d\boldsymbol\iota \right)^2.
\end{aligned}$$

Repeating then the splitting ansatz for the integral and the estimation arguments for the energy difference in J_U and $J_{\mathbb{R}^2\setminus U}$ yields

$$\begin{aligned}
J_U &\le \frac{4\mathcal{S}}{\pi^2} \int_0^{\alpha_t^{-1}(\bar v_{\mathrm{n}}+|\bar v_{\mathrm{t}}|)} \int_0^{\alpha_s^{-1}} \left(\alpha_s \left(1 + \frac{|\bar v_{\mathrm{t}}|}{\bar v_{\mathrm{n}}}\right) \iota_1 + \frac{\alpha_t}{\bar v_{\mathrm{n}}}\iota_2 \right) \mathcal{F}_{H_1}(\iota_1,\iota_2)\, d\iota_1\, d\iota_2 \\
&\le \frac{4\mathcal{S}}{\pi^2} \int_0^\infty \frac{1-\cos\iota}{\iota^2} d\iota \left(\alpha_s \left(1 + \frac{|\bar v_{\mathrm{t}}|}{\bar v_{\mathrm{n}}}\right) \left(\int_0^1 \frac{1-\cos\iota}{\iota} d\iota + \int_1^{\alpha_s^{-1}} \frac{1-\cos\iota}{\iota} d\iota \right) \right. \\
&\qquad \left. + \frac{\alpha_t}{\bar v_{\mathrm{n}}} \left(\int_0^1 \frac{1-\cos\iota}{\iota} d\iota + \int_1^{\alpha_t^{-1}(\bar v_{\mathrm{n}}+|\bar v_{\mathrm{t}}|)} \frac{1-\cos\iota}{\iota} d\iota \right) \right) \\
&\le \frac{2\mathcal{S}}{\pi} \left(\alpha_s \left(1 + \frac{\bar v_{\mathrm{t}}}{\bar v_{\mathrm{n}}}\right) \left(c + 2\ln\left(\frac{1}{\alpha_s}\right)\right) + \frac{\alpha_t}{\bar v_{\mathrm{n}}} \left(c + 2\ln\left(\frac{\bar v_{\mathrm{n}} + |\bar v_{\mathrm{t}}|}{\alpha_t}\right)\right)\right),
\end{aligned}$$

with $c = \int_0^1 (1-\cos\iota)/\iota\, d\iota$ and

$$\begin{aligned}
J_{\mathbb{R}^2\setminus U} &\le 4\mathcal{E}_0 \left(\int_0^\infty \int_{\alpha_s^{-1}}^\infty \mathcal{F}_{H_1}(\iota_1,\iota_2)\, d\iota_1\, d\iota_2 + \int_{\alpha_t^{-1}(\bar v_{\mathrm{n}}+|\bar v_{\mathrm{t}}|)}^\infty \int_0^{\alpha_s^{-1}} \mathcal{F}_{H_1}(\iota_1,\iota_2)\, d\iota_1\, d\iota_2 \right) \\
&\le \frac{4\mathcal{E}_0}{\pi} \left(\alpha_s + \frac{\alpha_t}{(\bar v_{\mathrm{n}} + |\bar v_{\mathrm{t}}|)} \right). \qquad \square
\end{aligned}$$

In the limit $\alpha_i \to 0$, $i = s,t$, the support of the smoothing function $G_{\boldsymbol{\alpha}}$ tends to be the whole $\mathbb{R}^2$. This is unrealistic, as the fiber length l prescribes a natural upper bound for the spatial smoothing parameter α_s. Thus, $\alpha_s = l_{\mathrm{T}}/l$ is certainly a reasonable value for the macroscopic smoothing of the turbulent flow effects on the fiber. The temporal flow and fiber scales are related to the spatial ones by the respective velocities $\bar{\mathbf{u}}$ and $\partial_t \mathbf{r}$. The choice of $\alpha_t = \alpha_s \|\partial_t \mathbf{r}\|_2 / \|\bar{\mathbf{u}}\|_2$ seems likely. Consequently, the actual quality of the similarity estimates (65) and (66) is determined by the scales of the considered fiber-flow problem. Moreover, it depends crucially on the relation between fiber direction $\mathbf{t}$ and mean relative velocity $\bar{\mathbf{v}}$. Be aware that the estimates do not hold for linear dependence, because the amplitude $\mathbf{D}$ of the underlying uncorrelated velocity fluctuation field $\mathbf{z}$ is then not defined; cf. (51), (57). However, these events might be viewed as elements of a nullset, since the perturbing influence of the turbulence and the fiber inertia prevents the fiber from moving continuously within the mean streamlines.

4.4. Correlated and uncorrelated global force. After having provided the correlated local forces $\mathbf{g}_{cc}^{\sigma,\tau}$ and their uncorrelated asymptotic limits $\mathbf{g}_{uc}^{\sigma,\tau}$, we conclude this section with the statement of the corresponding global forces. According to the Global-from-Local Force Concept (42) and the linearization approach of (47), the correlated and uncorrelated global aerodynamic forces read

$$\begin{aligned} \mathbf{f}_{cc}^{air}(\mathbf{r}(.),s,t) &= \langle \mathbf{g}_{cc}^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)} \\ &= \langle \mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau),\partial_s \mathbf{r}(\sigma,\tau))\rangle_{N(\mathbf{r}(.),s,t)} + \langle \mathbf{L}^{\mathbf{f}}(\sigma,\tau)\ \mathbf{w}_f^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)}, \end{aligned} \tag{73}$$

$$\begin{aligned} \mathbf{f}_{uc}^{air}(\mathbf{r}(.),s,t) &= \langle \mathbf{g}_{uc}^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)} \\ &= \langle \mathbf{f}(\bar{\mathbf{v}}(\sigma,\tau),\partial_s \mathbf{r}(\sigma,\tau))\rangle_{N(\mathbf{r}(.),s,t)} + \langle \mathbf{L}^{\mathbf{f}}(\sigma,\tau)\ \mathbf{z}^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)}, \end{aligned} \tag{74}$$

where

$$\begin{aligned} \langle \mathbf{L}^{\mathbf{f}}(\sigma,\tau)\ \mathbf{z}^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)} &= \sqrt{\langle \mathbf{L}^{\mathbf{f}}(\sigma,\tau)(\mathbf{D}^{\sigma,\tau})^2(\mathbf{L}^{\mathbf{f}}(\sigma,\tau))^t\rangle_{N(\mathbf{r}(.),s,t)}}\ \mathbf{p}(s,t) \\ &= \sqrt{\frac{1}{|N(\mathbf{r}(.),s,t)|}\int_{N(\mathbf{r}(.),s,t)} \mathbf{L}^{\mathbf{f}}(\sigma,\tau)(\mathbf{D}^{\sigma,\tau})^2(\mathbf{L}^{\mathbf{f}}(\sigma,\tau))^t\, d\sigma\, d\tau}\ \mathbf{p}(s,t) \end{aligned}$$

by means of Ito-calculus and the integration rule of independent Gaussian random fields. Here, $(\mathbf{p}_{s,t}, (s,t) \in [0,l] \times \mathbb{R}_0^+)$ describes as $\mathbb{R}^3$-valued Gaussian white noise a centered homogeneous generalized Gaussian random field on a two-dimensional parameter set, i.e.,

$$\lim_{(\triangle s, \triangle t)\to \mathbf{0}} \sqrt{\triangle s \triangle t}\ \mathbf{p}(s,t) \sim \mathcal{N}(\mathbf{0},\mathbf{I}).$$

The global forces (73), (74) inherit thereby the proven approximation quality of the local forces on a macroscopic fiber scale because of the applied linear averaging procedure $\langle\cdot\rangle$.

The local flow quantities hardly ever differ in the fiber region N, since it is contained in the turbulence domain M of (12). This fact, in combination with the assumption of a locally linear fiber, motivates the skipping of the averaging procedure. For further theoretical and numerical treatment it is hence convenient to consider the following approximative forces:

$$\hat{\mathbf{f}}_{cc}^{air}(\mathbf{r}(.),s,t) = \mathbf{f}(\bar{\mathbf{v}}(s,t),\partial_s \mathbf{r}(s,t)) + \mathbf{L}^{\mathbf{f}}(s,t)\ \langle \mathbf{w}_f^{\sigma,\tau}(s,t)\rangle_{N(\mathbf{r}(.),s,t)}, \tag{75}$$

$$\hat{\mathbf{f}}_{uc}^{air}(\mathbf{r}(.),s,t) = \mathbf{f}(\bar{\mathbf{v}}(s,t),\partial_s \mathbf{r}(s,t)) + \mathbf{L}^{\mathbf{f}}(s,t)\ \mathbf{D}^{s,t}\ \mathbf{p}(s,t). \tag{76}$$

Analogously to (39), the averaging brackets in (75) can be explicitly formulated as Ito-integrals with the Wiener process/Brownian motion ($\mathcal{W}_{\sigma,\tau}, (\sigma,\tau) \in [0,l] \times \mathbb{R}_0^+$):

$$\langle \mathbf{w}_f^{\sigma,\tau}(s,t) \rangle_{N(\mathbf{r}(.),s,t)} = \frac{1}{\sqrt{|N(\mathbf{r}(.),s,t)|}} \int_{N(\mathbf{r}(.),s,t)} \mathbf{w}_f^{\sigma,\tau}(s,t)\, d\mathcal{W}_{\sigma,\tau}.$$

Whereas the functional dependence between $\hat{\mathbf{f}}_{cc}^{air}$ and $\mathbf{r}$ remains as a consequence of the realization of the correlation structure of the underlying local velocity fluctuation fields $\mathbf{w}_f^{\sigma,\tau}$, the applied simplification localizes the uncorrelated global force in (76), i.e., $\hat{\mathbf{f}}_{uc}^{air}(\mathbf{r}(.),s,t) = \hat{\mathbf{f}}_{uc}^{air}(\mathbf{r}(s,t), \partial_s\mathbf{r}(s,t),\, \partial_t\mathbf{r}(s,t), s, t)$. Thus, the resulting fiber motion is given by a wave-like system of stochastic PDEs with algebraic constraint.

5. Conclusions and outlook. Our presented Global-from-Local Force Concept in combination with the linearization approach (47) allows the approximation of the constructed correlated random aerodynamic force by Gaussian white noise with flow-dependent amplitude in the case of a macroscopic description of the fiber dynamics. The stated general results are applicable to concrete practical problems with fiber-turbulence interaction scales that yield negligibly small deviations in the $\mathcal{L}^2$- and $\mathcal{L}^\infty$-estimates of (65) and (66). Choose therefore a specific air drag model $\mathbf{f}$ and derive an appropriate linear drag operator $\mathbf{L}^{\mathbf{f}}$; then the global aerodynamic force $\hat{\mathbf{f}}_{uc}^{air}$ of (76) leads to a stochastic partial differential system with additive white noise for the fiber dynamics, (7), which can efficiently be handled numerically. For the choice of an empirically motivated, nearly quadratic drag model in a melt-spinning process, the effects of the correlated global force and its uncorrelated asymptotic limit that are imposed on the fiber by the turbulent flow are quantified and numerically compared in a subsequent paper.

THE LINEAR LIMIT OF THE DIPOLE PROBLEM FOR THE THIN FILM EQUATION*

MARK BOWEN† AND THOMAS P. WITELSKI‡

Abstract. We investigate self-similar solutions of the dipole problem for the one-dimensional thin film equation on the half-line $\{x \geq 0\}$. We study compactly supported solutions of the linear moving boundary problem and show how they relate to solutions of the nonlinear problem. The similarity solutions are generally of the second kind, given by the solution of a nonlinear eigenvalue problem, although there are some notable cases where first-kind solutions also arise. We examine the conserved quantities connected to these first-kind solutions. Difficulties associated with the lack of a maximum principle and the non–self-adjointness of the fundamental linear problem are also considered. Seeking similarity solutions that include sign changes yields a surprisingly rich set of (coexisting) stable solutions for the intermediate asymptotics of this problem. Our results include analysis of limiting cases and comparisons with numerical computations.

Key words. thin-film equations, similarity solutions, dipole problem

1. Introduction.

The dipole problem for the one-dimensional "absolute-valued" thin-film equation

$$\frac{\partial h}{\partial t} = -\frac{\partial}{\partial x}\left(|h|^n \frac{\partial^3 h}{\partial x^3}\right), \tag{1.1}$$

where n is a real constant, is defined as an initial-boundary value problem on the half-line $\{x \geq 0\}$, starting from bounded compactly supported initial data

$$h(x,0) = h_0(x) \qquad \text{for } 0 \leq x \leq \ell_0, \tag{1.2}$$

with $h(x,0) \equiv 0$ for $x \geq \ell_0$. At the origin, we impose the boundary conditions [11, 21, 38]

$$h = h_x = 0 \qquad \text{at } x = 0. \tag{1.3}$$

For $n > 0$, it is well known that compactly supported solutions of (1.1) exist with fronts that have a finite speed of propagation (see, for example, [6, 7, 8, 9, 10]). Meanwhile, for $n = 0$, where (1.1) is linear, solutions starting from compact initial data instantaneously gain support over the entire domain for $t > 0$. In [12], Bernis, Hulshof, and Quiros compared the $n \to 0$ limit with the $n = 0$ (linear) behavior in the Cauchy problem for (1.1). In a similar spirit, we will study related issues for the more complicated problem of second-kind similarity solutions for the dipole problem (1.1)–(1.3).

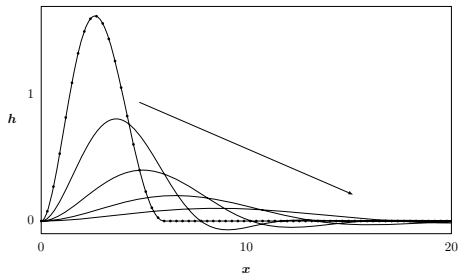

FIG. 1.1. *Numerical simulation of the dynamics of the dipole initial-boundary value problem for* (1.1) *with* $n = 0.1$. *Starting from nonnegative compact initial data (dotted curve), the dynamics approach a self-similar mixed draining/spreading evolution with the appearance of sign changes.*

To this end, we consider solutions of the moving boundary problem on $0 \le x \le \ell(t)$ with boundary conditions [32]

$$h = h_x = |h|^n h_{xxx} = 0 \qquad \text{as } x \to \ell^-(t), \tag{1.4}$$

where $\ell(0) \equiv \ell_0$. From formal considerations, we can write the equation for interface motion as

$$\frac{d\ell}{dt} = \lim_{x \to \ell^-(t)} |h|^{n-1} h_{xxx}. \tag{1.5}$$

A sample numerical simulation of the dynamics for (1.1)–(1.3) with small positive n is shown in Figure 1.1. We will present evidence that, for appropriate initial data, the dipole similarity solutions accurately predict the dynamics of (1.1).

The dipole problem for (1.1) was first referred to by Barenblatt [1] as an extension of the analogous problem for the porous medium equation [3, 4, 28, 29],

$$\partial_t h = \partial_x \left(|h|^m \partial_x h \right); \tag{1.6}$$

a comparison between dipole similarity solutions of (1.6) and experimental results on gravity currents was undertaken in [33]. Barenblatt noted that the properties of the thin-film equation (1.1) were likely to yield an intricate set of nontrivial similarity solutions. An important difference between (1.6) and (1.1) is that the thin-film equation does not have a maximum principle. That is, solutions starting from nonnegative initial data do not necessarily stay nonnegative [16, 18, 19]; indeed, observe Figure 1.1.

Equation (1.1) with $n > 0$ arises in the study of surface tension–driven thin films [9, 15, 16, 17, 18, 23, 34, 35, 36]. For these problems, $h(x,t)$ is representative of the thickness of the fluid film, and from physical considerations, the solutions must be nonnegative, $h(x,t) \ge 0$. More recently, similar higher-order nonlinear degenerate parabolic equations have been applied to image processing problems [25, 26]. In this paper, we are primarily interested in the mathematical structure of solutions to (1.1) for small n, and we will admit solutions that change sign (consequently, the usual h^n in the thin-film equation is written as $|h|^n$ in (1.1)). Removing the positivity requirement means that $x = \ell(t)$ in (1.5) is not necessarily the first point in the solution of (1.1) at which $h = 0$, in contrast with the study in [12]. This yields a much richer set of solutions, including the traditional nonnegative solution and new classes of solutions with sign changes.

In section 2 we introduce a similarity solution of (1.1) and clarify our use of the terminology "first-kind" and "second-kind." The latter class of solution will be most prevalent herein, reducing the thin-film equation (1.1) to a fourth-order non–self-adjoint eigenvalue problem that will be the main focus of the paper. Section 3 considers the fundamental linear problem for (1.1) in terms of the known conserved quantities of (1.1)–(1.4). We focus on the linear case in detail in section 4. Classes of solutions with compact support or with support on the half-line are obtained and shown to be consistent with the conserved quantity results of section 3. In section 5, we return to the fully nonlinear problem and consider the limit $n \to 0$. This small n study links the solutions of the nonlinear problem to the linear results found in section 4. In section 6, numerical simulations of (1.1) are compared with the predictions given by the dipole solutions. We conclude, in section 7, with a discussion of the results obtained in the previous sections.

2. Similarity solutions. We seek self-similar solutions of the thin film equation (1.1) taking the form

$$h = \tau^{-\alpha} H(\eta), \qquad \eta = x/\tau^{\beta}, \qquad \tau = t + t_0. \tag{2.1}$$

Similarity solutions of this general form solve many different classes of initial and boundary value problems for (1.1): source-type solutions of the Cauchy problem, draining solutions of the Dirichlet problem, and Boltzmann solutions of the dam-break problem [13, 20, 22, 32, 38]. Moreover, these special solutions often act as large-time attractors for solutions starting from much wider classes of initial conditions; we also expect this to be true for the dipole problem.

Substituting (2.1) into (1.1) and separating temporal and spatial variables forces the relation

$$n\alpha + 4\beta = 1, \tag{2.2}$$

with the similarity function $H(\eta)$ satisfying a boundary value problem on $0 \le \eta \le L$ for the nonlinear ordinary differential equation,

$$\alpha H + \tfrac{1}{4}(1 - n\alpha)\eta H' - \left(|H|^n H'''\right)' = 0, \tag{2.3a}$$

$$\text{with} \quad H = H' = 0 \qquad \text{at } \eta = 0, \tag{2.3b}$$

$$\text{and} \quad H = H' = |H|^n H''' = 0 \qquad \text{as } \eta \to L^-. \tag{2.3c}$$

We will refer to (2.3) as problem (P). Here, L is a constant corresponding to the free boundary (1.4) of the form $\ell(t) = L\tau^{\beta}$. Problem (P) has been previously investigated by application of dynamical systems techniques [21, 27].

If a second independent relation between α and β were known, then these scaling constants could be determined explicitly. For the Cauchy problem, the conserved quantity $\int h\,dx$ determines $\alpha = \beta$, and hence $\alpha = \beta = 1/(n+4)$ [13, 32]. For the Dirichlet problem, boundary conditions set $\beta = 0$, and hence $\alpha = 1/n$ [22, 38], while for dam-break, appropriate boundary conditions set $\alpha = 0$ and $\beta = 1/4$ [20]. All of these scenarios are classified as similarity solutions of the *first kind*; see Barenblatt [1]. For the dipole problem, there is in general no such direct second relation between α and β. In (2.3a), β has been eliminated via $\beta = (1 - n\alpha)/4$, but α is left undetermined.

Consequently problem (P) is a challenging nonlinear eigenvalue problem for the scaling constant α, and the similarity solution (2.1) is said to be of the *second kind* [1]. There are, however, two exceptional cases (which we will come to in sections 3 and 6.1).

We note that problem (P) is invariant under the rescaling $H(\eta) \to \lambda^{4/n}\hat{H}(\hat{\eta})$, $\eta \to \lambda\hat{\eta}$ for any $\lambda > 0$ when $n \neq 0$. In addition, for the $n = 0$ linear problem, H and η can be rescaled independently. Therefore, to uniquely specify a solution of (P), an additional arbitrary normalization condition must be imposed. For this, we choose to set the average of the square of the similarity solution to be unity, i.e.,

$$\frac{1}{L}\int_0^L H^2\,d\eta = 1; \tag{2.3d}$$

this is a simple condition on the L^2 norm of the solution, which will be convenient in our numerical scheme for solving the boundary value problem. A different, local, normalization condition was used in [21], which was more convenient for their shooting method calculations.

For self-similar solutions (2.1), the quantity $\int h\,dx$ scales as $O(\tau^{\beta-\alpha})$. It was proved rigorously in [11] that a solution of problem (P) exists only for $n < 2$ and necessarily has $\alpha > \beta$. We therefore restrict attention to solutions where $\frac{d}{dt}\int h\,dx < 0$, and hence from (2.2), $\alpha > 1/(n+4)$. Previous analysis [21] has also indicated that there exists a critical value of $n = n_c$, such that $-4 < n_c < 0$, below which solutions of the form (2.1) do not exist; we return to this issue in a later section.

Rather than trying to construct solutions to (P) directly, we split it into two subproblems:

$$(\mathrm{P}_A) = \{(\mathrm{P}) \text{ with (2.3c) replaced by } \quad H = H' = 0 \quad \text{at} \quad \eta = L\} \tag{2.4}$$

and

$$(\mathrm{P}_B) = \{(\mathrm{P}) \text{ with (2.3c) replaced by } \quad H = |H|^n H''' = 0 \quad \text{at} \quad \eta = L\}\,. \tag{2.5}$$

For a given value of L, both (P_A) and (P_B) define fourth-order boundary value problems, with α playing the role of an eigenvalue. Consequently, we expect nontrivial solutions to the subproblems to exist only for specific values of α at each L: there will be continuous families of solutions of these problems defined by curves in the (L, α) parameter plane; see Figure 4.6(left). Intersections of the solution curves for problems (P_A) and (P_B) then identify solutions of the original problem (P), that is, $\mathrm{P} = \mathrm{P}_A \cap \mathrm{P}_B$ (see Figure 4.6(right)). We will develop this in sections 4–6.

3. Conserved quantities. As described above, similarity solutions are said to be of the first kind if the scaling parameters α, β can be obtained directly by combining (2.2) with another relation. Additional scaling relations can often be obtained from equations for conserved quantities, such as the conservation of $\int h\,dx$, or of an energy functional. For the dipole problem, conserved quantities are known for only two specific values of n, namely the first moment, $\int_0^\infty xh\,dx$, for $n = 1$ [11, 21, 31] (which will be discussed further in section 6.1), and $\int_0^\infty gh\,dx$ for $n = 0$, where we specify possible functions $g(x,t)$ below. There is a subtle difference between these two conserved integrals. The former conserved quantity provides a unique specification of $\alpha = 1/3$ for all solutions, whereas, as will become evident in what follows, the latter (through the choice of g) provides a countably infinite set of viable first-kind similarity solutions.

Consider the linear problem, (1.1) with $n = 0$. From (2.2), $\beta = 1/4$, but α is undetermined in (2.1). Suppose that α can be determined by finding a function $g(x,t)$ such the integral of the product gh is conserved [31]. From integration by parts (with appropriate assumptions on the decay of h as $x \to \infty$), we find that

$$\frac{d}{dt}\left(\int_0^\infty gh\,dx\right) = \int_0^\infty (g_t - g_{xxxx})h\,dx - [gh_{xxx} - g_x h_{xx} - g_{xx}h_x - g_{xxx}h]\Big|_0^\infty = 0. \tag{3.1}$$

In other words, g should satisfy the backward fourth-order linear diffusion equation, $g_t - g_{xxxx} = 0$, and the boundary terms should vanish, i.e., $g(0,t) = g_x(0,t) = 0$ [21]. There are, in fact, an infinite number of suitable polynomial solutions for $g(x,t)$ given by

$$g(x,t) = \sum_{m=0}^{k} \frac{x^{4m+2}t^{k-m}}{(4m+2)!(k-m)!} \quad \text{or} \quad \sum_{m=0}^{k} \frac{x^{4m+3}t^{k-m}}{(4m+3)!(k-m)!}, \tag{3.2}$$

for $k = 0, 1, 2, 3, \ldots$. Each choice of $g(x,t)$ provided by (3.2) therefore specifies a conserved quantity for $n = 0$ via (3.2), which can then be used to identify corresponding similarity solutions. Using the relationship $x = \eta t^{1/4}$ allows (3.2) to be written as separable functions of η and t:

$$g_{2k}(x,t) = t^{k+2/4} \sum_{m=0}^{k} \frac{\eta^{4m+2}}{(4m+2)!(k-m)!},$$
$$g_{2k+1}(x,t) = t^{k+3/4} \sum_{m=0}^{k} \frac{\eta^{4m+3}}{(4m+3)!(k-m)!}, \tag{3.3}$$

where the index of g corresponds to the parity of its terms. Writing the integral in (3.2) in terms of self-similar variables and requiring it to be time-independent then yields two sequences of critical exponents for (2.1),

$$\bar{\alpha}_{2k} = k + \tfrac{3}{4}, \qquad \bar{\alpha}_{2k+1} = k + 1, \tag{3.4}$$

arising from the corresponding choices for g in (3.3). We have therefore constructed a countably infinite set of first-kind similarity solutions for $n = 0$. We note that (3.3) can then be written in the form

$$g_j(x,t) = t^{\bar{\alpha}_j - 1/4}\bar{G}_j(\eta) \quad \text{for} \quad j = 0, 1, 2, 3\ldots, \tag{3.5}$$

and the value of the conserved integral $\int_0^\infty g_j(x,t)h(x,t)\,dx = \int_0^\infty \bar{G}_j(\eta)\bar{H}(\eta)\,d\eta$, for similarity solutions (2.1).

We also note the existence of transformations connecting these critical $\bar{\alpha}$ values and the corresponding $\bar{H}(\eta)$ similarity solutions. Since, for $n = 0$, equation (1.1) is linear, if $h(x,t)$ is a solution, then its derivatives are also solutions (subject to the boundary conditions). Taking a ∂_x-derivative of the similarity solution (2.1) yields another solution of the form $h(x,t) = t^{-[\bar{\alpha}+1/4]}\bar{H}'(\eta)$, and hence the transformation

$$\{\bar{\alpha}_{2k}, \bar{H}(\eta)\} \to \{\bar{\alpha}_{2k} + \tfrac{1}{4}, \bar{H}'(\eta)\}. \tag{3.6}$$

Similarly, taking the ∂_t-derivative of (2.1) yields the transformation

$$\{\bar{\alpha}_j, \bar{H}(\eta)\} \to \{\bar{\alpha}_j + 1, -\bar{\alpha}_j \bar{H}(\eta) - \tfrac{1}{4}\eta \bar{H}'(\eta)\}. \tag{3.7}$$

Note that (3.7) can be applied to any $\bar{\alpha}$ in (3.4), $\bar{\alpha}_j \to \bar{\alpha}_{j+2}$, but (3.6) only maps even to odd modes, $\bar{\alpha}_{2k} \to \bar{\alpha}_{2k+1}$. This is due to the constraints imposed by the boundary conditions at $x = 0$ given in (1.3). These two transformations can be used to obtain the solutions for all k in terms of the first solution, with $\bar{\alpha}_0 = 3/4$.

4. Similarity solutions of the $n = 0$ linear problem. We consider subproblem (P_A) with $n = 0$, that is, the linear problem,

$$\alpha H + \tfrac{1}{4}\eta H' - H'''' = 0, \qquad 0 \le \eta \le L, \tag{4.1a}$$

$$H(0) = H'(0) = 0, \qquad H(L) = H'(L) = 0. \tag{4.1b}$$

The structure of the set of solutions for this boundary value problem is nontrivial; for any fixed value of the support, L, this is a fourth-order non–self-adjoint eigenvalue problem for the compactly-supported second-kind similarity solutions $\{\alpha, H(\eta)\}$.

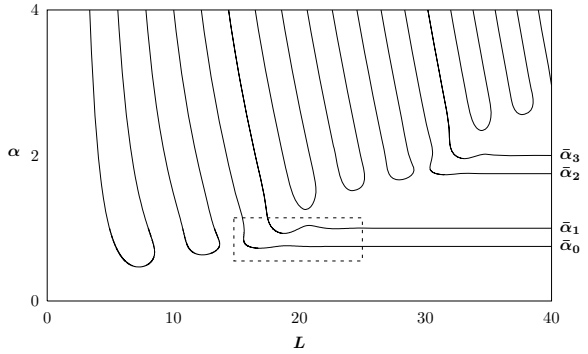

FIG. 4.1. *Branches of solution curves in the (L, α) parameter plane for the $n = 0$ (P_A) subproblem,* (4.1). *Details of the structure in the boxed region will be discussed later (see Figure* 4.5*).*

The results from a computational study for the set of nontrivial solutions of (P_A) are shown in Figure 4.1. The arrangement of the solution branches exhibits interesting regular patterns in different regions of the (L, α) parameter space. These patterns correspond to different qualitative forms of the $H(\eta)$ solution profiles (see Figure 4.3). In this section, we perform an asymptotic analysis of (4.1) in the two distinct limits, $L \to \infty$ and $\alpha \to \infty$, in an effort to understand the structure of Figure 4.1. In the process, we determine the solutions defined on the half-line that correspond to the critical $\bar{\alpha}$ values (3.4). Interestingly, these first-kind solutions are limiting cases of sequences of compactly supported second-kind solutions with increasing support (and increasing numbers of sign changes).

4.1. Limiting behavior for $L \to \infty$. The analysis of this limit problem is composed of two stages. First, we obtain analytic solutions of (4.1) on the half-line $\{\eta \ge 0\}$ in terms of an integral representation and employ steepest descents to construct the leading-order asymptotic approximation to $H(\eta)$. This approach yields the critical values (3.4) from an argument independent of section 3. Second, we consider the leading-order behavior of solutions for large but finite L; this will explain the "wavy" structure of the solution curves and the "bends" shown in Figure 4.1.

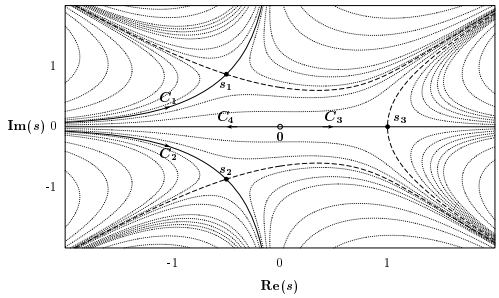

FIG. 4.2. *The steepest descent contours defining the solutions* (4.4) *in the complex plane.* s_1, s_2, s_3 *are the saddle points of* $\phi(s) = \eta s - s^4$.

4.1.1. Solutions on the half-line. We can express the solutions of (4.1) in terms of a generalized Laplace transform,

$$H(\eta) = \int_C Y(s) e^{\eta s}\, ds, \tag{4.2}$$

with (4.1a) then taking the form

$$\int_C \left[\alpha Y - \frac{1}{4}\frac{d}{ds}(sY) - s^4 Y\right] e^{\eta s}\, ds = -sY(s)e^{\eta s}\Big|_C. \tag{4.3}$$

Choosing the contour C appropriately so that the boundary terms vanish yields a first-order equation for $Y(s)$ with solution $Y(s) = s^{4\alpha-1}e^{-s^4}$. Therefore, we define four linearly independent solutions of (4.1a) as

$$\hat{H}_k(\eta) = \int_{C_k} s^{4\alpha-1} e^{-s^4} e^{\eta s}\, ds, \tag{4.4}$$

for $k = 1, 2, 3, 4$. The boundary terms in (4.3) vanish for $|s| \to \infty$ in sectors centered along the real and imaginary axes. The boundary terms in (4.3) also vanish at the origin, $s = 0$. The four contours can therefore be defined as shown in Figure 4.2. Deforming contours $C_{1,2}$ onto the real and imaginary axes, we can express these integrals more explicitly as the complex conjugate solutions

$$\hat{H}_{1,2}(\eta) = e^{\pm i\pi(4\alpha-1)} \int_0^\infty t^{4\alpha-1} e^{-t^4} e^{-\eta t}\, dt + e^{\pm i2\pi\alpha} \int_0^\infty t^{4\alpha-1} e^{-t^4} e^{\pm i\eta t}\, dt, \tag{4.5}$$

which can also be written in terms of generalized hypergeometric functions. Using steepest descents [5], we can obtain the leading-order asymptotic behaviors of these solutions as $\eta \to \infty$ from the contributions of the three saddle points of the phase function $\phi(s) = \eta s - s^4$ (that is, $\phi'(s_k) = 0$, with $s_{1,2} = (\eta/4)^{1/3} e^{\pm i2\pi/3}$ and $s_3 = (\eta/4)^{1/3}$). Solutions $\hat{H}_{1,2}(\eta)$ are exponentially decaying as $\eta \to \infty$,

$$\hat{H}_{1,2}(\eta) \sim \sqrt{\frac{\pi}{6}} \left(\frac{\eta}{4}\right)^{2(2\alpha-1)/3} e^{\pm i\pi(8\alpha-1)/3} e^{-3(\eta/4)^{4/3}[1\mp i\sqrt{3}]/2}. \tag{4.6}$$

The third solution $\hat{H}_3(\eta)$ is exponentially growing as $\eta \to \infty$ and cannot contribute to the bounded solutions of (4.1a) on $0 \le \eta < \infty$,

$$\hat{H}_3(\eta) = \int_0^\infty t^{4\alpha-1} e^{-t^4} e^{\eta t}\, dt \sim \sqrt{\frac{\pi}{6}} \left(\frac{\eta}{4}\right)^{2(2\alpha-1)/3} e^{3(\eta/4)^{4/3}}. \tag{4.7}$$

The final linearly independent solution is given by a contour from the origin to infinity along the negative real axis,

$$\hat{H}_4(\eta) = e^{i\pi(4\alpha-1)} \int_0^\infty t^{4\alpha-1} e^{-t^4} e^{-\eta t}\, dt. \tag{4.8}$$

Laplace's method applied to this integral yields the leading-order algebraic decay behavior as $\eta \to \infty$,

$$\hat{H}_4(\eta) \sim e^{-(4\alpha-1)[1-i\pi]} \sqrt{\frac{2\pi}{4\alpha-1}} \left(\frac{4\alpha-1}{\eta}\right)^{4\alpha}. \tag{4.9}$$

A local analysis of the solutions of (4.1a) at $\eta = 0$ shows that there are four regular, linearly independent solutions with power series in η^4, starting with terms $1, \eta, \eta^2$, and η^3, respectively. Noting that (4.9) is singular as $\eta \to 0$ suggests that WKB analysis would yield that the origin is a turning point of (4.1a) [5]. Because the asymptotic formulae for $\hat{H}_k(\eta)$ are not uniformly valid down to $\eta = 0$, we must apply the boundary conditions (4.1b) directly to the linear combination of the integral forms for the solutions, (4.5) and (4.8). Specifically, imposing the conditions that $H(0) = H'(0) = 0$ and that $H''(0)$ is real and positive yields

$$H(\eta) = \left(2\mathrm{Re}(e^{-i\pi(2\alpha+3/4)}\hat{H}_1(\eta)) + B(\alpha)\hat{H}_4(\eta)\right), \tag{4.10}$$

with

$$B(\alpha) = e^{-i4\pi\alpha}\left(2\cos(\pi[2\alpha+1/4]) - \sqrt{2}\right). \tag{4.11}$$

Since (4.9) decays algebraically as $\eta \to \infty$, while (4.6) decays exponentially, if $B(\alpha) \neq 0$, then $H(\eta) \sim B(\alpha)\hat{H}_4(\eta)$. However, since $|\hat{H}_4(\eta)|$ given by (4.9) is strictly positive and monotone decreasing, then only the trivial solution would satisfy the interface boundary conditions (4.1b). Hence we conclude that $B(\alpha) = 0$, corresponding to the infinite sequence of roots $\bar{\alpha}$,

$$\bar{\alpha}_{2p} = p + \tfrac{3}{4}, \qquad \bar{\alpha}_{2p+1} = p + 1, \qquad \text{for } p = 0, 1, 2, 3, \ldots. \tag{4.12}$$

Using (4.6) in (4.10), the leading-order behavior of solutions of (4.1) on the half-line for $\eta \to \infty$ is then given by

$$\bar{H}(\eta) \sim \sqrt{\frac{2\pi}{3}} \left(\frac{\eta}{4}\right)^{\frac{4}{3}(\bar{\alpha}-\frac{1}{2})} e^{-\frac{3}{2}(\eta/4)^{4/3}} \cos\left(\tfrac{3\sqrt{3}}{2}\left(\tfrac{\eta}{4}\right)^{4/3} + \tfrac{\pi}{3}[2\bar{\alpha} + \tfrac{11}{4}]\right). \tag{4.13}$$

Similarly, expanding (4.10) for $\eta \to 0$ yields the local behavior of the solution near the origin,

$$\bar{H}(\eta) \sim \frac{1 + \cos(2\pi\bar{\alpha}) - \sin(2\pi\bar{\alpha})}{2\sqrt{2}} \sum_{k=0}^{\infty} \left(\frac{\Gamma(k+\frac{5}{4})}{\Gamma(4k+3)}\eta^{4k+2} - \frac{\Gamma(k+\frac{3}{2})}{\Gamma(4k+4)}\eta^{4k+3}\right). \tag{4.14}$$

Indeed, (4.12) coincides exactly with (3.4). The form of (4.13) is suggestive of the strongly damped oscillatory solutions shown in Figure 4.3 (right). In Figure 4.4 we show the excellent agreement between (4.13) for $\bar{\alpha}_0 = 3/4$ and a numerically computed solution on the first branch of solutions at large L. Next, we improve upon this result by determining the oscillatory structure of the branches of solutions at large L as they approach the singular values, $\alpha(L) \to \bar{\alpha}$.

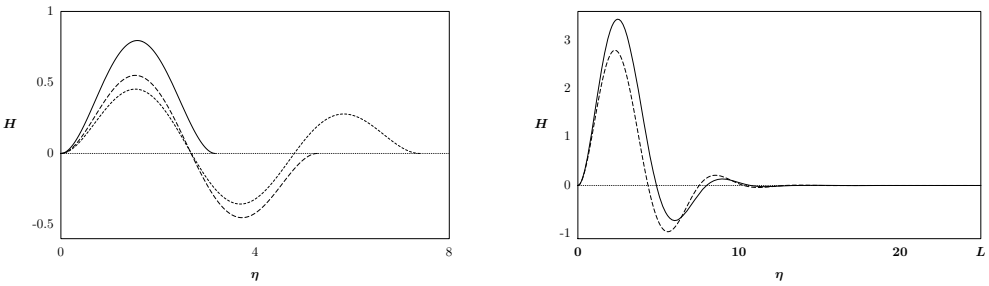

FIG. 4.3. *Examples of numerically computed solutions $H(\eta)$ of* (4.1)*: (left) weakly decaying oscillatory solutions from the first three solution branches (different L's) for fixed $\alpha = 5$, and (right) strongly damped solutions from the first two branches for fixed $L = 25$ with different values of α.*

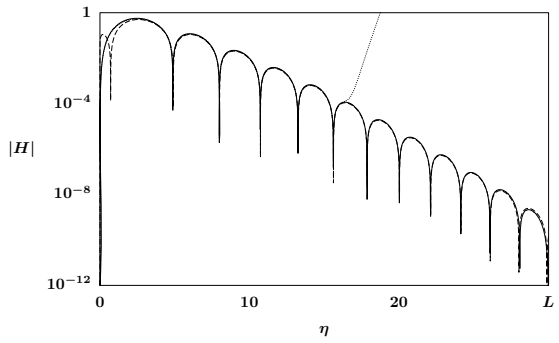

FIG. 4.4. *Log-linear plot comparing the asymptotic solution $\bar{H}(\eta)$ of the half-line problem (dashed curve for* (4.13)*, dotted curve using the first twenty terms of* (4.14)*) for $\bar{\alpha}_0 = 3/4$ with a numerically computed solution for $L = 30$ (solid curve) from the first branch of solutions of* (P_A).

4.1.2. Behavior for $L \to \infty$. Having obtained the $\bar{\alpha}$ scaling exponents for the half-line problem, we now consider how these values are approached in the limit $L \to \infty$. In what follows, we shall use $\bar{\alpha}$ to denote the values taken from (4.12); where necessary, additional subscripts will be used to distinguish special cases. We will obtain the asymptotic behavior of $\alpha(L) \sim \bar{\alpha} + \delta(L)$, with $\delta \to 0$ as $L \to \infty$.

The general solution of (4.1a) can be written as

$$H(\eta) = c_1\hat{H}_1(\eta) + c_2\hat{H}_2(\eta) + c_3\hat{H}_3(\eta) + c_4\hat{H}_4(\eta). \tag{4.15}$$

On the half-line, the contribution from $\hat{H}_3$ was omitted ($c_3 = 0$), as it was inconsistent with the required far-field behavior as $\eta \to \infty$. However, for finite L, the contribution of $\hat{H}_3$ is bounded and and must be retained in (4.15). We begin by imposing $H(0) = H'(0) = 0$ from (4.1b) on (4.15). This yields c_1, c_2, and c_4 in terms of c_3:

$$\begin{aligned} c_1 &= \tfrac{1}{4}(-1-i)\omega + ic_3\omega, \qquad c_2 = \tfrac{1}{4}(-1+i)\omega^{-1} - ic_3\omega^{-1}, \\ c_4 &= \tfrac{1}{4}(1+i)\omega - \tfrac{1}{2}\omega^2 + \tfrac{1}{4}(1-i)\omega^3 + c_3(-i\omega + \omega^2 + i\omega^3), \end{aligned} \tag{4.16}$$

where $\omega = e^{-i2\pi\alpha}$ (setting $c_3 = 0$ recovers (4.10), (4.11)). The remaining boundary conditions from (4.1b), namely $H(L) = H'(L) = 0$, are then imposed on (4.15) to yield a system of equations relating c_3, δ, L. These equations can be simplified using

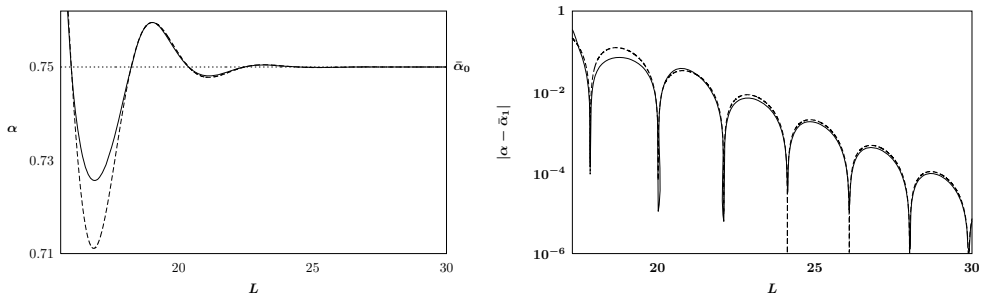

FIG. 4.5. *Details from Figure* 4.1*: comparison between the numerical results (solid curves) and the asymptotic results* $\alpha(L) = \bar{\alpha} + \delta(L)$*,* (4.18)*, (dashed curve) for large* L*. (left) for* $\bar{\alpha}_0 = 3/4$*, and (right)* $|\alpha - \bar{\alpha}|$ *compared with* $|\delta(L)|$ *for* $\bar{\alpha}_1 = 1$*.*

the asymptotics of the $\hat{H}_k(\eta)$ from section 4.1.1 and the knowledge that $c_3 \to 0$ and $\delta \to 0$ in the limit $L \to \infty$. We postulate that the relevant leading-order balance in the $H'(L) = 0$ equation is between the $\hat{H}_3'$ and $\{\hat{H}_1', \hat{H}_2'\}$ terms. These terms dominate as the process of differentiation introduces into them an additional factor of $(L/4)^{1/3}$. Working through the algebra yields the leading-order asymptotic expression for $L \to \infty$,

$$c_3 \sim -\tfrac{1}{\sqrt{2}} \exp\left(-\tfrac{9}{2}[L/4]^{4/3}\right) \sin\left(\tfrac{\pi}{3}\left(\tfrac{11}{4} - 2\bar{\alpha}\right) - \tfrac{3\sqrt{3}}{2}[L/4]^{4/3}\right). \tag{4.17}$$

To obtain a corresponding expression for $\delta(L)$ we consider the $H(L) = 0$ equation. As $\hat{H}_4(\eta)$ is inherently linked to the requirement that $B(\bar{\alpha}) = 0$ from (4.11) (when L is infinite), we expect this term to contribute in the analysis of the limit $L \to \infty$. This is indeed the case, and $\hat{H}_4(\eta)$ balances with all of the terms from (4.15). We also make the a priori assumption that c_3, as given by (4.17), decays more rapidly than δ as $L \to \infty$. Expanding complex exponentials as Taylor series, $e^{i\rho\alpha} \sim e^{i\rho\bar{\alpha}}(1 + i\rho\delta)$, and imposing $B(\bar{\alpha}) = 0$ removes the leading-order contribution from $\hat{H}_4(\eta)$, leaving the higher-order terms to balance with the remaining leading-order terms; this becomes obvious once c_3 is substituted in from (4.17), as this shows that $\hat{H}_3(\eta)$ and $\{\hat{H}_1, \hat{H}_2\}$ have the same decay rate as $L \to \infty$. The result of this analysis is an expression that can be simplified (exploiting the asymptotic ordering $c_3 \ll \delta \ll 1$ as $L \to \infty$) to give

$$\delta \sim \pm \frac{[L/\sqrt{2}]^{\frac{2}{3}(8\bar{\alpha}-1)}}{\pi\sqrt{2}\,(4\bar{\alpha}-1)^{4\bar{\alpha}-\frac{1}{2}}} \exp\left(4\bar{\alpha} - 1 - \tfrac{3}{2}[L/4]^{4/3}\right) \sin\left(\tfrac{\pi}{3}\left(\tfrac{9}{4} - 2\bar{\alpha}\right) - \tfrac{3\sqrt{3}}{2}[L/4]^{4/3}\right). \tag{4.18}$$

The positive sign is taken for $\bar{\alpha}_{\text{odd}}$, while the negative is used for $\bar{\alpha}_{\text{even}}$. It is clear that (4.18) decays more slowly than (4.17) as $L \to \infty$, thereby justifying our original assumption on the ordering $c_3 \ll \delta$; (4.18) contains an algebraically growing factor absent from (4.17) as well as having a slower exponential decay rate. Figure 4.5 shows a comparison between (4.18) and the computed solution branches from Figure 4.1.

4.2. Limiting behavior for $\alpha \to \infty$. Turning to the limit of large α, to balance the αH term in (4.1a) as $\alpha \to \infty$, the solution must have large gradients, with $d/d\eta = O(\alpha^{1/4})$. We employ a change of variables to write the solution as

$$H(\eta) = A(z), \qquad \eta = Lz, \tag{4.19}$$

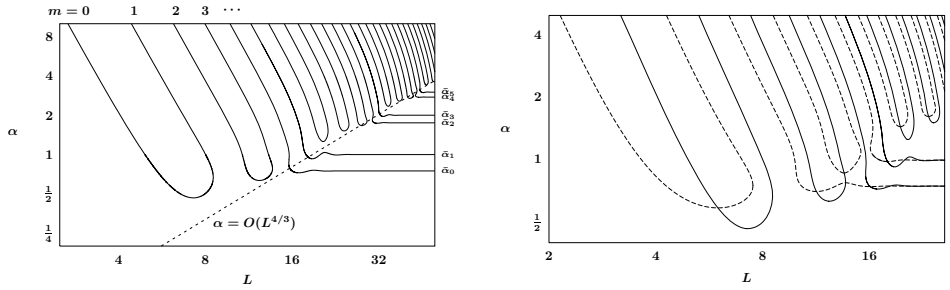

FIG. 4.6. *Log-log plots of the solution branches in the* (L, α) *parameter plane: (left) solutions of* (P_A) *with asymptotic regimes for* $L \to \infty$ *and* $\alpha \to \infty$ *connected at "bends" by* (4.26)*, and (right) solution branches for* (P_A) (4.1) *(solid curves) and* (P_B) (4.27) *(dashed curves).*

with $0 \le z \le 1$. The limit $\alpha \to \infty$ suggests that $L \sim \gamma/\alpha^{1/4}$, where γ is a positive constant. Equation (4.1a) then takes the form

$$A - \frac{1}{\gamma^4} A'''' = \frac{1}{4\alpha} z A'. \tag{4.20}$$

Writing $A(z)$ as a regular perturbation series, $A = A_0(z) + \alpha^{-1} A_1(z) + O(\alpha^{-2})$, yields the leading-order problem

$$A_0'''' - \gamma^4 A_0 = 0, \qquad A_0(0) = A_0'(0) = 0, \qquad A_0(1) = A_0'(1) = 0. \tag{4.21}$$

This is a fourth-order linear self-adjoint eigenvalue problem. Two linearly independent solutions of (4.21) that satisfy the boundary conditions at $z = 0$ are

$$A_a(z) = \cosh(\gamma z) - \cos(\gamma z), \qquad A_b(z) = e^{\gamma z} - \sin(\gamma z) - \cos(\gamma z). \tag{4.22}$$

Using these, we can write the solution satisfying the boundary condition $A_0(1) = 0$ as

$$A_0(z) = C[A_a(z)/A_a(1) - A_b(z)/A_b(1)], \tag{4.23}$$

where C is a normalization constant. Finally, imposing the remaining boundary condition, $A_0'(1) = 0$, yields the condition $\cos(\gamma)\cosh(\gamma) = 1$. This transcendental equation has an infinite number of positive solutions, and for large γ the values approach the asymptotic form for $m \to \infty$,

$$\underline{\gamma}_m \sim [m + \tfrac{3}{2}]\pi, \tag{4.24}$$

where m is a nonnegative integer ($m = 0, 1, 2, \ldots$). Consequently, for any fixed value of m, we obtain an estimate for the solutions of (P_A) as

$$H(\eta) \sim A_0(\eta/L), \qquad \underline{\alpha}_m \sim \left([m + \tfrac{3}{2}]\pi/L\right)^4, \qquad L \to 0. \tag{4.25}$$

The index m gives the number of sign changes of the nearly periodic solutions (see the $m = 0, 1, 2$ solutions in Figure 4.3(left)). As seen in (4.20), the decay of the oscillations is a weak effect in the limit $\alpha \to \infty$ as it enters at next order. In this regime, the index m parametrizes the solution branches in the (L, α) plane, as shown in Figure 4.6(left). In contrast, for $L \to \infty$ we found very different limiting behavior, $\alpha \to \bar{\alpha}_q$, (4.12).

The boundary between these two asymptotic regimes can be estimated by determining where (4.18) yields $O(1)$ corrections to α as $L \to \infty$. The dominant balance of the algebraic powers in (4.18) as $\bar{\alpha} \to \infty$ yields the estimate

$$\alpha = O(L^{4/3}), \qquad L \to \infty, \tag{4.26}$$

for the location of the overlap region where (4.12) and (4.25) must match together; see Figure 4.6(left).

4.3. The boundary value problem (P_B). Now consider the boundary value problem (P_B) for $n = 0$, where the $H'(L) = 0$ condition in (4.1) is replaced by $H'''(L) = 0$:

$$\alpha H + \tfrac{1}{4}\eta H' - H'''' = 0, \qquad 0 \le \eta \le L, \tag{4.27a}$$

$$H(0) = H'(0) = 0, \qquad H(L) = H'''(L) = 0. \tag{4.27b}$$

As in the case of (4.1), we expect this problem to produce continuous families of solutions on curves in the (L, α) parameter plane. The analysis of the solutions of (4.27) closely follows the results given above for (P_A), and so we omit most of the details. For the limit $\alpha \to \infty$, the solutions are given by

$$H(\eta) \sim A_0(\eta/L), \qquad \underline{\alpha}_m \sim ([m+1]\pi/L)^4, \qquad L \to 0, \tag{4.28}$$

for $m = 0, 1, 2, \ldots$. Note that these solution branches for (P_B) alternate in the plane with (4.25) for $\alpha \to \infty$, as shown in Figure 4.6(right). Since the results of the analysis given in section 4.1.1 are independent of the details of the boundary conditions at $\eta = L$, they also apply to the solutions of (P_B). That is, for $L \to \infty$, the solutions of (4.27) also approach $\bar{\alpha}$ given by (4.12), but the details of the oscillatory corrections (4.18) will be somewhat different (see Figure 4.6(right)).

4.4. The structure of the set of dipole similarity solutions. We now combine what has been learned about the structures of subproblems (P_A), (P_B) to obtain the similarity solutions of (P). The dipole solutions are given by the isolated intersection points of the solution branches of the two subproblems, as shown in Figure 4.6(right) and Figure 4.7.

We note that there are no intersections for $L \to 0$ and large α. This is because the branches given by (4.25) and (4.28) are uniformly spaced in this case. Recalling that (4.25) and (4.28) were obtained in the limit where (4.1a) reduced to a formally self-adjoint equation, we can attribute the more complicated structure of the solution branches for moderate values of α, L to the influence of non–self-adjoint effects. In particular, at finite α, these branches are observed either (i) to connect to an adjacent branch, corresponding to solutions with one more (or one less) sign change, to form a *loop*[1] with L bounded from above, or (ii) to extend to $L \to \infty$ by connecting through a bend to one of the branches approaching the first-kind half-line solutions specified by (4.12). In the latter case, from (4.13), the sequence of compactly supported solutions with m sign-changes approaches the half-line solutions, with the size of the support behaving like $L = O(m^{3/4})$ as $m \to \infty$.

[1]With the number of sign changes becoming degenerate, as one zero occurs at $\eta = L$ at the minimum of the loop, where $d\alpha/dL = 0$.

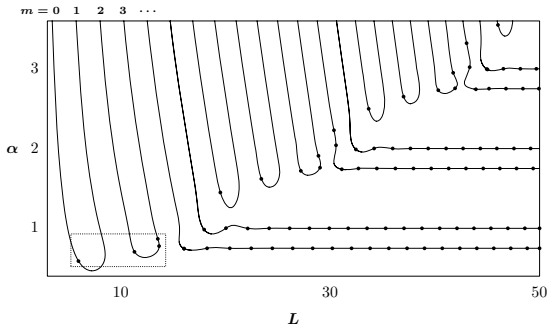

FIG. 4.7. *Dipole similarity solutions (solid dots) shown in the* (L, α) *parameter plane as determined by points on the branches of the linear subproblem* (P_A) *(curves)* (4.1) *where the flux at the interface,* $H'''(L)$*, vanishes. The four solutions enclosed in the boxed region will be considered further in section* 5.3.

In the loop case, we can show that there must be at least one dipole solution on each loop. Consider a loop for (P_A) with solutions given by (4.25) for $L \to 0$. Depending on m, the flux at the interface for small L is either positive or negative along a branch, with

$$H'''(L) \sim \tfrac{1}{2}(-1)^m e^{-(m+\frac{3}{2})\pi}, \qquad L \to 0. \tag{4.29}$$

Since the flux is continuous on a (P_A) loop and the sign of the flux on consecutive branches is opposite, there must be at least one zero of the flux on each loop, and the result follows. Figure 4.7 shows the dipole solutions marked as solid dots on the (P_A) solution branches. Recalling the interpretation of the index m as the number of sign changes of $H(\eta)$, this figure indicates one solution for $m = 0$ (the unique nonnegative solution), no solution for $m = 1$, one solution for $m = 2$, two solutions for $m = 3$, and so on.[2] In contrast to this partially ordered set of solutions, for self-adjoint problems, we would expect exactly one solution for each value of m. The nonexistence or nonuniqueness of solutions with m sign changes is an interesting result of the non–self-adjoint structure of this problem.

5. Limiting behavior for $n \to 0$. Having completely analyzed the linear problem, we build upon it to describe the nonlinear problem for small n. Similar to the "slightly nonlinear" limit used in [22], we express the nonlinear mobility coefficient in (2.3a) as

$$|H|^n = e^{n \ln |H|} \sim 1 + n \ln |H| + O(n^2), \tag{5.1}$$

this expansion being valid everywhere that $|H| \gg e^{-1/n}$, that is, everywhere except exponentially narrow boundary layers at zeros of the solution. Careful analysis is required to fully resolve the local structure there [37], but this will not be crucial in the current problem. Substituting (5.1) into (4.1a) yields the problem

$$\alpha H + \tfrac{1}{4}\eta H' - H'''' = n\left[\tfrac{1}{4}\alpha\eta H' + (\ln|H|H''')'\right] + O(n^2). \tag{5.2}$$

We consider two limits of this problem to describe the influence of weak nonlinearity on the solutions for $n \to 0$.

[2] Observe that there is one solution for $m = 4$, two for $m = 5$, and three for $m = 6$. We will see that the numbers of solutions also depends on n.

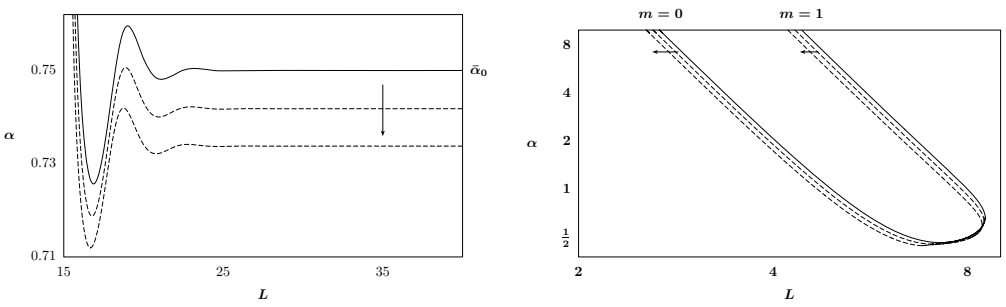

FIG. 5.1. *Shifts of the solution curves in the* (L, α) *plane for* $n \to 0$*: (left) the shift to the* $\bar{\alpha}$ *values for* $n \to 0$*, accurately predicted by* (5.7)*; (right) the first solution loop for* $n = 0$ *(solid curve) and the corresponding curve for* $n = 0.1, 0.2$ *(dashed curves). The shift of the curve for large* α *is accurately predicted by* (5.12).

5.1. Weakly nonlinear solutions on the half-line. Building on the results from section 4.1.1, we seek solutions for the nonlinear problem on the half-line in the form of a regular expansion,

$$H(\eta) = H_0(\eta) + nH_1(\eta) + O(n^2), \qquad \alpha = \alpha_0 + n\alpha_1 + O(n^2), \tag{5.3}$$

where the leading-order solution is $H_0 = \bar{H}(\eta)$, $\alpha_0 = \bar{\alpha}$, given by (4.13) and (4.12). Then, at next order, (5.2) yields

$$\alpha_0 H_1 + \tfrac{1}{4}\eta H_1' - H_1'''' = \tfrac{1}{4}\alpha_0 \eta H_0' + (\ln|H_0| H_0''')' - \alpha_1 H_0. \tag{5.4}$$

We will focus on determining the eigenvalue correction, α_1. To this end, we must enforce the Fredholm alternative on the right-hand side of (5.4) to yield a solvability condition. That is, the inner product of the right-hand side with the solution of the homogeneous adjoint problem must vanish. The linear adjoint problem is

$$\alpha_0 \bar{G} - \tfrac{1}{4}(\eta \bar{G}\,)' - \bar{G}'''' = 0, \qquad \bar{G}(0) = \bar{G}'(0) = 0. \tag{5.5}$$

Note that we have already made use of the solutions of the adjoint problem in section 3 to compute the critical $\bar{\alpha}$ values (3.4). From (3.3), the solutions are the polynomials

$$\{(\bar{G}(\eta); \bar{\alpha})\} = \{(\eta^2; \tfrac{3}{4}), (\eta^3; 1), (\eta^2 + \tfrac{1}{360}\eta^6; \tfrac{7}{4}), \ldots\}. \tag{5.6}$$

Hence, for a given half-line solution, the correction to the $n = 0$ value of $\bar{\alpha}$ is

$$\alpha_1 = -\left(\tfrac{1}{4}\bar{\alpha}\int_0^\infty (\eta\bar{G}\,)'\bar{H}\,d\eta + \int_0^\infty \bar{G}' \ln|\bar{H}|\bar{H}'''\,d\eta\right) \Big/ \int_0^\infty \bar{G}\bar{H}\,d\eta. \tag{5.7}$$

Figure 5.1(left) illustrates the predicted uniform downward shift to the $\bar{\alpha}_0 = \frac{3}{4}$ branch for $n = 0.01, 0.02$ with $\alpha_1 \approx -0.82$.

5.2. Weakly nonlinear solutions for $L \to 0$. Recalling the results of section 4.2, we consider this case in terms of the limit $\alpha \to \infty$ with $L = \gamma/\alpha^{1/4}$ and

$$H(\eta) = A(z), \qquad \eta = \gamma\alpha^{-1/4} z, \tag{5.8}$$

with $0 \le z \le 1$. We then expand the solution of (5.2) as a perturbation series for $n \to 0$,

$$A(z) = A_0(z) + nA_1(z) + O(n^2), \qquad \gamma = \gamma_0 + n\gamma_1 + O(n^2). \tag{5.9}$$

For $\alpha \to \infty$, at leading order we recover (4.21) with solution (4.23) and $\gamma_0 = \underline{\gamma}$, (4.24). Similarly, at next order in n,

$$A_1'''' - \gamma_0^4 A_1 = 4\gamma_1\gamma_0^3 A_0 - \tfrac{1}{4}\gamma_0^4 z A_0' - (\ln|A_0|A_0''')', \tag{5.10}$$

where we have simplified the right-hand side using (4.21).

This problem is self-adjoint, and the Fredholm alternative provides a solvability condition to determine γ_1 from the integral of the product of the right-hand side of (5.10) with $A_0(z)$,

$$\gamma_1 = -\frac{\gamma_0}{32} - \frac{1}{4\gamma_0^3}\left(\int_0^1 A_0' \ln|A_0|A_0'''\,dz \Big/ \int_0^1 A_0^2\,dz\right), \tag{5.11}$$

where we have used $\int_0^1 zAA'\,dz = -\frac{1}{2}\int_0^1 A^2\,dz$. Consequently, the asymptotic form of the eigenvalue curves for the joint limit $L \to 0$ and $n \to 0$ is given by

$$\underline{\alpha} \sim \left([\gamma_0 + n\gamma_1]/L\right)^4. \tag{5.12}$$

This analytical prediction agrees very closely with the numerically computed curves for $m = 0$ ($\gamma_1 \approx -1.04$) and $m = 1$ ($\gamma_1 \approx -1.81$), as shown in Figure 5.1(right). We note that $\gamma_1 < 0$ for all m, and hence all of the curves translate to the left as n increases.

5.3. Computing the solutions of the nonlinear problem. Having established the properties of the similarity solutions for $n = 0$ in section 4 and observing the continuous dependence of the solutions on n for $n \to 0$, we now seek to cast these results in a form that will be convenient for the numerical study of the nonlinear problem. Rescaling the similarity variable so that the solution is defined on a fixed domain, $0 \le z \le 1$,

$$H(\eta) = \mathcal{H}(z), \qquad \eta = Lz, \tag{5.13}$$

the boundary value problem (P_A) then takes the form

$$L^4[\alpha\mathcal{H} + \tfrac{1}{4}(1 - n\alpha)z\mathcal{H}'] - (|\mathcal{H}|^n\mathcal{H}''')' = 0, \tag{5.14a}$$

$$\mathcal{H}(0) = \mathcal{H}'(0) = 0, \qquad \mathcal{H}(1) = \mathcal{H}'(1) = 0, \qquad \int_0^1 \mathcal{H}^2\,dz = 1. \tag{5.14b}$$

Here, the computational domain, $0 \le z \le 1$, is fixed, while L and α both appear in (5.14a) as eigenvalues. (The complete problem, (5.14) with $|\mathcal{H}|^n\mathcal{H}'''(1) = 0$, could be referred to as a nonlinear *double-eigenvalue problem* [24].) We solve this system numerically using Newton–Raphson relaxation for a finite-difference discretization of the problem. Continuation methods [30] are used to trace the solution branches of (5.14) and to obtain the dependence of one parameter on the other, say $\mathcal{H}(z)$ and L in terms of α (and, inherently, n). The dipole similarity solutions are then found at (L, α) values where the no-flux condition at $z = 1$ is also satisfied. A plot of the decay exponent α as a function of n for the first few dipole solutions is shown in Figure 5.2. As expected from (5.3) and (5.12), the figure shows that the $n = 0$ solutions can be smoothly continued to nonzero n over finite ranges. Note the strong influence of n as the two branches of solutions with three zeroes coalesce in a saddle-node-type bifurcation at a negative value of $n \approx -0.056$.

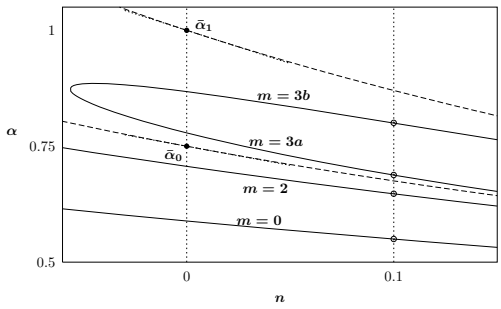

FIG. 5.2. *Numerically computed values of α as a function of n for the first four compactly supported dipole solutions (highlighted in Figure 4.7 for $n = 0$) (solid curves), along with $\bar{\alpha}(n)$ for the halfline solutions (dashed curves), as predicted by $\alpha \sim \bar{\alpha} + n\alpha_1$ (5.7) (dotted lines). Dipole solutions are denoted by their numbers of zeros, m, with two solutions for $m = 3$ labeled 3a and 3b.*

There are various approaches to handling the degeneracy of (1.1) when performing numerical computations of solutions with sign-changes. The numerical scheme employed in this paper involved the introduction of a regularization to smooth the absolute-value function,

$$|\mathcal{H}|^n \to (\mathcal{H}^2 + \epsilon^2)^{n/2}, \tag{5.15}$$

for a small regularization parameter, $\epsilon \ll 1$. Additionally, local analysis for $z \to 0$ and $z \to 1$ carried out in [11, 21] was used to appropriately implement the boundary conditions (5.14b) for different ranges of n.

6. Numerical simulations of the thin-film evolution equation (1.1). Up to this point, we have analyzed the dipole similarity solutions as solutions of the boundary value problem (2.3). We now take the opportunity to examine the role of these solutions in terms of the dynamics of the nonlinear evolution equation (1.1).

Making use of the regularization (5.15) with $\epsilon = 10^{-4}$, we consider general numerical solutions of the thin-film equation (1.1) via the regularized evolution equation

$$\partial_t h = -\partial_x([h^2 + \epsilon^2]^{n/2} h_{xxx}) \tag{6.1}$$

on a finite domain, $0 \le x \le 40$, with boundary conditions $h = h_x = 0$ at both boundaries. Note that this regularization differs from the nonnegativity-preserving form suggested by Bernis and Friedman [10], frequently used in numerical studies of (1.1) [18, 19], as we wish to explore what happens when the solutions are allowed to change sign.

We illustrate different aspects of the dipole solutions within the dynamics of the thin film equation in the following two numerical simulations, first for $n = 1$ and then for n small ($n = 0.1$).

6.1. Dynamics for $n = 1$. We consider (6.1) with $n = 1$ and nonnegative compactly supported initial data, $h(x, 0) = h_0(x) \equiv (1 - [x - 5]^2)^2$ for $4 \le x \le 6$, and $h(x, 0) \equiv 0$ elsewhere (see Figure 6.1(upper left)). For initial value problems for the thin-film equation with $n > 0$, regions of support are known to vary in time with finite speed of propagation. Hence, until the support has grown to include the boundaries $x = 0$ and $x = 40$, those respective boundary conditions will not influence the evolution of the solution. Indeed, this leads to several stages of *intermediate dynamics* [2], as follow:

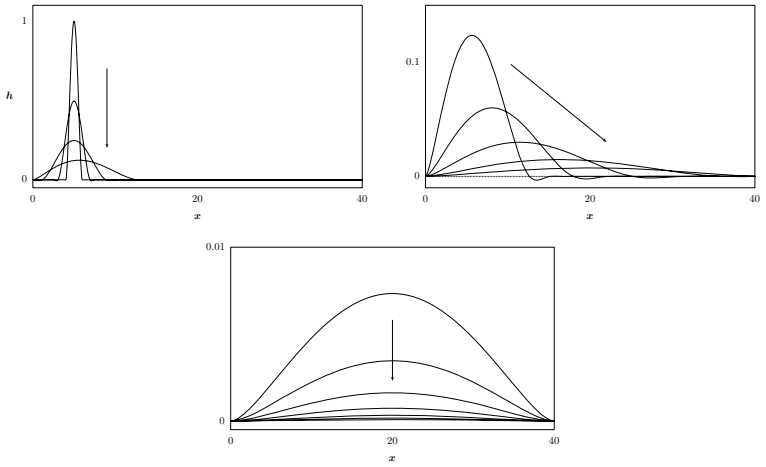

FIG. 6.1. *Profiles at various times from a numerical simulation of* (1.1) *with* $n = 1$*, illustrating the three stages of self-similar intermediate dynamics: (upper left) pure spreading of the Cauchy-type solution, (upper right) mixed spreading/draining in the dipole problem, (bottom) pure draining on the bounded domain.*

1. *Source-type evolution for the Cauchy problem.* For short times, before either boundary is within the region of support, the solution is effectively expanding within a homogeneous region of unlimited extent, and hence will take the form of the source-type similarity solution of the Cauchy problem [9, 13, 14]. This is a first-kind similarity solution with $\alpha = \beta = 1/5$ for $n = 1$ and $h(x,t) = \tau^{-\alpha} H(\eta)$, with

$$H(\eta) = \left(1 - \eta^2\right)^2 \quad \text{for } |\eta| \le 1, \qquad \eta = (x - x_0)/\tau^{1/5}. \tag{6.2}$$

   This solution conserves both $\int h\,dx$ and $\int xh\,dx$. Note that for convenience our initial data was selected to be exactly of this form, with $x_0 = 5$ and the scaled time variable $\tau = 120t + 1$. The similarity solution is stable and acts as an attractor for more general initial data [14]. This solution expands in a symmetric manner with respect to x_0, and we refer to this dynamical regime as being *pure-spreading*. This regime ends when the support extends to the $x = 0$ near-boundary (see Figure 6.1(upper left)).
2. *Mixed "spreading/draining" behavior for the dipole problem.* Once the $x = 0$ boundary has been reached, the boundary conditions dictate that $\int h\,dx$ is no longer conserved. Meanwhile, the right-interface for the region of support continues to expand into the domain; this suggests a transition to the dipole problem, which can also be described as *mixed spreading/draining*. A simple calculation for the first moment for $n > 0$ shows that

$$\frac{d}{dt}\left(\int_0^\infty xh\,dx\right) = \frac{1}{2}n(n-1)\int_0^\infty |h|^{n-2} h_x^3\,dx, \tag{6.3}$$

   subject to contributions from boundary terms vanishing. So, for $n = 1$ the first moment is a conserved quantity (see [11]). Consequently, we can determine $\alpha = 1/3$, $\beta = 1/6$ for this special case, and the dipole similarity solution is of the first kind. This regime ends when the support extends to the $x = 40$ far-boundary (see Figure 6.1(upper right)).

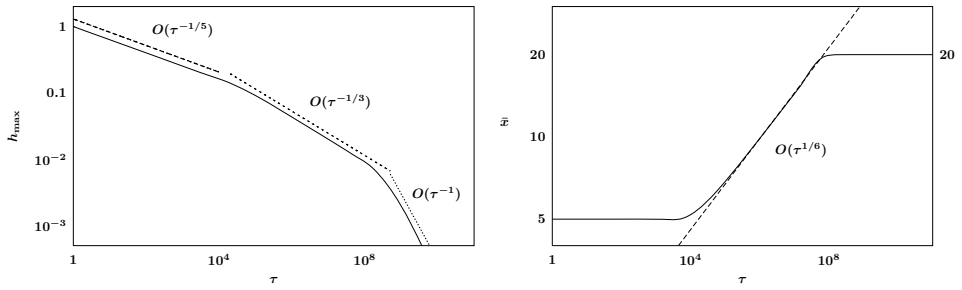

FIG. 6.2. *Graphs illustrating changes in the self-similar regimes for $n = 1$: (left) the solid curve is $h_{\max}(t)$ from the numerical computation, while the dashed lines have slopes $-1/5, -1/3$, and -1 corresponding to analytic predictions for self-similar pure spreading, mixed spreading/draining, and pure draining respectively; (right) similarly, the computed and predicted values of $\bar{x}$. The appropriately scaled/shifted time-variable here is $\tau = 120t + 1$.*

3. *"Pure draining" behavior on the finite domain.* Once the region of support has extended to the entire domain, the behavior of the solution will be controlled by the boundary conditions at both edges. The solution approaches a separable form

$$h(x,t) = \tau^{-1} H(x - 20), \tag{6.4}$$

and hence $\alpha = 1$ and $\beta = 0$, as studied in [22, 38]; the symmetry of (6.4) is apparent in Figure 6.1(bottom).

We note that the transitions between stages that we are outlining also occur for the analogous porous medium problem, where the origin of the dipole solution is usually justified by other means (see, for instance, [2]); the equivalent analysis for the one-dimensional heat equation can be found in [1].

Some comments on the influence of the regularization in (6.1) are necessary. The solutions of this modified PDE can be hoped to agree with results from the thin-film equation everywhere that $|h| \gg \epsilon$. The regularization is nonnegligible for $|h| \lesssim \epsilon$, where (6.1) effectively becomes a rescaled version of the $n = 0$ linear problem. This can make accurate statements about the edge of the support and details of the solutions at sign changes obtained from the numerical simulations open to question. Indeed, the solutions in Figure 6.1(upper left) and (upper right) do become negative (see also Figure 1.1), and interestingly the dipole solution appears to have only a single sign change ($m = 1$) (a solution not present for the $n \to 0$ limit). Furthermore, for longer times (not shown), when the solution everywhere satisfies $|h| \lesssim \epsilon$, the evolution will be dominated by the regularization to yield a linear "draining" behavior (see section 5.1 of [22]). To circumvent these difficulties, we use two measures that are not sensitive to the regularization to establish the agreement of the simulations with the analytic predictions given above: (i) the maximum of the solution, $h_{\max}(t) = \max_x |h(x,t)|$, and (ii) the quantity $\bar{x} = \int xh\,dx / \int h\,dx$ (see Figure 6.2). The slope of $h_{\max}(t)$ on a log-log graph gives the decay exponent α; the position of the maximum, $x_{\max}(t)$, would similarly yield the spreading exponent β.

While the special property of the $n = 1$ case, provided by the conservation law (6.3), gives an analytic prediction for the value of α, this means that all similarity solutions for $n = 1$ of the form (2.1) are first-kind and will have $\alpha = 1/3$. Hence plots of $h_{\max}(t)$ cannot be used to distinguish between different similarity solutions that may coexist. Our numerical calculations for (2.3) suggest that at least two solutions

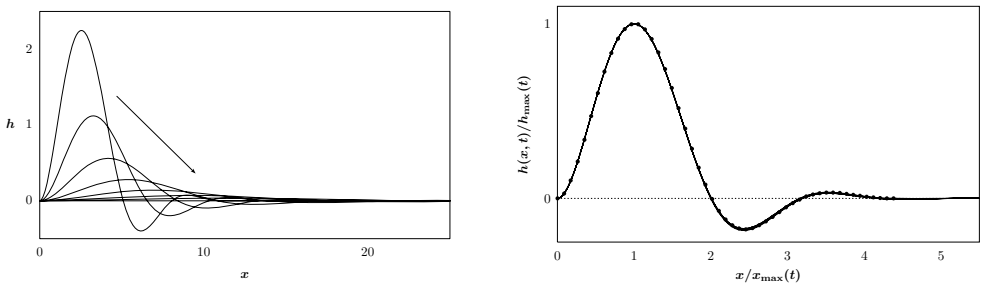

FIG. 6.3. *(left) Solution profiles for* (6.1) *with* $n = 0.1$ *starting from the* $m = 2$ *dipole profile* $H(x)$*; (right) the same profiles rescaled by* $x_{\max}(t)$*,* $h_{\max}(t)$ *(seven almost indistinguishable solid curves) and compared with the compactly supported similarity solution (dots).*

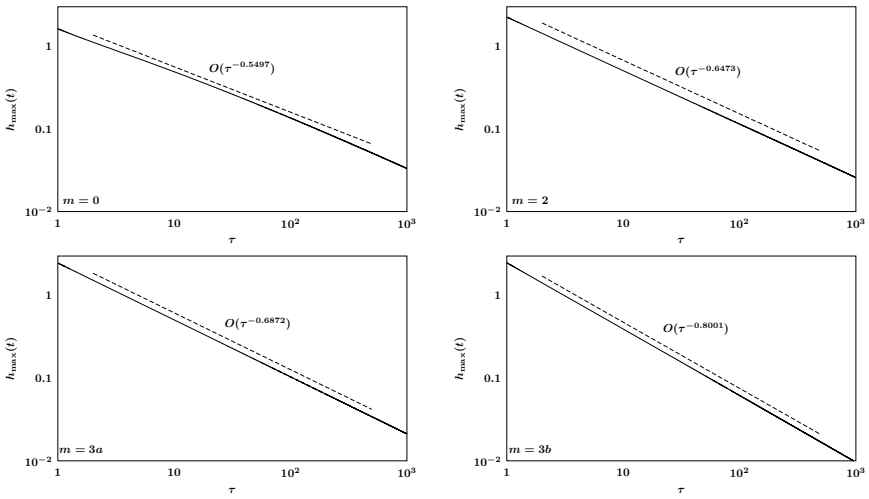

FIG. 6.4. *Log-log plots of* $h_{\max}(t)$ *versus* $\tau = 1 + t$ *for numerical solutions of* (6.1) *with* $n = 0.1$ *and initial conditions given by self-similar profiles* $H(x)$*. Comparisons are shown with the expected decay rates (dashed lines) for the respective dipole similarity solutions:* $m = 0\,(\alpha \approx 0.5497)$*,* $m = 2\,(\alpha \approx 0.6473)$ *(see Figure* 6.3*),* $m = 3a\,(\alpha \approx 0.6872)$*,* $m = 3b\,(\alpha \approx 0.8001)$*.*

($m = 0$ (positive), and $m = 1$ (single sign change)), and maybe more, exist at $n = 1$; the stability of these solutions is still an open problem.

We now turn to numerical simulations for $n \neq 1$, where $h_{\max}(t)$ can be used to provide numerical evidence for the coexistence of multiple stable similarity solutions.

6.2. Coexistence of multiple stable dipole solutions. We consider numerical simulations of (6.1) with $n = 0.1$ on a sufficiently large domain. For this value of n we have predictions for the dipole similarity solutions (see Figure 5.2). We use the compactly supported numerical solutions of (2.3) as the initial conditions for the simulations of (1.1), $h_0(x) = H(x)$ for $0 \le x \le L$, and $h_0 \equiv 0$ for $x > L$, i.e., at $t = 0$, $x = \eta$ with $\tau = t + 1$. We carry out four such computations for evolutions starting from the similarity profile for $m = 0$ (the unique nonnegative solution), $m = 2$ (the unique two-sign-change solution), and the two similarity profiles with three sign changes (called $m = 3a$ and $m = 3b$ in Figure 5.2). Figure 6.3 shows the evolution starting from the $m = 2$ profile—the regularization appears to have negligible influence on the collapse of the rescaled profiles onto the similarity profile. In fact, Figure 6.4 shows that in all

four of the simulations, the evolution follows the predicted self-similar scalings found from the dipole similarity solutions. The conclusion suggested by these simulations is that all of these similarity solutions are observable in the solution dynamics of (1.1) and are stable with respect to the perturbations introduced by the numerics and the regularization.

The sense of their "stability" needs to be qualified slightly. The compactly supported solutions of the similarity solution problem (2.3) do not precisely satisfy (6.1) on the entire domain due to lack of higher order smoothness at the moving interface. In fact, the dynamics will include very slow-scale evolution towards one of the analytic similarity solutions $\bar{H}(\eta)$ defined on the entire half-line for very long times. This drift is slightly visible in the plot for $m = 0$ in Figure 6.4 but has negligible influence for the higher-order solutions, where the discontinuities at the moving interface are slightly less pronounced. This behavior is generic for $n = 0$ and n small with the regularization (6.1).

7. Discussion. The (L, α) pair for a dipole solution provides information on both the decay rate of solutions (via (2.1)) and the speed of the interface, i.e., $\ell'(t) \sim \beta L \tau^{\beta-1}$. The (L, α) parameter plane for $n = 0$, illustrated in Figure 4.7, indicates the complexity associated with finding second-kind similarity solutions for (1.1). For a given value of n, multiple second-kind similarity solutions can be constructed, and there is no complete natural ordering for the solutions in terms of the number of sign-changes that they possess. For example, when $n = 0$, somewhat surprisingly, no dipole solutions with a single sign-change exist, while it is possible to find two solutions that change sign three times. This is consistent with the absence of a theory for higher-order problems analogous to the Sturm–Louiville theory, which yields a well-ordered set of solutions for second-order problems.

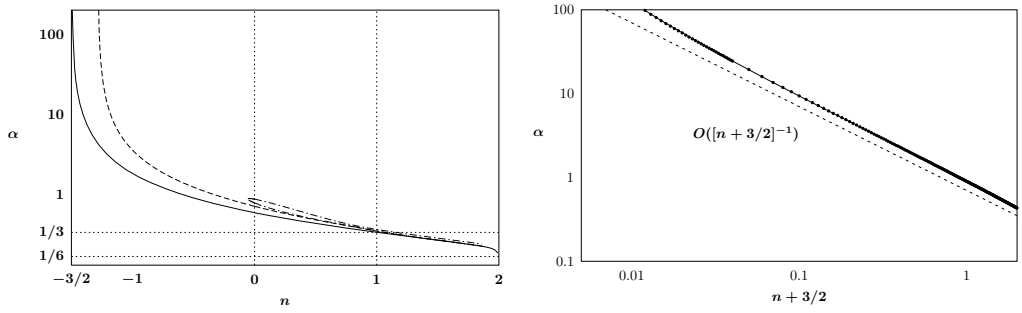

FIG. 7.1. *(left) The decay exponent α for the first few dipole similarity solutions, calculated from* (5.14) *over a wide range of n values. The positive ($m = 0$) solution exists on $-3/2 < n < 2$, while the solutions with sign-changes exist on subsets of this interval. (right) A log-log plot of numerically calculated values for the $m = 0$ solution (solid curve with dots), illustrating the approach to $\alpha \sim O([n + 3/2]^{-1}) \to \infty$ (dashed curve) as $n \to -3/2^+$.*

Figure 7.1 shows the n-dependence of the decay exponent for the dipole solutions over a wider range of n. One of the most important features of the figure is that as $n \to -3/2^+$ we lose existence of not only the sign-change solutions, but also the nonnegative dipole solution. Previous studies of mass-conserving similarity solutions and separable solutions, of which (6.2) and (6.4) are respectively representative, have shown that the former is valid down to $n = -4$, while the latter is applicable as long as $n > 0$. As the boundary conditions on the dipole solutions effectively combine parts of both problems, it is expected that $-4 < n_c < 0$, where n_c indicates the value

of n below which dipole solutions of the form (2.1) no longer exist; the work [11] has shown that, for large enough negative n, finite time extinction dipole solutions can be expected. The numerical simulations are extremely compelling in suggesting that $n_c = -3/2$ (see Figure 7.1(right)), although we do not have any analytical verification of this hypothesis. The effect of the global conservation law for $n = 1$, (6.3), is also clearly seen in Figure 7.1. The self-similar dipole solutions, by definition, satisfy (6.3) and so have α-exponents which should all approach $\alpha = 1/3$ as $n \to 1$. The small discrepancies are a consequence of errors introduced into the simulations by the regularization (6.1).

We have shown, when $n = 0$, that there are critical values of α (see (3.4)) for which first-kind similarity solutions exist featuring an infinite number of sign-changes. These solutions necessarily have $L = \infty$, and the results (4.17) and (4.18) yield that for each first-kind similarity solution there exists a compactly supported, second-kind solution where $|\alpha - \bar{\alpha}| < \delta$ for arbitrary δ; the size of the support $L \to \infty$ as $\delta \to 0$. This can lead to difficulties distinguishing sensitive details of the dynamics of solutions.

EXACT ARTIFICIAL BOUNDARY CONDITIONS FOR CONTINUUM AND DISCRETE ELASTICITY*

SUNMI LEE†, RUSSEL E. CAFLISCH‡, AND YOUNG-JU LEE†

Abstract. For the continuum and discrete elastic equations, we derive exact artificial boundary conditions (ABCs), often referred to as transparent boundary conditions, that can be applied at a planar interface below which there are no forces. Solution of the elasticity equations can then be performed using this interface as an artificial boundary, often with greatly reduced computational effort, but without loss of accuracy. A general solvability requirement is presented for the existence of an artificial boundary operator for discrete systems (such as discrete elasticity) on an unbounded (semi-infinite) domain. The solvability requirement is validated by introducing a sum-of-exponentials ansatz for the solution below the artificial boundary. We also derive a new expression for the total energy for the system, involving only the region above the artificial boundary. Numerical examples are provided to confirm and illustrate the accuracy and effectiveness of the results.

Key words. elasticity, discrete elasticity, artificial boundary conditions, transparent boundary conditions, atomistic strain

1. Introduction.

Many of the boundary value problems arising in applied mathematics are formulated on unbounded domains. It is in general a nontrivial task to solve such problems numerically [6], since the numerical solution naturally requires boundary conditions at a finite depth in the body.

The main motivation of the present work comes from the numerical simulation of strain fields in semi-infinite domains. For the strain equations, the use of a physical boundary condition, such as the zero displacement field at a certain depth, has been a common practice [21]. On the other hand, due to the long range of elastic interactions, the zero boundary condition must be imposed at considerable depth in order to accurately compute the strain field [4], which entails large computational cost.

The purpose of this paper is to derive exact *artificial boundary conditions* (ABCs) such that the solution on the (bounded) computational domain coincides with the exact solution on the unbounded domain. Such exact artificial boundary conditions are oftentimes referred to as *transparent boundary conditions* (TBCs) [6].

There have been various works on ABCs for a wide range of problems. For example, certain ABCs for the Poisson and Helmholtz equations on infinite domains are investigated in [1] using domain decomposition and Fourier techniques. For general elliptic problems, approximate ABCs and error estimates are performed within the finite element framework in [3]. Boundary element methods for homogeneous elasto-

static and elastodynamic cases, linear elastostatic problems, time dependent heat and wave equations, and electromagnetic scattering problems are also treated in an exact manner using the Dirichlet to Neumann boundary condition in [2, 7, 8, 9].

For the elasticity problem, several local and nonlocal artificial boundary conditions are provided in terms of the finite element formulation in [12, 13, 14]. For a discrete elastic strain model for an epitaxial thin film, ABCs were derived recently by Russo and Smereka [20] using a formulation that is somewhat different from our model.

In the present work, we perform an analysis for the equations of both continuum and discrete elastic models. The discrete elastic equations correspond to an atomistic strain model introduced in the recent work by Schindler et al. [21]. Although full details are provided only for a discrete strain model, a general solvability requirement is formulated, which results in the well-posedness or the solvability of the system in an infinite domain. This work is a discrete analogue of the work by Hagstrom and Keller [11]. The solvability requirement is then validated by analyzing the solution on the exterior domain using a sum-of-exponentials ansatz. This framework, on the one hand, leads us to derive the abstract ABC operator in the form of a Schur complement operator and, on the other hand, guides the construction of the explicit ABC operator for actual implementations. Thanks to the ABC operator, the force balance equation that needs to be solved in the infinite domain can be posed as a reduced equation on the bounded domain, whose solution has been shown to coincide with the exact solution on the full (unbounded) domain. In addition, a new formula is derived for the total elastic energy of the system, involving only the solution above the artificial boundary. The latter is particularly important for practical applications such as thin epitaxial film growth simulations.

The rest of the paper is structured as follows. In section 2, we introduce some preliminaries and notation to ease the presentation. The ABCs, total energy formula, and variational principle for continuum elasticity are derived in section 3. In section 4, we briefly review the discrete elastic strain model and introduce the general solvability requirement, present an abstract form of the ABC operator, and derive explicit ABCs for a specific discrete strain model. The total energy formula and the variational principle for the discrete strain model are also presented. Several illustrative numerical results are provided in section 5. Conclusions are discussed in section 6. Some details are saved for the appendix.

2. Preliminaries. Suppose that the domain Ω is a half-infinite body, e.g., $\Omega = \{(x, y, z) \in \mathbb{R}^3 : z < h(x, y)\}$ for $h : \mathbb{R}^2 \mapsto \mathbb{R}$ being a bounded function. See Figure 2.1 for a schematic description. The interface Γ_2 on which the artificial boundary will be imposed is illustrated in Figure 2.1. For both the continuum and discrete problems, the domain Ω is divided into a finite part Ω_1 and a semi-infinite part (an exterior domain) $\Omega_2 = \Omega \backslash \Omega_1$. The requirement on the choice of Ω_2 is that its boundary Γ_2 is planar and normal to the depth variable and that there are no external forces in Ω_2. For the boundary condition for both continuum and discrete elasticity equations, we assume that the periodic conditions are imposed in x- and y-directions (lateral directions) and that the Neumann condition (i.e., the variational principle with no constraint at the boundary) is imposed on the top layer Γ_1 unless explicitly stated otherwise. Use of the Neumann condition is only for simplicity and to ensure that the problem is well-posed; it does not influence the resulting ABCs.

We use boldface lower case letters for vectors in $\mathbb{R}^d$ with $d = 2$ or 3 and boldface capital letters for symmetric tensors or square matrices. The differential operator ∂_k denotes the partial derivative with respect to the kth coordinate variable, i.e., $\partial/\partial x_k$,

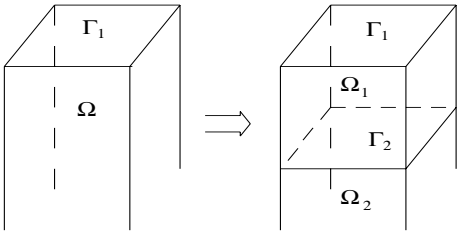

FIG. 2.1. *The domain decomposition: An artificial boundary* Γ_2 *(the horizontal plane) divides* Ω *into* Ω_1 *and* Ω_2. Γ_1 *is the top boundary (surface) of* Ω.

and the operator $\nabla\cdot$ is the standard *divergence* operator defined through

$$\nabla\cdot = (\partial/\partial x, \partial/\partial y)\cdot \qquad \text{for } d = 2,$$
$$\nabla\cdot = (\partial/\partial x, \partial/\partial y, \partial/\partial z)\cdot \qquad \text{for } d = 3.$$

The notation ∇ denotes the usual *gradient* operator for $d = 2$ and $d = 3$ given, respectively, as

$$\nabla = \begin{pmatrix} \partial/\partial x \\ \partial/\partial y \end{pmatrix}, \quad \nabla = \begin{pmatrix} \partial/\partial x \\ \partial/\partial y \\ \partial/\partial z \end{pmatrix},$$

and Δ is the *Laplace* operator $\nabla\cdot\nabla$.

For two vectors $\mathbf{u}$ and $\mathbf{v}$, $\mathbf{u}\cdot\mathbf{v}$ is the dot product; for a vector $\mathbf{v} = (v_k)_{k=1,\dots,d}$ and a tensor $\mathbf{N} = (N_{kl})_{k,l=1,\dots,d}$, $\mathbf{v}\cdot\mathbf{N} = \sum_{k=1}^{d} v_k N_{k\ell}$. The magnitude of a vector $\mathbf{u}$ will be denoted by $|\mathbf{u}| = (\mathbf{u}\cdot\mathbf{u})^{1/2}$.

Although the letters i, j, k are used for indices, we shall also use $\imath$ to denote the imaginary unit $\sqrt{-1}$, and the complex conjugate of a complex number v shall be denoted by $\overline{v}$. Also, for the matrix $\mathbf{N}$, $\mathbf{N}^H$ and $\mathbf{N}^T$ denote the complex conjugate transpose and the real transpose of $\mathbf{N}$, respectively. Finally, we shall use χ to denote the usual characteristic function that is defined as

$$\chi(x) = \begin{cases} 1 & \text{for } x \in \Omega_1, \\ 0 & \text{for } x \notin \Omega_1. \end{cases} \tag{2.1}$$

Some other notation will be introduced in each section as necessary.

3. The ABCs for continuum elasticity. In this section, we review the continuum elastic equations from an energetic viewpoint. We then derive the artificial boundary (or ABC) operator $\mathcal{A}$, as well as a new expression for the total energy and a formulation of the force balance equations depending on only the displacement on and above the interface Γ_2 on which the artificial boundary condition is given.

3.1. Continuum elasticity. Continuum elasticity is formulated in terms of a displacement field $\mathbf{u} = \mathbf{u}(\mathbf{x}) = \mathbf{y}(\mathbf{x}) - \mathbf{x}$ between the equilibrium position $\mathbf{x}$ of a material point and the elastically deformed position $\mathbf{y}(\mathbf{x})$ of that point. The strain tensor $\mathbf{S}$ has components defined as $S_{k\ell} = (\partial_k u_\ell + \partial_\ell u_k)/2$ in which u_k are the components of $\mathbf{u}$.

The derivation of the linear elasticity equations can be made via a variational principle for the total energy $\mathcal{E}$ in a domain Ω, namely,

$$\delta\mathcal{E} = 0. \tag{3.1}$$

The total elastic energy $\mathcal{E}$ for the linear elasticity is given as follows:

$$\mathcal{E} = \int_\Omega E d\mathbf{x}, \tag{3.2}$$

where the integrand is the energy density

$$E = \frac{1}{2}\sum_{k,\ell} S_{k\ell} T_{k\ell} - \mathbf{u}\cdot\mathbf{f}\,\chi, \tag{3.3}$$

$\mathbf{f} = (f_k)$ is a body force, and $\mathbf{T} = (T_{k\ell})$ is the stress tensor defined, for an isotropic material, as

$$T_{k\ell} = \lambda\delta_{k\ell}\sum_i S_{ii} + 2\tau S_{k\ell}. \tag{3.4}$$

The parameters λ and τ are the Lamé constants. In the absence of external force on the boundary Γ_1, (3.1) reduces to the classical Navier equations of linear elasticity, i.e.,

$$\begin{aligned} -\nabla\cdot\mathbf{T} &= \mathbf{f}\chi \quad \text{in } \Omega, \\ \mathbf{n}\cdot\mathbf{T} &= 0 \quad \text{on } \Gamma_1, \end{aligned} \tag{3.5}$$

where $\mathbf{n}$ is the outer unit normal vector.

For linear elasticity with cubic symmetry, the elastic energy density E is the following:

$$E = \frac{C_{11}}{2}\sum_i S_{ii}^2 + 2C_{44}\sum_{k\neq\ell} S_{k\ell}^2 + C_{12}\sum_{k\neq\ell} S_{kk}S_{\ell\ell}, \tag{3.6}$$

where C_{11}, C_{44}, and C_{12} are the cubic elastic moduli, i.e., the Voigt constants. The linear elasticity equations with cubic symmetry are

$$\begin{aligned} -C_{11}\partial_k\partial_k u_k - C_{44}\sum_{l\neq k}\partial_l\partial_l u_k \\ -(C_{12}+C_{44})\sum_{l\neq k}\partial_k\partial_l u_l = f_k\chi \quad \text{in } \Omega \end{aligned} \tag{3.7}$$

for $k = 1,\dots,d$. Note that the isotropic linear elasticity equations (3.5) can be recovered from (3.7) by choosing the following Voigt constants:

$$(C_{11}, C_{44}, C_{12}) = (\lambda+2\tau, \tau, \lambda). \tag{3.8}$$

For the study of the ABCs for continuum elasticity, we restrict our attention to the isotropic linear elasticity, namely, (3.7) with the Voigt constants given in (3.8), for simplicity. It is easily generalized to the anisotropic case.

3.2. Two dimensional case. In this section, we construct the artificial boundary operator $\mathcal{A}$ for the two dimensional case. The main idea is to analytically solve the force balance equation (3.7) on the exterior domain Ω_2 by introducing a sum-of-exponentials ansatz, which must be modified to include algebraic terms.

We assume that the solution is periodic in the x-direction with 2π periodicity and that the interface Γ_2 is a line, i.e., $\Gamma_2 = \{(x,y) \in \mathbb{R}^2 : y = 0\}$. We first look for a modal solution $\mathbf{u}(x,y)$ for $y < 0$ as

$$\begin{aligned}\mathbf{u}(x,y) &= \widehat{\mathbf{u}}(\mu,y)\,\mathrm{e}^{\imath\mu x} \\ &= \widehat{\mathbf{u}}(\mu)\,\mathrm{e}^{\beta y}\,\mathrm{e}^{\imath\mu x} = \begin{pmatrix} \hat{u}(\mu) \\ \hat{v}(\mu) \end{pmatrix}\mathrm{e}^{\beta y}\,\mathrm{e}^{\imath\mu x}.\end{aligned} \tag{3.9}$$

Since $\mathbf{u}$ in (3.9) is the solution to (3.7), for each μ, $\widehat{\mathbf{u}}(\mu)$ should satisfy the following linear system:

$$\mathbf{M}(\mu,\beta)\widehat{\mathbf{u}}(\mu) = 0,$$

where $\widehat{\mathbf{u}}(\mu) = (\widehat{u}(\mu), \widehat{v}(\mu))^T$ and

$$\mathbf{M}(\mu,\beta) = \begin{pmatrix} -(\lambda+2\tau)\mu^2 + \tau\beta^2 & \imath\mu(\lambda+\tau)\beta \\ \imath\mu(\lambda+\tau)\beta & -\tau\mu^2 + (\lambda+2\tau)\beta^2 \end{pmatrix}.$$

A nontrivial solution can be attained only if

$$\det \mathbf{M}(\mu,\beta) = \tau(\lambda+2\tau)(\beta^2-\mu^2)^2 = 0, \tag{3.10}$$

which implies that $\beta = \pm|\mu|$. Since the solution $\mathbf{u}$ should decay as $y \to -\infty$, then $\beta = |\mu|$ is the proper choice. Note that for $\mu = 0$, the only solution is $\beta = 0$, which corresponds to a trivial solution, the constant displacement field.

We now compute the zero eigenvector for $\mathbf{M}(\mu,|\mu|)$. It is easy to see that the matrix $\mathbf{M}(\mu,|\mu|)$ has a zero eigenvector given by $\mathbf{q}_1 = (\imath, \mu/|\mu|)^T$ and a generalized eigenvector $\mathbf{q}_2 = (0, -c/\mu)^T$ satisfying $\mathbf{M}(\mu)\mathbf{q}_1 = 0$ and $\mathbf{M}(\mu)\mathbf{q}_2 = -(\lambda+3\tau)|\mu|\mathbf{q}_1$ with $c = (\lambda+3\tau)/(\lambda+\tau)$, from which we obtain the general solution to the equation (3.7) as follows:

$$\widehat{\mathbf{u}}(\mu,y) = ((a_\mu + b_\mu y)\mathbf{q}_1 + b_\mu \mathbf{q}_2)\,\mathrm{e}^{\imath\mu x + |\mu| y}, \tag{3.11}$$

where

$$a_\mu = -\widehat{u}(\mu,0)\imath \quad \text{and} \quad b_\mu = -c^{-1}(\mu\widehat{v_0}(\mu,0) + \imath|\mu|\widehat{u}(\mu,0)). \tag{3.12}$$

From this, we obtain the following simple but important lemma.

LEMMA 3.1. *A solution to* (3.7) *on the domain* Ω_2 *with a given boundary value* $\mathbf{u}_0(x)$ *on* Γ_2 *is given by the following:*

$$\mathbf{u}(x,y) = \frac{1}{2\pi}\int_0^{2\pi} \mathbf{G}(x-x',y)\mathbf{u}_0(x')dx', \tag{3.13}$$

where $\mathbf{G}$ *is defined, using* $c = (\lambda+3\tau)/(\lambda+\tau)$, *as*

$$\begin{aligned}\mathbf{G}(x-x',y) &= \sum_{\mu=-\infty}^{\infty} \mathbf{G}_\mu(x-x',y), \\ \mathbf{G}_\mu(x-x',y) &= \begin{pmatrix} 1+\frac{|\mu|}{c}y & -\frac{\mu}{c}\imath y \\ -\frac{\mu}{c}\imath y & 1-\frac{|\mu|}{c}y \end{pmatrix}\mathrm{e}^{|\mu|y}\,\mathrm{e}^{\imath\mu(x-x')}.\end{aligned}$$

This analytic expression for the solution $\mathbf{u}$ on the domain Ω_2 is used to derive the ABC operator.

3.3. The ABC operator for the two dimensional case. In this section, using Lemma 3.1, we construct the ABC operator. First, consider the expression of the solution $\mathbf{u}$ in the exterior domain Ω_2 given in (3.13). By taking the derivative of $\mathbf{u}$ with respect to y, one finds that

$$\partial_y(\mathbf{u}(x,y)) = \frac{1}{2\pi}\int_0^{2\pi} \partial_y(\mathbf{G}_\mu(x-x',y))\mathbf{u}_0(x')\,dx'. \tag{3.14}$$

Note that the normal component of the stress tensor $\mathbf{n}\cdot\mathbf{T}$ is given by

$$\mathbf{n}\cdot\mathbf{T} = \begin{pmatrix} \tau(\partial_y u + \partial_x v) \\ (\lambda+2\tau)\partial_y v + \lambda\partial_x u \end{pmatrix}, \tag{3.15}$$

and observe that it can be written in terms of $\mathbf{u}$ on the interface Γ_2 as follows:

$$\mathbf{n}\cdot\mathbf{T} = \sum_{\mu=-\infty}^{\infty} \frac{1}{2\pi}\int_0^{2\pi} \mathbf{A}_\mu \mathbf{u}_0(x')\,dx', \tag{3.16}$$

where

$$\mathbf{A}_\mu = \frac{2}{\lambda+3\tau}\begin{pmatrix} \tau(\lambda+2\tau)|\mu| & \tau^2\imath\mu \\ -\tau^2\imath\mu & \tau(\lambda+2\tau)|\mu| \end{pmatrix} \mathrm{e}^{\imath\mu(x-x')}. \tag{3.17}$$

Define the artificial boundary operator $\mathcal{A}$ by the following:

$$\mathcal{A}\mathbf{u}_0(x) = \sum_{\mu=-\infty}^{\infty} \frac{1}{2\pi}\int_0^{2\pi} \mathbf{A}_\mu \mathbf{u}_0(x')\,dx'. \tag{3.18}$$

It is interesting to note that the operator $\mathcal{A}$ is real and symmetric since $\mathbf{A}_\mu(x-x') = \mathbf{A}_\mu^H(x'-x)$.

3.4. The ABC operator for the three dimensional case. We now extend the previous analysis to the three dimensional case by constructing the solution of the homogeneous linear elasticity problem in a semi-infinite domain, Ω_2. Assume that Γ_2 is the plane $z=0$. As in the two dimensional case, assume that in the lateral direction, the solution is periodic with 2π periodicity for both variables, x and y. The following result is the analogue to Lemma 3.1.

LEMMA 3.2. *A solution to* (3.7) *with given boundary data* $\mathbf{u}_0(x,y)$ *on the interface* Γ_2 *is given by the following:*

$$\mathbf{u}(x,y,z) = \frac{1}{4\pi^2}\int_0^{2\pi}\int_0^{2\pi} \mathbf{G}(x-x',y-y',z)\mathbf{u}_0(x',y')\,dx'dy', \tag{3.19}$$

where $\mathbf{G}$ *is defined, using* $c=(\lambda+3\tau)/(\lambda+\tau)$ *and* $d=|(\mu,\nu)|$, *as*

$$\begin{aligned}&\mathbf{G}(x-x',y-y',z)\\ &= \sum_{\mu,\nu=-\infty}^{\infty}\begin{pmatrix} 1+\frac{\mu^2}{cd}z & \frac{\mu\nu}{cd}z & -\frac{\mu}{c}\imath z \\ \frac{\mu\nu}{cd}z & 1+\frac{\nu^2}{cd}z & -\frac{\nu}{c}\imath z \\ -\frac{\mu}{c}\imath z & -\frac{\nu}{c}\imath z & 1-\frac{d}{c}z \end{pmatrix}\mathrm{e}^{dz}\mathrm{e}^{\imath(\mu,\nu)\cdot(x-x',y-y')}.\end{aligned}$$

For the definition of the artificial boundary operator $\mathcal{A}$, note that the normal component of the stress tensor $\mathbf{T}$ is

$$\mathbf{n}\cdot\mathbf{T}=\begin{pmatrix}\mu(\partial_z u+\partial_x w)\\ \mu(\partial_z v+\partial_y w)\\ (\lambda+2\tau)\partial_z w+\lambda(\partial_x u+\partial_y v)\end{pmatrix}, \tag{3.20}$$

where $\mathbf{n}$ is the outer unit normal vector to the interface Γ_2. It is easy to see that

$$\mathbf{n}\cdot\mathbf{T}=\sum_{\mu,\nu=-\infty}^{\infty}\frac{1}{4\pi^2}\int_0^{2\pi}\int_0^{2\pi}\mathbf{A}_{\mu,\nu}\mathbf{u}_0(x',y')\,dx'dy', \tag{3.21}$$

where

$$\mathbf{A}_{\mu,\nu}=\begin{pmatrix}\tau\left(\frac{\mu^2}{cd}+d\right) & \tau\frac{\mu\nu}{cd} & \frac{2\tau^2}{\lambda+3\tau}\imath\mu\\ \tau\frac{\mu\nu}{cd} & \tau\left(\frac{\nu^2}{cd}+d\right) & \frac{2\tau^2}{\lambda+3\tau}\imath\nu\\ -\frac{2\tau^2}{\lambda+3\tau}\imath\mu & -\frac{2\tau^2}{\lambda+3\tau}\imath\nu & (\lambda+2\tau)\left(-\frac{d}{c}+d\right)\end{pmatrix}\mathrm{e}^{\imath(\mu,\nu)\cdot(x-x',y-y')}.$$

Define the artificial boundary operator $\mathcal{A}$ as follows:

$$\mathcal{A}\mathbf{u}_0(x,y)=\sum_{\mu,\nu=-\infty}^{\infty}\frac{1}{4\pi^2}\int_0^{2\pi}\int_0^{2\pi}\mathbf{A}_{\mu,\nu}\mathbf{u}_0(x',y')\,dx'dy'. \tag{3.22}$$

Similarly to the two dimensional case, the operator $\mathcal{A}$ is symmetric.

3.5. The total energy and force balance equation. In this section, we find an alternative total energy formula for (3.2) and also a force balance equation for (3.5) that involve only the domain Ω_1 and Γ_2, using the ABC operator constructed in the previous sections. For convenience, denote $\mathbf{u}_0$ to be the displacement field of $\mathbf{u}$ at Γ_2.

Write the total elastic energy in Ω in terms of the total energy $\mathcal{E}_1$ in Ω_1 and the total energy $\mathcal{E}_2$ in Ω_2 as follows:

$$\begin{aligned}\mathcal{E}_{total}&=\frac{1}{2}\int_\Omega\mathbf{S}:\mathbf{T}\,d\mathbf{x}-\int_\Omega\mathbf{u}\cdot\mathbf{f}\chi\,d\mathbf{x}\\ &=\frac{1}{2}\left\{\int_{\Omega_1}\mathbf{S}:\mathbf{T}\,d\mathbf{x}-\int_{\Omega_1}\mathbf{u}\cdot\mathbf{f}\,d\mathbf{x}\right\}+\frac{1}{2}\int_{\Omega_2}\mathbf{S}:\mathbf{T}\,d\mathbf{x}\\ &=\mathcal{E}_1+\mathcal{E}_2.\end{aligned}$$

Let $\mathcal{L}$ denote the linear elasticity operator:

$$\mathcal{L}\mathbf{u}=\tau\Delta\mathbf{u}+(\lambda+\tau)\nabla(\nabla\cdot\mathbf{u}).$$

Note that $\mathcal{E}_2$ can be written in terms of the boundary data $\mathbf{u}_0(\mathbf{x})$ on the interface Γ_2 as follows:

$$\begin{aligned}\mathcal{E}_2&=\frac{1}{2}\int_{\Omega_2}\mathbf{S}:\mathbf{T}\,d\mathbf{x}\\ &=-\frac{1}{2}\int_{\Omega_2}\mathbf{u}\cdot\mathcal{L}\mathbf{u}\,d\mathbf{x}+\frac{1}{2}\int_{\Gamma_2}\mathbf{u}_0\cdot(\mathbf{n}\cdot\mathbf{T})\,d\Gamma\\ &=\frac{1}{2}\int_{\Gamma_2}\mathbf{u}_0\cdot\mathcal{A}\mathbf{u}_0\,d\Gamma,\end{aligned}$$

where we use the fact that $\mathcal{L}\mathbf{u} = 0$ in the domain Ω_2 and the definition (3.22) of the artificial boundary operator $\mathcal{A}$.

Consequently, the total energy $\mathcal{E}_{total}$ in the domain Ω is

$$\begin{aligned}\mathcal{E}_{total} &= \mathcal{E}_1 + \mathcal{E}_2 \\ &= \frac{1}{2}\int_{\Omega_1} \mathbf{S} : \mathbf{T}\, d\mathbf{x} - \int_{\Omega_1} \mathbf{u}\cdot\mathbf{f} + \frac{1}{2}\int_{\Gamma_2} \mathbf{u}_0 \cdot \mathcal{A}\mathbf{u}_0\, d\Gamma.\end{aligned} \tag{3.23}$$

This is the new formula for the total energy (3.2) that involves only the domain Ω_1 and Γ_2. Now apply integration by parts to the first term in (3.23) and obtain

$$\begin{aligned}\mathcal{E}_{total} = &-\frac{1}{2}\int_{\Omega_1} \mathbf{u}\cdot\mathcal{L}\mathbf{u}\, d\mathbf{x} - \int_{\Omega_1} \mathbf{u}\cdot\mathbf{f}\, d\mathbf{x} \\ &+\frac{1}{2}\int_{\Gamma_2} \mathbf{u}_0\cdot\mathcal{A}\mathbf{u}_0 - \mathbf{u}_0\cdot(\mathbf{n}\cdot\mathbf{T})\, d\Gamma.\end{aligned} \tag{3.24}$$

Application of the variational principle for the new expression of the total energy (3.24) results in the following force balance equations, which use the ABC operator $\mathcal{A}$ in the ABC on Γ_2:

$$\begin{aligned}-\mathcal{L}\mathbf{u} &= \mathbf{f} \qquad \text{in } \Omega_1, \\ \mathbf{n}\cdot\mathbf{T} &= \mathcal{A}\mathbf{u}_0 \quad \text{on } \Gamma_2.\end{aligned}$$

4. The ABCs for discrete elasticity. In this section, we study the analogue of the ABCs for discrete elasticity. In particular, we discuss the solvability (well-posedness) of the discrete strain model in an unbounded or semi-infinite domain.

It is not trivial to show directly the well-posedness of the discrete strain model in an infinite domain. As discussed in Hagstrom and Keller [11], the well-posedness can be derived from a so-called solvability requirement, which is a solvability condition for the exterior domain problem for which the force term is zero. Generally, the validation of this solvability requirement is done by introducing a sum-of-exponentials ansatz for the solution below the artificial boundary. It is difficult, however, to validate this condition fully in an analytic manner [11] except for simple problems such as the Laplace equation. Numerical validation is partially used, since an analytic validation could not be made fully for the current problem of interest.

The importance of the framework developed in this section is that it identifies how the solvability requirement can be used to show well-posedness of the discrete equations posed on the unbounded domain, and also clarifies why an appropriate use of the ABC operator leads to the exact boundary condition. To the best of our knowledge, it is the first attempt to formulate a general discussion on the solvability of discrete systems in an infinite domain in terms of solvability requirements. Furthermore, this formal discussion leads to an understanding of the ABC operator as a Schur complement operator and reveals various properties of the resulting reduced system on the finite domain. These properties of the reduced system are important when one attempts to develop an appropriate solver for the reduced system (see the concluding remark in section 6).

Throughout this section, we assume that the lattice of the discrete strain model is connected [19]. We begin this section by briefly reviewing the discrete elastic model introduced in [21].

4.1. Discrete elasticity. To describe the strain energy at each atom, $\mathbf{i} = (i, j, k)$, introduce the translation operators, $T_k^{\pm}$, and the discrete difference operators, $D_k^{\pm}$, D_k^0, defined as follows:

$$\begin{aligned} T_k^{\pm} f(\mathbf{i}) &= f(\mathbf{i} \pm \mathbf{e_k}), \\ D_k^{+} f(\mathbf{i}) &= \frac{(T_k^{+} - 1) f(\mathbf{i})}{h}, \\ D_k^{-} f(\mathbf{i}) &= \frac{(1 - T_k^{-}) f(\mathbf{i})}{h}, \\ D_k^{0} f(\mathbf{i}) &= \frac{(T_k^{+} - T_k^{-}) f(\mathbf{i})}{2h}, \end{aligned}$$

where h is the lattice constant and $\mathbf{e}_k$ is the vector in the kth direction for $k = 1, 2, 3$ with $\|\mathbf{e}_k\| = h$. Throughout this paper, we assume the lattice constant $h = 1$ for simplicity. We use i for the depth-like index, with $-\infty < i \leq n$. Here n is the maximum height of the material. An ABC is sought at $i = 0$, assuming that there is no force for $i < 0$.

Let $\mathbf{u}(\mathbf{i}) = (u_k(\mathbf{i}))_{k=1,\dots,d}$ be the displacement at the discrete point $\mathbf{i}$ relative to an equilibrium lattice. The discrete strain components defined below ((4.1) and (4.2)) can be used to describe the discrete elastic energy. For $k, \ell = 1, 2, 3$ and $p, q = \pm$,

$$S_{k\ell}^{\pm}(\mathbf{u}(\mathbf{i})) = D_{\ell}^{\pm} u_k(\mathbf{i}), \tag{4.1}$$

$$S_{k\ell}^{pq}(\mathbf{u}(\mathbf{i})) = \frac{1}{2}(D_{\ell}^{q} u_k(\mathbf{i}) + D_k^{p} u_{\ell}(\mathbf{i})). \tag{4.2}$$

The discrete energy density at a point $\mathbf{i}$ is then given by

$$E(\mathbf{i})(\mathbf{u}, \mathbf{u}) = \sum_{k,p} \alpha_k^p (S_{kk}^p(\mathbf{u}))^2 + \sum_{k \neq \ell, p, q} \left\{ 2\beta_{k\ell}^{pq} (S_{k\ell}^{pq}(\mathbf{u}))^2 + \gamma_{k\ell}^{pq} S_{kk}^p(\mathbf{u}) S_{\ell\ell}^q(\mathbf{u}) \right\}.$$

The subsequent discussion uses three constant displacement fields, denoted by $\mathbf{1}_k$ for $k = 1, 2, 3$, for a constant displacement in the kth component. For convenience, denote $\mathbf{1}$ for any constant vector. With some abuse of notation, it is used to denote a constant vector formed by taking the linear combinations of $\mathbf{1}_k$ and $\mathbf{1}_\ell$ with $k \neq \ell$.

The elastic constants should be chosen to ensure positivity of the (total) energy density, as discussed, for example, in [17]. A sufficient condition for the positivity is

$$\min_{k,p} \alpha_k^p \geq \max_{pq} \gamma^{pq} + c \tag{4.3}$$

for some positive constant $c > 0$. One consequence of positivity is that rigid body motions are the only local displacements that entail no internal energy.

A discrete version of the elastic energy density E at a lattice point $\mathbf{i} = (i, j, k)$ is then given as follows:

$$\mathcal{E}_{total} = \mathcal{E}_{total}(\mathsf{U}, \mathsf{U}) = \widetilde{\mathcal{E}}(\mathsf{U}, \mathsf{U}) - (\mathsf{F}, \mathsf{U}), \tag{4.4}$$

where

$$\widetilde{\mathcal{E}}(\mathsf{U}, \mathsf{U}) = \sum_{\mathbf{i}} E(\mathbf{i})(\mathbf{u}, \mathbf{u}), \tag{4.5}$$

$$\begin{aligned} \mathsf{U} &= (U_n, \dots, U_1, U_0, U_{-1}, \dots)^T, \\ \mathsf{F} &= (F_n, \dots, F_1, F_0, F_{-1}, \dots)^T, \end{aligned} \tag{4.6}$$

where U_i and F_i are the vectors of size N consisting of displacement components $\mathbf{u}$ and force components $\mathbf{f}$ at depth i. The total energy formula (4.4) is modified in section 5.3 to include effects of lattice mismatch. Under traction-free (i.e., Neumann) boundary conditions on the surface Γ_1, the external force vector F must be orthogonal to any constant vector field. As shown in (5.6) in section 5.3, this is also true for the effective force due to lattice mismatch in a thin film. Now, due to the boundary condition, the periodic condition in the lateral direction, and Neumann condition on the surface Γ_1, and from the assumption that the lattice is connected, it follows that

$$\widetilde{\mathcal{E}}(\mathsf{U},\mathsf{U}) = 0 \quad \Longleftrightarrow \quad \mathsf{U} = \mathbf{1}; \tag{4.7}$$

see also Martinsson and Babuska [19] for further discussion on connectivity.

As described in detail in section 4.5, the total energy $\mathcal{E}_{total}$ has the following alternative form:

$$\mathcal{E}_{total} = \mathcal{E}_{total}(\mathsf{U},\mathsf{U}) = \frac{1}{2}(\mathbf{H}\mathsf{U},\mathsf{U}) - (\mathsf{F},\mathsf{U}), \tag{4.8}$$

where

$$\mathbf{H} = \begin{pmatrix} \cdots & \cdots & 0 & 0 & 0 & 0 & \cdots \\ \cdots & A_{i+1i+1} & A_{i+1i} & 0 & \ddots & 0 & \vdots \\ \vdots & A_{ii+1} & A_{ii} & A_{ii-1} & 0 & \ddots & \vdots \\ \vdots & 0 & A_{i-1i} & A_{i-1i-1} & A_{i-1i-2} & 0 & \vdots \\ \vdots & \cdots & 0 & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & \cdots & \ddots & \ddots & \vdots \end{pmatrix}. \tag{4.9}$$

The discrete strain equations are derived from the following optimization problem:

$$\min \mathcal{E}_{total} = \min \left(\frac{1}{2}(\mathbf{H}\mathsf{U},\mathsf{U}) - (\mathsf{F},\mathsf{U}) \right). \tag{4.10}$$

Note that the off-diagonal block matrices satisfy $A_{i+1i} = A_{ii+1}^T$ for all $i \le n$. Furthermore, since the material is homogeneous below the artificial boundary, $A_{ii+1} = A_{-10}$ and $A_{ii} = A_{00}$ are independent of i for all $i < 0$. Both A_{00} and A_{-10} are invertible. In particular, the proof that A_{-10} is invertible is included in the appendix.

Denote

$$\mathsf{U} = \begin{pmatrix} \mathsf{U}^+ \\ U_0 \\ \mathsf{U}^- \end{pmatrix} \quad \text{and} \quad \mathsf{F} = \begin{pmatrix} \mathsf{F}^+ \\ F_0 \\ 0 \end{pmatrix}, \tag{4.11}$$

in which U^- and U^+ are vectors consisting of all U_i for $i < 0$ and $i > 0$, respectively. The vector F^+ of forces is defined similarly. Correspondingly, write $\mathbf{H}$ as follows:

$$\mathbf{H} = \begin{pmatrix} \mathsf{A}_{II} & \mathsf{A}_{I0}^T & 0 \\ \mathsf{A}_{I0} & A_{00} & \mathsf{B}^T \\ 0 & \mathsf{B} & \mathsf{M} \end{pmatrix}, \tag{4.12}$$

where A_{II} acts on U^+, A_{00} acts on U_0, and M acts on U^-.

An analysis in section 4.2 shows that under an appropriate solvability condition, the optimization problem (4.10) leads to the force balance equation

$$\mathbf{H}\mathsf{U} = \mathsf{F}. \tag{4.13}$$

Moreover, the analysis shows that (4.13) and the optimization problem (4.10) are well-posed.

Since the displacement $\mathbf{u}$ decays as $i \to -\infty$, one might expect that the space ℓ^2 would be the appropriate admissible solution space for the optimization problem (4.10). Coercivity of the operator $\mathbf{H}$ fails, however, for the space ℓ^2, so that it is difficult to show the solvability of the problem (4.10) directly. The solvability requirement of the next section remedies this lack of coercivity.

4.2. The solvability requirement and the general form of the ABC operator. In the region $i < 0$, i.e., below the artificial boundary, the solution of the problem (4.10) satisfies

$$\begin{aligned} A_{-10}U_0 + A_{00}U_{-1} + A_{-10}^T U_{-2} &= 0, \\ A_{-10}U_{-1} + A_{00}U_{-2} + A_{-10}^T U_{-3} &= 0, \\ A_{-10}U_{-2} + A_{00}U_{-3} + A_{-10}^T U_{-4} &= 0, \\ &\vdots\ . \end{aligned} \tag{4.14}$$

The solvability condition is phrased in terms of solutions for (4.14) that are decaying or constant.

Condition 4.1. *There exists an invertible matrix* C *such that for any* $U_0 \in \mathbb{R}^{\mathrm{N}}$, *the vector* $(U_0, U_{-1}, U_{-2}, \dots)$ *with*

$$U_i = \mathsf{C}^i U_0 \quad \forall i \le 0 \tag{4.15}$$

(where C^0 *is the identity matrix) satisfies* (4.14). *In addition,*

$$\mathsf{C}^i U_0 = U_0 \quad \forall i \le 0, \quad \forall\, U_0 \in \operatorname{span}\{\mathbf{1}_k : k = 1, 2, 3\} \quad \textit{and} \tag{4.16}$$

$$\mathsf{C}^i U_0 \to 0 \quad \textit{as} \quad i \to -\infty \quad \forall\, U_0 \in \operatorname{span}\{\mathbf{1}_k : k = 1, 2, 3\}^{\perp}. \tag{4.17}$$

Note that the constant displacement field is a trivial solution to (4.14) since it is the discretization of the differential operator $\mathcal{L}$, which is reflected in the statement (4.16). The second statement (4.17) says that if U_0 is orthogonal to all constant fields, then the solution decays to 0 at infinity.

Condition 4.1, which is validated in section 4.3, has a number of important consequences, as described in the following subsections.

4.2.1. On the general ABC operator $\mathcal{A}$. The general form of the ABC operator, under Condition 4.1, is described in this subsection.

Define the following two special vector spaces:

$$\Theta = \left\{ \mathsf{V} = (V_{-1}, V_{-2}, \dots) : \inf_{\xi \in \mathbb{R}} \|\mathsf{V} + \xi \mathbf{1}\|_{\ell^2} < \infty \quad \Psi(V_i) = 0 \quad \forall i < -1 \right\},$$

where

$$\Psi(V_i) = A_{-10}V_{i+1} + A_{00}V_i + A_{-10}^T V_{i-1}, \tag{4.18}$$

and

$$\Theta^* = \{\mathsf{G} = (G_{-1}, 0, \dots, 0, \dots) : G_{-1} \in \mathbb{R}^{\mathrm{N}}\}. \tag{4.19}$$

It is clear that both spaces Θ and Θ^* are finite dimensional. In particular, due to the constraints (4.18), the space Θ is completely determined by the first two vectors V_{-1} and V_{-2}. Due to Condition 4.1, the dimension of the space Θ is at least N; in fact, as shown below, its dimension is exactly N. By defining $\|\mathsf{V}\|_\Theta = \sum_{k=-1,-2} \|V_k\|_{\ell^2}$ as a norm on Θ, the space Θ is a Banach space, as is Θ^*. The following lemma is simple but important for the subsequent discussion (the proof can be found in the appendix).

LEMMA 4.1. *Under Condition* 4.1*, the matrix* M*, given as*

$$\mathsf{M} = \begin{pmatrix} A_{00} & A_{-10}^T & 0 & 0 & 0 & \cdots \\ A_{-10} & A_{00} & A_{-10}^T & 0 & 0 & \vdots \\ 0 & A_{-10} & A_{00} & A_{-10}^T & 0 & \vdots \\ \vdots & 0 & A_{-10} & A_{00} & \cdots & \vdots \\ \vdots & 0 & \ddots & \ddots & \ddots & \vdots \\ \vdots & \cdots & \cdots & \ddots & \ddots & \vdots \end{pmatrix}, \tag{4.20}$$

is an isomorphic mapping from Θ *to* Θ^**.*

Since M is isomorphic, the following equation is solvable:

$$\mathsf{M}\mathsf{U}^- = \mathsf{G}, \tag{4.21}$$

where

$$\mathsf{U}^- = (U_{-1}, U_{-2}, U_{-3}, \dots)^T$$
$$\text{and} \quad \mathsf{G} = (-A_{-10}U_0, 0, 0, \dots)^T.$$

In particular, $\mathsf{U}^- = \mathsf{M}^{-1}\mathsf{G}$. Multiplying both sides of this equation by $\mathsf{B} = (A_{-10}^T, 0, \dots, 0)$ yields the relation

$$A_{-10}^T U_{-1} = -\mathsf{B}\mathsf{M}^{-1}\mathsf{B}^T U_0. \tag{4.22}$$

The general form of the ABC operator $\mathcal{A}$ is defined by

$$\mathcal{A} = \mathsf{B}\mathsf{M}^{-1}\mathsf{B}^T. \tag{4.23}$$

Note that the operator $\mathcal{A}$ relates U_{i-1} and U_i for $i \le 0$. Since U^- belongs to the space Θ, U_i should decay as $i \to -\infty$, unless U_0 has a nonzero component that is a constant vector.

4.2.2. The total energy formula for the system above the artificial boundary. This section introduces the new energy formula that is a by-product of the ABC operator.

Since $A_{-10}U_{i+1} + A_{00}U_i + A_{-10}^T U_{i-1} = 0$ and $F_i = 0$ for $i < 0$, the total energy

$\mathcal{E}_{total}$ from (4.8) can be written as follows:

$$\begin{aligned}\mathcal{E}_{total} &= \sum_{i\geq 0} \frac{1}{2}\left(U_i, (A_{ii+1}U_{i+1} + A_{ii}U_i + A_{ii-1}U_{i-1})\right) - (U_i, F_i)\\ &= \frac{1}{2}\left(U_0, \left(A_{01}U_1 + A_{00}U_0 + A_{-10}^T U_{-1}\right)\right) - (U_0, F_0)\\ &\quad + \sum_{i>0} \frac{1}{2}\left(U_i, (A_{ii+1}U_{i+1} + A_{ii}U_i + A_{ii-1}U_{i-1})\right) - (U_i, F_i)\,.\end{aligned}$$

This formula, however, depends on the displacement field U_{-1} below the artificial boundary. To remove this dependence and obtain an energy formula (and a reduced force balance equation) that involves displacement fields only above the artificial boundary, use the operator $\mathcal{A}$ to obtain the following alternative formula:

$$\begin{aligned}\mathcal{E}_{total} &= \frac{1}{2}\left(U_0, (A_{01}U_1 + (A_{00} - \mathcal{A})U_0)\right) - (U_0, F_0)\\ &\quad + \sum_{i>0} \frac{1}{2}\left(U_i, (A_{ii-1}U_{i-1} + A_{ii}U_i + A_{ii+1}U_{i+1})\right) - (U_i, F_i)\,.\end{aligned} \tag{4.24}$$

Note that the energy formula given in (4.24) depends only on the displacement fields U_0 and U^+ above the artificial boundary, but it includes the energy in the strain field below the artificial boundary. In addition, optimization of this formula for the energy yields the reduced equation on the upper domain with the ABC using the operator $\mathcal{A}$, as shown in the next subsection.

4.2.3. The force balance equation. Define the following admissible solution space for the optimization problem (4.10):

$$\mathbf{V} = \left\{\mathsf{V} = (V_n, \dots, V_0, V_{-1}, \dots) : \inf_{\xi\in\mathbb{R}} \|\mathsf{V} + \xi\mathbf{1}\|_{\ell^2} < \infty, \quad \Psi(V_i) = 0 \quad \forall i < 0\right\}.$$

Thanks to Condition 4.1, the force balance equation that results from minimizing the total energy in its reduced form (4.24) is

$$\widehat{\mathbf{H}}\begin{pmatrix}\mathsf{U}^+\\ U_0\end{pmatrix} = \begin{pmatrix}\mathsf{A}_{II} & \mathsf{A}_{I0}^T\\ \mathsf{A}_{I0} & A_{00} - \mathcal{A}\end{pmatrix}\begin{pmatrix}\mathsf{U}^+\\ U_0\end{pmatrix} = \begin{pmatrix}\mathsf{F}^+\\ F_0\end{pmatrix}. \tag{4.25}$$

The reduced form (4.25) of the force balance equation, as well as its properties, is the main result of this work. Note that (4.25) involves the *Schur complement* of the matrix A_{00} in the original force balance equation (4.13).

The properties of the matrices $\mathcal{A}$ and $\widehat{\mathbf{H}}$ are summarized in the following lemma, whose proof is provided in the appendix.

LEMMA 4.2. *The matrix $\mathcal{A}$ is symmetric and positive definite, the matrix $\widehat{\mathbf{H}}$ is symmetric and nonnegative definite, and the null space of $\widehat{\mathbf{H}}$ consists of the constant displacement fields* $\operatorname{span}\{\mathbf{1}_k : k = 1, 2, 3\}$.

The analysis in this section is performed for the Neumann boundary condition at the top boundary Γ_1, by which we mean that the variational principle (4.10) involves no constraint on the solution at Γ_1. In this case, it is most important to note that (4.25) is solvable since (F^+, F_0) belongs to the range of $\widehat{\mathbf{H}}$; namely, (F^+, F_0) is orthogonal to the constant vector fields, which is exactly the null space of $\widehat{\mathbf{H}}$ as noted in Lemma 4.2. In addition, the solution to (4.25) is determined up to a constant

vector. However, the additional contribution of the constant vector does not affect the total energy evaluation since the total energy is invariant with respect to the constant displacement. Furthermore, use of the Neumann condition is only to simplify the analysis. It does not affect the ABC operator $\mathcal{A}$, which can be used for any choice of boundary conditions on the top.

In passing to the next section, we summarize the most important properties of the ABC operator $\mathcal{A}$, which guide its construction.

P1 The operator $\mathcal{A}$ is a symmetric and positive definite matrix mapping $\mathbb{R}^N$ to $\mathbb{R}^N$.

P2 The relation between U_{-1} and U_0 is that $U_{-1} = -(A_{-10}^T)^{-1}\mathcal{A}U_0 = \mathsf{C}U_0$.

4.3. Validation of the solvability requirement, Condition 4.1. In this section, Condition 4.1 is derived by introducing a sum-of-exponentials ansatz. Much of the derivation, including the most crucial steps, is analytic, but some steps are based on numerical evidence. In related work on the Laplace equation, Hagstrom and Keller [11] performed a completely analytic validation of the analogue of Condition 4.1.

The following presentation is mostly based on the thesis of Lee [18] and is similar to the work by Russo and Smereka [20], which used the palindromic eigenvalue problem [15, 16]. Although these works did not state a general solvability condition like Condition 4.1, their analysis is equivalent to a validation of this condition. Throughout this section, denote $\mathcal{F}$ and $\mathcal{F}^{-1}$ to be the discrete forward and backward Fourier transforms, respectively.

4.3.1. Two dimensional case. The force balance equations at a point $(x_m, y_i) = (m, i)$ are

$$\begin{aligned} -(\mathcal{L}\mathbf{u})_1 &= -C_{11}D_x^+D_x^-u - C_{44}D_y^+D_y^-u - (C_{12}+C_{44})D_y^0D_x^0v = 0, \\ -(\mathcal{L}\mathbf{u})_2 &= -C_{44}D_x^+D_x^-v - C_{11}D_y^+D_y^-v - (C_{12}+C_{44})D_x^0D_y^0u = 0. \end{aligned} \tag{4.26}$$

Since the solution is periodic in the x-direction, we introduce the following ansatz:

$$\begin{aligned} \mathbf{u}(m,i) &= \frac{1}{N_x}\sum_{\mu=0}^{N_x-1}\widehat{\mathbf{u}}(\mu,i)\,\mathrm{e}^{2\pi\imath\mu m/N_x} \\ &= \frac{1}{N_x}\sum_{\mu=0}^{N_x-1}\widehat{\mathbf{u}}(\mu)\gamma^i\,\mathrm{e}^{2\pi\imath\mu m/N_x}, \end{aligned} \tag{4.27}$$

where N_x is such that $\mathbf{u}(m,i) = \mathbf{u}(N_x+m,i)$ for all m.

From (4.27), the force balance equations (4.26) become

$$P(\mu,\gamma)\widehat{\mathbf{u}}(\mu,i) = \left(\gamma^2\widehat{A}_{-10}(\mu) + \gamma\widehat{A}_{00}(\mu) + \widehat{A}_{-10}^H(\mu)\right)\widehat{\mathbf{u}}(\mu,i) = 0 \tag{4.28}$$

for $\mu = 0, 1, \ldots, N_x - 1$, where

$$\widehat{A}_{-10}(\mu) = \begin{pmatrix} -C_{44} & -\imath\frac{C_{12}+C_{44}}{2}\sin(2\pi\mu/N_x) \\ -\imath\frac{C_{12}+C_{44}}{2}\sin(2\pi\mu/N_x) & -C_{11} \end{pmatrix},$$

$$\widehat{A}_{00}(\mu) = \begin{pmatrix} 2C_{44}+2C_{11}(1-\cos(2\pi\mu/N_x)) & 0 \\ 0 & 2C_{11}+2C_{44}(1-\cos(2\pi\mu/N_x)) \end{pmatrix},$$

and $\widehat{A}_{-10}^H$ is the complex transpose of the matrix $\widehat{A}_{-10}$.

Nontrivial solutions for this system require that

$$\det P(\mu,\gamma)=0. \tag{4.29}$$

This is the well-known palindromic eigenvalue problem [15, 16, 20]. Note that for $\mu=0$, which corresponds to the constant vector in the Fourier expansion of the solution ansatz (4.27), the only solution to (4.29) is $\gamma=1$, which corresponds to the constant solution to (4.14).

For $\mu\neq 0$, (4.29) has four solutions that occur in pairs $(\gamma_k,\overline{\gamma}_k{}^{-1})$ for $k=1,2$, since

$$\det(P(\mu,\gamma))=0 \quad\Longleftrightarrow\quad \overline{\det(P(\mu,\gamma))}=0 \tag{4.30}$$

and

$$\overline{P(\mu,\gamma)}=\overline{\gamma}^2 P(\mu,\overline{\gamma}^{\,-1}).$$

We then pick a pair of solutions (γ_1,γ_2) with $|\gamma_k|>1$ for $k=1,2$, which are the relevant choices since the corresponding solution is decaying as $i\to-\infty$ for $\mu\neq 0$, and we also pick two linearly independent eigenvectors $\mathbf{q}_1(\mu)$ and $\mathbf{q}_2(\mu)$ that correspond to γ_1 and γ_2, respectively [10, 20]; i.e.,

$$P(\mu,\gamma_1)\mathbf{q}_1(\mu)=P(\mu,\gamma_2)\mathbf{q}_2(\mu)=0. \tag{4.31}$$

It is possible that $|\gamma_k|=1$ or that $\gamma_1=\gamma_2$ and there is a generalized eigenvector, but these possibilities have not been seen numerically. Indeed, the occurrence of a generalized eigenvector in the continuous case (cf. section 3.2) does not seem to have consequences for the discrete case.

We then arrive at the general solution for $\widehat{\mathbf{u}}(\mu,i)$ given as follows:

$$\widehat{\mathbf{u}}(\mu,i)=\mathbf{q}_1(\mu)\gamma_1^i+\mathbf{q}_2(\mu)\gamma_2^i. \tag{4.32}$$

For the zero mode $\mu=0$, two linearly independent vectors $\mathbf{q}_k(0)$ are $\mathbf{q}_1=(1,0)^T$ and $\mathbf{q}_2=(0,1)^T$. Note that omitting this mode would make 0 an eigenvalue for the operator $\mathcal{A}$, but that $\mathcal{A}$ should be positive definite as indicated in property **P1** in subsection 4.2.3.

4.3.2. Three dimensional case. As in the two dimensional case, consider the force balance equations at a point $(x_m,y_n,z_i)=(m,n,i)$:

$$\begin{aligned}
-(\mathcal{L}\mathbf{u})_1 &= -C_{11}D_x^+D_x^-u-C_{44}(D_y^+D_y^-u+D_z^+D_z^-u)\\
&\quad -(C_{12}+C_{44})(D_y^0D_x^0v+D_z^0D_x^0w)\\
&= 0,\\
-(\mathcal{L}\mathbf{u})_2 &= -C_{11}D_y^+D_y^-v-C_{44}(D_x^+D_x^-v+D_z^+D_z^-v)\\
&\quad -(C_{12}+C_{44})(D_y^0D_x^0u+D_z^0D_y^0w)\\
&= 0,\\
-(\mathcal{L}\mathbf{u})_3 &= -C_{11}D_z^+D_z^-w-C_{44}(D_x^+D_x^-w+D_y^+D_y^-w)\\
&\quad -(C_{12}+C_{44})(D_z^0D_x^0u+D_z^0D_y^0v)\\
&= 0.
\end{aligned} \tag{4.33}$$

Introduce the solution ansatz as follows:

$$\mathbf{u}(m,n,i) = \frac{1}{N_x N_y}\sum_{\mu=0}^{N_x-1}\sum_{\nu=0}^{N_y-1}\widehat{\mathbf{u}}(\mu,\nu,i)\,\mathrm{e}^{(2\pi\imath\mu m)/N_x+(2\pi\imath\nu n)/N_y} = \frac{1}{N_x N_y}\sum_{\mu=0}^{N_x-1}\sum_{\nu=0}^{N_y-1}\widehat{\mathbf{u}}(\mu,\nu)\gamma^i\,\mathrm{e}^{(2\pi\imath\mu m)/N_x+(2\pi\imath\nu n)/N_y}, \tag{4.34}$$

where N_x and N_y are the periods in x and y for $\mathbf{u}$. From ansatz (4.34), the force balance equations become

$$P(\mu,\nu,\gamma)\widehat{\mathbf{u}}(\mu,\nu,i) = \left(\gamma^2\widehat{A}_{-10}(\mu,\nu)+\gamma\widehat{A}_{00}(\mu,\nu)+\widehat{A}^H_{-10}(\mu,\nu)\right)\widehat{\mathbf{u}}(\mu,\nu,i) = 0 \tag{4.35}$$

for each $\mu = 0,1,\ldots,N_x$ and $\nu = 0,1,\ldots,N_y$, where $\widehat{A}_{-10} = \widehat{A}_{-10}(\mu,\nu)$ and $\widehat{A}_{00} = \widehat{A}_{00}(\mu,\nu)$ are given by

$$\widehat{A}_{-10} = \begin{pmatrix} -C_{44} & 0 & -s_1 \\ 0 & -C_{44} & -s_2 \\ -s_1 & -s_2 & -C_{11} \end{pmatrix},$$

$$\widehat{A}_{00} = \begin{pmatrix} a_{11} & a_{12} & 0 \\ a_{21} & a_{22} & 0 \\ 0 & 0 & a_{33} \end{pmatrix},$$

in which

$$s_1 = \imath\frac{C_{12}+C_{44}}{2}\sin(2\pi\mu/N_x),$$
$$s_2 = \imath\frac{C_{12}+C_{44}}{2}\sin(2\pi\nu/N_y)$$

and

$$\begin{aligned} a_{11} &= 2C_{11}(1-\cos(2\pi\mu/N_x)) + 2C_{44}(1-\cos(2\pi\nu/N_y)) + 2C_{44},\\ a_{12} &= -(C_{12}+C_{44})\sin(2\pi\mu/N_x)\sin(2\pi\nu/N_y),\\ a_{21} &= a_{12},\\ a_{22} &= 2C_{44}(1-\cos(2\pi\mu/N_x)) + 2C_{11}(1-\cos(2\pi\nu/N_y)) + 2C_{44},\\ a_{33} &= 2C_{44}(1-\cos(2\pi\mu/N_x)) + 2C_{44}(1-\cos(2\pi\nu/N_y)) + 2C_{11}. \end{aligned}$$

A nontrivial solution can be found only if

$$\det P(\mu,\nu,\gamma) = 0. \tag{4.36}$$

As in the two dimensional case, for $\mu = \nu = 0$, the only solution is $\gamma = 1$, and for $(\mu,\nu) \neq (0,0)$, there are three pairs of eigenvalues, namely $(\gamma_k, \overline{\gamma}_k{}^{-1})$ with $|\gamma_k| > 1$ for $k = 1,2,3$, and corresponding eigenvectors $\mathbf{q}_k(\mu,\nu)$ that are mutually linearly independent, from which the general solution can be given as follows:

$$\widehat{\mathbf{u}}(\mu,\nu,i) = \mathbf{q}_1(\mu,\nu)\gamma_1^i + \mathbf{q}_2(\mu,\nu)\gamma_2^i + \mathbf{q}_3(\mu,\nu)\gamma_3^i. \tag{4.37}$$

Note that if the three values γ_k are distinct, then it can be seen directly that there exist three linearly independent eigenvectors $\mathbf{q}_k(\mu,\nu)$ corresponding to the three eigenvalues γ_k (see the appendix). Often in our computation, as seen in the work by Russo and Smereka [20], it happens that $\gamma_k = \gamma_\ell$ with $k \neq \ell$. When this happens, it is difficult to establish analytically the existence of linearly independent eigenvectors; this is always found to be the case, however, in the numerical computations.

4.4. On the discrete ABC operator $\mathcal{A}$ and Condition 4.1. In this section, the ABC operator $\mathcal{A}$ is constructed for the three dimensional case only, since the two dimensional construction is similar but simpler. We first construct the operator C that relates U_{i-1} and U_i by $U_{i-1} = \mathsf{C}U_i$, as indicated in **P2**. We then construct $\mathcal{A} = -(A_{-10}^T)\mathsf{C}$. Finally, we discuss the validation of Condition 4.1.

Note that the Fourier transforms $\widehat{A}_{-10}$ and $\widehat{A}_{00}$ of A_{-10} and A_{00} consist of 3×3 block matrices $\widehat{A}_{-10}(\mu,\nu)$ and $\widehat{A}_{00}(\mu,\nu)$. Since the vectors $\mathbf{q}_i(\mu,\nu)$ from (4.37) are mutually independent, define the following mutually orthonormal vectors:

$$\widetilde{\mathbf{q}}_i = c_i(\mathbf{q}_{i'} \times \mathbf{q}_{i''}),$$

in which each triple (i,i',i'') is a rearrangement of $(1,2,3)$ and the constants c_i's are chosen so that

$$\widetilde{\mathbf{q}}_i \cdot \mathbf{q}_j = \delta_{ij} \quad \text{for } i,j = 1,2,3. \tag{4.38}$$

It follows that

$$\widehat{\mathbf{u}}(\mu,\nu,k-1) = \mathbf{C}(\mu,\nu)\widehat{\mathbf{u}}(\mu,\nu,k), \tag{4.39}$$

in which

$$\mathbf{C}(\mu,\nu) = \begin{pmatrix} \widetilde{\mathbf{q}}_1^T \\ \widetilde{\mathbf{q}}_2^T \\ \widetilde{\mathbf{q}}_3^T \end{pmatrix}^{-1} \begin{pmatrix} \gamma_1^{-1}\widetilde{\mathbf{q}}_1^T \\ \gamma_2^{-1}\widetilde{\mathbf{q}}_2^T \\ \gamma_3^{-1}\widetilde{\mathbf{q}}_3^T \end{pmatrix}. \tag{4.40}$$

The matrix C is

$$\mathsf{C} = \mathcal{F}^{-1}\mathbf{C}\mathcal{F}, \tag{4.41}$$

in which

$$\mathbf{C} = \operatorname{diag}(\mathbf{C}(\mu,\nu))_{\mu=0,\ldots,N_x-1,\nu=0,\ldots,N_y-1}. \tag{4.42}$$

To construct the ABC operator $\mathcal{A}$, multiply $-\widehat{A}_{-10}^H(\mu,\nu)$ by $\mathbf{C}(\mu,\nu)$. Note that $\mathcal{A} = \mathcal{F}^{-1}\mathbf{A}\mathcal{F}$, where $\mathbf{A}$ is a diagonal block matrix consisting of the submatrices $\mathbf{A}(\mu,\nu) = -\widehat{A}_{-10}^H(\mu,\nu)\mathbf{C}(\mu,\nu)$ for $\mu = 0,\ldots,N_x-1$ and $\nu = 0,\ldots,N_y-1$, namely,

$$\mathbf{A} = \operatorname{diag}(\mathbf{A}(\mu,\nu))_{\mu=0,\ldots,N_x-1,\,\nu=0,\ldots,N_y-1}, \tag{4.43}$$

and also for both two and three dimensional cases, the operator $\mathcal{A} = \mathcal{F}^{-1}\mathbf{A}\mathcal{F}$ is symmetric and positive definite. It is quite difficult to see this directly from the Fourier analysis discussed in this section, but it follows from the variational principle based on the general form of the ABC operator as discussed in section 4.2.

Finally, Condition 4.1 can be validated from the construction of the matrix C. For any data $U_0 \in \mathbb{R}^{\mathrm{N}}$ which consists of displacement $\mathbf{u}$ on the interface $i = 0$, the vectors U_i for all $i < 0$ can be written as follows:

$$U_i = \mathcal{F}^{-1}\mathbf{C}^i\mathcal{F}U_0 = \mathsf{C}^i U_0. \tag{4.44}$$

The matrix C is invertible. It satisfies (4.17), because $|\gamma| > 1$ for $(\mu, \nu) \neq 0$, while for $(\mu, \nu) = 0$, $\gamma = 1$ and the corresponding term in (4.34) has no dependence on m and n, so that (4.16) is also satisfied. This completes the validation of Condition 4.1.

4.5. Total energy. In this section we derive alternative general energy formulas that involve a product of stress and strain. Note that in the section 4.2, the energy and the variational principle are written in terms of displacement times force. For some applications, such as a heteroepitaxial thin film, as described in section 5.3, it is much more convenient to write the energy in the form of stress times strain, as in (4.3).

The analysis of this section relies on the following "summation by parts" formulas:

$$\sum_{j\le 0}(D^+f)_j g_j = f_1 g_0 - \sum_{j\le 0} f_j (D^- g)_j, \tag{4.45}$$

$$\sum_{j\le 0}(D^-f)_j g_j = f_0 g_1 - \sum_{j\le 0} f_j (D^+ g)_j, \tag{4.46}$$

$$\sum_{j\le 0}(D^0f)_j g_j = \frac{1}{2}\left(f_1 g_0 + f_0 g_1\right) - \sum_{j\le 0} f_j (D^0 g)_j, \tag{4.47}$$

where D^+, D^-, and D^0 are the forward, backward, and centered finite difference operators, respectively. The total energy can be decomposed into two parts:

$$\mathcal{E}_{total} = \mathcal{E}_{i\ge 0} + \mathcal{E}_{i\le -1}, \tag{4.48}$$

where $\mathcal{E}_{i\ge 0} = \sum_{i\ge 0} E_i$ and $\mathcal{E}_{i\le -1} = \sum_{i\le -1} E_i$, and $i = 0$ is the layer in which the ABCs are imposed. Use (4.45)–(4.47) to derive the following relations, in two and three space dimensions, respectively:

$$\begin{aligned}\mathcal{E}_{i\le -1} = &\sum_{i_1} \alpha v_0 (D_y^+ v)_{-1} + \beta u_0 (D_y^+ u)_{-1} \\ &+ \sum_{i_1} \alpha v_{-1} (D_y^- v)_0 + \beta u_{-1} (D_y^- u)_0 \\ &+ \sum_{i_1} \big[\beta (u_0 (D_x^0 v)_{-1} + u_{-1} (D_x^0 v)_0) \\ &\qquad + \gamma \left(v_0 (D_x^0 u)_{-1} + v_{-1} (D_x^0 u)_0\right)\big] \\ &- \sum_{i_1, i\le -1} \frac{1}{2}\mathbf{u}_i \cdot (\mathcal{L}\mathbf{u}_i) - \mathbf{u}_i \cdot \mathbf{f}_i\end{aligned} \tag{4.49}$$

and

$$
\begin{aligned}
(4.50)\quad \mathcal{E}_{i\le -1} = &\sum_{i_1,i_2} \alpha w_0 (D_z^+ w)_{-1} + \beta (u_0 (D_z^+ u)_{-1} + v_0 (D_z^+ v)_{-1}) \\
&+ \sum_{i_1,i_2} \alpha w_{-1} (D_z^- w)_0 + \beta (u_{-1} (D_z^- u)_0 + v_{-1} (D_z^- v)_0) \\
&+ \sum_{i_1,i_2} \big[\beta \left(v_0 (D_y^0 w)_{-1} + v_{-1} (D_y^0 w)_0 + u_0 (D_x^0 w)_{-1} + u_{-1} (D_x^0 w)_0\right) \\
&\qquad + \gamma \left(w_0 (D_y^0 v)_{-1} + w_{-1} (D_y^0 v)_0 + w_{-1} (D_x^0 u)_0 + w_0 (D_x^0 u)_{-1}\right)\big] \\
&- \sum_{i_1,i_2,i\le -1} \frac{1}{2} \mathbf{u}_i \cdot (\mathcal{L} \mathbf{u}_i) - \mathbf{u}_i \cdot \mathbf{f}_i,
\end{aligned}
$$

in which $\mathcal{L}$ is the operator introduced in (4.26) and (4.33) and $\mathbf{f}_i$ is the force. In these formulas, the subscript refers to the depth-like index i.

Due to the assumption that $\mathbf{f}_i = 0$ for $i \le -1$, the last terms are zero in both the two and three dimensional cases. This leads to the following formulas:

$$
\begin{aligned}
(4.51)\qquad \mathcal{E}_{total} = &\mathcal{E}_{i\ge 0} + \sum_{i_1} \alpha v_0 (D_y^+ v)_{-1} + \beta u_0 (D_y^+ u)_{-1} \\
&+ \sum_{i_1} \alpha v_{-1} (D_y^- v)_0 + \beta u_{-1} (D_y^- u)_0 \\
&+ \sum_{i_1} \big[\beta (u_0 (D_x^0 v)_{-1} + u_{-1} (D_x^0 v)_0) \\
&\qquad + \gamma \left(v_0 (D_x^0 u)_{-1} + v_{-1} (D_x^0 u)_0\right)\big]
\end{aligned}
$$

in two dimensions and

$$
\begin{aligned}
(4.52)\quad \mathcal{E}_{total} = &\mathcal{E}_{i\ge 0} + \sum_{i_1,i_2} \alpha w_0 (D_z^+ w)_{-1} + \beta (u_0 (D_z^+ u)_{-1} + v_0 (D_z^+ v)_{-1}) \\
&+ \sum_{i_1,i_2} \alpha w_{-1} (D_z^- w)_0 + \beta (u_{-1} (D_z^- u)_0 + v_{-1} (D_z^- v)_0) \\
&+ \sum_{i_1,i_2} \big[\beta \left(v_0 (D_y^0 w)_{-1} + v_{-1} (D_y^0 w)_0 + u_0 (D_x^0 w)_{-1} + u_{-1} (D_x^0 w)_0\right) \\
&\qquad + \gamma \left(w_0 (D_y^0 v)_{-1} + w_{-1} (D_y^0 v)_0 + w_{-1} (D_x^0 u)_0 + w_0 (D_x^0 u)_{-1}\right)\big]
\end{aligned}
$$

in three dimensions. In both (4.51) and (4.52), we replace U_{-1} by $\mathsf{C}U_0$ whenever $\mathbf{u}_{-1}$ appears.

If the ABCs are imposed on the layer $i = 0$ where there is no force, then the total energy could be computed by the following new energy formulas that do not involve U_{-1} or the operator C:

$$
\begin{aligned}
(4.53)\qquad \mathcal{E}_{total} = &\mathcal{E}_{i>0} + \sum_{i_1} \alpha v_1 (D_y^+ v)_0 + \beta u_1 (D_y^+ u)_0 \\
&+ \sum_{i_1} \alpha v_0 (D_y^- v)_1 + \beta u_0 (D_y^- u)_1 \\
&+ \sum_{i_1} \big[\beta (u_1 (D_x^0 v)_0 + u_0 (D_x^0 v)_1) \\
&\qquad + \gamma \left(v_1 (D_x^0 u)_0 + v_0 (D_x^0 u)_1\right)\big]
\end{aligned}
$$

in two space dimensions and

$$\begin{aligned}(4.54)\quad \mathcal{E}_{total} = \mathcal{E}_{i>0} &+ \sum_{i_1,i_2} \alpha w_1(D_z^+ w)_0 + \beta(u_1(D_z^+ u)_0 + v_1(D_z^+ v)_0) \\ &+ \sum_{i_1,i_2} \alpha w_0(D_z^- w)_1 + \beta(u_0(D_z^- u)_1 + v_0(D_z^- v)_1) \\ &+ \sum_{i_1,i_2} \big[\beta\left(v_1(D_y^0 w)_0 + v_0(D_y^0 w)_1 + u_1(D_x^0 w)_0 + u_0(D_x^0 w)_1\right) \\ &\qquad + \gamma\left(w_1(D_y^0 v)_0 + w_0(D_y^0 v)_1 + w_0(D_x^0 u)_1 + w_1(D_x^0 u)_0\right)\big]\end{aligned}$$

in three space dimensions, respectively. In both (4.53) and (4.54), we replace U_{-1} by $-(A_{-10}^T)^{-1}\mathcal{A}U_0$ whenever $\mathbf{u}_{-1}$ appears.

5. Numerical results. In this section, sample computations are performed to validate and illustrate the ABCs developed in previous sections. Throughout this section, the elastic constants C_{11}, C_{12}, C_{44} are assumed to be $C_{11} = 8$, $C_{12} = 4$, and $C_{44} = 4$ unless explicitly stated otherwise.

5.1. The ABCs for continuum elasticity. This section shows the effectiveness of the ABCs for continuum elasticity equations (3.7). The Lamé constants are chosen to be $\lambda = 1$ and $\tau = 1$.

The test problem is (3.7) on $\Omega = [0, 2\pi)\times(-\infty, 0)$ with data on $\Gamma_1 = [0, 2\pi)\times\{y = 0\}$. Periodicity is assumed in the lateral direction, and there is no body force; i.e., $\mathbf{f} = 0$. The interface Γ_2 at which the artificial boundary condition is imposed is the line $[0, 2\pi) \times \{y = -1\}$.

The Dirichlet data given on Γ_1 is as follows:

$$\mathbf{u} = (u, v) = (\cos x + \sin 2x, 0),$$

for which the exact solution to (3.7) is

$$(5.1)\qquad \mathbf{u} = \left(\left(1 + \frac{y}{2}\right)\cos x\, \mathrm{e}^y + (1 + y)\sin 2x\, \mathrm{e}^{2y}, \frac{7}{2}\sin x\, \mathrm{e}^y - y\cos 2x\, \mathrm{e}^{2y}\right).$$

This exact solution is compared to the solution of (3.7) with the exact artificial boundary condition (3.16) on the interface Γ_2 and also to the solutions with the following two alternative boundary conditions:

- The zero Dirichlet boundary condition $\mathbf{u}(x, -1) = 0$.
- The Neumann boundary condition $\mathbf{n}\cdot\mathbf{T} = 0$ on $y = -1$.

Figure 5.1 shows the u-displacement field at the line $y = -0.75$ for the exact solution, the solution using ABCs, and the two alternative solutions. Although there is still error, due to discretization of the continuum equation, it is clear that the solution obtained with the exact ABCs (3.16) is in good agreement with the analytic solution (5.1). On the other hand, the solutions obtained with the other two boundary conditions are in error by about 20%–30% at the peaks.

5.2. The ABCs for discrete elasticity. In this section, we investigate the ABCs for the discrete elastic equations for both two and three space dimensions with the Dirichlet data given on the boundary Γ_1. As in the continuum case, there are no external forces, and periodic boundary conditions are imposed in the lateral directions.

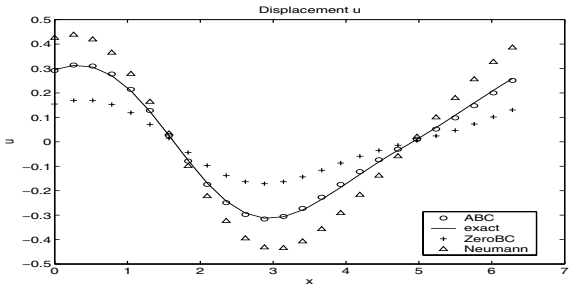

FIG. 5.1. *Test of the ABCs for the continuum solution in two space dimensions. Comparison of the u-displacement field of* $\mathbf{u} = (u, v)$ *given at* $y = -0.75$ *for the exact solution (line) and for the following boundary conditions: ABC (circle), zero-displacement (plus), and Neumann (triangle).*

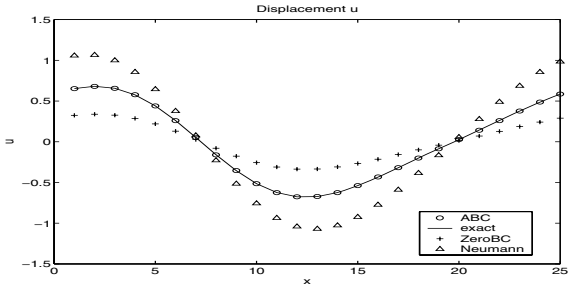

FIG. 5.2. *Test of the exact discrete ABCs in two dimensions: a comparison of the u-displacement field of* $\mathbf{u} = (u, v)$ *at* $(x, y) = (x, 3)$. *The boundary* Γ_1 *is at* $y = 1$, *and the interface* Γ_2 *is at* $y = 5$ *for the exact solution (line) and for the following boundary conditions: ABC (circle), zero-displacement (plus), and Neumann (triangle).*

More precisely, for the two dimensional case, the lattice Ω consists of $N_x = 25$ layers in the x-direction and $N_y = 5$ in the y-direction, and the prescribed Dirichlet boundary condition for $\mathbf{u}$ on $\Gamma_1 = \{y = 1\}$ is

$$\mathbf{u} = (\cos x + \sin 2x, \sin x). \tag{5.2}$$

For the three dimensional case, the lattice Ω consists of $N_x = N_y = 25$ layers in the x- and y-directions and $N_z = 4$ layers in the z-direction, and the Dirichlet data on $\Gamma_1 = \{z = 1\}$ is

$$\mathbf{u} = (\cos x + \sin 2x, \sin y, \sin x). \tag{5.3}$$

Numerical results are plotted in Figures 5.2 and 5.3. For numerical experiments, the exact ABCs and other approximate boundary conditions are imposed on $\Gamma_2 = \{y = 5\}$ for the two dimensional case and $\Gamma_2 = \{z = 4\}$ for the three dimensional case, respectively. The results show that the solution with the ABCs is much more accurate than those from the Dirichlet and Neumann boundary conditions. Indeed, the accuracy obtained with the ABCs operator is within the round-off error, i.e., $O(10^{-14})$.

5.3. Numerical simulations for thin films. In heteroepitaxial growth, a thin film of one material (e.g., Ge) is grown on top of a substrate of a second material (e.g., Si), with perfect, single crystalline structure in both materials and with the lattice

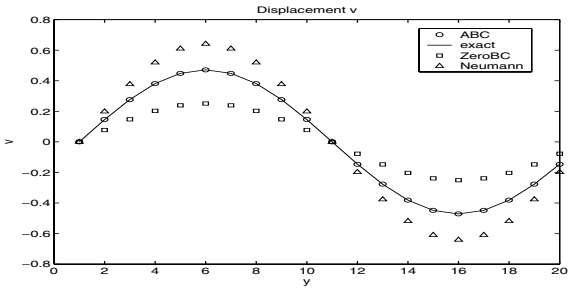

FIG. 5.3. *Test of the exact discrete ABCs in three dimensions: a comparison of the v-displacement field of* $\mathbf{u} = (u, v, w)$ *at* $(x, y, z) = (10, y, 3)$. *The boundary* Γ_1 *is at* $z = 1$, *and the interface* Γ_2 *is at* $z = 4$ *for the exact solution (line) and for the following boundary conditions: ABC (circle), zero-displacement (square), and Neumann (triangle).*

structure of the film determined by the substrate. If the lattice constants a_f and a_s for the film and substrate are different (e.g., $a_{Ge} = 1.04 \times a_{Si}$), then strain is generated in the film. This strain has important effects on the material structure, as well as on its electronic properties.

For this system, it is most convenient to define the atomic displacement relative to a single reference lattice, for example, the equilibrium lattice of the substrate, so that the displacement $\mathbf{u}$ in the film is defined relative to a nonequilibrium reference lattice. The bond displacement $\mathbf{d}^{\mathbf{k}\pm}$ is then

$$\mathbf{d}^{\mathbf{k}\pm}(\mathbf{i}) = (d_1^{k\pm}, d_2^{k\pm}, d_3^{k\pm}) = D_k^{\pm}\mathbf{u}(\mathbf{i}) - \epsilon \mathbf{e}_{\mathbf{k}}\chi, \tag{5.4}$$

in which $\epsilon = \frac{a_f - a_s}{a_s}$ is the relative lattice displacement, and χ is 0 in the substrate and 1 in the film. The resulting discrete strain equations have a force of size ϵ along the film/substrate interface, and the energy has the form

$$\mathcal{E}_{total} = \frac{1}{2}(\mathbf{H}\mathsf{U}, \mathsf{U}) - (\mathsf{F}, \mathsf{U}) + \mathcal{G}(\epsilon), \tag{5.5}$$

where

$$(\mathsf{F}, \mathsf{U}) = \sum_i \sum_{p=\pm, k=1,2,3} \epsilon\, D_k^p u_k \chi. \tag{5.6}$$

Further details are given, for example, in [5].

In this section, we compare the displacement fields $\mathbf{u}$ that are computed with the ABCs and with zero boundary conditions for a heteroepitaxial thin film. Since the forces lie on the film/substrate boundary, the artificial boundary can be taken to be any plane below this interface. Our computational domain is three dimensional with Γ_2 being of size 10×10. As in the last section, we denote NC to be the thickness of the substrate, including Γ_2. Note that on the top boundary Γ_1, the homogeneous Neumann boundary condition (no external force) is imposed.

To demonstrate the effectiveness of the ABCs, we first compute the displacement field $\mathbf{u}$ by imposing the ABCs on Γ_2 with substrate thickness NC = 1 and take it as the reference solution. We then compute two displacement fields that are generated by imposing zero boundary conditions on the bottom boundary with NC = 2 and NC = 8. For these three solutions, Figure 5.4 shows a comparison of the u component

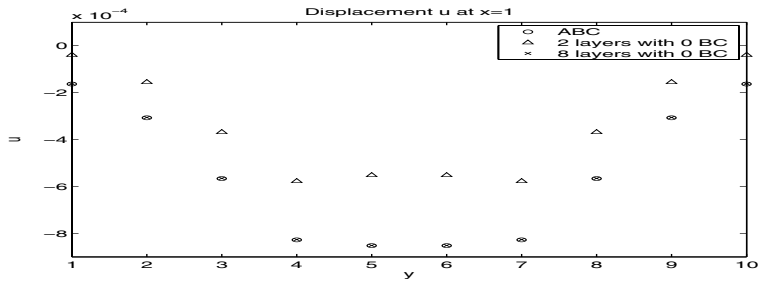

FIG. 5.4. *The comparison of u-displacement on the second layer from the top boundary* Γ_1 *with* $x = 1$. *The u-displacement computed with the ABC (circle) imposed on the first substrate layer and u-displacement computed with zero boundary condition with* NC $= 2$ *(triangle) and* NC $= 8$ *(cross).*

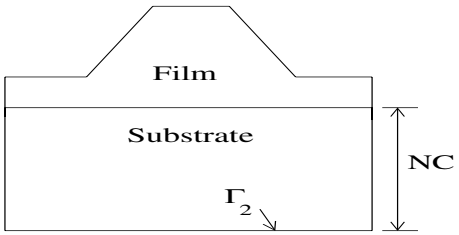

FIG. 5.5. *Schematic drawing of quantum dot geometry.*

of the displacement vector $\mathbf{u} = (u, v, w)$ on the line $x = 1$ in the second layer from the top. It is clear that the displacement field computed with the zero boundary conditions approaches the reference displacement field as the number of substrate layers increases. In addition (not shown in Figure 5.4), the results from the ABC are found to be independent (i.e., within round-off error) of the depth at which the ABC is applied.

5.4. Energy computation. This section presents results to validate the total energy formulas (4.51) and (4.52) derived in section 4.5. As in the previous section, NC denotes the number of substrate layers, including Γ_2 itself. In addition, E_A denotes the total energy computed by imposing the ABC on Γ_2, and E_Z denotes the total energy computed with the zero boundary condition on Γ_2.

For computational purposes, we take a geometry corresponding to a periodic array of quantum dots. A typical geometry is illustrated in Figure 5.5. For two space dimensions, Γ_2 is one dimensional with the material system of size $N_x = 128$ and the quantum dot of base size 64. For three space dimensions, Γ_2 is two dimensional with the material system of size $N_x = N_y = 10$ and the quantum dot of base size 8×8.

In order to validate the total energy formulas (4.51) and (4.52), by numerical computation we show first that the total energy E_A does not depend on the thickness of the substrate NC and second that the total energy E_Z obtained by imposing zero boundary conditions on Γ_2 approaches the total energy E_A as the thickness of substrates NC increases. These computational results are demonstrated in Figure 5.6, in which the thickness of the substrate NC varies from NC $= 2$ to NC $= 120$ for two space dimensions and from NC $= 2$ to NC $= 14$ for three space dimensions. The units of the total energy are 10^{12}dyne/cm^2.

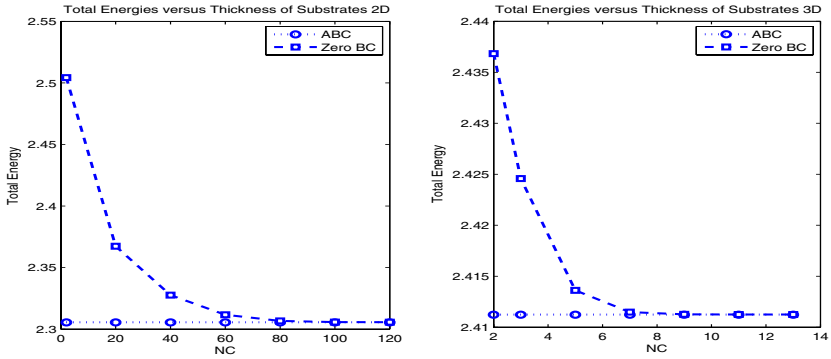

FIG. 5.6. *Total energies obtained by applying the ABC (circle) and zero boundary condition (square) as a function of the thickness of substrates for two dimensions (left) ($N_x = 128$) and three dimensions (right) ($N_x = N_y = 10$).*

6. Conclusions. In this paper, we have derived the ABCs for continuum and discrete elasticity equations. A solvability condition has been formulated and validated, under which the discrete equations in an unbounded domain can be shown to be well-posed and the reduced force balance equation can be derived. Its solution coincides with the exact solution when restricted to the bounded domain. Furthermore, a new total energy formula has been derived so that it can be computed by using only the displacement field in the region above the artificial boundary.

These results are currently being used for modeling and simulation of the growth of thin epitaxial films. By exploiting the symmetry of the resulting force balance equations in further work, we shall combine the ABCs with a multigrid method to get an accelerated simulation method for various applications.

Appendix. Several technical lemmas.

LEMMA A.1. *The matrix A_{-10} is invertible.*

Proof. Observe that

$$A_{-10}U_i = \mathcal{F}^{-1}\widehat{A}_{-10}\mathcal{F}(U_i), \tag{A.1}$$

where $\mathcal{F}$ and $\mathcal{F}^{-1}$ are Fourier and inverse Fourier transformations and $\widehat{A}_{-10}$ is a 3×3 (2×2 in two space dimensions) block matrix, such that for any given Fourier mode (μ,ν),

$$\widehat{A}_{-10}(\mu,\nu) = \begin{pmatrix} -C_{44} & 0 & -s_1 \\ 0 & -C_{44} & -s_2 \\ -s_1 & -s_2 & -C_{11} \end{pmatrix}, \tag{A.2}$$

where

$$s_1 = \imath\frac{(C_{12}+C_{44})}{2}\sin\left(\frac{2\pi\mu}{N_x}\right),$$
$$s_2 = \imath\frac{(C_{12}+C_{44})}{2}\sin\left(\frac{2\pi\nu}{N_y}\right).$$

The eigenvalues for $\widehat{A}_{-10}(\mu,\nu)$ can be obtained by solving the following equation:

$$\begin{aligned}\det(\widehat{A}_{-10}(\mu,\nu)-\lambda \mathrm{I}) &= -(C_{44}+\lambda)\left[(C_{44}+\lambda)(C_{11}+\lambda)-s_1^2-s_2^2\right]\\ &= -(C_{44}+\lambda)\left[\lambda^2+(C_{11}+C_{44})\lambda+C_{11}C_{44}\right.\\ &\qquad +\sin^2(2\pi\mu/N_x)(C_{12}+C_{44})^2/4\\ &\qquad \left.+\sin^2(2\pi\nu/N_y)(C_{12}+C_{44})^2/4\right].\end{aligned} \tag{A.3}$$

Hence, three eigenvalues λ_1,λ_2, and λ_3 are given as follows:

$$\begin{aligned}\lambda_1 &= -C_{44},\\ 2\lambda_2 &= -(C_{11}+C_{44})\\ &\quad +\sqrt{(C_{11}-C_{44})^2-(\sin^2(2\pi\mu/N_x)+\sin^2(2\pi\nu/N_y))(C_{12}+C_{44})^2},\\ 2\lambda_3 &= -(C_{11}+C_{44})\\ &\quad -\sqrt{(C_{11}-C_{44})^2-(\sin^2(2\pi\mu/N_x)+\sin^2(2\pi\nu/N_y))(C_{12}+C_{44})^2}.\end{aligned}$$

The eigenvalue with the smallest magnitude is λ_2 with $\sin(2\pi\nu/N_x)=\sin(2\pi\mu/N_y)=0$, in which case

$$2\lambda_2 = (-(C_{11}+C_{44})+|C_{11}-C_{44}|) = -2\min(C_{11},C_{44}). \tag{A.4}$$

It follows that no eigenvalues can be zero; hence A_{-10} is invertible. This completes the proof. ∎

LEMMA A.2. *For $\gamma_i \neq \gamma_j$, the corresponding eigenvectors $\mathbf{q}_i$ and $\mathbf{q}_j$ are linearly independent.*

Proof. Consider the linear reformulation of the palindromic eigenvalue problem (4.30) by introducing $x=\gamma y$ as follows: With $P(\mu,\nu,\gamma)=\gamma^2\widehat{A}_{-10}+\gamma\widehat{A}_{00}+\widehat{A}_{-10}^H$,

$$\begin{pmatrix} 0 & I \\ -\widehat{A}_{-10}^H & -\widehat{A}_{00}\end{pmatrix}\begin{pmatrix} y\\ x\end{pmatrix} = \gamma\begin{pmatrix} I & 0\\ 0 & \widehat{A}_{-10}\end{pmatrix}\begin{pmatrix} y\\ x\end{pmatrix}. \tag{A.5}$$

From the fact that $\widehat{A}_{-10}$ is invertible, it is obvious that the eigenvectors $\mathbf{q}_i$ and $\mathbf{q}_j$ that correspond to different eigenvalues γ_i and γ_j must be linearly independent. ∎

LEMMA A.3. *Under Condition* 4.1, *the matrix* M *given in* (4.20) *is an isomorphic mapping from* Θ *to* Θ^*.

Proof. For $\mathsf{V}^- = (V_{-1},V_{-2},\dots)^T \in \Theta$ with $V_i = \mathsf{C}^i V_0$ for $i\le 0$, as in Condition 4.1,

$$\begin{aligned}\mathsf{M}\mathsf{V}^- &= (-A_{-10}V_0,0,\dots,0,\dots)^T\\ &= \mathsf{G} = (G_{-1},0,\dots,0,\dots)^T\end{aligned} \tag{A.6}$$

if $G_{-1}=-A_{-10}V_0$. Since A_{-10} is invertible, this shows that the matrix M is onto.

To show that M is one to one, it is enough to show that $\mathsf{M}\mathsf{V}^-=0$ implies $\mathsf{V}^-=0$. Consider the energy

$$\mathcal{E}^- = \sum_{i<0} E_i \tag{A.7}$$

over the space Θ and observe that

$$(\mathsf{M}\mathsf{V}^-,\mathsf{V}^-) = \widehat{\mathcal{E}}^-, \tag{A.8}$$

in which $\widehat{\mathcal{E}}^-$ is $\mathcal{E}^-$ for $V_0 = 0$. Therefore, $\mathsf{MV}^- = 0$ implies that $\widehat{\mathcal{E}}^- = 0$. Connectivity of the lattice and $U_0 = 0$ then imply that $U_i = 0$ for all $i < 0$. This shows that the matrix M is one to one. Therefore, $\mathsf{M} : \Theta \mapsto \Theta^*$ is isomorphic. ∎

Proof of Lemma 4.2.

First, we show that $\mathcal{A}$ is symmetric. For any $\mathsf{U} = (0, 0, \dots, 0, U_0, U_{-1}, \dots, \dots)^T$ and $\mathsf{V} = (0, 0, \dots, 0, V_0, V_{-1}, \dots, \dots)^T$ that belong to the space $\mathbf{V}$, Condition 4.1 implies that

$$A_{-10}^T V_{-1} = -\mathcal{A} V_0 \quad \text{and} \quad A_{-10}^T U_{-1} = -\mathcal{A} U_0. \tag{A.9}$$

Note also that $\widetilde{\mathcal{E}}(\mathsf{U}, \mathsf{V}) = \widetilde{\mathcal{E}}(\mathsf{V}, \mathsf{U})$; i.e.,

$$\begin{aligned} \widetilde{\mathcal{E}}(\mathsf{U}, \mathsf{V}) &= \frac{1}{2}\left(U_0, \left(A_{00} V_0 + A_{-10}^T V_{-1}\right)\right) \\ &= \frac{1}{2}\left(V_0, \left(A_{00} U_0 + A_{-10}^T U_{-1}\right)\right) = \widetilde{\mathcal{E}}(\mathsf{V}, \mathsf{U}). \end{aligned} \tag{A.10}$$

Use (A.9) in (A.11) to obtain

$$(U_0, (A_{00} V_0 - \mathcal{A} V_0)) = (V_0, (A_{00} U_0 - \mathcal{A} U_0)).$$

Since A_{00} is symmetric, this implies that $(U_0, \mathcal{A} V_0) = (V_0, \mathcal{A} U_0)$ for all $U_0, V_0 \in \mathbb{R}^N$ and therefore, that $\mathcal{A}$ is symmetric. The symmetry of the operator $\mathcal{A}$ implies that the matrix $\widehat{\mathbf{H}}$ is symmetric.

Next, we show that $\mathcal{A}$ is positive definite since for $U_0 \neq 0 \in \mathbb{R}^N$,

$$\begin{aligned} (U_0, \mathcal{A} U_0) &= (U_0, \mathsf{B}\mathsf{M}^{-1}\mathsf{B}^T U_0) = (\mathsf{B}^T U_0, \mathsf{M}^{-1}\mathsf{B}^T U_0) \\ &= (\mathsf{M}\mathsf{U}^-, \mathsf{M}^{-1}\mathsf{M}\mathsf{U}^-) = (\mathsf{M}\mathsf{U}^-, \mathsf{U}^-) = \widehat{\mathcal{E}}^- > 0, \end{aligned}$$

where U^- is the unique solution of $\mathsf{M}\mathsf{U}^- = \mathsf{B}^T U_0$. Finally, we show that the matrix $\widehat{\mathbf{H}}$ is nonnegative definite. First note that $\widehat{\mathbf{H}}\mathbf{1} = 0$. Furthermore, there is no other null space for $\widehat{\mathbf{H}}$, since

$$\begin{aligned} \widehat{\mathbf{H}} \begin{pmatrix} \mathsf{U}^+ \\ U_0 \end{pmatrix} = 0 &\Longleftrightarrow (U_0, (A_{01} U_1 + (A_{00} - \mathcal{A}) U_0)) \\ &\quad + \sum_{i>0} (U_i, (A_{ii-1} U_{i-1} + A_{ii} U_i + A_{ii+1} U_{i+1})) = 0 \\ &\Longleftrightarrow \widetilde{\mathcal{E}}(\mathsf{U}, \mathsf{U}) = 0 \quad \text{with} \quad \mathsf{U} \in \mathbf{V} \\ &\Longleftrightarrow \mathsf{U} = \mathbf{1} \quad \text{by connectivity of the lattice.} \end{aligned}$$

This completes the proof of Lemma 4.2. ∎

DYNAMIC BEHAVIOR OF A PACED CARDIAC FIBER*

JOHN W. CAIN†

Abstract. Consider a typical experimental protocol in which one end of a one-dimensional fiber of cardiac tissue is periodically stimulated, or paced, resulting in a train of propagating action potentials. There is evidence that a sudden change in the pacing period can initiate abnormal cardiac rhythms. In this paper, we analyze how the fiber responds to such a change in a regime without arrhythmias. In particular, given a fiber length L and a tolerance η, we estimate the number of beats $N = N(\eta, L)$ required for the fiber to achieve approximate steady-state in the sense that spatial variation in the diastolic interval (DI) is bounded by η. We track spatial DI variation using an infinite sequence of linear integral equations which we derive from a standard kinematic model of wave propagation. The integral equations can be solved in terms of generalized Laguerre polynomials. We then estimate N by applying an asymptotic estimate for generalized Laguerre polynomials. We find that, for fiber lengths characteristic of cardiac tissue, it is often the case that N effectively exhibits no dependence on L. More exactly, (i) there is a critical fiber length L^* such that, if $L < L^*$, the convergence to steady-state is slowest at the pacing site, and (ii) often, L^* is substantially larger than the diameter of the whole heart.

Key words. cardiac fiber, pacing, transient behavior, restitution, kinematic model, generalized Laguerre polynomials

1. Introduction.

Cardiac cells have the property of *excitability*: when a stimulus current of sufficient strength is applied to a quiescent cell, the transmembrane voltage v undergoes a prolonged elevation, called an *action potential*, before eventually returning to its resting value. Repeatedly stimulated, or *paced*, cardiac cells exhibit sequences of action potentials. By specifying a threshold voltage $v = v_{\text{thr}}$, one may define the *action potential duration (APD)* as the amount of time in which $v > v_{\text{thr}}$ during an action potential. The recovery time during which $v < v_{\text{thr}}$ between successive action potentials is called the *diastolic interval (DI)*. As illustrated in Figure 1, we shall denote the APD following the nth stimulus by A_n and the subsequent DI by D_n.

Periodic pacing leads to one of several types of phase-locked responses depending on the underlying pacing period B. For large B, cells exhibit a 1:1 response in which every stimulus yields an identical action potential. For smaller B, one sometimes observes a period-2 response, known as *alternans*, in which APD and DI values exhibit beat-to-beat alternation [21, 23, 24, 28, 29]. If B is decreased even further, cells exhibit a 2:1 response in which only every other stimulus yields an action potential [15, 21, 35]. In what follows, we shall assume that all pacing periods are sufficiently large to ensure a 1:1 steady-state response.

In spatially extended tissue, neighboring cells are coupled electrically via gap junctions, allowing action potentials to propagate through the tissue [19, 25]. Below,

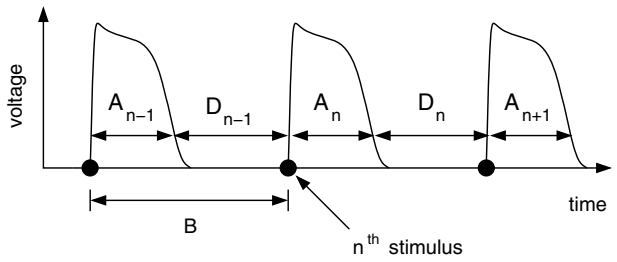

FIG. 1. *Voltage trace of several action potentials in a paced cardiac cell.*

we shall study the dynamics of a paced cardiac fiber composed of cylindrical cells joined together in an end-to-end fashion. We assume that voltage exhibits negligible radial dependence, varying only as a function of a length variable x; that is, the fiber can be treated as one-dimensional. Moreover, we shall assume that pacing is performed at one end of the fiber which we identify with $x = 0$.

Typically, propagation of action potentials in a one-dimensional fiber is modeled using a reaction-diffusion equation known as the *cable equation*, which, after nondimensionalization, takes the form

$$\frac{\partial v}{\partial t} = \frac{\partial^2 v}{\partial x^2} + g(v, w). \tag{1}$$

Here, $v = v(x, t)$ is the transmembrane voltage and w is a vector of various dynamic variables that are used in modeling the ionic mechanism of the action potential. For a derivation of the cable equation, see the texts of Plonsey and Barr [25] and Keener and Sneyd [19]. Examples of studies in which the cable equation is used to model cardiac dynamics include [5, 6, 7, 18, 22].

Although the cable equation serves as a popular model, we remark that arrhythmias, by nature, concern the *timing* of excitation and recovery of the cells. Therefore, it is often desirable to track the progress of propagating action potentials without regard to the structure of the voltage profile. Indeed, many recent studies [4, 8, 11, 12, 16, 30, 34] have employed *kinematic* models [19, 27] of wave propagation in cardiac fibers.

In this paper, we use a kinematic model to investigate how a fiber of length L responds to a sudden change in the pacing period, say from B_{old} to B_{new}. Changing the pacing period introduces spatial variation in APD and DI. Our primary goal is to estimate the number of beats required for the fiber to "adjust" to the new pacing period, i.e., the number of beats required to reach approximate steady-state in the sense that spatial variation in DI is small. No previous studies have analyzed the transient behavior following a change in the pacing period. In the course of solving our main problem, we shall provide such an analysis. Describing the persistence of spatial DI variation under such a pacing protocol may lead to an improved understanding of the mechanisms for initiation of arrhythmias such as discordant alternans [34].

To establish notation, refer to Figure 2, which illustrates both the spatial variation in DI induced by changing the pacing period from B_{old} to $B_{\text{new}} < B_{\text{old}}$ and the aforementioned convergence to a steady-state. Here, $D_n = D_n(x)$ denotes the nth DI following the change in the pacing period—in particular, $n = 1$ corresponds to the first beat with period B_{new}. Figure 2(a) shows $D_n(x)$ for $n = 1, \ldots, 4$ and Figure 2(b) shows $D_n(x)$ for $n = 7, 8$. Note that $D_n(x)$ appears to converge pointwise to a constant

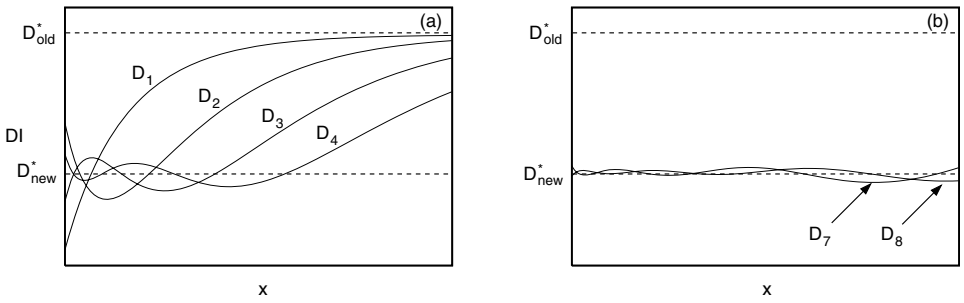

FIG. 2. *Spatial variation in DI after changing the pacing period from* B_{old} *to* $B_{\text{new}} < B_{\text{old}}$. (a) *the curves* $D_n(x)$ *for* $n = 1, \ldots, 4$; (b) *the curves* $D_n(x)$ *for* $n = 7, 8$.

D^*_{new} as $n \to \infty$.

More quantitatively, our main problem may be stated as follows. Let $\eta > 0$ be a given tolerance, and let n and D^*_{new} be as in the preceding paragraph.

Goal: Estimate the number of beats $N = N(\eta, L)$ such that $|D_n(x) - D^*_{\text{new}}| < \eta$ for all $x \in [0, L]$, $n \geq N$.

Our analysis shows that, for fibers shorter than a critical length $L = L^*$, the convergence is slowest at the pacing site $x = 0$. In other words, $N(\eta, L)$ does not depend on the fiber length L provided that $L < L^*$. Moreover, we find that $L^* \to \infty$ as the slope of the restitution curve at $DI = D^*_{\text{new}}$ tends to 1. Hence, $N(\eta, L)$ is especially unlikely to exhibit any length dependence as we approach the bifurcation to alternans.

The remainder of this paper is organized as follows. In section 2, we recall a kinematic model [19, 27] of wave propagation, which allows us to follow the progress of each action potential without tracking the complete voltage profile $v(x, t)$. From the kinematic model, we derive a recursive sequence of linear equations which can be solved to yield approximations $y_n(x)$ of $D_n(x) - D^*_{\text{new}}$, allowing us to monitor the convergence to steady-state. As explained in section 3, the functions $y_n(x)$ can be expressed in terms of generalized Laguerre polynomials. The behavior of the functions $y_n(x)$ can be approximated by recalling a large-n asymptotic estimate for the generalized Laguerre polynomials. This allows us to estimate the maximum of $|y_n(x)|$ on the interval $[0, L]$, thereby leading to an estimate of $N(\eta, L)$. The estimate of $N(\eta, L)$ is given by one of two formulas according to whether $L < L^*$ or $L > L^*$. Section 4 contains a summary and discussion of our results.

2. Derivation of the governing equations. We begin this section with a brief discussion of the restitution and dispersion curves. We then recall a kinematic model of action potentials propagating in a paced fiber. From the equations of the kinematic model, we derive a sequence of linear equations which will allow us to solve the main problem.

2.1. Restitution and dispersion curves. Cardiac cells exhibit electrical *restitution*: The steady-state APD at a given pacing period B decreases as B is shortened. Nolasco and Dahlen [23] were among the first to model restitution with a mapping

$$A_{n+1} = f(D_n) = f(B - A_n). \tag{2}$$

Guevara et al. [14] later showed that alternans can result from a period-doubling bifurcation of (2) as the pacing period B is decreased. The function f is called the *restitution function*, and its graph is called the *restitution curve*. The restitution curve is typically monotone increasing; i.e., more recovery time yields longer excitations. Many authors (see, for example, [1, 2, 15]) have fit restitution data with exponential functions of the form

$$f(DI) = APD_{\max} - ke^{-DI/\tau}, \tag{3}$$

where $APD_{\max}$, k, and τ are positive constants. We shall not specify a functional form for the restitution function but will assume that f has the same qualitative shape as (3).

Just as APD depends upon the preceding DI, the wave front velocity of an action potential in a fiber depends upon the preceding (local) DI. This dependence is often displayed graphically via the *dispersion curve*, which typically has the same qualitative shape as the restitution curve. We shall denote the functional form of the dispersion curve by $c(DI)$.

2.2. Kinematic model of wave propagation. To solve the problem of estimating $N(\eta, L)$, we need only track the progress of action potentials, not their complete structure. Hence, we shall employ a kinematic model of wave propagation [19, 27]. In doing so, we implicitly assume that recovery always occurs via a phase wave [9, 33]; i.e. the wave back of each action potential is not greatly affected by diffusion. We also adopt the following assumptions, the last two of which are specific to the pacing protocol described in the introduction:

- (A1) To a reasonable approximation, the tissue does not exhibit *memory*: As implicitly assumed in (2), A_{n+1} depends only upon D_n and is not greatly influenced by the past pacing history. Likewise, the wave front velocity of the $(n+1)$st action potential depends only upon $D_n(x)$, the preceding local DI.
- (A2) The restitution and dispersion curves are monotone increasing.
- (A3) To implement the pacing protocol outlined in the introduction, the interval between the nth and $(n+1)$st stimuli is B_{old} if $n \leq 0$ and B_{new} if $n > 0$.
- (A4) Prior to the change in the pacing period (i.e., for $n \leq 0$), the long-term pacing with period B_{old} leads to a 1:1 steady-state response in which DI is a constant,[1] say D^*_{old}. In particular, $D_0(x) \equiv D^*_{\text{old}}$.

We now recall how to use the information contained in the restitution and dispersion curves to track the wave fronts and wave backs of the action potentials. If we pace one end (say $x = 0$) of a fiber and plot $v(x,t)$ versus x and t, we obtain a surface in three-dimensional space. Taking the intersection of this surface with the plane $v = v_{\text{thr}}$, we generate a sequence of curves which we identify with the wave fronts and wave backs of the action potentials. Projecting these curves onto the xt plane yields a schematic space-time plot of the wave fronts and wave backs as illustrated in Figure 3. Here, $\phi_n(x)$ (resp., $\beta_n(x)$) denotes the time at which the nth wave front (resp., wave back) arrives at x, and

$$CL_n(x) = \phi_{n+1}(x) - \phi_n(x) \tag{4}$$

[1] Referring to (2) with $B = B_{\text{old}}$, note that D^*_{old} is the unique DI satisfying the equation $DI + f(DI) = B_{\text{old}}$.

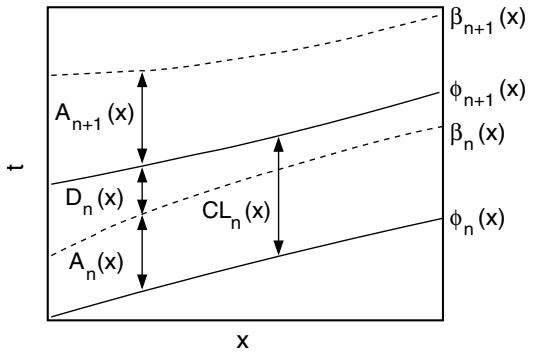

FIG. 3. *Schematic diagram of wave fronts (solid curves) and wave backs (dashed curves).*

is called the *cycle length*. Since

$$A_n(x) = \beta_n(x) - \phi_n(x) \quad \text{and} \quad D_n(x) = \phi_{n+1}(x) - \beta_n(x), \tag{5}$$

we may also express the cycle length as

$$CL_n(x) = A_n(x) + D_n(x). \tag{6}$$

From our assumption that recovery occurs via a phase wave, we may apply the restitution function locally at each x along the fiber:

$$A_n(x) = f(D_{n-1}(x)) \qquad (0 \le x \le L). \tag{7}$$

The slope of $\phi_n(x)$ is related to the speed of the nth wave front:

$$\frac{d\phi_n}{dx} = \frac{1}{c(D_{n-1}(x))} \qquad (0 < x < L). \tag{8}$$

By (6) and (7), the cycle length satisfies an algebraic condition

$$CL_n(x) = D_n(x) + f(D_{n-1}(x)), \tag{9}$$

and by (4) and (8), the cycle length also satisfies a differential equation

$$\frac{dCL_n}{dx} = \frac{1}{c(D_n(x))} - \frac{1}{c(D_{n-1}(x))}. \tag{10}$$

Combining (9) and (10), we obtain a sequence of differential equations involving only DI values:

$$\frac{d}{dx}\left[D_n(x) + f(D_{n-1}(x))\right] = G(D_n(x)) - G(D_{n-1}(x)), \tag{11}$$

where

$$G(DI) = \frac{1}{c(DI)}. \tag{12}$$

From assumption (A3) above, pacing at $x = 0$ yields the boundary condition

$$D_n(0) = \begin{cases} B_{\text{old}} - f(D_{n-1}(0)), & n \le 0, \\ B_{\text{new}} - f(D_{n-1}(0)), & n > 0, \end{cases} \tag{13}$$

while assumption (A4) yields an initial condition

$$D_0(x) \equiv D^*_{\text{old}}. \tag{14}$$

Combining (11), (13), and (14), we obtain a sequence of equations that can be solved iteratively to determine $D_n(x)$ for $n > 0$ and $0 \le x \le L$.

