From this we deduce also that the sequence S_x^κ converges pointwise almost everywhere. To see this, let $y_\kappa = S_x^\kappa$, $v_\kappa = [S_x^\kappa]_\kappa$ and $v = \lim_{\kappa\to 0} v_\kappa$. From

$$y_\kappa^4 = v_\kappa^2(\kappa^2 + y_\kappa^2) = v_\kappa^2\kappa^2 + v_\kappa^2 y_\kappa^2$$

we conclude

$$y_\kappa^4 - v_\kappa^2\kappa^2 - v_\kappa^2 y_\kappa^2 = 0, \tag{4.7}$$

and hence

$$y_\kappa^2 = \frac{v_\kappa^2 + \sqrt{v_\kappa^4 + 4v_\kappa^2\kappa^2}}{2},$$

since the second solution of (4.7) is negative. Therefore, for $\kappa \to 0$,

$$y_\kappa^2 = \frac{v_\kappa^2 + \sqrt{v_\kappa^4 + 4v_\kappa^2\kappa^2}}{2} \to \frac{v^2 + \sqrt{v^4}}{2} = v^2.$$

From the fact that $\mathrm{sign}(v_\kappa) = \mathrm{sign}(y_\kappa)$ we thus obtain

$$\begin{aligned} |y_\kappa - v_\kappa|^2 &= y_\kappa^2 - 2y_\kappa v_\kappa + v_\kappa^2 \\ &= y_\kappa^2 - 2|y_\kappa||v_\kappa| + v_\kappa^2 \to v^2 - 2|v||v| + |v|^2 = 0, \end{aligned} \tag{4.8}$$

and hence

$$\lim_{\kappa\to 0} S_x^\kappa = \lim_{\kappa\to 0} y_\kappa = \lim_{\kappa\to 0} v_\kappa = v = \lim_{\kappa\to 0} [S_x^\kappa]_\kappa.$$

Therefore S_x^κ converges pointwise almost everywhere in Q_{T_e}. Since $S_x^\kappa \rightharpoonup S_x$ weakly in $L^{\frac{4}{3}}(Q_{T_e})$, we conclude from Lemma 4.2 that $S_x^\kappa \to S_x$ and $[S_x]^\kappa \to S_x$ almost everywhere in Q_{T_e}. This proves (4.3) and (4.4). Relation (4.4) yields $[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \to S_x|S_x|$ almost everywhere in Q_{T_e}, which implies that the limit function G of $[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa$ is equal to $S_x|S_x|$. This proves (4.6).

To prove (4.5) we note that the estimate $|[S_x^\kappa]_\kappa| = |S_x^\kappa|_\kappa \le |S_x^\kappa|$ and the inequality (4.1) together imply that the sequences $[S_x^\kappa]_\kappa$ and $|S_x^\kappa|_\kappa$ are uniformly bounded in $L^{\frac{4}{3}}(Q_{T_e})$. Thus, (4.5) is a consequence of (4.4) and Lemma 4.2. ∎

Proof of Theorem 1.1. Define the functions u and T by

$$\begin{aligned} u(t,x) &= u^* \left(\int_a^x S(t,y)dy - \frac{x-a}{d-a} \int_a^d S(t,y)dy \right) + w(t,x), \\ T(t,x) &= D(\varepsilon^* - \bar\varepsilon)S - D\varepsilon^* \frac{1}{d-a} \int_a^d S(t,y)dy + \sigma(t,x), \end{aligned} \tag{4.9}$$

where for S we insert the limit function of the sequence S^κ given in (4.2), and where $u^* \in \mathbb{R}^3$, $\varepsilon^* \in \mathcal{S}^3$, and (w,σ) are the same constants and functions as in (2.9) and (2.10). We prove that (u,T,S) is a weak solution of problem (1.7)–(1.12).

To this end note that (3.4) and (4.2) imply $S \in L^\infty(Q_{T_e})$. From this relation, from the above definition of u and T, and from $(w,\sigma) \in C^{2,1}(\bar Q_{T_e}) \times C^{1,1}(\bar Q_{T_e})$, we immediately see that u and T satisfy (1.14) and (1.15). Observe next that $\|S^\kappa\|_{L^\infty(0,T_e;H_0^1(\Omega))} \le C$, by (3.6). This implies $S \in L^\infty(0,T_e;H_0^1(\Omega))$, since we can select a subsequence of S^κ which converges weakly to S in this space. Thus, S satisfies (1.16).

It is shown in [3] that the functions u and T defined in this way satisfy (1.7), (1.8), and (1.11). (We remarked this previously.) It therefore suffices to show that (1.9) and (1.12) are fulfilled in the weak sense. By definition, these equations are satisfied in the weak sense if the relation (1.17) holds. To verify (1.17) we use that, by construction, (T^κ, S^κ) solves (2.4), (2.6), and (2.7). If we multiply (2.4) by a test function $\varphi \in C_0^\infty((-\infty,T_e)\times\Omega)$ and integrate the resulting equation over Q_{T_e}, we obtain

$$\begin{aligned} 0 &= (S_t^\kappa, \varphi)_{Q_{T_e}} + \big(-(c\nu|S_x^\kappa|_\kappa + \kappa)S_{xx}^\kappa - c\big(T^\kappa\cdot\bar\varepsilon - \hat\psi'(S^\kappa)\big)|S_x^\kappa|_\kappa, \varphi\big)_{Q_T} \\ &= -(S_0^\kappa, \varphi(0))_\Omega - (S^\kappa, \varphi_t)_{Q_{T_e}} + \big(c\nu \int_0^{S_x^\kappa} |y|_\kappa dy + \kappa S_x^\kappa, \varphi_x\big)_{Q_{T_e}} \\ &\quad + \big(c\big(T^\kappa\cdot\bar\varepsilon - \hat\psi'(S^\kappa)\big)|S_x^\kappa|_\kappa, \varphi\big)_{Q_{T_e}}. \end{aligned}$$

Equation (1.17) follows from this relation if we show that

$$(S_0^\kappa, \varphi(0))_\Omega \to (S_0, \varphi(0))_\Omega, \tag{4.10}$$

$$(S^\kappa, \varphi_t)_{Q_{T_e}} \to (S, \varphi_t)_{Q_{T_e}}, \tag{4.11}$$

$$\left(\int_0^{S_x^\kappa} |y|_\kappa dy, \varphi_x\right)_{Q_{T_e}} \to \left(\frac{1}{2}|S_x|S_x, \varphi_x\right)_{Q_{T_e}}, \tag{4.12}$$

$$\left(\left(T^\kappa \cdot \bar\varepsilon - \hat\psi'(S^\kappa)\right)|S_x^\kappa|_\kappa, \varphi\right)_{Q_{T_e}} \to \left(\left(T \cdot \bar\varepsilon - \hat\psi'(S)\right)|S_x|, \varphi\right)_{Q_{T_e}}, \tag{4.13}$$

$$(\kappa S_x^\kappa, \varphi_x)_{Q_{T_e}} \to 0, \tag{4.14}$$

for $\kappa \to 0$. Now, the relation (4.10) follows from (3.3), the relation (4.11) is a consequence of (4.2), and the relation (4.14) is obtained from (4.1). To prove (4.12) we use that

$$\begin{aligned}\int_0^{S_x^\kappa} |y|_\kappa dy - \frac{1}{2}S_x|S_x| &= \left(\int_0^{S_x^\kappa} |y|_\kappa dy - \frac{1}{2}[S_x]_\kappa |S_x|_\kappa\right) + \frac{1}{2}\left([S_x]_\kappa |S_x|_\kappa - S_x|S_x|\right)\\ &=: I_1 + I_2.\end{aligned} \tag{4.15}$$

The relation (4.6) implies

$$\|I_2\|_{L^{\frac{4}{3}}(0,T_e;L^2(\Omega))} \to 0 \tag{4.16}$$

for $\kappa \to 0$. Moreover,

$$\begin{aligned}|I_1| &= \left|\int_0^{S_x^\kappa} |y|_\kappa dy - \int_0^{S_x^\kappa} |y| dy\right| = \left|\int_0^{S_x^\kappa} \left(\frac{y^2}{\sqrt{\kappa^2+y^2}} - |y|\right) dy\right|\\ &\le \int_0^{|S_x^\kappa|} \frac{|y|}{\sqrt{\kappa^2+y^2}} \left|\sqrt{\kappa^2+y^2} - |y|\right| dy \le \int_0^{|S_x^\kappa|} \kappa dy = \kappa |S_x^\kappa|,\end{aligned}$$

whence (3.6) implies

$$\|I_1\|_{L^{\frac{4}{3}}(0,T_e;L^2(\Omega))} \le C\|I_1\|_{L^2(Q_{T_e})} \le C\kappa \to 0$$

for $\kappa \to 0$. From this relation and from (4.15), (4.16) we obtain

$$\left\|\int_0^{S_x^\kappa} |y|_\kappa dy - \frac{1}{2}S_x|S_x|\right\|_{L^{\frac{4}{3}}(0,T_e;L^2(\Omega))} \to 0,$$

which implies (4.12). To verify (4.13) we note that (2.10) and (4.9) yield

$$\begin{aligned}&T^\kappa(t,x) - T(t,x)\\ &= D(\varepsilon^* - \bar\varepsilon)(\chi_\kappa * S^\kappa - S)(t,x) - \frac{D\varepsilon^*}{d-a}\int_a^d (\chi_\kappa * S^\kappa - S)(t,y)dy.\end{aligned} \tag{4.17}$$

From (2.1) and (4.2) we conclude that

$$\begin{aligned}\|\chi_\kappa * S^\kappa - S\|_{L^{\frac{4}{3}}(Q_{T_e})} &\le \|\chi_\kappa * (S^\kappa - S)\|_{L^{\frac{4}{3}}(Q_{T_e})} + \|(S - \chi_\kappa * S)\|_{L^{\frac{4}{3}}(Q_{T_e})} \\ &\le \|(S - \chi_\kappa * S)\|_{L^{\frac{4}{3}}(Q_{T_e})} + \|S^\kappa - S\|_{L^{\frac{4}{3}}(Q_{T_e})} \to 0\end{aligned}$$

for $\kappa \to 0$. Since ε^* and $\bar{\varepsilon}$ are constants, we infer from this relation and from (4.17) that

$$\|T - T^\kappa\|_{L^{\frac{4}{3}}(Q_{T_e})} \to 0$$

for $\kappa \to 0$. Thus, after selecting a subsequence we have $T^\kappa \to T$ almost everywhere in Q_{T_e}. Putting this together with (4.3) and (4.4), we see that $(T^\kappa \cdot \bar{\varepsilon} - \hat{\psi}'(S^\kappa))|S_x^\kappa|_\kappa$ tends to $(T \cdot \bar{\varepsilon} - \hat{\psi}'(S))|S_x|$ almost everywhere in Q_{T_e}. Since (3.6) and (3.5) imply that $(T^\kappa \cdot \bar{\varepsilon} - \hat{\psi}'(S^\kappa))|S_x^\kappa|_\kappa$ is uniformly bounded in $L^2(Q_{T_e})$, we deduce from Lemma 4.2 that

$$(T^\kappa \cdot \bar{\varepsilon} - \hat{\psi}'(S^\kappa))|S_x^\kappa|_\kappa \rightharpoonup (T \cdot \bar{\varepsilon} - \hat{\psi}'(S))|S_x|,$$

weakly in $L^2(Q_{T_e})$, which implies (4.13). Consequently (1.17) holds.

It remains to prove that the solution has the regularity properties stated in (1.18) and (1.19). The relation $S_t \in L^{\frac{4}{3}}(Q_{T_e})$ is implied by (4.2). To verify the second assertion in (1.18), we use estimate (3.11) to get

$$\int_0^{T_e} \|[S_x^\kappa]_\kappa\|_{L^q(\Omega)}^{\frac{8}{3}} dt \le C$$

for any $1 < q < \infty$, since Ω is bounded. Using this estimate and (4.4), we infer from Lemma 4.2 that $[S_x^\kappa]_\kappa \rightharpoonup S_x$ in $L^{\frac{8}{3}}(0, T_e; L^q(\Omega))$, whence $S_x \in L^{\frac{8}{3}}(0, T_e; L^q(\Omega))$ follows.

To prove (1.19), we recall that $[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa$ converges to $|S_x|S_x$ strongly in the space $L^{\frac{4}{3}}(0, T_e; L^2(\Omega)) \subset L^{\frac{4}{3}}(Q_{T_e})$ and that $([S_x^\kappa]_\kappa |S_x^\kappa|_\kappa)_x$ is uniformly bounded in $L^{\frac{4}{3}}(Q_{T_e})$ for $\kappa \to 0$, by (3.10). This taken together implies that $(|S_x|S_x)_x \in L^{\frac{4}{3}}(Q_{T_e})$. Finally, to prove the second assertion of (1.19) we choose a test function $\varphi \in L^4(0, T_e; W_0^{1,4}(\Omega))$, multiply (2.4) by $-\varphi_x$, and integrate the resulting equation over Q_{T_e} to obtain

$$0 = (S_t^\kappa - \mathcal{R}_\kappa, -\varphi_x)_{Q_{T_e}} = (S_{xt}^\kappa, \varphi)_{Q_{T_e}} + (\mathcal{R}_\kappa, \varphi_x)_{Q_{T_e}}, \tag{4.18}$$

with $\mathcal{R}_\kappa$ defined in (3.32). Invoking the estimates (3.6), (3.5), and (3.8), we deduce that

$$\|\mathcal{R}_\kappa\|_{L^{\frac{4}{3}}(Q_{T_e})} \le C,$$

and hence (4.18) yields

$$(S_{xt}^\kappa, \varphi)_{Q_{T_e}} \le \|\mathcal{R}_\kappa\|_{L^{\frac{4}{3}}(Q_{T_e})} \|\varphi_x\|_{L^4(Q_{T_e})} \le C\|\varphi\|_{L^4(0,T_e;W_0^{1,4}(\Omega))},$$

which means that S_{xt}^κ is uniformly bounded in $L^{\frac{4}{3}}(0, T_e; W^{-1,\frac{4}{3}}(\Omega))$. From this estimate and from $S_t^\kappa \rightharpoonup S_t$ in $L^{\frac{4}{3}}(Q_{T_e})$ we deduce easily that S_{xt} belongs to the dual space of $L^4(0, T_e; W_0^{1,4}(\Omega))$, which is $L^{\frac{4}{3}}(0, T_e; W^{-1,\frac{4}{3}}(\Omega))$. ∎

Appendix. Background of the model. We briefly sketch the physical background, the sharp interface model, and the derivation of the diffusive interface model (1.1)–(1.5) from this sharp interface model.

Material phases are characterized by the structure of the crystal lattice, in which the atoms are arranged. An interface between different material phases moves if the crystal lattice in front of the interface is transformed from one structure to the other. Often phase transformations are triggered by diffusion processes. A well-known model for diffusion dominated transformations is the Cahn–Hilliard equation. Here we consider a sharp interface model for diffusionless transformations, also called martensitic transformations; cf. [9, p. 162]. This sharp interface model is an initial-boundary value problem for the unknown functions u, T and for the unknown interface $\Gamma(t) \subseteq \Omega$ between two material phases, which is a free boundary. It consists of (1.1), (1.2); of the interface conditions

$$s(t,x)[S](t,x) = c\left(-\langle T\rangle(t,x)\cdot\bar{\varepsilon}\,[S](t,x) + [\hat{\psi}(S)](t,x)\right), \tag{A.1}$$

$$[u](t,x) = 0, \qquad [T](t,x)n(t,x) = 0, \tag{A.2}$$

which must hold for $x \in \Gamma(t)$; of a Dirichlet boundary condition for u; and of the initial condition (1.5). We use the notation $[f] = f^+ - f^-$ and $\langle f\rangle = \frac{1}{2}(f^+ + f^-)$, where f^+, f^- are the limit values of the function f on both sides of $\Gamma(t)$. Moreover, $s(t,x) \in \mathbb{R}^3$ denotes the normal speed of the interface $\Gamma(t)$, which is measured as positive in the direction for which $[S](t,x)$ is positive. Here c is a positive constant.

Equation (A.1), a constitutive equation, determines the normal speed s of the phase interface as a function of the term $-\langle T\rangle\cdot\bar{\varepsilon}[S] + [\hat{\psi}(S)]$. Some computations show that this term is equal to the expression $n\cdot[C]n$ with the Eshelby tensor C and the normal vector n to $\Gamma(t)$ (cf. [3]) and thus is a configurational force. We assume that s depends linearly on the configurational force, which is the most simple constitutive assumption. Thus, in this model the evolution of the phase interface is driven by the configurational force along the interface, an assumption appropriate for martensitic transformations.

Though configurational forces were introduced in the first half of the last century, it was clearly stated for the first time in [1] that (1.1), (1.2), (A.1), (A.2) form a closed initial-boundary value problem. Applications of this model can be found, for example, in [6, 13, 15], where equilibrium configurations for materials with phase transitions are determined, and in [10], where the evolution of phase interfaces in ferroelectric materials is modeled. In a sense, this free initial-boundary value problem from solid mechanics is comparable to the Stefan problem in fluid mechanics.

The initial-boundary value problem (1.1)–(1.5) can be considered to be a regularization of this sharp interface model, which could be used to prove existence of solutions of the sharp interface model, and it can also be considered to be a diffusive interface model for martensitic phase transitions, which is useful by itself and avoids some disadvantages of the model with sharp interfaces. We are interested in both aspects.

The derivation of (1.1)–(1.5) given in [2, 3] uses a rigorous method. To make the model plausible, we derive the model here in a different, short, but formal way. To this end we replace the phase interface $\Gamma(t)$, across which the order parameter jumps from 0 to 1, by finitely many interfaces parallel to the original interface, and consider a new order parameter, again denoted by S, with small jumps across these interfaces, such that the sum of the jumps is equal to 1. We assume that the new order

parameter satisfies (A.1) and (A.2) along all interfaces. If we increase the number of interfaces and decrease the jump height, the new order parameter will converge to a continuous or even differentiable order parameter, for which the normal speed of the level manifolds is equal to the limit of the normal speed of the interfaces. For this limit speed we obtain from (A.1)

$$s(t,x) = c \lim_{[S]\to 0} (-\langle T\rangle \cdot \bar{\varepsilon} + \hat{\psi}'(S^*)) = c(-T\cdot\bar{\varepsilon} + \hat{\psi}'(S)) = c\,\psi_S(\varepsilon(\nabla_x u), S).$$

The limit order parameter thus satisfies the Hamilton–Jacobi transport equation

$$S_t = -c\,\psi_S(\varepsilon(\nabla_x u), S)\,|\nabla_x S|, \tag{A.3}$$

since the level manifolds of solutions of this equation have this normal speed.

The idea suggests itself to approximate the solution of the sharp interface model by smooth solutions (u, T, S) of the system (1.1), (1.2), (A.3). Yet, examples in one space dimension show that in general the function S in such a smooth solution develops a jump after finite time. The reason for this is that the function $\hat{\psi}'$ appearing in ψ_S is not monotone, since $\hat{\psi}$ is a double well potential. After S has developed a jump, (A.3) can no longer be used to govern the evolution of S. To avoid this problem and to force solutions to stay smooth, (A.3) has been replaced by (1.3), which contains the regularizing term $\nu|\nabla_x S|\Delta_x S$ with the small positive parameter ν. This yields the model (1.1)–(1.5).

The choice of this special regularizing term follows from the second law of thermodynamics, which every model must satisfy. This law requires that there exist a free energy ψ^* and a flux q such that $\frac{\partial}{\partial t}\,\psi^* + \operatorname{div}_x q \le b\cdot u_t$ holds; cf. [4]. If we choose

$$\psi^*(\varepsilon, S, \nabla_x S) = \psi(\varepsilon, S) + \frac{\nu}{2}|\nabla_x S|^2, \quad q(\varepsilon, u_t, S, \nabla_x S, S_t) = -(Tu_t) - \nu\,(S_t \nabla_x S),$$

it follows by a short computation for solutions (u, T, S) of (1.1), (1.2) that

$$\frac{\partial}{\partial t}\psi^*(\varepsilon, S, \nabla_x S) - \operatorname{div}_x(Tu_t) - \nu\operatorname{div}_x(S_t\nabla_x S) - b\cdot u_t = (\psi_S(\varepsilon, S) - \nu\Delta_x S)S_t.$$

Inserting (1.3) into this equation shows that the right-hand side is nonpositive, whence the second law is fulfilled. This would not be true for the standard regularization $S_t = -c\psi_S(\varepsilon(\nabla_x u), S)\,|\nabla_x S| + \nu\Delta S$ of (A.3).

PERIODIC STATIONARY PATTERNS GOVERNED BY A CONVECTIVE CAHN–HILLIARD EQUATION*

MICHAEL A. ZAKS†, ALLA PODOLNY‡, ALEXANDER A. NEPOMNYASHCHY§, AND ALEXANDER A. GOLOVIN¶

Abstract. We investigate bifurcations of stationary periodic solutions of a convective Cahn–Hilliard equation, $u_t+Duu_x+(u-u^3+u_{xx})_{xx}=0$, describing phase separation in driven systems, and study the stability of the main family of these solutions. For the driving parameter $D<D_0=\sqrt{2}/3$, the periodic stationary solutions are unstable. For $D>D_0$, the periodic stationary solutions are stable if their wavelength belongs to a certain stability interval. It is therefore shown that in a driven phase-separating system that undergoes spinodal decomposition the coarsening can be stopped by the driving force, and formation of stable periodic structures is possible. The modes that destroy the stability at the boundaries of the stability interval are also found.

1. Introduction.

In recent decades, the spontaneous formation of spatially inhomogeneous patterns has been an object of extensive investigations. Many phenomena have been understood by using the *complex Ginzburg–Landau equation* [1] as a basic model. However, this equation is not valid when the growth or decay of a spatially homogeneous disturbance is forbidden by symmetry arguments or by a conservation law, and therefore such a disturbance is neutrally stable. The instability spectrum contains a neutrally stable mode, with the zero wavenumber corresponding to infinitesimal shift of the stationary solution [2]. In this case the situation is much more intricate, and there is a variety of different order parameter equations that describe the nonlinear evolution of long-wave disturbances, depending on the symmetry of the problem [3].

In the case of a monotonic instability, the nonlinear evolution of long-wave disturbances is typically described by the *Kuramoto–Sivashinsky* (KS) *equation*

$$u_t + u_{xxxx} + u_{xx} - \kappa_1 (u^2)_x = 0, \tag{1.1}$$

where $u(x,t)$ is the order parameter and κ_1 is a constant. This equation has been derived in a large number of physical contexts; e.g., it describes the instability of oscillations in reaction-diffusion systems [4], the instability of a flame front [5], film flow instability [6, 7], and instability of solidification fronts [8, 9, 10]. Though for

the KS equation there exists an interval of locally stable spatially periodic stationary solutions [7, 11, 12], the most remarkable type of dynamics is spatio-temporal chaos [13, 14].

If the problem is invariant with respect to the reflection $x \to -x$, as well as to the transformation $u \to -u$, the appropriate order parameter equation is the *Cahn–Hilliard* (CH) *equation*,

$$u_t + u_{xxxx} + u_{xx} - \kappa_2 (u^3)_{xx} = 0. \tag{1.2}$$

This equation, originally proposed as a model of the phase-transition kinetics with a conserved order parameter [15], arises in many physical problems, including faceting transition by a temperature change [16, 17], secondary flows produced by the instability of the Kolmogorov flow [18], and zigzag instability of convection patterns [19]. Unlike the KS equation, the CH equation is potential; i.e., it has a Lyapunov functional that monotonically decreases with time. The characteristic feature of the dynamics governed by the CH equation is the formation of kinks, i.e., domain walls between domains with nearly constant values of the order parameter. Stationary solutions of the CH equation, which can be represented as equidistant sequences of kinks, are unstable with respect to disturbances that change the distances between kinks [20, 18] and lead to an exponentially slow *coarsening* of the structure [21, 22].

Recently, a nonpotential modification of the CH equation, the *convective* (or *driven*) *Cahn–Hilliard* (CCH) *equation*,

$$u_t + u_{xxxx} + u_{xx} - \kappa_1 (u^2)_x - \kappa_2 (u^3)_{xx} = 0, \tag{1.3}$$

has been attracting a great deal of attention. This equation, containing nonlinearities typical of both KS and CH equations, has been proposed to describe several physical processes, namely spinodal decomposition of phase separating systems in an external field [23, 24, 25], step instability on a crystal surface [26], faceting of growing thermodynamically unstable surfaces [27, 28, 29, 30, 31], as well as dewetting of a thin film flowing down an inclined plane [32]. A coordinate-invariant form of this equation has been derived in [33, 34]. Depending on the value of the parameter $D = 2\kappa_1/\kappa_2^{1/2}$ that characterizes the relative "strength" of the two nonlinearities, one can observe the coarsening of kinks (for small D) [25, 28, 29, 31], spatio-temporal chaos (for large D) [26, 30], as well as other dynamic regimes [26, 30]. A characteristic feature of the dynamics governed by the CCH equation at intermediate values of D is the appearance of wavy regimes with a simple *temporal* behavior (stationary and traveling waves) but with a complicated *spatial* structure [30].

The present paper is devoted to the investigation of stationary patterns governed by the CCH equation. The bifurcations of stationary solutions are discussed in section 2. The stability analysis is performed in section 3.

2. Stationary solutions.

2.1. Formulation of the problem. Let us rescale the variable u, $u(x) = U(x)/(\kappa_2)^{1/2}$, and define $D = 2\kappa_1/\kappa_2^{1/2}$. The CCH equation (1.3) is transformed into the form

$$U_t + (U_{xx} + U - U^3)_{xx} - \frac{D}{2}(U^2)_x = 0. \tag{2.1}$$

In the present paper we consider stationary solutions $U = U(x)$ of (2.1) in the infinite region $-\infty < x < \infty$. Only solutions bounded at infinity are relevant. Integrating the corresponding ordinary differential equation ((2.1) with $U_t = 0$), one

obtains the following problem:

$$U_{xxx} + (U - U^3)_x - \frac{D}{2}U^2 = -\frac{D}{2}A, \qquad -\infty < x < \infty, \tag{2.2}$$

$$x \to \pm\infty, \qquad |U| < \infty. \tag{2.3}$$

Recall that for $D = 0$, which corresponds to the CH equation, all stationary solutions of (2.2) can be found analytically [35]. In the opposite limit, $D \to \infty$ (the KS equation), the set of stationary solutions is much more complicated than in the case of the CH equation. Bifurcations of periodic stationary and traveling-wave solutions of the KS equation were studied in [36, 37]. Later, without loss of generality, we assume $D > 0$.

It is convenient to investigate the bifurcations of stationary states of (2.1) in terms of the dynamical system defined by (2.2) with parameters D and A. Notably, this dynamical system is measure-preserving. It is also reversible, i.e., invariant with respect to inversion, $x \to -x$, $U \to -U$, as well as invariant with respect to translation $x \to x + C$. Accordingly, all stationary solutions are either invariant with respect to these transformations, or (up to an arbitrary shift along x) exist in pairs: if $U(x+C)$ is a family of solutions, then $-U(C - x)$ is also a family of solutions. Both families may coincide.

2.2. Constant and heteroclinic solutions. For $A = 0$ the only bounded solution of the problem (2.2), (2.3) is the trivial equilibrium solution $U = 0$. The linearized problem possesses three eigenvalues on the imaginary axis: $\lambda_1 = 0$ and $\lambda_{2,3} = \pm i$; accordingly, the equilibrium state is structurally unstable. Increasing A removes the degeneracy: the equilibrium splits into two constant solutions, $U = U^{\pm} = \pm\sqrt{A}$; besides, the imaginary eigenvalues are responsible for the creation of the periodic (with respect to x) orbit with period $\approx 2\pi$ whose amplitude locally grows as $\sim \sqrt{A}$ (for small A); below, this orbit will be referred to as the "main family."

In fact, the equilibria and the closed orbit are merely the simplest solutions born in the course of unfolding the degeneracy: formation of the complicated invariant set was investigated for the KS equation, where it was called the "cocoon bifurcation" [38]. For our purposes, however, these simple stationary states suffice.

Let us start the analysis of the problem (2.2), (2.3) with the consideration of the equilibrium points $U = U^{\pm} = \pm\sqrt{A}$. Consider perturbations of the constant solution, $U = U^{\pm} + \tilde{U}(x)$, $\tilde{U}(x) \sim e^{\lambda x}$, and linearize (2.2) to obtain the following equation for the eigenvalues:

$$\lambda^3 + (1 - 3A)\lambda \mp D\sqrt{A} = 0. \tag{2.4}$$

All eigenvalues are real if

$$D^2 \le D_*^2 = \frac{4(3A-1)^3}{27A}, \qquad A > \frac{1}{3}. \tag{2.5}$$

Otherwise, two eigenvalues are complex conjugate, and the third one is real. For the equilibrium point $U = U^+ = \sqrt{A}$, one of the eigenvalues is positive and the other two eigenvalues are either negative or have negative real parts. The unstable manifold $W^u(U^+)$ is one-dimensional, while the stable manifold $W^s(U^+)$ is two-dimensional. For the symmetric counterpart of U^+, the solution $U^- = -\sqrt{A}$, the eigenvalues have

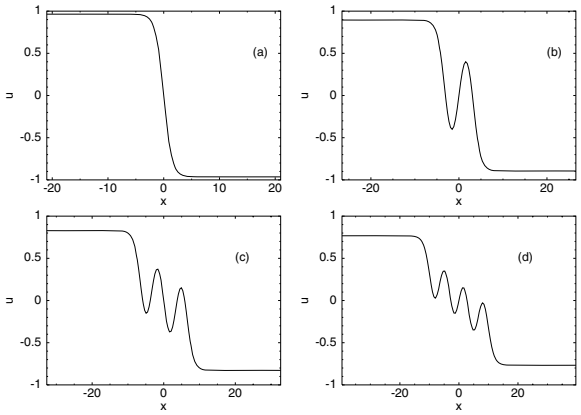

FIG. 1. *Different negative kinks at* $D = 0.1$: (a) $A = 0.929289$ *(solution* (2.7)*),* (b) $A = 0.799874$, (c) $A = 0.685489$, (d) $A = 0.588339$.

opposite signs; hence its stable manifold $W^s(U^-)$ is one-dimensional, and its unstable manifold $W^u(U^-)$ is two-dimensional.

Heteroclinic solutions ("kinks") joining the equilibrium points $U = U^+$ and $U = U^-$ correspond to trajectories on $M_+ = W^u(U^-) \cap W^s(U^+)$ ("positive kinks") and $M_- = W^u(U^+) \cap W^s(U^-)$ ("negative kinks"). As a matter of fact, there are *exact* solutions of this kind [23], one for a positive kink with $A = A_+ = 1 + D/\sqrt{2}$,

$$U = U_+(x) = U_+^0 \tanh \frac{U_+^0}{\sqrt{2}}(x - x_0), \tag{2.6}$$
$$U_+^0 = \sqrt{1 + D/\sqrt{2}}, \quad x_0 = const,$$

and the other for a negative kink with $A = A_- = 1 - D/\sqrt{2}$, $D < \sqrt{2}$,

$$U = U_-(x) = -U_-^0 \tanh \frac{U_-^0}{\sqrt{2}}(x - x_0), \tag{2.7}$$
$$U_-^0 = \sqrt{1 - D/\sqrt{2}}, \quad x_0 = const.$$

Since the manifolds $W^s(U^+)$ and $W^u(U^-)$ are two-dimensional for any $A > 0$, their intersection in the three-dimensional phase space is generic, and therefore the solution (2.6) is a representative of a *family* of positive kinks $U_+(x; A)$. A negative kink requires matching of two one-dimensional manifolds in the three-dimensional space, which is not generic, but a codimension-2 event. The symmetry reduces the codimension of this event to 1. Accordingly, we can expect that, for a given D, negative kinks exist only for isolated values of A. Solution (2.7) appears to have the largest value of A and the simplest spatial profile among the possible negative kinks. Several examples of negative kinks are shown in Figure 1.

Among the presented negative kinks only the solution (2.7) is monotonic; the others have additional humps. At very small values of D these humps almost reach the value U_+^0; as D grows, the humps become smaller, and for $D > 0.3$ the profiles of all negative kinks become practically monotonic. As seen in Figure 2, on the parameter plane of D and A the lines of existence of negative kinks issue from the singular point $D = 0$, $A = 1$. With growth of D the corresponding values of A rapidly decrease; in the

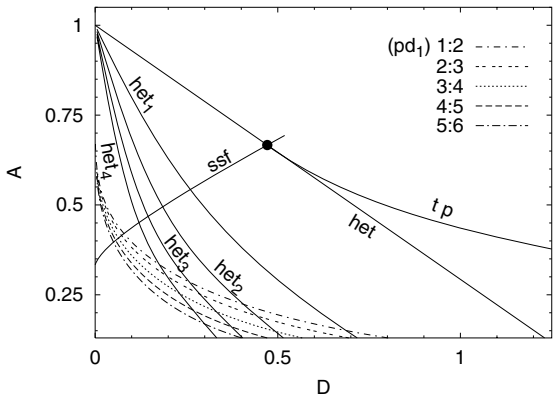

FIG. 2. *Parameter plane for small values of D. $het, het_1, \ldots, het_4$: curves of existence of heteroclinic contours; ssf: equilibria turn from saddle-foci into saddles; tp: ultimate saddle-center bifurcation of the main family; p:q-marked dash-dotted lines: branching of period-q-upled orbits from the main periodic solution, multipliers of the latter being* $\exp(2\pi ip/q)$*; filled circle: point* $(D_0, A = 1 - D_0/\sqrt{2})$.

domain of small A, where the equilibrium solutions approach each other (recall that $A = 0$ corresponds to the saddle-center bifurcation), these lines become involved in the intricate pattern of the "cocoon bifurcation" [38]. Bifurcation curves for periodic solutions were obtained with the help of the original code, which combines the Newton algorithm on a suitable Poincaré surface with polynomial continuation in the extended parameter space.

In the phase space, a negative kink provides a connection from $U = U^+ = U^0_-$ to $U = U^- = -U^0_-$; since the positive kink is generic, the "backward" link is always there, and hence the presence of the negative kink implies the existence of a heteroclinic contour that connects the points U^+ and U^-. Accordingly, in the parameter plane each point that represents a negative kink also corresponds to a heteroclinic contour.

The scenario of the breakup of a heteroclinic contour depends on the eigenvalues of participating points of the equilibrium. The lines of existence of all contours start in the domain where the inequality (2.5) holds, all eigenvalues are real, and the equilibria are saddle points. With the increase of D these lines cross the boundary (curve ssf in Figure 2) on which saddles turn into saddle-foci.

The heteroclinic contour that includes the solution (2.7) (located on the line het in Figure 2) plays the principal role in the evolution of stationary patterns. For this contour the eigenvalues of the points $U^\pm = \pm\sqrt{A}$ are

$$\lambda_1 = \frac{\mp\left(\sqrt{1 - D/\sqrt{2}} + \sqrt{1 - 3D/\sqrt{2}}\right)}{\sqrt{2}},$$

$$\lambda_2 = \frac{\mp\left(\sqrt{1 - D/\sqrt{2}} - \sqrt{1 - 3D/\sqrt{2}}\right)}{\sqrt{2}},$$

$$\lambda_3 = \pm\sqrt{1 - D/\sqrt{2}} \cdot \sqrt{2}.$$

These eigenvalues are real if $D \le D_0 = \sqrt{2}/3 \approx 0.47$; otherwise two of them are complex conjugate and the third one is real.

2.3. Bifurcations of periodic solutions. Let us now consider solutions of (2.2) satisfying the periodicity condition

$$U(x+l) = U(x), \quad l > 0. \tag{2.8}$$

Obviously, for this class of solutions

$$A = \langle U^2 \rangle = \frac{1}{l}\int_0^l U^2(x)dx. \tag{2.9}$$

Since the dynamical system (2.2) is volume-preserving, the product of Floquet multipliers (eigenvalues of the monodromy matrix) for every periodic solution equals 1. Accordingly, such solutions have either two complex-conjugate multipliers on the unit circle (periodic orbit of *elliptic* type) or two real eigenvalues, one of them outside of the unit circle (periodic orbit of *hyperbolic* type). For an elliptic orbit, variation of parameters lets multipliers $\mu_{1,2} = \exp(\pm 2\pi i\phi)$ wander along the circle; passage of ϕ through each rational number p/q is accompanied by the "period q-tupling": branching of a periodic solution whose period is q times larger than the period of the original orbit. The details of the branching depend on q [39, 40]. For $q = 2$ and $q \ge 5$ the bifurcation is "one-sided": in the parameter space the newborn periodic solutions exist on only one side of the branching point. For $q = 3$ and $q = 4$, on the contrary, the bifurcation is "two-sided" (transcritical): new branches exist on both sides of the critical parameter value. On one of these branches the periodic solutions are of elliptic type (and, therefore, give rise to secondary sequences of similar bifurcations); the other branch corresponds to solutions of hyperbolic type.

One can see that, due to the symmetry properties of the equation, if $U(x)$ is a periodic solution of (2.2) with a certain value of A and

$$\langle U \rangle = \frac{1}{l}\int_0^l U(x)dx = C,$$

then $\tilde{U}(x) = -U(2x_0 - x)$, $x_0 = const$, is also a solution of (2.2) for the same value of A; obviously, $\langle \tilde{U} \rangle = -C$. The solutions $U(x)$ and $\tilde{U}(x)$ can coincide. In this case the solution $U(x)$ is odd (antisymmetric to reflections) with respect to the point $x = x_0$, and $C = 0$.

In the present paper, we focus on the "main" family of odd stationary periodic solutions: the family which bifurcates from the trivial solution $U(x) = 0$ with the increase of A from zero. In the case of the CH equation, $D = 0$, this family exhausts the set of odd stationary solutions that can be calculated analytically (using elliptic Jacobi functions). The wavelength l grows monotonically with A. In the limit $A \to 1$, the wavelength tends to infinity, and the periodic solution is transformed into heteroclinic (kink) solutions $U(x) = \pm\tanh((x - x_0)/\sqrt{2})$.

For $D \ne 0$, the main family with finite values of A was calculated numerically. For small values of A the periodic orbit is elliptic; with the increase of A it undergoes a countable set of bifurcations that create new periodic orbits (see [39, 40]). Several curves corresponding to such bifurcations are shown by dashed and dash-dotted lines in Figure 2. The last of those bifurcations is the period-doubling, which occurs on the line pd_1 where the main solution has two multipliers equal to –1; immediately beyond this line the solution is hyperbolic.

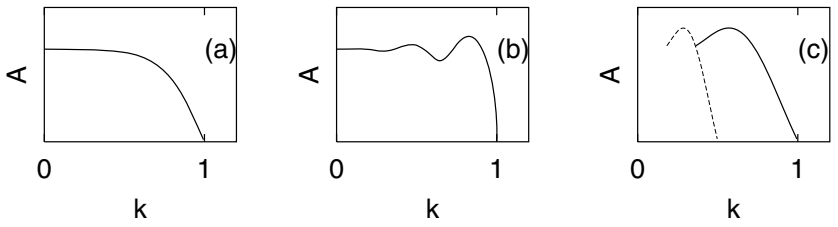

FIG. 3. *Sketch of the dependence $A = \langle U^2 \rangle$ on the wavenumber K of the main stationary solution.* (a) $D < D_0 = 0.4714\ldots$, (b) $D_0 < D < D_1 = 0.8254\ldots$, (c) $D > D_1$; *the dashed curve corresponds to the stationary solution with doubled period. The main family terminates in the "noose bifurcation."*

Depending on D, one can distinguish three different types of interrelation between A and the wavelength of the periodic solution (Figure 3).

In the region $0 < D < D_0 = \sqrt{2}/3$, the main family exists for $0 < A < A_- = 1 - D/\sqrt{2}$, i.e., just for all A below the value corresponding to the principal heteroclinic contour discussed above (see Figure 2, line *het*). The dependence of the wavelength l on the parameter A (or the dependence of A on the wavenumber $K = 2\pi/l$) is monotonic, and the wavelength tends to infinity as A approaches A_-.

In the region $D_0 < D < D_1 \approx 0.8254$, the solutions which belong to the main family exist for any $l > 2\pi$, but the dependence of A on l becomes nonmonotonic, and thus the inverse dependence of l on A is not univalued (see Figure 3(b)). There exists a countable set of values of l for which the function $A(l)$ has maxima and minima. At the extrema of $A(l)$ that can be called *turning points*, a pair of periodic solutions appears/disappears through a saddle-center bifurcation. Note that in the turning point both multipliers of the periodic orbit equal 1; accordingly, each turning point is a joint of two segments: one hyperbolic and the other elliptic. On the elliptic segment a new set of q-tupling bifurcations takes place. The absolute maximum of $A(l)$ is, in a sense, the "ultimate" saddle-center bifurcation: numerical evidence suggests that beyond this value of A no periodic solutions of (2.2) exist. In the bifurcation diagram of (2.2), displayed in Figure 2, the last saddle-center bifurcation is shown by the line *tp*, which (as well as the countable set of lines of other saddle-center bifurcations) starts in the point $D = D_0$, $A = 1 - D_0/\sqrt{2} = 2/3$, and proceeds to higher values of D.

In the case $D > D_1$, the configuration of the main branch of periodic solutions changes again (see Figure 3(c)): there remains only one turning point. Plotting, instead of $l(A)$, the dependence of a suitable geometrical characteristic of the orbit (we use for this purpose the value of du/dx at $u = 0$) on A, we observe in Figure 4 that the curve of the main family goes back and closes onto itself, forming a kind of a noose. This phenomenon was described in the context of the KS equation [36, 37, 41], where, for obvious reasons, it was named the *noose bifurcation*. The noose closes in the point of the period-doubling bifurcation (line pd_1 in bifurcation diagram of Figure 2). More precisely, the stationary periodic solution, antisymmetric with respect to the point $x = x_0$, can be expanded into a Fourier series

$$U(x; A) = \sum_{n=1}^{\infty} a_n(A) \sin \frac{2\pi n}{l}(x - x_0). \tag{2.10}$$

On the upper branch of the noose, when A decreases and approaches the bifurcation

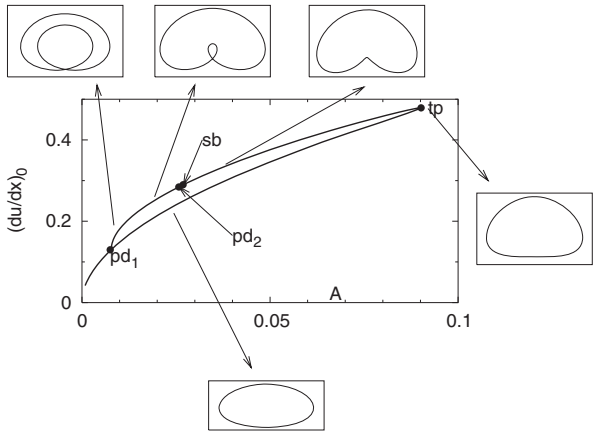

FIG. 4. *Transformations of the phase portrait along the noose branch; $D = 5$. Bifurcation points: $pd_{1,2}$ = period-doubling bifurcations, tp = turning point (saddle-center), sb = symmetry-breaking (pitchfork).*

value A_{pd_1}, all coefficients with odd values of n tend to zero. Thereby, the solution with the period l from the upper branch tends to the solution with the period $2l$ from the lower branch. Subplots of Figure 4 show different stages of continuous transformation of the phase portrait from the closed curve with two loops into the curve with one loop. An additional loop of the orbit, created by the period-doubling bifurcation, decreases in size during the motion along the upper branch of the noose and finally disappears in the small cusp.

Note that the period-doubling bifurcation pd_1 exists for all nonzero values of D, but at $D < D_1$ the orbit with the doubled period which branches off at pd_1 does not return to the main family. At $D = D_1$ a reconnection of branches by means of transcritical bifurcation takes place. Let us have a closer look at the details of this transition, since it is typical for the changes which transform the relatively simple set of stationary periodic solutions of the CH equation into the rich and diversified set of such solutions of the KS equation.

Along with the main family, we track several families of relatively simple secondary orbits which branch off the main family in the course of, respectively, period-doubling, period-tripling, and period-quadrupling. It is known that for reversible systems the period-tripling is a transcritical bifurcation: the 3-looped periodic orbit exists on both sides of the parameter value at which the multipliers of the main (1-looped) orbit equal $\exp(\pm 4\pi i/3)$.

For very small values of D the behavior of periodic states with the increase of A is reminiscent of the behavior typical of pure CH equations: their wavelength is a monotonically growing function of A, and solutions which bifurcate from the main family end up in respective heteroclinic contours. Due to pronounced additional humps of negative kinks, a contour formed by an m-humped negative kink and its positive counterpart is a closed curve with $m + 1$ loops. Accordingly, the periodic solution born via the period-doubling bifurcation on the line pd_1 of the parameter plane terminates on the line het_1, the solution born on the line $2 : 3$ ends up on the line het_2, etc. As D grows, the curves of existence of contours cross the line ssf (Figure 2), the saddle points in the contour are replaced by saddle-foci, and the periodic orbits approach such contours in a nonmonotonic way, developing turning

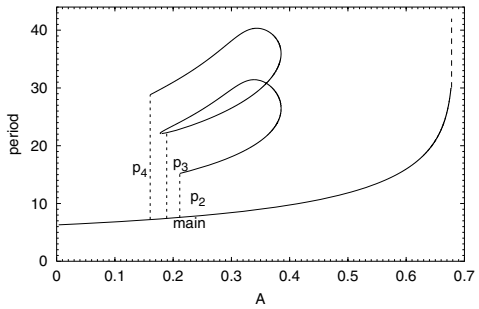

FIG. 5. *Dependence of period on A for periodic states at $D = 0.45$. Dashed lines are bifurcations of the main family: p_2 = period-doubling, p_3 = period-tripling, p_4 = period-quadrupling.*

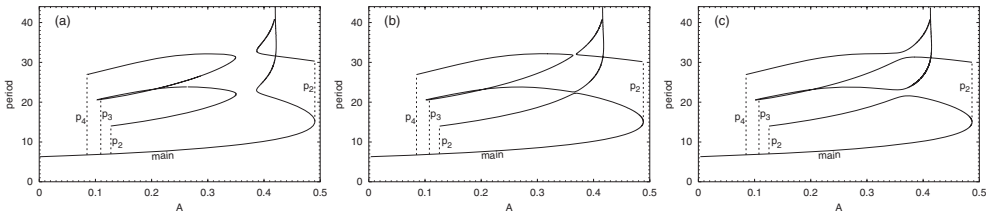

FIG. 6. *Recombinations of curves of periodic solutions. Notation as in Figure* 5. (a) $D = 0.82$, (b) $D = 0.8256$, (c) $D = 0.84$.

points and segments of ellipticity. As D is further increased, the families of periodic orbits detach from heteroclinic contours, and the respective curves on the "period-A" diagram recombine. The configuration of those curves, typical for values of D slightly below D_0, is presented in Figure 5.

It can be seen that the branch which is born from the main solution in the period-doubling bifurcation joins (by means of the turning point) one of the branches of the period-tripled family, whereas the second "tripled" branch matches with the period-quadrupled branch. Thereby, the doubled, tripled, and quadrupled orbits form, in fact, one family, in which the shape of the orbit continuously changes, acquiring and losing loops in the phase space. A similar effect for solutions of the KS equation was described in [42].

As discussed above, the turning point appears on the curve of the main family as soon as D exceeds the value D_0. The corresponding interval of ellipticity is bounded by the point in which both multipliers equal –1. This adds a new element to the picture shown in Figure 5: an additional period-doubling bifurcation of the main family which occurs only for $D > D_0$. In the parameter plane the corresponding bifurcation curve pd_3 is located slightly below the curve tp. (In Figure 2 they practically coincide graphically, and therefore pd_3 is not shown.) Like the main family, the newborn 2-looped solution has a (twice encircled) principal heteroclinic contour as an asymptote: as A is varied, its wavelength grows unboundedly.

This configuration of periodic curves exists until D reaches the value D_1; it is easily recognizable in Figure 6(a). When D is increased, the rightmost turning point of the main family approaches the turning point that joins the period-doubled and the period-tripled family. At $D = D_1 = 0.8254\ldots$ these turning points coalesce, and

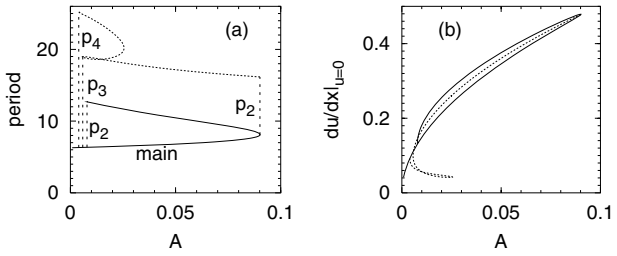

FIG. 7. *Periodic solutions at $D = 5$. Notation as in Figure 5. Solid line: main family; dotted line: secondary solutions.* (a) *Dependence of period on A;* (b) *geometric characteristics of orbit as a function of A.*

a transcritical bifurcation takes place. The segments of the curves recombine: for $D > D_1$ the main family joins the period-doubled branch (thereby forming a noose), whereas the period-tripled branch acquires the asymptotics of long periods and ends up in the principal heteroclinic contour.

Solution curves for $D = 0.8256$ (i.e., just above D_1) are shown in Figure 6(b). Besides the noose formed by the main family, one can notice that the system is close to the next transcritical bifurcation: the turning point which joins the second period-tripled and period-quadrupled branches gets close to the turning point on the curve of the period-doubled solution born at pd_3. This transcritical bifurcation takes place at $D = 0.8257\ldots$; results of recombination of solution curves are seen in Figure 6(c): now the period-tripled branch ends at the period-doubling bifurcation, whereas the period-quadrupled solution terminates in the heteroclinic contour.

In Figure 6(c) there are still two branches of periodic solutions connected to the principal heteroclinic contour. Since for $D > \sqrt{2}$ the contour is absent, those branches detach from it in the course of increase of D and interconnect. As a result, for moderate and high values of D one observers the picture typical of the KS equation [42] (Figure 7(a)). In terms of geometric characteristics of the orbit, the discussed families of secondary solutions merge into a single curve which has two turning points. It starts at the period-quadrupling bifurcation of the main family and terminates in the period-doubling bifurcation close to the turning point of the main family (Figure 7(b)).

Let us mention two more bifurcations of the main periodic solution, which occur in the range of moderate and large values of D and produce new families of stationary periodic solutions different from the main family. The *symmetry-breaking* bifurcation *sb* (see Figure 8) is a pitchfork bifurcation which generates two families of stationary periodic solutions $U_{up}(x)$, $U_{down}(x) = -U_{up}(2x_0 - x)$ with *nonzero* mean values $\langle U_{up}\rangle = -\langle U_{down}\rangle \neq 0$. These two types of solutions are shown in Figure 9(a),(b).

In this bifurcation point the periodic orbit has two multipliers equal to 1. The symmetry-breaking bifurcation, which happens only in presence of the noose, i.e., for $D > D_1$, is a consequence of the symmetry caused by reversibility of the dynamical system (2.2); for families of solutions which do not share the left-right symmetry (e.g., for traveling waves) such bifurcation is precluded. In the course of further evolution the wavelength of the solutions $U_{up}(x)$, $U_{down}(x)$ tends to infinity, and they terminate in the homoclinic orbits of equilibrium points $\pm\sqrt{A_h}$, respectively, where A_h corresponds to the line hom_1 in Figure 8. The other important bifurcation is also a period-doubling bifurcation (line pd_2 in Figure 8) that produces a new family of odd stationary periodic solutions with a zero mean value, which looks like a sequence of

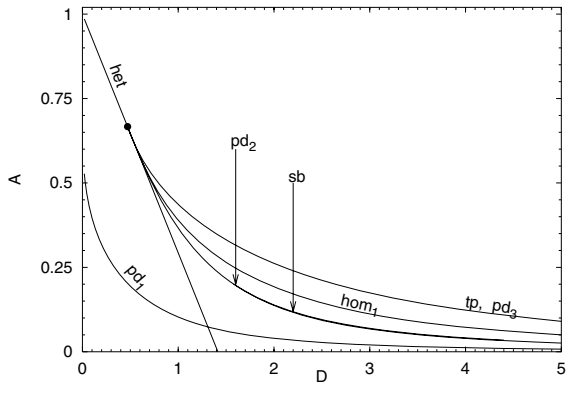

FIG. 8. *Basic bifurcation curves of the main family and its offspring. het: existence of the principal heteroclinic contour; tp: ultimate saddle-center bifurcation of the main family; pd_1, pd_2, pd_3: period-doubling bifurcations of the main family; sb: symmetry-breaking bifurcation (creation of "ups" and "downs"); hom_1: formation of homoclinic orbits to saddle-focus equilibria; filled circle: point* $(D_0,\, A = 1 - D_0/\sqrt{2})$.

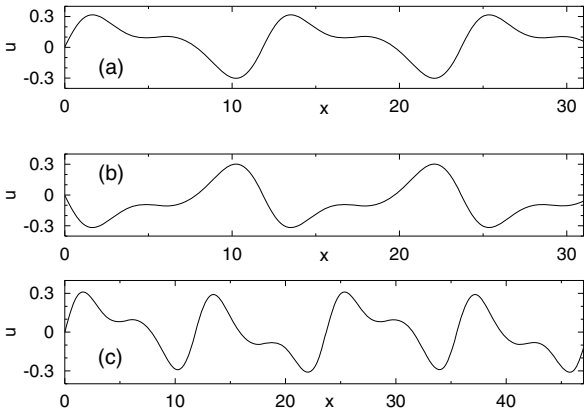

FIG. 9. *Solutions of* (2.2) *for* $D = 5$: (a) *the "up" solution,* (b) *the "down" solution,* (c) *the superposition of "up" and "down."*

alternating "up"- and "down"-elements as shown in Figure 9(c). The corresponding bifurcation value of A for the pd_2-bifurcation is slightly lower than that for the *sb*-bifurcation.

As seen in Figure 8, in the parameter plane the point $(D_0,\, A_0 = 1 - D_0/\sqrt{2})$ serves as a kind of an organizing center, origin of several bifurcation curves (in fact, there is also a countable set of curves of secondary homoclinics to a saddle-focus U^+, which starts from this point).

3. Stability of stationary periodic solutions. In this section we investigate the linear stability of the above-mentioned *main family* of spatially periodic stationary solutions of the convective CH equation (2.1) with respect to arbitrary infinitesimal perturbations in the infinite region. Stability of other families of stationary solutions of (2.1) is beyond the scope of the present paper.

3.1. Eigenvalue problem. Let $U(x)$ be a stationary periodic solution satisfying (2.1) with periodic boundary conditions $U(x) = U(x + l)$. Recall that for the main family of periodic solutions

$$\int_0^l U(x)dx = 0,$$

because $U(x)$ is odd.

Add a small perturbation $\widetilde{u}$ to the stationary solution, and linearize (2.1) to obtain the following problem for $\widetilde{u}$:

$$\widetilde{u}_t = -\widetilde{u}_{xx} - \widetilde{u}_{xxxx} + D(U\widetilde{u})_x + 3(U^2\widetilde{u})_{xx}, \tag{3.1}$$

$$|\widetilde{u}| < \infty \quad \text{for } |x| \to \infty.$$

Following the standard approach of the linear stability theory, consider normal-mode solutions of (3.1),

$$\widetilde{u}(x,t) = e^{t\sigma}V(x;\sigma). \tag{3.2}$$

Substitute (3.2) into (3.1) to obtain the equation

$$V(x)\sigma = -V_{xx} - V_{xxxx} + D(UV)_x + 3(U^2V)_{xx}. \tag{3.3}$$

Generally, (3.3) has four linearly independent solutions for any value of x, $V_j(x)$, $j = 1, 2, 3, 4$. Because of the periodicity of $u(x)$, the functions $V_j(x)$ and $V_j(x + L)$ are simultaneously the solutions of (3.3). Therefore,

$$V_j(x + L) = \sum_{k=1}^{4} B_{jk}(\sigma)V_k(x), \tag{3.4}$$

where $\hat{B}(\sigma) = \{B_{jk}(\sigma)\}$ is the monodromy matrix. We are interested only in bounded solutions of (3.3),

$$V(x) = \sum_{k=1}^{4} C_jV_j(x), \qquad |V(x)| < \infty \quad \text{for } x \to \pm\infty, \tag{3.5}$$

which correspond to the eigenvectors of the monodromy matrix,

$$\sum_{k=1}^{4} B_{jk}(\sigma)C_k = B(\sigma)C_j, \tag{3.6}$$

with the eigenvalues satisfying the additional condition,

$$|B(\sigma)| = 1. \tag{3.7}$$

Hence, one can represent the eigenfunctions $V(x)$ in the form

$$V(x) = v(x)e^{iqx}, \tag{3.8}$$

where $v(x)$ is a periodic function, $v(x+L) = v(x)$, and $q = \arg(B(\sigma))/L$ is a real number ("quasi wavenumber"). The function $V(x)$ is called the Floquet–Bloch function [43, 44].

The quasi wavenumber q can be taken from the interval

$$-\frac{\pi}{l} \le q \le \frac{\pi}{l} \tag{3.9}$$

(i.e., inside the "Brillouin zone" [45]). Substituting (3.8) into (3.3), one obtains the following eigenvalue problem:

$$\begin{aligned} \sigma(q)v(x) &= \mathcal{D}_q^2[(3U^2(x)-1)v(x)] - \mathcal{D}_q^4 v(x) + D\mathcal{D}_q[U(x)v(x)], \\ v(x+l) &= v(x), \end{aligned} \tag{3.10}$$

where $\mathcal{D}_q = d/dx + iq$. If there exists an eigenvalue $\sigma(q)$ with $\mathrm{Re}\sigma(q) > 0$, the solution $U(x)$ is unstable.

3.2. Long-wave asymptotics. For $q = 0$, (3.10) always has a solution $v(x) = U_x(x)$ corresponding to $\sigma(0) = 0$. Indeed, differentiate (2.2) twice with respect to x, to find

$$-v_{xxxx} - v_{xx} + D(Uv)_x + 3(U^2 v)_{xx} = 0. \tag{3.11}$$

The disturbance $v(x) = U_x(x)$ corresponds to an infinitesimal homogeneous translation of the stationary solution $U(x)$. One can expect that $\mathrm{Re}\sigma(q)$ can become positive at small q. In the present subsection we investigate the eigenvalue problem for long-wave disturbances, which correspond to nonhomogeneous translations applied to the stationary solution.

First, let us introduce the variable $X = Kx$, where $K = 2\pi/l$ is the wavenumber of the stationary regime, and rewrite the problem for the main-family stationary solutions as

$$\begin{aligned} -K^4 U'''' - K^2 U'' + DKUU' + K^2 (U^3)'' &= 0, \\ U(X+2\pi) &= U(X), \end{aligned} \tag{3.12}$$

where a prime means differentiation with respect to X. Note that

$$\int_0^{2\pi} U(X)dX = 0. \tag{3.13}$$

Later on, we shift the origin $X = 0$ in such a way that the stationary solution is an odd function of X, and therefore its Fourier series is

$$U = \sum_{n=1}^{N} a_n(K) \sin nX. \tag{3.14}$$

Equation (3.10) can be written as

$$\begin{aligned} \sigma(Q)v(X) &= K^2\mathcal{D}_Q^2[(3U^2(X)-1)v(X)] - K^4\mathcal{D}_Q^4 v(X) + DK\mathcal{D}_Q[U(X)v(X)], \\ v(X+2\pi) &= v(X), \end{aligned} \tag{3.15}$$

where $\mathcal{D}_Q = d/dX + iQ$, $Q \equiv q/K$. According to (3.9), one can choose $|Q| \le 1/2$.

Let Q be small. We are looking for a solution in the form

$$v = \sum_{n=0}^{\infty} v_n Q^n, \qquad \sigma = \sum_{n=0}^{\infty} \sigma^{(n)} Q^n, \tag{3.16}$$

where v_n are periodic functions of X with period 2π. Substituting (3.16) into (3.15), one obtains the sequence of problems in successive orders of Q.

In the zeroth order of Q one has

$$-K^4 v_0'''' + K^2[(3U^2-1)v_0]'' + DK(Uv_0)' - \sigma^{(0)} v_0 = 0, \tag{3.17}$$

$$v_0(X+2\pi) = v_0(X),$$

where prime denotes differentiation with respect to X. As shown above, the solution $v_0 = U'$, $\sigma^{(0)} = 0$ always exists. Later on, we assume that there are no other 2π-periodic solutions with $\sigma^{(0)} = 0$ for the chosen values of K and D. This assumption fails for the values of parameters corresponding to the symmetry-breaking bifurcation (line *sb* in Figure 8).

For every integer $i > 0$, the equation for v_i has the form

$$-k^4 v_i'''' + k^2[(3U^2-1)v_i]'' + Dk(Uv_i)' = R_i, \qquad v_i(X+2\pi) = v_i(X), \tag{3.18}$$

where R_i is some linear combination of the functions $v_j(X)$, $0 \le j < i$, and their derivatives. One can show that the left-hand side of (3.18) is a derivative of a periodic function. Therefore, the integral of the right-hand-side, R_i, over X from 0 to 2π must be zero.

In the first order of Q one obtains

$$\begin{aligned} &-K^4 v_1'''' + K^2[(3U^2-1)v_1]'' + DK(Uv_1)' \\ &= \sigma^{(1)} v_0 - iDUv_0 - 2iK^2[(3U^2-1)v_0]' + 4iK^4 v_0''', \end{aligned} \tag{3.19}$$

$$v_1(X+2\pi) = v_1(X).$$

In order to find the solution of (3.19), let us differentiate (3.12) with respect to the parameter K:

$$\begin{aligned} &-K^4[\partial_K U]'''' + K^2[(3U^2-1)\partial_K U]'' + DK[U\partial_K U]' \\ &\quad - 4K^3 U'''' - 2KU'' + DUU' + 6K[U^2U']' = 0. \end{aligned} \tag{3.20}$$

Comparing (3.19) with (3.20), one finds

$$v_1 = iK\partial_K U - \sigma^{(1)} f_1(X) + const\ U', \tag{3.21}$$

where $f_1(X)$ is the solution of the equation

$$-K^4 f_1'''' - K^2 f_1'' + DK(Uf_1)' + 3K^2(U^2 f_1)'' = U',$$

$$f_1(X+2\pi) = f_1(X).$$

Note that $f_1(X)$ is an even function.

In the second order of Q,

$$\begin{aligned} &-K^2 v_2'' - K^4 v_2'''' + DK(Uv_2)' + 3K^2(U^2 v_2)'' \\ &= (\sigma^{(1)} - iDKU)v_1 + 4iK^4 v_1''' + 2iK^2[(1-3U^2)v_1]' \\ &\quad + \sigma^{(2)} v_0 - 6K^4 v_0'' + K^2(3U^2-1)v_0, \end{aligned} \tag{3.22}$$

$$v_2(X + 2\pi) = v_2(X).$$

Integrating (3.22) over the period and substituting into (3.21), one finds

$$\left[\sigma^{(1)}\right]^2 = -\frac{K^2 \int_0^{2\pi} dX U \partial U/\partial K}{\int_0^{2\pi} dX f_1(X)} = -\frac{K^2}{2}\frac{dA(K)/dK}{\langle f_1 \rangle}, \tag{3.23}$$

where $A = \langle U^2 \rangle$.

If $[\sigma^{(1)}]^2 > 0$, two real roots with opposite signs exist. One of them is positive; therefore the stationary solution is unstable. If $[\sigma^{(1)}]^2 < 0$, there are two imaginary roots. In the latter case, the stability with respect to perturbations with small Q depends on the sign of $\sigma^{(2)}$, which can be obtained in a similar way from the equation in the third order of Q.

Thus, one can expect that there are boundaries between the regions of stability and instability of stationary solutions with respect to long-wave disturbances that coincide with the extrema of the function $A(K)$.

Note that a similar relation between the nonmonotonicity of the dependence between the amplitude and the wavenumber was established for the KS equation [7] and the reaction-diffusion equation [46].

3.3. Numerical method for finding eigenvalues. For arbitrary values of q the problem (3.10) is solved numerically. We use the *Fourier transform* of a function $v(x, q)$,

$$v(x,q) = \sum_{n=-\infty}^{\infty} \widehat{v}_n(q) e^{inkx}, \qquad k = \frac{2\pi}{l}. \tag{3.24}$$

Substituting (3.24) into (3.10), we get the following matrix equation for the eigenvalues and eigenvectors:

$$\sum_{n=-\infty}^{\infty} [M_{mn} - \sigma(q)\delta_{mn}]\widehat{v}_n = 0, \qquad -\infty < m < +\infty, \tag{3.25}$$

where

$$\begin{aligned} M_{mn} &= [(mk+q)^2 - (mk+q)^4]\delta_{mn} \\ &\quad + iD(mk+q)\widehat{U}_{m-n} - 3(mk+q)^2(\widehat{U^2})_{m-n}. \end{aligned} \tag{3.26}$$

The infinite system of equations (3.25) was replaced by a finite system,

$$\sum_{n=-N}^{N} [M_{mn} - \sigma(q)\delta_{mn}]\widehat{v}_n = 0, \qquad -N < m < N, \tag{3.27}$$

and solved numerically using Matlab. Numerical calculations were done with double precision. The results of the numerical calculations are described in the next subsection.

3.4. Results of the numerical analysis. First, we check that our approach confirms the known results concerning the stability of stationary periodic solutions for the KS equation (the case $D \to \infty$). Indeed, for the KS equation we have reproduced the results formerly obtained in [7, 8, 9, 10, 11, 12]. The stability interval is $0.766 < K < 0.838$. The left end of the stability interval is determined by the condition $\sigma^{(2)} = 0$ in the expansion (3.16). Here we observe an oscillatory instability for small quasi wavenumbers, $q \to 0$. At the right end of the interval, which coincides with the maximum of the function $A(K) = \langle U^2 \rangle(K)$, we obtain a monotonic instability, also for $q \to 0$.

For $D \le D_0$ the dependence $A(K)$ for stationary solutions is monotonic (see section 2), and it turns out that $[\sigma^{(1)}]^2 > 0$ for any K (see section 3.2). Therefore, there is no stability interval in this region.

TABLE 1

Boundaries of the stability intervals. Abbreviations: osc. is oscillatory instability, mon. is monotonic instability.

D	K_{left}	K_{right}
∞	0.766 osc.,$q \to 0$	0.838 mon.,$q \to 0$
5	0.677 osc.,$q \to 0$	0.775 mon.,$q \to 0$
2	0.537 osc., $q \to K/2$	0.640 mon.,$q \to 0$
1	0.376 osc.,$q \to K/2$	0.4752 mon.,$q \to 0$
0.8	0.314059 mon.,$q \to 0$	0.4065 mon.,$q \to 0$
0.5	0.111 mon.,$q \to K/2$	0.1767048 mon.,$q \to 0$

The investigation of the stability of main-family stationary solutions for $D > D_0$, where the dependence $A(K)$ is not monotonic, has been done numerically. The eigenvalue problem (3.27) determines $2N+1$ eigenvalues. Let $\sigma_1(q)$ be the eigenvalue with the maximum real part (see Figures 10–13). The analysis reveals the existence of the stability interval. The boundaries of the stability interval are presented in Table 1. Both boundaries move into the long-wave region with the decrease of D and tend to zero when D approaches $\sqrt{2}/3$. In order to obtain accurate eigenvalues for decreasing D it was sufficient to increase the size of matrix (number N in (3.27)). For example, for $D = 5$, $D = 2$, and $D = 1$ we used matrices of the size $N = 17$; for $D = 0.8$, $N = 33$; and for $D = 0.5$, $N = 33$ and $N = 129$. For each case we tried to find the minimum size of the matrix that allowed us to obtain the correct result for a given value of D. This was done by comparing the solutions obtained for different N and checking the convergence.

We have found that the right boundary of the stability interval always coincides with the global maximum of the function $A(K)$, which corresponds to (3.23) with $\langle f_1 \rangle > 0$. Therefore, on the right boundary of the stability interval a monotonic

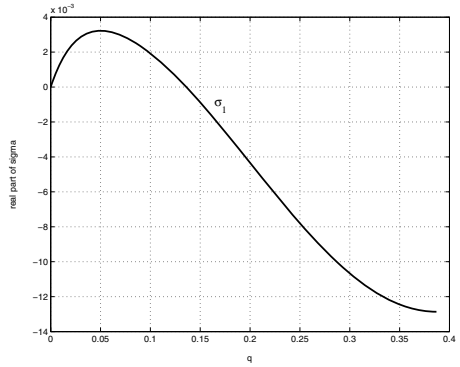

FIG. 10. *Dependence of σ_1, the eigenvalue with the maximal real part, on q; $D = 5$, $K = 0.775$. The case of long-wave monotonic instability.*

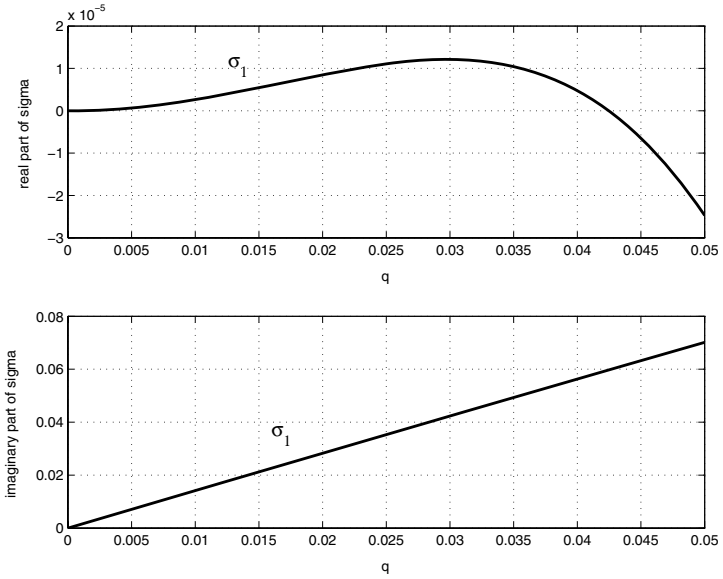

FIG. 11. *The real and imaginary parts of σ_1, for small q; $D = 5$, $K = 0.677$. The oscillatory long-wave instability is found.*

long-wave instability always occurs (see Figure 10).

The type of the instability on the left boundary of the stability interval depends on D. For sufficiently large values of D ($D = 5$), as in the case of the KS equation, the destabilization of the stationary solutions for $K < 0.677$ is due to the oscillatory instability with $q \to 0$ (Figure 11). One can see from Figure 11 that for $q \ll 1$ $\mathrm{Im}[\sigma_1(q)] = O(q)$, $\mathrm{Re}[\sigma_1(q)] = O(q^2)$ for $q \ll 1$. This is in accordance with the results described in section 3.2.

For smaller values of D ($D = 2$ and $D = 1$), the dependence of $\mathrm{Re}[\sigma]$ on the quasi wavenumber q has two maxima near the left stability boundary. We have found that the destabilization scenario in this case is different: now the most "dangerous" oscillatory perturbation (the one with the largest real part of σ_1) at the left end of the stability interval corresponds to $q \to K/2$ (see Figure 12).

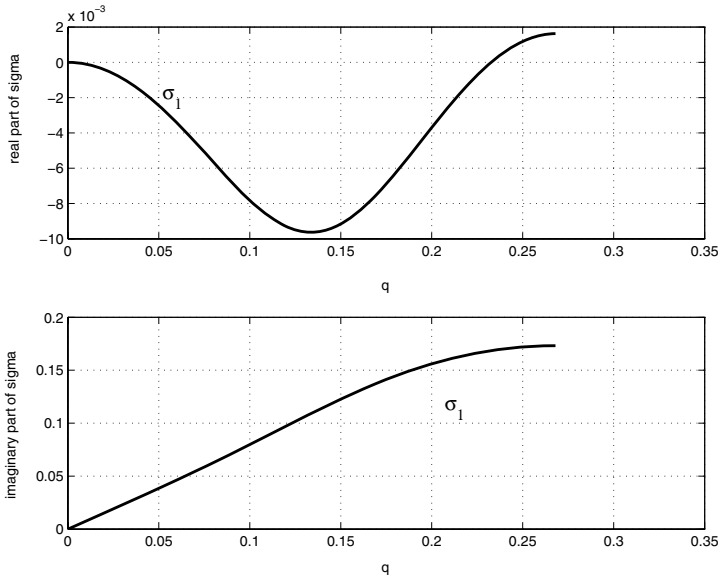

FIG. 12. *Dependence of the real and imaginary parts of σ_1 on q; $D = 2$, $K = 0.537$. The short-wave oscillatory instability is found.*

For $D = 0.8$, we have obtained a monotonic instability with $q \to 0$ at *both* ends of the interval (see Figure 13). Note that the left boundary of the monotonic instability is not connected with the extrema of $A(K)$. As a matter of fact, in the point $K = 0.314059$ the eigenvalue problem (3.17) has one more eigenfunction with $\sigma^{(0)} = 0$, in addition to the solution $v_0 = U'$. This eigenfunction has a nonzero mean value and is related to the bifurcation *sb* of another family of asymmetric stationary solutions with a nonzero mean value (see Figure 8).

For smallest values of D ($D = 0.5$), at the left end of the interval we have a monotonic instability for $q \to K/2$.

In [30], equation (2.1) was solved numerically in a long domain with periodic boundary conditions. It was found that stationary solutions with a definite wavelength are selected in the interval $1 < D < 5$ (see Figure 14). It is clear that the black points which correspond to the stationary solutions obtained in simulations [30] are inside the stability intervals obtained in our computations.

4. Conclusions. We have studied bifurcations of stationary solutions of a convective Cahn–Hilliard equation (2.1) that is generic for a wide class of systems exhibiting phase separation in the presence of external driving (e.g., growth or external field) and have analyzed the stability of the main family of the periodic stationary solutions.

The stability analysis was done for odd stationary periodic solutions of (2.1) (the *main family* of solutions) that bifurcate from the trivial state $u \equiv 0$ as a result of a spinodal decomposition instability. The effect of the driving force, characterized by the parameter D in (2.1), has been investigated. We have found that in the region $0 < D < D_0 = \sqrt{2}/3$ these solutions are unstable. One can expect that the coarsening (Ostwald ripening) of domains with two different phases occurs in this case. For $D > D_0$ the periodic stationary solutions are stable if their wavelength belongs to

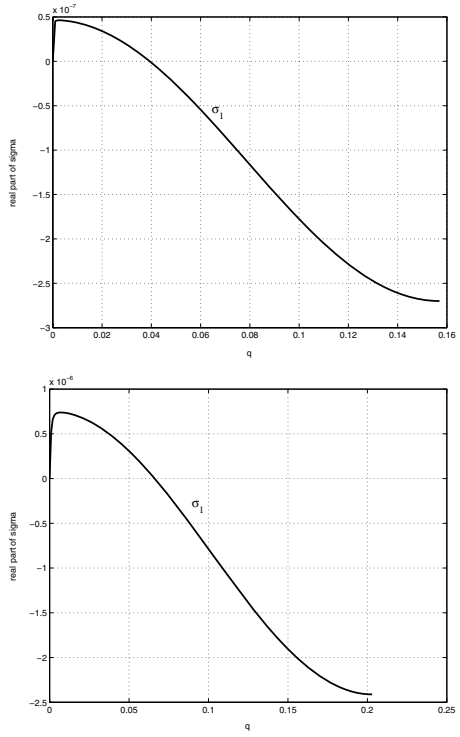

FIG. 13. *Dependence of σ_1 on q, for $D = 0.8$, at the two ends of the stability interval: $K = 0.314059$ (upper figure) and $K = 0.4065$ (lower figure). The case of long-wave monotonic instability.*

a certain stability interval. The instabilities of the periodic stationary solutions out of the stability interval can give rise to other classes of solutions that may be stable.

Thus, we have shown that in a driven phase-separating system that undergoes spinodal decomposition, the coarsening can be stopped by the driving force, and the formation of stable periodic structures is possible. This shows an opportunity to control the formation of spatially periodic structures in various phase-separating systems (e.g., phase-separating polymer films) by adjusting the driving force (e.g.,

external field). Note that some two-dimensional generalizations of convective CH models that exhibit the formation of stationary two-dimensional periodic patterns are investigated numerically in [47].

CALIBRATION OF THE EXTENDED CIR MODEL*

HONGTAO YANG†

Abstract. In this paper we shall prove that the calibration problem for the extended CIR model in [J. Hull and A. White, *Rev. Financial Studies*, 3 (1990), pp. 573–592] has a unique solution. The constructive proof leads to a numerical algorithm for computing the approximations of the time-dependent parameters and the zero-coupon bond prices. The results are also extended to multifactor CIR (Cox–Ingersoll–Ross) models. Numerical results are presented to examine the accuracy of our algorithm and to compare the extended CIR model with the Vasicek models.

Key words. extended CIR model, calibration, inverse problem, solution uniqueness and existence, numerical solutions

1. Introduction.

The CIR model of the term structure of interest rates was proposed by Cox, Ingersoll, and Ross in [4]. Unlike the Vasicek model [18], the CIR model does not permit negative interest rates. The interest rates under the CIR model can always be positive under certain conditions, and thus American calls and European calls on zero-coupon bonds have the same value [4], [15]. However, critics of this model (and other models with constant parameters) note that it does not provide a perfect fit to the initial term structure of interest rates. In [7] and [8], Hull and White extended the Vasicek and CIR models to allow time-dependent parameters. The extended models are consistent with both the current term structure of interest rates and either the current volatilities of all spot interest rates or the current volatilities of all forward interest rates. Recent theoretical study on the CIR model and the extended CIR model can be found in [5], [14], and references cited therein.

The important problem both in practice and in theory is to determine the time-dependent parameters of the extended models. Since both the extended Vasicek model and the extended CIR model are affine term structure models, the bond prices can be determined by a system of ordinary differential equations with final conditions (see section 2 for the Extended CIR model). By using the current market date, we can add several initial conditions to the system and then formulate an inverse problem to determine its solution and time-dependent coefficients [7]. The inverse problem can be solved analytically in the case of the extended Vasicek model. However, for the extended CIR model, it seems that numerical methods have to be used. Additionally, to the best of our knowledge, the following is still an open problem: Does the inverse problem proposed in [7] have a solution? The main objective of this paper is to prove that the inverse problem for the extended CIR model has a unique solution under appropriate assumptions. Since our proof is a constructive one, its numerical implementation provides a numerical algorithm for computing the approximations of the time-dependent parameters and the discount bond prices. This makes it possible

for practitioners to evaluate interest rate derivatives under the extended CIR model when it is fitted to the current market data.

The outline of the paper is as follows. In section 2, we introduce the inverse problem for determining the time-dependent parameters of the extended CIR model. The solution existence and uniqueness of the inverse problem are established by a constructive proof in section 3. We extend the results to the multifactor CIR models in section 4. In section 5, a fourth order numerical algorithm is proposed to compute the approximations of the time-dependent parameters and the bond prices. Numerical results are presented in section 6 to examine the accuracy of our algorithm and to compare the extended CIR model with the Vasicek models. Conclusions are in section 7.

2. An inverse problem to calibrate the extended CIR model. In this section, we introduce the inverse problem for the CIR model proposed in [7]. There are two different economic approaches to the bond market: the equilibrium modeling and the martingale modeling, which lead to the same partial differential equations. Here we shall adopt the latter approach and assume the existence of a risk-neutral measure [1] since we consider only the related mathematical problems.

For the extended CIR model, the process of interest rates, $r(t)$, is assumed to follow the stochastic differential equation

$$dr(t) = (\phi(t) - \psi(t)r(t))dt + \sigma(t)\sqrt{r(t)}dW(t), \tag{2.1}$$

under the risk-neutral measure, where $\psi(t)$ is the speed of adjustment at time t, $\phi(t)/\psi(t)$ is the interest rate of mean reversion at time t, $\sigma(t)$ is a function of t related to the volatility of short rates, and $W(t)$ is a Wiener process. Consider a discount bond with face value \$1 and expiration date T not greater than some positive number T^*. The bond price $P(r,t,T)$ is the solution of the following partial differential equation of the parabolic type (see Proposition 3.4 of [1]):

$$P_t + (\phi(t) - \psi(t)r)P_r + d(t)rP_{rr} - rP = 0, \qquad r > 0,\ 0 < t \le T,$$

with the final condition

$$P(r,T,T) = 1, \quad r \ge 0,$$

where $d(t) = \frac{1}{2}\sigma(t)^2$. It has been proved that $P(r,t,T)$ takes the following form (see [1] and [16]):

$$P(r,t,T) = A(t,T)e^{-B(t,T)r}. \tag{2.2}$$

Then $A(t,T)$ and $B(t,T)$ are the solution of the final value problem

$$A_t(t,T) - \phi(t)A(t,T)B(t,T) = 0, \quad 0 \le t \le T, \tag{2.3}$$

$$B_t(t,T) - \psi(t)B(t,T) - d(t)B^2(t,T) + 1 = 0, \quad 0 \le t \le T, \tag{2.4}$$

$$A(T,T) = 1, \tag{2.5}$$

$$B(T,T) = 0. \tag{2.6}$$

As shown in [7], $A(0,T)$ and $B(0,T)$ can be determined by the current term structure of interest rates and the current term structure of spot rate or forward rate volatilities. The function $\sigma(t)$ can be chosen to reflect the current and future

volatilities of the short-term interest rate. Therefore, we have the following inverse problem:

$$\text{(IP)} \quad \begin{cases} \textit{For given functions } \sigma(t),\ a(t),\ \textit{and } b(t) \textit{ defined on } [0,T^*],\ \textit{determine functions } A(t,T),\ B(t,T),\ \phi(t),\ \textit{and } \psi(t) \textit{ such that they satisfy } (2.3)\text{–}(2.6) \textit{ and } A(0,T)=a(T) \textit{ and } B(0,T)=b(T) \textit{ for } T\in[0,T^*]. \end{cases}$$

In the next section, we shall show that the inverse problem has a unique solution. The solution existence means that the model can be fitted to the current term structure of interest rates. In particular, our constructive proof leads to a natural numerical algorithm for computing the time-dependent parameters $\phi(t)$ and $\psi(t)$ and the bond prices.

3. Solution existence and uniqueness of the inverse problem. First, we study how to determine $B(t,T)$ and $\psi(t)$. Since (2.4) is a Riccati equation, by using the standard transform

$$B(t,T) = -\frac{u_t(t,T)}{d(t)u(t,T)},$$

we have the following second order linear differential equation for the new unknown function $u(t,T)$:

$$-u_{tt}(t,T) + \nu(t)u_t(t,T) + d(t)u(t,T) = 0, \quad 0 < t < T, \tag{3.1}$$

where $\nu(t) = \psi(t) + d'(t)/d(t)$. Let $u_1(t)$ and $u_2(t)$, respectively, be solutions to the following initial value problems:

$$-u_1''(t) + \nu(t)u_1'(t) + d(t)u_1(t) = 0, \qquad 0 < t \le T^*,\ u_1(0) = 1,\ u_1'(0) = 0, \tag{3.2}$$

$$-u_2''(t) + \nu(t)u_2'(t) + d(t)u_2(t) = 0, \qquad 0 < t \le T^*,\ u_2(0) = 0,\ u_2'(0) = 1. \tag{3.3}$$

It is apparent that $u_1(t)$ and $u_2(t)$ are two linearly independent solutions. The general solution of (3.1) is thus a linear combination of $u_1(t)$ and $u_2(t)$. Hence we have

$$B(t,T) = -\frac{c(T)u_1'(t) + u_2'(t)}{d(t)(c(T)u_1(t) + u_2(t))},$$

where $c(T)$ is a function of T. It follows from (2.6) that $c(T)u_1'(T) + u_2'(T) = 0$; i.e., $c(T) = -u_2'(T)/u_1'(T)$. Then we have

$$B(t,T) = -\frac{u_1'(T)u_2'(t) - u_2'(T)u_1'(t)}{d(t)(u_1'(T)u_2(t) - u_2'(T)u_1(t))}, \qquad 0 \le t \le T,\ 0 \le T \le T^*. \tag{3.4}$$

Letting $t = 0$, we get

$$u_1'(T) = g(T)u_2'(T), \quad 0 \le T \le T^*, \tag{3.5}$$

where

$$g(T) = d(0)B(0,T) = d(0)b(T), \quad 0 \le T \le T^*.$$

Substituting (3.5) into (3.4), we have

$$B(t,T) = -\frac{g(T)u_2'(t) - u_1'(t)}{d(t)(g(T)u_2(t) - u_1(t))}, \qquad 0 \le t \le T,\ 0 \le T \le T^*. \tag{3.6}$$

Integrating (3.5) from 0 to t plus integration by parts gives

$$u_1(t) = 1 + g(t)u_2(t) - \int_0^t g'(s)u_2(s)ds, \quad 0 \le t \le T^*. \tag{3.7}$$

Eliminating $\nu(t)$ from (3.2) and (3.3), we obtain

$$\frac{u_1'(t)}{u_2'(t)} = \frac{u_1''(t) - d(t)u_1(t)}{u_2''(t) - d(t)u_2(t)}, \quad 0 \le t \le T^*.$$

Substituting (3.5) and (3.7) into the above equation, we have after simplification

$$u_2'(t) = -\frac{d(t)}{g'(t)} \int_0^t g'(s)u_2(s)ds + \frac{d(t)}{g'(t)}, \quad 0 \le t \le T^*. \tag{3.8}$$

Integration leads to

$$u_2(t) + \int_0^t K(t,s)u_2(s)ds = f(t), \quad 0 \le t \le T^*, \tag{3.9}$$

where

$$f(t) = \int_0^t \frac{d(s)}{g'(s)}ds, \quad K(t,s) = (f(t) - f(s))g'(s).$$

Equation (3.9) is a Volterra integral equation of the second kind for $u_2(t)$. By Theorem 3.1 of [11], it has a unique solution $C[0,T^*]$ (the set of all continuous functions on $[0,T^*]$) if $f(t)$ and $g'(t)$ are continuous in $0 \le t \le T^*$.

Once $u_2(t)$ is determined by (3.9), we can compute $u_1(t)$ by (3.7) and then $B(t,T)$ by (3.6). It follows from (3.3) that

$$\nu(t) = \frac{u_2''(t) - d(t)u_2(t)}{u_2'(t)}.$$

Thus parametric function $\psi(t)$ is determined by

$$\psi(t) = \nu(t) - \frac{d'(t)}{d(t)} = \frac{u_2''(t) - d(t)u_2(t)}{u_2'(t)} - \frac{d'(t)}{d(t)}.$$

By using (3.8) twice, we get the following simple formula for computing $\psi(t)$ in terms of $u_2(t)$ and $u_2'(t)$:

$$\psi(t) = -\frac{g''(t)}{g'(t)} - 2d(t)\frac{u_2(t)}{u_2'(t)}, \quad 0 \le t \le T^*. \tag{3.10}$$

Next we discuss how to determine $A(t,T)$ and $\phi(t)$. Solving (2.3) with the final condition (2.5), we get

$$A(t,T) = \exp\left(-\int_t^T \phi(s)B(s,T)ds\right), \qquad 0 \le t \le T,\ 0 \le T \le T^*. \tag{3.11}$$

Letting $t = 0$ and taking the natural logarithm, we have

$$\int_0^T \phi(s)B(s,T)ds = -\ln(a(T)), \quad T \in [0,T^*], \tag{3.12}$$

where $A(0,T)$ was replaced by $a(T)$. Recall that $B(T,T)=0$ on $[0,T^*]$. The above equation is a Volterra integral equation of the first kind with a degenerate kernel. To remove this difficulty, we differentiate both sides of (3.12) to get

$$\int_0^T \phi(s)B_T(s,T)ds = -\frac{a'(T)}{a(T)}, \quad 0 \le T \le T^*. \tag{3.13}$$

This is still a Volterra integral equation of the first kind. It follows from $B(T,T)=0$ that $B_T(T,T) = -B_t(T,T)$. Letting $t=T$ in (2.4), we have $B_t(T,T)=-1$ and thus $B_T(T,T)=1$ for $0 \le T \le T^*$. Therefore, (3.13) has a nice kernel. Differentiating (3.13), we get the following Volterra integral equation of the second kind for $\phi(t)$:

$$\phi(T) + \int_0^T \phi(s)B_{TT}(s,T)ds = \frac{a'(T)^2 - a(T)a''(T)}{a(T)^2}, \quad T \in [0,T^*]. \tag{3.14}$$

Again, by Theorem 3.1 of [11], equation (3.14) has a unique solution in $C[0,T^*]$ if $B_{TT}(s,T)$ is continuous in $0 \le s \le T \le T^*$ and $a''(T)$ is continuous in $0 \le T \le T^*$.

In order to validate the above calculations, we make the following assumptions:

(H1) $a(T),\ b(T) \in C^2[0,T^*]$, $d(T) \in C^1[0,T^*]$.

(H2) *$a(T)$, $d(T)$, and $b'(T)$ have positive lower bounds on $[0,T^*]$.*

(H3) $a(0)=1$, $b(0)=0$, $b'(0)=1$

(H4) *The derivative of the solution $u_2(t)$ of (3.9) is positive on $[0,T^*]$.*

Here we use $C^k[0,T^*]$ to denote the space of all kth continuously differentiable functions on $[0,T^*]$ for a given positive integer k.

Assumption (H1) is for the regularity requirements of the calculations. Assumption (H3) follows from (2.5), (2.6), and $B_T(T,T)=1$. It is necessary to assume that $a(T)$ and $d(T)$ have positive lower bounds on $[0,T^*]$. Recall that the current bond price $P(r(0),0,T) = A(0,T)\exp(-B(0,T)r(0))$ is a decreasing function of the expiration date T. We may assume that $B(0,T)=b(T)$ is an increasing function of T, which means that $b'(T)$ has a positive lower bound on $[0,T^*]$. This assumption is also implied by $b'(0)=B_T(0,0)=1$. If we evaluate options under the extended CIR (ECIR) model, we need only to know the bond price $P(r,t,T)$ for $t \in [0,S]$, where S is the option expiration date. In this case, it follows from (3.6) that $b'(t)>0$ on $t \in [0,S]$ is sufficient. Assumption (H4) is needed to define $\psi(t)$ by (3.10).

Now we are in a position to show the solution existence and uniqueness of the inverse problem (IP).

THEOREM 1. *Under assumptions* (H1)–(H4)*, the inverse problem* (IP) *has a unique classic solution: $B(t,T),\ A(t,T) \in C^1(\Omega)$, $\phi(t),\ \psi(t) \in C[0,T^*]$, where $\Omega = \{(t,T):\ 0 \le t \le T \le T^*\}$.*

Proof. It is not difficult to check that (3.9) satisfies the conditions of Theorem 3.6 of [11] when assumptions (H1)–(H2) hold. So it has a unique solution $u_2(t)$ in $C^2[0,T^*]$ which also satisfies (3.8). Letting $t=0$ in (3.8) and (3.9), we have $u_2'(0)=1$ and $u_2(0)=0$, where the assumption (H3) was used. Then by assumption (H4), $\psi(t)$ defined by (3.10) is in $C[0,T^*]$, and thus $u_2(t)$ is the unique solution of the initial value problem (3.3). It is easy to check that $u_1(t)$ defined by (3.7) is the unique solution of the initial value problem (3.2) in $C^2[0,T^*]$. Therefore, function $B(t,T)$ defined by (3.6) is the unique solution of (2.4) with the final condition (2.6) and the initial condition $B(0,T)=b(T)$. Notice from (3.6) that $B_{TT}(t,T)$ is a continuous function on Ω. By Theorem 3.1 of [11], the integral equation (3.14) has a unique solution $\phi(T)$ in $C[0,T^*]$, and thus $A(t,T) \in C^1(\Omega)$ determined by (3.11) is the unique solution of (2.3) with the final condition (2.5) and the initial condition $A(0,T)=a(T)$. ∎

We may relax the conditions about the smoothness of functions $a(t)$, $b(t)$, and $d(t)$. Since such conditions are quite complicated, we refer the interested reader to Chapter 3 of [11] for a general consideration. Define

$$K\phi(t) = \int_0^t K(t,s)\phi(s)ds, \qquad L\phi(t) = \int_0^t g'(s)\phi(s)ds\,.$$

Then we have from (3.9)

$$u_2(t) = (I+K)^{-1}f(t) = \sum_{n=0}^{\infty}(-K)^n f(t).$$

Since

$$(K\phi)'(t) = f'(t)L\phi(t),$$

we have after some calculation

$$u_2'(t) = f'(t)(1-Lf(t)) + f'(t)L\sum_{m=0}^{\infty} K^{2m+1}(I-K)f(t).$$

Notice that integral operators K and L have positive kernels and $f(t)$ and $f'(t)$ are positive. We propose the following sufficient conditions for $u_2'(t) > 0$ on $t \in [0, T^*]$:

$$1 - Lf(T^*) > 0, \qquad (I-K)f(T^*) > 0.$$

The first inequality implies the second one and can be rewritten as

$$\int_0^{T^*} \frac{d(t)(g(T^*)-g(t))}{g'(t)}dt < 1. \tag{3.15}$$

Hence assumption (H4) can be replaced by this stronger condition.

The extended CIR model can also be calibrated by assuming that $\psi(t)$ and $\sigma(t)$ are constant or that $\phi(t)$ and $\psi(t)/\sigma^2(t)$ are constant. In the first case, we need to determine only $\psi(t)$ by (3.13) or (3.14) (see [4]). For the latter case, $\sigma(t)$ and $\psi(t)$ can be determined analytically [17].

4. The multifactor CIR models. In this section, we extend the results in the previous section to the multifactor CIR models. Empirical studies have shown that multifactor models have more flexibility to capture more variability of interest rates (see [3], [6], [13], and references therein). Without loss of generality, we consider only the two-factor CIR model, which has the models in [3] and [13] as two specific cases mathematically. The model specifies that the short rate process $r(t)$ is the sum of two square root processes $x_1(t)$ and $x_2(t)$; i.e.,

$$\begin{aligned} r(t) &= x_1(t) + x_2(t), \\ x_i(t) &= (\phi_i(t) - \psi_i(t)x_i(t))dt + \sigma_i(t)\sqrt{x_i(t)}dW_i(t), \quad i = 1, 2, \end{aligned}$$

where $(W_1(t), W_2(t))$ is a two-dimensional standard Brownian motion under the risk-neural measure. Let $P(x_1, x_2, t, T)$ be the price of the zero-coupon bond which pays \$1 at time T. Then it is the solution of the following fundamental partial differential equation (see [1], [13], and [16]):

$$P_t + \sum_{i=1}^{2}\left(\frac{1}{2}\sigma_i(t)^2 x_i P_{ii} + (\phi_i(t) - \psi_i(t)x_i)P_i - x_i P\right) = 0,$$

where P_i and P_{ii} denote the first and second order derivatives with respect to x_i. Write

$$P(x_1, x_2, t, T) = A(t, T) \exp(-B(t, T)x_1 - C(t, T)x_2). \tag{4.1}$$

Then we have the following ordinary differential equations for $A(t, T)$, $B(t, T)$, and $C(t, T)$:

$$A_t(t, T) - (\phi_1(t)B(t, T) + \phi_2(t)C(t, T))A(t, T) = 0, \quad 0 \le t \le T, \tag{4.2}$$

$$B_t(t, T) - \psi_1(t)B(t, T) - \frac{1}{2}\sigma_1(t)^2 B^2(t, T) + 1 = 0, \quad 0 \le t \le T, \tag{4.3}$$

$$C_t(t, T) - \psi_2(t)C(t, T) - \frac{1}{2}\sigma_2(t)^2 C^2(t, T) + 1 = 0, \quad 0 \le t \le T. \tag{4.4}$$

Similarly to the one-factor model, we have the following final conditions:

$$A(T, T) = 1, \tag{4.5}$$

$$B(T, T) = C(T, T) = 0. \tag{4.6}$$

When all parametric functions are constant, the above final value problem can be solved analytically (see Example 6.2).

Assume that $\sigma_1(t)$, $\sigma_2(t)$, $A(0, T)$, $B(0, T)$, and $C(0, T)$ are determined by using the current market data. Then, as in section 3, we can determine $\psi_1(t)$, $B(t, T)$, $\psi_2(t)$, and $C(t, T)$ from (4.3), (4.4), and (4.6). Solving (4.2) for $A(t, T)$, we get

$$A(t, T) = \exp\left(-\int_t^T (\phi_1(s)B(s, T) + \phi_2(s)C(s, T))ds\right).$$

Letting $t = 0$ and taking the natural logarithm, we get

$$\int_0^T (\phi_1(s)B(s, T) + \phi_2(s)C(s, T))\, ds = -\ln(A(0, T)).$$

Since only one function can be determined by this integral equation, we need one of the following assumptions:

(H5) $\phi_1(t)$ or $\phi_2(t)$ is constant.

(H6) $\phi_1(t)$ and $\phi_2(t)$ are linear dependent; i.e., for some constant λ, $\phi_1(t) = \lambda\phi_2(t)$.

(H7) The mean reversion value, $\phi_i(t)/\psi_i(t)$, is constant for $i = 1$ or 2.

Then we have the integral equations similar to (3.13) and (3.14) for $\phi_1(t)$ or $\phi_2(t)$.

Based on the above discussion, we can prove the following result similar to Theorem 1.

THEOREM 2. *The parametric functions $\phi_i(t)$ and $\psi_i(t)$ $(i = 1, 2)$ of the two-factor CIR model can be uniquely determined in $C([0, T^*])$ from* (4.2)–(4.6) *together with known $\sigma_1(t)$, $\sigma_2(t)$, $A(0, T)$, $B(0, T)$, and $C(0, T)$ under the assumptions similar to* (H1)–(H4) *for $A(0, T)$, $B(0, T)$, and $C(0, T)$ and assumption* (H5), (H6), *or* (H7).

Here we have assumed that $dW_1(t)$ and $dW_2(t)$ are uncorrelated. If their correlation is ρdt for some nonzero constant ρ, then the zero-coupon bond price $P(x_1, x_2, t, T)$ can not be expressed in the form of (4.1). Indeed, it satisfies the following partial differential equation:

$$P_t + \sum_{i=1}^{2}\left(\frac{1}{2}\sigma_i(t)^2 x_i P_{ii} + (\phi_i(t) - \psi_i(t)x_i)P_i - x_i P\right) + \rho\sqrt{x_1 x_2}P_{12} = 0,$$

where P_{12} are the mixed second derivatives. In this case, the inverse problem is to determine $P(x_1, x_2, t, T)$ and the parametric functions from the above parabolic partial differential equation together with the current term structure and the other market information. Usually, it is difficult to show the solution existence of such inverse problems and to solve them numerically. Interested readers are referred to [9] for the theory of inverse problems for partial differential equations, and [2] and [10] for the inverse problems for stock option problems.

5. Numerical solutions of the inverse problem (IP). In this section we shall consider approximate solutions to the inverse problem (IP). To this end, we summarize the proof of Theorem 1 as the following algorithm:

Step 1. Solve (3.9) for $u_2(t)$.
Step 2. Compute $u_2'(t)$ by (3.8).
Step 3. Compute $u_1(t)$ and $u_1'(t)$ by (3.7) and (3.5), respectively.
Step 4. Compute $B(t,T)$, $B_T(t,T)$, and $B_{TT}(t,T)$ by using (3.6).
Step 5. Compute $\psi(t)$ by (3.10).
Step 6. Solve (3.13) or (3.14) for $\phi(t)$.
Step 7. Compute $A(t,T)$ by (3.11).
Step 8. Compute the bond price $P(r,t,T)$ by (2.2).

The crucial steps of the above algorithm are Steps 1 and 6, in which we need to solve Volterra equations. There is a large literature in numerical methods and their error analysis for Volterra equations. Interested readers are referred to [11] and references cited therein. In the following, we outline the block-by-block method in section 7.6 of [11] for (3.7) and (3.14) and propose a numerical implementation of our algorithm with the accuracy of order 4.

For an even positive integer M, let the step size $h = T^*/M$, $t_m = mh$ for $m = 0, 1, \ldots, M$, and $t_{m+1/2} = t_m + h/2$ for $m = 0, 1, \ldots, M-1$. Denote by $u_{2,m}$ the approximation of $u_2(t_m)$. Then the block-by-block method for (3.9) reads as follows: for $m = 0, 1, \ldots, M/2 - 1$, compute $u_{2,2m+1}$ and $u_{2,2m+2}$ by

$$\begin{cases} a_m u_{2,2m+1} + b_m u_{2,2m+2} = p_m, \\ c_m u_{2,2m+1} + d_m u_{2,2m+2} = q_m, \end{cases} \tag{5.1}$$

where

$$a_m = 1 + \frac{h}{2}K(t_{2m+1}, t_{2m+1/2}) + \frac{h}{6}K(t_{2m+1}, t_{2m+1}), \qquad b_m = -\frac{h}{12}K(t_{2m+1}, t_{2m+1/2}),$$

$$c_m = \frac{4h}{3}K(t_{2m+2}, t_{2m+1}), \qquad d_m = 1 + \frac{h}{2}K(t_{2m+2}, t_{2m+2}),$$

$$p_m = f(t_{2m+1}) + \frac{h}{6}K(t_{2m+1}, t_{2m})u_{2,2m} - \frac{h}{4}K(t_{2m+1}, t_0)u_{2,0} - \frac{h}{3}\sum_{i=0}^{2m} w_{m,i}K(T_{2m+1}, t_i),$$

$$q_m = f(t_{2m+2}) - \frac{h}{3}\sum_{i=0}^{2m} w_{m,i}K(T_{2m+2}, t_i),$$

where $\{w_{m,0}, w_{m,1}, \ldots, w_{m,m-1}, w_{m,m}\} = \{1, 4, 2, \ldots, 2, 4, 1\}$. The above block-by-block method is derived by using Simpson's rule as the numerical integration formula. System (5.1) has a unique solution when h is small enough. Furthermore, for sufficiently smooth $K(t,s)$ and $f(t)$, we have the following error estimate:

$$\max_{1 \le m \le M} |u_2(t_m) - u_{2,m}| \le Ch^4$$

for some constant C independent of h (see Chapter 7 of [11]).

We can also apply the above block-by-block method to (3.14) for $\phi(t)$. Since $b''(T)$ ($g''(T)$) has to be computed in order to compute $B_{TT}(t,T)$ by (3.6), the accuracy of computation would be reduced when $b(t)$ is obtained by using the current market data through curve fitting. Instead, we may solve (3.13) by block-by-block methods, for example, the method in section 9.4 of [11].

Now consider the approximations of $u_1(t_m)$, $u_1'(t_m)$, and $u_2'(t_m)$. When m is even, the integral in (3.8) can be approximated by Simpson's rule at the mesh points $t_0, t_1, \ldots, t_m$, and thus $u_2'(t_m)$ can be computed with the error of order 4. When m is odd, $u_2'(t_m)$ will be computed by a fourth order interpolation formula on even mesh points. The approximation of $u_1'(t_m)$ is then obtained by (3.5) with the same accuracy. By (3.7) and (3.8), we have the following formula to compute $u_1(t)$ in terms of $u_2'(t)$:

$$u_1(t) = g(t)u_2(t) - \frac{g'(t)u_2'(t)}{d(t)}, \qquad 0 \le t \le T^*.$$

Then we can compute the approximations of $\psi(t_m)$ and $B(t_i,t_m)$ by (3.10) and by (3.6), respectively. Differentiating (3.6) with respect to T, we get the following formulas for computing $B_T(t_i,t_m)$ and $B_{TT}(t_i,t_m)$:

$$B_T(t,T) = -\frac{g'(T)(u_1'(t)u_2(t) - u_1(t)u_2'(t))}{d(t)(g(T)u_2(t) - u_1(t))^2},$$

$$B_{TT}(t,T) = -\frac{(g''(T)(g(T)u_2(t) - u_1(t)) - 2g'(T)^2u_2(t))(u_1'(t)u_2(t) - u_1(t)u_2'(t))}{d(t)(g(T)u_2(t) - u_1(t))^3}.$$

Finally, we discuss how to compute $A(t_i,t_m)$. When $m-i$ is even, the integral in (3.11) can be approximated by Simpson's rule on mesh points. When i is even and m is odd, we rewrite (3.11) as

$$A(t,T) = A(0,T)\exp\left(\int_0^t \phi(s)B(s,T)ds\right), \qquad 0 \le t \le T,\ 0 \le T \le T^*.$$

The integral in the above formula can also be approximated by Simpson's rule on mesh points. Therefore, $A(t_i,T_m)$ can be computed with an error of order 4 in these two cases. For the other cases, $A(t_i,T_m)$ will be computed by a fourth order interpolation formula.

To sum up, our algorithm in the beginning of this section can be implemented numerically with fourth order accuracy.

6. Numerical examples. In this section, we will present numerical results to examine the accuracy of the numerical implementation of our algorithm and to compare the extended CIR model (ECIR) with the Vasicek and the extended Vasicek models. Our C++ codes were run on a Dell 2.4 GHz PC with Red Hat 7.3. Although the numerical experiments are also done for computation of $\phi(t)$ using (3.13), we present the numerical results when the approximations of $\phi(t)$ are computed using (3.14). We observed that both approaches give very accurate approximations for the model problems considered below.

Example 6.1. Consider the CIR model; i.e., $\sigma(t)$, $\psi(t)$, and $\phi(t)$ are constant functions in (2.1). The constants are denoted by σ_0, ψ_0, and ϕ_0, respectively. Then we have (see [4])

$$A(t,T) = \left(\frac{c_1e^{c_2s}}{c_2(e^{c_1s}-1)+c_1}\right)^{c_3}, \qquad B(t,T) = \frac{e^{c_1s}-1}{c_2(e^{c_1s}-1)+c_1}, \qquad s = T^* - t,$$

TABLE 6.1

$$c_1 = (\psi_0^2 + 2\sigma_0^2)^{\frac{1}{2}}, \quad c_2 = \frac{(\psi_0 + c_1)}{2}, \quad c_3 = \frac{2\phi_0}{\sigma_0^2}.$$

Let $a(T) = A(0,T)$, $b(T) = B(0,T)$, and $\sigma(t) = \sigma_0$ in the inverse problem (IP). It is apparent that $\psi(t) \equiv \psi_0$, $\phi(t) \equiv \phi_0$, $A(t,T)$, and $B(t,T)$ are the exact solution of the inverse problem (IP).

Take $\sigma = 0.2$, the long-term interest rate $\theta = 10\%$, the adjustment speed $\kappa = 0.4$, and $T^* = 10$. Then $\psi = \kappa\theta = 0.04$ and $\phi = \kappa = 0.4$. In Table 6.1, we display the relative root mean squared errors and the CPU times in seconds. The CPU time includes computing the approximations of $\psi(t_i)$, $\phi(t_i)$, $A(t_j,t_i)$, $B(t_j,t_i)$ for all $i = 0,1,\ldots,M$, $j = 0,1,\ldots,i$, and errors. The results show that the proposed numerical algorithm is very accurate and fast. One can check that the error ratios in each column of Table 6.1 are approximately 16, which agrees with the theoretical prediction of the convergence order 4.

Example 6.2. In this example, we shall calibrate the ECIR model by the Vasicek model. The interest rate process $r(t)$ of the Vasicek model follows

$$dr(t) = \kappa(\theta - r(t))dt + \sigma dW(t).$$

The bond price is given by (2.2) with

$$B(t,T) = \frac{1 - e^{-\kappa(T-t)}}{\kappa},$$
$$A(t,T) = \exp\left(\frac{(2\kappa^2\theta - \sigma^2)(B(t,T) - T + t)}{2\kappa^2} - \frac{\sigma^2}{4\kappa}B^2(t,T)\right).$$

Take $\sigma = 0.06$, the adjustment speed $\kappa = 0.4$, and the long-term interest rate $\theta = 10\%$. The face value is \$100. Assume that the initial short rate $r(0)$ is 9%. Let $a(t) = A(0,T)$ and $b(t) = B(0,T)$ in the inverse problem (IP). For the ECIR model, we set $\sigma(t) = 0.06/\sqrt{0.09} = 0.2$. As indicated in [7], this ensures that the initial short rate volatility equals that in the Vasicek model.

Numerical results show that $u_2'(t)$ is a strictly increasing function, and its graph looks like an exponential function, while the stronger condition (3.15) holds only for $T^* < 22.5$. We display the graphs of $\psi(t)$ and $\phi(t)/\psi(t)$ in Figure 6.1. The figure shows that $\psi(t)$ is a decreasing function having a horizontal asymptote $\psi = 0.2828$ and that $\phi(t)/\psi(t)$ is an increasing function having a horizontal asymptote $\phi/\psi = 0.1071$. Thus the long-term adjustment speed for the ECIR model is approximately 0.2828, which is smaller than that (0.4) for the Vasicek model, and the long-term interest rate for the ECIR model is approximately 10.71%, which is greater than that (10%) for the Vasicek model. In Figure 6.2, we display the contour maps of the differences of the

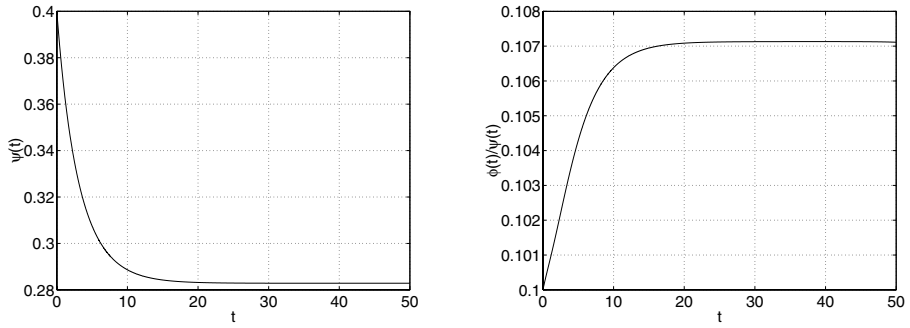

FIG. 6.1. *The graphs of $\psi(t)$ and $\phi(t)/\psi(t)$.*

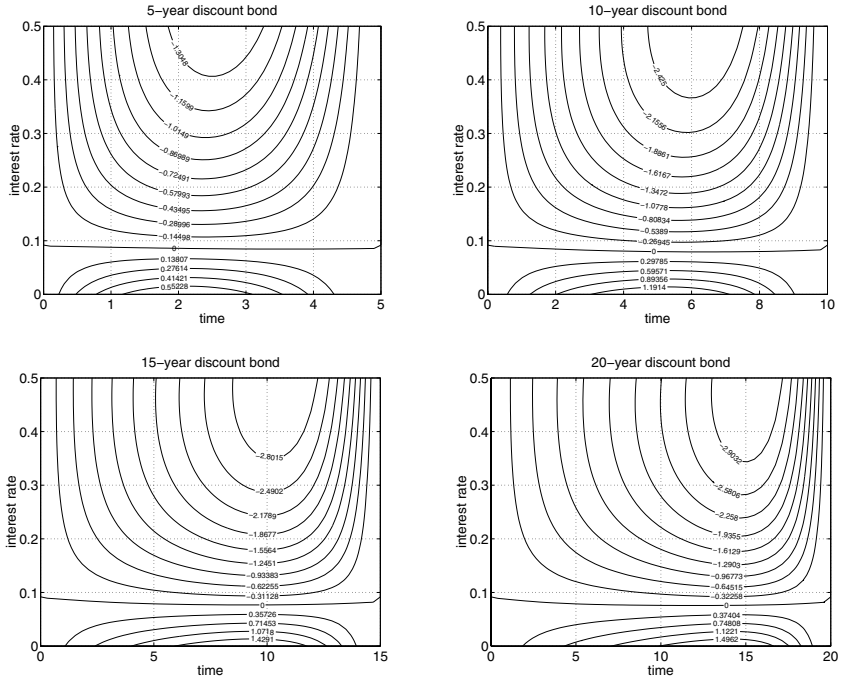

FIG. 6.2. *Contour plots of price differences.*

bond prices under the extended Vasicek model and the ECIR model. We observed that the whole computing domain is divided into two parts. In the part corresponding to small interest rates, the bond price under the extended Vasicek model is greater than that under the ECIR model, and the reverse is true in the other part corresponding to large interest rates. This is because high interest rates have a greater chance of occurring under the ECIR model. The graphs of bond prices are displayed in Figure 6.3. We observe that the bond price is an increasing function of time and a decreasing function of interest rates, which is as expected both in theory and in practice.

Example 6.3. As in [7], in this example we assume that the initial term structure is determined by the two-factor CIR model with constant parameters. Then the discount bond price is given by

$$P(x_1, x_2, t, T) = A(t, T) \exp(-x_1 B_1(t, T) - x_2 B_2(t, T)),$$

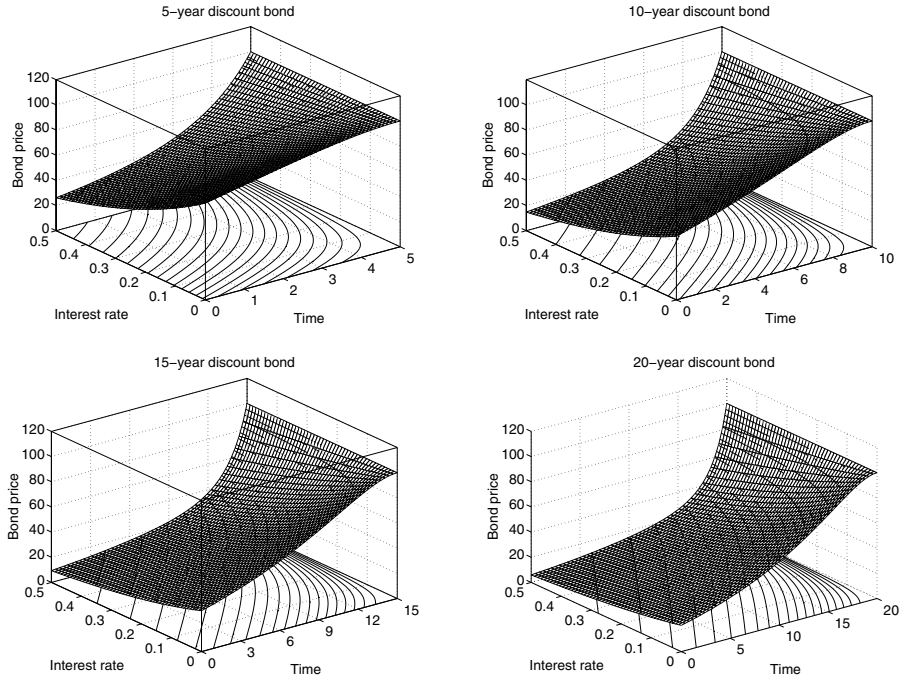

FIG. 6.3. *Bond prices.*

where $A(t,T) = A_1(t,T)A_2(t,T)$, and $A_i(t,T)$ and $B_i(t,T)$ are given by the corresponding formulas, as in Example 6.1. The extended Vasicek model is fitted to the two-factor CIR model as follows (see [7]):

$$\sigma = \sqrt{\sigma_1^2 x_1(0) + \sigma_2^2 x_2(0)},$$
$$\sigma B(0,T) = \sqrt{\sigma_1^2 x_1(0) B_1(0,T)^2 + \sigma_2^2 x_2(0) B_2(0,T)^2},$$
$$P(r(0),0,T) = A(0,T)e^{-B(0,T)r(0)}.$$

Similarly, we fit the ECIR model as follows:

$$\sigma\sqrt{r(0)} = \sqrt{\sigma_1^2 x_1(0) + \sigma_2^2 x_2(0)},$$
$$\sigma\sqrt{r(0)}B(0,T) = \sqrt{\sigma_1^2 x_1(0) B_1(0,T)^2 + \sigma_2^2 x_2(0) B_2(0,T)^2},$$
$$P(r(0),0,T) = A(0,T)e^{-B(0,T)r(0)},$$

where $r(0) = x_1(0) + x_2(0)$. The parameter values are as follows:

$$\sigma_1 = 0.1, \quad \psi_1 = 0.2, \quad \phi_1 = 0.01, \quad x_1(0) = 0.06,$$
$$\sigma_2 = 0.1, \quad \psi_2 = 0.3, \quad \phi_2 = 0.009, \quad x_2(0) = 0.02.$$

The bond face value is \$100.

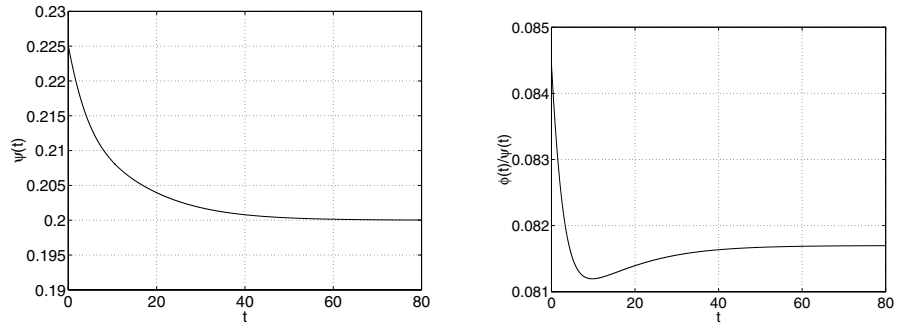

FIG. 6.4. *The graphs of $\psi(t)$ and $\phi(t)/\psi(t)$.*

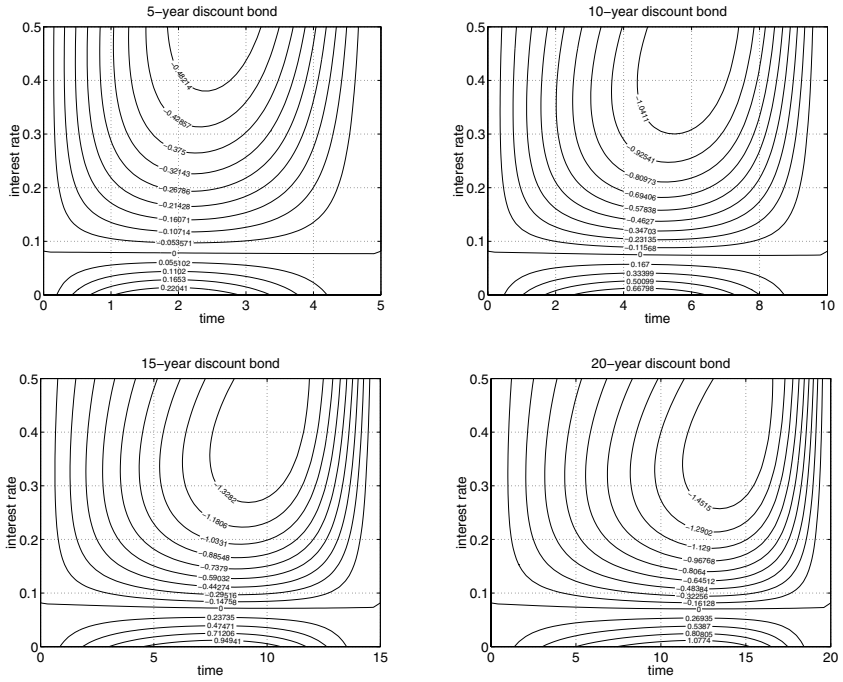

FIG. 6.5. *Contour plots of price differences.*

Numerical results show that $u_2'(t)$ is a strictly increasing function, and its graph looks like an exponential function, while the stronger condition (3.15) holds only for $T^* < 53.29$. The graphs of $\psi(t)$ and $\phi(t)/\psi(t)$ are displayed in Figure 6.4, which shows that the long-term adjustment speed of ECIR model is approximately 0.2, which is the same as the smaller one of the TCIR model. The figure also shows that $\psi(t)$ is a decreasing function while $\phi(t)/\psi(t)$ is not monotone. We observed that the long-term interest rate of the ECIR model is approximately 8.17%, which is smaller than that (9%) of the TCIR model. We display the contour maps of the differences of the bond prices under the extended Vasicek model and the ECIR model and graphs of bond prices in Figure 6.5 and 6.6, respectively. We have the same observations from these pictures as in Example 1.

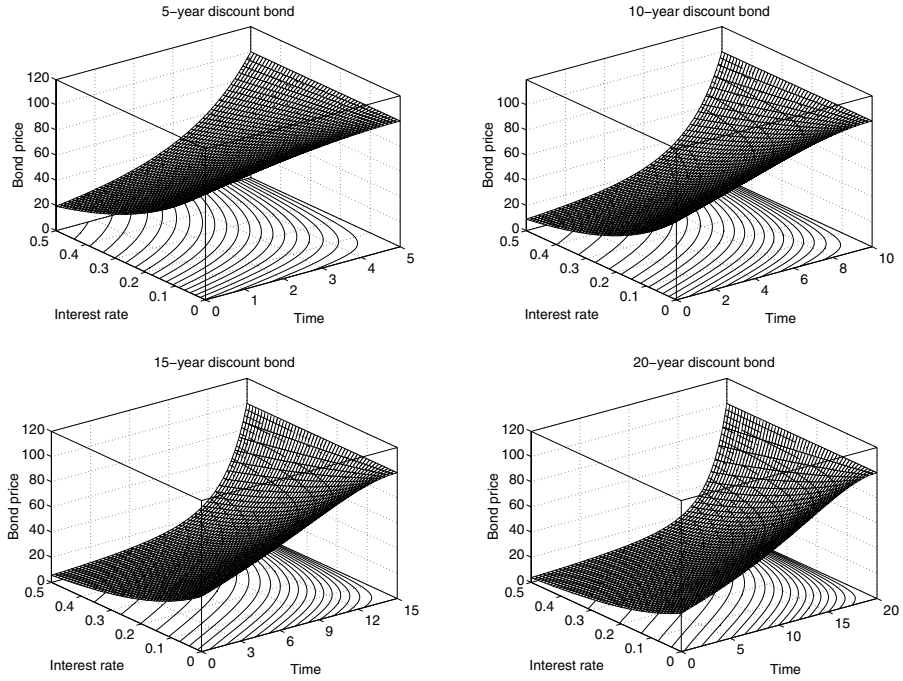

FIG. 6.6. *Bond prices.*

7. Conclusions. In this paper we studied the inverse problem for calibrating the extended CIR model. The solution existence and uniqueness of the problem are established under appropriate assumptions. In other words, the time-dependent parameters of the extended CIR model can be uniquely determined by the current term structure of interest rates and either the current volatilities of all spot interest rates or the current volatilities of all forward interest rates. A fourth order algorithm is proposed to compute the approximations of the time-dependent parameters and the discount bond prices. Numerical results have shown that our algorithm is very accurate and rapid. Comparisons with the Vasicek model and the extended Vasicek model are also presented, and we find that the extended CIR model gives higher/lower discount bond prices for high/lower interest rates. As expected, the bond price is an increasing function of time and a decreasing function of interest rate. Work is ongoing to study numerical methods for pricing other interest rate derivatives, for example, bond options and caps, under the extended CIR model.

THE CONVERGENCE OF REGULARIZED MINIMIZERS FOR CAVITATION PROBLEMS IN NONLINEAR ELASTICITY*

JEYABAL SIVALOGANATHAN†, SCOTT J. SPECTOR‡, AND VIVEKA TILAKRAJ§

Abstract. Consider a nonlinearly elastic body which occupies the region $\Omega \subset \mathbb{R}^m$ $(m = 2, 3)$ in its reference state and which is held in tension under prescribed boundary displacements on $\partial\Omega$. Let $\mathbf{x}_0 \in \Omega$ be any fixed point in the body. It is known from variational arguments that, for sufficiently large boundary displacements, there may exist discontinuous weak solutions of the equilibrium equations corresponding to a hole forming at $\mathbf{x}_0$ in the deformed body (this is the phenomenon of cavitation). For each $\epsilon > 0$, define the regularized domains $\Omega_\epsilon = \Omega \backslash \overline{B_\epsilon(\mathbf{x}_0)}$ which contain a preexisting hole of radius $\epsilon > 0$ centered on $\mathbf{x}_0$. Now consider the corresponding mixed displacement/traction problem on Ω_ϵ in which the boundary $\partial\Omega$ is subject to the same boundary displacements and the deformed cavity surface (i.e., the image of ∂B_ϵ) is required to be stress-free. It follows from variational arguments that there exists a weak solution $\mathbf{u}_\epsilon$ of this problem for each $\epsilon > 0$. In this paper we prove convergence of these regularized minimizers $\mathbf{u}_\epsilon$ in the limit as $\epsilon \to 0$. In particular, we show that if $\epsilon_n \to 0$, then, passing to a subsequence, $\mathbf{u}_{\epsilon_n} \to \mathbf{u}$, where $\mathbf{u}$ is a minimizer for the original pure displacement problem on Ω.

Finally, we study the effect on cavitation of regularizing the variational problem by introducing a surface energy term which penalizes the formation and growth of cavities.

1. Introduction.

Let $\Omega \subset \mathbb{R}^m$ $(m = 2, 3)$ denote the region occupied by a nonlinearly elastic body in its reference configuration. A deformation of the body corresponds to a map $\mathbf{u} : \Omega \to \mathbb{R}^m$ that lies in the Sobolev space $W^{1,1}(\Omega; \mathbb{R}^m)$, is one-to-one a.e., and satisfies

$$\det \nabla \mathbf{u}(\mathbf{x}) > 0 \quad \text{for a.e. } \mathbf{x} \in \Omega. \tag{1.1}$$

In hyperelasticity the total energy stored under such a deformation is given by

$$E(\mathbf{u}) = \int_\Omega W(\mathbf{x}, \nabla \mathbf{u}(\mathbf{x}))\, d\mathbf{x}, \tag{1.2}$$

where $W : \overline{\Omega} \times \mathrm{M}^{m\times m}_+ \to [0, \infty)$ is the stored energy function of the material and $\mathrm{M}^{m\times m}_+$ denotes the set of real $m \times m$ matrices with positive determinant. We consider

the displacement problem in which we require

$$\mathbf{u}(\mathbf{x}) = \mathbf{A}\mathbf{x} \quad \text{for } \mathbf{x} \in \partial\Omega, \tag{1.3}$$

where $\mathbf{A} \in \mathrm{M}^{m\times m}_{+}$ is fixed.

The radial problem. Following Ball's seminal paper [1], much work has been carried out in the variational setting on the existence of discontinuous radial minimizers for (1.2) corresponding to cavitation (see, e.g., the review article [12] and the references therein). In this approach $\mathbf{A} = \lambda\mathbf{I}$, $\lambda > 0$, $\Omega = B$ is the unit ball in $\mathbb{R}^m$, and deformations are of the form

$$\mathbf{u}(\mathbf{x}) = r(R)\frac{\mathbf{x}}{|\mathbf{x}|},$$

where $r : [0,1] \to [0,\infty)$ and $R = |\mathbf{x}|$. It is known that there are large classes of physically reasonable W for which there exists a critical value of the boundary displacement λ_{crit} such that

(i) for $\lambda \le \lambda_{\text{crit}}$, the unique radial energy minimizer is the homogeneous deformation corresponding to $r(R) \equiv \lambda R$;

(ii) for $\lambda > \lambda_{\text{crit}}$, the unique radial energy minimizer satisfies $r(0) > 0$, corresponding to a deformation that produces a hole at the center of the initially perfect ball (this is the phenomenon of cavitation).

Example 1.1. A typical class of stored energy functions for which the above results hold is given by

$$W(\mathbf{x},\mathbf{F}) = c|\mathbf{F}|^p + \Gamma(\det\mathbf{F}) \quad \forall\,\mathbf{F} \in \mathrm{M}^{m\times m}_{+} \text{ and } \mathbf{x} \in \overline{\Omega}, \tag{1.4}$$

where $c > 0$, $1 \le p < m$, and Γ is a convex function that grows superlinearly and satisfies $\Gamma(d) \to +\infty$ as $d \to 0^+$.

The discontinuous minimizers with r as in (ii) are weak solutions of the corresponding equilibrium equations (see, e.g., [1]). Earlier approaches to cavitation had not been variational and tended to model cavitation as the growth of small preexisting voids in the material (see, e.g., [9] in the context of nonlinear elasticity and [10] in the context of elastoplasticity).

There are various ways of reconciling the two approaches. In particular, results of [18] in the variational setting (see also the example in [11]) show that radial equilibrium solutions

$$\mathbf{u}_\epsilon(\mathbf{x}) = r_\epsilon(R)\frac{\mathbf{x}}{|\mathbf{x}|}$$

for the mixed displacement/zero-traction problem in which B is replaced by $B_\epsilon = \{\mathbf{x} : \epsilon < |\mathbf{x}| < 1\}$ (i.e., a ball with a preexisting hole of radius ϵ in the reference configuration) converge to the radial minimizer for B studied in [1] as $\epsilon \to 0$. In particular, $\sup_{R\in[\epsilon,1]} |r_\epsilon(R) - r(R)| \to 0$ as $\epsilon \to 0$, where $r(R)$ is the minimizer given in (i) and (ii) above (see Figure 1 and also the discussion in [1] for the case of incompressible elasticity).

The nonsymmetric case. The first results extending Ball's original variational approach to nonsymmetric situations while allowing cavitation (i.e., discontinuities) to occur at any point in the body are contained in Müller and Spector [16]. A key element in their approach is an analytical restriction on the class of admissible

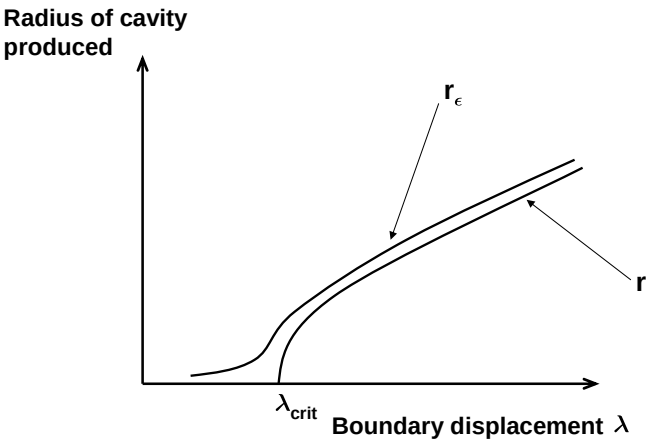

FIG. 1. *Bifurcation diagram for solid and punctured balls.*

deformations $\mathbf{u}$ called condition (INV). Condition (INV) is the requirement that $\mathbf{u}$ be monotone[1] in the sense of Lebesgue and that, roughly speaking, holes created in one part of the body cannot be filled by material from elsewhere (see section 2.3 for the precise definition). Subsequent work in [19], in the variational setting, proposed an alternative model in which cavitation could occur only at a, possibly large, number of infinitesimal flaws in the material. This was modelled mathematically by using admissible deformations whose possible point discontinuities are constrained to be at the specified flaw points: let $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_n \in \Omega$ be the flaw points and minimize the total energy (1.2) in the class of deformations that satisfy (1.1), (1.3), condition (INV), and

$$\mathrm{Det}\nabla\mathbf{u} = (\det \nabla\mathbf{u})\mathcal{L}^m + \sum_{i=0}^{n} \alpha_i \delta_{\mathbf{x}_i},$$

where $\mathrm{Det}\nabla\mathbf{u}$ denotes the distributional Jacobian of $\mathbf{u}$, $\mathcal{L}^m$ denotes m-dimensional Lebesgue measure, $\delta_{\mathbf{x}_i}$ is the Dirac measure supported at $\mathbf{x}_i$, and $\alpha_i \geq 0$ is the volume of the hole formed at $\mathbf{x}_i$ by the deformation $\mathbf{u}$ (see section 2.4 for further details). The existence of a minimizer in this class follows from [19], and it is a consequence of a result in [21] that if the matrix $\mathbf{A}$ in the boundary condition (1.3) is "sufficiently large,"[2] then any minimizer $\mathbf{u}$ must satisfy $\alpha_i > 0$ for at least one i.

In analogy with the radial problems outlined earlier, an alternative approach is to regularize by replacing the flaw points with preexisting voids in the reference configuration of maximum radius $\epsilon > 0$. The purpose of this paper is to examine the behavior of energy minimizers for these more regular problems in the limit as $\epsilon \to 0$. In particular we consider the case of one flaw point at $\mathbf{x}_0 \in \Omega$ and study the convergence of minimizers for these regularized problems to the minimizers obtained in [19]. For the convenience of the reader, we next outline the main convergence result in the case of the class of stored energy functions (1.4), deferring precise technical details to later in the paper. However, it should be noted that the results of this paper apply to much more general polyconvex energy functions (see hypotheses (H1)–(H4) in section 3).

[1] Condition (INV) requires, in particular, that $\mathbf{u} \in W^{1,p}(\Omega, \mathbb{R}^m)$, $p > m - 1$.

[2] This is the case, in particular, if $\mathbf{A} = t\mathbf{B}$, where $\mathbf{B} \in \mathrm{M}^{m\times m}_+$ is fixed and $t > 0$ is sufficiently large.

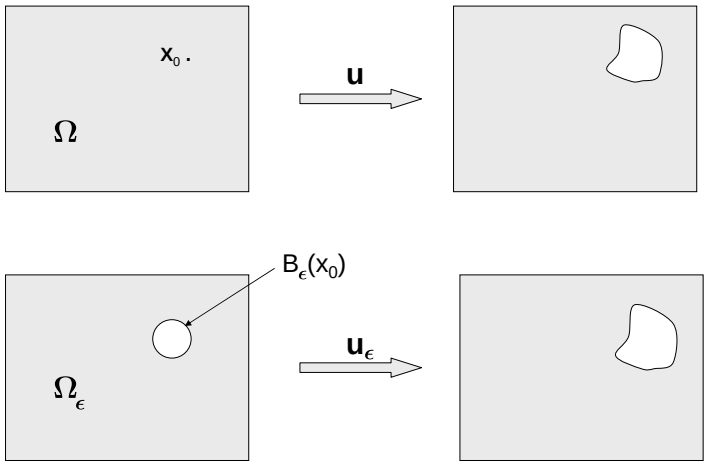

FIG. 2. *Deformations of the original and regularized domains.*

The underlying pure displacement problem. In essence, the underlying problem is to minimize the integral functional E given by (1.2) on a class of deformations[3,4] $\mathbf{u} \in W^{1,p}(\Omega, \mathbb{R}^m)$, $p \in (m-1, m)$, that satisfy (1.1), (1.3), condition (INV) on Ω, and

$$\mathrm{Det}\nabla\mathbf{u} = (\det \nabla\mathbf{u})\mathcal{L}^m + \alpha_0\delta_{\mathbf{x}_0},\ \alpha_0 \geq 0.$$

The existence of a minimizer for this problem follows from [19].

The regularized mixed displacement/traction problem. For each $\epsilon > 0$, define the domains $\Omega_\epsilon = \Omega\backslash\overline{B_\epsilon(\mathbf{x}_0)}$ which contain a preexisting hole of radius $\epsilon > 0$ centered on $\mathbf{x}_0$ (see Figure 2). Now consider the mixed displacement/traction problem on Ω_ϵ in which the outer boundary $\partial\Omega$ is subject to the same boundary displacements (1.3) and the deformed cavity surface (i.e., the image of ∂B_ϵ) is required to be stress-free. The corresponding variational problem is to minimize

$$E_\epsilon(\mathbf{u}_\epsilon) = \int_{\Omega_\epsilon} W(\mathbf{x}, \nabla\mathbf{u}_\epsilon(\mathbf{x}))\, d\mathbf{x}$$

on a class of deformations[5] $\mathbf{u}_\epsilon \in W^{1,p}(\Omega_\epsilon, \mathbb{R}^m)$, $p \in (m-1, m)$, that satisfy (1.3), condition (INV) on Ω_ϵ,

$$\det \nabla\mathbf{u}_\epsilon > 0 \text{ a.e. in } \Omega_\epsilon,$$

and

$$\mathrm{Det}\nabla\mathbf{u}_\epsilon = (\det \nabla\mathbf{u}_\epsilon)\mathcal{L}^m.$$

[3] In fact, for technical reasons, we work with the homogeneous extension $\mathbf{u}^e$ of $\mathbf{u}$ which is defined on a slightly larger domain $\Omega^e \supset \Omega$. It is obtained by extending $\mathbf{u}$ by the homogeneous deformation $\mathbf{Ax}$ (see section 2.3 and Remark 3.2).

[4] For interesting results in the borderline case, $p = m - 1$, see Conti and De Lellis [4].

[5] As in the pure displacement problem, we work with homogeneous extensions of these maps.

In Theorem 4.2 we prove convergence of minimizers for these regularized problems in the limit as $\epsilon \to 0$. In particular, we show that if $\epsilon_n \to 0$ and $(\mathbf{u}_{\epsilon_n})$ is a corresponding sequence of minimizers, then, passing to a subsequence if necessary, $\mathbf{u}_{\epsilon_n} \to \mathbf{u}$, where $\mathbf{u}$ is a minimizer for the pure displacement problem on the original domain Ω.

The above results are quite general and do not depend on the shape of the excluded regions used to obtain Ω_ϵ. In particular, the balls $B_\epsilon(\mathbf{x}_0)$ which are removed to produce Ω_ϵ could be replaced by a nested sequence of (nonspherical) regions around $\mathbf{x}_0$ whose diameters converge to zero as $\epsilon \to 0$.

In section 5, we consider the effect of regularizing the pure displacement variational problem by adding a surface energy term to the total energy which penalizes the formation and growth of cavities. In the standard model, in which surface energy is proportional to the new surface area created, cavitation is still energetically favorable for sufficiently severe boundary displacements. However, in this case we show that there is no longer bifurcation from a homogeneous deformation in the sense that there do not exist discontinuous energy minimizers producing cavities of arbitrarily small volume. Our results thus generalize the recent results of Dollhofer et al. [5], who show that the addition of surface energy in radial cavitation of an incompressible neo-Hookean material will induce the sudden formation of a single cavity of finite radius, rather than the gradual opening of a hole from zero volume.

2. Background.

2.1. Notation. Let Ω denote a nonempty, bounded, connected, open subset of $\mathbb{R}^m$ with Lipschitz boundary $\partial\Omega$ (see [6] or [13]). We denote by $L^p(\Omega)$ and $W^{1,p}(\Omega)$ the usual spaces of p-summable and Sobolev functions, respectively. We use the notation $L^p(\Omega;\mathbb{R}^m)$, etc., for vector-valued maps. A function ϕ is in $L^p_{\text{loc}}(\Omega)$ if $\phi \in L^p(U)$ for all open sets $U \subset\subset \Omega$; i.e., $U \subset K_U \subset \Omega$ for some compact set K_U. Weak convergence in these spaces will be indicated by the half arrow $\rightharpoonup$.

We denote m-dimensional Lebesgue measure by $\mathcal{L}^m$ and k-dimensional Hausdorff measure by $\mathcal{H}^k$. We write

$$B(\mathbf{z},\epsilon) := \{\mathbf{x} \in \mathbb{R}^m : |\mathbf{x}-\mathbf{z}| < \epsilon\}$$

for the open ball of radius $\epsilon > 0$ centered at $\mathbf{z} \in \mathbb{R}^m$ (we also use the notation $B_\epsilon(\mathbf{z})$ for $B(\mathbf{z},\epsilon)$).

Let $\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$ with $1 \le p < m$. We will be interested in pointwise properties of $\mathbf{u}$ as well as restrictions of $\mathbf{u}$ to lower-dimensional sets. We will not identify maps that are equal a.e. and choose to work with the precise representative $\mathbf{u}^* : \Omega \to \mathbb{R}^m$ defined by

$$\mathbf{u}^*(\mathbf{x}) := \begin{cases} \lim\limits_{\rho\to 0^+} \dfrac{1}{\mathcal{L}^m(B(\mathbf{x},\rho))} \displaystyle\int_{B(\mathbf{x},\rho)} \mathbf{u}(\mathbf{z})\, d\mathbf{z} & \text{if the limit exists,} \\ \mathbf{0} & \text{otherwise.} \end{cases}$$

We shall make use of the fact that if $\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$ with $1 \le p < m$, then the above limit exists for every $\mathbf{x} \in \Omega\backslash P$, where $\mathcal{H}^{m-1}(P) = 0$. Thus, in particular, one can use the precise representative as a representative of the trace on $(m-1)$-dimensional surfaces. Moreover, if $p > m-1$, then $\mathcal{H}^1(P) = 0$, and consequently for each $\mathbf{z} \in \Omega$ the above limit is defined at *every* point on $\partial B(\mathbf{z},r)$ for almost every $r \in (0, r_{\mathbf{z}})$, where $r_{\mathbf{z}} = \text{dist}(\mathbf{z},\partial\Omega)$. For a thorough discussion of precise representative we refer the reader to [6].

2.2. The topological image. In this section we briefly recall some facts about the Brouwer degree (see, e.g., [7] or [22] for more details). Let $\mathbf{u} : \overline{\Omega} \to \mathbb{R}^m$ be a C^1 map. If $\mathbf{y}_0 \in \mathbb{R}^m \backslash \mathbf{u}(\partial\Omega)$ is such that $\det \nabla \mathbf{u}(\mathbf{x}) \neq 0$ for all $\mathbf{x} \in \mathbf{u}^{-1}(\mathbf{y}_0)$, then the degree is defined by

$$\deg(\mathbf{u}, \Omega, \mathbf{y}_0) := \sum_{\mathbf{x} \in \mathbf{u}^{-1}(\mathbf{y}_0)} \operatorname{sgn}[\det \nabla \mathbf{u}(\mathbf{x})], \tag{2.1}$$

where $\operatorname{sgn}(t) = 1$ for $t > 0$ and $\operatorname{sgn}(t) = -1$ for $t < 0$. In particular, if $\mathbf{g} : \overline{\Omega} \to \mathbb{R}^m$ is a diffeomorphism with $\det \nabla \mathbf{g} > 0$ on Ω, then from (2.1) we conclude that

$$\deg(\mathbf{g}, \Omega, \mathbf{y}_0) = \begin{cases} 1 & \text{if } \mathbf{y}_0 \in \mathbf{g}(\Omega), \\ 0 & \text{if } \mathbf{y}_0 \in \mathbb{R}^m \backslash \mathbf{g}(\overline{\Omega}). \end{cases}$$

If ϕ is a C^∞ function supported in the connected component of $\mathbb{R}^m \backslash \mathbf{u}(\partial\Omega)$ that contains $\mathbf{y}_0$, then one can show that

$$\int_\Omega \phi(\mathbf{u}(\mathbf{x})) \det \nabla \mathbf{u}(\mathbf{x})\, d\mathbf{x} = \deg(\mathbf{u}, \Omega, \mathbf{y}_0) \int_{\mathbb{R}^m} \phi(\mathbf{y})\, d\mathbf{y}.$$

One can now define $\deg(\mathbf{u}, \Omega, \mathbf{y})$ for any continuous function $\mathbf{u} : \Omega \to \mathbb{R}^m$ and any $\mathbf{y} \in \mathbb{R}^m \backslash \mathbf{u}(\partial\Omega)$ by using this formula and approximating by C^∞ functions. Moreover, the degree depends only on $\mathbf{u}|_{\partial\Omega}$. Accordingly we can write $\deg(\mathbf{u}, \partial\Omega, \mathbf{y})$ instead of $\deg(\mathbf{u}, \Omega, \mathbf{y})$.

DEFINITION 2.1. *Let $B(\mathbf{z}, r) \subset \Omega$ and suppose that $\overline{\mathbf{u}} : \partial B(\mathbf{z}, r) \to \mathbb{R}^m$ is continuous. We define the topological image of $B(\mathbf{z}, r)$ under $\overline{\mathbf{u}}$ by*

$$\operatorname{im}_{\mathrm{T}}(\overline{\mathbf{u}}, B(\mathbf{z}, r)) := \{\mathbf{y} \in \mathbb{R}^m \backslash \overline{\mathbf{u}}(\partial B(\mathbf{z}, r)) : \ \deg(\overline{\mathbf{u}}, \partial B(\mathbf{z}, r), \mathbf{y}) \neq 0\}. \tag{2.2}$$

Remark 2.2. Let $\mathbf{g} : \overline{B(\mathbf{z}, r)} \to \mathbb{R}^m$ be a homeomorphism. If $\overline{\mathbf{u}} : \partial B(\mathbf{z}, r) \to \mathbb{R}^m$ is such that $\overline{\mathbf{u}}(\partial B(\mathbf{z}, r)) = \mathbf{g}(\partial B(\mathbf{z}, r))$, then

$$\operatorname{im}_{\mathrm{T}}(\overline{\mathbf{u}}, B(\mathbf{z}, r)) = \mathbf{g}(B(\mathbf{z}, r)).$$

2.3. Invertibility condition (INV). In nonlinear elasticity one is interested in globally invertible maps since, in general, matter cannot interpenetrate itself. We say that $\mathbf{u} \in W^{1,p}(\Omega, \mathbb{R}^m)$, $p \geq 1$, is *one-to-one* a.e. if there is a Lebesgue null set $N \subset \Omega$ such that $\mathbf{u}|_{\Omega \backslash N}$ is injective. Unfortunately, if $p < m$, the weak limit of a sequence of maps which are one-to-one a.e. need not be one-to-one a.e. (see, e.g., [16, section 11]). A property that is slightly stronger than one-to-one a.e. is therefore needed.

DEFINITION 2.3. *Let $r_{\mathbf{z}} = \operatorname{dist}(\mathbf{z}, \partial\Omega)$. We say that $\mathbf{u} : \Omega \to \mathbb{R}^m$ satisfies invertibility condition* (INV) *on Ω, provided that for every $\mathbf{z} \in \Omega$ there exists an $\mathcal{L}^1$ null set $N_{\mathbf{z}}$ such that, for all $r \in (0, r_{\mathbf{z}}) \backslash N_{\mathbf{z}}$,*

(o) *$\mathbf{u}|_{\partial B(\mathbf{z}, r)}$ is continuous;*

(i) *$\mathbf{u}(\mathbf{x}) \in \operatorname{im}_{\mathrm{T}}(\mathbf{u}, B(\mathbf{z}, r)) \cup \mathbf{u}(\partial B(\mathbf{z}, r))$ for $\mathcal{L}^m$ a.e. $\mathbf{x} \in \overline{B(\mathbf{z}, r)}$;*

(ii) *$\mathbf{u}(\mathbf{x}) \in \mathbb{R}^m \backslash \operatorname{im}_{\mathrm{T}}(\mathbf{u}, B(\mathbf{z}, r))$ for $\mathcal{L}^m$ a.e. $\mathbf{x} \in \Omega \backslash \overline{B(\mathbf{z}, r)}$.*

The next results show that condition (INV) is preserved under weak convergence and that mappings that satisfy condition (INV) and have nonzero Jacobian a.e. are one-to-one a.e.

PROPOSITION 2.4 (see [16, Lemma 3.3]). *Let $p > m-1$ and suppose that $(\mathbf{u}_n^*)$ is a sequence in $W^{1,p}(\Omega;\mathbb{R}^m)$ that satisfies condition* (INV). *Suppose also that*

$$\mathbf{u}_n \rightharpoonup \mathbf{u} \quad \text{in} \quad W^{1,p}(\Omega;\mathbb{R}^m).$$

Then $\mathbf{u}^*$ satisfies condition (INV).

PROPOSITION 2.5 (see [16, Lemma 3.4]). *Let $\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$ with $p > m-1$. Suppose that $\det \nabla \mathbf{u} \neq 0$ a.e. and that $\mathbf{u}^*$ satisfies condition* (INV). *Then $\mathbf{u}$ is one-to-one a.e.*

DEFINITION 2.6. *We say that the function $\mathbf{u}$ satisfies condition* (INV) *on $\Omega\backslash\{\mathbf{x}_0\}$ if $\mathbf{u}$ satisfies condition* (INV) *on $\Omega\backslash\overline{B(\mathbf{x}_0,\delta)}$ for every sufficiently small $\delta > 0$.*

Homogeneous extensions of maps. Let $\Omega \subset\subset \Omega^{\mathrm{e}}$, where Ω^{e} is a bounded, open, connected set with smooth boundary and suppose that $\mathbf{u}^{\mathrm{h}} : \Omega^{\mathrm{e}} \to \mathbb{R}^m$ is the orientation preserving homogeneous map

$$\mathbf{u}^{\mathrm{h}}(\mathbf{x}) \equiv \mathbf{A}\mathbf{x},$$

where $\mathbf{A} \in \mathrm{M}^{m\times m}_+$. If $\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$ satisfies $\mathbf{u} = \mathbf{u}^{\mathrm{h}}$ on $\partial\Omega$, then we define its homogeneous extension $\mathbf{u}^e : \Omega^{\mathrm{e}} \to \mathbb{R}^m$ by

$$\mathbf{u}^e(\mathbf{x}) := \begin{cases} \mathbf{u}(\mathbf{x}) & \text{if } \mathbf{x} \in \Omega, \\ \mathbf{A}\mathbf{x} & \text{if } \mathbf{x} \in \Omega^{\mathrm{e}}\backslash\Omega \end{cases} \tag{2.3}$$

and note that $\mathbf{u}^e \in W^{1,p}(\Omega^{\mathrm{e}};\mathbb{R}^m)$. More generally, let $\mathbf{x}_0 \in \Omega$ and $\epsilon \geq 0$ satisfy $B(\mathbf{x}_0,\epsilon) \subset\subset \Omega \subset\subset \Omega^{\mathrm{e}}$ and define

$$\Omega_\epsilon := \Omega\backslash\overline{B(\mathbf{x}_0,\epsilon)}, \qquad \Omega^{\mathrm{e}}_\epsilon := \Omega^{\mathrm{e}}\backslash\overline{B(\mathbf{x}_0,\epsilon)} \tag{2.4}$$

(this corresponds to a preexisting void of radius ϵ in the reference configuration). If $\mathbf{u}_\epsilon \in W^{1,p}(\Omega_\epsilon;\mathbb{R}^m)$ satisfies $\mathbf{u}_\epsilon = \mathbf{u}^{\mathrm{h}}$ on $\partial\Omega$, then we define its homogeneous extension $\mathbf{u}^e_\epsilon : \Omega^{\mathrm{e}}_\epsilon \to \mathbb{R}^m$ by

$$\mathbf{u}^e_\epsilon(\mathbf{x}) := \begin{cases} \mathbf{u}_\epsilon(\mathbf{x}) & \text{if } \mathbf{x} \in \Omega_\epsilon, \\ \mathbf{A}\mathbf{x} & \text{if } \mathbf{x} \in \Omega^{\mathrm{e}}\backslash\Omega \end{cases} \tag{2.5}$$

and note that[6] $\mathbf{u}^e_\epsilon \in W^{1,p}(\Omega^{\mathrm{e}}_\epsilon;\mathbb{R}^m)$. The use of such an extension allows us to obtain the following result, whose proof we omit since it is similar to that of Theorem TL in [17].

LEMMA 2.7. *Let $\mathbf{u}_\epsilon \in W^{1,p}(\Omega_\epsilon;\mathbb{R}^m)$, $p > m-1$, $\epsilon \geq 0$, satisfy $\mathbf{u}_\epsilon = \mathbf{u}^{\mathrm{h}}$ on $\partial\Omega$. Suppose that its homogeneous extension $\mathbf{u}^e_\epsilon$, given by* (2.5), *is one-to-one a.e. on $\Omega^{\mathrm{e}}_\epsilon$. Then*

$$\mathbf{u}_\epsilon(\mathbf{x}) \in \mathbf{u}^{\mathrm{h}}(\overline{\Omega}) \quad \textit{for a.e. } \mathbf{x} \in \Omega_\epsilon.$$

[6] If $\epsilon = 0$, then there is no preexisting hole. In this case, $\Omega_0 = \Omega$, $\Omega^{\mathrm{e}}_0 = \Omega^{\mathrm{e}}$, and thus $\mathbf{u}_0 = \mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$ and $\mathbf{u}^e_0 = \mathbf{u}^e \in W^{1,p}(\Omega^{\mathrm{e}};\mathbb{R}^m)$ in accordance with the earlier definition (2.3).

2.4. The distributional Jacobian. Given a mapping $\mathbf{u} \in W^{1,p}(\Omega, \mathbb{R}^m)$, with $p > \frac{m^2}{m+1}$, it follows (using the Sobolev embedding theorem) that the distributional Jacobian defined by

$$(\mathrm{Det}\nabla\mathbf{u})(\phi) := -\int_\Omega \frac{1}{m}\left([\mathrm{adj}\,\nabla\mathbf{u}]\mathbf{u}\right)\cdot\nabla\phi\,d\mathbf{x} \quad \forall\phi \in C_0^\infty(\Omega) \tag{2.6}$$

is a well-defined distribution (where $\mathrm{adj}\,\nabla\mathbf{u}$ denotes the adjugate matrix of $\nabla\mathbf{u}$, that is, the transposed matrix of cofactors of $\nabla\mathbf{u}$). The definition follows from the well-known formula for expressing $\det\nabla\mathbf{u}$ as a divergence (see, e.g., [14] for further details and references).

Next, suppose that $\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$, $p > m-1$, satisfies (INV) on Ω. Then $\mathbf{u} \in L^\infty_{\mathrm{loc}}(\Omega)$, and hence $\mathrm{Det}\,\nabla\mathbf{u}$ is again a well-defined distribution. Moreover, it follows from [16, Lemma 8.1] that if $\mathbf{u}$ further satisfies $\det\nabla\mathbf{u} > 0$ a.e., then $\mathrm{Det}\,\nabla\mathbf{u}$ is a Radon measure and

$$\mathrm{Det}\,\nabla\mathbf{u} = (\det\nabla\mathbf{u})\mathcal{L}^m + \mu^s,$$

where μ^s is singular with respect to $\mathcal{L}^m$. In this paper we will be interested in the case when μ^s is a Dirac measure[7] of the form $\alpha\delta_{\mathbf{x}_0}$ (where $\alpha > 0$ and $\mathbf{x}_0 \in \Omega$) which corresponds to $\mathbf{u}$ creating a cavity of volume α at the point $\mathbf{x}_0$.[8]

Example 2.8. Let $\Omega = B$ be the unit ball in $\mathbb{R}^3$ (i.e., $m = 3$) and let

$$\mathbf{u}(\mathbf{x}) = (|\mathbf{x}| + c)\frac{\mathbf{x}}{|\mathbf{x}|}, \quad c > 0. \tag{2.7}$$

Then $\mathbf{u}$ produces a hole of radius c at the center of the deformed ball. In this case it can be shown that

$$\mathrm{Det}\,\nabla\mathbf{u} = (\det\nabla\mathbf{u})\mathcal{L}^3 + \frac{4}{3}\pi c^3\delta_{\mathbf{0}}. \tag{2.8}$$

The last expression (2.8) is to be interpreted in the sense of distributions so that

$$(\mathrm{Det}\,\nabla\mathbf{u})(\phi) = \int_\Omega (\det\nabla\mathbf{u}(\mathbf{x}))\phi(\mathbf{x})\,d\mathbf{x} + \frac{4}{3}\pi c^3\phi(0) \quad \forall\phi \in C_0^\infty(\Omega)$$

(notice that the coefficient of $\delta_{\mathbf{0}}$ in (2.8) is the volume of the hole that is formed at the origin under the deformation (2.7)).

3. The energy: Existence of minimizers. We consider an m-dimensional elastic body which, in its reference state, occupies the region $\Omega \subset \mathbb{R}^m$. We let $W \in C(\overline{\Omega} \times \mathrm{M}^{m\times m}_+; [0,\infty))$ denote the stored energy function for the body. For ease of exposition we state the following conditions on W in the case of three dimensions (i.e., $m = 3$). Let $p > 2 = m-1$, $D = \mathrm{M}^{3\times3} \times \mathrm{M}^{3\times3} \times (0,\infty)$; then we will refer to the following hypotheses on W:

(H1) (polyconvexity) there exists $\Phi : \Omega \times D \to \overline{\mathbb{R}}$ such that for a.e. $\mathbf{x} \in \Omega$

$$W(\mathbf{x},\mathbf{F}) = \Phi(\mathbf{x}, (\mathbf{F}, \mathrm{adj}\,\mathbf{F}, \det\mathbf{F})) \quad \forall\,\mathbf{F} \text{ such that } \det\mathbf{F} > 0,$$

where $\Phi(\mathbf{x},\cdot) : D \to \overline{\mathbb{R}}$ is convex for a.e. $\mathbf{x} \in \Omega$;

[7] Other assumptions on the support of the singular measure μ^s may be relevant for modelling different forms of fracture. See also [15] for further results on the singular support of the distributional Jacobian.

[8] Note that such a cavity need not be spherical.

(H2) (continuity) $\Phi(\mathbf{x},\cdot) : D \to \overline{\mathbb{R}}$ is continuous for a.e. $\mathbf{x} \in \Omega$ and $\Phi(\cdot, N) : \Omega \to \overline{\mathbb{R}}$ is measurable for every $N \in D$;

(H3) (coercivity) $W(\mathbf{x},\mathbf{F}) \geq C|\mathbf{F}|^p + \Gamma(\det \mathbf{F}) + K$ for a.e. $\mathbf{x} \in \Omega$, where $C > 0$, K are constants, and $\Gamma : (0,\infty) \to \mathbb{R}$ is a convex function satisfying $\Gamma(t)/t \to +\infty$ as $t \to +\infty$;

(H4) $\Gamma(t) \to +\infty$ as $t \to 0^+$.

Now fix $\mathbf{x}_0 \in \Omega$ and for each $0 \leq \epsilon < \operatorname{dist}(\mathbf{x}_0, \partial\Omega)$ recall the definition of the homogeneous extension of a map given in section 2.3 (see (2.3)–(2.5) in particular). For each such ϵ we seek a minimizer for the total elastic energy

$$E_\epsilon(\mathbf{u}_\epsilon) = \int_{\Omega_\epsilon} W(\mathbf{x}, \nabla \mathbf{u}_\epsilon(\mathbf{x}))\, d\mathbf{x}$$

in the class of admissible functions

$$\mathcal{A}_\epsilon(\mathbf{x}_0) = \{\mathbf{u}_\epsilon \in W^{1,p}(\Omega_\epsilon;\mathbb{R}^m) : \mathbf{u}_\epsilon|_{\partial\Omega} = \mathbf{u}^{\mathrm{h}},\ (\mathbf{u}_\epsilon^e)^* \text{ satisfies (INV) on } \Omega_\epsilon^{\mathrm{e}},\ \det \nabla \mathbf{u}_\epsilon > 0 \text{ a.e.},\ \operatorname{Det} \nabla \mathbf{u}_\epsilon^e = (\det \nabla \mathbf{u}_\epsilon^e)\mathcal{L}^m\}$$

if $\epsilon > 0$, and in the class

$$\mathcal{A}_0(\mathbf{x}_0) = \{\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m) : \mathbf{u}|_{\partial\Omega} = \mathbf{u}^{\mathrm{h}},\ (\mathbf{u}^e)^* \text{ satisfies (INV) on } \Omega^{\mathrm{e}},\ \det \nabla \mathbf{u} > 0 \text{ a.e.},\ \operatorname{Det} \nabla \mathbf{u}^e = (\det \nabla \mathbf{u}^e)\mathcal{L}^m + \alpha_{\mathbf{u}} \delta_{\mathbf{x}_0}\} \tag{3.1}$$

if $\epsilon = 0$, where $\alpha_{\mathbf{u}} \geq 0$ is a scalar depending on the map $\mathbf{u}$ and $\delta_{\mathbf{x}_0}$ denotes the Dirac measure with support at $\mathbf{x}_0$. Thus, $\mathcal{A}_0(\mathbf{x}_0)$ contains maps $\mathbf{u}$ that produce a cavity of volume $\alpha_{\mathbf{u}}$ located at $\mathbf{x}_0 \in \Omega$.

PROPOSITION 3.1 (see [19, Theorem 4.1]). *Let $p > m-1$ and $\epsilon \geq 0$. Suppose that $W \in C(\overline{\Omega} \times \mathrm{M}^{m\times m}_+; [0,\infty))$ satisfies hypotheses* (H1)–(H4). *Then E_ϵ attains its infimum on $\mathcal{A}_\epsilon(\mathbf{x}_0)$.*[9]

Thus both the *mixed displacement/traction problem* ($\epsilon > 0$) and the *pure displacement problem* ($\epsilon = 0$) have energy minimizers. In the next section we will show that a subsequence of the minimizers of the mixed problems converges to a minimizer of the displacement problem as the preexisting hole size shrinks to zero.

Remark 3.2. The reasons for requiring that the homogeneous extensions $\mathbf{u}^e, \mathbf{u}_\epsilon^e$, rather than the original maps $\mathbf{u}, \mathbf{u}_\epsilon$, satisfy condition (INV) are to, first, prevent the phenomenon of cavitation at the boundary of Ω (see [16, p. 55]) and, second, to prevent leakage at the boundary (see [16, p. 56] and [17, p. 975]). For interesting related results see Swanson and Ziemer [25, 26].

Remark 3.3. Suppose that in the above theorem $\mathbf{A} = \lambda \mathbf{I}$ and $\lambda > \lambda_{\mathrm{crit}}$ (where λ_{crit} is the critical boundary displacement after which radial cavitation occurs). Suppose further that the energy grows sufficiently slowly with respect to $|\mathbf{F}|$; e.g., W is given by (1.4) for some $c > 0$ and $p \in (m-1, m)$ with Γ as in (H3) and (H4). It then follows from results on radial cavitation (see [20]) that any minimizer $\mathbf{u}$ given by the above result with $\epsilon = 0$ must satisfy $\alpha_{\mathbf{u}} > 0$; i.e., it must form a new cavity.

4. Convergence of minimizers. In this section we show that, as $\epsilon \to 0^+$, minimizers $\mathbf{u}_\epsilon$ of the mixed displacement/traction problem given by Proposition 3.1 converge to a minimizer of the pure displacement problem $\mathbf{u} \in \mathcal{A}_0(\mathbf{x}_0)$. More precisely, we prove the following main theorem of the paper.

[9] We refer the reader to [4] for interesting analytical difficulties that arise in the borderline case $p = m - 1$.

THEOREM 4.1. *Let $\mathbf{x}_0 \in \Omega$ be fixed and let $W \in C(\overline{\Omega} \times \mathrm{M}^{m\times m}_+; [0,\infty))$ satisfy* (H1)–(H4). *Suppose that (ϵ_n) is a monotone decreasing sequence converging to zero and let $(\mathbf{u}_{\epsilon_n})$ be a corresponding sequence of minimizers whose existence is given by Proposition* 3.1. *Then there exists $\mathbf{u} \in \mathcal{A}_0(\mathbf{x}_0)$ and a subsequence $(\mathbf{u}_{\epsilon_{n_j}})$ such that*

$$\mathbf{u}_{\epsilon_{n_j}} \rightharpoonup \mathbf{u} \quad \text{as} \quad j \to \infty \quad \text{in} \quad W^{1,p}(\Omega^{\mathrm{e}}_\delta; \mathbb{R}^m)$$

for any $\delta > 0$. Moreover, $\mathbf{u}$ is a minimizer of E_0 on $\mathcal{A}_0(\mathbf{x}_0)$.

The proof of this theorem is contained in the remainder of this section. Throughout this section (ϵ_n) will denote a fixed monotone decreasing sequence converging to zero, while $(\mathbf{u}_{\epsilon_n})$ will denote a corresponding sequence of minimizers whose existence is given by Proposition 3.1.

The convergence proof is split into three parts: We first identify a map $\mathbf{u} \in W^{1,p}(\Omega; \mathbb{R}^m)$ such that for a subsequence $(\mathbf{u}_{\epsilon_{n_j}})$ of $(\mathbf{u}_{\epsilon_n})$ we have $\mathbf{u}_{\epsilon_{n_j}} \rightharpoonup \mathbf{u}$ in $W^{1,p}(\Omega_\delta; \mathbb{R}^m)$ as $j \to \infty$ for any $\delta > 0$ sufficiently small. It then follows from Proposition 2.4 and Definition 2.6 that $\mathbf{u}$ satisfies condition (INV) on $\Omega\backslash\{\mathbf{x}_0\}$. In section 4.2 we show in Theorem 4.3 that it then follows that $\mathbf{u}$ satisfies (INV) on Ω and in Lemma 4.5 that $\operatorname{Det}\nabla\mathbf{u} = (\det\nabla\mathbf{u})\mathcal{L}^m + \alpha_{\mathbf{u}}\delta_{\mathbf{x}_0}$. Thus we can conclude that $\mathbf{u} \in \mathcal{A}_0(\mathbf{x}_0)$. Finally, in section 4.3 in Theorem 4.6 we prove that $\mathbf{u}$ is a minimizer of the energy E_0 on $\mathcal{A}_0(\mathbf{x}_0)$ using lower semicontinuity arguments.

4.1. Identifying a weak limit for the sequence of minimizers.

THEOREM 4.2. *Let $(\mathbf{u}_{\epsilon_n})$ be a sequence of minimizers given by Proposition* 3.1. *Then there is a subsequence $(\mathbf{u}_{\epsilon_{n_j}})$ and a mapping $\mathbf{u} : \Omega \to \mathbb{R}^m$ such that, for any $\delta > 0$, $\mathbf{u} \in W^{1,p}(\Omega\backslash\overline{B_\delta}; \mathbb{R}^m)$ and*

$$\mathbf{u}_{\epsilon_{n_j}} \rightharpoonup \mathbf{u} \quad \text{as} \quad j \to \infty \quad \text{in} \quad W^{1,p}(\Omega\backslash\overline{B(\mathbf{x}_0,\delta)}; \mathbb{R}^m).$$

Proof. Let $(\mathbf{u}_{\epsilon_n})$ be a sequence of minimizers given by Proposition 3.1. We first note that, since W is continuous and nonnegative on the compact set $\overline{\Omega} \times \{\mathbf{A}\}$, the homogeneous deformation $\mathbf{u}^{\mathrm{h}}$ has finite energy. Hence for any $n \in \mathbb{N}$,

$$E_{\epsilon_n}(\mathbf{u}^{\mathrm{h}}) = \int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \mathbf{A})\, d\mathbf{x} \le \int_\Omega W(\mathbf{x}, \mathbf{A})\, d\mathbf{x} < \infty. \tag{4.1}$$

Next, by the convexity of Γ and its growth at zero and infinity ((H3) and (H4)) it follows that Γ is bounded below. Thus, by the coercivity condition (H3) and the Poincaré inequality, we find that for any $N \in \mathbb{N}$ and $n > N$

$$E_{\epsilon_N}(\mathbf{u}_{\epsilon_n}) \ge C_1 \|\mathbf{u}_{\epsilon_n}\|^p_{W^{1,p}(\Omega_{\epsilon_N})} - C_2\mathcal{L}^m(\Omega_{\epsilon_N}), \tag{4.2}$$

where C_1 and C_2 are positive constants. In addition, W is nonnegative and $\Omega_{\epsilon_N} \subset \Omega_{\epsilon_n}$ so that

$$\begin{aligned} E_{\epsilon_N}(\mathbf{u}_{\epsilon_n}) &= \int_{\Omega_{\epsilon_N}} W(\mathbf{x}, \nabla\mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x} \\ &\le \int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla\mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x} \quad = \quad E_{\epsilon_n}(\mathbf{u}_{\epsilon_n}). \end{aligned} \tag{4.3}$$

Also, $\mathbf{u}^{\mathrm{h}} \in \mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$ and $\mathbf{u}_{\epsilon_n}$ is a minimizer of E_{ϵ_n} on $\mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$, and so

$$E_{\epsilon_n}(\mathbf{u}_{\epsilon_n}) \le E_{\epsilon_n}(\mathbf{u}^{\mathrm{h}}). \tag{4.4}$$

Therefore by (4.1)–(4.4) the sequence $(\mathbf{u}_{\epsilon_n})$ is bounded in the reflexive Banach space $W^{1,p}(\Omega_{\epsilon_N};\mathbb{R}^m)$, and consequently there exists a subsequence, still labeled $(\mathbf{u}_{\epsilon_n})$, converging weakly to some function $\mathbf{u}^N$ in $W^{1,p}(\Omega_{\epsilon_N};\mathbb{R}^m)$; that is,

$$\mathbf{u}_{\epsilon_n} \rightharpoonup \mathbf{u}^N \quad \text{in} \quad W^{1,p}(\Omega_{\epsilon_N};\mathbb{R}^m) \quad \text{as} \quad n \to \infty.$$

Now inductively take successive subsequences with $N = 1, 2, 3, \dots$ and then choose a diagonal sequence to obtain a subsequence, labeled $(\mathbf{u}_{\epsilon_{n_j}})$, of $(\mathbf{u}_{\epsilon_n})$, that satisfies

$$\mathbf{u}_{\epsilon_{n_j}} \rightharpoonup \mathbf{u} \quad \text{in} \quad W^{1,p}(\Omega_{\epsilon_N};\mathbb{R}^m) \quad \text{as} \quad j \to \infty,$$

where $\mathbf{u} : \Omega\backslash\{\mathbf{x}_0\} \to \mathbb{R}^m$ is defined by

$$\mathbf{u}(\mathbf{x}) := \begin{cases} \mathbf{u}^1(\mathbf{x}) & \text{if } \mathbf{x} \in \Omega_{\epsilon_1}, \\ \mathbf{u}^N(\mathbf{x}) & \text{if } \mathbf{x} \in \Omega_{\epsilon_N}\backslash\Omega_{\epsilon_{N-1}}, \end{cases}$$

for $N = 2, 3, 4, \dots$. By construction $\mathbf{u} \in W^{1,p}(\Omega_{\epsilon_N};\mathbb{R}^m)$ for any N. ∎

Note that $\mathbf{u}$ is well defined by the uniqueness of weak limits. We will henceforth use $(\mathbf{u}_{\epsilon_n})$ to denote the subsequence of minimizers $(\mathbf{u}_{\epsilon_{n_j}})$ obtained in Theorem 4.2. It now follows from standard arguments that the limit function $\mathbf{u}$ identified in the above theorem lies in $W^{1,p}(\Omega;\mathbb{R}^m)$ for $p > m - 1$. For example, let $\psi \in C^\infty(\mathbb{R})$ be a fixed monotone increasing function that satisfies

$$\psi(t) = \begin{cases} 0 & \text{if } t \le 1, \\ 1 & \text{if } t \ge 4/3. \end{cases}$$

For each $n \in \mathbb{N}$, extend $\mathbf{u}_{\epsilon_n} : \Omega_{\epsilon_n} \to \mathbb{R}^m$ to a mapping $\tilde{\mathbf{u}}_{\epsilon_n} : \Omega \to \mathbb{R}^m$ by defining

$$\tilde{\mathbf{u}}_{\epsilon_n}(\mathbf{x}) := \begin{cases} \psi\left(\frac{2|\mathbf{x}-\mathbf{x}_0|}{|\mathbf{x}-\mathbf{x}_0|+\epsilon_n}\right)\mathbf{u}_{\epsilon_n}(\mathbf{x}) & \text{for } \mathbf{x} \in \Omega_{\epsilon_n}, \\ 0 & \text{otherwise.} \end{cases}$$

Then verify that $\tilde{\mathbf{u}}_{\epsilon_n} \rightharpoonup \mathbf{u}$ in $W^{1,p}(\Omega;\mathbb{R}^m)$ as $n \to \infty$.

4.2. The weak limit u lies in $\mathcal{A}_0(\mathbf{x}_0)$. In this section we prove that the weak limit $\mathbf{u}$ of the sequence $(\mathbf{u}_{\epsilon_n})$ is in the class of admissible functions $\mathcal{A}_0(\mathbf{x}_0)$. Since $\mathbf{u}_{\epsilon_n} \rightharpoonup \mathbf{u}$ in $W^{1,p}(\Omega_{\epsilon_N};\mathbb{R}^m)$ for any N, standard results imply that $\mathbf{u} = \mathbf{u}^{\mathrm{h}}$ on $\partial\Omega$, and the arguments in the proof of Theorem 4.1 in [19] show that $\det\nabla\mathbf{u}^e > 0$ a.e. Since $\mathbf{u}^{\mathrm{h}}$ is a diffeomorphism, it follows that $\mathbf{u}^{\mathrm{h}}(\overline{\Omega})$ is closed, and, since we may assume $\mathbf{u}_{\epsilon_n} \to \mathbf{u}$ a.e. in Ω, we conclude that $\mathbf{u}(\mathbf{x}) \in \mathbf{u}^{\mathrm{h}}(\overline{\Omega})$ for a.e. $\mathbf{x} \in \Omega$ and consequently

$$\mathbf{u}^e(\mathbf{x}) \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}}) \quad \text{for a.e. } \mathbf{x} \in \Omega^{\mathrm{e}}. \tag{4.5}$$

We next prove that if $\mathbf{u}^e$ satisfies condition (INV) on $\Omega^{\mathrm{e}}\backslash\{\mathbf{x}_0\}$, then $\mathbf{u}^e$ satisfies condition (INV) on Ω^{e}. Following this, we then prove in Lemma 4.5 that the distributional Jacobian of $\mathbf{u}^e$ has the appropriate form, which will complete the proof that $\mathbf{u}^e$ lies in $\mathcal{A}_0(\mathbf{x}_0)$.

THEOREM 4.3. *Let $p > m - 1$ and suppose that $\mathbf{u}_{\epsilon_n} \in \mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$ is the sequence of minimizers given in Proposition* 3.1. *Suppose further that there exists $\mathbf{u}^e \in W^{1,p}(\Omega^{\mathrm{e}};\mathbb{R}^m)$ such that $\det\nabla\mathbf{u}^e > 0$ a.e. and that for any fixed $N \in \mathbb{N}$*

$$\mathbf{u}^e_{\epsilon_n} \rightharpoonup \mathbf{u}^e \quad \text{in} \quad W^{1,p}(\Omega^{\mathrm{e}}_{\epsilon_N};\mathbb{R}^m). \tag{4.6}$$

Then $(\mathbf{u}^e)^*$ satisfies (INV) *on Ω^{e}.*

Proof. Without loss of generality we take $\mathbf{u}^e_{\epsilon_n} = (\mathbf{u}^e_{\epsilon_n})^*$, $\mathbf{u}^e = (\mathbf{u}^e)^*$, and fix $\mathbf{x}_1 \in \Omega^{\mathrm{e}}$. Then we must show that for $\mathcal{L}^1$ a.e. $r \in (0, \operatorname{dist}(\mathbf{x}_1, \partial\Omega^{\mathrm{e}}))$

$$\begin{aligned} &\text{(i)} \quad \mathbf{u}^e(\mathbf{x}) \in \operatorname{im}_{\mathrm{T}}(\mathbf{u}^e, B_r(\mathbf{x}_1)) \cup \mathbf{u}^e(\partial B_r(\mathbf{x}_1)) \text{ for a.e. } \mathbf{x} \in \overline{B_r(\mathbf{x}_1)};\\ &\text{(ii)} \quad \mathbf{u}^e(\mathbf{x}) \in \mathbb{R}^m \backslash \operatorname{im}_{\mathrm{T}}(\mathbf{u}^e, B_r(\mathbf{x}_1)) \text{ for a.e. } \mathbf{x} \in \Omega^{\mathrm{e}} \backslash \overline{B_r(\mathbf{x}_1)}, \end{aligned} \tag{4.7}$$

where $B_r(\mathbf{x}_1) := B(\mathbf{x}_1, r)$.

Let N be fixed and suppose that $n > N$. By definition of $\mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$ the minimizers $\mathbf{u}^e_{\epsilon_n}$ satisfy condition (INV) on $\Omega^{\mathrm{e}}_{\epsilon_N}$ and $\det \nabla \mathbf{u}^e_{\epsilon_n} > 0$ a.e. Consequently, by (4.6) and Proposition 2.4, $\mathbf{u}^e$ satisfies condition (INV) on $\Omega^{\mathrm{e}}_{\epsilon_N}$. Since N is arbitrary, it follows that $\mathbf{u}^e$ satisfies condition (INV) on $\Omega^{\mathrm{e}} \backslash \{\mathbf{x}_0\}$. Next, fix $r_1 > 0$ such that $B(\mathbf{x}_1, r_1) \subset \Omega^{\mathrm{e}}$ and $\mathbf{x}_0 \notin \partial B(\mathbf{x}_1, r_1)$. Then for all r sufficiently close to r_1 either $\mathbf{x}_0 \in B(\mathbf{x}_1, r)$ or $\mathbf{x}_0 \in \Omega^{\mathrm{e}} \backslash \overline{B(\mathbf{x}_1, r)}$. In the former case define

$$U_r := \Omega^{\mathrm{e}} \backslash \overline{B(\mathbf{x}_1, r)} \quad \text{and} \quad V_r := B(\mathbf{x}_1, r) \tag{4.8}$$

and in the latter case define

$$U_r := B(\mathbf{x}_1, r) \quad \text{and} \quad V_r := \Omega^{\mathrm{e}} \backslash \overline{B(\mathbf{x}_1, r)}.$$

Since $\partial\Omega^{\mathrm{e}}$ is smooth, U_r and V_r are each open sets with C^1 boundary.

We prove the result in the first case, $\mathbf{x}_0 \in B(\mathbf{x}_1, r)$ and (4.8), and note that the proof in the second case is similar. Let $\delta > 0$ be sufficiently small. Then by [16, Theorem 9.1] (see the appendix) there exists an $\epsilon_0 > 0$ such that for a.e. $r \in (r_1 - \epsilon_0, r_1 + \epsilon_0)$

$$\begin{aligned} &\text{(o)} \quad \mathbf{u}^e|_{\partial U_r} \in W^{1,p}(\partial U_r, \mathbb{R}^m) \cap C(\partial U_r, \mathbb{R}^m);\\ &\text{(i)} \quad \mathbf{u}^e(\mathbf{x}) \in \operatorname{im}_{\mathrm{T}}(\mathbf{u}^e, U_r) \cup \mathbf{u}^e(\partial U_r) \ \text{ for a.e. } \mathbf{x} \in \overline{U_r};\\ &\text{(ii)} \quad \mathbf{u}^e(\mathbf{x}) \in \mathbb{R}^m \backslash \operatorname{im}_{\mathrm{T}}(\mathbf{u}^e, U_r) \ \text{ for a.e. } \mathbf{x} \in \Omega^{\mathrm{e}} \backslash (\overline{U_r} \cup \overline{B(\mathbf{x}_0, \delta)}\,). \end{aligned} \tag{4.9}$$

Fix one such r. For each $n \in \mathbb{N}$ we successively take $\delta = \epsilon_n$ in $(4.9)_3$. Then since the countable union of null sets is a null set, as is the set $\{\mathbf{x}_0\}$, we conclude that

$$\begin{aligned} &\text{(i)}' \quad \mathbf{u}^e(\mathbf{x}) \in \operatorname{im}_{\mathrm{T}}(\mathbf{u}^e, U_r) \cup \mathbf{u}^e(\partial U_r) \ \text{ for a.e. } \mathbf{x} \in \overline{U_r} = \overline{\Omega^{\mathrm{e}}} \backslash B_r(\mathbf{x}_1);\\ &\text{(ii)}' \quad \mathbf{u}^e(\mathbf{x}) \in \mathbb{R}^m \backslash \operatorname{im}_{\mathrm{T}}(\mathbf{u}^e, U_r) \ \text{ for a.e. } \mathbf{x} \in \Omega^{\mathrm{e}} \backslash \overline{U_r} = B_r(\mathbf{x}_1). \end{aligned} \tag{4.10}$$

In order to obtain (4.7) we first note that V_r, U_r, and ∂V_r are pairwise disjoint sets with V_r and U_r open, ∂V_r compact, and $\Omega^e = V_r \cup U_r \cup \partial V_r$. Thus standard properties of degree[10] imply

$$\deg(\mathbf{u}^e, \Omega^{\mathrm{e}}, \mathbf{y}) = \deg(\mathbf{u}^e, U_r, \mathbf{y}) + \deg(\mathbf{u}^e, V_r, \mathbf{y}) \tag{4.11}$$

for all $\mathbf{y} \notin \mathbf{u}^e(\partial\Omega^{\mathrm{e}} \cup \partial V_r)$ (note that $\partial\Omega^{\mathrm{e}} \cup \partial V_r = \partial U_r$).

Next, $\mathbf{u}^{\mathrm{h}}$ is an orientation-preserving diffeomorphism whose degree satisfies $\deg(\mathbf{u}^{\mathrm{h}}, \Omega^{\mathrm{e}}, \mathbf{y}) = 1$ if $\mathbf{y} \in \operatorname{im}_{\mathrm{T}}(\mathbf{u}^{\mathrm{h}}, \Omega^{\mathrm{e}}) = \mathbf{u}^{\mathrm{h}}(\Omega^e)$ and $\deg(\mathbf{u}^{\mathrm{h}}, \Omega^{\mathrm{e}}, \mathbf{y}) = 0$ if $\mathbf{y} \in \mathbb{R}^m \backslash \mathbf{u}^{\mathrm{h}}(\overline{\Omega}^{\mathrm{e}})$. Since $\mathbf{u}^{\mathrm{h}}$ and $\mathbf{u}^e$ assume the same boundary values on $\partial\Omega^{\mathrm{e}}$ and since the degree depends only on the boundary values, it follows that their degrees are equal:

$$\deg(\mathbf{u}^e, \Omega^{\mathrm{e}}, \mathbf{y}) = \begin{cases} 1 & \text{if } \mathbf{y} \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}}), \\ 0 & \text{if } \mathbf{y} \in \mathbb{R}^m \backslash \mathbf{u}^{\mathrm{h}}(\overline{\Omega}^{\mathrm{e}}). \end{cases}$$

[10] These are the domain decomposition and excision properties; see, e.g., [7] or [22].

Consequently, in view of (4.11), if $\mathbf{y} \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}})$ and $\mathbf{y} \notin \mathbf{u}^e(\partial U_r)$, then

$$\deg(\mathbf{u}^e, U_r, \mathbf{y}) + \deg(\mathbf{u}^e, V_r, \mathbf{y}) = 1. \tag{4.12}$$

We next recall that $\mathbf{x}_0 \in B_r(\mathbf{x}_1) = V_r$ and that $\mathbf{u}^e$ satisfies (INV) on $U_r = \Omega^{\mathrm{e}} \backslash \overline{V_r} \subset \Omega^{\mathrm{e}} \backslash \{\mathbf{x}_0\}$. Therefore (4.10) and the proof of [16, Theorem 9.1] yield

$$\deg(\mathbf{u}^e, U_r, \mathbf{y}) = \begin{cases} 1 & \text{if } \mathbf{y} \in \mathrm{im}_{\mathrm{T}}(\mathbf{u}^e, U_r), \\ 0 & \text{if } \mathbf{y} \in \mathbb{R}^m \backslash (\mathrm{im}_{\mathrm{T}}(\mathbf{u}^e, U_r) \cup \mathbf{u}^e(\partial U_r)), \end{cases}$$

which, together with (4.12), allows us to conclude that if $\mathbf{y} \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}})$, then

$$\deg(\mathbf{u}^e, V_r, \mathbf{y}) = \begin{cases} 0 & \text{if } \mathbf{y} \in \mathrm{im}_{\mathrm{T}}(\mathbf{u}^e, U_r), \\ 1 & \text{if } \mathbf{y} \in \mathbb{R}^m \backslash (\mathrm{im}_{\mathrm{T}}(\mathbf{u}^e, U_r) \cup \mathbf{u}^e(\partial U_r)). \end{cases} \tag{4.13}$$

We are now ready to prove $(4.7)_1$: by (4.5) we may assume that $\mathbf{u}^e(\mathbf{x}) \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}})$ for a.e. $\mathbf{x} \in \overline{B_r(\mathbf{x}_1)}$. By $(4.10)_2$ and $(4.13)_2$ it follows that for a.e. $\mathbf{x} \in B_r(\mathbf{x}_1)$

$$\mathbf{u}^e(\mathbf{x}) \in \mathbf{u}^e(\partial U_r) \quad \text{or} \quad \deg(\mathbf{u}^e, V_r, \mathbf{u}^e(\mathbf{x})) = 1 \ .$$

However, $\mathbf{u}^e(\partial U_r) = \mathbf{u}^e(\partial V_r) \cup \mathbf{u}^e(\partial \Omega^{\mathrm{e}})$, $\mathbf{u}^e(\partial \Omega^{\mathrm{e}}) \cap \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}}) = \emptyset$, and by (4.5) we have $\mathbf{u}^e(\mathbf{x}) \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}})$ for a.e. $\mathbf{x} \in B_r(\mathbf{x}_1)$. Therefore $(4.7)_1$ follows from the definition of the topological image (2.2). Similarly, by (4.5), $(4.10)_1$, and $(4.13)_1$ it follows that for a.e. $\mathbf{x} \in U_r = \Omega^e \backslash \overline{B_r(\mathbf{x}_1)}$

$$\mathbf{u}^e(\mathbf{x}) \in \mathbf{u}^e(\partial V_r) \quad \text{or} \quad \deg(\mathbf{u}^e, V_r, \mathbf{u}^e(\mathbf{x})) = 0,$$

and so $(4.7)_2$ follows from (2.2). ∎

Remark 4.4. The containment condition $\mathbf{u}^e(\mathbf{x}) \in \mathbf{u}^{\mathrm{h}}(\Omega^{\mathrm{e}})$ for a.e. $\mathbf{x} \in \Omega^{\mathrm{e}}$, which follows from Lemma 2.7, is crucial to the argument in the last proof.

The following lemma combined with the last two subsections will allow us to conclude that $\mathbf{u}^e$ lies in $\mathcal{A}(\mathbf{x}_0)$.

LEMMA 4.5. *Let $m = 3$, let $p > 2 = m - 1$, and suppose that $\mathbf{u}_{\epsilon_n} \in \mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$ is the sequence of minimizers of the mixed displacement/traction problem. Let $\mathbf{u} \in W^{1,p}(\Omega; \mathbb{R}^m)$ be the weak limit of the sequence as given in Theorem 4.2, so that the precise representative of its homogeneous extension $(\mathbf{u}^e)^* \in W^{1,p}(\Omega^{\mathrm{e}}; \mathbb{R}^m)$ satisfies* (INV) *on Ω^{e} and*

$$\mathbf{u}_{\epsilon_n} \rightharpoonup \mathbf{u}^e \quad \text{in} \quad W^{1,p}(\Omega^{\mathrm{e}}_{\epsilon_N}; \mathbb{R}^m)$$

for any $N \in \mathbb{N}$. Then there exists $\alpha_{\mathbf{u}} \geq 0$ such that

$$\mathrm{Det}\, \nabla \mathbf{u}^e = (\det \nabla \mathbf{u}^e)\mathcal{L}^m + \alpha_{\mathbf{u}} \delta_{\mathbf{x}_0},$$

where $\delta_{\mathbf{x}_0}$ denotes the Dirac measure supported at $\mathbf{x}_0$.