2.3. Derivation of the main sequence of equations. To analyze the transient behavior following the change in the pacing period, we linearize (11), (13) for $n \ge 0$. The resulting sequence of initial value problems (see (16), (17)) leads to our main sequence of equations (see (23)), which we solve exactly in the next section to obtain approximations of the functions $D_n(x)$ for $n \ge 0$.

To linearize (11), (13) for $n \ge 0$, let D^*_{new} denote the steady-state DI associated with long-term pacing with period B_{new} and let $y_n(x)$ denote our approximation of $D_n(x) - D^*_{\text{new}}$. By (14), we have

$$y_0(x) = D^*_{\text{old}} - D^*_{\text{new}}, \tag{15}$$

a constant. For $n > 0$, the linearization of (11), (13) about D^*_{new} is given by

$$\frac{d}{dx}\left[y_n(x) + \alpha y_{n-1}(x)\right] = -\lambda\left[y_n(x) - y_{n-1}(x)\right], \tag{16}$$

$$y_n(0) = -\alpha y_{n-1}(0) \qquad (n > 0), \tag{17}$$

where

$$\alpha = f'(D^*_{\text{new}}) \tag{18}$$

denotes the slope of the restitution curve evaluated at D^*_{new} and

$$-\lambda = G'(D^*_{\text{new}}). \tag{19}$$

The negative sign in (19) emphasizes that $G(DI) = 1/c(DI)$ is a monotone decreasing function, which follows from assumption (A2) in the previous subsection. We remark that

- α is dimensionless and λ has units of $(\text{length})^{-1}$;
- in the linearized dynamics, the rate of convergence to steady-state at the $x = 0$ boundary is determined by α, the Floquet multiplier [31] of the map $A_{n+1} = f(B_{\text{new}} - A_n)$.

Let us solve (16), (17) for $y_n(x)$ in terms of $y_{n-1}(x)$, resulting in a recursive sequence of equations. Rewriting (16) as

$$\frac{d}{dx}\left[y_n(x) + \alpha y_{n-1}(x)\right] = -\lambda\left[y_n(x) + \alpha y_{n-1}(x)\right] + (\alpha+1)\lambda y_{n-1}(x), \tag{20}$$

we use $e^{\lambda x}$ as an integrating factor to obtain

$$\frac{d}{dx}\left\{e^{\lambda x}\left[y_n(x) + \alpha y_{n-1}(x)\right]\right\} = (\alpha+1)\lambda e^{\lambda x} y_{n-1}(x). \tag{21}$$

Integration yields

$$e^{\lambda x}\left[y_n(x) + \alpha y_{n-1}(x)\right] = y_n(0) + \alpha y_{n-1}(0) + (\alpha+1)\lambda \int_0^x e^{\lambda s} y_{n-1}(s)\, ds. \tag{22}$$

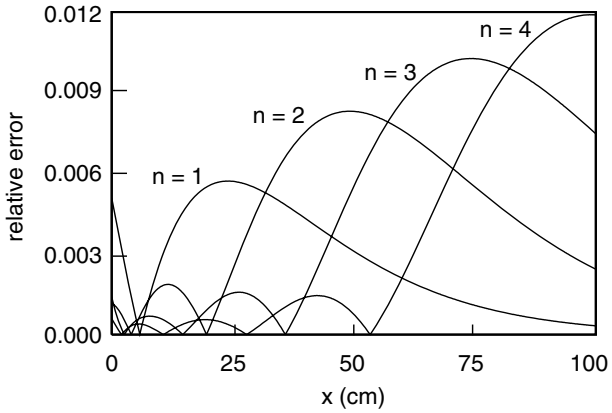

FIG. 4. *Relative error in using $y_n(x)$ to approximate $D_n(x) - D^*_{\text{new}}$ for $n = 1, \ldots, 4$.*

Finally, applying boundary condition (17) and rearranging terms, we obtain our main sequence of equations,

$$y_n(x) = -\alpha y_{n-1}(x) + (\alpha+1)\lambda \int_0^x e^{-\lambda(x-s)} y_{n-1}(s)\, ds \qquad (n \geq 1). \tag{23}$$

Numerical evidence suggests that solutions of the linearized equations (23) exhibit good quantitative agreement with solutions of the original nonlinear equations (11) and (13). Figure 4 shows the relative error $|D_n(x) - D^*_{\text{new}} - y_n(x)|/D_n(x)$ versus x for $n = 1, \ldots, 4$ after shortening the pacing period from $B_{\text{old}} = 340$ ms to $B_{\text{new}} = 320$ ms. The functions $D_n(x)$ were generated by numerical solution of (11) and (13) with f and c chosen as in (73) and (74), respectively. The functions $y_n(x)$ were generated by numerical solution of (23) with the same choices for f and c. We remark that these restitution and dispersion curves provide physiologically realistic APD values and propagation speeds for mammalian ventricular tissue [1, 13]. Note that the relative error (at least through four beats) never exceeds 0.012 even at the "un-physiological" distance of one meter from the stimulus site.

3. Estimating the rate of convergence to steady-state. Equation (23) allows us to determine y_n provided that y_{n-1} is known. In our case, $y_0(x)$ is a constant since $D_0(x) \equiv D^*_{\text{old}}$. We remark that, due to the simple form of $y_0(x)$, the recursive sequence of equations (23) can be solved exactly by successive substitutions. In doing so, it is advantageous to introduce some abstract notation (subsections 3.1 and 3.2) which helps us recognize that solutions of (23) can be expressed in terms of generalized Laguerre polynomials. Then, by applying a large-n asymptotic approximation of the Laguerre polynomials, we derive the desired estimate of $N(\eta, L)$ (see subsections 3.3 and 3.4).

3.1. Step 1: A Volterra integral operator. Motivated by (23), we define an operator $T = -\alpha I + (\alpha+1)\lambda K$ on the Banach space $(C[0, L], \|\cdot\|_\infty)$, where I denotes the identity operator and

$$(K\psi)(x) = \int_0^x e^{-\lambda(x-s)} \psi(s)\, ds. \tag{24}$$

Then clearly $y_n = Ty_{n-1} = T^n y_0$. Our goal is to estimate the rate of convergence[2] of $y_n = T^n y_0$ to 0. To do so, we exploit the fact that y_0 is a constant function; i.e.,

$$\|T^n y_0\|_\infty = |y_0| \cdot \|T^n 1\|_\infty, \tag{25}$$

where y_0 is a constant. Our main problem can now be stated as

$$\text{Given any } \eta > 0, \text{ determine } N = N(\eta, L) \text{ such that } \|T^n 1\|_\infty < \frac{\eta}{|y_0|} \text{ for all } n > N. \tag{26}$$

In the next subsection, we derive a formula for the function $(T^n 1)(x)$. Later, we will use asymptotics to learn more about the extrema of this function, using our results to estimate $\|T^n 1\|_\infty$.

3.2. Step 2: Computing powers of the operator T. Recalling that $T = -\alpha I + (\alpha+1)\lambda K$, we may apply the binomial theorem to obtain

$$(T^n\varphi)(x) = \sum_{m=0}^{n} \binom{n}{m} (-\alpha)^{n-m} (\alpha+1)^m \lambda^m (K^m\varphi)(x). \tag{27}$$

Powers of the operator K are straightforward to compute. For $m \geq 1$, we find that

$$(K^m\varphi)(x) = \int_0^x \int_0^{s_1} \cdots \int_0^{s_{m-1}} e^{-\lambda(x-s_m)} \varphi(s_m)\, ds_m\, ds_{m-1} \cdots ds_1. \tag{28}$$

Reversing the order of integration, the iterated integral (28) simplifies to a single integral

$$(K^m\varphi)(x) = \int_0^x \frac{(x-s_m)^{m-1}}{(m-1)!} e^{-\lambda(x-s_m)} \varphi(s_m)\, ds_m. \tag{29}$$

Combining (27) and (29) yields

$$(T^n\varphi)(x) = (-\alpha)^n \varphi(x) + \int_0^x \Psi_n(x-s)\, \varphi(s)\, ds \;=\; (-\alpha)^n \varphi(x) + \int_0^x \Psi_n(s)\, \varphi(x-s)\, ds, \tag{30}$$

where

$$\Psi_n(s) = e^{-\lambda s} \sum_{m=1}^{n} \binom{n}{m} (-\alpha)^{n-m} (\alpha+1)^m \lambda^m \frac{s^{m-1}}{(m-1)!}. \tag{31}$$

It follows that

$$(T^n 1)(x) \;=\; (-\alpha)^n + \int_0^x \Psi_n(s)\, ds. \tag{32}$$

The functions Ψ_n can be expressed in terms of generalized Laguerre polynomials, a well-known class of special functions which can be defined as in the following definition (see Szegő [32]).

[2]We remark that the trivial estimate $\|y_n\|_\infty = \|T^n y_0\|_\infty \leq \|T\|^n \|y_0\|_\infty$ is too weak since $\|T\|$ can exceed 1. This is especially true close to the onset of alternans (i.e., as $\alpha \to 1^-$), in which case T is a contraction only for very short fiber lengths. However, it is straightforward [10, 26] to show that the spectral radius of T is simply α. Hence, if $\alpha < 1$, then $\|T^n y_0\|_\infty$ converges to 0 as $n \to \infty$.

DEFINITION 3.1. *Let $\beta > -1$ and $n \geq 0$. Then the* generalized Laguerre polynomial $L_n^{(\beta)}(x)$ *is defined by*

$$L_n^{(\beta)}(x) = \sum_{m=0}^{n} \binom{n+\beta}{n-m} \frac{(-x)^m}{m!}. \tag{33}$$

Comparing (31) and (33) with $\beta = 1$, it is straightforward to verify that

$$\Psi_n(s) = (-\alpha)^{n-1}(\alpha+1)\lambda\, e^{-\lambda s}\, L_{n-1}^{(1)}\left(\frac{\lambda(\alpha+1)s}{\alpha}\right). \tag{34}$$

By (32) and (34), we have

$$\begin{aligned}(T^n 1)(x) &= (-\alpha)^n + (-\alpha)^{n-1}(\alpha+1)\lambda \int_0^x e^{-\lambda s}\, L_{n-1}^{(1)}\left(\frac{\lambda(\alpha+1)s}{\alpha}\right) ds \\ &= (-\alpha)^n \left(1 - \int_0^{\frac{\lambda(\alpha+1)x}{\alpha}} e^{-\frac{\alpha s}{\alpha+1}}\, L_{n-1}^{(1)}(s)\, ds\right). \end{aligned} \tag{35}$$

3.3. Step 3: Large-n asymptotic estimate of $\|T^n 1\|_\infty$. In order to estimate $\|T^n 1\|_\infty$, we must approximate the integral in (35). To do so, we will make use of an asymptotic estimate for the generalized Laguerre polynomials. However, because the estimate we will use is not uniformly valid throughout the region of integration, we will split the region of integration into two subregions.

The following asymptotic approximation as $n \to \infty$ for the generalized Laguerre polynomials appears in Szegő [32, p. 199].

THEOREM 3.2. *Let $\beta > -1$ and $n \to \infty$. Then*

$$L_n^{(\beta)}(x) = \pi^{-\frac{1}{2}}\, e^{\frac{x}{2}}\, x^{-\frac{\beta}{2}-\frac{1}{4}}\, n^{\frac{\beta}{2}-\frac{1}{4}} \left[\cos\left(\sqrt{4nx} - \frac{\beta\pi}{2} - \frac{\pi}{4}\right) + (nx)^{-\frac{1}{2}} O(1)\right]. \tag{36}$$

Moreover, given positive constants c and ω, the error term holds uniformly on the interval $cn^{-1} \leq x \leq \omega$.

Because the asymptotic approximation given by Theorem 3.2 breaks down for x small, we estimate (35) by splitting the interval of integration into two subintervals. For the boundary between the two subintervals, we use an approximation of the first root of $L_{n-1}^{(1)}$. Setting $\beta = 1$, note that the first two zeros of the approximation given by (36) occur when the argument of the cosine term is $-\pi/2$ or $\pi/2$. The $(nx)^{-1/2}$ error term influences the location of the first zero of (36) because it is not negligible for $x = O(1/n)$. Figure 5 suggests that we may approximate[3] the first root of $L_n^{(1)}(x)$ as the value of x for which the cosine term in (36) is $\pi/2$, not $-\pi/2$. That is, $x = C/n$, where

$$C = \frac{25\pi^2}{64} = 3.8553\ldots. \tag{37}$$

In what follows, we will use $C/(n-1)$ as the boundary between the two subintervals of integration.

[3] A more precise estimate of $x_{1n}^{(\beta)}$, the first root of $L_n^{(\beta)}(x)$, appears in Szegő [32]: $\lim_{n\to\infty}(n\, x_{1n}^{(\beta)}) = (j_1^{(\beta)}/2)^2 = 3.6705\ldots$, where $j_1^{(\beta)} = 3.8317\ldots$ denotes the first positive zero of the Bessel function $J_\beta(x)$.

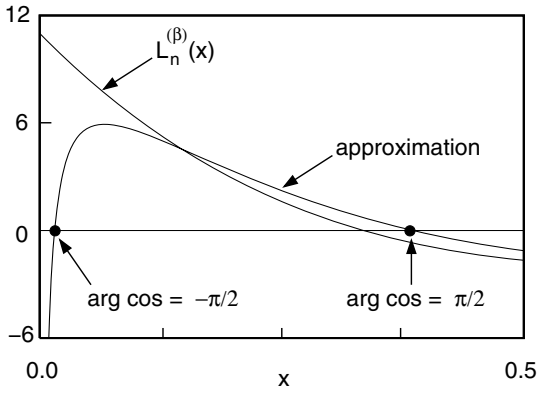

FIG. 5. *Comparison of the generalized Laguerre polynomial $L_n^{(\beta)}(x)$ with the approximation given by Theorem* 3.2 *for $n = 10$ and $\beta = 1$. As indicated in the figure, the first two roots of the approximation* (36) *occur when the argument of the cosine function is $-\pi/2$ or $\pi/2$.*

To estimate the integral in (35), we write

(38)
$$\int_0^{\frac{\lambda(\alpha+1)x}{\alpha}} e^{-\frac{\alpha s}{\alpha+1}}\, L_{n-1}^{(1)}(s)\, ds = \underbrace{\int_0^{\frac{C}{n-1}} e^{-\frac{\alpha s}{\alpha+1}}\, L_{n-1}^{(1)}(s)\, ds}_{\mathbf{I_1}} + \underbrace{\int_{\frac{C}{n-1}}^{\frac{\lambda(\alpha+1)x}{\alpha}} e^{-\frac{\alpha s}{\alpha+1}}\, L_{n-1}^{(1)}(s)\, ds.}_{\mathbf{I_2}}$$

Our expression for $(T^n 1)(x)$ now reads

$$(T^n 1)(x) = (-\alpha)^n \left(1 - \mathbf{I_1} - \mathbf{I_2}\right). \tag{39}$$

Estimating $\mathbf{I_1}$. To estimate the integral $\mathbf{I_1}$ in (38), we treat the two factors in the integrand separately. The factor $L_{n-1}^{(1)}(s)$ can be approximated by a quadratic function $q_{n-1}(s)$ by matching $L_{n-1}^{(1)}(s)$ and its derivative at $s = 0$ and using the fact that $L_{n-1}^{(1)}(C/(n-1)) \approx 0$. By algebra, we find that the polynomial

$$q_{n-1}(s) = \frac{n(n-1)^2}{C^2}\left(\frac{C}{2} - 1\right) s^2 - \frac{1}{2} n(n-1)s + n \tag{40}$$

approximates the function $L_{n-1}^{(1)}(s)$ in the interval $[0, C/(n-1)]$. Because the exponential factor in the integrand of $\mathbf{I}_1$ is $1+O(1/n)$ throughout the region of integration, we neglect this factor and compute

$$\mathbf{I_1} \approx \int_0^{\frac{C}{n-1}} q_{n-1}(s)\, ds = \frac{2C}{3} - \frac{C^2}{12} + O\left(\frac{1}{n}\right). \tag{41}$$

In what follows, we will approximate $\mathbf{I_1}$ by

$$\mathbf{I_1} \;\approx\; \frac{2C}{3} - \frac{C^2}{12} \;=\; 1.3315\ldots\,. \tag{42}$$

Estimating $\mathbf{I_2}$. Integral $\mathbf{I_2}$ in (38) can be approximated by applying Theorem 3.2 with $\beta = 1$. Setting

$$\gamma = \frac{1-\alpha}{2(1+\alpha)}, \tag{43}$$

we have

$$\mathbf{I_2} \approx \pi^{-\frac{1}{2}}(n-1)^{\frac{1}{4}} \int_{\frac{C}{n-1}}^{\frac{\lambda(\alpha+1)x}{\alpha}} s^{-\frac{3}{4}}\, e^{\gamma s}\, \cos\left(\sqrt{4(n-1)s} - \frac{3\pi}{4}\right) ds. \tag{44}$$

Upon substituting $s \mapsto \sqrt{s}$, (44) becomes

$$\mathbf{I_2} \approx 2\pi^{-\frac{1}{2}}(n-1)^{\frac{1}{4}} \int_{\sqrt{\frac{C}{n-1}}}^{\sqrt{\frac{\lambda(\alpha+1)x}{\alpha}}} s^{-\frac{1}{2}}\, e^{\gamma s^2}\, \cos\left(\sqrt{4(n-1)}\cdot s - \frac{3\pi}{4}\right) ds. \tag{45}$$

Integrating (45) by parts,

(46)

$$\mathbf{I}_2 \approx \left.\frac{s^{-\frac{1}{2}}\, e^{\gamma s^2} \sin\left(\sqrt{4(n-1)}\cdot s - \frac{3\pi}{4}\right)}{\sqrt{\pi}(n-1)^{\frac{1}{4}}}\right|_{\sqrt{\frac{C}{n-1}}}^{\sqrt{\frac{\lambda(\alpha+1)x}{\alpha}}}$$
$$- \frac{1}{\sqrt{\pi}(n-1)^{\frac{1}{4}}} \int_{\sqrt{\frac{C}{n-1}}}^{\sqrt{\frac{\lambda(\alpha+1)x}{\alpha}}} \left(-\frac{1}{2}s^{-\frac{3}{2}} + 2\gamma s^{\frac{1}{2}}\right) e^{\gamma s^2} \sin\left(\sqrt{4(n-1)}\cdot s - \frac{3\pi}{4}\right) ds.$$

At first, the two terms in (46) appear to be of the same order, namely $O(n^{-1/4})$. However, for large n the rapid oscillation of the integrand of the volume term leads to cancellation, and hence the volume term is small relative to the boundary term. (This can also be seen by integrating by parts a second time.) Thus, we approximate $\mathbf{I_2}$ by retaining only the boundary terms in (46):

$$\mathbf{I_2} \approx \frac{u(x)}{(n-1)^{\frac{1}{4}}} \sin\left(\sqrt{\frac{4\lambda(\alpha+1)(n-1)x}{\alpha}} - \frac{3\pi}{4}\right)$$
$$- \left(\frac{1}{C\pi^2}\right)^{\frac{1}{4}} e^{\frac{C(1-\alpha)}{2(1+\alpha)(n-1)}} \sin\left(\sqrt{4C} - \frac{3\pi}{4}\right), \tag{47}$$

where

$$u(x) = \left(\frac{\alpha}{\pi^2\lambda(\alpha+1)x}\right)^{\frac{1}{4}} e^{\frac{\lambda(1-\alpha)x}{2\alpha}}. \tag{48}$$

The first term in (47) is bounded by

$$\frac{u(x)}{(n-1)^{\frac{1}{4}}}, \tag{49}$$

and, for large n, the second term of (47) is approximately

$$\left(\frac{1}{C\pi^2}\right)^{\frac{1}{4}} \sin\left(\sqrt{4C} - \frac{3\pi}{4}\right) = \left(\frac{1}{C\pi^2}\right)^{\frac{1}{4}} = 0.4026\ldots. \tag{50}$$

By (39), (42), (49), and (50), we obtain the following approximate upper bound for $|(T^n 1)(x)|$:

$$|(T^n 1)(x)| \lesssim \alpha^n \left|1 - 1.3315 + 0.4026 + \frac{u(x)}{(n-1)^{\frac{1}{4}}}\right|$$
$$= \alpha^n \left(0.0711 + \frac{u(x)}{(n-1)^{\frac{1}{4}}}\right) \quad (n \to \infty). \tag{51}$$

3.4. Step 4: Estimates for $N(\eta, L)$. Referring to the definition (48) of $u(x)$, note that the $x^{-1/4}$ factor is dominant for small x while the exponential factor is dominant for large x. Hence, we expect $u(x)$ to have a single extremum—a global minimum. Letting L^* denote the x value at which the global minimum of $u(x)$ is attained (see (53) below), we are led to consider two cases when estimating $N(\eta, L)$: the case $L < L^*$ and the case $L > L^*$. In the former case, we shall demonstrate that $|(T^n 1)(x)|$ is always maximal at $x = 0$, indicating that the convergence to steady-state is slowest at the pacing site. In the latter case, $|(T^n 1)(x)|$ is maximal either at $x = 0$ or near $x = L$.

To determine L^*, we differentiate $u(x)$ with respect to x:

$$u'(x) = \left(\frac{\alpha}{\pi^2\lambda(\alpha+1)}\right)^{\frac{1}{4}} e^{\frac{\lambda(1-\alpha)x}{2\alpha}} \left(-\frac{1}{4}x^{-\frac{5}{4}} + \frac{\lambda(1-\alpha)}{2\alpha}x^{-\frac{1}{4}}\right). \tag{52}$$

The unique x value for which $u'(x)$ has a root is

$$L^* = \frac{\alpha}{2\lambda(1-\alpha)}. \tag{53}$$

With the above considerations in mind, we now derive our estimates for $N(\eta, L)$.

Case 1. $L < L^*$. From our preceding remarks, we see that the function $(T^n 1)(x)$ exhibits damped oscillatory behavior for $x < L^*$. Hence, $|(T^n 1)(x)|$ is maximal either at $x = 0$ or at the first local extremum of $(T^n 1)(x)$. In fact, we shall see that $|(T^n 1)(x)|$ is always maximal at $x = 0$.

PROPOSITION 3.3. *Let $x^{(1)}_{1(n-1)}$ denote the first root of $L^{(1)}_{n-1}(x)$. Then the first local extremum of $(T^n 1)(x)$ occurs at*

$$x_{\text{ext}} = \frac{\alpha}{\lambda(\alpha+1)} x^{(1)}_{1(n-1)} \approx \frac{\alpha}{\lambda(\alpha+1)} \cdot \frac{C}{n-1}. \tag{54}$$

Proof. Differentiating (32) with respect to x, we obtain

$$(T^n 1)'(x) \;=\; \Psi_n(x) \;=\; (-\alpha)^{n-1}(\alpha+1)\lambda\, e^{-\lambda x}\, L^{(1)}_{n-1}\left(\frac{\lambda(\alpha+1)x}{\alpha}\right). \tag{55}$$

The only factor in (55) that can change sign as x varies is $L^{(1)}_{n-1}$. Hence, the first sign change of $\Psi_n(x)$ occurs when the $L^{(1)}_{n-1}$ factor has its first root, which occurs at $x = x_{\text{ext}}$. This x value corresponds to the first local extremum of $(T^n 1)(x)$. ∎

Equation (35) gives the exact value of $|(T^n 1)(x)|$ at the $x = 0$ boundary, namely

$$|(T^n 1)(0)| = \alpha^n. \tag{56}$$

To estimate the value of $(T^n 1)(x)$ at its first local extremum, we refer to (51) and (54). By (54), we obtain the approximation

$$\frac{u(x_{\text{ext}})}{(n-1)^{\frac{1}{4}}} \to \left(\frac{1}{C\pi^2}\right)^{\frac{1}{4}} \;\approx\; 0.4026 \qquad (n \to \infty), \tag{57}$$

and (51) yields

$$|(T^n 1)(x_{\text{ext}})| \lesssim (0.0711 + 0.4026)\,\alpha^n \qquad (n \to \infty). \tag{58}$$

Note that the coefficient of α^n in (58) is less than 1. Therefore, if $L < L^*$, we conclude that the convergence to steady-state is slowest at the $x = 0$ boundary. That is,

$$\|T^n 1\|_\infty = |(T^n 1)(0)| = \alpha^n. \tag{59}$$

With η and y_0 as in (26), we can now estimate the number of beats required to reach approximate steady-state:

$$N_1 = N_1(\eta) = \frac{\ln(\eta) - \ln|y_0|}{\ln(\alpha)}. \tag{60}$$

The subscript on N emphasizes that we presently consider the first case, $L < L^*$. Note that N_1 does not depend upon L, and the convergence to steady-state is slowest at the pacing site, $x = 0$.

Case 2. $L > L^*$. In this case, the function $u(x)$ may achieve its maximum at the right boundary of the interval $[C/(n-1), L]$. By (51),

$$|(T^n 1)(L)| \lesssim \alpha^n \left(0.0711 + \frac{u(L)}{(n-1)^{\frac{1}{4}}}\right) \qquad (n \to \infty). \tag{61}$$

We wish to determine $N(\eta, L)$ such that

$$\alpha^n \left(0.0711 + \frac{u(L)}{(n-1)^{\frac{1}{4}}}\right) < \frac{\eta}{|y_0|} \qquad (\text{for all } n > N). \tag{62}$$

Taking logarithms and dividing through by $\ln\alpha$, we obtain

$$n + \frac{\ln\left(0.0711 + u(L)(n-1)^{-\frac{1}{4}}\right)}{\ln\alpha} > N_1, \tag{63}$$

where N_1 is given by (60) above. Motivated by inequality (63), we define the function

$$g(n) = n + \frac{\ln\left(0.0711 + u(L)(n-1)^{-\frac{1}{4}}\right)}{\ln\alpha} - N_1 \tag{64}$$

and estimate the value of n for which $g(n)$ has a root. Because N_1 is large if $\eta/|y_0| \ll 1$, we use it as an initial guess and calculate

$$g(N_1) = \frac{\ln\left(0.0711 + u(L)(N_1-1)^{-\frac{1}{4}}\right)}{\ln\alpha}. \tag{65}$$

An improved estimate for the root of $g(n)$ is then given by

$$N_1 - g(N_1) \;=\; N_1 - \frac{\ln\left(0.0711 + u(L)(N_1-1)^{-\frac{1}{4}}\right)}{\ln\alpha}. \tag{66}$$

Comparing (66) with the expression (60), we obtain the desired estimate for $N(\eta, L)$ by taking the maximum of these two expressions:

$$N(\eta, L) = N_1 - \frac{\left[\ln\left(0.0711 + u(L)(N_1-1)^{-\frac{1}{4}}\right)\right]_+}{\ln\alpha}, \tag{67}$$

where

$$[a]_+ = \begin{cases} a, & a > 0, \\ 0 & \text{otherwise.} \end{cases} \tag{68}$$

In summary, the above approximations demonstrate that $|y_n(x)| = |y_0| \cdot |(T^n 1)(x)|$ is maximal near the boundaries of the interval $[0, L]$. The location of the maximum of $|(T^n 1)(x)|$ depends in part on whether the fiber length L exceeds a critical value L^*. The function $(T^n 1)(x)$ exhibits damped oscillatory behavior for $x < L^*$. Hence, if $L < L^*$, we conclude that $|(T^n 1)(x)|$ is maximal either at $x = 0$ or at the first local extremum of the function $(T^n 1)(x)$. Our computations rule out the latter case, and we find that $|(T^n 1)(x)|$ is always maximal at $x = 0$ if $L < L^*$. For $x > L^*$, the function $(T^n 1)(x)$ exhibits oscillations of growing amplitude and, in the worst case scenario, $|(T^n 1)(x)|$ is maximal at $x = L$. Our estimate of $N(\eta, L)$ is given by either (60) or (67) depending on whether L exceeds L^*.

A discussion of the physiological interpretation of the above results is provided in the next section.

4. Discussion and conclusions. We have described how a paced cardiac fiber responds when the pacing period is suddenly changed from B_{old} to B_{new}, providing the first analysis of the transient behavior resulting from such a pacing protocol. We estimated the number of beats $N(\eta, L)$ required for the spatial variation in DI to be small in the sense that

$$|D_n(x) - D^*_{\text{new}}| < \eta \quad \text{for all } x \in [0, L], \quad \text{for all } n \geq N.$$

The estimate is given by either (60) or (67) depending on whether the fiber length exceeds the critical value L^* defined by (53). According to our approximations, for $L < L^*$, the convergence to steady-state is slowest at the pacing site and the rate of convergence is determined by the slope α of the restitution curve evaluated at D^*_{new}.

To test these predictions, we performed numerical simulations of (11), (13), and (14) for a range of parameter values. In particular, we used the restitution and dispersion curves in the appendix (see (73), (74)), varying the parameters (69) within physiologically reasonable regimes for the mammalian ventricular action potential [1, 13] (e.g., peak conduction velocity of 60 ± 20 cm/sec). We also repeated the numerical simulations using simple exponential restitution and dispersion curves (see (3)), again for a range of parameter values. As expected, for short fiber lengths ($L < L^*$) the convergence is always slowest at the pacing site, and the transient lasts much longer as $\alpha \to 1^-$. Moreover, the estimate of $N(\eta, L)$ given by (60) typically provides a very accurate estimate (within several beats) of the actual number of beats required to achieve approximate steady-state. Not surprisingly, the estimate given by (60) breaks down if $|B_{\text{old}} - B_{\text{new}}|$ is large (on the order of hundreds of milliseconds) or if α is very close to 1.

For long fibers ($L > L^*$), the spatial DI profiles generated by numerical simulations are qualitatively similar to those shown in Figure 2(a)—in particular, the convergence $D_n(x) \to D^*_{\text{new}}$ is slowest at the far end of the fiber. In this case, (67) typically provides an accurate estimate of $N(\eta, L)$, with the same notable exceptions as in the case of short fibers (see preceding paragraph).

We remark that L^* is often so large that fibers of length $L > L^*$ are unrealistically long—on the order of tens of centimeters or even meters. For example, consider the restitution and dispersion curves in the appendix with parameter values given by (69).

Using $B_{\text{new}} = 266$ ms, one computes that $\alpha = 0.900$ and $\lambda = 0.127$ cm^{-1}, which by (53) yields a critical fiber length L^* in excess of 35 cm. Equation (53) suggests that the critical length blows up as we approach the bifurcation to alternans: $L^* \to \infty$ as the slope $\alpha = f'(D^*_{\text{new}}) \to 1^-$, a prediction consistent with all of our numerical simulations. Therefore, N is especially unlikely to exhibit any length dependence if we are pacing in a regime close to the onset of alternans.

In closing, we remark that extending our results to the case of alternans may be quite challenging. If $\alpha > 1$, the operator T no longer has the property that $\|T^n\varphi\|_\infty \to 0$ as $n \to \infty$ for all $\varphi \in C[0, L]$. Thus, a similar analysis of the alternans regime would require a substantially different approach, which we hope to provide in a future study.

Appendix. Sample restitution and dispersion curves. For the purpose of numerical simulation, we provide sample formulas for restitution and dispersion curves (73) and (74) for a particular choice of parameters. Using asymptotics, such formulas can be derived [4, 20] from the equations of an idealized ionic model [17, 20]; we omit the details here. Below, we measure DI values in ms and we use the following parameters:

$$\tau_{\text{in}} = 0.1\,\text{ms}, \quad \tau_{\text{out}} = 2.4\,\text{ms}, \quad \tau_{\text{open}} = 130\,\text{ms}, \quad \tau_{\text{close}} = 150\,\text{ms}, \quad \kappa = 10^{-3}\,\frac{\text{cm}^2}{\text{ms}}. \tag{69}$$

Let

$$h(DI) = 1 - (1 - h_{\min})\, e^{-DI/\tau_{\text{open}}} \tag{70}$$

and

$$V_\pm(DI) = \frac{1}{2}\left(1 \pm \sqrt{1 - \frac{h_{\min}}{h(DI)}}\right), \tag{71}$$

where

$$h_{\min} = \frac{4\tau_{\text{in}}}{\tau_{\text{out}}}. \tag{72}$$

Note that $h(DI)$ and $V_\pm(DI)$ are dimensionless. In all numerical simulations, we use the restitution function

$$f(DI) = \tau_{\text{close}} \ln\left[\frac{h(DI)}{h_{\min}}\right] \tag{73}$$

and the dispersion function

$$c(DI) = \max\left\{\left[\frac{1}{2}V_+(DI) - V_-(DI)\right]\sqrt{\frac{2\,\kappa\,h(DI)}{\tau_{\text{in}}}},\ 0\right\}. \tag{74}$$

Note that $f(DI)$ has units of ms and $c(DI)$ has units of cm/ms.

CYLINDER BUCKLING: THE MOUNTAIN PASS AS AN ORGANIZING CENTER*

JIŘÍ HORÁK†, GABRIEL J. LORD‡, AND MARK A. PELETIER§

Abstract. We revisit the classical problem of the buckling of a long thin axially compressed cylindrical shell. By examining the energy landscape of the perfect cylinder, we deduce an estimate of the sensitivity of the shell to imperfections. Key to obtaining this estimate is the existence of a mountain pass point for the system. We prove the existence on bounded domains of such solutions for almost all loads and then numerically compute example mountain pass solutions. Numerically the mountain pass solution with lowest energy has the form of a single dimple. We interpret these results and validate the lower bound against some experimental results available in the literature.

Key words. imperfection sensitivity, subcritical bifurcation, single dimple

1. Introduction.

1.1. Buckling of cylinders under axial loading.

A classical problem in structural engineering is the prediction of the load-carrying capacity of an axially loaded cylinder. In addition to being a commonly used structural element, the axially loaded cylinder is the archetype of unstable, imperfection-sensitive buckling, and this has led to a large body of theoretical and experimental research.

In the decades before and after the Second World War, a central problem was understanding the large discrepancy between theoretical predictions and experimental observations, as shown in Figure 1.1. A variety of different explanations has been put forward, but with the experimental work of Tennyson [30] and the theoretical work of Almroth [1] it became clear that this discrepancy is mostly due to imperfections in loading conditions and in the shape of the specimens. Further experimental and theoretical work by many others has confirmed this conclusion [14, 33, 36].

For near-perfect cylinders, the linear and weakly nonlinear theories (see section 1.2) adequately describe the experimental buckling load[1] and the deformation just before failure (see, e.g., [4]). Cylinders used in practical applications, however, are far too imperfect, and thus the weakly nonlinear theory does not apply. From a practical point of view, the problem of predicting the failure load is still open.

There is good reason to believe that it will never be possible to accurately predict failure loads for cylinders that are used in practice. For simple materials, such as metals, it is believed that current numerical methods can describe the local material behavior with enough accuracy that correct prediction of the complete behavior of the cylinder—including its failure—is feasible. This could be achieved provided the geometrical and material imperfections, as well as the loading conditions, are determined

[1]In this paper the terms "experimental buckling load" and "failure load" are used interchangeably.

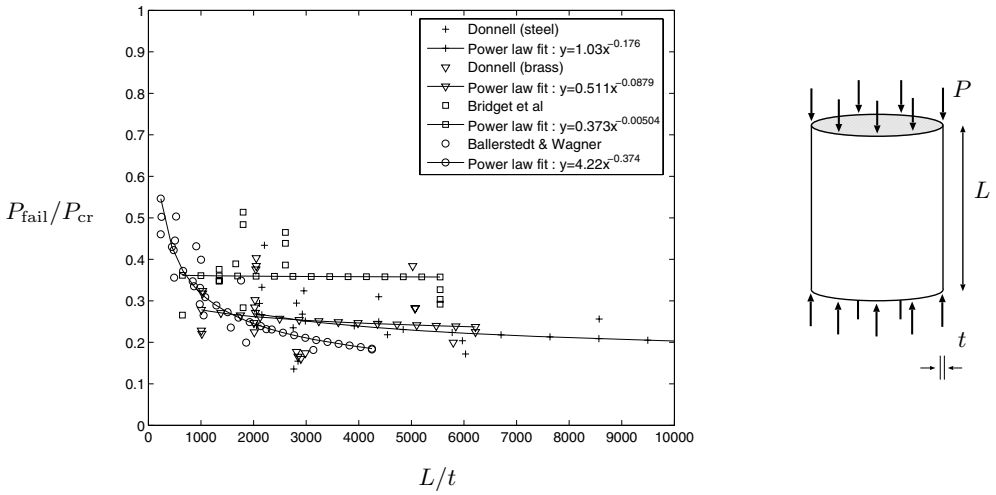

FIG. 1.1. *Experimental data from various research groups, all representing failure loads of axially loaded cylinders. The horizontal axis is the ratio of the cylinder length and the wall thickness; the vertical axis is the ratio of the failure load and the theoretical critical load as predicted for perfect cylinders. Note that all tested cylinders fail at loads significantly lower than that predicted by theory; the latter would correspond to failure load* $P_{\rm fail}/P_{\rm cr} = 1$*, and in some cases failure occurred at less than one-fifth of this value. Power-law fitting lines are added to emphasize the dependence of the failure load on the geometry. The data are from* [10, 7, 5].

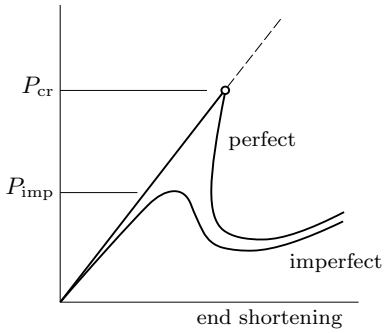

FIG. 1.2. *Illustration of perfect and imperfect bifurcation curves. For the unperturbed system, the undeformed state (the straight line) is always an equilibrium; this state loses stability at a bifurcation point at load* $P_{\rm cr}$*, and a curve of nonzero equilibria branches off. Perturbing the system generically converts the sharp bifurcation into a smooth transition. In the case of the cylinder, the postbuckling path is strongly unstable, and the perturbed path therefore has a lower limit load of* $P_{\rm imp}$.

in sufficient detail. The difficulty lies in the qualifier "in sufficient detail," since an extremely accurate measurement of the geometric imperfections would be necessary [4], and in the design phase both the loading conditions and the geometric and material imperfections in the finalized product are known only in vague terms. Therefore, in recent decades the attention of theoretical research has turned to characterizing the failure load in weaker ways, preferably in the form of a lower (safe) bound.

1.2. Characterizing sensitivity to imperfections. Viewed as a bifurcation problem, the buckling of the cylinder is a subcritical symmetry-breaking pitchfork bifurcation (Figure 1.2). Generically, imperfections in the structure eliminate the

bifurcation and round off the branch of solutions,[2] resulting in a turning point at a load P_{imp} strictly below the critical (bifurcation) load P_{cr} of the perfect structure. In an experiment in which the load is slowly increased, the system will fail (i.e., make a large jump in state space) at load P_{imp}.

Again, if the imperfections in geometry and loading are fully known, then calculation of P_{imp} is a practical rather than a theoretical problem, and we do not address this problem here. For the more difficult question of characterizing P_{imp} under incomplete information, various strategies have been proposed. A classical line of thought originates with Koiter [22], in which the imperfections are chosen a priori within certain finite-dimensional sets. Common choices are the sets spanned by the eigenvector at the bifurcation point of the perfect structure or by the eigenvectors associated with the first n bifurcations. This approach might be termed weakly nonlinear, as it is based on an expansion of the energy close to the bifurcation point, in the directions suggested by the bifurcation point itself. It gives predictions that are correct if the imperfections are very small—much smaller than those encountered in practice.

Since the a priori choice of imperfections is a weak point of this method, a natural step is to optimize over all possible perturbations. Deml and Wunderlich pioneered this approach, in which a numerical algorithm is used to find a "worst geometric imperfection" [9]. This "worst imperfection" is defined as that imperfection that produces a turning point of minimal load. Some constraint on the magnitude of allowable perturbations is necessary, of course, to prevent the running of a steam roller over the cylinder being interpreted as an admissible imperfection. The authors of [9] and [35] first suggest constraining the L^∞-norm of the perturbation displacement, but they immediately replace the L^∞-norm with an L^p-norm for computational convenience.

This method has an interesting aspect that is often glossed over in the engineering literature. By definition, the failure load obtained by this method is a lower bound for the failure load of all systems that have perturbations of lesser or equal magnitude. The measure of magnitude is defined by the choice of constraint. Therefore the choice of constraint on the imperfections is critical, since it implicitly defines a class of imperfections that produce either the same failure load or a higher one.

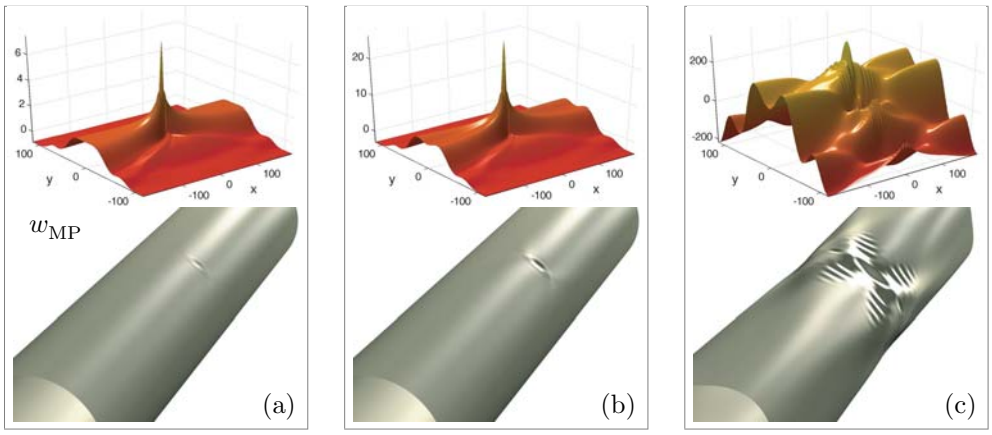
1.3. Main results. In this paper we follow a related, but distinct, line of reasoning. Instead of studying the actual behavior of imperfect cylinders, we deduce an estimate of the sensitivity to imperfections from the energy landscape of the perfect cylinder. The final result is a lower bound on the failure load similar to the above lower bound, and the approach gives additional insight into the problem.

The key result is the existence of a *mountain pass point*, an equilibrium state that is straddled between two valleys in the energy landscape; one valley surrounds the unbuckled state, and the other contains many buckled, large-deformation states.

This mountain pass point has a number of interesting properties, as follows:

1. It has the appearance of a *single-dimple solution*, a small buckle in the form of a single dent (see Figure 1.3(a)). Single-dimple deformations have appeared in engineering literature in a number of different ways (see section 6), but a theoretical understanding of this phenomenon is still lacking. Localization (concentration) of deformation is commonly known to appear in extended structures [21], and in the cylinder localization in the axial direction has been studied theoretically and numerically [20, 24, 25]. Whether localization

[2] Koiter actually used this elimination of a bifurcation point as a *definition* of "perfect system" and "perturbed system" [22].



(a) $\dots V(\lambda) = F_\lambda(w_{\mathrm{MP}}) \approx 4.84$
(b) $\dots F_\lambda(w) \approx -15.57$
(c) $\dots F_\lambda(w) \approx -5.5 \cdot 10^4$

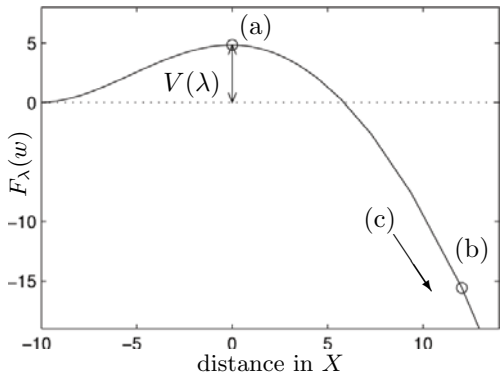


FIG. 1.3. *Part* (a) *shows a numerical computation of a solution* w_{MP} *that is a mountain pass point of the energy* F_λ *for a load* $\lambda = 1.5$. *We show the graph of the displacement* $w_{\mathrm{MP}}(x, y)$ *as a function of* (x, y) *as well as its rendering on a cylinder. At* w_{MP} *there exist two directions in the state space* X *in which the energy* F_λ *decreases. By perturbing* w_{MP} *in these directions and following a gradient flow of* F_λ, *we move away from* w_{MP}. *In one direction the dimple shrinks and disappears (not shown) and in the opposite its direction grows in amplitude and extent* ((b) *and* (c)).

is possible in the tangential direction has been an open problem for some time; it is interesting that our simulations for the perfect structure show solutions that are localized in both axial and tangential directions.

2. Like all mountain pass points, this single-dimple solution is unstable, in the sense that there are directions in state space in which the energy decreases. In one direction the dimple roughly shrinks and disappears, and in the opposite direction it grows and multiplies (Figures 1.3(b)–(c)). It is remarkable, however, that our numerical results indicate that the single-dimple solution has an alternative characterization as a *constrained global minimizer* (a global minimizer of the strain energy under prescribed end shortening).
3. The equations can be rescaled so that the only remaining parameters are the load level and the domain. The geometry of the mountain pass solution we calculate even appears to be independent of the domain size.

This mountain pass point is central in an estimate of the sensitivity to perturbations. For the system to escape from the neighborhood of the unbuckled state,

it must possess at least the energy associated with this mountain pass point. The mountain pass energy level is therefore an indication of the degree of stability of the unbuckled state. Implicitly it defines a class of perturbations for which the unbuckled state is stable. This approach is related to the "perturbation-energy" approach first suggested by Kröplin, Dinkler, and Hillmann [23], Duddeck et al. [11], and Wagenhuber and Duddeck [32], but differs in some essential points; see the discussion in section 5.

1.4. Methods. We use both analytical and numerical methods. In section 2 we introduce the von Kármán–Donnell equations, which form the basis of this paper, and rescale them in an appropriate manner. In section 3 we present the functional setting that we use, show that the energy functional has the geometry associated with a mountain pass, and prove the existence of mountain pass points (Lemma 3.6). There are certain interesting technical issues. By their localized nature, single-dimple solutions are most naturally defined on an unbounded domain; however, we are only able to prove existence of mountain pass points on bounded domains, and consequently we work on finite domains that become large in the limit of thin shells. Similarly, the noncoercive nature of the energy functional implies that we prove the existence of mountain pass points for almost all load levels (see Lemma 3.5).

In section 4 we turn to numerical investigation. We use a variety of different algorithms to find solutions of the discretized von Kármán–Donnell equations. With a discrete mountain pass algorithm we find solutions that are, by construction, mountain pass points. The solution of Figure 1.3(a) was found in this manner. With a constrained gradient flow we also find local minima of the strain energy under prescribed end shortening. Some of these solutions appear to coincide with those found by the discrete mountain pass algorithm, and the mountain pass solutions are stable under this gradient flow. These observations lead us to conjecture that the global mountain pass solution is also a global constrained minimizer of the strain energy. By a constrained version of the discrete mountain pass algorithm, we also find critical points of higher Morse index.

Section 5 is devoted to an interpretation of these results in the context of imperfection sensitivity, as mentioned above, and in section 6 we wrap up with the main conclusions.

2. The von Kármán–Donnell equations. We consider a cylindrical shell of radius R, thickness t, Young's modulus E, and Poisson's ratio ν that is subject to a compressive axial force P. In Appendix B we derive the dimensionless von Kármán–Donnell equations

$$\varepsilon^2\Delta^2\overline{w} + \bar{\lambda}\overline{w}_{xx} - \overline{\phi}_{xx} - 2[\overline{w},\overline{\phi}] = 0, \tag{2.1}$$

$$\Delta^2\overline{\phi} + [\overline{w},\overline{w}] + \overline{w}_{xx} = 0, \tag{2.2}$$

where subscripts x and y denote differentiation with respect to the spatial variables, the Laplacian Δ is given by $\Delta u = u_{xx} + u_{yy}$, and the bracket $[\cdot,\cdot]$ is defined as

$$[a,b] = \frac{1}{2}a_{xx}b_{yy} + \frac{1}{2}a_{yy}b_{xx} - a_{xy}b_{xy}.$$

The function $\overline{w}$ is the inward radial displacement measured from an unbuckled (fundamental) state, $\overline{\phi}$ is the Airy stress function, $\varepsilon^2 = t^2(192\pi^4R^2(1-\nu^2))^{-1}$, and the nondimensional load parameter is given by $\bar{\lambda} = P(8\pi^3ERt)^{-1}$. The unknowns $\overline{w}$ and $\overline{\phi}$ are defined on the two-dimensional spatial domain $(-\ell,\ell)\times(-1/2,1/2)$, where

$x \in (-\ell, \ell)$ is the axial and $y \in (-1/2, 1/2)$ is the tangential coordinate. Since the y-domain $(-1/2, 1/2)$ represents the circumference of the cylinder, the functions $\overline{w}$ and $\overline{\phi}$ are periodic in y; at the axial ends $x \in \{-\ell, \ell\}$ they satisfy the boundary conditions

$$\overline{w}_x = (\Delta \overline{w})_x = \overline{\phi}_x = (\Delta \overline{\phi})_x = 0.$$

For the experiments that we are interested in, the parameter ε is small, ranging from 10^{-2} to 10^{-4}. Here we rescale (2.1)–(2.2) such that the equations themselves are ε-independent, at the cost of a dependence on ε in the size of the spatial domain. Set

$$\overline{w} \mapsto \varepsilon w, \qquad \overline{\phi} \mapsto \varepsilon^2 \phi, \qquad x \mapsto \varepsilon^{1/2} x, \qquad y \mapsto \varepsilon^{1/2} y, \qquad \bar{\lambda} \mapsto \varepsilon \lambda, \tag{2.3}$$

so that the equations become

$$\Delta^2 w + \lambda w_{xx} - \phi_{xx} - 2\,[w, \phi] = 0, \tag{2.4}$$

$$\Delta^2 \phi + [w, w] + w_{xx} = 0. \tag{2.5}$$

The domain of definition of w and ϕ is now

$$\Omega := (-\ell \varepsilon^{-1/2}, \ell \varepsilon^{-1/2}) \times (-\tfrac{1}{2}\varepsilon^{-1/2}, \tfrac{1}{2}\varepsilon^{-1/2}),$$

which expands to $\mathbb{R}^2$ as $\varepsilon \to 0$. When not indicated otherwise, we choose the aspect ratio $2\ell = 1$; in section 4.3 we comment on the influence of domain size and aspect ratio.

The boundary conditions for w and ϕ now are

$$w \text{ is periodic in } y \quad \text{and} \quad w_x = (\Delta w)_x = 0 \text{ at } x = \pm \tfrac{1}{2}\varepsilon^{-1/2}, \tag{2.6a}$$

$$\phi \text{ is periodic in } y \quad \text{and} \quad \phi_x = (\Delta \phi)_x = 0 \text{ at } x = \pm \tfrac{1}{2}\varepsilon^{-1/2}. \tag{2.6b}$$

Equations (2.4)–(2.5) are related to the stored energy E and the average axial shortening S given by

$$E(w) := \frac{1}{2}\int_\Omega \left(\Delta w^2 + \Delta \phi^2\right) \qquad \text{and} \qquad S(w) := \frac{1}{2}\int_\Omega w_x^2. \tag{2.7}$$

Note that the function ϕ in (2.7) is determined from w by solving (2.5) with boundary conditions (2.6b); this uniquely defines ϕ up to an additive constant.

Solutions of (2.4)–(2.5) are stationary points of the total potential

$$F_\lambda(w) := E(w) - \lambda S(w). \tag{2.8}$$

This can be recognized as follows: If we substitute for w the perturbed function $w_\eta := w + \eta \tilde{w}$, then the perturbed Airy stress function ϕ_η solves

$$\Delta^2 \phi_\eta + [w, w] + 2\eta[w, \tilde{w}] + \eta^2 [\tilde{w}, \tilde{w}] + w_{xx} + \eta \tilde{w}_{xx} = 0.$$

Therefore $\phi_\eta = \phi + \eta \tilde{\phi} + O(\eta^2)$, where the perturbation $\tilde{\phi}$ solves

$$\Delta^2 \tilde{\phi} + 2[w, \tilde{w}] + \tilde{w}_{xx} = 0$$

with boundary condition (2.6b). Then

$$\begin{aligned} F'_\lambda(w)\cdot\tilde{w} &= \int_\Omega \Big[\Delta w\Delta\tilde{w} + \Delta\phi\Delta\tilde{\phi} - \lambda w_x\tilde{w}_x\Big] \\ &= \int_\Omega \Big[\Delta w\Delta\tilde{w} - \phi\big(2[w,\tilde{w}] + \tilde{w}_{xx}\big) - \lambda w_x\tilde{w}_x\Big] \\ &= \int_\Omega \Big[\Delta w\Delta\tilde{w} - \tilde{w}\big(2[w,\phi] + \phi_{xx}\big) - \lambda w_x\tilde{w}_x\Big], \end{aligned}$$

and this is a weak formulation of (2.4). Besides being stationary points of F_λ, solutions of (2.4)–(2.5) are also stationary points of E under the constraint of constant S; in this case λ is a Lagrange multiplier. We use both properties below.

3. The mountain pass: Overview. We briefly recall the general context of the Mountain Pass Theorem of Ambrosetti and Rabinowitz [2]. Let I be a functional defined on a Banach space X, and let w_1, w_2 be two distinct points in X. Consider the family Γ of all paths in X connecting w_1 and w_2 and define

$$c = \inf_{\gamma\in\Gamma}\max_{w\in\gamma} I(w), \tag{3.1}$$

that is, the infimum of the maxima of the functional I along paths in Γ. If $c > \max\{I(w_1), I(w_2)\}$, then the paths have to cross a "mountain range," and one may conjecture that there exists a critical point w_{MP} of I at the level c, called a mountain pass point.

We will apply this idea to the von Kármán–Donnell equations in the following way. We take for I the total potential F_λ (see (2.8)) at some fixed value of λ, and for the end point w_1 the origin. We will obtain a mountain pass solution by the following steps:

- MP1. We first show that $w_1 = 0$ is a strict local minimizer, or more precisely, that there exist $\varrho, \alpha > 0$ such that $F_\lambda(w) \geq \alpha$ for all w with $\|w\|_X = \varrho$ (Lemma 3.1).
- MP2. If ε is small enough, then there exists w_2 with $F_\lambda(w_2) \leq 0$ (Corollary 3.4).
- MP3. Given a sequence of paths γ_n that approximates the infimum in (3.1), we extract a (Palais–Smale) sequence of points $w_n \in \gamma_n$, each one close to the maximum along γ_n, and show that this sequence converges in an appropriate manner (Lemmas 3.5 and 3.6).

In this way it follows that there exists a mountain pass critical point w with $F_\lambda(w) = c$, provided that ε is sufficiently small (or that the domain is sufficiently large). For technical reasons (lack of coerciveness of the functional F_λ) this procedure can be performed only for almost all $0 < \lambda < 2$ (see Lemma 3.5).

In the rest of this section we detail the steps outlined above.

3.1. Choice of spatial domain. We are interested in mountain pass solutions of the system of equations (2.4)–(2.5) that are quasi independent of the domain size $\varepsilon^{-1/2}$, in the sense that they converge to a nontrivial solution on $\mathbb{R}^2$ as $\varepsilon \to 0$. This point of view suggests considering the problem on the whole of $\mathbb{R}^2$ rather than on a sequence of domains of increasing size; however, there are two reasons for not doing this. To start with, the numerical calculations described below are necessarily done on a bounded domain; more important, for the proof of existence of mountain pass points, boundedness of the domain is necessary. For these reasons we concentrate on bounded domains, while keeping the context of the unbounded domain in mind.

3.2. Functional setting and linearization. We introduce a functional setting for the functions w that is suggested by the linearization of the stored energy functional E. Writing $\phi = \phi_1 + \phi_2$, where

$$\Delta^2\phi_1 = -w_{xx} \qquad \text{and} \qquad \Delta^2\phi_2 = -[w,w], \tag{3.2}$$

we can expand the energy functional E as

$$E(w) = \frac{1}{2}\int_\Omega \Delta w^2 + \frac{1}{2}\int_\Omega \Delta\phi_1^2 + \int_\Omega \Delta\phi_1\Delta\phi_2 + \frac{1}{2}\int_\Omega \Delta\phi_2^2. \tag{3.3}$$

Since ϕ_2 is quadratic in w, the second derivative of E is given by

$$d^2E(0)\cdot u\cdot v = \int_\Omega \Delta u\Delta v + \int_\Omega \Delta\phi_1^u\Delta\phi_1^v,$$

where $\phi_1^{u,v}$ are obtained from u and v by replacing w with u or v in (3.2) and solving this equation for ϕ_1 with boundary conditions (2.6b). Inspired by this linearization of E, we define

$$X = \left\{\psi \in H^2(\Omega) : \psi_x\left(\pm\frac{1}{2}\varepsilon^{-1/2},\cdot\right) = 0,\ \psi \text{ is periodic in } y, \text{ and } \int_\Omega \psi = 0\right\}$$

with norm

$$\|w\|_X^2 = \int_\Omega \big(\,\Delta w^2 + \Delta\phi_1^2\,\big),$$

where $\phi_1 \in H^2(\Omega)$ is the unique solution of

$$\Delta^2\phi_1 = -w_{xx}, \qquad \phi_1 \text{ satisfies (2.6b)}, \qquad \text{and} \qquad \int_\Omega \phi_1 = 0.$$

This norm is equivalent to the H^2-norm on the set X, and with the appropriate inner product the space X is a Hilbert space.

We now address the requirements of the mountain pass theorem mentioned above in MP1–MP3.

3.3. The origin is a local minimizer. The norm in X is related in a natural manner to the shortening S, as demonstrated by the (sharp) estimate

$$\begin{aligned} 2S(w) &= \int_\Omega w_x^2 = -\int_\Omega w w_{xx} = \int_\Omega w\Delta^2\phi_1 \\ &= \int_\Omega \Delta w\Delta\phi_1 \le \frac{1}{2}\int_\Omega \Delta w^2 + \frac{1}{2}\int_\Omega \Delta\phi_1^2 = \frac{1}{2}\|w\|_X^2\,. \end{aligned} \tag{3.4}$$

This inequality strongly suggests that for $\lambda < 2$ the origin is a strict local minimum for the functional $F_\lambda(w) = E(w) - \lambda S(w)$.

LEMMA 3.1. *For any $\lambda < 2$, there exists $\varrho > 0$ such that*

$$\inf\big\{\ F_\lambda(w) : \|w\|_X = \varrho\ \big\} > 0.$$

Proof. Split $\phi = \phi_1 + \phi_2$ as in (3.2), and note that the function $\nabla\phi_1$ is bounded in L^∞ by the Sobolev imbedding $\{\psi \in H^3 : \int\psi = 0\} \hookrightarrow L^\infty$:

$$\|\nabla\phi_1\|_{L^\infty}^2 \le C\left\|\Delta^2\phi_1\right\|_{L^2}^2 = C\|w_{xx}\|_{L^2}^2\,.$$

The third term on the right-hand side of (3.3) can now be rewritten as

$$\int_\Omega \Delta\phi_1\Delta\phi_2 = \int_\Omega \phi_1[w,w] = \int_\Omega \phi_1(w_{xx}w_{yy} - w_{xy}^2) = \int_\Omega (\phi_{1y}w_x w_{xy} - \phi_{1x}w_x w_{yy}),$$

which we estimate by

$$\left|\int_\Omega \Delta\phi_1\Delta\phi_2\right| \le 2\,\|\nabla\phi_1\|_{L^\infty}\,\|w_x\|_{L^2}\,\|\Delta w\|_{L^2} \le C\,\|w_x\|_{L^2}\,\|\Delta w\|_{L^2}^2 \le C\sqrt{S(w)}\,\|w\|_X^2\,.$$

Since $\lambda < 2$, choose $0 < \varrho < (2-\lambda)/2C$ and define $\eta = (1/2)(1 - C\varrho - \lambda/2) > 0$. Then on the set $\mathcal{C} = \{w : \|w\|_X = \varrho\}$, using (3.4), we find that

$$\begin{aligned} F_\lambda(w) &= E(w) - \lambda S(w) \\ &\ge \frac{1}{2}\,\|w\|_X^2 - C\sqrt{S(w)}\,\|w\|_X^2 - \lambda S(w) \\ &\ge \frac{\varrho^2}{2} - C\varrho^3\frac{1}{2} - \lambda\frac{\varrho^2}{4} \\ &= \frac{\varrho^2}{2}\left(1 - C\varrho - \frac{\lambda}{2}\right) \\ &= \eta\varrho^2. \qquad \square \end{aligned}$$

This lemma implies that by choosing w_1 to be the origin we have shown condition MP1.

Remark 3.2. Although inequality (3.4) suggests that the origin should be a local minimizer for any domain Ω, bounded or not, the proof above applies only to bounded domains. F. Otto has constructed a proof of this result that is valid on any domain (private communication). Interestingly, this proof uses not only the cubic energy term $\int_\Omega \Delta\phi_1\Delta\phi_2$, but also the quartic term $\int_\Omega \Delta\phi_2^2$, and appears to break down without this latter term.

3.4. Periodic solutions exist with negative F_λ. To satisfy MP2 we show in this section that for any $\lambda > 0$, functions $w \in X$ exist, for which $F_\lambda(w) = E(w) - \lambda S(w) < 0$. To do this we construct a sequence of functions w_δ with specific scaling properties.

LEMMA 3.3. *There exists a sequence of functions w_δ, 1-periodic on $\mathbb{R}^2$, such that as $\delta \to 0$,*

1. $\displaystyle\int_{[-1/2,1/2]^2} w_{\delta x}^2 \longrightarrow c \quad$ *for some $c > 0$,*
2. $\displaystyle\int_{[-1/2,1/2]^2} \Delta w_\delta^2 = O(\delta^{-1})$

   and $\displaystyle\int_{[-1/2,1/2]^2} \Delta\phi_\delta^2 = O(\delta^{2-\alpha}) \quad$ *for any $\alpha > 0$.*

Here the functions w_δ and ϕ_δ solve (2.5) *with periodic boundary conditions. In addition, w_δ and ϕ_δ satisfy boundary conditions* (2.6) *on the boundary of $[-1/2,1/2]^2$.*

The proof, given in Appendix A, is inspired by the so-called *Yoshimura pattern* [37], a folding pattern by which a flat sheet of paper, or a cylindrical sheet of thin material, can be folded into a macroscopically cylindrical structure with zero Gaussian curvature but locally infinite total curvature (Figure 3.1). The functions w_δ are smoothed versions of the Yoshimura pattern, adapted to the geometrically

FIG. 3.1. *Yoshimura folding pattern.*

linear setting of the von Kármán–Donnell equations, and δ measures the width of the fold.

COROLLARY 3.4.

1. *Fix $\lambda > 0$. If ε is sufficiently small, then there exists $w \in X$ such that $F_\lambda(w) < 0$.*
2. *Fix ε sufficiently small. Then there exists $\lambda_0(\varepsilon) \in [0, 2)$ such that for all $\lambda > \lambda_0$, there exists $w \in X$ with $F_\lambda(w) < 0$.*

Proof. By scaling the functions w_δ of Lemma 3.3, the claims can be fulfilled as follows: Let $\delta = \varepsilon^{2/3}$, and set

$$\tilde{w}_\varepsilon(x, y) = \varepsilon^{-1} w_{\varepsilon^{2/3}}(x\varepsilon^{1/2}, y\varepsilon^{1/2}), \qquad \tilde{\phi}_\varepsilon(x, y) = \varepsilon^{-2}\phi_{\varepsilon^{2/3}}(x\varepsilon^{1/2}, y\varepsilon^{1/2});$$

then $\tilde{w}_\varepsilon \in X$, and (2.5) is invariant under this scaling; in addition, choosing $\alpha = 1/6$, we obtain

$$Q_\varepsilon := \frac{\displaystyle\int_{\Omega_\varepsilon} \left[\Delta\tilde{w}_\varepsilon^2 + \Delta\tilde{\phi}_\varepsilon^2\right]}{\displaystyle\int_{\Omega_\varepsilon} \tilde{w}_{\varepsilon x}^2} = O\big(\varepsilon^{1/6}\big) \qquad \text{as } \varepsilon \to 0.$$

Therefore $\lim_{\varepsilon\to 0} Q_\varepsilon = 0$, proving the first claim. For the second claim, we fix ε such that $Q_\varepsilon < 2$; then for all $\lambda > Q_\varepsilon$, $F_\lambda(\tilde{w}_\varepsilon) < 0$. ∎

3.5. Convergence of selected sequences. For given $\lambda \in (0, 2)$ and for sufficiently small $\varepsilon > 0$, the two previous sections provide two points: the origin $w_1 = 0$ that satisfies MP1, and a point w_2 with $F_\lambda(w_2) < 0$, such that

$$c(\lambda) := \inf_{\gamma\in\Gamma} \max_{w\in\gamma} F_\lambda(w) > 0, \tag{3.5}$$

where Γ is the set of curves connecting 0 and w_2,

$$\Gamma = \{\gamma \in C([0, 1]; X) : \gamma(0) = 0,\ \gamma(1) = w_2\}$$

(actually, Γ depends on λ through the dependence on w_2, but w_2 can be taken independently of λ in a neighborhood of a given $\lambda \in (0, 2)$).

We were unable to prove the classical Palais–Smale condition, which reads as follows:

> For any sequence $w_n \in X$ such that $F_\lambda(w_n) \to c$ and $F'_\lambda(w_n) \to 0$ in X', there exists a subsequence that converges in X.

The difficulty lies in the lack of coerciveness of the functional F_λ: the quotient $F_\lambda(w)/\|w\|_X^2$ is not bounded away from zero, implying that Palais–Smale sequences may be unbounded in X.

The "Struwe monotonicity trick" [29] provides a way of proving the boundedness of Palais–Smale sequences for at least *almost all* $\lambda \in (0,2)$. The pertinent observation is that for fixed w, $F_\lambda(w)$ is decreasing in λ; consequently, $c(\lambda)$ is a decreasing function of λ and therefore differentiable in almost all $\lambda \in (0,2)$. If $\gamma(t)$ is the highest point of a near-optimal curve γ at some λ_0, then $c'(\lambda_0)$ should be close to $-S(\gamma(t))$. Finiteness of c' at λ_0 thus implies that near–mountain pass points have bounded S, and this additional information suffices for the construction of bounded sequences.

LEMMA 3.5. *Let $\lambda \in (0,2)$ be such that $c'(\lambda)$ exists. Then there exists a bounded Palais–Smale sequence w_n, i.e., a sequence satisfying that*

1. *w_n is bounded in X;*
2. *$F'_\lambda(w_n) \to 0$ in X' and $F_\lambda(w_n) \to c(\lambda)$;*
3. *there exists a sequence of curves $(\gamma_n) \subset \Gamma$ such that $w_n \in \gamma_n([0,1])$ and $\max_{t\in[0,1]} F_\lambda(\gamma_n(t)) \to c(\lambda)$.*

In [28] this same argument was used to study mountain pass points for the related one-dimensional functional

$$J_\lambda(u) = \int_{\mathbb{R}} \Big\{ \frac{1}{2} u''^2 - \frac{\lambda}{2} u'^2 + F(u) \Big\},$$

where F is a nonnegative double- or single-well potential. The proof of Lemma 3.5 repeats verbatim the proof of [28, Prop. 5], and we omit it here.

LEMMA 3.6. *The sequence w_n given by Lemma 3.5 is compact in X, and a subsequence converges to a stationary point $w \in X$ of F_λ.*

Strictly speaking, the stationary point given by this lemma may not be a mountain pass point itself, in the sense that there may not be a curve $\gamma \in \Gamma$ of which w is the highest point. Property 3 of Lemma 3.5, however, states that w has an approximate mountain pass character.

Proof. We extract a subsequence that converges weakly in X and strongly in H^1 and L^∞ to a limit w. Defining ϕ_{1n} and ϕ_{2n} by (3.2), we find that the right-hand sides in (3.2) are bounded in L^2 and L^1, and therefore that ϕ_{1n} and ϕ_{2n} converge strongly (up to extracting a subsequence, which we do without changing notation) in H^2 to functions $\phi_{1,2}$. Both functions $\phi_{1,2}$ are again related to w by (3.2); for ϕ_2 this follows from remarking that for given $\zeta \in C_c^\infty(\Omega)$,

$$\lim_{n\to\infty} \int_\Omega \zeta[w_n, w_n] = \lim_{n\to\infty} \int_\Omega w_n[\zeta, w_n] = \int_\Omega w[\zeta, w] = \int_\Omega \zeta[w, w],$$

so that the right-hand side converges in the sense of distributions. Similarly, it follows from the strong H^2-convergence of $\phi_n = \phi_{1n} + \phi_{2n}$ that

$$\lim_{n\to\infty} \int_\Omega \phi_n[w_n, w - w_n] = \lim_{n\to\infty} \int_\Omega w_n[\phi_n, w - w_n] = 0.$$

To show that w_n converges strongly in X, note that the derivative $F'_\lambda(w_n)$ can be characterized as

$$F'_\lambda(w_n) \cdot v = \int_\Omega \Delta w_n \Delta v - \int_\Omega \phi_n\big(v_{xx} + 2[w_n, v]\big) - \lambda \int_\Omega w_{nx} v_x.$$

We now calculate

$$\lim_{n\to\infty}\left\{\int_\Omega \Delta w^2 - \int_\Omega \Delta w_n^2\right\} = \lim_{n\to\infty}\int_\Omega \Delta w_n \Delta(w-w_n)$$
$$= \lim_{n\to\infty}\left\{F_\lambda'(w_n)\cdot(w-w_n) + \int_\Omega \phi_n\big((w-w_n)_{xx} + 2[w_n, w-w_n]\big) + \lambda\int_\Omega w_{nx}(w-w_n)_x\right\} = 0.$$

The strong convergence of w_n in X now follows from the uniform convexity of X. ∎

4. Numerical results.

4.1. Description of the algorithm. Our goal in this section is to find, numerically, critical points of F_λ. Although we will focus on mountain pass points described above and sketch the method used to find them, numerical approximations of other critical points of F_λ will be shown as well. More details on all the numerical methods used are given in a companion paper [17].

In order to employ the mountain pass algorithm, we discretize (2.4)–(2.8) using finite differences. The algorithm was first proposed in [8] for a second-order elliptic problem in one dimension. It was later used in [18] for a fourth-order problem in two dimensions.

The main idea of the algorithm is illustrated in Figure 4.1. We take a discretized path connecting $w_1 = 0$ with a point w_2 such that $F_\lambda(w_2) < 0$. After finding the point z_m at which F_λ is maximal along the path, this point is moved a small distance in the direction of the steepest descent of F_λ. Thus the path has been deformed and the maximum of F_λ lowered. This deforming of the path is repeated until the maximum along the path cannot be lowered any more: a critical point w_{MP} has been reached.

Figure 4.2(a) shows a numerical solution of (2.4)–(2.5) obtained by this algorithm with $\lambda = 1.1$. The graph in each panel shows the radial displacement w as a function

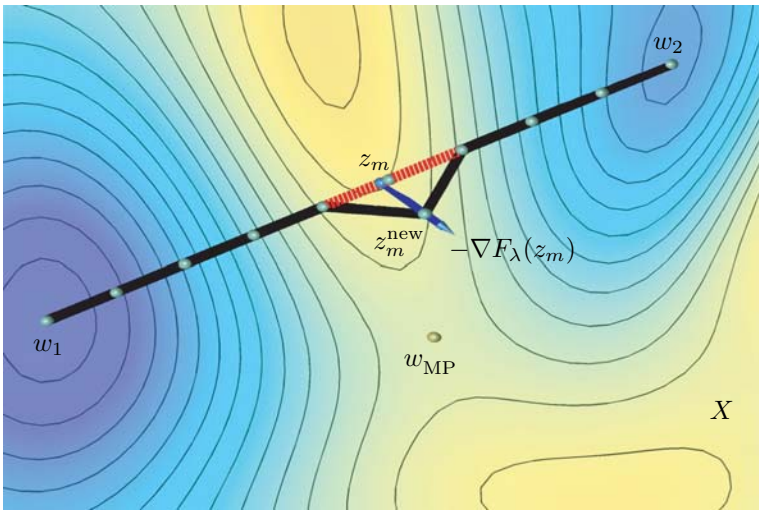

FIG. 4.1. *Deforming the path in the main loop of the mountain pass algorithm: point z_m is moved a small distance in the direction $-\nabla F_\lambda(z_m)$ and becomes z_m^{new}. This step is repeated until the mountain pass point w_{MP} is reached.*

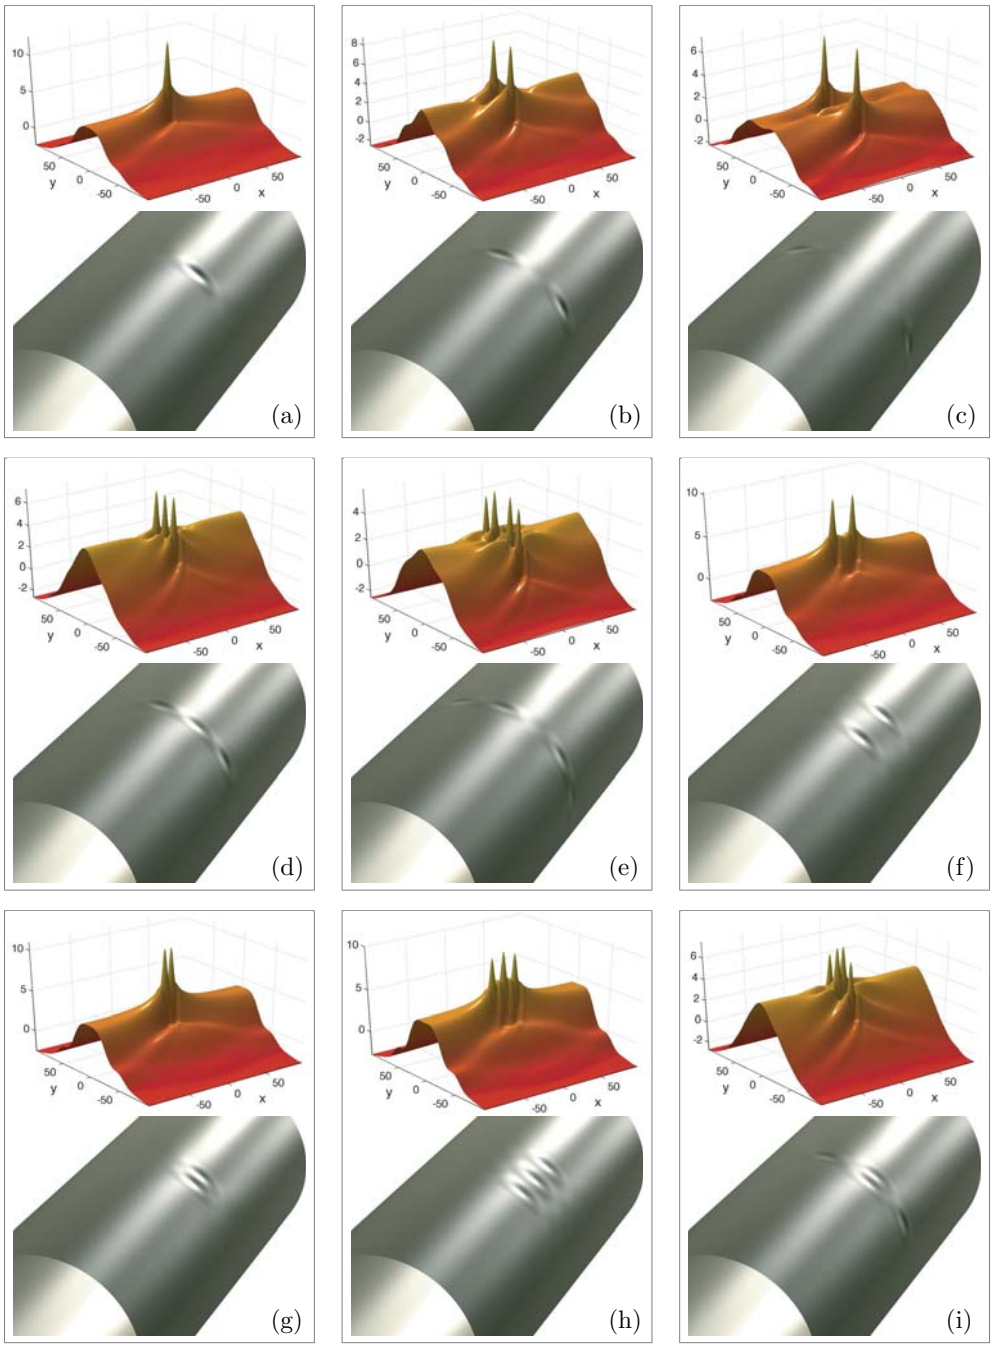

FIG. 4.2. *Numerical solutions found using the (constrained) mountain pass algorithm, constrained steepest descent method, and the Newton algorithm. The figures show both the graph of* $w(x, y)$ *and its rendering on a cylinder.*

of x and y. Rendered on a cylinder, this solution represents a single dimple, as can be seen below the graphs.

We restrict our computations to functions that are even about the x- and y-axes, i.e., to the subspace

$$\mathscr{S} = \{\psi \in X : \psi(x,y) = \psi(-x,y),\ \psi(x,y) = \psi(x,-y)\},$$

thus reducing the computational domain Ω to one quarter, e.g., $(0, \frac{1}{2}\varepsilon^{-1/2})\times(0, \frac{1}{2}\varepsilon^{-1/2})$. The boundary conditions (2.6a) then become

$$w_x = (\Delta w)_x = 0 \text{ for } x \in \{0, \tfrac{1}{2}\varepsilon^{-1/2}\} \quad \text{and} \quad w_y = (\Delta w)_y = 0 \text{ for } y \in \{0, \tfrac{1}{2}\varepsilon^{-1/2}\}.$$

This symmetry assumption has many numerical advantages, but on the other hand it a priori excludes solutions that do not belong to $\mathscr{S}$.

For the mountain pass algorithm, we always use the unbuckled state $w_1 = 0$ as the first end point of the paths. The choice of the second end point w_2 has a nontrivial influence on the solution to which the mountain pass algorithm converges. Corollary 3.4 guarantees the existence of $w_2 \in \mathscr{S}$ with $F_\lambda(w_2) < 0$; in the numerical implementation, however, we found such a w_2 by a steepest descent method (rather than by taking the function constructed in the proof of Lemma 3.3): starting from a function w_0 that has one peak located in the center of the domain Ω, we solved the initial value problem

$$\frac{d}{dt}w(t) = -\nabla F_\lambda(w(t)), \quad w(0) = w_0, \tag{4.1}$$

on an interval $(0,T)$ until $F_\lambda(w(T)) < 0$. We then defined $w_2 = w(T)$.

A different choice of w_2 (or, more precisely, of the starting point w_0 of (4.1)) can lead to a different solution of the problem, as Figures 4.2(b) and (f) show. Here w_0 was chosen to have two peaks with centers on the axes $x = 0$ and $y = 0$, respectively. The algorithm then converged to a numerical solution with two dimples in the circumferential and axial directions, respectively.

Note that the numerical solution w_{MP} selected by the mountain pass algorithm has the mountain pass property in a certain neighborhood only: there exists a ball $B_\rho(w_{\mathrm{MP}})$ and two points $\tilde{w}_1, \tilde{w}_2 \in B_\rho(w_{\mathrm{MP}})$ such that

$$F_\lambda(w_{\mathrm{MP}}) = \inf_{\gamma\in\tilde{\Gamma}} \max_{w\in\gamma} F_\lambda(w) > \max\{F_\lambda(\tilde{w}_1), F_\lambda(\tilde{w}_2)\},$$

where $\tilde{\Gamma}$ is the set of curves in $B_\rho(w_{\mathrm{MP}})$ connecting $\tilde{w}_1$ and $\tilde{w}_2$. The reason for this is that the algorithm deforms a certain initial path connecting w_1 and w_2 which is fixed. In order to recover the global character, one would need to run the algorithm for all possible initial paths.

The rest of the numerical solutions shown in Figure 4.2 were obtained under a prescribed value of shortening S by the constrained steepest descent method and the constrained mountain pass algorithm [16, 17].

4.2. Calculation of $F_\lambda(w_{\mathrm{MP}})$. In the preceding sections we showed that

1. for a sufficiently large domain Ω, a function w_2 on Ω exists with $F_\lambda(w_2) < 0$;
2. for each such function w_2 and for almost all $0 < \lambda < 2$, a mountain pass solution $w_{\mathrm{MP}} = w_{\mathrm{MP}}(\lambda, \Omega, w_2)$ exists.

Different end points w_2 may give rise to different mountain pass points, as we have observed in the numerical experiments described above. We therefore define the mountain pass energy function V on $(0,2)$ by

$$V(\lambda,\Omega) := \inf_{w_2}\{\, F_\lambda\big(w_{\mathrm{MP}}(\lambda,\Omega,w_2)\big) : F_\lambda(w_2) < 0\,\}. \tag{4.2}$$

For a given λ, the value of $V(\lambda,\Omega)$ is the lowest height (or energy level) at which one may pass from the origin to a point with negative total potential F_λ. We now derive some of its properties and calculate it numerically.

LEMMA 4.1 (properties of $V(\lambda,\Omega)$).

1. *For sufficiently large Ω there exists $\lambda_0(\Omega) \geq 0$ such that $V(\lambda,\Omega) < \infty$ for almost all $\lambda \in (\lambda_0, 2)$.*
2. *V is a decreasing function of λ.*
3. *For sufficiently large Ω, there exists $c(\Omega) > 0$ such that*

$$V(\lambda,\Omega) \leq c(2-\lambda)^3$$

for sufficiently small $2-\lambda > 0$.

Proof. Part 1 is a reformulation of the main result of section 3, making use of Corollary 3.4. For part 2 we remark that for each fixed w, $F_\lambda(w)$ is a decreasing function of λ; the infimum of a set of decreasing functions is again decreasing.

For part 3, let us set

$$E(w) = E_2(w) + E_3(w) + E_4(w),$$

where

$$E_2(w) := \frac{1}{2}\,\|w\|_X^2 = \frac{1}{2}\int_\Omega \big(\Delta w^2 + \Delta\phi_1^2\big), \quad E_3(w) := \int_\Omega \Delta\phi_1\Delta\phi_2,$$
$$\text{and} \quad E_4(w) := \frac{1}{2}\int_\Omega \Delta\phi_2^2,$$

where ϕ_1 and ϕ_2 are determined from w by (3.2) (see also (3.3)). Note that E_n has homogeneity n, i.e., $E_n(\mu w) = \mu^n E_n(w)$.

A classical result in the engineering literature of cylinder buckling (see, e.g., [20]) states that there exists a periodic function w on $\mathbb{R}^2$ such that

$$E_2(w) = 2S(w) \qquad \text{and} \qquad E_3(w) + E_4(w) < 0.$$

Here and below we consider the integrals that define $E_n(w)$ and $S(w)$ as taken over a single period cell. For sufficiently small $2-\lambda > 0$ the inequality above gives that $F_\lambda(w) = (2-\lambda)S(w) + E_3(w) + E_4(w)$ is negative, implying that w is an admissible end point w_2 for definition (4.2) of $V(\lambda,\Omega)$, and the connecting line segment $\{\mu w : 0 \leq \mu \leq 1\}$ is therefore an admissible curve in Γ. Consequently,

$$V(\lambda) \leq \sup_{0\leq\mu\leq 1} F_\lambda(\mu w) = \sup_{0\leq\mu\leq 1} \mu^2(2-\lambda)S(w) + \mu^3 E_3(w) + \mu^4 E_4(w).$$

The supremum on the right-hand side is obtained at

$$\mu = \frac{3\,|E_3(w)|}{8E_4(w)}\left\{1 - \sqrt{1 - \frac{32(2-\lambda)S(w)E_4(w)}{9E_3(w)^2}}\right\}$$
$$= \frac{2S(w)}{3\,|E_3(w)|}\,(2-\lambda) + o(1) \quad \text{as } \lambda \to 2,$$

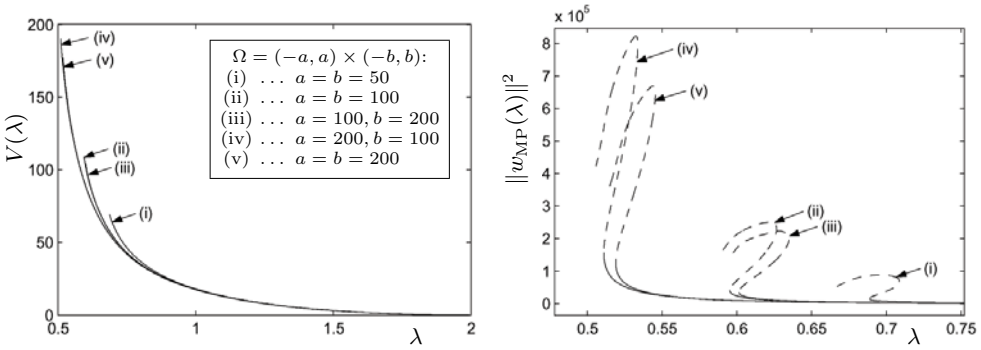

FIG. 4.3. *Left: The mountain pass energy $V(\lambda, \Omega)$ found numerically for various sizes of domain Ω. Right: The solid line shows the same computation as on the left, but plotted for the norm of $w_{\mathrm{MP}}(\lambda)$ squared. The dashed curve was obtained by continuation of the solid curve; the solutions on the dashed curve do not represent mountain pass points.*

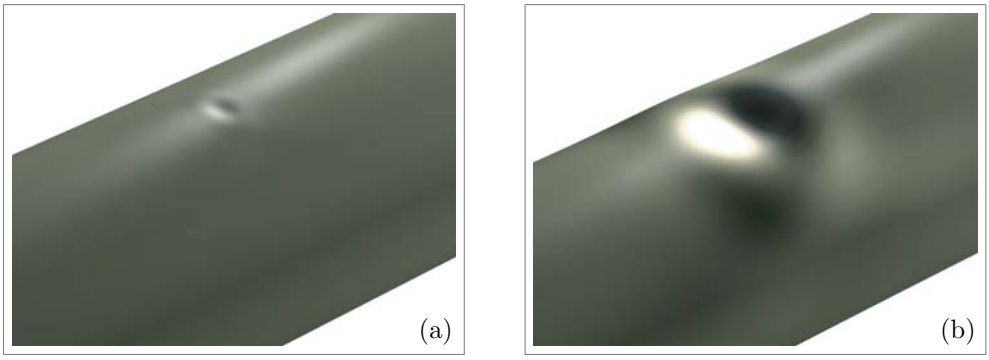

FIG. 4.4. *The numerical mountain pass solution w_{MP} of the scaled equations* (2.4)–(2.5) *for a given value of λ rendered on two cylinders of the same radius R but a different thickness t:* (a) $t/R = 0.003$, (b) $t/R = 0.04$.

implying that the claim holds for periodic functions. The generalization to nonperiodic functions on large domains Ω (i.e., for small ε) is made by filling the domain with a large number of periodic cells of the function w and connecting the function smoothly to the boundary of Ω. □

Figure 4.3 shows graphs of the mountain pass energy $V(\lambda, \Omega)$ computed for various sizes of domain Ω. For each domain, the mountain pass algorithm was employed to compute w_{MP} for several values of λ. These mountain pass solutions were then continued in λ using numerical path following.

4.3. Influence of the domain. The localized nature of the solutions calculated above suggests that they should be independent of domain size, in the sense that for a sequence of domains of increasing size the solutions converge (for instance, pointwise on compact subsets). Such a convergence would also imply convergence of the associated energy levels. Similarly, we would expect that the aspect ratio of the domain is of little importance in the limit of large domains.

We have tested these hypotheses by computing mountain pass solutions on domains of different sizes and aspect ratios. Generally solutions on different domains compare well; the maximal difference between the second derivatives of w is two or

three orders of magnitude smaller than the supremum norm of the same derivative (the details of this comparison are given in [17]).

Here we include only a calculation of the mountain pass energy level $V(\lambda, \Omega)$ for different aspect ratios and sizes of domain Ω (see Figure 4.3).

The comparison of solutions computed on different domains and their respective energies suggests that for each λ we are indeed dealing with a single, localized function defined on $\mathbb{R}^2$, of which our computed solutions are finite-domain adaptations. In the rest of this paper we adopt this point of view, and consequently we will write $V(\lambda)$ instead of $V(\lambda, \Omega)$.

A consequence of this point of view is that dimples in cylinders with different geometric parameters are mapped to the same rescaled solution, or equivalently, that the same single-dimple solution of (2.4)–(2.5) corresponds to differently sized dimples on an actual cylinder, as a function of the parameters (see Figure 4.4).

5. Interpretation: Imperfection sensitivity. We now turn to the relevance of the mountain pass in the context of a loading problem. This relevance can be best understood in the context of imperfections in the loading conditions (rather than geometric imperfections) such as in the case of a (small) lateral loading.

Under a small lateral load, an equilibrium w_0, which is a local minimum of the functional F_λ, may be perturbed into an equilibrium $\tilde{w}_0$ of a perturbed functional $\tilde{F}_\lambda$. Since w_0 is a local minimum, $F_\lambda(\tilde{w}_0) > F_\lambda(w_0)$; i.e., with respect to the unperturbed system, $\tilde{w}_0$ has a higher total potential than w_0. The level of F_λ that is reached is a measure of the magnitude of the imperfection—a different measure than is commonly used, but one that has distinct advantages.

By definition, the number $V(\lambda)$ is the lowest energy level at which it is possible to move between the basins of attraction of w_1 and w_2 (Figure 5.1). If the loading imperfection is interpreted, as above, as a mechanism capable of maintaining the system at a higher energy level than that of the neighboring fundamental minimizer, then the number $V(\lambda)$ is critical: as long as the imperfection is so small that the energy is never raised by more than $V(\lambda)$, the new stationary point will be part of the same basin of attraction as w_1. For larger imperfections, however, it becomes possible to leave the fundamental basin of attraction, resulting in a large jump in state space.

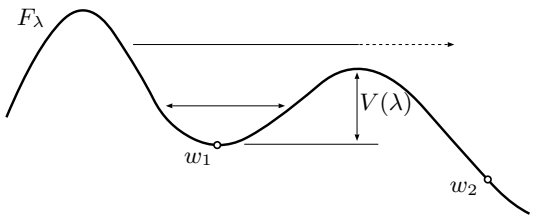

FIG. 5.1. *In order to leave the basin of attraction of w_1, the surplus energy should exceed $V(\lambda)$.*

This line of reasoning provides a natural measure of the size of imperfections, namely, the maximal increase in energy (in the perfect structure) that an imperfection can achieve. It also provides a natural measure of the stability of the unbuckled state, since a higher mountain pass energy level implies a larger class of loading imperfections under which the state remains in the fundamental basin of attraction. This observation allows us to connect systems with different geometrical characteristics and compare their relative sensitivity to imperfections.

5.1. Calibrating the mountain pass energy. Comparing cylinders of varying geometries requires a common measure of imperfection sensitivity. It is not a priori clear which measure to take; e.g., one might consider either the mountain pass energy itself or the average spatial density of this energy, which will result in different comparisons for cylinders of different wall volumes. Here we choose to rescale the mountain pass energy level by the other energy level present in the loaded cylinder, i.e., the energy that is stored in the homogeneous compression of the unbuckled shell.

This calculation can be done in two slightly different ways. The first and most straightforward is to rescale the dimensional mountain pass energy (see (B.11) and (2.3)),

$$64\pi^6 EtR^2\varepsilon^3 V(\lambda) = \frac{Et^4}{8(3(1-\nu^2))^{3/2}R}\, V(\lambda),$$

by the elastic strain energy stored in the full length of the compressed cylinder of length L,

$$\frac{L}{4\pi ERt}\, P^2 = \frac{\pi t^3 EL}{12(1-\nu^2)R}\, \lambda^2,$$

to give an energy ratio, or a rescaled mountain pass energy level,

$$\alpha = \frac{1}{2\pi\sqrt{3(1-\nu^2)}}\, \frac{t}{L}\, \frac{V(\lambda)}{\lambda^2}. \tag{5.1}$$

From this expression and the calculation shown in Figure 4.3, curves may be drawn in a plot of load versus the ratio L/t (see Figure 5.2). Note that to obtain this figure from Figure 4.3 the curve $V(\lambda)$ was fitted to extend the range of λ. Figure 5.2 shows the following two remarkable features:

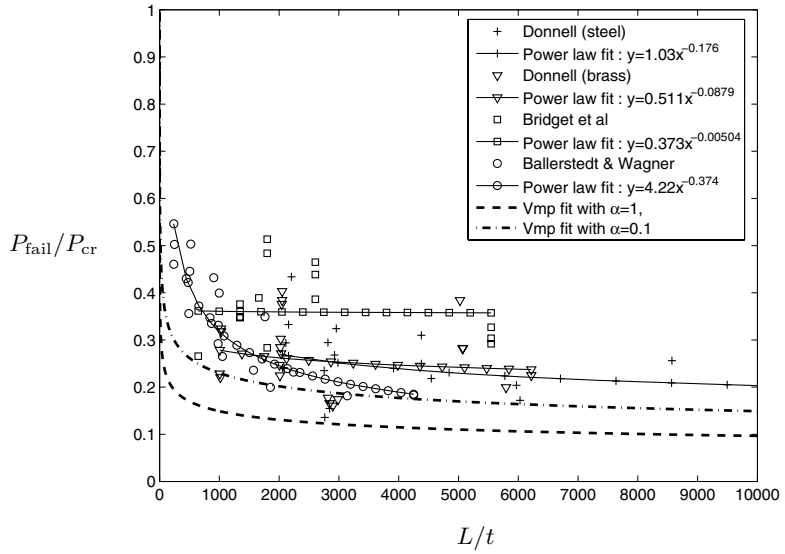

FIG. 5.2. *Shown are the same data as in Figure* 1.1*, with the addition of two curves of constant* $\alpha = 1$*,* $\alpha = 0.1$*, where* α *is given in* (5.1)*. Note that the load at which the mountain pass energy equals the stored energy in the prebuckled cylinder* ($\alpha = 1$) *appears to be a lower bound on the data.*

1. The general trend of the constant-α curves is very similar to the trend of the experimental data.
2. The $\alpha = 1$ curve, which indicates the load at which the mountain pass energy equals the stored energy in the prebuckled cylinder, appears to be a lower bound on the data.

One may also consider an alternative way of rescaling energy. The cylinder is a long structure, and it is not clear to what extent the length of the structure is relevant for the imperfection sensitivity. It may be reasonable to compare the energy of the mountain pass with the stored energy contained in a representative section of the cylinder; the radius R provides a natural length scale for such a representative section.

Similar to Figure 5.2, Figure 5.3 presents curves of constant β, where β is the ratio of mountain pass energy to stored energy in a section of length $2\pi R$:

$$\beta = \frac{1}{4\pi^2\sqrt{3(1-\nu^2)}}\,\frac{t}{R}\,\frac{V(\lambda)}{\lambda^2}. \tag{5.2}$$

Once again, to obtain Figure 5.3 we fitted $V(\lambda)$ from Figure 4.3 to extend the range of λ.

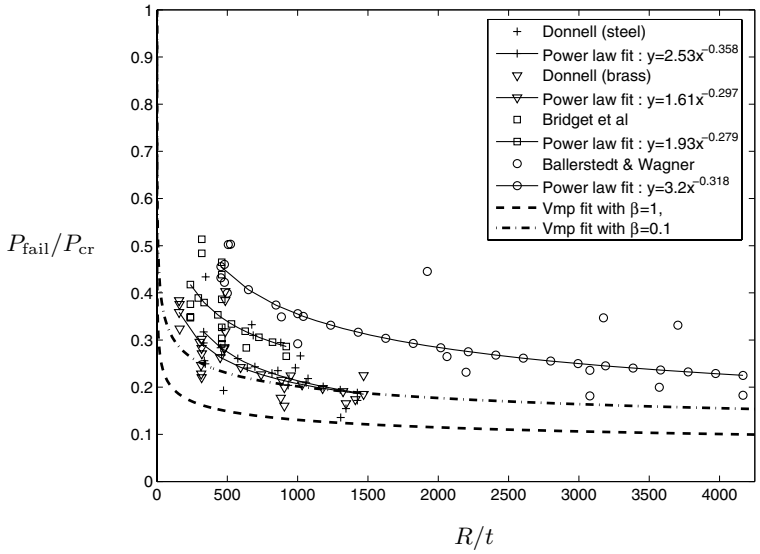

FIG. 5.3. *Experimental data and fit to V_{mp} with $\beta = 1$ and $\beta = 0.1$ in (5.2). Again, the load at which the mountain pass energy equals the stored energy in a representative portion of the prebuckled cylinder ($\beta = 1$) appears to be a lower bound on the data.*

6. Discussion and conclusions. The mathematical results and their interpretation in the context of a loading problem have brought about a number of new and improved insights.

6.1. The cylinder has doubly localized solutions. The subcritical nature of the bifurcation in Figure 1.2 strongly suggests that equilibria exist with deformation localized to a small portion of the cylinder length. In [20, 24, 25] such solutions are indeed calculated numerically and investigated analytically; these solutions are periodic around the cylinder and have exponential decay in the axial direction.

The localization in the axial direction demonstrated by these solutions is consistent with results on simpler systems, such as the laterally supported strut [21, 26]. The behavior of the cylinder in the tangential direction is not as well understood. The lack of localization in the simply supported flat plate [13] suggests that the cylinder should also prefer tangentially delocalized solutions, as do most of the experiments. The single- and multiple-dimple solutions of this paper, however, clearly demonstrate that doubly localized solutions do exist, and that some of these can be stable under constrained shortening.

6.2. The mountain pass is a single-dimple solution. The fact that the mountain pass solution exists follows essentially from two features, the local minimality of the unbuckled state and the existence of a large-deflection state of lower energy. The former is a simple consequence[3] of the subcritical load level, but the latter is based on an essential property of the cylinder: for a sequence of cylinders for which $R/t \to \infty$, the nondimensionalized load-carrying capacity (the highest load at which the unbuckled state is not only a local but also a global energy minimizer) decreases to zero. This property was demonstrated implicitly by Hoff, Madsen, and Mayers [15], and Lemma 3.3 provides a simplified proof of this result and a simple sequence of functions that illustrates the property.

However, the fact that the mountain pass solution is localized, and even is the most localized solution that is possible—a single dimple—is interesting in its own right and provides a complementary view of the discussion of localization above. A different way of formulating this result is that "creating the first dimple is the major obstacle"; afterwards one may increase the size of the dimple and add further dimples without ever returning to the same high energy level. In itself this interpretation points to a relationship between single dimples and imperfection sensitivity.

6.3. Single dimples in other contexts. Interestingly, single dimples have appeared in the literature in a number of seemingly unrelated ways:

- In the celebrated high-speed camera images of Eßlinger [12], the first visible deformation is a single, well-developed dimple halfway between the ends of the cylinder. New dimples quickly appear next to this first dimple, and the deformation then spreads around the cylinder in an axial direction. It is remarkable, though, that the first visible deformation is a single dimple.
- Some of the "worst" imperfections calculated by Deml and Wunderlich [9] and Wunderlich and Albertin [35] are in the form of a single dimple; as the load decreases, the dimple contracts and becomes even more concentrated.
- Hühne et al. [19] assert that single dimples are also *realistic* and *stimulating* imperfections in the sense of [34].
- Zhu, Mandal, and Calladine [38] base their analysis of the scaling behavior of the experimental buckling load on the behavior of a single dimple in other structural situations (such as the point-loaded cylinder and the sphere under uniform external pressure).

Note that the single-dimple appearances above are of three different types. Eßlinger's dimple is an experimental observation; the dimples of Wunderlich and coworkers and of Hühne et al. are geometric imperfection profiles; and the dimples studied by Zhu, Mandal, and Calladine are only analogies, since they are solutions of different problems.

[3] On a finite domain this consequence is indeed simple; on an infinite domain it appears that not only the third-order term but also the fourth-order term in the energy has to be taken into account, as remarked in section 3.

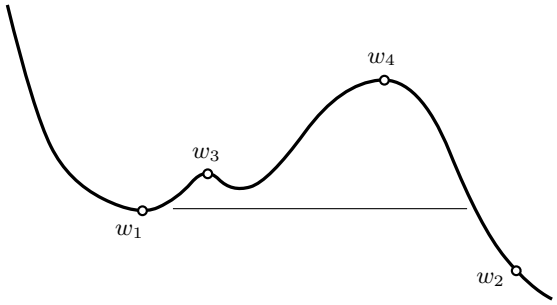

FIG. 6.1. *While a local algorithm for finding a critical point may settle on a minor critical point such as w_3, the mountain pass algorithm, by its global setup, will converge to the essential obstacle w_4.*

6.4. Scale-invariance of the localized solutions. It is an interesting observation that the von Kármán–Donnell equations can be rescaled to depend only on the (rescaled) load level. For localized solutions, for which the boundary plays no role of importance, this implies that the set of solutions reduces to a one-parameter family. This not only allows for efficient computation of the behavior of such solutions but also gives interesting insight into the relationship between dimples in cylinders of varying geometry (see, e.g., Figure 4.4).

Naturally the scale-invariance is expected to break upon replacing the von Kármán–Donnell equations with a different (probably more detailed) shell model. Nonetheless, it may be reasonably expected that much of the understanding of the relationship between cylinders of different geometries remains roughly correct.

We certainly also expect that the large-scale geometry of the energy landscape does not depend on the specific model of the cylinder. Using a discrete mountain pass algorithm to find mountain pass points therefore does not depend on the von Kármán–Donnell equations and should give similar results regardless of which shell model is used.

6.5. Connection with sensitivity to imperfections and "perturbation energy." Kröplin, Dinkler, and Hillmann [23]; Duddeck et al. [11]; and Wagenhuber and Duddeck [32] were the first to suggest an estimate of the stability of the unbuckled state in terms of the ratio of a "perturbation energy" (*Störenergie*) to the prebuckling energy. In early papers [23, 11] the perturbations are still fixed rather than determined, but from both the introduction and the final results in [32] it may be deduced that an optimization is done over all perturbations (although this is simultaneously contradicted on page 333 of [32]). Unfortunately, these papers do not provide enough details for determining exactly what the authors calculate.

There is one aspect in which our method can clearly be seen to differ from these earlier approaches. The discrete mountain pass algorithm takes into account *global* features of the energy landscape and provides a global measure of the separation barrier between two states that lie far apart. This is different from the papers mentioned above, in which the method uses only local information (reflected, for instance, in the assumption that the equilibria in question lie on the same bifurcation branch). This difference is illustrated in Figure 6.1, where a local analysis might find stationary point w_2, but the mountain pass algorithm will find the more important obstacle w_4.

Appendix A. Proof of Lemma 3.3. Lemma 3.3 states that *there exists a*

sequence of functions w_δ, 1-periodic on $\mathbb{R}^2$, such that

$$\int_{[-1/2,1/2]^2} w_{\delta x}^2 \sim 1, \qquad \int_{[-1/2,1/2]^2} \Delta w_\delta^2 = O(\delta^{-1}), \tag{A.1}$$

$$\text{and} \qquad \int_{[-1/2,1/2]^2} \Delta \phi_\delta^2 = O(\delta^{2-\alpha}) \quad \text{as} \quad \delta \to 0$$

for any $\alpha > 0$. Here the function ϕ_δ solves (2.5) *with periodic boundary conditions. In addition, w_δ and ϕ_δ satisfy* (2.6) *on the boundary of $[-1/2, 1/2]^2$.*

The proof consists of three parts. In the first part we construct the functions w_δ; in the second part we study the symmetry properties and the support of the right-hand side of (2.5); and in the third part we show that this sequence has the asserted scaling.

A.1. Construction of w_δ. Let f_δ be given by

$$f_\varepsilon''(s) = \begin{cases} \dfrac{1}{4\delta}, & \operatorname{dist}(s,\mathbb{Z}) < \delta, \\ 0 & \text{otherwise,} \end{cases} \qquad \text{with} \qquad f_\delta(0) = f_\delta'(0) = 0.$$

Note that f is even and that $f(1) = 1/4$. Define

$$w_\delta(x,y) = f_\delta(y+x) + f_\delta(y-x) - \frac{1}{2} f_\delta(2x) - \frac{1}{2} y^2.$$

We shall drop the subscript δ and simply write w and f.

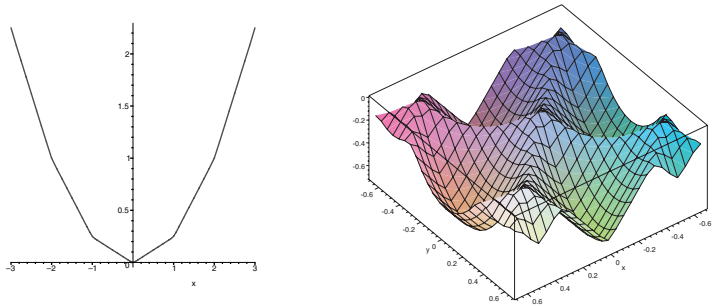

FIG. A.1. *The functions f and $-w$; on the right the plotting area is slightly larger than one period.*

The function w is periodic on $\mathbb{R}^2$ with period 1 in each direction. To show this, we prove that the first two derivatives match up on opposite sides of $[-1/2, 1/2] \times [-1/2, 1/2]$ as follows:

- By the symmetry of f, the function w is even in both x and y. Consequently w takes the same values on $(1/2, y)$ and $(-1/2, y)$; the same holds for $(x, \pm 1/2)$.
- For the comparison of the first derivatives, we calculate

$$\int_{-1/2}^{1/2} w_{xx}(x,y)\,dx = \int_{-1/2}^{1/2} f''(y+x)\,dx + \int_{-1/2}^{1/2} f''(y-x)\,dx - 2\int_{-1/2}^{1/2} f''(2x)\,dx = 0,$$

implying that $w_x(-1/2,y) = w_x(1/2,y)$; by the symmetry of w it follows that $w_x(-1/2,y) = w_x(1/2,y) = 0$. Similarly, using the definition of f_δ we find that

$$\int_{-1/2}^{1/2} w_{yy}(x,y)\,dy = \int_{-1/2}^{1/2} f''(y+x)\,dy + \int_{-1/2}^{1/2} f''(y-x)\,dy - 1 = 0,$$

implying that $w_y(x,-1/2) = w_y(x,1/2) = 0$.

Periodicity on $\mathbb{R}^2$ then follows from the remark that all second derivatives of w are periodic with period 1 in x and y.

A.2. Support, symmetry, and boundary conditions. Next we investigate the right-hand side of (2.5). We find

$$\begin{aligned}[w,w] + w_{xx} &= \big\{(f''(y+x) + f''(y-x) - 2f''(2x))(f''(y+x) + f''(y-x) - 1)\\ &\qquad - (f''(y+x) - f''(y-x))^2\big\}\\ &\qquad + (f''(y+x) + f''(y-x) - 2f''(2x))\\ &= 4f''(y+x)f''(y-x) - 2f''(2x)(f''(y+x) + f''(y-x)).\end{aligned}$$

This expression has a zero integral over $[-1/2,1/2]^2$. This follows from the periodicity of w,

$$\int_{-1/2}^{1/2}\int_{-1/2}^{1/2} w_{xx}w_{yy}\,dxdy = \int_{-1/2}^{1/2}\int_{-1/2}^{1/2} w_{xy}^2\,dxdy, \tag{A.2}$$

by partial integration. More is true, however; we analyze the support of $[w,w] + w_{xx}$ in $[-1/2,1/2]^2$ in more detail.

The value of f'' is either $(4\delta)^{-1}$ or zero; in order to determine $[w,w] + w_{xx}$ it is therefore sufficient to calculate the measures of the pairwise intersections of the supports of $f''(y+x)$, $f''(y-x)$, and $f''(2x)$ as follows:

- The intersection of the supports of $f''(y+x)$ and $f''(y-x)$ has total area $4\delta^2$ (see Figure A.2).
- The intersection of the supports of $f''(y+x)$ and $f''(2x)$ also has total area $4\delta^2$ (see Figure A.3).

Since the support of $[w,w] + w_{xx}$ is concentrated on a discrete set of points, let us examine the behavior at one of these points. For small δ the support forms disjoint sets in $[-1/2,1/2]^2$, and we can restrict our attention to the origin alone.

If $|s| < 1/2$, then $f_\delta''(s)$ can be written as

$$f_\delta''(s) = \frac{1}{\delta}\,g\left(\frac{s}{\delta}\right),$$

where

$$g(\sigma) = \begin{cases} \dfrac{1}{4}, & |\sigma| < 1,\\ 0 & \text{otherwise.}\end{cases}$$

Therefore, as long as $|(x,y)| < 1/4$, then

$$\begin{aligned}&4f_\delta''(y+x)f_\delta''(y-x) - 2f_\delta''(2x)(f_\delta''(y+x) + f_\delta''(y-x))\\ &\qquad = \frac{4}{\delta^2}\,g\left(\frac{y+x}{\delta}\right)g\left(\frac{y-x}{\delta}\right) - \frac{2}{\delta^2}g\left(\frac{2x}{\delta}\right)\left[g\left(\frac{y+x}{\delta}\right) + g\left(\frac{y-x}{\delta}\right)\right]\\ &\qquad = \frac{1}{\delta^2}\,F\big(\delta^{-1}(x,y)\big),\end{aligned} \tag{A.3}$$

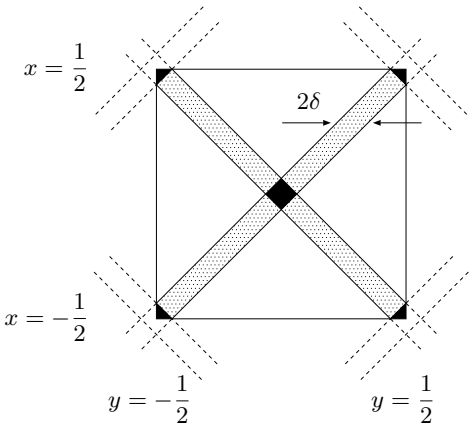

FIG. A.2. *The areas of the black regions add up to* $4\delta^2$.

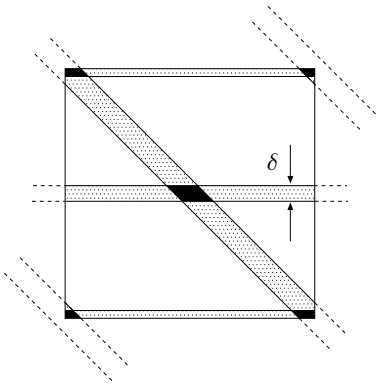

FIG. A.3. *The areas of the black regions add up to* $4\delta^2$.

where we introduce a new function F, which does not depend on δ, to summarize the line above. Note that $\operatorname{supp} F \subset [-2,2]^2$. Note also that by (A.2) the function F has zero integral; in addition, since f_δ'' is even, the function $4f_\delta''(y+x)f_\delta''(y-x) - 2f_\delta''(2x)(f_\delta''(y+x) + f_\delta''(y-x))$ is also even in x and in y. Therefore

$$\int_{\mathbb{R}^2} xF\big((x,y)\big)\,dxdy = \int_{\mathbb{R}^2} yF\big((x,y)\big)\,dxdy = 0.$$

This property will be used below.

The assertion also states that the functions w and ϕ satisfy (2.6) on the boundary of $[-1/2,1/2]^2$. We first note that w and ϕ are periodic in the following sense:

$$w(x \pm 1/2, y \pm 1/2) = w(x,y) \qquad \text{and} \qquad \phi(x \pm 1/2, y \pm 1/2) = \phi(x,y). \tag{A.4}$$

For w this is a simple consequence of the functional form of w; for ϕ it is a consequence of the uniqueness of solutions of (2.5) under periodic boundary conditions. The periodicity of w and ϕ in the y-direction in (2.6) then follows from a repeated application of (A.4). Similarly, the symmetry conditions in x in (2.6) follow from a combination of the symmetry of w and ϕ around $\{y = 0\}$ in combination with (A.4).

A.3. Scaling properties. We now use the information gathered above to show that the sequence w_δ has the scaling properties of (A.1). All function spaces are on $[-1/2,1/2]^2$.

First, f'_δ remains bounded on bounded sets as $\delta \to 0$; therefore $\int_\Omega w_{\delta x}^2$ converges to a finite, positive value. In addition, all second derivatives of w_δ remain bounded in L^1, so that

$$\|\Delta w_\delta\|_{L^1} \le C.$$

The second derivative f''_δ is bounded by $1/4\delta$, so that we can estimate

$$\|\Delta w_\delta\|_{L^2}^2 \le \|\Delta w_\delta\|_{L^1} \|\Delta w_\delta\|_{L^\infty} \le \frac{C}{\delta}.$$

Turning to ϕ_δ, we start by remarking that $[w_\delta, w_\delta] + w_{\delta xx}$ is bounded in L^1, since

$$\int_{|(x,y)|<1/4} \big|[w_\delta, w_\delta] + w_{\delta xx}\big| = \frac{1}{\delta^2} \int_{|(x,y)|<2\delta} \big|F\big(\delta^{-1}(x,y)\big)\big| = O(1).$$

Since $W^{2,p} \hookrightarrow L^\infty$ for all $p > 1$, the solution of

$$\Delta^2 \psi = h$$

satisfies

$$\|\Delta\psi\|_{L^{p'}} = \sup_\zeta \frac{\int_\Omega \Delta\psi\Delta\zeta}{\|\Delta\zeta\|_{L^p}} = \sup_\zeta \frac{\int_\Omega h\zeta}{\|\Delta\zeta\|_{L^p}} \le C\,\|h\|_{L^1} \frac{\|\zeta\|_{L^\infty}}{\|\zeta\|_{W^{2,p}}} \le C\,\|h\|_{L^1},$$

so that

$$\|\phi_\delta\|_{W^{2,p'}} \le C\,\|[w_\delta, w_\delta] + w_{\delta xx}\|_{L^1} \le C,$$

where $1/p + 1/p' = 1$. Using $W^{2,p'} \hookrightarrow C^{1,1-2/p'}$ we find

$$\|\phi_\delta\|_{C^{1,1-2/p'}} \le C\,\|\phi_\delta\|_{W^{2,p'}} \le C.$$

Writing, locally at the origin,

$$\phi_\delta(x,y) = \phi_\delta(0,0) + \nabla\phi_\delta(0,0)\cdot(x,y) + O\big(|(x,y)|^{2(1-1/p')}\big),$$

we find, by multiplying (2.5) by ϕ_δ and integrating,

$$\begin{aligned}
\|\Delta\phi_\delta\|^2_{L^2([-1/2,1/2]^2)} &= 2\int_{[-1/4,1/4]^2} \phi_\delta\big\{[w_\delta, w_\delta] + w_{\delta xx}\big\} \\
&= 2\frac{\phi_\delta(0,0)}{\delta^2} \int_{[-1/4,1/4]^2} F\big(\delta^{-1}(x,y)\big) \\
&\qquad + 2\frac{\nabla\phi_\delta(0,0)}{\delta^2} \cdot \int_{[-1/4,1/4]^2} (x,y) F\big(\delta^{-1}(x,y)\big) + O\big(\delta^{2(1-1/p')}\big) \\
&= O\big(\delta^{2(1-1/p')}\big),
\end{aligned}$$

since the zeroth and first moments of F are zero. Since p' may be chosen arbitrarily large, this estimate concludes the proof.

Appendix B. Derivation of the von Kármán–Donnell equations. The common aim of the many elastic shell theories is to approximate three-dimensional elasticity by a reduced description in which the unknowns are functions of not three but two spatial variables; see, for example, [6]. For the von Kármán–Donnell cylinder the central approximation is the *director Ansatz*, which states that a normal to the center surface remains normal through deformation. By this Ansatz the displacement is fully characterized by the displacement vector (u, v, w), a function of the two in-plane spatial variables x and y, where u, v, and w are the displacements in the axial (x-), tangential (y-), and radial directions, respectively. Apart from some rescaling, the function w is the same as the unknown w in the rest of this paper.

In the formulation of section 2 the unknowns u and v are replaced with the Airy stress function ϕ, which is derived by minimization with respect to the displacements u and v for fixed w. This minimization argument is well known in the context of the von Kármán plate theory and can be found in many textbooks. Determining the boundary conditions that the function ϕ satisfies, however, is not straightforward (see also the discussion in [27]), and it is for this reason that we now describe the argument in detail. The main goal is to show that the function ϕ is periodic in the tangential direction.

B.1. Energy and shortening. All quantities in this appendix are dimensional. We assume a cylinder of thickness t, length L, and radius R, and we set $\Omega = [0, L] \times [0, 2\pi R]$. The stored energy given by [31] is

$$E_1 = \frac{t^3 E}{24(1-\nu^2)} \int_\Omega \Delta w^2 + \frac{t}{2E} \int_\Omega \big[(\sigma_{11}+\sigma_{22})^2 - 2(1+\nu)(\sigma_{11}\sigma_{22} - \sigma_{12}^2)\big]$$

for a linear material of Young's modulus E and Poisson's ratio ν. Under the assumption of plane stress, the stress and strain tensors are related by

$$\sigma = \frac{E}{1-\nu^2}\big[(1-\nu)\varepsilon + \nu \operatorname{tr}\varepsilon\, I\big] = \frac{E}{1-\nu^2}\begin{pmatrix} \varepsilon_{11}+\nu\varepsilon_{22} & (1-\nu)\varepsilon_{12} \\ (1-\nu)\varepsilon_{12} & \varepsilon_{22}+\nu\varepsilon_{11} \end{pmatrix}, \tag{B.1}$$

and under the small-angle approximation the strain tensor can be expressed in the displacements as

$$\varepsilon = \begin{pmatrix} u_x + \frac{1}{2}w_x^2 & \frac{1}{2}u_y + \frac{1}{2}v_x + \frac{1}{2}w_x w_y \\ \frac{1}{2}u_y + \frac{1}{2}v_x + \frac{1}{2}w_x w_y & v_y + \frac{1}{2}w_y^2 - \rho w \end{pmatrix}. \tag{B.2}$$

These choices for the energy and for the stress and strain tensors are very similar to those for a flat plate. The intrinsic curvature of the cylinder, of magnitude $\rho = 1/R$, appears only in the last term of ε_{22}, $-\rho w$, which expresses the fact that radial displacement creates extensional strain in the y-direction.

The average axial shortening is given by

$$S_1 = -\frac{1}{2\pi R}\int_0^{2\pi R} \big[u(L,y) - u(0,y)\big]\, dy = -\frac{1}{2\pi R}\int_\Omega u_x \, dxdy,$$

and an equilibrium (u, v, w) at load level P is a stationary point of the total potential $V_1 = E_1 - PS_1$.

B.2. Boundary conditions. At the boundaries $y = 0, 2\pi R$ it is natural to assume that u, v, and w are periodic, but at $x = 0, L$ there is a certain amount of choice.

The boundary conditions on w (see (2.6a)) are

$$w_x = (\Delta w)_x = 0 \qquad \text{at } x = 0, L, \tag{B.3}$$

and these conditions signify a fixed angle ($w_x = 0$) and zero radial force ($(\Delta w)_x = 0$). They may also be understood as symmetry boundary conditions, as in the case of a sequence of cylinders stacked on top of each other. For u and v we assume boundary conditions

$$u_y = 0 \qquad \text{and} \qquad \sigma_{12} = 0 \qquad \text{at } x = 0, L, \tag{B.4}$$

which signify that the ends of the cylinder are rigid in the x-direction and that there is no friction between the cylinder and the apparatus holding it. Note that the pair of boundary conditions $\sigma_{12} = 0$ and $(\Delta w)_x = 0$ together states that the loading apparatus exerts only axial forces on the cylinder.

The boundary conditions on w are invariant under the addition of a constant to w, i.e., under the replacement of w with $w + c$; for stationary points we may exploit this fact.

LEMMA B.1. *If (u, v, w) is a stationary point of $E_1 - PS_1$ under boundary conditions* (B.3)–(B.4)*, then*

$$\int_\Omega \sigma_{22} = 0. \tag{B.5}$$

Proof. Under the replacement $w \mapsto w + c$, we have

$$\frac{d\sigma}{dc} = -\frac{E\rho}{1-\nu^2}\begin{pmatrix} \nu & 0 \\ 0 & 1 \end{pmatrix},$$

and therefore

$$\begin{aligned} 0 &= \frac{d}{dc}(E_1 - PS_1) \\ &= -\frac{t\rho}{1-\nu^2}\int_\Omega \big[(\sigma_{11} + \sigma_{22})(\nu + 1) - (1 + \nu)(\sigma_{11} + \nu\sigma_{22})\big] = -t\rho \int_\Omega \sigma_{22}. \end{aligned}$$

∎

B.3. Derivation of the Airy stress function ϕ. The energy (2.7) and the Airy stress function ϕ are derived from the total potential $E_1 - PS_1$ by minimization with respect to the displacements u and v for fixed w. Performing this minimization on the second term in E_1 yields the classical plate equilibrium equations

$$\sigma_{11x} + \sigma_{12y} = 0 \qquad \text{and} \qquad \sigma_{12x} + \sigma_{22y} = 0.$$

Note that the derivative of S_1 with respect to u only creates boundary terms. By applying three times the well-known characterization of divergence-free vector fields as rotations of scalar fields (see, e.g., [3, Thm. XII.3.5]) we obtain the *local* existence of a function ϕ satisfying

$$\sigma_{11} = E\phi_{yy}, \qquad \sigma_{12} = -E\phi_{xy}, \qquad \text{and} \qquad \sigma_{22} = E\phi_{xx}, \tag{B.6}$$

where we use the traditional scaling of ϕ by Young's modulus.

B.4. Boundary conditions on ϕ. The existence of the function ϕ is the result of a local differential-geometric argument, and as such gives no reason for ϕ to be periodic in y. The following theorem shows that after a normalization transformation, the function ϕ can indeed be assumed to be periodic in y, and may be taken to satisfy the same boundary conditions as the function w.

THEOREM B.2. *If u, v, and w are periodic in y and satisfy boundary conditions* (B.3)–(B.4)*, then there exists a function ϕ that satisfies*

$$\sigma_{11} - \frac{1}{|\Omega|}\int_\Omega \sigma_{11} = E\phi_{yy}, \qquad \sigma_{12} = -E\phi_{xy}, \qquad \text{and} \qquad \sigma_{22} = E\phi_{xx}; \tag{B.7}$$

is periodic in y; and satisfies boundary conditions

$$\phi_x = (\Delta\phi)_x = 0 \qquad \text{at } x = 0, L. \tag{B.8}$$

Remark B.3. Mechanically the normalization of ϕ with $\int_\Omega \sigma_{11}$ means that ϕ represents the *deviation* from the unbuckled in-plane stress state.

Proof. As discussed above, there exists a function ϕ satisfying (B.6); we will construct in stages a new function $\hat{\phi}$ which satisfies (B.7) and the boundary conditions.

We first convert condition (B.6) into (B.7). Set

$$p(x) := \frac{1}{2\pi R}\int_0^{2\pi R} \phi_{yy}(x,y)\,dy = \frac{1}{2\pi R}\big[\phi_y(x,2\pi R) - \phi_y(x,0)\big].$$

Since the second derivatives of ϕ can be expressed in terms of derivatives of u, v, and w, the second and higher derivatives of ϕ are automatically periodic in y. Therefore

$$\frac{d}{dx}p(x) = \frac{1}{2\pi R}\big[\phi_{xy}(x,2\pi R) - \phi_{xy}(x,0)\big] = 0,$$

implying that p is actually independent of x. (A mechanical argument provides the same result: $Etp(x) = t\int_0^{2\pi R}\sigma_{11}(x,y)dy$ is the total force applied at a virtual cut at level x, and mechanical equilibrium implies that this force is independent of x.) Therefore

$$|\Omega|\,p = 2\pi R\int_0^L p\,dx = \int_\Omega \phi_{yy} = \frac{1}{E}\int_\Omega \sigma_{11},$$

so that the new function

$$\tilde{\phi}(x,y) := \phi(x,y) - \frac{p}{2}y^2$$

satisfies (B.7). Note that this implies

$$\int_\Omega \tilde{\phi}_{yy} = 0. \tag{B.9}$$

We now turn to the periodicity in the y-direction. It remains to show that $\tilde{\phi}$, $\tilde{\phi}_x$, and $\tilde{\phi}_y$ are the same at $y = 0$ and $y = 2\pi R$. Again the periodicity of the second derivatives implies that

$$\frac{d^2}{dx^2}\big[\tilde{\phi}(x,2\pi R) - \tilde{\phi}(x,0)\big] = \tilde{\phi}_{xx}(x,2\pi R) - \tilde{\phi}_{xx}(x,0) = 0,$$

so that $\tilde{\phi}(x, 2\pi R) - \tilde{\phi}(x, 0) = ax + b$ for some $a, b \in \mathbb{R}$. Defining

$$\hat{\phi}(x, y) := \tilde{\phi}(x, y) - \frac{by}{2\pi R} = \phi(x, y) - \frac{p}{2}y^2 - \frac{by}{2\pi R},$$

the function $\hat{\phi}$ still satisfies (B.7), and

$$\hat{\phi}(x, 2\pi R) - \hat{\phi}(x, 0) = ax.$$

Finally, we find that

$$a = \hat{\phi}_x(0, 2\pi R) - \hat{\phi}_x(0, 0) = \int_0^{2\pi R} \hat{\phi}_{xy}(0, y)\, dy = \frac{1}{E}\int_0^{2\pi R} \sigma_{12}(0, y)\, dy \overset{(B.4)}{=} 0,$$

and therefore that $\hat{\phi}(x, 2\pi R) - \hat{\phi}(x, 0) = 0$ for all x. The same follows for $\hat{\phi}_x(x, 2\pi R) - \hat{\phi}_x(x, 0)$ by differentiation.

To show that ϕ_y also matches,

$$\frac{d}{dx}\big[\hat{\phi}_y(x, 2\pi R) - \hat{\phi}_y(x, 0)\big] = \big[\phi_{xy}(x, 2\pi R) - \phi_{xy}(x, 0)\big] = 0,$$

and therefore $\phi_y(x, 2\pi R) - \phi_y(x, 0)$ is constant in x; by (B.9) this constant is zero. This proves that $\hat{\phi}$ satisfies (B.7) and is periodic in y.

We finally discuss the boundary conditions at $x = 0, L$, and we follow the line of reasoning of [27]. By (B.4) and (B.1), $\varepsilon_{12} = 0$ at $x = 0, L$, so that by (B.3) and (B.4),

$$v_{xy} = \frac{\partial}{\partial y}(2\varepsilon_{12} - u_y - w_x w_y) = 0 \qquad \text{at } x = 0, L.$$

Therefore

$$\varepsilon_{22x} = v_{xy} + w_y w_{xy} - \rho w_x \overset{(B.4)}{=} 0 \qquad \text{at } x = 0, L.$$

Using $E\varepsilon_{22} = \sigma_{22} - \nu\sigma_{11}$, we then find

$$\hat{\phi}_{xxx} - \nu\hat{\phi}_{xyy} = \phi_{xxx} - \nu\phi_{xyy} = \frac{1}{E}\frac{d}{dx}(\sigma_{22} - \nu\sigma_{11}) = \varepsilon_{22x} = 0,$$

and by adding $(1 + \nu)\hat{\phi}_{xyy} = -(1/E)(1 + \nu)\sigma_{12y} = 0$ it follows that

$$(\Delta\hat{\phi})_x = \hat{\phi}_{xxx} + \hat{\phi}_{xyy} = 0 \qquad \text{at } x = 0, L,$$

which proves one part of (B.8).

From $\hat{\phi}_{xy} = -\sigma_{12}/E = 0$ we find that

$$\hat{\phi}_x(0, y) = c_0 \qquad \text{and} \qquad \hat{\phi}_x(L, y) = c_L \qquad \text{for all } y \in [0, 2\pi R].$$

Writing

$$2\pi R(c_L - c_0) = \int_\Omega \hat{\phi}_{xx} = \frac{1}{E}\int_\Omega \sigma_{22} \overset{(B.5)}{=} 0$$

we find that $c_L = c_0$. Now the function

$$\overline{\phi}(x, y) := \hat{\phi}(x, y) - c_0 x = \phi(x, y) - \frac{p}{2}y^2 - \frac{by}{2\pi R} - c_0 x$$

satisfies (B.7) and (B.8) and is periodic in y. This concludes the proof. ∎

Remark B.4. It is instructive to note that the periodicity of ϕ is a result of the specific choice of boundary conditions, and will in fact not hold if different boundary conditions are taken. For instance, if a tangential shear stress τ is applied at the cylinder ends (i.e., the cylinder is loaded under torsion), then the coefficient a in the derivation above will not vanish, and ϕ_x will not be periodic in y.

B.5. Putting it all together. By an elementary but lengthy calculation we find that ϕ, as provided by Theorem B.2, satisfies the equation

$$\Delta^2\phi + \rho w_{xx} + [w,w] = 0 \qquad \text{in } \Omega, \tag{B.10}$$

and that the second term in E_1 can be written as

$$\frac{tE}{2}\int_\Omega \Big[\Delta\phi^2 - 2(1+\nu)[\phi,\phi]\Big].$$

By the boundary conditions given by Theorem B.2 the second term vanishes, and the total stored energy functional can therefore be written as

$$E_2(w) := \frac{t^3E}{24(1-\nu^2)}\int_\Omega \Delta w^2 + \frac{tE}{2}\int_\Omega \Delta\phi^2.$$

Note that this energy is a function of w alone; the function ϕ in this definition is assumed to be given by (B.10), with the boundary conditions of Theorem B.2. Similarly, we rewrite the average shortening as

$$\begin{aligned} S_2(w) := S_1(u) &= -\frac{1}{2\pi R}\int_\Omega u_x \\ &\overset{(B.2)}{=} -\frac{1}{2\pi R}\int_\Omega \left[\varepsilon_{11} - \frac{1}{2}w_x^2\right] \\ &\overset{(B.1)}{=} -\frac{1}{2\pi RE}\int_\Omega \big[\sigma_{11} - \nu\sigma_{22}\big] + \frac{1}{4\pi R}\int_\Omega w_x^2 \\ &\overset{(B.7)}{=} -\frac{1}{2\pi R}\int_\Omega \big[\phi_{yy} - \nu\phi_{xx}\big] + \frac{1}{4\pi R}\int_\Omega w_x^2 \\ &= \frac{1}{4\pi R}\int_\Omega w_x^2. \end{aligned}$$

A stationary point w of $E_2 - PS_2$ satisfies the Euler equation

$$\frac{t^2}{12(1-\nu^2)}\Delta^2 w + \frac{P}{2\pi REt}w_{xx} - \rho\phi_{xx} - 2[w,\phi] = 0,$$

where again ϕ is related to w by (B.10). With the nondimensionalization

$$w = 4\pi^2 R\,\overline{w}, \qquad \phi = 16\pi^4R^2\,\overline{\phi}, \qquad x \mapsto 2\pi R\,x, \qquad y \mapsto 2\pi R\,y,$$

we then obtain (2.4) and (2.5), and the dimensional energy E_2 and average shortening S_2 above can be expressed in these variables as

$$E_2 = \frac{\pi^2t^3E}{6(1-\nu^2)}\int \Delta\overline{w}^2 + 32\pi^6tER^2\int \Delta\overline{\phi}^2, \qquad S_2 = 4\pi^3R\int \overline{w}_x^2. \tag{B.11}$$

CONVERGENCE OF STRONG SHOCK IN A VAN DER WAALS GAS*

RAJAN ARORA†‡ AND V. D. SHARMA†

Abstract. Strong cylindrical and spherical shock waves, collapsing at the center (or axis) of symmetry, are studied for a Van der Waals gas. The perturbation technique applied in this paper provides a global solution to the implosion problem, yielding the results for Guderley's local self-similar solution, which is valid only in the vicinity of the center/axis of implosion. The similarity exponents are found along with the corresponding amplitudes in the vicinity of the shock-collapse. The flow parameters and the shock trajectory have been computed for different values of the adiabatic coefficient and the Van der Waals excluded volume.

Key words. shock waves, convergence, Van der Waals gas

1. Introduction.

The study of shock waves is motivated by its application in a variety of fields such as aerodynamics, astrophysics, nuclear science, and plasma physics, and shock waves generated by spherical and cylindrical pistons in a gas have received much attention in the past four decades. Converging shock waves have been a field of growing interest since the early 1940s from both mathematical and physical points of view. They are one of the means of generating high pressure and high temperatures at the center/axis of convergence. Applications range from nuclear weapons to plasmas; in medical science, shock wave lithotripsy is used to treat kidney stone disease. This work has been motivated by the fact that such shocks are an essential part of the mechanism responsible for sonoluminescence, that is, the light which under certain conditions is emitted from a bubble of gas trapped in a liquid and compressed by incident sound waves.

A theoretical investigation of shock wave behavior near the center of convergence was first done by Guderley in 1942 [1]. We also note the work of Lazarus and Richtmyer [2], Van Dyke and Guttmann [3], Hafner [4], Wu and Roberts [5], and Madhumita and Sharma [6] as major contributions towards the investigation of the implosion problem.

Wu and Roberts have found that for small values of the Van der Waals excluded volume (b), there is only one branch of similarity solutions that resembles the Guderley solutions and is well described by the CCW (Chester–Chisnell–Whitham)approximation [7]; however, for larger values of b, they predict another branch of the solution, which is distinct from the Guderley-type branch and which cannot be obtained by the CCW approximation.

In the present paper, we successfully apply the technique of Van Dyke and Guttmann [3] to the shock implosion problem in a Van der Waals gas, which provides a global solution to the imploding shock problem. This global solution is valid

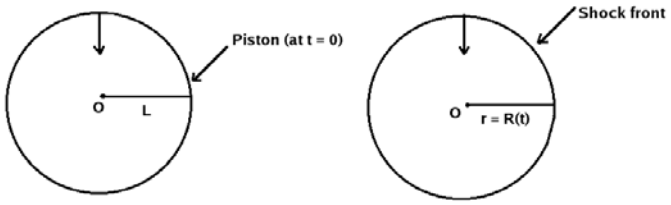

FIG. 1. *The spherical piston is initially of radius L. At time $t = 0$ the piston begins to contract with a very large constant velocity V, driving ahead of it a spherical shock of radius $R(t)$ collapsing at the point of implosion O, where $R(t)$ is to be determined.*

throughout the flow field almost up to the instant of collapse. From this global solution we are able to extract with good accuracy the Guderley local solution at the instant of shock collapse; this is in excellent agreement with a solution branch obtained by Wu and Roberts. Wu and Roberts reported that a second solution branch may exist within the range of the first solution branch, and for certain values of γ and b the similarity solution may cease to exist; for instance, it is reported that for $\gamma = 5/3$, one solution arises in the range $0 \leq b \leq 0.05$, while the other solution exists in the range $0.005 \leq b \leq 0.035$, and no similarity solution could be obtained in the range $0.0001 \leq b \leq 0.05$ for $\gamma = 6/5$. The present method does not exhibit any computational difficulty, enables us to compute successfully the similarity exponent for all such values of b and γ, and yields only one solution that matches well with the Guderley solution.

Guderley's local solution provides us only the first dominant similarity exponent, but we have found, through this technique, the other similarity exponents and the corresponding amplitudes.

We consider a spherical or cylindrical piston that is filled with a Van der Waals gas of constant density. The piston collapses with constant inward speed, greater than the speed of sound, generating a strong shock wave collapsing at the center/axis of symmetry; see Figure 1.

Computations are performed to obtain the similarity exponents and the corresponding amplitudes in the vicinity of the shock-collapse. Computations are carried out for different values of adiabatic coefficient γ and Van der Waals excluded volume b. Distributions of the flow variables at the rear of the shock wave are presented. The results are given for cylindrical and spherical fronts propagating into the medium. Our results match well with those obtained by Wu and Roberts [5] and Guderley's method [1].

2. Basic equations with solutions analytic in time. We consider a cylindrical or spherical piston of initial radius L and filled with Van der Waals gas. Let the initial conditions be given by

$$v = 0, \quad \rho = \rho_0, \quad p = p_0, \tag{1}$$

where v, ρ, and p are, respectively, the outward radial velocity, density, and pressure; ρ_0 and p_0 are appropriate positive constants. At time $t = 0$, the container starts to contract with very large constant velocity V; this produces a cylindrical or spherical shock wave whose radius $R(t)$ is to be determined. The equations of one-dimensional

adiabatic motion of a Van der Waals gas are (Wu and Roberts [5])

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho v)}{\partial r} + \frac{m\rho v}{r} = 0, \tag{2}$$

$$\frac{\partial v}{\partial t} + v\,\frac{\partial v}{\partial r} + \frac{1}{\rho}\,\frac{\partial p}{\partial r} = 0, \tag{3}$$

$$\frac{\partial p}{\partial t} + v\,\frac{\partial p}{\partial r} - \frac{\gamma p}{\rho(1-b\rho)}\left(\frac{\partial \rho}{\partial t} + v\,\frac{\partial \rho}{\partial r}\right) = 0, \tag{4}$$

where t is the time, r is the distance of the particle from the center of symmetry, b is the Van der Waals excluded volume, γ is the adiabatic exponent, and m takes values 1 and 2 depending on whether the piston is cylindrical or spherical. The Rankine–Hugoniot (R-H) conditions just behind the shock wave are given by (Wu and Roberts [5])

$$v = \frac{2(1-b)}{(\gamma+1)}\dot{R}, \quad \rho = \frac{(\gamma+1)}{(\gamma-1+2b)}\,\rho_0, \quad p = \frac{2(1-b)\rho_0}{(\gamma+1)}\,(\dot{R})^2 \quad \text{at} \quad r = R(t). \tag{5}$$

The condition of no flow through the piston yields

$$v = -V \qquad \text{at} \quad r = L - Vt. \tag{6}$$

For our convenience we measure the distance $x = L - r$ inward, and let $u = -v$ be the corresponding inward velocity. Making use of the conical nature of the basic flow, we introduce a new variable

$$z = \frac{2}{(\gamma-1)}\left(\frac{x}{Vt} - k\right) \tag{7}$$

that varies from $-2(k-1)/(\gamma-1)$ at the piston to unity at the basic position of the shock wave, where the constant k is to be determined.

Now we nondimensionalize the variables ρ, u, p, b, x, and t by referring lengths to L, speed to V, density to ρ_0, pressure to $\rho_0 V^2$, Van der Waals excluded volume b to $1/\rho_0$, and time to L/V. Then the differential equations (2), (3), and (4) become

$$\left(1 - \left(k + \frac{1}{2}(\gamma-1)z\right)t\right)\left(\rho\frac{\partial u}{\partial z} + \left(u - k - \frac{1}{2}(\gamma-1)z\right)\frac{\partial \rho}{\partial z} + \frac{1}{2}(\gamma-1)t\frac{\partial \rho}{\partial t}\right) = \frac{1}{2}(\gamma-1)mt\rho u, \tag{8}$$

$$\rho\left(u - k - \frac{1}{2}(\gamma-1)z\right)\frac{\partial u}{\partial z} + \frac{1}{2}(\gamma-1)t\rho\frac{\partial u}{\partial t} + \frac{\partial p}{\partial z} = 0, \tag{9}$$

$$\left(u - k - \frac{1}{2}(\gamma-1)z\right)\left(\rho(1-b\rho)\frac{\partial p}{\partial z} - \gamma p\frac{\partial \rho}{\partial z}\right) + \frac{1}{2}(\gamma-1)t\left(\rho(1-b\rho)\frac{\partial p}{\partial t} - \gamma p\frac{\partial \rho}{\partial t}\right) = 0; \tag{10}$$

the boundary conditions (5) and (6) become

$$u = \frac{2(1-b)}{\gamma+1}\dot{X}, \qquad \rho = \frac{(\gamma+1)}{(\gamma-1+2b)}, \qquad p = \frac{2(1-b)}{(\gamma+1)}(\dot{X})^2 \tag{11}$$

at $z = (2/(\gamma-1))\,(X/t-k)$; and

$$u = 1 \qquad \text{at} \quad z = \frac{-2(k-1)}{(\gamma-1)}. \tag{12}$$

Assuming that the solution is analytic in time, we expand the unknown position of the shock wave in a Taylor series as

$$X(t) = \sum_{n=1}^{\infty} X_n t^n, \tag{13}$$

and similarly we expand the flow variables as

$$u = \sum_{n=1}^{\infty} U_n(z) t^{n-1}, \qquad \rho = \sum_{n=1}^{\infty} R_n(z) t^{n-1}, \qquad p = \sum_{n=1}^{\infty} P_n(z) t^{n-1}. \tag{14}$$

Substituting (14) into (8), (9), (10) and using (11), (12), (13), we find, on equating the terms on both the sides which are independent of t,

$$\begin{gathered} U_1 = 1, \qquad R_1 = \frac{(\gamma+1)}{(\gamma-1+2b)}, \qquad P_1 = \frac{(\gamma+1)}{2(1-b)}, \\ X_1 = \frac{(\gamma+1)}{2(1-b)}, \qquad k = \frac{2+b(\gamma-1)}{2(1-b)}. \end{gathered} \tag{15}$$

The coefficients U_2, R_2, and P_2 for the second approximation satisfy the following first-order linear ordinary differential equations:

$$R_1 U_2' - \left(k - 1 + \frac{1}{2}(\gamma-1)z\right) R_2' + \frac{1}{2}(\gamma-1) R_2 = \frac{1}{2}(\gamma-1) m R_1, \tag{16}$$

$$\frac{1}{2}(\gamma-1) R_1 U_2 - \left(k - 1 + \frac{1}{2}(\gamma-1)z\right) R_1 U_2' + P_2' = 0, \tag{17}$$

$$\begin{aligned} &\frac{(\gamma-1)}{2}\Big((1-bR_1)R_1 P_2 - \gamma P_1 R_2\Big) \\ &- \left(k - 1 + \frac{1}{2}(\gamma-1)z\right)\Big((1-bR_1)R_1 P_2' - \gamma P_1 R_2'\Big) = 0, \end{aligned} \tag{18}$$

where the prime denotes the derivative with respect to the variable z and where U_1, R_1, and P_1 are given in (15).

The boundary condition (12) on the piston yields

$$U_n(z) = 0 \qquad \text{at} \quad z = \frac{-2(k-1)}{\gamma-1} \qquad \text{for} \quad n = 2, 3, 4, \ldots . \tag{19}$$

Also the boundary conditions (11) give

$$U_2(1) = \frac{4(1-b)}{(\gamma+1)} X_2, \qquad R_2(1) = 0, \qquad P_2(1) = 4X_2. \tag{20}$$

From (16)–(19) we find that

$$U_2''(z) = R_2''(z) = P_2''(z) = 0, \tag{21}$$

which together with the boundary conditions (19) and (20) yields

$$
\begin{aligned}
U_2 &= \frac{\gamma m}{2(2\gamma-1)}\left(\frac{b(\gamma+1)}{(1-b)}+(\gamma-1)z\right),\\
R_2 &= \frac{(1-b)(\gamma-1)^2\ (\gamma+1)m}{(\gamma-1+2b)^2\ (2\gamma-1)}(1-z),\\
P_2 &= \frac{\gamma(\gamma+1)(\gamma-1+2b)m}{2(1-b)^2\ (2\gamma-1)},\\
X_2 &= \frac{\gamma(\gamma+1)(\gamma-1+2b)m}{8(1-b)^2\ (2\gamma-1)}.
\end{aligned}
\tag{22}
$$

The forms of U_2, R_2, and P_2 suggest that in higher approximations the coefficients U_n, R_n, and P_n are polynomials in z of degree $n-1$, of the following form:

$$
U_n(z)=\sum_{j=1}^{n} U_{nj}z^{j-1},\quad R_n(z)=\sum_{j=1}^{n} R_{nj}z^{j-1},\quad P_n(z)=\sum_{j=1}^{n} P_{nj}z^{j-1}. \tag{23}
$$

Substituting these values into the differential equations (8)–(10) and the shock conditions (11), and equating the like powers of z as well as t, we have for the nth approximation a system of $3n+1$ linear algebraic equations in $3n+1$ coefficients U_{nj}, R_{nj}, P_{nj} $(j=1,\ 2,\ldots,n)$ and X_n; solving the system for the third approximation we obtain the position of the shock wave

$$
\begin{aligned}
X(t) = t\ &(\gamma+1)/[2(1-b)] + t^2 m\gamma(\gamma+1)(\gamma-1+2b)/[8(1-b)^2(2\gamma-1)]\\
&+ t^3 m(\gamma+1)(\gamma-1+2b)[1+\gamma^3(4-21m)-\gamma m+\gamma^2(13m-9)\\
&\qquad +\gamma^4(12+13m)+b(6\gamma-20\gamma^2 m-2(m+1)+\gamma^3(26m-8))]\\
&/[48(1-b)^3(2\gamma-1)^2(7\gamma-5)]+\cdots\ .
\end{aligned}
\tag{24}
$$

The above result fully recovers the ideal gas ($b=0$) case discussed by Van Dyke and Guttmann [3].

3. Computation of coefficients X_n, U_n, R_n, and P_n. We have written a program using MATHEMATICA to find $X_n,\ U_n,\ R_n$, and P_n for $n \geq 3$. Table 1 consists of coefficients X_n, where n is between 1 and 44. We have performed the computations for cylindrical ($m=1$) and spherical ($m=2$) pistons with adiabatic coefficient $\gamma = 6/5,\ 7/5$, and $5/3$ and with Van der Waals excluded volume $b =$ 0.00006, 0.0004, 0.003, 0.01, 0.05, 0.1, 0.2, and 0.25. Although we have shown the coefficients rounded up to 15 significant digits, we have carried out all computations using 32 significant digits. We provide the graphs for the computed values of the flow variables $\rho,\ u$, and p, starting from the piston and extending to the shock before its collapse and almost up to the instant of collapse; see the figures in section 6.

4. Determination of the radius of convergence. We observe that all the coefficients found in Table 1 are positive, indicating that the nearest singularity of the shock position $X(t)$ is positive. We shall investigate whether this is the Guderley singularity, corresponding to collapse of the shock onto the axis/center. There is a steady increase in the coefficients, which indicates that the radius of convergence is less than unity. We obtain this radius of convergence assuming that the nearest singularity has the form

$$
R(t)=1-X(t)=1-\sum X_n t^n \sim A_1\left(1-\frac{t}{t_c}\right)^{\alpha_1} \quad \text{as} \quad t\to t_c, \tag{25}
$$

where α_1 and A_1 are the leading exponent and amplitude, respectively.

Hence,

$$\frac{X_n}{X_{n-1}} \sim \frac{1}{t_c}\left(1 - \frac{1+\alpha_1}{n}\right) \quad \text{as} \quad n \to \infty. \tag{26}$$

We assume that, when n is large, the ratio X_n/X_{n-1} approximates the value of $1/t_c$. We construct a sequence X_n/X_{n-1} $(n = 35, 36, \ldots, 44)$ and thereafter refine this estimate of $1/t_c$ by forming a Neville table (Gaunt and Guttmann [8]). Neville's algorithm is a recursive procedure in which the given set of data points are interpolated by a Lagrange polynomial. In our case we fit an rth degree polynomial in $1/n$ to $r+1$

points $e_n^0, e_{n-1}^0, \ldots, e_{n-r}^0$. Given a sequence e_n^0, we can construct a triangular array of elements e_n^0, where n labels the rows and $r = 0, 1, 2, 3, \ldots, n$ the columns. The elements of the rth column are generated from the $(r-1)$th column by using the formula [8]

$$e_n^r = \frac{n e_n^{r-1} - (n-r) e_{n-1}^{r-1}}{r}, \tag{27}$$

where e_n^r is the intercept on the $1/n = 0$ axis of the rth degree curve. Hence, $r = 1$ corresponds to the linear intercepts, $r = 2$ to the quadratic intercepts, $r = 3$ to the cubic intercepts, and so on. The Neville table so formed provides a refined estimate for e_n^0. For constructing a Neville table for $1/t_c$, we compute the sequence X_n/X_{n-1} ($n = 35, 36, \ldots, 44$) and take this as the initial sequence e_n^0; this gives the first column of Table 2. Then we use (27) to compute the sequence e_n^1 ($n = 35, 36, \ldots, 44$), and this forms the second column of Table 2. Again using the sequence e_n^1, we construct the sequence e_n^2 ($n = 35, 36, \ldots, 44$), and this forms the third column of Table 2. All other columns of the Neville table are formed similarly, which show that the sequences $e_n^0, e_n^1, e_n^2, \ldots$ approach a limiting value of $1/t_c$. From Tables 2, 3, and 4, the values of $1/tc$, α_1, and t_c for a spherical piston with $\gamma = 7/5$ and $b = 0.05$ are 1.79783, 0.66069, and 0.556226, respectively, and the corresponding values for an ideal gas ($b = 0$) are 1.609021, 0.7171, and 0.621496, respectively.

To verify that the nearest singularity of the shock position $X(t)$ corresponds to collapse of the shock wave onto the axis, we calculate the time t_0 for $X(t)$ to reach unity. We construct a Neville table, Table 4, using these values of t_0 as the initial sequence e_n^0. We find from Table 4 that $t_c = 0.556226$. Therefore the values of t_c obtained from Tables 2 and 4 are almost the same. The time of collapse of the shock

wave for different values of γ, b, and m are listed in Table 5, showing thereby that for given values of γ and m, increase in b causes t_c to decrease.

5. Guderley's local solution. Ours is a global solution that is valid throughout the flow field almost up to the instant of collapse. We now extract Guderley's local singular behavior, which is valid in the neighborhood of collapse. According to Guderley's conjecture, the radius of the shock in the vicinity of collapse is prescribed by an expansion:

$$R(t) = 1 - X(t) \sim \sum_{j=1} A_j \left(1 - \frac{t}{t_c}\right)^{\alpha_j}. \tag{28}$$

Guderley [1] computed only the first exponent α_1; the other exponents α_j and amplitudes A_j were unknown. Van Dyke and Guttmann [3] calculated all the real exponents and the corresponding amplitudes for an ideal gas using the method given by Baker and Hunter [9].

Using our estimates for t_c, given in Table 5, we rewrite the series (13) for $X(t)$ in powers of the new variable τ defined by $t = t_c[1 - \exp(-\tau)]$, then multiply the nth term in (28) by $n!$, and then finally sum over n to obtain the series for the auxiliary function

$$\mathcal{R}(\tau) = \sum_{j=1} \frac{A_j}{(1 + \alpha_j \tau)}, \tag{29}$$

which is meromorphic and has simple poles at $\tau = -1/\alpha_j$ with corresponding residues A_j/α_j. Quantities α_j and A_j are evaluated by forming Pade approximants (Baker [10]) to $\mathcal{R}(\tau)$. The $[(N-1)/N]$ Pade approximant is a rational function approximation to a Taylor's series expansion. The idea of Pade approximants is to replace a power series $S(w)$ by a rational function $P_{N-1}(w)/Q_N(w)$, where $P_{N-1}(w)$ and $Q_N(w)$ are polynomials of degree $N-1$ and N, respectively. The coefficients of $P_{N-1}(w)$ and $Q_N(w)$ are determined by equating the like powers of w in the equation

$$S(w) - \frac{P_{N-1}(w)}{Q_N(w)} = O(w^{2N}),$$

where N can be varied up to 22 at the most, since we have a series (13) with 44 terms; the entire computational work has been carried out using MATHEMATICA. The exponents (α_j) and the amplitudes (A_j) are listed in the Table 6.

6. Results and conclusion. We have found a global solution to the imploding shock problem in a Van der Waals gas using a technique proposed by Van Dyke and Guttmann [3]. From this global solution the Guderley's local solution is extracted at

the instant of collapse. Guderley's local solution provides us only the first dominant similarity exponent, but we have found, through this technique, the other three less dominant similarity exponents and the corresponding amplitudes. These similarity exponents and the corresponding amplitudes are listed in Table 6. The values of the leading exponents α_1 for cylindrical and spherical symmetry for $\gamma = 6/5, 7/5$, and $5/3$, and for different values of b (0.00006, 0.0004, 0.003, 0.01, 0.05, 0.1, 0.2, and 0.25) are shown in Table 7; these values compare well with the numerical results obtained by Wu and Roberts [5] and Guderley [1]. We observe that the present method shows no evidence of another branch of solutions that arises in the work of Wu and Roberts. It may be recalled that Wu and Roberts [5] have reported that they were unable to determine the similarity exponents for $\gamma = 6/5$ and the values of b lying in the range $[0.0001, 0.05)$; indeed, we have successfully obtained the exponents in this range and compared them with the corresponding exponents found by Guderley's method in Table 7. Wu and Roberts also reported that for $\gamma = 5/3$ there exists one branch of solution for b lying in the range $[0, 0.05]$ and another branch of solution for b lying in the range $[0.005, 0.035]$; however, the present approach reveals only one solution for

6 that increase in either of the parameters b or m, or decrease in γ, causes the leading similarity exponent α_1 to decrease and consequently the shock acceleration to increase as it approaches the center/axis. We also notice that the shock is continuously accelerated, since α_1 is always less than one; in fact, the shock speed becomes unbounded as $t \to t_c$, but less rapidly than $(t - t_c)^{-1}$. Figures 2(a)–2(d) and 3(a)–3(d) show that the velocity decreases monotonically behind the shock as we move towards the piston, whereas the density increases in the region behind the shock; this is because of geometrical convergence or area contraction of the shock, which causes velocity to decrease and density to increase. We also observe from these figures that an increase in b causes the particle velocity to increase and density to decrease. Figures 4(a)–4(d) indicate that the gas pressure remains constant in most of the region except in the vicinity of the front, where it exhibits a maximum; this is due to the fact that the gas, which is highly compressed by the shock, gets cooled down in the region behind the shock. It is also observed that an increase in b causes the gas pressure to increase in the region behind the shock. Table 5 shows that, for given values of γ and m, an increase in b causes t_c to decrease; the results are depicted in Figures 5(a)–5(d), which show that an increase in b causes the time of shock collapse to decrease, i.e., the shock reaches the center/axis much faster with the increase of Van der Waals excluded volume b.

ON THE SOLUTION OF LONG'S EQUATION WITH SHEAR*

MAYER HUMI†

Abstract. Long's equation describes two dimensional stratified flow over terrain. Its numerical solutions under various approximations were investigated by many authors under the assumption that the base flow field is without shear. Special attention was paid to the properties of the gravity waves that are predicted to be generated as a result. In this paper we address, analytically, the nature and properties of these solutions when shear is present and derive some constraints on the possible generation of gravity waves under these circumstances.

Key words. gravity waves, Long's equation, shear

1. Introduction. Long's equation [1, 2, 3, 4] models the flow of stratified incompressible fluid (in the Boussinesq approximation) in two dimensions over terrain. When the base state of the flow (that is, the unperturbed flow field far upstream) is without shear, the numerical solutions (in the form of steady lee waves) of this equation in various settings and approximations were studied by many authors [5, 6, 7, 8, 9, 10, 11, 12, 13]. The most common approximation in these studies was to set Brunt–Väisälä frequency to a constant or a step function over the computational domain. Moreover, the values of the parameters β and μ which appear in this equation were set to zero. In this (singular) limit the nonlinear terms and one of the leading second order derivatives in the equation drop out and the equation reduces to that of a linear harmonic oscillator over a two dimensional domain. Careful studies [8] showed that these approximations are justified unless wave breaking is present in the solution [9].

Long's equation also provides the theoretical framework for the analysis of experimental data [15, 16, 17] under the assumption of shearless base flow. (An assumption which, in general, is not supported by the data.) An extensive list of references appears in [18, 19, 20].

An analytic approach to the study of this equation and its solutions was initiated recently by the author [14]. We showed that for a base flow without shear and under rather mild restrictions the nonlinear terms in the equation can be simplified. We also identified the "slow variable" that controls the nonlinear oscillations in this equation and, using phase averaging approximation, derived a formula for the attenuation of the stream function perturbation with height. This result is generically related to the presence of the nonlinear terms in Long's equation.

The objective of this paper is to study the nature of the solutions to Long's equation when shear is present in the base flow and Brunt–Väisälä frequency is a continuous function of height. Using conditions which depend solely on the base flow and Brunt–Väisälä frequency we characterize the qualitative nature of the perturbations from the base flow and how their amplitude varies with height. These results

†Department of Mathematical Sciences, Worcester Polytechnic Institute, 100 Institute Road, Worcester, MA 01609 (mhumi@wpi.edu).

are independent of the actual detailed description of the terrain that caused these perturbations. Furthermore we derive conditions under which these perturbations are not oscillatory; i.e., no gravity waves are generated by the flow. To the best of our knowledge this issue was never considered in the literature before (in the context of Long's equation).

The plan of the paper is as follows: In section 2 we present a short review of the derivation of Long's equation and the solution of its linearized version. In section 3 we derive constraints on the solutions of this equation in a general setting and in particular in the presence of shear. In section 4 solutions to this equation with different shear profiles are studied explicitly. In section 5 we carry out simulations of Long's equation for shearless and shear base flows. We end in section 6 with summary and conclusions.

2. Long's equation: A short review. In two dimensions (x, z) the flow of a steady inviscid and incompressible stratified fluid (in the Boussinesq approximation) is modeled by the following equations:

$$u_x + w_z = 0, \tag{2.1}$$

$$u\rho_x + w\rho_z = 0, \tag{2.2}$$

$$\rho(uu_x + wu_z) = -p_x, \tag{2.3}$$

$$\rho(uw_x + ww_z) = -p_z - \rho g, \tag{2.4}$$

where subscripts indicate differentiation with respect to the indicated variable, $\mathbf{u} = (u, w)$ is the fluid velocity, ρ is its density, p is the pressure, and g is the acceleration of gravity.

We can nondimensionalize these equations by introducing

$$\bar{x} = \frac{x}{L}, \quad \bar{z} = \frac{N_0}{U_0} z, \quad \bar{u} = \frac{u}{U_0}, \quad \bar{w} = \frac{LN_0}{U_0^2} w,$$
$$\bar{\rho} = \frac{\rho}{\rho_0}, \quad \bar{p} = \frac{N_0}{gU_0\rho_0} p, \tag{2.5}$$

where L represents a characteristic length and U_0, ρ_0 represent, respectively, the free stream velocity and density. N_0 is the characteristic Brunt–Väisälä frequency

$$N_0^2 = -\frac{g}{\rho_0} \frac{d\rho_0}{dz}. \tag{2.6}$$

In these new variables, (2.1)–(2.4) take the following form (for brevity we drop the bars):

$$u_x + w_z = 0, \tag{2.7}$$

$$u\rho_x + w\rho_z = 0, \tag{2.8}$$

$$\beta\rho(uu_x + wu_z) = -p_z, \tag{2.9}$$

$$\beta\rho(uw_x + ww_z) = -\mu^{-2}(p_z + \rho), \tag{2.10}$$

where

$$\beta = \frac{N_0 U_0}{g}, \tag{2.11}$$

$$\mu = \frac{U_0}{N_0 L}. \tag{2.12}$$

β is the Boussinesq parameter [13] which controls stratification effects (assuming $U_0 \neq 0$), and μ is the long wave parameter which controls dispersive effects (or the deviation from the hydrostatic approximation). In the limit $\mu = 0$ the hydrostatic approximation is fully satisfied [20].

In view of (2.7) we can introduce a stream function ψ so that

$$u = \psi_z, \quad w = -\psi_x. \tag{2.13}$$

From (2.8) and (2.13) we infer that $\rho = \rho(\psi)$ and (after some algebra) derive the following equation for ψ [13]:

$$\psi_{zz} + \mu^2 \psi_{xx} - N^2(\psi)\left[z + \frac{\beta}{2}(\psi_z^2 + \mu^2 \psi_x^2)\right] = G(\psi), \tag{2.14}$$

where

$$N^2(\psi) = -\frac{\rho_\psi}{\beta \rho} \tag{2.15}$$

is the nondimensional Brunt–Väisälä frequency. $G(\psi)$ is some unknown function which is determined from the base flow, which henceforth we assume to be a function of z only. To carry out this determination we consider (2.14) at $x = -\infty$ and express the left-hand side of this equation in terms of ψ only (assuming that disturbances do not propagate far upstream [19]). Equation (2.14) is referred to as Long's equation.

For example, if we let

$$\psi(-\infty, z) = z, \tag{2.16}$$

i.e., consider a shearless base flow with $u(-\infty, z) = 1$, then

$$G(\psi) = -N^2(\psi)\left(\psi + \frac{\beta}{2}\right) \tag{2.17}$$

and (2.14) becomes

$$\psi_{zz} + \mu^2 \psi_{xx} - N^2(\psi)\left[z - \psi + \frac{\beta}{2}(\psi_z^2 + \mu^2 \psi_x^2 - 1)\right] = 0. \tag{2.18}$$

However, it is evident that different profiles for the base flow at $x = -\infty$ will lead to different forms of $G(\psi)$ (for examples, see section 4).

For a general base flow in an unbounded domain over topography with shape $f(x)$ and maximum height H the following boundary conditions are imposed on ψ:

$$\psi(-\infty, z) = \psi^0(z), \tag{2.19}$$

$$\psi(x, \epsilon f(x)) = \text{constant}, \quad \epsilon = \frac{H N_0}{U_0}, \tag{2.20}$$

where the constant in (2.20) is (usually) set to zero. As to the boundary condition on $\psi(\infty, z)$ we observe that Long's equation contains no dissipation terms and therefore only radiation boundary conditions can be imposed in this limit. Similarly at $z = \infty$ it is customary to impose (following [7]) radiation boundary conditions. For the perturbation from the shearless base flow

$$\phi = \psi - z, \tag{2.21}$$

(2.18) becomes

$$\phi_{zz} - \alpha^2\phi_z^2 + \mu^2(\phi_{xx} - \alpha^2\phi_x^2) - N^2(\phi)(\beta\phi_z - \phi) = 0, \tag{2.22}$$

where

$$\alpha^2 = \frac{N^2(\psi)\beta}{2}. \tag{2.23}$$

Since ψ is set to zero at the bottom topography, the corresponding (approximate) boundary condition on ϕ for small ϵ will be

$$\phi(x, 0) = -\epsilon f(x). \tag{2.24}$$

Thus for small amplitude topography the boundary condition can be applied at $z = 0$.

In the limits $\beta = 0$, $\mu = 0$ and when $N(\psi)$ is a constant whose value over the domain is N, (2.22) reduces to a linear equation

$$\phi_{zz} + N^2\phi = 0. \tag{2.25}$$

We observe that the limit $\beta = 0$ can be obtained by letting either $U_0 \to 0$ or $N_0 \to 0$. In the following we assume that this limit is obtained as $U_0 \to 0$ (so that stratification persists in this limit). The general solution of (2.25) is

$$\phi(x, z) = p(x)\cos(Nz) + q(x)\sin(Nz), \tag{2.26}$$

where the functions $p(x), q(x)$ have to be chosen so that the boundary conditions derived from (2.19), (2.20) and the radiation boundary conditions are satisfied. These boundary conditions lead in general to an integral equation for $p(x)$ and $q(x)$:

$$q(x)\cos(\epsilon N f(x)) + H[q(x)]\sin(\epsilon N f(x)) = -\epsilon f(x), \tag{2.27}$$

where $H[q(x)]$ is the Hilbert transform of q(x). This equation has to be solved numerically [6, 7].

It is clear from the form of the general solution given by (2.26) that it represents a wave in the z-direction, and the properties of this wave (under varied physical conditions) were investigated by the authors mentioned in section 1. It should be observed, however, that (2.25) is a "singular limit" of Long's equation, as one of the leading second order derivatives drops when $\mu = 0$ and the nonlinear terms drop when $\beta = 0$. This approximation and its limitations were considered numerically and analytically [6, 7, 14] and were found to be justified under the assumption that the base flow is shearless. It is used in the actual analysis of atmospheric data [16, 17, 18].

3. Properties of solutions to Long's equation with shear. In this section we address the nature and properties of the perturbation from the base flow when shear is present. To simplify our notation and treatment we set $\mu = 1$ since we can always scale x as $\bar{x} = x/\mu$ (and drop the bars on $\bar{x}$). We also assume that

$$\lim_{x\to-\infty} \psi(x,z) = \psi^0(z). \tag{3.1}$$

Long's equation with shear is then

$$(\psi_{zz} - \alpha^2\psi_z^2) + (\psi_{xx} - \alpha^2\psi_x^2) - N^2(\psi)z = G(\psi), \tag{3.2}$$

and in the limit $x \to -\infty$, $G(\psi)$ must satisfy

$$G(\psi^0) = \psi^0_{zz} - N^2(\psi^0)\left[z + \frac{\beta}{2}(\psi^0_z)^2\right]. \tag{3.3}$$

To treat the perturbation from the base state we write

$$\psi(x,z) = \psi^0(z) + \phi(x,z). \tag{3.4}$$

Substituting this in (3.2) and linearizing using (3.3) we obtain

$$\nabla^2\phi - 2\alpha^2\psi^0_z\phi_z - (N^2)'(\psi^0)z\phi - G'(\psi^0)\phi = 0, \tag{3.5}$$

where primes denote differentiation with respect to ψ.

Since ψ^0 is a function of z only, this equation is separable and we can deduce the properties of its solution by applying separation of variables. Introducing

$$\phi(x,z) = \chi(x)\eta(z), \tag{3.6}$$

we obtain

$$\chi(x)_{xx} + \lambda\chi(x) = 0 \tag{3.7}$$

and

$$\eta(z)_{zz} - 2\alpha^2\psi^0_z\eta_z - [\lambda + (N^2)'(\psi^0)z + G'(\psi^0)]\eta = 0, \tag{3.8}$$

where λ is the separation of variables constant. Equation (3.8) can be rewritten as

$$\frac{d}{dz}\left(e^{-2\alpha^2\psi^0}\frac{d}{dz}\eta(z)\right) - H(z)\eta = 0, \tag{3.9}$$

where

$$H(z) = e^{-2\alpha^2\psi^0}[\lambda + (N^2)'(\psi^0)z + G'(\psi^0)]. \tag{3.10}$$

Equations (3.9)–(3.10) demonstrate that the properties of the perturbation as a function z depend only on λ (i.e., the wave number in the x direction) and the initial state of the flow.

To obtain further information about the properties of η we observe that $e^{-2\alpha^2\psi^0} \geq 0$ and it is possible to apply to (3.9) the comparison theorem of Strum and Picone [21]. A direct application of these theorems leads to the following result.

Assume that on the interval $[a, z]$

$$0 < m \leq e^{-2\alpha^2\psi^0} \leq M, \tag{3.11}$$

$$k \leq H(z) \leq K. \tag{3.12}$$

Then the following hold:

1. If $0 < k$, the solution of (3.9) is not oscillatory (no waves on the interval [a,z]).
2. If $k < 0$ and

$$\frac{-\pi^2}{(z-a)^2} < \frac{k}{m}, \tag{3.13}$$

then the solution of (3.9) is not oscillatory (no waves).

3. A sufficient condition for (3.9) to have an oscillatory solution with n zeros is that

$$\frac{K}{M} \leq \frac{-n^2\pi^2}{(z-a)^2}. \tag{3.14}$$

That is, the wavenumber of the wave will increase as K becomes more negative. We observe also that the estimate for k depends on the value of λ. As $0 < \lambda$ increases, this estimate for the lower bound of $H(z)$ will increase and when k satisfies the inequality (3.13), the solution for η will become nonoscillatory (that is, the wave is trapped). This demonstrates the "coupling" between the horizontal wavenumber of oscillations and the nature of the solution in the vertical direction.

To obtain further insight into the nature of the solution for $\eta(z)$ we multiply (3.8) by η and integrate over [0,z]. Using integration by parts we obtain

$$[\eta\eta' - \alpha^2\psi_z^0\eta^2]\Big|_0^z = \int_0^z \{(\eta')^2 + [\alpha^2\psi_{zz}^0 + F(z)]\eta^2\}dz, \tag{3.15}$$

where

$$F(z) = \frac{1}{2}[\lambda + (N^2)'(\psi^0)z + G'(\psi^0)]. \tag{3.16}$$

Assuming that $\eta(0) = 0$ (i.e., the amplitude of the perturbation at ground level is 0), (3.15) can be written as

$$\frac{1}{2}\frac{d\eta^2}{dz}(z) = \alpha^2\psi_z^0(z)\eta^2(z) + \int_0^z (\eta')^2 dz + \int_0^z [\alpha^2\psi_{zz}^0 + F(z)]\eta^2 dz. \tag{3.17}$$

Hence we conclude that the amplitude of the perturbation will increase with height if

$$\psi_z^0(z) > 0, \;\; \alpha^2\psi_{zz}^0 + F(z) > 0 \tag{3.18}$$

on the interval $[0, z]$.

To proceed we now invoke the (modified) Poincaré inequality on the interval $[0, z]$. This inequality states that if η is smooth enough and $\eta(0) = 0$, then

$$\int_0^z (\eta')^2(s)ds \geq \frac{\pi^2}{4z^2}\int_0^z \eta^2(s)ds. \tag{3.19}$$

(For the proof of this inequality see the appendix.)

To apply this inequality we rewrite (3.15) (assuming $\eta(0) = 0$) as

$$\frac{1}{2}\frac{d\eta^2}{dz}(z) \le \alpha^2\psi_z^0(z)\eta^2(z) + \int_0^z (\eta')^2 dz + max[\alpha^2\psi_{zz}^0 + F(z)]\int_0^z \eta^2 dz. \tag{3.20}$$

Using the Poincaré inequality to estimate the integral of η^2 yields

$$\frac{1}{2}\frac{d\eta^2}{dz}(z) \le \alpha^2\psi_z^0(z)\eta^2(z) + \left\{1 + \frac{4z^2}{\pi^2}max[\alpha^2\psi_{zz}^0 + F(z)]\right\}\int_0^{z_0} (\eta')^2 dz. \tag{3.21}$$

Hence if

$$\psi_z^0 < 0, \ \left\{1 + \frac{4z^2}{\pi^2}max[\alpha^2\psi_{zz}^0 + F(z)]\right\} < 0 \tag{3.22}$$

on the interval $[0, z]$, then the perturbation η will decay with height.

We observe that the conditions (3.18) and (3.22) depend only on the properties of the base flow and the variation of N^2 with height.

3.1. Some special cases.

1. $\psi^0(z) = z$ and $N =$ constant.

This is essentially the only case that has been treated in the literature on Long's equation. It represents a shearless base state with constant Brunt–Väisälä frequency.

In this case $G(\psi)$ is given by (2.17), and (3.8) reduces to

$$\eta_{zz} - 2\alpha^2\eta_z + (N^2 - \lambda)\eta = 0, \tag{3.23}$$

whose solution is [14]

$$\eta = Ae^{\alpha^2 z}\cos(mz + \gamma), \tag{3.24}$$

where $m = \sqrt{(N^2 - \lambda)}$ and γ is a constant.

2. $\alpha = 0$.

When α is very small we can neglect the second term in (3.8) which reduces then to

$$\eta_{zz} = 2F(z)\eta. \tag{3.25}$$

Introducing

$$v = \frac{\eta_z}{\eta} = \frac{d\ln|\eta|}{dz}, \tag{3.26}$$

this equation becomes

$$v_z + v^2 = 2F(z). \tag{3.27}$$

Hence $v_z = 2F(z) - v^2 \le 2F(z)$. We can conclude therefore that if $F(z) < 0$, then v and hence $\frac{d\ln|\eta|}{dz}$ are decreasing with height; i.e., the perturbation is being dissipated. On the other hand, if $F(z) > 0$, then v is increasing when $2F(z) - v^2$ is positive and decreasing when this quantity is negative, and therefore there will be oscillations in the amplitude of η.

4. Some examples with shear. In this section we consider some examples whose base flow is not shearless and derive explicitly the corresponding equations for the perturbations. We use then analytic methods to explore the properties of the solutions to these equations.

4.1. $\psi^0 = z^2$, N = constant. For this base flow $u = z$; that is, u increases linearly with height. Using (3.3) we find that

$$G(\psi) = 2 - N^2(\psi)[\psi^{1/2} + 2\beta\psi] \tag{4.1}$$

and Long's equation (3.2) for ψ (with $\mu = 1$) becomes

$$(\psi_{zz} - \alpha^2\psi_z^2) + (\psi_{xx} - \alpha^2\psi_x^2) - N^2(\psi)z = 2 - N^2(\psi)[\psi^{1/2} + 2\beta\psi]. \tag{4.2}$$

To derive an equation for a perturbation from the base flow, we set $\psi = z^2 + \phi(x, z)$. Substituting this in (4.2) and linearizing, we obtain

$$\nabla^2\phi - 4\alpha^2 z\frac{\partial\phi}{\partial z} + \left(\frac{N^2}{2z} + 4\alpha^2\right)\phi = 0. \tag{4.3}$$

This equation is separable, and we can consider three types of solutions:
1. $\phi(x, z) = e^{-kx}\eta(z)$ with $k > 0$.
2. $\phi(x, z) = \sin(kx)\eta(z)$ with $k > 0$.
3. $\phi(x, z) = \eta(z)$ (that is, a vertical perturbation, $k = 0$).

In all three cases we obtain for $\eta(z)$ the following equation:

$$\eta'' - 4\alpha^2 z\eta' + \left(4\alpha^2 \pm k^2 + \frac{N^2}{2z}\right)\eta = 0. \tag{4.4}$$

The solution of this equation is given by Heun biconfluent functions [22]. To explore analytically when the solution $\eta(z)$ is oscillatory, we rewrite (4.4) in the form

$$[e^{-2\alpha^2 z^2}\eta']' + \left(4\alpha^2 \pm k^2 + \frac{N^2}{2z}\right)e^{-2\alpha^2 z^2}\eta = 0. \tag{4.5}$$

This equation has the same form as (3.9), and therefore we can apply the oscillation theorems of Strum and Picone. In fact, since $0 < e^{-2\alpha^2 z^2} \leq 1$, oscillations can occur only if $(4\alpha^2 \pm k^2 + \frac{N^2}{2z})$ is positive enough. (See (3.11), (3.12), and (3.14) and note that there is a minus sign in front of $H(z)$ in (3.9).) This can happen for proper values of N^2 and α^2 in cases 1 and 3 above. It can also happen when k is small in the second case, but $4\alpha^2 + \frac{N^2}{2z}$ is large enough. Furthermore, one can show numerically that in all cases the amplitude of the perturbation grows with height. Thus the perturbation will always feed on the energy of the base flow. (However, it should be kept in mind that the amplitude of the perturbation cannot grow indefinitely. Once it violates the assumptions made to derive Long's equation and the approximations that led to (4.4), this solution becomes invalid.)

4.2. $G(\psi) = 0$, N = constant. In this case, instead of choosing the base flow and deriving $G(\psi)$ using (3.3), we make the ansatz that $G(\psi) = 0$ and compute the corresponding base flow. With this assumption (3.3) becomes

$$\psi_{zz}^0 - N^2\left[z + \frac{\beta}{2}(\psi_z^0)^2\right] = 0. \tag{4.6}$$

Introducing $y = \psi_z^0$, we obtain a Ricatti equation for $y(z)$:

$$y' - \alpha^2 y^2 - N^2 z = 0. \tag{4.7}$$

This equation can be linearized by the transformation

$$y(z) = -\frac{1}{\alpha^2}\frac{v(z)'}{v(z)}, \tag{4.8}$$

which leads to

$$v(z)'' + \alpha^2 N^2 z v(z) = 0. \tag{4.9}$$

This can be identified as a Bessel equation whose solution is

$$v(z) = C\sqrt{z} J_{1/3}\left(\frac{2}{3} N\alpha z^{3/2}\right), \tag{4.10}$$

and hence

$$\psi^0(z) = -\frac{1}{\alpha^2}\ln(|v(z)|). \tag{4.11}$$

The resulting Long's equation for this base flow is (3.2) with $G(\psi) = 0$. This equation can be linearized by the transformation $\xi = e^{-\alpha^2\psi}$, and we obtain

$$\nabla^2\xi + N^2\alpha^2 z\xi = 0. \tag{4.12}$$

This equation (for the full flow) is separable, and the nature of the solution will depend on the separation constant. We distinguish three cases:

1. $\xi(x, z) = \xi(z)$.
   In this case ξ satisfies (4.9) and hence ξ is given by (4.10).
2. $\xi(x, z) = e^{-nx}\eta(z)$, $n > 0$.
   This lead to

$$\eta'' + [N^2\alpha^2 z + n^2]\eta = 0. \tag{4.13}$$

3. $\xi(x, z) = \sin(nx)\eta(z)$, $n > 0$.
   The equation for η becomes

$$\eta'' + [N^2\alpha^2 z - n^2]\eta = 0. \tag{4.14}$$

The solution to equations (4.13), (4.14) is given in terms of Airy functions. However, the qualitative nature of the solution of these equations can be deduced from the comparison theorems of Strum and Picone [21]. (In this case the function $e^{-2\alpha^2\psi^0}$ in (3.9) is replaced by 1, and hence $m = M = 1$ in (3.11).) Thus for the second case we have $[N^2\alpha^2 z + n^2] > 0$ and therefore the solution for η will be oscillatory. Moreover, the wavenumber of the oscillations will increase with height. On the other hand, for the third case the solution will be nonoscillatory for small z but may become oscillatory with height, viz. when $[N^2\alpha^2 z - n^2]$ becomes positive.

4.3. $\psi^0 = -\cos(az)$, N = constant. For this base flow $u = a\sin(az)$; that is, u oscillates with the height.

In this case we obtain for $G(\psi)$ the expression

$$G(\psi) = -a^2\psi - N^2\left[\frac{\pi - \arccos(\psi)}{a} + \frac{\beta a^2}{2}(1-\psi^2)\right]. \tag{4.15}$$

The linearized equation for the perturbation $\phi(x,z)$ from the base flow is

$$\nabla^2\phi - 2\alpha^2 a\sin(az)\frac{\partial\phi}{\partial z} + \left[a^2 + 2\alpha^2 a^2\cos(az) - \frac{N^2}{a\sin(az)}\right]\phi = 0. \tag{4.16}$$

For a solution of the form $\phi(x,z) = e^{-kx}\eta(z)$ or $\phi(x,z) = \sin(kx)\eta(z)$ this yields

$$\left[e^{2\alpha^2 cos(az)}\eta'\right]' + e^{2\alpha^2 cos(az)}\left[a^2 \pm k^2 + 2\alpha^2 a^2\cos(az) - \frac{N^2}{a\sin(az)}\right]\eta = 0. \tag{4.17}$$

Oscillations in the solution of this equation will occur whenever the expression in the square brackets of the last term is positive. Since $\sin(az)$ takes both positive and negative values and $\frac{N^2}{asin(az)}$ is dominant when $az \approx 0$ or $az \approx \pi$, the solution will exhibit different qualitative behavior in different regions (i.e., oscillatory in some and nonoscillatory in others).

5. Numerical simulations for shear flow. In previous sections we discussed from an analytical point of view the impact of shear on the generation of gravity waves using first order perturbation expansion. To elicit more insight on this issue we compare numerically in this section the solutions of Long's equation with and without shear over the same topography and with the same values of the geophysical parameters (viz. μ, β, and N^2). Without loss of generality we set $\mu = 1$ in the following (see remark at the beginning of section 3).

The equation for a perturbation from a shearless base flow (without approximations) is given by (2.22). Similarly the exact equation for the perturbation from pure shear flow (see section 4.1) is given by

$$\nabla^2\phi - \alpha^2\left[4z\phi_z + \phi_z^2 + \phi_x^2 - 4\,\phi\right] + N^2[\sqrt{z^2+\phi} - z] = 0. \tag{5.1}$$

To simplify (2.22) and (5.1) we introduce

$$\eta = e^{-\alpha^2\phi}, \quad \alpha \neq 0, \tag{5.2}$$

and observe that

$$-\frac{1}{\alpha^2\eta}\eta_{zz} = \phi_{zz} - \alpha^2\phi_z^2. \tag{5.3}$$

Substituting this result for the second order derivatives of x and z, (2.22) and (5.1) transform, respectively, to

$$\nabla^2\eta - 2\alpha^2\eta_z + N^2\eta\ln\eta = 0, \tag{5.4}$$

$$\nabla^2\eta + \alpha^2\left\{-4z\eta_z + \eta\left[4\ln(\eta) + N^2\left(z - \sqrt{\frac{\alpha^2 z^2 - \ln(\eta)}{\alpha^2}}\right)\right]\right\} = 0. \tag{5.5}$$

These equations are linear in the derivatives of η and nonlinear only in terms which contain η itself. This simplifies the numerical algorithm for their solution.

To solve (5.4), (5.5) we implement Newton's iteration scheme. To this end we define $F(\eta)$ as the left-hand side (of each) of these equations and take its Frechet derivative, i.e., compute

$$F(\eta_0 + \delta) \cong F(\eta_0) + L(\eta_0)\delta + O(\delta^2), \tag{5.6}$$

where $L(\eta_0)$ is a linear operator. A short computation using (5.4) yields

$$L_1(\eta_0) = \nabla^2 + N^2 \left[(1 + \ln \eta_0) - \beta \frac{\partial}{\partial z}\right]. \tag{5.7}$$

Similarly, for (5.5) we obtain

(5.8)

$$L_2(\eta_0) = \nabla^2 + \alpha^2 \left[-4z\frac{\partial}{\partial z} + 4(1 + \ln \eta_0) + N^2 \left(z - \sqrt{z^2 - \frac{\ln(\eta_0)}{\alpha^2}} + \frac{1}{2\alpha^2\sqrt{z^2 - \frac{ln(\eta_0)}{\alpha^2}}}\right)\right].$$

To use Newton's iteration scheme to solve (5.4), (5.5) we now let $F(\eta_0 + \delta) = 0$ in (5.6) with $\delta = \eta_{m+1} - \eta_m$ (where the index m denotes the iteration number). This leads, respectively, to the following iteration schemes for the solution of these equations:

$$L_1(\eta_m)\eta_{m+1} = N^2\eta_m, \tag{5.9}$$

$$L_2(\eta_m)\eta_{m+1} = \left[4\alpha^2 + \frac{N^2}{2\sqrt{z^2 - \frac{ln(\eta_m)}{\alpha^2}}}\right]\eta_m. \tag{5.10}$$

To solve these equations over a finite two dimensional domain $[-a, a] \times [0, b]$ with bottom topography, we used central finite differences with a grid of 151×101 points. The (approximate) boundary conditions which were imposed on η in (5.9), (5.10), respectively, were

$$\eta(-a, z) = 1, \;\; \eta(a, z) = 1, \;\; \eta(x, b) = 1, \;\; \eta(x, 0) = e^{\alpha^2 \epsilon f(x)}, \tag{5.11}$$

$$\eta(-a, z) = 1, \;\; \eta(a, z) = 1, \;\; \eta(x, b) = 1, \;\; \eta(x, 0) = e^{\alpha^2 \epsilon^2 f^2(x)}. \tag{5.12}$$

To mimic radiation boundary conditions and avoid reflection of the outgoing wave we used "sponge boundaries" at $x = a$ and $z = b$ (as is done in the NCAR/MM5 mesoscale model [23] and others). The following values of the parameters were used, respectively, in these simulations:

$$\epsilon = 0.35, \;\; N = 1, \;\; \beta = 4.10^{-3} \tag{5.13}$$

with topography shape function

$$f(x) = \frac{1}{(1 + x^2)^{3/2}}. \tag{5.14}$$

The convergence criterion for the iterations was $\max |\eta_{m+1} - \eta_m| \leq 10^{-10}$. Figures 1 and 2 compare the results obtained for the perturbation $\phi(x, z)$ by using (5.9) and (5.10). We see that Figure 1 (for the shearless base flow) displays a clear pattern of gravity waves. On the other hand, Figure 2 shows that the perturbation from the shear flow feeds on the energy of the base flow and creates a vortex high above the topography.

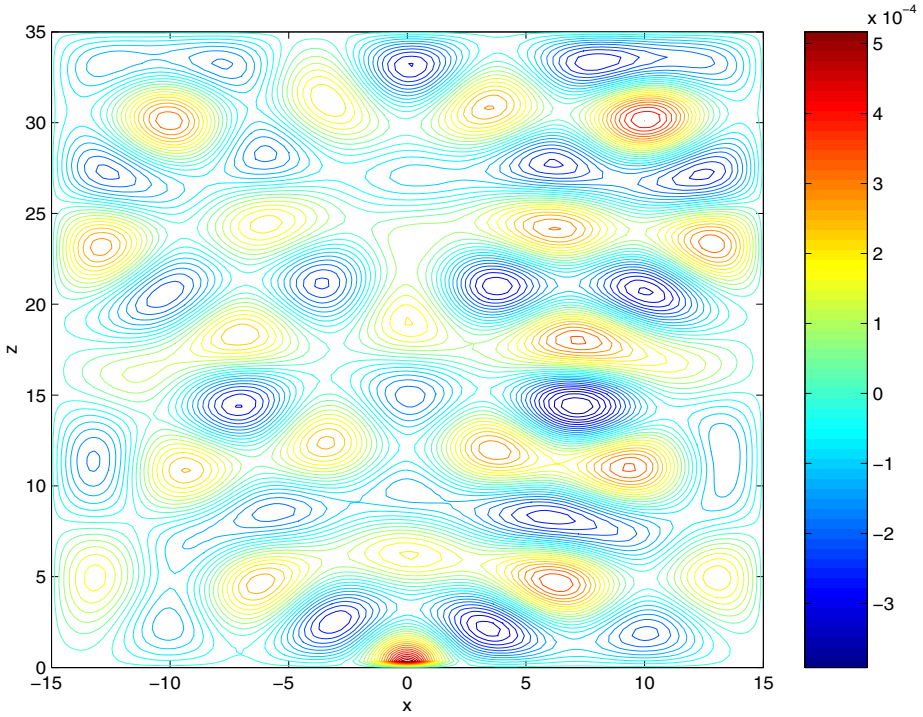

FIG. 1. *Contour plot of* $\alpha^2\phi$ *using* (5.9) *(shearless base flow).*

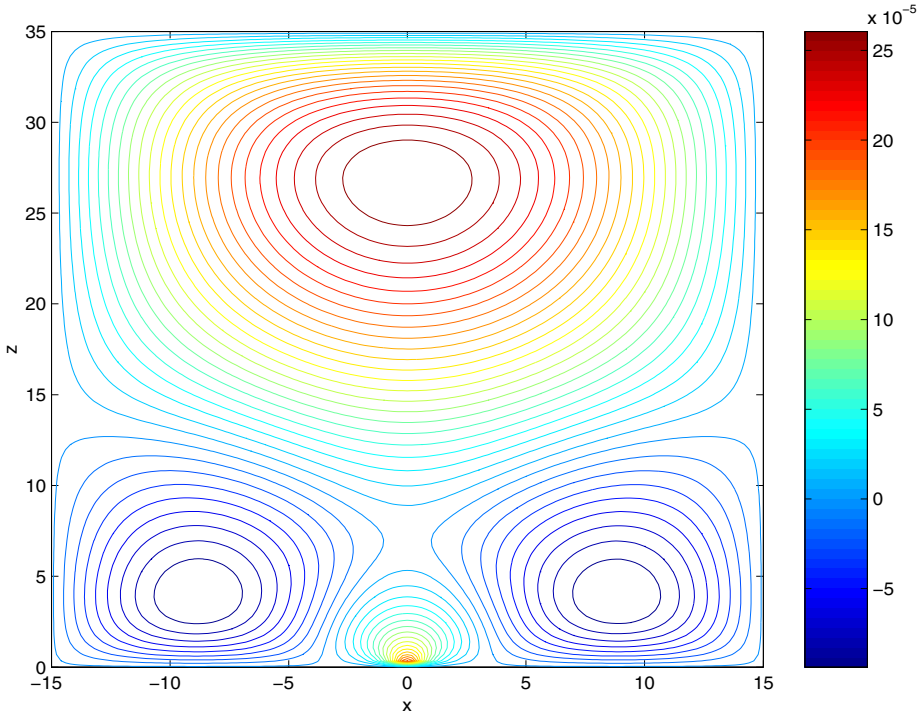

FIG. 2. *Contour plot of* $\alpha^2\phi$ *using* (5.10) *(shear base flow).*

6. Summary and conclusions. We derived in this paper some criteria for the excitation of gravity waves by a flow over topography using Long's equation. These criteria depend on only the nature of the base flow and the variation of N^2 with height. From an operational point of view these criteria will be useful both experimentally and theoretically. Currently the experimental practice is to ignore the shear in the base flow and attempt to deduce the quantitative attributes of the gravity waves using the shearless Long's equation. This procedure can be refined now by taking this important feature into account. Our analysis also shows that no simulation of Long's equation over actual topography is needed to determine the qualitative nature of the perturbation that is generated by the topography.

We also demonstrated that in some cases this perturbation will be damped by the shear, while in other cases the perturbation will grow, feeding on the energy that is present in the base flow.

Appendix: Poincaré inequality.

THEOREM A.1. *Let $u(x)$ be a bounded differentiable function on $[0, a]$ with $u(0) = 0$; then*

$$\int_0^a [u'(x)]^2 dx \geq \frac{\pi^2}{4a^2} \int_0^a u^2(x) dx. \tag{A.1}$$

Proof. To prove this inequality we introduce

$$h(x) = \frac{\pi}{2a} \tan\left(\frac{\pi(x-a)}{2a}\right). \tag{A.2}$$

This function satisfies $h(a) = 0$ and the differential equation

$$h' - h^2 = \frac{\pi^2}{4a^2}. \tag{A.3}$$

We now consider the integral

$$\int_0^a [uh + u']^2 dx \geq 0, \tag{A.4}$$

$$\int_0^a [uh + u']^2 dx = \int_0^a u^2 h^2 dx + \int_0^a (u')^2 dx + 2 \int_0^a uhu' dx \geq 0, \tag{A.5}$$

but

$$\begin{aligned} \int_0^a uu'h dx &= \frac{u^2 h}{2}\bigg|_0^a - \frac{1}{2} \int_0^a u^2 h' dx \\ &= \frac{1}{2}[u^2(a)h(a) - u^2(0)h(0)] - \frac{1}{2} \int_0^a u^2 h' dx \\ &= -\frac{1}{2} \int_0^a u^2 h' dx. \end{aligned} \tag{A.6}$$

Hence from (A.5),

$$\int_0^a (u')^2 dx \geq \int_0^a u^2 h' dx - \int_0^a u^2 h^2 dx = \int_0^a u^2 (h' - h^2) dx = \frac{\pi^2}{4a^2} \int_0^a u^2 dx, \tag{A.7}$$

which proves the theorem. □

EXTINCTION CRITERIA IN STAGE-STRUCTURED POPULATION MODELS WITH IMPULSIVE CULLING*

R. R. L. SIMONS† AND S. A. GOURLEY†

Abstract. We propose stage-structured population models for species whose adult members are subject to culling, with a view to understanding the culling regimes that are likely to result in eradication of the species. A purely time-dependent model is proposed in which culling occurs at particular discrete times, not necessarily equally spaced. Then a reaction-diffusion model is proposed for a situation in which the adults can diffuse; in this model the culling is continuous in time but occurs only at particular discrete points in space. Such a model might be appropriate for pheromone trapping of insects. For both models conditions are obtained that are sufficient for species eradication.

Key words. stage-structure, delay, impulse, pest control

1. Introduction.

Many species are subject to some form of culling. Often this is for reasons of pest control, and the aim of culling in this case might well be the localized eradication of the pest. In other situations the reason for culling is simply to keep numbers under control for the protection of habitats or other species, and complete eradication is not the aim.

Unlike natural mortality which one might reasonably suppose to occur continuously, the mortality attributable to culling is often more likely to take place only at certain times. Sometimes these times may be prescribed by law, as in the case of game bird and wildfowl shooting in the UK, which takes place in prescribed seasons lasting only a few months. Also, where animals such as deer (which as adults have no natural predators in the UK or Ireland) are culled for habitat protection, culling often occurs only at certain times of the year. In the UK, badgers, which are believed to spread tuberculosis to cattle, are subjected to culling by trapping and shooting, but again there are restrictions on the timing of the culls in an attempt to reduce the problem of badger cubs being orphaned and starving to death. Crop spraying as a way to control insect pests is also a method of control likely to be happening at certain discrete times (sometimes chosen to coincide with critical stages in the insects' development).