Proof. We first note that $\mathbf{u}^e \in W^{1,p}(\Omega^{\mathrm{e}}; \mathbb{R}^m)$, $\det \nabla \mathbf{u}^e > 0$ a.e., and $(\mathbf{u}^e)^*$ satisfies condition (INV) on Ω^{e}. Therefore, $\mathrm{Det}\, \nabla \mathbf{u}^e$ is a Radon measure and

$$\mathrm{Det}\, \nabla \mathbf{u}^e = (\det \nabla \mathbf{u}^e)\mathcal{L}^m + \mu^s, \tag{4.14}$$

where μ^s is a (nonnegative) Radon measure that is singular with respect to $\mathcal{L}^m$ (see section 2.4).

Next, $\mathbf{u}_{\epsilon_n} \rightharpoonup \mathbf{u}^e$ in $W^{1,p}(\Omega^{\mathrm{e}}_{\epsilon_N};\mathbb{R}^m)$ for any N and $\mathbf{u}_{\epsilon_n}$ satisfies (INV) on $\Omega^{\mathrm{e}}_{\epsilon_N}$. Therefore, by Lemma 3.3 in [19], there exists a subsequence (still labeled $\mathbf{u}_{\epsilon_n}$) that satisfies

$$\mathbf{u}_{\epsilon_n} \to \mathbf{u}^e \ \text{ in } L^q_{\mathrm{loc}}(\Omega^{\mathrm{e}}_{\epsilon_N};\mathbb{R}^m) \tag{4.15}$$

for every $1 < q < \infty$. Moreover, since $p > m-1$,

$$\operatorname{adj}\nabla\mathbf{u}_{\epsilon_n} \rightharpoonup \operatorname{adj}\nabla\mathbf{u}^e \quad \text{in } L^{\frac{p}{m-1}}(\Omega^{\mathrm{e}}_{\epsilon_N};\mathbb{R}^m) \tag{4.16}$$

(see [2, Theorem 3.4]). Consequently, by (4.15) and (4.16) (see [19, Lemma 6.7]),

$$(\operatorname{adj}\nabla\mathbf{u}_{\epsilon_n})\mathbf{u}_{\epsilon_n} \rightharpoonup (\operatorname{adj}\nabla\mathbf{u}^e)\mathbf{u}^e \quad \text{in } L^1_{\mathrm{loc}}(\Omega^{\mathrm{e}}_{\epsilon_N};\mathbb{R}^m),$$

and hence, in view of (2.6),

$$(\operatorname{Det}\nabla\mathbf{u}_{\epsilon_n})(\phi) \to (\operatorname{Det}\nabla\mathbf{u}^e)(\phi) \tag{4.17}$$

for every $\phi \in C_0^\infty(\Omega^{\mathrm{e}}_{\epsilon_N})$. Since $\mathbf{u}_{\epsilon_n} \in \mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$, the sequence $\mathbf{u}_{\epsilon_n}$ satisfies

$$\operatorname{Det}\nabla\mathbf{u}_{\epsilon_n} = (\det\nabla\mathbf{u}_{\epsilon_n})\mathcal{L}^m \ \text{ on } \ \Omega^{\mathrm{e}}_{\epsilon_N}. \tag{4.18}$$

Now, by (4.1), (4.3), (4.4), and hypothesis (H3), for any $N \in \mathbb{N}$ and all $n > N$

$$\int_{\Omega_{\epsilon_N}} \Gamma(\det\nabla\mathbf{u}_{\epsilon_n})\,d\mathbf{x} \le \int_\Omega W(\mathbf{x},\mathbf{A})\,d\mathbf{x} < \infty,$$

where Γ is the convex, superlinear function given in (H3). Thus, by the de la Vallée Poussin and Dunford–Pettis criteria (see, e.g., [19, Theorem 4.1]), there is a $\theta \in L^1(\Omega_{\epsilon_N})$ such that (for a subsequence) $\det\nabla\mathbf{u}_{\epsilon_n} \rightharpoonup \theta$ in $L^1(\Omega^{\mathrm{e}}_{\epsilon_N})$. Moreover, Lemma 3.2 in [19] implies that $\theta = \det\nabla\mathbf{u}^e$ a.e. in $\Omega^{\mathrm{e}}_{\epsilon_N}$. Therefore,

$$\det\nabla\mathbf{u}_{\epsilon_n} \rightharpoonup \det\nabla\mathbf{u}^e \quad \text{in } L^1(\Omega^{\mathrm{e}}_{\epsilon_N};\mathbb{R}^m), \tag{4.19}$$

and in view of (4.17)–(4.19) we find that, for every $\phi \in C_0^\infty(\Omega^{\mathrm{e}}_{\epsilon_N})$,

$$(\operatorname{Det}\nabla\mathbf{u}^e)(\phi) = \int_{\Omega^{\mathrm{e}}_{\epsilon_N}} \phi(\mathbf{x})\det\nabla\mathbf{u}^e(\mathbf{x})\,d\mathbf{x}$$

and consequently that

$$(\operatorname{Det}\nabla\mathbf{u}^e)(\Omega^{\mathrm{e}}_{\epsilon_N}) = \int_{\Omega^{\mathrm{e}}_{\epsilon_N}} \det\nabla\mathbf{u}^e(\mathbf{x})\,d\mathbf{x}. \tag{4.20}$$

Finally, (4.14) and (4.20) imply that for every $N \in \mathbb{N}$

$$\mu^s(\Omega^{\mathrm{e}}_{\epsilon_N}) = 0.$$

Thus, since

$$\Omega^{\mathrm{e}} \subset \{\mathbf{x}_0\} \cup \bigcup_{N=1}^{\infty} \Omega^{\mathrm{e}}_{\epsilon_N},$$

we find that

$$\mu^s(\Omega^{\mathrm{e}}) \le \mu^s(\{\mathbf{x}_0\}) + \sum_{N=1}^{\infty} \mu^s(\Omega^{\mathrm{e}}_{\epsilon_N}) = \mu^s(\{\mathbf{x}_0\}),$$

which yields the desired result (set $\alpha_{\mathbf{u}} = \mu^s(\{\mathbf{x}_0\})$). ∎

4.3. u is a minimizer for the pure displacement problem. Thus far we have shown that the weak limit $\mathbf{u}$ of a subsequence of the minimizers $\mathbf{u}_{\epsilon_n}$ of the mixed displacement/traction boundary value problem lies in $\mathcal{A}(\mathbf{x}_0)$. Next, we will prove that $\mathbf{u}$ is a minimizer of the pure displacement boundary value problem considered in Proposition 3.1. Throughout this section we will use $\mathbf{u}_{\epsilon_n}$ to denote this convergent subsequence identified in sections 4.1 and 4.2.

THEOREM 4.6. *Suppose that E_0 and $\mathcal{A}_0(\mathbf{x}_0)$ are as defined in section 3 and that $\mathbf{u} \in \mathcal{A}(\mathbf{x}_0)$ is the weak limit of the sequence of minimizers $(\mathbf{u}_{\epsilon_n})$ of the mixed displacement/traction problems. Then $E_0(\mathbf{u}) \leq E_0(\tilde{\mathbf{u}})$ for all $\tilde{\mathbf{u}} \in \mathcal{A}_0(\mathbf{x}_0)$.*

Proof. Define

$$\lambda := \liminf_{n\to\infty} \int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x}$$

and let N be fixed. Then, since W is nonnegative, for any $n > N$

$$\int_{\Omega_{\epsilon_N}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x} \leq \int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x}. \tag{4.21}$$

Next, by sequential weak lower semicontinuity of E_{ϵ_N} (see [3, Theorem 7.1] and [19, pp. 93–100]) and since $\mathbf{u}_{\epsilon_n} \rightharpoonup \mathbf{u}$ in $W^{1,p}(\Omega_{\epsilon_N}; \mathbb{R}^m)$ as $n \to \infty$, we have

$$\int_{\Omega_{\epsilon_N}} W(\mathbf{x}, \nabla \mathbf{u}(\mathbf{x}))\, d\mathbf{x} \leq \liminf_{n\to\infty} \int_{\Omega_{\epsilon_N}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x}. \tag{4.22}$$

If we combine (4.21) and (4.22) we find that

$$\int_{\Omega_{\epsilon_N}} W(\mathbf{x}, \nabla \mathbf{u}(\mathbf{x}))\, d\mathbf{x} \leq \lambda$$

and hence by the monotone convergence theorem that

$$\int_{\Omega} W(\mathbf{x}, \nabla \mathbf{u}(\mathbf{x}))\, d\mathbf{x} \leq \lambda. \tag{4.23}$$

Now, suppose that $\tilde{\mathbf{u}} \in \mathcal{A}_0(\mathbf{x}_0)$. Then $\tilde{\mathbf{u}}|_{\Omega_\epsilon} \in \mathcal{A}_\epsilon(\mathbf{x}_0)$ for every sufficiently small ϵ, and thus

$$\int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x} \leq \int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla \tilde{\mathbf{u}}(\mathbf{x}))\, d\mathbf{x}.$$

Then since W is nonnegative,

$$\int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x} \leq \int_{\Omega} W(\mathbf{x}, \nabla \tilde{\mathbf{u}}(\mathbf{x}))\, d\mathbf{x},$$

and if we take the liminf we conclude that

$$\lambda = \liminf_{n\to\infty} \int_{\Omega_{\epsilon_n}} W(\mathbf{x}, \nabla \mathbf{u}_{\epsilon_n}(\mathbf{x}))\, d\mathbf{x} \leq \int_{\Omega} W(\mathbf{x}, \nabla \tilde{\mathbf{u}}(\mathbf{x}))\, d\mathbf{x},$$

which together with (4.23) yields the desired result. ∎

We conclude from the results in section 4 that minimizers of E_{ϵ_n} on $\mathcal{A}_{\epsilon_n}(\mathbf{x}_0)$ converge to a minimizer of E_0 on $\mathcal{A}_0(\mathbf{x}_0)$ as $\epsilon_n \to 0$, i.e., that (a subsequence of) the minimizers of the mixed displacement/traction boundary value problem converge weakly to a minimizer of the pure displacement boundary value problem. This completes the proof of Theorem 4.1.

Remark 4.7. We cannot conclude in general that any sequence of minimizers $(\mathbf{u}_{\epsilon_n})$ of the mixed problem necessarily converges to a minimizer $\mathbf{u}$ of the pure displacement problem; this follows only after passing to a subsequence, since we do not know whether the minimizers given by Theorem 3.1 are unique.

5. Surface energy. In this section we examine the effect of regularizing our pure displacement variational problem by adding a surface energy term which penalizes the formation and growth of cavities. In particular, we consider the case of a typical surface energy term proportional to the surface area[11] of the holes produced. This modification is partly motivated by experimental observations of Gent [8], which indicate that such surface energy effects are relevant in certain situations involving cavitation. In this case, the original energy functional is replaced by the augmented functional:

$$\tilde{E}(\mathbf{u}) = \int_\Omega W(\nabla \mathbf{u}(\mathbf{x}))\, d\mathbf{x} \;+\; \kappa \operatorname{Per}(\operatorname{im}(\mathbf{u}, \Omega)) = E(\mathbf{u}) + \kappa \operatorname{Per}(\operatorname{im}(\mathbf{u}, \Omega)), \tag{5.1}$$

where $\kappa > 0$ is a constant and $\operatorname{Per}(\operatorname{im}(\mathbf{u}, \Omega))$ corresponds to the perimeter or surface area of the holes produced (see [16] for a precise definition of the perimeter of the measure-theoretic image of Ω under $\mathbf{u}$). Again we consider the displacement boundary value problem in which the admissible deformations are required to satisfy the boundary condition (1.3). If W satisfies the hypotheses of section 3 (with $1 \le p < 3$), then analogous arguments to those given in [21, Theorem 2] show that, for "large $\mathbf{A}$,"[12] the homogeneous deformation $\mathbf{u}^{\mathrm{h}}(\mathbf{x}) \equiv \mathbf{A}\mathbf{x}$ is no longer the global minimizer of the energy (5.1). In particular, the energy can be lowered through the introduction of holes, or cavities, in the material. However, in contrast to the bifurcation diagram (Figure 1) for the radial problem without surface energy, we will show that these discontinuous minimizers do not bifurcate[13] from the trivial homogeneous deformations (i.e., that there do not exist discontinuous minimizers producing holes of arbitrarily small volume).

Our proof will consist of a simple energy estimate; however, for ease of presentation we will restrict our attention to the following class of homogeneous energy functions (but our arguments apply to much more general[14] stored energy functions):

$$W(\mathbf{F}) = c|\mathbf{F}|^p + \Gamma(\det \mathbf{F}),$$

where $2 < p < 3$, $c > 0$, and Γ is convex and differentiable. Let $\mathbf{u} \in \tilde{\mathcal{A}}$,

$$\tilde{\mathcal{A}} = \{\mathbf{u} \in W^{1,1}(\Omega; \mathbb{R}^m) : \mathbf{u}|_{\partial\Omega} = \mathbf{u}^{\mathrm{h}},\ (\mathbf{u}^{\mathrm{e}})^* \text{ satisfies (INV) on } \Omega^{\mathrm{e}},\ \det \nabla \mathbf{u} > 0 \text{ a.e.}\},$$

[11] As argued in [16], this may be criticized on the grounds that it assigns the same energy to creating the surface of a new cavity as it does to stretching the surface of a preexisting cavity.

[12] This is the case, in particular, if $\mathbf{A} = t\mathbf{B}$ for large $t > 0$, where $\mathbf{B} \in \mathrm{M}^{3\times 3}_+$ is any fixed matrix.

[13] See also [1, p. 608], which studies the addition of surface energy for radial deformations of a ball of incompressible material.

[14] In particular, our arguments clearly extend to stored energy functions of the form $W(\mathbf{F}) = W_0(\mathbf{F}) + c|\mathbf{F}|^p + \Gamma(\det \mathbf{F})$, $2 < p < 3$, where W_0 is $W^{1,p}$-quasiconvex.

and suppose that $\tilde{E}(\mathbf{u}) < \tilde{E}(\mathbf{u}^{\mathrm{h}})$, where $\mathbf{u}^{\mathrm{h}}(\mathbf{x}) \equiv \mathbf{A}\mathbf{x}$ and $\tilde{E}$ is given by (5.1). From the definition of $\tilde{E}$ it then follows that $E(\mathbf{u}) < E(\mathbf{u}^{\mathrm{h}})$. Next, by the convexity of the mapping $\mathbf{F} \mapsto |\mathbf{F}|^p$ and the boundary condition $\mathbf{u}|_{\partial\Omega} = \mathbf{u}^{\mathrm{h}}$,

$$c \int_\Omega |\mathbf{A}|^p \, d\mathbf{x} \leq c \int_\Omega |\nabla \mathbf{u}|^p \, d\mathbf{x},$$

and hence

$$\begin{aligned} 0 < E(\mathbf{u}^{\mathrm{h}}) - E(\mathbf{u}) &= \int_\Omega c|\mathbf{A}|^p - c|\nabla \mathbf{u}|^p + \Gamma(\det \mathbf{A}) - \Gamma(\det \nabla \mathbf{u}) \, d\mathbf{x} \\ &\leq \int_\Omega \Gamma(\det \mathbf{A}) - \Gamma(\det \nabla \mathbf{u}) \, d\mathbf{x} \\ &\leq \int_\Omega \Gamma'(\det \mathbf{A})(\det \mathbf{A} - \det \nabla \mathbf{u}) \, d\mathbf{x}, \end{aligned} \tag{5.2}$$

where we have used the convexity of Γ in the last step. The above estimate will allow us to bound the decrease in the bulk energy due to the formation of a cavity by a constant times the volume of the cavity.

Suppose for a contradiction that there exists a sequence of matrices $\mathbf{A}_n \to \mathbf{A}$ and a corresponding sequence of deformations $\mathbf{u}_n \in \tilde{\mathcal{A}}$, with $\mathbf{u}_n(\mathbf{x}) = \mathbf{A}_n\mathbf{x}$ for all $\mathbf{x} \in \partial\Omega$ and

$$\operatorname{Det} \nabla \mathbf{u}_n = (\det \nabla \mathbf{u}_n)\mathcal{L}^3 + \mu_n, \tag{5.3}$$

such that $\tilde{E}(\mathbf{u}_n) < \tilde{E}(\mathbf{u}_n^{\mathrm{h}})$ for all n and $\mu_n(\Omega) \to 0$ as $n \to \infty$, where $\mathbf{u}_n^{\mathrm{h}}(\mathbf{x}) \equiv \mathbf{A}_n\mathbf{x}$. Then by (5.2), (5.1), and (5.3)

$$\begin{aligned} 0 < \tilde{E}(\mathbf{u}_n^{\mathrm{h}}) - \tilde{E}(\mathbf{u}_n) &\leq \Gamma'(\det \mathbf{A}_n) \int_\Omega (\det \mathbf{A} - \det \nabla \mathbf{u}_n) \, d\mathbf{x} - \kappa \operatorname{Per}(\operatorname{im}(\mathbf{u}_n, \Omega)) \\ &= \Gamma'(\det \mathbf{A}_n)\mu_n(\Omega) - \kappa \operatorname{Per}(\operatorname{im}(\mathbf{u}_n, \Omega)). \end{aligned} \tag{5.4}$$

The intuitive idea now is that $\mu_n(\Omega)$ represents the volume of the holes formed and $\operatorname{Per}(\operatorname{im}(\mathbf{u}_n, \Omega))$ represents the surface areas produced. Since by assumption $\mu_n(\Omega) \to 0$, the above inequality yields a contradiction for large n. Mathematically, this argument is made rigorous through the use of an isoperimetric inequality. By the definition of $\tilde{E}$ (see (5.1)) it follows that if $\tilde{E}(\mathbf{u}) < \infty$, then $\operatorname{Per}(\operatorname{im}(\mathbf{u}, \Omega)) < \infty$, and so by [16, Theorem 8.4]

$$\operatorname{Det} \nabla \mathbf{u}_n = (\det \nabla \mathbf{u}_n)\mathcal{L}^3 + \sum_{i=1}^{\infty} \alpha_i^{(n)} \delta_{\mathbf{x}_i}, \tag{5.5}$$

where $\alpha_i^{(n)} \geq 0$ for all i and n. Moreover,

$$\sum_{i=1}^{\infty} \left(\alpha_i^{(n)}\right)^{2/3} \leq \bar{c} \operatorname{Per}(\operatorname{im}(\mathbf{u}_n, \Omega)),$$

where $\bar{c} > 0$ is the isoperimetric constant.

Without loss of generality we may assume that $0 \leq \Gamma'(\det \mathbf{A}_n) \leq K$ for all n (the first inequality follows from the main result in [23] and the second by the assumed convergence of $(\mathbf{A}_n)$ to $\mathbf{A}$). Hence, by (5.4) and the above expression,

$$0 < K \sum_{i=1}^{\infty} \alpha_i^{(n)} - \frac{\kappa}{\bar{c}} \sum_{i=1}^{\infty} \left(\alpha_i^{(n)}\right)^{2/3}. \tag{5.6}$$

Now, in view of (5.5), $\mu_n(\Omega) = \sum_{i=1}^{\infty} \alpha_i^{(n)} \to 0$ as $n \to \infty$. Therefore, given $l \in \mathbb{N}$, let $N_l \in \mathbb{N}$ be such that $\alpha_i^{(n)} < \frac{1}{2^{3l}}$ for all $n > N_l$ and $i \in \mathbb{N}$. Then, by (5.6),

$$0 < \left(\frac{K}{2^l} - \frac{\kappa}{\bar{c}}\right) \sum_{i=1}^{\infty} \left(\alpha_i^{(n)}\right)^{2/3} \quad \forall n > N_l \,,$$

which yields a contradiction for l sufficiently large. □

Remark 5.1. We note that the arguments used in section 4 can be adapted to show that if $\kappa_n \to 0$ and $(\mathbf{u}_n)$ is a corresponding sequence of minimizers of $\tilde{E}_n$ (given by (5.1) with $\kappa = \kappa_n$) on $\mathcal{A}_0(\mathbf{x}_0)$ (given by (3.1)), then, passing to a subsequence if necessary, $(\mathbf{u}_n)$ converges weakly in $W^{1,p}(\Omega)$ to a minimizer of E on $\mathcal{A}_0(\mathbf{x}_0)$.

6. Concluding remarks. It is interesting to note that the convergence result given in Theorem 4.1 could form the rigorous basis for a numerical method to compute approximations to the singular minimizers whose existence is given in Proposition 3.1. In particular, it is sufficient to compute regular minimizers on Ω_ϵ whose existence is given by Proposition 3.1 for small ϵ.

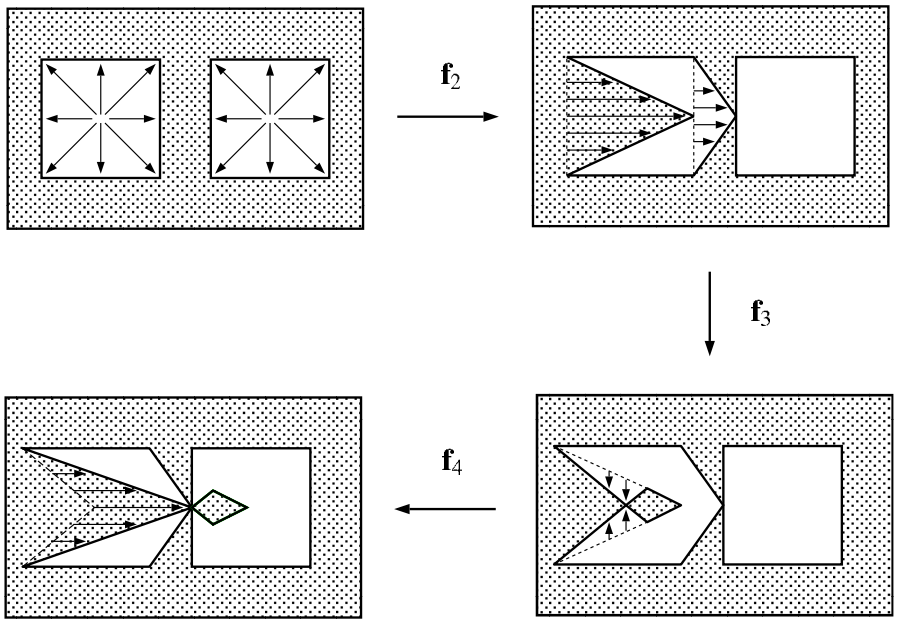

FIG. 3. *Leakage between holes.*

We next mention the main difficulty encountered in trying to extend the convergence result of Theorem 4.1 to the situation where we have, say, two (or more) flaw points located at $\{\mathbf{x}_0, \mathbf{x}_1\}$. Most of the arguments extend to this case; however, a map $\mathbf{u}$ satisfying (INV) on $\Omega \backslash \{\mathbf{x}_0, \mathbf{x}_1\}$ need not satisfy (INV) on Ω. The difficulty is related to the counterexample given in [17]: it is possible to construct a mapping $\mathbf{u} \in W^{1,p}(\Omega, \mathbb{R}^m)$ with $p > m - 1$ which satisfies (INV) on $\Omega^e \backslash \{\mathbf{x}_0, \mathbf{x}_1\}$ but which does not satisfy (INV) on Ω; consider a map which forms two adjacent cavities and which allows leakage from one cavity into the other (see Figure 3). Such a map can be produced, for example, as a composition of a two-hole cavitating map $\mathbf{f}_1$ with three Lipschitz maps $\mathbf{f}_2, \mathbf{f}_3$, and $\mathbf{f}_4$. Explicit formulae for some of the mappings can be found in [16].

Appendix. We note that our results depend crucially on Theorem 9.1 in [16], which extends condition (INV) from balls to other regions. However, the original proof of this result contains a small error. We therefore include here a corrected proof.

THEOREM A.1 (see [16, Theorem 9.1]). *Let* $\mathbf{u} \in W^{1,p}(\Omega;\mathbb{R}^m)$ *with* $p > m-1$. *Suppose that* $\det \nabla \mathbf{u} > 0$ *a.e. and that* $\mathbf{u}^*$ *satisfies condition* (INV). *Assume that* $U \subset\subset \Omega$ *is open with* C^1 *boundary and that there exists an* $\varepsilon_0 > 0$, *an open neighborhood* N *of* ∂U, *and a (surjective) diffeomorphism* $\mathbf{w} : \partial U \times (-\varepsilon_0, \varepsilon_0) \to N$ *that satisfies* $\mathbf{w}(\mathbf{x}, 0) = \mathbf{x}$ *and* $\mathbf{w}_\varepsilon(\mathbf{x}, 0) \cdot \mathbf{n}(\mathbf{x}) > 0$ *for all* $\mathbf{x} \in \partial U$, *where* $\mathbf{n}(\mathbf{x})$ *is the outward unit normal to* U *and* $\mathbf{w}_\varepsilon$ *is the partial derivative of* $\mathbf{w}$ *with respect to its second argument. Define*

$$U_\varepsilon := (U \backslash N) \cup \mathbf{w}\big(\partial U \times (-\varepsilon_0, \varepsilon)\big).$$

Then for a.e. $\varepsilon \in (-\varepsilon_0, \varepsilon_0)$

(o) $\mathbf{u}^*|_{\partial U_\varepsilon} \in W^{1,p}(\partial U_\varepsilon;\mathbb{R}^m) \cap C^0(\partial U_\varepsilon;\mathbb{R}^m)$;

(i) $\mathbf{u}^*(\mathbf{x}) \in (\mathrm{im}_{\mathrm{T}}(\mathbf{u}^*, U_\varepsilon) \cup \mathbf{u}^*(\partial U_\varepsilon))$ *for a.e.* $\mathbf{x} \in \overline{U}_\varepsilon$;

(ii) $\mathbf{u}^*(\mathbf{x}) \in \mathbb{R}^m \backslash \mathrm{im}_{\mathrm{T}}(\mathbf{u}^*, U_\varepsilon)$ *for a.e.* $\mathbf{x} \in \Omega \backslash U_\varepsilon$.

Proof. Let $\theta \in C_0^\infty(\mathbb{R}^m)$ satisfy $\theta \geq 0$ and suppose that $\mathbf{g} \in C^\infty(\mathbb{R}^m;\mathbb{R}^m) \cap L^\infty(\mathbb{R}^m;\mathbb{R}^m)$ satisfies $\operatorname{div} \mathbf{g} = \theta$. Then, as in section 8 in [16], the map $\mu_\theta : C_0^\infty(\Omega) \to \mathbb{R}$ given by

$$\mu_\theta(\varphi) := -\int_\Omega \nabla\varphi \cdot (\operatorname{adj} \nabla \mathbf{u})(\mathbf{g} \circ \mathbf{u})\, d\mathbf{x}$$

is a distribution on Ω. If we let φ_t be a standard sequence of (radial) mollifiers, then we find that the computation that leads to equation (8.4) in [16] will now yield

$$(\varphi_t * \mu_\theta)(\mathbf{x}) = -\int_0^t \psi_t'(r) \int_{\mathbb{R}^m} (\operatorname{div} \mathbf{g}) \deg(\mathbf{u}, S(\mathbf{x}, r), \mathbf{y})\, d\mathbf{y}\, dr,$$

where $\varphi(\mathbf{x}) = \psi(|\mathbf{x}|)$ and we have written $\mathbf{u}$ for $\mathbf{u}^*$. Since $\operatorname{div} \mathbf{g} = \theta \geq 0$, the reasoning used in the proof of [16, Lemma 8.1] therefore implies that μ_θ is a Radon measure, for each θ, and that

$$\begin{aligned} \mu_\theta(\overline{B(\mathbf{b}, r)}) &= \int_{\mathbb{R}^m} \theta(\mathbf{y}) \deg(\mathbf{u}, S(\mathbf{b}, r), \mathbf{y})\, d\mathbf{y} \\ &= \int_{\mathbb{R}^m} \theta \chi_{\mathrm{im}_{\mathrm{T}}(\mathbf{u}, B(\mathbf{b}, r))}\, d\mathbf{y} \end{aligned} \tag{A.1}$$

for $\mathcal{L}^1$ a.e. $r \in (0, r_{\mathbf{b}})$.

We next show that for $\mathcal{L}^1$ a.e. $\varepsilon \in (-\varepsilon_0, \varepsilon_0)$

$$\mu_\theta(U_\varepsilon) = \int_{\mathbb{R}^m} \theta(\mathbf{y}) \deg(\mathbf{u}, \partial U_\varepsilon, \mathbf{y})\, d\mathbf{y}. \tag{A.2}$$

Let $\psi \in C^\infty(\mathbb{R})$ satisfy $\psi(s) = 1$ for $s < -\varepsilon_0/2$ and $\psi(s) = 0$ for $s > \varepsilon_0/2$ and define $\varphi := \psi \circ \omega$, where the function $\omega : N \to (-\varepsilon_0, \varepsilon_0)$ denotes the last component of the diffeomorphism $\mathbf{w}^{-1}$. We note that $\nu := \nabla\omega/|\nabla\omega|$ is the outward unit normal to the surfaces ∂U_ε and apply the coarea formula for the C^1 function ω to get

$$\begin{aligned} \mu_\theta(\varphi) &= -\int_\Omega (\psi' \circ \omega)|\nabla\omega| \nu \cdot (\operatorname{adj} \nabla \mathbf{u})(\mathbf{g} \circ \mathbf{u})\, d\mathbf{x} \\ &= \int_{-\varepsilon_0}^{\varepsilon_0} \psi'(s) \int_{\omega = s} (\operatorname{adj} \nabla \mathbf{u})^T \nu \cdot (\mathbf{g} \circ \mathbf{u})\, d\mathcal{H}^{m-1}\, ds. \end{aligned}$$

An application of the area formula together with the fact that $\mathbf{g}$ is bounded shows that the inner integral is an $\mathcal{L}^1$ function in the variable s. If we choose a suitable increasing sequence $\psi_k \nearrow \chi_{(-\infty,\varepsilon)}$, then we find, with the aid of Proposition 2.1 in [16], that (A.2) is satisfied.

We note that it follows from (A.1) and (8.3) in [16] that

$$\mu_\theta(\overline{B(\mathbf{b},r)}) \le (\sup\theta)(\operatorname{Det}\nabla\mathbf{u})(\overline{B(\mathbf{b},r)})$$

for $\mathcal{L}^1$ a.e. $r \in (0, r_{\mathbf{b}})$. This implies that each of the measures μ_θ is absolutely continuous with respect to $\operatorname{Det}\nabla\mathbf{u}$.

Next, let $\Theta \subset C_0^\infty(\mathbb{R}^m;\mathbb{R}^{\geq})$ be a countable set that is dense in $L^2(\mathbb{R}^m;\mathbb{R}^{\geq})$ and fix $\varepsilon \in (-\varepsilon_0,\varepsilon_0)$ so that (o) is satisfied and (A.2) is satisfied for every $\theta \in \Theta$. Let $N_{\mathbf{b}}$ be the $\mathcal{L}^1$ null set of Lemma 7.3 in [16] and let $\hat{N}_{\mathbf{b}}$ be an $\mathcal{L}^1$ null set such that (A.1) is satisfied for every $\theta \in \Theta$ and every $r \in (0, r_{\mathbf{b}})\backslash\hat{N}_b$. Writing $\tilde{N}_{\mathbf{b}} = N_{\mathbf{b}} \cup \hat{N}_{\mathbf{b}}$ we consider the family of closed balls

$$\mathcal{F} := \{\overline{B(\mathbf{b},r)} : \mathbf{b} \in U_\varepsilon,\ r \in (0,r_{\mathbf{b}})\backslash\tilde{N}_{\mathbf{b}},\ (\operatorname{Det}\nabla\mathbf{u})(\partial B(\mathbf{b},r)) = 0\}.$$

Then, since the set of radii for which $(\operatorname{Det}\nabla\mathbf{u})(\partial B(\mathbf{b},r)) > 0$ is at most countable, for each $\mathbf{b} \in U_\varepsilon$

$$\inf\{r : \overline{B(\mathbf{b},r)} \in \mathcal{F}\} = 0,$$

and hence we can apply the Besicovitch covering theorem to get a sequence of pairwise disjoint closed balls $\overline{B(\mathbf{b}_k,r_k)} \subset U_\varepsilon$ such that

$$(\mathcal{L}^m + \operatorname{Det}\nabla\mathbf{u})\left(U_\varepsilon \setminus \bigcup_{k=1}^{\infty} \overline{B(\mathbf{b}_k,r_k)}\right) = 0. \tag{A.3}$$

Therefore, since the sets $\overline{B(\mathbf{b}_k,r_k)}$ are pairwise disjoint, (A.1)–(A.3) together with the absolute continuity of each measure μ_θ with respect to $\operatorname{Det}\nabla\mathbf{u}$ imply that

$$\int_{\mathbb{R}^m} \theta(\mathbf{y}) \deg(\mathbf{u},\partial U_\varepsilon,\mathbf{y})\, d\mathbf{y} = \sum_{k=1}^{\infty} \int_{\mathbb{R}^m} \theta\chi_{\operatorname{im_T}(\mathbf{u},B(\mathbf{b}_k,r_k))}\, d\mathbf{y}$$

for every $\theta \in \Theta$. Since Θ is dense in $\mathcal{L}^2(\mathbb{R}^m;\mathbb{R}^{\geq})$ and since the sets $\operatorname{im_T}(\mathbf{u},B(\mathbf{b}_k,r_k))$ are pairwise disjoint, the bounded convergence theorem and the last equation yield

$$\deg(\mathbf{u},\partial U_\varepsilon,\cdot\,) = \sum_{k=1}^{\infty} \chi_{\operatorname{im_T}(\mathbf{u},B(\mathbf{b}_k,r_k))} \text{ a.e.}$$

Consequently, since the sets $\operatorname{im_T}(\mathbf{u},B(\mathbf{b}_k,r_k))$ are pairwise disjoint, $\deg(\mathbf{u},\partial U_\epsilon,\mathbf{y})$ assumes only the values 0 and 1, and hence $\deg(\mathbf{u},\partial U_\epsilon,\cdot\,) = \chi_{\operatorname{im_T}(\mathbf{u},U_\epsilon)}$: thus,

$$\chi_{\operatorname{im_T}(\mathbf{u},U_\varepsilon)} = \sum_{k=1}^{\infty} \chi_{\operatorname{im_T}(\mathbf{u},B(\mathbf{b}_k,r_k))} \text{ a.e.} \tag{A.4}$$

We note that, by the area formula, the sets $\mathbf{u}(\partial B(\mathbf{b}_k,r_k))$ and $\mathbf{u}(\partial U_\varepsilon)$ are each Lebesgue null sets. Consequently, since the sets $\operatorname{im_T}(\mathbf{u},B(\mathbf{b}_k,r_k))$ are pairwise disjoint, (A.4) implies that there exist Lebesgue null sets M_1 and M_2 such that

$$\bigcup_{k=1}^{\infty} E(\mathbf{u},B(\mathbf{b}_k,r_k)) \subset M_1 \cup E(\mathbf{u},U_\varepsilon) \tag{A.5}$$

and

$$\text{im}_{\text{T}}(\mathbf{u}, U_\varepsilon) \subset M_2 \cup \bigcup_{k=1}^{\infty} \text{im}_{\text{T}}(\mathbf{u}, B(\mathbf{b}_k, r_k)). \tag{A.6}$$

Finally, since $\det \nabla \mathbf{u} > 0$ a.e., it follows from the area formula (see, e.g., [24, Lemma 2]) that $\mathbf{u}^{-1}(M_1)$ and $\mathbf{u}^{-1}(M_2)$ are Lebesgue null sets. Therefore (i) of this theorem follows from (A.5) and (i) of condition (INV), while (A.6) and (ii) of condition (INV) yield (ii) of this theorem. □

DYNAMICS OF ROTATING BOSE–EINSTEIN CONDENSATES AND ITS EFFICIENT AND ACCURATE NUMERICAL COMPUTATION *

WEIZHU BAO†, QIANG DU‡, AND YANZHI ZHANG§

Abstract. In this paper, we study the dynamics of rotating Bose–Einstein condensates (BEC) based on the Gross–Pitaevskii equation (GPE) with an angular momentum rotation term and present an efficient and accurate algorithm for numerical simulations. We examine the conservation of the angular momentum expectation and the condensate width and analyze the dynamics of a stationary state with a shift in its center. By formulating the equation in either the two-dimensional polar coordinate system or the three-dimensional cylindrical coordinate system, the angular momentum rotation term becomes a term with constant coefficients. This allows us to develop an efficient time-splitting method which is time reversible, unconditionally stable, efficient, and accurate for the problem. Moreover, it conserves the position density. We also apply the numerical method to study issues such as the stability of central vortex states and the quantized vortex lattice dynamics in rotating BEC.

Key words. rotating Bose–Einstein condensation, Gross–Pitaevskii equation, angular momentum rotation, time-splitting, ground state, central vortex state, energy, condensate width, angular momentum expectation

1. Introduction.

Since its realization in dilute bosonic atomic gases [3, 20, 21], Bose–Einstein condensation of alkali atoms and hydrogen has been produced and studied extensively in the laboratory [45] and has permitted an intriguing glimpse into the macroscopic quantum world. In view of potential applications [26, 43, 44], the study of quantized vortices, which are well-known signatures of superfluidity, is one of the key issues. Different research groups have obtained quantized vortices in Bose–Einstein condensates (BEC) experimentally, e.g., the JILA group [39], the ENS group [36, 37], and the MIT group [45]. Currently, there are at least two typical ways to generate quantized vortices from the ground state of BEC: (i) impose a laser beam rotating with an angular velocity on the magnetic trap holding the atoms to create an harmonic anisotropic potential [17, 33, 1, 13]; (ii) add to the stationary magnetic trap a narrow, moving Gaussian potential, representing a far-blue detuned laser [29, 7]. The recent experimental and theoretical advances in the exploration of quantized vortices in BEC have spurred great excitement in the atomic physics community and renewed interest in studying superfluidity.

The properties of BEC in a rotational frame at temperature T much smaller than the critical condensation temperature T_c are well described by the macroscopic

wave function $\psi(\mathbf{x},t)$, whose evolution is governed by a self-consistent, mean field nonlinear Schrödinger equation (NLSE) in a rotational frame, also known as the Gross–Pitaevskii equation (GPE) with an angular momentum rotation term [26, 17, 24, 25, 15]:

(1.1)
$$i\hbar\partial_t\psi(\mathbf{x},t) = \left(-\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{x}) + NU_0|\psi|^2 - \Omega L_z\right)\psi(\mathbf{x},t), \quad \mathbf{x}\in\mathbb{R}^3, \quad t\geq 0,$$

where $\mathbf{x} = (x,y,z)^T$ is the Cartesian coordinate vector, m is the atomic mass, $\hbar$ is the Planck constant, N is the number of atoms in the condensate, Ω is the angular velocity of the rotating laser beam, and $V(\mathbf{x})$ is an external trapping potential. When an harmonic trap potential is considered, $V(\mathbf{x}) = \frac{m}{2}\left(\omega_x^2x^2+\omega_y^2y^2+\omega_z^2z^2\right)$ with ω_x, ω_y, and ω_z being the trap frequencies in the x-, y-, and z-direction, respectively. $U_0 = \frac{4\pi\hbar^2a_s}{m}$ describes the interaction between atoms in the condensate with a_s (positive for repulsive interaction and negative for attractive interaction) the s-wave scattering length, and $L_z = xp_y - yp_x = -i\hbar\left(x\partial_y - y\partial_x\right)$ is the z-component of the angular momentum $\mathbf{L} = \mathbf{x}\times\mathbf{P}$ with the momentum operator $\mathbf{P} = -i\hbar\nabla = (p_x,p_y,p_z)^T$. It is convenient to normalize the wave function by requiring that

(1.2)
$$\|\psi(\cdot,t)\|^2 := \int_{\mathbb{R}^3}|\psi(\mathbf{x},t)|^2d\mathbf{x} = 1.$$

Under such a normalization, we introduce the dimensionless variables as follows: $t\to t/\omega_m$ with $\omega_m = \min\{\omega_x,\omega_y,\omega_z\}$, $\Omega\to\omega_m\Omega$, $\mathbf{x}\to a_0\mathbf{x}$ with $a_0 = \sqrt{\frac{\hbar}{m\omega_m}}$, and $\psi\to\psi/a_0^{3/2}$. We also let

$$\gamma_x = \frac{\omega_x}{\omega_m}, \quad \gamma_y = \frac{\omega_y}{\omega_m}, \quad \gamma_z = \frac{\omega_z}{\omega_m}, \quad \beta = \frac{U_0N}{a_0^3\hbar\omega_m} = \frac{4\pi a_sN}{a_0}.$$

The dimensionless angular momentum rotational term then becomes

(1.3)
$$L_z = -i(x\partial_y - y\partial_x) = i(y\partial_x - x\partial_y) = -i\partial_\theta$$

with (r,θ) being the polar coordinates in two dimensions (2D) and (r,θ,z) the cylindrical coordinates in three dimensions (3D). In the disk-shaped condensation, i.e., $\omega_y\approx\omega_x$ and $\omega_z\gg\omega_x$ ($\Leftrightarrow\gamma_x = 1$, $\gamma_y\approx 1$, and $\gamma_z\gg 1$ with choosing $\omega_m = \omega_x$), the three-dimensional GPE can be reduced to a two-dimensional GPE [13]. Thus, here we consider the dimensionless GPE with a rotational term in the d-dimensions ($d = 2,3$) [13]:

(1.4)
$$i\partial_t\psi(\mathbf{x},t) = -\frac{1}{2}\nabla^2\psi + V_d(\mathbf{x})\psi + \beta_d|\psi|^2\psi - \Omega L_z\psi, \quad \mathbf{x}\in\mathbb{R}^d, \quad t>0,$$

(1.5)
$$\psi(\mathbf{x},0) = \psi_0(\mathbf{x}), \quad \mathbf{x}\in\mathbb{R}^d, \quad \text{with} \quad \|\psi_0\|^2 := \int_{\mathbb{R}^d}|\psi_0(\mathbf{x})|^2d\mathbf{x} = 1,$$

where

(1.6)
$$\beta_d = \begin{cases}\beta\sqrt{\gamma_z/2\pi}, & \\ \beta, & \end{cases} \qquad V_d(\mathbf{x}) = \begin{cases}(\gamma_x^2x^2+\gamma_y^2y^2)/2, & d=2,\\ (\gamma_x^2x^2+\gamma_y^2y^2+\gamma_z^2z^2)/2, & d=3,\end{cases}$$

with $\gamma_x > 0$, $\gamma_y > 0$, and $\gamma_z > 0$ being constants. Two important invariants of (1.4) are the *normalization of the wave function*

$$N(\psi) = \int_{\mathbb{R}^d} |\psi(\mathbf{x},t)|^2 d\mathbf{x} \equiv \int_{\mathbb{R}^d} |\psi(\mathbf{x},0)|^2 d\mathbf{x} = N(\psi_0) = 1, \qquad t \geq 0, \tag{1.7}$$

and the *energy*

$$\begin{aligned} E_{\beta,\Omega}(\psi) &= \int_{\mathbb{R}^d} \left[\frac{1}{2}|\nabla\psi|^2 + V_d(\mathbf{x})|\psi|^2 + \frac{\beta_d}{2}|\psi|^4 - \Omega \mathrm{Re}(\psi^* L_z \psi) \right] d\mathbf{x} \\ &\equiv E_{\beta,\Omega}(\psi_0), \qquad t \geq 0, \end{aligned} \tag{1.8}$$

where f^* and $\mathrm{Re}f$ denote the conjugate and the real part of the function f, respectively.

In order to study effectively the dynamics of BEC, especially in the strong repulsive interaction regime, i.e., $\beta_d \gg 1$ in (1.4), an efficient and accurate numerical method is one of the key issues. For nonrotating BEC, i.e., $\Omega = 0$ in (1.4), many numerical methods were proposed in the literature. For example, Bao, Jaksch, and Markowich [7], Bao and Jaksch [6], and Bao and Zhang [14] proposed a fourth-order time-splitting sine or Fourier pseudospectral (TSSP) method, and Bao and Shen [11] presented a fourth-order time-splitting Laguerre–Hermite (TSLH) pseudospectral method for the GPE when the external trapping potential is radially or cylindrically symmetric in 2D or 3D. The key ideas for the numerical methods in [7, 4, 6, 14, 11, 9, 10] are based on (i) a time-splitting technique being applied to decouple the nonlinearity in the GPE [7, 6, 9, 10]; (ii) proper spectral basis functions being chosen for a linear Schrödinger equation with a potential such that the ODE system in phase space is diagonalized and thus can be integrated exactly [14, 11]. These methods are explicit, unconditionally stable, and of spectral accuracy in space and fourth-order accuracy in time. Thus they are very efficient and accurate for computing the dynamics of nonrotating BEC in 3D [8] and for multicomponent [4]. Some other numerical methods for nonrotating BEC include the finite difference method [18, 41, 40], the particle-inspired scheme [19, 40], and the Runge–Kutta pseudospectral method [16, 40]. Due to the appearance of the angular momentum rotation term in the GPE (1.4), the TSSP and TSLH methods proposed in [7, 14, 11] can no longer be used for rotating BEC. Currently, the numerical methods proposed in the literature for studying the dynamics of rotating BEC remain limited [1, 22, 33], and they usually are low-order methods. Thus it is of great interest to develop an efficient, accurate, and unconditionally stable numerical method for the GPE (1.4) with an angular momentum rotation term. Such a numerical method is proposed here and is applied to the study of the dynamics of the rotating BEC. The key features of our numerical method are based on (i) the application of a time-splitting technique for decoupling the nonlinearity in the GPE; (ii) the adoption of polar coordinates or cylindrical coordinates so as to make the coefficient of the angular momentum rotation term constant; (iii) the utilization of Fourier pseudospectral discretization in the transverse direction and a second- or fourth-order finite difference or finite element discretization in the radial direction. Our extensive numerical results demonstrate that the method is very efficient and accurate.

The paper is organized as follows. In section 2, the conservation of the angular momentum expectation and the dynamics of condensate widths are first established. We then analyze the stationary state with a shift in its center and provide some study on the decrease of the total density in the presence of dissipation. In section 3, a

numerical method is presented for the efficient and accurate simulation of GPE (1.4) in 2D and 3D. It is then applied to study the vortex state and the dynamics of rotating BEC in section 4. Finally, some conclusions are drawn in section 5.

2. Dynamics of rotating BEC. In this section, we provide some analytical results on the conservation of the angular momentum expectation in a symmetric trap, i.e., $\gamma_x = \gamma_y$ in (1.6), derive a second-order ODE for time evolution of the condensate width, and present some dynamic laws of a stationary state with a shifted center in rotating BEC.

2.1. Conservation of angular momentum expectation. As a measure of the vortex flux, we define the angular momentum expectation:

$$\langle L_z\rangle(t) := \int_{\mathbb{R}^d} \psi^*(\mathbf{x},t) L_z \psi(\mathbf{x},t)\, d\mathbf{x} = i\int_{\mathbb{R}^d} \psi^*(\mathbf{x},t)(y\partial_x - x\partial_y)\psi(\mathbf{x},t) d\mathbf{x} \tag{2.1}$$

for any $t \geq 0$. For the dynamics of angular momentum expectation in rotating BEC, we have the following lemma.

LEMMA 2.1. *Suppose $\psi(\mathbf{x},t)$ is the solution of the problem* (1.4)–(1.5)*; then we have*

$$\frac{d\langle L_z\rangle(t)}{dt} = \left(\gamma_x^2 - \gamma_y^2\right)\delta_{xy}(t), \quad \textit{where } \delta_{xy}(t) = \int_{\mathbb{R}^d} xy|\psi(\mathbf{x},t)|^2 d\mathbf{x}, \quad t \geq 0. \tag{2.2}$$

Consequently, the angular momentum expectation and energy for the nonrotating part are conserved; that is, for any given initial data $\psi_0(\mathbf{x})$ in (1.5)*,*

$$\langle L_z\rangle(t) \equiv \langle L_z\rangle(0), \quad E_{\beta,0}(\psi) \equiv E_{\beta,0}(\psi_0), \quad t \geq 0, \tag{2.3}$$

at least for radially symmetric trap in 2D or cylindrically symmetric trap in 3D, i.e., $\gamma_x = \gamma_y$.

Proof. Differentiating (2.1) with respect to t, noticing (1.4), integrating by parts, and taking into account that ψ decreases to 0 exponentially when $|\mathbf{x}| \to \infty$, we have

$$\begin{aligned}
&\frac{d\langle L_z\rangle(t)}{dt} \\
&= i\int_{\mathbb{R}^d} \left[\psi_t^*(y\partial_x - x\partial_y)\psi + \psi^*(y\partial_x - x\partial_y)\psi_t\right] d\mathbf{x} \\
&= \int_{\mathbb{R}^d} \left[(-i\psi_t^*)\,(x\partial_y - y\partial_x)\psi + (i\psi_t)\,(x\partial_y - y\partial_x)\psi^*\right] d\mathbf{x} \\
&= \int_{\mathbb{R}^d} \Bigg[\left(-\frac{1}{2}\nabla^2\psi^* + V_d(\mathbf{x})\psi^* + \beta_d|\psi|^2\psi^* - i\Omega(x\partial_y - y\partial_x)\psi^*\right)(x\partial_y - y\partial_x)\psi \\
&\qquad + \left(-\frac{1}{2}\nabla^2\psi + V_d(\mathbf{x})\psi + \beta_d|\psi|^2\psi + i\Omega(x\partial_y - y\partial_x)\psi\right)(x\partial_y - y\partial_x)\psi^*\Bigg] d\mathbf{x} \\
&= \int_{\mathbb{R}^d} \Bigg[-\frac{1}{2}\left[\nabla^2\psi^*(x\partial_y - y\partial_x)\psi + \nabla^2\psi(x\partial_y - y\partial_x)\psi^*\right] \\
&\qquad + \left(V_d(\mathbf{x}) + \beta_d|\psi|^2\right)\left[\psi^*(x\partial_y - y\partial_x)\psi + \psi(x\partial_y - y\partial_x)\psi^*\right]\Bigg] d\mathbf{x} \\
&= -\int_{\mathbb{R}^d} |\psi|^2(x\partial_y - y\partial_x)V_d(\mathbf{x}) d\mathbf{x} = \left(\gamma_x^2 - \gamma_y^2\right)\int_{\mathbb{R}^d} xy|\psi|^2 d\mathbf{x}, \quad t \geq 0,
\end{aligned} \tag{2.4}$$

which gives (2.2). As for the conservation properties, since $\gamma_x = \gamma_y$, (2.2) reduces to the first-order ODE:

$$\frac{d\langle L_z\rangle(t)}{dt} = 0, \qquad t \geq 0. \tag{2.5}$$

We thus get the conservation of $\langle L_z\rangle$ immediately.

Noticing $E_{\beta,\Omega}(\psi) = E_{\beta,0}(\psi) - \Omega \mathrm{Re}\langle L_z\rangle$ and $\mathrm{Re}\langle L_z\rangle = \langle L_z\rangle$, we get (2.3) from (2.5) and (1.8). ∎

2.2. Dynamics of condensate widths. Another quantity characterizing the dynamics of rotating BEC is the condensate width defined as

$$\sigma_\alpha(t) = \sqrt{\delta_\alpha(t)}, \quad \text{where } \delta_\alpha(t) = \langle \alpha^2\rangle(t) = \int_{\mathbb{R}^d} \alpha^2 |\psi(\mathbf{x},t)|^2 d\mathbf{x} \tag{2.6}$$

for $t \geq 0$ and α being x, y, or z. For the dynamics of condensate widths, we have the following lemmas.

LEMMA 2.2. *Suppose $\psi(\mathbf{x},t)$ is the solution of problem (1.4)–(1.5); then we have*

$$\begin{aligned}\frac{d^2\delta_\alpha(t)}{dt^2} = \int_{\mathbb{R}^d} \Big[&(\partial_y \alpha - \partial_x \alpha)\left(4i\Omega\psi^*(x\partial_y + y\partial_x)\psi + 2\Omega^2(x^2-y^2)|\psi|^2\right) \\ &+ 2|\partial_\alpha \psi|^2 + \beta_d |\psi|^4 - 2\alpha|\psi|^2 \partial_\alpha(V_d(\mathbf{x}))\Big] d\mathbf{x}, \qquad t \geq 0,\end{aligned} \tag{2.7}$$

$$\delta_\alpha(0) = \delta_\alpha^{(0)} = \int_{\mathbb{R}^d} \alpha^2 |\psi_0(\mathbf{x})|^2 d\mathbf{x}, \qquad \alpha = x, y, z, \tag{2.8}$$

$$\dot{\delta}_\alpha(0) = \delta_\alpha^{(1)} = 2\int_{\mathbb{R}^d} \alpha \left[-\Omega|\psi_0|^2 (x\partial_y - y\partial_x)\alpha + \mathrm{Im}\left(\psi_0^* \partial_\alpha \psi_0\right)\right] d\mathbf{x}, \tag{2.9}$$

where $\mathrm{Im}(f)$ *denotes the imaginary part of* f.

Proof. Differentiating (2.6) with respect to t, applying (1.4), and integrating by parts, we obtain

$$\begin{aligned}\frac{d\delta_\alpha(t)}{dt} &= \frac{d}{dt}\int_{\mathbb{R}^d} \alpha^2 |\psi(\mathbf{x},t)|^2 d\mathbf{x} = \int_{\mathbb{R}^d} \alpha^2 \left(\psi \partial_t \psi^* + \psi^* \partial_t \psi\right) d\mathbf{x} \\ &= \int_{\mathbb{R}^d} \left[\frac{i}{2}\alpha^2 \left(\psi^* \nabla^2 \psi - \psi \nabla^2 \psi^*\right) + \Omega \alpha^2 \left(x\partial_y - y\partial_x\right)|\psi|^2\right] d\mathbf{x} \\ &= \int_{\mathbb{R}^d} \left[i\alpha \left(\psi \partial_\alpha \psi^* - \psi^* \partial_\alpha \psi\right) - 2\Omega\alpha|\psi|^2 \left(x\partial_y - y\partial_x\right)\alpha\right] d\mathbf{x}.\end{aligned} \tag{2.10}$$

Differentiating the above equation again, applying (1.4), and integrating by parts, we get

$$\begin{aligned}&\frac{d^2\delta_\alpha(t)}{dt^2} \\ &= \int_{\mathbb{R}^d} \Big[i\alpha \left(\partial_t \psi \partial_\alpha \psi^* + \psi \partial_{\alpha t} \psi^* - \partial_t \psi^* \partial_\alpha \psi - \psi^* \partial_{\alpha t} \psi\right) \\ &\qquad - 2\Omega\alpha \left(\psi \partial_t \psi^* + \psi^* \partial_t \psi\right)\left(x\partial_y - y\partial_x\right)\alpha\Big] d\mathbf{x} \\ &= \int_{\mathbb{R}^d} \Big[2i\alpha \left(\partial_t \psi \partial_\alpha \psi^* - \partial_t \psi^* \partial_\alpha \psi\right) + i\left(\psi^* \partial_t \psi - \psi \partial_t \psi^*\right) \\ &\qquad - 2\Omega\alpha (x\partial_y - y\partial_x)\alpha \left(\frac{i}{2}\left(\psi^* \nabla^2 \psi - \psi \nabla^2 \psi^*\right) + \Omega (x\partial_y - y\partial_x)|\psi|^2\right)\Big] d\mathbf{x},\end{aligned} \tag{2.11}$$

$$
\begin{aligned}
&\frac{d^2\delta_\alpha(t)}{dt^2}\\
&= \int_{\mathbb{R}^d}\Bigg[-\alpha\left(\partial_\alpha\psi^*\nabla^2\psi + \partial_\alpha\psi\nabla^2\psi^*\right) + 2\alpha\left(V_d(\mathbf{x}) + \beta_d|\psi|^2\right)\left(\psi\partial_\alpha\psi^* + \psi^*\partial_\alpha\psi\right)\\
&\qquad -2i\Omega\alpha\left[\partial_\alpha\psi\left(x\partial_y - y\partial_x\right)\psi^* - \partial_\alpha\psi^*\left(x\partial_y - y\partial_x\right)\psi\right] - \frac{1}{2}\left(\psi^*\nabla^2\psi + \psi\nabla^2\psi^*\right)\\
&\qquad +2\left(V_d(\mathbf{x})|\psi|^2 + \beta_d|\psi|^4\right) - i\Omega\left[\psi\left(x\partial_y - y\partial_x\right)\psi^* - \psi^*\left(x\partial_y - y\partial_x\right)\psi\right]\\
&\qquad -2i\Omega\psi^*\left[\partial_x\alpha\left(\alpha\partial_y + y\partial_\alpha\right)\psi - \partial_y\alpha\left(\alpha\partial_x + x\partial_\alpha\right)\psi\right]\\
&\qquad +2\Omega^2|\psi|^2\left[\left(y^2 - \alpha x\right)\partial_x\alpha + \left(x^2 - \alpha y\right)\partial_y\alpha\right]\Bigg] d\mathbf{x}\\
&= \int_{\mathbb{R}^d}\Big[-4i\Omega\psi^*\left[\partial_x\alpha\left(\alpha\partial_y + y\partial_\alpha\right)\psi - \partial_y\alpha\left(\alpha\partial_x + x\partial_\alpha\right)\psi\right] + 2|\partial_\alpha\psi|^2 + \beta_d|\psi|^4\\
&\qquad +2\Omega^2|\psi|^2\left[\left(y^2 - \alpha x\right)\partial_x\alpha + \left(x^2 - \alpha y\right)\partial_y\alpha\right] - 2\alpha|\psi|^2\partial_\alpha\left(V_d(\mathbf{x})\right)\Big] d\mathbf{x}\\
&= \int_{\mathbb{R}^d}\Big[\left(\partial_y\alpha - \partial_x\alpha\right)\left[4i\Omega\psi^*(x\partial_y + y\partial_x)\psi + 2\Omega^2\left(x^2 - y^2\right)|\psi|^2\right]\\
&\qquad +2|\partial_\alpha\psi|^2 + \beta_d|\psi|^4 - 2\alpha|\psi|^2\partial_\alpha\left(V_d(\mathbf{x})\right)\Big] d\mathbf{x}. \qquad (2.12)
\end{aligned}
$$

Furthermore, noticing (1.5), (2.6), and (2.10) with $t = 0$, we get (2.8) and (2.9) immediately. □

LEMMA 2.3. (i) *In 2D with a radial symmetric trap, i.e., $d = 2$ and $\gamma_x = \gamma_y := \gamma_r$ in* (1.4)*, for any initial data $\psi_0 = \psi_0(x, y)$, we have, for any $t \geq 0$,*

$$
\delta_r(t) = \frac{E_{\beta,\Omega}(\psi_0) + \Omega\langle L_z\rangle(0)}{\gamma_r^2}\left[1 - \cos(2\gamma_r t)\right] + \delta_r^{(0)}\cos(2\gamma_r t) + \frac{\delta_r^{(1)}}{2\gamma_r}\sin(2\gamma_r t), \qquad (2.13)
$$

where $\delta_r(t) = \delta_x(t) + \delta_y(t)$, $\delta_r^{(0)} := \delta_x(0) + \delta_y(0)$, and $\delta_r^{(1)} := \dot\delta_x(0) + \dot\delta_y(0)$. Furthermore, when the initial condition $\psi_0(x, y)$ in (1.5) *satisfies*

$$
\psi_0(x, y) = f(r)e^{im\theta} \quad \text{with} \quad m \in \mathbb{Z} \quad \text{and} \quad f(0) = 0 \quad \text{when} \quad m \neq 0, \qquad (2.14)
$$

we have, for any $t \geq 0$,

$$
\begin{aligned}
\delta_x(t) = \delta_y(t) &= \frac{1}{2}\delta_r(t)\\
&= \frac{E_{\beta,\Omega}(\psi_0) + m\Omega}{2\gamma_x^2}\left[1 - \cos(2\gamma_x t)\right] + \delta_x^{(0)}\cos(2\gamma_x t) + \frac{\delta_x^{(1)}}{2\gamma_x}\sin(2\gamma_x t). \qquad (2.15)
\end{aligned}
$$

This and (2.6) *imply that*

$$
\sigma_x = \sigma_y = \sqrt{\frac{E_{\beta,\Omega}(\psi_0) + m\Omega}{2\gamma_x^2}\left[1 - \cos(2\gamma_x t)\right] + \delta_x^{(0)}\cos(2\gamma_x t) + \frac{\delta_x^{(1)}}{2\gamma_x}\sin(2\gamma_x t)}. \qquad (2.16)
$$

Thus in this case, the condensate widths $\sigma_x(t)$ and $\sigma_y(t)$ are periodic functions with frequency doubling the trapping frequency.

(ii) *For all other cases, we have, for any* $t \geq 0$,

$$\delta_\alpha(t) = \frac{E_{\beta,\Omega}(\psi_0)}{\gamma_\alpha^2} + \left(\delta_\alpha^{(0)} - \frac{E_{\beta,\Omega}(\psi_0)}{\gamma_\alpha^2}\right)\cos(2\gamma_\alpha t) + \frac{\delta_\alpha^{(1)}}{2\gamma_\alpha}\sin(2\gamma_\alpha t) + f_\alpha(t), \tag{2.17}$$

where $f_\alpha(t)$ *is the solution of the following second-order ODE:*

$$\frac{d^2 f_\alpha(t)}{dt^2} + 4\gamma_\alpha^2\, f_\alpha(t) = F_\alpha(t), \qquad f_\alpha(0) = \frac{df_\alpha(0)}{dt} = 0, \tag{2.18}$$

with

$$\begin{aligned} F_\alpha(t) = \int_{\mathbb{R}^d} \Big[& 2|\partial_\alpha\psi|^2 - 2|\nabla\psi|^2 - \beta_d|\psi|^4 + \left(2\gamma_\alpha^2\alpha^2 - 4V_d(\mathbf{x})\right)|\psi|^2 + 4\Omega\psi^* L_z\psi \\ & + (\partial_y\alpha - \partial_x\alpha)\left(4i\Omega\psi^*\left(x\partial_y + y\partial_x\right)\psi + 2\Omega^2(x^2-y^2)|\psi|^2\right)\Big] d\mathbf{x}. \end{aligned}$$

Proof. From (2.7) with $d = 2$, we have

$$\begin{aligned} & \frac{d^2\delta_x(t)}{dt^2} + 2\gamma_x^2\delta_x(t) \\ & = \int_{\mathbb{R}^2}\left[2|\partial_x\psi|^2 + \beta_2|\psi|^4 - 4i\Omega\psi^*\left(x\partial_y + y\partial_x\right)\psi - 2\Omega^2\left(x^2-y^2\right)|\psi|^2\right] d\mathbf{x}, \end{aligned} \tag{2.19}$$

$$\begin{aligned} & \frac{d^2\delta_y(t)}{dt^2} + 2\gamma_y^2\delta_y(t) \\ & = \int_{\mathbb{R}^2}\left[2|\partial_y\psi|^2 + \beta_2|\psi|^4 + 4i\Omega\psi^*\left(x\partial_y + y\partial_x\right)\psi + 2\Omega^2\left(x^2-y^2\right)|\psi|^2\right] d\mathbf{x}. \end{aligned} \tag{2.20}$$

For case (i) with $\gamma_x = \gamma_y := \gamma_r$ in (1.4), summing up (2.19) and (2.20) together and applying (1.8) and (2.3), we have the following ODE for $\delta_r(t)$:

$$\begin{aligned} \frac{d^2\delta_r(t)}{dt^2} &= -2\gamma_r^2\delta_r(t) + \int_{\mathbb{R}^2}\left[2|\nabla\psi|^2 + 2\beta_2|\psi|^4\right] d\mathbf{x} \\ &= -2\gamma_r^2\delta_r(t) - 4\int_{\mathbb{R}^2}\left[V_2(\mathbf{x})|\psi|^2 - \Omega\psi^* L_z\psi\right] d\mathbf{x} \\ &\quad + 4\int_{\mathbb{R}^2}\left[\frac{1}{2}|\nabla\psi|^2 + V_2(\mathbf{x})|\psi|^2 + \frac{\beta_2}{2}|\psi|^4 - \Omega\psi^* L_z\psi\right] d\mathbf{x} \\ &= -2\gamma_r^2\delta_r(t) - 2\gamma_r^2\delta r(t) + 4\Omega\langle L_z\rangle(t) + 4E_{\beta,\Omega}(\psi(\cdot,t)) \\ &= -4\gamma_r^2\delta_r(t) + 4E_{\beta,\Omega}(\psi_0) + 4\Omega\langle L_z\rangle(0), \qquad t \geq 0, \end{aligned} \tag{2.21}$$

$$\delta_r(0) = \delta_r^{(0)}, \qquad \dot{\delta}_r(0) = \delta_r^{(1)}. \tag{2.22}$$

Thus, (2.13) is the unique solution of the second-order ODE (2.21) with the initial data (2.22). Furthermore, when the initial data $\psi_0(\mathbf{x})$ in (1.5) satisfies (2.14), due to symmetry, the solution $\psi(\mathbf{x},t)$ of (1.4)–(1.5) satisfies

$$\psi(x,y,t) = g(r,t)e^{im\theta} \quad \text{with} \quad g(r,0) = f(r). \tag{2.23}$$

This implies

$$\begin{aligned}\delta_x(t) &= \int_{\mathbb{R}^2} x^2|\psi(x,y,t)|^2\,d\mathbf{x} = \int_0^\infty\int_0^{2\pi} r^2\cos^2\theta|g(r,t)|^2 r\,d\theta dr\\ &= \pi\int_0^\infty r^2|g(r,t)|^2 r\,dr = \int_0^\infty\int_0^{2\pi} r^2\sin^2\theta|g(r,t)|^2 r\,d\theta dr\\ &= \int_{\mathbb{R}^2} y^2|\psi(x,y,t)|^2\,d\mathbf{x} = \delta_y(t), \qquad t\ge 0. \end{aligned} \tag{2.24}$$

Since $\gamma_x = \gamma_y$, by Lemma 2.1, we know in this case that

$$\begin{aligned}\langle L_z\rangle(t) &= \langle L_z\rangle(0) = -i\int_{\mathbb{R}^2}\psi_0^*(x,y)\partial_\theta\psi_0(x,y)\,d\mathbf{x}\\ &= 2\pi m\int_0^\infty |f(r)|^2 r\,dr = m\|\psi_0\|^2 = m.\end{aligned} \tag{2.25}$$

Thus, (2.15) is a combination of (2.13), (2.24), and (2.25).

(ii) From (2.7) and noticing the energy conservation (1.8), we have

$$\begin{aligned}\frac{d^2\delta_\alpha(t)}{dt^2} &= \int_{\mathbb{R}^d}\Big[(\partial_y\alpha-\partial_x\alpha)\left[4i\Omega\psi^*(x\partial_y+y\partial_x)\psi+2\Omega^2\left(x^2-y^2\right)|\psi|^2\right]\\ &\qquad +2|\partial_\alpha\psi|^2+\beta_d|\psi|^4-2\gamma_\alpha^2\alpha^2|\psi|^2\Big]\,d\mathbf{x}\\ &= -4\gamma_\alpha^2\delta_\alpha(t)+4\int_{\mathbb{R}^2}\left[\frac{1}{2}|\nabla\psi|^2+V_d(\mathbf{x})|\psi|^2+\frac{\beta_d}{2}|\psi|^4-\Omega\psi^*L_z\psi\right]d\mathbf{x}\\ &\quad+\int_{\mathbb{R}^d}\Big[2|\partial_\alpha\psi|^2-2|\nabla\psi|^2-\beta_d|\psi|^4+\left(2\gamma_\alpha^2\alpha^2-4V_d(\mathbf{x})\right)|\psi|^2+4\Omega\psi^*L_z\psi\\ &\qquad+(\partial_y\alpha-\partial_x\alpha)\left(4i\Omega\psi^*\left(x\partial_y+y\partial_x\right)\psi+2\Omega^2(x^2-y^2)|\psi|^2\right)\Big]d\mathbf{x}\\ &= -4\gamma_\alpha^2\delta_\alpha(t)+4E_{\beta,\Omega}(\psi(\cdot,t))+F_\alpha(t)\\ &= -4\gamma_\alpha^2\delta_\alpha(t)+4E_{\beta,\Omega}(\psi_0)+F_\alpha(t), \qquad t\ge 0.\end{aligned} \tag{2.26}$$

Thus (2.17) is the unique solution of the second-order ODE (2.26) with the initial data (2.8), (2.9). ∎

2.3. Dynamics of a stationary state with its center shifted. Let $\phi_e(\mathbf{x})$ be a stationary state of the GPE (1.4) with a chemical potential μ_e [13, 12], i.e., (μ_e,ϕ_e) satisfying

$$\mu_e\phi_e(\mathbf{x}) = -\frac{1}{2}\nabla^2\phi_e+V_d(\mathbf{x})\phi_e+\beta_d|\phi_e|^2\phi_e-\Omega L_z\phi_e, \qquad \|\phi_e\|^2=1. \tag{2.27}$$

If the initial data $\psi_0(\mathbf{x})$ in (1.5) is chosen as a stationary state with a shift in its center, one can construct an exact solution of the GPE (1.4) with an harmonic oscillator potential (1.6). This kind of analytical construction can be used, in particular, in the benchmark and validation of numerical algorithms for the GPE. In [27], a similar kind of solution was constructed for the GPE and a second order ODE system was derived for the dynamics of the center, but the results there were valid only for nonrotating BEC, i.e., $\Omega = 0$. Modifications must be made for the rotating BEC, i.e., $\Omega \neq 0$. Later, in [15], similar results were extended to the case of a general Hamiltonian but

without specifying the initial data for the ODE system. For the convenience of the reader, here we present a simple derivation of the dynamic laws for rotating BEC.

LEMMA 2.4. *If the initial data* $\psi_0(\mathbf{x})$ *in* (1.5) *is chosen as*

$$\psi_0(\mathbf{x}) = \phi_e(\mathbf{x} - \mathbf{x}_0), \qquad \mathbf{x} \in \mathbb{R}^d, \tag{2.28}$$

where $\mathbf{x}_0$ *is a given point in* $\mathbb{R}^d$*, then the exact solution of* (1.4)–(1.5) *satisfies*

$$\psi(\mathbf{x}, t) = \phi_e(\mathbf{x} - \mathbf{x}(t))\, e^{-i\mu_e t}\, e^{iw(\mathbf{x},t)}, \quad \mathbf{x} \in \mathbb{R}^d, \quad t \geq 0, \tag{2.29}$$

where for any time $t \geq 0$*,* $w(\mathbf{x}, t)$ *is linear for* $\mathbf{x}$*, i.e.,*

$$w(\mathbf{x}, t) = \mathbf{c}(t) \cdot \mathbf{x} + g(t), \quad \mathbf{c}(t) = (c_1(t), \ldots, c_d(t))^T, \quad \mathbf{x} \in \mathbb{R}^d, \quad t \geq 0, \tag{2.30}$$

and $\mathbf{x}(t)$ *satisfies the following second-order ODE system:*

$$\ddot{x}(t) - 2\Omega\dot{y}(t) + \left(\gamma_x^2 - \Omega^2\right) x(t) = 0, \tag{2.31}$$

$$\ddot{y}(t) + 2\Omega\dot{x}(t) + \left(\gamma_y^2 - \Omega^2\right) y(t) = 0, \qquad t \geq 0, \tag{2.32}$$

$$x(0) = x_0, \quad y(0) = y_0, \quad \dot{x}(0) = \Omega y_0, \quad \dot{y}(0) = -\Omega x_0. \tag{2.33}$$

Moreover, if in $3D$*, another ODE needs to be added:*

$$\ddot{z}(t) + \gamma_z^2 z(t) = 0, \quad z(0) = z_0, \quad \dot{z}(0) = 0. \tag{2.34}$$

Proof. For $d = 2$, we introduce

$$J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad A = \begin{pmatrix} \gamma_x^2 & 0 \\ 0 & \gamma_y^2 \end{pmatrix}, \quad \nabla = \begin{pmatrix} \partial_x \\ \partial_y \end{pmatrix}.$$

Differentiating (2.29) with respect to t and $\mathbf{x}$, respectively, plugging into (1.4), changing variable $\mathbf{x} - \mathbf{x}(t) \to \mathbf{x}$, and noticing (2.27), we obtain for $\phi_e = \phi_e(\mathbf{x})$ and $w = w(\mathbf{x} + \mathbf{x}(t), t)$ that

$$\begin{aligned} \phi_e \partial_t w + i\dot{\mathbf{x}}(t) \cdot \nabla\phi_e = \frac{1}{2}\left[i\phi_e \nabla^2 w - \phi_e |\nabla w|^2 - \mathbf{x}(t)^T A(2\mathbf{x} + \mathbf{x}(t))\phi_e\right] \\ + i\nabla\phi_e \cdot \nabla w - \phi_e \Omega(\mathbf{x} + \mathbf{x}(t)) \cdot (J\nabla w) + i\Omega\mathbf{x}(t) \cdot (J\nabla\phi_e). \end{aligned} \tag{2.35}$$

Taking the real and imaginary parts in (2.35) and noticing (2.30), we have

$$[\dot{\mathbf{x}}(t) - \nabla w(\mathbf{x} + \mathbf{x}(t), t) - \Omega J\mathbf{x}(t)] \cdot \nabla\phi_e = 0, \tag{2.36}$$

$$\left[\partial_t w + \frac{1}{2}|\nabla w|^2 + \frac{1}{2}\mathbf{x}(t)^T A(2\mathbf{x} + \mathbf{x}(t)) - \Omega(\mathbf{x} + \mathbf{x}(t)) \cdot (J\nabla w)\right] \phi_e = 0. \tag{2.37}$$

We thus get

$$\dot{\mathbf{x}}(t) = \nabla w(\mathbf{x} + \mathbf{x}(t), t) + \Omega J\mathbf{x}(t), \tag{2.38}$$

$$\begin{aligned} \partial_t w(\mathbf{x} + \mathbf{x}(t), t) = -\frac{1}{2}\left[|\nabla w|^2 + \mathbf{x}(t)^T A(2\mathbf{x} + \mathbf{x}(t))\right] \\ + \Omega(\mathbf{x} + \mathbf{x}(t)) \cdot (J\nabla w). \end{aligned} \tag{2.39}$$

Differentiating (2.38) and (2.39) with respect to t and $\mathbf{x}$, respectively, and noticing (2.30), which implies that $|\nabla w|^2$ is independent of $\mathbf{x}$, we obtain

$$\begin{aligned}
0 &= \ddot{\mathbf{x}}(t) - \partial_t(\nabla w(\mathbf{x}+\mathbf{x}(t),t)) - \Omega J\dot{\mathbf{x}}(t)\\
&= \ddot{\mathbf{x}}(t) - \nabla(\partial_t w(\mathbf{x}+\mathbf{x}(t),t)) - \dot{\mathbf{x}}(t)\,\nabla^2 w(\mathbf{x}+\mathbf{x}(t),t) - \Omega J\dot{\mathbf{x}}(t)\\
&= \ddot{\mathbf{x}}(t) - \nabla(\partial_t w(\mathbf{x}+\mathbf{x}(t),t)) - \Omega J\dot{\mathbf{x}}(t)\\
&= \ddot{\mathbf{x}}(t) + A\mathbf{x}(t) - \Omega J\,[\dot{\mathbf{x}}(t) - \Omega J\mathbf{x}(t)] - \Omega J\dot{\mathbf{x}}(t)\\
&= \ddot{\mathbf{x}}(t) - 2\Omega J\dot{\mathbf{x}}(t) + (A+\Omega^2 J^2)\mathbf{x}(t)\\
&= \ddot{\mathbf{x}}(t) - 2\Omega J\dot{\mathbf{x}}(t) + (A-\Omega^2 I)\mathbf{x}(t), \qquad t\ge 0. \qquad (2.40)
\end{aligned}$$

From (2.29) with $t=0$, we get

$$\mathbf{x}(0)=\mathbf{x}_0, \quad w(\mathbf{x},0)\equiv 0, \quad \mathbf{x}\in\mathbb{R}^d. \qquad (2.41)$$

Thus (2.33) is a combination of (2.41) and (2.38) with $t=0$. For $d=3$, the proof is similar, and the details are omitted here. □

In the literature, constructions similar to the above are often numerically verified by directly simulating the dynamics of the GPE in nonrotating BEC [14, 27]. To our knowledge, the above lemma gives the first rigorous derivation for rotating BEC.

Notice that if $\mathbf{u}=\dot{\mathbf{x}}(t)-\Omega J\mathbf{x}(t)$, then (2.40) gives a coupled first-order system

$$\begin{cases} \dot{\mathbf{x}}(t) = \Omega J\mathbf{x}(t) + \mathbf{u},\\ \dot{\mathbf{u}}(t) = -A\mathbf{x}(t) + \Omega J\mathbf{u},\\ \mathbf{x}(0)=\mathbf{x}_0, \ \ \mathbf{u}(0)=0, \end{cases} \qquad (2.42)$$

which is a Hamiltonian system with the Hamiltonian $H(\mathbf{x},\mathbf{u}) = \Omega\mathbf{u}^T J\mathbf{x} + (\mathbf{u}^T\mathbf{u} + \mathbf{x}^T A\mathbf{x})/2$. The characteristic roots λ of the system are given by the equation

$$\lambda^4 + (\gamma_x^2+\gamma_y^2+2\Omega^2)\lambda^2 + (\gamma_x^2-\Omega^2)(\gamma_y^2-\Omega^2) = 0. \qquad (2.43)$$

The exact solutions of (2.42) may thus be completely determined.

We note not only that results on the dynamics of a stationary state with its center shifted are physically interesting this type of exact solution of the time-dependent GPE can also serve as a good benchmark for numerical algorithms and is useful in the mathematical studies of the dynamic stabilities of the vortex state in BEC. In section 4.2, we will study this kind of dynamics by directly simulating the GPE in a rotational frame and explore different motion patterns of a stationary state center under different rotation speed Ω.

2.4. Dynamics of the total density in the presence of dissipation. Consider a more general GPE of the form

$$(i-\lambda)\partial_t\psi(\mathbf{x},t) = -\frac{1}{2}\nabla^2\psi + V(\mathbf{x},t)\psi + \beta_d|\psi|^2\psi - \Omega L_z\psi, \quad \mathbf{x}\in\mathbb{R}^d, \quad t>0, \qquad (2.44)$$

$$\psi(\mathbf{x},0)=\psi_0(\mathbf{x}), \quad \mathbf{x}\in\mathbb{R}^d, \qquad (2.45)$$

where $\lambda\ge 0$ is a real parameter that models a dissipation mechanism [2, 30, 32] and $V(\mathbf{x},t) = V_d(\mathbf{x}) + W(\mathbf{x},t)$ with $W(\mathbf{x},t)$ an external driven field [16, 31]. Typical external driven fields used in physics literature include a Delta kicked potential [31]

$$W(x,t) = K_s\cos(k_s x)\sum_{n=-\infty}^{\infty}\delta(t-n\tau), \qquad (2.46)$$

with K_s being the kick strength, k_s the wavenumber, τ the time interval between kicks, and $\delta(\tau)$ the Dirac delta function, or a far-blue detuned Gaussian laser beam stirrer [16]

$$W(\mathbf{x},t) = W_s(t)\exp\left[-\left(\frac{|\mathbf{x}-\mathbf{x}_s(t)|^2}{w_s/2}\right)\right] \tag{2.47}$$

with $W_s(t)$ being the height, w_s the width, and $\mathbf{x}_s(t)$ the position of the stirrer. In addition, we note that to study the onset of energy dissipation in BEC stirred by a laser field, another possibility is to view the beam as an translating *obstacle* [2] instead of introducing the Gaussian potential.

While the total density remains constant with $\lambda = 0$, in the more general case, we have the following lemma for the dynamics of the total density.

LEMMA 2.5. *Let $\psi(\mathbf{x},t)$ be the solution of (2.44)–(2.45); then the total density satisfies*

$$\dot{N}(\psi)(t) = \frac{d}{dt}\int_{\mathbb{R}^d}|\psi(\mathbf{x},t)|^2\,d\mathbf{x} = -\frac{2\lambda}{1+\lambda^2}\mu_{\beta,\Omega}(\psi), \qquad t\geq 0, \tag{2.48}$$

where

$$\mu_{\beta,\Omega}(\psi) = \int_{\mathbb{R}^d}\left[\frac{1}{2}|\nabla\psi|^2 + V(\mathbf{x},t)|\psi|^2 + \beta_d|\psi|^4 - \Omega\mathrm{Re}(\psi^* L_z\psi)\right]d\mathbf{x}.$$

Consequently, the total density decreases when $\lambda > 0$ and $|\Omega| \leq \gamma_{xy} := \min\{\gamma_x,\gamma_y\}$.

Proof. Dividing (2.44) by $(i-\lambda)$, multiplying it by ψ^* and summing with its complex conjugate, and integrating by parts, we obtain

$$\begin{aligned}
\frac{dN(\psi)}{dt} &= \int_{\mathbb{R}^d}\Bigg[-\frac{i+\lambda}{1+\lambda^2}\left(-\frac{1}{2}\nabla^2\psi + V(\mathbf{x},t)\psi + \beta_d|\psi|^2\psi - \Omega L_z\psi\right)\psi^* \\
&\qquad + \frac{i-\lambda}{1+\lambda^2}\left(-\frac{1}{2}\nabla^2\psi^* + V(\mathbf{x},t)\psi^* + \beta_d|\psi|^2\psi^* - \Omega(L_z)^*\psi^*\right)\psi\Bigg]d\mathbf{x} \\
&= \frac{\lambda}{1+\lambda^2}\int_{\mathbb{R}^d}\Bigg[\frac{1}{2}\left(\psi^*\nabla^2\psi + \psi\nabla^2\psi^*\right) - 2\left(V(\mathbf{x},t)|\psi|^2 + \beta_d|\psi|^4\right) \\
&\qquad\qquad + \Omega\left(\psi^* L_z\psi + \psi(L_z)^*\psi^*\right)\Bigg]d\mathbf{x} \\
&= \frac{-2\lambda}{1+\lambda^2}\int_{\mathbb{R}^d}\left[\frac{1}{2}|\nabla\psi|^2 + V(\mathbf{x},t)|\psi|^2 + \beta_d|\psi|^4 - \Omega\mathrm{Re}(\psi^* L_z\psi)\right]d\mathbf{x} \\
&= \frac{-2\lambda}{1+\lambda^2}\mu_{\beta,\Omega}(\psi). \qquad (2.49)
\end{aligned}$$

When $\gamma > 0$ and $|\Omega| < \gamma_{xy}$, by a completion of square [1, 13], we have

$$\frac{1}{2}|\nabla\psi|^2 + V(\mathbf{x},t)|\psi|^2 - \Omega\mathrm{Re}(\psi^* L_z\psi) = \frac{1}{2}|(\nabla - i\mathbf{A})\psi|^2 + \left[V(\mathbf{x},t) - \frac{|\Omega|^2}{2}(x^2+y^2)\right]|\psi|^2$$

for a vector potential $\mathbf{A} = \mathbf{A}(x,y) = (y,-x)\Omega$ in 2D and $\mathbf{A} = \mathbf{A}(x,y,z) = (y,-x,0)\Omega$ in 3D. Thus, $\mu_{\beta,\Omega}(\psi) > 0$. Consequently, we get

$$\frac{dN(\psi)}{dt} < 0, \qquad t\geq 0, \tag{2.50}$$

which immediately implies the decreasing of the total density. ∎

3. Numerical methods. In this section, we will present an efficient and accurate numerical method to solve the following GPE for the dynamics of rotating BEC.

Due to the trapping potential $V_d(\mathbf{x})$ given by (1.6), the solution $\psi(\mathbf{x},t)$ of (2.44)–(2.45) decays to zero exponentially fast when $|\mathbf{x}| \to \infty$. Thus in practical computation, we truncate the problem (2.44)–(2.45) into a bounded computational domain with the homogeneous Dirichlet boundary condition:

$$(i-\lambda)\partial_t\psi(\mathbf{x},t) = -\frac{1}{2}\nabla^2\psi + V(\mathbf{x},t)\psi + \beta_d|\psi|^2\psi - \Omega L_z\psi, \quad \mathbf{x}\in\Omega_{\mathbf{x}}, \quad t>0, \tag{3.1}$$

$$\psi(\mathbf{x},t) = 0, \quad \mathbf{x}\in\Gamma = \partial\Omega_{\mathbf{x}}, \quad t\geq 0, \tag{3.2}$$

$$\psi(\mathbf{x},0) = \psi_0(\mathbf{x}), \qquad \mathbf{x}\in\bar{\Omega}_{\mathbf{x}}, \tag{3.3}$$

where we choose $\Omega_{\mathbf{x}} = \{(x,y),\ r=\sqrt{x^2+y^2} < R\}$ in 2D and, respectively, $\Omega_{\mathbf{x}} = \{(x,y,z),\ r=\sqrt{x^2+y^2}<R,\ a<z<b\}$ in 3D with R, $|a|$, and b sufficiently large. The use of more sophisticated radiation boundary conditions is an interesting topic that remains to be examined in the future.

3.1. Time-splitting. We choose a time step size $\Delta t>0$. For $n=0,1,2,\ldots,$ from time $t=t_n=n\Delta t$ to $t=t_{n+1}=t_n+\Delta t$, the GPE (3.1) is solved in two splitting steps. One first solves

$$(i-\lambda)\ \partial_t\psi(\mathbf{x},t) = -\frac{1}{2}\nabla^2\psi - \Omega L_z\psi \tag{3.4}$$

for the time step of length Δt, followed by solving

$$(i-\lambda)\ \partial_t\psi(\mathbf{x},t) = V(\mathbf{x},t)\psi + \beta_d|\psi|^2\psi \tag{3.5}$$

for the same time step. Equation (3.4) will be discretized in detail in the next two subsections. For $t\in[t_n,t_{n+1}]$, after dividing (3.5) by $(i-\lambda)$, multiplying it by ψ^*, and adding with its complex conjugate, we obtain the following ODE for $\rho(\mathbf{x},t) = |\psi(\mathbf{x},t)|^2$:

$$\partial_t\rho(\mathbf{x},t) = -\frac{2\lambda}{1+\lambda^2}\left[V(\mathbf{x},t)\rho(\mathbf{x},t) + \beta_d\rho^2(\mathbf{x},t)\right], \quad \mathbf{x}\in\Omega_{\mathbf{x}}, \quad t_n\leq t\leq t_{n+1}. \tag{3.6}$$

The ODE for the phase angle $\phi(\mathbf{x},t)$ (determined as $\psi=\sqrt{\rho}e^{i\phi}$) is given by

$$\phi_t = -\frac{1}{1+\lambda^2}\left[V(\mathbf{x},t) + \beta_d\rho(\mathbf{x},t)\right], \quad \mathbf{x}\in\Omega_{\mathbf{x}}, \quad t_n\leq t\leq t_{n+1}. \tag{3.7}$$

For $\lambda\neq 0$, by (3.6), the above is equivalent to

$$\phi_t = \frac{1}{2\lambda}\partial_t\ln\rho, \quad \mathbf{x}\in\Omega_{\mathbf{x}}, \quad t_n\leq t\leq t_{n+1}. \tag{3.8}$$

Denoting $V_n(\mathbf{x},t) = \int_{t_n}^t V(\mathbf{x},\tau)d\tau$, we can solve (3.6) to get

$$\rho(\mathbf{x},t) = \frac{\rho(\mathbf{x},t_n)\ \exp[\frac{-2\lambda V_n(\mathbf{x},t)}{1+\lambda^2}]}{1+\rho(\mathbf{x},t_n)\frac{2\lambda\beta_d}{1+\lambda^2}\int_{t_n}^t \exp[\frac{-2\lambda V_n(\mathbf{x},\tau)}{1+\lambda^2}]\ d\tau}. \tag{3.9}$$

Consequently, in the special case $V(\mathbf{x},t) = V(\mathbf{x})$, we have some exact analytical solutions given by

$$\rho(\mathbf{x},t) = \begin{cases} \rho(\mathbf{x},t_n), & \lambda = 0, \\ \dfrac{(1+\lambda^2)\rho(\mathbf{x},t_n)}{(1+\lambda^2)+2\lambda\beta_d(t-t_n)\rho(\mathbf{x},t_n)}, & V(\mathbf{x}) = 0, \\ \dfrac{V(\mathbf{x})\rho(\mathbf{x},t_n)\ \exp[\frac{-2\lambda V(\mathbf{x})(t-t_n)}{1+\lambda^2}]}{V(\mathbf{x})+\left(1-\exp[\frac{-2\lambda V(\mathbf{x})(t-t_n)}{1+\lambda^2}]\right)\beta_d\rho(\mathbf{x},t_n)}, & V(\mathbf{x}) \neq 0. \end{cases} \tag{3.10}$$

Plugging (3.9) into (3.5), we get, for $t \in [t_n, t_{n+1}]$,

$$\psi(\mathbf{x},t) = \psi(\mathbf{x},t_n)\sqrt{U_n(\mathbf{x},t)}\exp\left[-\frac{i}{1+\lambda^2}\left(V_n(\mathbf{x},t)+\beta_d\int_{t_n}^{t}\rho(\mathbf{x},\tau)d\tau\right)\right], \tag{3.11}$$

where

$$U_n(\mathbf{x},t) = \frac{\exp[\frac{-2\lambda V_n(\mathbf{x},t)}{1+\lambda^2}]}{1+|\psi(\mathbf{x},t_n)|^2\frac{2\lambda\beta_d}{1+\lambda^2}\int_{t_n}^{t}\exp[\frac{-2\lambda V_n(\mathbf{x},\tau)}{1+\lambda^2}]\,d\tau}. \tag{3.12}$$

Again, with $V(\mathbf{x},t) = V(\mathbf{x})$, we can integrate exactly to get

$$\psi(\mathbf{x},t) = \psi(\mathbf{x},t_n)\begin{cases} \exp\left[-i(\beta_d|\psi(\mathbf{x},t_n)|^2+V(\mathbf{x}))(t-t_n)\right], & \lambda = 0, \\ \sqrt{\hat{U}_n(\mathbf{x},t)}\exp[\frac{i}{2\lambda}\ln\hat{U}_n(\mathbf{x},t)], & \lambda \neq 0, \end{cases} \tag{3.13}$$

where

$$\hat{U}_n(\mathbf{x},t) = \begin{cases} \dfrac{1+\lambda^2}{1+\lambda^2+2\lambda\beta_d(t-t_n)|\psi(\mathbf{x},t_n)|^2}, & V(\mathbf{x}) = 0, \\ \dfrac{V(\mathbf{x})\exp[-\frac{2\lambda(t-t_n)V(\mathbf{x})}{1+\lambda^2}]}{V(\mathbf{x})+\left(1-\exp[-\frac{2\lambda(t-t_n)V(\mathbf{x})}{1+\lambda^2}]\right)\beta_d|\psi(\mathbf{x},t_n)|^2}, & V(\mathbf{x}) \neq 0. \end{cases}$$

Remark 3.1. If the function $V_n(\mathbf{x},t)$ as well as other integrals in (3.9), (3.11), and (3.12) cannot be evaluated analytically, numerical quadrature can be used, e.g.,

$$V_n(\mathbf{x},t_{n+1}) = \int_{t_n}^{t_{n+1}} V(\mathbf{x},\tau)\,d\tau \approx \frac{\Delta t}{6}\left[V(\mathbf{x},t_n)+4V(\mathbf{x},t_n+\Delta t/2)+V(\mathbf{x},t_{n+1})\right].$$

3.2. Discretization in 2D. To solve (3.4), we try to formulate the equation in a variable separable form. When $d = 2$, we use the polar coordinate (r,θ) and discretize in the θ-direction by a Fourier pseudospectral method, in the r-direction by a finite element method (FEM), and in time by a Crank–Nicolson (C–N) scheme. Assume that

$$\psi(r,\theta,t) = \sum_{l=-L/2}^{L/2-1}\widehat{\psi}_l(r,t)\ e^{il\theta}, \tag{3.14}$$

where L is an even positive integer and $\widehat{\psi}_l(r,t)$ is the Fourier coefficient for the lth mode. Plugging (3.14) into (3.4) and noticing the orthogonality of the Fourier functions, we obtain, for $-\frac{L}{2} \le l \le \frac{L}{2} - 1$ and $0 < r < R$,

$$(i-\lambda)\,\partial_t \widehat{\psi}_l(r,t) = -\frac{1}{2r}\frac{\partial}{\partial r}\left(r\frac{\partial \widehat{\psi}_l(r,t)}{\partial r}\right) + \left(\frac{l^2}{2r^2} - l\Omega\right)\widehat{\psi}_l(r,t), \tag{3.15}$$

$$\widehat{\psi}_l(R,t) = 0 \quad (\text{for all } l), \qquad \widehat{\psi}_l(0,t) = 0 \quad (\text{for } l \neq 0). \tag{3.16}$$

Let P^k denote all polynomials with degree at most k, let $M > 0$ be a chosen integer, and $0 = r_0 < r_1 < r_2 < \cdots < r_M = R$ be a partition for the interval $[0, R]$ with a mesh size $h = \max_{0\le m<M}\{r_{m+1} - r_m\}$. Define a FEM subspace by

$$U^h = \left\{u^h \in C[0,R] \mid \ u^h\big|_{[r_m, r_{m+1}]} \in P^k,\ 0 \le m < M,\ u^h(R) = 0\right\}$$

for $l = 0$, and for $l \neq 0$,

$$U^h = \left\{u^h \in C[0,R] \mid \ u^h\big|_{[r_m, r_{m+1}]} \in P^k,\ 0 \le m < M,\ u^h(0) = u^h(R) = 0\right\};$$

then we obtain the FEM approximation for (3.15)–(3.16): Find $\hat{\psi}_l^h = \hat{\psi}_l^h(\cdot,t) \in U^h$ such that for all $\phi^h \in U^h$ and $t_n \le t \le t_{n+1}$,

$$(i-\lambda)\frac{d}{dt}A(\hat{\psi}_l^h(\cdot,t),\phi^h) = B(\hat{\psi}_l^h(\cdot,t),\phi^h) + l^2 C(\hat{\psi}_l^h,\phi^h) - l\Omega A(\hat{\psi}_l^h,\phi^h), \tag{3.17}$$

where

$$A(u^h,v^h) = \int_0^R r\ u^h(r)\ v^h(r)\ dr, \qquad B(u^h,v^h) = \int_0^R \frac{r}{2}\ \frac{du^h(r)}{dr}\ \frac{dv^h(r)}{dr}\ dr,$$
$$C(u^h,v^h) = \int_0^R \frac{1}{2r}\ u^h(r)\ v^h(r)\ dr, \qquad u^h,\ v^h \in U^h.$$

The ODE system (3.17) is then discretized by the standard C–N scheme in time. Although an implicit time discretization is applied for (3.17), the one-dimensional nature of the problem makes the coefficient matrix for the linear system band-limited. For example, if the piecewise linear polynomial is used, i.e., $k = 1$ in U^h, the matrix is tridiagonal. Fast algorithms can be applied to solve the resulting linear systems.

In practice, we always use the second-order Strang splitting [49]; i.e., from time $t = t_n$ to $t = t_{n+1}$ (i) evolve (3.5) for half time step $\Delta t/2$ with initial data given at $t = t_n$; (ii) evolve (3.4) for one time step Δt starting with the new data; (iii) evolve (3.5) for half time step $\Delta t/2$ with the newer data. For more general discussion on splitting methods, we refer the reader to [28, 38] for more details.

For the discretization considered here, the total memory requirement is $O(ML)$ and the total computational cost per time step is $O(ML \ln L)$. Furthermore, following the similar proofs in [6, 7, 14], the total density can be shown to be conserved in the discretized level when $\lambda = 0$ and to be decreased in the discretized level when $\lambda > 0$.

Remark 3.2. As noticed in [35, 34], another way for discretizing (3.15)–(3.16) is to use the finite difference in space on a mesh with a shifted grid and the C–N scheme in time. Choose an integer $M > 0$, a mesh size $\Delta r = 2R/(2M+1)$, and grid points

$r_m = (m-1/2)\Delta r$ for $0 \le m \le M+1$. Let $\hat{\psi}_{l,m}(t)$ be the approximation of $\hat{\psi}_l(r_m,t)$. A second-order finite difference discretization for (3.15)–(3.16) in space is

$$(i-\lambda)\frac{d\hat{\psi}_{l,m}(t)}{dt} = -\frac{r_{m+1/2}\hat{\psi}_{l,m+1}(t) - 2r_m\hat{\psi}_{l,m}(t) + r_{m-1/2}\hat{\psi}_{l,m-1}(t)}{2(\Delta r)^2 r_m} + \left(\frac{l^2}{2r_m^2} - l\Omega\right)\hat{\psi}_{l,m}(t), \quad m = 1,2,\ldots,M, \quad t_n \le t \le t_{n+1}, \tag{3.18}$$

with essential boundary conditions:

$$\hat{\psi}_{l,0}(t) = (-1)^l\hat{\psi}_{l,1}(t), \quad \hat{\psi}_{l,M+1}(t) = 0, \quad t_n \le t \le t_{n+1}. \tag{3.19}$$

The ODE system (3.18)–(3.19) may then be discretized in time by the C–N scheme so that only a tridiagonal linear system is to be solved with $O(M)$ arithmetic operations. We may further obtain a fourth-order finite difference discretization [35] for (3.15)–(3.16) on the interval $t \in [t_n, t_{n+1}]$:

$$\begin{aligned}(i-\lambda)\frac{d\hat{\psi}_{l,m}(t)}{dt} &= \left(\frac{l^2}{2r_m^2} - l\Omega\right)\hat{\psi}_{l,m}(t) \\ &\quad - \frac{-\hat{\psi}_{l,m+2}(t) + 16\hat{\psi}_{l,m+1}(t) - 30\hat{\psi}_{l,m}(t) + 16\hat{\psi}_{l,m-1}(t) - \hat{\psi}_{l,m-2}(t)}{24(\Delta r)^2} \\ &\quad - \frac{-\hat{\psi}_{l,m+2}(t) + 8\hat{\psi}_{l,m+1}(t) - 8\hat{\psi}_{l,m-1}(t) + \hat{\psi}_{l,m-2}(t)}{24\Delta r\ r_m}, \quad 1 \le m \le M, \end{aligned} \tag{3.20}$$

$$\begin{aligned}(i-\lambda)\frac{d\hat{\psi}_{l,M+1}(t)}{dt} &= \left(\frac{l^2}{2r_{M+1}^2} - l\Omega\right)\hat{\psi}_{l,M+1}(t) \\ &\quad - \frac{11\hat{\psi}_{l,M+2}(t) - 20\hat{\psi}_{l,M+1}(t) + 6\hat{\psi}_{l,M}(t) + 4\hat{\psi}_{l,M-1}(t) - \hat{\psi}_{l,M-2}(t)}{24(\Delta r)^2} \\ &\quad - \frac{3\hat{\psi}_{l,M+2}(t) + 10\hat{\psi}_{l,M+1}(t) - 18\hat{\psi}_{l,M}(t) + 6\hat{\psi}_{l,M-1}(t) - \hat{\psi}_{l,M-2}(t)}{24\Delta r\ r_{M+1}}, \end{aligned} \tag{3.21}$$

$$\hat{\psi}_{l,-1}(t) = (-1)^l\hat{\psi}_{l,2}(t), \quad \hat{\psi}_{l,0}(t) = (-1)^l\hat{\psi}_{l,1}(t), \quad \hat{\psi}_{l,M+1}(t) = 0. \tag{3.22}$$

Again the ODE system (3.20)–(3.22) may be discretized in time by the C–N scheme, and only a pentadiagonal linear system is to be solved, which can be done very efficiently too, i.e., via $O(M)$ arithmetic operations.

3.3. Discretization in 3D. When $d = 3$ in (3.4), we use the cylindrical coordinate (r,θ,z) and discretize in the θ-direction by the Fourier pseudospectral method, in the z-direction by the sine pseudospectral method, and in the r-direction by the finite element or finite difference method and in time by the C–N scheme. Assume that

$$\psi(r,\theta,z,t) = \sum_{l=-L/2}^{L/2-1}\sum_{k=1}^{K-1}\widehat{\psi}_{l,k}(r,t)\ e^{il\theta}\ \sin(\mu_k(z-a)), \tag{3.23}$$

where L and K are two even positive integers, $\mu_k = \frac{\pi k}{b-a}$ $(k = 1,\ldots,K-1)$, and $\widehat{\psi}_{l,k}(r,t)$ is the Fourier-sine coefficient for the (l,k)th mode. Plugging (3.23) into

(3.4) with $d = 3$ and noticing the orthogonality of the Fourier-sine modes, we obtain, for $-\frac{L}{2} \le l \le \frac{L}{2} - 1$, $1 \le k \le K - 1$, and $0 < r < R$, that

$$(i - \lambda)\,\partial_t \widehat{\psi}_{l,k}(r,t) = -\frac{1}{2r}\frac{\partial}{\partial r}\left(r\frac{\partial \widehat{\psi}_{l,k}(r,t)}{\partial r}\right) + \left(\frac{l^2}{2r^2} + \frac{\mu_k^2}{2} - l\Omega\right)\widehat{\psi}_{l,k}(r,t) \tag{3.24}$$

with essential boundary conditions

$$\widehat{\psi}_{l,k}(R,t) = 0 \text{ (for all } l), \qquad \widehat{\psi}_{l,k}(0,t) = 0 \text{ (for } l \neq 0). \tag{3.25}$$

The discretization of (3.24)–(3.25) is similar as that for (3.15)–(3.16) and is omitted here.

For the algorithm in 3D, the total memory requirement is $O(MLK)$ and the total computational cost per time step is $O(MLK \ln(LK))$.

4. Numerical simulations. In this section, we first test the accuracy of our numerical method. Then we apply it to study the dynamics of condensate width, a central vortex state with a shift in its center, and a quantized vortex lattice. Properties such as the conservation of energy and the angular momentum expectation and the stability of central vortices in rotating BEC are also discussed.

4.1. Numerical accuracy. To test the accuracy of our method, we take $d = 2$, $\lambda = 0$, $\gamma_x = \gamma_y = 1$, $\Omega = 0.8$, and $W(\mathbf{x}, t) \equiv 0$ in (2.44). The initial condition in (2.45) is taken as

$$\psi_0(\mathbf{x}) = \frac{2^{1/4}}{\pi^{1/2}} e^{-(x^2+2y^2)/2}, \qquad \mathbf{x} \in \mathbb{R}^2.$$

We take $R = 12$ for the bounded computational domain $\Omega_{\mathbf{x}}$ and the piecewise linear polynomial for U^h. Let ψ be the *exact* solution which is obtained numerically using our method with a very fine mesh and small time step, e.g., $\Delta r = \frac{1}{1024}$, $\Delta\theta = \frac{\pi}{128}$, and $\Delta t = 0.0001$, and let $\psi^{(\Delta r, \Delta\theta, \Delta t)}$ be the numerical solution obtained with mesh size $(\Delta r, \Delta\theta)$ and time step Δt.

First, we test the spectral accuracy in the θ-direction by choosing a very small mesh size in the r-direction $\Delta r = \frac{1}{1024}$ and the time step $\Delta t = 0.0001$ and by solving the problem for each fixed β_2 with different mesh size $\Delta\theta$ so that the discretization errors in the r-direction and in time can be neglected comparing to that in the θ-direction. The errors $||\psi(t) - \psi^{(\Delta r, \Delta\theta, \Delta t)}(t)||_{l^2}$ at $t = 2.0$ are shown in Table 4.1 for different values of β_2 and $\Delta\theta$.

Then we test the second-order accuracy in the r-direction by choosing a very fine mesh size $\Delta\theta = \frac{\pi}{128}$ and time step $\Delta t = 0.0001$ and by solving the problem with different values of β_2 and Δr. Table 4.2 shows the errors at $t = 2.0$ for different values of β_2 and Δr.

TABLE 4.1

$\beta_2 = 100$	0.5445	0.3044	0.1032	2.654E-2	6.319E-3

Next, we test the second-order accuracy in time. Table 4.3 lists the errors at $t = 2.0$ for different values of β_2 and time steps Δt with a very fine mesh in space, e.g., $\Delta r = \frac{1}{1024}$ and $\Delta\theta = \frac{\pi}{128}$.

From Tables 4.1–4.3, we can conclude that our method is of spectral-order accuracy in the θ-direction, second-order accuracy in time, and second-order accuracy in the r-direction when the piecewise linear FEM is used. Usually, for given parameter's setup and initial data, the bigger the β_2, the larger the errors. This implies that more grid points and a small time step should be used when β_2 is larger in order to get high accuracy. Furthermore, additional numerical experiments have been tested to verify the fourth-order accuracy in the r-direction when the continuous piecewise cubic element space is used. Such cubic elements are always used for the U^h in the following simulations.

4.2. Dynamics of a stationary state with a shifted center. To verify the analytical solution (2.29) and to study the dynamics of a stationary state with a shifted center through the direct simulation of the GPE for the rotating BEC, we take $d = 2$, $\lambda = 0$, $\gamma_x = \gamma_y = 1$, $\beta_2 = 100$, and $W(\mathbf{x}, t) \equiv 0$ in (2.44). The initial condition in (2.45) is taken as

$$\psi_0(\mathbf{x}) = \phi_e(\mathbf{x} - \mathbf{x}_0), \quad \phi_e(\mathbf{x}) = f(r)e^{i\theta}, \quad \mathbf{x} \in \mathbb{R}^2,$$

where $\phi_e(\mathbf{x})$ is a central vortex state with winding number $m = 1$ under the same parameter set; i.e., $f(r)$ is found numerically by the methods proposed in [5, 13]. This setup corresponds to a shift of the trap center from the origin to $-\mathbf{x}_0$. We take $\mathbf{x}_0 = (1, 1)^T$, $R = 12$ for $\Omega_{\mathbf{x}}$, mesh size $\Delta r = 0.004$, $\Delta\theta = \frac{\pi}{64}$, and time step $\Delta t = 0.0001$. The trajectory and position of the central vortex center with respect to time t are shown in Figure 1 for different rotation speed Ω. Notice that for the parameters chosen, the characteristic roots of (2.43) are given by $\pm(|\Omega| \pm 1)i$. When $\Omega = 0$ or $\Omega = \pm 1$, we get roots with higher multiplicities; otherwise, we have four distinct pure imaginary roots, and the periodicity of the orbits is thus implied for rational values of the frequency Ω. For $\Omega = 0$, (2.31)–(2.33) reduces to $\ddot{\mathbf{x}}(t) + \mathbf{x}(t) = 0$ with $\dot{\mathbf{x}}(0) = 0$. It is easy to see that the trajectory is a straight line. For $\Omega = \pm 1$, (2.31)–(2.33) reduces to $\ddot{\mathbf{x}}(t) \mp 2J\dot{\mathbf{x}}(t) = 0$, which leads to $\dot{\mathbf{x}}(t) = Q(\pm 2t)\dot{\mathbf{x}}(0)$ with $Q(2t)$ being a rotation of angle $\pm 2t$. The trajectory thus stays as a circle. In addition,

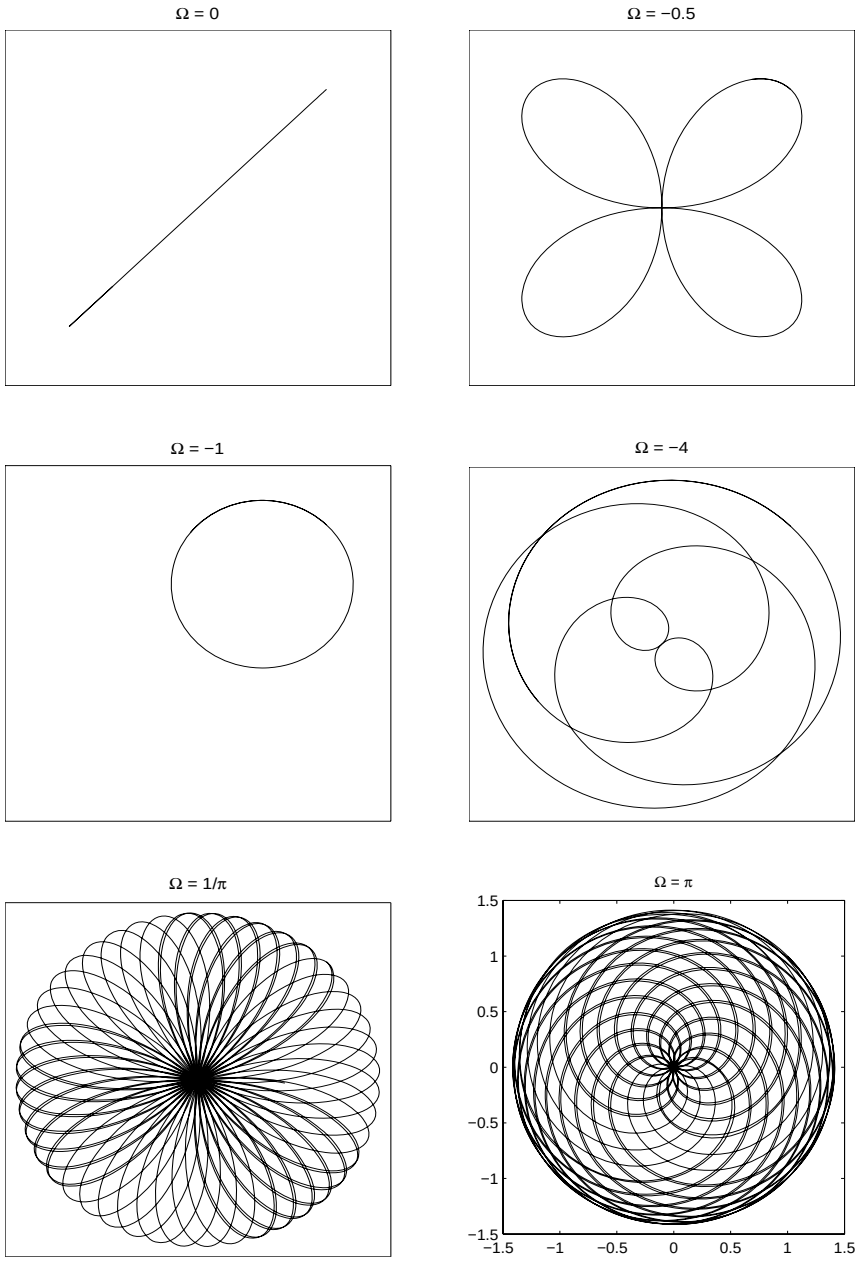

FIG. 1. *Trajectory of the central vortex center,* $\mathbf{x}(t) = (x(t), y(t))^T$ *for* $0 \le t \le 100$*, for different rotation speed* Ω*.*

for all other values of Ω, we can check that the equation is invariant under the rotation transformation, due to the fact that $Q(\theta)J = JQ(\theta)$ for any rotation matrix $Q(\theta)$. Thus, if $\Omega \neq 0, \pm 1$, and Ω is a rational number, there always exists a time t such that $e^{\pm i(\Omega \pm 1)t} = -1$; the trajectory thus always has the inversion symmetry (with respect to the origin). Other symmetries may also be explored for special values of Ω.

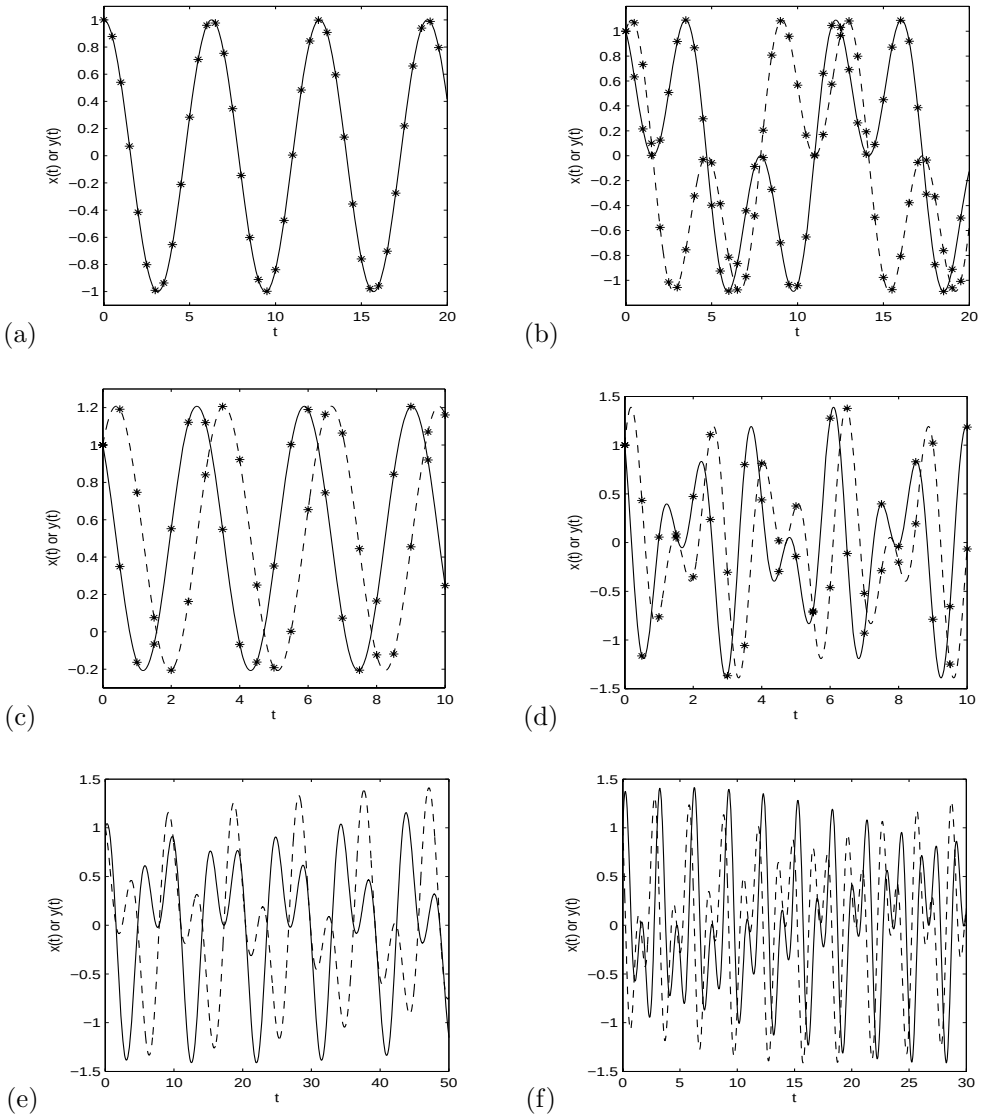

FIG. 1. (cont'd)*: Coordinates of the trajectory* $\mathbf{x}(t) = (x(t), y(t))^T$ *(solid line:* $x(t)$*; dashed line:* $y(t)$*).* (a): $\Omega = 0$*;* (b): $\Omega = -0.5$*;* (c): $\Omega = -1$*;* (d): $\Omega = -4$*;* (e): $\Omega = 1/\pi$*;* (f): $\Omega = \pi$*. In* (a)–(d)*, the solid and dashed lines are obtained from solving the GPE* (1.4)*, where "*" *is obtained from solving the ODE* (2.31)–(2.33)*.*

From Figure 1, we indeed see that when $\Omega = 0$, the center moves like a pendulum with period $T = 2\pi$; when $\Omega = -1$, it moves along a circle with period $T = \pi$. For other cases, the trajectory curve has inversion symmetry as predicted through the theoretical analysis. The solution trajectory and the coordinates in Figure 1 are obviously consistent with the above description of the solutions of the ODE system (2.31)–(2.33) for any given Ω. This provides a numerical verification of the exact solution constructed earlier for the GPE with an angular momentum rotation term and the reliability of our numerical scheme. Furthermore, based on Figure 1 and additional numerical experiments conducted, we find the following: (i) When Ω is a

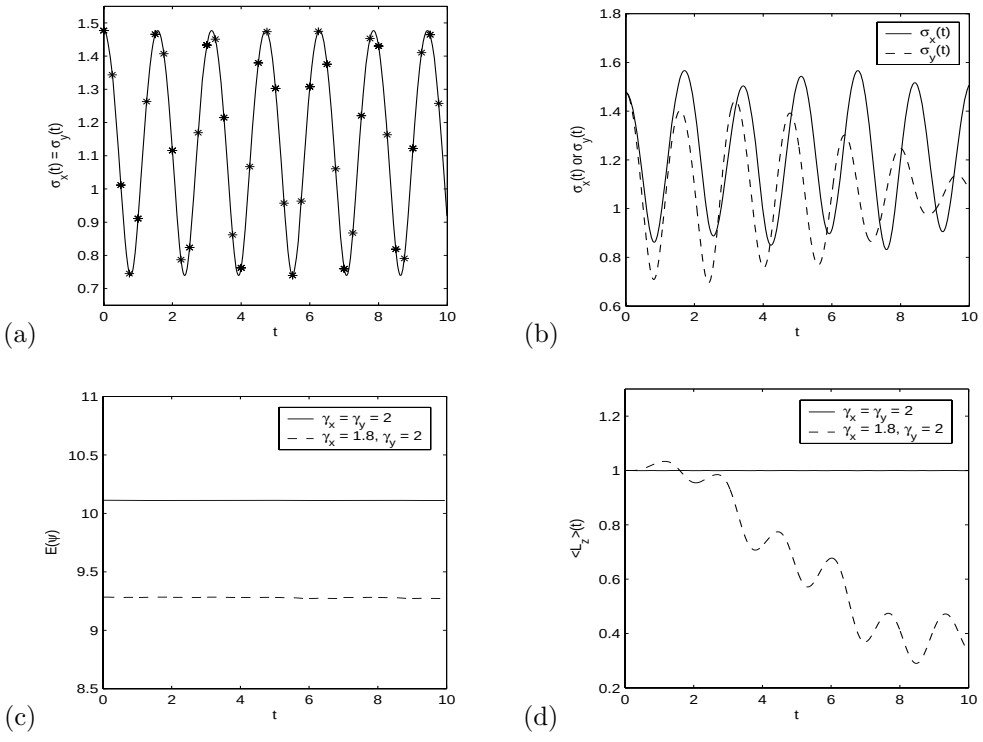

FIG. 2. *Time evolution of condensate widths (cf.* (a)*:* $\gamma_x = \gamma_y = 2$*;* (b)*:* $\gamma_x = 1.8$ *and* $\gamma_y = 2$*), energy* $E(\psi) := E_{\beta,\Omega}(\psi)$ *(cf.* (c)*) and angular momentum expectation (cf.* (d)*). In* (a)*, the solid line is obtained from solving the GPE* (1.4) *and "*" is obtained from the analytical solution* (2.15)*.*

rational number, i.e., $|\Omega| = q/p$ with q and p nonnegative integers and no common factor, then the trajectory of the vortex center moves periodically with period $p\pi$ if q and p are odd integers, and $2p\pi$ otherwise. (ii) When Ω is an irrational number, the trajectory of the vortex center moves chaotically, but the envelope of the trajectory is a circle centered at the origin with radius $r = |\mathbf{x}_0| = \sqrt{2}$ in our example (cf. Figure 1).

4.3. Dynamics of condensate width, energy, and angular momentum expectation. To verify the conservation of energy and angular momentum expectation as well as dynamics of condensate width, we take $d = 2$, $\lambda = 0$, $\beta_2 = 100$, $\Omega = 0.8$, and $W(\mathbf{x}, t) \equiv 0$ in (2.44). The initial condition in (2.45) is taken as the central vortex state with winding number $m = 1$ of the GPE with $\gamma_x = \gamma_y = 1$ [5, 14, 13], which is computed numerically by the method proposed in [5, 13]. Then at $t = 0$, we change the trap frequency by setting $\gamma_x = \gamma_y = 2$, or $\gamma_x = 1.8$ and $\gamma_y = 2$, respectively. Figure 2 shows the time evolution of condensate widths $\sigma_x(t)$ and $\sigma_y(t)$, the energy $E_{\beta,\Omega}(\psi)$, and the angular momentum expectation.

From Figure 2, we can see that (i) the condensate widths $\sigma_x(t)$ and $\sigma_y(t)$ are periodic functions of period $T = \pi/2$ when $\gamma_x = \gamma_y = 2$ (cf. Figure 2(a)) and periodic functions of period $T = \pi/2$ with a perturbation when $1.8 = \gamma_x \neq \gamma_y = 2$ (cf. Figure 2(b)), again confirming the analytical results (2.16) and (2.17), respectively; (ii) the energy $E_{\beta,\Omega}(\psi)$ is conserved in the discretized level (cf. Figure 2(c)); (iii) the angular momentum expectation is conserved when $\gamma_x = \gamma_y$ (cf. Figure 2(d) and the analytical result (2.3)). Furthermore, when $\gamma_x \neq \gamma_y$ and the initial condition is chosen as a

central vortex state with winding number $m = 1$, the angular momentum expectation is no longer conserved (cf. Figure 2(d)). We note that in the literature, there have been more studies both analytically and numerically on the thermodynamic stability of the central vortex state, though there is not much discussion available on the dynamic stability in real time. The experimental results shown here are thus of interest.

4.4. Dynamics of a quantized vortex lattice. Now we present the simulation results, via the algorithm discussed here, on the dynamics of a vortex lattice in rotating BEC under an anisotropic external perturber. We take $d = 2$, $\lambda = 0$, $\beta_2 = 1000$, $\gamma_x = \gamma_y = 1 := \gamma_r$, and $\Omega = 0.9$ in (2.44). The initial condition in (2.45) is taken as the ground state [13, 1] of the GPE with $W(\mathbf{x}, t) \equiv 0$, which is computed numerically by the normalized gradient flow with the backward Euler finite difference discretization proposed in [13]. For $t \geq 0$, an external perturber is introduced; i.e., $W(\mathbf{x}, t)$ in (2.44) is chosen as

$$W(\mathbf{x}, t) = \frac{\varepsilon}{2}\gamma_r^2 \left[(x^2 - y^2)\cos(2\tilde{\Omega}t) + 2xy\sin(2\tilde{\Omega}t)\right], \quad \mathbf{x} \in \mathbb{R}^2, \quad t \geq 0.$$

This implies the total potential $V(\mathbf{x}, t)$ in (2.44) is taken as

$$V(\mathbf{x}, t) = \frac{1}{2}\gamma_r^2 \left[(1+\epsilon)X(t)^2 + (1-\epsilon)Y(t)^2\right],$$

where $X(t) = x\cos(\tilde{\Omega}t) + y\sin(\tilde{\Omega}t)$, $Y(t) = y\cos(\tilde{\Omega}t) - x\sin(\tilde{\Omega}t)$.

This kind of time-dependent potential was used in [46] for studying the dynamics of nonrotating BEC. In our computation, we take $\epsilon = 0.35$, $\tilde{\Omega} = 0.75$, $R = 30$ for $\Omega_{\mathbf{x}}$, mesh size $\Delta r = 0.0075$ and $\Delta\theta = \frac{\pi}{128}$, and time step $\Delta t = 0.0001$. Figure 3 shows contour plots of the density function $|\psi(\mathbf{x}, t)|^2$ at different time steps.

For Figure 3, at $t = 0$, there are about 45 quantized vortices in the ground state. During the time evolution, the lattice is rotated due to the angular momentum term with different lattice patterns being formed due to the anisotropic external stirrer $W(\mathbf{x}, t)$. One may compare our numerical results with the experimental observations in [23], where the anisotropic compression of the vortex lattices was observed due to the dynamic distortion of the trap potentials.

4.5. Stability of central vortex states. Similarly as in [14, 16, 29, 30] for nonrotating BEC, we hereby also study numerically the stability of central vortex states in rotating BEC. We take $d = 2$, $\gamma_x = \gamma_y = 1$, $\beta_2 = 100$, $\Omega = -0.8$, and $\lambda = 0$ in (2.44). The initial condition in (2.45) is taken as a central vortex state [14, 5, 13] with winding number m of the GPE with $W(\mathbf{x}, t) \equiv 0$; i.e., $\psi_0(\mathbf{x}) = f_m(r)e^{im\theta}$, where $f_m(r)$ is computed numerically by the method proposed in [5, 14]. In order to study the stability, when $t \in [0, \pi/2]$, we introduce a far-blue detuned Gaussian laser beam stirrer (2.47), and when $t \geq \pi/2$, the perturber is removed. The parameters in (2.47) are chosen as

$$(x_s(t), y_s(t)) \equiv (3, 0), \quad \omega_s = 1, \quad W_s(t) = \begin{cases} 5\sin^2(2t), & t \in [0, \pi/2], \\ 0, & t \geq \pi/2. \end{cases}$$

In our computation, we take $R = 12$ for $\Omega_{\mathbf{x}}$, mesh size $\Delta r = 0.004$ and $\Delta\theta = \frac{\pi}{64}$, and time step $\Delta t = 0.0001$.

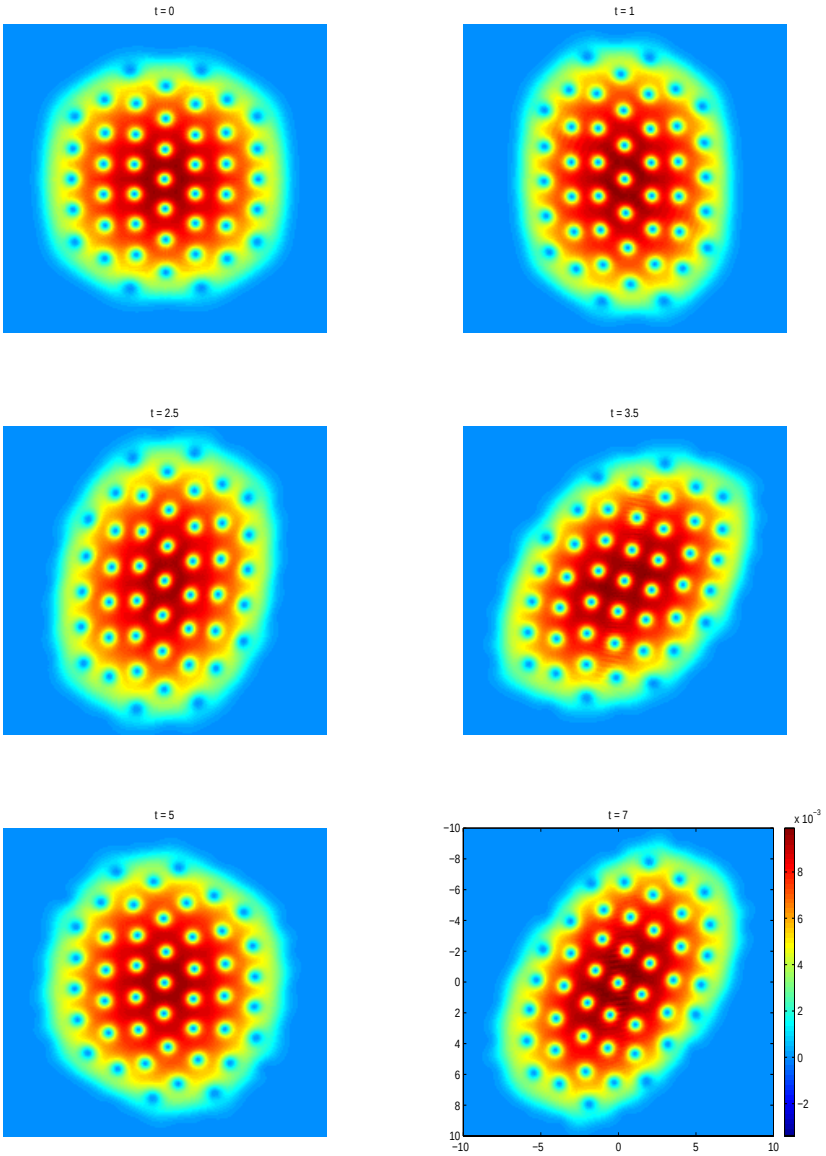

FIG. 3. *Contour plots of the density function* $|\psi(\mathbf{x}, t)|^2$ *for dynamics of a vortex lattice at different times.*

To quantitatively analyze the numerical results, we define the hydrodynamic velocity as

$$\mathbf{u} = (u, v) = \mathrm{Im}(\psi^* \nabla \psi)/|\psi|^2.$$

Figure 4 shows the velocity fields during the time evolution of the central vortex states with winding number $m = 1$ and $m = 2$, while the dynamic evolution of the energy and that of the angular momentum expectation are shown in Figure 5.

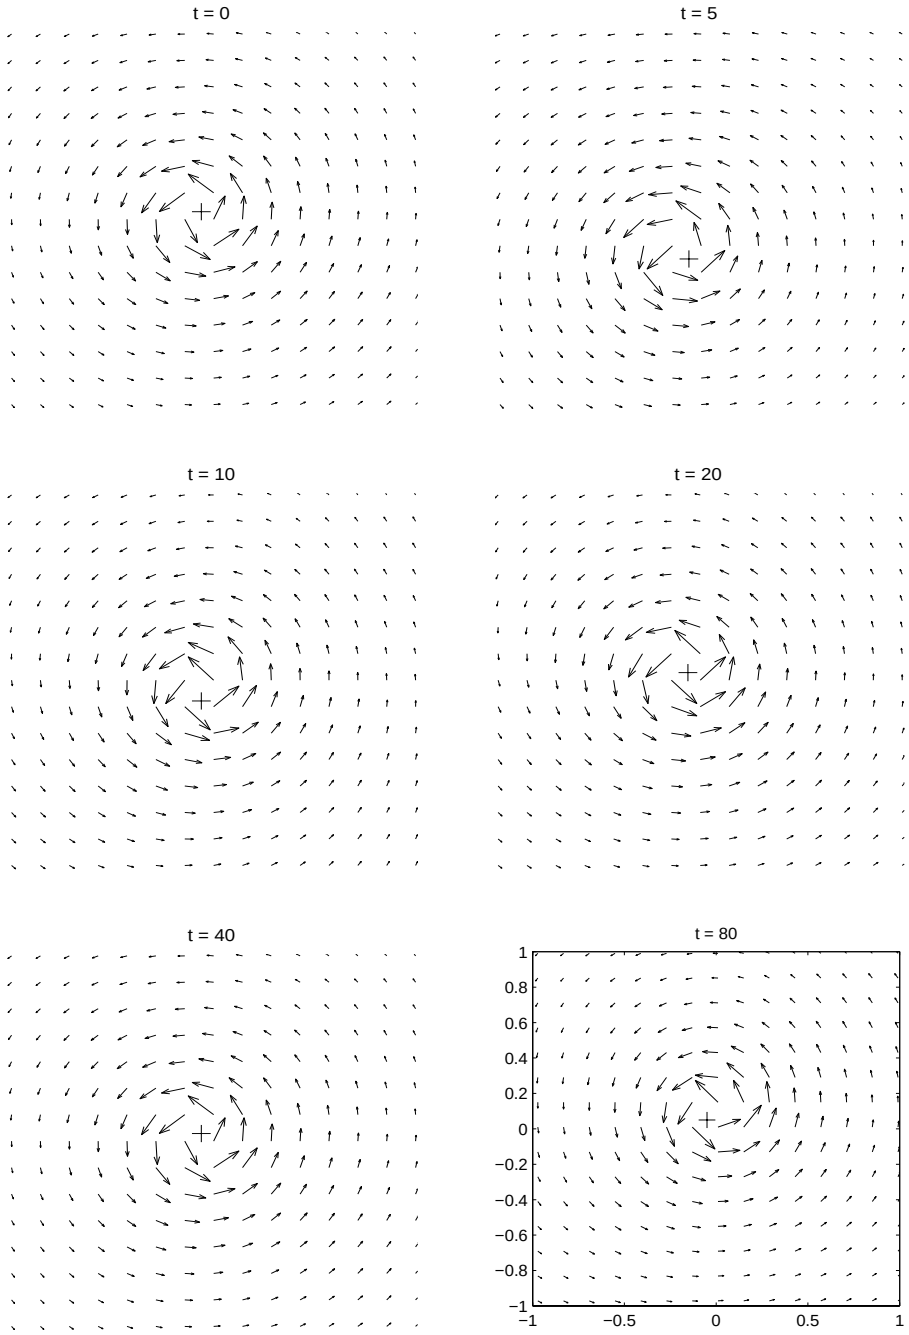

FIG. 4. *Velocity field at different times for stability of a central vortex state.* I. *For winding number* $m = 1$.

From Figure 4 and additional numerical experiments conducted, we find that the central vortex states with an index (or degree, winding number) $m = \pm 1$ are dynamically stable, but they are unstable when $|m| > 1$ in rotating BEC. Furthermore, Figure 5 depicts the increase in the energy and the decrease of the angular momentum

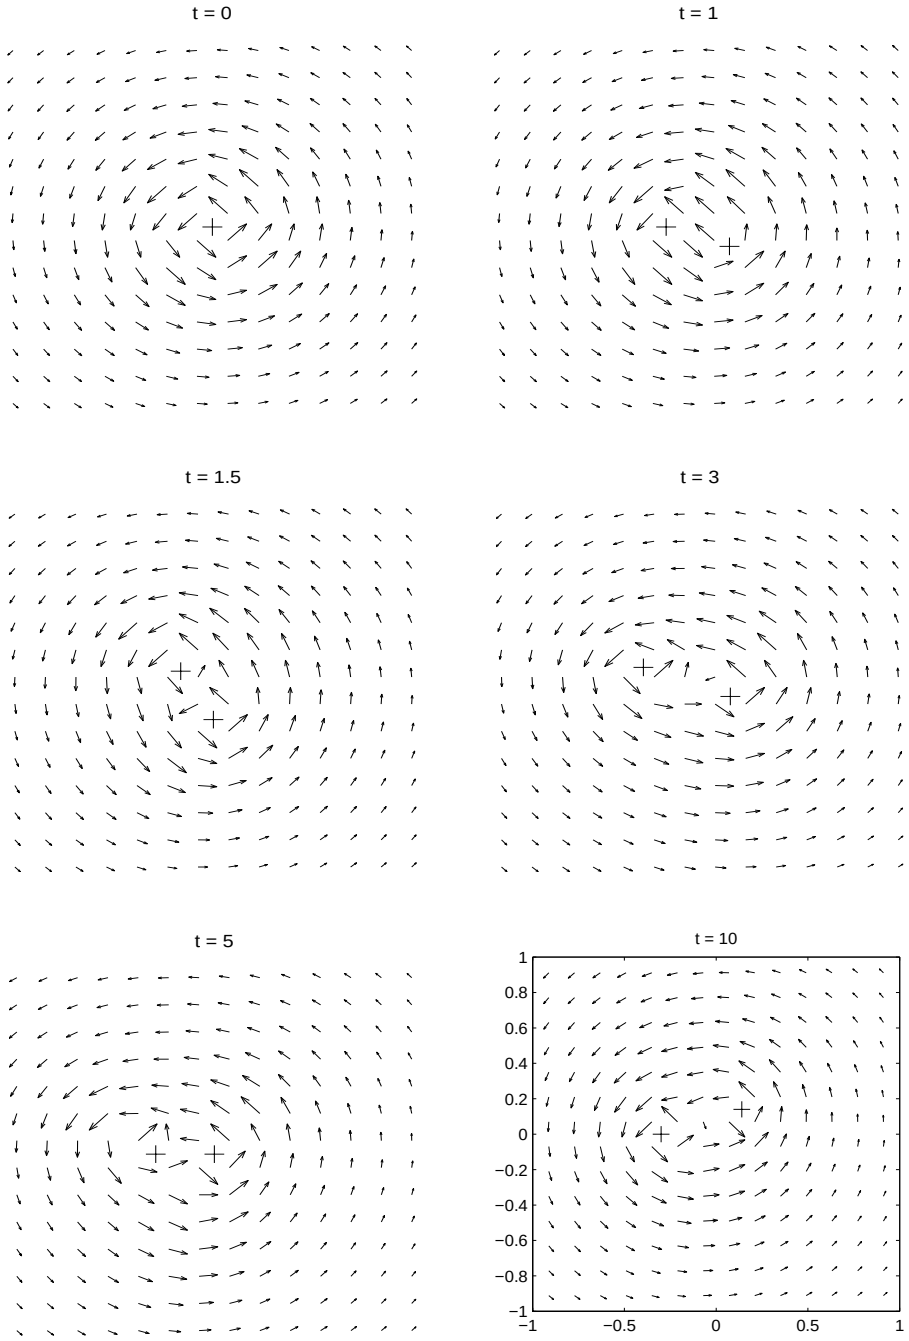

FIG. 4. (cont'd): II. *For* $m = 2$.

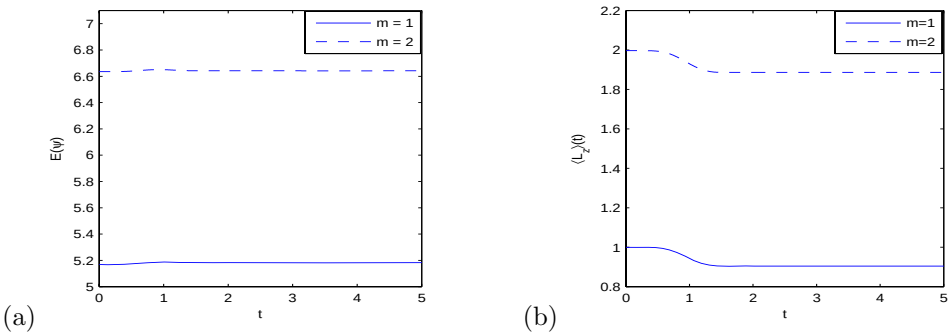
expectation when $t \in [0, \pi/2]$ due to the appearance of the perturber. After removing the perturber at $t = \pi/2$, they are conserved with time, which again confirm the conservation laws (1.8) and (2.3).



(a) (b)

FIG. 5. *Time evolution of energy* $E(\psi) := E_{\beta,\Omega}(\psi)$ *and angular momentum expectation* $\langle L_z \rangle$ *in studying the stability of central vortex states.*

4.6. Dissipation effect on the GPE. In order to study the effect of the damping mechanism in the GPE (2.44), we take $d = 2$, $\gamma_x = 1$, $\gamma_y = 1.1$, $\beta_2 = 500$, $\Omega = 0.9$, and $W(\mathbf{x}, t) \equiv 0$ in (2.44). The initial condition in (2.45) is taken as

$$\psi_0(\mathbf{x}) = \frac{(\gamma_x \gamma_y)^{1/4}}{\sqrt{\pi}} \, e^{-(\gamma_x x^2 + \gamma_y y^2)/2}, \qquad \mathbf{x} \in \mathbb{R}^2.$$

We take $R = 30$ for $\Omega_{\mathbf{x}}$, mesh size $\Delta r = 0.0075$ and $\Delta\theta = \frac{\pi}{64}$, and time step $\Delta t = 0.0001$. Figure 6 shows the normalized density $\frac{|\psi(\mathbf{x},t)|^2}{\|\psi(\cdot,t)\|^2}$ at different times for $\lambda = 0.03$, while Figure 7 illustrates the time evolution of the energy and angular momentum expectation per particle, i.e., $\frac{E_{\beta,\Omega}(\psi)}{\|\psi(\cdot,t)\|^2}$ and $\frac{\langle L_z \rangle}{\|\psi(\cdot,t)\|^2}$ for different $\lambda > 0$.

From Figures 6 and 7, we can see that when a dissipation term is applied to the GPE, a dent appears in the center of the density function during time evolution. The larger the damping parameter λ, the faster the energy per particle decreases and the slower the angular momentum expectation per particle increases. In fact, the change in the angular momentum expectation is due to the anisotropy of the external trapping potential, i.e., $\gamma_x \neq \gamma_y$.

5. Conclusion. We have studied the dynamics of the Gross–Pitaevskii equation with an angular momentum rotation term for rotating BEC both analytically and numerically. Along the analytical front, we proved the conservation of the angular momentum expectation when the external trapping potential is radially symmetric in 2D and, respectively, cylindrically symmetric in 3D. A second-order ODE was also derived to describe the time evolution of the condensate width as a periodic function with/without a perturbation, and the frequency of the periodic function doubles the trapping frequency. We also presented an ODE system with a complete initial data that governs the dynamics of a stationary state with a shifted center, and we also illustrated the decrease in the total density when a damping term is applied in the GPE. On the numerical side, we proposed an efficient, accurate, and unconditionally stable numerical method for simulating the rotating BEC with/without a time-dependent external perturber or a damping term. We also applied the new method to study numerically the dynamics of condensate including the condensate widths, energy, and angular momentum expectation as well as a quantized vortex lattice and a stationary state with a shifted center. We numerically found that, for the

real time dynamics, the central vortex states are dynamically stable only for the one with index (or winding number) $m = \pm 1$. In the future, this efficient and accurate numerical method can be used to study the dynamics and interaction of vortex line states in 3D for rotating BEC and to make more close comparisons with experimental findings [42, 47, 48].

THERMOPHORETIC MOTION OF A SLIGHTLY DEFORMED SPHERE THROUGH A VISCOUS FLUID*

ARUNA MOHAN† AND HOWARD BRENNER†

Abstract. This paper provides a general approach to the solution of the problem of nonisothermal Stokes flow relative to a heat-conducting particle having the shape of a slightly deformed sphere, taking account of Maxwell's [J. C. Maxwell, *Philos. Trans. R. Soc. Lond.*, 170 (1879), pp. 231–256] thermal creep condition at the surface of the particle. The results, which are of interest in connection with the phenomenon of thermophoresis, have potential applications in aerosol technology, and in the nonisothermal transport and processing of particulate matter. For the specific case of thermally nonconducting particles, the results obtained herein accord with Morrison's [F. A. Morrison, *J. Colloid Interface Sci.*, 34 (1970), pp. 210–214] proof in the comparable electrophoretic case that the phoretic velocity of a nonconducting, force- and torque-free, nonspherical particle undergoing electrophoresis in a fluid that is otherwise at rest is independent of the size, shape and orientation of the particle, and is identical to that of a sphere.

Key words. Stokes flow, thermal creep, thermophoresis

1. Introduction.

The no-slip boundary condition, conventionally applied to the velocity of a fluid at a solid surface, is known to fail when applied to a gas at its boundary with a nonuniformly heated solid. Under such nonisothermal conditions, the thermal slip (or thermal creep) condition first proposed by Maxwell [16] must instead be used. This boundary condition is given for a gas of Maxwellian molecules [7, 11] by the expression

$$\mathbf{v} - \mathbf{U} = \frac{3}{4}\frac{\mu}{\rho T}(\mathbf{I} - \hat{\mathbf{n}}\hat{\mathbf{n}}) \cdot \nabla T \tag{1}$$

on the solid boundary, where $\mathbf{v}$, $\mathbf{U}$, T, μ and ρ denote, respectively, the gas velocity, wall velocity, temperature, viscosity and density of the gas, $\mathbf{I}$, the idemfactor, and $\hat{\mathbf{n}}$ the unit normal to the surface. Because Maxwell's derivation of the thermal slip condition assumes the distribution function of the gas molecules in the Knudsen layer to be the same as that in the bulk gas, the 3/4 coefficient is subject to some uncertainty, as was pointed out by Maxwell himself. Note that (1) automatically satisfies the condition $\hat{\mathbf{n}} \cdot (\mathbf{v} - \mathbf{U}) = 0$ that the solid be impermeable to mass flow through its surface.

As discussed by Kogan [11], in order to find the correct boundary conditions to be imposed on the gas velocity at the solid surface, the Boltzmann equation must be solved both inside the Knudsen layer proximate to the surface as well as in the bulk gas. The subsequent matching of these inner and outer solutions at the outer limit of the Knudsen layer yields the tangential velocity boundary condition to be imposed on the continuum hydrodynamic equations governing the velocity in the bulk gas. The difference between the boundary condition on velocity thereby obtained

†Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, MA 02139 (aruna@mit.edu, hbrenner@mit.edu).

and the velocity of the wall arises due to thermal slip. Various such derivations of the thermal slip condition are summarized in [12], with the form of the resulting boundary condition being identical to Maxwell's slip condition, (1); however, the numerical coefficient appearing therein, namely, 3/4 in Maxwell's case, is found to depend on the potential of interactions between the molecules of the gas and the solid surface.

It is evident from (1) that the characteristic velocity of gas flow induced by thermal slip scales with the ratio of its kinematic viscosity $\nu = \mu/\rho$ to the length scale $L \equiv \|\nabla \ln T\|^{-1}$ of the externally imposed temperature variation, wherein the modulus bars denote an appropriate norm. Thus, when L is large compared with the characteristic size, say a, of a small particle present in the gas whose surface constitutes the solid boundary, the appropriate Reynolds number Re governing the gas flow scales as $a/L \ll 1$. As a result, the inertial term $\rho\mathbf{v} \cdot \nabla\mathbf{v}$ of the momentum equation proves to be negligible in comparison with the viscous term, $\mu\nabla^2\mathbf{v}$. Similarly, the Peclet number Pe = RePr, with the Prandtl number Pr being $O(1)$ for gases [7], scales as a/L, whence the convective term $\mathbf{v} \cdot \nabla T$ of the thermal energy equation proves to be negligible in comparison with the conduction term, $\alpha\nabla^2 T$. Although density is a function of temperature, it is readily proved, by making use of the resulting heat conduction equation, in conjunction with the fact that $\rho T = \text{const}$ for ideal gases when the pressure remains (approximately) constant throughout the gas, that the incompressible continuity equation, $\nabla \cdot \mathbf{v} = 0$, is valid. As a result, the equations governing $\mathbf{v}$ are the equations of incompressible Stokes flow, subject to the thermal creep boundary condition. The applicability of Stokes equations satisfying this boundary condition to slow, nonisothermal gas flow is discussed in [9].

In the presence of temperature gradients, the inclusion of the Burnett thermal stresses [7] alongside the Newtonian viscous stress tensor of the Navier–Stokes equations has also been found necessary [13]. However, as was first deduced by Maxwell, and elaborated in [9], when the imposed temperature gradient is sufficiently small, such that the inertial and convective terms of the respective momentum and energy equations are negligible in comparison with the viscous and conduction terms appearing therein, the contribution of such thermal stresses to the flow vanishes. In this approximation, these stresses do not contribute to the force or torque acting on the particle immersed in the gas [9].

The thermophoretic motion of a solid particle in a nonisothermal gas, arising from the thermally-induced slip of the gas at the solid surface, has applications in aerosol technology, as a method of microcontamination control in the semiconductor industry, and in the fabrication of optical fibers. It also has potential applications in microgravity manufacturing processes. All of the above applications are reviewed by Zheng [26].

The thermophoretic motion of a sphere in a gas, which occurs in the direction opposite to that of the imposed temperature gradient, was first calculated by Epstein [8] based upon Maxwell's thermal creep condition. Subsequent analyses of the problem are summarized by Zheng [26]. Most known solutions of the problem, however, deal only with the motion of spherical particles, whereas many particles encountered in practical applications are irregularly shaped. Existing theoretical studies of the thermophoresis of nonspherical particles are currently available only for axisymmetric flows, wherein the imposed temperature gradient lies parallel to the particle's axis of symmetry [24, 25]. Reference [14] provides a numerical solution for asymmetric thermophoretic flow around a two-sphere aggregate. Given this dearth of information on nonsymmetric thermophoretic particle motions, we were motivated to study a "simple" example of such motion.

The present investigation develops an asymptotic expansion of the equations of Stokes flow satisfying the thermal slip condition at the surface of a heat-conducting, arbitrarily deformed sphere, wherein the deviation from the spherical shape is small, while the imposed temperature gradient is arbitrarily oriented with respect to the particle's geometry. In principle, the asymptotic solution may be obtained correct to any order in the perturbation parameter, which measures the deviation from the spherical shape, for arbitrarily deformed particles. We here provide the explicit solution, correct to the first order, for the specific case of an ellipsoidal particle. For the special case of a force- and torque-free, thermally insulated (i.e., nonconducting) particle, it is found that the thermophoretic velocity of the particle reduces to that of a sphere moving under the same temperature gradient in a gas otherwise at rest. This result accords with the related findings of Morrison [18], namely that the phoretic velocity of an insulated particle is independent of its shape and orientation, as well as of its size. (Morrison's proof, though offered in the context of electrophoresis, is equally applicable to the thermophoretic case, provided that the particle is nonconducting, i.e., thermally insulated in the latter case.)

While the specific problem considered here is that of flow of gas around a deformed, conducting sphere under nonisothermal conditions, the results are also generally applicable to other situations for which the fluid is known to slip at the surface of the solid. Such slip conditions have been proposed in order to explain the thermally-induced motion of particles in liquids [21, 22, 23], using an approach analogous to the treatment of phoretic motion in liquids [1]. With the use of an appropriate slip coefficient, the results of the present paper may thus be applied to thermophoretic motion in liquids.

Furthermore, our results are applicable to other sources of slip occurring at solid surfaces, such as electrokinetic slip at an insulated surface, wherein the electric potential of the electrolytic liquid is governed by equations mathematically identical in form to those governing the temperature field in the present nonisothermal situation. In such circumstances, the liquid's electrokinetic slip velocity at the particle surface is proportional to the gradient of the electric potential, analogous to the corresponding thermal slip condition, (1).

The detailed solution for the case of isothermal Stokes flow around a slightly deformed sphere (subject to no slip at its surface) was presented by Brenner and his collaborators [3, 4, 10, 20]. That solution is here extended to allow for slip at the surface of the deformed sphere arising from temperature inhomogeneities in the fluid.

2. Problem formulation. Consider the incompressible Stokes flow around a slightly deformed sphere moving without rotation at a velocity of $\mathbf{U}$ through a fluid across which an otherwise uniform temperature gradient, here denoted by the space-fixed constant vector $\mathbf{G}$, has been imposed under undisturbed flow conditions, i.e., in the absence of the particle. It is assumed that the surface of the particle, S_p, is described geometrically in invariant form by the equation

$$r = a\left[1 + \epsilon \sum_n \mathbf{A}_n \boxed{n} \mathbf{P}_n(\hat{\mathbf{r}}) + O(\epsilon^2)\right], \tag{2}$$

where $\mathbf{A}_n$ is an $O(1)$ body-fixed polyadic of rank n describing the shape of the deformed body. The nth-rank polyadics

$$\mathbf{P}_n(\hat{\mathbf{r}}) = (-1)^n (n!)^{-1} r^{n+1} \overbrace{\nabla\nabla\ldots\nabla}^{n \text{ times}} (1/r)$$

are the polyadic surface harmonics of order n [4, 20], whose argument $\hat{\mathbf{r}}$ is the space-fixed unit position vector, $\hat{\mathbf{r}} = \mathbf{r}/r$, while $\epsilon \ll 1$ is a small, dimensionless quantity, inseparable from the term $\sum_n \mathbf{A}_n \boxed{n} \mathbf{P}_n(\hat{\mathbf{r}})$ describing the deformation of the surface. The $r = |\mathbf{r}|$ radial coordinate is measured from an origin situated at the center of the undeformed sphere of radius a. Since the surface spherical harmonics constitute a complete set of orthonormal polynomials in the surface coordinates (θ, ϕ), any function thereof, say $f(\hat{\mathbf{r}})$, may be expanded in invariant form in terms of the polyadics $\mathbf{P}_n(\hat{\mathbf{r}})$, analogous to the well-known scalar spherical harmonic expansion of an arbitrary function $f(\theta, \phi)$ [15]; hence, (2) is the general equation characterizing the surface of any arbitrarily shaped body whose deviation from a spherical shape is small. The symbol $\boxed{n}$ refers to n successive dot-product contraction operations performed in the order prescribed by the nesting convention of [4], wherein the n indices of the corresponding polyadics are contracted sequentially, beginning with the innermost indices. It follows that $\mathbf{A}_n \boxed{n} \mathbf{P}_n(\hat{\mathbf{r}}) = \mathbf{P}_n(\hat{\mathbf{r}}) \boxed{n} \mathbf{A}_n$, whence the surface S_p may also be equivalently described by the alternate expression

$$r = a\left[1 + \epsilon \mathbf{P}_n(\hat{\mathbf{r}}) \boxed{n} \mathbf{A}_n + O(\epsilon^2)\right], \tag{3}$$

wherein we have here invoked the summation convention, which will be used throughout, with the repeated index n implying a sum over that index.

The unit normal to S_p is given by the expression $\hat{\mathbf{n}} = \nabla f / |\nabla f|$, with f defined by the relation $f(\mathbf{r}) = r - a\left[1 + \epsilon \mathbf{P}_n \boxed{n} \mathbf{A}_n + O(\epsilon^2)\right] = 0$. Together with the use of the gradient operator in invariant spherical coordinates,

$$\nabla = \hat{\mathbf{r}} \left(\frac{\partial}{\partial r}\right)_{\hat{\mathbf{r}}} + \frac{1}{r}\left(\frac{\partial}{\partial \hat{\mathbf{r}}}\right)_r, \tag{4}$$

one thus obtains

$$\hat{\mathbf{n}} = \hat{\mathbf{r}} - \epsilon \hat{\nabla} \mathbf{P}_n \boxed{n} \mathbf{A}_n + O(\epsilon^2), \tag{5}$$

wherein $\hat{\nabla} = (\partial/\partial \hat{\mathbf{r}})_r$ is the surface gradient operator. In deriving the latter, we have used the identities $\hat{\mathbf{r}}\hat{\mathbf{r}} \cdot \hat{\nabla} = 0$ and $(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}) \cdot \hat{\nabla} = \hat{\nabla}$, arising from the orthonormality of the coordinate axes.

The equations of Stokes flow, describing the flow around the deformed sphere, are

$$\nabla \cdot \mathbf{v} = 0, \tag{6}$$

$$\mu \nabla^2 \mathbf{v} = \nabla p, \tag{7}$$

where p denotes the pressure. The boundary conditions imposed upon the fluid's velocity require that the latter approach the particle-free, undisturbed fluid motion at infinity,

$$\mathbf{v} \to \mathbf{0} \text{ as } r \to \infty, \tag{8}$$

and that the thermal slip condition on S_p, (1), satisfy

$$\mathbf{v} = \mathbf{U} + C_s (\mathbf{I} - \hat{\mathbf{n}}\hat{\mathbf{n}}) \cdot \nabla T_s, \tag{9}$$

where T_s denotes the temperature within the solid (with $T_s = T$ on S_p), and C_s is the thermal slip coefficient, which in the case of gases takes the value $3/4\,(\mu/\rho T)$, according to Maxwell. In that case, C_s is a constant, owing to the inverse relationship

existing between ρ and T from the ideal gas law, with the transport coefficient μ assumed constant, at least for small temperature gradients. For liquids, Semenov [23] has provided a formula whereby C_s can be calculated from the properties of the liquid and the solid particle. Values of C_s for the thermophoretic motion of silica particles in several solvents are found to be of the order of 10^{-8}–10^{-7} cm^2 s^{-1} K^{-1} [23]. Values of similar order of magnitude for various particle-liquid systems have been found in the experimental study of [19]. Thermal creep in liquids has also been proposed to exist in [2], where C_s is given by the product of the liquid's coefficient of thermal expansion and its thermometric diffusivity.

Since the boundary condition on velocity, namely (9), may be expressed as the sum of the particle velocity $\mathbf{U}$ and the thermal slip velocity $C_s\,(\mathbf{I}-\hat{\mathbf{n}}\hat{\mathbf{n}})\cdot\nabla T_s$, we will restrict ourselves, initially, to solving for the flow caused by thermal slip alone. Later, the flow arising from the motion $\mathbf{U}$ of the particle will be linearly superposed.

The temperature fields within the fluid and the solid are governed by the respective equations

$$\nabla^2 T = 0,$$
$$\nabla^2 T_s = 0, \tag{10}$$

subject to the joint boundary conditions

$$T = T_s, \tag{11}$$
$$\hat{\mathbf{n}}\cdot\nabla T = \gamma\hat{\mathbf{n}}\cdot\nabla T_s, \tag{12}$$

on S_p, where γ denotes the ratio k_s/k of the thermal conductivity of the solid, k_s, to that of the fluid, k. In addition, we have the further conditions that the temperature within the particle remains finite at $r = 0$, while that within the fluid at infinity is given by the expression

$$T\,(r\to\infty) = \text{const} + \mathbf{G}\cdot\mathbf{r}. \tag{13}$$

The constant appearing in (13) is physically irrelevant, whence we may set it to zero. Perturbation solutions will now be developed for the flow and temperature fields in terms of the perturbation parameter, ϵ.

3. Temperature fields. Define *vector* temperature fields in the fluid and the solid, $\mathbf{T}$ and $\mathbf{T}_s$, respectively, through the relations

$$T = \mathbf{T}\cdot\mathbf{G},$$
$$T_s = \mathbf{T}_s\cdot\mathbf{G}. \tag{14}$$

Since the scalar temperature fields satisfy Laplace's equation, and whereas the gradient at infinity, $\mathbf{G}$, is an arbitrary constant, it follows from (10)–(12) that the vector temperature fields satisfy the respective equations

$$\nabla^2\mathbf{T} = \mathbf{0},$$
$$\nabla^2\mathbf{T}_s = \mathbf{0}, \tag{15}$$

subject to the boundary conditions

$$\mathbf{T} = \mathbf{T}_s \tag{16}$$

and

$$\hat{\mathbf{n}} \cdot \nabla \mathbf{T} = \gamma \hat{\mathbf{n}} \cdot \nabla \mathbf{T}_s, \tag{17}$$

on the surface S_p of the deformed sphere. We expand the vector temperature fields in powers of ϵ,

$$\begin{aligned} \mathbf{T}(\mathbf{r};\epsilon) &= \mathbf{T}^{(0)}(\mathbf{r}) + \epsilon \mathbf{T}^{(1)}(\mathbf{r}) + O(\epsilon^2), \\ \mathbf{T}_s(\mathbf{r};\epsilon) &= \mathbf{T}_s^{(0)}(\mathbf{r}) + \epsilon \mathbf{T}_s^{(1)}(\mathbf{r}) + O(\epsilon^2). \end{aligned} \tag{18}$$

The temperature fields inside and outside of the particle at various perturbation orders, subject to the boundary conditions on S_p given by (16) and (17), may be obtained from the solution of a sequence of problems satisfying appropriate boundary conditions on the surface of the *undeformed* sphere. These latter boundary conditions, to be imposed on the sphere surface, are obtained by a Taylor series expansion of (16) and (17) about $r = a$. Thus, expansion of (16) while making use of (2) furnishes the following conditions to be imposed at $r = a$ on the $O(1)$ and $O(\epsilon)$ vector temperature fields:

$$\mathbf{T}^{(0)}\Big|_a = \mathbf{T}_s^{(0)}\Big|_a, \tag{19}$$

$$\mathbf{T}^{(1)}\Big|_a + a\mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial \mathbf{T}^{(0)}}{\partial r}\Big|_a = \mathbf{T}_s^{(1)}\Big|_a + a\mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial \mathbf{T}_s^{(0)}}{\partial r}\Big|_a. \tag{20}$$

Similarly, upon expanding $\nabla \mathbf{T}|_{S_p}$ and $\nabla \mathbf{T}_s|_{S_p}$ in Taylor series about $r = a$ and making use of (5), it follows from (17) that

$$\hat{\mathbf{r}} \cdot \nabla \mathbf{T}^{(0)}\Big|_a = \gamma\, \hat{\mathbf{r}} \cdot \nabla \mathbf{T}_s^{(0)}\Big|_a \tag{21}$$

and

$$\begin{aligned} &\hat{\mathbf{r}} \cdot \nabla \mathbf{T}^{(1)}\Big|_a + a\mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial}{\partial r} \hat{\mathbf{r}} \cdot \nabla \mathbf{T}^{(0)}\Big|_a - \hat{\nabla}\left(\mathbf{P}_n \boxed{n} \mathbf{A}_n\right) \cdot \nabla \mathbf{T}^{(0)}\Big|_a \\ &= \gamma\, \hat{\mathbf{r}} \cdot \nabla \mathbf{T}_s^{(1)}\Big|_a + a\gamma \mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial}{\partial r} \hat{\mathbf{r}} \cdot \nabla \mathbf{T}_s^{(0)}\Big|_a - \gamma \hat{\nabla}\left(\mathbf{P}_n \boxed{n} \mathbf{A}_n\right) \cdot \nabla \mathbf{T}_s^{(0)}\Big|_a. \end{aligned} \tag{22}$$

The leading-order, undeformed sphere problem is described by the set of equations

$$\begin{aligned} \nabla^2 \mathbf{T}^{(0)} &= \mathbf{0}, \\ \nabla^2 \mathbf{T}_s^{(0)} &= \mathbf{0}, \end{aligned} \tag{23}$$

subject to boundary conditions (19) and (21). Accordingly, the leading-order vector temperature fields are readily found to be

$$\begin{aligned} \mathbf{T}^{(0)} &= \left[1 + \left(\frac{1-\gamma}{2+\gamma}\right)\left(\frac{a}{r}\right)^3\right]\mathbf{r}, \\ \mathbf{T}_s^{(0)} &= \frac{3}{2+\gamma}\mathbf{r}. \end{aligned} \tag{24}$$

Upon applying the gradient operator, given by (4), to (24), and noting that $(\partial\hat{\mathbf{r}}/\partial\hat{\mathbf{r}})_r = \mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}$, we obtain

$$\nabla\mathbf{T}^{(0)} = \left[1 - 2\left(\frac{1-\gamma}{2+\gamma}\right)\frac{a^3}{r^3}\right]\hat{\mathbf{r}}\hat{\mathbf{r}} + \left[1 + \left(\frac{1-\gamma}{2+\gamma}\right)\left(\frac{a}{r}\right)^3\right](\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}),$$

$$\nabla\mathbf{T}_s^{(0)} = \frac{3}{2+\gamma}\mathbf{I}. \tag{25}$$

Making use of (25) furnishes the following $O(\epsilon)$ boundary conditions from (20) and (22):

$$\mathbf{T}^{(1)}\Big|_a = \mathbf{T}_s^{(1)}\Big|_a + 3\left(\frac{1-\gamma}{2+\gamma}\right)a\mathbf{A}_n \boxed{n} \mathbf{P}_n\mathbf{P}_1 \tag{26}$$

[wherein we have substituted $\mathbf{P}_1(\hat{\mathbf{r}})$ for $\hat{\mathbf{r}}$], and

$$\hat{\mathbf{r}}\cdot\nabla\mathbf{T}^{(1)}\Big|_a + 6\left(\frac{1-\gamma}{2+\gamma}\right)\mathbf{A}_n \boxed{n} \mathbf{P}_n\mathbf{P}_1 - 3\left(\frac{1-\gamma}{2+\gamma}\right)\hat{\nabla}\mathbf{P}_n \boxed{n} \mathbf{A}_n$$

$$= \gamma\,\hat{\mathbf{r}}\cdot\nabla\mathbf{T}_s^{(1)}\Big|_a. \tag{27}$$

The $O(\epsilon)$ vector temperature fields are governed by the equations

$$\nabla^2\mathbf{T}^{(1)} = \mathbf{0},$$

$$\nabla^2\mathbf{T}_s^{(1)} = \mathbf{0}, \tag{28}$$

subject to the boundary conditions given by (26) and (27). Since it is convenient to expand $\mathbf{T}^{(1)}$ and $\mathbf{T}_s^{(1)}$ as linear combinations of solid harmonics, these boundary conditions must be expressed as linear combinations of the polyadic surface harmonics.

4. Flow field. Next, expand the velocity and pressure fields as perturbation expansions in ϵ:

$$\mathbf{v}(\mathbf{r};\epsilon) = \mathbf{v}^{(0)}(\mathbf{r}) + \epsilon\mathbf{v}^{(1)}(\mathbf{r}) + O(\epsilon^2),$$

$$p(\mathbf{r};\epsilon) = p^{(0)}(\mathbf{r}) + \epsilon p^{(1)}(\mathbf{r}) + O(\epsilon^2). \tag{29}$$

At each order, the perturbation fields $\mathbf{v}^{(i)}$ and $p^{(i)}$ obey the Stokes equations,

$$\nabla\cdot\mathbf{v}^{(i)} = 0, \tag{30}$$

$$\mu\nabla^2\mathbf{v}^{(i)} = \nabla p^{(i)}. \tag{31}$$

The thermal slip boundary condition on the surface S_p of a stationary particle is, upon setting $\mathbf{U} = \mathbf{0}$ in (9),

$$\mathbf{v} = C_s\,(\mathbf{I} - \hat{\mathbf{n}}\hat{\mathbf{n}})\cdot\nabla T_s. \tag{32}$$

In addition, the velocity fields at all orders vanish at infinity. Expansion of the velocity at the surface S_p of the deformed sphere in a Taylor series about $r = a$ gives

$$\mathbf{v}|_{S_p} = \mathbf{v}^{(0)}\Big|_{r=a} + \epsilon\left(\mathbf{v}^{(1)}\Big|_{r=a} + a\mathbf{A}_n \boxed{n} \mathbf{P}_n\,\frac{\partial\mathbf{v}^{(0)}}{\partial r}\Big|_{r=a}\right) + O(\epsilon^2). \tag{33}$$

A similar expansion of the temperature gradient ∇T_s on S_p about $r = a$ yields

$$\nabla T_s|_{S_p} = \nabla T_s^{(0)}\Big|_{r=a} + \epsilon \left(\nabla T_s^{(1)}\Big|_{r=a} + a\mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial}{\partial r} \nabla T_s^{(0)}\Big|_{r=a} \right) + O(\epsilon^2). \tag{34}$$

Substitution of (5), (33) and (34) into (32) furnishes the following $O(1)$ and $O(\epsilon)$ boundary conditions at $r = a$:

$$\mathbf{v}^{(0)}\Big|_{r=a} = C_s \left(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}\right) \cdot \nabla T_s^{(0)}\Big|_{r=a} \tag{35}$$

and

$$\begin{aligned} \mathbf{v}^{(1)}\Big|_{r=a} = &- a\mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial \mathbf{v}^{(0)}}{\partial r}\Big|_{r=a} + C_s \left\{ \hat{\mathbf{r}} \hat{\nabla} \left(\mathbf{P}_n \boxed{n} \mathbf{A}_n \right) \right. \\ &\left. + \hat{\nabla} \left(\mathbf{P}_n \boxed{n} \mathbf{A}_n \right) \hat{\mathbf{r}} \right\} \cdot \nabla T_s^{(0)}\Big|_{r=a} + C_s \left(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}\right) \cdot \nabla T_s^{(1)}\Big|_{r=a} \\ &+ C_s a \left(\mathbf{A}_n \boxed{n} \mathbf{P}_n \right) \left(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}\right) \cdot \frac{\partial}{\partial r} \nabla T_s^{(0)}\Big|_{r=a}. \end{aligned} \tag{36}$$

The leading-order velocity field, which vanishes at infinity and is subject to the thermal slip condition, given by (35) taken in conjunction with the leading-order temperature gradient on S_p from (25), corresponds to the flow around an undeformed sphere. It is found, using the method of [5], to be

$$\mathbf{v}^{(0)} = \frac{3C_s}{2+\gamma} \left[\left(\frac{a}{2r} + \frac{a^3}{2r^3} \right) \mathbf{I} + \left(\frac{a}{2r} - \frac{3a^3}{2r^3} \right) \hat{\mathbf{r}}\hat{\mathbf{r}} \right] \cdot \mathbf{G}. \tag{37}$$

Equations (25) and (37) in combination with (36) yield

$$\begin{aligned} \mathbf{v}^{(1)}\Big|_{r=a} = &\frac{6C_s}{2+\gamma} \left(\mathbf{A}_n \boxed{n} \mathbf{P}_n \right) \left(\mathbf{I} - 2\hat{\mathbf{r}}\hat{\mathbf{r}}\right) \cdot \mathbf{G} \\ &+ \frac{3C_s}{2+\gamma} \left[\hat{\mathbf{r}} \hat{\nabla} \left(\mathbf{P}_n \boxed{n} \mathbf{A}_n \right) + \hat{\nabla} \left(\mathbf{P}_n \boxed{n} \mathbf{A}_n \right) \hat{\mathbf{r}} \right] \cdot \mathbf{G} \\ &+ C_s \left(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}\right) \cdot \nabla T_s^{(1)}\Big|_{r=a}. \end{aligned} \tag{38}$$

We have now obtained the governing equations and concomitant boundary conditions for the $O(\epsilon)$ temperature and velocity problems. However, the completely general solution of these problems, requiring use of general recurrence relations relating the various polyadic surface harmonics and their gradients, is extremely complicated algebraically. Accordingly, in lieu of attempting a completely general calculation, we instead provide the solution only for the specific case of a general triaxial ellipsoid by way of illustrating the general scheme.

5. Nonisothermal flow around an ellipsoid. Consider the ellipsoid,

$$\left(\frac{x_1}{a_1}\right)^2 + \left(\frac{x_2}{a_2}\right)^2 + \left(\frac{x_3}{a_3}\right)^2 = 1, \tag{39}$$

where (x_1, x_2, x_3) are Cartesian coordinates fixed in the ellipsoid, with the coordinate axes pointing along the principal axes of the ellipsoid, and with (a_1, a_2, a_3) the semi-lengths of these axes. Oblate and prolate spheroids, for which two of the three

principal axes are equal, are obtained as special cases of the ellipsoid, while a circular disk and a needle-shaped object may be approximated by an oblate and a prolate spheroid, respectively, one of whose semi-axes shrinks to zero.

In invariant form, the equation of the ellipsoid may be expressed as [6]

$$\mathbf{r}\cdot\mathbf{D}\cdot\mathbf{r}=1, \tag{40}$$

where $\mathbf{D}$ is the body-fixed dyadic

$$\mathbf{D}=\frac{\mathbf{i}_1\mathbf{i}_1}{a_1^2}+\frac{\mathbf{i}_2\mathbf{i}_2}{a_2^2}+\frac{\mathbf{i}_3\mathbf{i}_3}{a_3^2}, \tag{41}$$

in which $(\mathbf{i}_1,\mathbf{i}_2,\mathbf{i}_3)$ are body-fixed Cartesian unit vectors directed along the principal axes of the ellipsoid. Consider the case where the ellipsoid is a slightly deformed sphere, with the semi-lengths of the principal axes given by $a_1=a(1+\epsilon\alpha_1)$, $a_2=a(1+\epsilon\alpha_2)$ and $a_3=a(1+\epsilon\alpha_3)$, where $\epsilon\ll 1$. Since $\mathbf{i}_1\mathbf{i}_1+\mathbf{i}_2\mathbf{i}_2+\mathbf{i}_3\mathbf{i}_3=\mathbf{I}$, it follows that

$$\mathbf{D}=\frac{\mathbf{I}}{a^2}-\frac{2\epsilon}{a^2}\mathbf{B}+O(\epsilon^2), \tag{42}$$

where $\mathbf{B}$ is the body-fixed dyadic

$$\mathbf{B}=\alpha_1\mathbf{i}_1\mathbf{i}_1+\alpha_2\mathbf{i}_2\mathbf{i}_2+\alpha_3\mathbf{i}_3\mathbf{i}_3. \tag{43}$$

For a given ellipsoid, whose volume is $V=4\pi a_1a_2a_3/3$, it is convenient to choose the radius a of the sphere such that its volume, $4\pi a^3/3$, is equal to that of the ellipsoid; that is, $a^3=a_1a_2a_3$. Since $a_i=a(1+\epsilon\alpha_i)$, this requires that $\alpha_1+\alpha_2+\alpha_3=0$, i.e., $\mathbf{I}:\mathbf{B}=0$, or, alternatively,

$$\mathrm{Tr}(\mathbf{B})=0, \tag{44}$$

where, for any dyadic $\mathbf{B}$, $\mathrm{Tr}(\mathbf{B})$ denotes the trace, $\mathbf{B}:\mathbf{I}$.

Upon combining (40) and (42) and making use of the symmetry of $\mathbf{B}$ together with the identity $\hat{\mathbf{r}}\hat{\mathbf{r}}=2\mathbf{P}_2(\hat{\mathbf{r}})/3+\mathbf{I}/3$, we obtain

$$r=a\left[1+\frac{2}{3}\epsilon\mathbf{B}:\mathbf{P}_2(\hat{\mathbf{r}})+O(\epsilon^2)\right]. \tag{45}$$

$\mathbf{B}$ is diagonal, and, hence, symmetric in the body-fixed coordinate system. As a result, it is symmetric in any basis.

The detailed derivation of the $O(\epsilon)$ temperature fields outside and within the ellipsoid is presented in Appendix A. The resulting solutions are

$$\mathbf{T}^{(1)}=-\frac{6}{5}\left(\frac{1-\gamma}{2+\gamma}\right)^2\frac{a^3}{r^2}\mathbf{P}_1\cdot\mathbf{B}+\frac{6}{5}\left(\frac{1-\gamma}{2+\gamma}\right)\frac{a^5}{r^4}\mathbf{P}_3:\mathbf{B} \tag{46}$$

and

$$\mathbf{T}_s^{(1)}=-\frac{18}{5}\frac{1-\gamma}{(2+\gamma)^2}\mathbf{r}\cdot\mathbf{B}. \tag{47}$$

The $O(\epsilon)$ boundary condition on velocity, (38), thus reduces to

$$\begin{aligned}\mathbf{v}^{(1)}\Big|_{r=a}=\frac{2C_s}{2+\gamma}\Big[&2\mathbf{B}:\mathbf{P}_2\left(\mathbf{I}-2\hat{\mathbf{r}}\hat{\mathbf{r}}\right)+\hat{\mathbf{r}}\hat{\nabla}\mathbf{P}_2:\mathbf{B}+\hat{\nabla}\left(\mathbf{P}_2:\mathbf{B}\right)\hat{\mathbf{r}}\\&-\frac{9}{5}\left(\frac{1-\gamma}{2+\gamma}\right)\left(\mathbf{I}-\hat{\mathbf{r}}\hat{\mathbf{r}}\right)\cdot\mathbf{B}\Big]\cdot\mathbf{G}.\end{aligned} \tag{48}$$

The force on the ellipsoid can be obtained without solving the detailed boundary value problem by making use of the following expression for the force on a body of arbitrary shape [4]:

$$\mathbf{F} = -\frac{3}{2}\mu a \int_{S_1} \mathbf{v}|_{r=a}\, d\Omega, \tag{49}$$

where the integration is to be carried out over the surface of a unit sphere, S_1, and wherein $d\Omega = d^2\hat{\mathbf{r}}$ is a differential element of solid angle. The analogous expression for the torque on the body about the origin is [4]:

$$\mathbf{T} = 3\mu a^2 \boldsymbol{\varepsilon} : \int_{S_1} \hat{\mathbf{r}}\ \mathbf{v}|_{r=a}\, d\Omega, \tag{50}$$

where $\boldsymbol{\varepsilon} = -\mathbf{I} \times \mathbf{I}$ is the alternating unit triadic. Following [10], we introduce the translational hydrodynamic resistance dyadic $\mathbf{K}$ via the expression

$$\mathbf{F} = -\mu \mathbf{K} \cdot \mathbf{G}. \tag{51}$$

Expansion of $\mathbf{F}$ and $\mathbf{K}$ in powers of ϵ gives, for the leading-order terms,

$$\mathbf{F}^{(0)} = -\frac{3}{2}\mu a \int_{S_1} \mathbf{v}^{(0)}\Big|_{r=a}\, d\Omega = -\mu \mathbf{K}^{(0)} \cdot \mathbf{G}, \tag{52}$$

whence, from (35) [17],

$$\mathbf{K}^{(0)} = \frac{9C_s a}{2(2+\gamma)} \int_{S_1} (\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}})\, d\Omega = \frac{12\pi C_s a}{2+\gamma}\mathbf{I}, \tag{53}$$

in which we have used the identity $\int_{S_1} (\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}})\, d\Omega = 8\pi\mathbf{I}/3$. Similarly, for the first-order terms, we find that

$$\mathbf{F}^{(1)} = -\frac{3}{2}\mu a \int_{S_1} \mathbf{v}^{(1)}\Big|_{r=a}\, d\Omega = -\mu \mathbf{K}^{(1)} \cdot \mathbf{G}, \tag{54}$$

where

$$\begin{aligned}\mathbf{K}^{(1)} = \frac{3C_s a}{2+\gamma} \Bigg[& 2\int_{S_1} \mathbf{P}_2\, (\mathbf{I} - 2\hat{\mathbf{r}}\hat{\mathbf{r}}) : \mathbf{B} d\Omega + \int_{S_1} \hat{\mathbf{r}}\hat{\nabla}\mathbf{P}_2 : \mathbf{B} d\Omega + \int_{S_1} \hat{\nabla}\mathbf{P}_2 : \mathbf{B}\hat{\mathbf{r}} d\Omega \\ & -\frac{9}{5}\left(\frac{1-\gamma}{2+\gamma}\right) \int_{S_1} (\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}) \cdot \mathbf{B} d\Omega \Bigg].\end{aligned} \tag{55}$$

Details pertaining to the calculation of $\mathbf{K}^{(1)}$ are given in Appendix B, with the result being

$$\mathbf{K}^{(1)} = -\frac{24\pi}{5} C_s a \frac{1-4\gamma}{(2+\gamma)^2}\mathbf{B}. \tag{56}$$

We have now obtained the force acting on the stationary ellipsoid due to the thermal creep-induced flow. When the ellipsoid moves through the fluid at a velocity of $\mathbf{U}$, the preceding solution is superposed on the additional Stokes flow $(\mathbf{v}', p')$ satisfying the boundary conditions

$$\begin{aligned}\mathbf{v}' &= \mathbf{U} \text{ on } S_p, \\ \mathbf{v}'(r \to \infty) &\to \mathbf{0}.\end{aligned} \tag{57}$$

Analogous to (35) and (48), we require that

$$\mathbf{v}'^{(0)}\Big|_{r=a} = \mathbf{U},$$

$$\mathbf{v}'^{(1)}\Big|_{r=a} = -a\mathbf{A}_n \boxed{n} \mathbf{P}_n \frac{\partial \mathbf{v}'^{(0)}}{\partial r}\Big|_{r=a}. \tag{58}$$

The leading-order velocity field $\mathbf{v}'^{(0)}$ in invariant form is given by the expression [5, 10]

$$\mathbf{v}'^{(0)} = \left[\frac{3a}{4r}\left(\mathbf{I} + \hat{\mathbf{r}}\hat{\mathbf{r}}\right) + \frac{a^3}{4r^3}\left(\mathbf{I} - 3\hat{\mathbf{r}}\hat{\mathbf{r}}\right)\right] \cdot \mathbf{U}, \tag{59}$$

which, in combination with (58), yields

$$\mathbf{v}'^{(1)}\Big|_{r=a} = \frac{3}{2}\left(\mathbf{A}_n \boxed{n} \mathbf{P}_n\right)\left(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}\right) \cdot \mathbf{U}. \tag{60}$$

At leading order, the force on the ellipsoid is given by Stokes' law, $\mathbf{F}'^{(0)} = -6\pi\mu a\mathbf{U}$, whereas at $O(\epsilon)$, we obtain

$$\mathbf{F}'^{(1)} = -\frac{3\mu a}{2}\int_{S_1} \mathbf{v}'^{(1)}\Big|_{r=a} d\Omega = -\mu\mathbf{K}'^{(1)} \cdot \mathbf{U}, \tag{61}$$

where

$$\begin{aligned}\mathbf{K}'^{(1)} &= \frac{3}{2}a\mathbf{B} : \int_{S_1} \mathbf{P}_2\left(\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}}\right) d\Omega \\ &= -\frac{6\pi}{5}a\mathbf{B}.\end{aligned} \tag{62}$$

Equation (62) is in exact agreement with the corresponding result of [4] satisfying (57), wherein the surface of the deformed sphere was expressed as an expansion in scalar spherical harmonics.

The net force on the ellipsoid is obtained from the superposition of the force acting on a stationary ellipsoid under an externally imposed temperature gradient together with the force acting on an ellipsoid translating at a velocity of $\mathbf{U}$ under isothermal conditions:

$$\mathbf{F}_{\text{net}} = -\mu\left(\mathbf{K} \cdot \mathbf{G} + \mathbf{K}' \cdot \mathbf{U}\right). \tag{63}$$

It can be seen from (35) and (48) that the torque $\mathbf{T}$ acting on the ellipsoid about its center, given by (50), vanishes. Under isothermal conditions, the centroid of the ellipsoid is a center of hydrodynamic stress. The existence of such a center for a nonskew body such as an ellipsoid implies that no torque acts about its centroid as the ellipsoid translates without slip [10].

Accordingly, the force- and torque-free ellipsoid will move, without rotation, under the influence of the externally imposed temperature gradient $\mathbf{G}$ at a velocity $\mathbf{U} = -\left(\mathbf{K}'\right)^{-1} \cdot \mathbf{K} \cdot \mathbf{G}$, where

$$\mathbf{K}' = 6\pi a\left[\mathbf{I} - \frac{\epsilon}{5}\mathbf{B} + O(\epsilon^2)\right], \tag{64}$$

and

$$\mathbf{K} = \frac{12\pi C_s a}{2+\gamma}\left[\mathbf{I} - \epsilon\frac{2}{5}\left(\frac{1-4\gamma}{2+\gamma}\right)\mathbf{B} + O(\epsilon^2)\right]. \tag{65}$$

In view of the identity $\left[\mathbf{I}+\epsilon\mathbf{C}+O(\epsilon^2)\right]^{-1}=\mathbf{I}-\epsilon\mathbf{C}+O(\epsilon^2)$, valid for any dyadic $\mathbf{C}$, this makes

$$\mathbf{U}=-\frac{2C_s}{2+\gamma}\left[\mathbf{I}+\epsilon\frac{9}{5}\frac{\gamma}{2+\gamma}\mathbf{B}+O(\epsilon^2)\right]\cdot\mathbf{G}. \tag{66}$$

This constitutes the principal result of our ellipsoid calculation.

In the special case where the ellipsoid is nonconducting, $\gamma=0$, whereupon the above reduces simply to

$$\mathbf{U}=-C_s\mathbf{G}\left[1+O(\epsilon^2)\right]. \tag{67}$$

As such, to at least terms of first order in the deformation, the ellipsoid's thermophoretic velocity is independent of its shape, size and orientation, and hence is identical to that of a sphere. While we have formally demonstrated the latter result only to the first order, according to Morrison's theory this nonconducting result should hold to all orders in the ellipsoid deformation ϵ.

6. Discussion. We have developed an asymptotic solution of flow around a heat-conducting, slightly deformed sphere under an imposed temperature gradient, wherein the fluid slips at the surface of the deformed sphere. Although we have provided an explicit solution only for the case wherein the deformed sphere is an ellipsoid, to first order in the perturbation scheme, the technique may be readily applied to arbitrarily deformed bodies whose deviation from a spherical shape is small. In principle, the perturbation solution can be carried out to any order. For the specific case of nonconducting particles, we confirm Morrison's generic deduction [18] that the phoretic velocity of a particle is independent of its size, shape and orientation.

Appendix A. We here solve in detail the $O(\epsilon)$ temperature problem for the flow around the ellipsoid. From (26) and (27), the boundary conditions for the $O(\epsilon)$ temperature problem appropriate to this geometry reduce to

$$\mathbf{T}^{(1)}\Big|_a=\mathbf{T}_s^{(1)}\Big|_a+2\left(\frac{1-\gamma}{2+\gamma}\right)a\mathbf{B}:\mathbf{P}_2\mathbf{P}_1 \tag{A1}$$

and

$$\hat{\mathbf{r}}\cdot\nabla\mathbf{T}^{(1)}\Big|_a+2\left(\frac{1-\gamma}{2+\gamma}\right)\left[2\mathbf{B}:\mathbf{P}_2\mathbf{P}_1-\hat{\nabla}\mathbf{P}_2:\mathbf{B}\right]=\gamma\,\hat{\mathbf{r}}\cdot\nabla\mathbf{T}_s^{(1)}\Big|_a. \tag{A2}$$

Since $\mathbf{P}_1(\hat{\mathbf{r}})=\hat{\mathbf{r}}$ and $\mathbf{P}_2(\hat{\mathbf{r}})=\left(3\hat{\mathbf{r}}\hat{\mathbf{r}}-\mathbf{I}\right)/2$, we obtain

$$\mathbf{P}_2\mathbf{P}_1=\frac{3}{2}\hat{\mathbf{r}}\hat{\mathbf{r}}\hat{\mathbf{r}}-\frac{1}{2}\mathbf{I}\hat{\mathbf{r}}, \tag{A3}$$

which, in combination with the expression [4]

$$\hat{\mathbf{r}}\hat{\mathbf{r}}\hat{\mathbf{r}}=\frac{2}{5}\mathbf{P}_3+\frac{1}{5}\left[(\mathbf{I}\mathbf{P}_1)+(\mathbf{I}\mathbf{P}_1)^{\dagger}+(\mathbf{P}_1\mathbf{I})\right], \tag{A4}$$

yields

$$\mathbf{P}_2\mathbf{P}_1=\frac{3}{5}\mathbf{P}_3-\frac{1}{5}(\mathbf{I}\mathbf{P}_1)+\frac{3}{10}(\mathbf{I}\mathbf{P}_1)^{\dagger}+\frac{3}{10}(\mathbf{P}_1\mathbf{I}). \tag{A5}$$

Straightforward differentiation of $\mathbf{P}_2$ yields

$$\hat{\nabla}\mathbf{P}_2 = \frac{3}{2}\left[\mathbf{I}\hat{\mathbf{r}} + (\mathbf{I}\hat{\mathbf{r}})^\dagger - 2\hat{\mathbf{r}}\hat{\mathbf{r}}\hat{\mathbf{r}}\right], \tag{A6}$$

where the transposition symbol † entails the interchange of the two indices immediately preceding or succeeding it, according as it follows or precedes the argument to which it is affixed. Therefore, upon making use of (A4), we obtain

$$\hat{\nabla}\mathbf{P}_2 = \frac{9}{10}\left[\mathbf{I}\mathbf{P}_1 + (\mathbf{I}\mathbf{P}_1)^\dagger\right] - \frac{6}{5}\mathbf{P}_3 - \frac{3}{5}\mathbf{P}_1\mathbf{I}. \tag{A7}$$

Equations (A1) and (A2) now simplify to

$$\mathbf{T}^{(1)}\Big|_a = \mathbf{T}_s^{(1)}\Big|_a + 2\left(\frac{1-\gamma}{2+\gamma}\right) a\mathbf{B} : \left[\frac{3}{5}\mathbf{P}_3 - \frac{1}{5}\mathbf{I}\mathbf{P}_1 + \frac{3}{10}(\mathbf{I}\mathbf{P}_1)^\dagger + \frac{3}{10}\mathbf{P}_1\mathbf{I}\right] \tag{A8}$$

and

$$\begin{aligned}&\frac{\partial\mathbf{T}^{(1)}}{\partial r}\Big|_a + 2\left(\frac{1-\gamma}{2+\gamma}\right)\left\{2\mathbf{B} : \left[\frac{3}{5}\mathbf{P}_3 - \frac{1}{5}\mathbf{I}\mathbf{P}_1 + \frac{3}{10}(\mathbf{I}\mathbf{P}_1)^\dagger + \frac{3}{10}\mathbf{P}_1\mathbf{I}\right]\right.\\ &\left. - \left[\frac{9}{10}\mathbf{I}\mathbf{P}_1 + \frac{9}{10}(\mathbf{I}\mathbf{P}_1)^\dagger - \frac{6}{5}\mathbf{P}_3 - \frac{3}{5}\mathbf{P}_1\mathbf{I}\right] : \mathbf{B}\right\} = \gamma\,\frac{\partial\mathbf{T}_s^{(1)}}{\partial r}\Big|_a.\end{aligned} \tag{A9}$$

Owing to the symmetry of $\mathbf{B}$, the boundary conditions, (A8) and (A9), may be rewritten in the forms

$$\mathbf{T}^{(1)}\Big|_a = \mathbf{T}_s^{(1)}\Big|_a + \frac{6}{5}\left(\frac{1-\gamma}{2+\gamma}\right) a\left(\mathbf{P}_1\cdot\mathbf{B} + \mathbf{P}_3 : \mathbf{B}\right) \tag{A10}$$

and

$$\frac{\partial\mathbf{T}^{(1)}}{\partial r}\Big|_a - \frac{6}{5}\left(\frac{1-\gamma}{2+\gamma}\right)\left[\mathbf{P}_1\cdot\mathbf{B} - 4\mathbf{P}_3 : \mathbf{B}\right] = \gamma\,\frac{\partial\mathbf{T}_s^{(1)}}{\partial r}\Big|_a. \tag{A11}$$

Upon expanding $\mathbf{T}^{(1)}$ and $\mathbf{T}_s^{(1)}$ in solid harmonics and imposing the boundary conditions, (A10) and (A11), in conjunction with the vanishing of $\mathbf{T}^{(1)}$ at infinity and the finiteness of $\mathbf{T}_s^{(1)}$ at $r = 0$, we eventually obtain the respective expressions given in (46) and (47).