One might also envisage situations where some form of culling takes place continuously in time but only at discrete points in space. A good example would be the trapping system used in Australia to control the blowfly *Lucilia cuprina* which is a substantial nuisance to sheep farmers. Female flies lay their eggs in a sheep's fleece. The eggs hatch into larvae which feed on the sheep's damaged skin, creating a wound that can attract other flies. The larval and pupal stages may total around 14 days [6]. One approach to controlling the fly populations is by using pesticides, but this raises concerns regarding pesticide residue on the wool as well as environmental and occupational health and safety. An alternative is to trap the blowflies using specially

†Department of Mathematics, University of Surrey, Guildford, Surrey, GU2 7XH, United Kingdom (s.gourley@surrey.ac.uk).

designed translucent buckets fixed to trees at about the height at which the blowflies work. Entrance cones allow blowflies to enter but not leave the buckets, which contain a chemical attractant which smells like the blowflies' food sources—rotting fleece, carcasses, urine, and feces. Manufacturers of the buckets offer advice regarding where they should be placed. The second model of the present paper, which we study in section 3, proposes a possible model for such trapping of blowflies continuously in time but only at discrete points in a one-dimensional space. The traps in our model do not have to be equally spaced apart, and neither do they all have to be equally effective.

The use of impulsive differential equations as models of pest control seems to be a relatively undeveloped application area. Liu, Zhang, and Chen [8], motivated by the topic of pest control, proposed and studied a Lotka–Volterra predator prey model with impulsive effects (but no delay). Their model exhibits complex dynamics including quasi periodicity and chaos. Models of vaccination are another obvious application area (Hui and Chen [7]). However, impulsive differential equations, as a topic in their own right, have received some attention. See, for example, Wu [10] or the book by Gopalsamy [4]. A number of papers give conditions for existence of periodic solutions and oscillation properties more generally, but this is not our interest in the present paper.

Section 2 of this paper analyzes a purely time-dependent model for culling that occurs only at particular discrete times, while section 3 analyzes a reaction-diffusion model incorporating culling that is continuous in time but discrete in space.

2. Culling at discrete times. In this section we propose a model for a stage structured population with two stages: immature and mature, in which births and naturally occurring deaths occur continuously but culling or trapping occurs only at certain particular times, namely at times t_j with $0 < t_1 < t_2 < \cdots < t_j < \cdots$ and $t_j \to \infty$ as $j \to \infty$. At the cull which occurs at time t_j a proportion b_j of the adult population is culled, causing a sharp decrease in the population and consequently a discontinuity in the evolution at time t_j.

Let $u(t,a)$ be the density of individuals at time t of age a, and assume that an individual becomes mature on reaching the age τ. We will assume that the total number of mature adults $u_m(t)$, defined by

$$u_m(t) = \int_\tau^\infty u(t,a)\,da,$$

obeys an evolution equation of the form

$$u_m'(t) = u(t,\tau) - d(u_m(t)) - \sum_{j=1}^{\infty} b_j u_m(t_j^-)\delta(t-t_j), \tag{2.1}$$

where $u(t,\tau)$ is the number of individuals of age exactly τ and therefore represents adult recruitment, $-d(u_m(t))$ is naturally occurring deaths, and the last term is the culling term. It will be assumed that the immatures are governed by the standard McKendrick–von Foerster model for an age-structured population, namely

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial a} = -\mu u, \qquad t > 0, \quad 0 < a < \tau, \tag{2.2}$$

with $\mu > 0$ constant, the initial condition

$$u(0,a) = u_0(a) \geq 0, \qquad a \geq 0, \tag{2.3}$$

and also the assumption that the birth rate $u(t,0)$ is a function of the total number of adults so that

$$u(t,0) = b(u_m(t)). \tag{2.4}$$

For the present section the mathematical assumptions on the death function $d(u_m)$ and the birth function $b(u_m)$ are listed in (2.7) below. As our results are for the linearized model it is the properties of these functions at low densities that matter in this paper. Two typical birth functions used in much of the literature seem to be $b(u_m) = Pu_m e^{-Au_m}$ and $b(u_m) = Pu_m^2 e^{-Au_m}$, both of which decrease at large densities due to crowding effects. Note that the second of these has $b'(0) = 0$, which is motivated by the fact that in some populations the per capita growth rate at low densities is very small due to lack of group defense and low mating probability. This function does not satisfy (2.7) below.

The solution of (2.2) subject to (2.3) and (2.4) is

$$u(t,a) = \begin{cases} u_0(a-t)\exp(-\mu t), & t < a, \\ b(u_m(t-a))\exp(-\mu a), & t > a. \end{cases} \tag{2.5}$$

From this expression we see that if $t > \tau$, then

$$u(t,\tau) = \exp(-\mu\tau) b(u_m(t-\tau)),$$

whereas if $t < \tau$, then $u(t,\tau) = u_0(\tau - t)\exp(-\mu t)$. Insertion of these expressions for $u(t,\tau)$ into (2.1) yields one nonautonomous evolution equation valid for times $t \in (0,\tau)$ and another autonomous delay equation valid for all times larger than τ. It is common practice in the literature on these types of models to consider only the latter equation, but to consider it for all times $t > 0$ with prescribed initial data on $[-\tau, 0]$. This is what we shall do in the present paper (model (2.6) below). This practice does raise certain issues related to initial data, an issue which is discussed in detail in Bocharov and Hadeler [2]. Strictly speaking, the initial data is prescribed at time $t = 0$ only and is just the function $u_0(a)$. One should proceed by first solving (2.1) with $u(t,\tau) = u_0(\tau - t)\exp(-\mu t)$ for t in the interval $(0,\tau)$, and then by solving the delay equation in (2.6) for times $t > \tau$. One can understand from this procedure that only certain initial data for problem (2.6) is actually related to the original problem. However, since this paper is concerned mainly with the linearized equations, we do not feel this will be too much of a concern.

Our model thus takes the form

$$\begin{aligned} &u_m'(t) = e^{-\mu\tau} b(u_m(t-\tau)) - d(u_m(t)) - \sum_{j=1}^{\infty} b_j u_m(t_j^-)\delta(t - t_j), \quad t > 0, \\ &u_m(t) = \phi(t) \geq 0 \quad \text{for} \quad t \in [-\tau, 0); \quad u_m(0) = u_m^0 > 0, \end{aligned} \tag{2.6}$$

where $\mu > 0$ represents juvenile mortality, $u_m(t)$ is the total number of adults at time t, $u_m(t_j^-)$ is the population just before the impulsive cull at time t_j, τ is the maturation time, b_j is the proportion of the mature species trapped or culled at time t_j, and δ denotes the Dirac delta function. In this model $b(u_m(t))$ is a function representing the birth rate of the species, and $d(u_m(t))$ is the natural death rate of the mature species. The $e^{-\mu\tau} b(u_m(t-\tau))$ term is the rate at which immature individuals become mature, known as the maturation rate. This term incorporates the delay τ and is essentially the birth rate τ time units ago, corrected to allow for juvenile mortality.

Models having the form of (2.6) without impulsive effects have been considered in detail by Cooke, van den Driessche, and Zou [3].

In the present section we will assume the following:

$$
\begin{aligned}
&0 < t_1 < t_2 < \cdots < t_j \to \infty \quad \text{as} \quad j \to \infty,\\
&b_j \in [0,1] \quad \forall j = 1,2,3,\ldots,\\
&b(0) = 0, \quad b'(0) > 0, \quad b(u_m) > 0 \quad \forall u_m > 0,\\
&d(0) = 0, \quad d \in C^1[0,\infty), \quad d(u_m) > 0 \quad \forall u_m > 0.
\end{aligned} \tag{2.7}
$$

Note that if we integrate the delay equation in (2.6) from t_j^- to t_j^+, we obtain

$$u_m(t_j^+) = u_m(t_j^-) - b_j u_m(t_j^-).$$

As a consequence, model (2.6) can be reformulated as

$$
\begin{aligned}
&u_m'(t) = e^{-\mu\tau} b(u_m(t-\tau)) - d(u_m(t)), \quad t \neq t_j,\\
&u_m(t_j^+) = (1-b_j) u_m(t_j^-),\\
&u_m(t) = \phi(t) \geq 0 \quad \text{for} \quad t \in [-\tau, 0); \quad u_m(0) = u_m^0 > 0.
\end{aligned} \tag{2.8}
$$

The two formulations (2.6) and (2.8) of the model are both useful. For most of the analysis in this section we shall be concerned only with linearized versions of these models near the zero solution. The Laplace transform provides a powerful tool for the investigation of these linearized models, but one has to take careful note of the fact that the solution $u_m(t)$ of either (2.6) or the alternative formulation (2.8) will, in general, be discontinuous at the times t_j. The well-known formula

$$\mathcal{L}\{u'(t)\} = sU - u(0) \tag{2.9}$$

for the Laplace transform of the derivative of a function assumes the function $u(t)$ to be continuous for all $t > 0$. Here, U is the Laplace transform of u, and s is the transform variable. For a function $u(t)$ which is continuous except for discontinuous jumps at the times $t = t_j$, the corresponding formula is

$$\mathcal{L}\{u'(t)\} = sU - u(0) + \sum_{j=1}^{\infty} e^{-st_j} \left(u(t_j^-) - u(t_j^+) \right). \tag{2.10}$$

Due care needs to be taken on this issue; otherwise there is a possibility of the discontinuities being taken care of twice over, and if this happens incorrect results are produced by the analysis. Even though the solution of (2.6) will not be continuous, in the treatment of the linearized equation the Laplace transform of the derivative term needs to be calculated using the formula (2.9) which assumes continuity. The discontinuities in the solution are correctly furnished by the Laplace transform analysis because of the presence of the Dirac delta function in (2.6). The alternative approach would be to carry out a Laplace transform analysis of the linearization of (2.8). In this case the derivative term has to be dealt with using (2.10). It can be shown that the two approaches yield the same equation for the transformed state variable and are therefore equivalent. It must be stressed, however, that one has to stick to one approach or the other. The use of (2.10) in a Laplace transform analysis of the linearized version of (2.6) produces incorrect results.

2.1. Positivity. Next, we shall show that solutions of (2.6) or (2.8) enjoy a positivity preserving property.

PROPOSITION 2.1. *Assume* (2.7) *holds; then the solution* $u_m(t)$ *of* (2.6), *or the alternative formulation* (2.8), *satisfies* $u_m(t) \geq 0$ *for all* $t > 0$.

Proof. The proof is by the method of steps and starts by establishing positivity for $t \in (0, \tau]$. First note that positivity (in fact, strict positivity) holds if all the b_j are zero. In this case,

$$u_m'(t) \geq -d(u_m(t)) \qquad \text{when} \qquad t \in (0, \tau].$$

By comparison, $u_m(t) \geq \hat{u}_m(t)$ where $\hat{u}_m(t)$ is the solution of

$$\hat{u}_m'(t) = -d(\hat{u}_m(t)), \quad t \in (0, \tau],$$

satisfying $\hat{u}_m(0) = u_m^0 > 0$. From the assumptions on the function d contained within (2.7), it follows by Taylor's theorem that $d(\hat{u}_m(t)) = \hat{u}_m(t)d'(\theta(t))$ for some function $\theta(t)$. Therefore the above differential equation for $\hat{u}_m(t)$ has zero as one of its solutions and is also of such a form that, given initial data, we are assured of a unique solution. With $\hat{u}_m(0) > 0$ it follows that $\hat{u}_m(t) > 0$ for all $t > 0$; otherwise uniqueness is violated. Therefore $u_m(t) > 0$ for all $t \in (0, \tau]$ in the case when the b_j are all zero. From the method of steps it is clear that if the b_j are zero, then strict positivity of $u_m(t)$ holds for all $t > 0$.

The case when some or all of the b_j are nonzero does not represent a significant complication. They are all in $[0, 1]$, by (2.7), and so by (2.8) the solution is always reset from a nonnegative value to a nonnegative value at one of the times t_j (note, however that if one or more of the b_j is 1, then the solution is reset to zero at the corresponding time t_j, so *strict* positivity of solutions cannot be anticipated in this case). From what we have already shown the solution is certainly strictly positive before the first impulse time t_1, and at time t_1 is reset to some nonnegative value. An argument much like that described in the previous paragraph, but with initial time t_1 rather than 0, then assures us of the nonnegativity of $u_m(t)$ until the next time t_2 at which a resetting occurs, but then the argument just described applies again until the next time t_3 and so on. The proof of Proposition 2.1 is complete. ∎

2.2. Criteria for extinction. Linearizing (2.6) about the steady state $u_m = 0$, we get

$$u_m'(t) = e^{-\mu\tau} b'(0) u_m(t-\tau) - d'(0) u_m(t) - \sum_{j=1}^{\infty} b_j u_m(t_j^-) \delta(t - t_j). \tag{2.11}$$

Integrating from t_j^- to t_j^+ yields the following alternative formulation for the linearized equation:

$$\begin{aligned} &u_m'(t) = e^{-\mu\tau} b'(0) u_m(t-\tau) - d'(0) u_m(t), \quad t \neq t_j, \\ &u_m(t_j^+) = (1 - b_j) u_m(t_j^-). \end{aligned} \tag{2.12}$$

Remark 1. Positivity preservation, Proposition 2.1, also holds for the linearized problem (2.12).

2.2.1. The case when $e^{-\mu\tau}b'(0) < d'(0)$. In this subsection we will prove linear stability of the zero solution of (2.8) under the condition $e^{-\mu\tau}b'(0) < d'(0)$. The ecological interpretation of this condition is that, at low densities, adult recruitment is insufficient to outweigh naturally occurring deaths. Our result confirms that, as we would anticipate, under these circumstances the population will still become extinct when impulsive trapping or culling is introduced whatever the intensity and however frequent or infrequent the culling occurs.

THEOREM 2.2. *Let* (2.7) *hold and assume additionally that*

$$e^{-\mu\tau}b'(0) < d'(0). \tag{2.13}$$

Then the solution $u_m(t)$ *of the linearized problem* (2.12) *satisfies* $u_m(t) \to 0$ *as* $t \to \infty$.

Proof. Applying the Laplace transform

$$\mathcal{L}\{u(t)\} = \int_0^\infty u(t)e^{-st}\,dt$$

to (2.12), using formula (2.10) to take care of the anticipated discontinuities in the solution as explained earlier, and also noting that the Laplace transform of the delay term can be written as

$$\mathcal{L}\{e^{-\mu\tau}b'(0)u_m(t-\tau)\} = e^{-\mu\tau}b'(0)\left(\int_{-\tau}^0 u_m(\eta)e^{-s(\eta+\tau)}d\eta + e^{-s\tau}U\right),$$

where $U = U(s)$ is the Laplace transform of $u_m(t)$, (2.12) gives

$$\begin{aligned}[s - e^{-\mu\tau}b'(0)e^{-s\tau} + d'(0)]U = u_m(0) &- \sum_{j=1}^\infty e^{-st_j}(u_m(t_j^-) - u_m(t_j^+)) \\ &+ e^{-\mu\tau}b'(0)\int_{-\tau}^0 u_m(\eta)e^{-s(\eta+\tau)}\,d\eta.\end{aligned}$$

Using the impulse condition from (2.12) to replace $u_m(t_j^+)$, we get

$$\begin{aligned}[s - e^{-\mu\tau}b'(0)e^{-s\tau} + d'(0)]U = u_m(0) &+ e^{-\mu\tau}b'(0)\int_{-\tau}^0 u_m(\eta)e^{-s(\eta+\tau)}d\eta \\ &- \sum_{j=1}^\infty e^{-st_j}b_j u_m(t_j^-).\end{aligned} \tag{2.14}$$

Now define $y(t)$ by

$$\begin{aligned} y'(t) &= e^{-\mu\tau}b'(0)y(t-\tau) - d'(0)y(t), \qquad t > 0, \\ y(t) &= 0 \quad \text{for} \quad t \in [-\tau, 0); \quad y(0) = 1, \end{aligned} \tag{2.15}$$

the continuous analogy of (2.12) without impulses. It is easy to show (similarly to the proof of Proposition 2.1) that $y(t) > 0$ for all $t > 0$.

Applying the Laplace transform to (2.15), and letting $Y = Y(s) = \mathcal{L}\{y(t)\}$, gives

$$sY - 1 = e^{-\mu\tau}b'(0)\left[\int_{-\tau}^0 y(\xi)e^{-s(\xi+\tau)}d\xi + e^{-s\tau}Y\right] - d'(0)Y$$

so that, since $y(t) = 0$ for $t \in [-\tau, 0)$,

$$Y = \frac{1}{s + d'(0) - e^{-\mu\tau} b'(0) e^{-s\tau}} \tag{2.16}$$

and so

$$y(t) = \mathcal{L}^{-1}\left\{ \frac{1}{s + d'(0) - e^{-\mu\tau} e^{-s\tau} b'(0)} \right\}. \tag{2.17}$$

From this it is easy to see that $y(t) \to 0$ as $t \to \infty$. To deduce this conclusion it suffices (by the inversion formula for Laplace transforms) to show that all the poles of the function Y (i.e., the zeros of the denominator of (2.16)) are strictly in the left half of the complex plane. For a contradiction, assume a zero $\hat{s}$ exists satisfying $\operatorname{Re} \hat{s} \geq 0$. Then

$$|\hat{s} + d'(0)| = e^{-\mu\tau} b'(0) |e^{-\hat{s}\tau}| = e^{-\mu\tau} b'(0) e^{-\tau \operatorname{Re} \hat{s}} \leq e^{-\mu\tau} b'(0)$$

so that $\hat{s}$ lies in the closed disk in the complex plane centered at $-d'(0)$ and of radius $e^{-\mu\tau} b'(0)$. But condition (2.13) implies that this disk is entirely within the open left half of the complex plane, and this contradicts $\operatorname{Re} \hat{s} \geq 0$. Thus $y(t) \to 0$ as $t \to \infty$.

The denominator of the right-hand side of (2.16) appears on the left-hand side of (2.14). Dividing by this quantity and taking inverse Laplace transforms gives

$$\begin{aligned}
u_m(t) &= u_m(0) y(t) + \mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau} b'(0) \int_{-\tau}^{0} u_m(\eta) e^{-s(\eta+\tau)} d\eta}{s + d'(0) - e^{-\mu\tau} b'(0) e^{-s\tau}} \right\} \\
&\quad - \sum_{j=1}^{\infty} b_j u_m(t_j^-) \mathcal{L}^{-1}\left\{ \frac{e^{-s t_j}}{s + d'(0) - e^{-\mu\tau} b'(0) e^{-s\tau}} \right\} \\
&= u_m(0) y(t) + \mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau} b'(0) \int_{-\tau}^{0} u_m(\eta) e^{-s(\eta+\tau)} d\eta}{s + d'(0) - e^{-\mu\tau} b'(0) e^{-s\tau}} \right\} \\
&\quad - \sum_{j=1}^{\infty} b_j u_m(t_j^-) \int_0^t y(t-s) \delta(s - t_j)\, ds \\
&= u_m(0) y(t) + \mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau} b'(0) \int_{-\tau}^{0} u_m(\eta) e^{-s(\eta+\tau)} d\eta}{s + d'(0) - e^{-\mu\tau} b'(0) e^{-s\tau}} \right\} \\
&\quad - \sum_{j=1}^{\infty} b_j u_m(t_j^-) H(t - t_j) y(t - t_j),
\end{aligned} \tag{2.18}$$

where $H(t - t_j)$ is the Heaviside function. In this calculation we have used the convolution theorem for the Laplace transform.

Our intention is to deduce from this that $u_m(t) \to 0$ as $t \to \infty$ under condition (2.13). We already know that $y(t) \to 0$ under this condition. The second term in the expression (2.18) for $u_m(t)$ also tends to zero as $t \to \infty$. This is because it is the inverse Laplace transform of a ratio in which the numerator is an analytic function of s while the denominator has all of its zeros in $\operatorname{Re} s < 0$ as has already been shown.

From nonnegativity of $u_m(t)$ for $t > 0$, and strict positivity of $y(t)$, we know the sign of the last term in the expression (2.18) for $u_m(t)$ and so we can write

$$0 \leq u_m(t) \leq u_m(0) y(t) + \mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau} b'(0) \int_{-\tau}^{0} u_m(\eta) e^{-s(\eta+\tau)} d\eta}{s + d'(0) - e^{-\mu\tau} b'(0) e^{-s\tau}} \right\}.$$

Hence $u_m(t) \to 0$ as $t \to \infty$. □

2.2.2. The case when $e^{-\mu\tau}b'(0) > d'(0)$. In this subsection we shall show that the zero solution of (2.8) can also be asymptotically linearly stable (i.e., the population will be driven to extinction) in the case when adult recruitment outweighs deaths at low densities if culling occurs in sufficient measure and with sufficient frequency in the sense to be described below. Note that from the alternative formulation of the original model (2.8) if the b_j's are close to 1, then it means that aggressive culling is taking place and a large majority of the mature species population is wiped out at each time t_j. We can also see that even if the b_j's were exactly equal to 1 and all the mature species were wiped out, this would not necessarily cause extinction, because immatures conceived at a previous time may mature at a later date. However, it is reasonable to speculate that if the b_j's are close enough to 1 and culling takes place sufficiently frequently in some sense, then the population would be driven to extinction.

For reasons that will become clear later, we need to understand the properties of the function $\phi(t)$ defined by

$$\begin{aligned} &\phi'(t) = e^{-\mu\tau}b'(0)\phi(t-\tau) - e^{-\mu\tau}b'(0)\phi(t), \\ &\phi(t) = 0, \quad t \in [-\tau, 0), \quad \phi(0) = 1. \end{aligned} \tag{2.19}$$

PROPOSITION 2.3. *The solution $\phi(t)$ of (2.19) is strictly positive for all $t > 0$ and satisfies*

$$\lim_{t\to\infty} \phi(t) = \frac{1}{1 + e^{-\mu\tau}b'(0)\tau}. \tag{2.20}$$

Consequently, the quantity $\phi^* := \inf_{t\geq 0} \phi(t)$ satisfies $\phi^* > 0$.

Proof. Strict positivity of $\phi(t)$ for $t > 0$ follows from arguments similar to those in the first part of the proof of Proposition 2.1. Strict positivity together with (2.20) immediately yields the last statement in the proposition, that $\phi^* > 0$. Therefore, it remains to prove only (2.20). Taking the Laplace transform of (2.19) and letting $\Phi = \Phi(s)$ denote the Laplace transform of ϕ, we obtain

$$s\Phi - 1 = e^{-\mu\tau}b'(0)\left[\int_{-\tau}^{0} \phi(\xi)e^{-s(\xi+\tau)}d\xi + e^{-s\tau}\Phi\right] - e^{-\mu\tau}b'(0)\Phi.$$

Since $\phi(t) = 0$ for $t \in [-\tau, 0)$,

$$\Phi = \frac{1}{s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0)}$$

so that

$$\begin{aligned} \phi(t) &= \mathcal{L}^{-1}\left\{\frac{1}{s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0)}\right\} \\ &= \frac{1}{2\pi i}\int_{\sigma-i\infty}^{\sigma+i\infty} \frac{e^{st}\,ds}{s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0)} \end{aligned} \tag{2.21}$$

in which the integral is the standard Bromwich integral. The quantity σ in (2.21) can be taken as any real number which strictly exceeds the supremum of the real parts of the zeros of the denominator in the integrand. In this case we can take any real $\sigma > 0$ as we now explain. Evaluation of the integral (2.21) will be via Cauchy's

residue theorem, which requires us to identify the poles of the integrand, i.e., the zeros of its denominator. By inspection, one of these is clearly $s = 0$. We claim that the equation $s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0) = 0$ has no roots satisfying $\operatorname{Re} s \geq 0$ other than the root $s = 0$. Indeed, if $\operatorname{Re} s \geq 0$, then

$$|s + e^{-\mu\tau}b'(0)| = e^{-\mu\tau}b'(0)|e^{-s\tau}| \leq e^{-\mu\tau}b'(0)e^{-\tau \operatorname{Re} s} \leq e^{-\mu\tau}b'(0)$$

so that s is in the closed disk in $\mathbf{C}$ with center $-e^{-\mu\tau}b'(0)$ and radius $e^{-\mu\tau}b'(0)$. But this disk contains no points s with $\operatorname{Re} s \geq 0$ apart from $s = 0$. Therefore the poles of the integrand in (2.21) consist of the pole at $s = 0$ (which is easily checked to be simple) together with the remaining zeros of the integrand's denominator, all of which satisfy $\operatorname{Re} s < 0$. Evaluation of (2.21) by Cauchy's residue theorem gives an expression of the form

$$\phi(t) = \sum \operatorname{res}\left\{ \frac{e^{st}}{s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0)},\ \ s \in \mathbf{P} \right\}, \tag{2.22}$$

where $\mathbf{P}$ is the set of all roots of $s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0) = 0$. But we know that the roots of this equation are $s = 0$ together with other roots, all of which satisfy $\operatorname{Re} s < 0$. It is well known that for a function $f(s)$ of the form $f(s) = h(s)/k(s)$ with $h(s)$ and $k(s)$ analytic functions of s, $h(a) \neq 0$, $k(a) = 0$, and $k'(a) \neq 0$, that the residue of $f(s)$ at the simple pole $s = a$ is given by $\operatorname{res}\{f(s);\ s = a\} = h(a)/k'(a)$. Applying this formula to the calculation of the residue at any $s \in \mathbf{P}$ with $\operatorname{Re} s < 0$ yields that the residue is an exponentially decaying function of t. Therefore

$$\begin{aligned}\phi(t) &= \operatorname{res}\left\{ \frac{e^{st}}{s - e^{-s\tau}e^{-\mu\tau}b'(0) + e^{-\mu\tau}b'(0)},\ s = 0 \right\} \\ &\quad + \text{exponentially decaying terms in } t \\ &= \frac{1}{1 + e^{-\mu\tau}b'(0)\tau} + \text{exponentially decaying terms in } t,\end{aligned}$$

and thus (2.20) holds. The proof of Proposition 2.3 is complete. □

Remark 2. Although we are assured of the strict positivity of the quantity ϕ^* defined in the statement of Proposition 2.3, we point out that ϕ^* is not necessarily equal to the limit in (2.20). It can be shown that the convergence to the limit in (2.20) will be nonmonotone if $e^{-\mu\tau}b'(0)\tau$ is sufficiently large,

Our next main result, Theorem 2.4 below, presents some conditions under which extinction of the population is predicted. Even though the problem under consideration is the linearized problem (2.12), analysis thereof is difficult. Our method of analysis involves the use of the Euler–Maclaurin summation formula [1], a technique for converting sums to integrals or vice versa. We can only retain certain terms in the use of this formula (those that do not involve the Bernoulli numbers), and as a consequence the following theorem must be interpreted in an approximate sense. Nevertheless, it is quite insightful as we will discuss later. We draw the reader's attention to the function $t(\cdot)$ referred to in the statement of Theorem 2.4 below. This function is not uniquely defined, but a sensible choice would be one that is piecewise linear but smoothed at the integers so as to be differentiable. The function $t(\cdot)$ tells us something about the spacing of the impulse times t_j (for example, if its derivative t' is very small, then the impulse times are rather close together; under these circumstances we might expect that extinction would be more likely, and this is what Theorem 2.4 indeed predicts). Condition (2.23) in the theorem essentially states that

the impulses must occur sufficiently close together in some sense depending on the proportion of the species that is removed at each impulse and also, not surprisingly, on the per capita natural death rate and adult recruitment rate at low densities.

THEOREM 2.4. *Let* (2.7) *hold, and let* $t(\xi) : [0,\infty) \to [0,\infty)$ *be a strictly monotonically increasing differentiable function with the property that* $t(i) = t_i$, $i = 1, 2, 3, \ldots$, *and* $t(0) = 0$. *If*

$$e^{-\mu\tau} b'(0) > d'(0)$$

and

$$\inf_{j \in \mathbf{N}} \{ b_j - (e^{-\mu\tau} b'(0) - d'(0)) t'(j) \} > 0, \tag{2.23}$$

then the solution $u_m(t)$ *of the linearized problem* (2.12) *satisfies* $u_m(t) \to 0$ *as* $t \to \infty$ *according to an analysis based on the Euler–Maclaurin summation formula.*

Proof. It will be convenient to rewrite (2.12) in the form

$$\begin{aligned} &u_m'(t) = e^{-\mu\tau} b'(0) u_m(t-\tau) - e^{-\mu\tau} b'(0) u_m(t) + (e^{-\mu\tau} b'(0) - d'(0)) u_m(t), \quad t \neq t_j, \\ &u_m(t_j^+) = (1 - b_j) u_m(t_j^-). \end{aligned} \tag{2.24}$$

Taking Laplace transforms of (2.24) and using formula (2.10) gives

$$\begin{aligned} (s - e^{-\mu\tau} e^{-s\tau} b'(0) + e^{-\mu\tau} b'(0)) U = u_m(0) + e^{-\mu\tau} e^{-s\tau} b'(0) \int_{-\tau}^{0} e^{-s\xi} u_m(\xi)\, d\xi \\ + (e^{-\mu\tau} b'(0) - d'(0)) U - \sum_{j=1}^{\infty} b_j u_m(t_j^-) e^{-s t_j}. \end{aligned} \tag{2.25}$$

Using (2.21) and taking inverse Laplace transforms of (2.25), we get

$$\begin{aligned} u_m(t) &= f(t) + \mathcal{L}^{-1}\left\{ \frac{(e^{-\mu\tau} b'(0) - d'(0)) U}{s - e^{-\mu\tau} e^{-s\tau} b'(0) + e^{-\mu\tau} b'(0)} \right\} \\ &\quad - \sum_{j=1}^{\infty} b_j u_m(t_j^-) \mathcal{L}^{-1}\left\{ \frac{e^{-s t_j}}{s - e^{-\mu\tau} e^{-s\tau} b'(0) + e^{-\mu\tau} b'(0)} \right\} \\ &= f(t) + (e^{-\mu\tau} b'(0) - d'(0)) \int_0^t \phi(t-s) u_m(s)\, ds \\ &\quad - \sum_{j=1}^{\infty} b_j u_m(t_j^-) \int_0^t \phi(t-s) \delta(s - t_j)\, ds \\ &= f(t) + (e^{-\mu\tau} b'(0) - d'(0)) \int_0^t \phi(t-s) u_m(s)\, ds \\ &\quad - \sum_{j=1}^{\infty} b_j u_m(t_j^-) \phi(t - t_j) H(t - t_j), \end{aligned} \tag{2.26}$$

where we recall that $\phi(t)$ is defined by (2.19), and where

$$f(t) = u_m(0)\phi(t) + \mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau} b'(0) e^{-s\tau} \int_{-\tau}^{0} e^{-s\xi} u_m(\xi) d\xi}{s - e^{-\mu\tau} e^{-s\tau} b'(0) + e^{-\mu\tau} b'(0)} \right\}. \tag{2.27}$$

If we substitute $t = t_i^-$ into (2.26) and let

$$u_i = u_m(t_i^-), \qquad f_i = f(t_i^-),$$

we obtain, noting that $\phi(t)$ is continuous,

$$\begin{aligned} u_i &= f_i + (e^{-\mu\tau}b'(0) - d'(0)) \int_0^{t_i} \phi(t_i - s)u_m(s)ds - \sum_{j=1}^{i-1} b_j u_j \phi(t_i - t_j) \\ &= f_i + (e^{-\mu\tau}b'(0) - d'(0)) \int_0^{i} \phi(t(i) - t(\xi))u_m(t(\xi))t'(\xi)\, d\xi - \sum_{j=1}^{i-1} b_j u_j \phi(t_i - t_j), \end{aligned}$$

having made the substitution $s = t(\xi)$ in the integral term.

We now convert the integral in the above expression into a sum. This will be achieved by using a first approximation of the Euler–Maclaurin formula:

$$\int_0^n h(k)\, dk \approx \sum_{k=1}^{n-1} h_k + \frac{h(0) + h(n)}{2}. \tag{2.28}$$

Applying this, we get

(2.29)

$$\begin{aligned} u_i = f_i + (e^{-\mu\tau}b'(0) - d'(0)) &\left(\sum_{j=1}^{i-1} \phi(t_i - t_j)u_j t'(j) + \frac{\phi(t_i)u_m(0)t'(0) + \phi(0)u_i t'(i)}{2} \right) \\ &- \sum_{j=1}^{i-1} b_j u_j \phi(t_i - t_j). \end{aligned}$$

We now claim that the function $f(t)$ defined by (2.27) above tends to a strictly positive limit $C > 0$ as $t \to \infty$ (so that also $f_i \to C$ as $i \to \infty$). By Proposition 2.3, $\phi(t)$ certainly approaches a strictly positive limit. The second term in the expression for $f(t)$ does so as well, as can be shown similarly to a contour integral argument discussed earlier where the singularities were the same: a simple pole at the origin and various other poles all with strictly negative real part. By the inversion formula for Laplace transforms and Cauchy's residue theorem,

$$\begin{aligned} &\mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau}b'(0)e^{-s\tau} \int_{-\tau}^0 e^{-s\xi}u_m(\xi)\, d\xi}{s - e^{-\mu\tau}e^{-s\tau}b'(0) + e^{-\mu\tau}b'(0)} \right\} \\ &= \operatorname{res}\left\{ \frac{e^{-\mu\tau}b'(0)e^{st}\, e^{-s\tau} \int_{-\tau}^0 e^{-s\xi}u_m(\xi)\, d\xi}{s - e^{-\mu\tau}e^{-s\tau}b'(0) + e^{-\mu\tau}b'(0)},\ s = 0 \right\} \\ &\quad + \text{exponentially decreasing terms in } t. \end{aligned}$$

Thus

$$\lim_{t\to\infty} \mathcal{L}^{-1}\left\{ \frac{e^{-\mu\tau}b'(0)e^{-s\tau} \int_{-\tau}^0 e^{-s\xi}u_m(\xi)\, d\xi}{s - e^{-\mu\tau}e^{-s\tau}b'(0) + e^{-\mu\tau}b'(0)} \right\} = \frac{e^{-\mu\tau}b'(0) \int_{-\tau}^0 u_m(\xi)\, d\xi}{1 + \tau e^{-\mu\tau}b'(0)}.$$

Hence $f(t)$ tends to a limit as $t \to \infty$. Writing (2.29) a different way, and recalling that $\phi(0) = 1$,

$$\begin{aligned} & u_i \left(1 - \frac{(e^{-\mu\tau}b'(0) - d'(0))t'(i)}{2}\right) \\ &= \sum_{j=1}^{i-1} u_j \phi(t_i - t_j) \left[\left(e^{-\mu\tau}b'(0) - d'(0)\right) t'(j) - b_j\right] \\ &\quad + f_i + \tfrac{1}{2}(e^{-\mu\tau}b'(0) - d'(0))\phi(t_i)u_m(0)t'(0). \end{aligned}$$

Since f_i and $\phi(t_i)$ both approach limits as $i \to \infty$, there exists C^* such that the totality of the last two terms in the above expression is bounded above by C^* for all i. Using this fact, and also adding $\lambda \sum_{j=1}^{i-1} u_j$ to both sides,

$$\begin{aligned} & u_i \left(1 - \frac{(e^{-\mu\tau}b'(0) - d'(0))t'(i)}{2}\right) + \lambda \sum_{j=1}^{i-1} u_j \\ &\leq \sum_{j=1}^{i-1} u_j \left\{\lambda + \phi(t_i - t_j) \left[\left(e^{-\mu\tau}b'(0) - d'(0)\right) t'(j) - b_j\right]\right\} + C^*, \end{aligned}$$

with $\lambda > 0$ to be chosen. Recall that $\phi(t) \geq \phi^* > 0$, where ϕ^* is defined in the statement of Proposition 2.3, and note also that the hypotheses of the theorem imply that $(e^{-\mu\tau}b'(0) - d'(0))\, t'(j) - b_j < 0$ for each j. Hence

$$\lambda + \phi(t_i - t_j) \left[\left(e^{-\mu\tau}b'(0) - d'(0)\right) t'(j) - b_j\right] \leq \lambda + \phi^* \left[\left(e^{-\mu\tau}b'(0) - d'(0)\right) t'(j) - b_j\right]$$

which we should like to be negative for all j. Therefore we choose any $\lambda > 0$ such that

$$\lambda \leq \phi^* \inf_{j \in \mathbf{N}} \left\{b_j - \left(e^{-\mu\tau}b'(0) - d'(0)\right) t'(j)\right\},$$

which is possible because the infimum is strictly positive by hypothesis. With this choice of λ we have

$$u_i \left(1 - \frac{(e^{-\mu\tau}b'(0) - d'(0))t'(i)}{2}\right) + \lambda \sum_{j=1}^{i-1} u_j \leq C^*.$$

Finally note that $(e^{-\mu\tau}b'(0) - d'(0))t'(i) < b_i \leq 1$ for each i. Hence

$$\frac{1}{2}u_i + \lambda \sum_{j=1}^{i-1} u_j \leq u_i \left(1 - \frac{(e^{-\mu\tau}b'(0) - d'(0))t'(i)}{2}\right) + \lambda \sum_{j=1}^{i-1} u_j \leq C^*.$$

This is true for all i, and furthermore $u_i \geq 0$ for each i. Hence $\sum_{j=1}^{\infty} u_j < \infty$, and so $u_i \to 0$ as $i \to \infty$. The proof is complete. □

3. Culling at discrete points in space. Up to now we have examined a purely time-dependent model in which the culling occurs only at specific times. The present section will examine a reaction-diffusion model for the situation in which the adults (but not the juveniles) can move around in a random way and where culling occurs

continuously in time but only at specific points x_j in a one-dimensional infinite spatial domain $x \in (-\infty, \infty)$. The equation we will analyze is

$$\begin{aligned} \frac{\partial u_m}{\partial t}(x,t) &= D\frac{\partial^2 u_m}{\partial x^2}(x,t) + e^{-\mu\tau} b(u_m(x,t-\tau)) - d(u_m(x,t)) \\ &\quad - \sum_{j=-\infty}^{\infty} B_j u_m(x_j,t)\delta(x-x_j), \\ u_m(x,t) &= \phi(x,t) \geq 0 \quad \text{for} \quad (x,t) \in (-\infty,\infty)\times[-\tau,0] \\ &\quad \text{with } \phi(\cdot,t) \in L^2 \text{ for each } t \in [-\tau,0] \text{ and } u_m(x,0) \not\equiv 0. \end{aligned} \tag{3.1}$$

Model (3.1) is only appropriate if the juvenile members do not diffuse. This is because we are using the same derivation for the adult recruitment term $e^{-\mu\tau}b(u_m(x,t-\tau))$ as was used to derive model (2.6). However, if the juveniles diffuse, then a diffusion term would have to be added to (2.2) with the consequence that the solution of the latter would no longer be (2.5). Thus, our model (3.1) is for the case when only the adults diffuse. Fortunately, this assumption is quite realistic in many species. For example, in many insect species the juveniles are larvae and move very little or not at all. Locust larvae attach themselves to tree roots and do not move at all, whereas adult locusts can move great distances. The blowfly *Lucilia cuprina* larvae live in sheep and might move a little in the sense of being carried about by their host sheep within a farm, but it is only the adults that can move great distances and thereby transfer infestations from farm to farm.

Situations in which the juveniles do move appreciably can be studied too. As previously noted, one would need to add to (2.2) a term representing the mobility of the juveniles, with the consequence that instead of (3.1) we would have an equation containing a spatial nonlocality caused by the mobility of the juveniles. Such equations have been studied extensively in recent years; see, for example, So, Wu, and Zou [9] or the recent survey article by Gourley and Wu [5].

The quantities B_j, $j = 0, \pm 1, \pm 2, \ldots$, in (3.1) have a somewhat different ecological interpretation to the corresponding quantities b_j in model (2.6). The quantity B_j is not the proportion removed at x_j but rather is a measure of the culling effort at that location (as will become clear in the next paragraph) and can be any nonnegative number. It is reasonable to anticipate that if the B_j's are large, then the population would become extinct if either the x_j's are sufficiently close together or the diffusivity D is sufficiently large. This is because in the limiting case when the B_j's are all infinite, one can imagine that the problem effectively would decompose into infinitely many uncoupled problems each consisting of the partial differential equation in (3.1) on the finite domain consisting of the interval between two adjacent culling locations, subject to homogeneous Dirichlet boundary conditions.

The positioning of the delta function in (3.1) is such that the solution $u_m(x,t)$ will be continuous in x, but its derivative $\partial u_m/\partial x$ will not. If we integrate (3.1) from x_j^- to x_j^+, the result is

$$D\left[\left(\frac{\partial u_m}{\partial x}\right)_{x_j^+} - \left(\frac{\partial u_m}{\partial x}\right)_{x_j^-}\right] = B_j u_m(x_j,t). \tag{3.2}$$

Keeping in mind that the Laplacian representation for diffusion comes about from using the formula $J = -D\partial u_m/\partial x$ for the flux $J(x,t)$ (defined as the net rate at which individuals cross x in the positive x direction), then if we imagine the domain to be broken up into subdomains defined by the culling locations, (3.2) has the

interpretation that individuals that leave the subdomain $[x_j, x_{j+1}]$ at x_j do so either by being culled at x_j, or by entering the adjacent subdomain $[x_{j-1}, x_j]$. The culling effort at x_j is B_j, and the culling yield at this location is $B_j u_m(x_j, t)$ per unit time, i.e., proportional to the density at x_j. This leads us to expect that (3.1) should have a positivity preserving property, which is what we shall prove next. For the analysis of the present section, assumption (2.7) will be replaced by the following:

$$
\begin{aligned}
&\cdots < x_{-2} < x_{-1} < x_0 < x_1 < x_2 < \cdots \\
&\text{with } x_n \to \infty \text{ and } x_{-n} \to -\infty \text{ as } n \to \infty, \\
&B_j \geq 0 \quad \forall j = 0, \pm 1, \pm 2, \ldots, \\
&b(0) = 0, \quad b'(0) > 0, \quad b(u_m) > 0 \quad \forall u_m > 0, \\
&d(0) = 0, \quad d \in C^1[0, \infty), \quad d'(0) > 0, \quad d(u_m) > 0 \quad \forall u_m > 0.
\end{aligned} \tag{3.3}
$$

PROPOSITION 3.1. *Let* (3.3) *hold. Then all solutions of* (3.1) *which decay to zero as* $|x| \to \infty$ *for all* $t \geq 0$ *remain nonnegative for all* $t > 0$.

Proof. Let us make a C^1 extension to the definition of the death function to $u_m < 0$ by defining $d(u_m) = d'(0)u_m$ when $u_m < 0$. Then $d \in C^1(\mathbf{R})$. Let us first prove nonnegativity of $u_m(x,t)$ for $t \in (0, \tau]$ only. The proof is by contradiction. Suppose u_m goes negative on this time interval. Since $u_m(\pm\infty, t) = 0$, $u_m(x,t)$ must then attain a negative global minimum on the set $(x,t) \in (-\infty, \infty) \times (0, \tau]$. Let us first consider the possibility that the minimum is attained at a point (x^*, t^*) where x^* is not one of the culling sites x_j. Then x^* is in some open interval throughout which the delta function in (3.1) is inactive. Thus, $u_m(x^*, t^*) < 0$, $u_{m,xx}(x^*, t^*) \geq 0$, and $u_{m,t}(x^*, t^*) \leq 0$ (noting that the minimum could be at a point with $t^* = \tau$). Since $t^* - \tau \leq 0$, the adult recruitment term in (3.1) is nonnegative at (x^*, t^*). Using our extension of the death function to $u_m < 0$, it follows that

$$
\underbrace{\frac{\partial u_m}{\partial t}(x^*, t^*)}_{\leq 0} = \underbrace{D \frac{\partial^2 u_m}{\partial x^2}(x^*, t^*)}_{\geq 0} + e^{-\mu\tau} \underbrace{b(u_m(x^*, t^* - \tau))}_{\geq 0} - d'(0) \underbrace{u_m(x^*, t^*)}_{< 0},
$$

which is a contradiction. Now suppose that the negative global minimum is attained at a point (x^*, t^*) where x^* is one of the x_j. The delta function is active, and the above argument fails. As a function of x, the function $u_m(x,t)$ must now show cusp-like behavior, with $u_m(x^*, t^*) < 0$, $u_{m,x}(x^{*-}, t^*) \leq 0$, and $u_{m,x}(x^{*+}, t^*) \geq 0$ (if, for example, the second of these were violated, then, for x just larger than x^*, $u_m(x, t^*)$ would be below $u_m(x^*, t^*)$, contradicting (x^*, t^*) being the global minimum). Using this information in (3.2) at time t^* gives

$$
D \underbrace{\left(\frac{\partial u_m}{\partial x} \right)_{x^{*+}}}_{\geq 0} - D \underbrace{\left(\frac{\partial u_m}{\partial x} \right)_{x^{*-}}}_{\leq 0} = B_j \underbrace{u_m(x^*, t^*)}_{< 0},
$$

a contradiction. Thus $u_m(x,t) \geq 0$ for times $t \in (0, \tau]$. By the method of steps, $u_m(x,t) \geq 0$ for all $t > 0$, and the proof is complete. ∎

The linearization of (3.1) about the zero solution is

$$
\begin{aligned}
\frac{\partial u_m}{\partial t}(x,t) = D \frac{\partial^2 u_m}{\partial x^2}(x,t) &+ e^{-\mu\tau} b'(0) u_m(x, t-\tau) - d'(0) u_m(x,t) \\
&- \sum_{j=-\infty}^{\infty} B_j u_m(x_j, t) \delta(x - x_j).
\end{aligned} \tag{3.4}
$$

We will prove the following theorem giving conditions under which it is predicted that extinction will result. The quantity $B_{\inf}$ defined below embodies information on the spacing of the culling locations. The analysis uses the Euler–Maclaurin summation formula and therefore has to be interpreted in an approximate sense.

THEOREM 3.2. *Let* (3.3) *hold. Let* $X(\xi) : \mathbf{R} \to \mathbf{R}$ *be a strictly monotonically increasing differentiable function with the property that* $X(j) = x_j$ *for each* $j \in \mathbf{Z}$, *and let* $B(\xi) : \mathbf{R} \to [0, \infty)$ *be the piecewise linear function such that* $B(j) = B_j$ *for all* $j \in \mathbf{Z}$. *If*

$$e^{-\mu\tau} b'(0) < d'(0) + B_{\inf}, \tag{3.5}$$

where

$$B_{\inf} = \inf_{y \in \mathbf{R}} \left\{ \frac{B(y)}{X'(y)} \right\},$$

then, provided the derivative of the function $\xi \to B(\xi) u_m^2(X(\xi), t)$ *is not too high, the solution* $u_m(x, t)$ *of the linearized problem* (3.4) *satisfies* $u_m(x, t) \to 0$ *in* L^2 *as* $t \to \infty$, *according to an analysis based on the Euler–Maclaurin summation formula.*

Proof. First note the following alternative formula for $B_{\inf}$:

$$B_{\inf} = \inf_{y \in \mathbf{R}} \left\{ B(X^{-1}(y))(X^{-1})'(y) \right\}. \tag{3.6}$$

We multiply (3.4) by $u_m(x, t)$ and then integrate with respect to x over $(-\infty, \infty)$. As in the previous section, care needs to be taken to ensure that the effect of the delta function is not taken care of twice over. One approach (the approach we shall adopt) is to remove the last term in (3.4) and account for its presence in the way we treat the Laplacian term, using (3.2). The Laplacian term will be dealt with via integration by parts, and (3.2) will be used to take account of the effect of the discontinuities in the spatial derivative of u_m, thereby fully accounting for the effect of the delta function in (3.4). In fact,

$$\begin{aligned}
&D \int_{-\infty}^{\infty} u_m \frac{\partial^2 u_m}{\partial x^2}\, dx \\
&= D \sum_{j=-\infty}^{\infty} \int_{x_{j-1}}^{x_j} u_m \frac{\partial^2 u_m}{\partial x^2}\, dx \\
&= D \sum_{j=-\infty}^{\infty} \left(u_m(x_j, t) \frac{\partial u_m}{\partial x}(x_j^-, t) - u_m(x_{j-1}, t) \frac{\partial u_m}{\partial x}(x_{j-1}^+, t) - \int_{x_{j-1}}^{x_j} \left(\frac{\partial u_m}{\partial x} \right)^2 dx \right) \\
&= \sum_{j=-\infty}^{\infty} \left(- B_j u_m^2(x_j, t) + D u_m(x_j, t) \frac{\partial u_m}{\partial x}(x_j^+, t) - D u_m(x_{j-1}, t) \frac{\partial u_m}{\partial x}(x_{j-1}^+, t) \right. \\
&\quad \left. - D \int_{x_{j-1}}^{x_j} \left(\frac{\partial u_m}{\partial x} \right)^2 dx \right) \quad \text{using (3.2)} \\
&= - \sum_{j=-\infty}^{\infty} B_j u_m^2(x_j, t) - D \int_{-\infty}^{\infty} \left(\frac{\partial u_m}{\partial x} \right)^2 dx
\end{aligned}$$

since a telescoping series is involved. Therefore (3.4) becomes

$$\frac{1}{2}\frac{d}{dt}\|u_m(t)\|^2 = -D\int_{-\infty}^{\infty}\left(\frac{\partial u_m}{\partial x}\right)^2 dx + e^{-\mu\tau}b'(0)\int_{-\infty}^{\infty} u_m(x,t)u_m(x,t-\tau)\,dx$$

$$-d'(0)\|u_m(t)\|^2 - \sum_{j=-\infty}^{\infty} B_j u_m^2(x_j,t), \tag{3.7}$$

where

$$\|u_m(t)\| = \|u_m(\cdot,t)\| = \left(\int_{-\infty}^{\infty} u_m^2(x,t)\,dx\right)^{\frac{1}{2}}.$$

For compactness of notation, where $u_m(x,t)$ appears under a norm we shall write it simply as $u_m(t)$. Our aim is to show convergence of $u_m(x,t)$ to zero in L^2, i.e., that $\|u_m(t)\| \to 0$ as $t \to \infty$. From (3.7) it follows that

$$\|u_m(t)\|\frac{d}{dt}\|u_m(t)\| \le e^{-\mu\tau}b'(0)\|u_m(t)\|\|u_m(t-\tau)\| - d'(0)\|u_m(t)\|^2$$

$$-\sum_{j=-\infty}^{\infty} B_j u_m^2(x_j,t), \tag{3.8}$$

where we used the Cauchy–Schwarz inequality on the delay term.

Euler–Maclaurin summation can be used to approximate the last term in (3.8) as

$$\sum_{j=-\infty}^{\infty} B_j u_m^2(x_j,t) \approx \int_{-\infty}^{\infty} B(\xi)u_m^2(X(\xi),t)\,d\xi$$

which, on making the substitution $y = X(\xi)$, becomes

$$\int_{-\infty}^{\infty} B(X^{-1}(y))u_m^2(y,t)(X^{-1})'(y)\,dy \tag{3.9}$$

$$\ge \inf_{y\in\mathbf{R}}\left\{B(X^{-1}(y))(X^{-1})'(y)\right\}\|u_m(t)\|^2 \tag{3.10}$$

$$= B_{\inf}\|u_m(t)\|^2$$

by the alternative formula (3.6) for $B_{\inf}$. Using this estimate in (3.8) and dividing through by $\|u_m(t)\|$, we get

$$\frac{d}{dt}\|u_m(t)\| \le e^{-\mu\tau}b'(0)\|u_m(t-\tau)\| - (d'(0) + B_{\inf})\,\|u_m(t)\|. \tag{3.11}$$

From this, we can conclude (using similar methods to those discussed earlier) that $\|u_m(t)\| \to 0$ as $t \to \infty$ if

$$d'(0) + B_{\inf} > e^{-\mu\tau}b'(0), \tag{3.12}$$

which holds by hypothesis. The proof is complete. □

The quantity $B_{\inf}$ has the interpretation of being an infimum culling rate per unit density per unit length, and (3.5) states that it must exceed the adult recruitment rate minus the natural death rate, per unit density per unit length, at low densities.

Let us discuss the situations in which the Euler–Maclaurin summation as used here might lose its ability to predict accurate results. Essentially, we are assuming that the derivative of the function $\xi \to B(\xi)u_m^2(X(\xi),t)$ is not too high, and one situation in which this assumption might lose its validity is if the culling is aggressive but the culling sites are spaced far apart. Very aggressive culling would result in the population being effectively zero at the actual culling sites, but if these are far apart (or if there is very low diffusion), there is no reason why the species should not survive within at least some of the (now decoupled) subdomains $[x_j, x_{j+1}]$, essentially since individuals would be unlikely to wander into a culling site. This can be investigated by solving (3.4) (without the summation term) on the domain $x \in (x_j, x_{j+1})$ subject to homogeneous Dirichlet boundary conditions. Trial solutions of the form

$$u_m(x,t) = e^{\lambda t} \sin\left\{\frac{n\pi(x-x_j)}{x_{j+1}-x_j}\right\}, \qquad n = 1,2,3,\ldots,$$

exist whenever

$$\lambda + \frac{Dn^2\pi^2}{(x_{j+1}-x_j)^2} + d'(0) = b'(0)e^{-\mu\tau}e^{-\lambda\tau}, \tag{3.13}$$

which is another transcendental equation for λ that can be tackled using ideas similar to those presented earlier. Specifically it is possible to show that if

$$e^{-\mu\tau}b'(0) < d'(0) + \frac{D\pi^2}{(x_{j+1}-x_j)^2},$$

then all roots λ of (3.13) satisfy $\operatorname{Re}\lambda < 0$ for every $n = 1,2,3,\ldots$, giving a condition for extinction of the species inhabiting $[x_j, x_{j+1}]$, in this case of intensive culling at sites spaced far apart. This condition says that, at low densities, adult recruitment is not sufficient to offset deaths together with losses at the ends of the domain where culling is occurring. If the above condition is reversed, then one can show that (3.13) (with $n = 1$) has a real positive root λ, so that the species can survive in the subdomain $[x_j, x_{j+1}]$.

4. Discussion. For the purely time-dependent model the most important result we have proved concerning (2.8) is Theorem 2.4, which addresses the situation when, at low densities, adult recruitment outweighs natural mortality. In this situation condition (2.23) essentially describes culling regimes that will result in extinction. The condition involves the proportions b_j removed at the cull times t_j, and a function $t(\xi)$, the derivative of which can be viewed as a measure of the spacing of the cull times t_j.

From condition (2.23) one can make several inferences. If the culling effort is very small, i.e., at each cull only a small proportion b_j of the individuals are removed (which could still vary from cull to cull), then no matter how small this effort is, provided $\inf_{j\in\mathbf{N}} b_j > 0$, extinction can still result if the culling occurs sufficiently frequently in the sense that $t'(j)$ is sufficiently small for each j. A period of more aggressive culling (i.e., larger b_j for several consecutive j) can result in extinction even when the culls are less frequent. An obvious particular case is that in which the culls are equally spaced in time; i.e., $t_j = jT$ for $j = 1,2,3,\ldots$ and some constant $T > 0$, and the same proportion b^* is removed at each cull. In this case the only obvious choice for the function $t(\xi)$ is $t(\xi) = T\xi$, and thus condition (2.23) can be put in the form

$$e^{-\mu\tau}b'(0) < d'(0) + \frac{b^*}{T}$$

which says that, at low densities, the per capita death rate plus the proportion culled per unit time is too high to be compensated for by adult recruitment. Thus, the condition makes sense and is what we would expect in this particular case of a fixed proportion being culled at equally spaced culling times.

Condition (2.23) fails if even just one of the b_j is zero; i.e., there is a "cull," which we might call a zero cull, at which no animals are killed. However, provided only a finite number of the b_j are zero, there will exist a time beyond which all culls are "proper" culls (i.e., culls with $b_j > 0$), and one could shift the origin of time appropriately so that in condition (2.23) the infimum would be taken starting at the first proper cull having no subsequent zero culls. More interesting is the possibility of infinitely many zero culls. Mathematically, the most obvious solution is to remove them by relabelling the sequence t_j (i.e., passing to a subsequence of the original). This would, however, have the effect of changing the interpolating function $t(\xi)$ and in particular of increasing its derivative so that (2.23) would be less likely to hold. The outcome is that the population is less likely to be driven to extinction as expected.

For the model of section 3, which attempts to study culling continuously in time but at discrete points in space, one can draw inferences analogous to those above for the time-dependent model. The condition in Theorem 3.2 predicts extinction if the culling effort as described by the function $B(y)$ is sufficiently large in a sense that also involves the spacing apart of the culling sites (as described by the function $X(y)$) as we would anticipate. If the culling sites are close together, then X will have a small derivative and so B_{inf} is more likely to be large enough to satisfy (3.5).

Acknowledgment. We would like to thank the referees for their valuable suggestions which are much appreciated.

RAY SOLUTION OF A SINGULARLY PERTURBED ELLIPTIC PDE WITH APPLICATIONS TO COMMUNICATIONS NETWORKS*

DIEGO DOMINICI† AND CHARLES KNESSL‡

Abstract. We analyze a second order, linear, elliptic PDE with mixed boundary conditions. This problem arose as a limiting case of a Markov-modulated queueing model for data handling switches in communications networks. We use singular perturbation methods to analyze the problem. In particular we use the ray method to solve the PDE in the limit where convection dominates diffusion. We show that there are both interior and boundary caustics, as well as a cusp point where two caustics meet, an internal layer, boundary layers, and a corner layer. Our analysis leads to approximate formulas for the queue length (or buffer content) distribution at the switch.

Key words. asymptotics, elliptic PDE, ray method, probability distribution

1. Introduction.

In a model proposed by Anick, Mitra, and Sondhi [1], a buffer receives messages from N statistically independent and identical information sources, which asynchronously alternate between exponentially distributed periods in the "on" and "off" states. While "on," a source transmits data at unit rate. The buffer depletes through an output channel, with a given maximum rate of transmission C. The rate at which a source turns "on" is equal to λ, and the "off" rate is μ. If $C < N$, the buffer may be nonempty, and the condition $\frac{\lambda}{\lambda+\mu}N < C$ is needed for stability. This simply says that the mean number of "on" sources (each transmitting data at unit rate) must be less than the total transmission capacity of the channel. This model is analyzed exactly in [1], and the asymptotic limit $N \to \infty$, with $\frac{C}{N} = \frac{\lambda}{\lambda+\mu} + O\left(N^{-\frac{1}{2}}\right)$, is studied in [21]. This limit is referred to as "heavy traffic."

Analyzing the steady state joint probability distribution of the number of active sources and the buffer content involves solving a system of N linear ODEs. In heavy traffic this can be simplified to a backward-forward parabolic PDE of the type in (1.2). This model has the disadvantage of treating the buffer content as a deterministic fluid.

These types of fluid models have received much recent attention in the literature. They have been used as models of production lines with multiple stages [29], statistical multiplexers in asynchronous transfer mode (ATM) networks [25, 26, 30], packet speech multiplexers [31], buffer storage in manufacturing models [32], buffer memory in store-and-forward systems [15], and voice packet communications systems [8].

Among the main quantities of interest in fluid models are tail probabilities, i.e., the probability that the fluid or buffer level exceeds some prescribed large value. These were studied in [10, 27, 22]. The tail probabilities can be used to estimate loss

of information (of say, voice) on packet switched models. The tail behavior may be computed via the type of asymptotic analysis presented here.

A modification of the basic model in [1], which allows for service variability, is as follows. Again there are N independent and identical sources. When a source is "on" it generates a Poisson arrival stream to a queue. In the "off" state no arrivals are generated. The service time distribution is allowed to be general. The model just described may be called a Markov-modulated M/G/1 queue.

In [20] it is shown that the joint steady state distribution of the number of active sources, the queue length, and the elapsed service time of the customer currently being served satisfies a complicated system of integro-differential equations. In the heavy traffic limit, where $N \to \infty$ and the average arrival rate is close to the mean service rate, this system may be approximated by the following BVP:

$$\begin{aligned} Df_{yy} + (c-\xi)f_y + f_{\xi\xi} + (\xi f)_\xi &= 0, \qquad 0 < y < \infty,\ -\infty < \xi < \infty, \\ Df_y(0,\xi) + (c-\xi)f(0,\xi) &= 0, \qquad -\infty < \xi < \infty, \\ \int_{-\infty}^{\infty}\int_0^{\infty} f(y,\xi)\,dy\,d\xi &= 1. \end{aligned} \tag{1.1}$$

Here the variable y is related to the queue length, ξ corresponds to a scaled measure of the number of "on" sources above their mean value, $c > 0$ is the normalized excess of the service rate over the mean arrival rate, and $D > 0$ measures variability effects in the service time distribution.

The exact solution to (1.1) was analyzed in [20]. It is not completely explicit and involves finding one eigenvector of an infinite matrix, whose elements are complicated expressions involving Laguerre functions. This (infinite!) eigenvector must be computed numerically. In the same paper the limit $D \to \infty$ was considered. Now the matrix becomes diagonally dominant, and much more explicit results can be obtained.

The (highly singular) limit $D \to 0$ was studied in [9], resulting in a very complicated asymptotic solution involving contour integrals of parabolic cylinder and Airy functions. When $D = 0$ we see that the problem (1.1) degenerates into a parabolic one that is forward parabolic for $\xi > c$ and backward parabolic for $\xi < c$:

$$\begin{aligned} (c-\xi)\Im_y + \Im_{\xi\xi} + (\xi\Im)_\xi &= 0, \qquad 0 < y < \infty,\ -\infty < \xi < \infty, \\ \Im(0,\xi) &= 0, \qquad c < \xi, \\ \int_{-\infty}^{\infty} \Im(\infty,\xi)\,d\xi &= 1. \end{aligned} \tag{1.2}$$

Now $\Im$ is a density in ξ and a distribution in y. The problem (1.2) corresponds to the heavy traffic limit of the fluid model in [1]. Knessl and Morrison [21] derived the exact solution of (1.2). The limit $c \to \infty$ was studied in [22] by using the saddle point method and in [23] by using the ray method [18].

The study of backward-forward parabolic PDEs goes back to [12], and more recent analyses appear in [3, 4, 5, 11, 19]. Such problems arise in a wide variety of applications, such as counter-current separators [14], mean exit times [13], the Milne problem of statistical physics [6], neutron transport theory [16], and diffusion in spatially varying convection fields [17]. The interesting mathematical feature of these problems is that the initial (or boundary) conditions can be imposed only where the PDE is forward parabolic. This "half-boundary condition" makes these problems difficult to analyze.

In this paper we will solve (1.1) asymptotically in the limit $c \to \infty$ by using the ray method, the boundary layer method, and asymptotic matching [7]. In doing so, we shall analyze no fewer than seven different scales, and one more will be briefly discussed in the conclusion section. The asymptotic structure of (1.1) proves much more complicated than that of (1.2) in the same limit [23].

To analyze (1.1) for large c, it is convenient to introduce the new variables $\eta = \xi/c$ and $x = y/c$ and the small parameter $\varepsilon = c^{-2}$. Then (1.1) becomes the following problem for $F(x,\eta) = \varepsilon^{-1} f(y,\xi)$:

$$\begin{aligned} \varepsilon(DF_{xx} + F_{\eta\eta}) + (1-\eta)F_x + \eta F_\eta + F = 0, \quad & x \geq 0, \ -\infty < \eta < \infty, \\ D\varepsilon F_x(0,\eta) + (1-\eta)F(0,\eta) = 0, \quad & -\infty < \eta < \infty, \\ \int_{-\infty}^{\infty}\int_{0}^{\infty} F(x,\eta)dxd\eta = 1. & \end{aligned} \tag{1.3}$$

The boundary condition together with the normalization condition implies that the marginal distribution in η is the Gaussian

$$\int_0^\infty F(x,\eta)dx = \frac{1}{\sqrt{2\pi\varepsilon}} \exp\left(-\frac{\eta^2}{2\varepsilon}\right). \tag{1.4}$$

An important quantity to compute is the marginal distribution in the x variable, i.e.,

$$M(x) = \int_{-\infty}^{\infty} F(x,\eta)d\eta. \tag{1.5}$$

In section 2 we consider the case when x is close to 0 and $\eta < 1$; this will be very useful to match with other asymptotic solutions. Section 3 is dedicated to using the ray method to analyze (1.3) for $\varepsilon \to 0$ with x, η fixed. This yields asymptotic solutions in two main regions separated by the curve $x = \eta - \ln(\eta) - 1$, $\eta > 1$. We also derive boundary layer solutions for $x = O(\varepsilon^{\frac{2}{3}})$ and $\eta > 1$, $x = O(\varepsilon)$ and $\eta > 1$, a corner layer solution in the neighborhood of the point $(0,1)$, and in section 4 a transition layer solution along $x = \eta - \ln(\eta) - 1$. We show that all the solutions asymptotically match to each other in the appropriate limits and also agree with the approximation found in section 2. In section 5 we summarize and discuss the main results. In section 6 we check the identity (1.4) for $F(x,\eta)$ and compute the marginal distribution in x.

2. An expansion for small x. To solve (1.3) for ε small, we will first consider the scaling $x = O(\varepsilon)$. Thus we introduce the variable $v = x/\varepsilon$ and convert (1.3) into the problem

$$\begin{aligned} DF_{vv} + (1-\eta)F_v + \varepsilon(\eta F_\eta + F) + \varepsilon^2 F_{\eta\eta} = 0, \quad & v \geq 0, \ -\infty < \eta < \infty, \\ DF_v(0,\eta) + (1-\eta)F(0,\eta) = 0, \quad & -\infty < \eta < \infty, \\ \int_{-\infty}^{\infty}\int_{0}^{\infty} F(v,\eta)dvd\eta = \frac{1}{\varepsilon}. & \end{aligned} \tag{2.1}$$

On this scale (1.4) transforms to

$$\int_0^\infty F(v,\eta)dv = \frac{\varepsilon^{-\frac{3}{2}}}{\sqrt{2\pi}} \exp\left(-\frac{\eta^2}{2\varepsilon}\right). \tag{2.2}$$

We consider solutions to (2.1) which have the asymptotic form

$$F(v,\eta) \sim \frac{\varepsilon^{-\frac{3}{2}}}{\sqrt{2\pi}} \exp\left(-\frac{\eta^2}{2\varepsilon}\right)\left[F^{(0)}(v,\eta) + \sqrt{\varepsilon}F^{(1)}(v,\eta) + O(\varepsilon)\right]. \tag{2.3}$$

Substituting (2.3) into (2.1) and equating the coefficients of like powers of ε we get to leading order the equation

$$DF^{(0)}_{vv} + (1-\eta)F^{(0)}_v = 0 \tag{2.4}$$

with boundary condition

$$DF^{(0)}_v(0,\eta) + (1-\eta)F^{(0)}(0,\eta) = 0, \quad -\infty < \eta < \infty. \tag{2.5}$$

Solving for $F^{(0)}(v,\eta)$ and taking into account (2.2) we have obtained the following proposition.

PROPOSITION 2.1. *For $x = v\varepsilon = O(\varepsilon)$, (1.3) has the asymptotic solution to leading order*

$$F(v,\eta) \sim \varepsilon^{-\frac{3}{2}} \frac{1-\eta}{D\sqrt{2\pi}} \exp\left[-\frac{\eta^2}{2\varepsilon} - \frac{(1-\eta)v}{D}\right], \quad \eta < 1. \tag{2.6}$$

We see that for $\eta = \overline{\eta}\sqrt{\varepsilon}$, $\overline{\eta} = O(1)$, the solution decouples into a Gaussian in $\overline{\eta}$ times an exponential function of v,

$$F(v,\overline{\eta}) \sim \varepsilon^{-\frac{3}{2}} \frac{1}{\sqrt{2\pi}} \exp\left\{-\frac{\overline{\eta}^2}{2}\right\} \times \frac{1}{D} \exp\left\{-\frac{v}{D}\right\}. \tag{2.7}$$

Such a decoupling was also observed in [20], where (1.3) was analyzed in the limit $D \to \infty$ with c fixed. The cases where x is small and $\eta > 1$ or $\eta \approx 1$ are treated in subsections 3.6 and 3.7.

3. The ray expansion. Now we consider solutions of (1.3) which have the asymptotic form

$$F(x,\eta) \sim \varepsilon^{\nu_1} \exp\left[\frac{1}{\varepsilon}\Psi(x,\eta)\right] K(x,\eta). \tag{3.1}$$

We substitute (3.1) into (1.3) and equate the coefficients of the lowest power of ε to get the eikonal equation for Ψ,

$$D\left(\Psi_x\right)^2 + \left(\Psi_\eta\right)^2 + \eta\left(\Psi_\eta - \Psi_x\right) + \Psi_x = 0, \quad \Psi_x(0,\eta) = \frac{\eta - 1}{D}. \tag{3.2}$$

Equating the coefficients of the next power of ε yields the transport equation for K,

$$DK\Psi_{xx} + K_x + 2DK_x\Psi_x + K\Psi_{\eta\eta} + \eta K_\eta + 2K_\eta\Psi_\eta - \eta K_x + K = 0, \quad K_x(0,\eta) = 0.$$

3.1. The rays. We solve (3.2) by introducing the characteristic curves or rays $[x(t),\eta(t)]$, written in terms of a parameter t. We first consider rays starting from the η-axis, and impose the initial conditions $[x(0),\eta(0)] = [0,s]$. The characteristic ODEs for (3.2) are

$$\begin{aligned}
\frac{dx}{dt} &= -2D\Psi_x + \eta - 1, \quad x(0) = 0,\\
\frac{d\eta}{dt} &= -2\Psi_\eta - \eta, \quad \eta(0) = s,\\
\frac{d\Psi_x}{dt} &= 0, \quad \frac{d\Psi_\eta}{dt} = \Psi_\eta - \Psi_x,\\
\frac{d\Psi}{dt} &= \Psi_x\frac{dx}{dt} + \Psi_\eta\frac{d\eta}{dt} = -D\left(\Psi_x\right)^2 - \left(\Psi_\eta\right)^2.
\end{aligned} \tag{3.3}$$

From (2.6) we note that $\Psi(0,\eta) = -\eta^2/2$, which implies that $\Psi\,[x(0),\eta(0)] = \Psi(0,s) = -s^2/2$.

Setting $\Psi_x(0,s) = A$, $\Psi_\eta(0,s) = B$ and solving (3.3) yields

$$\begin{aligned} x &= (A-B)e^t - (A+B+s)e^{-t} - (2DA+2A+1)t + 2B + s,\\ \eta &= (A-B)e^t + (A+B+s)e^{-t} - 2A,\\ \Psi_x &= A, \quad \Psi_\eta = (B-A)e^t + A,\\ \Psi &= -\frac{1}{2}(A-B)^2e^{2t} + 2A(A-B)e^t - A^2(D+1)t + AB - \frac{3}{2}A^2 + \frac{1}{2}B^2 - \frac{s^2}{2}. \end{aligned} \tag{3.4}$$

The constants A, B can be determined by evaluating the eikonal equation (3.2) at $x = 0$ (corresponding to $t = 0$), and also using the boundary condition from (1.3). This yields $A = \frac{s-1}{D}$ and $B = -s$ or $B = 0$. To decide which value of B is the right one, we take the derivative of Ψ with respect to s at $t = 0$,

$$-s = \frac{d}{ds}\Psi(0,s) = A\frac{d}{ds}x(0,s) + B\frac{d}{ds}\eta(0,s) = B. \tag{3.5}$$

Replacing A, B in (3.4) we get

$$\begin{aligned} x &= e^t - 1 - t - \frac{(D+1)(2t-e^t) + D + e^{-t}}{D}(s-1),\\ \eta &= e^t + \frac{e^{-t} + (D+1)e^t - 2}{D}(s-1),\\ \Psi &= -\frac{1}{2}e^{2t} + \frac{2e^t - (D+1)e^{2t} - 1}{D}(s-1)\\ &\quad + \frac{-1 + [4e^t - 2(t+1)](D+1) - e^{2t}(D+1)^2}{2D^2}(s-1)^2. \end{aligned} \tag{3.6}$$

For $t \geq 0$ and each value of s, the first two equations in (3.6) determine a ray in the (x,η)-plane, which starts from $(0,s)$ at $t = 0$. For $s = 1$ and $s = \frac{1}{D+1}$, we can eliminate t from (3.6) and obtain the explicit expressions

$$\begin{aligned} &x = X_0(\eta) = \eta - \ln(\eta) - 1, \quad s = 1, \quad \eta \geq 1,\\ &x = \frac{1}{D+1} - \eta - \ln(2 - \eta - D\eta), \quad s = \frac{1}{D+1}, \quad \frac{1}{D+1} \leq \eta < \frac{2}{D+1}. \end{aligned} \tag{3.7}$$

For $s > \frac{1}{D+1}$, we have both $x(t)$ and $\eta(t)$ increasing for $t > 0$. For $s = \frac{1}{D+1}$, $x(t)$ increases and $\eta(t)$ is asymptotic to $\frac{2}{D+1}$.

For $s < \frac{1}{D+1}$ the rays "turn around" and return to $x = 0$ for some $t^* > 0$, with $x(t^*) = 0$, $\eta(t^*) < s$. The maximum value in x reached by the ray occurs at $t = t_{x\,\max}$:

$$t_{x\,\max} = \ln\left[\frac{-2sD + D + 2 - 2s + \sqrt{D\,(4s^2D - 4sD - 8s + 4s^2 + D + 4)}}{2(1 - s - Ds)}\right].$$

For $0 < s < \frac{1}{D+1}$ the ray reaches its maximum in η at $t = t_{\eta\,\max}$:

$$t_{\eta\,\max} = \frac{1}{2}\ln\left[\frac{1-s}{1-s-Ds}\right], \quad \eta\,(t_{\eta\,\max}) = 2\frac{1-D}{s} + \frac{2s + 2D - 2 - s^2D - sD^2}{s\sqrt{(1-s)\,(1-s-Ds)}}.$$

For $s \leq 0$, $\eta(t)$ decreases for $0 < t < t^*$.

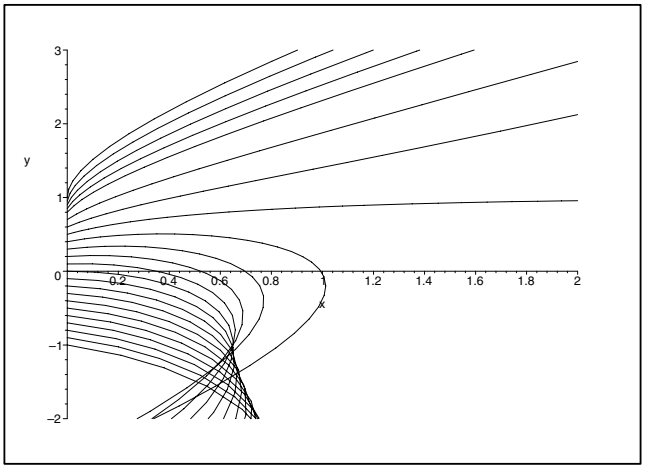

FIG. 3.1. *A sketch of the rays in Region* I *for* $D = 1$.

Solving for s in the η-equation (3.6) yields

$$s = \frac{e^{-t} + e^{t} - 2 + D\eta}{e^{-t} + (D+1)e^{t} - 2}, \tag{3.8}$$

and solving in the x-equation gives

$$s = \frac{-e^{t} + e^{-t} + Dt + 2t - Dx}{-De^{t} - e^{t} + e^{-t} + 2Dt + 2t + D}. \tag{3.9}$$

Equating (3.8) and (3.9) we get the implicit equation $R \equiv 0$ for the rays, where

$$\begin{aligned} R(x,\eta,t) = {} & \left[e^{-t} + (D+1)e^{t} - 2\right] x + (3 - D\eta - t - Dt - \eta)e^{t} + (1 + t + \eta)e^{-t} \\ & - 4 - 2t + D\eta + 2t\eta + 2D\eta t. \end{aligned}$$

We sketch several of the rays in Figure 3.1. They fill Region I, defined as

$$\text{Region I} \equiv \{x > X_0 = \eta - \ln(\eta) - 1, \quad \eta > 1\} \cup \{x > 0, \quad \eta \le 1\}. \tag{3.10}$$

3.2. Caustics and cusps. The Jacobian of the transformation in (3.6) from Cartesian to ray coordinates is

$$\begin{aligned} J = \frac{dx}{dt}\frac{d\eta}{ds} - \frac{dx}{ds}\frac{d\eta}{dt} = {} & \left[2(t-2)(s-1)D^{-2} + (-2t - 5s + 4ts + 2)D^{-1} - s + 2ts + 1\right] e^{t} \\ & + \left[-2(t+2)(s-1)D^{-2} + (2t - 2ts + 2 - 3s)D^{-1}\right] e^{-t} + 8(s-1)D^{-2} + 4(2s-1)D^{-1}. \end{aligned}$$

When $J = 0$ we can solve for s as a function of t, $S_0 = s\,|_{J=0}$:

$$S_0 = \frac{(-2D - D^2 - 4 + 2Dt + 2t)e^{2t} + 4(D+2)e^{t} - 2(2 + D + Dt + t)}{(-D^2 - 5D - 4 + 2t + 4Dt + 2tD^2)e^{2t} + 8(D+1)e^{t} - 3D - 4 - 2t - 2Dt}. \tag{3.11}$$

The equation for the *caustic(s)*, i.e., the points in the (x,η)-plane at which the Jacobian is zero, can be given in parametric form. We replace s by S_0 in the equation

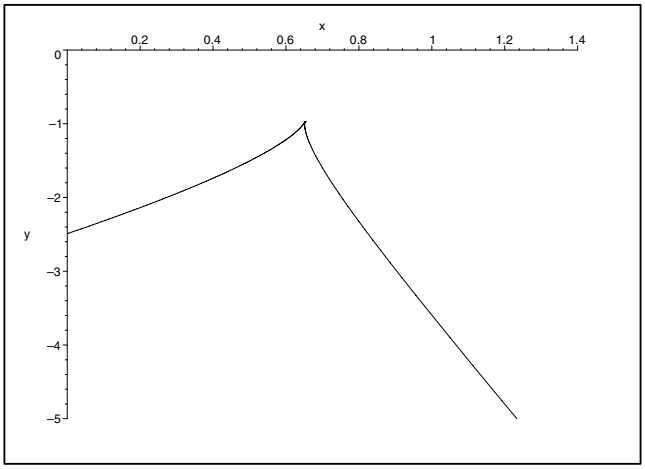

FIG. 3.2. *A sketch of the caustic curves for* $D = 1$.

of the rays, and let $x_{ca} = x(t, S_0)$, $\eta_{ca} = \eta(t, S_0)$:

(3.12)
$$x_{ca} = \left[-(D+1)^2 e^{3t} + (2D^2t^2 - 3tD + D^2t + 2t^2 - 4t + D^2 + 4t^2D + 6D + 8)e^{2t} - 2(3D+7)e^t - e^{-t} + 2(D+1)t^2 + (3D+4)t + 2(D+4)\right] / \left[(2D^2t + 4Dt - 4 + 2t - D^2 - 5D)e^{2t} + 8(D+1)e^t - (3D+4) - 2(D+1)t\right],$$

(3.13)
$$\eta_{ca} = \frac{-(D+1)^2 e^{3t} + 2(2tD + 2t + 2D - 1)e^{2t} + 2(4 - 2t - 2tD - D)e^t + e^{-t} - 6}{(2D^2t + 4Dt - 4 + 2t - D^2 - 5D)e^{2t} + 8(D+1)e^t - (3D+4) - 2(D+1)t}.$$

In Figure 3.2 we sketch the caustic curves for $D = 1$. There is also a cusp where the two caustics meet. Our numerical studies show that the basic structure (i.e., the two caustics coming together as a cusp) occurs for all $D > 0$.

Outside the caustic region, the correspondence between (t, s) and (x, η) is one-to-one. When we are exactly on the caustic curves, the correspondence is two-to-one, and inside the region bounded by the two caustics it is three-to-one. In Figure 3.3 we sketch more densely the rays for $D = 1$ to indicate this correspondence. The evaluation of (3.1) near caustics and cusps is discussed in more detail in section 5.

3.3. The transport equation. Now we shall solve the transport equation by using (3.3) to write it as an ODE along a ray:

$$\frac{dK}{dt} = (D\Psi_{xx} + \Psi_{\eta\eta} + 1)K. \tag{3.14}$$

After some algebra, we can show that

$$D\Psi_{xx} + \Psi_{\eta\eta} + 1 = \frac{1}{2} - \frac{1}{2J}\frac{dJ}{dt}, \tag{3.15}$$

and hence

$$K(x, \eta) = k(s)\frac{e^{\frac{t}{2}}}{\sqrt{J}}. \tag{3.16}$$

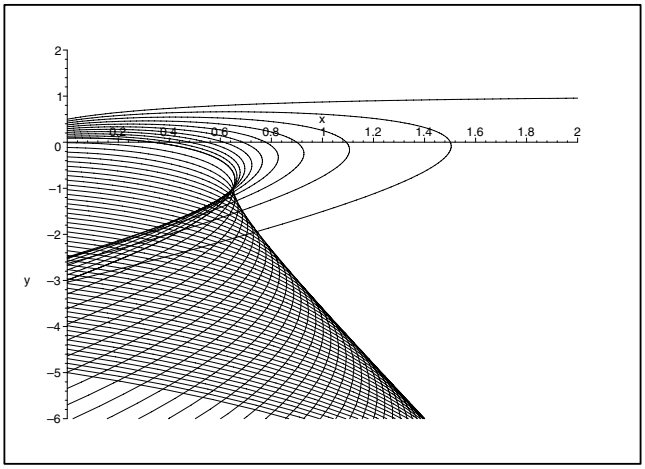

FIG. 3.3. *A sketch of the rays in Region* I *for* $D = 1$.

To determine $k(s)$ we evaluate the previous result at $t = 0$, $K(0, s) = k(s)\frac{1}{\sqrt{1-s}}$. Using the approximation (2.6) and the fact that $s = \eta$ at $t = 0$, we get

$$k(s) = \frac{1}{\sqrt{2\pi D}}(1-s)^{\frac{3}{2}}, \quad s < 1, \quad \text{and} \quad \nu_1 = -\frac{3}{2}. \tag{3.17}$$

The same result can be obtained by using the BC $K_x(0, \eta) = 0$ and fixing the multiplicative constant by normalization. So far we have determined Ψ and K only for $s < 1$. Thus we divide the half-plane $x \geq 0$, $-\infty < \eta < \infty$, into two parts. The portion filled by the rays for $s < 1$ we call Region I, and the remainder of the half-plane we call Region II. The latter is a shadow of the rays (see also Figure 3.1).

To summarize, we have established the following proposition.

PROPOSITION 3.1. *The solution of* (1.3) *in Region* I *is asymptotically given by*

$$F(x, \eta) \sim \varepsilon^{-\frac{3}{2}} K(x, \eta) \exp\left[\frac{1}{\varepsilon}\Psi(x, \eta)\right], \tag{3.18}$$

where

$$\begin{aligned} K(x, \eta) &= \frac{1}{\sqrt{2\pi}}(1-s)^{\frac{3}{2}} \frac{e^{\frac{t}{2}}}{\sqrt{J(t, s)}}, \\ \Psi(x, \eta) &= -\frac{1}{2}e^{2t} + \frac{2e^t - (D+1)e^{2t} - 1}{D}(s-1) \\ &\quad + \frac{-1 + [4e^t - 2(t+1)](D+1) - e^{2t}(D+1)^2}{2D^2}(s-1)^2, \end{aligned} \tag{3.19}$$

(x, η) is related to (t, s) by (3.6)*, and $J(t, s)$ is defined by* (3.11).

3.4. Region II. For this region, we consider solutions of (1.3) which have the asymptotic form

$$F(x, \eta) \sim \varepsilon^{\nu_2} \exp\left[\frac{1}{\varepsilon}\Phi(x, \eta) + \frac{1}{\varepsilon^{\frac{1}{3}}}\Gamma(x, \eta)\right] L(x, \eta). \tag{3.20}$$

The term $\varepsilon^{-\frac{1}{3}}\Gamma(x,\eta)$ in the exponent must be included in order for the expansion to asymptotically match those valid for small x and $\eta > 1$, which we construct later.

It follows that Φ satisfies (3.2), L satisfies the transport equation, and for Γ we get the following PDE:

$$(\eta - 1 - 2D\Phi_x)\Gamma_x - (2\Phi_\eta + \eta)\Gamma_\eta = 0, \tag{3.21}$$

which is equivalent to $\frac{d\Gamma}{d\tau} = 0$. Thus we conclude that Γ is a function of σ only and write $\Gamma(x,\eta) = \Gamma(\sigma)$. Here (τ,σ) are the new parameters for the ray which apply in Region II. Thus a ray starts at $\tau = 0$ from $\eta = \sigma > 1$ and enters the domain for $\tau > 0$.

The solutions of the characteristic equations are

$$\begin{aligned} x &= (b-a)e^{\tau} + (a+b-\sigma)e^{-\tau} + [2a(D+1)-1]\tau - 2b + \sigma, \\ \eta &= (b-a)e^{\tau} - (a+b-\sigma)e^{-\tau} + 2a, \\ \Phi_x &= -a, \quad \Phi_\eta = (a-b)e^{\tau} - a, \\ \Phi &= -a^2(D+1)\tau + 2a\,(a-b)\,(e^{\tau}-1) - \frac{1}{2}\,(a-b)^2\left(e^{2\tau}-1\right) + \Phi_0(\sigma). \end{aligned} \tag{3.22}$$

Here $\Phi_0(\sigma)$ is the value of Φ at $\tau = 0$, which corresponds to the η-axis for $\eta > 1$.

Since from the result for Region I $\frac{dx}{dt} = \frac{(s-1)}{D} = 0$ for $s = 1$, we impose the condition $\frac{dx}{d\tau}(0,\sigma) = 0$ for all $\sigma > 1$. This means that the boundary $x = 0$ will be a caustic curve for $\eta > 1$. Then a has the value

$$a(\sigma) = \frac{1-\sigma}{2D}. \tag{3.23}$$

Evaluating (3.2) at $x = 0$ we get

$$Da^2 + b^2 + \sigma(b-a) + a. \tag{3.24}$$

Using (3.23) in (3.24) and solving for b we find that

$$b = \frac{\sigma}{2} \pm \frac{\sqrt{\beta(\sigma)}}{2\sqrt{D}}, \quad \beta(\sigma) = D\sigma^2 + (\sigma-1)^2\,. \tag{3.25}$$

For small τ we get from (3.22) and (3.23) that $x \sim \left(b - \frac{\sigma}{2}\right)\tau^2$, $\tau \to 0$, and this implies that the solution $b = \frac{\sigma}{2} - \frac{\sqrt{\beta(\sigma)}}{2\sqrt{D}}$ must be rejected, in order that the rays enter the domain $x \geq 0$ as τ increases. Hence,

$$b(\sigma) = \frac{\sigma}{2} + \frac{\sqrt{\beta(\sigma)}}{2\sqrt{D}}. \tag{3.26}$$

To find $\Phi_0(\sigma)$ we impose the continuity condition $\Phi_0(1) = \Psi(0,1) = -\frac{1}{2}$. Since

$$\frac{d}{d\sigma}\Phi(0,\sigma) = -a\frac{d}{d\sigma}x(0,\sigma) - b\frac{d}{d\sigma}\eta(0,\sigma) = -b, \tag{3.27}$$

we conclude that

$$\begin{aligned} \Phi_0(\sigma) = -\frac{1}{2} - \int_1^{\sigma} b\,(u)\,du = -\frac{1}{4} - \frac{\sigma^2}{4} - \frac{1}{4\sqrt{D}}\left\{\left(\sigma - \frac{1}{D+1}\right)\sqrt{\beta(\sigma)}\right. \\ \left. + \frac{D}{(D+1)^{\frac{3}{2}}}\,\mathrm{arcsinh}\left[\frac{(D+1)\sigma - 1}{\sqrt{D}}\right] - \frac{D^{\frac{3}{2}}\sigma}{(D+1)} - \frac{D}{(D+1)^{\frac{3}{2}}}\,\mathrm{arcsinh}\left(\sqrt{D}\right)\right\}. \end{aligned} \tag{3.28}$$

As before, the transport equation can be solved to obtain

$$L(\tau,\sigma) = L_0(\sigma)\frac{e^{\frac{\tau}{2}}}{\sqrt{\widetilde{J}}}, \tag{3.29}$$

where

$$\begin{aligned}\widetilde{J} = \frac{dx}{d\tau}\frac{d\eta}{d\sigma} - \frac{dx}{d\sigma}\frac{d\eta}{d\tau} = &\left\{\left[-\sigma+1+\frac{1}{2}\tau(\sigma-1)\right]D^{-2} + \left[\frac{1}{2}\sqrt{\beta(\sigma)}(\tau-1)\right]D^{-\frac{3}{2}}\right.\\ &\left. + \left(-\sigma-\frac{1}{2}\tau+\tau\sigma\right)D^{-1} + \frac{1}{2}\tau\sqrt{\beta(\sigma)}D^{-\frac{1}{2}} + \frac{1}{2}\tau\sigma\right\}e^{\tau}\\ + &\left\{\left(\frac{1}{2}\tau+1\right)(1-\sigma)D^{-2} + \left[\frac{1}{2}\sqrt{\beta(\sigma)}(\tau+1)\right]D^{-\frac{3}{2}}\right.\\ &\left. + \left(-\sigma+\frac{1}{2}\tau-\tau\sigma\right)D^{-1} + \frac{1}{2}\tau\sqrt{\beta(\sigma)}D^{-\frac{1}{2}} - \frac{1}{2}\tau\sigma\right\}e^{-\tau} + 2(\sigma-1)D^{-2} + 2\sigma D^{-1}.\end{aligned}$$

In Region II, $\widetilde{J}=0$ only for $\tau=0$. To determine $L_0(\sigma)$ and $\Gamma(\sigma)$ we shall analyze the problem for small x, and we will find that not one but two boundary layer expansions are needed to satisfy the boundary conditions (1.3) in this region.

3.5. Approximation for $x = O(\varepsilon^{\frac{2}{3}})$, $\eta > 1$ (inner solution). We introduce the stretched variable $\mu = \varepsilon^{-\frac{2}{3}}x$ and transform (1.3) into

$$(1-\eta)F_\mu + \varepsilon^{\frac{1}{3}}DF_{\mu\mu} + \varepsilon^{\frac{2}{3}}(\eta F_\eta + F) + \varepsilon^{\frac{5}{3}}F_{\eta\eta} = 0. \tag{3.30}$$

We represent F in the asymptotic form

$$F \sim \varepsilon^{\nu_3}\exp\left\{\varepsilon^{-1}\Phi_0(\eta) + \varepsilon^{-\frac{1}{3}}\left[\frac{\eta-1}{2D}\mu + \Gamma(\eta)\right]\right\}\left[R_0(\mu,\eta) + \varepsilon^{\frac{1}{3}}R_1(\mu,\eta)\right], \tag{3.31}$$

which, when inserted into (3.30), gives the following PDEs for R_0, R_1:

$$\begin{aligned}&2D^2\frac{\partial^2 R_0}{\partial\mu^2} + [2\Phi_0'(\eta)+\eta][2D\Gamma'(\eta)+\mu]R_0 = 0,\\ &2D^2\frac{\partial^2 R_1}{\partial\mu^2} + [2\Phi_0'(\eta)+\eta][2D\Gamma'(\eta)+\mu]R_1\\ &\qquad + 2D\left\{[2\Phi_0'(\eta)+\eta]\frac{\partial R_0}{\partial\eta} + [\Phi_0''(\eta)+1]R_0\right\} = 0.\end{aligned} \tag{3.32}$$

Solving (3.32), we get

$$R_0 = C_1(\eta)\mathrm{Ai}\left\{2^{-\frac{1}{3}}D^{-\frac{5}{6}}\beta(\eta)^{\frac{1}{6}}[\mu + 2D\Gamma'(\eta)]\right\}, \tag{3.33}$$

where $\mathrm{Ai}(\cdot)$ denotes the Airy function and $\beta(\eta)$ is given by (3.25). Using (3.33) and solving for R_1, we obtain

$$\begin{aligned}R_1 = &\frac{1}{24}2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{-\frac{5}{6}}C_1(\eta)\beta'(\eta)\overline{\mu}^2\mathrm{Ai}(\overline{\mu}) + [2D\beta(\eta)]^{\frac{1}{3}}C_1(\eta)\Gamma''(\eta)\overline{\mu}\mathrm{Ai}(\overline{\mu}) + C_2(\eta)\mathrm{Ai}(\overline{\mu})\\ &+ \left\{2^{\frac{2}{3}}[D\beta(\eta)]^{\frac{1}{6}}C_1'(\eta) - 2^{-\frac{1}{3}}D^{\frac{2}{3}}\beta(\eta)^{-\frac{1}{3}}C_1(\eta) + \frac{1}{3}2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{-\frac{5}{6}}\alpha(\eta)C_1(\eta)\right\}\mathrm{Ai}'(\overline{\mu})\end{aligned} \tag{3.34}$$

with

$$\overline{\mu} = 2^{-\frac{1}{3}} D^{-\frac{5}{6}} \beta(\eta)^{\frac{1}{6}} \left[\mu + 2D\Gamma'(\eta)\right], \quad \alpha(\eta) = (D+1)\,\eta - 1. \tag{3.35}$$

The function $C_1(\eta)$ will be determined below. This solution can't satisfy the boundary condition (1.3), and thus we require another boundary layer expansion, where $x = o(\varepsilon^{\frac{2}{3}})$.

3.6. Approximation for $x = O(\varepsilon)$, $\eta > 1$ (inner-inner solution). We introduce the variable $v = x/\varepsilon$ and transform (1.3) to

$$DF_{vv} + (1-\eta)F_v + \varepsilon(\eta F_\eta + F) + \varepsilon^2 F_{\eta\eta} = 0, \quad DF_v(0,\eta) + (1-\eta)F(0,\eta) = 0. \tag{3.36}$$

We seek solutions of the form

$$F \sim \varepsilon^{\nu_4} \exp\left\{\frac{1}{\varepsilon}\Phi_0(\eta) + \frac{1}{\varepsilon^{\frac{1}{3}}}\Gamma(\eta) + \frac{1}{2}\frac{\eta-1}{D}v\right\} W(v,\eta). \tag{3.37}$$

Using (3.37) in (3.36) and taking into account that

$$\Phi_0'(\eta) = -b(\eta) = -\left(\frac{\eta}{2} + \frac{\sqrt{D\eta^2 + (\eta-1)^2}}{2\sqrt{D}}\right) \tag{3.38}$$

yields

$$DW_{vv} + (1-\eta)W_v + \Phi_0'(\eta)\left[\Phi_0'(\eta) + \eta\right] W = 0, \quad 2DW_v(0,\eta) + (1-\eta)W(0,\eta) = 0,$$

whose general solution is

$$W(v,\eta) = w(\eta)\left[\frac{1}{2D}(\eta-1)v + 1\right]. \tag{3.39}$$

The next step will be finding a corner layer solution valid in a neighborhood of the point $(0,1)$ that matches to both the approximation (2.6) and the inner-inner solution. This will allow us to determine ν_4 and $w(\eta)$ explicitly.

3.7. Corner layer. Let us first write $F(x,\eta) = \varepsilon^{\nu_5} \exp\left(-\frac{\eta^2}{2\varepsilon}\right) \overline{G}(x,\eta)$, which transforms (1.3) into

$$D\varepsilon\overline{G}_{xx} - \eta\overline{G}_\eta + \varepsilon\overline{G}_{\eta\eta} + (1-\eta)\overline{G}_x = 0, \quad D\varepsilon\overline{G}_x(0,\eta) + (1-\eta)\overline{G}(0,\eta) = 0. \tag{3.40}$$

Then we introduce the stretched variables $\mu = \varepsilon^{-\frac{2}{3}}x$ and $\gamma = \varepsilon^{-\frac{1}{3}}(\eta-1)$, and (3.40) becomes

$$\varepsilon^{\frac{2}{3}}\overline{G}_{\gamma\gamma} - \varepsilon^{\frac{1}{3}}\gamma\overline{G}_\gamma + D\overline{G}_{\mu\mu} - \gamma\overline{G}_\mu - \overline{G}_\gamma = 0, \quad D\overline{G}_\mu(0,\gamma) - \gamma\overline{G}(0,\gamma) = 0. \tag{3.41}$$

To leading order $\overline{G}(\mu,\gamma) \sim G(\mu,\gamma)$, where

$$DG_{\mu\mu} - \gamma G_\mu - G_\gamma = 0, \quad DG_\mu(0,\gamma) - \gamma G(0,\gamma) = 0. \tag{3.42}$$

The solution to (3.42) matches to (2.6) (with $\mu = 0$) if

$$\varepsilon^{\nu_5} G(0,\gamma) \sim \frac{1-\eta}{\sqrt{2\pi}D}\varepsilon^{-\frac{3}{2}} = -\frac{\gamma}{\sqrt{2\pi}D}\varepsilon^{-\frac{7}{6}}, \quad \gamma \to -\infty, \tag{3.43}$$

so that $\nu_5 = -\frac{7}{6}$. In [24] an explicit solution to (3.42) and (3.43) was obtained, with

$$G(\mu,\gamma) = \frac{\exp\left\{\frac{1}{\varepsilon}\left[\frac{\mu\gamma}{2D} - \frac{\gamma^3}{12D}\right]\right\}}{\sqrt{2\pi}2^{\frac{1}{3}}D^{\frac{2}{3}}}\frac{1}{2\pi i}\int_{Br}\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\lambda\right\}\frac{\mathrm{Ai}\left(\lambda + 2^{-\frac{1}{3}}D^{-\frac{2}{3}}\mu\right)}{\left[\mathrm{Ai}\,(\lambda)\right]^2}d\lambda,$$

where Br is a vertical contour in the complex λ-plane on which $\mathrm{Re}(\lambda) \geq 0$ and $\mathrm{Ai}(\cdot)$ is the Airy function.

By combining the preceding results we have, on the corner scale,

$$\begin{aligned} F(x,\eta) &\sim \varepsilon^{-\frac{7}{6}}\exp\left\{\Psi_C(\mu,\gamma)\right\}L_C(\mu,\gamma) \equiv \widetilde{F}(\mu,\gamma), \\ \Psi_C(\mu,\gamma) &= -\frac{\eta^2}{2\varepsilon} + \frac{\mu\gamma}{2D} - \frac{\gamma^3}{12D}, \\ L_C(\mu,\gamma) &= \frac{1}{\sqrt{2\pi}2^{\frac{1}{3}}D^{\frac{2}{3}}}\frac{1}{2\pi i}\int_{Br}\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\lambda\right\}\frac{\mathrm{Ai}\left(\lambda + 2^{-\frac{1}{3}}D^{-\frac{2}{3}}\mu\right)}{\left[\mathrm{Ai}\,(\lambda)\right]^2}d\lambda, \end{aligned} \tag{3.44}$$

where $\mu = \varepsilon^{-\frac{2}{3}}x$ and $\gamma = \varepsilon^{-\frac{1}{3}}(\eta - 1)$.

In [24, Theorem 4] several asymptotic expansions for a function closely related to (3.44) were obtained. We use these results in the following sections in order to match the different solutions that we have found so far and determine the unknown functions and constants.

3.8. Matching the solution in Region II and the inner solution. From (3.22) we get the local inversion between (τ,σ) and (x,η) for $x \to 0$:

$$\begin{aligned} \tau &\sim \sqrt{2}D^{\frac{1}{4}}\beta(\eta)^{-\frac{1}{4}}x^{\frac{1}{2}} + \frac{2}{3}\frac{\alpha(\eta)}{\beta(\eta)}x + \frac{\sqrt{2}}{36}\beta(\eta)^{-\frac{7}{4}}D^{-\frac{1}{4}}\left[14\beta(\eta) + 11D\beta(\eta) - 20D\right]x^{\frac{3}{2}}, \\ \sigma &\sim \eta - \sqrt{2}D^{\frac{1}{4}}\beta(\eta)^{-\frac{1}{4}}x^{\frac{1}{2}} + \frac{1}{3}\frac{\alpha(\eta)}{\sqrt{D\beta(\eta)}}x + \frac{\sqrt{2}}{36}\beta(\eta)^{-\frac{5}{4}}D^{-\frac{3}{4}}\left[10\beta(\eta) + D\beta(\eta) - 4D\right]x^{\frac{3}{2}}. \end{aligned} \tag{3.45}$$

Using (3.45) in (3.29), we obtain

$$L \sim L_0(\eta)2^{-\frac{1}{4}}\left[\frac{D}{\beta(\eta)}\right]^{\frac{1}{8}}x^{-\frac{1}{4}} + O(x^{\frac{1}{4}}), \quad x \to 0. \tag{3.46}$$

Expanding (3.33) for $\mu \to \infty$ yields

$$R_0 \sim C_1(\eta)\beta(\eta)^{-\frac{1}{24}}2^{-\frac{11}{12}}D^{\frac{5}{24}}\frac{1}{\sqrt{\pi}}\mu^{-\frac{1}{4}}\exp\left[-\frac{\sqrt{2}}{3}\beta(\eta)^{\frac{1}{4}}D^{-\frac{5}{4}}\mu^{\frac{3}{2}} - \sqrt{2}\beta(\eta)^{\frac{1}{4}}D^{-\frac{1}{4}}\Gamma'(\eta)\mu^{\frac{1}{2}}\right].$$

Using the above in (3.31) yields the expansion of F in (3.31) as $\mu \to \infty$. By expanding $\Phi(x,\eta)$ for small x we see that the exponential parts match automatically, and the matching of the algebraic factors implies that

$$\varepsilon^{\nu_2}L_0(\eta)2^{-\frac{1}{4}}\left[\frac{D}{\beta(\eta)}\right]^{\frac{1}{8}}x^{-\frac{1}{4}} = \varepsilon^{\nu_3}C_1(\eta)D^{\frac{5}{24}}\beta(\eta)^{-\frac{1}{24}}2^{-\frac{11}{12}}\frac{1}{\sqrt{\pi}}\mu^{-\frac{1}{4}}. \tag{3.47}$$

Hence, we have $\nu_2 = \nu_3 + \frac{1}{6}$ and

$$L_0(\eta) = C_1(\eta)D^{\frac{1}{12}}\beta(\eta)^{\frac{1}{12}}2^{-\frac{2}{3}}\frac{1}{\sqrt{\pi}}. \tag{3.48}$$

3.9. Matching the inner and inner-inner solutions. We take the limit $\mu \to 0$ in (3.33) and (3.34) to get

(3.49)
$$R_0 \sim C_1(\eta)\left\{\mathrm{Ai}\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right] + \frac{1}{2}2^{\frac{2}{3}}D^{-\frac{5}{6}}\beta(\eta)^{\frac{1}{6}}\,\mathrm{Ai}'\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right]\mu\right\}$$

and

$$\begin{aligned} R_1 \sim & \left[\frac{1}{6}\sqrt{\frac{D}{\beta(\eta)}}C_1(\eta)\beta'(\eta)\left(\Gamma'(\eta)\right)^2 + C_2(\eta) + 2\sqrt{D\beta(\eta)}C_1(\eta)\Gamma''(\eta)\Gamma'(\eta)\right] \\ & \times \mathrm{Ai}\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right] \\ & + 2^{\frac{2}{3}}\left[D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}C_1'(\eta) - \frac{1}{2}D^{\frac{2}{3}}\beta(\eta)^{-\frac{1}{3}}C_1(\eta) + \frac{1}{3}D^{\frac{1}{6}}C_1(\eta)\alpha\beta^{-\frac{5}{6}}\right] \\ & \times \mathrm{Ai}'\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right]. \end{aligned} \tag{3.50}$$

In order to complete the matching with the inner-inner solution, we must have

$$\varepsilon^{\nu_4}\, W(v,\eta)|_{v\to\infty} \sim \varepsilon^{\nu_3}\left[R_0(\mu,\eta) + \varepsilon^{\frac{1}{3}}R_1(\mu,\eta)\right]_{\mu\to 0}. \tag{3.51}$$

From (3.39), (3.49), and (3.50), we conclude that $\nu_3 + \frac{1}{3} = \nu_4$, and

$$\mathrm{Ai}\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right] = 0, \tag{3.52}$$

$$C_1(\eta)\frac{1}{2}2^{\frac{2}{3}}D^{-\frac{5}{6}}\beta(\eta)^{\frac{1}{6}}\,\mathrm{Ai}'\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right] = w(\eta)\frac{1}{2D}(\eta-1), \tag{3.53}$$

$$\begin{aligned} w(\eta) = & 2^{\frac{2}{3}}\left[D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}C_1'(\eta) - \frac{1}{2}D^{\frac{2}{3}}\beta(\eta)^{-\frac{1}{3}}C_1(\eta) + \frac{1}{3}D^{\frac{1}{6}}C_1(\eta)\alpha\beta^{-\frac{5}{6}}\right] \\ & \times \mathrm{Ai}'\left[2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\Gamma'(\eta)\right]. \end{aligned}$$

If we denote by r_0 the smallest (in absolute value) of the roots of Ai, i.e.,

$$r_0 = \max\{z : \mathrm{Ai}(z) = 0\} \simeq -2.33810741, \tag{3.54}$$

then we have from (3.52) that

$$\Gamma'(\eta) = 2^{-\frac{2}{3}}D^{-\frac{1}{6}}\beta(\eta)^{-\frac{1}{6}}r_0. \tag{3.55}$$

From (3.53)–(3.55) we obtain an ODE for $C_1(\eta)$,

$$C_1'(\eta) + \left[\frac{1}{4}\frac{\alpha(\eta)}{D\beta(\eta)} - \frac{1}{4\sqrt{D\beta(\eta)}} - \frac{1}{6}\frac{\alpha(\eta)}{\beta(\eta)} - \frac{1}{\eta-1}\right]C_1(\eta) = 0, \tag{3.56}$$

and a relation between $C_1(\eta)$ and $w(\eta)$,

$$w(\eta) = \frac{1}{\eta-1}C_1(\eta)2^{\frac{2}{3}}D^{\frac{1}{6}}\beta(\eta)^{\frac{1}{6}}\,\mathrm{Ai}'(r_0), \quad \eta > 1. \tag{3.57}$$

The solution of (3.56) is

$$C_1(\eta) = k_0(\eta-1)\beta(\eta)^{-\frac{1}{6}}\left[\frac{\alpha(\eta)}{\sqrt{D+1}} + \sqrt{\beta(\eta)}\right]^{\frac{\sqrt{D}}{2\sqrt{D+1}}} \tag{3.58}$$

with k_0 a constant to be determined.

3.10. Matching the corner and Region II solutions. From [24, Theorem 4(iv)] we have

(3.59)
$$\widetilde{F}(\mu,\gamma)\sim\varepsilon^{-\frac{7}{6}}L_{II}(\mu,\gamma)\exp\left\{\Psi_{II}(\mu,\gamma)\right\},\quad L_{II}(\mu,\gamma)=D^{-\frac{5}{6}}\frac{1}{\pi}\frac{1}{\left[\mathrm{Ai}'(r_0)\right]^2}2^{-\frac{29}{12}}\gamma\mu^{-\frac{1}{4}},$$
$$\Psi_{II}(\mu,\gamma)=-\frac{1}{2\varepsilon}\eta^2-\frac{1}{12D}\gamma^3+\frac{1}{2D}\mu\gamma-\frac{1}{3D}\sqrt{2}\mu^{\frac{3}{2}}+\frac{1}{2}2^{\frac{1}{3}}D^{-\frac{1}{3}}r_0\gamma-2^{-\frac{1}{6}}D^{-\frac{1}{3}}r_0\sqrt{\mu}$$
(3.60)

which are valid when μ and $\gamma\to\infty$, with $\gamma-\sqrt{\mu}\to\infty$.

Combining (3.46), (3.48), and (3.58), we have

$$L\sim k_0 2^{-\frac{11}{12}}\frac{1}{\sqrt{\pi}}\left[\frac{D}{\sqrt{D+1}}+\sqrt{D}\right]^{\frac{\sqrt{D}}{2\sqrt{D+1}}}(\eta-1)x^{-\frac{1}{4}},\quad x\to 0,\tag{3.61}$$

which agrees with (3.59) if

$$k_0=D^{-\frac{5}{6}}\frac{1}{\sqrt{\pi}}\frac{1}{\left[\mathrm{Ai}'(r_0)\right]^2}2^{-\frac{3}{2}}\left[\frac{D}{\sqrt{D+1}}+\sqrt{D}\right]^{-\frac{\sqrt{D}}{2\sqrt{D+1}}}.\tag{3.62}$$

Since in Region II $F(x,\eta)\sim\varepsilon^{\nu_2}\exp\left[\varepsilon^{-1}\Phi(x,\eta)+\varepsilon^{-\frac{1}{3}}\Gamma(x,\eta)\right]L(x,\eta)$, we must have $\nu_2=-\frac{4}{3}$. We use (3.45) in (3.22), (3.28), and (3.55) and find that, as $(x,\eta)\to(0,1)$,

$$\Phi(x,\eta)\sim-\frac{1}{2}-(\eta-1)-\frac{1}{2}(\eta-1)^2-\frac{1}{12D}(\eta-1)^3+\frac{1}{2D}x(\eta-1)-\frac{1}{3D}\sqrt{2}x^{\frac{3}{2}},$$
$$\Gamma(\sigma)\sim\Gamma(1)+\frac{1}{2}2^{\frac{1}{3}}D^{-\frac{1}{3}}r_0(\eta-1)-2^{-\frac{1}{6}}D^{-\frac{1}{3}}r_0\sqrt{x},$$

and from (3.60) we conclude that $\Gamma(1)=0$.

We have now determined all the unknown functions from the previous sections and summarize them below:

$$L(x,\eta)=D^{-\frac{3}{4}}(\sigma-1)\frac{1}{\pi}2^{-\frac{5}{2}}\beta(\sigma)^{-\frac{1}{12}}\left[\frac{\alpha(\sigma)+\sqrt{\beta(\sigma)(D+1)}}{D+\sqrt{D(D+1)}}\right]^{\frac{\sqrt{D}}{2\sqrt{D+1}}}\times\frac{1}{\left[\mathrm{Ai}'(r_0)\right]^2}\frac{e^{\frac{\tau}{2}}}{\sqrt{\widetilde{J}}},\tag{3.63}$$

$$\Gamma(\sigma)=2^{-\frac{2}{3}}D^{-\frac{1}{6}}r_0\int_1^\sigma\beta(u)^{-\frac{1}{6}}\,du,\tag{3.64}$$

$$R_0(\mu,\eta)=(\eta-1)D^{-\frac{5}{6}}\frac{1}{\sqrt{\pi}}2^{-\frac{3}{2}}\beta(\eta)^{-\frac{1}{6}}\left[\frac{\alpha(\eta)+\sqrt{\beta(\eta)(D+1)}}{D+\sqrt{D(D+1)}}\right]^{\frac{\sqrt{D}}{2\sqrt{D+1}}}\times\frac{\mathrm{Ai}\left[2^{-\frac{1}{3}}D^{-\frac{5}{6}}\beta(\eta)^{\frac{1}{6}}\mu+r_0\right]}{\left[\mathrm{Ai}'(r_0)\right]^2},\tag{3.65}$$

$$W(v,\eta) = 2^{-\frac{5}{6}}\frac{1}{\sqrt{\pi}}D^{-\frac{2}{3}}\left[\frac{\alpha(\eta)+\sqrt{\beta(\eta)(D+1)}}{D+\sqrt{D(D+1)}}\right]^{\frac{\sqrt{D}}{2\sqrt{D+1}}} \times \frac{1}{\mathrm{Ai}'(r_0)}\left[\frac{1}{2D}(\eta-1)v+1\right]. \tag{3.66}$$

With (3.63) and (3.64) we have completely determined the ray expansion in Region II, with (3.65) we have the inner solution (for $x = O(\varepsilon^{\frac{2}{3}})$ and $\eta > 1$), and with (3.66) we have the inner-inner solution (for $x = O(\varepsilon)$ and $\eta > 1$). We have also shown that $\nu_2 = -\frac{4}{3}$, $\nu_3 = -\frac{3}{2}$, and $\nu_4 = -\frac{7}{6}$.

4. Transition layer. Finally, we shall find the boundary layer solution near the curve $x = X_0(\eta)$ defined by (3.7), which separates Regions I and II. We introduce the stretched variable $\omega = (x - X_0)\varepsilon^{-\frac{1}{3}}$, and (1.3) becomes

$$-2\eta^2(\eta-1)F_\omega + \eta^2(\eta F_\eta + F)\varepsilon^{\frac{1}{3}} + \beta F_{\omega\omega}\varepsilon^{\frac{2}{3}} - \left[2\eta(\eta-1)F_{\omega\eta} + F_\omega\right]\varepsilon + \eta^2 F_{\eta\eta}\varepsilon^{\frac{4}{3}} = 0. \tag{4.1}$$

When $s = 1$ ($\sigma = 1$), $t = \ln(\eta)$ ($\tau = \ln(\eta)$), and we have

$$j = J\left[\ln(\eta),1\right] = 2\left(1+\frac{1}{D}\right)\ln(\eta)\,\eta + \frac{1}{D}\left(4-3\eta-\frac{1}{\eta}\right) = 2\widetilde{J}\left[\ln(\eta),1\right] = 2j_1. \tag{4.2}$$

Since

$$\Psi \sim -\frac{1}{2}\eta^2 - \frac{\eta}{2Dj}(x-X_0)^2, \quad x \to X_0, \tag{4.3}$$

we should look for solutions of the form

$$F \sim \varepsilon^{\nu_6}\exp\left\{-\frac{1}{2\varepsilon}\eta^2 - \frac{\eta}{2Dj}\omega^2\varepsilon^{-\frac{1}{3}}\right\}\Upsilon(\omega,\eta). \tag{4.4}$$

Using (4.4) in (4.1) yields for Υ the equation

$$2D^2j^2\omega\beta(\eta)\Upsilon_w + \eta^2D^3j^3\Upsilon_\eta + \beta(\eta)\left[D^2j^2 - 2\omega^3(\eta-1)\right]\Upsilon = 0, \tag{4.5}$$

whose general solution is

$$\Upsilon(\omega,\eta) = g\left(\frac{\eta\omega}{Dj}\right)\sqrt{\frac{\eta}{Dj}}\exp\left\{-\frac{\omega^3}{2\eta D^3j^3}\left[(2\eta-1)\left(2D\eta^2+2\eta^2-2\eta+1\right)\right]\right\}, \tag{4.6}$$

where g is a function still unknown. It will be determined in the next section by matching with the corner solution.

4.1. Matching the corner and transition layer solutions. Let us first introduce the new variable Ω defined by

$$\Omega = \frac{1}{(2D)^{\frac{1}{3}}}\left(\mu - \frac{1}{2}\gamma^2\right)\frac{1}{\gamma}. \tag{4.7}$$

From [24, Theorem 4(ii)] we have the following result for $\mu, \gamma \to \infty$, Ω fixed:

$$\varepsilon^{-\frac{7}{6}}e^{\frac{\eta^2}{2\varepsilon}}F(\mu,\gamma) \sim \varepsilon^{-\frac{7}{6}}\frac{2^{\frac{5}{6}}}{4\pi\sqrt{D\gamma}}\wp(\Omega)\exp\left\{\frac{\Omega^3}{6} - \frac{1}{4}\gamma\Omega^2 2^{\frac{2}{3}}D^{-\frac{1}{3}}\right\}, \tag{4.8}$$

where

$$\wp(\Omega) = \frac{1}{2\pi i}\int_{Br} \frac{e^{-\lambda\Omega}}{\left[\mathrm{Ai}\left(2^{\frac{1}{3}}\lambda\right)\right]^2} d\lambda. \tag{4.9}$$

The following properties of $\wp(\Omega)$ are established in [24]:

$$\wp(0) = 2^{-\frac{1}{3}}, \quad \wp(\Omega) \sim \Omega^{\frac{3}{2}}\sqrt{\pi}2^{-\frac{5}{6}}\exp\left\{-\frac{\Omega^3}{24}\right\}, \quad \Omega \to \infty,$$

$$\wp(\Omega) \sim -\frac{\Omega 2^{-\frac{2}{3}}}{\left[\mathrm{Ai}'(r_0)\right]^2}\exp\left\{-2^{-\frac{1}{3}}r_0\Omega\right\}, \quad \Omega \to -\infty.$$

In order to match with (4.6), we first note that

$$\omega \sim (2D)^{\frac{1}{3}}(\eta-1)\Omega, \quad \eta \to 1. \tag{4.10}$$

Thus, the right-hand side of (4.4) behaves as

$$\begin{aligned}&\varepsilon^{\nu_6} g\left[(2D)^{-\frac{2}{3}}\Omega\right]\frac{1}{\sqrt{2D(\eta-1)}}\exp\left\{-\frac{1}{8}\frac{2D+1}{D^2}\Omega^3 - \frac{1}{4}\Omega^2 2^{\frac{2}{3}}D^{-\frac{1}{3}}(\eta-1)\varepsilon^{-\frac{1}{3}}\right\}\\ &= \varepsilon^{\nu_6} g\left[(2D)^{-\frac{2}{3}}\Omega\right]\frac{1}{\varepsilon^{\frac{1}{6}}\sqrt{2D\gamma}}\exp\left\{-\frac{1}{8}\frac{2D+1}{D^2}\Omega^3 - \frac{1}{4}\Omega^2 2^{\frac{2}{3}}D^{-\frac{1}{3}}\gamma\right\}.\end{aligned}$$

Comparing the above with (4.8), we must have $\nu_6 = -1$ and

$$g\left[(2D)^{-\frac{2}{3}}\Omega\right] = \exp\left\{\frac{\Omega^3}{6} + \frac{1}{8}\frac{2D+1}{D^2}\Omega^3\right\}\frac{1}{\pi}2^{-\frac{2}{3}}\wp(\Omega), \tag{4.11}$$

which implies that

$$g(Z) = \exp\left\{\frac{Z^3}{6}\left(4D^2+6D+3\right)\right\}\frac{1}{\pi}2^{-\frac{2}{3}}\wp\left[(2D)^{\frac{2}{3}}Z\right]. \tag{4.12}$$

We conclude by writing the complete transition layer solution in (4.4):

$$\begin{aligned}F \sim \frac{1}{\varepsilon\pi}2^{-\frac{2}{3}}\sqrt{\frac{\eta}{Dj}}\wp\left[\frac{2^{\frac{2}{3}}}{D^{\frac{1}{3}}}\frac{\eta\omega}{j}\right]\exp\left\{-\frac{\eta^2}{2\varepsilon} - \frac{\eta}{2Dj\varepsilon^{\frac{1}{3}}}\omega^2 + \frac{1}{6}\left(4D^2+6D+3\right)\left(\frac{\eta\omega}{Dj}\right)^3\right.\\ \left. - \frac{\omega^3}{2\eta D^3 j^3}\left[(2\eta-1)\left(2D\eta^2+2\eta^2-2\eta+1\right)\right]\right\} \equiv \varepsilon^{-1}L_{X_0}(\omega,\eta)\exp\left\{\Psi_{X_0}(\omega,\eta;\varepsilon)\right\}.\end{aligned} \tag{4.13}$$

We can show that (4.13) matches to both of the solutions in Regions I and II.

5. Multivaluedness of the ray expansion. In that part of Region I outside the caustic region (cf. Figure 3.2) the mapping between (t,s) and (x,η) is one-to-one, and K and Ψ are unambiguously determined by the formulas in Proposition 3.1. Inside the caustic region the mapping is three-to-one, and we should rewrite (3.1) as

$$\varepsilon^{-\frac{3}{2}}\left[K_1\exp\left(\frac{1}{\varepsilon}\Psi_1\right) + K_2\exp\left(\frac{1}{\varepsilon}\Psi_2\right) + K_3\exp\left(\frac{1}{\varepsilon}\Psi_3\right)\right],$$

where Ψ_j and K_j correspond to the three different values of (t, s) leading to the same (x, η). When $t = 0$ let us define the starting points on the η-axis of these three rays by the ordering $s_1 < s_2 < s_3$, where s_j corresponds to Ψ_j and K_j. We denote the two caustics by C_+ and C_- and the cusp where they meet as (x_c, η_c). Note that the cusp location depends only on D.

The curve C_+ has $\eta \to -\infty$ as $x \to \infty$, while C_- reaches the η-axis at some critical point $(0, \eta_*)$ where again $\eta_* = \eta_*(D)$. We have verified numerically that along C_+ we have $s_1 = s_2$, $\Psi_1 = \Psi_2$, and K_1, K_2 develop singularities. However, here $\Psi_3 > \Psi_1 = \Psi_2$ and K_3 remains finite. Thus we have $F \sim \varepsilon^{-\frac{3}{2}} K_1 \exp\left(\frac{1}{\varepsilon}\Psi_1\right)$ on and near C_+. Similarly, along C_- we have $s_2 = s_3$, $\Psi_2 = \Psi_3$, and K_2, K_3 develop singularities. But $\Psi_1 > \Psi_2 = \Psi_3$, and K_1 remains finite. Thus the result in Proposition 3.1 remains valid near the caustics, except near the cusp point where all three Ψ_j are approximately equal. Here the expansion in Proposition 3.1 breaks down.

Our preliminary results suggest that a new expansion must be constructed near the cusp with the scaling

$$x - x_c = O(\sqrt{\varepsilon}), \quad \eta - \eta_c - A_c(x - x_c) = O(\varepsilon^{\frac{3}{4}}).$$

Here A_c is the slope at which both C_+ and C_- hit the cusp. We have thus far not been able to complete this analysis. We also note that while the expansion near the cusp presents an interesting problem in asymptotics, it is not needed for computing the marginal distribution $M(x)$ (1.5), which is the most important quantity from the point of view of applications, and which we calculate in the next section.

6. Marginal distributions. The last "piece of the puzzle" is to verify that (1.4) is satisfied, and also to compute the marginal distribution $M(x)$ in (1.5).

We evaluate the integral in (1.4) for $\varepsilon \to 0$. For $\eta < 1$, $F(x, \eta)$ is concentrated near $x = 0$, and the result follows from the approximation (2.6). The cases $\eta > 1$ and $\eta \approx 1$ will be considered below.

6.1. $\eta > 1$. In this region $F(x, \eta)$ is concentrated near $x = X_0$, and using (4.13) and (4.10) we have

$$\begin{aligned} F &\sim \exp\left\{-\frac{\eta^2}{2\varepsilon} - \frac{\eta}{2Dj\varepsilon^{\frac{1}{3}}}\omega^2\right\} \frac{1}{\varepsilon\pi} 2^{-\frac{2}{3}} \sqrt{\frac{\eta}{Dj}}\wp(0) \\ &= \exp\left\{-\frac{\eta^2}{2\varepsilon} - \frac{\eta}{2Dj\varepsilon}(x - X_0)^2\right\} \frac{1}{2\pi\varepsilon}\sqrt{\frac{\eta}{Dj}}, \quad x \to X_0, \end{aligned}$$

and hence, by Laplace's method,

$$\int_0^\infty F(x, \eta)dx \sim \int_{-\infty}^\infty \exp\left\{-\frac{\eta^2}{2\varepsilon} - \frac{\eta}{2Dj\varepsilon}(x - X_0)^2\right\} \frac{1}{2\pi\varepsilon}\sqrt{\frac{\eta}{Dj}}dx = \frac{1}{\sqrt{2\pi\varepsilon}} \exp\left(-\frac{\eta^2}{2\varepsilon}\right).$$

This verifies (1.4) (at least asymptotically as $\varepsilon \to 0$) for $\eta > 1$.

6.2. $\eta \approx 1$. For $\eta \to 1$ and x small we use the corner layer expansion, i.e.,

$$\begin{aligned} F(x, \eta) \sim{}& \varepsilon^{-\frac{7}{6}} \frac{1}{\sqrt{2\pi} 2^{\frac{1}{3}} D^{\frac{2}{3}}} \exp\left\{-\frac{\eta^2}{2\varepsilon} + \frac{\gamma\mu}{2D} - \frac{\gamma^3}{12D}\right\} \\ &\times \frac{1}{2\pi i}\int_{Br} \exp\left\{2^{-\frac{2}{3}} D^{-\frac{1}{3}}\gamma\lambda\right\} \frac{\operatorname{Ai}\left(\lambda + 2^{-\frac{1}{3}} D^{-\frac{2}{3}}\mu\right)}{[\operatorname{Ai}(\lambda)]^2} d\lambda, \end{aligned}$$

where $x = \mu\varepsilon^{\frac{2}{3}}$ and $\eta - 1 = \gamma\varepsilon^{\frac{1}{3}}$. In the local variable μ, (1.4) becomes

$$\int_0^\infty F(x,\eta)d\mu = \varepsilon^{-\frac{7}{6}}\frac{1}{\sqrt{2\pi}}\exp\left\{-\frac{\eta^2}{2\varepsilon}\right\}; \tag{6.1}$$

thus we have to show that

$$\Lambda(\gamma) = 2^{\frac{1}{3}}D^{\frac{2}{3}}\exp\left\{\frac{\gamma^3}{12D}\right\}, \tag{6.2}$$

where

$$\begin{aligned}\Lambda(\gamma) &= \int_0^\infty \frac{1}{2\pi i}\int_{Br}\exp\left\{\left(\frac{\mu}{2D}+2^{-\frac{2}{3}}D^{-\frac{1}{3}}\lambda\right)\gamma\right\}\frac{\mathrm{Ai}\left(\lambda+2^{-\frac{1}{3}}D^{-\frac{2}{3}}\mu\right)}{\left[\mathrm{Ai}\,(\lambda)\right]^2}d\lambda d\mu \\ &= 2^{\frac{1}{3}}D^{\frac{2}{3}}\frac{1}{2\pi i}\int_{Br}\int_\lambda^{\infty+i\mathrm{Im}(\lambda)}\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\rho\right\}\frac{\mathrm{Ai}\,(\rho)}{\left[\mathrm{Ai}\,(\lambda)\right]^2}d\rho d\lambda. \end{aligned} \tag{6.3}$$

Taking the derivative of Λ and using [2] $\mathrm{Ai}''(\rho) = \rho\mathrm{Ai}\,(\rho)$ yields

$$\begin{aligned}\Lambda'(\gamma) &= 2^{\frac{1}{3}}D^{\frac{2}{3}}\frac{1}{2\pi i}\int_{Br}\int_\lambda^{\infty+i\mathrm{Im}(\lambda)}2^{-\frac{2}{3}}D^{-\frac{1}{3}}\rho\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\rho\right\}\frac{\mathrm{Ai}\,(\rho)}{\left[\mathrm{Ai}\,(\lambda)\right]^2}d\rho d\lambda \\ &= 2^{-\frac{1}{3}}D^{\frac{1}{3}}\frac{1}{2\pi i}\int_{Br}\int_\lambda^{\infty+i\mathrm{Im}(\lambda)}\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\rho\right\}\frac{\mathrm{Ai}''(\rho)}{\left[\mathrm{Ai}\,(\lambda)\right]^2}d\rho d\lambda. \end{aligned} \tag{6.4}$$

Two integrations by parts give

$$\begin{aligned}&\int_\lambda^{\infty+i\mathrm{Im}(\lambda)}\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\rho\right\}\mathrm{Ai}''(\rho)\,d\rho \\ &= \left[\mathrm{Ai}\,(\lambda)\right]^2\frac{d}{d\lambda}\left[\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\lambda\right\}\frac{1}{\mathrm{Ai}\,(\lambda)}\right] \\ &\quad+\left(2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\right)^2\int_\lambda^{\infty+i\mathrm{Im}(\lambda)}\exp\left\{2^{-\frac{2}{3}}D^{-\frac{1}{3}}\gamma\rho\right\}\mathrm{Ai}\,(\rho)\,d\rho,\end{aligned}$$

which, when used in (6.4), leads to the differential equation

$$\Lambda'(\gamma) = \frac{1}{4D}\gamma^2\Lambda(\gamma). \tag{6.5}$$

Solving (6.5) yields

$$\Lambda(\gamma) = \Lambda_0\exp\left\{\frac{\gamma^3}{12D}\right\}, \tag{6.6}$$

where Λ_0 is a constant. To determine Λ_0, we let $\gamma \to -\infty$ in (6.3). Expanding the double integral by a combination of the Laplace and saddle point methods leads to

$$\Lambda(\gamma) \sim D^{\frac{2}{3}}2^{\frac{1}{3}}\exp\left\{\frac{\gamma^3}{12D}\right\}, \quad \gamma \to -\infty. \tag{6.7}$$

Comparing this to (6.6) we obtain $\Lambda_0 = D^{\frac{2}{3}}2^{\frac{1}{3}}$, which verifies (6.2).

6.3. The marginal distribution $M(x)$. To evaluate (1.5) by Laplace's method, we find where Ψ and Φ are maximal as functions of η. We thus examine the equations $\Psi_\eta = 0$ and $\Phi_\eta = 0$. We recall from (3.22) that $\Phi_\eta = (a-b)e^\tau - a$. The equation $\Phi_\eta = 0$ then reads

$$e^\tau = \frac{\sqrt{D}(\sigma-1)}{\sqrt{D}(\sigma-1) + D^{\frac{3}{2}}\sigma + D\sqrt{D\sigma^2 + (\sigma-1)^2}} < 1 \quad \text{for all} \quad D>0,\ \sigma>1.$$

We conclude that there is no solution to $\Phi_\eta = 0$ for $\tau > 0$, and hence $\Phi_\eta < 0$ in Region II.

From (3.4), $\Psi_\eta = (A-B)e^t - A$, and consequently

$$\Psi_\eta = 0 \quad \Leftrightarrow \quad t = \ln\left[\frac{1-s}{1-(D+1)s}\right], \tag{6.8}$$

which, when used in (3.6), yields

$$\begin{aligned} &\Psi_\eta = 0 \quad \Leftrightarrow \quad x = X_1(\eta), \quad 0 \le \eta < \frac{1}{D+1}, \\ &X_1(\eta) = -2\eta - \frac{1}{D}\left(2D\eta - D + 2\eta - 2\right)\ln\left[\frac{1-\eta}{1-(D+1)\eta}\right]. \end{aligned} \tag{6.9}$$

The equation $x = X_1(\eta)$ implicitly defines η as a function of x, $\eta = E(x)$. We introduce the function $\Psi_1(x) \equiv \Psi\left[x, E(x)\right]$ and from (3.6) we get

$$\Psi_1(x) = \frac{E(x)\left[1-E(x)\right]}{D} + \frac{D+1}{D^2}\left[1-E(x)\right]^2 \ln\left[\frac{1-(D+1)E(x)}{1-E(x)}\right]. \tag{6.10}$$

From the defining equation

$$-2E(x) + \frac{1}{D}\left[2(D+1)E(x) - D - 2\right]\ln\left[\frac{1-(D+1)E(x)}{1-E(x)}\right] = x, \tag{6.11}$$

we obtain the asymptotic results

$$\begin{aligned} &E(x) \sim \frac{x}{D} - \frac{1}{2}\frac{x^2}{D} + \frac{1}{6}\frac{D-4}{D^2}x^3, \quad x \to 0, \\ &E(x) \sim \frac{1}{D+1} - \frac{D}{(D+1)^2}\exp\left(-x - \frac{2}{D+1}\right), \quad x \to \infty. \end{aligned} \tag{6.12}$$

Use of Laplace's method to evaluate the integral in (1.5) as $\varepsilon \to 0$ yields

$$M(x) \sim \varepsilon^{-\frac{3}{2}} K\left[x, E(x)\right]\sqrt{2\pi}\frac{1}{\sqrt{-\varepsilon^{-1}\Psi_{\eta\eta}\left[x, E(x)\right]}}\exp\left\{\frac{1}{\varepsilon}\Psi_1(x)\right\}, \tag{6.13}$$

and from (3.6), after some algebra, we have

$$\begin{aligned} M(x) &\sim \varepsilon^{-1}\frac{\left[1-E(x)\right]^2}{\sqrt{\Delta}}\exp\left\{\frac{1}{\varepsilon}\Psi_1(x)\right\}, \\ \Delta &= \frac{2\left[1-(D+1)E(x)\right]\left[1-E(x)\right]\left[x+2E(x)\right](D+1)D}{2(D+1)E(x) - D - 2} \\ &\quad + D\left[D + 2E(x) - 2(D+1)E(x)^2\right]. \end{aligned}$$

We can get more explicit results if x is either small or large, using (6.12). We obtain

$$M(x) \sim \varepsilon^{-1} \frac{1}{D}\left(1-\frac{x}{D}\right)\exp\left\{\frac{1}{\varepsilon}\left(-\frac{x}{D}+\frac{x^2}{2D^2}\right)\right\}, \quad x \to 0,$$

$$M(x) \sim \varepsilon^{-1}\left[\frac{D}{(1+D)^2}+\frac{2D+1}{D(1+D)^2}\exp\left(-x-\frac{2}{D+1}\right)\right] \tag{6.14}$$

$$\times \exp\left[-\frac{1}{\varepsilon}\left(\frac{x}{1+D}+\frac{1}{(1+D)^2}\right)\right], \quad x \to \infty.$$

The first result in (6.14) shows that $M(x)$ is concentrated in the range $x = O(\varepsilon)$, and the second result is consistent with the spectral solution to (1.3) obtained in [20].

7. Discussion and numerical studies. As discussed in the introduction, a numerical method for solving (1.1) (or (1.3)) appears in [20]. However, it becomes very difficult to apply when c is large. Furthermore, the present asymptotic analysis yields a great deal of information about the model, as described below.

We recall that x represents a (scaled) queue length or buffer level, while η is a measure of the input to the queue above some mean value. As long as $\eta < 1$, the server has sufficient time to process the input, and no queue develops.

Our analysis first showed that if $|\eta|$ is small (i.e., the input flow is near its average value) and the buffer is also scaled to be small, the buffer and input processes decouple, and the distribution becomes Gaussian in η and exponential in x. But if η and/or x are not small, we obtain very different behaviors.

For example, given a fixed $\eta < 1$, we showed that the conditional buffer content is exponentially distributed, with mean $D/(1-\eta)$ (cf. (2.6)). This shows that if the input is below the maximum processing capacity, the buffer will tend to be small. But if $\eta > 1$, our analysis shows that the buffer content is approximately $x = X_0(\eta) = \eta - \ln(\eta) - 1$, with a Gaussian spread about this value. The transition from small buffers with exponential spread to large buffers with Gaussian spread occurs for $(x, \eta) \approx (0, 1)$ (more precisely, $x = O(\varepsilon^{2/3})$, $\eta - 1 = O(\varepsilon^{1/3})$). Thus, given a fixed $\eta \approx 1$ we obtain intermediate sized buffers, with the conditional buffer distribution now involving a contour integral of the Airy function (cf. (3.44)).

Our results also show that given a buffer level $x > 0$, the level of the input process is most likely to be $\eta = E(x)$, with $E(x)$ defined in (6.11). We also obtained the marginal distribution of the buffer level asymptotically, and our approximation is valid both for x small (where most mass concentrates) as well as $x = O(1)$ (the tail). Getting an accurate approximation to the latter is important in applications, since this can be used to estimate loss rates.

Next, we discuss the numerical accuracy of our asymptotic approximations. We use the numerical method in [20] to calculate $F(x, \eta)$ in (1.3) as a spectral expansion. We take $D = 1$ and $c = 5$, so that $\varepsilon = .04$. In Figure 7.1 we plot the "surface" $F(x, \eta)$ obtained by the numerical method and compare this to our approximation in (3.18). We take the range $-1 < \eta < 1$ and $0 < x < 0.3$. The figure shows that the surfaces are quite similar, and that our analysis correctly predicts the "ridge" at $\eta = E(x)$, along which F is maximal in x, for fixed η.

In Figure 7.2 we plot the numerical and asymptotic values of $F(0, \eta)$ for $-0.3 < \eta < 0.2$. This corresponds to the distribution of the input level if we are given an empty buffer. The asymptotic and numerical results lead to nearly indistinguishable curves. Also, our analysis correctly predicts that the maximum of $F(0, \eta)$ occurs at a value $\eta < 0$, and correctly predicts the skewness, or deviation from Gaussian

behavior. Indeed, (2.6) shows that the maximum should be at $\eta \sim -\varepsilon = -.04$, while the numerics yields $-.036782659$.

In Figure 7.3(a) we plot the exact and numerical marginal buffer distributions in the range $x \in [0, 0.3]$. Note that our approximation is $M(x)$ in (6.14), that $M(0) = c^2 = \varepsilon^{-1}$ exactly, and that $M(x)$ is quite concentrated near $x = 0$. Again we see that the asymptotic and numerical curves nearly coincide. Finally, we plot in Figure 7.3(b) asymptotic and numerical values of $M(x)$ for x in the range $[0.6, 1]$. This shows that the asymptotic formula also accurately estimates the tail of the distribution.

Thus, we have shown that the asymptotic analysis yields both highly accurate approximations and qualitative insights about the joint, marginal, and conditional distributions of the input level and buffer processes.

SUPPRESSION OF THE DIRICHLET EIGENVALUES OF A COATED BODY*

STEVE ROSENCRANS† AND XUEFENG WANG†

Abstract. We consider the problem of protecting from overheating the interiors of anisotropically heat-conducting bodies whose boundaries are maintained at a high temperature. The bodies are composites consisting of a thin anisotropic insulating coating surrounding an isotropically conducting interior (e.g., a space shuttle painted with an insulator). This anisotropy is a common feature of the *nanocomposite* materials used as insulators. Denote by A the thermal tensor (matrix) of the coated body and consider the Dirichlet eigenvalues of the elliptic operator $u \mapsto -\nabla \cdot (A\nabla u)$ on the coated body. The eigenfuction expansion of the interior temperature shows that small eigenvalues favor insulation of the interior. This is the motivation for studying the idealized mathematical problem of suppression of the Dirichlet eigenvalues. Suppose A is a constant matrix $\overline{A}$ on the coating. The focus of this paper is estimation of the elliptic eigenvalues and qualitative description of the eigenfunctions using *only* the eigenvalues of $\overline{A}$, the scalar conductivity of the uncoated body, and certain scalar characteristics of the geometry of the uncoated body. We study the effect of small matrix eigenvalues, small thickness of the coating, and their interplay. If the thermal tensor of the coating is spatially varying and optimally configured so that the minimum eigenvalue has eigenvector normal to the body at all boundary points of the body (and remains equal to that normal vector at each point in the coating on the straight line in that normal direction), only that minimum eigenvalue need be small. A by-product is a new characterization of the first positive Neumann eigenvalue in terms of a sequence of *second* Dirichlet eigenvalues.

1. Introduction: Suppression of Dirichlet eigenvalues.

In this paper we consider the problem of protecting interior subregions of anisotropically heat-conducting bodies whose boundaries are maintained at a high temperature. If $A = (a_{ij})$ is the thermal tensor of the conducting medium (i.e., the matrix of thermal diffusion coefficients, assumed symmetric, positive-definite), then heat flow is *isotropic* (the same in all directions) if and only if A is invariant under all coordinate rotations, which is equivalent to $A = kI$ for a scalar coefficient k (I is the identity matrix). Every thermal tensor not of this form is associated with *anisotropic* heat conduction. Currently, good insulators can be created by proper designing of nanocomposite materials,[1] which, at the macroscale, commonly exhibit such anisotropy. When isotropic nanoscale (for example, periodic) structure is averaged out by the process of homogenization (see [2] for the periodic case), the resulting effective diffusion is generally anisotropic. See the paper [6] of Zheng et al. for a calculation of the thermal tensor explicitly showing its dependence on nanostructural parameters (volume fraction of inclusion, orientation, and the like).

[1]For example, nanoclay platelets are added to traditional polymers to enhance thermal, mechanical, or gas permeability properties.

We consider composites consisting of a (thin) nanocoating surrounding an isotropically conducting interior requiring protection (e.g., a space shuttle painted with a nanoinsulator).

The temperature $T(t, \mathbf{x})$ in the body Ω satisfies the heat equation

$$\begin{cases} T_t = \nabla \cdot (A \nabla T), & \mathbf{x} \in \Omega,\ t > 0, \\ T = T_0(\mathbf{x}), & \mathbf{x} \in \Omega,\ t = 0, \\ T = H, & \mathbf{x} \in \partial\Omega,\ t > 0, \end{cases} \tag{1}$$

where T_0 is the initial temperature distribution and H is some positive constant (temperature) that is large compared to the values of T_0. The evolution of the temperature T is obtained from the its expansion in Dirichlet eigenfunctions of the elliptic operator $u \to -\nabla \cdot (A \nabla u)$,

$$\begin{cases} \nabla \cdot (A \nabla u) + \lambda u = 0 & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega. \end{cases} \tag{2}$$

Let λ_1 be the principal (i.e., smallest) Dirichlet eigenvalue and ϕ_1 the positive (in the interior) normalized ($\int \phi_1^2 = 1$) principal eigenfunction. Let (λ_m, ϕ_m), $m = 2, 3, \dots$ be the higher eigenvalues and normalized eigenfunctions, $\lambda_1 < \lambda_2 \le \lambda_3 \le \cdots$, where the eigenvalues are repeated according to their geometric multiplicity. Then

$$T - H = \sum_{m \ge 1} e^{-\lambda_m t} \phi_n(\mathbf{x}) \int_\Omega \phi_n(\mathbf{x}') \left(T_0(\mathbf{x}') - H\right) \, d\mathbf{x}'. \tag{3}$$

Thus $T(\mathbf{x}, t)$ eventually converges to H as $t \to \infty$. To protect the interior from overheating, we want to slow down this process; i.e., we desire that for a long period of time T not diverge too far from its initial value T_0. To achieve this, the following considerations are important:

(i) Even though $\lambda_i \to \infty$ as $i \to \infty$, we can make $T(\mathbf{x}, t)$ remain close to $T_0(\mathbf{x})$ for a long period of time by making λ_i as small as possible for as many i as possible.

(ii) Thus the first thing to do is to make the principal eigenvalue λ_1 small. Indeed, for t large enough ($t \gg 1/\lambda_2$), $T - H$ is well approximated by the first term,

$$T - H \approx e^{-\lambda_1 t} \phi_1(\mathbf{x}) \int_\Omega \phi_1(\mathbf{x}') \left(T_0(\mathbf{x}') - H\right) \, d\mathbf{x}'; \tag{4}$$

therefore small values of λ_1 favor insulation of the interior.

(iii) The shape of the principal eigenfunction $\phi_1(\mathbf{x})$ indicates what part of Ω is well protected. Large values of ϕ_1 in some subdomain can mitigate the overheating, by compensating to some extent for insufficiently small λ_1, because the small exponential $e^{-\lambda_1 t}$ is multiplied by ϕ_1. Small values of ϕ_1 tend to encourage overheating.

(iv) The shapes of the higher eigenmodes $\phi_i(\mathbf{x})$ help us to understand the evolution more completely: For example, if many higher eigenmodes are small in a subdomain Ω' of Ω, then (4) is valid in Ω' for t not necessarily large.

We emphasize that having small λ_i's is not enough to prevent overheating. This is elucidated by an example in section 2.2.

In most of this paper we suppose that the thermal tensor A is a constant matrix $\overline{A}$ on the coating. One certainly expects the coating to be a better insulator if all

eigenvalues of the *matrix* $\overline{A}$ are small. This is confirmed and quantified by estimation of the elliptic eigenvalues and qualitative description of the eigenfunctions using *only* the eigenvalues of the thermal tensor (matrix) $\overline{A}$ of the coating, the scalar conductivity of the coated body, and certain scalar characteristics of the geometry of the coated body. We study in detail the effect of small matrix eigenvalues, small thickness of the coating, and their interplay.

If the thermal tensor of the coating varies spatially, i.e., $\overline{A} = \overline{A}(\mathbf{x})$, its eigenvalues and their eigenvectors vary from point to point in the coating. The optimum configuration of coating relative to body would be that in which the smallest eigenvalue has an eigenvector normal to the body boundary. In this case we prove some of the same results as for a constant thermal tensor, assuming only that the smallest eigenvalue is small. The magnitude of the other eigenvalues is not significant. See section 3.3.

For discussions of the issue of *how* to design the nanostructure (of the coating material) so that its thermal tensor has small eigenvalues, see [5].

If an elastic body is reinforced by a hard coating, or shell, the very same spectral problem (2) occurs; the eigenvalues are related to vibration frequencies, and the purpose of the coating is the reduction of the frequencies. After completion of our work we became aware of Friedman's interesting 1980 paper [3] in this context. His concern is suppression of the principal eigenvalue. In section 1.1 we compare our results with his. An overall technical difference is that Friedman's proofs need estimates on the second derivatives of eigenfunctions; we use only estimates of the H^1 norm, which are easily obtained via variational characterization of the eigenvalues. We note that we measure thickness of the coating in the normal direction from the body whereas [3] measures thickness using the *conormal* direction determined by (what is here called) the thermal tensor of the coating.

1.1. Summary of our results. We consider a region Ω_1 composed of some isotropically conducting material protected by an external insulator coating Ω_2 with thermal tensor $(\overline{a}_{ij})$. See Figure 1.

Let $A(\mathbf{x}) = (a_{ij}(\mathbf{x}))$ (the thermal tensor of the *composite* material, i.e., the coated body) be a 3×3 or 2×2 thermal tensor, $\mathbf{x} \in \overline{\Omega} = \overline{\Omega}_1 \cup \overline{\Omega}_2$:

$$A(\mathbf{x}) = (a_{ij}(\mathbf{x})) = \begin{cases} kI_{n\times n}, & \mathbf{x} \in \Omega_1, \\ (\overline{a}_{ij})_{n\times n}, & \mathbf{x} \in \Omega_2, \end{cases} \tag{5}$$

where $k > 0$ is the constant thermal conductivity of the body occupying Ω_1, $(\overline{a}_{ij})$ is a constant positive-definite matrix ($n = 2$ or $n = 3$), and I is the identity matrix. Denote by $\overline{\sigma}_1, \overline{\sigma}_2, \ldots, \overline{\sigma}_n$ the eigenvalues of the thermal tensor of the coating. Let the largest and smallest be denoted by $\overline{\sigma}_{\max}$ and $\overline{\sigma}_{\min}$. After an appropriate rotation of coordinates (in two dimensions (2D) or three dimensions (3D)) the tensor $(\overline{a}_{ij})$ and hence also $(a_{ij}(\mathbf{x}))$ are diagonalized. From now on we work in this principal coordinate system.

Here follows a sketch, not complete, of our results.

Coating fixed, not thin. (In [3] this is called "thick reinforcement.") Suppose the thermal tensor of the coating depends on a small parameter ϵ in such a way that for some constants $\sigma_1, \ldots, \sigma_n$, $\overline{\sigma}_i \sim \epsilon\sigma_i$ as $\epsilon \downarrow 0$. Then there exist $\alpha_m(\Omega)$, $m \geq 1$, such that the Dirichlet eigenvalues $\lambda_m \sim \epsilon\alpha_m(\Omega)$ as $\epsilon \downarrow 0$, $m \geq 1$. The principal eigenfunction is close to a plateau over the body. The $\{\alpha_m(\Omega)\}$ are characterized as eigenvalues of a Rayleigh quotient in a certain Hilbert space. See Theorems 1 and 2. *Thus the evolution varies uniformly according to a slow time ϵt.* The paper [3] has the result for $m = 1$ but with a different characterization of α_1.

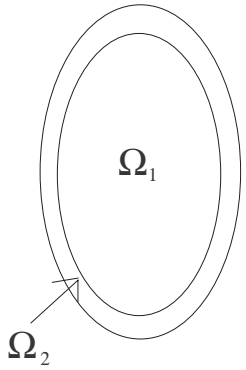

FIG. 1. *The* completely *coated body is the domain* $\Omega = \Omega_2 \cup \overline{\Omega}_1$*, the coating is the open set* Ω_2*, the uncoated body* Ω_1 *is a proper subdomain of the coated body, and the distance between* $\partial\Omega_1$ *and* $\partial\Omega$ *is positive. The uncoated body may have holes, also protected. Thus the coating* Ω_2 *may be disconnected.*

Section 2.2 has some comments on incompletely coated bodies.

All $\overline{\sigma}_i = \mathrm{o}(\delta)$. Suppose the thickness of the coating is δ, that as $\delta \downarrow 0$ all eigenvalues of the thermal tensor of the coating are $\mathrm{o}(\delta)$, and that $\overline{\sigma}_{\max}/\overline{\sigma}_{\min}$ is bounded. Then $\lambda_1 = \mathrm{o}(1)$ as $\delta \downarrow 0$: For small enough δ,

$$\frac{|\partial\Omega_1|}{|\Omega_1|}\frac{\overline{\sigma}_{\min}}{\delta}(1+\mathrm{o}(1)) \le \lambda_1 \le \frac{|\partial\Omega_1|}{|\Omega_1|}\frac{\overline{\sigma}_{\max}}{\delta}(1+\mathrm{o}(1)).$$

Moreover, the normalized positive principal eigenfunction ϕ_1 converges to the constant $1/\sqrt{|\Omega|}$ strongly in $L^2(\Omega_1)$ as $\delta \downarrow 0$. See Theorems 3 and 4. The paper [3] has this result in terms of the "conormal" thickness δ' rather than δ, with a more complicated proof.[2] Our Theorem 3 actually implies the upper bound *without* assuming $\overline{\sigma}_{\max} = \mathrm{o}(\delta)$. Theorems 6 and 7 generalize the above results to the optimally aligned case.

All $\overline{\sigma}_i = \mathrm{o}(\delta^2)$. Assume $\overline{\sigma}_{\max}/\overline{\sigma}_{\min}$ is bounded as $\delta \downarrow 0$. If the $\overline{\sigma}_i$ are *very small*, i.e., all $\overline{\sigma}_i = \mathrm{o}(\delta^2)$, then the higher eigenvalues are all $\mathrm{O}(\overline{\sigma}_{\max}/\delta^2) = \mathrm{o}(1)$ while $\lambda_1 = \mathrm{O}(\overline{\sigma}_{\max}/\delta) = \mathrm{o}(\delta)$ as $\delta \downarrow 0$. The normalized higher eigenfunctions converge to zero strongly in $L^2(\Omega_1)$. See Theorem 9. In this case, changes occur very slowly until eventually (4) holds and thereafter the changes are even slower. Theorem 11 generalizes this to the optimally aligned case.

All $\overline{\sigma}_i = \mathrm{o}(\delta)$ *while all* $\overline{\sigma}_i/\delta^2 \to \infty$. If, on the other hand, all the $\overline{\sigma}_i$ are small but not *very small*, i.e., $\overline{\sigma}_i = \mathrm{o}(\delta)$ while all $\overline{\sigma}_i/\delta^2 \to \infty$ as $\delta \downarrow 0$, then $\lambda_1 = \mathrm{o}(1)$ while $\lambda_2 \to k\mu_2$ as $\delta \downarrow 0$, where μ_2 is the first positive Neumann eigenvalue of $-\Delta$ on Ω_1. *So we have a new interpretation of the first positive Neumann eigenvalue in terms of a sequence of second Dirichlet eigenvalues.* See Theorem 8. In this case (4) is accurate after an $\mathrm{O}(1)$ time, after which changes are slow. Theorem 10 generalizes this to the optimally aligned case.

Thermal tensor of coating scaled by $\beta\delta'$ for some constant β, and conormal thickness $\delta' \downarrow 0$. It is shown in [3] that λ_1 converges to a certain (conormal) Robin eigenvalue. We did not treat this case.

[2]The paper [3] allows more general elliptic operators, including first-order terms, in the coating and the body. If the body operator has no such terms and if the coating operator is multiplied by a scalar $\mu = \mathrm{o}(\delta')$, then it is shown in [3] that $\lambda_1\delta'/\mu \to |\partial\Omega_1|/|\Omega_1|$.

2. Fixed coating. In this section the coating Ω_2 is fixed. In section 2.1 we assume that the body is completely coated; see Figure 1. In section 2.2 we briefly consider how our results change for incompletely coated bodies.

Suppose that the anisotropic thermal tensor $(\overline{a}_{ij})$ depends on a small parameter ϵ, $0 < \epsilon < 1$. From now on write ϕ as ϕ^ϵ.

2.1. Completely coated bodies.

THEOREM 1. *Assume the body Ω_1 is completely coated, as explained in the caption to Figure 1, and assume the eigenvalues $\overline{\sigma}_1, \overline{\sigma}_2, \dots, \overline{\sigma}_n$ of the thermal tensor of the coating satisfy*

$$\overline{\sigma}_i = \epsilon\sigma_i + o(\epsilon) \quad \text{as } \epsilon \downarrow 0, \quad i = 1, \dots, n, \tag{6}$$

for some positive $\sigma_1, \dots, \sigma_n$.

(i) *As $\epsilon \downarrow 0$*

$$\lambda_1(\Omega) = \epsilon\alpha_1(\Omega) + o(\epsilon),$$

and in the $L^2(\Omega)$-sense the normalized positive principal eigenfunction satisfies

$$\phi_1^\epsilon = \phi_1^0 + o(1),$$

where

$$\begin{cases} 0 < \alpha_1(\Omega) = \inf\limits_{u \in H,\, u \not\equiv 0} \dfrac{\int_\Omega \sigma_1 u_{x_1}^2 + \cdots + \sigma_n u_{x_n}^2}{\int_\Omega u^2}, \\ H := \left\{ u \in H_0^1(\Omega) | u \text{ is constant on } \Omega_1 \right\} \end{cases} \tag{7}$$

and ϕ_1^0 is the unique minimizer of (7) with $\int_\Omega (\phi_1^0)^2 = 1$ and $\phi_1^0 > 0$ on Ω. (Thus the shape of ϕ_1^ϵ is close to a plateau over Ω_1.)

(ii) *$\alpha_1(\Omega)$ is less than the principal (smallest) eigenvalue $\widetilde{\lambda}(\Omega_2)$ of the Dirichlet problem*

$$\begin{cases} \sigma_1 u_{x_1 x_1} + \cdots + \sigma_n u_{x_n x_n} + \lambda u = 0, & \mathbf{x} \in \Omega_2, \\ u = 0, & \mathbf{x} \in \partial\Omega_2. \end{cases} \tag{8}$$

Remark 1. By rescaling k in (5) to be 1 we see that the small "o" terms are uniformly small over k if k is bounded away from zero.

Proof of Theorem 1. *Step* 1. The set H introduced in the statement of the theorem is a Hilbert subspace of $H_0^1(\Omega)$. By the Banach theorem and the Kondrachov compact imbedding, $H \hookrightarrow L^2(\Omega)$, $\alpha_1(\Omega)$ is achieved by a minimizer $\phi_1^0 \in H$ with $\phi_1^0 \geq 0$ and $\int_\Omega \left(\phi_1^0\right)^2 = 1$. In fact, any minimizer must be of one sign. The Euler–Lagrange equation is

$$\int_\Omega \sigma_1 \left(\phi_1^0\right)_{x_1} v_{x_1} + \cdots + \sigma_n \left(\phi_1^0\right)_{x_n} v_{x_n} - \alpha_1(\Omega)\phi_1^0 v = 0 \quad \text{for all } v \in H. \tag{9}$$

In particular (by taking $v \in H_0^1(\Omega_2) \subset H_0^1(\Omega)$), we have

$$\begin{cases} \sigma_1 \left(\phi_1^0\right)_{x_1 x_1} + \cdots + \sigma_n \left(\phi_1^0\right)_{x_n x_n} + \alpha_1(\Omega)\phi_1^0 = 0, & \mathbf{x} \in \Omega_2, \\ \phi_1^0 = 0, & \mathbf{x} \in \partial\Omega, \\ \phi_1^0 = \text{const} = C^0 \geq 0, & \mathbf{x} \in \partial\Omega_1. \end{cases} \tag{10}$$

We claim that $C^0 > 0$. Multiplying both sides of (10) by $v \in H$ we have

$$0 = \int_{\Omega_2} \sigma_1 \phi^0_{1x_1} v_{x_1} + \cdots + \sigma_n \phi^0_{1x_n} v_{x_n} - \alpha_1(\Omega)\phi^0 v - \int_{\partial\Omega_1} \left(\sigma_1 \phi^0_{1x_1}\nu_1 + \cdots + \sigma_n \phi^0_{1x_n}\nu_n\right) v, \tag{11}$$

where ν is the outer normal of Ω_2 on $\partial\Omega_1$. Now subtract (9) from (11):

$$\int_{\Omega_1} \alpha_1(\Omega)\phi^0_1 v - \int_{\partial\Omega_1} \left(\sigma_1 \phi^0_{1x_1}\nu_1 + \cdots + \sigma_n \phi^0_{1x_n}\nu_n\right) v = 0.$$

Since $v|_{\partial\Omega_1} = \text{const}$ for $v \in H$, we have

$$\int_{\Omega_1} \alpha_1(\Omega)\phi^0_1 = \int_{\partial\Omega_1} \left(\sigma_1 \phi^0_{1x_1}\nu_1 + \cdots + \sigma_n \phi^0_{1x_n}\nu_n\right). \tag{12}$$

If $\phi^0_1|_{\partial\Omega_1} = 0$, then by the Hopf boundary point lemma (recall $\phi^0_1 \geq 0$ in Ω) we have that the integrand on the right-hand side of (12) is negative. On the other hand, since $\phi^0_1|_{\Omega_1}$ is constant, $\phi^0_1|_{\Omega_1} = 0$ if $\phi^0_1|_{\partial\Omega_1} = 0$. We have reached a contradiction and thus $\phi^0_1|_{\partial\Omega_1} > 0$.

Step 2. We prove $\limsup_{\epsilon\downarrow 0} \lambda_1(\Omega)/\epsilon \leq \alpha_1(\Omega)$. By the variational characterization[3]

$$\begin{aligned}
\lambda_1(\Omega) &= \inf_{u\in H^1_0(\Omega), u\not\equiv 0} \frac{\int_\Omega a_{ij}(\mathbf{x}) u_{x_i} u_{x_j}}{\int_\Omega u^2} \\
&\leq \frac{\int_\Omega a_{ij}(\mathbf{x}) \left(\phi^0_1\right)_{x_i} \left(\phi^0_1\right)_{x_j}}{\int_\Omega \left(\phi^0_1\right)^2} \\
&= \epsilon \int_\Omega \left(\sigma_1 + \mathrm{o}(1)\right) \left(\phi^0_1\right)^2_{x_1} + \cdots + \left(\sigma_n + \mathrm{o}(1)\right) \left(\phi^0_1\right)^2_{x_n}.
\end{aligned}$$

(Note $\nabla\phi^0_1 = 0$ in Ω_1.) This completes Step 2.

Step 3. By Step 2 we have

$$\mathrm{O}(\epsilon) = k \int_\Omega |\nabla \phi^\epsilon_1|^2 + \epsilon \int_{\Omega_2} \left(\sigma_1 + \mathrm{o}(1)\right) \left(\phi^\epsilon_1\right)^2_{x_1} + \cdots + \left(\sigma_n + \mathrm{o}(1)\right) \left(\phi^\epsilon_1\right)^2_{x_n}. \tag{13}$$

Thus ϕ^ϵ_1 is bounded in $H^1_0(\Omega)$ as $\epsilon \downarrow 0$. So for each sequence $\epsilon \downarrow 0$ there exists a subsequence (still denoted by ϵ) such that $\phi^\epsilon_1 \to \widetilde{\phi}^0_1 \in H^1_0(\Omega)$ and strongly in $L^2(\Omega)$. In particular $\widetilde{\phi}^0_1 \geq 0$ and $\int_\Omega \left(\widetilde{\phi}^0_1\right)^2 = 1$. By (13) we easily see $\widetilde{\phi}^0_1$ is constant on Ω_1.

[3]Here and henceforth we use the summation convention.

Thus $\widetilde{\phi}_1^0 \in H$ and

$$\begin{aligned}\liminf_{\epsilon\downarrow 0}\frac{\lambda_1(\Omega)}{\epsilon} &\geq \liminf_{\epsilon\downarrow 0}\int_{\Omega_2}(\sigma_1+\mathrm{o}(1))\,(\phi_1^\epsilon)_{x_1}^2+\cdots+(\sigma_n+\mathrm{o}(1))\,(\phi_1^\epsilon)_{x_n}^2\\ &\geq \int_{\Omega_2}\sigma_1\left(\widetilde{\phi}_1^0\right)_{x_1}^2+\cdots+\sigma_n\left(\widetilde{\phi}_1^0\right)_{x_n}^2\\ &= \frac{\int_{\Omega_2}\sigma_1\left(\widetilde{\phi}_1^0\right)_{x_1}^2+\cdots+\sigma_n\left(\widetilde{\phi}_1^0\right)_{x_n}^2}{\int_\Omega\left(\widetilde{\phi}_1^0\right)^2}\\ &\geq \alpha_1(\Omega).\end{aligned}$$

This and Step 2 imply $\lim_{\epsilon\downarrow 0}\lambda_1(\Omega)/\epsilon=\alpha_1(\Omega)$. The above arguments also show that $\widetilde{\phi}_1^0$ is a minimizer of $\alpha_1(\Omega)$.

Step 4. We show that $\alpha_1(\Omega)<\widetilde{\lambda}(\Omega_2)$. Let ψ be an eigenfunction of (8) corresponding to $\widetilde{\lambda}(\Omega_2)$, with $\psi>0$ on Ω_2. That is, (8) holds with $u=\psi$ and $\lambda=\widetilde{\lambda}(\Omega_2)$. Multiplying it by ϕ_1^0 and integrating by parts, we have

$$\begin{aligned}-\int_{\Omega_2}\sigma_1\psi_{x_1}\phi_{1x_1}^0+\cdots+\sigma_n\psi_{x_n}\phi_{1x_n}^0+\int_{\partial\Omega_1}\phi_1^0\left(\sigma_1\psi_{x_1}\nu_1+\cdots+\sigma_n\psi_{x_n}\nu_n\right)\\ +\widetilde{\lambda}(\Omega_2)\int_{\Omega_2}\psi\phi_1^0=0.\end{aligned}\tag{14}$$

In (9) take $v=\psi$ and then add (9) to (14). We then have

$$\left(\widetilde{\lambda}(\Omega_2)-\alpha_1(\Omega)\right)\int_{\Omega_2}\psi\phi_1^0+\int_{\partial\Omega_1}\phi_1^0\left(\sigma_1\psi_{x_1}\nu_1+\cdots+\sigma_n\psi_{x_n}\nu_n\right)=0.$$

The Hopf boundary point lemma applied to ψ and the fact that $\phi_1^0|_{\partial\Omega_1}>0$ imply $\widetilde{\lambda}(\Omega_2)-\alpha_1(\Omega)>0$.

Step 5. We prove the uniqueness of the minimizer for $\alpha_1(\Omega)$. We just need to show $\phi_1^0=\widetilde{\phi}_1^0$. As in Step 1, we have $\widetilde{\phi}_1^0\big|_{\partial\Omega_1}>0$. Since both $\widetilde{\phi}_1^0\big|_{\partial\Omega_1}$ and $\phi_1^0\big|_{\partial\Omega_1}$ are constants, there is a constant μ such that $(\widetilde{\phi}_1^0+\mu\phi_1^0)\big|_{\partial\Omega_1}=0$. Define $\theta=\widetilde{\phi}_1^0+\mu\phi_1^0$. Then θ satisfies

$$\begin{cases}\sigma_1\theta_{x_1x_1}+\cdots+\sigma_n\theta_{x_nx_n}+\alpha_1(\Omega)\theta=0, & \mathbf{x}\in\Omega_2,\\ \theta=0, & \mathbf{x}\in\partial\Omega_2,\\ \theta=0, & \mathbf{x}\in\Omega_1,\\ \theta\in H.\end{cases}$$

If $\theta\not\equiv 0$, then $\alpha_1(\Omega)$ is an eigenvalue of (8). This contradicts Step 4. The uniqueness is proved.

(The subsequence of ϵ's that was found in Step 2 is actually not needed. By the uniqueness of the minimizer, $\phi^\epsilon\to\phi^0$ strongly in $L^2(\Omega)$, $\lambda(\Omega)/\epsilon\to\alpha_1(\Omega)$, without passing to a subsequence.) □

We next prove that all *higher* eigenvalues $\lambda_m(\Omega)$ are of order $\mathrm{O}(\epsilon)$; in fact we shall give first-order expansions in ϵ for $\lambda_m(\Omega)$ as well as ϕ_m^ϵ. Before doing so we discuss eigenvalues of the Rayleigh quotient (7) in the space H:

$$I(u)=\frac{\int_\Omega\sigma_1u_{x_1}^2+\cdots+\sigma_nu_{x_n}^2}{\int_\Omega u^2}.$$

The eigenvalue problem associated to $I(u)$ in H is

$$\int_\Omega \sigma_1 u_{x_1} v_{x_1} + \cdots + \sigma_n u_{x_n} v_{x_n} = \alpha \int_\Omega uv \quad \text{for all } v \in H.$$

If this equation has a nontrivial solution $u \in H$ for some α, then α is called an eigenvalue of $I(u)$ on H, and u is a corresponding eigenfunction. (If H were replaced by $H_0^1(\Omega)$, then we would have the classical Dirichlet eigenvalue problem.) By standard variational arguments (using among other things the compact imbedding $H \hookrightarrow L^2(\Omega)$; see [4] for the Dirichlet case) we have that

(i) all the eigenvalues of $I(u)$ on H form an unbounded sequence

$$\alpha_1(\Omega) < \alpha_2(\Omega) \le \alpha_3(\Omega) \le \cdots \to \infty;$$

(ii) corresponding to each $\alpha_m(\Omega)$, there exists a normalized eigenfunction satisfying the orthogonality condition

$$\int_\Omega \phi_m^0 \phi_l^0 = 0 = \int_\Omega \sigma_1 \left(\phi_m^0\right)_{x_1} \left(\phi_l^0\right)_{x_1} + \cdots + \sigma_n \left(\phi_m^0\right)_{x_n} \left(\phi_l^0\right)_{x_n}, \quad m \ne l; \tag{15}$$

(iii) $\alpha_1(\Omega)$ is described as in Theorem 1 and the other eigenvalues can be characterized variationally as

$$\alpha_m(\Omega) = \inf_{\substack{u \in H \\ \int_\Omega u\phi_l^0 = 0,\ 1 \le l \le m-1}} I(u);$$

(iv) each eigenvalue is repeated according to its geometric multiplicity.

THEOREM 2. *Assume the conditions of Theorem* 1. *Then as* $\epsilon \downarrow 0$, $\lambda_m(\Omega) = \epsilon\alpha_m(\Omega) + o(\epsilon)$, *and in the* L^2*-sense, after passing to a subsequence,* $\phi_m^\epsilon \to \widetilde{\phi}_m^0$, $m = 1, 2, \ldots$, *where* $\widetilde{\phi}_m^0$ *is a normalized eigenfunction corresponding to* $\alpha_m(\Omega)$.

Proof. Step 1. We prove $\limsup_{\epsilon \downarrow 0} \lambda_m(\Omega)/\epsilon \le \alpha_m(\Omega)$. Let

$$V_m = \operatorname{span}\{\phi_1^0, \ldots, \phi_m^0\} \subset H.$$

By the Poincaré principle (see, for example, [1, p. 97]),

$$\begin{aligned}
\lambda_m(\Omega) &\le \max_{u \in V_m} \frac{\int_\Omega a_{ij}(\mathbf{x}) u_{x_i} u_{x_j}}{\int_\Omega u^2} \\
&= \epsilon \max_{u \in V_m} \frac{\int_\Omega (\sigma_1 + \mathrm{o}(1)) u_{x_1}^2 + \cdots + (\sigma_n + \mathrm{o}(1)) u_{x_n}^2}{\int_\Omega u^2} \quad (\text{note that } \nabla u = 0 \text{ in } \Omega_1) \\
&= \epsilon(\alpha_m(\Omega) + \mathrm{o}(1)).
\end{aligned}$$

In the last equation, we used (15) and the elementary fact

$$\frac{a_1 + \cdots + a_n}{b_1 + \cdots + b_n} \le \max\left\{\frac{a_1}{b_1}, \ldots, \frac{a_n}{b_n}\right\} \quad \text{for positive } a\text{'s and } b\text{'s}. \tag{16}$$

Step 2. We prove $\liminf_{\epsilon \downarrow 0} \lambda_m(\Omega)/\epsilon \ge \alpha_m(\Omega)$. For $m = 1$ this has been proved in Theorem 1. For $m = 2$, arguing as in Step 3 of Theorem 1, we have that, after passing to a subsequence, $\phi_2^\epsilon \to$ some $\widetilde{\phi}_2^0$, where $\widetilde{\phi}_2^0$ satisfies

$$\widetilde{\phi}_2^0 \in H, \quad \int_\Omega \left(\widetilde{\phi}_2^0\right)^2 = 1, \quad \int_\Omega \phi_1^0 \widetilde{\phi}_2^0 = 0;$$

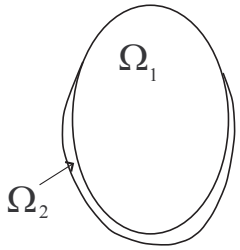

FIG. 2. *Incompletely coated body.*

thus

$$\begin{aligned}\liminf_{\epsilon\downarrow 0}\frac{\lambda_2(\Omega)}{\epsilon} &\geq \liminf_{\epsilon\downarrow 0}\int_{\Omega_2}(\sigma_1+\mathrm{o}(1))\,(\phi_2^\epsilon)^2_{x_1}+\cdots+(\sigma_n+\mathrm{o}(1))\,(\phi_2^\epsilon)^2_{x_n}\\ &\geq \int_{\Omega_2}\sigma_1\left(\widetilde{\phi}_2^0\right)^2_{x_1}+\cdots+\sigma_n\left(\widetilde{\phi}_2^0\right)^2_{x_n}\\ &= I(\widetilde{\phi}_2^0)\\ &\geq \alpha_2(\Omega).\end{aligned}$$

This and Step 1 imply that $\lim_{\epsilon\downarrow 0}\lambda_2(\Omega)/\epsilon=\alpha_2(\Omega)$ and that $\widetilde{\phi}_2^0$ is an eigenfunction corresponding to $\alpha_2(\Omega)$. Repeating the above argument, we complete the proof of the theorem. □

2.2. Incompletely coated bodies. In case Ω_2 does not completely coat Ω_1 (see Figure 2), we can show, for fixed $k>0$,

$$\lambda_1(\Omega)=\epsilon\widetilde{\lambda}(\Omega_2)+\mathrm{o}(\epsilon),\quad \epsilon\downarrow 0 \tag{17}$$

($\widetilde{\lambda}(\Omega_2)$ is defined as in part (2) of Theorem 1), and in the $L^2(\Omega)$-sense

$$\phi_1^\epsilon=\phi^0+\mathrm{o}(1), \tag{18}$$

where ϕ^0 on Ω_2 is the normalized eigenfunction corresponding to $\widetilde{\lambda}(\Omega_2)$ and ϕ^0 is understood as being zero on Ω_1. This can be proved by slightly modifying the proof of Theorem 1. One might be tempted to conclude, on the basis of (17), that even an incomplete coating will protect the body: The principal Dirichlet eigenvalue remains small if ϵ is small enough.[4] It is, however, physically obvious that the coating ought to be complete and that incomplete coating *is* unsatisfactory. The mathematical resolution has to do with the issue raised in item (iii) of section 1: By (18) the eigenfunction is *small* on the body, and hence the body is *not* protected from overheating.

In addition to (18), the size of ϕ_1^ϵ on Ω_1 can also be estimated more explicitly in terms of ϵ as follows. On Ω_1, we have

$$\Delta\phi_1^\epsilon=-\frac{\lambda_1(\Omega)}{k}\phi_1^\epsilon\,,$$

and so $\|\Delta\phi_1^\epsilon\|_{L^2(\Omega_1)}=\mathrm{O}(\epsilon/k)$. On the other hand,

$$\mathrm{O}(\epsilon)=\lambda_1(\Omega)\geq k\int_{\Omega_1}|\nabla\phi_1^\epsilon|^2\geq k\mu(\Omega_1)\int_{\Omega_1}(\phi_1^\epsilon)^2,$$

[4] Although if the coating is a tiny bump on the body, the coefficient of ϵ is very large.

where $\mu(\Omega_1)$ is the first eigenvalue of $-\Delta$ with Dirichlet boundary conditions on $\partial\Omega_1 \backslash \partial\Omega_2$, and Neumann on $\partial\Omega_1 \cap \partial\Omega_2$ (*assumed nonempty*). Thus $\|\phi_1^\epsilon\|_{L^2} = \mathrm{O}(\sqrt{\epsilon/k})$. By interior and boundary elliptic estimates, we infer

$$\|\phi_1^\epsilon\|_{H^2(K)} = \mathrm{O}(\sqrt{\epsilon/k}),$$

where K is any subdomain of Ω_1 with $\mathrm{dist}(K, \partial\Omega_2) > 0$. By the Sobolev imbedding $H^2(K) \subset L^\infty(K)$ (in 2D or 3D), $\|\phi_1^\epsilon\|_{L^\infty(K)} = \mathrm{O}(\sqrt{\epsilon/k})$.

3. How thin can the coating Ω_2 be? In this section, we assume that the coating Ω_2 has uniform thickness δ. In the intended applications, δ is much smaller than the length scale of the protected body Ω_1. We wish to find conditions that keep $\lambda_1(\Omega)$ small, while keeping Ω_2 as thin as possible. (If the coating is too thin, it can't insulate well. We will quantify this.)

Let $\mathbf{n}(p)$ be the unit outward normal vector field of $\partial\Omega_1$ at point p. For any small positive δ, define a mapping F as follows:

$$F : (p, \tau) \in \partial\Omega_1 \times [-\delta, \delta] \to (x_1, \ldots, x_n) \in R^n, \quad n > 1,$$

$$(x_1, \ldots, x_n) = F(p, \tau) = p + \tau \mathbf{n}(p).$$

If δ is small enough,

$$\delta \times (\text{maximum of the principal curvatures of } \partial\Omega_1) < 1$$

and perhaps smaller, then F is a diffeomorphism. We shall assume this throughout this section. We take

$$\Omega_2 = F(\partial\Omega_1 \times (0, \delta)), \tag{19}$$

and thus the thickness of Ω_2 is δ.

3.1. Upper bounds for $\lambda_1(\Omega)$.

THEOREM 3. *For any thermal diffusion coefficient $k > 0$ (see (5))*

$$\lambda_1(\Omega) \le \begin{cases} \dfrac{\overline{\sigma}_{\max}}{\delta|\Omega_1|}\left(|\partial\Omega_1| - \delta\left(\dfrac{\pi\chi(\partial\Omega_1)}{2} + \dfrac{|\partial\Omega_1|^2}{3|\Omega_1|}\right) + O(\delta^2)\right) & \text{in } 2D \\ \dfrac{\overline{\sigma}_{\max}}{\delta|\Omega_1|}\left(|\partial\Omega_1| - \delta\left(\overline{H} + \dfrac{|\partial\Omega_1|^2}{3|\Omega_1|}\right) + O(\delta^2)\right) & \text{in } 3D, \end{cases}$$

where $\overline{\sigma}_{max}$ is the largest of the eigenvalues of the thermal tensor of the coating Ω_2, $\overline{H}$ (in 3D) is the integral of the mean curvature of $\partial\Omega_1$ over $\partial\Omega_1$, and $\chi(\partial\Omega_1) = 2(1 - $ the number of holes in $\Omega_1)$ is the Euler characteristic of $\partial\Omega_1$.

Remark 2. Thus to keep $\lambda_1(\Omega)$ small, we just need to have $\overline{\sigma}_{\max}/\delta$ small. We emphasize that these upper bounds are independent of k (they apply even when the coated body is a near perfect conductor, $k \to \infty$), and in 2D, of the geometry of Ω_1. (In 2D, the upper bound depends only on the *topology* of Ω_1 and the relative magnitudes of $|\partial\Omega_1|$ and $|\Omega_1|$.) In 3D, the upper bound is more geometry-dependent but still only in a global way.

Proof. By the variational characterization,

$$\lambda_1(\Omega) = \inf_{u \in H_0^1(\Omega), u \not\equiv 0} \frac{\int_\Omega a_{ij}(\mathbf{x}) u_{x_i} u_{x_j}}{\int_\Omega u^2},$$

where (a_{ij}) is the thermal tensor of the composite; see (5).

We take

$$\phi(x_1,x_2,x_3)=\begin{cases}1-\dfrac{\tau}{\delta}, & 0\le\tau\le\delta,\ p\in\partial\Omega_1,\\ 1 & \text{otherwise,}\end{cases}$$

where we have used the coordinates introduced in (19). Then

$$\lambda_1(\Omega)\le\overline{\sigma}_{\max}\frac{\int_{\Omega_2}|\nabla\phi|^2}{\int_\Omega\phi^2}. \tag{20}$$

To compute this Rayleigh-type quotient in the three-dimensional case we need to use a convenient coordinate system. For every $q\in\partial\Omega_1$, parametrize $\partial\Omega_1$ near q by $p=p(u,v)$ (u, v real) such that on $\partial\Omega_1$ the curves $u\to p(u,v)$ and $v\to p(u,v)$ are curves of principal curvature of $\partial\Omega_1$ with speed equal to 1:

$$\begin{cases}|\partial p/\partial u|=1,\\ |\partial p/\partial v|=1,\\ \partial p/\partial u\perp\partial p/\partial v,\\ (\partial/\partial u)\mathbf{n}(p(u,v))=-k_1(p(u,v))(\partial/\partial u)p(u,v),\\ (\partial/\partial v)\mathbf{n}(p(u,v))=-k_2(p(u,v))(\partial/\partial u)p(u,v).\end{cases}$$

Here k_1 and k_2 are principal curvatures of $\partial\Omega_1$ (with the convention that they are positive if Ω_1 is convex).

Then the surface element on $\partial\Omega_1$ is given by

$$dS_p=\left|\frac{\partial p}{\partial u}\times\frac{\partial p}{\partial v}\right|du\,dv=du\,dv.$$

The volume element on Ω_2 is

$$\begin{aligned}dx_1\,dx_2\,dx_3&=\left|\left(\frac{\partial F}{\partial u}\times\frac{\partial F}{\partial v}\right)\cdot\frac{\partial F}{\partial\tau}\right|du\,dv\,d\tau\\&=\left|\left((p_u+\tau\mathbf{n}_u)\times(p_v+\tau\mathbf{n}_v)\right)\cdot\mathbf{n}\right|du\,dv\,d\tau\\&=\left|\left[(1-\tau k_1(p))p_u\times(1-\tau k_2(p))p_v\right]\cdot\mathbf{n}\right|du\,dv\,d\tau\\&=\left|(1-\tau k_1(p))(1-\tau k_2(p))\right|du\,dv\,d\tau\\&=(1-\tau k_1(p))(1-\tau k_2(p))\,dS_p\,d\tau\\&=\left(\tau^2G(p)-2\tau H(p)+1\right)\,dS_p\,d\tau,\end{aligned}$$

where $G(p)=k_1k_2$ is the Gauss curvature and $H(p)$ is the mean curvature of $\partial\Omega_1$.

By the chain rule, $\partial\phi/\partial u=\nabla_{(x_1,x_2,x_3)}\phi\cdot\frac{\partial F}{\partial u}=(1-\tau k_1(p))\,\nabla_{(x_1,x_2,x_3)}\phi\cdot p_u$ and also $\partial\phi/\partial v=(1-\tau k_2(p))\,\nabla_{(x_1,x_2,x_3)}\phi\cdot p_v$ and $\partial\phi/\partial\tau=\nabla_{(x_1,x_2,x_3)}\phi\cdot\mathbf{n}$. Thus

$$\left|\nabla_{(x_1,x_2,x_3)}\phi\right|^2=\phi_\tau^2+\frac{\phi_u^2}{(1-\tau k_1)^2}+\frac{\phi_v^2}{(1-\tau k_2)^2}.$$

Now we go back to (20) to compute

$$\begin{aligned}\int_{\Omega_2}\left|\nabla_{(x_1,x_2,x_3)}\phi\right|^2&=\int_0^\delta\int_{\partial\Omega_1}\phi_\tau^2(\tau^2G(p)-2\tau H(p)+1)\,dS_p\,d\tau\\&=\frac{1}{\delta^2}\int_0^\delta\int_{\partial\Omega_1}\left(\tau^2G(p)-2\tau H(p)+1\right)\,dS_p\,d\tau.\end{aligned}$$

Introducing $\overline{H} = \int_{\partial\Omega_1} H(p)\, dS_p$ and using the Gauss–Bonnet theorem $\int_{\partial\Omega_1} G(p) dS_p = 2\pi\chi(\partial\Omega_1)$, we have

$$\begin{aligned}\int_{\Omega_2} \left|\nabla_{(x_1,x_2,x_3)}\phi\right|^2 &= \frac{1}{\delta^2}\int_0^\delta \left(2\pi\chi(\partial\Omega_1)\tau^2 - 2\tau\overline{H} + |\partial\Omega_1|\right)\, d\tau \\ &= \frac{1}{\delta}\left[|\partial\Omega_1| - \delta\overline{H} + \frac{2\pi\chi(\partial\Omega_1)\delta^2}{3}\right]\end{aligned}$$

while

$$\begin{aligned}\int_\Omega \phi^2 &= |\Omega_1| + \int_0^\delta \left(1-\frac{\tau}{\delta}\right)^2 \left(|\partial\Omega_1| - 2\overline{H}\tau + 2\pi\chi(\partial\Omega_1)\tau^2\right) d\tau \\ &= |\Omega_1| + \frac{|\partial\Omega_1|\delta}{3} + O(\delta^2).\end{aligned}$$

When the quotient is assembled, and expanded for small δ, the result is the theorem in the three-dimensional case.

In the two-dimensional case we simply parametrize the curve $\partial\Omega_1$ by the arclength variable s (so $u = s$). In the computation of the Rayleigh quotient, set $G(p) = 0$ and $2H(p) = K(p)$, the curvature of $\partial\Omega_1$. In 2D the Gauss–Bonnet theorem is reduced to $\int_{\partial\Omega_1} K(p)\, ds = \pi\chi(\partial\Omega_1)$. We now have

$$\begin{aligned}\int_\Omega |\nabla\phi|^2 &= \frac{1}{\delta^2}\int_0^\delta \left(|\partial\Omega_1| - \pi\chi(\partial\Omega_1)\tau\right) d\tau \\ &= \frac{1}{\delta}\left(|\partial\Omega_1| - \frac{\pi\chi(\partial\Omega_1)\delta}{2}\right)\end{aligned}$$

and

$$\begin{aligned}\int_\Omega \phi^2 &= |\Omega_1| + \int_0^\delta \left(1-\frac{\tau}{\delta}\right)^2 \left(|\partial\Omega_1| - \pi\chi(\partial\Omega_1)\tau\right)\, d\tau \\ &= |\Omega_1| + \frac{|\partial\Omega_1|\delta}{3} + O(\delta^2).\end{aligned}$$

The two-dimensional inequality of the theorem now follows from assembling the quotient and expanding for small δ. □

3.2. Theorem 3 is sharp. We now show that Theorem 3 is sharp. This is accomplished by studying the situation in which $\delta \downarrow 0$ and k and the thermal tensor are allowed to vary with δ. As mentioned previously, the upper bound for $\lambda_1(\Omega)$ in Theorem 3 is *universal*: It is valid even when $k \to \infty$. The point of allowing the thermal tensor to vary with δ is to identify exactly the scaling relationships among δ, k, and the thermal tensor in determining the size of $\lambda_1(\Omega)$.

THEOREM 4. *Let $\overline{\sigma}_{\max}$ and $\overline{\sigma}_{\min}$ be the largest and smallest of the eigenvalues of the thermal tensor of the coating Ω_2. Assume that as $\delta \downarrow 0$*

$$\frac{\overline{\sigma}_{\max}}{\delta k} \to 0 \tag{21}$$

($k > 0$ is the thermal diffusion coefficient of the uncoated body) and

$$\frac{\overline{\sigma}_{\max}}{\overline{\sigma}_{\min}} \quad \textit{is bounded.} \tag{22}$$

Then

$$\liminf_{\delta\downarrow 0} \frac{\lambda_1(\Omega)\delta}{\overline{\sigma}_{\min}} \geq \frac{|\partial\Omega_1|}{|\Omega_1|}. \tag{23}$$

Moreover, the normalized eigenfunction ϕ_1 *corresponding to* $\lambda_1(\Omega)$ *converges to* $1/\sqrt{|\Omega_1|}$ *strongly in* $L^2(\Omega_1)$ *and* $C^2_{\rm loc}(\Omega_1)$ *as* $\delta \downarrow 0$.

Proof. Step 1. Let

$$\lambda_\delta = \inf_{u\in H^1_0(\Omega), u\not\equiv 0} \frac{k\int_{\Omega_1}|\nabla u|^2 + \overline{\sigma}_{\min}\int_{\Omega_2}|\nabla u|^2}{\int_\Omega u^2}. \tag{24}$$

Then $\lambda_1(\Omega) \geq \lambda_\delta$. Denote by ϕ^δ the normalized ($\int_\Omega(\phi^\delta)^2 = 1$) minimizer of (24). It is positive on Ω and is the weak solution of

$$\begin{cases} \sum(a(\mathbf{x})u_i)_i + \lambda_\delta u = 0 & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega, \end{cases}$$

where $u_i \equiv \partial u/\partial x_i$ and

$$a(\mathbf{x}) = \begin{cases} k & \text{in } \Omega_1, \\ \overline{\sigma}_{\min} & \text{in } \Omega_2. \end{cases}$$

By the De Giorgi–Nash estimates (see [4, Theorem 8.29]), ϕ^δ is Hölder-continuous throughout $\overline{\Omega}$. Since

$$\Delta\phi^\delta = -\frac{\lambda_\delta}{k}\phi^\delta \quad \text{in } \Omega_1$$

with $\lambda_\delta/k \leq \lambda_1(\Omega)/k \leq O(\frac{\overline{\sigma}_{\max}}{\delta k}) = o(1)$ (by Theorem 3 and (21)), we have, by the interior elliptic estimates and a bootstrap argument, that ϕ^δ is compact in $C^2_{\rm loc}(\Omega_1)$ as $\delta \downarrow 0$.

Step 2. Since $\int_{\Omega_1}|\nabla\phi^\delta|^2 \leq \lambda_\delta/k \to 0$ as $\delta \downarrow 0$, we have that, after passing to a subsequence of $\delta \downarrow 0$,

$$\phi^\delta \to \text{ some constant } m, \text{ weakly in } H^1(\Omega_1) \text{ and strongly in } L^2(\Omega_1). \tag{25}$$

Because ϕ^δ is compact in $C^2_{\rm loc}(\Omega_1)$ as $\delta \downarrow 0$, we also have

$$\phi^\delta \to m \text{ in } C^2_{\rm loc}(\Omega_1) \text{ as } \delta \downarrow 0 \tag{26}$$

after possibly passing to yet another subsequence.

By Lemma 5 and (22),

$$\int_{\Omega_2}(\phi^\delta)^2 \leq O(\delta^2)\int_{\Omega_2}|\nabla\phi^\delta|^2 \leq O\left(\frac{\delta^2}{\overline{\sigma}_{\min}}\right)\lambda_\delta \leq O\left(\frac{\delta^2\overline{\sigma}_{\max}}{\overline{\sigma}_{\min}\delta}\right) \to 0 \quad \text{as } \delta \downarrow 0.$$

Thus

$$1 = \int_\Omega(\phi^\delta)^2 = \int_{\Omega_1} m^2 + o(1) \quad \text{as } \delta \downarrow 0$$

and hence

$$m = \frac{1}{\sqrt{|\Omega_1|}}. \tag{27}$$

The proof that the eigenfunction ϕ_1 converges to $1/\sqrt{|\Omega_1|}$ is similar.

Step 3. We now show

$$\lim_{\delta \downarrow 0} \int_{\partial\Omega_1} \phi^\delta = m|\partial\Omega_1|. \tag{28}$$

Near $\partial\Omega_1$ think of ϕ^δ as a function of τ and $p \in \partial\Omega_1$ through the dependence $\phi^\delta = \phi^\delta(F(p,\tau))$. Fix a small $\delta_0 > 0$. Then

$$\left|\phi^\delta(-\delta_0, p) - \phi^\delta(0,p)\right| = \left|\int_0^{-\delta_0} \frac{\partial \phi^\delta}{\partial \tau}\, d\tau\right| \le \left(\int_{-\delta_0}^0 \left(\frac{\partial \phi^\delta}{\partial \tau}\right)^2 d\tau\right)^{1/2} \delta_0^{1/2}$$

and thus

$$\begin{aligned}
\int_{\partial\Omega_1} \left(\phi^\delta(-\delta_0,p) - \phi^\delta(0,p)\right)^2 dS_p &\le \delta_0 \int_{\partial\Omega_1} \int_{-\delta_0}^0 \left(\frac{\partial \phi^\delta}{\partial \tau}\right)^2 d\tau\, dS_p \\
&\le \frac{\delta_0}{1 - O(\delta_0)} \int_{\partial\Omega_1} \int_{-\delta_0}^0 \left(\frac{\partial \phi^\delta}{\partial \tau}\right)^2 \left(1 - 2\tau H(p) + \tau^2 G(p)\right) d\tau\, dS_p \\
&\le \frac{\delta_0}{1 - O(\delta_0)} \int_{F(\partial\Omega_1 \times (-\delta_0, 0))} \left|\nabla_{(x_1,x_2,x_3)} \phi^\delta\right|^2 dx\, dy\, dz \\
&\to 0 \quad \text{as } \delta \downarrow 0.
\end{aligned}$$

Thus

$$\begin{aligned}
\lim_{\delta \downarrow 0} \int_{\partial\Omega_1} \phi^\delta(0,p)\, dS_p &= \lim_{\delta \downarrow 0} \int_{\partial\Omega_1} \phi^\delta(-\delta_0, p)\, dS_p \\
&= m|\partial\Omega_1| \quad \text{by (26)}.
\end{aligned}$$

Step 4.

$$\begin{aligned}
\int_{\partial\Omega_1} \phi^\delta(0,p)\, dS_p &= \int_{\partial\Omega_1} \left(\phi^\delta(0,p) - \phi^\delta(\delta,p)\right) dS_p \\
&= \int_{\partial\Omega_1} \int_\delta^0 \frac{\partial \phi^\delta}{\partial \tau}\, d\tau\, dS_p \\
&\le \left(\int_{\partial\Omega_1} \int_0^\delta \left(\frac{\partial \phi^\delta}{\partial \tau}\right)^2 d\tau\, dS_p\right)^{1/2} \left(\delta|\partial\Omega_1|\right)^{1/2},
\end{aligned}$$

which implies

$$\begin{aligned}
\left(\int_{\partial\Omega_1} \phi^\delta(0,p)\, dS_p\right)^2 &\le \delta|\partial\Omega_1| \int_{\partial\Omega_1} \int_0^\delta \left(\frac{\partial \phi^\delta}{\partial \tau}\right)^2 d\tau\, dS_p \\
&\le \frac{\delta|\partial\Omega_1|}{1 - O(\delta)} \int_{\partial\Omega_1} \int_0^\delta \left(\frac{\partial \phi^\delta}{\partial \tau}\right)^2 \left(1 - 2\tau H(p) + \tau^2 G(p)\right) d\tau\, dS_p \\
&\le \frac{\delta|\partial\Omega_1|}{1 - O(\delta)} \int_{\Omega_2} \left|\nabla_{(x_1,x_2,x_3)} \phi^\delta\right|^2 dx_1\, dx_2\, dx_3 \\
&\le \frac{\delta|\partial\Omega_1|}{1 - O(\delta)} \frac{\lambda_\delta}{\overline{\sigma}_{\min}}.
\end{aligned}$$

Consequently,

$$\liminf_{\delta\downarrow 0} \frac{\delta\lambda_\delta}{\overline{\sigma}_{\min}} \geq \frac{(m|\partial\Omega_1|)^2}{|\partial\Omega_1|} = \frac{|\partial\Omega_1|}{|\Omega_1|}. \qquad \square$$

LEMMA 5. *For all small $\delta > 0$ and $\phi \in H^1(\Omega_2)$ with $\phi = 0$ on the outer boundary of Ω_2,*

$$\int_{\Omega_2} |\nabla\phi|^2 \geq \frac{\pi^2\left(1 - 2\delta H_{\max} + \delta^2 G_{\min}\right)}{4\delta^2\left(1 - 2\delta H^-_{\min} + \delta^2 G_{\max}\right)} \int_{\Omega_2} \phi^2,$$

where $H_{\max} \equiv \max_{p\in\partial\Omega_1} H(p)$, $H^-_{\min} \equiv \min\left(0, \min_{p\in\partial\Omega_1} H(p)\right)$ and $G_{\max}$ and $G_{\min}$ are the maximum and minimum of G on $\partial\Omega_1$. In 2D, $G(p) \equiv 0$ and $2H(p)$ is understood as $K(p)$.