Appendix B. Here, we present the detailed computation of $\mathbf{K}^{(1)}$, which is given by (55). Since $P_0 = 1$, and $\hat{\mathbf{r}}\hat{\mathbf{r}} = 2\mathbf{P}_2/3 + \mathbf{I}/3$, it follows that

$$\int_{S_1}\mathbf{P}_2\left(\mathbf{I} - 2\hat{\mathbf{r}}\hat{\mathbf{r}}\right)d\Omega = -\frac{4}{3}\int_{S_1}\mathbf{P}_2\mathbf{P}_2 d\Omega, \tag{B1}$$

where we have used the orthogonality of the polyadics $\mathbf{P}_n$. We make use of (A7) to write

$$\begin{aligned}\int_{S_1}\hat{\mathbf{r}}\hat{\nabla}\mathbf{P}_2 d\Omega = {}& \frac{9}{10}\int_{S_1}\mathbf{P}_1\mathbf{I}\mathbf{P}_1 d\Omega + \frac{9}{10}\int_{S_1}\mathbf{P}_1(\mathbf{I}\mathbf{P}_1)^\dagger d\Omega\\ & -\frac{6}{5}\int_{S_1}\mathbf{P}_1\mathbf{P}_3 d\Omega - \frac{3}{5}\int_{S_1}\mathbf{P}_1\mathbf{P}_1 d\Omega\mathbf{I}.\end{aligned} \tag{B2}$$

We know that $\int_{S_1} \mathbf{P}_1\mathbf{P}_1 d\Omega = 4\pi\mathbf{I}/3$, and $\int_{S_1} \mathbf{P}_1\mathbf{P}_3 d\Omega = \mathbf{0}$. Reverting to Cartesian tensor notation in order to calculate the remaining integrals in (B1) and (B2) yields

$$\int_{S_1} (\mathbf{P}_2\mathbf{P}_2)_{ijkl}\, d\Omega = \frac{\pi}{5}\left(-2\delta_{ij}\delta_{kl} + 3\delta_{ik}\delta_{jl} + 3\delta_{il}\delta_{jk}\right), \tag{B3}$$

$$\int_{S_1} (\mathbf{P}_1\mathbf{I}\mathbf{P}_1)_{ijkl}\, d\Omega = \frac{4\pi}{3}\delta_{il}\delta_{jk}, \tag{B4}$$

$$\int_{S_1} \left[\mathbf{P}_1(\mathbf{I}\mathbf{P}_1)^\dagger\right]_{ijkl} d\Omega = \frac{4\pi}{3}\delta_{ik}\delta_{jl} \tag{B5}$$

and, hence,

$$\int_{S_1} \left(\hat{\mathbf{r}}\hat{\nabla}\mathbf{P}_2\right)_{ijkl} d\Omega = \frac{2\pi}{5}\left(3\delta_{il}\delta_{jk} + 3\delta_{ik}\delta_{jl} - 2\delta_{ij}\delta_{kl}\right). \tag{B6}$$

Since $\mathbf{B}$ is a traceless, symmetric dyadic, $\delta_{il}\delta_{jk} : \mathbf{B} = \delta_{ik}\delta_{jl} : \mathbf{B} = \mathbf{B}$, and $\delta_{ij}\delta_{kl} : \mathbf{B} = \mathrm{Tr}(\mathbf{B})\mathbf{I} = \mathbf{0}$.

Similarly,

$$\begin{aligned}\int_{S_1} \hat{\nabla}\mathbf{P}_2 : \mathbf{B}\hat{\mathbf{r}} d\Omega = {} & \frac{9}{10}\int_{S_1} \mathbf{I}\mathbf{P}_1 : \mathbf{B}\mathbf{P}_1 d\Omega + \frac{9}{10}\int_{S_1} (\mathbf{I}\mathbf{P}_1)^\dagger : \mathbf{B}\mathbf{P}_1 d\Omega \\ & -\frac{6}{5}\int_{S_1} \mathbf{P}_3 : \mathbf{B}\mathbf{P}_1 d\Omega - \frac{3}{5}\int_{S_1} \mathbf{P}_1\mathbf{I} : \mathbf{B}\mathbf{P}_1 d\Omega.\end{aligned} \tag{B7}$$

Again, we evaluate (B7) in Cartesian tensor notation to obtain

$$\int_{S_1} \hat{\nabla}\mathbf{P}_2 : \mathbf{B}\hat{\mathbf{r}} d\Omega = \frac{12\pi}{5}\mathbf{B}. \tag{B8}$$

Finally,

$$\int_{S_1} (\mathbf{I} - \hat{\mathbf{r}}\hat{\mathbf{r}})\, d\Omega = \frac{8\pi}{3}\mathbf{I}. \tag{B9}$$

In invariant notation, we finally obtain, upon substitution of (B1), (B3), (B6), (B8) and (B9) in (55), the result for $\mathbf{K}^{(1)}$ given in (56).

MULTIPLE FOCUS AND HOPF BIFURCATIONS IN A PREDATOR-PREY SYSTEM WITH NONMONOTONIC FUNCTIONAL RESPONSE*

DONGMEI XIAO† AND HUAIPING ZHU‡

Abstract. In this paper, we develop a criterion to calculate the multiplicity of a multiple focus for general predator-prey systems. As applications of this criterion, we calculate the largest multiplicity of a multiple focus in a predator-prey system with nonmonotonic functional response $p(x) = \frac{x}{ax^2+bx+1}$ studied by Zhu, Campbell, and Wolkowicz [*SIAM J. Appl. Math.*, 63 (2002), pp. 636–682] and prove that the degenerate Hopf bifurcation is of codimension two. Furthermore, we show that there exist parameter values for which this system has a unique positive hyperbolic stable equilibrium and exactly two limit cycles, the inner one unstable and outer one stable. Numerical simulations for the existence of the two limit cycles bifurcated from the multiple focus are also given in support of the criterion.

Key words. predator-prey, Liénard system, multiple focus, Hopf bifurcation, codimension two, limit cycles

1. Introduction.

The existence and number of limit cycles are important topics in the study of most applied mathematical models. Such study has made possible a better understanding of many real world oscillatory phenomena in nature [1, 11, 17]. For predator-prey systems, it is well known that the existence of limit cycles is related to the existence, stability, and bifurcation of a positive equilibrium. In a positively invariant region, if there exists a unique positive equilibrium which is unstable, then there must exist at least one limit cycle according to the theory of Poincaré-Bendixson. On the other hand, if the unique positive equilibrium of a predator-prey system is locally stable but not hyperbolic, there might be more than one limit cycle created via Hopf bifurcation(s). Numerical simulations of Hofbauer and So [8] indicated that this is indeed the case: there can exist at least two limit cycles for some two-dimensional predator-prey systems. It was proved by Zhu, Campbell, and Wolkowicz [26] that a predator-prey system with nonmonotonic functional response can undergo a degenerate Hopf bifurcation which produces two limit cycles, and the system can also have two limit cycles through a saddle node bifurcation of limit cycles. These two limit cycles can disappear through either supercritical Hopf or/and homoclinic bifurcations. Kuang [9] and Wrzosek [22] also observed that some predator-prey systems can even have more than two limit cycles. We shall point out that in all the models studied in [8, 9, 22] the death rate of the predator is nonlinear, but ours in [19, 26] is linear.

Hopf bifurcation theory is a powerful tool for studying the existence, number, and properties of the limit cycles in mathematical biology. However, the largest number

of limit cycles which can be created via a Hopf bifurcation is determined by the multiplicity of a multiple focus [2, 14] or correspondingly the codimension of the Hopf bifurcation. Therefore, the resolution of the multiplicity of a multiple focus plays a key role in determining the number of limit cycles for predator-prey systems.

In this paper, we first consider a general predator-prey system, taken to have the form

$$\begin{cases} \dot{x} = a(x) - b(y)p(x), \\ \dot{y} = c(y)q(x), \end{cases} \tag{1.1}$$

which has a positive nondegenerate equilibrium in the first quadrant and is a center-type equilibrium. A predator-prey system in the form of (1.1) often involves the Hopf bifurcation(s), and it is essential to identify the multiplicity of a multiple focus in order to determine the codimension of the Hopf bifurcation. There are formulas available for calculating the Lyapunov coefficients [2, 3, 10, 14], which can be used to decide the multiplicity, yet such calculations usually become very challenging if the multiple focus has multiplicity greater than or equal to two. In this paper, we shall first transform the general predator-prey system (1.1) into a generalized Liénard-type system. Then a criterion will be established for calculating the multiplicity of a focus for the general predator-prey system.

As applications of this criterion, following [26] we continue our study on the predator-prey systems with nonmonotonic functional response of the form

$$\begin{cases} \dot{x} = rx\Big(1 - \dfrac{x}{K}\Big) - yp(x), \\ \dot{y} = y\big(-d + cp(x)\big), \end{cases} \tag{1.2}$$

where x and y are functions of time representing population densities of prey and predator, respectively; $r > 0$ is the maximum growth rate, and $K > 0$ is the carrying capacity of the prey; $d > 0$ is the death rate of the predator. The functional response is of Holling type IV, and

$$p(x) = \frac{mx}{ax^2 + bx + 1}. \tag{1.3}$$

Here we write $p(x)$ as in [26] with $b > -2\sqrt{a}$ such that functional response $p(x)$ remains nonnegative for all $x \geq 0$. Note that if $b = 0$, $p(x)$ is reduced to the function used in [19]. For detailed biological interpretation and motivation of the model, interested readers may consult the work [19, 26] and the references therein.

Global qualitative and bifurcation analysis by Rothe and Shafer [18] and Zhu, Campbell, and Wolkowicz [26] show that system (1.2) with the functional response (1.3) has very interesting and rich dynamics. More precisely, by allowing b to be negative but $b > -2\sqrt{a}$, $p(x)$ is concave up for small values of $x > 0$ as it is for the sigmoidal functional response. It was shown in [26] that there exists a Bogdanov–Takens bifurcation point of codimension 3, which acts as an organizing center for the bifurcation diagram described in (b, d, K) space with $d, K > 0$ and $b > -2\sqrt{a}$. Then the bifurcation sequences were given for parameters (b, K) in each meaningful subregion of the (b, K) plane and the death rate of the predator, d, was varied. The bifurcation sequences involving Hopf bifurcations and homoclinic bifurcations as well as the saddle node bifurcations of limit cycles are determined using information from the study of the Bogdanov–Takens bifurcation of codimension 3 and an exhaustive

utilization of the geometry of isolines of the system. In particular, the Hopf bifurcation of codimension one was completely described in the parameter space (b, d, K) with $d, K > 0$ and $b > -2\sqrt{a}$. Also, a curve segment, or the so-called degenerate Hopf bifurcation curve, was defined in [26]. But there is one thing missing: when the parameters took the value along the degenerate Hopf bifurcation curve, the order of the Hopf bifurcation or the multiplicity of the multiple focus was left unknown, and for the parameters (b, K) in some subset, the bifurcation sequences were not complete (cf. Theorem 6.22 in [26]).

In this paper, we shall fill the gap of [26] and complete the study of the multiple focus and the degenerate Hopf bifurcation. We focus on the case when system (1.2) has a positive equilibrium. We shall prove that the equilibrium is a multiple focus of multiplicity at most two and can be exactly two. By using the Hopf bifurcation theorem, and combining the existing results regarding the Hopf bifurcations in [26], we shall give a complete description of a bifurcation diagram for Hopf bifurcation of codimension two. Furthermore, we investigate the existence of exactly two limit cycles of system (1.2). To the best of our knowledge, there are no references in which the existence of exactly two limit cycles in any predator-prey system has been rigorously proved. The difficulty is that, though there are theorems on the existence of exactly two limit cycles for certain Liénard-type systems (Zhang [24] and Zhou [25]), they are not applicable to the predator-prey systems that may have two limit cycles.

This paper is organized as follows. In section 2 we develop a criterion of the multiplicity of a multiple focus for the general system (1.1). System (1.2) with the functional response (1.3) is a typical example of the general predator-prey system with nonmontonic functional response. As applications, we will study (1.2) by focusing on the calculation of the multiplicity of the multiple focus and the description of the degenerate Hopf bifurcation. We shall prove that the multiplicity of the unique multiple focus is at most two and that there exist parameter values such that system (1.2) with the functional response (1.3) has a multiple focus whose multiplicity is exactly two. We shall also prove that system (1.2) with the functional response (1.3) has exactly two limit cycles for some parameter values. A Hopf bifurcation diagram involving the Hopf bifurcation of codimension two will also be given based on the results related to the Hopf bifurcation of codimension one from [26]. We end section 3 by giving numerical simulations of the two limit cycles. The paper ends with a brief discussion in section 4.

2. The multiplicity of a multiple focus in a general predator-prey system. In [21] Wolkowicz proposed a general form of the predator-prey model for studying the impact of the group defense. And Kazarinoff and van den Driessche in [13] studied a predator-prey system by incorporating a fairly general functional response. Here, we consider a general predator-prey system of the form

$$\begin{cases} \dot{x} = a(x) - b(y)p(x), & x(0) \geq 0, \\ \dot{y} = c(y)q(x), & y(0) \geq 0, \end{cases} \tag{2.1}$$

where x and y are functions of t representing the density of prey and predator populations, respectively, at a given time $t \geq 0$. Based on the biological meaning, we will restrict ourselves to the first quadrant, and in particular we make the following assumptions:

(A1) the growth function of the prey $a(x)$ is C^1 for $x \in [0, +\infty)$ and $a(0) = 0$;

(A2) $b(y)$, $c(y) \in C^1[0, +\infty)$, $b(0) = c(0) = 0$ and $b'(y) > 0$, $c'(y) > 0$ for all $y \geq 0$;

(A3) $p(x) \in C^1[0, +\infty)$, $p(0) = 0$, and $p(x) > 0$ for all $x \geq 0$;
(A4) $q(x) \in C^1[0, +\infty)$, and there exists $x_0 > 0$ such that

$$q(x_0) = 0, \quad \frac{a(x_0)}{p(x_0)} > 0, \quad \text{and } q'(x_0) > 0.$$

With the above assumptions, one can verify that both the x- and y-axes are invariant. Therefore, the first quadrant is positively invariant. Furthermore, a straightforward computation can verify that if the assumptions (A1)–(A4) hold, then system (2.1) has a positive equilibrium (x_0, y_0), which is nondegenerate, where $y_0 = b^{-1}(a(x_0)/p(x_0))$ and b^{-1} is the inverse function of $b(y)$. Thus, there exists a neighborhood Ω of (x_0, y_0) in the first quadrant such that system (2.1) has no other equilibria except (x_0, y_0) in Ω. It is clear that in the generic case any predator-prey system can have a positive equilibrium, which is a focus or a center or a node or a saddle point. Note that by (A2) we have $c(y_0) > 0$; hence in order for the positive equilibrium (x_0, y_0) to be a center-type focus, we have to further assume the following:

(A5) $a'(x_0) = b(y_0)p'(x_0)$.

Then, under assumptions (A1)–(A5), system (2.1) has an isolated positive equilibrium (x_0, y_0) in Ω, which is a center-type equilibrium.

Recall that many of the classical predator-prey systems can be written in the form of (2.1) with assumptions (A1)–(A5) satisfied. For example, the predator-prey system with response function of Holling type falls into this category [6, 19, 13, 21, 26]. There have been extensive studies on stability and bifurcations for predator-prey systems (see [8, 9, 18, 19, 21, 22, 23, 26] and references therein), but it is not an easy task to study the number of limit cycles which can be born through the bifurcation of a center-type focus, and the question remains unanswered for the predator-prey systems (2.1). It is well known that there are formulas available to calculate the first Lyapunov coefficient and the higher order Lyapunov coefficients (e.g., cf. [2, 14]); however, in general it is technically very challenging to draw conclusions from the formula directly due to its complexities. Pilyugin and Waltman [15, 16] develop a divergence criterion for a generic planar system, and the applications were made successfully to the study of multiple limit cycles in the chemostat with variable yield and other planar systems.

In this paper, we are going to develop some criteria to determine the multiplicity and stability of the multiple focus for the general predator-prey system (2.1). We can do this thanks to the magic of the Liénard-type system, which has been playing an increasingly important role in current research on the existence and uniqueness of limit cycles for predator prey systems (cf. [23] and reference therein). Hence it is not surprising that the equivalent form of (1.1), a Liénard-type system, can be simpler in calculating the multiplicity for a focus.

Consider the general Liénard-type system

$$\begin{cases} \dfrac{dx}{dt} = \phi(y) - F(x), \\ \dfrac{dy}{dt} = -g(x), \end{cases} \tag{2.2}$$

where $xg(x) > 0$ for $x \neq 0$. We first introduce a very useful lemma of [7] by Han.

LEMMA 2.1. *Suppose that $\phi(y)$, $F(x)$, and $g(x)$ are C^∞ smooth functions in a neighborhood of the origin, and that*

$$\phi(0) = g(0) = F(0) = F'(0) = 0, \quad \phi'(0) > 0, \quad \textit{and} \quad g'(0) > 0.$$

Let $G(x) = \int_0^x g(s)ds$. *If there exists a* C^∞ *smooth function* $\alpha(x)$, $\alpha(x) = -x+O(x^2)$, *such that* $G(\alpha(x)) \equiv G(x)$ *and*

$$F(\alpha(x)) - F(x) = \sum_{i\geq 1} B_i x^i,$$

then the equilibrium $(0,0)$ *of* (2.2) *is a multiple focus of multiplicity* k *if* $B_j = 0$, $j = 1, 2, \ldots, 2k$, *and* $B_{2k+1} \neq 0$. *Furthermore, it is locally stable (unstable) if* $B_{2k+1} < 0$ $(B_{2k+1} > 0$, *respectively).*

The key to the proof of Lemma 2.1 is to transform (2.2) into

$$\begin{cases} \dfrac{du}{d\tau} &= v - K(v)F^*(u), \\ \dfrac{dv}{d\tau} &= -u \end{cases} \tag{2.3}$$

by a C^∞ transformation of variables (x, y) near the origin and time t. Then let

$$F_e(u) = \frac{1}{2}(F^*(u) + F^*(-u)), \qquad F_o(u) = \frac{1}{2}(F^*(u) - F^*(-u)).$$

By the principle of symmetry, the orbits of the system

$$\begin{cases} \dfrac{du}{d\tau} &= v - K(v)F_e(u), \\ \dfrac{dv}{d\tau} &= -u \end{cases} \tag{2.4}$$

near the origin are symmetric with respect to the v-axis. In a small neighborhood of the origin, introducing the polar coordinates $u = r\cos\theta$ and $v = r\sin\theta$ to (2.3) and (2.4), one can get two equations:

$$\frac{dr}{d\theta} = \frac{\cos\theta K(r\sin\theta)F^*(r\cos\theta)}{1 - \sin\theta K(r\sin\theta)F^*(r\cos\theta)/r} \tag{2.5}$$

and

$$\frac{dr}{d\theta} = \frac{\cos\theta K(r\sin\theta)F_e(r\cos\theta)}{1 - \sin\theta K(r\sin\theta)F_e(r\cos\theta)/r}, \tag{2.6}$$

respectively. According to the classical method of Lyapunov, we can define the displacement map $d(r_0)$ of (2.5) as

$$d(r_0) = r\left(-\frac{3\pi}{2}, r_0\right) - r\left(\frac{\pi}{2}, r_0\right)$$

for $0 < r_0 \ll 1$. From the technical analysis of $d(r_0)$, the conclusions of the lemma can be obtained. For more details on the proof of the lemma and its applications, we refer the reader to [7] by Han.

We next utilize the technique developed in [23] to transform the general predator-prey system (2.1) into a Liénard-type system, and use Lemma 2.1 to establish conditions to determine the multiplicity of the center-type focus. We focus our attention on system (2.1) with assumptions (A1)–(A5) in the open set Ω.

Since $p(x) > 0$, rescaling the time t of system (2.1) by

$$\tau = \int_0^t p(x(s))ds, \tag{2.7}$$

we obtain

$$\begin{cases} \dfrac{dx}{d\tau} &= \dfrac{a(x)}{p(x)} - b(y), \\ \dfrac{dy}{d\tau} &= c(y)\dfrac{q(x)}{p(x)}. \end{cases} \tag{2.8}$$

System (2.8) has an equilibrium at (x_0, y_0). Let

$$x = -u + x_0, \qquad y = h(v) + y_0; \tag{2.9}$$

we translate the equilibrium (x_0, y_0) of system (2.8) to the origin, where $h(v)$ is a solution of the following initial problem:

$$\frac{dh(v)}{dv} = c(h(v) + y_0), \qquad h(0) = 0. \tag{2.10}$$

Since $c'(y) > 0$, $h(v)$, the solution to the initial value problem (2.10) exists for $v > 0$ and is unique. Thereby the inverse function of $h(v)$ exists. Let us denote the inverse function by h^{-1}. Thus, there exists an inverse transformation of (2.9) such that system (2.8) in Ω can be transformed to

$$\begin{cases} \dfrac{du}{d\tau} &= [b(h(v) + y_0) - b(y_0)] - \left[\dfrac{a(-u + x_0)}{p(-u + x_0)} - b(y_0)\right], \\ \dfrac{dv}{d\tau} &= -\left[-\dfrac{q(-u + x_0)}{p(-u + x_0)}\right], \end{cases} \tag{2.11}$$

in the neighborhood of the origin. If we define

$$\begin{aligned} \phi(v) &= b(h(v) + y_0) - b(y_0), \\ F(u) &= \frac{a(-u + x_0)}{p(-u + x_0)} - b(y_0), \\ g(u) &= -\frac{q(-u + x_0)}{p(-u + x_0)}, \end{aligned}$$

then system (2.11) becomes

$$\begin{cases} \dfrac{du}{d\tau} &= \phi(v) - F(u), \\ \dfrac{dv}{d\tau} &= -g(u). \end{cases} \tag{2.12}$$

System (2.12) is a Liénard-type system in the neighborhood of the origin, and it can be observed that

$$\phi(0) = g(0) = F(0) = F'(0) = 0, \quad \phi'(0) > 0, \quad \text{and } g'(0) > 0.$$

Applying Lemma 2.1 to system (2.12), we obtain the following result.

THEOREM 2.2. *Assume that* (A1)–(A5) *hold for system* (2.1). *Suppose that* $b(y)$ *and* $c(y)$ *are* C^∞ *functions of* y *in a neighborhood of* y_0, *and that* $a(x)/p(x)$ *and* $q(x)/p(x)$ *are* C^∞ *functions of* x *in a neighborhood of* x_0. *Let*

$$G(x) = \int_0^x -\frac{q(-u+x_0)}{p(-u+x_0)}du. \tag{2.13}$$

If there exists a C^∞ *function* $\alpha(x)$, $\alpha(x) = -x + O(x^2)$, *such that* $G(\alpha(x)) \equiv G(x)$ *and*

$$F(\alpha(x)) - F(x) = \frac{a(-\alpha(x)+x_0)}{p(-\alpha(x)+x_0)} - \frac{a(-x+x_0)}{p(-x+x_0)} = \sum_{i\geq 1} B_i x^i, \tag{2.14}$$

and if $B_j = 0$, $j = 1, 2, \ldots, 2k$, *and* $B_{2k+1} \neq 0$, *then the equilibrium* (x_0, y_0) *of* (2.1) *is a multiple focus of multiplicity* k, *which is locally stable (unstable) if* $B_{2k+1} < 0$ *(*$B_{2k+1} > 0$, *respectively).*

3. Multiple focus and degenerate Hopf bifurcation. Now we consider system (1.2). From the work of [18, 4] to [19] and [26] and the references therein, there have been extensive studies of various bifurcations for system (1.2). It follows from [26] that system (1.2) undergoes bifurcations including saddle node bifurcation, Hopf bifurcation(s), homoclinic bifurcation, and saddle node bifurcation of limit cycles. Note that system (1.2) with the functional response (1.3) involves an extra parameter b. As indicated in [26], by varying this parameter b one can connect all the bifurcation branches to the organizing center, which is a Bogdanov–Takens bifurcation of codimension three. Although the bifurcation study for (1.2) in [26] is almost exhaustive, the codimension of the degenerate Hopf bifurcation was left untouched, and the multiplicity of the multiple focus is unknown.

It follows from the discussion in [26] that by rescaling the state variables and time, one can eliminate three parameters from the system (1.2). For the purpose of combining the results from [19] and [26] regarding the bifurcations, here we eliminate a, m, and c by using

$$\begin{aligned} &(t,\ x,\ y) \longrightarrow \left(\frac{\sqrt{a}}{mc}t,\ \frac{1}{\sqrt{a}}x,\ \frac{c}{\sqrt{a}}y\right), \\ &(r,\ K,\ b,\ d) \longrightarrow \left(\frac{mc}{\sqrt{a}}r,\ \frac{1}{\sqrt{a}}K,\ \sqrt{a}b,\ \frac{1}{\sqrt{a}}d\right). \end{aligned} \tag{3.1}$$

Then system (1.2) with the functional response (1.3) becomes

$$\begin{cases} \dot{x} = rx\Big(1 - \dfrac{x}{K}\Big) - \dfrac{xy}{x^2+bx+1}, \\ \dot{y} = y\Big(-d + \dfrac{x}{x^2+bx+1}\Big). \end{cases} \tag{3.2}$$

System (3.2) involves four parameters b, d, K, and r, where $r > 0$ is not a bifurcation parameter for the equilibria. It follows from the results in [26] that we need three parameters to unfold the Bogdanov–Takens bifurcation of codimension three, and hence it is natural to describe the degenerate Hopf bifurcation curve in the parameter space (b, d, K). We start first by summarizing the results from [26] regarding the Hopf bifurcations for system (3.2), then we apply Theorem 2.2 to determine the multiplicity of the multiple focus and complete the diagram of Hopf bifurcation.

In [26], the geometry of the isoclines plays an important role in understanding both the equilibria and their bifurcations. Denote the prey isoline of (3.2) as (still using the notation in [26] but with a hat)

$$\hat{F}(x) = r\left(1 - \frac{x}{K}\right)(x^2 + bx + 1). \tag{3.3}$$

It follows from the linear stability analysis in [26] that besides the equilibria at the origin and $(K, 0)$, if $d < \frac{1}{b+2}$, system (3.2) may have up to two possible positive equilibria $(x_i, y_i = \hat{F}(x_i))$ $(i = 1, 2, x_1 < x_2)$ if x_1 and x_2 are positive and smaller than K, where

$$\begin{aligned} x_1 &= \frac{1 - bd - \sqrt{(b^2-4)d^2 - 2bd + 1}}{2d}, \\ x_2 &= \frac{1 - bd + \sqrt{(b^2-4)d^2 - 2bd + 1}}{2d}. \end{aligned} \tag{3.4}$$

Note that x_1 and x_2 are the real roots of the quadratic equation

$$\hat{g}(x) = dx^2 - (1 - bd)x + d = 0, \tag{3.5}$$

and we also have

$$x_1 + x_2 = \frac{1 - bd}{d}, \qquad x_1 x_2 = 1. \tag{3.6}$$

The equilibrium (x_2, y_2) is always a hyperbolic saddle if $0 < x_1 < x_2 < K$. The stability of (x_1, y_1) as a hyperbolic focus (or node) can be found in [26]. Here we are interested only in the equilibrium (x_1, y_1) and related Hopf bifurcations. Recall from [26] that (x_1, y_1) may undergo a Hopf bifurcation if $\hat{F}'(x_1) = 0$. The prey isocline can have two humps $(H_m, \hat{F}(H_m))$ and $(H_M, \hat{F}(H_M))$, where

$$\begin{aligned} H_m &= \frac{1}{3a}\left[aK - b - \sqrt{a^2K^2 + abK + b^2 - 3a}\,\right], \\ H_M &= \frac{1}{3a}\left[aK - b + \sqrt{a^2K^2 + abK + b^2 - 3a}\,\right]. \end{aligned} \tag{3.7}$$

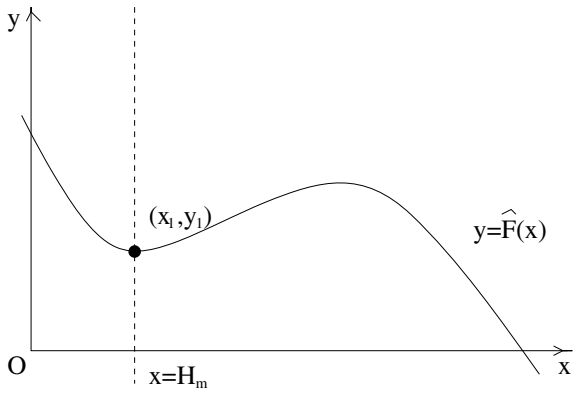
As shown in Figure 1, when a Hopf bifurcation occurs, it occurs at either the left hump $(H_m, \hat{F}(H_m))$ or the right hump $(H_M, \hat{F}(H_M))$. By (3.6) we know that $x_1 \le 1$. Hence for the Hopf bifurcation to occur at a hump of $\hat{F}(x)$, the hump cannot be at the right of the vertical line $x = 1$ (Corollary 4.2 in [26]).

If the Hopf bifurcation occurs, it occurs at one of the humps of $\hat{F}(x)$ or where $\hat{F}'(x) = 0$. Hence the Hopf bifurcation can only occur at either $x_1 = H_m$ or $x_1 = H_M$. Note that we can also solve $\hat{F}'(x_1) = 0$ in terms of K; then when the Hopf bifurcation occurs at $x = x_1$, we should also have

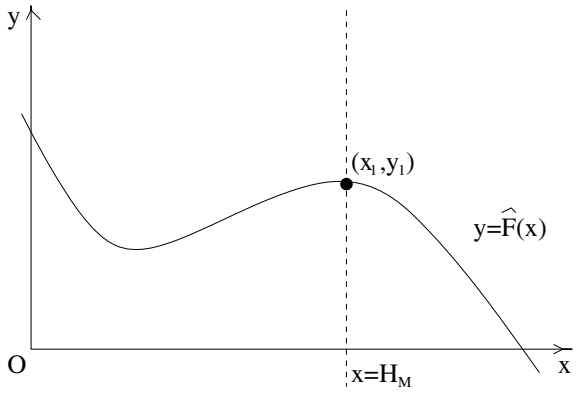
$$K = \frac{1 + 2bx_1 + 3x_1^2}{b + 2x_1}. \tag{3.8}$$

Substituting x_1 into (3.8) or eliminating x from $\hat{g}(x) = 0$ and $\hat{F}'(x) = 0$, one gets the Hopf bifurcation surface (equation (4.2) in [26]) in the parameter space (b, K, d):

$$\Sigma_H : (4 - b^2)(K^2 + bK + 1)d^2 + 2(bK^2 + 2(b^2 - 2)K + b)d + 3(1 - bK) = 0. \tag{3.9}$$



(a) At the left hump, the Hopf bifurcation can be both subcritical and supercritical



(b) At the right hump, the Hopf bifurcation is always supercritical

FIG. 1. *Hopf bifurcation occurs at the humps of the prey isocline.*

Solving for d, we obtain

$$d_{\pm}(b,K) = \frac{-(bK^2+2(b^2-2)K+b) \pm (2+bK)\sqrt{K^2+bK+b^2-3}}{(4-b^2)(K^2+bK+1)}. \tag{3.10}$$

Hence for any (b,K) such that $\hat{F}(x)$ has an hump to the left of the vertical line $x=1$, if $d=d_-$ or $d=d_+$, the Hopf bifurcation may occur. By using the formula given by Wolkowicz [21], the first Lyapunov coefficient was calculated in [26], and

$$\sigma(x) = -\frac{p(x)\hat{F}''(x)p''(x)}{p'(x)} + p(x)\hat{F}'''(x) + 2p'(x)\hat{F}''(x). \tag{3.11}$$

It was then proved that for the Hopf bifurcation occurring at the right hump, i.e., $x_1 = H_M$, we have $\sigma(H_M) < 0$. Hence if the Hopf bifurcation occurs at the right

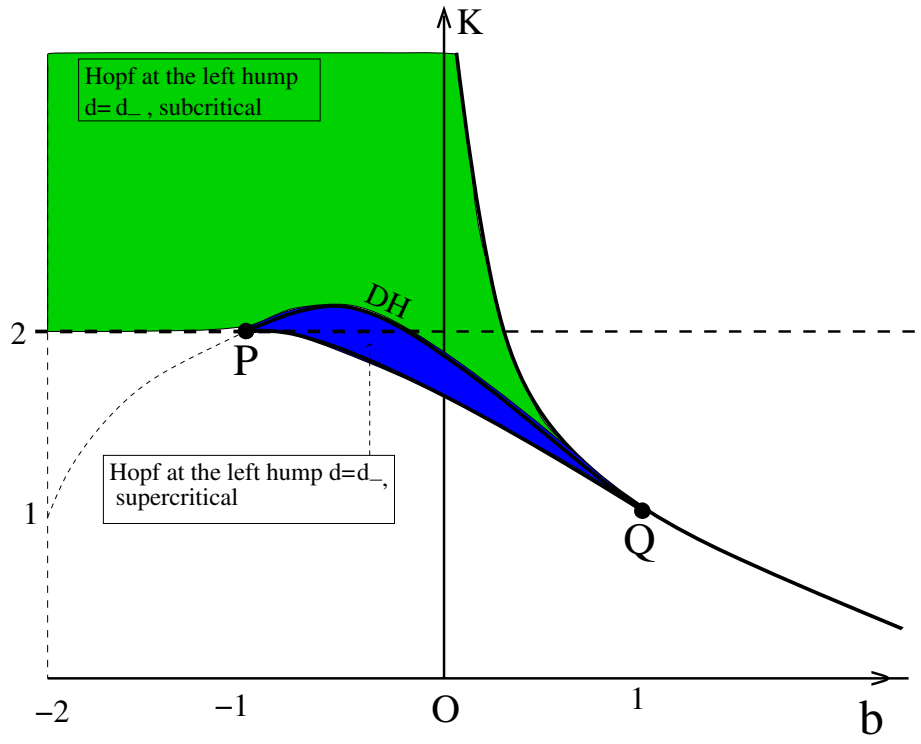


FIG. 2. *Hopf bifurcation occurs at the left hump when* $d = d_-(b, K)$. *The curve segment* DH, *the projection of the curve segment* C_{DH} *into the* bK *plane, is plotted. It separates the colored region into two: for* (b, k) *in the blue (darkest) region and* $d = d_-$, *the Hopf bifurcation at the left hump is supercritical; for* (b, k) *in the green (lighter shaded) region and* $d = d_-$, *the Hopf bifurcation at the left hump is subcritical* [26]. *Here* C_1: $K = \frac{1}{2}[\sqrt{3(4-b^2)} - b]$, $-2 \le b \le 1$; C_2: $K = \frac{1}{b}$, $b > 0$. *For* (b, K) *below* C_1, $\hat{F}(x)$ *does not have any humps; to the right of* C_2, *there is only the right hump in the positive cone. Above the line* $K = 2$, *only one hump is to the left of* $x = 1$.

hump, it is always supercritical. For the Hopf bifurcation occurring at the left hump, when $d = d_-$, it can be both subcritical and supercritical.

Plugging x_1 from (3.4) into $\sigma(x_1) = 0$, in [26] a degenerate Hopf bifurcation curve was defined. Let

(3.12)
$$C_{DH} = \left\{ (b, d, K) \;\middle|\; \begin{array}{l} d = d_-(b, K) \ \text{ and} \\ \quad 16K^4 + b(8 - 3b^2)K^3 - (144 - 15b^2)K^2 \\ \quad -8b(9 - b^2)K + 16b^4 - 144b^2 + 300 = 0, \end{array} \quad -1 < b < 1 \right\}.$$

Then it follows from the results in [26] that C_{DH} is a curve segment in the Hopf bifurcation surface Σ_H, and the projection of the curve onto the (b, K) plane was plotted in Figure 2; it is a curve segment with endpoints at $P(-1, 2)$ and $Q(1, 1)$. In the next proposition, we summarize the result regarding the Hopf bifurcation(s) of codimension one from [26].

PROPOSITION 3.1. *If the Hopf bifurcation occurs at the right hump when* $d = d_+$, *it is always supercritical. For the Hopf bifurcation occurring at the left hump when* $d = d_-$, *as shown in Figure* 2, *it is subcritical if* (b, K) *is above* DH *and is supercritical if* (b, K) *is below* DH. *For* $(b, K) \in DH$ *and* $d = d_-$, *a degenerate Hopf bifurcation*

occurs.

By an easy computation from (3.8) and (3.4), when a Hopf bifurication occurs, we have

$$\begin{aligned} K &= K_0(b,d) = \frac{2-\sqrt{(1-bd)^2-4d^2}}{1-\sqrt{(1-bd)^2-4d^2}}x_1 \\ &= \left(1+\frac{1}{1-\sqrt{(1-bd)^2-4d^2}}\right)x_1. \end{aligned} \tag{3.13}$$

Since the equilibrium (x_1, y_1) is isolated in the interior of the first quadrant, there exists a neighborhood Ω of (x_1, y_1) such that system (3.2) has no other equilibria in Ω except (x_1, y_1). Next we investigate the multiplicity of the multiple focus (x_1, y_1) of system (3.2) when $(b, d, K) \in C_{DH}$ or, equivalently, when $K = K_0(b, d)$ and $d = d_-$. Note that in manipulating the expressions for conclusion, the relation (3.6) of x_1 and x_2 with the coefficients of the quadratic equation $\hat{g}(x) = 0$ will be repeatedly used.

Taking $h(v) = y_1(e^v-1)$, we transform system (3.2) in Ω to a Liénard-type system by transformations (2.7) and (2.9) when $K = K_0(b, d)$ and $d = d_-$. For simplicity, we still denote u, v, and τ by x, y, and t, respectively. Then system (1.2) can be written as

$$\begin{cases} \dfrac{dx}{dt} = \phi(y) - F(x), \\ \dfrac{dy}{dt} = -g(x), \end{cases} \tag{3.14}$$

where

$$\begin{aligned} &\phi(y) = y_1(e^y - 1), \\ &F(x) = \hat{F}(-x + x_1) - y_1 = r\left(\left(1 - \frac{b+3x_1}{K_0}\right)x^2 + \frac{x^3}{K_0}\right), \\ &g(x) = \frac{d}{p(-x+x_1)} - 1 = \frac{dx(x - x_1 + x_2)}{x_1 - x}, \end{aligned}$$

where $(x, y) \in \Omega_1$, a neighborhood of the origin which comes from Ω under the transformation (2.9).

It is clear that $\phi(y)$, $F(x)$, and $g(x)$ are C^∞ smooth functions in Ω_1, and

- $\phi(0) = g(0) = F(0) = F'(0) = 0$,
- $\phi'(0) = y_1 > 0$,
- $g'(0) = \frac{p'(x_1)}{p^2(x_1)} = d(\frac{x_2}{x_1} - 1) > 0$ and

$$G(x) = \int_0^x \left[\frac{d}{p(-u+x_1)} - 1\right] du = -d\left(\frac{1}{2}x^2 + x_2x + x_1x_2 \ln\frac{x_1 - x}{x_1}\right). \tag{3.15}$$

A straightforward computation can verify that there exists a C^∞ smooth function

$$\alpha(x) = -x + a_2x^2 + a_3x^3 + a_4x^4 + O(x^5) \tag{3.16}$$

such that $G(\alpha(x)) \equiv G(x)$, where

$$\begin{aligned} a_2 &= -\frac{G'''(0)}{3G''(0)} = -\frac{2(p'(x_1))^2 - p(x_1)p''(x_1)}{3p(x_1)p'(x_1)} = -\frac{2x_2}{3x_1(x_2-x_1)}, \\ a_3 &= -a_2^2, \\ a_4 &= a_2\left(2a_2^2 + \frac{3a_2}{2x_1} + \frac{3}{5x_1^2}\right). \end{aligned} \tag{3.17}$$

Performing a Taylor expansion of function $F(\alpha(x)) - F(x)$ at $x = 0$, we obtain

$$F_2(\alpha(x)) - F_2(x) = r\left(A_3x^3 + A_4x^4 + A_5x^5 + O(x^6)\right),$$

where

$$\begin{aligned} A_3 &= \frac{1}{3}[F'''(x_1) - 3a_2F''(x_1)] = -2a_2\left(1 - \frac{b+3x_1}{K_0}\right) - \frac{2}{K_0}, \\ A_4 &= \left(1 - \frac{b+3x_1}{K_0}\right)(a_2^2 - 2a_3) + \frac{3a_2}{K_0}, \\ A_5 &= \left(1 - \frac{b+3x_1}{K_0}\right)(2a_2a_3 - 2a_4) + \frac{3a_3 - 3a_2^2}{K_0}. \end{aligned} \tag{3.18}$$

It follows from (3.11) and (3.17) that

$$\begin{aligned} A_3 &= \frac{1}{3p(x_1)}\left[pF'''(x_1) + \frac{2(p'(x_1))^2 - p(x_1)p''(x_1)}{p'(x_1)}F''(x_1)\right] \\ &= \frac{1}{3p(x_1)}\sigma(x_1). \end{aligned} \tag{3.19}$$

Hence if $\sigma(x_1) \neq 0$, $A_3 \neq 0$, the equilibrium $(0,0)$ of system (3.14) is a multiple focus of multiplicity one.

Along the curve C_{DH} where $\sigma(x_1) = 0$, we have $A_3 = 0$. Then the equilibrium $(0,0)$ is a multiple focus of multiplicity at least two and we have to calculate $A_4, A_5, \ldots$ in order to determine the multiplicity of equilibrium $(0,0)$. For the purpose of identifying the sign for A_5, we need the fact that along DH, $A_3 = 0$, and it is equivalent to

$$x_2 = \frac{(3b+6x_1)x_1^2}{12x_1^2 + 9bx_1 + 2(b^2-1)}. \tag{3.20}$$

Assuming that $A_3 = 0$ and using the expressions of a_i $(i = 2,3,4)$ and condition (3.20), we compute

$$\begin{aligned} A_4 &= -\frac{1}{a_2K_0}\left(a_2^2 - 2a_3\right) + \frac{3a_2}{K_0} = 0, \\ A_5 &= -\frac{1}{a_2K_0}(2a_2a_3 - 2a_4) + \frac{3a_3 - 3a_2^2}{K_0} \\ &= \frac{3}{5K_0x_1}\left(5a_2 + \frac{2}{x_1}\right) \\ &= -\frac{2(3x_1 + 2x_2)}{5K_0x_1^2(x_2 - x_1)} < 0. \end{aligned} \tag{3.21}$$

Thus, equilibrium $(0,0)$ is a stable multiple focus of multiplicity two by Theorem 2.2. Summarizing the above arguments, we obtain the following.

THEOREM 3.2. *For $(b,d,K) \in C_{DH}$, or equivalently, if $(b,K) \in DH$ with $-1 < b < 1$ and $d = d_-$, the origin of system (3.14) (i.e., equilibrium (x_1,y_1) of system (3.2)) is a multiple focus of multiplicity two, which is locally asymptotically stable.*

From Theorem 3.2, we immediately have the next result regarding the degenerate Hopf bifurcation.

THEOREM 3.3. *For $(b,d,K) \in C_{DH}$, system (3.2) undergoes a Hopf bifurcation of codimension two, and the diagram for the Hopf bifurcation occurring at the left hump, Figure 2, is complete.*

Remark 3.1. It follows from the expression (3.21) that A_5 goes to infinity if x_1 and x_2 are getting close enough. This is consistent with the fact that the degenerate Hopf curve C_{DH} is connected to the Bogdanov–Takens bifurcation point of codimension three, where x_1 and x_2 coincide at the infection point of the prey isocline $y = \hat{F}(x)$.

Using the standard Hopf bifurcation theorem in [2] and [14], we can see that system (3.2) undergoes a *supercritical Hopf bifurcation of codimension one* and a *subcritical Hopf bifurcation of codimension one* in succession when $d = d_-$ and as (b,K) moves from below to above of the curve DH. Therefore, exactly two limit cycles may appear.

To discuss the exact number of limit cycles of system (3.2) via Hopf bifurcations, by restricting our analysis to the case $b = 0$, we can prove that system (3.2) has no limit cycles if system (3.2) has a multiple focus of multiplicity two. More precisely, we have the following theorem.

THEOREM 3.4. *Consider system (3.2) with $b = 0$. Assume that $0 < x_1 < K \le K_0$ and $\sqrt{\frac{3}{18+2\sqrt{6}}} \le d < \frac{\sqrt{3}}{4}$; then the equilibrium (x_1,y_1) of system (3.2) is globally stable in the interior of R^2_+. (Note that (x_1,y_1) of system (3.2) is a multiple focus of multiplicity two when $b = 0$, $K = K_0$, and $d = \sqrt{\frac{3}{18+2\sqrt{6}}}$.)*

Proof. It is clear that system (3.2) has a unique positive equilibrium (x_1,y_1) if $b = 0$, $0 < x_1 < K \le K_0$, and $\sqrt{\frac{3}{18+2\sqrt{6}}} \le d < \frac{\sqrt{3}}{4}$. Since the solutions of (3.2) in the interior of R^2_+ are positive and eventually bounded (i.e., there exists a positive number T such that $0 < x(t) < K$ for $t > T$), we claim that the unique positive equilibrium (x_1,y_1) of system (3.2) is globally stable in the interior of R^2_+. We prove the result by showing that system (3.2) has no closed orbits in the domain Ω_2, where

$$\Omega_2 = \{(x,y) :\ 0 < x < K,\ \ 0 < y < +\infty\}.$$

Taking $h(v) = y_1(e^v - 1)$, we transform system (3.2) in Ω_2 to the following Liénard-type system by transformations (2.7) and (2.9) when $b = 0$, $0 < x_1 < K \le K_0$, and $\sqrt{\frac{3}{18+2\sqrt{6}}} \le d < \frac{\sqrt{3}}{4}$ (we still denote u, v, and τ by x, y, and t, respectively):

$$\begin{aligned} \frac{dx}{dt} &= \phi_1(y) - F_1(x), \\ \frac{dy}{dt} &= -g_1(x) \end{aligned} \tag{3.22}$$

in the domain Ω_3, where $\phi_1(y) = y_1(e^y - 1)$, $F_1(x) = \frac{rx}{K}(x^2 + (K - 3x_1)x + x_1(x_2 + 3x_1 - K))$, $g_1(x) = \frac{dx(x-x_1+x_2)}{x_1-x}$, and

$$\Omega_3 = \{(x,y) :\ x_1 - K < x < x_1,\ \ -\infty < y < +\infty\}.$$

Note that the problem of existence of closed orbits of system (3.2) in the domain Ω_2 is equivalent to that of system (3.22) in the domain Ω_3.

By the Filippov transformation, we can see that system (3.22) has no closed orbits if $\frac{f_1(x)}{g_1(x)} \le \frac{f_1(u)}{g_1(u)}$ holds for any (u,x) satisfying $G_1(x) = G_1(u)$ with $x_1 - K < u < 0$ and $0 < x < x_1$ (cf. Theorem 2.5 in [23]), where $G_1(x) = \int_0^x g_1(s)ds$ and

$$f_1(x) \overset{\text{def}}{=} F_1'(x) = \frac{r}{k}\big(3x^2 + 2(K - 3x_1)x + x_1(x_2 + 3x_1 - K)\big).$$

Next we claim that $u + x < 0$ if $G_1(u) = G_1(x)$ with $x_1 - K < u < 0$ and $0 < x < x_1$. In fact, if

$$G_1(u) = G_1(x)$$

as $x_1 - K < u < 0$ and $0 < x < x_1$, then

$$\frac{1}{2}(x-u)(x+u) + x_2(x-u) - x_1x_2 \ln\frac{x_1-u}{x_1-x} = 0.$$

Note that $2\frac{x-y}{x+y} \le \ln\frac{x}{y}$ as $0 < y \le x$, and the equality holds if and only if $x = y$. Hence, we have

$$(x+u)\left(x_1 - x_2 - \frac{1}{2}(x+u)\right) > 0,$$

which implies that $2(x_1 - x_2) < u + x < 0$.

As $G_1(u) = G_1(x)$ with $x_1 - K < u < 0$ and $0 < x < x_1$, we consider

$$\begin{aligned}
\frac{f_1(x)}{g_1(x)} - \frac{f_1(u)}{g_1(u)} &= \frac{r}{Kdxu(x - x_1 + x_2)(u - x_1 + x_2)}\Big([3x^2 + 2(K - 3x_1)x \\
&\quad + x_1(x_2 + 3x_1 - 2K)](x_1 - x)u(u - x_1 + x_2) - [3u^2 + 2(K - 3x_1)u \\
&\quad + x_1(x_2 + 3x_1 - 2K)](x_1 - u)x(x - x_1 + x_2)\Big) \\
&= \frac{r(x-u)}{Kdxu(x - x_1 + x_2)(u - x_1 + x_2)}\Big(- 3u^2x^2 - 3(x_2 - x_1)xu(x+u) \\
&\quad - (2Kx_2 + 2Kx_1 - 10x_1x_2)xu + (2K - x_2 - 3x_1)x_1^2(x+u) \\
&\quad + x_1^2(2K - x_2 - 3x_1)(x_2 - x_1)\Big) \\
&= \frac{r(x-u)}{Kdxu(x - x_1 + x_2)(u - x_1 + x_2)}\Big(- 3u^2x^2 - 3(x_2 - x_1)xu(x+u) \\
&\quad + (10x_1x_2 - 2Kx_2 - 2Kx_1)xu \\
&\quad - (x_2 + 3x_1 - 2K)x_1^2(x + u + x_2 - x_1)\Big).
\end{aligned}$$

Because $\sqrt{\frac{3}{18+2\sqrt{6}}} \le d < \frac{\sqrt{3}}{4}$ and $0 < x_1 < K \le K_0 = (3x_1 + x_2)/2$, $10x_1x_2 - 2Kx_2 - 2Kx_1 \ge 0$ and $x_2 + 3x_1 - 2K > 0$. On the other hand, $x + u + x_2 - x_1 > x_2 - K > 0$. Therefore,

$$\frac{f_1(x)}{g_1(x)} - \frac{f_1(u)}{g_1(u)} > 0.$$

Multiple focus	$\sqrt{\frac{3}{18+2\sqrt{6}}}$	$K_0 = 1.809766597$	.4283729906	2.334414218
Perturbed	$\sqrt{\frac{3}{18+2\sqrt{6}}} + 0.01$	$K_0 = 1.809766597 + .01$	.4459113886	2.242598026

From above arguments and Theorem 2.5 in [23], we know that system (3.22) does not have any closed orbits in the range Ω_3, which implies that (x_1, y_1) is globally stable. □

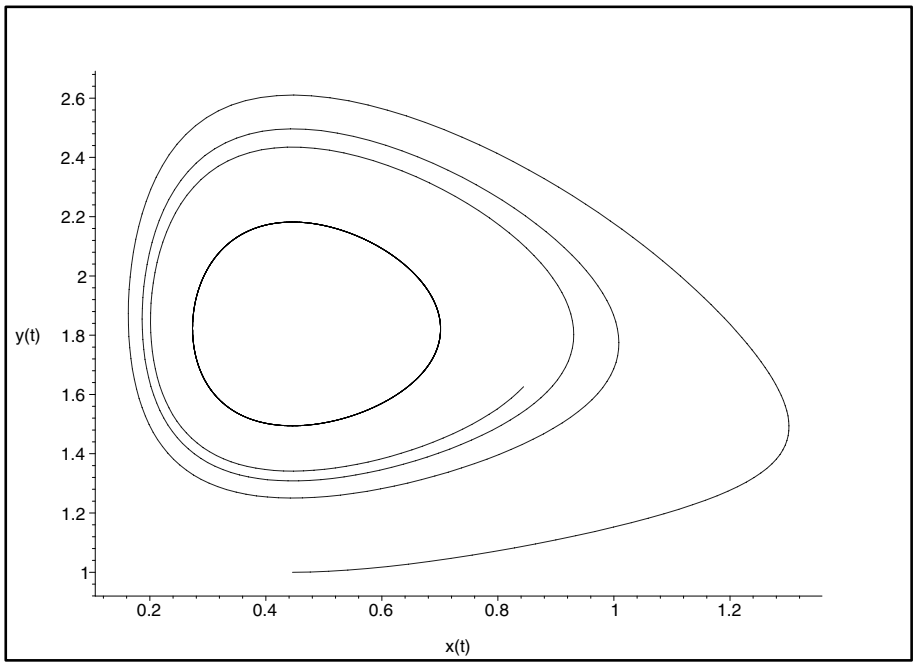
In Figure 3, a numerical simulation was carried out using MAPLE [20] to verify the existence of two limit cycles. For the simulation, we take $r = 2$ and $b = 0$; the other parameters are given in Table 1, where the system has a unique positive equilibrium which is a multiple focus of multiplicity two. We then perturb the parameters d and K; the new perturbed system has two limit cycles, as illustrated in Figure 3(a) and (b).

Remark 3.2. In [26], the saddle node bifurcation of limit cycles was studied, and the existence of two limit cycles was proved. In fact, it follows from the results in [26] and Theorems 3.2 and 3.4 that the bifurcation of the multiple focus of multiplicity two produces two limit cycles, and these two cycles can either disappear through the Hopf bifurcations or one Hopf bifurcation and one supercritical homoclinic bifurcation, or disappear through the saddle node bifurcation of limit cycles.

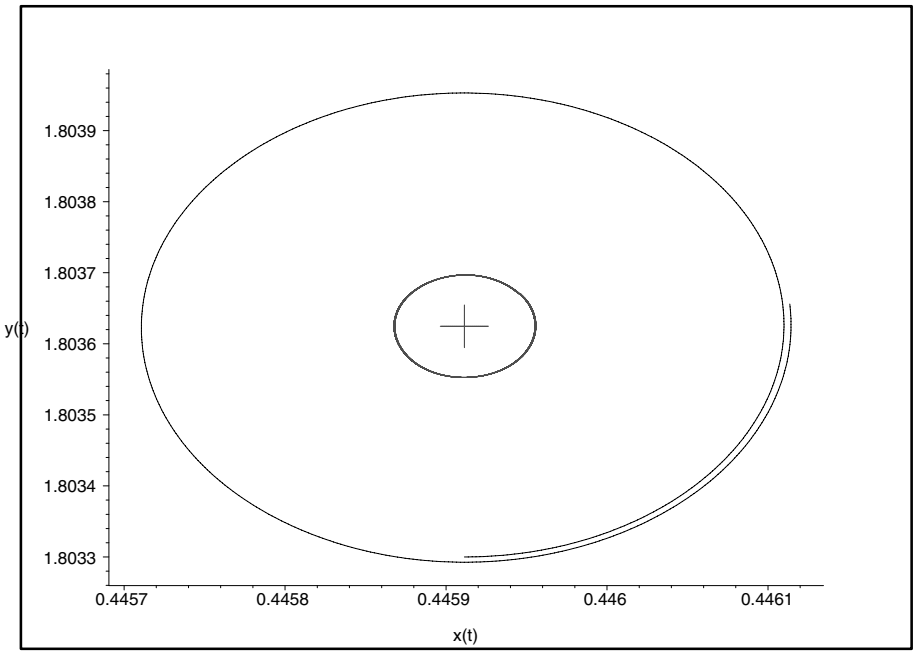
Remark 3.3. In Theorem 6.22 of [26], for parameters (b, K) in certain region near the curve segment DH, the bifurcation sequences were given but not complete. There we could not exclude the saddle node bifurcations of limit cycles and supercritical homoclinic bifurcations. By the above Theorem 3.4, we can now conclude that the sequences given in Theorem 6.22 are complete for (b, K) in the neighborhood of $b = 0$ and near the curve segment DH.

4. Discussion. The existence of limit cycles in predator-prey systems can be used to explain many real-world oscillatory phenomena, such as the Canadian lynx-snowshoe hare 10-year cycles. However, the classical Lotka–Volterra predator-prey system does not exhibit periodic fluctuations since the positive equilibrium is globally stable. One can perturb the classical Lotka–Volterra predator-prey system to obtain a unique nonconstant periodic orbit (see Freedman [5]). The second method for modifying the Lotka–Volterra predator-prey model so that it exhibits periodic solutions is to introduce a functional response function. Various forms of functional response functions have been proposed. In general, most of these functional response functions are monotone and have self-saturation effect. The dynamics of the generalized Gause-type predator-prey systems with general monotonic functional response have been extensively studied and very well understood. Multiple limit cycles were observed in predator-prey systems for cases when the predator death rate is both linear [26] and nonlinear (Hofbauer and So [8], Kuang [9], Wrzosek [22], etc.). However, the existence of exactly two limit cycles in predator-prey systems has not been studied yet.

Nonmonotonic functional response has been used to model the group defense phenomenon in population dynamics and inhibition in microbial dynamics (Freedman and Wolkowicz [6], Mischaikow and Wolkowicz [12], Rosenzweig [17], and Wolkowicz [21]), and very rich and interesting dynamics have been observed in Gause-type predator-



(a) The outer stable limit cycle



(b) The equilibrium (x_1, y_1) is stable, and the trajectory nearby spirals outwards, which indicates the existence of an unstable limit cycle

FIG. 3. *Two limit cycles bifurcated from the multiple focus of multiplicity two. The figures were produced using MAPLE* [20].

prey models with nonmonotonic functional response and only linear predator death rate ([18, 19, 26]). However, it is difficult to discuss the degenerate Hopf bifurcation for these models since it is hard to determine the multiplicity of a multiple focus by usual methods in [2, 14]. In this paper, we introduce a new method for solving the problem successfully. For the Gause-type predator-prey model with nonmonotonic functional response as in (1.2), we have shown that it has a multiple focus with multiplicity exactly two, and there exist some parameter values for which system (1.2) with the functional response (1.3) has exactly two limit cycles. These results also extend the bifurcation analysis of (3.2) by Ruan and Xiao [19] and Zhu, Campbell, and Wolkowicz [26].

It is natural that the predator-prey interaction has the tendency or potential to produce periodic oscillations. Hence one always needs to study the multiplicity of multiple focus and Hopf bifurcations in such predator-prey systems. The machinery developed in this paper can also be applied to the study of the multiplicity of multiple focus of other predator-prey systems with linear death rate for the predator, even with harvesting.

Acknowledgments. The authors are grateful to the anonymous referees and the handling editor for their valuable comments and suggestions. The authors also thank one referee for pointing us towards the reference [16].

EFFECTIVE MASS THEOREMS FOR NONLINEAR SCHRÖDINGER EQUATIONS*

CHRISTOF SPARBER†

Abstract. We consider time-dependent nonlinear Schrödinger equations subject to smooth lattice-periodic potentials plus additional confining potentials, slowly varying on the lattice scale. After an appropriate scaling we study the homogenization limit for vanishing lattice spacing. Assuming well-prepared initial data, the resulting effective dynamics is governed by a homogenized nonlinear Schrödinger equation with an effective mass tensor depending on the initially chosen Bloch eigenvalue. The given results rigorously justify the use of the effective mass formalism for the description of Bose–Einstein condensates on optical lattices.

Key words. nonlinear Schrödinger equation, effective mass theorems, Bloch waves, homogenization limit, Bose–Einstein condensate

DOI. 10.1137/050623759

1. Introduction. Recent experiments on *Bose–Einstein condensates* (BECs) study the influence of *optical lattices* (or superlattices) on the dynamics of the condensate; cf. [12, 14, 28, 32]. The theoretical description of such systems is usually based on the famous *Gross–Pitaevskii equation*, i.e.,

$$i\hbar\partial_t\psi = -\frac{\hbar^2}{2m}\Delta\psi + V(x)\psi + U_0(x)\psi + N\alpha_0|\psi|^2\psi, \quad x \in \mathbb{R}^3,\, t \in \mathbb{R}, \tag{1.1}$$

where m is the atomic mass, $\hbar$ is the Planck constant, N is the number of atoms in the condensate, and

$$\alpha_0 = \frac{4\pi\hbar^2 a}{m}, \tag{1.2}$$

with $a \in \mathbb{R}$ being the s-wave scattering length derived from the corresponding N-particle theory; cf. [36]. Depending on the sign of a, the condensate is said to be either *repulsive* (stable) or *attractive* (unstable). In the nonlinear Schrödinger equation (NLS) (1.1), the potential $U_0(x)$ models some given external *confinement*, whereas $V(x)$ represents the *lattice-potential*, satisfying

$$V(x+\gamma) = V(x) \quad \forall x \in \mathbb{R}^3,\ \gamma \in \underline{\Gamma}, \tag{1.3}$$

where $\underline{\Gamma} \simeq \mathbb{Z}^3$ denotes some given *regular lattice*, generated through a basis $\{\underline{\zeta}_1, \underline{\zeta}_2, \underline{\zeta}_3\}$, $\underline{\zeta}_l \in \mathbb{R}^3$, i.e.,

$$\underline{\Gamma} = \left\{ \gamma \in \mathbb{R}^3 :\ \gamma = \sum_{l=1}^{3} \gamma_l \underline{\zeta}_l,\ \gamma_l \in \mathbb{Z} \right\}. \tag{1.4}$$

†Wolfgang Pauli Institute & Faculty of Mathematics, Vienna University, Nordbergstraße 15, A-1090 Vienna, Austria (christof.sparber@univie.ac.at).

Of course the nonlinear dynamics described by (1.1) can be highly involved. In the physics literature it is therefore frequently proposed (cf. [27, 38, 41]) that one consider the following simplifications: First it is assumed that the matter wave-field $\psi(t)$ can be characterized by a (fixed) central wave vector $k_0 \in \mathbb{R}^3$, and second one tries to capture the rapid oscillations in the wave function $\psi(t)$ by performing an asymptotic expansion in terms of *Bloch waves* $\chi_n(y, k_0)$ (see (2.4) below for their precise definition). The center of mass of the wave function is then described by a slowly varying envelope function $f(t, x)$, the dynamics of which is *formally* found to be governed by an *effective-mass NLS*. These types of approximations are well known in solid-state physics [8], though mostly in a time-independent setting [35], where one considers the motion of electrons in a crystal. It is the purpose of this work to *rigorously justify* the described approach specifically within the considered nonlinear context. To this end we shall consider a more general NLS than that originally proposed in (1.1), namely,

$$\begin{cases} i\hbar\partial_t\psi = -\dfrac{\hbar^2}{2m}\Delta\psi + V(x)\psi + U_0(t,x)\psi + \alpha|\psi|^{2\sigma}\psi, \quad x \in \mathbb{R}^d,\ t \in \mathbb{R}, \\ \psi\big|_{t=0} = \psi_I(x), \end{cases} \tag{1.5}$$

where $\alpha \in \mathbb{R}$ and $\sigma \in \mathbb{N}$. To motivate the choice $\sigma \geq 1$, we note that for $d < 3$ higher order nonlinearities are frequently used in the description of BECs; cf. [26, 29]. Moreover, different NLS-type models of the form (1.5) also appear in nonlinear optics and laser physics; cf. [42] (see also [24] for a rigorous derivation). We assume $\psi_I \in L^2(\mathbb{R}^d)$ to be normalized such that

$$\int_{\mathbb{R}^d} |\psi_I(x)|^2 dx = 1. \tag{1.6}$$

This normalization condition is henceforth conserved during the time-evolution. Again V is assumed to be periodic w.r.t. some regular lattice $\underline{\Gamma} \simeq \mathbb{Z}^d$, and U_0 denotes some, in general time-dependent, smooth external potential. Now, we rescale (1.5) in order to precisely identify the asymptotic regime we shall be dealing with in what follows. We have in mind a situation where the potential U_0 is slowly varying on the lattice-scale corresponding to V. Hence, there are essentially two scales in this problem. First, the *macroscopic length-* and *time-scales*, denoted L and T, respectively, which are introduced via U_0 by rewriting it in the following dimensionless form:

$$U_0(t,x) = \frac{mL^2}{T^2}\, U\left(\frac{t}{T}, \frac{x}{L}\right). \tag{1.7}$$

In other words, the scaled potential U is such that a free particle of mass m under the influence of U_0 will travel the distance L in the time-unit T. On the other hand, we can also introduce a couple of *microscopic scales*, λ and τ, via a rescaling of the periodic potential V such that

$$V(x) = \frac{m\lambda^2}{\tau^2}\, V_\Gamma\left(\frac{x}{\lambda}\right). \tag{1.8}$$

The *rescaled lattice* Γ is henceforth generated through a basis $\{\zeta_l\}_{l=1}^3$, where $\zeta_l = \underline{\zeta}_l/\lambda$, and the microscopic time-unit τ is then given by

$$\tau = \frac{m\lambda^2}{\hbar}. \tag{1.9}$$

We consequently define two *small dimensionless parameters*, ε and δ, as being the length- and time-ratios, respectively, i.e.,

$$\varepsilon = \frac{\lambda}{L}, \quad \delta = \frac{\tau}{T}. \tag{1.10}$$

In the following, both of these are assumed to be *small*, i.e., $\varepsilon \ll 1$, $\delta \ll 1$, but in general *not necessarily equal*. Next we introduce new space- and time-variables $\tilde{x}$ and $\tilde{t}$ via

$$\tilde{x} = \frac{x}{L}, \quad \tilde{t} = \frac{t}{T}, \tag{1.11}$$

and rescale the NLS (1.5) in dimensionless form. Having in mind the normalization condition (1.6), we also need to rescale the wave function ψ by

$$\tilde{\psi}(\tilde{t}, \tilde{x}) = L^{d/2}\psi(t, x). \tag{1.12}$$

After multiplying (1.5) by $T^2/(mL^2)$, we consequently arrive at the following dimensionless two-parameter model (where we again omit all "˜" for simplicity):

$$\begin{cases} ih\partial_t\psi = -\dfrac{h^2}{2}\Delta\psi + \dfrac{h^2}{\varepsilon^2}V_\Gamma\left(\dfrac{x}{\varepsilon}\right)\psi + U(t,x)\psi + \kappa\,|\psi|^{2\sigma}\psi, \\ \psi\big|_{t=0} = \psi_I(x). \end{cases} \tag{1.13}$$

Here we introduced two additional dimensionless parameters,

$$h := \frac{\hbar T}{mL^2}, \quad \kappa := \frac{\alpha T^2}{mL^{d\sigma+2}}, \tag{1.14}$$

the former of which can be considered to be Planck's constant in the macroscopic variables. Note that the following important relation holds,

$$\varepsilon^2 = h\delta, \tag{1.15}$$

connecting the ratio of the length-scales ε with the corresponding time-scale ratio δ. Finally, since we are aiming for nonlinearities of order $\mathcal{O}(1)$, we shall impose from now on that

$$|\kappa| \equiv \frac{|\alpha|T^2}{mL^{d\sigma+2}} = 1, \quad \text{or, equivalently,} \quad T = \sqrt{\frac{mL^{d\sigma+2}}{|\alpha|}}, \tag{1.16}$$

hence relating the macroscopic length- and time-scales in a specific way. We remark that in the linear case a scaling analogous to (1.13) has been introduced in [37]. A brief discussion on several aspects of this scaling procedure is now in order. First note that if we choose $h = \varepsilon$, hence, in view of (1.15), $\varepsilon = \delta$; i.e., if we choose the *same* ratio for both the length- and the time-scales, then (1.13) simplifies to a one-parameter model given by

$$i\varepsilon\partial_t\psi = -\frac{\varepsilon^2}{2}\Delta\psi + V_\Gamma\left(\frac{x}{\varepsilon}\right)\psi + U(t,x)\psi + \kappa\,|\psi|^{2\sigma}\psi. \tag{1.17}$$

This is nothing but the standard *semiclassical scaling* for (nonlinear) Schrödinger-type equations including an additional *highly oscillatory periodic potential* V_Γ. Recently the

rigorous study of the corresponding asymptotic regime $\varepsilon \to 0$, known as the *combined semiclassical and adiabatic approximation*, attracted lots of interest. Particularly in the linear setting, i.e., $\kappa = 0$, different mathematical approaches are currently at hand, e.g., *WKB-type expansions* [6, 21], *Wigner transformation techniques* [30, 18], and the so-called *space-adiabatic perturbation theory* [33, 44], which gives the most sophisticated mathematical results so far. Including nonlinear effects, the literature is not so abundant. To the author's knowledge the only result in this direction is a recent paper by Carles, Markowich, and the current author [11]. The results given there, however, are valid only for weak nonlinearities, in the sense that we need to assume $\kappa \sim \mathcal{O}(\varepsilon)$. Therefore a different rescaling of the original NLS (1.5) has been introduced in [11].

Remark 1.1. Additionally there exists a related work on the semiclassical limit of the so-called Schrödinger–Poisson system [5] in a crystal. There, however, additional assumptions have to be imposed which are out of the realm of the present setting (like truly mixed-state initial data).

In the following our focus is not on the semiclassical regime. Rather, we shall study the asymptotic behavior of the scaled NLS (1.13) for $\varepsilon \ll 1$ but with a fixed h of order $\mathcal{O}(1)$. Note that, by (1.15), this implies $\delta \sim \mathcal{O}(\varepsilon^2)$, and hence we are considering our system on a much larger macroscopic time-scale T than we do by fixing a macroscopic length-scale L via (1.10). In particular, we are dealing with much larger times T, as in the semiclassical studies described above. Roughly speaking, the semiclassical regime can be seen to be an asymptotic description for *ballistic scales*, whereas we shall be dealing in the following with *dispersive scales* (sometimes also called *diffusive scales*). As we shall see, this indeed turns out to be the asymptotic regime where one can rigorously justify the effective-mass formalism discussed at the beginning. We note, however that, in contrast to what is noted in [3], the considered regime is *not* equivalent to the one obtained after rescaling time in the semiclassical equation (1.17) by $t \to \varepsilon t$. The reason for this is the different orders of magnitude in the external potential U and in the nonlinearity. To have a more concrete feeling of the involved time- and length-scales we come back to our original equation (1.1). Thus we consider (1.13) in $d = 3$, with $\sigma = 1$ and therefore $\kappa = 4\pi\hbar^2 a T^2/(mL^5)$ by (1.14). A particular example for the periodic potentials used in physical experiments is then given by [14, 36]

$$V(x) = \sum_{l=1}^{3} \frac{\hbar^2 \xi_l^2}{m} \sin^2(\xi_l x_l), \quad \xi_l \in \mathbb{R}, \tag{1.18}$$

where $\xi = (\xi_1, \xi_2, \xi_3)$ denotes the wave vector of the laser field which generates the optical lattice. Hence we readily identify $\lambda = (\lambda_1, \lambda_2, \lambda_3)$ as $\lambda_l = 1/\xi_l$. Moreover, the slowly varying external potential U_0 is usually modeled to be static and of harmonic oscillator type (isotropic or anisotropic), i.e.,

$$U_0(x) = \frac{m\omega_0^2}{2} |x|^2, \quad \omega_0 \in \mathbb{R},\ x \in \mathbb{R}^3. \tag{1.19}$$

In this case, a natural choice for the macroscopic length-scale is therefore given by $L = a_0$, where a_0 denotes the length of the harmonic oscillator ground state corresponding to $U_0(x)$, i.e.,

$$a_0 := \sqrt{\frac{\hbar}{\omega_0 m}}. \tag{1.20}$$

The assumption $\varepsilon \ll 1$ is then of course equivalent to $\lambda \ll a_0$. In an actual physical experiment this requirement can be easily satisfied, as a typical ground state length would be $a_0 \approx 10^{-6}[m]$, whereas the wave vectors ξ_l of the laser fields are usually tuned from $10^6[1/m]$ to $10^9[1/m]$, the latter case therefore being suitable in our situation. The corresponding relation for the time-scales, however, is more subtle. From the condition (1.16) we see that T has to be chosen such

$$T^2 = \frac{a_0^5 m^2}{4\pi N|a|\hbar^2} \gg \tau^2, \qquad \text{since } \delta \ll 1.$$

With τ given by (1.9), this finally leads to the requirement

$$\frac{a_0^5}{4\pi N|a|} \gg \lambda^4.$$

In particular, in the so-called *moderate interaction regime*, characterized by the fact that $4\pi N|a| \approx a_0$ [4], this is again equivalent to $a_0 \gg \lambda$, and in this case we compute

$$T^2 = \frac{a_0}{4\pi N|a|\omega_0^2} \approx \frac{1}{\omega_0^2}.$$

Note that this is precisely what one would get in the corresponding linear situation. From a mathematical point of view the limit $\varepsilon \to 0$ with δ fixed corresponds to the so-called *homogenization limit* of (1.13). In view of the classical homogenization results as described in, e.g., [6, 23], the main new difficulty, apart from the appearing nonlinearity, stems from the *large factor* $1/\varepsilon^2$ in front of the periodic potential, which furnishes a highly *singularly perturbed* term. It is therefore not a surprise that, even in the linear case, this type of homogenization problem has been rigorously studied only very recently [2]. In particular, (linear) time-dependent Schrödinger-type equations have been considered in [3] and in [37]. The latter result relies on the use of *Wigner measures*, a technique which cannot be applied in the given nonlinear situation. The former work is more closely related to ours, as it combines classical homogenization techniques, most notably *two-scale convergence methods* [1], with Bloch wave decomposition [13]. However, we want to stress the fact that the nonlinear case we shall be dealing with is by no means a straightforward generalization of the linear results. More precisely, one should note that the scaling of (1.13) in general prohibits the derivation of suitable, i.e., *uniformly* in ε, a priori estimates, except for the basic L^2 estimate corresponding to the conservation of mass. In the majority of cases, the derivation of such uniform estimates is crucial to gaining sufficient control on the limiting behavior of the appearing nonlinearities, a problem which cannot be handled by using weak-convergence methods (such as Wigner measures or two-scale convergence).

Remark 1.2. Also, for the same reasons, our results do not fit into the framework of *H-measures* [43] or *G-convergence* [34].

We note that in [2, 3] the authors propose the use of a *factorization principle* in order to extend their results to the nonlinear case. However, this approach remains unproven there and, moreover, is known to be applicable only in situations where the initial data ψ_I is *concentrated at the minimum of the first Bloch band* (see [2, 3] for more details on this). In comparison to that, the results given below are indeed *independent* of the number of the Bloch band, and also they do *not* require that ψ_I be concentrated at a local minimum of the considered band. On the other hand, we do need the initial data ψ_I to be *well prepared* in a sense to be made more precise

below; cf. Assumption 4.3. Additionally we need to assume sufficient regularity on the potentials U, V as well as on the initial data ψ_I. The reasons for these assumptions are first the fact that we shall use a more traditional *multiple-scales expansion method*, similar to those introduced in [6]. This approach will allow us to obtain, in a rather transparent way, an asymptotic description of $\psi(t)$ for small $\varepsilon \ll 1$, and also to determine the corresponding *effective homogenized NLS*. Second, in order to prove that the given asymptotic solution is indeed *stable* under the nonlinear time-evolution governed by (1.13), we shall adapt an approach originally introduced to prove the accuracy of *nonlinear geometrical optics expansions* (cf. [15, 20, 39]) for the results most closely related to the present work. The given proof will then again rely heavily on the fact that we have sufficient regularity properties and well-prepared initial data. A similar strategy recently proved to be successful when applied to the weakly nonlinear semiclassical situation studied in [11]. The main goal of this paper, though, is not the introduction of new methods but rather a complete and correct treatment of the problem at hand. Moreover, one should keep in mind that for completely arbitrary initial data $\psi_I \in L^2(\mathbb{R}^d)$ one cannot expect an effective mass-type dynamics to be valid. In other words, to obtain an equation of the form (1.22) the initial data ψ_I needs to be (asymptotically) of the same type as stated below, at least in leading order, and the additional well-preparedness assumptions we shall need concern only the higher order terms within the asymptotic expansion. We note that only in linear cases does the superposition principle allow for more general states ψ_I.

At the expense of not completely well-defined assumptions (to be made precise later on), let us now state the typical *effective mass theorem* we shall prove in what follows.

THEOREM 1.3. *Let V_Γ and U be smooth real-valued potentials such that V_Γ is Γ-periodic and U is subquadratic. Assume that for some $k_0 \in \mathbb{R}$ the initial data ψ_I is of the following form:*

$$\psi_I(x) = f_I(x)\chi_n\left(\frac{x}{\varepsilon}, k_0\right) e^{ik_0\cdot x/\varepsilon} + \varepsilon\eta^\varepsilon(x),$$

where $f_I \in \mathcal{S}(\mathbb{R}^d;\mathbb{C})$; $\chi_n(y,k)$ is an eigenfunction of Bloch's spectral cell problem, corresponding to a simple eigenvalue $E_n(k)$; and the corrector $\eta^\varepsilon \sim \mathcal{O}(1)$ is such that ψ_I is well prepared, up to sufficiently large $K \in \mathbb{N}$, in the sense of Assumption 4.3 below. Then there exists an $\varepsilon_0 > 0$ such that for $\varepsilon \le \varepsilon_0$ the following asymptotic estimate holds:

$$\sup_{t\in[-\tau_0,\tau_0]} \|\psi(t) - v_0^\varepsilon(t)\|_{L^2(\mathbb{R}^d)} = \mathcal{O}(\varepsilon), \quad \tau_0 < \tau, \tag{1.21}$$

where $\tau > 0$ is the maximum existence-time for a smooth solution $f(t,x)$ for the homogenized NLS

$$ih\partial_t f = -\frac{h^2}{2}\,\mathrm{div}(M^*\nabla)f + U(x)\psi + \kappa^*\,|f|^{2\sigma} f, \tag{1.22}$$

with effective mass tensor $M^* = D^2E_n(k_0)$ and an effective coupling $\kappa^* \in \mathbb{R}$, given by (3.21) below. Moreover, the leading order approximate solution v_0^ε is found to be

$$v_0^\varepsilon(t,x) = f\left(t, x - \frac{ht}{\varepsilon}\nabla_k E_n(k_0)\right)\chi_n\left(\frac{x}{\varepsilon}, k_0\right) e^{ik_0\cdot x/\varepsilon} e^{-ihE_n(k_0)t/\varepsilon^2}. \tag{1.23}$$

We note that the estimate (1.21) implies a strong two-scale convergence statement as defined in [1, 2, 3]. Also note that, apart from the nonlinearity, our approach represents a refinement of the classical multiple-scales expansions given in [6], in the sense that we can include possibly appearing *large drifts* (clearly visible in (1.23) in the second argument of f) in order to resolve the underlying dispersive behavior. The possibility of large drifts present in the asymptotic solution can be seen as the aftermath of the ballistic regime known from the semiclassical situation, a fact which has already been noticed in linear situations [3, 16].

The paper is now organized as follows. In section 2 we collect some preliminary results and important notation used throughout this work. We then proceed along the lines of [11] and next present in section 3 the multiple-scales expansion method, whereas its nonlinear stability shall be proved in section 4.

2. Preliminaries. For simplicity we restrict ourselves in this work to *static external potentials* $U = U(x)$, although all results could be generalized to the case of time-dependent potentials $U(t,x)$, which are smooth w.r.t. $t \in \mathbb{R}$. (Indeed, we could as well include smoothly time-dependent coupling factors $\kappa(t) \in \mathbb{R}$.) Thus we study in the following the asymptotic behavior as $\varepsilon \to 0$ of

$$\begin{cases} ih\partial_t\psi = -\dfrac{h^2}{2}\,\Delta\psi + \dfrac{h^2}{\varepsilon^2}V_\Gamma\left(\dfrac{x}{\varepsilon}\right)\psi + U(x)\psi + \kappa\,|\psi|^{2\sigma}\psi, \\ \psi\big|_{t=0} = \psi_I(x). \end{cases} \tag{2.1}$$

All results given below are then valid for potentials which satisfy the following basic assumption.

Assumption 2.1. The potentials U and V_Γ are such that $V_\Gamma, U \in C^\infty(\mathbb{R}^d;\mathbb{R})$, and moreover they satisfy the following:

(i) V_Γ is Γ-periodic: $V_\Gamma(x+\gamma) = V_\Gamma(x)\ \forall x \in \mathbb{R}^d$, $\gamma \in \Gamma \simeq \mathbb{Z}^d$.

(ii) U is subquadratic: $\partial^\alpha U \in L^\infty(\mathbb{R}^d)\ \forall \alpha \in \mathbb{N}^d$ such that $|\alpha| \geq 2$.

Remark 2.2. These are the same assumptions that were used in [11]. In particular, they include the cases of isotropic harmonic potentials $U(x) = |x|^2$, as well as those corresponding to anisotropic ones, like $U(x) = \sum \omega_j^2 x_j^2$. Moreover, we can take U to be identically zero, or include a linear component such as $E \cdot x$, $E \in \mathbb{R}$, modeling constant electric fields, for example.

We proceed by recalling Bloch's famous eigenvalue problem [7].

2.1. Bloch's eigenvalue problem. From now on we denote by $\mathfrak{C}$ the *elementary lattice cell*, i.e., the centered *fundamental domain* of the lattice Γ, i.e.,

$$\mathfrak{C} := \left\{ \gamma \in \mathbb{R}^d :\ \gamma = \sum_{l=1}^{d} \gamma_l \zeta_l,\ \gamma_l \in \left[-\frac{1}{2}, \frac{1}{2}\right] \right\}, \tag{2.2}$$

whereas the corresponding basic cell of the dual lattice will be denoted by $\mathfrak{C}^*$. In solid-state physics $\mathfrak{C}^*$ is usually called the (first) *Brillouin zone*; hence we shall also write $\mathfrak{B} \equiv \mathfrak{C}^*$. Also let us introduce the so-called *Bloch Hamiltonian* (or shifted Hamiltonian) given by

$$H_\Gamma(k) := \frac{1}{2}\,(-i\nabla_y + k)^2 + V_\Gamma(y), \quad k \in \mathbb{R}^d. \tag{2.3}$$

Then Bloch's eigenvalue problem is given by the following spectral cell equation:

$$\begin{cases} H_\Gamma(k)\chi_n(y,k) = E_n(k)\chi_n(y,k) & n \in \mathbb{N},\ y \in \mathfrak{C}, \\ \chi_n(y+\gamma,k) = \chi_n(y,k) & \text{for } \gamma \in \Gamma, \end{cases} \tag{2.4}$$

and $E_n(k) \in \mathbb{R}$, $k \in \mathfrak{B}$, is then called the nth *Bloch eigenvalue* corresponding to the potential V_Γ. We shall now briefly collect some well-known facts for this eigenvalue problem (cf. [31, 40, 45]). Since V_Γ is smooth and periodic, $H_\Gamma(k)$, for every fixed $k \in \mathfrak{B}$, is self-adjoint on $H^2(\mathbb{T}^d)$, $\mathbb{T}^d = \mathbb{R}^d/\Gamma$, with compact resolvent. Hence its spectrum is given by

$$\sigma(H_\Gamma(k)) = \{E_n(k) \in \mathbb{R} \ ; \ k \in \mathfrak{B}, \, n \in \mathbb{N}^*\}.$$

The eigenvalues $E_n(k)$ can then be ordered according to their magnitude and multiplicity, i.e.,

$$E_1(k) \leq \cdots \leq E_n(k) \leq E_{n+1}(k) \leq \cdots .$$

Moreover, every $E_n(k)$ is periodic w.r.t. Γ^* and $E_n(k) = E_n(-k)$ holds. The set

$$\{E_n(k) \in \mathbb{R} : E_n(k) \leq E_{n+1}(k), \, k \in \mathfrak{B}\}$$

is then usually named the nth *energy band* (or Bloch band). The associated eigenfunction, the so-called *Bloch waves*, $\chi_n(y,k)$ form (for every fixed $k \in \mathfrak{B}$) a complete orthonormal basis in $L^2(\mathfrak{C})$ and are smooth w.r.t. $y \in \mathfrak{C}$. For the following we choose the usual normalization

$$\langle \chi_n(\cdot,k), \chi_m(\cdot,k) \rangle_{L^2(\mathfrak{C})} \equiv \int_{\mathfrak{C}} \overline{\chi_n(y,k)} \chi_m(y,k) dy = \delta_{n,m}, \quad n, \, m \in \mathbb{N}. \tag{2.5}$$

Regularity of the χ_n w.r.t. their dependence on $k \in \mathfrak{B}$ is more subtle. It has been shown [31] that for any $n \in \mathbb{N}$ there exists a closed subset $\mathfrak{A} \subset \mathfrak{B}$ such that $E_n(k)$ is analytic. Similarly the eigenfunctions $\chi_n(\cdot,k)$ are found to be analytic and quasi-periodic in k for all $k \in \mathfrak{O} := \mathfrak{B} \backslash \mathfrak{A}$. Moreover, it holds that

$$E_{n-1}(k) < E_n(k) < E_{n+1}(k) \quad \forall \, k \in \mathfrak{O}. \tag{2.6}$$

If this condition is satisfied for all $k \in \mathfrak{B}$, then $E_n(k)$ is said to be an *isolated Bloch band* [44]. Finally we remark that the set where one encounters the so-called *band crossings* is indeed of measure zero, i.e.,

$$\operatorname{meas} \mathfrak{A} = \operatorname{meas} \{k \in \mathfrak{B} \mid E_n(k) = E_m(k), \ n \neq m\} = 0.$$

Remark 2.3. Note that in the case $d = 1$ all band crossings can be removed through a proper analytic continuation of the bands; cf. [40].

From the eigenvalue equation (2.4) we obtain the following useful identities. Differentiating (2.4) w.r.t. k (assuming for the moment that everything is sufficiently smooth) yields

$$(\nabla_k H_\Gamma(k) - \nabla_k E_n(k))\chi_n + (H_\Gamma(k) - E_n(k))\nabla_k \chi_n = 0. \tag{2.7}$$

Hence, taking the scalar product with χ_n, we obtain a formula for $\nabla_k E_n(k)$ by

$$\begin{aligned} \langle \chi_n, \, \nabla_k H_\Gamma(k) \chi_n \rangle_{L^2(\mathfrak{C})} &\equiv \langle \chi_n, \, (-i\nabla_y + k)\chi_n \rangle_{L^2(\mathfrak{C})} \\ &= \nabla_k E_n(k), \end{aligned} \tag{2.8}$$

since H_Γ is self-adjoint. Similarly we obtain the following expression for the entries of the Hessian matrix $D^2 E_n(k)$:

$$\begin{aligned} \partial^2_{k_j k_l} E_n(k) = \delta_{j,l} &+ \langle \chi_n, \, (-i\partial_{y_j} + k_j)\chi_n \rangle + \langle \chi_n, \, (-i\partial_{y_l} + k_l)\partial_{k_j}\chi_n \rangle \\ &- \langle \chi_n, \, (\partial_{k_l} E_n(k))\partial_{k_j}\chi_n + (\partial_{k_j} E_n(k))\partial_{k_l}\chi_n \rangle, \end{aligned} \tag{2.9}$$

where $\delta_{j,l}$ denotes the Kronecker symbol for $j,l=1,\dots,d$. (Below we shall assume $E_n(k)$ to be a simple eigenvalue, which implies sufficient regularity to justify all differentiations above.)

2.2. Existence of smooth solutions for NLS. As a final preparatory step we state a basic existence and uniqueness result for NLS of the form (2.1). (See also [9, 42] for a general introduction.)

LEMMA 2.4. *Let Assumption* 2.1 *be satisfied, and let* $\psi_I \in \mathcal{S}(\mathbb{R}^d)$*, the Schwartz space. Let* $s > d/2$*. Then there exists* $t = t(\varepsilon,h) > 0$ *and a unique solution* $\psi \in C(]-t,t[\,;H^s(\mathbb{R}^d))$ *satisfying* (2.1)*. Moreover,* $x^\alpha\psi \in C(]-t,t[\,;H^s(\mathbb{R}^d))$ *for any* $\alpha\in\mathbb{N}^d$*,* $s\in\mathbb{N}$*, and the following conservation law holds:*

$$\frac{d}{dt}\,\|\psi(t)\|_{L^2}=0\,. \tag{2.10}$$

Proof. See the proof of Lemma 4.3 in [11]. ∎

Remark 2.5. In general, one cannot expect global-in-time existence for solutions to the NLS. For example, if κ is negative and if $\sigma > 2/d$, finite time blow-up may occur; see, e.g., [10, 42] (see also [9] for the case $\sigma = 2/d$).

3. Multiple-scales expansion. We now establish the asymptotic behavior of $\psi(t)$, the solution to (2.1), for $0<\varepsilon\ll 1$, by means of a multiple-scales expansion. In the following $h>0$ is kept fixed, though we shall not simply set it equal to 1, since we want to keep track of its appearance in order to compare our results with the semiclassical situation of [11]; cf. Remark 3.9 below. As in [3], we shall first consider the easier situation where no large drifts appear, and then include them in a second step, using a more general asymptotic expansion method.

3.1. Homogenization without drift. In this subsection we seek an asymptotic expansion for solutions to (1.13) in the following form:

$$\begin{cases} \psi(t,x) = u^\varepsilon\left(t,x,\dfrac{x}{\varepsilon}\right)\exp\left(i\left(\dfrac{k_0\cdot x}{\varepsilon}+\dfrac{\beta t}{\varepsilon^2}\right)\right), \\ u^\varepsilon(t,x,y)\sim \displaystyle\sum_{j=0}^{\infty}\varepsilon^j u_j(t,x,y), \end{cases} \tag{3.1}$$

where $k_0\in\mathbb{R}^d$ is induced by the initial condition and $\beta\in\mathbb{R}$ is some arbitrary constant to be determined below. The precise meaning of the symbol "$\sim$" in terms of an asymptotic series will be discussed in section 4 below. Moreover, we impose that $u^\varepsilon(t,x,y)\in\mathbb{C}$ satisfies

$$u^\varepsilon(\cdot,\cdot,y+\gamma)=u^\varepsilon(\cdot,\cdot,y)\quad\forall\, y\in\mathbb{R}^d,\,\gamma\in\Gamma,$$

in order to capture precisely those oscillations which are introduced via V_Γ.

Remark 3.1. This particular form of a multiple-scale ansatz is suggested by the linear results given in [2, 3]. Indeed, one could have started with a more general ansatz, imposing appropriate periodicity or quasi-periodicity assumptions. It then turns out that one ends up again with the same form as given in (3.1). Also, the ansatz (3.1) might not be so surprising when compared to the *two-scale WKB approach* used in [6, 11, 21] (see also Remark 3.9 below).

As usual in asymptotic expansion methods we have to henceforth assume that the initial condition ψ_I is compatible with (3.1).

Assumption 3.2 (well-prepared initial data I). The initial data ψ_I is assumed to be of the following form:

$$\psi_I(x) = u_I^\varepsilon\left(x, \frac{x}{\varepsilon}\right) e^{ik_0\cdot x/\varepsilon} \quad \text{for some given } k_0 \in \mathbb{R}, \tag{3.2}$$

where $u_I^\varepsilon(x,y)$ is Γ-periodic w.r.t. y and $u_I^\varepsilon \in \mathcal{S}(\mathbb{R}^{2d})$.[1]

Assuming for the moment that u^ε is sufficiently smooth, we (formally) plug the ansatz (3.1) into (2.1) and compare equal powers in ε. This yields

$$\frac{1}{\varepsilon^2}L_0u^\varepsilon + \frac{1}{\varepsilon}L_1u^\varepsilon + L_2u^\varepsilon + \kappa|u^\varepsilon|^{2\sigma}u^\varepsilon = 0, \tag{3.3}$$

where the linear differential operators L_0 and L_1 are defined by

$$\begin{aligned} L_0u^\varepsilon &:= h\beta + h^2H_\Gamma(k_0),\\ L_1u^\varepsilon &:= -h^2\nabla_x\cdot\nabla_y u^\varepsilon + ih^2k_0\cdot\nabla_x u^\varepsilon, \end{aligned} \tag{3.4}$$

with $H_\Gamma(k)$ being the Bloch Hamiltonian as given in (2.3). We also define

$$L_2u^\varepsilon := -ih\,\partial_t u^\varepsilon - \frac{h^2}{2}\,\Delta_x u^\varepsilon + U(x)u^\varepsilon. \tag{3.5}$$

Since $u^\varepsilon \sim \sum \varepsilon^j u_j$ we shall in the following expand (3.3) in powers of ε and derive conditions on u_j such that all resulting terms are zero up to sufficient high orders in ε. Setting the leading order term, i.e., the term of order $\mathcal{O}(\varepsilon^{-2})$, equal to zero gives

$$H_\Gamma(k_0)u_0 + \frac{\beta}{h}\,u_0 = 0, \tag{3.6}$$

from which we readily see that we need to choose

$$\beta = -hE_n(k_0). \tag{3.7}$$

Now, if we assume that $E_n(k_0)$ is indeed a *simple* Bloch-eigenvalue, then (3.6) implies that u_0 can be decomposed as

$$u_0(t,x,y) = f_0(t,x)\chi_n(y,k_0) \quad \forall\, t\in\mathbb{R},\ x\in\mathbb{R}^d, \tag{3.8}$$

with some yet undetermined function $f(t,x)\in\mathbb{C}$. This now leads directly to the following important assumption.

Assumption 3.3 (well-prepared initial data II). Initially, the leading order "amplitude" u_0 is assumed to be concentrated in a single Bloch band $E_n(k_0)$ corresponding to a simple eigenvalue of $H_\Gamma(k_0)$, i.e.,

$$u_0(0,x,y) \equiv f_0(0,x)\chi_n(y,k_0), \tag{3.9}$$

where $f_0(0,\cdot)\equiv f_I(\cdot)\in\mathcal{S}(\mathbb{R}^d;\mathbb{C})$ is some given initial data.

An important consequence of $E_n(k_0)$ being simple is that in this case it is known to be infinitely differentiable in a vicinity of k_0. We have seen that in leading order $\psi(t)$ can be written as

$$\psi(t,x) \sim f_0(t,x)\chi_n\left(\frac{x}{\varepsilon},k_0\right)e^{ik_0\cdot x/\varepsilon}e^{-ihE_n(k_0)t/\varepsilon^2} + \mathcal{O}(\varepsilon), \tag{3.10}$$

[1] That is, u_I^ε is smooth and rapidly decaying w.r.t. x and smooth w.r.t. y

where the f_0 is yet to be determined. To this end we proceed with our asymptotic expansion by setting terms of order $\mathcal{O}(\varepsilon^{-1})$ equal to zero. This yields

$$(H_\Gamma(k_0) - E_n(k_0))u_1 = \nabla_x \cdot \nabla_y u_0 - ik_0 \cdot \nabla_x u_0, \tag{3.11}$$

which, by inserting (3.8), can be rewritten as

$$\begin{aligned}(H_\Gamma(k_0) - E_n(k_0))u_1 =& -i\nabla_x f_0 \cdot (-i\nabla_y \chi_n + k_0 \chi_n) \\ =& -i\nabla_x f_0 \cdot \nabla_k H_\Gamma(k_0)\chi_n,\end{aligned} \tag{3.12}$$

where the second equality follows from the definition of $H_\Gamma(k)$ in (2.3). It remains to ask whether this equation is solvable for u_1. By Fredholm's alternative the necessary and sufficient condition for solving it is that the right-hand side be orthogonal (in $L^2(\mathfrak{C})$) to $\chi_n(y, k_0)$. Hence we have to impose that

$$\begin{aligned}0 =& -i\nabla_x f_0 \cdot \langle \chi_n, \nabla_k H_\Gamma(k_0)\chi_n \rangle_{L^2(\mathfrak{C})} \\ =& -i\nabla_x f_0 \cdot \nabla_k E_n(k_0),\end{aligned} \tag{3.13}$$

where for the second equality we used the identity (2.8). Thus we are led to the restriction that k_0 has to be a critical point of $E_n(k)$, i.e.,

$$\nabla_k E_n(k_0) = 0. \tag{3.14}$$

This situation is analogous to the one discussed in the first part of [3], though the arguments given there are different. Assuming that (3.14) indeed holds true, we get from (3.12), together with (2.7), that the order $\mathcal{O}(\varepsilon)$ *corrector* u_1 in general can be written in the following form:

$$u_1(t, x, y) = -i\nabla_x f_0(t, x) \cdot \nabla_k \chi_n(y, k_0) + f_1(t, x)\chi_n(y, k_0) \tag{3.15}$$

for any given function f_1. Note that we cannot choose $u_1(0, x, y)$ completely arbitrary, once $u_0(0, x, y)$ is fixed; i.e., the initial data u_I^ε given in Assumption 3.2 (formally) has to be of the form

$$u_I^\varepsilon(x, y) \sim (f_0(0, x) + \varepsilon f_1(0, x))\chi_n(y, k_0) - i\varepsilon \nabla_x f_0(0, x) \cdot \nabla_k \chi_n(y, k_0) + \mathcal{O}(\varepsilon^2) \tag{3.16}$$

in order to be consistent with our asymptotic description. In the following we shall choose $f_1(0, x) \equiv 0$ for simplicity. Proceeding with our ε-expansion of (3.3), we next consider terms of order $\mathcal{O}(1)$ to obtain the following equation:

$$L_0 u_2 + L_1 u_1 + L_2 u_0 + \kappa |u_0|^{2\sigma} u_0 = 0. \tag{3.17}$$

Again, by Fredholm's alternative, it can be solved for u_2 iff

$$\int_{\mathfrak{C}} \overline{\chi_n(y, k_0)} \left(L_1 u_1 + L_2 u_0 + \kappa |u_0|^{2\sigma} u_0 \right) dy = 0. \tag{3.18}$$

Plugging into this identity the precise forms of u_0 and u_1, respectively defined in (3.8) and (3.15), and using formula (2.9), given the fact that $\nabla_k E_n(k_0) = 0$, we obtain after some lengthy but straightforward calculations the following solvability condition:

$$\begin{cases} ih\partial_t f_0 = -\dfrac{h^2}{2} \operatorname{div}_x(M^* \nabla_x) f_0 + U(x) f_0 + \kappa^* |f_0|^{2\sigma} f_0, \\ f_0\big|_{t=0} = f_I(x). \end{cases} \tag{3.19}$$

This is nothing but the *homogenized NLS*, or the *effective mass NLS*, where the so-called *effective mass tensor* $M^* \in \mathbb{R}^{d\times d}$ is defined by

$$M^*_{j,l} := \partial^2_{k_j,k_l} E_n(k_0), \qquad j,l = 1,\dots,d. \tag{3.20}$$

Moreover, the *effective coupling constant* $\kappa^* \in \mathbb{R}$ within the nth Bloch band is defined by

$$\kappa^*(k_0) := \kappa \int_{\mathfrak{C}} |\chi_n(y,k_0)|^{2\sigma+2}\, dy. \tag{3.21}$$

The effective NLS (3.19) describes the dispersive dynamics, as $\varepsilon \to 0$, of (2.1) for long macroscopic time-scales. However, it should not be confused with the so-called effective Hamiltonian, as determined in [31, 44]. Note that in general M^* is *neither positive nor definite*, and thus (3.19) in general also includes the class of so-called *nonelliptic NLS* [17, 25, 42].

Remark 3.4. The formulas (3.19)–(3.21) can be shown to be exactly the same as in the physics literature [38, 41] and moreover simplify to the ones given in [3, 37] in the linear case. If M^* is scalar, its inverse $m^* = 1/M^*$ is called the *effective mass*.

In the next subsection we shall show how to get rid of the additional assumption (3.14) that k_0 is a critical point of $E_n(k)$.

3.2. General situation including drifts. In order to generalize the expansion to situations where $\nabla_k E_n(k) \neq 0$ we have to modify our multiple-scales ansatz. It turns out that instead of (3.1) we need to consider

$$\psi(t,x) \sim u^\varepsilon\left(t,\tilde{x},\frac{x}{\varepsilon}\right)\exp\left(i\left(\frac{k_0\cdot x}{\varepsilon} - \frac{hE_n(k_0)t}{\varepsilon^2}\right)\right), \tag{3.22}$$

where $u^\varepsilon \sim \sum \varepsilon^j u_j$ and the new spatial coordinate $\tilde{x}$ is given by

$$\tilde{x} := x - \frac{h}{\varepsilon}\,\omega(k_0)t, \quad \text{with } \omega(k_0) := \nabla_k E_n(k_0). \tag{3.23}$$

Thus $\tilde{x}$ comprises a *macroscopically large drift* with a drift-velocity proportional to $\nabla_k E_n(k_0)$. Note that the fast scale x/ε remains unchanged; hence in situations where $\nabla_k E_n(k) = 0$ we are clearly back to our old situation. As before, we plug (3.22) into (2.1), which yields

$$\frac{1}{\varepsilon^2}L_0 u^\varepsilon + \frac{1}{\varepsilon}\tilde{L}_1 u^\varepsilon + L_2 u^\varepsilon + \kappa|u^\varepsilon|^{2\sigma}u^\varepsilon = 0, \tag{3.24}$$

where the linear differential operators L_0, L_2 are defined as in (3.4), (3.5), respectively, but with x replaced by $\tilde{x}$. However, instead of L_1 we have

$$\tilde{L}_1 u^\varepsilon := -h^2\nabla_{\tilde{x}}\cdot\nabla_y u^\varepsilon + ih^2(k_0+\omega(k_0))\cdot\nabla_{\tilde{x}} u^\varepsilon. \tag{3.25}$$

Then, by exactly the same arguments as above, we obtain that the leading order amplitude is given by

$$u_0(t,\tilde{x},y) = f_0(t,\tilde{x})\chi_n(y,k_0) \quad \forall\, t\in\mathbb{R}, x\in\mathbb{R}^d. \tag{3.26}$$

However, setting next the $\mathcal{O}(\varepsilon^{-1})$-term equal to zero yields, instead of (3.12),

$$(H_\Gamma(k_0) - E_n(k_0))u_1 = -i\nabla_x f_0\cdot(\nabla_k H_\Gamma(k_0)\chi_n - \omega(k_0)\chi_n). \tag{3.27}$$

In this case, the solvability condition requires

$$\begin{aligned} 0 &= \langle \chi_n, (\nabla_k H_\Gamma(k_0) - \omega(k_0))\chi_n \rangle_{L^2(\mathfrak{C})} \\ &= \nabla_k E_n(k_0) - \omega(k_0), \end{aligned} \tag{3.28}$$

where we have used the normalization $\langle \chi_n, \chi_n \rangle_{L^2(\mathfrak{C})} = 1$. But (3.28), of course, is identically fulfilled by definition of $\omega(k_0) := \nabla_k E_n(k_0)$. Thus, by identity (2.7), we formally obtain the same $\mathcal{O}(\varepsilon)$-corrector u_1,

$$u_1(t, \tilde{x}, y) = -i\nabla_x f_0(t, \tilde{x}) \cdot \nabla_k \chi_n(y, k_0) + f_1(t, \tilde{x})\chi_n(y, k_0), \tag{3.29}$$

for any given function f_1. (As above, we set f_1 to be identically zero at $t = 0$, for simplicity.) Thus by transforming the x-coordinate into $\tilde{x}$ by (3.23), we can now proceed with our asymptotic expansion, having gained the additional freedom to include the case $\nabla_k E_n(k_0) \neq 0$. The equation of order $\mathcal{O}(1)$ now gives

$$L_0 u_2 + \tilde{L}_1 u_1 + L_2 u_0 + \kappa |u_0|^{2\sigma} u_0 = 0. \tag{3.30}$$

It is clear now that, as before, the corresponding solvability condition, i.e.,

$$\int_{\mathfrak{C}} \overline{\chi_n(y, k_0)} \left(\tilde{L}_1 u_1 + L_2 u_0 + \kappa |u_0|^{2\sigma} u_0 \right) dy = 0, \tag{3.31}$$

yields a homogenized NLS equation of the same form as in (3.19), namely,

$$ih\partial_t f_0 = -\frac{h^2}{2} \operatorname{div}(M^* \nabla) f_0 + U(x) f_0 + \kappa^* |f_0|^{2\sigma} f_0. \tag{3.32}$$

One can easily check that even though $\nabla_k E_n(k_0) \neq 0$ in this case, all additional terms appearing in (3.31) cancel out identically; hence (3.32) remains.

Remark 3.5. In the physics literature [38, 41] the variable-transformation $x \to \tilde{x} := x - h\omega(k_0)t/\varepsilon$ is sometimes reverted, leading to an additional convective term on the left-hand side of (3.32). This, however, can be considered as only a formal statement, since consequently the large factor ε^{-1} would appear then in the homogenized NLS, a somewhat inconsistent formalism.

To prove the existence of smooth solutions for the homogenized NLS we shall impose the following ellipticity assumption.

Assumption 3.6 (ellipticity). We assume that at $k_0 \in \mathfrak{B}$ the following holds:

$$\xi^T M^* \xi \equiv \sum_{k,l=1}^{d} \partial^2_{k_j k_l} E_n(k_0) \xi_j \xi_l \geq C|\xi|^2 \quad \text{for } \xi \in \mathbb{R}^d,\ C > 0. \tag{3.33}$$

Clearly, condition (3.33) is valid if $k_0 \in \mathfrak{B}$ is indeed a local minimum of $E_n(k)$. It may very well be possible to relax the above assumption; cf. Remark 3.8 below. Here we mainly introduced this condition for definiteness, since it is then straightforward to prove that the effective NLS (3.19) (or equivalently (3.32)) has a smooth solution, at least locally-in-time.

LEMMA 3.7. *Let Assumptions* 2.1 *and* 3.6 *be satisfied, and let* $f_I \in \mathcal{S}(\mathbb{R}^d)$. *Then there exists* $\tau = \tau(h) > 0$ *and a unique solution* $f_0 \in C(]-\tau, \tau[; H^s(\mathbb{R}^d))$, $s > d/2$, *satisfying* (3.19) *or equivalently* (3.32). *Moreover,* $x^\alpha f_0 \in C(]-\tau, \tau[; H^s(\mathbb{R}^d))$ *for any* $\alpha \in \mathbb{N}^d$, $s \in \mathbb{N}$.

Proof. By Assumption 3.6 we have that $-\operatorname{div}(M^*\nabla)$ is uniformly elliptic, and since U is subquadratic, the operator $-\operatorname{div}(M^*\nabla)+U$ is therefore well known to be essentially self-adjoint on $C_0^\infty(\mathbb{R}^d)$; cf. [40]. The existence of a smooth solution $f_0(t,\cdot)\in H^s(\mathbb{R}^d)$, $s>d/2$, therefore follows by the same arguments as it does for the standard NLS [9]. The higher order regularity is then also proved similarly to, e.g., [9, 22] (see also the proof of Lemma 4.3 in [11] for the main strategy). ∎

Remark 3.8. Indeed, one can expect similar existence results to be true under much weaker conditions, as given by (3.33); cf. [25]. It is beyond the scope of this work, though, to study the weakest possible assumptions needed (also including, for example, degenerate cases), but rather we refer the reader to [42] and the references given therein. Here we only remark that in the case where M^* is *diagonal*, the existence of smooth local-in-time solutions is known even in the nonelliptic case [17].

Thus, at least for $t\in\,]-\tau,\tau[$, we have that u_0, and hence also u_1, is smooth w.r.t. x,y and, moreover, in $H^s(\mathbb{R}^d)$ w.r.t. x for any $s\in\mathbb{N}$. It is clear that in general we cannot expect smooth global-in-time solutions of the effective NLS (3.19). However, a situation where one indeed has globally smooth solutions, i.e., $\tau=\infty$, is furnished by condition (3.33) together with Assumption 2.1 and imposing that, in addition, $\kappa>0$.

Remark 3.9. Let us briefly compare the obtained leading order asymptotic description of $\psi(t)$ with the one derived in [11] for the weakly nonlinear semiclassical scaling. If we formally set $h=\varepsilon$ in (3.10), (3.26), we obtain

$$\psi(t,x)\sim f_0(t,x-\omega(k_0)t)\chi_l\left(\frac{x}{\varepsilon},k_0\right)e^{i(k_0\cdot x-E_n(k_0)t)/\varepsilon}+\mathcal{O}(\varepsilon), \tag{3.34}$$

which is exactly of the same form as the two-scale WKB ansatz used in [11] (see also [6, 21] for the linear case). In this case the highly oscillatory WKB-phase is simply given by $\phi(t,x)=k_0\cdot x-E_n(k_0)t$. Note that this ϕ solves the nth band *semiclassical Hamilton–Jacobi equation* with vanishing external field and plane wave initial data, i.e.,

$$\begin{cases}\partial_t\phi+E_n(\nabla_x\phi)=0,\\ \phi\big|_{t=0}=k_0\cdot x.\end{cases} \tag{3.35}$$

Moreover, with this choice of ϕ (and since U vanishes), one easily checks that the transport equation for the leading order WKB-amplitude, as derived in [11], simplifies to

$$\begin{cases}\partial_t f_0+\omega(k_0)\cdot\nabla_x f_0=0,\\ f_0\big|_{t=0}=f_I(x).\end{cases} \tag{3.36}$$

Clearly, the solution of (3.36) is then simply given by

$$f_0(t,x)=f_I(t,x-\omega(k_0)t), \tag{3.37}$$

and is hence consistent with our approach.

3.3. Higher order expansions. We henceforth proceed with our ε-expansion of (3.3). Denote the projector onto the nth Bloch band corresponding to a simple eigenvalue $E_n(k)$ by

$$\mathbb{P}_n(k):=|\chi_n(y,k)\rangle\langle\chi_n(y,k)|$$

(using the convenient Dirac notation), and moreover define

$$\mathbb{Q}_n(k) := \mathrm{id} - \mathbb{P}_n(k).$$

This operator is smooth in a vicinity of k_0, and hence, by elliptic inversion, a partial inverse for $L_0 \equiv L_0(k_0)$ can be defined on its range; i.e., $L_0^{-1}\mathbb{Q}(k_0)$ is well defined and smooth. Coming back to (3.30), we can decompose u_2 as

$$u_2(t,x,y) = f_2(t,x)\chi_n\left((y,k_0)\right) + u_2^{\perp}(t,x,y), \tag{3.38}$$

where the function f_2 is yet unknown and $u_2^{\perp}$ is such that

$$\mathbb{P}_n(k_0)u_2^{\perp}(t,x,\cdot) = \langle \chi_n(\cdot,k_0), u_2^{\perp}(t,x,\cdot)\rangle_{L^2(\mathfrak{C})} = 0 \quad \forall\,(t,x) \in \left]-\tau,\tau\right[\times \mathbb{R}^d.$$

Now, $u_2^{\perp}$ is determined by (3.30) via

$$u_2^{\perp} = -L_0^{-1}\mathbb{Q}_n(k_0)\left(\tilde{L}_1 u_1 + L_2 u_0 + \kappa|u_0|^{2\sigma}u_0)\right), \tag{3.39}$$

which implies $u_2^{\perp} \in C(]-\tau,\tau[; H^s(\mathbb{R}^d))$, since this already holds for u_0 and u_1, by Lemma 3.7. As before, (3.39) henceforth induces a particular form of the $\mathcal{O}(\varepsilon^2)$-corrector in the initial amplitude $u_I^{\varepsilon} \sim \sum \varepsilon^j u_j$. The next higher order in ε leads us to the following *linear* problem (after a Taylor expansion of the nonlinearity around u_0):

$$L_0 u_3 + \tilde{L}_1 u_2 + L_2 u_1 + \kappa\left((2\sigma+1)|u_0|^{2\sigma}u_1 + 2\sigma|u_0|^{2\sigma-2}u_0^2\bar{u}_1\right) = 0. \tag{3.40}$$

The corresponding solvability condition then determines $f_1(t,x) \in \mathbb{C}$, i.e., the amplitude corresponding to the *polarized part* of the first order amplitude $u_1(t,x,y)$ given in (3.15). This then leads to a homogenized *linear* Schrödinger-type equation for $f_1(t,x)$, where we have the freedom to choose $f_1(0,x) = 0$. By this procedure, all higher order terms $u_j(t,x,y)$, $j \geq 1$, of the asymptotic solution (3.22) can be obtained, and it is now clear that we can always choose $g_j(0,x)$, i.e., the polarized part of $u_j(0,x,y)$, to be identically zero. In the *globally periodic case*, i.e., $U(x) = 0$ and $\kappa = 0$, the nonvanishing higher order terms $u_j^{\perp}(t,x,y)$, $j \geq 1$, are found to be combinations of higher order derivatives w.r.t. k and x, respectively, of χ_n and f_0; cf. [6, 13]. Although this is no longer true in our case, we still have that $u_j \in C(]-\tau,\tau[; H^s(\mathbb{R}^d))$ for all $j \geq 1$. At each step, though, an additional condition is imposed (recursively) for the initial data ψ_I. This can be seen to be analogous to the situation encountered in [11] and can be understood in the framework of so-called *super-adiabatic subspaces* as constructed in [33].

Remark 3.10. Note that the above given construction can be extended to the case where $E_n(k)$ is an *m-fold degenerate* family of eigenvalues, i.e.,

$$E_n(k_0) = E_*(k_0) \quad \forall\, n \in I \subset \mathbb{N},\ |I| = m,$$

under the additional assumption that there exists a smooth orthonormal basis $\chi_l(y,k_0)$, $l = 1,\dots,m$, of $\operatorname{ran}\mathbb{P}_I(k)$, where $\mathbb{P}_I(k_0)$ denotes the spectral projector corresponding to $E_*(k)$. In this case the leading order asymptotic description would be

$$\psi(t,x) \sim \sum_{l=1}^{m} f_{0,l}(t,\tilde{x})\chi_l\left(\frac{x}{\varepsilon},k_0\right)e^{ik_0\cdot x/\varepsilon}e^{-ihE_n(k_0)t/\varepsilon^2} + \mathcal{O}(\varepsilon). \tag{3.41}$$

In this case, however, we would be forced to consider a *coupled system of homogenized equations*. The corresponding analysis is then analogous to the given one but requires rather tedious computations, a situation which we wanted to avoid for simplicity. For an extensive study of such situations in the linear case we refer to the last section of [3].

4. Nonlinear stability of the asymptotic solution. To prove that the above given multiple-scale expansion indeed yields a good approximation of the exact solution $\psi(t)$ for $\varepsilon \ll 1$, a nonlinear stability result is needed. Note that due to the scaling of (2.1) we cannot hope for any uniform (w.r.t. ε) bound in, say, $H^s(\mathbb{R}^d)$ for $\psi(t)$. On the other hand, the uniform L^2 estimate (2.10) is clearly not sufficient to pass to the limit in the nonlinearity. This motivates the introduction of the following ε-scaled spaces.

DEFINITION 4.1. *For $s \in \mathbb{N}$ let*

$$Y_\varepsilon^s := \left\{ f^\varepsilon \in L^2(\mathbb{R}^d) \; ; \; \sup_{0<\varepsilon\leq 1} \|f^\varepsilon\|_{Y_\varepsilon^s} < +\infty \right\},$$

where

$$\|f^\varepsilon\|_{Y_\varepsilon^s} := \sum_{|\alpha|+|\beta|\leq s} \left\| (\varepsilon x)^\alpha (\varepsilon\partial)^\beta f^\varepsilon \right\|_{L^2(\mathbb{R}^d)}.$$

Remark 4.2. Similar spaces, but without the extra weight ε^α, have been used in the semiclassical study given in [11]. Both variants can be seen as an extension of the H_ε^s-spaces defined by

$$\|f^\varepsilon\|_{H_\varepsilon^s} := \sum_{|\beta|\leq s} \left\| (\varepsilon\partial)^\beta f^\varepsilon \right\|_{L^2(\mathbb{R}^d)}, \tag{4.1}$$

which in the context of geometrical optics expansion were first introduced in [20] (see also [39] and the references given therein). In our case the additional factor $(\varepsilon x)^\alpha$ is needed because we want to include subquadratic potentials $U(x)$ (and due to our scaling we cannot work in the X_ε^s-spaces introduced in [11]). If we would allow $U(x)$ to grow only sublinearly, we could work in H_ε^s as well.

Notation. Let $(\alpha^\varepsilon)_{0<\varepsilon\leq 1}$ and $(\beta^\varepsilon)_{0<\varepsilon\leq 1}$ be two families of positive numbers. From now on we shall write

$$\alpha^\varepsilon \lesssim \beta^\varepsilon$$

if there exists a $C > 0$, independent of $\varepsilon \in]0,1]$ (but possibly dependent on other parameters), such that

$$\alpha^\varepsilon \leq C\beta^\varepsilon \quad \forall \varepsilon \in]0,1].$$

Since for the following results the value of h, appearing in (2.1), is indeed irrelevant, we shall set $h \equiv 1$ throughout this section. Moreover, we shall no longer distinguish between the usual spatial coordinate x and its shifted value $\tilde{x}$, since our results apply in both situations. Next, let us precisely specify the class of well-prepared initial data which we need to consider.

Assumption 4.3 (well-prepared initial data III). The initial data ψ_I^ε satisfies Assumptions 3.2 and 3.3 such that for some $K \in \mathbb{N}$ the following holds:

$$u_I^\varepsilon(x) = \sum_{j=0}^{K} \varepsilon^j u_j(x,y)\Big|_{y=x/\varepsilon} + \mathcal{O}\left(\varepsilon^{K+1}\right) \quad \text{in } Y_\varepsilon^s \text{ for any } s \in \mathbb{N}. \tag{4.2}$$

Moreover, with u_0 and u_1 given by (3.9) and (3.16), respectively, and with $F(z) := |z|^{2\sigma}z$, the functions u_j, $j \geq 2$, are recursively given by

$$u_j = -L_0^{-1}\mathbb{Q}(k_0)\left(\tilde{L}_1 u_{j-1} + L_2 u_{j-2} + \kappa \frac{d^{j-2}}{ds^{j-2}}\, F\left(u_0 + \sum_{l=1}^{j-2} s^l u_l\right)\bigg|_{s=0}\right).$$

After what we have encountered in the construction of higher order asymptotic solutions, this assumption should not come as a surprise. In the linear case the Assumption 4.3 is needed if one aims for refined asymptotic estimates. As we shall see, the inclusion of higher order asymptotics in our case is needed to control the nonlinear term in the proof of the stability result. To this end we need the following existence result for well-prepared initial data.

LEMMA 4.4. *There exists $\psi_I \in \mathcal{S}(\mathbb{R}^d)$ such that Assumption* 4.3 *holds true for any $K \in \mathbb{N}$.*

Proof. The proof follows from Borel's theorem; cf. Theorem 4.2 in [39]. ∎

For the following, define the Nth order asymptotic solution by

$$v_N^\varepsilon(t,x) := \left(\sum_{j=0}^{N} \varepsilon^j u_j\left(t, x, \frac{x}{\varepsilon}\right)\right) e^{ik_0\cdot x/\varepsilon} e^{-ihE_n(k_0)t/\varepsilon^2}, \tag{4.3}$$

and moreover let

$$H^\varepsilon := -\frac{1}{2}\Delta + \frac{1}{\varepsilon^2}V_\Gamma\left(\frac{x}{\varepsilon}\right) + U(x) \tag{4.4}$$

denote the linear part of the Hamiltonian operator. (Note that the scaling of (4.4) is different from the standard semiclassical one as used in [11, 33].) In the foregoing section we obtained the following preliminary result.

PROPOSITION 4.5. *Let ψ_I satisfy Assumption* 4.3 *for any $K \in \mathbb{N}$ and let $\tau > 0$ be the existence-time of smooth solutions to* (3.32). *Then for any $N \in \mathbb{N}$, $v_N^\varepsilon(t)$ solves*

$$\begin{cases} i\partial_t v_N^\varepsilon - H^\varepsilon v_N^\varepsilon = \kappa |v_N^\varepsilon|^{2\sigma} v_N^\varepsilon + \varepsilon^N r_N^\varepsilon, \\ \qquad v_N^\varepsilon\big|_{t=0} = \psi_I + \varepsilon^{N+1}\eta_{N+1}^\varepsilon, \end{cases} \tag{4.5}$$

where $r_N^\varepsilon \in C(]-\tau,\tau[;\, H^s(\mathbb{R}^d))$, $\eta_{N+1}^\varepsilon \in \mathcal{S}(\mathbb{R}^d)$ are such that $r_N^\varepsilon \in L^\infty_{\mathrm{loc}}(]-\tau,\tau[;\, Y_\varepsilon^s)$ and $\|\,\eta_{N+1}^\varepsilon\,\|_{Y_\varepsilon^s} = \mathcal{O}(1)$ for any $s \in \mathbb{N}$.

The main result we shall prove is then given by the following theorem.

THEOREM 4.6. *Let ψ_I satisfy Assumption* 4.3 *for any $K \in \mathbb{N}$, $\tau > 0$ be the existence-time of smooth solutions to* (3.32), *and v_N^ε be given by* (4.3). *Then for any $\tau_0 < \tau$ there exists $\varepsilon_0 > 0$ such that for $0 < \varepsilon \leq \varepsilon_0$, the solution $\psi(t)$ to* (2.1) *is defined on the time-interval $[-\tau_0, \tau_0]$, and moreover*

$$\sup_{t\in[-\tau_0,\tau_0]} \|\psi(t) - v_N^\varepsilon(t)\|_{Y_\varepsilon^s} = \mathcal{O}\left(\varepsilon^{N+1}\right) \tag{4.6}$$

holds for any $N \in \mathbb{N}$ and $s \in \mathbb{N}$.

The above given result shows that if $f(t)$ does not blow up in finite time, then neither does $\psi(t)$, at least for ε sufficiently small. Further, notice that if $\tau = \infty$, then the above given estimate (4.6) holds for any bounded time-interval $[\tau_0, \tau_0] \in \mathbb{R}_t$, in contrast to the (nonlinear) semiclassical situation [11], where the appearance of

caustics usually causes the WKB approach to break down in finite time. Note that in this result, Assumption 4.3 on the initial data ψ_I has to be valid for any $K \in \mathbb{N}$. We shall show in Proposition 4.8 below how to relax this restriction.

Proof. The proof is similar to that given in [11]. Due to the different scaling of our equation, we shall present it here in more detail, which should benefit the reader. Define the difference between the exact and the asymptotic solutions as

$$w_N^\varepsilon(t,x) := \psi(t,x) - v_N^\varepsilon(t,x).$$

Then, from (2.1) and (4.5), w_N solves

$$\begin{cases} i\partial_t w_N^\varepsilon = H^\varepsilon w_N^\varepsilon + \kappa\left(|\psi|^{2\sigma}\psi - |v_N|^{2\sigma}v_N\right) - \varepsilon^N r_N^\varepsilon, \\ w_N^\varepsilon\big|_{t=0} = \varepsilon^{N+1}\eta_{N+1}^\varepsilon. \end{cases} \tag{4.7}$$

By Lemma 3.7 and the well-known Gagliardo–Nirenberg inequality, we have that v_N^ε is uniformly bounded in $L^\infty([-\tau_0,\tau_0]\times\mathbb{R}^d)$. We shall now prove that w_N^ε is also bounded in $L^\infty([-\tau_0,\tau_0]\times\mathbb{R}^d)$, by using a continuity argument which shows that $w_N\varepsilon$ is actually small in that space, for N sufficiently large. To this end we first note that the following important relation holds:

$$\|f^\varepsilon\|_{H^s} = \varepsilon^{-d/2}\|f^\varepsilon\|_{H_\varepsilon^s} \lesssim \varepsilon^{-d/2}\|f^\varepsilon\|_{Y_\varepsilon^s}, \tag{4.8}$$

where the scaling factor $\varepsilon^{-d/2}$ can be easily seen by Fourier transformation. This then directly leads us to an ε-scaled Gagliardo–Nirenberg-type inequality, i.e.,

$$\|w\|_{L^\infty(\mathbb{R}^d)} \lesssim \|w\|_{H^s(\mathbb{R}^d)} \lesssim \varepsilon^{-d/2}\|w\|_{Y_\varepsilon^s} \quad \text{for } s > \frac{d}{2}, \tag{4.9}$$

which we shall use heavily in the following. Multiplying (4.7) by $\overline{w_N^\varepsilon}$, integrating over $\mathbb{R}^d$, and taking the imaginary part yields

$$\partial_t\|w_N^\varepsilon(t)\|_{L^2} \lesssim \left\| |\psi|^{2\sigma}\psi - |v_N^\varepsilon|^{2\sigma}v_N^\varepsilon\right\|_{L^2} + \varepsilon^N\|r_N^\varepsilon(t)\|_{L^2}, \tag{4.10}$$

since H^ε is self-adjoint and $|\kappa| = 1$ by (1.16). To proceed further we recall the following Moser-type lemma, the proof of which is a straightforward generalization of those given in [11, 39].

LEMMA 4.7. *Let $R > 0$, $s \in \mathbb{N}$, and $F(z) = |z|^{2\sigma}z$ for $\sigma \in \mathbb{N}$. Then there exists $C = C(R,s,\sigma,d)$ such that if v satisfies*

$$\left\|(\varepsilon x)^\alpha(\varepsilon\partial)^\beta v\right\|_{L^\infty(\mathbb{R}^d)} \le R \qquad \forall |\alpha| + |\beta| \le s$$

and w satisfies $\|w\|_{L^\infty(\mathbb{R}^d)} \le R$, then it holds that

$$\sum_{|\alpha|+|\beta|\le s} \left\|(\varepsilon x)^\alpha(\varepsilon\partial)^\beta\left(F(v+w) - F(v)\right)\right\|_{L^2(\mathbb{R}^d)} \le C \sum_{|\alpha|+|\beta|\le s} \left\|(\varepsilon x)^\alpha(\varepsilon\partial)^\beta w\right\|_{L^2(\mathbb{R}^d)}.$$

We shall now use this lemma to factor out w_N^ε in the right-hand side of (4.10) and then take advantage of the smallness of the remainder. By construction, $w_N^\varepsilon(0,x) = \mathcal{O}(\varepsilon^{N+1})$ in any Y_ε^s. By Lemma 3.7 we can find for fixed $\tau_0 < \tau$ an $R > 0$ such that if $N + 1 > d/2$, then

$$\|w_N^\varepsilon(t)\|_{L^\infty} \le R \tag{4.11}$$

for ε sufficiently small. Hence, as long as (4.11) holds, (4.10) and the above given Lemma 4.7, with $s = 0$, imply

$$\partial_t \|w_N^\varepsilon(t)\|_{L^2} \leq C\|w_N^\varepsilon(t)\|_{L^2} + C\varepsilon^N \|r_N^\varepsilon(t)\|_{L^2}.$$

Thus by a Gronwall-type estimate, we get, as long as (4.11) holds, that

$$\|w_N^\varepsilon(t)\|_{L^2} \lesssim \varepsilon^N \tag{4.12}$$

for $t \leq \tau$. Next we shall show how to obtain similar estimates for the momenta and derivatives of w_N^ε. Applying the operator $\varepsilon\nabla_x$ to (4.7) yields (where, as before, $F(z) := |z|^{2\sigma} z$)

$$\begin{aligned} i\partial_t(\varepsilon\nabla_x w_N^\varepsilon) = H^\varepsilon(\varepsilon\nabla_x w_N^\varepsilon) + \kappa\,\varepsilon\nabla_x\left(F(\psi) - F(v_N^\varepsilon)\right) \\ + [\varepsilon\nabla_x, H^\varepsilon]\, w_N^\varepsilon - \varepsilon^{N+1}\nabla_x r_N^\varepsilon, \end{aligned}$$

and hence we obtain the following energy estimate:

$$\begin{aligned} \partial_t\|\varepsilon\nabla_x w_N^\varepsilon(t)\|_{L^2} \lesssim \|\varepsilon\nabla_x\left(F(\psi) - F(\mathfrak{v}_N^\varepsilon)\right)\|_{L^2} + \|[\varepsilon\nabla_x, H^\varepsilon]\, w_N^\varepsilon\|_{L^2} \\ + \varepsilon^N\|\varepsilon\nabla_x r_N^\varepsilon\|_{L^2}. \end{aligned} \tag{4.13}$$

On the other hand, we compute from (4.4) that

$$[\varepsilon\nabla_x, H^\varepsilon] = \frac{1}{\varepsilon^2}\nabla_x V_\Gamma\left(\frac{x}{\varepsilon}\right) + \varepsilon\nabla_x U(x).$$

Since ∇V_Γ is bounded and ∇U is sublinear, (4.13) consequently yields

$$\begin{aligned} \partial_t\|\varepsilon\nabla_x w_N^\varepsilon(t)\|_{L^2} \lesssim \|\varepsilon\nabla_x\left(F(\psi) - F(v_N^\varepsilon)\right)\|_{L^2} + \frac{1}{\varepsilon^2}\|w_N^\varepsilon\|_{L^2} + \|\varepsilon x\, w_N^\varepsilon\|_{L^2} \\ + \varepsilon^N\|\varepsilon\nabla_x r_N^\varepsilon\|_{L^2}. \end{aligned}$$

Thus, again using Lemma 4.7 (with $s = 1$) together with Proposition 4.5 and the estimate (4.12), we get

$$\partial_t\|\varepsilon\nabla_x w_N^\varepsilon(t)\|_{L^2} \lesssim \|\varepsilon\nabla_x w_N^\varepsilon\|_{L^2} + \|\varepsilon x\, w_N^\varepsilon\|_{L^2} + \varepsilon^{N-2}. \tag{4.14}$$

(Note the difference in the last term as compared to the semiclassical estimate obtained in [11].) To obtain an estimate for $\|\varepsilon x\, w_N^\varepsilon\|_{L^2}$, we proceed analogously to obtain the following moment estimate:

$$\begin{aligned} \partial_t\|\varepsilon x\, w_N^\varepsilon(t)\|_{L^2} \lesssim \|\varepsilon x\left(F(\psi) - F(v_N^\varepsilon)\right)\|_{L^2} + \|[\varepsilon x, H^\varepsilon]\, w_N^\varepsilon\|_{L^2} \\ + \varepsilon^N\|\varepsilon x\, r_N^\varepsilon\|_{L^2}. \end{aligned} \tag{4.15}$$

But, since $[\varepsilon x, H^\varepsilon] = -\varepsilon\nabla_x$, we get, as long as (4.11) holds,

$$\begin{aligned} \partial_t\|\varepsilon x\, w_N^\varepsilon(t)\|_{L^2} &\lesssim \|\varepsilon x\left(F(\psi) - F(v_N^\varepsilon)\right)\|_{L^2} + \|\varepsilon\nabla_x w_N^\varepsilon\|_{L^2} + \varepsilon^N\,\|\varepsilon x\, r_N^\varepsilon\|_{L^2} \\ &\lesssim \|\varepsilon x\, w_N^\varepsilon(t)\|_{L^2} + \|\varepsilon\nabla_x w_N^\varepsilon\|_{L^2} + \varepsilon^N. \end{aligned} \tag{4.16}$$

Putting (4.14) and (4.16) together, we have

$$\partial_t\left(\|\varepsilon\nabla_x w_N^\varepsilon\|_{L^2} + \|\varepsilon x\, w_N^\varepsilon(t)\|_{L^2}\right) \lesssim \|\varepsilon\nabla_x w_N^\varepsilon\|_{L^2} + \|\varepsilon x\, w_N^\varepsilon(t)\|_{L^2} + \varepsilon^{N-2}.$$

Hence a Gronwall lemma yields

$$\|w_N^\varepsilon(t)\|_{Y_\varepsilon^1} \lesssim \varepsilon^{N-2} \tag{4.17}$$

as long as (4.11) holds, and by induction one arrives at

$$\|w_N^\varepsilon(t)\|_{Y_\varepsilon^s} \lesssim \varepsilon^{N-2s}\,. \tag{4.18}$$

For $s > d/2$, and as long as (4.11) holds, the Gagliardo–Nirenberg-type inequality (4.9) therefore implies

$$\|w_N^\varepsilon(t)\|_{L^\infty(\mathbb{R}^d)} \lesssim \varepsilon^{-d/2}\|w_N^\varepsilon(t)\|_{Y_\varepsilon^s} \lesssim \varepsilon^{N-2s-d/2}.$$

Hence, if indeed $N-2s-d/2>0$ holds true, a continuity argument shows that (4.11) is valid up to times $|t|=\tau$, provided that ε is sufficiently small. In particular, w_N^ε, and hence ψ, is well defined up to times $|t|=\tau_0<\tau$, for $0<\varepsilon\le\varepsilon(\tau)$. It remains to prove the estimate (4.6). Fix $s,N\in\mathbb{N}$ and let $s_1\ge s$ be such that $s_1>d/2$, as well as $N_1\ge 2s_1+N+1$. From (4.18) we conclude that

$$\sup_{t\in[-\tau_0,\tau_0]} \left\|w_{N_1}^\varepsilon(t)\right\|_{Y_\varepsilon^{s_1}} \lesssim \varepsilon^{N_1-2s_1} \lesssim \varepsilon^{N+1}.$$

Since $N_1>N$, it is therefore straightforward that

$$\sup_{t\in[-\tau_0,\tau_0]} \left\|v_N^\varepsilon(t)-v_{N_1}^\varepsilon(t)\right\|_{Y_\varepsilon^{s_1}} \lesssim \varepsilon^{N+1},$$

and hence we deduce that (4.6) holds for any $s,N\in\mathbb{N}$. ∎

In the proof given above, the initial data ψ_I is assumed to be well prepared up to any order $K\in\mathbb{N}$. This rather strong assumption can be relaxed, as the next result will show. To this end we introduce the following notation.

Notation. For every $\alpha\in\mathbb{R}$ we denote by $[\alpha]\in\mathbb{N}$ the *ceiling of* α, i.e., the smallest integer which is larger than or equal to α.

PROPOSITION 4.8. *Let $\widetilde{\psi}(t)$ be the solution of* (2.1) *corresponding to an initial data $\widetilde{\psi}_I$, which satisfies Assumption* 4.3 *for any $K\in\mathbb{N}$. On the other hand, let $\psi(t)$ be the solution corresponding to an initial data ψ_I, where ψ_I is such that Assumption* 4.3 *is satisfied for $K\ge[3d/2]$. Then for any $\tau_0\in\,]-\tau,\tau[$ there exists $\varepsilon_0>0$ such that for $0<\varepsilon\le\varepsilon_0$, $\psi^\varepsilon(t)$ is defined up to times $|t|\le\tau_0$, and moreover the following holds:*

$$\sup_{t\in[-\tau_0,\tau_0]} \left\|\psi(t)-\widetilde{\psi}(t)\right\|_{Y_\varepsilon^s} = \mathcal{O}\left(\varepsilon^{K+1-2s}\right) \quad \textit{for } s\ge 0\,.$$

Proof. Since the proof follows the lines of that for Theorem 4.6, we shall be rather brief. As before, we introduce

$$\widetilde{w}(t,x) := \psi(t,x)-\widetilde{\psi}(t,x).$$

Then $\widetilde{w}(t)$ solves

$$\begin{cases} i\partial_t\widetilde{w} = H^\varepsilon\widetilde{w} + \kappa\left(|\psi|^{2\sigma}\psi - |\widetilde{\psi}|^{2\sigma}\widetilde{\psi}\right), \\ \widetilde{w}\big|_{t=0} = \mathcal{O}\left(\varepsilon^{K+1}\right) \quad \text{in } Y_\varepsilon^s \text{ for any } s\in\mathbb{N}. \end{cases}$$

(Note that there is no remainder r_N^ε in this case.) We can then argue as in the above given proof. We have that initially the following holds:

$$\|\widetilde{w}(0,\cdot)\|_{L^\infty} \lesssim \varepsilon^{-d/2}\|\widetilde{w}(0,\cdot)\|_{Y_\varepsilon^s} \lesssim \varepsilon^{K+1-d/2}, \quad \text{provided } s > \frac{d}{2}.$$

With $K+1 \geq [3d/2]+1 > d/2$, the same arguments as in the proof of Theorem 4.6 yield

$$\|\widetilde{w}(t)\|_{Y_\varepsilon^s} \lesssim \varepsilon^{K+1-2s},$$

as long as (4.11) holds. Since $K+1 > d$, we can choose $s > d/2$ such that $K+1-2s > d/2$; i.e., we can choose s such that $K+1 > [d/2+2s] = [3d/2]$. Therefore the above given estimate and (4.9) show that (4.11) holds up to times $|t| = \tau_0$, for $\varepsilon \ll 1$. ∎

Theorem 4.6 and Proposition 4.8 then finally lead to the following statement, proving also Theorem 1.3.

COROLLARY 4.9. *If ψ_I satisfies Assumption 4.3 with $K \geq [3d/2]$, then there exists $\varepsilon_0 > 0$ such that for $0 < \varepsilon \leq \varepsilon_0$ the solution $\psi(t)$ to (2.1) is defined on the time interval $[-\tau_0, \tau_0]$ for any $\tau_0 < \tau$ and the following estimate holds:*

$$\sup_{t\in[-\tau_0,\tau_0]} \|\psi(t) - v_0^\varepsilon(t)\|_{L^2(\mathbb{R}^d)} = \mathcal{O}(\varepsilon). \tag{4.19}$$

Additionally, if $K > [3d/2]$, then we have

$$\sup_{t\in[-\tau_0,\tau_0]} \|\psi(t) - v_0^\varepsilon(t)\|_{L^\infty(\mathbb{R}^d)} = \mathcal{O}(\varepsilon). \tag{4.20}$$

Proof. From Proposition 4.8 we deduce that Theorem 4.6 holds with $K \geq [3d/2]$. The L^2 estimate (4.19) then is nothing but (4.6) with $N = s = 0$. The L^∞ estimate (4.20) follows similarly from Theorem 4.6 and (4.9). ∎

In other words we deduce that the solution of (2.1) can be, up to an error of $\mathcal{O}(\varepsilon)$, approximated by the leading order asymptotic solution v_0, obtained from the multiple-scales expansion, if the initial data is well prepared, i.e., including correctors up to $K = [3d/2]$, which is slightly stronger than what was required for the semiclassical result given in [11]. There the analogous condition for the correctors was $K \geq d$. On the other hand, one might guess that the leading order estimates (4.19), (4.20) are true even if the initial data is "correct" only up to leading order. However, the techniques used in the above proofs do not allow the conclusion that this is indeed the case. Note, however, that the higher order correctors in the initial data tend to zero as $\varepsilon \to 0$ in practically every reasonable sense.

Remark 4.10. Finally, let us remark that one could also study the semiclassical asymptotic behavior of the homogenized NLS, i.e., the limit $h \to 0$ of (3.19), although, in view of the given scaling arguments and Remark 3.9, the word "semiclassical" should rather be understood here in a purely mathematical sense. To this end, the well-known WKB-type method derived in [19] can be adapted under suitable conditions on M^*. In this case, however, one can only hope for local-in-time results, i.e., results up to caustics. The combined limit $\varepsilon/h \to 0$, $h \to 0$ seems to be more subtle, in particular due to the somewhat hidden dependence of τ on h in the above results.

THE ROLE OF COINFECTION IN MULTIDISEASE DYNAMICS*

MAIA MARTCHEVA† AND SERGEI S. PILYUGIN‡

Abstract. We investigate an epidemic model of two diseases. The primary disease is assumed to be a slowly progressing disease, and the density of individuals infected with it is structured by age since infection. Hosts that are already infected with the primary disease can become coinfected with a secondary disease. We show that in addition to the disease-free equilibrium, there exists a unique dominance equilibrium corresponding to each disease. Without coinfection there are no coexistence equilibria; however, with coinfection the number of coexistence equilibria may vary. For some parameter values, there exist two coexistence equilibria. We also observe competitor-mediated oscillatory coexistence. Furthermore, weakly subthreshold (which occur when exactly one of the reproduction numbers is below one) and strongly subthreshold (which occur when both reproduction numbers are below one) coexistence equilibria may exist. Some of those are a result of a two-parameter backward bifurcation. Bistability occurs in several regions of the parameter space. Despite the presence of coinfection, coexistence of the two diseases appears possible only for relatively small values of the reproduction numbers—for large values of the reproduction numbers the typical outcome of competition is the dominance of one of the diseases, including bistable dominance where the competition outcome is initial condition dependent.

Key words. coinfection, infection-age structure, subthreshold coexistence, backward bifurcation, Hopf bifurcation, oscillatory dominance, oscillatory coexistence, restricted pathogenic diversity

1. Introduction.

Coinfection is a simultaneous infection of one host with multiple pathogens that may be the causative agents of different diseases or variants of the same parasite. Coinfections are common for individuals infected with the human immunodeficiency virus (HIV). Since HIV compromises the immune system, the carrier becomes vulnerable to other infections commonly called opportunistic infections [10]. For instance, the case of HIV-HSV (herpes simplex virus) coinfection has been well documented. Such coinfection typically leads to reactivation of HSV, which accelerates the progression of HIV disease towards AIDS. HIV-HSV infected individuals are also more likely to unwittingly transmit HSV via an increased shedding common in HIV-infected patients. The treatment of HIV-HSV coinfected patients may present additional challenges since the HSV is likely to be more resistant to antiviral therapy [22]. Coinfections may also occur when a patient is already infected with a slowly progressing disease which lasts for decades. In tuberculosis (TB), for example, coinfection even with a minor illness can trigger a reactivation of TB.

Many mathematical studies exist on single diseases, both general theoretic and those treating a specific disease. At the same time, few studies exist that address the interaction of two or more diseases. On an epidemiological level, Courchamp et al. [7] studied a model of two feline retroviruses. Two recent articles—one by Allen,

Langlais, and Phillips [1] and another by Gumel et al. [9]—also consider two infections in a single host. On an immunological level, the interactions between *Mycobacterium tuberculosis* and HIV-1 are investigated in [11]. Statistical aspects of mapping two diseases are the focus of [8]. Coinfection has been studied from a general perspective in [14]. In [16], a connection between superinfection and coinfection with different strains, and the impact of both on the coexistence and the evolution of virulence, is discussed.

In this paper, we study an epidemic model with two diseases that can coinfect a single host. We include infection-age structure in the primary disease to account for slowly progressing and/or persistent diseases that affect the immune status of individuals over time. Infection-age structure has been previously shown to cause qualitative changes, namely oscillatory behavior, in case of a single disease dynamics [2, 19, 15, 12, 20]. Although the model discussed here is relatively simple, we find complex dynamic behavior: oscillatory dominance and coexistence, two-parameter backward bifurcation, multiple and subthreshold coexistence equilibria, and bistability. These phenomena have important epidemiological consequences for disease management. Most of them have been illustrated in the single-disease case. In particular, backward bifurcation which leads to multiple and subthreshold equilibria has been attracting significant attention in the literature (see [13] and the references therein). However, to the best of our knowledge, backward bifurcations have not been studied in the context of multiple infectious agents.

This paper is organized as follows. In the next section, we introduce the two-disease coinfection model. In section 3, we introduce the reproduction numbers of the primary and secondary diseases $\mathcal{R}_1$, $\mathcal{R}_2$ and discuss the equilibria of the model. The values of the disease-free equilibrium and the two boundary equilibria are given explicitly. We also present sufficient conditions for the existence of a coexistence equilibrium. In section 4, we consider scenarios for extinction of either disease or both. Section 5 focuses on the local stability of equilibria. We show that both the primary disease equilibrium and coexistence equilibria can lose stability, leading to sustained oscillations. Section 6 is devoted to the derivation of necessary and sufficient conditions for the backward bifurcation in $\mathcal{R}_1$ and $\mathcal{R}_2$. In section 7, we present several numerical simulations to illustrate the various complex dynamic phenomena. In section 8, we discuss the epidemiological implications of our model. Section 9 contains a summary of our results and concludes the paper.

2. A model of coinfection of two diseases. Two diseases are spreading in a population of total size $N(t)$. They both compete for the same pool of susceptible individuals, whose number at time t is denoted by $S(t)$. We assume that the first disease is a slowly progressing one, and we structure the class of infected individuals with respect to the time since infection, a. The age-density is denoted by $i(a,t)$. The total number of individuals infected with the first disease is denoted by $I_1(t)$. Population members who eventually contract both diseases are assumed to be infected by the slowly progressing disease first. Consequently we call it the *primary disease*. A susceptible becomes infected with the primary disease at a rate $\beta_1(a)$. The number of individuals infected with the second disease is denoted by $I_2(t)$. The secondary disease is transmitted by the class I_2 to susceptibles at a rate β_2. An individual already infected with the primary disease can be coinfected with the secondary disease at a rate $\delta(a)$ and thus become jointly infected with both diseases. We denote the number of jointly infected (coinfected) individuals by $J(t)$. The individuals infected with both diseases can infect susceptibles with the primary disease at a rate γ_1 and

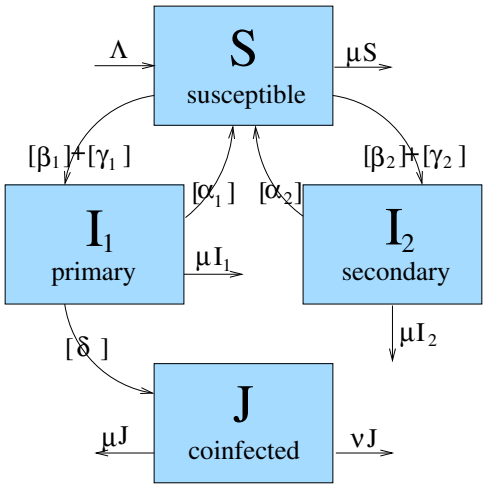

FIG. 2.1. *The flow diagram of the model* (2.1). *The primary infection rate is shown as* $[\beta_1]+[\gamma_1]$, *where* $[\beta_1] = \frac{S}{N}\int_0^\infty \beta_1(a)i(a)\,da$ *and* $[\gamma_1] = \gamma_1\frac{SJ}{N}$. *The secondary infection rate is shown as* $[\beta_2]+[\gamma_2]$, *where* $[\beta_2] = \beta_2\frac{SI_2}{N}$ *and* $[\gamma_2] = \gamma_2\frac{SJ}{N}$. *The coinfection rate is shown as* $[\delta] = \frac{I_2}{N}\int_0^\infty \delta(a)i(a)\,da$. *The primary and secondary recovery rates are shown as* $[\alpha_1] = \int_0^\infty \alpha_1(a)i(a)\,da$ *and* $[\alpha_2] = \alpha_2 I_2$. *The parameters* Λ, μ, *and* ν *represent the birth/recruitment rate, the background mortality rate, and the disease-induced mortality associated with coinfection, respectively.*

with the secondary disease at a rate γ_2. Figure 2.1 presents a schematic flow diagram of the mathematical model that takes the form

$$
\begin{aligned}
S' &= \Lambda - \frac{S}{N}\int_0^\infty \beta_1(a)i(a,t)\,da - \beta_2\frac{SI_2}{N} - (\gamma_1+\gamma_2)\frac{SJ}{N} - \mu S \\
&\qquad + \int_0^\infty \alpha_1(a)i(a,t)\,da + \alpha_2 I_2, \\
(\partial_t + \partial_a)i(a,t) &= -\alpha_1(a)i(a,t) - \delta(a)\frac{I_2}{N}i(a,t) - \mu i(a,t), \\
i(0,t) &= \frac{S}{N}\int_0^\infty \beta_1(a)i(a,t)\,da + \gamma_1\frac{SJ}{N}, \qquad (2.1) \\
I_2' &= \beta_2\frac{SI_2}{N} + \gamma_2\frac{SJ}{N} - (\mu+\alpha_2)I_2, \\
J' &= \frac{I_2}{N}\int_0^\infty \delta(a)i(a,t)\,da - (\mu+\nu)J,
\end{aligned}
$$

where μ is natural death rate. We assume that either disease by itself is not lethal but that the two in combination can be. The biological motivation of this assumption is the case of HIV/AIDS, where coinfections in late stages of the HIV (considered the primary disease) can be terminal. Specifically, we assume that jointly infected individuals do not recover and that coinfections cause disease-induced mortality at a rate ν. Individuals infected with either primary or secondary disease alone may be potentially treated and recover at rates $\alpha_1(a)$, α_2, respectively. The functions $\alpha_1(a)$, $\beta_1(a)$, and $\delta(a)$ are nonnegative and bounded. The parameters β_2, γ_1, γ_2, ν, α_2 are nonnegative, whereas $\Lambda > 0$ and $\mu > 0$. A standard argument can be used to show that the model (2.1) is well posed.

The total population size $N(t)$ is the sum of all individuals in all classes:

$$N(t) = S(t) + \int_0^\infty i(a,t)da + I_2(t) + J(t). \tag{2.2}$$

The total population size satisfies the equation $N'(t) = \Lambda - \mu N - \nu J$. We introduce the notation

$$\pi_1(a) = e^{-\int_0^a \alpha_1(s)ds}.$$

To understand the biological meaning of the quantity $\pi_1(a)$ we note that $\pi_1(a)e^{-\mu a}$ is the probability that an individual will remain infected with the primary disease a time units after infection. In addition, we define the quantity

$$\Delta = \int_0^\infty \alpha_1(a)\pi_1(a)e^{-\mu a}da, \tag{2.3}$$

which gives the probability of leaving the primary disease infectious period via recovery. Since individuals can leave the primary infected class only via recovery or death, the sum of the probabilities of recovery and death equals one; that is,

$$\int_0^\infty \alpha_1(a)\pi_1(a)e^{-\mu a}\,da + \mu\int_0^\infty \pi_1(a)e^{-\mu a}\,da = \int_0^\infty (\mu+\alpha_1(a))e^{-\int_0^a(\mu+\alpha_1(s))ds}\,da = 1.$$

It immediately follows that $\Delta < 1$.

3. Equilibria of the model with coinfection. We introduce the reproduction numbers of the two diseases. The reproduction number of the primary disease is

$$\mathcal{R}_1 = \int_0^\infty \beta_1(a)\pi_1(a)e^{-\mu a}\,da, \tag{3.1}$$

and the reproduction number of the secondary disease is

$$\mathcal{R}_2 = \frac{\beta_2}{\mu+\alpha_2}. \tag{3.2}$$

We note that the coinfection rate $\delta(a)$ does not affect the reproduction numbers since coinfection does not lead to additional infections. We will adopt the notation $s = S/N^*$, $i_2 = I_2/N^*$, $j = J/N^*$ and will use $i(a)$ to denote the normalized version of the equilibrium value of $i(a,t)$, $i^*(a)$. The quantity N^* is given by the sum (2.2) at an equilibrium. Let us define

$$\Gamma(a;i_2) = e^{-i_2\int_0^a \delta(\sigma)d\sigma}. \tag{3.3}$$

Notice that $\Gamma(a;0) = 1$. Setting the derivatives with respect to time to zero, we obtain a system of algebraic equations and one ODE for the equilibria of (2.1). The ODE in the system can be solved to yield

$$i(a) = i(0)\Gamma(a;i_2)\pi_1(a)e^{-\mu a}. \tag{3.4}$$

Substituting for i in the integrals, one obtains

$$\int_0^\infty \beta_1(a)i(a)\,da = i(0)\int_0^\infty \beta_1(a)\Gamma(a;i_2)\pi_1(a)e^{-\mu a}\,da = i(0)B(i_2)$$

and

$$\int_0^\infty \alpha_1(a)i(a)\,da = i(0)\int_0^\infty \alpha_1(a)\Gamma(a;i_2)\pi_1(a)e^{-\mu a}\,da = i(0)A(i_2).$$

Finally,

$$\int_0^\infty \delta(a)i(a)\,da = i(0)\int_0^\infty \delta(a)\Gamma(a;i_2)\pi_1(a)e^{-\mu a}\,da = i(0)D(i_2).$$

We notice that $A(i_2) < 1$ and $i_2D(i_2) + A(i_2) < 1$ because

$$\begin{aligned} i_2D(i_2) + A(i_2) &= \int_0^\infty (\alpha_1(a) + i_2\delta(a))e^{-\int_0^a(\alpha_1(\sigma)+i_2\delta(\sigma))\,d\sigma}e^{-\mu a}\,da \\ &< \int_0^\infty (\alpha_1(a) + i_2\delta(a))e^{-\int_0^a(\alpha_1(\sigma)+i_2\delta(\sigma))\,d\sigma}\,da = 1. \end{aligned}$$

With this notation the system for the equilibria becomes

$$\begin{aligned} &0 = \mu - si(0)B(i_2) - \beta_2 si_2 - (\gamma_1+\gamma_2)sj - \mu s + i(0)A(i_2) + \alpha_2 i_2 + \nu j,\\ &i(0) = i(0)sB(i_2) + \gamma_1 sj,\\ &0 = \beta_2 si_2 + \gamma_2 sj - (\mu+\alpha_2)i_2,\\ &0 = i(0)i_2D(i_2) - (\mu+\nu)j. \end{aligned} \tag{3.5}$$

This system has three boundary equilibria, as follows:

1. The disease-free equilibrium

$$\mathcal{E}_0 = (1,0,0,0)\,.$$

   The disease-free equilibrium always exists.

2. The primary disease equilibrium exists if and only if $\mathcal{R}_1 > 1$. The steady distribution of infectives in the primary disease equilibrium is given by

$$i(a) = i(0)\pi_1(a)e^{-\mu a}, \qquad \text{where} \quad i(0) = \frac{\mu\left(1-\frac{1}{\mathcal{R}_1}\right)}{1-\Delta}.$$

   Thus, the equilibrium is

$$\mathcal{E}_1 = \left(\frac{1}{\mathcal{R}_1}, i(a), 0, 0\right).$$

3. The secondary disease equilibrium exists if and only if $\mathcal{R}_2 > 1$ and is given by

$$\mathcal{E}_2 = \left(\frac{1}{\mathcal{R}_2}, 0, \left(1-\frac{1}{\mathcal{R}_2}\right), 0\right).$$

Notice that the values of the two dominance equilibria do not depend on the coinfection. These exact same equilibria are present even if $\delta(a) = 0$.

We introduce the invasion reproduction numbers for each of the diseases. The invasion reproduction number of the first disease measures the ability of the primary disease to invade an equilibrium of the secondary disease. We define the invasion reproduction number of the primary disease as

$$\hat{\mathcal{R}}_1 = \frac{1}{\mathcal{R}_2}B(\hat{i}_2) + \frac{\gamma_1}{\mu+\nu}\frac{1}{\mathcal{R}_2}\left(1-\frac{1}{\mathcal{R}_2}\right)D(\hat{i}_2), \quad \text{where } \hat{i}_2 = \left(1-\frac{1}{\mathcal{R}_2}\right). \tag{3.6}$$

The invasion reproduction number of the secondary disease measures its ability to invade an equilibrium of the primary disease, and it is defined as

$$\hat{\mathcal{R}}_2 = \frac{(\mathcal{R}_1 - 1)\mu\gamma_2 D(0)}{\mathcal{R}_1(\mu+\alpha_2)(\mu+\nu)(\mathcal{R}_1 - \mathcal{R}_2)(1-\Delta)} \qquad \text{if } \mathcal{R}_1 > \mathcal{R}_2. \tag{3.7}$$

It is important to point out that, due to the asymmetry of the model, $\hat{\mathcal{R}}_1$ is defined if $\mathcal{R}_2 > 1$, and $\hat{\mathcal{R}}_2$ is defined if $\mathcal{R}_1 > \max(1, \mathcal{R}_2)$. In addition, it is possible that $\hat{\mathcal{R}}_1 > 1$ even if $\mathcal{R}_1 < 1$; that is, the dominance equilibrium $\mathcal{E}_1$ of the primary disease does not exist, and yet the primary disease can invade the dominance equilibrium of the secondary disease. It is also possible that $\hat{\mathcal{R}}_2 > 1$ even if $\mathcal{R}_2 < 1$; that is, the dominance equilibrium $\mathcal{E}_2$ of the secondary disease does not exist, but the secondary disease can invade the dominance equilibrium of the primary disease.

LEMMA 3.1. *The curves* $\mathcal{C}_1 = \{(\mathcal{R}_1, \mathcal{R}_2) | \hat{\mathcal{R}}_1 = 1\}$ *and* $\mathcal{C}_2 = \{(\mathcal{R}_1, \mathcal{R}_2) | \hat{\mathcal{R}}_2 = 1\}$ *enclose a nontrivial region in the positive* $(\mathcal{R}_1, \mathcal{R}_2)$ *quadrant. The interior of this region always contains an unbounded component given by inequalities* $\hat{\mathcal{R}}_1, \hat{\mathcal{R}}_2 < 1$.

Proof. Using the fact that $B(0) = \mathcal{R}_1$, the curve $\mathcal{C}_1 = \{(\mathcal{R}_1, \mathcal{R}_2) | \hat{\mathcal{R}}_1 = 1\}$ is given by the graph

$$\mathcal{R}_1 = \frac{B(0)}{B(\hat{i}_2)} \left(\mathcal{R}_2 - \frac{\gamma_1 \hat{i}_2 D(\hat{i}_2)}{\mu + \nu} \right) =: \mathcal{F}_1(\mathcal{R}_2),$$

where $\mathcal{R}_2 \geq 1$ and $\hat{i}_2 = 1 - 1/\mathcal{R}_2 \geq 0$. The definition of $\mathcal{F}_1$ implies that $\mathcal{F}_1(1) = 1$, and for large values of $\mathcal{R}_2$ the function

$$\mathcal{F}_1(\mathcal{R}_2) \approx \frac{B(0)}{B(1)} \mathcal{R}_2 + \frac{B(0)B'(1)}{B^2(1)} - \frac{\gamma_1 B(0) D(1)}{(\mu+\nu)B(1)} \qquad \text{for } \mathcal{R}_2 \gg 1$$

is approximately linear in $\mathcal{R}_2$ with a slope $B(0)/B(1) > 1$. On the other hand, the curve $\mathcal{C}_2 = \{(\mathcal{R}_1, \mathcal{R}_2) | \hat{\mathcal{R}}_2 = 1\}$ is given by the graph

$$\mathcal{R}_2 = \mathcal{R}_1 - \left(1 - \frac{1}{\mathcal{R}_1}\right) \frac{\mu\gamma_2 D(0)}{(\mu+\alpha_2)(\mu+\nu)(1-\Delta)} =: \mathcal{F}_2(\mathcal{R}_1),$$

where $\mathcal{R}_1 \geq 1$. It is easy to see that $\mathcal{F}_2(1) = 1$, and for large values of $\mathcal{R}_1$ the function

$$\mathcal{F}_2(\mathcal{R}_1) \approx \mathcal{R}_1 - \frac{\mu\gamma_2 D(0)}{(\mu+\alpha_2)(\mu+\nu)(1-\Delta)} \qquad \text{for } \mathcal{R}_1 \gg 1$$

is approximately linear in $\mathcal{R}_1$ with a unit slope. Consequently, when both $\mathcal{R}_1$ and $\mathcal{R}_2$ are large, the curve $\mathcal{C}_1$ lies below and to the right of the curve $\mathcal{C}_2$. The unbounded region enclosed by these curves is therefore given by the inequalities $\mathcal{R}_2 < \mathcal{F}_2(\mathcal{R}_1)$ and $\mathcal{R}_1 < \mathcal{F}_1(\mathcal{R}_2)$, which are equivalent to the inequalities $\hat{\mathcal{R}}_1, \hat{\mathcal{R}}_2 < 1$. ∎

In Figure 3.1, we present a simple diagram depicting the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ and identify various parts of the region enclosed by these curves. The following theorem establishes the existence of at least one coexistence equilibrium for any point in the $(\mathcal{R}_1, \mathcal{R}_2)$ plane that lies between the curves $\mathcal{C}_1$ and $\mathcal{C}_2$. In what follows, we will refer to the region between the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ as the *coexistence region*.

THEOREM 3.2. *Let*

$$\begin{aligned}
\mathcal{D}_- &= \{\mathcal{R}_1, \mathcal{R}_2 > 0 | 1 < \mathcal{R}_1 \leq \mathcal{R}_2, \hat{\mathcal{R}}_1 > 1\},\\
\mathcal{D}_+ &= \{\mathcal{R}_1, \mathcal{R}_2 > 0 | 1 < \mathcal{R}_2 < \mathcal{R}_1, \hat{\mathcal{R}}_1 > 1, \hat{\mathcal{R}}_2 > 1\},\\
\mathcal{D}_1 &= \{\mathcal{R}_1, \mathcal{R}_2 > 0 | \mathcal{R}_2 < 1 < \mathcal{R}_1, \hat{\mathcal{R}}_2 > 1\},\\
\mathcal{D}_2 &= \{\mathcal{R}_1, \mathcal{R}_2 > 0 | \mathcal{R}_1 < 1 < \mathcal{R}_2, \hat{\mathcal{R}}_1 > 1\},\\
\mathcal{D}_3 &= \{\mathcal{R}_1, \mathcal{R}_2 > 0 | 1 < \mathcal{R}_2 < \mathcal{R}_1, \hat{\mathcal{R}}_1 < 1, \hat{\mathcal{R}}_2 < 1\};
\end{aligned}$$

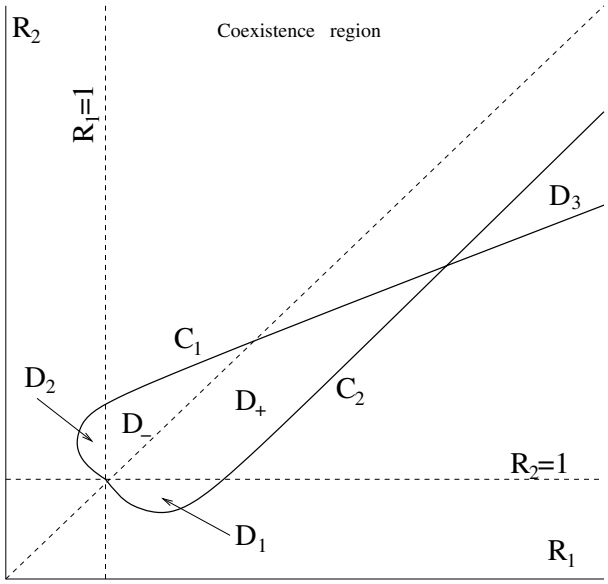

FIG. 3.1. *A schematic diagram representing the coexistence region in the* $(\mathcal{R}_1, \mathcal{R}_2)$ *plane. The boundary of the coexistence region is formed by the curves* $\mathcal{C}_1 : \hat{\mathcal{R}}_1 = 1$ *and* $\mathcal{C}_2 : \hat{\mathcal{R}}_2 = 1$. *The coexistence region (as shown) consists of the following five components:* D_-, *where* $1 < \mathcal{R}_1 < \mathcal{R}_2$ *and* $\hat{\mathcal{R}}_1 > 1$; D_+, *where* $1 < \mathcal{R}_2 < \mathcal{R}_1$ *and* $\hat{\mathcal{R}}_1$; $\hat{\mathcal{R}}_2 > 1$; D_1, *where* $\mathcal{R}_2 < 1 < \mathcal{R}_1$ *and* $\hat{\mathcal{R}}_2 > 1$; D_2, *where* $\mathcal{R}_1 < 1 < \mathcal{R}_2$ *and* $\hat{\mathcal{R}}_1 > 1$; *and finally,* D_3, *where* $1 < \mathcal{R}_2 < \mathcal{R}_1$ *and* $\hat{\mathcal{R}}_1, \hat{\mathcal{R}}_2 < 1$. D_3 *is the only component of the coexistence region that is always nonempty; the other components may or may not exist, depending on the parameter values.*

then for any $(\mathcal{R}_1, \mathcal{R}_2)$ *in the coexistence region* $\mathcal{D}_c = \mathcal{D}_- \cup \mathcal{D}_+ \cup \mathcal{D}_1 \cup \mathcal{D}_2 \cup \mathcal{D}_3$ *there exists at least one coexistence equilibrium for the two diseases.*

Proof. The fourth equation in (3.5) implies that at a coexistence equilibrium,

$$j = \frac{i(0) i_2 D(i_2)}{\mu + \nu}.$$

Substituting this expression into the second equation in (3.5), we find that

$$s = \left(B(i_2) + \frac{\gamma_1 i_2 D(i_2)}{\mu + \nu} \right)^{-1} =: \mathcal{S}(i_2). \tag{3.8}$$

Now we substitute (3.8) into the third equation in (3.5) and solve for j to obtain the expressions

$$j = \frac{(\mu + \alpha_2)(1 - \mathcal{R}_2 \mathcal{S}(i_2)) i_2}{\gamma_2 \mathcal{S}(i_2)}, \quad \mathcal{R}_2 = \frac{\beta_2}{\mu + \alpha_2},$$

and

$$i(0) = \frac{(\mu + \nu) j}{i_2 D(i_2)} = \frac{(\mu + \nu)(\mu + \alpha_2)(1 - \mathcal{R}_2 \mathcal{S}(i_2))}{\gamma_2 \mathcal{S}(i_2) D(i_2)}.$$

Finally, we express j and i_1 as follows:

$$j = \frac{i_2 (\mu + \alpha_2)(1 - \mathcal{R}_2 \mathcal{S}(i_2))}{\gamma_2 \mathcal{S}(i_2)} =: \mathcal{J}(i_2) \tag{3.9}$$

and

(3.10)
$$i_1 = \int_0^\infty i(a)\, da = i(0)G(i_2) = \frac{(\mu+\nu)(\mu+\alpha_2)G(i_2)(1-\mathcal{R}_2\mathcal{S}(i_2))}{\gamma_2\mathcal{S}(i_2)D(i_2)} =: \mathcal{I}(i_2),$$

where

$$G(i_2) = \int_0^\infty \Gamma(a;i_2)\pi_1(a)e^{-\mu a}da > 0, \quad G(0) = \frac{1-\Delta}{\mu}.$$

Since we are working with rescaled variables, the relation $s + i_1 + i_2 + j = 1$ implies that

$$\mathcal{M}(i_2) := i_2 + \mathcal{S}(i_2) + \mathcal{I}(i_2) + \mathcal{J}(i_2) = 1.$$

We note that the function $\mathcal{S}(i_2)$ is positive for all $i_2 \geq 0$, and both functions $\mathcal{I}(i_2)$, $\mathcal{J}(i_2)$ are positive if $i_2 > 0$ and $\mathcal{R}_2\mathcal{S}(i_2) < 1$. To prove the existence of a coexistence equilibrium it suffices to show the existence of a positive root of the equation $\mathcal{M}(i_2) = 1$ that satisfies $\mathcal{R}_2\mathcal{S}(i_2) < 1$. We also note that the function $\mathcal{M}(i_2)$ can be equivalently expressed as

$$\mathcal{M}(i_2) := i_2 + \mathcal{S}(i_2) + \frac{(\mu+\alpha_2)(1-\mathcal{R}_2\mathcal{S}(i_2))}{\gamma_2\mathcal{S}(i_2)}\left(i_2 + \frac{G(i_2)(\mu+\nu)}{D(i_2)}\right).$$

We observe that $\mathcal{S}(0) = 1/\mathcal{R}_1$, and therefore

$$\begin{aligned}\mathcal{M}(0) &= \frac{1}{\mathcal{R}_1} + \frac{(\mu+\nu)(\mu+\alpha_2)G(0)(1-\mathcal{R}_2\mathcal{S}(0))}{\gamma_2\mathcal{S}(0)D(0)} \\ &= \frac{1}{\mathcal{R}_1} + \frac{(1-\Delta)(\mu+\nu)(\mu+\alpha_2)(\mathcal{R}_1-\mathcal{R}_2)}{\mu\gamma_2 D(0)}.\end{aligned}$$

Suppose that $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_-$, that is, $1 < \mathcal{R}_1 \leq \mathcal{R}_2$ and $\hat{\mathcal{R}}_1 > 1$. It follows that $\mathcal{M}(0) \leq 1/\mathcal{R}_1 < 1$ because $\mathcal{R}_1 \leq \mathcal{R}_2$. Using the definition of $\hat{\mathcal{R}}_1$, we find that $\hat{\mathcal{R}}_1 > 1$ implies that $\mathcal{R}_2\mathcal{S}(\hat{i}_2) < 1$. Therefore, there exist the following three possibilities:

1. If $\mathcal{M}(\hat{i}_2) = 1$, then we are done because both $\mathcal{I}(\hat{i}_2)$ and $\mathcal{J}(\hat{i}_2)$ are positive.
2. If $\mathcal{M}(\hat{i}_2) > 1$, then one of the following holds:
   - There exists $i_2^* \in [0, \hat{i}_2)$ such that $\mathcal{R}_2\mathcal{S}(i_2^*) = 1$ and $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in (i_2^*, \hat{i}_2]$. In this case, we have that
   $$\mathcal{M}(i_2^*) = i_2^* + \frac{1}{\mathcal{R}_2} = 1 + i_2^* - \hat{i}_2 < 1,$$
   and since $\mathcal{M}(\hat{i}_2) > 1$, there exists a number $i_2 \in (i_2^*, \hat{i}_2)$ such that $\mathcal{M}(i_2) = 1$, where both $\mathcal{I}(i_2)$ and $\mathcal{J}(i_2)$ are positive.
   - $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in (0, \hat{i}_2]$. Then since $\mathcal{M}(0) < 1$ and $\mathcal{M}(\hat{i}_2) > 1$, there exists a number $i_2 \in (0, \hat{i}_2)$ such that $\mathcal{M}(i_2) = 1$, where both $\mathcal{I}(i_2)$ and $\mathcal{J}(i_2)$ are positive.
3. If $\mathcal{M}(\hat{i}_2) < 1$, then one of the following holds:
   - There exists $i_2^* \in (\hat{i}_2, 1]$ such that $\mathcal{R}_2\mathcal{S}(i_2^*) = 1$ and $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in (\hat{i}_2, i_2^*)$. In this case, we have that
   $$\mathcal{M}(i_2^*) = i_2^* + \frac{1}{\mathcal{R}_2} = 1 + i_2^* - \hat{i}_2 > 1,$$
   and since $\mathcal{M}(\hat{i}_2) < 1$, there exists a number $i_2 \in (\hat{i}_2, i_2^*)$ such that $\mathcal{M}(i_2) = 1$, where both $\mathcal{I}(i_2)$ and $\mathcal{J}(i_2)$ are positive.

- $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in [\hat{i}_2, 1)$. Then we have that $\mathcal{M}(1) \geq 1 + \mathcal{S}(1) > 1$, and since $\mathcal{M}(\hat{i}_2) < 1$, there exists a number $i_2 \in (\hat{i}_2, 1)$ such that $\mathcal{M}(i_2) = 1$, where both $\mathcal{I}(i_2)$ and $\mathcal{J}(i_2)$ are positive.

Therefore, there exists a coexistence equilibrium for all $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_-$.

Now suppose that $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_+$, that is, $1 < \mathcal{R}_2 < \mathcal{R}_1$ and $\hat{\mathcal{R}}_1, \hat{\mathcal{R}}_2 > 1$. The inequality $\hat{\mathcal{R}}_2 > 1$ implies that $\mathcal{M}(0) < 1$, and the inequality $\hat{\mathcal{R}}_1 > 1$ implies that $\mathcal{R}_2\mathcal{S}(\hat{i}_2) < 1$. From this point forward, the proof of this case is analogous to the proof of the case $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_-$.

Suppose that $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_2$, that is, $\mathcal{R}_1 < 1 < \mathcal{R}_2$ and $\hat{\mathcal{R}}_1 > 1$. As before, the inequality $\hat{\mathcal{R}}_1 > 1$ implies that $\mathcal{R}_2\mathcal{S}(\hat{i}_2) < 1$. On the other hand, we have that $\mathcal{R}_2\mathcal{S}(0) = \mathcal{R}_2/\mathcal{R}_1 > 1$. Now, if $\mathcal{M}(\hat{i}_2) \leq 1$, the proof is analogous to the proof of the case $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_-$. If $\mathcal{M}(\hat{i}_2) > 1$, then there exists $i_2^* \in (0, \hat{i}_2)$ such that $\mathcal{R}_2\mathcal{S}(i_2^*) = 1$ and $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in (i_2^*, \hat{i}_2]$. In addition, we have that $\mathcal{M}(i_2^*) = i_2^* + 1/\mathcal{R}_2 = 1 + i_2^* - \hat{i}_2 < 1$. Consequently, there exists a number $i_2 \in (i_2^*, \hat{i}_2)$ such that $\mathcal{M}(i_2) = 1$. This concludes the proof of the case $(\mathcal{R}_1, \mathcal{R}_2) \in D_2$.

Suppose that $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_1$, that is, $\mathcal{R}_2 < 1 < \mathcal{R}_1$ and $\hat{\mathcal{R}}_2 > 1$. As before, the inequality $\hat{\mathcal{R}}_2 > 1$ implies that $\mathcal{M}(0) < 1$, but the value of $\hat{i}_2 = 1 - 1/\mathcal{R}_2 < 0$ since $\mathcal{R}_2 < 1$. Instead, we have that $\mathcal{R}_2\mathcal{S}(0) = \mathcal{R}_2/\mathcal{R}_1 < 1$. Suppose that there exists $i_2^* \in (0, 1)$ such that $\mathcal{R}_2\mathcal{S}(i_2^*) = 1$ and $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in (0, i_2^*)$. Then we have that $\mathcal{M}(i_2^*) = i_2^* + 1/\mathcal{R}_2 > 1/\mathcal{R}_2 > 1$ and there exists a number $i_2 \in (0, i_2^*)$ such that $\mathcal{M}(i_2) = 1$. If no such i_2^* exists, we have that $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in (0, 1)$. Since $\mathcal{M}(1) \geq 1 + \mathcal{S}(1) > 1$, there exists a number $i_2 \in (0, 1)$ such that $\mathcal{M}(i_2) = 1$. This concludes the proof of the case $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_1$.

Finally, suppose that $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_3$, that is, $1 < \mathcal{R}_2 < \mathcal{R}_1$ and $\hat{\mathcal{R}}_1, \hat{\mathcal{R}}_2 < 1$. The inequality $\hat{\mathcal{R}}_2 < 1$ implies that $\mathcal{M}(0) > 1$, and the inequality $\hat{\mathcal{R}}_1 < 1$ implies that $\mathcal{R}_2\mathcal{S}(\hat{i}_2) > 1$. In addition, since $\mathcal{R}_1 > \mathcal{R}_2$, we have that $\mathcal{R}_2\mathcal{S}(0) < \mathcal{R}_1\mathcal{S}(0) = 1$. Therefore, there exists $i_2^* \in (0, \hat{i}_2)$ such that $\mathcal{R}_2\mathcal{S}(i_2^*) = 1$ and $\mathcal{R}_2\mathcal{S}(i_2) < 1$ for all $i_2 \in [0, i_2^*)$. Since $\mathcal{M}(i_2^*) = 1 + i_2^* - \hat{i}_2 < 1$, there exists a number $i_2 \in (0, i_2^*)$ such that $\mathcal{M}(i_2) = 1$. This concludes the proof of the theorem. ∎

Remark. Each of the subregions comprising the coexistence region $\mathcal{D}_c$ has a clear epidemiological interpretation. These regions are presented in Figure 3.1.

If $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_- \cup \mathcal{D}_+$, then both dominance equilibria $\mathcal{E}_1$ and $\mathcal{E}_2$ exist, and each disease can invade the equilibrium of the other disease. The difference between $\mathcal{D}_-$ and $\mathcal{D}_+$ is that $\hat{\mathcal{R}}_2$ is defined only for $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_+$.

If $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_1$, then only the dominance equilibrium of the primary disease $\mathcal{E}_1$ exists, and the secondary disease can invade the equilibrium of the primary disease. Although the secondary disease cannot persist in the absence of the primary disease, the presence of the primary disease mediates the coexistence.

If $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_2$, then only the dominance equilibrium of the secondary disease $\mathcal{E}_2$ exists, and the primary disease can invade the equilibrium of the secondary disease. Although the primary disease cannot persist in the absence of the secondary disease, the presence of the secondary disease mediates the coexistence.

If $(\mathcal{R}_1, \mathcal{R}_2) \in \mathcal{D}_3$, then both dominance equilibria $\mathcal{E}_1$ and $\mathcal{E}_2$ exist, but neither disease can invade the equilibrium of the other disease.

4. Extinction of one or both diseases. In this section we provide the conditions that guarantee that one of the diseases or both of them will be eliminated from the population. These are global conditions in the sense that if they are satisfied, extinction occurs for all other values of the parameters and all initial conditions. As we show in section 6, there could be a backward bifurcation with respect to both $\mathcal{R}_1$

and $\mathcal{R}_2$, and therefore there could exist multiple coexistence equilibria even if $\mathcal{R}_1 < 1$ and $\mathcal{R}_2 < 1$. Thus, $\mathcal{R}_1 < 1$ and $\mathcal{R}_2 < 1$ by themselves do not necessarily imply extinction of one or both diseases. In what follows, we show that the diseases vanish if, in addition, $\gamma_1 = 0$ or $\gamma_2 = 0$.

We denote the initial conditions by $S(0) = S^0$, $i(a,0) = i_0(a)$, $I_2(0) = I_2^0$, and $J(0) = J^0$.

THEOREM 4.1. *Assume that $i_0(a)$ is integrable. If $\gamma_1 = 0$ or $\gamma_2 = 0$ and $\mathcal{R}_1 < 1$, $\mathcal{R}_2 < 1$, then both diseases become extinct in the sense that $\lim_{t\to\infty} i(a,t) = 0$ pointwise for every a, $I_2 \to 0$ as $t \to \infty$, and $J \to 0$ as $t \to \infty$.*

Proof. Assume $\gamma_1 = 0$. Let $\mathcal{B}(t) = i(0,t)$. Neglecting the term dependent on I_2, we obtain a differential inequality for the primary disease. Integrating this inequality along the characteristic lines, we have

$$i(a,t) \le \begin{cases} i_0(a-t)\dfrac{\pi(a)}{\pi(a-t)}e^{-\mu t}, & a \ge t, \\ \mathcal{B}(t-a)\pi(a)e^{-\mu a}, & a < t. \end{cases} \tag{4.1}$$

Since $\gamma_1 = 0$ we have

$$\mathcal{B}(t) \le \int_0^t \beta_1(a)\mathcal{B}(t-a)\pi_1(a)e^{-\mu a}da + e^{-\mu t}\int_t^\infty \beta_1(a)i_0(a-t)da.$$

Consequently, taking a limsup of both sides as $t \to \infty$, we obtain $\limsup_{t\to\infty} \mathcal{B} \le \mathcal{R}_1 \limsup_{t\to\infty} \mathcal{B}(t)$. Since $\mathcal{R}_1 < 1$ and $\limsup_{t\to\infty} \mathcal{B} < \infty$, this inequality can be satisfied only if $\limsup_{t\to\infty} \mathcal{B}(t) = 0$. This, in particular, implies that $i(a,t)$ approaches zero as $t \to \infty$ for every fixed a. From the equation for J we then have the following inequality:

$$J(t) \le e^{-(\mu+\nu)t}J_0 + \int_0^t e^{-(\mu+\nu)s}\int_0^\infty \delta(a)i(a,t-s)dads.$$

Since $\delta(a)$ is bounded and the integral of $i(a,t)$ goes to zero, $I_1(t) \to 0$ as $t \to \infty$, we get that $\limsup_{t\to\infty} J(t) = 0$. Consequently, the equality for I_2 in (2.1) leads to the following differential inequality: $I_2' \le \beta_2 I_2 + \gamma_2 J(t) - (\mu + \alpha_2)I_2$. Integrating this inequality, we obtain

$$I_2(t) \le e^{-(\mu+\alpha_2)t}I_2(0) + \beta_2\int_0^t e^{-(\mu+\alpha_2)\tau}I_2(t-\tau)d\tau + \gamma_2\int_0^t e^{-(\mu+\alpha_2)\tau}J(t-\tau)d\tau.$$

Taking a limsup as $t \to \infty$ on both sides of this inequality, we obtain $\limsup_{t\to\infty} I_2(t) \le \mathcal{R}_2 \limsup_{t\to\infty} I_2(t)$. Since $\mathcal{R}_2 < 1$, this inequality implies $\limsup_{t\to\infty} I_2(t) = 0$.

If $\gamma_2 = 0$, then the proof is symmetrical and somewhat analogous. Thus, it will be omitted. That concludes the proof of this theorem. □

As a special case of the theorem above, we have the following results on extinction of one of the diseases.

COROLLARY 4.2. *Assume that $i_0(a)$ is integrable. If $\gamma_1 = 0$ and $\mathcal{R}_1 < 1$, then the primary disease becomes extinct in the sense that $\lim_{t\to\infty} i(a,t) = 0$ pointwise for every a. As a consequence, $J(t) \to 0$ as $t \to \infty$.*

A similar result for the secondary disease is also valid.

COROLLARY 4.3. *If $\gamma_2 = 0$ and $\mathcal{R}_2 < 1$, then the secondary disease becomes extinct; that is, $I_2(t) \to 0$ as $t \to \infty$. As a consequence, $J(t) \to 0$ as $t \to \infty$.*

A special instance which deserves consideration is the one with $\delta(a) = 0$. In this case there is no coinfection, and the jointly infected class J vanishes. Only three equilibria are possible—the coexistence equilibrium does not exist. The main question is: does the competitive exclusion principle hold for the two diseases with no coinfection? This question can be answered positively in the case when all coefficients are constant and the model (2.1) consists of ODEs only. Then, with $\delta = 0$, it becomes a particular case of a more general model considered in [4]. The results there imply that the competitive exclusion holds and that only the disease with higher reproduction number persists in the population; the other one becomes extinct.

We have not been able to establish whether competitive exclusion for the model (2.1) with $\delta(a) = 0$ is the only possible outcome in the strictly age-structured case. Although there is no coexistence equilibrium, coexistence might still be possible in the form of, say, a stable oscillatory solution. Such a situation has been found to occur in model ecosystems such as the chemostat [3, 5, 18]. This option is even more plausible here, given that the dominance equilibrium of the primary disease can lose stability due to the age-structure, and oscillatory solutions are present (see section 5.2 for more detailed discussion). Despite the oscillatory solutions, simulations lead to extinction of the disease with lower reproduction number. Thus, we conjecture that competitive exclusion is still the norm. A rigorous justification, however, remains an open problem.

5. Local stability of equilibria. In this section we investigate the local stability of the equilibria. In particular, we derive conditions for the stability of the disease-free equilibrium and of the secondary disease dominance equilibrium. We also show that Hopf bifurcation occurs in the coexistence equilibrium. The stability of equilibria determines conditions under which the ultimate outcome will be elimination of both diseases, dominance of the primary disease, dominance of the secondary disease, or endemic presence of both of them.

To investigate the stability of the equilibria, we linearize the model (2.1). In particular, let $x(t)$, $y(a,t)$, $z(t)$, and $w(t)$ be the perturbations of, respectively, S^*, $i^*(a)$, I_2^*, and J^*. That is, $S = S^* + x$, $i = i^* + y$, $I_2 = I_2^* + z$, $J = J^* + w$. Thus the perturbations satisfy a linear system. Further, we consider the eigenvalue problem for the linearized system. We will denote the eigenvector again with x, $y(a)$, z, and w. These satisfy the following linear eigenvalue problem (here s, i, i_2, and j are the proportions in the corresponding equilibrium):

$$
\begin{aligned}
\lambda x &= -s\int_0^\infty \beta_1(a)y(a)da - xi(0)B(i_2) - \beta_2 sz - \beta_2 x i_2 + \int_0^\infty \alpha_1(a)y(a)da \\
&\qquad - (\gamma_1+\gamma_2)sw - (\gamma_1+\gamma_2)xj - \mu x + \alpha_2 z, \\
y'(a) &= -\lambda y - \alpha_1(a)y - \delta(a)i_2 y - \delta(a)i(a)z - \mu y, \\
y(0) &= s\int_0^\infty \beta_1(a)y(a)da + xi(0)B(i_2) + \gamma_1 sw + \gamma_1 xj, \\
\lambda z &= \beta_2 sz + \beta_2 i_2 x + \gamma_2 sw + \gamma_2 jx - (\mu+\alpha_2)z, \\
\lambda w &= i_2\int_0^\infty \delta(a)y(a)da + zi(0)D(i_2) - (\mu+\nu)w.
\end{aligned}
\tag{5.1}
$$

5.1. Stability of the disease-free equilibrium. For the disease-free equilibrium we have $i(0) = 0$, $i_2 = 0$, $j = 0$, and $s = 1$. Thus the system above simplifies to the following system:

(5.2)
$$\begin{aligned}
&\lambda x = -\int_0^\infty \beta_1(a)y(a)da - \beta_2 z - (\gamma_1+\gamma_2)w - \mu x + \int_0^\infty \alpha_1(a)y(a)da + \alpha_2 z,\\
&y'(a) = -\lambda y - \alpha_1(a)y - \mu y,\\
&y(0) = \int_0^\infty \beta_1(a)y(a)da + \gamma_1 w,\\
&\lambda z = \beta_2 z + \gamma_2 w - (\mu+\alpha_2)z,\\
&\lambda w = -(\mu+\nu)w.
\end{aligned}$$

From this system we will establish the following result regarding the local stability of the disease-free equilibrium $\mathcal{E}_0$.

PROPOSITION 5.1. *If $\mathcal{R}_1 < 1$ and $\mathcal{R}_2 < 1$, then the disease-free equilibrium $\mathcal{E}_0$ is locally asymptotically stable. If $\mathcal{R}_1 > 1$ or $\mathcal{R}_2 > 1$, then the disease-free equilibrium $\mathcal{E}_0$ is unstable.*

Proof. To see this, first notice that from the last equation we have either $\lambda = -(\mu+\nu)$, which is the first eigenvalue, or $w = 0$. From the second-to-last equation we have $\lambda z = \beta_2 z - (\mu+\alpha_2)z$, where either $\lambda = \beta_2 - (\mu+\alpha_2)$ or $z = 0$. This eigenvalue $\lambda = \beta_2 - (\mu+\alpha_2) < 0$ if and only if $\mathcal{R}_2 < 1$. Thus, if $\mathcal{R}_2 > 1$, the disease-free equilibrium $\mathcal{E}_0$ is unstable because this eigenvalue is positive. Further, from the second equation we have that the remaining eigenvalues satisfy the equation, also referred to as the characteristic equation,

$$\int_0^\infty \beta_1(a)e^{-(\lambda+\mu)a}\pi_1(a)da = 1. \tag{5.3}$$

Denoting the left-hand side of the equation above by $\mathcal{G}(\lambda)$, where λ is in general a complex number, assume $\Re\lambda \geq 0$. For such λ we have $|\mathcal{G}(\lambda)| \leq \mathcal{G}(\Re\lambda)$. Furthermore, $\mathcal{G}(\Re\lambda)$ is a decreasing function of $\Re\lambda$. Consequently,

$$|\mathcal{G}(\lambda)| \leq \mathcal{G}(\Re\lambda) \leq \mathcal{G}(0) = \mathcal{R}_1 < 1.$$

Thus, if both $\mathcal{R}_1 < 1$ and $\mathcal{R}_2 < 1$, all eigenvalues have negative real part, and the disease-free equilibrium $\mathcal{E}_0$ is locally asymptotically stable. If only $\mathcal{R}_1 > 1$, then if we consider $\mathcal{G}(\lambda)$ for λ real, we see that $\mathcal{G}(\lambda)$ is a decreasing function of λ approaching zero as λ approaches infinity. Since $\mathcal{G}(0) = \mathcal{R}_1 > 1$, that implies that there is a positive eigenvalue $\lambda^* > 0$, and the disease-free equilibrium $\mathcal{E}_0$ is unstable. This concludes the proof. ∎

5.2. Stability of the primary disease equilibrium. In this subsection we discuss the local stability of the equilibrium $\mathcal{E}_1$ and derive conditions for dominance of the primary disease. We show that the equilibrium $\mathcal{E}_1$ can lose stability, and dominance of the first disease is possible in the form of sustained oscillation. In this case $i_2 = 0$, $j = 0$, $s = \frac{1}{\mathcal{R}_1}$, and $i(a) = i(0)\pi_1(a)e^{-\mu a}$, where

$$i(0) = \frac{\mu\left(1 - \frac{1}{\mathcal{R}_1}\right)}{1-\Delta}. \tag{5.4}$$

The eigenvalue problem takes the form

$$
\begin{aligned}
\lambda x &= -s\int_0^\infty \beta_1(a)y(a)da - xi(0)B(0) - \beta_2 s\, z \\
&\quad -(\gamma_1+\gamma_2)sw - \mu x + \int_0^\infty \alpha_1(a)y(a)da + \alpha_2 z, \\
y'(a) &= -\lambda y - \alpha_1(a)y - \delta(a)i(a)z - \mu y, \\
y(0) &= s\int_0^\infty \beta_1(a)y(a)da + xi(0)B(0) + \gamma_1 s\, w, \\
\lambda z &= \beta_2 sz + \gamma_2 sw - (\mu+\alpha_2)z, \\
\lambda w &= zi(0)D(0) - (\mu+\nu)w.
\end{aligned} \tag{5.5}
$$

From the last equation we have

$$w = \frac{zi(0)D(0)}{\lambda+\mu+\nu}.$$

Substituting in the equation for z, assuming z is nonzero, and canceling z, we arrive at the following characteristic equation:

$$\frac{\gamma_2 si(0)D(0)}{(\lambda+\mu+\nu)(\lambda+\mu+\alpha_2-\beta_2 s)} = 1. \tag{5.6}$$

We are now ready to establish the first result.

PROPOSITION 5.2. *Let $\mathcal{R}_1 > 1$ and $\mathcal{R}_1 > \mathcal{R}_2$. Then the equilibrium $\mathcal{E}_1$ is unstable if the secondary disease can invade the equilibrium of the primary disease, that is, $\hat{\mathcal{R}}_2 > 1$. If $\hat{\mathcal{R}}_2 < 1$, then all solutions to the characteristic equation* (5.6) *have negative real part.*

Proof. To see these results, denote by $\mathcal{G}(\lambda)$ the left-hand side of the characteristic equation (5.6). First, we notice that, using the values of s and $i(0)$, we have

$$\mathcal{G}(0) = \frac{\gamma_2 si(0)D(0)}{(\mu+\nu)(\mu+\alpha_2-\beta_2 s)} = \frac{\mu\gamma_2\left(1-\frac{1}{\mathcal{R}_1}\right)D(0)}{(1-\Delta)(\mu+\alpha_2)(\mu+\nu)(\mathcal{R}_1-\mathcal{R}_2)} = \hat{\mathcal{R}}_2. \tag{5.7}$$

First, in the case $\hat{\mathcal{R}}_2 > 1$ we have that $\mathcal{G}(0) > 1$. In addition, if $\mathcal{G}(\lambda)$ is considered as a function of a real variable, we see that $\mathcal{G}(\lambda) \to 0$ as $\lambda \to \infty$. Since $\mathcal{R}_1 > \mathcal{R}_2$, $\mathcal{G}(\lambda)$ is also a continuous function of λ for $\lambda \geq 0$. Consequently, there exists $\lambda^* > 0$ such that $\mathcal{G}(\lambda^*) = 1$. Thus, $\mathcal{E}_1$ is unstable.

In the case when $\hat{\mathcal{R}}_2 < 1$ we have for λ's with $\Re\lambda \geq 0$

$$
\begin{aligned}
|\mathcal{G}(\lambda)| &= \frac{\gamma_2 si(0)D(0)}{|\lambda+\mu+\nu||\lambda+\mu+\alpha_2-\beta_2 s|} \\
&\leq \frac{\gamma_2 si(0)D(0)}{(\Re\lambda+\mu+\nu)(\Re\lambda+\mu+\alpha_2-\beta_2 s)} \leq \mathcal{G}(0) = \hat{\mathcal{R}}_2 < 1.
\end{aligned}
$$

Consequently, the equation $\mathcal{G}(\lambda) = 1$ has no solutions with nonnegative real parts. This concludes the proof of the proposition. ∎

We note that the fact that all solutions to the characteristic equation (5.6) have negative real part does not yet imply that $\mathcal{E}_1$ is stable, since there is a second characteristic equation associated with this case. For stability both characteristic equations must have only roots with negative real parts.

Next, we extend the result above to the case $\mathcal{R}_1 < \mathcal{R}_2$. In particular, we have the following result.

PROPOSITION 5.3. *Let $\mathcal{R}_1 > 1$. If $\mathcal{R}_1 < \mathcal{R}_2$, then the equilibrium $\mathcal{E}_1$ is unstable.*

Proof. To see that, we rewrite the characteristic equation (5.6) in the form

$$\frac{\gamma_2 s i(0) D(0)}{\lambda + \mu + \nu} = \lambda + \mu + \alpha_2 - \beta_2 s. \tag{5.8}$$

We notice that $\mu + \alpha_2 - \beta_2 s = (\mu + \alpha_2)(1 - \frac{\mathcal{R}_2}{\mathcal{R}_1})$, which is negative. Let $\lambda^* = -(\mu + \alpha_2 - \beta_2 s) > 0$. Thus for $\lambda \geq \lambda^*$ the expression $\lambda + \mu + \alpha_2 - \beta_2 s$, considered as a function of the real variable λ, is increasing from zero to infinity. On the other hand, for $\lambda \geq \lambda^*$ the expression

$$\frac{\gamma_2 s i(0) D(0)}{\lambda + \mu + \nu}$$

is decreasing from some positive value to zero. Thus, there is a unique positive (actually larger than λ^*) solution of (5.8). Consequently, $\mathcal{E}_1$ is unstable. This completes the proof. ∎

We continue with our consideration of the system (5.5). If we assume that $z = 0$, that implies $w = 0$. In this case the remaining two equations become

$$\begin{aligned} &\lambda x = -s \int_0^\infty \beta_1(a) y(a) da - x i(0) B(0) - \mu x + \int_0^\infty \alpha_1(a) y(a) da, \\ &y'(a) = -\lambda y - \alpha_1(a) y - \mu y, \\ &y(0) = s \int_0^\infty \beta_1(a) y(a) da + x i(0) B(0). \end{aligned} \tag{5.9}$$

Solving the differential equation, substituting in the equation for x and the initial condition, we obtain a system in x and $y(0)$ which has a nontrivial solution if and only if the following characteristic equation is satisfied:

$$(\lambda + \mu) s B_2(\lambda) = \lambda + \mu + i(0) B(0)(1 - A_2(\lambda)), \tag{5.10}$$

where the following notation has been used:

$$B_2(\lambda) = \int_0^\infty \beta_1(a) \pi_1(a) e^{-(\lambda+\mu)a} da, \quad A_2(\lambda) = \int_0^\infty \alpha_1(a) \pi_1(a) e^{-(\lambda+\mu)a} da.$$

If we define

$$E_2(\lambda) = \int_0^\infty \pi_1(a) e^{-(\lambda+\mu)a} da,$$

we can notice that integration by parts leads to the equality $1 - A_2(\lambda) = (\lambda + \mu) E_2(\lambda)$. Consequently the characteristic equation (5.10) has one eigenvalue equal to $-\mu$. The remaining eigenvalues satisfy the following reduced characteristic equation:

$$s B_2(\lambda) = 1 + i(0) B(0) E_2(\lambda). \tag{5.11}$$

This equation clearly does not have real nonnegative solutions since for λ real and nonnegative the left-hand side is smaller than one, while the right-hand side is larger than one. However, the dominant eigenvalue is not necessarily real—it may be complex

with nonnegative real part. Thus, the dominance equilibrium of the primary disease may lose stability, and oscillations are possible. We include an example and results of simulations later in this section. First, we show that the mechanism responsible for the instability of the primary disease equilibrium is the presence of infection-age structure and variable infectivity. Indeed, if $\beta_1(a) = \beta_1$ and $\alpha_1(a) = \alpha_1$ are constants, then $i(0)B(0) = \beta_1 i$, where i is the proportion infected with primary disease. In addition, $B_2(\lambda) = \beta_1 E_2(\lambda)$ and $E_2(\lambda) = (\lambda + \mu + \alpha_1)^{-1}$. Hence, in the constant coefficient case the characteristic equation (5.11) becomes $\lambda + \mu + \alpha_1 + \beta_1 i - \beta_1 s = 0$. Since $\beta_1 s = \mu + \alpha_1$, the only eigenvalue is $-\beta_1 i$ and is clearly negative. We formulate this result in the following proposition.

PROPOSITION 5.4. *Let $\beta_1(a) = \beta_1$ and $\alpha_1(a) = \alpha_1$ be constants. Let $\mathcal{R}_1 > 1$. Assume that $\mathcal{R}_1 > \mathcal{R}_2$ and that the secondary disease cannot invade the equilibrium of the primary disease; that is, $\hat{\mathcal{R}}_2 < 1$. Then the equilibrium $\mathcal{E}_1$ is locally asymptotically stable. If $\hat{\mathcal{R}}_2 > 1$, the equilibrium $\mathcal{E}_1$ is unstable.*

We conclude this section with an example that the presence of infection-age structure may lead to loss of stability of the dominance equilibrium of the primary disease and oscillations. For this specific example the characteristic equation (5.11) has a complex root with a positive real part. Simulations show the presence of a stable oscillatory solution with persistence of the primary disease only.

Consider the following values for the parameters: $\delta(a) = 0$, $\mu = 0.05$, $\gamma_1 = 0.1$, $\nu = 0$. The recovery rate for the primary disease is

$$\alpha_1(a) = \begin{cases} 0, & 0 \le a < 3, \\ 1.58259, & a \ge 3. \end{cases} \tag{5.12}$$

The transmission coefficient for the primary disease is

$$\beta_1(a) = \begin{cases} 2.33193e^{2a}, & 0 \le a < 1, \\ 0, & a \ge 1. \end{cases} \tag{5.13}$$

The parameters related to the secondary disease are not relevant as $I_2 \to 0$ and $J \to 0$, but they were chosen as follows: $\beta_2 = 0.2$, $\alpha_2 = 0.1$, $\gamma_2 = 8$. The recruitment rate $\Lambda = 1$. With these parameters the reproduction numbers are $\mathcal{R}_1 = 7.207464746$ and $\mathcal{R}_2 = 1.3333$. The characteristic equation (5.11) has a root $0.05 + i\frac{\pi}{2}$ (here i denotes the imaginary unit, $i = \sqrt{-1}$). The initial conditions for the primary disease are chosen close to the equilibrium: $S_0 = 2.77$, $I_2(0) = 0$, $J_0 = 0$,

$$i_0(a) = \begin{cases} 5.2e^{-0.05a}, & 0 \le a < 3, \\ 5.2e^{-1.58259(a-3)}e^{-0.05a}, & a \ge 3. \end{cases} \tag{5.14}$$

The results of the simulations are given in Figure 5.1. The step-size is 0.01, and the integration in age is for up to 100 units. Both figures give the dynamics of the proportion of all cases of the primary disease in the total population as a function of time, that is $\frac{I_1}{N}$, where I_1 is the integral in age of $i(a,t)$.

In the first figure all oscillations are presented. They are so dense that the space they occupy looks like a solid. The oscillations grow in magnitude up to time unit 1000, and then they stabilize in magnitude. The solution takes a long time to stabilize into sustained oscillations because the real part of the eigenvalue with positive real part is relatively small: 0.05. In the second figure a zoomed-in picture is presented for the oscillations between time units 1900 and 1950.

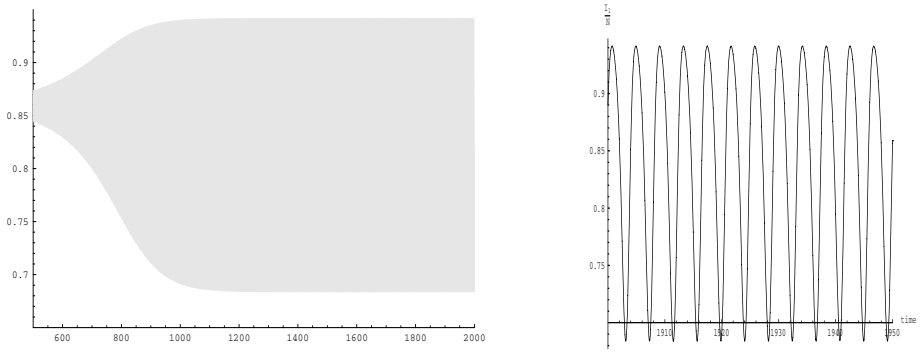

FIG. 5.1. *Left: the proportion of individuals infected with the primary disease* $\frac{I_1}{N}$*, where* I_1 *is the integral in age of* $i(a,t)$ *for up to* 2000 *time units. The horizontal axis shows the time. Right: a sample of the solution between the time units* 1900 *and* 1950*. The numerical solution exhibits sustained oscillations.*

5.3. Stability of the secondary disease equilibrium. In this subsection we establish the local stability properties of the equilibrium $\mathcal{E}_2$ whenever it exists. Thus, unlike $\mathcal{E}_1$, the presence of host age-structure does not lead to oscillations in the dominance equilibrium of the secondary disease. In this case $i(0) = 0$, $j = 0$, $s = \frac{1}{\mathcal{R}_2}$, and $i_2 = \hat{i}_2 = 1 - \frac{1}{\mathcal{R}_2}$. The linear eigenvalue problem becomes

$$
\begin{aligned}
\lambda x &= -s\int_0^\infty \beta_1(a)y(a)da - \beta_2 sz - \beta_2 x i_2 \\
&\quad -(\gamma_1+\gamma_2)sw - \mu x + \int_0^\infty \alpha_1(a)y(a)da + \alpha_2 z, \\
y'(a) &= -\lambda y - \alpha_1(a)y - \delta(a)i_2 y - \mu y, \\
y(0) &= s\int_0^\infty \beta_1(a)y(a)da + \gamma_1 sw, \\
\lambda z &= \beta_2 sz + \beta_2 i_2 x + \gamma_2 sw - (\mu+\alpha_2)z, \\
\lambda w &= i_2\int_0^\infty \delta(a)y(a)da - (\mu+\nu)w.
\end{aligned}
\tag{5.15}
$$

From the last equation we have

$$
w = \frac{i_2}{\lambda+\mu+\nu}\int_0^\infty \delta(a)y(a)da.
$$

From the equation for $y(a)$ we have

$$
y(a) = y(0)\Gamma(a;i_2)\pi_1(a)e^{-(\lambda+\mu)a}.
$$

Substituting in the equation for the initial condition $y(0)$ and assuming that $y(0) \neq 0$, we obtain the following characteristic equation:

$$
sB_1(\lambda) + \frac{\gamma_1 s i_2}{\lambda+\mu+\nu}D_1(\lambda) = 1, \tag{5.16}
$$

where we have used the notation

$$B_1(\lambda) = \int_0^\infty \beta_1(a)\Gamma(a; i_2)\pi_1(a)e^{-(\lambda+\mu)a}da,$$
$$D_1(\lambda) = \int_0^\infty \delta(a)\Gamma(a; i_2)\pi_1(a)e^{-(\lambda+\mu)a}da.$$

Clearly, $B_1(0) = B(i_2)$ and $D_1(0) = D(i_2)$. Now we are ready to prove the main result in this subsection.

THEOREM 5.5. *Let $\mathcal{R}_2 > 1$. Assume that the primary disease cannot invade the equilibrium of the secondary disease; that is, $\hat{\mathcal{R}}_1 < 1$. Then the equilibrium $\mathcal{E}_2$ is locally asymptotically stable, and the secondary disease dominates in the population. If $\hat{\mathcal{R}}_1 > 1$, the equilibrium $\mathcal{E}_2$ is unstable.*

Proof. Denote by $\mathcal{G}(\lambda)$ the left-hand side of the characteristic equation (5.16). We notice that

$$\mathcal{G}(0) = \hat{\mathcal{R}}_1.$$

First we assume that $\hat{\mathcal{R}}_1 > 1$. We consider $\mathcal{G}(\lambda)$ as a function of a real variable. We have $\mathcal{G}(0) = \hat{\mathcal{R}}_1 > 1$. In addition, $\mathcal{G}(\lambda) \to 0$ as $\lambda \to \infty$. Consequently, there exists $\lambda^* > 0$ such that $\mathcal{G}(\lambda^*) = 1$ and the equilibrium $\mathcal{E}_2$ is unstable.

Next, we assume $\hat{\mathcal{R}}_1 < 1$. For λ's with real part $\Re\lambda \geq 0$ we have

$$\begin{aligned}|\mathcal{G}(\lambda)| &\leq s|B_1(\lambda)| + \frac{\gamma_1 s i_2}{|\lambda+\mu+\nu|}|D_1(\lambda)| \\ &\leq sB_1(\Re\lambda) + \frac{\gamma_1 s i_2}{\Re\lambda+\mu+\nu}D_1(\Re\lambda) \\ &\leq sB(i_2) + \frac{\gamma_1 s i_2}{\mu+\nu}D(i_2) = \hat{\mathcal{R}}_1 < 1.\end{aligned}$$

Thus, the characteristic equation (5.16) has no solution with nonnegative real part. Furthermore, for $y(0) = 0$ we have that $y(a) = 0$ and $w = 0$. The remaining two equations become

$$\begin{aligned}\lambda x &= -\beta_2 s z - \beta_2 x i_2 - \mu x + \alpha_2 z, \\ \lambda z &= \beta_2 s z + \beta_2 i_2 x - (\mu+\alpha_2)z.\end{aligned} \tag{5.17}$$

We express x from the first equation,

$$x = \frac{(-\beta_2 s + \alpha_2)z}{\lambda+\mu+\beta_2 i_2},$$

and substitute in the equation for z. Assuming that z is nonzero, we cancel it to obtain the following characteristic equation:

$$(\lambda+\mu)(\lambda+\mu+\alpha_2+\beta_2 i_2-\beta_2 s) = 0.$$

Noticing that $\beta_2 s = \mu+\alpha_2$, we obtain the eigenvalues $-\mu$ and $-\beta_2 i_2$, which are both negative. Consequently, the equilibrium $\mathcal{E}_2$ is locally asymptotically stable. This concludes the proof. ∎

5.4. Loss of stability of a coexistence equilibrium—Oscillatory coexistence. The stability of the coexistence equilibria depends on the analysis of the perturbation equations (5.1). For the general case, however, it is difficult to derive the corresponding characteristic equation, let alone analyze the positions of its roots. Since the main thrust is that a characteristic equation of this complexity is likely to have roots with positive real part, we address the more interesting and tractable question of whether a Hopf bifurcation of a coexistence equilibrium can occur in the absence of age structure, that is, in the case when $\beta_1(a) = \beta_1$, $\alpha_1(a) = \alpha_1$, and $\delta(a) = \delta$. We established that in the constant coefficient case the two dominance equilibria are locally stable. Some additional but simple argument shows that in the absence of the second disease, the solutions converge to the dominance equilibrium, provided that the reproduction number is larger than one and that no oscillations are possible. Thus, if a Hopf bifurcation occurs, the loss of stability of the coexistence equilibrium is due to the presence of the competitor.

It turns out that a Hopf bifurcation of the coexistence equilibrium occurs for a limiting and much simpler form of the original system (2.1) taken with constant coefficients corresponding to $\alpha_1 = \alpha_2 = \gamma_1 = \nu = 0$. Since $\nu = 0$, the total population size is asymptotically constant, $N(t) \to \frac{\Lambda}{\mu} = N^*$. We will restrict our analysis to this invariant subspace [21]. We further rescale all state variables by $1/N^*$ and consider the system

$$\begin{aligned} i_1' &= \beta_1 s i_1 - \mu i_1 - \delta i_1 i_2, \\ i_2' &= \beta_2 s i_2 + \gamma_2 s j - \mu i_2, \\ j' &= \delta i_1 i_2 - \mu j, \end{aligned} \tag{5.18}$$

where $s \equiv 1 - i_1 - i_2 - j$. We establish the existence of Hopf bifurcation for values of the parameters satisfying the inequalities $\beta_2 < \mu < \beta_1 < \gamma_2$. In this case, we have that

$$\mathcal{R}_1 = \frac{\beta_1}{\mu} > 1 > \frac{\beta_2}{\mu} = \mathcal{R}_2,$$

which implies that $\mathcal{E}_2$ does not exist, and the secondary disease alone is always eliminated. Hence, the coexistence of both diseases must be mediated by the presence of the competitor, that is, the primary disease.

It is convenient to fix the parameters μ, β_1, β_2, and γ_2 and treat δ as a bifurcation parameter. Solving for positive coexistence equilibria, we find

$$s = \frac{\mu\gamma_2 + \gamma_2\delta - \beta_1\mu}{\gamma_2(\delta + \beta_1) - \beta_1\beta_2}, \qquad i_1 = \frac{\mu^2 - \beta_2\mu s}{\gamma_2\delta s}, \qquad i_2 = \frac{\beta_1 s - \mu}{\delta}, \qquad j = \frac{\delta i_1 i_2}{\mu}.$$

Under the above conditions, s and i_1 are automatically positive. The value of i_2 is positive if and only if $\delta > \delta^*$, where

$$\delta^* = \frac{\mu\beta_1(\beta_1 - \beta_2)}{\gamma_2(\beta_1 - \mu)}.$$

Since we consider δ as a bifurcation parameter, we view the values of the positive equilibrium as functions of delta: $s = s(\delta)$, $i_1 = i_1(\delta)$, $i_2 = i_2(\delta)$, $j = j(\delta)$. The variational matrix of the system (5.18) at the positive equilibrium (i_1, i_2, j) is given

by

$$A(\delta) = \begin{pmatrix} -\beta_1 i_1 & -(\beta_1+\delta)i_1 & -\beta_1 i_1 \\ -\beta_2 i_2 - \gamma_2 j & \beta_2 s - \mu - \beta_2 i_2 - \gamma_2 j & \gamma_2(s-j) - \beta_2 i_2 \\ \delta i_2 & \delta i_1 & -\mu \end{pmatrix}. \tag{5.19}$$

Calculating the determinant of $A(\delta)$, we find that $\det A(\delta) = \delta i_1 i_2[\beta_1\mu - \gamma_2(\mu+\delta)]$. Hence, $\det A(\delta) < 0$ whenever $\delta > \delta^*$ (since then $i_2 > 0$). Since $s(\delta^*) = \frac{\mu}{\beta_1}$, $i_1(\delta^*) = 1 - \frac{\mu}{\beta_1}$, and $i_2(\delta^*) = j(\delta^*) = 0$, we have that

$$A(\delta^*) = \begin{pmatrix} \mu - \beta_1 & (\beta_1+\delta)\frac{\mu-\beta_1}{\beta_1} & \mu - \beta_1 \\ 0 & \left(\frac{\beta_2}{\beta_1} - 1\right)\mu & \frac{\gamma_2\mu}{\beta_1} \\ 0 & \delta^*\frac{\beta_1-\mu}{\beta_1} & -\mu \end{pmatrix}.$$

The eigenvalues of $A(\delta^*)$ are given by $\lambda_1 = \mu - \beta_1 < 0$, $\lambda_2 = (\frac{\beta_2}{\beta_1} - 2)\mu < 0$, $\lambda_3 = 0$. Using the continuity of eigenvalues with respect to δ, we conclude that $A(\delta)$ has three negative eigenvalues when δ is slightly greater than δ^*. Hence, the positive equilibrium is stable for "small" $\delta > \delta^*$.

Next we argue that the positive equilibrium is unstable for sufficiently large values of δ. First we notice that $\lim_{\delta\to\infty} s(\delta) = 1$. Furthermore,

$$\lim_{\delta\to\infty} \delta i_1(\delta) = \frac{\mu^2 - \beta_2\mu}{\gamma_2}, \quad \lim_{\delta\to\infty} \delta i_2(\delta) = \beta_1 - \mu, \quad \lim_{\delta\to\infty} j(\delta) = 0.$$

Thus, we have that

$$\lim_{\delta\to\infty} A(\delta) = A_\infty = \begin{pmatrix} 0 & -\frac{\mu^2-\beta_2\mu}{\gamma_2} & 0 \\ 0 & \beta_2 - \mu & \gamma_2 \\ \beta_1 - \mu & \frac{\mu^2-\beta_2\mu}{\gamma_2} & -\mu \end{pmatrix}.$$

The characteristic polynomial of A_∞ has the form

$$p_\infty(\lambda) = \lambda^3 + (2\mu - \beta_2)\lambda^2 + (\beta_1 - \mu)(\mu^2 - \beta_2\mu).$$

Since $2\mu - \beta_2 > 0$ and $(\beta_1 - \mu)(\mu^2 - \beta_2\mu) > 0$, $p_\infty(\lambda)$ has one real negative and two complex roots with positive real parts. We conclude that the positive equilibrium changes stability as we increase δ. Since the determinant of the variational matrix remains negative for all $\delta > \delta^*$, the change of stability corresponds to a Hopf bifurcation. The rigorous analysis of this bifurcation is outside of the scope of this paper.

A continuation argument can establish that this bifurcation must also occur when the parameters α_1, α_2, γ_1, and ν are small and positive. In Figure 5.2 we demonstrate the presence of oscillatory coexistence when α_1, α_2, and γ_1 are small and positive. The figure shows a periodic orbit in the three-dimensional space of the variables $I_1(t)$, $I_2(t)$, and $J(t)$. In this example the parameter values are taken as $\beta_1 = 10$, $\beta_2 = 0.2$, $\alpha_1 = 1$, $\alpha_2 = 0.1$, $\mu = 1$, $\delta = 4$, $\nu = 0$, $\gamma_1 = 0.1$, $\gamma_2 = 80$, $\Lambda = 1$. Since $\frac{\Lambda}{\mu} = 1$ the values of I_1, I_2, and J are also the values of the proportions. The reproduction number of the primary disease is $\mathcal{R}_1 = 5$, while the reproduction number of the secondary disease is below one, $\mathcal{R}_2 = 0.18182$. Despite the fact that $\mathcal{R}_1 \gg \mathcal{R}_2$, the prevalence for the secondary disease I_2 is much higher than that of the primary disease I_1—a result of the very high rate at which the jointly infected individuals can infect with the secondary disease $\gamma_2 = 80$.

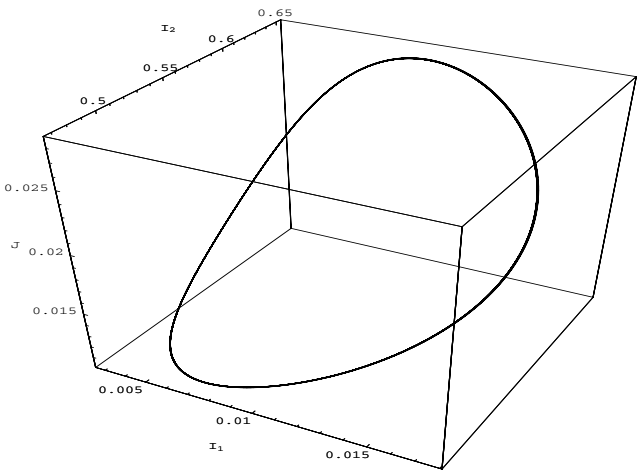

FIG. 5.2. *Existence of a periodic orbit for the age-independent case. Values of the parameters are as in the text.*

6. Backward bifurcation. In this section we analyze the existence of backward bifurcations in the system (2.1). In the single disease case, a backward bifurcation occurs when the equilibrium number (or proportion) of infectives bifurcates at the critical value of the reproduction number $\mathcal{R} = 1$ not forward but backward, and there are nontrivial equilibria when the reproduction number is below one.

In the case of two diseases, an analogous phenomenon occurs when the equilibrium number (or proportion) of infectives with each disease i_1 and i_2 bifurcates backward in both parameters $\mathcal{R}_1$ and $\mathcal{R}_2$, and nontrivial equilibria exist for values of both reproduction numbers below one. We will call this phenomenon *a two-parameter backward bifurcation*. In what follows we derive necessary and sufficient conditions for two-parameter backward bifurcation.

We treat $\beta_1(a)$ and β_2 (equivalently, $\mathcal{R}_1$ and $\mathcal{R}_2$) as bifurcation parameters and assume that all other parameters are fixed. Specifically, we define

$$\beta_1(a, \varepsilon_1) = \tilde{\beta}_1(a)(1 + \varepsilon_1 \tilde{v}_1(a)), \quad \beta_2(\varepsilon_2) = \tilde{\beta}_2(1 + \varepsilon_2),$$

so that $\tilde{\beta}_2 = \alpha_2 + \mu$ and the functions $\tilde{\beta}_1(a)$ and $\tilde{v}_1(a)$ are normalized as follows:

$$\int_0^\infty \tilde{\beta}_1(a)\pi_1(a)e^{-\mu a}\, da = \int_0^\infty \tilde{\beta}_1(a)\tilde{v}_1(a)\pi_1(a)e^{-\mu a}\, da = 1.$$

In this setting, the choice $\varepsilon_1 = \varepsilon_2 = 0$ corresponds to the basic reproduction numbers of both strains being equal to unity, that is, $\mathcal{R}_1 = \mathcal{R}_2 = 1$. We also introduce the auxiliary functions

$$B(i_2, \varepsilon_1) = \int_0^\infty \tilde{\beta}_1(a)(1 + \varepsilon_1 \tilde{v}_1(a))\Gamma(a; i_2)\pi_1(a)e^{-\mu a}\, da, \tag{6.1}$$

$$G(i_2) = \int_0^\infty \Gamma(a; i_2)\pi_1(a)e^{-\mu a}\, da, \tag{6.2}$$

where $\Gamma(a; i_2)$ is given by (3.3). Previously, we have shown that the fraction of sus-

ceptible individuals at the coexistence equilibrium must equal

$$s = \left(B(i_2, \varepsilon_1) + \frac{\gamma_1 i_2 D(i_2)}{\mu + \nu} \right)^{-1} = S(i_2, \varepsilon_1),$$

where i_2 is the fraction of individuals infected by secondary infection. Solving for $i(0)$, we find that

$$i(0) = (\mu + \nu)(\mu + \alpha_2) \frac{1 - (1 + \varepsilon_2) S(i_2, \varepsilon_1)}{\gamma_2 S(i_2, \varepsilon_1) D(i_2)} = T(i_2, \varepsilon_1, \varepsilon_2),$$

and thus the total fraction of individuals infected by primary infection is given by $i_1 = G(i_2) T(i_2, \varepsilon_1, \varepsilon_2)$. The fraction of individuals carrying both infections can be expressed as

$$j = \frac{i_2 D(i_2) T(i_2, \varepsilon_1, \varepsilon_2)}{\mu + \nu}.$$

The relation $s + i_1 + i_2 + j = 1$ now can be written as

$$M(i_2, \varepsilon_1, \varepsilon_2) = i_2 + S(i_2, \varepsilon_1) + G(i_2) T(i_2, \varepsilon_1, \varepsilon_2) + \frac{i_2 D(i_2) T(i_2, \varepsilon_1, \varepsilon_2)}{\mu + \nu} = 1.$$

Since

$$S(0,0) = \frac{1}{B(0,0)} = \left(\int_0^\infty \tilde{\beta}_1(a) \pi_1(a) e^{-\mu a} \, da \right)^{-1} = 1,$$

we find that $T(0,0,0) = 0$ and $M(0,0,0) = 1$. For a given pair $(\varepsilon_1, \varepsilon_2)$, we define the equilibrium values of $i_2(\varepsilon_1, \varepsilon_2)$ as an implicit solution of the equation $M(i_2, \varepsilon_1, \varepsilon_2) = 1$. The corresponding equilibrium values $i_1(\varepsilon_1, \varepsilon_2)$ are obtained from $i_1 = G(i_2) T(i_2, \varepsilon_1, \varepsilon_2)$. The backward bifurcation occurs whenever both functions $i_1(\varepsilon_1, \varepsilon_2)$ and $i_2(\varepsilon_1, \varepsilon_2)$ have positive values for (perhaps some) $\varepsilon_1, \varepsilon_2 < 0$. To pose the conditions for backward bifurcation we need all partial derivatives $\frac{\partial i_m}{\partial \varepsilon_n}(0,0)$, where $m, n = 1, 2$.

We compute the required partial derivatives. First, we have

$$\frac{\partial B}{\partial i_2}(0,0) = -\int_0^\infty \tilde{\beta}_1(a) \pi_1(a) e^{-\mu a} \left(\int_0^a \delta(s) \, ds \right) da = -\hat{\delta} < 0.$$

Next, if we define

$$\sigma = \hat{\delta} - \frac{\gamma_1 D(0)}{\mu + \nu}, \quad \tau = \frac{(\mu + \nu)(\mu + \alpha_2)}{\gamma_2 D(0)},$$

then the remaining partial derivatives are given by

$$\frac{\partial S}{\partial \varepsilon_1}(0,0) = -1, \quad \frac{\partial S}{\partial i_2}(0,0) = \sigma, \quad \frac{\partial T}{\partial \varepsilon_1}(0,0,0) = \tau,$$
$$\frac{\partial T}{\partial \varepsilon_2}(0,0,0) = -\tau, \quad \frac{\partial T}{\partial i_2}(0,0,0) = -\tau\sigma.$$

Finally, we have that

$$\begin{aligned} \frac{\partial M}{\partial i_2}(0,0,0) &= 1 + (1 - G(0)\tau)\sigma, \\ \frac{\partial M}{\partial \varepsilon_1}(0,0,0) = -1 + G(0)\tau, &\quad \frac{\partial M}{\partial \varepsilon_2}(0,0,0) = -G(0)\tau. \end{aligned} \tag{6.3}$$

Using the implicit function theorem, we find the derivatives of i_2 and, as a result, those of i_1:

$$\frac{\partial i_2}{\partial \varepsilon_1}(0,0) = \frac{1-G(0)\tau}{1+(1-G(0)\tau)\sigma}, \qquad \frac{\partial i_1}{\partial \varepsilon_1}(0,0) = \frac{G(0)\tau}{1+(1-G(0)\tau)\sigma}, \tag{6.4}$$

$$\frac{\partial i_2}{\partial \varepsilon_2}(0,0) = \frac{G(0)\tau}{1+(1-G(0)\tau)\sigma}, \qquad \frac{\partial i_1}{\partial \varepsilon_2}(0,0) = \frac{-G(0)\tau(1+\sigma)}{1+(1-G(0)\tau)\sigma}. \tag{6.5}$$

Since $G(0)\tau > 0$, all of these partial derivatives are negative if and only if

$$1+(1-G(0)\tau)\sigma < 0 \quad \text{and} \quad 1-G(0)\tau > 0. \tag{6.6}$$

Note that (6.6) enforces $\sigma < -1$.

Since we consider a two-parameter bifurcation, it may occur for all pairs $(\varepsilon_1, \varepsilon_2)$ or only for some pairs $(\varepsilon_1, \varepsilon_2)$. We will call a backward bifurcation *total* if the positive equilibrium exists for *all* pairs $(\varepsilon_1, \varepsilon_2)$ with sufficiently small $\varepsilon_k < 0$, $k = 1, 2$. We will call a backward bifurcation *partial* if the positive equilibrium exists for *some* pairs $(\varepsilon_1, \varepsilon_2)$ with sufficiently small $\varepsilon_k < 0$, $k = 1, 2$. In what follows, we argue that the model (2.1) admits only total backward bifurcations.

Indeed, a partial backward bifurcation occurs if and only if there exist pairs of positive numbers (ω_1, ω_2) such that

$$\omega_1 \frac{\partial i_1}{\partial \varepsilon_1}(0,0) + \omega_2 \frac{\partial i_1}{\partial \varepsilon_2}(0,0) < 0,$$
$$\omega_1 \frac{\partial i_2}{\partial \varepsilon_1}(0,0) + \omega_2 \frac{\partial i_2}{\partial \varepsilon_2}(0,0) < 0.$$

In contrast, total backward bifurcation occurs if the above inequalities are valid for all pairs of nonnegative numbers (ω_1, ω_2). These inequalities are equivalent to

$$\frac{(1-G(0)\tau)+\omega G(0)\tau}{1+(1-G(0)\tau)\sigma} < 0, \tag{6.7}$$

$$\frac{G(0)\tau(1-\omega(1+\sigma))}{1+(1-G(0)\tau)\sigma} < 0, \tag{6.8}$$

where $\omega = \omega_2/\omega_1 > 0$ (we assume $\omega_1 > 0$). We also note that $G(0)\tau > 0$.

Suppose that $1+(1-G(0)\tau)\sigma > 0$. Then (6.7)–(6.8) imply that $\sigma > -1$ and

$$\frac{1}{1+\sigma} < \omega < \frac{G(0)\tau - 1}{G(0)\tau},$$

and thus $G(0)\tau < (G(0)\tau - 1)(1+\sigma)$. The last inequality clearly contradicts $1+(1-G(0)\tau)\sigma > 0$. No backward bifurcations occur in this case.

Now suppose that $1+(1-G(0)\tau)\sigma < 0$. Then (6.7)–(6.8) imply that

$$\omega > \frac{G(0)\tau - 1}{G(0)\tau}, \quad 1-\omega(1+\sigma) > 0.$$

If $1+\sigma > 0$, then the second inequality implies that

$$\frac{G(0)\tau - 1}{G(0)\tau} < \omega < \frac{1}{1+\sigma},$$

and thus $G(0)\tau > (G(0)\tau - 1)(1+\sigma)$, which is a contradiction. If $1+\sigma < 0$, then $1-\omega(1+\sigma) > 0$ holds for all $\omega > 0$. On the other hand, we must have that $\sigma < 0$ and

$$G(0)\tau < \frac{1+\sigma}{\sigma} < 1.$$

Therefore, $(1-G(0)\tau) + \omega G(0)\tau > 0$ also holds for all $\omega \geq 0$. In this case, the backward bifurcation is total. We conclude that only total backward bifurcations may occur in this model, and the criterion is given by (6.6). We summarize this result in the following proposition.

PROPOSITION 6.1. *The model* (2.1) *exhibits the backward bifurcation if and only if*

$$1 + (1 - G(0)\tau)\sigma < 0 \quad \text{and} \quad 1 - G(0)\tau > 0. \tag{6.9}$$

If at least one of the inequalities in (6.9) *does not hold, then the model* (2.1) *does not admit any nontrivial equilibria with* $\mathcal{R}_1, \mathcal{R}_2 < 1$. *If both inequalities in* (6.9) *hold, then the backward bifurcation is total; that is, there exists a sufficiently small* $0 < \varepsilon_0 < 1$ *such that the model* (2.1) *admits nontrivial equilibria for all pairs of the reproduction numbers* $(\mathcal{R}_1, \mathcal{R}_2)$ *such that* $1 - \varepsilon_0 < \mathcal{R}_1, \mathcal{R}_2 < 1$.

7. Numerical results. In this section we consider several types of complex behavior which stem largely from the presence of coinfection. These regimes have important consequences for the development and eradication of one or both diseases.

We consider the following phenomena: subthreshold coexistence equilibria, multiple coexistence equilibria, and bistable dominance. Subthreshold coexistence equilibria may be generated by two-parameter backward bifurcation. These are multiple coexistence equilibria (two in our case), but multiple coexistence equilibria may also exist superthreshold. Finally, we consider the bistability of the dominance equilibria, which is defined as dominance of one of the diseases depending on the initial conditions. All these are illustrated in Figure 7.1. The figure is generated with the following values of the parameters: $\alpha_1 = 14$, $\alpha_2 = 25$, $\mu = 3.9$, $\nu = 0.1$, $\delta = 20$,

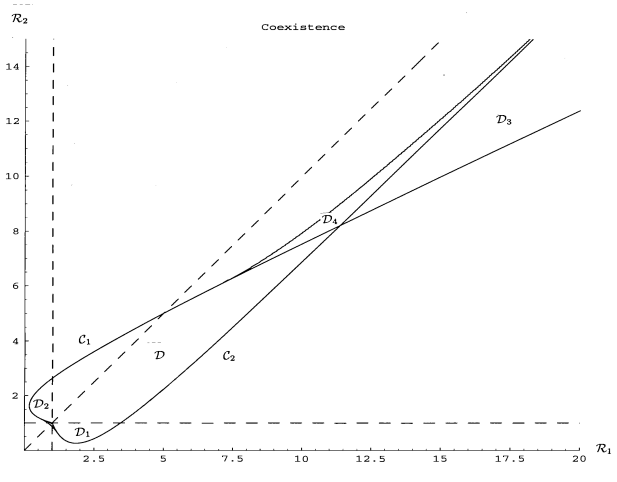

FIG. 7.1. *Boundaries of coexistence and stability of dominance equilibria. Parameters as in text.*

$\gamma_1 = 20$, $\gamma_2 = 20$. The values of $\mathcal{R}_1$ and $\mathcal{R}_2$ are treated as operating parameters that are directly related to the values of β_1 and β_2. In this section, we consider only the case where $\beta_1(a) \equiv \beta_1$ is age-independent. The values of $\mathcal{R}_1$ and $\mathcal{R}_2$ are plotted on the x and y axes, respectively. The upper of the two curves that originate at $(1, 1)$ is obtained from the equation $\hat{\mathcal{R}}_1 = 1$, while the lower is obtained from the equation $\hat{\mathcal{R}}_2 = 1$. We denoted these curves by $\mathcal{C}_1$ and $\mathcal{C}_2$, respectively. The geometry of these curves was analyzed in Lemma 3.1.

7.1. Backward bifurcation and subthreshold equilibria. The presence of subthreshold equilibria has important implications for the control of a single disease. It means that the disease might not be eradicated by reducing its reproduction number slightly below one. Instead, it is necessary to reduce the reproduction number below the minimal transition value $\mathcal{R}^*$ such that there are no nontrivial equilibria for values of the reproduction number below $\mathcal{R}^*$.

When multiple diseases are present the situation is more complex. We call a coexistence equilibrium *subthreshold* if it occurs when at least one of the reproduction numbers is below one. Furthermore, there are two distinct cases with different consequences for the control of the diseases. In the first scenario, coexistence equilibria occur when exactly one of the reproduction number is below one. We will call those *weakly subthreshold* equilibria. In Figure 7.1 weakly subthreshold coexistence equilibria occur both in the case $\mathcal{R}_1 < 1$, $\mathcal{R}_2 > 1$ and in the case $\mathcal{R}_1 > 1$, $\mathcal{R}_2 < 1$. Those are to be found to the right of the curve $\mathcal{C}_1$ but to the left of the line $\mathcal{R}_1 = 1$ (Figure 7.1, region $\mathcal{D}_2$) and above the curve $\mathcal{C}_2$ but below the line $\mathcal{R}_2 = 1$ correspondingly (Figure 7.1, region $\mathcal{D}_1$). Given coinfection $\delta \neq 0$, a necessary condition for the first area to be nonempty is that $\gamma_1 \neq 0$; similarly, the second area can be nonempty only if $\gamma_2 \neq 0$. In both of these areas there is a unique coexistence equilibrium not obtained as a result of a backward bifurcation. In terms of disease control the presence of weakly subthreshold equilibria leads to the fact that reducing only one of the reproduction numbers below unity does not necessarily lead to the disappearance of the corresponding disease. Thus, eradicating only one of the two diseases may be difficult, particularly as the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ pass very close to the corresponding axes. However, if both reproduction numbers are brought slightly below unity, both diseases will be eliminated. We note here that we may have weakly subthreshold coexistence equilibria only with $\mathcal{R}_1 < 1$, $\mathcal{R}_2 > 1$ without having such with $\mathcal{R}_1 > 1$, $\mathcal{R}_2 < 1$ or vice versa (not shown). In this case only the primary disease cannot be eliminated by reducing $\mathcal{R}_1$ below one, while the secondary will be eliminated if $\mathcal{R}_2$ is reduced below one. Weakly subthreshold equilibria also appear as a consequence of backward bifurcation (see Figure 7.2) and are discussed more in the next subsection.

In the second scenario, coexistence equilibria occur when both of the reproduction numbers are below one. We call those *strongly subthreshold* coexistence equilibria. Strongly subthreshold equilibria in our model are the result of a backward bifurcation in two parameters, namely $\mathcal{R}_1$ and $\mathcal{R}_2$. We established necessary and sufficient conditions for the two-parameter backward bifurcation in the previous section. If we consider J^* as the coexistence variable and we view it as a function of $\mathcal{R}_1$ and $\mathcal{R}_2$, then the surface $J^* = f(\mathcal{R}_1, \mathcal{R}_2)$ bifurcates backwards along the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ near the critical point $(1, 1)$ and then turns around and heads in the direction of increasing values of $\mathcal{R}_1$ and $\mathcal{R}_2$. The projection of the turning curve on the plane $(\mathcal{R}_1, \mathcal{R}_2)$ is the curve that connects $\mathcal{C}_1$ and $\mathcal{C}_2$ (see Figure 7.2, region $\mathcal{S} = \mathcal{S}_1 \cup \mathcal{S}_2 \cup \mathcal{S}_3$). In analogy with the single disease case, we will call this curve the *minimal transition curve*. In Figure 7.2 the area enclosed by the curves $\mathcal{C}_1$, $\mathcal{C}_2$ and the minimal transition curve,

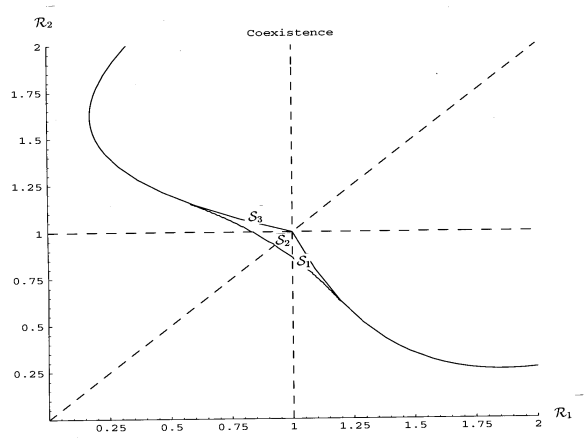

FIG. 7.2. *This is a zoom-in of the area from Figure* 7.1 *near the critical point where both reproduction numbers are near one.*

$\mathcal{S}$, is the projection of the overlapping branches of the surface $J^* = f(\mathcal{R}_1, \mathcal{R}_2)$. Thus, in this area there are two distinct coexistence equilibria. Figure 7.2 is a zoom-in of the part of Figure 7.1 near the critical point $(1, 1)$.

Next, we show that backward bifurcation occurs if and only if the angle between the tangent lines to the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ (see Figure 7.1) at the point $(1, 1)$ is sufficiently small—smaller than 180°. Let l_1 be the tangent to $\mathcal{C}_1$ with slope m_1, and l_2 be the tangent to the curve $\mathcal{C}_2$ with slope m_2. Along the curve $\mathcal{C}_1$ we have $i_1(\varepsilon_1, \varepsilon_2) = 0$. Along the curve $\mathcal{C}_2$ we have $i_2(\varepsilon_1, \varepsilon_2) = 0$. The slopes of l_1 and l_2 are given by $\frac{d\varepsilon_2}{d\varepsilon_1}$, which is obtained for each curve by differentiating implicitly. Thus, by (6.4) and (6.5),

$$m_1 = \frac{1}{1+\sigma}, \qquad m_2 = -\frac{1 - G(0)\tau}{G(0)\tau}.$$

The angle between the tangents is obtuse if $m_2 < m_1 < 0$. The angle between the tangents is larger than 180° and backward bifurcation does not occur if $m_1 < m_2 < 0$. Consequently, the conditions for the angle to be obtuse are

$$\frac{G(0)\tau - 1}{G(0)\tau} < \frac{1}{1+\sigma} < 0.$$

It is easy to see that these inequalities are equivalent to the inequalities (6.9).

The fact that backward bifurcation occurs only if the angle between the tangent lines of the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ at the point $(1, 1)$ is obtuse implies that strongly subthreshold coexistence equilibria are present only in conjunction with both types of weakly subthreshold coexistence equilibria. Thus, the existence of strongly subthreshold coexistence equilibria through two-parameter backward bifurcation is the analogue of the backward bifurcation in the single disease case. It has the same implication for the disease control—reducing both reproduction numbers slightly below one does not lead to the eradication of either disease. It is necessary to reduce both reproduction numbers in the square $[0, 1] \times [0, 1]$ below the minimal transition curve.

7.2. Multiple coexistence equilibria. Bistability. The presence of multiple equilibria, and particularly of multiple stable equilibria, can have significant impact on the outcome of the disease, as for a fixed set of parameters this outcome depends on the initial status of the population. For the present model and parameter values, as in Figure 7.1, results in previous sections and simulations suggested the presence of multiple coexistence equilibria in two areas.

The first such area is the subthreshold area $\mathcal{S}$ illustrated also in Figure 7.2. As we discussed above, the multiple equilibria there are obtained from backward bifurcation. In this case there are two coexistence equilibria. If they are ordered in increasing order of J^*, simulations suggest that the lower one is unstable, while the upper one is locally stable. In the subregion $\mathcal{S}_2$ there is also the disease-free equilibrium which is locally stable. Thus, in that region the two diseases might coexist, or they might both disappear depending on the initial conditions. Looking at Figure 7.2, we see that the area of backward bifurcation overlaps also with the regions $\mathcal{R}_1 > 1$, $\mathcal{R}_2 < 1$ forming region $\mathcal{S}_1$ and $\mathcal{R}_1 < 1$, $\mathcal{R}_2 > 1$ forming region $\mathcal{S}_3$. Consequently, we have multiple weakly subthreshold coexistence equilibria. In those regions the disease-free equilibrium is unstable. However, in addition to the locally stable coexistence equilibrium, in the region $\mathcal{S}_1$ the equilibrium $\mathcal{E}_1$ is also locally stable, while in the second region $\mathcal{S}_3$ the equilibrium $\mathcal{E}_2$ is also locally stable. Thus, the ultimate outcome is either dominance of one of the diseases or coexistence, depending on the initial conditions.

The second area where multiple coexistence equilibria exist is the superthreshold area in Figure 7.1, where the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ cross and a third curve touches both of them forming a curvilinear triangle, denoted by $\mathcal{D}_4$. There are two coexistence equilibria in that area; the lower one there is stable, while the upper one is unstable. The disease-free equilibrium is again unstable. Both dominance equilibria $\mathcal{E}_1$ and $\mathcal{E}_2$ exist; however, $\mathcal{E}_1$ is unstable and $\mathcal{E}_2$ is locally stable. Consequently, if the combination of the reproduction numbers forms a point in that area, there are two possible outcomes for the long-term dynamics of the diseases: dominance of the secondary disease or coexistence. Which of the two will materialize depends on the initial status of the population.

A unique coexistence equilibrium exists in the area $\mathcal{D} = \mathcal{D}_- \cup D_+ \cup D_1 \cup D_2$ between the curves $\mathcal{C}_1$ and $\mathcal{C}_2$, which for most parameter values is locally stable. When it loses stability, oscillatory coexistence occurs.

7.3. Bistable dominance. One of distinctive features of this model is that the two curves that define the boundaries of stability of the dominance equilibria $\mathcal{E}_1$ and $\mathcal{E}_2$ always intersect (see Lemma 3.1 for details).

In the constant coefficient case, there is a unique intersection of the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ that occurs at the point $(\mathcal{R}_1^*, \mathcal{R}_2^*)$, where $\mathcal{R}_1^* > 1$ and $\mathcal{R}_2^* > 1$. This intersection creates a region between the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ with $\mathcal{R}_1 > \mathcal{R}_1^*$ and $\mathcal{R}_2 > \mathcal{R}_2^*$ (see Figure 7.1, area $\mathcal{D}_3$), where both dominance equilibria $\mathcal{E}_1$ and $\mathcal{E}_2$ are locally stable and the outcome of the competition between the diseases depends on the initial conditions. In other words, based only on the parameters values we cannot predict which disease will persist in the population. Figures 7.3 and 7.4 show the possible outcomes with two sets of initial conditions which differ only in the value of J_0. In the first figure $J_0 = 0.05$, while in the second $J_0 = 0.04$.

The curve $\mathcal{C}_1$ will not cross below the diagonal if $\gamma_1 = 0$, given that there is coinfection ($\delta \neq 0$). Thus the bistable dominance occurs as a result of the possibility that the jointly infected individuals can infect with the primary disease $\gamma_1 \neq 0$.

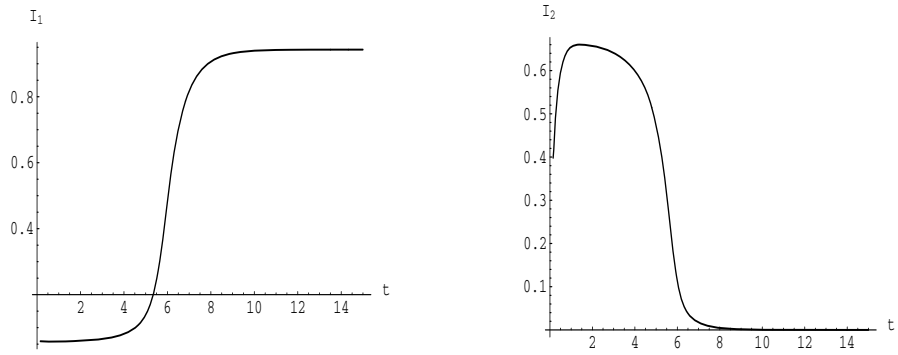

FIG. 7.3. *Primary disease persists, secondary disease dies out. Parameters are as in Figure* 7.1 *with* $\mathcal{R}_1 = 17.5$ *and* $\mathcal{R}_2 = 12$ *(from region* $\mathcal{D}_3$*). Initial conditions are* $S_0 = 0.2$, $I_1(0) = 0.01$, $I_2(0) = 0.05$, $J_0 = 0.05$.

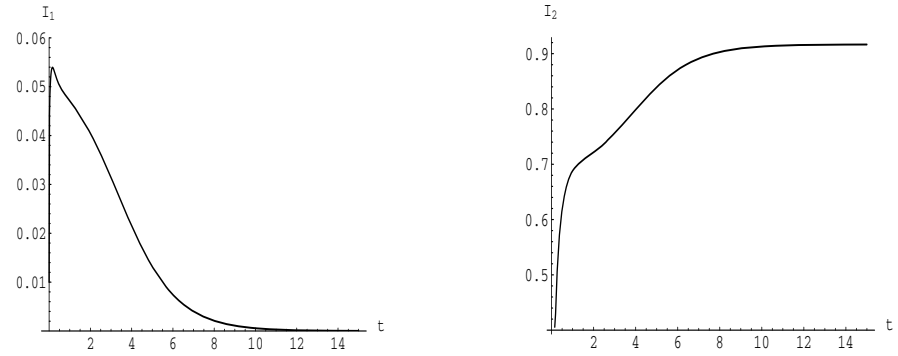

FIG. 7.4. *Primary disease dies out, secondary disease persists. Parameters as in Figure* 7.1 *with* $\mathcal{R}_1 = 17.5$ *and* $\mathcal{R}_2 = 12$ *(from region* $\mathcal{D}_3$*). Initial conditions are* $S_0 = 0.2$, $I_1(0) = 0.01$, $I_2(0) = 0.05$, $J_0 = 0.04$.

8. Discussion. At any given time thousands of diseases cocirculate in a population. Many of them participate in joint infections of a single host. New diseases like SARS appear; others fade only to re-emerge later with strains that are more difficult to treat. The complexity of interactions of the diseases through the host population can have a significant impact on the dynamics and management of each disease.

In this paper we introduce and investigate a simple epidemiological model with two diseases that can coinfect a single host. We compute the reproduction numbers and the invasion reproduction numbers of both diseases. We observe a variety of complex dynamic phenomena with significant consequences for disease control.

1. *Cooperative subthreshold coexistence.* First, we establish that the dominance equilibria $\mathcal{E}_1$ and $\mathcal{E}_2$ are present only if $\mathcal{R}_1 > 1$ and $\mathcal{R}_2 > 1$, correspondingly. That implies that neither disease can exist by itself when its reproduction number is below one. However, the "cooperation" of the two leads to subthreshold coexistence. Consequently, both diseases can persist concurrently for values of the reproduction numbers below one. We call this phenomenon *cooperative subthreshold coexistence.* We show two types of cooperative subthreshold coexistence: weakly subthreshold coexistence (occurs when exactly one of the reproduction numbers is below one) and strongly subthreshold coexistence (occurs when both reproduction numbers are below one). The strongly subthreshold coexistence is a result of backward bifurcation in both $\mathcal{R}_1$

and $\mathcal{R}_2$. Weakly subthreshold coexistence can result from backward bifurcation or from expansion of the coexistence region between the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ to the below threshold areas. We derive necessary and sufficient conditions for existence of backward bifurcation. We show that the bifurcation is always *total*; that is, it occurs for all pairs of $(\mathcal{R}_1, \mathcal{R}_1)$ which are close to $(1, 1)$. A sufficient condition for backward bifurcation is that the angle between the tangents to those curves at the critical point $(1, 1)$ be obtuse, which occurs if both γ_1 and γ_2 are large. We establish that $\gamma_1 = 0$ leads to extinction of the primary disease if $\mathcal{R}_1 < 1$, and $\gamma_2 = 0$ with $\mathcal{R}_2 < 1$ leads to extinction of the secondary disease. No backward bifurcation occurs in these cases. One consequence of the observation is that public health mechanisms that lead to reduction of spread of either disease by the jointly infected individuals—like isolating those who are infected with both diseases—can have very dramatic effects on the eradication of one or both diseases. Furthermore, disease-induced mortality in the jointly infected class ν is a mechanism that impedes the backward bifurcation. This suggests that diseases which are more lethal in a combination are easier to manage from an epidemiological perspective.

2. *Restricted pathogenic diversity. Bistable dominance.* The dynamics of two diseases is reminiscent of the dynamics of two variants of the same pathogen. In many instances coexistence in stable form occurs in unbounded domains of the parameter space [17]. This is not the case here. The curves $\mathcal{C}_1$ and $\mathcal{C}_2$ intersect, thus making the region $\hat{\mathcal{R}}_1 > 1$, $\hat{\mathcal{R}}_2 > 1$ finite (Figure 7.1). We find coexistence in domains outside that one—namely, the area of backward bifurcation (Figure 7.2) and the area of two coexistence equilibria adjacent to the cross-point of $\mathcal{C}_1$ and $\mathcal{C}_2$. It appears from the simulations that these two areas are also finite. Consequently, stable coexistence is limited to finite regions in the $(\mathcal{R}_1, \mathcal{R}_2)$ plane and does not occur if the reproduction numbers are sufficiently large. We call this *restricted pathogenic diversity.* In other words, if evolution maximizes the reproduction numbers, then under this scenario it works against pathogenic diversity. It is interesting to know what mechanisms would lead to such an effect. In our case this is the ability of the jointly infected individuals to spread the primary diseases, $\gamma_1 \neq 0$. The intersection of the curves $\mathcal{C}_1$ and $\mathcal{C}_2$ also leads to emergence of a region between them where $\hat{\mathcal{R}}_1 < 1$, $\hat{\mathcal{R}}_2 < 1$. Simulations suggest that in this region there is still a unique coexistence equilibrium which is unstable. At the same time the two boundary equilibria are both locally stable. A situation like this has been described as occurring in a two-sex two-strain model of STD [6]. The result is bistable dominance—which disease persists and which dies out depend on the initial conditions, and the outcome can be very sensitive (Figures 7.3 and 7.4). In fact, bistability is somewhat common for the model (2.1). We find bistability in several regions of the $(\mathcal{R}_1, \mathcal{R}_2)$ plane, particularly where multiple coexistence equilibria exist. In all remaining cases, however, one of the possible outcomes is stable coexistence; the other is either dominance of one of the diseases or extinction.

9. Summary. In this paper, we have analyzed an epidemic model of two diseases with age-since-infection structure in the primary disease. We have obtained expressions for the basic reproduction numbers $\mathcal{R}_i$ for both diseases, and showed that the unique primary (resp., secondary) single disease equilibrium exists if and only if $\mathcal{R}_1 > 1$ (resp., $\mathcal{R}_2 > 1$). We have also shown that the disease-free equilibrium is locally stable if $\mathcal{R}_1, \mathcal{R}_2 < 1$ and unstable if $\mathcal{R}_i > 1$ for some $i = 1, 2$ (Proposition 5.1), and obtained sufficient conditions for the extinction of one or both diseases (section 4).

We have computed the invasion reproduction numbers $\hat{\mathcal{R}}_i$ for both single disease equilibria. We presented the necessary condition for the local stability of the pri-

mary disease equilibrium in Propositions 5.2 and 5.3. In the case of the secondary disease equilibrium, we presented the necessary and sufficient condition for the local stability in Proposition 5.5. In Theorem 3.2, we presented sufficient conditions for the presence of coexistence equilibria. In Proposition 6.1, we showed that multiple coexistence equilibria may exist via the backward bifurcation. In the absence of the age structure, we showed that a coexistence equilibrium can lose stability via a Hopf bifurcation (section 5.4). In general, the stability of coexistence equilibria remains an open problem. Finally, we presented results of numerical simulations that illustrate different dynamic outcomes of the interactions between the two diseases.

Acknowledgments. The authors are grateful to the anonymous referee and the handling editor for their valuable comments and suggestions.

ON THE ROUTE TO EXTINCTION IN NONADIABATIC SOLID FLAMES*

J. H. PARK†, A. BAYLISS†, B. J. MATKOWSKY†, AND A. A. NEPOMNYASHCHY‡

Abstract. We consider nonadiabatic gasless solid fuel combustion employing a reaction sheet model. We derive an integrodifferential equation for the location of the interface separating the fresh fuel from the burned products. There are two parameters in our model, the Zeldovich number Z, related to the activation energy of the exothermic chemical reaction, and the heat loss parameter Γ. For any value of Z there is an extinction limit Γ_m, so that if $\Gamma > \Gamma_m$, the combustion wave cannot be sustained. For all values of Z and $\Gamma < \Gamma_m$ the model admits a uniformly propagating combustion wave. This solution is subject to a pulsating instability for Z sufficiently large. The effect of heat losses is destabilizing in the sense that pulsations occur for smaller values of Z when heat loss is considered.

We consider the dynamics of the combustion wave as Γ increases, thus, describing the dynamics of the model on the route to extinction. We consider values of Z below the adiabatic stability limit, so that for $\Gamma = 0$ the only stable steady state solution is the uniformly propagating combustion wave. We find that for Z near the adiabatic stability limit, the effect of heat loss is to promote a period doubling cascade leading to chaotic behavior prior to extinction. We also find an interval of laminar behavior within the chaotic window, corresponding to a secondary period doubling sequence. Specifically, we find solutions of period $12T, 24T, 48T$. We show that for smaller values of Z the full period doubled sequence does not necessarily occur. Rather, extinction follows after a finite, possibly small, number of periodic solutions.

Key words. nonadiabatic combustion wave dynamics, solid flame, chaos, period doubling sequence

1. Introduction.

The model of gasless solid fuel combustion describes the SHS (Self-propagating High Temperature Synthesis) process of materials synthesis. In this process reactants are ground into a powder, cold pressed, and ignited at one end. A high temperature combustion wave then propagates through the sample converting reactants into products. When gas plays no significant role in the process, the resulting gasless combustion wave is referred to as a "solid flame" and can be modeled, as in this paper, as gasless, solid fuel combustion. The process was pioneered in the former Soviet Union, and has subsequently been the focus of a great deal of research, e.g., [12, 13, 15]. The SHS process enjoys a number of advantages over conventional technology, in which the sample is placed into a furnace and "baked" until it is "well done." The advantages include (i) simpler equipment; (ii) significantly shorter synthesis times; (iii) greater economy, since the internal energy of the chemical reactions is employed rather than the costly external energy of the furnace; (iv) greater product purity; due to volatile impurities being burned off by the very high combustion temperatures of

the propagating combustion wave; and (v) no intrinsic limit on the size of the sample to be synthesized, as exists in conventional technology.

It is known that in many instances the combustion wave does not propagate in a uniform spatial and temporal manner, but rather nonuniformities can develop in the front speed and in the temperature along the front. Since the mode of propagation determines the microstructure of the product, i.e., the nature of the final product, a study of different modes of propagation is important for technological applications of the SHS process. For example, if the temperature is different at two different spatial points during the synthesis process, the product at these points will be different. It is known that for sufficiently large activation energies (more precisely Zeldovich numbers, defined below) the uniformly propagating combustion wave is unstable. In this case the only stable planar mode is the planar pulsating mode (autooscillatory combustion), in which there is no spatial structure along the front, i.e., the combustion wave remains planar. However, the front speed and temperature on the front oscillate in time in a periodic, quasiperiodic or chaotic fashion, (see, e.g., [1, 2, 3, 4, 5, 8, 9, 11, 14, 16, 17]). We note that for some parameters there exist various types of nonplanar modes, e.g., hot spots traveling on a helical path on the surface of a cylindrical sample, and other modes exhibiting yet more complex spatiotemporal dynamics. However, in this paper we only consider planar modes of propagation.

Most planar computations consider adiabatic combustion and study the effect of increasing the activation energy or Zeldovich number on the nonlinear dynamics. Computations have shown that in this case the nonlinear dynamics exhibits a period doubling sequence [3, 4, 5]. While the period doubling route to chaos for adiabatic solid fuel combustion as the Zeldovich number Z increases has been fairly well established, the role of heat loss has not been considered as extensively. In this paper we consider nonadiabatic combustion and focus on the nonlinear dynamics occurring prior to extinction. We consider the case that Z is below the pulsating stability boundary, so that pulsations arise solely due to heat loss. This problem was considered in [6] which demonstrated that increasing heat loss promotes the pulsating instability, and in [11] which computed period T and period $2T$ behavior. It should be noted that the route to chaos does not always proceed by period doubling. For example, if the effect of melting of the solid fuel prior to combustion is accounted for, the route to chaos is via intermittency [3, 16]. Moreover, there are a number of successive windows in which there is period T behavior, followed by period $2T$ behavior, followed by a return to period T behavior prior to the onset of intermittency.

We consider the route to extinction for one-dimensional nonadiabatic gasless solid fuel combustion. Specifically, we consider the reaction sheet model and derive an integrodifferential equation for the motion of the interface separating the fresh fuel from the burned products. The model, which has a basic solution describing a uniformly propagating planar wave, depends on various parameters, including the Zeldovich number Z (a nondimensional measure of the activation energy of the exothermic chemical reaction) and the nondimensional heat loss parameter Γ. Increasing Z above a critical value Z_c or increasing Γ above a critical value Γ_c destabilizes the basic solution to pulsations. We consider in particular the parameter regime below the pulsating boundary Z_c so that without heat loss the uniformly propagating combustion wave is stable and there are no pulsations. We show that as the heat loss Γ increases the system undergoes transitions to chaos via a period doubling sequence. We are able to compute nT periodic solutions where $n = 1, 2, 4, 8, 16$ denotes the the degree of doubling of the period, i.e., a T solution is a singly periodic solution while a $2T$ solution is a solution which has undergone one period doubling. While we have not

computed period doubled solutions beyond $16T$, we did compute apparently chaotic solutions near the extinction limit. We also show that within the chaotic window, there is a region containing a secondary period doubling sequence. Specifically, we computed solutions with periods $12T$, $24T$, and $48T$. We note that the adiabatic problem ($\Gamma = 0$) was reformulated as an integral equation in [7] which investigated T periodic relaxation oscillations and [5] which computed a period doubling route to chaos as Z increased, thus recovering the results in [3, 4].

In section 2 we describe the mathematical model and the basic solution which describes a uniformly propagating planar combustion wave. In section 3 we consider the linear stability of the basic solution and identify the pulsating stability boundary, while in section 4 we derive the integrodifferential equation which describes the motion of the interface. In section 5 we describe the numerical method which we employ and in section 6 we describe the results of our computations. Finally, in section 7 we summarize our results.

2. Mathematical model and basic solution. We consider a planar combustion front propagating in a solid fuel in the direction $-x_*$. We account for heat losses which are assumed to be proportional to the difference between the local temperature T_* and an ambient temperature T_0. The temperature field $T_*(x_*, t_*)$ and the concentration field $C_*(x_*, t_*)$ of the deficient reaction component are governed by

$$\frac{\partial T_*}{\partial t_*} = \kappa \frac{\partial^2 T_*}{\partial x_*^2} - \gamma(T_* - T_0) + QW(T_*, C_*), \qquad \frac{\partial C_*}{\partial t_*} = -W(T_*, C_*), \tag{1}$$

$$-\infty < x_* < \infty, \quad 0 < t_* < \infty,$$

where κ is the thermal diffusivity of the fuel, the constant γ is the heat loss coefficient, and the constant Q denotes the heat release of the exothermic chemical reaction, all scaled by ρc, where ρ denotes the fuel density and c its specific heat. We have assumed that the fuel sample is sufficiently long to permit a traveling wave to be established, so that the domain is taken to be $-\infty < x_* < \infty$. The reaction rate $W(T_*, C_*)$ is generally taken to be of Arrhenius form

$$W(T_*, C_*) = kC_* e^{\frac{-E}{RT_*}}, \tag{2}$$

where E is the activation energy of the reaction, R is the universal gas constant and k is the preexponential factor. The reaction zone in combustion reactions is typically thin since the activation energy is typically large. Therefore, we employ the reaction sheet assumption, i.e., we replace the Arrhenius reaction kinetics by delta-function kinetics [6, 8, 9],

$$W = w \exp\left[\frac{E}{2RT_a^2}(T_* - T_a)\right] \delta(x_* - \xi_*(t_*)), \tag{3}$$

located at the interface $x_* = \xi_*(t_*)$ separating the fresh fuel where $C_* = C_{*0}$ from the burned products where $C_* = 0$ corresponding to complete consumption of the fuel. Here,

$$T_a = T_0 + QC_{*0} \tag{4}$$

is the adiabatic interface temperature, i.e., the burned temperature in the absence of the heat losses, and w is a constant proportional to k. The reaction sheet assumption in solid fuel combustion is motivated by analogy with the case of gaseous

combustion, where it was systematically derived [10] for large activation energies. For solid fuel combustion, as considered here, it was "derived" by formal truncation of an asymptotic series for large Z [8].

The condition of complete consumption of fuel determines the dependence of the interface velocity on the reaction rate

$$\left(-\frac{d\xi_*}{dt_*}\right) C_{*0} = w \exp\left[\frac{E}{2RT_a^2}(T_*(\xi_*(t_*), t_*) - T_a)\right]. \tag{5}$$

Solving the system (1), (3), (5) with the boundary conditions

$$T_*(-\infty, t) = T_*(\infty, t) = T_0 \tag{6}$$

under the assumption of steady propagation,

$$\xi_*(t_*) = \xi_*(0) - v_f t_*, \tag{7}$$

we obtain the temperature profiles,

$$T_*(x_*, t_*) = T_0 + (T_{*f} - T_0) e^{k_-(x_* - \xi_*(t_*))}, \quad x_* - \xi_*(t_*) \le 0, \tag{8}$$

$$T_*(x_*, t_*) = T_0 + (T_{*f} - T_0) e^{-k_+(x_* - \xi_*(t_*))}, \quad x_* - \xi_*(t_*) \ge 0,$$

where

$$k_\pm = \frac{v_f}{2\kappa}\left[\mp 1 + \sqrt{1 + \frac{4\kappa\gamma}{v_f^2}}\,\right], \qquad T_{*f} = T_0 + \frac{QC_{0*}}{\sqrt{1 + 4\kappa\gamma/v_f^2}}. \tag{9}$$

Substituting (7) and (8) into (5) and employing (4), we find the following equation for the interface velocity v_f

$$v_f = \frac{w}{C_{0*}} \exp\left[\frac{EQC_{0*}}{2RT_a^2}\left(\frac{1}{\sqrt{1 + 4\kappa\gamma/v_f^2}} - 1\right)\right]. \tag{10}$$

In contrast to the adiabatic case $\gamma = 0$, where $v_f = w/C_{0*}$ is the sole solution of (10), for $\gamma > 0$, (10) may have several solutions.

We define the nondimensional quantities

$$Z = \frac{QEC_{*0}}{2RT_a^2} \tag{11}$$

(Zeldovich number),

$$H = \frac{4\kappa\gamma C_{*0}^2}{w^2}, \qquad V = \frac{v_f C_{*0}}{w} \tag{12}$$

and rewrite (10) in nondimensional form as

$$V = \exp\left[Z\left(\frac{1}{\sqrt{1 + H/V^2}} - 1\right)\right]. \tag{13}$$

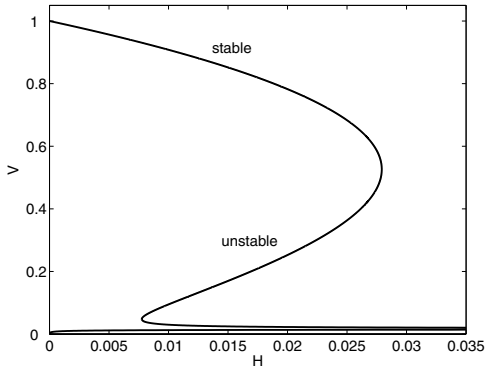

FIG. 1. *Plot of V vs. H based on* (14).

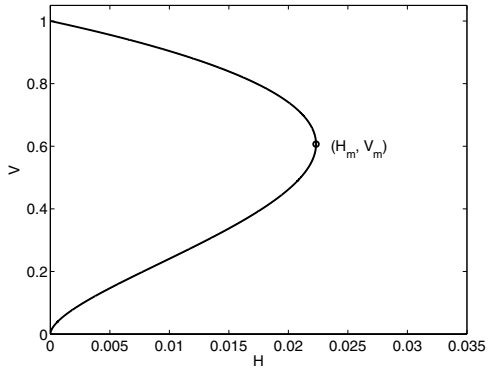

FIG. 2. *Plot of V vs. H based on* (15).

Solving (13) for H, we find

$$H = V^2 \left[\frac{1}{(1 + \ln V/Z)^2} - 1 \right]. \tag{14}$$

The expression on the right-hand side of (14) is positive in the interval $\exp(-2Z) < V < 1$. Only for sufficiently small Z is $H(V)$, given by (14), monotonic, so that $V(Z)$ is single valued. For $Z \gg 1$, which is typical for solid combustion, under the physically reasonable condition $V \gg \exp(-Z)$, formula (14) can be written to leading order as

$$H = -\frac{2V^2 \ln V}{Z}. \tag{15}$$

Equation (15) has *two* solution branches $V(H)$ if $H < H_m = \frac{1}{eZ}$ and *no* solutions if $H > H_m$ (see Figure 2). At the value $H = H_m$, which corresponds to the extinction limit, the two solution branches merge at $V = V_m = 1/\sqrt{e}$, corresponding to $H = H_m$, and disappear for larger H. It will be shown below that the solution with the higher value of V is monotonically stable, while the solution with the lower value of V is monotonically unstable, in agreement with the predictions of [6]. There is a third solution branch of (14), with exponentially small velocity V, as well as a yet smaller fourth solution branch (see Figure 1), and a still smaller fifth solution branch, which are unphysical and are to be ignored. Indeed, the fourth solution branch of (14) is not a solution of (13), since it corresponds to $1 + \frac{\ln V}{Z} < 0$, and the fifth solution branch corresponds to $H < 0$ and is also not a solution of (13) (this branch, which approaches the origin, is not plotted in Figure 1).

After finding the physically relevant value of the steadily propagating front velocity, we can further simplify the description of the problem by introducing the following nondimensional variables: $x = (x_* - \xi_*(0))v_f/\kappa$, $t = t_* v_f^2/\kappa$, $T = (T_* - T_0)/C_{*0}Q$. In these nondimensional variables, the problem reads

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} - \Gamma T - \frac{d\xi}{dt}\delta(x - \xi(t)), \quad -\infty < x < \infty, \quad 0 < t < \infty, \tag{16}$$

$$T(x, 0) = T_i(x), \quad -\infty < x < \infty, \tag{17}$$

$$T(-\infty, t) = T(\infty, t) = 0, \quad 0 \le t < \infty, \tag{18}$$

$$-\frac{d\xi}{dt} = \exp\{Z(T(\xi(t),t) - T_f)\}, \tag{19}$$

where

$$\Gamma = \frac{\gamma\kappa}{v_f^2} > 0 \tag{20}$$

can be considered as the dimensionless heat loss parameter and simultaneously as a dimensionless inverse square interface velocity, and T_f is the dimensionless interface temperature. Note that we have assumed that $\Gamma > 0$, since for $\Gamma = 0$ the boundary condition for $T(\infty, t)$ would not be that given in (18). The particular solution (7), (8), corresponding to an interface uniformly propagating with the velocity v_f, is given by

$$\xi(t) = -t,$$

$$T(x,t) = T_f e^{K_-(x+t)}, \quad x+t<0; \qquad T(x,t) = T_f e^{-K_+(x+t)}, \quad x+t>0, \tag{21}$$

where

$$K_\pm = (\mp 1 + \sqrt{1+4\Gamma})/2; \qquad T_f = \frac{1}{\sqrt{1+4\Gamma}}. \tag{22}$$

We refer to this solution as the basic solution. Equation (13), which reads

$$f(\Gamma) = \Gamma^{1/2} \exp\left(\frac{Z}{\sqrt{1+4\Gamma}}\right) = H^{1/2} \exp Z, \tag{23}$$

determines values of Γ corresponding to given values of Z and H. Extinction occurs at $\Gamma_m = H_m/4V_m^2 = 1/4Z$ (in the limit $Z \gg 1$). Note that the solution with $V > V_m$ has $\Gamma < \Gamma_m$, while the solution with $V < V_m$ has $\Gamma > \Gamma_m$.

3. Linear stability of the basic solution. We rewrite the system (16)–(18) in a reference frame moving with the interface as

$$\frac{\partial T}{\partial t} - \frac{d\xi}{dt}\frac{\partial T}{\partial X} = \frac{\partial^2 T}{\partial X^2} - \Gamma T - \frac{d\xi}{dt}\delta(X), \quad -\infty < X < \infty,\ 0 < t < \infty, \tag{24}$$

$$T(-\infty, t) = T(\infty, t) = 0, \quad 0 \le t < \infty, \tag{25}$$

where $X = x - \xi(t)$. Linearizing equations (24), (25) about the basic solution (21), we obtain the following eigenvalue problem for the infinitesimal temperature perturbation $\tilde{T}(X)\exp(\sigma t)$ and the interface velocity perturbation $\tilde{v}\exp(\sigma t)$

$$\sigma\tilde{T} - \tilde{v}T' + \tilde{T}' = \tilde{T}'' - \Gamma\tilde{T}, \quad X \neq 0, \tag{26}$$

$$\tilde{T}(0^-) = \tilde{T}(0^+) \equiv \tilde{T}(0), \quad \tilde{T}'(0^+) - \tilde{T}'(0^-) - \tilde{v} = 0, \tag{27}$$

$$\tilde{T}(\pm\infty) = 0. \tag{28}$$

Linearization of (19) provides a relation between the velocity perturbation $\tilde{v}$ and the interface temperature perturbation $\tilde{T}(0)$,

$$\tilde{v} = -Z\tilde{T}(0). \tag{29}$$

We are interested in two types of stability boundaries, the monotonic boundary corresponding to $\sigma = 0$ and the oscillatory boundary corresponding to $\sigma = i\omega$, with ω real.

If $\sigma = 0$, the temperature perturbations are given by

$$\tilde{T} = e^{K_- X} + \frac{ZT_f K_-}{\sqrt{1+4\Gamma}} X e^{K_- X}, \quad X < 0, \tag{30}$$

$$\tilde{T} = e^{-K_+ X} + \frac{ZT_f K_+}{\sqrt{1+4\Gamma}} X e^{-K_+ X}, \quad X > 0, \tag{31}$$

and the expression for the monotonic stability boundary $Z = Z_m(\Gamma)$, i.e., the curve which separates stable from unstable basic solutions, is given by

$$Z = Z_m(\Gamma) = \frac{(1+4\Gamma)^{3/2}}{4\Gamma}. \tag{32}$$

The function $Z_m(\Gamma)$ has a minimum, given by $Z_c = 3^{3/2}/8$. Note that our approach is valid only for Z sufficiently large and Γ sufficiently small, hence only the left branch of the curve (32) has physical meaning. The curve (32), which separates stable and unstable solutions, corresponds to the extinction limit [6]. Inverting $Z = Z_m(\Gamma)$ determines the extinction line $\Gamma = \Gamma_m(Z)$ discussed in the previous section. As mentioned above, for a fixed value of Z, solutions with a value of Γ smaller than the critical value $\Gamma_m(Z)$, i.e., those corresponding to the larger of the two interface velocities v_f, are stable (with respect to monotonic disturbances), while solutions with a value of Γ larger than the critical value, i.e., those corresponding to the smaller of the two interface velocities, are unstable, in agreement with the predictions of [6].

If $\sigma = i\omega$, the eigenfunction of the problem (26)–(29) has the form

$$\tilde{T} = e^{k_- X} - \frac{iZT_f K_+}{\omega}\left(e^{-K_+ X} - e^{-k_+ X}\right), \quad X > 0, \tag{33}$$

where

$$k_\pm = \frac{\mp 1 + \sqrt{1+4\Gamma+4i\omega}}{2}. \tag{34}$$

The oscillatory stability boundary $Z_o(\Gamma)$ and the frequency ω are obtained from the real and imaginary parts of the dispersion relation

$$Z_o\{\omega + iT_f[K_+(K_+ - k_+) - K_-(K_- - k_-)]\} - (k_+ + k_-)\omega = 0. \tag{35}$$

We find that

$$Z_o(\Gamma) = \frac{2 + \sqrt{4 + (1+4\Gamma)^2}}{\sqrt{1+4\Gamma}}, \tag{36}$$

$$\omega^2(\Gamma) = Z_o \frac{1 + 16\Gamma^2 - 4\Gamma\sqrt{4 + (1+4\Gamma)^2}}{(1+4\Gamma)^{3/2}}. \tag{37}$$

The expression for ω^2 is positive only for $\Gamma < \Gamma_*$, where Γ_* is the positive root of the cubic equation

$$1 - 48\Gamma_*^2 - 128\Gamma_*^3 = 0.$$

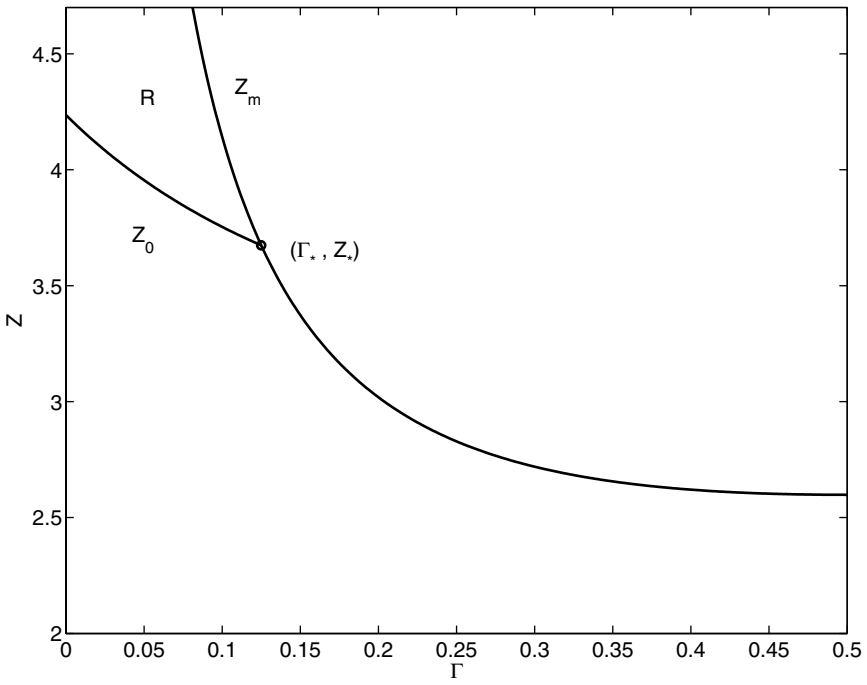

FIG. 3. *Region R in parameter space in which solution behavior is computed.*

The point $(\Gamma_*, Z_* = Z_o(\Gamma_*) = Z_m(\Gamma_*))$ is a codimension-two point where the monotonic and oscillatory boundaries merge. In the interval $0 < \Gamma < \Gamma_*$, $Z_o(\Gamma)$ is a monotonically decreasing function; the curve $Z = Z_o(\Gamma)$ is situated below and to the left of the curve $Z = Z_m(\Gamma)$. We conclude that for a fixed value Z in the interval $Z_* < Z < 2 + \sqrt{5}$, as Γ grows, pulsations precede extinction. The region in (Γ, Z) parameter space in which we compute solution behavior is shown in Figure 3.

4. Integrodifferential equation for the interfacial motion. We now turn to the nonlinear problem (16)–(19). The term with heat losses is eliminated by the transformation

$$T(x,t) = \Theta(x,t)e^{-\Gamma t}. \tag{38}$$

Substituting (38) into (16), we obtain the inhomogeneous heat equation for $\Theta(x,t)$,

$$\frac{\partial \Theta(x,t)}{\partial t} = \frac{\partial^2 \Theta(x,t)}{\partial x^2} - e^{\Gamma t}\frac{d\xi}{dt}\delta(x - \xi(t)), \quad -\infty < x < \infty,\ 0 < t < \infty \tag{39}$$

subject to the initial condition

$$\Theta(x,0) = T_i(x), \quad -\infty < x < \infty, \tag{40}$$

and the boundary conditions

$$\Theta(-\infty,t) = \Theta(\infty,t) = 0, \quad 0 \le t < \infty. \tag{41}$$

The solution of the problem (39)–(41) is given by

$$\Theta(x,t) = \int_{-\infty}^{\infty} \frac{1}{2\sqrt{\pi t}} e^{-(x-y)^2/4t} T_i(y)dy$$
$$+ \int_0^t d\tau \int_{-\infty}^{\infty} dy \frac{1}{2\sqrt{\pi(t-\tau)}} e^{\Gamma\tau} e^{-(x-y)^2/4(t-\tau)} \left[-\frac{d\xi}{d\tau}(\tau)\right] \delta(y-\xi(\tau)). \tag{42}$$

In terms of the variable $T(x,t)$, we obtain

$$T(x,t) = e^{-\Gamma t} \int_{-\infty}^{\infty} \frac{1}{2\sqrt{\pi t}} e^{-(x-y)^2/4t} T_i(y)dy$$
$$+ \int_0^t d\tau \int_{-\infty}^{\infty} dy \frac{1}{2\sqrt{\pi(t-\tau)}} e^{-\Gamma(t-\tau)} e^{-(x-y)^2/4(t-\tau)} \left[-\frac{d\xi}{d\tau}(\tau)\right] \delta(y-\xi(\tau)). \tag{43}$$

Evaluating the integral containing the δ-function and substituting into (19), we find the self-consistency condition for $\xi(t)$,

$$-\frac{d\xi}{dt}(t) = \exp\left\{ Z \left[e^{-\Gamma t} \int_{-\infty}^{\infty} \frac{1}{2\sqrt{\pi t}} e^{-(\xi(t)-y)^2/4t} T_i(y)dy \right.\right.$$
$$\left.\left. + \int_0^t d\tau \frac{e^{-\Gamma(t-\tau)}}{2\sqrt{\pi(t-\tau)}} e^{-(\xi(t)-\xi(\tau))^2/4(t-\tau)} \left[-\frac{d\xi}{d\tau}(\tau)\right] - T_f \right] \right\}, \tag{44}$$

where T_f is the undisturbed front temperature determined by (22). This is a closed integrodifferential equation for the function $\xi(t)$ defined for $t > 0$.

The first term on the right-hand side of (44), which depends on the initial conditions, decays in time. Thus, for large t it can be disregarded. Employing the change of variable $\tau = t - s$, the second integral is transformed to

$$\int_0^t ds \frac{e^{-\Gamma s}}{2\sqrt{\pi s}} e^{-(\xi(t)-\xi(t-s))^2/4s} \left[-\frac{d\xi(t-s)}{dt}\right].$$

Thus, we finally obtain that $\xi(t)$ is the solution of

$$\frac{d\xi}{dt}(t) = -\exp\left\{ -Z \left[T_f + \int_0^t ds \frac{e^{-\Gamma s}}{2\sqrt{\pi s}} e^{-(\xi(t)-\xi(t-s))^2/4s} \left[\frac{d\xi(t-s)}{dt}\right] \right] \right\}. \tag{45}$$

This integrodifferential equation describes the location of the interface $\xi(t)$ separating the fresh fuel from the burned products, for large times, after transients have died out.

5. Numerical method. We now describe the numerical method employed in the solution to (45). We note that we solve the initial value problem for (45) and march forward in time until steady state is achieved. As a result, all steady state solutions that we compute are necessarily stable. For conciseness, we introduce the symbol $\dot{\xi} = \frac{d\xi}{dt}$ to denote the front velocity. Note that we have assumed that the front propagates in the negative x direction so that $\dot{\xi} < 0$ for all t. We first take the natural logarithm of both sides of (45) to obtain

$$\ln(-\dot{\xi}(t)) = Z \left\{ -T_f + \int_0^t ds \frac{e^{-\Gamma s}}{2\sqrt{\pi s}} e^{-(\xi(t)-\xi(t-s))^2/4s} \left(-\dot{\xi}(t-s)\right) \right\}. \tag{46}$$

We next introduce the integration variable $\sigma = t - s$, so that (46) becomes

$$\ln(-\dot{\xi}(t)) = Z\left\{-T_f + \int_0^t d\sigma \frac{e^{-\Gamma(t-\sigma)}}{2\sqrt{\pi(t-\sigma)}} e^{-(\xi(t)-\xi(\sigma))^2/4(t-\sigma)} \left(-\dot{\xi}(\sigma)\right)\right\}. \tag{47}$$

Equation (47) will be solved on a nonuniform grid t_i with $t_0 = 0$. The grid will be chosen adaptively based on the size of $-\dot{\xi}(t)$ as described below. In order to solve for $\dot{\xi}(t_n)$ we split the integral in (47) into two parts,

$$\begin{aligned}\int_0^{t_n} d\sigma \frac{F(t_n,\sigma)}{2\sqrt{\pi(t_n-\sigma)}} &= \int_{t_{n-1}}^{t_n} d\sigma \frac{F(t_n,\sigma)}{2\sqrt{\pi(t_n-\sigma)}} + \int_0^{t_{n-1}} d\sigma \frac{F(t_n,\sigma)}{2\sqrt{\pi(t_n-\sigma)}} \\ &= I_n + S,\end{aligned} \tag{48}$$

where

$$F(t_n,\sigma) = e^{-\Gamma(t_n-\sigma)} e^{-(\xi(t_n)-\xi(\sigma))^2/4(t_n-\sigma)} \left(-\dot{\xi}(\sigma)\right),$$

and

$$I_n = \int_{t_{n-1}}^{t_n} d\sigma \frac{F(t_n,\sigma)}{2\sqrt{\pi(t_n-\sigma)}}, \qquad S = \int_0^{t_{n-1}} d\sigma \frac{F(t_n,\sigma)}{2\sqrt{\pi(t_n-\sigma)}}.$$

We approximate I_n by taking the average value of $F(t_n,\sigma)$ over the domain of integration ($t_{n-1} \le \sigma \le t_n$) to obtain

$$I_n \approx \frac{1}{2\sqrt{\pi}} \left[\frac{F(t_n,t_n) + F(t_n,t_{n-1})}{2}\right] \int_{t_{n-1}}^{t_n} \frac{d\sigma}{\sqrt{t_n-\sigma}}. \tag{49}$$

The computation of $F(t_n,t_{n-1})$ presents no difficulty but $F(t_n,t_n)$ must be treated in the limit as $\sigma \to t_n$,

$$\lim_{\sigma \to t_n} F(t_n,\sigma) = -\dot{\xi}(t_n)$$

so that

$$I_n \approx \frac{1}{2}\sqrt{\frac{h_n}{\pi}} \left\{-\dot{\xi}(t_n) + F(t_n,t_{n-1})\right\}, \tag{50}$$

where $h_n = t_n - t_{n-1}$. Substituting (50) into (47) yields

$$\ln\left(-\dot{\xi}(t_n)\right) = \frac{Z}{2}\sqrt{\frac{h_n}{\pi}} \left(-\dot{\xi}(t_n)\right) + Z\left\{-T_f + S_{n-1} + S\right\}, \tag{51}$$

where

$$S_{n-1} = \frac{1}{2}\sqrt{\frac{h_n}{\pi}} F(t_n,t_{n-1}).$$

Equation (51) is a transcendental equation of the form

$$\ln\left(-\dot{\xi}(t_n)\right) = m\left(-\dot{\xi}(t_n)\right) + b, \tag{52}$$

where

$$m = \frac{Z}{2}\sqrt{\frac{h_n}{\pi}}, \qquad b = Z\left\{-T_f + S_{n-1} + S\right\},$$

which must be solved at each timestep. We note that m is proportional to $\sqrt{h_n}$, the local timestep. For clarity we rewrite (52) as

$$H(w) = mw - \ln w + b = 0, \tag{53}$$

where $w = -\dot{\xi}(t_n)$. It is easy to see that $H(w)$ is minimized when $w = 1/m$ and that the value of the minimum is $1 + b + \ln m$. Thus, if

$$\ln m > -(1 + b),$$

there is no solution to (52) and the computation cannot continue. This typically occurs when $-\dot{\xi}$ is large and necessitates a reduction in the timestep.

Finally, we approximate S over the interval $0 \le \sigma \le t_{n-1}$ using the trapezoidal rule with nonuniform grid spacing,

$$S = \frac{1}{2\sqrt{\pi}} \int_0^{t_{n-1}} \frac{d\sigma}{\sqrt{t_n - \sigma}} F(t_n, \sigma) \approx \frac{1}{2\sqrt{\pi}} \sum_{i=1}^{n-1} h_i \frac{1}{2} \left(\frac{F(t_n, t_i)}{\sqrt{t_n - t_i}} + \frac{F(t_n, t_{i-1})}{\sqrt{t_n - t_{i-1}}} \right). \tag{54}$$

We have found that the exponentially decaying tail of the integral in S can be truncated with minimal loss of accuracy but significant savings in computational cost. We compute the sum in (54) starting with $i = n - 1$ and continuing to lower i until the relative change due to taking one additional term is less than 10^{-16}.

The solution is typically highly relaxational, with long periods of nearly quiescent behavior juxtaposed with brief periods of rapid variation, which are manifested by spikes in the front speed over very short time intervals. In order to address the relaxational behavior as well as to insure that the solvability condition described above for (52) will be satisfied, it is necessary to employ a timestep which varies in t according to the nature of the solution. Clearly, h_n should decrease as $|\dot{\xi}(t_n)|$ increases. We employed the following empirical formula to adjust the local timestep,

$$h_{n+1} = \min \left(\Delta t_0, \left(\frac{2\sqrt{\pi}}{Z \; A(-\dot{\xi}(t_n)^{3/2}} \right)^2 \right), \tag{55}$$

where A is a constant. The values $\Delta t_0 = 0.01$, as well as $A = 17$ for $Z = 4.12$ and $A = 12$ for $Z = 4.0$, were employed in the calculations presented in this paper. Finally, after solving for $\dot{\xi}$ at time t_n, ξ must be updated to t_{n+1}. This is done using the Adams–Bashforth method with nonuniform spacing,

$$\xi(t_{n+1}) = \xi(t_n) + h_{n+1} \left\{ \dot{\xi}(t_n) + \frac{1}{2} \frac{h_{n+1}}{h_n} \left(\dot{\xi}(t_n) - \dot{\xi}(t_{n-1}) \right) \right\}.$$

The initial condition for ξ is irrelevant since only differences in ξ appear in (45).

It is characteristic of the pulsating solutions in solid fuel combustion that they become increasingly relaxational in both space and time as parameters are pushed further into the nonlinear regime. Thus, a typical solution will propagate slowly for a long period of time exhibiting relatively gradual spatial and temporal variations in temperature, followed by a short period of rapid spatial and temporal variation. Therefore, computations require adaptive procedures in both space and time. The present method eliminates the spatial coordinate by restricting consideration to the motion of the interface. Thus, there is no longer a need for spatial adaptivity. Temporal adaptivity is still required as described above. Indeed, the relaxational behavior

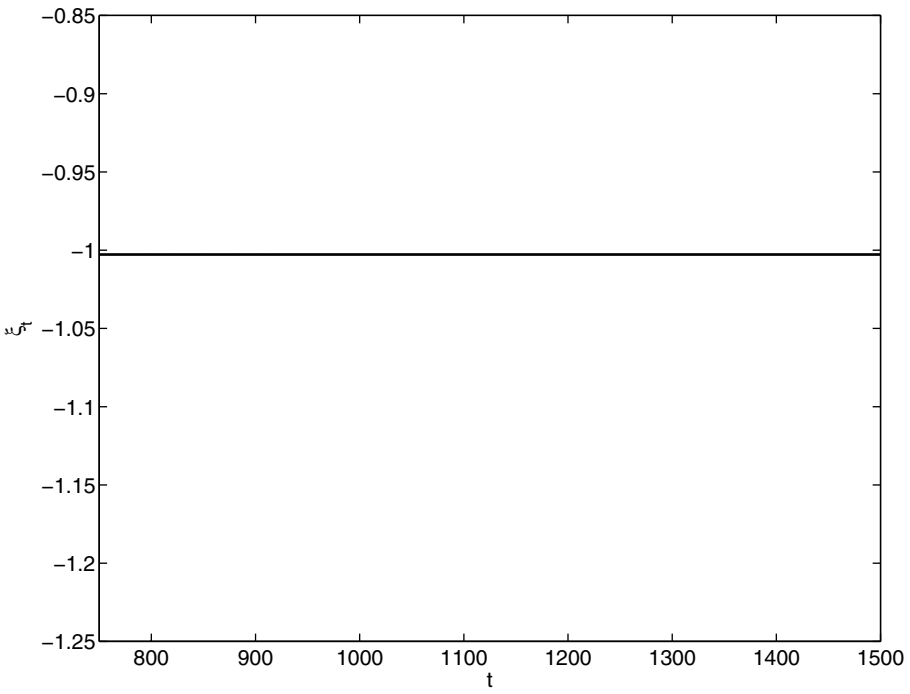

FIG. 4. *Uniformly propagating solution,* $Z = 4.12$, $\Gamma = 0.01$.

of the solution is enhanced, presumably due to the reaction sheet model employed for the kinetics rather than the distributed Arrhenius kinetics typically employed when the problem is solved as a system of partial differential equations. The cost of the present method is clearly in storage as the solution should in principle be stored for all values of time, due to the convolution nature of the integral in (45). We have addressed this issue to some extent by truncating the tail of the integral in S, as described above. Thus, employing the integrodifferential equation appears to be effective for the problem considered here. We note however, that the storage problem becomes more acute as Z is increased, since smaller timesteps are required. Finally, we note that our computations have been validated under timestep refinement.

6. Results. We employ the integrodifferential equation (45) governing the motion of the interface separating the fresh fuel and the burned products in a nonadiabatic solid flame to compute solutions in the form of a period doubling cascade as the heat loss Γ is increased toward extinction. We consider the Zeldovich number $Z = 4.12$, below the adiabatic ($\Gamma = 0$) pulsating stability limit $Z = 4.22$. Thus, for $\Gamma = 0$, the solution is uniformly propagating. In Figures 4–10 we plot the interface velocity $\dot{\xi}$ as a function of t for a sequence of increasing values of Γ.

Figure 4 shows a uniformly propagating solution for $\Gamma = 0.01$. Note that the computed value of ξ_t differs from the exact value $\xi_t = -1$ by less than 0.5%. In Figure 5 we show a $1T$ solution obtained for $\Gamma = 0.04$. In Figure 6 we show a $2T$ solution for $\Gamma = 0.053$. It is known that for period doubling cascades the intervals for each period doubling become progressively smaller. While we have not attempted to delineate these intervals, we show $4T$, $8T$ and $16T$ solutions in Figures 7–9. The corresponding values of Γ are $\Gamma = .05353$ ($4T$), $\Gamma = .053545$ ($8T$), and $\Gamma = .0535475$ ($16T$). We have not found $32T$ or higher period solutions. We assume that this is

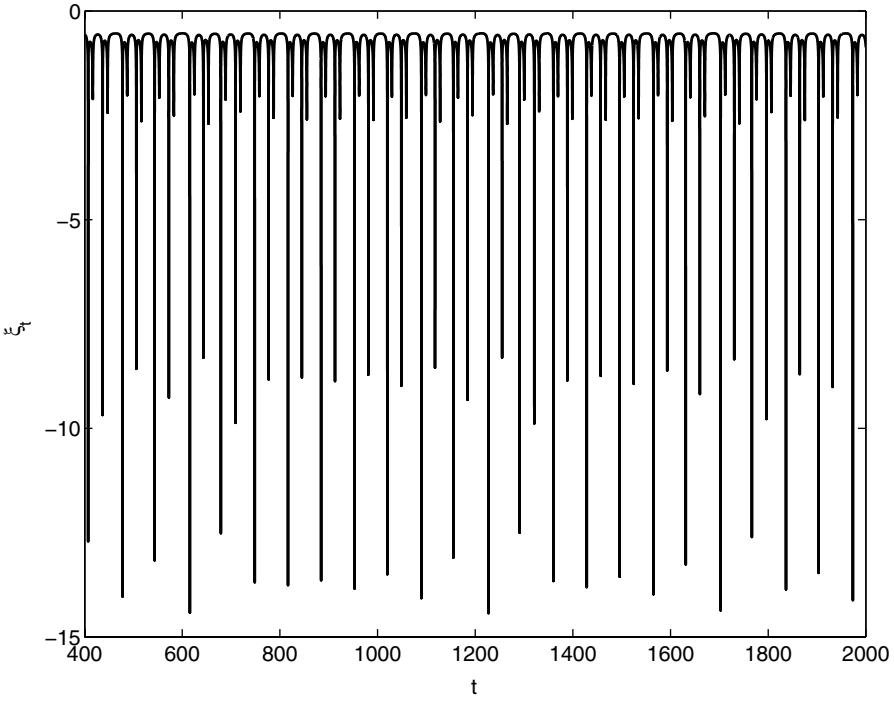

FIG. 10. *Apparently chaotic solution,* $Z = 4.12$, $\Gamma = 0.05355$.

due to the small intervals of existence of these solutions. We note the similarity of these figures to those obtained for adiabatic combustion in the pulsating regime as Z is increased (e.g., [3]). The solutions are highly relaxational with long periods of slow propagation interrupted by sharp spikes (in this case large negative velocities) corresponding to rapid propagation. The relaxational nature of the solution, i.e., the time duration of the spikes, becomes progressively smaller as Γ increases. We note that this relaxational behavior is not related to the period doubling cascade. Similar behavior was observed in [3] for a model with melting where the transition to chaos was via intermittency. The different dynamical behaviors are manifested by variations in the amplitudes of the spikes.

In Figure 10 we show an apparently chaotic solution for $\Gamma = 0.05355$ beyond the period doubling cascade. For period doubling cascades, windows of laminar behavior exist within the chaotic region, e.g., [18]. In Figures 11 and 12 we show the evolution in time and the return map, respectively, for the $12T$ solution found for $\Gamma = 0.0535522$. In Figure 13 we show the return map for the $24T$ solution found for $\Gamma = 0.05355236$. In Figures 14 and 15 we show blowups of the upper left and lower right regions of Figure 13. In Figure 16 we show the return map for the $48T$ solution, found for $\Gamma = 0.0535524$. In Figures 17 and 18 we show blowups of the upper left and lower right regions of Figure 16. Finally, in Figure 19 we show a chaotic solution for $\Gamma = 0.053553$, illustrating a return to chaos after the window of periodic solutions. We note that for this value of Z the extinction limit Γ_e lies in the interval $0.053555 \leq \Gamma_e \leq 0.053557$.

For smaller values of Z, though there are larger intervals in Γ prior to extinction (since $\Gamma_e = O(1/Z)$ is larger), the range of dynamical behavior is more limited since smaller Z is less unstable. Thus, we do not necessarily get a full period doubling

sequence followed by chaos. Rather, the sequence may be truncated after a finite number of periods. An extreme example of this occurs for $Z = 4.0$, where we find only $1T$ solutions for the full range of Γ that we have investigated up to extinction. In Figure 20 we plot the $1T$ solution for $\Gamma = 0.063453$, and in Figure 21 we show that for $\Gamma = 0.0634535$, the system attempts to establish a $2T$ solution. However, the $2T$ solution is apparently unstable, as the two spike amplitudes begin to diverge from one another and eventually the solution becomes extinct.

7. Summary. We derived an integrodifferential equation for the position of the interface in one dimensional nonadiabatic solid fuel combustion from the reaction sheet model. The equation permits computation of the dynamics of the reaction front without the necessity of spatial discretization for the temperature and mass fraction profiles thereby affording a savings in computational resources.

We computed solution behavior describing complex dynamics when the Zeldovich number Z is below the pulsating stability boundary. The control parameter employed is the heat loss coefficient Γ. For values of Z near the pulsating stability boundary we find that a cascade of period doublings occur as Γ increases, leading to chaotic behavior prior to extinction. Specifically, we compute T, $2T$, $4T$, $8T$ and $16T$ solutions as Γ increases. Beyond the $16T$ solution, we find a window of apparently chaotic behavior prior to extinction. Within the chaotic window, we find a subwindow corresponding to a period doubling sequence beginning with a $12T$ solution. Specifically, we compute $12T$, $24T$, and $48T$ solutions. Finally, for smaller values of Z, though there are larger intervals in Γ prior to extinction, the range of dynamical behavior is more limited since smaller Z is less unstable. Thus, we do not necessarily get a full period doubling sequence followed by chaos. Rather, the sequence may be truncated after a finite

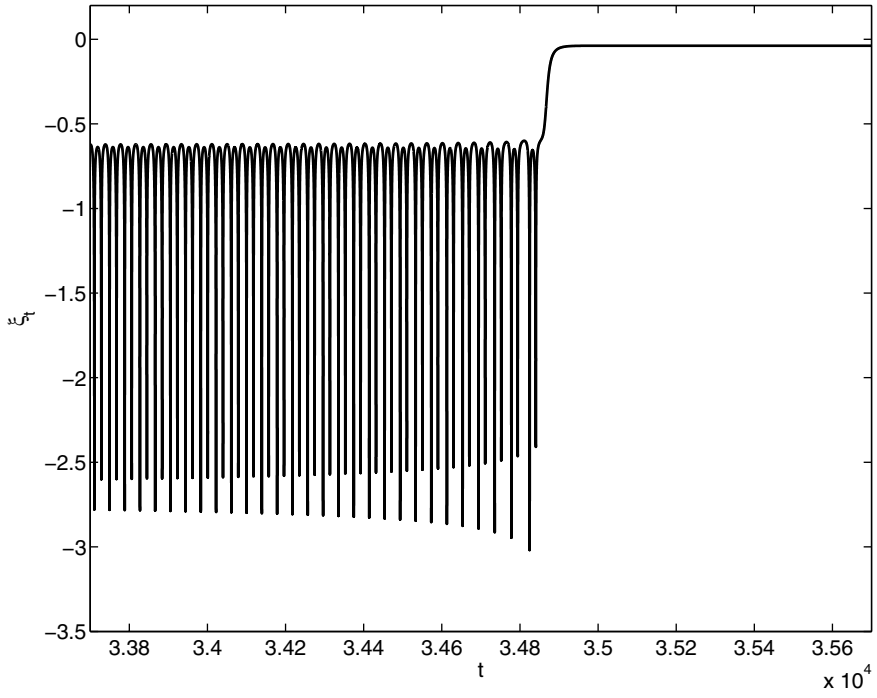

FIG. 21. *Evolution to extinction,* $Z = 4.0$, $\Gamma = 0.0634535$.

number of periods. In an extreme example of this, we find only $1T$ solutions for the full range of Γ that we have investigated up to extinction.

A MODEL FOR THE DYNAMICS OF LARGE QUEUING NETWORKS AND SUPPLY CHAINS*

D. ARMBRUSTER†, P. DEGOND‡, AND C. RINGHOFER†

Abstract. We consider a supply chain consisting of a sequence of buffer queues and processors with certain throughput times and capacities. Based on a simple rule for releasing parts, i.e., batches of product or individual product items, from the buffers into the processors, we derive a hyperbolic conservation law for the part density and flux in the supply chain. The conservation law will be asymptotically valid in regimes with a large number of parts in the supply chain. Solutions of this conservation law will in general develop concentrations corresponding to bottlenecks in the supply chain.

1. Introduction. This paper is concerned with the development and analysis of continuum models for supply chains. We consider a chain of M suppliers or processors $S_0, \ldots, S_{M-1}$. In the generic picture of a supply chain (see cf. [12] for an overview) each supplier processes a certain good (measured in units of parts) and passes it on to the next supplier in the chain. Labeling the parts by the index n, we denote by $\tau(m, n)$ the time at which part number n passes from supplier number $m-1$ to supplier number m. The goal of supply chain modeling and control is to derive rules governing the evolution of the times $\tau(m, n)$ and, in further consequence, to design such rules to, in some predefined sense, optimally manage the supply chain. There is a hierarchy of models available for this purpose. If the times $\tau(m, n)$ are used as primary variables, and therefore each part is considered individually, this leads to so-called discrete event simulation models (see [7] for an overview), which represent the most exact, and computationally most expensive, simulation tool. On the other end of the spectrum lie so-called fluid models, which replace the individual parts by a continuum and use rate equations for the flow of product through a supplier (see [1], [8] for an overview). For a large number of parts, fluid models are much less expensive but necessarily represent an approximation to the actual situation. As a compromise between the two extremes, so-called traffic flow models have received a lot of attention recently. The name derives from the analogy of the parts moving like cars on a highway and the use of a large already developed body of theory for modeling traffic flows. This theory employs the methodology of an even older and better developed theory, namely that of gas dynamics. So, discrete event simulation takes the place of particle based (i.e., Monte Carlo-type) models for gases, which can be approximated by the equations of gas dynamics (see [10] for an overview) and so on. The analogy is of course not one to one since the basic rules governing the parts

in a supply chain, the cars on a highway and the molecules in a gas, will be different [2], [3], [4], [6], [11], [16].

This paper is concerned with the derivation of a type of traffic flow model, namely a conservation law for a partial differential equation, out of very simple principles governing the evolution of the times $\tau(m,n)$. Given the times $\tau(m,n)$ conservation of the number of parts is expressed via the introduction of so-called N-curves (originally defined by Newell [17]). The N-curve $U(t)$ at supplier S_m is given by the number of parts which have passed from processor S_{m-1} to processor S_m at time t, i.e., by

$$U(m,t) = \sum_{n=0}^{\infty} H(t - \tau(m,n)), \tag{1}$$

where H denotes the usual Heaviside function. The flux from processor S_{m-1} into processor S_m is given by the derivative of $U(m,t)$, i.e.,

$$F(m,t) = \frac{d}{dt}U(m,t) = \sum_{n=0}^{\infty} \delta(t - \tau(m,n)), \quad m = 0, \ldots, M, \tag{2}$$

which holds with $F(0,t)$ and $F(M,t)$ the total influx and outflux of the supply chain. So N-curves are just the antiderivatives of fluxes. The work in progress (WIP) $W(m,t)$ of processor S_m, the total number of parts currently at the supplier S_m at time t, is now given by the difference of two consecutive N-curves, i.e.,

$$W(m,t) = U(m,t) - U(m+1,t) + K(m), \quad m = 0, \ldots, M-1, \tag{3}$$

where the time independent constants $K(m)$ are determined from the initial situation. Combining (2) and (3) yields the conservation law

$$\frac{d}{dt}W(m,t) = F(m,t) - F(m+1,t) \tag{4}$$

for the WIP $W(m,t)$ and the flux $F(m,t)$, both given in terms of the transition times $\tau(m,n)$. Note that in (4) $W(m,t)$ is a step function in time while $F(m,t)$ is a superposition of δ-functions. Furthermore, if each of the suppliers S_m has a given minimal processing time $T(m)$, $\tau(m+1,n) \geq \tau(m,n)+T(m)$ will hold, which implies, amongst other things, that the WIP $W_m(t)$ can never become negative. Fluid and traffic models replace the WIP W and the flux F by continuous functions and eliminate the dependence on individual parts, either by ad hoc assumptions, constitutive relations derived from stochastic queuing theory in a quasi-steady state (see cf. [9]), or via asymptotic methodology borrowed from the theory of gas dynamics [4], [5], [14], [15], [18]. In the simplest fluid models, the fluxes $F(m,t)$ in (4) are prescribed and the WIP's $W(m,t)$ are computed from F. Constraints have to be placed on the fluxes in order to guarantee nonnegative WIPs. This is usually done in a linear programming framework [19].

The basic concept of the approach presented in this paper is somewhat different. Rather than artificially constraining the fluxes, we will derive a continuum model which contains as an input parameter a service rate μ, and in which the WIP's $W(m,t)$ will always be nonnegative. The model is based on very simple assumptions, namely that each supplier functions as a single processor with a processing time T and a buffer queue in front of it. Based on this assumption, we derive, in a continuum limit,

a conservation law of the form

$$\partial_t \rho + \partial_x \min\left\{\mu, \frac{W}{T}\right\} = 0, \tag{5}$$

where the artificial continuous variable x indexes the suppliers and the $\rho(x,t)$ denotes the product density over x, i.e., $W = \int \rho\, dx$ holds. If the number of parts considered is very large, then solving the conservation law (5) is obviously much more effective than to directly compute the $\tau(m,n)$.

In contrast to previously presented approaches [2], [3], [4], [5], the approach in this paper is based on first principles. While purely fluid dynamic approaches rely on constitutive laws (usually for the equivalent of the pressure tensor [4]), we derive the conservation law (5) rigorously from a simple recursion of the arrival times $\tau(m,n)$.

This paper is organized as follows. In section 2 we define the basic rule governing the transition times $\tau(m,n)$, modeling one supplier in the chain as a processor with a given throughput time and a linear buffer queue in front of it. We heuristically derive simplified formulas to compute the WIP density ρ and the flux from the transition times. These formulas are simpler than (2) and (3), in the sense that they depend only locally on the $\tau(m,n)$. This will allow us to derive simple constitutive relations for the flux and WIP density leading to the conservation law (5). However, with this simple constitutive relation, the conservation law (5) will be satisfied only approximately. In section 3 we show that (5) is satisfied asymptotically in the limit for a large number of suppliers. The main difficulty here is that, as it turns out, the conservation law (5) will in general have only distributional solutions. $\rho(x,t)$ will develop δ-function concentrations, corresponding to bottlenecks in the supply chain. We will resolve this problem by instead deriving the corresponding hyperbolic equation for the N-function U in (1). This will also allow us to numerically compute the distributional solutions of (5) in a reasonable way. The assumption of a large number of nodes in the supply chain is actually unreasonable for many applications. In section 4 we remove this assumption by replacing one individual supplier with an arbitrary number of virtual suppliers, allowing us to pass to a continuum limit in almost every situation. Section 5 is devoted to numerical experiments. We demonstrate the asymptotic validity of the continuum model on two examples, one with only a few nodes in the supply chain where we utilize the concept of virtual suppliers, and one example of a long supply chain with randomly generated processing times and capacities.

2. The basic model. In this section we first define the basic rules governing the supply chain. We then give a more or less heuristic reasoning for a formula which expresses the flux and the density of parts locally in time, i.e., it is dependent only on differences of neighboring transition times τ, in what is essentially a large time regime. With these local formulas we derive in Theorem 1 a constitutive relation which expresses the flux in terms of the density. We first present the basic model for a single node in the supply chain. We assume that the node consists of a processor which processes parts at a rate μ. In front of this "machine" we assume a buffer queue, i.e., parts arrive at the end of the queue, wait until they reach the front, and then are fed into the processor. We denote by a_n, $n = 0, 1, \ldots$, the time part number n arrives at the end of the queue and by b_n the "release time," i.e., the time part number n, reaches the front of the queue and is fed into the processor. If the queue is full, the interval between two consecutive release times b_n will be given by the processing rate μ, i.e.,

$$b_n = b_{n-1} + \frac{1}{\mu}$$

will hold as long as $a_n \leq b_{n-1} + \frac{1}{\mu}$ holds, meaning that part number n has already arrived when we want to feed it into the processor. If, on the other hand, the queue is empty, i.e., if at the desired release time $b_{n-1}+\frac{1}{\mu}$ part number n has not arrived yet at the end of the queue, then we wait for its arrival and then immediately feed it into the processor. So, $a_n > b_{n-1} + \frac{1}{\mu}$ will imply $b_n = a_n$. This gives altogether the relation

$$b_n = \max\left\{a_n, b_{n-1} + \frac{1}{\mu}\right\}. \tag{6}$$

We assume that the processor takes a time T to finish the part and denote by $e_n = b_n + T$ the time the part leaves the processor (and enters the next queue). Inserting this relation into (6) gives

$$e_n = \max\left\{a_n + T, e_{n-1} + \frac{1}{\mu}\right\} \tag{7}$$

as the basic law relating the arrival times a_n to the exit times e_n. We now consider a chain of M suppliers $S_0, \ldots, S_{M-1}$ and denote with $\tau(m, n)$ the time part number n arrives at supplier S_m. Using the obvious change of notation $a_n \to \tau(m, n)$ and $e_n \to \tau(m + 1, n)$, we obtain from (7)

$$\begin{aligned}\tau(m+1,n) =& \max\left\{\tau(m,n) + T(m), \tau(m+1,n-1)\right.\\ &\left. + \frac{1}{\mu(m,n-1)}\right\}, \quad m = 0, \ldots, M_1,\ n \geq 1.\end{aligned} \tag{8}$$

Here $T(m)$ denotes the processing time of processor S_m, and we have made the processing rates μ time dependent, i.e., dependent on the part index n as well. The reason for the latter is that the service rates μ are used to control the supply chain. So, after part number $n - 1$ has been fed into processor S_m, we wait a time interval $\frac{1}{\mu(m,n-1)}$ before feeding in the next part. We assume that the processor belonging to the node S_m has a finite capacity $C(m)$, so

$$\mu(m, n) \leq C(m), \quad m = 0, \ldots, M - 1,\ n \geq 0 \tag{9}$$

has to hold, but otherwise the μ's can be chosen arbitrarily. The recursion (8) still needs initial and boundary conditions. They are of the form

$$\tau(0, n) = \tau^A(n), \quad n \geq 0, \quad \tau(m, 0) = \tau^I(m), \quad m = 0, \ldots, M.$$

$\tau^A(n)$ simply denotes the arrival time of part n in the first processor of the chain. The interpretation of $\tau^I(m)$ is somewhat more subtle. Obviously, $\tau^I(m)$ denotes the time the first part has arrived at supplier S_m. So, $\tau^I(m + 1) - \tau^I(m) - T(m)$ denotes the time the first part has waited in the buffer in front of the processor at S_m. Assuming a constant service rate μ in the past, $\mu(m, 0)[\tau^I(m + 1) - \tau^I(m) - T(m)]$ would be the number of parts in the queue at the time part number 0 arrives. This, in a sense, records the history of what has happened in the system before the first part went through and determines the queue length at the initial time. This somewhat awkward definition is necessitated by the fact that, for an actual simulation, we have to start somewhere. This issue will be resolved once the problem is formulated in terms of an approximate conservation law.

The goal of this paper is to asymptotically replace (8) by a conservation law with a simple constitutive relation. The rest of this section is devoted to considerations of what the appropriate form of the constitutive relation $F = F(W)$ in (4) should be. In the next section we will then show that with this relation, an equivalent of (5), holds in a weak sense. We start by redefining the flux. First, we map (4) onto a grid in an artificial spatial variable x, called the "degree of completion" (DOC). We define a mesh $0 = x_0 < \cdots < x_M = X$ and replace $F(m,t)$ by $F(x_m,t)$. So, parts enter the supply chain at the DOC $x = 0$ and leave at the DOC $x = X$. Next, we observe that, for an arbitrary test function $\psi(t)$,

$$\int_{\tau^I(m)}^{\infty} \psi(t)F(x_m,t)\ dt = \sum_{n=0}^{\infty} \psi(\tau(m,n))$$

holds. We rewrite this into a Riemann sum for an integral as

$$\int_{\tau^I(m)}^{\infty} \psi(t)F(x_m,t)\ dt = \sum_{n=0}^{\infty} \psi(\tau(m,n))\Delta_n\tau(m,n)f(x_m,\tau(m,n)), \tag{10}$$

where $\Delta_n\tau$ denotes the difference of $\tau(m,n)$ in the index n and the function $f(x,t)$ is given at $x = x_m$ and $t = \tau(m,n)$ as the reciprocal difference, i.e.,

$$\text{(a) } \Delta_n\tau(m,n) := \tau(m,n+1) - \tau(m,n), \quad \text{(b) } f(x_m,\tau(m,n)) := \frac{1}{\Delta_n\tau(m,n)} \tag{11}$$

holds. On a time scale, where $\Delta_n\tau$ is small, (10) becomes

$$\int_{\tau^I(m)}^{\infty} \psi(t)F(x_m,t)\ dt \approx \int_{\tau^I(m)}^{\infty} \psi(t)f(x_m,t)\ dt.$$

So (11)(b) will be the definition of our approximate flux f, which is given on the grid $\tau(m,n)$ for $x = x_m$. To find an approximate expression for the density ρ of parts per unit DOC, we consider the case when the arrival times τ would be distributed continuously, i.e., if they were given as a function $\tau(x,y)$. In this case (11)(b) would become $f(x,\tau(x,y)) = \frac{1}{\partial_y\tau(x,y)}$. The N-function $U(x,t)$, the antiderivative of the flux, would then satisfy the relations

$$\begin{aligned} &\text{(a) } \frac{d}{dy}U(x,\tau(x,y)) = \partial_t U(x,\tau)\partial_y\tau = 1, \\ &\text{(b) } \frac{d}{dx}U(x,\tau(x,y)) = \partial_x U(x,\tau) + \partial_t U(x,\tau)\partial_x\tau. \end{aligned} \tag{12}$$

Setting $\rho(x,t) = K(x) - \partial_x U(x,t)$ for an arbitrary function K, in analogy to (3), (12) becomes

$$\frac{d}{dx}U(x,\tau(x,y)) = K(x) - \rho(x,\tau) + f(x,\tau)\partial_x\tau.$$

Now (12)(a) implies that $\frac{d}{dx}U(x,\tau(x,y))$ is a function of the DOC variable x only, which we set equal to the arbitrarily chosen function $K(x)$. So, for a continuum $\tau(x,y)$ of arrival times, we set $f(x,\tau) = \frac{1}{\partial_y\tau}$ and $\rho(x,\tau) = \frac{\partial_x\tau}{\partial_y\tau}$. Direct calculus yields that, if so defined, ρ and f satisfy a conservation law of the form $\partial_t\rho + \partial_x f = 0$.

Motivated by this, we define the approximate density ρ and the approximate flux f from the arrival times τ by

$$\begin{aligned} &\text{(a) } \mathrm{f}(\mathrm{x_m}, \tau(\mathrm{m}, \mathrm{n})) = \frac{1}{\Delta_n \tau(m,n)}, \quad m = 0, \dots, M,\ n = 0, 1, \dots, \\ &\text{(13) (b) } \rho(x_m, \tau(m+1,n)) = \frac{\Delta_m \tau(m, n+1)}{h_m \Delta_n \tau(m+1, n)}, \quad m = 0, \dots, M-1,\ n = 0, 1, \dots, \\ &\text{(c) } \Delta_m \tau(m,n) := \tau(m+1,n) - \tau(m,n), \quad h_m := x_{m+1} - x_m. \end{aligned}$$

The density and flux defined by (13) are approximate in the sense that they will, as will be seen in section 3, satisfy an approximate or discretized version of the conservation law. However, the definition (13) allows us to derive a simple constitutive relation of the form $f = f(\rho)$. Under what circumstances ρ and f satisfy an approximate conservation law will be the subject of the next section. We have the following.

THEOREM 1. *Let the arrival times $\tau(m,n)$ satisfy the recursion* (8). *Let the approximate density ρ and flux f be defined by* (13). *Then the approximate flux can be written in terms of the approximate density via a constitutive relation of the form*

$$f(x_m, \tau(m,n)) = \phi_{mn}(\rho(x_{m-1}, \tau(m,n))), \quad m = 1, \dots, M,\ n \geq 0,$$

with the flux function ϕ_m given by

$$\phi_{mn}(\rho) = \min\left\{\mu(m-1,n), \frac{h_{m-1}\rho}{T(m-1)}\right\}. \tag{14}$$

The proof of Theorem 1 is rather lengthy and therefore deferred to the appendix.

The advantage of the approximative constitutive law (14) over the exact law given by (2) and (3) lies in the fact that it does not involve the transition times $\tau(m,n)$ anymore. The subject of the next two sections will be if, and in what sense, ρ and f will still satisfy a conservation law of the form $\partial_t \rho + \partial_x f = 0$.

3. Asymptotic validity of the conservation law. In this section we show that the approximate density ρ and flux f defined by (13) satisfy, in a certain sense, a conservation law of the form $\partial_t \rho + \partial_x f = 0$ asymptotically. The asymptotic regime we consider is one for a large number of nodes in the supply chain and for large time scales. The assumption of a large number of nodes is to some extent artificial and will be removed in section 4. As it turns out the limiting density ρ will in general not be a classical function but a distribution. We therefore show the asymptotic validity for the corresponding hyperbolic differential equation for the limiting N-curve U in (1).

3.1. Scaling and dimensionless formulation. We define by T_0 the average processing time, i.e.,

$$T_0 = \frac{1}{M} \sum_{m=0}^{M-1} T(m)$$

holds. So MT_0 would be the time for a part to be processed in the empty system, without waiting in any queue. This is chosen as the overall time scale, whereas we scale the individual processing times $T(m)$ and service rates $\mu(m,n)$ by T_0. Denoting scaled variables with the subindex s, this gives

$$\tau(m,n) = MT_0 \tau_s(m,,n), \quad T(m) = T_0 T_s(x_m), \quad \mu(m,n) = \frac{\mu_s(x_m, \tau_s(m+1,n))}{T_0}. \tag{15}$$

We will consider a regime where $M >> 1$ holds and will set $\varepsilon = \frac{1}{M} << 1$ from here on. With this scaling the recursion (8) becomes

(16)

$$\text{(a) } \tau_s(m+1,n+1) = \max\left\{\tau_s(m,n+1) + \varepsilon T_s(x_m), \tau_s(m+1,n) + \frac{\varepsilon}{\mu_s(x_m, \tau_s(m+1,n))}\right\}, m = 0,\dots,M-1,\ n = 0,1,\dots,$$

$$\text{(b) } \tau_s(0,n) = \tau_s^A(n), \quad n \geq 0, \quad \tau_s(m,0) = \tau_s^I(m), \quad m = 0,\dots,M,$$

where we have scaled τ^A and τ^I in the same way as $\tau(m,n)$. Also we have made grid functions out of the throughput times and processing times. We assume that the differences between two consecutive arrival times τ are of the same order as the average processing time T_0. This is reasonable since otherwise the total WIP would either go to zero or infinity. So we set

$$\Delta_n \tau(m,n) = \tau(m,n+1) - \tau(m,n) = T_0 \Delta_{ns} \tau_s(m,n),$$
$$\Delta_m \tau(m,n) = \tau(m+1,n) - \tau(m,n) = T_0 \Delta_{ms} \tau_s(m,n),$$

giving

$$\tau_s(m+1,n) = \tau_s(m,n) + \varepsilon \Delta_{ms} \tau_s(m,n), \quad \tau_s(m,n+1) = \tau_s(m,n) + \varepsilon \Delta_{ns} \tau_s(m,n).$$

In accordance with (13), we scale the density ρ and the flux f by

$$f(x,t) = \frac{1}{T_0} f_s\left(x, \frac{t}{MT_0}\right), \quad \rho(x,t) = \frac{M}{X} \rho_s\left(x, \frac{t}{MT_0}\right),$$

where X is the length of the DOC interval. This gives

(17)

$$\text{(a) } f_s(x_m, \tau_s(m,n)) = \frac{1}{\Delta_{ns}\tau_s(m,n)}, \quad m = 0,\dots,M,\ n = 0,1,\dots,$$

$$\text{(b) } \rho_s(x_m, \tau_s(m+1,n)) = \frac{\varepsilon X \Delta_{ms}\tau_s(m,n+1)}{h_m \Delta_{ns}\tau_s(m+1,n)}, \quad m = 0,\dots,M-1,\ n = 0,1,\dots,$$

as a definition for the scaled flux and density with $f_s, \rho_s = O(1)$. The scaled version of the constitutive relation (14) then reads

(18)

$$\text{(a) } f_s(x_m, \tau_s(m,n)) = \phi_s(x_{m-1}, \tau_s(m,n), \rho_s(x_{m-1}, \tau_s(m,n))),$$

$$\text{(b) } \phi_s(x_{m-1}, t, \rho_s) = \min\left\{\mu_s(x_{m-1}, t), \frac{h_{m-1}\rho_s}{\varepsilon X T_s(x_{m-1})}\right\}.$$

(18)(b) suggests a natural choice for the grid in x-direction, namely

(19)

$$h_m = \varepsilon X T_s(x_m) = \frac{XT(m)}{\sum_{m'=0}^{M-1} T(m')}, \quad m = 0,\dots,M-1,$$

which makes the propagation velocity in (18) equal to unity, i.e., we assign an interval in the DOC variable x to processor S_m which is proportional to its processing time. We will use this choice of the mesh from here on. Also, from now on we will drop the subscript s for simplicity.

3.2. Interpolation and weak formulation. We now proceed to show the asymptotic validity of a conservation law in the limit $\varepsilon \to 0$. The goal is an initial boundary value problem for a conservation law of the form

$$\partial_t \rho + \partial_x f = 0, \quad f = \min\{\mu(x,t), \rho\}, \quad f(0,t) = f^A(t), \tag{20}$$

together with some initial condition. There are several complications in this approach.

- First, the resulting initial boundary value problem cannot be defined on a strip in (x,t) plane but on a domain bounded by $t > \tau^I$. This is more of a notational inconvenience, but impacts the definition of initial conditions.
- From the original definition of the problem we cannot assume any kind of smooth relation between two consecutive processors, i.e., we cannot assume that the throughput times $T(x_m)$ and service rates $\mu(x_m,t)$, defined by (15), will converge to a smooth function in the limit $\varepsilon \to 0$. The limiting problem therefore has to be defined weakly.
- The most severe problem is that the flux function f can become discontinuous. This can be seen from the following consideration. Since we cannot assume any smooth relation between consecutive processors, we have to allow for the possibility of a sharp drop in the service rate μ, i.e., $\mu(x_m,t) > \mu(x_{m+1},t)$, which does not vanish in the limit $M \to \infty$. At this point we can easily construct a situation where $f(x_m,t) > \mu(x_{m+1},t)$ holds. Since $f(x_{m+1},t)$ is cut off by the min-function, the limiting flux f will have to be discontinuous. Because mass still has to be conserved, this discontinuity has to be compensated by a δ-function concentration in the density ρ at this point. This corresponds to a bottleneck situation, where we feed into a processor at a rate higher than its capacity over a significant period of time. Consequently, the queues will grow, which is expressed as a δ-function in the limit. This situation will actually occur right in the beginning of the supply chain if the boundary flux $f^B(t)$ is chosen larger than the capacity of the first processor.

We deal with the above problem by redefining our concept of a solution. Instead of deriving a conservation law for the density ρ we derive a hyperbolic equation for the limiting N-function U in (2). We denote its approximation by u, set $\rho(x,t) = -\partial_x u(x,t)$, and integrate (20) once with respect to x. This gives

$$\partial_t u = \min\{\mu(x,t), -\partial_x u\}, \quad \lim_{x \to 0-} u(x,t) = g^A(t), \quad \frac{d}{dt} g^A(t) = f^A(t). \tag{21}$$

Clearly, if the solution $u(x,t)$ is continuous and has a bounded x-derivative, we obtain a solution $\rho(x,t)$ of (20) by differentiating u with respect to x. However, (21) allows for shock solutions which result in δ-functions in the variable ρ. Although the x-derivative of u in this case becomes unbounded, the flux will remain bounded because of the min-function. ($-\partial_x u = \rho$ will always be bounded from below by zero.) We will therefore show that, in the limit $\varepsilon \to 0$, the N-function u satisfies a hyperbolic problem of the form (21) weakly in x and t. To do so, we first have to define the variables given on the nonuniform and nonrectangular mesh in (x,t) for continuous arguments by piecewise constant interpolation. For a given gridpoint x_m we first interpolate the

grid functions ρ and f defined by (17) in time direction by

$$\begin{aligned}
&\text{(a) } f_1(x_m,t) = f(x_m,\tau(m,n)), \quad \tau(m,n) \le t < \tau(m,n+1),\\
&\qquad\qquad m = 0,\dots,M-1,\ n \ge 0\\
&\text{(b) } \rho_1(x_m,t) = \rho(x_m,\tau(m+1,n-1)), \quad \tau(m+1,n-1) \le t < \tau(m+1,n),\\
&\qquad\qquad m = 0,\dots,M-1,\ n \ge 1,\\
&\text{(c) } f^A(t) = \frac{1}{\Delta_n \tau^A(n)}, \quad \tau^A(n) \le t < \tau^A(n+1).
\end{aligned} \tag{22}$$

Next we define the N-function $u(x_m,t)$ by

$$u_1(x_{m+1},t) = u_1(x_m,t) - \frac{h_m}{X}\rho_1(x_m,t), \quad m = 0,\dots,M-1, \quad u_1(x_0,t) = \int_{\tau(0,0)}^{t} f^A(s)\ ds. \tag{23}$$

Given the functions ϕ_1, u_1 which are now defined for continuous time and discrete space, we define the functions

$$\begin{aligned}
&\text{(a) } f_2(x,t) = f_1(x_{m+1},t), \quad x_m \le x < x_{m+1},\ m = 0,\dots,M-1,\\
&\text{(b) } \tau_2^I(x) = \tau^I(m+1), \quad x_m \le x < x_{m+1},\ m = 0,\dots,M-1,\\
&\text{(c) } u_2(x,t) = u_1(x_{m+1},t), \quad x_m \le x < x_{m+1},\ m = 0,\dots,M-1,
\end{aligned} \tag{24}$$

as functions of continuous space and time.

3.3. The limit $\varepsilon \to 0$. We can now show that the so defined interpolant u_2, f_2 satisfies a weak version of (21). We have the following theorem.

THEOREM 2. *Given the scaled density and flux at the discrete points $x_m, \tau(m,n)$, as defined in* (16)*, let the piecewise constant interpolant u_2 and f_2 be defined as in* (22)*. Let the scaled throughput times $T(x_m)$ stay uniformly bounded, i.e., $h_m = O(\varepsilon)$ holds uniformly in m. Assume finitely many bottlenecks for a finite amount of time, i.e., let $\Delta_m\tau(m,n)$ be bounded for $\varepsilon \to 0$ except for a certain number of nodes m and a finite number of parts n, which stays bounded as $\varepsilon \to 0$. Then, for $\varepsilon \to 0$ and $\max h_m \to 0$ the interpolated N-function and flux u_2, f_2 satisfy the initial boundary value problem*

$$\begin{aligned}
&\text{(a) } \partial_t u_2 = f_2, \quad t > \tau_2^I(x),\ 0 < x < X,\\
&\text{(b) } u_2(x,\tau^I(x)) = 0, \quad \lim_{x\to 0-} u_2(x,t) = \int_{\tau_2(0,0)}^{t} f^A(s)\ ds,
\end{aligned} \tag{25}$$

in the limit $\varepsilon \to 0$, weakly in x and t.

The proof of Theorem 2 is deferred to the appendix.

Remark. Theorem 2 establishes the asymptotic validity of the integrated conservation law (25)(a) for any N-curve u and any flux function f, derived from an arbitrary sequence τ via the definition (13) and the interpolation formulas (22) and (24). The constitutive relation $f_2 = \min\{\mu, -\partial_x u_2\}$ is a consequence of the recursion relation satisfied by the sequence $\{\tau(m,n)\}$ and, consequently, of Theorem 1.

Remark. In unscaled variables Theorem 2 implies that the density $\rho(x,t)$ can be approximately computed as $\rho = -\partial_x u$ where the unscaled N-function $u(x,t)$ is the solution of

$$\partial_t u = \min\left\{\mu_-, -\frac{X}{MT_0}\partial_x u\right\}, \quad 0 < x < X, \quad \lim_{x\to 0-} u(x,t) = \int_{\tau(0,0)}^{t} f^A(s)\ ds, \tag{26}$$

$$\mu_-(x,t) := \lim_{y \to x-0} \mu(y,t).$$

Remark. The assumptions of Theorem 2 state that the number of nodes in the supply chain is large, that the number of bottlenecks is small compared to the number of processors, and that each of the processing times is small compared to the overall throughput time, i.e., $T(m) << \sum_{m'=0}^{M-1} T(m')$ holds. At first glance, these assumptions might seem rather restrictive. We will remove these restrictions in the next section by introducing the concept of virtual processors, which will allow us to arbitrarily increase M.

3.4. An exact solution for a single bottleneck. To illustrate the dynamics induced by the conservation law (20), we compute an exact solution for the special case of a single bottleneck. Suppose (20) is posed on the interval $x \in [0,1]$, with a bottleneck at $x = \frac{1}{2}$, and we prescribe an arrival rate f^A which can be processed by the processors in front of the bottleneck but is larger than the capacity of the processors behind the bottleneck. So we have

$$\mu(x) = \begin{cases} \mu_1 & \text{for} \quad 0 < x < \frac{1}{2}, \\ \mu_2 & \text{for} \quad \frac{1}{2} < x < 1, \end{cases} \qquad \mu_2 < f^A(t) < \mu_1.$$

The solution $\rho(x,t)$ will then be given by a classical part $\rho_c(x,t)$, with a jump discontinuity at $x = \frac{1}{2}$, and a δ-function of the form $q(t)\delta(x - \frac{1}{2})$, compensating the jump in the fluxes. The classical part ρ_c will just satisfy a one way wave equation with constant velocity. So, we have

$$\partial_t \rho_c + \partial_x \rho_c = 0, \ x \in \left(0, \frac{1}{2}\right) \cup \left(\frac{1}{2}, 1\right), \quad \rho_c(0,t) = f^A(t), \quad \rho_c\left(\frac{1}{2}+, t\right) = \mu_2,$$

whose solution is given via characteristics by

$$\rho_c(x,t) = \begin{cases} f^A(t-x) & \text{for} \quad 0 < x < \frac{1}{2}, \\ \mu_2 & \text{for} \quad \frac{1}{2} < x < 1. \end{cases} \tag{27}$$

In order for the whole solution $\rho(x,t) = \rho_c(x,t) + q(t)\delta(x - \frac{1}{2})$ to be a spatially weak solution of the conservation law (20), we have to satisfy

$$\int_0^1 \phi(x)\partial_t \rho(x,t) - \min\{\mu(x), \rho(x,t)\}\partial_x \phi(x)\ dx = \phi(0) f^A(t) - \phi(1)\min\{\mu_2, \rho(1,t)\}$$

for any arbitrarily smooth test function $\phi(x)$. Integrating by parts separately on the intervals $(0, \frac{1}{2})$ and $(\frac{1}{2}, 1)$ gives

$$\begin{aligned} &\int_0^1 \phi(x)\partial_t \rho_c(x,t)\ dx + q'(t)\phi\left(\frac{1}{2}\right) + \int \phi(x)\partial_x \min\{\mu(x), \rho_c(x,t)\}\ dx \\ &- \min\left\{\mu_1, \rho_c\left(\frac{1}{2}-, t\right)\right\}\phi\left(\frac{1}{2}\right) + \min\{\mu_1, \rho_c(0,t)\}\phi(0) + \min\left\{\mu_2, \rho_c\left(\frac{1}{2}+, t\right)\right\}\phi\left(\frac{1}{2}\right) \\ &= \phi(0) f^A(t). \end{aligned}$$

Since $\rho_c(x,t) < \mu(x)$ will hold everywhere and $\rho_c(0,t) = f^A(t)$ holds, this reduces to

$$q'(t) = f^A\left(t - \frac{1}{2}\right) - \mu_2 = 0. \tag{28}$$

Thus, away from the bottleneck at $x = \frac{1}{2}$ the solution is given by (27), and the bottleneck produces a buildup of the queue (a δ-function in this framework) with strength (or queue length) q, which is governed by (28).

4. Virtual processors. As pointed out in section 3, the asymptotic validity of the differential equation (26) is given only for the case when the number M of processors is large and each of the individual processing times $T(m)$ is small compared to the total processing time $MT_0 = \sum_{m=0}^{M-1} T(m)$. So, it excludes cf. the situation where one processor takes up half of the overall processing time. In this section we will relax this restriction by introducing the concept of virtual processors. The basic idea is that one processor with a processing time T and a service rate μ can be replaced by K virtual processors with the same service rate μ and processing times $\frac{T}{K}$. Thus, we can make the total number of processors as large as we like, and the relative processing times as small as we like, by introducing enough virtual processors. The purpose of this section is to make this statement precise. Since, in doing so, we will keep the service rates μ constant but decrease the processing times T, eventual bottlenecks will occur only in the first virtual processor, and the queues of the additional virtual processors will always remain empty. Given the recursion formula (8), we therefore derive a condition for queues being always empty.

LEMMA 1. *Given the recursion* (8) *for the arrival times* $\tau(m,n)$*, let the arrival rate in node* S_m *be below the service rate* μ*, i.e., let*

$$\tau(m,n+1) - \tau(m,n) \geq \frac{1}{\mu(m,n)}, \quad n = 0, \ldots, \tag{29}$$

hold. Furthermore let the queue be empty at the arrival of the first part, i.e., let

$$\tau(m,1) + T(m) \geq \tau(m+1,0) + \frac{1}{\mu(m,0)} \tag{30}$$

hold. Then

$$\tau(m+1,n) = \tau(m,n) + T(m), \quad n = 1, \ldots,$$

holds.

Proof of Lemma 1. Define waiting time in the queue number m as $Q(m,n) = \tau(m+1,n) - \tau(m,n) - T(m)$. Inserting this into (8) gives

$$Q(m,n+1) = \max\left\{0, Q(m,n) + \tau(m,n) - \tau(m,n+1) + \frac{1}{\mu(m,n)}\right\} \tag{31}$$

as a recursion for the waiting times $Q(m,n)$. In particular,

$$Q(m,1) = \max\left\{0, \tau(m+1,0) - T(m) - \tau(m,1) + \frac{1}{\mu(m,0)}\right\} = 0$$

holds because of (30). Because of (29), the term $\tau(m,n) - \tau(m,n+1) + \frac{1}{\mu(m,n)}$ is always nonpositive and therefore the recursion (31) has the trivial solution $Q(m,n) = 0$ for $n \geq 1$. ∎

Lemma 1 will provide the basic tool to split a processor into K virtual processors. The basic building block of the underlying idea is to split one processor into two. Without loss of generality we perform this split on the first node in the supply chain. We have the following lemma.

LEMMA 2. *Let the flow of parts in processor* S_0 *be governed by*

$$\tau(1,n+1) = \max\left\{\tau(0,n+1) + T(0), \tau(1,n) + \frac{1}{\mu(0,n)}\right\}, \tag{32}$$

with $\tau(0,n),\ n \geq 0$ *and* $\tau(1,0)$ *given and satisfying the compatibility condition* $\tau(1,0) \geq \tau(0,0) + T(0)$. *We replace* (32) *by two virtual nodes with the same processing rates and the same total throughput time, i.e.,*

(33)

$$\text{(a) } \hat{\tau}(1,n+1) = \max\left\{\hat{\tau}(0,n+1) + \hat{T}(0), \hat{\tau}(1,n) + \frac{1}{\mu(0,n)}\right\},$$

$$\text{(b) } \hat{\tau}(2,n+1) = \max\left\{\hat{\tau}(1,n+1) + \hat{T}(1), \hat{\tau}(2,n) + \frac{1}{\mu(0,n)}\right\},$$

$$\text{(c) } \hat{\tau}(0,n) = \tau(0,n), \quad n = 0,1\ldots, \qquad \hat{\tau}(1,0) = \tau(1,0) - \hat{T}(1), \quad \hat{\tau}(2,0) = \tau(1,0),$$

holds with $\hat{T}(0) + \hat{T}(1) = T(0)$. *Then the system* (33) *produces the same outflux as the system* (32), *i.e.,* $\hat{\tau}(2,n) = \tau(1,n)\ n \geq 0$ *holds.*

Proof of Lemma 2. We show that the second virtual processor, i.e., the times $\hat{\tau}(1,n)$ and $\hat{\tau}(2,n)$, satisfy the assumptions of Lemma 1. Because of (33)(a)

$$\hat{\tau}(1,n+1) \geq \hat{\tau}(1,n) + \frac{1}{\mu(0,n)}, \quad n \geq 0,$$

holds, giving (29). To show (30) we note that

$$\hat{\tau}(1,1) + \hat{T}(1) \geq \hat{\tau}(1,0) + \hat{T}(1) + \frac{1}{\mu(0,0)} = \tau(1,0) + \frac{1}{\mu(0,0)} = \hat{\tau}(2,0) + \frac{1}{\mu(0,0)}$$

holds. Because of Lemma 1

$$\hat{\tau}(2,n) = \hat{\tau}(1,n) + \hat{T}(1), \quad n = 1,\ldots, \tag{34}$$

holds, and (34) trivially holds for $n = 0$ as well because of the initial condition (33)(c). We now eliminate $\hat{\tau}(1,n)$ by inserting $\hat{\tau}(1,n) = \hat{\tau}(2,n) - \hat{T}(1)$ into (33)(a) and obtain

$$\hat{\tau}(2,n+1) = \max\left\{\hat{\tau}(0,n+1) + T, \hat{\tau}(2,n) + \frac{1}{\mu(0,n)}\right\},$$

i.e., $\hat{\tau}(0,n), \hat{\tau}(2,n)$ satisfy the same difference equation and initial and boundary conditions as $\tau(0,n), \tau(1,n)$. □

By repeatedly using Lemma 2, we immediately obtain the following theorem, as a corollary.

THEOREM 3. *Let the first processor* S_0 *in the chain be governed by* (8). *If we replace the single processor by* K *virtual processors with the same processing rates and the same total throughput time, i.e., by*

$$\hat{\tau}(m+1,n+1) = \max\left\{\hat{\tau}(m,n+1) + \frac{T(0)}{K}, \hat{\tau}(m+1,n) + \frac{1}{\mu(m,n)}\right\}, \quad m = 0,\ldots,K-1,$$

$$\hat{\tau}(0,n) = \tau(0,n), \quad \hat{\tau}(m,0) = \tau(1,0) - \left(1 - \frac{m}{K}\right)T(0), \quad m = 1,\ldots,K,$$

then we obtain the same outflux, i.e.,

$$\hat{\tau}(K,n) = \tau(1,n),\ n \geq 0,$$

holds.

So, in order to create the conditions appropriate for the application of Theorem 2, we would proceed as follows:

1. Given the processing times $T(m)$, $m = 0, \dots, M-1$, cut each of the processors S_m, $m = 0, \dots, M-1$, into $K(m)$ virtual processors, such that $T_1 = \frac{T}{K}$ is roughly equidistributed, giving $M_1 = \sum_{m=0}^{M-1} K(m)$ virtual processors.
2. If the number of virtual processors M_1 is still too small for the asymptotic regime in Theorem 2 to be valid, cut each of the virtual processors into additional L subprocessors to arrive at $M_2 = LM_1$ total processors.

Clearly, the number M_2 of virtual processors can be made as large as we like. No additional bottlenecks are created by this procedure since μ remains constant within each virtual processor belonging to one real processor, and a bottleneck can occur only if there is a drop in the processing rate μ. So, the number of bottlenecks remains finite as $M_2 \to \infty$. There is, however, a limit to this process since we have used the average processing time T_0 also to scale the service rates μ in (15). So, sending $T_0 \to 0$ would result in the scaled service rates μ, and therefore also the fluxes, going to zero. To obtain a reasonable limiting problem we should choose M_2 and T_0 in such a way that $T_0 C_0 = O(1)$ holds, where C_0 is some characteristic value for the capacities, the bounds on μ in (9). So, with the introduction of virtual nodes in the supply chain, the results of section 3 really apply to the case when $C_0 M_2 T_0 = C_0 \sum_{m=0}^{M-1} T(m) >> 1$ holds. For a stochastic queuing model in a steady state, this is, according to Little's law (see cf. [13]), a measure of the number of parts in the system. So the hyperbolic equation (25) in Theorem 2 is asymptotically valid for a large number of individual parts, i.e., precisely in situations where continuum models are computationally more efficient than discrete event simulators.

5. Numerical experiments. In this section we conduct two numerical experiments to verify Theorem 2 by comparing the solution of the hyperbolic problem (26) with the direct solution of the recursion (8) for the transition times τ. In both cases we solve (8); compute the WIP W, the N-curve U, and the flux F according to (1), (2), and (3); and compare it to ρ, u, and f computed from the solution of the hyperbolic equation (26). The hyperbolic problem for the approximate N-curve u is solved via a standard finite difference scheme of the form

(35)

(a) $$u(x_m, t_{n+1}) = u(x_m, t_n) + \Delta t f(x_m, t_n), \quad m = 0, \dots, M, \quad \Delta t = t_{n+1} - t_n,$$

(b) $$f(x_m, t) = \begin{pmatrix} \min\{\mu(x_{m-1}, t), -\frac{X}{MT_0 \Delta x_{m-1}}[u(x_m, t) - u(x_{m-1}, t)]\} & m = 1, \dots, M \\ f^A(t_n) & m = 0 \end{pmatrix}.$$

For simplicity, we use constant time steps satisfying a CFL condition of the form $\Delta t \le \frac{MT_0}{X} \min\{\Delta x_m\}$. If the spatial meshsizes Δx_m of the discretization of the conservation law are chosen equal to the h_m in (19), i.e., if we assign one gridpoint to one node in the supply chain, this would give $\Delta x_m = \frac{XT(m)}{MT_0}$, $m = 0, \dots, M-1$, and a CFL condition $\Delta t \le \min\{T(m)\}$. While this seems a natural choice it is not a necessary one. In particular, in regions where the service rates μ vary slowly, a larger spatial meshsize might be appropriate. Regardless of the choice of the spatial mesh the node S_m in the supply chain will always occupy an interval of length h_m. The influx f^A is computed according (11)(b) by

$$f^A(\tau^A(n)) = \frac{1}{\tau^A(n+1) - \tau^A(n)}$$

and piecewise linear interpolation. Note, that the discretization (35) is equivalent to discretizing the conservation law directly, i.e., if we define the discretized density ρ by

$$\rho(x_m, t_n) = -\frac{u(x_{m+1}, t_n) - u(x_m, t_n)}{\Delta x_m}, \quad m = 0, \ldots, M-1,$$

the discrete equation (35) becomes

(36)

(a) $$\rho(x_m, t_{n+1}) = \rho(x_m, t_n) - \frac{\Delta t}{\Delta x_m}[f(x_{m+1}, t_n) - f(x_m, t_n)], \quad m = 0, \ldots, M-1,$$

(b) $$f(x_m, t) = \begin{pmatrix} \min\{\mu(x_{m-1}, t), \frac{X\rho(x_{m-1}, t)}{MT_0}\} & m = 1, \ldots, M \\ f^A(t_n) & m = 0 \end{pmatrix}.$$

So, the discretization (35) is equivalent to directly discretizing the conservation law for the density ρ, ignoring the issue of distributional solutions. Of course u in (35) will still be discontinuous at bottlenecks, and ρ in (36) will grow like $\frac{1}{\Delta x}$ at these gridpoints. The discretization (36) represents only the simplest first order upwinding scheme for the hyperbolic conservation law. One could of course solve the hyperbolic problem (26) by more sophisticated high resolution methods on a correspondingly coarser mesh. Since this paper is concerned with the model per se, we felt that using a higher order method would somehow cloud the issue of model properties by introducing the artifacts of the numerical method.

In the first example we consider a supply chain of 3 suppliers with throughput times $T(0) = 1, T(1) = 3, T(2) = 1$ time units and capacities $C(0) = 15, C(1) = 10, C(2) = 15$ parts per time unit. Setting the characteristic value for the capacity $C_0 = 10$, this gives a value of $C_0 M T_0 = 50 >> 1$ for the average number of parts in a steady state. Thus, we can create the regime of Theorem 2 by introducing virtual processors according to section 4. We split the nodes S_0 and S_2 into 10 virtual nodes each with capacities of 15 parts per unit time and node S_1 into 30 virtual nodes with capacities of 10 parts per unit time. All of the 50 virtual nodes now have a throughput time of 0.1 time units and, setting the length X of the DOC interval equal to unity, the original suppliers will occupy the intervals $[0, 0.2], [0.2, 0.8], [0.8, 1]$. We simply set the service rates μ equal to the capacities, giving

$$\mu(x, t) = \begin{pmatrix} 15 & \text{for} & 0 < x < 0.2 \\ 10 & \text{for} & 0.2 < x < 0.8 \\ 15 & \text{for} & 0.8 < x < 1 \end{pmatrix}.$$

We expect 2 possible bottlenecks, namely at $x = 0.2$, where the capacity drops, and possibly at $x = 0$ if the influx exceeds 15 parts per unit time. We first solve the recursion (8) for the transition times τ, starting with all empty queues, i.e., $\tau^I(m+1) - \tau^I(m) = T(m) = 0.1$ holds, and set $\tau^I(M) = 0$. We compute the arrival times randomly according to $\tau^A(n+1) - \tau^A(n) = \frac{1}{f^A(\tau^A(n))}$, $\tau^A(0) = \tau^I(0)$. To study the development of bottlenecks, we choose a function $f^A(t)$ as the influx rate, which is first below the minimum capacity $C(1) = 10$, then between the minimum and the maximum capacity 10 and 15, then above the maximum capacity, and finally drops back to its original value. We add a random perturbation to a piecewise constant function. The influx rate f^A is shown in Figure 1. We compute fluxes and densities from the recursion (8) and the discretized conservation law (36). Figure 2 shows the

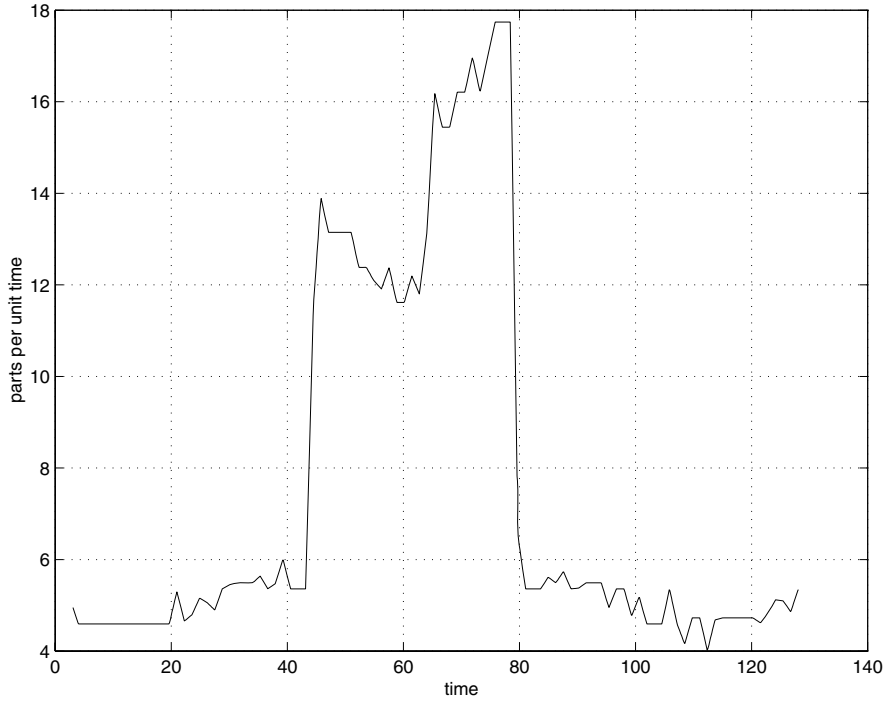

FIG. 1. *Influx.*

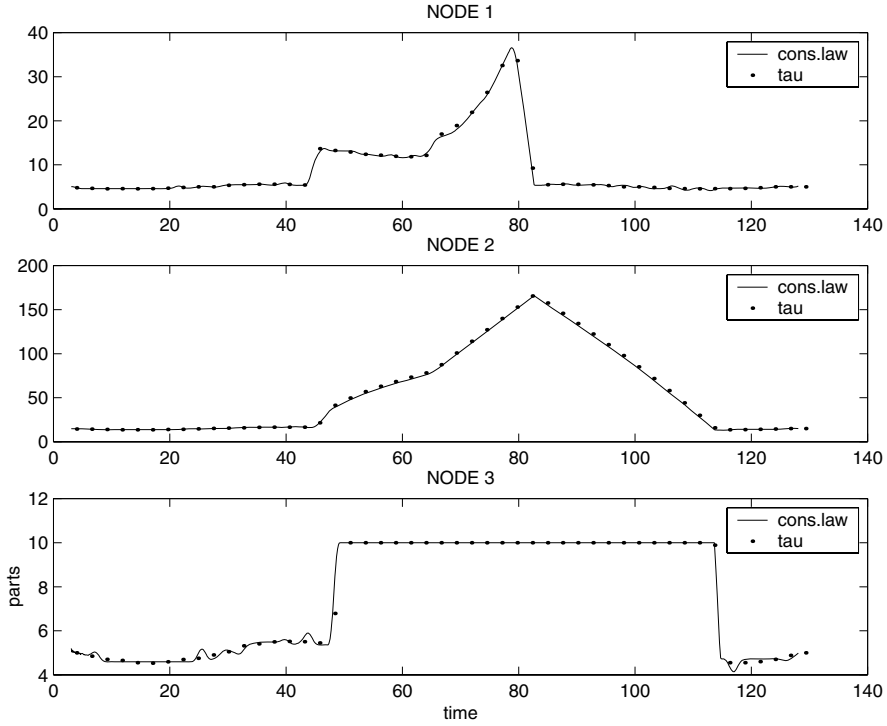

FIG. 2. *Work in progress.*

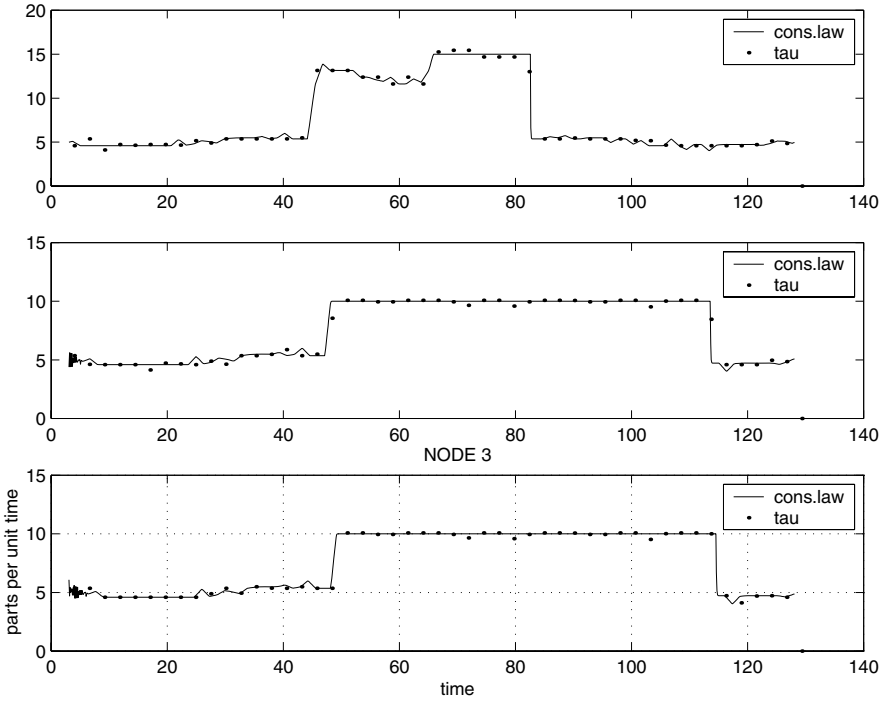

FIG. 3. *Outflux.*

corresponding WIP and Figure 3 shows the outflux of each node in the supply chain. The dots are computed from a time averaging of the solution of the recursion (8) for the transition times τ, and the solid line is computed from the conservation law (36). So, the WIP of node $S_0 m$ in the chain is computed as $\int_0^{0.2} \rho(x,t)\, dx$.

Figures 4, 5, and 6 depict the solution of the hyperbolic problem. Figure 4 shows the antiderivative of the density ρ in the DOC direction, i.e., $-u(x,t) + u(0,t)$, and Figure 5 shows the flux. As expected, we see bottlenecks, i.e., discontinuities, developing and vanishing again at $x = 0$ and $x = 0.2$. As long as the nodes in the supply chain work below capacity, i.e., as long as the governing equation is $\partial_t \rho + \frac{X}{MT_0} \partial_x \rho = 0$, we see the propagation of the fluctuations in the influx f^A through the system. As soon as the nodes go into saturation, i.e., as soon as $\partial_t \rho + \partial_x \mu$ holds, the solution becomes constant but develops discontinuities at the bottlenecks. Figure 6 shows the density ρ, which develops concentrations at $x = 0$ and $x = 0.2$, on a logarithmic scale.

As a second example, we consider a "long" supply chain with unstructured throughput times and capacities. We choose $M = 80$ and choose 80 random throughput times between $T = 1$ and $T = 5$ time units. For simplicity, we set $C(m) = \mu(m) = \frac{1}{T(m)}$, $m = 0, \ldots, M-1$. So each processor handles only 1 part per unit time, and we use the maximally possible relase rates μ. Figure 7 shows the corresponding mesh in the DOC variable $0 \le x \le X = 1$ and the capacities. So the meshsizes h_m are according to (19) randomly distributed. All the assumptions of Theorem 2 are satisfied, except that we cannot guarantee a relatively small number of bottlenecks, since

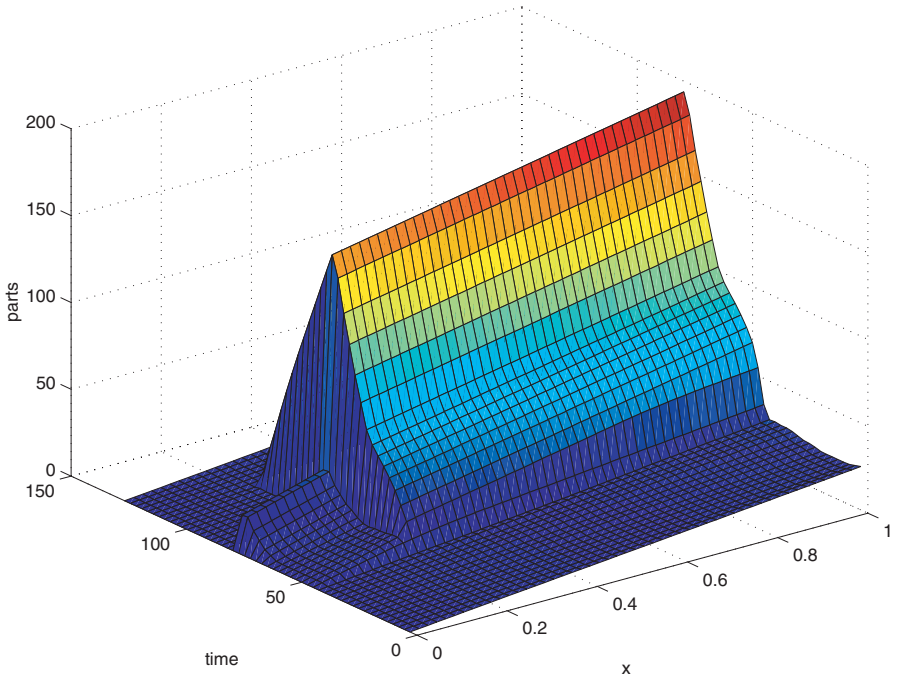

FIG. 4. N-*curve:* $u(0,t) - u(x,t)$.

the service rates μ now have an arbitrary number of significant drops. We choose $\Delta x_m = h_m$, i.e., we assign precisely one gridpoint per node for the numerical solution of the partial differential equation. Again, this goes beyond standard convergence theory since we do not resolve the rapidly varying function $\mu(x)$ in the continuous formulation. Figure 8 shows the influx and the outflux of the last node in the supply chain. Again, the dots denote the time averaged results computed from the recursion formula (8). The influx is chosen at and below the minimum capacity $C_{min} = 0.2$, with a spike at $t \approx 1500$. Figure 9 shows the corresponding total WIP of the whole supply chain. We observe almost perfect agreement although we have not resolved the service rate function $\mu(x)$ on the computational mesh. Figure 10 shows the density ρ on a logarithmic scale. We see the development of six bottlenecks. So, although the relationship between capacities of neighboring processors is completely random, the supply chain organizes itself to produce only a few bottlenecks and the assumptions of Theorem 2 are still satisfied.

6. Conclusions. We have derived a partial differential equation modeling a supply chain of arbitrary length with a large number of parts. Other than in similar approaches, this model is not based on some quasi-steady-state assumptions about the stochastic behavior of the involved queues, but rather on a simple deterministic rule for releasing parts from the buffer queues into the processors. The presented model incorporates the concept of the capacity of a processor in a natural way in a transient setting, while models based on queuing theory have to achieve this through a relation between throughput time and work in progress which is somehow extrapolated from the steady state situation. The model contains a distributed parameter (the service rates), which is constrained by the capacities, and can be used to control the behavior of the supply chain. It can be expected that relatively simple rules can be found governing these service rates which guarantee a certain behavior of the supply chain,

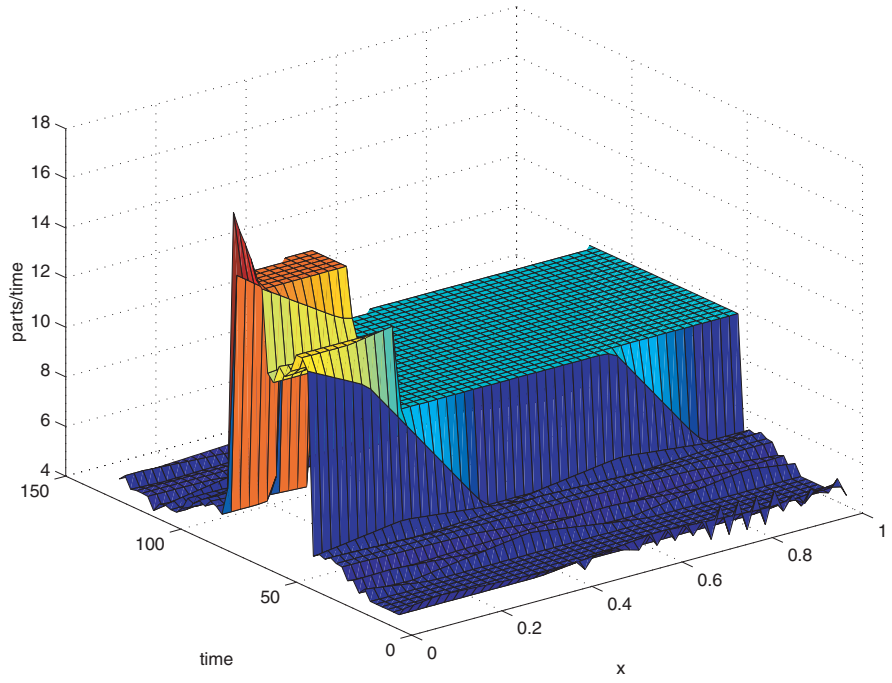

FIG. 5. *Flux* f.

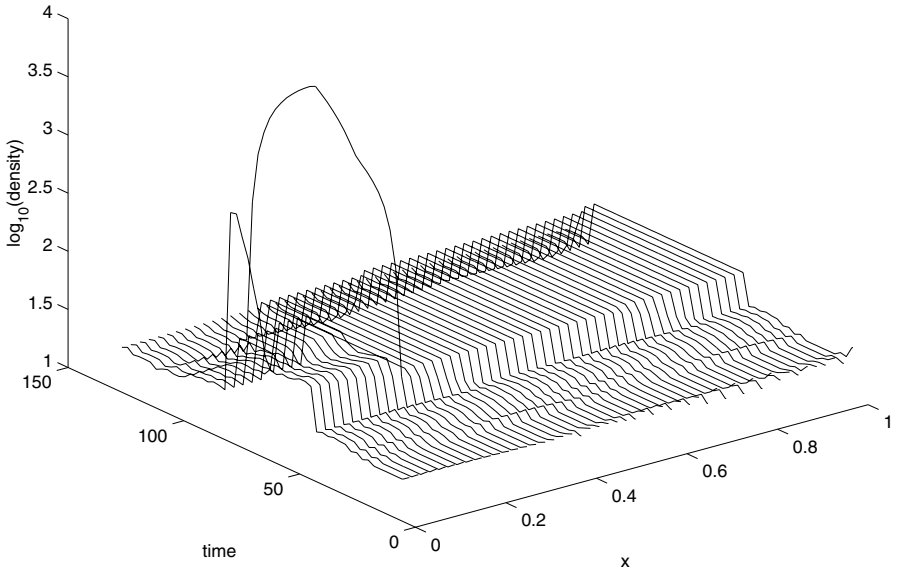

FIG. 6. *Density* ρ.

cf. the avoidance of bottlenecks.

7. Appendix.

Proof of Theorem 1. We first rewrite (8). Defining

$$\Delta_n \tau(m,n) := \tau(m,n+1) - \tau(m,n), \quad \Delta_m \tau(m,n) := \tau(m+1,n) - \tau(m,n),$$

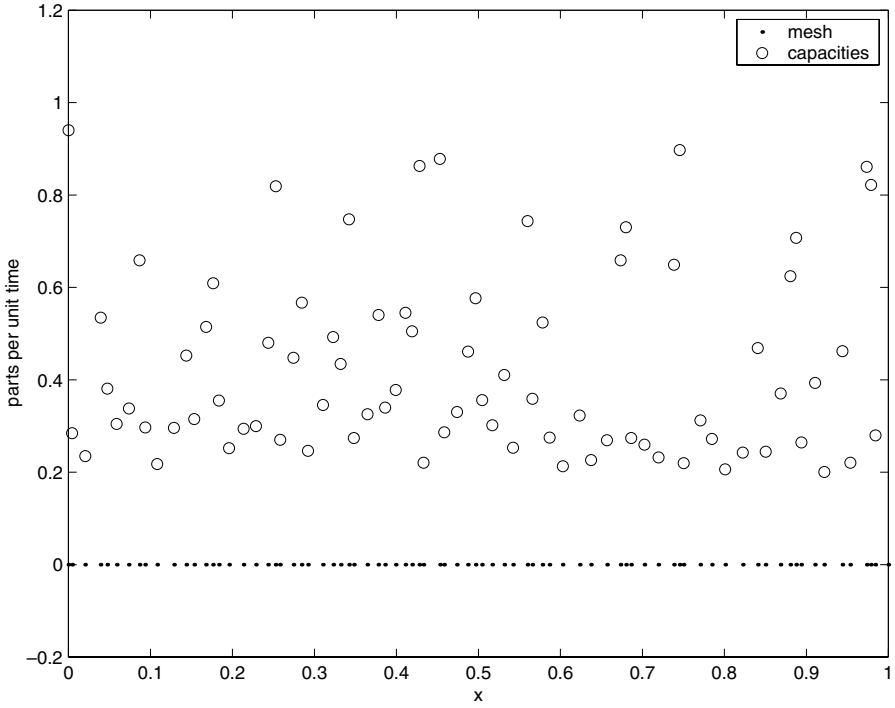

FIG. 7. *Mesh and capacities.*

(8) can be written as

$$0 = \min\left\{\Delta_m \tau(m-1,n+1) - T(m-1), \Delta_n \tau(m,n) - \frac{1}{\mu(m-1,n)}\right\}.$$

Using the definition (13) of ρ and f, this is equivalent to

$$0 = \min\left\{\frac{h_{m-1}\rho(x_{m-1},\tau(m,n))}{f(x_m,\tau(m,n))} - T(m-1), \frac{1}{f(x_m,\tau(m,n))} - \frac{1}{\mu(m-1,n)}\right\}.$$

To simplify the notation, we will drop the indices m and n and write the above as $\min\{\frac{h\rho}{f} - T, \frac{1}{f} - \frac{1}{\mu}\} = 0$. Furthermore, we will write this relation in the variable $z = \frac{1}{f}$. So we have to invert the function $\alpha(z,\rho)$, given by

$$y = \alpha(z,\rho) = \min\left\{h\rho z - T, z - \frac{1}{\mu}\right\}$$

as a function of z for any given parameter ρ, i.e., find a function $\beta(y,\rho)$ satisfying

$$y = \alpha(z,\rho) \quad \Longleftrightarrow \quad z = \beta(y,\rho).$$

If this is possible, then f is given in terms of ρ as $f = \frac{1}{\beta(0,\rho)} = \phi(\rho)$. There are two different cases to consider, namely the case $0 < h\rho < 1$ and the case $h\rho \geq 1$.

Case 1: $h\rho \geq 1$. In this case α is piecewise defined as

$$y = \alpha(z,\rho) = \begin{pmatrix} zh\rho - T & \text{for} & z < z_0 = \frac{T - \frac{1}{\mu}}{h\rho - 1} \\ z - \frac{1}{\mu} & \text{for} & z > z_0 \end{pmatrix}. \tag{37}$$

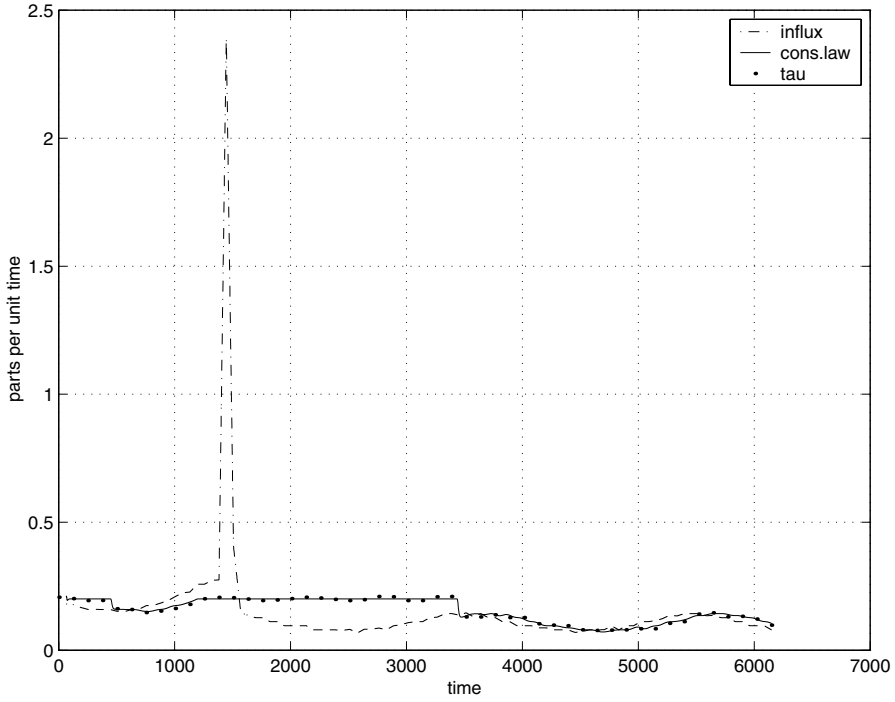

FIG. 8. *Influx and outflux.*

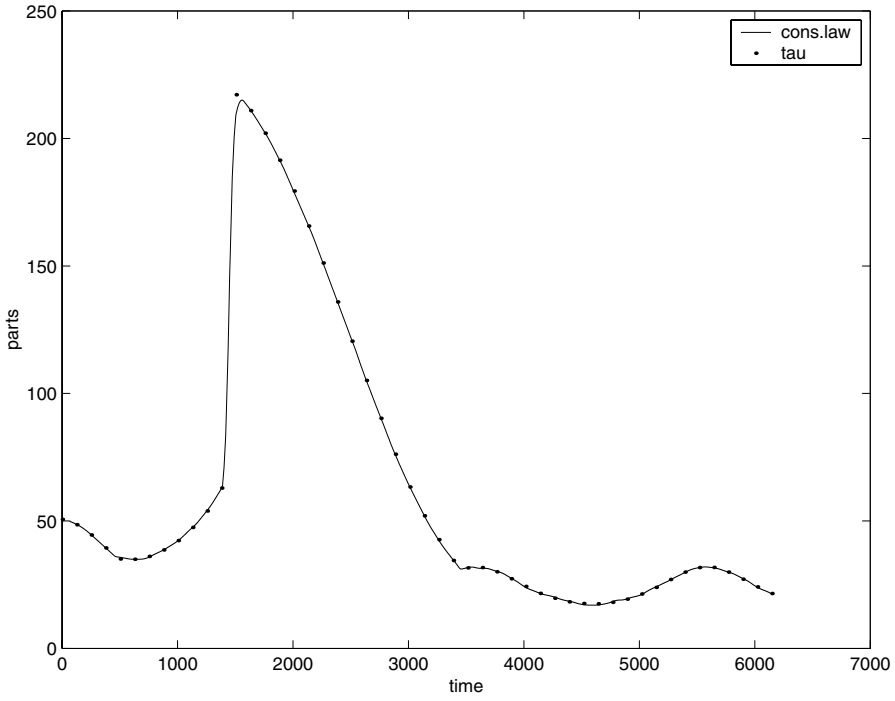

FIG. 9. *Total work in progress.*

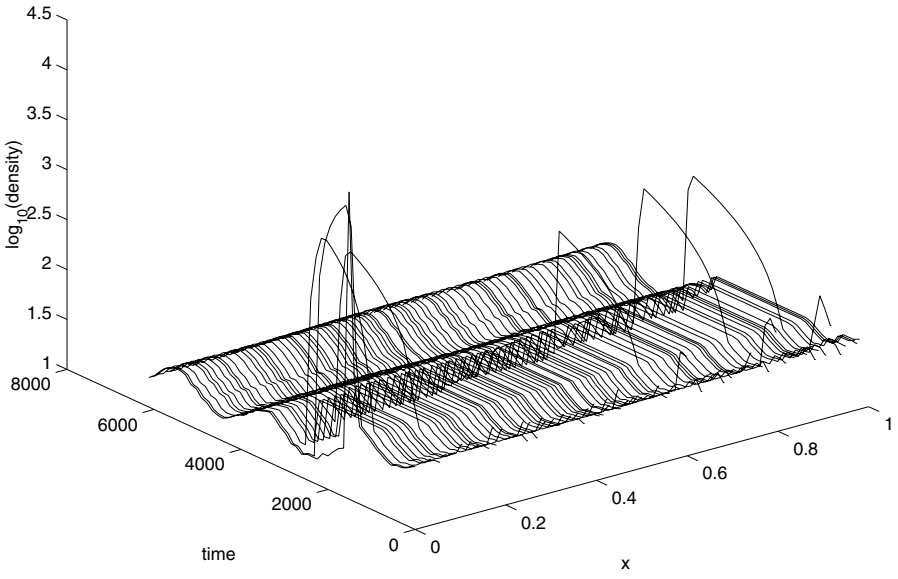

FIG. 10. *Part density* ρ.

(In the case $h\rho = 1$ the second case in (37) simply never occurs.) This monotonically increasing and piecewise linear function of z can be inverted as

$$z = \beta(y,\rho) = \begin{pmatrix} \frac{y+T}{h\rho} & \text{for} & y < y_0 := z_0 - \frac{1}{\mu} \\ y + \frac{1}{\mu} & \text{for} & y > y_0 \end{pmatrix}.$$

Evaluating β at $y = 0$ gives

$$\beta(0,\rho) = \begin{pmatrix} \frac{T}{h\rho} & \text{for} & 0 < y_0 = \frac{T - \frac{h\rho}{\mu}}{h\rho - 1} \\ \frac{1}{\mu} & \text{for} & 0 > y_0 \end{pmatrix} = \begin{pmatrix} \frac{T}{h\rho} & \text{for} & \frac{1}{\mu} < \frac{T}{h\rho} \\ \frac{1}{\mu} & \text{for} & \frac{1}{\mu} > \frac{T}{h\rho} \end{pmatrix} = \max\left\{\frac{1}{\mu}, \frac{T}{h\rho}\right\}.$$

Case 2: $0 < h\rho < 1$. In this case, we proceed in the same way obtaining the piecewise linear definition

$$y = \alpha(z,\rho) = \begin{pmatrix} z - \frac{1}{\mu} & \text{for} & z < z_0 = \frac{T - \frac{1}{\mu}}{h\rho - 1} \\ zh\rho - T & \text{for} & z > z_0 \end{pmatrix}$$

for the function α. Note, that the ranges for the linear pieces of α are now switched. Inverting α gives

$$z = \beta(y,\rho) = \begin{pmatrix} y + \frac{1}{\mu} & \text{for} & y < y_0 := z_0 - \frac{1}{\mu} \\ \frac{y+T}{h\rho} & \text{for} & y > y_0 \end{pmatrix},$$

and evaluating β at $y = 0$ gives

$$\beta(0,\rho) = \begin{pmatrix} \frac{1}{\mu} & \text{for} & 0 < y_0 = \frac{T - Dh\rho}{h\rho - 1} \\ \frac{T}{h\rho} & \text{for} & 0 > y_0 \end{pmatrix} = \begin{pmatrix} \frac{1}{\mu} & \text{for} & \frac{1}{\mu} > \frac{T}{h\rho} \\ \frac{T}{h\rho} & \text{for} & \frac{1}{\mu} < \frac{T}{h\rho} \end{pmatrix} = \max\left\{\frac{1}{\mu}, \frac{T}{h\rho}\right\}.$$

So, in both cases we obtain the same value for the inverse β evaluated at $y = 0$. Setting $\phi(\rho) = \frac{1}{\beta(0,\rho)}$ gives (14). ∎

Proof of Theorem 2. In order to avoid dealing with the boundary conditions, we extend the definition of the variables ρ, f, u, τ onto the whole real line $x \in \mathbb{R}$. We define

$$x_m = -mh_0 \text{ for } m \le -1, \quad x_m = X + (m-M)h_{M-1} \quad \text{for } m \ge M+1.$$

Next we extend the values of the arrival times τ for $m < 0$ and $m > M$. We set

$$\begin{aligned}
\tau^I(m) &= \tau^I(0) + mh_0, \quad m < 0,\\
\tau^I(m) &= \tau^I(M) + (m-M)h_{M-1}, \quad m > M,\\
\tau(m, n+1) &= \tau(m,n) + \varepsilon \Delta_n \tau^A(n), \quad m \le 0,\ n \ge 0,\\
\tau(m, n+1) &= \tau(m,n) + \varepsilon \Delta_n \tau(M,n), \quad m > M,\ n \ge 0.
\end{aligned}$$

With this definition the values of the flux function f_1 in (22) satisfy

$$f(x_m, \tau(m,n)) = \frac{1}{\Delta_n \tau(m,n)} = f^A(\tau(m,n)), \quad m < 0,\ n \ge 0,$$

and the corresponding interpolant f_2 in the continuous x-variable satisfies

$$\lim_{x \to 0-} f_2(x,t) = f^A(t). \tag{38}$$

Now we consider a compactly supported test function $\psi(x,t)$ and its discrete antiderivative Ψ given by

$$\Psi(x_m, t) = \sum_{m'=-\infty}^{m-1} h_{m'} \psi(x_{m'}, t), \quad \Psi(x_{m+1}, t) - \Psi(x_m, t) = h_m \psi(x_m, t). \tag{39}$$

Since ψ and Ψ are compactly supported in the time direction, we have for any fixed index n the trivial equality

$$\sum_{m=-\infty}^{\infty} [\Psi(x_{m+1}, \tau(m+1,n)) - \Psi(x_m, \tau(m,n))] = 0 \quad \forall n,$$

which we sum over the index n and multiply by ε, giving

$$0 = \varepsilon \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} [\Psi(x_{m+1}, \tau(m+1,n)) - \Psi(x_m, \tau(m,n))] = A - B,$$

and A and B are defined by

$$\begin{aligned}
\text{(a) } A &= \varepsilon \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} [\Psi(x_{m+1}, \tau(m+1,n)) - \Psi(x_m, \tau(m+1,n))]\\
&= \varepsilon \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} h_m \psi(x_m, \tau(m+1,n)),\\
\text{(b) } B &= \varepsilon \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} [\Psi(x_m, \tau(m,n)) - \Psi(x_m, \tau(m+1,n))].
\end{aligned} \tag{40}$$

We first estimate the spatial difference A. From the definition of the interpolant f_1 and the definition (17) of f, we have

$$\int_{\tau(m,n)}^{\tau(m,n+1)} f_1(x_m,t) = \varepsilon \Delta_n \tau(m,n) f(x_m, \tau(m,n)) = \varepsilon.$$

Inserting this into (40)(a) gives

$$\begin{aligned} A &= \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} h_m \psi(x_m, \tau(m+1,n)) \int_{\tau(m+1,n)}^{\tau(m+1,n+1)} f_1(x_{m+1},t)\ dt \\ &= \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} h_m \int_{\tau(m+1,n)}^{\tau(m+1,n+1)} \psi(x_m,t) f_1(x_{m+1},t)\ dt + O(\varepsilon) \\ &= \sum_{m=-\infty}^{\infty} h_m \int_{\tau^I(m+1)}^{\infty} \psi(x_m,t) f_1(x_{m+1},t)\ dt + O(\varepsilon), \end{aligned}$$

where we have committed an $O(\varepsilon)$ error by taking the test function ψ inside the integral. Because of the definition (24) of the interpolant f_2 in the spatial direction, the term $h_m f_1(x_{m+1},t)$ can be written as an integral with respect to x giving

$$A = \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} \psi(x_m,t) \left[\int_{x_m}^{x_{m+1}} H(t-\tau_2^I(x)) f_2(x,t)\ dx \right]\ dt + O(\varepsilon),$$

$$A = \int\int H(t-\tau_2^I(x)) \psi(x,t) f_2(x,t)\ dx dt + O(\varepsilon), \tag{41}$$

where we have committed another $O(\varepsilon)$ error by taking the test function ψ inside the x-integral. Here H denotes the usual Heaviside function.