Proof. The smallest eigenvalue of $-d^2/dx^2$ on $(0,\delta)$ with Neumann condition on the left and Dirichlet on the right is $\frac{\pi^2}{4\delta^2}$. Thus

$$\int_0^\delta \left(\frac{\partial\phi(\tau,p)}{\partial\tau}\right)^2 d\tau \geq \frac{\pi^2}{4\delta^2}\int_0^\delta \phi^2(\tau,p)\,d\tau,$$

which implies

$$\frac{1}{1 - 2\delta H_{\max} + \delta^2 G_{\min}} \int_{\partial\Omega_1}\int_0^\delta \left(\frac{\partial\phi}{\partial\tau}\right)^2 \left(1 - 2\tau H(p) + \tau^2 G(p)\right)\, d\tau\, dS_p$$
$$\geq \frac{\pi^2}{4\delta^2} \frac{\int_{\partial\Omega_1}\int_0^\delta \phi^2(\tau,p)\left(1 - 2\tau H(p) + \tau^2 G(p)\right)\, d\tau\, dS_p}{1 - 2\delta H^-_{\min} + \delta^2 G_{\max}}.$$

Now the conclusion follows from the fact that the integral on the left is less than or equal to $\int_{\Omega_2} |\nabla\phi|^2$. $\square$

3.3. Optimally aligned coating. If the thermal tensor of the coating varies spatially, i.e., $\overline{a}_{ij} = \overline{a}_{ij}(\mathbf{x})$, then it is possible for the principal Dirichlet eigenvalue to be small, as in Theorem 2, even if *not all* the eigenvalues of this thermal tensor are small. We call the coating *optimally aligned* if the smallest of the eigenvalues has, at each boundary point of the coated body, eigenvector normal to the boundary (and this persists into the coating; see below). Only *that* eigenvalue needs to be controlled (assumed small everywhere); the size of the others is irrelevant. An example is the two-dimensional disk of radius $1-\delta$ coated by an annulus of thickness δ, the annulus having thermal tensor

$$A = \begin{pmatrix} \epsilon x^2 + y^2 & xy(-1+\epsilon) \\ xy(-1+\epsilon) & x^2 + \epsilon y^2 \end{pmatrix}. \tag{29}$$

The eigenvalues are $x^2 + y^2$ and $\epsilon(x^2 + y^2)$ with eigenvectors angular and radial, respectively.

THEOREM 6. *Suppose for all $p \in \partial\Omega_1$ and all points $\mathbf{x} = p + \tau\mathbf{n}(p)$ $(\tau > 0)$ in Ω_2 the smallest eigenvalue $\overline{\sigma}^{\rm op}_{\min}(\mathbf{x})$ of $\overline{a}_{ij}(\mathbf{x})$ has eigenvector $\mathbf{n}(p)$. Let*

$$\overline{\sigma}^{\rm op}_{\min} = \max_{\mathbf{x}\in\overline{\Omega}_2} \overline{\sigma}^{\rm op}_{\min}(\mathbf{x}).$$

Then

$$\lambda_1(\Omega) \le \begin{cases} \dfrac{\overline{\sigma}^{\rm op}_{\rm min}}{\delta|\Omega_1|}\left(|\partial\Omega_1| - \delta\left(\dfrac{\pi\chi(\partial\Omega_1)}{2} + \dfrac{|\partial\Omega_1|^2}{3|\Omega_1|}\right) + O(\delta^2)\right) & \textit{in } 2D, \\ \dfrac{\overline{\sigma}^{\rm op}_{\rm min}}{\delta|\Omega_1|}\left(|\partial\Omega_1| - \delta\left(\overline{H} + \dfrac{|\partial\Omega_1|^2}{3|\Omega_1|}\right) + O(\delta^2)\right) & \textit{in } 3D. \end{cases}$$

Proof. The proof is a slight modification of that of Theorem 3. Using the same test function ϕ and observing that $\nabla\phi(x_1, x_2, x_3) = \frac{\partial\phi}{\partial\tau}\mathbf{n}(p) = -\frac{\mathbf{n}(p)}{\delta}$ is an eigenvector of $\overline{a}_{ij}(\mathbf{x})$ corresponding to $\overline{\sigma}^{\rm op}_{\rm min}(\mathbf{x})$, we have

$$\begin{aligned} \lambda_1(\Omega) &\le \frac{\int_{\Omega_2} \overline{a}_{ij}(\mathbf{x})\phi_{x_i}\phi_{x_j}}{\int_\Omega \phi^2} \\ &= \frac{\int_{\Omega_2} \overline{\sigma}^{\rm op}_{\rm min}(\mathbf{x})|\nabla\phi|^2}{\int_\Omega \phi^2} \\ &\le \frac{\overline{\sigma}^{\rm op}_{\rm min}}{\delta^2}\frac{\int_{\Omega_2} 1}{\int_\Omega \phi^2}. \end{aligned}$$

The remaining calculations will be the same as in the proof of Theorem 3. ∎

THEOREM 7. *Let*

$$\underline{\sigma}^{\rm op}_{\rm min} = \min_{\mathbf{x}\in\overline{\Omega}_2} \overline{\sigma}^{op}_{min}(\mathbf{x}).$$

If

$$\lim_{\delta\downarrow 0}\frac{\overline{\sigma}^{\rm op}_{\rm min}}{\delta k} = 0 \quad \textit{and} \quad \frac{\overline{\sigma}^{\rm op}_{\rm min}}{\underline{\sigma}^{\rm op}_{\rm min}} \quad \textit{is bounded,}$$

then

$$\liminf_{\delta\downarrow 0}\frac{\lambda_1(\Omega)\delta}{\underline{\sigma}^{\rm op}_{\rm min}} \ge \frac{|\partial\Omega_1|}{|\Omega_1|},$$

and the normalized eigenfunction ϕ_1 corresponding to $\lambda_1(\Omega)$ converges to $1/\sqrt{|\ \Omega_1\ |}$ (strongly in $L^2(\Omega_1)$ and $C^2_{\rm loc}(\Omega_1)$) as $\delta \downarrow 0$.

Proof. The proof is the same as the proof of Theorem 4 but with $\overline{\sigma}_{\rm min} \to \underline{\sigma}^{\rm op}_{\rm min}$, $\overline{\sigma}_{\rm max} \to \overline{\sigma}^{\rm op}_{\rm min}$, and "Theorem 3" → "Theorem 6." ∎

4. Estimation of higher eigenpairs. A fuller understanding of the long-time behavior (i.e., of the accuracy of the truncated eigenfunction expansion approximation) can be achieved by estimating the higher eigenpairs $\lambda_m(\Omega)$, $\phi^\delta_m(\mathbf{x})$, $m \ge 2$. A by-product is a new characterization of the first positive Neumann eigenvalue as the limit of a sequence of second Dirichlet eigenvalues.

4.1. The case in which all eigenvalues of the thermal tensor are small.

THEOREM 8. *Assume the conditions of Theorem 4 with $k > 0$ fixed. Suppose also that*

$$\frac{\delta^2}{\overline{\sigma}_{\rm min}} \downarrow 0 \quad \textit{as } \delta \downarrow 0. \tag{30}$$

Then

$$\lim_{\delta\downarrow 0}\lambda_2(\Omega)=k\mu_2(\Omega_1),$$

where $\mu_2(\Omega_1)$ is the first positive eigenvalue of the Neumann eigenproblem

$$\begin{cases}\Delta u+\mu u=0 & \text{in } \Omega_1,\\ \dfrac{\partial u}{\partial \mathbf{n}}=0 & \text{on } \partial\Omega_1,\ \mathbf{n} \text{ the unit outward normal to } \partial\Omega_1.\end{cases}\tag{31}$$

Moreover, after passing to a subsequence the normalized eigenfunction ϕ_2^δ corresponding to $\lambda_2(\Omega)$ converges to a normalized eigenfunction ψ_2^0 associated to $\mu_2(\Omega_1)$ strongly in $L^2(\Omega_1)$ and $C^2_{\rm loc}(\Omega_1)$.

Proof. Step 1. We prove $\limsup_{\delta\downarrow 0}\lambda_2(\Omega)\le k\mu_2(\Omega_1)$. Recall the Poincaré principle

$$\lambda_2(\Omega)=\min_{\dim V_2=2}\max_{u\in V_2}\frac{\int_\Omega a_{ij}(\mathbf{x})u_iu_j\,d\mathbf{x}}{\int_\Omega u^2\,d\mathbf{x}},\tag{32}$$

where the minimum is taken over all two-dimensional subspaces V_2 of $H_0^1(\Omega)$. Let ψ^0 be a fixed normalized eigenfunction associated to $\mu_2(\Omega_1)$. Since $\psi^0\in C^2(\overline{\Omega}_1)$ we can extend it so that $\psi^0\in C^2(R^n)$. Let ϕ_1^δ be the normalized eigenfunction corresponding to $\lambda_1(\Omega)$. In (32) take $V_2=\operatorname{span}\{\phi_1^\delta,\phi\psi^0\}$, where ϕ is as defined in the proof of Theorem 3. For any $u\in V_2$ write $u=c_1\phi_1^\delta+c_2\phi\psi^0$, where c_1 and c_2 are constants. Now by (32)

$$\begin{aligned}\lambda_2&\le\max_{u\in V_2}\frac{\int_\Omega a_{ij}(\mathbf{x})u_iu_j\,d\mathbf{x}}{\int_\Omega u^2\,d\mathbf{x}}\\&\le\max_{(c_1,c_2)\in R^2}\frac{c_1^2\,(\lambda_1(\Omega)+A)+c_2^2(B+A)}{c_1^2(1-D)+c_2^2(C-D)},\end{aligned}\tag{33}$$

where

$$\begin{aligned}A&=\left|\int_\Omega a_{ij}(\mathbf{x})(\phi_1^\delta)_{x_i}(\phi\psi^0)_{x_j}\right|\\&\le\left(\int_\Omega a_{ij}(\mathbf{x})(\phi_1^\delta)_{x_i}(\phi_1^\delta)_{x_j}\right)^{1/2}\left(\int_\Omega a_{ij}(\mathbf{x})(\phi\psi^0)_{x_i}(\phi\psi^0)_{x_j}\right)^{1/2}\\&=\sqrt{\lambda_1(\Omega)}\sqrt{B};\\B&=\int_\Omega a_{ij}(\mathbf{x})(\phi\psi^0)_{x_i}(\phi\psi^0)_{x_j}\\&=k\int_{\Omega_1}|\nabla\psi^0|^2+\int_{\Omega_2}\overline{a}_{ij}(\phi_{x_i}\psi^0+\phi\psi^0_{x_i})(\phi_{x_j}\psi^0+\phi\psi^0_{x_j})\\&\le k\int_{\Omega_1}|\nabla\psi^0|^2+2\int_{\Omega_2}\overline{a}_{ij}\phi_{x_i}\phi_{x_j}(\psi^0)^2+2\int_{\Omega_2}\overline{a}_{ij}\psi^0_{x_i}\psi^0_{x_j}\phi^2\\&\le k\mu_2(\Omega_1)+\mathrm{O}\left(\frac{\overline{\sigma}_{\max}}{\delta}\right)+\mathrm{O}(\delta);\\C&=\int_\Omega(\phi\psi^0)^2\end{aligned}$$

$$
\begin{aligned}
&= \int_{\Omega_1} (\psi^0)^2 + \int_{\Omega_2} (\phi\psi^0)^2 \geq 1;\\
D &= \left| \int_\Omega \phi_1^\delta \phi\psi^0 \right| \\
&\leq \left| \int_{\Omega_1} \phi_1^\delta \psi^0 \right| + \left| \int_{\Omega_2} \phi_1^\delta \phi\psi^0 \right| \\
&\leq \left| \int_{\Omega_1} \left(\phi_1^\delta - \frac{1}{\sqrt{|\Omega_1|}} \right) \psi^0 \right| + \left(\int_{\Omega_2} (\psi^0)^2 \right)^{1/2} \left(\int_\Omega (\phi_1^\delta)^2 \right)^{1/2} \\
&\leq \left(\int_{\Omega_2} \left(\phi_1^\delta - \frac{1}{\sqrt{|\Omega_1|}} \right)^2 \right)^{1/2} \left(\int_{\Omega_1} (\psi^0)^2 \right)^{1/2} + \left(\int_{\Omega_2} (\psi^0)^2 \right)^{1/2} \\
&= \mathrm{o}(1) + \mathrm{O}(\sqrt{\delta}) \quad \text{(by Theorem 4).}
\end{aligned}
$$

These estimates, the fact that $\lambda_1(\Omega) = \mathrm{O}(\overline{\sigma}_{\max}/\delta)$, and (33) imply

$$\lambda_2(\Omega) \leq \frac{c_1^2 \mathrm{o}(1) + c_2^2 \left(k\mu_2(\Omega_1) + \mathrm{o}(1) \right)}{c_1^2(1 - \mathrm{o}(1)) + c_2^2(1 - \mathrm{o}(1))}.$$

From the elementary inequality $\frac{a+b}{c+d} \leq \max\left(\frac{a}{c}, \frac{b}{d}\right)$ for positive a, b, c, d we infer

$$\lambda_2(\Omega) \leq \max\left(\frac{\mathrm{o}(1)}{1 - \mathrm{o}(1)}, \frac{k\mu_2(\Omega_1) + \mathrm{o}(1)}{1 - \mathrm{o}(1)} \right).$$

Step 2. We prove $\liminf_{\delta \downarrow 0} \lambda_2(\Omega) \geq k\mu_2(\Omega_1)$. Observe that

$$\lambda_2(\Omega) \geq k \int_{\Omega_1} |\nabla \phi_2^\delta|^2 + \overline{\sigma}_{\min} \int_{\Omega_2} |\nabla \phi_2^\delta|^2,$$

where $\int_\Omega (\phi_2^\delta)^2 = 1$ and $\int_\Omega \phi_1^\delta \phi_2^\delta = 0$. In particular ϕ_2^δ is bounded in $H^1(\Omega_1)$, and hence after passing to a subsequence, $\phi_2^\delta \to$ some ψ_2^0 weakly in $H^1(\Omega_1)$ and strongly in $L^2(\Omega_1)$. Applying interior elliptic estimates to $\Delta\phi_2^\delta + \lambda_2(\Omega)\phi_2^\delta = 0$, we also have $\phi_2^\delta \to \psi_2^0$ in $C^2_{\mathrm{loc}}(\Omega_1)$. From this it follows that

$$\liminf_{\delta \downarrow 0} \lambda_2(\Omega) \geq k \int_{\Omega_1} |\nabla \psi_2^0|^2 \tag{34}$$

and that

$$
\begin{aligned}
0 &= \lim_{\delta \downarrow 0} \int_\Omega \phi_1^\delta \phi_2^\delta \\
&= \lim_{\delta \downarrow 0} \left(\int_{\Omega_1} + \int_{\Omega_2} \right) \phi_1^\delta \phi_2^\delta \\
&= \int_{\Omega_1} \frac{1}{\sqrt{|\Omega_1|}} \psi_2^0 + \lim_{\delta \downarrow 0} \left(\mathrm{O}\left(\frac{\delta \overline{\sigma}_{\max}}{\overline{\sigma}_{\min}} \right) \right)^{1/2} \quad \text{(by Theorem 4 and its proof)} \\
&= \int_{\Omega_1} \frac{1}{\sqrt{|\Omega_1|}} \psi_2^0;
\end{aligned}
$$

i.e.,

$$\int_{\Omega_1} \psi_2^0 = 0. \tag{35}$$

Moreover, by Lemma 5, we have

$$\int_{\Omega_2} \left(\phi_2^\delta\right)^2 \le \mathrm{O}(\delta^2) \int_{\Omega_2} |\nabla \phi_2^\delta|^2 = \mathrm{O}\left(\frac{\delta^2}{\overline{\sigma}_{\min}}\right) \lambda_2(\Omega) = \mathrm{o}(1)$$

and thus

$$1 = \lim_{\delta \downarrow 0} \left(\int_{\Omega_1} \left(\phi_2^\delta\right)^2 + \int_{\Omega_2} \left(\phi_2^\delta\right)^2 \right) = \int_{\Omega_1} \left(\psi_2^0\right)^2.$$

Now this and (35) imply

$$\mu_2(\Omega) = \inf_{\int_{\Omega_1} u = 0} \frac{\int_{\Omega_1} |\nabla u|^2}{\int_{\Omega_1} u^2} \le \frac{\int_{\Omega_1} |\nabla \psi_2^0|^2}{\int_{\Omega_1} \left(\psi_2^0\right)^2} = \int_{\Omega_1} |\nabla \psi_2^0|^2.$$

This and (34) yield the desired conclusion.

Step 3. Combining Steps 1 and 2 we have

$$\lim_{\delta \downarrow 0} \lambda_2(\Omega) = k \mu_2(\Omega_1).$$

The arguments in Step 2 show that ψ_2^0 is a normalized eigenfunction corresponding to $\mu_2(\Omega_1)$. □

THEOREM 9.

(i) *For any $k > 0$ (see (5)) and $m = 2, 3, \ldots,$*

$$\lambda_m(\Omega) \le \begin{cases} \dfrac{\overline{\sigma}_{\max} m^2 \pi^2}{\delta^2} \left(1 + \dfrac{\delta \pi}{|\partial \Omega_1|} |\chi(\partial \Omega_1)| + O(\delta^2)\right) & \text{in } 2D, \\ \dfrac{\overline{\sigma}_{\max} m^2 \pi^2}{\delta^2} \left(1 + \dfrac{2\delta}{|\partial \Omega_1|} |\overline{H}| + O(\delta^2)\right) & \text{in } 3D. \end{cases}$$

In particular, if

$$\frac{\overline{\sigma}_{\max}}{\delta^2} \to 0 \quad \left(\iff \frac{\delta^2}{\overline{\sigma}_{\max}} \to \infty \right) \quad \text{as } \delta \downarrow 0, \tag{36}$$

then $\lambda_m(\Omega) \to 0$ as $\delta \downarrow 0$ uniformly in $k > 0$.

(ii) *Fix $k > 0$ and assume (36) and (22). Then the normalized eigenfunction ϕ_m^δ corresponding to $\lambda_m(\Omega)$ converges to zero strongly in $L^2(\Omega_1)$ and $C^2_{\mathrm{loc}}(\Omega_1)$ as $\delta \downarrow 0$, $m \ge 2$.*

(iii) *Under the same conditions as in part* (ii) *above, there exists a positive constant C such that*

$$\lambda_2(\Omega) \ge C \frac{\overline{\sigma}_{\max}}{\delta^2}.$$

Thus for $m \ge 2$ each $\lambda_m(\Omega)$ is of order $\overline{\sigma}_{\max}/\delta^2$, while $\lambda_1(\Omega)$ is of order $\overline{\sigma}_{\max}/\delta$.

Proof of (i). Fix $w \in H_0^1(\Omega_2) \subset H_0^1(\Omega)$, which depends only on $\tau \in [0,\delta]$. We compute the Rayleigh quotient

$$\begin{aligned}\frac{\int_\Omega a_{ij}(\mathbf{x}) w_i w_j \, d\mathbf{x}}{\int_\Omega w^2 \, d\mathbf{x}} &\le \frac{\overline{\sigma}_{\max} \int_{\Omega_2} |\nabla w|^2 \, d\mathbf{x}}{\int_{\Omega_2} w^2 \, d\mathbf{x}} \\ &= \overline{\sigma}_{\max} \frac{\int_0^\delta \int_{\partial\Omega_1} w_\tau^2 \left(\tau^2 G(p) - 2\tau H(p) + 1\right) \, dS_p \, d\tau}{\int_0^\delta \int_{\partial\Omega_1} w^2 \left(\tau^2 G(p) - 2\tau H(p) + 1\right) \, dS_p \, d\tau} \\ &\le \overline{\sigma}_{\max} \frac{\left(|\partial\Omega_1| - 2\delta \min(0, \overline{H}) + \mathrm{O}(\delta^2)\right) \int_0^\delta w_\tau^2 \, d\tau}{\left(|\partial\Omega_1| - 2\delta \max(0, \overline{H}) + \mathrm{O}(\delta^2)\right) \int_0^\delta w^2 \, d\tau} \\ &= \overline{\sigma}_{\max} \left(1 + \frac{2\delta|\overline{H}|}{|\partial\Omega_1|} + \mathrm{O}(\delta^2)\right) \frac{\int_0^\delta w_\tau^2 \, d\tau}{\int_0^\delta w^2 \, d\tau}.\end{aligned}$$

Take an m-dimensional subspace of $H_0^1(\Omega_2) \subset H_0^1(\Omega)$:

$$V_m = \operatorname{span}\left\{\sin\frac{\pi\tau}{\delta}, \sin\frac{2\pi\tau}{\delta}, \ldots, \sin\frac{m\pi\tau}{\delta}\right\}.$$

Then by the Poincaré principle

$$\begin{aligned}\lambda_m(\Omega) &\le \max_{w \in V_m} \frac{\int_\Omega a_{ij}(\mathbf{x}) w_i w_j \, d\mathbf{x}}{\int_\Omega w^2 \, d\mathbf{x}} \\ &\le \overline{\sigma}_{\max} \left(1 + \frac{2\delta|\overline{H}|}{|\partial\Omega_1|} + \mathrm{O}(\delta^2)\right) \max_{w \in V_m} \frac{\int_0^\delta w_\tau^2 \, d\tau}{\int_0^\delta w^2 \, d\tau} \\ &= \overline{\sigma}_{\max} \left(1 + \frac{2\delta|\overline{H}|}{|\partial\Omega_1|} + \mathrm{O}(\delta^2)\right) \frac{m^2\pi^2}{\delta^2}. \qquad \square\end{aligned}$$

Proof of (ii). By Theorem 4 and its proof, ϕ_1^δ (the normalized eigenfunction corresponding to $\lambda_1(\Omega)$) and ϕ_m^δ satisfy

$$\phi_1^\delta \to \frac{1}{\sqrt{|\Omega_1|}} \quad \text{and} \quad \phi_m^\delta \to \text{constant } C_m \quad \text{strongly in } L^2(\Omega_1) \text{ and } C^2_{\mathrm{loc}}(\Omega_1)$$

as $\delta \downarrow 0$. On the other hand,

$$0 = \int_\Omega \phi_1^\delta \phi_m^\delta = \int_{\Omega_1} \phi_1^\delta \phi_m^\delta + \int_{\Omega_2} \phi_1^\delta \phi_m^\delta,$$

while

$$\int_{\Omega_1} \phi_1^\delta \phi_m^\delta \to \frac{C_m |\Omega_1|}{\sqrt{|\Omega_1|}}$$

and

$$\left| \int_{\Omega_2} \phi_1^\delta \phi_m^\delta \right| \le \left(\int_{\Omega_2} \left(\phi_1^\delta\right)^2 \right)^{1/2} \left(\int_\Omega \left(\phi_m^\delta\right)^2 \right)^{1/2} = \mathrm{O}\left(\frac{\overline{\sigma}_{\max}\delta}{\overline{\sigma}_{\min}} \right) \to 0.$$

Thus $C_m = 0$. $\square$

Proof of (iii). Suppose there exists a sequence $\delta \downarrow 0$ such that

$$\frac{\delta^2 \lambda_2(\Omega)}{\overline{\sigma}_{\max}} \to 0. \tag{37}$$

Observe that

$$\begin{aligned}
1 &= \int_\Omega \left(\phi_2^\delta\right)^2 \\
&= \int_{\Omega_1} \left(\phi_2^\delta\right)^2 + \int_{\Omega_2} \left(\phi_2^\delta\right)^2 \\
&= \mathrm{o}(1) + \mathrm{O}(\delta^2) \int_{\Omega_2} |\nabla \phi_2^\delta|^2 \quad \text{by (ii) and Lemma 5} \\
&\le \mathrm{o}(1) + \frac{\mathrm{O}(\delta^2)}{\overline{\sigma}_{\min}} \lambda_2(\Omega) \\
&= \mathrm{o}(1) + \mathrm{O}(1) \frac{\delta^2 \lambda_2(\Omega)}{\overline{\sigma}_{\max}} \\
&= \mathrm{o}(1) \quad \text{by (37)},
\end{aligned}$$

which is a contradiction. □

4.2. The optimally aligned case.

THEOREM 10. *Let all the conditions of Theorem* 7 *hold with thermal conductivity coefficient* $k > 0$ *(see* (5)*) fixed. Assume also that*

$$\frac{\delta^2}{\underline{\sigma}^{\mathrm{op}}_{\min}} \to 0 \quad \textit{as } \delta \downarrow 0.$$

Then $\lim_{\delta \downarrow 0} \lambda_2(\Omega) = k\mu_2(\Omega_1)$ *and after passing to a subsequence* $\lim_{\delta \downarrow 0} \psi_2^\delta = \phi_2^0$ *in* $L^2(\Omega_1)$ *and* $C^2_{\mathrm{loc}}(\Omega_1)$.

Proof. We slightly modify the proof of Theorem 8. The first modification occurs in the estimate for B, where we use the fact that $\nabla\phi$ is an eigenvector of $(\overline{a}_{ij}(\mathbf{x}))$ associated with eigenvalue $\overline{\sigma}^{\mathrm{op}}_{\min}(\mathbf{x})$, and hence "$\mathrm{O}(\overline{\sigma}_{\max}/\delta)$" can be replaced by "$\mathrm{O}(\overline{\sigma}^{\mathrm{op}}_{\min}/\delta)$." The term "$\mathrm{O}(\delta)$" is kept unchanged because $\overline{a}_{ij}(\mathbf{x})$ is bounded on Ω_2. The other modifications are obvious ones: "Theorem 4" → "Theorem 7," $\overline{\sigma}_{\min} \to \underline{\sigma}^{\mathrm{op}}_{\min}$, and $\overline{\sigma}_{\max} \to \overline{\sigma}^{\mathrm{op}}_{\min}$. □

THEOREM 11.

(i) *For any thermal diffusion constant* $k > 0$ *(see* (5)*) and* $m = 2, 3, \ldots,$

$$\lambda_m(\Omega) \le \begin{cases} \dfrac{\overline{\sigma}^{\mathrm{op}}_{\min} m^2 \pi^2}{\delta^2} \left(1 + \dfrac{\delta\pi}{|\partial\Omega_1|} |\chi(\Omega_1)| + O(\delta^2)\right) & \textit{in } 2D, \\ \dfrac{\overline{\sigma}^{\mathrm{op}}_{\min} m^2 \pi^2}{\delta^2} \left(1 + \dfrac{2\delta|\overline{H}|}{|\partial\Omega_1|} + O(\delta^2)\right) & \textit{in } 3D. \end{cases}$$

In particular, if

$$\overline{\sigma}^{\mathrm{op}}_{\min}/\delta^2 \to 0 \quad \textit{as} \quad \delta \downarrow 0, \tag{38}$$

then $\lambda_m(\Omega) \to 0$ *as* $\delta \downarrow 0$, *uniformly for* $k > 0$.

(ii) *Fix* $k > 0$ *and assume* (38) *and that* $\overline{\sigma}^{\mathrm{op}}_{\min}/\underline{\sigma}^{\mathrm{op}}_{\min}$ *is bounded. Then* $\phi_m^\delta \to 0$ *strongly in* $L^2(\Omega_1)$ *and* $C^2_{\mathrm{loc}}(\Omega_1)$ *as* $\delta \downarrow 0$.

(iii) *Under the conditions in part* (ii)*, there exists a positive constant* c *such that* $c\overline{\sigma}^{\mathrm{op}}_{\min}/\delta^2 \leq \lambda_2(\Omega)$.

Proof. Modify the proof of Theorem 9 with the same obvious changes listed in the proof of Theorem 10. The key observation is that if $w = w(\tau)$, then in Ω_2, ∇w is an eigenvector of $\overline{a}_{ij}(\mathbf{x})$ associated to $\overline{\sigma}_{\min}(\mathbf{x})$. □

Acknowledgments. We would like to thank Greg Forest, who started us thinking about these questions and invited us to the February 2004 SAMSI conference, Workshop on Multi-scale Challenges in Soft Matter Materials, which we found very stimulating. Later we had several very useful conversations with Greg Forest, Rob Lipton, Wei-Ming Ni, and Hans Weinberger. We thank the referee for suggesting the consideration of spatially varying thermal tensors, and for several other helpful remarks. Part of the work of X. Wang was performed while he was supported by Wei-Ming Ni during his visit to University of Minnesota.

CORRIGENDUM: SUPPRESSION OF THE DIRICHLET EIGENVALUES OF A COATED BODY*

STEVE ROSENCRANS† AND XUEFENG WANG†

Abstract. In our paper [*SIAM J. Appl. Math.*, 66 (2006), pp. 1895–1916] there are several mistakes in signs in the statements of Theorems 3 and 6.

Key words. nanocomposite, Dirichlet eigenvalue, anisotropic heat conduction, thermal tensor, thermal management, insulation, reinforcement

AMS subject classifications. 35J05, 35J20, 80A20, 80M30, 80M40

DOI. 10.1137/070705404

In the upper bounds on $\lambda_1(\Omega)$ stated in Theorems 3 and 6, there should be "$-$" signs in front of π and $\overline{H}$.

On page 1905 all "$-$" signs in front of the principal curvatures k_1 and k_2 should be changed to "$+$" signs. This leads to some obvious minor changes in the rest of the proof of Theorem 3 and the statement and proof of Lemma 5. The speed of the curves of principal curvature are 1 only at q, and so the six equations following "speed equal to 1" hold only at q.

These corrections necessitate *only* the above-mentioned changes in the statements of Theorems 3 and 6. The statements of all the other theorems remain unchanged.

RETURN MAP CHARACTERIZATIONS FOR A MODEL OF BURSTING WITH TWO SLOW VARIABLES*

ROGER E. GRIFFITHS† AND MARK PERNAROWSKI‡

Abstract. Various physiological systems display bursting electrical activity (BEA). There exist numerous three-variable models to describe this behavior. However, higher-dimensional models with two slow processes have recently been used to explain qualitative features of the BEA of some experimentally observed systems [T. Chay and D. Cook, *Math. Biosci.*, 90 (1988), pp. 139–153; P. Smolen and J. Keizer, *J. Memb. Biol.*, 127 (1992), pp. 9–19; R. Bertram et al., *Biophys. J.*, 79 (2000), pp. 2880–2892; R. Bertram et al.,, *Biophys. J.*, 68 (1995), pp. 2323–2332; J. Keizer and P. Smolen, *Proc. Nat. Acad. Sci. USA*, 88 (1991), pp. 3897–3901]. In this paper we present a model with two slow and two fast variables. For some parameter values the system has stable equilibria, while for other values there exist bursting solutions. Singular perturbation methods are used to define a one-dimensional return map, wherein fixed points correspond to singular bursting solutions. We analytically demonstrate that bursting solutions may exist even with a combination of activating and inactivating slow processes. We also demonstrate that for different parameters, bursting solutions may coexist with stable equilibria. Hence small variations in the initial conditions may drastically affect the dynamics.

Key words. bursting, return map, singular perturbation solutions

1. Introduction.

Bursting electrical activity (BEA) is a phenomenon in which the membrane potential of a cell goes through a succession of alternating active (spiking) and silent states (cf. Figure 1.1). Such patterns of electrical activity were first observed experimentally in the electrical activity of the Aplysia R-15 neuron [52, 1]. Biophysical mechanisms of bursting in the pancreatic β-cell were proposed by Atwater et al. [2], which were later used by Chay and Keizer [15] to create the first "minimal" mathematical model based on the Hodgkin–Huxley model. Since then, there have been a large number of β-cell models [14, 27, 31, 46, 32, 13, 49] and other cellular models exhibiting bursting behavior [18, 26, 56, 55, 8, 33].

Most mathematical models of BEA are variants of the Hodgkin–Huxley model [29] of the squid giant axon. Generically, these models make up a set of (dimensional) differential equations,

$$C_m \frac{dv}{dt} = -\sum_X I_X(v,z), \tag{1.1}$$

$$\frac{dz_i}{dt} = \frac{(z_{i\infty}(v) - z_i)}{\tau_i(v)}, \quad i = 1, 2, \ldots, n, \tag{1.2}$$

where t is time, v is the transmembrane potential, and z_i are typically channel activation (resp., inactivation) variables. In some instances, z_i may be concentrations of regulatory chemicals. Regardless, all such models have a current balance equation

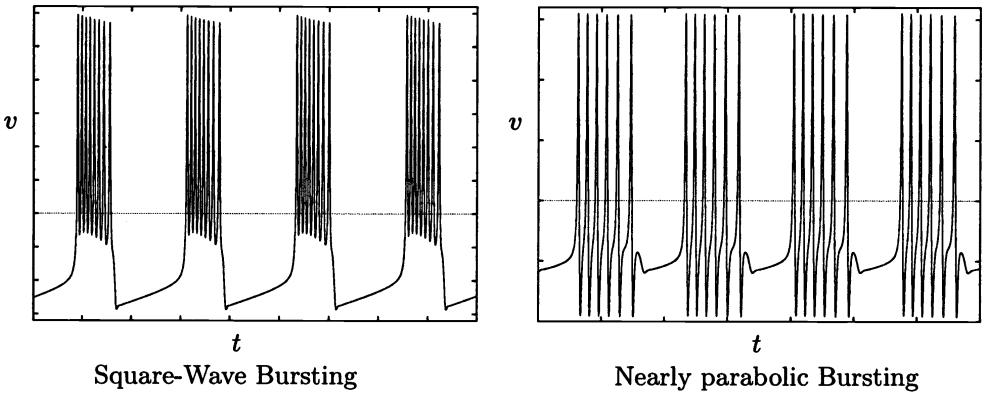

FIG. 1.1. *Some examples of bursting, with their classification type indicated. Here voltage v is plotted against time t.*

such as (1.1), where C_m is the cell's total capacitance and I_X are currents (of type X, i.e., voltage-gated calcium) thought to be relevant to the particular cell being examined. In models of BEA, the time constants τ_i often have greatly different magnitudes. Thus, from a modeling (resp., mathematical) perspective, bursting depends on processes with distinctly different time scales, typically termed *fast* and *slow*. The fast processes remain in quasi-steady state except for the rapid transitions between states, while the slow processes modulate the fast dynamics between the silent and active states.

The nonlinearities essential in biophysical models of bursting such as (1.1)–(1.2) make any form of analysis difficult. Consequently, phenomenological models have often been used to explore issues related to bursting (see Hindmarsh and Rose [28], Pernarowski [36], Baer, Rinzel, and Carrillo [3]). Regardless of what type of model is studied, the vast majority of models involve multiple time scales and can be written as a system of the form

$$\frac{dx}{dt} = f(x,y)\,, \quad x \in \mathbb{R}^2, \tag{1.3}$$

$$\frac{dy}{dt} = \varepsilon g(x,y)\,, \quad y \in \mathbb{R}^K, \tag{1.4}$$

where $\varepsilon \ll 1$ is a small parameter. Cast in this form, x are fast variables, while y are slow variables.

Many models of BEA consisting of one slow variable ($K = 1$) have been studied. The goals of such studies have varied. Some studies use numerical methods to simulate postulated models to explain cell mechanisms. Such is the case in numerous studies of the insulin-secreting pancreatic β-cell [15, 12, 46, 45, 43, 17, 44]. In other studies, the goal has been to use singular perturbation ideas and methods to classify the different type of oscillations which can arise from such systems. Such classification studies originated with work by Rinzel [41] and were subsequently continued by others [36, 4, 16, 30]. Lastly, other studies have focused on proving the existence of periodic bursting orbits. For instance, Terman [53] formalized the singular perturbation construction. Interest in such fast-slow systems with one slow variable has even spawned studies of

topological-based proof techniques [24].

Other models of BEA have more than one slow variable [14, 49, 5, 32, 6, 40]. In some recent studies, bursting cycles have been characterized using two-dimensional maps to aid in the construction of singular solutions [51, 9]. In other recent works, one-dimensional maps have been used to explore bifurcations in systems with one slow variable [34]. In all of these works, periodic bursting cycles equate to fixed points of the map, making the use of the map construct simplistically elegant. Despite such recent uses of maps to describe bursting cycles, explicit singular perturbation and numerical constructions of the maps for models exhibiting bursting remain scant.

In this paper we study a phenomenological model of bursting with two slow variables. As in previous works, singular perturbation methods are used here to define a return map to describe the bursting cycle. Unlike previous analyses of models having two slow and two fast variables, our return map is one-dimensional. Also, because the model is simple, many of the perturbation calculations can be performed analytically. The goal of this work is three-fold: (1) to outline new analytical and numerical techniques for such singular constructions; (2) to analytically demonstrate that bursting solutions can exist even when the slow processes are activating and inactivating; and (3) to demonstrate that bursting solutions can coexist with stable equilibria. The latter result, for example, can be used to explain why some isolated pancreatic β-cells burst while others do not [50]. The implications and importance of these results are discussed in the conclusion.

In section 2, the model is introduced and its leading-order fast, slow, and averaged fast subsystems are defined. Since the model is an extension of a previously studied model [36, 37, 16], stability analyses related to the fast subsystem are referenced. A detailed multiple scales averaging calculation used to derive the averaged fast subsystem in section 2 is included in an appendix. This derivation is a multivariable generalization of the single slow variable derivation presented in [39].

As each of the slow and averaged fast subsystems is two-dimensional, each defines a two-dimensional map between the transition curves[1] between the silent and active phases. These maps and their dimensionality reduction are carefully defined in section 3. Singular bursting solutions are determined by the fixed points of the composition ϕ of these maps.

When the time constants $\tau_i, i = 1, 2$, of the slow variables are equal, a transformation is used in section 4 to demonstrate that the model dynamics can be described by a single slow variable. As a consequence, singular bursting solutions exist even if one slow variable is activating and the other is inactivating. Furthermore, we show that the map ϕ defined in section 3 can be computed explicitly. However, when the time constants τ_i are not equal, these analyses do not apply. For this case, a numerical method for computing ϕ is developed and implemented in section 5. The method uses AUTO [19] to solve two one-parameter families of boundary value problems whose solutions can then be used to construct ϕ.

Lastly, in section 6, we present numerical simulations which demonstrate that for certain parameter values the model exhibits bistability between stable equilibria and bursting solutions. There, this dynamic is shown to relate to the domains of the maps used to construct the singular bursting solutions.

[1] Saddle-node and homoclinic bifurcation curves of the fast subsystem.

2. Model and subsystem definitions. In this paper we will study the following two slow variable models:

$$\frac{d\mathbf{u}}{dt} = \mathbf{F}(\mathbf{u},\mathbf{z}) = \begin{pmatrix} f(u) - w - x - \gamma y \\ g(u) - w \end{pmatrix}, \tag{2.1}$$

$$\frac{d\mathbf{z}}{dt} = \varepsilon \mathbf{G}(\mathbf{u},\mathbf{z}) = \varepsilon \begin{pmatrix} \frac{h_1(u)-x}{\tau_1} \\ \frac{h_2(u)-y}{\tau_2} \end{pmatrix}, \tag{2.2}$$

where $0 < \varepsilon \ll 1$, $\mathbf{u} = (u,w)^T$ are fast variables and $\mathbf{z} = (x,y)^T$ are slow variables.

In the model, τ_1, τ_2, and γ are constants; the equations

$$f(u) = -\frac{a}{3}u^3 + a\mu u^2 + (1 - a(\mu^2 - \eta^2))u\,, \tag{2.3}$$

$$g(u) = \left(1 - \frac{a}{3}\right)u^3 + a\mu u^2 - (2 + a(\mu^2 - \eta^2))u - 3 \tag{2.4}$$

are the same functions used in [36, 37], and (a,μ,η) are parameters. The complicated form of the polynomials f and g is due in part to their derivation from a Liénard form in Pernarowski [37]. An advantage of the Liénard form is the availability of the Melnikov theory to analytically approximate homoclinic bifurcation points [39, 36]. Also, as shall be seen in the next section, the location of the fast subsystem equilibria does not depend on (a,μ,η). We mention these facts here for reference purposes only, and will not need them in subsequent analysis.

Finally,

$$h_i(u) = \beta_i(u - \alpha_i), \quad i = 1,2, \tag{2.5}$$

where α_i and β_i are also constants.

In this model u should be interpreted as the membrane potential, whereas w is a fast conductance and x, y are slow conductances for gating channels of the same ion. Hereafter we shall refer to (2.1)–(2.2) as (FULL). Lastly, we note that throughout this paper the notation $\dot{(\,)}$ will be used to denote differentiation in t, as in $\dot{u} = \frac{du}{dt}$.

In the next few sections the fast subsystem (FS), slow subsystem (SS) and averaged fast subsystem (AFS) associated with (FULL) will be defined. These preliminary definitions will be needed to accurately define the return map in section 3.

2.1. (FS) dynamics. On the fast t time scale the dynamics of (FULL) is governed by the (FS) obtained by letting $\varepsilon = 0$,

$$\frac{du}{dt} = f(u) - w - z\,, \quad z \equiv x + \gamma y\,, \tag{2.6}$$

$$\frac{dw}{dt} = g(u) - w\,, \tag{2.7}$$

with the slow variables x and y treated as parameters and combined as shown above. In Figure 2.1 we show a numerically generated (FS) bifurcation diagram in $z = x + \gamma y$. The projection of the equilibria of (FS) onto the (u,z)-plane yields a Z-shaped curve

$$z = G(u) \equiv f(u) - g(u) = -u^3 + 3u + 3. \tag{2.8}$$

Note here that despite the dependence of f and g on the fast parameter set $\lambda_f = (a,\mu,\eta)$, G depends on no parameters. For the remainder of this paper we fix these

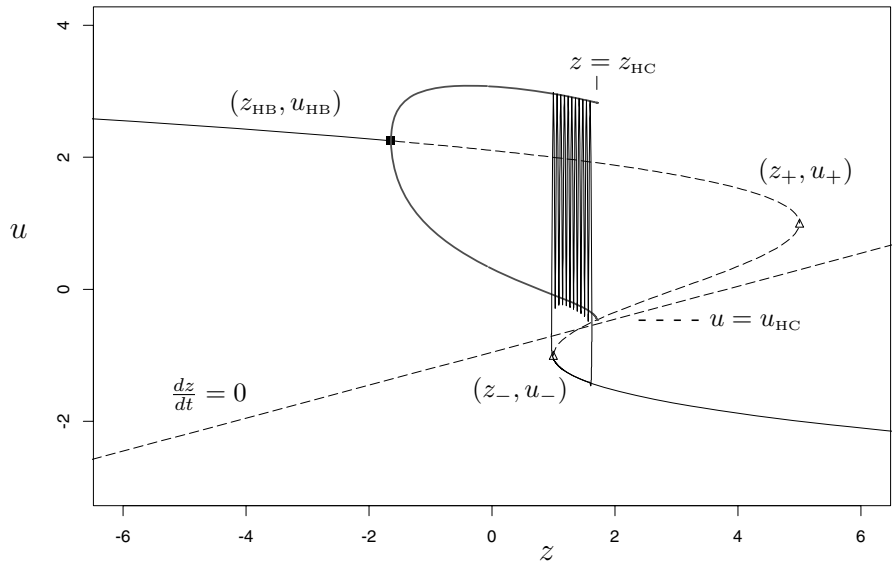

FIG. 2.1. *(FS) bifurcation diagram for* (2.6)–(2.7) *when* $\lambda_f = (a, \eta, \mu) = \left(\frac{1}{4}, \frac{3}{4}, \frac{3}{2}\right)$ *with a bursting solution superimposed. Other parameter values for this illustration are* $\beta = 4, \alpha = -0.954, \varepsilon = 0.0025$.

fast-parameter values at $(a, \mu, \eta) = \left(\frac{1}{4}, \frac{3}{4}, \frac{3}{2}\right)$; for details on fast parameter selection, see [36].

In Figure 2.1, solid lines on the $z = G(u)$ equilibria curve indicate stable equilibria, whereas the dashed portion indicates unstable equilibria. Equilibria on the lower branch are stable nodes, whereas equilibria on the middle branch are saddle points. The stability of the steady states on the upper branch changes at a supercritical Hopf bifurcation at $z = z_{\rm HB}$. Though Figure 2.1 was computed numerically using XPPAUT [21], the aforementioned stabilities and bifurcations were proven analytically in [36]. Stable periodic orbits (the dark, thick lines) emanate from the Hopf point and terminate at a homoclinic bifurcation on the middle branch at $z = z_{\rm HC}$. The upper and lower portions indicate the extreme values of u on the limit cycles of the (FS). Saddle-node bifurcations are indicated at $z = z_-$ and $z = z_+$. Note that the (FS) has a region of bistability, where stable lower branch equilibria and periodic orbits coexist for $z \in (z_-, z_{\rm HC})$. In later sections we will make reference to the values $u_+, u_-, u_{\rm HC}$ as the u value at which the upper saddle-node, lower saddle-node, and homoclinic bifurcations occur, respectively. Also, as indicated in Figure 2.1, when we refer to $u_{\rm HC}$ we mean the u value on the middle branch when $z = z_{\rm HC}$.

The (FS) bifurcation diagram in z described above is identical to that of the one slow variable model discussed in [37]. In that model, z evolves according to the differential equation

$$\frac{dz}{dt} = \varepsilon(h(u) - z), \tag{2.9}$$

where $h(u) = \beta(u - \alpha)$; α and β are parameters; and $\beta > 0$. Collectively, (2.6), (2.7), and (2.9) define the one slow variable model in [37]. Before we examine bursting solutions of (FULL), we briefly describe a bursting cycle of the aforementioned one slow variable model for comparison. Toward this end, the z (slow) nullcline associated with (2.9) is superimposed on the (FS) bifurcation diagram in Figure 2.1 (dashed line

passing through the middle branch of the Z curve). Here we have used the slow parameter values $(\alpha, \beta) = (-0.954, 4)$.

In this example with $\beta > 0$, $\dot{z}$ is negative only below the nullcline. Thus, z slowly increases above the nullcline and decreases below it. Keeping this in mind, a bursting solution of the one slow variable model (2.6), (2.7), (2.9) is superimposed on the (FS) bifurcation diagram in Figure 2.1. In what is often referred to as the "silent phase," trajectories lie close to the lower branch of equilibria. Since $\dot{z} < 0$ on the lower branch, trajectories move to the left until bistability is lost at the saddle-node bifurcation point (z_-, u_-). As z decreases below z_-, trajectories are then attracted to the (FS) limit cycles, initiating the "active phase" marked by high-frequency oscillations. In the active phase, $\dot{z} > 0$ so that solutions slowly drift to the right until bistability is lost at the homoclinic bifurcation point at $z = z_{\text{HC}}$. Trajectories are then attracted to the lower branch, initiating the silent phase again.

This explanation of the resulting "square wave" bursting cycle was given by Rinzel in [41], where he classified several other types of bursting cycles depending on their fast (and slow) subsystem structure. In a later classification scheme [4], the cycle depicted in Figure 2.1 is known as type I bursting. In a subsequent and more extensive classification scheme [30], the same cycle is described as a "fold/homoclinic burster"; its name is due to the fact that the silent phase ends via a *fold* bifurcation and the active phase terminates via a saddle *homoclinic* orbit bifurcation.

Though the (FS) of (FULL) is identical to that of the one slow variable model just discussed, in (FULL) the slow variables x and y do not evolve according to (2.9) but by (2.2). Instead, silent phase trajectories of (FULL) are attracted to the stable manifold

$$\mathbb{S}_L = \{(u, w, x, y) : x + \gamma y = G(u), w = g(u), u < u_-\}, \tag{2.10}$$

formed by the lower branch equilibria of the (FS). In contrast to the single slow variable model, this is a two-dimensional manifold in $\mathbb{R}^4$, making the preceding explanation of the bursting cycle using (2.9) inapplicable. Later, we shall make use of the fact that bursting cycles of (FULL) are conveniently described by projecting them onto the (x, y)-plane. Toward this end, we define the projection $P(\mathbb{S}_L)$ of $\mathbb{S}_L$ onto the (x, y)-plane as

$$S_L = \{(x, y) : x + \gamma y = G(u), u < u_-\}. \tag{2.11}$$

The reason we distinguish S_L from $\mathbb{S}_L$ is that later it will become easier to visualize trajectories on S_L rather than on $\mathbb{S}_L$. We note, for instance, that equilibria of (FULL) truly exist only on $\mathbb{S}_L$.

2.2. (SS) dynamics. In this section we define the (SS) of (FULL). Using the (slow time) transformation $\tau = \varepsilon t$ in (FULL) and then setting $\varepsilon = 0$ results in the system

$$z = x + \gamma y = G(u), \tag{2.12}$$

$$w = g(u), \tag{2.13}$$

$$\frac{dx}{d\tau} = \frac{h_1(u) - x}{\tau_1}, \tag{2.14}$$

$$\frac{dy}{d\tau} = \frac{h_2(u) - y}{\tau_2}. \tag{2.15}$$

Collectively, (2.12)–(2.15) define the (SS) of (FULL) as long as $u < u_-$. Solutions of (2.12)–(2.15) yield trajectories on $\mathbb{S}_L$ which are leading-order approximations to the silent phase of (FULL).

Equations (2.12)–(2.13) are algebraic conditions which ensure the (SS) flow remains on $\mathbb{S}_L$. Rewritten, this condition is equivalent to the cubic

$$u^3 - 3u - 3 + z = 0. \tag{2.16}$$

Roots of (2.16) can be explicitly computed. Here we use the trigonometric form of these roots discussed in [7]. Since the root associated with $\mathbb{S}_L$ has $u < u_-$, it is readily verified that on the lower branch of the (FS),

$$u = u_{\text{LB}}(z) = \begin{cases} 2\cos\left(\frac{1}{3}\arccos\left(\frac{3-z}{2}\right) + \frac{2\pi}{3}\right), & 1 \le z \le 5, \\ -2\cosh\left(\frac{1}{3}\ln\left(\frac{z-3}{2} + \sqrt{\left(\frac{z-3}{2}\right)^2 - 1}\right)\right), & z > 5. \end{cases} \tag{2.17}$$

This allows one to rewrite (2.14)–(2.15) as

$$\frac{dx}{d\tau} = F_1(x,y) \equiv \frac{\beta_1(u_{\text{LB}}(z) - \alpha_1) - x}{\tau_1}, \tag{2.18}$$

$$\frac{dy}{d\tau} = F_2(x,y) \equiv \frac{\beta_2(u_{\text{LB}}(z) - \alpha_2) - y}{\tau_2}. \tag{2.19}$$

Solutions of (2.18)–(2.19) are leading-order silent phase approximations of (FULL) projected onto the (x,y)-plane when initial conditions are close to $\mathbb{S}_L$. In section 3, system (2.18)–(2.19) will be used to define the portion of the map needed to describe the dynamics of (FULL) in the silent phase.

At this point we also note that the (FS) and the (SS) depend on different parameters. For future reference, we define the *fast* parameter set λ_f as those parameters which occur explicitly in the (FS) but not in the (SS). In this case, $\lambda_f = (a, \eta, \mu)$. In a similar fashion, we define the *slow* parameter set λ_s as those parameters which occur explicitly in the (SS) but not in the (FS). For (FULL), $\lambda_s = (\beta_1, \beta_2, \alpha_1, \alpha_2, \tau_1, \tau_2)$.

2.3. (AFS). In this section we define the (AFS) associated with (FULL). Like the (SS), the (AFS) is a leading-order approximation for the x and y components of (FULL) valid for slow times $\tau = O(1)$. In contrast to the (SS), the (AFS) is an approximation valid only for initial conditions near the (FS) limit cycles.[2] The details of the expansions, assumptions, and multiple scales procedure used to derive the (AFS) are included in the appendix. Here we merely summarize the relevant points.

Defining the set

$$S_A = \{(x,y) : z_{HB} < x + \gamma y < z_{\text{HC}}\}, \tag{2.20}$$

we note from Figure 2.1 that the (FS) has a stable $T(z)$-periodic limit cycle $(u,w) = \Omega(t,z)$ for every $(x,y) \in S_A$. Here the limit cycle $\Omega(t,z)$ and its associated period T

[2]Since the averaging is performed over these (FS) limit cycles, we named the system the "averaged fast subsystem." This naming scheme was chosen to avoid confusion were the averaging performed over periodic orbits lying near the slow manifold of the (SS). Indeed, in [25], the (SS) is shown to possess Hopf bifurcations for some parameter values. An exploration of averaged slow subsystems near such Hopf points is not done in this paper.

are functions of $z = x + \gamma y$ alone. If we define the average

$$\hat{u}(z) \equiv \frac{1}{T(z)} \int_0^{T(z)} \Omega_1(\eta, z) d\eta, \tag{2.21}$$

where $\Omega(t,z) = (\Omega_1(t,z), \Omega_2(t,z))$, and take advantage of the linearity of $h_i(u)$, $i = 1, 2$, in u, the (AFS) of (FULL) is

$$\frac{dx}{d\tau} = \widehat{G}_1(x,y) = \frac{h_1(\hat{u}(x+\gamma y)) - x}{\tau_1}\ , \tag{2.22}$$

$$\frac{dy}{d\tau} = \widehat{G}_2(x,y) = \frac{h_2(\hat{u}(x+\gamma y)) - y}{\tau_2}\ . \tag{2.23}$$

For initial conditions sufficiently close to Ω, solutions of (2.22)–(2.23) are leading-order asymptotic approximations of (x,y) in (FULL) for times $\tau = O(1)$ as long as $(x(\tau), y(\tau)) \in S_A$. In the singular limit, bistability of the (FS) is lost when $z = z_{\rm HC}$, at which point a transition to the silent phase occurs.

Subsequently, we will need to perform computations using the (AFS). For these calculations we used AUTO [19] to compute $\hat{u}(z)$ for a range of z values. These values are shown in Figure 2.2, where they are compared to an approximating function $\hat{u}_a(z)$ of the form

$$\widehat{u}_a(z) = u_{\rm HC} + a_0 \left(z_{\rm HC} - z\right)^{\frac{1}{p}} + a_1 \left(z_{\rm HC} - z\right). \tag{2.24}$$

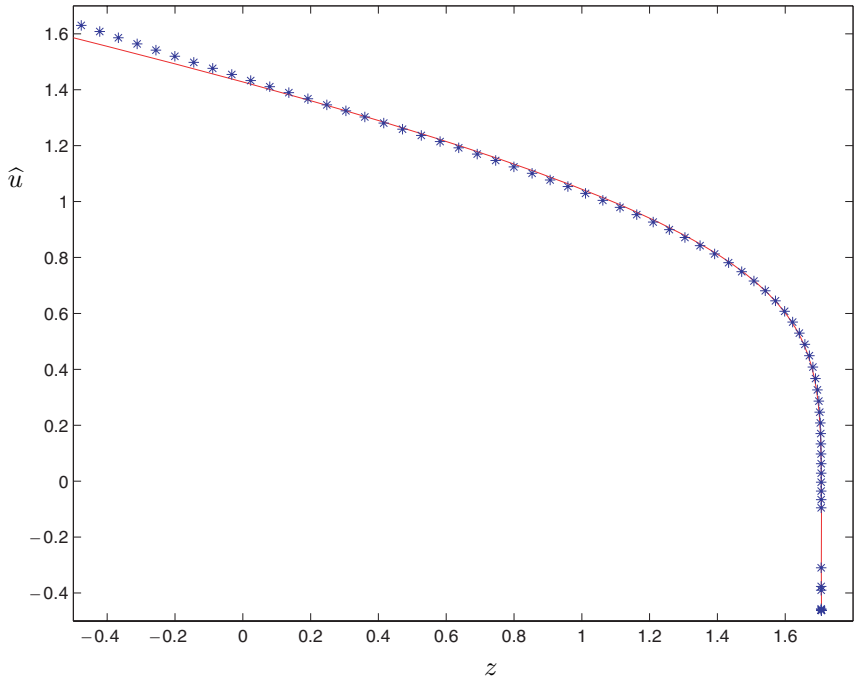

FIG. 2.2. *$\widehat{u}(z)$ plotted as AUTO-generated data along with the approximating function $\widehat{u}_a(z)$. $\widehat{u}(z)$ is u averaged over the limit cycles $\Omega(t,z)$. The AUTO-generated data are plotted as *'s and the superimposed curve is the approximating function $\widehat{u}_a(z)$ defined in* (2.24).

As can be seen in Figure 2.2, for the choice $(p, a_0, a_1) = (8, 1.378, 0.260)$, $\hat{u}(z)$ and $\hat{u}_a(z)$ are almost indistinguishable over the active phase range $z_- < z < z_{\rm HC}$. Here $z_- = 1$ and $(z_{\rm HC}, u_{\rm HC}) \simeq (1.70633, -0.46466)$ were estimated using AUTO. We note that (2.24) may be viewed as a two term asymptotic expansion for $\hat{u}(z)$. However, we currently have no theoretical explanation as to why $\hat{u}_a(z)$ approximates $\hat{u}(z)$ so well.

We conclude this section with a numerical example showing how well the (AFS) approximates (FULL) in the active phase. In Figure 2.3, an active phase trajectory of (FULL) projected into the (x, y)-plane is shown together with a solution of the (AFS) with the same initial conditions. Superimposed is the line $x + \gamma y = z_{\rm HC}$, labeled as $\Gamma_{\rm HC}$ in the figures. On this line the (FS) has a homoclinic bifurcation. For the

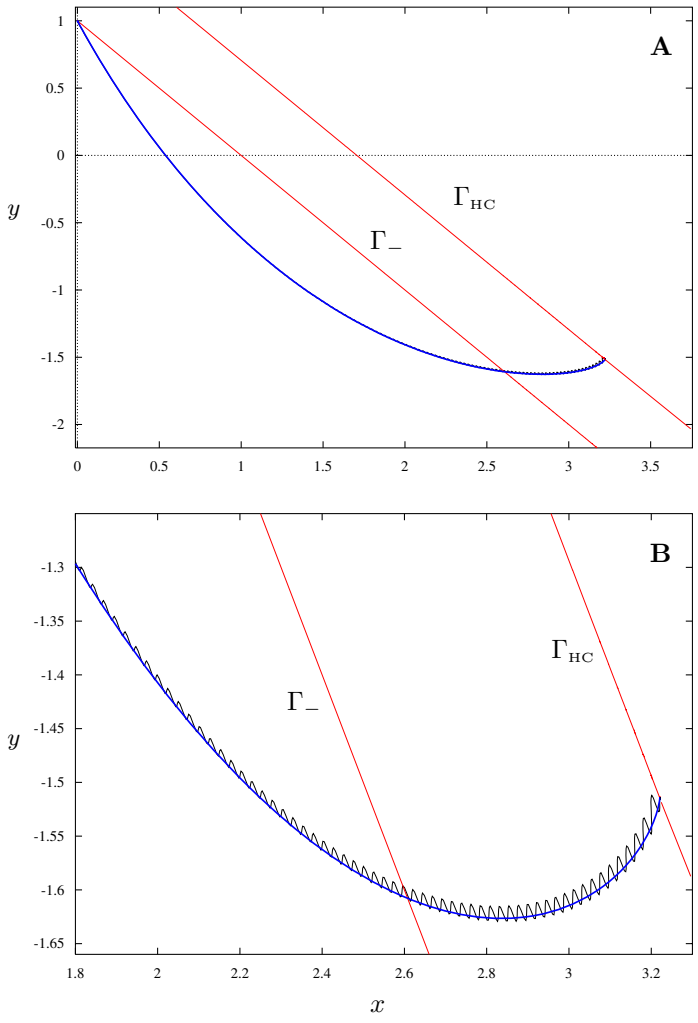

FIG. 2.3. *Both figures show an active phase trajectory of (FULL) projected into the (x, y)-plane along with the (AFS) approximation using* (2.24), $\lambda_s = (\beta_1, \beta_2, \alpha_1, \alpha_2, \tau_1, \tau_2) = (4, -1, -1, -0.7, 1, 0.5)$, *and* $\varepsilon = 0.0025$. **A** *shows the entire active phase, whereas in* **B** *we have enlarged the region near the jump to the silent phase at the homoclinic bifurcation of the (FS). The lines Γ_{HC} and Γ_- are defined in* (3.1), (3.2), *respectively.*

(x, y) values above Γ_{HC} the (FS) does not have periodic orbits. Thus, for those values the (AFS) is undefined. Moreover, to leading order, as trajectories of (FULL) cross above Γ_{HC}, a rapid transition back to the silent phase occurs. Analogous transitions of (FULL) from the silent phase into the active phase would occur as trajectories traverse below the line $x + \gamma y = z_-$. This line, labeled as Γ_-, is also superimposed in the figures purely for reference purposes and represents the (x, y) pairs for which the (FS) has a saddle-node bifurcation. A more complete discussion of these transition curves and their relevance to an overall bursting cycle is relegated to the next section, where the return maps for the leading dynamics are defined. Here, the point is simply to illustrate just how well the (AFS) using (2.24) approximates (FULL) in the active phase. In this particular example, parameter values were chosen so that the projected active phase solution of (FULL) extended over a wide range of $z = x + \gamma y$ for which the (FS) has limit cycles. The figures illustrate that the projected trajectory $(x(t), y(t))$ of (FULL) is very well approximated by the (AFS) trajectories over just such a large range of z values. Indeed, even in the enlargement shown in Figure 2.3B, the trajectories remain very close in the region between Γ_- and Γ_{HC}, where the (FS) is bistable.

3. Definition of the return map. We define a bursting solution of (FULL) as a trajectory which both is periodic and traverses the active and silent phases once during each period. By a singular bursting solution of (FULL) we mean a bursting solution whose leading-order approximation consists of a silent phase portion approximated by the (SS), an active phase portion approximated by the (AFS), and two rapid transitions between each phase at $z = z_-$ and $z = z_{\text{HC}}$, as illustrated in Figure 2.1.

The return map we construct to describe singular bursting solutions of (FULL) is actually the composition of two maps, as illustrated in Figure 3.1. One map accounts for the silent phase and the other for the active phase. The silent phase portion of the singular solution is constructed from a trajectory $\tilde{\gamma}_x(\tau)$ of the (SS) which starts at $\mathbf{X} = (x, y)$ on the curve

$$\Gamma_{\text{HC}} = \{(x, y) : x + \gamma y = z_{\text{HC}}\} \subset \overline{S}_A \tag{3.1}$$

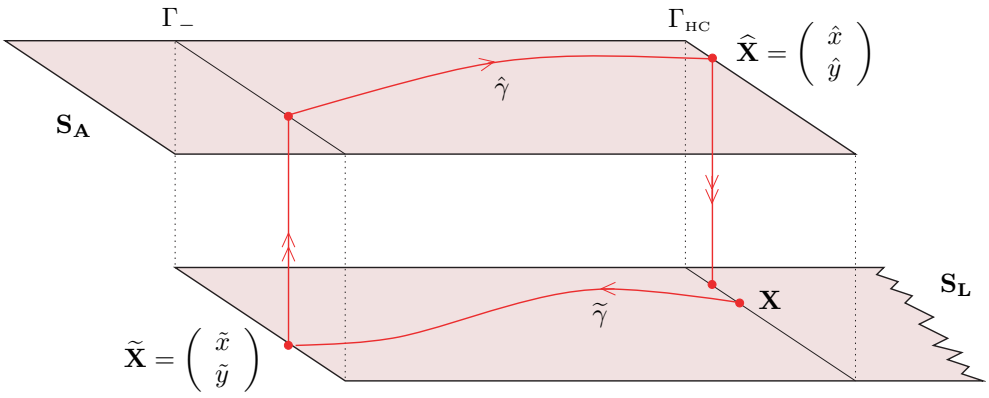

FIG. 3.1. *Illustration of the return map definition for singular bursting solutions. Illustration S_L is shown on bottom with a trajectory of the (SS) $\tilde{\gamma}$ beginning at $\mathbf{X} = (x, y) \in \Gamma_{HC}$. After a fast transition to S_A on the top, the (AFS) trajectory $\hat{\gamma}$ is shown to terminate at $\widehat{\mathbf{X}} \in \Gamma_{HC}$.*

and terminates at $\widetilde{\mathbf{X}}$ on

$$\Gamma_- = \{(x,y) : x + \gamma y = z_-\} \subset \overline{S}_A \tag{3.2}$$

after time T_s. When such transitions occur, this defines a map $\widetilde{\Phi} : \Gamma_{\text{HC}} \to \Gamma_-$ such that $\widetilde{\mathbf{X}} = \widetilde{\Phi}(\mathbf{X})$.

Similarly, the active phase portion is constructed from a trajectory $\hat{\gamma}_x(\tau)$ of the (AFS) which starts at $\widetilde{\mathbf{X}}$ on the lower saddle-node curve Γ_- and terminates at $\widehat{\mathbf{X}}$ on the curve Γ_{HC}, which forms a boundary of S_A. This transition defines a map $\widehat{\Phi} : \Gamma_- \to \Gamma_{\text{HC}}$ such that $\widehat{\mathbf{X}} = \widehat{\Phi}(\widetilde{\mathbf{X}})$.

The composition of these two maps may be written as $\Phi : \Gamma_{\text{HC}} \to \Gamma_{\text{HC}}$, $\mathbf{X} = (x,y)$,

$$\Phi(\mathbf{X}) = \left(\widehat{\Phi} \circ \widetilde{\Phi}\right)(\mathbf{X}). \tag{3.3}$$

Given these definitions, there is then a 1-1 correspondence between singular bursting solutions and fixed points of Φ.

At this point we also remark that $\widetilde{\Phi}$ and $\widehat{\Phi}$ are, technically, maps from $\mathbb{R}^2$ into $\mathbb{R}^2$, but they have restricted domains, i.e., $\Gamma_{\text{HC}} \subset \mathbb{R}^2$ for $\widetilde{\Phi}$. Clearly such domain restrictions are not needed. For instance, one could have defined $\widehat{\Phi}$ as the flow function associated with the (SS) defined on $D_\Phi = \{(x,y) : x + \gamma y > z_-\}$. Although such a definition has much theoretical appeal, our subsequent dimensionality reduction below is slightly more transparent using the domain restrictions.

A feature we use to our advantage is that y is a function of x on both Γ_- and Γ_{HC}—specifically, on Γ_-: $y = \frac{z_- - x}{\gamma}$ and on Γ_{HC}: $y = \frac{z_{\text{HC}} - x}{\gamma}$. As such, $\widehat{\Phi}$ reduces to a one-dimensional map $\widehat{\phi} : \mathbb{R} \to \mathbb{R}$, $\widehat{\phi}(x_0) = \hat{x}(T_a)$, where T_a is the active phase duration. Here $\widehat{x}_0 = \widehat{\phi}(x_0)$ is the x-coordinate of an (AFS) trajectory, where bistability is lost at $z = z_{\text{HC}}$ and a transition to the silent phase occurs. Adopting this convention, the domain of the map $\widehat{\phi}$ can be written

$$D(\widehat{\phi}) = \{x \in \mathbb{R} \,|\, \exists T_a < \infty \ni \widehat{\gamma}_x(T_a) \cap \Gamma_{\text{HC}} \neq \emptyset\},$$

where $\emptyset$ is the empty set.

An analogous one-dimensional map for the (SS) may be defined. Again exploiting the functional relationship of x and y on Γ_{HC} and Γ_-, we define the map $\widetilde{\phi} : \mathbb{R} \to \mathbb{R}$ with domain

$$D(\widetilde{\phi}) = \{x \in \mathbb{R} \,|\, \exists T_s < \infty \ni \widetilde{\gamma}_x(T_s) \cap \Gamma_- \neq \emptyset\},$$

where T_s is the silent phase duration.

Then, as with the map Φ, there is a 1-1 correspondence of singular bursting solutions and fixed points $\bar{x}$ of the map

$$\phi(x) = (\widehat{\phi} \circ \widetilde{\phi})(x), \quad x \in D(\phi) = \{x \in \mathbb{R} \,|\, x \in D(\widetilde{\phi})\,,\ \widetilde{\phi}(x) \in D(\widehat{\phi})\}.$$

Domain issues associated with the map are complicated, but some will be addressed in section 6. If $R(\widehat{\phi})$ is the range of $\widehat{\phi}$, then, given our previous definitions, the set $W \equiv R(\widehat{\phi}) \cap D(\widetilde{\phi})$ could be empty, equal to $D(\widetilde{\phi})$, or a (nonempty) strict subset of $D(\widetilde{\phi})$. In the next section we show that for a subset of slow parameter space, singular bursting solutions exist and W is nonempty. The case when W is a strict subset of $D(\widetilde{\phi})$ relates to bistability between bursting solutions and stable equilibria on $\mathbb{S}_L$. This will be discussed in section 6.

4. Degenerate case. In this section we examine a degenerate case of (FULL), where the time constants τ_1 and τ_2 are equal. In this degenerate case, (FULL) is shown to have a three-dimensional manifold on which (for certain parameter values) bursting solutions exist. Furthermore, we explicitly compute the maps defined in the previous section and the fixed point of ϕ associated with the singular bursting solution.

We accomplish these goals using the following linear transformation of the slow variables:

$$\mathbf{p} = A\mathbf{z} + \mathbf{b} = \begin{bmatrix} a_{11} & a_{12} \\ 1 & \gamma \end{bmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} b_1 \\ 0 \end{pmatrix}, \quad \mathbf{z} = (x, y)^T, \tag{4.1}$$

where $\mathbf{p} = (p, z)^T$ are the new slow variables, $z = x + \gamma y$ are as before, and a_{11}, a_{12}, b_1 are to be determined. Since z is one of the new variables, the new (FS) of the transformed (FULL) will depend solely on z. Assuming $a_{11}\gamma - a_{12} \neq 0$ so that A is invertible, (4.1) and (2.2) imply

$$\frac{d\mathbf{p}}{dt} = \varepsilon A\mathbf{G}\left(u, A^{-1}(\mathbf{p} - \mathbf{b})\right). \tag{4.2}$$

Since $\mathbf{G}(u, \mathbf{z})$ depends linearly on u, x, and y, (4.2) can be equivalently written as

$$\frac{d\mathbf{p}}{dt} = \begin{bmatrix} \eta_{11} & \eta_{12} & \eta_{13} \\ \eta_{21} & \eta_{22} & \eta_{23} \end{bmatrix} \begin{pmatrix} u \\ z \\ p \end{pmatrix} + \begin{pmatrix} \zeta_1 \\ \zeta_2 \end{pmatrix} \tag{4.3}$$

for appropriate definitions of η_{ij}, ζ_i. To ensure that the new differential equation for z does not depend explicitly on p, we require that $\eta_{23} = 0$. Since calculations reveal

$$\eta_{23} = \frac{\gamma(\tau_1 - \tau_2)}{\tau_1\tau_2 \; detA},$$

the new slow variable p will be decoupled from the resulting (u, w, z) system only if $\tau_1 = \tau_2$ (which is precisely how we defined the degenerate case).

By assuming $\tau_1 = \tau_2$, the choice

$$a_{11} = 1\,, \quad a_{12} = -\frac{\beta_1\tau_2}{\beta_2\tau_1}\,, \quad b_1 = \beta_1(\alpha_1 - \alpha_2) + 1 \tag{4.4}$$

then results in the transformed system

$$\frac{du}{dt} = f(u) - w - z, \tag{4.5}$$

$$\frac{dw}{dt} = g(u) - w, \tag{4.6}$$

$$\frac{dz}{dt} = \varepsilon\frac{H(u) - z}{\tau_1}, \tag{4.7}$$

$$\frac{dp}{dt} = \varepsilon\frac{1 - p}{\tau_1}, \tag{4.8}$$

where

$$H(u) = \beta^*(u - \alpha^*), \tag{4.9}$$

$$\beta^* = \beta_1 + \gamma\beta_2, \tag{4.10}$$

$$\alpha^* = \frac{\beta_1\alpha_1 + \gamma\beta_2\alpha_2}{\beta_1 + \gamma\beta_2}. \tag{4.11}$$

As claimed, we see that the variable p is decoupled from the rest of the system (4.5)–(4.7), showing the reduction of (FULL) to a one slow variable model (4.5)–(4.7). Furthermore, we see in (4.8) that as $t \to \infty$, $p \to 1$. In other words, $p = 1$ is a globally stable three-dimensional manifold on which the dynamics are determined by (4.5)–(4.7). Given (4.1) and (4.4), this implies that the projected trajectories of (FULL) are attracted to the line

$$y = \frac{\beta_2}{\beta_1}x + \beta_2(\alpha_1 - \alpha_2) \tag{4.12}$$

in the (x, y)-plane.

By comparing (4.7) to (2.9) and making the identification $(\beta, \alpha) = (\beta^*, \alpha^*)$, it is evident that on $p = 1$ there exist (β^*, α^*) with $\beta^* > 0$ such that (FULL) has bursting solutions. This assures us, in this degenerate case, that for some subset of slow parameter space there must exist a fixed point $\bar{x}$ for the return map $\phi(x)$.

We illustrate one such bursting solution and fixed point in Figure 4.1. There, XPPAUT [21] was used to numerically integrate (FULL) for the degenerate case $\lambda_s = (\beta_1, \beta_2, \alpha_1, \alpha_2, \tau_1, \tau_2) = (3, 0.5, -1, -3, 1, 1)$ with $\gamma = 0.7$. In Figure 4.1A we see square-wave bursting in the u versus t time trace for this run. In Figure 4.1B we see how the projected trajectory is attracted to the line $y = \frac{\beta_2}{\beta_1}x + \beta_2(\alpha_1 - \alpha_2)$, indicated as $p = 1$. Also superimposed in Figure 4.1B are the two curves Γ_- and Γ_{HC}. Lastly, we note that for this run, since $\beta_1 > 0$ and $\beta_2 > 0$, both x and y are activation variables. Given (4.10), it is clear that the signs of β_i need not be the same for β^* to be positive. Thus, in the degenerate case, combinations of activating and inactivating variables can result in bursting solutions.

4.1. Explicit construction of ϕ in the degenerate case. In this section we find an explicit formula for the map ϕ in the degenerate case. We do this by separately deriving $\widetilde{\phi}$ and $\widehat{\phi}$, after which a direct composition yields ϕ.

First, we determine the silent phase duration T_s. Differentiating (2.12) and using (4.7),

$$\frac{dz}{d\tau} = G'(u)\frac{du}{d\tau} = \frac{H(u) - G(u)}{\tau_1}.$$

Integrating this result,

$$\int_{u_{\text{HC}}}^{u_-} \frac{G'(u)}{H(u) - G(u)}\, du = \int_0^{T_s} \frac{1}{\tau_1}\, d\tau,$$

one may solve for

$$T_s = \tau_1 \int_{u_{\text{HC}}}^{u_-} \frac{G'(u)}{H(u) - G(u)}\, du. \tag{4.13}$$

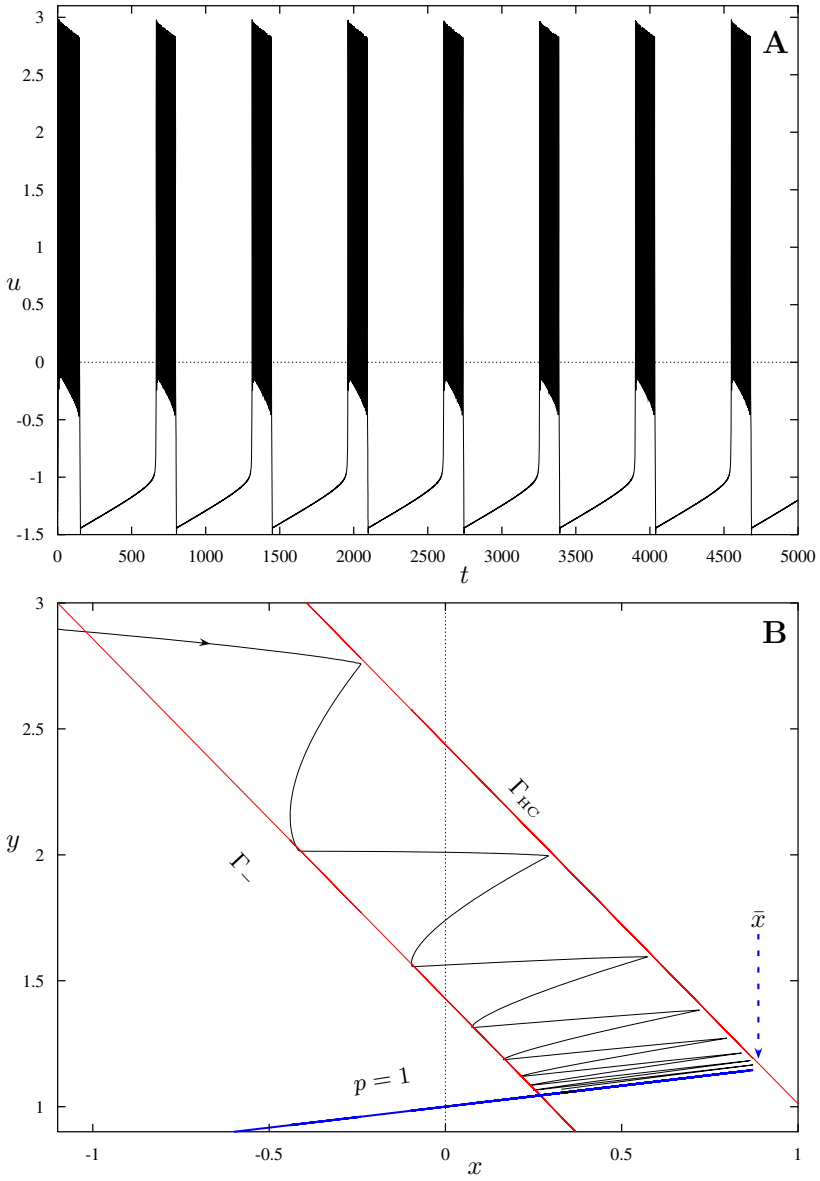

FIG. 4.1. *Illustration of the attraction of projected trajectories to $p = 1$ in the degenerate case.* **A** *shows u versus t for this run. In* **B** *we see the compression of trajectories projected into the (x, y)-plane to the line $y = \frac{\beta_2}{\beta_1} x + \beta_2(\alpha_1 - \alpha_2)$. Parameter values for the run are listed in the text.*

This is the time taken by a projected (SS) trajectory to traverse from $\mathbf{X}_n \in \Gamma_{\rm HC}$ to $\mathbf{X}_{n+1} \in \Gamma_-$, as illustrated in Figure 4.2. Also shown is the line $p = 1$, to which such trajectories are attracted, and the p coordinates p_n and p_{n+1} on $\Gamma_{\rm HC}$ and Γ_-, respectively.

Having found T_s, we integrate (4.8) in the slow time τ,

$$\int_{p_n}^{p_{n+1}} \frac{1}{1-p}\, dp = \int_0^{T_s} \frac{1}{\tau_1}\, d\tau,$$

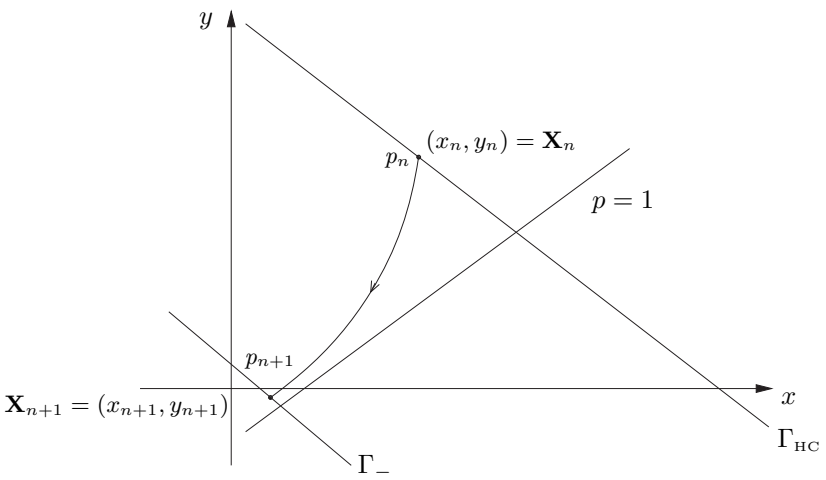

FIG. 4.2. *Projected trajectories on S_L associated with $\widetilde{\phi}$, the degenerate $\tau_1 = \tau_2$ case.*

and find that

$$\ln\left|\frac{1-p_n}{1-p_{n+1}}\right| = \frac{T_s}{\tau_1}. \tag{4.14}$$

However, (4.8) guarantees that $1-p_n$ and $1-p_{n+1}$ have the same sign, so we may drop the absolute values sign in (4.14) and solve for p_{n+1}:

$$p_{n+1} = 1 - (1-p_n)\, e^{\frac{-T_s}{\tau_1}}. \tag{4.15}$$

To convert this expression back into our original (x, y)-coordinate system, we note that by using $\tau_1 = \tau_2$ and (4.4) in (4.1) one finds

$$p = \bar{P}(x, y) = x - \frac{\beta_1}{\beta_2} y + \beta_1(\alpha_1 - \alpha_2) + 1. \tag{4.16}$$

Thus, (4.15) becomes

$$\bar{P}\left(x_{n+1}, \frac{z_- - x_{n+1}}{\gamma}\right) = 1 - \left(1 - \bar{P}\left(x_n, \frac{z_{\text{HC}} - x_n}{\gamma}\right)\right) e^{\frac{-T_s}{\tau_1}}, \tag{4.17}$$

which when solved for x_{n+1} allows us to finally obtain

$$x_{n+1} = \widetilde{\phi}(x_n) = e^{\frac{-T_s}{\tau_1}} x_n + b_s, \tag{4.18}$$

where

$$b_s = \bar{B}(T_s, z_-, z_{\text{HC}}) \equiv \frac{\left(1 - e^{\frac{-T_s}{\tau_1}}\right)\beta_1\beta_2\gamma(\alpha_2 - \alpha_1) + \beta_1\left(z_- - z_{\text{HC}} e^{\frac{-T_s}{\tau_1}}\right)}{\beta_1 + \gamma\beta_2}. \tag{4.19}$$

In a fashion analogous to the derivation of $\widetilde{\phi}$, we compute $\widehat{\phi}$ by integrating (4.8) over the active phase duration T_a. A leading-order value for T_a can be computed by integrating the averaged fast subsystem corresponding to the transformed system

(4.5)–(4.8). Applying the method of averaging to system (4.5)–(4.8), one finds its associated (AFS) is

$$\frac{dz}{d\tau} = \frac{\widehat{H}(z) - z}{\tau_1}, \tag{4.20}$$

$$\frac{dp}{d\tau} = \frac{1-p}{\tau_1}, \tag{4.21}$$

where

$$\widehat{H}(z) = H(\hat{u}(z)) = \beta^*(\hat{u}(z) - \alpha^*), \tag{4.22}$$

and $\hat{u}(z)$ is as defined in (2.21).

In order to compute the active phase duration T_a, we integrate (4.20) as follows:

$$\int_{z_-}^{z_{\rm HC}} \frac{dz}{\widehat{H}(z) - z} = \int_0^{T_a} \frac{1}{\tau_1}\, d\tau,$$

and then solve for T_a to find

$$T_a = \tau_1 \int_{z_-}^{z_{\rm HC}} \frac{dz}{\widehat{H}(z) - z}. \tag{4.23}$$

We let p_n be the p coordinate of an (AFS) trajectory with initial conditions $(x_n, y_n) \in \Gamma_-$. Similarly, we define p_{n+1} to be the p-coordinate of the (AFS) trajectory as it leaves the active phase at $(x_{n+1}, y_{n+1}) \in \Gamma_{\rm HC}$. Then, integrating (4.21),

$$\int_{p_n}^{p_{n+1}} \frac{1}{1-p}\, dp = \int_0^{T_a} \frac{1}{\tau_1}\, d\tau,$$

and proceeding exactly as we did in (4.14)–(4.17) while using the value of T_a from (4.23), we find

$$x_{n+1} = \widehat{\phi}(x_n) = e^{\frac{-T_a}{\tau_1}} x_n + b_a\,, \quad b_a = \bar{B}(T_a, z_{\rm HC}, z_-), \tag{4.24}$$

where the function $\bar{B}$ was defined in (4.19). Also, since $\phi(x) = \widehat{\phi}(\widetilde{\phi}(x))$, (4.18) and (4.24) imply

$$\phi(x) = e^{\frac{-(T_s+T_a)}{\tau_1}} x + b_{as}\,, \tag{4.25}$$

where $b_{as} = e^{\frac{-T_a}{\tau_1}} b_s + b_a$.

From this expression, the fixed point $\bar{x}$ of ϕ is easily computed as

$$\bar{x} = \frac{b_{as}}{1 - e^{\frac{-(T_s+T_a)}{\tau_1}}}. \tag{4.26}$$

It should be noted that the dependence of $\bar{x}$ on the active and silent durations in (4.26) is misleading. As can be seen in Figure 4.1, the fixed point can also be computed as that x value, where the line $p = 1$ intersects $\Gamma_{\rm HC}$. Using (4.16), this value can be found by solving $\bar{P}(x, y) = 1$ and $x + \gamma y = z_{\rm HC}$ for x to find

$$\bar{x} = \frac{\gamma\beta_1\beta_2(\alpha_2 - \alpha_1) + \beta_1 z_{\rm HC}}{\beta_1 + \gamma\beta_2} = \frac{\gamma\beta_1\beta_2(\alpha_2 - \alpha_1) + \beta_1 z_{\rm HC}}{\beta^*}. \tag{4.27}$$

However, given the previous definitions, it is readily verified that (4.26) indeed simplifies to (4.27).

To conclude this section we make some observations about the dependence of the map ϕ on the (activation/inactivation) parameters β_1 and β_2. As was pointed out earlier, β_1 and β_2 need not be of the same sign for ϕ to have the fixed point calculated in (4.27). The issue here is, what degrees of activation and inactivation can lead to such degenerate bursting solutions? Since (4.8) has no dependence on these parameters, the answer to this question is equivalent to knowing the parameter sets (α^*, β^*) for which (4.5)–(4.7) has bursting solutions. A complete description of the set $\mathcal{B}$ of (α^*, β^*) pairs for which such bursting solutions exist is complex but well studied. For instance, for an appropriate $\beta^* > 0$, as α^* is varied the system makes a transition from bursting to continuous spiking via a complex sequence of bifurcations [54]. However, one can glean a few simple results from the explicit expressions for $\bar{x}$ and $\phi(x)$.

For example, when $\beta^* < 0$, system (4.5)–(4.7) typically does not have a bursting solution. Now suppose β^* is initially positive and $\beta_1 < 0$ (inactivation) is decreased while $\beta_2 > 0$ (activation) and $\alpha_k, k = 1, 2$ are held fixed. Given (4.10) and (4.27), one then sees that $\beta^* \to 0+$ and $|\bar{x}| \to \infty$. Alternately, as inactivation increases (with other parameters fixed), the fixed point of the map ϕ will increase in magnitude.

Lastly, we emphasize that other limiting cases may be possible since (α^*, β^*) depend on all $\beta_1, \beta_2, \alpha_1$, and α_2. However, from (4.25),

$$|\phi'(\bar{x})| = e^{\frac{-(T_s+T_a)}{\tau_1}} < 1$$

implies that no such limiting cases in the degenerate case can involve a destabilization of the fixed point $\bar{x}$. Moreover, the singular bursting solutions are always stable (in this degenerate case).

5. Numerically approximating ϕ in the nondegenerate case. In the nondegenerate case when $\tau_1 \neq \tau_2$, explicit formulas for $\widehat{\phi}$ and $\widetilde{\phi}$ remain elusive. In this section we outline a continuation technique for approximating these maps numerically. The technique requires recasting the map values as boundary conditions in two point boundary value problems which are homotopic to simpler problems whose solutions are known.

To be specific, the map $\widetilde{\phi}$ for the slow flow on $\mathbb{S}_L$ is computed as a solution of the following boundary value problem:

$$\frac{dx}{d\tau} = Tf_1(x, y, \lambda) = T\left(-(1-\lambda)x + \lambda F_1(x, y)\right), \tag{5.1}$$

$$\frac{dy}{d\tau} = Tf_2(x, y, \lambda) = T\left(-(1-\lambda)y + \lambda F_2(x, y)\right), \tag{5.2}$$

$$x(0) = x_0, \tag{5.3}$$

$$y(0) = (z_{\text{HC}} - x_0)/\gamma, \tag{5.4}$$

$$x(1) = x_f, \tag{5.5}$$

$$y(1) = (z_- - x_f)/\gamma, \tag{5.6}$$

where the vector field $\mathbf{F} = (F_1, F_2)$ is that of the (SS) in (2.18)–(2.19), T is a constant, λ is a homotopy parameter, and $\mathbf{f}(x, y, \lambda) \equiv (f_1, f_2)$. The boundary conditions (5.3)–(5.4) imply $(x(0), y(0)) \in \Gamma_{\text{HC}}$. Similarly, (5.5)–(5.6) imply $(x(1), y(1)) \in \Gamma_-$. Thus, solutions of this boundary value problem describe trajectories which start on Γ_{HC} and terminate on Γ_-. When $\lambda = 1$, $\mathbf{f}(x, y, 1) = \mathbf{F}(x, y)$, so that $x_f = \widetilde{\phi}(x_0)$ providing

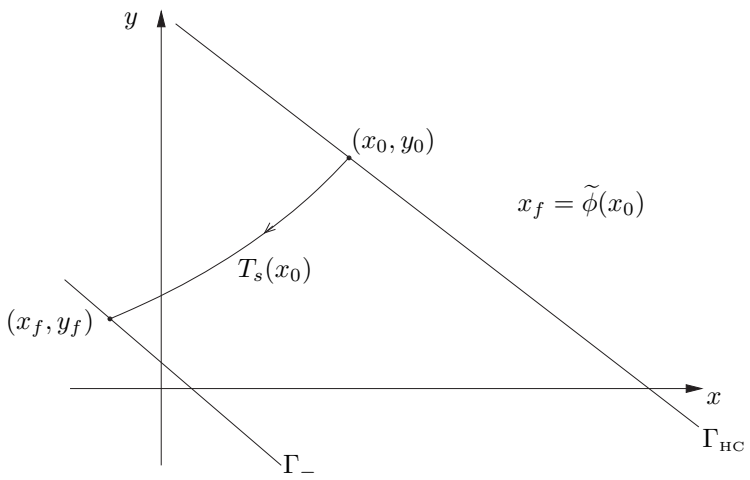

FIG. 5.1. *An illustration of $\widetilde{\phi}$ and the (SS) projected into the (x, y)-plane.*

$T = T_s$, the silent phase duration. A diagram illustrating this $\lambda = 1$ case is shown in Figure 5.1.

When $\lambda = 0$, the solution of (5.1)–(5.6) is known explicitly:

$$x(\tau) = x_0 e^{-\tau T}, \quad y(\tau) = \frac{z_{\rm HC} - x_0}{\gamma} e^{-\tau T}, \quad T = ln\left(\frac{z_{\rm HC}}{z_-}\right), \quad x_f = x_0 e^{-T}.$$

AUTO [19, 20] was then used to numerically continue this known solution to the $\lambda = 1$ case while letting the three parameters (λ, x_f, T) vary. Then, keeping $\lambda = 1$ fixed, (x_0, x_f, T) are allowed to vary in a subsequent run over a prescribed range of initial x values x_0. Given Figure 5.1, the resulting x_f values are $\widetilde{\phi}(x_0)$, and T is the silent phase duration T_s.

Results of these calculations are illustrated in Figures 5.2(a) and 5.2(b). There, $\widetilde{\phi}(x)$ is illustrated for the two-parameter sets listed in Table 5.1. For the $(+,+)$ case (Figures 5.2(a), (c), (e)) where $\beta_i > 0$, both x and y model activating variables in (FULL). In an analogous fashion, the $(+,-)$ case (Figures 5.2(b), (d), (f)) models the competing effect of activating and inactivating variables. Superimposed on the figures is the line $y = x$ as a point of reference. As a note, however, the fixed points of $\widetilde{\phi}(x)$ do not correspond to bursting solutions of (FULL).

The technique for generating $\widehat{\phi}$ from the (AFS) is similar. One first defines the boundary value problem

$$\frac{dx}{d\tau} = T g_1(x, y, \lambda) = T\left(x(1-\lambda) + \lambda \widehat{G}_1(x, y)\right), \tag{5.7}$$

$$\frac{dy}{d\tau} = T g_2(x, y, \lambda) = T\left(\lambda \widehat{G}_2(x, y)\right), \tag{5.8}$$

$$x(0) = x_0, \tag{5.9}$$

$$y(0) = (z_- - x_0)/\gamma, \tag{5.10}$$

$$x(1) = x_f, \tag{5.11}$$

$$y(1) = (z_{\rm HC} - x_f)/\gamma, \tag{5.12}$$

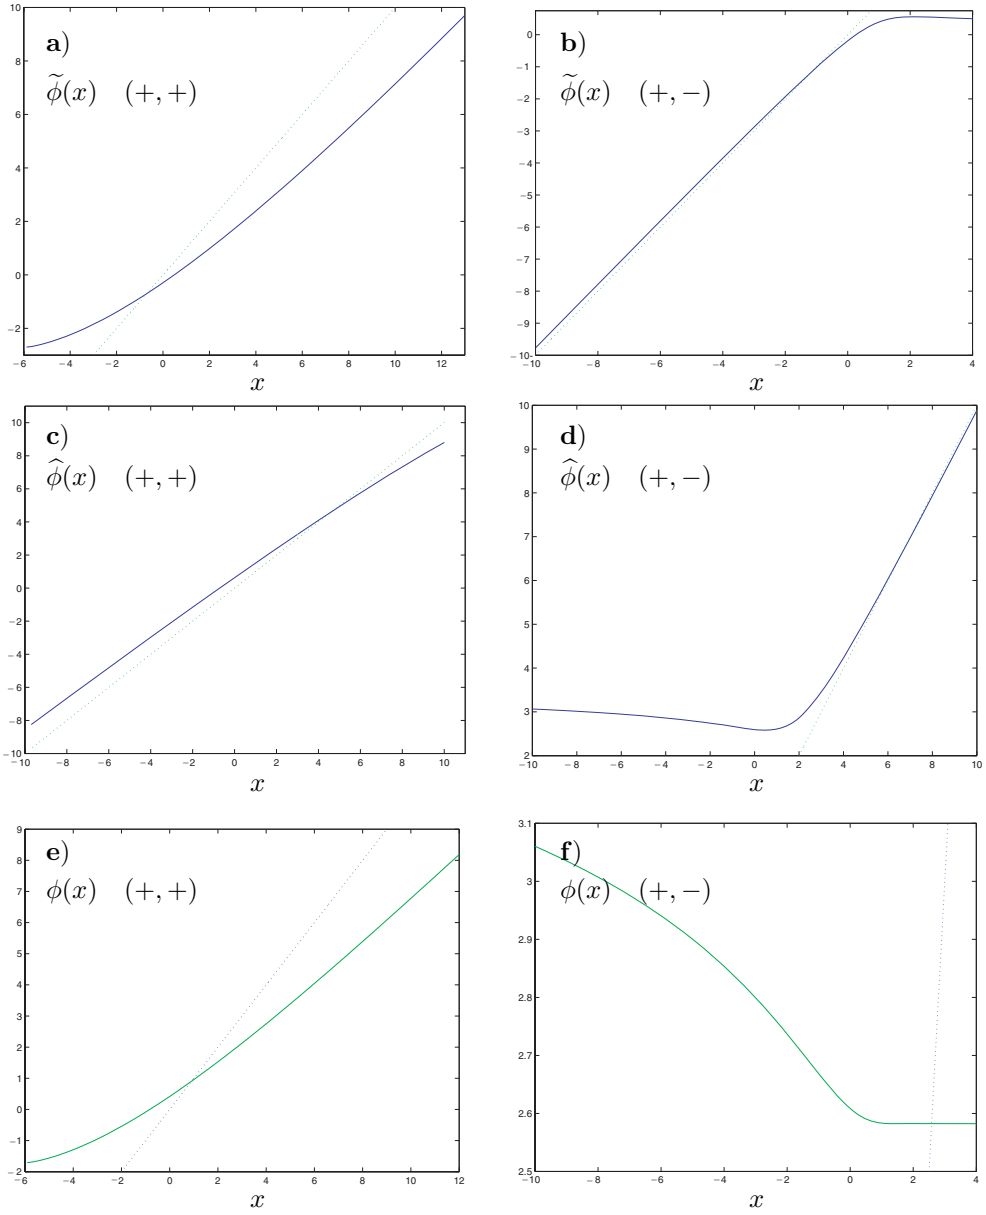

FIG. 5.2. *Maps $\widetilde{\phi}, \widehat{\phi}$, and $\phi(x)$ generated numerically using AUTO. Shown are $\widetilde{\phi}(x)$, $\widehat{\phi}(x)$, and $\phi(x)$ for a range of initial x values; the $(+,+)$ case is shown in* **a**, **c**, **e**; *the $(+,-)$ case in* **b**, **d**, **f**. *Parameter values for each computation are tabulated in Table* 5.1.

where the vector field $\widehat{\mathbf{G}} = (\widehat{G}_1, \widehat{G}_2)$ is that defined in (2.22)–(2.23), and $\mathbf{g}(x, y, \lambda) \equiv (g_1, g_2)$. As before, $\mathbf{g}(x, y, 1) = \widehat{\mathbf{G}}(x, y)$ implies $x_f = \widehat{\phi}(x_0)$ when T is the active phase duration T_a.

However, the problem (5.7)–(5.12) differs from (5.1)–(5.6) in an essential way. In the former, the vector field $\mathbf{g}(x, y, 0) = (x, 0)$ was chosen to match the flow direction of the (AFS) *from* Γ_- to Γ_{HC}. In contrast, the flow direction of $\mathbf{f}(x, y, 0) = (-x, -y)$ was chosen so that trajectories starting on Γ_{HC} would terminate on Γ_-. The choice of initial ($\lambda = 0$) vector fields is not unique. Here we have chosen simple ones which retain the flow directionality of each subsystem and whose analytic solution is known. For the choice $\mathbf{g}(x, y, 0) = (x, 0)$, the exact initial solution is

$$x(\tau) = x_0 e^{\tau T}, \quad y(\tau) = \frac{z_- - x_0}{\gamma}, \quad T = ln\left(\frac{z_{\text{HC}} - z_- + x_0}{x_0}\right), \quad x_f = x_0 e^T.$$

In an analogous fashion, AUTO was used to continue this solution in λ and then in x_0 to generate the map $x_f = \widehat{\phi}(x_0)$. In all these runs the approximation (2.24) of $\hat{u}(z)$ was used.

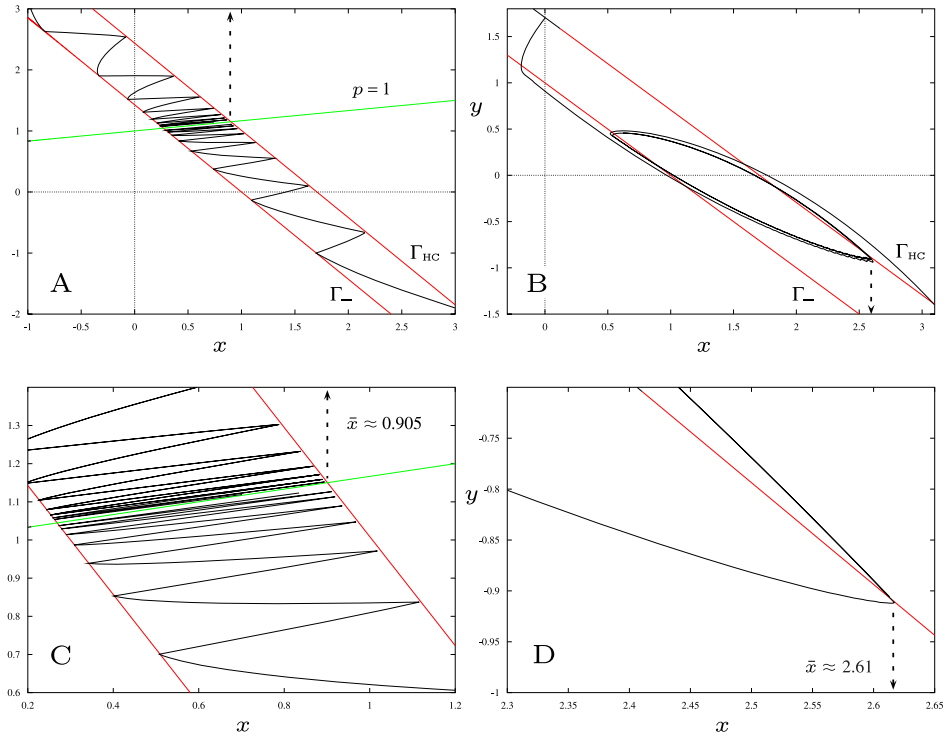

FIG. 5.3. *Verification of the fixed point $\bar{x} = \phi(\bar{x})$ obtained in the map composition illustrated in Figure 5.2. The two figures on the left are the $(+,+)$ case and the two on the right are the $(+,-)$ case. In* **A** *we see the projection of two trajectories of (FULL) into the (x, y)-plane appearing to compress toward the superimposed line $p = 1$. In* **C** *we have enlarged the region of interest about the map fixed point $\bar{x} \approx 0.905$. Also shown in* **A** *and* **C** *are the curves Γ_- and Γ_{HC}. In* **B** *we also see the projection of two trajectories of (FULL) into the (x, y)-plane, but in the $(+,-)$ case. The two projected trajectories wind onto a cycle in the (x, y)-plane. In* **D** *we are able to discern the map fixed point of $\bar{x} \approx 2.61$.*

Results of the calculations for $\widehat{\phi}$ and the respective compositions $\underset{\sim}{\phi} = \widehat{\phi} \circ \widetilde{\phi}$ are shown in Figure 5.2 for the same parameter values used to compute ϕ. The latter compositions were computed by numerically composing the data which generated $\widehat{\phi}$ and $\widetilde{\phi}$. Superimposed on the graphs of $\phi(x)$ is the line $y = x$ to indicate the location of the fixed point $\bar{x}$ corresponding to bursting solutions of (FULL). The interpolated values of the fixed points found in this manner were $\bar{x} \approx 0.905$ and $\bar{x} \approx 2.58$ for the $(+,+)$ and $(+,-)$ cases, respectively.

To separately verify these fixed point values, (FULL) was numerically integrated in Figure 5.3 over many silent and active phase cycles for the parameter values in Table 5.1. As can be seen, the projections of these solutions ultimately approach a periodic orbit, and the fixed point values computed from these figures closely agree with those computed from Figure 5.2. In all, these numerical results suggest that singular bursting solutions persist for nondegenerate parameter values. In the (+,+) case shown in Figure 5.3A, the parameter set is "nearly" degenerate and the projected bursting solution lies near the line $p = 1$. In contrast, the bursting cycle in the $(+,-)$ (activation/inactivation) case does not lie near the $p = 1$ line. In fact, the projected active and silent phase trajectories of that $(+,-)$ case are nearly tangent to the transition curves Γ_{HC} and Γ_{-}. From this observation, one might conjecture that bursting solutions do not persist for all parameter values. For example, the presence of a strongly attractive equilibria of (FULL) on $\mathbb{S}_L$ might significantly alter the (SS) flow to the point that trajectories may not be attracted to a bursting solution. These issues are explored in the next section.

6. A bistable case. In this section we demonstrate numerically that system (FULL) can exhibit bistability between bursting solutions and equilibria on $\mathbb{S}_L$. Just such an example is illustrated in Figure 6.1. Slow parameters λ_s were chosen so that (FULL) had a stable fixed point $\mathbf{X}_e$ on the lower branch $\mathbb{S}_L$ (see [25] for a detailed treatment of how to determine equilibria location and stability dependence on λ_s). In Figure 6.1B the u component of a bursting solution resulting from a particular set of initial conditions is shown. The projection of this solution onto the xy-plane is shown in Figure 6.1A. However, by choosing initial conditions near $\mathbb{S}_L$ in the basin of attraction of $\mathbf{X}_e$, the solution of (FULL) is shown to approach $\mathbf{X}_e$ in Figures 6.1C, D. The projection of the bursting solution in Figure 6.1A is also shown in Figure 6.1C for comparison.

For the bistability demonstrated in Figure 6.1 to occur, a few things must happen simultaneously. Minimally, (FULL) must have a stable equilibrium $\mathbf{X}_e$ on $\mathcal{S}_L$. However, even if parameters are chosen so that $\mathbf{X}_e \in \mathcal{S}_L$, it is not immediately clear if $\mathbf{X}_e$ will be stable or if the map ϕ can simultaneously have a stable fixed point. In this section, we shall give a brief synopsis of some issues regarding these points. First, we address issues concerning equilibria stability and location. Later, we determine some necessary conditions that map domains and ranges must satisfy for this type of bistability to occur.

The equilibria $\mathbf{X}_e$ of (FULL) have coordinates $\mathbf{X}_e = (\bar{u}, \bar{w}, \bar{x}, \bar{y})$ where, given (2.8), $\bar{u}$ are roots of

$$\Delta(u) = -G(u) + h_1(u) + \gamma h_2(u) = u^3 + au + b, \tag{6.1}$$

where

$$a = \beta_1 + \gamma\beta_2 - 3, \tag{6.2}$$

$$b = -(\alpha_1\beta_1 + \gamma\alpha_2\beta_2 + 3), \tag{6.3}$$

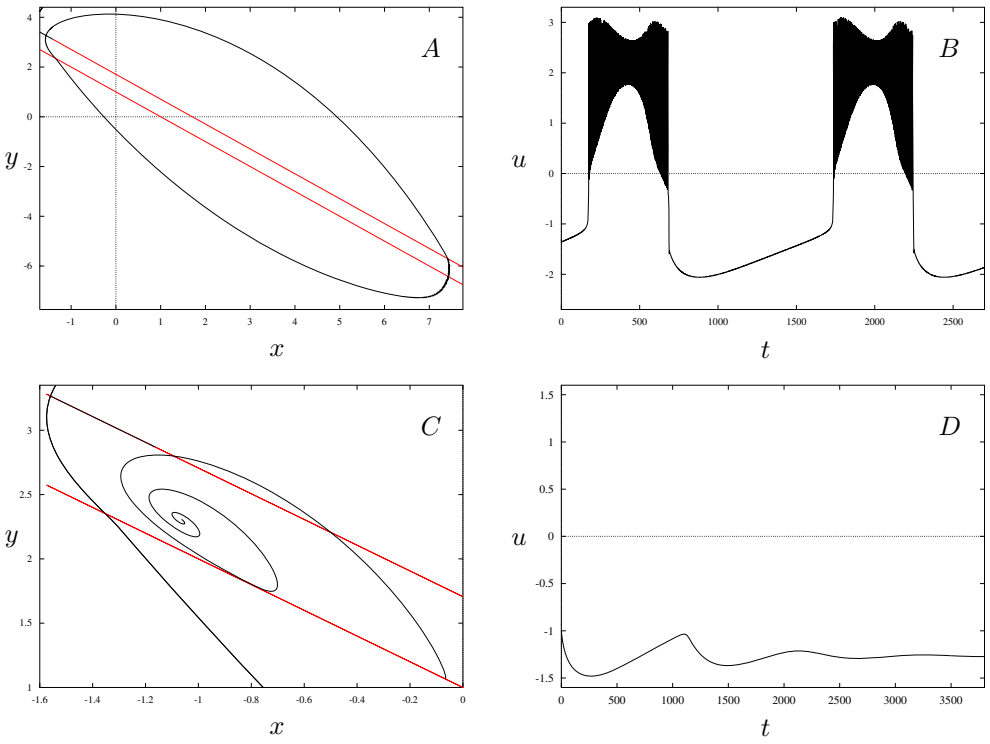

FIG. 6.1. *Numerical illustration of bistability. In both simulations the slow parameters were* $\lambda_s = (\beta_1, \beta_2, \alpha_1, \alpha_2, \tau_1, \tau_2) = (4, -3, -1, -0.5, 1, 0.3)$. *A and C are projections of the solutions of (FULL) for different initial conditions. B and D show the corresponding* $u(t)$ *component in each simulation.*

and $\bar{w} = g(\bar{u})$, $\bar{x} = h_1(\bar{u})$, and $\bar{y} = h_2(\bar{u})$. From this we note that $\mathbf{X}_e \in \mathcal{S}_L$ only if (a, b) is an element of the parameter space:

$$D_L = \{(a, b) : b = -ua - u^3, u < u_- = -1\}.$$

Thus, D_L can be characterized as the union of all those lines in the (a, b)-plane having slope $-u$ and that intercept $-u^3$ with $u < u_-$. We note, however, that even if the slow parameters λ_s are chosen so that $(a, b) \in D_L$, (FULL) may have other equilibria (see [25] for a detailed treatment of how to determine equilibria numbers and locations). Moreover, if equilibria occur on the upper branch ($u > u_+$) near the limit cycles of the (FS), it is possible that the (AFS) itself can have a fixed point. With the dynamics of the (AFS) changed, bursting solutions may no longer be possible. Thus, when searching a parameter space for the type of bistability described in this section, it is reasonable to restrict oneself to seeking parameters for which (FULL) has a unique equilibrium on $\mathcal{S}_L$. Given the cubic form of $\Delta(u)$, (FULL) will have a *unique* equilibrium $\mathbf{X}_e \in \mathcal{S}_L$ if and only if $(a, b) \in D_L$ and the discriminant

$$D_\Delta = \frac{b^2}{4} + \frac{a^3}{27} > 0. \tag{6.4}$$

Next, we address the stability of the (unique) equilibrium $\mathbf{X}_e \in \mathcal{S}_L$. Toward this end, we define $P(\lambda)$ as the characteristic polynomial of the Jacobian $D\vec{\mathbf{F}}(\mathbf{X}_e)$ of

(FULL) at $\mathbf{X}_e$ with roots λ of P being the eigenvalues. Similarly, we define $P_0(\lambda)$ as the characteristic polynomial of the Jacobian of the (FS). Using these definitions and the expansion

$$\lambda = \lambda_0 + \varepsilon\lambda_1 + \varepsilon^2\lambda_2 + \cdots$$

in $P(\lambda)$, one finds

$$P(\lambda) = \lambda_0^2 P_0(\lambda_0) + \varepsilon P_1(\lambda_0, \lambda_1) + \varepsilon^2 P_2(\lambda_0, \lambda_1, \lambda_2) + O(\varepsilon^3), \tag{6.5}$$

where for the moment we do not explicitly state the functions P_0, P_1, P_2. Since (FULL) has two fast variables and two slow variables, two of the eigenvalues $\lambda = O(1)$, while the remaining two eigenvalues $\lambda = O(\varepsilon)$. For $\mathbf{X}_e$ to be stable we require all four eigenvalues to have $\Re e(\lambda) < 0$. Clearly, if $\mathbf{X}_e \in \mathcal{S}_L$, the two $O(1)$ eigenvalues have $\Re e(\lambda) < 0$ since such λ's equal λ_0 to leading order and the roots $\lambda_0 \neq 0$ of P_0 are the same eigenvalues as in the (FS). Thus, it suffices to examine the $O(\varepsilon)$ eigenvalues, whose expansions have $\lambda_0 = 0$.

For the $\lambda_0 = 0$ case, it is easily verified that

$$P_1(0, \lambda_1) = 0 \qquad \forall \lambda_1.$$

So the "small" $O(\varepsilon)$ eigenvalues associated with the (SS) require examining the $O(\varepsilon^2)$ term in (6.5). Explicit calculations reveal

$$P_2(0, \lambda_1, \lambda_2) = Q(\lambda_1) \equiv q_2\lambda_1^2 + q_1\lambda_1 + q_0, \tag{6.6}$$

where the coefficients of Q in (6.6) are given by

$$q_2 = -G'(\bar{u}), \tag{6.7}$$

$$q_1 = \frac{\beta_1\tau_2 + \gamma\beta_2\tau_1 - G'(\bar{u})(\tau_1 + \tau_2)}{\tau_1\tau_2}, \tag{6.8}$$

$$q_0 = \frac{\beta_1 + \gamma\beta_2 - G'(\bar{u})}{\tau_1\tau_2}. \tag{6.9}$$

Notice that there is no dependence on λ_2 in $P_2(0, \lambda_1, \lambda_2)$, and that Q is quadratic in λ_1. Also, for the remainder of this section we drop the overbar notation on u.

The leading term λ_1 of these small eigenvalues is determined as the roots of Q in (6.6):

$$\lambda_1^{\pm} = \frac{-q_1 \pm \sqrt{q_1^2 - 4q_2q_0}}{2q_2}. \tag{6.10}$$

Since $u < u_- = -1$ on $\mathcal{S}_L$, the quantity $G'(u) = -3u^2 + 3$ is negative on $\mathcal{S}_L$ and

$$\mathbf{X}_e \in \mathcal{S}_L \Rightarrow q_2 > 0. \tag{6.11}$$

This result and the signs of the coefficients (q_1, q_0), based on the signs of the activation parameters[3] (β_1, β_2), are organized in Table 6.1 and are discussed in the following text. Given the signs of the coefficients q_i, we are then able to determine the stability of $\mathcal{S}_L$ equilibria. Throughout, recall $0 < \gamma,\ 0 < \tau_i,\ i = 1, 2$, and (6.11), i.e., $q_2 > 0$.

[3]Recall that x is a slow activation variable if $\beta_1 > 0$ and is a slow inactivation variable if $\beta_1 < 0$. Analogous remarks hold for y and β_2.

TABLE 6.1

Stability dependence of the equilibria $\mathbf{X}_e \in \mathcal{S}_L$ on the activation/inactivation parameters (β_1, β_2), where (q_2, q_1, q_0) are the coefficients of the quadratic $Q(\lambda)$ defined in (6.6). In the "Case" column, $(+,-)$ indicates the respective signs of β_1 and β_2. In the other columns, $+/-$ indicates that both signs of the column quantity are possible. In both the $(+,-)$ and $(-,+)$ cases, the equilibria $\mathbf{X}_e$ can undergo a Hopf bifurcation, and thus may be stable or unstable.

Case	sign(q_2)	sign(q_1)	sign(q_0)	Equilibria $\mathbf{X}_e$
$(+,+)$	$+$	$+$	$+$	stable
$(-,-)$	$+$	$+$	$+$	stable
		$+/-$	$-$	saddle
$(+,-)$	$+$	$+/-$	$+/-$	Hopf bifurcation possible
$(-,+)$	$+$	$+/-$	$+/-$	Hopf bifurcation possible

When $(\beta_1, \beta_2) = (+,+)$, i.e., both are positive, one sees immediately that $q_1 > 0$ and $q_0 > 0$ as well. As such, any $\mathcal{S}_L$ equilibria in this case will be stable, as noted in Table 6.1.

When $(\beta_1, \beta_2) = (-,-)$, it is possible for q_0 to be positive or negative. To understand this case we first note from (6.1) that

$$\Delta'(u) = -G'(u) + (\beta_1 + \gamma\beta_2). \tag{6.12}$$

If $q_0 > 0$, then $G'(u) < \beta_1 + \gamma\beta_2$, and we may conclude $\Delta'(u) > 0$. Rewriting q_1 in terms of $\Delta(u)$, we find

$$q_1 = \frac{\Delta'(u)}{\tau_1} + \frac{\Delta'(u)}{\tau_2} - \frac{\gamma\beta_2}{\tau_1} - \frac{\beta_1}{\tau_2}. \tag{6.13}$$

We now see that if $(\beta_1, \beta_2) = (-,-)$ and $q_0 > 0$, then $q_1 > 0$ so that $\mathbf{X}_e \in \mathcal{S}_L$ are stable.

If $(\beta_1, \beta_2) = (-,-)$ and $q_0 < 0$, then q_1 may be positive or negative. Moreover, in this case, $\sqrt{q_1^2 - 4q_2q_0} > |q_1|$ so that $\lambda_1^{\pm}$ are both real and have opposite signs. Then, $\mathbf{X}_e$ has a one-dimensional unstable manifold and a three-dimensional stable manifold. We list such unstable equilibria $\mathbf{X}_e$ of (FULL) in Table 6.1 as "saddles" since the associated equilibria $(\bar{x}, \bar{y})$ of the (SS) will be saddles.

Finally, we consider the $(\beta_1, \beta_2) = (+,-)$ and $(\beta_1, \beta_2) = (-,+)$ cases together. It is not hard to see in that restrictions on the sign of q_0 do not place similar restrictions on the sign of q_1; any sign is possible. Thus, $\lambda_1^{\pm}$ may be complex conjugate pairs, and transverse crossings of the imaginary axis could be possible. We do not discuss the details of this here but merely note that $\mathbf{X}_e$ may be stable or unstable and that Hopf bifurcations of such equilibria are possible (see [25] for a detailed treatment).

At this stage we summarize some of the previous results. First, to ensure there is a unique equilibria $\mathbf{X}_e \in \mathcal{S}_L$, slow parameters must be chosen so that $(a, b) \in D_L$ while simultaneously satisfying (6.4). The stability of such equilibria will largely depend on the sign of the activation/inactivation parameters (β_1, β_2). This dependence is summarized in Table 6.1. In Figure 6.1, the slow parameters were chosen to satisfy these conditions in the $(\beta_1, \beta_2) = (+,-)$ case. Moreover, in this case $\lambda_1^{\pm}$ were complex conjugates to create the spiral motion depicted in Figure 6.1C. We do not exclude the possibility of bistability for the other cases in Table 6.1. Even if this issue is resolved, it does not address issues concerning the simultaneous coexistence of a stable fixed point of the map ϕ needed to ensure the existence of a stable bursting solution. To address this latter issue, we examine the map domains and ranges defined in previous sections.

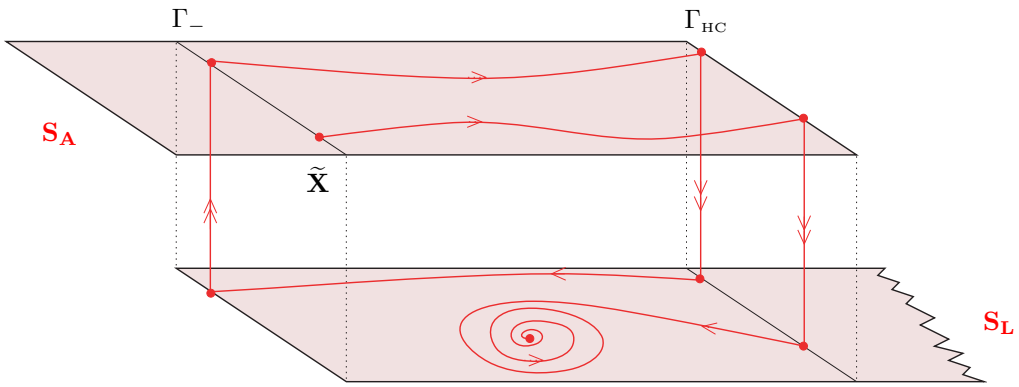

FIG. 6.2. *Illustration of bistability between bursting solutions and stable equilibria of (FULL). One solution illustrated has an initial condition $\widetilde{\mathbf{X}} \in S_A$ in the active phase but with $\hat{\Phi}(\widetilde{\mathbf{X}})$ in the basin of attraction of an equilibria of (FULL) on S_L. Also shown is a bursting cycle associated with the fixed point of Φ.*

First, we note that Figure 6.2 illustrates the simulations shown in Figure 6.1. In the following discussion we assume the domain $D(\widehat{\phi}) = \mathbb{R}$, whereas $D(\widetilde{\phi})$ is a proper subset of $\mathbb{R}$. While shortly it will become evident that the latter is necessary for bistability, we acknowledge that the former assumption is not. For example, for other parameter values the (AFS) may itself have a stable fixed point. For simplicity, we assume this is not the case in the following discussion.

For the system to exhibit the bistability illustrated in Figure 6.2, some trajectories of the (SS) originating along Γ_{HC} must be attracted to the equilibria $\mathbf{X}_e$ on $\mathbb{S}_L$. Since $D(\widetilde{\phi})$ consists only of initial x-coordinates for which the (SS) trajectories starting on Γ_{HC} reach Γ_-, we conclude that in the bistable case, $D(\widetilde{\phi})$ must be a proper subset of $\mathbb{R}$.

Now, consider an initial condition where $\widetilde{\mathbf{X}} = (x_0, y_0) \in \Gamma_-$ and the fast variables are sufficiently near the (FS) limit cycle $\Omega(t, z_0), z_0 = x_0 + \gamma y_0$. To leading order, the resulting trajectory $\gamma_{\widetilde{X}}$ will traverse the active phase as described by the (AFS). Since $x_0 \in D(\widehat{\phi})$, $\gamma_{\widetilde{X}}$ will eventually reach Γ_{HC} and exit to the silent phase. Such a trajectory will enter the silent phase at an x-coordinate $\widehat{\phi}(x_0) \in R(\widehat{\phi})$.[4] The next issue is whether $\widehat{\phi}(x_0) \in D(\widetilde{\phi})$. If $\widehat{\phi}(x_0) \in D(\widetilde{\phi})$, then the trajectory starting in the active phase will eventually traverse the entire slow manifold and make a transition back to the active phase. The set of x values on the slow manifold for which this is possible is the previously discussed set $W = R(\widehat{\phi}) \cap D(\widetilde{\phi})$. Since $D(\widetilde{\phi})$ must be a proper subset of $\mathbb{R}$ in the bistable case, it follows that W must also necessarily be a proper subset of $\mathbb{R}$. The next issue is whether W is equal to or is a proper subset of $D(\widetilde{\phi})$. Clearly, $W \neq D(\widetilde{\phi})$; if it were, no (AFS) trajectory making a transition into the silent phase would ever be in the basin of attraction of the equilibria $\mathbf{X}_e$ on $\mathbb{S}_L$, and bistability would not be possible. To summarize, two necessary conditions for the system to exhibit bistability are

$$D(\widetilde{\phi}) \subset \mathbb{R}, \quad W = R(\widehat{\phi}) \cap D(\widetilde{\phi}) \subset D(\widetilde{\phi}),$$

with the understanding that the inclusions are proper.

[4]The range $R(\widehat{\phi})$ of $\widehat{\phi}$.

To conclude this section we remark that the above conditions, though necessary, may not be sufficient for bistability. For example, even if $\widehat{\phi}(x_0) \in D(\widetilde{\phi})$, in the next iterate it may be that $(\widehat{\phi} \circ \widetilde{\phi} \circ \widehat{\phi})(x_0) \notin D(\widetilde{\phi})$—in which case the trajectory would eventually be attracted to the equilibria $\mathbf{X}_e$. To completely resolve these types of details, accurate estimations of the map domains and ranges are paramount. We do not make such estimates in this paper, but some progress toward resolving these issues is presented in [25].

7. Conclusion and discussion. In this paper we have shown how singular approximations of bursting solutions of a model with two slow variables can be identified with fixed points of a one-dimensional map. When the time constants of the slow variables are equal (the degenerate case), the map and fixed point can be computed explicitly. Such a calculation is possible because, in that case, the system decouples under a simple transformation. Furthermore, from the transformed system (4.5)–(4.8) it was deduced that the original model has singular bursting solutions even if the slow variables are activating ($\beta_1 > 0$) and inactivating ($\beta_2 < 0$). In other studies both slow variables were inhibitory [51]. It was also shown that as inactivation was increased in this degenerate case, the magnitude of the fixed point $\bar{x}$ increased. Further, given the negative slope of the curve Γ_{HC}, as $\bar{x}$ increases the associated $\bar{y}$ value decreases. Insofar as the model studied in this paper is homotopic to other two slow variable models exhibiting bursting, the $(\bar{x}, \bar{y})$ would represent the extreme values of the slow regulatory variables (i.e., calcium concentration, channel activation variable) at the start of the silent phase. Thus, experimentally, if the slow regulatory variables have similar time constants, one might expect to see these extreme values increase and decrease inversely as inactivation of one process is increased. However, independent of the levels of activation and inactivation, no bifurcations of the bursting solution through a destabilization of the map fixed point are possible in the degenerate case. Moreover, as previously noted, the singular bursting solutions are always stable in this degenerate case.

In the more generic nondegenerate case when the time constants of the slow variables are not equal, it was demonstrated in section 5 how the maps used to determine bursting solutions can be computed by solving two one-parameter families of boundary value problems. There, AUTO [19] was used to homotope from known solutions to a solution which describes trajectories of the (SS) and the (AFS) of the original model. The methods described in section 5 would be substantially faster than using multiple integrations of (FULL) to compute the Poincaré return maps. Moreover, since AUTO automatically detects a variety of bifurcations, the aforementioned methods would be far better suited for numerical studies of bifurcations of bursting solutions in systems with two slow variables.

Some of the numerical techniques presented in section 5 might be adaptable to other models of bursting. For instance, in other models, slow subsystems can often be computed explicitly so that system (5.1)–(5.2) can be coded. However, in models such as (1.1)–(1.2), saddle-node and homoclinic bifurcation points of the associated fast subsystems are not known explicitly. Thus, it may not be possible to explicitly code boundary conditions such as (5.4) and (5.6). One possible resolution to this difficulty is to augment (5.1)–(5.6) with the (FS) of the model. It should be noted that similar issues would arise when attempting to code (5.7)–(5.12) in other models. In addition to the aformentioned issues, the vector field of the (AFS) of other models is not explicitly known. However, this issue can be circumvented by first calculating averaged quantities over a grid of slow variable values. Then, intermediate values can

be computed using interpolation from this tabulated data within the AUTO code. In [25] such a method was implemented to determine $\hat{\phi}$ for the model defined in this paper.

Of additional importance is the bistability between bursting solutions and equilibria of (FULL) demonstrated in section 6. This is a fundamentally new type of bistability. In two variable neuron models, such as the FitzHugh–Nagumo model [23, 35], one variable is often slow and the other fast. The resulting (FS) exhibits bistability between equilibria. Bistability in the (FS) of three variable models exhibiting bursting is typically between stable equilibria and planar limit cycles. Such is the case in the (FS) of the model studied here. Even this type of bistability should be contrasted with bistability between stable periodic solutions such as that studied by Canavier et al. [10, 11]. Shilnikov, Calabrese, and Cymbalyuk [47] have also examined bistability between bursting solutions and (tonic) periodic solutions in a neuronal model with one slow variable. In this study, the bistability discussed in section 6 is between equilibria and (four-dimensional) bursting solutions. Regarding (FULL) as a model of neural activity, this type of bistability suggests some interesting potential neural dynamics. For instance, certain perturbations could switch the neural activity between bursting modes and quiescent modes. Since bursting typically acts on a time scale an order of magnitude larger than tonic spiking, this might have functional relevance in regulating physiological processes on time scales of the order of many bursts.

The former type of bistability is also of interest as it relates to the issue of why some isolated pancreatic β-cells burst while others do not [50]. Bursting electrical activity is observed in β-cells that are still intact in the islets [42]. At elevated temperatures (e.g., 30° C), bursting is also observed in β-cells that are isolated from the islets [48]. Yet, in other experiments at room temperature, isolated β-cells exhibit irregular spiking but do not burst [22]. Some researchers have discussed how the fundamental stochasticity of the β-cells might explain these different behaviors [42]. In other studies [37, 38], cell heterogeneity and diffusive coupling was a premise used to explain this experimental fact. There it was shown that if collections of cells with a stable equilibria were diffusively coupled to collections of bursting cells, the coupled system could burst synchronously. However, this explanation used a model with a sole slow variable. Since most recent models of β-cell electrical activity have two or more slow variables, it now appears that cell bistability might also play a role. For instance, if for some parameter sets these newer models exhibit the same sort of bistability demonstrated in section 6, then the experimental preparation could play a role. Some extracted cells may not burst merely because those preparations have slow variable values in the basin of attraction of the stable equilibria on S_L. Moreover, if the latter basin of attraction were sufficiently large, then even noise would not affect the result. Alternately, the sporadic spiking of "nonbursters" might be due to the noise (or channel stochasticity) being sufficiently large so that the (SS) trajectories traverse close to the basin of attraction of the equilibria $\mathbf{X_e}$. When properly exploring such ideas using a model, the size of the map domains become especially important. Also, in this case, the analytical and numerical tools developed in this paper may be particularly useful.

We note, however, that it is not known if the more recent β-cell models can exhibit such bistability for other parameter values. Additionally, we currently have no systematic way of determining such parameter sets. For the model used in this paper, some advances in solving this latter problem are presented in [25]. Although it is not too difficult to determine parameter sets where (FULL) has stable equilibria

on S_L, it is difficult to determine a subset of such a parameter space where the model simultaneously exhibits bursting. As mentioned previously, the latter is intimately connected with domain issues of the maps $\tilde{\phi}$ and $\hat{\phi}$, which requires knowledge of certain global information about the slow and averaged fast subsystems.

The bistability discussed in section 6 also presents some other interesting modeling possibilities. For instance, if collections of such cells are coupled, then aggregate behavior would depend greatly on initial conditions. In reaction diffusion systems where bistability is between equilibria, traveling wave phenomena are ubiquitous. If the bistability is between equilibria and bursting solutions, the question arises if wavefronts separating such behaviors are possible. Even if no such (stable) wave phenomena exist, it is not known if strongly coupled aggregates exhibit bistable synchronous solutions. For instance, synchronous (monostable) solutions are present in heterogeneous collections of cells which are diffusively coupled with strong coupling [38].

Lastly, the approximation of the average quantity $\widehat{u}(z)$ in (2.24) is of some mathematical interest. In Figure 2.2, the functions $\widehat{u}_a(z)$ and $\widehat{u}(z)$ are shown to be very close over a wide range of z. This closeness suggests that (2.24) is a two term asymptotic approximation of the average $\widehat{u}(z)$. If this is the case, we are unaware of a systematic (analytical) method for estimating the parameters p, a_0, and a_1 in that approximation. Moreover, we are not aware how robust this approximation is when fast parameter values are altered. In Figure 2.2 the fast parameters are fixed and the comparison is over different values of z. Regardless, such approximation methods would be of interest, as they might apply to the more complicated Hodgkin–Huxley based models with two fast variables. For instance, were such methods available and the dependence of a_0 on fast parameters derivable, then it would be easier to predict how things such as the active phase duration might depend on fast conductances and other biological quantities.

Appendix. Here we use a multiple scales procedure to derive the (AFS) summarized in section 2.3. We assume that the (FS) has $T(\mathbf{z})$-periodic solutions $\Omega(t, \mathbf{z})$ which satisfy

$$\frac{d\Omega}{dt} = \mathbf{F}(\Omega, \mathbf{z}) \quad \forall \mathbf{z} \in S_A\,. \tag{A.1}$$

We seek an asymptotic approximation of (2.1)–(2.2) valid to $O(\varepsilon)$ for $t = O(\frac{1}{\varepsilon})$. Toward that end, we assume an expansion of the form

$$\mathbf{u}(t) = U(s, \tau, \varepsilon) = U_0(s, \tau) + \varepsilon U_1(s, \tau) + O(\varepsilon^2)\,, \tag{A.2}$$

$$\mathbf{z}(t) = Z(s, \tau, \varepsilon) = Z_0(s, \tau) + \varepsilon Z_1(s, \tau) + O(\varepsilon^2)\,, \tag{A.3}$$

where τ is a slow time,

$$\tau = \varepsilon t, \tag{A.4}$$

and the strained (fast) time s is defined by

$$\frac{ds}{dt} = \omega(\tau) \tag{A.5}$$

for a function ω as yet to be determined.

As with other multiple scales methods, it is possible to choose an appropriate ω so that U_0 is 1-periodic in s. In addition to the aforementioned periodicity, we want

our leading-order approximation $U_0(s,\tau)$ close to $u(t)$ for times $\tau = O(1)$. With U_0 and Z_0 suitably determined, we also require $U_i(s,\tau)$ and $Z_i(s,\tau)$ to be 1-periodic in s for $i = 0, 1, 2, \ldots$. The periodicity of U_i and Z_i in s ensures the functions U, Z are bounded in s, so that, for instance, $|U - U_0| = O(\varepsilon)$ for $\tau = O(1)$.

Using these definitions, the time derivatives of $U(s,\tau,\varepsilon)$ are

$$\frac{dU}{dt} = \omega\frac{\partial U}{\partial s} + \varepsilon\frac{\partial U}{\partial \tau}\,, \tag{A.6}$$

$$\frac{d^2U}{dt^2} = \omega^2\frac{\partial^2 U}{\partial s^2} + 2\varepsilon\omega\frac{\partial^2 U}{\partial s\partial\tau} + \varepsilon\frac{\partial\omega}{\partial\tau}\frac{\partial U}{\partial s} + \varepsilon^2\frac{\partial^2 U}{\partial\tau^2}\,, \tag{A.7}$$

with similar expressions for $Z(s,\tau,\varepsilon)$.

Expanding $\mathbf{F}(\mathbf{u},\mathbf{z})$ about (U_0, Z_0) gives

$$\mathbf{F}(\mathbf{u},\mathbf{z}) = \mathbf{F}(U_0,Z_0) + \varepsilon D_{\mathbf{u}}\mathbf{F}(U_0,Z_0)U_1 + \varepsilon D_{\mathbf{z}}\mathbf{F}(U_0,Z_0)Z_1 + O(\varepsilon^2)\,, \tag{A.8}$$

where, for $\mathbf{F} = (F_1, F_2)^T$,

$$D_{\mathbf{u}}\mathbf{F} = \begin{bmatrix} \frac{\partial F_1}{\partial u} & \frac{\partial F_1}{\partial w} \\ \frac{\partial F_2}{\partial u} & \frac{\partial F_2}{\partial w} \end{bmatrix}, \tag{A.9}$$

and in a similar fashion, $D_{\mathbf{z}}\mathbf{F}$ is the Jacobian of $\mathbf{F}$ in $\mathbf{z}$.

Putting this all together, (2.1)–(2.2) become

$$\omega\frac{\partial U_0}{\partial s} + \varepsilon\left(\frac{\partial U_0}{\partial\tau} + \omega\frac{\partial U_1}{\partial s}\right) = \mathbf{F}^{(0)} + \varepsilon\left(D_{\mathbf{u}}\mathbf{F}^{(0)}U_1 + D_{\mathbf{z}}\mathbf{F}^{(0)}Z_1\right) + O(\varepsilon^2)\,, \tag{A.10}$$

$$\omega\frac{\partial Z_0}{\partial s} + \varepsilon\left(\frac{\partial Z_0}{\partial\tau} + \omega\frac{\partial Z_1}{\partial s}\right) = \varepsilon\mathbf{G}(U_0,Z_0) + O(\varepsilon^2)\,, \tag{A.11}$$

where the superscript$^{(0)}$ in (A.10) means evaluated at (U_0, Z_0). These equations can be written as a system of partial differential equations. The $O(1)$ terms from (A.10)–(A.11) are

$$\omega\frac{\partial U_0}{\partial s} = \mathbf{F}(U_0,Z_0)\,, \tag{A.12}$$

$$\frac{\partial Z_0}{\partial s} = 0\,, \tag{A.13}$$

and the $O(\varepsilon)$ terms,

$$\frac{\partial U_0}{\partial\tau} + \omega\frac{\partial U_1}{\partial s} = D_{\mathbf{u}}\mathbf{F}(U_0,Z_0)U_1 + D_{\mathbf{z}}\mathbf{F}(U_0,Z_0)Z_1\,, \tag{A.14}$$

$$\frac{\partial Z_0}{\partial\tau} + \omega\frac{\partial Z_1}{\partial s} = \mathbf{G}(U_0,Z_0)\,. \tag{A.15}$$

From (A.13) it is evident that Z_0 does not depend on s. Henceforth, we write $Z_0 = Z_0(\tau)$.

Since $\Omega(s,\mathbf{z})$ is $T(\mathbf{z})$-periodic in s, then $\Omega(Ts,\mathbf{z})$ is 1-periodic in s. Letting $\psi(\tau)$ be a slowly varying phase, then

$$U_0(s,\tau) = \Omega(sT(Z_0(\tau)) + \psi(\tau), Z_0(\tau)) \tag{A.16}$$

will also be a 1-periodic function of s. Moreover, since Ω solves (A.1), the U_0 defined in (A.16) also solves (A.12), provided we choose

$$\omega(\tau) = \frac{1}{T(Z_0(\tau))}\,. \tag{A.17}$$

With this choice of ω the strained time s is completely defined in terms of the original time t via (A.5) once $Z_0(\tau)$ has been determined. Although a subsequent determination of the dependence of U_0 on t additionally depends on the slowly varying phase ψ, it will shortly be shown that the leading-order evolution of Z_0 does not depend on ψ.

We now turn our attention to the Z equation. The requirement that Z_1 be 1-periodic in s helps us derive necessary conditions for Z_0. Integrating (A.15) over $s \in (0,1)$, we get

$$\int_0^1 \mathbf{G}(U_0(s,\tau), Z_0(\tau))ds = \int_0^1 \left(\frac{\partial Z_0}{\partial \tau} + \omega(\tau)\frac{\partial Z_1}{\partial s}(s,\tau) \right) ds \tag{A.18}$$

$$= \frac{\partial Z_0}{\partial \tau} + \omega(\tau)[Z_1(1,\tau) - Z_1(0,\tau)]\,. \tag{A.19}$$

Thus, choosing Z_0 as a solution to

$$\frac{\partial Z_0}{\partial \tau} = \int_0^1 \mathbf{G}(U_0(s,\tau), Z_0(\tau))ds = \int_0^1 \mathbf{G}\left(\Omega(sT(Z_0) + \psi(\tau)), Z_0\right) ds \tag{A.20}$$

implies $Z_1(1,\tau) = Z_1(0,\tau)$ for all τ. This in itself does not prove that Z_1 is periodic in s. However, one need only note that (A.15) is invariant under the transformation $s \to s + \bar{\psi}$ to make this inference. Using this transformation, the preceding integration of (A.15) would then imply $Z_1(1+\bar{\psi},\tau) = Z_1(\bar{\psi},\tau)$ for an arbitrary $\bar{\psi}$, from which one concludes that if Z_0 solves (A.20), then Z_1 is 1-periodic in s.

Lastly, as mentioned previously, the slowly varying phase ψ is not needed to determine the dependence of Z_0 on τ. In order to show this, we introduce the change of coordinates $\eta = sT(Z_0) + \psi(\tau)$ to rewrite (A.20) as

$$\frac{\partial Z_0}{\partial \tau} = \frac{1}{T}\int_{\psi}^{T+\psi} \mathbf{G}(\Omega(\eta, Z_0), Z_0)d\eta\,. \tag{A.21}$$

Since $\mathbf{G}(\Omega(\eta, Z_0), Z_0)$ is $T(Z_0)$-periodic in η, we have

$$\frac{\partial Z_0}{\partial \tau} = \frac{1}{T}\int_0^T \mathbf{G}(\Omega(\eta, Z_0), Z_0)d\eta \equiv \widehat{\mathbf{G}}(Z_0)\,, \tag{A.22}$$

showing that the value of the integral does not depend on $\psi(\tau)$. The right-hand equality in (A.22) has been added to emphasize that there is no explicit dependence on τ in $\widehat{G}$. Also, in summary, we may now conclude that if

$$\frac{dZ_0}{d\tau} = \widehat{\mathbf{G}}(Z_0)\,, \tag{A.23}$$

then Z_1 is 1-periodic in s so that $|Z - Z_0| = O(\varepsilon)$ for $\tau = O(1)$. Given the definition of $\mathbf{G}$ and the linearity of $h_i(u)$ in u, we see that (A.23) written out in component form is precisely (2.22)–(2.23).

SURFACE TENSION-DRIVEN FLOW IN A SLENDER WEDGE*

J. BILLINGHAM†

Abstract. We consider an inviscid fluid, initially at rest inside a wedge, bounded by one free surface and one solid surface. When $t = 0$, we allow the contact angle to change discontinuously, which leads the free surface to recoil under the action of surface tension. As noted by Keller and Miksis [*SIAM J. Appl. Math.*, 43 (1983), pp. 268–277], a similarity scaling is available, with lengths scaling like $t^{2/3}$. We consider the situation when the wedge is slender, with angle $\epsilon \ll 1$, and the contact angle changes from ϵ to $\lambda\epsilon$. The leading order asymptotic problem for $\lambda = O(1)$, a pair of nonlinear ordinary differential equations, was considered by King [*Quart. J. Mech. Appl. Math.*, 44 (1991), pp. 173–192], numerically for $\lambda = O(1)$ and asymptotically for $|\lambda - 1| \ll 1$. In this paper, we begin by considering this system when $1 \ll \lambda \ll \epsilon^{-1}$, and use Kuzmak's method to construct the asymptotic solution. When $\lambda = O(\epsilon^{-1})$, the slope of the free surface becomes of $O(1)$, and it is no longer possible to reduce the problem to ordinary differential equations alone. However, we can approach this problem in a similar manner, even though the underlying oscillator is the solution of a nonlinear boundary value problem for Laplace's equation, and construct an asymptotic solution. In fact, the solution takes the form of a modulated set of waves on fluid of finite depth, with the underlying analytical solution given by Kinnersley [*J. Fluid Mech.*, 77 (1976), pp. 229–241]. The case $\lambda\epsilon = 90^\circ$ is the solution for the inviscid recoil of a wedge of fluid with two free surfaces and semiangle $\epsilon \ll 1$, which was discussed by Billingham and King [*J. Fluid Mech.*, 533 (2005), pp. 193–221]. We also show that no non-self-intersecting solution is available for $\lambda\epsilon > 90^\circ$ as $\epsilon \to 0$, and compare our asymptotic solutions with numerical, boundary integral solutions of the full, nonlinear free boundary problem.

1. Introduction.

In this paper, we study the response of a wedge of inviscid fluid, initially at rest, bounded by a free surface and a solid surface, to a discontinuous change in the contact angle that it makes with the solid surface. Such a change could be brought about by, for example, an abrupt change in temperature or chemical composition. For a viscous fluid, modelling the motion of this contact line is complicated by the force singularity at the contact line associated with the no slip boundary condition (Dussan and Davis (1974)). Although it is possible to make progress by modifying the no slip boundary condition (Cox (1986)), some unresolved issues remain (see Shikhmurzaev (1997) for a review). However, at sufficiently large times, the solution is likely to asymptote to the inviscid similarity form discussed in this paper, as has been demonstrated in comparable problems (see, for example, Billingham (1999), Billingham and King (2005)).

Inviscid, surface tension-driven flow in a fluid wedge was first studied by Keller and Miksis (1983), who noted that a similarity solution, with lengths scaling like $t^{2/3}$, is available. These scalings have since been used by many other authors to study related problems, for example, Lawrie (1990), Lawrie and King (1994), King

(1991), Billingham and King (1995), King, Billingham, and Popple (1999), Decent and King (2001), Keller, Milewski, and Vanden-Broeck (2000, 2002), and Sierou and Lister (2004). Such flows are also relevant to situations where bodies of fluid rupture and recoil under the action of surface tension. Indeed, for a contact angle of 90°, by symmetry, the problem that we study here is equivalent to the recoil of a wedge of fluid with two free surfaces.

We begin our analysis in section 2, where we derive the nonlinear free boundary problem that governs similarity solutions of the initial value problem. In section 3, we discuss the one-dimensional approximation to the solution that is possible when the new contact angle is sufficiently small. This was first studied by King (1991). We show that if the new contact angle is small, but much larger than the wedge angle, it is possible to construct a solution using Kuzmak's method. The free surface is then a slowly varying nonlinear oscillator. In section 4, we consider the solution when the new contact angle is of $O(1)$. In this case, we can still use Kuzmak's method to solve the problem, but the underlying nonlinear oscillator is the solution of a two-dimensional, nonlinear free boundary problem. We are able to make progress because this free boundary problem has a family of analytical solutions, which was first studied in the context of capillary waves on fluid of finite depth by Kinnersley (1976). We also show that, for ϵ sufficiently small, non-self-intersecting solutions exist only if the contact angle is less than 90°. In section 5, we make a comparison between the asymptotic solution and numerical solutions of the full problem obtained using the boundary integral method.

2. Similarity solution of the initial value problem. We consider the two-dimensional flow of an inviscid fluid, initially at rest inside a wedge of angle ϵ, as shown in Figure 2.1. The fluid is bounded by a solid surface at $y = 0$, while its other surface is free and subject to a constant, uniform surface tension, σ. We denote by D the domain that contains the fluid. Since the flow is initially irrotational, it remains irrotational, and we can describe the flow using a velocity potential ϕ, with the fluid velocity given by $\mathbf{u} = \nabla\phi$. The potential satisfies Laplace's equation

$$\nabla^2\phi = 0 \quad \text{in } D. \tag{2.1}$$

The kinematic and dynamic boundary conditions are

$$\frac{\partial y_s}{\partial t} = \frac{\partial \phi}{\partial y} - \frac{\partial \phi}{\partial x}\frac{\partial y_s}{\partial x} \quad \text{at } y = y_s(x,t), \tag{2.2}$$

$$\frac{\partial \phi}{\partial t} + \frac{1}{2}\left|\nabla\phi\right|^2 = \frac{\sigma}{\rho}\frac{\partial^2 y_s}{\partial x^2}\left\{1 + \left(\frac{\partial y_s}{\partial x}\right)^2\right\}^{3/2} \quad \text{at } y = y_s(x,t). \tag{2.3}$$

There is no normal flux through the solid surface so that

$$\frac{\partial \phi}{\partial y} = 0 \quad \text{at } y = 0. \tag{2.4}$$

The contact angle condition is

$$\frac{\partial y_s}{\partial x} = \tan(\lambda\epsilon) \quad \text{at } y = 0,\ x = x_c(t). \tag{2.5}$$

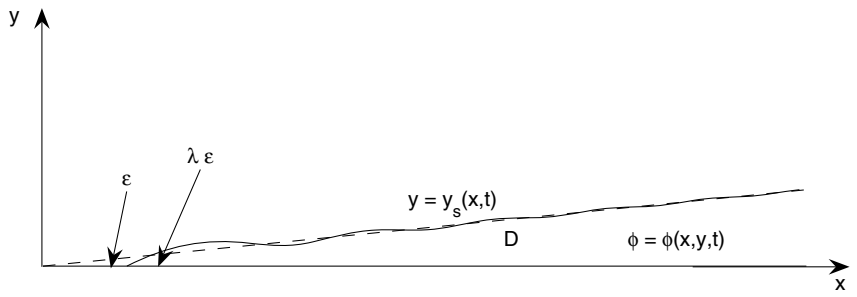

FIG. 2.1. *The initial geometry (broken line) and subsequent recoil.*

The fluid is at rest in the far field so that

$$\phi(x,y,t) \to 0 \quad \text{as } x^2+y^2 \to \infty. \tag{2.6}$$

The initial conditions are

$$\phi = 0, \quad y_s = x\tan\epsilon \quad \text{when } t = 0. \tag{2.7}$$

There is no geometrical lengthscale in this problem, and the only dimensional quantities involved are ρ and σ. As noted by Keller and Miksis (1983), dimensional analysis shows that we can define the independent similarity variables

$$\bar{x} = \frac{\rho^{1/3}x}{\sigma^{1/3}t^{2/3}}, \quad \bar{y} = \frac{\rho^{1/3}y}{\sigma^{1/3}t^{2/3}}, \tag{2.8}$$

and look for a solution of the form

$$\bar{\phi} = \frac{\rho^{2/3}\phi}{\sigma^{2/3}t^{1/3}} \equiv \bar{\phi}(\bar{x},\bar{y}), \quad \bar{y}_s = \frac{\rho^{1/3}y_s}{\sigma^{1/3}t^{2/3}} \equiv \bar{y}_s(\bar{x}). \tag{2.9}$$

In terms of these similarity variables, the initial value problem (2.1)–(2.6) becomes the boundary value problem

$$\nabla^2\bar{\phi} = 0 \quad \text{for } 0 < \bar{y} < \bar{y}_s(\bar{x}),\ \bar{x} > \bar{x}_c, \tag{2.10}$$

$$\frac{1}{3}\bar{\phi} - \frac{2}{3}\left(\bar{x}\frac{\partial\bar{\phi}}{\partial\bar{x}} + \bar{y}\frac{\partial\bar{\phi}}{\partial\bar{y}}\right) + \frac{1}{2}\left|\nabla\bar{\phi}\right|^2 = \frac{\bar{y}_s''}{(1+\bar{y}_s'^2)^{3/2}} \quad \text{at } \bar{y} = \bar{y}_s, \tag{2.11}$$

$$\frac{\partial\bar{\phi}}{\partial\bar{y}} + \frac{2}{3}\bar{x}\bar{y}_s' - \frac{2}{3}\bar{y}_s - \frac{\partial\bar{\phi}}{\partial\bar{x}}\bar{y}_s' = 0 \quad \text{at } \bar{y} = \bar{y}_s, \tag{2.12}$$

$$\frac{\partial\bar{\phi}}{\partial\bar{y}} = 0 \quad \text{at } \bar{y} = 0 \tag{2.13}$$

subject to

$$\bar{y}_s' = \tan(\lambda\epsilon) \quad \text{at } \bar{x} = \bar{x}_c, \tag{2.14}$$

$$\bar{y}_s - \bar{x}\tan\epsilon \to 0 \quad \text{as } \bar{x} \to \infty, \tag{2.15}$$

$$\bar{\phi} \to 0 \quad \text{as } \bar{x}^2+\bar{y}^2 \to \infty, \tag{2.16}$$

where a prime denotes $d/d\bar{x}$ and $\bar{x}_c$ is a constant to be determined.

3. The one-dimensional slender wedge limit, $\epsilon \ll 1$, $\lambda = O(1)$. King (1991) showed that an appropriate scaling in the limit of a slender wedge, $\epsilon \ll 1$, with a small change in the contact angle, $\lambda = O(1)$, is

$$\bar{x} = \epsilon^{1/3}\xi, \quad \bar{y} = \epsilon^{4/3}\eta, \quad \bar{\phi} = \epsilon^{2/3}\Phi, \quad \bar{y}_s = \epsilon^{4/3}Y. \tag{3.1}$$

In terms of these variables, (2.10)–(2.16) become

$$\epsilon^2 \frac{\partial^2 \Phi}{\partial \xi^2} + \frac{\partial^2 \Phi}{\partial \eta^2} = 0 \quad \text{for } 0 < \eta < Y(\xi),\ \xi > \xi_c, \tag{3.2}$$

$$\frac{1}{3}\Phi - \frac{2}{3}\left(\xi\frac{\partial \Phi}{\partial \xi} + \eta\frac{\partial \Phi}{\partial \eta}\right) + \frac{1}{2}\left\{\left(\frac{\partial \Phi}{\partial \xi}\right)^2 + \frac{1}{\epsilon^2}\left(\frac{\partial \Phi}{\partial \eta}\right)^2\right\} = \frac{Y''}{(1+\epsilon^2 Y'^2)^{3/2}} \quad \text{at } \eta = Y, \tag{3.3}$$

$$\frac{1}{\epsilon^2}\frac{\partial \Phi}{\partial \eta} + \frac{2}{3}\xi Y' - \frac{2}{3}Y - \frac{\partial \Phi}{\partial \xi}Y' = 0 \quad \text{at } \eta = Y, \tag{3.4}$$

$$\frac{\partial \Phi}{\partial \eta} = 0 \quad \text{at } \eta = 0 \tag{3.5}$$

subject to

$$Y' = \frac{1}{\epsilon}\tan(\lambda\epsilon) \quad \text{at } \xi = \xi_c, \tag{3.6}$$

$$Y - \xi\frac{\tan\epsilon}{\epsilon} \to 0 \quad \text{as } \xi \to \infty, \tag{3.7}$$

$$\Phi \to 0 \quad \text{as } \xi^2 + \epsilon^2\eta^2 \to \infty. \tag{3.8}$$

We make the expansions

$$\Phi = \Phi_0 + \epsilon^2\Phi_2 + O(\epsilon^4), \quad Y = Y_0 + O(\epsilon^2)$$

and substitute into (3.2)–(3.8). King (1991) showed that $\Phi_0 \equiv \Phi_0(\xi)$ and $\Phi_2 = -\frac{1}{2}\eta^2\Phi_0'' + D(\xi)$. The leading order problem is then a nonlinear boundary value problem for $\Phi_0(\xi)$ and $Y_0(\xi)$. In order to formulate this problem on a known domain, we define $\hat{\xi} = \xi - \xi_c$, and the resulting coupled, nonlinear ordinary differential equations are

$$\frac{1}{3}\Phi_0 - \frac{2}{3}\left(\hat{\xi} + \xi_c\right)\Phi_0' + \frac{1}{2}\Phi_0'^2 - Y_0'' = 0, \tag{3.9}$$

$$-\left(Y_0\Phi_0'\right)' + \frac{2}{3}\left(\hat{\xi} + \xi_c\right)Y_0' - \frac{2}{3}Y_0 = 0, \tag{3.10}$$

to be solved for $\hat{\xi} > 0$ subject to

$$Y_0(0) = 0, \quad Y_0'(0) = \lambda, \tag{3.11}$$

$$Y_0 - \hat{\xi} - \xi_c \to 0, \quad \Phi_0 \to 0 \quad \text{as } \hat{\xi} \to \infty, \tag{3.12}$$

where a prime now denotes $d/d\hat{\xi}$.

King (1991) examined the far field solution of (3.9) and (3.10) and showed that

$$\Phi_0 \sim \frac{F}{\hat{\xi}^2} \exp\left(\frac{4i\hat{\xi}^{3/2}}{9C^{1/2}}\right), \quad Y_0 \sim C\hat{\xi} + \xi_c + \frac{G}{\hat{\xi}^{3/2}} \exp\left(\frac{4i\hat{\xi}^{3/2}}{9C^{1/2}}\right) \quad \text{as } \hat{\xi} \to \infty, \tag{3.13}$$

and, to satisfy (3.12), $C = 1$. The far field solution therefore consists of decaying capillary waves. King (1991) demonstrated that there is a weak nonuniformity in the far field solution when $\eta\hat{\xi}^{1/2} = O(\epsilon^{-1})$ and the flow becomes two-dimensional. Rescaling into a region with $\hat{\xi}$, $\eta = O(\epsilon^{-2/3})$ then completes the solution structure. We will not consider the detailed structure of the two-dimensional flow here but refer the interested reader to King (1991).

3.1. Numerical solution. We can solve (3.9) and (3.10) subject to (3.11) and (3.12) numerically using the MATLAB routine bvp4c, which uses an adaptive gridding method. Since we know that $\Phi_0 = 0$, $Y_0 = \hat{\xi}$, and $\xi_c = 0$ when $\lambda = 1$, it is straightforward to use continuation to find the solution for $\lambda > 1$. However, we did find it convenient to first make the transformation $Y_0 \mapsto \lambda^{4/3} Y_0$, $\Phi_0 \mapsto \lambda^{2/3}\Phi_0$, $\hat{\xi} \mapsto \lambda^{1/3}\hat{\xi}$, $\xi_c \mapsto \lambda^{1/3}\xi_c$, which leaves (3.9)–(3.12) unchanged, except that the first relation in (3.12) becomes $Y_0 - \lambda^{-1}(\hat{\xi} + \xi_c) \to 0$ as $\hat{\xi} \to \infty$. This allowed us to find a numerical solution up to $\lambda \approx 105$, a somewhat larger value than was possible for the system in its original form. Note that it is tempting to suggest that, when $\lambda \gg 1$, we simply need to look for a solution with $Y_0 \to 0$ as $\hat{\xi} \to \infty$. However, the far field behavior, (3.13), shows that no such solution exists, since we cannot take $C = 0$.

Figure 3.1 shows the solution for various values of λ. As λ increases, both the amplitude and the frequency of the oscillations of the free surface increase, as does the size of the potential, Φ_0. Figure 3.2 shows the numerical solution for $\lambda = 100$, along with the asymptotic solution for its envelope, which we will determine in section 3.2. Figure 3.3 shows the numerically calculated behavior of the position of the contact line, ξ_c, as a function of λ. Also shown is the asymptotic behavior for $|\lambda - 1| \ll 1$, $\xi_c \sim 0.80755(\lambda - 1)$, determined by King (1991), and the asymptotic behavior for $\lambda \gg 1$, which we shall determine in section 3.2.

3.2. Asymptotic solution for $\lambda \gg 1$. The numerical solutions presented above suggest that the asymptotic solution for $\lambda \gg 1$ takes the form of a large amplitude oscillation of the free surface, varying slowly over a long lengthscale. This suggests that we can find the solution using Kuzmak's method (see, for example, Bourland and Haberman (1988), and King, Billingham, and Otto (2003)), which is a version of the method of multiple scales that works for nonlinear oscillators.

By looking for an asymptotic balance, we find that appropriate scaled variables are

$$Y_0 = \lambda^{2/3}\bar{Y}(\psi, X), \quad \Phi_0 = \lambda^{4/3}\hat{\Phi}(X) + \lambda^{1/3}\bar{\Phi}(\psi, X), \quad \hat{\xi} = \lambda^{-1/3}\bar{\xi}, \quad \xi_c = \lambda^{2/3}\bar{\xi}_c, \tag{3.14}$$

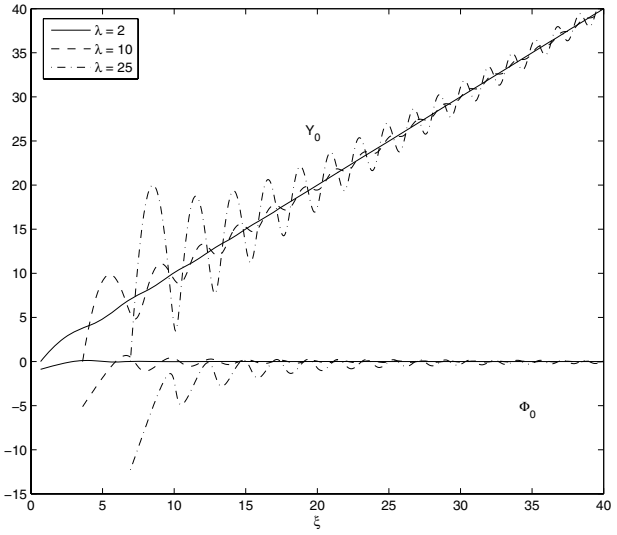

FIG. 3.1. *The numerical solution for* $\lambda = 2$, 10, *and* 25.

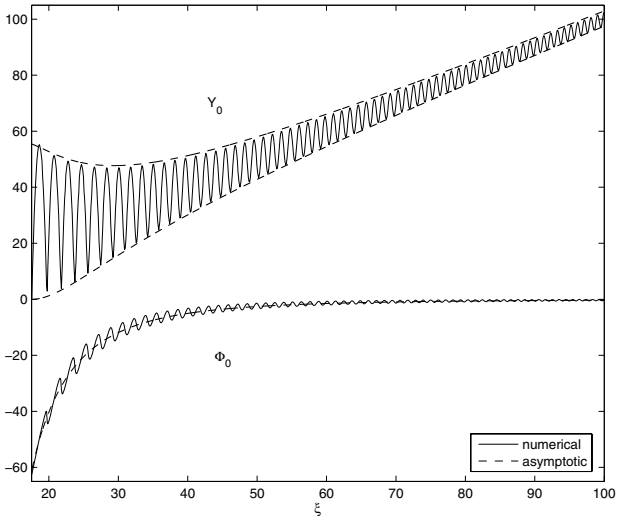

FIG. 3.2. *The numerical solution for* $\lambda = 100$, *along with the asymptotic solution for the envelope of* Y_0 *and the leading order behavior of* Φ_0.

where $X = \lambda^{-1}\bar{\xi}$ is a slow space variable and $\psi = \lambda\theta(X) + p(X)$ is a fast space variable, with $\theta(0) = p(0) = 0$. Note that

$$\frac{d}{d\bar{\xi}} = \left\{\omega(X) + \lambda^{-1}p'(X)\right\}\frac{\partial}{\partial\psi} + \lambda^{-1}\frac{\partial}{\partial X},$$

where $\omega(X) \equiv \theta'(X) = O(1)$ is the frequency of the underlying oscillatory solution, which we will choose so that the solution has unit period in terms of the fast variable,

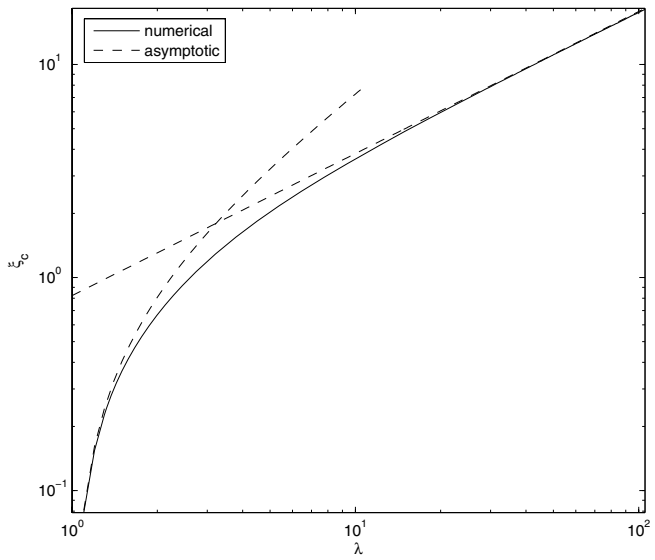

FIG. 3.3. *The position of the contact line, ξ_c, determined numerically for $\lambda > 1$, along with the asymptotic estimates for $|\lambda - 1| \ll 1$ and $\lambda \gg 1$.*

ψ. The function $p(X) = O(1)$ is the phase. In terms of these variables, (3.9)–(3.12) become

$$\frac{1}{3}\left(\hat{\Phi} + \lambda^{-1}\bar{\Phi}\right) - \frac{2}{3}\left(\bar{\xi}_c + X\right)\left\{\left(\omega + \lambda^{-1}p'\right)\bar{\Phi}_\psi + \hat{\Phi}' + \lambda^{-1}\bar{\Phi}_X\right\}$$

$$+\frac{1}{2}\left\{\left(\omega + \lambda^{-1}p'\right)\bar{\Phi}_\psi + \hat{\Phi}' + \lambda^{-1}\bar{\Phi}_X\right\}^2 \tag{3.15}$$

$$-\left\{\left(\omega + \lambda^{-1}p'\right)^2\bar{Y}_{\psi\psi} + 2\lambda^{-1}\left(\omega + \lambda^{-1}p'\right)\bar{Y}_{\psi X} + \lambda^{-2}\bar{Y}_{XX} + \lambda^{-1}\left(\omega' + \lambda^{-1}p''\right)\bar{Y}_\psi\right\} = 0,$$

$$-\bar{Y}\left\{\left(\omega + \lambda^{-1}p'\right)^2\bar{\Phi}_{\psi\psi} + 2\lambda^{-1}\left(\omega + \lambda^{-1}p'\right)\bar{\Phi}_{\psi X}\right.$$

$$\left.+\lambda^{-1}\left(\hat{\Phi}'' + \lambda^{-1}\bar{\Phi}_{XX}\right) + \lambda^{-1}\left(\omega' + \lambda^{-1}p''\right)\bar{\Phi}_\psi\right\} \tag{3.16}$$

$$-\left\{\left(\omega + \lambda^{-1}p'\right)\bar{Y}_\psi + \lambda^{-1}\bar{Y}_X\right\}\left\{\left(\omega + \lambda^{-1}p'\right)\bar{\Phi}_\psi + \hat{\Phi}' + \lambda^{-1}\bar{\Phi}_X\right\}$$

$$+\frac{2}{3}\left(\bar{\xi}_c + X\right)\left\{\left(\omega + \lambda^{-1}p'\right)\bar{Y}_\psi + \lambda^{-1}\bar{Y}_X\right\} - \frac{2}{3}\lambda^{-1}\bar{Y} = 0,$$

to be solved for $\bar{\xi} > 0$, $X > 0$ subject to

$$\bar{Y}(0,0) = 0, \quad (\omega(0) + \lambda^{-1}p'(0))\bar{Y}_\psi(0,0) + \lambda^{-1}\bar{Y}_X(0,0) = 1, \tag{3.17}$$

$$\bar{Y} - \bar{\xi} - \bar{\xi}_c \to 0, \quad \hat{\Phi} + \lambda^{-1}\bar{\Phi} \to 0 \ \text{ as } \bar{\xi} \to \infty. \tag{3.18}$$

We now expand

$$\bar{Y} = \bar{Y}_0 + \lambda^{-1}\bar{Y}_1 + O(\lambda^{-2}), \quad \bar{\Phi} = \bar{\Phi}_0 + \lambda^{-1}\bar{\Phi}_1 + O(\lambda^{-2}), \quad \bar{\xi}_c = \bar{\xi}_{c0} + \lambda^{-1}\bar{\xi}_{c1} + O(\lambda^{-2}).$$

As we shall see, we can find the leading order solution up to some unknown functions of X by solving the equations at leading order but must consider secularity conditions for the equations at $\mathrm{O}(\lambda^{-1})$ to determine the slow time behavior of the leading order solution, with the exception of the phase, $p(X)$. In order to determine the slow drift in the phase, we would have to solve at $O(\lambda^{-1})$ and determine a secularity condition from the equations at $O(\lambda^{-2})$. This proves to be intractable, and we will not address this issue here. The strategy for finding $p(X)$ is described in King, Billingham, and Otto (2003) for a simple model problem.

3.2.1. Solution at leading order. At leading order, (3.15) and (3.16) give

$$-\omega^2\bar{Y}_0\bar{\Phi}_{0\psi\psi} - \omega\bar{Y}_{0\psi}\left(\omega\bar{\Phi}_{0\psi} + \hat{\Phi}'\right) + \frac{2}{3}\left(\bar{\xi}_{c0} + X\right)\omega\bar{Y}_{0\psi} = 0, \tag{3.19}$$

$$\frac{1}{3}\hat{\Phi} - \frac{2}{3}\left(\bar{\xi}_{c0} + X\right)\left(\omega\bar{\Phi}_{0\psi} + \hat{\Phi}'\right) + \frac{1}{2}\left(\omega\bar{\Phi}_{0\psi} + \hat{\Phi}'\right)^2 - \omega^2\bar{Y}_{0\psi\psi} = 0. \tag{3.20}$$

We can integrate (3.19) once to give

$$\omega\bar{\Phi}_{0\psi} = -\hat{\Phi}' + \frac{2}{3}\left(\bar{\xi}_{c0} + X\right) - \frac{d_0(X)}{\bar{Y}_0}, \tag{3.21}$$

where $d_0(X)$ is to be determined. As we shall see, $\bar{Y}_0$ is a periodic function of ψ, whose period we normalize to unity by an appropriate choice of $\omega(X)$. In order that $\bar{\Phi}_0$ remains bounded as $\psi \to \infty$ (the secularity condition), we must choose

$$\hat{\Phi}' = \frac{2}{3}\left(\bar{\xi}_{c0} + X\right) - d_0(X)\overline{\left(\frac{1}{\bar{Y}_0}\right)}, \tag{3.22}$$

where an overbar indicates the mean value over the unit period of the oscillation,

$$\overline{f(\psi)} \equiv \int_0^1 f(\psi)\, d\psi.$$

Substituting (3.22) into (3.21) gives

$$\omega\bar{\Phi}_{0\psi} = d_0(X)\left\{\overline{\left(\frac{1}{\bar{Y}_0}\right)} - \frac{1}{\bar{Y}_0}\right\}. \tag{3.23}$$

Now that we have an expression for $\bar{\Phi}_0$, we can substitute this into (3.20) to give

$$\omega^2\bar{Y}_{0\psi\psi} - \frac{1}{3}\hat{\Phi} + \frac{2}{9}\left(\bar{\xi}_{c0} + X\right)^2 - \frac{d_0^2}{2\bar{Y}_0^2} = 0. \tag{3.24}$$

We can integrate this equation once and write the result as

$$\bar{Y}_{0\psi}^2 = \frac{1}{\omega^2}\left\{\frac{4}{9}\left(\bar{\xi}_{c0} + X\right)^2 - \frac{2}{3}\hat{\Phi}\right\}\frac{\left(\bar{Y}_+ - \bar{Y}_0\right)\left(\bar{Y}_0 - \bar{Y}_-\right)}{\bar{Y}_0}, \tag{3.25}$$

where $\bar{Y}_+(X)$ and $\bar{Y}_-(X)$ are related by

$$\bar{Y}_+\bar{Y}_- = \frac{d_0^2}{\frac{4}{9}\left(\bar{\xi}_{c0}+X\right)^2 - \frac{2}{3}\hat{\Phi}}. \tag{3.26}$$

It is clear from the form of (3.25) that $\bar{Y}_0$ is an oscillatory function of ψ and varies between $\bar{Y}_-$ and $\bar{Y}_+ > \bar{Y}_-$. In fact, we can integrate (3.25) and write the solution for the first half-period of the oscillation in implicit form as (see Byrd and Friedman (1954))

$$\frac{1}{\omega}\left\{\frac{4}{9}\left(\bar{\xi}_{c0}+X\right)^2 - \frac{2}{3}\hat{\Phi}\right\}^{1/2}\psi$$

$$= 2\sqrt{\bar{Y}_+}\left\{\mathbf{E}\left(\sqrt{1-\frac{\bar{Y}_-}{\bar{Y}_+}}\right) - E\left(\sin^{-1}\left(\sqrt{\frac{\bar{Y}_+-\bar{Y}_0}{\bar{Y}_+-\bar{Y}_-}}\right);\sqrt{1-\frac{\bar{Y}_-}{\bar{Y}_+}}\right)\right\}, \tag{3.27}$$

where E is the incomplete elliptic integral of the second kind, and $\mathbf{E}$ is the complete elliptic integral of the second kind. We can now choose $\omega(X)$ so that the period of this oscillation is unity, which gives

$$\omega(X) = \frac{\left\{\frac{4}{9}\left(\bar{\xi}_{c0}+X\right)^2 - \frac{2}{3}\hat{\Phi}\right\}^{1/2}}{4\bar{Y}_+^{1/2}\mathbf{E}\left((1-R)^{1/2}\right)}, \tag{3.28}$$

where $R \equiv \bar{Y}_-/\bar{Y}_+$. We also note that, now that we know $\bar{Y}_0$, exact integral formulas given in Byrd and Friedman (1954) show that

$$\overline{\left(\frac{1}{\bar{Y}_0}\right)} = \frac{1}{\bar{Y}_+}\frac{\mathbf{K}\left((1-R)^{1/2}\right)}{\mathbf{E}\left((1-R)^{1/2}\right)}, \tag{3.29}$$

$$\overline{\bar{Y}_0} = \frac{1}{3}\bar{Y}_+\left\{2\left(1+R\right) - R\frac{\mathbf{K}\left((1-R)^{1/2}\right)}{\mathbf{E}\left((1-R)^{1/2}\right)}\right\}, \tag{3.30}$$

where $\mathbf{K}$ is the complete elliptic integral of the first kind.

Note that, for a given value of the slow time variable, X, $\bar{Y}_0$ is an even, periodic function with unit period and $\bar{Y}_{0\psi} = 0$ at $\psi = 0$. At first sight, this makes it impossible to satisfy the leading order initial condition, given by (3.17) as $\bar{Y}_0 = 0$, $\omega(0)\bar{Y}_{0\psi} = 1$ at $\psi = X = 0$. However, this is only the case if $d_0(0) > 0$. We can see from (3.24) that if $d_0(0) = 0$, $\bar{Y}_0$ is quadratic in ψ, and we can satisfy these initial conditions. A closer examination of the behavior as $X \to 0$ leads to the conditions

$$d_0 \sim \frac{8X}{9\left\{\frac{4}{9}\bar{\xi}_{c0}^2 - \frac{2}{3}\hat{\Phi}(0)\right\}}, \quad \bar{Y}_- \sim d_0^2, \quad \bar{Y}_+ \to \frac{1}{\frac{4}{9}\bar{\xi}_{c0}^2 - \frac{2}{3}\hat{\Phi}(0)} \quad \text{as } X \to 0. \tag{3.31}$$

We should also consider what happens as $X \to \infty$. Since (3.18) shows that $\bar{Y}_0 \sim X + \bar{\xi}_{c0}$, we must have $\bar{Y}_+ \sim \bar{Y}_- \sim X + \bar{\xi}_{c0}$. Then (3.26) and (3.28) show that

$$d_0 \sim \frac{2}{3}\left(X+\bar{\xi}_{c0}\right)^2, \quad \omega \sim \frac{1}{3\pi}\left(X+\bar{\xi}_{c0}\right)^{1/2} \quad \text{as } X \to \infty. \tag{3.32}$$

This means that $\theta(X) \sim 2\left(X+\bar{\xi}_{c0}\right)^{3/2}/9\pi$ and hence that

$$\bar{Y}_0 \sim \bar{\xi}_{c0} + X + \frac{1}{2}\left(\bar{Y}_+ - \bar{Y}_-\right)\cos\left\{\frac{4\lambda}{9}\left(X+\bar{\xi}_{c0}\right)^{3/2} + p'\right\}.$$

This is consistent with (3.13) and shows that we should find

$$\bar{Y}_+ - \bar{Y}_- = O((\bar{\xi}_c + X)^{-3/2}) \quad \text{for } X \gg 1. \tag{3.33}$$

We will confirm this later.

3.2.2. Secularity conditions at $O(\lambda^{-1})$. At $O(\lambda^{-1})$, (3.16) again leads to an equation that we can integrate once, to find that

$$\omega\bar{\Phi}_{1\psi} = -\bar{\Phi}_{0X} + \frac{d_0\bar{Y}_1}{\bar{Y}_0^2} + \frac{d_1}{\bar{Y}_0}$$

$$+\frac{1}{\omega\bar{Y}_0}\left(d_0'\psi - \frac{4}{3}\bar{Z}_0\right) - \frac{p'}{\omega}\left\{\frac{2}{3}\left(\bar{\xi}_{c0}+X\right) - \hat{\Phi}'\right\} + \frac{2}{3}\bar{\xi}_{c1}, \tag{3.34}$$

where $d_1(X)$ is a function of integration and

$$\bar{Z}_0 = \int_0^\psi \bar{Y}_0(\hat{\psi}, X)\, d\hat{\psi}.$$

In order that $\bar{\Phi}_1$ remains bounded as $\psi \to \infty$, we require

$$d_0' = \frac{4}{3}\overline{\bar{Y}_0}. \tag{3.35}$$

Equation (3.15) at $O(\lambda^{-1})$, after using (3.34) to eliminate $\bar{\Phi}_1$, gives

$$\omega^2\bar{Y}_{1\psi\psi} + \frac{d_0^2\bar{Y}_1}{\bar{Y}_0^3} = -2\omega p'\bar{Y}_{0\psi\psi} - 2\omega\bar{Y}_{0\psi X} - \omega'\bar{Y}_{0\psi} + \frac{1}{3}\bar{\Phi}_0$$

$$+\frac{d_0}{\omega\bar{Y}_0^2}\left(d_0p' - \omega d_1 - \frac{4}{3}\overline{\bar{Y}_0}\psi + \frac{4}{3}\bar{Z}_0\right) - \frac{4}{9}\bar{\xi}_{c1}\left(\bar{\xi}_{c0}+X\right). \tag{3.36}$$

Since $\bar{Y}_1 = \bar{Y}_{0\psi}$ is a solution of this equation, the secularity condition is that the integral over one period of $\bar{Y}_{0\psi}$ times the right-hand side should be zero. Taking into account the parity of the various terms on the right-hand side, this means that

$$\int_0^1 \bar{Y}_{0\psi}\left\{-2\omega\bar{Y}_{0\psi X} - \omega'\bar{Y}_{0\psi} + \frac{1}{3}\bar{\Phi}_0 - \frac{4d_0}{3\omega\bar{Y}_0^2}\left(\overline{\bar{Y}_0}\psi - \bar{Z}_0\right)\right\} d\psi = 0. \tag{3.37}$$

After integration by parts, making use of (3.35), we find that

$$\frac{d}{dX}\int_0^1 \omega\bar{Y}_{0\psi}^2\, d\psi = \frac{5d_0}{3\omega}\left\{1 - \overline{\bar{Y}_0}\overline{\left(\frac{1}{\bar{Y}_0}\right)}\right\}. \tag{3.38}$$

From (3.27), we have

$$\int_0^1 \omega \bar{Y}_{0\psi}^2 \, d\psi = \frac{2^{5/2}\bar{Y}_+^{3/2}}{3} \left\{ \frac{2}{9} \left(\bar{\xi}_{c0} + X \right)^2 - \frac{1}{3}\hat{\Phi} \right\}^{1/2} \left\{ (1+R)\, \mathbf{E}\left((1-R)^{1/2} \right) \right.$$

$$\left. -2R\, \mathbf{K}\left((1-R)^{1/2} \right) \right\}. \tag{3.39}$$

Now, making use of (3.22), (3.26), (3.28), (3.35), (3.38), and (3.39), we find, after considerable manipulation, that we can obtain ordinary differential equations for $\hat{\Phi}$, R, and d_0:

$$\hat{\Phi}' = \frac{2}{3}\left(\bar{\xi}_{c0} + X \right) - \sqrt{R} \frac{\mathbf{K}((1-R)^{1/2})}{\mathbf{E}((1-R)^{1/2})} \left\{ \frac{4}{9}\left(\bar{\xi}_{c0} + X \right)^2 - \frac{2}{3}\hat{\Phi} \right\}^{1/2}, \tag{3.40}$$

$$R' = -\frac{4\left(\bar{\xi}_{c0} + X \right)}{27\left\{ \frac{4}{9}\left(\bar{\xi}_{c0} + X \right)^2 - \frac{2}{3}\hat{\Phi} \right\}} \frac{R}{1-R} \left\{ 1 + R - 2R \frac{\mathbf{K}((1-R)^{1/2})}{\mathbf{E}((1-R)^{1/2})} \right\}$$

$$- \frac{2\sqrt{R}}{9\left\{ \frac{4}{9}\left(\bar{\xi}_{c0} + X \right)^2 - \frac{2}{3}\hat{\Phi} \right\}^{1/2}} \frac{1}{1-R} \left\{ R\,(1+R)\, \frac{\mathbf{K}((1-R)^{1/2})}{\mathbf{E}((1-R)^{1/2})} - 2\left(4R^2 - 7R + 4 \right) \right\}, \tag{3.41}$$

$$d_0' = \frac{4 d_0}{9R^{1/2}\left\{ \frac{4}{9}\left(\bar{\xi}_{c0} + X \right)^2 - \frac{2}{3}\hat{\Phi} \right\}^{1/2}} \left\{ 2\,(1+R) - R \frac{\mathbf{K}((1-R)^{1/2})}{\mathbf{E}((1-R)^{1/2})} \right\}. \tag{3.42}$$

Note that, although (3.42) is not coupled to (3.40) and (3.41), it is convenient to consider all three equations together. Equations (3.40)–(3.42) are to be solved subject to

$$R \sim \frac{64X^2}{81\left\{ \frac{4}{9}\bar{\xi}_{c0}^2 - \frac{2}{3}\hat{\Phi}(0) \right\}}, \quad d_0 \sim \frac{8X}{9\left\{ \frac{4}{9}\bar{\xi}_{c0}^2 - \frac{2}{3}\hat{\Phi}(0) \right\}} \quad \text{as } X \to 0, \tag{3.43}$$

$$R \to 1, \quad \hat{\Phi} \to 0, \quad d_0 \sim \frac{2}{3}\left(\bar{\xi}_{c0} + X \right)^2 \quad \text{as } X \to \infty. \tag{3.44}$$

It is now helpful to make this system autonomous by the transformation

$$\hat{\Phi} = \left(\bar{\xi}_{c0} + X \right)^2 \tilde{\Phi}(s), \quad R = \tilde{R}(s), \quad d_0 = \tilde{d}_0(s), \quad s = \log\left(1 + \frac{X}{\bar{\xi}_{c0}} \right),$$

which gives

$$\frac{d\tilde{\Phi}}{ds} = -2\tilde{\Phi} + \frac{2}{3} - \sqrt{\tilde{R}} \frac{\mathbf{K}((1-\tilde{R})^{1/2})}{\mathbf{E}((1-\tilde{R})^{1/2})} \left(\frac{4}{9} - \frac{2}{3}\tilde{\Phi} \right)^{1/2}, \tag{3.45}$$

$$\frac{d\tilde{R}}{ds} = -\frac{4}{27\left(\frac{4}{9}-\frac{2}{3}\tilde{\Phi}\right)}\frac{\tilde{R}}{1-\tilde{R}}\left\{1+\tilde{R}-2\tilde{R}\frac{\mathbf{K}((1-\tilde{R})^{1/2})}{\mathbf{E}((1-\tilde{R})^{1/2})}\right\}$$

$$-\frac{2\sqrt{\tilde{R}}}{9\left(\frac{4}{9}-\frac{2}{3}\tilde{\Phi}\right)^{1/2}}\frac{1}{1-\tilde{R}}\left\{\tilde{R}\left(1+\tilde{R}\right)\frac{\mathbf{K}((1-\tilde{R})^{1/2})}{\mathbf{E}((1-\tilde{R})^{1/2})}-2\left(4\tilde{R}^2-7\tilde{R}+4\right)\right\}, \tag{3.46}$$

$$\frac{d\tilde{d}_0}{ds} = \frac{4\tilde{d}_0}{9\tilde{R}^{1/2}\left(\frac{4}{9}-\frac{2}{3}\tilde{\Phi}\right)^{1/2}}\left\{2\left(1+\tilde{R}\right)-\tilde{R}\frac{\mathbf{K}((1-\tilde{R})^{1/2})}{\mathbf{E}((1-\tilde{R})^{1/2})}\right\}, \tag{3.47}$$

$$\tilde{R}\sim\frac{64s^2}{81\left\{\frac{4}{9}-\frac{2}{3}\tilde{\Phi}(0)\right\}},\quad \tilde{d}_0\sim\frac{8s}{9\bar{\xi}_{c0}\left\{\frac{4}{9}-\frac{2}{3}\tilde{\Phi}(0)\right\}}\ \text{ as } s\to 0, \tag{3.48}$$

$$\tilde{R}\to 1,\quad \tilde{\Phi}=o(e^{-2s}),\quad \tilde{d}_0\sim\frac{2}{3}\bar{\xi}_{c0}^2e^{2s}\ \text{ as } s\to\infty. \tag{3.49}$$

As $\tilde{R}\to 1$ and $\tilde{\Phi}\to 0$, the linearized equations for $\tilde{R}$ and $\tilde{\Phi}$ are

$$\frac{d\tilde{R}}{ds}\sim-\frac{5}{2}\left(\tilde{R}-1\right),\quad \frac{d\tilde{\Phi}}{ds}\sim-\frac{3}{2}\tilde{\Phi}.$$

First, we note that this means that $R=O((\bar{\xi}_{c0}+X)^{-5/2})$ for $X\gg 1$, consistent with (3.33). Second, the point $(0,1)$ in the $(\tilde{\Phi},\tilde{R})$-phase plane is a stable node, and locally all solutions have $\tilde{\Phi}=O(e^{-3s/2})$ as $s\to\infty$, with the exception of the solution associated with the eigenvector in the $\tilde{R}$-direction. Condition (3.49) shows that this is the solution we require. It is straightforward to determine this solution numerically and find where the solution meets the $\tilde{\Phi}$-axis. We used the routine ode45 in MATLAB, which is an implementation of the fifth order Runge–Kutta method with adaptive stepping. We obtain $\tilde{\Phi}(0)\approx -0.1939$. If we then define $\bar{d}_0=\bar{\xi}_{c0}\tilde{d}_0$, we find that $\bar{d}_0$ also satisfies (3.47) and that

$$\bar{d}_0\sim\frac{8s}{9\left\{\frac{4}{9}-\frac{2}{3}\tilde{\Phi}(0)\right\}}\ \text{ as } s\to 0,\ \ \bar{d}_0\sim\frac{2}{3}\bar{\xi}_{c0}^3e^{2s}\ \text{ as } s\to\infty. \tag{3.50}$$

It is again straightforward to solve numerically for $\tilde{R}$, $\tilde{\Phi}$, and $\bar{d}_0$ subject to (3.48) and (3.50), integrating forward until $\bar{d}_0$ is large, and then determine from the behavior of $\bar{d}_0$ as $s\to\infty$ that $\bar{\xi}_{c0}\approx 0.8231$ from (3.50) when $s\gg 1$. Figure 3.3 confirms that $\xi_c\sim\bar{\xi}_{c0}\lambda^{1/3}$ as $\lambda\to\infty$. Figure 3.4 shows how R, $\hat{\Phi}$, and d_0 vary with s. It is now straightforward to calculate $\bar{Y}_+$ and $\bar{Y}_-$ from (3.26). These provide an envelope for the solution and are shown in Figure 3.2 to be in excellent agreement with the numerical solution of the full problem when $\lambda=100$. Figure 3.2 also shows that the asymptotic solution for $\hat{\Phi}(X)$ is in good agreement with the numerical solution. Note that the oscillatory part of Φ_0 has amplitude of $O(\lambda^{-1})$ smaller than the slowly varying part and is given by $\lambda^{-1}\bar{\Phi}$. Figure 3.5 shows a direct comparison of the numerical and asymptotic solutions for $\lambda=100$. The agreement is good in terms of the amplitude, as we would expect from the results shown in Figure 3.2, but we can see a slow drift of the phase as ξ increases. This is because we have taken $p(X)=0$ in the definition of the fast space variable. As discussed earlier, to determine $p(X)$ we would need to solve completely at $O(\lambda^{-1})$ and examine the secularity condition at $O(\lambda^{-2})$, which is not tractable.

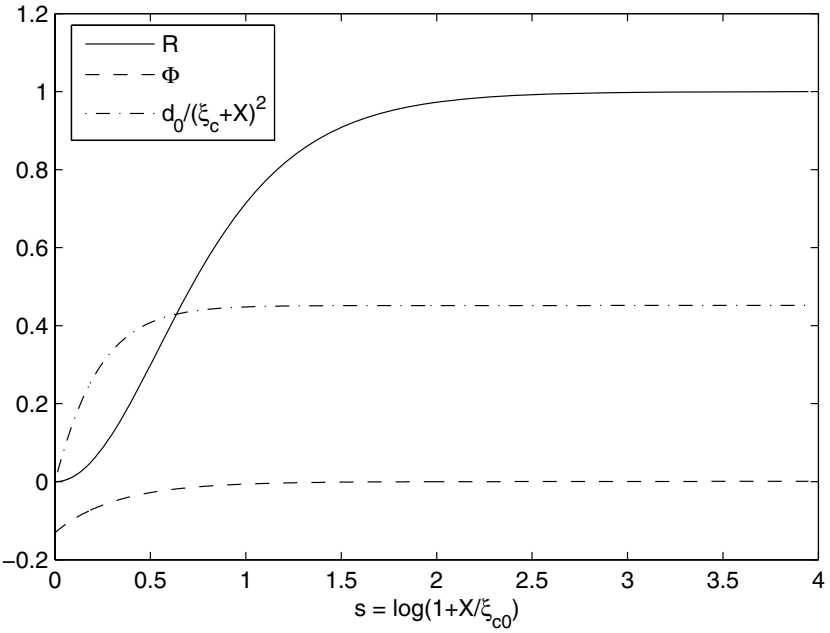

FIG. 3.4. *The variation of R, $\hat{\Phi}$, and d_0 with s.*

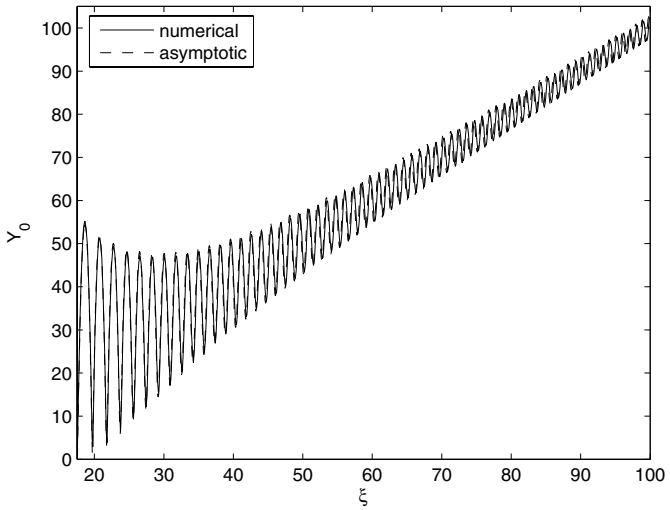

FIG. 3.5. *The numerical and asymptotic solutions for $\lambda = 100$.*

4. The fully nonlinear slender wedge limit, $\epsilon \ll 1$, $\lambda = O(\epsilon^{-1})$. We expect the asymptotic solution that we constructed in the previous section to remain valid for $\lambda = o(\epsilon^{-1})$. When $\lambda = O(\epsilon^{-1})$, the slope of the free surface is $\lambda\epsilon = O(1)$ at the contact line, so we would not expect to be able to reduce the problem to a set

of ordinary differential equations. We define $\bar{\lambda} = \lambda\epsilon = O(1)$ for $\epsilon \ll 1$. The scaled variables (3.1) and (3.14) then suggest that we define new scaled variables

$$\bar{x} = \epsilon^{-1/3}\tilde{\xi}_c + \epsilon^{2/3}\tilde{\xi}, \quad \bar{y} = \epsilon^{2/3}\tilde{\eta}, \quad \bar{y}_s = \epsilon^{2/3}\tilde{Y}, \quad \bar{\phi} = \epsilon^{-2/3}\Phi_0 + \epsilon^{1/3}\tilde{\Phi}. \tag{4.1}$$

Apart from the large shift of the origin, the spatial scalings are those given by King (1991) for the far field of the problem with $\lambda = O(1)$. Indeed, we can think of $\lambda = O(\epsilon^{-1})$ as the limit in which the two-dimensional flow in the far field becomes comparable with the one-dimensional flow in the near field and the new scalings (4.1) emerge.

4.1. The underlying periodic solution. Although we will be using Kuzmak's method to solve the problem in terms of the variables (4.1) for $\epsilon \ll 1$, it will make things clearer if we study the underlying periodic solution first. For the moment, we assume that Φ_0 is a constant, but we will see later that it is a function of the slow variable.