Now, we turn to the term B in (40)(b). We replace the difference in the time direction by a partial derivative, giving

$$B = -\varepsilon^2 \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \partial_t \Psi(x_m, \tau(m+1,n)) \Delta_m \tau(m,n) + O(\varepsilon).$$

Again, we commit only an error of order $O(\varepsilon)$ in doing so, even if, according to the assumptions, a bounded number of the $\Delta_m \tau(m,n)$ is of order $O(\frac{1}{\varepsilon})$, since the test function Ψ will be bounded. We split the $n=0$ term in the sum and write

$$\begin{aligned} B = &-\varepsilon^2 \sum_{n=1}^{\infty} \sum_{m=-\infty}^{\infty} \partial_t \Psi(x_m, \tau(m+1,n)) \Delta_m \tau(m,n) \\ &-\varepsilon^2 \sum_{m=-\infty}^{\infty} \partial_t \Psi(x_m, \tau^I(m+1)) \Delta_m \tau^I(m) + O(\varepsilon). \end{aligned}$$

Clearly, the second term is of order $O(\varepsilon)$ again and can be neglected. Using the definition (17)(b) of ρ, we obtain

$$B = -\varepsilon \sum_{n=1}^{\infty} \sum_{m=-\infty}^{\infty} \frac{h_m}{X} \partial_t \Psi(x_m, \tau(m+1,n)) \rho(x_m, \tau(m+1,n-1)) \Delta_n \tau(m+1,n-1) + O(\varepsilon).$$

Now, we repeat essentially the same procedure used for the term A. From (17) and the definition of ρ_1 we obtain

$$\int_{\tau(m+1,n-1)}^{\tau(m+1,n)} \rho_1(x_m,t)\ dt = \varepsilon\Delta_n\tau(m+1,n-1)\rho(x_m,\tau(m+1,n-1))$$

$$\begin{aligned} B &= -\sum_{n=1}^{\infty}\sum_{m=-\infty}^{\infty} \frac{h_m}{X}\partial_t\Psi(x_m,\tau(m+1,n)) \int_{\tau(m+1,n-1)}^{\tau(m+1,n)} \rho_1(x_m,t)\ dt + O(\varepsilon) \\ &= -\sum_{m=-\infty}^{\infty} \frac{h_m}{X}\int_{\tau^I(m+1)}^{\infty} \partial_t\Psi(x_m,t)\rho_1(x_m,t)\ dt + O(\varepsilon). \end{aligned}$$

Using the definition of ρ_1 as the spatial difference of $-u_1$ gives

$$\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty} H(t-\tau^I(m+1))\partial_t\Psi(x_m,t)[u_1(x_{m+1},t)-u_1(x_m,t)]\ dt + O(\varepsilon).$$

Regrouping the terms in the above expression yields

$$\begin{aligned} B &= -\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty} H(t-\tau^I(m))\partial_t[\Psi(x_m,t)-\Psi(x_{m-1},t)]u_1(x_m,t)\ dt + O(\varepsilon) \\ &= -\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty} H(t-\tau^I(m))h_{m-1}\partial_t\psi(x_{m-1},t)u_1(x_m,t)\ dt + O(\varepsilon) \\ &= -\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty} \partial_t\psi(x_{m-1},t)\left[\int_{x_{m-1}}^{x_m} H(t-\tau_2^I(x))u_2(x,t)\ dx\right]\ dt + O(\varepsilon), \end{aligned}$$

giving altogether

$$B = -\int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty} \partial_t\psi(x,t)H(t-\tau_2^I(x))u_2(x,t)\ dx\right]\ dt + O(\varepsilon). \tag{42}$$

Combining (41) and (42) gives

$$\int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty} H(t-\tau_2^I(x))[\psi(x,t)f_2(x,t)+\partial_t\psi(x,t)u_2(x,t)]\ dx\right]\ dt = O(\varepsilon),$$

which, in the limit $\varepsilon\to 0$, is the weak formulation of

$$\partial_t u_2 = f_2,\ x\in\mathbb{R},\ t>\tau_2^I(x), \quad u_2(x,\tau^I(x)) = 0.$$

Because of the definition of $u_1(x_0,t)$ in (23) this is the solution of (25) on the interval $[0,X]$. □

STOCHASTIC MODELING AND SIMULATION OF TRAFFIC FLOW: ASYMMETRIC SINGLE EXCLUSION PROCESS WITH ARRHENIUS LOOK-AHEAD DYNAMICS*

ALEXANDROS SOPASAKIS† AND MARKOS A. KATSOULAKIS†

Abstract. A novel traffic flow model based on stochastic microscopic dynamics is introduced and analyzed. Vehicles advance based on the energy profile of their surrounding traffic implementing the "look-ahead" rule and following an underlying asymmetric exclusion process with Arrhenius spin-exchange dynamics. Monte Carlo simulations produce numerical solutions of the microscopic traffic model. Fluctuations play an important role in profiling observationally documented but, at the simulation level, elusive traffic phenomena. Furthermore, based on scaling and limit arguments we obtain a macroscopic description of this microscopic dynamics formulation which up to leading term of the expansions takes the form of integrodifferential Burgers or higher-order dispersive partial differential equations. We outline connections and comparisons of the hierarchical models presented here (microscopic, macroscopic) with other well-known traffic flow models.

Key words. traffic flow, look-ahead stochastic Arrhenius microscopic dynamics, Monte Carlo simulations

1. Introduction and overview.

Building on the idea presented in [61], a new modeling approach of traffic flow is developed, which, based on Arrhenius microscopic stochastic dynamics [66], is adapted to vehicular traffic. We construct an asymmetric single exclusion process (ASEP) whose dynamics include interactions with other vehicles ahead ("look-ahead" rule). The model has remarkable attributes and similarities when compared to known observed traffic behavior and is able to predict most of the widely accepted traffic states at the microscopic level.

Traffic states that are commonly observed by researchers at the microscopic level are quite complex and at times even chaotic [22, 28, 29]. Some of the major traffic states that are commonly observed at the microscopic level are free flow, congested flow, synchronized traffic, and wide moving jams. Free flow is easily recognized by the ability of drivers to attain their desired speeds under very little, if any, interaction with other vehicles. Congested flow, in contrast, is characterized by heavy vehicular interactions and usually very low flows. In general in the regime above some critical density ($\approx$20% jam density), we usually observe the most interesting microscopic vehicular traffic phenomena. Among them, the phenomenon of synchronized traffic, as recently observed [29], may occur when above critical density and displays complex behavior. Synchronized traffic usually occurs at on ramps when vehicles are added to an already crowded highway. Although the corresponding flows are widely scattered, synchronized traffic is characterized by high vehicle flows and at the same time increasing vehicle densities [22, 27]. It has been observed [23, 28] that synchronized traffic breaks down (known as the "break-down" phenomenon) with a variety of "stop-

and-go" traffic waves and occurrence of even more chaotic phenomena [22, 28, 15]. Meta-stability and hysteresis [65, 9] effects (as vehicle densities increase) may also be associated with this behavior. Last, the so-called wide moving jams are localized structures moving upstream and are characterized by long (widthwise) waves whose "fronts are shorter than their width" [58]. Naturally vehicle speeds change sharply through the two fronts making up the wide moving jam. As those waves travel slowly upstream vehicles are forced to interact with a number of them. Wide moving jams appear also at densities above critical density [27, 29]. In general vehicles first transition from free flow to synchronized flow and then later, at a different location, we observe the transition to a wide moving jam [27, 58].

Attempts to model vehicular traffic date as far back as 1932 [19]. At first such attempts were mainly empirical and emphasized fitting parameters to the particular conditions at hand. However it is generally agreed that the "parameters of the model should be intuitively easy to calibrate and the corresponding values should be realistic" [22]. As a result, modeling approaches evolved and a variety of models and new approaches emerged, ranging from car-following to gas-dynamic to hydrodynamic and more recently cellular automaton to counter this problem.

Car-following (or follow-the-leader) models [17, 16, 54, 12, 69] appeared as a way of obtaining equations which can be used in a wider context than their (empirical) predecessors. As the name denotes, car-following models describe traffic behavior based on the vehicle leading closely up front. In some of these models [67] vehicles try to converge to their preferred (following) distance, relative to the vehicle in the front, thus creating an oscillatory behavior due to imperfect perception [29]. Clearly these models are not suitable, or designed, for large traffic streams.

The emergence of gas-dynamics-like (mesoscopic) [31, 25, 23, 64, 60, 59] and hydrodynamic-like (macroscopic) [52, 68] traffic models starting in the 1960s produced partial differential equations which attempt to describe traffic parameters of interest such as the density, velocity, and flow at larger time and spatial scales, thus encompassing larger traffic streams. Among them the fundamental model of Lighthill and Whitham [42], reflecting conservation of vehicles, is prominent. In its diffusive version [68], assuming a linear type of equilibrium velocity-density relationship [19], $V_{equil} = V_{max}(1 - c/c_{max})$ it takes the form of the Burgers equation,

$$\frac{\partial g}{\partial t} + g\frac{\partial g}{\partial r} = D\frac{\partial^2 g}{\partial r^2}, \tag{1.1}$$

where $D > 0$ is a diffusion constant, $g = V_{max}\,(1 - 2c/c_{max})$, and c denotes the density. We refer to [24] for further comments and references.

Optimal velocity models [47, 2, 64] emerged at almost the same time as car-following models. Newell [54] was the first to propose the following formulation for the equation of motion:

$$\frac{dx_j(t+\tau)}{dt} = V(\Delta x_j(t)),$$

where $x_j(t)$ is the position of vehicle j at time t and τ is a delay time. Here $\Delta x_j(t)$ is the headway of vehicle j at time t while V denotes a known optimal velocity rule. It has been shown [48] that some such optimal velocity traffic models can also be interpreted through the well-known mass transfer problem. Optimal velocity models have been used [47, 48, 34] to derive some of the well-known nonlinear wave equations such as Burgers, KdV, and modified KdV. Solutions of those nonlinear

wave equations are subsequently shown [48, 47] to describe different traffic regions: free flow, metastable region, unstable region. For an extended review of optimal velocity models see further comments and references in [48] and [6].

More recently, with the help of faster computers, cellular automaton (CA) microscopic traffic models have produced promising results when compared to traffic observations of similar spatial and time scales. Von Neumann introduced CA in 1950 in his abstract theory to study the logical conditions for self-reproducing machines [7]. It was, however, first due to Conway's game of life and later Wolfram [62, 70], which made CA well known in the dynamical systems community. The now famous rule CA 184, which has been studied in detail as a surface growth [36] (see also [14] for more comments), is widely implemented in CA traffic models. Since then the concept of CA has been applied and extended to model a wide variety of systems [39, 45].

To our knowledge [6] the first CA model for vehicular traffic was introduced by Cremer and Ludwig [8]. However, it was due to the contributions of Nagel and Schreckenberg [50] that CA models became widely known in traffic modeling. A number of improvements [32, 33, 49, 3] have been proposed since the original Nagel–Schreckenberg CA model, which also introduced random effects. These effects are deemed to better predict chaotic behavior of observed traffic at the microscopic scale. More recently a new CA, coded CA 184a, has been proposed by Nelson for traffic flow [53]. Similarly, development of discrete models proposed by Li [44], allows essential features of traffic to be captured and a better description of complex nonlinear phenomena to be studied.

In this work we extend the usual lattice-gas dynamics to vehicles. Based on an underlying stochastic model we reproduce some of the observed behavior of vehicular traffic when scrutinized under similar temporal and spatial scales. We assume a one-dimensional periodic (single-lane loop highway) lattice while we refer to [11] for generalizations (two-lane highway with entrances and exits). We start by obtaining suitable interpretations of many of the usual parameters of Ising systems and in many instances absorb as many of those parameters as possible to adapt our model to vehicular traffic observations. Special attention must be exercised to the application of the proper microscopic stochastic dynamics. Spin-exchange (diffusion) dynamics are therefore implemented to enforce conservation of vehicles. Overall we introduce the ASEP [13, 35, 40], guaranteeing that vehicles do not occupy the same site. An added novelty of this model is that vehicles are forced to move toward one direction since the dynamics, depending on spatial forward Arrhenius interactions, implement one-sided potentials and a look-ahead feature which can be considered to represent driver behavior. A variety of ASEP models without look-ahead Arrhenius interactions have been studied in [18]. Numerically we implement a kinetic Monte Carlo algorithm simulating aperiodic, consecutive (not parallel) microscopic stochastic dynamics. Among its many features the proposed stochastic model is able to predict spontaneous jam formation, "slow to start" (retarded acceleration) [63], and timely braking [58].

We also obtain kinetic mesoscopic PDEs derived in suitable asymptotic limits from the microscopic model which predict traffic observables for the appropriate validity ranges of these equations. Up to leading order we obtain Burgers and/or dispersive-type PDEs. We outline several connections between the hierarchical macroscopic models obtained through our expansions and other well-known traffic flow models [68, 54, 47, 34, 48, 28] and equations [26] of similar form. We examine these features in detail.

We start with an overview and derivation of the full model and present the details of the dynamics comprising our stochastic process in section 2. We subsequently

calibrate the free parameters of the stochastic model and produce the fundamental diagram (an important traffic engineering flow-density relationship) and other relevant solutions for our model in the numerical Monte Carlo simulations in section 3. In section 4 we obtain deterministic limit closures of our stochastic microscopic model, thus obtaining mesoscopic and macroscopic PDEs and systems of finite difference equations. Numerical comparisons of those models are presented in the same section. Final remarks and conclusions can be found in section 5. In the appendix we analyze briefly actual and theoretical data-gathering techniques which are in general of fundamental importance for the comparisons carried out in this work and elsewhere.

2. ASEP with Arrhenius look-ahead dynamics. We propose here an ASEP specifically equipped with conservative Arrhenius dynamics including a novel look-ahead parameter L. As a result we obtain a microscopic traffic flow model and its corresponding semigroup generator while introducing the notation to be used and general underlying assumptions.

We start by defining our physical space on a one-dimensional, periodic lattice, representing a one-lane loop highway. We partition our lattice into N cells, $\mathcal{L} = \{1, 2, \ldots, N\}$. On each of the lattice points $x \in \mathcal{L}$ we define an order parameter $\sigma(x)$ via

$$\sigma(x) = \begin{cases} 1 & \text{if a vehicle occupies site } x, \\ 0 & \text{if site at } x \text{ is empty (no vehicle).} \end{cases} \tag{2.1}$$

A spin configuration σ is an element of the configuration space $\Sigma = \{0,1\}^{\mathcal{L}}$ and we write $\sigma = \{\sigma(x) : x \in \mathcal{L}\}$ denoting by $\sigma(x)$ the spin at x.

Similarly to the Arrhenius dynamics for Ising systems [66] we let the interaction potential (which here will dictate the local behavior of vehicles) have the form

$$U(x, \sigma) = \sum_{\substack{y \in \mathcal{L} \\ y > x}} J(y - x)\sigma(y), \tag{2.2}$$

where J denotes an anisotropic short range intervehicle interaction potential,

$$J(x, y) = \gamma V\left(\gamma(y - x)\right), \quad x, y \in \mathcal{L}, \tag{2.3}$$

where $\gamma = 1/(2L+1)$ is a parameter prescribing the range of microscopic interactions and therefore L denotes the potential radius. Note that (2.2) in effect implements the interactions with vehicles up to range L ahead of the vehicle at position x, thus enforcing the look-ahead rule. Physically since a vehicle (or cell) length is taken to be 22 feet, then the look-ahead rule which is enforced by (2.2) allows drivers to see traffic at a physical distance which is $L \cdot 22$ feet ahead of their vehicle. Specifically we let $V : R \to R$ and set

$$V(r) = 0, \quad r \in R^{-} \quad \text{and} \quad V(r) = 0 \quad \text{for} \quad r \geq 1.$$

Note that the interaction potential $U(x)$ could be further enriched with the addition of an external potential h. This potential $h \equiv h(x, t)$ could vary in space but also time if so desired to account for temporal and spatial traffic situations (i.e., rush hour traffic).

There are several different choices for dynamics which we can employ: Arrhenius, Metropolis, Kawasaki, etc. We implement spin-exchange Arrhenius dynamics. Under this engine the simulation is driven based on the energy barrier a particle has

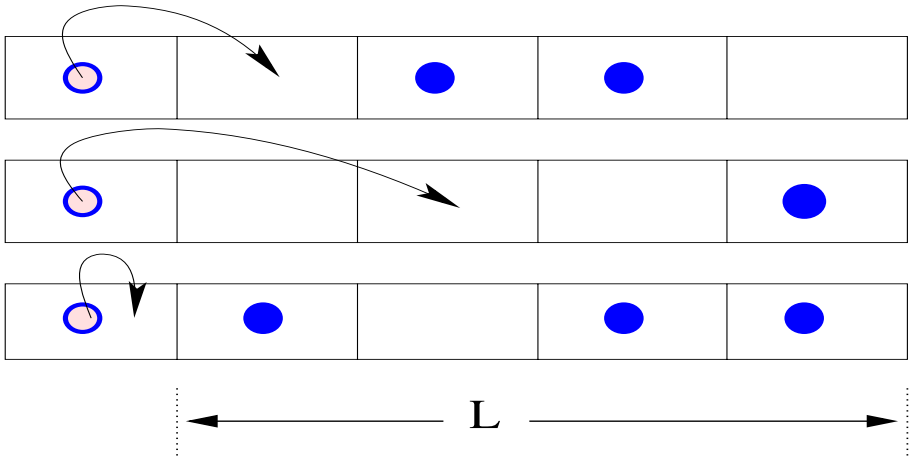

FIG. 1. *Simple schematic of the look-ahead rule (for $L = 4$ cells) pertaining to vehicle motion in the lattice for three different traffic examples. The process automatically simulates effects such as braking, acceleration, and simple exclusion rule through the interaction potential $U(x, \sigma)$ (2.2) for the provided range, L.*

to overcome in changing from one state to another. This energy barrier is found by calculating the potential energy of each vehicle based on (3.1) and performing a move only if that energy is higher than a given threshold. (Note that these dynamics are different from the usual Metropolis dynamics, where a move is encouraged whenever the energy difference between the current position and the new position is high enough.)

During such a spin-exchange between nearest neighbor sites x and y the system will actually allow the order parameter $\sigma(x)$ at location x to exchange value with the one at y. This is interpreted as advancing a vehicle from the site at x to the empty site at y. Note that based on the construction of our potential U it is not possible to move from an occupied site to another occupied cite; see Figure 1. In general, the rate at which a process will do this for spin-exchange Arrhenius dynamics is

$$c(x, y, \sigma) = \begin{cases} c_0 \exp[-U(x, \sigma)] & \text{if } y = x + 1, \text{ and } \sigma(x) = 1, \ \sigma(y) = 0, \\ & \text{if } \sigma(x) = 0 \ \ \sigma(y) = 1, \\ 0 & \text{otherwise} \end{cases} \tag{2.4}$$

The parameters comprising the dynamics here are

$$c_0 = 1/\tau_0 \tag{2.5}$$

with τ_0 the characteristic or relaxation time for the process and $U(x, \sigma)$ as in (2.2).

Overall given (2.4) and the dynamics just described the probability of spin-exchange between x and y during time $[t, t + \Delta t]$ is

$$c(x, y, \sigma)\Delta t + O(\Delta t^2). \tag{2.6}$$

Clearly for one-lane traffic y corresponds to either $x - 1$ or $x + 1$ in (2.4). Note that the exchange, due to the specific construction of the interaction potential J in (2.3), can take effect if and only if the location at x is occupied while the location at y is not. A simple schematic of the lattice and some simple interactions are provided in Figure 1. At the same time, vehicles are restricted (exclusion rule) with performing

an exchange move backward—an unrealistic move for vehicular traffic—by definition of the dynamics (2.4). Note we do not allow backward moves at all since they are not part of the dynamics.

In summary this model is determined by the characteristic time, interaction strength, and look-ahead

$$\tau_0, J_0 \text{ and } L,$$

respectively, and driven by our Arrhenius dynamics stochastic process $\{\sigma_t\}_{t\geq 0}$ with rate (2.4).

The parameter c_0 will allow us to set the maximum speed of vehicles (which we do in the calibration section (3.1)) while the other parameters L and J_0 will be chosen appropriately based on known traffic behavior or other physical constraints which we present in our numerical investigations.

More rigorously we can define the generator for this stochastic process $\{\sigma_t\}_{t\geq 0}$. Let f be an arbitrary test function defined on $L^\infty(\Sigma)$, where Σ is the configuration space $\Sigma = \{0,1\}^{\mathcal{L}}$. Then the generator, M, of the process is defined,

$$Mf(\sigma) = \sum_{x\in\mathcal{L}} c_0\sigma(x)(1-\sigma(x+1))\exp(-U(x,\sigma))[f(\sigma^{x,x+1}) - f(\sigma)] \tag{2.7}$$

with c_0 from (2.5) and

$$\sigma^{x,x+1} = \begin{cases} \sigma(y), & y \neq x, x+1, \\ \sigma(x+1), & y = x, \\ \sigma(x), & y = x+1, \end{cases}$$

denotes an exchange of the spins between locations x and $x+1$. We refer to [40, 41] for background on generators and exclusion processes.

3. Monte Carlo simulations and benchmarks. We now present numerical implementations of the microscopic stochastic traffic flow model derived in section 2. We start by physically interpreting the nondimensional model variables and subsequently calibrating our model for the free parameters τ_0, J_0 and L with respect to well-known quantities from real traffic data. Last, as a basic benchmark, we also obtain the fundamental diagram corresponding to the flow-density relationship dictated by our model.

In the simulations we choose a simple constant potential of the form

$$V(r) = \begin{cases} J_0 & \text{if } 0 < r < 1 \\ 0 & \text{otherwise} \end{cases} \quad \text{for} \quad J_0 > 0, \tag{3.1}$$

where J_0 is a parameter which based on its sign describes attractive repulsive or no-interactions. In our simulations we implement $J_0 > 0$, which implies that vehicles are attracted by the empty space in front of them. Note that (3.1) imposes only forward interactions and the dynamics (2.4) do not allow for backward moves. Thus vehicles move toward the empty space in the highway with an exclusion rule since we allow only one vehicle per site; see Figure 1. We have therefore created an ASEP [35] with interactions in one direction. In fact, the proposed dynamics reduce to an ASEP-type evolution if a particle/vehicle does not have any other vehicles in front of it beyond the interaction radius L in (2.3). In our numerical simulations we implement piecewise constant ($J_0 = 1$), short-range local interactions. However, we can also impose a V, in the form of a one-sided Maxwellian, which could be more realistic.

We let the actual physical length of each cell to be 22 feet. This allows for the average vehicle length plus safe distance. Therefore for a vehicle which has an average speed of 65 miles per hour we obtain a natural estimate of time to cross a cell,

$$\Delta t_{cell} = \frac{22 \text{ feet}}{65 \text{ miles/hour}} \approx \frac{1}{4} \text{ sec.} \tag{3.2}$$

In this work we start by modeling an infinite length road (ring road) with no entrances or exits so as to observe certain known traffic behavior and compare with other similar works [50].

Given the (one-sided) structure of the potential (2.2) we allow vehicles (or drivers) to be able to perceive traffic forward of their position up to a possible distance (look-ahead) of four cells or up to 88 feet—vehicle lengths plus safe distance. This is automatically implemented in the calculation of the interaction potential (2.2) and therefore plays a decisive role in the decision for making a move to a new location ahead through (2.4) and subsequently (2.6). However, we have also run simulations (not presented here) with a look-ahead of three and two vehicle lengths for comparison purposes. Further remarks regarding the influence of the look-ahead parameter can be found in section 4.4 and especially Figure 9.

We implement a kinetic Monte Carlo (KMC) simulation based on [4]. We refer to [61] for details on how the spin-exchange Arrhenius dynamics algorithm is applied. As expected, a KMC algorithm produces no null steps and therefore every iteration is a success. In that respect our KMC algorithm continues to choose and move vehicles at every step by skipping the idle waiting which occurs in usual Monte Carlo simulations and simply adjusting the simulation time by the appropriate amount, as if it had waited for that long. This is quite useful for the cases of high densities of vehicles or even more generally when a process reaches equilibration.

3.1. Calibration and validity. We start by calibrating our code through the free parameters J_0 and τ_0 by simulating a free-flow regime where we expect all vehicles to drive at their desired speed. We set such a speed to be 65 miles per hour. This is accomplished by the characteristic time τ_0, which allows us to calibrate the maximum velocity at which vehicles would like to drive assuming no other vehicles up front. Naturally, due to the stochasticity inherent in our simulation some vehicles will drive faster while some slower than the set limit of 65 miles per hour. As pointed out earlier the free parameter J_0 indirectly influences how drivers react to conditions in front of them and subsequently allows us to set the velocity of an upstream front (which researchers estimate it to be approximately -10 miles per hour [22, 58]). In Figure 2 we record all the parameters used and the average velocities of a stream of traffic which is initially randomly distributed under free-flow conditions. Note that for the chosen parameters $\tau_0 = .23$ and $J_0 = 6$ we obtain the desired velocity of 65 miles per hour and velocity out of a jam of ≈ -10 miles per hour. Also note that other pairs of τ_0 and J_0 are possible which easily adjust the traffic model for different standards set in other countries or regions.

3.2. Monte Carlo simulations. Using the calibrated parameters for J_0 and τ_0 from section 3.1 we now obtain the fundamental diagram (see the Appendix for details), the density—flow relationship in Figure 3, and the flow-velocity relationship in Figure 4. In general we can implement a number of different types of initial conditions which we make specific for each example considered. For these figures we use a random initial vehicle distribution and observe the behavior of the traffic stream as density increases incrementally.

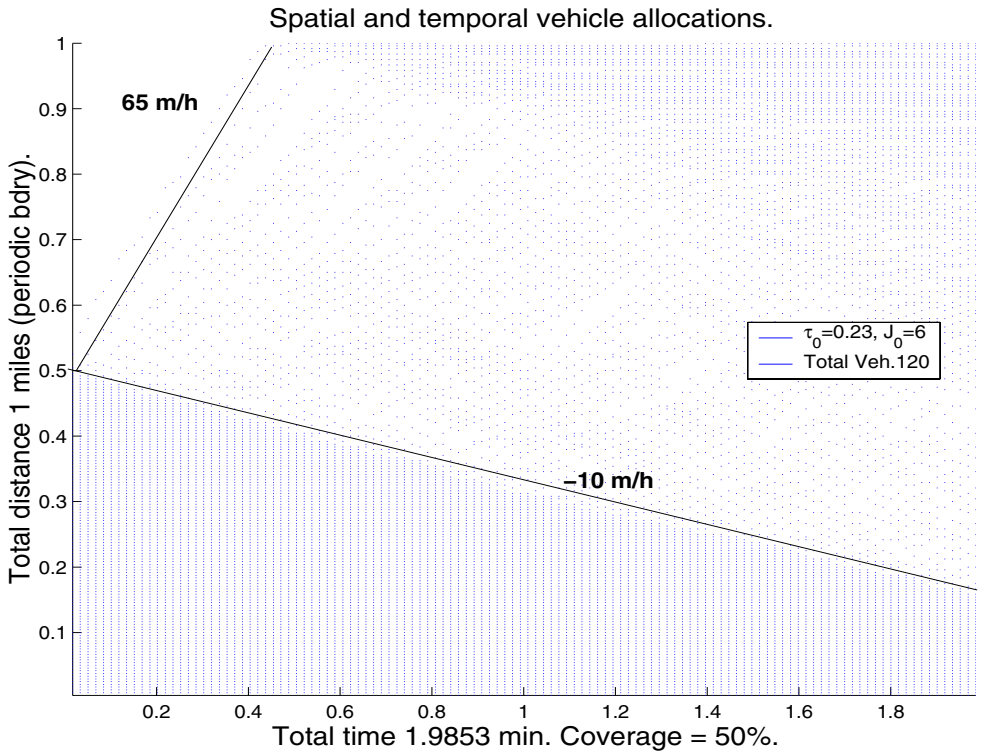

FIG. 2. *Calibration of parameters permitting a desired vehicle speed of* 65 *miles per hour and upstream front velocity of* ≈ -10 *miles per hour. We take a look-ahead of* $L = 4$. *Initial density corresponds to a traffic release problem (i.e., bumper-to-bumper vehicles up to* 0.5 *miles and no vehicles after that).*

It is of particular interest to analyze the simulated results for the well-established behavior of actual traffic at high densities, which includes stop-and-go waves, congested traffic, and other such interesting phenomena, all of which could be identified at the microscopic level. The phenomena observed at small time scales disappear in long averaged runs of the microscopic models. Cassidy [5] and Munoz and Daganzo [56] suggest how to eliminate two-regime flow by appropriately filtering the data. It is clear that these traffic states could not possibly be predicted, at their full complexity, as solutions of deterministic systems of differential equations [10] since they almost disappear as we aggregate observables. This is a very important point which should be emphasized. It is in fact possible that a given PDE traffic model could be just an extension (in the correct asymptotic limit) of a given microscopic model. In fact, we show how this can be done for our stochastic traffic flow model in the following section. Note, however, that caution is in order here since long-time averages may be unreliable due to the possible presence of phase transitions. In this model, since metastability is expected, for some concentration regimes (near c_{crit}), the simulations should be analyzed under small-time averages (see the appendix). Metastability, phase transitions, and hysteresis effects in general are quite difficult to conclusively detect and as such we propose to further study them in a forthcoming publication.

Several very interesting observations can be made from Figures 3 and 4. We compare our results with those of Nagel and Schreckenberg [50] but also with observations

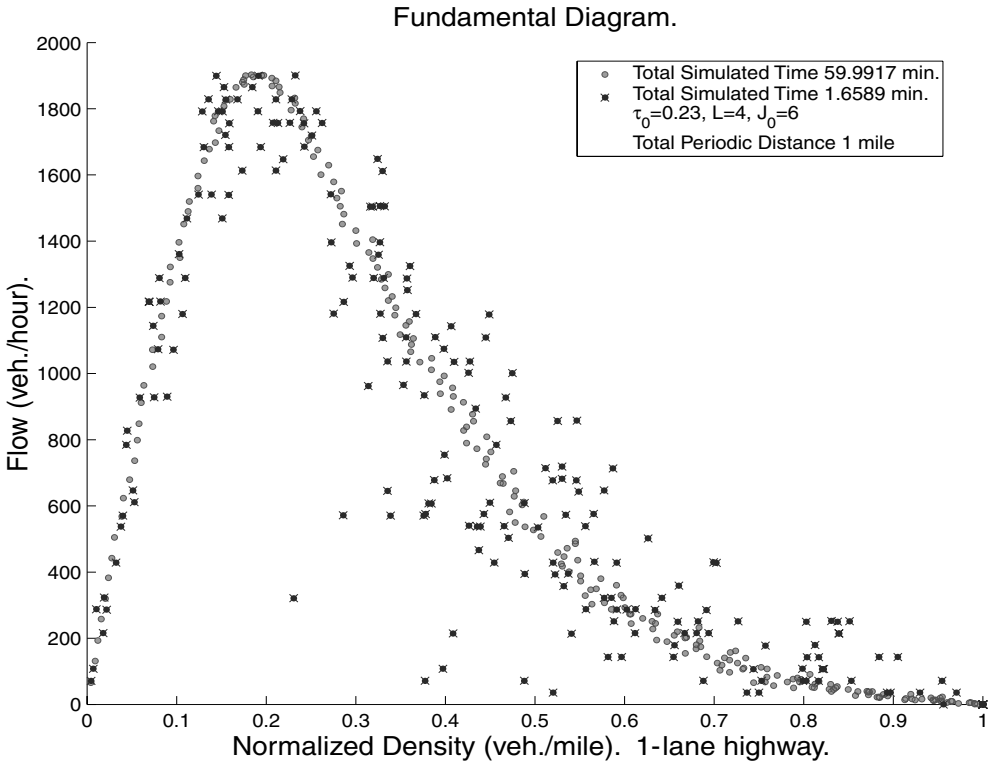

FIG. 3. *The flow density relationship for one-lane highway. Spatial periodic length of* 1 *mile, relaxation time* $\tau_0 = .23$*, interaction strength* $J_0 = 6$*, and look-ahead* $L = 4$ *cells. We superimpose two plots in this figure. In the first plot each point of the fundamental diagram is averaged over the usual* 1.65 *minutes aggregation time of data while in the second we display the long averaged flow and density for an aggregation time of a total of* 1 *hour. The aggregation time of* 1.65 *minutes was selected so that we can compare with observed data in* [51].

from Wiedemann [69] and observe qualitative agreement. Specifically, the region of free flow is clearly displayed up to approximately 50 vehicles per mile. Note here that the value of $c_{crit} = 50$ vehicles per mile is not forced on our simulation but instead is naturally created by the process dynamics through the calibration of the two parameters J_0 and τ_0. Similarly we observe a maximum vehicle flow of approximately 2000 vehicles per hour, which also agrees with observations [69], [51], and Figure 1(b) from [22]. (The aggregation time of 1.65 minutes was selected so that we can compare with observed data in [51].) An interesting question is whether this long averaged flux coincides with the equivalent mesoscopic partial differential equation of the stochastic limit. We answer this in section 4. The fluctuations in vehicle flows shown in Figures 3 and 4 are sizable for densities above c_{crit} and display a smeta-stable stop-and-go region. We should point out here that we did not fit parameters to obtain c_{crit} or q_{max} yet these parameters scale (for one-lane traffic) in agreement with observations of $c_{crit} \approx 50$ vehicles per miles and $q_{max} \approx 2000$ vehicles per hour [69].

In Figure 5 we display a close-up of vehicle trajectories for a congested traffic setup (50% jam density). In that figure we also observe that jams randomly form and sometimes disappear in time. In fact it can be easily calculated that these jams move backward in traffic with a speed of ≈ -10 miles per hour, which closely agrees with the reported speed of -15 ± 5 km per hour from [29, 58, 22].

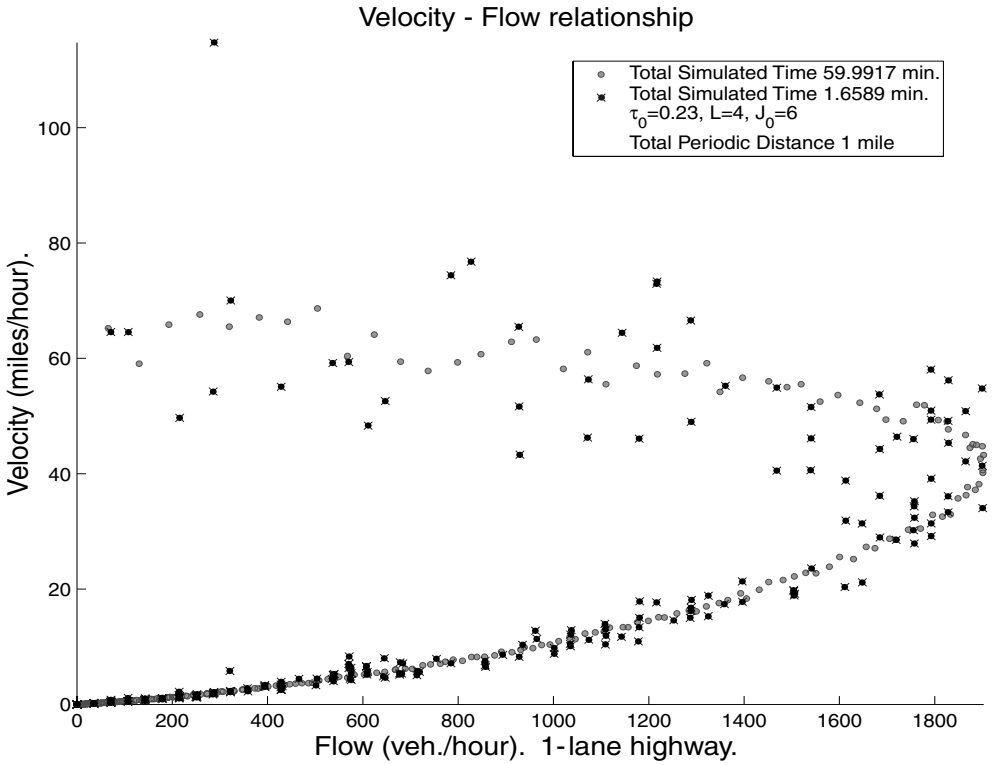

FIG. 4. *Velocity versus flow relationship for one-lane highway. Spatial periodic length of* 1 *mile, relaxation time* $\tau_0 = .23$*, interaction strength* $J_0 = 6$*, and look-ahead* $L = 4$ *cells. Once again we superimpose the* 1.65*-minutes aggregation time over the* 1*-hour aggregation time. This figure also compares favorably with observed data in* [51].

A consequence of the model versatility and ease of calibration presented is that calculations can be performed in real time for prediction purposes. The size of the traffic stream simulated in the numerical simulations here is small (< 3000 vehicles) and therefore the algorithm presented can easily produce real-time predictions. However, an improvement applicable for large traffic streams (> 3000 vehicles) is under development in [11], which uses a coarse graining idea and also produces real-time predictions. This has obvious important consequences since, as an example, we could possibly obtain the traffic input at a section of a highway in real time and immediately predict whether a traffic jam for the given highway capacity is imminent downstream, thus diverting traffic before the problem occurs.

4. Average behavior and deterministic closures. Although the emphasis of this paper is on new stochastic models we would like to establish connections with known CA and PDE models in various asymptotic regimes where mean field theory applies. Therefore we formally derive here a kinetic formulation of the stochastic model which is subsequently used to obtain an approximating finite difference (FD) scheme from (4.2) in the case of weak long-range interactions. Further, we also derive a PDE by a rescaling argument.

From our definition of a generator (2.7) we have

$$\frac{d}{dt}Ef(\sigma) = EMf(\sigma) \tag{4.1}$$

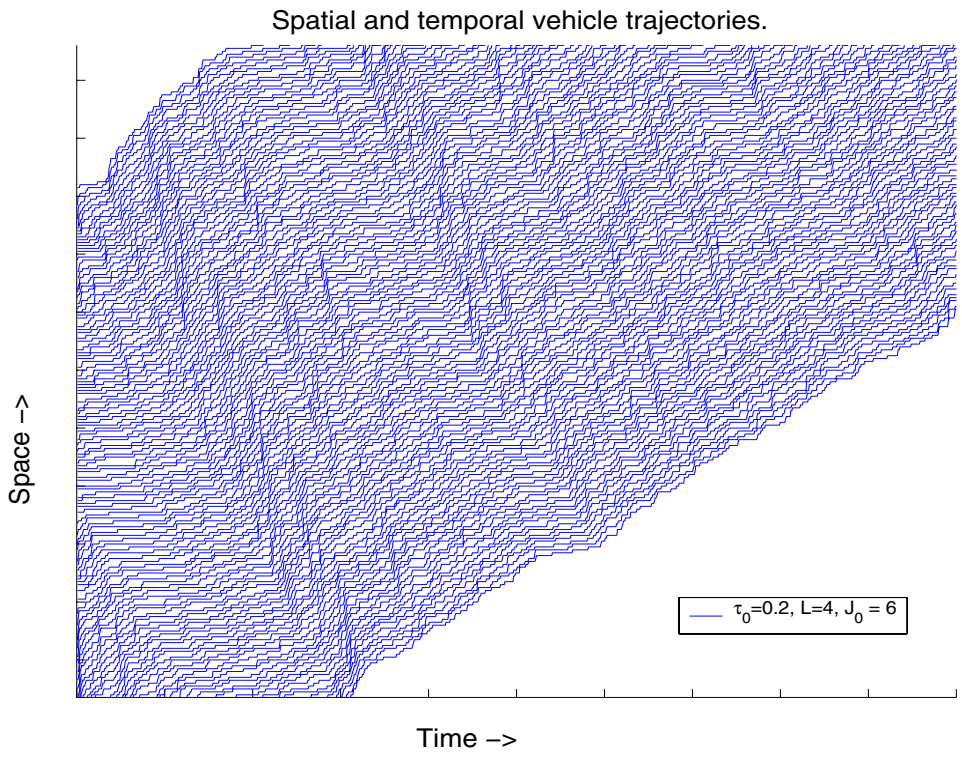

FIG. 5. *Vehicle stream lines in time and space. Spatial periodic length of* 1 *mile (corresponding to a total of* 240 *cells). We allow* 50% *initial capacity, relaxation time* $\tau_0 = .23$*, interaction strength* $J_0 = 6$*, and look-ahead* $L = 4$ *cells. Note the traffic waves in the stream displaying fronts and rarefactions.*

for any test function f, where $\sigma = \{\sigma_t : t \geq 0\}$ is the process corresponding to (2.7) and E denotes expected value. In particular we pick $f(\sigma) = \sigma(z)$ for z fixed in $\mathcal{L}$. Therefore

$$f(\sigma^{x,x+1}) = \sigma^{x,x+1}(z) = \begin{cases} \sigma(z), & x \neq z, x \neq z-1, \\ \sigma(z+1), & x = z, \\ \sigma(z-1), & x = z-1, \end{cases}$$

and based on (2.7) we have

$$f(\sigma^{x,x+1}) - f(\sigma) = \begin{cases} 0, & z \neq x, x+1, \\ \sigma(z+1) - \sigma(z), & x = z, \\ \sigma(z-1) - \sigma(z), & x = z-1. \end{cases}$$

By (2.7) and (4.1) we have the relation

(4.2)
$$\frac{d}{dt} E\sigma_t(z) = -Ec_0\sigma(z)(1-\sigma(z+1))e^{-U(z,\sigma)} + Ec_0\sigma(z-1)(1-\sigma(z))e^{-U(z-1,\sigma)}.$$

Note that relation (4.2) is exact and can be used to evaluate the closures discussed below. However, it is not yet a closed equation for $E\sigma_t(x) = \text{Prob}(\sigma_t(x) = 1)$.

4.1. Finite difference scheme. Suppose now that J (for J_0 fixed) has fairly long and weak interaction. We may assume that the stochastic process in (2.7) is a perturbation of the simple exclusion process considered in [40]. This process has a Bernoulli product invariant measure; thus at local equilibrium the probability measure is expected to be approximately a product measure. As in [57] we assume "propagation of chaos" for the microscopic system, in which case the fluctuations of the spins $\{\sigma(x), x \in \mathcal{L}\}$ about their mean values are independent and the law of large numbers formally applies. Thus the fluctuations of $\sum_{y\neq x} J(y-x)\sigma(y)$ about their mean will be small such that in the long-range interaction limit we have

$$Ee^{-U(x,\sigma)} = Ee^{-\sum_{y\neq x} J(y-x)\sigma(y)} \overset{N,L\to\infty}{\approx} e^{-\sum_{y\neq x} J(y-x)E\sigma(y)} + o_N(1). \tag{4.3}$$

Using the product property in (4.3) we formally obtain that the right-hand side of (4.2) becomes

$$-E\sigma(z)E(1-\sigma(z+1))c_0e^{-J\circ E\sigma(z)} + E\sigma(z-1)E(1-\sigma(z))c_0e^{-J\circ E\sigma(z-1)} + o_N(1), \tag{4.4}$$

where for an arbitrary function $v(z)$ we define

$$J\circ v(z) := \sum_{\substack{y\in\mathcal{L}\\ y>z}} J(y-z)v(y).$$

Next we drop $o_N(1)$ in (4.4) and define the density $u(z,t) = E\sigma_t(z)$. ($u(z,t)$ is the probability that site z is occupied at time t.) Then (4.2) and (4.4) give the following approximate semidiscrete FD scheme:

$$\begin{aligned}\frac{d}{dt}u(z,t) =& -c_0u(z,t)(1-u(z+1,t))\exp(-J\circ u(z,t))\\ &+c_0u(z-1,t)(1-u(z,t))\exp(-J\circ u(z-1,t)) \quad \text{for all } z\in\mathcal{L}.\end{aligned} \tag{4.5}$$

Note that our semidiscrete FD scheme (4.5) is conservative. Simply define

$$F(z,t) = c_0u(z-1,t)(1-u(z,t))\exp(-J\circ u(z-1,t)) \tag{4.6}$$

and without loss of generality, assuming a periodic lattice of N nodes, we sum the right-hand side of (4.5) and obtain

$$\begin{aligned}\sum_{z=0}^{N-1} c_0[-F(z+1,t)+F(z,t)] &= c_0[F(0,t)-F(N-1,t)]\\ &= c_0[u(-1,t)(1-u(0,t))\exp(-J\circ u(-1,t))\\ &\quad -u(N-1,t)(1-u(N,t))\exp(-J\circ u(N-1,t))] = 0\end{aligned}$$

since $u(-1,t) = u(N-1,t)$ and $u(0,t) = u(N,t)$ due to spatial periodicity.

Note that based on (4.6) we can rewrite (4.5) as

$$\frac{du(z,t)}{dt} + F(z+1,t) - F(z,t) = 0.$$

4.2. PDE limit. We now formally obtain the resulting PDE from (4.5) and make connections with other known traffic flow models. We start by expanding the spatial variables in Taylor series. We set $h = \Delta x$ and use

$$u(z \pm 1, t) = u(z,t) \pm h u_z(z,t) + \frac{h^2}{2} u_{zz}(z,t) + \cdots .$$

Substituting into (4.5) we obtain

$$\frac{d}{dt}u + h\left[u(1-u)c_0 \exp(-J \circ u)\right]_z = O(h^2). \tag{4.7}$$

Rescaling time in (4.5),

$$t \to th^{-1},$$

to absorb h and by omitting the $O(h^2)$ terms we have

$$\frac{d}{dt}u + [u(1-u)c_0 \exp(-J \circ u)]_z = 0 \tag{4.8}$$

$$\text{for } z \in R \quad \text{and} \quad J \circ u(z) = \int_z^\infty J(y-z)u(y)\, dy.$$

The transport equation obtained is

$$u_t + F(u)_z = 0, \tag{4.9}$$

where

$$F(u) = u(1-u)c_0 \exp(-J \circ u). \tag{4.10}$$

It is interesting to point out here that (4.10) under the simplest case of no interactions ($J_0 = 0$) corresponds to the well-known [68, 42] Lighthill–Whitham flux (1.1), thus producing a traffic stream formulation equivalent in form to the Burgers equation.

Note that in fact (4.5), when fully discretized, provides a natural finite difference scheme for (4.9),

$$\begin{aligned} u(z, t^{n+1}) = u(z,t^n) + \frac{\Delta t}{h}[&u(z-1,t^n)(1-u(z,t^n))c_0 \exp(-J \circ u(z-1,t^n)) \\ &- u(z,t^n)(1-u(z+1,t^n))c_0 \exp(-J \circ u(z,t^n))]. \end{aligned} \tag{4.11}$$

4.3. Stochastic versus semidiscrete approximation. We numerically compare the solutions of the stochastic model (4.2) against the semidiscrete scheme (4.5). In that respect we implement the same initial normalized density of vehicles (a traffic light release type) for both schemes with the following form:

$$u(z,0) = \begin{cases} 1 & \text{for cells in } 20 < z < 40, \\ 0 & \text{otherwise.} \end{cases} \tag{4.12}$$

The comparisons are performed under the assumption in (4.3) (i.e., $L = 240$ cells) for the semidiscrete scheme while the stochastic is averaged over several realizations to obtain an approximation of $E(\sigma_t(z))$. The solutions are shown in Figures 6 and 7 for the semidiscrete and stochastic models, respectively. The final profiles of these

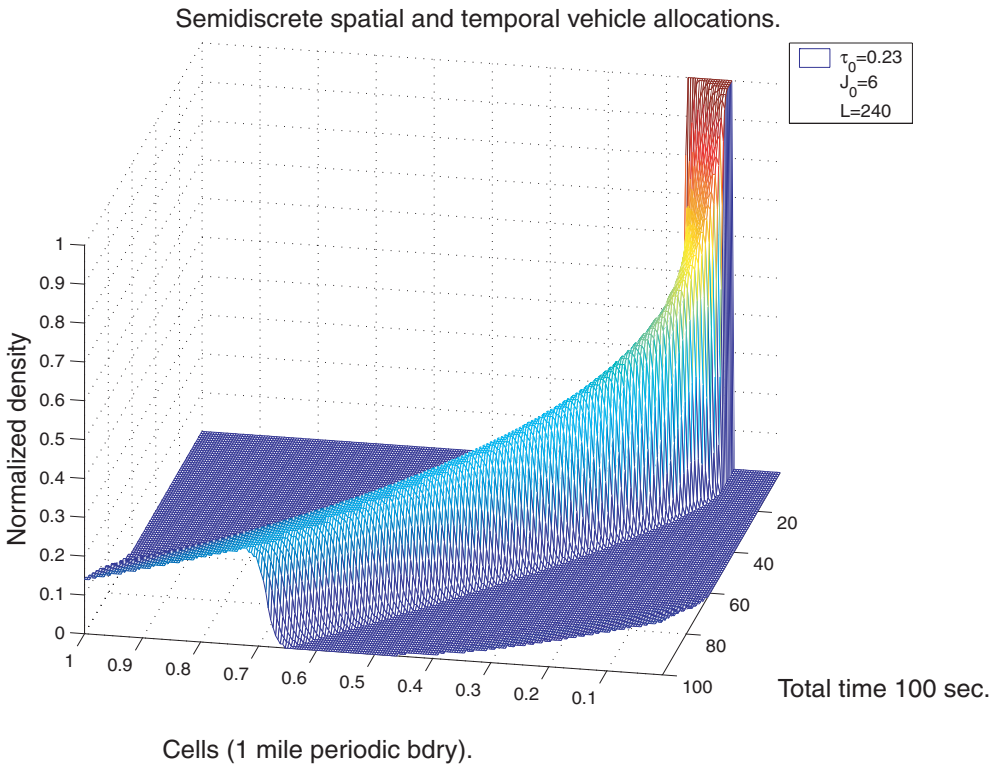

FIG. 6. *Solution of the semidiscrete scheme* (4.5) *in time and space for a traffic light type of initial condition* (4.12). *We set* $L = 240$ *based on the assumption in* (4.3). *Parameters:* $\tau_0 = .23$ *and* $J_0 = 6$.

solutions are compared in Figure 7. We clearly observe the expected rarefaction wave on one side and shock wave on the other.

In Table 4.1 we display the l_1 relative error estimates of the solutions of each model for different sizes of the interaction potential L at a specific time. The relative l_1 error is calculated from the final (in time) solutions of the semidiscrete and stochastic densities u_{sd} and u_{stoch}, respectively,

$$\frac{|u_{sd} - u_{stoch}|_{l_1}}{|u_{stoch}|_{l_1}} = \frac{\sum_z |u_{sd}(z, t_{final}) - u_{stoch}(z, t_{final})|}{\sum_z |u_{stoch}(z, t_{final})|}.$$

We observe the smallest relative errors in Table 4.1 for the case of $L = 240$. This is expected based on assumption (4.3). We compare the resulting stochastic microscopic (4.1) and FD PDE (4.11) models against each other and give possible connections with other well-known models in the following section.

4.4. Connections and comparisons between models and parameters. The task in this section is twofold. First we display possible connections between our derived models (4.1) and (4.11) with other well-known traffic flow models. Second, to further understand how parameters influence the fundamental diagram (more precisely the flux) of our derived mesoscopic formulations we also compare these formulations (4.10, 6.1) against each other to understand their possible limitations and range of predictions.

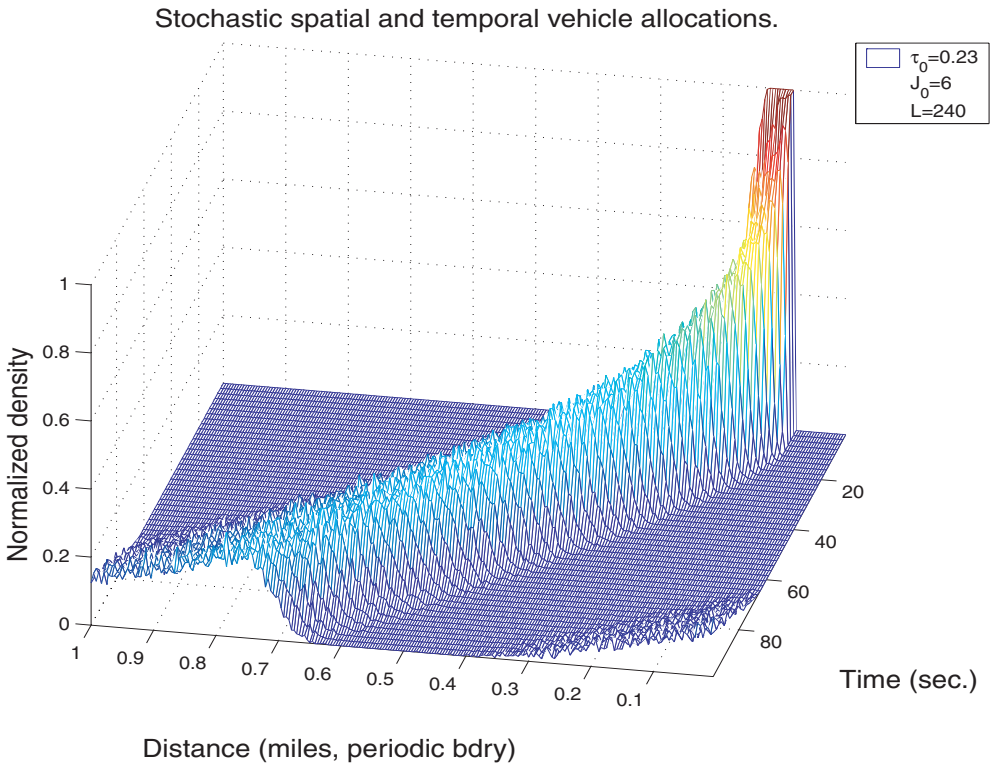

FIG. 7. *Solution of the stochastic model* (4.2) *in time and space for a traffic light type of initial condition* (4.12). *We average* 500 *realizations to produce the averaged density presented. Parameters:* $\tau_0 = .23, J_0 = 6$, *and* $L = 240$.

Relative error of final solutions, similar to that presented in Figure 8, *comparing the semi-discrete FD scheme* (4.5) *against the stochastic model* (4.2) *solution for different sizes of the potential radius* L. *The stochastic solution has been averaged over* 500 *realizations. Other parameters:* $\tau_0 = .23$ *and* $J_0 = 6$.

Potential Radius L	240	100	50	10	4	1
l_1 Rel. Error	.0013	.0029	.0051	.0066	.0126	.02

4.4.1. Theoretical connections. We obtain here hierarchical connections with other well-known traffic flow models based on expansions of our underlying macroscopic equation (4.9) with (4.10),

$$u_t + [u(1-u)c_0 \exp(-J \circ u)]_z = 0. \tag{4.13}$$

We start by expanding the convolution term $J \circ u$,

$$J \circ u = \int_z^\infty V(y-z)u(y)\,dy \overset{x=y-z}{=} \int_0^\infty V(x)u(x+z)\,dx = J_0 u + J_1 u_z + J_2 u_{zz} + \cdots, \tag{4.14}$$

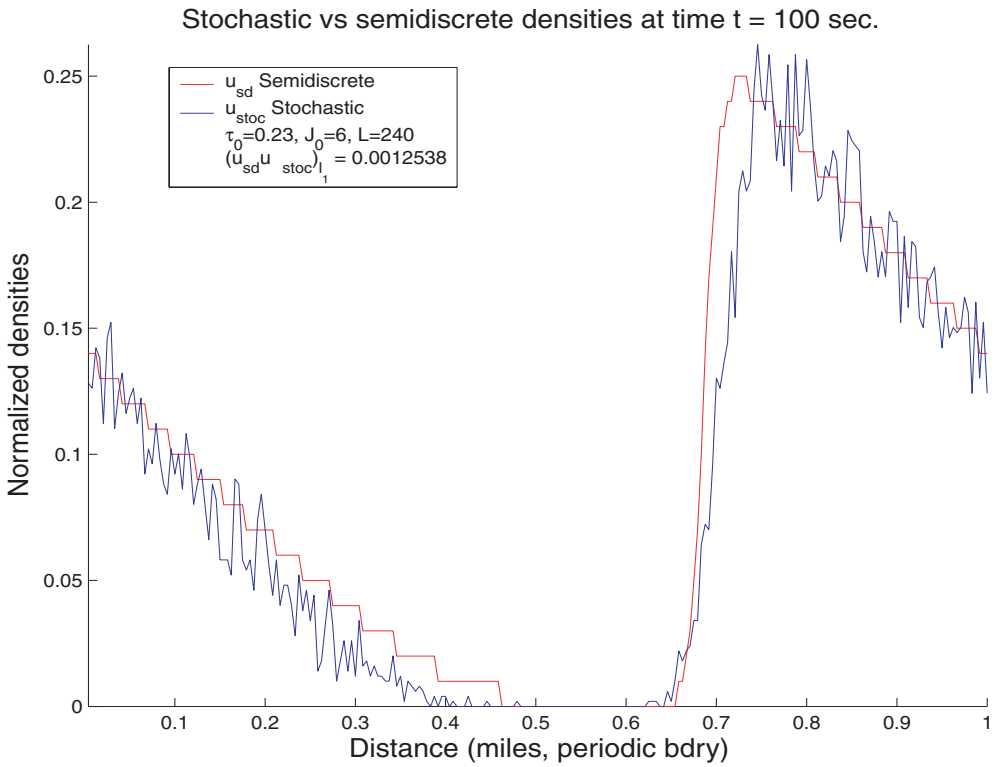

FIG. 8. *Density comparisons at final time $t = 100$ seconds. The error at that time in l_1 is also displayed. Once again, the stochastic is averaged over* 500 *realizations. Note the agreement between the solutions in both quantity and form. Parameters: $\tau_0 = .23$ and $J_0 = 6$ for $L = 240$.*

where assuming $V > 0$ (recall that the positive uniform potential we use here (3.1) implies that vehicles are attracted to the empty space in front of them) gives

(4.15)
$$J_0 = \int_0^\infty V(x)\,dx > 0, \quad J_1 = \int_0^\infty xV(x)\,dx > 0 \quad J_2 = \int_0^\infty \frac{x^2}{2}V(x)\,dx > 0.$$

We can therefore approximate the exponential as

$$e^{-J\circ u} \approx e^{-[J_0 u + J_1 u_z + J_2 u_{zz}]} = e^{-J_0 u} e^{-J_1 u_z - J_2 u_{zz}} \approx e^{-J_0 u}[1 - J_1 u_z - J_2 u_{zz}],$$

which based on (4.13) gives the higher-order traffic flow model

$$u_t + c_0[u(1-u)e^{-J_0 u}]_z = c_0[J_1 u(1-u)e^{-J_0 u} u_z]_z + c_0[J_2 u(1-u)e^{-J_0 u} u_{zz}]_z \tag{4.16}$$

with J_0, J_1, and J_2 from (4.15). Note that (4.16) is a third-order dispersive PDE with diffusion which is similar in form to the PDEs derived from optimal velocity models and usually referred to as modified KdV in [47, 48, 54].

We make general remarks below about the behavior of (4.16) as well as the more general (4.13) under different scales and/or parameters:

- Assuming first that there are no interactions $J = 0$ in the potential (4.10) of (4.13) we obtain $F(u) = c_0 u(1-u)$, which gives the well-known diffusive Lighthill–Whitham or Burgers equation flux.

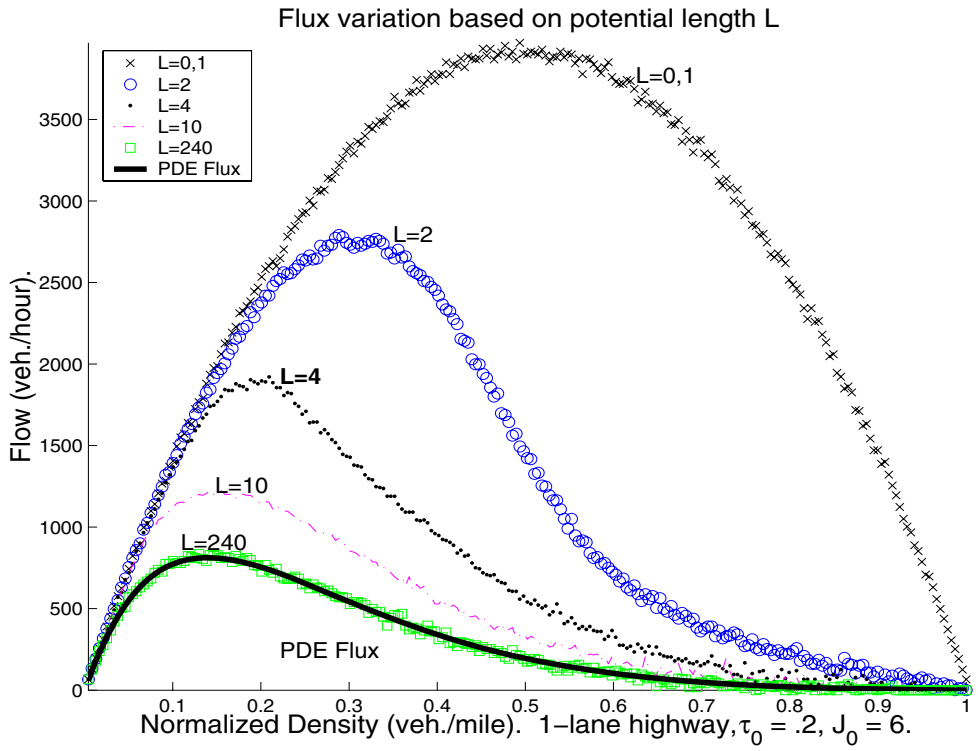

FIG. 9. *Long time averages. Comparing how the flux* (6.1) *changes with respect to increasing* L. *We set* $J_0 = 6, \tau_0 = .23$ *and run all microscopic simulations for the same total time and under the same initial conditions before plotting the flow per concentration. Note that for long-range interactions we observe that the PDE flux* (4.10) *coincides with the long-range interaction* ($L = 240$) *microscopic model flux* (4.17) *which fluctuates around it.*

- In the opposite case, however, of long-range interactions between vehicles, $L = N$, we obtain the following nonlocal flux from (4.10):

$$F(u) = c_0 u(1-u)\exp(-J_0\bar{u}). \tag{4.17}$$

  As we will see below (see Figure 9), under this long-range interaction case the flux of the stochastic model and that of the PDE (4.9, 4.10) agree.
- Note further that the hyperbolic equation obtained by including terms up to J_0 in the convolution (4.14) (disregarding J_1, etc.),

$$u_t + c_0[u(1-u)\exp(-J_0 u)]_z = 0, \tag{4.18}$$

  has a nonconvex flux. Indeed note in Figure 10 that if $J_0 \geq 3$ the flux is neither convex nor concave.
- If on the other hand we include terms up to order J_1 in (4.14), then (4.16) takes the form of a nonlinear diffusive Lighthill–Whitham type equation [68, 54, 48].
- Returning to the higher-order dispersive PDE (4.16) we note the similarities with other usual higher-order traffic flow models found in [34, 47, 48, 28, 38], although the coefficients obtained here include nonlinearities. Coherent structures can emerge as solutions of (4.16) which are similar to Figures 7 and 6 and

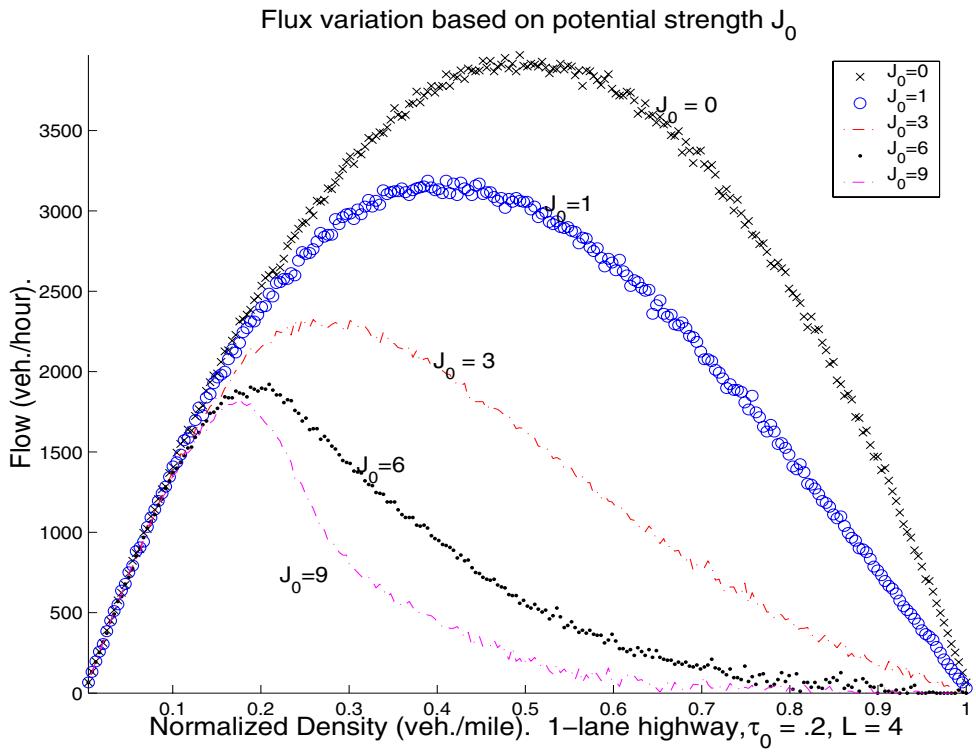

FIG. 10. *Long time averages. Comparing the influence of potential strength J_0 in the stochastic flux* (6.1). *In these comparisons we keep $L = 4$ and run all microscopic simulations for the same total time before plotting the flow per concentration.*

especially the profile density solution presented in Figure 8. It is known that traveling wave solutions of the Payne–Whitham model [37], [28] with nonconcave fundamental diagrams, which resemble the form of our higher-order PDEs, are asymptotically stable under small perturbations for a subcharacteristic type of condition [43]. It would be interesting to further examine traveling wave solutions of (4.13) as well as the higher-order approximation (4.16) and compare them with observed soliton, kink-antikink, or mixtures of other density solutions as have been noted in [34, 47, 28].

- Further, we remark that equations similar in form to (4.16) have also been studied in [26]. Diffusive and dispersive KdV type equations are emerging from Chapman-Enskog expansions of hyperbolic models with coexisting diffusion and relaxation contributions. The structure of the wave solutions which are shown to emerge for the dispersive, KdV type, equation presented there consists of enhanced solitary waves.

4.4.2. Numerical comparisons of fluxes. Clearly the microscopic model contains the maximum amount of information while the PDE is a rough averaging of the same system. It is also important, in terms of applicability of each model, to identify the range of parameters for which the PDE corresponds to our microscopic description. In that respect we expect certain parameters such as the interaction potential radius, the interaction size L, and the potential strength J_0 to be of significance. We

therefore display, in Figure 9, numerical simulations of the microscopic model predictions for different potential lengths L while keeping all other parameters the same. In that same figure we also plot the flux as obtained from our PDE formulation for a uniform potential strength value of $J_0 = 6$ and $\tau_0 = .23$ (to match the value implemented in our stochastic simulations). Note that, remarkably, the PDE flux and the microscopic flux corresponding to $L = 240$ (the maximum number of potential length) coincide (excluding the small fluctuations)! Respectively we also note that the PDE is a reasonable approximation for any microscopic model with $L > 10$ look-ahead. This is unfortunate, however, since physically we do not expect that drivers would (or even could) have a perception of traffic up front for more than possibly five vehicles. Notably the discrepancy between the microscopic and PDE fluxes is substantial for $L \approx 100$ cells or less. Such differences between long and short values for L have also been recorded in [66] for catalytic surface diffusion models.

We similarly examine how the potential strength J_0 influences the corresponding flux for either formulation (4.1) and (4.9) in Figure 10. We plot the microscopic flux for potential length of $L = 4$, which is more appropriate for actual traffic conditions. The case of $J_0 = 6$ connects Figure 9 to Figure 10 and allows for comparisons between the two. It is interesting to note how the expected concavity of traffic flow flux changes in Figure 10 as potential strength increases. In fact for values of $J_0 \geq 3$ the flux is neither concave not convex. Observe this loss of convexity also for $L \geq 2$ in Figure 9, thus producing a richer behavior than the typical Lighthill–Whitham (or Burgers) type traffic model predicts. On the other hand, in both Figures 9 and 10 we obtain one of the most basic traffic flow fluxes, the diffusive Lighthill–Whitham [68] (or Burgers) flux for the trivial case of either $J_0 = 0$ or $L = 0, 1$.

We also note the similarities of the simulated flux depicted in Figure 10 obtained here for $J_0 = 0$ and $J_0 = 6$ with Figures 2 and 3 from [50], respectively, as well as Figure 2 from [44]. Similar such agreement is also observed between Figure 10 (case of $J_0 = 6$) here and the observed data in Figure 1(b) and simulations in Figure 8 of [22].

5. Conclusions. In this work we have presented a stochastic microscopic model for traffic flow. The modeling and subsequent Monte Carlo simulations relied on simple calibration procedures of just three parameters: the potential interaction length of J_0, the relaxation time τ_0, and the look ahead L. Note that J_0 indirectly influences the desired speed of vehicles while τ_0 and L set the speed as vehicles are emerging out of a jam. Based on these settings we were able to produce realistic fundamental diagrams, for one-lane traffic, with qualitatively meaningful flows ($q_{max} \approx$2000 vehicles per hour and $c_{crit} \approx$50 vehicles per mile) which display many of the observed traffic states including phenomena such as stop-and-go traffic, spontaneous jam generation, retarded acceleration [63], and timely braking [58]. Overall the ease of calibration and richness of solution behavior make this stochastic model valuable in terms of describing, even at this simple one-lane setting, complex traffic flows.

Furthermore we derived (in the weak, long-range interactions limit) the corresponding macroscopic traffic model from our microscopic stochastic description. Subsequently we compared the solutions of each model for a variety of parameters making connections, for those regimes, with other well-known CA and PDE models for traffic flow. We obtain, up to leading order terms, hierarchical macroscopic diffusive and/or dispersive PDEs which resemble other well-known traffic flow models [68, 54, 28] of the same order. It would be interesting to examine our hierarchical macroscopic models (4.18), (4.16), and (4.13) for coherent structure solutions exhibiting behavior similar to that observed in [26, 48, 47, 28] (solitons, kink-antikink, etc.).

Last we point out that the simulations presented here can be performed in real time for the current one-lane traffic model proposed but also for multilane traffic which will be presented in a forthcoming work [11]. Extending the current one-dimensional stochastic microscopic model to multilane traffic will further allow us to directly compare our simulated results with available observational data [51, 69]. To further improve the model we also include entrances and exits by implementing two different, nonconservative (in contrast to the conservative spin exchange studied here) dynamics mechanisms: adsorption/desorption and surface diffusion.

6. Appendix: Data gathering and analysis techniques. The underlying method of recording, comparing, and analyzing traffic data for both the simulations and the observations is of paramount importance and must be clearly explained. Studies have been curried out by Athol [1] and more recently others [20, 46, 53] regarding proper data collecting procedures and underlying assumptions put forth in theory and in practice.

Observational traffic data can be obtained via a variety of methods: visual observations (video cameras), single or double loop detectors, magnetic overhead detectors, satellites, etc. In the majority, traffic data are gathered via detector loop techniques. In the case of double detector loops, for instance, pneumatic tubes (or, more recently, point detectors) are placed in close proximity on the highway and each is connected to a detector which records occurrences as vehicles pass on top of each tube. Quantities of interest that need to be determined from the collected data are usually the flow and velocity.

In general (regardless of detection method) the flow is measured as the number of vehicles $n(\tau)$ passing a detector at a given time interval τ via

$$q = \frac{1}{\tau} n(\tau) \tag{6.1}$$

(therefore flow cannot be found based on a single snapshot of vehicles over a length of interval). Usually flow is reported in number of vehicles per hour although the actual time length of recorded observation is much smaller (1/2 to 2 minutes). As a result some concerns have been raised regarding sustainability of such high volumes when data correspond to measurements over time intervals which are less than 15 minutes [21].

Average velocity on the other hand requires observations over both time and space. There are two ways to calculate velocity: time mean speed and space mean speed. As the name suggests, we calculate the time mean speed and space mean speed respectively through

$$\bar{u}_\tau = \frac{1}{N} \sum_{i=1}^{N} u_i \quad \text{and} \quad \bar{u}_s = \frac{s}{\frac{1}{N} \sum_{i=1}^{N} t_i}.$$

Here N denotes the number of time observations, s is the total distance covered in that time, and t_i is the corresponding time per observation. Note that in terms of (6.1) the following holds: $\tau = \sum_i t_i$. It is important to note here that the two definitions for mean speed provided above differ, as shown by Wardrop [67], by the ratio of the variance to the mean of the space mean speed,

$$\bar{u}_\tau = \bar{u}_s + \frac{\sigma_s^2}{\bar{u}_s}.$$

Therefore although they are similar for free-flow conditions they actually differ, especially near the highest flow regimes [20], for the key regions of stop-and-go and traffic breakdown. In practice double loop detectors are well suited to collect correctly space mean speeds. In this work (for comparative and other reasons which become clear below) we report our findings by computing space mean speed instead of time mean speed.

Density on the other hand is a quantity which is quite hard to measure empirically [46] and can be measured only along a length [20]. Having flow and space mean speeds, collected as described above, it is not uncommon to estimate the density from the well known macroscopic formula ("fundamental identity") as originally developed by Wardrop [67],

$$q = c\bar{v}. \tag{6.2}$$

A lot has been written regarding (6.2) but most importantly, as pointed out by Hall [20, p. 10], "its use has often exceeded the underlying assumptions." Clearly by applying (6.2) researchers introduce an assumption in terms of scales, ranges, and even continuity of observed variables [55] for which such an equation is valid. The validity of (6.2) is therefore sometimes questionable and its application varies among researchers, based on concentration, [30] (away from jam concentrations), [58]. The underlying problem of applying (6.2) to obtain the concentration is that (6.2) holds under "some very restrictive conditions" [20] which among other things imply that both space and time measurement intervals approach zero.

If point measurements are taken the best way [46] to estimate density is to instead calculate the lane occupancy, OC, of the traffic stream [20, 46]. Occupancy is the fraction of time that vehicles are over the detector,

$$OC = \frac{\text{total time detector is occupied by vehicle}}{\text{total study time}} = \frac{(L+D)/v}{\text{headway}} = c(L+D),$$

where L denotes the average vehicle length, D the detector length, and v the speed. (The headway is understood here as a time headway.) Therefore vehicle density c is found as

$$c = \frac{OC}{L+D}. \tag{6.3}$$

It is important to point out a common discrepancy: "almost all the theoretical work done prior to 1985 either ignores occupancy ... or else uses it ... as a surrogate for, density. On the other hand much of the freeway traffic management work ... (practical as opposed to theoretical work) relied on occupancy" [20].

In the simulations presented in our work we use virtual detectors in an effort of reproducing real traffic data collection procedures. As a result we place our virtual detector in a specific cell of our lattice and collect data on observables at that cell. Flow is computed based on (6.1) while density is found through calculation of occupancy as explained above and in the same fashion as done in [50] and similar other works. The data are averaged over small intervals of time (which we make precise in each of the presented simulations) as in real traffic data collection practices. In this work we simulate a closed round road without entrances or exits (race track) which we initialize with a specified total density (which naturally remains constant through the simulation) of randomly distributed vehicles. The fundamental diagrams are constructed by collecting data with a given density and then increasing that density and repeatedly restarting the complete simulation over again.

TRAVELING WAVE SOLUTIONS TO A COUPLED SYSTEM OF SPATIALLY DISCRETE NAGUMO EQUATIONS*

MICHAEL D. BATEMAN† AND ERIK S. VAN VLECK†

Abstract. We consider a coupled system of discrete Nagumo equations and derive traveling wave solutions to this system using McKean's caricature of the cubic. A certain form of this system is used to model ephaptic coupling between pairs of nerve axons. We study the difference $g(c) = a_1 - a_2$ between the detuning parameters a_i that is required to make both waves move at the same speed c. Of particular interest is the effect of a coupling parameter α and an "alignment" parameter A on the function g. Numerical investigation indicates that for fixed A, there exists a time delay value β that results in $g = 0$, and for large enough wave speeds, multiple such β values exist. Also, numerical results indicate that the perturbation of α away from zero will yield additional solutions with positive wave speed when $A = \frac{1}{2}$. We employ both analytical and numerical results to demonstrate our claims.

Key words. discrete Nagumo equations, ephaptic coupling, traveling waves

1. Introduction.

In myelinated nerve axons, transmembrane ion flow occurs only at the spatially periodic nodes of Ranvier, and the activity at these nodes may affect the activity at nodes of neighboring fibers. This so-called ephaptic coupling is an electrical effect that causes neighboring fibers to interact and possibly synchronize with each other. Accompanying the problem of ephaptic coupling is the issue of the relative positioning of the nodes of Ranvier on the different fibers. That is, given two parallel nerve fibers, the nodes on one fiber may or may not align perfectly with the nodes on the other fiber.

Our contribution in this paper is to derive a solution to a system that models these phenomena and use this model to show that coupling decreases the size of the range of propagation failure when the nodes of Ranvier are staggered, but that coupling increases the size of this range when the nodes are perfectly aligned. To do this, we consider a system of two myelinated nerve axons coupled ephaptically. In particular, our goal is to study the effect of this coupling and the effect of nonalignment on the propagation of action potentials. Different types of coupling between fibers are possible. In [2], Binczak, Eilbeck, and Scott model "saltatory" conduction present in these myelinated neurons with equations used to govern the behavior of electrical circuits and introduce the effect of ephaptic coupling between two myelinated neurons. In [1] a different type of coupling, called "ohmetric" coupling, is considered and it is shown that the introduction of this kind of coupling causes waves on two adjacent myelinated axons to match speeds with each other. Earlier work of Keener [13] and Bose and Jones [4, 5] addressed the issue of ohmetric coupling.

The strength of the ephaptic coupling α depends on the electrical resistance R_{int} inside the axons (assumed to be the same for both axons) and the resistance R_o of the medium between the axons. We must also consider the positioning of the axons

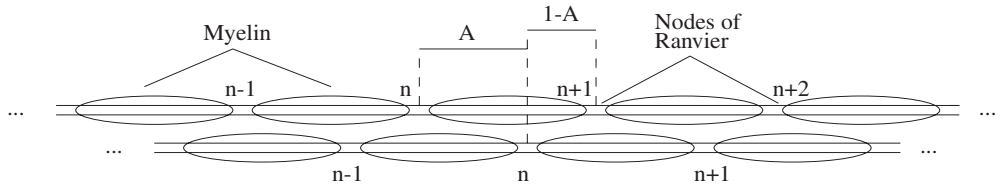

FIG. 1. *Diagram of two myelinated nerve axons.*

relative to each other: here we assume that they are parallel, that the nodes on a given fiber are evenly spaced, and that the distance between nodes is the same on both fibers, but we allow the nodes of Ranvier to line up or not line up, as shown in Figure 1. That is, we will introduce an alignment parameter A that will reflect the positioning of the nodes on one fiber relative to those on the other. We will also introduce a parameter β that will act as a time delay on one of the fibers. Specifically, we consider a system of differential equations on two one-dimensional lattices coupled together. Study of the uncoupled case [6, 11, 10, 14] provides an idea of the kind of behavior to expect from the coupled system and also serves as a precedent to which our results may be compared.

We consider the system

$$\begin{aligned}
\dot{V}_n^{(1)} + f_1(V_n^{(1)}) &= \frac{1}{1-\alpha^2}[D_1(\bar{L}V^{(1)})_n - \alpha D_2(\bar{L}V^{(2)})_n - \alpha A(\bar{N}V^{(2)})_n \\
&\qquad - \alpha^2 A(\bar{N}V^{(1)})_{n+1}], \\
\dot{V}_n^{(2)} + f_2(V_n^{(2)}) &= \frac{1}{1-\alpha^2}[-\alpha D_1(\bar{L}V^{(1)})_n + D_2(\bar{L}V^{(2)})_n + \alpha^2 A(\bar{N}V^{(2)})_n \\
&\qquad + \alpha A(\bar{N}V^{(1)})_{n+1}],
\end{aligned} \tag{1.1}$$

where $(\bar{L}V)_n = V_{n+1} - 2V_n + V_{n-1}$, $(\bar{N}V^{(i)})_n = (\dot{V^{(i)}}_{n-1} - \dot{V^{(i)}}_n) + (f_i(V_{n-1}^{(i)}) - f_i(V_n^{(i)}))$, $D_1, D_2 > 0$ are diffusion coefficients, $A \in [0,1)$ is the alignment parameter, and $\alpha \in [0,1)$ is the coupling coefficient. When $\alpha = 0$, the ephaptic coupling is completely turned off, and increasing α increases the strength of the coupling. When $A = 0$, the nodes are in perfect alignment; setting $A = \frac{1}{2}$, for example, staggers the nodes so that the nth node on one fiber is equidistant from the nth and $(n+1)$th nodes on the other fiber. The nonlinearities $f_i : \mathbb{R} \to \mathbb{R}$ are often cubics of the form $f_i(u) = u(u - a_i)(u - 1)$, where the $a_i \in (0,1)$ are "detuning" parameters, and the quantities $V_n^{(i)}$ represent the ionic flow through the membrane at the nth node of the respective fibers. However, to facilitate the construction of a solution, we consider an idealized, piecewise linear f_i known as McKean's caricature of the cubic (see [15, 17, 12, 22, 23, 6, 11, 8, 9]). When considering one fiber, it is only necessary to think of the detuning parameter $a \in (0, \frac{1}{2})$ because of symmetry in the relationship between the detuning parameter and the wave speed. A priori, we do not know if the same is true when considering two fibers. However, we will see in Theorem 4.4 and Corollary 4.5 that certain symmetries do hold in the coupled problem.

In general, the wave speed c depends on all the other parameters in the problem. Here, however, we approach the issue from a different angle: we fix all parameters except the detuning parameters a_i and assume that the wave speed c is the same for

both fibers. This way we "solve," in a sense, for the detuning parameters. Instead of fixing the detuning parameters, and studying how they affect the wave speeds, we demand that the wave speeds be the same and determine which pairs of detuning parameters give us this effect.

Although our particular model is motivated by this neurological application, similar models may also be used to study action potentials in cardiac cells, among other things (see [3, 16, 20, 21]). The authors in [1] also mention the possible application of coupled two-dimensional lattices to the study of image processing. For this reason, we consider a more general system and allow the parameters to range over values that may not be physically reasonable for our particular application.

This paper is organized as follows: we start by using a piecewise linear nonlinearity f to derive candidate solutions using a Fourier transform method. To make this process easier, we make a key assumption about the shape of our solutions—this assumption will be verified after we have obtained the candidate solutions. The details of the construction have been left to an appendix. After proving the existence of traveling backs, we look at some properties held by these solutions. We investigate the relationship between the wave speed c and the detuning parameters a_i, as well as the effects of the coupling coefficient α and the alignment parameter A on this system. We have interspersed some numerical computations throughout the paper to illustrate the analytical results and provide insight into the problem.

1.1. Derivation of the system. The system considered here is a version of the model used in [18] (see pp. 177–183) and [2]. The variables used here are as follows: I_n is the mesh current, a term used to analyze circuits using Kirchhoff's equations; $I_{ion,n}$ is a cubic modeling the ionic current (taking into consideration both sodium and potassium); $V_n^{(i)}$ is the voltage across a node of Ranvier, and V_b is a constant representing the Nernst potential for sodium ions; $R_{i,j}$ is the resistance inside fiber j, R_o is the resistance outside the axons, and R_f is a constant representing the internodal resistance, and is on the same order as $R_{i,j}$; and C is the capacitance of a node plus the capacitance of the adjacent internodal myelin sheath.

Using the circuit diagrams presented in [2] and [18], we sum the voltages around the mesh and set the result to zero. Note that here we will use A to represent the amount that fiber 1 leads fiber 2. This gives us

$$\begin{aligned} v_n^{(1)} - v_{n+1}^{(1)} &= (R_{i,1} + R_o)I_n^{(1)} + R_o(AI_{n-1}^{(2)} + (1-A)I_n^{(2)}), \\ v_n^{(2)} - v_{n+1}^{(2)} &= (R_{i,2} + R_o)I_n^{(2)} + R_o(AI_{n+1}^{(1)} + (1-A)I_n^{(1)}). \end{aligned} \tag{1.2}$$

In addition, we have the following relationship between the mesh currents and the voltages:

$$I_{n-1}^{(j)} - I_n^{(j)} = C\frac{dv_n^{(j)}}{dt} + I_{ion,n}^{(j)}, \quad j = 1, 2. \tag{1.3}$$

Now we multiply (1.2) by $\frac{R_f}{V_b(R_{i,j}+R_o)}$ and (1.3) by $\frac{R_f}{V_b}$. Using the notation

$$V_n^{(j)} = \frac{v_n^{(j)}}{V_b}, \quad i_n^{(j)} = \frac{R_f I_n^{(j)}}{V_b}, \quad D_j = \frac{R_f}{R_{i,j}+R_o}, \text{ and } \alpha_j = \frac{R_o}{R_{i,j}+R_o}, \tag{1.4}$$

we arrive at

$$\begin{aligned} D_1(V_n^{(1)} - V_{n+1}^{(1)}) &= i_n^{(1)} + \alpha(Ai_{n-1}^{(2)} + (1-A)i_n^{(2)}), \\ D_2(V_n^{(2)} - V_{n+1}^{(2)}) &= i_n^{(2)} + \alpha(Ai_{n+1}^{(1)} + (1-A)i_n^{(1)}), \end{aligned} \tag{1.5}$$

$$
\begin{aligned}
i_{n-1}^{(1)} - i_n^{(1)} &= R_f C \dot{V}_n^{(1)} + f_1(V_n^{(1)}),\\
i_{n-1}^{(2)} - i_n^{(2)} &= R_f C \dot{V}_n^{(2)} + f_2(V_n^{(2)}).
\end{aligned} \tag{1.6}
$$

As noted in [2], experimental results indicate that $R_o \ll R_{i,j} \approx R_f$, so we take $\alpha_1 = \alpha_2$ but allow $D_1 \neq D_2$.

Using (1.5) and (1.6), we have

$$
\begin{bmatrix} 1 & \alpha \\ \alpha & 1 \end{bmatrix} \begin{bmatrix} i_n^{(1)} \\ i_n^{(2)} \end{bmatrix} = \begin{bmatrix} X_n^{(1)} \\ X_n^{(2)} \end{bmatrix}, \tag{1.7}
$$

where

$$
\begin{aligned}
X_n^{(1)} &= D_1(V_n^{(1)} - V_{n+1}^{(1)}) - \alpha A(R_f C \dot{V}_n^{(2)} + f(V_n^{(2)})),\\
X_n^{(2)} &= D_2(V_n^{(2)} - V_{n+1}^{(2)}) + \alpha A(R_f C \dot{V}_{n+1}^{(1)} + f(V_{n+1}^{(1)})),
\end{aligned} \tag{1.8}
$$

which gives us

$$
i_n^{(1)} = \frac{1}{1-\alpha^2}(X_n^{(1)} - \alpha X_n^{(2)}), \quad i_n^{(2)} = \frac{1}{1-\alpha^2}(X_n^{(2)} - \alpha X_n^{(1)}). \tag{1.9}
$$

Substituting into (1.6), we have

$$
\begin{aligned}
R_f C \dot{V}_n^{(1)} + f_1(V_n^{(1)}) &= \frac{1}{1-\alpha^2}[(X_{n-1}^{(1)} - X_n^{(1)}) - \alpha(X_{n-1}^{(2)} - X_n^{(2)})],\\
R_f C \dot{V}_n^{(2)} + f_2(V_n^{(2)}) &= \frac{1}{1-\alpha^2}[(X_{n-1}^{(2)} - X_n^{(2)}) - \alpha(X_{n-1}^{(1)} - X_n^{(1)})].
\end{aligned} \tag{1.10}
$$

Computing $X_{n-1}^{(j)} - X_n^{(j)}$ for $j = 1, 2$ and inserting the resulting expressions into (1.10) brings us to system (1.1). Note that we will take $R_f C = 1$ since changing these parameters will only amount to a rescaling of the wave speed c after we impose a traveling wave ansatz.

2. Construction of a solution. In the construction of our solution, the speed c is assumed to be nonzero unless otherwise noted, and the nonlinearity f_i will be the idealized cubic-like function

$$
f_i(u) = u - h(u - a_i), \tag{2.1}
$$

where h denotes the Heaviside step function

$$
h(u) = \begin{cases} 0 & \text{if } u < 0,\\ [0,1] & \text{if } u = 0,\\ 1 & \text{if } u > 0. \end{cases} \tag{2.2}
$$

Note that $h(u)$ is a set-valued function, evaluating to the interval $[0, 1]$ when $u = 0$ and evaluating to a singleton everywhere else. This results in the $f_i(u)$ being set-valued functions as well. Thus, (1.1) with f_i given in (2.1) and (2.2) should be interpreted as a differential inclusion when $V_n^{(i)} = a_i$.

After imposing the traveling wave ansatz $V_n^{(i)}(t) = \varphi_i(n - ct)$, and letting $\xi = n - ct$, we have

$$
\begin{aligned}
(2.3)\quad -c\varphi_1'(\xi) + f_1(\varphi_1(\xi)) &= \frac{1}{1-\alpha^2}\left[D_1(L\varphi_1)(\xi) - \alpha D_2(L\varphi_2)(\xi)\right. \\
&\qquad \left. - \alpha A(N\varphi_2)(\xi) - \alpha^2 A(N\varphi_1)(\xi+1)\right], \\
-c\varphi_2'(\xi) + f_2(\varphi_2(\xi)) &= \frac{1}{1-\alpha^2}\left[-\alpha D_1(L\varphi_1)(\xi) + D_2(L\varphi_2)(\xi)\right. \\
&\qquad \left. + \alpha^2 A(N\varphi_2)(\xi) + \alpha A(N\varphi_1)(\xi+1)\right],
\end{aligned}
$$

where

$$
\begin{aligned}
(L\varphi)(\xi) &= \varphi(\xi+1) - 2\varphi(\xi) + \varphi(\xi-1), \\
(N\varphi)(\xi) &= -c[\varphi'(\xi-1) - \varphi'(\xi)] + [f(\varphi(\xi-1)) - f(\varphi(\xi))]. \qquad (2.4)
\end{aligned}
$$

It is natural to require the boundary conditions

$$
\varphi_i(-\infty) = 0, \qquad \varphi_i(+\infty) = 1 \qquad (2.5)
$$

for $i = 1, 2$. To help construct solutions to this system, we will initially assume that each φ_i satisfies $\varphi_i(\beta_i) = a_i$ for only one value, and we may assume one of these values to be zero by simply translating the argument. That is, we assume

$$
\varphi_i(\xi) \begin{cases} < a_i & \text{for} \quad \xi < \beta_i, \\ = a_i & \text{for} \quad \xi = \beta_i, \\ > a_i & \text{for} \quad \xi > \beta_i, \end{cases} \qquad (2.6)
$$

where we will take $\beta_1 = 0$ and $\beta_2 = \beta$. After we construct our candidate solutions, we will verify that they satisfy these assumptions.

With (2.6), we have that $h(\varphi_i(\xi) - a_i) = h(\xi - \beta_i)$, which gives us $f(\varphi_i(\xi)) = \varphi_i(\xi) - h(\xi - \beta_i)$. Now the system (2.3) becomes

$$
\begin{aligned}
(2.7)\quad -c\varphi_1'(\xi) &= \frac{1}{1-\alpha^2}\left[D_1(L\varphi_1)(\xi) - \alpha D_2(L\varphi_2)(\xi)\right. \\
&\qquad \left. - \alpha A(N\varphi_2)(\xi) - \alpha^2 A(N\varphi_1)(\xi+1)\right] - \varphi_1(\xi) + h(\xi), \\
-c\varphi_2'(\xi) &= \frac{1}{1-\alpha^2}\left[-\alpha D_1(L\varphi_1)(\xi) + D_2(L\varphi_2)(\xi)\right. \\
&\qquad \left. + \alpha^2 A(N\varphi_2)(\xi) + \alpha A(N\varphi_1)(\xi+1)\right] - \varphi_2(\xi) + h(\xi-\beta).
\end{aligned}
$$

Notice the presence of several Heaviside functions in each equation of (2.7). Each instance of the Heaviside function results in a discontinuity of the first derivative of the functions φ_i. For example, we expect to have discontinuities in the first derivative of φ_1 at $\xi = 0$, $\xi = 1$, $\xi = \beta$, and $\xi = \beta + 1$. Further, an appearance of $\varphi'(\xi + 1)$ in the first equation leads us to expect a discontinuity in the first derivative of φ_1 at $\xi = -1$. These discontinuities will be reflected in the solution we compute.

As outlined in Appendix A, candidate solutions to this system can be expressed as

$$
\varphi_i(\xi) = \frac{1}{2} + \frac{1}{2\pi}\int_0^\infty \sum_{j \in M_i} F_{i,j}(s)\cos(s(\xi - j)) + G_{i,j}(s)\frac{1}{s}\sin(s(\xi - j))ds, \qquad (2.8)
$$

where $M_i = \{\beta_i, \beta_i + 1, \beta_i - 1, \beta_{i^*}, \beta_{i^*} + 1\}$, $1^* = 2$ and $2^* = 1$, and

(2.9)
$$\begin{aligned}
F_{i,\beta_i}(s) &= [W(s)(1+2Q) - R_{i^*}(s)Y(s)], \quad & G_{i,\beta_i}(s) &= [X(s)(1+2Q) - R_{i^*}(s)Z(s)],\\
F_{i,\beta_i+1}(s) &= -QW(s), & G_{i,\beta_i+1}(s) &= -QX(s),\\
F_{i,\beta_i-1}(s) &= -QW(s), & G_{i,\beta_i-1}(s) &= -QX(s),\\
F_{i,\beta_{i^*}}(s) &= -\alpha(1-A)R_{i^*}(s)Y(s), & G_{i,\beta_{i^*}}(s) &= -\alpha(1-A)R_{i^*}(s)Z(s),\\
F_{i,\beta_{i^*}+1}(s) &= -\alpha A R_{i^*}(s)Y(s), & G_{i,\beta_{i^*}+1}(s) &= -\alpha A R_{i^*}(s)Z(s),
\end{aligned}$$

where

$$\begin{aligned}
W(s) &= \frac{B(s)}{\det M(s)} - \frac{B(-s)}{\det M(-s)} = \frac{2c[b_2c^2s^2 + b_2 - b_0]}{|\det M(s)|^2},\\
X(s) &= \frac{B(s)}{\det M(s)} + \frac{B(-s)}{\det M(-s)} = \frac{2[(b_2+b_1)c^2s^2 + b_2 + b_1 + b_0]}{|\det M(s)|^2},\\
Y(s) &= \frac{1}{\det M(s)} - \frac{1}{\det M(-s)} = \frac{2c[2b_2 + b_1]}{|\det M(s)|^2},\\
Z(s) &= \frac{1}{\det M(s)} + \frac{1}{\det M(-s)} = \frac{2[-b_2c^2s^2 + b_2 + b_1 + b_0]}{|\det M(s)|^2},
\end{aligned} \tag{2.10}$$

and

(2.11)
$$\begin{aligned}
Q &= k\alpha^2 A(1-A), \quad & \det M(s) &= b_2(s)B(s)^2 + b_1(s)B(s) + b_0(s) = a(s) + ib(s),\\
R_i(s) &= 2kD_iC(s), & a(s) &= (1 - c^2s^2)b_2(s) + b_1(s) + b_0(s),\\
k &= \frac{1}{1-\alpha^2}, & b(s) &= -cs(2b_2(s) + b_1(s)),\\
B(s) &= 1 - ics, & b_0(s) &= 4kD_1D_2C^2(s),\\
C(s) &= \cos(s) - 1, & b_1(s) &= -2kC(s)(D_1 + D_2),\\
E(s) &= 1 - e^{is}, & b_2(s) &= 1 - 2k\alpha^2 A(1-A)C(s).
\end{aligned}$$

Notice that the set M_i consists of all values at which the first derivative of φ_i is discontinuous. This agrees with our prediction based on inspection of the equations (2.7).

For convenience, we will suppress the s-dependence of the functions a, b, b_0, b_1, and b_2. Our next proposition establishes some basic properties of the φ_i, but to do this, we need to bound the integrands in the solutions (2.8). This is accomplished by the following lemma.

LEMMA 2.1. *Let $\alpha \in [0,1)$, $A \in [0,1)$, $\beta \in \mathbb{R}$, and $c \neq 0$. Then*

$$|\det M(s)|^2 \geq 1 \tag{2.12}$$

for $s \in \mathbb{R}$.

Proof. We leave the proof of this lemma to the second appendix. ∎

PROPOSITION 2.2. *Use the definition of φ_i as given in* (2.8)*, and let $A \in [0,1), \alpha \in [0,1)$, $\beta \in \mathbb{R}$, $\xi \in \mathbb{R}$, and $c \neq 0$. Then φ_i is continuous in A, α, β, ξ, and c.*

Proof. The previous lemma gives us a lower bound on the denominator of the integrands in (2.8), except when $s = 0$. However, the s appears in the denominator

only when there is a sine in the numerator. The numerators of the integrands are also bounded, and from the definitions (2.8), we see that the integrands are continuous in the variables listed above. Also note from the definitions in (2.10) and (2.11) that the integrands are $O(s^{-2})$ as $s \to \infty$, making the integral in (2.8) absolutely convergent. The continuity claims follow from this fact. ∎

3. Existence.

3.1. Proof of existence. Recall that the candidate solutions were derived using the assumptions given in (2.6).

THEOREM 3.1. *Let $A \in [0,1)$, $\beta \in \mathbb{R}$, and $c \neq 0$, and consider our solutions as functions of α and ξ. That is, let $\varphi_i = \varphi_i(\alpha, \xi)$. Also recall $\beta_1 = 0$ and $\beta_2 = \beta$. Suppose the following conditions are met:*

C1. *The φ_i are continuous in α for all $\xi \in \mathbb{R}$ and for $\alpha \in [0,1)$.*

C2. *There exists $\delta = \delta(A, \beta, D_1, D_2, c) > 0$ such that $\varphi_i'(0,\xi) > 0$ for $\xi \neq \beta_i$ in the interval $(\beta_i - \delta, \beta_i + \delta)$ (where $'$ indicates differentiation with respect to ξ).*

Then there exists a range of α for which $\varphi_i(\alpha,\xi) > a_i$ when $\xi > \beta_i$ and $\varphi_i(\alpha,\xi) < a_i$ when $\xi < \beta_i$,

Proof. Consider the functions

$$h_i(\alpha,\xi) = \varphi_i(\alpha,\xi) - \varphi_i(\alpha,\beta_i). \tag{3.1}$$

From the work done in [6], we know that $h_i(0,\xi) > 0$ for $\xi > \beta_i$ and $h_i(0,\xi) < 0$ for $\xi < \beta_i$ for $i = 1,2$. We also know that the h_i are continuous in α since, by Proposition 2.2, the φ_i are continuous in α. These two facts, together with the boundary conditions, guarantee that there is an α^* such that for $\alpha \in [0,\alpha^*)$, $h_i(\alpha,\xi) > 0$ for $\xi \geq \beta_i + \delta$ and $h_i(\alpha,\xi) < 0$ for $\xi \leq \beta_i - \delta$. So let $\alpha \in [0,\alpha^*)$. To ensure that $h_i(\alpha,\xi) > 0$ for $\xi \in (\beta_i, \beta_i + \delta)$ and $h_i(\alpha,\xi) < 0$ for $\xi \in (\beta_i - \delta, \beta_i)$, we must also require that $\varphi_i'(0,\xi) > 0$ for $\xi \in (\beta_i - \delta, \beta_i + \delta)\backslash\{\beta_i\}$ (where, once again, $'$ denotes differentiation with respect to ξ). So, condition C2 gives us that $\varphi_i(0,\xi) > 0$ for $\xi \in (\beta_i - \delta, \beta_i + \delta)\backslash\{\beta_i\}$, which satisfies the requirement given above. ∎

It remains to verify the hypotheses of Theorem 3.1. The strict monotonicity result from the $\alpha = 0$ case done in [6] is enough to satisfy condition C2 (this is true because when $\alpha = 0$, the solution is the same, up to a translation, for all β) and Proposition 2.2 satisfies condition C1. We now verify that the φ_i satisfy our boundary conditions.

PROPOSITION 3.2. *For $i = 1,2$,*

$$\lim_{\xi\to-\infty} \varphi_i(\xi) = 0 \qquad \text{and} \qquad \lim_{\xi\to+\infty} \varphi_i(\xi) = 1. \tag{3.2}$$

Proof. Recall the definition of φ_i given in (2.8), and assume $\xi > 0$. Now use the change of variables $s \to \frac{s}{\xi}$ and take the limit as $\xi \to +\infty$, using the Lebesgue dominated convergence theorem. We have

$$\begin{aligned}
\lim_{\xi\to+\infty} \varphi_i(\xi) &= \frac{1}{2} + \frac{1}{2\pi} \lim_{\xi\to+\infty} \int_0^\infty \sum_{j\in M_i} \left[\frac{1}{\xi} F_{i,j}\left(\frac{s}{\xi}\right) \cos\left(s - \frac{sj}{\xi}\right) \right. \\
&\qquad \left. + G_{i,j}\left(\frac{s}{\xi}\right) \frac{1}{s} \sin\left(s - \frac{sj}{\xi}\right) \right] ds \\
&= \frac{1}{2} + \frac{1}{2\pi} \int_0^\infty \sum_{j\in M_i} \left[0 \cdot F_{i,j}(0) \cos(s) + G_{i,j}(0) \frac{1}{s} \sin(s) \right] ds \\
&= \frac{1}{2} + \frac{1}{2\pi} \int_0^\infty \frac{\sin(s)}{s} X(0) ds = \frac{1}{2} + \frac{1}{\pi} \int_0^\infty \frac{\sin(s)}{s} ds = 1.
\end{aligned}$$

Proof for the limit as $\xi \to -\infty$ is the same, except we assume $\xi < 0$. But note that when $\xi < 0$, the change of variables $s \to \frac{s}{\xi}$ results in the limits of integration becoming zero to $-\infty$, and everything else remains unchanged. The last expression then becomes

$$\frac{1}{2} + \frac{1}{\pi}\int_0^{-\infty} \frac{\sin(s)}{s} ds = \frac{1}{2} - \frac{1}{\pi}\int_{-\infty}^{0} \frac{\sin(s)}{s} = 0, \tag{3.3}$$

giving us the result. □

To summarize, we know there is an $\alpha^* > 0$ such that solutions exist for all $\alpha \in [0, \alpha^*)$. This next proposition gives a condition that implies our candidate solutions are not solutions of (2.7).

PROPOSITION 3.3. *Fix $A \in [0,1), \alpha \in [0,1)$, $\beta \in \mathbb{R}$, and $c \neq 0$. If either $\varphi_i(\beta_i) > 1$ or $\varphi_i(\beta_i) < 0$, then the candidate solutions given in* (2.8) *are not solutions of* (2.7).

Proof. By Proposition 3.2, $\varphi_i(\xi) \to 1$ as $\xi \to \infty$. Hence if $\varphi_i(\beta_i) > 1$, there will be a $\xi > \beta_i$ for which $\varphi_i(\xi) < \varphi_i(\beta_i)$, violating our original assumptions (2.6). Recall also that $\varphi_i(\xi) \to 0$ as $\xi \to -\infty$, so if $\varphi_i(\beta_i) < 0$, we have violated the assumption that $\varphi_i(\xi) < \varphi_i(\beta_i)$ for all $\xi < \beta_i$. □

Having proved the existence of our solutions, we turn our attention to uncovering some basic properties of these solutions and to plots of several solution curves.

3.2. Plots of waveforms. We wish to show the form of the traveling wave solutions, but first, a few comments about our numerical studies are in order. Because we have an explicit formula for our candidate solutions, we are able to compute a broad range of numerical results. That said, we must also note that the large number of parameters in this problem makes it unfeasible to completely canvass the parameter space. Instead, we have focused on parameter values we expect will be representative of a larger range of values or on those that illustrate interesting phenomena. We approximate the integrals using the adaptive Gaussian quadrature code `adapt` of [19] and to find zeros we use the combined secant/bisection code `zero` of [19].

In Theorem 3.1, we proved the existence of solutions for some range of α. The size of this range is unknown, and it is important to keep in mind that the existence of our candidate solutions may not be guaranteed for all combinations of parameter values explored in this section. We have, however, checked the necessary condition that $a_i \in (0,1)$, as mentioned in Proposition 3.3 for most of the parameter values in this section. In some instances, we have taken the additional step of numerically verifying (an admittedly finite range of) the candidate solutions themselves to verify that they satisfy our original assumptions. In particular, we have numerically determined waveforms with $D_1 = D_2 = 1$, $A = \beta = 0$, and c values of $10^{-1}, 10^0$, and 10^1, for α between 0 and .95, with a step size of .05.

Our intent in providing numerical results is twofold: to illustrate some of the results from the theoretical sections and to use numerical evidence to extend our knowledge of the problem and to possibly provide ideas for further study. (In particular, we wish to answer, at least tentatively, the questions of the effects of ephaptic coupling and nonalignment on the propagation of action potentials.) Figure 2 shows plots of wave forms for a small wave speed. Notice the large jumps; these correspond to discontinuities in the first derivative of the functions φ_i. A larger wave speed results in waves with much less pronounced jumps. An example of wave forms with larger c is given later in Figure 6, but we withhold these plots for now since we will use them to illustrate a different phenomenon.

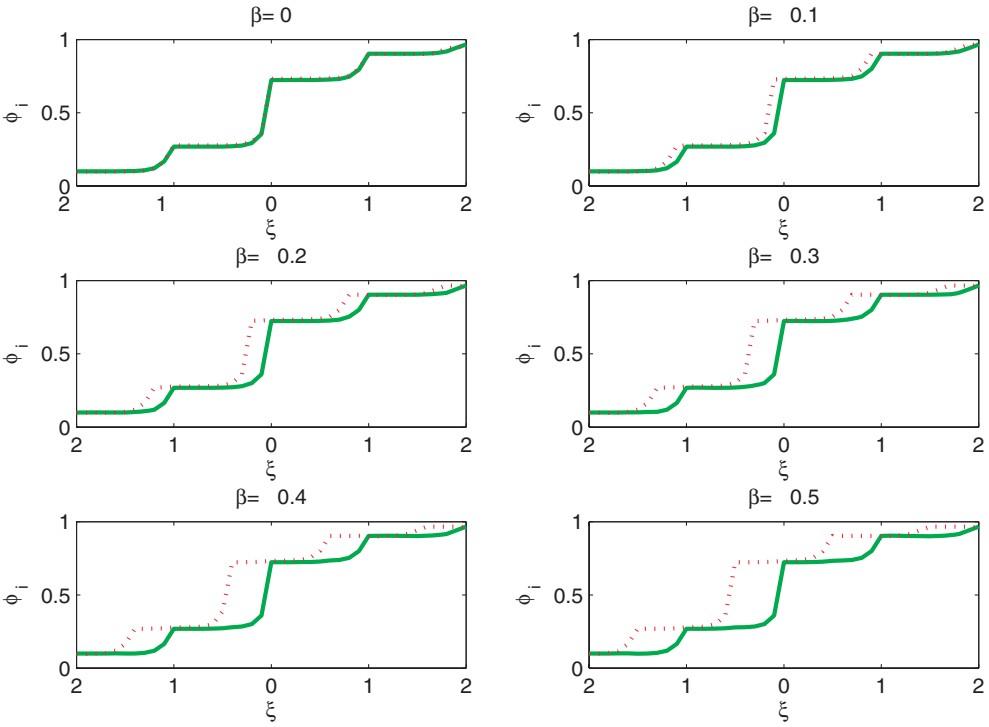

FIG. 2. *Wave profiles for* $c = .1$, $A = .5$, $\alpha = .1$, *and* $D_1 = D_2 = 1$. *The steep jumps are due to the small wave speed.*

4. Some properties of the solution. Recall that, from the outset, we have required both φ_1 and φ_2 to have the same wave speed c, because we are interested in solutions that move together. Also recall that we are declaring c and then allowing this choice of c to determine the values for a_i. The idea is this: given a wave speed c, we want to know how much the detuning parameters will have to change under different circumstances in order for the waves to stay together. We start by writing the a_i as functions of c and then by investigating the behavior of these functions. In particular, to find the range of propagation failure, we will compute the value of a_i as c approaches zero; this will tell us which values of a_i can support a nonzero wave speed. We also give an expression for the rate of change in the range of propagation failure when α moves away from zero, and we evaluate this expression explicitly in a few special cases.

4.1. Plots of $a_i(c)$ curves. Recall that from our original assumptions (2.6), we have that

$$a_i(c) = \varphi_i(\beta_i). \tag{4.1}$$

In Figures 3 and 4 we present $a_i(c)$ curves, which relate a given wave speed to the detuning parameters a_i. Take special note of the distance between $a_i(c)$ and $\frac{1}{2}$ at $c = 0$: this is the range of propagation failure mentioned several times already. Also note that smaller values of the diffusion constants D_i result in larger ranges of propagation failure. For $D_1 = D_2$, increasing the value of the D_i results in a smaller value of the detuning parameter required to achieve a certain wave speed.

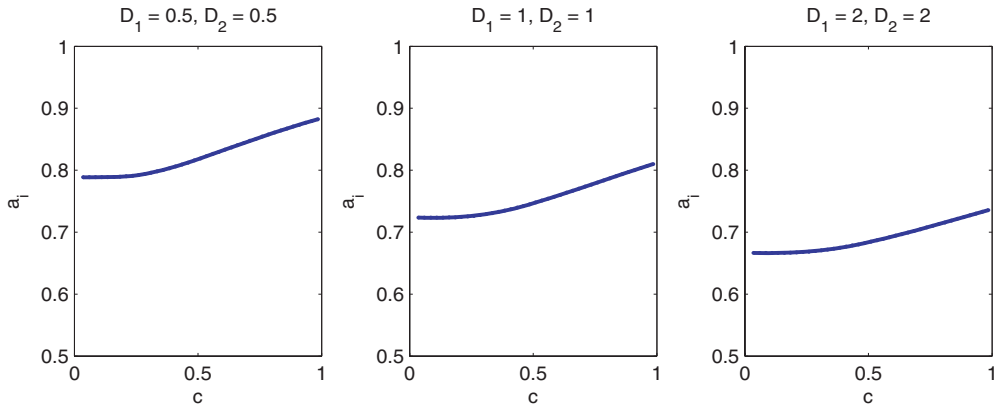

FIG. 3. *$a_i(c)$ curves for $A = .5, \beta = -.5$, and $\alpha = 0.1$. In this case, $a_1 = a_2$. Notice that $lim_{c\to 0}\ a_i(c)$ is significantly greater than $\frac{1}{2}$, implying a nontrivial range of propagation failure. Also notice that, for a given c, $a_i(c)$ decreases as $D_1 = D_2$ increases. Similar plots result in the case $A = 0 = \beta$.*

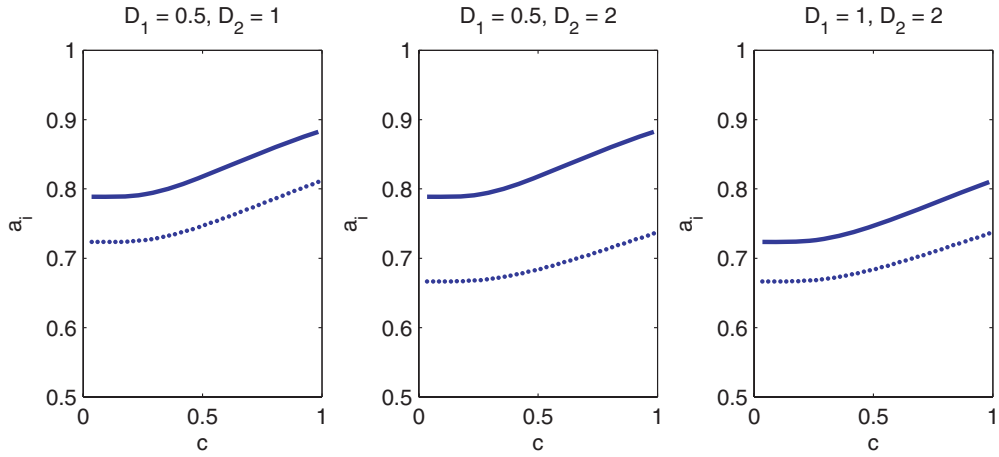

FIG. 4. *$a_i(c)$ curves for $A = .5, \beta = -.5$, and $\alpha = 0.1$, when $D_1 \neq D_2$. The solid line represents a_1, and the dotted line represents a_2. Similar plots result in the case $A = 0 = \beta$.*

4.2. Analytical results related to the $a_i(c)$ relationship. We comment on notation: some of the functions introduced in this section depend on several parameters; since there are so many parameters, we consider all parameters to be fixed except the ones listed explicitly in the argument of the function. Now consider the quantity

$$\Gamma_i(c) = a_i(c) - \frac{1}{2} = \frac{1}{2\pi}\int_0^\infty \sum_{j\in M_i} F_{i,j}(s)\cos(s(\beta_i - j)) + G_{i,j}(s)\frac{1}{s}\sin(s(\beta_i - j))ds. \tag{4.2}$$

Also define

$$g(c) = a_1(c) - a_2(c) = \Gamma_1(c) - \Gamma_2(c), \tag{4.3}$$

and note that this quantity represents the difference in the detuning parameters a_i required to make both waves travel at speed c. This definition allows us to state several important questions: 1. Given a noncoupled system with certain parameter

values, what happens to the quantity g when the coupling coefficient α moves away from zero? 2. Given a coupled, aligned system with certain parameter values, what happens to the quantity g when the alignment coefficient A moves away from zero? In this section we begin to answer these questions.

The following results about the oddness of the Γ_i illustrate the symmetry held by these functions under certain circumstances.

PROPOSITION 4.1. *Let $\Gamma_i(c)$ be defined as in* (4.2)*, and let $c \neq 0$. Then Γ_i is odd in c if and only if*

$$\int_0^\infty \sum_{j \in M_i} G_{i,j}(s) \frac{1}{s} \sin(s(\beta_i - j)) ds = 0 \tag{4.4}$$

for all $c \neq 0$. Further,

$$\lim_{c \to \pm\infty} \Gamma_i(c) = \frac{1}{2}. \tag{4.5}$$

Proof. Note that $X(s)$ and $Z(s)$, as given in (2.10), are even with respect to c, $W(s)$ and $Y(s)$ are odd with respect to c, and all other terms in Γ_i are independent of c. If the condition (4.4) holds, then we see from the definitions of $F_{i,j}$ and $G_{i,j}$ that all appearances of $X(s)$ and $Z(s)$ vanish, leaving us with Γ_i odd. Conversely, if the condition does not hold, then the dependence of Γ_i on c is not odd.

For the second statement, we use the change of variables $s \to \frac{s}{c}$, interchange the limiting process with the integration, and then evaluate the result:

$$\begin{aligned} \lim_{c \to +\infty} \Gamma_i(c) &= \frac{1}{2\pi} \int_0^\infty \lim_{c \to \infty} \sum_{j \in M_i} \cos\left(\frac{-sj}{c}\right) F_{i,j}\left(\frac{s}{c}\right) ds \qquad (4.6) \\ &= \frac{1}{2\pi} \int_0^\infty \lim_{c \to \infty} W\left(\frac{s}{c}\right) ds \\ &= \frac{1}{\pi} \int_0^\infty \frac{s^2+1}{s^4+2s^2+1} ds = \frac{1}{2}. \qquad (4.7) \end{aligned}$$

Once again, the limit as $c \to -\infty$ is evaluated in the same way, but the limits of integration change, much like in the proof of Proposition 3.2, giving us the result stated above. □

The second claim in this last theorem implies that increasing the wave speed to arbitrarily large values requires the detuning parameters to be very close to zero or one.

We also have the following corollary.

COROLLARY 4.2. *In particular, Γ_i is odd in the following cases:*

1. $\alpha = 0$,
2. $A = 0$ *and* $\beta = 0$,
3. $A = \frac{1}{2}$ *and* $\beta = -\frac{1}{2}$.

Proof. Conditions 1, 2, and 3 all imply (4.4) for all $c \neq 0$. □

Note that conditions 1, 2, and 3 are enough to imply the oddness of Γ_i, regardless of the values of the other parameters. It is not clear, however, whether there exist other solutions to the equation in (4.4), much less whether there exist other solutions that are independent of the other parameters.

Now consider the functions

$$P_Y(c) = \frac{1}{2\pi}\int_0^\infty \sum_{j\in M_1} F_{1,j}(s)\cos(s(\beta_1 - j)) - \sum_{j\in M_2} F_{2,j}(s)\cos(s(\beta_2 - j))ds$$

$$= \frac{k}{\pi}\int_0^\infty Y(s)C(s)[D_1 - D_2][1 + \alpha(1-A)\cos(s\beta) + \alpha A\cos(s(\beta+1))]ds, \tag{4.8}$$

$$P_Z^*(c) = \frac{1}{2\pi}\int_0^\infty \sum_{j\in M_1} G_{1,j}(s)\sin(s(\beta_1 - j)) - \sum_{j\in M_2} G_{2,j}(s)\sin(s(\beta_2 - j))ds$$

$$= \frac{k}{\pi}\int_0^\infty \frac{1}{s}Z(s)C(s)[D_1 + D_2][(1-A)\sin(s\beta) + A\sin(s(\beta+1))]ds. \tag{4.9}$$

In fact an α factors out of P_Z^*, so we will denote

$$P_Z(c) = \frac{P_Z^*(c)}{\alpha}, \tag{4.10}$$

which allows us to write

$$g(c) = P_Y(c) + \alpha P_Z(c), \tag{4.11}$$

where $g(c)$ is the difference between the detuning parameters a_1 and a_2, as given in (4.3). This representation of g will be helpful in proving the following results.

THEOREM 4.3. *Let g be defined as above. If either $\alpha = 0$ or $P_Z(c) = 0$, then*

$$c > 0 \Rightarrow g(c)\begin{cases} < 0 & \text{for } D_1 > D_2, \\ = 0 & \text{for } D_1 = D_2, \\ > 0 & \text{for } D_1 < D_2, \end{cases} \qquad c < 0 \Rightarrow g(c)\begin{cases} > 0 & \text{for } D_1 > D_2, \\ = 0 & \text{for } D_1 = D_2, \\ < 0 & \text{for } D_1 < D_2. \end{cases}$$

Proof. Clearly, if either assumption is true, then $g(c) = P_y(c)$. The only remaining task is to determine the sign of $P_y(c)$. To do this, note that $Y(s,c) > 0$ when $c > 0$ and $Y(s,c) < 0$ when $c < 0$ and that $C(s) \le 0$. Further, we have that

$$1 + \alpha(1-A)\cos(s\beta) + \alpha A\cos(s(\beta+1)) \tag{4.12}$$

$$> 1 - \alpha(1-A) - \alpha A = 1 - \alpha > 0, \tag{4.13}$$

and these estimates give the result above. ∎

The previous theorem determines the sign of g for a number of cases, since if either condition 2 or condition 3 from Corollary 4.2 is met, then $P_Z(c) \equiv 0$. The following results provide more examples of the symmetries of the functions Γ_i and g.

THEOREM 4.4. *Fix $\alpha \in [0,1)$. Then for $A \in (0,1)$,*

$$\Gamma_i(D_1, D_2, c, A, \beta) = -\Gamma_{i^*}(D_2, D_1, -c, A, \beta) = \Gamma_{i^*}(D_2, D_1, c, 1-A, -\beta - 1), \tag{4.14}$$

and for $A = 0$,

$$\Gamma_i(D_1, D_2, c, 0, \beta) = -\Gamma_{i^*}(D_2, D_1, -c, 0, \beta) = \Gamma_{i^*}(D_2, D_1, c, 0, -\beta). \tag{4.15}$$

Proof. Follows from the definitions of the functions $F_{i,j}$ and $G_{i,j}$ given in (2.9) and the definition of Γ_i given in (4.2). ∎

COROLLARY 4.5. *Fix $\alpha \in [0,1)$. Then for $A \in (0,1)$,*

$$\Gamma_i(D_1, D_2, c, A, \beta) = -\Gamma_i(D_1, D_2, -c, 1-A, -\beta - 1) \quad \text{and} \tag{4.16}$$

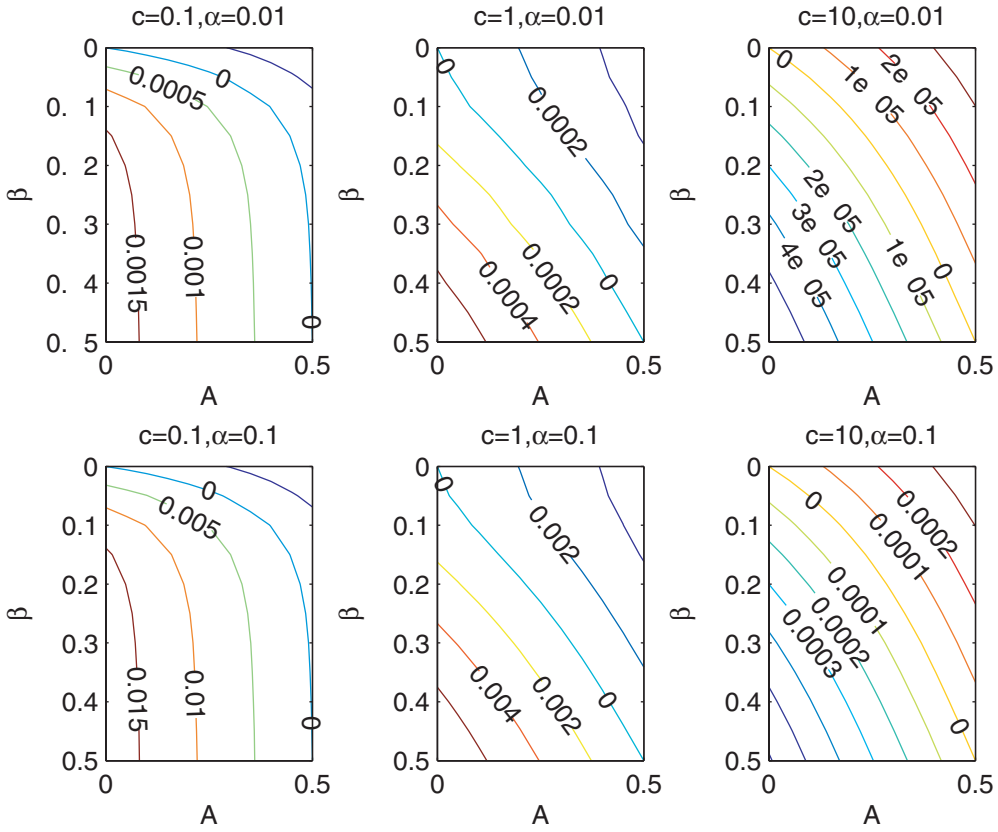

FIG. 5. *Contours of $g(A,\beta)$ for $D_1 = D_2 = 1$. Notice that for all $A \in [0, \frac{1}{2}]$, there is a β such that $g(A,\beta) = 0$.*

$$g(D_1, D_2, c, A, \beta) = -g(D_2, D_1, c, 1 - A, -\beta - 1) \tag{4.17}$$

$$= -g(D_1, D_2, -c, 1 - A, -\beta - 1) = g(D_2, D_1, -c, A, \beta), \tag{4.18}$$

and for $A = 0$,

$$\Gamma_i(D_1, D_2, c, 0, \beta) = -\Gamma_i(D_1, D_2, -c, 0, -\beta) \quad \textit{and} \tag{4.19}$$

$$g(D_1, D_2, c, 0, \beta) = -g(D_2, D_1, c, 0, -\beta) \tag{4.20}$$

$$= -g(D_1, D_2, -c, 0, -\beta) = g(D_2, D_1, -c, 0, \beta). \tag{4.21}$$

Proof. The proof follows from Theorem 4.4 and the definitions of Γ_i and g given in (4.2) and (4.3). □

Note that (4.14), (4.16), and (4.17) are also true for $A = 0$, but the statements given in (4.15), (4.19), and (4.20) are better results. We turn our attention now to the issue of nonalignment.

4.3. Numerical results related to nonalignment. We mentioned earlier that it is important to note which values of the parameters cause $a_1 = a_2$. This is equivalent, of course, to finding the zeros of our function g. The contour plots in Figure 5

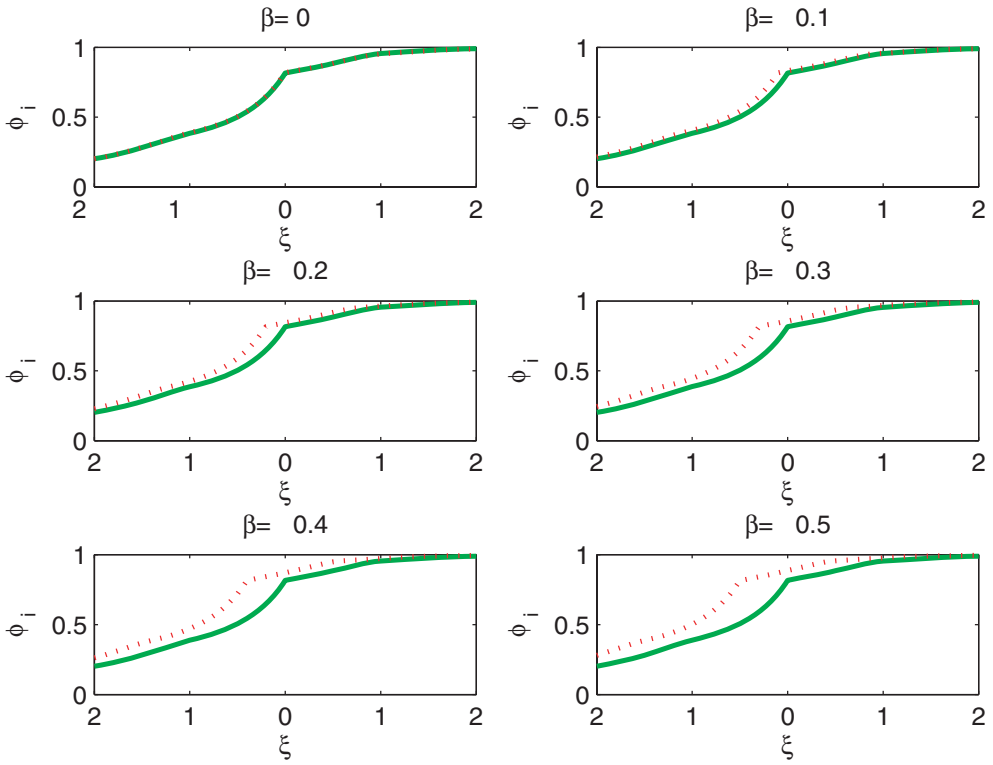

FIG. 6. *Wave profiles for* $D_1 = D_2 = 1$, $\alpha = .1$, $c = 1$, *and* $A = .3$. *The cusps in the graphs at* $a_i(\beta_i)$ *are the result of the Heaviside functions switching from* 0 *to* 1. *The solid line represents* φ_1, *and the dotted line represents* φ_2.

of $g = 0$ show that, given conditions with $A = 0$ that yield $g = 0$, we may move A away from zero, and, as long as we adjust β appropriately, g will remain zero.

For example, consider the bottom middle plot, in which $c = 1$ and $\alpha = .1$. When $A = 0 = \beta$, we see that $g(A, \beta) = 0$. In addition, for any $A \in [0, \frac{1}{2}]$, there is a $\beta \in [-\frac{1}{2}, 0]$ such that $g(A, \beta) = 0$. we see that this last statement is true of all plots in Figure 5, although we have not proved that such a β exists in $[-\frac{1}{2}, 0]$ in all circumstances.

Here we will fix α and examine the effects of moving the alignment parameter A away from zero. Recall our earlier mentioning of the parameter β as a time-delay. It is our contention that, loosely speaking, problems caused by moving A away from zero can be remedied by moving β a corresponding (but not necessarily equal) distance from zero. Consider, for instance, the case $\beta = 0$. Recalling our traveling wave ansatz $\xi = n - ct$, we see that at time $t = 0$, for instance, $\xi = 0$ will correspond with $n = 0$ for both fibers. However, if $A > 0$, then wave 2 will be "ahead" of wave 1. To make this notion a little more precise, we will speak of the "location" of a wave as being at β_i. Moving β below zero corrects this problem by having wave 2 reach a given node at a time β later than wave 1 reaches the same node. The upper left plot in Figure 6 gives an example of two waves that are lined up with respect to ξ when $\beta = 0$. Since $A \neq 0$, however, this lining up actually corresponds to one wave leading the other. It is only when β is moved below zero that the waves travel together, as indicated by the other plots in Figure 6.

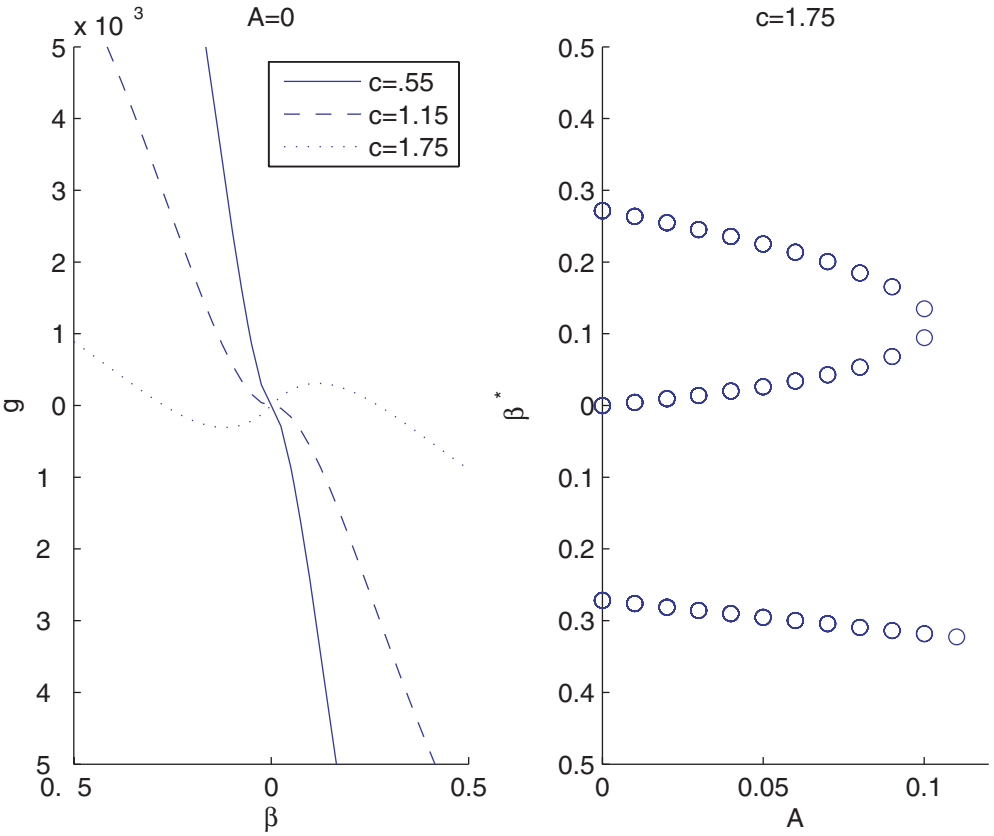

FIG. 7. *Left: plots of $g(\beta)$ for $A = 0$. When $c = 1.75$, we see that $g(\beta) = 0$ for three different values of β. Right: zeros of $g(\beta)$ for $c = 1.75$. This plot shows how the three zeros shown in the left plot for $c = 1.75$ change as A changes. In both plots, $D_1 = D_2 = 1$ and $\alpha = .1$.*

The relationship between A and β has been relatively unexplored analytically. We want to know if A and β are independent of each other, or if fixing a value of A determines a value of β. Consider an uncoupled system in which $D_1 = D_2$, and note that this is equivalent to the condition $a_1 = a_2$. We want to know, given fixed values of A and $\alpha > 0$, whether there exists a critical value of β that still results in $a_1 = a_2$. This section provides evidence that such a β does exist for a variety of combinations of A, α and c (see Tables 4.1 and 4.2).

Further, these numerical results show that multiple such β values exist for certain combinations of these parameters, particularly for higher wave speeds. We find evidence for the existence of a pitchfork bifurcation in the parameter c with respect to these critical β values. That is, fixing all parameters but c, there exists a c^* (dependent on the other parameters) such that for $c \leq c^*$ there is only one critical β value, but that for $c > c^*$, there are three critical β values. The left plot in Figure 7 shows the cubic-like shape of $g(\beta)$ and shows the transition between $g(\beta)$ having one zero to $g(\beta)$ having three zeros in the range shown. The plot on the right shows implicitly the dependence of this value c^* on the parameter A in particular. For smaller values of A, a wave speed of $c = 1.75$ results in three critical β values, whereas for large enough values of A, there is only one critical β value for which $g(\beta, c) = 0$. The possible implications of a pitchfork bifurcation are interesting. For instance, if the

single traveling wave before the bifurcation is stable, which is reasonable to expect for small values of the coupling parameter α (see [7]), then we might expect an exchange of stability at the bifurcation point.

The existence of multiple β values that result in $g = 0$ suggests that perhaps the two waves can travel at the same speed even if one wave is lagging behind the other. This allows for the possibility of two waves traveling together even if their respective nerve fibers were not activated at exactly the same time. Other numerical results indicate that the value of c^* increases as A increases. This suggests that in the case of staggered nodes, higher wave speeds are required in order to have multiple critical β values. The implications of this would be very interesting if there is in fact an exchange of stability at the bifurcation point. If the middle branch becomes unstable after the bifurcation, then this would imply that the middle branch stays stable for a larger range of the wave speed when the nodes are staggered than when they are aligned.

5. Propagation failure.

5.1. Analytical results on propagation failure. As mentioned earlier, propagation failure is a well-documented phenomenon in lattice differential equations (see [6] and [11], among others), and it is certainly important to compute the range of a_i that result in a zero wave speed. We address this issue here. This section involves a few lengthy calculations, so we highlight the most important results of this section with a few theorems and then proceed with the calculations that lead to the results. To determine the range of propagation failure, we need to compute $\lim_{c\to 0}\Gamma_i(c)$. In light of the symmetries of Γ_i presented previously, we will focus on the computation of $\lim_{c\to 0+}\Gamma_i(c)$. Also, we will start by considering only the case where $\Gamma_i(c)$ is odd, and the consideration of the other case will follow. These steps are carried out in the following proposition.

PROPOSITION 5.1. *Let $\alpha \in [0,1)$, $A \in [0,1)$, $\beta \in \mathbb{R}$, and $\gamma_i = \lim_{c\to 0+}\Gamma_i(c)$. Then*

$$\gamma_i = \lim_{c\to 0+}\Gamma_i(c) = \sum_{j\in M_i}\frac{1}{2\pi p}\int_0^\infty\int_0^p F^*_{i,j}\left(\frac{t}{c},s\right)\cos(s(\beta_i-j))dsdt + \int_0^\infty [G_{i,j}(s)]_{c=0}\frac{1}{s}\sin(s(\xi-j))ds. \tag{5.1}$$

Proof. We will compute $\lim_{c\to 0}\int_0^\infty F_{i,j}(s)\cos(s(\beta_i - j))ds$ individually for a given (i,j) pair. First, let's assume $\beta_i - j$ is rational, and then define

$$p_{i,j} := p^*_{i,j}2\pi := \operatorname{lcm}\left(2\pi, \frac{2\pi}{\beta_i - j}\right), \tag{5.2}$$

the common period of the periodic functions that define $F_{i,j}$, and

$$p = \operatorname{lcm}(p_{i,j}), \tag{5.3}$$

the least common multiple over all i and j of the $p_{i,j}$. For notational purposes, we consider W, X, Y, and Z as functions of two variables, e.g., $W(s) = W(u,v)$: the first argument will go in place of all nonperiodic instances of s, and the second argument will go in place of all periodic instances of s. As an example, we would write the function $q(s) = as^4 + bs^2 + sin(s)$ as $q(u,v) = au^4 + bu^2 + \sin(v)$.

For the $F_{i,j}$ and $G_{i,j}$ we will use the same convention. So, for instance,

$$F_{1,0}(u,v) = [W(u,v)(1+2Q) - R_2(v)Y(u,v)], \tag{5.4}$$

and $F_{i,j}(s,s) = F_{i,j}(s)$. Then

(5.5)

$$\begin{aligned}\frac{1}{2\pi}\int_0^\infty F_{i,j}(s)\cos(s(\beta_i - j))ds &= \frac{1}{2\pi}\sum_{n=0}^{\infty}\int_{np}^{(n+1)p} F_{i,j}(s)\cos(s(\beta_i - j))ds \\ &= \frac{1}{2\pi}\sum_{n=0}^{\infty}\left(\int_{np}^{(n+1)p} F_{i,j}(np,s)\cos(s(\beta_i - j))ds + E_n\right) \\ &:= \Phi + \frac{1}{2\pi}\sum_{n=0}^{\infty} E_n,\end{aligned}$$

where

$$E_n = \int_{np}^{(n+1)p} F_{i,j}(s)\cos(s(\beta_i - \xi))ds - \int_{np}^{(n+1)p} F_{i,j}(np,s)\cos(s(\beta_i - j))ds \tag{5.6}$$

and

$$\Phi = \frac{1}{2\pi}\sum_{n=0}^{\infty}\int_{np}^{(n+1)p} F_{i,j}(np,s)\cos(s(\beta_i - j))ds. \tag{5.7}$$

We will show in an appendix that

$$\sum_{n=0}^{\infty} E_n \to 0 \quad \text{as} \quad c \to 0, \tag{5.8}$$

but for now, we will assume this is true and complete the calculation of Φ. From the definitions of W and Y given in (2.10), notice that c factors out of the $F_{i,j}$. This allows us to write

$$F_{i,j}(s) = cF^*_{i,j}(s), \tag{5.9}$$

and we will denote

$$P_{i,j}(t) = \frac{1}{p}\int_0^p F^*_{i,j}(\frac{t}{c}, s)\cos(s(\beta_i - j))ds. \tag{5.10}$$

Then

$$\begin{aligned}\Phi &= \frac{c}{2\pi}\sum_{n=0}^{\infty}\int_{np}^{(n+1)p} F^*_{i,j}(np, s)\cos(s(\beta_i - j))ds \\ &= \frac{pc}{2\pi}\sum_{n=0}^{\infty}\frac{1}{p}\int_0^p F^*_{i,j}(np, s)\cos(s(\beta_i - j))ds \\ &= \frac{pc}{2\pi}\sum_{n=0}^{\infty} P_{i,j}(npc).\end{aligned} \tag{5.11}$$

Viewing this final quantity as a Riemann sum, we arrive at

$$\Phi = \frac{1}{2\pi}\int_0^{\infty} P_{i,j}(t)dt = \frac{1}{2\pi p}\int_0^{\infty}\int_0^p F^*_{i,j}\left(\frac{t}{c}, s\right)\cos(s(\beta_i - j))dsdt. \tag{5.12}$$

This brings us to the expression, for Γ_i odd,

$$\gamma_i = \lim_{c\to 0}\Gamma_i(c) = \sum_j \frac{1}{2\pi p}\int_0^{\infty}\int_0^p F^*_{i,j}\left(\frac{t}{c}, s\right)\cos(s(\beta_i - j))dsdt. \tag{5.13}$$

If Γ_i is not odd, then we need to consider the effect of the $G_{i,j}$. However, this is much easier to compute since

$$\lim_{c\to 0}\int_0^{\infty} G_{i,j}(s)\frac{1}{s}\sin(s(\xi - j))ds = \int_0^{\infty}\left[G_{i,j}(s)\right]_{c=0}\frac{1}{s}\sin(s(\xi - j))ds, \tag{5.14}$$

and so we have the general formula

$$\begin{aligned}\gamma_i = \lim_{c\to 0}\Gamma_i(c) = &\sum_j \frac{1}{2\pi p}\int_0^{\infty}\int_0^p F^*_{i,j}\left(\frac{t}{c}, s\right)\cos(s(\beta_i - j))dsdt \\ &+ \int_0^{\infty}\left[G_{i,j}(s)\right]_{c=0}\frac{1}{s}\sin(s(\xi - j))ds. \qquad \square\end{aligned} \tag{5.15}$$

One of our goals here is to investigate the changes in this quantity with respect to a change in α and, in particular, the difference in the range of propagation failure between when $\alpha = 0$ and when $\alpha > 0$. To this end, we let $\gamma_i = \gamma_i(\alpha)$, calculate $\gamma_i'(\alpha)$, and evaluate this expression at $\alpha = 0$. In a few special cases, we have an explicit value for $\gamma_i'(\alpha)$ in terms of D_1 and D_2. The following theorem gives this result.

THEOREM 5.1. *Let $D_1 = D_2 := D$, and consider the function $\gamma_i = \gamma_i(\alpha)$.*

1. *If $A = 0 = \beta$, then*

$$\gamma_i'(0) = \frac{D}{(4D+1)^{\frac{3}{2}}} > 0. \tag{5.16}$$

2. *If $A = \frac{1}{2}$ and $\beta = -\frac{1}{2}$, then*

$$\gamma_i'(0) = 0. \tag{5.17}$$

Recall that $\gamma_i = \lim_{c\to 0+} a_i(c) - \frac{1}{2}$. If $\gamma_i > 0$, then there is a positive range of propagation failure. The results above quantify how the size of this range changes as α moves away from zero. Before we proceed with the proof of this theorem, let us interpret the results in terms of the ephaptic coupling model. This theorem states that turning the coupling on results in an increase in the range of propagation failure when the nodes are aligned, but that turning the coupling on results in a decrease in the range of propagation failure when the nodes are staggered. Intuitively, it seems reasonable that staggering the nodes would result in a decrease in this range. The two-fiber problem with staggering seems very much like the one-fiber problem with twice as many nodes squeezed into the same space. A shorter internodal distance is reflected by an increase in the diffusion coefficient, which has the effect of decreasing the range of propagation failure. As the coupling increases, the fibers interact more, increasing the effect of the shorter internodal distance.

The result for the aligned case is more easily understood by thinking about the system (2.7). When $A = 0 = \beta$, we are left with

$$\begin{aligned} -c\varphi_1'(\xi) &= \frac{1}{1-\alpha^2}\left[D_1(L\varphi_1)(\xi) - \alpha D_2(L\varphi_2)(\xi)\right] - \varphi_1(\xi) + h(\xi), \\ -c\varphi_2'(\xi) &= \frac{1}{1-\alpha^2}\left[-\alpha D_1(L\varphi_1)(\xi) + D_2(L\varphi_2)(\xi)\right] - \varphi_2(\xi) + h(\xi), \end{aligned} \tag{5.18}$$

and when $D_1 = D_2$, we expect to have $\varphi_1 = \varphi_2$. In this situation, the system would become two copies of the equation

$$\begin{aligned} -c\varphi'(\xi) &= \frac{1}{1-\alpha^2}\left[D(1-\alpha)(L\varphi)(\xi)\right] - \varphi(\xi) + h(\xi) \\ &= \frac{D}{1+\alpha}(L\varphi)(\xi) - \varphi(\xi) + h(\xi), \end{aligned} \tag{5.19}$$

which is just the one-fiber problem with diffusion coefficient $\frac{D}{1+\alpha}$. This makes it easy to see that increasing α decreases the diffusion coefficient in this related one-fiber problem, which has the effect of increasing the range of propagation failure. Using the value of γ computed for the one-fiber problem in [6], and viewing γ as a function of α, we have

$$\gamma(\alpha) = \frac{1}{2(1+\frac{4D}{1+\alpha})^{\frac{1}{2}}} \tag{5.20}$$

and

$$\gamma'(\alpha) = \frac{D}{(1+\alpha)^2(1+\frac{4D}{1+\alpha})^{\frac{3}{2}}}. \tag{5.21}$$

In particular,

$$\gamma'(0) = \frac{D}{(1+4D)^{\frac{3}{2}}}, \tag{5.22}$$

which is in agreement with the result obtained in the theorem. This formula also sheds light on how the range of propagation failure might decrease for all values of α. Unfortunately, such an argument cannot be made when $A \neq 0$. However, the reasoning used here works for any nonlinearity f for which the wave speed increases

with the diffusion coefficient. In particular, we expect a similar claim holds for a cubic nonlinearity, although we are not able to determine the size of the range quantitatively in that case.

Note that here we have an expression for $\gamma'(0)$ when $A = 0 = \beta$ and when $A = \frac{1}{2}, \beta = -\frac{1}{2}$, but not for values of A in $(0, \frac{1}{2})$. We are interested in the quantity $\gamma'(0)$ primarily when $a_1 = a_2$. That is, if we consider $\gamma = \gamma(\alpha, A, \beta)$, we want to compute $\left.\frac{\partial \gamma}{\partial \alpha}\right|_{(\alpha,A,\beta^*)=(0,A,\beta^*)}$ for $A \in (0, \frac{1}{2})$, where β^* is such that $a_1 = a_2$. The difficulty in extending the results of Theorem 5.1 to $A \in (0, \frac{1}{2})$ lies in determining analytically the relationship between A and β^*.

We now turn our attention to the proof of Theorem 5.1.

Proof. Let $\gamma_i = \gamma_i(\alpha)$ and let $W, X, Y, Z, F_{i,j}$, and $G_{i,j}$ be functions of α as well. We would like to calculate $\gamma_i'(0)$. To do this note that

$$W'(0) = X'(0) = Y'(0) = Z'(0) = Q'(0) = 0, \tag{5.23}$$

and from this we obtain

$$F'_{i,\beta_i}(0) = F'_{i,\beta_i+1}(0) = F'_{i,\beta_i-1}(0) = G'_{i,\beta_i}(0) = G'_{i,\beta_i+1}(0) = G'_{i,\beta_i-1}(0) = 0 \tag{5.24}$$

and

$$\begin{aligned} F'_{i,\beta^*}(0) &= -(1-A)R_{i^*}Y, \\ F'_{i,\beta^*+1}(0) &= -AR_{i^*}Y, \\ G'_{i,\beta^*}(0) &= -(1-A)R_{i^*}Z, \\ G'_{i,\beta^*+1}(0) &= -AR_{i^*}Z. \end{aligned} \tag{5.25}$$

Since $D_1 = D_2 := D$, we have $R_1 = R_2 := R$, and

$$\gamma_i'(0) = \frac{2}{\pi p}\int_0^p \int_0^\infty \frac{T(s)}{(t^2 + T^2(s))^2} P(s)dtds - \frac{1}{\pi}\int_0^\infty \frac{1}{sT^2(s)}Q(s)ds, \tag{5.26}$$

where

$$\begin{aligned} T(s) &= 2DC(s) - 1, \\ P(s) &= R(s)\left[(1-A)\cos\left(s(\beta_i - \beta_{i^*})\right) + A\cos\left(s(\beta_i - (\beta_{i^*}+1))\right)\right], \\ Q(s) &= R(s)\left[(1-A)\sin\left(s(\beta_i - \beta_{i^*})\right) + A\sin\left(s(\beta_i - (\beta_{i^*}+1))\right)\right]. \end{aligned} \tag{5.27}$$

Some calculation yields that the complex equation $T(z) = 0$ has roots in

$$\left\{ z = a + ib \;\middle|\; a = 2m\pi \text{ for } m \in \mathbb{Z}, b = \cosh^{-1}\left(1 + \frac{1}{2D}\right)\right\}. \tag{5.28}$$

We focus on the calculation of the inner integral in the first term of (5.26). The complex roots of $z^2 + T^2(s))^2 = 0$ are $z = \pm iT(s)$. Note that since $T(s) < 0$ for real s, $P_1 = -iT(s)$ lies in the upper half-plane. Denoting

$$f(z) = \frac{1}{(z^2 + T^2(s))^2} = \frac{1}{(z - iT(s))^2(z + iT(s))^2}, \tag{5.29}$$

we have that

$$\operatorname{res}_f(P_1) = \frac{i}{4T^3(s)}. \tag{5.30}$$

Then

$$\int_0^\infty \frac{T(s)}{(t^2+T^2(s))^2}P(s)dt = \pi i \mathrm{res}_f(P_1) = \frac{-\pi}{4T^3(s)} \tag{5.31}$$

and

$$\frac{2}{\pi p}\int_0^p \int_0^\infty \frac{T(s)}{(t^2+T^2(s))^2}P(s)dtds = -\frac{1}{2p}\int_0^p \frac{1}{T^2(s)}P(s)dt := \Psi. \tag{5.32}$$

Let

$$p^* = \mathrm{lcm}(p^*_{i,j}), \text{ and } q_{i,j} = \frac{p^*}{p^*_{i,j}}. \tag{5.33}$$

To compute the integral Ψ, we use the change of variables $z = e^{\frac{is}{p^*}}$, $dz = \frac{i}{p^*}e^{\frac{is}{p^*}}ds = \frac{iz}{p^*}ds$, which results in a contour integral around the unit circle. Now we may write

(5.34)

$$T(z) = 2D\left(\frac{z^{p^*}+z^{-p^*}}{2}-1\right)-1,$$

$$P(z) = 2D\left(\frac{z^{p^*}+z^{-p^*}}{2}-1\right)\left[(1-A)\left(\frac{z^{q_{i,\beta_{i^*}}}+z^{-q_{i,\beta_{i^*}}}}{2}\right)+A\left(\frac{z^{q_{i,\beta_{i^*+1}}}+z^{-q_{i,\beta_{i^*+1}}}}{2}\right)\right].$$

Multiplying the top and bottom of the integrand by z^{2p^*-1} leaves the denominator as the square of a quadratic in z^{p^*}, with zeros given by

$$z_\pm^{p^*} = 1+\frac{1}{2D}\pm\frac{\sqrt{4D+1}}{2D}. \tag{5.35}$$

We have $|z_-^{p^*}|<1<|z_+^{p^*}|$, so the integrand has p^* distinct poles inside the unit circle, each of order 2. Labeling these poles $r_1,\dots,r_{p^*}$ we have

$$\Psi = -\frac{q}{i}\frac{1}{2p}2\pi i \mathrm{res}\sum_{m=1}^{q}\left(\frac{P(z)}{T^2(z)},r_i\right) = -\frac{1}{2}\mathrm{res}\sum_{m=1}^{q}\left(\frac{P(z)}{T^2(z)},r_i\right). \tag{5.36}$$

This quantity can be computed explicitly in several special cases. We will start with $A=0$, $\beta=0$. In this case, $P(s)=R(s)$, $p^*=1$, and $Q(s)=0$. Then we have

$$r_1 = 1+\frac{1}{2D}-\frac{\sqrt{4D+1}}{2D} \tag{5.37}$$

and

$$\mathrm{res}\left(\frac{P(z)}{T^2(z)},r_1\right) = \frac{-2D}{(4D+1)^{\frac{3}{2}}}, \tag{5.38}$$

which gives us

$$\gamma_i'(0) = \frac{D}{(4D+1)^{\frac{3}{2}}} > 0. \tag{5.39}$$

For $A = \frac{1}{2}$, $\beta = -\frac{1}{2}$, we have $P(s) = R(s)cos(\frac{s}{2})$, $p^* = 2$, and $Q(s) = 0$. We use the roots

$$r_1, r_2 = \pm \frac{\sqrt{2D(2D + 1 - \sqrt{4D + 1})}}{2D} \tag{5.40}$$

and

$$\operatorname{res}\left(\frac{P(z)}{T^2(z)}, r_1\right) + \operatorname{res}\left(\frac{P(z)}{T^2(z)}, r_2\right) = 0, \tag{5.41}$$

implying $\gamma_i'(0) = 0$ in this case. □

Unfortunately, explicit results like those given above are very difficult to find for more general parameter values. The problem lies in the computation of the second integral in equation (5.26). In an attempt to carry out this calculation, we see that the integral

$$\Omega = \frac{1}{\pi} \int_0^\infty \frac{Q(z)}{zT^2(z)} dz \tag{5.42}$$

can be evaluated using the calculus of residues. The poles of this integrand are given by

$$r_m = 2m\pi + i\cosh^{-1}\left(1 + \frac{1}{2D}\right), \tag{5.43}$$

which are of order 2. Then

$$\Omega = \pi i \sum_{m=-\infty}^{\infty} \operatorname{res}\left(\frac{Q(z)}{zT^2(z)}, r_m\right). \tag{5.44}$$

Now using $'$ to denote differentiation with respect to the complex variable z, we write

$$\operatorname{res}\left(\frac{Q(z)}{zT^2(z)}, r_m\right) = -\frac{Q'(r_m)}{r_m(4D + 1)} + \frac{Y(r_m)}{r_m D(4D + 1)}\left[\frac{1}{r_m} - \frac{i(2D + 1)\sqrt{4D + 1}}{4D + 1}\right]. \tag{5.45}$$

Since $\beta_i - \beta_{i^*}$ may take on any rational value, it is very difficult to simplify, in general, the expressions for $Q'(r_m)$ and $Y(r_m)$.

5.2. Numerical results on propagation failure. Figures 8 and 9 illustrate the effect of moving the coupling parameter α away from zero. Notice that when $A = 0$, $\beta = 0$, an increase in the coupling parameter α results in an increase in the range of propagation failure. However, when $A = .5$, $\beta = -.5$, this range decreases when α increases, suggesting that in the case of myelinated axons, nonalignment of the nodes of Ranvier allows for propagation in a larger range of values of the detuning parameter.

The plots in Figure 10 show the effects of coupling for positive wave speeds away from zero. Note that although our analytical expressions describe a_i as a function of c, these plots allow us to see what happens to the wave speed if we fix a value for $a_1 = a_2$ and then begin coupling. The results are especially interesting for small wave speeds: these plots indicate that coupling increases the wave speed for small wave

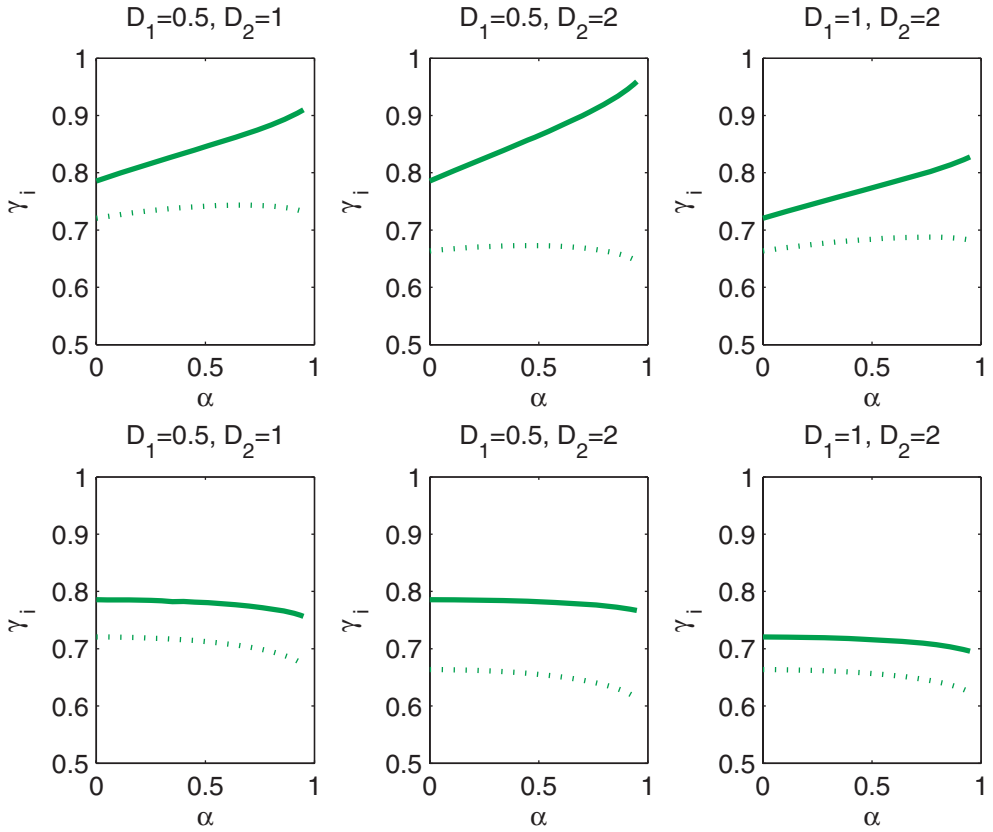

FIG. 8. *In the top plots, $A = 0 = \beta$; in the bottom plots, $A = .5$, $\beta = -.5$. The plots show the range of propagation failure when $D_1 \neq D_2$. The solid line represents a_1 and the dotted line a_2. (Note: values for failure were computed at $c = 10^{-2}$.)*

speeds when $A = .5$ and $\beta = -.5$ but that the same is not true when $A = 0 = \beta$. This also agrees with the results shown in Figure 9 when $D_1 = D_2$, and the results obtained for $\gamma_i'(\alpha)|_{\alpha=0}$ in previous sections.

6. Conclusion. We have shown that traveling back solutions to our system exist (at least) for small values of the coupling coefficient α, although further study is required to know the size of the range of α for which solutions exist. Using these solutions, we find that if the nodes are perfectly lined up or evenly staggered, and the waves travel together, then the sign of $g(c) = a_1 - a_2$ remains unchanged for all $\alpha \in [0, 1)$.

If we limit ourselves to the case $D_1 = D_2$, we can comment on the questions we set out to answer: namely, what are the effects of nonalignment and ephaptic coupling on the propagation of action potentials? We find that (a) if the nodes are perfectly lined up and the waves travel together, then the introduction of ephaptic coupling increases the size of the range of propagation failure, and (b) if the nodes are evenly staggered and the waves travel together, then the introduction of ephaptic coupling decreases the the size of the range of propagation failure.

The first result, in particular, agrees in spirit with results obtained in [2] with the cubic nonlinearity. There the authors use numerical methods to show that larger

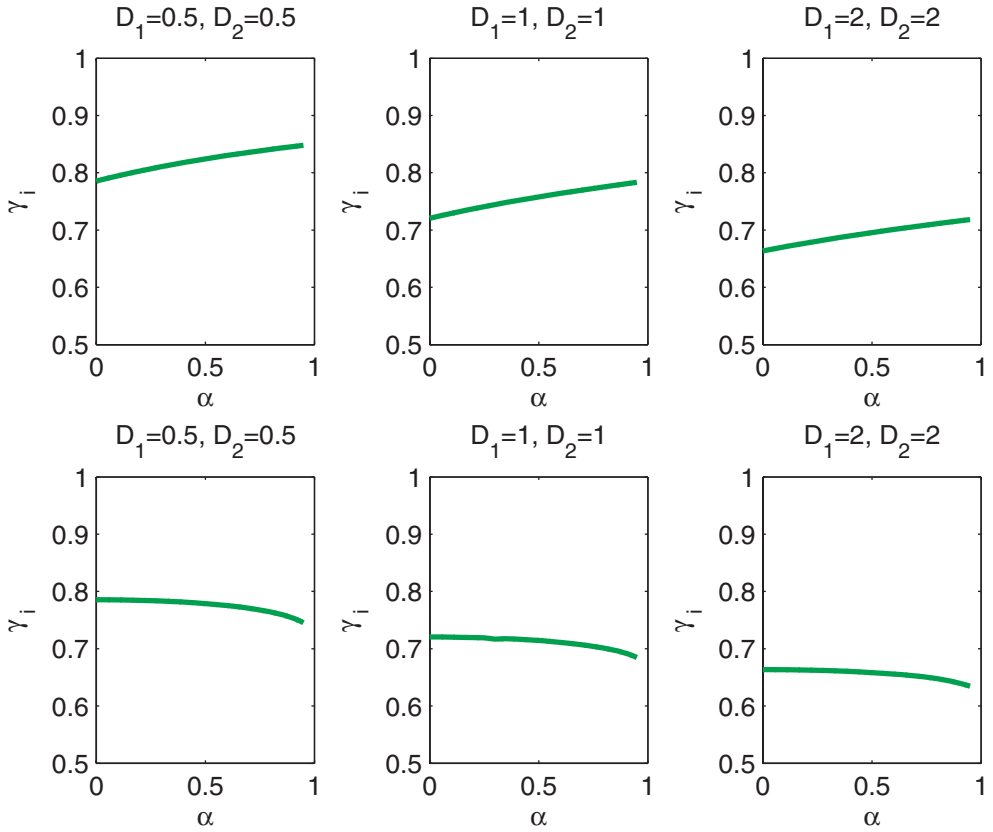

FIG. 9. *In the top plots, $A = 0 = \beta$; in the bottom plots, $A = .5$, $\beta = -.5$. The plots show the range of propagation failure when $D_1 = D_2$. In this case, $a_1 = a_2$. Note how the ranges increase as α increases on the top but decrease as α increases on the bottom. (Note: values for failure were computed at $c = 10^{-2}$.)*

values of the diffusion coefficient are required to achieve a given wave speed (in particular, small wave speeds) as the coupling increases. They give similar results when the nodes are staggered, except that for small wave speeds, coupling appears to have little or no effect on the value of the diffusion coefficient required to achieve a certain wave speed. These results may not be compared directly to ours, however, since the results in [2] relate to the effect of coupling on the diffusion coefficient, whereas our results relate to the effect of coupling on the detuning parameters. In [20] and [21], evidence is given that ephaptic coupling can have a significant effect on the propagation of action potentials in a model for cardiac cells, but these results focus on the length of time required for an action potential on one fiber to affect the action potential on the other fiber, as opposed to the amount of time required for action potentials to proceed along a given fiber. The work [20, 21] considers two types of coupling at once, ephaptic and ohmetric, and that approach may provide further insight into the dynamics of our present problem. The work in [3] is concerned with ephaptic coupling in nonmyelinated nerve fibers that might be modeled with (1.1) with large D. In [16], the authors focus on the effects of demyelination of nerve fibers in large bundles and observe a reduction in the speed of action potential propagation when the nodes of Ranvier are aligned.

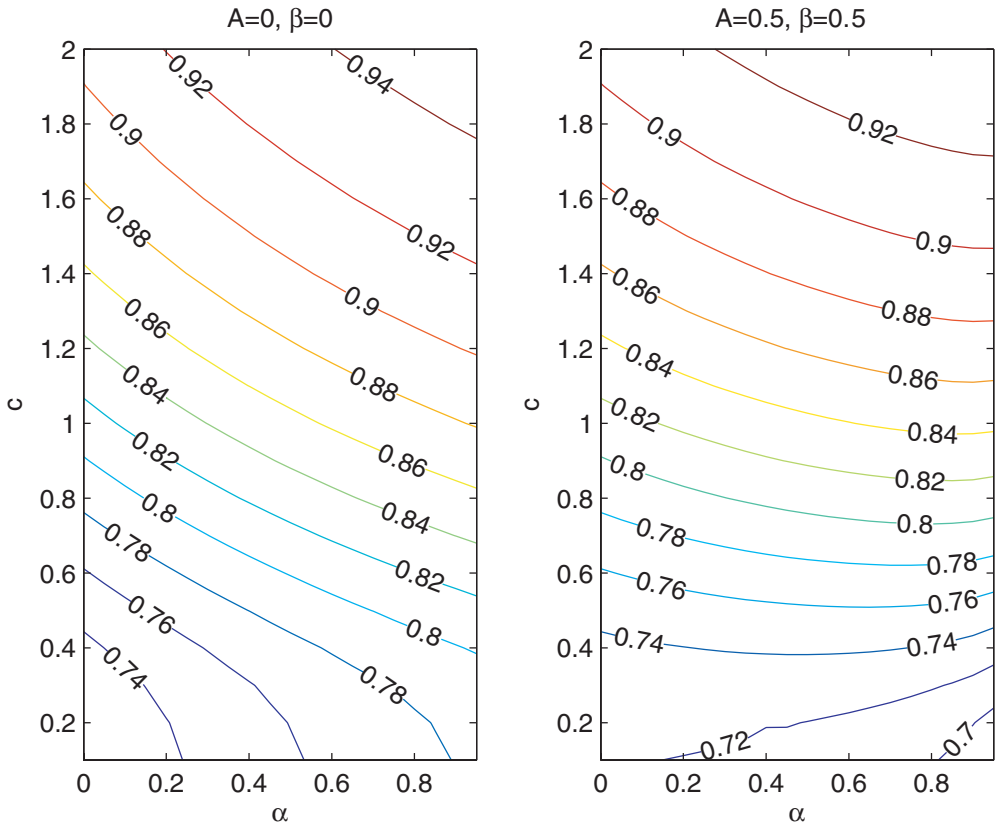

FIG. 10. *Level curves of $a_1(\alpha, c)$ when $D_1 = D_2 = 1$. Note that this implies $a_1 = a_2$ for both plots. In the right plot, the value of $a_i(c)$ decreases with α for small c, whereas in the left plot, the value of $a_i(c)$ increases with α for small c. This is another illustration of the claim that coupling decreases the range of propagation failure when the nodes are staggered but increases the range when the nodes are aligned.*

In addition, we have shown that for any value of A, there is a value of β such that $a_1 = a_2$. This means that regardless of the alignment of the nodes, we can have a situation in which the fibers are the same (i.e., $D_1 = D_2$ and $a_1 = a_2$) and the waves travel together. Perhaps a more surprising result is that with some parameter configurations, there are multiple such β values. The existence of these multiple β values gives rise to questions involving the stability of the solutions that we cannot answer with any certainty. The results in [2], and those in [1], point to the tendency of the two waves to match speeds (although in [1] a stronger type of coupling is considered). Given this fact, it seems reasonable that the same-speed solutions would be stable. However, the earlier results deal with waves that travel together at the same speed, and our results suggest the possibility of waves that travel at the same speed, with one wave lagging behind the other. This difference may give rise to interesting behavior with respect to the stability of the solutions.

Experience with the uncoupled case suggests that the piecewise linear and cubic problems may exhibit qualitatively similar behavior for small values of c and small ($D \leq 1$) values of D. It is reasonable to expect that qualitatively similar results related to propagation failure may hold in the cubic case, provided D is not too large.

7. Appendix A. We now present the details of the construction of our solution.

LEMMA 7.1. *Let* (φ_1, φ_2) *be a solution to* (2.5), (2.7). *Then there exists* $\varepsilon_0 > 0$ *such that for* $i = 1, 2$,

$$|\varphi_i(\xi)| \leq Ke^{\varepsilon_0 \xi} \text{ for } \xi < \min\{-1, \beta\} \tag{7.1}$$

for some $K > 0$.

Proof. Let $\psi_i(\xi) = \varphi_i(-\xi)$, and note that from our boundary conditions, $\psi_i(\xi) \to 0$ as $\xi \to \infty$. Then from the system (2.7), we have

$$\begin{aligned} c\psi_1'(\xi) + \psi_1(\xi) = \frac{1}{1-\alpha^2}[&D_1(L\psi_1)(\xi) - \alpha D_2(L\psi_2)(\xi) \\ &- \alpha A(N^*\psi_2)(\xi) - \alpha^2 A(N * \psi_1)(\xi + 1)], \\ c\psi_2'(\xi) + \psi_2(\xi) = \frac{1}{1-\alpha^2}[&-\alpha D_1(L\psi_1)(\xi) + D_2(L\psi_2)(\xi) \\ &+ \alpha^2 A(N^*\psi_2)(\xi) + \alpha A(N^*\psi_1)(\xi + 1)] \end{aligned}$$

for all $\xi > \max\{1, -\beta\}$, where

$$(N^*\psi_i)(\xi) = c(\psi'(\xi + 1) - \psi'(\xi)) + \psi(\xi + 1) - \psi(\xi). \tag{7.2}$$

For this proof only, let $\hat{\psi}_i$ denote the Laplace transform

$$\hat{\psi}_i(s) = \frac{1}{2\pi} \int_0^\infty e^{-s\xi} \psi_i(\xi) d\xi. \tag{7.3}$$

After applying the transform, we obtain the matrix equation

$$M^*(s) \begin{bmatrix} \hat{\psi}_1(s) \\ \hat{\psi}_2(s) \end{bmatrix} = J^*(s) \begin{bmatrix} \psi_1(0) \\ \psi_2(0) \end{bmatrix} + K^*(s), \tag{7.4}$$

where M^* and J^* are 2×2 matrix functions with entries

$$\begin{aligned} M_{11}^*(s) &= B^*(s) - 2kD_1C^*(s) + k\alpha^2 AE(s)B(s), \\ M_{12}^*(s) &= 2k\alpha D_2C^*(s) - k\alpha AE(-s)B(s), \\ M_{21}^*(s) &= 2k\alpha D_1C^*(s) - k\alpha AE(s)B(s), \\ M_{22}^*(s) &= B^*(s) - 2kD_2C^*(s) + k\alpha^2 AE(-s)B(s), \end{aligned} \tag{7.5}$$

and

$$\begin{aligned} J_{11}^*(s) &= c(1 + k\alpha^2 AE^*(-s)), \\ J_{12}^*(s) &= -ck\alpha AE^*(s), \\ J_{21}^*(s) &= -ck\alpha AE^*(-s), \\ J_{22}^*(s) &= c(1 + k\alpha^2 AE^*(s)), \end{aligned} \tag{7.6}$$

$$\begin{aligned} k &= \frac{1}{1-\alpha^2}, \\ C^*(s) &= \cosh(s) - 1, \\ B^*(s) &= 1 + cs, \\ E^*(s) &= 1 - e^s, \end{aligned} \tag{7.7}$$

and K^* is a vector with entries

$$\begin{aligned} K_1^*(s) &= k(D_1\Delta_1 - \alpha D_2\Delta_2) + k\alpha A(\Omega_2 + \alpha\Omega_1), \\ K_2^*(s) &= k(D_2\Delta_2 - \alpha D_1\Delta_1) - k\alpha A(\Omega_1 + \alpha\Omega_1), \end{aligned} \tag{7.8}$$

where

$$\begin{aligned} \Delta_i &= e^{-s}\int_{-1}^{0} e^{-s\xi}\psi_i(\xi)d\xi - e^{s}\int_{0}^{1} e^{-s\xi}\psi_i(\xi)d\xi, \\ \Omega_i &= \pm e^{\mp s}\left(\int_{\mp 1}^{0} e^{-s\xi}\psi_i'(\xi)d\xi + \int_{\mp 1}^{0} e^{-s\xi}\psi_i(\xi)d\xi\right). \end{aligned}$$

Integrating by parts, we see that

$$\int_0^1 e^{-s\xi}\psi_i(\xi) = \left.\frac{-e^{-s\xi}\psi_i(\xi)}{s}\right|_{\xi=0}^{1} + \frac{1}{s}\int_0^1 e^{-s\xi}\psi_i'(\xi)d\xi \tag{7.9}$$

and

$$\int_0^1 e^{-s\xi}\psi_i'(\xi) = \left.\frac{-e^{-s\xi}\psi_i'(\xi)}{s}\right|_{\xi=0}^{1} + \frac{1}{s}\int_0^1 e^{-s\xi}\psi_i''(\xi)d\xi \tag{7.10}$$

As long as these integrals are defined, we see that $K(s) = O(|s|^{-1})$ as $|\text{Im } s| \to \infty$, uniformly for Re s bounded. Assuming M^* is invertible, we obtain

$$\begin{bmatrix} \hat{\psi}_1(s) \\ \hat{\psi}_2(s) \end{bmatrix} = (M^*)^{-1}J^*(s)\begin{bmatrix} \psi_1(0) \\ \psi_2(0) \end{bmatrix} + O(|s|^{-2}) \quad \text{as} \quad |\text{Im } s| \to \infty \tag{7.11}$$

uniformly for Re s bounded, since $(M^*)^{-1} = O(|s|^{-2})$. This justifies the inversion of the Laplace transform, as well as the shift of contour around singularities on the imaginary axis. This gives us

$$\begin{aligned} \psi_i(\xi) &= \frac{1}{2\pi i}\int_{\varepsilon_0 - i\infty}^{\varepsilon_0 + i\infty} e^{s\xi}\hat{\psi}_i(s)ds \\ &= \frac{1}{2\pi i}\int_{-\varepsilon_0 - i\infty}^{-\varepsilon_0 + i\infty} e^{s\xi}\hat{\psi}_i(s)ds + \frac{1}{2\pi i}\sum_{\text{Re } s=0} e^{s\xi}\text{res}(\hat{\psi}_i, s), \end{aligned} \tag{7.12}$$

where the first equality results from the Laplace inversion formula, and the second is a contour shift around any poles of $\hat{\psi}_i$ in the imaginary axis, and where ε_0 is small enough so that there are no poles of $\hat{\psi}_i$ for $-\varepsilon_0 \le \text{Re } s < 0$. Further, if

$$(M^*)^{-1}J^*(s)\begin{bmatrix} \psi_1(0) \\ \psi_2(0) \end{bmatrix} = O(|s|^{-1}) \text{as} \quad |\text{Im } s| \to \infty \tag{7.13}$$

for $\varepsilon < 0$, then $\hat{\psi}_i = O(|s|^{-1})$ as $|\text{Im } s| \to \infty$.

We know that this condition is met, since $(M^*(s))^{-1} = O(|s|^{-1})$ and J^* oscillates as $|\text{Im } s| \to \infty$. Since we also have, from our boundary conditions, that $\psi_i(\xi) \to 0$ as $\xi \to \infty$, it is clear that

$$\text{res}(\hat{\psi}_i, s) = 0 \quad \text{for} \quad \text{Im } s = 0. \tag{7.14}$$

This fact, together with (7.11) and (7.12), gives us that

$$\psi_i(\xi)| \leq Ke^{-\varepsilon_0\xi} \quad \text{for} \quad \xi > \max\{1, -\beta\} \tag{7.15}$$

for $K > 0$, which is equivalent to the claim made in the statement of the lemma. □

Now define

$$\varphi_{i,\varepsilon}(\xi) = e^{-\varepsilon\xi}\varphi_i(\xi), \tag{7.16}$$

where $\varepsilon > 0$ is sufficiently small. By Lemma 7.1, if (φ_1, φ_2) satisfies (2.5), (2.7), then $\varphi_{i,\varepsilon}(\xi) \to 0$ exponentially fast as $\xi \to +\infty$ and $\xi \to -\infty$.

After writing the system (2.7) in terms of the $\varphi_{i,\varepsilon}(\xi)$, we multiply both sides of each equation by appropriate factors, integrate over $\mathbb{R}$, and solve for the Fourier transforms of the $\varphi_{i,\varepsilon}$. Using the Fourier transform

$$\hat{\varphi}_{i,\varepsilon}(s) = \int_{-\infty}^{+\infty} e^{-is\xi}\varphi_{i,\varepsilon}(\xi)d\xi \tag{7.17}$$

we obtain the matrix equation

$$M(s - i\varepsilon)\begin{bmatrix} \hat{\varphi}_{1,\varepsilon}(s) \\ \hat{\varphi}_{2,\varepsilon}(s) \end{bmatrix} = \frac{1}{is + \varepsilon}N(s), \tag{7.18}$$

where M is a 2×2 matrix function with entries

$$\begin{aligned} M_{11}(s) &= B(s) - 2kD_1C(s) + k\alpha^2AE(s)B(s), \\ M_{12}(s) &= 2k\alpha D_2C(s) - k\alpha AE(-s)B(s), \\ M_{21}(s) &= 2k\alpha D_1C(s) - k\alpha AE(s)B(s), \\ M_{22}(s) &= B(s) - 2kD_2C(s) + k\alpha^2AE(-s)B(s), \end{aligned} \tag{7.19}$$

N is a vector with entries

$$\begin{aligned} N_1(s) &= 1 - k\alpha A[E(-s)e^{-is\beta} - \alpha E(s)], \\ N_2(s) &= e^{-is\beta} - k\alpha A[E(s) - \alpha E(-s)e^{-is\beta}], \end{aligned}$$

and

$$\begin{aligned} k &= \frac{1}{1-\alpha^2}, \\ C(s) &= \cos(s) - 1, \\ B(s) &= 1 - ics, \\ E(s) &= 1 - e^{is}. \end{aligned} \tag{7.20}$$

The result given in Lemma 2.1 allows us to invert the matrix M, and we arrive at the solution of the matrix equation (7.18):

$$\hat{\varphi}_{1,\varepsilon}(s) = \frac{M_{22}(s - i\varepsilon)N_1(s - i\varepsilon) - M_{12}(s - i\varepsilon)N_2(s - i\varepsilon)}{(is + \varepsilon)\det M(s - i\varepsilon)}, \tag{7.21}$$

$$\hat{\varphi}_{2,\varepsilon}(s) = \frac{M_{11}(s - i\varepsilon)N_2(s - i\varepsilon) - M_{21}(s - i\varepsilon)N_1(s - i\varepsilon)}{(is + \varepsilon)\det M(s - i\varepsilon)}. \tag{7.22}$$

Then using the Fourier inversion formula and the definition in (7.16), we have

(7.23)
$$\varphi_1(\xi) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} e^{\xi(is+\varepsilon)}\hat{\varphi}_{i,\varepsilon}(s)ds = \frac{1}{2\pi i}\int_{-i\varepsilon-\infty}^{-i\varepsilon+\infty} \frac{e^{is\xi}}{s}\frac{M_{22}(s)N_1(s) - M_{12}(s)N_2(s)}{\det(M(s))},$$
$$\varphi_2(\xi) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} e^{\xi(is+\varepsilon)}\hat{\varphi}_{i,\varepsilon}(s)ds = \frac{1}{2\pi i}\int_{-i\varepsilon-\infty}^{-i\varepsilon+\infty} \frac{e^{is\xi}}{s}\frac{M_{11}(s)N_2(s) - M_{21}(s)N_1(s)}{\det(M(s))}.$$

Applying the Cauchy integral formula, we shift the contour of integration to the real axis, with a semicircle around the origin. That is, we rewrite the integral in the form

$$\varphi_1(\xi) = \frac{1}{2\pi i}\left(\int_{-\infty}^{-\varepsilon} + \int_{\varepsilon}^{\infty} + \int_{C_\varepsilon}\right)\frac{e^{is\xi}}{s}\frac{M_{22}(s)N_1(s) - M_{12}(s)N_2(s)}{\det(M(s))}, \tag{7.24}$$

where C_ε is lower semicircle of radius ε around the origin. We may use a standard residue calculation for the third of these integrals, and the first two may be combined by using a change of variables in the first integral. After this, we use Euler's formula $\exp(ix) = \cos(x) + i\sin(x)$, and then we simplify by collecting sines and cosines according to their arguments. This leaves us with

$$\varphi_i(\xi) = \frac{1}{2} + \frac{1}{2\pi}\int_0^{\infty}\sum_{j\in M_i} F_{i,j}(s)\cos(s(\xi-\xi_j)) + G_{i,j}(s)\frac{1}{s}\sin(s(\xi-\xi_j))ds, \tag{7.25}$$

where $F_{i,j}$ and $G_{i,j}$ are as in (2.9).

8. Appendix B. We now present the proof of Lemma 2.1.

LEMMA 8.1. *Let $\alpha \in [0,1)$, $A \in [0,1)$, $\beta \in \mathbb{R}$, and $c \neq 0$. Then*

$$|\det M(s)|^2 \geq 1 \tag{8.1}$$

for $s \in \mathbb{R}$.

Proof. Using the definitions above, we may write $|\det M(s)|^2$ as

$$|\det M(s)|^2 = a^2 + b^2 = c^4 s^4 (b_2^2) + c^2 s^2 (2b_2^2 + b_1^2 + 2b_2(b_1 - b_0)) + (b_2 + b_1 + b_0)^2. \tag{8.2}$$

Clearly $b_2^2 \geq 0$ for $s \in \mathbb{R}$. Also,

$$b_2 + b_1 + b_0 = 1 - 2kC(s)[D_1 + D_2 - 2D_1D_2C(s) + \alpha^2 A(1-A)] \geq 1 \tag{8.3}$$

since $C(s) \leq 0$. It remains to show that the coefficient of c^2s^2 is nonnegative. Sorting by powers of $C(s)$, we have

$$\begin{aligned} 2b_2^2 + b_1^2 + 2b_2(b_1 - b_0) = {} & C^3(s)[16k^2 D_1 D_2 \alpha^2 A(1-A)] \\ & + C^2(s)4k\left(\left[k[2\alpha^2 A(1-A)(D_1 + D_2 + \alpha^2 A(1-A)) \right.\right. \\ & \qquad \left.\left. + (D_1 + D_2)^2] - 2D_1D_2\right]\right) \\ & + C(s)4k[-2\alpha^2 A(1-a) - (D_1 + D_2)] \\ & + 2, \end{aligned} \tag{8.4}$$

from which we see that the coefficient of $C^0(s)$ is positive and that of $C^1(s)$ is negative, as desired. It is convenient to express the order 2 and order 3 terms as

$$\begin{aligned} &C^2(s)\left(4k^2\left[2\alpha^2 A(1-A)(D_1+D_2+\alpha^2 A(1-A))\right]\right) \\ &+ C^2(s)\left(4k[(D_1+D_2)^2 k - 2kD_1D_2 + C(s)4kD_1D_2\alpha^2 A(1-A)]\right), \end{aligned} \tag{8.5}$$

where once again the terms on the top row are nonnegative. Finally, we have the estimate for the coefficient on the bottom

$$\begin{aligned} &k[D_1^2+D_2^2+4kD_1D_2C(s)\alpha^2A(1-A)] + 2D_1D_2(k-1) \\ &\geq k[D_1^2+D_2^2+4kD_1D_2C(s)\alpha^2A(1-A)] \\ &\geq D_1^2+D_2^2-2D_1D_2 \geq 0 \end{aligned} \tag{8.6}$$

since $-2 \leq C(s) \leq 0$, $\alpha < 1$, and $4A(1-A) \leq 1$ for $A \in [0,1)$. Hence the coefficient of c^2s^2 in $|\det M(s)|^2$ is greater than or equal to two. This estimate gives us the result stated above. ∎

9. Appendix C. We now prove the claim (5.8) by showing that $\sum_{n=0}^{\infty} E_n \to 0$ as $c \to 0$. Recall

$$\begin{aligned} |E_n| &= \left| \int_{np}^{(n+1)p} F_{i,j}(s)\cos(s(\beta_i - j))ds - \int_{np}^{(n+1)p} F_{i,j}(np,s)\cos(s(\beta_i-\xi_j))ds \right| \\ &\leq \left| \int_{np}^{(n+1)p} [F_{i,j}(s) - F_{i,j}(np,s)]ds \right|. \end{aligned} \tag{9.1}$$

Also, since $|R_i(s)| \leq 2$ and all other terms in the $F_{i,j}$ are constant, it will suffice to look at

$$\left| \int_{np}^{(n+1)p} [W(s) - W(np,s)]ds \right| \quad \text{and} \quad \left| \int_{np}^{(n+1)p} [Y(s) - Y(np,s)]ds \right|. \tag{9.2}$$

The following applies to both cases. First, make a change of variables $s \to \frac{s}{c}$ in both terms of the difference. Also, the differences $W(s) - W(np,s)$ and $Y(s) - Y(np,s)$ may be expressed in the form

$$\frac{\gamma_2(s)s^2 + \gamma_0(s)}{\delta_4(s)s^4 + \delta_2(s)s^2 + \delta_0(s)} - \frac{\gamma_2(s)(npc)^2 + \gamma_0(s)}{\delta_4(s)(npc)^4 + \delta_2(s)(npc)^2 + \delta_0(s)}, \tag{9.3}$$

where the γ and δ are functions of s, but we will suppress this dependence to make the notation lighter. Then for $n \geq 1$,

(9.4)

$$
\begin{aligned}
|E_n| &\le \int_{npc}^{(n+1)pc} ((npc)^2 - s^2) \frac{\gamma_2\delta_4(npc)^2 s^2 + \gamma_0\delta_4((npc)^2 + s^2) + \gamma_0\delta_2 - \gamma_2\delta_0}{(\delta_4 s^4 + \delta_2 s^2 + \delta_0)(\delta_4(npc)^4 + \delta_2(npc)^2 + \delta_0)} ds \\
&\le \int_{npc}^{(n+1)pc} (2n+1)(pc)^2 \frac{\gamma_2\delta_4(npc)^2 s^2 + \gamma_0\delta_4((npc)^2 + s^2) + \gamma_0\delta_2 - \gamma_2\delta_0}{(\delta_4 s^4 + \delta_2 s^2 + \delta_0)(\delta_4(npc)^4 + \delta_2(npc)^2 + \delta_0)} ds \\
&\le \int_{npc}^{(n+1)pc} (2n+1)(pc)^2 \frac{\gamma_2\delta_4(npc)^2 s^2 + \gamma_0\delta_4((npc)^2 + s^2) + \gamma_0\delta_2 - \gamma_2\delta_0}{(\delta_4 s^4 + \delta_2 s^2 + \delta_0)(\frac{\delta_4}{16} s^4 + \frac{\delta_2}{4} s^2 + \delta_0)} ds \\
&\le 16 \int_{npc}^{(n+1)pc} (2n+1)(pc)^2 \frac{\gamma_2\delta_4(npc)^2 s^2 + \gamma_0\delta_4((npc)^2 + s^2) + \gamma_0\delta_2 - \gamma_2\delta_0}{(s^2+1)^4} ds \\
&\le 16 \int_{npc}^{(n+1)pc} (2n+1)(pc)^2 \frac{\gamma_2\delta_4 s^4 + 2\gamma_0\delta_4 s^2 + \gamma_0\delta_2 - \gamma_2\delta_0}{(s^2+1)^4} ds \\
&\le 16 \int_{npc}^{(n+1)pc} 3spc \frac{\gamma_2\delta_4 s^4 + 2\gamma_0\delta_4 s^2 + \gamma_0\delta_2 - \gamma_2\delta_0}{(s^2+1)^4} ds \\
&\le 48pc \int_{npc}^{(n+1)pc} Ks \frac{s^4 + 2s^2 + 1}{(s^2+1)^4} ds \\
&\le 48pcK \int_{npc}^{(n+1)pc} \frac{s}{(s^2+1)^2} ds,
\end{aligned}
$$

where K is a constant. Similarly,

$$
\begin{aligned}
|E_0| &\le (pc)^2 \int_0^{pc} \frac{\gamma_0\delta_4(pc)^2 + \gamma_0\delta_2 - \gamma_2\delta_0}{(\delta_4 s^4 + \delta_2 s^2 + \delta_0)\delta_0} ds \\
&\le K'(pc)^2 \int_0^{pc} \frac{1}{(s^1+1)^2} ds \to 0 \quad \text{as} \quad c \to 0
\end{aligned} \tag{9.5}
$$

where K' is a constant. Using these estimates, we see that

$$
\sum_{n=0}^{\infty} |E_n| \le |E_0| + 48pcK \int_{pc}^{\infty} \frac{s}{(s^2+1)^2} ds \to 0 \quad \text{as} \quad c \to 0, \tag{9.6}
$$

which justifies our claim in (5.8).

Acknowledgments. The authors are grateful to Chris Elmer and Weishi Liu for discussions related to this work and to the referees for helpful comments on an earlier version of this paper.

QUALITATIVE ASPECTS IN DUAL-PHASE-LAG THERMOELASTICITY*

RAMÓN QUINTANILLA† AND REINHARD RACKE‡

Abstract. We consider the system of dual-phase-lag thermoelasticity proposed by Chandrasekharaiah and Tzou. First, we prove that the solutions of the problem are generated by a semigroup of quasi-contractions. Thus, the problem of the third order in time is well-posed. Then the exponential stability is investigated. Finally the spatial behavior of solutions is analyzed in a semi-infinite cylinder and a result on the domain of influence is obtained.

Key words. hyperbolic model in thermoelasticity, well-posedness, spatial evolution in a semi-infinite cylinder, exponential stability

1. Introduction.

It is well known that the usual theory of heat conduction based on Fourier's law predicts infinite heat propagation speed. Heat transmission at low temperature has been observed to propagate by means of waves. These aspects have caused intense activity in the field of heat propagation. Extensive reviews on the so-called second sound theories (hyperbolic heat conduction) are given in Chandrasekharaiah [3] and in the books of Müller and Ruggeri [20] and Jou, Casas-Vazquez, and Lebon [18]. A theory of heat conduction in which the evolution equation contains a third-order derivative with respect to time was proposed in [8]. Several instability results have been obtained for the theory (see, e.g., [7, 23]) as well as proof of the nonexistence of global solutions in the nonlinear theory [29].

In 1995, Tzou [34] proposed a theory of heat conduction in which the Fourier law is replaced by an approximation of the equation

$$\mathbf{q}(\mathbf{x}, t+\tau_q) = -k\nabla\theta(\mathbf{x}, t+\tau_\theta), \quad \tau_q > 0,\ \tau_\theta > 0, \tag{1.1}$$

where τ_q is the phase-lag of the heat flux and τ_θ is the phase-lag of the gradient of temperature. The relation (1.1) states that the gradient of temperature at a point in the material at time $t+\tau_\theta$ corresponds to the heat flux vector at the same point at time $t+\tau_q$. The delay time τ_θ is caused by microstructural interactions such as phonon scattering or phonon-electron interactions. The delay τ_q is interpreted as the relaxation time due to fast-transient effects of thermal inertia. The thermoelastic model was proposed in [3],

$$\mu u_{i,jj} + (\lambda+\mu)u_{j,ji} - m\theta_{,i} = \rho\ddot{u}_i, \tag{1.2}$$

$$-q_{i,i} - m\theta_0\dot{u}_{i,i} = c\dot{\theta}, \tag{1.3}$$

$$q_i(\cdot, t+\tau_q) = -k\theta_{,i}(\cdot, t+\tau_\theta), \tag{1.4}$$

where ρ, θ_0, c are positive constants. $\mu > 0$ and λ are the Lamé moduli satisfying $\mu^* > 0$, where μ^* is defined in (2.16) depending on the space dimension.

Here and in what follows we use the Einstein summation convention with indices in the range $1 \dots n$, where $n = 1, 2, 3$ denotes the space dimension. Instead of Fourier's law, being equivalent to assuming

$$\tau_q = \tau_\theta = 0 \tag{1.5}$$

and leading to the classical hyperbolic-parabolic system of thermoelasticity together with the physical paradoxon of infinite propagation speed through the heat conduction part, we consider the model proposed by Chandrasekharaiah [3] and Tzou [34], where

$$\tau_q > 0, \quad \tau_\theta > 0$$

are positive relaxation times and where a second-order approximation for $\mathbf{q}$ and a first-order approximation for θ are used, turning (1.4) into

$$q_i + \tau_q \dot{q}_i + \frac{\tau_q^2}{2} \ddot{q}_i = -k\theta_{,i} - k\tau_\theta \dot{\theta}_{,i}. \tag{1.6}$$

Thus, in this paper, we consider the theory developed by taking a Taylor series expansion on both sides of (1.1) and retaining terms up to the second order in τ_q, but only to the first order in τ_θ. The model that we consider here involves a system of two coupled partial differential equations. It is of hyperbolic type (section 3). One of them is the usual second order in time equation of motion in the major part of thermoelastic systems and the other has a third-order derivative with respect to time. This system of equations has not received much attention in the literature (until now), but Hetnarski and Ignaczak consider it within the nonclassical approach of thermoelasticity in their review [10]. However, we can recall several references in the case that we do not consider mechanical deformations [15, 25]. It is known that when $\tau_\theta = 0$, solutions of heat conduction are not determined by means of a semigroup [9, p. 125]. However in [25], it was established that whenever $\tau_\theta > 0$, one can obtain solutions by means of a semigroup. Thus, the term $\tau_\theta \triangle \dot{\theta}$ plays a role in the stabilization for the equation. In this paper we extend some of the results on existence and stability obtained for the heat conduction to the thermoelastic problem.

The case $\tau_\theta > 0$ but $\tau_q = 0$, also leading to a hyperbolic system, the system of Lord and Shulman, has been studied before, and, for example, the exponential stability has been obtained for bounded reference configurations as well as the nonlinear stability near the equilibrium; see [31, 32].

A natural question is the determination of the time parameters τ_q and τ_θ (see [10]) and our work is motivated by this question. One might expect that mathematical analysis of existence, uniqueness, and stability issues, for example, would furnish certain restrictions on the parameters. One condition to be satisfied by solutions of a heat equation should be exponential stability (or at least stability). In [25], exponential stability (for the heat conduction) was established whenever

$$\tau_\theta > \tau_q/2. \tag{1.7}$$

We also recall that in [10] Hetnarski and Ignaczak asked (p. 474) for a *general domain of influence theorem as well as a principle of Saint-Venant's type* for this theory. We note that results of this kind were obtained in [15] for heat conduction. In this paper

we also extend some of the results concerning the time asymptotic and the spatial behavior obtained for heat conduction in order to include mechanical deformations.

Thus, under condition (1.7), one has a heat theory with a third-order derivative in time in the equation that predicts stability. This is of interest in the light of the results obtained in the theory proposed in [8]. By means of several exact solutions instability of solutions was also established in [25] whenever the condition (1.7) is violated. Thus, one may assume that the condition (1.7) must be satisfied in order to use this model to describe heat transmission. In fact one of the objects of this paper is to extend stability results to the thermoelastic problem. In [26] it was demonstrated for a bounded interval $(0, L) \subset \mathbb{R}$ that for the boundary conditions

$$u = \theta_x = 0 \tag{1.8}$$

which allows a nice series expansion of the solutions into $\sin(nx), \cos(nx)$ terms, exponential stability is to be expected since the relevant spectrum of the associated stationary operator lies strictly in the right-half complex plane.

We shall investigate here the more complicated boundary conditions

$$u = 0, \quad \theta = 0 \tag{1.9}$$

and prove the exponential stability of the associated semigroup.

In this paper we study three kinds of questions. One is to determine the suitable frame where the third-order problem of thermoelasticity of Chandrasekharaiah and Tzou type is well-posed and where the solutions are stable. The second is to prove the exponential stability for bounded reference configurations, and the third is to determine the spatial behavior of the solutions of the thermoelasticity in a semi-infinite cylinder in $\mathbb{R}^3$.

This paper is organized as follows. In section 2 we set down the field equations and the boundary and initial conditions of the problem we consider in this paper. A uniqueness and existence result is proved in section 3. In section 4 we prove the exponential stability for bounded reference configurations. In section 5, we obtain some results of Saint-Venant's type concerning the spatial behavior of solutions in a semi-infinte cylinder and some consequences of them as obtained in section 6. The last section is devoted to the study of the spatial behavior of solutions of a nonstandard problem.

When we study the spatial behavior of solutions of some problems concerning the dual-phase-lag thermoelastic system we shall denote the three-dimensional semi-infinite cylinder R with cross section D. The finite end face of the cylinder is in the plane $x_3 = 0$. The boundary ∂D is supposed regular enough to allow the use of the divergence theorem. We denote by $R(z)$ the set of points of the cylinder R such that x_3 is greater than z and by $D(z)$ the cross section of the points such that $x_3 = z$. The spatial evolution with distance from the end for solutions of elliptic equations is relevant to the study of Saint-Venant's principle in continuum mechanics (see, e.g., [6, 11, 12, 13] for reviews of this work). Such results for parabolic equations have also been obtained (see [6, 11, 12, 13, 14]) and more recently for hyperbolic equations (see [2] and the references cited therein).

2. Preliminaries. We consider the homogeneous isotropic case. In this paper we study solutions $(\mathbf{u}, \theta) = (\mathbf{u}(\mathbf{x}, t), \theta(\mathbf{x}, t))$ of the thermoelastic system for the Chandrasekharaiah–Tzou theory. The equations are

$$\mu u_{i,jj} + (\lambda + \mu) u_{j,ji} - m\theta_{,i} = \rho \ddot{u}_i, \tag{2.1}$$

$$k\hat{\theta}_{,ii} - m\theta_0\dot{\tilde{u}}_{i,i} = c\dot{\tilde{\theta}}. \tag{2.2}$$

We have used the notation

$$\hat{f} = f + \tau_\theta \dot{f}, \;\; \tilde{f} = f + \tau_q \dot{f} + \frac{\tau_q^2}{2}\ddot{f}, \tag{2.3}$$

where $\tau_\theta > 0$, $\tau_q > 0$ are the dimensionless time lag parameters.

We study the qualitative behavior of classical solutions subject to the initial conditions

$$u_i(\mathbf{x},0) = u_i^0(\mathbf{x}), \;\; \dot{u}_i(\mathbf{x},0) = v_i^0(\mathbf{x}), \theta(\mathbf{x},0) = \theta^0(\mathbf{x}), \;\; \dot{\theta}(\mathbf{x},0) = \vartheta^0(\mathbf{x}), \;\; \ddot{\theta}(\mathbf{x},0) = \phi^0(\mathbf{x}) \tag{2.4}$$

and the boundary conditions

$$u_i(\mathbf{x},t) = \theta(\mathbf{x},t) = 0, \;\; \mathbf{x} \in \partial D \;\times\; [0,\infty), \tag{2.5}$$

$$u_i(x_1, x_2\,, 0,\; t) \;= f_i(x_\alpha\,, t) \;\; \theta(x_1, x_2\,, 0,\; t) \;= g(x_\alpha\,, t) \quad \text{on } D(0) \;\times\; [0,\infty), \tag{2.6}$$

where the prescribed boundary data f_i, g on the end $x_3 = 0$ is such that $f_i(x_\alpha, 0) = u_i^0(x_\alpha)$, $g(x_\alpha, 0) = \theta^0(x_\alpha)$, and f_i, g are assumed to vanish on $\partial D(0) \times [0,\infty)$. We will not make any a priori assumption regarding the behavior of solutions as $x_3 \longrightarrow \infty$.

Observe that in the limit as τ_θ and $\tau_q \to 0$, we recover from (2.1) or (2.2) the usual thermoelastic system where, in this limiting case, only the three first of (2.4) are assumed to hold. In this limit the existence, stability and the spatial evolution of solutions have been studied in a variety of contexts (see, e.g., [17, 24, 4] and the references cited therein). When τ_q and τ_θ are positive, the results to be described in what follows will be seen to be similar to those obtained previously for such equations (see, e.g., [2] and the references cited therein).

In the course of our calculations, we will use the fact that the eigenvalues of the real symmetric positive definite matrix

$$\begin{pmatrix} a & b \\ b & l \end{pmatrix} \tag{2.7}$$

are

$$\lambda^{\pm} = \frac{1}{2}\Big(a + l \pm \sqrt{(a-l)^2 + 4b^2}\Big), \tag{2.8}$$

so that the smallest eigenvalue is

$$\lambda^{-} = \frac{1}{2}\Big(a + l - \sqrt{(a-l)^2 + 4b^2}\Big). \tag{2.9}$$

We will use (2.7) in two particular cases. When

$$a = \tau_q + \tau_\theta, \;\; b = \frac{\tau_q^2}{2}, \;\; l = \frac{\tau_q^2 \tau_\theta}{2}, \tag{2.10}$$

it can be easily verified using (1.7) that the matrix (2.7) is indeed positive definite and so its smallest positive eigenvalue, denoted by λ_0, is given by

$$\lambda_0 = \frac{1}{2}\left(\tau_q + \tau_\theta + \frac{1}{2}\tau_q^2\tau_\theta - \sqrt{\tau_q^4 + \tau_q^2 + \tau_\theta^2 + \frac{1}{4}\tau_q^4\tau_\theta^2 + 2\tau_q\tau_\theta - \tau_\theta^2\tau_q^2 - \tau_q^3\tau_\theta}\right). \tag{2.11}$$

When

$$a = \frac{2}{\gamma} + (\tau_q + \tau_\theta), \quad b = \frac{1}{2}\tau_q^2 \ , \quad l = \frac{1}{2}\tau_q^2\tau_\theta + \frac{2}{\gamma}\left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right), \quad \gamma > 0, \tag{2.12}$$

the matrix (2.9) is again positive definite with the smallest eigenvalue, denoted by μ_γ, given by

$$\mu_\gamma = \frac{1}{2\gamma}\left(2 + \gamma(\tau_q + \tau_\theta) + \frac{\gamma}{2}\tau_q^2\tau_\theta + 2\left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right)\right.$$
$$\left. -\sqrt{\left[2 + \gamma(\tau_q + \tau_\theta) - \frac{\gamma}{2}\tau_q^2\tau_\theta - 2\left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right)\right]^2 + \gamma^2\tau_q^4}\right). \tag{2.13}$$

To be used later, it will be worth using the following notation:

$$T_{ij} = \mu u_{i,j} + (\lambda + \mu)\delta_{ij}u_{r,r} - m\delta_{ij}\theta. \tag{2.14}$$

We have that the estimate

$$T_{ji}T_{ji} \le (1 + \epsilon)\mu^*[\mu u_{i,j}u_{i,j} + (\lambda + \mu)u_{r,r}u_{s,s}] + 3m^2(1 + \epsilon^{-1})\theta^2 \tag{2.15}$$

is satisfied, for every positive ϵ, where

$$\mu^* = \begin{cases} 2\mu + \lambda, & n = 1, \\ \max\{\mu, 2\lambda + 3\mu\}, & n = 2, \\ \max\{\mu, 3\lambda + 4\mu\}, & n = 3. \end{cases} \tag{2.16}$$

μ^* is the maximal positive eigenvalue of the quadratic form [4]

$$Q(\zeta) := \mu\zeta_{ij}\zeta_{ij} + (\lambda + \mu)\zeta_{rr}\zeta_{ss}.$$

When we study the qualitative aspects concerning existence, uniqueness, and exponential stability, and without loss of generality, we assume $\rho = c = 1$. However, when we study the spatial behavior of solutions we relax this condition to assume that mass density and thermal capacity are positive because we wish to demonstrate the dependence of the decay parameters on ρ, c explicitly.

3. Well-posedness. We shall formulate the problem for the semi-infinite cylinder R in three space dimensions, but the well-posedness holds for general domains; see the remarks following Theorem 3.3.

The well-posedness result for the third order in time system can be achieved by an appropriately sophisticated choice of variables and spaces which reflect the special structure of the system.

We first transform the system (2.1)–(2.6) to zero boundary conditions on all of ∂R by defining

(3.1)
$$v_i(x_\alpha, 0, t) := u_i(x_\alpha, 0.t) - f_i(x_\alpha, t), \qquad v_i(x_\alpha, x_3, t) := u_i(x_\alpha, x_3.t) \quad \text{for } x_3 > 0,$$

(3.2)
$$\psi(x_\alpha, 0, t) := \theta(x_\alpha, 0, t) - g(x_\alpha, t), \qquad \psi(x_\alpha, x_3, t) := \theta(x_\alpha, x_3, t) \quad \text{for } x_3 > 0,$$

and using (u_i, θ) instead of (v_i, ψ) again, we obtain the initial boundary value problem

$$\mu u_{i,jj} + (\lambda+\mu)u_{j,ji} - m\theta_{,i} = \ddot{u}_i - h_i, \tag{3.3}$$

$$k\hat{\theta}_{,ii} - m\theta_0 \dot{\tilde{u}}_{i,i} = \dot{\tilde{\theta}} - p, \tag{3.4}$$

(3.5)
$$u_i(\mathbf{x},0) = u_i^0(\mathbf{x}),\ \dot{u}_i(\mathbf{x},0) = v_i^0(\mathbf{x}), \theta(\mathbf{x},0) = \theta^0(\mathbf{x}),\ \dot{\theta}(\mathbf{x},0) = \vartheta^0(\mathbf{x}),\ \ddot{\theta}(\mathbf{x},0) = \phi^0(\mathbf{x}),$$

$$u_i(\mathbf{x},t) = \theta(\mathbf{x},t) = 0,\ \ \mathbf{x} \in \partial R\ \times\ [0,\infty), \tag{3.6}$$

where the given external force $\mathbf{h}$ and heat supply p arise from the transformation (3.1), (3.2) in terms of the boundary data $\mathbf{f}$ and g, respectively.

For the transformation to a first-order system that finally will be characterized by a semigroup, we apply the differential operator $\tilde{}$ from (2.3) to the differential equation (3.3) and obtain

$$\mu\tilde{u}_{i,jj} + (\lambda+\mu)\tilde{u}_{j,ji} - m\tilde{\theta}_{,i} = \ddot{\tilde{u}}_i + \tilde{h}_i. \tag{3.7}$$

We remark that finding a solution $(\tilde{\mathbf{u}}, \theta)$ allows to determine the desired solutions $(\mathbf{u}, \theta)$ of the original system.

Defining

$$\mathbf{V} := (\tilde{\mathbf{u}}, \tilde{\mathbf{u}}_t, \theta, \theta_t, \theta_{tt})'$$

we obtain

$$\mathbf{V}_t = A\mathbf{V} + \mathbf{F}, \qquad V(0) = V^0 \tag{3.8}$$

with the (yet formal) differential operator A given by the symbol

$$A_f := \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ \mu\Delta + (\lambda+\mu)\nabla\nabla' & 0 & -m\nabla & -\tau_q m\nabla & -\dfrac{\tau_q^2 m}{2}\nabla \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & -\dfrac{2m\theta_0}{\tau_q^2}\nabla' & \dfrac{2k}{\tau_q^2}\Delta & \dfrac{2}{\tau_q^2}(k\tau_\theta\Delta - 1) & -\dfrac{2}{\tau_q} \end{pmatrix},$$

the right-hand side $\mathbf{F}$ given by

$$\mathbf{F} := (0, \mathbf{h}, 0, 0, 0, p)',$$

and the initial value

$$\mathbf{V}^0(\mathbf{x}) := (\tilde{\mathbf{u}}, \tilde{\mathbf{u}}_t, \theta, \theta_t, \theta_{tt})'(\mathbf{x}, 0)$$

with its components being given in terms of the originally prescribed initial data in (3.5) by using the differential equations.

As underlying Hilbert space we choose

$$\mathcal{H} := (H_0^1(R))^n \times (L^2(R))^n \times H_0^1(R) \times H_0^1(R) \times L^2(R)$$

with inner product

$$\langle V, W, \rangle_{\mathcal{H}} := \frac{4}{\tau_q^4}\left(\langle \theta_0 V^2, W^2\rangle + \langle \theta_0 \mu \nabla V^1, \nabla W^1\rangle + \langle \theta_0(\lambda+\mu)\nabla' V^1, \nabla' W^1\rangle\right)$$
$$+ \left\langle \frac{2}{\tau_q^2} V^4, W^4 \right\rangle + \left\langle \frac{2\tau_\theta k}{\tau_q^2}\nabla V^4, \nabla W^4\right\rangle + \langle V^5, W^5\rangle + \left\langle \frac{2k}{\tau_q^2}\nabla V^3, \nabla W^4\right\rangle$$
$$+ \left\langle \frac{2k}{\tau_q^2}\nabla V^4, \nabla W^3\right\rangle + b_0\langle \nabla V^3, \nabla W^3\rangle,$$

where $\langle\cdot,\cdot\rangle$ denotes the usual $L^2(R)$-inner product and where b_0 is chosen appropriately large in dependence of the coefficients to ensure that the bilinear form $\langle\cdot,\cdot\rangle_{\mathcal{H}}$ is positive definite. The operator A is now given as

$$A : D(A) \subset \mathcal{H} \mapsto \mathcal{H}, \qquad AV := A_f V$$

with

$$D(A) := \{V \in \mathcal{H} \mid V^2 \in H_0^1(R)^n,\, V^5 \in H_0^1(R),\, A_f V \in \mathcal{H}\}.$$

The choice of the inner product is special, of course, and extends similar considerations from [25] for the pure heat conduction problem.

LEMMA 3.1. *There exists a constant $c_1 > 0$ such that for all $V \in D(A)$*

$$|\langle AV, V\rangle_{\mathcal{H}}| \le c_1 \|V\|_{\mathcal{H}}^2$$

holds.

Proof. We have

$$\langle AV, V\rangle_{\mathcal{H}} = -\frac{4m\theta_0}{\tau_q^4}\langle \nabla V^3, V^2\rangle - \frac{4m\theta_0}{\tau_q^3}\langle \nabla V^4, V^2\rangle - \frac{2}{\tau_q}\langle V^5, V^5\rangle$$
$$+\frac{2k}{\tau_q^2}\langle \nabla V^4, \nabla V^4\rangle + b_0\langle \nabla V^4, \nabla V^3\rangle,$$

which implies the assertion. ∎

As a consequence we see that for $d > c_1$ the operator $A - d$ is dissipative and invertible.

LEMMA 3.2. *For all $d > c_1$ we have that the range of $A - d$ is all of $\mathcal{H}$.*

Proof. The solvability of $(A-d)V = F$ is equivalent to solving

$$V^2 - dV^1 = F^1, \tag{3.9}$$

$$\mu\Delta V^1 + (\lambda+\mu)\nabla\nabla' V^1 - m\nabla V^3 - \tau_q m\nabla V^4 - \frac{\tau_q^2 m}{2}\nabla V^5 - dV^2 = F^2, \tag{3.10}$$

$$V^4 - dV^3 = F^3, \tag{3.11}$$

$$V^5 - dV^4 = F^4, \tag{3.12}$$

$$-\frac{2m\theta_0}{\tau_q^2}\nabla' V^2 + \frac{2k}{\tau_q^2}\Delta V^3 + \frac{2}{\tau_q^2}(k\tau_\theta\Delta - 1)V^4 - \frac{2}{\tau_q}V^5 - dV^5 = F^5. \tag{3.13}$$

Eliminating V^2, V^4, and V^5 and using

$$E := -\mu\Delta - (\lambda+\mu)\nabla\nabla'$$

we have to solve

$$-EV^1 - d^2V^1 - \underbrace{\left(m + \tau_q md + \frac{\tau_q^2 md^2}{2}\right)}_{=:\alpha_1}\nabla V^3 = F^2 + dF^1 + \left(\tau_q m + \frac{\tau_q^2 md}{2}\right)\nabla F^3$$

$$+ \frac{\tau_q^2 m}{2}\nabla F^4, \tag{3.14}$$

$$-\underbrace{\left(\frac{2k}{\tau_q^2} + \frac{2k\tau_\theta d}{\tau_q^2}\right)}_{=:\gamma_1}\Delta V^3 + \underbrace{\left(\frac{2d}{\tau_q^2} + \frac{2d^2}{\tau_q} + d^3\right)}_{=:\delta_1}V^3 + \underbrace{\frac{2m\theta_0 d}{\tau_q^2}}_{=:\beta_1}\nabla' V^1$$

$$= -F^5 - \frac{2m\theta_0}{\tau_q^2}\nabla' F^1 - \frac{2}{\tau_q^2}F^3 - \left(\frac{2}{\tau_q} + d\right)(dF^3 + F^4) + \frac{2k\tau_\theta}{\tau_q^2}\Delta F^3. \tag{3.15}$$

Hence we consider for $G^1 \in L^2(R)^3$ and $G^2 \in H^{-1}$, the dual space to $H_0^1(R)$, the system

$$EV^1 + d^2V^1 + \alpha_1\nabla V^3 = G^1, \tag{3.16}$$

$$-\gamma_1\Delta V^3 + \delta_1 V^3 + \beta_1\nabla' V^1 = G^2, \tag{3.17}$$

where $\alpha_1, \beta_1, \gamma_1, \delta_1$ are positive. If $(V^1, V^3) \in (H_0^1(R))^n \times H_0^1(R)$ solve (3.16), (3.17), then V^2, V^4, and V^5 can be determined from the equations (3.9), (3.11), and (3.12), respectively, and $V \in D(A)$ will solve $(A - d)V = F$.

$E + d^2$ can be regarded as a positive self-adjoint operator, the inverse of which maps $L^2(R)^3 \mapsto (H^2(R) \cap H_0^1(R))^n$, and hence V^1 should satisfy

$$V^1 = (E + d^2)^{-1}(G^1 - \alpha_1\nabla V^3).$$

Plugging this into (3.17) it remains to determine V^3 as a solution in $H_0^1(R)$ of

$$-\gamma_1\Delta V^3 + \delta_1 V^3 - \alpha_1\beta_1\nabla'(E + d^2)^{-1}\nabla V^3 = G^2 - \beta_1\nabla'(E + d^2)^{-1}G^1. \tag{3.18}$$

But (3.18) can be solved easily because the bilinear form

$$B(g, h) := \gamma_1\langle\nabla g, \nabla h\rangle + \delta_1\langle g, h\rangle + \alpha_1\beta_1\langle(E + d^2)^{-1/2}\nabla g, (E + d^2)^{-1/2}\nabla h\rangle$$

is positive on $H_0^1(R)$, and hence the Lax and Milgram lemma yields the solvability of (3.18) for any right-hand side in H^{-1}. This proves the assertion of the lemma. □

Now we conclude from the last two lemmas that A generates a C_0-semigroup, and hence the initial (boundary) value problem (3.8) is uniquely solvable.

THEOREM 3.3. *For any $F \in C^0([0, \infty), D(A))$ or $F \in C^1([0, \infty), \mathcal{H})$ and any $V^0 \in D(A)$ there is a unique solution V to* (3.8) *with $V \in C^1([0, \infty), \mathcal{H}) \cap C^0([0, \infty), D(A))$.*

The well-posedness consideration in this section extends naturally to other domains $\Omega \subset \mathbb{R}^n$, $n = 1, 2, 3$, instead of the three-dimensional cylinder R, e.g., literally to smoothly bounded domains and to convex domains (where elliptic H^2-regularity up to the boundary holds).

The system under consideration is of hyperbolic type, as we shall demonstrate in the one-dimensional case. Here the differential equations (3.7), (3.4) turn into

$$\tilde{u}_{tt} = \alpha_* \tilde{u}_{xx} - \frac{\tau_q^2 m}{2}\theta_{ttx} - \tau_q m \theta_{tx} - m\theta_x, \tag{3.19}$$

$$\theta_{ttt} = -\frac{2}{\tau_q}\theta_{tt} - \frac{2}{\tau_q^2}\theta_t - \frac{2m\theta_0}{\tau_q^2}\tilde{u}_{tx} + \frac{2\tau_\theta k}{\tau_q^2}\theta_{txx} + \frac{2k}{\tau_q^2}\theta_{xx}, \tag{3.20}$$

where $\alpha_* := 2\mu + \lambda$ and the right-hand sides are assumed to be zero.

Defining

$$\mathbf{W} := (\tilde{u}_x, \tilde{u}_t, \theta_x, \theta_t, \theta_{tx}, \theta_{tt})'$$

we obtain

$$\mathbf{W}_t = B\mathbf{W}_x + D\mathbf{W},$$

where

$$B := \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ \alpha_* & 0 & 0 & 0 & 0 & -\frac{\tau_q^2 m}{2} \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & -\frac{2m\theta_0}{\tau_q^2} & \frac{2k}{\tau_q^2} & 0 & \frac{2\tau_\theta k}{\tau_q^2} & 0 \end{pmatrix}$$

and

$$D := \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -m & 0 & -\tau_q m & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -\frac{2}{\tau_q^2} & 0 & -\frac{2}{\tau_q} \end{pmatrix}.$$

The eigenvalues of B are

$$\lambda_1 = \lambda_2 = 0,$$

$$\lambda_{3|4|5|6} = \pm\frac{1}{\sqrt{2}}\sqrt{\left(m^2\theta_0 + \frac{2\tau_\theta k}{\tau_q^2} + \alpha_*\right) \pm \sqrt{\left(m^2\theta_0 + \frac{2\tau_\theta k}{\tau_q^2} + \alpha_*\right)^2 - \frac{8\alpha_*\tau_\theta k}{\tau_q^2}}},$$

which are all real, thus characterizing a hyperbolic system. The hyperbolicity also becomes apparent in the results on the domains of dependence in the following sections.

4. Exponential stability. We recall that in classical thermoelasticity as well as in several other thermoelastic models like the Lord–Shulman theory or the model of type III, the exponential stability of the system could be proved for bounded domains in one space dimension as well as for radially symmetric situations in higher

dimensions; see, e.g., [17, 31, 32, 28]. We shall demonstrate the exponential stability in one space dimension. Let (u, θ) satisfy ((3.7), (3.4) or (3.19), (3.20))

$$\tilde{u}_{tt} - \alpha_* \tilde{u}_{xx} + m\tilde{\theta}_x = 0, \tag{4.1}$$

$$\tilde{\theta}_t + m\theta_0 \tilde{u}_{tx} - k\hat{\theta}_{xx} = 0 \tag{4.2}$$

with boundary conditions

$$u = \theta = 0 \qquad \text{for } x = 0, L \tag{4.3}$$

and initial conditions given in terms of the original initial conditions $u(\cdot, 0)$, $u_t(\cdot, 0)$, $\theta(\cdot, 0)$. As in the previous section we define

$$\mathbf{V} := (\tilde{\mathbf{u}}, \tilde{\mathbf{u}}_t, \theta, \theta_t, \theta_{tt})'$$

and we have

$$\begin{aligned} \|V(t)\|_{\mathcal{H}} &= \int_0^L \left\{ \frac{4\theta_0}{\tau_q^4}\tilde{u}_t^2 + \frac{4\theta_0\alpha_*}{\tau_q^4}\tilde{u}_x^2 + \frac{2}{\tau_q^2}\theta_t^2 + \frac{2\tau_\theta k}{\tau_q^2}\theta_{tx}^2 + \theta_{tt}^2 + \frac{4k}{\tau_q^2}\theta_x\theta_{tx} + b_0\theta_x^2 \right\} dx \\ &\equiv 2E_{\mathcal{H}}(t) \end{aligned} \tag{4.4}$$

defining the first "energy" term $E_{\mathcal{H}}(t)$. Another energy term is defined by

$$E(t) := \frac{1}{2}\int_0^L \left\{ \theta_0\tilde{u}_t^2 + \theta_0\alpha_*\tilde{u}_x^2 + \tilde{\theta}^2 + \frac{\tau_q^2\tau_\theta k}{2}\theta_{tx}^2 + k(\tau_q + \tau_\theta)\theta_x^2 + k\tau_q^2\theta_x\theta_{tx} \right\} dx. \tag{4.5}$$

The aim will be to find a suitable Lyapunov functional for the energy terms that proves the exponential stability.

Multiplying the differential equation (4.1) by $\theta_0\tilde{u}_t$ and (4.2) by $\tilde{\theta}$, integrating and performing partial integrations we obtain

$$\begin{aligned} \frac{d}{dt}E(t) &= -k\int_0^L \theta_x^2 dx - \tau_q\left(\tau_\theta - \frac{\tau_q}{2}\right)k\int_0^L \theta_{tx}^2 dx \\ &\le -c_1\int_0^L \left\{\theta_x^2 + \theta_{tx}^2\right\} dx \end{aligned} \tag{4.6}$$

for some positive constant c_1, if the condition (1.7) holds. Then (4.6) reflects the dissipative character of the system. We shall assume (1.7) in the rest of this paper, [26], where the sufficiency and necessity of (1.7) were investigated for the boundary conditions (1.8).

Multiplying the differential equation (4.2) by θ_{tt} and integrating we get

$$\begin{aligned} \frac{d}{dt}\frac{1}{2}\int_0^L \left\{ \theta_{tt}^2 + \frac{2}{\tau_q^2}\theta_t^2 + \frac{4k}{\tau_q^2}\theta_x\theta_{tx} + \frac{2k\tau_\theta}{\tau_q^2}\theta_{tx}^2 \right\} dx &= -\frac{2}{\tau_q}\int_0^L \theta_{tt}^2 dx + \frac{2k}{\tau_q^2}\int_0^L \theta_{tx}^2 dx \\ &\quad - \frac{2m\theta_0}{\tau_q^2}\int_0^L \tilde{u}_{tx}\theta_{tt} dx. \end{aligned} \tag{4.7}$$

Moreover,

$$\frac{d}{dt}\frac{1}{2}\int_0^L b_0\theta_x^2 dx = \int_0^L b_0\theta_x\theta_{tx} dx \le \frac{b_0}{2}\int_0^L \theta_x^2 dx + \frac{b_0}{2}\int_0^L \theta_{tx}^2 dx. \tag{4.8}$$

Multiplying (4.1) by $\frac{4\theta_0}{\tau_q^4}\tilde{u}_t$ and integrating we obtain

$$\frac{d}{dt}\frac{1}{2}\int_0^L \left\{\frac{4\theta_0}{\tau_q^4}\tilde{u}_t^2 + \frac{4\theta_0\alpha_*}{\tau_q^4}\tilde{u}_x^2\right\}dx = \frac{2m\theta_0}{\tau_q^2}\int_0^L \theta_{tt}\tilde{u}_{tx}dx - \frac{4m\theta_0}{\tau_q^3}\int_0^L \theta_{tx}\tilde{u}_t dx - \frac{4m\theta_0}{\tau_q^4}\int_0^L \theta_x\tilde{u}_t dx. \tag{4.9}$$

We conclude from (4.7)–(4.9)

$$\begin{aligned}\frac{d}{dt}E_{\mathcal{H}}(t) &\le -\frac{2}{\tau_q}\int_0^L \theta_{tt}^2 dx + \frac{2k}{\tau_q^2}\int_0^L \theta_{tx}^2 dx + \frac{b_0}{2}\int_0^L \theta_x^2 dx + \frac{b_0}{2}\int_0^L \theta_{tx}^2 dx \\ &\quad - \frac{4m\theta_0}{\tau_q^3}\int_0^L \theta_{tx}\tilde{u}_t dx - \frac{4m\theta_0}{\tau_q^4}\int_0^L \theta_x\tilde{u}_t dx \\ &\le -\frac{2}{\tau_q}\int_0^L \theta_{tt}^2 dx + \left(\frac{b_0}{2} + \frac{4m\theta_0}{\tau_q^4\epsilon_1}\right)\int_0^L \theta_x^2 dx + \left(\frac{2k}{\tau_q^2} + \frac{b_0}{2} + \frac{4m\theta_0}{\tau_q^3\epsilon_1}\right)\int_0^L \theta_{tx}^2 dx \\ &\quad + 2\epsilon_1\int_0^L \tilde{u}_t^2 dx, \end{aligned} \tag{4.10}$$

where $\epsilon_1 > 0$ will be chosen later appropriately small. Combining (4.6) and (4.10) we get

$$\begin{aligned}\frac{d}{dt}(E_{\mathcal{H}}(t) + KE(t)) &\le -\frac{2}{\tau_q}\int_0^L \theta_{tt}^2 dx - \left[Kk - \left(\frac{4m\theta_0}{\tau_q^4\epsilon_1} + \frac{b_0}{2}\right)\right]\int_0^L \theta_x^2 dx \\ &\quad - \left[Kk\tau_q\left(\tau_\theta - \frac{\tau_q}{2}\right) - \left(\frac{4m\theta_0}{\tau_q^3\epsilon_1} + \frac{b_0}{2} + \frac{2k}{\tau_q^2}\right)\right]\int_0^L \theta_{tx}^2 dx \\ &\quad + 2\epsilon_1\int_0^L \tilde{u}_t^2 dx, \end{aligned} \tag{4.11}$$

where $K > 0$ will be chosen below appropriately large. Once ϵ_1 will be fixed, we shall fix K such that the coefficients in $[\cdot]$-brackets in front of the two integrals of the right-hand side in (4.11) will be strictly positive.

Now we follow an ansatz described in [17] for classical thermoelasticity but we have to add essential modifications in order to deal with the higher-order system and the different structure under investigation.

If we multiply the differential equation (4.1) by $\frac{1}{\alpha_*}\tilde{u}_{xx}$ and integrate we obtain after partial integrations

$$\frac{1}{\alpha_*}\frac{d}{dt}\int_0^L \tilde{u}_{tx}\tilde{u}_x dx \le -\frac{2}{3}\int_0^L \tilde{u}_{xx}^2 dx + \frac{1}{\alpha_*}\int_0^L \tilde{u}_{tx}^2 dx + C\int_0^L \tilde{\theta}_x^2 dx, \tag{4.12}$$

where capital C will denote a positive constant that may change from line to line in the sequel. Multiplying the differential equation (4.2) by $\frac{3}{\alpha_* m\theta_0}\tilde{u}_{tx}$ and integrating, using (4.1), yields

$$\begin{aligned}\frac{3}{\alpha_*}\int_0^L \tilde{u}_{tx}^2 dx &= -\frac{3}{\alpha_* m\theta_0}\int_0^L \tilde{\theta}_t\tilde{u}_{tx}dx - \frac{3k}{\alpha_* m\theta_0}\frac{d}{dt}\int_0^L \hat{\theta}_x\left(\frac{1}{\alpha_*}\tilde{u}_{tt} + \frac{m}{\alpha_*}\tilde{\theta}_x\right)dx \\ &\quad + \frac{3k}{\alpha_* m\theta_0}\int_0^L \hat{\theta}_{tx}\tilde{u}_{xx} + \frac{3k}{\alpha_* m\theta_0}[\hat{\theta}_x\tilde{u}_{tx}]_{x=0}^{x=L}, \end{aligned}$$

hence

(4.13)
$$\frac{3}{\alpha_*^2 m\theta_0}\frac{d}{dt}\int_0^L\{\hat\theta_x\tilde u_{tt}+m\hat\theta_x\tilde\theta_x\}dx\le-\frac{2}{\alpha_*}\int_0^L\tilde u_{tx}^2dx+\frac16\int_0^L\tilde u_{xx}^2dx+C\int_0^L\{\hat\theta_{tx}^2+\tilde\theta_t^2\}dx + C\|\hat\theta_x\|_{L^\infty(\{0,L\})}\|\tilde u_{tx}\|_{L^\infty(\{0,L\})},$$

where $\|f\|_{L^\infty(\{0,L\})}:=\max\{|f(0)|,|f(L)|\}$ denotes the sup-norm on the boundary. Combining (4.12) and (4.13) we obtain

$$\frac{d}{dt}\int_0^L\left\{\frac{1}{\alpha_*}\tilde u_{tx}\tilde u_x+\frac{3k}{\alpha_*^2 m\theta_0}\hat\theta_x\tilde u_{tt}+\frac{3k}{\alpha_*^2\theta_0}\hat\theta_x\tilde\theta_x\right\}dx\le-\frac{1}{\alpha_*}\int_0^L\tilde u_{tx}^2dx-\frac12\int_0^L\tilde u_{xx}^2dx + C\int_0^L\{\tilde\theta_x^2+\hat\theta_{tx}^2+\tilde\theta_t^2\}dx+\frac{C}{\epsilon_2}\|\hat\theta_x\|_{L^\infty(\{0,L\})}^2+\epsilon_2\|\tilde u_{tx}\|_{L^\infty(\{0,L\})}^2, \tag{4.14}$$

where $\epsilon_2>0$ will be chosen appropriately small later. The differential equation (4.2) yields

$$\int_0^L\hat\theta_{xx}^2dx\le C\int_0^L\{\tilde\theta_t^2+\tilde u_{tx}^2\}dx.$$

Using this and the Sobolev imbedding $W^{1,1}((0,L))\hookrightarrow L^\infty((0,L))$ we arrive at

$$\|\hat\theta_x\|_{L^\infty(\{0,L\})}^2\le\frac{C}{\epsilon_2^2}\int_0^L\{\hat\theta_x^2+\tilde\theta_t^2\}dx+C\epsilon_2^2\int_0^L\tilde u_{tx}^2dx.$$

Inserting this into (4.14) we conclude for sufficiently small ϵ_2

$$\frac{d}{dt}\int_0^L\left\{\frac{1}{\alpha_*}\tilde u_{tx}\tilde u_x+\frac{3k}{\alpha_*^2 m\theta_0}\hat\theta_x\tilde u_{tt}+\frac{3k}{\alpha_*^2\theta_0}\hat\theta_x\tilde\theta_x\right\}dx\le-\frac{1}{2\alpha_*}\int_0^L\tilde u_{tx}^2dx-\frac12\int_0^L\tilde u_{xx}^2dx + \frac{C}{\epsilon_2^3}\int_0^L\{\tilde\theta_x^2+\hat\theta_{tx}^2+\tilde\theta_t^2\}dx+C_1\epsilon_2\|\tilde u_{tx}\|_{L^\infty(\{0,L\})}^2 \tag{4.15}$$

with a constant $C_1>0$. In order to estimate the boundary term, we use a well-known technique exploiting in the multipliers a smooth extension of the normal at the boundary which means in one dimension to use the following function Φ with

$$\Phi(x):=\frac12-\frac{x}{L}. \tag{4.16}$$

Differentiation of (4.1) with respect to t, multiplying with $\Phi\tilde u_{tx}$ and partially integrating yields

$$0=\frac{d}{dt}\int_0^L\tilde u_{tt}\Phi\tilde u_{tx}dx+\frac12\int_0^L\Phi_x(\tilde u_{tt}^2+\alpha_*\tilde u_{tx}^2)dx+\frac{\alpha_*}{4}(\tilde u_{tx}^2(0)+\tilde u_{tx}^2(L)) +m\int_0^L\left(\theta_{tx}+\tau_q\theta_{ttx}+\frac{\tau_q^2}{2}\theta_{tttx}\right)\Phi\tilde u_{tx}dx$$

whence

$$\frac{d}{dt}\int_0^L\tilde u_{tt}\Phi\tilde u_{tx}dx\le-\frac{\alpha_*}{4}(\tilde u_{tx}^2(0)+\tilde u_{tx}^2(L))+C\int_0^L\{\tilde u_{tt}^2+\tilde u_{tx}^2+\theta_{tx}^2+\theta_{ttx}^2\}dx -\frac{m\tau_q^2}{2}\int_0^L\theta_{tttx}\Phi\tilde u_{tx}dx \tag{4.17}$$

follows. Using the differential equation (4.2) again, we obtain

(4.18)
$$
\begin{aligned}
-m\theta_0\int_0^L \theta_{tttx}\Phi\tilde{u}_{tx}dx &= -k\frac{d}{dt}\int_0^L \theta_{ttx}\Phi\hat{\theta}_{xx}dx + k\int_0^L \theta_{ttx}\Phi\hat{\theta}_{txx}dx + \int_0^L \theta_{ttt}\Phi\theta_{tx}dx\\
&\quad + \int_0^L \theta_{ttt}\Phi_x\theta_t dx + \tau_q\int_0^L \theta_{ttt}\Phi\theta_{ttx}dx + \tau_q\int_0^L \theta_{ttt}\Phi_x\theta_{tt}dx\\
&\quad + \frac{\tau_q^2}{4}\int_0^L \Phi_x\theta_{ttt}^2dx\\
&\le -k\frac{d}{dt}\int_0^L \theta_{ttx}\Phi\hat{\theta}_{xx}dx + \frac{k}{\tau_\theta}\int_0^L \hat{\theta}_{tx}\Phi\hat{\theta}_{txx}dx - \frac{k}{\tau_\theta}\int_0^L \theta_{tx}\Phi\hat{\theta}_{txx}dx\\
&\quad + C\int_0^L \{\theta_t^2+\theta_{tt}^2+\theta_{tx}^2+\theta_{ttt}^2+\theta_{ttx}^2\}dx\\
&= -k\frac{d}{dt}\int_0^L \theta_{ttx}\Phi\hat{\theta}_{xx}dx - \frac{k}{4\tau_\theta}[\hat{\theta}_{tx}^2(0)+\hat{\theta}_{tx}^2(L)]\\
&\quad - \frac{d}{dt}\frac{k}{\tau_\theta}\int_0^L \theta_{tx}\Phi\hat{\theta}_{xx}dx + \frac{k}{\tau_\theta}\int_0^L \theta_{ttx}\Phi\hat{\theta}_{xx}dx\\
&\quad + C\int_0^L \{\theta_t^2+\theta_{tt}^2+\theta_{tx}^2+\theta_{ttt}^2+\theta_{ttx}^2\}dx.
\end{aligned}
$$

Inserting (4.18) into (4.17) and using (4.1) again we get

$$
\begin{aligned}
\frac{d}{dt}\int_0^L \left\{\tilde{u}_{tt}\Phi\tilde{u}_{tx} + \frac{k\tau_q^2}{2\theta_0}\theta_{ttx}\Phi\hat{\theta}_{xx} + \frac{k\tau_q^2}{2\theta_0\tau_\theta}\theta_{tx}\Phi\hat{\theta}_{xx}\right\}dx \le\ & -\frac{\alpha_*}{4}(\tilde{u}_{tx}^2(0)+\tilde{u}_{tx}^2(L))\\
& + C\int_0^L \{\tilde{u}_{tx}^2+\tilde{u}_{xx}^2+\theta_t^2+\theta_x^2+\theta_{tt}^2+\theta_{tx}^2+\theta_{ttt}^2+\theta_{ttx}^2+\hat{\theta}_{xx}^2\}dx. \qquad (4.19)
\end{aligned}
$$

We still have to produce a term $-\int_0^L \hat{\theta}_{xx}^2dx$-term on the right-hand side. This is obtained as follows. We have from (4.2)

$$\hat{\theta}_{xx} = \frac{1}{k}\tilde{\theta}_t + \frac{m\theta_0}{k}\tilde{u}_{tx},$$

which, inserted into (4.19), yields

$$
\begin{aligned}
\frac{d}{dt}\int_0^L \left\{\tilde{u}_{tt}\Phi\tilde{u}_{tx} + \frac{k\tau_q^2}{2\theta_0}\theta_{ttx}\Phi\hat{\theta}_{xx} + \frac{k\tau_q^2}{2\theta_0\tau_\theta}\theta_{tx}\Phi\hat{\theta}_{xx}\right\}dx \le\ & -\frac{\alpha_*}{4}(\tilde{u}_{tx}^2(0)+\tilde{u}_{tx}^2(L))\\
& + C_2\int_0^L \{\tilde{u}_{tx}^2+\tilde{u}_{xx}^2+\theta_t^2+\theta_x^2+\theta_{tt}^2+\theta_{tx}^2+\theta_{ttt}^2+\theta_{ttx}^2\}dx \qquad (4.20)
\end{aligned}
$$

with a constant $C_2 > 0$. A multiplication of (4.20) by $\epsilon_3 > 0$ and then a combination

with (4.15) yields

$$\frac{d}{dt}\int_0^L \left\{ \frac{1}{\alpha_*}\tilde{u}_{tx}\tilde{u}_x + \frac{3k}{\alpha_*^2 m\theta_0}\hat{\theta}_x\tilde{u}_{tt} + \frac{3k}{\alpha_*^2\theta_0}\hat{\theta}_x\tilde{\theta}_x + \epsilon_3\tilde{u}_{tt}\Phi\tilde{u}_{tx} \right.$$
$$\left. + \epsilon_3\frac{k\tau_q^2}{2\theta_0}\theta_{ttx}\Phi\hat{\theta}_{xx} + \epsilon_3\frac{k\tau_q^2}{2\theta_0\tau_\theta}\theta_{tx}\Phi\hat{\theta}_{xx} \right\} dx$$
$$\leq -\frac{1}{2\alpha_*}\int_0^L \tilde{u}_{tx}^2 dx - \frac{1}{2}\int_0^L \tilde{u}_{xx}^2 dx + \frac{C}{\epsilon_2^3}\int_0^L \{\tilde{\theta}_t^2 + \hat{\theta}_{tx}^2 + \tilde{\theta_x}^2\} dx$$
$$- \left[\frac{\alpha_*\epsilon_3}{4} - C_1\epsilon_2\right](\tilde{u}_{tx}^2(0) + \tilde{u}_{tx}^2(L))$$
$$+ C_2\epsilon_3\int_0^L \{\tilde{u}_{tx}^2 + \tilde{u}_{xx}^2\} dx + C_2\varepsilon_3\int_0^L \{\theta_t^2 + \theta_{tt}^2 + \theta_{tx}^2 + \theta_{ttt}^2 + \theta_{ttx}^2 + \tilde{\theta}_x^2\} dx.$$

Now choosing

$$\epsilon_3 := \min\left\{\frac{1}{4\alpha_* C_2}, \frac{1}{2C_2}\right\}$$

and then

$$\epsilon_2 := \frac{\alpha_*\epsilon_3}{4C_1}$$

we obtain

$$\frac{d}{dt}\int_0^L \left\{ \frac{1}{\alpha_*}\tilde{u}_{tx}\tilde{u}_x + \frac{3k}{\alpha_*^2 m\theta_0}\hat{\theta}_x\tilde{u}_{tt} + \frac{3k}{\alpha_*^2\theta_0}\hat{\theta}_x\tilde{\theta}_x + \epsilon_3\tilde{u}_{tt}\Phi\tilde{u}_{tx} \right.$$
$$\left. + \epsilon_3\frac{k\tau_q^2}{2\theta_0}\theta_{ttx}\Phi\hat{\theta}_{xx} + \epsilon_3\frac{k\tau_q^2}{2\theta_0\tau_\theta}\theta_{tx}\Phi\hat{\theta}_{xx} \right\} dx$$
$$\leq -\frac{1}{4\alpha_*}\int_0^L \tilde{u}_{tx}^2 dx - \frac{1}{4}\int_0^L \tilde{u}_{xx}^2 dx$$
$$+ C\int_0^L \{\theta_t^2 + \theta_{tt}^2 + \theta_{tx}^2 + \theta_{ttt}^2 + \theta_{ttx}^2 + \tilde{\theta}_t^2 + \tilde{\theta}_x^2\} dx. \tag{4.21}$$

We observe that by Poincaré's estimates and (4.1) we have

$$\int_0^L \{\tilde{u}_t^2 + \tilde{u}_x^2\} dx \leq C\int_0^L \{\tilde{u}_{tx}^2 + \tilde{u}_{xx}^2\} dx, \quad \int_0^L \tilde{u}_{tt}^2 dx \leq C\int_0^L \{\tilde{u}_{xx}^2 + \tilde{\theta}_x^2\} dx. \tag{4.22}$$

Now let $E(t)$ and $E_{\mathcal{H}}(t)$ be given as defined in (4.4) and (4.5), respectively, and define for $K > 0$ (yet to be determined)

$$W_1(t) \equiv E_1(u, \theta; t) := E_{\mathcal{H}}(t) + KE(t), \qquad W_2(t) := W_1(u_t, \theta_t; t),$$

and the final energy term

$$\mathcal{W}(t) := W_1(t) + W_2(t),$$

where we now choose ϵ_1 small enough such that the terms $2\epsilon_1 \int_0^L \{\tilde{u}_t^2 + \tilde{u}_{tt}^2\} dx$ are absorbed by arising corresponding negative terms (see (4.21), (4.22)). Then we choose K large enough to make sure that the coefficients in $[\cdot]$ brackets in (4.11) are positive. Defining for $\epsilon > 0$ the Lyapunov functional L by

$$L(t) := \frac{1}{\epsilon}\mathcal{W}(t) + \int_0^L \left\{ \frac{1}{\alpha_*}\tilde{u}_{tx}\tilde{u}_x + \frac{3k}{\alpha_*^2 m\theta_0}\hat{\theta}_x\tilde{u}_{tt} + \frac{3k}{\alpha_*^2\theta_0}\hat{\theta}_x\tilde{\theta}_x + \epsilon_3\tilde{u}_{tt}\Phi\tilde{u}_{tx} \right.$$
$$\left. + \epsilon_3\frac{k\tau_q^2}{2\theta_0}\theta_{ttx}\Phi\hat{\theta}_{xx} + \epsilon_3\frac{k\tau_q^2}{2\theta_0\tau_\theta}\theta_{tx}\Phi\hat{\theta}_{xx} \right\} dx,$$

we now find from (4.11), (4.21), (4.22), observing

$$\frac{k}{8m\theta_0\alpha_*}\int_0^L \hat{\theta}_{xx}^2 dx \le \frac{1}{8\alpha_*}\int_0^L \tilde{u}_{tx}^2 dx + \frac{1}{8m\theta_0\alpha_*}\int_0^L \tilde{\theta}_t^2 dx$$

and choosing ϵ small enough that

$$\frac{d}{dt}L(t) \le -C_3\mathcal{W}(t) \tag{4.23}$$

for some constant $C_3 > 0$. Moreover, we have for ϵ small enough

$$\exists\, K_1, K_2 > 0\ \forall\, t \ge 0: \quad K_1\mathcal{W}(t) \le L(t) \le K_2\mathcal{W}(t). \tag{4.24}$$

Combining (4.23) and (4.24) we have thus proved the exponential stability

THEOREM 4.1. *The system* (4.1)–(4.3) *is exponentially stable,*

$$\exists\, d_1, d_2 > 0 \forall\, t \ge 0: \quad \mathcal{W}(t) \le d_1 \mathrm{e}^{-d_2 t}\mathcal{W}(0).$$

The Dirichlet–Neumann-type boundary conditions

$$u_x = \theta = 0 \qquad \text{for } x = 0, L$$

or

$$u = \theta_x = 0 \qquad \text{for } x = 0, L$$

could be treated similarly. It is even likely that one can work just with the first energy $W_1(t)$ (instead of $W_1(t) + W_2(t)$). Moreover, the radially symmetric case in two or three space dimensions should be accessible.

The exponential stability result is first a result for θ and $\tilde{u}$. But we obtain an exponential decay result also for u itself observing that for functions $w, h : [0, \infty) \times (0, L) \to \mathbb{R}$ satisfying

$$\ddot{w} + \frac{2}{\tau_q}\dot{w} + \frac{2}{\tau_q^2}w = h \quad (:= \tilde{u}(t, x))$$

and

$$\exists\, d_1, d_2 > 0\ \ \forall\, t \ge 0: \quad \int_0^L |h(x,t)|^2 dx \le d_1 \mathrm{e}^{-2d_2 t}C_0^2,$$

where C_0 depends on the initial data according to Theorem 4.1, we conclude for $\mathbf{z} := (w, \dot{w})'$,

$$\exists\, d_3, d_4 > 0 \;\; \forall\, t \geq 0 : \;\; \int_0^L |\mathbf{z}(x,t)|^2 dx \leq d_3 \mathrm{e}^{-2d_4 t} \left(\int_0^L |\mathbf{z}(x,0)|^2 dx + C_0^2 \right).$$

Here d_4 can be any positive number smaller than $\min\{1/\tau_q, d_2\}$ which becomes apparent observing that the characteristic values for the ODE for w are

$$\beta_{1,2} = -\frac{1}{\tau_q} \pm \mathrm{i}\frac{1}{\tau_q}.$$

5. Some spatial estimates. In this section we establish results on the spatial evolution of solutions of (2.1)–(2.6), provided that the initial data of (2.4) are assumed to be bounded in a certain energy norm.

We begin by considering

$$F(z,t) = -\int_0^t \int_{D(z)} \left(\tilde{T}_{i3} \dot{\tilde{u}}_i + \frac{1}{\theta_0} k \hat{\theta}_{,3} \tilde{\theta} \right) dA ds. \tag{5.1}$$

From (5.2) we find that

$$\frac{\partial F(z,t)}{\partial t} = -\int_{D(z)} \left(\tilde{T}_{i3} \dot{\tilde{u}}_i + \frac{1}{\theta_0} k \hat{\theta}_{,3} \tilde{\theta} \right) dA, \tag{5.2}$$

and, on using (2.1), the divergence theorem on $D(z)$ and (2.4), (2.5), we obtain

$$\begin{aligned} \frac{\partial F(z,t)}{\partial z} = -\frac{1}{2} \int_{D(z)} \Bigg(& \rho \dot{\tilde{u}}_i \dot{\tilde{u}}_i + \mu \tilde{u}_{i,j} \tilde{u}_{i,j} + (\lambda + \mu) \tilde{u}_{r,r} \tilde{u}_{s,s} + \frac{c}{\theta_0} (\tilde{\theta})^2 \\ & + \frac{k}{\theta_0} \Big((\tau_q + \tau_\theta) |\nabla \theta|^2 + \frac{1}{2} \tau_q^2 \tau_\theta |\nabla \dot{\theta}|^2 + \tau_q^2 \nabla \theta \nabla \dot{\theta} \Big) \Bigg) dA \end{aligned} \tag{5.3}$$

$$- \int_0^t \int_{D(z)} \frac{k}{\theta_0} \left(|\nabla \theta|^2 + \left(\tau_\theta \tau_q - \frac{1}{2} \tau_q^2 \right) |\nabla \dot{\theta}|^2 \right) dA ds + E_1(z),$$

where

$$E_1(z) = \frac{1}{2} \int_{D(z)} \Big(\rho \tilde{v}_i^0 \tilde{v}_i^0 + \mu \tilde{u}_{i,j}^0 \tilde{u}_{i,j}^0 + (\lambda + \mu) \tilde{u}_{r,r}^0 \tilde{u}_{s,s}^0 \Big) dA \tag{5.4}$$

$$+ \frac{1}{2\theta_0} \int_{D(z)} \left(c(\tilde{\theta}^0)^2 + k \left((\tau_q + \tau_\theta) |\nabla \theta^0|^2 + \frac{1}{2} \tau_q^2 \tau_\theta |\nabla \vartheta^0|^2 + \tau_q^2 \nabla \theta^0 \nabla \vartheta^0 \right) \right) dA.$$

Note that $E_1(z)$ depends only on the initial data (2.4) and we note that several time derivative at time zero can be obtained assuming the continuity of the solutions at time $t = 0$. Rewriting (5.3) with z replaced by the variable η, and integrating with

respect to η from 0 to z, we get

$$F(z,t)-F(0,t)=-\frac{1}{2}\int_0^z\int_{D(\eta)}\Big(\rho\dot{\tilde{u}}_i\dot{\tilde{u}}_i+\mu\tilde{u}_{i,j}\tilde{u}_{i,j}+(\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s}\Big)dV \tag{5.5}$$
$$-\frac{1}{2\theta_0}\int_0^z\int_{D(\eta)}\left(c(\tilde{\theta})^2+k\left((\tau_q+\tau_\theta)|\nabla\theta|^2+\frac{k}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2+k\tau_q^2\nabla\theta\nabla\dot{\theta}\right)\right)dV$$
$$-\frac{k}{\theta_0}\int_0^t\int_0^z\int_{D(\eta)}\left(|\nabla\theta|^2+\left(\tau_\theta\tau_q-\frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right)dVds$$
$$+\frac{1}{2}\int_0^z\int_{D(\eta)}\Big(\rho\tilde{v}_i^0\tilde{v}_i^0+\mu\tilde{u}_{i,j}^0\tilde{u}_{i,j}^0+(\lambda+\mu)\tilde{u}_{r,r}^0\tilde{u}_{s,s}^0\Big)dV$$
$$+\frac{1}{2\theta_0}\int_0^z\int_{D(\eta)}\left(c(\tilde{\theta}^0)^2+k\left((\tau_q+\tau_\theta)|\nabla\theta^0|^2+\frac{1}{2}\tau_q^2\tau_\theta|\nabla\vartheta^0|^2+\tau_q^2\nabla\theta^0\nabla\vartheta^0\right)\right)dV.$$

Our next step is to establish an inequality between the time and spatial derivatives of $F(z,t)$. By virtue of (1.7), the second integral on the right in (5.3) is nonnegative. The last three terms in the integrand in the first integral on the right in (5.3) are a quadratic form and may be bounded below using the smallest positive eigenvalue λ_0 of (2.7), (2.10) given in (2.11). Thus we find that

$$\frac{\partial F(z,t)}{\partial z}\le-\frac{1}{2}\int_{D(z)}\Bigg(\rho\dot{\tilde{u}}_i\dot{\tilde{u}}_i+\mu\tilde{u}_{i,j}\tilde{u}_{i,j}+(\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s}$$
$$+\frac{c}{\theta_0}(\tilde{\theta})^2+\frac{k\lambda_0}{\theta_0}(|\nabla\theta|^2+|\nabla\dot{\theta}|^2)\Bigg)dA+E_1(z). \tag{5.6}$$

Applying Schwarz's inequality in (5.3) and using (2.3), we get

$$\left|\frac{\partial F}{\partial t}\right|\le\frac{1}{2}\int_{D(z)}\left[\frac{\epsilon_1}{\rho}\tilde{T_{ij}}\tilde{T_{ij}}+\frac{\rho}{\epsilon_1}\dot{\tilde{u}}_i\dot{\tilde{u}}_i+\frac{c}{\epsilon_2\theta_0}(\tilde{\theta})^2+\frac{\epsilon_2k^2}{c\theta_0}\hat{\theta}_{,3}\hat{\theta}_{,3}\right]dA \tag{5.7}$$
$$\le\frac{1}{2}\int_{D(z)}\left[\frac{\epsilon_1}{\rho}(1+\epsilon)\mu^*[\mu\tilde{u}_{i,j}\tilde{u}_{i,j}+(\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s}\right]+\frac{1}{\epsilon_1}(\rho\dot{\tilde{u}}_i\dot{\tilde{u}}_i)$$
$$+\left(\frac{1}{\epsilon_2}+\frac{3m^2\epsilon_1\theta_0}{\rho c}(1+\epsilon^{-1})\right)\frac{c}{\theta_0}(\tilde{\theta})^2+\frac{\epsilon_2k(1+\tau_\theta^2)}{c\lambda_0}\left[\frac{k\lambda_0}{\theta_0}(|\nabla\theta|^2+|\nabla\dot{\theta}|^2)\right]dA,$$

where the weighted arithmetic-geometric mean inequality has been employed and where ϵ_i are arbitrary positive constants.

Now, we equate the coefficients of the energetic terms in the last integral of the (5.7). We get

$$\frac{1}{\epsilon_1}=\frac{\epsilon_1}{\rho}(1+\epsilon)\mu^*=\frac{1}{\epsilon_2}+\frac{3m^2\epsilon_1\theta_0}{\rho c}(1+\epsilon^{-1})=\frac{\epsilon_2k(1+\tau_\theta^2)}{c\lambda_0}. \tag{5.8}$$

That is,

$$\epsilon_1=\beta^{-1},\epsilon_2=\frac{c\lambda_0\beta}{k(1+\tau_\theta^2)},\ \beta=\sqrt{\frac{(1+\epsilon_0)\mu^*}{\rho}}, \tag{5.9}$$

where ϵ_0 is the positive root of the second-order equation

$$x^2 + \left(1 - \frac{\rho k(1+\tau_0^2)}{\mu^* \lambda_0 c} - \frac{3m^2\theta_0}{\mu^* c}\right) x - \frac{3m^2\theta_0}{\mu^* c} = 0. \tag{5.10}$$

In view of (5.6) we can write (5.7) as

$$\left|\frac{\partial F}{\partial t}\right| + \beta \frac{\partial F}{\partial z} \leq \beta E_1(z), \tag{5.11}$$

where β is defined at (5.9).

The inequality (5.11) implies that

$$\frac{\partial F}{\partial t} + \beta \frac{\partial F}{\partial z} \leq \beta E_1(z) \tag{5.12}$$

and

$$\frac{\partial F}{\partial t} - \beta \frac{\partial F}{\partial z} \geq -\beta E_1(z). \tag{5.13}$$

Integrating (5.12) and recalling the definition of $E_1(z)$ in (5.4) we obtain

$$F(z, \beta^{-1}(z - z^*)) \leq \frac{1}{2}\int_{z^*}^{z}\int_{D(\eta)} \Big(\rho \tilde{v}_i^0 \tilde{v}_i^0 + \mu \tilde{u}_{i,j}^0 \tilde{u}_{i,j}^0 + (\lambda+\mu)\tilde{u}_{r,r}^0 \tilde{u}_{s,s}^0\Big) dV, \tag{5.14}$$

$$+ \frac{1}{2\theta_0}\int_{z^*}^{z}\int_{D(\eta)} \left(c(\tilde{\theta}^0)^2 + k\left((\tau_q+\tau_\theta)|\nabla\theta^0|^2 + \frac{1}{2}\tau_q^2\tau_\theta|\nabla\vartheta^0|^2 + \tau_q^2 \nabla\theta^0\nabla\vartheta^0\right)\right) dV,$$

where $z \geq z^*$. Similarly, by integrating (5.13) we obtain

$$F(z, \beta^{-1}(z^{**} - z)) \geq -\frac{1}{2}\int_{z}^{z^{**}}\int_{D(\eta)} \Big(\rho \tilde{v}_i^0 \tilde{v}_i^0 + \mu \tilde{u}_{i,j}^0 \tilde{u}_{i,j}^0 + (\lambda+\mu)\tilde{u}_{r,r}^0 \tilde{u}_{s,s}^0\Big) dV, \tag{5.15}$$

$$- \frac{1}{2\theta_0}\int_{z}^{z^{**}}\int_{D(\eta)} \left(c(\tilde{\theta}^0)^2 + k\left((\tau_q+\tau_\theta)|\nabla\theta^0|^2 + \frac{1}{2}\tau_q^2\tau_\theta|\nabla\vartheta^0|^2 + \tau_q^2 \nabla\theta^0\nabla\vartheta^0\right)\right) dV,$$

where $z^{**} \geq z$. Let

$$\mathcal{E}(z,t) := \frac{1}{2}\int_{R(z)} \Big(\rho \dot{\tilde{u}}_i \dot{\tilde{u}}_i + \mu \tilde{u}_{i,j}\tilde{u}_{i,j} + (\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s}\Big) dV \tag{5.16}$$

$$+ \frac{1}{2\theta_0}\int_{R(z)} \left(c(\tilde{\theta})^2 + k\left((\tau_q+\tau_\theta)|\nabla\theta|^2 + \frac{k}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2 + k\tau_q^2\nabla\theta\nabla\dot{\theta}\right)\right) dV$$

$$+ \frac{k}{\theta_0}\int_0^t\int_{R(z)} \left(|\nabla\theta|^2 + \left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right) dV ds.$$

If we now assume that the initial data (2.4) is such that

$$\mathcal{E}(0,0) = \frac{1}{2}\int_R \Big(\rho \tilde{v}_i^0 \tilde{v}_i^0 + \mu \tilde{u}_{i,j}^0 \tilde{u}_{i,j}^0 + (\lambda+\mu)\tilde{u}_{r,r}^0 \tilde{u}_{s,s}^0\Big) dV \tag{5.17}$$

$$+\frac{1}{2\theta_0}\int_R\left(c(\tilde{\theta}^0)^2+k\left((\tau_q+\tau_\theta)|\nabla\theta^0|^2+\frac{1}{2}\tau_q^2\tau_\theta|\nabla\vartheta^0|^2+\tau_q^2\nabla\theta^0\nabla\vartheta^0\right)\right)dV<\infty,$$

then the inequalities (5.14), (5.15) imply that for each finite time t,

$$\lim_{z\to\infty}F(z,t)=0. \tag{5.18}$$

Thus, we may rewrite

$$\begin{aligned}F(z,t)&=\frac{1}{2}\int_{R(z)}\left(\rho\dot{\tilde{u}}_i\dot{\tilde{u}}_i+\mu\tilde{u}_{i,j}\tilde{u}_{i,j}+(\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s}\right)dV\\&+\frac{1}{2\theta_0}\int_{R(z)}\left(c(\tilde{\theta})^2+k\left((\tau_q+\tau_\theta)|\nabla\theta|^2+\frac{k}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2+k\tau_q^2\nabla\theta\nabla\dot{\theta}\right)\right)dV\\&+\frac{k}{\theta_0}\int_0^t\int_{R(z)}\left(|\nabla\theta|^2+\left(\tau_\theta\tau_q-\frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right)dVds\\&-\frac{1}{2}\int_{R(z)}\left(\rho\tilde{v}_i^0\tilde{v}_i^0+\mu\tilde{u}_{i,j}^0\tilde{u}_{i,j}^0+(\lambda+\mu)\tilde{u}_{r,r}^0\tilde{u}_{s,s}^0\right)dV.\end{aligned} \tag{5.19}$$

$$-\frac{1}{2\theta_0}\int_{R(z)}\left(c(\tilde{\theta}^0)^2+k\left((\tau_q+\tau_\theta)|\nabla\theta^0|^2+\frac{1}{2}\tau_q^2\tau_\theta|\nabla\vartheta^0|^2+\tau_q^2\nabla\theta^0\nabla\vartheta^0\right)\right)dV.$$

Now the inequality (5.12) implies that

$$\mathcal{E}(z,t)\le\mathcal{E}(z^*,0), \tag{5.20}$$

where z, z^*, and t are related by $t=\beta^{-1}(z-z^*)$. In a similar way we get

$$\mathcal{E}(z,t)\ge\mathcal{E}(z^{**},0) \tag{5.21}$$

for $t=\beta^{-1}(z^{**}-z)$. From the inequalities (5.20) and (5.21) we conclude that

$$\mathcal{E}(z,t)\le\mathcal{E}(z^*,t^*) \tag{5.22}$$

for $|t-t^*|\le\beta^{-1}(z-z^*)$. Thus, we have proved the next theorem.

THEOREM 5.1. *Let* $(\mathbf{u},\theta)$ *be a solution of the initial boundary value problem* (2.1)–(2.6). *Then the energy function* $\mathcal{E}(z,t)$ *defined in* (5.16) *satisfies the inequality* (5.22) *whenever* $|t-t^*|\le\beta^{-1}(z-z^*)$, *provided that the initial data satisfy* (5.17).

We note that this result gives an answer to the question proposed by Hetnarski and Ignaczak [10, p. 474] a principle of Saint-Venant's type in this theory.

If one defines the measure

$$\mathcal{E}^*(z,t)=\int_0^t\mathcal{E}(z,s)ds, \tag{5.23}$$

the following inequalities can be obtained as in [2]:

$$\mathcal{E}^*(z,t)\le\beta^{-1}\int_{z-\beta t}^z\mathcal{E}(\eta,0)d\eta,\ \beta t\le z, \tag{5.24}$$

$$\mathcal{E}^*(z,t)\le\beta^{-1}\int_0^z\mathcal{E}(\eta,0)d\eta+\left(1-\frac{z}{\beta t}\right)\mathcal{E}^*(0,t),\ \beta t\ge z. \tag{5.25}$$

6. Consequences of the estimates (5.22), (5.24), (5.25). In this section we show some consequences of the estimates (5.22), (5.24), and (5.25).

First, we assume that the initial conditions (2.4) are homogeneous. In this case we see that $\mathcal{E}(0,0)=0$. Estimate (5.22) implies that $\mathcal{E}(z,t)=0$ whenever $\beta t \leq z$. In view of the definition (5.20) we obtain that

$$\tilde{u}_i = 0, \;\; \theta = 0 \tag{6.1}$$

whenever $\beta t \leq z$. Then for every $\mathbf{x}=(x_1,x_2,z)$ such that $\beta t \leq z$, the functions $u_i(\mathbf{x},t)$ satisfy the ordinary differential equation $\tilde{u}_i = 0$ with null initial conditions. Thus, we also conclude that

$$u_i = 0 \tag{6.2}$$

when $\beta t \leq z$. This is a result of the kind of the domain of dependence of the solutions. We have proved the next theorem.

THEOREM 6.1. *Let $(\mathbf{u},\theta)$ be a solution of the initial boundary value problem* (2.1)–(2.6) *when the initial conditions are null. Then $(\mathbf{u},\theta)=(\mathbf{0},0)$ whenever $\beta t \leq z$.*

We note that this result gives an answer to the question proposed by Hetnarski and Ignaczak [10, p. 474] concerning a general domain of influence theorem in this theory.

In this situation it is natural to look for estimates for

$$\mathcal{H}(z,t) := \int_z^\infty \mathcal{E}(\xi,t)d\xi, \tag{6.3}$$

where $z \leq \beta t$. We have that

$$\mathcal{H}(z,t) = \int_z^{\beta t} \mathcal{E}(\xi,t)d\xi. \tag{6.4}$$

But

$$\mathcal{E}(z,t) \leq \mathcal{E}(0,z^*) \tag{6.5}$$

when $z^* \geq t - \beta^{-1}z \geq 0$. Thus, it follows that

$$\mathcal{H}(z,t) \leq \frac{\beta t - z}{t}\int_0^t \mathcal{E}(0,s)ds = \frac{\beta t - z}{t}\mathcal{E}^*(0,t). \tag{6.6}$$

The second natural question we are interested in is to obtain spatial estimates for some norm of the solutions. We had obtained the estimates (5.22), (5.24), and (5.25), but they are expressed in a combination of the solution and its time derivatives. Now, we give explicit spatial estimates. From (5.20), (5.22), (5.24), and (5.25) we have

$$\begin{aligned}\mathcal{J}(z,t) &= \frac{1}{2\theta_0}\int_{R(z)}\left(k\left((\tau_q+\tau_\theta)|\nabla\theta|^2 + \frac{1}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2 + \tau_q^2\nabla\theta\nabla\dot{\theta}\right)\right)dV \\ &+ \frac{k}{\theta_0}\int_0^t\int_{R(z)}\left(|\nabla\theta|^2 + \left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right)dVds \leq \mathcal{E}(z,t)\end{aligned} \tag{6.7}$$

for $|t-t^*| \leq \beta^{-1}(z-z^*)$. Also, we obtain that

$$\mathcal{J}^*(z,t) \leq \beta^{-1}\int_{z-\beta t}^z \mathcal{E}(\eta,0)d\eta, \;\; \beta t \leq z, \tag{6.8}$$

and

$$\mathcal{J}^*(z,t) \leq \beta^{-1}\int_0^z \mathcal{E}(\eta,0)d\eta + (1-\frac{z}{\beta t})\mathcal{E}^*(0,t), \quad \beta t \geq z, \tag{6.9}$$

where

$$\mathcal{J}^*(z,t) = \int_0^t \mathcal{J}(z,s)ds. \tag{6.10}$$

Now, we will obtain estimates for the mechanical part. To this end, we note that

$$\begin{aligned}\int_0^t (\tilde{f})^2 ds = \int_0^t \left(f^2 + \frac{\tau_q^4}{4}(\ddot{f})^2\right) ds + \tau_q\left(f^2(t) + \tau_q f(t)\dot{f}(t) + \frac{\tau_q^2}{2}\dot{f}^2(t)\right)\\ - \tau_q\left(f^2(0) + \tau_q f(0)\dot{f}(0) + \frac{\tau_q^2}{2}\dot{f}^2(0)\right).\end{aligned} \tag{6.11}$$

It is worth noting that the expression

$$\tau_q\left(f^2(t) + \tau_q f(t)\dot{f}(t) + \frac{\tau_q^2}{2}\dot{f}^2(t)\right)$$

is positive in the sense that it is equivalent to the measure defined by $f^2(t) + \dot{f}^2(t)$. Thus, if we define

$$\begin{aligned}\mathcal{M}^*(z,t) = \frac{1}{2}\int_0^t\int_{R(z)}\Bigg(\rho\left(\dot{u}_i\dot{u}_i + \frac{\tau_q^4}{4}\dddot{u}_i\dddot{u}_i\right) + \mu\left(u_{i,j}u_{i,j} + \frac{\tau_q^4}{4}\ddot{u}_{i,j}\ddot{u}_{i,j}\right)\\ + (\lambda+\mu)\left(u_{r,r}u_{s,s} + \frac{\tau_q^4}{4}\ddot{u}_{r,r}\ddot{u}_{s,s}\right)\Bigg)dVds\end{aligned}$$

$$\begin{aligned}+\frac{\tau_q}{2}\int_{R(z)}\Bigg(\rho\left(\dot{u}_i\dot{u}_i + \tau_q\dot{u}_i\ddot{u}_i + \frac{\tau_q^2}{2}\ddot{u}_i\ddot{u}_i\right) + \mu\left(u_{i,j}u_{i,j} + \tau_q u_{i,j}\dot{u}_{i,j} + \frac{\tau_q^2}{2}\dot{u}_{i,j}\dot{u}_{i,j}\right)\\ + (\lambda+\mu)\left(u_{r,r}u_{s,s} + \tau_q u_{r,r}\dot{u}_{s,s} + \frac{\tau_q^2}{2}\dot{u}_{r,r}\dot{u}_{s,s}\right)\Bigg)dV,\end{aligned} \tag{6.12}$$

we obtain the estimates

$$\mathcal{M}^*(z,t) \leq \beta^{-1}\int_{z-\beta t}^z \mathcal{E}(\eta,0)d\eta + \mathcal{P}(z), \quad \beta t \leq z, \tag{6.13}$$

and

$$\mathcal{M}^*(z,t) \leq \beta^{-1}\int_0^z \mathcal{E}(\eta,0)d\eta + (1-\frac{z}{\beta t})\mathcal{E}^*(0,t) + \mathcal{P}(z), \quad \beta t \geq z, \tag{6.14}$$

where

(6.15)
$$\mathcal{P}(z)=\frac{\tau_q}{2}\int_{R(z)}\left(\rho\left(v_i^0v_i^0+\tau_qv_i^0z_i^0+\frac{\tau_q^2}{2}z_i^0z_i^0\right)+\mu\left(u_{i,j}^0u_{i,j}^0+\tau_qu_{i,j}^0v_{i,j}^0+\frac{\tau_q^2}{2}v_{i,j}^0v_{i,j}^0\right)\right.$$
$$\left.+(\lambda+\mu)\left(u_{r,r}^0u_{s,s}^0+\tau_qu_{r,r}^0v_{s,s}^0+\frac{\tau_q^2}{2}v_{r,r}^0v_{s,s}^0\right)\right)dV$$

and

$$z_i^0=(\mu u_{i,j}^0+(\lambda+\mu)u_{r,r}^0\delta_{ij}+m\delta_{ij}\theta)_{,j}. \tag{6.16}$$

It is worth noting that it is also possible to obtain estimates in the L^2-norm of the temperature and its two first times derivatives in a similar way of the estimates (6.13), (6.14).

7. A nonstandard problem for (2.1), (2.2). In this section, we briefly discuss the behavior of solutions of (2.1), (2.2) subject to the boundary condition (2.5), (2.6) and the nonstandard conditions

$$u_i(\mathbf{x},T)=\alpha u_i(\mathbf{x},0),\ \dot{u}_i(\mathbf{x},T)=\alpha\dot{u}_i(\mathbf{x},0),$$
$$\theta(\mathbf{x},T)=\alpha\theta(\mathbf{x},0),\ \dot{\theta}(\mathbf{x},T)=\alpha\dot{\theta}(\mathbf{x},0),\ \ddot{\theta}(\mathbf{x},T)=\alpha\ddot{\theta}(\mathbf{x},0), \tag{7.1}$$

where $\alpha>1$. Such nonstandard conditions have been the subject of much recent attention (see, e.g., [1, 16, 33] in the context of the heat equation, [21] for generalized heat conduction and [22] for viscous flows, [19] for the isothermal elasticity, and [30], [27] for some thermoelastic theories).

The boundary data in (2.6) are assumed compatible with (6.1), (6.2).

The analysis begins by considering the function

$$F_\gamma(z)=-\int_0^T\int_{D(z)}\exp(-\gamma s)\left(\tilde{T}_{i3}\dot{\tilde{u}}_i+\frac{1}{\theta_0}k\hat{\theta}_{,3}\tilde{\theta}\right)dAds, \tag{7.2}$$

where, guided by results established in [1, 16, 33], the positive constant γ is given by

$$\gamma=\frac{2}{T}\ln\alpha. \tag{7.3}$$

We have

(7.4)
$$F_\gamma(z)=F_\gamma(0)+\frac{\gamma}{2}\int_0^T\int_0^z\int_{D(\eta)}\exp(-\gamma s)\left(\rho\dot{\tilde{u}}_i\dot{\tilde{u}}_i+\mu\tilde{u}_{i,j}\tilde{u}_{i,j}+(\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s}\right.$$
$$\left.+\frac{c}{\theta_0}(\tilde{\theta})^2+\frac{k}{\theta_0}\left((\tau_q+\tau_\theta)|\nabla\theta|^2+\frac{1}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2+\tau_q^2\nabla\theta\nabla\dot{\theta}\right)\right)dA$$
$$+\gamma\frac{k}{\theta_0}\int_0^T\int_0^z\int_{D(\eta)}\exp(-\gamma s)\left(\frac{1}{\gamma}|\nabla\theta|^2+\frac{1}{\gamma}\left(\tau_\theta\tau_q-\frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right)dVds.$$

An argument similar to the one used in the case of the standard initial conditions leads to the estimate

$$|F_\gamma|\le\gamma\beta_\gamma\frac{\partial F_\gamma}{\partial z}, \tag{7.5}$$

where β_γ is defined in the same form of β defined in (5.9) but with changing the parameter λ_0 by μ_γ defined at (2.13).

This inequality is well known in the study of spatial decay estimates. It implies that

$$F_\gamma \leq \gamma\beta_\gamma \frac{\partial F_\gamma}{\partial z} \text{ and } -F_\gamma \leq \gamma\beta_\gamma \frac{\partial F_\gamma}{\partial z}. \tag{7.6}$$

From (7.6), we can obtain an alternative of Phragmen–Lindelöf type, which states (see [5]) that either the solutions grow exponentially for z sufficiently large or solutions decay exponentially in the form

$$\mathcal{E}_\gamma(z) \leq \mathcal{E}_\gamma(0)\exp\Big(-\gamma^{-1}\beta_\gamma^{-1}z\Big) \tag{7.7}$$

for all $z \geq 0$, where

$$\begin{aligned}\mathcal{E}_\gamma(z) = \frac{\gamma}{2}\int_0^T\int_0^z\int_{D(\eta)} \exp(-\gamma s)\Bigg(&\rho\dot{\tilde{u}}_i\dot{\tilde{u}}_i + \mu\tilde{u}_{i,j}\tilde{u}_{i,j} + (\lambda+\mu)\tilde{u}_{r,r}\tilde{u}_{s,s} \\ &+ \frac{c}{\theta_0}(\tilde{\theta})^2 + \frac{k}{\theta_0}\left((\tau_q+\tau_\theta)|\nabla\theta|^2 + \frac{1}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2 + \tau_q^2\nabla\theta\nabla\dot{\theta}\right)\Bigg)dVds \\ &+ \frac{k}{\theta_0}\int_0^T\int_0^z\int_{D(\eta)}\exp(-\gamma s)\left(|\nabla\theta|^2 + \left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right)dVds.\end{aligned} \tag{7.8}$$

The decay rate in (7.7) depends explicitly on γ given in (7.3). Thus, we have proved the next theorem.

THEOREM 7.1. *Let $(\mathbf{u},\theta)$ be a solution of the initial boundary value problem* (2.1), (2.2), (2.5), (2.6), *and* (7.1). *Then either the solutions grow exponentially or the estimate* (7.7) *is satisfied, where $\mathcal{E}_\gamma$ is defined at* (7.8).

Estimate (7.7) implies that

$$\mathcal{J}_\gamma(z) \leq \mathcal{E}_\gamma(0)\exp\left(-\gamma^{-1}\beta_\gamma^{-1}z\right), \tag{7.9}$$

where

$$\begin{aligned}\mathcal{J}_\gamma(z) = \frac{\gamma}{2\theta_0}\int_0^T\int_{R(z)}\exp(-\gamma s)\left(k\left((\tau_q+\tau_\theta)|\nabla\theta|^2 + \frac{1}{2}\tau_q^2\tau_\theta|\nabla\dot{\theta}|^2 + \tau_q^2\nabla\theta\nabla\dot{\theta}\right)\right)dVds \\ + \frac{k}{\theta_0}\int_0^T\int_{R(z)}\exp(-\gamma s)\left(|\nabla\theta|^2 + \left(\tau_\theta\tau_q - \frac{1}{2}\tau_q^2\right)|\nabla\dot{\theta}|^2\right)dVds.\end{aligned} \tag{7.10}$$

To obtain an estimate on the mechanical part, we first note that

$$\begin{aligned}\int_0^T\exp(-\gamma s)(\tilde{f})^2ds = \int_0^T\exp(-\gamma s)\Bigg(&\left(f^2 + \frac{\tau_q^4}{4}(\ddot{f})^2\right) \\ &+ \gamma\tau_q\left(f^2 + \tau_q f\dot{f} + \frac{\tau_q^2}{2}\dot{f}^2\right)\Bigg)ds \\ + \exp(-\gamma T)&\left(\tau_q\left(f^2(T) + \tau_q f(T)\dot{f}(T) + \frac{\tau_q^2}{2}\dot{f}^2(T)\right)\right) \\ &- \tau_q\left(f^2(0) + \tau_q f(0)\dot{f}(0) + \frac{\tau_q^2}{2}\dot{f}^2(0)\right).\end{aligned} \tag{7.11}$$

If we define

$$\mathcal{M}_\gamma(z) = \frac{1}{2}\int_0^T \int_{R(z)} \exp(-\gamma s)\Bigg(\rho\left(\dot{u}_i\dot{u}_i + \frac{\tau_q^4}{4}\dddot{u}_i\dddot{u}_i\right) + \mu\left(u_{i,j}u_{i,j} + \frac{\tau_q^4}{4}\ddot{u}_{i,j}\ddot{u}_{i,j}\right)$$
$$+ (\lambda+\mu)\left(u_{r,r}u_{s,s} + \frac{\tau_q^4}{4}\ddot{u}_{r,r}\ddot{u}_{s,s}\right)\Bigg)dVds$$
$$+ \frac{\gamma\tau_q}{2}\int_0^T \int_{R(z)} \exp(-\gamma s)\left(\rho\left(\dot{u}_i\dot{u}_i + \tau_q\dot{u}_i\ddot{u}_i + \frac{\tau_q^2}{2}\ddot{u}_i\ddot{u}_i\right)\right.$$
$$+ \mu\left(u_{i,j}u_{i,j} + \tau_q u_{i,j}\dot{u}_{i,j} + \frac{\tau_q^2}{2}\dot{u}_{i,j}\dot{u}_{i,j}\right)$$
$$\left.+ (\lambda+\mu)\left(u_{r,r}u_{s,s} + \tau_q u_{r,r}\dot{u}_{s,s} + \frac{\tau_q^2}{2}\dot{u}_{r,r}\dot{u}_{s,s}\right)\right)dVds, \tag{7.12}$$

we obtain the estimate

$$\mathcal{M}_\gamma(z) \le \mathcal{E}_\gamma(0)\exp\left(-\gamma^{-1}\beta_\gamma^{-1}z\right), \tag{7.13}$$

which is a spatial decay estimate.

ACOUSTIC SCATTERING BY MILDLY ROUGH UNBOUNDED SURFACES IN THREE DIMENSIONS*

SIMON N. CHANDLER-WILDE†, ERIC HEINEMEYER‡, AND ROLAND POTTHAST‡

Abstract. For a nonlocally perturbed half-space we consider the scattering of time-harmonic acoustic waves. A second kind boundary integral equation formulation is proposed for the sound-soft case, based on a standard ansatz as a combined single- and double-layer potential but replacing the usual fundamental solution of the Helmholtz equation with an appropriate half-space Green's function. Due to the unboundedness of the surface, the integral operators are noncompact. In contrast to the two-dimensional case, the integral operators are also strongly singular, due to the slow decay at infinity of the fundamental solution of the three-dimensional Helmholtz equation. In the case when the surface is sufficiently smooth (Lyapunov) we show that the integral operators are nevertheless bounded as operators on $L^2(\Gamma)$ and on $L^2(\Gamma) \cap BC(\Gamma)$ and that the operators depend continuously in norm on the wave number and on Γ. We further show that for *mild* roughness, i.e., a surface Γ which does not differ too much from a plane, the boundary integral equation is uniquely solvable in the space $L^2(\Gamma) \cap BC(\Gamma)$ and the scattering problem has a unique solution which satisfies a limiting absorption principle in the case of real wave number.

Key words. boundary integral equation method, rough surface scattering, Helmholtz equation

1. Introduction.

The simulation of scattering of acoustic or electromagnetic waves is of great importance for a large number of application areas ranging from medical imaging to seismic exploration. To carry out this simulation, boundary integral equation (BIE) methods have become very popular in recent decades. For scattering by bounded obstacles in two or three dimensions a very complete theory of the boundary integral equation method has been developed (e.g., [14, 20]), and the method forms the basis of very effective numerical algorithms (e.g., [12]).

This paper is concerned with the problem of scattering by *unbounded* surfaces for which the mathematical theory is much less well developed. More precisely, we are concerned with what are termed *rough surface scattering problems* in the engineering literature. We use the phrase *rough surface*, as is the practice in this literature, to denote a surface which is a (usually nonlocal) perturbation of an infinite plane surface such that the whole surface lies within a finite distance of the original plane. In particular we have in mind what is the usual case in the engineering literature where the scattering surface Γ is the graph of some bounded continuous function $f : \mathbb{R}^2 \to \mathbb{R}$, i.e.,

$$\Gamma := \big\{x = (x_1, x_2, x_3) \in \mathbb{R}^3 : x_3 = f(x_1, x_2)\big\}. \tag{1.1}$$

We will focus on a typical problem of this type, namely acoustic scattering by a rough, sound soft surface, the acoustic medium of propagation occupying the perturbed half-

space

$$D := \{x = (x_1, x_2, x_3) : x_3 > f(x_1, x_2)\} \tag{1.2}$$

above the scattering surface Γ. The paper is concerned, particularly, with the theory of BIE methods for such problems, in the case when f is a sufficiently smooth function (Γ is Lyapunov).

Rough surface scattering problems arise frequently in applications, for example modelling acoustic and electromagnetic wave propagation over outdoor ground and sea surfaces or, at a very different scale, optical scattering from the surface of materials in nanotechnology. The mathematical and computational modelling of these problems has a large literature; see, e.g., the reviews and monographs by Ogilvy [22], Voronovich [28], Saillard and Sentenac [25], Warnick and Chew [29], and DeSanto [15]. The simulation of these scattering problems, requiring discretizations of sections of three-dimensional (3D) surfaces of diameter large compared to the wavelength, is a substantial scientific computing problem for which BIE methods are very popular, with many effective, specialized numerical algorithms developed [27, 25, 29, 31].

Although BIE methods are applied widely to rough surface scattering problems, the mathematical basis of the method is still poorly developed, especially in the 3D case. In fact, there are a number of severe difficulties in extending the theory of BIE methods from bounded to unbounded scatterers.

The first of these difficulties is that, due to the slow decay at infinity of the standard fundamental solution, $\Phi(x, y)$, of the Helmholtz equation (like $|x-y|^{-(n-1)/2}$ in n dimensions), the standard boundary integral operators are not bounded on any of the standard function spaces when the surface is unbounded. We will see that this difficulty can be overcome by modifying the usual kernels so as to obtain bounded integral operators and corresponding novel BIE formulations.

A second difficulty is that of loss of compactness of boundary integral operators associated with the noncompactness of the unbounded scattering surface. This is a severe barrier to establishing existence of solution to the BIEs. We recall that, in the case of scattering by smooth bounded obstacles, compactness arguments (the Riesz–Fredholm theory) lead directly to proofs of well-posedness for second kind boundary integral equation formulations (e.g., [14]). In the case of nonsmooth (Lipschitz) obstacles, compactness arguments are no longer sufficient but still play an essential role in establishing well-posedness (e.g., [26]).

For the two-dimensional (2D) rough surface scattering case much progress has been made in terms of deriving well-posed BIEs for a variety of acoustic, electromagnetic, and elastic wave problems [9, 8, 32, 2]. Surprisingly, none of the analysis for the 2D case extends straightforwardly to three dimensions; indeed most of the 2D analysis appears to be unsuitable in the 3D case.

In more detail, in the 2D case bounded integral operators have been obtained by replacing the standard fundamental solution by the Dirichlet or impedance Green's function for a half-plane that contains the domain D of propagation (see, e.g., [8, 32]). This modification leads to kernels of boundary integral operators that are weakly singular in their asymptotic behavior at infinity so that the integral operators are bounded on $L^p(\Gamma)$ for $1 \le p \le \infty$ and on $BC(\Gamma)$, the space of bounded continuous functions on Γ. In this paper we will employ the analogous modification for the 3D case, replacing the standard fundamental solution with the Dirichlet Green's function for a half-space that contains D. But this modification leads to kernels of the integral operators that are strongly rather than weakly singular. As a consequence,

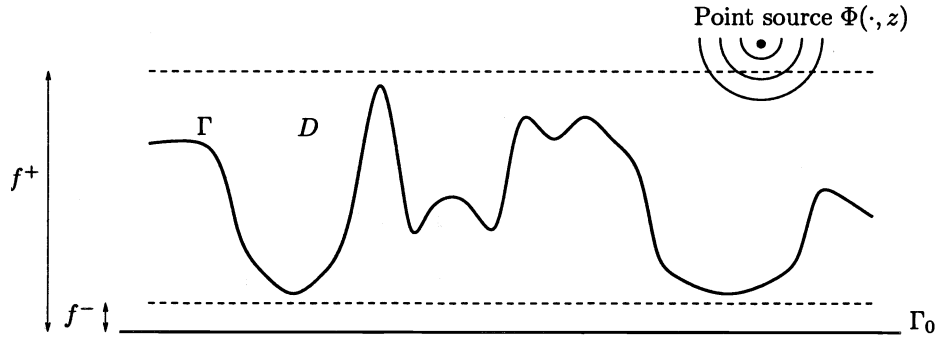

FIG. 1.1. *Geometrical setting of the scattering problem.*

the boundary integral operators are no longer well defined as operators on $BC(\Gamma)$ or $L^\infty(\Gamma)$. We are, however, able to show the boundedness of the operators on $L^2(\Gamma)$ by more elaborate arguments, expressing each integral operator as the sum of products of convolution and multiplication operators plus a well-behaved remainder, each multiplication operator a multiplication by an L^∞ function. To complete the proof of boundedness of the integral operators, one of the main results of the paper, we show, by explicit computations, that the Fourier transform of each convolution kernel is bounded. We note that our technique of expressing the kernel as the sum of products of convolution and multiplication operators plus a short-range remainder has been used previously [27, 31] but as a computational rather than a theoretical tool, as a device for matrix compression and acceleration of matrix-vector multiplications in iterative solvers.

To establish existence of solution and well-posedness in the 2D case, generalizations of part of the Riesz theory of compact operators have been developed [24, 11, 10] which require only local compactness rather than compactness and enable existence of solution in $BC(\Gamma)$ to be deduced from uniqueness of solution. In fact, injectivity of the second kind BIE in $BC(\Gamma)$ implies well-posedness in $BC(\Gamma)$ and in the space $L^p(\Gamma)$, $1 \leq p \leq \infty$ [3]. But this theory does not seem relevant for 3D rough surface scattering problems given that the corresponding boundary integral operators are not well defined as operators on $BC(\Gamma)$. In the absence of these tools we will prove existence of solution to the BIE (and the corresponding scattering problem) by perturbation arguments, used for the much simpler 2D case in [7]. The perturbation arguments we employ will prove to be sufficient to establish existence in the case when Γ is sufficiently close to a flat plane.

The results contained in this paper are as follows. We suppose that the rough surface is given by (1.1) with f continuously differentiable with Hölder continuous first derivative ($f \in BC^{1,\alpha}(\mathbb{R}^2)$ for some $\alpha \in (0, 1]$). As mentioned above, we investigate the mapping properties of the single- and double-layer potentials when the kernel is the Dirichlet Green's function for a half-space, consisting of the standard fundamental solution minus the same function with a point source mirrored in a plane. By *Fourier techniques* on a 2D plane and appropriate *decompositions* of the operators into a local and a global part we show that these layer potentials exist as bounded operators on $L^2(\Gamma)$. After these results, of significant interest in their own right, we consider the problem of acoustic scattering by the rough surface Γ in the case when the surface is sound soft (the field vanishes on Γ) and the incident field is due to a source distribution

with compact support in D. We reduce this scattering problem to a second kind boundary integral equation via an ansatz for the solution as a combined single- and double-layer potential. (The analogous ansatz was used for the 2D rough surface scattering case in [32], based on the analogous approach for scattering by bounded obstacles dating back to [4].) For a *flat surface*, unique solvability of the BIE is shown by explicit computation of a symbol. We then prove *continuous dependence* of the boundary integral operators on *variations of the boundary* and use these results and *perturbation arguments* to show that the scattering problem has a solution for all surfaces in a neighborhood of the plane, i.e., for *mildly rough* unbounded surfaces. Moreover, we show that the solution we compute by the BIE method satisfies a *limiting absorption principle*. For the convenience of the reader our main results are collected together and precisely stated at the end of section 2.

We should point out that a rigorous mathematical theory for BIE methods for 3D rough surface scattering has been developed previously for two special cases, both instances where the integral equation can be reduced to one on a finite domain so that compactness arguments can be applied. The first is the case of scattering by a locally perturbed plane, where the unbounded surface coincides with a plane in the exterior of some ball. This case can be reduced to a BIE on a finite domain, related to the local perturbation; we refer the reader to [30, 19, 5] and the references therein. The second is the case when the surface is a diffraction grating (the function f in (1.1) is biperiodic) and the incident field is a plane wave. In this case the BIE can be reduced to one on a finite part of the surface that is a single period; see [21, 17].

Finally, we note that, since our results assume boundary data in the space $L^2(\Gamma)$, they do not include the interesting and problematic case of plane wave incidence, which is included in the analogous theory that has been developed for the 2D problem [8, 32]. For a partial theoretical justification for BIE methods for 3D rough surface scattering with plane wave incidence, namely a justification, with some provisos, of Green's representation formula, see [16].

Notation. Throughout the paper x and y will denote points in $\mathbb{R}^3$ with components $x = (x_1, x_2, x_3)$ and $y = (y_1, y_2, y_3)$. The reflection of $y \in \mathbb{R}^3$ in the plane $\Gamma_0 := \{x \in \mathbb{R}^3 : x_3 = 0\}$ will be denoted by $y' := (y_1, y_2, -y_3)$. By $\mathbf{x}$ we will denote $(x_1, x_2) \in \mathbb{R}^2$, as well as the projection $(x_1, x_2, 0)$ of x onto the plane Γ_0. Similarly $\mathbf{y}$ denotes (y_1, y_2) and the projection of y onto Γ_0. The standard scalar product in $\mathbb{R}^2$ is denoted by $\mathbf{x} \cdot \mathbf{y}$ and $|\cdot|$ is the Euclidean norm in $\mathbb{R}^n$. Let $H^+ := \{z \in \mathbb{C} : \mathrm{Im} z \geq 0, \mathrm{Re} z > 0\}$. Given an unbounded closed set $S \subset \mathbb{R}^n$, $n = 2, 3$, $BC(S)$ will denote the set of bounded continuous real- or complex-valued functions on S, a Banach space with the norm $||\cdot||_{BC(S)}$ defined by $||F||_{BC(S)} = \sup_{x \in S} |F(x)|$. We will employ this notation particularly often in the cases $S = \Gamma \subset \mathbb{R}^3$ and $S = \mathbb{R}^2$. Similarly, for $0 < \alpha \leq 1$, let $BC^{1,\alpha}(\mathbb{R}^2)$ denote the set of those bounded continuously differentiable functions $F : \mathbb{R}^2 \to \mathbb{R}$ that have the property that ∇F is bounded and uniformly Hölder continuous with index α, so that

$$||F||_{BC^{1,\alpha}(\mathbb{R}^2)} := \sup_{\mathbf{x} \in \mathbb{R}^2} |F(\mathbf{x})| + \sup_{\mathbf{x} \in \mathbb{R}^2} |\nabla F(\mathbf{x})| + \sup_{\mathbf{x}, \mathbf{y} \in \mathbb{R}^2,\, \mathbf{x} \neq \mathbf{y}} \frac{|\nabla F(\mathbf{x}) - \nabla F(\mathbf{y})|}{|\mathbf{x} - \mathbf{y}|^\alpha} < \infty.$$

$BC^{1,\alpha}(\mathbb{R}^2)$ is a Banach space under the norm $||\cdot||_{BC^{1,\alpha}(\mathbb{R}^2)}$. It is convenient also to have a shorthand for the intersection of the sets $L^2(\Gamma)$ and $BC(\Gamma)$, so we define

$$X := L^2(\Gamma) \cap BC(\Gamma).$$

Since $L^2(\Gamma)$ and $BC(\Gamma)$ are Banach spaces equipped with their respective norms, so also is X, equipped with the norm $||\cdot||_X$ defined by

$$||F||_X := \max(||F||_{L^2(\Gamma)}, ||F||_{BC(\Gamma)}).$$

2. Scattering by rough surfaces in $\mathbb{R}^3$. Time-harmonic ($e^{-i\omega t}$ time dependence) acoustic waves are modelled by the Helmholtz equation

$$\triangle u + \kappa^2 u = 0, \tag{2.1}$$

where $\kappa = \kappa_0 + i\kappa_1$ denotes the *wave number* for which we will assume that $\kappa \in H^+$, i.e., $\kappa_0 > 0$ and $\kappa_1 \geq 0$. We define the *domain of propagation* D by (1.2), where $f \in BC^{1,\alpha}(\mathbb{R}^2)$ is a strictly positive function, so that there exist constants $f^+ > f^- > 0$ with

$$f^- \leq f(\mathbf{x}) \leq f^+, \quad \mathbf{x} \in \mathbb{R}^2.$$

We denote the boundary of D by Γ, so that Γ is given by (1.1). (For a sketch of the geometry see Figure 1.1.) Whenever we wish to denote explicitly the dependence of the domain on the boundary function f we will write D_f for D and Γ_f for Γ. This of course includes the case of the constant function $f \equiv h \in \mathbb{R}^+ := (0, \infty)$.

We will consider the scattering of an *incident acoustic wave* u^i by the surface Γ. For the *total field*

$$u := u^i + u^s, \tag{2.2}$$

which is the sum of the incident field and the *scattered field* u^s, we assume on Γ the *Dirichlet* boundary condition

$$u(x) = 0, \quad x \in \Gamma. \tag{2.3}$$

We require that the scattered field is bounded in D, i.e.,

$$|u^s(x)| \leq c, \quad x \in D, \tag{2.4}$$

for some constant $c > 0$. In the case $\kappa > 0$ we also require that u satisfies the following *limiting absorption principle*: denoting u temporarily by $u^{(\kappa)}$ to indicate its dependence on κ, we suppose that for all sufficiently small $\epsilon > 0$ a solution $u^{(\kappa+i\epsilon)}$ exists and that, for all $x \in D$,

$$u^{(\kappa+i\epsilon)}(x) \to u^{(\kappa)}(x), \quad \epsilon \to 0. \tag{2.5}$$

The limiting absorption principle plays the role of a radiation condition for real κ to single out the physical solution.

Before proceeding further to define the scattering problem precisely, we want to take a look, in the important case when the wave number is real, at the fundamental solution

$$\Phi(x, y) := \frac{1}{4\pi} \frac{e^{i\kappa|x-y|}}{|x-y|}, \quad x, y \in \mathbb{R}^3,\ x \neq y, \tag{2.6}$$

of the Helmholtz equation in $\mathbb{R}^3$ and the ordinary boundary layer potentials, e.g., the single-layer potential

$$\int_\Gamma \Phi(x, y)\varphi(y)\, ds(y), \quad x \in \mathbb{R}^3. \tag{2.7}$$

For an unbounded surface Γ the integral (2.7) converges (for $\kappa > 0$) only if φ decreases sufficiently rapidly at infinity. This is due to the slow decay of the fundamental solution in $\mathbb{R}^3$ at infinity. Letting $B_R(x) := \{y \in \mathbb{R}^3 : |x - y| < R\}$ denote the open ball of radius R centered at x, an easy calculation yields that, for $x \in D$, $p > 0$, and $\kappa > 0$,

$$\int_{\Gamma \cap B_R(x)} |\Phi(x,y)|^p \, ds(y) = \int_{\Gamma \cap B_R(x)} \frac{1}{|x-y|^p} \, ds(y) \to \infty, \quad R \to \infty,$$

for $p \leq 2$. Thus we observe that the trace of $\Phi(x, \cdot)$ on Γ is not integrable; indeed $\Phi(x, \cdot) \notin L^p(\Gamma)$ for $p \leq 2$. Thus, for every $x \in D$, the single-layer potential (2.7) is not well defined for all $\varphi \in L^2(\Gamma)$.

In order to get a faster decaying kernel we will, following what has been proposed for the analogous 2D rough surface scattering case [32], replace $\Phi(x, y)$ by an appropriate half-space Green's function for the Helmholtz equation. Specifically, we will work with the function

$$G(x,y) := \Phi(x,y) - \Phi(x,y'), \tag{2.8}$$

with $y' = (y_1, y_2, -y_3)$, which is the Dirichlet Green's function for the half-space $\{x : x_3 > 0\}$. Thus we will use layer potentials with $\Phi(x, y)$ replaced by $G(x, y)$, so that we define the *single-layer potential operator* by

$$(S\varphi)(x) := 2 \int_\Gamma G(x,y)\varphi(y) \, ds(y), \quad x \in \Gamma, \tag{2.9}$$

and the *double-layer potential operator* by

$$(K\varphi)(x) := 2 \int_\Gamma \frac{\partial G(x,y)}{\partial \nu(y)} \varphi(y) \, ds(y), \quad x \in \Gamma, \tag{2.10}$$

where the normal $\nu(y)$ is directed into D. Whenever we wish to denote explicitly the dependence of S and K on the boundary function f we will write S_f and K_f for S and K, respectively.

It is a straightforward calculation (cf. (3.7) below) to see that, for $y \in \Gamma$,

$$|G(x,y)| \sim \frac{x_3 y_3 |\kappa|}{2\pi} \, \frac{e^{-\kappa_1 |x-y|}}{|x-y|^2}, \quad |y| \to \infty. \tag{2.11}$$

This decay and the analogous decay at infinity (3.11) that we show for the kernel of the double-layer potential operator are fast enough for (2.9) and (2.10) to be well defined as improper integrals, for every $x \in \bar{D}$ and $\varphi \in C(\Gamma) \cap L^2(\Gamma)$, in particular in the case $\kappa_1 = 0$. Further, we will show, via Fourier techniques in section 5, as a main result of the paper, that this decay is fast enough for S and K to be bounded operators on $L^2(\Gamma)$.

Because, for $x \in \Gamma$,

$$\int_{\Gamma \cap B_R(x) \setminus B_1(x)} \frac{1}{|x-y|^2} \, ds(y) \to \infty, \quad R \to \infty,$$

the decay of $G(x, y)$ as $y \to \infty$ is not fast enough when $\kappa > 0$ for S to be well defined as an operator on the space of bounded continuous functions. Thus integral equation

methods for the 3D rough surface scattering problem are essentially different from the 2D case studied in [7, 9, 8, 32, 3].

Returning to the scattering problem, we wish to develop an analysis that is applicable whenever the incident wave is due to sources of the acoustic field located in some compact set $M \subset D$. Since waves with sources in a bounded set $M \subset \mathbb{R}^3$ can be represented as superpositions of point sources located in the same set, we will concentrate on the case when the incident field is due to a point source located at some point $z \in D$, i.e., $u^i = \Phi(\cdot, z)$. Thus the following is the specific problem that we will consider in this paper:

PROBLEM 1 (point source rough surface scattering problem). *Let $u^i = \Phi(\cdot, z)$ be the incident field due to a point source at $z \in D$. Then we seek a scattered field $u^s \in C^2(D) \cap C(\bar{D})$ such that u^s is a solution to the Helmholtz equation* (2.1) *in D, the total field satisfies the sound-soft boundary condition* (2.3)*, and the bound* (2.4) *holds. In the case $\kappa > 0$, we also require that the limiting absorption principle* (2.5) *holds.*

We will convert this scattering problem to a boundary value problem. To do this we will seek the scattered field as the sum of a mirrored point source $\Phi'(\cdot, z) := -\Phi(\cdot, z')$, where z' is the reflection of z in the flat plane Γ_0, plus some unknown remainder v, i.e., $u^s = v + \Phi'(\cdot, z)$. Note that $\Phi'(\cdot, z)$ is a solution to the scattering problem in the special case that $\Gamma = \Gamma_0$. Using the boundary condition $u^s + \Phi(\cdot, z) = 0$ on $\Gamma = \partial D$, we obtain the boundary condition on v that

$$v(x) = -\{\Phi(x, z) - \Phi(x, z')\} = -G(x, z) =: g(x), \quad x \in \Gamma. \tag{2.12}$$

Clearly, $g \in BC(\Gamma)$ and it follows from (2.11) that $g \in L^2(\Gamma)$, so that $g \in X = L^2(\Gamma) \cap BC(\Gamma)$. Thus u^s satisfies the above scattering problem if and only if v satisfies the following Dirichlet problem with g given by (2.12).

PROBLEM 2 (BVP). *Given $g \in X$, find $v \in C^2(D) \cap C(\bar{D})$, which satisfies the Helmholtz equation* (2.1) *in D, the Dirichlet boundary condition $v = g$ on Γ, the bound* (2.4)*, and, for $\kappa > 0$, the limiting absorption principle* (2.5)*.*

In this paper we will look for a solution to this boundary value problem as the *combined single- and double-layer potential*

$$v(x) := u_2(x) - i\eta\, u_1(x), \quad x \in D, \tag{2.13}$$

with some parameter $\eta \geq 0$, where for a given function $\varphi \in X$ we define the *single-layer potential*

$$u_1(x) := \int_\Gamma G(x, y)\varphi(y)\, ds(y), \quad x \in \mathbb{R}^3, \tag{2.14}$$

and the *double-layer potential*

$$u_2(x) := \int_\Gamma \frac{\partial G(x, y)}{\partial \nu(y)} \varphi(y)\, ds(y), \quad x \in \mathbb{R}^3. \tag{2.15}$$

Seeking the solution in this form we will see that the boundary condition (2.12) is satisfied if and only if the BIE

$$(I + K - i\eta S)\varphi = 2g \tag{2.16}$$

holds on Γ, where I is the identity operator.

The following are the main results in the remainder of the paper. In the next two sections we examine the kernels of the integral operators K and S and recall relevant properties of convolution and more general integral operators that we need to study K and S. The properties we discuss are exploited in section 5. In particular we show the following result.

THEOREM 2.1. *The single- and double-layer potential operators S and K, defined by* (2.9) *and* (2.10)*, are bounded operators on $L^2(\Gamma)$ and on X.*

We also establish that the single- and double-layer potential operators S and K depend continuously on $\kappa_1 = \operatorname{Im}\kappa$ in the norm topology on the set of bounded linear operators on $L^2(\Gamma)$; this result is needed to establish the limiting absorption principle. Moreover, we show, for S and K, continuous dependence in norm on the boundary Γ, in a sense we make precise.

In the final section, section 6, we establish existence and uniqueness of solution of the BIE and boundary value problem, at least in certain cases. As the first step we justify the integral equation (2.16) as a reformulation of the boundary value problem, showing the following result.

THEOREM 2.2. *Suppose that v is defined by* (2.13)–(2.15) *with $\varphi \in X$. Then, in the case $\kappa_1 > 0$, v satisfies the boundary value problem if and only if φ satisfies the BIE* (2.16)*. In the case $\kappa_1 = 0$ (i.e., $\kappa > 0$), if v satisfies the boundary value problem, then φ satisfies* (2.16)*. Conversely, if $\kappa > 0$, $\varphi^{(\kappa+i\epsilon)} \in X$ satisfies the integral equation* (2.16) *with κ replaced by $\kappa + i\epsilon$, for all sufficiently small $\epsilon > 0$, and $||\varphi - \varphi^{(\kappa+i\epsilon)}||_{L_2(\Gamma)} \to 0$ as $\epsilon \to 0$, then v satisfies the boundary value problem.*

We further establish the following result.

THEOREM 2.3. *The boundary value problem has at most one solution.*

Then we study the invertibility of the operator $I + K - i\eta S$, first for the case when Γ is flat and the operator $I + K - i\eta S$ is a convolution operator and then for the case when Γ is mildly rough by perturbation arguments. Our main result is the following.

THEOREM 2.4. *Suppose that $h > 0$ and that either $\eta > 0$ or $\eta = 0$ and $\operatorname{Im}\kappa = \kappa_1 > 0$. Then, provided $\|f - h\|_{BC^{1,\alpha}(\mathbb{R}^2)}$ is sufficiently small (so that Γ_f is sufficiently close to the flat surface $f \equiv h$), it holds that the integral equation* (2.16) *has a unique solution $\varphi \in L^2(\Gamma)$ for every $g \in L^2(\Gamma)$, so that $(I + K - i\eta S)^{-1}$ exists and is bounded as an operator on $L^2(\Gamma)$. If, further, $g \in X$, then $\varphi \in X$, so that $(I + K - i\eta S)^{-1}$ is also a bounded operator on X.*

Combining these results we have a final corollary concerning the solvability of the boundary value problem.

THEOREM 2.5. *If $h > 0$ and $\|f - h\|_{BC^{1,\alpha}(\mathbb{R}^2)}$ is sufficiently small (so that Γ_f is sufficiently close to the flat surface $f \equiv h$), then the boundary value problem has exactly one solution. Further, for some constant $c > 0$, independent of g,*

$$|v(x)| \le c\, ||g||_X, \quad x \in \bar{D}.$$

3. Properties of the 3D fundamental solution. We start with an investigation of properties of the fundamental solution $\Phi(x, y)$ and its derivatives. The key results are the expansions (3.7) and (3.11) needed to prove mapping properties of the boundary integral operators S and K in section 5.

For the first derivative of $\Phi(x, y)$ with respect to y_3 we calculate

$$\frac{\partial \Phi(x,y)}{\partial y_3} = -\frac{i\kappa}{4\pi}\frac{(x_3 - y_3)}{|x-y|^2}e^{i\kappa|x-y|} + \frac{1}{4\pi}\frac{(x_3 - y_3)}{|x-y|^3}e^{i\kappa|x-y|}. \tag{3.1}$$

The second derivative is given by

$$\frac{\partial^2\Phi(x,y)}{\partial y_3^2} = \frac{1}{4\pi}\left\{ i\kappa\frac{e^{i\kappa|x-y|}}{|x-y|^2} - \kappa^2\frac{(x_3-y_3)^2}{|x-y|^3}e^{i\kappa|x-y|} - 2i\kappa\frac{(x_3-y_3)^2}{|x-y|^4}e^{i\kappa|x-y|} \right.$$
$$\left. - \frac{e^{i\kappa|x-y|}}{|x-y|^3} - i\kappa\frac{(x_3-y_3)^2}{|x-y|^4}e^{i\kappa|x-y|} + 3\frac{(x_3-y_3)^2}{|x-y|^5}e^{i\kappa|x-y|} \right\}. \tag{3.2}$$

For the third derivative with respect to y_3 we obtain

$$\frac{\partial^3\Phi(x,y)}{\partial y_3^3} = \frac{3\kappa^2}{4\pi}\frac{(x_3-y_3)}{|x-y|^3}e^{i\kappa|x-y|} + O\left(\frac{1}{|x-y|^4}\right). \tag{3.3}$$

This holds in the sense that, given $c>0$ and a compact subset S of H^+, there exists a constant $C>0$ such that

$$\left|\frac{\partial^3\Phi(x,y)}{\partial y_3^3} - \frac{3\kappa^2}{4\pi}\frac{(x_3-y_3)}{|x-y|^3}e^{i\kappa|x-y|}\right| \le \frac{C}{|x-y|^4}$$

for all $x,\ y\in\mathbb{R}^3$, $x\neq y$, with $x_3,\ y_3\in[0,c]$ and all $\kappa\in S$. The similar equations below, in particular (3.7) and (3.11), are to be understood in an analogous fashion.

We use Taylor's expansion for the fundamental solution $\Phi(x,y)$ with respect to variations of x_3 and y_3. From Taylor's theorem, if $g\in C^3[0,\infty)$, then

$$g(s) = g(0) + g'(0)s + \frac{1}{2}g^{(2)}(0)s^2 + \frac{1}{3!}\int_0^s (s-t)^2 g^{(3)}(t)\,dt, \quad s>0. \tag{3.4}$$

Applying (3.4) to $g(s) := \Phi(x,\mathbf{y}+se_3)$, where e_3 is the unit vector in the x_3-direction, with $\mathbf{y}=(y_1,y_2,0)\in\Gamma_0$ and $s\in[0,c]$ with some constant c, we obtain

$$\Phi(x,\mathbf{y}+se_3) = \frac{1}{4\pi}\frac{e^{i\kappa|x-\mathbf{y}|}}{|x-\mathbf{y}|} - \frac{i\kappa}{4\pi}\frac{x_3\,e^{i\kappa|x-\mathbf{y}|}}{|x-\mathbf{y}|^2}\,s$$
$$+ \frac{i\kappa}{4\pi}\frac{e^{i\kappa|x-\mathbf{y}|}}{|x-\mathbf{y}|^2}\,\frac{s^2}{2} + O\left(\frac{1}{|x-\mathbf{y}|^3}\right). \tag{3.5}$$

To estimate the properties of single- and double-layer potentials on $L^2(\Gamma)$ we need to use Taylor's expansion also with respect to x_3. We treat all the terms of (3.5) separately and obtain, after some calculations,

$$\Phi(\mathbf{x}+he_3,\mathbf{y}+se_3) = \frac{1}{4\pi}\frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|}$$
$$+ \frac{1}{4\pi}\frac{i\kappa\,e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^2}\,\frac{(h-s)^2}{2} + O\left(\frac{1}{|\mathbf{x}-\mathbf{y}|^3}\right). \tag{3.6}$$

Altogether we obtain

$$G(\mathbf{x}+he_3,\mathbf{y}+se_3) = -\frac{1}{4\pi}\frac{i\kappa\,e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^2}\,2hs + O\left(\frac{1}{|\mathbf{x}-\mathbf{y}|^3}\right), \tag{3.7}$$

in the sense that, given $c>0$ and a compact subset S of H^+, there exists a constant $C>0$ such that

$$\left|G(\mathbf{x}+he_3,\mathbf{y}+se_3) + \frac{2hs}{4\pi}\frac{i\kappa\,e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^2}\right| \le \frac{C}{|\mathbf{x}-\mathbf{y}|^3}$$

for all $\mathbf{x}, \mathbf{y} \in \mathbb{R}^2$ with $\mathbf{x} \neq \mathbf{y}$, all $\kappa \in S$, and all $h, s \in [0, c]$. Arguing precisely as in [7] in the case $|x - y| > 1$, we can also show the bound that (cf. [7, equations (3.6) and (3.8)]), given a compact subset $S \subset H^+$, there exists a constant $C > 0$ such that

$$|G(x, y)| \leq \frac{C(1 + x_3)(1 + y_3)}{|x - y|^2} \tag{3.8}$$

for all $x, y \in \mathbb{R}^3$ with $x, y \neq 0$ and $x_3, y_3 \geq 0$ and all $\kappa \in S$.

For the normal derivative of G, noting that $\partial\Phi(x, y')/\partial\nu(y) = \partial\Phi(x', y)/\partial\nu(y)$ and introducing the notation $\boldsymbol{\nu}(y) := (\nu_1(y), \nu_2(y))$, we derive

$$\begin{aligned} 4\pi \frac{\partial G(x, y)}{\partial \nu(y)} = &- i\kappa\, \boldsymbol{\nu}(y) \cdot (\mathbf{x} - \mathbf{y}) \left\{ \frac{e^{i\kappa|x-y|}}{|x-y|^2} - \frac{e^{i\kappa|x-y'|}}{|x-y'|^2} \right\} \\ &+ \boldsymbol{\nu}(y) \cdot (\mathbf{x} - \mathbf{y}) \left\{ \frac{e^{i\kappa|x-y|}}{|x-y|^3} - \frac{e^{i\kappa|x-y'|}}{|x-y'|^3} \right\} \\ &- i\kappa \frac{\nu_3(y)(x_3 - y_3)}{|x-y|^2}\, e^{i\kappa|x-y|} + \frac{\nu_3(y)(x_3 - y_3)}{|x-y|^3}\, e^{i\kappa|x-y|} \\ &- i\kappa \frac{\nu_3(y)(x_3 + y_3)}{|x-y'|^2}\, e^{i\kappa|x-y'|} + \frac{\nu_3(y)(x_3 + y_3)}{|x-y'|^3}\, e^{i\kappa|x-y'|}. \end{aligned} \tag{3.9}$$

We proceed as in (3.6) and calculate

$$\frac{e^{i\kappa|x-y|}}{|x-y|^2} = \frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^2} + \frac{i\kappa e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^3} \frac{(x_3 - y_3)^2}{2} + O\left(\frac{1}{|\mathbf{x}-\mathbf{y}|^4}\right). \tag{3.10}$$

We use this to transform (3.9) into

$$\begin{aligned} 4\pi \frac{\partial G(\mathbf{x} + he_3, \mathbf{y} + se_3)}{\partial \nu(y)} = &-\kappa^2 \boldsymbol{\nu}(y) \cdot \frac{(\mathbf{x} - \mathbf{y})}{|\mathbf{x} - \mathbf{y}|} \frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^2}\, 2hs \\ &- i\kappa\nu_3(y) \frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{|\mathbf{x}-\mathbf{y}|^2}\, 2h + O\left(\frac{1}{|\mathbf{x}-\mathbf{y}|^3}\right), \end{aligned} \tag{3.11}$$

this equation holding in the same sense as (3.7).

4. Convolution and related integral operators. To establish that S and K are bounded operators on $L^2(\Gamma)$ and on X we need tools from the theory of convolution operators and the Fourier and Hankel transforms. In this section we briefly recall the relevant results and compute explicitly certain Fourier transforms that we will need. The results in the first three paragraphs are contained, for example, in [23].

For $\ell \in L^1(\mathbb{R}^2) \cup L^2(\mathbb{R}^2)$ we define the Fourier transform of ℓ, $\mathcal{F}\ell$, by

$$(\mathcal{F}\ell)(\mathbf{k}) = \frac{1}{2\pi} \int_{\mathbb{R}^2} e^{-i\mathbf{k}\cdot\mathbf{y}} \ell(\mathbf{y})\, d\mathbf{y}, \quad \mathbf{k} \in \mathbb{R}^2. \tag{4.1}$$

In the case $\ell \in L^1(\mathbb{R}^2)$ the integral (4.1) exists in the ordinary Lebesgue sense, and $\mathcal{F}\ell \in BC(\mathbb{R}^2)$. If $\ell \in L^2(\mathbb{R}^2)$, then the integral (4.1) exists for almost all $\mathbf{k} \in \mathbb{R}^2$ as the limit

$$\lim_{R\to\infty} \frac{1}{2\pi} \int_{\mathbb{R}^2 \cap B_R(0)} e^{-i\mathbf{k}\cdot\mathbf{y}} \ell(\mathbf{y})\, d\mathbf{y},$$

and $\mathcal{F}\ell \in L^2(\mathbb{R}^2)$, with $||\mathcal{F}\ell||_{L^2(\mathbb{R}^2)} = ||\ell||_{L^2(\mathbb{R}^2)}$. Further, the mapping $\mathcal{F} : L^2(\mathbb{R}^2) \to L^2(\mathbb{R}^2)$ is surjective and thus an isometric isomorphism. If $\ell \in L^1(\mathbb{R}^2) \cap L^2(\mathbb{R}^2)$, then the two interpretations of (4.1) coincide and $\mathcal{F}\ell \in X_0 := L^2(\mathbb{R}^2) \cap BC(\mathbb{R}^2)$.

For $\ell, \psi \in L^2(\mathbb{R}^2)$ we define $\ell * \psi$, the *convolution* of ℓ and ψ, by

$$(\ell * \psi)(\mathbf{x}) := \int_{\mathbb{R}^2} \ell(\mathbf{x} - \mathbf{y})\psi(\mathbf{y})\, d\mathbf{y}, \quad \mathbf{x} \in \mathbb{R}^2.$$

The integral is defined in the ordinary Lebesgue sense, and $\ell * \psi \in BC(\mathbb{R}^2)$. If also $\mathcal{F}\ell \in L^\infty(\mathbb{R}^2)$, then $\ell * \psi \in X_0$, with

$$\ell * \psi = 2\pi\mathcal{F}^{-1}((\mathcal{F}\ell)(\mathcal{F}\psi)) \tag{4.2}$$

so that the *convolution operator* L, defined by $L\psi = \ell * \psi$, maps $L^2(\mathbb{R}^2)$ to $L^2(\mathbb{R}^2)$ and is bounded, with norm

$$||L||_{L^2(\mathbb{R}^2)\to L^2(\mathbb{R}^2)} \le 2\pi||\mathcal{F}\ell||_{L^\infty(\mathbb{R}^2)}.$$

We shall need in our arguments to also consider integral operators with kernels of a more general type. Suppose that $l : \mathbb{R}^2 \times \mathbb{R}^2 \to \mathbb{C}$ is such that $l(\mathbf{x}, \cdot)$ is measurable for all $\mathbf{x} \in \mathbb{R}^2$, and let L be the integral operator with kernel l, so that

$$(L\psi)(\mathbf{x}) = \int_{\mathbb{R}^2} l(\mathbf{x}, \mathbf{y})\psi(\mathbf{y})\, d\mathbf{y}, \quad \mathbf{x} \in \mathbb{R}^2. \tag{4.3}$$

One case of relevance to our later arguments is that in which

$$l(\mathbf{x}, \mathbf{y}) = m_1(\mathbf{x})\ell(\mathbf{x} - \mathbf{y})m_2(\mathbf{y}), \tag{4.4}$$

with $m_1, m_2 \in BC(\mathbb{R}^2)$, $\ell \in L^2(\mathbb{R}^2)$, $\mathcal{F}\ell \in L^\infty(\mathbb{R}^2)$. In this case, if $\psi \in L^2(\mathbb{R}^2)$, then (4.3) exists in the Lebesgue sense for all $\mathbf{x} \in \mathbb{R}^2$, $L\psi \in X_0$, and L is a bounded operator on $L^2(\mathbb{R}^2)$ with norm

$$||L||_{L^2(\mathbb{R}^2)\to L^2(\mathbb{R}^2)} \le 2\pi||m_1||_{BC(\mathbb{R}^2)}\, ||\mathcal{F}\ell||_{L^\infty(\mathbb{R}^2)}\, ||m_2||_{BC(\mathbb{R}^2)}. \tag{4.5}$$

Clearly, L is also a bounded operator on $L^2(\mathbb{R}^2)$ if it is a sum of operators of this form.

Another case of relevance is that in which

$$|l(\mathbf{x}, \mathbf{y})| \le \ell(\mathbf{x} - \mathbf{y}), \tag{4.6}$$

with $\ell \in L^p(\mathbb{R}^2)$, for some $p \in [1, \infty)$. In this case, if ψ is continuous and compactly supported, then (4.3) exists in the Lebesgue sense for all $\mathbf{x} \in \mathbb{R}^2$, $L\psi \in L^s(\mathbb{R}^2)$, for $s \ge 1$, and, from Young's inequality [23], it follows that

$$||L\psi||_{L^s(\mathbb{R}^2)} \le ||\ell||_{L^p(\mathbb{R}^2)}\, ||\psi||_{L^r(\mathbb{R}^2)}, \tag{4.7}$$

where $r^{-1} = 1 + s^{-1} - p^{-1}$. Since the set of continuous compactly supported functions is dense in $L^r(\mathbb{R}^2)$, we can extend the domain of L by density so that L is a bounded operator from $L^r(\mathbb{R}^2)$ to $L^s(\mathbb{R}^2)$ with norm $\le ||\ell||_{L^p(\mathbb{R}^2)}$. Further, if $\ell \in L^1(\mathbb{R}^2)$ and $\psi \in L^\infty(\mathbb{R}^2)$, then, trivially, (4.3) exists in the Lebesgue sense for all $\mathbf{x} \in \mathbb{R}^2$ and (4.7) holds.

We will use the bound (4.7) particularly often in the case $\ell \in L^1(\mathbb{R}^2)$, in which case it implies that

$$||L||_{L^q(\mathbb{R}^2)\to L^q(\mathbb{R}^2)} \le ||\ell||_{L^1(\mathbb{R}^2)}, \tag{4.8}$$

for $1 \le q \le \infty$. A further consequence of (4.7) is the following result that will be used to prove Lemma 5.1.

LEMMA 4.1. *Suppose that L is the integral operator given by* (4.3)*, and that the bound* (4.6) *holds with $\ell \in L^1(\mathbb{R}^2) \cap L^p(\mathbb{R}^2)$, for some $p \in (1,2)$. Then, for some $n \in \mathbb{N}$, L^n is a bounded operator from $L^2(\mathbb{R}^2)$ to $L^\infty(\mathbb{R}^2)$.*

Proof. Note first that $\ell \in L^1(\mathbb{R}^2) \cap L^p(\mathbb{R}^2)$ implies that $\ell \in L^{\tilde{p}}(\mathbb{R}^2)$ for $1 < \tilde{p} < p$. Let $\omega := p/(p-1) > 2$. Define the finite or infinite sequence (r_j) iteratively by

$$r_0 := 2, \quad r_{j+1} := \left(\frac{1}{p} + \frac{1}{r_j} - 1\right)^{-1} = \frac{r_j}{1 - \frac{r_j}{\omega}}, \quad j = 0, 1, 2, \ldots, \tag{4.9}$$

continuing the definition (4.9) for as long as $r_j < \omega$. Let $J \subset \mathbb{N}_0 := \mathbb{N} \cup \{0\}$ denote the set of indices j for which r_j is defined. We will show that the set J is finite, so that $J = \{0, 1, \ldots, N\}$ with $r_N \ge \omega$. Then, by (4.7), it follows that L is a bounded operator from $L^{r_{j-1}}(\mathbb{R}^2)$ to $L^{r_j}(\mathbb{R}^2)$ for $j = 1, \ldots, N$. Further, defining $\tilde{p} := r_N/(r_N - 1)$, we observe that $1 < \tilde{p} < p$ and $\frac{1}{\tilde{p}} + \frac{1}{r_N} = 1$, so that, by (4.7), L is a bounded operator from $L^{r_N}(\mathbb{R}^2)$ to $L^\infty(\mathbb{R}^2)$, and so L^{N+1} is a bounded operator from $L^2(\mathbb{R}^2)$ to $L^\infty(\mathbb{R}^2)$.

We complete the proof by showing that J is finite. Suppose otherwise. Then $r_j < \omega$ for all $j \in J = \mathbb{N}_0$. It follows from (4.9), by induction, that the sequence (r_j) is monotonically increasing. Thus the sequence (r_j) is convergent to some limit r, with $2 \le r \le \omega$. Rearranging (4.9) and taking limits, we see that $(1 - r/\omega)r = r$, so that $r = 0$, a contradiction. ∎

Examining (3.7) and (3.9) we see that large parts of the kernels of the operators S and K have the form (4.4), where, moreover, ℓ has certain symmetries that simplify the calculation of its Fourier transform. For the remainder of this section, for $\mathbf{y} \in \mathbb{R}^2$ let $r := |\mathbf{y}|$ and $\hat{\mathbf{y}} := \mathbf{y}/|\mathbf{y}|$. The specific symmetries that arise are those where ℓ has the form

$$\ell(\mathbf{y}) = F(r) Y_n^j(\hat{\mathbf{y}}), \tag{4.10}$$

with $n = 0$ or 1, and $j = 0, \ldots, n$, where the functions Y_n^j are spherical harmonics of order n defined on the unit circle $\Omega \subset \mathbb{R}^2$ by

$$Y_0^0(\hat{\mathbf{y}}) := 1, \quad Y_1^0(\hat{\mathbf{y}}) := \cos\theta, \quad Y_1^1(\hat{\mathbf{y}}) := \sin\theta, \quad \hat{\mathbf{y}} = (\cos\theta, \sin\theta) \in \Omega. \tag{4.11}$$

Integrating the product of the *Jacobi–Anger expansion* [13, equation (3.66)] (a Fourier series of $e^{ir\mathbf{k}\cdot\hat{\mathbf{y}}}$) with the spherical harmonics of order n over the unit circle we deduce the *Funk–Hecke formulae* in $\mathbb{R}^2$,

$$\int_\Omega e^{-ir\mathbf{k}\cdot\hat{\mathbf{y}}}\, Y_n^j(\hat{\mathbf{y}})\, ds(\hat{\mathbf{y}}) = 2\pi\, i^n\, J_n(rk)\, Y_n^j(\hat{\mathbf{k}}), \tag{4.12}$$

where we define $k := |\mathbf{k}|$ and $\hat{\mathbf{k}} := \mathbf{k}/k$ and J_n denotes the Bessel function of order n.

If $\ell \in L^1(\mathbb{R}^2) \cup L^2(\mathbb{R}^2)$ has the form (4.10), then it holds for almost all $\mathbf{k} \in \mathbb{R}^2$ that

$$\begin{aligned}(\mathcal{F}\ell)(\mathbf{k}) &= \lim_{R\to\infty} \frac{1}{2\pi} \int_{|\mathbf{y}|<R} e^{-i\mathbf{k}\cdot\mathbf{y}} \ell(\mathbf{y})\, d\mathbf{y} \\ &= \frac{1}{2\pi} \lim_{R\to\infty} \int_0^R \left(\int_\Omega e^{-ir\mathbf{k}\cdot\hat{\mathbf{y}}}\, Y_n^j(\hat{\mathbf{y}})\, ds(\hat{\mathbf{y}}) \right) F(r)\, r\, dr \\ &= i^n Y_n^j(\hat{\mathbf{k}}) \lim_{R\to\infty} \int_0^R F(r) J_n(kr)\, r\, dr \qquad (4.13) \\ &= \frac{i^n Y_n^j(\hat{\mathbf{k}})}{\sqrt{k}}\, \mathcal{H}_n\big(\sqrt{\cdot}\, F(\cdot)\big)(k), \qquad (4.14)\end{aligned}$$

where $\mathcal{H}_n$ denotes the *Hankel transform of order* n, i.e.,

$$(\mathcal{H}_n F)(k) := \lim_{R\to\infty} \int_0^R F(r)\, J_n(kr)\sqrt{kr}\, dr, \quad k \in \mathbb{R}^+, \quad n \in \mathbb{N}. \qquad (4.15)$$

We note that (4.13) can be used to extend the domain of the Fourier transform. Precisely, whenever ℓ has the form (4.10) and the limit (4.13) exists, (4.13) can be used to define a Fourier transform of ℓ, this definition coinciding with the usual one if $\ell \in L^1(\mathbb{R}^2) \cup L^2(\mathbb{R}^2)$. An example is the function ℓ defined, for some $h > 0$, by

$$\ell(\mathbf{y}) := W_h(|\mathbf{y}|), \quad W_h(r) := \frac{1}{4\pi} \frac{e^{i\kappa\sqrt{r^2+4h^2}}}{\sqrt{r^2+4h^2}}, \quad r > 0. \qquad (4.16)$$

The relevance of this example is that, defining $x_h := (0, 0, 2h)$, $\ell = \Phi(\cdot, x_h)$ is the trace of $\Phi(\cdot, x_h)$ on the plane Γ_0. It is not difficult to see, from the asymptotic behavior of the Bessel function J_n in (4.20), that, for $F = W_h$, the limit (4.13) is well defined except for $k = \kappa$ in the case $\kappa > 0$. Explicitly, from (4.14) with $n = 0$ and the Hankel transforms in section 8.2 of [18], namely formula (24) for $\kappa_1 > 0$ and formulae (41) and (50) for $\kappa_1 = 0$, we find after some elementary calculations that, for all $\mathbf{k} \in \mathbb{R}^2$ with $k = |\mathbf{k}| \neq \kappa$,

$$(\mathcal{F}\ell)(\mathbf{k}) = (\mathcal{F}\Phi(\cdot, x_h))(\mathbf{k}) = \int_0^\infty W_h(r) J_0(kr) r\, dr = \frac{1}{4\pi} \frac{e^{-2h\sqrt{k^2-\kappa^2}}}{\sqrt{k^2-\kappa^2}}, \qquad (4.17)$$

where the square root is chosen so that its argument lies in $[-\pi/2, 0]$.

We now use the representation (4.13) to calculate the Fourier transforms of parts of the kernels of the operators S and K. We suppose that ℓ is given by (4.10), with $n = 0$ or 1 and

$$F(r) := \frac{e^{i\kappa r}}{\beta + r^2}, \quad r \geq 0, \qquad (4.18)$$

for some $\beta > 0$. The relevance of this example to the operators S and K is that the explicitly written terms on the right-hand side of (3.7) and (3.9) all take the form (4.4) if ℓ is given by (4.10) and (4.18) with $\beta = 0$ and if $\mathbf{x} + he_3$ and $\mathbf{y} + se_3$ lie on Γ.

Clearly, $\ell \in L^2(\mathbb{R}^2)$ (for $\beta > 0$). We will show also that the Fourier transform of ℓ is bounded, so that the operation of convolution with ℓ is bounded on $L^2(\mathbb{R}^2)$. To this end we show that the improper integral

$$I(k) := \int_0^\infty F(r) J_n(kr)\, r\, dr \qquad (4.19)$$

is bounded on $[0, \infty)$.

With the help of the asymptotic expansion of the Bessel function (see, e.g., [1]),

$$J_n(z) = \sqrt{\frac{2}{\pi z}} \cos\left(z - \frac{n\pi}{2} - \frac{\pi}{4}\right)\left\{1 + O\left(\frac{1}{z}\right)\right\}, \quad |z| \to \infty, \tag{4.20}$$

we see that $e^{iz}J_n(z)$ is bounded in $0 \le \arg z \le \theta$ for every $\theta \in (0, \pi/2)$. Since $\mathrm{Re}(i(\kappa - k)z) = -(\kappa_0 - k)\mathrm{Im}z - \kappa_1 \mathrm{Re}z$ and $F(z)$ is a holomorphic function in $\mathrm{Re}\, z > 0$, we see that for $0 \le k < \kappa_0$ we may transform the integral

$$I(k) = \int_0^\infty \frac{e^{i(\kappa - k)z}}{\beta + z^2}\, e^{ikz} J_n(kz)\, z\, dz \tag{4.21}$$

into

$$I(k) = \int_\gamma \frac{e^{i(\kappa - k)z}}{\beta + z^2}\, e^{ikz} J_n(kz)\, z\, dz \tag{4.22}$$

with $\gamma = \{(1+i)t : t \ge 0\}$. This integral is bounded for $0 \le k \le \kappa_0/2$.

For $k \ge \kappa_0/2$ we can use (4.20) and that $J_n(z)$ is continuous and thus, by (4.20), bounded on $[0, \infty)$ to estimate that, for some constants C_1 and C_2,

$$\left| \int_0^\infty F(r) J_n(kr)\, r\, dr \right| \le C_1 + C_2 \int_1^\infty \frac{1}{r^{3/2}}\, dr. \tag{4.23}$$

We conclude that I is bounded on $[0, \infty)$ for $n = 0, 1$, so that, by (4.13), $\mathcal{F}\ell \in L^\infty(\mathbb{R}^2)$ for $n = 0, 1$.

We will be interested in the last section of the paper, in order to establish a limiting absorption principle, in the dependence of ℓ on κ_1. Denote, temporarily, ℓ and I by ℓ_{κ_1} and I_{κ_1} to indicate their dependence on κ_1. Then, from (4.22), since $e^{iz}J_n(z)$ is bounded on $\gamma = \{(1+i)t : t \ge 0\}$, we see that, for some constant $C > 0$,

$$|I_{\kappa_1}(k) - I_0(k)| \le C \int_0^\infty e^{-\kappa_0 t/2}(1 - e^{-\kappa_1 t})\, dt$$

for $0 \le k \le \kappa_0/2$, $\kappa_1 \ge 0$, so that $I_{\kappa_1}(k) \to I_0(k)$ as $\kappa_1 \to 0$, uniformly on $[0, \kappa_0/2]$. Similarly, using (4.21) and (4.20) (cf. (4.23)), we can show that $I_{\kappa_1}(k) \to I_0(k)$ as $\kappa_1 \to 0$, uniformly on $[\kappa_0/2, \infty]$. Thus the following lemma holds.

LEMMA 4.2. *If ℓ is given by* (4.10) *and* (4.18) *with $\beta > 0$ and $n = j = 0$, or $n = 1$ and $j = 0$, or 1, then $\mathcal{F}\ell \in L^\infty(\mathbb{R}^2)$ so that the convolution integral operator L, with kernel $\ell(\mathbf{x} - \mathbf{y})$, is a bounded operator on $L^2(\mathbb{R}^2)$. Further, denoting ℓ and L by ℓ_{κ_1} and L_{κ_1} to indicate their dependence on κ_1, we have that $||\mathcal{F}\ell_{\kappa_1} - \mathcal{F}\ell_0||_{L^\infty(\mathbb{R}^2)} \to 0$ as $\kappa_1 \to 0$, so that L_{κ_1} tends to L_0 in norm as $\kappa_1 \to 0$.*

5. Properties of single- and double-layer potentials. In this section we prove that the single- and double-layer operators are well defined when considered as operators on $L^2(\Gamma)$. We further investigate the jump relations for unbounded regions and show continuity properties of the boundary operators with respect to variations of the boundary.

We first prove Theorem 2.1, stated at the end of section 2. To prove this result we split the operators into a local and a global part with the help of an appropriate *cut-off function*. To this end let $\chi : [0, \infty) \to \mathbb{R}$ be a continuous function with

$$\chi(t) := \begin{cases} 0, & t < 1/2, \\ 1, & t \ge 1, \end{cases} \qquad \text{and} \qquad 0 \le \chi(t) \le 1 \quad \forall t \ge 0. \tag{5.1}$$

Let A with kernel a denote one of the operators S or K, respectively. We define the *global part*

$$(A_1\varphi)(x) := \int_\Gamma \chi(|x-y|)a(x,y)\varphi(y)\,ds(y), \quad x \in \Gamma, \tag{5.2}$$

and the *local part*

$$(A_2\varphi)(x) := \int_\Gamma \Big(1-\chi(|x-y|)\Big)a(x,y)\varphi(y)\,ds(y), \quad x \in \Gamma. \tag{5.3}$$

This yields the decomposition $A = A_1 + A_2$, and we can study the mapping properties of A_1 and A_2 as operators on $L^2(\Gamma)$ and on X separately. We start by proving the following lemma.

LEMMA 5.1. *A_2 is a bounded operator on $L^q(\Gamma)$ for $1 \le q \le \infty$, is a bounded operator from $L^\infty(\Gamma)$ to $BC(\Gamma)$, and is a bounded operator on X. Further, for some $n \in \mathbb{N}$, A_2^n is a bounded operator from $L^2(\Gamma)$ to X.*

Proof. The kernel a_2 of A_2 has compact support and is weakly singular. Precisely, since (cf. [7, equation (4.23)])

$$|\nu(y)\cdot(x-y)| \le |\mathbf{x}-\mathbf{y}|^{1+\alpha}||f||_{BC^{1,\alpha}(\mathbb{R}^2)}, \quad x,y \in \Gamma, \tag{5.4}$$

it holds in the double-layer case $A = K$ that, for some constant $C > 0$,

$$|a_2(x,y)| \le C\ell(\mathbf{x}-\mathbf{y}), \quad x,y \in \Gamma,\ x \ne y, \tag{5.5}$$

where

$$\ell(\mathbf{y}) := \begin{cases} |\mathbf{y}|^{\alpha-2}, & |\mathbf{y}| \le 1, \\ 0, & |\mathbf{y}| > 1. \end{cases} \tag{5.6}$$

The same bound holds (but is not sharp) in the single-layer case $A = S$.

Since $\ell \in L^p(\mathbb{R}^2)$, for $1 \le p < 2/(2-\alpha)$, we see from (4.8) that A_2 is a bounded operator on $L^q(\Gamma)$ for $1 \le q \le \infty$. Since $a_2(x,y)$ is also continuous for $x \ne y$, it follows, moreover, that A_2 maps $L^\infty(\Gamma)$ to $BC(\Gamma)$. Thus A_2 is a bounded operator on X. By Lemma 4.1, A_2^m is a bounded operator from $L^2(\Gamma)$ to $L^\infty(\Gamma)$, for some $m \in \mathbb{N}$, so that A_2^{m+1} is a bounded operator from $L^2(\Gamma)$ to X. ∎

We now consider the global part and prove a lemma on the mapping properties of A_1. Together, Lemmas 5.1 and 5.2 provide a proof of Theorem 2.1.

LEMMA 5.2. *A_1 is a bounded operator on $L^2(\Gamma)$ and is a bounded operator from $L^2(\Gamma)$ to X.*

Proof. From the decompositions (3.7) and (3.11) it follows that the kernel a_1 of A_1 can be written, in both the cases $A = S$ and $A = K$, in the form

$$a_1(x,y) = l^*(\mathbf{x},\mathbf{y}) + l(\mathbf{x},\mathbf{y}), \tag{5.7}$$

where l^* is a sum of terms each of the form (4.4), with $m_1, m_2 \in BC(\mathbb{R}^2)$ and ℓ given by (4.10) and (4.18) with $\beta = 1$, and with $n = 0$ or 1. Further, l^* can be chosen so that l satisfies the bound, for some constant $C > 0$,

$$|l(\mathbf{x},\mathbf{y})| \le C\tilde{\ell}(\mathbf{x}-\mathbf{y}), \quad \mathbf{x},\mathbf{y} \in \mathbb{R}^2, \tag{5.8}$$

where $\tilde{\ell}(\mathbf{y}) := (1+|\mathbf{y}|)^{-3}$, so that $\tilde{\ell} \in L^1(\mathbb{R}^2)$. In detail, in the case $A = S$ we see from (3.7) that an appropriate choice is to take

$$l^*(\mathbf{x},\mathbf{y}) = -\frac{i\kappa f(\mathbf{x}) f(\mathbf{y})}{2\pi} \frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{1+|\mathbf{x}-\mathbf{y}|^2}, \tag{5.9}$$

while, in the case $A = K$ we see from (3.11) that we can take

$$l^*(\mathbf{x},\mathbf{y}) = -\frac{\kappa^2 f(\mathbf{x}) f(\mathbf{y})}{2\pi} \boldsymbol{\nu}(y) \cdot \frac{\mathbf{x}-\mathbf{y}}{|\mathbf{x}-\mathbf{y}|} \frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{1+|\mathbf{x}-\mathbf{y}|^2} - \frac{i\kappa f(\mathbf{x})\nu_3(y)}{2\pi} \frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{1+|\mathbf{x}-\mathbf{y}|^2}. \tag{5.10}$$

It follows from (4.5) and Lemma 4.2 applied to the integral operator with kernel l^*, and (4.8) applied to the integral operator with kernel l, that A_1 is a bounded operator on $L^2(\Gamma)$.

Note, from the above representation (5.7), that also

$$|a_1(x,y)| \le \ell^*(\mathbf{x}-\mathbf{y}), \quad x, y \in \Gamma,$$

for some $\ell^* \in L^2(\mathbb{R}^2)$; this is true since $\tilde{\ell} \in L^2(\mathbb{R}^2)$ and since each term of (5.9) and (5.10) can be bounded in this way. It follows from (4.7) that A_1 maps $L^2(\Gamma)$ to $L^\infty(\Gamma)$; in fact, since also a_1 is continuous, it holds that A_1 maps $L^2(\Gamma)$ to $BC(\Gamma)$. ∎

Remark 5.3. For $C_2 > C_1 > 0$ let

$$B = B(C_1, C_2) := \big\{ f \in BC^{1,\alpha}(\mathbb{R}^2) : C_1 \le f(\mathbf{y}),\ \mathbf{y} \in \mathbb{R}^2, \quad \|f\|_{BC^{1,\alpha}(\mathbb{R}^2)} \le C_2 \big\}. \tag{5.11}$$

We note that, given $C_2 > C_1 > 0$ and $\kappa_0 > 0$, we can choose $C > 0$ such that the estimates (5.5) and (5.8) hold for all $f \in B$ and all $\kappa_1 \ge 0$. (For (5.8) this follows from (3.7) and (3.11).) This observation will be helpful in establishing continuous dependence of A on f and on κ_1.

Combining the above lemmas we deduce Theorem 2.1 and have also the following corollary.

COROLLARY 5.4. *For all sufficiently large $n \in \mathbb{N}$ it holds that A^n is a bounded map from $L^2(\Gamma)$ to X.*

As part of the proof of Theorem 2.2 we need to show that our modified single- and double-layer potentials u_1 and u_2, over the unbounded surface Γ, behave in a similar way to the corresponding standard layer potentials supported on a smooth bounded surface. This is done in the following theorem, in which $M := \{x : 0 < x_3 < f(\mathbf{x})\}$ denotes the region between Γ and Γ_0.

THEOREM 5.5. *Let u_1 and u_2 denote the single- and double-layer potentials with density $\varphi \in X$, defined by* (2.14) *and* (2.15)*, respectively. The following hold:*

(i) *For $n = 1, 2$, $u_n \in C^2(D \cup M)$ and $\Delta u_n + k^2 u_n = 0$ in $D \cup M$.*

(ii) *u_1 and u_2 can be continuously extended from D to $\bar{D}$ and from M to $\bar{M}$, with limiting values*

$$u_{1,\pm}(x) = \int_\Gamma G(x,y)\varphi(y)\, ds(y), \quad x \in \Gamma, \tag{5.12}$$

and

$$u_{2,\pm}(x) = \int_\Gamma \frac{\partial G(x,y)}{\partial \nu(y)} \varphi(y)\, ds(y) \pm \frac{1}{2}\varphi(x), \quad x \in \Gamma, \tag{5.13}$$

where $u_{n,\pm}(x) := \lim_{\epsilon\to 0+} u_n(x \pm \epsilon\nu(x))$*, for* $n = 1, 2$ *and* $x \in \Gamma$*, and* $\nu(x)$ *denotes the unit normal at* $x \in \Gamma$ *directed into* D*.*

(iii) *Given constants* $C_2 > C_1 > 0$ *and a compact subset* S *of* H^+*, there exists a constant* $C > 0$ *such that*

$$|u_n(x)| \le C||\varphi||_X, \quad x \in D \cup M,\ n = 1, 2, \tag{5.14}$$

for all $\varphi \in X$*,* $\kappa \in S$*, and* $f \in B = B(C_1, C_2)$*.*

(iv) *Given constants* $C_2 > C_1 > 0$ *and* $\epsilon > 0$ *and a compact subset* S *of* H^+*, there exists a constant* $C > 0$ *such that*

$$|u_n(x)| \le C||\varphi||_{L^2(\Gamma)}, \quad n = 1, 2, \tag{5.15}$$

for all $x \in D \cup M$ *with* $|x_3 - f(x_1, x_2)| > \epsilon$*, all* $\varphi \in X$*, all* $\kappa \in S$*, and all* $f \in B = B(C_1, C_2)$*.*

Proof. We first show that $u \in C(D \cup M)$ and establish (ii) and (iii). We use the cut-off function χ given by (5.1). Let u denote one of u_1 and u_2, and let a denote the kernel of u so that $a(x, y) := G(x, y)$ and $a(x, y) := \partial G(x, y)/\partial\nu(y)$ in the respective cases. We have, for $x \in D \cup M$, that

$$u(x) = \int_\Gamma \chi(|x - y|)a(x, y)\varphi(y)\, ds(y) + \int_\Gamma \big[1 - \chi(|x - y|)\big]a(x, y)\varphi(y)\, ds(y).$$

The first term has a continuous kernel that is bounded at infinity by the estimate (3.7) or (3.9) and, since $\varphi \in L^2(\Gamma)$, is continuous in $\{x : x_3 > 0\}$. The second term is clearly continuous in $D \cup M$; to see that it can be continuously extended up to Γ from above and below and to compute its limiting values we observe that, keeping x within some ball centered at some $x_0 \in \Gamma$, it holds that the integrand is supported in a finite patch of the surface. We can extend this surface patch to a bounded obstacle with boundary of class $C^{1,\alpha}$ and, since $\varphi \in C(\Gamma)$, use the jump relations for bounded obstacles as presented in [14].

To show that the first term satisfies the bound (5.14) we recall that G satisfies the bound (3.8) and point out that, by interior elliptic regularity estimates for solutions of the Helmholtz equation (e.g., [9, Lemma 2.7]), it follows that $\nabla_y G(x, y)$ satisfies the same bound for all $\kappa \in S$ (with a different constant C), provided $x_3, y_3 > 0$ and $|x - y| > 1/4$; further we calculate directly that C can be chosen so that this bound also holds for $0 < |x - y| \le 1/4$. Thus, for some constant $C' > 0$, whether a is the kernel of the single- or double-layer potential, it holds for all $\kappa \in S$ that

$$|\chi(|x - y|)a(x, y)| \le C' \frac{(1 + x_3)(1 + y_3)}{1 + |x - y|^2}, \quad x, y \in \mathbb{R}^3,\ x_3, y_3 \ge 0. \tag{5.16}$$

Applying the Cauchy–Schwarz inequality we have that the first term is bounded, for $x \in \{x : x_3 > 0\}$, by $C'(1 + f_+)I(x)\|\varphi\|_{L^2(\Gamma)}$, where

$$\begin{aligned}[I(x)]^2 &= (1 + x_3)^2 \int_\Gamma \frac{ds(y)}{(1 + |x - y|^2)^2} \\ &\le (1 + x_3)^2(1 + ||\nabla f||_{BC(\Gamma)})^{1/2} \int_{\mathbb{R}^2} \frac{d\mathbf{y}}{(1 + |\mathbf{x} - \mathbf{y}|^2 + (x_3 - f(\mathbf{y}))^2)^2}.\end{aligned}$$

Thus, for some constant $c > 0$ it holds, for all $x \in \{y : y_3 > 0\}$ and all $f \in B$, that $[I(x)]^2 \le cF(x_3)$, where

$$F(x_3) := (1 + x_3)^2 \int_0^\infty \frac{r\, dr}{(1 + x_3^2 + r^2)^2} = \frac{(1 + x_3)^2}{x_3^2} \int_0^\infty \frac{s\, ds}{(x_3^{-2} + 1 + s^2)^2}.$$

Clearly, F is bounded on $[0, \infty)$. Thus the first term satisfies the bound (5.14).

To treat the second term we argue analogously to the corresponding 2D case [7]. We remark that $1-\chi(|x-y|)$ is zero for $|x-y| \geq 1$. We consider only the double-layer case $u = u_1$. (The argument is similar but simpler in the single-layer case.) Directly from the definitions (see (3.9)) we see that there exists a constant $C > 0$ such that

$$|(1-\chi(|x-y|))a(x,y)| \leq C\frac{|\nu(y)\cdot(x-y)|}{|x-y|^3}, \quad x \in D \cup M,\ y \in \Gamma,$$

for all $\kappa \in S$ and all $f \in B$. Define $x^* := (\mathbf{x}, f(\mathbf{x})) \in \Gamma$, $\delta := |f(\mathbf{x}) - x_3|$, and note that, by the triangle inequality,

$$\left(|\mathbf{x}-\mathbf{y}|^2+\delta^2\right)^{1/2} \leq |x-y| + |f(\mathbf{x})-f(\mathbf{y})| \leq \left(1+||\nabla f||_{BC(\Gamma)}\right)|x-y|.$$

Using this inequality, and (5.4) to bound $|\nu(y)\cdot(x^*-y)|$, we see that, for some $C' > 0$,

$$|(1-\chi(|x-y|))a(x,y)| \leq C'\,\frac{|\mathbf{x}-\mathbf{y}|^{1+\alpha}+\delta}{\left(|\mathbf{x}-\mathbf{y}|^2+\delta^2\right)^{3/2}}, \quad x \in D \cup M,\ y \in \Gamma,$$

for all $\kappa \in S$ and $f \in B$. Thus, defining $C'' = C'\left(1+||\nabla f||_{BC(\Gamma)}\right)^{1/2}$, the second term is bounded by

$$C''\,||\varphi||_{BC(\Gamma)} \int_{|\mathbf{y}|<1} \frac{|\mathbf{y}|^{1+\alpha}+\delta}{\left(|\mathbf{y}|^2+\delta^2\right)^{3/2}}\,d\mathbf{y} \leq 2\pi C''\,||\varphi||_{BC(\Gamma)} \int_0^1 \frac{r^{1+\alpha}+\delta}{r^2+\delta^2}\,dr,$$

for all $\kappa \in S$ and $f \in B$, so that the second term satisfies the bound (5.14).

To establish (iv) we modify the argument used to show (iii). We have remarked above that both $G(x,y)$ and $\nabla_y G(x,y)$ satisfy the bound (3.8). Thus (cf. (5.16)), for every $\epsilon > 0$ there exists $C_\epsilon > 0$ such that

$$|a(x,y)| \leq C_\epsilon \frac{(1+x_3)(1+y_3)}{1+|x-y|^2} \tag{5.17}$$

for all $x, y \in \mathbb{R}^3$ with $x_3, y_3 \geq 0$ and $|x-y| \geq \epsilon$ and all $\kappa \in S$. Applying the Cauchy–Schwarz inequality, as in the proof of (5.14), we see that it holds, for some constant $C'_\epsilon > 0$, that

$$|u_n(x)| \leq C'_\epsilon(1+f_+)I(x)\|\varphi\|_{L^2(\Gamma)}, \quad n = 1, 2,$$

for all $x \in D \cup M$ with $|x_3 - f(x_1,x_2)| \geq \epsilon$ and all $\kappa \in S$ and $f \in B$. In view of the bound on $I(x)$ already shown above, we see that we have established (5.15).

We complete the proof by establishing (i). This is clear when φ is compactly supported. The general case follows from the density in $L^2(\Gamma)$ of the set of those elements of X that are compactly supported, from the bound (5.15), and from the fact that limits of uniformly convergent sequences of solutions of the Helmholtz equation satisfy the Helmholtz equation (e.g., [9, Remark 2.8]). □

We continue this section by proving that the single- and double-layer potential operators depend continuously on variations in the boundary Γ. In the statement of the following theorem, $B = B(C_1, C_2)$ is the set defined in Remark 5.3 for some constants $C_2 > C_1 > 0$. We use the notation A_f for either S or K defined on a surface Γ_f given by some $f \in B$. With the help of the isomorphism

$$I_f : L^2(\Gamma_f) \to L^2(\mathbb{R}^2), \quad (I_f\varphi)(\mathbf{y}) = \varphi((\mathbf{y}, f(\mathbf{y}))), \quad \mathbf{y} \in \mathbb{R}^2, \tag{5.18}$$

we associate A_f with the element $\tilde{A}_f = I_f A_f I_f^{-1}$ of the set of bounded linear operators on $L^2(\mathbb{R}^2)$ for each $f \in B$. Denoting the kernel of $\tilde{A}_f$ by a_f, we see that, where $x = (\mathbf{x}, f(\mathbf{x}))$, $y = (\mathbf{y}, f(\mathbf{y}))$, and $a(x,y) := G(x,y)$ or $a(x,y) := \partial G(x,y)/\partial\nu(y)$, in the respective cases $A_f = S$ and $A_f = K$, it holds that

$$a_f(\mathbf{x},\mathbf{y}) = a(x,y)J_f(\mathbf{y}), \quad J_f(\mathbf{y}) := \sqrt{1+|\nabla f(\mathbf{y})|^2}.$$

THEOREM 5.6. *The single- and double-layer potential operators depend continuously on the boundary Γ_f of the unbounded domain D_f in the sense that*

$$\sup_{\substack{f,g\in B \\ \|f-g\|_{BC^{1,\alpha}(\mathbb{R}^2)}\le\epsilon}} \|\tilde{A}_f - \tilde{A}_g\|_{L^2(\mathbb{R}^2)\to L^2(\mathbb{R}^2)} \to 0, \quad \epsilon \to 0. \tag{5.19}$$

Proof. Similarly to how we proceeded when proving Theorem 2.1, we decompose the operator $\tilde{A}_f - \tilde{A}_g$ into a global and a local part, i.e., $\tilde{A}_f - \tilde{A}_g = A_1 + A_2$ with A_1, A_2 defined similarly to (5.2) and (5.3). We now carry out the proof for the case of the single-layer operator. The necessary changes for the double-layer operator are straightforward.

The global operator. The kernel of the global operator A_1 is given by

$$a_1(\mathbf{x},\mathbf{y}) := \chi(|\mathbf{x}-\mathbf{y}|)[a_f(\mathbf{x},\mathbf{y}) - a_g(\mathbf{x},\mathbf{y})]. \tag{5.20}$$

We use the expansion (5.7) and (5.9), denoting l by l_f, to indicate its dependence on f. We obtain

$$\begin{aligned} a_1(\mathbf{x},\mathbf{y}) = {} & \frac{i\kappa}{2\pi}\frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{1+|\mathbf{x}-\mathbf{y}|^2}\Big\{f(\mathbf{x})[f(\mathbf{y})-g(\mathbf{y})] + [f(\mathbf{x})-g(\mathbf{x})]g(\mathbf{y})\Big\}J_f(\mathbf{y}) \\ & + \Big(l_f(\mathbf{x},\mathbf{y}) - l_g(\mathbf{x},\mathbf{y})\Big)J_f(\mathbf{y}) \\ & + \Big(\frac{i\kappa g(\mathbf{x})g(\mathbf{y})}{2\pi}\frac{e^{i\kappa|\mathbf{x}-\mathbf{y}|}}{1+|\mathbf{x}-\mathbf{y}|^2} + l_g(\mathbf{x},\mathbf{y})\Big)(J_f(\mathbf{y}) - J_g(\mathbf{y})) \end{aligned} \tag{5.21}$$

for $\mathbf{x},\mathbf{y} \in \mathbb{R}^2$, $\mathbf{x} \neq \mathbf{y}$.

The integral operator whose kernel is the first term of (5.21) can be bounded using Lemma 4.2 and (4.5). Similarly, the integral operator whose kernel is the last term of (5.21) can be bounded using Lemma 4.2, (4.5), (5.8), and (4.8), noting that Remark 5.3 guarantees the uniformity of (5.8) for $f \in B$. To bound the integral operator whose kernel is the second term of (5.21), we construct, for every $\eta \in (0,1)$, a function $\ell_\eta \in L^1(\mathbb{R}^2)$ such that

$$\Big|\Big(l_f(\mathbf{x},\mathbf{y}) - l_g(\mathbf{x},\mathbf{y})\Big)J_f(\mathbf{y})\Big| \le \ell_\eta(\mathbf{x}-\mathbf{y}), \quad \mathbf{x},\mathbf{y}\in\mathbb{R}^2, \tag{5.22}$$

whenever $f, g \in B$ and $\|f-g\|_{BC^{1,\alpha}(\mathbb{R}^2)}$ is sufficiently small, and such that $||\ell_\eta||_{L^1(\mathbb{R}^2)} \to 0$ as $\eta \to 0$, and then we use the estimate (4.8). Together, the bounds on the three parts of A_1 show (5.19) for the global part of the operator.

The construction of ℓ_η is as follows. We choose (possible by Remark 5.3) a constant $C > 0$ so that (5.8) holds for all $f \in B$. We choose another constant $C' > 0$ that is a bound for $||J_f||_{L^\infty(\mathbb{R}^2)}$ for $f \in B$. Then, where $\tilde{\ell} \in L^1(\mathbb{R}^2)$ is defined as in Lemma 5.2, we set

$$\ell_\eta(\mathbf{y}) := \begin{cases} \eta^3, & \eta < |\mathbf{y}| < \eta^{-1}, \\ 2C\,C'\tilde{\ell}(\mathbf{y}) & \text{otherwise.} \end{cases}$$

Clearly, this satisfies that $||\ell_\eta||_{L^1(\mathbb{R}^2)} \to 0$ as $\eta \to 0$. Since, for every $\eta \in (0,1)$, $|l_f(\mathbf{x},\mathbf{y}) - l_g(\mathbf{x},\mathbf{y})| \to 0$ as $\|f-g\|_{BC^{1,\alpha}(\mathbb{R}^2)} \to 0$, uniformly in f and g for $f,g \in B$, and uniformly in $\mathbf{x}$ and $\mathbf{y}$ for $\eta \le |\mathbf{x}-\mathbf{y}| \le \eta^{-1}$, the bound (5.22) holds for all $f,g \in B$ with $\|f-g\|_{BC^{1,\alpha}(\mathbb{R}^2)}$ sufficiently small.

The local operator. For the local operator we argue in a similar way as for the global operator, in particular in a similar way as for the integral operator corresponding to the second term in (5.21). In particular, where a_2 is the kernel of the local operator, it holds for every $\eta > 0$ that $|a_2(\mathbf{x},\mathbf{y})| \to 0$ as $\|f-g\|_{BC^{1,\alpha}(\mathbb{R}^2)} \to 0$, uniformly in f and g for $f,g \in B$, and uniformly in $\mathbf{x}$ and $\mathbf{y}$ for $|\mathbf{x}-\mathbf{y}| \ge \eta$, and (5.5) takes the role of (5.8). ∎

We have just established continuous dependence of the single- and double-layer potential operators on the boundary Γ_f. To show later that the limiting absorption condition (2.5) is satisfied in the case $\kappa > 0$ we need to also establish continuous dependence on κ, which we do by similar arguments.

LEMMA 5.7. *Denote S and K temporarily by S_{κ_1} and K_{κ_1} to indicate their dependence on κ_1. Then, where A_{κ_1} denotes either S_{κ_1} or K_{κ_1}, it holds that*

$$||A_{\kappa_1} - A_0||_{L^2(\Gamma)\to L^2(\Gamma)} \to 0 \tag{5.23}$$

as $\kappa_1 \to 0$.

Proof. As we did when proving Theorem 2.1 we split A_{κ_1} into global and local parts, as $A_{\kappa_1} = A_1 + A_2$, with A_1, A_2 defined by (5.2) and (5.3). As in the proofs of Lemma 5.1 and 5.2 we denote the kernel of A_j by a_j.

To show (5.23) for the local part A_2 we note that $a_2(x,y)$ depends continuously on κ_1, uniformly in x and y for $|x-y| \ge \eta$ and every $\eta > 0$, and that, by Remark 5.3, the bound (5.5) holds uniformly in κ_1 for $\kappa_1 \in [0,1]$. We then argue as for the local part in the proof of Theorem 5.6, showing that the kernel of the local part of $A_{\kappa_1} - A_0$ is bounded by an L^1 convolution kernel $\ell(\mathbf{x}-\mathbf{y})$ with $||\ell||_{L^1(\mathbb{R}^2)} \to 0$ as $\kappa_1 \to 0$. Finally, we apply (4.8).

To show (5.23) for the global part A_2 we use the representation (5.7) for $a_1(x,y)$, which splits a_1 into a weakly singular part $l(\mathbf{x},\mathbf{y})$, bounded by (5.8), and a strongly singular part $l^*(\mathbf{x},\mathbf{y})$, given explicitly by (5.9) or (5.10). To show (5.23) for the weakly singular part of A_2 we argue exactly as we did in the proof of Theorem 5.6, noting that, by Remark 5.3, (5.8) holds uniformly in κ_1 for $\kappa_1 \in [0,1]$, and that $l(\mathbf{x},\mathbf{y})$ depends continuously on κ_1, uniformly in $\mathbf{x}$ and $\mathbf{y}$ for $\eta \le |\mathbf{x}-\mathbf{y}| \le \eta^{-1}$, for every $\eta \in (0,1)$. That (5.23) holds for the strongly singular part of A_2 follows from Lemma 4.2 and (4.5). ∎

6. Uniqueness and existence results. In this section we prove, for the case when the surface is mildly rough, uniqueness and existence for our integral equation formulation and for the boundary value problem and the scattering problem defined in section 2. As the first step in this argument we prove Theorem 2.2 on the equivalence of the integral equation (2.16) and the boundary value problem.

Proof of Theorem 2.2. Let v be the combined single- and double-layer potential v, defined in (2.13), with density $\varphi \in X$. By Theorem 5.5, $v \in C^2(D) \cap C(\bar{D})$ and satisfies the Helmholtz equation in D. Further, due to the jump relations (5.12) and (5.13), $v = g \in X$ on Γ if and only if the density φ satisfies the boundary integral equation (2.16). Applying Theorem 5.5 again, we see that v satisfies the bound (2.4). This yields the equivalence statement for $\kappa_1 > 0$.

For real κ, in addition, we need to show the limiting absorption principle (2.5).

Let $a(x,y) = \partial G(x,y)/\partial\nu(y) - i\eta G(x,y)$, so that

$$v(x) = \int_\Gamma a(x,y)\varphi(y)\,ds(y), \quad x \in D. \tag{6.1}$$

Suppose, as stated in the theorem, that $\varphi^{(\kappa+i\epsilon)} \in X$ satisfies the integral equation (2.16) with κ replaced by $\kappa + i\epsilon$, for all sufficiently small $\epsilon > 0$, and that $||\varphi - \varphi^{(\kappa+i\epsilon)}||_{L_2(\Gamma)} \to 0$ as $\epsilon \to 0$. Let $a^{(\kappa+i\epsilon)}$ denote a with κ replaced with $\kappa + i\epsilon$, and define $v^{(\kappa+i\epsilon)}$ by (6.1) with a, φ replaced by $a^{(\kappa+i\epsilon)}$, $\varphi^{(\kappa+i\epsilon)}$, respectively. We have shown in the previous paragraph that $v^{(\kappa+i\epsilon)}$ satisfies Problem 2 (with κ replaced by $\kappa + i\epsilon$). To show the limiting absorption principle (2.5) we need to show that $v^{(\kappa+i\epsilon)}(x) \to v(x)$ as $\epsilon \to 0$. We have

$$\begin{aligned} v^{(\kappa+i\epsilon)}(x) - v(x) = &\int_\Gamma \left(a^{(\kappa+i\epsilon)}(x,y) - a(x,y)\right)\varphi^{(\kappa+i\epsilon)}(y)\,ds(y) \\ &+ \int_\Gamma a(x,y)\left(\varphi^{(\kappa+i\epsilon)}(y) - \varphi(y)\right)\,ds(y). \end{aligned}$$

We see that the second term tends to zero as $\epsilon \to 0$ by the bound (5.15). Clearly, $a^{(\kappa+i\epsilon)}(x,y) - a(x,y) \to 0$ as $\epsilon \to 0$ for every $y \in \Gamma$. Thus, applying the Cauchy–Schwarz inequality and then the dominated convergence theorem, noting that the bound (5.17) holds uniformly in κ, we see that the first term tends to 0 as $\epsilon \to 0$. ∎

We obtain uniqueness of solution for the boundary value problem (proving Theorem 2.3) as follows. Due to [6, Theorem 1] (see also [24, Theorem 3.1]), a solution $u \in C^2(G) \cap C(\overline{G})$ to the Helmholtz equation (2.1) with $\mathrm{Im}(\kappa) > 0$ on an open set $G \subset \mathbb{R}^n$ which satisfies the growth condition $|u(x)| \le Ce^{\theta|x|}$, with some constant $\theta < \mathrm{Im}(\kappa)$, and the boundary condition $u(x) = 0$ for $x \in \partial G$ will vanish identically on G. This result directly implies uniqueness for the scattering problem and the boundary value problem for $\kappa_1 > 0$. For $\kappa_1 = 0$ uniqueness is a consequence of the limiting absorption principle we require, i.e., of the convergence (2.5).

Next we turn to establishing existence of solution in the mildly rough case. But first we prove a preliminary lemma which shows that to establish unique solvability of the integral equation in the space X it is enough to study solvability in $L^2(\Gamma)$.

LEMMA 6.1. *Suppose that the integral equation* (2.16) *has exactly one solution* $\varphi \in L^2(\Gamma)$ *for every* $g \in L^2(\Gamma)$. *Then also* (2.16) *has exactly one solution* $\varphi \in X$ *for every* $g \in X$, *so that* $(I + K - i\eta S)^{-1}$ *exists and is bounded as an operator on* X.

Proof. If the assumptions of the lemma hold, then (2.16) has exactly one solution $\varphi \in L^2(\Gamma)$ for every $g \in X \subset L^2(\Gamma)$. Further, defining $A = K - i\eta S$, it holds that $\varphi = A\varphi + 2g$ and, by induction, that, for every $n \in \mathbb{N}$,

$$\varphi = A^n\varphi + 2(A^{n-1} + \cdots + A^0)g.$$

Now, by Theorem 2.1, A is a bounded operator on X and, by Corollary 5.4, A^n is a bounded operator from $L^2(\Gamma)$ to X for some $n \in \mathbb{N}$. Thus $\varphi \in X$. We have shown that (2.16) has exactly one solution $\varphi \in X$ for every $g \in X$, so that $(I + K - i\eta S)^{-1}$ exists as an operator on X. Since X is a Banach space it follows as a standard corollary of the open mapping theorem that $(I + K - i\eta S)^{-1}$ is bounded. ∎

As a corollary of Theorems 2.2 and 2.3 and Lemmas 5.7 and 6.1 we have the following result.

COROLLARY 6.2. *If $(I+K-i\eta S)^{-1}$ exists as a bounded operator on $L^2(\Gamma)$, then the boundary value problem and scattering problem have exactly one solution.*

Proof. In the case $\kappa_1 > 0$ this result is clear from Theorems 2.2 and 2.3 and Lemma 6.1.

In the case $\kappa_1 = 0$ we note that, by Lemma 5.7 and standard operator perturbation arguments (e.g., [23]), if $(I+K-i\eta S)^{-1}$ exists as a bounded operator on $L^2(\Gamma)$ for $\kappa = \kappa_0 > 0$, then $(I+K-i\eta S)^{-1}$ exists and is a bounded operator on $L^2(\Gamma)$ for $\kappa = \kappa_0 + i\kappa_1$, $0 \le \kappa_1 \le c$, for some $c > 0$. Moreover, $(I+K-i\eta S)^{-1}$ depends continuously in the norm topology on κ_1 for $\kappa_1 \in [0,c]$. Thus, provided $g \in L^2(\Gamma)$ depends continuously in norm on κ_1, for $\kappa_1 \in [0,c]$, it holds that $(I+K-i\eta S)^{-1}g$ depends continuously in norm on $\kappa_1 \in [0,c]$ in $L^2(\Gamma)$. If g is given by (2.12), then, from the continuity of $\Phi(x,y)$ as a function of κ_1, uniformly in $x, y \in \mathbb{R}^3$, $x \neq y$, the bound (3.8), and the dominated convergence theorem, it follows that $g \in L^2(\Gamma)$ depends continuously in norm on κ_1 for $\kappa_1 \in [0,c]$. Thus the result follows by Theorems 2.2 and 2.3 and Lemma 6.1. ∎

To make use of this result it remains to establish that $(I+K-i\eta S)$ is invertible as an operator on $L^2(\Gamma)$. We will show this first for the case of a flat surface $\Gamma_h = \{y = (\mathbf{y}, h) : \mathbf{y} \in \mathbb{R}^2\}$, with $h > 0$. In this case the kernels of K and S depend only on the difference $\mathbf{x} - \mathbf{y}$, and thus, identifying Γ_h with $\mathbb{R}^2$, the operators are convolution operators on $L^2(\mathbb{R}^2)$.

In terms of the function W_h defined by (4.16), it follows from (3.9) that we can write the kernel of the double-layer potential operator as $P_h(\mathbf{x}-\mathbf{y})$, where $P_h(\mathbf{y}) := p_h(|\mathbf{y}|)$ and

$$p_h(r) := -\frac{i\kappa h}{\pi}\frac{e^{i\kappa\sqrt{r^2+4h^2}}}{(\sqrt{r^2+4h^2}\,)^2} + \frac{h}{\pi}\frac{e^{i\kappa\sqrt{r^2+4h^2}}}{(\sqrt{r^2+4h^2}\,)^3} = -\frac{\partial}{\partial h}\{W_h(r)\}, \quad r > 0.$$

The kernel of the single-layer potential operator is $Q_h(\mathbf{x}-\mathbf{y})$, where $Q_h(\mathbf{y}) := q_h(|\mathbf{y}|)$ and

$$q_h(r) := 2\left\{\frac{1}{4\pi}\frac{e^{i\kappa r}}{r} - \frac{1}{4\pi}\frac{e^{i\kappa\sqrt{r^2+4h^2}}}{\sqrt{r^2+4h^2}}\right\} = 2W_0(r) - 2W_h(r), \quad r > 0.$$

Hence, the integral equation (2.16) is transformed into

$$\varphi(\mathbf{x}) + \int_{\mathbb{R}^2} \big\{P_h(\mathbf{x}-\mathbf{y}) - i\eta\, Q_h(\mathbf{x}-\mathbf{y})\big\}\varphi(\mathbf{y})\, d\mathbf{y} \;=\; 2g(\mathbf{x}), \quad \mathbf{x} \in \mathbb{R}^2. \tag{6.2}$$

To prove invertibility in $L^2(\Gamma_h)$ we compute the 2D Fourier transforms of P_h and Q_h. From (4.13), for almost all $\mathbf{k} \in \mathbb{R}^2$, where $k := |\mathbf{k}|$,

$$(\mathcal{F}P_h)(\mathbf{k}) = -\int_0^\infty \frac{\partial W_h(r)}{\partial h} J_0(kr) r\, dr.$$

To evaluate this integral we reverse the order of integration and differentiation and use (4.17) to get that, for almost all $\mathbf{k} \in \mathbb{R}^2$,

$$(\mathcal{F}P_h)(\mathbf{k}) = -\frac{\partial}{\partial h}\left\{\frac{1}{4\pi}\frac{e^{-2h\sqrt{k^2-\kappa^2}}}{\sqrt{k^2-\kappa^2}}\right\} = \frac{1}{2\pi}\, e^{-2h\sqrt{k^2-\kappa^2}}. \tag{6.3}$$

The interchange of integration and differentiation with respect to h is certainly justified whenever $k > 0$ and $k \neq \kappa$. For then the integral (4.17) is well defined, and,

using (4.20), we see that for every $H > 0$ there exists a constant $C > 0$ such that

$$\left|\frac{\partial W_h(r)}{\partial h} J_0(kr) r\right| = \left|\frac{\partial}{\partial h}\left\{\frac{1}{4\pi}\frac{e^{i\kappa\sqrt{r^2+4h^2}}}{\sqrt{r^2+4h^2}}\right\} J_0(kr) r\right| \le \frac{C}{r^{3/2}} \tag{6.4}$$

for $r \ge 1$ and $0 \le h \le H$.

The Fourier transform of Q_h can also be evaluated using (4.17). We obtain that

$$(\mathcal{F}Q_h)(\mathbf{k}) = \frac{1}{2\pi}\left\{\frac{1}{\sqrt{k^2-\kappa^2}} - \frac{e^{-2h\sqrt{k^2-\kappa^2}}}{\sqrt{k^2-\kappa^2}}\right\} \tag{6.5}$$

for all $\mathbf{k} \in \mathbb{R}^2$ with $k \ne \kappa$. We combine the Fourier transforms of P_h and Q_h to derive for the Fourier transform of the kernel $R_h := P_h - i\eta\, Q_h$ of $K - i\eta S$ the formula $(\mathcal{F}R_h)(\mathbf{k}) = \hat{r}_h(k)$, for almost all $\mathbf{k} \in \mathbb{R}^2$, where

$$\hat{r}_h(k) := \frac{1}{2\pi}\left\{e^{-2h\sqrt{k^2-\kappa^2}} - i\eta\,\frac{1 - e^{-2h\sqrt{k^2-\kappa^2}}}{\sqrt{k^2-\kappa^2}}\right\}, \quad k \ge 0. \tag{6.6}$$

From (4.2) we see that, for $\psi \in L^2(\mathbb{R}^2)$,

$$(I + K - i\eta S)\psi = \mathcal{F}^{-1}((1 + 2\pi\mathcal{F}R_h)(\mathcal{F}\psi)).$$

Since $\mathcal{F}$ is an isomorphism on $L^2(\mathbb{R}^2)$ it follows that the inverse of $I + K - i\eta S$ exists as a bounded operator from $L^2(\Gamma_h)$ into $L^2(\Gamma_h)$ if and only if

$$\operatorname{ess.}\inf_{\mathbf{k}\in\mathbb{R}^2} |1 + 2\pi\,(\mathcal{F}R_h)(\mathbf{k})| = \inf_{k\ge 0} |1 + 2\pi\,\hat{r}_h(k)| > 0. \tag{6.7}$$

We need to investigate $K(k) := 1 + 2\pi\,\hat{r}_h(k) = A(h\sqrt{k^2-\kappa^2})$, for $k \ge 0$, where

$$A(z) := 1 + e^{-2z} - \frac{ih\eta}{z}\left(1 - e^{-2z}\right). \tag{6.8}$$

We recall that (see (4.17)) the square root is to be taken with $\sqrt{k^2-\kappa^2} \in V := \{z \in \mathbb{C} : \mathrm{Re}z \ge 0, \mathrm{Im}z \le 0\}$. Indeed, in the case that $\kappa_1 > 0$, so that $\mathrm{Im}(k^2-\kappa^2) < 0$, it is clear that $\sqrt{k^2-\kappa^2}$ lies in the interior of V. Now A is an entire function (the singularity at 0 is removable) so that K is continuous on $[0,\infty)$. Further, $K(k) \to 1$ as $k \to \infty$. Thus, to show (6.7) it is enough to show that $K(k) \ne 0$ for $k \ge 0$, which holds if $A(z) \ne 0$ for $z \in V$; indeed, in the case $\kappa_1 > 0$, we need only show that $A(z) \ne 0$ for all z in the interior of V.

So suppose $\eta \ge 0$, and consider first the case when $z = z_0 - iz_1$, with $z_0 > 0$, $z_1 \ge 0$. It holds that

$$A(z) = -i\,\left(1 + e^{-2z}\right)\left(\frac{h\eta\tanh z}{z} + i\right),$$

and straightforward calculations yield

$$\mathrm{Im}\left(\frac{\tanh z}{z}\right) = \frac{z_0\sin(2z_1) + z_1\sinh(2z_0)}{2[\sinh^2 z_0 + \cos^2 z_1](z_0^2 + z_1^2)} \ge 0,$$

since $|\sin t| \le t \le \sinh t$ for $t \ge 0$. Thus (6.7) holds if $\eta \ge 0$ and $\kappa_1 > 0$.

In the case $\kappa_1 = 0$ we need to show, additionally, that $A(z) \neq 0$ when $z = -iz_1$ with $z_1 \geq 0$, in order to establish that $A(z) \neq 0$ for all $z \in V$. Now $A(0) = 2 - 2i\eta h$ and, for $z_1 > 0$, from (6.8), $A(-iz_1) = 2\cos z_1 - \frac{2ih\eta}{z_1}\sin z_1$. Thus, provided $\eta > 0$, $A(-iz_1) \neq 0$ for $z_1 \geq 0$, so $A(z) \neq 0$ for $z \in V$. Thus (6.7) holds if $\eta > 0$.

We have proven, in the case $\eta > 0$ and in the case $\eta = 0$, $\kappa_1 > 0$, that (6.7) holds, and thus we have shown the invertibility of $I + K - i\eta S$ and the boundedness of the inverse operator in $L^2(\Gamma_h)$. Thus we have established the solvability of (2.16) in the space $L^2(\Gamma)$ for flat surfaces. If Γ_f is mildly rough, we may use a perturbation argument to show that the integral equation remains solvable. We state our result precisely in the following theorem.

THEOREM 6.3. *Suppose that $h > 0$ and that either $\eta > 0$ or $\eta = 0$ and $\kappa_1 > 0$. Then, provided $\|f - h\|_{BC^{1,\alpha}(\mathbb{R}^2)}$ is sufficiently small (so that Γ_f is sufficiently close to the flat surface $f \equiv h$), it holds that $(I + K - i\eta S)^{-1}$ exists and is bounded as an operator on $L^2(\Gamma_f)$.*

Proof. Let $A = I + K - i\eta S$, and then denote A by A_f to denote its dependence on f. With the help of the isomorphism $I_f : L^2(\Gamma_f) \to L^2(\mathbb{R}^2)$ defined by (5.18) we associate A_f with the element $\tilde{A}_f = I_f A_f I_f^{-1}$ of the set of bounded linear operators on $L^2(\mathbb{R}^2)$. Now $\tilde{A}_h$ is invertible with bounded inverse, by our analysis above for the flat plane case. Moreover, by the continuity of $\tilde{A}_f$ with respect to f as proven in Theorem 5.6 it follows from standard arguments that $\tilde{A}_f$ is boundedly invertible on $L^2(\mathbb{R}^2)$ for $\|f - h\|_{BC^{1,\alpha}(\mathbb{R}^2)}$ sufficiently small, and so A_f is boundedly invertible on $L^2(\Gamma_f)$. ∎

Combining Theorem 6.3 with Lemma 6.1 we deduce Theorem 2.4. Combining Theorem 6.3 with Corollary 6.2 we establish Theorem 2.5.

MATERIAL SURFACE DESIGN TO COUNTER ELECTROMAGNETIC INTERROGATION OF TARGETS*

H. T. BANKS†, K. ITO†, G. M. KEPLER†, AND J. A. TOIVANEN†

Abstract. Utilization of controllable ferromagnetic layers coating a conducting object to provide an attenuation capability against electromagnetic interrogation is discussed. The problem is formulated as a differential game and/or a robust optimization. The scattered field due to interrogation can be attenuated with the assumption of an uncertainty in the interrogation wave numbers. The controllable layer composed of ferromagnetic materials [H. How and C. Vittoria, *Implementation of Microwave Active Nulling*, private communication; H. How and C. Vittoria, *IEEE Trans. Microwave Theory Tech.*, 52 (2004), pp. 2177–2182] is incorporated in a mathematical formulation based on the time-harmonic Maxwell equation. Fresnel's law for the reflectance index is extended to the electromagnetic propagation in anisotropic composite layers of ferromagnetic and electronic devices and is used to demonstrate feasibility of control of reflections. Our methodology is also tested for a nonplanar geometry of the conducting object (an NACA airfoil) in which we report our findings in the form of reduced radar cross sections (RCS).