At leading order, a solution of wavelength L in the $\tilde{\xi}$-direction satisfies

$$\nabla^2\tilde{\Phi} = 0 \quad \text{for } 0 < \tilde{\eta} < \tilde{Y},\ 0 < \tilde{\xi} < L, \tag{4.2}$$

$$\frac{1}{3}\Phi_0 - \frac{2}{3}\tilde{\xi}_c\frac{\partial\tilde{\Phi}}{\partial\tilde{\xi}} + \frac{1}{2}|\nabla\tilde{\Phi}|^2 = \frac{\tilde{Y}''}{(1+\tilde{Y}'^2)^{3/2}} \quad \text{at } \tilde{\eta} = \tilde{Y} \text{ for } 0 < \tilde{\xi} < L, \tag{4.3}$$

$$\frac{\partial\tilde{\Phi}}{\partial\tilde{\eta}} + \frac{2}{3}\tilde{\xi}_c\tilde{Y}' - \frac{\partial\tilde{\Phi}}{\partial\tilde{\xi}}\tilde{Y}' = 0 \quad \text{at } \tilde{\eta} = \tilde{Y} \text{ for } 0 < \tilde{\xi} < L, \tag{4.4}$$

$$\frac{\partial\tilde{\Phi}}{\partial\tilde{\eta}} = 0 \quad \text{at } \tilde{\eta} = 0 \text{ for } 0 < \tilde{\xi} < L. \tag{4.5}$$

If we now subtract off a uniform flow in the $\tilde{\xi}$-direction by defining

$$\tilde{\Phi} = \bar{\Phi} + \frac{2}{3}\tilde{\xi}_c\tilde{\xi} + P, \tag{4.6}$$

where P is an arbitrary constant (later, a function of the slow variable), (4.2)–(4.5) become

$$\nabla^2\bar{\Phi} = 0 \quad \text{for } 0 < \tilde{\eta} < \tilde{Y},\ 0 < \tilde{\xi} < L, \tag{4.7}$$

$$\frac{1}{2}|\nabla\bar{\Phi}|^2 = \frac{1}{2}c^2 + \frac{\tilde{Y}''}{(1+\tilde{Y}'^2)^{3/2}} \quad \text{at } \tilde{\eta} = \tilde{Y} \text{ for } 0 < \tilde{\xi} < L, \tag{4.8}$$

$$\frac{\partial\bar{\Phi}}{\partial\tilde{\eta}} - \frac{\partial\bar{\Phi}}{\partial\tilde{\xi}}\tilde{Y}' = 0 \quad \text{at } \tilde{\eta} = \tilde{Y} \text{ for } 0 < \tilde{\xi} < L, \tag{4.9}$$

$$\frac{\partial\bar{\Phi}}{\partial\tilde{\eta}} = 0 \quad \text{at } \tilde{\eta} = 0 \text{ for } 0 < \tilde{\xi} < L, \tag{4.10}$$

where $c = \sqrt{\frac{4}{9}\tilde{\xi}_c^2 - \frac{2}{3}\Phi_0}$. Equation (4.8) is the standard Bernoulli equation, and (4.9) is the equation for no flux through the free surface. We have therefore reduced the system to that of periodic capillary waves on a finite layer of fluid with wavespeed c. A similar approach was used by Billingham and King (2005) for the related problem of flow external to a thin, wedge-shaped void, although the resulting equations had no solution. We have more success here, since there exists a remarkable analytical solution describing capillary waves on fluid of finite depth first elucidated by Kinnersley (1976), building on the work of Crapper (1957), and put into a more systematic framework using complex variable theory by Crowdy (1999). As we shall see when we use Kuzmak's method, the solution of the fully nonlinear wedge problem can therefore be described in terms of capillary waves on fluid of finite depth, modulated in wavelength and amplitude on a long lengthscale.

Case I described by Kinnersley (1976) is the solution of relevance to us. The detailed investigation of this case given in Kinnersley (1976) spares us a lot of hard work, since each of the three limiting cases that he studied is one that we need to understand for our purposes. The solution is given implicitly in terms of Jacobian elliptic functions as

$$\tilde{\xi} = \frac{\mathrm{sn}B\,\mathrm{cd}B}{c^2}\left\{\frac{2k(1-k^2)\,\mathrm{sd}\phi\,\mathrm{nd}\phi}{\mathrm{dn}\psi + k\,\mathrm{cd}\phi} + (1-k^2)\phi - 2E(\phi) + 2k^2\,\mathrm{sn}\phi\,\mathrm{cd}\phi\right\}, \tag{4.11}$$

$$\tilde{\eta} = \frac{\mathrm{sn}B\,\mathrm{cd}B}{c^2}\left\{\frac{2(1-k^2)\,\mathrm{sn}\psi\,\mathrm{cn}\psi}{\mathrm{dn}\psi + k\,\mathrm{cd}\phi} + (1+k^2)\psi - 2E(\psi)\right\}, \tag{4.12}$$

where $\phi = A\bar{\Phi}$, $\psi = A\Psi + B$, Ψ is the streamfunction, $A \equiv c/(1-k^2)\,\mathrm{sn}B\,\mathrm{cd}B$, and B and k parameterize the solution. Note that we have adopted the convention used by Kinnersley (1976), that $\mathrm{sn}\phi \equiv \mathrm{sn}(\phi, k)$, $\mathrm{sn}\psi \equiv \mathrm{sn}(\psi, \sqrt{1-k^2})$, $\mathrm{sn}B \equiv \mathrm{sn}(B, \sqrt{1-k^2})$, and similarly for the other Jacobian elliptic functions, and

$$E(\phi) \equiv E\left(\sin^{-1}(\,\mathrm{sn}\phi)\,; k\right), \quad E(B) \equiv E\left(\sin^{-1}(\,\mathrm{sn}B)\,; \sqrt{1-k^2}\right).$$

It is a feature of the solution that each streamline represents a possible position of the free surface. We will take the free surface to be given by the streamline with $\psi = B$. At the solid surface, $\tilde{\eta} = 0$, we have $\psi = 0$. This solution has period $4\mathbf{K}(k)$ in terms of ϕ, which gives the wavelength as

$$L = \frac{4\,\mathrm{sn}B\,\mathrm{cd}B}{c^2}\left\{2\mathbf{E}(k) - (1-k^2)\mathbf{K}(k)\right\}.$$

We also note that the peak-to-trough amplitude of the solution is

$$a = \frac{4k\,\mathrm{sn}B\,\mathrm{sd}B}{c^2}, \tag{4.13}$$

and the height of the wave, given by the depth of water at the trough, is

$$h = \frac{\mathrm{sn}B\,\mathrm{cd}B}{c^2}\left\{2\,\mathrm{sc}B(\,\mathrm{dn}B - k) + (1+k^2)B - 2E(B)\right\}. \tag{4.14}$$

Figure 4.1(a) shows the streamlines for $B = 2$ and $k = 0.25$ over a single wavelength ($-4\mathbf{K}(k) \le \phi \le 0$). Note that for larger values of B, the free surface becomes self-intersecting and does not represent a valid solution.

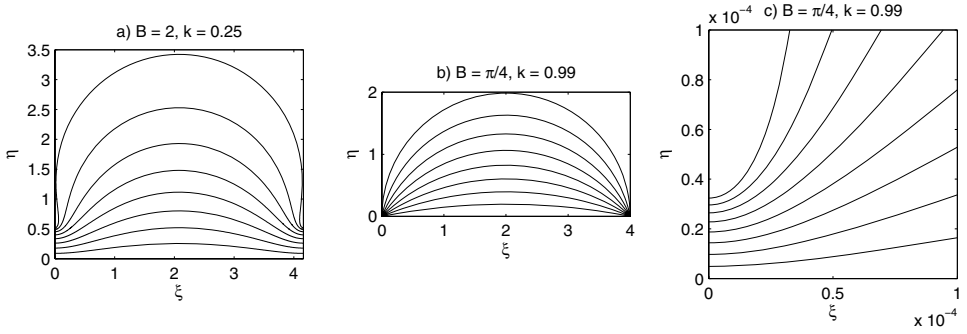

FIG. 4.1. *Some solutions given by* (4.11) *and* (4.12)*, all with* $c = 1$*. The free surface and bulk streamlines, each of which is also a possible position of the free surface, are shown.*

4.2. Limiting cases. We need to understand the behavior of the solution in each of the three limits $k \to 0$, $k \to 1$, and $B \to 0$. Fortunately, these are precisely the limits studied by Kinnersley (1976), so we will briefly summarize his results here.

4.2.1. The linear capillary wave limit, $k \to 0$. As $k \to 0$ with $B = O(1)$, the solution takes the form of small amplitude capillary waves. The free surface is given by

$$Y \sim \frac{\tanh B}{c^2}\left\{B - 2k \sinh B \cos\left(\frac{c^2\tilde{\xi}}{\tanh B}\right)\right\},$$

with

$$L \sim \frac{2\pi \tanh B}{c^2}, \quad a \sim \frac{4k \tanh B \sinh B}{c^2}, \quad h \sim \frac{B \tanh B}{c^2}.$$

This form of the solution will appear in the far field when we use Kumak's method.

4.2.2. The "string of beads" limit, $k \to 1$. As $k \to 1$, the solution takes the form of a sequence of "beads" of fluid bounded by segments of ellipses, as shown in Figure 4.1(b), connected by small inner "neck" regions, with size of $O((1-k)^2)$, as shown in Figure 4.1(c). We will not repeat the analysis of these two regions presented by Kinnersley (1976), but note that, at leading order, the free surface in the outer region (the "beads") is given by

$$\left(\frac{2\tilde{\xi}}{L}\right)^2 = \left(1 - \frac{\tilde{\eta}}{a}\right)\left(1 + \frac{\tilde{\eta}}{a}\tan^2 B\right),$$

with

$$a \sim \frac{4\sin^2 B}{c^2}, \quad L \sim \frac{8 \sin B \cos B}{c^2}.$$

This form of solution allows us to satisfy the contact angle boundary condition when we use Kuzmak's method. In particular, the free surface makes an angle $2B$ with the $\tilde{\xi}$-axis, and a non-self-intersecting solution exists only for $B \leq \pi/4$, with the free surface becoming semicircular when $B = \pi/4$. This is a point of some significance, to which we shall return later.

4.2.3. The shallow water limit, $B \to 0$. As $B \to 0$,

$$L \sim \frac{4B}{c^2}\left(2\mathbf{E}(k) - (1-k^2)\mathbf{K}(k)\right), \quad a \sim \frac{4B^2 k}{c^2}, \quad h \sim \frac{B^2(1-k)^2}{c^2},$$

and the free surface is given by

$$\tilde{\xi} \sim \frac{B}{c^2}\left\{(1-k^2)\phi - 2E(\phi) + 2k\,\mathrm{sn}\phi\right\}, \tag{4.15}$$

$$Y \sim \frac{B^2}{c^2}\left(\,\mathrm{dn}\phi - k\,\mathrm{cn}\phi\right)^2. \tag{4.16}$$

We can see that, although a and h tend to zero as $B \to 0$, $a/h \sim 4k/(1-k)^2 = O(1)$, so that the slope is finite. This is the limit corresponding to shallow water theory. More importantly for us, this is the limit in which we should recover the solution (3.27) for $\lambda = O(1)$ that we constructed in section 3, which takes the form of a single equation. This suggests that we should be able to reduce (4.15) and (4.16) to the same form. We can do this using a Landen transformation, as suggested by Crowdy (1999). The identities

$$\mathrm{dn}\phi - k\,\mathrm{cn}\phi \equiv (1-k)\,\mathrm{nd}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right),$$

$$\mathrm{sn}\phi \equiv \frac{2}{1+k}\,\mathrm{sn}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\,\mathrm{cn}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\,\mathrm{nd}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right),$$

$$2E(\phi) - (1-k^2)\phi + 2k\,\mathrm{sn}\phi \equiv 2(1+k)E\left(\sin^{-1}\left\{\,\mathrm{sn}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\right\}; \frac{2k^{1/2}}{1+k}\right),$$

which follow from the Landen transformation (see Byrd and Friedman (1954)), show that

$$\tilde{\xi} \sim \frac{B}{c^2}\left\{\frac{8k}{1+k}\,\mathrm{sn}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\,\mathrm{cn}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\,\mathrm{nd}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\right.$$

$$\left. -2(1+k)E\left(\sin^{-1}\left\{\,\mathrm{sn}\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right)\right\}; \frac{2k^{1/2}}{1+k}\right)\right\},$$

$$\tilde{Y} \sim \frac{B^2}{c^2}(1-k)^2\,\mathrm{nd}^2\left(\frac{1}{2}(1+k)\phi; \frac{2k^{1/2}}{1+k}\right).$$

This allows us to eliminate ϕ and obtain

$$\tilde{\xi} \sim \frac{2}{c}\left\{\sqrt{\frac{(\tilde{Y}-\tilde{Y}_-)(\tilde{Y}_+-\tilde{Y})}{\tilde{Y}}} - \tilde{Y}_+^{1/2}E\left\{\sin^{-1}\left(\frac{\tilde{Y}_+^{1/2}(\tilde{Y}-\tilde{Y}_-)^{1/2}}{\tilde{Y}^{1/2}(\tilde{Y}_+-\tilde{Y}_-)^{1/2}}\right); \sqrt{1-\frac{\tilde{Y}_-}{\tilde{Y}_+}}\right\}\right\},$$

where

$$\tilde{Y}_+ = \frac{B^2}{c^2}(1+k)^2, \quad \tilde{Y}_- = \frac{B^2}{c^2}(1-k)^2$$

are the maximum and minimum values of $\tilde{Y}$. Finally, the addition formula (117.0.1) in Byrd and Friedman (1954) shows that

$$\tilde{\xi} \sim -\frac{2\tilde{Y}_+^{1/2}}{c^2}\left[\mathbf{E}\left(\sqrt{1-\frac{\tilde{Y}_-}{\tilde{Y}_+}}\right) - E\left\{\sin^{-1}\left(\sqrt{\frac{\tilde{Y}_+-\tilde{Y}}{\tilde{Y}_+-\tilde{Y}_-}}\right); \sqrt{1-\frac{\tilde{Y}_-}{\tilde{Y}_+}}\right\}\right].$$

This has the same form as (3.27), the solution for $\lambda = O(1)$, with the minus sign arising because we have taken $\phi < 0$ here.

4.3. Solution using Kuzmak's method. We define slow and fast space variables as

$$X = \epsilon\tilde{\xi}, \quad x = \epsilon^{-1}\theta(X) + p(X), \quad y = \tilde{\eta}, \quad p(0) = \theta(0) = 0.$$

We have used x and y to tidy up our notation, and these should not be confused with the original variables x and y. We seek a solution of the form

$$Y = Y(x, X), \quad \Phi_0 = \Phi_0(X), \quad \tilde{\Phi} = \tilde{\Phi}(x, y, X),$$

where we have dropped the tildes from the spatial variables, again for notational convenience. In terms of these variables, (2.10)–(2.16) become, after first using (4.1),

$$(\omega+\epsilon p')^2\frac{\partial^2\tilde{\Phi}}{\partial x^2} + \frac{\partial^2\tilde{\Phi}}{\partial y^2} + 2\epsilon(\omega+\epsilon p')\frac{\partial^2\tilde{\Phi}}{\partial x\partial X}$$

$$+\epsilon(\omega'+\epsilon p'')\frac{\partial\tilde{\Phi}}{\partial x} + \epsilon^2\frac{\partial^2\tilde{\Phi}}{\partial X^2} + \epsilon\Phi_0'' = 0 \quad \text{for } x > 0,\ 0 < y < Y, \tag{4.17}$$

$$\frac{1}{3}(\Phi_0+\epsilon\tilde{\Phi}) - \frac{2}{3}\left[(\xi_c+X)\left\{(\omega+\epsilon p')\frac{\partial\tilde{\Phi}}{\partial x} + \epsilon\frac{\partial\tilde{\Phi}}{\partial X} + \Phi_0'\right\} + \epsilon y\frac{\partial\tilde{\Phi}}{\partial y}\right]$$

$$+\frac{1}{2}\left[\left(\frac{\partial\tilde{\Phi}}{\partial y}\right)^2 + \left\{(\omega+\epsilon p')\frac{\partial\tilde{\Phi}}{\partial x} + \epsilon\frac{\partial\tilde{\Phi}}{\partial X} + \Phi_0'\right\}^2\right]$$

$$= \left[1 + \left\{(\omega+\epsilon p')\frac{\partial Y}{\partial x} + \epsilon\frac{\partial Y}{\partial X}\right\}^2\right]^{-3/2} \tag{4.18}$$

$$\times\left[(\omega+\epsilon p')^2\frac{\partial^2 Y}{\partial x^2} + 2\epsilon(\omega+\epsilon p')\frac{\partial^2 Y}{\partial x\partial X} + \epsilon(\omega'+\epsilon p'')\frac{\partial Y}{\partial x} + \epsilon^2\frac{\partial^2 Y}{\partial X^2}\right] \text{ at } y = Y \text{ for } x > 0,$$

$$\frac{\partial\tilde{\Phi}}{\partial y} + \frac{2}{3}(\xi_c+X)\left\{(\omega+\epsilon p')\frac{\partial Y}{\partial x} + \epsilon\frac{\partial Y}{\partial X}\right\} - \frac{2}{3}\epsilon Y$$

(4.19)
$$-\left\{(\omega+\epsilon p')\frac{\partial Y}{\partial x}+\epsilon\frac{\partial Y}{\partial X}\right\}\left\{(\omega+\epsilon p')\frac{\partial\tilde{\Phi}}{\partial x}+\epsilon\frac{\partial\tilde{\Phi}}{\partial X}+\Phi_0'\right\}=0 \quad \text{at } y=Y \text{ for } x>0,$$

$$\frac{\partial\tilde{\Phi}}{\partial y}=0 \quad \text{at } y=0 \text{ for } x>0, \tag{4.20}$$

where $\omega(X)\equiv\theta'(X)$, subject to

$$Y(0,0)=0, \quad (\omega(0)+\epsilon p'(0))\frac{\partial Y}{\partial x}(0,0)+\epsilon\frac{\partial Y}{\partial X}(0,0)=\tan\bar{\lambda}, \tag{4.21}$$

$$Y-\frac{\tan\epsilon}{\epsilon}(\xi_c+X)\to 0, \quad \Phi_0+\epsilon\tilde{\Phi}\to 0 \quad \text{as } X\to\infty. \tag{4.22}$$

We now expand

$$\tilde{\Phi}=\tilde{\Phi}_1(x,y,X)+\epsilon\tilde{\Phi}_2(x,y,X)+O(\epsilon^2), \quad Y=Y_1(x,X)+\epsilon Y_2(x,X)+O(\epsilon^2),$$

$$\xi_c=\xi_{c0}+\epsilon\xi_{c1}+O(\epsilon^2), \quad P=P_1(X)+\epsilon P_2(X)+O(\epsilon^2),$$

where $P(X)$ appears in the transformation (4.6). At leading order, we obtain equations governing the underlying periodic solution that we discussed in the previous section, but here x is scaled with ω. The solution is

$$\frac{x}{\omega}=\frac{\mathrm{sn}B\,\mathrm{cd}B}{c^2}\left\{\frac{2k(1-k^2)\,\mathrm{sd}\phi\,\mathrm{nd}\phi}{\mathrm{dn}\psi+k\,\mathrm{cd}\phi}+(1-k^2)\phi-2E(\phi)+2k^2\,\mathrm{sn}\phi\,\mathrm{cd}\phi\right\}, \tag{4.23}$$

$$y=\frac{\mathrm{sn}B\,\mathrm{cd}B}{c^2}\left\{\frac{2(1-k^2)\,\mathrm{sn}\psi\,\mathrm{cn}\psi}{\mathrm{dn}\psi+k\,\mathrm{cd}\phi}+(1+k^2)\psi-2E(\psi)\right\}, \tag{4.24}$$

where $\phi=A\bar{\Phi}_1$, $\psi=A\Psi+B$, $A=c/(1-k^2)\,\mathrm{sn}B\,\mathrm{cd}B$, $c(X)=\sqrt{\frac{4}{9}(\xi_{c0}+X)^2-\frac{2}{3}\Phi_0}$, and $B(X)$ and $k(X)$ vary on the slow lengthscale. We have also used (4.6) so that

$$\tilde{\Phi}_1=\bar{\Phi}_1+\frac{1}{\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}x+P_1(X). \tag{4.25}$$

In order that this solution has unit wavelength, we choose

$$\omega(X)=\frac{\frac{4}{9}(\xi_{c0}+X)^2-\frac{2}{3}\Phi_0}{4\,\mathrm{sn}B\,\mathrm{cd}B\,\{2\mathbf{E}(k)-(1-k^2)\mathbf{K}(k)\}}. \tag{4.26}$$

In order to satisfy the contact angle condition, the solution must take the "string of beads" form discussed in section 4.2.2 so that

$$k\to 1, \quad B\to\frac{1}{2}\bar{\lambda} \quad \text{as } X\to 0. \tag{4.27}$$

In the far field, the amplitude of the disturbance of the free surface must decay to zero; thus we need the linear capillary wave form of the solution, discussed in section 4.2.1, so that

$$\Phi_0\to 0, \quad k\to 0, \quad B\sim\frac{4}{9}(\xi_{c0}+X)^3 \quad \text{as } X\to\infty. \tag{4.28}$$

4.3.1. Secularity conditions. We now have the functional form of the leading order solution but still need to find the ordinary differential equations that determine $\Phi_0(X)$, $k(X)$, $B(X)$, and the eigenvalue, ξ_{c0}. This is the same situation that arose in section 3, and we proceed in the same manner to determine secularity conditions.

Now, $\tilde{\Phi}_1$ must be periodic and not grow linearly with x. Since $\bar{\Phi}_1$ changes by $-4\mathbf{K}(k)/A$ over a period, (4.25) shows that the first secularity condition is

$$\frac{1}{\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}-\frac{4\mathbf{K}(k)(1-k^2)\,\mathrm{sn}B\,\mathrm{cd}B}{c}=0.$$

From the definitions of $c(X)$ and $\omega(X)$, this gives the ordinary differential equation for Φ_0,

$$\Phi_0'=\frac{2}{3}(\xi_{c0}+X)-\frac{\mathbf{K}(k)(1-k^2)\sqrt{\frac{4}{9}(\xi_{c0}+X)^2-\frac{2}{3}\Phi_0}}{2\mathbf{E}(k)-(1-k^2)\mathbf{K}(k)}. \tag{4.29}$$

In the limit $B\to 0$, we can show that (4.29) reduces to (3.40) by using a Gauss transformation (Byrd and Friedman (1954)).

In order to obtain the two remaining secularity conditions, we need to consider the problem at $O(\epsilon)$. Over one wavelength of the leading order solution, the field equation and boundary conditions can be written in the form

$$\nabla^2\tilde{\Phi}_2=F(x,y,X)\ \text{ for } 0<\bar{x}<\frac{1}{\omega},0<y<Y_1, \tag{4.30}$$

$$L_1(\tilde{\Phi}_2,\bar{Y}_2)\equiv\frac{\partial\tilde{\Phi}_2}{\partial s}-\frac{1}{\partial\bar{\Phi}_1/\partial\bar{x}}\frac{\partial}{\partial s}\left(\frac{\partial Y_2/\partial s}{1+(\partial Y_1/\partial\bar{x})^2}\right)$$

$$-\frac{\partial}{\partial y}\left\{\sqrt{\left(\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}\right)^2+\left(\frac{\partial\bar{\Phi}_1}{\partial y}\right)^2}\right\}Y_2=g(s,X)\ \text{ at } y=Y_1 \text{ for } 0<\bar{x}<\frac{1}{\omega}, \tag{4.31}$$

$$L_2(\tilde{\Phi}_2,\bar{Y}_2)\equiv\mathbf{n}\cdot\nabla\tilde{\Phi}_2-\frac{\partial}{\partial s}\left(Y_2\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}\right)=f(s,X)\ \text{ at } y=Y_1 \text{ for } 0<\bar{x}<\frac{1}{\omega}, \tag{4.32}$$

$$L_3(\tilde{\Phi}_2,\bar{Y}_2)\equiv\frac{\partial\tilde{\Phi}_2}{\partial y}=0\ \text{ at } y=0 \text{ for } 0<\bar{x}<\frac{1}{\omega}, \tag{4.33}$$

where $\bar{x}\equiv x/\omega$, $\mathbf{n}$ is the outward unit normal at the boundary, and s measures arc length along the free surface. The forcing functions F, f, and g are, recalling the definition (4.25) of $\tilde{\Phi}_1$,

$$F(\bar{x},y,X)\equiv-\frac{2p'}{\omega}\frac{\partial^2\tilde{\Phi}_1}{\partial\bar{x}^2}-2\frac{\partial^2\tilde{\Phi}_1}{\partial\bar{x}\partial X}-\frac{\omega'}{\omega}\frac{\partial\tilde{\Phi}_1}{\partial\bar{x}}-\Phi_0'', \tag{4.34}$$

$$f(s,X)\equiv\left\{1+\left(\frac{\partial Y_1}{\partial\bar{x}}\right)^2\right\}^{-1/2}\left\{\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}\left(\frac{p'}{\omega}\frac{\partial Y_1}{\partial\bar{x}}+\frac{\partial Y_1}{\partial X}\right)\right.$$

$$-\frac{2}{3}\xi_{c1}\frac{\partial Y_1}{\partial \bar{x}}+\frac{2}{3}Y_1+\frac{\partial Y_1}{\partial \bar{x}}\left(\frac{p'}{\omega}\frac{\partial \tilde{\Phi}_1}{\partial \bar{x}}+\frac{\partial \tilde{\Phi}_1}{\partial X}\right)\Bigg\}, \tag{4.35}$$

$$g(s,X)\equiv -\frac{1}{\partial\bar{\Phi}_1/\partial\bar{x}}\left\{1+\left(\frac{\partial Y_1}{\partial \bar{x}}\right)^2\right\}^{-1/2}\Bigg[-\frac{1}{3}\tilde{\Phi}_1-\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}\left(\frac{p'}{\omega}\frac{\partial\tilde{\Phi}_1}{\partial\bar{x}}+\frac{\partial\tilde{\Phi}_1}{\partial X}\right)$$

$$+\frac{2}{3}\xi_{c1}\left(\frac{\partial\tilde{\Phi}_1}{\partial\bar{x}}+\Phi_0'\right)+\frac{2}{3}Y_1\frac{\partial\tilde{\Phi}_1}{\partial y}-3\frac{\partial Y_1}{\partial\bar{x}}\frac{\partial^2 Y_1}{\partial\bar{x}^2}\left(\frac{p'}{\omega}\frac{\partial Y_1}{\partial\bar{x}}+\frac{\partial Y_1}{\partial X}\right)\left\{1+\left(\frac{\partial Y_1}{\partial\bar{x}}\right)^2\right\}^{-5/2} \tag{4.36}$$

$$+\left(2\frac{p'}{\omega}\frac{\partial^2 Y_1}{\partial\bar{x}^2}+2\frac{\partial^2 Y_1}{\partial\bar{x}\partial X}+\frac{\omega'}{\omega}\frac{\partial Y_1}{\partial\bar{x}}\right)\left\{1+\left(\frac{\partial Y_1}{\partial\bar{x}}\right)^2\right\}^{-3/2}\Bigg].$$

Now, let $\tilde{\Phi}_2=G(\bar{x},y,X)$, $Y_2=H(\bar{x},y,X)$ be a solution of the unforced problem, $\nabla^2 G=0$, $L_1(G,H)=L_2(G,H)=L_3(G,H)=0$. Green's theorem shows that

$$\int\int_D\left(G\nabla^2\tilde{\Phi}_2-\tilde{\Phi}_2\nabla^2 G\right)dA\equiv\int_{\partial D}\left(G\,\mathbf{n}\cdot\nabla\tilde{\Phi}_2-\tilde{\Phi}_2\,\mathbf{n}\cdot\nabla G\right)ds,$$

where D is the domain of solution and ∂D its boundary. Using (4.30)–(4.33) and integrating by parts twice, we arrive at

$$\int\int_D G\,F(\bar{x},y,X)\,d\bar{x}\,dy=\int_0^l\left\{G\,f(s,X)-H\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}g(s,X)\right\}ds,$$

where l is the length of the free surface.

One obvious solution of the unforced problem is $G=1$, $H=0$, which gives

$$\int\int_D F(\bar{x},y,X)\,d\bar{x}\,dy=\int_0^l f(s,X)\,ds. \tag{4.37}$$

Another solution, as we would expect since these equations govern the correction to the leading order solution, is $G=\partial\bar{\Phi}_1/\partial\bar{x}$, $H=\partial Y_1/\partial\bar{x}$, which gives

$$\int\int_D\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}F(\bar{x},y,X)\,d\bar{x}\,dy=\int_0^l\left\{\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}f(s,X)-\frac{\partial Y_1}{\partial\bar{x}}\frac{\partial\bar{\Phi}_1}{\partial\bar{x}}g(s,X)\right\}ds. \tag{4.38}$$

As we shall see, (4.37) and (4.38) provide us with the two remaining ordinary differential equations for $k(X)$ and $B(X)$.

If we substitute (4.34) and (4.35) into (4.37) and use the fact that $\tilde{\Phi}_1$ is odd and Y_1 even in $\bar{x}$, noting that we are able to reduce the double integral to a surface integral, we arrive at

$$\frac{d}{dX}\int_0^1\omega Y_1\frac{\partial\bar{\Phi}_1}{\partial x}dx=-\frac{4}{3}\int_0^1 Y_1\,dx. \tag{4.39}$$

This is consistent with the solution that we constructed in section 3, since, using the current notation, $d_0\equiv-\omega Y_1\partial\bar{\Phi}_1/\partial x$, which we recall is a function of X alone for $\bar{\lambda}\ll 1$, so that (4.39) is equivalent to (3.35).

Similarly, (4.38) leads to

$$\frac{d}{dX}\int\int_D \omega\left(\frac{\partial\bar\Phi_1}{\partial x}\right)^2 dx\,dy = \left[\frac{\omega'}{\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}-\frac{7}{3}+\Phi_0''\right]\int_0^1 Y_1\frac{\partial\bar\Phi_1}{\partial x}dx$$

$$-\int_0^1 \frac{\partial Y_1}{\partial x}\left[\frac{2}{3}\omega^2 Y_1\frac{\partial\bar\Phi_1}{\partial x}\frac{\partial Y_1}{\partial x}-3\omega^3\frac{\partial Y_1}{\partial x}\frac{\partial^2 Y_1}{\partial x^2}\frac{\partial Y_1}{\partial X}\left\{1+\omega^2\left(\frac{\partial Y_1}{\partial x}\right)^2\right\}^{-5/2}\right. \tag{4.40}$$

$$\left.+\left(2\omega\frac{\partial^2 Y_1}{\partial x\partial X}+\omega'\frac{\partial Y_1}{\partial x}\right)\left\{1+\omega^2\left(\frac{\partial Y_1}{\partial x}\right)^2\right\}^{-3/2}\right]dx-\frac{1}{3\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}\int_0^1 Y_1\,dx.$$

We can show that this is consistent with (3.38) by first noting that when $B\ll 1$ (which corresponds to $\bar\lambda\ll 1$), $Y_1=O(B^2)$, $\bar\Phi_1=O(B)$, and $\omega=O(B^{-1})$, so that (4.40) becomes

$$\frac{d}{dX}\int\int_D \omega\left(\frac{\partial\bar\Phi_1}{\partial x}\right)^2 dx\,dy \sim \left[\frac{\omega'}{\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}-\frac{7}{3}+\Phi_0''\right]\int_0^1 Y_1\frac{\partial\bar\Phi_1}{\partial x}dx$$

$$-\int_0^1 \frac{\partial Y_1}{\partial x}\left[2\omega\frac{\partial^2 Y_1}{\partial x\partial X}+\omega'\frac{\partial Y_1}{\partial x}\right]dx-\frac{1}{3\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}\int_0^1 Y_1\,dx.$$

From the definition of d_0, we find that

$$\frac{d}{dX}\int\int_D \omega\left(\frac{\partial\bar\Phi_1}{\partial x}\right)^2 dx\,dy \sim \frac{d}{dX}\int_0^1 \omega Y_1\left(\frac{\partial\bar\Phi_1}{\partial x}\right)^2 dx \sim -\frac{d}{dX}\left(d_0\int_0^1\frac{\partial\bar\Phi_1}{\partial x}\,dx\right)$$

$$\sim\frac{4}{3\omega}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}\int_0^1 Y_1\,dx+\frac{\omega'}{\omega}Y_1\frac{\partial\bar\Phi_1}{\partial x}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}-Y_1\frac{\partial\bar\Phi_1}{\partial x}\left(\frac{2}{3}-\Phi_0''\right),$$

and combining these equations gives

$$\frac{d}{dX}\int_0^1\left\{\omega\left(\frac{\partial Y_1}{\partial x}\right)^2\right\}dx\sim\frac{5d_0}{3\omega}\left[1-\frac{1}{d_0}\left\{\frac{2}{3}(\xi_{c0}+X)-\Phi_0'\right\}\int_0^1 Y_1\,dx\right].$$

Equation (3.22) then gives us (3.38), as required.

In order to determine k' and B' from (4.39) and (4.40), we need to use the solution (4.23) and (4.24) for $\bar\Phi_1$ and Y_1. The resulting integrals can be evaluated only numerically. We must also be very careful in evaluating the derivatives, since (4.23) and (4.24) give x and y as functions of $\bar\Phi$ and Ψ. For example, after integrating (4.39) by parts and noting that $\phi=-4\mathbf{K}(k)$ at $x=1$ and $\phi=0$ at $x=0$, we can write

$$-\int_{-4\mathbf{K}(k)}^0\left\{\frac{\omega}{A}\left.\frac{\partial Y_1}{\partial X}\right|_x-\frac{d}{dX}\left(\frac{\omega}{A}\right)\phi\left.\frac{\partial Y_1}{\partial\phi}\right|_X-\frac{\omega}{A}\left.\frac{\partial\phi}{\partial X}\right|_x\left.\frac{\partial Y_1}{\partial\phi}\right|_X+\frac{4}{3}Y_1\left.\frac{\partial x_1}{\partial\phi}\right|_X\right\}d\phi$$

$$=4\frac{d}{dX}\left(\frac{\mathbf{K}(k)\omega}{A}\right),$$

where $x_1(\phi, X)$ is the value of x on the free surface and the subscripts to the derivative indicate the variable to be held constant. We then use

$$\left.\frac{\partial \phi}{\partial X}\right|_x = -\left.\frac{\partial x_1}{\partial X}\right|_\phi \Big/ \left.\frac{\partial x_1}{\partial \phi}\right|_X, \quad \left.\frac{\partial Y_1}{\partial X}\right|_x = \left.\frac{\partial Y_1}{\partial X}\right|_\phi - \left.\frac{\partial x_1}{\partial X}\right|_\phi \left.\frac{\partial Y_1}{\partial \phi}\right|_X \Big/ \left.\frac{\partial x_1}{\partial \phi}\right|_X,$$

$$\left.\frac{\partial \phi}{\partial x}\right|_X = \left.\frac{\partial x_1}{\partial \phi}\right|_X \Big/ \left\{\omega^2 \left(\left.\frac{\partial Y_1}{\partial \phi}\right|_X\right)^2 + \left(\left.\frac{\partial x_1}{\partial \phi}\right|_X\right)^2\right\}$$

to write the derivatives in a form for which we can use (4.23) and (4.24), and rewrite the X-derivatives using

$$\left.\frac{\partial}{\partial X}\right|_\phi = k' \left.\frac{\partial}{\partial k}\right|_{\phi,B,c} + B' \left.\frac{\partial}{\partial B}\right|_{\phi,k,c} + c' \left.\frac{\partial}{\partial c}\right|_{\phi,k,B},$$

noting that

$$c' = c^{-1}\left\{\frac{2}{9}(\xi_{c0} + X) + \frac{4\mathbf{K}(k)\omega}{3A}\right\}.$$

In this way, we can write (4.39) as a linear equation in k' and B'. A similar but algebraically more complicated procedure reduces (4.40) to a linear equation, and we can thereby extract k' and B'.

We used Mathematica to determine the integrands and simplify them as far as possible. It is worth noting that Mathematica is not very good at simplifying expressions involving Jacobian elliptic functions. We found that an effective strategy was to delete the definitions of all the Jacobian elliptic functions except sn and cn, and teach Mathematica that $\mathrm{sn}^2(u;k) + \mathrm{cn}^2(u;k) \equiv 1$. Once the integrands had been simplified, we then replaced obvious expressions (e.g., $\sqrt{1 - k^2\,\mathrm{sn}^2(u;k)} = \mathrm{dn}(u;k)$), and cut and pasted the integrands, which run to several printed pages, into MATLAB. In this way, we could write a routine to evaluate Φ_0', k', and B' as functions of Φ_0, k, B, and X, using quadl and dblquad to evaluate the necessary single and double integrals. Note that our knowledge of the asymptotic behavior of (4.39) and (4.40) as $B \to 0$ proved invaluable in debugging the code.

In order to find the solution, we must solve a nonlinear eigenvalue problem, with $\Phi_0(0)$ and ξ_{c0} the two eigenvalues. In this case, there is no convenient transformation that will make the equations autonomous. We solve the three ordinary differential equations for Φ_0, k, and B with the MATLAB routine ode45. The initial conditions are given by (4.27), and the conditions (4.28) must be satisfied as $X \to \infty$. We find that the solution automatically satisfies $k \to 0$ as $X \to \infty$. However, there is a problem when $k \ll 1$, since both (4.39) and (4.40) give the leading order equation

$$B' = \frac{B \tanh B \left(c' + \frac{4}{3}\right)}{c\,(\tanh B + B\,\mathrm{sech}^2 B)}, \tag{4.41}$$

with the equation for k' given by the $O(k^2)$ correction. This means that our method of calculating k' becomes very inaccurate when k is small. However, when $k \ll 1$, the solution takes the form of small amplitude capillary waves on a flat free surface. We do not, therefore, need to calculate the amplitude of these waves, for which we would need to know k, in order to determine whether the solution satisfies (4.28). We simply need to solve (4.29) and (4.41) once k becomes sufficiently small (we used $k < 10^{-3}$).

We determined the eigenvalues $\Phi_0(0)$ and ξ_{c0} using a shooting method and Newtonian iteration, which typically converged after one cycle, calculating the Jacobian by finite differences. We used the asymptotic solution

$$\Phi_0(0) \sim -0.1314\bar{\lambda}^{4/3}, \quad \xi_{c0} \sim 0.8231\bar{\lambda}^{2/3} \quad \text{as } \bar{\lambda} \to 0 \tag{4.42}$$

as the initial guess for $\bar{\lambda} \ll 1$, and then continuation for larger values of $\bar{\lambda}$, scaling the previous values with $\bar{\lambda}^{4/3}$ and $\bar{\lambda}^{2/3}$, respectively, to improve the rate of convergence.

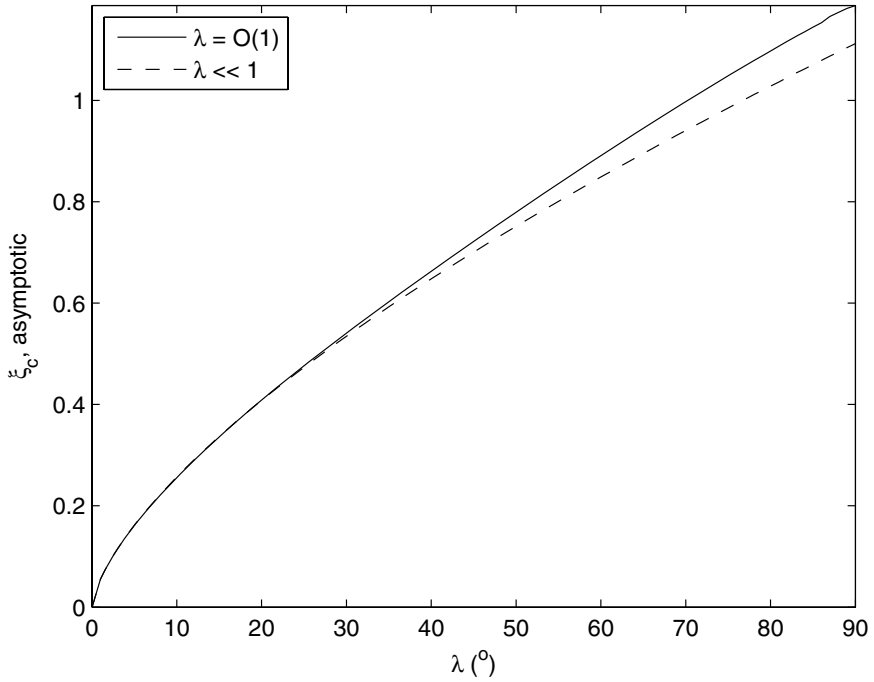

FIG. 4.2. *The position of the tip of the wedge for* $\epsilon \ll 1$ *and* $\bar{\lambda} = O(1)$ *(solid line) and* $\bar{\lambda} \ll 1$ *(broken line).*

Figure 4.2 shows the leading order asymptotic estimate of the position of the tip of the wedge, ξ_{c0}, both for $\bar{\lambda} = O(1)$, as calculated using Kuzmak's method described above, and for $\bar{\lambda} \ll 1$, as given by (4.42). We can see that there is little difference between these two curves and that they are in excellent agreement with each other for contact angles less than about 30°.

5. Boundary integral solutions. We would now like to compare the asymptotic solution that we have constructed for $\bar{\lambda} = O(1)$ and $\epsilon \ll 1$ with the solution of the full problem. In order to solve the full nonlinear boundary value problem given by (2.10)–(2.16) numerically, we use the boundary integral method.

5.1. Numerical method. The approach that we have used is a development of the method described in Billingham and King (2005), and we refer the interested reader to this paper for full details. The free surface was discretized using straight line elements and lies at $(x, y) = (X(s), Y(s))$, where s is arc length. For the boundary

integral equation, the potential, $\bar{\phi}$, was assumed to vary linearly along each element, and the integral along each element then calculated analytically. The arc length equation, $X_s^2 + Y_s^2 = 1$, was evaluated on each element using central differences. Derivatives in the dynamic boundary condition (2.11) were evaluated using a four-point finite difference approximation. The resulting system of nonlinear algebraic equations was solved using Newton's method and continuation, reusing the Jacobian as often as possible. We started with $\epsilon = \bar{\lambda}$, for which the solution is $Y = X \tan\epsilon$, $\bar{\phi} = 0$, and gradually decreased ϵ, using the known solution as the initial estimate of the new solution.

In contrast to the method used by Billingham and King (2005), we have introduced two new features. First, we have been able to calculate the Jacobian used in Newton's method analytically, which speeds up our calculations to the point where the LU decomposition of the Jacobian is the most costly step of the algorithm. Second, we used adaptive gridding, increasing the density of grid points close to the high curvature, "neck" regions of the solution. For each new value of ϵ, we changed the length of the element at the first five local minima of the free surface to be small enough to resolve the local curvature, and allowed the element length to grow slowly with distance from each "neck," up to a maximum of 0.01. For $s > 10$, we allowed the length of the elements to gradually increase to 0.25, and extended the domain of solution to $s = 15$.

In this manner we were able to compute solutions until the maximum curvature was about 200. We were unable to resolve more highly curved solutions with the computing resources available to us. However, we note from our asymptotic solution that for $1 - k \ll 1$, the "neck" region (see Figure 4.1) has size of $O((1-k)^2)$ and therefore curvature of $O((1-k)^{-2})$. At the first "neck," $1-k = O(\epsilon)$ for $\epsilon \ll 1$, so that the curvature is of $O(\epsilon^{-2})$ and therefore, in terms of the original variable, which we use to calculate the numerical solution, the curvature is of $O(\epsilon^{-8/3})$. The minimum element length must therefore scale with $\epsilon^{8/3}$ as $\epsilon \to 0$. Moreover, as ϵ decreases, the number of "necks" at which the curvature is high and scales in the same manner is of $O(\epsilon^{-1})$. That we struggle to resolve this highly multiscale solution numerically is therefore not surprising and suggests that our asymptotic method is the correct way to attack the problem.

5.2. Comparison of numerical and asymptotic solutions. Figure 5.1 shows the position of the free surface and the potential at the free surface for $\bar{\lambda} = 45°$ and $\epsilon = 0.0105$. This is the smallest value of ϵ for which we could obtain a numerical solution. Recall that the leading order asymptotic solution for $\bar{\phi}$, shown here, is a smoothly increasing function; the oscillatory part is given by the next term in the asymptotic expansion. We note that the agreement between the asymptotic prediction and numerical calculation of the position of the tip of the wedge and the free surface and potential close to the tip is not perfect, although the period and amplitude are reasonably well predicted.

Figure 5.2 shows the same functions for $\bar{\lambda} = 90°$. Since this corresponds to the case of a recoiling wedge with two free surfaces, we have also plotted the reflection of y in the x-axis. It is easy to see that the region next to the tip is approximately circular and that successive "beads" are approximately elliptical, as predicted. However, the disagreement between numerical and asymptotic solutions is more marked in this case, although, again, the amplitude and period of the oscillations are reasonably well predicted.

We can go some way to explaining this discrepancy by noting that ϵ is unlikely to

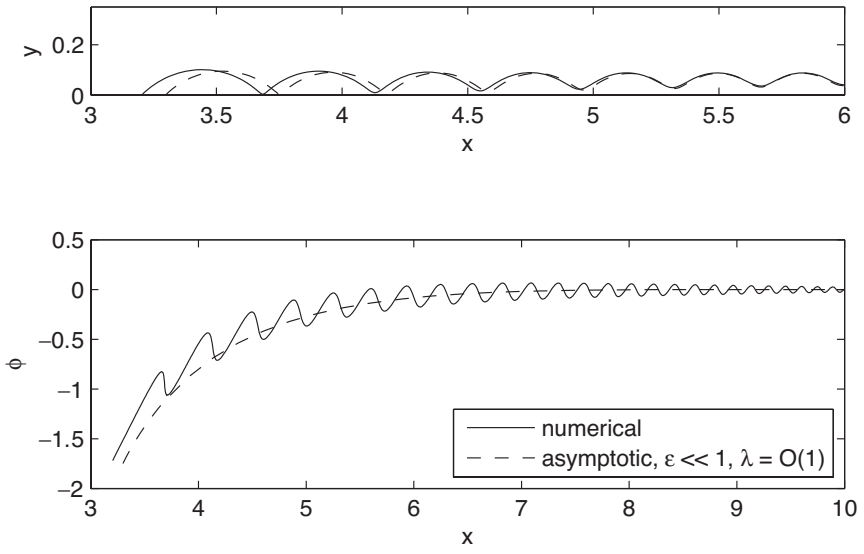

FIG. 5.1. *The position of the free surface and the potential at the free surface calculated numerically for* $\bar{\lambda} = 45^\circ$ *and* $\epsilon = 0.0105$. *Also shown is the asymptotic prediction for* $\epsilon \ll 1$ *and* $\bar{\lambda} = O(1)$.

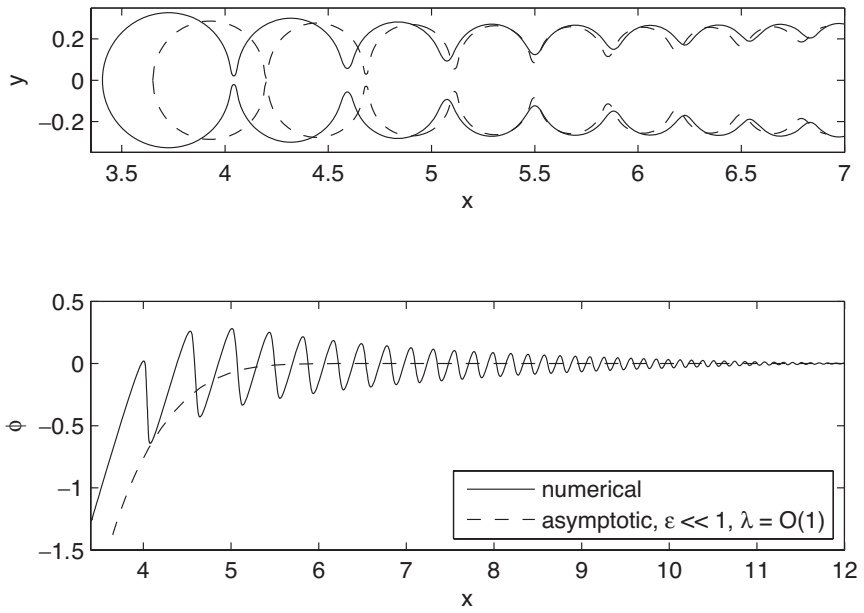

FIG. 5.2. *The position of the free surface and the potential at the free surface calculated numerically for* $\bar{\lambda} = 90^\circ$ *and* $\epsilon = 0.0344$. *Also shown is the asymptotic prediction for* $\epsilon \ll 1$ *and* $\bar{\lambda} = O(1)$.

be small enough to produce good agreement. Note, in particular, that the oscillations in the potential at the free surface shown in Figure 5.2 are of an amplitude comparable to the mean value—an indication that the asymptotic form has yet to be reached. However, there is a very curious feature of these solutions that is rather harder to explain. Figure 5.3 shows the position of the tip of the wedge, $X(0)$, as a function

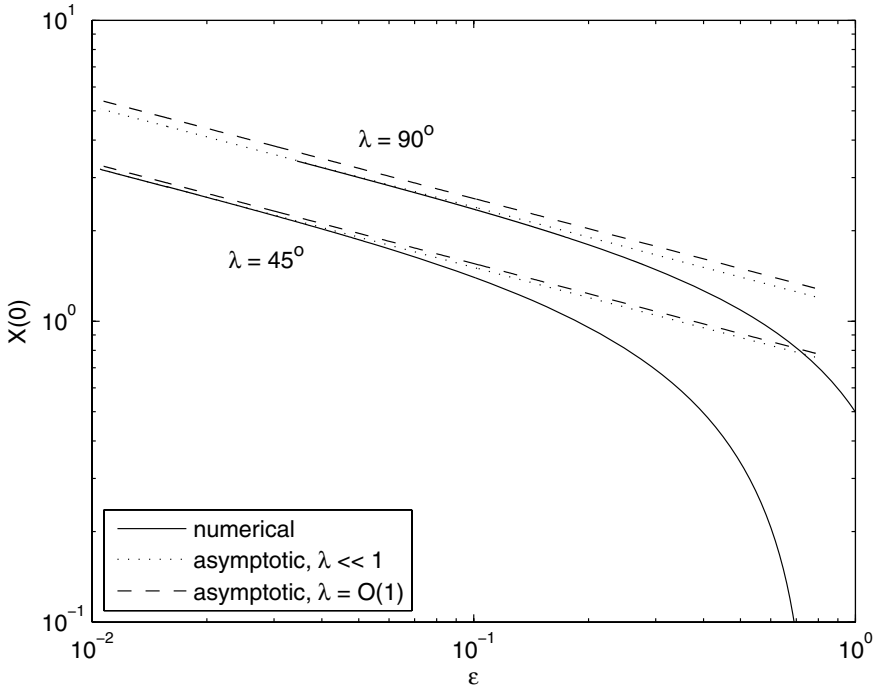

FIG. 5.3. *The position of the tip of the wedge calculated numerically for* $\bar{\lambda} = 45°$ *and* $90°$ *(solid lines). Also shown are the asymptotic predictions for* $\epsilon \ll 1$ *and* $\bar{\lambda} = O(1)$ *(broken lines) and* $\bar{\lambda} \ll 1$ *(dotted lines).*

of ϵ for $\bar{\lambda} = 45°$ and $90°$. Although $X(0)$ appears to asymptote to a multiple of $\epsilon^{-1/3}$ as expected, it is the leading order estimate that comes from the asymptotic analysis presented in section 3, valid for $\bar{\lambda} \ll 1$, namely $0.8231\bar{\lambda}^{2/3}\epsilon^{-1/3}$, that is in best agreement with the numerical solution. As we can see from Figure 4.2, the leading order estimate of the coefficient valid for $\bar{\lambda} = O(1)$ is slightly larger than $0.8231\bar{\lambda}^{2/3}$. This is all the more puzzling because the asymptotic solution for $\bar{\lambda} \ll 1$, although we have not shown it here, bears no resemblance to the numerical solution, except that the position of its tip accurately predicts the numerically calculated position. If our numerical solution of the full problem is correct and there is some error in our asymptotic analysis when $\bar{\lambda} = O(1)$, it is hard to see how the correct asymptotic position of the tip of the wedge could be of the similarity form, scaling with $\bar{\lambda}$, for all $\bar{\lambda} \leq 90°$. Conversely, it is hard to see how an error in our implementation of the numerical solution of the full problem could result in this similarity form for the position of the tip of the wedge. For the moment, our best explanation is that, for smaller ϵ than we can at present access numerically, the numerical solution will start to approach the asymptotic solution, although we cannot say that this is a fully satisfactory explanation.

Finally, we note that another prediction of our analysis is that there is no asymptotic solution for any $\bar{\lambda} > 90°$ for sufficiently small ϵ. This can be confirmed by solving the full problem numerically for a moderately small value of ϵ. Figure 5.4 shows some numerical solutions of the full problem with $\epsilon = 5°$. As $\bar{\lambda}$ increases, the first two

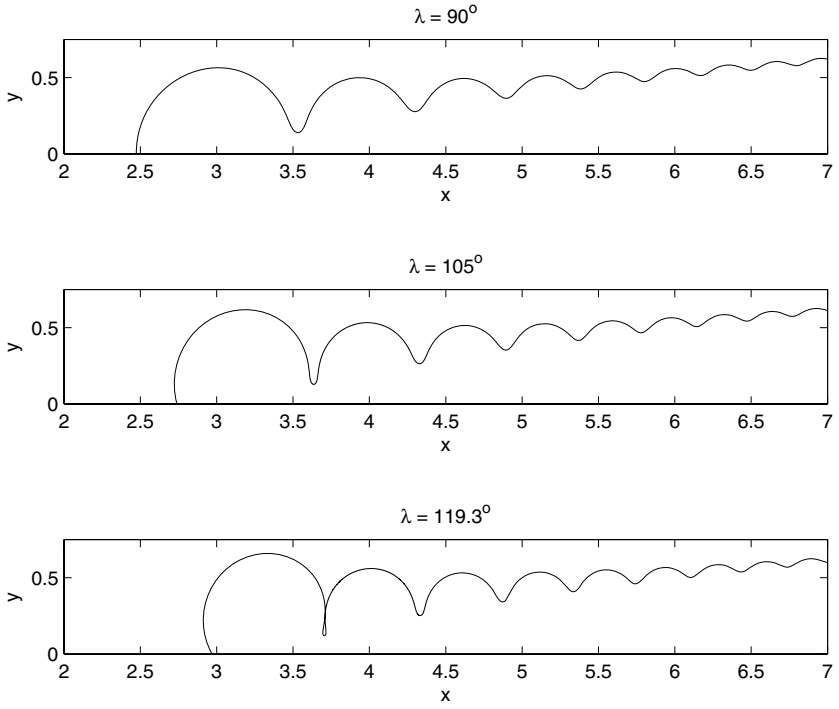

FIG. 5.4. *The position of the free surface calculated numerically for various* $\bar{\lambda}$ *and* $\epsilon = 5°$.

"beads" approach each other and meet when $\bar{\lambda} = \bar{\lambda}_c \approx 119.3°$, so that the free surface becomes self-intersecting. This raises the interesting question of what happens in the initial value problem when $\bar{\lambda} > \bar{\lambda}_c$, since no self-similar solution is available. The likely answer is that the problem can be regularized by the inclusion of the effect of viscosity at small times, and that a sequence of pinch-off events will occur as the flow develops. A similar problem is investigated in Billingham and King (2005), where the arguments that lead to this conclusion are presented.

6. Conclusions. In this paper, we have shown how Kuzmak's method can be used to analyze the response of a slender wedge of inviscid fluid to an abrupt change in contact angle. When the contact angle is of $O(1)$, although the underlying nonlinear oscillator is a nonlinear free boundary problem, we found that we could still make analytical progress. There are two related problems that may be amenable to this type of analysis.

First, the axisymmetric recoil of a slender cone of inviscid fluid bears many resemblances to the equivalent two-dimensional problem. However, there are two important differences. The first is that in the two-dimensional problem, the contact angle is a natural continuation parameter to move from a simple known solution to the required solution. No such parameter exists for the axisymmetric problem, since there is no equivalent of the moving contact line problem. The second difference is that, as far as we know, there is no axisymmetric equivalent of Kinnersley's analytical solution for the underlying nonlinear oscillator. The solution of the underlying axisymmetric nonlinear problem would therefore have to be obtained numerically, along with all of

the derivatives required for the secularity conditions. Although these solutions can be determined using the boundary integral method, this significantly increases the computational complexity of the problem. Some progress on the axisymmetric problem has been made using a one-dimensional approximation (Decent and King (2001)).

Second, it would be of interest to study the two-fluid version of the two-dimensional problem. In common with the axisymmetric problem, there is the difficulty that, again as far as we know, there exists no two-fluid version of Kinnersley's analytical solution. Moreover, it is not obvious how to modify the asymptotic scalings used here to accomodate the presence of an outer fluid. The two-fluid problem can be thought of as a combination of a recoiling slender void, described by Billingham and King (2005), and the problem we have studied here. Both the axisymmetric and two-fluid problems represent significant challenges in asymptotic analysis.

CONVECTION EFFECTS IN THIN REACTION ZONES: APPLICATIONS TO BIACORE*

DAVID A. EDWARDS†

Abstract. Surface-volume reactions occur in many physical systems such as biological and industrial processes. Though traditionally modeled as a surface, the reaction zone is usually a thin layer (often a gel) abutting a flowing fluid or gas. Therefore, one would expect a more realistic model for the reacting zone to include the effects of transport in the gel. In this paper we examine the BIAcore, a device for measuring rate constants which has this geometry. To explain anomalous measurements from the device, it has been proposed that some flow penetrates into the dextran (gel) layer, thus enhancing transport. To analyze the reversible kinetics, asymptotic and singular perturbation techniques are used, yielding linear and nonlinear integrodifferential equations. Explicit and asymptotic solutions are constructed for cases motivated by experimental design. The results indicate that such flow penetration effects are bound to be negligible in surface-volume reactions, regardless of the flow model used.

Key words. asymptotic expansions, BIAcore, biochemical reactions, integrodifferential equations, reaction zone, singular perturbations

1. Introduction.

In many physical systems, so-called "surface-volume" reactions occur. In the simplest model, one reactant (herein called the *receptor*) is confined to a two-dimensional surface, while the other (the *ligand*) floats free in (a possibly stirred) solution, and the reaction occurs only when the ligand interacts with the surface. However, since the receptors are three-dimensional molecules, they either form or are embedded in a thin *reaction zone* (such as a gel) near the surface. Given that many of these systems occur in the presence of an active flow, it is natural to inquire into the effects of the flow on the reaction zones.

Models of this type are applicable to various industries. The creation of alginate gel in the food industry is enhanced by the addition of a convective flow of reactant [27]. In bubble reactors, gas reacts with the liquid which impinges on the bubble surfaces [19]. Corrosive processes occur in such geometries [13]. Inorganic material synthesis can be enhanced if the templates are immersed in flow, rather than fixed-batch, reactors [20]. In high-pressure continuous-flow fixed-bed reactors, gels are introduced at the reaction surface to minimize hydrodynamics effects [14]. Harmful blood clots form when platelets adhere to foreign objects in the presence of blood flow [12]. Various biological processes ensue when ligands floating in the bloodstream bind to cell receptors which occupy a thin reaction zone about the cell membrane [11].

1.1. The BIAcore.

For the purposes of this paper, we focus on the BIAcore, which is a surface plasmon resonance (SPR) device for measuring rate constants. The configuration of the BIAcore is described in great detail elsewhere [16], [17], [18], [26]. For the purposes of this manuscript, we may consider the BIAcore to consist

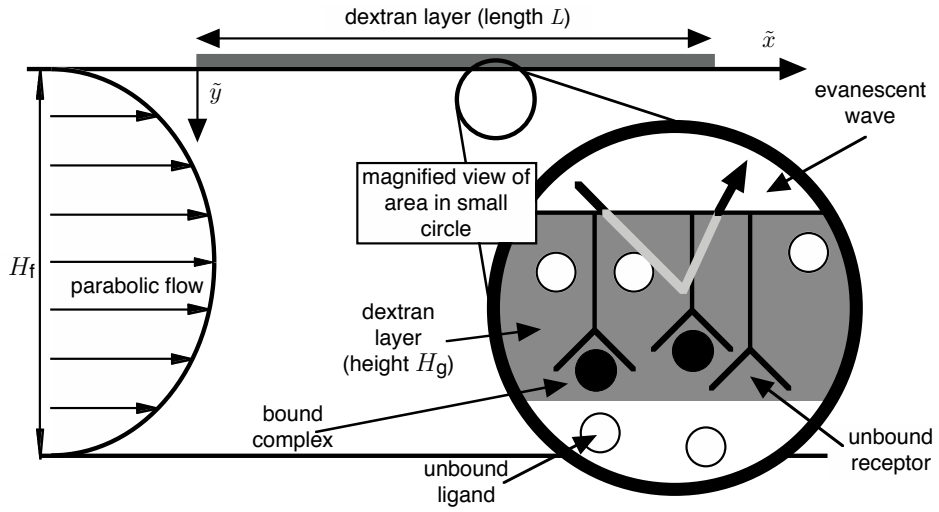

FIG. 1.1. *Schematic of BIAcore device. The coordinate system has its origin at the intersection of the $\tilde{y}$-axis and the dextran-flow interface.*

of a rectangular channel through which the ligand is convected in standard two-dimensional Poiseuille flow from $\tilde{x} = 0$, the inlet position (see Figure 1.1). Receptors are embedded in a thin dextran gel attached to the ceiling of the channel. Hence this device can serve as a representative of many physical systems of the type described above.

As the ligand diffuses to receptor sites, the binding process is measured by an evanescent wave that tracks mass changes in the dextran gel, as described more fully in section 6. This *sensogram* data is then transferred to a regression program which estimates the rate constants. During recent years, mathematical models of the BIAcore have become increasingly more sophisticated, treating many facets of its transport processes, including depletion of the free-flowing ligand along the channel [2], [3], [8], [21], [22]; diffusion in the gel [5], [25], [30], [31]; and signal decay associated with the measuring wave [6], [18], [25]. However, discrepancies still occur between measurements and simulations using the most sophisticated models [16], [24], [29].

To explain some anomalous observations, Witz [29] proposed that some of the buffer flow in the channel penetrates into the dextran gel, thus enhancing transport. In [7], Edwards formulated a mathematical model for this flow and analyzed it in the case where the reacting zone is treated as a surface. Now we shall treat the reaction zone as a layer.

As a first approximation, we model the dextran gel as a viscous fluid; others have treated it as a polymer brush [29]. We show that the physical parameter measuring penetration is $H_r = H_g/H_f$, the ratio of the heights of the gel and bulk flow regions. To leading order the flow adds a local depletion term to the mass action law for the bound state. When the Damköhler number Da is small, we obtain detailed expressions for the effect of penetration on the measurements. When $\mathrm{Da} = O(1)$ a nonlinear integral equation results, but the rate constants can easily be estimated using short-time asymptotics. We consider not only association, but also dissociation experiments. We also include the effect of evanescent wave decay in the measurement device.

All of our results indicate that flow penetration effects are very small. Such a conclusion arises from the geometry of the device, rather than from the model chosen for the dextran. Since the gel layer is so narrow compared to the rest of the device, velocities there will be small, no matter the actual transport model used. Clearly this result can be extended to the other physical systems described above.

2. Preliminaries. We consider the BIAcore to be divided into two regions, as shown in Figure 1.1: the open channel (the region $0 \le \tilde{y} \le H_{\rm f}$, where the subscript "f" stands for "flow") and the dextran gel layer (the region $-H_{\rm g} \le \tilde{y} \le 0$, where the subscript "g" stands for "gel"). We are interested in only that portion of the dextran layer which has length L, and so we take both regions to have $0 \le \tilde{x} \le L$.

2.1. Velocity profiles. The Reynolds number is small [7], so the flow in the channel is described by a simple one-dimensional laminar model. On the other hand, the dextran is a gel, and any true description of the flow therein would be quite complicated. For instance, Witz [29] considers the gel to be a polymer brush. For the purposes of this paper, we treat it merely as a very viscous fluid. This will necessarily misstate some quantitative features of the flow, but we shall show that such errors are negligible when analyzing sensogram data.

For simplicity, we introduce the following scalings for $\tilde{y}$ and the velocity field $\tilde{v}$:

$$y_{\rm f} = \frac{\tilde{y}}{H_{\rm f}}, \quad v_{\rm f}(y_{\rm f}) = \frac{\tilde{v}_{\rm f}(\tilde{y})}{V_{\rm f}}, \quad V_{\rm f} = \frac{\Delta p H_{\rm f}^2}{2\mu_{\rm f} L}, \quad y_{\rm g} = \frac{\tilde{y}}{H_{\rm g}}, \quad v_{\rm g}(y_{\rm g}) = \frac{\tilde{v}_{\rm g}(\tilde{y})}{V_{\rm g}}, \tag{2.1a}$$

$$V_{\rm g} = \frac{H_{\rm r}}{\mu_{\rm r}} V_{\rm f}, \quad H_{\rm r} = \frac{H_{\rm g}}{H_{\rm f}}, \quad \mu_{\rm r} = \frac{\mu_{\rm g}}{\mu_{\rm f}}, \tag{2.1b}$$

where μ is the bulk viscosity, V is the characteristic velocity in each region, and Δp is the (constant) pressure differential, which can be related to the known flow rate. Here (and throughout), if the same symbol appears both with and without tildes, the symbol with a tilde has dimensions, while the symbol without a tilde is dimensionless.

In (2.1b) the subscript "r" refers to "ratio," and we will use it in the same way (gel to flow) throughout. Using these scalings, it can be shown [7] that with suitable boundary and interface conditions, the velocity profiles are given by

$$v_{\rm f}(y_{\rm f}) = 1 - y_{\rm f}^2 + \frac{(y_{\rm f} - 1)(\mu_{\rm r} - H_{\rm r}^2)}{H_{\rm r} + \mu_{\rm r}}, \tag{2.2a}$$

$$v_{\rm g}(y_{\rm g}) = H_{\rm r}(1 - y_{\rm g}^2) + \frac{(y_{\rm g} + 1)(\mu_{\rm r} - H_{\rm r}^2)}{H_{\rm r} + \mu_{\rm r}}. \tag{2.2b}$$

Since solid dextran corresponds to $\mu_{\rm r} = \infty$, we might consider $\mu_{\rm r}$ as a large parameter to use in a perturbation approach. However, we can solve our problem for *any* $\mu_{\rm r}$ if we choose $H_{\rm r} \ll 1$, as motivated by its value in Table 4.1 below. Since $H_{\rm r}$ is simply a geometric parameter, such a choice will extend our results to other physical systems with thin reaction zones.

In the limit of small $H_{\rm r}$, (2.2b) becomes a nearly linear profile, corresponding to flow driven largely by shear from the bulk interface. Though using a more complicated polymer brush model for the gel leads to exponential and Bessel-function velocity profiles, these also reduce to linear profiles for small $H_{\rm r}$ [29]. Thus the two approaches are equivalent with a proper choice of $\mu_{\rm r}$.

2.2. Transport in the flow. In the flow, the ligand (concentration $\tilde{C}_{\rm f}$) travels both by convection and diffusion. However, the Peclét number in the flow, defined as

$$\text{Pe}_{\rm f} = \frac{H_{\rm f}^2/\tilde{D}_{\rm f}}{L/V_{\rm f}} = \frac{\text{characteristic diffusion time in flow}}{\text{characteristic convection time in flow}}, \tag{2.3}$$

is large (for a typical value, see Table 4.1 below). Here $\tilde{D}_{\rm f}$ is the molecular diffusion coefficient of the ligand in the flow. Hence one needs consider only the thin Lévêque boundary layer near $\tilde{y} = 0$ [3], which motivates the following scalings:

$$x = \frac{\tilde{x}}{L}, \quad y = \text{Pe}_{\rm f}^{1/3} y_{\rm f}, \quad t = \tilde{k}_{\rm on} C_{\rm u} \tilde{t}, \quad \tilde{C}_{\rm f}(\tilde{x}, \tilde{y}, \tilde{t}) = C_{\rm u}[1 - \text{Da} C_{\rm f}(x, y, t)], \tag{2.4}$$

where $\tilde{k}_{\rm on}$ is the association rate constant and $C_{\rm u}$ is the ligand concentration entering the device, which is used to create the dimensionless ligand concentration $C_{\rm f}$. Note that with our choice of scalings, the reaction time scale is the one of interest.

Here Da is the *Damköhler number*

$$\text{Da} = \frac{\tilde{k}_{\rm on}\tilde{R}_{\rm T}}{\tilde{D}_{\rm f}/(H_{\rm f}\text{Pe}_{\rm f}^{-1/3})} = \frac{\text{reaction ``velocity''}}{\text{diffusion ``velocity'' in boundary layer}}, \tag{2.5}$$

where $\tilde{R}_{\rm T}$ is the area density of receptor sites in the device. Da, which measures the effect of transport on the chemical reaction, characterizes the size of ligand depletion induced by the reaction, as shown in (2.4). Since $\text{Pe}_{\rm f} \propto V_{\rm f}$, $\text{Da} = 0$ corresponds to the case of infinitely fast flow where no depletion occurs. Most experiments are designed so that Da is small; hence the choice of scaling in (2.4) makes $C_{\rm f}$ a perturbation.

With these scalings, it can be shown [7] that the governing equations for $C_{\rm f}$ are

$$\frac{\partial^2 C_{\rm f}}{\partial y^2} = (v_0 + v_1 y)\frac{\partial C_{\rm f}}{\partial x}, \qquad C_{\rm f}(0, y, t) = 0, \quad C_{\rm f}(x, \infty, t) = 0, \tag{2.6a}$$

$$v_0 \equiv v_{\rm f}(0)\text{Pe}_{\rm f}^{1/3} = \frac{H_{\rm r}\text{Pe}_{\rm f}^{1/3}(H_{\rm r}+1)}{H_{\rm r}+\mu_{\rm r}}, \qquad v_1 \equiv v_{\rm f}'(0) = \frac{\mu_{\rm r} - H_{\rm r}^2}{H_{\rm r}+\mu_{\rm r}}. \tag{2.6b}$$

The scaling of v_0 in (2.6b) is chosen so that our results transition smoothly to the solid dextran case in the limit of large $\mu_{\rm r}$.

For the size of the transport processes to be comparable, the length scale in the Lévêque boundary layer in the fluid (where convection and diffusion balance) should be on the order of that in the gel. This implies that

$$H_{\rm g} = O(H_{\rm f}\text{Pe}_{\rm f}^{-1/3}) \Longrightarrow H_{\rm r} = O(\text{Pe}_{\rm f}^{-1/3}). \tag{2.7}$$

Such a scaling makes v_0 into an $O(1)$ quantity as long as we treat $\mu_{\rm r}$ as $O(1)$. Equation (2.7) also motivates the choice of $H_{\rm r}$ as a small parameter, since $\text{Pe}_{\rm f} \gg 1$. Unfortunately, (2.7) is rather a weak bound. From Table 4.1 below we have that $H_{\rm r} \ll \text{Pe}_{\rm f}^{-1/3}$, and so velocities in the gel will be comparatively small. Again, this result will hold for other systems with similar geometries.

To solve for $C_{\rm f}$, we use Laplace transforms (denoted with a hat) in the x-direction. To understand the gel dynamics, we need the value of $\hat{C}_{\rm f}$ only at the flow-gel interface $y = 0$. In particular, it can be shown [7] that $\hat{C}_{\rm f}$ satisfies

$$\hat{C}_{\rm f}(0, t) = \frac{\text{Ai}(s^{1/3}v_0/v_1^{2/3})}{(sv_1)^{1/3}\,\text{Ai}'(s^{1/3}v_0/v_1^{2/3})}\frac{\partial \hat{C}_{\rm f}}{\partial y}(0, t). \tag{2.8}$$

3. Dynamics in the dextran layer.

3.1. Transport. In the dextran gel, the reaction occurs only inside the pores, so it is the concentration of ligand *per fluid volume* that is important. To convert to this quantity, we simply divide $\tilde{C}_{\mathrm{g}}$, the concentration of ligand in the gel matrix, by the volume fraction ϕ of pores in the gel. (ϕ is also called the *partition coefficient*.) Motivated by this reasoning and (2.4), we choose the following scaling for $\tilde{C}_{\mathrm{g}}$:

$$\tilde{C}_{\mathrm{g}}(\tilde{x},\tilde{y},\tilde{t}) = \phi C_{\mathrm{u}}[1 - \mathrm{Da} C_{\mathrm{g}}(x, y_{\mathrm{g}}, t)]. \tag{3.1a}$$

Because the dextran layer is often treated as a surface, $\tilde{R}_{\mathrm{T}}$ is usually quoted as an *area* concentration. To convert this to a volume concentration, we simply divide by the width of the layer H_{g}, and hence we have an appropriate scaling for $\tilde{B}$:

$$B_{\mathrm{g}}(x, y_{\mathrm{g}}, t) = \frac{H_{\mathrm{g}}}{\tilde{R}_{\mathrm{T}}} \tilde{B}_{\mathrm{g}}(\tilde{x},\tilde{y},\tilde{t}). \tag{3.1b}$$

Though the receptor density may initially be nonuniform [15], [23], for now we take it to be uniform, since the error introduced from such an assumption is small [9].

In the dextran gel, the ligand travels both by convection and diffusion. Its evolution is also affected by binding. Since the concentration of available receptors is so much greater than the ligand concentration [5], the $\partial C_{\mathrm{g}}/\partial t$ term in the transport equation may be neglected. Moreover, $H_{\mathrm{g}} \ll L$, and so diffusion in the x-direction can be neglected.

Lastly, the Peclet number in the gel is given by

$$\mathrm{Pe}_{\mathrm{g}} = \frac{H_{\mathrm{g}}^2/\tilde{D}_{\mathrm{g}}}{L/V_{\mathrm{g}}} = \frac{H_{\mathrm{r}}^3}{\mu_{\mathrm{r}}} \frac{\tilde{D}_{\mathrm{f}}}{\tilde{D}_{\mathrm{g}}} \mathrm{Pe}_{\mathrm{f}} = \frac{1}{\mu_{\mathrm{r}}} \frac{\tilde{D}_{\mathrm{f}}}{\tilde{D}_{\mathrm{g}}} O(v_0^3), \tag{3.2}$$

where we have used (2.1) and (2.7). Here $\tilde{D}_{\mathrm{g}}$ is the diffusion constant in the dextran gel. The analysis in [7], which considers the case of a surface reaction, contains terms only up to $O(v_0)$. The same sort of analysis will hold here (as shown below), and thus we may ignore convection in the ligand transport equation. Physically, the small size of Pe_{g} in (3.2) shows that diffusion is the dominant transport process in the layer, not convection. Thus the dominant effect of flow penetration is a slip condition on the bulk flow.

Hence the leading-order dimensionless ligand transport equation is given by

$$\frac{\partial^2 C_{\mathrm{g}}}{\partial y_{\mathrm{g}}^2} = -D \frac{\partial B}{\partial t}, \tag{3.3a}$$

$$D = \frac{\tilde{D}_{\mathrm{f}}/(H_{\mathrm{f}} \mathrm{Pe}_{\mathrm{f}}^{-1/3})}{\phi \tilde{D}_{\mathrm{g}}/H_{\mathrm{g}}} = \frac{\text{diffusion velocity in diffusive boundary layer}}{\text{diffusion velocity in dextran}}. \tag{3.3b}$$

We solve (3.3a) by writing our solution as the sum of a particular solution A_{p} and a homogeneous solution A_{h}, as follows:

$$C_{\mathrm{g}}(x, y_{\mathrm{g}}, t) = -D A_{\mathrm{p}}(x, y_{\mathrm{g}}, t) + A_{\mathrm{h}}(x, y_{\mathrm{g}}, t), \tag{3.4}$$

where A_{p} satisfies

$$\frac{\partial^2 A_{\mathrm{p}}}{\partial y_{\mathrm{g}}^2} = \frac{\partial B}{\partial t}, \qquad \frac{\partial A_{\mathrm{p}}}{\partial y_{\mathrm{g}}}(x, -1, t) = 0, \qquad A_{\mathrm{p}}(x, 0, t) = 0. \tag{3.5}$$

The homogeneous problem is most easily solved in Laplace transform space. Solving the homogeneous form of the operator in (3.3a) subject to a no-flux condition at the channel wall $y = -1$, we determine that $\hat{A}_\mathrm{h}$ is a function of t only. At the flow-gel interface, the flux and ligand concentration per fluid volume must be continuous. Combining these conditions with (2.8) and using the transform of (3.4), we obtain

$$\hat{A}_\mathrm{h}(t) = -\frac{\mathrm{Ai}(s^{1/3}v_0/v_1^{2/3})}{(sv_1)^{1/3}\,\mathrm{Ai}'(s^{1/3}v_0/v_1^{2/3})}\frac{\partial \hat{A}_\mathrm{p}}{\partial y_\mathrm{g}}(0,t). \tag{3.6}$$

Since we cannot invert (3.6) in closed form, we use the fact that we consider the dextran to be a very viscous fluid, so $v_0 \to 0$. Formally, there are two ways to justify this from (2.6b). The first, physically intuitive, reasoning is to say that $\mu_\mathrm{r} \to \infty$. The second, more consistent from a mathematical point of view, is to take $H_\mathrm{r} \to 0$. Then expanding (3.6) to leading two orders in v_0 and inverting, we obtain the following:

$$A_\mathrm{h}(x,t) = \frac{1}{(3v_1)^{1/3}\Gamma(2/3)}\int_0^x \frac{\partial A_\mathrm{p}}{\partial y_\mathrm{g}}(x-\xi,0,t)\frac{d\xi}{\xi^{2/3}} - \frac{v_0}{v_1}\frac{\partial A_\mathrm{p}}{\partial y_\mathrm{g}}(x,0,t) + O(v_0^2). \tag{3.7}$$

Note from (3.5) that

$$\frac{\partial A_\mathrm{p}}{\partial y_\mathrm{g}}(x,0,t) = \int_{-1}^0 \frac{\partial B}{\partial t}\,dy_\mathrm{g};$$

in other words, the derivative is simply the average rate of binding in the layer at fixed x. Thus the integral term in (3.7) has an elegant physical interpretation, namely that the deficit in the ligand concentration at position x is the accumulation of the reaction that has occurred upstream. The effect of the slip velocity is to introduce the *local* reaction into the computation of the ligand deficit through the second term in (3.7).

When expanding (3.6) to obtain the expansion in (3.7), we tacitly assumed that $s^{1/3}v_0 \ll 1$. However, Laplace transform theory states that small x corresponds to large s, so this assumption does not hold in the limit of small x. Fortunately, the BIAcore returns measurements not of B, but of its average over the entire layer and some scanning range $x_\mathrm{min} \le x \le x_\mathrm{max}$:

$$\bar{B}(t) = \frac{1}{x_\mathrm{max} - x_\mathrm{min}}\int_{x_\mathrm{min}}^{x_\mathrm{max}}\int_{-1}^0 B(x,y_\mathrm{g},t)\,dy_\mathrm{g}\,dx, \tag{3.8}$$

where x_min is bounded away from zero. Since $x = 0$ is out of the scanning range, we may confidently use our results to analyze sensogram data.

3.2. Reaction. The bound state evolves according to a standard bimolecular mass action law. Using the scalings in (2.4) and (3.1) leads to the dimensionless form

$$\frac{\partial B}{\partial t} = (1-B)(1-\mathrm{Da}C_\mathrm{g}) - KB, \quad K = \frac{\tilde{k}_\mathrm{off}}{\tilde{k}_\mathrm{on}C_\mathrm{u}}, \tag{3.9a}$$

$$B(x,y_\mathrm{g},0) = B_\mathrm{i}, \tag{3.9b}$$

where $\tilde{k}_\mathrm{off}$ is the dissociation rate constant and K is the dimensionless affinity constant. Though the theory can handle general initial conditions for B, in practice the initial condition is always spatially uniform. For an association experiment, initially there is no bound state. For a dissociation experiment, we start with the steady state of (3.9a), which will be shown to be a constant.

Since A_{p} depends on $\partial B/\partial t$, substitution of (3.4) and (3.7) into (3.9a) would yield a nonlinear integrodifferential equation, and an exact solution would have to be obtained numerically. However, asymptotic results can be derived in physically relevant regimes.

4. Small Da results. Equation (3.9a) shows that $\mathrm{Da} = 0$ corresponds to the well-mixed case where there is no depletion. When designing experiments, scientists strive to keep Da as small as possible to minimize transport effects [28]. Therefore, we now specialize to the case of small Da by introducing the following expansion:

$$B(x, y_{\mathrm{g}}, t) = B_0(x, y_{\mathrm{g}}, t) + \mathrm{Da} B_1(x, y_{\mathrm{g}}, t) + o(\mathrm{Da}). \tag{4.1}$$

4.1. Association experiment. We begin by considering an association experiment as described in section 3. If we substitute (4.1) into (3.9), we find to leading order that the ligand concentration does not contribute. Hence we are in the well-mixed case, the solution of which is given by

$$B_0(x, y_{\mathrm{g}}, t) = \frac{1 - e^{-\alpha t}}{\alpha} + B_{\mathrm{i}} e^{-\alpha t} = \bar{B}_0(t), \tag{4.2}$$

which leads to the following expression for A_{p}:

$$A_{\mathrm{p}} = \frac{dB_0}{dt} \frac{y_{\mathrm{g}}(y_{\mathrm{g}} + 2)}{2}. \tag{4.3}$$

Since A_{p} is independent of x, it is simple to use (4.3) in (3.7) and compute that

$$A_{\mathrm{h}}(x, t) = \frac{dB_0}{dt} h(x), \qquad h(x) = \frac{3^{2/3} x^{1/3}}{v_1^{1/3} \Gamma(2/3)} - \frac{v_0}{v_1}. \tag{4.4}$$

The value of $A_{\mathrm{h}}(x, t)$ in (4.4) is exactly the value of $C_{\mathrm{f}}(x, 0, t)$ obtained if the reacting zone is treated as (instead of a layer) a two-dimensional surface at $x = 0$. In that case, $D = 0$, and hence there is no contribution from A_{p} in (3.4).

Substituting (4.3) and (4.4) into (3.4), we obtain

$$C_{\mathrm{g}}(x, y_{\mathrm{g}}, t) = \frac{dB_0}{dt} h_{\mathrm{g}}(x, y_{\mathrm{g}}), \qquad h_{\mathrm{g}}(x, y_{\mathrm{g}}) = \left[-D \frac{y_{\mathrm{g}}(y_{\mathrm{g}} + 2)}{2} + h(x) \right]. \tag{4.5}$$

Thus, as in [5], the effects of the variables x and y decouple. We also note that (4.3) is exactly the same as in [5], which considered the no-penetration case. Hence the effect of flow penetration appears only in the homogeneous part. Since the velocity in the layer is negligible at this order, the flow simply provides a slip condition for the bulk, which then couples to the receptor layer through the flow-gel interface conditions.

Substituting (4.2) and (4.5) into the next order of our expansion of (3.9) and solving, we have the following:

$$B_1 = \left[\frac{(e^{-\alpha t} - 1)\chi}{\alpha} - Kt \right] \frac{\chi e^{-\alpha t}}{\alpha} h_{\mathrm{g}}(x, y_{\mathrm{g}}). \tag{4.6}$$

Then averaging, we obtain

$$\bar{B}_1 = \frac{\chi e^{-\alpha t}}{\alpha} \left[\frac{(e^{-\alpha t} - 1)\chi}{\alpha} - Kt \right] \bar{h}_{\mathrm{g}}, \qquad \bar{h}_{\mathrm{g}} = \frac{D}{3} + \bar{h}. \tag{4.7}$$

Parameter values for Figures 4.1 *and* 4.2.

Parameter	Value	Parameter	Value
B_{i}	0	Pe_{f}	3.72×10^{2}
C_{T} (mol/cm^3)	10^{-11}	t	$10^{-3}\,\tilde{t}$/s
D	1.20×10^{-1}	$x_{\max}$	7.92×10^{-1}
Da	10^{-1}	$x_{\min}$	2.08×10^{-1}
H_{r}	2×10^{-3}	α	2
K	1	χ	1
$\tilde{k}_{\mathrm{on}}$(cm^{3}mol^{-1}s^{-1})	10^{8}		

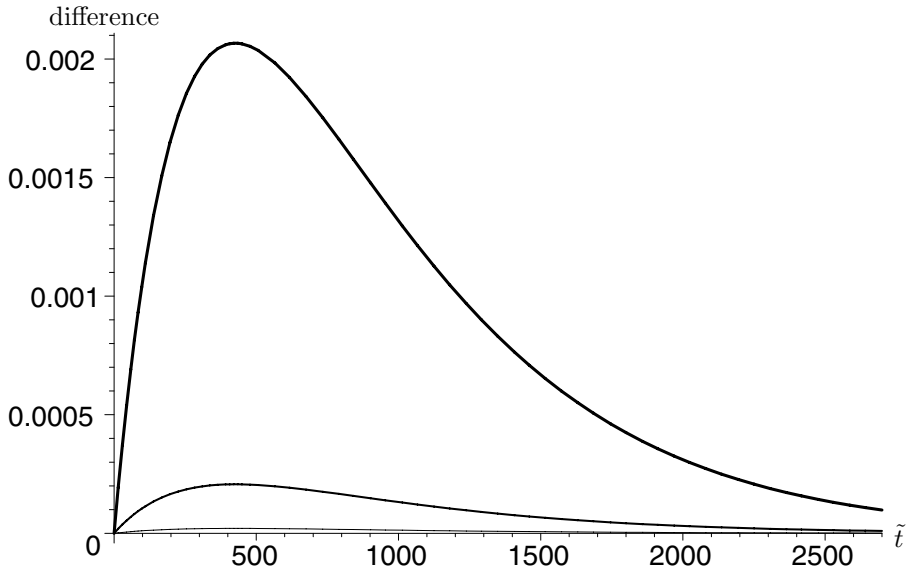

FIG. 4.1. *Absolute difference between* (4.7) *with* $\mu_{\mathrm{r}} = \infty$ (*solid dextran*) *and* μ_{r} *finite for* (*in decreasing order of thickness*) $\mu_{\mathrm{r}} = 1,\ 10,\ 100$. *Relative difference is about* 1%. *Association experiment.*

Aficionados of perturbation theory will note the term in (4.7) proportional to $te^{-\alpha t}$, similar to a secularity in a two-timing exercise. As $t \to \infty$, $B_0 = O(1)$ and $\mathrm{Da}B_1 \ll B_0$, so from an experimental standpoint, this is not a problem. However, it can be shown [3], [8] that a multiple-scale expansion is formally required. Though we could construct such an expansion for this case, it will not be illuminating.

We use the parameters listed in Table 4.1 to plot our solutions. The parameter values are from [7], with the exception of the value for D, which is from [6].

Figure 4.1 shows the effect of μ_{r} on $\bar{B}_1$ plotted against the *dimensional* time $\tilde{t}$ (in seconds) for various values of μ_{r}. We use the dimensional time in order to compare better with sensogram data. Note that in every case the difference is quite small due to the low value of H_{r}. In particular, even the error for $\mu_{\mathrm{r}} = 1$ (corresponding to the absence of a dextran layer) is only $O(H_{\mathrm{r}})$. In addition, the difference is positive; that is, allowing the flow to penetrate into the dextran layer enhances the association process. Since H_{r} is a geometrical parameter, this order estimate holds for other physical systems of this type.

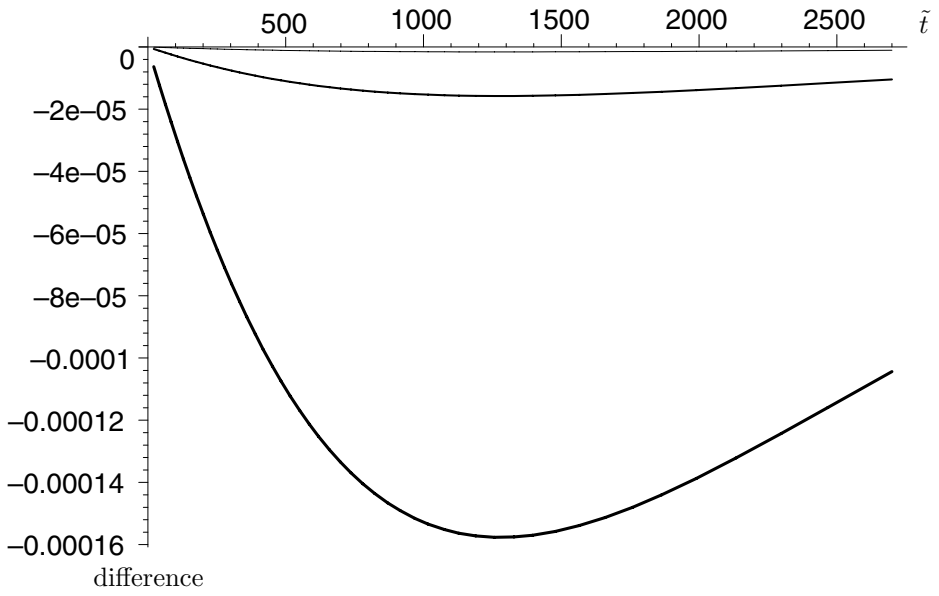

FIG. 4.2. *Absolute difference between effective rate constant solution* $\bar{B}$ *of* (4.8) *with* $\mu_r = \infty$ (*solid dextran*) *and* μ_r *finite for* (*in decreasing order of thickness*) $\mu_r = 1, 10, 100$. *Relative difference is about* 0.04%. *Association experiment.*

In Figure 4.1 (and throughout this manuscript) we graph the absolute difference because it is that difference which will be measured by the device and plotted on the sensogram. Obviously small differences will be masked by the underlying noise in any experiment. However, for comparison purposes and to extend our results to other physical systems, we also compute the relative difference. The case with $\mu_r = \infty$, graphed in Figure 1 of [5], shows that B_1 is on the order of 0.2, so the differences shown in Figure 4.1 are on the order of 1%. (Note this is the difference in $\bar{B}_1$, not in the whole solution, which would include the much greater contribution from $\bar{B}_0$.)

These results may be stated more simply in the context of an *effective rate constant* (ERC) equation, as outlined in [5], [8], and [21]. Substituting (4.5) into (3.9a), we have

$$\frac{\partial B}{\partial t} = (1 - B)\left[1 - \mathrm{Da}\frac{dB_0}{dt}h_g(x)\right] - KB + O(\mathrm{Da}^2),$$

which we may rearrange and average to obtain

$$\frac{d\bar{B}}{dt} = \frac{1 - \alpha\bar{B}}{1 + \mathrm{Da}(1 - \bar{B})\bar{h}_g} + O(\mathrm{Da}^2). \tag{4.8}$$

Equation (4.8) is an ODE for $\bar{B}$, the actual sensogram data produced by the BIAcore, and hence the solution requires no postprocessing averaging step. Equation (4.8) is in the form obtained previously [5], albeit with a different value of $\bar{h}$. This is consistent with [4], where it is shown that if B_0 is spatially uniform, the ERC approximation is robust to *any* geometry or flow.

Figure 4.2 shows the effect of μ_r on our ERC solution. The absolute error here is an order of magnitude smaller than that in Figure 4.1. This is because Figure 4.1

shows errors in $\bar{B}_1$, which have to be multiplied by Da (0.1 in our graphs) to obtain the error in the full solution as shown in Figure 4.2. The relative error here is around 0.1%, as can be seen by comparison with the full solution in Figure 1 of [8]. As before, flow penetration enhances the association process.

4.2. Dissociation experiment. A typical BIAcore experimental run begins with an association experiment run to completion. At this stage, pure buffer solution (inlet concentration zero) is injected into the device, initiating the dissociation process. This second experiment then provides additional data for rate constant estimation.

The initial condition for this phase of the experiment is the steady state of (3.9a). Since there is no flux of ligand through the exterior wall, one finds from (3.3a) that the steady state of C_{g} must be a constant. By using continuity arguments at the interface, one finds that this constant must be zero. Thus the steady state of (3.9a) is

$$B_{\mathrm{s}} = \alpha^{-1}, \tag{4.9}$$

where the subscript "s" refers to "steady state." Since (4.9) provides the initial condition for the dissociation problem, we are justified in always taking a constant initial condition for B.

With no ligand injected into the device, the equation analogous to (3.9a) becomes

$$\frac{\partial B}{\partial t} = (1-B)(-\mathrm{Da}C_{\mathrm{g}}) - KB. \tag{4.10}$$

Thus in this case $C_{\mathrm{g}} \leq 0$. The analysis proceeds in a manner analogous to the association experiment; the relevant results are given by

$$B_0(x,t) = \bar{B}_0(t) = \frac{e^{-Kt}}{\alpha}, \tag{4.11a}$$

$$\bar{B}_1 = \frac{K}{\alpha}\left(t + \frac{e^{-Kt}-1}{K\alpha}\right)\bar{h}_{\mathrm{g}}e^{-Kt}, \tag{4.11b}$$

where $\bar{h}_{\mathrm{g}}$ is given in (4.7). The same secularity problem appears with more obvious effects, since in the dissociation experiment the second term in the expansion can become larger than the first. Again, we restrict ourselves to the case where $\mathrm{Da}t = O(1)$, since constructing the multiple-scale expansion is not illuminating.

With the inlet value 1 absent from the concentration term in (4.10), the expression analogous to (4.8) is given by

$$\frac{d\bar{B}}{dt} = \frac{-K\bar{B}}{1+\mathrm{Da}(1-\bar{B})\bar{h}_{\mathrm{g}}} + O(\mathrm{Da}^2), \tag{4.12}$$

as in [5].

5. Moderate Da results. Since C_{g} depends on B, (3.9a) is nonlinear if $\mathrm{Da} = O(1)$. Thus to obtain analytic solutions we resort to short-time asymptotics by assuming a solution of the form

$$B(x,y_{\mathrm{g}},t) = B_{\mathrm{i}} + \beta(x,y_{\mathrm{g}})t + o(t), \qquad A_{\mathrm{p}}(x,y_{\mathrm{g}},t) = A_{\mathrm{p},1}(x,y_{\mathrm{g}}) + o(1), \tag{5.1a}$$

$$A_{\mathrm{h}}(x,t) = A_{\mathrm{h},1}(x) + o(1). \tag{5.1b}$$

5.1. Association experiment. Substituting (5.1) into (3.4), (3.9a), and (3.5), we have, to leading order in t,

$$C_{\mathrm{g}} = -DA_{\mathrm{p},1} + A_{\mathrm{h},1},$$

$$\beta = (1 - B_{\mathrm{i}})[1 - \mathrm{Da}(-DA_{\mathrm{p},1} + A_{\mathrm{h},1})] - KB_{\mathrm{i}}, \tag{5.2a}$$

$$\frac{\partial^2 A_{\mathrm{p},1}}{\partial y_{\mathrm{g}}^2} = \beta, \qquad \frac{\partial A_{\mathrm{p},1}}{\partial y_{\mathrm{g}}}(x,-1) = 0, \qquad A_{\mathrm{p},1}(x,0) = 0. \tag{5.2b}$$

Since (5.2a) is linear, it is most convenient to work in Laplace transform space. The relationship between $\hat{A}_{\mathrm{h},1}$ and $d\hat{A}_{\mathrm{p},1}/dy_{\mathrm{g}}(0)$ is exactly the same as in the transform of (3.7). Upon substituting that expression into the transform of (5.2) and solving, we obtain a form for $\hat{A}_{\mathrm{p},1}$ that depends explicitly on $d\hat{A}_{\mathrm{p},1}/dy_{\mathrm{g}}(0)$. Some algebraic manipulation eliminates the unknown from our solution, yielding

$$\hat{A}_{\mathrm{p},1} = -\frac{\chi}{\lambda_{\mathrm{a}}^2 r_{\mathrm{a}} s}\left[1 - \frac{\cosh\lambda_{\mathrm{a}}(y_{\mathrm{a}}+1)}{\cosh\lambda_{\mathrm{a}}}\right]\left(1 + \frac{\nu_{\mathrm{a}}^{1/3}}{s^{1/3}}\right)^{-1}, \tag{5.3}$$

$$r_{\mathrm{a}} = 1 - (1 - B_{\mathrm{i}})\mathrm{Da}\frac{v_0}{v_1}\frac{\tanh\lambda_{\mathrm{a}}}{\lambda_{\mathrm{a}}}, \qquad \lambda_{\mathrm{a}}^2 = D\mathrm{Da}(1 - B_{\mathrm{i}}), \tag{5.4a}$$

$$\nu_{\mathrm{a}} = \frac{1}{3v_1}\left\{\frac{\Gamma(2/3)}{\Gamma(1/3)}\left[\frac{1}{\mathrm{Da}(1-B_{\mathrm{i}})}\frac{\lambda_{\mathrm{a}}}{\tanh\lambda_{\mathrm{a}}} - \frac{v_0}{v_1}\right]\right\}^{-3}, \tag{5.4b}$$

where the subscript "a" denotes "association." We have written (5.4b) in a form where the correction due to v_0 can be easily seen. Recall that in deriving this form, we have already taken an asymptotic limit for small v_0. Thus, we should expect that (5.3) will hold only for those Da where the first bracketed term is much larger than the second.

To simplify the interpretation of the data, we write the average (3.8) in dimensional form with the aid of (2.4):

$$\bar{B}(\tilde{t}) \sim B_{\mathrm{i}} + S\tilde{t}, \quad \tilde{t} \to 0,$$

$$S = \frac{\tilde{k}_{\mathrm{on}} C_{\mathrm{u}}\{\mathcal{I}[\beta; x_{\max}] - \mathcal{I}[\beta; x_{\min}]\}}{x_{\max} - x_{\min}}, \tag{5.5a}$$

$$\mathcal{I}[\beta; x] \equiv \int_0^x \int_{-1}^0 \beta(\xi, y_{\mathrm{g}})\, dy_{\mathrm{g}}\, d\xi. \tag{5.5b}$$

Substituting (5.3) into the Laplace transform of (5.2b) and inverting, we have

$$\mathcal{I}[\beta; x] = \frac{\chi e^{-\nu_{\mathrm{a}} x}}{\nu_{\mathrm{a}} r_{\mathrm{a}}}\left[e^{\nu_{\mathrm{a}} x} - 1 - \left|P\left(\frac{4}{3}, -\nu_{\mathrm{a}} x\right)\right| + \left|P\left(\frac{5}{3}, -\nu_{\mathrm{a}} x\right)\right|\right]\frac{\tanh\lambda_{\mathrm{a}}}{\lambda_{\mathrm{a}}}, \tag{5.6a}$$

where P is the normalized *lower* incomplete gamma function whose definition is [1]

$$P\left(\frac{m}{3}, -\nu_{\mathrm{a}} x\right) = \frac{\gamma(m/3, -\nu_{\mathrm{a}} x)}{\Gamma(m/3)}. \tag{5.6b}$$

In the limit that $D \to 0$, $\lambda_{\mathrm{a}} \to 0$ and (5.6a) reduces to the result in the surface reaction case [7].

To estimate the rate constants from an experiment, we first run the association experiment to steady state. This will yield an estimate for α, and hence K, from (4.9). To calculate $\tilde{k}_{\mathrm{on}}$, we use the linear fit S from our short-time data in (5.5a) to

TABLE 5.1
Parameter values for Figures 5.1 *and* 5.2.

Parameter	Value	Parameter	Value
$\tilde{D}_{\mathrm{f}}$ (cm^2/s)	2.8×10^{-7}	L (cm)	2.4×10^{-1}
$\tilde{D}_{\mathrm{g}}$ (cm^2/s)	3.36×10^{-8}	R_{T} (mol/cm^2)	10^{-12}
$\tilde{k}_{\mathrm{off}}$ (s^{-1})	8.9×10^{-3}	ϕ	1

obtain $\tilde{k}_{\mathrm{on}}$. Since Da also depends on $\tilde{k}_{\mathrm{on}}$, the relationship between S and $\tilde{k}_{\mathrm{on}}$ is not a simple linear one. Using our estimates for K and $\tilde{k}_{\mathrm{on}}$ together, we may calculate $\tilde{k}_{\mathrm{off}}$.

We may asymptotically determine the behavior of S for small $\tilde{k}_{\mathrm{on}}$, which corresponds to small k. For small k, $r_{\mathrm{a}} \to 1$, $\lambda_{\mathrm{a}} \to 0$, and $\nu_{\mathrm{a}} \to 0$, so we have

$$S \sim \tilde{k}_{\mathrm{on}} C_{\mathrm{u}} \chi, \qquad \tilde{k}_{\mathrm{on}} \to 0. \tag{5.7}$$

Equation (5.7) merely shows that if there is no forward reaction ($\tilde{k}_{\mathrm{on}} = 0$), then there will be no change in the bound concentration from the initial state ($S = 0$).

At the other extreme, we cannot ascertain the behavior in the case that $k \to \infty$ due to the form of (5.4b). As k increases, so will Da, thus eventually causing the assumed ordering in (5.4b) to be violated. Essentially, because of the faster reaction, we cannot simply take the first-order convection correction; we must include additional terms in our analysis.

Since $\tanh \lambda_{\mathrm{a}} < 1$, we can still satisfy our ordering if we replace $\tanh \lambda_{\mathrm{a}}$ with 1 for simplicity. By doing so, we may construct a specific bound using the parameters in Table 5.1 (which come from [6] and [7]). The bound is calculated to be

$$k \ll 232 \mu_{\mathrm{r}}^2, \tag{5.8}$$

which is quadratic in μ_{r}—a much less restrictive bound than the linear bound in the surface reaction case [7].

5.2. Dissociation experiment. For the dissociation case, the initial condition is the steady state from the association problem, given in (4.9). In addition, the leading-order concentration is now 0, not 1. Essentially, only the parameters in the problem have changed, not the general structure. Therefore, the solution process follows as before, and our expression for $\mathcal{I}$ is

$$\mathcal{I}[\beta; x] = -\frac{K e^{-\nu_{\mathrm{d}} x}}{\alpha \nu_{\mathrm{d}} r_{\mathrm{d}}} \left[e^{\nu_{\mathrm{d}} x} - 1 - \left| P\left(\frac{4}{3}, -\nu_{\mathrm{d}} x\right) \right| + \left| P\left(\frac{5}{3}, -\nu_{\mathrm{d}} x\right) \right| \right] \frac{\tanh \lambda_{\mathrm{d}}}{\lambda_{\mathrm{d}}}, \tag{5.9}$$

$$\lambda_{\mathrm{d}}^2 = D \mathrm{Da} \left(\frac{K}{\alpha}\right), \qquad r_{\mathrm{d}} = 1 - \left(\frac{K}{\alpha}\right) \mathrm{Da} \frac{v_0}{v_1} \frac{\tanh \lambda_{\mathrm{d}}}{\lambda_{\mathrm{d}}}, \tag{5.10a}$$

$$\nu_{\mathrm{d}} = \frac{1}{3 v_1} \left\{ \frac{\Gamma(2/3)}{\Gamma(1/3)} \left[\frac{1}{\mathrm{Da}(K/\alpha)} \frac{\lambda_{\mathrm{d}}}{\tanh \lambda_{\mathrm{d}}} - \frac{v_0}{v_1} \right] \right\}^{-3}, \tag{5.10b}$$

where the subscript "d" refers to "dissociation." Similar to the previous subsection, in the limit that $D \to 0$, our results reduce to the surface reaction case in [7].

Using our new initial condition, we write our average as

$$\bar{B}(t) \sim \frac{1}{\alpha} + S\tilde{t}, \quad \tilde{t} \to 0,$$

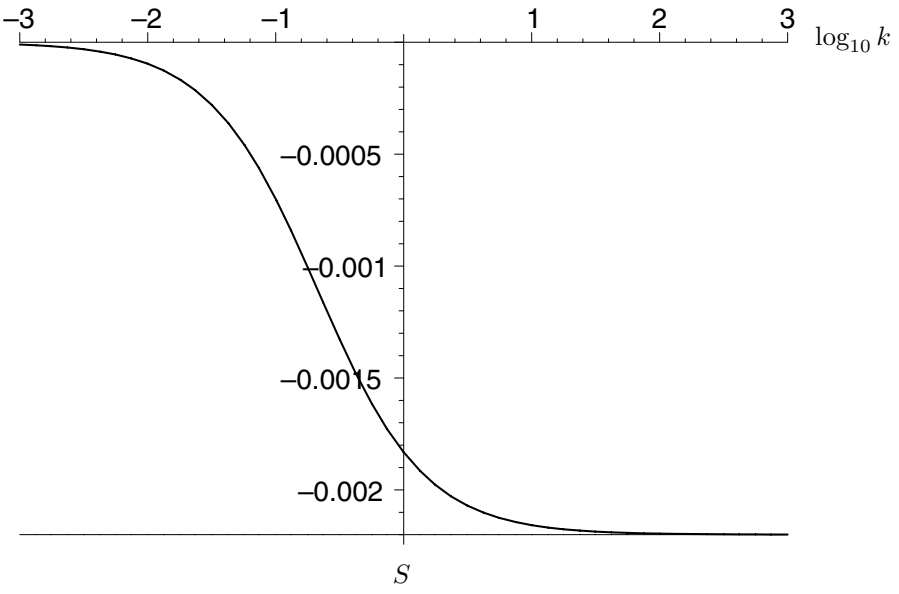

FIG. 5.1. *Thick line: S versus $\log_{10} k$, keeping $\tilde{k}_{\text{off}}$ fixed. Thin line: large-k asymptote. Dissociation experiment, $v_0 = 0$.*

where S is defined in (5.5a). Note from (5.9) that the slope is now negative, as expected for our dissociation problem.

We carefully analyze the behavior of S with respect to k, beginning with the case where $v_0 = 0$. In [5], the author kept K fixed and varied $\tilde{k}_{\text{on}}$, which necessitated (tacitly) varying $\tilde{k}_{\text{off}}$. In contrast, here we wish to keep $\tilde{k}_{\text{off}}$ fixed, which means that K will vary as $\tilde{k}_{\text{on}}$ does. This approach was taken in the study of flow penetration on the surface reaction case [7]. The value chosen for $\tilde{k}_{\text{off}}$ is listed in Table 5.1 and comes from [7].

In order to visualize the relationship between S and $\tilde{k}_{\text{on}}$, in Figure 5.1 we construct a curve using the parameters in Table 5.1 with $\mu_{\text{r}} = \infty$ (the solid dextran case). For convenience, we define the new variable

$$k = 10^{-9} \tilde{k}_{\text{on}} \frac{\text{mol} \cdot \text{s}}{\text{cm}^3}. \tag{5.11}$$

Since we take $B_{\text{i}} = 0$ for the association case, $\chi = 1$ and the solution is independent of K. It can be shown that the only qualitative difference between the graph here and with K fixed is in the asymptotes. (See [7] for a related discussion of the layer reaction case.)

For the small-$\tilde{k}_{\text{on}}$ asymptote, we first note from (5.10) that as $\tilde{k}_{\text{on}} \to 0$, $\lambda_{\text{d}} \to 0$, which causes the λ_{d} contribution to disappear, as in the previous subsection. In addition, $r_{\text{d}} \to 1$ and $\nu_{\text{d}} \to 0$. Thus we have that

$$S \sim -\tilde{k}_{\text{on}} C_{\text{u}}, \qquad \tilde{k}_{\text{on}} \to 0. \tag{5.12}$$

Note that (5.12) holds regardless of the value of v_0.

For the large-$\tilde{k}_{\text{on}}$ asymptote, we must restrict ourselves to the case with no flow:

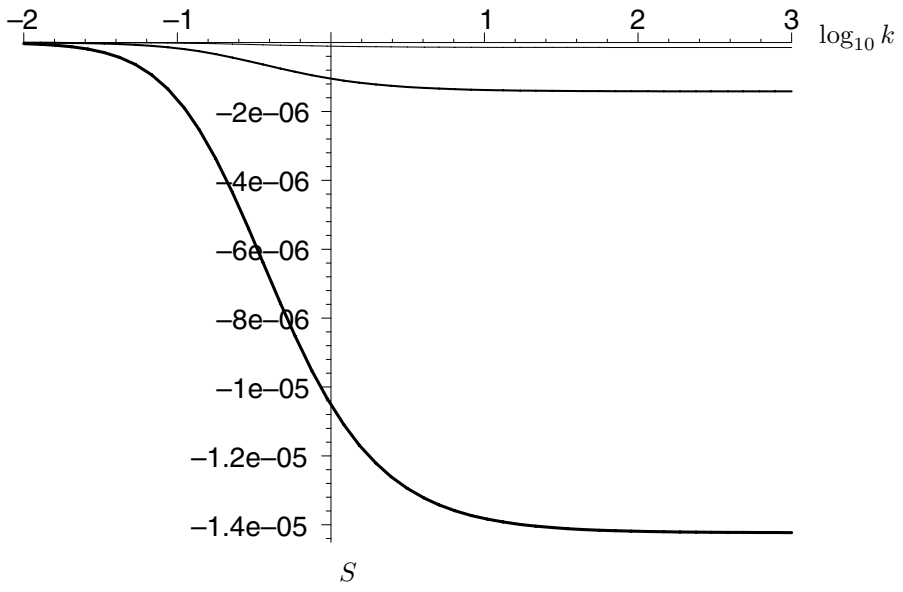

FIG. 5.2. *Absolute difference between S with $\mu_r = \infty$ (solid dextran) and μ_r finite versus $\log_{10} k$ for (in decreasing order of thickness) $\mu_r = 1$, 10, 100. Relative difference is about 1%. Dissociation experiment.*

$v_0 = 0$ and $v_1 = 1$, so $r_d = 1$. First, it is convenient to estimate λ_d in this limit:

$$\lim_{\tilde{k}_{on}\to\infty} \lambda_d \equiv \lambda_\infty = \left(\frac{\tilde{R}_T H_g}{\phi \tilde{D}_g} \frac{\tilde{k}_{off}}{C_u} \right)^{1/2}. \tag{5.13a}$$

In addition, we may use (5.10b) to calculate ν_∞ for this case:

$$\nu_\infty = \frac{1}{3\mathrm{Pe}_f} \left[\frac{\Gamma(1/3)}{\Gamma(2/3)} \frac{\tilde{R}_T H_f}{\tilde{D}_f} \frac{\tilde{k}_{off}}{C_u} \frac{\tanh \lambda_\infty}{\lambda_\infty} \right]^3, \quad v_0 = 0. \tag{5.13b}$$

Equations (5.13) illustrate a key difference between our analysis and that of [5]. In that work, K was kept fixed, so λ_d was unbounded as $\tilde{k}_{on} \to \infty$. This simplified $\mathcal{I}[\beta; x]$ greatly, leading to a relatively simple result. In our case, the asymptote has no convenient closed-form solution, but upon substituting (5.13) into (5.6a) and (5.5a), we obtain $S = -2.20 \times 10^{-3}$, which is exactly the asymptote in Figure 5.1.

Now that we have a baseline result for comparison, we next vary the viscosity ratio μ_r. Again we must preserve the assumed size ordering in (5.10b). Substituting our parameters into the above, we have

$$4.74 \times 10^{-1} \ll 16.2\mu_r, \tag{5.14}$$

which is simply a bound on μ_r that is always satisfied experimentally. Thus our expressions do not break down for large k as in the association case.

In Figure 5.2 we examine the effect of varying viscosity on the short-time asymptote S. As expected, the corrections are again small. The decrement to S increases

with decreasing μ_r, as lower μ_r means more convective transport, which enhances dissociation. By examining Figure 5.1, we see that the relative difference is about 1%.

6. Evanescent wave effects. The way in which an SPR device like the BIAcore measures binding is quite involved; here we present a brief summary. As binding occurs in the gel, the gel's index of refraction changes. A polarized light beam is aimed at the sensor surface at various angles. A sharp decrease in reflectivity is noted for a certain incidence angle, which can be related to the index of refraction and hence the binding. Since the strength of the evanescent wave (electric field) decays as it penetrates into the gel, the effect of binding on signal decays further from the surface $\tilde{y} = -H_g$ [10], [18].

By using a simple exponential decay model for the signal, we obtain the following result for the average $\bar{B}$, which replaces (3.8):

(6.1)
$$\bar{B}(t;\delta) = \frac{\delta}{(1-e^{-\delta})(x_{\max}-x_{\min})}\int_{x_{\min}}^{x_{\max}}\int_{-1}^{0} e^{-\delta(y_g+1)}B(x,y_g,t)\,dy_g\,dx, \qquad \delta = \frac{H_g}{H_w},$$

where H_w is the characteristic decay length of the wave. Here we include δ explicitly in the notation for $\bar{B}$ to indicate that we are including wave effects.

The only change to our work from previous sections is the calculation of averages. Since the leading-order solutions are independent of y_g, their averages do not change with the decaying signal strength.

6.1. Results for small Da. We begin by examining the small Da case. Using our averaging scheme in (6.1) to average h_g as given in (4.5) yields

$$\bar{h}_g(t;\delta) = D\frac{\delta^2 + 2[(\delta+1)e^{-\delta}-1]}{2\delta^2(1-e^{-\delta})} + \bar{h}. \tag{6.2}$$

It can be shown [6] that the term multiplying D is bounded between 1/3 (as in (4.7)) and 1/2; hence we expect the effect of the evanescent wave layer to be minimal. In order to plot some curves to verify this, we choose a typical decay length H_w from [25] and a typical gel width from [31]:

$$H_w = 9.5\times 10^{-6}\text{ cm}, \qquad H_g = 10^{-5}\text{ cm} \Longrightarrow \delta = 1.05. \tag{6.3}$$

As a naïve first approach, we might try to create a graph similar to Figure 4.1 to illustrate the changes of varying viscosity. However, we note from (4.4) and (6.2) that the only term involving μ_r is $\bar{h}$ (through the v_0 term). Hence the D term will always vanish when calculating

$$\bar{B}_1(\mu_r = \infty) - \bar{B}_1(\mu_r \neq \infty),$$

as in Figure 4.1. Since the D term includes the effect of decay, a graph of the above quantity will be the same whether or not decay is included.

The ERC solution does not have the unusual property described above, so to include the wave decay we substitute (6.2) into (4.8). In Figure 6.1 we plot the difference between the no-flow and viscous-flow cases of the ERC solution, including the wave decay. The graph is virtually indistinguishable from its analogue Figure 4.2, so the effect of decay is slight and the relative error is again around 0.04%.

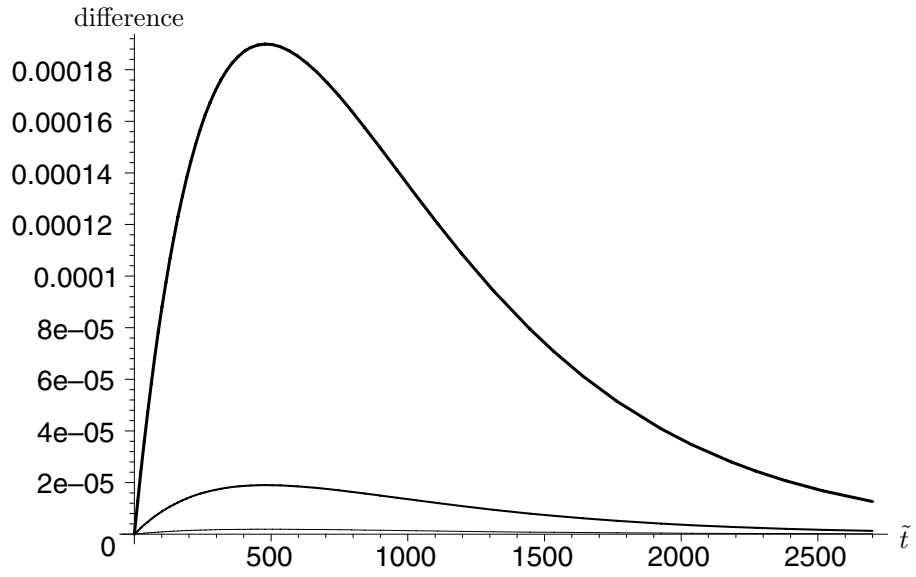

FIG. 6.1. *Difference between wave decay effective rate constant solution* $\bar{B}$ *of* (4.8) (*using* (6.1) *and* (6.2)) *with* $\mu_r = \infty$ (*solid dextran*) *and* μ_r *finite for* (*in decreasing order of thickness*) $\mu_r = 1$, 10, 100. *Relative difference is about* 0.04%. *Association experiment.*

For the dissociation experiment, the analysis is exactly analogous. The only difference is that rather than substituting (6.2) into (4.8), we substitute it into (4.12).

6.2. Results for moderate Da. The wave decay effect is more pronounced in the moderate Da case, in some cases leading to nonunique parameter estimates for the same data [6]. Proceeding in a manner analogous to (5.6a), we find that including the decay yields

$$\mathcal{I}[\beta;x] = \frac{\chi e^{-\nu_a x}}{2r_a\nu_a \cosh\lambda_a}\left[e^{\nu_a x} - 1 - \left|P\left(\frac{4}{3}, -\nu_a x\right)\right| + \left|P\left(\frac{5}{3}, -\nu_a x\right)\right|\right]$$
$$\times\left[\frac{e^{(\lambda_a-\delta)}-1}{\lambda_a-\delta} - \frac{e^{-(\lambda_a+\delta)}-1}{\lambda_a+\delta}\right]\frac{\delta}{1-e^{-\delta}}. \tag{6.4}$$

Note that the x-dependence is unchanged since the decay operates only in the y-direction.

Upon taking the limit for small $\tilde{k}_{on}$, the fact that $\lambda_a \to 0$ forces all the δ terms in the last line of (6.4) to cancel. Thus (5.7) still holds. This is because in this limit, the reaction is so slow that all transport effects are unimportant. Thus the binding will be uniform, and the wave decay cannot be discerned.

We demonstrate our results for varying μ_r in Figure 6.2. Since this is an association graph, the relevant restriction on k is given by (5.8), so the graphs end for different values of k. As before, the addition to S increases with decreasing μ_r, as lower μ_r means more convective transport, which enhances association. The actual value of S is essentially the negative of that shown in Figure 6.3, as can be seen from Figure 3 in [5]; hence the relative difference is about 1%.

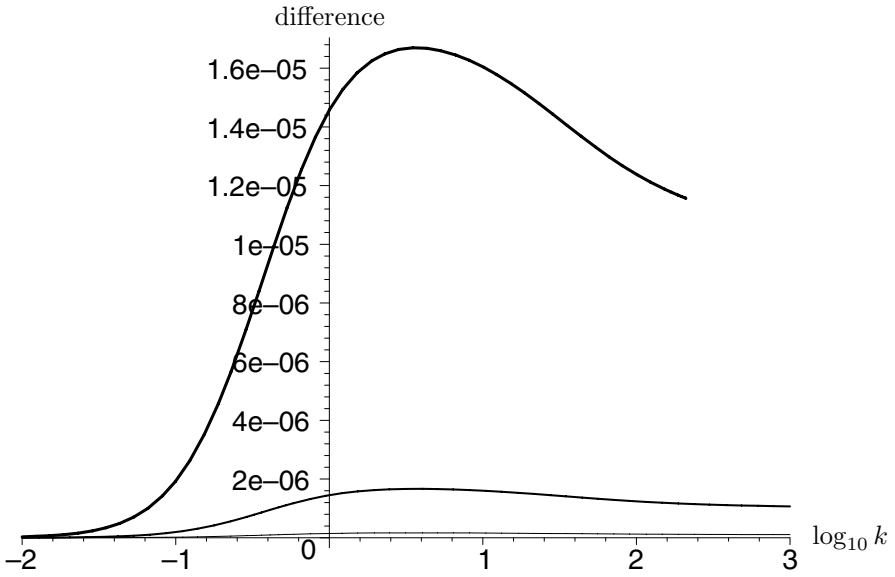

FIG. 6.2. *Absolute difference between S with $\mu_r = \infty$ (solid dextran) and μ_r finite versus $\log_{10} k$ for (in decreasing order of thickness) $\mu_r = 1$, 10, 100. Relative difference is about 1%. Association experiment, decay included.*

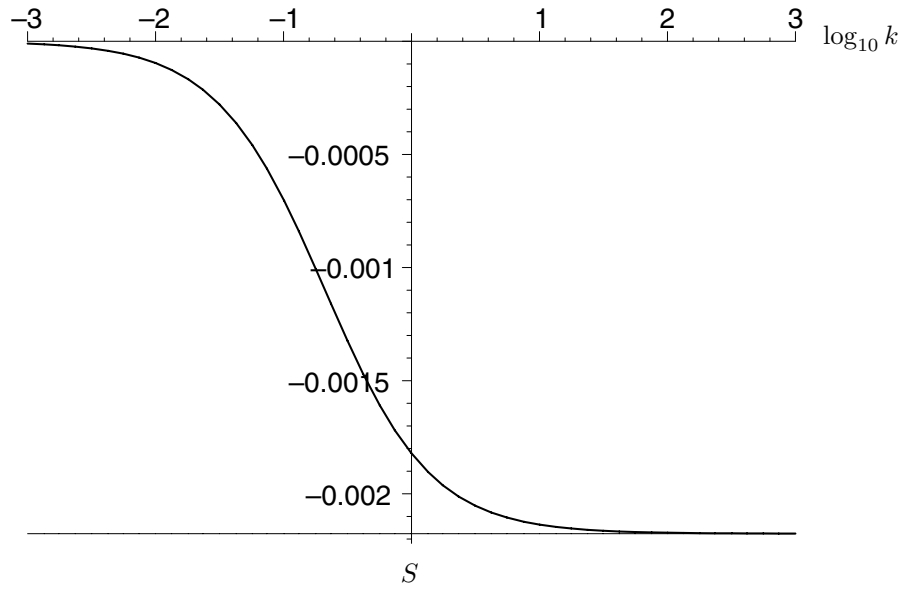

FIG. 6.3. *Thick line: S versus $\log_{10} k$, keeping $\tilde{k}_{\text{off}}$ fixed. Thin line: large-k asymptote. Dissociation experiment, $v_0 = 0$, wave decay considered.*

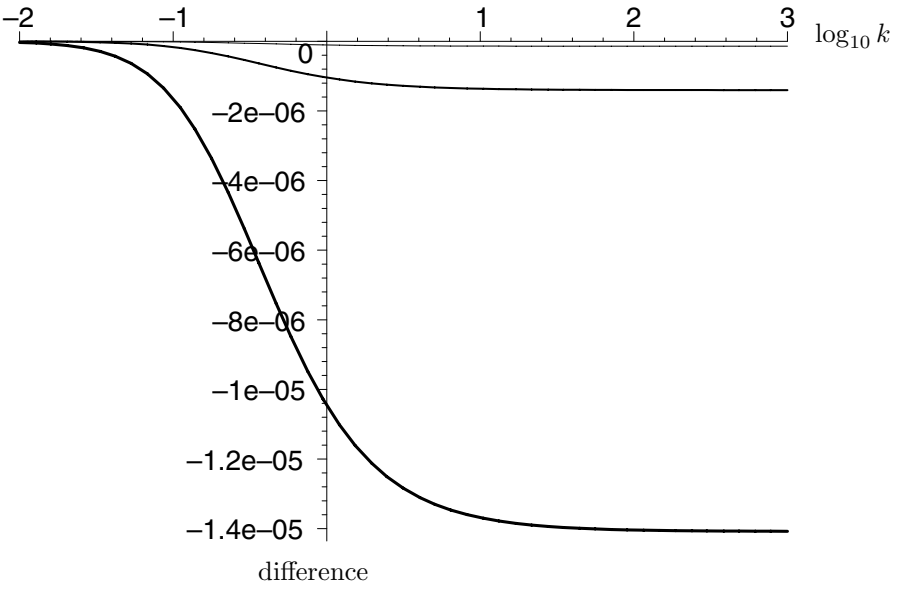

FIG. 6.4. *Absolute difference between S with $\mu_r = \infty$ (solid dextran) and μ_r finite versus $\log_{10} k$ for (in decreasing order of thickness) $\mu_r = 1$, 10, 100. Relative difference is about 1%. Dissociation experiment, decay included.*

For the dissociation case, the arguments are similar. The equation analogous to (5.9) is

$$\mathcal{I}[\beta; x] = -\frac{Ke^{-\nu_d x}}{2\alpha r_d \nu_d \cosh \lambda_d} \left[e^{\nu_d x} - 1 - \left| P\left(\frac{4}{3}, -\nu_d x\right)\right| + \left| P\left(\frac{5}{3}, -\nu_d x\right)\right|\right]$$

$$\times \left[\frac{e^{(\lambda_d - \delta)} - 1}{\lambda_d - \delta} - \frac{e^{-(\lambda_d + \delta)} - 1}{\lambda_d + \delta} \right] \frac{\delta}{1 - e^{-\delta}}. \tag{6.5}$$

As for the case without wave decay, earlier studies of the moderate Da case have kept K fixed and varied $\tilde{k}_{on}$ [6]. Thus, as in the previous subsection, in Figure 6.3 we present a demonstration graph to show what happens when we keep $\tilde{k}_{off}$ fixed instead. Again, the main difference lies in the asymptotes.

As above, when taking the limit for small $\tilde{k}_{on}$, the δ terms cancel. Thus the expression (5.12) for the small-$\tilde{k}_{on}$ asymptote still holds. For the large-$\tilde{k}_{on}$ asymptote in the no-flow case, we must use the expressions in (5.13). Substituting these parameters and our value of δ into (6.5) and (5.5a), we obtain $S = -2.18 \times 10^{-3}$, which is exactly the asymptote in Figure 6.3.

Lastly, we vary the viscosity ratio μ_r in Figure 6.4. Note that the corrections are again small and negative, as convection enhances dissociation. As in Figure 5.4, there are no restrictions on k because (5.14) is always satisfied. Therefore, our graphs go all the way to the right. Comparison with Figure 6.3 shows that the relative difference is again around 1%.

7. Conclusions. To explain BIAcore data that did not fit the traditional models, Witz [29] proposed that buffer flow from the channel penetrates into the dextran gel layer, enhancing transport. We have formulated a new model to include this effect. The key dimensionless parameter in this study is the small parameter H_r, which

measures the ratio of the widths of the gel and flow and hence characterizes the size of the velocity v_0 within the dextran gel. Its effect can be most readily seen in (3.7), where the slip condition at the flow-gel interface introduces a local depletion term that augments the integral depletion term from the no-flow case.

Since (3.9a) is a nonlinear equation, we obtained analytical results by introducing experimentally relevant simplifications. Most experiments are designed to have $\mathrm{Da} \ll 1$ to minimize transport effects, so we calculated the $O(\mathrm{Da})$ correction to the standard well-mixed case. The only effect of penetration is to introduce an additional term in $h(x)$, as defined in (4.4). We derived not only solution profiles for B, but also an ERC equation which can be used to fit sensogram data directly.

Some experiments cannot be designed such that $\mathrm{Da} \ll 1$, so we analyzed the moderate Da case by considering the short-time slope of the sensogram data. Corrections due to flow penetration appeared only in the parameter definitions in (5.4) and (5.10); the rest of the theory is the same as in the no-flow case [5]. The nature of our small-v_0 expansion dictated that we could not construct results for the case where $\mathrm{Da} \to \infty$; however, such conditions do not occur experimentally.

As in the small Da case, we examined both the association and dissociation phases of an experiment, providing (when possible) both the large- and small-$\tilde{k}_{\mathrm{on}}$ behavior of the short-time slope. In order to obtain results more consistent with experimental practice, we kept $\tilde{k}_{\mathrm{off}}$ fixed, in contrast to [5]. However, any differences between the papers were minor. In addition, since the inherent decay in the evanescent measuring wave affects only the averaging, not the transport, it was a simple matter to recast our previous results in this context.

In this manuscript we studied convection by modeling the dextran gel as a viscous fluid, though others have used more realistic polymer brush models [29]. Despite the simplicity of our model, the small thickness of the gel layer indicates that more realistic models will not produce qualitative changes in our results. We thus conclude that flow penetration effects are not likely to explain anomalous BIAcore measurements, and other effects, such as steric hindrance effects or conformational changes, should be investigated instead.

Moreover, since the size of the penetration effects are dictated by geometry, rather than properties of the gel, flow, or reactants, these insights can be extended to many similar physical systems. In particular, one may use gels and other compounds in reacting zones to reduce the size of hydrodynamic convective effects (as in [14]).

Acknowledgments. Portions of this manuscript were prepared during sabbatical stays at the Mathematical Biosciences Institute at The Ohio State University and the University of Maryland, Baltimore County.

MODEL DEVELOPMENT FOR ATOMIC FORCE MICROSCOPE STAGE MECHANISMS*

RALPH C. SMITH†, ANDREW G. HATCH†, TATHAGATA DE‡, MURTI V. SALAPAKA‡, RICARDO C. H. DEL ROSARIO§, AND JULIE K. RAYE¶

Abstract. In this paper, we develop nonlinear constitutive equations and resulting system models quantifying the nonlinear and hysteretic field-displacement relations inherent to lead zirconate titanate (PZT) devices employed in atomic force microscope stage mechanisms. We focus specifically on PZT rods utilizing d_{33} motion and PZT shells driven in d_{31} regimes, but the modeling framework is sufficiently general to accommodate a variety of drive geometries. In the first step of the model development, lattice-level energy relations are combined with stochastic homogenization techniques to construct nonlinear constitutive relations which accommodate the hysteresis inherent to ferroelectric compounds. Second, these constitutive relations are employed in classical rod and shell relations to construct system models appropriate for presently employed nanopositioner designs. The capability of the models for quantifying the frequency-dependent hysteresis inherent to the PZT stages is illustrated through comparison with experimental data.

1. Introduction.

Stage mechanisms employing the ferroelectric material lead zirconate titanate (PZT) have played a fundamental role in scanning tunneling microscope (STM) and atomic force microscope (AFM) design since their inception due to the high set point accuracy, large dynamic range, and relatively small temperature sensitivity exhibited by the compounds [14]. To illustrate, consider the prototypical AFM design depicted in Figure 1. To ascertain the three-dimensional (3-D) surface structure of a sample, it is moved laterally along a predetermined x-y grid by a PZT-driven stage. The response of a highly flexible microcantilever to changing atomic surface forces is monitored by a reflected laser beam measured via a photodiode, and forces corresponding to the cantilever displacement changes are determined via Hooke's law. A feedback law is used to determine voltages to a transverse PZT stage which produces displacements in the z-direction to maintain constant forces. A complete scan in this manner provides a surface image of the compounds. Additionally, PZT actuators are often used to drive the microcantilevers at resonance to achieve the tapping mode operation used to reduce damage to specimens. The reader is referred

to [11, 13, 14] for additional details regarding AFM applications and design.

Two representative stage designs are depicted in Figure 2. The first employs stacked PZT actuators utilizing d_{33} electromechanical motion to achieve longitudinal positioning along the prespecified x-y grid. A second stage provides the transverse motion required to ascertain the sample topography. Rod models with linear and nonlinear electromechanical input relations are constructed to quantify the PZT transducer dynamics in this design. The second geometry employs a cylindrical shell—with half poled d_{33} to provide horizontal (x-y) motion and half poled d_{31} for vertical (z) motion, as depicted in Figure 2(b)—to enhance vibration isolation and reduce hysteresis and constitutive nonlinearities. Thin shell models are developed to characterize this stage design.

To illustrate issues which must be addressed by models, field-displacement data from the stacked actuator depicted in Figure 2(a) is plotted in Figures 3 and 4. The data in Figure 3 was collected at 0.1 Hz and illustrates the nested, hysteretic relation between input fields and generated displacements in a nearly quasi-static regime. The data in Figure 4 was collected at frequencies ranging from 0.279 Hz to 27.9 Hz

to illustrate the frequency-dependence of the hysteresis as well as certain dynamic effects.

At low frequencies, the inherent hysteresis can be accommodated through proportional-integral-derivative (PID) or robust control designs [7, 8, 22, 29]. However, at the higher frequencies required for applications including real-time monitoring of biological processes (e.g., protein unfolding), comprehensive product diagnostics, and single electron spin detection [28, 40], increasing noise-to-data ratios and diminishing

high-pass characteristics of control filters preclude a sole reliance on feedback laws to eliminate hysteresis.

Alternatively, it is illustrated in [20, 21] that use of charge- or current-controlled amplifiers can essentially eliminate hysteresis. However, this mode of operation can be prohibitively expensive when compared with the more commonly employed voltage-controlled amplifiers, and current control is ineffective if maintaining DC offsets, as is the case when the x-stage of an AFM is held in a fixed position while a sweep is performed with the y-stage.

The need to significantly increase scanning speeds with general amplifiers motivates the development of models and model-based control designs which accommodate the frequency-dependent hysteresis inherent to the PZT actuators employed in the AFM stages. As detailed in [30], there exist a number of general approaches and frameworks for quantifying the constitutive nonlinearities and hysteresis in the general class of ferroelectric materials which encompass PZT. These include phenomenological macroscopic models [24], Preisach models [12, 27], domain wall models [33, 34], micromechanical models [6, 18, 19], mesoscopic energy relations [5, 17], and homogenized energy models [32, 39]. Within the context of AFM design, Croft, Shed, and Devasia [7] have employed a combination of a viscoelastic creep model and nonlinear Preisach representation to compensate for hysteresis and creep in an AFM stage, whereas a domain wall model was employed in [35] for the characterization of hysteresis in certain stage constructs. Primary requirements for nonlinear hysteresis models for the PZT actuators in an AFM are (i) flexibility with regard to frequency-dependent hysteresis effects (the frameworks of [7, 35] are limited in this regard), (ii) exact or approximate invertibility for linear control design, and (iii) sufficient efficiency for real-time implementation at the speeds required for present and future applications.

In this paper, we develop AFM transducer models, based on a homogenized energy framework for characterizing hysteresis and constitutive nonlinearities in ferroelectric materials, which meet these criteria. In section 2, we summarize the framework developed in [15, 31, 37, 38, 39] for quantifying hysteresis in the field-polarization relation and develop constitutive equations which characterize the elastic and electromechanical behavior of the PZT material. These constitutive relations are employed in section 3 to construct rod and shell models for the stages depicted in Figure 2, and the well-posedness of the models is established in section 4. Numerical approximation techniques for the transducer models are summarized in section 5, and the capability of the framework to quantify the biased and frequency-dependent hysteresis behavior of the transducers is illustrated in section 6 through a comparison with the experimental data plotted in Figures 2 and 3.

To place this framework in perspective, we briefly summarize the manner in which it compares and contrasts with previous models. As illustrated in [30, 36], the homogenized energy framework provides an energy basis for certain extended Preisach models. However, it also differs in five fundamental ways, and these are detailed in Remark 4 in section 2.4, following the model development. The domain wall model employed in the constitutive relations of [35] is efficient for characterizing hysteresis when inputs are known a priori. As detailed in [30], however, it does not guarantee the closure of biased minor loops in quasi-static regimes, nor does it provide the capability for including frequency-dependent effects due to thermal activation or creep. Hence the present framework, which automatically incorporates these mechanisms, provides significantly more flexibility for the range of operating regimes required for present and future atomic force microscopy applications. Certain preliminary aspects

of the model are presented in [16], which includes the rod model with initial model validation as a prelude for open loop control design. The present work significantly extends that modeling framework through the unified consideration of rod and shell geometries with extensive experimental validation and the presentation of analysis to establish model well-posedness.

The capability of the framework for characterizing frequency-dependent effects, and hence achieving criterion (i), is illustrated in section 6. With regard to criteria (ii) and (iii), the construction and experimental implementation of model inverses to linearize the nonlinear dynamics is demonstrated in [16]. Hence the models provide a framework for characterizing the hysteresis and nonlinear dynamics inherent to PZT-based nanopositioners in a manner which promotes stage and control design.

2. Constitutive relations. In this section, we summarize the development of constitutive relations which quantify the nonlinear and hysteretic map between input fields E and stresses σ and the polarization P and strains ε generated in ferroelectric materials. These relations are developed in three steps. In the first, Helmholtz and Gibbs energy relations are constructed at the lattice level to quantify the *local* dependence of P and ε on E and σ for regimes in which relaxation due to thermal processes is either negligible or significant. In the second step of the development, material nonhomogeneities, polycrystallinity, and variable field effects are incorporated through the assumption that certain material properties are manifestations of underlying distributions rather than constants. Stochastic homogenization in this manner yields macroscopic models which quantify the bulk hysteretic E-P behavior measured in ferroelectric materials. Finally, necessary conditions associated with minimization of the Gibbs energy are invoked to obtain 1-D and 2-D constitutive relations quantifying the elastic and electromechanical behavior of the transducer materials.

2.1. Helmholtz and Gibbs energy relations. As detailed in [39], an appropriate Helmholtz energy relation is

$$\psi(P,\varepsilon) = \psi_P(P) + \frac{1}{2}Y\varepsilon^2 - a_1\varepsilon P - a_2\varepsilon P^2, \tag{1}$$

where the component

$$\psi_P(P) = \begin{cases} \frac{1}{2}\eta(P+P_R)^2, & P \le -P_I, \\ \frac{1}{2}\eta(P-P_R)^2, & P \ge P_I, \\ \frac{1}{2}\eta(P_I-P_R)\left(\frac{P^2}{P_I}-P_R\right), & |P| < P_I, \end{cases}$$

quantifies the internal energy due to dipole processes. As shown in Figure 5, P_I is the positive inflection point that delineates the transition between stable and unstable regions, P_0 denotes the unstable equilibrium, and P_R is the value of P at which the positive local minimum of ψ occurs. The parameter η is the reciprocal of the slope of the E-P relation after switching occurs. The second term on the right-hand side of (1) quantifies the elastic energy, whereas the third and fourth terms quantify electromechanical coupling effects. Here Y denotes the Young's modulus, and a_1 and a_2 are electromechanical coupling coefficients.

The Gibbs energy relation

$$G(E,\sigma,P,\varepsilon) = \psi_P(P) + \frac{1}{2}Y\varepsilon^2 - a_1\varepsilon P - a_2\varepsilon P^2 - EP - \sigma\varepsilon \tag{2}$$

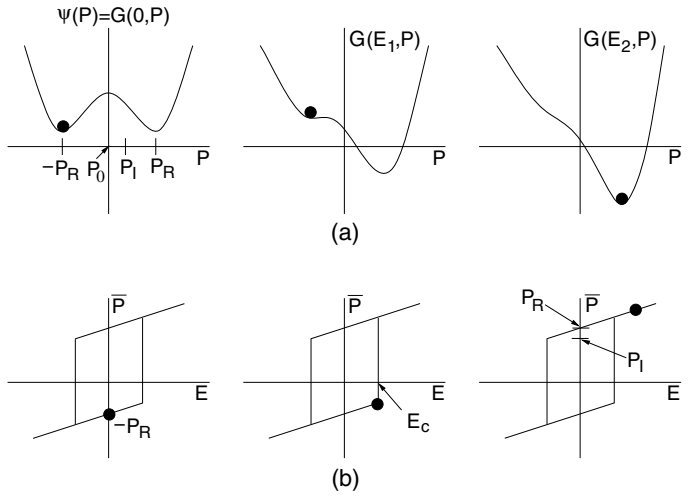

FIG. 5. (a) *Helmholtz energy ψ and Gibbs energy G for $\sigma = 0$ and increasing fields E.* (b) *Switch in the local polarization $\overline{P}$ that occurs as E is increased beyond the local coercive field E_c given by* (4) *in the absence of thermal activation.*

incorporates the elastic work $\sigma\varepsilon$ and electromechanical work EP. This provides the functional that is minimized or balanced with the relative thermal energy to provide local E-P relations and global electromechanical constitutive equations. The reader is referred to [30, 32] for details regarding the manner in which the Gibbs energy incorporates the dependent variables ε and P in terms of the independent variables σ and E.

2.2. Polarization kernel—Negligible thermal activation. For operating regimes in which relaxation or creep due to thermal processes is negligible, the local E-P relation is determined from the equilibrium conditions

$$\frac{\partial G}{\partial P} = 0, \qquad \frac{\partial^2 G}{\partial P^2} > 0.$$

For the piecewise quadratic functional (2), this yields a polarization kernel of the form

$$\overline{P}(E) = \frac{E}{\eta - 2a_2\varepsilon} + \delta\frac{P_R\eta + \delta a_1\varepsilon}{\eta - 2a_2\varepsilon}, \tag{3}$$

where $\delta = 1$ for positively oriented dipoles and $\delta = -1$ for those having negative orientation. To specify δ, and hence $\overline{P}$, in terms of the initial dipole configurations and previous switches, we let $\delta_0 = \pm 1$ designate the initial dipole orientation and let

$$E_c = \eta(P_R - P_I) \tag{4}$$

define the local coercive field at which the negative well ceases to exist and hence a dipole switch occurs. The local polarization is then given by

$$[\overline{P}(E; E_c, \delta_0)](t) = \begin{cases} \frac{E}{\eta - 2a_2\varepsilon} + \delta_0\frac{P_R\eta + \delta_0 a_1\varepsilon}{\eta - 2a_2\varepsilon}, & \tau = \emptyset, \\ \frac{E(t) - P_R\eta + a_1\varepsilon}{\eta - 2a_2\varepsilon}, & \tau \neq \emptyset,\ E(\max\tau) = -E_c, \\ \frac{E(t) + P_R\eta + a_1\varepsilon}{\eta - 2a_2\varepsilon}, & \tau \neq \emptyset,\ E(\max\tau) = E_c. \end{cases} \tag{5}$$

Here $\emptyset$ denotes the empty set, and the set of transition times is designated by

$$\tau = \{t \in (0, t_f] \,|\, E(t) = -E_c \text{ or } E(t) = E_c\},$$

where t_f denotes the final time under consideration.

Remark 1. For the drive levels employed for nanopositioning, the stress effects on the polarization are typically negligible, which motivates taking $\varepsilon = 0$ in (3) and (5). Hence the relations

$$\overline{P}(E) = \frac{1}{\eta}E + P_R\delta$$

or

$$[\overline{P}(E; E_c, \delta_0)](t) = \begin{cases} \frac{E(t)}{\eta} + P_R\delta_0, & \tau = \emptyset, \\ \frac{E(t)}{\eta} - P_R, & \tau \neq \emptyset,\ E(\max\tau) = -E_c, \\ \frac{E(t)}{\eta} + P_R, & \tau \neq \emptyset,\ E(\max\tau) = E_c, \end{cases} \tag{6}$$

are usually employed when characterizing AFM stages.

2.3. Polarization kernel—Thermal activation. If thermal relaxation or creep is significant, the Gibbs energy G and relative thermal energy kT/V are balanced through the Boltzmann relation

$$\mu(G) = Ce^{-GV/kT}. \tag{7}$$

Here k is Boltzmann's constant, V denotes a reference volume chosen to ensure physical relaxation behavior, and C is chosen to ensure integration to unity for the complete set of admissible inputs. As detailed in [30, 39], this yields the local polarization relation

$$\overline{P} = x_+ \langle P_+ \rangle + x_- \langle P_- \rangle . \tag{8}$$

The fractions x_+ and x_- of positively and negatively oriented dipoles are quantified by the differential equations

$$\dot{x}_+ = -p_{+-}x_+ + p_{-+}x_-,$$
$$\dot{x}_- = -p_{-+}x_- + p_{+-}x_+,$$

which can be simplified to

$$\dot{x}_+ = -p_{+-}x_+ + p_{-+}(1 - x_+)$$

through the identity

$$\dot{x}_+ + \dot{x}_- = 1.$$

The expected polarizations due to positively and negatively oriented dipoles are

$$\langle P_+ \rangle = \frac{\int_{P_I}^{\infty} Pe^{-G(E,P)V/kT}dP}{\int_{P_I}^{\infty} e^{-G(E,P)V/kT}dP}, \qquad \langle P_- \rangle = \frac{\int_{-\infty}^{-P_I} Pe^{-G(E,P)V/kT}dP}{\int_{-\infty}^{-P_I} e^{-G(E,P)V/kT}dP}, \tag{9}$$

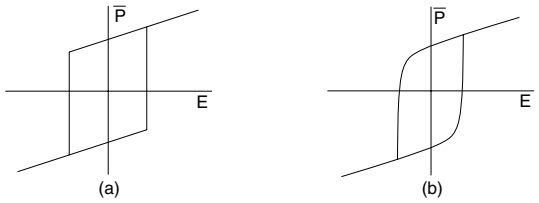

FIG. 6. *Hysteron provided by* (a) *the relation* (6) *with negligible thermal relaxation, and* (b) *the relation* (8)*, which incorporates relaxation mechanisms.*

where the denominator results from the evaluation of C in (7). The likelihoods of switching from positive to negative, and conversely, are given by

$$p_{+-} = \frac{1}{\mathcal{T}(T)} \frac{\int_{P_I-\epsilon}^{P_I} e^{-G(E,P)V/kT} dP}{\int_{P_I-\epsilon}^{\infty} e^{-G(E,P)V/kT} dP}, \quad p_{-+} = \frac{1}{\mathcal{T}(T)} \frac{\int_{-P_I}^{-P_I+\epsilon} e^{-G(E,P)V/kT} dP}{\int_{-\infty}^{-P_I+\epsilon} e^{-G(E,P)V/kT} dP}, \tag{10}$$

where ϵ is taken to be a small positive constant. The relaxation time $\mathcal{T}$ is the reciprocal of the frequency at which dipoles attempt to switch. It is proven in [30, 39] that $\overline{P}$ given by (8) converges to the local polarization (6) in the limit $kT/V \to 0$ of negligible thermal activation.

Remark 2. When constructing the expected polarization relations (9) and likelihoods (10), we use the notation $G(E, P)$ to indicate that we take $\varepsilon = \sigma = 0$ in (2) in accordance with the assumption that stress effects on the polarization are negligible at the drive levels employed in AFM stages. This approximation is employed only when defining the stress-independent polarization, and the full expression (2) is employed when constructing elastic constitutive relations in section 2.5.

2.4. Macroscopic polarization model. The local polarization relations (6) and (8) exhibit the behavior depicted in Figure 6 and provide reasonable characterization of the E-P behavior of certain single crystal compounds. However, to incorporate the effects of material and stress nonhomogeneities, polycrystallinity, and variable effective fields $E_e = E + E_I$, we assume that the interaction field E_I and local coercive field E_c given by (4) are manifestations of underlying distributions rather than constants. If we designate the associated densities by ν_1 and ν_2, the macroscopic field-polarization behavior is quantified by the relation

$$[P(E)](t) = \int_0^{\infty} \int_{-\infty}^{\infty} \nu_1(E_c)\nu_2(E_I)[\overline{P}(E + E_I; E_c, \xi)](t)\, dE_I\, dE_c, \tag{11}$$

where the kernel $\overline{P}$ is given by (6) or (8).

As detailed in [30, 32], the densities ν_1 and ν_2 are assumed to satisfy the physical criteria

$$\begin{aligned} &\text{(i)} && \nu_1(x) \ \text{ defined for } \ x > 0, \\ &\text{(ii)} && \nu_2(-x) = \nu_2(x), \\ &\text{(iii)} && |\nu_1(x)| \le c_1 e^{-a_1 x}, \\ & && |\nu_2(x)| \le c_2 e^{-a_2|x|} \end{aligned} \tag{12}$$

for positive c_1, a_1, c_2, a_2. The restricted domain in (i) reflects the fact that the coercive field E_c is positive, whereas the symmetry enforced in the interaction field through (ii) yields the symmetry observed in low-field Rayleigh loops. Hypothesis (iii) incorporates the physical observation that the coercive and interaction fields decay as a function of distance, and guarantees that integration against the piecewise linear kernel yields finite polarization values.

2.4.1. Model implementation. Approximation of (11) through Gaussian quadrature techniques yields the approximate relation

$$[P(E)](t) = \sum_{i=1}^{N_i} \sum_{j=1}^{N_j} \nu_1(E_{c_i}) \nu_2(E_{I_j}) [\overline{P}(E_{I_j} + E; E_{c_i}, \xi_j)](t) v_i w_j, \tag{13}$$

where E_{I_j}, E_{c_i} denote the abscissas associated with respective quadrature formulae and v_i, w_j are the respective weights—e.g., see [30]. Highly efficient algorithms for implementing the approximate polarization model (13) with the kernel (6) for the case of negligible thermal activation can be found in [30, 39]. Algorithms for implementing the model with the thermally active kernel (8) are presented in [4]. MATLAB code for both cases can be accessed at the website http://www.siam.org/books/fr32 associated with [30].

2.4.2. Density estimation. Techniques for identifying the densities ν_1 and ν_2 are illustrated in [30, 32]. For certain applications, reasonable accuracy is provided by a priori functions satisfying the physical criteria (12) and having a small number of parameters to be estimated through least squares fits to data—e.g., variances and means in normal and lognormal relations. For more general applications requiring high accuracy for a wide range of operating conditions, the $N_i + N_j$ discretized density values $\nu_1(E_{c_i})$ and $\nu_2(E_{I_j})$ can be estimated through the least squares techniques detailed in [30, 32].

Remark 3. From the perspective of both numerical and experimental implementation and the establishment of the well-posedness of resulting transducer models, it is important to quantify the regularity between input fields and the polization predicted by (11). In the appendix, it is established that P given by (11) is continuous with respect to E.

Remark 4. The formulation of the model as a superposition of kernels bears some resemblance to Preisach models, and it is illustrated in [30, 36] that the framework provides an energy basis for certain extended Preisach formulations. However, the energy framework differs from the classical Preisach model, characterized by the properties of deletion and congruency, in five aspects which prove crucial for actuator characterization and model-based control design. (i) For certain density choices, parameters can be correlated with attributes of the data to facilitate model construction and updating. (ii) The incorporation of relative thermal energy provides the thermal activation mechanisms required to characterize relaxation and creep. (iii) Stress and temperature-dependencies (e.g., see [1, 26]) are incorporated into the kernel rather than weights, as is the case for Preisach models, which eliminates the necessity of vector-valued lookup tables. (iv) Derivation of the kernels using Ising theory yields hysterons which accommodate measured noncongruencies and avoids the input or output-dependent densities associated with Preisach models. (v) The framework automatically incorporates low-field reversible behavior without the extensions required by Preisach theory.

2.5. Constitutive relations. To obtain elastic constitutive relations, the equilibrium condition

$$\frac{\partial G}{\partial \varepsilon} = 0$$

is invoked to obtain

$$\sigma = Y\varepsilon - a_1 P - a_2 P^2,$$

which reduces to Hooke's law when $P = 0$. To incorporate internal damping, we posit that in the absence of electromechanical effects, stress is proportional to a linear combination of strain and strain rate (the Kelvin–Voigt damping hypothesis). Finally, we note that the PZT stage mechanisms are poled and hence operate about the remanence polarization $P = P_R$ rather than the depoled state $P = 0$. (The remanence polarization is that which remains when the applied field is reduced to zero following positive saturation.) When combined with the polarization model (11), this yields the 1-D constitutive relations

$$\begin{aligned} &\sigma = Y\varepsilon + C\dot{\varepsilon} - a_1(P - P_R) - a_2(P - P_R)^2, \\ &[P(E)](t) = \int_0^\infty \int_{-\infty}^\infty \nu_1(E_c)\nu_2(E_I)[\overline{P}(E + E_I; E_c, \xi)](t)\, dE_I\, dE_c, \end{aligned} \tag{14}$$

where C is the Kelvin–Voigt damping coefficient. These relations are employed when constructing rod models to characterize the hysteretic dynamics shown in Figures 3 and 4 for the stacked actuators employed in the stage construction depicted in Figure 2(a).

The constitutive behavior of the PZT shell depicted in Figure 2(b) differs from that of the rod in two fundamental aspects: (i) the longitudinal actuation is due to d_{31} rather than d_{33} electromechanical coupling mechanisms and (ii) longitudinal and circumferential stresses and strains are coupled due to the curvature. To designate the coupled material behavior, we let ε_x, σ_x and $\varepsilon_\theta, \sigma_\theta$ denote the normal strains and stresses in the longitudinal and circumferential directions, respectively, and we denote shear strains and stresses by $\varepsilon_{x\theta}$ and $\sigma_{x\theta}$. Finally, we let ν denote the Poisson ratio for the material. The resulting 2-D constitutive relations

$$\begin{aligned} \sigma_x &= \frac{Y}{1-\nu^2}(\varepsilon_x + \nu\varepsilon_\theta) + \frac{C}{1-\nu^2}(\dot{\varepsilon}_x + \nu\dot{\varepsilon}_\theta) - \frac{1}{1-\nu}\left[a_1(P - P_R) + a_2(P - P_R)^2\right], \\ \sigma_\theta &= \frac{Y}{1-\nu^2}(\varepsilon_\theta + \nu\varepsilon_x) + \frac{C}{1-\nu^2}(\dot{\varepsilon}_\theta + \nu\dot{\varepsilon}_x) - \frac{1}{1-\nu}\left[a_1(P - P_R) + a_2(P - P_R)^2\right], \\ \sigma_{x\theta} &= \frac{Y}{2(1+\nu)}\varepsilon_{x\theta} + \frac{C}{2(1+\nu)}\dot{\varepsilon}_{x\theta}, \\ [P(E)](t) &= \int_0^\infty \int_{-\infty}^\infty \nu_1(E_c)\nu_2(E_I)[\overline{P}(E + E_I; E_c, \xi)](t)\, dE_I\, dE_c \end{aligned} \tag{15}$$

are employed when constructing transducer models for cylindrical nanopositioning stages.

3. Transducer models for stacked and cylindrical AFM stages. We now employ the 1-D constitutive relation (14) and 2-D relation (15) to construct models for the stacked and cylindrical AFM stages depicted in Figure 2. For the stacked actuator, we consider two frameworks: (i) a distributed PDE model, which quantifies displacements along the rod length as a function of the input field, and (ii) a lumped model, which exploits the assumption of uniform stresses and fields along the rod length to motivate an ODE quantifying displacements only at the rod end. A comparison between characterization capabilities provided by the two frameworks is provided in section 6. For the cylindrical shell design, we summarize a Donnell–Mushtari model which quantifies vertical motion provided by the z-component of the stage depicted in Figure 2(b).

3.1. Rod model for the stacked actuator.

3.1.1. Distributed rod model. We consider first the development of a distributed rod model which quantifies the displacement $u(t,x)$ along the rod length. In accordance with present stage design, one end of the rod is assumed fixed, while the other encounters resistance due to the connecting mechanisms, as depicted in Figure 7. We assume that this latter contribution can be modeled as a damped elastic system with mass m_ℓ, stiffness k_ℓ, and damping coefficient c_ℓ. The density, cross-sectional area, and length of the rod are denoted by ρ, A, and ℓ, and, in accordance with (14), the Young's modulus and Kelvin–Voigt damping parameter are denoted by Y and C.

Force balancing yields the relation

$$\rho A \frac{\partial^2 u}{\partial t^2} = \frac{\partial \mathcal{N}}{\partial x}, \tag{16}$$

where the resultant $N = \int_A \sigma dA$ is given by

$$N = YA\frac{\partial u}{\partial x} + CA\frac{\partial^2 u}{\partial x \partial t} - a_1[P(E) - P_R] - a_2[P(E) - P_R]^2,$$

once the linear relation $\varepsilon = \frac{\partial u}{\partial x}$ is employed for the strains in (14). The nonlinear and hysteretic map between input fields E and the polarization P is specified by (11). The fixed-end condition yields $u(t,0) = 0$, and balancing forces at $x = \ell$ yields the energy dissipating end condition

$$N(t,\ell) = -k_\ell u(t,\ell) - c_\ell \frac{\partial u}{\partial t}(t,\ell) - m_\ell \frac{\partial^2 u}{\partial t^2}(t,\ell).$$

Finally, initial conditions are taken to be $u(0,x) = u_0(x)$ and $\frac{\partial u}{\partial t}(0,x) = u_1(x)$. This provides a strong formulation of the stacked actuator model.

To define a weak or variational form of the model which is appropriate for well-posedness analysis, approximation, or control design, states $z = (u(\cdot), u(\ell))$ are con-

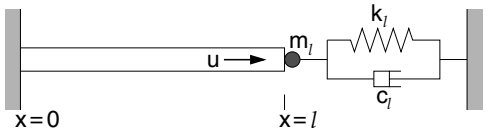

FIG. 7. *Rod of length ℓ and cross-sectional area A with a fixed end at $x = 0$ and energy dissipating boundary conditions at $x = \ell$.*

sidered in the state space $X = L^2(0,\ell) \times \mathbb{R}$ with the inner product

$$\langle \Phi_1, \Phi_2 \rangle_X = \int_0^\ell \rho A \phi_1 \phi_2 dx + m_\ell \varphi_1 \varphi_2, \tag{17}$$

where $\Phi_1 = (\phi_1, \varphi_1), \Phi_2 = (\phi_2, \varphi_2)$ with $\varphi_1 = \phi_1(\ell)$, $\varphi_2 = \phi_1(\ell)$. The space of test functions is taken to be

$$V = \left\{ \Phi = (\phi, \varphi) \in X \,|\, \phi \in H^1(0,\ell), \phi(0) = 0, \phi(\ell) = \varphi \right\}$$

with the inner product

$$\langle \Phi_1, \Phi_2 \rangle_V = \int_0^\ell Y A \phi_1' \phi_2' dx + k_\ell \varphi_1 \varphi_2. \tag{18}$$

Multiplication by $\phi \in H_0^1(0,\ell) = \{\phi \in H^1(0,\ell) \,|\, \phi(0) = 0\}$ and integration by parts in space yields the weak model formulation

$$\begin{aligned} &\int_0^\ell \rho A \frac{\partial^2 u}{\partial t^2} \phi dx + \int_0^\ell \left[Y A \frac{\partial u}{\partial x} + C A \frac{\partial^2 u}{\partial x \partial t} \right] \frac{d\phi}{dx} dx \\ &\qquad = \int_0^\ell f \phi dx + A \left[a_1 (P - P_R) + a_2 (P - P_R)^2 \right] \int_0^\ell \frac{d\phi}{dx} dx \\ &\qquad\quad - \left[k_\ell u(t,\ell) + c_\ell \frac{\partial u}{\partial t}(t,\ell) + m_\ell \frac{\partial^2 u}{\partial t^2}(t,\ell) \right] \phi(\ell), \end{aligned} \tag{19}$$

which must be satisfied for all $\phi \in V$.

3.1.2. Lumped rod model. The assumption that fields and stresses are uniform along the rod length motivates the conclusion that strains (relative displacements) also exhibit negligible x-dependence. Since the position of the sample is dictated by the position of the rod tip at $x = \ell$, this motivates the development of a lumped model which quantifies $u_\ell(t) = u(t,\ell)$.

From the assumption of uniform strains along the rod length, we take

$$\varepsilon(t) = \frac{u_\ell(t)}{\ell}$$

in (14). Balancing the forces σA for the rod with those of the restoring mechanism yields the lumped model

$$\begin{aligned} \rho A \ell \frac{d^2 u_\ell}{dt^2}(t) + \frac{CA}{\ell} \frac{du_\ell}{dt}(t) + \frac{YA}{\ell} u_\ell(t) &= -m_\ell \frac{d^2 u_\ell}{dt^2}(t) - c_\ell \frac{du_\ell}{dt}(t) - k u_\ell(t) \\ &\quad + A a_1 [P(E(t)) - P_R] + A a_2 [P(E(t)) - P_R]^2 \end{aligned}$$

or, equivalently,

$$m \frac{d^2 u_\ell}{dt^2}(t) + c \frac{du_\ell}{dt}(t) + k u_\ell(t) = \widetilde{a}_1 [P(E(t)) - P_R] + \widetilde{a}_2 [P(E(t)) - P_R]^2, \tag{20}$$

where

$$m = \rho A \ell + m_\ell, \quad c = \frac{CA}{\ell} + c_\ell, \quad k = \frac{YA}{\ell} + k_\ell, \quad \widetilde{a}_1 = A a_1, \quad \widetilde{a}_2 = A a_2, \tag{21}$$

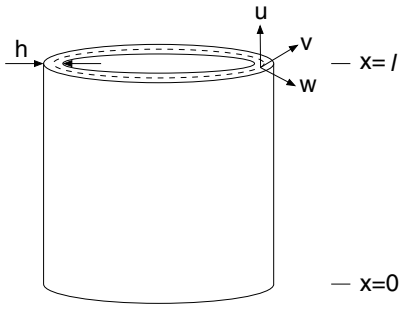

FIG. 8. *Orientation of the shell geometry used when quantifying the longitudinal, circumferential, and transverse displacements u, v, and w.*

and the initial conditions are $u_\ell(0) = u_0$ and $\frac{du_\ell}{dt}(0) = u_1$. The polarization P is specified by the model (11) or discretized model (13).

The model can also be written as the first-order system

$$\begin{aligned} \dot{\vec{u}}_\ell(t) &= A\vec{u}_\ell(t) + \vec{\mathcal{P}}(E(t)), \\ \vec{u}_\ell(0) &= \vec{u}_0, \end{aligned} \tag{22}$$

where $\vec{u}_\ell(t) = [u_\ell(t), \dot{u}_\ell(t)]^T$, $\vec{u}_\ell(0) = [u_0, u_1]^T$ and

$$A = \begin{bmatrix} 0 & 1 \\ -k/m & -c/m \end{bmatrix},$$

$$\vec{\mathcal{P}}(E(t)) = \frac{1}{m}\left[\widetilde{a}_1(P(E(t)) - P_R) + \widetilde{a}_2(P(E(t)) - P_R)^2\right] \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

3.2. Cylindrical shell model. To quantify the dynamics of the cylindrical stage depicted in Figure 2(b), we construct a linear shell model with nonlinear inputs quantified by the 2-D constitutive relation (15). We focus on the actuator employed for transverse displacements since real-time control of this component is required to maintain constant forces between the sample and microcantilever. The mass of the shell employed for horizontal translation is combined with the mass of the sample to provide an inertial force acting on the free end of the vertical actuator.

For modeling purposes, we assume that the shell has length ℓ, thickness h, and radius R. The axial direction is specified along the x-axis, and the longitudinal, circumferential, and transverse displacements are respectively denoted by u, v, and w, as depicted in Figure 8. The density is designated by ρ, and the region occupied by the reference or middle surface of the shell is specified by $\Gamma_0 = [0, \ell] \times [0, 2\pi]$. In accordance with the constitutive relations (15), Y, C, and ν denote the Young's modulus, Kelvin–Voigt damping coefficient, and Poisson ratio for the material. We point out that $\varepsilon_x, \varepsilon_\theta$, and $\varepsilon_{x\theta}$ in (15) denote strains at points throughout the shell thickness, whereas 2-D shell models are formulated in terms of strains e_x, e_θ, and $e_{x\theta}$ in the reference surface of the shell. The relationship between the two is established through the assumption that displacements are linear through the shell thickness, which comprises one of the fundamental tenets of linear shell theory [3, 30].

We consider the case in which the bottom edge of the shell ($x = 0$) is clamped and the opposite end ($x = \ell$) is acted upon only by the inertial force associated with the combined mass m of the x-y actuator and the sample.

As detailed in [3, 30], force and moment balancing yield the Donnell–Mushtari shell equations

$$
\begin{aligned}
&R\rho h\frac{\partial^2 u}{\partial t^2} - R\frac{\partial N_x}{\partial x} - \frac{\partial N_{x\theta}}{\partial \theta} = 0,\\
&R\rho h\frac{\partial^2 v}{\partial t^2} - \frac{\partial N_\theta}{\partial \theta} - R\frac{\partial N_{x\theta}}{\partial x} = 0,\\
&R\rho h\frac{\partial^2 w}{\partial t^2} - R\frac{\partial^2 M_x}{\partial x^2} - \frac{1}{R}\frac{\partial^2 M_\theta}{\partial \theta^2} - 2\frac{M_{x\theta}}{\partial x\partial \theta} + N_\theta = 0,
\end{aligned}
\tag{23}
$$

where the force and moment resultants are

$$
\begin{aligned}
N_x &= \frac{Yh}{1-\nu^2}(e_x + \nu e_\theta) + \frac{Ch}{1-\nu^2}(\dot{e}_x + \nu \dot{e}_\theta) - \frac{h}{1-\nu}[a_1(P-P_R) + a_2(P-P_R)^2],\\
N_\theta &= \frac{Yh}{1-\nu^2}(e_\theta + \nu e_x) + \frac{Ch}{1-\nu^2}(\dot{e}_\theta + \nu \dot{e}_x) - \frac{h}{1-\nu}[a_1(P-P_R) + a_2(P-P_R)^2],\\
N_{x\theta} &= \frac{Yh}{2(1+\nu)}e_{x\theta} + \frac{Ch}{2(1+\nu)}\dot{e}_{x\theta}
\end{aligned}
\tag{24}
$$

and

$$
\begin{aligned}
M_x &= \frac{Yh^3}{12(1-\nu^2)}(\kappa_x + \nu\kappa_\theta) + \frac{Ch^3}{12(1-\nu^2)}(\dot{\kappa}_x + \nu\dot{\kappa}_\theta),\\
M_\theta &= \frac{Yh^3}{12(1-\nu^2)}(\kappa_\theta + \nu\kappa_x) + \frac{Ch^3}{12(1-\nu^2)}(\dot{\kappa}_\theta + \nu\dot{\kappa}_x),\\
M_{x\theta} &= \frac{Yh^3}{24(1+\nu)}\kappa_{x\theta} + \frac{Ch^3}{24(1+\nu)}\dot{\kappa}_{x\theta}.
\end{aligned}
\tag{25}
$$

The midsurface strains and changes in curvature are

$$
\begin{aligned}
&e_x = \frac{\partial u}{\partial x}, \quad e_\theta = \frac{1}{R}\frac{\partial v}{\partial \theta} + \frac{w}{R}, \quad e_{x\theta} = \frac{\partial v}{\partial x} + \frac{1}{R}\frac{\partial u}{\partial \theta},\\
&\kappa_x = -\frac{\partial^2 w}{\partial x^2}, \quad \kappa_\theta = -\frac{1}{R^2}\frac{\partial^2 w}{\partial \theta^2}, \quad \kappa_{x\theta} = -\frac{2}{R}\frac{\partial^2 w}{\partial x\partial \theta}.
\end{aligned}
\tag{26}
$$

The boundary conditions for the fixed-end at $x = 0$ are taken to be

$$u = v = w = \frac{\partial w}{\partial x} = 0,$$

whereas the conditions

$$
\begin{aligned}
&N_x = -m\frac{\partial^2 u}{\partial t^2}, \qquad && N_{x\theta} + \frac{M_{x\theta}}{R} = 0,\\
&Q_x + \frac{1}{R}\frac{\partial M_{x\theta}}{\partial \theta} = 0, \qquad && M_x = 0,
\end{aligned}
$$

are employed at $x = \ell$. The first resultant condition incorporates the inertial force due to the mass m of the PZT actuator employed for x-y translation along with the mass of the sample.

To reduce smoothness requirements for approximation and eliminate the Dirac behavior of external inputs at $x = \ell$, we also consider a weak formulation of the model. The state is taken to be $z = (u(\cdot,\cdot), v(\cdot,\cdot), w(\cdot,\cdot), u(\ell,\cdot))$ in the state space

$$X = L^2(\Omega) \times L^2(\Omega) \times L^2(\Omega) \times L^2(0, 2\pi),$$

where

$$\Omega = [0, \ell] \times [0, 2\pi]$$

denotes the shell region. The space of test functions is specified as

$$V = \left\{ \Phi = (\phi_1, \phi_2, \phi_3, \eta) \in X \,|\, \phi_1 \in H_0^1(\Omega), \phi_2 \in H_0^1(\Omega), \phi_3 \in H_0^2(\Omega) \right\},$$

where $\eta(\theta) = \phi_1(\ell, \theta)$ and

$$\begin{aligned} H_0^1(\Omega) &= \left\{ \phi \in H^1(\Omega) \,|\, \phi(0,\theta) = 0 \right\}, \\ H_0^2(\Omega) &= \left\{ \phi \in H^2(\Omega) \,|\, \phi(0,\theta) = \phi'(0,\theta) = 0 \right\}. \end{aligned} \tag{27}$$

Through either variation principles—e.g., see [3]—or integration by parts, one obtains the weak formulation of the thin shell model,

$$\begin{aligned} &\int_\Omega \left\{ R\rho h \frac{\partial^2 u}{\partial t^2}\phi_1 + RN_x \frac{\partial \phi_1}{\partial x} + N_{x\theta}\frac{\partial \phi_1}{\partial \theta} \right\} d\omega = 0, \\ &\int_\Omega \left\{ R\rho h \frac{\partial^2 v}{\partial t^2}\phi_2 + N_\theta \frac{\partial \phi_2}{\partial \theta} + RN_{x\theta}\frac{\partial \phi_2}{\partial x} \right\} d\omega = 0, \\ &\int_\Omega \left\{ R\rho h \frac{\partial^2 w}{\partial t^2}\phi_3 - RM_x \frac{\partial^2 \phi_3}{\partial x^2} - 2M_{x\theta}\frac{\partial^2 \phi_3}{\partial x \partial \theta} - \frac{1}{R} M_\theta \frac{\partial^2 \phi_3}{\partial \theta^2} + N_\theta \phi_3 \right\} d\omega = 0, \end{aligned} \tag{28}$$

which must be satisfied for all $\Phi \in V$. The resultants are given by (24) and (25) with midsurface strains and changes in curvature designated in (26).

Remark 5. It is noted that the d_{31} poling, used to generate vertical motion in the stage, produces no polarization contributions to the moments. However, transverse displacements w in the shell model are generated by the N_θ resultant in the w relation, and hence all three components of the displacement are coupled.

3.3. Frequency-dependent dynamics. One of the requirements of the nanopositioner models is the capability to characterize the frequency-dependent behavior shown in Figure 2. This behavior is due to a combination of dielectric losses, thermal relaxation processes, and elastic and damping properties, and it is incorporated in the framework in two places. The dielectric losses and relaxation behavior are incorporated through the balance of the Gibbs and relative thermal energies via the Boltzmann relation (7) and subsequent average polarization relations (9) and likelihood expressions (10). Hence this component of the polarization model incorporates the property that dipole dynamics can lag behind field dynamics as frequencies are increased. Dynamics associated with inertial, elastic, and internal damping properties of the actuators are incorporated through the force balances (16) and (23) and resultant definitions. In combination, this provides the framework with significant flexibility regarding a range of dynamics operating regimes.

4. Model well-posedness.

4.1. Rod model. To provide a framework which facilitates the establishment of criteria that guarantee the existence of a unique solution to the distributed rod model with nonlinear inputs, we consider a Hilbert space formulation of the weak model formulation (19) with the state and test function spaces

$$X = L^2(0,\ell) \times \mathbb{R},$$
$$V = \left\{\Phi = (\phi,\varphi) \in X \,|\, \phi \in H^1(0,\ell), \phi(0) = 0, \phi(\ell) = \varphi\right\}$$

and inner products

$$\begin{aligned} \langle \Phi_1, \Phi_2 \rangle_X &= \int_0^\ell \rho A \phi_1 \phi_2 dx + m_\ell \varphi_1 \varphi_2, \\ \langle \Phi_1, \Phi_2 \rangle_V &= \int_0^\ell Y A \phi_1' \phi_2' dx + k_\ell \varphi_1 \varphi_2, \end{aligned} \tag{29}$$

where $\Phi_1 = (\phi_1, \varphi_1), \Phi_2 = (\phi_2, \varphi_2)$ with $\varphi_1 = \phi_1(\ell)$, $\varphi_2 = \phi_1(\ell)$.

It is observed that V is densely and continuously embedded in X with $|\Phi|_X \leq c|\Phi|_V$; this is expressed by $V \hookrightarrow X$. Moreover, when one defines conjugate dual spaces X^* and V^*—e.g., V^* denotes the linear space of all conjugate linear continuous functionals on V—two observations are important: (i) X^* can be identified with X through the Riesz map and (ii) $X^* \hookrightarrow V^*$. Hence the two spaces comprise what is termed a Gelfand triple, $V \hookrightarrow X \cong X^* \hookrightarrow V^*$ with pivot space X and duality pairing (duality product) $\langle \cdot, \cdot \rangle_{V^*,V}$. The latter is defined as the extension by continuity of the inner product $\langle \cdot, \cdot \rangle_X$ from $V \times X$ to $V^* \times X$. Hence elements $v^* \in V^*$ have the representation $v^*(v) = \langle v^*, v \rangle_{V^*,V}$.

We now define the stiffness and damping sesquilinear forms $\sigma_i : V \times V \to \mathbb{C}$, $i = 1, 2$, by

$$\begin{aligned} \sigma_1(\Phi_1, \Phi_2) &= \langle \Phi_1, \Phi_2 \rangle_V, \\ \sigma_2(\Phi_1, \Phi_2) &= \int_0^\ell C A \phi_1' \phi_2' dx + c_\ell \varphi_1 \varphi_2. \end{aligned} \tag{30}$$

It can be directly verified that the stiffness form satisfies

$$\begin{aligned} &\text{(H1)} \quad |\sigma_1(\Phi_1, \Phi_2)| \leq c_1 |\Phi_1|_V |\Phi_2|_V \text{ for some } c_1 \in \mathbb{R} \qquad \text{(bounded)}, \\ &\text{(H2)} \quad \operatorname{Re} \sigma_1(\Phi_1, \Phi_1) \geq c_2 |\Phi_1|_V^2 \text{ for some } c_2 > 0 \qquad (V\text{-elliptic}), \\ &\text{(H3)} \quad \sigma_1(\Phi_1, \Phi_2) = \overline{\sigma_1(\Phi_2, \Phi_1)} \qquad \text{(symmetric)}, \end{aligned}$$

for all $\psi, \phi \in V$. Moreover, the damping term σ_2 satisfies

$$\begin{aligned} &\text{(H4)} \quad |\sigma_2(\Phi_1, \Phi_2)| \leq c_3 |\Phi_1|_V |\Phi_2|_V \text{ for some } c_3 \in \mathbb{R} \qquad \text{(bounded)}, \\ &\text{(H5)} \quad \operatorname{Re} \sigma_2(\Phi_1, \Phi_1) \geq c_4 |\Phi_1|_V^2 \text{ for some } c_4 > 0 \qquad (V\text{-elliptic}). \end{aligned} \tag{31}$$

The input space is taken to be the Hilbert space $U = \mathbb{R}$, and the input operator $B : U \to V^*$ is defined by

$$\langle [B(E)](t), \Phi \rangle_{V^*,V} = \left[a_1(P(E(t)) - P_R) + a_2(P(E(t)) - P_R)^2\right] \int_0^\ell \phi' \, dx \tag{32}$$

for $\Phi = (\phi, \varphi)$ with $\varphi = \phi(\ell)$. It is observed that B can be expressed as

$$[B(E)](t) = [b(E)](t) \cdot g, \qquad g \in V^*, \tag{33}$$

where

$$\begin{aligned} &[b(E)](t) = (P(E(t)) - P_R) + a_2(P(E(t)) - P_R)^2, \\ &g(\Phi) = \int_0^\ell \phi' \, dx. \end{aligned} \tag{34}$$

The model (19) can then be written in the abstract weak formulation

$$\begin{aligned} &\langle \ddot{u}(t), \Phi \rangle_{V^*,V} + \sigma_2(\dot{u}(t), \Phi) + \sigma_1(u(t), \Phi) = \langle [B(E)](t), \Phi \rangle_{V^*,V}, \\ &u(0) = u_0, \quad \dot{u}(0) = u_1, \end{aligned} \tag{35}$$

for all $\Phi \in V$.

Alternatively, one can define the operators $A_i \in \mathcal{L}(V, V^*), i = 1, 2$, by

$$\langle A_i \Phi_1, \Phi_2 \rangle_{V^*,V} = \sigma_i(\Phi_1, \Phi_2) \tag{36}$$

and formulate the model in operator form as

$$\begin{aligned} &\ddot{u}(t) + A_2 \dot{u}(t) + A_1 u(t) = [B(E)](t), \\ &u(0) = u_0, \quad \dot{u}(0) = u_1, \end{aligned} \tag{37}$$

in the dual space V^*. This formulation illustrates the analogy between the infinite-dimensional, strongly damped elastic model and the familiar finite-dimensional relations (22).

4.1.1. Model well-posedness. As a prelude to establishing the well-posedness of the beam model with hysteretic E-P relations, we provide a lemma which quantifies the smoothness of the input operator.

LEMMA 1. *Consider field inputs $E \in C[0,T]$. The input operator B defined by* (32) *then satisfies*

$$B(E) \in L^2(0, T; V^*). \tag{38}$$

Proof. In the appendix, we establish that for continuous input fields E the polarization satisfies $P \in C[0,T]$, which implies that b defined by (34) satisfies $b(\cdot) : C[0,T] \to C[0,T]$. Hence the norm

$$\|[B(E)](t)\|_{V^*} = \sup_{v \in V} \frac{|[b(E)](t) \cdot g(v)|}{\|v\|_V}$$

exists for each $t \in [0,T]$. Since $\|[B(E)](t)\|_{V^*} = |[b(E)](t)| \cdot \|g\|_{V^*}$, it follows that

$$\|B(E)\|^2_{L^2(0,T;V^*)} \leq \max_{t \in [0,T]} \left\{ |[b(E)](t)|^2 \right\} \cdot T \cdot \|g\|^2_{V^*},$$

which implies that

$$B(E) \in L^2(0, T; V^*). \qquad \square$$

The well-posedness of the model is established by the following theorem, whose proof follows directly from Theorem 4.1 of [3] or Theorem 2.1 and Remark 2.1 of [2].

THEOREM 2. *Let σ_1 and σ_2 be given by* (30)*, and consider continuous field inputs $E \in C[0,T]$. There then exists a unique solution w to* (35)*, or equivalently* (37)*, which satisfies*

$$u \in C(0,T;V),$$
$$\dot{u} \in C(0,T;X).$$

4.2. Shell model. Similar well-posedness results can be obtained for the shell model (28) through consideration of an analogous Hilbert space formulation of the model. Details regarding the construction of appropriate inner product spaces, sesquilinear forms, and operators can be found in [30, 35].

5. Numerical approximation techniques. To implement the distributed models for either the rectangular stacked actuator or the cylindrical actuator, it is necessary to develop appropriate approximation techniques to discretize the modeling PDE. To accomplish this, we consider general Galerkin methods in which basis functions are comprised of spline or spline-Fourier tensor products. The resulting methods can accommodate a variety of boundary conditions, are sufficiently accurate to resolve fine-scale dynamics, and can be employed for constructing reduced-order proper orthogonal decomposition approximates for real-time implementation.

5.1. Stacked actuator model. To approximate the weak form of the stacked actuator model (19), we employ a finite element discretization and a finite difference discretization in time. The semidiscrete system resulting from the finite element approximation is appropriate for finite-dimensional continuous time control design, whereas the fully discrete system is amenable to simulations and control implementation.

To obtain a semidiscrete system, we consider a uniform partition of $[0,\ell]$ with points $x_j = jh$, $j = 0,1,\dots,N$, with step size $h = \ell/N$, where N denotes the number of subintervals. The spatial basis $\{\phi_j\}_{j=1}^N$ is then comprised of linear splines

$$\phi_j(x) = \frac{1}{h}\begin{cases} (x - x_{j-1}), & x_{j-1} \le x < x_j, \\ (x_{j+1} - x), & x_j \le x \le x_{j+1}, \\ 0, \quad \text{otherwise}, \end{cases} \qquad i = 1,\dots,N-1,$$

$$\phi_N(x) = \frac{1}{h}\begin{cases} (x - x_{N-1}), & x_{N-1} \le x \le x_N, \\ 0, \quad \text{otherwise} \end{cases}$$

(see [25] for details regarding the convergence analysis for the method). The solution $u(t,x)$ to (19) is subsequently approximated by the expansion

$$u^N(t,x) = \sum_{j=1}^{N} u_j(t)\phi_j(x)\,.$$

Through construction, the approximate solution satisfies the essential boundary condition $u^N(t,0) = 0$ and can attain arbitrary displacements at $x = \ell$.

The projection of the problem (19) onto the finite-dimensional subspace V^N yields the semidiscrete system

$$\begin{aligned} &\dot{\mathbf{z}}(t) = \mathbb{A}\,\mathbf{z}(t) + A\left[a_1(P(t)-P_R) + a_2(P(t)-P_R)^2\right]\mathbf{B}, \\ &\mathbf{z}(0) = \mathbf{z}_0, \end{aligned} \tag{39}$$

where $\mathbf{z}(t) = [u_1(t), \ldots, u_N(t), \dot{u}_1(t), \ldots, \dot{u}_N(t)]^T$ and

$$\mathbb{A} = \begin{bmatrix} 0 & \mathbb{I} \\ -\mathbb{M}^{-1}\mathbb{K} & -\mathbb{M}^{-1}\mathbb{Q} \end{bmatrix}, \qquad \mathbf{B} = \begin{bmatrix} 0 \\ \mathbb{M}^{-1}\mathbf{b} \end{bmatrix}. \tag{40}$$

The mass, stiffness, and damping matrices have the components

$$[\mathbb{M}]_{ij} = \begin{cases} \displaystyle\int_0^\ell \rho A \phi_i \phi_j \, dx, & i \neq N \text{ or } j \neq N, \\ \displaystyle\int_0^\ell \rho A \phi_i \phi_j \, dx + m_\ell, & i = N \text{ and } j = N, \end{cases}$$

$$[\mathbb{K}]_{ij} = \begin{cases} \displaystyle\int_0^\ell Y A \phi_i' \phi_j' \, dx, & i \neq N \text{ or } j \neq N, \\ \displaystyle\int_0^\ell Y A \phi_i' \phi_j' \, dx + k_\ell, & i = N \text{ and } j = N, \end{cases}$$

and

$$[\mathbb{Q}]_{ij} = \begin{cases} \displaystyle\int_0^\ell c A \phi_i' \phi_j' \, dx, & i \neq N \text{ or } j \neq N, \\ \displaystyle\int_0^\ell c A \phi_i' \phi_j' \, dx + c_\ell, & i = N \text{ and } j = N\,, \end{cases}$$

and the force vector is defined by

$$[\mathbf{b}\,]_i = \int_0^\ell \phi_i' dx.$$

The system (39) can be employed for finite-dimensional control design. For subsequent implementation, we consider a temporal discretization of (39) using a modified trapezoid rule. For temporal stepsizes Δt, this yields the difference equation

$$\mathbf{z}_{k+1} = \mathbb{W}\mathbf{z}_k + \frac{1}{2}\left[a_1\widetilde{P}(t_k) + a_1\widetilde{P}(t_{k+1}) + a_2\widetilde{P}^2(t_k) + a_2\widetilde{P}^2(t_{k+1})\right]\mathbb{V}\mathbf{B}, \tag{41}$$

where $\widetilde{P} = P - P_R$, $t_j = j\Delta t$, $\mathbf{z}_j$ approximates $\mathbf{z}(t_j)$, and

$$\mathbb{W} = \left(\mathbb{I} - \frac{\Delta t}{2}\mathbb{A}\right)^{-1}\left(\mathbb{I} + \frac{\Delta t}{2}\mathbb{A}\right), \qquad \mathbb{V} = \Delta t\left(\mathbb{I} - \frac{\Delta t}{2}\mathbb{A}\right)^{-1}.$$

This yields an A-stable method requiring moderate storage and providing moderate accuracy.

5.2. Cylindrical actuator model. Due to the inherent coupling between longitudinal, circumferential, and transverse displacements in combination with the 2-D support of the middle surface, the numerical approximation of the model for the cylindrical actuator is significantly more complicated than the approximation of the stacked actuator model. Among the issues which must be addressed when constructing finite element or general Galerkin methods for the shell is the choice of elements which avoid shear and membrane locking and the maintenance of boundary conditions. We summarize here a spline-based Galerkin method developed in [9] for thin shells and direct the reader to that source for details regarding the construction of constituent matrices and convergence properties of the method. Details regarding the use of this approximation method for LQR (linear quadratic regulator) control of shells utilizing PZT actuators can be found in [10].

The bases for the u, v, and w displacements are respectively taken to be

$$\Phi_{u_k}(\theta, x) = e^{im\theta}\phi_{u_n}(x), \quad \Phi_{v_k}(\theta, x) = e^{im\theta}\phi_{v_n}(x), \quad \Phi_{w_k}(\theta, x) = e^{im\theta}\phi_{w_n}(x),$$

where ϕ_{u_n}, ϕ_{v_n}, and ϕ_{w_n} are cubic B-splines modified to satisfy the boundary conditions (e.g., see p. 79 of [25]). The approximating subspaces are

$$V_u^N = \operatorname{span}\{\Phi_{u_k}\}_{k=1}^{N_u}, \quad V_v^N = \operatorname{span}\{\Phi_{v_k}\}_{k=1}^{N_v}, \quad V_w^N = \operatorname{span}\{\Phi_{w_k}\}_{k=1}^{N_w},$$

and the approximate displacements are represented by the expansions

$$\begin{aligned} u^N(t,\theta,x) &= \sum_{k=1}^{N_u} u_k(t)\Phi_{u_k}(\theta,x), \\ v^N(t,\theta,x) &= \sum_{k=1}^{N_v} v_k(t)\Phi_{v_k}(\theta,x), \\ w^N(t,\theta,x) &= \sum_{k=1}^{N_w} w_k(t)\Phi_{w_k}(\theta,x). \end{aligned} \tag{42}$$

The restriction of the problem (28) to the approximating subspaces and construction of the forcing vectors subsequently yields the matrix system

$$\begin{aligned} &\dot{\mathbf{z}}^N(t) = \mathbb{A}\,\mathbf{z}(t) + \left[a_1(P(t) - P_R) + a_2(P(t) - P_R)^2\right]\mathbf{B}, \\ &\mathbf{z}(0) = \mathbf{z}_0, \end{aligned} \tag{43}$$

where $\mathbf{z} = [\boldsymbol{\vartheta}(t), \dot{\boldsymbol{\vartheta}}(t)]^T$, with $\boldsymbol{\vartheta}(t) = [\mathbf{u}(t), \mathbf{v}(t), \mathbf{w}(t)]^T$, and

$$\mathbb{A} = \begin{bmatrix} 0 & \mathbb{I} \\ -\mathbb{M}^{-1}\mathbb{K} & -\mathbb{M}^{-1}\mathbb{Q} \end{bmatrix}, \qquad \mathbf{B} = \begin{bmatrix} 0 \\ \mathbb{M}^{-1}\mathbf{b} \end{bmatrix}.$$

The reader is referred to [9, 30] for details concerning the construction of the mass, stiffness, and damping matrices $\mathbb{M}, \mathbb{K}$, and $\mathbb{Q}$.

6. Model validation.

6.1. Characterization of the stacked actuator. We consider the capability of the modeling framework for characterizing the dynamics of the stacked actuator depicted in Figure 2(a). The PZT actuator had a length of $\ell = 2 \times 10^{-2}$ m and a

TABLE 1
Parameters employed in the distributed (PDE) model (19) *and lumped (ODE) model* (20) *for the stacked actuator.*

Distributed model					
Parameter	ρ	Y	C	m_ℓ	
value	7600	7×10^{10}	5×10^6	4.015	
Parameter	k_ℓ	c_ℓ	a_1	a_2	
value	8.49×10^{-5}	440	1.54×10^{11}	0	
Lumped model					
Parameter	m	k	c	$\widetilde{a}_1$	$\widetilde{a}_2$
value	4.21	8.75×10^7	1.52×10^5	8.75×10^7	0

square cross-sectional face of width $w = 5 \times 10^{-3}$ m, so that the cross-sectional area is $A = 2.5 \times 10^{-5}$ m^2. As illustrated in Figure 7, one end of the actuator was considered fixed, whereas the other encountered elastic, damping, and inertial effects due to the attached components of the stage mechanism.

To validate and illustrate properties of the models, we consider three regimes: (i) end displacements quantified by the lumped model (20) with the thermally inactive kernel (6) employed in the polarization model (14), (ii) displacements characterized by the lumped model with the thermally active polarization kernel (8), and (iii) end displacements quantified by the discretization (41) of the distributed model (19). It is illustrated that whereas the latter choice incorporates the distributed rod nature of the device, the fact that fields and stresses are uniform along the rod length implies that relative displacements are also uniform. A comparison of the ODE and PDE model predictions at the rod tip ($x = \ell$) illustrates that, as a result, the ODE provides a highly accurate characterization with significantly less computation cost. Hence the ODE model is advantageous for real-time experimental implementation.

The construction of the models requires the estimation of elastic, damping, and electromechanical parameters in addition to identification of the densities ν_1 and ν_2. The densities were estimated through least squares fits to the data using the techniques detailed in [30, 32]. The manufacturer specifications $\rho = 7600$ kg/m^3 and $Y = 7 \times 10^{10}$ N/m^2 were employed for the density and Young's modulus, and remaining parameters were estimated through a least squares fit to the data. The resulting values are summarized in Table 1. The relation between the rod and spring parameters is provided by (21).

6.1.1. Lumped model—No thermal activation in polarization relation. We consider first the characterization of the biased minor loop data shown in Figure 3 and frequency-dependent data from Figure 4 using the lumped model (20) with the thermally inactive kernel (6) employed in the polarization model (14). It should be noted that the stage was disassembled between the quasi-static biased minor loop experiments and the frequency-dependent experiments, which necessitated the re-identification of densities for the two cases.

In the first set of experiments, displacement data measured with an LVDT (linear variable differential transformer) was collected at a sample rate of 0.1 Hz and four input field levels to generate a set of biased and nested transducer responses ranging from nearly linear to hysteretic and nonlinear, as shown in Figures 3 and 9. The densities ν_1 and ν_2 and parameters summarized in Table 1 were obtained through a least squares fit to the full data set comprised of four loops. The resulting model accurately quantifies both the nest behavior and the hysteresis measured at increasing

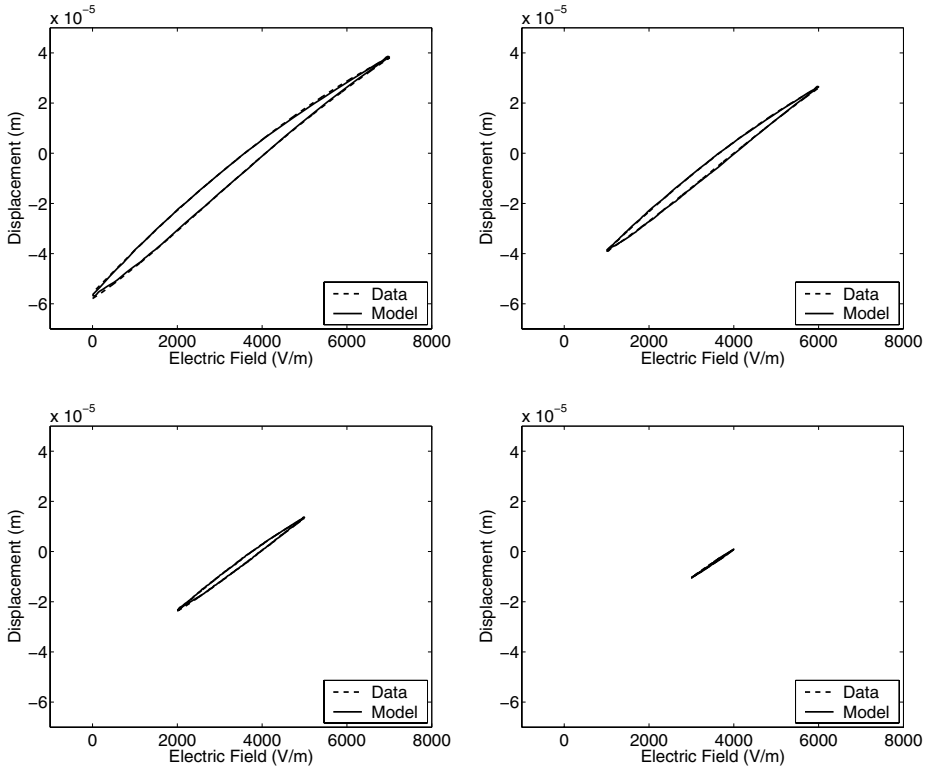

FIG. 9. *Characterization of AFM field-displacement behavior at* 0.1 *Hz using the ODE model* (20) *with the thermally inactive kernel* (6).

input levels.

In a second set of experiments, data was collected at frequencies ranging from 0.279 Hz to 27.9 Hz, yielding the behavior shown in Figure 4. These experiments took longer (approximately 30 minutes), which led to slight heating and accompanying changes in the material constitutive behavior. To accommodate these operating conditions, the data from four frequencies was used to reidentify parameters in the polarization model, thus yielding the fits shown in Figure 10. It is observed that the model characterizes the augmented hysteresis arising at higher frequencies but slightly overpredicts the increase in displacement following field reversal that is due primarily to inertial effects.