Key words. electromagnetic, inverse scattering, attenuation

1. Introduction.

In this paper we discuss an optimal attenuation problem; i.e., we attempt to maximize attenuation capabilities of interrogating signals by utilizing a controllable dielectric layer on the surface of a conducting object. The objective of the interrogator is to detect and identify the location and shape of the conducting object based on the scattered field from an interrogation incident field, i.e., the solution of an inverse scattering problem [2, 7]. In the plane wave case the incident electromagnetic (EM) field has the form $(\vec{E}^{(i)}, \vec{H}^{(i)})\, e^{i\vec{k}\cdot\vec{x}}$ and the interrogator has control over the wave numbers $\vec{k}$. The attenuation problem is to minimize or diminish the detection capability of interrogation by either grating [14] or fabrications on the object surface. In this paper we consider the utilization of thin controllable dielectric surface layers on the object as a method for achieving the attenuation capability. Here "controllable" means that we have the capability of adjusting the material properties of the surface layers parametrically. The technical ideas developed here also have the potential to aid in the design of *medical shields* employed to protect parts of an irradiated target or to focus radiation to pinpoint specific regions of the target.

In these initial investigations, we investigate a design case in which one determines values of the dielectric permittivity and magnetic permeability of the controllable layer in order to attenuate reflections. From a control theoretic viewpoint this is a "passive" or open loop control strategy. But our efforts here lay the foundations for "active" or closed loop control strategies in which one combines controllable layer dynamics with a sensor for incoming interrogating signals to develop real time feedback controls for adaptive choice of the permittivity and permeability of the controllable layer.

†Center for Research in Scientific Computation, North Carolina State University, Raleigh, NC 27695-8205 (htbanks@unity.ncsu.edu, kito@ncsu.edu, gmkepler@ncsu.edu, jatoivan@ncsu.edu).

To investigate feasibility, we first formulate the problem as a differential game. For example, we assume the time-harmonic incident EM plane wave is impinging on the surface at $z = 0$ and we control the effective dielectric constant ϵ of the surface layer on top of the conducting material. The scattered field due to the interrogation can be evaluated based on the time-harmonic Maxwell equations [7]. In the case when the dielectric constant is homogeneous in the horizontal directions (planar geometry), the reflectance index $R = R(\vec{k}, \epsilon)$ is determined by Fresnel's law (see [15] and section 4). Thus, the problem of nullifying the scattered field can be cast as the minimization of the scattering EM wave in terms of $|R|^2$, i.e.,

$$\min_{\epsilon \in Q} \max_{\vec{k} \in K} |R|^2, \tag{1.1}$$

where Q is a set of admissible dielectric constants and K is a set of possible interrogation wave numbers. In order to determine the admissible set Q we must describe controllable mechanisms of the dielectric layer. Thus, the problem of nullifying the scattered field can be formulated as the min-max problem of minimizing the largest reflectance by interrogations over $\vec{k} \in K$, over all possible designs ($\epsilon \in Q$ in this case). This game theoretic formulation is used in many other design problems. It does not assume any information on the uncertainty of interrogations and thus it may lead to a conservative design. An alternative formulation can be given in a more robust form, i.e.,

$$\min_{\epsilon \in Q} \int_K |R|^2 \, d\mathcal{K}(\vec{k}), \tag{1.2}$$

where $\mathcal{K}$ is a probability distribution function on the wave numbers $\vec{k}$. This formulation then needs information about the distribution function $\mathcal{K}$ of the interrogating plane wave. As demonstrated in section 2, better knowledge of the distribution function greatly improves the performance of minimizing the scattered field.

After demonstrating attenuation capabilities, we turn to the general case of a nonplanar conducting medium with a controllable coating layer. The far field pattern $F(\theta)$ of the scattered field (see [7] and section 5) is then a function of the wave number $\vec{k}$ of the incident plane wave and the material properties (ϵ, μ) of the controllable layer, i.e.,

$$F(\theta) = U(\vec{k}, (\epsilon, \mu); \theta), \quad 0 \le \theta \le 2\pi. \tag{1.3}$$

One can select the performance index $J(\vec{k}, (\epsilon, \mu)) = \Phi(F)$ to perform specific alterations of the scattered field, which of course depend on the inverse techniques employed by the interrogator. Here $\Phi(F)$ is some performance index for the far field pattern $F(\theta)$. We investigate optimal radar cross sections (RCS) for one class of such problems.

We note that the existence of solutions to a general min-max problem is guaranteed under the condition that given $\epsilon \in Q$ the value function $V(\epsilon) = \sup_{\vec{k} \in K} J(\vec{k}, \epsilon)$ is lower semicontinuous, which is typically satisfied under very mild conditions (e.g., see [13]) when Q is compact. The saddle point property of a solution pair $(\vec{k}_0, \epsilon_0)$,

$$J(\vec{k}, \epsilon_0) \le J(\vec{k}_0, \epsilon_0) \le J(\vec{k}_0, \epsilon) \quad \text{for all } \epsilon \in Q, \ \vec{k} \in K, \tag{1.4}$$

holds locally if the Hessian of $J(\vec{k}, \epsilon)$ is hyperbolic at $(\vec{k}_0, \epsilon_0)$. The existence of solutions to the robust formulation then simply follows from the continuity of $J(\vec{k}, \epsilon_0)$ with respect to $(\vec{k}, \epsilon) \in K \times Q$.

A brief outline of our presentation here is as follows. In section 2 we consider the exact problem for the planar geometry, present representative numerical calculations for optimal design of the dielectric layer based on a robust formulation, and demonstrate the feasibility of this approach and the effectiveness of the design. In section 3 we discuss a controllable layer composed of ferromagnetic and ferroelectric materials as proposed by How and Vittoria [10, 11]. This composite model is designed so that a control mechanism for the material properties of the layers can be achieved in both a parametric and a dynamic manner. In section 4 we mathematically formulate the forward problem for the controllable composite layers, including the tensor permeability in the ferrite layer, by calculating the scattered field R as a function of the interrogating wave and the near surface composition. We consider the time-harmonic case with plane wave interrogations of the planar geometry (i.e., the composite layers are homogeneous in (x, y)). In this case we construct the plane wave solution and an analytic expression for the reflectance index R. Another important feature of our formulation is the possible identification of the interrogating wave in terms of its distribution $\mathcal{K}$. Since the plane wave calculation also yields surface currents as an explicit function of the incident interrogations, the surface current measurements can, in principle, be used to identify the distribution $\mathcal{K}$ of the interrogations $\vec{k}$. In sections 5–7 we present results for our formulation when applied to a nonplanar geometry by considering the NACA0012 airfoil [16]. In general (and in particular in this case) we do not have an analytic expression for the far field pattern F and thus we use a numerical computation of the scattered field. In this case, our numerical computations for the scattered field F are implemented using the finite element method (in section 6). Our numerical findings are presented for an optimal homogeneous coating layer.

2. Feasibility study. In this section we first demonstrate the feasibility of our approach. We consider an incident parallel polarized (TE_x mode) plane wave $\vec{H} = (H_x^{(i)}, 0, 0)e^{i\,\vec{k}\cdot\vec{x}}$ impinging on the interface of the first and second layers at $z = 0$, as depicted in Figure 1. The interface between the second and third layers is located at $z = -d$, where the third layer is a perfect conductor. We control the effective dielectric constant $\epsilon^{(2)}$ of the second layer coating the conducting material. By Fresnel's law (see [4, 15] and the discussion in section 4) we have that the reflection coefficient or reflectance index is given by

$$R = \frac{\dfrac{\epsilon^{(2)}k_z^{(1)} - \epsilon^{(1)}k_z^{(2)}}{\epsilon^{(2)}k_z^{(1)} + \epsilon^{(1)}k_z^{(2)}} + e^{-2ik_z^{(2)}d}}{1 + \dfrac{\epsilon^{(2)}k_z^{(1)} - \epsilon^{(1)}k_z^{(2)}}{\epsilon^{(2)}k_z^{(1)} + \epsilon^{(1)}k_z^{(2)}}\, e^{-2ik_z^{(2)}d}}, \tag{2.1}$$

where

$$\begin{aligned} k_z^{(1)} &= \frac{2\pi}{\lambda}\sqrt{1 - \sin^2\varphi_0}, \\ k_z^{(2)} &= \frac{2\pi}{\lambda}\sqrt{\epsilon^{(2)} - \epsilon^{(1)}\sin^2\varphi_0}. \end{aligned} \tag{2.2}$$

Here φ_0 is the incident angle with respect to the normal to the surface ($\tan\varphi_0 = \frac{k_y^{(1)}}{k_z^{(1)}}$, $k_x^{(1)} = 0$) and λ is the wavelength of the incident wave. We note from (2.1) that R depends on the ratio $\epsilon^{(2)}/\epsilon^{(1)}$ and hence without loss of generality we may normalize the parameters so that $\epsilon^{(1)} = 1$. The reflectance index R is a function of (λ, φ_0),

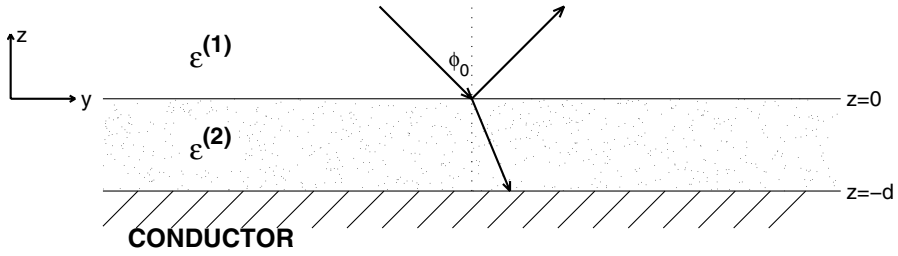

FIG. 1. *Schematic representation of the reflection of a plane wave incident with angle ϕ_0 on a planar three-layer stack. The top two layers are dielectric media. The third layer is a perfect conductor.*

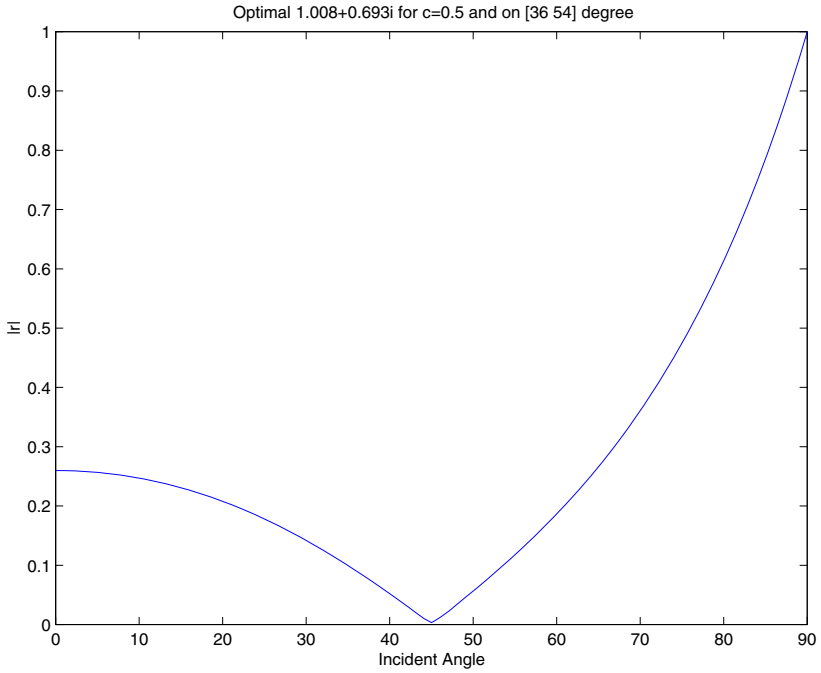

FIG. 2. *The reflected intensity $|R|$ as a function of the incident angle φ_0. The uncertainty interval is $[36, 54]$ degrees.*

the normalized dielectric constant $\epsilon^{(2)}$, and the thickness d of the surface layer. We assume that d is positive and fixed. We parameterize the incident wave in terms of (λ, φ_0).

In Figures 2 and 3 we depict the robustness of the optimal solution by plotting the reflectance intensity $|R|$ as a function of the incident angle and the normalized thickness/wavelength ratio, defined as $a = \frac{d}{\lambda}$. In Figure 2 we assume that the uncertainty in wave numbers is due only to uncertainty in the incident angle φ_0, which is uniformly distributed on the interval $[36, 54]$ degrees and graph the intensity $|R|$ corresponding to the optimal dielectric constant $\epsilon^{(2)} = 1.008 + .693i$ as a function of the incident angle. The integration of $|R|^2$ over φ_0 is performed using Simpson's rule. The intensity of the reflection is well attenuated over the uncertainty interval $[36, 54]$ degrees.

Next, we assume that there is uncertainty in both the incident angle φ_0 and the normalized thickness/wavelength ratio a, which are uniformly distributed on a rectangle $[36, 54] \times [0.3, 0.7]$. In Figure 3 we plot the intensity $|R|$ corresponding to the optimal dielectric constant $\epsilon^{(2)} = 1.4309 + 1.0724i$ for several sampled incident points in the frequency. A reasonable attenuation over the uncertainty box is obtained in this example. It is clear that the performance depends on the quality of the information on the distribution of the interrogating wave, as demonstrated by the better attenuation results in the first case (Figure 2) than in the second case (Figure 3).

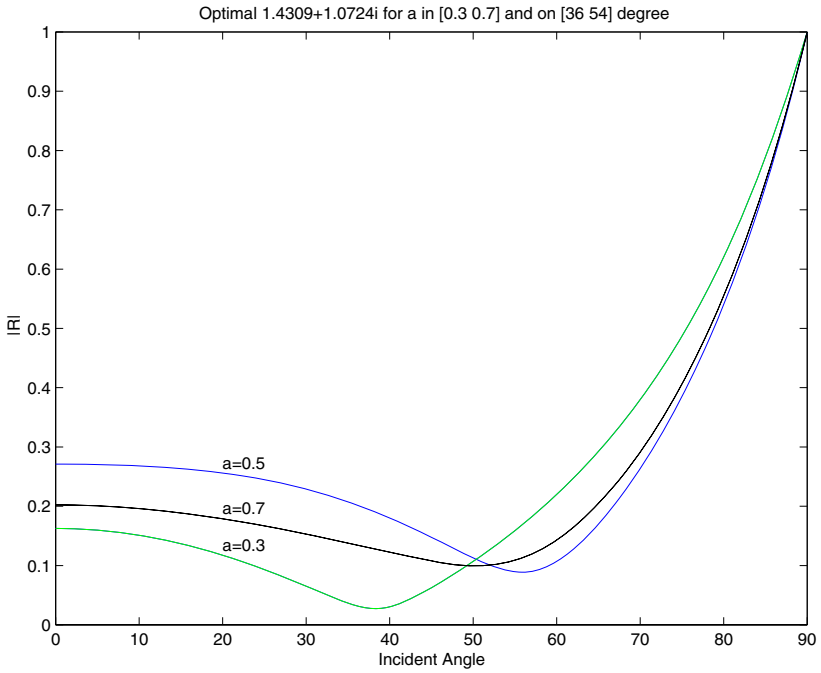

FIG. 3. *The reflected intensity* $|R|$ *as a function of the incident angle* φ_0 *and the normalized thickness/wavelength ratio* a. *The uncertainty box is* $[36, 54] \times [0.3, 0.7]$.

3. Controllable sublayers composed of ferromagnetic and ferroelectric materials. In this section we describe an experimental device that can be used to control the dielectric permittivity (and magnetic permeability) in a coating layer as discussed in the previous sections. In Figure 4 we present a schematic of the configuration of an active reflecting device proposed and investigated experimentally by How and Vittoria in [10, 11]. The reflector contains a ferrite layer and a ferroelectric layer as constituents. The permanent magnet provides a common magnetic bias so that the ferromagnetic resonance (FMR) condition can be readily achieved and thereby facilitate sensitive magnetic tuning by the local Helmholtz coils. The dielectric properties of the ferroelectric layer are controlled through the ground plane bias field. The purpose of this reflector design is to provide phase and impedance control of the composite layers so that nullification and alteration of the scattered wave can be achieved in the response to an incident interrogating EM wave. The integrated circuits are designed so that the tuning sensitivity of the device is enhanced. The key element of the device is that the material properties $\mu(H)$ and $\epsilon(E)$ of the composite layers are controllable in terms of the magnetic mean in the ferrite layer and the electric

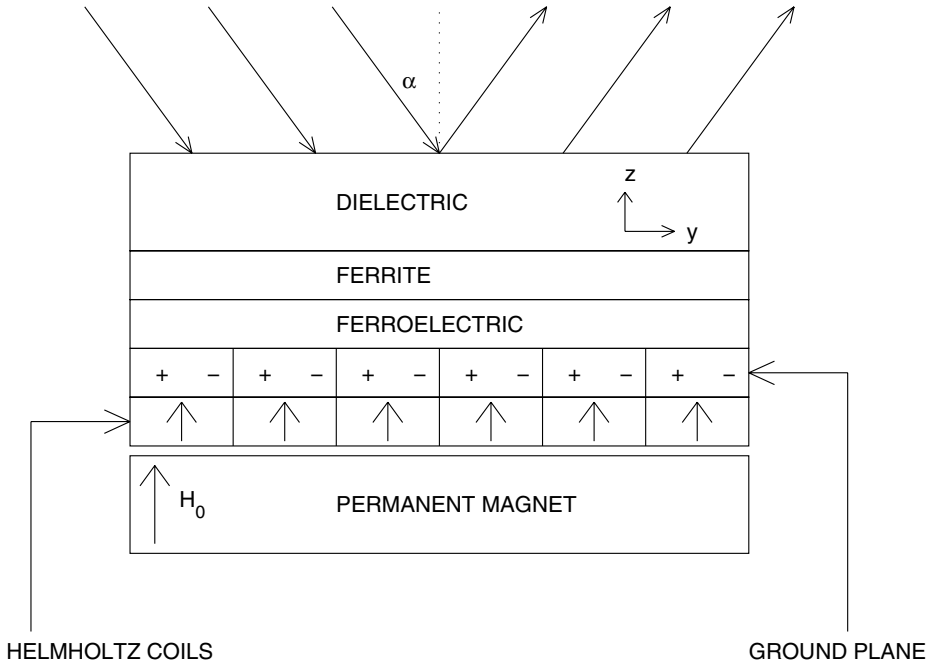

FIG. 4. *Composite sublayers composing an active reflector device.*

mean in the ferroelectric layer, and thus can support agile frequency attenuation.

The most important device characteristic of the ferrite in the investigation [10, 11] is that the magnetic permeability $\bar{\mu}$ is a tensor, so that, due to the gyromagnetic effect, EM propagation in the ferrite is anisotropic in the presence of a dc-bias magnetic field [12, 18]. For a ferrite magnetized in the y direction with damping and no demagnetization, the permeability tensor is given by [17]

(3.1)
$$\bar{\mu} = \begin{bmatrix} \mu & 0 & -i\kappa \\ 0 & \mu_0 & 0 \\ i\kappa & 0 & \mu \end{bmatrix}, \quad \text{where} \quad \mu = \mu_0 \left(1 + \frac{\bar{\omega}_0 \omega_m}{\bar{\omega}_0^2 - \omega^2}\right), \quad \kappa = \mu_0 \frac{\omega \omega_m}{\bar{\omega}_0^2 - \omega^2},$$
$$\omega_m = 4\pi\gamma M_z, \quad \bar{\omega}_0 = \omega_0 + i/\tau, \quad \omega_0 = \gamma H_0,$$

ω_0 is the precession frequency, H_0 is the impressed dc magnetic field, γ is the gyromagnetic ratio, M_z is the saturation magnetization, and τ is the relaxation time.

The ferrite device is most useful if it operates near the FMR frequency ω_0 so that the rapid change in magnetic permeability can be effectively utilized, either to obtain frequency-tuning capability or to remove the degeneracy between modes [10, 11].

4. Plane wave solution. We next discuss a plane wave solution as it interacts with a ferrite layer. Due to the tensor magnetic permeability $\bar{\mu}$, the electric and magnetic modes are coupled in the ferrite layer. In this section we present the detailed calculations for constructing the fundamental solution in the ferrite layer. First, the time-harmonic Maxwell equation (4.1) is reduced to a system (4.12) of the differential equations in the z (depth) direction and then the characteristic equation and the

form (4.16) of the fundamental solutions are established. A similar calculation can be carried out for the ferroelectric layer, but we shall not pursue that here.

The time-harmonic Maxwell equations are written as

$$\begin{aligned} \nabla \times H &= i\omega\epsilon\, E, \\ \nabla \times E &= -i\omega\bar{\mu}\, H, \\ \nabla \cdot (\bar{\mu} H) &= 0, \\ \nabla \cdot E &= 0. \end{aligned} \tag{4.1}$$

For the ferrite layer the permeability $\bar{\mu}$ is the tensor defined by (3.1), and thus the first three equations in (4.1) can be written as

$$\begin{pmatrix} \dfrac{\partial}{\partial y}H_z - \dfrac{\partial}{\partial z}H_y \\ \dfrac{\partial}{\partial z}H_x - \dfrac{\partial}{\partial x}H_z \\ \dfrac{\partial}{\partial x}H_y - \dfrac{\partial}{\partial y}H_x \end{pmatrix} = i\omega\epsilon \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix}, \tag{4.2}$$

$$\begin{pmatrix} \dfrac{\partial}{\partial y}E_z - \dfrac{\partial}{\partial z}E_y \\ \dfrac{\partial}{\partial z}E_x - \dfrac{\partial}{\partial x}E_z \\ \dfrac{\partial}{\partial x}E_y - \dfrac{\partial}{\partial y}E_x \end{pmatrix} = -i\omega \begin{pmatrix} \mu H_x - i\kappa H_z \\ \mu_0 H_y \\ i\kappa H_x + \mu H_z, \end{pmatrix}, \tag{4.3}$$

and

$$-\mu\left(\frac{\partial}{\partial x}H_x + \frac{\partial}{\partial z}H_z\right) = i\kappa\left(\frac{\partial}{\partial z}H_x - \frac{\partial}{\partial x}H_z\right) + \mu_0\,\frac{\partial}{\partial y}H_y. \tag{4.4}$$

Taking the cross product of (4.2) and using (4.3), we obtain (y-component)

$$i\omega\mu_0\, H_y = \frac{1}{i\omega\epsilon}\left(\frac{\partial^2}{\partial x^2}H_y + \frac{\partial^2}{\partial z^2}H_y - \frac{\partial}{\partial y}\left(\frac{\partial}{\partial x}H_x + \frac{\partial}{\partial z}H_z\right)\right). \tag{4.5}$$

Using the y-component of (4.2),

$$i\omega\epsilon\, E_y = \frac{\partial}{\partial z}H_x - \frac{\partial}{\partial x}H_z, \tag{4.6}$$

in (4.4) and substituting into (4.5), we have

$$\frac{\partial^2}{\partial x^2}H_y + \frac{\partial^2}{\partial z^2}H_y + \frac{\mu_0}{\mu}\,\frac{\partial^2}{\partial y^2}H_y + \omega^2\,\mu_0\epsilon\, H_y = \frac{\omega\kappa\epsilon}{\mu}\,\frac{\partial}{\partial y}E_y. \tag{4.7}$$

The components of (4.3) can be manipulated to yield the following equations:

$$\mu\left(\frac{\partial}{\partial y}E_z - \frac{\partial}{\partial z}E_y\right) + i\kappa\left(\frac{\partial}{\partial x}E_y - \frac{\partial}{\partial y}E_x\right) = -i\omega(\mu^2 - \kappa^2)H_x,$$

$$\frac{\partial}{\partial z}E_x - \frac{\partial}{\partial x}E_z = -i\omega\mu_0\, H_y, \tag{4.8}$$

$$-i\kappa\left(\frac{\partial}{\partial y}E_z - \frac{\partial}{\partial z}E_y\right) + \mu\left(\frac{\partial}{\partial x}E_y - \frac{\partial}{\partial y}E_x\right) = -i\omega(\mu^2 - \kappa^2)\, H_z.$$

Using the y-component of (4.2) and the first and last equations of (4.8), one can obtain

$$\frac{\partial}{\partial z}\left(\mu\left(\frac{\partial}{\partial y}E_z-\frac{\partial}{\partial z}E_y\right)+i\kappa\left(\frac{\partial}{\partial x}E_y-\frac{\partial}{\partial y}E_x\right)\right)$$
$$-\frac{\partial}{\partial x}\left(-i\kappa\left(\frac{\partial}{\partial y}E_z-\frac{\partial}{\partial z}E_y\right)+\mu\left(\frac{\partial}{\partial x}E_y-\frac{\partial}{\partial y}E_x\right)\right)=\omega^2\epsilon\left(\mu^2-\kappa^2\right)E_y.$$

This can be rearranged to obtain

$$-\mu\left(\frac{\partial^2}{\partial z^2}E_y+\frac{\partial^2}{\partial x^2}E_y\right)$$
$$+\frac{\partial}{\partial y}\left(\mu\left(\frac{\partial}{\partial z}E_z+\frac{\partial}{\partial x}E_x\right)-i\kappa\left(\frac{\partial}{\partial z}E_x-\frac{\partial}{\partial x}E_z\right)\right)=\omega^2\epsilon\left(\mu^2-\kappa^2\right)E_y.$$

Using this result with the y-component of (4.8) and the fourth equation of (4.1), we have

$$\frac{\partial^2}{\partial x^2}E_y+\frac{\partial^2}{\partial y^2}E_y+\frac{\partial^2}{\partial z^2}E_y+\frac{\omega^2\epsilon\left(\mu^2-\kappa^2\right)}{\mu}E_y=-\frac{\omega\mu_0\kappa}{\mu}\frac{\partial}{\partial y}H_y. \tag{4.9}$$

From (4.2)

$$i\omega\epsilon\begin{pmatrix}E_x\\E_z\end{pmatrix}=\begin{pmatrix}\dfrac{\partial}{\partial y}H_z-\dfrac{\partial}{\partial z}H_y\\[2ex]\dfrac{\partial}{\partial x}H_y-\dfrac{\partial}{\partial y}H_x\end{pmatrix}.$$

If we define

$$E^{\pm}=E_z\pm i\,E_x,\quad H^{\pm}=H_z\pm i\,H_x,$$

then it follows that

$$i\omega\epsilon\begin{pmatrix}E^+\\E^-\end{pmatrix}=\begin{pmatrix}-i\nabla^+H_y+i\dfrac{\partial}{\partial y}H^+\\[2ex]i\nabla^-H_y-i\dfrac{\partial}{\partial y}H^-\end{pmatrix}, \tag{4.10}$$

where

$$\nabla^{\pm}\phi=\frac{\partial}{\partial z}\phi\pm i\,\frac{\partial}{\partial x}\phi.$$

From (4.3)

$$-i\omega\begin{pmatrix}\mu\,H_x-i\kappa\,H_z\\\mu\,H_z+i\kappa\,H_x\end{pmatrix}=\begin{pmatrix}\dfrac{\partial}{\partial y}E_z-\dfrac{\partial}{\partial z}E_y\\[2ex]\dfrac{\partial}{\partial x}E_y-\dfrac{\partial}{\partial y}E_x\end{pmatrix},$$

and thus

$$-i\omega \begin{pmatrix} (\mu+\kappa)\, H^+ \\ (\mu-\kappa)\, H^- \end{pmatrix} = \begin{pmatrix} -i\nabla^+ E_y + i\dfrac{\partial}{\partial y} E^+ \\ i\nabla^- E_y - i\dfrac{\partial}{\partial y} E^- \end{pmatrix}. \tag{4.11}$$

From (4.10)–(4.11)

$$-\omega^2 \epsilon\,(\mu \pm \kappa)\, H^\pm - \frac{\partial^2}{\partial y^2} H^\pm \pm \omega\epsilon\, \nabla^\pm E_y + \frac{\partial}{\partial y} \nabla^\pm H_y = 0,$$

and we have

$$-\omega^2 \epsilon\,(\mu \pm \kappa)\, E^\pm - \frac{\partial^2}{\partial y^2} E^\pm \mp \omega(\mu \pm \kappa)\, \nabla^\pm H_y + \frac{\partial}{\partial y} \nabla^\pm E_y = 0.$$

Let $\hat{E}$ and $\hat{H}$ be the (partial) Fourier transform (in (x, y)) of E and H, i.e.,

$$\hat{E}(k_x, k_y, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} E(x, y, z) e^{-ik_x\, x - ik_y\, y}\, dxdy.$$

Then (4.9) and (4.7) can be written, respectively, as

$$\begin{aligned} &\frac{\partial^2}{\partial z^2} \hat{E}_y - \left(k_x^2 + k_y^2 - \omega^2 \epsilon \frac{\mu^2 - \kappa^2}{\mu} \right) \hat{E}_y = -i\omega\mu_0 k_y \frac{\kappa}{\mu}\, \hat{H}_y, \\ &\frac{\partial^2}{\partial z^2} \hat{H}_y - \left(k_x^2 + \frac{\mu_0}{\mu} k_y^2 - \omega^2 \mu_0 \epsilon \right) \hat{H}_y = i\omega\epsilon k_y \frac{\kappa}{\mu}\, \hat{E}_y \end{aligned} \tag{4.12}$$

and (4.10)–(4.11) as

$$\begin{aligned} \hat{E}^\pm &= \frac{-ik_y\, \nabla^\pm \hat{E}_y \pm \omega(\mu \pm \kappa)\, \nabla^\pm \hat{H}_y}{k_y^2 - \omega^2 \epsilon(\mu \pm \kappa)}, \\ \hat{H}^\pm &= \frac{-ik_y\, \nabla^\pm \hat{H}_y \mp \omega\epsilon\, \nabla^\pm \hat{E}_y}{k_y^2 - \omega^2 \epsilon(\mu \pm \kappa)}, \end{aligned} \tag{4.13}$$

where

$$\nabla^\pm = \frac{\partial}{\partial z} \mp k_x.$$

Thus the electric and magnetic modes are coupled by (4.12). Next we find the fundamental solution within the ferrite layer. Let

$$\tilde{A} = k_x^2 + \frac{\mu_0}{\mu} k_y^2 - \omega^2 \mu_0 \epsilon, \quad \tilde{B} = k_x^2 + k_y^2 - \omega^2 \epsilon \frac{\mu^2 - \kappa^2}{\mu},$$

$$\tilde{C} = i\omega\epsilon k_y \frac{\kappa}{\mu}, \quad \tilde{D} = i\omega\mu_0 k_y \frac{\kappa}{\mu}.$$

From the second equation of (4.12)

$$\hat{E}_y = \frac{\dfrac{\partial^2}{\partial z^2} \hat{H}_y - \tilde{A}}{\tilde{C}}\, \hat{H}_y,$$

and substituting this into the first equation of (4.12), we obtain

$$\frac{\partial^4}{\partial z^4}\hat{H}_y - (\tilde{A}+\tilde{B})\frac{\partial^2}{\partial z^2}\hat{H}_y + (\tilde{A}\tilde{B}-\tilde{C}\tilde{D})\hat{H}_y = 0.$$

Thus, we obtain the characteristic equation for system (4.12)

$$k^4 + (\tilde{A}+\tilde{B})k^2 + \tilde{A}\tilde{B} - \tilde{C}\tilde{D} = 0$$

for the exponential solution

$$\hat{H}_y = e^{ik\,z}, \;\; \hat{E}_y = -\frac{k^2+\tilde{A}}{\tilde{C}}\,\hat{H}_y.$$

The characteristic equation has four roots, $\pm k_+$ and $\pm k_-$. In each case, $\hat{E}_y$ is proportional to $\hat{H}_y$ so we proceed to consider solutions of the form

$$\hat{E}_y = i\eta\,\hat{H}_y. \tag{4.14}$$

Then η must satisfy

$$k_y^2 - \omega^2\epsilon\frac{\mu^2-\kappa^2}{\mu} - \omega\mu_0 k_y\frac{\kappa}{\mu\eta} = \frac{\mu_0}{\mu}k_y^2 - \omega^2\mu_0\epsilon - \omega\epsilon k_y\frac{\kappa}{\mu}\eta. \tag{4.15}$$

Equation (4.15) has two roots, which we designate as η_+ and η_-. Then $\hat{H}_y$ must satisfy either of the equations

$$\frac{\partial^2}{\partial z^2}\hat{H}_y - \left(k_x^2 + \frac{\mu_0}{\mu}k_y^2 - \omega^2\mu_0\epsilon - \eta_\pm\,\omega\epsilon k_y\frac{\kappa}{\mu}\right)\hat{H}_y = 0.$$

Thus, $\hat{E}_y$ and $\hat{H}_y$ can be written in the general form

$$\begin{aligned}\hat{E}_y &= i\eta_+\,(A_1\,e^{ik_+z} + B_1\,e^{-ik_+z}) + i\eta_-\,(A_2\,e^{ik_-z} + B_2\,e^{-ik_-z}),\\ \hat{H}_y &= A_1\,e^{ik_+z} + B_1\,e^{-ik_+z} + A_2\,e^{ik_-z} + B_2\,e^{-ik_-z},\end{aligned} \tag{4.16}$$

$$k_\pm = \sqrt{\omega^2\mu_0\epsilon + \eta_\pm\omega\epsilon k_y\frac{\kappa}{\mu} - k_x^2 - \frac{\mu_0}{\mu}k_y^2}\,.$$

Formulae (4.12)–(4.16) are given in [12, 18] without detailed derivations. These results allow us to construct the plane wave solution in a ferrite layer.

In a general dielectric (including ambient) medium, since $\kappa = 0$ and $\mu = \mu_0$, the system (4.12) is decoupled. Thus the fundamental solutions (in the partial Fourier domain formulation) are given by

$$\vec{E} = Ae^{ik_z} + Be^{-ik_z}, \quad \vec{H} = Ce^{ik_z} + De^{-ik_z}$$

with (4.1) and

$$k_z = \sqrt{\omega^2\epsilon\mu - k_x^2 - k_y^2}.$$

For example, we have

$$(\bar{E}_x, 0, 0)e^{ik_z z}, \quad \left(0, -\frac{k_z}{\omega\mu}\bar{E}_x, \frac{k_y}{\omega\mu}\bar{E}_x\right)e^{ik_z z} \tag{4.17}$$

for a perpendicular polarized (TM_x mode) incident wave and

$$\left(0, \frac{k_z}{\omega\epsilon}\bar{H}_x, -\frac{k_y}{\omega\epsilon}\bar{H}_x\right)e^{ik_z z}, \quad (\bar{H}_x, 0, 0)e^{ik_z z} \tag{4.18}$$

for a parallel polarized (TE_x mode) incident wave, where $\bar{E}_x$ and $\bar{H}_x$ are constants, when $k_x = 0$ and k_y are fixed.

Now we consider the case when a ferrite layer with thickness d on a perfectly conducting medium is impinged upon by the parallel polarized incident wave (4.17) $\vec{H}^{(i)}(x, y, z) = (H_x^{(i)}, 0, 0)e^{i\vec{k}\cdot\vec{x}}$ (its partial Fourier transform is $(H_x^{(i)}, 0, 0)e^{ik_z z}$) with $k_x = 0$ and k_y fixed. The transmitted wave $(\vec{E}^{(t)}, \vec{H}^{(t)})$ defined by (4.16) in the ferrite layer is generally not TE_x mode alone and thus has a nontrivial $E_x^{(t)}$. Hence, for a given incident wave, the reflected wave $(\vec{E}^{(r)}, \vec{H}^{(r)})e^{-ik_z z}$ in the ambient layer is a linear combination of the two fundamental solutions of the form (4.17)–(4.18) (with $k_z = -k_z$). Given the TE_x incident field, the constant weights $(E_x^{(r)}, H_x^{(r)})$ for the reflected wave can be determined by the system of equations

$$\begin{cases} H_x^{(i)} + H_x^{(r)} = \hat{H}_x^{(t)}(0), \\ \dfrac{k_z}{\omega\mu}(0 + E_x^{(r)}) = \hat{H}_y^{(t)}(0), \\ 0 + E_x^{(r)} = \hat{E}_x^{(t)}(0), \\ \dfrac{k_z}{\omega\epsilon}(H_x^{(i)} - H_x^{(r)}) = \hat{E}_y^{(t)}(0), \\ \hat{E}_x^{(t)}(-d) = \hat{E}_y^{(t)}(-d) = 0 \end{cases} \tag{4.19}$$

for $(A_1, B_1, A_2, B_2, E_x^{(r)}, H_x^{(r)})$ and the transmitted wave $(\vec{E}^{(t)}, \vec{H}^{(t)})$ determined by (4.13) and (4.16). The first two equations impose the continuity of H components, the next two equations impose the continuity of E components at $z = 0$ (the interface between the ambient and the ferrite layer), and the last equation enforces the perfectly conducting boundary conditions at $z = -d$. Moreover, the induced surface current $\vec{J}$ due to the incident wave is given by

$$\vec{J} = (\hat{H}_y(-d), -\hat{H}_x(-d), 0) = \vec{n} \times \vec{\hat{H}}.$$

This construction procedure can be readily extended to the case of the composite of sublayers.

4.1. Dielectric case (Fresnel's law). In this section we consider the dielectric layer ($\mu = \mu_0$, $\kappa = 0$) with thickness d on the perfectly conducting medium and show that (4.19) reduces to the usual Fresnel's law for the parallel polarized (TE_x) incident

wave. In this case we have $E_x^{(r)} = E_x^{(t)} = H_y^{(r)} = H_y^{(t)} = 0$ and

$$k_z^{(1)} = \sqrt{\omega^2 \mu_0 \epsilon^{(1)} - k_y^2},$$

$$k_+ = k_- = k_z^{(2)} = \sqrt{\omega^2 \mu_0 \epsilon^{(2)} - k_y^2}.$$

In the dielectric layer we have (in the partial Fourier domain)

$$\hat{H}_x^{(t)} = H_+^{(t)} e^{ik_z^{(2)} z} + H_-^{(t)} e^{-ik_z^{(2)} z},$$

$$\hat{E}_y^{(t)} = \frac{k_z^{(2)}}{\omega \epsilon^{(2)}} (H_+^{(t)} e^{ik_z^{(2)} z} - H_-^{(t)} e^{-ik_z^{(2)} z}),$$

where $H_\pm^{(t)}$ are constants. Thus, (4.19) becomes

$$\begin{cases} H_x^{(i)} + H_x^{(r)} = H_+^{(t)} + H_-^{(t)} \dfrac{k_z^{(1)}}{\omega \epsilon^{(1)}} (H_x^{(i)} - H_x^{(r)}) = \dfrac{k_z^{(2)}}{\omega \epsilon^{(2)}} H_+^{(t)} - \dfrac{k_z^{(2)}}{\omega \epsilon^{(2)}} H_-^{(t)}, \\ e^{-ik_z^{(2)} d} H_+^{(t)} - e^{ik_z^{(2)} d} H_-^{(t)} = 0. \end{cases}$$

Hence we obtain Fresnel's law

$$H_x^{(r)} = \frac{\dfrac{\epsilon^{(2)} k_z^{(1)} - \epsilon^{(1)} k_z^{(2)}}{\epsilon^{(2)} k_z^{(1)} + \epsilon^{(1)} k_z^{(2)}} + e^{-2ik_z^{(2)} d}}{1 + \dfrac{\epsilon^{(2)} k_z^{(1)} - \epsilon^{(1)} k_z^{(2)}}{\epsilon^{(2)} k_z^{(1)} + \epsilon^{(1)} k_z^{(2)}} e^{-2ik_z^{(2)} d}} H_x^{(i)}.$$

4.2. Numerical tests. In this section we demonstrate the feasibility of using the controllable property of the ferrite layer to attenuate reflections. We select $\epsilon_0 = 1$, $\mu_0 = 10$, and $d = .5$ (normalized). The magnetic permeability $\bar{\mu}$ of the ferrite layer is parameterized by

$$\mu = \mu_0 \left(0.3 + \frac{\beta}{100}\right), \quad \kappa = \mu_0 \left(-0.01 + \frac{\beta}{100}\right) \quad \text{for } 1 \le \beta \le 100,$$

where a parameter β plays a role of tuning the frequency ω_m in (3.1). In Figure 5 we depict $|(E_x^{(r)}, H_x^{(r)})|$ as a function of β for the three different incident angles $\phi_0 = 40°, 45°, 50°$. This figure establishes the attenuation capability of the ferrite layer that can be achieved by tuning the permeability. To reveal the phase dependence, in Figure 6 we graph the real and imaginary parts of $H_x^{(r)}$ as a function of the frequency for the incident angle $\phi = 45°$.

5. Optimization of material parameters of a coated airfoil. Having discussed the feasibility of tuning dielectric and magnetic properties of a coating on a perfect conductor in the previous sections, we turn in the next several sections to field calculations for a coated airfoil and demonstrate our ability to significantly affect the RCS by appropriate manipulation of the parameters ϵ and μ in the coating.

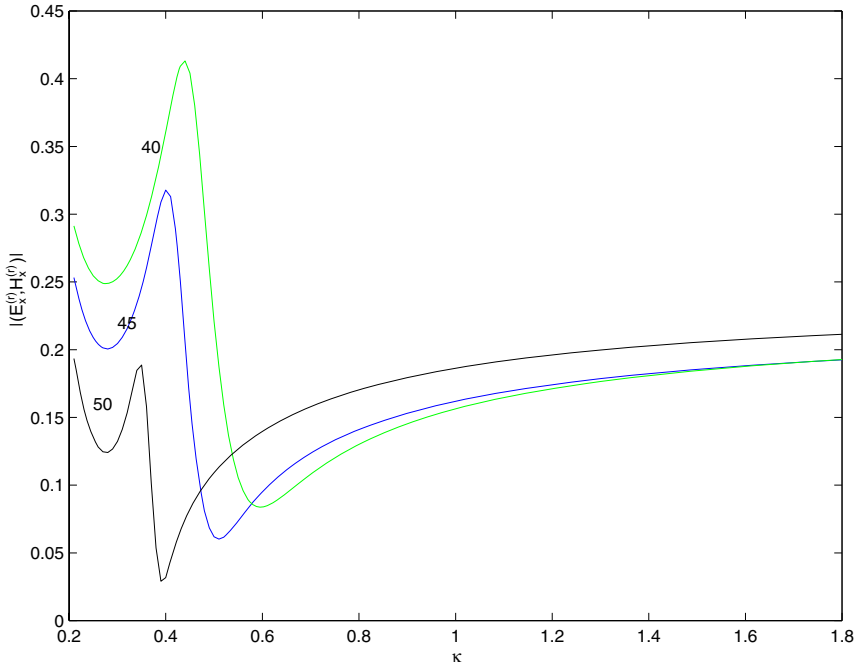

FIG. 5. *Attenuation capability.*

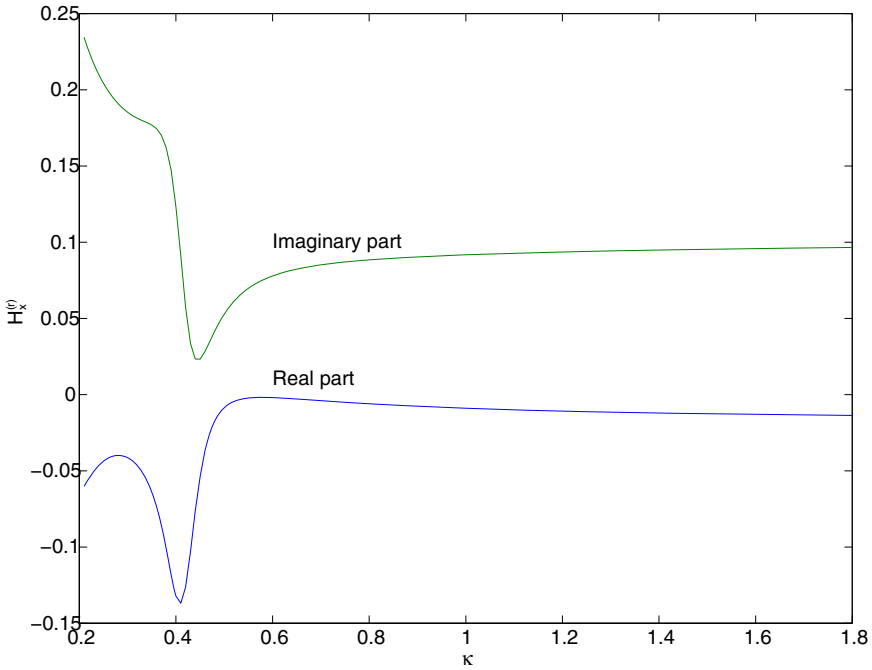

FIG. 6. *Phase shift property.*

5.1. Time-harmonic Maxwell equation for the transverse magnetic mode. We consider the scattering of a perfectly conducting airfoil coated by a layer of constant thickness. The interrogating electromagnetic incident wave is assumed to be a time-harmonic and transverse magnetic (more precisely, TM_x) mode. Thus, the time-harmonic electric and magnetic fields have the form

$$E = \begin{pmatrix} E_x \\ 0 \\ 0 \end{pmatrix} \qquad \text{and} \qquad H = -\frac{i}{\omega\mu} \begin{pmatrix} 0 \\ \frac{\partial}{\partial z} E_x \\ -\frac{\partial}{\partial y} E_x \end{pmatrix}, \tag{5.1}$$

where E_x is a function of y and z. We denote the airfoil by Ω and the coating layer by Ω_1; see Figure 7.

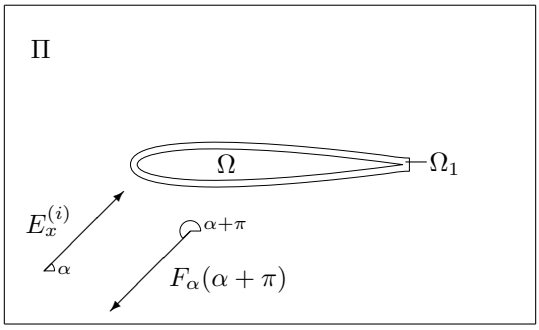

FIG. 7. *The computational domain, an interrogating wave $E_x^{(i)}$ with an interrogation angle α, and a far field pattern $F_\alpha(\alpha+\pi)$ of a scattered field $E_x^{(r)}$ to the direction $\alpha+\pi$.*

We decompose the total electric field E_x into two fields $E_x^{(i)}$ and $E_x^{(r)}$; that is, $E_x = E_x^{(r)} + E_x^{(i)}$. Furthermore, $E_x^{(i)}$ is chosen to coincide with the free space interrogating plane wave everywhere, i.e., in $\mathbb{R}^2 \backslash \bar{\Omega}$. With an interrogation angle $\alpha = (\pi/2 - \phi_0)$, $E_x^{(i)}$ is given by $E_x^{(i)}(y,z) = e^{i(k_y y + k_z z)}$, where $k_y = k\cos\alpha$, $k_z = k\sin\alpha$, $k = 2\pi/\lambda = \omega/c_0$ is the wave number, and λ is the wavelength. Thus, $E_x^{(i)}$ is the incident field outside the coated airfoil $\bar{\Omega} \cup \bar{\Omega}_1$, while in the coating layer Ω_1 the field $E_x^{(i)}$ is *nonphysical*. From this it follows that $E_x^{(r)}$ is the scattered field outside the coated airfoil, while neither of the fields $E_x^{(i)}$ and $E_x^{(r)}$ by itself has a physical meaning in the coating layer. That is, in Ω_1 they are simply a convenient computational decomposition of the total field and do not represent the individual coating-modified incident fields and reflected fields, respectively.

By eliminating the magnetic field from the Maxwell equation and substituting the time-harmonic electric field E of the form given in (5.1) into the resulting equation, we obtain the following Helmholtz equation:

$$\begin{aligned} \nabla \cdot \left(\frac{1}{\mu} \nabla E_x^{(r)} \right) + \epsilon\omega^2 E_x^{(r)} &= -\nabla \cdot \left(\frac{1}{\mu} \nabla E_x^{(i)} \right) - \epsilon\omega^2 E_x^{(i)} && \text{in } \mathbb{R}^2 \setminus \bar{\Omega}, \\ E_x = E_x^{(r)} + E_x^{(i)} &= 0 && \text{on } \partial\Omega, \\ \left[\frac{1}{\mu} \frac{\partial E_x}{\partial n} \right] = [E_x] &= 0 && \text{on } \partial\Omega_1 \setminus \partial\Omega, \end{aligned} \tag{5.2}$$

$$\lim_{r\to\infty} \sqrt{r}\left(\frac{\partial E_x^{(r)}}{\partial r} - ikE_x^{(r)}\right) = 0,$$

where $[\,\cdot\,]$ denotes the jump and n is a normal direction of the surface $\partial\Omega_1 \setminus \partial\Omega$. The far field behavior of the scattered field described by the Maxwell equation satisfies the Silver–Müller radiation condition [7]. For the time-harmonic TM_x mode this condition reduces to be the Sommerfeld radiation condition given by the limit in (5.2). The material permittivity ϵ and permeability μ are piecewise constant functions defined by

$$\epsilon(y,z) = \begin{cases} \epsilon_r\epsilon_0, & (y,z) \in \bar{\Omega}_1, \\ \epsilon_0 & \text{otherwise} \end{cases} \qquad \text{and} \qquad \mu(y,z) = \begin{cases} \mu_r\mu_0, & (y,z) \in \bar{\Omega}_1, \\ \mu_0 & \text{otherwise.} \end{cases}$$

5.2. Far field pattern. The far field pattern $F : [0, 2\pi] \to \mathbb{C}$ describes the intensity and phase of the scattered field $E_x^{(r)}$ far away from the scatterer [6, p. 340]. It can be defined as

$$F_\alpha(\theta) = \lim_{r\to\infty} \left(\sqrt{8\pi kr}\; e^{-i(kr+\pi/4)}\; E_x^{(r)}(r\cos\theta, r\sin\theta)\right), \tag{5.3}$$

where we have added the subscript α to denote the interrogation angle.

5.3. Backscatter reduction. In this optimization problem, we want to find constant material parameters ϵ_r and μ_r so that the intensity of the backscattered wave is minimized over a given sector $[\alpha_0, \alpha_1]$. The objective function is the integral

$$J(\epsilon_r, \mu_r) = \int_{\alpha_0}^{\alpha_1} |F_\alpha(\alpha + \pi)|^2 \, d\alpha. \tag{5.4}$$

The minimization problem is given by

$$\min_{(\epsilon_r,\mu_r)\in Q} J(\epsilon_r, \mu_r), \tag{5.5}$$

where Q is the set of admissible material parameters. In our considerations here, the set Q is chosen so that each material parameter belongs to a given interval of feasible values.

This objective function corresponds to a situation where the same radar is illuminating and detecting the scattered wave. The interrogation angle of the interrogating wave varies within the interval $[\alpha_0, \alpha_1]$ and the formulation (5.4) corresponds to an assumption of a uniform distribution on possible angles of interrogation.

We use the NAG Fortran Library's [19] E04UCF implementation of a sequential quadratic programming (SQP) method. This is a gradient-based optimization method which approximates the gradient using finite differences.

6. Approximation.

6.1. Truncation of domain and variational formulation. For the discretization of (5.2), we restrict the problem to a rectangular domain Π and impose a second-order absorbing boundary condition [1] on the artificial boundary $\partial\Pi$ to approximate the Sommerfeld radiation condition. Now the scattered field $E_x^{(r)}$ satisfies the follow-

ing equations:

$$
\begin{aligned}
\nabla\cdot\left(\frac{1}{\mu}\nabla E_x^{(r)}\right)+\epsilon\omega^2 E_x^{(r)} &= -\nabla\cdot\left(\frac{1}{\mu}\nabla E_x^{(i)}\right)-\epsilon\omega^2 E_x^{(i)} && \text{in } \Pi\setminus\bar{\Omega},\\
E_x^{(r)} &= -E_x^{(i)} && \text{on } \partial\Omega,\\
\left[\frac{1}{\mu}\frac{\partial E_x}{\partial n}\right] &= [E_x]=0 && \text{on } \partial\Omega_1\setminus\partial\Omega,\\
\frac{\partial E_x^{(r)}}{\partial n}-ikE_x^{(r)}-\frac{i}{2k}\frac{\partial^2 E_x^{(r)}}{\partial s^2} &= 0 && \text{on } \partial\Pi,\\
\frac{\partial E_x^{(r)}}{\partial s}-ik\frac{3}{2}E_x^{(r)} &= 0 && \text{at } C,
\end{aligned}
\tag{6.1}
$$

where n and s denote the normal and tangential directions of the boundary $\partial\Pi$, respectively, and C is the set of the corner points of Π.

The variational formulation of (6.1) is as follows:
Find $E\in\{v\in H^1(\Pi\setminus\bar{\Omega})\mid v|_{\partial\Pi}\in H^1(\partial\Pi),\ v=-E_x^{(i)} \text{ on } \partial\Omega\}$ such that

$$
\begin{aligned}
&\int_{\Pi\setminus\bar{\Omega}}\left(\frac{1}{\mu}\nabla E_x^{(r)}\cdot\nabla v-\epsilon\omega^2 E_x^{(r)}\,v\right)d\xi+\frac{i}{k\mu_0}\int_{\partial\Pi}\left(\frac{1}{2}\frac{\partial E_x^{(r)}}{\partial s}\frac{\partial v}{\partial s}-k^2E_x^{(r)}\,v\right)d\sigma\\
&+\frac{3}{4\mu_0}\sum_{(y,z)\in C}E_x^{(r)}(y,z)v(y,z)=-\int_{\Pi\setminus\bar{\Omega}}\left(\frac{1}{\mu}\nabla E_x^{(i)}\cdot\nabla v-\epsilon\omega^2E_x^{(i)}\,v\right)d\xi
\end{aligned}
\tag{6.2}
$$

for all $v\in\{v\in H^1(\Pi\setminus\bar{\Omega})\mid v|_{\partial\Pi}\in H^1(\partial\Pi),\ v=0 \text{ on } \partial\Omega\}$.

6.2. Finite element approximation. A finite element approximation as developed in [8, 9] was implemented using linear elements. The techniques in [8] and [9] are two-dimensional finite element methods for scattered electromagnetic solutions from noncoated and coated objects, respectively. We employ the same methods here. The mesh is constructed from two uniform triangular meshes. The finer mesh is for the coating layer, and the coarser is for the exterior domain outside the coating. The mesh step sizes are chosen in such a way that the number of nodes per wavelength is approximately the same in the air and in the coating. The finer mesh is locally fitted to the surfaces of the obstacle and the coating layer. The local fitting is done using the algorithm [5] with slight modifications. Between the meshes, there is a layer that fits the meshes together in a conforming way. An example of a part of a mesh is shown in Figure 8.

After the discretization of the variational formulation (6.2), we obtain a system of linear equations

$$Ax=b, \tag{6.3}$$

where the matrix A is a symmetric non-Hermitian complex matrix. The vector x contains the nodal values of the scattered field $E_x^{(r)}$, and the vector b corresponds to the right-hand terms in (6.2). The resulting systems of linear equations are solved using an iterative method which combines fictitious domain and domain decomposition methods [9].

The far field pattern $F_\alpha(\alpha+\pi)$ in (5.3) is computed as a surface integral [7] of the computed near field $E_x^{(r)}$ and its flux. Our particular implementation of the

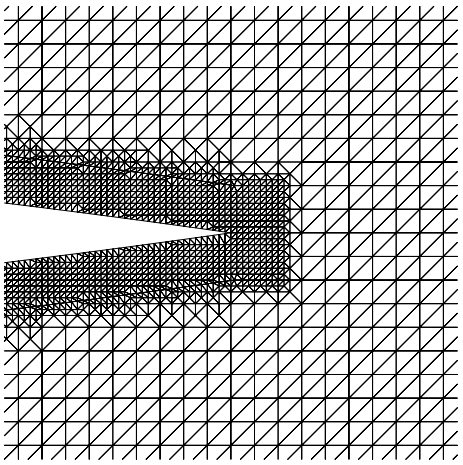

FIG. 8. *A magnified view of the mesh for a coated NACA*0012 *airfoil.*

computations is described in [8]. We need to evaluate the far field pattern $F_\alpha(\alpha+\pi)$ in (5.3) using the computed near field $E_x^{(r)}$. Our particular implementation of the computations is described in [8]. The basic idea of this procedure is the following. Let $\tilde{E}_x^{(r)}$ be the harmonic extension of $E_x^{(r)}$ from $\Pi \setminus (\bar{\Omega} \cup \Omega_1)$ to $\mathbb{R}^2$. We obtain this extension as a byproduct of our solution procedure. Then at the point η outside $\bar{\Omega} \cup \Omega_1$ the scattered field $\tilde{E}_x^{(r)}$ is given by

$$\tilde{E}_x^{(r)}(\eta) = \int_\Pi \left(\Delta \tilde{E}_x^{(r)}(\xi) + k^2 \tilde{E}_x^{(r)}(\xi) \right) \Phi(\eta, \xi)\, d\xi, \tag{6.4}$$

where $\Phi(\eta,\xi)$ is the fundamental solution of the homogeneous Helmholtz equation in $\mathbb{R}^2$ given by the Hankel function $\Phi(\eta,\xi) = \frac{i}{4} H_0^{(1)}(k|\eta-\xi|)$. By using Green's formula one can show that (6.4) is equivalent to

$$\tilde{E}_x^{(r)}(\eta) = \int_{\partial\Pi} \left(E_x^{(r)}(\sigma) \frac{\partial \Phi(\eta,\sigma)}{\partial n} - \frac{\partial E_x^{(r)}(\sigma)}{\partial n} \Phi(\eta,\sigma) \right) d\sigma,$$

which is a more traditional expression for $\tilde{E}_x^{(r)}(\eta)$ [7]. The far field pattern F_α is obtained by first discretizing the Helmholtz operator and integral in (6.4) and then taking the limit in (5.3). At the discrete level the previous procedure reduces to the evaluation of a sum of exponential functions. This can be performed easily and quickly.

We have compared numerical results computed using the proposed method and implementation with test cases presented at a workshop in Oxford (see [20]). The two-dimensional test cases did not include a coated NACA airfoil, but they did include a similar coated ogive (the intersection of two nonconcentric disks). We computed numerical results for 10 test cases. All of our numerical results and especially the radar cross sections were in very good agreement with the majority of the results presented in the workshop for each test case. Because of this, we expect our results to be accurate also for the coated NACA airfoils.

7. Numerical experiments. In our experiments, we minimize the backscatter by a coated NACA0012 airfoil. The length of the airfoil is one unit without coating,

and the trailing edge of the perfectly conducting material is at the origin. We minimize the backscatter for the interrogation angles in the sector $[\alpha_0, \alpha_1] = [0, \pi]$. We considered two wavelengths, $\lambda = 1/4$ and $\lambda = 1/10$. The thickness of the coating is taken as $\lambda/10$ to provide a comparison of coating layers of different thicknesses possessing similar material parameters.

We consider first the lower frequency experiments with a four-wavelength-long airfoil. The computational domain is $[-1.5, 0.5] \times [-0.6, 0.6]$. Our discretization has 20 nodes per wavelength in the ambient medium, leading to a triangulation with 22157 nodes and 43158 elements. A magnified view of the mesh at the trailing edge is shown in Figure 8. We perform several optimizations with different box constraints for the real and imaginary parts of ϵ_r and μ_r. The results of these optimizations are given in Table 1. A surface plot of the objective function is shown in Figure 9. The radar

8. Summary and conclusions. In summary, the efforts reported on in this paper are an important first step in developing an attenuation or anti-interrogation technology. We first considered the question of the feasibility of reduction in reflected electromagnetic waves from a planar layered coating on a perfect conductor. We demonstrated that even under uncertainty of the interrogating wavelengths (frequencies), one can achieve reduction of the reflection coefficient through optimizing the dielectric permittivity in a coating layer. We then considered a Maxwell equation-based formulation for a composite ferromagnetic-ferroelectric device built and experimentally tested by How and Vittoria. We derived the pertinent reflection field equations for time-harmonic interrogating TM_x mode plane waves and showed that substantial control of reflected waves (both magnitude and phase) can be obtained by tuning the magnetic permeability of a ferrite layer. We next turned to a nonplanar geometry, in this case a two-dimensional airfoil, with a coating layer wherein both the dielectric permittivity ϵ and the magnetic permeability μ can be optimized. Allowing a uniform uncertainty on the interrogating signal angles, we use computational methods from two-dimensional scattering theory (the Helmholtz equation with Sommerfeld far field radiation conditions) to verify that significant reduction in the far field reflection can be obtained by an optimal choice of ϵ and μ.

In ongoing efforts [3], we are continuing the investigations begun in this paper in

several directions. One includes allowing optimal design for the coating over ranges (distributions) of interrogating wavelengths and angles of incidence. We have also begun consideration of countermeasures for the anti-interrogation ideas outlined in this paper. These problems result in classical *static zero-sum two-player games* for evader and interrogator where each player must consider uncertainty in knowledge of the opposing player's capabilities. The resulting min-max games must be played over spaces of probability measures (see [3] for details of these interesting but challenging problems and our efforts with them).

All of the investigations discussed in this paper were pursued under an *active design* scenario and did not allow for online adaptivity of the coating layers. Future investigations of great interest include the feasibility of combining the formulations in this paper with real time sensing and adaptive (feedback) control of coatings such as those described above to develop an *active control* attenuation capability.

Acknowledgments. The authors would like to thank Dr. Richard Albanese of the AFRL, Brooks AFB, San Antonio, TX, for numerous stimulating and valuable comments and suggestions on this work. They are also grateful to Dr. Hoton How for several helpful conversations.

PREDATOR-PREY INTERACTIONS WITH DELAYS DUE TO JUVENILE MATURATION*

KENNETH L. COOKE†, RICHARD H. ELDERKIN†, AND WENZHANG HUANG‡

Abstract. This paper focuses on predator-prey models with juvenile/mature class structure for each of the predator and prey populations in turn, further classified by whether juvenile or mature individuals are active with respect to the predation process. These models include quite general prey recruitment at every stage of analysis, with mass action predation, linear predator mortality as well as delays in the dynamics due to maturation. As a base for comparison we briefly establish that the similar model without delays cannot support sustained oscillation, but it does have predator extinction or global approach to predator-prey coexistence depending on whether the ratio α of per predator predation at prey carrying capacity to the predator death rate is less than or greater than one.

Our first model shows the effect of introducing an invulnerable juvenile prey class, appropriate, e.g., for some host-parasite interactions. In contrast our second model shows the effect of limiting predation to a prey juvenile class. Finally, in a third model we consider an inactive juvenile predator class, which would be appropriate for many traditional situations in which the generation time for the predator is significantly larger than that of the prey. In all cases the introduction of a juvenile class results in a system of three delay-differential equations from which the two equations for the mature class and the nonstructured class can be decoupled. We obtain some global stability results and identify a parameter α, similar to the α of the unlagged model, which determines whether or not the predator is driven to extinction. With $\alpha > 1$, and considering the maturation age of the juvenile class as a bifurcation parameter, we obtain Hopf bifurcations in our second and third models, while in the case of juvenile prey (in the first model) the unique coexistence equilibrium remains stable for all positive delays. Although the delay is "physically present" in all three models, we obtain scaled, nondimensional replacement models with that physical presence scaled out. After analyzing the scaled equations we show that all our results hold for the original models.

We pursue the bifurcation in the inactive juvenile predator model with numerical simulations. Strikingly similar results over a variety of birth functions are observed. Increases of the maturation delay first produce Hopf bifurcation from steady state to periodic behavior. Even further increase in the delay produces instabilities of the bifurcating periodic solutions with corresponding interesting geometry in a two-dimensional plot of period vs. delay.

Key words. predator-prey, host-parasite, age structure, maturation delay, delay differential equations, bifurcation

1. Introduction.

It is well known that some predators may preferentially attack prey of certain ages or developmental stages. Likewise, the predators themselves may be distinguished in some cases between inactive juveniles and active adults. These situations may be modeled mathematically by dividing the populations into age classes. Our models of this are closely related to those of Hastings ([16], 1983), Murdoch et al. ([22], 1987), the very general ones of Nunney ([25],[26],[27]), and recent work of Gourley and Kuang ([13], 2004). In a model comparable to one of ours (5), Hastings uses a linear mature prey birth rate and a general predation functional

response to show the possibility of switches between stability and instability of the positive equilibrium as the time delay changes. In contrast we show that this is not possible for our model (5) with its nondecreasing birth rate $NB(N)$. It is known [8] that if $B(N)$ does not satisfy this hypothesis, more complicated dynamic behavior may occur even in a single species population model. In order to analyze models with nonlinear delayed recruitment, we limit our attention to a mass action (i.e., Holling Type I) predation response.

Nunney studied prey-predator systems which are similar to ours, but without the "physical presence" of the delay (that is, occurring outside the arguments of the time-varying states). Assuming the existence of a unique positive equilibrium, he derives a condition for its absolute stability (i.e., linear stability for all delays R). For our "host-parasite" model (section 3) this condition is satisfied; however, in addition we identify a parameter, α, which governs stability of the equilibrium with extinction of the predator. Nunney also considers a similar general system, but in which the delay is due to predator maturation, including our scaled system (50) as special case. Again he assumes existence of a positive equilibrium, and derives a condition for its absolute stability. However, in contrast, with our more specific functional forms we derive conditions on parameters which guarantee Hopf bifurcation to periodic solutions, building on the analysis of Cooke and van den Driessche [7].

Gourley and Kuang consider a model with inactive juvenile predators which is similar to ours in section 5, but with logistic prey recruitment, which we generalize. As in our case, they are faced with the physical presence of the delay in the equations, which causes them (and others) significant difficulty. We exhibit a scaling of the states and parameters which avoids those difficulties (e.g., (8)), yet causes no loss of detail or generality (section 7). Although their predation functional response is initially more general than ours, they specialize, as do we, to the mass-action response before deriving any results. Using our scaling, we are able to analytically produce results, while they relied on computational assistance for theirs. We also implement three examples of birth functions (affine, concave up, and concave down) and conduct numerical experimentation. Over parameter ranges of biological interest the numerical results are very similar across the three function types. However, by extending the maturation delay even further we first find interesting geometries of the bifurcated periodic solutions and at even greater delays find an apparent relation between onset of instabilities and a curious lack of monotonicity in a bifurcation diagram.

We intend our results to be a coherent study across a selection of models that deserve to be considered in the context of each other. We present theoretical results that can be compared across the variation of juvenile/adult roles, both active and inactive, and for both predator and prey. In studying these models, we seek to obtain as much information as we can about how the dynamics of the systems depend on the multiple parameters in the equations, such as attack and mortality rates and the maturation delay. In general, we are looking for conditions that ensure stable equilibrium or bifurcation phenomena. Basic questions are the following: (1) to what extent does the inclusion of the natural mortality parameters alter the qualitative or quantitative behavior of the systems as the maturation delay is varied? (2) is maturation delay more destabilizing in the prey or in the predator? (3) what kinds of destabilizations other than Hopf bifurcations occur as the maturation delay increases? We give partial answers to each of these questions and point the way to further investigation in each case. In general, we find that there is a considerable difference in dynamics depending on whether the prey or predator has a differently behaving

juvenile class, and on whether the adults or the juveniles are active with respect to the predation process. A moral is that any theoretical or practical study of these situations should carefully take account of the potential for such differences.

We begin the analysis of each of our models by scaling the equations to obtain a dimensionless system in which the delay is no longer physically present. This has the usual advantages of reducing the number of parameters and making the mathematical analysis somewhat simpler and more transparent. Implicit in this strategy is the expectation that the dynamics of the original and scaled systems will be "equivalent" or that the dynamics of one system will be "mirrored" by the dynamics of the other system. Since some of the coefficient parameters of the original system, and some of the transformations in the scaling, depend on the delay, and since we are probing how stability or destabilization depends on the delay, we have included a careful discussion of these and other aspects in section 7.

The structure of the paper is as follows. In section 2, as a point of departure for what is to come in subsequent sections, we consider a simple predator-prey model that does not include any age structure or resulting delay in recruitment. It consists of two ordinary differential equations in which there is a general prey recruitment function, mass-action predation, and linear mortality in both prey and predator. A simple and natural condition suffices to determine global asymptotic stability of equilibrium; there are no positive periodic solutions.

In section 3 we propose and analyze a model in which the prey has a juvenile class (in addition to an interactive adult class) that is invulnerable to predation while the predator is considered as a single class. For example, this might apply to the sheltered existence of human infants while breast-feeding in a world where parasitism is widespread. The results for our equivalent nondimensionalized system may be stated in terms of a single scaled parameter, α, which has a natural interpretation similar to that of R_0 in many population (especially epidemiological) models. In this case, the system is always dissipative, and when $\alpha > 1$ there is a unique equilibrium with both populations present, which must be locally asymptotically stable, independent of the delay. There is no bifurcation to periodic behavior as the delay increases. Later, in section 7, we discuss what this tells us about the original, nonscaled system.

In section 4 we present a model similar to the one in the preceding section in that there are juvenile and adult prey along with a single class of predators. However, we now assume that survival of juvenile prey is reduced in proportion to the mean population size of predators. Under this hypothesis, our system is now one with "distributed delay." In contrast with the previous case, it turns out that the positive equilibrium is stable for small maturation delays, but unstable with bifurcation to periodic behavior for large ones.

In section 5 we present a model in which there is a single prey population, but a predator with adult and juvenile classes in which the latter do not attack the prey. We show in this case that bifurcation is possible with periodic solutions emerging for large values of the delay under an additional condition on parameters. Here we calculate bifurcation diagrams for examples of the original and the scaled systems, and later in section 7, we discuss more general relationships.

In section 6 we present results of numerical studies of the bifurcations established in section 5. Before chosing parameter values, we briefly provide interpretations for the more important ones. Then we numerically compare a variety of birth functions in which one is concave down, another concave up, and yet another is affine (over the population range of interest). We arrange that all three resulting models have the same

interior equilibrium populations and the same populations that are analogous to a carrying capacity (in ODE models), and have the same birth rates at those population levels. We compare the three over a common range of parameters, finding strong similarities. In the case of the affine birth function we extend the Hopf bifurcation branch with increasing delay until a Floquet multiplier leaves the unit disk in the complex plane, signifying onset of instability of the bifurcating periodic solutions. Observing this in a two-dimensional plot of the period of the bifurcating solutions vs. the delay, we see this onset of instability simultaneously as the delay changes from increase to decrease along a backwards S shape just after the period has begun to decrease. At the other end of the backwards S where the delay begins increasing again, another multiplier leaves the unit disk and the period moves toward increase.

Section 7 addresses the correspondence between the nature of the original models and our analysis of their nondimensional replacements. This analysis is especially motivated by the appearance of the maturation delay physically in the predation coefficients as well as in the populations in the original models, but only within the arguments of the scaled populations in the scaled equations. We show in a precise sense that no bifurcation structure is lost as a result of these scalings.

2. A prototypical model. In order to provide a basis for comparison of our primary results on models with delays due to maturation, we first establish the basic properties exhibited by our model without age structure or corresponding delay. The basic ODE model for a prey population N and a predator population P is

$$\frac{dN}{dT} = NB(N) - aNP - dN, \tag{1a}$$

$$\frac{dP}{dT} = cNP - d_P P \tag{1b}$$

in which we assume that the per capita prey birth rate B satisfies

$$B(N) \geq 0 \quad \text{and} \quad B'(N) < 0 \qquad \text{for } N \geq 0, \tag{2a}$$

$$B(0) > d > B(\infty). \tag{2b}$$

The assumptions (2a) and (2b) are satisfied, for example, in each of the forms $B(N) = p/(q+N)$ and $B(N) = \exp(-pN)$ where p and q are positive constants (for appropriate d). However see section 3 where the latter form will not work. Furthermore, although (2a) is not satisfied by $B(N) = p - qN$, we adapt this form later to provide a viable example.

It is obvious that (1) always has a trivial equilibrium $(N, P) = (0, 0)$ which is an unstable saddle point. Another equilibrium is $(N_0, 0)$, where $N_0 > 0$ is the unique solution of $B(N) = d$, existing by (2). Some simplification of notation can be achieved by scaling N, P, T and various coefficients. In fact, if we set

$$x = N/N_0, \qquad t = d_P T, \qquad \alpha = cN_0/d_P,$$
$$y = aP/cN_0, \qquad b(x) = B(xN_0)/d_P, \qquad \gamma = d/d_P,$$

then the system (1) takes the (nondimensional) form

$$\frac{dx}{dt} = xb(x) - \alpha xy - \gamma x, \tag{3a}$$

$$\frac{dy}{dt} = \alpha xy - y. \tag{3b}$$

Notice that in this scaling the transfer from x to y by the scaled predation is perfectly efficient! The properties assumed in (2) take the simpler form

$$b(x) \geq 0 \quad \text{and} \quad b'(x) < 0 \qquad \text{for } x \geq 0, \tag{4a}$$

$$b(0) > \gamma > b(\infty) \quad \text{and} \quad b(1) = \gamma \tag{4b}$$

and the equilibria are now at $(0,0)$ and $(1,0)$.

LEMMA 1. *The system* (3) *is dissipative, that is, there is a compact set* Ω *(in this case of the form* $\{(x,y) : x, y \geq 0,\ x + y \leq m\}$ *for some* m*) such that each solution in the first quadrant of the* (x,y) *plane has a* T_0 *such that when* $t \geq T_0$, $(x(t), y(t)) \in \Omega$.

Proof. With $V(x,y) = x + y$ we have

$$\dot{V} \stackrel{def}{=} \frac{d}{dt} V(x(t), y(t)) = xb(x) - \gamma x - y.$$

When $x > 1$ this is negative, and when $x \leq 1$ it is negative for sufficiently large y. Standard Lyapunov function considerations complete the argument. ∎

THEOREM 2. *If* $\alpha \leq 1$*, then all positive solutions of* (3) *converge to the equilibrium* $(1,0)$ *as time* $t \to \infty$.

Proof. The first quadrant of the (x,y) plane is invariant and it follows from the first lemma that every positive solution is bounded. So Poincaré-Bendixson considerations obtain. There is no positive equilibrium; $(0,0)$ is a saddle point and its stable manifold lies on the y-axis; and $(1,0)$ is linearly stable. It follows then that $(x(t), y(t)) \to (1,0)$ as $t \to \infty$. ∎

It is easily seen that our hypotheses on the birth function $B(x)$ imply the following lemma.

LEMMA 3. *The system* (3) *has a positive equilibrium* (x^*, y^*) *if and only if* $\alpha > 1$*, in which case it is unique.*

For the remainder of this section we study the case when $\alpha > 1$. Since $b'(x^*) < 0$, it is easy to see that all eigenvalues of the Jacobian matrix J at (x^*, y^*) have negative real part, and hence (x^*, y^*) is locally asymptotically stable. However, we can establish the stronger result.

THEOREM 4. *If* $\alpha > 1$*, then* (x^*, y^*) *is globally asymptotically stable.*

Proof. We first establish that any positive nonconstant periodic solution of the system (3) must be asymptotically stable. Suppose that $(\tilde{x}(t), \tilde{y}(t))$ is a positive periodic solution and let $X' = A(t)X$ be the linearization of (3) around it. Then a straightforward calculation gives that

$$A(t) = \begin{bmatrix} b(\tilde{x}(t)) + \tilde{x}(t)b'(\tilde{x}(t)) - \alpha\tilde{y}(t) - \gamma & -\alpha\tilde{x}(t) \\ \alpha\tilde{y}(t) & \alpha\tilde{x}(t) - 1 \end{bmatrix}.$$

Let T be a period of this periodic solution. To establish its asymptotic stability it suffices to show that

$$\int_0^T \operatorname{tr} A(t)dt < 0,$$

but in fact

$$\begin{aligned} \int_0^T \operatorname{tr} A(t)dt &= \int_{\tilde{x}(0)}^{\tilde{x}(T)} \frac{dx}{x} + \int_0^T \tilde{x}(t)b'(\tilde{x}(t))\,dt + \int_{\tilde{y}(0)}^{\tilde{y}(T)} \frac{dy}{y} \\ &= 0 + \int_0^T \tilde{x}(t)b'(\tilde{x}(t))\,dt + 0 < 0 \end{aligned}$$

since $\tilde{x}(t)b'(\tilde{x}(t)) < 0$ by (4a).

Because of this we can now show that the system (3) has no positive periodic solution. Indeed, suppose there were a positive periodic orbit Γ. The α-limits of each point enclosed by Γ must be nonempty and also enclosed by Γ. Since both the positive equilibrium (x^*, y^*) and Γ are locally asymptotically stable, neither can be contained in an α-limit of a point enclosed by Γ. But there are no other equilibria, and any positive periodic solution must be locally asymptotically stable, so there can be no α-limits of points other than (x^*, y^*) (the α-limit of itself) enclosed by Γ. This is a contradiction.

Finally, it follows from Lemma 1 that every positive solution is bounded for $t \geq 0$, and therefore must have a nonempty ω-limit. By the preceding argument and Poincaré-Bendixson theory every such limit must contain at least one of the equilibria. However, the two boundary equilibria $(0, 0)$ and $(1, 0)$ cannot be contained in the necessarily bounded ω-limits of any other points. Hence (x^*, y^*) must be in the ω-limit of every interior solution, and since it is locally asymptotically stable it must be the entire limit set. □

3. Invulnerable juvenile prey: A host-parasite situation. We now consider the effect of taking into account a juvenile class of prey, which we assume to be invulnerable to predation from birth until an age large enough to warrant inclusion of the class in our model. Taking the model (1) as our starting point, we assume that the juvenile class, consisting of those prey from ages 0 to R, is subject to a constant mortality rate d_1 and so is given by

$$J(T) = \int_{T-R}^{T} N(s)\, B(N(s)) e^{-d_1(T-s)}\, ds,$$

where $N(t)$ is the population of adults of the prey species, and with elementary calculations we find its derivative is

$$J'(T) = N(T)\, B(N(T)) - N(T-R)\, B(N(T-R)) e^{-d_1 R} - d_1 J(T). \tag{5a}$$

Interpreting the three terms of the last expression, we find that the first is the current rate of juvenile births, while the second is the current rate of maturation of surviving juveniles to adulthood, and the third is current juvenile mortality. These considerations motivate the alteration of our original model to the form

$$N'(T) = N(T-R)B(N(T-R))e^{-d_1 R} - aN(T)P(T) - dN(T), \tag{5b}$$

$$P'(T) = cN(T)P(T) - d_P P(T). \tag{5c}$$

We suppose that (2a) continues to hold, as well as the obvious generalization of (2b),

$$B(0)e^{-d_1 R} > d > B(\infty)e^{-d_1 R}. \tag{6}$$

In this situation we define N_0 by the condition

$$B(N_0)\, e^{-d_1 R} = d.$$

In addition, for $N \geq 0$ we assume that

$$NB'(N) + B(N) \geq 0 \tag{7}$$

or equivalently that the "per capita" recruitment rate, $B(N)$, is kept from decreasing too fast in the sense that $B'(N) \geq -B(N)/N$. In contrast with the ODE case, by this assumption we no longer admit the case of $B(N) = \exp(-pN)$. See Cooke et al. [8], where it is shown in a model of a single population that dynamic behavior can be much more complicated when $B(N)$ has the exponential form. Since we want to concentrate on the effects of maturation delays in prey or predator, we have chosen to work with the simpler form. We also wish to point out that many studies in the literature deal with models in which the term aNP is replaced by $Pf(N)$, where f is called the functional response. We have retained the simpler form aNP in order to isolate the effects of delayed recruitment.

Since (5b, 5c) can be decoupled and solved independently from (5a), we can again restrict our attention to the differential equations (now with delays) for (N, P). We will again find that our analysis is facilitated by a scaling of the variables. If

$$\begin{array}{ccc} x = N/N_0, & t = d_P T, & \alpha = cN_0/d_P, \\ y = aP/cN_0, & r = d_P R, & \gamma = d/d_P, \\ & b(x) = B(xN_0)\, e^{-d_1 R}/d_P, & \end{array} \tag{8}$$

then the system (5) takes the (nondimensional) form

$$\frac{dx}{dt} = x(t-r)\, b(x(t-r)) - \alpha x(t)\, y(t) - \gamma x(t), \tag{9a}$$

$$\frac{dy}{dt} = \alpha x(t)\, y(t) - y(t). \tag{9b}$$

Notice that in this scaling the transfer from x to y by the scaled predation is again perfectly efficient, and the mortality factor, with its physical presence of the delay in $e^{-d_1 R}$, is scaled out. We will show in section 7 that there is no loss in generality for, e.g., bifurcation as R increases, resulting from this scaling. The properties assumed in (2a), (6), and (7) take the simpler form

$$b(x) \geq 0 \quad \text{and} \quad b'(x) < 0 \qquad \text{for } x \geq 0, \tag{10a}$$

$$b(0) > \gamma > b(\infty) \quad \text{and} \quad b(1) = \gamma, \tag{10b}$$

$$b(x) + xb'(x) \geq 0, \tag{10c}$$

and the boundary equilibria are now at $(0,0)$ and $(1,0)$.

LEMMA 5. *The system* (9) *is dissipative, that is, there is a compact set* Ω *(in this case of the form* $\{(x,y) : x, y \geq 0,\ x + y \leq m\}$*) such that each solution in the first quadrant of the* (x,y) *plane has a* T_0 *such that when* $t \geq T_0$, $(x(t), y(t)) \in \Omega$. *Moreover,* $\limsup_{t\to\infty} x(t) \leq 1$.

Proof. Since $b(0) > 0$ it is easy to check that the first quadrant is forwardly invariant under solutions of (9). With $V(x,y) = x + y$ we have

$$\dot{V} \overset{def}{=} \frac{d}{dt} V(x(t), y(t)) = x(t-r)\, b(x(t-r)) - \gamma x(t) - y(t).$$

To set up the analysis of $\dot{V}$, we first establish the boundedness of $x(t)$ for every positive solution.

Let $\bar{x} = \limsup_{t\to\infty} x(t)$. Suppose, contrary to our claim, that $\bar{x} > 1$. Since the case in which $\bar{x}$ is infinite is similar to the finite case, but slightly less complicated, we will consider only the finite case . Then we can find a sequence $\{t_n\}$ with $t_n \to \infty$

as $n \to \infty$ such that $x(t_n) \to \bar{x}, x'(t_n) \to 0$, and $\limsup_{n\to\infty} x(t_n - r) \le \bar{x}$. Then we have

$$\begin{aligned}\lim_{n\to\infty} x'(t_n) &\le \lim_{n\to\infty} \sup\left(x(t_n - r)\, b(x(t_n - r)) - \gamma x(t_n)\right)\\ &= \lim_{n\to\infty} \sup\left(x(t_n - r)\, b(x(t_n - r))\right) - \gamma\bar{x}\\ &\le \left(b(\bar{x}) - \gamma\right)\bar{x} < 0,\end{aligned}$$

contradicting our choice of $\{t_n\}$ so that $x'(t_n) \to 0$. Because of this every $x(t)$ has $\limsup_{t\to\infty} x(t) \le 1$.

Finally we want to show that $V(x(t), y(t))$ is decreasing whenever it has sufficiently large values. To this end, let $\tilde{x} > 1$ and then choose $\tilde{y}$ such that $xb(x) - y < 0$ when $x \le \tilde{x}$ and $y \ge \tilde{y}$. Now when $V(x(t), y(t)) > \tilde{x} + \tilde{y}$ for large t, we must have $x(t), x(t-r) \le \tilde{x}$ (by the previous paragraph) and hence $y(t) > \tilde{y}$ so that $\dot{V} < x(t-r)\, b(x(t-r)) - y(t) < \tilde{x} b(\tilde{x}) - \tilde{y} < 0$. Thus for any solution after sufficiently long time, we have $\dot{V} < 0$ whenever $V(x(t), y(t)) > \tilde{x} + \tilde{y}$. Standard Lyapunov function considerations complete the argument. □

COROLLARY 6. *Suppose* $\alpha < 1$. *Then all positive solutions of* (9) *converge to* $(1, 0)$ *as* $t \to \infty$.

Proof. First we establish that $y(t) \to 0$ as $t \to \infty$. Let $\beta > 0$ such that $\alpha < \beta < 1$, and let $(x(t), y(t))$ be a positive solution of (9). By Lemma 5 there is a sufficiently large t^* such that $\alpha x(t) \le \beta$ for all $t \ge t^*$. This implies that

$$y'(t) \le -(1 - \beta) y(t), \quad t \ge t^*.$$

Therefore for $t \ge t^*$ we have

$$0 \le y(t) \le y(t^*) e^{-(1-\beta)(t-t^*)} \to 0 \quad \text{as } t \to \infty.$$

It follows that $y(t) \to 0$ as $t \to \infty$.

Next we claim that

$$M = \lim_{t\to\infty} \inf x(t) > 0.$$

Suppose to the contrary that $M = 0$. Then since $x(t) > 0$ for all $t \ge 0$, one is able to choose a sequence $\{t_n\}$ having the properties that

$$\begin{aligned} x(t_n - r) &\ge x(t_n),\\ x'(t_n) &\le 0 \end{aligned} \tag{11}$$

for all $n \ge 1$ and

$$\lim_{n\to\infty} x(t_n) = \lim_{n\to\infty} x'(t_n) = 0.$$

Since $\lim_{n\to\infty} x(t_n) = 0$, for which there is a J such that

$$x(t_n) < \frac{1}{2}, \quad n \ge J, \tag{12}$$

and since $b(x)$ is strictly decreasing, there is an $\varepsilon > 0$ such that

$$b(x(t_n)) \ge b(1) + \varepsilon = \gamma + \varepsilon, \quad n \ge J. \tag{13}$$

Moreover since $y(t) \to 0$ as $t \to \infty$, there exists $J_1 \geq J$ such that

$$\alpha y(t_n) < \varepsilon, \quad n \geq J_1. \tag{14}$$

Then for $n \geq J_1$ we have from (11), the increasing of $xb(x)$ and (11), and (12–14) that

$$\begin{aligned} 0 &\geq x'(t_n) \\ &= x(t_n - r)b(x(t_n - r)) - [\alpha y(t_n) + \gamma]\, x(t_n) \\ &\geq x(t_n)\, b(x(t_n)) - [\alpha y(t_n) + \gamma]\, x(t_n) \\ &> x(t_n)(\gamma + \varepsilon) - [\alpha y(t_n) + \gamma]\, x(t_n) \\ &> 0. \end{aligned}$$

This contradiction establishes that $M = \lim_{t\to\infty} \inf x(t) > 0$.

Finally we can show that $M = 1$. Let $t_n \to \infty$ in such a way that $x(t_n) \to M$ as $n \to \infty$ and

$$\lim_{n\to\infty} x'(t_n) = 0. \tag{15}$$

Since $\{x(t_n - r)\}$ is a bounded sequence, without loss of generality (or by choosing a subsequence) we can suppose that $x(t_n - r)$ converges,

$$\lim_{n\to\infty} x(t_n - r) = M_1. \tag{16}$$

By Lemma 5 and the definition of M it is obvious that

$$M \leq M_1 \leq 1.$$

Therefore (15, 16) yield

$$\begin{aligned} 0 &= \lim_{n\to\infty} x'(t_n) \\ &= \lim_{n\to\infty} x(t_n - r)b(x(t_n - r)) - \gamma \lim_{n\to\infty} x(t_n) \\ &= M_1 b(M_1) - \gamma M. \end{aligned}$$

We now show that this equality forces $M = M_1 = 1$. For if $M < 1$, then either $M < M_1$ or $M = M_1 < 1$. If $M < M_1$, then we have

$$M_1 b(M_1) \geq M_1 b(1) = M_1 \gamma > \gamma M,$$

a contradiction of the established equality. On the other hand, if $M = M_1 < 1$, then

$$M_1 b(M_1) > M_1 b(1) = M_1 \gamma = \gamma M,$$

again contradicting the equality.

Hence $M = \liminf_{t\to\infty} x(t) = 1$, which, in conjunction with Lemma 5 gives $x(t) \to 1$. □

Now let us suppose $\alpha > 1$ (i.e., $cN_0 > d_P$). Then the system (9) has a unique positive equilibrium (x^*, y^*). We proceed to study the local stability of this positive equilibrium.

First, following a straightforward calculation one is able to verify that the linearization of (9) at the positive equilibrium takes the form

$$u'(t) = [x^* b'(x^*) + b(x^*)]\, u(t-r) - (\alpha y^* + \gamma) u(t) - \alpha x^* v(t), \tag{17a}$$

$$v'(t) = \alpha y^* u(t). \tag{17b}$$

THEOREM 7. *The interior equilibrium (x^*, y^*) (which exists if and only if $\alpha > 1$) is locally asymptotically stable for all $r \geq 0$.*

Proof. Let $K = [x^* b'(x^*) + b(x^*)]$. The characteristic equation of (17) is given by

$$\begin{aligned}\Delta(\lambda, r) &= \det \begin{bmatrix} Ke^{-\lambda r} - \lambda - (\alpha y^* + \gamma) & -\alpha x^* \\ \alpha y^* & -\lambda \end{bmatrix} \\ &= \lambda^2 - \lambda K e^{-\lambda r} + \lambda(\alpha y^* + \gamma) + \alpha^2 x^* y^*.\end{aligned}$$

Note that $b'(x^*) < 0 \quad \text{and} \quad b(x^*) = \alpha y^* + \gamma$. Hence from the assumption (10c) we have

$$\alpha y^* + \gamma > |K|. \tag{18}$$

We observe that

$$\Delta(\lambda, 0) = \lambda^2 + (\alpha y^* + \gamma - K)\lambda + \alpha^2 x^* y^*.$$

It follows from (18) that all coefficients of $\Delta(\lambda, 0)$ are positive, and hence all zeros of $\Delta(\lambda, 0)$ have the negative real parts. We claim that for each fixed $r > 0$, all zeros of $\Delta(\lambda, r)$ are located in the left half complex plane. If this is not true, then there must be a $r > 0$ and $v \in \Re$ such that $\Delta(iv, r) = 0$, or equivalently,

$$\Delta(iv, r) = -v^2 - ivKe^{-i\nu r} + iv(\alpha y^* + \gamma) + \alpha^2 x^* y^* = 0.$$

That is,

$$-v^2 + \alpha^2 x^* y^* + iv(\alpha y^* + \gamma) = ivKe^{-ivr}.$$

This yields that

$$\left|-v^2 + \alpha^2 x^* y^* + iv(\alpha y^* + \gamma)\right|^2 = |ivKe^{-ivr}|^2.$$

Hence we obtain that

$$(\alpha^2 x^* y^* - v^2)^2 + (\alpha y^* + \gamma)^2 v^2 = K^2 v^2.$$

However, since $(\alpha y^* + \gamma)^2 > K^2$, the above equality can never hold for $v \in \Re$. This contradiction establishes our result. ∎

4. Invulnerable mature prey. Next we consider a case similar to that in the previous section in distinguishing between juvenile and adult prey, but opposite from it in assuming that predation affects juvenile prey but not mature prey. As before, we begin with the idea that the class of juveniles at time T consists of all those prey surviving from birth in the time interval $[T - R, T]$ and write

$$J(T) = \int_{T-R}^{T} N(s)\, B(N(s)) e^{-M}\, ds,$$

where N and B respectively represent the mature prey class and its per capita birth rate and M represents mortality effects. In addition to the "natural" mortality given by a constant per capita rate d_1 and represented in the previous section by $-d_1(T-s)$, we now include mortality by predation that is jointly proportional to the length of time $(T-s)$ such predation can occur and the average size of the predator class (denoted by P as before) over the interval $[s,T]$, so that

$$M = d_1(T-s) + d_2(T-s)\left(\frac{1}{T-s}\int_s^T P(u)\,du\right) = \int_s^T [d_1 + d_2 P(u)]\,du$$

and hence

$$J(T) = \int_{T-R}^{T} N(s)\,B(N(s))e^{-\int_s^T [d_1+d_2P(u)]du}\,ds.$$

Then from elementary calculations we find that

$$\begin{aligned}(19)\qquad \frac{dJ}{dT}(T) &= N(T)\,B(N(T)) - N(T-R)\,B(N(T-R))\,e^{-\int_{T-R}^{T}[d_1+d_2P(u)]du} \\ &\quad - [d_1 + d_2P(T)]\,J(T).\end{aligned}$$

The three terms comprising dJ/dT have nice interpretations: the first as current births, the second as loss to maturation of those who survived from birth (at time $T-R$) to the present, and the third as current loss due to the combination of constant per capita mortality and "mass-action" predation.

Assuming no predation directly on mature prey we arrive at the system of equations for (J,N,P) (with notation similar to that in the previous section)

$$\begin{aligned}\frac{dN}{dT}(T) &= N(T-R)\,B(N(T-R))\,F\left(\int_{T-R}^{T} P(u)\,du\right) - dN(T), \\ \frac{dP}{dT}(T) &= kP(T)\,J(T) \quad - d_P P(T),\end{aligned}$$

wherein we assume about F only the conditions

$$1 \geq F(0) > 0, \quad F(\infty) = 0, \quad F'(Z) < 0, \quad Z > 0$$

as motivated by our considerations in (19) where $F(Z) = e^{-d_1R - d_2Z}$. Notice that if the juvenile prey $J(T)$ were a constant proportional part of the mature prey population then the last two equations would decouple from the first and could be solved independently. Thus, with the goal of facilitating comparison with our two other models, we make the a priori assumption that $J(T) = CN(T)$. Thus, we consider the system

$$\begin{aligned}(20)\qquad \frac{dN}{dT}(T) &= N(T-R)\,B(N(T-R))\,F\left(\int_{T-R}^{T} P(u)\,du\right) - dN(T), \\ \frac{dP}{dT}(T) &= cP(T)\,N(T) \quad - d_P P(T).\end{aligned}$$

In order to achieve a satisfactory scaling of the model we desire an N_0 that functions like a prey carrying capacity in the absence of predators. As before we suppose

that the conditions (2a) and (7) on B continue to hold, as well as the modification of (2b) given by

$$B(0)F(0) > d > B(\infty)F(0). \tag{21}$$

In this situation, N_0 is uniquely determined by the condition

$$B(N_0)F(0) = d,$$

providing an equilibrium at $(N_0, 0)$. Under the scaling

$$\begin{aligned} x &= N/N_0, \quad t = d_P T, \quad \alpha = cN_0/d_P, \\ y &= P/N_0, \quad r = d_P R, \quad \gamma = d/d_P, \\ b(x) &= B(xN_0)/d_P, \qquad f(z) = F\left(\frac{N_0}{d_P} z\right) \end{aligned}$$

we find that (20) becomes the dimensionless system

$$\begin{aligned} \frac{dx}{dt}(t) &= x(t-r)b(x(t-r))f\left(\int_{-r}^{0} y(t+s)ds\right) - \gamma x(t), \\ \frac{dy}{dt}(t) &= \alpha x(t)y(t) - y(t). \end{aligned} \tag{22}$$

Notice that time has again been scaled by the reciprocal of the predator death rate and that $b(\cdot)$ and $f(\cdot)$ satisfy conditions similar to (10) in section 3:

$$b(x) \geq 0 \quad \text{and} \quad b'(x) < 0 \qquad \text{for } x \geq 0, \tag{23}$$

$$b(0)f(0) > \gamma > b(\infty)f(0) \quad \text{and} \quad b(1)f(0) = \gamma, \tag{24}$$

$$b(x) + xb'(x) \geq 0, \tag{25}$$

$$1 \geq f(0) > 0, \quad f(\infty) = 0, \quad \frac{df}{dz} < 0, \quad z > 0. \tag{26}$$

Just as in the systems (3) and (9), this system has no strictly positive equilibrium if $\alpha < 1$ and has a unique positive equilibrium if $\alpha > 1$.

THEOREM 8. *If $\alpha < 1$, then all positive solutions of (22) converge to the equilibrium $(1, 0)$.*

Proof. Following essentially the same argument as in the second paragraph of the proof of Lemma 5, one establishes that $\limsup_{t\to\infty} x(t) \leq 1$. Given a positive solution $(x(t), y(t))$ we can find a T such that for $t \geq T$, $\alpha x(t) - 1$ is negative and bounded away from zero. Since

$$y'(t) \leq (\alpha x(t) - 1)\, y(t),$$

we find that $y(t) \to 0$ as claimed. The rest of the argument is similar to that given for proof of Corollary 6. ∎

For the rest of this section we consider the remaining case in which $\alpha > 1$. In this case an equilibrium (x^*, y^*) must satisfy $x^* = 1/\alpha < 1$ so that

$$b(x^*)f(z^*) - \gamma = 0$$

has a unique solution $z^* = ry^* > 0$. Thus for each fixed $r > 0$, (22) has the unique positive equilibrium $(x^*, y^*) = (1/\alpha, z^*/r)$. We will show that an increase of the time

delay r will destabilize the stability of this positive equilibrium and cause a Hopf bifurcation.

First a direct computation yields that the linearization of (22) around the positive equilibrium is given by

$$\begin{aligned} u'(t) &= au(t-r) - \gamma u(t) - b\int_{-r}^{0} v(t+s)ds, \\ v'(t) &= \alpha y^* u(t), \end{aligned}$$

where

$$a = [b(x^*) + x^* b'(x^*)]\, f(z^*), \tag{27a}$$

$$b = -x^* b(x^*) \frac{df}{dz}(z^*) > 0. \tag{27b}$$

Therefore the characteristic equation is given by

$$\begin{aligned} \Delta(\lambda, r) &= \det \begin{bmatrix} ae^{-\lambda r} - \gamma - \lambda & -b\int_{-r}^{0} e^{\lambda s} ds \\ \alpha y^* & -\lambda \end{bmatrix} \\ &= \lambda^2 + \gamma\lambda - a\lambda e^{-\lambda r} + \frac{\beta(1 - e^{-\lambda r})}{r\lambda} \qquad (28) \\ &= 0, \end{aligned}$$

where $\beta = \alpha b z^*$.

To study the location of eigenvalues of the characteristic equation (28), an important first step is to investigate the existence of eigenvalues that lie on the imaginary axis of the complex plane and the direction in which these eigenvalues cross that axis as the delay increases. We note that if $\Delta(iv, r) = 0$, then $\Delta(-iv, r) = 0$ so that we shall only search for eigenvalues iv with $v > 0$. Letting

$$h(\lambda, r) = r\lambda^3 + \gamma r\lambda^2 - ar\lambda^2 e^{-\lambda r} + \beta(1 - e^{-\lambda r}), \tag{29}$$

it is clear that $\Delta(\lambda, r) = 0$ if and only if $h(\lambda, r) = 0$ for $\lambda \neq 0$ and $r > 0$.

LEMMA 9. *There are infinitely many positive pairs of (iv, r) with $r > 0$ and $v = v(r) > 0$ such that $\Delta(iv, r) = 0$. However, there is an interval $0 < r < r_1$ such that $\Delta(\lambda, r)$ has no purely imaginary zeros.*

Proof. Note that with $r > 0$, $\gamma = b(x^*)f(z^*)$, the assumptions on b and f imply that

$$\gamma > |a|, \quad \beta > 0.$$

Notice that in $\Delta(\lambda, r)$, neither a nor β depends on r. Thus

$$\Delta(\lambda, 0) = \lambda^2 + (\gamma - a)\lambda + \beta \tag{30}$$

and the interval $(0, r_1)$ on which there are no purely imaginary characteristic zeros follows immediately from continuity.

Considering $\lambda = iv$, if

$$h(iv, r) = 0 \tag{31}$$

for some $v > 0$ and $r > 0$, then we have

$$\frac{-irv^3 + \beta - \gamma r v^2}{(\beta - arv^2)} = e^{-ivr} \tag{32}$$

so that

$$| - irv^3 + \beta - \gamma r v^2|^2 = |\beta - arv^2|^2, \tag{33}$$

or

$$r^2 v^6 + (\beta - \gamma r v^2)^2 = (\beta - arv^2)^2, \tag{34}$$

and finally

$$rv^4 + r(\gamma^2 - a^2)v^2 = 2\beta(\gamma - a). \tag{35}$$

We can solve (35) uniquely for $v^2 = v^2(r)$,

$$v^2 = \frac{1}{2}\left(-(\gamma^2 - a^2) + \sqrt{(\gamma^2 - a^2)^2 + \frac{8\beta(\gamma - a)}{r}}\right) . \tag{36}$$

Thus we have shown that if $h(iv, r) = 0$, then $v = v\,(r)$ with $v > 0$ must satisfy (36). However, it is really the converse question that we must answer: if $v\,(r)$ is the positive branch of (36), do we have $h\,(iv\,(r)\,, r) = 0$? However, for $v > 0$, (36) is equivalent to (33), so that if we let $W\,(r)$ denote the left-hand side of (32) with $v = v(r)$, then $|W\,(r)| = 1$ for all $r > 0$.

Multiplying (36) by r^2 we have

$$(rv)^2 = \frac{1}{2}\left(-r^2(\gamma^2 - a^2) + \sqrt{r^4(\gamma^2 - a^2)^2 + 8r^3\beta(\gamma - a)}\right). \tag{37}$$

From this, one immediately sees that

$$\lim_{r\to 0}[rv(r)]^2 = 0. \tag{38}$$

Moreover, rationalizing the numerator in (37) we have

$$(rv)^2 = \frac{8r^3\beta(\gamma - a)}{2\left(r^2(\gamma^2 - a^2) + \sqrt{r^4(\gamma^2 - a^2)^2 + 8r^3\beta(\gamma - a)}\right)}$$

which yields

$$\lim_{r\to\infty}[rv(r)]^2 = \infty. \tag{39}$$

It follows from (38) and (39) that

$$\lim_{r\to 0} rv(r) = 0 \qquad \text{and} \qquad \lim_{r\to\infty} rv(r) = \infty. \tag{40}$$

Next from (34) we have that $\beta - rav^2(r) > 0$ for all $r > 0$. For if this inequality does not hold for some $r > 0$, then we have $|\beta - arv^2(r)| = arv^2(r) - \beta$. Since $\gamma > a$ we have $\gamma r v^2(r) - \beta > arv^2(r) - \beta$. It would therefore follow that

$$r^2 v^6(r) + (\beta - \gamma r v^2(r))^2 > (\beta - arv^2(r))^2,$$

contradicting (34).

Finally, substitute $v = v(r)$ into (32). Letting r increase from 0 to ∞ and using (40), we find that e^{-irv} on the right side traces out the unit circle infinitely often, while on the left side $W(r)$ remains in the lower half of the unit circle. Now one easily sees that there are infinitely many positive r's such that $h(iv(r), r) = 0$. □

LEMMA 10. *Let $\lambda(r)$ be a branch of zeros of $h(\lambda, r)$ defined on an interval I such that for some $0 < r_0 \in I$, $\lambda(r_0) = iv_0$ with $v_0 > 0$. Then v_0 is a simple zero and*

$$\mathrm{Re}\left(\frac{d\lambda(r_0)}{dr}\right) > 0.$$

Proof. Since $h(\lambda(r), r) \equiv 0$, we have

$$\frac{\partial h(\lambda, r)}{\partial \lambda}\frac{d\lambda}{dr} = -\frac{\partial h(\lambda, r)}{\partial r}.$$

Hence

$$\overline{\left[\frac{\partial h(\lambda, r)}{\partial \lambda}\right]}\frac{\partial h(\lambda, r)}{\partial \lambda}\frac{d\lambda}{dr} = -\overline{\left[\frac{\partial h(\lambda, r)}{\partial \lambda}\right]}\frac{\partial h(\lambda, r)}{\partial r},$$

where $\overline{z}$ denotes the conjugate of a complex number z. It follows from this equality that

$$\mathrm{sign}\left(\mathrm{Re}\frac{d\lambda(r_0)}{dr}\right) = \mathrm{sign}\left(\mathrm{Re}\left\{-\overline{\left[\frac{\partial h(iv_0, r_0)}{\partial \lambda}\right]}\frac{\partial h(iv_0, r_0)}{\partial r}\right\}\right).$$

For notational simplicity from now on we use v and r instead of v_0 and r_0. First from (29) we deduce that

$$iv^3 + \gamma v^2 - av^2 e^{-ivr} = \frac{\beta}{r}(1 - e^{-ivr}), \tag{41}$$

or equivalently, after complex conjugation

$$v^2 + i\gamma v - iave^{ivr} = \frac{i\beta}{rv}(1 - e^{ivr}). \tag{42}$$

Following a straightforward computation and with the use of (41) and (42) we have

$$\begin{aligned}\overline{\left[\frac{\partial h(iv, r)}{\partial \lambda}\right]} &= r\left[-3v^2 - i2\gamma v + i2ave^{ivr} + (\beta - arv^2)e^{ivr}\right] \\ &= r\left[-3(v^2 + i\gamma v - iave^{ivr}) + i(\gamma - a)v + iav(1 - e^{ivr})\right] \\ &\quad + r(\beta - arv^2)e^{ivr} \\ &= r\left[i(\gamma - a)v + i(av - \frac{3\beta}{rv})(1 - e^{ivr}) + (\beta - arv^2)e^{ivr}\right],\end{aligned} \tag{43}$$

$$\begin{aligned}-\frac{\partial h(iv, r)}{\partial r} &= iv^3 + \gamma v^2 - av^2 e^{-ivr} - iv(\beta - arv^2)e^{-ivr} \\ &= \frac{\beta}{r}(1 - e^{-ivr}) - iv(\beta - arv^2)e^{-ivr}.\end{aligned} \tag{44}$$

Let

$$\Phi = -\overline{\left[\frac{\partial h(iv,r)}{\partial \lambda}\right]}\frac{\partial h(iv,r)}{\partial r}.$$

It is clear that if $\mathrm{Re}\Phi > 0$, then $\frac{\partial h(iv,r)}{\partial \lambda} \neq 0$ which will imply that $iv = iv_0$ is a simple eigenvalue and $\mathrm{Re}\frac{d\lambda(r_0)}{dr} > 0$. Hence to complete the proof of Lemma 10, it is sufficient to show that $\mathrm{Re}\Phi > 0$. First by (43) and (44) we have

$$\begin{aligned}\mathrm{Re}\Phi &= \mathrm{Re}\left\{\beta(1-e^{-ivr})\left[i(\gamma-a)v + (\beta - arv^2)e^{ivr}\right]\right\}\\ &\quad + \mathrm{Re}\left\{-ivr(\beta-arv^2)e^{-ivr}\left[-3v^2 - i2\gamma v + i2ave^{ivr}\right]\right\}\\ &= \mathrm{Re}\Phi_1 + \mathrm{Re}\Phi_2\end{aligned}$$

with

$$\begin{aligned}\Phi_1 &= \beta(1-e^{-ivr})\left[i(\gamma-a)v + (\beta-arv^2)e^{ivr}\right],\\ \Phi_2 &= -ivr(\beta-arv^2)e^{-ivr}\left[-3v^2 - i2\gamma v + i2ave^{ivr}\right].\end{aligned}$$

Following a further calculation we have

$$\begin{aligned}\mathrm{Re}\Phi_1 &= -\beta(\gamma-a)v\sin(vr) - \beta(\beta - arv^2)[1-\cos(vr)],\\ \mathrm{Re}\Phi_2 &= (\beta - arv^2)\left[3rv^3\sin(vr) - 2\gamma rv^2\cos(vr) + 2arv^2\right].\end{aligned} \tag{45}$$

Next, by separating the real and imaginary parts of (32) we obtain

$$\begin{aligned}(\beta - arv^2)\cos(vr) &= \beta - \gamma rv^2,\\ (\beta - arv^2)\sin(vr) &= rv^3.\end{aligned} \tag{46}$$

With the use of (35), (45), and (46) we finally arrive at

$$\begin{aligned}\mathrm{Re}\Phi &= -\beta(\gamma-a)v\sin(vr) - \beta(\beta-arv^2) + \beta(\beta-\gamma rv^2)\\ &\quad + 3r^2v^6 - 2\gamma rv^2(\beta-\gamma rv^2) + 2arv^2(\beta-arv^2)\\ &= -\beta(\gamma-a)v\sin(vr) - 3r\beta v^2(\gamma-a) + 3r^2v^6 + 2r^2v^4(\gamma^2-a^2)\\ &= -\beta(\gamma-a)v\sin(vr) + r^2v^6 + r\beta v^2(\gamma-a)\\ &\quad + 2r^2v^6 + 2r^2v^4(\gamma^2-a^2) - 4rv^2\beta(\gamma-a)\\ &= -\beta(\gamma-a)v\sin(vr) + r^2v^6 + r\beta v^2(\gamma-a)\\ &> \beta(\gamma-a)v\left[rv - \sin(vr)\right]\\ &\geq 0. \qquad \square\end{aligned}$$

Now we are ready to prove the following result.

THEOREM 11. *Suppose that $\alpha > 1$. Then there is a sequence $\{r_n\}_{n=1}^{\infty}$ with*

$$0 < r_1 < r_2 < \cdots < r_n < \cdots$$

such that the following hold:

1. *If $0 < r < r_1$, then the positive equilibrium $(x^*, y^*) = (1/\alpha, z^*/r)$ of (22) is linearly stable. If $r > r_1$ then that positive equilibrium is linearly unstable.*
2. *For each $n \in \mathbf{N}$ there is a $v_n > 0$ such that $\lambda = \pm iv_n$ are eigenvalues associated with the equilibrium (x^*, y^*) of (22) at $r = r_n$ and there is a Hopf bifurcation there.*

Proof. Using Lemmas 9 and 10 with the application of classical results on stability switches (for example, see [7]) and on Hopf bifurcation (e.g., [10], p. 291), we need only to show that all solutions of the characteristic equation

$$\Delta(\lambda, r) = \lambda^2 + \gamma\lambda - a\lambda e^{-\lambda r} + \frac{\beta(1 - e^{-\lambda r})}{r\lambda} = 0$$

have negative real parts for all $r \in [0, r_1)$, where r_1 is taken to be the smallest positive delay at which the characteristic function has a purely imaginary zero. The existence of r_1 is guaranteed by Lemma 9.

Now for a characteristic root $\lambda = \lambda(r) = u + iv$ with $r \geq 0$ and $u \geq 0$ we have

$$\begin{aligned} \left|1 - e^{-\lambda r}\right| &\leq \left|1 - e^{-ur} + e^{-ur}\left(1 - \cos(vr) + i\sin(vr)\right)\right| \\ &\leq \left|1 - e^{-ur}\right| + \left|1 - \cos(vr)\right| + \left|\sin(vr)\right| \\ &\leq |ur| + 2|vr| \leq 3|\lambda r|. \end{aligned}$$

From this we can conclude that

$$\left|\frac{\beta\left(1 - e^{-\lambda r}\right)}{r\lambda}\right| \leq 3\beta.$$

It now follows from this that there is a sufficiently large constant C such that for all $\lambda \in \mathbf{C}$ with $\mathrm{Re}(\lambda) \geq 0$ and $|\lambda| \geq C$,

$$\lambda^2 + \gamma\lambda - a\lambda e^{-\lambda r} + \frac{\beta(1 - e^{-\lambda r})}{r\lambda} \neq 0.$$

Since $\Delta(\lambda, r)$, with $\Delta(\lambda, 0)$ as in (30), is analytic in $\lambda \neq 0$ and continuous in $r \geq 0$, it follows that its number of zeros on $\mathrm{Re}\lambda \geq 0$ is constant for $r \in [0, r_1)$. Since $\Delta(\lambda, 0)$ has only zeroes with negative real part, our result holds. ∎

5. Inactive juvenile predators. We now consider the effect of taking into account an inactive juvenile class of predator. Thus all predation is done by the adult predators which we still denote by P, but we change J to denote the juvenile predators and keep N to denote the prey. Taking the model (1) again as our starting point, we assume that the juvenile class (consisting of those predators from ages 0 to R) is the direct beneficiary of predation and is subject to a constant mortality rate d_1 and so is given by

$$J(T) = \int_{T-R}^{T} cN(s)\,P(s)\,e^{-d_1(T-s)}\,ds$$

with derivative

$$J'(T) = cN(T)\,P(T) - cN(T-R)\,P(T-R)\,e^{-d_1 R} - d_1 J(T). \tag{47}$$

Interpreting the three terms of the last expression, we find that the first is the current rate of juvenile births, while the second is the current rate of maturation of surviving juveniles to adulthood, and the third is current juvenile mortality. Thus

$$N'(T) = N(T)B(N(T)) - aN(T)P(T) - dN(T) \tag{48a}$$

$$P'(T) = cN(T-R)\,P(T-R)\,e^{-d_1 R} - d_P P(T). \tag{48b}$$

We suppose that the conditions (2a), (2b), and (7) on B continue to hold. As in section 2 we define N_0 by the condition

$$B(N_0) = d.$$

Since (48a) and (48b) can be decoupled and solved independently from (47), we can again restrict our attention to the differential equations (with delays) for (N, P).

We will again find that our analysis is facilitated by a scaling of the variables. If

$$\begin{array}{ccc} x = N/N_0, & t = d_P T, & \alpha = ce^{-d_1 R} N_0/d_P, \\ y = ae^{d_1 R} P/cN_0, & r = d_P R, & \gamma = d/d_P, \\ & b(x) = B(xN_0)/d_P, & \end{array} \tag{49}$$

then the system (48) takes the (nondimensional) form (for scaled prey and adult predators, respectively x and y)

$$\frac{dx}{dt} = x(t)\, b(x(t)) - \alpha x(t)\, y(t) - \gamma x(t) \tag{50a}$$

$$\frac{dy}{dt} = \alpha x(t-r)\, y(t-r) - y(t). \tag{50b}$$

Notice that in this scaling the transfer from x to y by the scaled predation is again perfectly efficient, and the mortality factor, $e^{-d_1 R}$, is scaled out. The properties of b take the same form as in (10). The boundary equilibria are again at $(0,0)$ and $(1,0)$. A somewhat simplified version of the proof in the second paragraph of the proof for Lemma 7 gives us

LEMMA 12. *For every positive solution* $(x(t), y(t))$, $\limsup_{t\to\infty} x(t) \le 1$.

COROLLARY 13. *Suppose* $\alpha < 1$. *Then all positive solutions of* (50) *converge to* $(1,0)$ *as* $t \to \infty$.

Proof. Let $(x(t), y(t))$ be a positive solution. First we show that $y(t) \to 0$. If β is chosen such that $\alpha < \beta < 1$ then by the above lemma there is some t^* such that $\alpha x(t-r) \le \beta$ for all $t \ge t^*$ and so

$$y'(t) = \alpha x(t-r)\, y(t-r) - y(t) \le \beta y(t-r) - y(t). \tag{51}$$

Since $0 < \beta < 1$, all solutions of

$$w'(t) = \beta w(t-r) - w(t) \tag{52}$$

tend to zero as $t \to \infty$ ([5], section 2). Furthermore all solutions of (52) with positive initial data remain positive for all positive t. From these considerations we can conclude ([20]) that if a solution $w(t)$ of (52) shares positive initial data with $y(t)$ then $0 < y(t) \le w(t)$ for all $t \ge 0$. So

$$y(t) \to 0 \tag{53}$$

as claimed.

Setting $M = \liminf_{t\to\infty} x(t) > 0$, one shows that $M > 0$ in exactly the same way as in Corollary 6. Now we show $M = 1$. (Recall $b(1) = \gamma$.) Suppose not. Then by the previous lemma, $M \le 1$, so $0 < M < 1$. Let M_1 be such that $M < M_1 < 1$. Then $b(M_1) - \gamma > b(1) - \gamma = 0$. By (53), for all t larger than some T_1,

we have $0 < \alpha y(t) < (b(M_1) - \gamma)/2$ and $x(t) \geq M/2$. Hence whenever $t > T_1$ and $\frac{1}{2}M \leq x(t) \leq M_1$, we have

$$\begin{aligned} x'(t) &= x(t)(b(x(t)) - \alpha y(t) - \gamma) \\ &\geq \frac{M}{2}\left(b(M_1) - \frac{(b(M_1) - \gamma)}{2} - \gamma\right) \\ &= \frac{M}{2}(b(M_1) - \gamma)/2 \end{aligned}$$

providing a uniform positive lower bound on $x'(t)$ whenever t is large and $\frac{1}{2}M \leq x(t) \leq M_1$ if $M < 1$, another contradiction. Hence $M = 1$ and

$$\liminf_{t\to\infty} x(t) = \limsup_{t\to\infty} x(t) = \lim_{t\to\infty} x(t) = 1,$$

as desired. □

Finally we consider the case $\alpha > 1$. (For an interpretation of α, see section 6.) In this case $b(1/\alpha) > b(1) = \gamma$ and there is a positive equilibrium (x^*, y^*),

$$\begin{aligned} x^* &= 1/\alpha, \\ y^* &= (b(1/\alpha) - \gamma)/\alpha. \end{aligned}$$

To simplify notation somewhat, we let $b_* = b(x^*)$ and $b'_* = b'(x^*)$. Note that $b_* > \gamma$ and $b'_* < 0$ and that both b_* and b'_* depend on α.

THEOREM 14. *Consider* (50) *in the case* $\alpha > 1$, *that is, in the case that there is an interior equilibrium* (x^*, y^*).

1. *If* $\alpha(b_* - \gamma) + 2b'_* < 0$ *the equilibrium* (x^*, y^*) *is linearly stable for all delays* $r \geq 0$;
2. *If* $\alpha(b_* - \gamma) + 2b'_* > 0$ *then there is a critical delay* $r_1 > 0$ *such that the equilibrium* (x^*, y^*) *is linearly stable for all delays* $0 \leq r < r_1$ *and is linearly unstable for all delays* $r > r_1$. *A Hopf bifurcation occurs as* r *increases through* r_1.

Proof. The linearization of (50) about (x^*, y^*) is

$$\begin{aligned} u'(t) &= x^* b'_* u(t) - \alpha x^* v(t) \\ &= b'_* u(t)/\alpha - v(t) \\ v'(t) &= \alpha y^* u(t - r) + \alpha x^* v(t - r) - v(t) \\ &= (b_* - \gamma) u(t - r) + v(t - r) - v(t), \end{aligned}$$

yielding the linear equation for solutions of the form $(u(t), v(t)) = e^{zt}(u_0, v_0)$,

$$ze^{zt}\begin{bmatrix} u_0 \\ v_0 \end{bmatrix} = e^{zt}\begin{bmatrix} b'_*/\alpha & -1 \\ (b_* - \gamma)e^{-zr} & (e^{-zr} - 1) \end{bmatrix}\begin{bmatrix} u_0 \\ v_0 \end{bmatrix}$$

and the characteristic equation

$$\begin{aligned} 0 &= \det\begin{bmatrix} b'_*/\alpha - z & -1 \\ (b_* - \gamma)e^{-zr} & e^{-zr} - 1 - z \end{bmatrix} \\ &= \frac{1}{\alpha}\left(-b'_* - (b'_* - \alpha)z + \alpha z^2 + e^{-zr}(b'_* + \alpha b_* - \alpha\gamma - \alpha z)\right) \end{aligned}$$

or

$$0 = \alpha z^2 - (b'_* - \alpha)z - b'_* + e^{-zr}(-\alpha z + \alpha b_* + b'_* - \alpha\gamma). \tag{54}$$

We apply the results of Cooke and van den Driessche [7] to analyze the roots of the characteristic equation. In their notation, we set

$$P(z) = \alpha z^2 - (b'_* - \alpha) z - b'_*, \tag{55}$$
$$Q(z) = -\alpha z + \alpha (b_* - \gamma) + b'_*.$$

According to [7], $z = iy$ is a purely imaginary characteristic root only if $F(y) = 0$ where $F(y) = |P(iy)|^2 - |Q(iy)|^2$, and furthermore:

1. If $F(y) = 0$ has no positive roots and the equilibrium is stable when $r = 0$, then it is stable for all $r > 0$.
2. If $F(y) = 0$ has a positive root and each positive root is simple, then there is an r_1 such that the equilibrium is unstable for $r > r_1$ and the direction of a characteristic root crossing the imaginary axis is given by the sign of $F'(y)$.

To apply these results, we find

$$\begin{aligned} F(y) &= \left|-\alpha y^2 - (b'_* - \alpha) iy - b'_*\right|^2 - \left|-\alpha iy + \alpha (b_* - \gamma) + b'_*\right|^2 \\ &= \alpha^2 y^4 + b'^2_* y^2 - \alpha^2 b^2_* + 2\alpha^2 b_* \gamma - 2\alpha b_* b'_* - \alpha^2 \gamma^2 + 2\alpha b'_* \gamma. \end{aligned}$$

Let's examine the constant term of $F(y)$,

$$\alpha \left(-\alpha b^2_* + 2\alpha b_* \gamma - 2 b_* b'_* + 2 b'_* \gamma - \alpha \gamma^2\right) = -\alpha (b_* - \gamma) (2 b'_* + \alpha (b_* - \gamma)).$$

As mentioned just before this theorem, the assumption of $\alpha > 1$ gives us $b_* > \gamma$. Since $b'_* < 0$ the sign of the factor $2b'_* + \alpha (b_* - \gamma)$ can vary depending on the implementation of $b(x)$.

Clearly if $2b'_* + \alpha (b_* - \gamma) < 0$, then F has no real zeros and so the characteristic equation has no purely imaginary roots. According to [7], since the equilibrium is stable under zero delay (Theorem 4), it is stable under all nonnegative delays.

However, if $2b'_* + \alpha (b_* - \gamma) > 0$, then F will have exactly one positive zero, corresponding to a characteristic root with positive imaginary part. In this case the direction of a characteristic root crossing the imaginary axis is given by the sign of $F'(y)$ [7] which is positive when y is positive. So any crossing is transverse, from left to right. The second conclusion of the theorem now follows exactly from [7] and standard bifurcation theory (e.g. [14], p. 332). □

Since Theorem 14 concerns the dimensionless system (50) obtained by scaling out the physical presence of the delay from (48), we should explain how this theorem can be applied to the dimensional system (48). First note that $\alpha > 1$ is equivalent to $d_P e^{d_1 R}/c < N_0$, so that the latter is equivalent to the existence of a positive equilibrium. Upon a substitution of the original parameters into the inequality of part 1 in Theorem 14, we conclude that the positive equilibrium of system (48) exists and is linearly stable if $d_P e^{d_1 R}/c < N_0$ and $ce^{-d_1 R} N_0 \left(B(d_P e^{d_1 R}/c) - d\right) + 2B'(d_P e^{d_1 R}/c) N_0 d_P < 0$.

However, for the bifurcation at $F = 0$ one must proceed cautiously when translating the results from the nondimensional case of Theorem 14 to the dimensional case which motivates it. We naturally inquire if a bifurcation, such as given by Theorem 14 in the nondimensional case with r increasing, is mirrored by one in the corresponding original system (48) with R as the bifurcation parameter and all other parameters (except r) held fixed. However, such variation of parameters is inherently contradictory! Since

$$\alpha = ce^{-d_1 R} N_0 / d_P, \tag{56}$$

we see that if we seek bifurcation in the original system (48) with only R varying, then we must examine Theorem 14 as α varies, instead of relying on it to be constant, with $\alpha > 1$, as assumed in the hypotheses of the theorem. In particular, *if* we increase R while holding fixed all the other parameters in (48), then $\alpha = ce^{-d_1 R}N_0/d_P$ must decrease, eventually violating the theorem's hypothesis of $\alpha > 1$.

Fortunately, a bifurcation diagram for system (48) can be calculated in the $(R\,, c)$ parameter plane (while all parameters other than R, c are fixed). To proceed with this for each given $\alpha > 0$, let the curve Γ_α be the level curve of (56) in the (R, c) plane, i.e., the graph of the function

$$c = \alpha d_P e^{d_1 R}/N_0, \qquad (R \geq 0)$$

with (d_1, d_P, N_0) fixed. There is a positive equilibrium corresponding to some (R, c) on Γ_α if and only if $\alpha > 1$. For such α, let $r_1 = r_1(\alpha)$ be the unique positive value defined in part 2 of Theorem 14 and let $R_1 = R_1(\alpha) = r_1(\alpha)/d_p$. Then from Theorem 14 it immediately follows that such an equilibrium is linearly stable (respectively, unstable) if $R < R_1$ (respectively, $R > R_1$). Moreover, a Hopf bifurcation occurs as the point (R, c) passes through (R_1, c_1) along Γ_α, where $c_1 = c_1(\alpha) = \alpha d_P e^{d_1 R_1(\alpha)}/N_0$.

Let $K\,(\alpha)$ denote the critical quantity distinguishing the cases of Theorem 14:

$$K(\alpha) = \alpha(b(1/\alpha) - \gamma) + 2b\prime(1/\alpha) \qquad (\alpha > 1).$$

It is clear that

$$K(\alpha) \to +\infty \quad \text{as} \quad \alpha \to \infty.$$

Let us first consider the simple case in which there is a unique $\alpha^* > 1$ such that $K(\alpha^*) = 0$ and $K(\alpha) > 0$ for $\alpha > \alpha^*$. (In section 6 α^* exists and is given for birth function b_i by $\alpha^* = \alpha_i, i = 1, 2, 3.$) Then for each $\alpha > \alpha^*$, there is a unique bifurcation point $(R_1(\alpha), c_1(\alpha))$ in the curve Γ_α. It is obvious that the bifurcation point $(R_1(\alpha), c_1(\alpha))$ is continous with respect to α (but formulas are supplied below). Thus by varying α from α^* to ∞ we obtain a simple bifurcation curve in the (R, c) parameter plane that does not intersect itself. In what follows we shall show that the function $R_1(\alpha)$ has a nice property that

$$\lim_{\alpha \to \alpha^*} R_1(\alpha) = +\infty, \qquad \lim_{\alpha \to \infty} R_1(\alpha) = 0.$$

One readily finds closed form expression for the bifurcation delay r_1 in the nondimensional equations (50) as it depends on α. When $K\,(\alpha) > 0$ the function F in the proof of Theorem 14 has a unique positive zero y_0 and r_1 is the least positive solution of $P + e^{-iy_0 r}Q = 0$. Thus, remembering that P, Q, F, y_0 depend on α, r_1 is a composition of two functions:

$$y_0\,(\alpha) = \sqrt{\frac{1}{2A}\left(-B + \sqrt{B^2 - 4AC}\right)}, \tag{57}$$

where

(58)

$$A = \alpha^2, \qquad B = b'\,(1/\alpha)^2\,, \qquad C = -\alpha\,(b\,(1/\alpha) - \gamma)\,(2b'\,(1/\alpha) + \alpha\,(b\,(1/\alpha) - \gamma))\,,$$

followed by

$$r_1\,(\alpha) = \rho\,(\alpha) = \frac{1}{y_0\,(\alpha)} \arg\left(\frac{-Q\,(iy_0\,(\alpha)\,, \alpha)}{P\,(iy_0\,(\alpha)\,, \alpha)}\right), \tag{59}$$

where arg denotes the argument of a complex number. Using the expressions of P, Q one is able to verify that for all sufficiently large α,

$$0 < \arg\left(\frac{-Q(iy_0(\alpha),\alpha)}{P(iy_0(\alpha),\alpha)}\right) < \pi. \tag{60}$$

Furthermore, (57) and (58) yield that

$$\lim_{\alpha\to\infty} y_0(\alpha) = \sqrt{b(0)-\gamma}, \qquad \lim_{\alpha\to\infty} \frac{-Q(iy_0(\alpha),\alpha)}{P(iy_0(\alpha),\alpha)} = 1 \tag{61}$$

and it follows from (59) and (61) that

$$\lim_{\alpha\to\infty} R_1(\alpha) = \frac{1}{d_P}\lim r_1(\alpha) = \frac{1}{d_P\sqrt{b(0)-\gamma}}\arg(1) = 0. \tag{62}$$

Finally we easily see that

$$\lim_{\alpha\to\alpha^*} y_0(\alpha) = 0, \qquad \lim_{\alpha\to\alpha^*} \frac{-Q(iy_0(\alpha),\alpha)}{P(iy_0(\alpha).\alpha)} = -1 \tag{63}$$

which implies that

$$R_1(\alpha) \to +\infty \quad \text{as} \quad \alpha \searrow \alpha^*. \tag{64}$$

With the use of (62) and (64) we can describe the bifurcation diagram of the dimensional system (48) in the (R, c) plane (see Figure 1). The positive quadrant of the (R, c) plane is divided into three parts by the curves $\Gamma_1 : c = d_P e^{d_1 R}/N_0$ and $\Gamma = \{(R_1(\alpha), c_1(\alpha)) : \alpha \in (\alpha^*, \infty)\}$. The curve Γ is asymptotic to the graph $\Gamma_{\alpha^*} : c = \alpha^* d_P e^{d_1 R}/N_0$ as $\alpha \searrow \alpha^*$ and is asymptotic to the vertical line $R = 0$ as $\alpha \to \infty$. Region I corresponds to system (48) having no positive equilibrium; region II corresponds to system (48) having a stable positive equilibrium; and region III corresponds to system (48) with an unstable positive equilibrium. Γ is a hopf bifurcation curve.

We finally remark that if there is any pair of two numbers $1 < \alpha_1 < \alpha_2$ such that $K(\alpha_1) = K(\alpha_2) = 0$, with $K(\alpha) > 0, \alpha \in (\alpha_1, \alpha_2)$ then the curve $\{(R_1(\alpha), c_1(\alpha)) : \alpha \in (\alpha_1, \alpha_2)\}$ gives rise to a Hopf bifurcation curve that is asymptotic to the graph Γ_{α_i} as $\alpha \to \alpha_i$ for $i = 1, 2$.

The parameterization of Γ, $(R_1(\alpha), c_1(\alpha))$ can be found with $R_1(\alpha)$ explicitly and $c_1(\alpha)$ explicitly, using (59) and $c = \alpha d_P e^{d_1 R}/N_0$. Since

$$R_1 = r_1/d_P = \rho(\alpha)/d_P = \rho\left(ce^{-d_1 R_1} N_0/d_P\right)/d_P,$$

we have

$$R_1(\alpha) = r_1(\alpha)/d_P = \rho(\alpha)/d_P, \tag{65}$$

$$c_1(\alpha) = d_p e^{d_1 R_1(\alpha)} \sigma(d_P R_1(\alpha))/N_0 \tag{66}$$

if σ inverts ρ. When one has ρ numerically, σ just reverses the coordinates, so this is easy to plot.

We consider two examples. Since the physical presence of the delay is a key feature in (48), we simplify everything else as much as possible (but with some minimal care to respect biological interpretation of the parameters: see below), taking

$$a = d_1 = d_P = N_0 = 1,$$

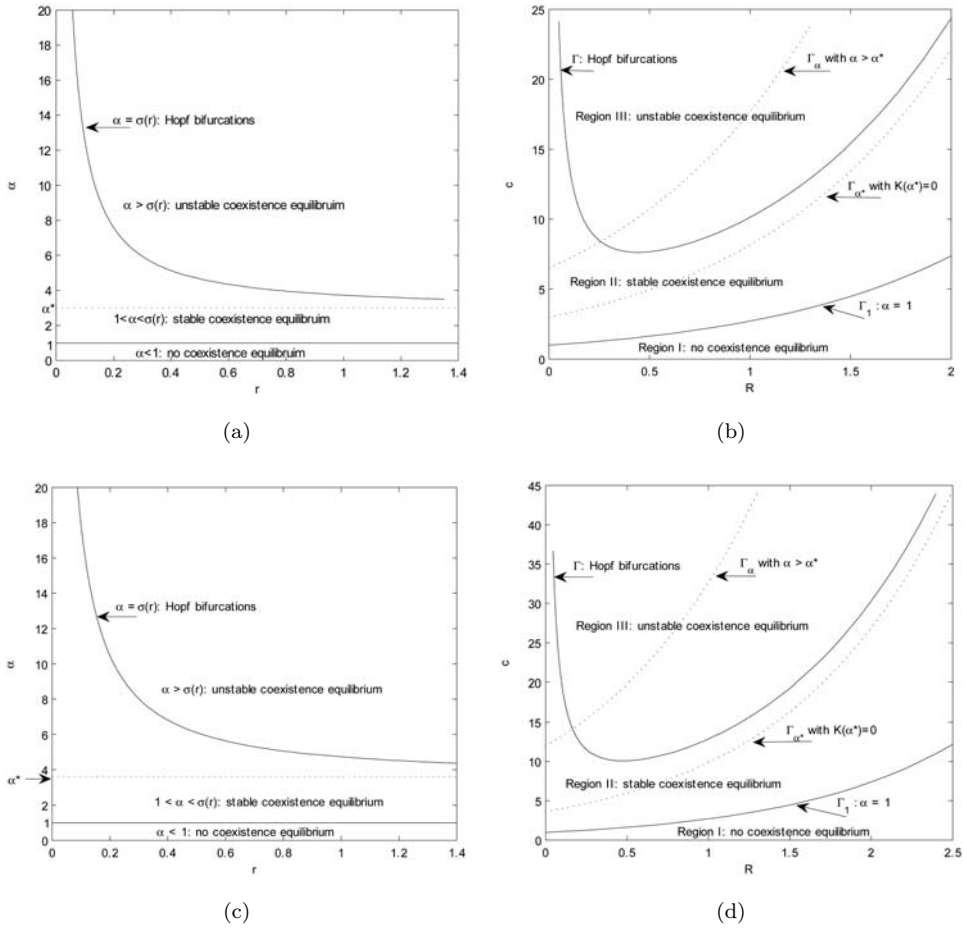

FIG. 1. (a) *Scaled system,* $b(x) = 8(1 - x/4)$; (b) *Dimensional system,* $B(X) = 8(1 - X/4)$; (c) *Scaled system,* $b(x) = 9/(1 + 0.5x)$; (d) *Dimensional system,* $B(X) = 9/(1 + 0.5X)$.

so that in the corresponding dimensionless system

$$\alpha = ce^{-R}, \quad t = T, \quad x(t) = N(t), \quad y(t) = e^{R}P(t)/c, \quad b(x) = B(x).$$

In the case of $B(X) = 8(1 - X/4)$ giving $\gamma = b(1) = 6$, we find bifurcation diagrams as in (a) and (b) of Figure 1, and then, when $B(X) = 9/(1 + 0.5X)$, again with $\gamma = b(1) = 6$, we find bifurcation diagrams as in (c) and (d) of Figure 1.

Notice in both examples that for appropriately large, fixed c with R increasing from 0 the dimensional system (48) goes first through a supercritical Hopf bifurcation, and then back through a subcritical one.

6. Numerical examples.

6.1. Interpretation of parameters. In choosing parameter values for numerical examples, it is helpful to think about the ideas they represent. Thus we consider:

1. t which is time scaled by $1/d_P$, which we may take as a measure of the expected lifespan for predators.
2. α, which has been a focus of attention, beginning with the condition $\alpha > 1$ as our condition for the existence of an interior equilibrium at $(x^*, y^*) =$

$(1/\alpha, (b(1/\alpha) - \gamma)/\alpha)$, and the key to an additional condition for a Hopf bifurcation at this equilibrium. We find that α is similar to R_0 in some ODE models, by first observing that in a complete absence of predators, N is steady at N_0 which functions as its carrying capacity. Then, if a very small number of predators is introduced and holds roughly constant (near the equilibrium), we find $ce^{-d_1 R} - d_P$ to be the net per unit rate of change of P and hence $\alpha = ce^{-d_1 R} N_0/d_P$ is the number of newly matured predators per adult predator, produced during a predator lifetime at prey carrying capacity. Thus we may interpret it as a *replacement ratio* and indeed similar to R_0. Likewise, $1/\alpha$ can be thought of as the fraction of an average adult predator's lifetime needed for self-replacement, at prey carrying capacity. All such considerations are with respect to a common unit of measure for predator and prey, for example, biomass.

3. $\gamma = d/d_P$, which is $b(1)$ in consequence of our scaling of x. Similarly to interpreting $1/d_P$ above, we find that γ is the ratio of the lifetime of a predator to that of a prey. In scenarios such as the present in which maturation time of predators is deemed important to include in the model, while that of prey is not, we expect $\gamma > 1$.
4. $b(x^*)/b(1) = B(x^* N_0)/d$ is the prey lifetime recruitment (per unit) at equilibrium.

6.2. Comparison of birth functions: Affine, concave up, and concave down. In this section we numerically investigate three implementations of the birth function,

$$b_1(x) = a\left(1 - \frac{x}{b}\right), \tag{67a}$$

$$b_2(x) = \frac{c}{1 + dx}, \tag{67b}$$

$$b_3(x) = p\left(1 + \frac{1}{x - q}\right), \tag{67c}$$

in order to better understand the behavior generally of the nondimensional models from section 5, especially with regard to the bifurcations guaranteed by Theorem 14. We determine the pairs of coefficients $((a, b), (c, d), (p, q))$ so that the implementations of the b_i have the same interior equilibrium (x^*, y^*), the same value of $b_i(x^*)$ and the same model coefficients α, γ, and with values so that the conditions for Hopf bifurcation are satisfied. Notice that over the domain of interest, b_1 is affine; b_2 is concave up; and b_3 is concave down. Although b_1 does not satisfy the condition $(xb(x))' \geq 0$ if $x > b/2$, we use it only on $0 < x < b/2$ where that condition is satisfied. The function can be redefined elsewhere to satisfy the condition if desired, with no effect on our computations. All the numerical computations use the Matlab-based package DDE-BIFTOOL [18].

Implementation. The interpretations above guide us in choosing values for $\beta = b(x^*)$ and $\gamma = b(1)$. The parameter α determines the equilibrium (x^*, y^*) through

$$x^* = 1/\alpha$$
$$y^* = (b(x^*) - b(1))\, x^* = (b(1/\alpha) - \gamma)/\alpha.$$

We then solve for the two parameters in each of the birth functions b_i. There are elementary but tedious details to be checked that all the requirements on the birth function and α are satisfied, which we omit. The resulting restrictions are listed here.

PROPOSITION 15. *For $i = 1, 2, 3$, there is an $\alpha_i > 1$ such that the condition (2) of Theorem 14 for bifurcation in the model based on b_i is satisfied if and only if $\alpha > \alpha_i$. (Thus the α_i satisfy the criteria of α^* above.) Furthermore, whenever $\beta > \gamma > 0$ and the restrictions immediately below hold, positive parameters for the birth function b_i are uniquely determined such that with $x^* = 1/\alpha < 1/\alpha_i$ we have $b_i(x^*) = \beta$ and $b_i(1) = \gamma$.*

Table 1 summarizes the relevant relations and conditions.

TABLE 1

$b_1(x) = a\left(1 - \frac{x}{b}\right)$	$a = \frac{\alpha\beta-\gamma}{\alpha-1}, b = \frac{\alpha\beta-\gamma}{\alpha(\beta-\gamma)}$ $(xb(x))' > 0$ if $\gamma < \beta < 2\gamma$ $\alpha_1 = 3$
$b_2(x) = \frac{c}{1+dx}$	$c = \beta\frac{\alpha-1}{\alpha-\beta/\gamma}, d = \alpha\frac{\beta/\gamma-1}{\alpha-\beta/\gamma}$ Both c, d are positive iff $\alpha > \beta/\gamma > 1$. $\alpha_2 = \left(3 + d + \sqrt{9 + 10d + d^2}\right)\Big/2$
$b_3(x) = p\left(1 + \frac{1}{x-q}\right)$	p = larger zero of $(\alpha-1)Z^2 - (\beta(2\alpha-1)-\gamma)Z + (\alpha-1)\beta\gamma$ $q = (\beta - p - p\alpha)/(\alpha(\beta-p))$ $(xb(x))' > 0$ if $q > \frac{3}{2} + \frac{1}{2}\sqrt{5} \approx 2.62$ $\alpha_3 = \frac{1}{2q}\left(3q - 1 + \sqrt{9q^2 - 10q + 1}\right)$

Discussion. We saw above that we must respect $0 < \gamma < \beta$, while numerically we observed that this together with $\beta \leq 3\gamma/2$ was necessary and sufficient for each b_i to be implemented over an interval for α including $[\alpha_i, 7]$ in its interior. For each b_i in combination with each of the pairs $(\beta, \gamma) = (4.5, 3), (8, 6)$ we computed a locus of Hopf bifurcation points in the (α, r) plane which included $5 \leq \alpha \leq 7$ in all cases. Then in each of the cases $\alpha = 5, 7$, we computed bifurcation diagrams with the delay r as bifurcation parameter, and plotted: (1) bifurcation diagrams, (2) profiles of the bifurcating periodic solutions (traces of the solutions $(x(t), y(t))$), and (3) the largest size of a nontrivial Floquet multiplier. (See [6] for more extensive graphics.) These computations were done for values of the delay r beginning at the bifurcation value and ending at about $r = 2$. Considering that we scaled time by the measure of a predator lifetime, $1/d_P$, a delay of $r = 2$ corresponds to a juvenile predator maturation that is twice this magnitude, and hence is more than adequate for biological considerations.

There were remarkable similarities across these computations.

1. All the bifurcation loci in the (α, r) plane were decreasing, concave up.
2. All the bifurcation diagrams of the x-amplitude of bifurcating period solutions vs. r were increasing, concave down, with the amplitude approaching 1 as r increased. (Recall that the "carrying capacity" for x is normalized to 1.)
3. All the bifurcation diagrams of the period of bifurcation periodic solutions vs. r were increasing and almost linear for a long range of r. However, this broke down as discussed below.
4. All the profile plots of the periodic solutions (that is, projections of periodic solutions $(x(t), y(t)$ into an (x, y) plane) showed initial nesting of each surrounding those of lesser r, expanding with increasing r but contained within a triangle adjacent to the origin and coordinate axes in the (x, y) plane, and then developing an "overhang." See Figure 2 for a typical scenario.
5. Floquet multipliers (These are eigenvalues of the linearized Poincaré map associated with each bifurcating periodic solution and always "trivially" in-

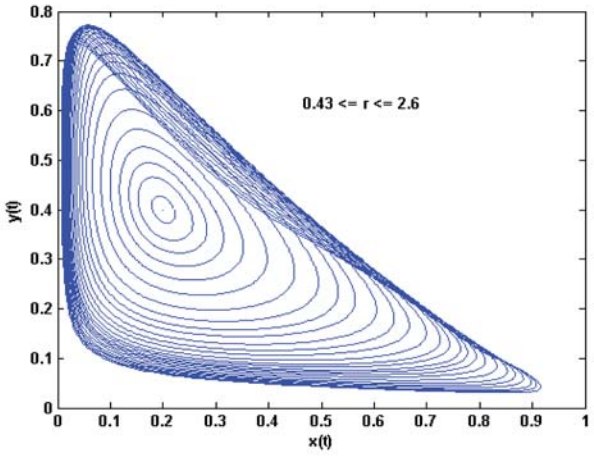

FIG. 2. *Overhang in bifurcating family of periodic solution profiles.*

clude 1 corresponding to the initial condition of the periodic solution. Only a finite number can lie outside any disk centered at the origin in the complex plane.): In plotting the largest magnitude of these (excepting the trivial 1) vs. r, we found rapid decrease to small values across all our examples, followed in some circumstances by eventual increase (but not in ranges of r that are biologically compelling).

Prompted by the eventual increase of Floquet multipliers for $r > 2$ we singled out the example case of birth function b_1 with $\alpha = 5$, $\beta = 8$, $\gamma = 6$ for further investigation and extended the delay r from the bifurcation value of about 0.43 to over 8. Some interesting aspects emerged, which although not of direct biological interest in the current context, might easily emerge in others. They include:

1. Self-crossover of periodic orbit profiles: At $r \approx 3.8$ we observe the beginnings of self-intersection within profiles of the bifurcating periodic orbits. See the sequence in Figure 3. Since the periods of these solutions increased approximately affinely with the delay over this regime, perhaps this extra looping of the profile can be understood as a mechanism by which the longer period is accommodated in a limited spatial region. There were no remarkable aspects of the Floquet multipliers (measures of stability) apparently associated with these behaviors.
2. The profiles of the self-intersecting orbits also approach the equilibrium at $(1, 0)$ (thereby slowing down) and develop folds and spikes in their upper left corner, again with the effect of enabling longer periods. See the sequence in Figure 3.
3. It is quite remarkable that over $0.43 < r < 8$ the bifurcation diagram of period vs. r is approximately affine with the notable exception of $7.12 < r < 7.29$ where it doubles over in a backwards S. Moreover, the vertical tangencies (in the period vs. delay bifurcation diagrams) at $r = 7.12, 7.29$ are accompanied by a Floquet multiplier leaving the unit disk in the complex plane. Notice that the self-crossovers remarked on above appear to be completely independent of the branch of multipliers that leaves the unit disk over $4.8 < r < 6.3$. See Figure 4.

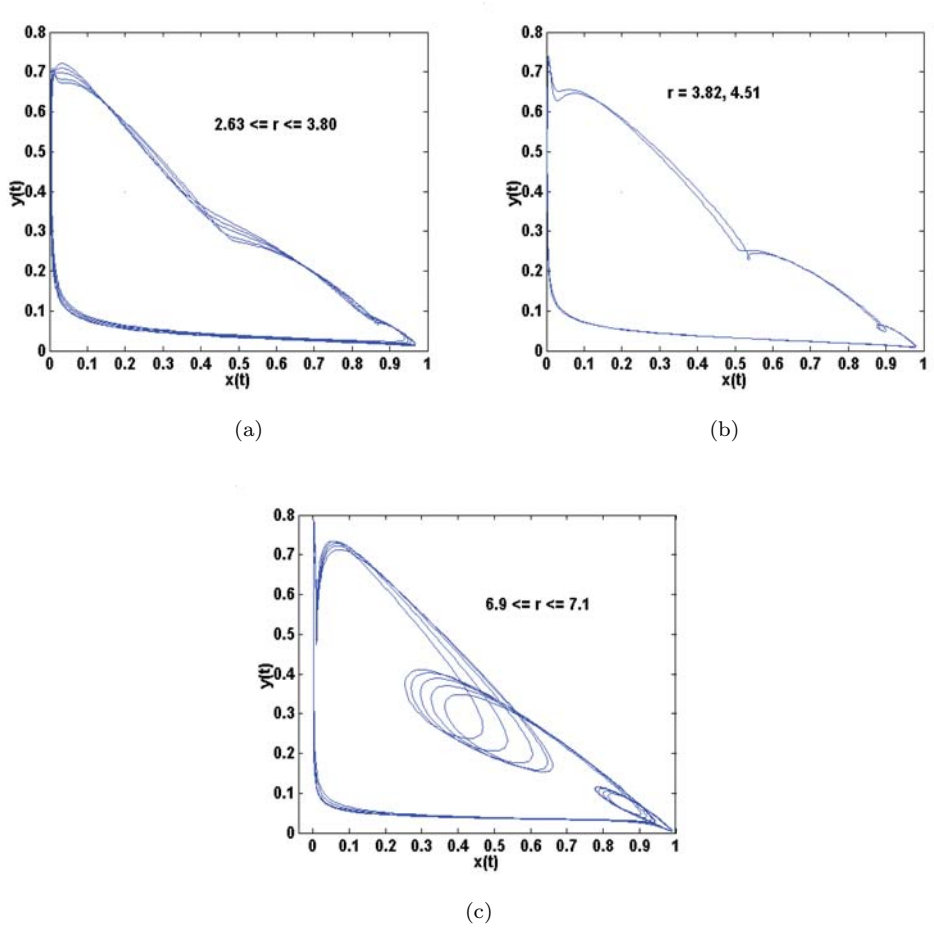

FIG. 3. *Progression of self-intersecting profiles of bifurcating period orbits. (a) As r increases to* 3.8*, a cusp develops (lower right) and early stages of a fold are seen (upper left). (b) Intermediate stages of both self-intersection and fold. (c) Late stages at large r.*

7. Equivalence of dimensional and nondimensional results. There are some concerns that might arise concerning the scaling of the original models (5) in the host-parasite case (and (48) in the predator-prey case) and how analysis of the resulting dimension-free resulting models (respectively, (9) and (50)) applies back to those original models. In particular, there might be some concern about the use of the scaled delay, r, as a bifurcation parameter in (50) after a coefficient in (48) which "physically" contained the original delay, R, has been scaled out. Furthermore, there might arise concern about the validity of the bifurcation analysis since the dimension of the parameter space is reduced from eight (including the delay and N_0) in the original models to three (including the scaled delay) in the corresponding dimension-free ones. Since the relation between (48) and (50) scales out the "physical" presence of the delay and is therefore more complicated, we will focus on that situation, leaving the other host-parasite situation of section 3 as an easy corollary. We should note that Beretta and Kuang [1] address these issues without passing to a scaled version of the model. Our situation, however, can be addressed directly.

Let us refer to (48a–48c), together with the assumptions (2a), (2b), and (7), as the dimensional model. Recall that we defined N_0 by the condition $B(N_0) = d$. Then

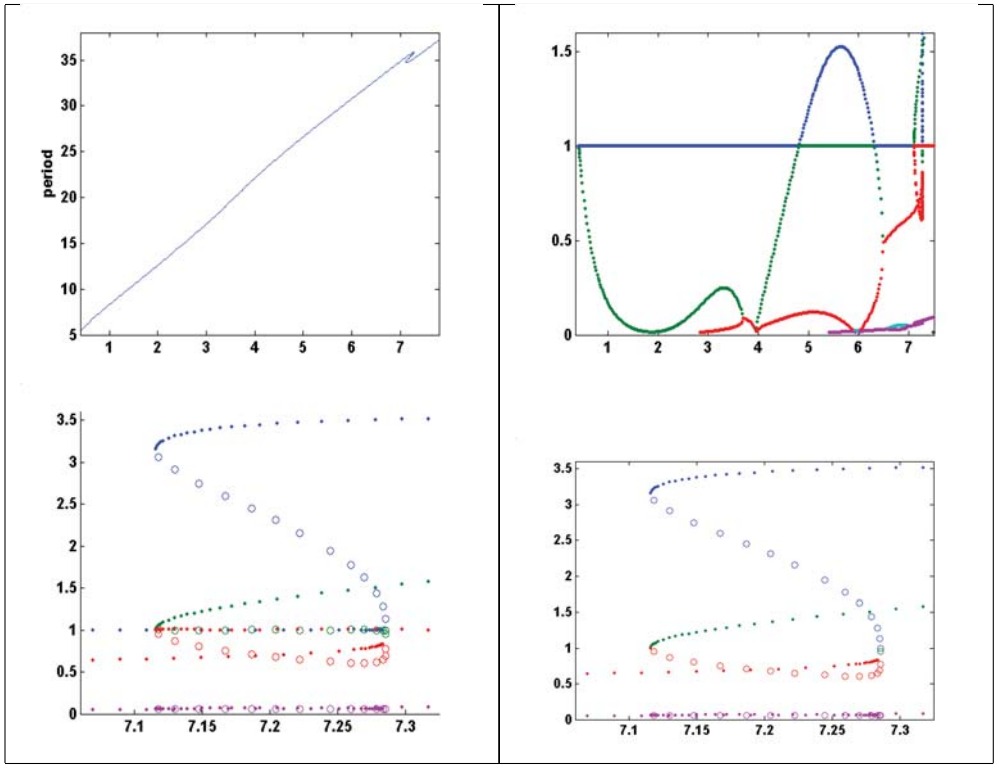

FIG. 4. *With the maturation delay, r, on the horizontal axis: Upper left shows periods, including the backwards S. All other frames show absolute values of Floquet multipliers larger than 0.01: Upper right shows values < 7.5. Lower frames have dots plotted as both r and the period increase, first over $7.05 < r < 7.29$ (corresponding to the top of the backwards S in the bifurcation diagram), and later over $7.12 < r < 7.35$ (corresponding to the bottom of the backwards S). To contrast circles are plotted as r decreases from 7.29 to 7.12 through the middle of the backwards S. The lower right is the same as lower left with values of 1 removed to fascilitate observation of a branch of complex conjugate multipliers (shown only in absolute value) becoming real at $r = 7.29$, with one leaving the unit disk there, and the other leaving after r decreases to 7.12.*

we scaled variables and parameters according to (49), resulting in the nondimensional model

$$\frac{dx}{dt} = x(t)\, b(x(t)) - \alpha x(t)\, y(t) - \gamma x(t), \tag{68a}$$

$$\frac{dy}{dt} = \alpha x(t-r)\, y(t-r) - y(t), \tag{68b}$$

satisfying

$$b(1) = \gamma. \tag{68c}$$

The purpose of this section is to show that bifurcation in the latter system (68) with respect to r implies bifurcation in the former, (48), with respect to R, and conversely.

Suppose now that $(\alpha, \gamma, r, b(\cdot))$ are given and consider the corresponding system (68). Also consider a system (48) in which $(a, c, d, d_1, d_P, N_0, R, B(\cdot))$ are given such

that the parametric relations of (49) hold, namely,

$$\begin{aligned} ce^{-d_1 R} N_0/d_P &= \alpha, \\ d/d_P &= \gamma, \\ d_P R &= r, \\ B\left(xN_0\right)/d_P &= b\left(x\right). \end{aligned} \tag{69}$$

Then, given a solution $(x(t), y(t))$ of (68), if

$$\begin{aligned} T &= t/d_P, \\ N(T) &= N_0 x\left(d_P T\right), \\ P(T) &= d_P \alpha y\left(d_P T\right)/a, \end{aligned} \tag{70}$$

it is easy to see that $(N(T), P(T))$ solves (48). In this way (while parameters are fixed and appropriately related), solutions of the two systems are related by a bicontinuous linear isomorphism. In this context, stability of equilibria and periodic solutions carries over from (68) to (48), and conversely.

In examining implications for bifurcation, we have already seen that it is not possible with our choice of scaling to vary only the delays, r and R. However, suppose again that $(\alpha, \gamma, r, b(\cdot))$ are given with $(\alpha, \gamma, b(\cdot))$ fixed, but with r varying, and let $(c, d, d_1, d_P, N_0, B(\cdot))$ be smooth functions of $R = r/d_P$ such that (69) and $B(N_0) = d$ continue to hold. Again, given a solution $(x(t), y(t))$ of (68), if (69) holds it is easy to see that $(N(T), P(T))$ solves (48) for each value of r with $R = r/d_P$. Moreover the triples $(x(\cdot), y(\cdot), r)$ and $(N(\cdot), P(\cdot), R)$ are related by a bicontinuous bijection, based on the bicontinuous linear isomorphism between $(x(\cdot), y(\cdot))$ and $(N(T), P(T))$ above, but with nonlinear inclusion of r. This correspondence maintains equilibrium, periodicity, and stability properties of solutions, so that if a bifurcation occurs in (68) with respect to r, then a corresponding one in (48) must also occur with respect to R.

To address the converse question regarding implications of bifurcations in (48) for bifurcations in (68), let us consider the case of R as bifurcation parameter in (48) with (a, c, d, d_1, d_P, N_0) held fixed. Then assuming our usual relations between that system and (68), we again have the triples $(N(\cdot), P(\cdot), R)$ and $(x(\cdot), y(\cdot), r)$ related by a bicontinuous bijection that preserves equilibrium, periodicity, and stability properties. Thus any bifurcation in (48) with respect to R is mirrored by one in (68) with respect to r, but with α also varying (as a function of r, through (56)), perhaps with consequences, e.g., for the existence of a coexistence equilibrium as α decreases through unity.

EXISTENCE AND STABILITY OF SPHERICALLY LAYERED SOLUTIONS OF THE DIBLOCK COPOLYMER EQUATION*

XIAOFENG REN† AND JUNCHENG WEI‡

Abstract. The relatively simple Ohta–Kawasaki density functional theory for diblock copolymer melts allows us to construct and analyze exact solutions to the Euler–Lagrange equation by singular perturbation techniques. First, we consider a solution of a single sphere pattern that models a cell in the spherical morphology. We show the existence of the sphere pattern and find a stability threshold, so that if the sphere is larger than the threshold value, the sphere pattern becomes unstable. Next we study a spherical lamellar pattern, which may be regarded as a defective lamellar pattern. We reduce the existence and the stability problems to some finite dimensional problems which are accurately solved with the help of a computer. We find two thresholds. Only when the size of the sample is larger than the first threshold value does a spherical lamellar pattern exist. This patten is stable only when the size of the sample is less than the second threshold value. As the stability of the spherical lamellar pattern changes at the second threshold, a bifurcating branch with a pattern of wriggled spherical interfaces appears. The free energy of the latter pattern is lower than that of the first pattern. A similar bifurcation phenomenon also occurs in the single sphere pattern at its stability threshold.

1. Introduction.

A diblock copolymer melt is a soft material, characterized by fluid-like disorder on the molecular scale and a high degree of order at a longer length scale. A molecule in a diblock copolymer is a linear subchain of A-monomers grafted covalently to another subchain of B-monomers. Because of the repulsion between the unlike monomers, the different types of subchains tend to segregate, but as they are chemically bonded in chain molecules, segregation of subchains cannot lead to a macroscopic phase separation. Only a local microphase separation occurs: microdomains rich in A-monomers and microdomains rich in B-monomers emerge as a result. These microdomains form morphology patterns/phases.

There are two types of phase separations in a diblock copolymer system: weak segregation and strong segregation. The weak segregation occurs when the temperature is relatively high. The microdomains are small and there are no clear interfaces separating them. When the temperature is lower, strong segregation is observed. The microdomains become larger and they are separated by narrow interfaces.

The self-consistent mean field theory [11, 13, 14, 15, 17, 18] is the most successful theory in modeling and capturing aspects of the phase separation. It consists of five equations for five field variables: two density fields of A- and B-monomers, two mean fields on A- and B-monomers simulating the interaction between the molecular chains, and a Lagrange multiplier field. Two of the five equations are nonlocal, while

the remaining three are algebraic [22]. The theory is derived from a microscopic description of interacting polymer chains. Based on a variational principle, the Gibbs canonical distribution is approximated by the distribution generated by the mean fields [7]. This theory is quite complex to which only numerical studies have been done. One of them is the spectral method of Matsen and Schick [22] that yields predictions with striking resemblances to experiments.

A limitation of such techniques or other test field based methods is that they proceed by assuming a periodic structure, computing its free energy and then comparing that free energy to the free energy of other candidate structures [3]. The patterns found by such methods in general do not exactly solve the self-consistent equations. However, finding analytic solutions to these equations is very difficult due to the complexity of the two nonlocal equations.

The density functional theory of Ohta and Kawasaki [28] is a much simpler model. The free energy of a diblock copolymer melt is an elegant functional of the A-monomer density field only. Unlike an earlier density functional theory of Leibler [20] that deals only with the weak segregation region, the Ohta–Kawasaki theory deals with both the weak- and strong-segregation phenomena. The Euler–Lagrange equation of the Ohta–Kawasaki free energy is an integro-differential equation (see (2.9)), which can also be viewed as a system of two elliptic partial differential equations (see (2.11)–(2.12)).

A close examination of the derivation of the density functional theory shows that it is a simplified version of the self-consistent mean field theory. We refer the reader to [7] for a detailed study of the simplification procedure. Here we briefly summarize the results of [7]. There are two approximation steps. First, we consider the relationship between the A-monomer density field u_a, the B-monomer density field u_b, and the mean fields U_A, U_B that act, respectively, on A- and B- monomers. In the self-consistent mean field theory one can express u_a and u_b in terms of U_A and U_B with the help of Feynman integrals, i.e., by solving some parabolic partial differential equations. In the density functional theory we simplify this relationship via linearization. This approximation is accurate if the temperature is not too low. Then we reverse the linearized relationship between u_a, u_b and U_A, U_B to express U_A, U_B in terms of u_a, u_b. An analysis in the Fourier space shows that this reversed relationship is described by a pseudodifferential, nonlocal operator. In the second approximation step we keep the long wave and the short wave parts of this operator and discard the intermediate wave effects. This way we end up with a sum of the Laplace operator $-\Delta$ and the inverse Laplace operator $(-\Delta)^{-1}$. When we finally express the free energy as a functional of u_a and u_b in the density functional theory, the Laplace operator gives rise to the local part of the functional and the inverse Laplace operator leads to the nonlocal part of the functional (see (2.2)).

Despite the shortcomings associated with these approximations, the density functional theory at least qualitatively captures the properties of diblock copolymers [21, 10]. Ohta and Kawasaki used their theory to study the common lamellar, cylindrical, and spherical phases [28]. More recently Teramoto and Nishiura found the less common double gyroid morphology by numerically simulating the theory [43]. Although Ohta and Kawasaki applied their theory only to test fields and did not construct exact solutions of the Euler–Lagrange equation, we will show that the simplicity of the theory actually makes it possible to study exact solutions analytically.

The weak segregation regime may be studied by the bifurcation theory rather easily. One starts with a uniform state and linearizes the Euler–Lagrange equation at the uniform state. For some parameter values the principal eigenvalue of the linearized problem is zero. Then a nonuniform state bifurcates from the uniform state. If one

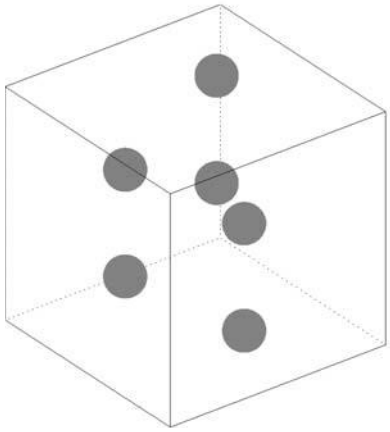

FIG. 1. *The spherical phase. The B-monomers form dark spheres and the A-monomers occupy the background. Not reflected in this figure is the body centered cubic pattern in which the spheres pack.*

can show that this nonuniform state is stable, then it gives the profile of a weakly segregated pattern.

In this paper we use the density functional theory to study the more complex strong segregation phenomenon. Strongly segregated patterns are too different from the uniform state to be treated as their bifurcating branches. The appropriate mathematical tool is the singular perturbation theory in calculus of variations and differential equations. We find exact solutions, or at least leading order terms of exact solutions, to the Euler–Lagrange equation of the free energy functional [26, 30, 32, 31, 35, 39, 40, 9, 6, 16]. Often these solutions may be carefully analyzed and their stability in space can be determined [33, 38].

The first strongly segregated pattern we study is the single sphere pattern. This pattern arises from the spherical phase of a diblock copolymer. When the monomer fraction is skewed in favor of A-monomers, the B-monomers form spherical microdomains; see Figure 1. We find a pattern with one sphere of B-monomers as a solution to the Euler–Lagrange equation. There is an optimal size for the sphere. The sphere of optimal size has lower free energy than those of other spheres. Then we linearize the Euler–Lagrange equation at the sphere solution and study the spectrum of the linearized operator. We will show that there is an upper bound for the size of the sphere. Beyond the upper bound, the sphere cannot be stable.

The second pattern is the spherical lamellar pattern. This pattern may be viewed as a defective lamellar pattern. Other defective patterns are considered in [44], where a model of a fourth-order differential equation is used. Given the number of interfaces we look for a solution that consists of spherical layers of microdomains separated by narrow interfaces. In this case the existence and stability problems are reduced by singular perturbation techniques to some finite dimensional problems. The reduced problems are easily solved with the help of a computer. Note that here we apply numerical methods to the reduced finite dimensional problems only. This way we obtain far more accurate and reliable results compared to results found from direct numerical simulations of infinite dimensional problems. There is an existence threshold. Only when the sample is greater than this threshold does a spherical lamellar pattern exist. There is also a stability threshold which is greater than the existence threshold.

When the sample is larger than the stability threshold, the spherical lamellar pattern becomes unstable.

We emphasize that all the results presented in this paper are mathematically rigorous. The informal style adopted here when we describe perturbation expansions can be changed to a strict mathematical framework, part of which is known as the Γ-convergence theory [8, 24, 23, 19].

2. Free energy. We review the density functional theory of Ohta and Kawasaki [28] in this section. We consider a diblock copolymer melt that occupies a region D in space. The system has the following parameters.

1. The polymerization index N that is the number of all the monomers in a chain molecule.
2. The A-monomer number N_A and the B-monomer number N_B in a chain. Note that $N_A + N_B = N$.
3. The number of chain molecules in the melt n. The average total monomer number density is $\rho_0 = \frac{nN}{V}$.
4. The Kuhn statistical length l measuring the average distance between two adjacent monomers in a chain molecule.
5. The inverse absolute temperature β.
6. The dimensionless Flory–Huggins parameter χ that measures the repulsion between unlike monomers; it is defined by

$$\chi = \beta\left(V_{AB} - \frac{V_{AA} + V_{BB}}{2}\right), \tag{2.1}$$

   where V_{AB} (and V_{AA} and V_{BB}, respectively) is the energy cost to bring an A-monomer (A-monomer and B-monomer, respectively) and a B-monomer (A-monomer and B-monomer, respectively) close to each other. This number is positive because the repulsion force between unlike monomers is stronger than those between like ones. Note that χ is inversely proportional to temperature.
7. The volume V of the sample. The domain D is nondimensionalized so that the size of D, denoted by $|D|$, is a convenient value. In this paper D is a ball, so we take the radius of D to be 1 and the size of D to be $|D| = 4\pi/3$.

The main field in the Ohta–Kawasaki theory is the relative A-monomer number density field $u(x)$. The melt is assumed to be incompressible, so when $u(x) = 1$ (or $u(x) = 0$, respectively), the point x in D is occupied by A-monomers only (or B-monomers only, respectively); if $0 < u(x) < 1$, a mixture of A- and B-monomers occupies x. The free energy F of the system is a functional of $u(x)$. In a dimensionless form we write

$$\frac{\beta F}{\chi \rho_0 V} = \int_D \left[\frac{\epsilon^2}{2}|\nabla u|^2 + W(u) + \frac{\epsilon\gamma}{2}|(-\Delta)^{-1/2}(u-a)|^2\right] dx. \tag{2.2}$$

On the right side of (2.2) we have introduced three dimensionless parameters:

$$\epsilon^2 = \frac{|D|^{2/3} l^2}{12a(1-a)\chi V^{2/3}}, \tag{2.3}$$

$$\gamma = \frac{18\sqrt{3}V}{|D| a^{3/2}(1-a)^{3/2}\chi^{1/2}N^2 l^3}, \tag{2.4}$$

$$a = \frac{N_A}{N}. \tag{2.5}$$

Note that the parameter $a = N_A/N$ is the average A-monomer density. The field u must satisfy the constraint

$$\overline{u} = a, \tag{2.6}$$

where $\overline{u} = \frac{1}{|D|}\int_D u(x)\,dx$ is the average of u.

The exact form of W is not given in [28]. In [7] an approximation

$$W(u) = \begin{cases} u - u^2 & \text{if } u \in [0,1], \\ \infty & \text{otherwise} \end{cases} \tag{2.7}$$

is found. A more accurate W should be a smooth double well function of equal depth. It must have a global minimum value 0 achieved at 0 and 1. It must have the symmetry $W(u) = W(1-u)$. 0 and 1 are nondegenerate: $W''(0) = W''(1) > 0$.

Central in (2.2) is the third term in the integrand. It is nonlocal and models the long range interaction between monomers due to the connectivity of the molecular chains. The operator $(-\Delta)^{-1/2}$ is the square root of the inverse of $-\Delta$ with the natural boundary condition. Alternatively in (2.2) one may write

$$\int_D |(-\Delta)^{-1/2}(u-a)|^2\,dx = \int_D\int_D (u(x)-a)G(x,y)(u(y)-a)\,dxdy, \tag{2.8}$$

where G is the Green's function of $-\Delta$ with the natural boundary condition.

The second term in (2.2) can be regarded as the internal energy field of the system, and the first and the third terms give the entropy of the system. As mentioned in the introduction we have taken only the long wave and short wave effects, modeled by the ∇ and $(-\Delta)^{-1/2}$ operators, into consideration in this model.

When we minimize (2.2), the first term in the integrand of (2.2) penalizes any space nonuniformity. The second term favors u being close either to 0 or close to 1 everywhere. The best profile for the third term is to have u close to a everywhere. However, this is not a good profile for the second term. The second best profile for the third term is for u to have many oscillations. Local minimizers of the free energy result from these three competing preferences.

The Euler–Lagrange equation of (2.2) is a nonlinear integro-differential equation

$$-\epsilon^2\Delta u + f(u) + \epsilon\gamma(-\Delta)^{-1}(u-a) = \eta \text{ in } D \tag{2.9}$$

subject to the natural boundary condition

$$\partial_\nu u = 0 \text{ on } \partial D. \tag{2.10}$$

Here $f = W'$. The constant η on the right side of (2.9) is a Lagrange multiplier coming from the constraint (2.6). Equation (2.9) may also be written as a system of elliptic partial differential equations

$$-\epsilon^2\Delta u + f(u) + \epsilon\gamma v = \eta, \tag{2.11}$$

$$-\Delta v = u - a \tag{2.12}$$

subject to the conditions

$$\partial_\nu u = \partial_\nu v = 0 \text{ on } \partial D, \quad \overline{u} - a = \overline{v} = 0. \tag{2.13}$$

Note that (2.9) always has the uniform solution $u(x) = a$. When ϵ is large, corresponding to high temperature, this solution is stable and it models the disordered phase. One may decrease ϵ to a value so that the principal eigenvalue of the linearized problem at $u(x) = a$ becomes 0. Then one finds a nonuniform solution bifurcating out of the uniform solution. This bifurcation solution explains the weak segregation phenomenon and the corresponding ϵ identifies the parameter range for weak segregation.

However, in the strong segregation regime ϵ is much smaller. In this case the free energy (2.2) is most easily analyzed in the parameter range

$$\epsilon \ll 1, \tag{2.14}$$

$$\gamma \sim 1. \tag{2.15}$$

Here the uniform solution $u(x) = a$ has much higher free energy than those of many other states and is hence thermodynamically unfavored. Under (2.14)–(2.15), we are in the strong segregation regime and have taken the volume of the sample to be of order

$$V \sim a^{3/2}(1-a)^{3/2}\chi^{1/2}N^2l^3. \tag{2.16}$$

We will see that in the parameter range (2.14)–(2.15) the number of microdomains is of order 1. Therefore the right side of (2.16) also predicts the size of a microdomain. Particularly we find the domain size $V^{1/3}$ to be proportional to $N^{2/3}$, which is the celebrated $N^{2/3}$ law [28].

Having a small ϵ makes (2.9) a singular perturbation problem. Although in mathematics the singular perturbation theory is much harder and less mature than the regular perturbation theory, a great deal of quantitative properties of solutions to (2.9) can be obtained, using the existing techniques in the theory. Many problems can be solved exactly in the leading order, and many other problems can be reduced to much simpler finite dimensional problems that are solved with the help of a computer.

3. Sphere pattern. When the monomer fraction a is close to 1, the diblock polymer typically exists in the spherical phase. B-rich microdomains form spheres and pack in a body centered cubic (BCC) pattern. Here we study a single sphere (see Figure 2) based on the model (2.2). Mathematically this must be done before we can analyze the BCC pattern. In a future publication we will "connect" several single sphere patterns to construct a BBC pattern solution in a general domain.

3.1. Existence. When one takes the domain D to be a unit ball, a radially symmetric solution $u(r)$ of (2.9) is found where u now is a function of $r = |x|$; see Figure 2. A narrow interface, whose thickness is of order ϵ, exists at some r_1, where $u(r_1) = 1/2$. The leading order of r_1 is determined by (2.6):

$$r_1 = (1-a)^{1/3} + O(\epsilon). \tag{3.1}$$

Inside the interface $u(r)$ is close to 0 and outside $u(r)$ is close to 1. The profile of u near r_1 is described by the inner expansion

$$u(r) = H\left(\frac{r-r_1}{\epsilon}\right) + \epsilon P\left(\frac{r-r_1}{\epsilon}\right) + O(\epsilon^2). \tag{3.2}$$

The leading order term H is the solution of

$$-H'' + f(H) = 0 \tag{3.3}$$

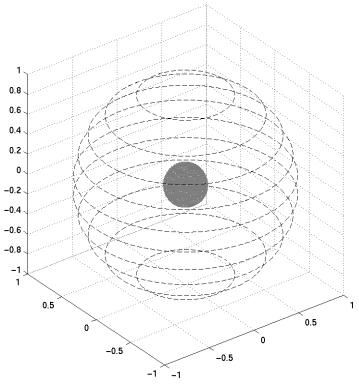

FIG. 2. *A single sphere solution with the natural boundary condition in the unit ball.*

with the conditions $H(-\infty) = 0$, $H(\infty) = 1$, and $H(0) = 1/2$. The next term P is the solution of

$$-P'' + f'(H)P - \frac{2H'}{r_1} + \frac{2\tau}{r_1} = 0, \quad P(0) = 0. \tag{3.4}$$

The definition of P involves r_1. Because $1/r_1$ is the mean curvature of the interface, the curvature affects the inner expansion of u in the ϵ order but not in the leading order, for H is independent of r_1.

In (3.4) we have a constant τ, which is the interface tension. For a general W,

$$\tau = \int_0^1 \sqrt{2W(s)}dx, \tag{3.5}$$

and for (2.7) we have

$$\tau = \frac{\sqrt{2}\pi}{8}. \tag{3.6}$$

The interface tension may also be calculated in the self-consistent mean field theory [12]. The value obtained there differs slightly from (3.6) of the density functional theory.

The free energy of this solution may be viewed as a sum of two parts. The first part comes from the two local terms of (2.2) and is equal to

$$4\pi r_1^2 \tau\epsilon + O(\epsilon^2). \tag{3.7}$$

Note that the first term on the right side is the area of the interface times τ times ϵ.

The second part of the free energy comes from the nonlocal term of (2.2) and is equal to

$$\frac{2\pi r_1^5 (r_1^3 - 3r_1 + 2)\gamma\epsilon}{15} + O(\epsilon^2). \tag{3.8}$$

Note that the free energy of the disordered phase modeled by the uniform solution $u(x) = a$ is $W(a)|D|$, a quantity of order 1, which is much larger than the free energy of the sphere pattern solution, which is of order ϵ. Hence under the condition (2.14)–(2.15) the system is in an ordered phase.

TABLE 1
The values of γ_o for various a.

a	.5	.525	.55	.575	.6	.625	.65	.675	.7	.725
γ_o	140	130	122	115	109	104	100	97	95	93

a	.75	.775	.8	.825	.85	.875	.9	.925	.95	.975
γ_o	92	92	93	95	99	106	117	137	176	290

3.2. Optimal size. There is a sphere pattern solution of (2.9) for any γ as long as ϵ is sufficiently small. This means that there is a solution for a wide range of V of the sample (the volume of the B-monomer sphere in the middle is then $(1-a)V$). It is natural to ask for which value of V the sphere pattern is most energetically favored. Intuitively we know that V cannot be too large or too small. By (2.3)–(2.4) we write $\epsilon = \tilde{\epsilon} V^{-1/3}$ and $\gamma = \tilde{\gamma} V$ so that $\tilde{\epsilon}$ and $\tilde{\gamma}$ no longer depend on V. Then by (3.7)–(3.8) we find that the leading term of the rescaled free energy of a sphere pattern is

$$4\pi r_1^2 \tau \tilde{\epsilon} V^{-1/3} + \frac{2\pi r_1^5 (r_1^3 - 3r_1 + 2)\tilde{\gamma}}{15} \tilde{\epsilon} V^{2/3}. \tag{3.9}$$

With respect to V, (3.9) is minimized at

$$V = V_o = \frac{15\tau}{r_1^3 (r_1^3 - 3r_1 + 2)\tilde{\gamma}}. \tag{3.10}$$

The optimal size of the sample is now given by (3.10). It is more convenient to express this in terms of the dimensionless γ. The optimal γ is denoted by γ_o, which is just

$$\gamma_o = \tilde{\gamma} V_o = \frac{15\tau}{r_1^3 (r_1^3 - 3r_1 + 2)}. \tag{3.11}$$

Table 1 reports the values of γ_o for various a.

3.3. Stability. We return to a sphere pattern solution with a general γ which is not necessarily equal to γ_o. Although a sphere solution of (2.9) is found for every γ, we will see that it is stable only if γ is not too large. A stable solution of (2.9) is a free energy local minimizer, which corresponds to a metastable state of the physical system. An unstable solution cannot be observed in experiments.

The stability analysis requires that we solve the eigenvalue problem

$$-\epsilon^2 \Delta \varphi + f'(u)\varphi - \overline{f'(u)\varphi} + \epsilon\gamma(-\Delta)^{-1}\varphi = \lambda\varphi. \tag{3.12}$$

The left side of (3.12) comes from linearizing the Euler–Lagrange equation (2.9) at a sphere pattern solution u. The eigenvalues λ are classified by the mode $l = 0, 1, 2, \ldots$. The eigenvalues whose modes are l are denoted by λ_l. Their corresponding eigenfunctions take the form

$$\varphi(x) = \phi_l(r) Y_{lm}(\theta, \omega), \tag{3.13}$$

where $m = 0, \pm 1, \ldots, \pm l$, and the Y_{lm}'s are the spherical harmonics. An eigenvalue either approaches 0, a critical eigenvalue, or stays positively away from 0 when $\epsilon \to 0$. Hence it suffices to consider the critical eigenvalues.

For the $l = 0$ mode there is one critical eigenvalue of order ϵ. It is of multiplicity 1 and has the form

$$\lambda_0 = \frac{3f'(0)r_1^2\epsilon}{\tau} + O(\epsilon^2). \tag{3.14}$$

This eigenvalue is positive, and $l = 0$ is a stable mode. The eigenfunction associated with this eigenvalue is radially symmetric. We denote it by $\phi_0(r)$. It has the expansion

$$\phi_0(r) = H'\left(\frac{r-r_1}{\epsilon}\right) + \epsilon P'\left(\frac{r-r_1}{\epsilon}\right) - \overline{\left[H'\left(\frac{r-r_1}{\epsilon}\right) + \epsilon P'\left(\frac{r-r_1}{\epsilon}\right)\right]} + O(\epsilon^2). \tag{3.15}$$

Here H' and P' are the derivatives of H and P, defined in (3.3)–(3.4), respectively.

For $l = 1$ there is one critical eigenvalue of order ϵ^2. It has multiplicity 3 and is of the form

$$\lambda_1 = \frac{\gamma r_1^4\epsilon^2}{\tau} + O(\epsilon^3). \tag{3.16}$$

This mode is again stable. The eigenfunctions associated with this eigenvalue are $(x/r)\phi_1(r)$, $(y/r)\phi_1(r)$, and $(z/r)\phi_1(r)$, where ϕ_1 has the expansion

$$\phi_1(r) = H'\left(\frac{r-r_1}{\epsilon}\right) + \epsilon P'\left(\frac{r-r_1}{\epsilon}\right) + O(\epsilon^2). \tag{3.17}$$

For each l greater than 1, there is one critical eigenvalue of order ϵ^2. This eigenvalue has multiplicity $2l + 1$ and has the form

$$\lambda_l = \left[\frac{l(l+1)-2}{r_1^2} + \frac{\gamma}{\tau}\left(\frac{r_1^4 - r_1}{3} + \frac{(l+1)r_1^{2l+2}}{l(2l+1)} + \frac{r_1}{2l+1}\right)\right]\epsilon^2 + O(\epsilon^3). \tag{3.18}$$

The quantity in (3.18) may not always be positive. One finds a threshold γ_s so that when $\gamma < \gamma_s$ all the eigenvalues in (3.18) are positive, but when $\gamma > \gamma_s$ at least for one l the eigenvalue λ_l in (3.18) is negative. Therefore the sphere solution u is stable if $\gamma < \gamma_s$ and unstable if $\gamma > \gamma_s$. The eigenfunctions associated with λ_l are $\phi_l(r)Y_{lm}$ with $m = 0, \pm 1, \ldots, \pm l$. ϕ_l has the same expansion as in (3.17).

The leading order of γ_s is determined from (3.18) following these steps:

1. For each $l \geq 2$, set the leading term

$$\frac{l(l+1)-2}{r_1^2} + \frac{\gamma}{\tau}\left(\frac{r_1^4 - r_1}{3} + \frac{(l+1)r_1^{2l+2}}{l(2l+1)} + \frac{r_1}{2l+1}\right) \tag{3.19}$$

   in (3.18) to be 0, and solve for γ. Denote the solution for γ by $\hat{\gamma}_l$. If this $\hat{\gamma}_l$ is less than or equal to 0, the mode l does not yield a zero eigenvalue. Discard such $\hat{\gamma}_l$.
2. Minimize the remaining $\hat{\gamma}_l$'s from the last step with respect to l. The minimum is achieved at a $\hat{\gamma}_l$ which is the leading order of γ_s.

Table 2 reports the leading order of γ_s for various a. At $\gamma = \gamma_s$ the smallest eigenvalue is 0. The mode l of this eigenvalue is also given in Table 2.

We compare the stability threshold γ_s to the optimal size γ_o in Table 1. All the γ_o's are significantly less than the corresponding γ_s's. Therefore, not surprisingly, the sphere with optimal size is stable.

TABLE 2
The (leading order) values of γ_s for various a and the corresponding mode l.

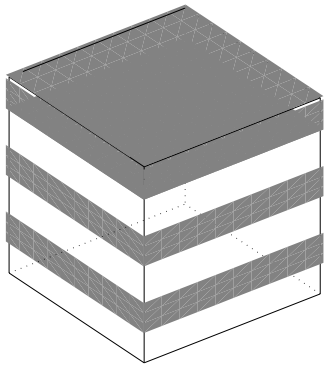

FIG. 3. *A perfect lamellar pattern.*

4. Spherical lamellar pattern. When a is close to $1/2$, the diblock copolymer exists in the lamellar phase. The perfect lamellar pattern consists of microdomains separated by parallel flat planes; see Figure 3. However, one often observes the lamellar pattern with topological defects such as dislocations, disclinations, grain boundaries, and tilt boundaries [44]. In this section we consider the spherical lamellar pattern (see Figure 4), which we view as a defective lamellar pattern.

Because it involves many interfaces, the study in this section is more complex. Nevertheless, we will show that by singular perturbation argument, solving the Euler–Lagrange equation (2.9) and analyzing the stability of the solution are reduced to studying some finite dimensional problems.

4.1. Existence. Unlike the existence problem for the sphere pattern, where no condition on γ is needed, the existence of a spherical lamellar pattern as a solution of (2.9) requires that γ is not too small. We now have an existence threshold $\gamma_{K,e}$. Given the number of interfaces $K \geq 2$ a K-interface spherical lamellar pattern solution of (2.9) exists if $\gamma > \gamma_{K,e}$. If $\gamma < \gamma_{K,e}$, there is no K-interface spherical lamellar solution.

When $\gamma > \gamma_{K,e}$, we define the interfaces r_j, $j = 1, 2, \ldots, K$, to be the radii, where $u(r_j) = 1/2$. They have the expansion

$$r_j = r_j^0 + O(\epsilon). \tag{4.1}$$

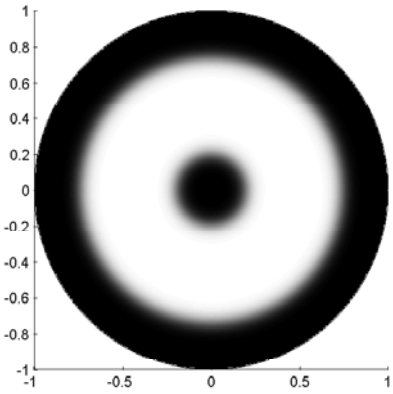

FIG. 4. *A cross section of a spherical lamellar pattern with two interfaces.*

The leading order r_j^0's are determined by solving a system of $K+1$ nonlinear equations

$$\frac{\tau}{r_j^0} + \frac{(-1)^j\gamma}{2}\mathcal{V}(r_j^0; r_1^0, r_2^0, \dots, r_K^0) = (-1)^j\eta^0, \quad j = 1, 2, \dots, K,$$

$$\sum_{j=1}^{K}(-1)^j(r_j^0)^3 + \frac{1-(-1)^K}{2} = a \tag{4.2}$$

for r_1^0, $r_2^0, \dots, r_K^0$, and η^0. Here η^0 is a Lagrange multiplier. The function $\mathcal{V}$ in (4.2) is the solution of

$$-\mathcal{V}'' - \frac{2}{r}\mathcal{V} = \mathcal{U} - a,\ \mathcal{V}'(0) = \mathcal{V}'(1) = 0,\ \overline{\mathcal{V}} = 0, \tag{4.3}$$

where

$$\mathcal{U}(r) = 0,\ \text{if } r \in (0, r_1^0),\ \text{and } \mathcal{U}(r) = 1 \text{ if } r \in (r_1^0, r_2^0), \dots . \tag{4.4}$$

Denote this solution by $\mathcal{V}(r; r_1^0, \dots, r_K^0)$, where we emphasize in its arguments that $\mathcal{V}$ depends on $r_1^0, \dots, r_K^0$. In (4.2) this $\mathcal{V}$ is evaluated at $r = r_j^0$.

The system (4.2) is the Euler–Lagrange equations of the minimizer of the function

$$J(q_1, q_2, \dots, q_K) = 3\tau\sum_{k=1}^{K} q_k^2 + \frac{3\gamma}{2}\int_0^1 \mathcal{V}'(r; q_1, \dots, q_K)^2 r^2 dr \tag{4.5}$$

subject to the constraint

$$-q_1^2 + q_2^3 + \cdots + (-1)^K q_K^3 + \frac{1-(-1)^K}{2} = a. \tag{4.6}$$

In the mathematics literature J is known as the Γ-limit of $(4\pi\epsilon/3)^{-1}I$. The Γ-limit theory thus reduces the study of the infinite dimensional problem I to the study of the finite dimensional problem J [30, 31].

Whether J has a minimizer depends on γ. In general, J has a minimizer only if γ is large. The border line is exactly the leading order of $\gamma_{K,e}$. For $K = 2$, Table 3 reports the leading order of $\gamma_{2,e}$ for various a.

TABLE 3
The leading order values of $\gamma_{2,e}$ for various a.

a	.5	.525	.55	.575	.6	.625	.65	.675	.7	.725
$\gamma_{2,e}$	171	175	180	186	194	204	216	230	249	271

a	.75	.775	.8	.825	.85	.875	.9	.925	.95	.975
$\gamma_{2,e}$	300	337	386	453	549	694	932	1379	2432	6590

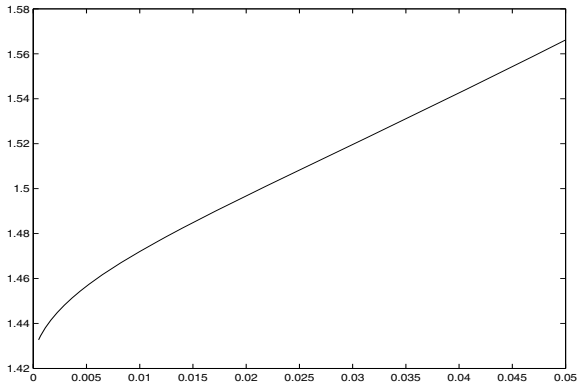

FIG. 5. *J as a function of y is increasing when $a = 1/2$ and $\gamma = 100$.*

Let us consider the $K = 2$ case in more detail. We introduce y so that

$$y = q_1^3, \quad y + a = q_2^3. \tag{4.7}$$

J can be viewed as a function of y only without the constraint (4.6). Take $a = 1/2$. For $\gamma = 100$, J is monotonically increasing in y; see Figure 5. Since $\gamma < \gamma_{2,e} \approx 171$ from Table 3, there is no 2-interface spherical lamellar solution of (2.9).