6.1.2. Lumped model—Thermal activation in polarization relation. We next employ the thermally active kernel (8) in the polarization model to incorporate relaxation effects. Parameters in the polarization model were again identified through a least squares fit to the four frequency data sets, thus yielding the model fit shown in Figure 11. It is observed that use of this more general kernel provides additional accuracy at higher frequencies. Whereas this improves characterization capabilities, the added accuracy comes at the cost of decreased efficiency, and the criteria of accuracy versus efficiency must be balanced when employing the model for real-time control design, as discussed in [16]. We note that use of the thermally active kernel (8) is required when characterizing the creep measured when one actuator is held fixed while a sweep is performed with the other.

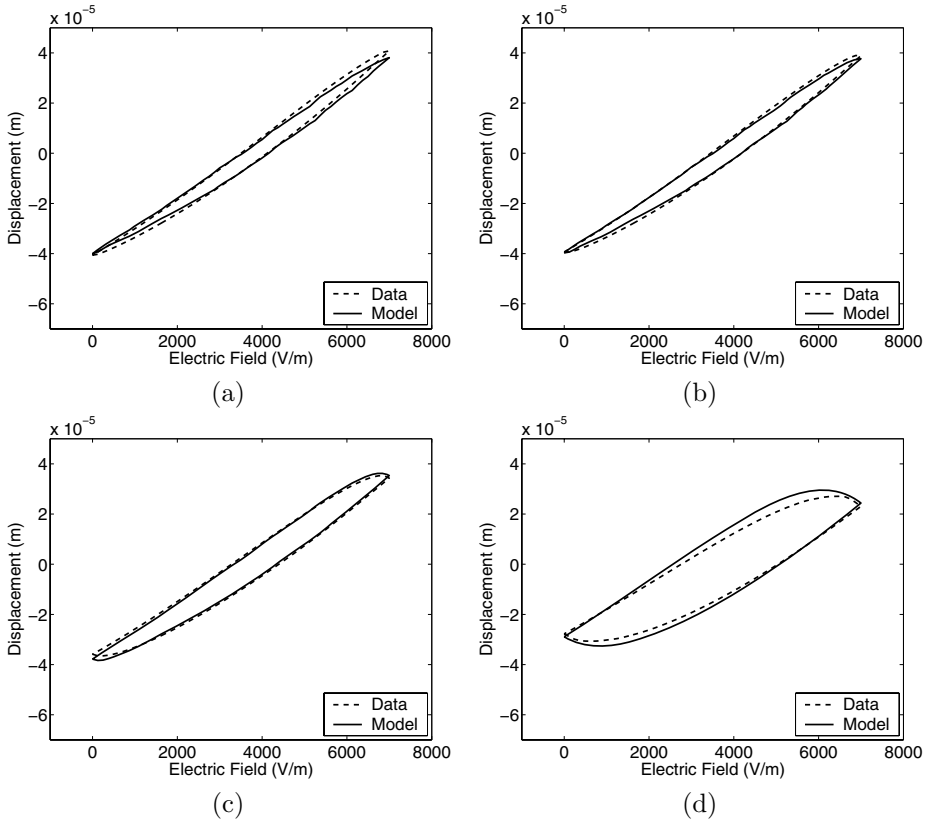

FIG. 10. *Characterization of AFM field-displacement behavior using the ODE model* (20) *with the* thermally inactive *kernel* (6)*, with sample rates of* (a) 0.279 *Hz,* (b) 1.12 *Hz,* (c) 5.58 *Hz, and* (d) 27.9 *Hz.*

6.1.3. Lumped model versus distributed model. It has been observed that whereas quantification of the physics of the stacked actuator leads to the rod model (19), the fact that stresses and fields are uniform along the rod length implies that relative displacements will also be uniform. This motivates consideration of the lumped model (20), which yielded the fits shown in Figures 10 and 11.

To illustrate the validity of this assumption, the difference between the displacement $u(t, \ell)$, given by the discretization (41) of (19) with $N = 16$ basis functions, and the displacement $u_\ell(t)$, resulting from (20), is plotted in Figure 12. We emphasize that when constructing the PDE model we employed the parameter values summarized in Table 1, which are *consistent* with the spring parameters due to the relation (21). The maximal difference of 5×10^{-10} is five orders of magnitude less than the micron-level displacements being characterized, thus verifying the validity of the ODE model in this regime. The accuracy of the ODE model has important ramifications for control design since the discretized ODE model is significantly more efficient to implement than the discretized PDE model.

6.2. Characterization of the shell actuator. We discuss here the performance of the cylindrical shell model detailed in section 3.2, when discretized using the Galerkin techniques summarized in section 5.2, for characterizing the longitudinal

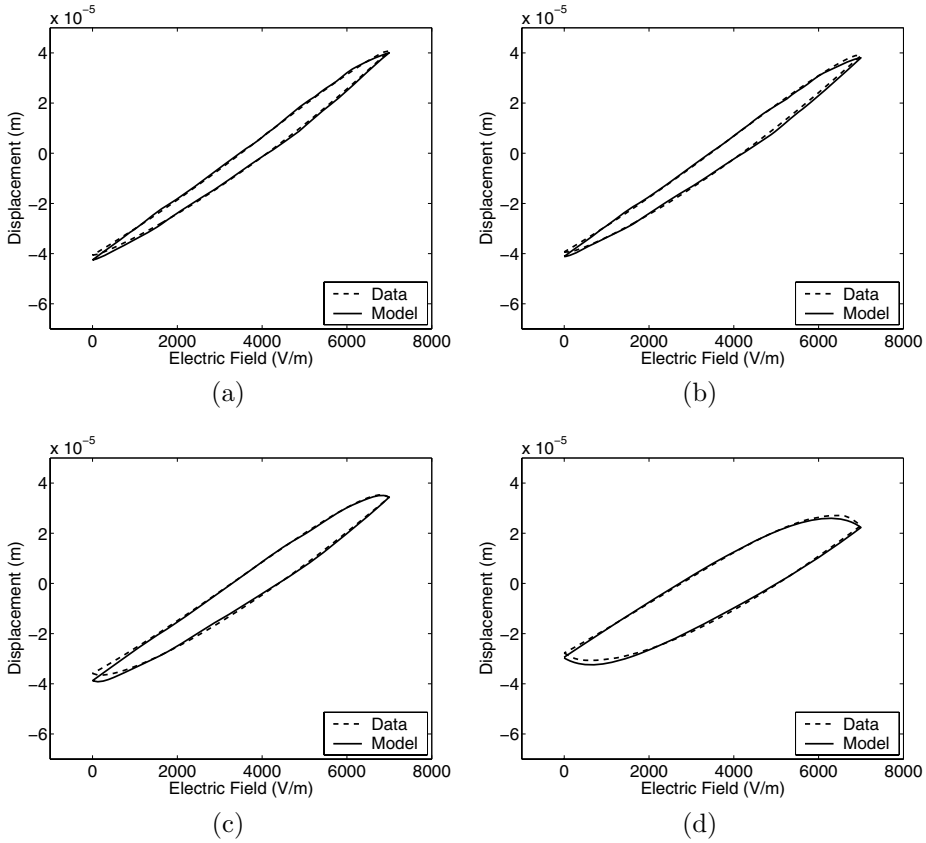

FIG. 11. *Characterization of AFM field-displacement behavior using the ODE model* (20) *with the* thermally active *kernel* (8)*, with sample rates of* (a) 0.279 *Hz,* (b) 1.12 *Hz,* (c) 5.58 *Hz, and* (d) 27.9 *Hz.*

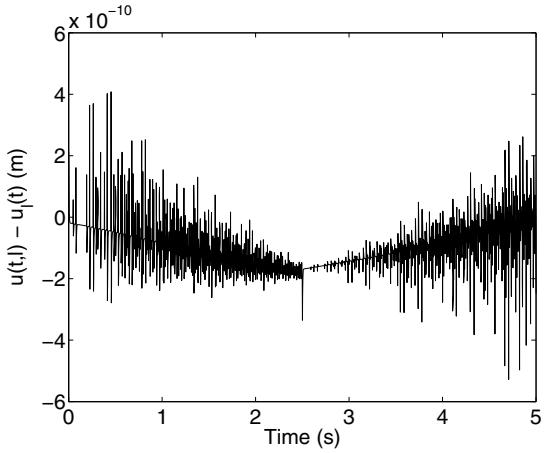

FIG. 12. *Difference between the displacement* $u(t, \ell)$ *given by the distributed model* (19) *and* $u_\ell(t)$ *given by the lumped model* (20).

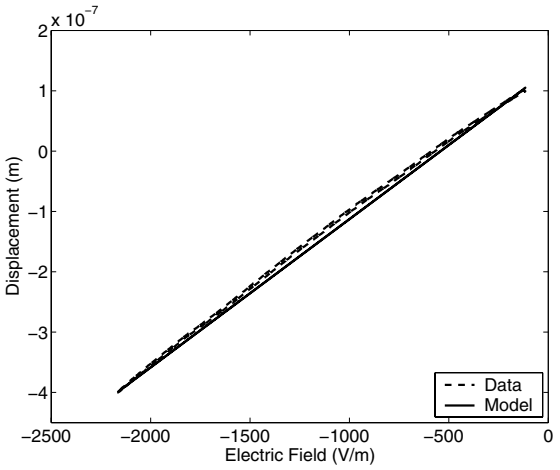

FIG. 13. *Characterization of the relation between the field and longitudinal displacements for the cylindrical actuator depicted in Figures* 2(b) *and* 7.

displacements of the cylindrical PZT shell transducer depicted in Figures 2(b) and 7. Whereas the cylindrical PZT elements employed in this design are more complex than the rod elements used in the stage design depicted in Figure 2(a), the overall transducer is simpler and has the advantage of enhanced vibration isolation and diminished hysteresis.

The experimental cylindrical transducer had a length of $\ell = 0.0396$ m, radius of $R = 0.0056$ m, and thickness of $h = 0.0015$ m. The manufacturer specifications $\rho = 7600$ kg/m^3 and $Y = 7.1 \times 10^10$ N/m^2 were employed for the density and Young's modulus, and remaining model parameters were estimated through a least squares fit to the data.

The longitudinal displacement u^N provided by (42) is compared in Figure 13 with experimental data collected under quasi-static operating conditions. We note that due to the inherent coupling between the longitudinal, circumferential, and transverse displacements, u, v, and w in the model (23), the approximate displacements (42) are also coupled and all are obtained through solution of (43)—we plot only u^N since it corresponds to measured data. For this operating regime, the dynamics were resolved with eight cubic B-splines in x and seven Fourier elements in θ, so $N_u = N_v = N_w = 56$.

The nearly linear behavior of the data reflects the low drive levels under consideration. The accurate fit provided by the model illustrates the property that the hysteretic E-P model (11) yields approximately linear behavior in low drive regimes. The fidelity of the model further illustrates the accuracy and flexibility of the modeling framework.

7. Concluding remarks. This characterization framework quantifies both the approximately linear and hysteretic properties of the PZT device employed in AFM positioning mechanisms. In the first step of the development, constitutive relations are constructed through a combination of energy analysis at the lattice level and stochastic homogenization techniques based on the assumption that certain parameters are manifestations of underlying distributions. These relations quantify the frequency-dependent hysteresis exhibited by the materials for general drive regimes

while reducing to approximately linear behavior at low drive regimes. In the second step of the development, these constitutive relations are used to construct lumped and distributed rod and shell models for the various PZT transducer geometries. The accuracy of the models is illustrated through comparison with experimental data from AFM stages.

An important property of the framework is the fact that resulting models can be approximately inverted with nearly the same efficiency as the forward models [16]. This provides a framework with the capability for providing inverse compensators for linear control design [22, 23]. The implementation of feedback control designs for high-speed scanning, using these model-based compensators, is under present investigation.

For either linear control designs employing model inverses or model-based nonlinear control designs, it is crucial that discretized models be implementable in real-time. For the stacked actuator model, discretization limits are sufficiently small (e.g., $2N = 32$ for the first-order system) to permit efficient implementation with present hardware. Furthermore, it was demonstrated that lumped models provide sufficient accuracy for the considered architecture. The behavior of the shell transducer is significantly more complex due to the coupling between longitudinal, circumferential and transverse displacements, and the construction of reduced-order models based on proper orthogonal decomposition (POD) techniques is under investigation.

Appendix. Continuity of the polarization model. We establish here the continuity of the homogenized energy model (11),

$$[P(E)](t) = \int_0^\infty \int_{-\infty}^\infty [\overline{P}(E + E_I; E_c, \xi)](t)\nu_1(E_c)\nu_2(E_I)\, dE_I\, dE_c, \tag{44}$$

as a function of both field and time in the case of negligible thermal activation. The densities ν_1 and ν_2 satisfy the conditions (12), and the kernel $\overline{P}$ has the form

$$\overline{P}(E) = \frac{E}{\eta} + P_R\delta(E; E_c, E_I)$$

specified in (6).

We first note that there are at most three values at which δ can change sign: $-E_c$, E_c, and $-E_c \le E_T \le E_c$. The third is determined by the initial dipole distribution ξ, as depicted in Figure 14(a), and is typically chosen so that $E_T = 0$ when $E + E_I = 0$.

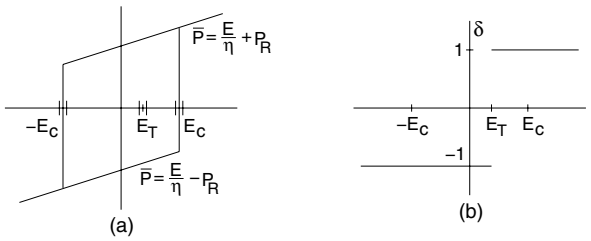

FIG. 14. (a) *Points* $E + E_I = -E_c, E_c$, *and* E_T *at which* $\delta = \pm 1$ *changes sign, and* (b) *behavior of* δ *associated with the initial dipole distribution at* $E + E_I = E_T$.

We also note that the decay conditions (12) dictate that ν_1 and ν_2 satisfy the relations

$$|\nu_2(E_I)| \leq c_2,$$

$$\int_{-\infty}^{\infty} \nu_2(E_I) dE_I \leq b_2,$$

$$\int_{0}^{\infty} \nu_1(E_c) dE_c \leq b_1,$$

where b_1, b_2, and c_2 are finite constants.

To establish the continuity of P with respect to E, we consider the behavior at field values E_0 and E_1, where without loss of generality we take $E_0 < E_1$. When integrating with respect to E_I, we decompose the interval $(-\infty, \infty)$ into seven regions delineated by the points $-E_c, E_c, E_T$, as shown in Figure 14(a). For this decomposition, we note that

$$\left|\overline{P}(E_1 + E_I; E_c, \xi) - \overline{P}(E_0 + E_I; E_c, \xi)\right| = \begin{cases} \frac{1}{\eta}(E_1 - E_0), & \text{region excludes} \\ & -E_c, E_c, E_T, \\ \frac{1}{\eta}(E_1 - E_0) + 2P_R, & \text{region includes} \\ & -E_c, E_c, E_T\,. \end{cases}$$

To consolidate notation, we define the integrals

$$I(a,b) = \int_a^b \frac{1}{\eta}(E_1 - E_0)\nu_2(E_I)\, dE_I,$$

$$I_{P_R}(a,b) = \int_a^b \left[\frac{1}{\eta}(E_1 - E_0) + 2P_R\right] \nu_2(E_I)\, dE_I.$$

It subsequently follows that

$$\begin{aligned} |P(E_1) - P(E_0)| \;\leq\; & \int_0^\infty \{|I(-\infty, -E_c - E_1)| + |I_{P_R}(-E_c - E_1, -E_c - E_0)| \\ & + |I(-E_c - E_0, E_T - E_1)| + |I_{P_R}(E_T - E_1, E_T - E_0)| \\ & + |I(E_T - E_0, E_c - E_1)| + |I_{P_R}(E_c - E_1, E_c - E_0)| \\ & + |I(E_c - E_0, \infty)|\}\, \nu_1(E_c)\, dE_c \\ \leq\; & (E_1 - E_0) \int_0^\infty \left\{\frac{4c_2}{\eta} + 3b_2\left[\frac{1}{\eta}(E_1 - E_0) + 2P_R\right]\right\} \nu_1(E_c)\, dE_c \\ \leq\; & (E_1 - E_0) b_1 \left(\frac{4c_2}{\eta} + 3b_2\left[\frac{1}{\eta}(E_1 - E_0) + 2P_R\right]\right). \end{aligned}$$

For $\varepsilon > 0$, take

$$\delta = \min\left\{\frac{\varepsilon}{b_1\left(\frac{4c_2}{\eta} + 3b_2\left[\frac{1}{\eta}(E_1 - E_0) + 2P_R\right]\right)}, 1\right\}.$$

Under the assumption that E is continuous in time and $E_0 = E(t_0), E_1 = E(t_1)$, for every $\delta > 0$ there exists $\widetilde{\delta} > 0$ such that if $|t_1 - t_0| < \widetilde{\delta}$, we are guaranteed that $|E_1 - E_0| < \delta$. It follows that if $|t_1 - t_0| < \widetilde{\delta}$, the polarization values satisfy the bound

$$|[P(E)](t_1) - [P(E)](t_0)| \leq \varepsilon,$$

thus establishing the continuity of the hysteresis model. This holds for all major and minor loops. As illustrated in Figure 6, the behavior of the model that incorporates thermal activation is smoother than the thermally inactive case considered here. For brevity, we omit the proof of this second case.

OSCILLATIONS IN A MATURATION MODEL OF BLOOD CELL PRODUCTION*

IVANA DROBNJAK†, A. C. FOWLER†, AND MICHAEL C. MACKEY‡

Abstract. We present a mathematical model of blood cell production which describes both the development of cells through the cell cycle, and the maturation of these cells as they differentiate to form the various mature blood cell types. The model differs from earlier similar ones by considering primitive stem cells as a separate population from the differentiating cells, and this formulation removes an apparent inconsistency in these earlier models. Three different controls are included in the model: proliferative control of stem cells, proliferative control of differentiating cells, and peripheral control of stem cell committal rate. It is shown that an increase in sensitivity of these controls can cause oscillations to occur through their interaction with time delays associated with proliferation and differentiation, respectively. We show that the characters of these oscillations are quite distinct and suggest that the model may explain an apparent superposition of fast and slow oscillations which can occur in cyclical neutropenia.

Key words. maturation, mathematical model, blood cell production, chronic myelogenous leukemia, delay equation, cyclical neutropenia

1. Introduction.

A number of hematological diseases are characterized by oscillations in the circulating density of various types of blood cells. These include chronic myelogenous leukemia (CML), cyclical neutropenia (CN), polycythemia vera (PV) and aplastic anemia (AA). Examples of blood cell counts for CML and CN are shown in Figures 1 and 2.

A review of the clinical data and a discussion of possible mechanisms for the oscillations are given by Haurie, Dale, and Mackey [10]. These mechanisms focus on the role of negative feedback control on proliferation and differentiation of blood cells within the bone marrow, together with time delays due to cell cycling and maturation. There are consequently a number of different ways in which oscillations can occur, and one object of mathematical modelling of blood cell development is to understand which of these effects may be responsible for these oscillations.

Blood cells are produced through a process of differentiation from primitive stem cells in the bone marrow. These pluripotential stem cells begin to develop along one of several different cell lineages, forming blast cells which eventually develop through a number of different stages to form the various kinds of blood cells. The most numerous are the red blood cells, or erythrocytes, whose normal density in the blood is about 5×10^6 cells $\mu\mathrm{l}^{-1}$. Their primary function is in transporting oxygen to the tissues. Platelets are formed by the fragmentation of megakaryocytes, which develop in the bone marrow. Platelets are present at levels of 5×10^5 cells $\mu\mathrm{l}^{-1}$, and their function is in blood clotting. Finally, there are a number of different white blood cells, the most

common of which are neutrophils (5000 cells μl^{-1}) and lymphocytes (2000 cells μl^{-1}), which form constituent parts of the immune system. The normal levels of these cells are controlled by a number of mechanisms, and an excess or deficit of the various cell types defines certain kinds of disease; for example, anemia refers to a low red blood cell count, below 4×10^6 cells μl^{-1}.

There are a number of features in Figures 1 and 2 which are of note. In CML, there are regular oscillations in white blood cell counts with a long period ranging from 40 to 80 days (see Fortin and Mackey [7]). The other cell lines (platelets and reticulocytes, i.e., erythrocyte precursors) also oscillate in a similar fashion (Figure 1 does not show this well; see Fortin and Mackey [7] for other examples).

A similar observation is true of cyclical neutropenia. Oscillation periods are on the order of 20 days, during which there is a marked collapse of the neutrophil count to vanishingly low levels (see Dale and Hammond [4] and Guerry et al. [9]). Other cell types oscillate, but only the neutrophils appear to oscillate fairly regularly: Oscillations in other cell types (e.g., red blood cells, platelets, reticulocytes, and lymphocytes) are marked by irregularity and high frequency noise (see Guerry et al. [9]). This latter feature is well illustrated in Figure 2.

The purpose of the present paper is to throw some light on these observations by the study of a model of blood cell proliferation and differentiation. This model is similar to those of previous authors, particularly that of Mackey and Rudnicki [13], and describes the stem cell and developing (blast) cell populations as functions of time, age (time through the proliferative cell cycle), and maturation (stage in the differentiation process). Fokas, Keller, and Clarkson [6] describe a model with discrete generations in the development of blast cells, while Mackey and Rudnicki

[13] develop a corresponding continuous model (i.e., the developmental stage is a continuous variable).

In this paper we use a continuous model to describe the development of a single cell lineage following the committal of stem cells. Three separate controls are implemented in the model, namely the proliferative control of stem cells, the proliferative control of developing blast cells, and the peripheral control of stem cell committal by circulating blood cell density. We show that variation of parameters in all three control systems can cause oscillations, and that the characters of these oscillations are very different. This allows us some potential insight into the mechanisms that may be operative in some of these dynamic blood diseases.

2. A model of maturation of blood cell production. We consider all cell lineages to consist of populations of two types, proliferative and resting phase (cf. Figure 3). These are denoted p and n, respectively, and are functions of age a (time since the inception of the proliferative cell cycle) and maturation m (degree of maturation, measured in maturation units (mat), which could be, for example, cell generation number). Also, p and n are functions of time t. Thus, we have $p = p(t, m, a)$ and $n = n(t, m, a)$. The dimensions of p and n are cells age^{-1} mat^{-1}.

In the cell population, there will be a finite number which are primitive and have not begun differentiation. These *cannot* be characterized in terms of p and n at $m = 0$, since the latter are cell densities with respect to a *and* m. The primitive stem cells are characterized by cell densities $p_0(t, a)$ and $n_0(t, a)$, such that $p_0\, da$ and $n_0\, da$ are the numbers of primitive stem cells (with $m = 0$) of age in $(a, a + da)$.

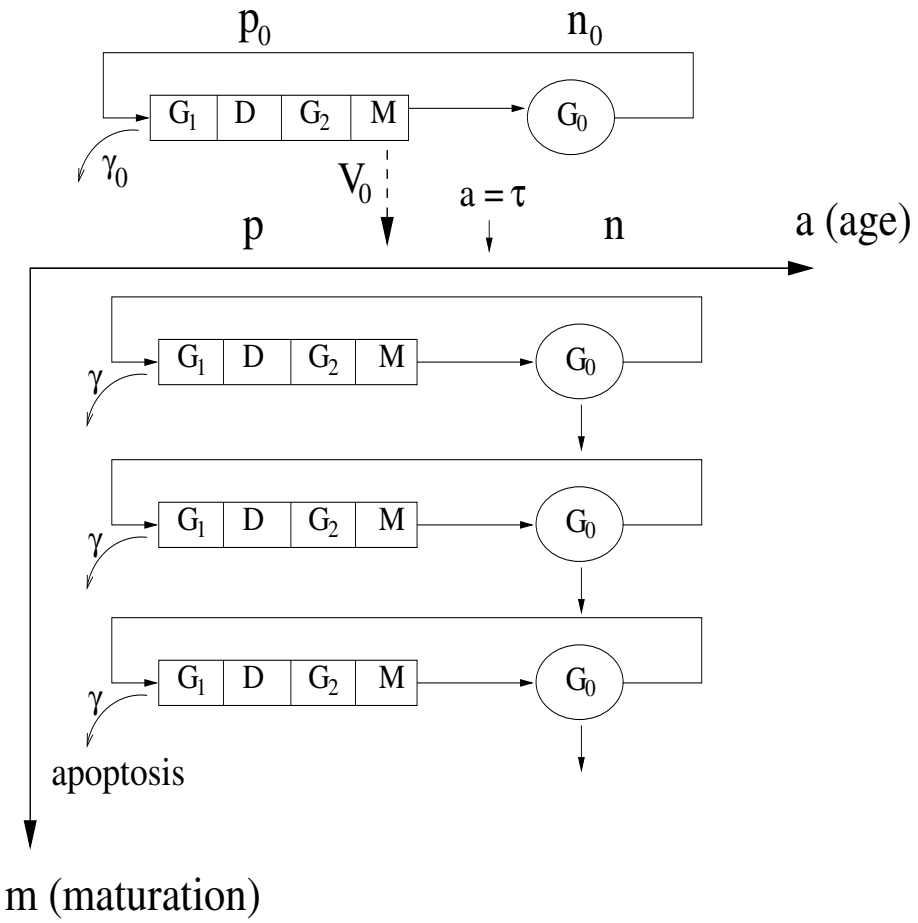

FIG. 3. *Schematic evolution of cells. Each cell ages as it goes through its cell cycle, before dividing and entering a resting (G_0) phase; at the same time, the cells mature. The time-like variables a (age) and m (maturation) are independent.*

The basic model is similar to that described by Mackey and Rudnicki [13]. It has been analyzed in various versions by Rey and Mackey [16], Crabb, Mackey, and Rey [3], and Mackey and Rudnicki [14]. However, a particular feature of these previous models was the assumption of zero maturation rate at maturation state zero. This leads to some odd behavior, which we believe arises because the model does not properly identify the role played by primitive stem cells. In our formulation of the model, we do not make this assumption.

Specifically, Mackey and Rudnicki [13], [14] assumed a model in which the cell density depended on stage of maturation m, age through the cell cycle a, and time t. As a consequence, the number of cells of zero age in the cell cycle is zero, as is the number of cells of zero maturation. As is common in age-structured population models, the migration of cells away from age zero through the cell cycle is balanced by a renewal equation, which here takes the form of recruitment from the resting cell population. However, there is in general no recruitment to the stem cell population at zero maturation, and as a consequence, the Mackey–Rudnicki model generally leads to a disappearance of the cells as they migrate down the maturation stage without

replenishment. In their model, they were able to avoid this unattractive option by allowing a rate of maturation $V(m)$ which tended to zero as $m \to 0$. The effect of this assumption is to make the time of maturation infinite, and in addition it causes strange irregular behavior to occur (see Dyson, Villella-Bresson, and Webb [5]). We consider that an implication of the lack of recruitment of stem cells is that they must be represented in the model as a compartment of finite number and therefore cannot be represented in terms of a density dependent on both m and a. In fact, consistent with previous models of stem cells (see Mackey [11], [12]), we suppose that the stem cell population can be represented as a density dependent on a and t only. This assumption removes the Mackey–Rudnicki awkwardness and does not require an artificial and unnatural choice (with its artificial consequences) of maturation rate.

The evolution of the system is illustrated schematically in Figure 3. We suppose that cell mortality occurs at a rate γ (for proliferating cells only), and that cell maturation occurs continuously at a rate V (for both proliferative and resting phases). We suppose that both γ and V may depend on maturation stage m, but not on t. Conservation of proliferative cells then implies

$$\frac{\partial p}{\partial t} + \frac{\partial p}{\partial a} + \frac{\partial (Vp)}{\partial m} = -\gamma p, \tag{2.1}$$

where the units of V are mat d^{-1} (maturation units per day). We suppose (2.1) applies during a cycle of length τ (which might depend on m), thus for $0 < a < \tau$. For $a > \tau$, the cells in the resting phase satisfy the equation

$$\frac{\partial n}{\partial t} + \frac{\partial n}{\partial a} + \frac{\partial (Vn)}{\partial m} = -Rn, \tag{2.2}$$

which differs from (2.1) by the rate of recruitment R back to the proliferative phase, where resting cell mortality is taken to be zero. Equation (2.2) applies for $a > \tau$.

At the end of the cell cycle, $a = \tau$, we apply a boundary condition describing the conversion of p to n. Mackey and Rudnicki [13] allow a very general condition, on the basis that cells at maturation M can divide to form cells at maturation $g(M) \le M$. Specifically, this implies $2p[t, M, \tau(M)]\, dM = n[t, g(M), \tau\{g(M)\}]\, dg$. If we write $m = g(M)$, $M = h(m)$ (thus $h = g^{-1}$), then this becomes

$$n[t, m, \tau(m)] = 2p[t, h(m), \tau\{h(m)\}]h'(m), \tag{2.3}$$

where $g(m) \le m$ implies $h(m) \ge m$.

A boundary condition for p at $a = 0$ follows from the recruitment condition (the renewal equation)

$$p(t, m, 0) = RN(t, m), \tag{2.4}$$

where we introduce the total resting cell density

$$N = \int_{\tau}^{\infty} n\, da. \tag{2.5}$$

Now we integrate (2.2) from $a = \tau$ to $a = \infty$, taking $n \to 0$ as $a \to \infty$ (which is necessary if there is a finite number of cells). We suppose that $V = V(m)$ is independent of a and t, and that $R = R(t, m)$ is independent of a. Then

$$\frac{\partial N}{\partial t} + \frac{\partial (VN)}{\partial m} = -RN + 2p[t, h(m), \tau\{h(m)\}]h'(m), \tag{2.6}$$

adopting (2.3).

We need to solve (2.1) for p. We use the method of characteristics and begin by applying the recruitment condition (2.4). Specifically, we apply the parametric conditions

$$t = s, \quad m = \mu, \quad a = 0, \quad p = R(s,\mu)N(s,\mu), \tag{2.7}$$

valid for $s, \mu > 0$; then the characteristic solution is

$$\begin{aligned} &a = t - s, \quad \int_{\mu}^{m} \frac{d\rho}{V(\rho)} = t - s, \\ &p = R(s,\mu)N(s,\mu) \exp\left[-\int_{s}^{t} [\gamma + V'(m)]\, dt \right]. \end{aligned} \tag{2.8}$$

Define a function $\nu(m,a)$ by

$$\int_{\nu}^{m} \frac{d\rho}{V(\rho)} = a. \tag{2.9}$$

Then $a = t - s$, $\mu = \nu(m,a)$. Also $dt = dm/V(m)$ on a characteristic; thus for $t > a$ (and also $\nu > 0$),

$$p(t,m,a) = R[t-a,\nu(m,a)]N[t-a,\nu(m,a)] \exp\left[-\int_{\nu(m,a)}^{m} \{\gamma + V'(\rho)\} \frac{d\rho}{V(\rho)} \right]. \tag{2.10}$$

Simplifying and putting $a = \tau$, we have

$$p(t,m,\tau) = R[t-\tau,\nu(m,\tau)]N[t-\tau,\nu(m,\tau)] \exp\left[-\int_{\nu(m,\tau)}^{m} \frac{\gamma\, d\rho}{V(\rho)} \right] \frac{V[\nu(m,\tau)]}{V(m)} \tag{2.11}$$

for $t > \tau$ and $\nu > 0$. Finally, (2.6) becomes

$$\begin{aligned} \frac{\partial N}{\partial t} + \frac{\partial}{\partial m}(VN) = &- RN \\ &+ 2h'(m)R[t-\tau,\nu\{h(m),\tau\}]N[t-\tau,\nu\{h(m),\tau\}] \\ &\times \exp\left[-\int_{\nu\{h(m),\tau\}}^{h(m)} \frac{\gamma\, d\rho}{V(\rho)} \right] \frac{V[\nu\{h(m),\tau\}]}{V[h(m)]}. \end{aligned} \tag{2.12}$$

Note that

$$\int_{\nu(m,\tau)}^{m} \frac{d\rho}{V(\rho)} \equiv \tau. \tag{2.13}$$

It is convenient to define a modified maturation variable ξ by

$$\xi = \int_{0}^{m} \frac{d\rho}{V(\rho)}; \tag{2.14}$$

ξ has units of time, and indeed it is equal to the elapsed time during maturation. Note that $\nu > 0$ if $\xi > \tau$. The lower limit can be chosen for convenience and allows

us to fix ξ at some reference point; here we choose this to be the initial maturation stage (note that this cannot be done if $V(0) = 0$). Define also

$$\eta(\xi) = \int_0^{h(m)} \frac{d\rho}{V(\rho)} \tag{2.15}$$

(note $\eta \geq \xi$ since $h \geq m$). Now if

$$F(m) \equiv f(\xi), \tag{2.16}$$

then we find

$$\begin{aligned} F[h(m)] &= f(\eta), \\ F[\nu\{h(m), \tau\}] &= f(\eta - \tau). \end{aligned} \tag{2.17}$$

We change the variable from m to ξ and define

$$\begin{aligned} v(\xi) &\equiv V(m), \\ M &\equiv NV \end{aligned} \tag{2.18}$$

(note that $Md\xi = Ndm$, so that M is cell density in terms of the variable ξ; the units of M are cells d^{-1}). After a little manipulation, we find

$$\frac{\partial M}{\partial t} + \frac{\partial M}{\partial \xi} = -RM + Q, \tag{2.19}$$

where

$$Q = 2\eta'(\xi) R[t - \tau, \eta - \tau] M[t - \tau, \eta - \tau] \exp\left[- \int_{\eta - \tau}^{\eta} \gamma \, d\xi \right], \tag{2.20}$$

where we write γ, R, and M as dependent on ξ rather than m. This equation applies if $t > \tau$ and $\eta > \tau$.

In order to find the form of the source term for $t < \tau$ or $\eta < \tau$, we must solve (2.1) for p using the initial data from $m = 0$ and $t = 0$. If, specifically, we have an initial condition

$$p = p_I(m, a) \quad \text{at} \quad t = 0, \tag{2.21}$$

then after some algebra we find that

$$Q = 2\eta'(\xi) p_I[\eta - t, \tau - t] v(\eta - t) \exp\left[- \int_{\eta - t}^{\eta} \gamma \, d\xi \right], \quad t < \tau, \quad \eta > t. \tag{2.22}$$

The definition of Q in $t > \eta$ and $\eta < \tau$ requires consideration of the stem cell evolution, and we now turn to this. Conservation laws for the stem cell densities p_0 and n_0 are

$$\begin{aligned} \frac{\partial p_0}{\partial t} + \frac{\partial p_0}{\partial a} &= -(\gamma_0 + V_0) p_0, \\ \frac{\partial n_0}{\partial t} + \frac{\partial n_0}{\partial a} &= -(V_0 + R_0) n_0, \end{aligned} \tag{2.23}$$

where V_0 is the rate of loss of stem cells to maturation, R_0 is the stem cell recruitment rate from the resting phase, and γ_0 is the mortality rate of stem cells in the proliferative

phase. We allow R_0, V_0, and γ_0 to depend on t, but we assume they are independent of a. Note that $V_0 \neq 0$, indeed $V_0 \neq V(0)$, as the units of V_0 and V are not even the same: V has units of mat d^{-1}, while V_0 has units of d^{-1}. Note also that p_0 and n_0 have units of cells age^{-1} (unlike p and n).

The primitive loss to maturation must balance the source for p and n at $m = 0$; thus

$$V_0 p_0 = (Vp)|_{m=0}, \quad V_0 n_0 = (Vn)|_{m=0}, \tag{2.24}$$

and the units are consistent.

Analogously to (2.4) and (2.3), we have

$$\begin{aligned} p_0(t,0) &= R_0(t) N_0(t), \\ n_0(t,\tau) &= 2p_0(t,\tau), \end{aligned} \tag{2.25}$$

where

$$N_0 = \int_\tau^\infty n_0 \, da. \tag{2.26}$$

Integration over a now yields

$$\frac{dN_0}{dt} = -V_0 N_0 - R_0 N_0 + 2p_0|_{a=\tau}, \tag{2.27}$$

and

$$(NV)|_{m=0} = N_0 V_0. \tag{2.28}$$

In order to find p_0 we must solve

$$\frac{\partial p_0}{\partial t} + \frac{\partial p_0}{\partial a} = -(\gamma_0 + V_0) p_0 \tag{2.29}$$

with parametric initial conditions

$$p_0 = p_{00}(\alpha), \quad a = \alpha > 0, \quad t = 0,$$

$$p_0 = R_0(s) N_0(s), \quad a = 0, \quad t = s > 0. \tag{2.30}$$

For $t > a$, the solution is

$$p_0 = R_0(t-a) N_0(t-a) \exp\left[-\int_{t-a}^t [\gamma_0(t') + V_0(t')] \, dt' \right], \tag{2.31}$$

whereas for $t < a$,

$$p_0 = p_{00}(a-t) \exp\left[-\int_0^t [\gamma_0(t') + V_0(t')] \, dt' \right]. \tag{2.32}$$

Putting $a = \tau$, we find

$$\frac{dN_0}{dt} = -(R_0 + V_0) N_0 + 2R_0(t-\tau) N_0(t-\tau) \exp\left[-\int_{t-\tau}^t [\gamma_0(t') + V_0(t')] \, dt' \right], \ t > \tau, \tag{2.33}$$

which prescribes the control system for N_0, analogously to that of Mackey [11]. For $t < \tau$, the equation for N_0 involves the initial condition for p_0, and we can equivalently simply prescribe initial data for N_0 there.

Finally, we complete the definition of Q in (2.19) by solving (2.1) using the initial data on $m = 0$:

$$m = 0, \quad a = \alpha > 0, \quad t = s > 0, \quad V(0)p = V_0(s)p_0(s, \alpha). \tag{2.34}$$

We find

$$p(t, \xi, a) = \frac{V_0(t-\xi)p_0(t-\xi, a-\xi)}{v(\xi)} \exp\left[-\int_0^\xi \gamma \, d\xi\right], \quad \xi < a, \quad \xi < t, \tag{2.35}$$

from which it follows that

$$Q = 2\eta'(\xi)V_0(t-\eta)p_0[t-\eta, \tau-\eta] \exp\left[-\int_0^\eta \gamma \, d\xi\right], \quad t > \eta, \quad \eta < \tau. \tag{2.36}$$

Along with (2.20) and (2.22), this completes the definition of Q for $t > 0$, $\eta > 0$ (and thus $\xi > 0$). In summary,

$$Q = \begin{cases} 2\eta'(\xi)R[t-\tau, \eta-\tau]M[t-\tau, \eta-\tau] \exp\left[-\displaystyle\int_{\eta-\tau}^\eta \gamma \, d\xi\right], & t > \tau, \quad \eta > \tau, \\ 2\eta'(\xi)p_I[\eta-t, \tau-t]v(\eta-t) \exp\left[-\displaystyle\int_{\eta-t}^\eta \gamma \, d\xi\right], & t < \tau, \quad \eta > t, \\ 2\eta'(\xi)V_0(t-\eta)p_0[t-\eta, \tau-\eta] \exp\left[-\displaystyle\int_0^\eta \gamma \, d\xi\right], & t > \eta, \quad \eta < \tau. \end{cases} \tag{2.37}$$

The two equations (2.33) and (2.19) are coupled through (2.28), which provides the requisite boundary condition for M at $\xi = 0$:

$$M = V_0 N_0 \quad \text{at} \quad \xi = 0. \tag{2.38}$$

We see that by an appropriate consideration of the primitive stem cells, we derive a coherent model which does not require $V(0) = 0$.

Many authors (for example, see Rey and Mackey [16] and Dyson, Villella-Bresson, and Webb [5]) study the differential equation (2.12) for N, under the assumption that V does tend to zero as $m \to 0$, for example,

$$V = rm. \tag{2.39}$$

The reasoning behind this is that, if primitive stem cells mature at a finite rate, then such cells will be immediately lost to $m > 0$, which makes no physiological sense, because the cell population then inexorably disappears. Only by choosing $V(0) = 0$ can we allow primitive stem cells to endure. In the present version of the model, it is also possible to allow $V(0) = 0$; for example, (2.39) would then imply

$$M \to 0 \quad \text{as} \quad \xi \to -\infty. \tag{2.40}$$

The sensitivity of the solution to this condition has led to the idea that the system may have unstable and even chaotic solutions (e.g., Crabb, Mackey, and Rey [3]), because of the degeneracy of the equation at $m = 0$. Our considerations here suggest that the requirement that $V(0) = 0$ is inaccurate, because it does not properly address the biological question of how the primitive stem cells should be described.

3. Dimensionless model. How we solve the model depends on the complexity of our assumptions about γ, R, η, and R_0. In the remainder of this paper we will assume $g(m) = m$ (thus $\eta = \xi$) and that γ and γ_0 are constant. The equation for the maturing cells, (2.19), is

$$\frac{\partial M}{\partial t} + \frac{\partial M}{\partial \xi} = -RM + Q, \tag{3.1}$$

and is a hyperbolic delay partial differential equation. Figure 4 shows the regions where the different definitions of Q apply. In regions II and segment (a) of region III, that is, for $t < \tau$ and all $\eta = \xi > 0$, Q depends on the initial data, either p_{I} (in II) or p_{00} (in III(a)). Thus we may equivalently simply choose instead to prescribe M in $0 < t < \tau$, and this we do. In fact, since ξ is finite, the part of the solution which depends on this initial data will wash out of the system in a finite time. It is therefore apparently of little concern.

We therefore confine ourselves to consideration of the definition of Q in regions I and III(b); with the assumptions we have made, we find that for $t > \tau$,

$$Q = \begin{cases} 2e^{-\gamma\tau} R[t-\tau, \xi-\tau] M[t-\tau, \xi-\tau], & \xi > \tau, \\ 2e^{-\gamma_0(\tau-\xi)} e^{-\gamma\xi} \exp\left[-\displaystyle\int_{t-\tau}^{t-\xi} V_0(t')\, dt' \right] V_0(t-\xi) R_0(t-\tau) N_0(t-\tau), & \xi < \tau. \end{cases} \tag{3.2}$$

We thus have to solve (3.1) with (3.2) in $t > \tau$, with the boundary condition (2.38) on $\xi = 0$, and prescription of an initial function for M in $0 < t < \tau$.

A principal issue of focus is how the recruitment rates R and R_0 and the committal rate V_0 depend on M, N_0, and ξ. There is very little to constrain our choice. In what follows, we assume $R_0 = R_0(N_0)$ (stem cell proliferation is controlled by stem cell density). We follow Mackey and Rudnicki [13] in supposing that R depends on the total differentiating cell population $\bar{M}$, where

$$\bar{M}(t) = \int_0^{\xi_F} M\, d\xi, \tag{3.3}$$

with ξ_F being the time of final maturation,

$$\xi_F = \int_0^{m_F} \frac{d\rho}{V(\rho)}, \tag{3.4}$$

and $m = m_F$ at full maturity. We suppose that the rate of committal V_0 should depend on the peripheral blood cell count, B, and thus $V_0 = V_0(B)$. A simple model for B is

$$\frac{dB}{dt} = M|_{\xi_F} - \gamma_B B, \tag{3.5}$$

where γ_B is the specific decay rate of the peripheral blood cells, and the source term $M|_{\xi_F}$ is the delivery rate to the blood from the maturation phase cells. Peripheral control models of similar type have been studied by Bernard, Bélair, and Mackey [1]. Assumptions of this type are liable to be important in the evolution of diseases such as cyclical neutropenia, which is thought to be due to an instability in the peripheral

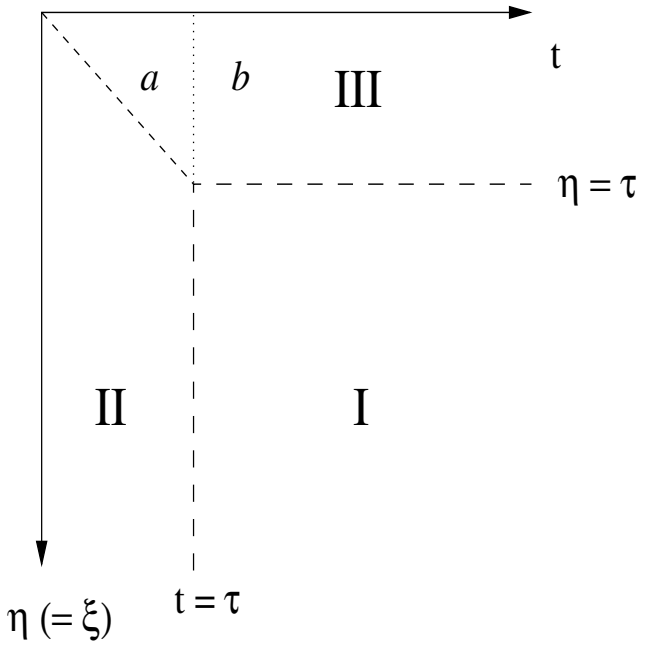

FIG. 4. *Regions of different definitions of* Q *in* (2.37). *Regions* I, II, *and* III *correspond to the first, second, and third definitions of* Q *and their locations of validity in the* (t, η) *plane. The vertical dotted line in region* III *(where* Q *is defined in terms of* p_0*) separates the region (a), where* (2.32) *applies (to the left), from (b), where* (2.31) *applies (to the right).*

control of stem cell committal. In addition, it is likely that other controls affect rate of apoptosis, maturation rate, cell cycle time, and so on.

The equation for N_0 (2.33) now takes the form

$$\dot{N}_0 = -[V_0 + R_0(N_0)]N_0 + 2e^{-\gamma_0\tau}R_0(N_{0\tau})N_{0\tau}\exp\left[-\int_{t-\tau}^{t} V_0[B(t')]\,dt'\right], \tag{3.6}$$

where $N_{0\tau} = N_0(t-\tau)$. This is precisely the model of Mackey [11] if V_0 is constant, and it has been studied by Fowler and Mackey [8] in the limit

$$V_0\tau \ll 1, \tag{3.7}$$

when it is shown that relaxation oscillations will occur for a further parameter $\mu_0 = [2e^{-(\gamma_0+V_0)\tau} - 1]/V_0\tau$ within a certain $O(1)$ range. (Note that in the notation of Fowler and Mackey's model, $\gamma = \gamma_0 + V_0$, $\delta = V_0$.) When such oscillations occur, they will propagate through the maturing cells; however, we show in this paper that the resultant amplitude of oscillations of mature blood cells is small unless amplification also occurs during maturation.

We can write (3.2) in abbreviated form as

$$Q = \begin{cases} 2e^{-\gamma\tau}R(\bar{M}_\tau)M_{\tau,\tau}, & \xi > \tau, \\ 2e^{-\gamma_0(\tau-\xi)}e^{-\gamma\xi}\exp\left[-\displaystyle\int_{t-\tau}^{t-\xi} V_0[B(t')]\,dt'\right] V_0[B(t-\xi)]R_0(N_{0\tau})N_{0\tau}, & \xi < \tau, \end{cases} \tag{3.8}$$

where $\bar{M}_\tau = \bar{M}(t-\tau)$, and $M_{\tau,\tau} = M(t-\tau, \xi-\tau)$.

We nondimensionalize the model by following the analysis of Fowler and Mackey [8], which motivates a choice of scales for the variables as follows:

$$t, \xi \sim \tau, \quad M \sim M^*, \quad N_0 = N_0^* S, \quad Q \sim \frac{M^*}{\tau},$$

$$R_0 = R_0^* h_0, \quad R = R^* h, \quad V_0 = V_0^* v_0, \quad B \sim \frac{M^*}{\gamma_B}, \tag{3.9}$$

where $R_0^*,\ R^*,\ V_0^*,\ N_0^*,\ M^*$ are determined by the control functions (so that they are $O(1)$ functions of $O(1)$ variables). For example, Mackey [11] chooses for R_0 the Hill function

$$R_0 = \frac{R_0^*}{1 + (N_0/\theta)^n}. \tag{3.10}$$

In this case, we would choose $N_0^* = \theta$, and h_0 is the Hill function

$$h_0(S) = \frac{1}{1+S^n}. \tag{3.11}$$

The dimensionless stem cell equation is

$$\dot{S} = b_0 \left[(1+\lambda_0) h_0(S_1) S_1 \exp\left(\varepsilon_0 \left\{ 1 - \int_{t-1}^{t} v_0[B(t')]\, dt' \right\} \right) - h_0 S \right] - \varepsilon_0 v_0 S, \tag{3.12}$$

where

$$\varepsilon_0 = V_0^* \tau, \quad \lambda_0 = 2e^{-(\gamma_0 + V_0^*)\tau} - 1, \quad b_0 = R_0^* \tau. \tag{3.13}$$

The dimensionless form of (3.8) is

$$\frac{\partial M}{\partial t} + \frac{\partial M}{\partial \xi} = -b h(\bar{M}) M + Q, \tag{3.14}$$

where

$$Q = \begin{cases} b(1+\lambda) & h(\bar{M}_1) M_{1,1}, \quad \xi > 1, \\ \nu b_0 (1+\lambda_0) & e^{-\alpha\xi} \exp\left[\varepsilon_0 \left\{ 1 - \displaystyle\int_{t-1}^{t-\xi} v_0[B(t')]\, dt' \right\} \right] v_0[B(t-\xi)] h_0(S_1) S_1 \quad \xi < 1, \end{cases} \tag{3.15}$$

in which

$$\nu = \frac{N_0^* V_0^*}{M^*}, \quad b = R^* \tau, \quad \lambda = 2e^{-\gamma\tau} - 1, \quad \alpha = (\gamma - \gamma_0)\tau. \tag{3.16}$$

This is analogous to the scaling used by Fowler and Mackey [8]. The boundary condition for M is

$$M = \nu v_0 S \quad \text{at} \quad \xi = 0, \tag{3.17}$$

and if

$$M = M_f \quad \text{at} \quad \xi = \xi_f, \tag{3.18}$$

then

$$\delta \dot{B} = M_f - B, \tag{3.19}$$

where

$$\delta = \frac{1}{\gamma_B \tau}, \quad \xi_f = \frac{\xi_F}{\tau}. \tag{3.20}$$

This completes the statement of the dimensionless form of the model.

Parameter values. Equation (3.12) is exactly that studied by Fowler and Mackey [8] (if $v_0 \equiv 1$). However, their model can also be interpreted as a lumped, or compartmentalized, version of (3.14) for the maturing cells. One way of enabling this is if we make the special assumption that the maturation rate $V \to 0$ as both $m \to 0$ and $m \to m_F$, as also assumed by Mackey and Rudnicki [13]. In this case the range of ξ is $(-\infty, \infty)$, and we have $M \to 0$ at both limits. Then integration of (3.14) over ξ again leads to an equation of the form of (3.12). In the present paper we assume V is finite at $m = m_F$, i.e., the mature blood cells are delivered to the bloodstream at a finite rate, and this is then the essential difference between the models with and without maturation.

In estimating the parameters, we follow Fowler and Mackey [8] in choosing $\tau \sim 2$ d, and we suppose that proliferative control is effected at typical rates $R^* \sim R_0^* \sim 2$ d^{-1}. We suppose that apoptosis rates are of order $\gamma \sim \gamma_0 \sim 0.2$ d^{-1} and that committal rates are of order $V_0^* \sim 0.05$ d^{-1}, and from these we find

$$b \sim b_0 \sim 4, \quad \lambda \sim \lambda_0 \sim 0.3, \quad \varepsilon_0 \sim 0.1. \tag{3.21}$$

The parameter α is not independent of the others, as

$$\alpha = \varepsilon_0 + \ln\left(\frac{1+\lambda_0}{1+\lambda}\right), \tag{3.22}$$

and plausibly $\alpha \approx \varepsilon_0$.

The remaining parameters are δ, ν, and ξ_f. For δ, we assume a half-life (γ_B^{-1}) of 7 hours, appropriate for neutrophils (but, for example, certainly not for erythrocytes); then

$$\delta \sim 0.15. \tag{3.23}$$

We can get some sense of the size of the remaining parameters ν and ξ_f by considering the nature of stem cells. These are difficult to isolate; indeed it is not yet clear whether genuine stem cells have ever really been isolated. The reason for this is that there are few of them, and maturing cells will typically undergo about (or at least) 20 divisions before emerging as mature blood cells. A typical numerical estimate for the total number of blast cells is 10^{12} per kg body weight, while for stem cells, a corresponding estimate is 10^6 (see Bernard, Bélair, and Mackey [1], Mackey [12]). If this is the case, then it successively implies that the parameter ν in (3.16) is very small ($\approx 10^{-6}$), and therefore also that the maturation time is long. Typical estimates of $\xi_F \approx 10$–20 days are consistent with values of $\xi_f \approx 5$–10, and in fact the small parameter ξ_f^{-1} then plays the role corresponding to that of the small parameter ε in Fowler and Mackey's [8] analysis.

Steady state. To elaborate this discussion, we now describe the steady state. For simplicity, we ignore the distinct definition of Q in $\xi < 1$ and extend the definition in $\xi > 1$ back to $\xi = 0$. The steady solution of (3.14) and (3.15) is, with $v_0 = S = 1$,

$$M = \nu e^{s\xi}, \tag{3.24}$$

where s is the unique positive solution of the pair

$$s = bh(\bar{M}) \left[(1+\lambda)e^{-s} - 1\right],$$

$$\bar{M} = \frac{\nu}{s}\left(e^{s\xi_f} - 1\right). \tag{3.25}$$

(Uniqueness follows from the fact that $\bar{M}$ is monotonically increasing with s, hence $h(\bar{M})$ is monotonically decreasing with s, and hence $bh(\bar{M})\left[(1+\lambda)e^{-s} - 1\right]$ is monotonically decreasing with s, while evidently s is increasing.) We can see that $s < \ln(1+\lambda)$, and s will be close to this value if b is large. Note also that by choosing λ_0 and ε_0 to have certain specific values which depend on λ, b, ν, and ξ_f, this solution consistently extends back to $\xi = 0$, even allowing for the distinct definition of Q in $\xi < 1$.

Numerical solutions do confirm the exponential variation of M with ξ. In general, it is found that M decreases for $0 < \xi < 1$, before subsequently increasing.

4. Periodic solutions. We are interested in finding whether periodic solutions can occur. There are three different controllers in the model, and thus three different ways in which oscillations can occur: These are described below. We utilize a reference set of parameters based on the estimates in Fowler and Mackey [8], and these are given in Table 1. They are those suggested by independent estimate, except that we take $\nu = 10^{-2}$ rather than 10^{-6}. This is partly for numerical expediency, as smaller values of ν require larger ξ_f and thus longer computation times, and also because the value of ν is not well constrained.

TABLE 1
The reference parameter values, based on estimates in Fowler and Mackey [8].

Symbol	Typical value
n	3
ε_0	0.1
λ_0	0.3
b_0	4
ν	10^{-2}
b	4
λ	0.3
ξ_f	5
δ	0.2
v^*	1
v'	1

We choose the Hill function controller (3.11) for both h and h_0; thus

$$h(\bar{M}) = \frac{1}{1+\bar{M}^n}, \quad h_0(S) = \frac{1}{1+S^n}, \tag{4.1}$$

and we take the peripheral controller v_0 to have the form

$$v_0 = [v^* - v'B]_+, \tag{4.2}$$

with default values of the amplitude and slope parameters to be $v^* = v' = 1$. The choice of a threshold in (4.2) is motivated by the observation that neutrophil populations can dwindle to zero in cyclical neutropenia, which would appear to require zero production for sufficiently high blood cell counts.

With this choice of the controller functions and using the default parameters, the steady state is stable. Instabilities arising from parameter variations are described below.

Numerical method. We have to solve the two ordinary differential equations (3.12) and (3.19), and the partial differential equation (3.14). The solution is complicated by the presence of the integral in (3.12). We define

$$U = S \exp\left[\varepsilon_0 \int^t v_0[B(t')]\, dt'\right], \tag{4.3}$$

and then S and U satisfy the pair of equations

$$\dot{S} = S\left[\frac{\dot{U}}{U} - \varepsilon_0 v_0\right],$$

$$\dot{U} = b_0\left[(1+\lambda)e^{\alpha} h_0(S_1)U_1 - h_0(S)U\right]. \tag{4.4}$$

On the assumption that S remains bounded, U grows exponentially as $U \sim \exp(\overline{v}_0 t)$, where $\overline{v}_0$ is the mean of v_0. This is likely to cause difficulty in numerical solutions, and this can be reduced by using the algebraically growing function $W = \ln U$, whence

$$\dot{S} = S\left[\dot{W} - \varepsilon_0 v_0\right],$$

$$\dot{W} = b_0\left[(1+\lambda)h_0(S_1)e^{\alpha + W_1 - W} - h_0(S)\right]. \tag{4.5}$$

In our numerical solutions, we solve (4.5) using the second order accurate improved Euler method, and we similarly solve (3.14) along the characteristics $\xi - t = \eta$, on which the function Q takes the form

$$Q = \begin{cases} b(1+\lambda)h(\bar{M}_1)M_1\,, & \xi > 1, \\ \\ b_0(1+\lambda)e^{\alpha(1-\xi)}M_0(\eta)h_0(S_1)\exp\left[W_1 - W(\eta)\right], & \xi < 1, \end{cases} \tag{4.6}$$

where $M_0(\eta) = M(\eta, 0)$ and $M_1 = M_{1,1}$, i.e., M delayed by one along the characteristic.

Accurate solutions are obtained with a time step $\Delta t = \Delta\xi = 0.05$, and these are checked against values $\Delta t = \Delta\xi = 0.02$ (which are used to give the figures).

Stem cell oscillations. Oscillations in the primitive stem cell population will occur for a finite range of the parameter λ_0/ε_0, as described by Fowler and Mackey [8], when $v_0 = 1$. For the default values of $b_0 = 4$, $n = 3$, the approximate range of instability is $0.5\varepsilon_0 \lesssim \lambda_0 \lesssim 1.5\varepsilon_0$, and this is modified in an obvious way when the peripheral controller alters the value of v_0. Figure 5 shows the oscillations which occur in the stem cell population when λ_0 is reduced to 0.05. It is an interesting fact that these oscillations are hardly manifested in the blood cell population. The apparent reason for this is that the small value of ν means that oscillations in M_0, and therefore also in M_f, are small because small perturbations propagate stably down the maturation axis. The blood cell population is therefore stable, and $B \approx M_f$.

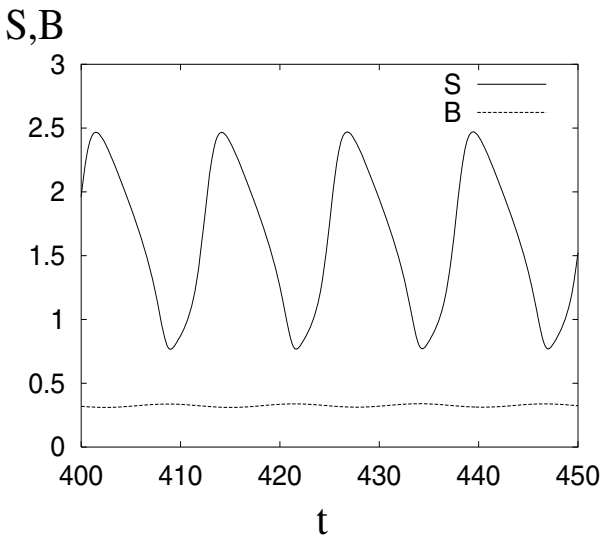

FIG. 5. *Default parameter values, except that* $\lambda_0 = 0.05$. *Stem cell oscillations are induced, without any significant effect on blood cells.*

Proliferation-controlled oscillations. We use the term proliferation-controlled oscillations to refer to oscillations induced by destabilization of the proliferative feedback control function $h(\bar{M})$. If we compare the stem cell model (3.12) (with $v_0 = 1$)

$$\dot{S} = b_0 \left[(1+\lambda_0)h_0(S_1)S_1 - h_0(S)S\right] - \varepsilon_0 S \tag{4.7}$$

with the blast cell model (along the characteristics)

$$\dot{M} = b\left[(1+\lambda)h(\bar{M}_1)M_{1,1} - h(\bar{M})M\right], \tag{4.8}$$

it is not difficult to sense that modification of the parameters b or λ may cause the blast maturation to proceed unstably.

This is what we find if λ is increased to 0.6, and the consequent oscillations are shown in Figure 6. The steady exponential proliferation of blast cells is unstable, which causes oscillations to occur in the maturation profile, and these oscillations propagate along the characteristics, as shown in Figure 7.

The oscillations have period equal to the cell cycling time, equal to one in our scaled model. A partial understanding of these oscillations is afforded by the observation that if h is constant and M is periodic with period $2\pi/\omega$, then (4.8) admits a solution

$$M = \sum_{p,q} c_{pq} e^{\sigma_q \xi + ip\omega(t-\xi)}, \tag{4.9}$$

provided that σ_q satisfies

$$\sigma = -A - Ge^{-\sigma}, \tag{4.10}$$

where

$$A = bh, \quad G = -bh(1+\lambda). \tag{4.11}$$

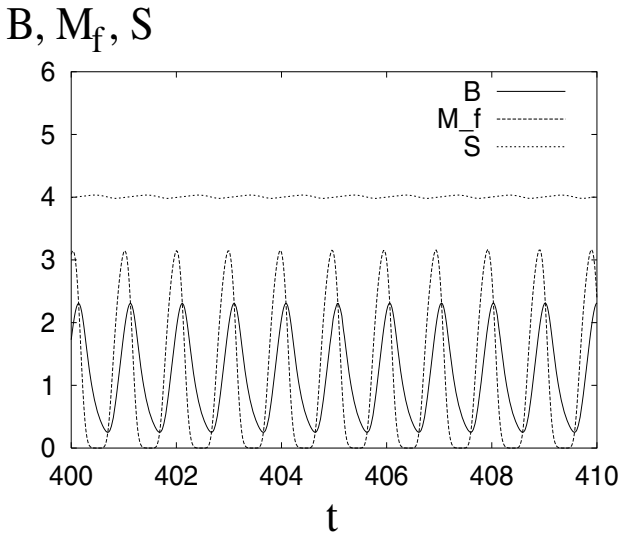

FIG. 6. *Proliferatively controlled oscillations due to increased proliferation. Default parameter values are used, except that* $\lambda = 0.6$.

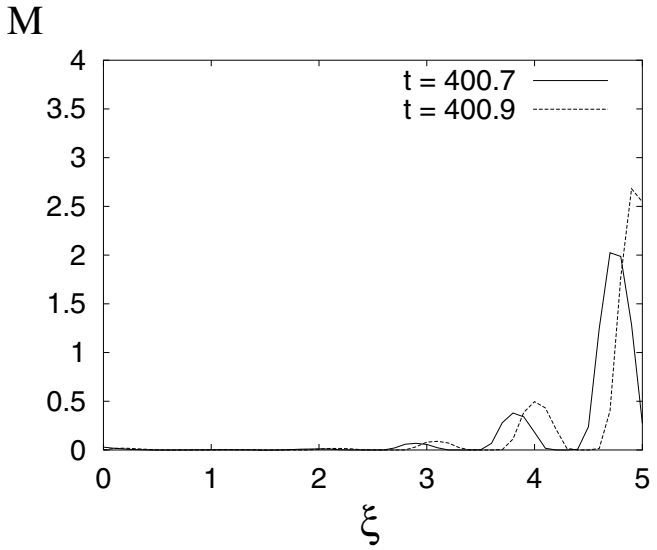

FIG. 7. *Two snapshots of the maturation profile for the numerical solution in Figure* 6. *An exponentially growing travelling wave propagates down the maturation axis.*

Since $\lambda > 0$, we have $G + A < 0$, and it is straightforward to show that there is always a single positive root, which can be labelled with $q = 0$. The others are complex (conjugates), and are labelled with increasing frequency as $q = \pm 1, \pm 2$, etc. Consideration of these complex roots then shows that for small $|G|$, $\mathrm{Re}\,\sigma_q < 0$, so that the effect of the oscillations dies away as the cells mature; this is what happens in Figure 5. However, for larger $|G|$, $\mathrm{Re}\,\sigma_q > 0$, and the oscillations grow in amplitude as the cells mature. This causes $\bar{M}$ to fluctuate, and thus also h, presumably entraining the period of the oscillations to that of the delay. This description is consistent with

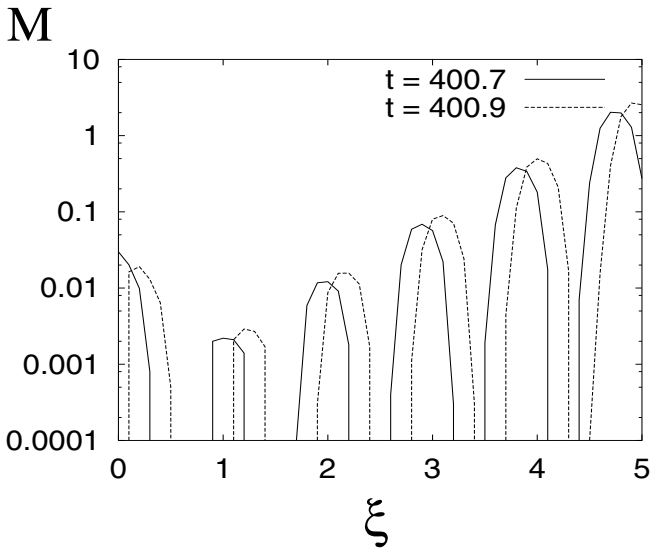

FIG. 8. *The same graph as in Figure* 7*, except that a logarithmic scale is used. The exponential increase with* ξ *is clearly seen.*

what is seen in Figure 7 (see also Figure 8). An approximate criterion for growth of periodic perturbations with ξ is when $G < -[A^2 + \pi^2]^{1/2}$, i.e.,

$$\lambda \gtrsim \left[1 + \left(\frac{\pi}{bh}\right)^2\right]^{1/2} - 1. \tag{4.12}$$

Differentiation-controlled oscillations. The final kind of oscillation that we see is induced by the peripheral control of stem cell committal through the function $v_0(B)$. These are essentially delay induced oscillations, where now the delay involved is the maturation time. Because we suppose maturation time is large, these are long period oscillations. They can be caused by increasing the sensitivity of the peripheral controller, as shown in Figure 9.

To understand the origin of these oscillations, let us suppose that $\xi_f \gg 1$, or $\xi_F \gg \tau$, meaning that the maturation time is significantly longer than the cell cycle time, or equivalently, that there are a large number of generations in the cell lineage. Let us define

$$\varepsilon = \frac{1}{\xi_m}, \tag{4.13}$$

and the slow time and maturation scales

$$T = \varepsilon t, \quad X = \varepsilon \xi. \tag{4.14}$$

We also define μ via

$$\lambda = \varepsilon \mu, \tag{4.15}$$

and suppose that $\mu = O(1)$. Essentially we are revisiting the relaxation oscillation analysis of Fowler and Mackey [8]. The partial differential equation for M takes the

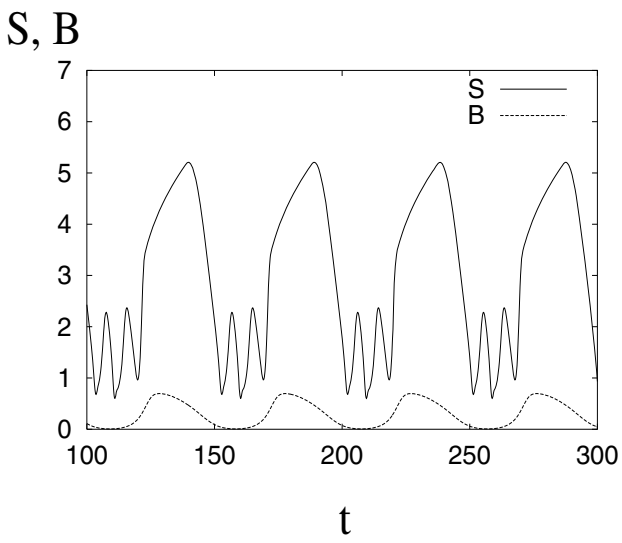

FIG. 9. *Differentiation-controlled oscillations due to enhancement of the peripheral controller function. Default parameters are used, except that* $v^* = v' = 2$.

form

$$\frac{\partial M}{\partial T} + \frac{\partial M}{\partial X} = \frac{b\left[h_{\varepsilon,\varepsilon} M_{\varepsilon,\varepsilon} - hM\right]}{\varepsilon} + \mu b h_{\varepsilon,\varepsilon} M_{\varepsilon,\varepsilon}, \tag{4.16}$$

and expanding in a Taylor series, we have

$$\frac{\partial[(1+bh)M]}{\partial T} + \frac{\partial[(1+bh)M]}{\partial X} \approx \mu b h M, \tag{4.17}$$

with the boundary condition (taking $S = 1$)

$$M = \nu v_0(B) \quad \text{at} \quad X = 0. \tag{4.18}$$

If we suppose h is constant (it is not, but it is not the dependence of h on $\bar{M}$ which causes the oscillations), then the solution of this is

$$M = \nu v_0[B(T-X)] \exp\left[\frac{\mu b h X}{1+bh}\right], \tag{4.19}$$

and the cell efflux at $X = 1$ ($\xi = \xi_f$) is

$$M(1) = \nu a v_0[B(T-1)], \tag{4.20}$$

where the amplification factor a is

$$a = \exp\left[\frac{\mu b h}{1+bh}\right]. \tag{4.21}$$

Therefore the blood cell conservation law (3.19) becomes the delay recruitment model

$$\varepsilon\delta \frac{dB}{dT} = \nu a v_0(B_1) - B. \tag{4.22}$$

This is a standard delay recruitment equation with a unique steady state. Oscillations will occur as a consequence of instability if there are solutions σ of (4.10), i.e.,

$$\sigma = -A - Ge^{-\sigma}, \tag{4.23}$$

with positive real part. The values of A and G are

$$A = \frac{1}{\varepsilon\delta}, \quad G = \frac{\nu a|v_0'|}{\varepsilon\delta}. \tag{4.24}$$

Equation (4.23) is well understood; see, for example, Mackey [11] or Murray [15, pp. 23–26]. It is a transcendental equation with an infinite number of complex roots which accumulate at the essential singularity at $\sigma = -\infty$. It follows that the set of $\operatorname{Re}\sigma$ is bounded above. Consequently, there is an instability criterion which determines when *all* the roots σ have negative real part, and this is indicated in Figure 10. The three curves in the figure are given by $G = -A$, $G = \exp[-(1 + A)]$, and the Hopf bifurcation curve $G = G_0(A)$, which is given parametrically by

$$A = -\frac{\Omega}{\tan\Omega}, \quad G_0 = \frac{\Omega}{\sin\Omega}, \tag{4.25}$$

where $\Omega \in [0, \pi]$. Since G and A are positive, oscillatory instability occurs precisely if $G > G_0(A)$. Since $G_0 \sim A$ as $A \to \infty$, the instability criterion for large A is simply $G \gtrsim A$, i.e.,

$$\nu|v_0'| \exp\left[\frac{\mu bh}{1 + bh}\right] > 1. \tag{4.26}$$

Instability is promoted by increasing $|v_0'|$, for example, as indicated in Figure 9.

5. Conclusions. In this paper we have studied the onset of oscillations in a model of blood cell production which includes a description of cell cycling and proliferation, and also of differentiation and maturation. The model formulation extends the work of previous authors by correcting an apparent inconsistency in the description of the primitive stem cell population, and also by including the simultaneous control of stem cell proliferation, stem cell committal, and blast cell proliferation. All three controls can cause oscillations for appropriate values of control parameters.

Previous results concerning stem cell oscillations are reproduced (see Figure 5), but these oscillations are harder to obtain when the parameter ν is small, and in addition they hardly affect the mature blood cell population without additional destabilization of the blast cell proliferation. The reason for this is that an $O(1)$ oscillation in the stem cell population causes only an $O(\nu)$ oscillation in the blast cell committal rate, and this amplitude propagates through the differentiating cells. Thus one consequence of stem cell paucity is that any instability in the stem cell population itself is hardly manifested in the blood cell production. From the point of view of survival and control, this is, of course, a positive result.

Instability in the proliferation of blast cells due to enhancement of the proliferative controller $h(\bar{M})$ causes oscillations which propagate down the maturation axis and are amplified as they progress. The result of this is shown in Figures 6, 7, and 8. The oscillations have a period equal to the cell cycling time. The mechanism for these oscillations appears to be a destabilization of the maturing cell amplification, together with a type of resonance which ties the period to the delay.

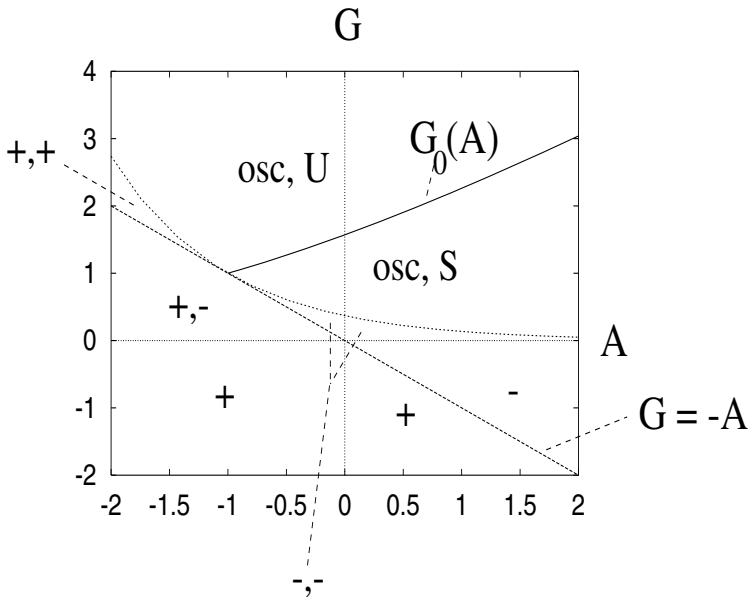

FIG. 10. *Stability map for* (4.23). *The plus and minus signs indicate the sign of real values of the growth rate* σ, *when these exist. A Hopf bifurcation occurs as* G *increases through* $G_0(A)$, *and* $G_0 \approx A$ *for large* A.

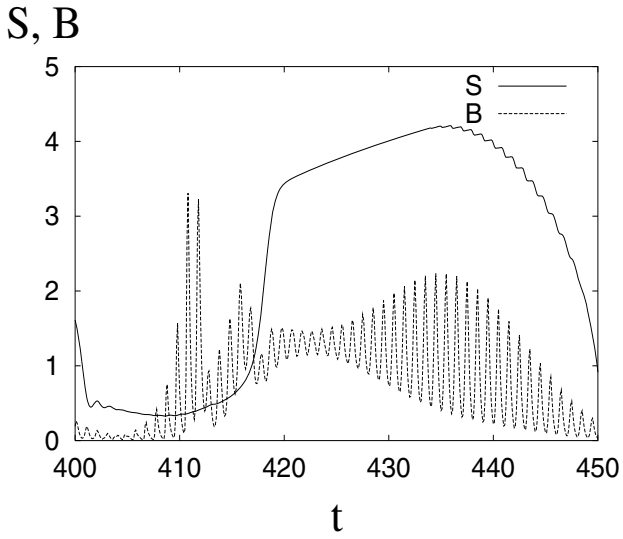

FIG. 11. *The effect of switching on all three instability mechanisms. Default parameters are used, except that* $v^* = v' = 2$, $\lambda_0 = 0.05$, *and* $\lambda = 0.6$.

The final kind of oscillation is induced by enhanced peripheral control, as seen in Figure 9. Stem cell paucity implies that $\nu \ll 1$ and, consequently, that $\xi_f \gg 1$, and thus that the oscillation period (controlled by the delay ξ_f) is long. This allows an approximate reduction of the partial differential delay equation to a simple first order differential delay equation, which is simply analyzed. In particular, if a threshold form of peripheral controller is used, blood cell counts can decrease to zero, as can be the case in cyclical neutropenia.

Finally, and as shown in Figure 11, a combination of all three destabilizing mech-

anisms can lead to oscillations which operate on both the slow, peripherally controlled time scale and the fast, proliferatively controlled one. We consider this observation to be a possible explanation of the apparent fact in Figure 2 that both reticulocytes and platelets appear to oscillate on a fast as well as a slow time scale. Further study of this behavior requires the extension of this model to accommodate multiple cell lineages.

CELLULAR TRACTION AS AN INVERSE PROBLEM*

D. AMBROSI†

Abstract. The evaluation of the traction exerted by a cell on a planar substrate is here considered as an inverse problem: shear stress is calculated on the basis of the measurement of the deformation of the underlying gel layer. The adjoint problem of the direct two-dimensional plain stress operator is derived by a suitable minimization requirement. The resulting coupled systems of elliptic partial differential equations (the direct and the adjoint problem) are solved by a finite element method and tested against experimental measures of displacement induced by a fibroblast cell's traction.

Key words. cellular traction, linear elasticity, inverse problem, finite element

Introduction. The study of the basic mechanisms of cell migration has greatly increased in the last few years. Cell locomotion occurs through a very complex interaction that involves, among others processes, actin polymerization, matrix degradation, chemical signaling, adhesion, and pulling on substrate and fibers [11]. All these ingredients occur not only in single cell migration but also in collective morphogenetic behaviors [15].

When focusing on mechanical aspects only, a major issue is the determination of the dynamical action of the cells on the environment during migration: the cells adhere, pull the surrounding matrix, and move. As a cell can have more than one hundred focal adhesion sites, each with thousands of integrins, it is quite difficult to obtain a pointwise description of the forces exerted by moving cells on a direct basis. Nevertheless, the striking improvement of nanotechnology has very recently lead to *direct* measurements of cell traction: cells are deposed on a bed of microneedles and, on the basis of the Young modulus and the moment of inertia, length, and displacement of the microneedles, one can directly obtain the exerted deflective force [4, 14]. However, these very recent experimental achievements still provide partial information on a very special configuration only: the resolution of the displacement field is at most the distance between two microneedles (2 microns), and, more important, this setting is far from being a natural migration environment.

These kinds of considerations suggests that the dynamics of cell locomotion can be fruitfully studied as an *inverse* problem, an idea that dates back to the seminal paper of Harris, Wild, and Stopak [8]. A thin elastic film over a fluid is deformed under cell traction in a wrinkled pattern, and the size of the crimps is correlated to the shear load. Unfortunately, buckling of a thin film is an essentially nonlinear phenomenon and a quantitative reconstruction of the exerted traction would call for a nontrivial stability analysis in nonlinear elasticity.

A quantitative methodology was proposed in 1996 by Dembo et al. [3], using prestressed silicone rubber, an approach further improved by Dembo and Wang in 1999

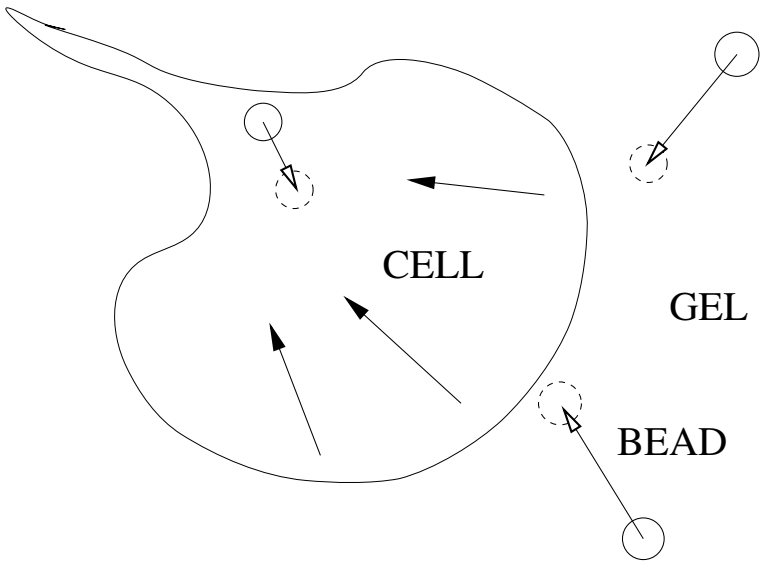

FIG. 1. *The experiment by Dembo and Wang. The cell exerts traction (filled arrows) on the gel. The beads, solidal with the substrate, move from the former position (continuous-line circle) to the new one (dashed circles). The difference in these positions gives the displacement of the gel (open arrows).*

[2]; see Figure 1. They deduce the traction exerted by a fibroblast on a polyacrilamide substrate from the measured displacement of several fluorescent beads merged into the upper layer of the gel. The gel is soft enough to remain in a linear elasticity regime, and no wrinkles form. The cellular traction is then computed by maximizing the total Bayesian likelihood of the markers displacement, predicted on the basis of the Boussinesq solution for the linear elastic half-plane with pointwise traction.

The same approach (in two spatial dimensions) is followed by Schwarz et al. [13], who numerically invert the Boussinesq integral operator, thus expressing the displacement in terms of the traction. They point out the strong dependence of the solution on small variations in the data, in particular those depending on experimental uncertainty. They therefore propose a regularization of the original problem according to the Tichonov method [7].

In this paper the same biomechanical issue studied by Dembo and Wang is addressed by a different mathematical approach, based on the classical functional analysis framework due to Lions [10]. On the basis of dimensional arguments, the three-dimensional elasticity system of equations is first reduced to a two-dimensional one. The inverse problem is then stated as minimization of the distance between the measured and the computed displacement under penalization of the force magnitude [12]. Standard derivation of the cost function leads to two sets of elastic-type problems: the direct and the adjoint. The unknown of the adjoint equation is just the shear force exerted by the cells we are looking for. The two systems of equations are then numerically solved by a coupled finite element discretization.

The paper is organized as follows. In section 1 the abstract formulation of the minimization of a cost functional is stated. The resulting adjoint problem is specified to the case of linear elasticity with an unknown body force in section 2. The methods and results of the numerical approximation of the system of equations are illustrated

in section 3, where the specific force field exerted by a fibroblast on a flat surface is calculated and qualitatively compared with the numerical results obtained by different approaches. The appendix details the assumptions that yield a two-dimensional *plain stress* system of equations in linear elasticity. Analogies and differences between the present approach and the ones reported in the relevant literature are discussed in the concluding remarks of section 4.

1. Abstract formulation. Let V be a Hilbert space equipped with the internal product $(\cdot,\cdot)$. Let $U \subset V$, and let $U = U_0 \otimes U_1$ be an orthogonal (nontrivial) decomposition of U in V. Consider the linear operator $A : U \to V$ and the problem

$$A\mathbf{u} = \mathbf{f}, \tag{1.1}$$

where $\mathbf{u} \in U$. We call the direct problem the determination of $\mathbf{u} \in U$ for a given $\mathbf{f} \in V$. If $\mathbf{u} \in U$ is given, by straightforward application of the operator A we get an $\mathbf{f} \in V$ and, in this sense, we denote $\mathbf{u} = \mathbf{u}(\mathbf{f})$. This is the inverse problem. Often only a partial knowledge of $\mathbf{u}$ is available. As a member of V, any $\mathbf{u} \in U$ can be orthogonally decomposed into two components $\mathbf{u} = \mathbf{u}_0 + \mathbf{u}_1$, where $\mathbf{u}_0 \in U_0$ and $\mathbf{u}_1 \in U_1$. If only the component $\mathbf{u}_0$ is known, the association $\mathbf{u} \to \mathbf{f}$ illustrated above cannot be carried out. Even worse, in general $\mathbf{u}_0$ and $\mathbf{u}_1$ are not in U, the domain of the operator A. These reasons make the problem ill-posed and call for a suitably supplementary condition to determine an optimal $\mathbf{f}$ on the basis of a partial knowledge of $\mathbf{u}$.

Let $\mathbf{u}_0 \in U_0$, and define the projector $P : U \to U_0$. We introduce the functional $J : V \to \mathbb{R}$:

$$J(\mathbf{f}) = (P\mathbf{u}(\mathbf{f}) - \mathbf{u}_0, \mathbf{u}(\mathbf{f}) - \mathbf{u}_0) + \varepsilon(\mathbf{f}, \mathbf{f}), \tag{1.2}$$

where $\varepsilon > 0$ is a penalty parameter.

We look for $\mathbf{g} \in V_c$ such that

$$J(\mathbf{g}) \le J(\mathbf{f}) \qquad \forall \mathbf{f} \in V_c, \tag{1.3}$$

where V_c is a convex and closed subset of V. In other words, we look for a value of $\mathbf{f}$ minimizing the distance between $\mathbf{u}$ and $\mathbf{u}_0$ under penalty of the norm of $\mathbf{f}$.

Taking the Gateaux derivative of J evaluated in $\mathbf{g}$, we obtain the equivalent condition,

$$J'[\mathbf{g}](\mathbf{f} - \mathbf{g}) \ge 0 \qquad \forall \mathbf{f} \in V_c; \tag{1.4}$$

that is,

$$(P\mathbf{u}(\mathbf{g}) - \mathbf{u}_0, \mathbf{u}(\mathbf{f}) - \mathbf{u}(\mathbf{g})) + \varepsilon(\mathbf{g}, \mathbf{f} - \mathbf{g}) \ge 0 \qquad \forall \mathbf{f} \in V_c. \tag{1.5}$$

Introduce the adjoint problem

$$A^*\mathbf{p} = P\mathbf{u}(\mathbf{g}) - \mathbf{u}_0, \tag{1.6}$$

where $A^* : V \to U_0$. Using the adjoint problem, (1.5) rewrites to

$$(\mathbf{p}, A(\mathbf{u}(\mathbf{f}) - \mathbf{u}(\mathbf{g}))) + \varepsilon(\mathbf{g}, \mathbf{f} - \mathbf{g}) \ge 0 \qquad \forall \mathbf{f} \in V_c \tag{1.7}$$

or

$$(\mathbf{p}, \mathbf{f} - \mathbf{g}) + \varepsilon(\mathbf{g}, \mathbf{f} - \mathbf{g}) \ge 0 \qquad \forall \mathbf{f} \in V_c. \tag{1.8}$$

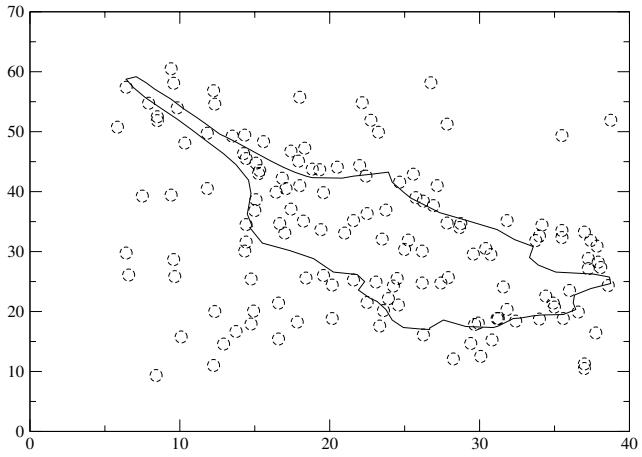

FIG. 2. *The domain Ω of the elasticity equation contains the subdomain Ω_c, the area covered by the cell and where the force applies: in the figure it is enclosed by the continuous line. The dashed circles are centered in the beads location, and their collection represents the Ω_0 subdomain where the displacement is known.*

Therefore we obtain

$$\mathbf{g} = -\frac{1}{\varepsilon}\mathbf{p}, \tag{1.9}$$

where $\mathbf{g} \in V_c$.

2. Linear elasticity. In this section we apply the general theory illustrated above to the specific problem of the small deformation of a homogeneous elastic body subject to body forces only. Let $\mathbf{u}(\mathbf{x})$ be the displacement vector field, $\mathbf{x} \in \Omega \subset \mathbb{R}^3$. Suppose that the displacement is known in a subset $\Omega_0 \subset \Omega$; the target function $\mathbf{u}_0(\mathbf{x})$ has support in Ω_0. In the problem at hand the force is exerted just on the portion of the domain where the cell lies; let us call this subdomain $\Omega_c \subset \Omega$ (see Figure 2). The cell actually adheres to the substrate just in specific small regions called focal adhesion sites, which can be experimentally localized [1]. Nothing prevents restricting the force support to these areas; this assumption is not applied here just because the information is missing for the experiment numerically reproduced in the final section.

The linear elasticity operator in strong form is

$$A\mathbf{u} = -\mu\Delta\mathbf{u} - (\mu + \lambda)\nabla\left(\nabla \cdot \mathbf{u}\right), \tag{2.1}$$

where μ and λ are the Lamé constants that characterize the material. The elasticity problem reads

$$A\mathbf{u} = \mathbf{f}, \qquad \mathbf{u}|_{\partial\Omega} = 0. \tag{2.2}$$

The direct problem consists in solving (2.2) for a given force field $\mathbf{f}$; the inverse problem is to determine the force that produces a known displacement. Here, as in all cases of practical interest, the displacement is not known in all the domain Ω, but just in Ω_0. In this case the inverse problem is ill-posed, and uniqueness of the solution has to be recovered by supplementing one more condition. Note that no issue of regularization in the sense of smooth dependence on initial data is addressed here directly: regularity will follow a posteriori.

After definition of the bilinear form

$$\sigma(\mathbf{u},\mathbf{v}) = \mu \int_\Omega \nabla\mathbf{u} : \nabla\mathbf{v}\, d\Omega + (\mu+\lambda)\int_\Omega (\nabla\cdot\mathbf{u})\,(\nabla\cdot\mathbf{v})\, d\Omega, \qquad \mathbf{u},\mathbf{v}\in H_0^1(\Omega), \tag{2.3}$$

the weak form of the problem (2.1) can be stated as follows: for a given function $\mathbf{f}\in L^2(\Omega)$, find the solution $\mathbf{u}\in H_0^1(\Omega)$ such that

$$\sigma(\mathbf{u},\mathbf{v}) = (\mathbf{f},\mathbf{v}) \qquad \forall\mathbf{v}\in H_0^1(\Omega). \tag{2.4}$$

The unique solution for the given $\mathbf{f}$ will be denoted by $\mathbf{u}(\mathbf{f})$ [5].

We note that any $\mathbf{u}\in H_0^1(\Omega)$ can be trivially rewritten as $\mathbf{u} = \chi_0\mathbf{u} + (1-\chi_0)\mathbf{u}$, where χ_o is the characteristic function of the Ω_0 set. This form provides an orthogonal decomposition of $\mathbf{u}$ as a member of $L^2(\Omega)$. Therefore we can define the projector P as follows:

$$P\mathbf{u} = \chi_o\mathbf{u}. \tag{2.5}$$

The mere knowledge of $\mathbf{u}_0$ does not allow us to obtain $\mathbf{f}$ straightforwardly. We therefore define the functional J as

$$\begin{aligned} J(\mathbf{f}) &= \int_{\Omega_0} |\mathbf{u}-\mathbf{u}_0|^2\, dV + \varepsilon\int_\Omega |\mathbf{f}|^2 dV \\ &= \int_\Omega (P\mathbf{u}-\mathbf{u}_0)\cdot(\mathbf{u}-\mathbf{u}_0)\, dV + \varepsilon\int_\Omega |\mathbf{f}|^2 dV, \end{aligned} \tag{2.6}$$

where ε is a real positive number. We look for $\mathbf{g}$ minimizing J:

$$J(\mathbf{g}) \le J(\mathbf{f}) \qquad \forall\mathbf{f}\in V_c, \tag{2.7}$$

where $V_c\subset L^2(\Omega)$ is the space of the finite energy functions with support in Ω_c. The minimization of J accomplishes the minimization of the distance of the solution from the measured value $\mathbf{u}_0$ under penalization of the magnitude of the associated force field $\mathbf{f}$. The penalty parameter ε balances the two requirements.

The minimum of J occurs in $\mathbf{g}$, where the Gateaux derivative satisfies

$$J'[\mathbf{g}](\mathbf{f}-\mathbf{g}) \ge 0 \qquad \forall\mathbf{f}\in V_c; \tag{2.8}$$

that is,

$$\int_\Omega (P\mathbf{u}(\mathbf{g})-\mathbf{u}_0)\cdot(\mathbf{u}(\mathbf{f})-\mathbf{u}(\mathbf{g}))\, dV + \varepsilon\int_\Omega \mathbf{g}\cdot(\mathbf{f}-\mathbf{g})\, dV \ge 0 \qquad \forall\mathbf{f}\in V_c. \tag{2.9}$$

Introduce the adjoint problem

$$\begin{aligned} A^*\mathbf{p} &= P\mathbf{u}-\mathbf{u}_0, \\ \mathbf{p}|_{\partial\Omega} &= 0. \end{aligned} \tag{2.10}$$

Because here A is self-adjoint, back-substitution into (2.8) gives

$$\int_\Omega A^*\mathbf{p}\cdot(\mathbf{u}(\mathbf{f})-\mathbf{u}(\mathbf{g}))\, dV + \varepsilon\int_\Omega \mathbf{g}\cdot(\mathbf{f}-\mathbf{g})\, dV \ge 0 \qquad \forall\mathbf{f}\in V_c \tag{2.11}$$

or

$$\int_\Omega \mathbf{p}\cdot(\mathbf{f}-\mathbf{g})\,dV+\varepsilon\int_\Omega \mathbf{g}\cdot(\mathbf{f}-\mathbf{g})\,dV\geq 0 \qquad \forall \mathbf{f}\in V_c, \tag{2.12}$$

and, finally, one finds the optimal body force in the sense of (2.7):

$$\mathbf{g}=-\frac{\chi_c}{\varepsilon}\mathbf{p}, \tag{2.13}$$

where χ_c is the characteristic function of the Ω_c set. The function $\mathbf{g}$ vanishes outside Ω_c because of our characterization of the set of admissible force fields V_c.

3. Numerical methods and results. For the specific application addressed in the present paper, the general three-dimensional theory illustrated above is restricted to two dimensions. The three-dimensional elasticity system of equations is approximated to a two-dimensional plain-stress one by vertical averaging along an *effective thickness* (see the appendix). The direct and inverse systems of partial differential equations deduced in section 2 now rewrite to

$$-\hat{\mu}\Delta\mathbf{u}-(\hat{\mu}+\hat{\lambda})\nabla(\nabla\cdot\mathbf{u})=-\frac{\chi_c}{\varepsilon}\mathbf{p}, \qquad \mathbf{u}|_{\partial\Omega}=0, \tag{3.1}$$

$$-\hat{\mu}\Delta\mathbf{p}-(\hat{\mu}+\hat{\lambda})\nabla(\nabla\cdot\mathbf{p})=\chi_o\mathbf{u}-\mathbf{u}_0, \qquad \mathbf{p}|_{\partial\Omega}=0. \tag{3.2}$$

Equations (3.1) and (3.2) have been discretized by a finite element method using linear basis functions on an unstructured mesh. The two resulting linear systems are solved by a global conjugate gradient method, thus avoiding any unnecessary iterative coupling [12].

The computational domain is a square with side of 100 microns. The effective Lamé constants are taken from [2], thus resulting in $\hat{\mu}=2100$ and $\hat{\lambda}=4150$ picoNewtons per micrometer. The measured displacement $\mathbf{u}_0$ and the cell contour are obtained from the same paper.

The value of the penalty parameter ε can be suitably chosen when reinterpreting the system of equations (3.1)–(3.2) as a filter. In fact, suppose for a moment that $\Omega_0=\Omega$ under periodic boundary conditions. The amplitude of the Fourier components of the solution u_k, p_k satisfies

$$\hat{\mu}k^2u_k\simeq-\frac{1}{\varepsilon}p_k, \tag{3.3}$$

$$\hat{\mu}k^2p_k\simeq u_k-u_{0,_k}; \tag{3.4}$$

that is,

$$u_k=\frac{u_{0,k}}{1+\varepsilon\hat{\mu}^2k^4}. \tag{3.5}$$

Equation (3.5) points out that the system of equations (3.1)–(3.2) acts as a filter damping the modes corresponding to wavenumbers $\gtrsim\varepsilon^{-1/4}\hat{\mu}^{-1/2}$. The penalty parameter used in the calculations illustrated below is $\varepsilon=10^{-6}$, thus algebraically damping wavelengths larger than 9 μm.

In Figure 3 a portion of the computational domain is shown: the cell contour, the displacement of the beads, and the computational mesh are plotted. The cell contour represents a boundary between internal and external elements. Note that some nodes of the mesh correspond to the original bead locations, while others do

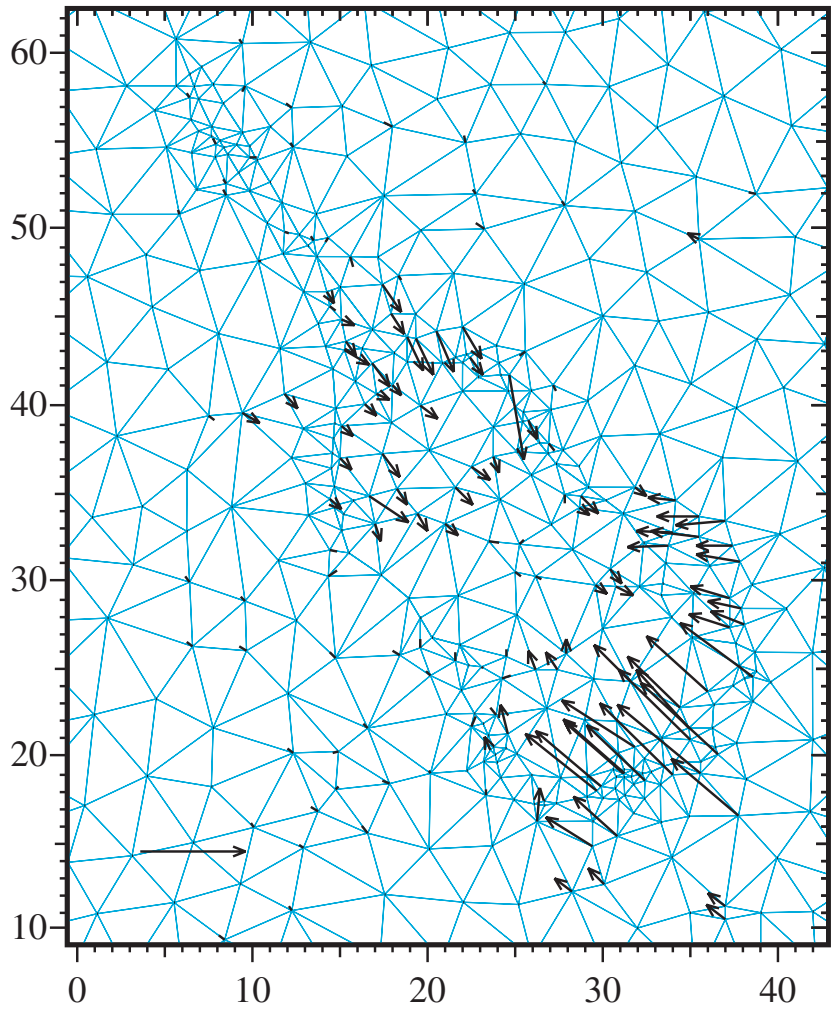

FIG. 3. *Experimental displacement of the beads merged in the upper layer of the gel, as taken from* [2]. *The computational mesh is represented in grey. The mesh satisfies two constraints: it has a node in every point where displacement has been measured, and a sequence of element sides coincides with the boundary of the cell. The reference vector at the bottom left corner is* 6 *microns long.*

not: they have been created for the sake of regularity of the computational grid. The present approach ensures full flexibility in this respect. According to the notation introduced in the preceding sections, the cell contour defines Ω_c, while the collection of the elements that have at least one node with measured displacement defines Ω_0. The computed displacement is shown in Figure 4. The mean difference between the calculated and the measured solution is

$$\frac{1}{n}\sum_{i=1}^{n}\sqrt{(\mathbf{u}_i-\mathbf{u}_{0,i})^2}=8.8\ 10^{-2}\,\mu\mathrm{m}, \tag{3.6}$$

where the sum runs over all the nodes at which $\mathbf{u}_0$ is known. The displacement of the gel matrix essentially occurs around the cell edge and, secondly, at the tail, as

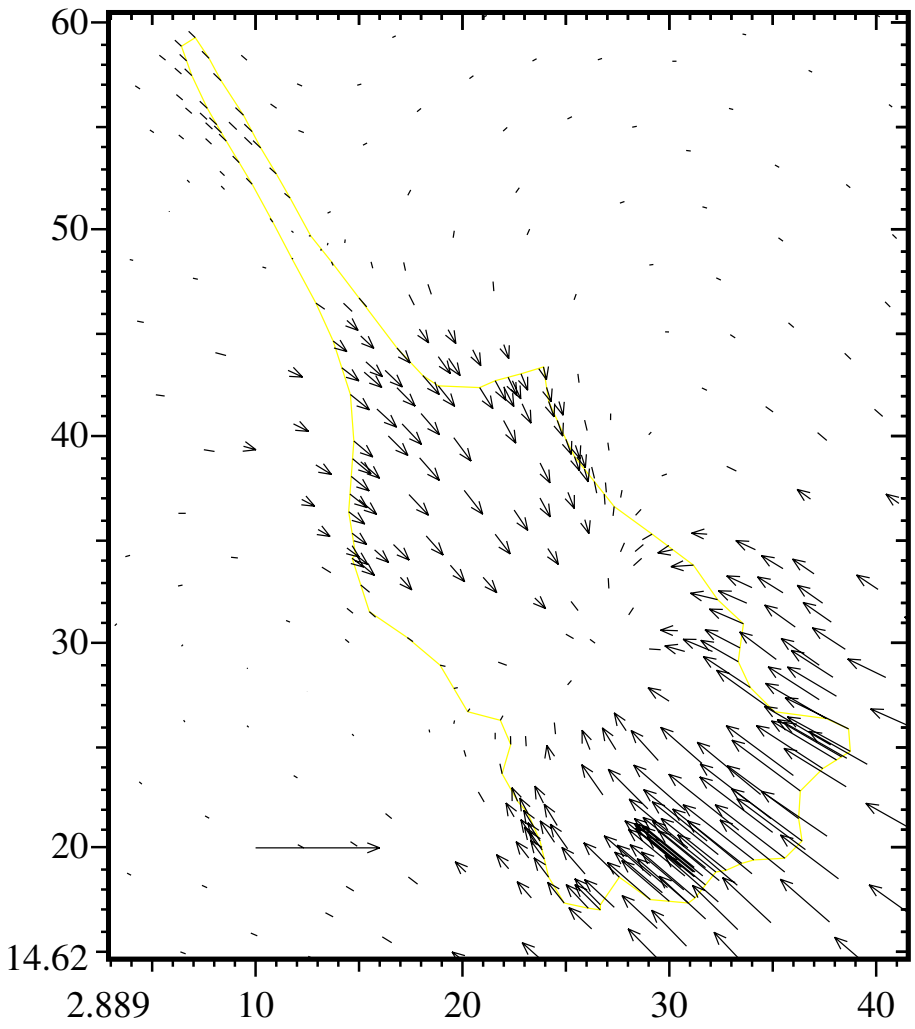

FIG. 4. *Computed displacement of the gel layer. The reference vector at the bottom left corner is* 6 *microns long.*

can be observed also in Figure 5, where the magnitude of the displacement field is represented. The computed force field is plotted in Figure 6. The qualitative behavior is very near to results shown by Dembo and Wang. The exerted force reaches the maximum value of some thousands of picoNewtons, corresponding to the remarkable stress of thousands of Pascals. A striking feature of the plot is that the cell is pulling both at the edge and at the tail, although the latter with less intensity. This result is in agreement with [2].

4. Final remarks. In this paper a novel method has been proposed for solving the inverse problem to obtain forces from displacement of an elastic body. The statement and functional derivation of a cost function yields two coupled systems of partial differential equations. The numerical solution of the inverse problem deduces the force acting on a surface on the basis of a partial knowledge of the deformation. As a specific application, the method has been applied to obtain a quantitative plot

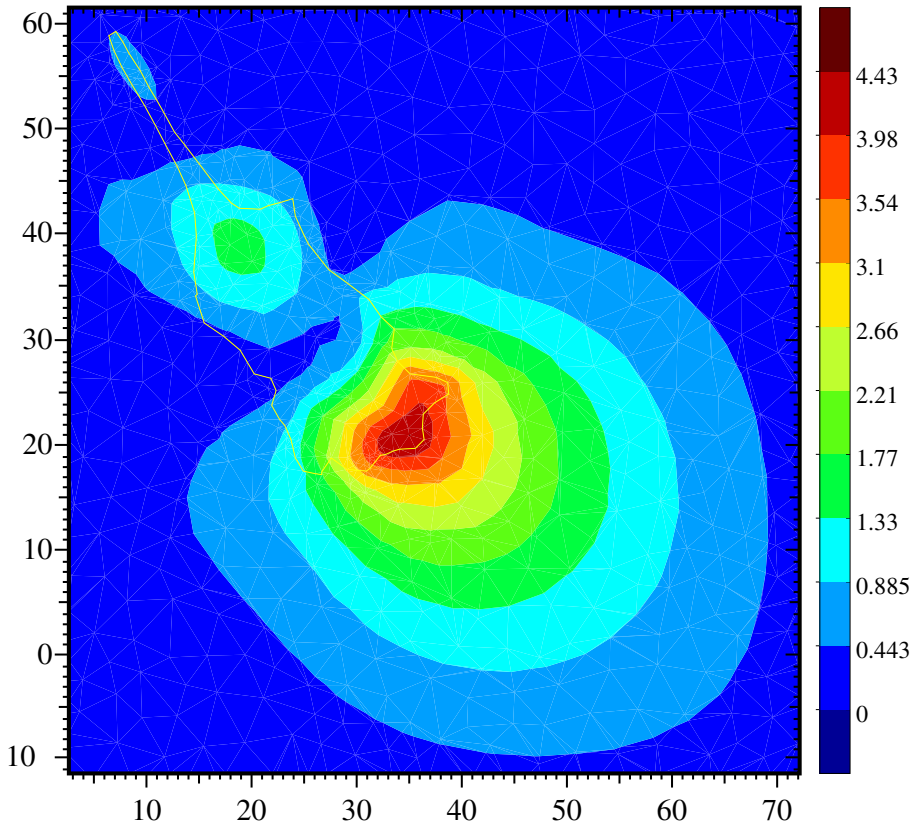

FIG. 5. *Color map of the magnitude of the computed displacement of the gel layer. The color scale is in microns.*

of the forces exerted by a fibroblast cell on a gel substratum.

The proposed approach is quite general in not assuming a pointwise nature of the surface force. The direct solution of the elasticity equations makes it possible, in principle, to apply the proposed methodology to a variety of situations for which the Boussinesq solution does not apply: for instance, nonhomogeneous substrate or nonisotropic prestress of the gel.

The deduction of the system of equations from a minimum principle provides a clear meaning to the regularization procedure, while the statement of the equations in precise functional spaces ensures the well-posedness of the direct and inverse problems. Finally, the numerical integration of the equations by a finite element discretization ensures full geometrical flexibility to account for the complicated contour of a cell or to operate local mesh refinements suggested by accuracy arguments.

Appendix. Two-dimensional modeling. The extracellular matrix is deformed by the traction exerted by the cell, and in principle the strain of the gel can be predicted solving the force balance equation for an elastic three-dimensional body with suitable boundary conditions. However, an a priori consideration of the characteristics of the displacement field in the elastic substrate suggests some suitable simplification of the full three-dimensional model.

As a matter of fact, the substrate layer is very shallow: its horizontal extension

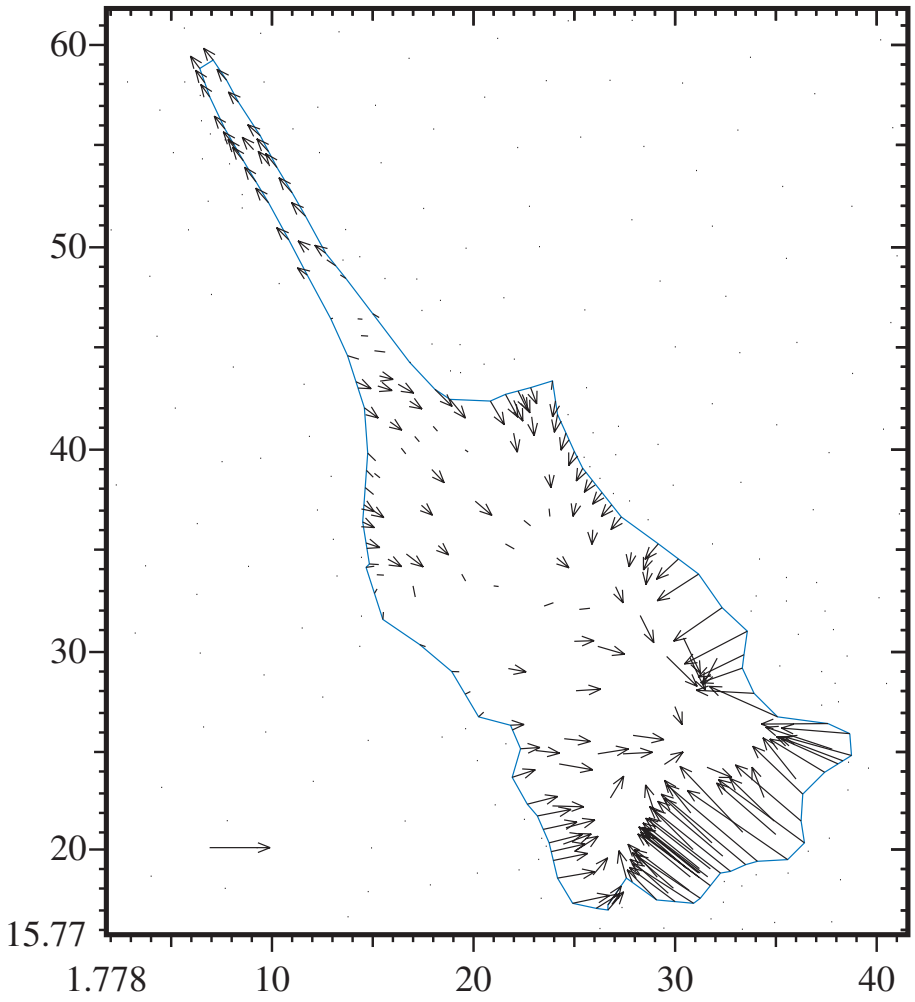

FIG. 6. *Computed force field exerted by the fibroblast on the gel layer. The magnitude of the reference vector at the bottom left corner corresponds to* 10^3 *picoNewtons.*

($\sim$ 1mm) is much larger than the vertical one ($\sim 10-100\mu$m). However, this geometrical scale ratio by itself does not allow any estimate of the behavior of the solution along the vertical direction, a consideration that could be helpful in addressing a suitable approximate model.

The useful observation is instead that the vertical displacement is very small when compared to the horizontal one. Let us denote by X and Z the typical scale lengths of the horizontal and vertical displacements, respectively. The length X is of the order of the diameter of a cell ($\sim 20\mu$m), while Z is to be determined. In the following we indicate by U and W the typical horizontal and vertical displacements.

The boundary conditions of the three-dimensional force balance equation at the cell-gel interface read

$$\mu(u_z + w_x) = \tau \qquad \text{at } z = 0, \tag{A.1}$$

$$(\mu + \lambda)w_z + \lambda u_x = 0 \qquad \text{at } z = 0. \tag{A.2}$$

As $\mu \sim \lambda$, inspection of (A.2) yields that it must be $W/Z \sim U/X$. According to the experimental evidence, the vertical displacement is much smaller than the horizontal one: $U \gg W$. Putting this observation into (A.1), one deduces that $|w_x| \ll |u_z|$, and therefore the horizontal derivative of the vertical displacement can be neglected therein.

It follows that to first order the horizontal displacement vanishes in the layer at the depth $Z \sim \mu U/\tau$. In the mentioned experiments

$$U_{max} = 6\,\mu\text{m}, \qquad \mu = \frac{E}{2(1+\nu)} = \frac{E}{3} = 2000\,p\text{N}/\mu\text{m}^2, \qquad \tau_{max} = 10^4\,p\text{N}/\mu\text{m}^2,$$

thus yielding $Z_{max} \sim 1\mu$m, much smaller than the height of the matrigel layer (70μm). According to the observations above, we adopt a two-dimensional "plain stress" model, obtained by vertical integration of the three-dimensional equation of the linearized elasticity along the effective thickness Z_{max}. Therefore one gets

$$-\hat{\mu}\Delta\mathbf{u} - (\hat{\mu} + \hat{\lambda})\nabla\,(\nabla \cdot \mathbf{u}) = \boldsymbol{\tau}, \tag{A.3}$$

where $\boldsymbol{\tau}$ is the shear stress at the surface. The quantities

$$\hat{\mu} = Z_{max}\frac{E}{2(1+\nu)}, \qquad \hat{\lambda} = Z_{max}\frac{E\nu}{1-\nu^2} \tag{A.4}$$

are the effective Lamé constants of the two-dimensional model and have the dimension of force per unit length [3, 9]. It is to be remarked that the above determination of Z_{max} is based on dimensional arguments only.

Acknowledgments. The author is indebted to Pierluigi Rozza, Enrico Serra, and Luigi Preziosi for fruitful discussions about the content of this paper.

HOMOGENIZATION OF A WIRE PHOTONIC CRYSTAL: THE CASE OF SMALL VOLUME FRACTION*

GUY BOUCHITTÉ† AND DIDIER FELBACQ‡

Abstract. We consider the diffraction of a monochromatic incident electromagnetic field by a bounded obstacle made of parallel high conducting metallic fibers of finite length which are periodically disposed. Our goal is to study the asymptotics of this three-dimensional Maxwell problem as the period, the thickness of the rods, and the resistivity are simultaneously small. We solve this problem in the case where the filling ratio of fibers vanishes but their capacity remains positive. We find a limit volumic density of current which results in a nonlocal constitutive relation between the electric and displacement fields. This extends previous results obtained in the polarized case where a two-dimensional effective local equation was found with a possibly negative effective permittivity.

Key words. Maxwell equations, metamaterials, homogenization, thin structures, two-scale convergence, capacitary potentials, nonlocal effects

1. Introduction.

Photonic crystals are artificial periodic structures which possess a photonic band gap: the propagation of electromagnetic waves is impossible in them over some intervals of frequencies [11]. This phenomenon is very close to that of the band structure for electrons in natural crystals. Many studies have been devoted to dielectric devices, that is, photonic crystals made with a dielectric material. However, there is a growing interest in metallic crystals, which now form an emerging field of research, because of their particular behavior in the low-frequency domain, i.e., their effective properties. One of these properties is the existence of a plasma frequency for structures made of wires: for frequencies below some cut frequency the electric field is evanescent in the structure. One of the pioneering studies in this domain was that of Pendry et al. [20], where the problem was analyzed in terms of plasmons and the renormalized effective mass of electrons due to their confinement in very thin wires. This work used a crude model for the metallic properties of the medium. We have presented in [14] another approach based on a homogenization method involving Maxwell equations only.

In this paper, we consider the diffraction of a given monochromatic incident electromagnetic field (wavenumber $k_0 = \frac{2\pi}{\lambda}$) by a bounded obstacle made of parallel high conducting metallic fibers of finite length. These fibers of cross section r are x_3-parallel and placed periodically in (x_1, x_2) (period η) in a cylinder $\Omega = \mathcal{D} \times (0, L)$, where $\mathcal{D}$ denotes a connected bounded open subset of $\mathbb{R}^2$. The fibers share the same conductivity represented by parameter σ.

We are interested in all possible asymptotics of the diffraction problem as the small parameters η, r, σ^{-1} tend simultaneously to zero. The situation is well understood in the case where Ω is an infinite cylinder $\mathcal{D} \times \mathbb{R}$ and the incident field is $E||$

or $H||$ polarized: if, for simplicity we take $\sigma = +\infty$ (perfectly conducting fibers), the diffraction problem reduces to a scalar Helmholtz equation with homogeneous Dirichlet ($E||$ case) or Neumann ($H||$ case) conditions on a perforated domain. Then the following results can be proved using the following classical homogenization techniques (see [7, 8, 9] in the case of diffusion equations). Two critical scales of the radius r_η of the scatterers appear to be relevant:

(1) $E||$ *case:* $\log r_\eta \sim -\eta^{-2}$. Denoting by γ^{-1} the limit of $\eta^2|\log r_\eta|$, the limit problem is equivalent to the diffraction by the whole set Ω filled up with a homogeneous medium of relative permittivity $\varepsilon^{\text{eff}} = 1 - 2\pi\gamma/k_0^2$. This simple fact has striking applications, namely the existence of a suitable frequency (called plasma frequency) under which ε^{eff} becomes negative and the field decreases exponentially inside Ω. When γ is infinite (in particular, when the size of the rods is of order η), the limit field vanishes and Ω behaves like a perfectly conducting medium. As shown by numerical experiments (see [14]), these behaviors are observed even if the ratio $\frac{\eta}{\lambda}$ is not so small.

(2) $H||$ *case:* $r_\eta \sim \eta$. In this case, Ω behaves like a homogeneous medium whose effective permittivity ε^{eff} is greater than 1 through a corrective term which is computed by solving as usual an elementary periodic Neumann problem on a unit cell. Additionally, the magnetic field induces a small turning current on the surface of each small cylinder, which as $\eta \to 0$ becomes a surface current on the boundary of Ω (accordingly the magnetic field becomes discontinuous across $\partial\Omega$). In case $r_\eta \ll \eta$ (as was assumed in the $E||$ case), the equivalent structure is transparent (i.e., $\varepsilon^{\text{eff}} = 1$).

Insofar as the Maxwell problem can be decomposed into two problems of type $E||$ and $H||$ (for instance, if perfectly conducting fibers with infinite length are considered), we can draw the conclusion that for an intermediate size of rods r_η (i.e., $r_\eta \ll \eta$ and $\gamma = +\infty$, for example $r_\eta \sim \eta^2$), the homogenized medium is perfectly reflective for the vertical component of the electric field, whereas it is transparent for that of the magnetic field. Hence very strong polarizing properties are obtained at any incidence.

However, when the diffracting domain Ω is bounded, it is no longer possible to split the original problem into independent problems of type $E||$ and $H||$. As a consequence we have to deal with the full three-dimensional (3D) Maxwell system, which is mathematically much more involved. In particular we will show that nonlocal effects appear in the limit as $\eta \to 0$.

In this paper, we deal only with the case where $r_\eta \ll \eta$, that is, the filling ratio θ_η of rods vanishes. The high conductivity is modeled as a stiff parameter depending on η:

$$\sigma_\eta = \frac{\kappa\,\varepsilon_0\omega}{\theta_\eta}, \tag{1.1}$$

where $\kappa > 0$ is a fixed (dimensionless) constant. Our model includes the case $\kappa = +\infty$, which corresponds to infinitely conducting fibers (see Remark 3.4).

Denoting by T_η the union of the rods, the relative permittivity is then defined as follows:

$$\varepsilon_\eta(x) = \begin{cases} 1 + i\,\dfrac{\kappa}{\theta_\eta} & \text{if } x \in T_\eta, \\ 1 & \text{if } x \in \mathbb{R}^3 \setminus T_\eta. \end{cases}$$

Let (E^i, H^i) denote a given incident electromagnetic wave. As it satisfies the harmonic Maxwell system in the vacuum (that is, $\operatorname{curl} E^i = i\,\omega\mu_0\,H^i$, $\operatorname{curl} H^i = -i\,\omega\varepsilon_0\,E^i$ in all

$\mathbb{R}^3$), it is smooth and solves the homogeneous Helmholtz equation on $\mathbb{R}^3$ with wave number k_0.

For every value of the parameter η, the total electromagnetic field (E_η, H_η) is then characterized as the unique solution of the time harmonic Maxwell system

$$\begin{cases} \operatorname{curl} E_\eta = i\omega\mu_0 H_\eta, \\ \operatorname{curl} H_\eta = -i\omega\varepsilon_0\varepsilon_\eta E_\eta \end{cases} \tag{1.2}$$

such that the diffracted field $(E_\eta^d, H_\eta^d) := (E_\eta - E^i,\ H_\eta - H^i)$ satisfies the so-called outgoing wave condition at infinity. This condition can be written in the following way due to Silver and Müller (see [22]):

$$(E_\eta^d, H_\eta^d) = O\left(\frac{1}{|x|}\right), \qquad \omega\varepsilon_0\left(\frac{x}{|x|} \wedge E_\eta^d\right) - k_0 H_\eta^d = o\left(\frac{1}{|x|}\right). \tag{1.3}$$

For the existence and the regularity of the solution (E_η, H_η), we refer, for instance, to [6].

The main mathematical issue of the paper consists in proving that (E_η, H_η) does converge weakly in $(L^2_{loc}(\mathbb{R}^3))^3$ and that the limit is characterized as the unique solution of a suitable diffraction problem.

It turns out that, like in the $E||$ case mentioned before (see [14]), the limit equation will depend on the *average capacity* of the fibers, which is described by the following limit:

$$\gamma := \lim_{\eta\to 0} (\log r_\eta\ \eta^2)^{-1}. \tag{1.4}$$

Clearly, assuming that such a limit is finite forces $r_\eta \ll \eta$, so that the fibers seem to disappear as $\eta \to 0$. However, it is crucial to record the information on the behavior of the electric field E_η in the fibers. To that aim, in the same spirit as in [3], we introduce the rescaled field

$$F_\eta = \kappa\, E_\eta \frac{1_{\mathbf{T}_\eta}}{\theta_\eta}.$$

This vector function F_η represents the average displacement field in the fibers. It can be seen (up to a multiplicative constant) as a density of current. We may rewrite the second equation in (1.2) as

$$\operatorname{curl} H_\eta = -i\omega\varepsilon_0(E_\eta + i\,\kappa F_\eta). \tag{1.5}$$

We are going to prove that the sequence $\{F_\eta\}$ is bounded in $L^1(\Omega)$ and that its weak limit F as a vector measure is parallel to the fibers and absolutely continuous with respect to the Lebesgue measure. Consequently we will write F in the form $F = J\,e_3$, where $J \in L^1(\Omega)$ can be seen as an effective density of current.

Assuming that (E_η, H_η) converges weakly to (E, H) in L^2_{loc}, we may write down the limit Maxwell system in the form

$$\begin{cases} \operatorname{curl} E = i\omega\mu_0 H, \\ \operatorname{curl} H = -i\omega\varepsilon_0(E + i\,Je_3). \end{cases} \tag{1.6}$$

The fundamental point is to derive a relation between the current density $J(x)$ and the macroscopic electric field $E(x)$. Our results show evidence of the three following important features:

– For $0 < \gamma < +\infty$, the constitutive relation found between J and E is nonlocal: J satisfies on Ω a propagation equation in the vertical direction with a source term depending on $E(x)$. It is then possible to express J in terms of E_3 as an integral of a suitable kernel with respect to x_3 (see (3.5)). Substituting this expression for J into (1.6) results in a nonlocal homogenized equation for E. This kind of situation has already been observed in the simpler scalar case of the heat equation (see [3]).

– The boundary condition satisfied by J on the bases of the cylinder Ω is not a Dirichlet condition as is expected by common knowledge in antenna theory. By a careful analysis involving the second order derivative of J (in the distributional sense), it is shown (see Lemma 2.8) that the correct boundary condition is of Neumann type, i.e., $\frac{\partial J}{\partial x_3} = 0$. In turn J has an internal trace on $\partial\Omega$ which balances the jump of the vertical component of E.

– In our diffraction problem, none of the fields E_η, H_η converges strongly in $L^2_{\rm loc}$. The defect of strong convergence is directly related to the dissipation of the system by Joule's effect in the fibers.

The paper is organized as follows. In section 2, we fix some notation and prove some preliminary estimates. In section 3 we state and prove the main convergence result. In section 4 we apply our results to the case of fibers with infinite length and present numerical results.

2. Notation and preliminary estimates. We denote by $\{e_1, e_2, e_3\}$ the canonical basis of $\mathbb{R}^3$. We consider a set of e_3-parallel fibers of finite length L disposed in a cylindrical domain $\Omega := \mathcal{D} \times]0, L[$, where $\mathcal{D}$ is a bounded connected open subset of $\mathbb{R}^2$ with smooth boundary. We denote the bases of this cylinder $\mathcal{D}_0 := \mathcal{D} \times \{0\}$ and $\mathcal{D}_L := \mathcal{D} \times \{L\}$.

For every $\eta > 0$, we consider a partition of $\mathcal{D}$ into a set of periodically distributed cells of size η:

$$Y^i_\eta = (\eta\, i_1, \eta\, i_2) + \left]-\frac{\eta}{2}, \frac{\eta}{2}\right[^2, \qquad i = (i_1, i_2) \in I_\eta \subset Z^2,$$

where $I_\eta := \{i \in Z^2;\ Y^i_\eta \subset \mathcal{D}\}$.

Given a small parameter r_η such that $r_\eta \ll \eta$, we define the following:

– $D^i_\eta :=$ two-dimensional (2D) disk centered at $(\eta\, i_1, \eta\, i_2)$ of radius r_η,

– $T^i_\eta := D^i_\eta \times]0, L[,\ T_\eta := \bigcup_{i \in I_\eta} T^i_\eta$.

The fibers are represented by the set of thin parallel cylinders T_η (see Figure 1) and are filled up with a metallic medium. This medium is assumed to be homogeneous with a very high conductivity, which we model through a stiff parameter $\sigma_\eta \to \infty$. Note that, by the definition of I_η, we have $D^i_\eta \subset \mathcal{D}$, so that the fibers do not intersect the lateral part of the boundary of Ω. The subset $\Omega \setminus T_\eta$ as well as the complement of Ω is assumed to have the electromagnetic parameters of the vacuum ε_0 (permittivity) and μ_0 (permeability). Recall that the wave number of a monochromatic wave of angular frequency ω is given by

$$k_0 = \omega\sqrt{\varepsilon_0 \mu_0}. \tag{2.1}$$

In order to simplify the mathematical presentation, the permeability will be kept constant and equal to μ_0 in the metal, and the relative permittivity ε_η is taken as follows:

$$\varepsilon_\eta(x) = 1 \quad \text{if } x \in \Omega \setminus T_\eta, \qquad \varepsilon_\eta(x) = 1 + i\frac{\sigma_\eta}{\varepsilon_0 \omega} \quad \text{if } x \in T_\eta. \tag{2.2}$$

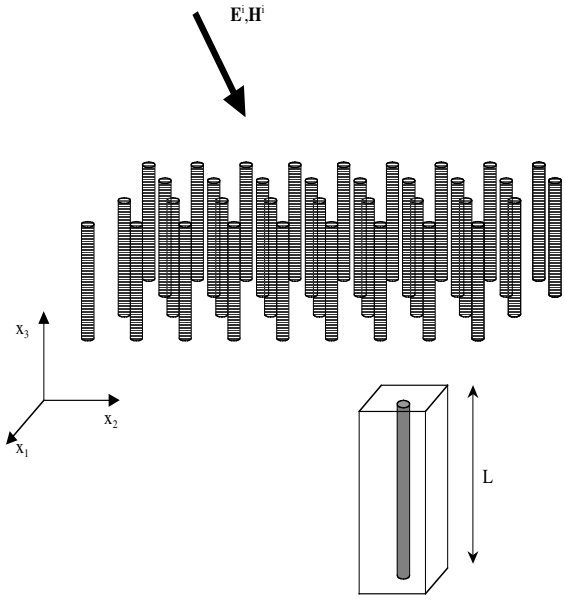

FIG. 1. *Schematic of the diffractive structure.*

Clearly the asymptotic behavior of (ε_η) in $L^1(\Omega)$ is characterized in terms of the filling ratio θ_η by the parameter

$$\kappa := \lim_\eta \theta_\eta \frac{\sigma_\eta}{\omega\varepsilon_0}, \qquad \text{where } \theta_\eta := \pi \frac{r_\eta^2}{\eta^2}. \tag{2.3}$$

If $0 \le \kappa < +\infty$, (ε_η) is bounded in $L^1(\Omega)$ and converges weakly star in the sense of measures to the constant function $1 + i\kappa$. (Notice that the sequence $\{\varepsilon_\eta\}$ is not equi-integrable in $L^1(\Omega)$ unless $\kappa = 0$.)

To simplify we keep constant the mean value of ε_η over Ω so that

$$\sigma_\eta = \frac{\kappa\omega\varepsilon_0}{\theta_\eta}. \tag{2.4}$$

Now we define a rescaled electric field in the fibers by setting

$$F_\eta = \kappa\, E_\eta \frac{1_{\mathbf{T}_\eta}}{\theta_\eta}. \tag{2.5}$$

Then taking into account (2.4), the Maxwell system (1.2) can be rewritten as

$$\begin{cases} \operatorname{curl} E_\eta = i\omega\mu_0 H_\eta, \\ \operatorname{curl} H_\eta = -i\omega\epsilon_0 (E_\eta + i\, F_\eta). \end{cases} \tag{2.6}$$

From now on, we choose a reference ball B of sufficiently large diameter such that $\Omega \subset\subset B$, and we start our analysis with a sequence (E_η, H_η) solving (2.6) such that

$$\sup_\eta \int_B (|E_\eta|^2 + |H_\eta|^2)\, dx \ < +\infty. \tag{2.7}$$

This estimate will be proved in section 3 in the case when (E_η, H_η) is associated with the diffraction of some incident wave. Possibly passing to a subsequence, we may assume that $(E_\eta, H_\eta) \rightharpoonup (E, H)$ weakly in L^2_{loc}. It is rather intuitive that the oscillations of (E_η, H_η) will take place only in a neighborhood of Ω. This fact is confirmed in a rigorous way as in the following claim.

LEMMA 2.1. *Let (E_η, H_η) be a solution of (1.2), and assume that (E_η, H_η) w converges weakly in $L^2(B)$ and that $(E_\eta - E^i_\eta,\ H_\eta - H^i_\eta)$ satisfies the outgoing wave condition (1.3) for a suitable sequence of incident waves (E^i_η, H^i_η) converging uniformly to (E^i, H^i). Then the convergence of (E_η, H_η) holds in $\mathcal{C}^\infty(K)$ for every compact subset $K \subset \mathbb{R}^3 \setminus \overline{\Omega}$. Furthermore, the limit field (E, H) solves the Helmholtz equation in $\mathbb{R}^3 \setminus \overline{\Omega}$, whereas $(E - E^i,\ H - H^i)$ satisfies (1.3).*

Proof. Since $\varepsilon_\eta = 1$ is constant in the complement of Ω, we infer from (1.2) that all the components of the fields E_η and H_η satisfy the Helmholtz equation $\Delta u + k_0^2 u = 0$ on the open set $\mathbb{R}^3 \setminus \overline{\Omega}$. By the properties of hypoelliptic operators (see, for example, [21]), the weak convergence of (E_η, H_η) to (E, H) in $L^2(B)$ implies its uniform convergence, as well as that of all its derivatives, on every compact subset of $B \setminus \overline{\Omega}$. We extend this convergence to all $\mathbb{R}^3 \setminus \overline{\Omega}$ as follows: we consider a sphere $S_R = \{|x| = R\}$, where R is chosen so large that $\Omega \subset\subset \{|x| \le R\} \subset\subset B$. Then we apply to the diffracted field $(E\eta^d, H^d_\eta) := (E_\eta - E^i_\eta,\ H_\eta - H^i_\eta)$ the following Stratton–Chu integral identities, which are in fact equivalent to (1.3) (see [6, 22]):

$$
\begin{aligned}
E^d_\eta(x) &= \int_{|y|=r} \left[i\omega\mu_0\, \Phi(x-y) \left(\frac{y}{|y|} \wedge H^d_\eta \right) + \nabla\Phi(x-y) \wedge \left(\frac{y}{|y|} \wedge E^d_\eta \right) \right] d\sigma, \\
H^d_\eta(x) &= \int_{|y|=r} \left[-i\omega\varepsilon_0\, \Phi(x-y) \left(\frac{y}{|y|} \wedge E^d_\eta \right) + \nabla\Phi(x-y) \wedge \left(\frac{y}{|y|} \wedge H^d_\eta \right) \right] d\sigma,
\end{aligned}
\tag{2.8}
$$

where $\Phi(x) = \frac{e^{ik_0 x}}{4\pi x}$ (recall that $\omega = \frac{k_0}{\sqrt{\varepsilon_0\mu_0}}$ is the angular frequency) and $d\sigma$ denotes the surface integral. Passing to the limit in above relations as $\eta \to 0$, we extend the definition of (E, H) outside B and obtain the convergence of (E_η, H_η) to (E, H) in $\mathcal{C}^\infty(K)$ for every compact subset $K \subset \mathbb{R}^3 \setminus \overline{\Omega}$. Clearly the integral relations (2.8) will hold for the limit diffracted field $(E - E^i,\ H - H^i)$, and therefore it satisfies the Silver–Müller conditions (1.3). ∎

Now we need a precise analysis of the oscillations of the electromagnetic wave in Ω. To that aim, we use a variant of the double scale convergence (see [1]) in a framework of periodic varying measures. This notion (introduced in [4, 5]) will allow us to account simultaneously for the oscillations at scale η and the 3D-1D reduction at the level of each period (recall that $r_\eta \ll \eta$). Although the oscillations of the system described above are expected only in the (x_1, x_2) variables, we will consider periodic test functions in $\mathbb{R}^3$ which oscillate in the directions of the three axes.

We need some further notation: let $Q = [-1/2, 1/2[^3$ and let us denote by $\mathbf{T}$ the 3D torus $\mathbb{R}^3/Q$. In what follows, Q-periodic functions will be systematically identified with functions on $\mathbf{T}$. For every $d \in \mathbb{N}$, we denote by $\mathbb{C}^\infty(\mathbf{T}; \mathbb{R}^d)$ the space of smooth Q-periodic functions from $\mathbb{R}^3$ to $\mathbb{R}^d$, and by $(L^2_\mu(\mathbf{T}))^d$ the space of Q-periodic functions belonging to $L^2_{\mu,\mathrm{loc}}(\mathbb{R}^3; \mathbb{C}^d)$. A Q-periodic measure can be seen as a linear form on the space of continuous periodic functions $C^0(\mathbf{T})$ or equivalently as a Radon measure on $\mathbb{R}^d$ such that $\mu(B + Q) = \mu(B)$ for every Borel subset $B \subset \mathbb{R}^d$. Given such a Q-periodic measure, we indicate by $\mu(x/\eta)$ the measure on $\mathbb{R}^3$ defined by $\langle \mu(x/\eta), \varphi \rangle = \eta^3 \int \varphi(\eta y) d\mu(y)$. Notice that the sequence $\{\mu(\frac{x}{\eta})\}$ converges

weakly star to the Lebesgue measure on $\mathbb{R}^3$ up to the multiplicative constant $c = \mu(Q)$, meaning that $\lim_{\eta\to 0} \langle \mu(x/\eta), \varphi\rangle = c \int_{\mathbb{R}^3} \varphi\, dy$ for every continuous compactly supported test function φ.

DEFINITION 2.2. *Let $\{\mu_\eta\}$ be a sequence of Q-periodic measures converging weakly star to μ. Then a sequence $\{v_\eta\} \subset L^2_{\mu_\eta}(B;\mathbb{R}^d)$ is said to be two-scale convergent to $v_0 \in L^2_{dx\otimes\mu}(B\times\mathbf{T};\mathbb{R}^d)$, and we write $v_\eta \rightharpoonup\!\!\!\!\rightharpoonup v_0$ if, for every test function $\varphi \in \mathcal{C}^\infty_0(B;\mathcal{C}^\infty(\mathbf{T};\mathbb{R}^d))$, the following holds:*

$$\lim_{\eta\to 0} \int_B v_\eta(x)\varphi\left(x,\frac{x}{\eta}\right) d\mu_\eta\left(\frac{x}{\eta}\right) = \iint_{B\times Q} v_0(x,y)\varphi(x,y)\,dx\otimes d\mu(y). \tag{2.9}$$

The sequence $\{v_\eta\}$ is said to be two-scale strongly convergent (denoted $v_\eta \rightarrow\!\!\!\!\rightarrow v_0$) if in addition

$$\operatorname*{limsup}_{\eta\to 0} \int_B |v_\eta(x)|^2 \left(x,\frac{x}{\eta}\right) d\mu_\eta\left(\frac{x}{\eta}\right) = \iint_{B\times Q} |v_0(x,y)|^2\,dx\otimes d\mu(y). \tag{2.10}$$

A straightforward generalization of the results of [4] (see [1] in the case when μ_η is the Lebesgue measure) is summarized in the following result.

PROPOSITION 2.3. *Let $\{v_\eta\}$ be a sequence of Borel functions from B to $\mathbb{R}^d$ such that*

$$\sup_\eta \int_B |v_\eta|^2 d\mu_\eta\left(\frac{x}{\eta}\right) < +\infty.$$

(i) *(compactness) There exists a subsequence $\{v_{\eta_k}\}$ and $v_0 \in L^2_{dx\otimes\mu}(B\times\mathbf{T};\mathbb{R}^d)$ such that $v_{\eta_k} \rightharpoonup\!\!\!\!\rightharpoonup v_0$. In addition, the sequence of measures $\{v_\eta\mu_\eta(\frac{x}{\eta})\}$ is uniformly bounded in total variation, and $v_{\eta_k}\mu_{\eta_k}(x/\eta_k)$ converges weakly star to $v dx$, where $v(x) = \int_Q v_0(x,y)d\mu(y)$.*

(ii) *(lower semicontinuity) If $v_\eta \rightharpoonup\!\!\!\!\rightharpoonup v_0$, then*

$$\liminf_\eta \int_B |v_\eta|^2 d\mu_\eta\left(\frac{x}{\eta}\right) \geq \iint_{B\times Q} |v_0(x,y)|^2\,dx\otimes d\mu(y).$$

(iii) *(weak-strong convergence) Let $\{v_\eta\}, \{w_\eta\}$ such that $v_\eta \rightharpoonup\!\!\!\!\rightharpoonup v_0$ and $w_\eta \rightarrow\!\!\!\!\rightarrow w_0$. Then, for every test function $\varphi \in \mathcal{C}^\infty_0(B;\mathcal{C}^\infty(\mathbf{T}))$, there holds*

$$\lim_{\eta\to 0} \int_B v_\eta \cdot w_\eta\ \varphi\left(x,\frac{x}{\eta}\right) d\mu\left(\frac{x}{\eta}\right) = \iint_{B\times D} v_0(x,y)\cdot w_0(x,y)\,\varphi(x,y)\,dx\otimes d\mu(y).$$

In particular, $v_\eta \cdot w_\eta \mu_\eta(\frac{x}{\eta}) \overset{*}{\rightharpoonup} p(x)dx$, where $p(x) = \int_Q v_0(x,y)\cdot w_0(x,y)\,d\mu(y)$.

We will apply Proposition 2.3 several times, choosing μ_η to be

$$\mu_\eta(dy) = a_\eta(y)dy, \qquad a_\eta(y) := \begin{cases} 1 & \text{if } y \notin S_\eta, \\ \frac{\kappa}{\theta_\eta} & \text{if } y \in S_\eta, \end{cases} \tag{2.11}$$

where S_η denotes the vertical cylinder $S_\eta := \{y_1^2 + y_2^2 \leq \frac{r_\eta^2}{\eta^2},\ |y_3| \leq 1/2\}$. It is easy to check that μ_η converges weakly star to the periodic measure μ defined by

$$\langle \mu, \varphi\rangle := \int_Q \varphi dy + \kappa \int_{S_0} \varphi\, \mathcal{H}^1(dy), \quad \varphi \in \mathcal{C}^0(\mathbf{T}), \tag{2.12}$$

$\mathcal{H}^1(dy)$ being the curvilinear abscissa and $S_0 = \{(0,0,y_3)\ :\ -1/2 \leq y_3 \leq 1/2\}$.

The fact that the rescaled vector field F^η introduced in (2.5) converges weakly to a vertical vector field in $L^2(\Omega)$ is a consequence of the following result.

PROPOSITION 2.4. *Let (E_η, H_η) be a solution of (1.2) such that $(E_\eta, H_\eta) \rightharpoonup (E, H)$ weakly in $L^2_{loc}(B;\mathbb{R}^3)$. Let μ_η be defined in (2.11). Then, we have*

(i) $\sup_\eta \ \frac{1}{\theta_\eta}\int_{T_\eta} |E_\eta|^2\,dx < +\infty$;

(ii) *there exist suitable subsequences of $\{E_\eta\}, \{\varepsilon_\eta E_\eta\}$ (still denoted $\{E_\eta\}, \{\varepsilon_\eta E_\eta\}$) and an element $J \in L^2(\Omega)$ such that*

(2.13)
$$E_\eta \rightharpoonup E_0(x,y), \qquad E_0(x,y) = \begin{cases} E(x) & \text{if } (x,y) \in B \times Q \setminus \Omega \times S_0, \\ \frac{J(x)}{\kappa}\, e_3 & \text{if } (x,y) \in \Omega \times S_0, \end{cases}$$

(2.14)
$$\varepsilon_\eta\, E_\eta \rightharpoonup D_0(x,y), \qquad D_0(x,y) = \begin{cases} E(x) & \text{if } (x,y) \in B \times Q \setminus \Omega \times S_0, \\ i\,\frac{J(x)}{\kappa}\, e_3 & \text{if } (x,y) \in \Omega \times S_0; \end{cases}$$

(iii) *the sequences $\{F_\eta\}$ and $\{\varepsilon_\eta E_\eta\}$ are bounded in $(L^1(B))^3$, and for suitable subsequences one has*

$$F_\eta \overset{*}{\rightharpoonup} J(x)\,1_\Omega(x)\,e_3, \qquad \varepsilon_\eta\, E_\eta \overset{*}{\rightharpoonup} D := E + i\,J(x)\,1_\Omega(x)\,e_3. \tag{2.15}$$

Proof. (i) Recalling (2.4) (where $\kappa < +\infty$), we have to show that $I_\eta := \frac{1}{\theta_\eta}\int_{\mathbf{T}_\eta} |E_\eta|^2$ remains uniformly bounded. Notice that this quantity represents up to a multiplicative factor the energy dissipated by Joule's effect. By using Maxwell equations (1.2) and by integrating by parts ($n(x)$ denotes the exterior normal on ∂B), we derive that

$$\begin{aligned} \int_{\partial B} (E_\eta \wedge \overline{H_\eta}) \cdot n(x) &= \int_B \left(\operatorname{curl} E_\eta \cdot \overline{H_\eta} - \operatorname{curl} \overline{H_\eta} \cdot E_\eta\right) \\ &= i\omega \int_B \left(\mu_0 |H_\eta|^2 - \varepsilon_0 |E_\eta|^2\right) - \frac{\omega \varepsilon_0 \kappa}{\theta_\eta} \int_{\mathbf{T}_\eta} |E_\eta|^2. \end{aligned} \tag{2.16}$$

The left-hand side of (2.16) is well defined, by Lemma 2.1, and converges to $\int_{\partial B} E \wedge \overline{H}$. Therefore by passing to the limit in the real parts of (2.16), we obtain that $\{I_\eta\}$ is uniformly bounded and eventually satisfies the following balance relation:

$$\Re\left(\int_{\partial B} E \wedge \overline{H}\right) = -\omega \varepsilon_0 \kappa \ \lim_{\eta \to 0} I_\eta. \tag{2.17}$$

(ii) and (iii). By (i), we have the uniform upperbound $\sup_\eta \int_B |E_\eta|^2 d\mu_\eta(\frac{x}{\eta}) < +\infty$. Therefore, up to a subsequence, we may assume that $E_\eta \rightharpoonup E_0$, where $E_0(x,y)$ is an element of $L^2_{dx\otimes\mu}(B \times \mathbf{T};\mathbb{R}^3)$ (see Definition 2.2). In addition, since θ_η goes to zero, we have

$$\int_{T_\eta} |E_\eta|^2 dx \to 0. \tag{2.18}$$

From Lemma 2.1 below, we know that the convergence of E_η to E holds with respect to the uniform norm on every compact subset of $B \setminus \overline{\Omega}$; it is then easy to check that $E_0(x,y) = E(x)$ for $x \in B \setminus \Omega$.

We now focus our attention on the set Ω. Due to the particular form of μ given by (2.12), for $x \in \Omega$, we may split E_0 as

$$E_0(x,y) = \tilde{E}_0(x,y) \quad \text{if } y \in Q \setminus S_0, \quad E_0(x,y) = \frac{1}{\kappa} J_0(x,y) \quad \text{if } y \in S_0, \tag{2.19}$$

where for a.e. $x \in \Omega$, $E_0(x,\cdot)$ and $J_0(x,\cdot)$ are respectively elements of $L^2(Q)$ and $L^2(S_0)$.

By (2.18), $E_\eta 1_{T_\eta} \to 0$ strongly in $L^2(\Omega)$, and the weak limit of $\{E_\eta 1_{\Omega\setminus T_\eta}\}$ on Ω coincides with E. Let us apply Proposition 2.3(iii) with $v_\eta = E_\eta$ and $w_\eta := 1_{\Omega\setminus T_\eta}$. We clearly have $w_\eta \rightharpoonup\!\!\!\rightharpoonup w_0(x,y) := 1_{\Omega\times Q\setminus S_0}$. Since $v_\eta w_\eta \mu_\eta(\frac{x}{\eta})$ coincides with $E_\eta 1_{\Omega\setminus T_\eta} dx$, we infer that

$$E(x) = \int_{Q\setminus S_0} E_0(x,y)\, \mu(dy) = \int_Q \tilde{E}_0(x,y)\, dy. \tag{2.20}$$

Now substituting w_η with $1 - w_\eta$, we obtain in a similar way that $E_\eta 1_{T_\eta}\, \mu_\eta(\frac{x}{\eta})$ (which by (2.5) coincides with $F_\eta\, dx$) converges weakly star to $F(x)dx$, where in view of (2.12) and (2.19),

$$F(x) = 1_\Omega(x) \int_{S_0} E_0(x,y)\, \mu(dy) = 1_\Omega(x) \int_{S_0} J_0(x,y)\, \mathcal{H}^1(dy). \tag{2.21}$$

In particular the sequence $\{F_\eta\}$ is bounded in $L^1(\Omega)$.

Eventually we apply Proposition 2.3(iii) with $v_\eta = E_\eta$ and $w_\eta := \frac{\varepsilon_\eta}{a_\eta}$. We find that $w_\eta \rightharpoonup\!\!\!\rightharpoonup w_0$, where $w_0(x,\cdot) := 1_{Q\setminus S_0} + i\, 1_{S_0}$. We deduce that $\varepsilon_\eta\, E_\eta \rightharpoonup\!\!\!\rightharpoonup D_0$, where

$$D_0(x,y) = \tilde{E}_0(x,y) \quad \text{if } y \in Q \setminus S_0, \quad E_0(x,y) = \frac{i}{\kappa}\, J_0(x,y) \quad \text{if } y \in S_0. \tag{2.22}$$

Furthermore $\{\varepsilon_\eta\, E_\eta\}$ is bounded in $L^1(\Omega)$ and converges weakly star to a limit $D(x)$ which, according to (2.20), (2.21), and (2.22), is given by

$$D(x) = \int_Q D_0(x,y)\ \mu(dy) = E(x) + i\, F(x).$$

Summarizing, we have proved the assertions (ii) and (iii) of Proposition 2.3, provided that we can show that $\tilde{E}_0(x,\cdot)$ and $J_0(x,\cdot)$ are constants and that $J_0(x,\cdot)$ is e_3-parallel. This is a consequence of the following claims: for Lebesgue almost all $x \in \Omega$, the vector fields $\tilde{E}_0(x,\cdot)$ and $J_0(x,\cdot)$ defined in (2.19) satisfy as distributions on the torus:

$$\operatorname{curl}_y \tilde{E}_0(x,\cdot) = 0 \quad \text{on } Q, \tag{2.23}$$

$$\operatorname{div}_y \tilde{E}_0(x,\cdot) = 0 \quad \text{on } Q \setminus S_0, \tag{2.24}$$

$$\operatorname{div}_y \big(J_0(x,\cdot)\delta_{S_0}\big) = 0 \quad \text{on } Q \tag{2.25}$$

(where in (2.25) δ_{S_0} stands for the measure associated with the curvilinear integral on S_0).

Indeed the curl-free condition in (2.23) implies that $\tilde{E}_0(x,\cdot)$ as an element of $L^2(\mathbf{T};\mathbb{R}^3)$ reads as $\tilde{E}_0(x,\cdot) = E(x) + \nabla_y w$, where w is a periodic potential in $W^{1,2}(Q)$. Now by the divergence-free condition (2.24), w is harmonic on $Q \setminus S_0$, and thus on the whole cube Q, since the segment S_0 has a vanishing capacity in $W^{1,2}$ (see, for

instance, [13, Theorem 3, p. 154]). Then the periodicity condition yields that w is constant, and thus by (2.20), we have $\tilde{E}_0(x,y) = E(x)$ for almost all $y \in Q$. On the other hand, by applying (2.25) to test functions of the kind $\varphi(y) = \beta(y_3)\Psi(y_1, y_2)$, we deduce that

$$\int_0^1 \left(a\,\beta'(s) J_0(x,s)\cdot e_3 + \beta(s) J_0(x,s)\cdot z\right)\, ds = 0,$$

where $a := \Psi(0,0)$; the horizontal direction $z := \nabla\Psi(0,0)$ and the function $\beta(s)$ as well can be chosen arbitrarily. It is then straightforward to infer that $J_0(x,\cdot)$ is e_3-parallel and constant along S_0, and thus of the form given in (2.13) with a suitable $J \in L^2(\Omega)$.

Proof of claim (2.23). Let us apply again Proposition 2.3(iii) with $v_\eta = E_\eta$ and $w_\eta := 1_{\Omega\setminus T_\eta} + \frac{\theta_\eta}{\kappa} 1_{T_\eta}$. As $\theta_\eta \to 0$, we have $w_\eta \twoheadrightarrow w_0(x,y) := 1_{\Omega\times Q\setminus S_0}$. Therefore, for every test function $\Psi \in \mathcal{C}_0^\infty(\Omega; \mathcal{C}^\infty(\mathbf{T};\mathbb{R}^3))$, we have in view of (2.19)

$$\begin{aligned}\lim_\eta \int_\Omega \Psi\left(x, \frac{x}{\eta}\right)\cdot E_\eta\, dx &= \lim_\eta \int_\Omega \Psi\left(x,\frac{x}{\eta}\right)\cdot v_\eta(x)\; w_\eta(x)\,\mu_\eta\left(\frac{x}{\eta}\right)\\ &= \iint_{\Omega\times(Q\setminus S_0)} \Psi(x,y)\cdot V_0(x,y)\, dx\otimes d\mu(y)\\ &= \iint_{\Omega\times Q} \Psi(x,y)\cdot \tilde{E}_0(x,y)\, dx\, dy.\end{aligned} \tag{2.26}$$

By the first Maxwell equation in (1.2) and (2.7), the sequence $\{\operatorname{curl} E_\eta\}$ is bounded in $L^2(\Omega)$ and $\eta \operatorname{curl} E_\eta \to 0$ in $L^2(\Omega)$. Taking $\Psi = \operatorname{curl}_y \varphi$ in (2.26), where $\varphi \in \mathcal{C}_0^\infty(\Omega; \mathcal{C}^\infty(\mathbf{T};\mathbb{R}^3))$, and integrating by parts, we deduce that

$$\begin{aligned} 0 = \lim_\eta \int_\Omega \eta\, E_\eta\cdot \operatorname{curl}_y \varphi\left(x,\frac{x}{\eta}\right) &= \lim_\eta \int_\Omega E_\eta\cdot \operatorname{curl}\left(\eta\,\varphi\left(x,\frac{x}{\eta}\right)\right)\, dx\\ &= \lim_\eta \int_O E_\eta\cdot (\operatorname{curl}_y\varphi)\left(x,\frac{x}{\eta}\right)\, dx\\ &= \iint_{\Omega\times Q} \tilde{E}_0(x,y)\cdot \operatorname{curl}_y\varphi(x,y)\, dx\, dy.\end{aligned} \tag{2.27}$$

The conclusion follows from (2.27) by choosing a test function φ of the kind $\varphi(x,y) = \beta(x)\varphi_0(y)$, where $\beta \in \mathcal{C}_0^\infty(\Omega)$ and $\varphi_0 \in \mathcal{C}_0^\infty(Q;\mathbb{R}^3)$, and by localizing with respect to x.

Proof of claim (2.24). By the second Maxwell equation in (1.2), the vector field $\varepsilon_\eta E_\eta$ is divergence-free. Thus by taking $\Psi = \nabla_y\varphi$ as a test function, where $\varphi \in \mathcal{C}_0^\infty(\Omega; \mathcal{C}^\infty(\mathbf{T}))$, we obtain (taking into account (2.22))

$$\begin{aligned} 0 &= \lim_\eta\ \eta \int_\Omega \nabla\left(\varphi\left(x,\frac{x}{\eta}\right)\right)\cdot \varepsilon_\eta E_\eta\, dx = \lim_\eta \int_\Omega \nabla_y\varphi\left(x,\frac{x}{\eta}\right)\cdot \varepsilon_\eta E_\eta\, dx\\ &= \iint_{\Omega\times Q} \nabla_y\varphi(x,y)\cdot D_0(x,y)\, dx\otimes d\mu(y)\\ &= \iint_{\Omega\times Q} \nabla_y\varphi(x,y)\cdot \tilde{E}_0(x,y)\, dx\, dy + \iint_{\Omega\times S_0} \nabla_y\varphi(x,y)\cdot J_0(x,y)\; dx\otimes \mathcal{H}^1(dy).\end{aligned} \tag{2.28}$$

Choosing φ of the kind $\varphi(x,y) = \beta(x)\varphi_0(y)$, where $\beta \in \mathcal{C}_0^\infty(\Omega)$ and φ_0 is smooth compactly supported in $Q \setminus S_0$, we easily recover the condition (2.24).

Proof of claim (2.25). From (2.23), (2.24), we have already deduced that $\tilde{E}_0(x,\cdot)$ is constant. Thus the first integral in the last line of (2.28) vanishes, and we are reduced to

$$0 = \int\!\!\int_{\Omega\times S_0} \nabla_y \varphi(x,y)\cdot J_0(x,y)\; dx \otimes \mathcal{H}^1(dy),$$

for every $\varphi \in \mathcal{C}_0^\infty(\Omega;\mathcal{C}^\infty(\mathbf{T}))$. The claim follows by localization. ∎

The aim of the end of this section is to recover a relation between J and E. It turns out that this relation is highly dependent on the parameter γ defined in (1.4). From now on we assume that

$$0 \;<\; \gamma := \lim_\eta (\eta^2 |\log r_\eta|)^{-1} \;< +\infty. \tag{2.29}$$

The borderline cases $\gamma = 0$ and $\gamma = +\infty$ will be discussed in section 3 (see Remark 3.4). We introduce a kind of capacitary potential w_η, which renders the transition between F_η on the fibers and the electric field E_η. Let $Y_\eta = (-\eta/2,\eta/2)^2$ and θ_η be the filling ratio parameter defined in (2.3). Then there exists a unique solution w_η in $W_0^{1,2}(Y_\eta)$ of

$$\frac{1}{2\pi\gamma}\Delta w_\eta = \begin{cases} -\theta_\eta^{-1} & \text{if } |x| \le r_\eta, \\ \left(\dfrac{\pi}{4} - \theta_\eta\right)^{-1} & \text{if } r_\eta < |x| \le \dfrac{\eta}{2}, \\ 0 & \text{otherwise.} \end{cases} \tag{2.30}$$

From now on we consider the η-periodization of w_η on the whole plane, and we consider $w_\eta = w_\eta(x_1,x_2)$ as a function on $\mathbb{R}^3$. The following lemma shows that w_η is very close to 1 (but nonconstant) on the fibers and also that it converges weakly to 0 in $W^{1,2}_{loc}$.

LEMMA 2.5. *The function $w_\eta(x_1,x_2)$ satisfies the following conditions:*

$$w_\eta \rightharpoonup 0 \;\; \textit{in } W^{1,2}_{loc}, \qquad \sup_{|x|\le r_\eta} |1 - w_\eta| \to 0, \quad |\nabla w_\eta| \le C\frac{r_\eta}{\theta_\eta}, \tag{2.31}$$

$$w_\eta \ge c_\eta \quad \textit{on } T_\eta, \qquad w_\eta \le c_\eta \quad \textit{on } \Omega \setminus T_\eta, \tag{2.32}$$

where C and c_η are suitable constants such that $C > 0$ and $c_\eta \to 1$.

Proof. w_η can be computed explicitly as a radial function. For every $x \in [-\eta/2,\eta/2[^3$, we set $w_\eta(x) = f_\eta(|x|)$, where

$$f_\eta(r) = \begin{cases} \dfrac{-\pi\gamma}{2\theta_\eta} r^2 + B_\eta & \text{if } r < r_\eta, \\ \dfrac{2\gamma}{1 - \frac{4\theta_\eta}{\pi}}\left(r^2 - \dfrac{\eta^2}{4}\right) - C_\eta \log\dfrac{2r}{\eta} & \text{if } r_\eta < r < \frac{\eta}{2}, \\ 0 & \text{otherwise.} \end{cases} \tag{2.33}$$

Here the constants B_η and C_η are chosen in such a way that f_η and f_η' are continuous at $r = r_\eta$ and $r = \eta/2$ (in particular, $f_\eta(\eta/2) = f_\eta'(\eta/2) = 0$); we find

$$C_\eta := \frac{\gamma\eta^2}{1 - \frac{4\theta_\eta}{\pi}}, \quad B_\eta := -\frac{\gamma}{1 - \frac{4\theta_\eta}{\pi}}\eta^2 \log r_\eta.$$

Set $c_\eta = f_\eta(r_\eta)$. Thanks to (2.29) we clearly have that $B_\eta \to 1$, $C_\eta \to 0$, and $c_\eta \to 1$. Then it is easy to check that w_η satisfies all the conditions (2.30), (2.31), and (2.32). ∎

A consequence of the positivity of γ (see (2.29)) is the following important estimate.

LEMMA 2.6. *There exists a constant $C = C(\gamma) > 0$ such that, for every $\varphi \in H^1(\Omega)$,*

$$\int_{T_\eta} |\varphi|^2 \;\le\; C\,\theta_\eta \int_\Omega \left(|\varphi|^2 + |\nabla\varphi|^2\right)\,dx. \tag{2.34}$$

Proof. By using Fubini's theorem, it is enough to prove the 2D version of (2.34); that is, setting $D_\eta := \bigcup_{i\in I_\eta} D^i_\eta$,

$$\int_{D_\eta} |\varphi|^2 \;\le\; C\,\theta_\eta \int_{\mathcal{D}} \left(|\varphi|^2 + |\nabla\varphi|^2\right)\,dx \quad \forall\varphi \in H^1(\mathcal{D}). \tag{2.35}$$

Let us define for every $\delta > 0$ (here $Y := (-1/2, 1/2)^2$)

$$A(\delta) := \inf\left\{ \int_Y |\nabla\varphi|^2 \quad : \quad \int_Y \varphi\,dy = 0, \quad \int_{|y|<\delta} |\varphi|^2 = 1 \right\}. \tag{2.36}$$

It turns out that $A(\delta)$ tends increasingly to infinity as $\delta \to 0$. More precisely we can prove the following estimate:

$$\liminf_{\delta\to 0}\; A(\delta)\,\delta^2 |\log\delta| \;\ge\; \frac{2}{\gamma}. \tag{2.37}$$

Let now fix $\varphi \in W^{1,2}(\mathcal{D})$. We consider the piecewise constant function φ_η on D defined by setting $\varphi_\eta = [\varphi]^i_\eta$ on each Y^i_η, where $[\varphi]^i_\eta$ denotes the mean value of φ. After an easy rescaling of (2.36), we obtain

$$\int_{Y^i_\eta} |\nabla\varphi|^2\,dx \;\ge\; \frac{1}{\eta^2}\,A\left(\frac{r_\eta}{\eta}\right) \int_{D^i_\eta} |\varphi - \varphi_\eta|^2\,dx.$$

After summing the previous inequality over $i \in I_\eta$, we derive

$$\begin{aligned}
\int_{D\eta} |\varphi|^2\,dx &\le 2\int_{D\eta} |\varphi_\eta|^2\,dx + 2\int_{D\eta} |\varphi - \varphi_\eta|^2\,dx \\
&\le 2\sum_i ([\varphi]^i_\eta)^2 |D^i_\eta| + 2\frac{\eta^2}{A(\frac{r_\eta}{\eta})} \sum_i \int_{Y^i_\eta} |\nabla\varphi|^2\,dx \\
&\le 2\,\theta_\eta \int_{\mathcal{D}} |\varphi|^2\,dx + 2\frac{\eta^2}{A(\frac{r_\eta}{\eta})} \int_{\mathcal{D}} |\nabla\varphi|^2\,dx.
\end{aligned}$$

Recalling (2.3), the estimate (2.35) follows by taking into account (2.37). Thus the proof of Lemma 2.6 is achieved if we show (2.37).

Proof of claim (2.37). We consider first a competitor $\varphi = v(r,\theta)$ in (2.36) such that v is compactly supported in the ball $\{r < 1/2\}$. For almost all $\theta \in [0, 2\pi)$, $v(\cdot,\theta)$ belongs to $W^{1,2}_{\rm loc}(0, 1/2)$ and vanishes at $r = 1/2$. Therefore, for every $\rho \in (0, \delta)$, we have

$$\int_0^{1/2} \left|\frac{\partial v}{\partial r}\right|^2 r dr \ge\; \inf\left\{ \int_\rho^{1/2} r\,{w'}^2\,dr \;:\; w(\rho) = v(\rho,\theta),\; w\left(\frac{1}{2}\right) = 0 \right\} = \frac{|v(\rho,\theta)|^2}{|\log(2\rho)|}.$$

Multiplying by $\rho|\log(2\rho)|$ and integrating with respect to (ρ,θ) over $(0,\delta)\times(0,2\pi)$, we derive the following estimate for $\varphi = v(r,\theta)$:

$$\int_Y |\nabla\varphi|^2\,dy \geq \frac{\int_{|y|<\delta}|\varphi|^2\,dy}{\int_0^\delta \rho|\log(2\rho)|\,d\rho} = \frac{2-\circ(\delta)}{\delta^2|\log(\delta)|}\int_{|y|<\delta}|\varphi|^2\,dy. \tag{2.38}$$

Then we conclude (2.37) by contradiction: assume that there exists a sequence $\{\varphi_\delta\}$ in $H^1(Y)$ such that

$$\int_Y |\nabla\varphi_\delta|^2\,dy \ \to 0, \quad \int_Y \varphi_\delta\,dy = 0, \quad \frac{1}{\delta^2|\log(\delta)|}\int_{|y|<\delta}|\varphi_\delta|^2\,dy = 1.$$

Clearly φ_δ converges strongly to 0 in $H^1(Y)$, and for every smooth cut-off function $\alpha\in C^\infty(Y;[0,1])$ compactly supported in $\{|y|<1/2\}$ such that $\alpha=1$ in $\{|y|<1/4\}$, the truncated function $\tilde\varphi_\delta := \alpha\varphi_\delta$ satisfies

$$\int_Y |\nabla\tilde\varphi_\delta|^2\,dy \ \to 0, \quad \frac{1}{\delta^2|\log(\delta)|}\int_{|y|<\delta}|\tilde\varphi_\delta|^2\,dy \to 1.$$

This is impossible, since $\tilde\varphi_\delta$ needs to verify (2.38). ∎

The sequences $\{E_{3,\eta}\Delta w_\eta\}$, $\{E_{3,\eta}\partial_{x_\alpha} w_\eta\}$, and $\{E_\eta\cdot\nabla w_\eta\}$ are bounded in $L^1(B)$. The next lemma is related to their weak star convergence in the sense of measures on B.

LEMMA 2.7. *For every $\varphi\in\mathcal{C}_0^\infty(B)$, there hold*

$$\lim_{\eta\to0}\int_B E_{3,\eta}\,\Delta w_\eta\,\varphi\,dx = 2\pi\gamma\int_\Omega\left(E_3-\frac{J}{\kappa}\right)\varphi\,dx, \tag{2.39}$$

$$\lim_{\eta\to0}\int_B E_{3,\eta}\,\frac{\partial w_\eta}{\partial x_\alpha}\,\varphi\,dx = 0 \qquad \textit{for } \alpha\in\{1,2\}, \tag{2.40}$$

$$\lim_{\eta\to0}\int_B E_\eta\cdot\nabla w_\eta\,\varphi\,dx = -i\int_\Omega J\frac{\partial\varphi}{\partial x_3}\,dx + \int_{\partial\Omega}\varphi\,d\nu, \tag{2.41}$$

where ν is a suitable bounded Radon measure on $\partial\Omega$.

Here we point out that the third limit, which is achieved a priori for a subsequence, will be found later to be unique (see the explicit expression of ν given in (2.51)). Therefore the whole sequence actually converges.

Proof. (i) We write (2.30) as $\Delta w_\eta = 2\pi\gamma\ g_\eta(x)\,a_\eta(\frac{x}{\eta})$, where a_η is defined in (2.11) and $g_\eta = g_\eta(x_1,x_2)$ is the η-periodization of

$$g_\eta(x) = \begin{cases} -\kappa^{-1} & \text{if } |x'|<r_\eta,\\ (\frac{\pi}{4}-\theta_\eta)^{-1} & \text{if } r_\eta<|x'|<\frac{\eta}{2},\\ 0 & \text{otherwise}\end{cases} \qquad (x'=(x_1,x_2)).$$

It is easy to check that $g_\eta \twoheadrightarrow g_0$, where

$$g_0(x,y) := \begin{cases} -\frac{1}{\kappa} & \text{if } y\in S_0,\\ \frac{4}{\pi} & \text{if } 0\leq|y|<\frac12,\\ 0 & \text{otherwise.}\end{cases}$$

By applying Proposition 2.3(iii) to the pair $(E_\eta, g_\eta\, e_3)$ and recalling (2.13), we obtain (2.39) as follows:

$$\begin{aligned}\lim_{\eta\to 0}\int_B E_{3,\eta}\ \Delta w_\eta\,\varphi\,dx &= 2\pi\gamma\ \lim_{\eta\to 0}\int_B g_\eta\, e_3\cdot E_\eta\,\varphi\ \mu_\eta\left(\frac{x}{\eta}\right)\\ &= 2\pi\gamma\ \iint_{B\times Q} g_0(x,y)\, e_3\cdot E_0(x,y)\,\varphi(x)\ dx\otimes d\mu(y)\\ &= 2\pi\gamma\ \int_\Omega\left(E_3(x)-\frac{J(x)}{\kappa}\right)\varphi(x)\,dx.\end{aligned}$$

(ii) Let us prove (2.40). Given $\psi=(\psi_1,\psi_2,0)$ a transverse test function in $\mathcal{C}_0^\infty(B)$, we multiply the first equation of (2.6) by Ψw_η and integrate by parts on B. We obtain

$$\begin{aligned}i\omega\mu_0\int_B H_\eta\cdot(\Psi w_\eta)\,dx &= \int_B \operatorname{curl} E_\eta\cdot(\Psi w_\eta)\,dx\\ &= \int_B E_\eta\cdot\operatorname{curl}(\Psi w_\eta)\,dx\\ &= \int_B (E_\eta\cdot\operatorname{curl}\Psi) w_\eta\,dx+\int_B E_\eta\cdot(\nabla w_\eta\wedge\Psi)\,dx.\end{aligned}$$

By the strong convergence of w_η to 0 in $L^2(B)$, we infer that

$$0=\lim_{\eta\to 0}\int_B E_\eta\cdot(\nabla w_\eta\wedge\Psi)\,dx=\lim_{\eta\to 0}\int_B E_\eta\cdot\left(\Psi_2\frac{\partial w_\eta}{\partial x_1}-\Psi_1\frac{\partial w_\eta}{\partial x_2}\right)dx,$$

and hence the conclusion by taking $\Psi=(\varphi,0,0)$ or $\Psi=(0,\varphi,0)$.

(iii) We consider the sequence $\{E_\eta\cdot\nabla w_\eta\}$. It is bounded in $L^1(B)$ and possibly passing to a subsequence; we may assume that it converges weakly star to some bounded measure m on B. By the uniform convergence of E_η on every compact subset of $B\setminus\overline{\Omega}$ obtained in Lemma 2.1 and the weak convergence of ∇w_η to 0 in $L^2(B)$, we find that m vanishes on $B\setminus\overline{\Omega}$ and therefore can be written in the form $m=m_\Omega+\nu$, where m_Ω and ν are Radon measures supported respectively in Ω and in $\partial\Omega$. Then proving (2.41) reduces to showing that, for every test function φ compactly supported in Ω, there holds

$$\langle m_\Omega,\varphi\rangle=\lim_{\eta\to 0}\int_\Omega E_\eta\cdot\nabla w_\eta\,\varphi\,dx=-i\int_\Omega J\frac{\partial\varphi}{\partial x_3}\,dx. \tag{2.42}$$

Let $\overline{w}_\eta$ denote the truncature of w_η defined by setting $\overline{w}_\eta:=\inf\{w_\eta,c_\eta\}$. Then by (2.31) we have $\overline{w}_\eta=c_\eta$ on T_η and $\nabla\overline{w}_\eta=1_{\Omega\setminus T_\eta}\nabla w_\eta$. Noticing that $\varepsilon_\eta E_\eta=E_\eta$ on $\Omega\setminus T_\eta$, we infer that

$$\begin{aligned}\int_\Omega E_\eta\cdot\nabla w_\eta\,\varphi\,dx\ &=\ A_\eta+B_\eta,\\ A_\eta&:=\int_\Omega\varepsilon_\eta E_\eta\cdot\nabla\overline{w}_\eta\,\varphi\,dx,\\ B_\eta&:=\int_{T_\eta} E_\eta\cdot\nabla w_\eta\,\varphi\,dx.\end{aligned} \tag{2.43}$$

Taking into account that $\varepsilon_\eta E_\eta$ is divergence-free, we may rewrite A_η as

$$\begin{aligned} A_\eta &= -\int_\Omega \overline{w}_\eta \varepsilon_\eta E_\eta \cdot \nabla\varphi \, dx \\ &= -\int_{\Omega\setminus T_\eta} w_\eta E_\eta \cdot \nabla\varphi \, dx - c_\eta \int_{T_\eta} \varepsilon_\eta E_\eta \cdot \nabla\varphi \, dx. \end{aligned}$$

By (2.15), we know that $\varepsilon_\eta E_\eta 1_{T_\eta} = i\kappa F_\eta$ does converge weakly star to $i\,J\,e_3$. Since $w_\eta \to 0$ in $L^2(\Omega)$, $c_\eta \to 1$, we deduce that

$$\lim_{\eta\to 0} A_\eta = -i \int_\Omega J(x)\, \frac{\partial\varphi}{\partial x_3}\, dx. \tag{2.44}$$

On the other hand, by the last inequality in (2.31), we have

$$|B_\eta| \;\le\; C\frac{r_\eta}{\theta_\eta} \int_{T_\eta} |E_\eta|\, dx = C r_\eta \int_\Omega |F_\eta|\, dx. \tag{2.45}$$

Since F_η is bounded in $L^1(\Omega)$, the claim (2.42) follows from (2.43), (2.44), and (2.45). □

LEMMA 2.8. *Under the assumptions of Proposition* 2.4*, the current density J defined in* (2.13) *belongs to $L^2(\mathcal{D}; W^{2,2}(0,L))$ and satisfies the boundary value problem*

$$\begin{cases} \frac{\partial^2 J}{\partial x_3^2} + (k_0^2 + \frac{2i\pi\gamma}{\kappa})\; J = 2i\,\pi\,\gamma\,E_3 & \text{on} \quad \Omega, \\ \qquad\qquad \frac{\partial J}{\partial x_3} = 0 & \text{on} \quad \mathcal{D}_0 \cup \mathcal{D}_L. \end{cases} \tag{2.46}$$

Proof. In order to recover boundary conditions over $\partial\Omega$, we consider a test function in $\varphi \in \mathcal{C}_0^\infty(B)$ and integrate over all $\mathbb{R}^3$. We multiply the second equation of (2.6) by $w_\eta\,\varphi(x)\,e_3$ and integrate by parts to obtain

$$\begin{aligned} -i\,\omega\,\varepsilon_0 \int (E_{3,\eta} + i\,F_{3,\eta})\, w_\eta \varphi \, dx &= \int \operatorname{curl} H_\eta \cdot (w_\eta \varphi\, e_3)\, dx \\ &= \int H_\eta \cdot [(\nabla w_\eta \wedge e_3)\varphi + (\nabla\varphi \wedge \varepsilon_3) w_\eta]\; dx. \end{aligned} \tag{2.47}$$

Recalling that, by Lemma 2.5, w_η does converge to 0 in L^2_{loc} and is uniformly close to 1 on the subset T_η, we can identify the limit of the integral in the left-hand member by applying Proposition 2.4(iii). We are led to

$$\omega\varepsilon_0 \int_\Omega J\,\varphi dx = \lim_{\eta\to 0} I_\eta, \qquad \text{where} \quad I_\eta := \int H_\eta \cdot (\nabla w_\eta \wedge \overrightarrow{e_3})\; \varphi\; dx. \tag{2.48}$$

Now we express I_η in terms of E_η by using the first equation in (2.6). By integrating once more by parts, we obtain

$$\begin{aligned} I_\eta &= \frac{1}{i\omega\mu_0} \int_\Omega E_\eta \cdot \operatorname{curl}\left[\varphi\,(\nabla w_\eta \wedge e_3)\right]\; dx \\ &= \frac{1}{i\omega\mu_0} \int \left[E_\eta \cdot (\nabla\varphi \wedge (\nabla w_\eta \wedge e_3)) + \varphi \operatorname{curl}(\nabla w_\eta \wedge\, e_3)\right]. \end{aligned}$$

Recalling that $w_\eta = w_\eta(x_1, x_2)$, we compute $\operatorname{curl}(\nabla w_\eta \wedge e_3) = -\Delta w_\eta\, e_3$. Thus we may write I_η as the sum of three terms:

(2.49)
$$I_\eta = \frac{1}{i\omega\mu_0}\left[\int E_\eta \cdot \nabla w_\eta \left(\frac{\partial\varphi}{\partial x_3}\right) dx - \int E_{3,\eta}\, \Delta w_\eta\, \varphi\, dx - \int E_{3,\eta}\, \nabla w_\eta \cdot \nabla\varphi\, dx\right].$$

The limits of the three integrals above are deduced from (2.41), (2.39), and (2.40), respectively. Therefore, by (2.48) and (2.49), we are led to

$$k_0^2 \int_\Omega J\,\varphi\, dx = -\int_\Omega J\,\frac{\partial^2\varphi}{\partial x_3^2}\, dx - i\int_{\partial\Omega} J\,\frac{\partial\varphi}{\partial x_3}\, d\nu + 2i\pi\gamma \int_\Omega \left(E_3 - \frac{J}{\kappa}\right)\varphi\, dx, \tag{2.50}$$

where we have multiplied by $\omega\mu_0$ and used the relation $k_0^2 = \varepsilon_0\mu_0\omega^2$. Choosing first φ compactly supported in Ω leads to the propagation equation in (2.46), which is satisfied in the distributional sense in Ω. Since E_3 belongs to $L^2(\Omega)$, this implies that J is an element of $L^2(\mathcal{D}; W^{2,2}(0,L))$. Therefore J and $\frac{\partial J}{dx_3}$ have traces on $\mathcal{D}_0 \cup \mathcal{D}_L$. Let us denote by j_L and j_0 respectively the traces of J on $\mathcal{D}_L$ and $\mathcal{D}_0$. Then by the integration by parts of the volume integrals in (2.50) and by taking into account (2.46), we are led to

$$-\int_{D_L}\left(J\frac{\partial\varphi}{\partial x_3} - \frac{\partial J}{\partial x_3}\right) d\sigma + \int_{D_0}\left(J\frac{\partial\varphi}{\partial x_3} - \frac{\partial J}{\partial x_3}\varphi\right) d\sigma - i\int_{\partial\Omega}\frac{\partial\varphi}{\partial x_3}\, d\nu = 0.$$

Since this relation holds for every $\varphi \in \mathcal{C}_0^\infty(B)$, we derive that

$$\frac{\partial J}{\partial x_3} = 0 \quad \text{on} \quad \mathcal{D}_0 \cup \mathcal{D}_L \qquad \text{and} \qquad \nu = i\,(j_L\,\Sigma_L - j_0\,\Sigma_0), \tag{2.51}$$

with Σ_0, Σ_L the surface integrals on $\mathcal{D}_0$ and $\mathcal{D}_L$, respectively. □

3. The main homogenization result. Thanks to the results of section 2, we are now in position to describe asymptotically the diffraction by the fibered structure depicted in Figure 1. Our main convergence theorem states that passing to the limit as the period η tends to zero leads to a coupled system of partial differential equations with suitable transmission conditions on the boundary of the structure.

In the following, (E^i, H^i) denotes a given incident electromagnetic wave. It satisfies the harmonic Maxwell system in the vacuum (i.e., $\operatorname{curl} E^i = i\,\omega\mu_0\, H^i$, $\operatorname{curl} H^i = -i\,\omega\varepsilon_0\, E^i$ in all $\mathbb{R}^3$). Recall that he total electromagnetic field (E_η, H_η) is then completely determined as the unique solution of (1.2) such that the diffracted field $(E_\eta^d, H_\eta^d) := (E_\eta - E^i,\, H_\eta - H^i)$ satisfies the outgoing wave condition at infinity (1.3).

THEOREM 3.1. *Let γ and κ be given by* (1.4) *and* (2.3), *respectively. Then, as $\eta \to 0$, the following convergences hold:*

$$(E_\eta, H_\eta) \rightharpoonup (E, H) \quad \textit{in } L^2_{loc} \quad , \quad F_\eta := \kappa\, E_\eta \frac{1_{T_\eta}}{\theta_\eta} \overset{*}{\rightharpoonup} J(x)\overrightarrow{e_3} \quad \textit{in } (L^1(\Omega))^3,$$

where E, H, J are the unique solutions (in the distributional sense) of the system

(3.1)
$$\begin{cases} \operatorname{curl} E &= i\omega\mu_0 H & \text{on } \mathbb{R}^3, \\ \operatorname{curl} H &= -i\omega\varepsilon_0(E + i\,J\,1_\Omega \overrightarrow{e_3}) & \text{on } \mathbb{R}^3, \\ \frac{\partial^2 J}{\partial x_3^2} + (k_0^2 + \frac{2i\pi\gamma}{\kappa})\,J &= 2i\pi\gamma\,E_3 & \text{on } \Omega, \\ \frac{\partial J}{\partial x_3} &= 0 & \text{on } \mathcal{D}_0 \cup \mathcal{D}_L, \\ (E - E^i, H - H^i) & \text{ satisfies the outgoing wave condition.} \end{cases}$$

Remark 3.2. In view of the improved regularity of (E, H, J) obtained in Lemma 3.5 below, it is possible to split (3.1) into two systems of equations (one on Ω, the other on $\mathbb{R}^3 \setminus \Omega$), to which we add suitable transmission conditions along the boundary of Ω:

(3.2)
$$\begin{cases} \operatorname{curl} E &= i\omega\mu_0 H \\ \operatorname{curl} H &= -i\omega\varepsilon_0(E + i\,J\,e_3) \qquad \text{on } \Omega, \\ \frac{\partial^2 J}{\partial x_3^2} + (k_0^2 + \frac{2i\pi\gamma}{\kappa})\,J &= 2i\pi\gamma\,E_3 \end{cases}$$

(3.3)
$$\begin{cases} \Delta E + k_0^2 E = \Delta H + k_0^2 H = 0 \qquad \text{on } \mathbb{R}^3 \setminus \Omega, \\ (E - E^i, H - H^i) \text{ satisfies the outgoing wave condition,} \end{cases}$$

(3.4)
$$\begin{cases} H & \text{continuous across} & \partial\Omega, \\ E & \text{continuous across} & \partial\mathcal{D} \times (0, L), \\ \frac{\partial J}{\partial x_3} = 0 & \text{on} & \mathcal{D}_0 \cup \mathcal{D}_L, \\ E_3 + i\,J\,1_\Omega\,e_3 & \text{continuous across} & \mathcal{D}_0 \cup \mathcal{D}_L. \end{cases}$$

Notice that, in (3.4), the continuity has to be understood in the sense of traces in the related Sobolev spaces (we refer to Duvaut and Lions [12] for further details). The last condition is a concise rewriting of the continuity of the normal trace of the divergence-free vector field $D := E + i\,J\,1_\Omega\,e_3$.

Remark 3.3. By using the third equation in (3.1) together with the Neumann condition, it is possible to express J in terms of E_3 as follows: let $K(s, \cdot)$ be, for every $s \in (0, L)$, the solution of the 1D problem

$$\begin{cases} y'' + (k_0^2 + \frac{2i\pi\gamma}{\kappa})\,y = \frac{2i\pi\gamma}{\kappa}\,\delta_s, \\ y'(0) = y'(L) \quad = 0. \end{cases}$$

Then there holds, for almost every $(x_1, x_2) \in \mathcal{D}$,

(3.5)
$$J(x_1, x_2, x_3) = \int_0^L K(x_3, s)\,E_3(s)\,ds, \quad x_3 \in (0, L).$$

Substituting this expression into the second equation in (3.1) leads to a nonlocal constitutive relation between E and the displacement field $D := E + i\,J\,1_\Omega\,e_3$.

Remark 3.4. The limit model is described by the two parameters γ (*capacity*) and κ (*stiffness*). It is clear from (1.4) and (2.3) that these constants can be tuned at will by playing with the size r_η of the fibers and the conductivity coefficient σ_η. In other words, *any problem of the kind* (3.1) *can be obtained as a limit as* $\eta \to 0$ *of classical diffraction problems.*

To complete the picture, some comments related to the extreme values of κ and γ are in order. Note that the conclusions we are drawing below are based on heuristical arguments.

(a) *Cases* $\kappa = 0$ *and* $\kappa = \infty$. Throughout the paper we assumed (1.1) with $\kappa > 0$. If we substitute κ with a sequence $\kappa_\eta \to 0$, it is clear that the fibers disappear in the limit process so that the structure becomes transparent. In other words, the conclusions of Theorem 3.1 hold with $J = 0$. In contrast, when $\kappa = \infty$ and if k_0^2 is not an eigenvalue of the Neumann problem on $(0, L)$ (i.e., if $k_0 \notin \{\frac{\pi n}{L} : n \in \mathbb{N}\}$), we find a nonvanishing limit current density J, and in (3.1) the propagation equation satisfied by J becomes $\frac{\partial^2 J}{\partial x_3^2} + k_0^2\, J = 2i\pi\gamma E_3$. Notice also that the dissipation of energy by Joule's effect given by (3.6) vanishes. This case will occur either when considering a sequence $\kappa_\eta \to \infty$ in (1.1) or when starting, for every η, with infinitely conducting fibers. In the latter situation, (E_η, H_η) vanishes in T_η as well as the tangential component of the trace of the electric field E_η, whereas the jump of the tangential component of the magnetic field H_η induces a microscopic current on ∂T_η which, as $\eta \to 0$, is responsible for the presence of J.

(b) *Cases* $\gamma = 0$ *and* $\gamma = \infty$. For $\gamma = 0$, the source term in the propagation equation (2.46) disappears. Thus J vanishes, and we are led to the same conclusions as for $\kappa = 0$. If $\gamma = +\infty$, the strong interaction between fibers and matrix forces the equality $J = \kappa\, E_3$. As a consequence, the relation between E and D on Ω remains local with an effective tensor ε^{eff} given by $\varepsilon^{\text{eff}} = \operatorname{diag}\{1, 1, 1 + i\,\kappa\}$. However, E_3 inherits the homogeneous Neumann boundary condition of J, and a jump of E_3 will still occur on $\mathcal{D}_0 \cup \mathcal{D}_L$.

The end of this section is devoted to the proof of Theorem 3.1, which crucially makes use of the uniqueness of the limit system.

LEMMA 3.5.

(i) *The solution of* (E, H, J) *of* (3.1)*, if it exists, is unique and satisfies* $E \in W^{1,2}_{\text{loc}}(\mathbb{R}^3 \setminus \mathcal{D}_0 \cup \mathcal{D}_L)$*,* $H \in W^{1,2}_{\text{loc}}(\mathbb{R}^3)$*, and* $J \in L^2(\mathcal{D}; W^{2,2}(0, L))$.

(ii) *Furthermore, denoting by* $\Re$*,* $\Im$ *the real and imaginary parts, we have*

$$-\Re\left(\int_{\partial B} \left(E \wedge \overline{H}\right) \cdot n(x)\right) = \frac{\omega\varepsilon_0}{\kappa} \int_\Omega |J|^2\, dx \quad (\textit{Joule's dissipation}), \tag{3.6}$$

$$\lim_{\eta\to 0} \frac{1}{\theta_\eta} \int_{T_\eta} |E_\eta|^2 = \frac{1}{\kappa} \int_\Omega |J|^2, \tag{3.7}$$

$$\lim_{\eta\to 0} \int_B \left(\mu_0\, |H_\eta|^2 - \varepsilon_0\, |E_\eta|^2\right) = \int_B \left(\mu_0\, |H|^2 - \varepsilon_0\, |E|^2\right) - \varepsilon_0\, \Im\left(\int_\Omega \overline{J} E_3\right). \tag{3.8}$$

Proof. (i) *Regularity.* We begin by noticing that for every open subset $\mathcal{O} \subset \mathbb{R}^3$ we have the identity (see [12] for a more precise statement including traces)

$$W^{1,2}_{\text{loc}}(\mathcal{O}; \mathbb{C}^3) = \left\{u \in L^2_{\text{loc}}(\mathcal{O}; \mathbb{C}^3) \ :\ \operatorname{curl} u \in L^2_{\text{loc}}(\mathcal{O}),\ \operatorname{div} u \in L^2_{\text{loc}}(\mathcal{O})\right\}. \tag{3.9}$$

By (3.1), H is divergence-free, and $\operatorname{curl} H$ belongs to $L^2_{\text{loc}}(\mathbb{R}^3)$. Therefore by (3.9), we have $H \in W^{1,2}_{\text{loc}}(\mathbb{R}^3)$. From the 1D propagation equation satisfied by J,

we infer easily that J belongs to $L^2(\mathcal{D}, W^{1,2}(0,L))$. In particular, the traces j_0, j_L of J on the basis belong to $L^2(\mathcal{D}_L)$ and $L^2(\mathcal{D}_0)$, respectively. On the other hand, $\operatorname{curl} E \in L^2_{\mathrm{loc}}(\mathbb{R}^3)$, and from the second equation in (3.1) the distributional divergence of E as a measure satisfies

$$\operatorname{div} E = -i\kappa \left(\frac{\partial J}{\partial x_3} 1_\Omega \, dx - j_L \, \mathcal{H}^2 \llcorner \mathcal{D}_L + j_0 \, \mathcal{H}^2 \llcorner \mathcal{D}_0 \right).$$

In particular, the trace of $\operatorname{div} E$ on the open set $\mathbb{R}^3 \setminus (\mathcal{D}_0 \cup \mathcal{D}_L)$ belongs to L^2_{loc}. It then follows from (3.9) that $E \in W^{1,2}_{\mathrm{loc}}(\mathbb{R}^3 \setminus \mathcal{D}_0 \cup \mathcal{D}_L)$.

Uniqueness. This will be a consequence of (3.6). Indeed, by linearity, we are reduced to showing that any solution (E, H, J) for (3.1) vanishes over all $\mathbb{R}^3$, provided that (E^i, H^i) is identically 0. In this case, by Silver–Müller radiation conditions, we know that $\Re \left(\int_{\partial B} E \wedge \overline{H} \right) \cdot n(x)$ is nonnegative. Then by (3.6), J is identically 0 on Ω, and (E, H) satisfies the equation $\Delta w + k_0^2 w = 0$ in all $\mathbb{R}^3$ and the outgoing wave condition at infinity. The conclusion $E = H = 0$ follows classically (see, for example, [6] or [10]).

(ii) By using the propagation equation for J in (3.1) together with the Neumann boundary condition, and after integrating by parts with respect to x_3, we are led to

$$-\int_\Omega \left| \frac{\partial J}{\partial x_3} \right|^2 dx + \int_\Omega \left(k_0^2 + \frac{2i\pi\gamma}{\kappa} \right) |J|^2 \, dx = \int_\Omega 2i\pi\gamma \, E_3 \overline{J} dx.$$

Thus, taking the imaginary parts,

$$\Re \left(\int_\Omega E_3 \overline{J} dx \right) = \frac{1}{\kappa} \int_\Omega |J|^2 \, dx. \tag{3.10}$$

Now from (3.1) we have

$$\int_B \left(\operatorname{curl} E \cdot \overline{H} - \operatorname{curl} \overline{H} \cdot E \right) dx = i\omega \int_B \left(\mu_0 |H|^2 - \varepsilon_0 |E|^2 \right) - \omega\varepsilon_0 \int_\Omega \overline{J} E_3 \, dx.$$

By integrating the left-hand side of the previous equality by parts and by taking into account (3.10), we deduce (3.6) together with the relation

$$\Im \left(\int_{\partial B} E \wedge \overline{H} \cdot n(x) \right) = \omega \int_B \left(\mu_0 |H|^2 - \varepsilon_0 |E|^2 \right) - \omega \, \varepsilon_0 \, \Im \left(\int_\Omega \overline{J} E_3 \right). \tag{3.11}$$

In a similar way, from (2.16), we derive that

$$\Im \left(\int_{\partial B} \left(E_\eta \wedge \overline{H_\eta} \right) \cdot n(x) \right) = \omega \int_B \left(\mu_0 |H_\eta|^2 - \varepsilon_0 |E_\eta|^2 \right). \tag{3.12}$$

The convergences (3.7), (3.8) are then a straightforward consequence of (3.6), (3.11) and of the convergence of the left-hand expression of (3.12) towards $\int_{\partial B} \left(E \wedge \overline{H} \right) \cdot n(x)$. □

Proof of Theorem 3.1. The proof proceeds in two steps.

Step 1. We assume that the boundedness condition (2.7) is satisfied. Then by Proposition 2.4, we deduce that there exists a triplet (E, H, J) $(L^2(B))^3 \times (L^2(B))^3 \times L^1(\Omega)$ such that a suitable subsequence of $\{(E_\eta, H_\eta, F_\eta)\}$ does converge (weakly and weakly star) to $(E, H, J\, e_3)$. Moreover, by Lemma 2.1, (E, H) can be extended to

all $\mathbb{R}^3$ so that (E,H) solves (3.3) and the convergence $(E_\eta,H_\eta)\to(E,H)$ holds in $C^\infty(K)$ for all compact $K\subset\mathbb{R}^3\setminus\Omega$. Then, by Proposition 2.8, passing to the limit in (2.6) with the help of Proposition 2.4(iii), we find that (E,H,J) solves the system (3.1). Owing to the uniqueness property proved in Lemma 3.5, we conclude that the whole sequence $\{(E_\eta,H_\eta,F_\eta)\}$ converges and that all the conclusions of Theorem 3.1 hold true.

Step 2. We normalize the electromagnetic fields as follows,

$$u_\eta:=\frac{E_\eta}{t_\eta},\quad v_\eta:=\frac{H_\eta}{t_\eta},\quad w_\eta:=\frac{F_\eta}{t_\eta},\qquad\text{where}\quad t_\eta:=\sqrt{\int_B(|E_\eta|^2+|H_\eta|^2)dx},$$

and prove (2.7) by contradiction, assuming that $t_\eta\to+\infty$. By linearity, the triplet (u_η,v_η,w_η) satisfies the diffraction problem (2.6) and the outgoing wave condition with respect to the rescaled incident wave $(\frac{E^i}{t_\eta},\frac{H^i}{t_\eta})$. As it is bounded in $L^2(B)$, we may apply the conclusions of Theorem 3.1, where we have substituted (E^i,H^i) with the vanishing limit of $(\frac{E^i}{t_\eta},\frac{H^i}{t_\eta})$. By the uniqueness property proved in Lemma 3.5, we find that $(u_\eta,v_\eta)\rightharpoonup 0$ in $L^2_{\rm loc}$ whereas $w_\eta\overset{*}{\rightharpoonup}0$ in $L^1(\Omega)$. Furthermore, by the second assertion of Lemma 3.5, we obtain

$$\lim_\eta\ \frac{1}{\theta_\eta}\int_{T_\eta}|u_\eta|^2=0,\quad \lim_\eta\int_B\left(\mu_0\,|v_\eta|^2-\varepsilon_0\,|u_\eta|^2\right)\,dx=0. \tag{3.13}$$

In particular, recalling that $\int_B(|u_\eta|^2+|v_\eta|^2)=1$, we infer that

$$\lim_\eta\int_B\mu_0\,|v_\eta|^2=\lim_\eta\int_B\varepsilon_0\,|v_\eta|^2=\frac{\varepsilon_0\mu_0}{\varepsilon_0+\mu_0}>0.$$

Therefore, in order to find a contradiction, we need only to prove that $v_\eta\to0$ strongly in $L^2(B)$. To that aim, we consider a bounded open subset $B'\supset\supset B$ and use the following claim:

$$w_\eta:=\frac{1}{\theta_\eta}E_\eta 1_{T\eta}\ \to0\qquad\text{strongly in } W^{-1,2}(B'). \tag{3.14}$$

Then by the weak convergence of u_η to 0 in $L^2_{\rm loc}$, we infer that

$$\operatorname{curl}v_\eta=-i\omega\varepsilon_0\,(u_\eta+iw_\eta)\ \to0\qquad\text{strongly in } W^{-1,2}(B').$$

Since v_η is divergence-free, by the div-curl lemma [23], we deduce that $|v_\eta|^2$ converges to 0 weakly star in $L^1(B')$. By localizing this convergence with a continuous test function $\varphi\in\mathcal{D}(B',[0,1])$ such that $\varphi=1$ on B, we arrive at $\int_B|v_\eta|^2\to0$, and hence the contradiction.

It remains to prove (3.14), which is a consequence of estimate (2.34). Indeed, for every $\varphi\in(\mathcal{D}(B'))^3$, we have

$$\begin{aligned}\int_{B'}w_\eta\cdot\varphi\,dx=\frac{\kappa}{\theta_\eta}\int_{T_\eta}u_\eta\cdot\varphi\,dx&\le\kappa\left[\frac{1}{\theta_\eta}\int_{T_\eta}|u_\eta|^2\,dx\right]^{1/2}\left[\frac{1}{\theta_\eta}\int_{T_\eta}|\varphi|^2\,dx\right]^{1/2}\\&\le C\left[\frac{1}{\theta_\eta}\int_{T_\eta}|u_\eta|^2\,dx\right]^{1/2}\|\varphi\|_{W^{1,2}(B')}.\end{aligned}$$

The claim (3.14) follows from the left-hand-side convergence statement in (3.13). The proof of Theorem 3.1 is finished. ∎

4. Fibers with infinite length and numerical examples. In this section we sketch the natural extension of our previous results to the case of fibers of infinite length and present some features of the associated limit model.

4.1. Fibers of infinite length. We wish to model the diffraction by e_3-parallel fibers of infinite length. To that aim, we choose $\Omega_L := \mathcal{D} \times (-L/2, L/2)$ to be our reference obstacle and consider the limit as $L \to \infty$. We expect some limit equations on the infinite cylinder $\Omega_\infty := \mathcal{D} \times (-\infty, +\infty)$ with suitable transmission conditions. In fact, there exist many ways to proceed, namely, the following:

(a) First we fix L and pass to the limit as $\eta \to 0$, exploiting the results of section 3. Then we pass to the limit as $L \to \infty$.

(b) First we consider for fixed η the diffraction problem associated with Ω_∞. This allows us to reduce the problem to a scalar diffraction problem in dimension two. Indeed, we may decompose the incident wave by means of a Fourier transform in x_3, and then we look for solutions with a multiplicative x_3-dependence in $\exp(i\beta x_3)$. In a second step, we pass to the limit as $\eta \to 0$.

Of course all intermediate situations between (a) and (b) could also be considered, that is, taking a length $L(\eta)$ tending to infinity as $\eta \to 0$. The case (b) has been investigated in [14], leading for $\kappa = +\infty$ to a homogenized medium characterized by a diagonal effective permittivity tensor with a possibly negative eigenvalue in the x_3-direction. Let us sketch out how the same result can be obtained by following the strategy (a).

Owing to Theorem 3.1 (see (3.1)), we have to find the equation satisfied by the limit as $L \to \infty$ of the solution (E_L, H_L, j_L) of

$$
\left\{
\begin{array}{lll}
\operatorname{curl} E_L & = i\omega\mu_0\, H_L & \text{on } \mathbb{R}^3,\\
\operatorname{curl} H_L & = -i\omega\varepsilon_0\,(E_L + i\kappa J_L\, 1_{\Omega_L} e_3) & \text{on } \mathbb{R}^3,\\
\frac{\partial^2 J_L}{\partial x_3^2} + (k_0^2 + \frac{2i\pi\gamma}{\kappa})\, J_L & = 2i\pi\gamma E_L \cdot e_3 & \text{on } \Omega_L,\\
\frac{\partial J_L}{\partial x_3} & = 0 & \text{on } \mathcal{D}_{\pm L/2},\\
(E_L - E^i, H_L - H^i) & \text{satisfies the outgoing wave condition.} &
\end{array}
\right. \tag{4.1}
$$

Let us denote by (E, H, J) such a limit in L^2_{loc} (possibly obtained after extracting a subsequence). Passing to the limit in the three first equations of (4.1), we are led to

$$
\left\{
\begin{array}{lll}
\operatorname{curl} E & = i\omega\mu_0\, H & \text{on } \mathbb{R}^3,\\
\operatorname{curl} H & = -i\omega\varepsilon_0\,(E + i\ J\, e_3) & \text{on } \mathbb{R}^3,\\
\frac{\partial^2 J}{\partial x_3^2} + (k_0^2 + \frac{2i\pi\gamma}{\kappa})\, J & = 2i\pi\,\gamma E_3 & \text{on } (-\infty, +\infty).
\end{array}
\right. \tag{4.2}
$$

The difficult task is now to determine the radiation condition satisfied by (E, H) at infinity. By Fourier transform with respect to x_3, it is possible to reduce to an incident wave with a multiplicative x_3-dependence in $\exp(i\beta x_3)$. Then the L^2_{loc} solutions (E, H, J) of (4.2) can be shown to have the same x_3-dependence, and therefore the solution J of the third equation in (4.2) reads as

$$
J = \frac{2i\pi\,\gamma}{k_0^2 - \beta^2 + \frac{2i\pi\gamma}{\kappa}}\, E_3. \tag{4.3}
$$

Writing $E_3^i(x) = u^i(x_1, x_2)\exp(i\beta x_3)$, $E_3(x) = u(x_1, x_2)\exp(i\beta x_3)$ and substituting into (4.2), we obtain that u is solution of the following bidimensional diffraction problem:

$$\begin{cases} \Delta u + (k_0^2\,\varepsilon(x) - \beta^2)\,u = 0 & \text{on } \mathbb{R}^2, \\ (u - u^i) & \text{satisfies the outgoing wave condition,} \end{cases} \tag{4.4}$$

where $\varepsilon(x)$ is defined on $\mathbb{R}^2$ by

$$\varepsilon(x) = \begin{cases} \varepsilon^{\text{eff}}(\beta) & \text{if } x \in \mathcal{D}, \\ \varepsilon_0 & \text{otherwise,} \end{cases} \qquad \varepsilon^{\text{eff}}(\beta) = 1 - \frac{2\pi\gamma}{k_0^2}\left[\frac{k_0^2 - \beta^2}{k_0^2 - \beta^2 + \frac{2i\pi\gamma}{\kappa}}\right], \tag{4.5}$$

and the outgoing wave condition has to be understood in the sense of Sommerfeld (see, for instance, [6] or [10]). The magnetic field H and the horizontal components of E are then deduced in a standard way.

To summarize, we have obtained that, for an off-plane incident wave (described by an $\exp(i\beta x_3)$ dependence), the infinite wire mesh photonic crystal behaves like an anisotropic homogeneous medium characterized by the effective permittivity tensor $\operatorname{diag}\{1, 1, \varepsilon^{\text{eff}}(\beta)\}$. The dependence of $\varepsilon^{\text{eff}}(\beta)$ with respect to β indicates that the limit behavior is spatially nonlocal: it involves a convolution with respect to the inverse Fourier transform of $\varepsilon^{\text{eff}}(\beta)$. However, this effect disappears as $\kappa \to \infty$. Indeed, we observe that, for $\kappa = +\infty$ (infinite conductivity), $\varepsilon^{\text{eff}}(\beta) = 1 - \frac{2\pi\gamma}{k_0^2}$ is independent of β. We recover the same results as in [14], where it was pointed out that ε^{eff} becomes negative below a cut-off wave number $k_p = \sqrt{2\pi\gamma}$.

4.2. Numerical results. In this section, we present some numerical results obtained for infinitely long and perfectly conducting fibers; that is, the effective permittivity is given by (4.5), where $\kappa = +\infty$. We consider a stack of ten diffraction gratings infinite in extent in the horizontal direction. The gratings are made of parallel, infinitely long and perfectly conducting fibers, and the period is denoted by d. The distance between each grating is equal to d. The radius of the fibers is $r = d/200$. The structure is illuminated by a plane wave under normal incidence (see Figure 2) and linearly polarized in $E_{||}$; that is, the incident field reads as $E^i(y) = e^{-ik_0 y}e^{-ik_0 ct}e_3$, where $k_0 = 2\pi/\lambda$, λ is the wavelength, and c is the speed of light in a vacuum. Below the stack, the electric field can be expanded in a Rayleigh series [18]:

$$E^t(y) = \Sigma_n a_n e^{-ik_n y}e_3, \tag{4.6}$$

where $k_n = \sqrt{k_0^2 - (n\pi/d)^2}$, the square root is defined with a cut along $i\mathbb{R}^-$, and the determination $\sqrt{-1} = i$. The sum in (4.6) splits into two parts: one finite sum for which k_n is real, and an infinite one for which k_n is imaginary. The latter corresponds to evanescent waves, that do not contribute to the far field. The transmitted field is computed numerically by means of a rigorous modal method [19]. We are interested in the behavior of the field when the wavelength is large with respect to the period. In normal incidence and for $\lambda/d > 1$ there is only one propagating wave in the finite sum above, and we plot the function $\lambda \to |a_0(\lambda)|^2$, the curve being given by the dashed line in Figure 3. It can be seen that for $\lambda/d > 5$ the transmission is strongly damped, corresponding to the forbidden band. In the homogenization result, it is stated that the structure behaves for large wavelengths as a homogeneous medium with permittivity $\varepsilon^{\text{eff}}(\lambda) = 1 - 2\pi\gamma/k_0^2$ (because of the polarization we have to make $\beta = 0$ in (4.5)). Our point is now to check numerically to what extent the real structure can be considered as homogeneous. To that aim we consider a homogeneous slab of

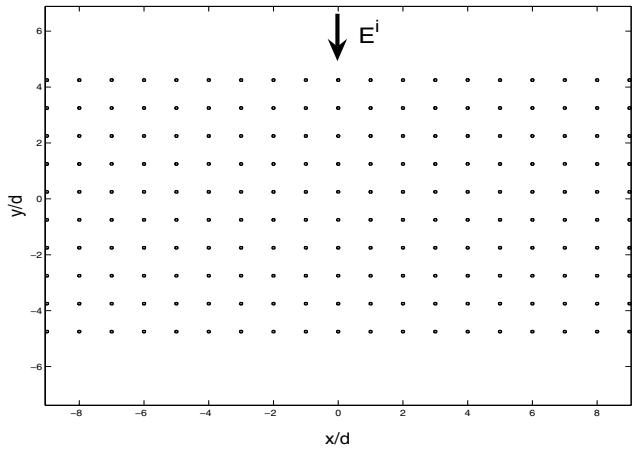

FIG. 2. *Cross section of the metallic photonic crystal.*

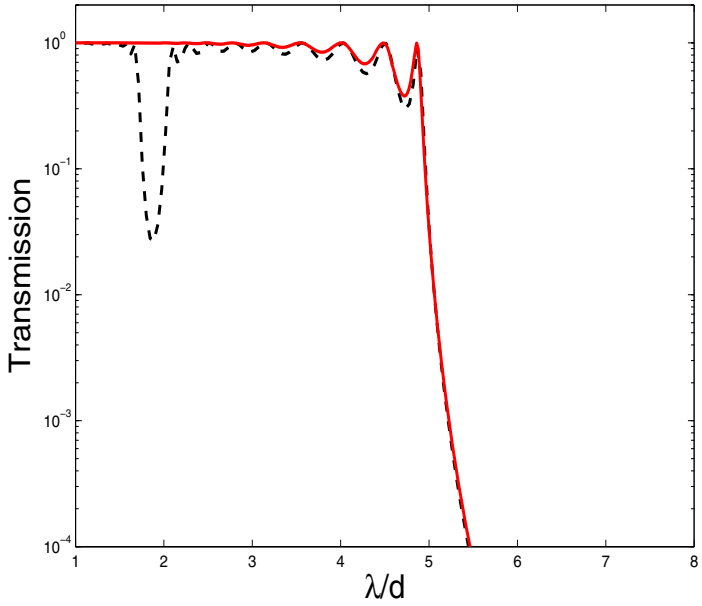

FIG. 3. *Transmitted energy through the device of Figure 2 (dashed line) and through the homogenized structure (solid line).*

height $10d$ with permittivity ε^{eff} illuminated under normal incidence by a plane wave, i.e., the same set-up as in the case of the heterogeneous structure. Below the slab, the electric field reads as $E^t(y) = t(\lambda)e^{-ik_0 y)}$, and we plot the function $\lambda \to |t(\lambda)|^2$. We expect a good fit between the curves at least for large wavelengths. One important parameter here is γ. A direct numerical application of (2.29) gives $\gamma \sim 0.2$, but we

must stress that this value is obtained as a limit as η tends to 0. The value of γ can be determined more precisely by studying correctors [16]. A numerical test shows that the value $\gamma = 0.25$ provides an excellent fit between the real transmission and that obtained from the slab (solid line in Figure 3). This shows that, up to a minor correction in the numerical value of γ, the homogeneous behavior reproduces very precisely that of the real device. Moreover, it can be seen in Figure 3 that the curves coincide for values of the wavelengths that are not very high, i.e., for $\lambda/d > 4$.

TWO-DIMENSIONAL HIGH-ACCURACY SIMULATION OF RESISTIVITY LOGGING-WHILE-DRILLING (LWD) MEASUREMENTS USING A SELF-ADAPTIVE GOAL-ORIENTED *hp* FINITE ELEMENT METHOD*

D. PARDO†, L. DEMKOWICZ‡, C. TORRES-VERDÍN§, AND M. PASZYNSKI¶

Abstract. We simulate electromagnetic (EM) measurements acquired with a logging-while-drilling (LWD) instrument in a borehole environment. The measurements are used to assess electrical properties of rock formations. Logging instruments as well as rock formation properties are assumed to exhibit axial symmetry around the axis of a vertical borehole. The simulations are performed with a self-adaptive goal-oriented *hp*-finite element method that delivers exponential convergence rates in terms of the quantity of interest (for example, the difference in the electrical current measured at two receiver antennas) against the CPU time. Goal-oriented adaptivity allows for accurate approximations of the quantity of interest without the need to obtain an accurate solution in the entire computational domain. In particular, goal-oriented *hp*-adaptivity becomes essential to simulating LWD instruments, since it reduces the computational cost by several orders of magnitude with respect to the global energy-norm-based *hp*-adaptivity. Numerical results illustrate the efficiency and high accuracy of the method, and provide physical interpretation of resistivity measurements obtained with LWD instruments. These results also describe the advantages of using magnetic buffers in combination with solenoidal antennas for strengthening the measured EM signal so that the "signal-to-noise" ratio is minimized.

1. Introduction.

A plethora of energy-norm-based algorithms intended to generate *optimal* grids have been developed throughout recent decades (see, for example, [10, 23] and references therein) to accurately solve a large class of engineering problems. However, the energy-norm is a quantity of limited relevance for most engineering applications, especially when a particular objective is pursued, such as simulating the electromagnetic response of geophysical resistivity logging instruments in a borehole environment. In these instruments, the amplitude of the measurement (for example, the electric field) is typically several orders of magnitude smaller at the receiver antennas than at the transmitter antennas. Thus, small relative errors of the solution in the energy-norm *do not* imply small relative errors of the solution at the receiver

antennas. Indeed, it is not uncommon to construct adaptive grids delivering a relative error in the energy-norm below 1% while the solution at the receiver antennas still exhibits a relative error above 1000% (see [18]).

Consequently, in order to accurately simulate logging-while-drilling (LWD) resistivity measurements in this paper, we develop a self-adaptive strategy to approximate a specific feature of the solution. Refinement strategies of this type are called *goal-oriented* adaptive algorithms [16, 22], and are based on minimizing the error of a prescribed *quantity of interest* mathematically expressed in terms of a linear functional (see [5, 12, 17, 16, 22, 24] for details).

In this paper, we formulate, implement, and study (both theoretically and numerically) a self-adaptive *hp* goal-oriented algorithm intended to solve electrodynamic problems. This algorithm is an extension of the fully automatic (energy-norm-based) *hp*-adaptive strategy described in [10, 23], and a continuation of concepts presented in [19, 25] for elliptic problems.

We apply the self-adaptive *hp* goal-oriented algorithm to accurately simulate induction LWD instruments in a borehole environment with axial symmetry. These instruments are widely used by the geophysical logging industry, and their simulation requires resolution of electromagnetic (EM) singularities generated by the LWD geometry and rock formation materials [28], as well as resolution of high material contrasts that occur between the mandrel and the borehole.

Other methods for simulation of LWD measurements include the transmission line matrix method [14], fast Fourier transform [29], and finite differences [26, 13]. In contrast to previous contributions, here we consider a detailed geometry of the logging instrument, which requires the resolution of strong singularities in the EM fields, we account for the finite conductivity of the mandrel, we incorporate magnetic buffers in both transmitter and receiver antennas, we consider the effect of the magnetic permeability of the mandrel, and we provide extremely accurate results with guaranteed relative error bounds below 0.1% (0.001% if desired). We also consider a high contrast in conductivity among different layers in the formation, and we present a comparison between using two and three receiver antennas.

The organization of this paper is as follows. In section 2, we describe the main characteristics of induction logging instruments. We also describe our problem of interest, composed of an induction LWD instrument in a borehole environment, and used for the assessment of the rock formation electrical properties. In section 3, we introduce Maxwell's equations, governing the EM phenomena and explaining the physics of resistivity measurements. We also derive the corresponding variational formulation for axisymmetric problems. A self-adaptive goal-oriented *hp* algorithm for electrodynamic problems is described in section 4. The corresponding details of implementation are discussed in the same section. Simulations and numerical results concerning the response of LWD instruments in a borehole environment are shown in section 5. Section 6 draws the main conclusions and outlines future lines of research. Finally, in the appendix, we compare numerical results with a semianalytical solution obtained using Bessel functions for a simplified LWD model problem. The comparison is intended to verify the code as well as to illustrate the high-accuracy results obtained with the self-adaptive goal-oriented *hp*-finite element method (FEM).

2. Alternate current (AC) logging applications. In this article, we consider an induction[1] LWD instrument operating at 2 MHz. The instrument makes use of one of the following two types of source antennas/coils:

- solenoidal coils (Figure 1, left panel), and
- toroidal coils (Figure 1, right panel).

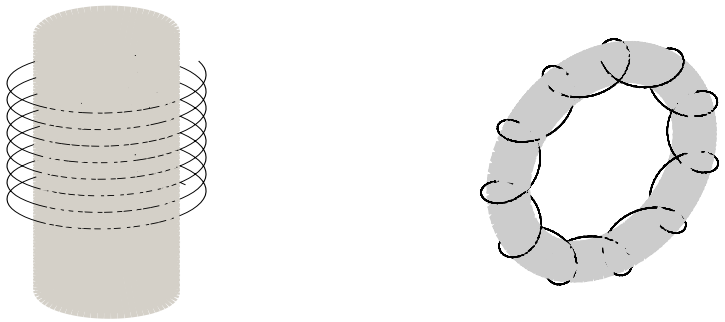

FIG. 1. *Two coil antennas: a solenoid antenna (left panel) composed of a wire wrapped around a cylinder, and a toroid antenna (right panel) composed of a wire wrapped around a toroid.*

2.1. Induction LWD instrumentsbased on solenoidal coils. For axisymmetric problems, these logging instruments generate a TM_ϕ field; i.e., the only nonzero components of the EM fields are E_ϕ, H_ρ, and H_z, where (ρ, ϕ, z) denote the cylindrical system of coordinates.

A solenoidal coil (Figure 1) produces an impressed current $\mathbf{J}^{imp}$ that we mathematically describe as

$$\mathbf{J}^{imp}(\mathbf{r}) = \hat{\phi} I \delta(\rho - a)\delta(z), \tag{2.1}$$

where I is the electric current measured in Amperes (A), δ is the Dirac's delta function, and a is the radius of the solenoid. In the numerical computations, we replace function $\delta(\rho - a)\delta(z)$ with an approximate function U_F that considers the finite dimensions of the coil, and such that $\int U_F d\rho dz = 1$.

The analytical electric far-field solution excited by a solenoidal coil of radius a radiating in homogeneous media is given in terms of the electric field by (see [15])

$$\mathbf{E} = \hat{\phi}\omega\mu k I \pi a^2 \frac{e^{-jkd}}{4\pi d}\left[1 - \frac{j}{kd}\right]\frac{\rho}{d}\,, \tag{2.2}$$

where $k = \sqrt{\omega^2\epsilon - j\omega\sigma}$ is the wave number; $j = \sqrt{-1}$ is the imaginary unit; ω is angular frequency; ϵ, μ, and σ stand for dielectric permittivity, magnetic permeability, and electrical conductivity of the medium, respectively; and d is the distance between the source coil and the receiver coil.

In order to avoid the dependence upon the dimensions of the solenoid, we impose a current on the solenoidal coil equal to $1/(\pi a^2)$A, i.e., equivalent to that of 1A with a

[1]Induction logging instruments are characterized by the fact that impressed current $\mathbf{J}^{imp}$ is divergence-free (i.e., $\nabla \cdot \mathbf{J}^{imp} = \mathbf{0}$).

vertical magnetic dipole (VMD). The corresponding far-field solution in homogeneous media is given by (see [15])

$$\mathbf{E} = \hat{\phi}\omega\mu k I \frac{e^{-jkd}}{4\pi d}\left[1 - \frac{j}{kd}\right]\frac{\rho}{d}\,. \tag{2.3}$$

Thus, solution (2.3) is independent of the dimensions of the coil.[2]

2.2. Induction LWD instruments based on toroidal coils. For axisymmetric problems, these logging instruments generate a TE_ϕ field; i.e., the only nonzero components of the EM fields are H_ϕ, E_ρ, and E_z.

A toroidal coil induces a *magnetic current* I_M in the azimuthal direction. If we place a toroid of radius a radiating in homogeneous media, the resulting magnetic far-field is given by (see [15])

$$\mathbf{H} = \hat{\phi}(\sigma + j\omega\epsilon)\pi a^2 I_M jk \frac{e^{-jkd}}{4\pi d}\left[1 - \frac{j}{kd}\right]\frac{\rho}{d}\,. \tag{2.4}$$

In order to avoid the dependence upon the dimensions of the toroid, we impose a magnetic current on the toroidal coil equal to that induced by a $(\sigma + j\omega\epsilon)$A electric current excitation with a vertical electrical dipole (VED), also known as a Hertzian dipole. The corresponding magnetic far-field solution in homogeneous media is given by (see [15])

$$\mathbf{H} = \hat{\phi}(\sigma + j\omega\epsilon) I jk \frac{e^{-jkd}}{4\pi d}\left[1 - \frac{j}{kd}\right]\frac{\rho}{d}\,. \tag{2.5}$$

In this case, $I_M = I/(\pi a^2)$.

2.2.1. Goal of the computations. We are interested in simulating the EM response of an induction LWD instrument in a borehole environment.

For a *solenoidal coil*, the main objective of our simulation is to compute the first difference of the voltage between the two receiving coils of radius a divided by the (vertical) distance Δz between them, i.e.,

$$\frac{V_1 - V_2}{\Delta z} = \left(\oint_{\mathbf{l}_1} \mathbf{E}(l)\, dl - \oint_{\mathbf{l}_2} \mathbf{E}(l)\, dl\right)/(\Delta z) = \frac{2\pi a}{\Delta z}(\mathbf{E}(l_1) - \mathbf{E}(l_2))\,, \tag{2.6}$$

where $\mathbf{l}_1$ and $\mathbf{l}_2$ are the first and second receiving coils, respectively, and $l_1 \in \mathbf{l}_1$, $l_2 \in \mathbf{l}_2$ are two arbitrary points located at the receiving coils. Notice that, due to the axisymmetry of the electric field, $\mathbf{E}(l_i^j) = \mathbf{E}(l_i^k)$ for all $l_i^j, l_i^k \in \mathbf{l}_i$.

This quantity of interest (first difference of voltage) is widely used in resistivity logging applications. Indeed, a first-order asymptotic approximation of the electric field response at low frequencies (Born's approximation) shows that the voltage at a receiver coil is proportional to the rock formation resistivity in the proximity of such a coil (see [15] for details). At higher frequencies (> 20 kHz), asymptotic approximations (see [3] for details) also indicate the dependence of the voltage upon the rock formation conductivity. Thus, an adequate approximation of the rock formation

[2] In resistivity logging applications, it is customary to consider solutions that have been divided by the *geometrical factor* (also called K-factor) [3], so that results are independent (as much as possible) of the logging instrument's geometry. Thus, solutions obtained from different logging instruments can be readily compared.

conductivity (which is unknown a priori in practical applications) can be estimated from the voltage measured at the receiving coils. Computing the first difference of the voltage between two receivers (rather than the voltage at one receiver) is convenient for improving the vertical resolution of the measurements. This well-known fact among well-logging practitioners will be illustrated here with numerical experiments.

For a *toroidal coil*, the main objective of these simulations is to compute the first difference of the electric current at the two receiving coils of radius a divided by the (vertical) distance Δz between them, i.e.,

$$\frac{I_1 - I_2}{\Delta z} = \left(\oint_{l_1} \mathbf{H}(l)\, dl - \oint_{l_2} \mathbf{H}(l)\, dl \right) / (\Delta z) = \frac{2\pi a}{\Delta z} (\mathbf{H}(l_1) - \mathbf{H}(l_2)) \,. \tag{2.7}$$

Notice that the main difference between a toroidal and a solenoidal coil is that the former generates an impressed magnetic current, while the latter produces an impressed electric current. This fact leads to the physical consideration that, if the voltage due to a solenoidal coil is proportional to the rock formation conductivity, then the electric current enforced by a toroidal coil is also proportional to the rock formation resistivity. Thus, the selection of the quantity of interest for toroidal coils (first difference of electric current) is dictated by the physical relation between solenoidal and toroidal coils and by the previous choice of a quantity of interest for solenoidal coils (first difference of voltage).

2.3. Description of an LWD instrument in a borehole environment. We consider an LWD instrument composed of the following axisymmetric materials (all dimensions are given in cm):

- one transmitter and two receiver coils defined on
  1. $\Omega_{C_1} = \{(\rho, \phi, z) : 7.1 < \rho < 7.3,\ -2.5 < z < 2.5\}$,
  2. $\Omega_{C_2} = \{(\rho, \phi, z) : 7.1 < \rho < 7.3,\ 98.75 < z < 101.25\}$, and,
  3. $\Omega_{C_3} = \{(\rho, \phi, z) : 7.1 < \rho < 7.3,\ 113.75 < z < 116.25\}$, respectively;
- three magnetic buffers with resistivity $10^4\ \Omega \cdot$m and relative permeability 10^4, defined on
  1. $\Omega_{B_1} = \{(\rho, \phi, z) : 6.675 < \rho < 6.985,\ -5 < z < 5\}$,
  2. $\Omega_{B_2} = \{(\rho, \phi, z) : 6.675 < \rho < 6.985,\ 97.5 < z < 102.5\}$, and,
  3. $\Omega_{B_3} = \{(\rho, \phi, z) : 6.675 < \rho < 6.985,\ 112.5 < z < 117.5\}$, respectively; and
- a metallic mandrel with resistivity $10^{-6}\ \Omega \cdot$m defined on $\Omega_M = \{(\rho, \phi, z) : \rho < 7.6\} - (\{(\rho, \phi, z) : 6.675 < \rho < 7.6,\ -5 < z < 5\} \cup \{(\rho, \phi, z) : 6.675 < \rho < 7.6,\ 97.5 < z < 102.5\} \cup \{(\rho, \phi, z) : 6.675 < \rho < 7.6,\ 112.5 < z < 117.5\})$.

This LWD instrument moves along the vertical direction (z-axis) in a subsurface borehole environment composed of

- a borehole mud with resistivity $0.1\ \Omega \cdot$m defined on
  1. $\Omega_{BH} = \{(\rho, \phi, z) : \rho < 10.795\} - (\cup_i \Omega_{B_i} \cup \Omega_M)$, and
- three formation materials of resistivities $100\ \Omega \cdot$m, $10000\ \Omega \cdot$m, and $1\ \Omega \cdot$m, defined on
  1. $\Omega_{M_1} = \{(\rho, \phi, z) : \rho \geq 10.795,\ (z < -50 \text{ or } z > 100)\}$,
  2. $\Omega_{M_2} = \{(\rho, \phi, z) : \rho \geq 10.795,\ -50 \leq z < 0\}$, and,
  3. $\Omega_{M_3} = \{(\rho, \phi, z) : \rho \geq 10.795,\ 0 \leq z \leq 100\}$, respectively.

Figure 2 shows the geometry of the described logging instrument and borehole environment.

3. Maxwell's equations. In this section, we first introduce the time-harmonic Maxwell equations in the frequency domain. They form a set of first-order partial

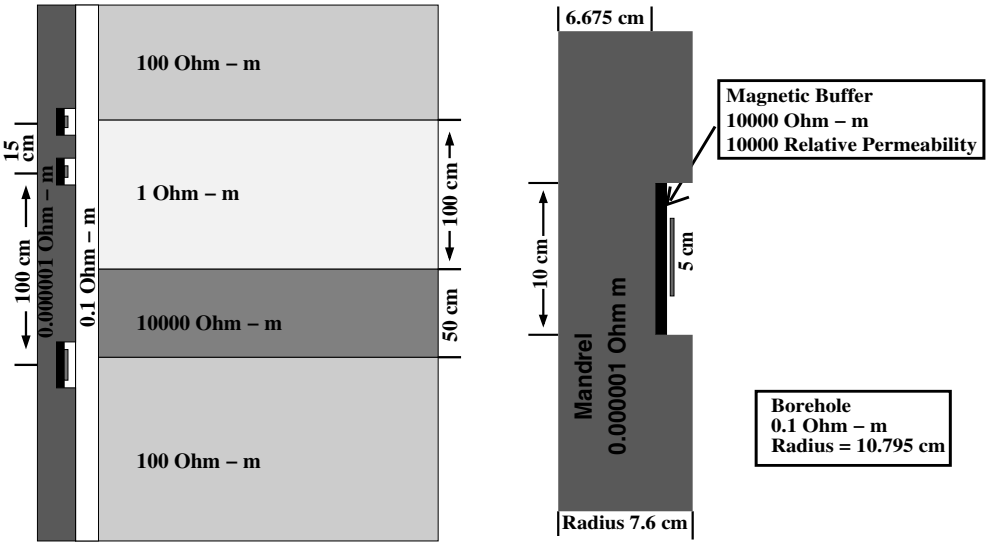

FIG. 2. *2D cross section of the geometry of an induction LWD problem composed of a metallic mandrel, one transmitter and two receiver coils equipped with magnetic buffers, a borehole, and four layers in the rock formation (with different resistivities). The right panel is an enlarged view of the geometry (left panel) in the vicinity of the transmitter antenna.*

differential equations (PDEs). Then, we describe boundary conditions needed for the simulation of our logging applications of interest. Finally, we derive a variational formulation in terms of either the electric or the magnetic field, and we reduce the dimension of the computational problem by considering axial symmetry.

3.1. Time-harmonic Maxwell equations. Assuming a time-harmonic dependence of the form $e^{j\omega t}$, where t denotes time and $\omega \neq 0$ is angular frequency, Maxwell's equations can be written as

$$
\left\{
\begin{array}{lll}
\nabla\times\mathbf{H} & = (\sigma + j\omega\epsilon)\mathbf{E} + \mathbf{J}^{imp} & \text{Ampere's law,} \\
\nabla\times\mathbf{E} & = -j\omega\mu\,\mathbf{H} - \mathbf{M}^{imp} & \text{Faraday's law,} \\
\nabla\cdot(\epsilon\mathbf{E}) & = \rho & \text{Gauss' law of electricity, and} \\
\nabla\cdot(\mu\mathbf{H}) & = 0 & \text{Gauss' law of magnetism.}
\end{array}
\right. \tag{3.1}
$$

Here $\mathbf{H}$ and $\mathbf{E}$ denote the magnetic and electric fields, respectively; $\mathbf{J}^{imp}$ is a prescribed, impressed electric current density; $\mathbf{M}^{imp}$ is a prescribed, impressed magnetic current density; ϵ, μ, and σ stand for dielectric permittivity, magnetic permeability, and electrical conductivity of the medium, respectively; and ρ denotes the electric charge distribution. We assume $\mu \neq 0$.

The equations described in (3.1) are to be understood in the distributional sense; i.e., they are satisfied in the classical sense in subdomains of regular material data, and they also imply appropriate interface conditions across material interfaces.

Energy considerations lead to the assumption that the absolute value of both electric field $\mathbf{E}$ and magnetic field $\mathbf{H}$ must be square integrable. According to $(3.1)_2$ and $(3.1)_4$, $\mathbf{M}^{imp}$ is divergence-free.

Maxwell's equations are not independent. Taking the divergence of Faraday's law

yields the Gauss' law of magnetism. By taking the divergence of Ampere's law, and by utilizing Gauss' electric law, we arrive at the so-called continuity equation,

$$\boldsymbol{\nabla} \cdot (\sigma \mathbf{E}) + j\omega\rho + \boldsymbol{\nabla} \cdot \mathbf{J}^{imp} = 0. \tag{3.2}$$

3.2. Boundary conditions (BCs). There exist a variety of BCs that can be incorporated into Maxwell's equations. In the following, we describe those BCs that are of interest for the logging applications discussed in this paper. At this point, we are considering general 3D domains. A discussion on boundary terms corresponding to the axisymmetry condition is postponed to section 3.4.

3.2.1. Perfect electric conductor (PEC). Maxwell's equations are to be satisfied in the whole space minus domains occupied by a PEC. A PEC is an idealization of a highly conductive media. Inside a region where $\sigma \to \infty$, the corresponding electric field converges to zero[3] by applying Ampere's law. Faraday's law implies that the tangential component of the electric field $\mathbf{E}$ must remain continuous across material interfaces in the absence of impressed magnetic surface currents. Consequently, the tangential component of the electric field must vanish along the PEC boundary, i.e.,

$$\boldsymbol{n} \times \mathbf{E} = \mathbf{0}, \tag{3.3}$$

where $\boldsymbol{n}$ is the unit normal (outward) vector.

Since the electric field vanishes inside a PEC, Faraday's law implies that the magnetic field should also vanish inside a PEC in the absence of magnetic currents. The same Faraday's law implies that the normal component of the magnetic field premultiplied by the permeability must remain continuous across material interfaces. Therefore, the normal component of the magnetic field must vanish along the PEC boundary, i.e.,

$$\boldsymbol{n} \cdot \mathbf{H} = 0. \tag{3.4}$$

The tangential component of magnetic field (surface current) and normal component of the electric field (surface charge density) need not be zero and may be determined a posteriori.

3.2.2. Source antennas. Antennas are modeled by prescribing an impressed volume current $\mathbf{J}^{imp}$. Using the equivalence principle (see, for example, [11]), we can replace the original impressed electric volume current $\mathbf{J}^{imp}$ with an equivalent electric surface current

$$\mathbf{J}_S^{imp} = [\mathbf{n} \times \mathbf{H}]_S, \tag{3.5}$$

defined on an arbitrary surface S enclosing the support of $\mathbf{J}^{imp}$, where $[\mathbf{n} \times \mathbf{H}]_S$ denotes

- the jump of $\mathbf{n} \times \mathbf{H}$ across S in the case of an interface condition, or
- simply $\mathbf{n} \times \mathbf{H}$ on S in the case of a boundary condition.

Similarly, an impressed magnetic volume current $\mathbf{M}^{imp}$ can be replaced by the equivalent magnetic surface current

$$\mathbf{M}_S^{imp} = -[\mathbf{n} \times \mathbf{E}]_{\mathbf{S}}, \tag{3.6}$$

defined on an arbitrary surface S enclosing the support of $\mathbf{M}^{imp}$.

[3] This result is true under the physical consideration that impressed volume current $\mathbf{J}^{imp}$ and $\sigma\mathbf{E}$ should remain finite, i.e., $\langle \mathbf{J}^{imp}, \psi \rangle, \langle \sigma\mathbf{E}, \psi \rangle < \infty$ for every test function ψ. See [21] for details.

3.2.3. Closure of the domain. We consider a bounded computational domain Ω. A variety of BCs can be imposed on the boundary $\partial\Omega$ such that the difference between solution of such a problem and solution of the original problem defined over $\mathbb{R}^3$ is small. For example, it is possible to use an infinite element technique (as described in [7]) or an absorption-type BC such as a perfect matched layer (PML) [6, 26, 13]. Also, since the EM fields and their derivatives decay exponentially in the presence of lossy media (nonzero conductivity), we may simply impose a homogeneous Dirichlet or Neumann BC on the boundary of a sufficiently large computational domain.

In the field of geophysical logging applications, it is customary to impose a homogeneous Dirichlet BC on the boundary of a large computational domain (for example, 2–20 meters in each direction from a 2 MHz source antenna in the presence of a resistive media). We will follow the same approach.

According to the BCs discussed above, we will divide boundary $\Gamma = \partial\Omega$ into the disjoint union of

- Γ_E, where $\mathbf{M}^{imp}_{\Gamma_E} = -[\mathbf{n}\times\mathbf{E}]_{\Gamma_\mathbf{E}}$ (with $\mathbf{M}^{imp}_{\Gamma_E}$ possibly zero), with
- Γ_H, where $\mathbf{J}^{imp}_{\Gamma_H} = [\mathbf{n}\times\mathbf{H}]_{\Gamma_H}$, (with $\mathbf{J}^{imp}_{\Gamma_H}$ possibly zero).

3.3. Variational formulation. From Maxwell's equations and the BCs described above, we derive the corresponding standard variational formulation in terms of the electric or magnetic field as follows.

First, we notice from Faraday's law that $\boldsymbol{\nabla}\times\mathbf{E} \in (L^2(\Omega))^3$ if and only if $\mathbf{M}^{imp} \in (L^2(\Omega))^3$. Since our objective is to find a solution $\mathbf{E} \in H(\mathbf{curl};\Omega) = \{\mathbf{F} \in (L^2(\Omega))^3 : \boldsymbol{\nabla}\times\mathbf{F} \in (L^2(\Omega))^3\}$, we shall assume in the case of the electric field formulation (E-formulation) derived below that $\mathbf{M}^{imp} \in (L^2(\Omega))^3$. If the prescribed $\mathbf{M}^{imp} \notin (L^2(\Omega))^3$, we may still solve Maxwell's equations with $H(\mathbf{curl})$-conforming finite elements for the magnetic field by using the H-formulation (3.3.2), or simply by prescribing an equivalent source $\tilde{\mathbf{M}}^{imp}$ such that $\mathbf{M}^{imp} - \tilde{\mathbf{M}}^{imp}$ does not radiate outside the antenna [27].

Similarly, for the H-formulation, we will assume that $\mathbf{J}^{imp} \in (L^2(\Omega))^3$.

3.3.1. E-formulation. By dividing Faraday's law by magnetic permeability μ, multiplying the resulting equation by $\boldsymbol{\nabla}\times\bar{\mathbf{F}}$, where $\mathbf{F} \in H_{\Gamma_E}(\mathbf{curl};\Omega) = \{\mathbf{F} \in H(\mathbf{curl};\Omega) \ : (\mathbf{n}\times\mathbf{F})|_{\Gamma_E} = 0\}$ is an arbitrary test function, and integrating over the domain Ω, we arrive at the identity

$$\int_\Omega \frac{1}{\mu}(\boldsymbol{\nabla}\times\mathbf{E})\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})dV = -j\omega\int_\Omega \mathbf{H}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})dV - \int_\Omega \frac{1}{\mu}\mathbf{M}^{imp}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})dV. \tag{3.7}$$

Integrating $\int_\Omega \mathbf{H}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV$ by parts, and applying Ampere's law, we obtain

$$\begin{aligned}\int_\Omega \mathbf{H}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV &= \int_\Omega(\boldsymbol{\nabla}\times\mathbf{H})\cdot\bar{\mathbf{F}}\,dV - \int_{\Gamma_H}\mathbf{n}\times\mathbf{H}\cdot\bar{\mathbf{F}}_t\,dS\\ &= \int_\Omega(\sigma+j\omega\epsilon)\mathbf{E}\cdot\bar{\mathbf{F}}\,dV + \int_\Omega \mathbf{J}^{imp}\cdot\bar{\mathbf{F}}\,dV - \int_{\Gamma_H}\mathbf{n}\times\mathbf{H}\cdot\bar{\mathbf{F}}_t\,dS.\end{aligned} \tag{3.8}$$

$\mathbf{F}_t = \mathbf{F} - (\mathbf{F}\cdot\mathbf{n})\cdot\mathbf{n}$ is the tangential component of vector $\mathbf{F}$ on Γ_H, and $\mathbf{n}$ is the unit normal outward (with respect to Ω if $\Gamma_H \subset \partial\Omega$) vector. Substitution of (3.8) into

(3.7) and use of (3.5) yields the following variational formulation:

$$
\left\{
\begin{array}{l}
\text{Find } \mathbf{E} \in \mathbf{E}_{\Gamma_E} + H_{\Gamma_E}(\mathbf{curl};\Omega) \text{ such that} \\
\displaystyle\int_\Omega \frac{1}{\mu}(\boldsymbol{\nabla}\times\mathbf{E})\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV - \int_\Omega k^2\mathbf{E}\cdot\bar{\mathbf{F}}\,dV = -j\omega\int_\Omega \mathbf{J}^{imp}\cdot\bar{\mathbf{F}}\,dV \\
\quad + j\omega\displaystyle\int_{\Gamma_H}\mathbf{J}^{imp}_{\Gamma_H}\cdot\bar{\mathbf{F}}_t\,dS - \int_\Omega\frac{1}{\mu}\mathbf{M}^{imp}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV \;\forall\,\mathbf{F}\in H_{\Gamma_E}(\mathbf{curl};\Omega),
\end{array}
\right. \tag{3.9}
$$

where $k^2=\omega^2\epsilon - j\omega\sigma$ is the wave number and $\mathbf{E}_{\Gamma_E}$ is a lift (typically $\mathbf{E}_{\Gamma_E}=0$) of the essential BC data $\mathbf{E}_{\Gamma_E}=-M^{imp}_{\Gamma_E}$ (denoted with the same symbol).

Conversely, we can derive (3.1), (3.3), and (3.5) from variational problem (3.9).

3.3.2. H-formulation. By dividing Ampere's law by $\sigma+j\omega\epsilon$, multiplying the resulting equation by $\boldsymbol{\nabla}\times\bar{\mathbf{F}}$, where $\mathbf{F}\in H_{\Gamma_H}(\mathbf{curl};\Omega)=\{\mathbf{F}\in H(\mathbf{curl};\Omega)\ :(\mathbf{n}\times\mathbf{F})|_{\Gamma_H}=0\,\}$ is an arbitrary test function, and integrating over the domain Ω, we arrive at the identity

$$
\begin{aligned}
-j\omega\int_\Omega\frac{1}{k^2}(\boldsymbol{\nabla}\times\mathbf{H})\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})dV &= \int_\Omega\mathbf{E}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV \\
&\quad - j\omega\int_\Omega\frac{1}{k^2}\mathbf{J}^{imp}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV.
\end{aligned} \tag{3.10}
$$

Integrating $\int_\Omega\mathbf{E}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV$ by parts and applying Faraday's law, we obtain

$$
\begin{aligned}
\int_\Omega\mathbf{E}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV &= \int_\Omega(\boldsymbol{\nabla}\times\mathbf{E})\cdot\bar{\mathbf{F}}\,dV - \int_{\Gamma_E}\mathbf{n}\times\mathbf{E}\cdot\bar{\mathbf{F}}_t\,dS \\
&= -j\omega\int_\Omega\mu\mathbf{H}\cdot\bar{\mathbf{F}}\,dV - \int_\Omega\mathbf{M}^{imp}\cdot\bar{\mathbf{F}}\,dV - \int_{\Gamma_E}\mathbf{n}\times\mathbf{E}\cdot\bar{\mathbf{F}}_t\,dS.
\end{aligned} \tag{3.11}
$$

Substitution of (3.11) into (3.10) and use of (3.6) yields the following variational formulation:

(3.12)

$$
\left\{
\begin{array}{l}
\text{Find } \mathbf{H} \in \mathbf{H}_{\Gamma_H} + H_{\Gamma_H}(\mathbf{curl};\Omega) \text{ such that} \\
\displaystyle\int_\Omega\frac{1}{\sigma+j\omega\epsilon}(\boldsymbol{\nabla}\times\mathbf{H})\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})dV + j\omega\int_\Omega\mu\mathbf{H}\cdot\bar{\mathbf{F}}dV = -\int_\Omega\mathbf{M}^{imp}\cdot\bar{\mathbf{F}}dV \\
\quad + \displaystyle\int_{\Gamma_E}\mathbf{M}^{imp}_{\Gamma_E}\cdot\bar{\mathbf{F}}_t\,dS + \int_\Omega\frac{1}{\sigma+j\omega\epsilon}\mathbf{J}^{imp}\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})dV\;\forall\,\mathbf{F}\in H_{\Gamma_H}(\mathbf{curl};\Omega),
\end{array}
\right.
$$

where $\mathbf{H}_{\Gamma_H}$ is a lift (typically $\mathbf{H}_{\Gamma_H}=0$) of the essential BC data $\mathbf{H}_{\Gamma_H}=J^{imp}_{\Gamma_H}$ (denoted with the same symbol).

3.4. Cylindrical coordinates and axisymmetric problems. We consider cylindrical coordinates (ρ,ϕ,z). For the geophysical logging applications considered in this article, we assume that both the logging instrument and the rock formation properties are axisymmetric (invariant with respect to the azimuthal coordinate ϕ) around the axis of the borehole. Under this assumption, we obtain that for any vector field $\mathbf{A}=\hat{\rho}A_\rho+\hat{\phi}A_\phi+\hat{z}A_z$,

$$
\boldsymbol{\nabla}\times\mathbf{A} = -\hat{\rho}\frac{\partial A_\phi}{\partial z} + \hat{\phi}\left(\frac{\partial A_\rho}{\partial z}-\frac{\partial A_z}{\partial\rho}\right) + \hat{z}\frac{1}{\rho}\frac{\partial(\rho A_\phi)}{\partial\rho}\ . \tag{3.13}
$$

3.4.1. E-formulation. Next, we consider the space of all test functions $\mathbf{F} \in H_D(\mathbf{curl};\Omega)$ such that $\mathbf{F} = (0, F_\phi, 0)$. According to (3.13),

$$\boldsymbol{\nabla}\times\mathbf{F} = -\hat{\rho}\frac{\partial F_\phi}{\partial z} + \hat{z}\frac{1}{\rho}\frac{\partial(\rho F_\phi)}{\partial \rho}\ . \tag{3.14}$$

Variational formulation (3.9) reduces to a formulation in terms of the scalar field E_ϕ only, namely,

$$\left\{\begin{array}{l} \text{Find } E_\phi \in E_{\phi,D} + \tilde{H}^1_D(\Omega) \text{ such that} \\ \displaystyle\int_\Omega \frac{1}{\mu}\left(\frac{\partial E_\phi}{\partial z}\frac{\partial \bar{F}_\phi}{\partial z} + \frac{1}{\rho^2}\frac{\partial(\rho E_\phi)}{\partial \rho}\frac{\partial(\rho \bar{F}_\phi)}{\partial \rho}\right) dV - \int_\Omega k^2 E_\phi\, \bar{F}_\phi\, dV \\ \qquad = -\,j\omega \displaystyle\int_\Omega J^{imp}_\phi\, \bar{F}_\phi\, dV + j\omega \int_{\Gamma_N} J^{imp}_{\phi,\Gamma_N}\, \bar{F}_\phi\, dS \\ \qquad - \displaystyle\int_\Omega \frac{1}{\mu}\left[-M^{imp}_\rho \frac{\partial \bar{F}_\phi}{\partial z} + M^{imp}_z \frac{1}{\rho}\frac{\partial(\rho \bar{F}_\phi)}{\partial \rho}\right] dV \quad \forall\, F_\phi \in \tilde{H}^1_D(\Omega), \end{array}\right. \tag{3.15}$$

where $\tilde{H}^1_D(\Omega) = \{E_\phi : (0, E_\phi, 0) \in H_D(\mathbf{curl};\Omega)\} = \{E_\phi \in L^2(\Omega) \ :\ \frac{1}{\rho}E_\phi + \frac{\partial E_\phi}{\partial \rho} \in L^2(\Omega),\ \frac{\partial E_\phi}{\partial z} \in L^2(\Omega),\ E_\phi|_{\Gamma_D} = 0\}$. Similarly, for a test function $\mathbf{F} = (F_\rho, 0, F_z)$, variational problem (3.9) simplifies to

$$\left\{\begin{array}{l} \text{Find } \mathbf{E} = (E_\rho, 0, E_z) \in \mathbf{E}_D + \tilde{H}_D(\mathbf{curl};\Omega) \text{ such that} \\ \displaystyle\int_\Omega \frac{1}{\mu}\left(\frac{\partial E_\rho}{\partial z} - \frac{\partial E_z}{\partial \rho}\right)\left(\frac{\partial \bar{F}_\rho}{\partial z} - \frac{\partial \bar{F}_z}{\partial \rho}\right) dV - \int_\Omega k^2(E_\rho \bar{F}_\rho + E_z \bar{F}_z)\, dV \\ = -\,j\omega \displaystyle\int_\Omega J^{imp}_\rho \bar{F}_\rho + J^{imp}_z \bar{F}_z\, dV + j\omega \int_{\Gamma_N} J^{imp}_{\rho,\Gamma_N}\bar{F}_\rho + J^{imp}_{z,\Gamma_N}\bar{F}_z\, dS \\ - \displaystyle\int_\Omega \frac{1}{\mu} M^{imp}_\phi \left[\frac{\partial \bar{F}_\rho}{\partial z} - \frac{\partial \bar{F}_z}{\partial \rho}\right] dV \quad \forall\, \mathbf{F} = (F_\rho, 0, F_z) \in \tilde{H}_D(\mathbf{curl};\Omega), \end{array}\right. \tag{3.16}$$

where $\tilde{H}_D(\mathbf{curl};\Omega) = \{(E_\rho, E_z) : \mathbf{E} = (E_\rho, 0, E_z) \in L^2(\Omega),\ (\boldsymbol{\nabla}\times\mathbf{E})|_\phi = \frac{\partial E_\rho}{\partial z} - \frac{\partial E_z}{\partial \rho} \in L^2(\Omega),\ (\mathbf{n}\times\mathbf{E})|_{\Gamma_D} = 0\}$.

In summary, problem (3.9) decouples into a system of two simpler problems described by (3.15) and (3.16).

Remark 1. It has been shown in [4, Lemma 4.9] that space $\tilde{H}^1_D(\Omega)$ can also be expressed as $\tilde{H}^1_D(\Omega) = \{E_\phi \in L^2(\Omega) \ :\ \frac{1}{\rho}E_\phi \in L^2(\Omega),\ \nabla_{(\rho,z)}E_\phi \in L^2(\Omega)\}$.

3.4.2. H-formulation. Using the same decomposition of test functions (i.e., $\mathbf{F} = (0, F_\phi, 0)$, and $\mathbf{F} = (F_\rho, 0, F_z)$) for variational problem (3.12), we arrive at the following two decoupled variational problems in terms of $(0, H_\phi, 0)$ (3.17) and $(H_\rho, 0, H_z)$ (3.18), respectively:

$$\left\{\begin{array}{l} \text{Find } H_\phi \in H_{\phi,D} + \tilde{H}^1_D(\Omega) \text{ such that} \\ \displaystyle\int_\Omega \frac{1}{\sigma + j\omega\epsilon}\left(\frac{\partial H_\phi}{\partial z}\frac{\partial \bar{F}_\phi}{\partial z} + \frac{1}{\rho^2}\frac{\partial(\rho H_\phi)}{\partial \rho}\frac{\partial(\rho \bar{F}_\phi)}{\partial \rho}\right) dV \\ \quad + j\omega \displaystyle\int_\Omega \mu H_\phi\, \bar{F}_\phi dV = -\int_\Omega M^{imp}_\phi\, \bar{F}_\phi\, dV + \int_{\Gamma_N} M^{imp}_{\phi,\Gamma_N}\, \bar{F}_\phi\, dS \\ \quad + \displaystyle\int_\Omega \frac{1}{\sigma + j\omega\epsilon}\left[-J^{imp}_\rho \frac{\partial \bar{F}_\phi}{\partial z} + J^{imp}_z \frac{1}{\rho}\frac{\partial(\rho \bar{F}_\phi)}{\partial \rho}\right] dV \quad \forall\, F_\phi \in \tilde{H}^1_D(\Omega)\ . \end{array}\right. \tag{3.17}$$

$$
\left\{
\begin{array}{l}
\text{Find } \mathbf{H} = (H_\rho, 0, H_z) \in \mathbf{H}_D + \tilde{H}_D(\mathbf{curl}; \Omega) \text{ such that} \\
\displaystyle\int_\Omega \frac{1}{\sigma + j\omega\epsilon} \left(\frac{\partial H_\rho}{\partial z} - \frac{\partial H_z}{\partial \rho} \right) \left(\frac{\partial \bar{F}_\rho}{\partial z} - \frac{\partial \bar{F}_z}{\partial \rho} \right) dV \\
\displaystyle + j\omega \int_\Omega \mu (H_\rho \bar{F}_\rho + H_z \bar{F}_z)\, dV = - \int_\Omega M_\rho^{imp} \bar{F}_\rho + M_z^{imp} \bar{F}_z \, dV \\
\displaystyle + \int_{\Gamma_N} M_{\rho,\Gamma_N}^{imp} \bar{F}_\rho + M_{z,\Gamma_N}^{imp} \bar{F}_z \, dS + \int_\Omega \frac{1}{\sigma + j\omega\epsilon} J_\phi^{imp} \left[\frac{\partial \bar{F}_\rho}{\partial z} - \frac{\partial \bar{F}_z}{\partial \rho} \right] dV \\
\qquad\qquad \forall\, \mathbf{F} = (F_\rho, 0, F_z) \in \tilde{H}_D(\mathbf{curl}; \Omega) \, .
\end{array}
\right. \tag{3.18}
$$

From the formulation of problems (3.15) through (3.18), we remark the following:

- Physically, solutions of problems (3.16) and (3.17) correspond to the TE_ϕ-mode (i.e., $E_\phi = 0$), and solutions of problems (3.15) and (3.18) correspond to the TM_ϕ-mode (i.e., $H_\phi = 0$).
- The axis of symmetry is not a boundary of the original 3D problem, and therefore, a BC should not be needed to solve this problem. Nevertheless, formulations of problems (3.15) through (3.18) require the use of spaces $\tilde{H}_D^1(\Omega)$ and $\tilde{H}_D(\mathbf{curl}; \Omega)$ described above. The former space involves the singular weight $\frac{1}{\rho}$, which implicitly requires a homogeneous Dirichlet BC along the axis of symmetry. The latter space can be considered as it is (by using 2D edge elements), and no BC is necessary[4] to solve the problem.

4. Self-adaptive goal-oriented *hp*-FEM. We are interested in solving variational problems (3.9) and (3.12) (or alternatively, (3.15), (3.16), (3.17), and (3.18)), which we state here in terms of sesquilinear form b and antilinear form f:

$$
\left\{
\begin{array}{l}
\text{Find } \mathbf{E} \in \mathbf{E}_D + \mathbf{V}, \\
b(\mathbf{E}, \mathbf{F}) = f(\mathbf{F}) \quad \forall \mathbf{F} \in \mathbf{V} \, ,
\end{array}
\right. \tag{4.1}
$$

where

- $\mathbf{E}_D$ is a lift of the essential (Dirichlet) BC.
- $\mathbf{V}$ is a Hilbert space.
- $f \in \mathbf{V}'$ is an antilinear and continuous functional on $\mathbf{V}$.
- b is a sesquilinear form. We have

$$
b(\mathbf{E}, \mathbf{F}) = \left\{
\begin{array}{ll}
\underbrace{\displaystyle\int_\Omega \frac{1}{\mu} (\boldsymbol{\nabla} \times \mathbf{E}) \cdot (\boldsymbol{\nabla} \times \bar{\mathbf{F}})\, dV}_{a^E(\mathbf{E},\mathbf{F})} - \underbrace{\displaystyle\int_\Omega k^2 \mathbf{E} \cdot \bar{\mathbf{F}}\, dV}_{c^E(\mathbf{E},\mathbf{F})} & \text{E-Form}, \\
\underbrace{\displaystyle\int_\Omega \frac{1}{k^2} (\boldsymbol{\nabla} \times \mathbf{E}) \cdot (\boldsymbol{\nabla} \times \bar{\mathbf{F}})\, dV}_{a^H(\mathbf{E},\mathbf{F})} - \underbrace{\displaystyle\int_\Omega \mu \mathbf{E} \cdot \bar{\mathbf{F}}\, dV}_{c^H(\mathbf{E},\mathbf{F})} & \text{H-Form},
\end{array}
\right. \tag{4.2}
$$

where sesquilinear forms a^E, a^H, c^E, and c^H are Hermitian, continuous, and

[4] From the computational point of view, this effect can be achieved by artificially *adding* a homogeneous natural (Neumann) BC.

semipositive definite. We define an "energy" inner product on $\mathbf{V}$ as

(4.3)
$$(\mathbf{E},\mathbf{F}) := \begin{cases} \underbrace{\int_\Omega \frac{1}{\mu}(\boldsymbol{\nabla}\times\mathbf{E})\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV}_{a^E(\mathbf{E},\mathbf{F})} + \underbrace{\int_\Omega |k^2|\mathbf{E}\cdot\bar{\mathbf{F}}\,dV}_{c^E(\mathbf{E},\mathbf{F})} & \text{E-Form,} \\ \underbrace{\int_\Omega \frac{1}{|k^2|}(\boldsymbol{\nabla}\times\mathbf{E})\cdot(\boldsymbol{\nabla}\times\bar{\mathbf{F}})\,dV}_{a^H(\mathbf{E},\mathbf{F})} + \underbrace{\int_\Omega \mu\mathbf{E}\cdot\bar{\mathbf{F}}\,dV}_{c^H(\mathbf{E},\mathbf{F})} & \text{H-Form,} \end{cases}$$

with the corresponding (energy) norm denoted by $\|\mathbf{E}\|$. Notice the inclusion of the material properties in the definition of the norm.

4.1. Representation of the error in the quantity of interest. Given an *hp*-FE subspace $\mathbf{V}_{hp} \subset \mathbf{V}$, we discretize (4.1) as follows:

$$\begin{cases} \text{Find } \mathbf{E}_{hp} \in \mathbf{E}_D + \mathbf{V}_{hp}, \\ b(\mathbf{E}_{hp},\mathbf{F}_{hp}) = f(\mathbf{F}_{hp}) \quad \forall \mathbf{F}_{hp} \in \mathbf{V}_{hp}\ . \end{cases} \tag{4.4}$$

The objective of goal-oriented adaptivity is to construct an optimal *hp*-grid, in the sense that it minimizes the problem size needed to achieve a given tolerance error for a given *quantity of interest* L, with L denoting a linear and continuous functional. By recalling the linearity of L, we have

$$\text{Error of interest} = L(\mathbf{E}) - L(\mathbf{E}_{hp}) = L(\mathbf{E}-\mathbf{E}_{hp}) = L(\mathbf{e}), \tag{4.5}$$

where $\mathbf{e} = \mathbf{E} - \mathbf{E}_{hp}$ denotes the error function. By defining the residual $\mathbf{r}_{hp} \in \mathbf{V}'$ as $\mathbf{r}_{hp}(\mathbf{F}) = f(\mathbf{F}) - b(\mathbf{E}_{hp},\mathbf{F}) = b(\mathbf{E}-\mathbf{E}_{hp},\mathbf{F}) = b(\mathbf{e},\mathbf{F})$, we look for the solution of the *dual problem*:

$$\begin{cases} \text{Find } \bar{\mathbf{W}} \in \mathbf{V}, \\ b(\mathbf{F},\mathbf{W}) = L(\mathbf{F}) \quad \forall \mathbf{F} \in \mathbf{V}. \end{cases} \tag{4.6}$$

Problem (4.6) has a unique solution in $\mathbf{V}$. The solution $\mathbf{W}$ is usually referred to as the *influence function*.

By discretizing (4.6) via, for example, $\mathbf{V}_{hp} \subset \mathbf{V}$, we obtain

$$\begin{cases} \text{Find } \bar{\mathbf{W}}_{hp} \in \mathbf{V}_{hp}, \\ b(\mathbf{F}_{hp},\mathbf{W}_{hp}) = L(\mathbf{F}_{hp}) \quad \forall \mathbf{F}_{hp} \in \mathbf{V}_{hp}\ . \end{cases} \tag{4.7}$$

Definition of the dual problem plus the Galerkin orthogonality for the original problem imply the final representation formula for the error in the quantity of interest, namely,

$$L(\mathbf{e}) = b(\mathbf{e},\mathbf{W}) = b(\mathbf{e},\underbrace{\mathbf{W}-\mathbf{F}_{hp}}_{\epsilon}) = \tilde{b}(\mathbf{e},\epsilon)\ .$$

At this point, $\mathbf{F}_{hp} \in \mathbf{V}_{hp}$ is arbitrary, and $\tilde{b}(\mathbf{e},\epsilon) = b(\mathbf{e},\bar{\epsilon})$ denotes the bilinear form corresponding to the original sesquilinear form.

Notice that, in practice, the dual problem is solved not for $\mathbf{W}$ but for its complex conjugate $\bar{\mathbf{W}}$, utilizing the bilinear form and *not* the sesquilinear form. The linear

system of equations is factorized only once, and the extra cost of solving (4.7) reduces to only one backward and one forward substitution (if a direct solver is used).

Once the error in the quantity of interest has been determined in terms of bilinear form $\tilde{b}$, we wish to obtain a sharp upper bound for $|L(\mathbf{e})|$ that depends upon the mesh parameters (element size h and order of approximation p) *only locally*. Then, a self-adaptive algorithm intended to minimize this bound will be defined.

First, using a procedure similar to the one described in [10], we approximate $\mathbf{E}$ and $\mathbf{W}$ with *fine grid* functions $\mathbf{E}_{\frac{h}{2},\, p+1}$, $\mathbf{W}_{\frac{h}{2},\, p+1}$, which have been obtained by solving the corresponding linear system of equations associated with the finite element subspace $\mathbf{V}_{\frac{h}{2},\, p+1}$. In the remainder of this article, $\mathbf{E}$ and $\mathbf{W}$ will denote the fine grid solutions of the direct and dual problems ($\mathbf{E} = \mathbf{E}_{\frac{h}{2},\, p+1}$, and $\mathbf{W} = \mathbf{W}_{\frac{h}{2},\, p+1}$, respectively), and we will restrict ourselves to discrete finite element spaces only.

Next, we bound the error in the quantity of interest by a sum of element contributions. Let b_K denote a contribution from element K to sesquilinear form b. It then follows that

$$|L(\mathbf{e})| = |b(\mathbf{e}, \boldsymbol{\epsilon})| \leq \sum_K |b_K(\mathbf{e}, \boldsymbol{\epsilon})| \,, \tag{4.8}$$

where summation over K indicates summation over elements.

4.2. Projection-based interpolation operator. Once we have a representation formula for the error in the quantity of interest in terms of the sum of element contributions given by (4.8), we wish to express this upper bound in terms of local quantities, i.e. in terms of quantities that *do not* vary globally when we modify the grid locally. For this purpose, we introduce the idea of *projection-based interpolation* operators.

First, in order to simplify the notation, we define the following three spaces of admissible solutions:

- $\mathbf{V} = H_D(\mathbf{curl}; \Omega)$,
- $\mathbf{V}^{2D} = \tilde{H}_D(\mathbf{curl}; \Omega)$, and
- $V^{1D} = \tilde{H}^1_D(\Omega)$.

The corresponding hp-finite element spaces will be denoted by $\mathbf{V}_{hp}$, $\mathbf{V}^{2D}_{hp}$, and V^{1D}_{hp}, respectively.

At this point, we introduce three *projection-based interpolation* operators that have been defined in [9, 8], and used in [10, 23] for the construction of the fully automatic energy-norm-based hp-adaptive algorithm:

- $\Pi^{curl,3D}_{hp} : \mathbf{V} \longrightarrow \mathbf{V}_{hp}$,
- $\Pi^{curl,2D}_{hp} : \mathbf{V}^{2D} \longrightarrow \mathbf{V}^{2D}_{hp}$, and
- $\Pi^{1D}_{hp} : V^{1D} \longrightarrow V^{1D}_{hp}$.

We shall also consider three Galerkin projection operators:

- $\mathbf{P}^{curl,3D}_{hp} : \mathbf{V} \longrightarrow \mathbf{V}_{hp}$,
- $\mathbf{P}^{curl,2D}_{hp} : \mathbf{V}^{2D} \longrightarrow \mathbf{V}^{2D}_{hp}$, and
- $P^{1D}_{hp} : V^{1D} \longrightarrow V^{1D}_{hp}$.

To further simplify the notation, we will utilize the unique symbol Π^{curl}_{hp} to denote all projection-based interpolation operators mentioned above. Depending upon the problem formulation (and corresponding space of admissible solutions), Π^{curl}_{hp} should be understood as $\Pi^{curl,3D}_{hp}$ for problems (3.9) and (3.12), $\Pi^{curl,2D}_{hp}$ for problems (3.16) and (3.18), or Π^{1D}_{hp} for problems (3.15) and (3.17). Similarly, we will use the unique

symbol $\mathbf{P}_{hp}^{curl}$ to denote either $\mathbf{P}_{hp}^{curl,3D}$, $\mathbf{P}_{hp}^{curl,2D}$, or P_{hp}^{1D}.

We define $\mathbf{E}_{hp} = \mathbf{P}_{hp}^{curl}\mathbf{E}$. Equation (4.8) then becomes

$$|L(\mathbf{e})| \leq \sum_K |b_K(\mathbf{E}, \boldsymbol{\epsilon})| = \sum_K |b_K(\mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}, \boldsymbol{\epsilon}) + b_K(\Pi_{hp}^{curl}\mathbf{E} - \mathbf{P}_{hp}^{curl}\mathbf{E}, \boldsymbol{\epsilon})| \,. \tag{4.9}$$

Given an element K, we conjecture that $|b_K(\Pi_{hp}^{curl}\mathbf{E} - \mathbf{P}_{hp}\mathbf{E}, \boldsymbol{\epsilon})|$ will be negligible compared to $|b_K(\mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}, \boldsymbol{\epsilon})|$. Under this assumption, we conclude that

$$|L(\mathbf{e})| \preceq \sum_K |b_K(\mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}, \boldsymbol{\epsilon})| \,. \tag{4.10}$$

In particular, for $\boldsymbol{\epsilon} = \mathbf{W} - \Pi_{hp}^{curl}\mathbf{W}$, we have

$$|L(\mathbf{e})| \preceq \sum_K |b_K(\mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}, \mathbf{W} - \Pi_{hp}^{curl}\mathbf{W})| \,. \tag{4.11}$$

By applying the Cauchy–Schwarz inequality, we obtain the next upper bound for $|L(\mathbf{e})|$:

$$|L(\mathbf{e})| \preceq \sum_K \|\tilde{\mathbf{e}}\|_K \|\tilde{\boldsymbol{\epsilon}}\|_K, \tag{4.12}$$

where $\tilde{\mathbf{e}} = \mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}$, $\tilde{\boldsymbol{\epsilon}} = \mathbf{W} - \Pi_{hp}^{curl}\mathbf{W}$, and $\|\cdot\|_K$ denotes energy-norm $\|\cdot\|$ restricted to element K.

4.3. Fully automatic goal-oriented *hp*-refinement algorithm. We describe an *hp* self-adaptive algorithm that utilizes the main ideas of the fully automatic (energy-norm-based) *hp*-adaptive algorithm described in [10, 23]. We start by recalling the main objective of the self-adaptive (energy-norm-based) *hp*-refinement strategy, which consists of solving the following maximization problem:

$$\begin{cases} \text{Find an optimal } \tilde{hp}\text{-grid in the following sense:} \\ \tilde{hp} = \arg\max_{\widehat{hp}} \sum_K \dfrac{\|\mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}\|_K^2 - \|\mathbf{E} - \Pi_{\widehat{hp}}^{curl}\mathbf{E}\|_K^2}{\Delta N} \,, \end{cases} \tag{4.13}$$

where

- $\mathbf{E} = \mathbf{E}_{\frac{h}{2},\, p+1}$ is the *fine grid* solution, and
- $\Delta N > 0$ is the increment in the number of unknowns from grid hp to grid $\widehat{hp}$.

Similarly, for goal-oriented *hp*-adaptivity, we propose the following algorithm based on estimate (4.12):

$$\begin{cases} \text{Find an optimal } \tilde{hp}\text{-grid in the following sense:} \\ \tilde{hp} = \arg\max_{\widehat{hp}} \sum_K \left[\dfrac{\|\mathbf{E} - \Pi_{hp}^{curl}\mathbf{E}\|_K \cdot \|\mathbf{W} - \Pi_{hp}^{curl}\mathbf{W}\|_K}{\Delta N} \right. \\ \qquad\qquad \left. - \dfrac{\|\mathbf{E} - \Pi_{\widehat{hp}}^{curl}\mathbf{E}\|_K \cdot \|\mathbf{W} - \Pi_{\widehat{hp}}^{curl}\mathbf{W}\|_K}{\Delta N} \right] \,, \end{cases} \tag{4.14}$$

where

- $\mathbf{E} = \mathbf{E}_{\frac{h}{2},\, p+1}$ and $\mathbf{W} = \mathbf{W}_{\frac{h}{2},\, p+1}$ are the *fine grid* solutions corresponding to the direct and dual problems, and
- $\Delta N > 0$ is the increment in the number of unknowns from grid hp to grid $\widehat{hp}$.

Implementation of the goal-oriented hp-adaptive algorithm is based on the optimization procedure used for energy-norm hp-adaptivity [10, 23], which utilizes a multistep approach (first optimization of edges, and then optimization of interior degrees of freedom). The subspace associated to an optimal finite element grid is always contained in the subspace associated with the finite element *fine* grid computed during the previous step.

4.4. Implementation details. In what follows, we discuss the main implementation details needed to extend the fully automatic (energy-norm-based) hp-adaptive algorithm [10, 23] to a fully automatic goal-oriented hp-adaptive algorithm.

1. First, the solution $\mathbf{W}$ of the dual problem on the fine grid is necessary. This goal can be attained either by using a direct (frontal) solver or an iterative (two-grid) solver (see [18]).
2. Subsequently, we should treat both solutions as satisfying two different PDEs. We select functions $\mathbf{E}$ and $\mathbf{W}$ as the solutions of the system of two PDEs.
3. We proceed to redefine the evaluation of the error. The energy-norm error evaluation of a 2D function is replaced by the product $\| \mathbf{E} - \Pi_{hp}^{curl}\mathbf{E} \| \cdot \| \mathbf{W} - \Pi_{hp}^{curl}\mathbf{W} \|$.
4. After these simple modifications, the energy-norm-based self-adaptive algorithm may now be utilized as a self-adaptive goal-oriented hp algorithm.

5. Numerical results. In this section, we apply the goal-oriented hp self-adaptive strategy described in section 4 to simulate the response of the induction LWD instrument operating at 2 MHz considered in section 2.3, using formulation (3.15) for solenoidal coils and (3.17) for toroidal coils. Exactly the same results are obtained with formulations (3.18) and (3.16), respectively, as predicted by the theory. Thus, formulations (3.18) and (3.16) have been used as an extra verification of the simulations, and the corresponding results have been omitted in this article to avoid duplicity.

Figure 3 displays the first vertical difference of the electric field (divided by the distance between the two receivers) for the described LWD instrument equipped with solenoidal coils (left and center panel). The right panel corresponds to the computation of the normalized second vertical difference of the electric field when considering an extra receiving antenna 15 cm above the second receiving antenna. The three curves (two for the second vertical difference of the electric field) correspond to

1. the rock formation with no mud-filtrate invasion,
2. the rock formation with a 2 Ω·m 40 cm horizontal mud layer invading the 1 Ω·m rock formation layer, and a 5Ω·m 90cm horizontal mud layer invading the 10000 Ω·m rock formation layer, and
3. the previous (mud-invaded) rock formation, using a mandrel with relative magnetic permeability of 100.

For toroidal antennas, we display in Figure 4 the first vertical difference of the magnetic field (divided by the distance between the two receivers). The three displayed curves correspond to the three situations discussed above.

These results illustrate the strong dependence of the LWD response on the rock formation resistivity. We observe that solenoidal antennas are more sensitive to highly conductive formations as well as to the electrical permeability of the mandrel, while

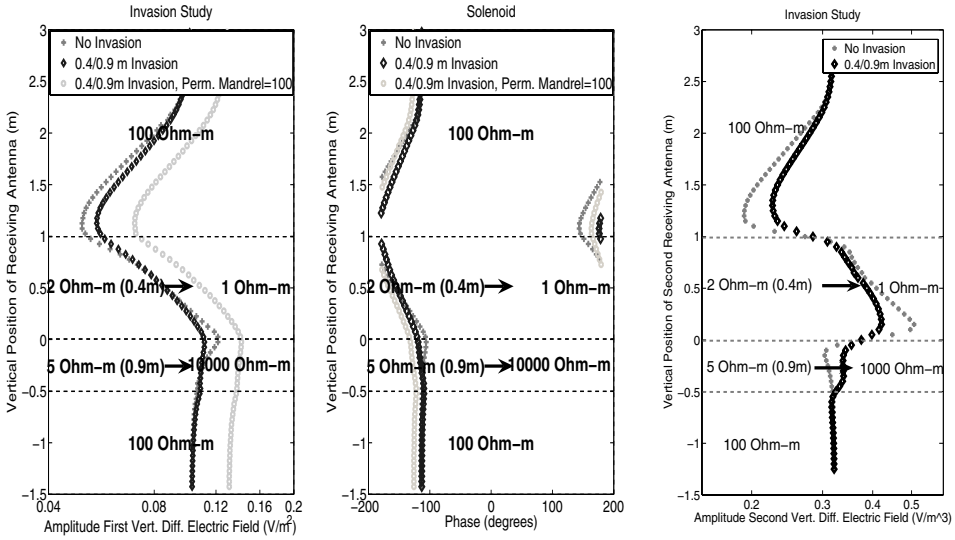

FIG. 3. *LWD problem equipped with a solenoidal source. Amplitude (left panel) and phase (center panel) of the first vertical difference of the electric field (divided by the distance between receivers) at the receiving coils. The normalized amplitude of the second vertical difference of the electric field is displayed in the right panel. Results obtained with the self-adaptive goal-oriented hp-FEM. The spatial distribution of electrical resistivity is also displayed to facilitate the physical interpretation of results.*

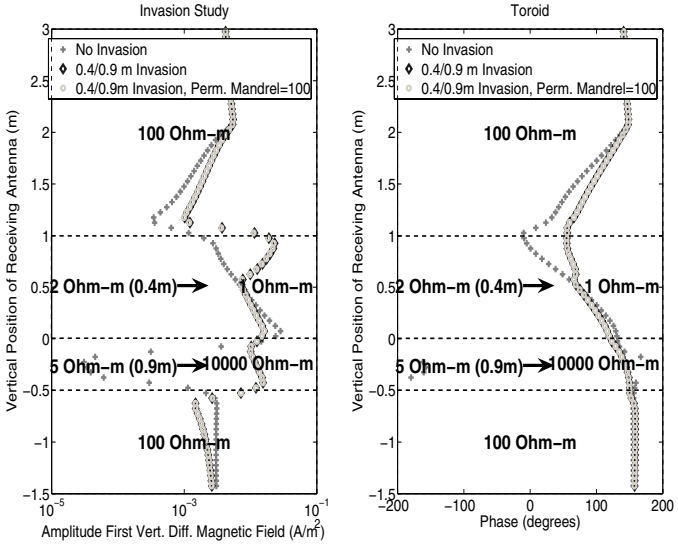

FIG. 4. *LWD problem equipped with a toroidal source. Amplitude (left panel) and phase (right panel) of the first vertical difference of the magnetic field (divided by the distance between receivers) at the receiving coils. Results obtained with the self-adaptive goal-oriented hp-FEM. The spatial distribution of electrical resistivity is also displayed to facilitate the physical interpretation of results.*

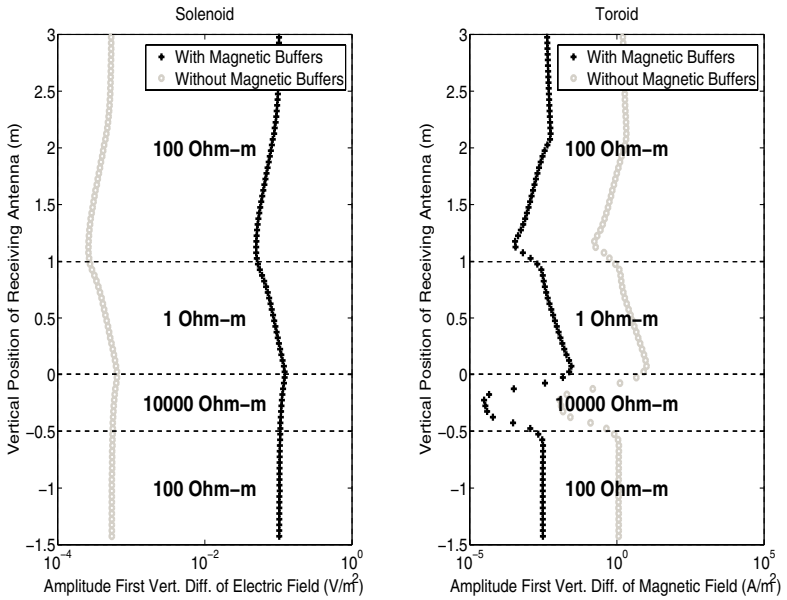

FIG. 5. *LWD problem equipped with a solenoidal source. Results obtained with the self-adaptive goal-oriented hp-FEM correspond to the use of solenoidal antennas (left panel), and toroidal antennas (right panel). The spatial distribution of electrical resistivity is also displayed to facilitate the physical interpretation of results.*

toroidal antennas are more sensitive to highly resistive formations. We also observe that the second vertical difference of the electric field is more sensitive to water invasion than the first vertical difference of the electric field (in both conductive and resistive formations).

Figure 5 illustrates the effect of the magnetic buffers. By removing the magnetic buffers from the logging instrument's design, the amplitude of the received signal decreases by a factor of up to 200 in the case of a solenoidal source. For practical applications, a strong signal on the receivers is desired to minimize the noise-to-signal ratio. Thus, it is appropriate to use magnetic buffers in combination with solenoidal antennas. In contrast, the use of magnetic buffers with toroidal antennas is not advisable since they weaken the received signal. In both cases, the phase and shape of the solution is not sensitive to the presence (or not) of magnetic buffers, and the corresponding results have been omitted.

The solver of linear equations utilized for these simulations is a multifrontal massively parallel sparse direct solver (MUMPS) [2, 1] running in a single-processor machine equipped with a Pentium IV 3.0 GHz processor. The total amount of time utilized by our FEM depends upon the choice of initial grid and the quantity of interest to be computed. Twelve minutes were needed to compute each curve—*log*—of Figure 5, composed of 80 points.

The exponential convergence obtained using the self-adaptive goal-oriented *hp*-FEM is shown in Figure 6 (left panel), by considering an arbitrary fixed position of the logging instrument for a solenoid antenna. The final grid delivers a relative error in the quantity of interest below 0.00001%; i.e., the first 7 significant digits of the quantity of interest are exact. In Figure 6 (right panel), we display the exponential

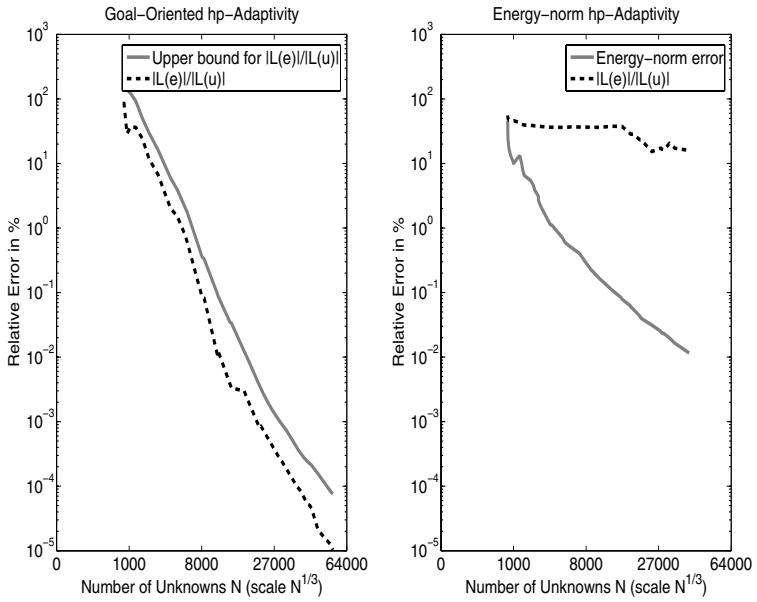

FIG. 6. *LWD problem equipped with a solenoidal source. convergence of the energy-norm-based *hp*-FEM. The final *hp*-grid delivers an energy-norm error below 0.01%. Nevertheless, the quantity of interest still contains a relative error above 15%.

A final goal-oriented *hp*-grid delivering a relative error in the quantity of interest of 0.1% is displayed in Figure 7.

6. Summary and conclusions. We have successfully applied a self-adaptive goal-oriented *hp*-FEM algorithm to simulate the axisymmetric response of an induction LWD instrument in a borehole environment. These simulations would not be possible with energy-norm adaptive algorithms. Also, the use of *hp*-FEM provides the flexibility needed to accurately approximate the solution within the formation (using the p method) as well as the strong singularities caused by the abrupt geometry of the mandrel (using the h method).

Numerical results illustrate the exponential convergence of the method (allowing for high accuracy simulations), the suitability of the presented formulations for axisymmetric electrodynamic problems, and the main physical characteristics of the presented induction LWD instrument. These results suggest the use of solenoidal antennas for the assessment of highly conductive rock formation materials, and toroidal antennas for the assessment of highly resistive materials. Solenoidal antennas should be used in combination with magnetic buffers to strengthen the measured EM signal, while the use of magnetic buffers with toroidal antennas should be avoided. Both types of antennas can be used to study mud-filtrate invasion. Second vertical differences of electromagnetic fields are more sensitive to mud-filtrate invasion than first

vertical differences.

Since the influence function used by the self-adaptive goal-oriented *hp*-adaptive algorithm is approximated via finite elements, the numerical method presented in this article is *problem independent*, and it can be applied to 1D, 2D, and 3D finite element discretizations of H^1-, $H(\mathbf{curl})$-, and $H(div)$-spaces.

Appendix. A loop-antenna radiating in a homogeneous lossy medium in the presence of a highly conductive metallic mandrel. In this appendix, we consider a problem with a known analytical solution. We use this problem as an additional mechanism to verify the code, as well as to provide comparative results between analytical and numerical solutions.

We consider a solenoid (or a toroid) of radius a radiating at a frequency of 2 MHz in a homogeneous lossy medium (with resistivity equal to $1\,\Omega\cdot\mathrm{m}$), in the presence of an infinitely large cylindrical mandrel (with resistivity equal to $10^{-6}\,\Omega\cdot\mathrm{m}$) of radius $b < a$. The coil and the mandrel exhibit axial symmetry (see Figure 8).

For a solenoidal coil located at $z = 0$, the resulting solution for $a \le \rho \le b$ is given by [15, 20]

$$E_\phi(\rho,z) = \frac{-\omega\mu}{4\pi a}\int_{-\infty}^{\infty}[J_1(k_\rho a) + \Gamma H_1^{(1)}(k_\rho a)]H_1^{(1)}(k_\rho\rho)e^{ik_z z}dk_\rho, \tag{A.1}$$

where $\Gamma = -J_1(k_\rho b)/H_1^{(1)}(k_\rho b)$, J_p and $H_p^{(1)}$ are the Bessel and Hankel functions, respectively, of the first type of order p, and $k_z = \sqrt{k^2 - k_\rho^2}$.

For a toroidal coil located at $z = 0$, the resulting solution for $a \le \rho \le b$ is given by

$$H_\phi(\rho,z) = \frac{-i}{4\pi a}\int_{-\infty}^{\infty}[J_1(k_\rho a) + \Gamma H_1^{(1)}(k_\rho a)]H_1^{(1)}(k_\rho\rho)e^{ik_z z}dk_\rho, \tag{A.2}$$

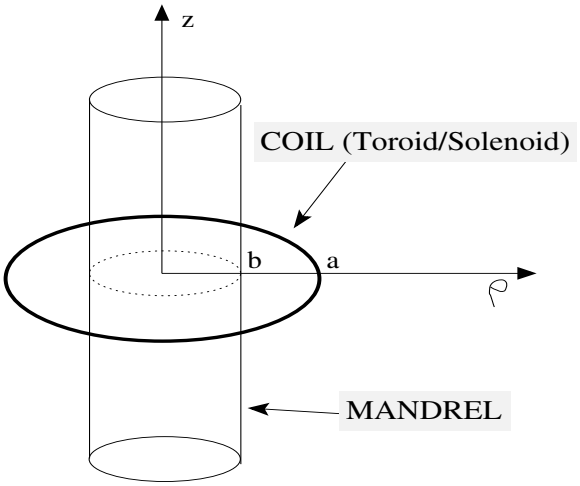

FIG. 8. *Geometry of a loop-antenna radiating in a homogeneous lossy medium in the presence of a highly conductive metallic mandrel.*

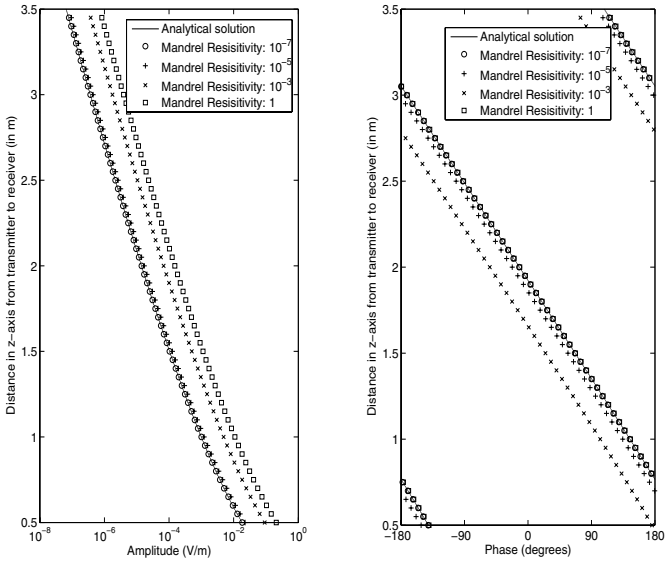

FIG. 9. *Solution (electric field) along the vertical axis passing through a solenoid radiating in a homogeneous medium in the presence of a metallic mandrel. Analytical solution (mandrel is a PEC) against the numerical solution for different mandrel resistivities (10^{-7}, 10^{-5}, 10^{-3}, and $1\ \Omega \cdot m$) obtained with the self-adaptive goal-oriented hp-FEM.*

where $\Gamma = -J_0(k_\rho b)/H_0^{(1)}(k_\rho b)$.

In Figures 9 and 10, we display a comparison between analytical and numerical results (obtained using the self-adaptive *hp* goal-oriented algorithm) for the solenoidal and toroidal coils, respectively. We selected $b = 0.0254$ cm and $a = 0.03048$ cm. The numerical results accurately reproduce the analytical ones, in terms of both amplitude

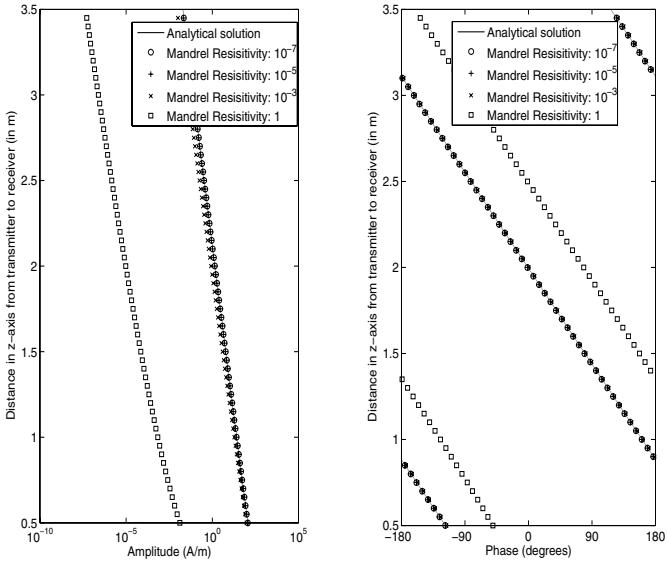

FIG. 10. *Solution (magnetic field) along a vertical axis passing through a toroid radiating in a homogeneous medium in the presence of a metallic mandrel. Analytical solution (mandrel is a PEC) against the numerical solution for different mandrel resistivities (10^{-7}, 10^{-5}, 10^{-3}, and $1\ \Omega \cdot m$) obtained with the self-adaptive goal-oriented hp-FEM.*

and phase.

When considering a solenoid, the logging instrument response using a mandrel of resistivity $10^{-5}\ \Omega \cdot \mathrm{m}$ or a PEC mandrel are indistinguishable in terms of amplitude. A similar situation occurs for a toroid. In terms of phase, induction instruments equipped with solenoidal coils appear to be more sensitive to the mandrel resistivity than those equipped with toroidal coils.

ANALYSIS OF NONLOCAL ELECTROSTATIC EFFECTS IN CHIRAL SMECTIC C LIQUID CRYSTALS*

JINHAE PARK† AND M. CARME CALDERER†

Abstract. We present modeling and analysis of smectic C phases of liquid crystals capable of sustaining spontaneous polarization. The layered liquid crystals are also assumed to be chiral. We study minimization of the total energy subject to electrostatic constraints. In order to determine mathematically and physically relevant boundary conditions, we appeal to the analogy between the current problem and the vorticity in fluids. We place a special emphasis on the nonlocal and self-energy effects arising from spontaneous polarization. We discuss examples pertaining to the electric field created by the liquid crystal in dielectric medium, and also to the possible role of a domain shape as an energy reduction mechanism.

Key words. chiral, energy minimizer, electrostatic self-interaction, ferroelectricity, helical filaments, liquid crystals, nonlocal effects, smectic C phase, smectic layers, vortex tubes

1. Introduction.

This article analyzes nonlocal electrostatic effects associated with polarized states of liquid crystals. We assume that the liquid crystals are of smectic type, possess spontaneous polarization, and may also be chiral. We study minimization of the total energy in $\mathbf{R}^3$, subject to electrostatic constraints.

In smectic liquid crystals, centers of mass of molecules are arranged locally in one-dimensional layers described by a complex field $\psi = \rho e^{i\omega}$; level sets of the phase function ω denote layer locations, with $\nabla\omega$ being parallel to the layer normal. Nonparallel unit vector fields $\mathbf{n}$ and $\mathbf{p}$ describe the orientational ordering of biaxial molecules. Another feature of smectic C phases is that the director $\mathbf{n}$ makes a preferred angle α with the layer normal vector. The angle α is a temperature- and material dependent quantity ranging typically from 0 to $\frac{\pi}{4}$. We visualize smectic C phases in terms of cones with axis along the layer normal and semiangle α. The director $\mathbf{n}$ is then parallel to a generating straight line of the cone. Since the systems that we consider are ferroelectric, that is, they have spontaneous polarization, we take $\mathbf{p}$ to be parallel to the polarization field $\mathbf{P}$; $\mathbf{n}$ corresponds to the uniaxial director measuring the average alignment of molecular long axes of either rod-like or bent-core molecules [33, 34]. The electrostatic potential φ is also a variable of the problem.

Many different types of liquid crystals form smectic C phases (i.e., one-dimensional layer structures). The earlier low molecular weight liquid crystals labeled as smectic C [25] owe ferroelectricity to the molecular dipoles associated with side chains. In such cases, the direction of $\mathbf{P}$ is determined and tends to be perpendicular to $\mathbf{n}$ and $\nabla\omega$. (This type of ferroelectricity, known as *improper* [21], is absent in the smectic A phase due to $\mathbf{n}$ being parallel to $\nabla\omega$.) Since the magnitude of the polarization is usually small, studies of such liquid crystals normally neglect nonlocal electric field

effects and assign constant values to applied fields. Many of the low molecular weight smectic C liquid crystals are cholesteric. On the other hand, B2 phases of bent-core molecule liquid crystals are mostly nonchiral and have large polarization values. In the B2 phase, the layers have a locally polar C_{2v} symmetry group in the Schoenflies symbols [40, p. 489]. Although $\mathbf{P}$ tends to be perpendicular to $\mathbf{n}$, the plane determined by these vectors is free to rotate about $\mathbf{n}$. Unlike the case of small molecule smectics, the B2 phases are not subject to the constraint of $\mathbf{P}$, that is, parallel to $\nabla\omega \times \mathbf{n}$. However, analysis of the latter requires accounting for nonlocal energy.

Throughout this work, we will assume that the liquid crystals are chiral and use the conventional notation C* to denote such chiral smectic phases. An important bulk configuration of chiral smectic C phases is that the variables $\mathbf{n}$ and $\mathbf{p}$ rotate spatially around the axis of the previously described cone, with $\mathbf{n}$ being parallel to a generating straight line of the cone. This accordingly results in zero net polarization over a helical pitch. In suppressing the helix by applying an external electric field or boundary conditions, ferroelectric states with opposite polarization emerge. The transition between the chiral state and the ferroelectric ones is not regarded as a typical phase transition; however, it is at the core of device applications of ferroelectric liquid crystals. Mathematically, we addressed in previous work [27] some stability properties with respect to boundary conditions and electric fields, in the case that nonlocal effects are neglected.

The total energy we analyze consists of nematic, smectic, Ginzburg–Landau, electrostatic, and surface contributions. The nematic and smectic free energy densities follow the forms of Oseen–Frank, de Gennes, and Chen–Lubensky, which penalize departure from preferred molecular alignment and orientation with respect to the layers. Other macroscopic theories of smectic C phases can be found in the literature [23, 33, 37]. Our choice is motivated by the covariant structure of the Lubensky form; this is quadratic in second order gradients of ψ and especially amenable to treatment by calculus of variations. We relax the constraint $\mathbf{p} \perp \{\mathbf{n}, \nabla\omega\}$ and instead incorporate a penalty energy into the model. The Ginzburg–Landau energy tends to select a preferred magnitude of the polarization according to temperature and material parameters. The current energy is appropriate to modeling B2 ferroelectric phases, provided that we omit the previously mentioned penalty term and chirality.

The electrostatic energy comprises a dielectric and a ferroelectric contribution. The latter accounts for the energy of self-interaction between the polarization and its own electric field, as well as the electrostatic energy outside the liquid crystal domain. So far, this situation is analogous to that of a ferroelectric solid. However, there are some fundamental differences between these two behaviors. In the solid, the directions of polarizations are determined by lattice directions; the latter are difficult to alter using an external field. The "softness" of a liquid crystal allows for changes in molecular alignments so as to reduce the energy. For instance, in the case of a liquid crystal located between conducting plates, the distribution of polarization is such that it gets compensated by free charges in the conductor, inducing a zero electric field outside. As a result, the nonlocal energy vanishes. Suppressing the helix in the smectic C* phase is a mechanism of reducing nonlocal energy. In a related work [19], Khachaturyan showed that a polarized homogeneous state of the nematic phase is unstable with respect to a slight dipole-dipole interaction, resulting in a symmetry breaking.

If a B2 liquid crystal is embedded in another liquid, such as its own isotropic phase, it may actually change its shape so that the nonlocal energy is zero. This gives a good explanation for the telephone-cord shape observed in many ferroelectric liquid

crystal filaments [5, 8, 16, 17]. Modeling of static liquid crystal helical filaments can be found in [2, 36]. Chevron structures with alternating domains of opposite polarization are also found in some materials [5]. The phenomenon of changing shape to reduce electrostatic energy has also been observed in thin polarized piezoelectric films (for example, ZnO nanobelt [20]).

In the current analysis, defects are not included. In particular, we assume that $\nabla\omega$ is defined everywhere on $\partial\Omega$ with possible exceptions on the edges of Ω. This, in turn, determines the type of the domain occupied by the liquid crystal, and the nature of boundary conditions on the phase function ω. We make use of analogies with the geometry of vortex tubes and sheets in fluid mechanics. Indeed, we take Ω to be a cylinder-like domain analogous to a vortex tube, which has the lateral surface Σ corresponding to a vortex sheet, and is contained between surfaces $\mathcal{S}_1$ and $\mathcal{S}_2$. We deal with two types of boundary conditions on ω: one corresponding to the layer structure reaching the boundary in a tangential fashion, and the other with layers being perpendicular to the boundary. The latter correspond to the geometry of the Clark–Lagerwall effect in ferroelectric displays [4, 14, 39]. We also prescribe the electrostatic potential on a part of the boundary. These boundary conditions together with assumptions for the constitutive parameters (see section 3) allow us to prove existence of minimizers of the total energy by using direct methods of calculus of variations. One important issue is whether the minimizers thus obtained correspond to chiral structures or ferroelectric ones. We apply asymptotic analysis to obtain a classification of minimizers [1].

In [18], Joo and Phillips studied the phase transitions between chiral nematic, smectic A*, and C* liquid crystals, and carried out extensive stability analyses. Their work gives a rigorous classification of the energy minimizing phase regimes. Another important merit of the article is establishing the coercivity of the smectic C* energy for the first time. For a mathematical analysis of the phase transitions between the chiral and smectic A* liquid crystals with focus on the analogies of the phase transition between conductor and superconductor, the reader is referred to [1]. Studies of periodic ferroelectric and antiferroelectric phases and analysis of time dependent problems arising in switching have also been carried out by the authors [28]. Experimental treatments and studies of smectic C* liquid crystals including the influence of an electric field are found in [10, 11, 12, 29, 30, 31]. For structural understanding and modeling of ferroelectricity, we refer to the books by Goody et al. [13], Lagerwall [21], Pikin [32], and by Muševič, Blinc, and Žekš [26].

This article is organized as follows. In section 2, we present free energy functions of smectic C* materials with concentration on the polarization and electrostatic energies. We discuss constraint relaxation and approximations of the electrostatic energies. In section 3, we prove existence of minimizers and study examples regarding the relationship between domain shapes and polarizations. We also present two different versions of the variational problem, with one of them corresponding to a liquid crystal placed between metallic plates. In the other formulation, the liquid crystal is placed in a dielectric medium, subject to the electric field generated by the material polarization. In section 4, we carry out asymptotic studies of the minimizers obtained in section 3 to determine whether they correspond to chiral or ferroelectric structures. We outline some conclusions in section 5.

2. Free energy functions. We present the energy functional for the smectic materials to be analyzed. This includes nematic, smectic, Ginzburg–Landau, surface, and electric contributions. We will also show how they give rise to simple forms found

in the literature.

Equilibrium configurations of smectic C* liquid crystals occupying a smooth domain Ω in $\mathbf{R}^3$ are given by quadruples $(\psi, \mathbf{n}, \mathbf{P}, \mathbf{E})$ of fields, $\psi : \Omega \to \mathbb{C}$, $\mathbf{n} : \Omega \to \mathbf{S}^2$, $\mathbf{P} : \Omega \to \mathbf{R}^3$, and $\mathbf{E} : \mathbf{R}^3 \to \mathbf{R}^3$, that are critical points of the total energy functional

$$\begin{aligned}\mathcal{E}(\mathbf{n}, \mathbf{P}, \psi, \mathbf{E}) = \int_\Omega \{F_N(\mathbf{n}, \mathbf{P}, \nabla \mathbf{n}) + F_{Sm}(\nabla \mathbf{n}, \nabla \psi, \nabla^2 \psi) \\ + F_P(\mathbf{n}, \mathbf{P}, \nabla \mathbf{P}, \nabla \psi)\}\, d\mathbf{x} + \int_{\partial\Omega} F_S(\mathbf{n}, \nu)\, dS \\ + \int_{\mathbf{R}^3} F_E(\mathbf{n}\chi_\Omega, \mathbf{P}\chi_\Omega, \mathbf{E}) d\mathbf{x},\end{aligned} \tag{2.1}$$

subject to Maxwell's equations

$$-\nabla \cdot \mathbf{D} = 0, \quad \nabla \times \mathbf{E} = \mathbf{0} \quad \text{in } \Omega, \tag{2.2}$$

where $\mathbf{D}$ is the electric displacement vector, $\mathbf{E}$ is the electric field, and the functions F_N, F_{Sm}, F_E, F_S, F_P represent the Oseen–Frank, the smectic, the electrostatic, the surface anchoring [6, p. 99], and the Ginzburg–Landau energy densities, respectively. χ_Ω denotes the characteristic function.

2.1. Dielectric, nonlocal, and self-interaction terms. The electrostatic energy density in $\mathbf{R}^3$ [7, 22] is given by[1]

$$F_E = -\frac{1}{2}\big((\varepsilon \mathbf{E} \cdot \mathbf{E})\chi_\Omega + (\mathbf{E} \cdot \mathbf{E})\chi_{\Omega^c}\big) - (\mathbf{P} \cdot \mathbf{E})\chi_\Omega, \tag{2.3}$$

$$\mathbf{D} = \varepsilon \mathbf{E}\chi_\Omega + \mathbf{E}\chi_{\Omega^c} + \mathbf{P}\chi_\Omega, \tag{2.4}$$

$$\varepsilon = \varepsilon_\perp \mathbf{I} + \varepsilon_a \mathbf{n} \otimes \mathbf{n}, \tag{2.5}$$

where ε, $\varepsilon_\perp$, and ε_a represent the susceptibility tensor, dielectric permittivity, and dielectric anisotropy, respectively.

Note that (2.3) can be written as

$$F_E = -\frac{1}{2}\Big[\varepsilon_\perp |\mathbf{E}|^2 + \varepsilon_a (\mathbf{n} \cdot \mathbf{E})^2 + |\mathbf{E}|^2 \chi_{\Omega^c}\Big] - (\mathbf{P} \cdot \mathbf{E})\chi_\Omega. \tag{2.6}$$

So, the electrostatic energy is given by

$$\begin{aligned}\int_{\mathbf{R}^3} F_E\, d\mathbf{x} = -\frac{1}{2}\int_\Omega \{\varepsilon_\perp |\mathbf{E}|^2 + \varepsilon_a (\mathbf{E} \cdot \mathbf{n})^2\}\, d\mathbf{x} \\ - \frac{1}{2}\int_{\mathbf{R}^3 - \Omega} |\mathbf{E}|^2\, d\mathbf{x} - \int_\Omega \mathbf{P} \cdot \mathbf{E}\, d\mathbf{x}.\end{aligned} \tag{2.7}$$

The two terms in the last row in (2.7) correspond to the self-interaction and nonlocal electrostatic energies, respectively. The term in the first row gives the dielectric contribution.

[1] We note that the electric displacement $\mathbf{D}$ is usually written as $\mathbf{D} = \varepsilon \mathbf{E}\chi_\Omega + \mathbf{E}\chi_{\Omega^c} + 4\pi \mathbf{P}$. For simplicity, we replace $4\pi \mathbf{P}$ by $\mathbf{P}$.

2.2. Nematic and smectic free energies. The Oseen–Frank free energy density is given by

$$F_N = K_1(\nabla\cdot\mathbf{n})^2 + K_2(\mathbf{n}\cdot\nabla\times\mathbf{n}+\tau)^2 + K_3|\mathbf{n}\times(\nabla\times\mathbf{n})+\gamma\mathbf{P}|^2 + (K_2+K_4)(tr(\nabla\mathbf{n})^2-(\nabla\cdot\mathbf{n})^2), \tag{2.8}$$

where K_i, $i=1,2,3,4$, denote elasticity constants. The scalar τ represents the chiral pitch of the helical structure of the cholesteric phases [9], and $K_3\gamma^2|\mathbf{P}|^2$ is an intrinsic bending stress [7, p. 384]. Here, γ is a parameter included for the purpose of dimensionalization; hereafter, we will take γ to be 1. Such a term appears only in connection with the modeling of the smectic C* since nematics with intrinsic bending have not been observed. Both quantities result from the loss of mirror symmetry of the smectic C* phases. The fourth term in $F_{\rm N}$ is a null-Lagrangian; its integral is determined by $\mathbf{n}$ on $\partial\Omega$. The classical Oseen–Frank energy corresponds to the case that $\mathbf{P}$ is zero. Existence and regularity of minimizers for the classical Oseen–Frank energy were studied by Hardt, Kinderlehrer, and Lin [15].

The free energy density associated with the smectic layering follows the covariant form presented in [3]:

$$F_{Sm} = D(\mathbb{D}^2\psi)(\mathbb{D}^2\psi)^* + [C_{||}n_in_j + C_\perp(\delta_{ij}-n_in_j)](\mathbb{D}_i\psi)(\mathbb{D}_j\psi)^* + r|\psi|^2 + \frac{g}{2}|\psi|^4, \tag{2.9}$$

with $\mathbb{D}\equiv\nabla - iq\mathbf{n}$, q the modulation wave number of the smectic layer, and $r = a(T-T^*)$, $a>0$; here T denotes the (constant) temperature of the material and T^* is the transition temperature from nematic to smectic. Model (2.9) yields the de Gennes model for smectic A* when $C_{||}-C_\perp = 0$ and $D=0$. The smectic C phase is characterized by $C_\perp<0$. Moreover, $C_\perp\geq 0$ in the smectic A*, and $C_\perp = 0$ characterizes the transition to smectic C. Equivalently, the energy (2.9) can also be written as follows:

$$F_{Sm} = D|\mathbb{D}^2\psi|^2 + C_\perp|\mathbb{D}\psi|^2 + C_a|\mathbf{n}\cdot\mathbb{D}\psi|^2 + r|\psi|^2 + \frac{g}{2}|\psi|^4. \tag{2.10}$$

Remark. The first term in (2.9) is obtained from [24] and is a modification of $D_\perp(\delta_{ij}-n_in_j)(\delta_{kl}-n_kn_l)(\mathbb{D}_i\mathbb{D}_j)(\mathbb{D}_k\mathbb{D}_l)^*$ in the original Chen–Lubensky model. The purpose of introducing the new term is to obtain coercivity of the energy. This fact was first observed in [18].

2.3. Anchoring energy. The anchoring energy is the Rapini–Papoular surface energy [7, 21] given by

$$F_S = \omega_n\big(1-\alpha_0(\mathbf{n}\cdot\nu)^2\big), \tag{2.11}$$

where ω_n and $|\alpha_0|<1$ are material constants, and ν denotes the unit normal to the surface. Note that the surface energy due to the polarization is not explicitly included in (2.11). In fact, the role of such a surface energy is an approximation to the nonlocal energy in (2.7), which we explicitly include in the problem.

2.4. Ginzburg–Landau energy with relaxation. The energy associated with the phase transition to the ferroelectric phases is given by the Ginzburg–Landau expression [22], $a_0|\mathbf{P}|^2 + b_0|\mathbf{P}|^4$, where $b_0>0$ and $a_0 = \alpha(T-T_c)$. Ferroelectric phases correspond to the case $T<T_c$.

In contrast to solids, the direction of polarization in many liquid crystals is determined by the direction $\mathbf{n}$ and the layer normal $\nabla\omega$. In fact, a symmetry argument shows that $\mathbf{P}$ is perpendicular to both $\mathbf{n}$ and $\nabla\omega$. For this reason, we express $\mathbf{P}$ as follows [7, p. 384]:

$$\mathbf{P} = \begin{cases} |\mathbf{P}| \frac{\nabla\omega\times\mathbf{n}}{|\nabla\omega\times\mathbf{n}|} & \text{if } \nabla\omega\times\mathbf{n} \neq \mathbf{0}, \\ \mathbf{0} & \text{if } \nabla\omega\times\mathbf{n} = \mathbf{0}. \end{cases} \tag{2.12}$$

Therefore, the Ginzburg–Landau energy with relaxation is given by

$$F_P = B|\nabla\mathbf{P}|^2 + a_0|\mathbf{P}|^2 + b_0|\mathbf{P}|^4 + \frac{1}{\epsilon^2}|(|\nabla\omega\times\mathbf{n}|)\mathbf{P} - |\mathbf{P}|(\nabla\omega\times\mathbf{n})|^2, \tag{2.13}$$

where $B > 0$, $a_0 < 0$, $b_0 > 0$, and $\epsilon > 0$. Here, we note that the last term in (2.13), $\frac{1}{\epsilon^2}|(|\nabla\omega\times\mathbf{n}|)\mathbf{P} - |\mathbf{P}|(\nabla\omega\times\mathbf{n})|^2$, is a penalty term for (2.12), and $|\nabla\mathbf{P}|^2$ is a regularizing term.

2.5. Electrostatic approximations. The presence of polarization in the sample causes a point charge density $\rho_p = -\nabla\cdot\mathbf{P}$ in the bulk, and $\sigma = \mathbf{P}\cdot\nu$, where σ is the surface density of charges [38]. This will help us interpret the energies $\int_{\mathbf{R}^3-\Omega}|\mathbf{E}|^2\,d\mathbf{x}$ and $\int_\Omega \mathbf{P}\cdot\mathbf{E}\,d\mathbf{x}$. For this, let us consider the special case that Ω is a ball of radius r_0 centered at $\mathbf{0}$, with the constant surface charge density σ. We calculate the electric potential φ [38] as

$$\varphi(\mathbf{x}) = \begin{cases} \frac{\sigma r_0^2}{|\mathbf{x}|} & \text{if } |\mathbf{x}| > r_0, \\ \sigma r_0 & \text{if } |\mathbf{x}| \le r_0. \end{cases}$$

Then for $|\mathbf{x}| > r_0$ we get

$$|\mathbf{E}(r)| = \frac{\sigma r_0^2}{r^2},$$

and hence

$$\begin{aligned} \int_{\mathbb{R}^3-\Omega}|\mathbf{E}|^2\,d\mathbf{x} &= \int_0^{2\pi}\int_0^{\pi}\int_{r_0}^{\infty}\frac{\sigma^2 r_0^4}{r^2}\sin\phi\,dr\,d\phi\,d\theta \\ &= r_0\int_{\partial\Omega}(\mathbf{P}\cdot\nu)^2\,dS. \end{aligned}$$

This explains why the term $\int_{\partial\Omega}(\mathbf{P}\cdot\nu)^2\,dS$ appears in liquid crystal models [21].

Now, let us consider the self-interaction energy. For our illustration, we consider the case that $\varepsilon_a \ll \varepsilon_\perp$, and we neglect ε_a in the model. It then follows that the self-interaction energy is related with the Coulomb energy by

$$\int_\Omega\int_\Omega \frac{\nabla\cdot\mathbf{P}(\mathbf{x})\nabla\cdot\mathbf{P}(\mathbf{y})}{|\mathbf{x}-\mathbf{y}|}\,d\mathbf{x}\,d\mathbf{y} = -4\pi\varepsilon_\perp\int_\Omega \mathbf{P}\cdot\mathbf{E}\,d\mathbf{x}.$$

We point out that the Coulomb energy is often approximated by the polar energy $\int_\Omega(\nabla\cdot\mathbf{P})^2\,d\mathbf{x}$ found in the literature [7, 21]. We summarize the total energy involved

in the electrostatic approximation without an external field as follows:

$$\mathcal{E}(\mathbf{n},\mathbf{P},\psi)=\int_\Omega\{F_N+F_{Sm}+G_P\}d\mathbf{x}+\int_{\partial\Omega}G_S\,dS, \tag{2.14}$$

$$\begin{aligned}G_S=\omega_p\left(1-\frac{\mathbf{P}\cdot\nu}{|\mathbf{P}|}\right)+\omega_r\left(1-\frac{(\mathbf{P}\cdot\nu)^2}{|\mathbf{P}|^2}\right)\\+\omega_n\Big(1-(\mathbf{n}\cdot\nu)^2\Big),\end{aligned} \tag{2.15}$$

$$G_P=F_P+B_1(\nabla\cdot\mathbf{P})^2. \tag{2.16}$$

Minimization of the energy (2.14) is studied in previous work [27].

3. Existence of minimizers. In this section, we study the boundary conditions for smectic C* layer configurations and prove existence of minimizers. We also discuss applications and provide examples that explain the relationship between domain shape and ferroelectricity.

Throughout this paper, we assume that the constitutive parameters satisfy

$$g>0,\quad q\geq 0,\quad \tau\geq 0,\quad r<0,\quad b_0>0,\quad \omega_n>0, \tag{3.1}$$

$$D>0,\quad C_\perp<0,\quad C_a>0,\quad c_1\geq K_2+K_4\geq c_0, \tag{3.2}$$

$$K_1\geq K_2+K_4,\quad K_3\geq K_2+K_4,\quad 0\geq K_4, \tag{3.3}$$

where c_0 and c_1 are positive constants. The latter inequalities are necessary conditions to ensure coercivity of the energy [1].

3.1. Boundary conditions. Let $\Omega\subset\mathbf{R}^3$ be a bounded, cylinder-like domain, with boundary $\partial\Omega=\Sigma\cup\mathcal{S}_1\cup\mathcal{S}_2$. We assume that the lateral surface Σ is of class C^2, and that $\mathcal{S}_1$ and $\mathcal{S}_2$ are plane cross sections with unit normal ν_1 and ν_2, respectively. Letting $\psi=\rho e^{i\omega}$, we rewrite F_{Sm} as

$$\begin{aligned}F_{Sm}&=D|\mathbb{D}^2\psi|^2+C_\perp|\mathbb{D}\psi|^2+C_a|\mathbf{n}\cdot\mathbb{D}\psi|^2+r|\psi|^2+\frac{g}{2}|\psi|^4\\&=D[(\Delta\rho-\rho|\nabla\omega-q\mathbf{n}|^2)^2+(\rho\nabla\cdot(\nabla\omega-q\mathbf{n})+2\nabla\rho\cdot(\nabla\omega-q\mathbf{n}))^2]\\&\quad+C_a[(\nabla\rho\cdot\mathbf{n})^2+\rho^2(\nabla\omega\cdot\mathbf{n}-q)^2]+r\rho^2+\frac{g}{2}\rho^4\\&\quad+C_\perp\left(|\nabla\rho|^2+\rho^2|\nabla\omega-q\mathbf{n}|^2\right).\end{aligned} \tag{3.4}$$

The following lemma based on Gauss' theorem motivates the boundary conditions taken into account.

LEMMA 3.1. *Let $\Omega\subset\mathbf{R}^3$ be as previously defined. Let f be a smooth scalar function defined in Ω. Then f satisfies the following identity:*

$$\begin{aligned}\int_\Omega|\triangle f|^2\,d\mathbf{x}&=\int_{\partial\Omega}\left[\nabla\cdot(\nabla f)(\nu\cdot\nabla f)-\frac{1}{2}\nabla(|\nabla f|^2)\cdot\nu\right]dS\\&\quad+\sum_{i,j=1,2,3}\int_\Omega(\partial_i\partial_j f)^2\,d\mathbf{x}.\end{aligned} \tag{3.5}$$

Let $k>q$ be a given constant. We assume that the boundary $\partial\Omega$ satisfies either

$$\begin{aligned}&\nabla\omega\cdot\nu=0\ \text{ on }\ \Sigma,\quad \nabla\omega\cdot\nu_i=k\ \text{ on }\ \mathcal{S}_i,\ i=1,2,\\&|\nabla\omega|^2=k^2\ \text{ on }\ \Sigma\cup\mathcal{S}_1\cup\mathcal{S}_2,\end{aligned} \tag{3.6}$$

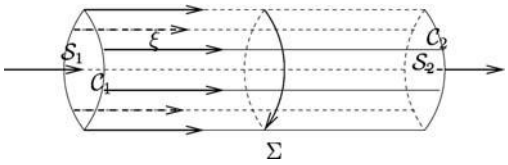

FIG. 3.1. *A vortex tube: $\mathcal{C}_1$ and $\mathcal{C}_2$ are the boundary curves of $\mathcal{S}_1$ and $\mathcal{S}_2$.*

or

$$\begin{aligned} &\nabla\omega\cdot\nu = \pm k \ \text{ on } \Sigma, \quad \nabla\omega\cdot\nu_i = 0 \ \text{ on } \ \mathcal{S}_i,\ i=1,2,\\ &|\nabla\omega|^2 = k^2 \ \text{ on } \ \Sigma\cup\mathcal{S}_1\cup\mathcal{S}_2. \end{aligned} \tag{3.7}$$

Such relations correspond to smectic layers reaching the boundary in a perpendicular and tangential fashion, respectively, with a prescribed wave number k. In case of (3.7), the surface integration in (3.5) becomes $\pm 2k^2\int_\Sigma H\,dS$, where H is the mean curvature. In contrast, with boundary conditions (3.6), the surface integration in (3.5) is zero.

Remark. The choice of domain and boundary conditions of the problem is motivated by vorticity geometry. Indeed, Ω and Σ play the roles of vortex tube and vortex sheet, respectively. Moreover, $\nabla\omega$ is analogous to the fluid vorticity ξ, as in Figure 3.1.

3.2. Existence of minimizers. For simplicity, we restrict ourselves to the case that ρ is constant (say $\rho = 1$), that is, no nematic defects are present in the sample, and rewrite the smectic energy as follows:

$$\begin{aligned} F_{Sm} = {} & D(\Delta\omega - q\nabla\cdot\mathbf{n})^2 + D\left(|\nabla\omega - q\mathbf{n}|^2 + \frac{C_\perp}{2D}\right)^2\\ & + C_a(\nabla\omega\cdot\mathbf{n} - q)^2 + \left(r + \frac{g}{2} - \frac{C_\perp^2}{4D}\right). \end{aligned} \tag{3.8}$$

We also assume that $\mathbf{D}$ and $\mathbf{E}$ satisfy Maxwell's equations (2.2). We use an electric potential φ satisfying $\mathbf{E} = \nabla\varphi$ and impose boundary conditions for φ so that (2.2) reads

$$\begin{cases} -\nabla\cdot((\varepsilon_\perp\mathbf{I} + \varepsilon_a\mathbf{n}\otimes\mathbf{n})\nabla\varphi) = \nabla\cdot\mathbf{P} \text{ in } \Omega,\\ \varphi = \varphi_0 \text{ on } \Sigma,\\ -\big((\varepsilon_\perp\mathbf{I} + \varepsilon_a\mathbf{n}\otimes\mathbf{n})\nabla\varphi\big)\cdot\nu = \mathbf{P}\cdot\nu \text{ on } \mathcal{S}_1\cup\mathcal{S}_2, \end{cases} \tag{3.9}$$

where $\varphi_0 \in H^{\frac{1}{2}}(\Sigma)$ is prescribed.

Define

$$\begin{aligned} &\mathcal{X} = \Big\{(\mathbf{n},\mathbf{P}) \in W^{1,2}(\Omega,\mathbf{S}^2)\times W^{1,2}(\Omega,\mathbf{R}^3) : ||P||_\infty \le P_0\Big\},\\ &\mathcal{H} = \{\omega \in W^{2,2}(\Omega) \mid \omega \text{ satisfies (3.6) or (3.7) on } \partial\Omega\},\\ &H^1_{\varphi_0} = \{\varphi \in H^1(\Omega) : \varphi = \varphi_0 \text{ on } \Sigma\},\\ &\mathcal{A}^* = \mathcal{H}\times\mathcal{X}, \quad \text{and}\\ &\mathcal{A} = \mathcal{A}^*\times H^1_{\varphi_0}, \end{aligned}$$

where P_0 is the given polarization saturation constant depending on the material and temperature. For constant potential φ_0, the boundary condition $\varphi = \varphi_0$ on Σ can be

considered as $\varphi = \varphi_0$ in $\mathbf{R}^3 - \Omega$. In this case, the nonlocal energy $\int_{\mathbf{R}^3-\Omega} |\mathbf{E}|^2 \, d\mathbf{x}$ is zero. For simplicity, we will drop the nonlocal energy in $\mathcal{E}$. We then rewrite the total energy functional $\mathcal{E}$ as a sum:

$$\mathcal{E} = \mathcal{W} - \frac{1}{2}\int_\Omega \{\varepsilon_\perp |\nabla\varphi|^2 + \varepsilon_a(\mathbf{n}\cdot\nabla\varphi)^2 + 2\mathbf{P}\cdot\nabla\varphi\}\, d\mathbf{x}, \tag{3.10}$$

where

$$\mathcal{W} = \int_\Omega \{F_N + F_{Sm} + F_P\}\, d\mathbf{x} + \int_{\partial\Omega} \omega_n((1-\alpha_0(\mathbf{n}\cdot\nu)^2)\, dS. \tag{3.11}$$

Since we are interested in the case that K_2 and K_3 are large, we assume that $\min\{K_2, K_3\} \geq 8c_1$ [1]. We note that for all $\mathbf{n} \in \mathbf{W}^{1,2}(\Omega, \mathbf{S}^2)$ the following identities hold:

$$\begin{aligned} &tr(\nabla\mathbf{n})^2 = |\nabla\mathbf{n}|^2 - |\nabla\times\mathbf{n}|^2, \\ &|\nabla\times\mathbf{n}|^2 = |\mathbf{n}\cdot\nabla\times\mathbf{n}|^2 + |\mathbf{n}\times\nabla\times\mathbf{n}|^2. \end{aligned}$$

Using these identities, we get

$$\begin{aligned} F_N = {} & (K_1 - K_2 - K_4)(\nabla\cdot\mathbf{n})^2 + (K_2+K_4)|\nabla\mathbf{n}|^2 - (K_2+K_4)|\nabla\times\mathbf{n}|^2 \\ & + K_2(\mathbf{n}\cdot\nabla\times\mathbf{n} + \tau)^2 + K_3|\mathbf{n}\times\nabla\times\mathbf{n} + \mathbf{P}|^2. \end{aligned} \tag{3.12}$$

Now, the following inequalities hold:

$$\begin{aligned} & K_2(\mathbf{n}\cdot\nabla\times\mathbf{n}+\tau)^2 + K_3|\mathbf{n}\times\nabla\times\mathbf{n} - \mathbf{P}|^2 - (K_2+K_4)|\nabla\times\mathbf{n}|^2 \\ & \geq 4c_1\left(\frac{1}{2}|\mathbf{n}\times\nabla\times\mathbf{n}|^2 - 2|\mathbf{P}|^2\right) + 2c_1(\mathbf{n}\cdot\nabla\times\mathbf{n}+\tau)^2 - (K_2+K_4)|\nabla\times\mathbf{n}|^2 \\ & \geq 2c_1|\nabla\times\mathbf{n} + \tau\mathbf{n}|^2 - 8c_1|\mathbf{P}|^2 - (K_2+K_4)|\nabla\times\mathbf{n}|^2 \\ & \geq 2c_1\left(\frac{1}{2}|\nabla\times\mathbf{n}|^2 - 2\tau^2\right) - 8c_1|\mathbf{P}|^2 - (K_2+K_4)|\nabla\times\mathbf{n}|^2 \\ & \geq (c_1 - K_2 - K_4)|\nabla\times\mathbf{n}|^2 - 4c_1(\tau^2 + 2|\mathbf{P}|^2) \\ & \geq -4c_1(\tau^2 + 2|\mathbf{P}|^2). \end{aligned} \tag{3.13}$$

It follows from (3.12), (3.13), and Lemma 3.1 that $\mathcal{W}$ is bounded below in $\mathcal{A}^*$. Therefore, we have

$$M_1 \leq \inf_{(\mathbf{n},\mathbf{P},\omega)\in\mathcal{A}^*} \mathcal{W}(\mathbf{n},\mathbf{P},\omega) < \infty$$

for some $M_1 \in \mathbf{R}$.

Now, we rewrite the Oseen–Frank energy in (3.12) as follows:

$$\begin{aligned} F_N = {} & (K_1 - K_2 - K_4)(\nabla\cdot\mathbf{n})^2 + (K_2+K_4)|\nabla\mathbf{n}|^2 - K_4\left(\mathbf{n}\cdot\nabla\times\mathbf{n} - \frac{\tau K_2}{K_4}\right)^2 \\ & + K\left|\mathbf{n}\times\nabla\times\mathbf{n} + \frac{K_3}{K}\mathbf{P}\right|^2 + \left(K_3 - \frac{K_3^2}{K}\right)|\mathbf{P}|^2 + \tau^2\left(K_2 - \frac{K_2^2}{|K_4|}\right), \end{aligned}$$

where $K = K_3 - K_2 - K_4$.

Let $\{(\mathbf{n}^j, \mathbf{P}^j, \omega^j)\}$ be a minimizing sequence for $\mathcal{W}$. Since $|\mathbf{n}^j| = 1$, we get

$$\begin{aligned}&\mathbf{n}^j \rightharpoonup \mathbf{n}^\infty \text{ in } W^{1,2}(\Omega),\\ &\mathbf{n}^j \to \mathbf{n}^\infty \text{ almost everywhere in } \Omega, \quad \text{and}\\ &\mathbf{P}^j \rightharpoonup \mathbf{P}^\infty \text{ in } W^{1,2}(\Omega)\end{aligned}$$

as $j \to \infty$. Furthermore, we have

$$\begin{aligned}&\mathbf{n}^j \times \nabla \times \mathbf{n}^j \rightharpoonup \mathbf{n}^\infty \times \nabla \times \mathbf{n}^\infty \text{ in } L^2(\Omega),\\ &\mathbf{n}^j \cdot \nabla \times \mathbf{n}^j \rightharpoonup \mathbf{n}^\infty \cdot \nabla \times \mathbf{n}^\infty \text{ in } L^2(\Omega)\end{aligned}$$

as $j \to \infty$. Note that for all j,

$$\int_\Omega |\nabla \omega^j|^2 \, d\mathbf{x} \le 2 \int_\Omega (|\nabla \omega^j - q\mathbf{n}^j|^2 + q^2) \, d\mathbf{x}, \quad \text{and} \tag{3.14}$$

$$\begin{aligned}\int_\Omega |\Delta \omega^j|^2 \, d\mathbf{x} &= \int_\Omega |\Delta \omega^j - q\nabla \cdot \mathbf{n}^j + q\nabla \cdot \mathbf{n}^j|^2 \, d\mathbf{x}\\ &\le 2 \int_\Omega \left[|\Delta \omega^j - q\nabla \cdot \mathbf{n}^j|^2 + q^2(\nabla \cdot \mathbf{n}^j)^2\right] \, d\mathbf{x}\end{aligned} \tag{3.15}$$

hold. From (3.14), (3.15), and Lemma 3.1, we get

$$||\omega^j||_{W^{2,2}(\Omega)} \le R$$

for some $R > 0$. Hence, we obtain that

$$\begin{aligned}&\omega^j \rightharpoonup \omega^\infty \text{ in } W^{2,2}(\Omega), \quad \text{and}\\ &\nabla \omega^j \times \mathbf{n}^j \to \nabla \omega^\infty \times \mathbf{n}^\infty \text{ in } L^2(\Omega)\end{aligned}$$

as $j \to \infty$. Using $||a| - |b|| \le |a - b|$ for a and b in $\mathbf{R}$, we show that

$$\left|(|\nabla \omega^j \times \mathbf{n}^j|)\mathbf{P}^j - |\mathbf{P}^j|(\nabla \omega^j \times \mathbf{n}^j)\right|^2 \to \left|(|\nabla \omega^\infty \times \mathbf{n}^\infty|)\mathbf{P}^\infty - |\mathbf{P}^\infty|(\nabla \omega^\infty \times \mathbf{n}^\infty)\right|^2$$

in L^1 as $j \to \infty$.

Since $\mathbf{n} \cdot \nu \in H^{\frac{1}{2}}(\partial\Omega) \subset L^2(\partial\Omega)$ with strong topology, $\int_{\partial\Omega} \omega_n(1 - \alpha_0(\mathbf{n} \cdot \nu)^2) \, dS$ is lower semicontinuous. Therefore, $\mathcal{W}$ is coercive and weakly lower semicontinuous; that is,

$$\mathcal{W}(\mathbf{n}^\infty, \mathbf{P}^\infty, \omega^\infty) \le \lim_{j \to \infty} \mathcal{W}(\mathbf{n}^j, \mathbf{P}^j, \omega^j).$$

Therefore we have the following lemma.

LEMMA 3.2. *Assuming that* $\min\{K_2, K_3\} \ge 8c_1$*, there exists a minimizing triple* $(\mathbf{n}, \mathbf{P}, \omega)$ *of the energy functional* $\mathcal{W}$ *in* $\mathcal{A}^*$.

Now, we prove existence of minimizers for $\mathcal{E}$ in $\mathcal{A}$. For any $(\mathbf{n}, \mathbf{P}, \omega) \in \mathcal{A}^*$, by the fundamental theory of elliptic PDEs (3.9) has a unique solution, which we denote by $\Phi_{\varphi_0}(\mathbf{n}, \mathbf{P})$, and thus $\Phi_{\varphi_0}(\mathbf{n}, \mathbf{P})$ is the unique minimizer of the functional $-\int_\Omega F_E \, d\mathbf{x}$ in $H^1_{\varphi_0}$. Substituting $\Phi_{\varphi_0}(\mathbf{n}, \mathbf{P})$ for φ in $\mathcal{E}$, we define $\mathcal{E}^*$ by

$$\mathcal{E}^*(\mathbf{n}, \mathbf{P}, \omega) = \mathcal{E}(\mathbf{n}, \mathbf{P}, \omega, \Phi_{\varphi_0}(\mathbf{n}, \mathbf{P})).$$

Let

$$D(\nabla\varphi, \mathbf{n}) = -(\varepsilon_\perp \mathbf{I} + \varepsilon_a \mathbf{n}\otimes\mathbf{n})\nabla\varphi, \tag{3.16}$$

$$A(\nabla\varphi, \mathbf{n}) = [(\varepsilon_\perp \mathbf{I} + \varepsilon_a \mathbf{n}\otimes\mathbf{n})\nabla\varphi]\cdot\nabla\varphi. \tag{3.17}$$

After modifying Theorem 4.1 in [15], we have the following theorem.

THEOREM 3.3. *A quadruple* $(\mathbf{n}, \mathbf{P}, \omega, \varphi)$ *is a critical point of* $\mathcal{E}$ *in* $\mathcal{A}$ *subject to* (3.9) *if and only if*

$$\varphi = \Phi_{\varphi_0}(\mathbf{n}, \mathbf{P}) \quad \text{and} \quad \delta\mathcal{E}^*(\mathbf{n}, \mathbf{P}, \omega) = 0 \text{ in } \mathcal{A}^*. \tag{3.18}$$

THEOREM 3.4. *For* φ_0 *as above and* $\min\{K_2, K_3\} \geq 8c_1$, *there exists a triple* $(\mathbf{n}, \mathbf{P}, \omega)$ *which minimizes* $\mathcal{E}^*$ *in* $\mathcal{A}^*$, *and therefore* $\mathcal{E}$ *achieves its minimum in* $\mathcal{A}$.

Proof. Let $(\tilde{\mathbf{n}}, \tilde{\mathbf{P}}, \tilde{\omega})$ be a minimizer of $\mathcal{W}$ in $\mathcal{A}^*$. Then

$$\inf_{(\mathbf{n},\mathbf{P},\omega)\in\mathcal{A}^*} \mathcal{E}^*(\mathbf{n}, \mathbf{P}, \omega) \leq \mathcal{E}^*(\tilde{\mathbf{n}}, \tilde{\mathbf{P}}, \tilde{\omega}) < \infty.$$

If $\tilde{\varphi}$ is some fixed $W^{1,2}$ extension of φ_0 to Ω, then for any $\eta > 0$,

$$\begin{aligned} -2\int_\Omega F_E\, d\mathbf{x} &= \int_\Omega [A(\nabla\Phi_{\varphi_0}(\mathbf{n}, \mathbf{P}), \mathbf{n}) + \mathbf{P}\cdot\nabla\Phi_{\varphi_0}(\mathbf{n}, \mathbf{P})]\, d\mathbf{x} \\ &\leq \int_\Omega [A(\nabla\tilde{\varphi}, \mathbf{n}) + \mathbf{P}\cdot\nabla\tilde{\varphi}]\, d\mathbf{x} \\ &\leq C(\Omega, \varphi_0), \end{aligned}$$

for some $C(\Omega, \varphi_0)$ depending on Ω and φ_0. Since $\mathcal{W}$ is bounded from below, it follows from the above that $\mathcal{E}^*$ is also bounded below.

Now, choose a minimizing sequence $(\mathbf{n}^i, \mathbf{P}^i, \omega^i)$ in $\mathcal{A}^*$ and set $\varphi^i = \Phi_{\varphi_0}(\mathbf{n}^i, \mathbf{P}^i)$. Using the same computation as in the proof of the previous lemma, we obtain that

$$\begin{aligned} &\mathbf{n}^j \rightharpoonup \mathbf{n}^\infty \text{ in } W^{1,2}, \\ &\mathbf{n}^j \to \mathbf{n}^\infty \text{ almost everywhere in } \Omega, \\ &\mathbf{P}^j \rightharpoonup \mathbf{P}^\infty \text{ in } W^{1,2}, \quad \text{and} \\ &\omega^j \rightharpoonup \omega^\infty \text{ in } W^{2,2} \end{aligned}$$

as $j \to \infty$. Since $(\mathbf{P}^j)$ converges strongly to $\mathbf{P}^\infty$ in L^2,

$$\int_\Omega \mathbf{P}^j\cdot\nabla\xi\, d\mathbf{x} \to \int_\Omega \mathbf{P}^\infty\cdot\nabla\xi\, d\mathbf{x} \quad \text{as } j\to\infty \tag{3.19}$$

for any $\xi \in H^1(\Omega)$. It follows from (3.9) and (3.19) that (φ^j) converges strongly to φ^∞ in $H^1_{\varphi_0}$.

Since φ^i is the minimizer of $-\int_\Omega F_E(\mathbf{n}^i, \mathbf{P}^i, \nabla\varphi)\, d\mathbf{x}$ for each fixed $\mathbf{n}^i$ and $\mathbf{P}^i$, we have

$$-\int_\Omega F_E(\mathbf{n}^i, \mathbf{P}^i, \nabla\varphi^i)\, d\mathbf{x} \leq -\int_\Omega F_E(\mathbf{n}^i, \mathbf{P}^i, \nabla\varphi^\infty)\, d\mathbf{x}.$$

By Lebesgue's theorem, we obtain

$$\lim_{i\to\infty}\left\{-\int_\Omega F_E(\mathbf{n}^i, \mathbf{P}^i, \nabla\varphi^i)\, d\mathbf{x}\right\} = -\int_\Omega F_E(\mathbf{n}^\infty, \mathbf{P}^\infty, \nabla\varphi^\infty)\, d\mathbf{x},$$

so that

$$\limsup_{i\to\infty}\left\{-\int_\Omega F_E(\mathbf{n}^i,\mathbf{P}^i,\nabla\varphi^i)\,d\mathbf{x}\right\}\le-\int_\Omega F_E(\mathbf{n}^\infty,\mathbf{P}^\infty,\nabla\varphi^\infty)\,d\mathbf{x}.$$

This implies that

$$\liminf_{i\to\infty}\int_\Omega F_E(\mathbf{n}^i,\mathbf{P}^i,\nabla\varphi^i)\,d\mathbf{x}\ge\int_\Omega F_E(\mathbf{n}^\infty,\mathbf{P}^\infty,\nabla\varphi^\infty)\,d\mathbf{x}.$$

Since $\mathcal{W}$ is lower semicontinuous, we finally conclude that

$$\mathcal{E}^*(\mathbf{n}^\infty,\mathbf{P}^\infty,\omega^\infty)=\inf_{(\mathbf{n},\mathbf{P},\omega)\in\mathcal{A}^*}\mathcal{E}^*(\mathbf{n},\mathbf{P},\omega).\qquad\square$$

3.3. Applications. Problems analogous to the model problem of the previous subsection are often found in applications. Let us discuss two examples. First we consider the case of a liquid crystal contained in a dielectric liquid medium with free ions that form a charged layer of density σ on the interface. Letting Ω be a bounded domain occupied by liquid crystals, we are interested in a minimization problem of the energy functional (3.10) with an electric potential $\varphi\in W^{1,2}(\mathbf{R}^3)$, satisfying

$$\text{(3.20)}\qquad\begin{cases}-\nabla\cdot((\varepsilon_\perp\mathbf{I}+\varepsilon_a\mathbf{n}\otimes\mathbf{n})\nabla\varphi)=\nabla\cdot\mathbf{P}\text{ in }\Omega,\\ -\Delta\varphi=0\text{ in }\mathbf{R}^3-\bar\Omega,\\ -[(\varepsilon_\perp\mathbf{I}+\varepsilon_a\mathbf{n}\otimes\mathbf{n})\nabla\varphi-\varepsilon_0\nabla\varphi]\cdot\nu=\mathbf{P}\cdot\nu+\sigma\text{ on }\partial\Omega,\end{cases}$$

where ε_0 is the dielectric coefficient of the medium.

If φ is a solution of (3.20), then $\varphi+C$ is also a solution of (3.20) for any constant C. Define

$$\mathcal{V}=\left\{v\in W^{1,2}(\mathbf{R}^3);\int_{\mathbf{R}^3}v\,d\mathbf{x}=0\right\}.$$

By the standard theory of elliptic PDEs and calculus of variations, for given $\mathbf{n},\mathbf{P}$, the solution of (3.20) is corresponding to the minimizer of the energy functional $\mathcal{F}$ on $\mathcal{V}$

$$\begin{aligned}\mathcal{F}=&\frac12\int_\Omega[(\varepsilon_\perp\mathbf{I}+\varepsilon_a\mathbf{n}\otimes\mathbf{n})\nabla\varphi]\cdot\nabla\varphi\,d\mathbf{x}+\frac12\int_{\mathbf{R}^3-\bar\Omega}\varepsilon_0\nabla\varphi\cdot\nabla\varphi\,d\mathbf{x}\\&+\int_{\mathbf{R}^3}\mathbf{P}\chi_\Omega\cdot\nabla\varphi\,d\mathbf{x}+\int_{\partial\Omega}\sigma\varphi\,dS.\end{aligned}$$

Since $\mathcal{F}$ is $\mathcal{V}$-elliptic, there exists a unique minimizer φ, denoted by $\Phi(\mathbf{n},\mathbf{P})$, of $\mathcal{F}$ on $\mathcal{V}$. We substitute $\nabla\Phi(\mathbf{n},\mathbf{P})$ for $\mathbf{E}$ in the electrostatic energy $\int_{\mathbf{R}^3}F_E\,d\mathbf{x}$. Using similar arguments as in Theorems 3.3, and 3.4, we obtain the following corollary.

COROLLARY 3.5. *Assume that* $\min\{K_2,K_3\}\ge 8c_1$. *Then there exists a minimizing quadruple* $(\mathbf{n},\mathbf{P},\omega,\varphi)$ *of* $\mathcal{E}$ *on* $\mathcal{A}^*\times\mathcal{V}$ *satisfying* (3.20).

The second case comes up in device applications. Now the liquid crystal domain Ω is confined between two conducting plates Ω_1 and Ω_2. We assume that there is no free charge in Ω, and we neglect end-effects. In this case, the boundary value problem is stated as follows: For a given potential $\tilde\varphi$, find φ satisfying the following conditions:

$$\text{(3.21)}\qquad\begin{cases}\nabla\cdot(D(\nabla\varphi,\mathbf{n}))=\nabla\cdot\mathbf{P}\text{ in }\Omega,\\ -\Delta\varphi=0\text{ in }\mathbf{R}^3-\overline{\Omega\cup\Omega_1\cup\Omega_2},\\ \Big(D(\nabla\varphi,\mathbf{n})+\nabla\varphi\Big)\cdot\nu=\mathbf{P}\cdot\nu\text{ on }\partial\Omega\cap\partial(\mathbf{R}^3-\overline{\Omega\cup\Omega_1\cup\Omega_2}),\\ \varphi=\varphi_i\text{ in }\Omega_i\text{ for }i=1,2,\\ \varphi\to0\text{ as }|\mathbf{x}|\to\infty,\end{cases}$$

where $D(\nabla\varphi, \mathbf{n})$ is defined in (3.16) and φ_i, $i = 1, 2$, are constant potential functions. If φ_i is set to zero, $\nabla\varphi$ gives the electric field created by the polar distribution. Analogous boundary value problems for ferroelectric solids are considered in [35]. Since φ_i, $i = 1, 2$, are constant, we can consider $\varphi = \varphi_i$ as Dirichlet boundary conditions on Ω_i.

Let

$$\tilde{\Omega} = \mathbf{R}^3 - \overline{\Omega \cup \Omega_1 \cup \Omega_2}.$$

Then the solution of the problem (3.21) can be sought as the solution $\varphi \in W^{1,2}(\mathbf{R}^3 - \Omega_1 \cup \Omega_2)$ satisfying

$$\text{(3.22)} \qquad \begin{cases} \nabla \cdot (D(\nabla\varphi, \mathbf{n})) = \nabla \cdot \mathbf{P} \text{ in } \Omega, \\ -\Delta\varphi = 0 \text{ in } \tilde{\Omega}, \\ \varphi = \varphi_i \text{ on } \partial\Omega_i, \quad i = 1, 2, \\ \Big(D(\nabla\varphi, \mathbf{n}) + \nabla\varphi\Big) \cdot \nu = \mathbf{P} \cdot \nu \text{ on } \partial\Omega \cap \partial\tilde{\Omega}. \end{cases}$$

Define

$$\tilde{\mathcal{V}} = \{v \in W^{1,2}(\mathbf{R}^3 - \Omega_1 \cup \Omega_2); v = \varphi_i \text{ on } \partial\Omega_i, i = 1, 2\},$$

and

$$\tilde{\mathcal{F}} = \int_\Omega \{[(\varepsilon_\perp \mathbf{I} + \varepsilon_a \mathbf{n} \otimes \mathbf{n})\nabla\varphi] \cdot \nabla\varphi + \mathbf{P} \cdot \nabla\varphi\}\, d\mathbf{x} + \int_{\tilde{\Omega}} |\nabla\varphi|^2\, d\mathbf{x}.$$

We see that $\tilde{\mathcal{F}}$ is $\tilde{\mathcal{V}}$-elliptic. There exists a unique minimizer φ, denoted by $\Phi(\mathbf{n}, \mathbf{P})$, of $\tilde{\mathcal{F}}$ on $\tilde{\mathcal{V}}$. Repeating the same arguments as in previous problem, we conclude the corollary as below.

COROLLARY 3.6. *Assume that* $\min\{K_2, K_3\} \geq 8c_1$. *Then there exists a minimizing quadruple* $(\mathbf{n}, \mathbf{P}, \omega, \varphi)$ *of* $\mathcal{E}$ *on* $\mathcal{A}^* \times \tilde{\mathcal{V}}$ *satisfying* (3.22).

3.4. Shapes and polarization. We close this section with examples to illustrate the relationship between the nonlocal energy and the shape of the domain.

Example 1. *Uniformly polarized rectilinear cylinder.* Let Ω be a cylinder in $\mathbf{R}^3$, $x^2 + y^2 \leq r_1^2$, occupied by a smectic C material such that

$$\nabla\omega = \mathbf{e}_r, \quad \mathbf{n} = f(r)\mathbf{e}_r + g(r)\mathbf{e}_\theta, \quad \mathbf{P} = P_0\mathbf{k}.$$

Let $\tilde{\Omega}$ denote a second cylinder, $x^2 + y^2 \leq r_2^2$, $r_1 < r_2$. Suppose that $\mathbf{E}$ is the electric field on the cylindrical surface $\partial\tilde{\Omega}$. Applying Gauss' theorem to $\tilde{\Omega}$, we get

$$\int_{\partial\tilde{\Omega}} \mathbf{E} \cdot \nu\, dS = 0$$

since the net charge inside $\tilde{\Omega}$ is zero. By symmetry, we observe that $|\mathbf{E}|$ is constant on $\partial\tilde{\Omega}$, $\mathbf{E} \cdot \nu = |\mathbf{E}|$, and thus

$$\int_{\mathbf{R}^3 - \Omega} |\mathbf{E}|^2\, d\mathbf{x} = 0.$$

We note that the electric field $\mathbf{E}$ due to the polarization may not be zero outside Ω if the shape is nonsymmetric. For instance, in the case of a bent cylindrical domain,

FIG. 3.2. *A polarized helical filament.*

the electric field created by the polarization is not rotationally symmetric. Therefore, we cannot conclude that $|\mathbf{E}|$ is constant on $\partial\tilde{\Omega}$, and so $\mathbf{E}$ is, in general, nonzero on $\partial\tilde{\Omega}$. In this case, the self energy $\int_{\mathbf{R}^3-\Omega} |\mathbf{E}|^2 \, d\mathbf{x}$ is also nonzero.

Example 2. *Polarized helical filament.* In Example 1, we replace Ω by a thin filament [2],

$$\Omega = \{\mathbf{x} \in \mathbf{R}^3 : \mathbf{x} = \mathcal{C}(s) + \xi\mathbf{e}, s \in [0, l], \, \xi \in [0, r], \, \mathbf{e} \cdot \mathbf{T} = 0, \mathbf{e} \cdot \mathbf{e} = 1\},$$

where $\mathcal{C} : [0, l] \to \mathbf{R}^3$ is a smooth curve and $\mathbf{T}$ is the unit tangent vector. The domain Ω is a thin filament and not necessarily a right cylinder, as in Figure 3.2. Let $\mathbf{N}$ and $\mathbf{B}$ denote the normal and binormal vectors, respectively, to the curve.

The curve $\mathcal{C}$ represents the center curve of the curvilinear cylindrical domain Ω. We assume that for each $s \in [0, r]$ the smectic layer normal is parallel to $\mathbf{T}$, and the director field $\mathbf{n}$ is parallel to the plane determined by $\mathbf{T}$ and $\mathbf{B}$, making a constant tilt angle with $\mathbf{T}$. Accordingly, we set

$$\nabla\omega = \mathbf{T}, \quad \mathbf{n} = \alpha\mathbf{T} + \beta\mathbf{B}, \alpha^2 + \beta^2 = 1, \quad \mathbf{P} = -P_0\mathbf{N}.$$

Define a coordinate system (s, ξ, θ) so that

$$\mathbf{e}_\xi = \cos\theta\mathbf{N} + \sin\theta\mathbf{B}, \qquad \mathbf{e}_\theta = -\sin\theta\mathbf{N} + \cos\theta\mathbf{B}.$$

Since the net charge in $\tilde{\Omega}$ is zero, by Gauss' theorem

$$\int_{\partial\tilde{\Omega}} \mathbf{E} \cdot \nu \, dS = 0.$$

In general, though, we cannot conclude that $\mathbf{E}$ is symmetric around the curve $\mathcal{C}$, and so $\mathbf{E}$ may not be zero outside the filament region. Now the question is whether or not there is a shape such that $\mathbf{E} = \mathbf{0}$ in $\mathbf{R}^3 - \Omega$. Heuristically, we can view such a shape as the limiting case of a helical filament as the pitch approaches zero. Note that this would allow us to recover the symmetry property of the domain and of the electric field, and conclude that $\int_{\mathbf{R}^3-\Omega} |\mathbf{E}|^2 \, d\mathbf{x}$ is negligible.

4. Classification of energy minimizers. We apply asymptotic arguments to determine whether energy minimizers correspond to either helical configurations or ferroelectric ones. In this section, we consider the energy as in (2.14). We wish to identify the smectic layer geometry and find parameter conditions leading to helical director configurations in the bulk with zero average polarization, as well as those giving homogeneous ferroelectric states. For this, we will consider a rectangular domain between two parallel plates:

$$\Omega = \{\mathbf{x} = (x, y, z) : \, 0 < y, z < L, \; 0 < x < d\},$$

for fixed $0 < L$, $0 < d$. Let $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ denote the corresponding orthonormal system of vectors.

4.1. Helical energy minimizers. We determine the structure of the energy minimizers $(\mathbf{n}, \omega, \mathbf{P})$ when K_2 and K_3 as well as the smectic coefficients dominate over the Ginzburg–Landau energy and surface energy parameters, and $C_\perp < 0$. Such a situation arises at temperatures below the threshold of the smectic A to smectic C transition, yielding helical configurations of $\mathbf{n}$ and $\mathbf{P}$. It is well known that in the higher temperature transition from nematic to smectic A, K_2 becomes unbounded and the smectic coefficient $C_\perp \geq 0$.

We take the admissible set so that

$$k = q\sqrt{\frac{|C_\perp|}{2Dq^2} + 1}. \tag{4.1}$$

We consider admissible fields such that $\mathbf{n}$ makes a constant angle α with the layer normal vector $\nabla\omega$. We also choose α such that

$$\tan\alpha = \sqrt{\frac{|C_\perp|}{2Dq^2}}. \tag{4.2}$$

Specifically, we let

$$\begin{cases} \mathbf{n}_0 = (a\cos\frac{\tau z}{a^2}, a\sin\frac{\tau z}{a^2}, c), \\ a = \sin\alpha \neq 0, \qquad c = \cos\alpha \neq 0, \qquad \frac{a^2}{c^2} = \frac{|C_\perp|}{2Dq^2}, \\ \mathbf{P}_0 = \frac{c\tau}{a}(-\sin\frac{\tau z}{a^2}\mathbf{i} + \cos\frac{\tau z}{a^2}\mathbf{j}), \\ \omega_0 = kz, \qquad k = \frac{q}{c}, \qquad \nu = \mathbf{i}. \end{cases} \tag{4.3}$$

A simple calculation gives

$$\begin{aligned} &\nabla\omega_0 \cdot \mathbf{n}_0 = q, \qquad \triangle\omega_0 = 0, \qquad |\nabla\omega_0 - q\mathbf{n}_0|^2 = \frac{|C_\perp|}{2D}, \\ &\nabla\cdot\mathbf{n}_0 = 0, \qquad \mathbf{n}_0\cdot\nabla\times\mathbf{n}_0 + \tau = 0, \qquad |\mathbf{n}_0\times(\nabla\times\mathbf{n}_0) + \mathbf{P}_0| = 0, \\ &\nabla\cdot\mathbf{P}_0 = 0, \qquad |\nabla\mathbf{P}_0| = \frac{c\tau^2}{a^3}, \qquad \mathbf{P}_0 = \nabla\omega_0\times\mathbf{n}_0. \end{aligned}$$

We observe that the quantity $\tan\alpha = \sqrt{\frac{|C_\perp|}{2Dq^2}}$ is of the order of $\tan\frac{\pi}{6}$ according to experimental measurements of the director tilt angle. This, together with available information on the wave number q in the smectic A phase, allows us to determine the relative value of the smectic parameters $|C_\perp|$ and D.

The total energy corresponding to the fields in (4.3) is given by

$$\begin{aligned} \mathcal{E}_0 = L^2 d\left[r + \frac{g}{2} - \frac{C_\perp^2}{4D} + (K_2+K_4)\frac{\tau^2}{a^2} + \frac{c^2\tau^2}{a^2}\left(B\frac{\tau^2}{a^4} + a_0 + b_0\frac{c^2}{a^2}\tau^2\right)\right] \\ + (2L^2 + 4dL)(C_p\omega_p + C_r\omega_r + C_n\omega_n), \end{aligned}$$

where C_r, C_p, C_n are expressions involving a, c, q, and τ.

Letting $K_0 = \frac{1}{2}\min\{K_2, K_3\}$, we write the Oseen–Frank energy as follows:

$$\begin{aligned} F_N = &(K_2 - K_0)(\mathbf{n}\cdot\nabla\times\mathbf{n} + \tau)^2 + (K_3 - K_0)|n\times\nabla\times\mathbf{n} + \mathbf{P}|^2 \\ &+ (K_1 - K_2 - K_4)(\nabla\cdot\mathbf{n})^2 + (K_2+K_4)|\nabla\mathbf{n}|^2 \\ &+ K_0|\mathbf{n}\cdot\nabla\times\mathbf{n} + \tau|^2 + K_0|\mathbf{n}\times\nabla\times\mathbf{n} + \mathbf{P}|^2 - (K_2+K_4)|\nabla\times\mathbf{n}|^2. \end{aligned} \tag{4.4}$$

We invoke the following estimate of the last three terms:

$$K_0(|\mathbf{n}\cdot\nabla\times\mathbf{n}+\tau|^2+|\mathbf{n}\times\nabla\times\mathbf{n}+\mathbf{P}|^2)-(K_2+K_4)|\nabla\times\mathbf{n}|^2 \geq -4c_1(\tau^2+2|\mathbf{P}|^2).$$

We then obtain the following estimates:

$$\int_{\partial\Omega} G_S\,dS \geq -\left[2|\omega_p|+2|\omega_r|+|\omega_n|(1+|\alpha|)\right](2L^2+4dL),$$
$$\int_{\Omega}(F_{Sm}+F_N+G_P)\,d\mathbf{x} \geq \left[r+\frac{g}{2}-\left(\frac{C_\perp^2}{4D}+\frac{(a_0-8c_1)^2}{4b_0}+4c_1\tau^2\right)\right]dL^2.$$

Letting $(\mathbf{n},\mathbf{P},\omega)$ denote an energy minimizer, we get

$$\begin{aligned}0 &\leq \mathcal{E}(\mathbf{n},\mathbf{P},\omega)+[2|\omega_p|+2|\omega_r|+|\omega_n|(1+|\alpha|)](2L^2+4dL)\\ &\quad+\left[\frac{C_\perp^2}{4D}+\frac{(a_0-8c_1)^2}{4b_0}+4c_1\tau^2-r-\frac{g}{2}\right]dL^2\\ &\leq \mathcal{E}_0+[2|\omega_p|+2|\omega_r|+|\omega_n|(1+|\alpha|)](2L^2+4dL)\\ &\quad+\left[\frac{C_\perp^2}{4D}+\frac{(a_0-4c_1)^2}{4b_0}+4c_1\tau^2-r-\frac{g}{2}\right]dL^2\equiv\bar{\mathcal{E}}_0.\end{aligned}\tag{4.5}$$

Since $\frac{|C_\perp|}{2Dq^2}$ is bounded, we note that the quantity on the right-hand side of the inequality is independent of D, $C_\perp$, K_1, K_2, and K_3, with the only K_i constants appearing as the sum K_2+K_4. From (4.5) together with (3.12) and (3.13) we get the following theorem.

THEOREM 4.1. *Let $q>0$, $\tau>0$ be fixed. Suppose that the constitutive parameters satisfy assumptions* (3.1)–(3.3). *Suppose that $K_2,K_3\geq 8c_1$ and $0<\frac{|C_\perp|}{2Dq^2}\leq 1$. If $(\mathbf{n},\mathbf{P},\omega)$ is a minimizer of $\mathcal{E}$, then the following estimates hold:*

$$||(\nabla\omega\times\mathbf{n})|\mathbf{P}|-\mathbf{P}(|\nabla\omega\times\mathbf{n}|)||_{2,\Omega}^2\leq\epsilon^2\bar{\mathcal{E}}_0,\tag{4.6}$$

$$||\nabla\mathbf{n}||_{2,\Omega}\leq\frac{\bar{\mathcal{E}}_0}{K_2+K_4},\tag{4.7}$$

$$||\mathbf{n}\times\nabla\times\mathbf{n}+\mathbf{P}||_{2,\Omega}^2\leq\frac{\bar{\mathcal{E}}_0}{\min\{K_2,K_3\}},\tag{4.8}$$

$$||\mathbf{n}\cdot\nabla\times\mathbf{n}+\tau||_{2,\Omega}^2\leq\frac{\bar{\mathcal{E}}_0}{\min\{K_2,K_3\}},\tag{4.9}$$

$$\left\|\left|\frac{1}{q}\nabla\omega-\mathbf{n}\right|^2-\frac{|C_\perp|}{2Dq^2}\right\|_{2,\Omega}^2\leq\frac{\bar{\mathcal{E}}_0}{Dq^2},\tag{4.10}$$

$$\left\|\frac{1}{q}\nabla\omega\cdot\mathbf{n}-1\right\|_{2,\Omega}^2\leq\frac{\bar{\mathcal{E}}_0}{C_a},\tag{4.11}$$

$$||\nabla\mathbf{P}||_{2,\Omega}\leq\frac{\bar{\mathcal{E}}_0}{B}.\tag{4.12}$$

Next, we proceed to take limits in (4.6)–(4.11). We use the following representation for $\mathbf{n}$:

$$\mathbf{n}=\sin\theta\cos\phi\mathbf{i}+\sin\theta\sin\phi\mathbf{j}+\cos\theta\mathbf{k},$$

where $\phi = \phi(x, y, z)$ and $\theta = \theta(x, y, z)$ are functions resulting from energy minimization.

THEOREM 4.2. *Suppose that the hypotheses of the previous theorem hold. Then the energy minimizing fields* $(\mathbf{n}, \mathbf{P}, \omega)$ *satisfy the following limiting relations:*

$$\lim_{C_a \to \infty} \nabla\omega \cdot \mathbf{n} = q, \tag{4.13}$$

$$\lim_{|C_\perp| \to \infty} |\nabla\omega| = q\sqrt{\frac{|C_\perp|}{2Dq^2} + 1}, \tag{4.14}$$

$$\lim_{\epsilon \to 0} \mathbf{P} = \cot\alpha\tau \frac{\mathbf{k} \times \mathbf{n}}{|\mathbf{k} \times \mathbf{n}|}, \quad \cot\alpha = \sqrt{\frac{2Dq^2}{|C_\perp|}}, \tag{4.15}$$

$$\lim_{K \to \infty} (\mathbf{n} \times \nabla \times \mathbf{n} + \mathbf{P}) = 0, \tag{4.16}$$

$$\lim_{K \to \infty} (\mathbf{n} \cdot \nabla \times \mathbf{n} + \tau) = 0, \tag{4.17}$$

where $K = \min\{K_2, K_3\}$. *Furthermore, we get*

$$\lim_{|C_\perp| \to \infty} \omega = \left(q\sqrt{\frac{|C_\perp|}{2Dq^2} + 1} \right) z, \tag{4.18}$$

$$\lim_{K \to \infty} \mathbf{n} = \sin\alpha \cos\frac{\tau}{a^2} z\mathbf{i} + \sin\alpha \sin\frac{\tau}{a^2} z\mathbf{j} + \cos\alpha\mathbf{k}. \tag{4.19}$$

Proof. From the geometry of the domain and the boundary conditions, it follows that $\nabla\omega = |\nabla\omega|\mathbf{k}$, which together with (4.10) and (4.11) yields (4.13), (4.14), and (4.18). It now follows from (4.13) and (4.14) that $\theta = \alpha$ is the constant given by (4.2). These together with (4.6) yield $\mathbf{P} = |\mathbf{P}|\frac{\mathbf{k}\times\mathbf{n}}{|\mathbf{k}\times\mathbf{n}|}$. Combining this equation with (4.16) and (4.17) gives $\phi = \frac{\tau}{a^2} z$ in (4.19). This also yields (4.15). ∎

Note that from the property $\lim_{D\to\infty}(\triangle\omega - q\nabla\cdot\mathbf{n}) = 0$ it follows that the limiting director field has zero divergence, in agreement with (4.19).

4.2. Ferroelectric energy minimizers. In the previous theorem, the elasticity constants K_2 and K_3 become unbounded with respect to the parameters of the polarization contribution to the energy. We will show that the ferroelectric configurations,

$$\mathbf{n} = \pm\sin\alpha\mathbf{j} + \cos\alpha\mathbf{k}, \quad \mathbf{P} = \pm P_0\mathbf{i}, \quad P_0 = \sqrt{\frac{|a_0|}{b_0}}, \tag{4.20}$$

with α the constant in (4.15), are limits of minimizers at the limit of K_1 large, and when the polar coefficients ω_p and ω_r dominate over the twist and bending elasticity constants K_2 and K_3. This situation occurs at temperatures lower than those of the helical regime. The role of the surface energy is also relevant in such a case.

Next, we take the following set of admissible fields to determine the ferroelectric limits:

$$\mathbf{n} = \pm\sin\alpha\mathbf{j} + \cos\alpha\mathbf{k}, \quad \mathbf{P} = \pm\sqrt{\frac{|a_0|}{b_0}}\mathbf{i}, \tag{4.21}$$

with $0 < \alpha < \frac{\pi}{2}$, and ω as in (4.15) and (4.18), respectively. We find that the energy $\mathcal{E}_1$ corresponding to such fields is

(4.22)
$$\mathcal{E}_1 = L^2 \left[\left(K_2 \tau^2 + \frac{|a_0|}{b_0} K_3 \right) d + 2 \left(\omega_p + \omega_r + \omega_n - \left(\frac{|a_0|}{b_0} \right)^2 \omega_r - \alpha_0 \omega_n \sin^2 \alpha \right) \right].$$

Replacing $\mathcal{E}_0$ with $\mathcal{E}_1$, the estimates of Theorem 4.1 hold. These allow us to establish the following asymptotic limits of minimizers:

$$\nabla \cdot \mathbf{n} = 0 \quad \text{as} \quad K_1 \to \infty, \tag{4.23}$$

$$|\nabla \omega| = k \quad \text{as} \quad |C_\perp| \to \infty. \tag{4.24}$$

Letting $D \to \infty$ and taking (4.23) into account, it follows that $\triangle \omega = 0$. This together with the boundary conditions on $\partial\Omega$ gives $\nabla\omega = (0, 0, k)$, with k as in (4.1). Moreover, letting $C_a \to \infty$ gives $\cos\alpha = \frac{q}{k}$, and $\mathbf{P} = \sqrt{\frac{|a_0|}{b_0}} \frac{\mathbf{k}\times\mathbf{n}}{|\mathbf{k}\times\mathbf{n}|}$ results by letting $\epsilon \to 0$ and using the expression for $\nabla\omega$. By letting $\omega_r \to \infty$, we get $\phi = \pm\frac{\pi}{2}$.

We finally make the following remarks:

1. The limiting fields $(\mathbf{n}, \mathbf{P}, \omega)$ given by (4.18) and (4.20) satisfy the Euler–Lagrange equations with the prescribed boundary conditions.

2. Likewise, $(\mathbf{n}, \mathbf{P}, \omega)$ as in (4.18) and (4.19) solve the Euler–Lagrange equations at the limit $|C_\perp| \to \infty$.

5. Conclusions. We studied modeling of ferroelectric smectic C* liquid crystals and investigated nonlocal electrostatic effects. We discussed how the proposed model is consistent with well-known approaches found in the physics literature. We proved existence of minimizers for the total energy by means of direct methods of calculus of variations, within the class of fields satisfying physically relevant boundary conditions, with respect to the layering configuration. We presented examples to illustrate the relationship between domain shape and reduction of the nonlocal energy. For instance, we argued that a thin filament may become helical in order to lower the nonlocal energy. We also studied the asymptotic properties of the energy minimizers as the parameters of the energy become unbounded upon the temperature reaching transition values from smectic C* to lower temperature ferroelectric limits.

Acknowledgments. The authors would like to thank professor Marta Lewicka and professor Baisheng Yan for many interesting comments and suggestions, and the referees for carefully reading the manuscript.

A MUMFORD–SHAH LEVEL-SET APPROACH FOR GEOMETRIC IMAGE REGISTRATION*

MARC DROSKE† AND WOLFGANG RING‡

Abstract. A new method for nonrigid registration of multimodal images is presented. Due to the large interdependence of segmentation and registration, the approach is based on simultaneous segmentation and edge alignment. The two processes are directly coupled and thus benefit from using complementary information of the entire underlying data set. The approach is formulated as a bivariate, variational, free discontinuity problem in the Mumford–Shah framework. A geometric variable describing the contour set and a functional variable which represents the underlying deformation are simultaneously identified. The contour set is represented by a level-set function. We derive a regularized gradient flow and describe an efficient numerical implementation using finite element discretization and multigrid techniques. Finally, we illustrate the method in several applications, such as multimodal intrapatient registration and reconstruction by registration to a reference object.

Key words. image registration, active contours, level-set method, shape sensitivity analysis, Mumford–Shah functional

1. Introduction.

We consider the problem of *image registration* for two given images which show different or complementary features of the same physical reality. Typical situations occur if the two images are obtained using different medical sensoring methods applied to the same patient or if the images show the same anatomical location but are obtained from different patients or from the same patient but at different times. Generally speaking, the aim of image registration is the assignment of complementary anatomical, physical, biological, functional, or other information obtained by different imaging devices to one geometric reference model. To do this, it is necessary to identify corresponding spatial points in the given image domains. The spatial equivalence of points in different images is expressed via a transformation map from one image domain into the other.

The need to register two data sets occurs in various applications, especially in medicine, geophysics, and computer vision. In the last two decades there has been a steep increase in the variety as well as the quality of modern (especially medical) imaging technology, thus making a large amount of information, either anatomical (e.g., computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, densitometry computed tomography (DXA)) or functional (e.g., functional MRI, positron

emission tomography (PET, SPECT)), available for routine clinical use. The ability to combine complementary information provided by different imaging devices has proved to be of significant benefit to the clinician. For instance, in radiotherapy treatment planning, CT is mainly used, while MRI allows a detailed analysis of the tumor tissue. For all forms of medical treatment where two or more imaging techniques are applied to examine a patient, or where images of different patients are compared and where accurate knowledge about the location of the relevant objects is necessary, registration is an unavoidable task. One of the most important applications of registration techniques is in surgery planning guided by complementary imaging devices. In Figure 3 two different images of the same patient using different types of MRI scanners are shown. The obtained spatial correspondence (the transformation map) between the two images is shown below using a nonlinearly distorted mesh as visualization of the transformation. We mention already at this point that we shall present an approach where features that are present in both images and have a certain type of *geometrical similarity* are mapped onto each other. Thus, reference and template images which have very different intensity distributions but have certain geometrical features in common can be registered. An example using synthetic multimodal images (i.e., images which contain very different information but share certain geometric properties) is presented in Figure 1.

The transformation (the spatial correspondence of like points) itself can also provide important additional information. A transformation between subsequent images obtained at a very low temporal resolution can give insight into growth processes of characteristic objects found in the image. In this context, the variations between subsequent image acquisitions may be substantial, leading to difficulties for differential approaches such as *optical-flow* estimation. Furthermore, the resulting transformation of a registration to a healthy reference dataset may be useful in measuring the extent of the pathology of the individual patient. Scale-space and multiresolution methods have become a widely used methodology for variational registration approaches [21, 35, 36, 46], and a wide range of regularization techniques and similarity measures are known [26, 39, 43, 45, 47, 62].

Depending on the nature of the underlying input data, the *richness* of the space of possible deformations plays an important role. If it is a priori known that the given multichannel data can be registered by a rigid transformation, the unknowns within the representation are only the offset and the angle of the rigid transformation. In that case, regularity of the deformation is automatically guaranteed by the choice of the space of admissible transformations. In many applications, especially interpatient-registration, it is, however, of crucial importance to choose a space of transformations with larger flexibility in order to be able to resolve local variations in fine geometrical details, offering the possibility of a comprehensive analysis of the deformation field. In case of medical time series analysis of a single patient, growth processes of pathological objects such as tumors are of significant interest for diagnosis as well as surgery planning. In what follows, the computational resolution of the discretization of the deformation will be the same as the resolution of the input images, thus allowing a registration of details down to pixel accuracy. However, we want to point out that different (coarser) spaces of deformations may be incorporated in our approach in a straightforward manner.

The paper is organized as follows. In section 2 the approach of coupling registration to segmentation by the Mumford–Shah functional is formulated as a bivariate, variational, free discontinuity problem. Furthermore, different regularization techniques are discussed. In section 3 we present the necessary shape sensitivity analysis

using the conceptional framework of shape derivatives. This eventually leads to the formulation of a gradient flow equation for the given cost functional. To stabilize the shape gradient method, we propose regularizations for both the descent directions for the shape variable and the functional variable. This is done in section 4. In section 5 we will describe the actual algorithm used to compute stationary points of the variational formulation proposed in section 2. Composite finite elements (CFEs) as introduced by Hackbusch and Sauter [34] (see also [55, 61]) provide an elegant approach for the discretization of PDEs on complicated domains and, further, allow one to circumvent numerical difficulties for problems with discontinuous coefficients, especially in the context of multigrid solvers. Since we will treat the variational formulation as a shape optimization problem with contours evolving according to the shape analysis, and—as it turns out—certain elliptic PDEs have to be solved in every gradient step, we chose the CFE framework to incorporate efficient multigrid solvers. This is described briefly in section 6. Finally, computational results are presented in section 7, and a final conclusion is drawn in section 8.

2. Problem formulation. It is the aim of this paper to find a registration between two given images based on a matching of the edges in the images. In their pioneering paper, Mumford and Shah [49] introduced the following energy functional:

$$E_{\mathrm{MS}}(u,\Gamma) = \mu \int_\Omega (u-u_d)^2 \,\mathrm{d}\mathbf{x} + \int_{\Omega\setminus\Gamma} |\nabla u|^2 \,\mathrm{d}\mathbf{x} + \alpha \mathcal{H}^{n-1}(\Gamma), \tag{2.1}$$

where u_d is a given image defined on an open bounded set $\Omega \subset \mathbb{R}^n$ and u is aimed to be an approximation of u_d which should be smooth on $\Omega \setminus \Gamma$, where Γ is the set of potential edges (i.e., subsets of Hausdorff dimension $n-1$ located at singularities of the given image). Here $\mathcal{H}^{n-1}$ denotes the $(n-1)$-dimensional Hausdorff measure, and μ, α are positive weights, which control the balance between data fit, regularization of the reconstruction u on $\Omega\setminus\Gamma$, and the length of the contour Γ, respectively. Existence theory for (2.1) was established after De Giorgi, Carriero, and Leaci [27] proposed considering the minimization of an equivalent energy depending on u only. In this formulation, the energy given by an integral over the entire domain Ω and Γ is represented by S_u, the complement set of Lebesgue points of u, i.e., the measure theoretic discontinuity set of u. It can be proved (cf. Ambrosio, Fusco, Pallara [2, sect. 7.2, pp. 347–354], Braides [9, sect. 2.4, pp. 36–38]) using compactness in $SBV(\Omega)$ and lower-semicontinuity theorems, that—under mild conditions—there exists a solution $u \in SBV(\Omega)$ with $\mathcal{H}^{n-1}(S_u) < \infty$. Here $SBV(\Omega)$ denotes the space of special functions of bounded variation, i.e., functions for which S_u is a σ-finite $(n-1)$-dimensional Borel set. From the numerical point of view, discretizing the singularity set poses a serious problem. Various approximations of the Mumford–Shah functional have been introduced and Γ-convergence results have been proved (cf., e.g., [3, 4, 7, 54]). Ambrosio and Tortorelli [4], for example, proposed a phase-field type regularization and introduced an auxiliary variable which itself is regularized by an elliptic functional. Here, we refer to Feng and Prohl [32] for the numerical analysis of the phase-field approximation. Bourdin and Chambolle [8] proved Γ-convergence of the corresponding discrete finite element schemes.

The Mumford–Shah model has turned out to be very versatile and has been extended and applied in various ways [15, 23, 24, 25, 48, 58]. Esedoglu and Shen [30] suggested an inpainting method based on the Mumford–Shah idea. Further modifications have been made concerning the data-fit term in the Mumford–Shah functional, where the simple L^2 distance has been replaced by more elaborate data-fit criteria

[58]. Recently Unal and Slabaugh [59] have introduced a joint regularization and segmentation algorithm using a piecewise constant Mumford–Shah model in the level-set context which is similar to our approach.

2.1. A Mumford–Shah functional for simultaneous segmentation and registration. In this paper we shall use a Mumford–Shah idea for simultaneously finding the singularity sets in two given images and mapping the respective sets (and with them the two images) onto each other. We do not use a reformulation of the Mumford–Shah functional in the sense of De Giorgi, Carriero, and Leaci [27]. Instead, we will discretize the discontinuity set Γ directly by a level-set function. For the purpose of segmentation and registration we can confine to simple interface sets, which can be elegantly described and propagated via the level-set approach of Osher and Sethian [53]. See also the monographs [56, 51] and the collection [52] for comprehensive introductions to level-set techniques. Level-set methods have been successfully applied in various geometric segmentation models [18, 12, 13, 41, 58, 44, 51, 60]. In [37] Hintermüller and Ring have derived a Newton-type regularized optimization algorithm for minimizing the Mumford–Shah functional by representing Γ by a level-set function.

In our approach to the segmentation-registration problem, the edge sets in the images are found as minimizers of Mumford–Shah functionals and are mapped onto each other by the registration mapping Φ. To be more precise, the edge sets are found in such a way that a level-set encoded contour describes the edge set in the reference image, and, simultaneously, a transformation of the contour by a regular deformation matches the edge set of the template image. This is demonstrated in Figure 1, where only a small part of the edges actually overlap. We emphasize that this viewpoint is different from splitting this process into successively identifying the edge sets first and determining the corresponding deformation which maps these sets onto each other afterwards.

Naturally, the strategy described above would determine the registration map only on the edge set. Therefore, an energy term acting on Φ is added to the Mumford–Shah energy to ensure uniqueness for the registration mapping away from the edge set. As mentioned above, we choose the formulation of the Mumford–Shah energy which is defined for independent geometric and functional variables as described, e.g., in [5, section 4.2.1]. In this formulation, the problem of minimizing the Mumford–Shah functional can be treated as a shape optimization problem and solved numerically using level-set techniques [16, 18, 17, 37]. More precisely, we consider the functional

$$E_{\mathrm{MS}}(\Gamma,\Phi,R,T) = \frac{1}{2}\int_D |R-R_0|^2\,\mathrm{d}\mathbf{x} + \frac{\mu}{2}\int_{D\setminus\Gamma} |\nabla R|^2\,\mathrm{d}\mathbf{x} + \frac{1}{2}\int_D |T-T_0|^2\,\mathrm{d}\mathbf{x} + \frac{\mu}{2}\int_{D\setminus\Gamma^\Phi} |\nabla T|^2\,\mathrm{d}\mathbf{x} + \alpha\mathcal{H}^{N-1}(\Gamma) \tag{2.2}$$

(the additional regularization term on Φ is omitted for the moment). Here $D \subset \mathbb{R}^n$ is the domain of definition of the images with $n = 2, 3$, the data T_0 and R_0 are the given template and reference images, $\Gamma \subset D$ is (an approximation of) the edge set of the given image R_0, and $\Gamma^\Phi = \Phi(\Gamma)$ is the transformed edge set Γ under the transformation Φ. Strictly speaking, the term "edge sets of the data images" does not make sense, since the input images only have to be in L^2. When using this term we mean (approximations of) the measure theoretic discontinuity sets of the SBV functions R and T which *approximate* R_0 and T_0 in the Mumford–Shah sense. In the following we make the simplifying assumption that $\Gamma = \partial\Omega$ for an open set Ω with

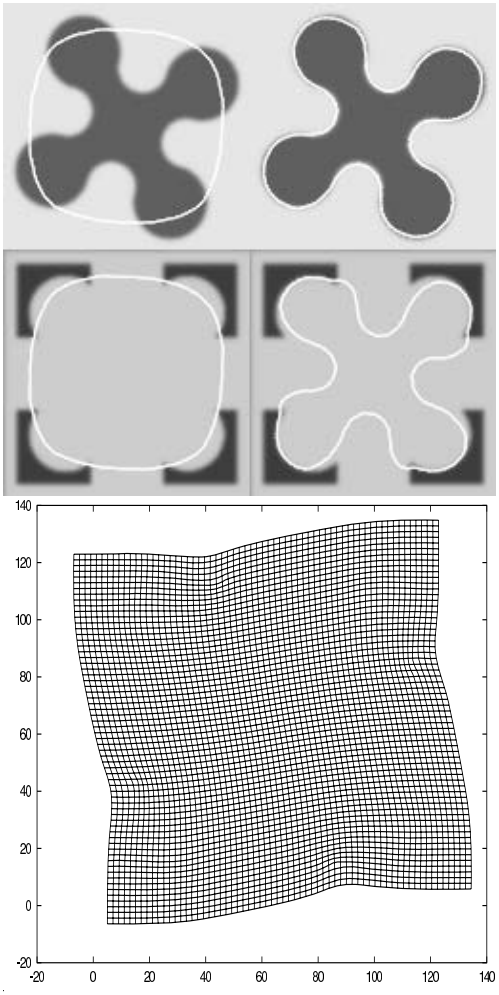

FIG. 1. *Multimodal complementary registration. The two images in the left column of the top figure show the initial contour* Γ *in the images* R *and* T*, where the initial deformation is the identity. In the right column the resulting contours, coupled by the deformation, are shown after* 75 *steps of the regularized gradient descent. The corresponding transformation is shown in the bottom figure using a distorted mesh for visualization.*

$\overline{\Omega} \subset D$. This assumption is justified if the edge sets in the data are related to object boundaries as is usually the case in medical data sets.

Let us point out here that different approaches can be used to drive the contour Γ towards the significant features of the images. A geodesic active contour model as proposed by Caselles, Kimmel, and Sapiro [14], would, e.g., lead to a coupled energy of the form

$$E_{\mathrm{ac}}(\Gamma, \Phi) = \int_{\Gamma} g_R d\mathcal{H}^{n-1} + \nu \int_{\Omega} g_R \, \mathrm{d}\mathbf{x} + \int_{\Gamma^{\Phi}} g_T d\mathcal{H}^{n-1} + \nu \int_{\Omega} g_T \, \mathrm{d}\mathbf{x}, \tag{2.3}$$

where g_R and g_T are suitable edge detectors for the images R and T. A common choice is, for example, $g_I(x) = \frac{1}{1+s|\nabla I|^2}$, $s > 0$, with $I = R$ or $I = T$. The idea of coupling segmentation with registration has also been proposed by Kapur, Yezzi,

and Zöllei [40]. So far the described methods depend on the matching of contours. Yet another approach for the registration of images is the matching of geometrical descriptors as described in [29]. The identification and subsequent matching of geometrical descriptors other than edges within a Mumford–Shah framework, however, have not yet been considered.

As already pointed out, the transformation Φ is not uniquely determined by the functional (2.2). Thus, an additional regularization term E_{reg} is necessary. Writing the transformation $\Phi = \mathbf{id} + \mathbf{d}$ with a displacement vector field $\mathbf{d} : D \to \mathbb{R}^2$, we use $\mathbf{d}$ as the optimization variable instead of Φ. We set

$$E(\Gamma, \mathbf{d}, R, T) = E_{\mathrm{MS}}(\Gamma, \mathbf{d}, R, T) + \nu E_{\mathrm{reg}}(\mathbf{d}). \tag{2.4}$$

In the following we will use Φ and $\mathbf{d}$ synonymously to denote the transformation.

There are a wide range of different choices of regularization energies in the literature. Apart from adding a Dirichlet integral, which corresponds to a regularization as proposed by Horn and Schunk in [38], and anisotropic inhomogeneous regularizations introduced by Nagel and Enkelmann in [50]—both originally appearing in the *optical-flow* context—linearized elastic regularizations are widely used. In [29] Droske and Rumpf proposed a nonlinear elastic polyconvex regularization energy [19] of the form

$$E_{\mathrm{reg}}(\mathbf{d}) = \int_\Omega \alpha \|\nabla \mathbf{d}\|^p + \beta \|\mathbf{Cof}\, \nabla \mathbf{d}\|^q + \gamma(\det \mathbf{d})\, \mathrm{d}\mathbf{x}, \tag{2.5}$$

where $\gamma(s) \to \infty$ for $s \to 0, \infty$. Here $\mathbf{Cof}\, A \in \mathbb{R}^{n\times n}$ denotes the cofactor matrix of a matrix $A \in \mathbb{R}^{n\times n}$. This approach allows one to utilize injectivity techniques for elasticity introduced by Ball [6] in order to ensure that the resulting deformation is a homeomorphism. In the context of aligning feature sets this is particularly important, since we want the transformed contour Γ^Φ to have the same topology as Γ. An extensive discussion of appropriation regularization terms penalizing the departure from rigidity in the context of image registration can be found in Keeling and Ring [42].

At this point of the investigation, the study of different regularization strategies is not our major objective. For the sake of simplicity we will use the Dirichlet integral

$$E_{\mathrm{reg}}(\mathbf{d}) = \|\mathbf{d}\|^2_{\mathbf{H}^1_0(D)} = \int_D \|\nabla \mathbf{d}\|^2\, \mathrm{d}\mathbf{x} \tag{2.6}$$

as regularization term for the remainder of this paper.

2.2. The reduced functional. The functional (2.4) is quadratic in the variables R and T. It is therefore possible to minimize E with respect to R and T for fixed Γ and $\mathbf{d}$ by solving a linear optimality system. With this, we can consider the reduced functional

$$\hat{E}(\Gamma, \mathbf{d}) = E(\Gamma, \mathbf{d}, R(\Gamma), T(\Gamma, \mathbf{d})), \tag{2.7}$$

where $R(\Gamma)$ and $T(\Gamma, \mathbf{d})$ denote the minimizers of (2.4) for fixed Γ and $\mathbf{d}$ with respect to R and T. It is obvious that $R(\Gamma)$ depends only on Γ, whereas $T(\Gamma, \mathbf{d})$ depends also on $\mathbf{d}$ via the domain of integration $D \setminus \Gamma^{\mathbf{d}} = D \setminus \Gamma^{\Phi(\mathbf{d})}$ in the last term in (2.2). If we specify the functional spaces for the variables R and T as $R \in H^1(D \setminus \Gamma)$ and

$T \in H^1(D \setminus \Gamma^{\mathbf{d}})$, we find $R(\Gamma)$ and $T(\Gamma, \mathbf{d})$ as solutions to the system of optimality conditions

$$\begin{aligned} \left\langle \frac{\partial E}{\partial R}, \varphi \right\rangle_{(H^1(D\setminus\Gamma))^*, H^1(D\setminus\Gamma)} &= 0 \quad \text{for all } \varphi \in H^1(D \setminus \Gamma), \\ \left\langle \frac{\partial E}{\partial T}, \psi \right\rangle_{(H^1(D\setminus\Gamma^{\mathbf{d}}))^*, H^1(D\setminus\Gamma^{\mathbf{d}})} &= 0 \quad \text{for all } \psi \in H^1(D \setminus \Gamma^{\mathbf{d}}). \end{aligned} \tag{2.8}$$

This yields

$$\mu \int_{D\setminus\Gamma} \langle \nabla R(\Gamma), \nabla \varphi \rangle \, \mathrm{d}\mathbf{x} + \int_{D\setminus\Gamma} R(\Gamma)\, \varphi \, \mathrm{d}\mathbf{x} = \int_{D\setminus\Gamma} R_0 \, \varphi \, \mathrm{d}\mathbf{x} \tag{2.9}$$

for all $\varphi \in H^1(D \setminus \Gamma)$ and

$$\mu \int_{D\setminus\Gamma^{\mathbf{d}}} \langle \nabla T(\Gamma, \mathbf{d}), \nabla \psi \rangle \, \mathrm{d}\mathbf{x} + \int_{D\setminus\Gamma^{\mathbf{d}}} T(\Gamma, \mathbf{d})\, \psi \, \mathrm{d}\mathbf{x} = \int_{D\setminus\Gamma^{\mathbf{d}}} T_0 \, \psi \, \mathrm{d}\mathbf{x} \tag{2.10}$$

for all $\psi \in H^1(D \setminus \Gamma^{\mathbf{d}})$.

3. Sensitivity analysis. In this section we derive the expressions for the derivatives $\langle \frac{\partial \hat{E}}{\partial \mathbf{d}}, \boldsymbol{\delta} \rangle$ and $d\hat{E}\,((\Gamma, \mathbf{d}), F)$. The latter expression denotes the Eulerian derivative of the functional $\hat{E}$ in the direction of a perturbation vector field of the form $F\,\mathbf{n}_\Gamma$, where $\mathbf{n}_\Gamma$ is the exterior unit normal vector field to Γ. We assume that $\Gamma = \partial\Omega \subset D$, and we specify $\mathbf{n}_\Gamma$ as being the *exterior* unit normal vector field with respect to Ω. See [57, 28] for the concepts of classical shape sensitivity analysis and [37, Appendix A.1] for a more level-set based derivation of the classical results. We refer also to [11], where a framework is presented which includes the concept of topological derivative in the level-set methodology.

3.1. Basic shape derivative formulas. Let us give a brief overview of the calculus of variations for energies which depend on a geometric variable such as a subdomain Ω of a fixed domain D or a submanifold Γ of D. For a smooth vector field $\vec{V} : D \to \mathbb{R}^n$ with $\overline{\Omega} \subset D$ let us first consider the initial value problem

$$\begin{aligned} X'(t) &= \vec{V}(X(t)), \\ X(0) &= X_0 \end{aligned} \tag{3.1}$$

for $X_0 \in D$. The flow $T_t : \Omega \to \mathbb{R}^n$ (with respect to $\vec{V}$) is then defined as $T_t(\mathbf{x}) = X(t)$, where $X(t)$ is the solution of (3.1) with $X_0 = \mathbf{x}$. For a functional $E : \mathcal{E} \to \mathbb{R}$ and a fixed perturbation vectorfield $\vec{V}$, the *Eulerian derivative* is defined by

$$dE(\Gamma; \vec{V}) = \lim_{t \searrow 0} \frac{E(T_t(\Gamma)) - E(\Gamma)}{t} \tag{3.2}$$

provided that the limit exists. Here $\mathcal{E} \subset 2^D$ denotes a suitable set of geometrical variables. The functional E is said to be shape-differentiable at Γ if the limit exists for all $\vec{V} \in B$ and if $dE(\Gamma) \in B'$, i.e., $dE(\Gamma)$ is a bounded linear functional on B, where B is a Banach space of perturbation vector fields. The analogous definitions apply to functions $E(\Omega)$ depending on open sets, not on submanifolds. We will need the following result [57, sect. 2.33, p. 115].

LEMMA 1. *Let Γ be a $\mathcal{C}^2$-hypersurface, and let $f \in H^2_{\mathrm{loc}}(\mathbb{R}^n)$. Then the functional*

$$E(\Gamma) = \int_\Gamma f \,\mathrm{d}\mathcal{H}^{N-1}$$

is shape-differentiable for any perturbation $\vec{V} \in \mathcal{C}^1_0(\mathbb{R}^n)$, and the shape derivative is given by

$$dE(\Gamma;\vec{V}) = \int_\Gamma \left(\nabla f \cdot \vec{V} + f \,\mathrm{div}_\Gamma \vec{V}\right) \mathrm{d}\mathcal{H}^{N-1} \tag{3.3}$$

$$= \int_\Gamma \left(\frac{\partial f}{\partial \mathbf{n}_\Gamma} + f\,\kappa\right) \vec{V} \cdot n_\Gamma \,\mathrm{d}\mathcal{H}^{N-1}, \tag{3.4}$$

where $\mathbf{n}_\Gamma$ denotes the normal to the interface Γ and κ is the additive curvature of Γ.

DEFINITION 1 (material derivative). *We consider a family of (sufficiently smooth) open sets $\mathcal{F}$ and suppose that we are given $f(\Omega) \in B(\Omega)$ for each $\Omega \in \mathcal{F}$, where $B(\Omega)$ is some Banach space of functions on Ω. Let us fix $\Omega_0 \in \mathcal{F}$ and suppose that $\vec{V} \in \mathcal{C}^1_0(\mathbb{R}^n, \mathbb{R}^n)$ is given. We set $\Omega_t = T_t(\Omega_0)$ and assume that $f(\Omega_t) \in B(\Omega_t)$. The limit*

$$\dot{f}(\Omega;\vec{V}) = \lim_{t \searrow 0} \frac{f(\Omega_t) \circ T_t - f(\Omega_0)}{t}$$

is called the (weak) material derivative if it exists in the strong (weak) topology on $B(\Omega_0)$.

DEFINITION 2 (shape derivative). *If the weak material derivative and the expression $\nabla f(\Omega) \cdot \vec{V}$ exist in $B(\Omega)$, then we set*

$$f'(\Omega;\vec{V}) = \dot{f}(\Omega;\vec{V}) - \langle \nabla f(\Omega), \vec{V}\rangle$$

and call it the shape derivative *of f at Ω in direction V.*

In the next section we will also need the following result [57, sect. 2.31, p. 112].

PROPOSITION 1. *Let $f(\Omega)$ be given such that the weak L^1-material derivative $\dot{f}(\Omega;\vec{V})$ and the shape derivative $f'(\Omega;\vec{V}) \in L^1(\Omega)$ exist. Then, the functional*

$$E(\Omega) = \int_\Omega f(\Omega, \mathbf{x}) \,\mathrm{d}\mathbf{x}$$

is shape-differentiable, and the derivative is given by

$$dE(\Omega;\vec{V}) = \int_\Omega f'(\Omega;\vec{V}) \,\mathrm{d}\mathbf{x} + \int_\Gamma f \,\langle \vec{V}, \mathbf{n}_\Gamma\rangle \,\mathrm{d}\mathcal{H}^{N-1}. \tag{3.5}$$

It can be shown (see [28, sect. 3.3, p. 348]) that the various concepts of (first) derivatives with respect to a geometric variable depend on the direction of perturbation V only via its projection

$$F = \langle \vec{V}, \mathbf{n}_\Gamma\rangle \tag{3.6}$$

onto the normal direction to Γ. We therefore subsequently write $dE(\Gamma;F)$ instead of $dE(\Gamma;\vec{V})$ and likewise for the other types of derivatives.

3.2. The first variation of the energy. In the following, we frequently use the coordinate transformation $\mathbf{x} \mapsto \mathbf{y} = \Phi(\mathbf{x}) = \mathbf{x} + \mathbf{d}(\mathbf{x})$ to switch between representations on the transformed and the original configurations. Finding first variations of the functional (2.4) with respect to the geometry Γ requires differentiation with respect to Γ of functionals $\int_\Omega g \, \mathrm{d}\mathbf{x}$ and $\int_{\Phi(\Omega)} h \, \mathrm{d}\mathbf{x}$, respectively, where $\partial\Omega \subset \Gamma$. For integrals of the first type, the results of section 3 directly apply. Suppose that $T_t(\mathbf{x})$ is a flow map which defines a perturbation of Γ with corresponding vector field $\vec{V}$. Then the perturbation of Γ^Φ is given by the flow map $S_t(\mathbf{y}) = \Phi(T_t(\Phi^{-1}(\mathbf{y})))$. The corresponding perturbation vector field has the form $\vec{W}(\mathbf{y}) = (\nabla\Phi \cdot \vec{V})(\Phi^{-1}(\mathbf{y}))$. With this, we can apply the results of section 3 to integrals defined in the transformed configuration. For later use, we recall the following transformation formulas [20, sect. 1.7, pp. 37–41]:

$$\mathbf{n}_{\Gamma^\Phi}(\mathbf{y}) = \frac{\mathbf{Cof}\, \nabla\Phi(\mathbf{x}) \cdot \mathbf{n}_\Gamma(\mathbf{x})}{\|\mathbf{Cof}\, \nabla\Phi(\mathbf{x}) \cdot \mathbf{n}_\Gamma(\mathbf{x})\|}, \tag{3.7a}$$

$$F_\Phi := \langle \vec{W}(\mathbf{y}), \mathbf{n}_{\Gamma^\Phi}(\mathbf{y}) \rangle = \frac{\det\nabla\Phi(\mathbf{x})}{\|\mathbf{Cof}\, \nabla\Phi(\mathbf{x}) \cdot \mathbf{n}_\Gamma(\mathbf{x})\|} \langle \vec{V}(\mathbf{x}), \mathbf{n}_\Gamma(\mathbf{x}) \rangle = \frac{\det\nabla\Phi(\mathbf{x})}{\|\mathbf{Cof}\, \nabla\Phi(\mathbf{x}) \cdot \mathbf{n}_\Gamma(\mathbf{x})\|} F, \tag{3.7b}$$

$$\int_{\Gamma^\Phi} g \, d\mathcal{H}^{N-1} = \int_\Gamma g \circ \Phi \, \|\mathbf{Cof}\, \nabla\Phi \cdot \mathbf{n}_\Gamma\| \, d\mathcal{H}^{N-1}. \tag{3.7c}$$

Proposition 1 (see also [57, sect. 2.31, p. 112]) implies that

$$\begin{aligned} d\hat{E}\,((\Gamma, \mathbf{d}); F) = {} & \frac{1}{2} \int_\Gamma \Big([\![|R(\Gamma) - R_0|^2]\!] + \mu [\![|\nabla R(\Gamma)|^2]\!] \Big) F \, d\mathcal{H}^{N-1} \\ & + \frac{1}{2} \int_{\Gamma^\Phi} \Big([\![|T(\Gamma, \mathbf{d}) - T_0|^2]\!] \, | + \mu [\![|\nabla T(\Gamma, \mathbf{d})|^2]\!] \Big) F_\Phi \, d\mathcal{H}^{N-1} \\ & + \left\langle \frac{\partial E}{\partial R}, R'_F \right\rangle_{(H^1(D\setminus\Gamma))^*, H^1(D\setminus\Gamma)} \\ & + \left\langle \frac{\partial E}{\partial T}, T'_{F_\Phi} \right\rangle_{(H^1(D\setminus\Gamma^\Phi))^*, H^1(D\setminus\Gamma^\Phi)} + \int_\Gamma \kappa \, F \, d\mathcal{H}^{N-1}, \end{aligned} \tag{3.8}$$

where $[\![\cdot]\!]$ denotes magnitudes of jump discontinuities across Γ (from inside to outside) and across Γ_Φ, respectively. As above, κ is the additive curvature of Γ, and R'_F and T'_{F^Φ} are the shape derivatives of R and T in the direction of the perturbation given by F and F_Φ, respectively.

We give a brief explanation of the terms occurring in (3.8). The integrals which compose the reduced cost functional (2.7) can be written as sums of integrals over the individual connected components Ω_i of $D \setminus \Gamma$. Thus, the shape sensitivity analysis of (2.7) can be performed by calculating the sensitivities of integrals over each Ω_i and adding up the results. For each component Ω_i of $D \setminus \Gamma$, boundary integrals of the form $\int_{\partial\Omega_i} f \, \langle \vec{V}, \mathbf{n} \rangle \, d\mathcal{H}^{n-1}$ with appropriate f's occur in the respective shape sensitivities due to Proposition 1. Here the vector $\mathbf{n}$ is the *exterior* normal vector to $\partial\Omega_i$. We have $\partial\Omega_i \subset \Gamma \cup \partial D$ and $\Gamma \cup \partial D = \cup_i \partial\Omega_i$. Thus, the sum of integrals over $\partial\Omega_i$ can be rewritten as an integral over Γ (the contributions on ∂D vanish since

$\vec{V}|_{\partial D} = 0$). Since each component of Γ separates two connected components Ω_i and Ω_j with opposite exterior normal vectors, the jumps of the respective quantities across Γ occur in (3.8).

It can be shown (interpreting the integrals in the weak equations (2.9) and (2.10) as shape functionals and applying Proposition 1; see also [57, sect. 3.2 and 2.29]) that R'_F is the solution to the inhomogeneous Neumann-type boundary value problems

$$\int_{\tilde{\Omega}} \left(\mu \langle \nabla R'_F, \nabla \varphi \rangle + R'_F\, \varphi\right) \mathrm{d}\mathbf{x} = -\int_{\partial\tilde{\Omega}} \left(\mu \langle \nabla_\Gamma R_F, \nabla_\Gamma \varphi \rangle + (R_F - R_0)\, \varphi\right) F\, d\mathcal{H}^{N-1}$$

on each connected component $\tilde{\Omega}$ of $D \setminus \Gamma$ and for all $\varphi \in H^1(\tilde{\Omega})$. An elliptic regularity result then shows that the solution $R'_F|_{\tilde{\Omega}} \in H^1(\tilde{\Omega})$ for each connected component $\tilde{\Omega}$ of $D \setminus \Gamma$ and hence $R'_F \in H^1(D \setminus \Gamma)$. Analogously we obtain $T'_{F_\Phi} \in H^1(D \setminus \Gamma^\Phi)$. Here we need to assume that the transformation Φ is sufficiently smooth. Consequently, we can use R'_F and T'_{F_Φ} as test functions in (2.8) to conclude that the terms including the shape derivatives R'_F and T'_{F_Φ} in (3.8) vanish. Transforming all expressions in (3.8) onto the undeformed configuration (using (3.7)) and replacing Φ by $\mathbf{id} + \mathbf{d}$ yields

(3.9)
$$\begin{aligned} d\hat{E}\left((\Gamma, \mathbf{d}); F\right) =& \frac{1}{2} \int_\Gamma \left([\![|R(\Gamma) - R_0|^2]\!] + \mu [\![|\nabla R(\Gamma)|^2]\!] \right) F\, d\mathcal{H}^{N-1} \\ &+ \frac{1}{2} \int_\Gamma \Big([\![|T(\Gamma, \mathbf{d}) - T_0|^2 \circ (\mathbf{id} + \mathbf{d})]\!] \\ &\qquad + \mu\, [\![|\nabla T(\Gamma, \mathbf{d})|^2 \circ (\mathbf{id} + \mathbf{d})]\!] \Big)\, |\det(I + \nabla \mathbf{d})|\, F\, d\mathcal{H}^{N-1} \\ &+ \alpha \int_\Gamma \kappa\, F\, d\mathcal{H}^{N-1}. \end{aligned}$$

We now consider variation with respect to the displacement $\mathbf{d}$. The cost functional depends on $\mathbf{d}$ via the domain of integration $D \setminus \Gamma^{\mathbf{d}}$ and implicitly via $T(\Gamma, \mathbf{d})$. The perturbation of the geometry has the form $\Gamma^{\mathbf{d}+t\,\boldsymbol{\delta}} = \Gamma^{\mathbf{d}} + t\,\boldsymbol{\delta}(\Gamma) = \Gamma^{\mathbf{d}} + t\left(\boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}(\Gamma^{\mathbf{d}})\right)$. It can be shown [28, Chap. 7] that this perturbation is equivalent to a perturbation of $\Gamma^{\mathbf{d}}$ with the velocity vector field $\boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}$. We can therefore apply the results in section 3.1 to obtain

$$\begin{aligned} \left\langle \frac{\partial \hat{E}}{\partial \mathbf{d}}, \boldsymbol{\delta} \right\rangle =& \left\langle \frac{\partial E}{\partial T}, T'\left(\Gamma^{\mathbf{d}}, \boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}\right) \right\rangle_{(H^1(D\setminus\Gamma^{\mathbf{d}}))^*, H^1(D\setminus\Gamma^{\mathbf{d}})} \\ &+ \frac{1}{2} \int_{\Gamma^{\mathbf{d}}} \left([\![|T(\Gamma, \mathbf{d}) - T_0|^2]\!] + \mu [\![|\nabla T(\Gamma, \mathbf{d})|^2]\!] \right) \\ &\cdot \langle \boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}, \mathbf{n}_{\Gamma^{\mathbf{d}}} \rangle\, d\mathcal{H}^{N-1} + \nu \left\langle \frac{\partial E_{\mathrm{reg}}}{\partial \mathbf{d}}, \boldsymbol{\delta} \right\rangle. \end{aligned}$$

As above, we argue that $T'\left(\Gamma^{\mathbf{d}}, \boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}\right) \in H^1(D \setminus \Gamma^{\mathbf{d}})$, and the first term vanishes due to (2.8). If the regularization term (2.7) is used, the Fréchet derivative of $\hat{E}$ with respect to $\mathbf{d}$ in direction $\boldsymbol{\delta}$ reads as

$$\begin{aligned} \left\langle \frac{\partial \hat{E}}{\partial \mathbf{d}}, \boldsymbol{\delta} \right\rangle =& \frac{1}{2} \int_{\Gamma^{\mathbf{d}}} \left([\![|T(\Gamma, \mathbf{d}) - T_0|^2]\!] + \mu [\![|\nabla T(\Gamma, \mathbf{d})|^2]\!] \right) \\ &\cdot \langle \boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}, \mathbf{n}_{\Gamma^{\mathbf{d}}} \rangle\, d\mathcal{H}^{N-1} + \nu \int_D \nabla \mathbf{d} : \nabla \boldsymbol{\delta}\, \mathrm{d}\mathbf{x}, \end{aligned} \tag{3.10}$$

where ":" stands for the matrix tensor product, i.e., the scalar product corresponding to the Frobenius norm.

We have not yet specified the function space for the displacement field $\mathbf{d}$. The natural choice corresponding to the choice of the regularization E_{reg} would be $\mathbf{d} \in \mathbf{H}_0^1(D) = H_0^1(D, \mathbb{R}^n)$. For the application of shape sensitivity results, however, we need more regularity for the transformation $\Gamma \mapsto (\mathbf{id} + \mathbf{d})(\Gamma)$. This issue will be discussed later on when we define updates for the displacement $\mathbf{d}$.

4. Choice of a descent direction. We now address the question of finding an appropriate descent direction, i.e., a direction $\boldsymbol{\delta}_d \in \mathbf{H}_0^1(D)$ and a scalar function F_d defined on Γ such that

$$\left\langle \frac{\partial \hat{E}}{\partial \mathbf{d}}, \boldsymbol{\delta}_d \right\rangle < 0 \quad \text{and} \quad d\hat{E}\left((\Gamma, \mathbf{d}); F_d\right) < 0. \tag{4.1}$$

The descent directions $\boldsymbol{\delta}_d$ and F_d are found by minimizing the linear approximations over the unit spheres of appropriate function spaces in which the admissible directions are chosen. This idea is closely related to the approach presented in [21, 22], where the descent direction is determined with respect to a regularizing metric. In our case the metric is the scalar product of the adequately chosen Hilbert space. We leave the question of choice of the correct function space for F_d open for the moment and start with finding a descent direction with respect to $\mathbf{d}$. We say that $\boldsymbol{\delta}_d$ is the direction of steepest descent for $\hat{E}$ with respect to $\mathbf{d}$ and the metric induced by the $\mathbf{H}_0^1(D)$-norm if and only if $\boldsymbol{\delta}_d$ is a solution to the constrained optimization problem

$$\min_{\substack{\boldsymbol{\delta} \in \mathbf{H}_0^1(D) \\ \|\boldsymbol{\delta}\|_{\mathbf{H}_0^1(D)} = 1}} \left\langle \frac{\partial \hat{E}}{\partial \mathbf{d}}(\Gamma, \mathbf{d}), \boldsymbol{\delta} \right\rangle. \tag{4.2}$$

Note that $\left\langle \frac{\partial \hat{E}}{\partial \mathbf{d}}(\Gamma, \mathbf{d}), \cdot \right\rangle$ defines a bounded linear functional on $\mathbf{H}_0^1(D)$ provided that $\mathbf{d}$ is smooth enough. To solve (4.2), we introduce the Lagrange function

$$\begin{aligned}
&\mathcal{L}_f(\boldsymbol{\delta}, \lambda_f) = \\
&\quad \frac{1}{2} \int_{\Gamma_{\mathbf{d}}} \left([\![|T(\Gamma, \mathbf{d}) - T_0|^2]\!] + \mu [\![|\nabla T(\Gamma, \mathbf{d})|^2]\!] \right) \langle \boldsymbol{\delta} \circ (\mathbf{id} + \mathbf{d})^{-1}, \mathbf{n}_{\Gamma_{\mathbf{d}}} \rangle \, d\mathcal{H}^{N-1} \\
&\qquad + \nu \int_D \nabla \mathbf{d} : \nabla \boldsymbol{\delta} \, \mathrm{d}\mathbf{x} + \lambda_f \left(\int_D |\nabla \boldsymbol{\delta}|^2 \, \mathrm{d}\mathbf{x} - 1 \right).
\end{aligned}$$

The optimality system for (4.2) reads as $\frac{\partial \mathcal{L}_f}{\partial \boldsymbol{\delta}}(\boldsymbol{\delta}_d, \lambda_d) = 0$ and $\frac{\partial \mathcal{L}_f}{\partial \lambda_f}(\boldsymbol{\delta}_d, \lambda_d) = 0$. Therefore, the direction of steepest descent $\boldsymbol{\delta}_d$ is found as the solution to

$$\begin{aligned}
\int_D \nabla \boldsymbol{\delta}_d : \nabla \boldsymbol{\xi} \, \mathrm{d}\mathbf{x} = -\frac{1}{\lambda_f} \Bigg(&\nu \int_D \nabla \mathbf{d} : \nabla \boldsymbol{\xi} \, \mathrm{d}\mathbf{x} \\
&+ \frac{1}{2} \int_{\Gamma_{\mathbf{d}}} \left([\![|T(\Gamma, \mathbf{d}) - T_0|^2]\!] + \mu [\![|\nabla T(\Gamma, \mathbf{d})|^2]\!] \right) \langle \boldsymbol{\xi} \circ (\mathbf{id} + \mathbf{d})^{-1}, \mathbf{n}_{\Gamma_{\mathbf{d}}} \rangle \, d\mathcal{H}^{N-1} \Bigg)
\end{aligned} \tag{4.3}$$

for all $\boldsymbol{\xi} \in \mathbf{H}_0^1(D)$, where the multiplier λ_f is chosen such that $\|\boldsymbol{\delta}_d\|_{\mathbf{H}_0^1(D)} = 1$.

Alternatively one might want to allow $\boldsymbol{\delta}_d \in \mathbf{H}^1$ instead of prescribing homogeneous Dirichlet conditions, which can be particularly important in case of large

translations between the reference and the template image. Then $\boldsymbol{\delta}_d$ is given as the solution to

$$\begin{aligned}(4.4)\quad \int_D \big(\langle \boldsymbol{\delta}_d, \boldsymbol{\xi}\rangle + \nabla\boldsymbol{\delta}_d : \nabla\boldsymbol{\xi}\big)\,\mathrm{d}\mathbf{x} = -\frac{1}{\lambda_f}\Bigg(\nu\int_D \nabla\mathbf{d} : \nabla\boldsymbol{\xi}\,\mathrm{d}\mathbf{x} \\ + \frac{1}{2}\int_{\Gamma^{\mathbf{d}}} \big(\llbracket |T(\Gamma,\mathbf{d}) - T_0|^2\rrbracket + \mu\llbracket|\nabla T(\Gamma,\mathbf{d})|^2\rrbracket\big)\,\langle \boldsymbol{\xi}\circ(\mathbf{id}+\mathbf{d})^{-1}, \mathbf{n}_{\Gamma^{\mathbf{d}}}\rangle\, d\mathcal{H}^{N-1}\Bigg)\end{aligned}$$

for all $\boldsymbol{\xi} \in \mathbf{H}^1(D)$.

Application of the transformation rules (3.7c) and (3.7b) to the surface integral on the right-hand side of (4.3) and (4.4) yields

$$(4.5)\quad \frac{1}{2}\int_\Gamma \big(\llbracket |T(\Gamma,\mathbf{d}) - T_0|^2\rrbracket + \mu\llbracket|\nabla T(\Gamma,\mathbf{d})|^2\rrbracket\circ(\mathbf{id}+\mathbf{d})\big)\,\langle \boldsymbol{\xi}, \mathbf{Cof}\,\nabla\mathbf{d}\cdot\mathbf{n}_\Gamma\rangle\, d\mathcal{H}^{N-1}$$

for these terms.

We now make a few comments concerning the regularity of the displacement $\mathbf{d}$. The update $\boldsymbol{\delta}_d$ which solves (4.3) is a function in $\mathbf{H}^1_0(D)$ which—in general—does not possess much additional regularity since the source term is a distribution which is localized on Γ, thus introducing a singularity $\boldsymbol{\delta}_d$ along Γ. For the above shape sensitivity results to hold, we require that the displacement be smooth in every step. To circumvent this difficulty, we can replace $\boldsymbol{\delta}_d$ by a smooth approximation $\boldsymbol{\delta}_d^\epsilon$ for the actual update of the transformation. If the approximation is close enough in the $\mathbf{H}^1_0(D)$-norm, the descent property (4.1) will still be satisfied and the theoretical arguments are justified. In the numerical realization it turns out that smoothing of the transformation is not necessary.

To find a descent direction for the geometrical variable Γ, we first have to specify the function space and the corresponding metric for the update direction F_d. By choosing the update direction $\boldsymbol{\delta}_d \in \mathbf{H}^1_0(D)$, the movement of the transformed geometry $\Gamma^{\mathbf{d}} \mapsto \Gamma^{\mathbf{d}+t\boldsymbol{\delta}_d}$ corresponds to a movement in normal direction with speed function given by

$$F_{\boldsymbol{\delta}_d} = \langle \boldsymbol{\delta}_d, \mathbf{n}_{\Gamma^{\mathbf{d}}}\rangle \in H^{\frac{1}{2}}(\Gamma^{\mathbf{d}}).$$

It is therefore natural to choose the descent direction F also with respect to the $H^{\frac{1}{2}}$-norm on Γ. This choice should give a good balance between the descents achieved by moving the geometrical variable Γ and the functional variable $\mathbf{d}$, respectively. More precisely, we choose the descent direction F_d as the solution to the problem

$$(4.6)\quad \min_{\substack{F\in H^{\frac{1}{2}}(\Gamma)\\ \|F\|_{H^{\frac{1}{2}}(\Gamma)}=1}} dE\big((\Gamma,\mathbf{d}), F\big).$$

We introduce again a Lagrange function

$$\mathcal{L}_g(F,\lambda_g) = d\hat{E}\,((\Gamma,\mathbf{d}); F) + \lambda_g\left(\|F\|^2_{H^{\frac{1}{2}}(\Gamma)} - 1\right).$$

The optimality system for F_d then has the form

$$(4.7)\quad (F_d, G)_{H^{\frac{1}{2}}(\Gamma)} = -\frac{1}{\lambda_g} d\hat{E}\,((\Gamma,\mathbf{d}); G)$$

for all $G \in H^{\frac{1}{2}}(\Gamma)$. To evaluate the inner product $(\cdot,\cdot)_{H^{\frac{1}{2}}(\Gamma)}$ we consider the boundary value problem

$$\begin{aligned} -\Delta v + v &= 0 \text{ on } \Omega, \\ \frac{\partial v}{\partial n}\Big|_\Gamma &= H \in H^{-\frac{1}{2}}(\Gamma). \end{aligned} \tag{4.8}$$

Here $\Omega \subset D$ is chosen such that $\Gamma = \partial\Omega$. In the level-set context below, Ω can be chosen as the set of all points with negative function values of the level-set function. The weak formulation for (4.8) is given by

$$\int_\Omega \left(\langle \nabla v, \nabla \varphi\rangle + v\,\varphi\right) \mathrm{d}\mathbf{x} = \left\langle H, \varphi|_\Gamma \right\rangle_{H^{-\frac{1}{2}}(\Gamma), H^{\frac{1}{2}}(\Gamma)} \tag{4.9}$$

for all $\varphi \in H^1(\Omega)$. We define the Neumann-to-Dirichlet map for the operator $-\Delta +$ id on Ω as the linear operator $\mathcal{N} : H^{-\frac{1}{2}}(\Gamma) \to H^{\frac{1}{2}}(\Gamma)$, which maps H in (4.8) to the Dirichlet trace $v|_\Gamma$ of the solution to (4.8). The operator $\mathcal{N}$ is invertible with $\mathcal{N}^{-1}$ given by the composition of the solution operator of the Dirichlet problem with inhomogeneous boundary conditions and the Neumann trace operator. By the closed graph theorem, $\mathcal{N}^{-1}$ is bounded; hence $\mathcal{N}$ constitutes an isomorphism between the spaces $H^{-\frac{1}{2}}(\Gamma)$ and $H^{\frac{1}{2}}(\Gamma)$. An inner product on $H^{\frac{1}{2}}(\Gamma)$ can be defined as

$$(F, G)_{H^{\frac{1}{2}}(\Gamma)} = \langle \mathcal{N}^{-1} F, G\rangle_{H^{-\frac{1}{2}}(\Gamma), H^{\frac{1}{2}}(\Gamma)}.$$

With this, we can write (4.7) as

$$\langle \mathcal{N}^{-1} F_d, G\rangle_{H^{-\frac{1}{2}}(\Gamma), H^{\frac{1}{2}}(\Gamma)} = -\frac{1}{\lambda_g} d\hat{E}\left((\Gamma, \mathbf{d}); G\right)$$

for all $G \in H^{\frac{1}{2}}(\Gamma)$. If we use (3.9), we obtain

$$\begin{aligned} F_d &= -\frac{1}{\lambda_g}\mathcal{N} F_g \text{ with} \\ F_g &= \frac{1}{2}\Big([\![|R(\Gamma) - R_0|^2]\!] + \mu [\![|\nabla R(\Gamma)|^2]\!] \\ &\quad + \left([\![|T(\Gamma, \mathbf{d}) - T_0|^2 \circ (\mathbf{id} + \mathbf{d})]\!] + \mu [\![|\nabla T(\Gamma, \mathbf{d})|^2 \circ (\mathbf{id} + \mathbf{d})]\!] \right) |\det(I + \nabla \mathbf{d})| \Big) \\ &\quad + \alpha\kappa \end{aligned} \tag{4.10}$$

on Γ.

5. Description of the algorithm. Let us now assemble all the discussed main building blocks into a regularized shape gradient descent algorithm within the level-set framework:

Step 1 Choose an initial level-set function u_0, choose an initial transformation $\mathbf{d}_0$. Set $u_c = u_0$, $\mathbf{d}_c = \mathbf{d}_0$.

Step 2 For the current level-set function u_c set $\Omega = \{\mathbf{x} \in D : u_c(\mathbf{x}) < 0\}$, $\Gamma = \{\mathbf{x} \in D : u_c(\mathbf{x}) = 0\}$. Solve (2.9) and (2.10) for R and T, respectively, for the current Γ and $\mathbf{d}_c$.

Step 3 Evaluate the expression F_g in (4.10).

Step 4 Solve the elliptic equation (4.8) with Neumann data given by F_g. Evaluate the Dirichlet trace to get F_d on Γ.
Step 5 Extend F_d to a function F_d^{ext} which is defined on a narrow band around Γ.
Step 6 Solve (4.3) for $\boldsymbol{\delta}_d$.
Step 7 Solve the level-set equation

$$u_t + F_d^{\text{ext}}|\nabla u| = 0 \quad \text{with } u(\cdot,0) = u_c.$$

Set the new $u_c = u(\cdot,\tau)$. Set $\mathbf{d}_c = \mathbf{d}_c + \tau\boldsymbol{\delta}_d$. Choose the step size τ according to a line search procedure.
Step 8 Stopping criterion. Else go to Step 2.

The finite element approximations of the functions R and T and the auxiliary variable v in (4.9) on the irregular domains $D \setminus \Gamma$, $D \setminus \Gamma^{\mathbf{d}}$, and Ω are done using composite finite elements (cf. [34]). The transformation vector field $\mathbf{d}$ is discretized using standard finite elements.

5.1. Step 2. Equations (2.9) and (2.10) are solved using CFEs for the solution of the second order elliptic equations on the variable and irregular domains $D \setminus \Gamma$ and $D \setminus \Gamma^{\mathbf{d}}$. The CFE code takes as input the function values of a level-set function, which defines the variable geometry, on a rectangular grid. For $D \setminus \Gamma$ the level-set function is given by u_c. For the transformed geometry $D \setminus \Gamma^{\mathbf{d}}$ a level-set function is given by $u_c^{\mathbf{d}} = u_c \circ (\mathbf{id} + \mathbf{d})^{-1}$. We introduce a triangulation $\mathcal{T}$ on D and approximate $\mathbf{d}$ by a piecewise affine transformation on $\mathcal{T}$.

5.2. Step 3. The data F_g are processed further in Step 4 as Neumann boundary data in (4.8). It follows from (4.9) that the data are used in the form $\int_\Gamma F_g\,\varphi_n\,d\mathcal{H}^{N-1}$ for all finite element basis functions φ_n. Hence, it is useful to determine the values of F_g on the intersection points of the rectangular finite element grid with Γ.

In F_g the jumps $R_i - R_e$ and $\nabla R_i - \nabla R_e$ occur, where R_i (interior) is the solution to (2.9) on Ω and R_e (exterior) is the solution to (2.9) on $D \setminus \overline{\Omega}$. We get the function values for R_i and R_e at the intersection points in a straightforward way from the respective finite element representations.

5.3. Step 4. In order to calculate F_d in (4.10), we solve

$$\langle \nabla\phi_i^{CFE}, \nabla\phi_j^{CFE}\rangle_{L^2(\Omega_1)}\bar{F}_{d,i} + \langle \phi_i^{CFE}, \phi_j^{CFE}\rangle_{L^2(\Omega_1)}\bar{F}_{d,i} = -\frac{1}{\lambda_g}\langle F_g, \phi_i\rangle_{L^2(\partial\Omega_1)},$$

where ϕ_i^{CFE} denotes the basis functions of the finite element space (cf. section 6), and $\bar{F}_{d,i}$ denotes the ith component of the vector $\bar{F}_d$, i.e., the coefficient vector of F_d with respect to the chosen basis.

5.4. Step 5. We now extend F_d given from the discrete contour Γ_h to a function F_d^{ext} defined on a neighborhood of Γ_h by solving the following transport equation:

$$\langle \nabla F_d^{\text{ext}}, \nabla d_\Gamma\rangle = 0 \quad \text{on} \quad \Omega \qquad \text{and} \qquad F_d^{\text{ext}} = F_d \quad \text{on} \quad \Gamma. \tag{5.1}$$

Here d_Γ denotes the signed distance function to Γ. Note that d_Γ and F_d^{ext} can be computed simultaneously by a modified fast marching method for solving the eikonal equation $|\nabla d| = 1$ (cf. [1] for a description of the algorithm).

5.5. Step 7. The discretization of the level-set equation

$$\partial_t u + F_d^{\text{ext}}|\nabla u| = 0 \quad \text{on} \quad \Omega \tag{5.2}$$

is carried out using an explicit upwind scheme. In our computations we have applied a third order accurate ENO-scheme (cf. [51, sect. 3.4, p. 33]).

6. Composite finite elements and multigrid. In this section we will briefly describe the spatial discretization of the H^1 function spaces on Ω_i, which are divided by the contour Γ, i.e., the zero level-set of u. Furthermore, we outline a multigrid method for the solution of (2.9), (2.10), (4.3), and (4.9). We use CFEs introduced by Hackbusch and Sauter [34]. Instead of resolving the Ω_i using a retriangulation or local adaptive refinement, we confine ourselves to a uniform quadrilateral (resp., hexahedral) grid $\mathcal{T}$ and define the triangulations $\mathcal{T}_i \subset \mathcal{T}$ for Ω_i with $\Omega_i \subseteq \overline{\bigcup_{T\in\mathcal{T}_i} T}$ by the following overlap condition:

$$T \in \mathcal{T}_i \iff T \in \mathcal{T}, \quad T \cap \Omega_i \neq \emptyset. \tag{6.1}$$

Let us denote by $V_h(\Omega_{\mathcal{T}})$ the usual finite element space given by the condition that for $U \in V_h(\Omega_{\mathcal{T}})$, $U\big|_T$ is a multilinear function for each $T \in \mathcal{T}$. The corresponding CFE space is then given by the restriction of the functions in $V_h(\Omega_{\mathcal{T}_i})$ to the domain Ω_i, i.e.,

$$V_h^{CFE}(\Omega_{\mathcal{T}_i}) := \{U|_{\Omega_i} \,|\, U \in V_h(\Omega_{\mathcal{T}_i})\}. \tag{6.2}$$

Hence, a basis $(\varphi_i^{CFE})_i$ of V_h^{CFE} is given by $\varphi_i^{CFE} := \varphi_i\big|_{\Omega_{\mathcal{T}_i}}$, where $(\varphi_i)_i$ denotes a basis of the space $V_h(\Omega_{\mathcal{T}_i})$.

For the assembling of the mass matrix $M_i = (\int_{\Omega_i} \varphi_i^{CFE}\varphi_j^{CFE}\,\mathrm{d}\mathbf{x})_{ij}$ and stiffness matrix $L_i = (\int_{\Omega_i} \nabla\varphi_i^{CFE}\nabla\varphi_j^{CFE}\,\mathrm{d}\mathbf{x})_{ij}$ we need to apply quadrature rules for functions on $T \cap \Omega_i$. On each cell T, which is crossed by the zero level-set of u, we generate on-the-fly a partition of $T \cap \Omega_i$ into simplices and apply a barycenter quadrature rule on each simplex.

In order to apply a multigrid method, we generate a sequence of nested CFE spaces by applying an appropriate coarsening process on the CFE triangulation on the finest level $l_{\max}$ ($\Omega_{\mathcal{T}_i}^{l_{\max}} := \Omega_{\mathcal{T}_i}$), i.e.,

$$\Omega_i \subset \Omega_{\mathcal{T}_i}^{l_{\max}} \subset \Omega_{\mathcal{T}_i}^{l_{\max}-1} \subset \cdots \subset \Omega_{\mathcal{T}_i}^{0}, \tag{6.3}$$

leading to correspondingly nested CFE spaces $V_h^{CFE}(\Omega_{\mathcal{T}_i}^{l})$, $0 \le l \le l_{\max}$. Prolongations and restrictions naturally have to be defined with respect to the CFE discretization; hence prolongation onto level l is defined by evaluation of the basis functions $\varphi_i^{CFE,l-1}$ for Lagrange nodes on level l. Convergence analysis for multigrid algorithms using CFEs has been presented by Hackbush and Sauter [34] and Warnke [61], and we refer to [33] for a comprehensive overview of geometric multigrid methods.

7. Numerical experiments. We have tested our approach in different scenarios. Figure 1 shows a synthetic image pair, which was designed to test the method in cases where only *very little common information* is contained in the images. The rotated shape on the upper left of the top figure is supposed to be fitted into the structure on the bottom left, which is hence determined only by the four small objects in the corners of the image. After 75 steps of the gradient descent, a deformation is found which rotates the propeller-like shape, and the resulting push-forward of the contour matches quite well to the rounded corners in the second structure in the bottom of the top figure. Hence this example shows the capability of a model-based inpainting, where the shape information of the inpainted contour is transformed from a reference image. Thus, complementary information originating from the first image, which is not present in the second image, is used for the segmentation of the second image. We assume that the deviations from the obvious solution of a pure rotation result from

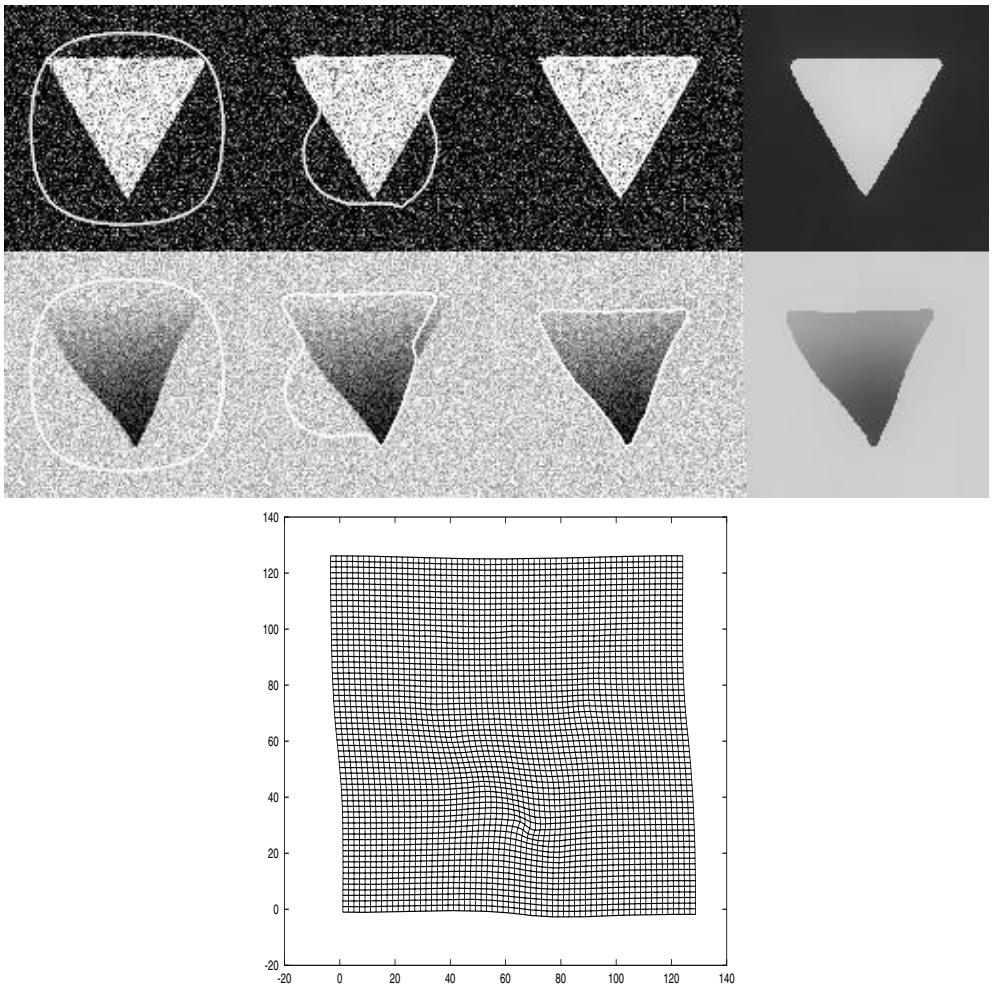

FIG. 2. *Simultaneous segmentation, registration, and denoising of two artificial test images. The smoothed reconstructions of both images are shown on the right-hand side of the top part of the figure.*

the fact that rigid transformations are not in the kernel of our regularization energy. We think that the result can be improved using a different regularization method, for example, a higher order method [46].

Figure 2 shows again the ability of the method to use complementary information from both images. In this situation, both images are contaminated by noise. The weak upper edge of the triangle in the second image is found accurately using information from the first image, where the corresponding edge is rather strong. As a by-product we also obtain smoothed reference and template images shown on the right-hand side of Figure 2 (top figure), where the edges detected by the segmentation are strongly enhanced. Note that the smoothed second image has a clearly recognizable upper edge.

In Figure 3 we have applied the algorithm to a pair of brain images. The top row shows a positron density (PD) scan, while the bottom row shows a T1-weighted

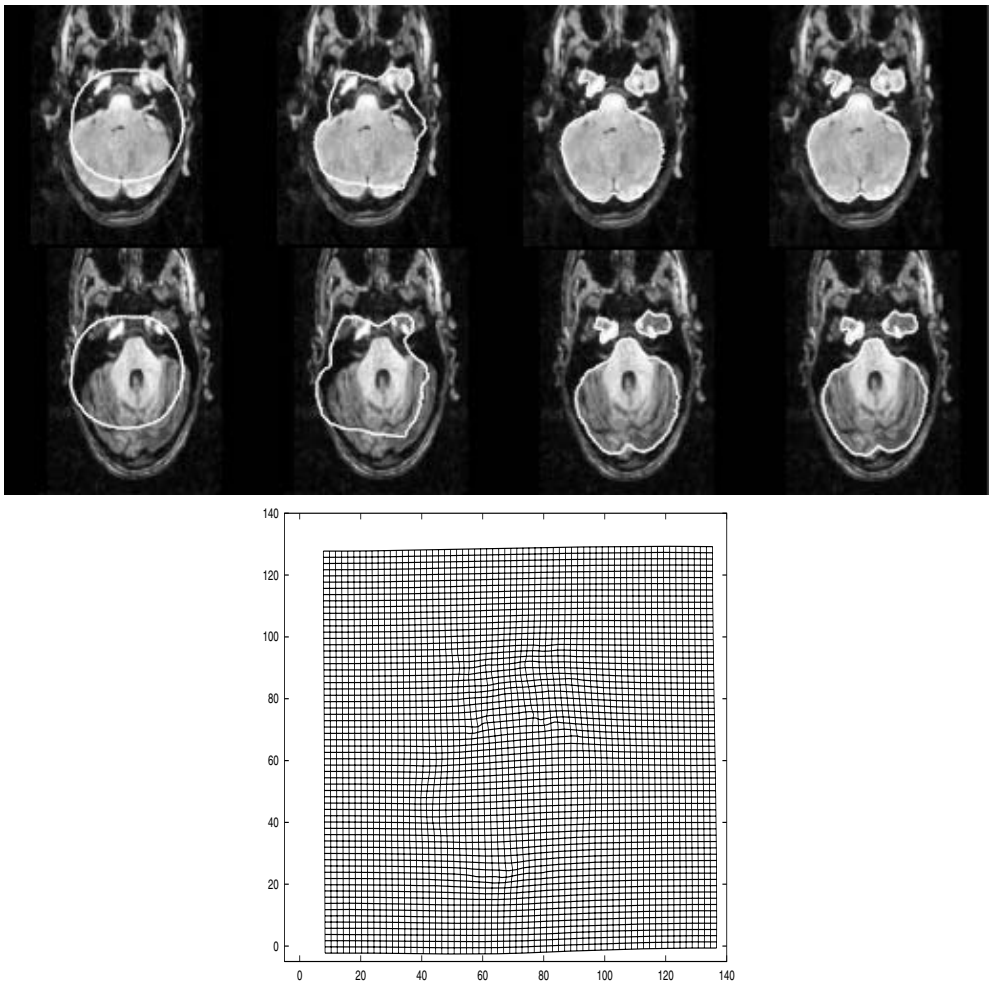

FIG. 3. *Top row: Reference image R (PD image of a human brain) and Γ. Bottom row: Template image T ($T1$-weighted MR image). The sequence shows the gradient descent for the iteration numbers $0, 10, 80$, and 180. The parameters were chosen as $\mu = 50$, $\alpha = 20$, $\nu = 500$. Images from the MPI of Cognitive Neuroscience, Leipzig, Germany.*

magnetic resonance image of the same patient. The initial difference of the image pair consists mainly of a translation of about 8-9 pixels. The algorithm finds the brain structure in both images well after about 80 steps, and the resulting deformation consists mainly of a shift enhanced by some minor locally detailed deformations. This example underlines the practicability of the level-set approach: After a few steps the initial contour splits into three different components which are henceforth independently mapped onto the corresponding segments in the template. Note also that the strong contrast between the brain and the other tissue in the first image helps to segment the outer brain boundary in the second image, where the contrast is not very strong and other edges are found in the vicinity of the boundary of the brain.

The last example in Figure 4 demonstrates the competing effect of the regularization and the energy contributions which pull the contour towards the edges. We can

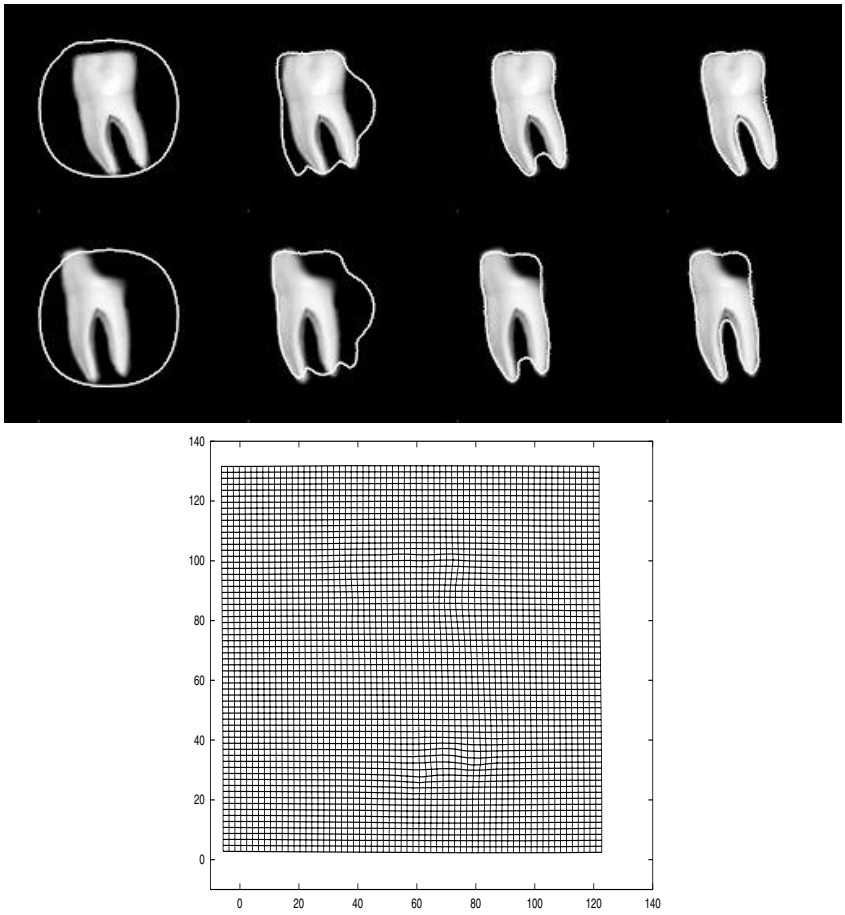

FIG. 4. *Matching a reference to a template with a destroyed region. The image in the bottom row of the top figure also differs nonrigidly from the image in the top row. The edge set of the reference is matched onto the contours of the template, where the alignment does not strongly decrease the regularity of the deformation. The parameters were chosen as* $\mu = 50$, $\alpha = 200$, *and* $\nu = 5000$. *The bottom image shows the deformation plot.*

exploit this in order to map an original reference shape (top row) to a given object, where the shape is partially corrupted (bottom row). Apart from the destroyed region, the shapes differ also by a nonrigid deformation plus a translation. This can be well observed in the second column. Here the deformation is still close to the identity, and hence the contours are aligning to the edges in the vicinity first until in subsequent iterations the deformation evolves in such a way that the contours map to the true edges in both images except on the border of the destroyed region. At this stage, the regularization dominates and prohibits the contour in the bottom row evolving towards the "visible" edge and prefers to adopt the contour from the reference image. This yields a reconstruction of the destroyed shape, which is optimal with respect to the regularization energy.

In this last example the optimal contours found by the algorithm depend significantly on the choice of the regularization parameter ν. The results shown in Figure 4 are obtained with a rather large value $\nu = 5000$, i.e., with a strong penalty on the

rigidity of the transformation Φ. If ν is chosen smaller, both contours become aligned with the edges in the images, which is only possible with a locally large deformation in the vicinity of the missing part of the tooth in the template image.

For all examples, the parameter μ does not have much influence on the segmentation and on the obtained transformation. It does, however, influence the character of the piecewise smooth approximations of the reference and template images R and T, respectively. Large μ yields approximations which are almost piecewise constant, whereas small μ allows a larger intensity variation within each segmented component. Finally, the algorithm seems to be rather insensitive with respect to the choice of the length parameter α.

8. Discussion. We have presented a level-set based algorithm for simultaenous segmentation and registration of images by incorporating a Mumford–Shah type energy on the reference image as well as on the template image, where the contour is transformed into the template image by a regularized deformation. The work presented here is motivated by the fact that, given an exact registration of two images of different modality, edge extraction and segmentation can be enhanced considerably by combining complementary feature information from both modalities. On the other hand, the process of registering a pair of images may rely on segmentations and feature extractions of both images, which often is a very tedious process, especially if, in some areas, the feature information is very weak. Due to the coupling of the edge sets by the smooth deformation, the edge in such areas is driven towards its correct shape.

We have demonstrated a further important application of this method, namely that this approach may also be used to perform a model-based reconstruction and inpainting of destroyed regions, without having to explicitly mark the region where the object is destroyed as long as there are no prominently dominating edges. Although the results are already very promising, there is still room for further conceptual modelling, e.g., to avoid competition of the broken edge and the reference edge along the boundary of the destroyed region.

Due to the regularization of the gradient flow, the minimization process has turned out to be stable and requires only a relatively small number of iterations until convergence. On the other hand, the regularization and necessity of determining the solutions of the Helmholtz equations in the regions Ω_1 and Ω_2 make each individual step rather expensive. In order to make the method efficient we have applied multigrid techniques which lead to an enormous speed-up of the algorithm.

We have performed all calculations using only the first variations of the energy. In further studies, one might investigate Levenberg–Marquart (cf. [10]) or pure Newton-type methods to further accelerate the minimization process.

Acknowledgments. The authors would like to thank Martin Rumpf for many helpful comments and Florian Liehr for his valuable advice concerning the composite finite element method. Furthermore, we want to thank Carlo Schaller for many stimulating discussions on medical imaging and computer-aided surgery.

ON THE TEMPERATURE-JUMP PROBLEM IN RAREFIED GAS DYNAMICS: THE EFFECT OF THE CERCIGNANI–LAMPIS BOUNDARY CONDITION*

ROSENEI FELIPPE KNACKFUSS† AND LILIANE BASSO BARICHELLO‡

Abstract. An analytical version of the discrete-ordinates method (the ADO method) is used to establish a solution to the temperature-jump problem in the rarefied gas dynamics field. Kinetic models derived from the linearized Boltzmann equation are used to formulate the problem in the one gas case and for a binary gas mixture. The gas-surface interaction is described by the Cercignani–Lampis kernel, which is written in terms of two accommodation coefficients. The solution is found to be very accurate and fast. Numerical results are presented not only for the temperature-jump coefficient but also for the density and temperature profiles. In particular, the effect of both accommodation coefficients on the temperature-jump coefficient is analyzed.

Key words. rarefied gas dynamics, temperature-jump coefficient, binary gas mixture, Cercignani–Lampis kernel, discrete ordinates

1. Introduction.

The increased interest in research fields related to the development of technologies associated with micro-electro-mechanical systems (MEMS) [1, 2] as well as other micro- and nanoflow applications [3] has brought attention to the rarefied gas dynamics field [4, 5, 6]. In fact, for these microsystems, where the characteristic length of the system is of the order of a mean-free path, and the gas flow is in the transition regime, the Boltzmann equation [7] has to be used in order to describe correctly the state of the gas. In this case the Knudsen number (Kn), defined as the ratio of the molecular mean-free path to a characteristic size, is close to the unity.

For a gas in a moderate state of rarefaction (Kn < 0.1), however, in order to take into account the rarefaction effects by using simpler models, it is usual to use the continuum mechanics equations to define the problem of interest, along with the velocity-slip and temperature-jump boundary conditions [3, 4, 5, 6, 7]. In particular, for the case of evaluating the temperature distribution in a rarefied gas restricted by a solid surface, the temperature-jump boundary condition is used to take into account the noted difference (proportional to the gradient of the temperature in the normal direction to the wall) between the temperature of the wall and the temperature of the gas near to the wall. In this way, the temperature-jump boundary condition is defined in terms of the temperature-jump coefficient [7, 8, 9].

Although the temperature-jump coefficient may be evaluated by solving either the Boltzmann equation or model equations (derived from the Bolztmann equation with simplified collision operators) [4, 10] it is usual to find its definition, as derived by Maxwell, written in terms of the accommodation coefficient of the gas [3]. This

approach is, according to the literature [11], just an estimation, since it is based on the assumption that the distribution function does not vary in the Knudsen layer. In fact, such an approach has been shown [11] to underestimate the value of the temperature-jump coefficient.

On the other hand, surface effects play a very important role in the analysis of the temperature in microscales, and so particular attention has to be given to the definition of the boundary conditions and to the choice of appropriate kernels to describe the gas-surface interaction [12, 13, 14].

In this work, we present a complete derivation of the solution of the temperature-jump problem for the one gas case (based on the S-model [15]) and a binary gas mixture (based on the McCormack model [16]). The solution is developed in terms of an analytical version of the discrete-ordinates method (the ADO method) [17]. In fact, the temperature-jump problem has been studied over the years, and previous results on this problem, based on numerical approaches, can be found in the literature [4, 6, 18, 19, 20, 21, 22, 23, 24]. The ADO method, which has been successfully applied to derive unified solutions for a wide class of problems in the rarefied gas dynamics field [25, 26, 27, 28], has been also applied to evaluate the temperature-jump coefficient [29, 30, 31, 32]. In particular, the ADO solution has been shown to be accurate and fast, in comparison with numerical based approaches.

Here, in addition to complete the class of problems solved by the ADO method, based on the kinetic S-model of the linearized Boltzmann equation [28], and to establish the relation between this formulation and its extension to the binary mixture case based on the McCormack model [32], we include, for the temperature-jump problem, a special treatment for the gas-surface interaction: the Cercignani–Lampis kernel [12]. In fact, considering the significance of the surface effect analysis on microflow applications and the good results obtained by the application of the ADO method to the solution of problems in this field, this kernel has been included in the treatment of channel problems by the ADO method [33, 34]. Differently from the commonly used Maxwell boundary condition [10], the Cercignani–Lampis kernel is defined in terms of two accommodation coefficients such that a better physical representation of the surface effects is allowed. In this work, a complete study of the dependence of the temperature-jump coefficient on different kinetic models as well as on the gas-surface interaction kernel is then carried out.

In this way, we develop in sections 2 and 3 the basic formulation for the one gas case, and we describe its ADO solution in section 4. We detail the McCormack model for a binary gas mixture in sections 5 and 6. In section 7 we present the discrete-ordinates solution for the mixture. We discuss computational aspects and numerical results in section 8 before presenting some concluding comments in section 9.

2. A model equation: The one gas case. To start this work, we follow Williams [10] and consider the steady-state nonlinear Boltzmann equation written, in a general form, as

$$\mathbf{v} \cdot \nabla_r f(\mathbf{r}, \mathbf{v}) = J(f', f), \tag{1}$$

where $f(\mathbf{r}, \mathbf{v})$ is the gas atom space and velocity distribution function (f and f' are associated with, respectively, before and after collision distributions) and J is the collision operator [10]. For the cases weakly far from the equilibrium, it is customary to write f as

$$f(\mathbf{r}, \mathbf{v}) = f_0(\mathbf{v})[1 + h(\mathbf{r}, \mathbf{v})], \tag{2}$$

where h is a perturbation caused, by the presence of the walls, to the absolute Maxwellian $f_0(\mathbf{v})$,

$$f_0(\mathbf{v}) = n_0(\lambda_0/\pi)^{3/2}\mathrm{e}^{-\lambda_0 v^2}, \quad \lambda_0 = m_0/(2kT_0). \tag{3}$$

Here k is the Boltzmann constant, T_0 is a reference temperature, m_0 is the mass, and n_0 is the equilibrium density of the gas. In this way, if we substitute (2) into (1) and use, along with properties of the collision operator [9], some physical considerations, we obtain, for the dimensionless velocity variable

$$\mathbf{c} = \mathbf{v}[(m/2kT_0)]^{1/2}, \tag{4}$$

the linearized Boltzmann equation written in terms of the perturbation function h as [10, 35]

$$c_y\frac{\partial}{\partial y}h(y,\mathbf{c}) + \varepsilon h(y,\mathbf{c}) = \varepsilon\pi^{-3/2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\mathrm{e}^{-c'^2}h(y,\mathbf{c}')F(\mathbf{c}':\mathbf{c})\mathrm{d}c'_x\mathrm{d}c'_y\mathrm{d}c'_z. \tag{5}$$

Here, in addition to the three components of the velocity vector (c_x, c_y, c_z) which are expressed in dimensionless units, we consider the dimensionless (written in terms of a mean-free path l) spatial variable $y > 0$, and

$$\varepsilon = \sigma_0^2 n_0 \pi^{1/2} l, \tag{6}$$

where σ_0 is the collision diameter of the gas particles (in the rigid-sphere approximation).

For rigid spheres, the scattering kernel $F(\mathbf{c}':\mathbf{c})$ can be expanded in terms of Legendre functions [36]. However, even if we consider a truncated form of this expansion, the problem of solving the resulting approximation of the linearized Boltzmann equation is still difficult from a numerical point of view [35]. For this reason, keeping in mind mathematical properties [7], one seeks to approximate the true kernel by physically meaningful approximations that can be more easily handled by analytical tools and numerical algorithms. In this way, the resulting equations are known as "model (kinetic) equations." Here we follow Siewert [33] and express the kernel, in (5), such that two of the well-known constant collision frequency models of the rarefied gas dynamics are represented:

$$F(\mathbf{c}':\mathbf{c}) = 1 + 2(\mathbf{c}'.\mathbf{c}) + (2/3)(c'^2 - 3/2)(c^2 - 3/2) + \widehat{\beta}M(\mathbf{c}':\mathbf{c}) \tag{7a}$$

with

$$M(\mathbf{c}':\mathbf{c}) = (4/15)(\mathbf{c}'.\mathbf{c})(c'^2 - 5/2)(c^2 - 5/2), \tag{7b}$$

where the case $\widehat{\beta} = 0$ defines the well-known BGK model equation [37] and the case $\widehat{\beta} = 1$ defines the S-model equation [15]. We note that, for both constant collision frequency models we use in this work, if we choose a mean-free path based on the viscosity to evaluate (6), we obtain [28, 35]

$$\varepsilon = \varepsilon_p = 1. \tag{8}$$

On the other hand, if we use a mean-free path based on thermal conductivity to evaluate (6), we get, respectively, for the BGK and the S-model

$$\varepsilon = \varepsilon_t = 1 \quad \text{and} \quad \varepsilon = \varepsilon_t = 3/2. \tag{9}$$

Taking into account the values listed in (8) and (9) we see that the evaluation of $\varepsilon_p/\varepsilon_t$ for the case of the S-model leads to a correct value for the Prandtl number (equal to 2/3). This aspect is considered an advantage of that model in comparison with the BGK model.

To complete the formulation of the temperature-jump problem, we write the boundary condition in terms of the Cercignani–Lampis kernel [12, 33],

$$h(0, c_x, c_y, c_z) = \int_0^\infty \int_{-\infty}^\infty \int_{-\infty}^\infty h(0, c'_x, -c'_y, c'_z) R(c'_x, -c'_y, c'_z : c_x, c_y, c_z) \mathrm{d}c'_x \mathrm{d}c'_z \mathrm{d}c'_y, \tag{10a}$$

where

$$R(c'_x, c'_y, c'_z : c_x, c_y, c_z) = \frac{2c'_y}{\pi \alpha_n \alpha_t (2 - \alpha_t)} T(c'_x : c_x) S(c'_y : c_y) T(c'_z : c_z) \tag{10b}$$

with

$$T(x : z) = \exp\left[-\frac{[(1 - \alpha_t)z - x]^2}{\alpha_t (2 - \alpha_t)} \right] \tag{10c}$$

and

$$S(x : z) = \exp\left[-\frac{[(1 - \alpha_n)^{1/2} z - x]^2}{\alpha_n} \right] \widehat{I}_0 \left[\frac{2(1 - \alpha_n)^{1/2} |xz|}{\alpha_n} \right]. \tag{10d}$$

For computational purposes, we write

$$\widehat{I}_0(w) = I_0(w) \mathrm{e}^{-w}, \tag{11a}$$

where $I_0(w)$ is the modified Bessel function,

$$I_0(w) = \frac{1}{2\pi} \int_0^{2\pi} \mathrm{e}^{w \cos \phi} \mathrm{d}\phi. \tag{11b}$$

Differently from the usual case of Maxwell boundary condition [10] defined in terms of one accommodation coefficient α, where it is assumed that some fraction α of the particles are reflected diffusely and the rest $(1 - \alpha)$ is reflected specularly, we can see in (10a) to (10d) that the Cercignani–Lampis kernel is defined in terms of two accommodation coefficients: $\alpha_t \in [0, 2)$ the accommodation coefficient of tangential momentum and $\alpha_n \in [0, 1)$ the accommodation coefficient of energy corresponding to the normal component of velocity. The use of more than one accommodation coefficient allows a better physical representation of the gas-surface interaction. In the case of the Cercignani–Lampis kernel, that is the case, according to the literature, mainly for roughness surfaces [24].

Still, to complete the definition of the temperature-jump problem, we have to specify the behavior of the solution at infinity. We impose the Welander condition [8]

$$\lim_{y \to \infty} \frac{\mathrm{d}}{\mathrm{d}y} T(y) = K, \tag{12}$$

where K is known and here the temperature perturbation is given, in terms of h as

$$T(y) = \frac{2}{3}\pi^{-3/2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathrm{e}^{-c'^2} h(y, c_x, c_y, c_z)\left(c^2 - \frac{3}{2}\right)\mathrm{d}c_x\mathrm{d}c_y\mathrm{d}c_z. \tag{13}$$

In solving the temperature-jump problem, in addition to the temperature perturbation already defined, another quantity we seek to compute is the density perturbation

$$N(y) = \pi^{-3/2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathrm{e}^{-c'^2} h(y, c_x, c_y, c_z)\mathrm{d}c_x\mathrm{d}c_y\mathrm{d}c_z. \tag{14}$$

By looking at the above definitions, (13) and (14), we see that we do not need to obtain the complete distribution h, but only some related integrals (moments), to compute those quantities. In this way, in what follows, we develop a procedure in order to get simpler problems, in terms of those moments, for which we will develop a solution with the ADO method.

3. A vector formulation–the S-model. In order to develop simpler formulations to evaluate the quantities of interest, we multiply (5) first by

$$\phi_1(c_x, c_z) = \frac{1}{\pi}\mathrm{e}^{-(c_x^2+c_z^2)} \tag{15}$$

and, in a second step by

$$\phi_2(c_x, c_z) = \frac{1}{\pi}(c_x^2 + c_z^2 - 2)\mathrm{e}^{-(c_x^2+c_z^2)}, \tag{16}$$

and, in both cases, we integrate over all c_x and c_z, such that, if we define

$$h_1(y, \xi) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \phi_1(c_x, c_z)h(y, c_x, c_y, c_z)\mathrm{d}c_x\mathrm{d}c_z, \tag{17}$$

$$h_2(y, \xi) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \phi_2(c_x, c_z)h(y, c_x, c_y, c_z)\mathrm{d}c_x\mathrm{d}c_z \tag{18}$$

and introduce the new notation $\xi = c_y$, we find that

$$\xi\frac{\partial}{\partial y}h_1(y, \xi) + \varepsilon h_1(y, \xi) = \varepsilon\int_{-\infty}^{\infty}\psi(\xi')\Big[\kappa_{11}(\xi', \xi)h_1(y, \xi') + \kappa_{12}(\xi', \xi)h_2(y, \xi')\Big]\mathrm{d}\xi' \tag{19}$$

and

$$\xi\frac{\partial}{\partial y}h_2(y, \xi) + \varepsilon h_2(y, \xi) = \varepsilon\int_{-\infty}^{\infty}\psi(\xi')\Big[\kappa_{21}(\xi', \xi)h_1(y, \xi') + \kappa_{22}(\xi', \xi)h_2(y, \xi')\Big]\mathrm{d}\xi', \tag{20}$$

with

$$\psi(\xi) = \pi^{-1/2}\mathrm{e}^{-\xi^2} \tag{21}$$

and

(22)
$$\kappa_{11}(\xi',\xi) = 1 + \frac{2}{3}\left(\xi^2 - \frac{1}{2}\right)\left(\xi'^2 - \frac{1}{2}\right) + \widehat{\beta}\left[2\xi'\xi + \frac{4}{15}\left(\xi'^2 - \frac{3}{2}\right)\left(\xi^2 - \frac{3}{2}\right)\xi'\xi\right],$$

(23)
$$\kappa_{12}(\xi',\xi) = \frac{2}{3}\left(\xi^2 - \frac{1}{2}\right) + \widehat{\beta}\left[\left(\frac{4}{15}\xi^2 - \frac{2}{5}\right)\xi\xi'\right],$$

(24)
$$\kappa_{21}(\xi',\xi) = \frac{2}{3}\left(\xi'^2 - \frac{1}{2}\right) + \widehat{\beta}\left[\left(\frac{4}{15}\xi'^2 - \frac{2}{5}\right)\xi\xi'\right],$$

(25)
$$\kappa_{22}(\xi',\xi) = \frac{2}{3} + \widehat{\beta}\frac{4}{15}\xi\xi'.$$

The same procedure, initiated in (15) and (16), is applied to the boundary condition, (10a), to define the components h_1 and h_2 at the boundary, which are written in the form

(26)
$$h_1(0,\xi) = \int_0^\infty h_1(0,-\xi')f(\xi',\xi)\mathrm{d}\xi'$$

and

(27)
$$h_2(0,\xi) = (1-\alpha_t)^2\int_0^\infty h_2(0,-\xi')f(\xi',\xi)\mathrm{d}\xi',$$

for ξ, $\xi'\in(0,\infty)$ and

(28)
$$f(\xi',\xi) = \frac{2\xi'}{\alpha_n}\exp\left[-\frac{[(1-\alpha_n)^{1/2}\xi - \xi']^2}{\alpha_n}\right]\widehat{I}_0\left[\frac{2(1-\alpha_n)^{1/2}\xi'\xi}{\alpha_n}\right].$$

In this way, we let $\mathbf{H}(y,\xi)$ be the vector with components $h_1(y,\xi)$ and $h_2(y,\xi)$ and rewrite (19) to (28) in a more appropriate matrix form as

(29)
$$\xi\frac{\partial}{\partial y}\mathbf{H}(y,\xi) + \varepsilon\mathbf{H}(y,\xi) = \varepsilon\int_{-\infty}^{\infty}\psi(\xi')\boldsymbol{K}(\xi',\xi)\mathbf{H}(y,\xi')\mathrm{d}\xi',$$

for $y>0$ and $\xi\in(-\infty,\infty)$. Here we note (21) to (25) and the definitions of

(30)
$$\mathbf{H}(y,\xi) = \begin{bmatrix} h_1(y,\xi) \\ h_2(y,\xi) \end{bmatrix}$$

and

(31)
$$\boldsymbol{K}(\xi',\xi) = \begin{bmatrix} \kappa_{11}(\xi',\xi) & \kappa_{12}(\xi',\xi) \\ \kappa_{21}(\xi',\xi) & \kappa_{22}(\xi',\xi \end{bmatrix}.$$

In regard to the boundary condition, we write

(32)
$$\mathbf{H}(0,\xi) = \mathbf{A}\int_0^\infty \mathbf{H}(0,-\xi')f(\xi',\xi)\mathrm{d}\xi',$$

with

$$\mathbf{A} = \begin{bmatrix} 1 & 0 \\ 0 & (1-\alpha_t)^2 \end{bmatrix}, \tag{33}$$

for ξ, $\xi' \in (0,\infty)$.

Finally, we also use the vector notation to express, respectively, the temperature and density perturbations, given in (13) and (14), in the form

$$T(y) = \frac{2}{3}\int_{-\infty}^{\infty} \begin{bmatrix} \xi^2 - 1/2 \\ 1 \end{bmatrix}^T \mathbf{H}(y,\xi)\psi(\xi)\mathrm{d}\xi \tag{34}$$

and

$$N(y) = \begin{bmatrix} 1 \\ 0 \end{bmatrix}^T \int_{-\infty}^{\infty} \mathbf{H}(y,\xi)\psi(\xi)\mathrm{d}\xi. \tag{35}$$

We now proceed to develop a discrete-ordinates solution for the vector problem. In what follows we chose to assume the S-model case ($\widehat{\beta} = 1$), to which the expression for the kernel and the development of the solution are more general. Much simpler expressions can be found for the BGK model, and the work of Barichello and Siewert [29] can be used to follow that derivation.

4. A discrete-ordinates solution (I). We now seek for a discrete-ordinates solution of the problem defined by (29) and (32) and the condition given by (12). In this sense, the analytical discrete-ordinates method we use in this work, the ADO method [17], is based on a half-range quadrature scheme, and so as a first step we write (29) in the form

$$\xi\frac{\partial}{\partial y}\mathbf{H}(y,\xi) + \varepsilon\mathbf{H}(y,\xi) = \varepsilon\int_0^{\infty} \psi(\xi')[\boldsymbol{K}(\xi',\xi)\mathbf{H}(y,\xi') + \boldsymbol{K}(-\xi',\xi)\mathbf{H}(y,-\xi')]\mathrm{d}\xi', \tag{36}$$

and we seek solutions of (36) of the form

$$\mathbf{H}(y,\xi) = \mathbf{\Phi}(\nu,\xi)\ \mathrm{e}^{-y\varepsilon/\nu}, \tag{37}$$

where the separation constants ν and the elementary (2×1 vector) solutions $\mathbf{\Phi}$ are to be determined. Substituting (37) into (36) we find that

$$\varepsilon(\nu-\xi)\mathbf{\Phi}(\nu,\xi) = \varepsilon\nu\int_0^{\infty} \psi(\xi')[\boldsymbol{K}(\xi',\xi)\mathbf{\Phi}(\nu,\xi') + \boldsymbol{K}(-\xi',\xi)\mathbf{\Phi}(\nu,-\xi')]\mathrm{d}\xi' \tag{38}$$

and

$$\varepsilon(\nu+\xi)\mathbf{\Phi}(\nu,-\xi) = \varepsilon\nu\int_0^{\infty} \psi(\xi')[\boldsymbol{K}(\xi',-\xi)\mathbf{\Phi}(\nu,\xi') + \boldsymbol{K}(-\xi',-\xi)\mathbf{\Phi}(\nu,-\xi')]\mathrm{d}\xi'. \tag{39}$$

Here we note, since

$$\boldsymbol{K}(\xi',-\xi) = \boldsymbol{K}(-\xi',\xi), \tag{40}$$

that

$$\mathbf{\Phi}(\nu,\xi) = \mathbf{\Phi}(-\nu,-\xi). \tag{41}$$

Continuing our development, we add and subtract (38) and (39), one from the other, to find that

$$\frac{1}{\xi^2}\left[\mathbf{V}(\nu,\xi) - \int_0^\infty \psi(\xi')\mathbf{P}(\xi',\xi)\mathbf{V}(\nu,\xi')\mathrm{d}\xi'\right] = \lambda\mathbf{V}(\nu,\xi) \tag{42}$$

and

$$\mathbf{U}(\nu,\xi) = \frac{\nu}{\xi}\left[\mathbf{V}(\nu,\xi) - \int_0^\infty \psi(\xi')[\boldsymbol{K}(\xi',\xi)\mathbf{V}(\nu,\xi') - \boldsymbol{K}(-\xi',\xi)\mathbf{V}(\nu,\xi')]\mathrm{d}\xi'\right], \tag{43}$$

where

$$\mathbf{U}(\nu,\xi) = \mathbf{\Phi}(\nu,\xi) + \mathbf{\Phi}(\nu,-\xi), \tag{44}$$

$$\mathbf{V}(\nu,\xi) = \mathbf{\Phi}(\nu,\xi) - \mathbf{\Phi}(\nu,-\xi), \tag{45}$$

and

$$\lambda = 1/\nu^2. \tag{46}$$

Still, we note that the separation constants ν occur in $(\pm)$ pairs, and

$$\begin{aligned}\mathbf{P}(\xi',\xi) = \frac{\xi}{\xi'}\Big[&[\boldsymbol{K}(\xi',\xi) + \boldsymbol{K}(-\xi',\xi)] + [\boldsymbol{K}(\xi',\xi) - \boldsymbol{K}(-\xi',\xi)]\Big] \\ -\int_0^\infty \psi(\xi'')\frac{\xi}{\xi''}&[\boldsymbol{K}(\xi',\xi'') - \boldsymbol{K}(-\xi',\xi'')][\boldsymbol{K}(\xi'',\xi) + \boldsymbol{K}(-\xi'',\xi)]\mathrm{d}\xi''.\end{aligned} \tag{47}$$

At this point, we introduce a half-range quadrature scheme, in $[0,\infty)$, defined by N nodes $\{\xi_k\}$ and weights $\{\omega_k\}$, and rewrite (42) and (43) evaluated at the quadrature points as

$$\frac{1}{\xi_i^2}\left[\mathbf{V}(\nu_j,\xi_i) - \sum_{k=1}^N \omega_k\psi(\xi_k)\mathbf{P}(\xi_k,\xi_i)\mathbf{V}(\nu_j,\xi_k)\right] = \lambda_j\mathbf{V}(\nu_j,\xi_i) \tag{48}$$

and

$$\mathbf{U}(\nu_j,\xi_i) = \frac{\nu_j}{\xi_i}\left[\mathbf{V}(\nu_j,\xi_i) - \sum_{k=1}^N \omega_k\psi(\xi_k)[\mathbf{K}(\xi_k,\xi_i)\mathbf{V}(\nu_j,\xi_k) - \mathbf{K}(-\xi_k,\xi_i)\mathbf{V}(\nu_j,\xi_k)]\right] \tag{49}$$

for $i = 1, 2, \ldots, N$. Once we solve our eigenvalue problem, defined by (48), we have the elementary solutions from

$$\mathbf{\Phi}(\nu_j,\xi_i) = \frac{1}{2}\Big[\mathbf{U}(\nu_j,\xi_i) + \mathbf{V}(\nu_j,\xi_i)\Big] \tag{50}$$

and

$$\mathbf{\Phi}(\nu_j,-\xi_i) = \frac{1}{2}\Big[\mathbf{U}(\nu_j,\xi_i) - \mathbf{V}(\nu_j,\xi_i)\Big]. \tag{51}$$

In (48) to (51) we use the subscript j to label the eigenvalues. For each j, (50) and (51) express $2N \times 1$ vectors.

Here it may be important to make a comment in regard to the eigenvalue problem defined in (42). In applying the ADO method we have found, for different model equations and for different classes of problems, specific eigenvalue problems. In most of those cases the problem is much simpler and expressed in a much more concise form than in the case of this work. Even the case of diagonal + rank one type matrix can be mentioned [17, 38]. In fact, for the specific derivation presented above, some properties of the kernel can also be used to derive a simpler eigenvalue problem, as shown by Scherer [39]. We chose, however, to keep the derivation as it is, in order to establish more close connections and analogies with the mixtures case we will present later on in this text.

Continuing, we consider (50) and (51) along with (46), we take the positive root ν_j, and we write the general discrete-ordinates solution to (29) as

$$\mathbf{H}(y, \pm\xi_i) = \sum_{j=1}^{2N} [A_j \mathbf{\Phi}(\nu_j, \pm\xi_i) \mathrm{e}^{-y\varepsilon/\nu_j} + B_j \mathbf{\Phi}(\nu_j, \mp\xi_i) \mathrm{e}^{y\varepsilon/\nu_j}], \tag{52}$$

for $i = 1, 2, \ldots, N$. Here the arbitrary constants are to be determined from the boundary condition and the imposed condition at infinity. Before doing that, however, we note that the eigenvalue problem yields two separation constants, say ν_1 and ν_2, that become unbounded. Because of this, we rewrite the general solution as

$$\mathbf{H}(y, \pm\xi_i) = \mathbf{H}^*(y, \pm\xi_i) + \sum_{j=3}^{2N} [A_j \mathbf{\Phi}(\nu_j, \pm\xi_i) \mathrm{e}^{-y\varepsilon/\nu_j} + B_j \mathbf{\Phi}(\nu_j, \mp\xi_i) \mathrm{e}^{y\varepsilon/\nu_j}], \tag{53}$$

$i = 1, 2, \ldots, N$, where we then introduced, in (53), four linear independent exact solutions of (29). In other words,

$$\mathbf{H}^*(y, \xi) = A_1 \mathbf{H}_1 + A_2 \mathbf{H}_2(\xi) + B_1 \mathbf{H}_3(\xi) + B_2 \mathbf{H}_4(\xi), \tag{54}$$

where, for the S-model,

$$\mathbf{H}_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \mathbf{H}_2(\xi) = \begin{bmatrix} \xi^2 - 1/2 \\ 1 \end{bmatrix}, \quad \mathbf{H}_3(\xi) = \begin{bmatrix} \xi \\ 0 \end{bmatrix}, \tag{55}$$

and

$$\mathbf{H}_4(y, \xi) = y\mathbf{G}_1(\xi) + \mathbf{F}_1(\xi) \tag{56a}$$

with

$$\mathbf{G}_1(\xi) = \begin{bmatrix} \xi^2 - 3/2 \\ 1 \end{bmatrix} \tag{56b}$$

and

$$\mathbf{F}_1(\xi) = \frac{-3\xi}{2\varepsilon} \mathbf{G}_1(\xi). \tag{56c}$$

In fact, in the process of finding the $\mathbf{H}_4$ solution, once that (56b) is an exact solution of (29), we can follow analogous procedure as the one proposed by Siewert [32], and we substitute (56a) into (29) to find that

$$\mathbf{F}_1(\xi) = -\frac{1}{\varepsilon}\xi\mathbf{G}_1(\xi) + \int_{-\infty}^{\infty} \psi(\xi')\boldsymbol{K}(\xi',\xi)\mathbf{F}_1(\xi')\mathrm{d}\xi'. \tag{57}$$

The form of the inhomogeneous term, in (57), as well as the the form of $\boldsymbol{K}(\xi',\xi)$ suggest that we look for solutions of the form

$$\mathbf{F}_1(\xi) = \sum_{\alpha=0}^{3} P_\alpha(\xi)\mathbf{F}_{1,\alpha}, \tag{58}$$

where $\mathbf{F}_{1,\alpha}$ are constant vectors and $P_\alpha(\xi)$ are orthogonal polynomials given by

$$P_0(\xi) = 1\ ,\quad P_1(\xi) = \xi\ ,\quad P_2(\xi) = \xi^2 - 1/2, \quad \text{and} \quad P_3(\xi) = \xi(\xi^2 - 3/2). \tag{59}$$

Thus, if we first substitute (58) into (57), and then we multiply the equation by $\psi(\xi)P_k(\xi)$, for $k = 0, 1, 2, 3$, to finally integrate over all ξ, we obtain an algebraic system (with 8 equations and rank 6)

$$\sum_{\alpha=0}^{3} P_\alpha(\xi)\mathbf{F}_{1,\alpha} = -\frac{1}{\varepsilon}\xi\mathbf{G}_1(\xi) + \int_{-\infty}^{\infty} \psi(\xi')\boldsymbol{K}(\xi',\xi)\sum_{\alpha=0}^{3} P_\alpha(\xi')\mathbf{F}_{1,\alpha}\mathrm{d}\xi', \tag{60}$$

for which a solution can be found explicitly, as the one given in (56a).

So, at this point we can go back to the issue of determining, in (53), the $4N$ arbitrary constants, such that our discrete-ordinates solution will be completely established. To start, if we consider the way that the solution is required to diverge at infinity, we take $B_j = 0$ for $j = 3, 4, \ldots, 2N$. In addition, when considering the Welander condition, given by (12) (and noting (34)), we find that

$$B_2 = K. \tag{61}$$

Still, we note that the solution $\mathbf{H}_1$, (55), satisfies the homogeneous boundary condition given by (32), and so the A_1 coefficient cannot be determined from that equation. However, following previous works [29, 40] we can impose on our solution an additional normalization condition

$$\lim_{y\to\infty}\left[N(y) + T(y)\right] = 0 \tag{62}$$

from where we get that

$$A_2 = -A_1. \tag{63}$$

In this way, we rewrite the general solution, (53), for $i = 1, 2, \ldots, N$, as

$$\mathbf{H}(y,\pm\xi_i) = A_2\mathbf{G}_1(\pm\xi_i) + B_1\mathbf{H}_3(\pm\xi_i) + K\mathbf{H}_4(y,\pm\xi_i) + \sum_{j=3}^{2N} A_j\boldsymbol{\Phi}(\nu_j,\pm\xi_i)\mathrm{e}^{-y\varepsilon/\nu_j}. \tag{64}$$

To determine the remaining $2N$ arbitrary constants, we substitute (64) into the discrete-ordinates version of the boundary condition given by (32)

$$\mathbf{H}(0,\xi_i) = \mathbf{A}\sum_{k=1}^{N}\omega_k \mathrm{e}^{-\xi_k{}^2}\mathbf{H}(0,-\xi_k)f(\xi_k,\xi_i), \tag{65}$$

for $i = 1, 2, \ldots, N$. We then obtain the following $2N \times 2N$ linear algebraic system:

$$\begin{aligned} A_2\mathbf{C^1}(\xi_i) + B_1\mathbf{C^2}(\xi_i) + \sum_{j=3}^{2N} A_j\left\{\mathbf{\Phi}_+(\nu_j) - \sum_{k=1}^{N}\omega_k f(\xi_k,\xi_i)\mathbf{A}^*\mathbf{\Phi}_-(\nu_j)\right\} \\ = K\left\{\sum_{k=1}^{N}\omega_k f(\xi_k,\xi_i)\mathbf{A}^*\mathbf{B}^*(-\xi_k) - \mathbf{B}^*(\xi_i)\right\}, \end{aligned} \tag{66}$$

where the components of the vectors $\mathbf{\Phi}_+(\nu_j)$ and $\mathbf{\Phi}_-(\nu_j)$ are given by (50) and (51),

$$\mathbf{C^1}(\xi_i) = \sum_{k=1}^{N}\omega_k f(\xi_k,\xi_i)\mathbf{A}^*\mathbf{R}^*(-\xi_k) - \mathbf{R}^*(\xi_i), \tag{67}$$

and

$$\mathbf{C^2}(\xi_i) = \mathbf{H}_3^*(\xi_i) - \sum_{k=1}^{N}\omega_k f(\xi_k,\xi_i)\mathbf{A}^*\mathbf{H}_3^*(-\xi_k). \tag{68}$$

Here $\mathbf{R}^*(\xi)$ is a $2N \times 1$ vector where each 2×1 component is

$$\mathbf{R}(\xi) = -\mathbf{G}_1(\xi) \tag{69}$$

for $\mathbf{G}_1(\xi)$ defined in (56b); $\mathbf{A}^*$ is a $2N \times 2N$ block diagonal matrix

$$\mathbf{A}^* = \mathrm{diag}\Big\{\mathbf{A}, \mathbf{A}, \ldots, \mathbf{A}, \mathbf{A}\Big\} \tag{70}$$

with $\mathbf{A}$ given in (33); $\mathbf{H}_3^*(\xi)$ and $\mathbf{B}^*(\xi)$ are $2N \times 1$ vectors where each 2×1 component is, respectively, defined in (55) and (56c). In addition, $f(\xi_k, \xi_i)$ is defined in (28).

Considering now the quantities we want to evaluate, we substitute (53) into the discrete-ordinates version of (34) and (35) to write the temperature perturbation

$$T(y) = Ky + A_2 + 2/3\sum_{j=3}^{2N} A_j\ (\mathrm{e}^{-y\varepsilon/\nu_j})M_1(\nu_j) \tag{71}$$

and the density perturbation

$$N(y) = -Ky - A_2 + \sum_{j=3}^{2N} A_j\ (\mathrm{e}^{-y\varepsilon/\nu_j})M_2(\nu_j), \tag{72}$$

where M_1 and M_2 are, respectively, the components of the vector given by

$$\mathbf{M}^*(\nu_j) = \pi^{-1/2}\sum_{k=1}^{N}\omega_k e^{-\xi_k{}^2}\begin{bmatrix} \xi_k^2 - 1/2 & 1 \\ 1 & 0 \end{bmatrix}[\mathbf{\Phi}(\nu_j,\xi_k) + \mathbf{\Phi}(\nu_j,-\xi_k)]. \tag{73}$$

Still, if we look now at the linear component of the temperature perturbation expression

$$T^*(y) = Ky + A_2 \tag{74}$$

we can define another quantity of interest, which relates the temperature perturbation at the wall with the gradient of the temperature, the temperature-jump coefficient ζ, as

$$T^*(0) = \zeta \frac{\mathrm{d}}{\mathrm{d}y} T^*(y)\Big|_{y=0} \tag{75}$$

such that

$$\zeta = A_2/K. \tag{76}$$

To be clear, we note that the normalization constant introduced in (62) does not affect the temperature-jump coefficient or the temperature perturbation. In fact, another choice of that constant would change only the density perturbation by the addition of a constant factor [30].

5. The McCormack model and a mixture of gases. In regard to a binary gas mixture, in this work we base our discussion on the McCormack model, as introduced by McCormack [16], following an appropriate notation proposed by Siewert [32]. In this way, to derive the balance equation, we consider the functions $h_\alpha(x, \mathbf{v})$ for the two types of particles ($\alpha = 1$ and 2) which denote perturbations from Maxwellian distributions for each species,

$$f_\alpha(y^*, \mathbf{v}) = f_{\alpha,0}(\mathbf{v})[1 + h_\alpha(y^*, \mathbf{v})], \tag{77}$$

where

$$f_{\alpha,0}(\mathbf{v}) = n_\alpha(\lambda_\alpha/\pi)^{3/2}\mathrm{e}^{-\lambda_\alpha v^2}, \quad \lambda_\alpha = m_\alpha/(2kT_0). \tag{78}$$

Here, again, k is the Boltzmann constant, m_α is the mass, n_α is the equilibrium density of the αth species, T_0 is a reference temperature, y^* is the spatial variable, and the vector $\mathbf{v}$, with magnitude v, is the particle velocity with components v_x, v_y, and v_z. It is found [16] that the balance equation is of the form

$$c_y \frac{\partial}{\partial y^*} h_\alpha(y^*, \mathbf{c}) + w_\alpha \gamma_\alpha h_\alpha(y^*, \mathbf{c}) = w_\alpha \gamma_\alpha \mathcal{L}_\alpha\{h_1, h_2\}(y^*, \mathbf{c}), \quad \alpha = 1, 2, \tag{79}$$

where $\mathbf{c}$, with magnitude c and components c_x, c_y, and c_z, is now a dimensionless velocity variable. In obtaining (79), we followed Siewert [32] and expressed the dimensionless variable $\mathbf{c}$ differently in the two equations: for the case $\alpha = 1$ we defined $\mathbf{c} = w_1\mathbf{v}$, and, analogously, for the case $\alpha = 2$ we defined $\mathbf{c} = w_2\mathbf{v}$, where

$$w_\alpha = [m_\alpha/(2kT_0)]^{1/2}, \quad \alpha = 1, 2. \tag{80}$$

Still, in (79), the γ_α are to be defined later, and the collision operator is written as

$$\mathcal{L}_\alpha\{h_1, h_2\}(y^*, \mathbf{c}) = \frac{1}{\pi^{3/2}} \sum_{\beta=1}^{2} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathrm{e}^{-c'^2} h_\beta(y^*, \mathbf{c}') \boldsymbol{K}_{\beta,\alpha}(\mathbf{c}', \mathbf{c}) \mathrm{d}c'_x \mathrm{d}c'_y \mathrm{d}c'_z, \tag{81}$$

with the kernels expressed, in a general form, as [32]

(82)
$$\boldsymbol{K}_{\beta,\alpha} = \boldsymbol{K}^{(1)}_{\beta,\alpha}(\mathbf{c}',\mathbf{c}) + \boldsymbol{K}^{(2)}_{\beta,\alpha}(\mathbf{c}',\mathbf{c}) + \boldsymbol{K}^{(3)}_{\beta,\alpha}(\mathbf{c}',\mathbf{c}) + \boldsymbol{K}^{(4)}_{\beta,\alpha}(\mathbf{c}',\mathbf{c}), \quad \alpha,\beta = 1,2.$$

To avoid a heavy notation in the middle of the text, explicit expressions for each of the components in (82) are listed in Appendix A.

As in the one gas case, in (5), we introduce a dimensionless spatial variable $y = y^*/l_0$, where now l_0 is the mean-free path suggested by Sharipov and Kalempa [41], based on viscosity, defined as

(83)
$$l_0 = \frac{\mu v_0}{P_0},$$

for

(84)
$$v_0 = \left(\frac{2kT_0}{m}\right)^{1/2}$$

and

(85)
$$m = \frac{n_1 m_1 + n_2 m_2}{n_1 + n_2}.$$

In regard to (81), we continue to follow Sharipov and Kalempa [41] and Siewert [32] and express the viscosity of the mixture in terms of the pressures P_α and the collision frequencies γ_α as

(86)
$$\mu = \frac{P_1}{\gamma_1} + \frac{P_2}{\gamma_2},$$

where

(87)
$$\frac{P_\alpha}{P_0} = \frac{n_\alpha}{n_1 + n_2},$$

(88a)
$$\gamma_1 = \frac{\Psi_1\Psi_2 - \nu^{(4)}_{1,2}\nu^{(4)}_{2,1}}{\Psi_2 + \nu^{(4)}_{1,2}},$$

and

(88b)
$$\gamma_2 = \frac{\Psi_1\Psi_2 - \nu^{(4)}_{1,2}\nu^{(4)}_{2,1}}{\Psi_1 + \nu^{(4)}_{2,1}}.$$

In addition,

(89a)
$$\Psi_1 = \nu^{(3)}_{1,1} - \nu^{(4)}_{1,1} + \nu^{(3)}_{1,2},$$

(89b)
$$\Psi_2 = \nu^{(3)}_{2,2} - \nu^{(4)}_{2,2} + \nu^{(3)}_{2,1}.$$

Again, we used above some definitions listed in Appendix A.

At this point, we introduce [32]

$$\sigma_\alpha = \gamma_\alpha \omega_\alpha l_0 \tag{90}$$

or, more explicitly,

$$\sigma_\alpha = \gamma_\alpha \frac{n_1/\gamma_1 + n_2/\gamma_2}{n_1 + n_2} \left(\frac{m_\alpha}{m}\right)^{1/2}, \tag{91}$$

such that, in the next section, we rewrite (79), in order to specifically define the temperature-jump problem based on the McCormack model, that we want to solve in this work, including the Cercignani–Lampis kernel.

6. A binary gas mixture. Taking into account the development presented in the previous section, our starting point is now, analogously to the one gas case, (5), the kinetic equation for the McCormack model written as

$$c_y \frac{\partial}{\partial y} h_\alpha(y, \mathbf{c}) + \sigma_\alpha h_\alpha(y, \mathbf{c}) = \sigma_\alpha \mathcal{L}_\alpha\{h_1, h_2\}(y, \mathbf{c}) \tag{92}$$

for $y > 0$, the dimensionless variable (measured in terms of the mean-free path l_0), σ_α given in (90), and the collision operator defined in (82) and in Appendix A. For defining the temperature-jump problem, we supplement (92) with boundary condition, written in terms of the Cercignani–Lampis kernel as

(93)
$$h_\alpha(0, c_x, -c_y, c_z) = \int_0^\infty \int_{-\infty}^\infty \int_{-\infty}^\infty h_\alpha(0, c'_x, c'_y, c'_z) R_\alpha(c'_x, c'_y, c'_z : c_x, -c_y, c_z) \mathrm{d}c'_x \mathrm{d}c'_z \mathrm{d}c'_y,$$

for $c_y > 0$, all c_x, c_z, and $\alpha = 1, 2$. Here

(94a)
$$R_\alpha(c'_x, c'_y, c'_z : c_x, c_y, c_z) = \frac{2c'_y}{\pi a_{n\alpha} a_{t\alpha}(2 - a_{t\alpha})} T_\alpha(c'_x : c_x) S_\alpha(c'_y : c_y) T_\alpha(c'_z : c_z),$$

$$T_\alpha(x : z) = \exp\left[-\frac{[(1 - a_{t\alpha})z - x]^2}{a_{t\alpha}(2 - a_{t\alpha})}\right], \tag{94b}$$

$$S_\alpha(x : z) = \exp\left[-\frac{[(1 - a_{n\alpha})^{1/2} z - x]^2}{a_{n\alpha}}\right] \widehat{I}_0\left[\frac{2(1 - a_{n\alpha})^{1/2} |xz|}{a_{n\alpha}}\right], \tag{94c}$$

and $\widehat{I}_0(z)$ is defined as in (11a). In addition, $a_{t\alpha}$ are the tangential momentum accommodation coefficients for each species α ($\alpha = 1, 2$), and $a_{n\alpha}$ are the normal accommodation coefficients for each species α ($\alpha = 1, 2$). The formulation of the temperature-jump problem will be complete with the use of the condition, at infinity, on the temperature perturbation, as we show later on in this text.

In addition to the temperature perturbation

$$T_\alpha(y) = \frac{2}{3}\pi^{-3/2} \int_{-\infty}^\infty \int_{-\infty}^\infty \int_{-\infty}^\infty \mathrm{e}^{-c'^2} h_\alpha(y, c_x, c_y, c_z) \left(\mathbf{c}^2 - \frac{3}{2}\right) \mathrm{d}c_x \mathrm{d}c_y \mathrm{d}c_z \tag{95}$$

we seek to compute also the density perturbation

$$N_\alpha(y) = \pi^{-3/2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathrm{e}^{-c'^2} h_\alpha(y, c_x, c_y, c_z) \mathrm{d}c_x \mathrm{d}c_y \mathrm{d}c_z. \tag{96}$$

Since we do not have to compute the complete distribution h, as we did for the one gas case, we develop a simpler formulation, by multiplying successively (92) by (15) and (16) and defining

$$g_{2\alpha-1}(y, \xi) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \phi_1(c_x, c_z) h_\alpha(y, c_x, \xi, c_z) \mathrm{d}c_x \mathrm{d}c_z \tag{97}$$

and

$$g_{2\alpha}(y, \xi) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \phi_2(c_x, c_z) h_\alpha(y, c_x, \xi, c_z) \mathrm{d}c_x \mathrm{d}c_z, \tag{98}$$

for $\alpha = 1, 2$. We then obtain four coupled equations, which we write in a matrix form, for the components of $\mathbf{G}(y, \xi)$ given by (97) and (98),

$$\xi \frac{\partial}{\partial y} \mathbf{G}(y, \xi) + \mathbf{\Sigma} \mathbf{G}(y, \xi) = \mathbf{\Sigma} \int_{-\infty}^{\infty} \psi(\xi') \boldsymbol{K}_M(\xi', \xi) \mathbf{G}(y, \xi') \mathrm{d}\xi', \tag{99}$$

with

$$\mathbf{\Sigma} = \mathrm{diag}\{\sigma_1, \sigma_1, \sigma_2, \sigma_2\} \tag{100}$$

and $\psi(\xi)$ given in (21). In regard to (99), we list the elements $k_{i,j}(\xi', \xi)$ of the (matrix) kernel $\boldsymbol{K}_M(\xi', \xi)$ in Appendix B.

To establish the matrix form of the boundary condition, once more, we use the projections defined by (15) and (16) along with (97) and (98) to obtain, from (93),

$$\mathbf{G}(0, \xi) = \mathbf{D} \int_0^{\infty} \mathbf{F}(\xi', \xi) \mathbf{G}(0, -\xi) \mathrm{d}\xi', \quad \xi > 0, \tag{101}$$

where

$$\mathbf{D} = \mathrm{diag}\left\{1, (1 - a_{t1})^2, 1, (1 - a_{t2})^2\right\} \tag{102}$$

and

$$\mathbf{F}(\xi', \xi) = \mathrm{diag}\left\{f_1(\xi', \xi), f_1(\xi', \xi), f_2(\xi', \xi), f_2(\xi', \xi)\right\}. \tag{103}$$

Here

$$f_1(\xi', \xi) = \frac{2\xi'}{a_{n1}} \exp\left[-\frac{[(1 - a_{n1})^{1/2}\xi - \xi']^2}{a_{n1}}\right] \widehat{I}_0\left[\frac{2(1 - a_{n1})^{1/2}\xi'\xi}{a_{n1}}\right] \tag{104}$$

and

$$f_2(\xi', \xi) = \frac{2\xi'}{a_{n2}} \exp\left[-\frac{[(1 - a_{n2})^{1/2}\xi - \xi']^2}{a_{n2}}\right] \widehat{I}_0\left[\frac{2(1 - a_{n2})^{1/2}\xi'\xi}{a_{n2}}\right], \tag{105}$$

for $\xi, \xi' \in (0, \infty)$.

Once we solve the vector problem, we can compute the density and the temperature perturbations, respectively, given by

$$N_\alpha(y) = \int_{-\infty}^{\infty} \psi(\xi) g_{2\alpha-1}(y,\xi)\mathrm{d}\xi, \quad \alpha = 1,2, \tag{106}$$

and

$$T_\alpha(y) = \frac{2}{3}\int_{-\infty}^{\infty} \psi(\xi)\left[\left(\xi^2 - \frac{1}{2}\right) g_{2\alpha-1}(y,\xi) + g_{2\alpha}(y,\xi)\right]\mathrm{d}\xi, \quad \alpha = 1,2, \tag{107}$$

and we write, in this new notation, the condition imposed to the behavior of the solution at infinity [32]

$$\lim_{y\to\infty} \frac{\mathrm{d}}{\mathrm{dy}}\mathbf{T}(y) = K\begin{bmatrix} 1 \\ 1 \end{bmatrix}. \tag{108}$$

Here K is considered known and $T_\alpha(y)$ are the components of the vector $\mathbf{T}(y)$.

In the next section we develop a discrete-ordinates solution for the problem defined by (99) to (108).

7. A discrete-ordinates solution (II). When seeking (4×1) solutions of (99) in the form

$$\mathbf{G}(y,\xi) = \mathbf{\Phi}(\nu,\xi)\ \mathrm{e}^{-y/\nu} \tag{109}$$

we follow the same steps described in section 4, when dealing with the one gas case. Then we do not repeat it here, but we write the eigenvalue problem relevant to this case:

$$(1/\xi_i^2)\left[\mathbf{\Sigma}^2\mathbf{V}(\nu_j,\xi_i) - \sum_{k=1}^{N}\omega_k\psi(\xi_k)\mathbf{P}(\xi_k,\xi_i)\mathbf{V}(\nu_j,\xi_k)\right] = \lambda_j\mathbf{V}(\nu_j,\xi_i) \tag{110}$$

with

$$\mathbf{U}(\nu_j,\xi_i) = (\nu_j/\xi_i)\mathbf{\Sigma}\Bigg[\mathbf{V}(\nu_j,\xi_i) - \sum_{k=1}^{N}\omega_k\psi(\xi_k)[\boldsymbol{K}_M(\xi_k,\xi_i)\mathbf{V}(\nu_j,\xi_k) - \boldsymbol{K}_M(-\xi_k,\xi_i)\mathbf{V}(\nu_j,\xi_k)]\Bigg] \tag{111}$$

for $i = 1,2,\ldots,N$. Here

$$\mathbf{P}(\xi',\xi) = (\xi/\xi')\mathbf{\Sigma}[\boldsymbol{K}_M(\xi',\xi) + \boldsymbol{K}_M(-\xi',\xi)]\mathbf{\Sigma} + \mathbf{\Sigma}^2[\boldsymbol{K}_M(\xi',\xi) - \boldsymbol{K}_M(-\xi',\xi)] - \int_0^{\infty}\psi(\xi'')(\xi/\xi'')\mathbf{\Sigma}[\boldsymbol{K}_M(\xi'',\xi) + \boldsymbol{K}_M(-\xi'',\xi)]\mathbf{\Sigma}[\boldsymbol{K}_M(\xi',\xi'') - \boldsymbol{K}_M(-\xi',\xi'')]\mathrm{d}\xi''. \tag{112}$$

We are also able to get the elementary solutions

$$\mathbf{\Phi}(\nu_j,\xi_i) = (1/2)\Big[\mathbf{U}(\nu_j,\xi_i) + \mathbf{V}(\nu_j,\xi_i)\Big] \tag{113}$$

and

$$\mathbf{\Phi}(\nu_j,-\xi_i) = (1/2)\Big[\mathbf{U}(\nu_j,\xi_i) - \mathbf{V}(\nu_j,\xi_i)\Big] \tag{114}$$

to write the general solution of the problem given by (99) as

$$\mathbf{G}(y,\pm\xi_i)=\sum_{j=1}^{4N}[A_j\mathbf{\Phi}(\nu_j,\pm\xi_i)\mathrm{e}^{-y/\nu_j}+B_j\mathbf{\Phi}(\nu_j,\mp\xi_i)\mathrm{e}^{y/\nu_j}] \tag{115}$$

for $i=1,2,\ldots,N$.

As noted in the one gas case, and as usual for conservative problems as these in the rarefied gas dynamics, we find again some unbounded separation constants: in this case the number is three. So, we rewrite the previous equation as

$$\mathbf{G}(y,\pm\xi_i)=\mathbf{G}^*(y,\pm\xi_i)+\sum_{j=4}^{4N}[A_j\mathbf{\Phi}(\nu_j,\pm\xi_i)\mathrm{e}^{-y/\nu_j}+B_j\mathbf{\Phi}(\nu_j,\mp\xi_i)\mathrm{e}^{y/\nu_j}] \tag{116}$$

for $i=1,2,\ldots,N$, where

$$\begin{aligned}\mathbf{G}^*(y,\xi)=&A_1\mathbf{G}_1+A_2\mathbf{G}_2+A_3\mathbf{G}_3+B_1\mathbf{G}_4(\xi)\\&+B_2[y\mathbf{H}_1(\xi)+\mathbf{F}_1(\xi)]+B_3[y\mathbf{H}_2(\xi)+\mathbf{F}_2(\xi)]\end{aligned} \tag{117}$$

with the exact solutions of (99) given by [32]

$$\mathbf{G}_1=\begin{bmatrix}1\\0\\0\\0\end{bmatrix},\qquad \mathbf{G}_2=\begin{bmatrix}0\\0\\1\\0\end{bmatrix}, \tag{118}$$

$$\mathbf{G}_3(\xi)=\begin{bmatrix}\xi^2-1/2\\1\\\xi^2-1/2\\1\end{bmatrix}\quad\text{and}\quad \mathbf{G}_4(\xi)=\begin{bmatrix}r\xi\\0\\\xi\\0\end{bmatrix}. \tag{119}$$

Considering, in addition, the functions

$$\mathbf{H}_1(\xi)=\begin{bmatrix}-1+c_1(\xi^2-1/2)\\c_1\\c_1(\xi^2-1/2)\\c_1\end{bmatrix}\quad\text{and}\quad \mathbf{H}_2(\xi)=\begin{bmatrix}c_2(\xi^2-1/2)\\c_2\\-1+c_2(\xi^2-1/2)\\c_2\end{bmatrix} \tag{120}$$

with

$$r=(m_1/m_2)^{1/2},\quad c_1=(n_1/n),\quad c_2=(n_2/n),\quad\text{and}\quad n=n_1+n_2, \tag{121}$$

we can then find functions $\mathbf{F}_1(\xi)$ and $\mathbf{F}_2(\xi)$ such that

$$\mathbf{G}_5(y,\xi)=y\mathbf{H}_1(\xi)+\mathbf{F}_1(\xi)\quad\text{and}\quad \mathbf{G}_6(y,\xi)=y\mathbf{H}_2(\xi)+\mathbf{F}_2(\xi) \tag{122}$$

complete the set of exact solutions we are looking for. In general,

$$\mathbf{F}_\beta(\xi)=-\xi\mathbf{\Sigma}^{-1}\mathbf{H}_\beta(\xi)+\int_{-\infty}^{\infty}\psi(\xi')\boldsymbol{K}(\xi',\xi)\mathbf{F}_\beta(\xi')\mathrm{d}\xi', \tag{123}$$

and, as we did previously in section 4, we write

$$\mathbf{F}_\beta(\xi) = \sum_{\alpha=0}^{3} P_\alpha(\xi)\mathbf{F}_{\beta,\alpha} \tag{124}$$

to find the components of the vectors $\mathbf{F}_{\beta,\alpha}$ required in (124). Here the linear algebraic system with 16 equations, defined to find those components, is rank deficient (rank 12). Since equations (120) are solutions of (99), we can write [32]

$$\mathbf{F}_\beta(\xi) = \mathbf{U}_\beta P_1(\xi) + \mathbf{V}_\beta P_3(\xi), \tag{125}$$

where now the constant vectors $\mathbf{U}_\beta$ and $\mathbf{V}_\beta$ are solutions of the (rank 8) linear systems

$$(\mathbf{I} - \mathbf{A}_1^*)\mathbf{U}_1 - \mathbf{C}_1^*\mathbf{V}_1 = \Big[(c_2/\sigma_1) \quad -(c_1/\sigma_1) \quad -(c_1/\sigma_2) \quad -(c_1/\sigma_2)\Big]^T, \tag{126}$$

$$(\mathbf{I} - \mathbf{D}_1^*)\mathbf{V}_1 - \mathbf{B}_1^*\mathbf{U}_1 = \Big[-(c_1/\sigma_1) \quad 0 \quad -(c_1/\sigma_2) \quad 0\Big]^T \tag{127}$$

and

$$\Big[0 \quad 0 \quad 1 \quad 0\Big]\mathbf{U}_1 = 0, \tag{128}$$

for $\beta = 1$. In addition,

$$(\mathbf{I} - \mathbf{A}_1^*)\mathbf{U}_2 - \mathbf{C}_1^*\mathbf{V}_2 = \Big[-(c_2/\sigma_1) \quad -(c_2/\sigma_1) \quad (c_1/\sigma_2) \quad -(c_2/\sigma_2)\Big]^T, \tag{129}$$

$$(\mathbf{I} - \mathbf{D}_1^*)\mathbf{V}_2 - \mathbf{B}_1^*\mathbf{U}_2 = \Big[-(c_2/\sigma_1) \quad 0 \quad -(c_2/\sigma_2) \quad 0\Big]^T \tag{130}$$

and

$$\Big[0 \quad 0 \quad 1 \quad 0\Big]\mathbf{U}_2 = 0, \tag{131}$$

for $\beta = 2$. Here (128) and (131) were made part of the linear system to guarantee a unique solution. Still, in the above expressions $\mathbf{I}$ is the identity matrix, the superscript T denotes transpose operation, and

$$\mathbf{A}_1^* = 2\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi(\xi')\psi(\xi)\boldsymbol{K}_M(\xi',\xi)P_1(\xi')P_1(\xi)\mathrm{d}\xi'\mathrm{d}\xi, \tag{132}$$

$$\mathbf{B}_1^* = (4/3)\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi(\xi')\psi(\xi)\boldsymbol{K}_M(\xi',\xi)P_1(\xi')P_3(\xi)\mathrm{d}\xi'\mathrm{d}\xi, \tag{133}$$

$$\mathbf{C}_1^* = 2\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi(\xi')\psi(\xi)\boldsymbol{K}_M(\xi',\xi)P_3(\xi')P_1(\xi)\mathrm{d}\xi'\mathrm{d}\xi \tag{134}$$

and

$$\mathbf{D}_1^* = (4/3)\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi(\xi')\psi(\xi)\boldsymbol{K}_M(\xi',\xi)P_3(\xi')P_3(\xi)\mathrm{d}\xi'\mathrm{d}\xi. \tag{135}$$

However, (132) to (135) can be evaluated, by means of the quadrature scheme, such that we rewrite them (using notation listed in the appendix) in a final form

$$\mathbf{A}_1^* = \begin{bmatrix} 1-\eta_{1,2}^{(1)} & -(1/2)\eta_{1,2}^{(2)} & r\eta_{1,2}^{(1)} & (r^3/2)\eta_{1,2}^{(2)} \\ -(1/2)\eta_{1,2}^{(2)} & (2/5)\beta_1 & (r/2)\eta_{1,2}^{(2)} & (2/5)\eta_{1,2}^{(6)} \\ s\eta_{2,1}^{(1)} & (s^3/2)\eta_{2,1}^{(2)} & 1-\eta_{2,1}^{(1)} & -(1/2)\eta_{2,1}^{(2)} \\ (s/2)\eta_{2,1}^{(2)} & (2/5)\eta_{2,1}^{(6)} & -(1/2)\eta_{2,1}^{(2)} & (2/5)\beta_2 \end{bmatrix}, \tag{136}$$

$$\mathbf{B}_1^* = \begin{bmatrix} -(1/2)\eta_{1,2}^{(2)} & (2/5)\beta_1 & (r/2)\eta_{1,2}^{(2)} & (2/5)\eta_{1,2}^{(6)} \\ 0 & 0 & 0 & 0 \\ (s/2)\eta_{2,1}^{(2)} & (2/5)\eta_{2,1}^{(6)} & -(1/2)\eta_{2,1}^{(2)} & (2/5)\beta_2 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \tag{137}$$

$$\mathbf{C}_1^* = \begin{bmatrix} -(3/4)\eta_{1,2}^{(2)} & 0 & (3r^3/4)\eta_{1,2}^{(2)} & 0 \\ (3/5)\beta_1 & 0 & (3/5)\eta_{1,2}^{(6)} & 0 \\ (3s^3/4)\eta_{2,1}^{(2)} & 0 & -(3/4)\eta_{2,1}^{(2)} & 0 \\ (3/5)\eta_{2,1}^{(6)} & 0 & (3/5)\beta_2 & 0 \end{bmatrix} \tag{138}$$

and

$$\mathbf{D}_1^* = \begin{bmatrix} (3/5)\beta_1 & 0 & (3/5)\eta_{1,2}^{(6)} & 0 \\ 0 & 0 & 0 & 0 \\ (3/5)\eta_{2,1}^{(6)} & 0 & (3/5)\beta_2 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}. \tag{139}$$

Thus, looking back to (116), the general discrete-ordinates solution for (99) can be written as

$$\mathbf{G}(y, \pm\xi_i) = \mathbf{G}^*(y, \pm\xi_i) + \sum_{j=4}^{4N} A_j \mathbf{\Phi}(\nu_j, \pm\xi_i) \mathrm{e}^{-y/\nu_j}, \tag{140}$$

taking into account that it is not allowed to diverge exponentially as y tends to infinity.

If we use (140) to evaluate (the discrete-ordinates version) (106) and (107) and we take the asymptotic part (the exponential terms were ignored) of the resulting expressions, we can write

$$N_1^*(y) = A_1 - B_2 y, \tag{141}$$

$$N_2^*(y) = A_2 - B_3 y, \tag{142}$$

$$T_1^*(y) = A_3 + (c_1 B_2 + c_2 B_3) y \tag{143}$$

and

$$T_2^*(y) = A_3 + (c_1 B_2 + c_2 B_3) y. \tag{144}$$

But again, as in the one gas case, two of the exact solutions, (118), satisfy the boundary condition, (101), such that the constants A_1 and A_2 cannot be determined from that boundary condition (density perturbations are not uniquely defined). As we did in the one gas case we make use of the condition given by (108) along with a normalization condition, similar to (62), to write

$$A_1 = -A_3, \tag{145}$$

$$A_2 = -A_3 \tag{146}$$

and

$$c_1 B_2 + c_2 B_3 = K. \tag{147}$$

In (147) we choose to write B_3 in terms of B_2 such that the general solution of the problem given by (99) is finally written as in (140) with

$$\begin{aligned}\mathbf{G}_*(y,\xi) = A_3\mathbf{R}(\xi) + B_1\mathbf{G}_4(\xi) + B_2\Big[[y\mathbf{H}_1(\xi) + \mathbf{F}_1(\xi)] - (c_1/c_2)[y\mathbf{H}_2(\xi) + \mathbf{F}_2(\xi)]\Big] \\ + (K/c_2)[y\mathbf{H}_2(\xi) + \mathbf{F}_2(\xi)].\end{aligned} \tag{148}$$

Here

$$\mathbf{R}(\xi) = \begin{bmatrix} \xi^2 - 3/2 \\ 1 \\ \xi^2 - 3/2 \\ 1 \end{bmatrix}. \tag{149}$$

The application of (140) in the discrete ordinates version of the boundary condition

$$\mathbf{G}(0,\xi_i) = \mathbf{D}\sum_{k=1}^{N}\omega_k\mathbf{F}(\xi_k,\xi_i)\mathbf{G}(0,-\xi_k) \tag{150}$$

results in the following linear system:

$$\begin{aligned}A_3\mathbf{C^3}(\xi_i) + B_1\mathbf{C^4}(\xi_i) + B_2\mathbf{C^5}(\xi_i) + \sum_{j=4}^{4N} A_j\left\{\mathbf{\Phi}_+(\nu_j) - \mathbf{D}^*\sum_{k=1}^{N}\omega_k\mathbf{F}^*(\xi_k,\xi_i)\mathbf{\Phi}_-(\nu_j)\right\} \\ = K\left\{-\mathbf{J}_1^*(\xi_i) + \mathbf{D}^*\sum_{k=1}^{N}\omega_k\mathbf{F}^*(\xi_k,\xi_i)\mathbf{J}_1^*(-\xi_k)\right\},\end{aligned} \tag{151}$$

where the components of the vectors $\mathbf{\Phi}_+(\nu_j)$ and $\mathbf{\Phi}_-(\nu_j)$ are given by (113) and (114),

$$\mathbf{C^3}(\xi_i) = \mathbf{R}^*(\xi_i) - \mathbf{D}^*\sum_{k=1}^{N}\omega_k\mathbf{F}^*(\xi_k,\xi_i)\mathbf{R}^*(-\xi_k), \tag{152}$$

$$\mathbf{C^4}(\xi_i) = \mathbf{G}_4^*(\xi_i) - \mathbf{D}^*\sum_{k=1}^{N}\omega_k\mathbf{F}^*(\xi_k,\xi_i)\mathbf{G}_4^*(-\xi_k) \tag{153}$$

and

$$\mathbf{C^5}(\xi_i) = \mathbf{K}_1^*(\xi_i) - \mathbf{D}^* \sum_{k=1}^{N} \omega_k \mathbf{F}^*(\xi_k, \xi_i)\mathbf{K}_1^*(-\xi_k). \tag{154}$$

Here $\mathbf{R}^*(\xi)$ is a $4N \times 1$ vector where each N component is of the type of (149); $\mathbf{K}_1^*(\xi)$ is a $4N \times 1$ vector defined by N components of the type

$$\mathbf{K}_1(\xi) = \mathbf{F}_1(\xi) - (c_1/c_2)\mathbf{F}_2(\xi), \tag{155}$$

and $\mathbf{J}_1^*(\xi)$ is a $4N \times 1$ vector where each N component is of the type

$$\mathbf{J}_1(\xi) = (1/c_2)\mathbf{F}_2(\xi). \tag{156}$$

In addition $\mathbf{D}^*$ and $\mathbf{F}^*(\xi_k, \xi)$ are $4N \times 4N$ diagonal matrices defined, looking back to (102) and (103), by

$$\mathbf{D}^* = \mathrm{diag}\Big\{\mathbf{D}, \mathbf{D}, \ldots, \mathbf{D}\Big\} \tag{157}$$

and

$$\mathbf{F}^*(\xi_k, \xi) = \mathrm{diag}\Big\{\mathbf{F}(\xi_1, \xi), \mathbf{F}(\xi_2, \xi), \ldots, \mathbf{F}(\xi_N, \xi)\Big\}. \tag{158}$$

Based on the derivation above we can write the density perturbation vector (two species) as

$$\mathbf{N}(y) = -\left[\begin{array}{c} A_3 + B_2 y \\ A_3 + \big(K/c_2 - (c_1/c_2)B_2\big)y \end{array}\right] + \sum_{j=4}^{4N} A_j \ \mathrm{e}^{-y/\nu_j} \ \mathbf{M}_1(\nu_j), \tag{159}$$

where

$$\mathbf{M}_1(\nu_j) = \pi^{-1/2} \sum_{k=1}^{N} \omega_k \mathrm{e}^{-{\xi_k}^2} \left[\begin{array}{cccc} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{array}\right] [\mathbf{\Phi}(\nu_j, \xi_k) + \mathbf{\Phi}(\nu_j, -\xi_k)]. \tag{160}$$

The components $T_\alpha(y)$, $\alpha = 1, 2$, define the temperature perturbation vector

$$\mathbf{T}(y) = (A_3 + Ky)\left[\begin{array}{c} 1 \\ 1 \end{array}\right] + \frac{2}{3} \sum_{j=4}^{4N} A_j \ \mathrm{e}^{-y/\nu_j} \ \mathbf{M}_2(\nu_j), \tag{161}$$

where

$$\mathbf{M}_2(\nu_j) = \pi^{-1/2} \sum_{k=1}^{N} \omega_k \mathrm{e}^{-{\xi_k}^2} \left[\begin{array}{cccc} \xi_k^2 - 1/2 & 1 & 0 & 0 \\ 0 & 0 & \xi_k^2 - 1/2 & 1 \end{array}\right] [\mathbf{\Phi}(\nu_j, \xi_k) + \mathbf{\Phi}(\nu_j, -\xi_k)]. \tag{162}$$

From (161), and taking into account (143) and (144), along with definitions (for each species) analogous to (75), we define the temperature-jump coefficient

$$\zeta = A_3/K, \tag{163}$$

which we found to be the same for both species of the gas.

8. Computational aspects and numerical results. To implement the ADO solution, in order to define the quantities of interest, the first step is to define the associated quadrature scheme. In this sense, for most of the problems in the rarefied gas dynamics field that have been solved by this method [25, 26, 27, 28, 29, 30] the following approach has been shown to be adequate: to map the interval of integration into the interval $[0, 1]$ and then map the Gauss–Legendre points linearly to this interval. In general, the expression

$$u(\xi) = \mathrm{e}^{-\xi} \tag{164}$$

is the one used to map the interval $[0, \infty)$ into $[0, 1]$. After that, the eigenvalue problem which defines the separation constants and the elementary solutions can be formulated and solved. Next, the linear systems which define the exact solutions have to be considered. Continuing, the linear algebraic system for the arbitrary constants of the general solution is solved and then the quantities of interest are evaluated. In this way, the algorithm is fast and easy to implement.

The results presented in Tables 1 to 14 (which we believe to be correct for all digits listed, plus or minus one in the last digit) were obtained with $N = 60$ quadrature points for the one gas case and $N = 80$ quadrature points for the mixtures case (except for $\alpha_n = 0.01$, where $N = 120$). For both cases we consider $K = 1$. The developed (and not particularly optimized) Fortran code requires around four seconds to yield, on a 3.0 GHz Pentium 4 machine, all quantities of interest for a general mixture case.

For the one gas case we used $\varepsilon = \varepsilon_t$ (according to (8) and (9)), in general, in order to obtain the numerical results shown (otherwise we added the statement $\varepsilon = \varepsilon_p$ in the table). We also note the notation DS and CL for referring to the use of, respectively, diffuse-specular and Cercignani–Lampis boundary condition. In fact, as we have worked on trying to establish a very general and complete comparison on results for different problems, provided by different model equations, we list in this work some results we obtained by the ADO method, for the temperature-jump problem, based on the BGK and S-models with diffuse-specular and Cercignani–Lampis boundary condition, which were not available.

Continuing, we note that, in Tables 8 to 11, and in the text below, we use the notation $a_{n\alpha}$ and $a_{t\alpha}$, for the species $\alpha = 1, 2$, to refer to the accommodation coefficients, respectively, of energy and tangential momentum.

In order to generate numerical results, we consider three mixtures cases related to the following gases: (i) Ne-Ar, (ii) He-Xe and (iii) He-Ar, as follow:

- Ne-Ar: $m_1 = 20.183$, $m_2 = 39.948$, and $d_2/d_1 = 1.406$
  - case I $a_{t1} = 0.849$, $a_{t2} = 0.916$, $a_{n1} = 0.1$, $a_{n2} = 0.4$
  - case II $a_{t1} = 0.31$, $a_{t2} = 0.67$, $a_{n1} = 0.1$, $a_{n2} = 0.4$
  - case III $a_{t1} = 0.849$, $a_{t2} = 0.916$, $a_{n1} = 0.082$, $a_{n2} = 0.222$
- He-Xe: $m_1 = 4.0026$, $m_2 = 131.30$, and $d_2/d_1 = 2.226$
  - case IV $a_{t1} = 0.20$, $a_{t2} = 0.95$, $a_{n1} = 0.01$, $a_{n2} = 0.7$
  - case V $a_{t1} = 0.20$, $a_{t2} = 0.95$, $a_{n1} = 0.05$, $a_{n2} = 0.4$
  - case VI $a_{t1} = 0.882$, $a_{t2} = 1.014$, $a_{n1} = 0.01$, $a_{n2} = 0.7$
- He-Ar: $m_1 = 4.0026$, $m_2 = 39.948$, and $d_2/d_1 = 1.665$
  - case VII $a_{t1} = 0.20$, $a_{t2} = 0.916$, $a_{n1} = 0.01$, $a_{n2} = 0.4$
  - case VIII $a_{t1} = 0.882$, $a_{t2} = 0.91$, $a_{n1} = 0.01$, $a_{n2} = 0.4$
  - case IX $a_{t1} = 0.20$, $a_{t2} = 0.916$, $a_{n1} = 0.01$, $a_{n2} = 0.222$

The data set used, and listed above, regarding the mass and diameter of the particles, was reproduced from [32, 41, 42].

In addition, we used experimental data for defining the values of the tangential momentum accommodation coefficient: cases II, IV, and V were formulated in terms of data provided by Lord [43]; in cases I, III, and VI, the value of that coefficient was reproduced from [11], which followed the experimental work of Porodnov et al. [44]. Cases VII to IX were formulated based on the previous cases.

Since, to the best of our knowledge, experimental results for the (normal) energy accommodation coefficient are not available, we chose numerical values based (order of magnitude) on the thermal accommodation coefficient of the gases listed above. We used, in this way, the works of Thomas [45] and Thomas and Lord [46].

The results were tabulated, for the three mixtures, in terms of the molar concentration defined in terms of the first particle as

$$C = \frac{n_1/n_2}{1 + n_1/n_2}. \tag{165}$$

In addition to provide results, which we believe were not available in the literature, for this problem, based on a more general law for describing the gas-surface interaction, we have been able to perform many simulations from which we try to point out some aspects, commented below.

First of all, we think that an important aspect of providing results, based on models related to the normal energy accommodation coefficient, which may not be measured, is the possibility of using quantities we are able to evaluate, in connection with a procedure for estimating parameters [47], in order to estimate that coefficient numerically. In this sense, we include in Tables 1 to 14, in addition to the temperature-jump coefficient, results for temperature and density perturbations, for several values of accommodation coefficients, and for different values of concentration, in the mixture cases.

In regard to the one gas case, based on the experience with previous analysis for other classes of problems [28], the fact of getting results for the BGK and S-model in agreement, in general, in one or two digits (for a choice of the mean-free path), was, in fact, used as a way of having some confidence in our program. In addition, we confirm previous observation [32] that both models lead to the same value for the temperature-jump coefficient but slightly different values for the temperature and density perturbation; we also simulate (considering $n_1 = 0$, $n_2 = 0$ or $m_1 = m_2$ and $d_1 = d_2$) the one gas case, from the McCormack model, and the results agree perfectly with the S-model, as observed previously [32].

Having used the ADO method, which is an analytical approach to the spatial variable, to deal with the temperature-jump problem for a wide class of model equations, in the one gas case, with Cercignani–Lampis and Maxwell boundary condition, and having compared with available results [48] based on the linearized Boltzmann equation (LBE), we can say that in general the evaluation of this coefficient is not sensitive to the model equation to be used (see Table 7); comparisons between results (see Tables 1 to 5) obtained by the S-model and the LBE show agreement in one to two digits.

We generate results, showed in Tables 2 to 4, for a small value of α_n, which is, in general, hard to obtain accurately or even very much time consuming, from numerical approaches, but is consistent, in order of magnitude, with experimental values available for the total energy accommodation coefficient. It is noted that the

temperature-jump coefficient is very sensitive to the normal energy accommodation coefficient. In fact, from the cases shown in Figures 1 and 2, it is clear that the temperature-jump coefficient depends on both accommodation coefficients (the same is observed for the mixtures cases later on) and the significant variation occurs mainly when α_n and α_t are lower than 0.5. In these cases, in comparison with the results shown in Table 1 based on the Maxwell boundary condition, we see great increase in the jump values.

In Tables 12 to 14, we present results for the temperature-jump coefficient for the mixtures cases I to IX described previously in this section. We included the cases of concentration equal to one ($n_1 = 1$ and $n_2 = 0$) and equal to zero ($n_1 = 0$ and $n_2 = 1$), which reproduce exactly the results obtained for the one gas case (respectively, gas 1 and gas 2) and that may show how mixing a very small quantity of a different species can produce significant change in the jump coefficient. In fact, as observed for the case of Maxwell boundary conditions [32, 42], in Table 13, we note a small decrease on the value of the coefficient when we simulate the one gas case (species one). It seems that the (bigger) molecular mass ratio can be a reason for noticing this behavior; however, the same (decreasing) behavior is observed in Table 14, for the case VIII, and then, based on comparisons with cases VII and IX, one can also see for the same mixture the influence of the accommodation coefficients. However, one has to remember that the real values for α_n are unknown, and it has to be considered as a limitation for more specific conclusions.

Finally, in Figures 3 to 6, we tried to analyze the influence of each one of the accommodation coefficients, for the mixtures cases, based on cases I to VI. It really shows that the temperature-jump coefficient depends on both accommodation coefficients and mainly on the value of α_n. In addition, from Figures 4 and 6, the influence of the mass ratio in the magnitude order of the jump coefficient can be seen.

9. Concluding comments. An analytical version of the discrete-ordinates method was used to develop a solution for the temperature-jump problem in rarefied gas dynamics, modeled by the S-model and the McCormack model, for the one gas and binary gas mixture cases, respectively. The gas-surface interaction was described by the Cercignani–Lampis boundary condition. The dependence of jump coefficient on both accommodation coefficients was shown, which points out the importance of special attention to the description of the gas-surface interaction. The evaluation of the jump coefficient for a binary mixture of gases shows more significant difference from the one gas case for a great mass ratio. Once more the discrete-ordinates solution was found to be very precise.

Appendix A. Basic definitions.
In (82),

$$\boldsymbol{K}^{(1)}_{1,1}(\mathbf{c}',\mathbf{c}) = 1 + \{2[1-\eta^{(1)}_{1,2}] - \eta^{(2)}_{1,2}(c'^2 - 5/2)\}\mathbf{c}'\cdot\mathbf{c}, \tag{A.1}$$

$$\boldsymbol{K}^{(2)}_{1,1}(\mathbf{c}',\mathbf{c}) = (2/3)[1-2r^*\eta^{(1)}_{1,2}](c'^2 - 3/2)(c^2 - 3/2), \tag{A.2}$$

$$\boldsymbol{K}^{(3)}_{1,1}(\mathbf{c}',\mathbf{c}) = 2\varpi_1[(\mathbf{c}'\cdot\mathbf{c})^2 - (1/3)c'^2c^2], \tag{A.3}$$

$$\boldsymbol{K}^{(4)}_{1,1}(\mathbf{c}',\mathbf{c}) = [(4/5)\beta_1(c'^2 - 5/2) - \eta^{(2)}_{1,2}](c^2 - 5/2)\mathbf{c}'\cdot\mathbf{c}, \tag{A.4}$$

$$\boldsymbol{K}^{(1)}_{2,1}(\mathbf{c}',\mathbf{c}) = r\{2\eta^{(1)}_{1,2} + \eta^{(2)}_{1,2}[r^2(c'^2 - 5/2) + c^2 - 5/2]\}\mathbf{c}'\cdot\mathbf{c}, \tag{A.5}$$

$$\boldsymbol{K}^{(2)}_{2,1}(\mathbf{c}',\mathbf{c}) = (4/3)r^*\eta^{(1)}_{1,2}(c'^2 - 3/2)(c^2 - 3/2), \tag{A.6}$$

$$\boldsymbol{K}^{(3)}_{2,1}(\mathbf{c}',\mathbf{c}) = 2\eta^{(4)}_{1,2}[(\mathbf{c}'\cdot\mathbf{c})^2 - (1/3)c'^2c^2], \tag{A.7}$$

$$\boldsymbol{K}^{(4)}_{2,1}(\mathbf{c}',\mathbf{c}) = (4/5)\eta^{(6)}_{1,2}(c'^2 - 5/2)(c^2 - 5/2)\mathbf{c}'\cdot\mathbf{c}, \tag{A.8}$$

$$\boldsymbol{K}^{(1)}_{2,2}(\mathbf{c}',\mathbf{c}) = 1 + \{2[1-\eta^{(1)}_{2,1}] - \eta^{(2)}_{2,1}(c'^2 - 5/2)\}\mathbf{c}'\cdot\mathbf{c}, \tag{A.9}$$

$$\boldsymbol{K}^{(2)}_{2,2}(\mathbf{c}',\mathbf{c}) = (2/3)[1-2s^*\eta^{(1)}_{2,1}](c'^2 - 3/2)(c^2 - 3/2), \tag{A.10}$$

$$\boldsymbol{K}^{(3)}_{2,2}(\mathbf{c}',\mathbf{c}) = 2\varpi_2[(\mathbf{c}'\cdot\mathbf{c})^2 - (1/3)c'^2c^2], \tag{A.11}$$

$$\boldsymbol{K}^{(4)}_{2,2}(\mathbf{c}',\mathbf{c}) = [(4/5)\beta_2(c'^2 - 5/2) - \eta^{(2)}_{2,1}](c^2 - 5/2)\mathbf{c}'\cdot\mathbf{c}, \tag{A.12}$$

$$\boldsymbol{K}^{(1)}_{1,2}(\mathbf{c}',\mathbf{c}) = s\{2\eta^{(1)}_{2,1} + \eta^{(2)}_{2,1}[s^2(c'^2 - 5/2) + c^2 - 5/2]\}\mathbf{c}'\cdot\mathbf{c}, \tag{A.13}$$

$$\boldsymbol{K}_{1,2}^{(2)}(\mathbf{c}',\mathbf{c}) = (4/3)s^*\eta_{2,1}^{(1)}(c'^2 - 3/2)(c^2 - 3/2), \tag{A.14}$$

$$\boldsymbol{K}_{1,2}^{(3)}(\mathbf{c}',\mathbf{c}) = 2\eta_{2,1}^{(4)}[(\mathbf{c}'\cdot\mathbf{c})^2 - (1/3)c'^2c^2] \tag{A.15}$$

and

$$\boldsymbol{K}_{1,2}^{(4)}(\mathbf{c}',\mathbf{c}) = (4/5)\eta_{2,1}^{(6)}(c'^2 - 5/2)(c^2 - 5/2)\mathbf{c}'\cdot\mathbf{c}. \tag{A.16}$$

In the definitions above it is used that

$$r = (m_1/m_2)^{1/2} \quad \text{and} \quad s = (m_2/m_1)^{1/2} \tag{A.17}$$

and

$$r^* = \frac{r^2}{1+r^2} \quad \text{and} \quad s^* = \frac{s^2}{1+s^2}. \tag{A.18}$$

In addition,

$$\varpi_1 = 1 + \eta_{1,1}^{(4)} - \eta_{1,1}^{(3)} - \eta_{1,2}^{(3)}, \tag{A.19}$$

$$\varpi_2 = 1 + \eta_{2,2}^{(4)} - \eta_{2,2}^{(3)} - \eta_{2,1}^{(3)}, \tag{A.20}$$

$$\beta_1 = 1 + \eta_{1,1}^{(6)} - \eta_{1,1}^{(5)} - \eta_{1,2}^{(5)}, \tag{A.21}$$

$$\beta_2 = 1 + \eta_{2,2}^{(6)} - \eta_{2,2}^{(5)} - \eta_{2,1}^{(5)}, \tag{A.22}$$

with

$$\eta_{i,j}^{(k)} = \frac{\nu_{i,j}^{(k)}}{\gamma_i}. \tag{A.23}$$

Continuing, following McCormack and Siewert's works [16, 32], we write

$$\nu_{\alpha,\beta}^{(1)} = \frac{16}{3}\frac{m_{\alpha,\beta}}{m_\alpha}n_\beta\Omega_{\alpha,\beta}^{11}, \tag{A.24}$$

$$\nu_{\alpha,\beta}^{(2)} = \frac{64}{15}\Big(\frac{m_{\alpha,\beta}}{m_\alpha}\Big)^2 n_\beta\Big(\Omega_{\alpha,\beta}^{12} - \frac{5}{2}\Omega_{\alpha,\beta}^{11}\Big), \tag{A.25}$$

$$\nu_{\alpha,\beta}^{(3)} = \frac{16}{5}\Big(\frac{m_{\alpha,\beta}}{m_\alpha}\Big)^2\frac{m_\alpha}{m_\beta}n_\beta\Big(\frac{10}{3}\Omega_{\alpha,\beta}^{11} + \frac{m_\beta}{m_\alpha}\Omega_{\alpha,\beta}^{22}\Big), \tag{A.26}$$

$$\nu_{\alpha,\beta}^{(4)} = \frac{16}{5}\Big(\frac{m_{\alpha,\beta}}{m_\alpha}\Big)^2\frac{m_\alpha}{m_\beta}n_\beta\Big(\frac{10}{3}\Omega_{\alpha,\beta}^{11} - \Omega_{\alpha,\beta}^{22}\Big), \tag{A.27}$$

$$\nu^{(5)}_{\alpha,\beta} = \frac{64}{15}\Big(\frac{m_{\alpha,\beta}}{m_\alpha}\Big)^3 \frac{m_\alpha}{m_\beta} n_\beta \Big[\Omega^{22}_{\alpha,\beta} + \Big(\frac{15m_\alpha}{4m_\beta} + \frac{25m_\beta}{8m_\alpha}\Big)\Omega^{11}_{\alpha,\beta} - \Big(\frac{m_\beta}{2m_\alpha}\Big)\Big(5\Omega^{12}_{\alpha,\beta} - \Omega^{13}_{\alpha,\beta}\Big)\Big] \tag{A.28}$$

and

$$\nu^{(6)}_{\alpha,\beta} = \frac{64}{15}\Big(\frac{m_{\alpha,\beta}}{m_\alpha}\Big)^3 \Big(\frac{m_\alpha}{m_\beta}\Big)^{3/2} n_\beta \Big[-\Omega^{22}_{\alpha,\beta} + \frac{55}{8}\Omega^{11}_{\alpha,\beta} - \frac{5}{2}\Omega^{12}_{\alpha,\beta} + \frac{1}{2}\Omega^{13}_{\alpha,\beta}\Big]. \tag{A.29}$$

Here

$$m_{\alpha,\beta} = \frac{m_\alpha m_\beta}{m_\alpha + m_\beta}. \tag{A.30}$$

Finally, the Ω functions are the Chapman–Cowling integrals [49, 50]

$$\Omega^{ij}_{\alpha,\beta} = \frac{(j+1)!}{8}\Big[1 - \frac{1+(-1)^i}{2(i+1)}\Big]\Big(\frac{\pi kT}{2m_{\alpha,\beta}}\Big)^{1/2}(d_\alpha + d_\beta)^2. \tag{A.31}$$

We note that here d_1 and d_2 are the diameters of the two types of particles and, as defined in the text, k is the Boltzmann constant and T_0 is a reference temperature.

Appendix B. The elements of the kernel.

We follow Siewert [32] and express the components of the matrix $\boldsymbol{K}_M(\xi',\xi)$ in (99) as

$$k_{1,1}(\xi',\xi) = 1 + f_{1,1}(\xi',\xi)\xi'\xi + (2/3)[1 - 2r^*\eta^{(1)}_{1,2} + 2\varpi_1](\xi'^2 - 1/2)(\xi^2 - 1/2), \tag{B.1}$$

$$k_{1,2}(\xi',\xi) = [(4/5)\beta_1(\xi^2 - 3/2) - \eta^{(2)}_{1,2}]\xi'\xi + (2/3)[1 - 2r^*\eta^{(1)}_{1,2} - \varpi_1](\xi^2 - 1/2), \tag{B.2}$$

$$k_{1,3}(\xi',\xi) = f_{1,3}(\xi',\xi)\xi'\xi + (4/3)[r^*\eta^{(1)}_{1,2} + \eta^{(4)}_{1,2}](\xi'^2 - 1/2)(\xi^2 - 1/2), \tag{B.3}$$

$$k_{1,4}(\xi',\xi) = [r^3\eta^{(2)}_{1,2} + (4/5)\eta^{(6)}_{1,2}(\xi^2 - 3/2)]\xi'\xi + (2/3)[2r^*\eta^{(1)}_{1,2} - \eta^{(4)}_{1,2}](\xi^2 - 1/2), \tag{B.4}$$

$$k_{2,1}(\xi',\xi) = [(4/5)\beta_1(\xi'^2 - 3/2) - \eta^{(2)}_{1,2}]\xi'\xi + (2/3)[1 - 2r^*\eta^{(1)}_{1,2} - \varpi_1](\xi'^2 - 1/2), \tag{B.5}$$

$$k_{2,2}(\xi',\xi) = (2/3)[1 - 2r^*\eta^{(1)}_{1,2}] + (1/3)\varpi_1 + (4/5)\beta_1\xi'\xi, \tag{B.6}$$

$$k_{2,3}(\xi',\xi) = [r\eta^{(2)}_{1,2} + (4/5)\eta^{(6)}_{1,2}(\xi'^2 - 3/2)]\xi'\xi + (2/3)[2r^*\eta^{(1)}_{1,2} - \eta^{(4)}_{1,2}](\xi'^2 - 1/2), \tag{B.7}$$

$$k_{2,4}(\xi',\xi) = (4/5)\eta_{1,2}^{(6)}\xi'\xi + (1/3)[4r^*\eta_{1,2}^{(1)} + \eta_{1,2}^{(4)}], \tag{B.8}$$

$$k_{3,1}(\xi',\xi) = f_{3,1}(\xi',\xi)\xi'\xi + (4/3)[s^*\eta_{2,1}^{(1)} + \eta_{2,1}^{(4)}](\xi'^2 - 1/2)(\xi^2 - 1/2), \tag{B.9}$$

$$k_{3,2}(\xi',\xi) = [s^3\eta_{2,1}^{(2)} + (4/5)\eta_{2,1}^{(6)}(\xi^2 - 3/2)]\xi'\xi + (2/3)[2s^*\eta_{2,1}^{(1)} - \eta_{2,1}^{(4)}](\xi^2 - 1/2), \tag{B.10}$$

$$k_{3,3}(\xi',\xi) = 1 + f_{3,3}(\xi',\xi)\xi'\xi + (2/3)[1 - 2s^*\eta_{2,1}^{(1)} + 2\varpi_2](\xi'^2 - 1/2)(\xi^2 - 1/2), \tag{B.11}$$

$$k_{3,4}(\xi',\xi) = [(4/5)\beta_2(\xi^2 - 3/2) - \eta_{2,1}^{(2)}]\xi'\xi + (2/3)[1 - 2s^*\eta_{2,1}^{(1)} - \varpi_2](\xi^2 - 1/2), \tag{B.12}$$

$$k_{4,1}(\xi',\xi) = [s\eta_{2,1}^{(2)} + (4/5)\eta_{2,1}^{(6)}(\xi'^2 - 3/2)]\xi'\xi + (2/3)[2s^*\eta_{2,1}^{(1)} - \eta_{2,1}^{(4)}](\xi'^2 - 1/2), \tag{B.13}$$

$$k_{4,2}(\xi',\xi) = (4/5)\eta_{2,1}^{(6)}\xi'\xi + (1/3)[4s^*\eta_{2,1}^{(1)} + \eta_{2,1}^{(4)}], \tag{B.14}$$

$$k_{4,3}(\xi',\xi) = [(4/5)\beta_2(\xi'^2 - 3/2) - \eta_{2,1}^{(2)}]\xi'\xi + (2/3)[1 - 2s^*\eta_{2,1}^{(1)} - \varpi_2](\xi'^2 - 1/2), \tag{B.15}$$

and

$$k_{4,4}(\xi',\xi) = (2/3)[1 - 2s^*\eta_{2,1}^{(1)}] + (1/3)\varpi_2 + (4/5)\beta_2\xi'\xi \tag{B.16}$$

with

$$f_{1,1}(\xi',\xi) = 2[1 - \eta_{1,2}^{(1)}] - \eta_{1,2}^{(2)}(\xi'^2 + \xi^2 - 3) + (4/5)\beta_1(\xi'^2 - 3/2)(\xi^2 - 3/2), \tag{B.17}$$

$$f_{3,3}(\xi',\xi) = 2[1 - \eta_{2,1}^{(1)}] - \eta_{2,1}^{(2)}(\xi'^2 + \xi^2 - 3) + (4/5)\beta_2(\xi'^2 - 3/2)(\xi^2 - 3/2), \tag{B.18}$$

$$\begin{aligned} f_{1,3}(\xi',\xi) = {} & 2r\eta_{1,2}^{(1)} + r\eta_{1,2}^{(2)}[r^2(\xi'^2 - 3/2) + \xi^2 - 3/2] \\ & + (4/5)\eta_{1,2}^{(6)}(\xi'^2 - 3/2)(\xi^2 - 3/2) \end{aligned} \tag{B.19}$$

$$\begin{aligned} f_{3,1}(\xi',\xi) = {} & 2s\eta_{2,1}^{(1)} + s\eta_{2,1}^{(2)}[s^2(\xi'^2 - 3/2) + \xi^2 - 3/2] \\ & + (4/5)\eta_{2,1}^{(6)}(\xi'^2 - 3/2)(\xi^2 - 3/2). \end{aligned} \tag{B.20}$$

Acknowledgments. The authors would like to thank K. Aoki, R. D. M. Garcia, M. Lampis, and V. Titarev for a special contribution in providing us some important references used in this work. We also thank to R. D. M. Garcia, C. E. Siewert, and F. Sharipov for helpful discussions in regard to the subject of this work.

AN ASYMPTOTIC ONE-DIMENSIONAL MODEL TO DESCRIBE FIRES IN TUNNELS III: THE TRANSIENT PROBLEM*

INGENUIN GASSER† AND HERBERT STEINRÜCK‡

Abstract. This is the third in a series of papers devoted to a model describing tunnel fire events (see [I. Gasser and J. Struckmeier, *Math. Methods Appl. Sci.*, 25 (2002), pp. 1231–1249] and [I. Gasser, *Math. Methods Appl. Sci.*, 26 (2003), pp. 1327–1347]). Here the transient behavior of the model is studied. In particular the stability of stationary solutions is analyzed. A good understanding of related bifurcation phenomena is obtained (at least numerically). This accelerates progress in the study of the stability of flow conditions in tunnels during a tunnel fire.

Key words. gasdynamics, low-Mach-number, fire in tunnels, stability

1. Introduction.

Due to some serious fire accidents in the recent past, tunnel fires have become an interesting topic not only for CFD engineers. In the last few decades various mathematical models based on a gas-dynamic description of the air in the tunnel have been proposed. A good overview of the modeling approaches is given in [BJL, P]. A recent survey of computer codes for tunnel fire simulations can be found in [OC] (and [F]). In this context the internet platform [FiT] should be mentioned also.

From a modeling point of view there are mainly three difficult issues:

- very low Mach numbers,
- large temperature differences such that significant heat transport takes place,
- the turbulent character of the flow.

In particular, the combination of the first two points induces a serious problem. The second point excludes a pure incompressible description (with the standard Boussinesq approximation for taking buoyancy effects into account). On the other hand, there is the known problem of fully compressible approaches in the low-Mach-number regime. Although these facts are known (even in the tunnel-fire literature; see [BJL]), they are often ignored due to the lack of alternatives.

From an application point of view a detailed knowledge of the three-dimensional flow is in general not necessary. The main question arising from an application can often be answered by one-dimensional models. In addition, one-dimensional approaches have important advantages over higher-dimensional models:

- there are simple ways to describe turbulence,
- numerical simulations are in general not very expensive,
- optimization strategies can be applied and solved in reasonable time.

Here we consider such a one-dimensional model, which was introduced in [GStr]. To our knowledge this is one of the first models derived from underlying fluid dynamics

equations. The single dimension refers to the longitudinal spatial extension. This model is derived in such a way that it allows us to combine both a good description in the low-Mach-number regime and significant heat transport. The results obtained show that the model seems to reflect the main features of tunnel fires. A good (at least qualitative) agreement with results from experiments has been obtained (see [GStr, G4]).

Stationary solutions of the model equation were discussed in [G1]. However, under some critical conditions the steady flow through the tunnel may become unstable. Then the transient behavior will become important. The goal of this paper is twofold. First we study the dynamics of the one-dimensional initial-boundary value problem. Second we determine stability conditions for the stationary solutions.

The paper is organized as follows. In section 2 we briefly present the model. Then in section 3 we state the existence theory for the transient problem, and in section 4 we show numerical examples of the dynamics. The stability analysis is presented in section 5.

2. The model. The model we are going to study here was derived in [GStr]. The purpose of the model is to describe fire events in a long tunnel. The starting points are the mass, momentum, and energy balances for a flow of compressible gas (air or air-smoke mixture) in the tunnel. Due to the small ratio of the diameter $\tilde{d}$ of the tunnel cross section and the length $\tilde{L}$ of the tunnel, a one-dimensional description can be applied. In addition, the flow in the tunnel (even with fire) is a typical low-Mach-number flow. Therefore an asymptotic analysis with respect to low Mach numbers has been performed. Since in case of fire significant heat sources are involved the densities cannot be assumed to be constant, and the resulting flow is compressible.

However, in the low-Mach-number limit the flow has characteristic properties of an incompressible flow (infinite velocity of sound) and of a compressible flow (large density variations) as well.

We briefly outline the derivation of the model. Let ρ, u, p, T be the dimensionless density, velocity, pressure, and temperature of the flow in the tunnel, respectively. In order to distinguish dimensionless quantities from their dimensional counterparts, the latter are marked by $\tilde{}$. The thermodynamic coordinates are scaled by their corresponding values of the ambient air, $\tilde{p}_R$, $\tilde{\rho}_R$, $\tilde{T}_R$, respectively. An appropriate reference value for the velocities is given by

$$\tilde{u}_R = \frac{\tilde{Q}(\gamma - 1)}{\tilde{A}\tilde{p}_R}, \tag{1}$$

where $\tilde{Q}$ is the strength of all heat sources (fires) in the tunnel and $\tilde{A}$ is the cross section of the tunnel. The space coordinate x is naturally scaled with the length of the tunnel $\tilde{L}$, and the time t is scaled with $\tilde{L}/\tilde{u}_R$. The constant $\gamma = \tilde{c}_p/\tilde{c}_v$ is the ratio of the specific heat capacities for constant pressure and constant volume of air, respectively. Neglecting viscous stresses and heat conduction in the longitudinal direction, the continuity equation, equation of motion, and energy equation in dimensionless form read

$$\begin{aligned} \rho_t + (\rho u)_x &= 0, \\ u_t + u u_x + \left(\frac{1}{\gamma M^2}\right)\frac{1}{\rho} p_x &= -p_{dv}\frac{u|u|}{2} - f_d \sin\alpha, \\ (\rho T)_t + (u\rho T)_x + (\gamma - 1) p u_x &= q_f. \end{aligned} \tag{2}$$

These have to be supplemented by the equation of state for an ideal gas, $p = \rho T$. In the equation of motion we have considered the pressure loss $p_{dv}u|u|/2$ and the buoyancy force $f_d \sin\alpha$. The scaled pressure loss coefficient $p_{dv} = \tilde{L}/\tilde{d}\,\xi(Re)$, where $\xi(Re)$ is the pressure loss coefficient of a fully developed pipe flow and is a function of the Reynolds number and the roughness of the pipe wall only. The buoyancy parameter f_d is defined by $f_d = \tilde{L}\tilde{g}/\tilde{u}_R^2$, where $\tilde{g}$ is the gravity acceleration. The Mach number $M = \tilde{u}_R/\tilde{c}$ is the ratio of the reference velocity $\tilde{u}_R$ to the speed of sound of the reference state $\tilde{c}^2 = \gamma\tilde{p}_R/\tilde{\rho}_R$.

Typical values corresponding to the above scaling are

$$\gamma = \frac{7}{5}, \quad \tilde{c} = 341\,\mathrm{ms}^{-1}, \quad M^2 = 8.6 \cdot 10^{-6}, \quad Re = 6.7 \cdot 10^5, \quad Pr = 0.72. \tag{3}$$

Due to $M \approx 3 \cdot 10^{-3}$ we are in the low-Mach-number regime. It is important to note that the calculated Reynolds number indicates that the flow in the tunnel is turbulent.

The low Mach number is the reason for the above-mentioned difficulties in the numerical treatment of (2). However, in the present application the Mach number is always small (in time and in space). Therefore an expansion with respect to a low Mach number (setting $\varepsilon = \gamma M^2$),

$$p = p_0 + \varepsilon p_1 + \mathcal{O}(\varepsilon^2), \tag{4}$$

is reasonable. This leads to $p_0 = p_0(t)$. Since the tunnel is an open region, the leading order pressure (which corresponds to the mean outside pressure) will not change in time. Therefore $p_0 = const.$ Obviously we have $p_0 = 1$ (such that the unscaled leading order pressure is equal to p_r). Then in leading order we have $T = \frac{1}{\rho}$.

The leading order equations (in ϵ) are given by

$$\rho_t + u\rho_x = -\rho q, \tag{5}$$

$$u_t + uu_x + \frac{1}{\rho}p_x = -p_{dv}\frac{u|u|}{2} - f_d \sin\alpha, \tag{6}$$

$$u_x = q, \tag{7}$$

with $q = q(x,t)$ as time and space dependent (scaled) heat source. For more details on the derivation of the model and scaling, see [GStr, G4].

As far as boundary data is concerned we prescribe Dirichlet data for the pressure p at the entrance and the exit

$$p(t,0) = p_l(t), \qquad p(t,1) = p_r(t) \quad \forall t > 0. \tag{8}$$

Moreover, assuming no fire at the entrance and exit, we have $q = 0$ at the boundaries, and therefore homogenous Neumann conditions for the velocity,

$$u_x(t,0) = u_x(t,1) = 0 \quad \forall t > 0, \tag{9}$$

hold. For the density we assume standard inflow boundary conditions

$$\rho(t,0) = \rho_l(t) \text{ if } u(t,0) > 0, \qquad \rho(t,1) = \rho_r(t) \text{ if } u(t,1) < 0 \quad \forall t > 0. \tag{10}$$

Initial data are prescribed for the density and the velocity:

$$u(0,x) = u_0(x), \qquad \rho(0,x) = \rho_0(x) \quad \forall x \in [0,1]. \tag{11}$$

Thus, our model consists of (5)–(6), the boundary conditions (8)–(10), and the initial conditions (11).

A first problem lies in the fact that we have two boundary conditions for the pressure but only a first derivative of the pressure in the model. There are at least two ways to resolve this problem. One possibility is to rewrite the model in the following way [GStr]. Equation (7) is substituted by the x-derived velocity equation (6),

$$\rho_t + u\rho_x = -\rho q, \tag{12}$$

$$\left(\frac{1}{\rho}p_x\right)_x = -p_{dv}q|u| - q_x u - q^2 - q_t - f_d \cos\alpha\, \alpha_x, \tag{13}$$

$$u_t + uq + \frac{1}{\rho}p_x = -p_{dv}\frac{u|u|}{2} - f_d \sin\alpha. \tag{14}$$

Thus we have an elliptic equation for the pressure which is consistent with two boundary conditions (for the pressure). This formulation has the advantage that it can be extended easily to higher dimensions [GST1, GST2, G4].

An alternative reformulation—restricted to one space dimension—is the following. We eliminate the pressure by multiplying (6) by ρ and integrating over $x \in [0,1]$. This gives

$$\int_0^1 \rho u_t dx + \int_0^1 \rho u u_x dx + p_r - p_l = -\int_0^1 p_{dv}\rho\frac{u|u|}{2}dx - \int_0^1 f_d \sin\alpha \rho dx. \tag{15}$$

Equation (7) gives

$$u(x,t) = v(t) + \int_0^x q(y,t)dy = v(t) + Q(x,t), \tag{16}$$

where $Q(x,t)$ is a known function. Then we obtain the system

$$\rho_t + (v+Q)\rho_x = -\rho q, \tag{17}$$

$$Rv_t + R_q v + \int_0^1 p_{dv}\rho\frac{(v+Q)|v+Q|}{2}dx = -R_{Q_t+Qq+f_d\sin\alpha} - p_r + p_l, \tag{18}$$

for ρ and v, where R, R_q, $R_{Q_t+Qq+f_d\sin\alpha}$ denote functionals applied to $\rho(x,t)$ defined by (for general f)

$$R(t) = \int_0^1 \rho(x,t)dx, \tag{19}$$

$$R_f(t) = \int_0^1 \rho(x,t)f(x,t)dx. \tag{20}$$

System (17)–(18) consists of an ordinary differential equation (ODE) for v and a partial differential equation (PDE) for the density ρ. The only boundary conditions needed are the inflow conditions (10) for the continuity equation. The conditions on the pressure appear as parameters in (18). The condition on the velocity (9) is automatically fulfilled by (16). In this paper we use this last formulation (17)–(18).

3. Global existence and uniqueness. In this section we focus on the global existence and uniqueness of solutions of (17)–(18) with boundary conditions (10) and initial conditions (11).

We formulate the following conditions:

(A1) On the data in the equations:
  (i) Let $q = q(x,t) \geq 0$ be a smooth function on $[0,1]\times[0,\infty)$ with $\operatorname{supp} q(.,t) \subset (0,1)\ \forall t \in [0,\infty)$.
  (ii) Let $p_{dv} = p_{dv}(x)$ be a smooth function on $[0,1]$ with $p_{dv}(x) > 0\ \forall x \in [0,1]$.
  (iii) Let $\alpha = \alpha(x)$ be a smooth function on $[0,1]$ with $-\frac{\pi}{2} < \alpha(x) < \frac{\pi}{2}$ $\forall x \in [0,1]$.

(A2) On the boundary data:
  (i) Let $\rho_l = \rho_l(t) > 0$ and $\rho_r = \rho_r(t) > 0$ be in $C^1[0,T]\ \forall T > 0$.
  (ii) Let $p_l = p_l(t)$ and $p_r = p_r(t)$ be smooth functions for $t \in [0,\infty)$.

(A3) On the initial data:
  (i) Let $u_0 = u_0(x) = v_0 + \int_0^x q(y,0)dy$ for some constant v_0.
  (ii) Let $\rho_0 = \rho_0(x) > 0$ be a piecewise continuous differentiable function for $x \in [0,1]$.

Before presenting the main existence result we state a result concerning lower and upper bounds of the solutions of the continuity equation (17). In the following we use the notation $f_{max}(T) = \max_{(x,t)\in[0,1]\times[0,T]} f(x,t)$.

LEMMA 3.1. *Let* (A1)(i) *hold. Let* $T > 0$. *Then for a given* $v \in C[0,T]$ *the continuity equation* (17) *with initial* ρ_0 *and boundary data* (10) *has a unique piecewise continuously differentiable solution* ρ *on* $(x,t) \in [0,1]\times[0,T]$. *It satisfies*

$$0 < \rho_{min}(T) \leq \rho(x,t) \leq \rho_{max}(T) \qquad \forall (x,t) \in [0,1]\times[0,T], \tag{21}$$

with

$$\rho_{min}(T) = \min_{t\in[0,T],\, x\in[0,1]} (\rho_l(t), \rho_r(t), \rho_0(x))\, e^{-q_{max}(T)}, \tag{22}$$

$$\rho_{max}(T) = \max_{t\in[0,T],\, x\in[0,1]} (\rho_l(t), \rho_r(t), \rho_0(x)). \tag{23}$$

We also present the proof since it involves the characteristics on which the main ideas of the existence analysis are based.

Proof. Consider a time interval $[0,T]$. The characteristic curves $\eta = \eta(t, x_0, t_0)$ for $t \in [0,T]$, $x, x_0 \in [0,1]$, are defined by

$$\frac{d\eta(t,x_0,t_0)}{dt} = u(\eta(t,x_0,t_0),t) = v(t) + Q(\eta(t,x_0,t_0),t), \qquad \begin{cases} \eta(0,x_0,0) &= x_0, \\ \eta(t_0,0,t_0) &= 0, \\ \eta(t_0,1,t_0) &= 1. \end{cases} \tag{24}$$

Given a continuous $v = v(t)$, the right-hand side in (24) is continuous (in η and t) and Lipschitz-continuous in η. The Lipschitz constant L satisfies $L \leq q_{max}(T)$. Therefore the characteristic curves are uniquely defined at every point (x,t) and do not intersect.

The continuity equation (17) reads along the characteristics

$$\frac{d\rho(\eta(t,x_0,t_0),t)}{dt} = -q(\eta(t,x_0,t_0),t)\rho(\eta(t,x_0,t_0),t), \tag{25}$$

with

$$\begin{aligned} \rho(\eta(0,x_0,0),0) &= \rho_0(x_0) && \text{for} && 0 < \eta(t,x_0,t_0) < 1 \quad \forall t \in [0,T], \\ \rho(0,t) &= \rho(\eta(t,0,t),t) = \rho_l(t) && \text{for} && u(0,t) > 0, \\ \rho(1,t) &= \rho(\eta(t,1,t),t) = \rho_r(t) && \text{for} && u(1,t) < 0. \end{aligned}$$

The density does not increase along the characteristics; it decreases at most exponentially in the region with nonvanishing heat-source q. This implies the estimates (21), (22), (23). □

Now we state the main global existence result.

THEOREM 3.1. *Let* (A1)–(A3) *hold. Then for all* $T > 0$ *there exists a unique solution* (ρ, v)*—*ρ *piecewise continuous differentiable in* $[0,1] \times [0,T]$ *and* $v \in C^1[0,T]$*—to* (17)–(18) *with boundary conditions* (10) *and initial conditions* (ρ_0, v_0) *from* (11).

The idea of the proof is a fixed point argument in the ODE (18). Clearly, in every step we have to control the coefficients of the ODE (18), which involve the solution of the PDE (17). Therefore, the proof becomes technical. Details on the proof are given in [GSte2].

4. The transient behavior. Here we would like to discuss the transient behavior of the solutions of our model with respect to the applications. In [G1] the stationary problem was analyzed. The result was that even in simple (realistic) cases (and even without fire) multiple (realistic) solutions of the stationary problem may exist. This depends mainly on the pressure difference at the entrance and exit and on the slope profile in the tunnel. In addition, numerical simulations indicate that in some cases more than one of these (multiple) solutions seem to be stable.

Numerical simulations in the transient problem for realistic tunnel examples have been performed in [G4, GStr] in which data from experiments have been included. Depending on the initial data, completely different long term behavior can be observed. Therefore, the dynamics of the transient problem is all but trivial. Clearly, this is of particular interest for the application.

Here we present an example to give an idea of the dynamics of the model (see Figures 1–3). The example starts with initial data corresponding to a no-fire situation in a tunnel with slope (see Table 1 for details). The pressure difference induces a steady downward flow (in Figure 1, downwards means to the left) in the tunnel. Then (in the time interval $t \in [10, 15]$ minutes) a fire of strength $Q = 6\,\mathrm{MW}$ is ignited in the middle of the tunnel. Buoyancy forces reduce the driving force of the flow, but they are too weak to compensate for the external pressure difference, and thus the flow is still downward. The flow adjusts rapidly to a new stationary state. Below (in Figure 1, to the left of) the heat source there is a hot air-smoke mixture; above the fire there is the fresh cold air. Later (in the time interval $t \in [60, 65]$ minutes) the heat production of the fire is increased (8 MW heat source) and the transition to the corresponding stationary state takes place (slowly). Now the buoyancy forces

TABLE 1
Data of tunnel and fire.

Length	4 km
Cross section	$100\,\mathrm{m}^2$
Slope	3%
Pressure loss coefficient ξ	0.0956
Pressure-difference $p(L) - p(0)$	1013.55 mbar

Mean initial velocity	$-5.0\,\mathrm{ms}^{-1}$
Heat source $q(x,t) = Q(t)\delta(x)$	$Q(t) = \begin{cases} 0\,\mathrm{MW} & t < 10\,\mathrm{min} \\ \text{linear cont.} & 10\,\mathrm{min} < t < 15\,\mathrm{min} \\ 6\,MW & 15\,\mathrm{min} < t < 60\,\mathrm{min} \\ \text{linear cont.} & 60\,\mathrm{min} < t < 65\,\mathrm{min} \\ 8\,MW & 65\,\mathrm{min} < t \end{cases}$

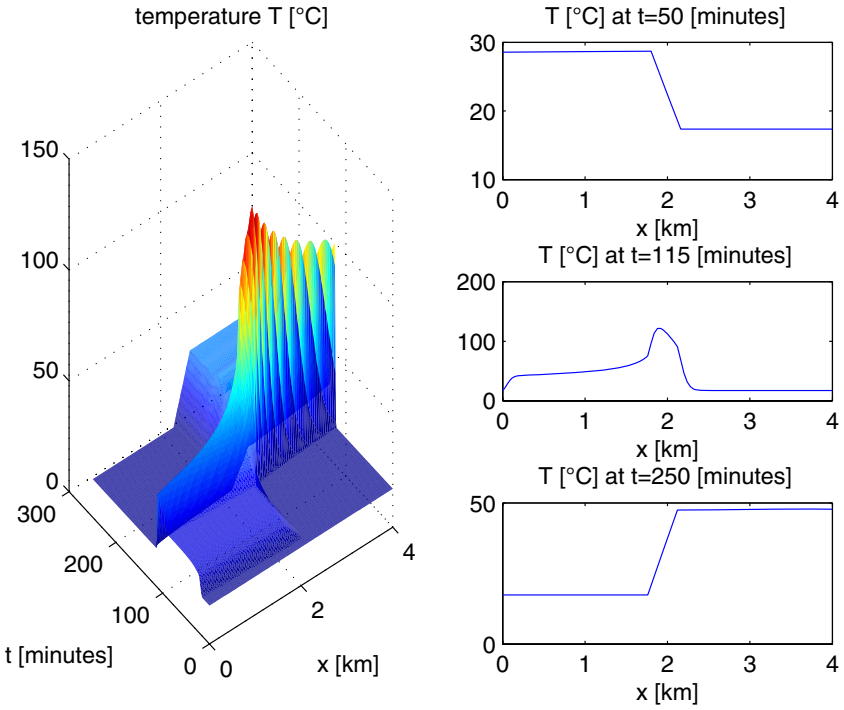

FIG. 1. *Temperature field (left) and the temperature at three time levels (right) in the transition between three different stationary states corresponding to the data in Table* 1.

acting on the hot air below the fire are strong enough to compensate for the outside pressure difference, and thus the flow velocity decreases and finally the flow changes its direction. When the flow velocity tends to zero the enthalpy produced by the fire is not removed from the fire, and thus the temperature at the fire rises dramatically, even enhancing the upward buoyancy forces. Then the air starts to flow upward, and buoyancy accelerates the flow. With the onset of the flow in the upward direction the fire is cooled again; however, the very hot air/smoke produced during the very slow flow phase is still in the tunnel. This hot gas induces a large upward buoyancy force, resulting in a positive velocity overshoot. From the left (lower) end, cold air is sucked in, and thus the temperature of the fire is cooled, resulting in a cooler hot air-smoke mixture above the fire, which in turn reduces the buoyancy and the upward velocity. In Figure 2 we can see the flow velocity. In the right of Figure 2 we observe the difference between the velocity at the entrance and the exit. This difference depends on the strength of the heat source and has its maximum value in the final state (8 MW heat source).

We want to point out the oscillating behavior that occurs as the fire is attaining the final state. The temperature distribution has a discontinuity due the inversion of the flow direction. This can be seen best in the contour plots of the temperature distribution (Figure 3). The flow changes direction shortly after the first particles of the air, which have been heated by the fire after its strength has been increased, reach the left end of the tunnel. After the inversion of the flow direction, cold air is sucked in. Therefore a contact discontinuity between the hot and the fresh cold air forms.

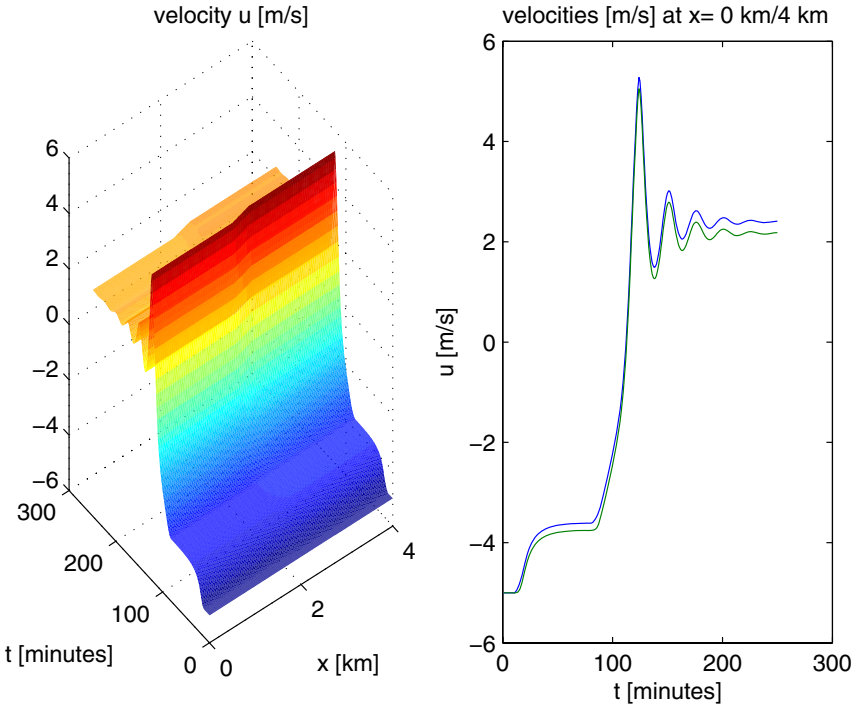

FIG. 2. *Velocity field (left) and the velocity at the entrance (upper curve) and exit (lower curve) of the tunnel as a function of time (right) in the transition between three stationary states corresponding to the data in Table* 1.

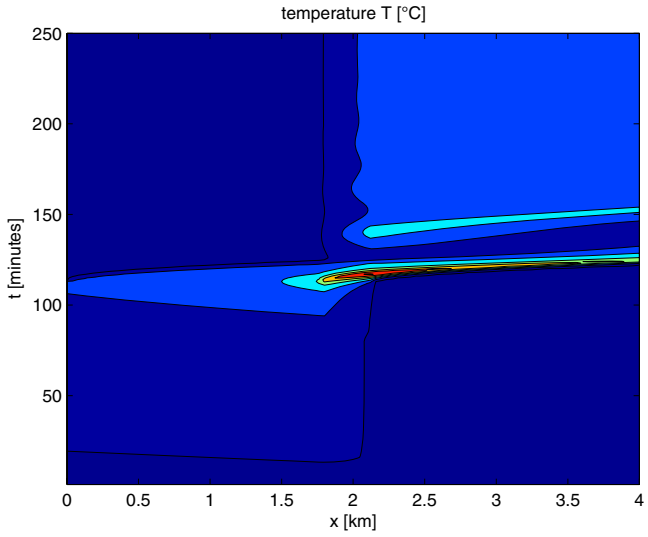

FIG. 3. *Contour plot of the temperature field in the transition between three stationary states corresponding to the data in Table* 1.

Obviously, the analysis in section 3 can be applied to such discontinuous solutions.

5. Stability of the stationary solutions. The starting point for the stability analysis is (17)–(18). The corresponding stationary problem was studied in [G1]. There the complete solution structure was analyzed. Depending on the data all the cases—no solution, exactly one solution, and multiple (nonvacuum) solutions—are possible. Especially from the application point of view it is important to know whether the solutions of the stationary problem are stable as solutions of the underlying transient problem. This is the main question in this section.

For this purpose we assume $q = q(x)$ and constant (in time) data ρ_l, ρ_r, p_l, p_r. Then we linearize (17)–(18) around a solution (ρ_s, v_s) of the stationary problem using

$$\rho(x,t) = \rho_s(x) + \rho_L(x,t), \qquad v(t) = v_s + v_L(t), \tag{26}$$

and obtain

$$\rho_{L;t} + (v_L + Q)\rho_{L;x} = -v_L\rho_{s;x} - q\rho_L, \tag{27}$$

$$R_s v_{L;t} + R_{s;q+p_{dv}(v_s+Q)} v_L = -R_{L;G}, \tag{28}$$

where we use the notation

$$R_{s;f}(t) = \int_0^1 \rho_s(x) f(x,t)dx, \qquad R_{L;f}(t) = \int_0^1 \rho_L(x,t) f(x,t)dx \tag{29}$$

and

$$G(x) = q(x)(v_s + Q(x)) + p_{dv}(x)\frac{(v_s + Q(x))|v_s + Q(x)|}{2} + f_d \sin\alpha(x). \tag{30}$$

The strategy is again to "solve" the continuity equation (27) and to evaluate the terms in (28) where the density is involved. Then one is left with an ODE for the velocity correction v_L only.

We now focus on the case of positive (constant) mass-flux $m = \rho_s(x)(v_s + Q(x))$. The case of negative mass-flux can be handled analogously. Remember that solutions with vanishing mass-flux imply (in case of nonvanishing heat-source) vacuum solutions which are not of interest in this application (see [G1]).

In case of a stationary solution the characteristic $\eta(t, x_0, t_0)$ of the continuity equation can be written in the form

$$\eta(t, x_0, t_0) = \eta^*(t - t_E(x_0, t_0)), \tag{31}$$

where $\eta^*(t) = \eta(t, 0, 0)$ and $t_E(x,t)$ is the time when the characteristic through x, t enters the interval $(0, 1)$.

Thus we have

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\eta^* = v_s + Q(\eta^*), \quad \eta^*(0) = 0, \tag{32}$$

$$t_E(x,t) := t - \int_0^x \frac{\mathrm{d}x'}{v_s + Q(x')} = t - t_l(x). \tag{33}$$

The time $t_l(x)$ is the time a particle needs to move from the entrance of the tunnel $(x = 0)$ to the position x. Along this characteristic curve the density evolves as

$$\rho_L(\eta^*(t - t_E), t) = -\int_{t_E}^t v_L(\tau)\rho_{s;x}(\eta^*(\tau - t_E)) \exp\left(-\int_\tau^t q(\eta^*(s - t_E))\,\mathrm{d}s\right)\mathrm{d}\tau \tag{34}$$

and

(35)
$$\rho_L(x,t) = -\int_{t_E(x,t)}^{t} v_L(\tau)\rho_{s;x}(\eta^*(\tau - t_E(x,t)))\exp\left(-\int_\tau^t q(\eta(s-t_E(t,x)))\,\mathrm{d}s\right)\mathrm{d}\tau.$$

Substituting

$$z = \eta^*(s - t + t_l(x)), \quad \mathrm{d}z = \eta^{*\prime}\,\mathrm{d}s = (v_s + Q(z))\,\mathrm{d}s \tag{36}$$

gives

(37)
$$\int_\tau^t q(\eta(s-t_E(t,x)))\,\mathrm{d}s = \int_{\eta^*(\tau-t+t_l(x))}^{\eta^*(t_l(x))=x} \frac{q(z)\mathrm{d}z}{v_s+Q(z)} = \ln\frac{v_s+Q(x)}{v_s+Q(\eta(\tau-t+t_l(x)))}$$

and

$$\begin{aligned}\rho_L(x,t) &= -\int_{t_0(x,t)}^{t} U_L(\tau)\rho_x(\eta(\tau-t_0(x,t)))\frac{v_s+Q(\eta(\tau-t_0(x,t)))}{v_s+Q(x)}\mathrm{d}\tau\\ &= -\frac{1}{v_s+Q(x)}\int_0^{t_l(x)} U_L(t-s)J(t_l(x)-s)\mathrm{d}s \qquad (38)\end{aligned}$$

with

$$J(t_l(x)-s) = \rho_x(\eta(t_l(x)-s))(v_s+Q(\eta(t_l(x)-s))). \tag{39}$$

Then we conclude

$$\begin{aligned}-\int_0^1 \rho_L(x,t)\,G(x)\,\mathrm{d}x &= \int_0^1\int_0^{t_l(x)} U(t-s)\frac{G(x)\,J(t_l(x)-s)}{v_s+Q(x)}\,\mathrm{d}s\,\mathrm{d}x\\ &= \int_0^{t_l(1)} U(t-s)\int_{\eta(s)}^1 \frac{G(x)\,J(t_l(x)-s)}{v_s+Q(x)}\,\mathrm{d}x\,\mathrm{d}s. \qquad (40)\end{aligned}$$

We summarize the resulting problem for v_L:

$$\frac{\mathrm{d}}{\mathrm{d}t}v_L = Av_L + \int_0^{t_l(1)} v_L(t-s)K(s)\mathrm{d}s, \tag{41}$$

$$A = -\frac{\int_0^1 \rho_s(q+\xi|v_s+Q|)\,\mathrm{d}x}{\int_0^1 \rho_s\,\mathrm{d}x} < 0, \tag{42}$$

$$K(s) = \frac{1}{\int_0^1 \rho_s\,\mathrm{d}x}\int_{\eta(s)}^1 \frac{G(x)}{v_s+Q(x)}J(t_l(x)-s)\,\mathrm{d}x. \tag{43}$$

This is a Volterra integro-differential equation. Before using standard results on such equations we remark the following.

Remark 5.1.

(i) We have

$$J(\tau) = (v_s+Q(\eta(\tau))\,\rho_{s;x}(\eta(\tau)) = -\rho_s(\eta(\tau)))\,q(\eta(\tau)) \le 0. \tag{44}$$

(ii) $G(x) > 0$ if $\alpha > 0$. In this case we have $K(s) \leq 0$.

Using Theorem 5.2.1 in [Bu], we can state the following result.

THEOREM 5.1. *If*

$$\int_0^{t_l} |K(\tau)| \, \mathrm{d}\tau < |A|, \tag{45}$$

then the trivial solution is asymptotically stable.

The proof goes along the lines of Theorem 5.2.1 in [Bu].

Remark 5.2. For appropriately "small" heat sources $||q||_1 < c$ the functions J and K are such that Theorem 5.1 holds.

Remark 5.3. For the case $\alpha \geq 0$ Theorem 5.1 does not take into account the fact that both A and K have the "good" negative sign. Therefore a stronger result can be expected.

5.1. Point-sources. For many applications (e.g., when the diameter of the region where the heat-source is active is small compared to the length of the tunnel) it might be useful to consider point-sources.

Here we discuss the case of a single point-source located at the position $x = x_q$, of the form

$$q(x,t) = q\delta(x - x_q). \tag{46}$$

Then we conclude

$$Q(x,t) = qH(x - x_q), \tag{47}$$

with H the Heavy-side function. We assume a time independent source q, since the aim is to study the stability of stationary solutions. Integrating the continuity equation over the support of $q(x,t)$, we obtain that the mass flux ρu is continuous at x_q:

$$\rho_s(x_{q-}, t)v = \rho_s(x_{q+}, t)(v + q) \qquad \text{at } x = x_q. \tag{48}$$

Then the continuity equation reads as

$$\begin{cases} \rho_t + v\rho_x = 0 & \text{for} \quad x < x_q, \\ \rho_t + (v+q)\rho_x = 0 & \text{for} \quad x > x_q. \end{cases} \tag{49}$$

Using the continuity of the mass flow at x_q, we can evaluate the integral

$$vR_q + R_{Qq} = \int_0^1 u\rho \, \mathrm{d}x = qv\rho(x_{q-})$$

and obtain the integrated momentum equation

$$Rv_t + q\rho_- v + \int_0^{x_q} p_{dv}\rho \frac{v|v|}{2} dx + \int_{x_q}^1 p_{dv}\rho \frac{(v+q)|v+q|}{2} dx = -R_{f_d \sin\alpha} - p_r + p_l. \tag{50}$$

Focusing again on the case of strictly positive mass fluxes, the stationary solution is given by

$$u_s = \begin{cases} v_s & \text{for} \quad x < x_q, \\ v_s + q & \text{for} \quad x > x_q, \end{cases} \tag{51}$$

and the stationary density results in

$$\rho_s = \begin{cases} \rho_{s-} &= \rho(0) & \text{for} \quad x < x_q, \\ \rho_{s+} &= \rho(0)\frac{v_s}{v_s+q} & \text{for} \quad x > x_q, \end{cases} \tag{52}$$

where v_s is a solution of the nonlinear equation

$$\begin{aligned} &q\rho_- v_s + p_{dv}\frac{\rho_- v_s}{2}\left(x_q|v_s| + (1-x_q)|v_s+q|\right) \\ &= \rho_- f_d\left(\int_0^{x_q}\sin(\alpha)\,\mathrm{d}x + \frac{v_s}{v_s+q}\int_{x_q}^1 \sin(\alpha)\,\mathrm{d}x\right) + p_l - p_r. \end{aligned} \tag{53}$$

In order to keep the calculations simple we consider the linearization for a constant p_{dv} and constant slope profile α. The solutions of the linearized equations are denoted by a subscript $_L$. The linearized continuity equation reads

$$\begin{cases} \rho_{L;t} + v_s\rho_{L;x} &= 0 & \text{for} \quad x < x_q, \\ v_L(t)\rho_{s-} + v_s\rho_{L,-} &= (v_s+q)\rho_{L+} + v_L\rho_{s+} & \text{for} \quad x = x_q, \\ \rho_{L;t} + (v_s+q)\rho_{L;x} &= 0 & \text{for} \quad x > x_q, \end{cases} \tag{54}$$

and the linearized equation (50) becomes

$$\begin{aligned} &(\rho_{s-}x_q + \rho_{s+}(1-x_q))v_{L;t} + (\rho_{s-}q + \rho_{s-}p_{dv}v_s x_q + \rho_{s+}p_{dv}(v_s+q)(1-x_q))v_L \\ &= -p_{dv}\frac{v_s^2}{2}\int_0^{x_q}\rho_L\mathrm{d}x - p_{dv}\frac{(v_s+q)^2}{2}\int_{x_q}^1\rho_L\mathrm{d}x - \int_{x_q}^1\rho_L f_d\sin\alpha\mathrm{d}x - \rho_{L-}qv_s. \end{aligned} \tag{55}$$

The solution of the continuity equation is given by (assuming vanishing density disturbances at the left boundary)

$$\rho_L = \begin{cases} 0 & & \text{for} \quad x < x_q, \\ \rho_L\left(x_q+, t-\frac{x-x_q}{v_s+q}\right) &= \frac{\rho_{s-}-\rho_{s+}}{v_s+q}v_L\left(t-\frac{x-x_q}{v_s+q}\right) & \text{for} \quad x > x_q, \end{cases} \tag{56}$$

for $t - \frac{x-x_q}{v_s+q} > 0$. Then with $\rho_{s-} - \rho_{s+} = \rho(0)\frac{q}{v_s+q}$ we obtain

$$\int_{x_q}^1 \rho_L dx = \rho(0)\frac{q}{v_s+q}\int_0^{\frac{1-x_q}{v_s+q}} v_L(t-s)ds. \tag{57}$$

Therefore (55) reads

$$v_{L;t} + av_L = b\int_0^{\frac{1-x_q}{v_s+q}} v_L(t-s)ds, \tag{58}$$

or with $t = \tau\frac{1-x_q}{v_s+q}$, $V(\tau) = v_l(\tau\frac{1-x_q}{v_s+q})$ we obtain

$$\begin{aligned} V_\tau + AV &= -B\int_0^1 V(\tau-\sigma)d\sigma, \\ A &= \frac{(v_s+q)(\rho_{s-}q + \rho_{s-}p_{dv}v_s x_q + \rho_{s+}p_{dv}(v_s+q)(1-x_q))}{(1-x_q)(\rho_{s-}x_q + \rho_{s+}(1-x_q))} > 0, \\ B &= \frac{(v_s+q)(p_{dv}\frac{(v_s+q)^2}{2} + f_d\sin\alpha)}{(1-x_q)(\rho_{s-}x_q + \rho_{s+}(1-x_q))}. \end{aligned} \tag{59}$$

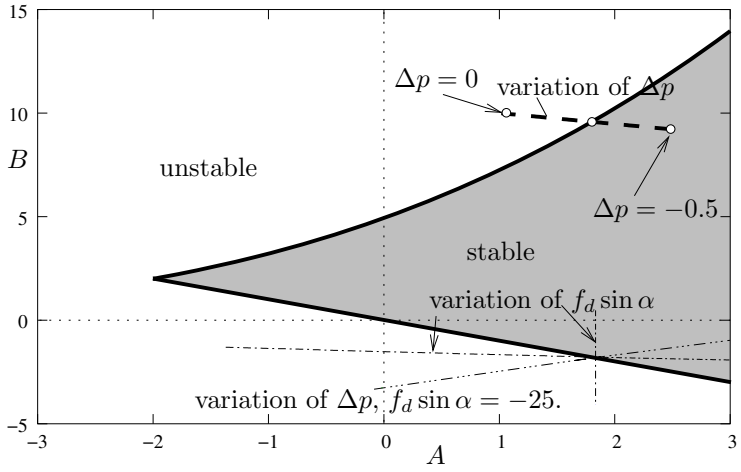

FIG. 4. *Stability diagram (detail). Parameter values A, B corresponding to the stationary solutions of the examples of section* 5.2 *are also indicated: variation of* Δp *for* $f_d = 0$*, dashed line; variation of* Δp *for* $f_d \sin\alpha = -25$*, dash-triple-dotted line; variation of* $f_d \sin\alpha$*, dash-dotted line.*

In order to find the stable and unstable parameter regions we make the ansatz $V(\tau) = e^{\zeta\tau}$ and obtain the characteristic equation

$$\zeta + A + B\frac{1 - e^{\zeta}}{\zeta} = 0. \tag{60}$$

Since we are interested in the location of the change of stability we look for solutions of (60) with vanishing real part. Thus we set $\zeta = is$ with s real, and compare the real and imaginary parts. This yields a parameterized curve in the A, B plane of the form

$$A = \frac{s \sin s}{1 - \cos s}, \qquad B = \frac{s^2}{1 - \cos s} \tag{61}$$

(a part of this curve is the upper border of the stable region in Figure 4). When crossing this curve at $s \neq 0$, the real part of a pair of complex conjugate eigenvalues changes sign. Thus we expect a Hopf-bifurcation to occur. It is easy to see that the integral equation (59) has nontrivial constant solutions if $A + B = 0$. This second curve is also indicated in the stability diagram Figure 4 (lower border of the stable region). Crossing this second curve, a bifurcation of the steady-state solutions is expected.

Figure 4 is a detail of the stability diagram (depending on the parameter values A and B). The formulation (60) allows us to reduce the stability analysis to two parameters A and B. These parameters combine many of the parameters of the model. The price of the reduction is that the parameters A and B cannot be interpreted easily from an application point of view.

In Figure 4 some possibilities for varying the original parameters are indicated. This will be discussed in the next section.

5.2. Numerical analysis. The main purpose here is to study in more detail the behavior of the solutions when stability is lost. The two examples that follow correspond to the situation on the upper and the lower borders, respectively, of the stable region in the stability diagram Figure 4.

As long as only solutions with positive flow velocities are involved, the density ρ has its boundary value ρ_l for $x < x_q$. Thus for solving the continuity equation we can reduce the domain of the numerical solution to the interval $(x_q, 1)$ and use the interface condition for ρ at x_q as an (inflow)-boundary condition. The discretization of the continuity and integrated momentum equation is just straightforward. We have used here a second order method.

For the numerical example we have taken $p_{dv} = 40$, $x_q = 0.5$, $\alpha = 0$, and $q = 1$, and varied $\Delta p = p_r - p_l$. It can be verified that the stationary solution is stable for $\Delta p < \Delta p^* = -0.254$ and unstable for $\Delta p > \Delta p^*$. This is in agreement with the linear stability analysis. The corresponding values of the parameters A and B are indicated in the stability diagram (Figure 4).

Taking the unstable stationary solution with a small perturbation as the initial condition, we observe that the transient solution oscillates with increasing amplitude around the stationary solution until negative velocities are obtained. In no case could a stable limit cycle with only positive velocities be obtained. This indicates that the Hopf-bifurcation at $\Delta p = \Delta p^*$ is subcritical.

In order to compute the (unstable) limit cycle we formulate a fixed point problem: We take the values of the density ρ_i at the grid points $x_i = x_q + (1 - x_q)i/N$ at $t = 0$ and the period t_p as unknowns. Thus the following equations have to be satisfied:

$$\rho(x_i, t_p) = \rho_i, \quad i = 1, \ldots, N, \quad \text{and} \quad v(t_p) = v(0). \tag{62}$$

The pressure difference Δp and the initial velocity $v(0)$ are prescribed appropriately. The resulting equations are solved using the NAGLIB routine C05NBF [NAG]. In the examples given here the number of grid points is N = 100 and 200, respectively.

The minimum and the maximum of the resulting limit cycle are indicated in Figure 5. Thus a subcritical Hopf-bifurcation is verified. However, the limit cycle with strictly positive velocity values exists only for a narrow pressure interval. Neglecting the modulus function in the friction term and the positivity of the density, this unstable limit cycle can be continued to negative velocities.

In order to obtain physically relevant solutions for negative velocities, a more sophisticated numerical analysis is necessary. Taking a conventional finite volume

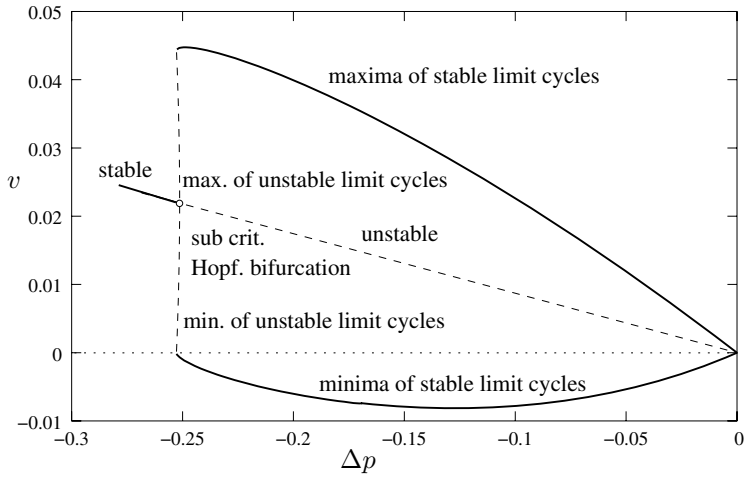

FIG. 5. *Numerical solution for $p_{dv} = 40$, $q = 1$, $\Delta x_0 = 0.5$, $u_L = 1$. The steady-state solution is stable for $\Delta p < \Delta p^*$. The limit cycles are represented by their maximum and minimum velocities.*

method or finite different scheme for the entire solution interval $x \in (0,1)$ may produce negative densities. In order to avoid this problem we employ the method of characteristics. Considering the jump condition of the density at $x = x_q$ for negative values of v which are larger than $-q$, we conclude that the only possibility of a nonnegative density is that $\rho(x_q-) = \rho(x_q+) = 0$ if $-q < v < 0$ holds. In that case the characteristics left of x_q point in the negative direction, and thus there will be a jump discontinuity of the density at a location $x_0(t) < x_q$, which moves with the fluid velocity $v(t)$ left of x_q. Thus $\rho(x,t) = 0$ for $x_0(t) < x < x_q$. For $0 < x < x_0(t)$ the density has the inflow value ρ_l at $x = 0$. Thus we construct the following numerical method: For the domain $0 < x < x_q$ the density distribution is completely described by $x_0(t)$, as long as $v > -q$. For $x > x_q$ we define the characteristics by

$$\frac{\mathrm{d}}{\mathrm{d}t}\bar{x}_i(t) = v + q, \quad \bar{x}_i(0) = x_i = x_q + (1 - x_q)i/N, \quad \rho_i = \rho(x_i, 0). \tag{63}$$

Every time a characteristic $\bar{x}_j(t)$ leaves the domain of consideration at $x = 1$ a new characteristic will be introduced at $x = x_q$, and ρ_j will be set to $\rho(x_q+, t)$, which is zero if $v < 0$, or $\rho(x_q-, t)v/(q + v)$ if $v > 0$. Note that $\rho(x_q-, t) = \rho_l$ if $x_0 = x_q$, or $\rho(x_q-, t) = 0$ if $x_0 < x_q$.

Employing this method in the case of the unstable stationary solution, the transient solution tends to a stable limit cycle which has time intervals with negative velocities. In Figure 5 the maximum and minimum values of the limit cycle are shown. This stable limit cycle connects to the unstable limit cycle where the minimum of the velocity is zero.

As a second example we consider an inclined tunnel. We assume p_{dv}, x_q, and q have the same values as in the first example. We vary $f_d \sin\alpha$ and $\Delta p = p_r - p_l$ such that $v_s = 0.023$ is a stationary solution. However, (53) for the stationary flows has in general more than one solution (as known from [G1]). We compute a second solution branch, which intersects the first (constant) solution branch when $A + B = 0$ holds; see Figure 4. The stability parameters A and B for both solution branches are indicated in the stability diagram, and we observe that at the intersection of the two branches a stability exchange occurs (Figure 6).

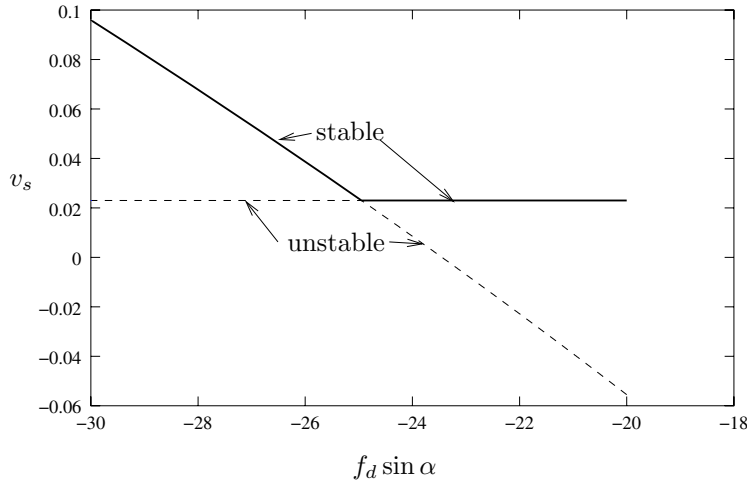

FIG. 6. *Variation of the buoyancy parameter $f_d \sin\alpha$. The pressure Δp is chosen such that $v_s = 0.023$ is a stationary solution. A second solution branch exists, which intersects the first.*

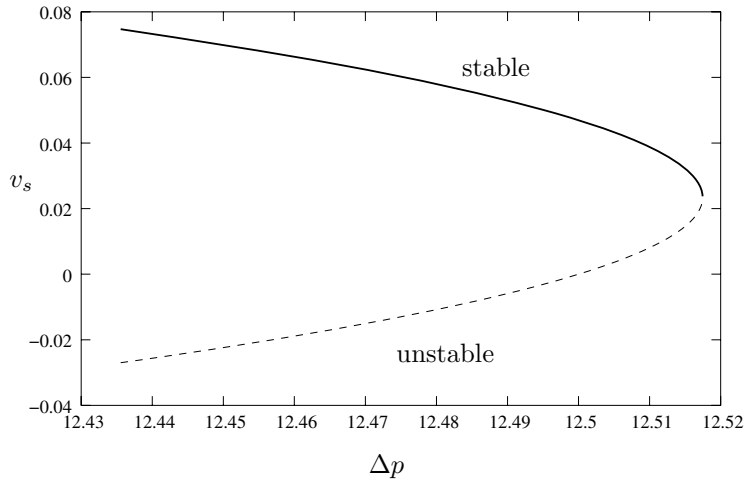

FIG. 7. *Variation of Δp for $f_d \sin\alpha = -25$. For Δp less than a critical value, two solution branches exist.*

In the third example we assume $f_d \sin\alpha = -25$ fixed and vary Δp. For Δp less than a limiting value Δp_c two solution branches exist. The upper one corresponds to a stable and the lower one to an unstable solution. At the limiting value Δp_c both solution branches are connected and terminate there (Figure 7).

Thus we have verified by numerical examples that, while crossing the upper limit of the stability domain, a subcritical Hopf-bifurcation occurs, and while crossing the lower bound of the stability domain, a bifurcation of stationary solution occurs.

6. Conclusions. We have studied the global dynamics for solutions of model equations for the description of tunnel fires. Also, the stability of the stationary solutions has been investigated. We see at least numerically that Hopf-like bifurcations occur and induce oscillation with large amplitudes and even, most dangerous for fire fighters, flow reversal can occur. The critical cases can be identified by a relatively small outside pressure difference. Since the Hopf-bifurcation seems to be subcritical, the large amplitude limit cycle can be attained even at conditions where the steady-state solution is still stable. Thus the presented analysis delivers a simple tool for determining the stability of flow conditions during a tunnel fire.

ERRATUM: GLOBAL STABILITY IN CHEMOSTAT-TYPE COMPETITION MODELS WITH NUTRIENT RECYCLING*

SHIGUI RUAN† AND XUE-ZHONG HE‡

Abstract. This note corrects some typos and errors in the paper [S. Ruan and X.-Z. He, *SIAM J. Appl. Math.*, 58 (1998), pp. 170–192].

Key words. competition, global stability, nutrient recycling

DOI. 10.1137/06065876X

The main error in the paper [1] is that conditions on the matrix B should be replaced by conditions on the matrix AB at four separate places.

1. On page 177, condition (iii) in Theorem 2.8 should read

(iii) *the matrix AB is semipositive definite.*

2. On page 182, there were a few typos in Theorem 3.8 and an error in condition (v). The corrected version of the theorem is as follows.

THEOREM 3.8. *Assume that*

(i) *system* (3.1) *has a positive equilibrium* $E^* = (S^*, N_1^*, N_2^*)$*;*

(ii) $D + D_i < m_i$, $b_i D_i < \mu_i p(S_i^*)$, $i = 1, 2$*;*

(iii) $T_f < \infty$, $T_i^* = (1/d_i^*) \int_0^\infty F(s)[e^{d_i^* s} - 1]\, ds < \infty$ *with* $d_i^* := (D + D_i) + \sum_{j=1}^2 \delta_{ij} m_j$, $i = 1, 2$*;*

(iv) $b_i D_i[(m_i + \sum_{j=1}^2 \delta_{ij} N_j^*) T_i^* + m_i T_f]/2 < \mu_i$, $i = 1, 2$*;*

(v) *The matrix AB is semipositive definite, where* $A = \mathrm{diag}(\alpha_1, \alpha_2)$ *with* $\alpha_i = [\mu_i p(S_i^*) - b_i D_i]/m_i$ $(i = 1, 2)$ *and* $B = (b_{ij})_{2\times 2}$, $b_{ij} \geq 0$ *defined by*

$$b_{ij} = \begin{cases} \delta_{ii} - \frac{T_f m_i}{2[\mu_i p(S^*) - b_i D_i] N_i^*} \sum_{j=1}^2 b_j D_j \delta_{ji} m_j & \text{if } i = j, \\ \delta_{ij} & \text{if } i \neq j. \end{cases} \tag{3.25}$$

Then E^* is global asymptotically stable.

3. On page 186, condition (iii) in Theorem 4.3 should read

(iii) *the matrix AB is semipositive definite.*

4. On page 188, Theorem 4.6 should read as follows.

THEOREM 4.6. *Assume that*

(i) *system* (4.11) *has a positive equilibrium* $E^* = (S^*, N_1^*, \ldots, N_n^*)$*;*

(ii) $D + D_i < m_i$, $b_i D_i < \mu_i p(S_i^*)$, $i = 1, 2, \ldots, n$*;*

(iii) $T_f < \infty$, $T_i^* = (1/d_i^*) \int_0^\infty F(s)[e^{d_i^* s} - 1]\, ds < \infty$, $i = 1, 2, \ldots, n$, *where* $d_i^* = (D + D_i) + \sum_{j=1}^n \delta_{ij} m_j$*;*

(iv) $b_i D_i[(m_i + \sum_{j=1}^n \delta_{ij} N_j^*) T_i^* + m_i T_f]/2 < \mu_i$, $i = 1, 2, \ldots, n$*;*

(v) *the matrix AB is semipositive definite, where* $A = \mathrm{diag}(\alpha_i)_{n\times n}$ *with* $\alpha_i =$