When $\gamma = 180 > \gamma_{2,e}$, J is no longer monotone; see Figure 6. In this case, J has a local minimum, and (2.9) has a 2-interface spherical lamellar solution.

If we further increase γ to 200, the local minimum of J becomes a global minimum; see Figure 7. The spherical lamellar solution continues to exist.

We now return to the general solution with K interfaces. Near each interface r_j the solution u again has a profile

$$u(r) = H\left(\frac{r - r_j}{\epsilon}\right) + \epsilon P_j\left(\frac{r - r_j}{\epsilon}\right) + O(\epsilon^2) \tag{4.8}$$

when j is odd and

$$u(r) = H\left(-\frac{r - r_j}{\epsilon}\right) + \epsilon P_j\left(-\frac{r - r_j}{\epsilon}\right) + O(\epsilon^2) \tag{4.9}$$

when j is even. H is the same function defined in (3.3) and P_j is defined by (3.2) with r_1 replaced by r_j.

The free energy of this solution is

$$\left[4\pi\tau \sum_{j=1}^{K} r_j^2 + 2\pi\gamma \int_0^1 \mathcal{V}'(r)^2 r^2 \, dr\right]\epsilon + O(\epsilon^2). \tag{4.10}$$

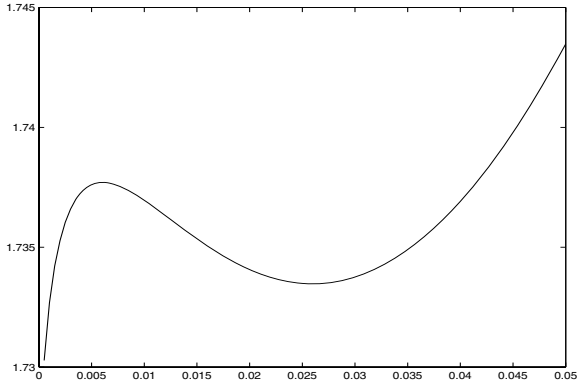

FIG. 6. *J as a function of y has a local minimum when $a = 1/2$ and $\gamma = 180$.*

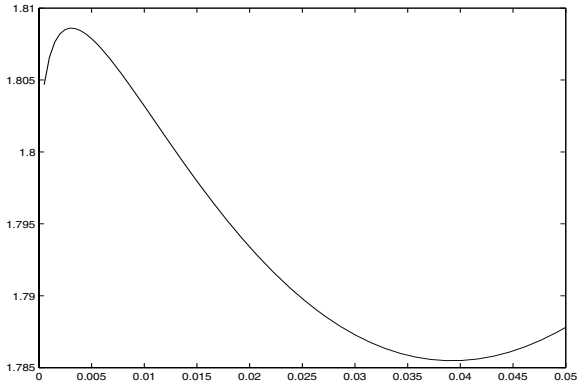

FIG. 7. *J as a function of y has a global minimum when $a = 1/2$ and $\gamma = 200$.*

4.2. Stability. Similar to the sphere pattern solution, a K-interface spherical lamellar solution is stable only if γ is not too large. More precisely, for any given number of interfaces K, there is a stability threshold $\gamma_{K,s}$, which is larger than the existence threshold $\gamma_{K,e}$, such that the K-interface spherical lamellar solution is stable if $\gamma_{K,e} < \gamma < \gamma_{K,s}$. The solution becomes unstable if $\gamma > \gamma_{K,s}$.

To verify these statements and determine $\gamma_{K,s}$ we again turn to the linearized problem (3.12). But this time u is the K-interface spherical lamellar solution found in section 4.1. The eigenvalues are again classified by the mode $l = 0, 1, 2, \ldots$. Denote the eigenvalues whose modes are l by λ_l. For each l the noncritical eigenvalues all stay positively away from 0, so it suffices to find the critical eigenvalues to determine whether u is stable.

When l is equal to 0, there exist K critical eigenvalues. All of them are simple. One of them is of order ϵ and has the expansion

$$\lambda_0 = \frac{3f'(0)\sum_{k=1}^{K}(r_k^0)^2}{\tau}\epsilon + O(\epsilon^2), \tag{4.11}$$

which is positive. The associated eigenfunction is

$$\phi_0(r) = \sum_{j=1}^{K} \left\{ H'\left(\frac{r-r_j}{\epsilon}\right) + \epsilon P_j'\left(\frac{r-r_j}{\epsilon}\right) - \overline{\left[H'\left(\frac{r-r_j}{\epsilon}\right) + \epsilon P_j'\left(\frac{r-r_j}{\epsilon}\right)\right]} \right\} + O(\epsilon^2). \tag{4.12}$$

The remaining $K-1$ eigenvalues of mode $l=0$ are of order ϵ^2. Let us expand them as

$$\lambda_0 = \mu_0 \epsilon^2 + O(\epsilon^3). \tag{4.13}$$

The determination of μ_0 is more complex.

First, we define a K by K matrix M whose kj-entry is

$$\begin{cases} (-\frac{2\tau}{(r_k^0)^2} + \gamma(-1)^k \mathcal{V}'(r_k^0)) + \gamma G_0(r_k^0, r_k^0) & \text{if} \quad k = j, \\ \gamma G_0(r_k^0, r_j^0) & \text{if} \quad k \neq j, \end{cases} \tag{4.14}$$

where G_0 is a Green's function:

$$G_0(r,s) = \begin{cases} \frac{s^2 r^2}{2} + s - \frac{9s^2}{5} + \frac{s^4}{2} & \text{if} \quad r < s, \\ \frac{s^2 r^2}{2} + \frac{s^2}{r} - \frac{9s^2}{5} + \frac{s^4}{2} & \text{if} \quad r \geq s. \end{cases} \tag{4.15}$$

Then we set a nonstandard inner product

$$\langle A, B \rangle = \sum_{k=1}^{K} A_k B_k (r_j^0)^2. \tag{4.16}$$

Let $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_K$ be an orthonormal basis with respect to the inner product (4.16) and

$$\mathbf{e}_1 = \frac{(1,1,\ldots,1)}{\sqrt{\langle (1,1,\ldots,1), (1,1,\ldots,1) \rangle}}. \tag{4.17}$$

The μ_0's are determined from a $K-1$ dimensional eigenvalue problem:

$$\sum_{m=2}^{K} d_m N_{mn} = \mu_0 \tau d_n, \quad n = 2, 3, \ldots, K. \tag{4.18}$$

The $K-1$ by $K-1$ matrix N is obtained by projecting the K by K matrix M into the $K-1$ dimensional subspace spanned by $\mathbf{e}_2, \mathbf{e}_3, \ldots, \mathbf{e}_K$:

$$N_{mn} = \langle M \mathbf{e}_m, \mathbf{e}_n \rangle, \quad m, n = 2, 3, \ldots, K. \tag{4.19}$$

The inner product in (4.19) is the one defined in (4.16).

These critical eigenvalues all turn out to be positive. This follows as a consequence of section 4.1. That N is positive definite is equivalent to the fact that r_j^0 minimizes J, defined in (4.5). The latter condition is fulfilled when $\gamma > \gamma_{K,e}$. Hence $l=0$ is a stable mode. To each one of these $k-1$ λ_0's, the corresponding eigenfunction $\phi_0(r)$ is given with the help of the eigenvector $(d_2, d_3, \ldots, d_K)$ of (4.18):

$$\phi_0(r) = \sum_{j=1}^{K} c_j \left[H'\left(\frac{r-r_j}{\epsilon}\right) + \epsilon P_j'\left(\frac{r-r_j}{\epsilon}\right) \right] + O(\epsilon^2), \tag{4.20}$$

TABLE 4
The (leading order) values of $\gamma_{2,s}$ for various a and the corresponding mode l.

a	.5	.525	.55	.575	.6	.625	.65	.675	.7	.725
$\gamma_{2,s}$	1162	1067	1002	956	931	919	924	943	951	939
l	4	3	3	3	3	3	3	3	2	2

a	.75	.775	.8	.825	.85	.875	.9	.925	.95	.975
$\gamma_{2,s}$	952	999	1077	1199	1393	1711	2241	3254	5684	15454
l	2	2	2	2	2	2	2	2	2	2

where

$$(c_1, c_2, \dots, c_K) = \sum_{n=2}^{K} d_n \mathbf{e}_n. \tag{4.21}$$

When l is greater than 0, there are K critical eigenvalues for each l. They all have multiplicity $2l+1$. All of them are of order ϵ^2. If we write

$$\lambda_l = \epsilon^2 \mu_l + O(\epsilon^3), \tag{4.22}$$

then the μ_l's are found by solving the K-dimensional eigenvalue problem

$$\left[\frac{(l(l+1)-2)\tau}{(r_k^0)^2} + (-1)^k \gamma \mathcal{V}(r_k^0)\right] c_k + \gamma \sum_{j=1}^{K} G_l(r_k^0, r_j^0) c_j = \mu_l \tau c_k,$$
$$k = 1, 2, \dots, K, \tag{4.23}$$

where G_l is another Green's function:

$$G_l(r,s) = \begin{cases} (\frac{s^{1-l}}{2l+1} + \frac{(l+1)s^{2+l}}{l(2l+1)}) r^l & \text{if} \quad r < s, \\ s^{2+l}(\frac{r^{-1-l}}{2l+1} + \frac{(l+1)r^l}{l(2l+1)}) & \text{if} \quad r \geq s. \end{cases} \tag{4.24}$$

These critical eigenvalues are not always positive. There exists a stability threshold $\gamma_{K,s}$ so that when $\gamma_{K,e} < \gamma < \gamma_{K,s}$ all the critical eigenvalues are positive, and hence the K-interface solution u is stable, and when $\gamma > \gamma_{K,s}$ at least one critical eigenvalue is negative and the K-interface solution u is unstable. To each λ_l the corresponding eigenfunctions are $\phi_l(r) Y_{lm}$, $m = 0, \pm 1, \dots, \pm l$. ϕ_l is determined with the help of the eigenvectors c_k in (4.23):

$$\phi_l(r) = \sum_{j=1}^{K} c_j \left[H'\left(\frac{r - r_j}{\epsilon}\right) + \epsilon P_j'\left(\frac{r - r_j}{\epsilon}\right)\right] + O(\epsilon^2). \tag{4.25}$$

Table 4 reports the stability threshold values for various a. Note that the $\gamma_{2,s}$'s are greater than the corresponding $\gamma_{2,e}$. Hence there is a range $(\gamma_{2,e}, \gamma_{2,s})$ for γ where the 2-interface spherical lamellar pattern is stable.

5. Discussion. The single sphere pattern studied in section 3 gives only a limited picture of the spherical phase of a diblock copolymer, where multiple spheres coexist. Moreover, the spheres are observed to pack in the BCC pattern. An analytic study of such a multisphere pattern requires more refined singular perturbation techniques. The main difficulty is that the spheres in such a phase are only approximately round. The following argument illustrates this point.

It is known that even in a general domain, which we call Ω, (2.9) has a singular limit as $\epsilon \to 0$ [30]. The leading order outer expansion u^0 of u, a solution of (2.9), has the property that for a.e. $x \in \Omega$ $u^0(x) = 0$ or $u^0(x) = 1$ and $\overline{u^0} = a$. Let S be the union of the interfaces that separate the regions $u^0 = 0$ (B-rich microdomains) from the regions $u^0 = 1$ (A-rich microdomains), and $v^0 = (-\Delta)^{-1}(u^0 - a)$. In the singular limit an interface is a two-dimensional surface, with no thickness. At every $x \in S$,

$$\tau\kappa(x) + \gamma v^0(x) = \eta^0, \tag{5.1}$$

where $\kappa(x)$ is the mean curvature of S at x viewed from the $u^0 = 1$ side, and η^0 is a Lagrange multiplier to be determined. Equation (5.1) is a generalization of (4.2). The constraint (4.2) is replaced by $\overline{u^0} = a$. If the free boundary problem (5.1) admits an isolated stable solution u^0, then near u^0 there exists a local minimizer solution u of (2.9). However, (5.1) is still a challenging nonlocal geometric problem. Even though Figure 1 suggests that we look for solutions with multiple spheres, (5.1) implies that for such a solution the curvature of the interface of a sphere is in general not constant (there is the impact of v^0), i.e., the spheres are not exactly round, unless we deal with the one sphere or the spherically lamellar solutions in a ball as in this paper.

Nevertheless, if we consider the situation where a is close to 0 (or 1), then v^0 is near constant throughout Ω, and hence κ becomes close to a constant and the spheres are approximately round. The spherical phase in Figure 1 is thus heuristically explained. One must realize that in the small a case, i.e., small droplet/high curvature case, the parameter ϵ should be significantly less than a; otherwise we cannot have morphologies with microdomains separated by sharp interfaces. It was shown in [40] that the borderline range for a in one dimension is $a \sim \epsilon^{1/2}$. It is not clear at the moment what the borderline values for a are in two and three dimensions.

The stability threshold γ_s (or $\gamma_{K,s}$) is related to a strong segregation bifurcation phenomenon (not to be confused with the bifurcation analysis in the weak segregation regime). When γ passes γ_s (or $\gamma_{K,s}$) a second solution bifurcates out of the sphere (or spherical lamellar) solution. The new solution differs from the old one by a quantity which is roughly proportional to the eigenfunction of the 0 principal eigenvalue at $\gamma = \gamma_s$ (or $\gamma_{K,s}$). Because the eigenfunction has the form (3.13), the new solution has a wiggling interface (or interfaces). The wiggles are determined by the spherical harmonics Y_{lm} in (3.13); see Figure 8. Such a wiggling interface solution can be regarded as another defective pattern. If we consider the free energy during the bifurcation process, the bifurcating branch lowers the nonlocal part of the free energy by introducing more oscillation but increases the interface energy. The overall free energy of the bifurcating branch is lower than that of the first branch.

We did not discuss the dynamics of a diblock copolymer system. The purpose of studying the critical eigenvalues of a solution of (2.9) in this paper is to determine whether the solution is a local minimizer of (2.2). However, the same critical eigenvalues also determine the local dynamics, near the solution, of the evolution equation

$$u_t = \epsilon^2\Delta u - f(u) - \epsilon\gamma(-\Delta)^{-1}(u - a) + \overline{f(u)}, \quad \partial_\nu u = 0 \text{ on } \partial D. \tag{5.2}$$

Note that $\int_D u(x)\,dx$ is conserved under (5.2) because $\frac{d}{dt}\int_D u(x)\,dx = 0$ after one integrates (5.2) over D. The eigenfunctions of the critical eigenvalues give the directions along which the dynamics of (5.2) runs slowly (the eigenfunctions of the noncritical eigenvalues are directions of fast dynamics).

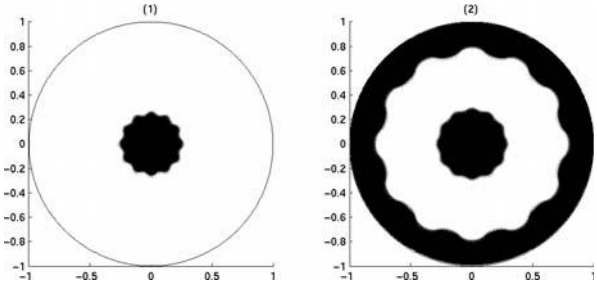

FIG. 8. *A cross section of a wiggling sphere solution and a cross section of a wriggled spherical lamellar solution with two interfaces.*

The critical eigenvalues in this context admit geometric interpretations. For the sphere pattern the eigenfunction of the critical eigenvalue λ_0 in (3.14) is radially symmetric. So the dynamics in this direction involves only the shape change of u in the radial direction. The eigenfunctions of the critical eigenvalue λ_1 in (3.16) have the forms $(x/r)\phi_1(r)$, $(y/r)\phi_1(r)$, and $(z/r)\phi_1(r)$. They lead to translations of u in x-, y-, or z-directions in the dynamics. Finally, the eigenfunctions of the critical eigenvalues λ_l, $l > 1$, in (3.18) give rise to oscillations of the interfaces. The same interpretations are also valid for the spherical lamellar pattern. Because all these eigenfunctions concentrate at the interface r_j by (3.15), (3.17), (4.12), (4.20), and (4.25), the dynamics along the directions of the critical eigenvalues is seen as the motion of the interfaces.

However, (5.2) is only one dynamical law that we can associate with (2.2). A more realistic one is the fourth-order partial differential equation [2]

$$u_t = \Delta(-\epsilon^2\Delta + f(u)) - \epsilon\gamma(u-a), \quad \partial_\nu u = \partial_\nu \Delta u = 0 \text{ on } \partial D. \tag{5.3}$$

Equation (5.3) generalizes the well-known Cahn–Hilliard equation [5]. Based on a spectral comparison argument [4], one shows that a steady state is stable under (5.2) if and only if it is stable under (5.3) [27]. Hence our results on the stability of the various steady states in this paper remain valid in the dynamics (5.3). An even more complex dynamical law considers a diblock copolymer melt as a fluid. It adds the velocity field and couples (5.3) with the Navier–Stokes equation of the velocity field [2].

We are mainly interested in stable solutions of (2.9). They are local minimizers of (2.2). We do not know whether or not any of the solutions found in this paper is a global minimizer. There also exist unstable spherical lamellar solutions even for $\gamma \in (\gamma_{K,e}, \gamma_{K,s})$. In Figures 6 and 7, when $\gamma > \gamma_{2,e}$, in addition to the minimum of J there exists a local maximum of J. This maximum point corresponds to an unstable spherical lamellar solution. This unstable solution exists for $\gamma \geq \gamma_{2,s}$ as well. The instability of this solution is caused by the $m = 0$ mode.

In the functional (2.2) the key ingredient is the nonlocal term. It describes a long range interaction. Many other important physical systems that exhibit self-organization and pattern formation share the same phenomenon [42]. Examples include charged Langmuir monolayers [1] and smectic liquid crystal films [41]. Many of the singular perturbation techniques presented here may be applied to these problems [29, 34, 37, 36].

The nonlocal interaction in (2.2) is of Coulomb type [25]. Some of the above-mentioned problems have different nonlocal interactions. In the charged monolayer

problem the nonlocal term is written as

$$\int_D \int_D (u(x) - a) G_c(x, y)(u(y) - a)\, dxdy, \tag{5.4}$$

which assumes the same form as (2.8). However, the kernel G_c is different. If D is a square, i.e., $(0, 1)^2$, with the periodic boundary condition, then G_c is translation invariant so that $G_c(x, y) = G_c(x - y)$. The Fourier series of G_c is

$$\hat{G}_c(\xi) = \frac{1}{|\xi|}. \tag{5.5}$$

Note that for the diblock copolymer problem the corresponding G on a square is

$$\hat{G}(\xi) = \frac{1}{|\xi|^2}. \tag{5.6}$$

Hence as $|\xi| \to \infty$, (5.6) has a faster decay rate than (5.5). Many properties, such as the optimal size discussed in section 3.2, are sensitive to these decay rates. In general with a slower decay rate, one finds smaller microdomains [34].

In the smectic liquid crystal film problem, the nonlocal interaction comes from a coupling effect with the director field. In this case, because of the unit length constraint on the director field, the nonlocal interaction is no longer quadratic [36].

6. Conclusion. We used asymptotic analysis to study the Ohta–Kawasaki density functional theory for diblock copolymers. We constructed a single sphere pattern in a unit ball. Such a pattern is a cell in the spherical morphology. We showed the existence of the sphere pattern as a solution of the Euler–Lagrange equation of the free energy. We identified the optimal size of such a cell with the least free energy. We also found a stability threshold. The sphere is stable if it is less than the threshold value and unstable if it is greater than the threshold value. The stability threshold value is greater than the optimal size. At the stability threshold, there is another solution, a bifurcating branch. It has an interface of a wriggled sphere. This solution has lower free energy than that of the first solution.

Next we studied a spherical lamellar pattern, which we view as a defective lamellar pattern. Singular perturbation analysis allowed us to reduce the existence and stability problems in infinite dimensions to existence and matrix problems in finite dimensions. We found two thresholds: an existence threshold and a larger, stability threshold. There is a spherical lamellar pattern only when the size of the sample is larger than the existence threshold value. This patten is stable only when the size of the sample is between the existence threshold and the stability threshold. At the stability threshold, there is a bifurcating branch with a pattern of wriggled spherical interfaces. The bifurcating branch again has lower free energy.

A STAGE-STRUCTURED PREDATOR-PREY MODEL OF BEDDINGTON–DEANGELIS TYPE*

SHENGQIANG LIU† AND EDOARDO BERETTA‡

Abstract. We formulate and study a robust stage structured predator-prey model of Beddington–DeAngelis-type functional response. The time delay is the time taken from birth to maturity. The Beddington–DeAngelis functional response is similar to the Holling type 2 functional response but contains an extra term describing mutual interference by predators. First we show that the predator coexists with prey permanently if and only if the predator's recruitment rate at the peak of prey abundance is larger than its death rate. Second, we show that if the system is permanent, then a sufficiently large degree of the predator interference can not only stabilize the system but also guarantee the stability of the system against the increase of the carrying capacity of prey and the increase of birth rate of the adult predator. Third, we show both analytically and numerically that stability switches of interior equilibrium may occur as maturation time delay increases: stability may change from stable to unstable to finally stable, implying that a large delay can be stabilizing.

1. Introduction.

The goal in this paper is to study a stage structured predator-prey model with Beddington–DeAngelis-type functional response. It is a central goal for ecologists to understand the relationship between predator and prey, and one significant component of the predator-prey relationship is the predator's functional responses or so-called predator's rate of feeding upon prey in other references [39], i.e., the rate of prey consumption by an average predator.

As for the mathematical predator-prey models, the description of a predator's instantaneous, per capita feeding rate, f, as a function of prey abundance x, is the classic definition of a predator's functional responses. There have been several famous functional response type: Holling types I–III [19], [20]; Hassell–Varley type [17]; Beddington–DeAngelis type by Beddington [6] and DeAngelis, Goldstein, and Neill [13] independently; the Crowley–Martin type [12]; and the recent well-known ratio-dependence type by Arditi and Ginzburg [3] later studied by Kuang and Beretta [27]. Of them, the Holling type I–III was labeled "prey-dependent" and the other types that consider the interference among predators were labeled "predator-dependent" by Arditi and Ginzburg [3]. Recently, "predator-dependent" type models have received much support from theoretical and empirical work in biology (see [4], [5], [11], [37], [38], [39], and the references therein). In [5], Abrams and Ginzburg even pointed out that "precise prey dependence and ratio dependence will both be rare" while "predator dependence will be common." In [39], by comparing the statistical evidence from

19 predator-prey systems with three predator-dependent functional responses, Skalski and Gilliam pointed out that the predator-dependent functional responses can provide better descriptions of predator feeding over a range of predator-prey abundances, and in some cases, the Beddington–DeAngelis-type functional response (hereafter the BD model) performed even better. Although the predator-dependent models that they considered fit those data reasonably well, no single functional response best describes all the data sets. The Beddington–DeAngelis response can be generated by a number of natural mechanisms [6], [11], [38] and because it admits rich but biologically reasonable dynamics [9], it is worthy for us to further study the BD model.

The per capita feeding rate of BD model takes the form [6]

$$f(x,y)=\frac{bx}{1+k_1x+k_2y}, \tag{1.1}$$

and thus the BD model takes the form

$$\begin{cases} x'(t)=rx(t)\left(1-\dfrac{x(t)}{K}\right)-\dfrac{bx(t)y(t)}{1+k_1x(t)+k_2y(t)},\\ y'(t)=\dfrac{nbx(t)y(t)}{1+k_1x(t)+k_2y(t)}-dy(t), \end{cases} \tag{1.2}$$

where x and y represent prey and predator densities; b (units: 1/time) and k_1 (units: 1/prey) are positive constants that describe the effects of capture rate and handling time, respectively, on the feeding rate; n is the birth rate of the predator; and $k_2 \geq 0$ (units: 1/predator) is a constant describing the magnitude of interference among predators [13]. The BD model is similar to the well-known Holling II type functional response (hereafter the H2 model) but has an extra term k_2y in the denominator modeling mutual interference among predators. Hence this kind of type functional response given in (1.1) is affected by both predator and prey, i.e., the so-called predator dependence by Arditi and Ginzburg [3]. Dynamics for the H2 model have been much studied ([22], [25], and references therein). Then how the mutual interference term affects the dynamic of the whole system is an interesting problem.

Many recent works have contributed to the BD model (1.2) [9], [10], [14], [23], [24], [33], [36]. Cantrell and Cosner [9] considered (1.2) and obtained the criteria for permanence, extinction, global stability of the interior equilibrium, and existence of periodic orbits. They showed that k_2 does affect the location and stability of the equilibrium for (1.2): (1) Adequate increase of k_2 may change the positive equilibrium from unstable to stable. (2) Having $k_2 > 0$ can stabilize the system by reducing the extent to which trajectories can exhibit "boom-bust" behavior. Therefore, the effect of k_2 in system (1.2) is to introduce a self-limiting term into the predator equation.

Hwang [23] showed that the interior equilibrium of system (1.2) is globally stable provided it is locally asymptotically stable. In [24], Hwang obtained the sufficient conditions for the uniqueness of limit cycles of (1.2).

Liu and Yuan [33] considered time delay τ in the response term $f(x,y)$ of (1.1) in the predator equation, that is,

$$\begin{cases} x'(t)=rx(t)\left(1-\dfrac{x(t)}{K}\right)-\dfrac{bx(t)y(t)}{1+k_1x(t)+k_2y(t)},\\ y'(t)=y(t)\left[-d+\dfrac{nbx(t-\tau)}{1+k_1x(t-\tau)+k_2y(t-\tau)}\right]. \end{cases} \tag{1.3}$$

In the second equation of (1.3), there is a nondelay term $y(t)$, which is similar to the delay models studied by Kuang [26] and Beretta and Kuang [7], where τ can be regarded as a gestation period or reaction time of the predations (see Martin and Ruan, [34]). By choosing the delay τ as a parameter, Liu and Yuan [33] showed that as τ crosses some critical values, Hopf bifurcation about the stability of interior equilibrium in (1.3) can occur.

Although much progress has been seen in the above work on BD model, such models are not well studied yet in the sense that all the known results are for models that ignore the enormous diversity during the life histories of the predator. Unfortunately, this is not realistic due to the following reasons:

1. Juvenile predators have a time lag from their birth to maturity.
2. Young predators are raised by their parents or are dependent on the nutrition from the eggs they stay in and they are much weaker than the mature predators, hence the juvenile predators cannot hunt the prey, nor can they breed.
3. Young predators reach maturity after surviving the immature stage; if the juvenile death rate (through-stage death rate) is nonzero, then not all immature predators can survive the juvenile stage.

Therefore, it is realistic and interesting for us to construct the stage-structured predator-prey model and study the combined effects of stage structure and mutual interference by predators. Most existing stage structure models (see [1], [28], [29], [30], [35], [2], and the references therein) deal with single species growth that assume a constant resource supply [15]. Recently, Gourley and Kuang [15] formulated a robust stage-structured predator-prey model with the assumption that stage-structured consumer species growth is a combined result of birth and death processes, both of which are closely linked to the dynamical supply of resource. Enlightened by the modeling methods in [15], we formulate the robust stage-structured BD model as follows:

$$
\begin{cases}
x'(t) = rx(t)\left(1 - \dfrac{x(t)}{K}\right) - \dfrac{bx(t)y(t)}{1 + k_1x(t) + k_2y(t)}, \\
y'(t) = \dfrac{nbe^{-d_j\tau}x(t-\tau)y(t-\tau)}{1 + k_1x(t-\tau) + k_2y(t-\tau)} - dy(t), \\
y_j'(t) = \dfrac{nbx(t)y(t)}{1 + k_1x(t) + k_2y(t)} - \dfrac{nbe^{-d_j\tau}x(t-\tau)y(t-\tau)}{1 + k_1x(t-\tau) + k_2y(t-\tau)} - d_jy_j(t), \\
x(\theta),\ y(\theta) \geq 0 \text{ are continuous on } -\tau \leq \theta \leq 0, \text{ and } x(0), y(0), y_j(0) > 0,
\end{cases} \tag{1.4}
$$

where $x(t)$ and $y(t)$ represent prey and the mature predator densities, respectively, and $y_j(t)$ denotes the immature or juvenile predator densities. We assume that juveniles suffer a mortality rate of d_j(the through-stage death rate) and take τ units of time to mature; thus $e^{-d_j\tau}$ is the surviving rate of each immature predator to reach maturity. And for the continuity of the solutions to system (1.4), in this paper, we require

$$
y_j(0) = bn\int_{-\tau}^{0} \frac{e^{d_j s}x(s)y(s)}{1 + k_1x(s) + k_2y(s)}\mathrm{d}s. \tag{1.5}
$$

By the third equation of system (1.4), the initial conditions (1.5), and using the arguments similar to Lemma 3.1 in [31, p. 672], we have

$$
y_j(t) = bn\int_{-\tau}^{0} \frac{e^{d_j s}x(t+s)y(t+s)}{1 + k_1x(t+s) + k_2y(t+s)}\mathrm{d}s, \tag{1.6}
$$

i.e., $y_j(t)$ is completely determined by $x(t), y(t)$, and thus the following system can be separated from system (1.4):

$$\begin{cases} x'(t) = rx(t)\left(1 - \dfrac{x(t)}{K}\right) - \dfrac{bx(t)y(t)}{1 + k_1x(t) + k_2y(t)}, \\ y'(t) = \dfrac{nbe^{-d_j\tau}x(t-\tau)y(t-\tau)}{1 + k_1x(t-\tau) + k_2y(t-\tau)} - dy(t), \\ x(\theta),\ y(\theta) \geq 0 \text{ is continuous on } -\tau \leq \theta \leq 0, \text{ and } x(0), y(0) > 0. \end{cases} \tag{1.7}$$

In the present paper, our main purpose is to study the global dynamics of our system (1.4) and to consider how the stage structure parameters $d_j\tau$ and the predator interference parameter k_2 affect the dynamical behaviors of system (1.4).

This paper is organized as follows. In the next section, we consider the equilibria for system (1.4) and give the conditions for the existence of the positive equilibrium. In section 3, we obtain the necessary and sufficient conditions for the extinction of predator and for the permanence of system (1.4). This is followed by a section on the global attractiveness of the positive equilibrium. The local stability of the equilibria of (1.4) is considered in section 5. The analysis of positive equilibrium is highly nontrivial and we provide only generic conditions for its stability switch, but we manage to give the sufficient conditions for the asymptotic stability of the positive equilibrium which require large k_2. To complement this analytic work, we also present some carefully designed simulation results. The paper ends with a discussion.

2. Equilibria. Because of (1.6), we only consider the equilibria (x, y) of system (1.7), which are solutions of the system

$$\begin{cases} rx\left(1 - \dfrac{x}{K}\right) - \dfrac{bxy}{1 + k_1x + k_2y} = 0, \\ \dfrac{nbe^{-d_j\tau}xy}{1 + k_1x + k_2y} - dy = 0. \end{cases} \tag{2.1}$$

It is easy to see that for all parameter values (1.7) has the equilibria $E_0 = (0, 0),\ E_1 = (K, 0)$. By (2.1), system (1.7) has the positive equilibrium $E = (x^*, y^*)$ iff

$$\frac{nbe^{-d_j\tau}K}{1 + k_1K} > d, \tag{2.2}$$

where

$$x^* = \frac{1}{2}\left(-B + \sqrt{B^2 + 4C}\right), \quad y^* = \frac{x^*(nbe^{-d_j\tau} - dk_1) - d}{dk_2} \tag{2.3}$$

with

$$B = \frac{K}{r}\left(\frac{nbe^{-d_j\tau} - dk_1}{ne^{-d_j\tau}k_2} - r\right); \quad C = \frac{Kd}{rne^{-d_j\tau}k_2}.$$

Hence the positive equilibrium E exists for all predation maturation times τ in the interval $I = [0, \tau^*)$, where

$$\tau^* = \frac{1}{d_j}\log\frac{Knb}{d(1 + Kk_1)}. \tag{2.4}$$

Increase of τ in I will lower y^* until E will coincide with E_1 at the finite value τ^*, and for higher τ there is no positive equilibrium.

On the other hand, k_2 does not affect the existence of the positive equilibrium since k_2 is not involved in (2.2). However, (2.3) indicates that increase of k_2 will lower y^* until E will coincide with E_1 at the infinite value k_2.

3. Permanence and extinction. Here the following results give conditions which are both necessary and sufficient for the permanence, extinction, of system (1.4), respectively.

THEOREM 3.1. $\lim_{t\to\infty}(x(t), y(t), y_j(t)) = (K, 0, 0)$ *holds true iff* $\frac{nbe^{-d_j\tau}K}{1+k_1K} \le d$ *holds true.*

THEOREM 3.2. *System* (1.4) *is permanent iff it satisfies* (2.2).

Theorem 3.1 and Theorem 3.2 directly generalize Theorem 3.1 in [9] into the stage-structured case.

Mathematically, Theorem 3.2 suggests that the permanence of (1.4) is equivalent to its existence of positive equilibrium. Biologically, Theorem 3.2 shows that the predator coexists with prey permanently iff the predator's recruitment rate at the peak of prey abundance is more than its death rate.

Let $k_2 = 0$, i.e., $f(x, y)$ in (1.1) becomes the H2 functional response. By Theorem 3.1 and Theorem 3.2, we directly have the following corollary.

COROLLARY 3.3. *Given system* (1.4) *with* $k_2 = 0$, *then* $\lim_{t\to\infty}(x(t), y(t), y_j(t)) = (K, 0, 0)$ *holds true iff* $\frac{nbe^{-d_j\tau}K}{1+k_1K} \le d$ *holds true.*

COROLLARY 3.4. *Given system* (1.4) *with* $k_2 = 0$, *then it is permanent iff it satisfies* $\frac{nbe^{-d_j\tau}K}{1+k_1K} > d$.

Let $k_1 = k_2 = 0$, i.e., $f(x, y)$ becomes the Holling type I functional response. By Theorem 3.1 and Theorem 3.2, we directly have the next corollary.

COROLLARY 3.5. *Given system* (1.4) *with* $k_1 = k_2 = 0$, *then* $\lim_{t\to\infty}(x(t), y(t), y_j(t)) = (K, 0, 0)$ *holds true iff* $nbe^{-d_j\tau}K \le d$ *holds true.*

COROLLARY 3.6. *Given system* (1.4) *with* $k_1 = k_2 = 0$, *then it is permanent iff it satisfies* $nbe^{-d_j\tau}K > d$.

For stage-structured predator-prey system with functional response of Holling I–II, Gourley and Kuang [15, Theorem 3.1] give the necessary and sufficient conditions on extinction of predator, which is included in our Corollaries 3.3 and 3.5. Further, Corollary 3.4 suggests that the stage-structured H2 and BD systems share the same permanence and extinction conditions. Hence, mutual interference coefficient k_2 does not affect the permanence of system (1.4), which is also an extension of the corresponding conclusions in [9].

To prove the above main results, we need some preliminary results. By arguments similar to Lemma 1 in [28], we have the following.

LEMMA 3.7. *Suppose* $y(\theta) \ge 0$ *is continuous on* $-\tau \le \theta \le 0$, *and* $x(0), y(0), y_j(0) > 0$. *Then the solution of system* (1.4) *satisfies* $x(t), y(t), y_j(t) > 0$ *for all* $t > 0$.

LEMMA 3.8. *Permanence of* $x(t), y(t)$ *in system* (1.4) *implies that of* $y_j(t)$.

Proof. Since $x(t), y(t)$ have positive ultimately upper and lower boundaries, using (1.6) we get

$$0 < \underline{\lim_{t\to\infty}} y_j(t) \le \overline{\lim_{t\to\infty}} y_j(t) < \infty,$$

proving Lemma 3.8. □

LEMMA 3.9. *System* (1.4) *is always dissipative in the first quadrant.*

Proof. By the first equation of system (1.4), $\dot{x}(t) < rx(t)(1 - \frac{x(t)}{K})$; thus we have

$$\overline{\lim_{t\to\infty}} x(t) \le K. \tag{3.1}$$

Let $W(t) = ne^{-d_j\tau}x(t) + y(t+\tau)$, then we have

$$\begin{aligned}\dot{W}(t)|_{(1.4)} &= -dy(t+\tau) + ne^{-d_j\tau}rx(t)\left(1 - \frac{x(t)}{K}\right)\\ &= -dW(t) + nde^{-d_j\tau}x(t) + ne^{-d_j\tau}rx(t)\left(1 - \frac{x(t)}{K}\right)\end{aligned}$$

By (3.1), there exist some positive constant B, T, such that $\dot{W}(t)|_{(1.4)} \le B - dW(t)$ for all $t \ge T$. Thus $\overline{\lim_{t\to\infty}} W(t) \le B/d$, and consequently $x(t), y(t)$ are ultimately bounded; using (1.6) we also have that $y_j(t)$ is ultimately bounded, proving Lemma 3.9. □

Proof of Theorem 3.1. For the sufficiency of the theorem, we consider two cases.

Case 1. $\frac{nbe^{-d_j\tau}K}{1+k_1K} < d$.

By Lemma 3.9, for the sufficiently small positive constant ϵ with $\frac{nbe^{-d_j\tau}(K+\epsilon)}{1+k_1(K+\epsilon)} < d$, there exists a $T = T_\epsilon > 0$ such that $x(t) < K + \epsilon$ for all $t > T$; substitute it into the second equation of (1.4), we get that for all $t > T + \tau$, there is

$$y'(t) < \frac{nbe^{-d_j\tau}(K+\epsilon)y(t-\tau)}{1 + k_1(K+\epsilon) + k_2y(t-\tau)} - dy(t) < \frac{nbe^{-d_j\tau}(K+\epsilon)y(t-\tau)}{1 + k_1(K+\epsilon)} - dy(t).$$

Since $\frac{nbe^{-d_j\tau}(K+\epsilon)}{1+k_1(K+\epsilon)} < d$, Lemma 2 of Liu et al. [28, p. 131] implies that the solution for the comparison equation

$$u'(t) = \frac{nbe^{-d_j\tau}(K+\epsilon)u(t-\tau)}{1 + k_1(K+\epsilon)} - du(t)$$

satisfies $\lim_{t\to\infty} u(t) = 0$, which with Lemma 3.7 proves $\lim_{t\to\infty} y(t) = 0$. Therefore by the third equation of (1.4) and the arguments by Liu et al. [28, p. 128], we get that $\lim_{t\to\infty} y(t) = 0$ implies $\lim_{t\to\infty} y_j(t) = 0$, hence by the first equation of system (1.4), we get $\lim_{t\to\infty} x(t) = K$, proving Case 1.

Case 2. $\frac{nbe^{-d_j\tau}K}{1+k_1K} = d$.

By the first equation of system (1.4), $x(t)$ is always decreasing when above K. We can prove that if there exists some $t_0 > 0$ such that $x(t_0) < K$, then $x(t) < K$ for all $t > t_0$. Otherwise there must exist some $t_1 > t_0$ such that $x(t_1) = K$ and $x'(t_1) \ge 0$. This is impossible. Hence, there are two possible cases, either

(1) $x(t) > K$ and $x(t) \to K$ as $t \to \infty$, or

(2) there exists some $t_0 > 0$ such that $x(t_0) < K$.

For the first of these cases, we only need to prove that $\lim_{t\to\infty} y(t) = 0$, since this implies $\lim_{t\to\infty} y_j(t) = 0$. Integrating the equation for $x(t)$ in (1.4), we have

$$\begin{aligned}x(t) - x(0) &= \int_0^t rx(s)\left(1 - \frac{x(s)}{K}\right)\mathrm{d}s - \int_0^t \frac{bx(s)y(s)}{1 + k_1x(s) + k_2y(s)}\mathrm{d}s\\ &< \int_0^t \underbrace{rx(s)\left(1 - \frac{x(s)}{K}\right)}_{x(s)\ge K}\mathrm{d}s - \int_0^t \frac{bKy(s)}{1 + k_1K + k_2y(s)}\mathrm{d}s\end{aligned}$$

for all $t \geq t_0$, and then

$$\int_0^t \frac{bKy(s)}{1+k_1K+k_2y(s)}\mathrm{d}s < x(0) - x(t) + \int_0^t \underbrace{rx(s)\left(1-\frac{x(s)}{K}\right)}_{\leq 0}\mathrm{d}s < x(0).$$

By the boundedness of $y(t)$, then $\int_0^t y(s)\mathrm{d}s$ is bounded for all $t \geq t_0$, and this implies $\lim_{t\to\infty} y(t) = 0$.

For the second of these cases, consider the function

$$V = y(t) + d\int_{t-\tau}^t y(s)\mathrm{ds}.$$

Then for all $t \geq t_0 + \tau$, we have

$$\begin{aligned}
\frac{dV}{dt}|_{(1.4)} &= \frac{nbe^{-d_j\tau}x(t-\tau)y(t-\tau)}{1+k_1x(t-\tau)+k_2y(t-\tau)} - dy(t) + d(y(t)-y(t-\tau)) \\
&= y(t-\tau)\cdot\left(\underbrace{\frac{nbe^{-d_j\tau}x(t-\tau)}{1+k_1x(t-\tau)+k_2y(t-\tau)}}_{x(t-\tau)<K} - d\right) \\
&< y(t-\tau)\cdot\left(\frac{nbe^{-d_j\tau}K}{1+k_1K+k_2y(t-\tau)} - d\right) \\
&= -\frac{dk_2y^2(t-\tau)}{1+k_1K+k_2y(t-\tau)} < 0,
\end{aligned}$$

which with Lemma 3.7 proves $\lim_{t\to\infty} y(t) = 0$. This proves $\frac{nbe^{-d_j\tau}K}{1+k_1K} \leq d$ is the sufficient condition for $\lim_{t\to\infty}(x(t), y(t), y_j(t)) = (K, 0, 0)$.

Now, we prove $\lim_{t\to\infty}(x(t), y(t), y_j(t)) = (K, 0, 0) \Longrightarrow \frac{nbe^{-d_j\tau}K}{1+k_1K} \leq d$. Assume the contrary, i.e., $\frac{nbe^{-d_j\tau}K}{1+k_1K} > d$; then system (1.4) has a positive equilibrium (x^*, y^*, y_j^*), contradicting $\lim_{t\to\infty}(x(t), y(t), y_j(t)) = (K, 0, 0)$ for all solution $(x(t), y(t), y_j(t))$. Hence there must be $\frac{nbe^{-d_j\tau}K}{1+k_1K} \leq d$, and this proves Theorem 3.1. □

To prove Theorem 3.2, we engage the persistence theory by Hale and Waltmann [16] for infinite dimensional systems; we also refer to Thieme [40]. Now, we present the persistence theory [16] as follows.

Consider a metric space X with metric d. T is a continuous semiflow on X, i.e., a continuous mapping $T:\ [0,\infty)\times X \to X$ with the following properties:

$$T_t \circ T_s = T_{t+s}, \quad t, s \geq 0; \quad T_0(x) = x,\ x \in X.$$

Here T_t denotes the mapping from X to X given by $T_t(x) = T(t, x)$. The distance $d(x, y)$ of a point $x \in X$ from a subset Y of X is defined by

$$d(x, y) = \inf_{y\in Y} d(x, y).$$

Recall that the positive orbit $\gamma^+(x)$ through x is defined as $\gamma^+(x) = \cup_{t\geq 0}\{T(t)x\}$, and its $\omega-$limit set is $\omega(x) = \cap_{\tau\geq 0} CL\cup_{t\geq\tau}\{T(t)x\}$, where CL means closure. Define $W^s(A)$ the stable set of a compact invariant set A as

$$W^s(A) = \{x:\ x \in X,\ \omega(x) \neq \phi,\ \omega(x) \subset A\};$$

define $\widetilde{A_\partial}$ the particular invariant sets of interest as

$$\widetilde{A_\partial} = \bigcup_{x \in A_\partial} \omega(x).$$

(H_1). Assume X is the closure of open set X^0; ∂X^0 is nonempty and is the boundary of X^0. Moreover the C^0-semigroup $T(t)$ on X satisfies

$$T(t): \ X^0 \to X^0, \ \ T(t): \ \partial X^0 \to \partial X^0.$$

LEMMA 3.10 (see [16, Theorem 4.1, p. 392]). *Suppose $T(t)$ satisfies* (H_1) *and*
(i) *there is a $t_0 \geq 0$ such that $T(t)$ is compact for $t > t_0$;*
(ii) *$T(t)$ is point dissipative in X;*
(iii) *$\widetilde{A_\partial}$ is isolated and has an acyclic covering M.*
Then $T(t)$ is uniformly persistent iff for each $M_i \in M$, $W^s(M_i) \bigcap X^0 = \phi$.

Proof of Theorem 3.2.

Claim 1. The condition (2.2) leads to the permanence of system (1.4).

We begin by showing Claim 1 holds true for system (1.7), the subsystem of system (1.4), as the first step, we verify that the boundary planes of $R^2_+ = \{(x, y) : \ x \geq 0, \ y \geq 0\}$ repel the positive solutions to system (1.7) uniformly.

Let $C^+([-\tau, 0], R^2_+)$ denote the space of continuous functions mapping $[-\tau, 0]$ into R^2_+. We choose

$$C_1 = \{(\varphi_0, \varphi_1) \in C^+([-\tau, 0], R^2_+): \ \varphi_0(\theta) \equiv 0, \ \varphi_1(\theta) > 0, \ \theta \in [-\tau, 0]\},$$

$$C_2 = \{(\varphi_0, \varphi_1) \in C^+([-\tau, 0], R^2_+): \ \varphi_0(\theta) > 0, \ \varphi_1(\theta) \equiv 0, \ \theta \in [-\tau, 0]\}.$$

Denote $C = C_1 \bigcup C_2$, $X = C^+([-\tau, 0], R^2_+)$, and $X^0 = \text{Int}C^+([-\tau, 0], R^2_+)$; then $C = \partial X^0$. It is easy to see that system (1.7) possesses, two constant solutions in $C = \partial X^0$: $\widetilde{E_0} \in C_1$, $\widetilde{E_1} \in C_2$ with

$$\widetilde{E_0} = \{(\varphi_0, \varphi_1) \in C^+([-\tau, 0], R^2_+): \ \varphi_0(\theta) \equiv \varphi_1(\theta) \equiv 0, \ \theta \in [-\tau, 0]\},$$

$$\widetilde{E_1} = \{(\varphi_0, \varphi_1) \in C^+([-\tau, 0], R^2_+): \ \varphi_0(\theta) \equiv K, \ \varphi_1(\theta) \equiv 0, \ \theta \in [-\tau, 0]\}.$$

We verify below that the conditions of Lemma 3.10 are satisfied. By the definition of X^0 and ∂X^0 and system (1.7), it is easy to see that conditions (i) and (ii) of Lemma 3.10 are satisfied and that X^0 and ∂X^0 are invariant. Hence (H_1) is also satisfied.

Consider condition (iii) of Lemma 3.10. We have

$$\dot{x}(t)|_{(\varphi_0, \varphi_1) \in C_1} \equiv 0,$$

thus $x(t)|_{(\varphi_0, \varphi_1) \in C_1} \equiv 0$ for all $t \geq 0$. Hence we have

$$\dot{y}(t)|_{(\varphi_0, \varphi_1) \in C_1} = -dy(t) \leq 0,$$

from which follows that all points in C_1 approach $\widetilde{E_0}$, i.e., $C_1 = W^s(\widetilde{E_0})$. Similarly we can prove that all points in C_2 approach $\widetilde{E_1}$, i.e., $C_2 = W^s(\widetilde{E_1})$. Hence $\widetilde{A_\partial} = \widetilde{E_0} \bigcup \widetilde{E_1}$ and clearly it is isolated. Noting that $C_1 \bigcap C_2 = \phi$, it follows from these structural features that the flow in $\widetilde{A_\partial}$ is acyclic, satisfying condition (iii) of Lemma 3.10.

Now we show that $W^s(\widetilde{E_i}) \bigcap X^0 = \phi$, $i = 0, 1$. By Lemma 3.7, we have $x(t), y(t) > 0$ for all $t > 0$. Assume $W^s(\widetilde{E_0}) \bigcap X^0 \neq \phi$, i.e., there exists a positive solution

$(x(t), y(t))$ with $\lim_{t\to\infty}(x(t), y(t)) = (0, 0)$, then using the first equation of (1.7), we get

$$\frac{\mathrm{d}(\ln x(t))}{\mathrm{d}t} = r(1 - \frac{x(t)}{K}) - \frac{by(t)}{1 + k_1x(t) + k_2y(t)} > \frac{r}{2}$$

for all sufficiently large t. Hence we have $\lim_{t\to\infty} x(t) = +\infty$, contradicting $\lim_{t\to\infty} x(t) = 0$; this proves $W^s(\widetilde{E_0}) \bigcap X^0 = \phi$.

Now we verify $W^s(\widetilde{E_1}) \bigcap X^0 = \phi$; assume the contrary, i.e., $W^s(\widetilde{E_1}) \bigcap X^0 \neq \phi$. Then there exists a positive solution $(x(t), y(t))$ to system (1.7) with $\lim_{t\to\infty}(x(t), y(t)) = (K, 0)$, and for sufficiently small positive constant ε with

$$\varepsilon < \min\left\{\frac{nbe^{-d_j\tau}K - d - dKk_1}{2(nbe^{-d_j\tau} - dk_1 + dk_2)}, \frac{nbe^{-d_j\tau}K - d - dKk_1}{2k_2d}\right\},$$

there exists a positive constant $T = T(\varepsilon)$ such that

$$x(t) > K - \varepsilon > 0, \quad y(t) < \varepsilon \ \text{ for all } t \geq T.$$

By the second equation of (1.7) we have

$$y'(t) > \frac{nbe^{-d_j\tau}(K - \varepsilon)y(t - \tau)}{1 + k_1(K - \varepsilon) + k_2y(t - \tau)} - dy(t), \quad t \geq T + \tau. \tag{3.2}$$

Consider the equation

$$\begin{cases} v'(t) = \dfrac{nbe^{-d_j\tau}(K - \varepsilon)v(t - \tau)}{1 + k_1(K - \varepsilon) + k_2v(t - \tau)} - dv(t), \quad t \geq T + \tau, \\ v(t) = y(t), \ t \in [T, T + \tau]. \end{cases} \tag{3.3}$$

By (3.2) and the comparison theorem, we have $y(t) \geq v(t)$ for all $t > T$. On the other hand, using Theorem 4.9.1 of [26, p. 159], we have $\lim_{t\to\infty} v(t) = v^*$ for all solutions to system (3.3), where $v^* = \frac{nbe^{-d_j\tau}(K-\varepsilon)-d-dk_1(K-\varepsilon)}{dk_2} > \varepsilon$ is the unique positive equilibrium of system (3.3). Hence we get $\lim_{\overline{t\to\infty}} y(t) \geq v^* > \varepsilon$, contradicting $y(t) < \varepsilon$ as $t \geq T$. Thus we have $W^s(\widetilde{E_i}) \bigcap X^0 = \phi$, $i = 0, 1$. Now we get that system (1.7) satisfies all conditions of Lemma 3.10, thus $(x(t), y(t))$ is uniformly persistent, i.e., there exists positive constants ϵ and $T = T(\epsilon)$ such that $x(t), y(t) \geq \epsilon$ for all $t \geq T$; noting Lemma 3.9 shows that (x, y) are ultimately bounded, and this proves the permanence of system (1.7). By Lemma 1.6, $y_j(t)$ is permanent, and this proves the permanence of system (1.4).

We verify below that permanence of system (1.4) indicates (2.2). Assume the contrary, i.e., $\frac{nbe^{-d_j\tau}K}{1+k_1K} \leq d$; then by Theorem 3.1, $x(t) \to K$, $y(t) \to 0$ as $t \to \infty$, contradicting permanence of (1.4). This proves Theorem 3.2. □

4. Global attractiveness. In this section, we consider the global stability of the interior equilibrium in system (1.7). We have the following result.

THEOREM 4.1. *The positive equilibrium E in system* (1.7) *is globally attractive provided that system* (1.7) *is permanent and*

$$k_2 > \max\left\{\frac{bK(nbe^{-d_j\tau} - k_1d)}{r[(nbe^{-d_j\tau} - dk_1)K - d]}, \frac{bK(nbe^{-d_j\tau} - k_1d)}{rd}, \frac{b}{r}\right\} \tag{4.1}$$

holds true.

Consider the following single species system with delay:

$$v'(t) = \frac{a_1 v(t-\tau)}{1 + a_2 v(t-\tau)} - a_3 v(t),\ v(t) = \phi(t) \geq 0,\ v(0) > 0,\quad t \in [-\tau, 0], \tag{4.2}$$

where $a_i > 0,\ i = 1, 2, 3$. Similar to Lemma 3.7, we have $v(t) > 0$ for all $t \geq 0$. From Theorem 4.9.1 in [26] we directly have the following lemma.

LEMMA 4.2. *System* (4.2) *has a unique positive equilibrium* $v^* = \frac{a_1 - a_3}{a_2 a_3}$ *that is globally asymptotically stable provided* $a_1 > a_3$.

Proof of Theorem 4.1. By first condition and Theorem 3.2, we have that (2.2) holds. By the first equation of (1.7) and the arguments to Lemma 3.9, for sufficiently small $\varepsilon > 0$, there is a $T_1 > 0$ such that $x(t) < K + \varepsilon = \overline{x_1}$ for $t \geq T_1$. Replacing this inequality into the second equation of (1.7), we have

$$y'(t) < \frac{nbe^{-d_j\tau}\overline{x_1} y(t-\tau)}{1 + k_1\overline{x_1} + k_2 y(t-\tau)} - dy(t),\quad t \geq T_1 + \tau.$$

Consider the system

$$\begin{cases} v'(t) = \dfrac{nbe^{-d_j\tau}\overline{x_1} v(t-\tau)}{1 + k_1\overline{x_1} + k_2 v(t-\tau)} - dv(t),\ t \geq T_1 + \tau, \\ v(t) \equiv y(t),\ t \in [T_1, T_1 + \tau]. \end{cases}$$

Noting $nbe^{-d_j\tau}\overline{x_1} - d(1 + k_1\overline{x_1}) > nbe^{-d_j\tau}K - d(1 + k_1 K) > 0$. Thus by Lemma 4.2, we have

$$\lim_{t\to\infty} v(t) = \frac{nbe^{-d_j\tau}\overline{x_1} - d(1 + k_1\overline{x_1})}{k_2 d} > 0.$$

By the comparison theorem, we have $y(t) \leq v(t),\ t \geq T_1 + \tau$. Then for the sufficiently small $\varepsilon > 0$, there exists $T_2 > T_1 + \tau$ such that

$$y(t) < \frac{nbe^{-d_j\tau}\overline{x_1} - d(1 + k_1\overline{x_1})}{k_2 d} + \varepsilon = \overline{y_1},\ t \geq T_2. \tag{4.3}$$

Replacing (4.3) into the first equation of (1.7), we have

$$x'(t) > rx(t)(1 - \frac{x(t)}{K}) - \frac{bx(t)\overline{y_1}}{1 + k_2\overline{y_1}},\quad t \geq T_2.$$

By (4.1), $r > \frac{b}{k_2} > \frac{b\overline{y_1}}{1 + k_2\overline{y_1}}$. Using the comparison theorem, for sufficiently small $\varepsilon > 0$, there is a $T_3 > T_2$ such that

$$x(t) > z^* - \varepsilon = \underline{x_1} > 0,\ t \geq T_3, \tag{4.4}$$

where $z^* = K \cdot [1 - \frac{b\overline{y_1}}{r(1 + k_2\overline{y_1})}] > 0$ is the positive root for the equation

$$rx(t)(1 - \frac{x(t)}{K}) - \frac{bx(t)\overline{y_1}}{1 + k_2\overline{y_1}} = 0.$$

Replacing (4.4) into the second equation of (1.7), we have

$$y'(t) > \frac{nbe^{-d_j\tau}\underline{x_1} y(t-\tau)}{1 + k_1\underline{x_1} + k_2 y(t-\tau)} - dy(t),\quad t \geq T_3 + \tau.$$

By (4.4), we have

$$\begin{aligned} nbe^{-d_j\tau}\underline{x_1} - d(1+k_1\underline{x_1}) &= (nbe^{-d_j\tau} - dk_1)\cdot\left\{K[1-\frac{b\overline{y_1}}{r(1+k_2\overline{y_1})}] - \varepsilon\right\} - d \\ &> (nbe^{-d_j\tau} - dk_1)\cdot\left\{K[1-\frac{b}{rk_2}] - \varepsilon\right\} - d \\ &= \frac{(nbe^{-d_j\tau} - dk_1)(K-\varepsilon) - d}{k_2} \\ &\quad\cdot\left\{k_2 - \frac{bK(nbe^{-d_j\tau} - dk_1)}{r[(nbe^{-d_j\tau} - dk_1)(K-\varepsilon) - d]}\right\}. \end{aligned}$$

Using (4.1), we can get

$$nbe^{-d_j\tau}\underline{x_1} - d(1+k_1\underline{x_1}) > 0 \quad \text{for sufficiently small } \varepsilon. \tag{4.5}$$

By Lemma 4.2 and the similar arguments to $\overline{y_1}$, for the above selected $\varepsilon > 0$, there exists $T_4 > T_3 + \tau$ such that

$$y(t) > \frac{nbe^{-d_j\tau}\underline{x_1} - d(1+k_1\underline{x_1})}{k_2 d} - \varepsilon = \underline{y_1} > 0,\ t \geq T_4. \tag{4.6}$$

Therefore we have that

$$\underline{x_1} < x(t) < \overline{x_1},\ \underline{y_1} < y(t) < \overline{y_1},\quad t \geq T_4,$$

hold for system (1.7).

Replacing (4.6) into the first equation of (1.7), we have

$$x'(t) < rx(t)(1-\frac{x(t)}{K}) - \frac{bx(t)\underline{y_1}}{1+k_2\underline{y_1}},\quad t \geq T_4.$$

Since $r - \frac{b\underline{y_1}}{1+k_2\underline{y_1}} > r - \frac{b\overline{y_1}}{1+k_2\overline{y_1}} > 0$, by the comparison theorem, for sufficiently small $\varepsilon > 0$, there is a $T_5 > T_4$ such that

$$x(t) < z_1^* + \varepsilon = \overline{x_2} > 0,\ t \geq T_5, \tag{4.7}$$

with $z_1^* = K\cdot[1 - \frac{b\underline{y_1}}{r(1+k_2\underline{y_1})}] > 0$. From the definition of $\overline{x_2}$ we get

$$\overline{x_2} < K < \overline{x_1}.$$

Replacing (4.7) into the second equation of (1.7), we have

$$y'(t) < \frac{nbe^{-d_j\tau}\overline{x_2}y(t-\tau)}{1+k_1\overline{x_2}+k_2y(t-\tau)} - dy(t),\quad t \geq T_5+\tau.$$

Since $\overline{x_2} > \underline{x_1}$ and noting (4.5), we have $nbe^{-d_j\tau}\overline{x_2} - d(1+k_1\overline{x_2}) > nbe^{-d_j\tau}\underline{x_1} - d(1+k_1\underline{x_1}) > 0$. Thus using arguments similar to above, for the sufficiently small $\varepsilon > 0$, there is a $T_6 > T_5 + \tau$ such that

$$y(t) < \frac{nbe^{-d_j\tau}\overline{x_2} - d(1+k_1\overline{x_2})}{k_2 d} + \varepsilon = \overline{y_2},\ t \geq T_6, \tag{4.8}$$

by (4.3), (4.8) we get $\overline{y_2} < \overline{y_1}$.

Replacing (4.8) into the first equation of (1.7), we have

$$x'(t) > rx(t)(1-\frac{x(t)}{K}) - \frac{bx(t)\overline{y_2}}{1+k_2\overline{y_2}}, \quad t \geq T_6.$$

From (4.1), $r > \frac{b}{k_2} > \frac{b\overline{y_1}}{1+k_2\overline{y_1}} > \frac{b\overline{y_2}}{1+k_2\overline{y_2}}$. Then by the comparison theorem, for sufficiently small $\varepsilon > 0$, there is a $T_7 > T_6$ such that

$$x(t) > z_2^* - \varepsilon = \underline{x_2} > 0, \ t \geq T_7, \tag{4.9}$$

with $z_2^* = K \cdot [1 - \frac{b\overline{y_2}}{r(1+k_2\overline{y_2})}] > 0$. By the definition of $\underline{x_2}$, we have $\underline{x_2} > \underline{x_1}$.

Replacing (4.9) into the second equation of (1.7), then by arguments similar to those for $\overline{y_2}$, we get that there exists a $T_8 > T_7 + \tau$ such that

$$y(t) > \frac{nbe^{-d_j\tau}\underline{x_2} - d(1+k_1\underline{x_2})}{k_2 d} - \varepsilon = \underline{y_2} > 0, \ t \geq T_8, \tag{4.10}$$

and we get $\underline{y_2} > \underline{y_1}$.

Therefore, we have

$$0 < \underline{x_1} < \underline{x_2} < x(t) < \overline{x_2} < \overline{x_1}, \quad 0 < \underline{y_1} < \underline{y_2} < y(t) < \overline{y_2} < \overline{y_1}, \quad t \geq T_8. \tag{4.11}$$

Repeating the above arguments, we get the four sequences $\{\overline{x_n}\}_{n=1}^{\infty}, \{\underline{x_n}\}_{n=1}^{\infty}$, $\{\overline{y_n}\}_{n=1}^{\infty}, \{\underline{y_n}\}_{n=1}^{\infty}$ with

$$\begin{aligned} &0 < \underline{x_1} < \underline{x_2} < \cdots < \underline{x_n} < x(t) < \overline{x_n} < \cdots < \overline{x_2} < \overline{x_1}, \\ &0 < \underline{y_1} < \underline{y_2} < \cdots < \underline{y_n} < y(t) < \overline{y_n} < \cdots < \overline{y_2} < \overline{y_1}, \quad t \geq T_{4n}. \end{aligned} \tag{4.12}$$

From (4.12) follows that the limit of each sequence in $\{\overline{x_n}\}_{n=1}^{\infty}, \{\underline{x_n}\}_{n=1}^{\infty}, \{\overline{y_n}\}_{n=1}^{\infty}$, $\{\underline{y_n}\}_{n=1}^{\infty}$ exists. Denote

$$\overline{x} = \lim_{n\to\infty} \overline{x_n}, \quad \overline{y} = \lim_{n\to\infty} \overline{y_n}, \quad \underline{x} = \lim_{n\to\infty} \underline{x_n}, \quad \underline{y} = \lim_{n\to\infty} \underline{y_n};$$

thus we get $\overline{x} \geq \underline{x}, \ \overline{y} \geq \underline{y}$. To complete the proof, it suffices to prove $\overline{x} = \underline{x}, \quad \overline{y} = \underline{y}$.

By the definition of $\overline{y_n}, \underline{y_m}$ we have

$$\overline{y_n} = \frac{nbe^{-d_j\tau}\overline{x_n} - d(1+k_1\overline{x_n})}{k_2 d} + \varepsilon, \quad \underline{y_m} = \frac{nbe^{-d_j\tau}\underline{x_m} - d(1+k_1\underline{x_m})}{k_2 d} - \varepsilon;$$

then we get

$$\overline{y_n} - \underline{y_m} = \frac{nbe^{-d_j\tau} - dk_1}{k_2 d} \cdot (\overline{x_n} - \underline{x_m}) + 2\varepsilon. \tag{4.13}$$

By the definition of $\overline{x_n}, \ \underline{x_n}$ and using (4.13), we have

$$\begin{aligned} \overline{x_n} - \underline{x_n} &= K \cdot \left[1 - \frac{b\underline{y_{n-1}}}{r(1+k_2\underline{y_{n-1}})}\right] - K \cdot \left[1 - \frac{b\overline{y_n}}{r(1+k_2\overline{y_n})}\right] + 2\varepsilon \\ &= \frac{bK}{r} \cdot \left[\frac{\overline{y_n} - \underline{y_{n-1}}}{(1+k_2\underline{y_{n-1}})(1+k_2\overline{y_n})}\right] + 2\varepsilon \\ &= \frac{bK}{r} \cdot \frac{[nbe^{-d_j\tau} - dk_1]/k_2 d \cdot (\overline{x_n} - \underline{x_{n-1}}) + 2\varepsilon}{(1+k_2\underline{y_{n-1}})(1+k_2\overline{y_n})} + 2\varepsilon \\ &< \frac{bK}{k_2 dr} \cdot [nbe^{-d_j\tau} - dk_1] \cdot (\overline{x_n} - \underline{x_{n-1}}) + 2\varepsilon\left(1 + \frac{bK}{r}\right). \end{aligned} \tag{4.14}$$

Let $n \to \infty$; then we have

$$\overline{x} - \underline{x} \le \frac{bK}{k_2 dr} \cdot [nbe^{-d_j\tau} - dk_1] \cdot (\overline{x} - \underline{x}) + 2\varepsilon \left(1 + \frac{bK}{r}\right),$$

thus

$$\left\{1 - \frac{bK}{k_2 dr} \cdot [nbe^{-d_j\tau} - dk_1]\right\} (\overline{x} - \underline{x}) \le 2\varepsilon \left(1 + \frac{bK}{r}\right).$$

From (4.1), we have $1 - \frac{bK}{k_2 dr} \cdot [nbe^{-d_j\tau} - dk_1] > 0$, and noting that ε can be arbitrarily small, then we have $\overline{x} = \underline{x}$. By (4.13) and let $n\ , m \to \infty$, we get $\overline{y} = \underline{y}$. This proves Theorem 4.1. □

5. Stability switches. Considering the characteristic equation of (1.7), we write (1.7) as

$$\underline{x}'(t) = \underline{F}(\underline{x}(t), \underline{x}(t-\tau))$$

and denote

$$G = \left(\frac{\partial \underline{F}}{\partial \underline{x}(t)}\right)_{\underline{x}^*}, \quad H = \left(\frac{\partial \underline{F}}{\partial \underline{x}(t-\tau)}\right)_{\underline{x}^*}.$$

Thus characteristic equation of (1.7) at the equilibrium $\underline{x}^*$ takes the form as follows:

$$\det(G + He^{-\lambda\tau} - \lambda I) = 0. \tag{5.1}$$

We have

$$G = \begin{pmatrix} r - 2\frac{r}{K}x - \frac{\partial g}{\partial x} & -\frac{\partial g}{\partial y} \\ 0 & -d \end{pmatrix}, \quad H = \begin{pmatrix} 0 & 0 \\ ne^{-d_j\tau}\frac{\partial g}{\partial x} & ne^{-d_j\tau}\frac{\partial g}{\partial y} \end{pmatrix},$$

where

(5.2)

$$g(x,y) = \frac{bxy}{1 + k_1 x + k_2 y}, \ \frac{\partial g(x,y)}{\partial x} = \frac{by(1+k_2 y)}{(1 + k_1 x + k_2 y)^2}, \ \frac{\partial g(x,y)}{\partial y} = \frac{bx(1+k_1 x)}{(1 + k_1 x + k_2 y)^2}.$$

Thus the characteristic equation of system (1.7) at some equilibrium (x^0, y^0) is as follows:

$$\begin{vmatrix} r - 2\frac{r}{K}x^0 - g'_x(x^0,y^0) - \lambda & -g'_y(x^0,y^0) \\ ne^{-(\lambda+d_j)\tau}g'_x(x^0,y^0) & ne^{-(\lambda+d_j)\tau}g'_y(x^0,y^0) - d - \lambda \end{vmatrix} = 0. \tag{5.3}$$

At the equilibrium $E_0 = (0,0)$ we have $g'_x(0,0) = g'_y(0,0) = 0$ and the characteristic equation (5.3) reduces to $\begin{vmatrix} r-\lambda & 0 \\ 0 & -d-\lambda \end{vmatrix} = 0$, i.e., E_0 is an unstable saddle point.

THEOREM 5.1. *The equilibrium $E_1 = (K, 0)$ is*

(i) *unstable if $\frac{nbe^{-d_j\tau}K}{1+k_1K} > d$;*

(ii) *linearly neutrally stable if $\frac{nbe^{-d_j\tau}K}{1+k_1K} = d$;*

(iii) *asymptotically stable if $\frac{nbe^{-d_j\tau}K}{1+k_1K} < d$.*

By Theorem 5.1 and the arguments to Theorem 3.1, we directly have that equilibrium $(K,0)$ of system (1.7) is globally asymptotically stable iff $\frac{nbe^{-d_j\tau}K}{1+k_1K} \le d$ holds true. Using (1.6), we can easily prove that the global asymptotic stability of $(K,0)$ in system (1.7) is equivalent to that of $(K,0,0)$ in system (1.4). Thus we have the next corollary.

COROLLARY 5.2. *The equilibrium* $(K,0,0)$ *of system* (1.4) *is globally asymptotically stable iff* $\frac{nbe^{-d_j\tau}K}{1+k_1K} \le d$ *holds true.*

Proof of Theorem 5.1. By (5.3), we get that the characteristic equation of (1.7) at the equilibrium E_1 is

$$(\lambda + r)[ne^{-(\lambda+d_j\tau)}bg'_y(K,0) - d - \lambda] = 0. \tag{5.4}$$

Hence, one characteristic root is $\lambda = -r < 0$. Since $g'_y(K,0) = \frac{K}{1+k_1K}$, then the other are the roots of

$$g(\lambda) = \lambda + d - \frac{nbK}{1+k_1K} \cdot e^{-d_j\tau}e^{-\lambda\tau} = 0.$$

(i) Assume that $\frac{nbe^{-d_j\tau}K}{1+k_1K} > d$; then $g(0) = d - \frac{nbe^{-d_j\tau}K}{1+k_1K} < 0$, and $g(+\infty) = \infty$. Hence $g(\lambda)$ has at least one positive root and E_1 is unstable.

(ii) As $\frac{nbe^{-d_j\tau}K}{1+k_1K} = d$, $g(\lambda) = \lambda + d - de^{-\lambda\tau}$ and $\lambda = 0$ is a root of $g(\lambda) = 0$. Furthermore, since $g'(\lambda) = 1 + \tau de^{-\lambda\tau}$, we have $g'(0) > 0$. Then, the root $\lambda = 0$ is simple.
Then if the other roots are $\lambda = \alpha + i\omega$ they must satisfy

$$(\alpha + d)^2 + \omega^2 = d^2e^{-2\alpha\tau}.$$

Hence we must have $\alpha \le 0$, i.e., all the other roots have real nonpositive parts. Therefore E_1 is linearly neutrally stable.

(iii) Assume now that $\frac{nbe^{-d_j\tau}K}{1+k_1K} < d$, i.e.,

$$d - \frac{nbK}{1+k_1K} \cdot e^{-d_j\tau}e^{-\lambda\tau} > 0.$$

Then $g(\lambda) = 0$ implies that

$$\lambda + d = \frac{nbK}{1+k_1K} \cdot e^{-d_j\tau}e^{-\lambda\tau}.$$

If $\mathrm{Re}(\lambda) \ge 0$, then

$$|\lambda + d| > d > \frac{nbK}{1+k_1K} \cdot e^{-d_j\tau}e^{-\lambda\tau}.$$

This shows that all roots of $g(\lambda) = 0$ must have negative real parts, and therefore E_1 is asymptotically stable, proving (iii). ∎

Now, we consider the stability switches of the interior equilibrium $E = (x^*, y^*)$ as maturation time delay τ increases. We will adopt the following nomenclature:

$$g^* = g(x^*,y^*), \quad g'_{x^*} = g'_x(x^*,y^*), \quad g'_{y^*} = g'_y(x^*,y^*).$$

By (5.3), we get that the characteristic equation at E is as follows:

$$D(\lambda,\tau) = P(\lambda,\tau) + Q(\lambda,\tau)e^{-\lambda\tau} = 0, \tag{5.5}$$

where

$$\begin{cases} P(\lambda,\tau)=\lambda^2+P_1(\tau)\lambda+P_0(\tau), \\ P_1(\tau)=d-R+g'_{x^*}, \\ P_0(\tau)=(-R+g'_{x^*})d, \end{cases} \tag{5.6}$$

$$\begin{cases} Q(\lambda,\tau)=\lambda Q_1(\tau)+Q_0(\tau), \\ Q_1(\tau)=-ne^{-d_j\tau}g'_{y^*}, \\ Q_0(\tau)=Rne^{-d_j\tau}g'_{y^*}, \end{cases} \tag{5.7}$$

where $R=r-2\frac{r}{K}x^*$.

Of course, the characteristic equation (5.5) must be considered in the interval $I=[0,\tau^*)$ of existence of the positive equilibrium.

First verify that $\lambda=0$ cannot be a root of (5.5) for any $\tau\in I$, i.e.,

$$P(0,\tau)+Q(0,\tau)\neq 0.$$

Noting

$$P(0,\tau)+Q(0,\tau)=P_0(\tau)+Q_0(\tau)=(-R+g'_{x^*})d+Rne^{-d_j\tau}g'_{y^*},$$

and

$$g'_y=\frac{g}{y}\left(1-\frac{k_2}{b}\frac{g}{x}\right), \qquad g'_x=\frac{g}{x}\left(1-\frac{k_1}{b}\frac{g}{y}\right),$$
$$R=\frac{g^*}{x^*}-\frac{r}{K}x^*, \qquad ne^{-d_j\tau}\frac{g^*}{y^*}=d,$$

we get

$$\begin{aligned} P(0,\tau)+Q(0,\tau) &= -Rd+dg'_{x^*}+Rne^{-d_j\tau}\frac{g^*}{y^*}\left(1-\frac{k_2}{b}\frac{g^*}{x^*}\right) \\ &= dg'_{x^*}-Rd\frac{k_2}{b}\frac{g^*}{x^*} \\ &= d\left(\frac{g^*}{x^*}\left(1-\frac{k_1}{b}\frac{g^*}{y^*}\right)-\frac{k_2}{b}\frac{g^*}{x^*}\left(\frac{g^*}{x^*}-\frac{r}{K}x^*\right)\right) \\ &= d\frac{g^*}{x^*}\left(1-\left(\frac{k_1}{b}\frac{g^*}{y^*}+\frac{k_2}{b}\frac{g^*}{x^*}\right)+\frac{k_2}{b}\frac{r}{K}g^*\right) \end{aligned}$$

Now remark that $\frac{1}{b}(\frac{k_1}{y^*}+\frac{k_2}{x^*})g^*=\frac{k_1x^*+k_2y^*}{1+k_1x^*+k_2y^*}$ and therefore

$$P(0,\tau)+Q(0,\tau)>0,$$

for all $\tau\in I=[0,\tau^*)$.

The characteristic equation (5.5) at $\tau=0$ becomes

$$P(\lambda,0)+Q(\lambda,0)=0,$$

i.e.,

$$\lambda^2+(P_1(0)+Q_1(0))\lambda+P_0(0)+Q_0(0)=0, \tag{5.8}$$

where $P_0(0)+Q_0(0)>0$ since $P_0(\tau)+Q_0(\tau)>0$ for all $\tau\in[0,\tau^*)$.

Let us give an explicit structure for $P_1(0) + Q_1(0)$. From (5.6), (5.7)

$$P_1(0) + Q_1(0) = d - R + g'_{x^*} - ng'_{y^*},$$

where at interior equilibrium (and at $\tau = 0$)

$$R = \frac{g^*}{x^*} - \frac{r}{K}x^*, \quad n\frac{g^*}{y^*} = d.$$

Hence,

$$\begin{aligned} P_1(0) + Q_1(0) &= d - \frac{g^*}{x^*} + \frac{r}{K}x^* + \frac{g^*}{x^*} - \frac{k_1}{b}\frac{(g^*)^2}{x^*y^*} - n\frac{g^*}{y^*}\left(1 - \frac{k_2}{b}\frac{g^*}{x^*}\right) \\ &= d - \frac{g^*}{x^*} + \frac{r}{K}x^* + \frac{g^*}{x^*} - \frac{k_1}{b}\frac{(g^*)^2}{x^*y^*} - d + d\frac{k_2}{b}\frac{g^*}{x^*} \\ &= \frac{r}{K}x^* + \frac{d}{b}\frac{g^*}{x^*}\left(k_2 - k_1\frac{1}{d}\frac{g^*}{y^*}\right) \\ &= \frac{r}{K}x^* + \frac{d}{b}\frac{g^*}{x^*}\left(k_2 - \frac{k_1}{n}\right). \end{aligned}$$

Then, the roots of (5.8) determine the stability properties of the interior equilibrium at $\tau = 0$. Stability switches for increasing τ in $I = [0, \tau^*)$ may occur only with a pair of roots $\lambda = \pm i\omega(\tau)$, $\omega(\tau)$ real positive, that cross the imaginary axis.

To determine the stability switch delay values we proceed as follows (see [8, section 4]).

Assume $\lambda = \pm i\omega(\tau), \omega(\tau) > 0$ in (5.5); we have

$$\begin{cases} P(i\omega, \tau) = -\omega^2 + i\omega P_1(\tau) + P_0(\tau), \\ P_R(i\omega, \tau) = P_0(\tau) - \omega^2, \quad P_I(i\omega, \tau) = \omega P_1(\tau), \end{cases} \tag{5.9}$$

$$\begin{cases} Q(i\omega, \tau) = i\omega Q_1(\tau) + Q_0(\tau), \\ Q_R(i\omega, \tau) = Q_0(\tau), \quad Q_I(i\omega, \tau) = \omega Q_1(\tau). \end{cases} \tag{5.10}$$

The first step is that of looking for the positive roots $\omega(\tau) > 0$ of

$$F(\omega, \tau) = |P(i\omega, \tau)|^2 - |Q(i\omega, \tau)|^2 = 0 \tag{5.11}$$

in $I = [0, \tau^*)$. Since

$$\begin{aligned} F(\omega, \tau) &= (P_0(\tau) - \omega^2)^2 + \omega^2 P_1(\tau)^2 - [Q_0^2(\tau) + \omega^2 Q_1^2(\tau)], \\ &= P_0^2(\tau) + \omega^4 - 2P_0(\tau)\omega^2 + \omega^2 P_1^2(\tau) - Q_0^2(\tau) - \omega^2 Q_1^2(\tau), \\ &= \omega^4 + \omega^2(-2P_0(\tau) + P_1^2(\tau) - Q_1^2(\tau)) + P_0^2(\tau) - Q_0^2(\tau), \end{aligned}$$

hence we have

$$\begin{cases} F(\omega, \tau) = \omega^4 + b(\tau)\omega^2 + c(\tau) = 0, \\ b(\tau) = -2P_0(\tau) + P_1^2(\tau) - Q_1^2(\tau), \\ c(\tau) = P_0^2(\tau) - Q_0^2(\tau). \end{cases} \tag{5.12}$$

Depending on the sign of $b(\tau)$ and $c(\tau)$ the system (5.12) may have no positive real roots, or the root

$$\omega_+(\tau) = \left[\frac{1}{2}\{-b(\tau) + \sqrt{b(\tau)^2 - 4c(\tau)}\}\right]^{1/2}, \quad \tau \in I_+ \subseteq I,$$

or otherwise the root

$$\omega_-(\tau) = \left[\frac{1}{2}\{-b(\tau) - \sqrt{b(\tau)^2 - 4c(\tau)}\}\right]^{1/2}, \quad \tau \in I_- \subseteq I,$$

or, as a last case, both the roots $\omega_+(\tau)$ and $\omega_-(\tau)$. Note that if system (5.12) has no positive roots $\omega(\tau)$ in I, then no stability switches can occur.

According to characteristic equation (5.5), we can say that at $\tau = 0$, i.e., without stage structure, a necessary and sufficient condition for the asymptotic stability of positive equilibrium E is that

$$P_1(0) + Q_1(0) > 0,$$

whereas if $P_1(0) + Q_1(0) < 0$ the positive equilibrium is unstable.

Of course, from the structure of $P_1(0)+Q_1(0)$, a sufficient condition for asymptotic stability of E at $\tau = 0$ is that k_2 is sufficiently large to ensure that

$$k_2 - \frac{k_1}{n} > 0.$$

Stability switches for increasing τ in $I = [0, \tau^*)$ may occur only with a pair of roots $\lambda = \pm i\omega(\tau)$, $\omega(\tau)$ real positive, that cross the imaginary axis.

Now, we prove that E is asymptotically stable provided that k_2 is sufficiently large. We have the next theorem.

THEOREM 5.3. *The positive equilibrium E of* (1.7) *is asymptotically stable provided that system* (1.7) *is permanent and*

$$k_2 > \max\left\{\frac{k_1}{n},\ 2 \cdot \frac{bK(nbe^{-d_j\tau} - dk_1)}{r\left[bnKe^{-d_j\tau} - d(1 + k_1K)\right]}\right\}. \tag{5.13}$$

Define $M^K_{k_2}, M^n_{k_2}$ with

$$M^K_{k_2} = \sup_{K>0}\left\{\frac{nbe^{-d_j\tau}K}{1 + k_1K} > d + \delta_0 \,\middle|\, \frac{k_1}{n},\ 2 \cdot \frac{bK(nbe^{-d_j\tau} - dk_1)}{r\left[bnKe^{-d_j\tau} - d(1 + k_1K)\right]}\right\},$$

$$M^n_{k_2} = \sup_{n>0}\left\{\frac{nbe^{-d_j\tau}K}{1 + k_1K} > d + \delta_0 \,\middle|\, \frac{k_1}{n},\ 2 \cdot \frac{bK(nbe^{-d_j\tau} - dk_1)}{r\left[bnKe^{-d_j\tau} - d(1 + k_1K)\right]}\right\},$$

where δ_0 is some positive constant, thus $0 < M^K_{k_2}, M^n_{k_2} < \infty$. Using Theorem 3.2 and Theorem 5.3, we directly have the next corollary.

COROLLARY 5.4. *Assume $k_2 > M^K_{k_2}$, $\frac{nbe^{-d_j\tau}K}{1+k_1K} > d + \delta_0$; then the positive equilibrium E of* (1.7) *is asymptotically stable for all $K > 0$.*

COROLLARY 5.5. *Assume $k_2 > M^n_{k_2}$, $\frac{nbe^{-d_j\tau}K}{1+k_1K} > d + \delta_0$; then the positive equilibrium E of* (1.7) *is asymptotically stable for all $n > 0$.*

Proof of Theorem 5.3. To complete the proof, it suffices to prove that E has no stability switches as τ increases and that E is stable at $\tau = 0$. Hence we only need to consider the roots of (5.5) with $\tau = 0$, i.e., (5.8). Noting $P_0(0) + Q_0(0) > 0$ and

$$P_1(0) + Q_1(0) = \frac{r}{K}x^* + \frac{d}{b}\frac{g^*}{x^*}\left(k_2 - \frac{k_1}{n}\right) > \frac{r}{K}x^* > 0,$$

the roots of (5.8) must have negative real parts, proving E is stable at $\tau = 0$. Now we show E has no stability switches as τ increases in $I = [0, \tau^*)$. Thus we only need to prove that (5.12) has no positive roots $\omega(\tau)$ in I.

By (2.3), (5.6), (5.7), and (5.12) we have

$$\begin{aligned} b(\tau) &= -2(-R+g'_{x^*})d + (d-R+g'_{x^*})^2 - (-ne^{-d_j\tau}g'_{y^*})^2,\\ c(\tau) &= (-R+g'_{x^*})^2d^2 - (Rne^{-d_j\tau}g'_{y^*})^2,\\ R &= r - 2\tfrac{r}{K}x^* = \tfrac{g^*}{x^*} - \tfrac{r}{K}x^*. \end{aligned} \tag{5.14}$$

By Theorem 3.2, permanence of system (1.7) implies (2.2). Thus from (5.13) follows

$$k_2 > 2\cdot\frac{nbe^{-d_j\tau}-dk_1}{nre^{-d_j\tau}}. \tag{5.15}$$

Using (2.3), (5.2) and noting that $x^* < K$ and that B in (2.3) is negative under (5.15), then we have

$$x^* > \frac{1}{2}(-B+|B|) = -B = K\cdot\left(1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}\right) > K/2 > 0; \tag{5.16}$$

$$0 < y^* < \frac{K(nbe^{-d_j\tau}-dk_1)-d}{dk_2}; \tag{5.17}$$

$$0 < g* = \frac{dy^*}{ne^{-d_j\tau}} < \frac{K(nbe^{-d_j\tau}-dk_1)-d}{nk_2e^{-d_j\tau}}; \tag{5.18}$$

$$\begin{aligned} 0 < g'_{y^*} &= \frac{bx^*(1+k_1x^*)}{(1+k_1x^*+k_2y^*)^2} = \frac{d^2(1+k_1x^*)}{bn^2e^{-2d_j\tau}x^*} < \frac{d^2(1+k_1K)}{bn^2e^{-2d_j\tau}}\cdot\frac{1}{x^*}\\ &< \frac{d^2(1+k_1K)}{bn^2Ke^{-2d_j\tau}}\Big/\left(1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}\right); \end{aligned} \tag{5.19}$$

$$R = r - 2\frac{r}{K}x^* < -r + \frac{2(nbe^{-d_j\tau}-dk_1)}{nk_2e^{-d_j\tau}} < 0. \tag{5.20}$$

Thus by (5.14), we get

$$\begin{cases} b(\tau) = d^2+R^2+(g'_{x^*})^2 - 2Rg'_{x^*} - (ne^{-d_j\tau}g'_{y^*})^2\\ \qquad > R^2+d^2-(ne^{-d_j\tau}g'_{y^*})^2\\ \qquad = R^2+(d-ne^{-d_j\tau}g'_{y^*})(d+ne^{-d_j\tau}g'_{y^*}),\\ \\ c(\tau) = [d(-R+g'_{x^*})+Rne^{-d_j\tau}g'_{y^*}]\cdot[d(-R+g'_{x^*})-Rne^{-d_j\tau}g'_{y^*}]\\ \qquad = [dg'_{x^*}-R(d-ne^{-d_j\tau}g'_{y^*})]\cdot[d(-R+g'_{x^*})-Rne^{-d_j\tau}g'_{y^*}]. \end{cases} \tag{5.21}$$

By (5.19),

$$\begin{aligned} d-ne^{-d_j\tau}g'_{y^*} &> d - \frac{d^2(1+k_1K)}{bnKe^{-d_j\tau}}\Big/\left(1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}\right)\\ &= d\cdot\left[1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}} - \frac{d(1+k_1K)}{bnKe^{-d_j\tau}}\right]\Big/\left(1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}\right)\\ &= d\cdot\left[\frac{bnKe^{-d_j\tau}-d(1+k_1K)}{bnKe^{-d_j\tau}} - \frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}\right]\Big/\left(1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}\right)\\ &= d\cdot\frac{\frac{bnKe^{-d_j\tau}-d(1+k_1K)}{bnk_2Ke^{-d_j\tau}}}{1-\frac{nbe^{-d_j\tau}-dk_1}{nrk_2e^{-d_j\tau}}}\cdot\left(k_2-\frac{bK(nbe^{-d_j\tau}-dk_1)}{r\left[bnKe^{-d_j\tau}-d(1+k_1K)\right]}\right) > 0. \end{aligned}$$

Then we have $b(\tau),\ c(\tau) > 0$. Thus $F(\omega, \tau) \neq 0$ for all $\tau \in I = [0, \tau^*)$, i.e., there are no stability switches for $\tau \in I = [0, \tau^*)$. This proves Theorem 5.3. □

The second step to find the τ values of the stability switches requires that for each positive root $\omega(\tau)$ of (5.12) we define the angle $\theta(\tau) \in (0, 2\pi)$ as a solution of

$$\begin{cases} \sin\theta(\tau) = \dfrac{-(P_0(\tau) - \omega^2(\tau))\omega(\tau)Q_1(\tau) + \omega(\tau)P_1(\tau)Q_0(\tau)}{\omega^2(\tau)Q_1^2(\tau) + Q_0^2(\tau)}, \\ \cos\theta(\tau) = -\dfrac{(P_0(\tau) - \omega^2(\tau))Q_0(\tau) + \omega^2(\tau)P_1(\tau)Q_1(\tau)}{\omega^2(\tau)Q_1^2(\tau) + Q_0^2(\tau)} \end{cases} \tag{5.22}$$

for every $\tau \in I_\omega$, $I_\omega \subseteq I$, where I_ω is the subset of I in which the positive root $\omega(\tau)$ of (5.12) is defined (i.e., I_ω is I_+ or I_-).

The third step requires the definition for each $\omega(\tau)$ solution of (5.12) of the functions $I_\omega \mapsto \mathbf{R}$

$$S_n(\tau) := \tau - \frac{\theta(\tau) + n^2\pi}{\omega(\tau)},\ n \in \mathbf{N}_0, \tag{5.23}$$

that are continuous and differentiable in I_ω.

Still according to Beretta and Kuang [8, section 4], the following theorem holds true.

THEOREM 5.6. *The characteristic equation* (5.5) *has a pair of simple and conjugate pure imaginary roots* $\lambda = \pm i\omega(\tau^*)$, $\omega(\tau^*)$ *real positive, at* $\tau^* \in I_\omega$ *if* $S_n(\tau^*) = 0$ *for some* $n \in \mathbf{N}_0$.

If $\omega(\tau^*) = \omega_+(\tau^*)$, *this pair of simple conjugate pure imaginary roots crosses the imaginary axis from left to right (as* τ *increases) if* $\delta_+(\tau^*) > 0$ *and from right to left if* $\delta_+(\tau^*) < 0$, *where*

$$\delta_+(\tau^*) = \operatorname{sign}\left\{\frac{\mathrm{d}\ \mathrm{Re}\lambda}{\mathrm{d}\tau}\Big|_{\lambda=\mathrm{i}\omega_+(\tau^*)}\right\} = \operatorname{sign}\left\{\frac{\mathrm{dS_n}(\tau)}{\mathrm{d}\tau}\Big|_{\tau=\tau^*}\right\}. \tag{5.24}$$

If $\omega(\tau^*) = \omega_-(\tau^*)$, *this pair of simple conjugate pure imaginary roots crosses the imaginary axis from left to right if* $\delta_-(\tau^*) > 0$, *and from right to left if* $\delta_-(\tau^*) < 0$, *where*

$$\delta_-(\tau^*) = \operatorname{sign}\left\{\frac{\mathrm{d}\ \mathrm{Re}\lambda}{\mathrm{d}\tau}\Big|_{\lambda=\mathrm{i}\omega_-(\tau^*)}\right\} = -\operatorname{sign}\left\{\frac{\mathrm{dS_n}(\tau)}{\mathrm{d}\tau}\Big|_{\tau=\tau^*}\right\}. \tag{5.25}$$

Now, we show some numeric results. Figure 5.1 shows the solutions of model (1.4) with different predator maturation times τ. It seems that the interior equilibrium E is stable at $\tau = 0.8$ and $x(t), y(t)$ are unstable and periodically oscillated as $\tau = 6$; when $\tau = 10$, though still periodically oscillated, the oscillation amplitudes of $x(t), y(t)$ are smaller than those for $\tau = 6$, suggesting that E at $\tau = 10$ is less unstable than that at $\tau = 6$; when τ reaches 14, E becomes stable again. This behavior is expected as result of Theorem 5.7, which, for the same set of parameters as in Figure 5.1, states that interior equilibrium E remains asymptotically stable for τ from 0 up to $\tau_{0_1}^+ = 1.28$, is unstable with sustained oscillations for τ in the interval $(\tau_{0_1}^+ = 1.28,\ \tau_{0_2}^+ = 11.83)$, and returns asymptotically stable for $\tau > \tau_{0_2}^+ = 11.83$.

We try to have Figure 5.2 reflect the above changes of stability of positive equilibrium E as τ increases from 0.8 to 15. For Figure 5.2, each vertical black strip corresponds to the component of $x(t)$ and $y(t)$ in that $t \in [200 * \tau, 500 * \tau]$, respectively.

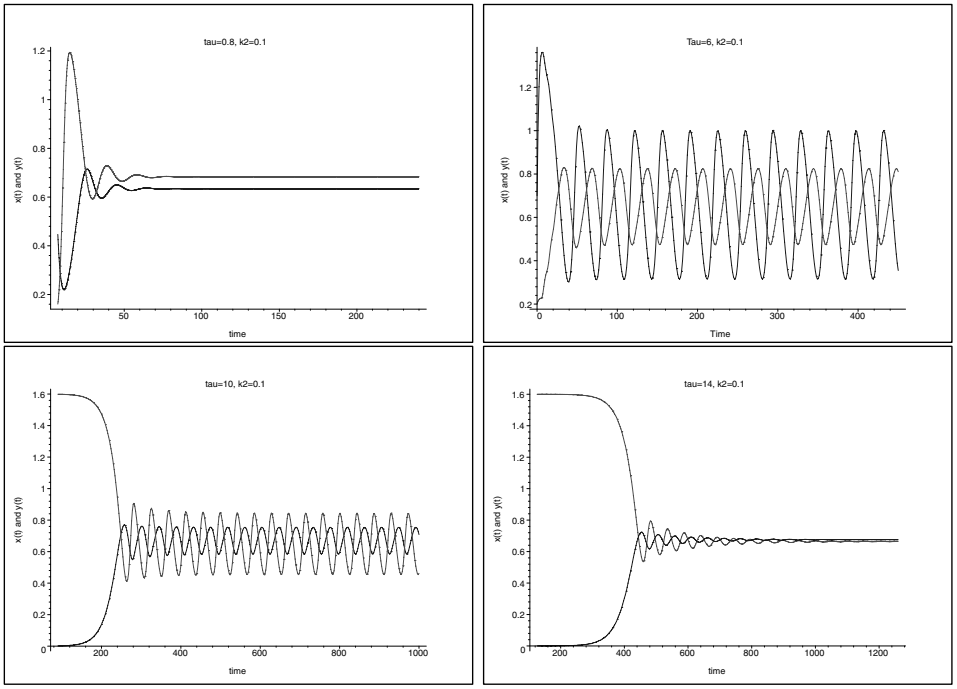

FIG. 5.1. *Solutions to system* (1.4) *with* $r = n = k_1 = 1$, $K = 1.6$, $b = 1.5$, $d = 0.5$, $k_2 = 0.1$, $d_j = 0.01$, $x(\theta) \equiv 0.7$, $y(\theta) \equiv 0.2$, $\theta \in [-\tau, 0]$.

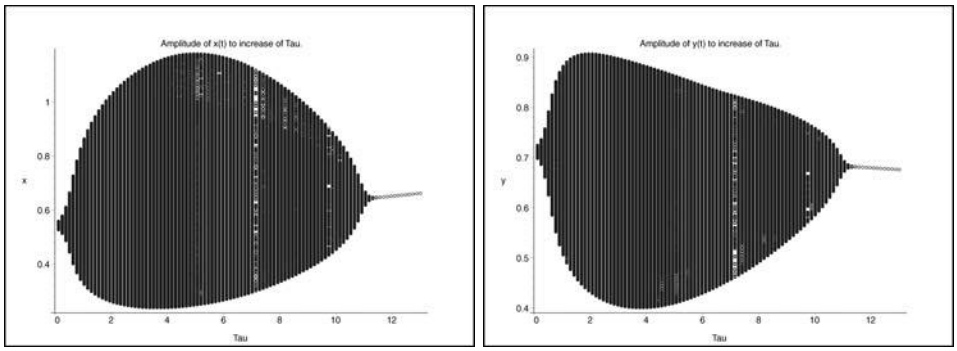

FIG. 5.2. *The ultimate oscillation interval of the solution to system* (1.4) *according to increase of predator maturation* τ, *where* $r = n = k_1 = 1$, $K = 1.6$, $b = 1.5$, $k_2 = 0.1$, $d = 0.5$, $d_j = 0.01$, $x(\theta) \equiv 0.7$, $y(\theta) \equiv 0.2$, $\theta \in [-\tau, 0]$.

From Figure 5.2, we see that if $\tau \in (0.2, 1)$ or $\tau > 12$, approximately, the vertical amplitudes of $x(t), y(t)$ are as small as a point, suggesting that E is asymptotically stable; if τ increases in the interval $(0.8, 6)$, approximately, the vertical amplitudes of $x(t), y(t)$ will becomes larger and larger, showing that E becomes more and more "unstable"; however, when τ smoothly increases in the interval $(6, 13)$, the points will become more concentrated and thus their amplitudes will become increasingly smaller until finally they gather into a point as $\tau > 11.83$, approximately. This shows that E becomes more stable as τ increases.

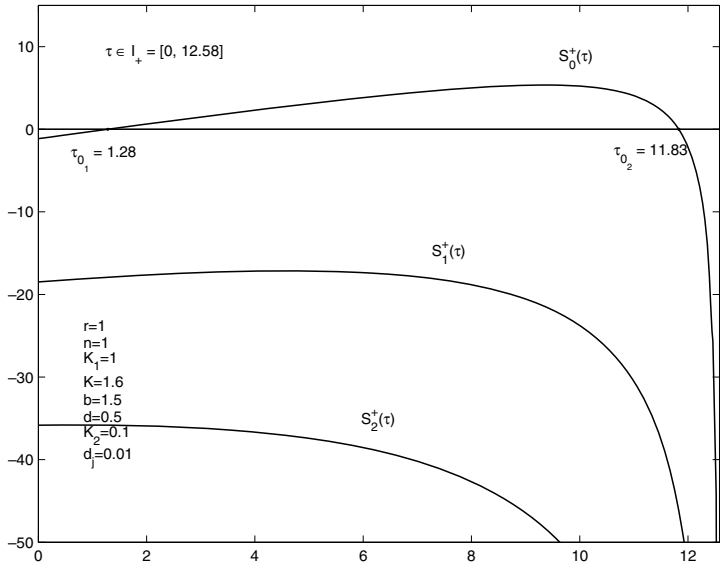

FIG. 5.3. *For the parameters choice* (5.26) *are depicted the curves* S_0^+, S_1^+, S_2^+ *in the interval of existence of* $\omega_+(\tau)$, *i.e.,* $\tau \in I_+ = [0, 12.58]$. *Only* S_0^+ *has two zeros* $\tau_{0_1} = 1.28$ *and* $\tau_{0_2}^+ = 11.83$.

Considering the case related to Figures 5.1 and 5.2, we have the following theorem.

THEOREM 5.7. *In system* (1.7), *let us choose the following parameters:*

$$r = n = k_1 = 1, \quad K = 1.6, \quad b = 1.5, \quad d = 0.5, \quad k_2 = 0.1, \quad d_j = 0.01. \tag{5.26}$$

Then system (1.7) *is asymptotically stable at* $\tau = 0$ *and remains asymptotically stable increasing* τ *up to the value* $\tau_{0_1}^+ = 1.28$, *which is a Hopf bifurcation value toward sustained oscillations around the positive equilibrium. The positive equilibrium remains unstable with sustained oscillations for* τ *up to the value* $\tau_{0_2}^+ = 11.83$, *at which there is a backward Hopf bifurcation value toward asymptotic stability. Whenever it exists the positive equilibrium remains asymptotically stable for* $\tau > \tau_{0_2}^+ = 11.83$.

Proof. For the proof, we have followed the algorithm presented previously in this section.

At $\tau = 0$ the roots of (5.8) are $\lambda = -0.0676 \pm i0.4581$ and therefore the positive equilibrium E is asymptotically stable. The equation (5.12) has only the positive root $\omega_+(\tau)$ in the interval $I_+ = [0, 12.58)$. According to the algorithm we have only the sequence $S_n^+(\tau)$, $\tau \in I_+$, $n \in \mathbf{N}_0$ of functions given by (5.23) (for which $S_n(\tau) > S_{n+1}(\tau)$ in I_+ for any $n \in \mathbf{N}_0$). By the algorithm presented for the characteristic equation (5.5), in Figure 5.3, we draw the curves S_0^+, S_1^+, S_2^+ in the interval of existence of $\omega_+(\tau)$. The $S_0^+(\tau)$ curve shows that for the parameter values (5.26), the function $S_0^+(\tau)$ has two zeros in I_+ the first at $\tau_{0_1} = 1.28$ and the second at $\tau_{0_2}^+ = 11.83$.

Thanks to Theorem 5.6, since in τ_{0_1} the slope of S_0^+ is positive, two pure imaginary roots $\lambda = \pm i\ \omega_+(\tau_{0_1})$ of (5.5) cross the imaginary axis entering in the right half complex plane and giving rise to two complex and conjugate roots with positive real part for $\tau > \tau_{0_1}$.

Hence the characteristic equation (5.5) has

(a) all roots with negative real parts if $\tau \in [0, \tau_{0_1})$;
(b) a pair of conjugate pure imaginary roots $\pm i\omega_+(\tau_{0_1})$, $\omega_+(\tau_{0_1}) > 0$, crossing the imaginary axis, and all other roots with negative real part if $\tau = \tau_{0_1}$;
(c) two roots with strictly positive real part if $\tau > \tau_{0_1}$ $(\tau < \tau_{0_2})$;
(d) and because of (b), all the roots λ $(\neq \pm i\ \omega_+(\tau_1))$ satisfy the condition $\lambda \neq i\ m\omega_+(\tau_1$, where m is any integer, if $\tau = \tau_{0_1}$.

Hence, at $\tau = \tau_{0_1}$ a Hopf bifurcation occurs (see [18, Chapter 11]).

Up to $\tau > \tau_{0_2}$ we have two complex and conjugate roots with positive real part giving rise to sustained oscillations. Since in τ_{0_2} the slope of S_0^+ is negative, two pure imaginary roots $\lambda = \pm i\omega_+(\tau_{0_2})$ of (5.5) cross the imaginary axis toward the left half complex plane and the total multiplicity of roots with positive real part returns to be zero for $\tau > \tau_{0_2}$. Similar to τ_{0_1} in τ_{0_2} we have another Hopf bifurcation toward asymptotic stability.

In conclusion, in $[0, \tau_{0_1})$ we have asymptotic stability of positive equilibrium E, in (τ_{0_1}, τ_{0_2}) sustained oscillations and in (τ_{0_2}, τ^*) asymptotic stability again. In τ_{0_1} there is a Hopf bifurcation toward sustained oscillations and in τ_{0_2} a Hopf bifurcation toward asymptotic stability. □

We observe that the outcomes of Theorem 5.7 are in agreement with the numeric simulations shown in Figure 5.1, where the solution of (1.7) is shown for the set of parameter values in (5.26). The agreement is the same for Figure 5.2.

For further analysis on the characteristic equation (5.5) it is worth noting that in the sequence $S_n,\ n \in \mathbf{N}_0$ (5.23), since $S_n(\tau) > S_{n+1}(\tau)$ for all $n \in \mathbf{N}$ and $\tau \in I_\omega$, the stability switches (Hopf bifurcations) occur only with the zeros of S_0. It is now interesting to study the role of predator interference coefficient k_2 on the stability of positive equilibrium E.

THEOREM 5.8. *In system* (1.7) *let us choose the following parameters:*

$$r = n = k_1 = 1, \quad K = 2.6, \quad b = 1.5,\ d = 0.5, \quad d_j = 0.01 \tag{5.27}$$

with varying k_2 *at the values* $k_2 = 0.2,\ 0.4,\ 0.6,\ 0.8$. *The positive equilibrium* E *undergoes stability switches from asymptotic stability to instability to asymptotic stability for increasing delay* τ *when* $k_2 = 0.2,\ 0.4,\ 0.6$ *and remains asymptotically stable for any* τ *when* $k_2 = 0.8$. *The delay instability interval has a decreasing width for increasing* k_2.

Proof. We have checked that parameter values (5.27), for each k_2 value, at $\tau = 0$ give rise to asymptotic stability of positive equilibrium E. By the algorithm presented for the characteristic equation (5.5), in Figure 5.4, we draw the curves S_0^+ versus τ for each k_2 value up to $k_2 = 0.7$. These curves S_0^+ correspond to the positive root $\omega_+(\tau)$ of (5.12) since for all k_2 values considered the root $\omega_-(\tau)$ of (5.12) is not feasible. For $k_2 > 0.7$ even the root $\omega_+(\tau)$ is not feasible, i.e., (5.12) does not have roots. Hence, no stability switches can occur for $k_2 > 0.7$, i.e., at $k_2 > 0.7$ the positive equilibrium E remains asymptotically stable for all $\tau \geq 0$ in its existence interval.

If we look at the curves S_0^+ in Figure 5.4, according to Theorem 5.6, we see that for each value $k_2 = 0.2,\ 0.4$, and 0.6 we have two stability switches, the first toward instability (since according to (5.24) at the first zero of $S_0{*}^+$ the slope of S_0^+ is positive) and the second toward asymptotic stability (since according to (5.24) at the second zero of S_0^+ the slope of S_0^+ is negative) with an unstable region in which sustained oscillations occur between the two stability switch delay values (Hopf bifurcations). Figure 5.4 shows that these delay instability regions have a decreasing

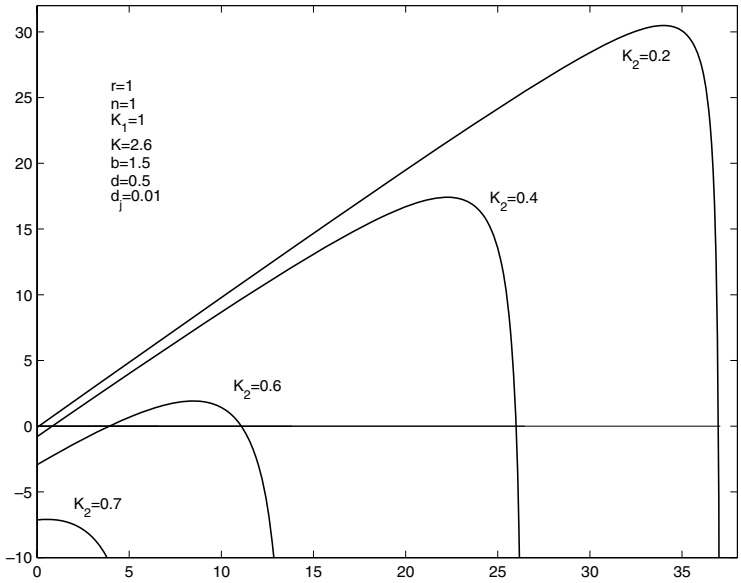

FIG. 5.4. *In the figure the curves* S_0^+ *are shown for the parameter values* (5.27) *and for the* k_2 *values* $k_2 = 0.2,\ 0.4,\ 0.6,\ 0.7$.

width for increasing values of k_2. At $k_2 = 0.7$ the curve S_0^+ has no zeros for $\tau \geq 0$ and therefore no stability switches can occur, i.e., the positive equilibrium E remains asymptotically stable for all τ in its existence interval. □

Figure 5.5, for the same parameters (5.27) of Theorem 5.8 and maturation time fixed at $\tau = 6$ show the behavior of $x(t), y(t)$ versus time at increasing values of k_2. At $k_2 = 0.2, 0.6$ we have sustained oscillations according to the fact that $\tau = 6$ falls within the instability intervals of S_0^+, whereas at $k_2 = 0.8$ S_0^+ is negative implying asymptotic stability of E.

For the parameter values (5.27) in Figure 5.6 we investigate the stabilizing role of predator interference coefficient k_2 on the positive equilibrium E by studying the zeros of the curves $S_0^+(\tau)$ for increasing values of k_2. The value of k_2, say, k_2^*, at which $S_0^+(\tau)$ has two coincident zeros (i.e., the delay instability region vanishes) is such that for $k_2 \geq k_2^*$ the positive equilibrium E does not undergo to stability switches and therefore E remains asymptotically stable in its existence interval $I = [0, \tau^*)$.

Figure 5.6 shows that $k_2^* = 0.6225$ when other parameters are fixed at values (5.27).

For the parameter values (5.27) and fixed maturation time delay $\tau = 6$ we try to have Figure 5.7 reflecting the above changes of stability of positive equilibrium E as k_2 increases from 0 to 0.9. For Figure 5.7, we see that if $k_2 \in (0, 0.64)$ the vertical amplitudes of $x(t),\ y(t)$ are oscillating showing that E is unstable. However, as k_2 smoothly increases in this interval, the points will become more concentrated and thus their amplitudes become smaller until finally, as that $k_2 > 0.64$ approximately, the vertical amplitudes of $x(t), y(t)$ will be small as a point, suggesting that E is asymptotically stable. This result is in good agreement with Figure 5.6.

The last case that we consider concerns Figure 5.8, which shows the interesting result that given enough large k_2 the predator and prey in system (1.4) will always coexist stably regardless how large K is.

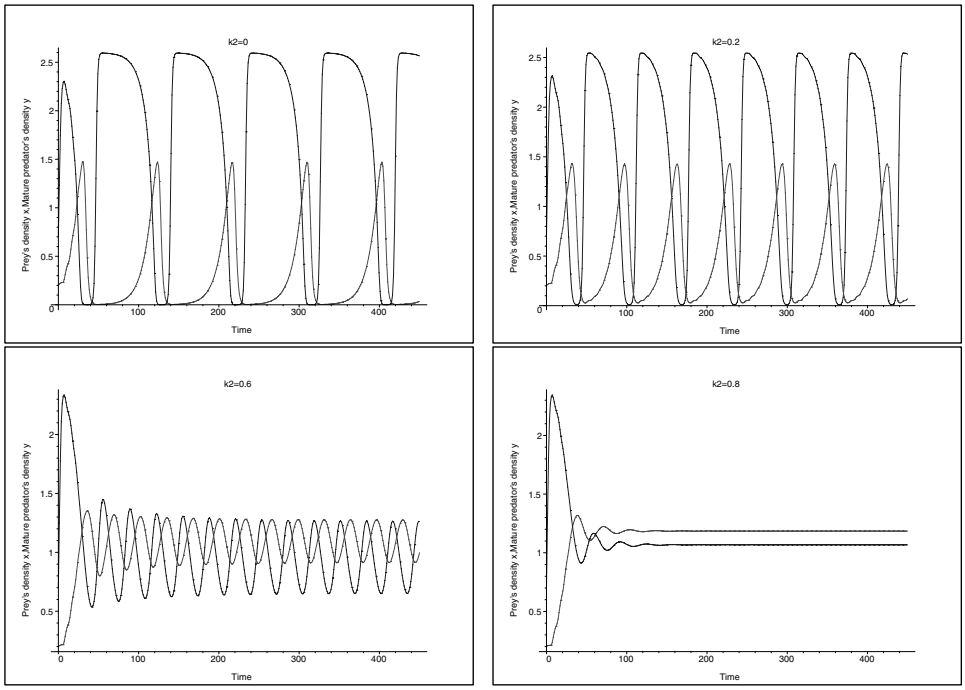

FIG. 5.5. *Solutions to system* (1.4) *with different predator interference coefficients* k_2*, here* $r = n = k_1 = 1$*,* $K = 2.6$*,* $b = 1.5$*,* $d = 0.5$*,* $\tau = 6$*,* $d_j = 0.01$*,* $x(\theta) \equiv 0.7$*,* $y(\theta) \equiv 0.2$*,* $\theta \in [-\tau, 0]$*.*

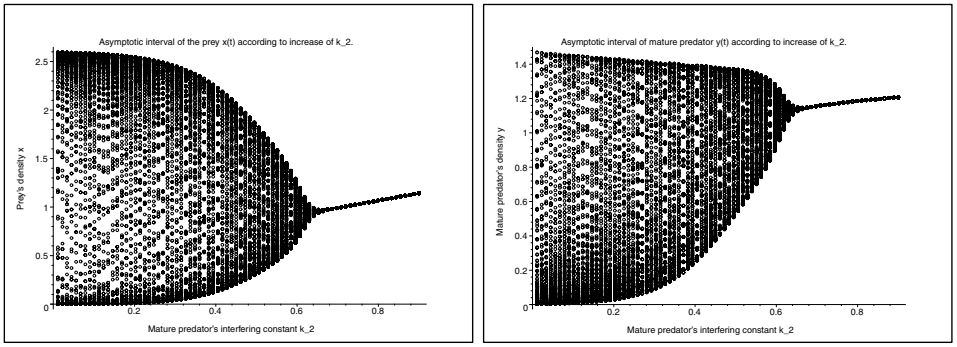

FIG. 5.7. *The ultimate oscillation interval of the solution to system* (1.4) *according to increase of predator interfering constant* k_2*, where* $r = n = k_1 = 1$*,* $K = 2.6$*,* $b = 1.5$*,* $d = 0.5$*,* $\tau = 6$*,* $d_j = 0.01$*,* $x(\theta) \equiv 0.7$*,* $y(\theta) \equiv 0.2$*,* $\theta \in [-\tau, 0]$.

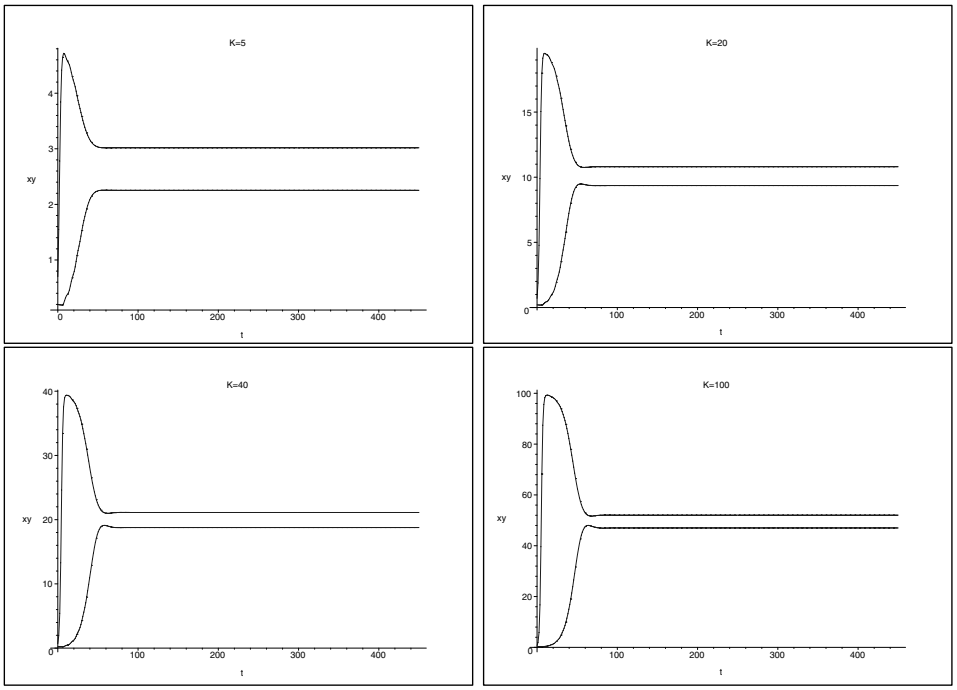

FIG. 5.8. *Solutions to system* (1.4) *with different carrying capacity* K*, here* $r = n = k_1 = 1$*,* $b = 1.5$*,* $d = 0.5$*,* $k_2 = 2$*,* $\tau = 6$*,* $d_j = 0.01$*,* $x(\theta) \equiv 0.7$*,* $y(\theta) \equiv 0.2$*,* $\theta \in [-\tau, 0]$.

The parameters are

$$r = n = k_1 = 1,\ b = 1.5,\ d = 0.5,\ k_2 = 2,\ d_j = 0.01 \tag{5.28}$$

with varying carrying capacity K at values $K = 5,\ 20,\ 40,\ 100$.

For each K we have checked that at $\tau = 0$ the roots of (5.8) have negative real part, i.e., at $\tau = 0$ the positive equilibrium is asymptotically stable.

Furthermore, (5.12) has no solutions in the existence interval $I = [0, \tau^*)$ of the positive equilibrium for each value of the considered carrying capacity. Hence, no sta-

bility switches can occur and the positive equilibrium E remains asymptotically stable in its existence interval for each considered value of carrying capacity, in agreement with the behavior shown by the solutions in Figure 5.8.

Figure 5.8 shows some interesting results: given enough large k_2, the predator and prey in system (1.4) will always coexist stably regardless how large K is. We have checked that the k_2 in Figure 5.8 does not satisfy (5.13); this shows that Theorem 5.3 has space to improve.

6. Discussion. In this paper, we study the stage-structured predator-prey model (1.4) of Beddington–DeAngelis-type functional response, which is an extension of both the ODE models studied by Cantrell and Cosner [9] and Hwang [23], [24] and the stage-structured predator-prey model of Holling II type functional response studied by Gourley and Kuang [15].

We give the conditions which are both necessary and sufficient for the permanence and extinction of system (1.4). Our results suggest that the predator coexists with prey permanently iff (2.2) holds true, i.e., predator's recruitment rate at the peak of prey abundance is larger than its death rate; and that the predator goes extinct iff $\frac{nbe^{-d_j\tau}K}{1+k_1K} \le d$ holds true, i.e., the predator's possible highest recruitment rate is less than or equal to its death rate. These results generalize the corresponding results in [9] and improve those in [15]. Comparing to the corresponding Theorem 3.1 in [9] for the ODE system (1.2), we find that there is an extra term $e^{-d_j\tau}$ in our permanence and extinction criteria, i.e., the surviving probability of each immature predator to become mature, which exists because of the stage structure. We can get that $d_j\tau$ has a negative effect on the persistence of the predator in that a proper increase of $d_j\tau$ (which is defined as the "degree of stage structure" by Liu et al. [28]) can directly destroy (2.2) and thus drive the predator into extinction, regardless how large $\frac{nbK}{1+k_1K}$ was.

On the other hand, even if (2.2) holds true, the proper increase of $d_j\tau$ may still cause the extinction of predators provided that demographic stochasticity were present: since y^* becomes smaller and smaller as $d_j\tau$ increases until $y^* = 0$ at $\frac{nbe^{-d_j\tau}K}{1+k_1K} = d$, then the predators will be at risk of stochastic extinction as the $d_j\tau$ holds the predator population to a sufficiently low level.

Therefore, the high death rate d_j or the long maturation of the juvenile predator τ may be responsible for the extinction of predators. These conclusions are analogous to those obtained for stage-structured predator-prey models of Holling I [35] and Holling II [15] type and similar to those for the stage-structured competitive system [28], [30], [31], [32], [2], [41].

We also find the stability switches of the interior equilibrium E due to the increase of τ: as τ increases, we see that oscillatory dynamics may appear and further increase of τ will return the oscillatory dynamics to the steady state form, implying that a large delay can be stabilizing.

Interesting results from this paper are the effects by the degree of predator interference k_2. First, we get that the permanence and extinction criteria for the stage structured BD model are independent of k_2. This shows that k_2 does not affect either the extinction or the permanence of the community, provided that the demographic stochasticity were ignored. Otherwise, as Cantrell and Cosner [9] argued for the non-stage-structured system (1.2), since $y^* \to 0$ as $k_2 \to \infty$, an increase of k_2 can lower y^* and may drive the predators into the risk of stochastic extinction when the predator population is at a sufficiently low level.

Second, k_2 can stabilize system (1.4):

(i) When E is unstable, having k_2 increasing from zero can reduce the oscillation amplitudes of solutions. This indicates that the interior equilibrium for the BD model is usually more stable than that for the corresponding H2 model.

(ii) Having a sufficiently large k_2 can directly drive E into the global attractiveness and the asymptotic stability.

Third, sufficiently large k_2 guarantees the robustness of the system against the increase of the carrying capacity K and the birth rate n of the adult predators. For the H2 model, Hsu, Hubbell, and Waltman [22, Lemma 4.5] showed that both the large carrying capacity K and the birth rate n of the predator can destabilize the positive equilibrium E and lead to the existence of periodic oscillation. Similar results can also be found in [25]. Hsu, Hubbell, and Waltman [21] even showed that an increase of K can cause E to be increasingly "unstable" by enlarging the amplitude of the limit cycle. However, we get completely different results for the BD model: Corollary 5.4 (or Corollary 5.5) shows that a sufficiently large k_2 can drive E stable regardless how large K (or n) is.

System (1.3) in [33] considers a gestation delay but not maturation delay of the BD model, while our model (1.4) accounts for maturation but not for gestation. Thus both (1.3) and (1.4) are the special cases of the following general model with both maturation and gestation effects:

(6.1)
$$\begin{cases} x'(t) = rx(t)\left(1 - \dfrac{x(t)}{K}\right) - \dfrac{bx(t)y(t)}{1 + k_1 x(t) + k_2 y(t)}, \\ y'(t) = \dfrac{nbe^{-d_j\tau}x(t-\tau-\tau_1)y(t-\tau)}{1 + k_1 x(t-\tau-\tau_1) + k_2 y(t-\tau-\tau_1)} - dy(t), \\ y_j'(t) = \dfrac{nbx(t-\tau_1)y(t)}{1+k_1 x(t-\tau_1)+k_2 y(t-\tau_1)} - \dfrac{nbe^{-d_j\tau}x(t-\tau-\tau_1)y(t-\tau)}{1+k_1 x(t-\tau-\tau_1)+k_2 y(t-\tau-\tau_1)} - d_j y_j(t), \\ x(\theta),\ y(\theta) \geq 0 \text{ are continuous on } -\tau \leq \theta \leq 0, \text{ and } x(0), y(0), y_j(0) > 0, \end{cases}$$

where τ, τ_1 are the maturation and the gestation delay, respectively. Then we have when $\tau = 0$, (6.1) becomes (1.3), and when $\tau_1 = 0$, (6.1) becomes (1.4). Thus system (6.1) unifies (1.3) and (1.4). It will be interesting for us to consider system (6.1); we leave this as our future work.

Acknowledgments. We are very grateful to two anonymous referees for their careful reading and very valuable comments, which led to an improvement of our original manuscript. We would like to thank Professor Horst Thieme, Dr. Dashun Xu and Dr. Yi Wang for the helpful discussions and Dr. Sanyi Tang, Dr. Yanni Xiao, and Dr. Margherita Carletti for their warm help on the numeric simulations. The first author acknowledges the financial support of Istituto di Biomatematica at Universitá di Urbino.

ON THE RELATIONSHIP BETWEEN SUPPLEMENTAL BALANCES IN TWO THEORIES FOR PURE INTERFACE MOTION*

ELIOT FRIED†

Abstract. A matched asymptotic analysis is used to exhibit the connection between supplemental balance equations arising in sharp-interface and phase-field theories for transformations between two rigid phases distinguished only by their constant free-energy densities. The analysis exposes the relationship between the forces and balances arising in the two theories.

Key words. configurational forces, phase transformations, sharp-interface theory, phase-field theory

1. Introduction.

The purpose of this paper is to examine the question of whether the configurational force balance can always be viewed merely as a rephrasing of the standard force balance. We address this question in the setting of a transformation between two rigid phases distinguished only by their constant free-energy densities. Because the phases are rigid, standard forces are extraneous and their balance is satisfied trivially. Nevertheless, configurational forces are essential and their balance is not implied by the standard force balance.

Standard forces are associated with the motion of material particles. Configurational forces first arose in the works of Peach and Koehler [29] and Eshelby [8, 9] on lattice defects and of Herring [25] on the sintering of powders. Beginning with appropriate energy functionals, those works derive configurational forces variationally by considering rearrangements of the relevant defects. The distinction between configurational forces and standard forces is evident from the derivations: whereas standard forces arise from variations in the placement of material particles, configurational forces arise from variations in the arrangement, relative to material particles, of nonmaterial defects. These derivations also show that, when deformation is taken into account, the necessary conditions for equilibrium in a defective medium include not only the Euler–Lagrange equations imposing the balance of standard forces at and away from defects but also an additional Euler–Lagrange equation valid at defects and involving configurational forces. Although the variations leading to these conditions are performed independently, the ensuing equilibrium conditions are generally coupled.

Aside from giving conditions for the description of equilibrium, the variational approach provides guidance on how configurational forces should enter the description of dissipative processes involving defect generation and evolution. Indeed, the conventional generalization of a variationally based theory for a defective medium involves replacing the relevant Euler–Lagrange equation with a gradient-flow equation requiring that the time-rate of the kinematical entity describing the configuration of the defect be proportional to the associated configurational force, with the sign of

the constant of proportionality assigned to rule out spurious growth of the underlying energy functional. In that setting, the rate term can be viewed as a configurational drag force that accounts for energy dissipation associated with the motion of defects relative to the underlying material.

The structure of classical theories of continua allows for a clear distinction to be drawn between basic laws and constitutive equations. Whereas the basic laws hold for large classes of materials, constitutive equations distinguish between different types of materials. However, because Euler–Lagrange and gradient-flow arguments rest on the provision of constitutive equations, the physical status of any supplemental equations they engender is unclear. Do such equations represent additional balances, above and beyond that involving standard forces, or do they simply represent additional constitutive information?

Commencing with a series of papers (Gurtin [18]; Angenent and Gurtin [2]; Gurtin and Struthers [23]) concerning phase transformations, Gurtin advocates the first of the alternative interpretations stated above. Those papers take a Gibbsian approach: phase interfaces are modeled as sharp nonmaterial surfaces across which the properties of the bulk phases may suffer discontinuities; to account for localized interactions between the phases, those surfaces are endowed with excess fields. Briefly, Gurtin's innovation centers on his treatment of configurational forces as primitive objects that expend power in conjunction with the motion of defects (relative to the underlying material) and are subject to a configurational balance distinct from and supplemental to that involving standard forces. The question of whether configurational forces are necessary for the description of three-dimensional bodies containing lower-dimensional defects has been addressed by Podio-Guidugli [31], who shows that when only standard forces are taken into account, the reasonable requirement that the power expended on a migrating referential control volume be invariant under changes of the tangential, and thus extrinsic, component of the velocity that describes the motion of the volume has a consequence that is generally untenable: the standard stress must be a pressure. To avoid that, it is necessary and sufficient to account for power expenditures above and beyond those associated with standard forces. That can be accomplished with the introduction of configurational forces. Gurtin's approach has been applied to the description of defect structures other than interfaces, including cracks (Gurtin and Podio-Guidugli [21, 22]; Gurtin and Shvartsman [24]; Kalpakides and Dascalu [26]), edges and junctions (Simha and Bhattacharya [32]), dislocations (Cermelli and Gurtin [7]), plasticity (Cermelli, Fried, and Sellers [4]), liquid-crystalline disclinations (Cermelli and Fried [5]), epitaxy (Gurtin and Jabbour [17]; Fried and Gurtin [15, 16], nematic-isotropic transformations in liquid crystals (Cermelli, Fried, and Gurtin [6]), and fluid-fluid phase transformations (Anderson, Cermelli, Fried, Gurtin and McFadden [1]). A comprehensive treatment of configurational forces and their applications is given in Gurtin's book [20].

Within Gurtin's framework, the distinction between the balances for configurational and standard forces is not merely an efficiency in capturing singularities. To illustrate this point, consider a setting involving a sharp interface $\mathcal{S}$ separating two phases, say α and β. For simplicity, neglect deformation, heat transport, and mass transport. Suppose that the free-energy density of phase $\gamma = \alpha, \beta$ is a constant, say Ψ_γ. Consider the problem of developing a theory that accounts for dependence of the interfacial free-energy density on the interfacial orientation and for dissipation associated with the growth of one phase at the expense of another. As shown by Gurtin [19, 20], such a theory involves a single equation governing the evolution of $\mathcal{S}$. Writing $\mathbf{n}$ for the unit orientation of $\mathcal{S}$, directed from the region occupied by phase-α

into the region occupied by phase-β, and $V_{\mathcal{S}}$ for the (scalar) normal velocity of $\mathcal{S}$ in the direction of $\mathbf{n}$, that equation is

$$\hat{b}_{\mathcal{S}}(\mathbf{n}, V_{\mathcal{S}})V_{\mathcal{S}} = \left\{\hat{\psi}_{\mathcal{S}}(\mathbf{n})\mathbf{P} + \frac{\partial^2 \hat{\psi}_{\mathcal{S}}(\mathbf{n})}{\partial \mathbf{n}^2}\right\} \cdot \mathbf{L} + [\![\Psi]\!], \tag{1.1}$$

where $\mathbf{P} = \mathbf{1} - \mathbf{n} \otimes \mathbf{n}$ is the interfacial projector, $\mathbf{L} = -\nabla_{\mathcal{S}}\mathbf{n}$ is the interfacial curvature tensor, $\hat{\psi}_{\mathcal{S}}$ is the free-energy per unit interfacial area, $\hat{b}_{\mathcal{S}}$ is the nonnegative kinetic modulus, and $[\![\Psi]\!] = \Psi_\beta - \Psi_\alpha$. Generally, the dependence of $\hat{\psi}_{\mathcal{S}}$ on $\mathbf{n}$ renders certain interfacial orientations more energetically favorable than others. Similarly, the dependence of $\hat{b}_{\mathcal{S}}$ on $\mathbf{n}$ allows for growth at different rates along different orientations. Further, the dependence of $\hat{b}$ on $V_{\mathcal{S}}$ allows for nonlinear growth kinetics. The nonnegativity of $\hat{b}_{\mathcal{S}}$ ensures satisfaction of the second law. If $\hat{\psi}_{\mathcal{S}}(\mathbf{n}) = \psi_{\mathcal{S}}$ and $\hat{b}_{\mathcal{S}}(\mathbf{n}, V_{\mathcal{S}}) = b_{\mathcal{S}}$ with $\psi_{\mathcal{S}}$ and $b_{\mathcal{S}}$ constant, the evolution equation (1.1) then reduces to

$$b_{\mathcal{S}}V_{\mathcal{S}} = \psi_{\mathcal{S}}K_{\mathcal{S}} + [\![\Psi]\!], \tag{1.2}$$

with $K_{\mathcal{S}} = \operatorname{tr}\mathbf{L} = -\operatorname{div}_{\mathcal{S}}\mathbf{n}$ (twice) the mean curvature. When $\Psi_\alpha = \Psi_\beta$, which would be the case for an interface separating two grains of a crystal, (1.2) reduces to $b_{\mathcal{S}}V_{\mathcal{S}} = \psi_{\mathcal{S}}K_{\mathcal{S}}$, the two-dimensional specialization of which was first proposed by Mullins [28] as a model for grain-boundary evolution. The two-dimensional version of (1.1), with $b_{\mathcal{S}}$ independent of $V_{\mathcal{S}}$, was proposed by Uhuwa [34]. The general equation (1.1) was first given by Gurtin [18]. A formulation of (1.1) using a variational definition of the curvature term is given by Taylor, Cahn, and Handwerker [33], who provide background and extensive references.

Within Gurtin's theory, the evolution equation (1.1) arises from the normal component of the interfacial configurational force balance

$$\operatorname{div}_{\mathcal{S}}\mathbf{C} + \mathbf{f} + [\![\mathbf{C}]\!]\mathbf{n} = \mathbf{0}, \tag{1.3}$$

in conjunction with the representations

$$\mathbf{C}_\gamma = \Psi_\gamma \mathbf{1} \qquad \text{and} \qquad \mathbf{C} = \psi_{\mathcal{S}}\mathbf{P} - \mathbf{n} \otimes \mathbf{c} \tag{1.4}$$

for the bulk and interfacial configurational stresses and constitutive relations

$$\psi_{\mathcal{S}} = \hat{\psi}_{\mathcal{S}}(\mathbf{n}), \qquad \mathbf{c} = -\frac{\partial \hat{\psi}_{\mathcal{S}}(\mathbf{n})}{\partial \mathbf{n}}, \qquad \text{and} \qquad \mathbf{f} \cdot \mathbf{n} = -\hat{b}_{\mathcal{S}}(\mathbf{n}, V_{\mathcal{S}})V_{\mathcal{S}}, \tag{1.5}$$

with $\hat{b}_{\mathcal{S}} \geq 0$, that determine the interfacial free-energy density $\psi_{\mathcal{S}}$, the interfacial configurational shear $\mathbf{c}$, and the normal component $\mathbf{f} \cdot \mathbf{n}$ of the internal interfacial configurational body force density $\mathbf{f}$.

Since the theory described above neglects deformation, the phases are rigid. Standard stresses are therefore indeterminate both in bulk and on the interface. The standard force balance is therefore extraneous. It is therefore difficult to conceive of how the interfacial configurational force balance (1.3) or (its consequence) the interfacial evolution equation (1.1) could be an expression of standard force balance. Nevertheless, because there do exist circumstances in which the configurational force balance is a derived consequence of the standard force balance, some researchers contend that the configurational force balance can *always* be viewed as a rephrasing of the standard force balance.

To eliminate that confusion, we use an alternative method to derive the interfacial evolution equation (1.1). Our approach involves considering a theory in which the phases are described by a phase field φ. In that theory, an interface is not a surface but is, rather, a transition layer across which φ varies smoothly. The thickness of layers is constitutively determined. We consider a version of the phase-field theory that, due to a special choice of constitutive equations and a special scaling, permits us to control the thickness of transition layers. We then investigate the ramifications of shrinking that thickness. The phase-field theory allows for two approaches to deriving sharp-interface equations. We refer to those approaches as "direct" and "indirect." While the direct and indirect approaches yield the same analytical results, they afford different insights. We illustrate the indirect approach in the simple case where the desired interfacial evolution equation is (1.2). In the indirect approach, which follows the work of Caginalp [3], that equation arises as a solvability condition imposed by the Fredholm alternative on the inner expansion of φ. This result renders problematic any attempt to interpret (1.2) as an expression of standard force balance, but otherwise leaves open the question of just what physical law underlies (1.2). The direct approach, which involves the configurational force balance of the phase-field theory, sheds light on that question. The smoothness of the phase field makes consideration of configurational forces or their balance unnecessary. Nevertheless, a configurational force balance can be derived within the phase-field theory, and considerations based on that balance prove to be useful. Specifically, we work with the component of the configurational force balance normal to time-dependent level sets of φ. In the direct approach, (1.1) arises by expanding and integrating that equation over a layer while simultaneously shrinking the thickness of that layer to zero. This shows clearly that the interfacial evolution equation (1.1) of the sharp-interface theory is an expression of configurational force balance and, bearing in mind that deformation is neglected, verifies that (1.1) is unrelated to the standard force balance.

The paper is organized as follows. We begin, in section 2, with a brief overview of the phase-field theory. In so doing, we present both the standard variational derivation, which yields the governing equation for φ as a gradient-flow equation, and the less conventional continuum-mechanical derivation due to Fried and Gurtin [12]. Next, in section 3, we derive the configurational force balance germane to the phase-field theory. Here, again, we consider two approaches. In the first approach, we mimick Maugin's [27] approach to the study of configurational forces associated with material inhomogeneities in elastic solids. Specifically, we multiply the evolution equation for φ by $\nabla\varphi$ and arrive at the desired result in a few simple steps. The second approach employs Gurtin's [19, 20] general framework for configurational forces. In section 4, we consider time-dependent level sets of φ and obtain the component of the evolution equation for φ normal to those sets. In section 5, we discuss the role of standard forces. In section 6, we specialize the constitutive equations of the phase-field theory to yield an unscaled version of the theory that leads to the simple sharp-interface equation (1.2). Section 7 is concerned with scaling. In section 8, we discuss expansions. In section 9, we obtain asymptotic results for the regions occupied by the bulk phases. In section 10, we obtain asymptotic results for a generic transition layer. In so doing, we first take the indirect approach and then take the direct approach. In section 11, we generalize the constitutive assumptions imposed in section 4 and derive (1.1) using only the direct approach. Finally, in section 12, we conclude with a brief discussion.

2. Phase-field theory. We present a simple theory for transformations between two phases as described by a dimensionless scalar-valued *phase field* φ. Intuitively, at an instant when both phases are present, we expect φ to vary smoothly between distinct values associated with each of the phases. Further, letting L denote a suitable characteristic length, the product $L|\nabla\varphi|$ should exhibit large values in any zone connecting the two phases. Otherwise, at an instant when only one phase is present, φ should be essentially uniform. Thus, φ can be thought of as a regularized characteristic function for one of the phases, and phase transformations are embodied in the evolution of the phase distribution, as described by φ.

2.1. Variational approach. The conventional approach to developing an equation governing the evolution of φ is variational. Assuming that the free-energy density, say ψ, is determined constitutively as a function $\hat{\psi}$ depending on φ and, to account for energetic contributions from the zones connecting the two phases, on $\nabla\varphi$, the total free energy of the body $\mathcal{B}$ is then given by the functional

$$\mathcal{F}(\varphi) = \int_{\mathcal{B}} \hat{\psi}(\varphi, \nabla\varphi)\, dv. \tag{2.1}$$

The evolution equation for φ then has the form of a gradient-flow equation,

$$\beta(\varphi, \nabla\varphi, \dot{\varphi})\dot{\varphi} = -\frac{\delta\mathcal{F}(\varphi)}{\delta\varphi}, \tag{2.2}$$

with $\beta \geq 0$ a constitutively determined *kinetic coefficient* and $\delta\mathcal{F}(\varphi)/\delta\varphi$ defined via the first variation of $\mathcal{F}$, viz.,

$$\frac{\delta\mathcal{F}(\varphi)}{\delta\varphi} = \frac{\partial\hat{\psi}(\varphi, \nabla\varphi)}{\partial\varphi} - \operatorname{div}\left\{\frac{\partial\hat{\psi}(\varphi, \nabla\varphi)}{\partial(\nabla\varphi)}\right\}. \tag{2.3}$$

Tacit to the foregoing discussion is an understanding that, to encompass the existence of two energetically viable phases, the restriction $\hat{\psi}(\cdot, \mathbf{0})$ of $\hat{\psi}$ to homogeneous values of φ should be a double-well potential.

2.2. Alternative approach. An alternative to the variational approach shown is provided by Fried and Gurtin [12]. That alternative hinges on distinguishing between kinematical ingredients, laws of balance and imbalance, and constitutive equations. The phase field φ is the sole kinematical variable of the theory. Under the recognition that power expenditures should accompany temporal variations of any kinematical descriptor and that such expenditures must involve conjugate forces, a vector-valued *microstress* $\boldsymbol{\xi}$ and a scalar-valued *internal microforce density* π are introduced. The basic laws of the theory then consist of the *balance of microforces* and the *imbalance of free energy*, which require that for each body part $\mathcal{P}$, with boundary $\partial\mathcal{P}$ and outward unit normal $\boldsymbol{\nu}$,

$$\int_{\partial\mathcal{P}} \boldsymbol{\xi}\cdot\boldsymbol{\nu}\, da + \int_{\mathcal{P}} \pi\, dv = 0 \tag{2.4}$$

and

$$\overline{\int_{\mathcal{P}} \psi\, dv}^{\cdot} \leq \int_{\partial\mathcal{P}} (\boldsymbol{\xi}\cdot\boldsymbol{\nu})\dot{\varphi}\, da. \tag{2.5}$$

The local equivalents of the global laws are the field equation

$$\operatorname{div}\boldsymbol{\xi} + \pi = 0 \tag{2.6}$$

and the free-energy inequality

$$\dot{\psi} + \pi\dot{\varphi} - \boldsymbol{\xi}\cdot\nabla\dot{\varphi} \leq 0. \tag{2.7}$$

Assuming that ψ, $\boldsymbol{\xi}$, and π are determined constitutively by smooth functions of φ, $\nabla\varphi$, and $\dot{\varphi}$, and requiring those functions to be consistent with (2.7) in all processes, then gives

$$\psi = \hat{\psi}(\varphi, \nabla\varphi), \quad \boldsymbol{\xi} = \frac{\partial\hat{\psi}(\varphi,\nabla\varphi)}{\partial(\nabla\varphi)}, \quad \text{and} \quad \pi = -\frac{\partial\hat{\psi}(\varphi,\varphi}{\partial\varphi} - \beta(\varphi,\nabla\varphi,\dot{\varphi})\dot{\varphi} \tag{2.8}$$

with $\beta \geq 0$. Finally, using (2.8) in the local microforce balance (2.6) yields

$$\beta(\varphi,\nabla\varphi,\dot{\varphi})\dot{\varphi} = \operatorname{div}\left\{\frac{\partial\hat{\psi}(\varphi,\nabla\varphi)}{\partial(\nabla\varphi)}\right\} - \frac{\partial\hat{\psi}(\varphi,\nabla\varphi)}{\partial\varphi}, \tag{2.9}$$

which is identical to the evolution equation arising from (2.2) and (2.3).

In view of (2.8), the free-energy inequality (2.7) yields an expression

$$\delta = -\beta(\varphi,\nabla\varphi,\dot{\varphi})\dot{\varphi}^2 \tag{2.10}$$

for the rate at which energy is dissipated per unit volume.

3. Configurational forces and their balance.

3.1. Formal approach. Consider the evolution equation (2.9). Multiplying each term of that equation by $\nabla\varphi$ and performing a few simple manipulations, one is led to the identity

$$\operatorname{div}\left\{\hat{\psi}(\varphi,\nabla\varphi)\mathbf{1} - \nabla\varphi\otimes\frac{\partial\hat{\psi}(\varphi,\nabla\varphi)}{\partial(\nabla\varphi)}\right\} + \beta(\varphi,\nabla\varphi,\dot{\varphi})\dot{\varphi}\nabla\varphi = \mathbf{0}. \tag{3.1}$$

The tensor

$$\hat{\psi}(\varphi,\nabla\varphi)\mathbf{1} - \nabla\varphi\otimes\frac{\partial\hat{\psi}(\varphi,\nabla\varphi)}{\partial(\nabla\varphi)} \tag{3.2}$$

appearing in (3.1) is immediately recognizable as the *configurational stress tensor* relevant to the present context (Eshelby [10]). Further, the vector

$$\beta(\varphi,\nabla\varphi,\dot{\varphi})\dot{\varphi}\nabla\varphi \tag{3.3}$$

represents a *configurational body force density*. Thus, the derived identity (3.1) can be viewed as a *configurational force balance* associated with the evolution equation (2.9). In the absence of defects, which would be associated with irregularities of φ, (3.1) is equivalent to (2.9) whenever $\nabla\varphi$ is nontrivial and, thus, superfluous.

Within the context of the phase-field theory, the configurational force balance (3.1) is a consequence of microforce balance (2.6) and the thermodynamically derived constitutive equations (2.8). In particular, neither standard forces nor their balance enter the derivation. Hence, (3.1) is unrelated to standard force balance.

3.2. Alternative approach. Like the variational derivation of (2.9), the above derivation of (3.1) is predicated on the provision of constitutive equations. An alternative derivation that is free from that restriction is due to Gurtin [19, 20]. That approach treats configurational forces as basic entities that are associated with the integrity of the material structure of a body and expend power in connection with the transfer of material and the evolution of defects. Specifically, a *configurational stress tensor* $\mathbf{C}$ and a *configurational body force density* $\mathbf{f}$ are introduced. These fields are required to satisfy the *configurational force balance*

$$\int_{\partial\mathcal{P}} \mathbf{C}\boldsymbol{\nu}\, da + \int_{\mathcal{P}} \mathbf{f}\, dv = \mathbf{0} \tag{3.4}$$

for each part $\mathcal{P}$ of $\mathcal{B}$, which is equivalent to the local configurational force balance

$$\operatorname{div}\mathbf{C} + \mathbf{f} = \mathbf{0}. \tag{3.5}$$

To characterize the manner in which configurational forces expend power, a means of capturing the kinematics associated with the transfer of material is needed. Gurtin [19, 20] accomplishes this with the aid of migrating control volumes. The evolution of a migrating control volume $\mathcal{R}$ can be generically described by a time-dependent field $\mathbf{q}$ defined over $\partial\mathcal{R}$, and the configurational traction $\mathbf{C}\boldsymbol{\nu}_{\partial\mathcal{R}}$ is assumed to be power conjugate to $\mathbf{q}$. Further, to properly reckon the power expended by the microtraction $\boldsymbol{\xi}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}}$ on $\mathcal{R}$, it is necessary to consider the convected time-rate $\dot{\varphi}+\nabla\varphi\cdot\mathbf{q}$ of φ following the motion of $\partial\mathcal{R}$. The net power expended on $\mathcal{R}$ by external agencies can then be expressed as

$$\int_{\partial\mathcal{R}} \{(\mathbf{C}+\nabla\varphi\otimes\boldsymbol{\xi})\boldsymbol{\nu}_{\partial\mathcal{R}}\cdot\mathbf{q} + (\boldsymbol{\xi}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}})\dot{\varphi}\}\, da. \tag{3.6}$$

Since the intrinsic motion of $\partial\mathcal{R}$ involves only the normal component $\mathbf{q}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}}$ of $\mathbf{q}$, the net power should be invariant with respect to the choice of the tangential component of $\mathbf{q}$. This invariance implies that $\mathbf{C}+\nabla\varphi\otimes\boldsymbol{\xi}=\alpha\mathbf{1}$ and, thus, that

$$\int_{\partial\mathcal{R}} \{(\mathbf{C}+\nabla\varphi\otimes\boldsymbol{\xi})\boldsymbol{\nu}_{\partial\mathcal{R}}\cdot\mathbf{q} + (\boldsymbol{\xi}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}})\dot{\varphi}\}\, da = \int_{\partial\mathcal{R}} (\alpha\mathbf{q}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}} + (\boldsymbol{\xi}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}})\dot{\varphi})\, da. \tag{3.7}$$

In view of the foregoing discussion, the free-energy imbalance for a migrating control volume $\mathcal{R}$ can then be expressed in the form

$$\dot{\int_{\mathcal{R}} \psi\, dv} \le \int_{\partial\mathcal{R}} (\alpha\mathbf{q}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}} + (\boldsymbol{\xi}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}})\dot{\varphi})\, da, \tag{3.8}$$

from which it follows that

$$\int_{\mathcal{R}} \dot{\psi}\, dv \le \int_{\partial\mathcal{R}} (\boldsymbol{\xi}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}})\dot{\varphi}\, da + \int_{\partial\mathcal{R}} (\alpha-\psi)\mathbf{q}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}}\, da. \tag{3.9}$$

Since it is always possible to find another control volume, say $\mathcal{R}'$, which coincides with $\mathcal{R}$ at a given instant but with normal velocity $\mathbf{q}'\cdot\boldsymbol{\nu}_{\partial\mathcal{R}}$ different from $\mathbf{q}\cdot\boldsymbol{\nu}_{\partial\mathcal{R}}$, it

therefore follows that $\alpha = \psi$ and that the configurational stress tensor must be of the form

$$\mathbf{C} = \psi\mathbf{1} - \nabla\varphi \otimes \boldsymbol{\xi}. \tag{3.10}$$

Finally, using (3.10) in the local configurational force balance (3.5) yields

$$\operatorname{div}(\psi\mathbf{1} - \nabla\varphi \otimes \boldsymbol{\xi}) + \mathbf{f} = \mathbf{0}. \tag{3.11}$$

In the absence of lower-dimensional defect structures, this equation *determines* the configurational body force density $\mathbf{f} = -\operatorname{div}(\psi\mathbf{1} - \nabla\varphi \otimes \boldsymbol{\xi})$. The balance (3.11) is independent of any particular constitutive assumptions. Only when one invokes (2.8) does it reduce to (3.1), in which case $\mathbf{f} = \beta(\varphi, \nabla\varphi, \dot{\varphi})\dot{\varphi}\nabla\varphi$.

4. Uniformity surfaces. Normal configurational force balance. In the phase-field theory, an interface is a diffuse transition layer, and each value that φ takes within such a layer can be thought of as representing a particular state of the material. For this reason the time-dependent level sets

$$\{\mathbf{x} : \varphi(\mathbf{x}, t) = \text{constant}\} \tag{4.1}$$

are important. We refer to such sets as *uniformity surfaces*.

Within transition layers, $\nabla\varphi$ should be nontrivial; this being the case, we see that

$$\mathbf{n} = \frac{\nabla\varphi}{|\nabla\varphi|} \tag{4.2}$$

and

$$V = -\frac{\dot{\varphi}}{|\nabla\varphi|} \tag{4.3}$$

represent a unit normal field and a corresponding (scalar) normal velocity field for uniformity surfaces, that

$$\mathbf{P} = \mathbf{1} - \mathbf{n} \otimes \mathbf{n} \tag{4.4}$$

projects vector fields onto their components tangent to uniformity surfaces, and that

$$\mathbf{L} = -(\nabla\mathbf{n})\mathbf{P} \qquad \text{and} \qquad K = \operatorname{tr}\mathbf{L} = -\operatorname{div}\mathbf{n} \tag{4.5}$$

are the curvature tensor and (twice) the mean curvature of uniformity surfaces.

From (4.2), $|\nabla\varphi|\nabla\mathbf{n} = \mathbf{P}\nabla\nabla\varphi$, and it follows that

$$\mathbf{L} = -\frac{1}{|\nabla\varphi|}\mathbf{P}(\nabla\nabla\varphi)\mathbf{P} \tag{4.6}$$

and

$$K = -\frac{1}{|\nabla\varphi|}(\Delta\varphi - \mathbf{n} \cdot (\nabla\nabla\varphi)\mathbf{n}). \tag{4.7}$$

Assuming that $\nabla\varphi \neq \mathbf{0}$, we may calculate the component of the configurational force balance (3.11) in the direction $\mathbf{n}$ normal to uniformity surfaces. Bearing in mind (4.2) and (4.6), that calculation yields an identity

$$\operatorname{div}(\psi\mathbf{n} - |\nabla\varphi|\boldsymbol{\xi}) + \psi K + \mathbf{f} \cdot \mathbf{n} = 0 \tag{4.8}$$

that we refer to as the *normal configurational force balance for uniformity surfaces*. In combination with the constitutive equations (2.8), the auxiliary consequence $\mathbf{f} = \beta(\varphi, \nabla\varphi, \dot{\varphi})\dot{\varphi}\nabla\varphi$ of (2.8), and (4.3), the balance (4.8) provides an evolution equation,

$$|\nabla\varphi|^2\beta(\varphi, \nabla\varphi, \dot{\varphi})V = \hat{\psi}(\varphi, \nabla\varphi)K + \operatorname{div}\left\{\hat{\psi}(\varphi, \nabla\varphi)\mathbf{n} - |\nabla\varphi|\frac{\partial\hat{\psi}(\varphi, \nabla\varphi)}{\partial(\nabla\varphi)}\right\}, \tag{4.9}$$

for φ. The evolution equation (4.9) is valid and equivalent to the evolution equation (2.9), provided that $\nabla\varphi \neq \mathbf{0}$. Otherwise, if $\nabla\varphi = \mathbf{0}$, we cannot impose (4.9), which was derived based on the assumption that $\nabla\varphi \neq \mathbf{0}$.

5. The role of standard forces. In the preceding discussion, we have ignored all mention of standard forces. If we allow for a *standard stress tensor* $\mathbf{S}$ and a *standard body force density* $\mathbf{b}$, the balances for forces and moments require that

$$\int_{\partial\mathcal{P}} \mathbf{S}\boldsymbol{\nu}\, da + \int_{\mathcal{P}} \mathbf{b}\, dv = \mathbf{0} \tag{5.1}$$

and

$$\int_{\partial\mathcal{P}} (\mathbf{x} - \mathbf{0}) \times \mathbf{S}\boldsymbol{\nu}\, da + \int_{\mathcal{P}} (\mathbf{x} - \mathbf{0}) \times \mathbf{b}\, dv = \mathbf{0} \tag{5.2}$$

for each part $\mathcal{P}$ of $\mathcal{B}$, or, equivalently, that

$$\operatorname{div}\mathbf{S} + \mathbf{b} = \mathbf{0} \qquad \text{and} \qquad \mathbf{S} = \mathbf{S}^{\top}. \tag{5.3}$$

Since the material is rigid, $\mathbf{S}$ is constitutively indeterminate and the field equation $(5.3)_1$ is satisfied trivially—that is, given an externally supplied body force density $\mathbf{b}$, $\mathbf{S}$ is any symmetric tensor field consistent with $(5.3)_1$.

With standard forces taken into account, it is reasonable to expect some modification of the configurational force system. We therefore write $\tilde{\mathbf{C}}$ and $\tilde{\mathbf{f}}$ for the configurational stress tensor and body force density and assume that these obey the configurational force balance

$$\int_{\partial\mathcal{P}} \tilde{\mathbf{C}}\boldsymbol{\nu}\, da + \int_{\mathcal{P}} \tilde{\mathbf{f}}\, dv = \mathbf{0} \tag{5.4}$$

for each part $\mathcal{P}$ of $\mathcal{B}$, or, equivalently,

$$\operatorname{div}\tilde{\mathbf{C}} + \tilde{\mathbf{f}} = \mathbf{0}. \tag{5.5}$$

Since the body is rigid, the standard force balance (5.1) ensures that the external power expended on any part $\mathcal{P}$ vanishes. However, for a control volume $\mathcal{R}$ whose boundary $\partial\mathcal{R}$ migrates with velocity $\mathbf{q}$, the power expenditure of the traction $\mathbf{S}\boldsymbol{\nu}_{\partial\mathcal{R}}$ distributed over $\partial\mathcal{R}$ is not generally trivial. Thus, when the body is rigid, standard stress is taken into account, the net power expended on a migrating control volume $\mathcal{R}$ is given by

$$\int_{\partial\mathcal{R}} \{(\tilde{\mathbf{C}} + \nabla\varphi \otimes \boldsymbol{\xi} + \mathbf{S})\boldsymbol{\nu}_{\partial\mathcal{R}} \cdot \mathbf{q} + (\boldsymbol{\xi} \cdot \boldsymbol{\nu}_{\partial\mathcal{R}})\dot{\varphi}\}\, da, \tag{5.6}$$

and the requirement that (5.6) be invariant with respect to the choice of the tangential component of the velocity $\mathbf{q}$ yields $\tilde{\mathbf{C}} + \nabla\varphi \otimes \boldsymbol{\xi} + \mathbf{S} = \alpha\mathbf{1}$. Thus, the free-energy

imbalance is unchanged from (3.8) and we find that, when the body is rigid and standard stress is taken into account, the configurational stress tensor admits the representation

$$\tilde{\mathbf{C}} = \psi\mathbf{1} - \nabla\varphi \otimes \boldsymbol{\xi} - \mathbf{S}. \tag{5.7}$$

Comparing (5.7) with (3.10), we see that $\tilde{\mathbf{C}} = \mathbf{C} - \mathbf{S}$. Further, in view of the standard force balance $(5.3)_1$ and the configurational force balance (5.5), it follows that $\tilde{\mathbf{f}} = \mathbf{f} - \mathbf{b}$. On the other hand, granted that $\tilde{\mathbf{C}} = \mathbf{C} - \mathbf{S}$ and $\tilde{\mathbf{f}} = \mathbf{f} - \mathbf{b}$, $(5.3)_1$ implies that

$$\operatorname{div}\tilde{\mathbf{C}} + \tilde{\mathbf{f}} = \operatorname{div}\mathbf{C} + \mathbf{f} = \mathbf{0}, \tag{5.8}$$

and we may conclude that, for a rigid body, standard forces have no impact on the configurational force balance and may be neglected without loss of generality.

6. Specialization. For simplicity, we suppose that the constitutive relation determining the free-energy density has the simple form

$$\psi = f(\varphi) + \Psi_\alpha(1 - g(\varphi)) + \Psi_\beta g(\varphi) + \frac{1}{2}\lambda|\nabla\varphi|^2, \tag{6.1}$$

where f is a double-well potential with equal minima at $\varphi = \varphi_\alpha$ and $\varphi = \varphi_\beta$, with $\varphi_\alpha < \varphi_\beta$, viz.,

$$0 = f(\varphi_\alpha) = f(\varphi_\beta) < f(\varphi) \qquad \text{for all } \varphi \neq \varphi_\alpha, \varphi_\beta; \tag{6.2}$$

g vanishes for $\varphi \leq \varphi_\alpha$, is equal to unity for $\varphi \geq \varphi_\beta$, and increases monotonically between $\varphi = \varphi_\alpha$ and $\varphi = \varphi_\beta$, viz.,

$$g(\varphi) = \begin{cases} 0 & 0 \leq \varphi_\alpha, \\ 1 & \varphi \geq \varphi_\beta \end{cases} \tag{6.3}$$

and

$$g'(\varphi) > 0 \qquad \text{for all } \varphi \in (\varphi_\alpha, \varphi_\beta); \tag{6.4}$$

λ is constant and strictly positive, viz.,

$$\lambda > 0; \tag{6.5}$$

and Ψ_α and Ψ_β are the constant energy densities of the bulk phases α and β. For a body $\mathcal{B}$, where the average of φ lies between φ_α and φ_β, the double-well structure of f lends energetic preference to distributions of φ consisting of regions with $\varphi = \varphi_\alpha$ and regions with $\varphi = \varphi_\beta$. On the other hand, the gradient term $\frac{1}{2}\lambda|\nabla\varphi|^2$ penalizes sharp transitions between such regions and in so doing facilitates the existence of equilibria in which φ is smooth and $\mathcal{B}$ contains interfacial layers separating regions with φ close to φ_α from regions with φ close to φ_β. Because the gradient term depends only on the magnitude $|\nabla\varphi|$ of $\nabla\varphi$, interfacial layers of all orientations are of equal energetic cost.

As a further simplification, we assume that the kinetic modulus β is constant and strictly positive, viz.,

$$\beta(\varphi, \nabla\varphi, \dot{\varphi}) = B > 0. \tag{6.6}$$

With the choice of (6.6), (2.10) specializes to $\delta = -B\dot{\varphi}^2$; thus, the rate at which energy is dissipated by the growth of either phase at the expense of another is quadratic in $\dot{\varphi}$ and is insensitive to layer orientation.

In view of the specializations (6.1) and (6.6), the evolution equation (2.9) becomes

$$B\dot{\varphi} = \lambda\Delta\varphi - f'(\varphi) - [\![\Psi]\!]g'(\varphi), \tag{6.7}$$

with $[\![\Psi]\!] = \Psi_\beta - \Psi_\alpha$, and the normal configurational force balance (4.9) for uniformity surfaces becomes

$$\begin{aligned} |\nabla\varphi|^2 BV = &\left\{ f(\varphi) + \Psi_\alpha(1-g(\varphi)) + \Psi_\beta g(\varphi) + \frac{1}{2}\lambda|\nabla\varphi|^2 \right\} K \\ &+ \operatorname{div}\left\{ (f(\varphi) + \Psi_\alpha(1-g(\varphi)) + \Psi_\beta g(\varphi) - \frac{1}{2}\lambda|\nabla\varphi|^2)\mathbf{n} \right\}. \end{aligned} \tag{6.8}$$

Since

$$\big\{\Psi_\alpha(1-g(\varphi)) + \Psi_\beta g(\varphi)\big\}K + \operatorname{div}\big\{\Psi_\alpha(1-g(\varphi)) + \Psi_\beta g(\varphi)\big\} = [\![\Psi]\!]\mathbf{n}\cdot\nabla g(\varphi), \tag{6.9}$$

(6.8) can be rewritten somewhat more concisely as

$$|\nabla\varphi|^2 BV = \left\{ f(\varphi) + \frac{1}{2}\lambda|\nabla\varphi|^2 \right\} K + \operatorname{div}\left\{ (f(\varphi) - \frac{1}{2}\lambda|\nabla\varphi|^2)\mathbf{n} \right\} + [\![\Psi]\!]\mathbf{n}\cdot\nabla g(\varphi), \tag{6.10}$$

and we will use this in lieu of (6.8). We emphasize that (6.8) (and, thus, (6.10)) is meaningful only if $\nabla\varphi \neq \mathbf{0}$ and that, if (6.10) is meaningful, it is equivalent to (6.7).

7. Scaling. We introduce characteristic measures

$$\mu = \frac{1}{2}(\Psi_\alpha + \Psi_\beta) \qquad \text{and} \qquad \nu = \max_{\varphi\in(\varphi_\alpha,\varphi_\beta)} f(\varphi) \tag{7.1}$$

for the free energies, per unit volume, of the bulk phases and interfacial transition layers, and assume that these yield a small dimensionless parameter

$$0 < \epsilon = \frac{\mu}{\nu} \ll 1. \tag{7.2}$$

Then, letting L denote a characteristic length and T a characteristic time, and labeling the dimensional (unscaled) fields with asterisks, we introduce the dimensionless independent and dependent variables

$$\mathbf{x} = \frac{\mathbf{x}^*}{L}, \qquad t = \frac{t^*}{T}, \qquad \varphi_\epsilon(\mathbf{x},t) = \varphi^*(\mathbf{x}^*,t^*), \tag{7.3}$$

and constitutive quantities

$$f(\varphi_\epsilon) = \frac{f^*(\varphi^*)}{\nu}, \quad \Psi_\alpha = \frac{\Psi_\alpha^*}{\mu}, \quad \Psi_\beta = \frac{\Psi_\beta^*}{\mu}, \quad \epsilon\lambda = \frac{\lambda^*}{\mu L^2}, \quad \epsilon B = \frac{B^*}{\mu T}, \tag{7.4}$$

where the dependence of the fields on the parameter ϵ has been made explicit and the quantities without asterisks in (7.4) are assumed to be of $O(1)$ in ϵ.

With this scaling, the dimensionless free-energy density is given by

$$\psi_\epsilon = \frac{\psi}{\mu} = \epsilon^{-1} f(\varphi_\epsilon) + \Psi_\alpha(1 - g(\varphi_\epsilon)) + \Psi_\beta g(\varphi_\epsilon) + \frac{1}{2}\epsilon\lambda|\nabla\varphi_\epsilon|^2, \tag{7.5}$$

and the governing evolution equation for φ_ϵ becomes

$$\epsilon B\dot{\varphi}_\epsilon = \epsilon\lambda\Delta\varphi_\epsilon - \epsilon^{-1} f'(\varphi_\epsilon) - [\![\Psi]\!] g'(\varphi_\epsilon). \tag{7.6}$$

Further, the normal configurational force balance (6.10) reads

$$\begin{aligned}\epsilon|\nabla\varphi_\epsilon|^2 BV_\epsilon = {} & \left\{\epsilon^{-1} f(\varphi_\epsilon) + \frac{1}{2}\epsilon\lambda|\nabla\varphi_\epsilon|^2\right\}K_\epsilon \\ & + \operatorname{div}\left\{\left\{\epsilon^{-1} f(\varphi_\epsilon) - \frac{1}{2}\epsilon\lambda|\nabla\varphi_\epsilon|^2\right\}\mathbf{n}_\epsilon\right\} + [\![\Psi]\!]\mathbf{n}_\epsilon \cdot \nabla g(\varphi_\epsilon),\end{aligned} \tag{7.7}$$

with (cf. (4.2), (4.3), and (4.7))

$$\mathbf{n}_\epsilon = \frac{\nabla\varphi_\epsilon}{|\nabla\varphi_\epsilon|}, \quad V_\epsilon = -\frac{\dot{\varphi}_\epsilon}{|\nabla\varphi_\epsilon|}, \quad \text{and} \quad K_\epsilon = -\frac{1}{|\nabla\varphi_\epsilon|}(\Delta\varphi_\epsilon - \mathbf{n}_\epsilon \cdot (\nabla\nabla\varphi_\epsilon)\mathbf{n}_\epsilon). \tag{7.8}$$

8. Expansions. Hereafter, we focus on a fixed part $\mathcal{P}$ of $\mathcal{B}$ that, over some time interval, consists of three evolving subregions $\mathcal{P}_\epsilon^\alpha$, $\mathcal{S}_\epsilon$, and $\mathcal{P}_\epsilon^\beta$. At each time t, $\mathcal{S}_\epsilon(t)$ is a transition layer consisting of points $\mathbf{x}$ in $\mathcal{B}$ with $\varphi_\alpha < \varphi_\epsilon(\mathbf{x}, t) < \varphi_\beta$, while $\mathcal{P}_\epsilon^\alpha(t)$ and $\mathcal{P}_\epsilon^\beta(t)$ consist of points $\mathbf{x}$ with $\varphi_\epsilon(\mathbf{x}, t) \approx \varphi_\alpha$ and $\varphi_\epsilon(\mathbf{x}, t) \approx \varphi_\beta$, respectively. We assume that the limit

$$\mathcal{S} = \lim_{\epsilon \to 0+} \mathcal{S}_\epsilon \tag{8.1}$$

exists, with $\mathcal{S}(t)$ a smoothly evolving surface and with

$$\mathcal{P} = \mathcal{P}^\alpha(t) \cup \mathcal{S}(t) \cup \mathcal{P}^\beta(t), \tag{8.2}$$

with $\mathcal{P}^\gamma(t) = \lim_{\epsilon \to 0} \mathcal{P}_\epsilon^\gamma(t)$ for $\gamma = \alpha, \beta$.

We write $\ell(\mathbf{x}, t)$ for the *signed distance* between a point $\mathbf{x}$ in $\mathcal{P}$ and the surface $\mathcal{S}(t)$, with $\ell(\mathbf{x}, t) < 0$ in $\mathcal{P}_\epsilon^\alpha(t)$ and $\ell(\mathbf{x}, t) > 0$ in $\mathcal{P}_\epsilon^\beta(t)$. Then

$$\mathbf{n}(\mathbf{x}, t) = \nabla\ell(\mathbf{x}, t) \qquad \text{and} \qquad V_{\mathcal{S}}(\mathbf{x}, t) = -\dot{\ell}(\mathbf{x}, t) \tag{8.3}$$

represent a unit normal field and corresponding scalar normal velocity field for $\mathcal{S}(t)$. We also assume that $\ell(\mathbf{x}, t)$ is smooth within $\mathcal{S}_\epsilon(t)$ and that given any $\mathbf{x}$ on $\mathcal{S}_\epsilon(t)$, there is a unique $\mathbf{z}$ on $\mathcal{S}(t)$ with $\mathbf{z} = \mathbf{x} - \ell(\mathbf{x}, t)\mathbf{n}(\mathbf{x}, t)$. The mapping $\mathbf{x} \mapsto \big(\ell(\mathbf{x}, t), \mathbf{z}(\mathbf{x}, t)\big)$ is then one-to-one on $\mathcal{S}_\epsilon(t)$; further, $\mathbf{n}(\mathbf{x}, t)$ and $V_{\mathcal{S}}(\mathbf{x}, t)$ are well defined and independent of $\ell(\mathbf{x}, t)$ at each $\mathbf{x}$ in $\mathcal{S}_\epsilon(t)$: $\mathbf{n}(\mathbf{x}, t) = \mathbf{n}(\mathbf{z}, t)$, $V_{\mathcal{S}}(\mathbf{x}, t) = V_{\mathcal{S}}(\mathbf{z}, t)$. Thus, writing $\nabla_{\mathcal{S}}$ and $\operatorname{div}_{\mathcal{S}}$ for the surface gradient and surface divergence on $\mathcal{S}$, the curvature tensor $\mathbf{L}$ and the total curvature $K_{\mathcal{S}}$ for $\mathcal{S}$,

$$\mathbf{L} = -\nabla_{\mathcal{S}}\mathbf{n} \qquad \text{and} \qquad K_{\mathcal{S}} = \operatorname{tr}\mathbf{L} = -\operatorname{div}_{\mathcal{S}}\mathbf{n} \tag{8.4}$$

are also independent of ℓ: $\mathbf{L}(\mathbf{x}, t) = \mathbf{L}(\mathbf{z}, t)$, $K_{\mathcal{S}}(\mathbf{x}, t) = K_{\mathcal{S}}(\mathbf{z}, t)$.

Within $\mathcal{S}_\epsilon(t)$, we stretch the coordinate normal to $\mathcal{S}(t)$ by letting

$$r(\mathbf{x}, t) = \epsilon^{-1}\ell(\mathbf{x}, t) \tag{8.5}$$

and, in accord with this, we assume that the thickness $h_\epsilon(t)$ of $\mathcal{S}_\epsilon(t)$ tends to zero with ϵ, but at a slightly slower rate, viz.,

$$\lim_{\epsilon\to 0} h_\epsilon = 0, \quad \lim_{\epsilon\to 0}(\epsilon^{-1}h_\epsilon) = +\infty, \quad \lim_{\epsilon\to 0}(\epsilon^{-1}h_\epsilon^2) = 0. \tag{8.6}$$

For the phase field φ_ϵ, we introduce an *outer expansion*

$$\varphi_\epsilon(\mathbf{x},t) = \varphi_0^{\text{out}}(\mathbf{x},t) + \epsilon\varphi_1^{\text{out}}(\mathbf{x},t) + O(\epsilon^2), \tag{8.7}$$

assumed valid within the regions $\mathcal{P}_\epsilon^\alpha$ and $\mathcal{P}_\epsilon^\beta$, and an *inner expansion*

$$\varphi_\epsilon(\mathbf{x},t) = \varphi_0^{\text{in}}\big(r(\mathbf{x},t),\mathbf{z}(\mathbf{x},t),t\big) + \epsilon\varphi_1^{\text{in}}\big(r(\mathbf{x},t),\mathbf{z}(\mathbf{x},t),t\big) + O(\epsilon^2), \tag{8.8}$$

assumed valid within the layer; here, $\varphi_0^{\text{out}}(\mathbf{x},t)$, $\varphi_1^{\text{out}}(\mathbf{x},t)$ and $\varphi_0^{\text{in}}(r,\mathbf{z},t)$, $\varphi_1^{\text{in}}(r,\mathbf{z},t)$ are smooth, bounded functions of their arguments. We further assume that these expansions are twice formally differentiable in their arguments in the sense that $\nabla\varphi_\epsilon = \nabla\varphi_0^{\text{out}} + \epsilon\nabla\varphi_1^{\text{out}} + O(\epsilon^2)$ for the outer expansion and, on letting $\acute{\varphi}_\epsilon$ denote the partial derivative of φ_ϵ with respect to r, $\acute{\varphi}_\epsilon = \acute{\varphi}_0^{\text{in}} + \epsilon\acute{\varphi}_1^{\text{in}} + O(\epsilon^2)$ for the inner expansion, and so forth.

Hence, we do not presume that $\mathcal{S}_\epsilon(t)$ is disjoint from $\mathcal{P}_\epsilon^\alpha(t)$ and $\mathcal{P}_\epsilon^\beta(t)$: the regions $\mathcal{S}_\epsilon(t)\cap\big(\mathcal{P}_\epsilon^\alpha(t)\cup\mathcal{P}_\epsilon^\beta(t)\big)$ of overlap represent sets where the outer and inner expansions agree. In particular, we have the matching condition

$$(\varphi_0^{\text{out}})^\pm(\mathbf{x},t) = \lim_{\ell(\mathbf{x},t)\to 0\pm}\varphi_0^{\text{out}}(\mathbf{x},t) = \lim_{r\to\pm\infty}\varphi_0^{\text{in}}(r,\mathbf{z},t) = (\varphi_0^{\text{in}})^\pm(r,\mathbf{z},t) \tag{8.9}$$

relating the $O(1)$ terms of the inner and outer expansions for φ_ϵ within the overlap region.

In terms of the variables $(r,\mathbf{z})$, the derivative with respect to $\mathbf{z}$ holding r fixed may be identified with the gradient $\nabla_{\mathcal{S}}$ on $\mathcal{S}$. Let

$$\mathbf{P} = \mathbf{1} - \mathbf{n}\otimes\mathbf{n}. \tag{8.10}$$

Then, since $\mathbf{z}(\mathbf{x},t) = \mathbf{x} - \ell(\mathbf{x},t)\mathbf{n}(\mathbf{x},t)$, it follows that

$$\nabla\mathbf{z} = \mathbf{P} + \ell\mathbf{M}_\epsilon, \tag{8.11}$$

with

$$\mathbf{M}_\epsilon = -\nabla\mathbf{n}. \tag{8.12}$$

To determine the dependence of $\mathbf{M}_\epsilon$ on ϵ, note that, since $|\ell| \le h_\epsilon = o(1)$ and $\acute{\ell} = \epsilon$, differentiating both sides of the relation $\mathbf{n}(\mathbf{x},t) = \mathbf{n}(\mathbf{z}(\mathbf{x},t),t)$ with respect to $\mathbf{x}$ yields

$$\mathbf{M}_\epsilon = (\mathbf{1}-\ell\mathbf{L})^{-1}\mathbf{L} = \mathbf{L} + o(1). \tag{8.13}$$

Thus, for Φ and $\mathbf{v}$ scalar- and vector-valued fields, we find that

$$\begin{cases} \nabla\Phi = \epsilon^{-1}\acute{\Phi}\mathbf{n} + (\mathbf{P}+\ell\mathbf{M}_\epsilon)\nabla_{\mathcal{S}}\Phi = \epsilon^{-1}\acute{\Phi}\mathbf{n} + \big(1+o(1)\big)\nabla_{\mathcal{S}}\Phi, \\ \nabla\mathbf{v} = \epsilon^{-1}\acute{\mathbf{v}}\otimes\mathbf{n} + (\nabla_{\mathcal{S}}\mathbf{v})(\mathbf{P}+\ell\mathbf{M}_\epsilon) = \epsilon^{-1}\acute{\mathbf{v}}\otimes\mathbf{n} + \big(1+o(1)\big)\nabla_{\mathcal{S}}\mathbf{v}, \end{cases} \tag{8.14}$$

so that

$$\begin{aligned} \nabla\nabla\Phi = {}& \epsilon^{-2}\acute{\acute{\Phi}}\mathbf{n}\otimes\mathbf{n} + \epsilon^{-1}\big(1+o(1)\big)\big(\nabla_{\mathcal{S}}\acute{\Phi}\otimes\mathbf{n} + \mathbf{n}\otimes\nabla_{\mathcal{S}}\acute{\Phi} - \acute{\Phi}\mathbf{L}\big) \\ & + (\nabla_{\mathcal{S}}\nabla_{\mathcal{S}}\Phi)O(1) + O(1)\nabla_{\mathcal{S}}\Phi, \end{aligned} \tag{8.15}$$

with the $O(1)$ and $o(1)$ estimates in (8.14) and (8.15) of appropriate tensorial order and independent of Φ and $\mathbf{v}$.

As a further consequence of the relation $\mathbf{z}(\mathbf{x},t) = \mathbf{x} - \ell(\mathbf{x},t)\mathbf{n}(\mathbf{x},t)$, it follows that

$$\dot{\mathbf{z}} = V_{\mathcal{S}}\mathbf{n} + \ell\mathbf{v}_\epsilon, \tag{8.16}$$

with

$$\mathbf{v}_\epsilon = -\dot{\mathbf{n}}. \tag{8.17}$$

To determine the dependence of $\mathbf{v}_\epsilon$ on ϵ, note that $\dot{\mathbf{n}} = \nabla\dot{\ell} = -\nabla V_{\mathcal{S}}$. Thus, since $\nabla V_{\mathcal{S}} = (\mathbf{P} + \ell\mathbf{M}_\epsilon)\nabla_{\mathcal{S}} V_{\mathcal{S}}$ and $\mathring{\mathbf{n}} = -\nabla_{\mathcal{S}} V_{\mathcal{S}}$, with $\mathring{\mathbf{n}}$ the time-rate of $\mathbf{n}$ following the normal trajectories of $\mathcal{S}$,

$$\mathbf{v}_\epsilon = (\mathbf{P} + \ell\mathbf{M}_\epsilon)\nabla_{\mathcal{S}} V_{\mathcal{S}} = \nabla_{\mathcal{S}} V_{\mathcal{S}} + o(1). \tag{8.18}$$

Thus, for Φ a scalar field,

$$\dot{\Phi} = -\epsilon^{-1} V_{\mathcal{S}}\acute{\Phi} + \ell\nabla_{\mathcal{S}}\Phi \cdot (\mathbf{P} + \ell\mathbf{L})\mathring{\mathbf{n}} + \Phi_t = -\epsilon^{-1} V_{\mathcal{S}}\acute{\Phi} + \Phi_t + o(1), \tag{8.19}$$

where Φ_t denotes the partial time-rate of Φ holding r and $\mathbf{z}$ fixed.

9. Bulk regions. Using the outer expansion (8.7) of φ_ϵ in the scaled evolution equation (7.6) and neglecting terms of $O(1)$ and smaller in ϵ, we find that $f'(\varphi_0^{\text{out}}) = 0$ so that, since f is a double-well potential with equal minima at φ_α and φ_β,

$$\varphi_0^{\text{out}} = \begin{cases} \varphi_\alpha & \text{on } \mathcal{P}_\epsilon^\alpha, \\ \varphi_\beta & \text{on } \mathcal{P}_\epsilon^\beta. \end{cases} \tag{9.1}$$

Further

$$f(\varphi_\epsilon) = o(\epsilon) \quad \text{and} \quad f'(\varphi_\epsilon) = o(1) \quad \text{on} \quad \mathcal{P}_\epsilon^\alpha \cup \mathcal{P}_\epsilon^\beta, \tag{9.2}$$

and

$$\dot{\varphi}_\epsilon, \nabla\varphi_\epsilon, \nabla\dot{\varphi}_\epsilon = O(\epsilon) \quad \text{on} \quad \mathcal{P}_\epsilon^\alpha \cup \mathcal{P}_\epsilon^\beta. \tag{9.3}$$

Thus, it follows that

$$\psi_\epsilon = \begin{cases} \Psi_\alpha + O(\epsilon) & \text{on } \mathcal{P}_\epsilon^\alpha, \\ \Psi_\beta + O(\epsilon) & \text{on } \mathcal{P}_\epsilon^\beta. \end{cases} \tag{9.4}$$

10. Transition layer.

10.1. Basic estimates. Applying $(8.14)_1$, $(8.14)_2$, and (8.19) to the inner expansion (8.8) of φ_ϵ, we find that

$$\begin{cases} \nabla\varphi_\epsilon = \epsilon^{-1}\acute{\varphi}_0^{\text{in}}\mathbf{n} + \nabla_{\mathcal{S}}\varphi_0^{\text{in}} + \acute{\varphi}_1^{\text{in}}\mathbf{n} + O(\epsilon), \\ |\nabla\varphi_\epsilon| = \epsilon^{-1}\acute{\varphi}_0^{\text{in}} + \acute{\varphi}_1^{\text{in}} + O(\epsilon), \\ \nabla\nabla\varphi_\epsilon = \epsilon^{-2}\ddot{\varphi}_0^{\text{in}}\mathbf{n}\otimes\mathbf{n} \\ \qquad\qquad + \epsilon^{-1}(\nabla_{\mathcal{S}}\acute{\varphi}_1^{\text{in}}\otimes\mathbf{n} + \mathbf{n}\otimes\nabla_{\mathcal{S}}\acute{\varphi}_1^{\text{in}} - \acute{\varphi}_0^{\text{in}}\mathbf{L} + \ddot{\varphi}_1^{\text{in}}\mathbf{n}\otimes\mathbf{n}) + O(1), \\ \Delta\varphi_\epsilon = \epsilon^{-2}\ddot{\varphi}_0^{\text{in}} - \epsilon^{-1}(K_{\mathcal{S}}\acute{\varphi}_0^{\text{in}} - \ddot{\varphi}_1^{\text{in}}) + O(1), \\ \dot{\varphi}_\epsilon = -\epsilon^{-1} V_{\mathcal{S}}\acute{\varphi}_0^{\text{in}} + O(1), \end{cases} \tag{10.1}$$

and, applying these estimates to (7.8), that

$$\mathbf{n}_\epsilon = \mathbf{n} + O(\epsilon), \qquad V_\epsilon = V_{\mathcal{S}} + O(\epsilon), \qquad \text{and} \qquad K_\epsilon = K_{\mathcal{S}} + o(1). \tag{10.2}$$

10.2. Equipartition of free-energy density and its consequences. Using the inner expansion of φ_ϵ and the estimates (10.1) in the scaled evolution equation (7.6) and neglecting terms of $O(1)$ and smaller, we find that φ_0^{in} must satisfy the ordinary differential equation

$$\lambda \ddot{\varphi}_0^{\text{in}} = f'(\varphi_0^{\text{in}}). \tag{10.3}$$

Further, in view of the matching condition (8.9) and the result (9.1) concerning φ_0^{out}, φ_0^{in} must satisfy

$$\varphi_0^{\text{in}} \to \begin{cases} \varphi_\alpha & \text{as } r \to -\infty, \\ \varphi_\beta & \text{as } r \to +\infty, \end{cases} \tag{10.4}$$

along with

$$\dot{\varphi}_0^{\text{in}} \to 0 \qquad \text{and} \qquad \ddot{\varphi}_0^{\text{in}} \to 0 \qquad \text{as } r \to \pm\infty. \tag{10.5}$$

Since f is a double-well potential with equal minima at φ_α and φ_β, the boundary-value problem formed by (10.3) and (10.4) possesses a unique solution φ_0^{in} that increases monotonically from the value φ_α at $r = -\infty$ to the value φ_β at $r = +\infty$. Further, φ_0^{in} must be independent of $\mathbf{z}$.

Granted that the boundary conditions $(10.4)_{2,3}$ hold, the differential equation $(10.3)_1$ possesses a first integral

$$\frac{1}{2}\lambda|\dot{\varphi}_0^{\text{in}}|^2 = f(\varphi_0^{\text{in}}), \tag{10.6}$$

which we interpret as an expression of the equipartition of the free-energy density within the layer (upto the most significant order in ϵ), between the double-well potential f and the gradient energy density $\frac{1}{2}\lambda|\nabla\varphi_\epsilon|^2$. Since f and f' vanish at $\varphi = \varphi_\alpha$ and $\varphi = \varphi_\beta$, φ_0^{in} must decay according to $\dot{\varphi}_0^{\text{in}}(r,\cdot) = O(e^{-c|r|})$ as $|r| \to \infty$, with $c > 0$ independent of r. Hence, $\dot{\varphi}_0^{\text{in}}$ is, as a function of r, square-integrable on $(-\infty, +\infty)$. Thus, by (10.6), (10.3), and (10.4),

$$\int_{-\infty}^{+\infty} \sqrt{\lambda}|\dot{\varphi}_0^{\text{in}}(r,\cdot)|^2\, dr = \int_{\varphi_\alpha}^{\varphi_\beta} \sqrt{2f(\varphi)}\, d\varphi. \tag{10.7}$$

For convenience, we introduce

$$\psi_{\mathcal{S}} = \sqrt{\lambda} \int_{\varphi_\alpha}^{\varphi_\beta} \sqrt{2f(\varphi)}\, d\varphi \tag{10.8}$$

and note that, if rewritten in terms of dimensional quantities, $\psi_{\mathcal{S}}$ would carry dimensions of free-energy per unit area. Granted that (10.8) holds, it follows from (10.7) that

$$\int_{-\infty}^{+\infty} \lambda|\dot{\varphi}_0^{\text{in}}(r)|^2\, dr = \psi_{\mathcal{S}}. \tag{10.9}$$

10.3. Interfacial evolution equation. Indirect approach. At $O(1)$, the scaled evolution equation (7.6) yields the linear but inhomogeneous equation

$$\lambda \ddot{\varphi}_1^{\text{in}} - f''(\varphi_0^{\text{in}})\varphi_1^{\text{in}} = -\rho, \tag{10.10}$$

with

$$\rho = BV_{\mathcal{S}}\varphi_0^{\prime\,\mathrm{in}} - \lambda K_{\mathcal{S}}\varphi_0^{\prime\prime\,\mathrm{in}} - [\![\Psi]\!]g'(\varphi_0^{\mathrm{in}}). \tag{10.11}$$

On differentiating (10.3) with respect to r, it follows that $\varphi_0^{\prime\,\mathrm{in}}$ must satisfy the homogeneous equation $\lambda\varphi_0^{\prime\prime\prime\,\mathrm{in}} - f''(\varphi_0^{\mathrm{in}})\varphi_0^{\prime\,\mathrm{in}} = 0$. Thus, by the Fredholm alternative, ρ and $\varphi_0^{\prime\,\mathrm{in}}$ must be orthogonal:

$$\int_{-\infty}^{+\infty} \rho\varphi_0^{\prime\,\mathrm{in}}\, dr = 0. \tag{10.12}$$

Evaluating the integral on the left side of (10.12), using (10.9) and the boundary conditions (10.4), and recalling from (6.3) that g vanishes at $\varphi = \varphi_\alpha$ and is equal to unity at $\varphi = \varphi_\beta$, we find that

$$b_{\mathcal{S}}V_{\mathcal{S}} = \psi_{\mathcal{S}}K_{\mathcal{S}} + [\![\Psi]\!], \tag{10.13}$$

where we have introduced

$$b_{\mathcal{S}} = \frac{B}{\sqrt{\lambda}}\int_{\varphi_\alpha}^{\varphi_\beta} \sqrt{2f(\varphi)}\, d\varphi = \frac{B\psi_{\mathcal{S}}}{\lambda}. \tag{10.14}$$

We note that, if rewritten in terms of dimensional quantities, $b_{\mathcal{S}}$ would carry dimensions of mass per unit time per unit area and would, therefore, represent interfacial reciprocal mobility.

On performing a suitable redimensionalization, we find that (10.13) is precisely the interfacial evolution equation (1.2) governing the evolution of a sharp phase interface endowed with a constant interfacial free energy per unit area $\psi_{\mathcal{S}}$ and reciprocal mobility $b_{\mathcal{S}}$ that separates bulk phases α and β with constant free-energy densities Ψ_α and Ψ_β.

10.4. Interfacial evolution equation. Direct approach. Within the layer, $\nabla\varphi_\epsilon$ is generally nontrivial. Thus, it is permissible to work with the scaled normal configurational force balance (7.7) for uniformity surfaces instead of the scaled evolution equation (7.6). Using the inner expansion of φ_ϵ and the estimates (10.1) and (10.2) in (7.7), and neglecting terms of $O(\epsilon^{-1})$ and smaller, we arrive once again at (10.3) and, bearing in mind (8.9), (9.1), and the properties of f, all the conclusions of section 9 follow. Next, at $O(\epsilon^{-1})$, (7.7) yields, in view of the result (10.6) concerning the partition of free-energy density,

$$BV_{\mathcal{S}}|\varphi_0^{\prime\,\mathrm{in}}|^2 = \lambda K_{\mathcal{S}}|\varphi_0^{\prime\,\mathrm{in}}|^2 + \overline{\left\{f'(\varphi_0^{\mathrm{in}})\varphi_1^{\mathrm{in}} - \lambda\varphi_0^{\prime\,\mathrm{in}}\varphi_1^{\prime\,\mathrm{in}}\right\}} + [\![\Psi]\!]\,\overline{g(\varphi_0^{\mathrm{in}})}^{\,\prime}. \tag{10.15}$$

By integrating (10.15) over r from $r = -\infty$ to $r = +\infty$ and utilizing the definitions (10.9) and (10.14), the boundary and far-field conditions (10.4) and (10.5), and properties of f and g, once again we obtain the evolution equation (10.13) obtained in the previous section by the Fredholm alternative. In this sense, (10.13) can be viewed as a consequence of the normal component of the configurational force balance for uniformity surfaces, obtained in passing to the limit $\epsilon \to 0$ a limit that corresponds to collapsing the transition layer into a surface.

We remarked earlier that, when φ_ϵ is regular, the configurational force balance contains no information beyond that already contained in the evolution equation for φ_ϵ. However, passing to the limit $\epsilon \to 0$ generates surfaces across which φ_ϵ is discontinuous and $\nabla\varphi_\epsilon$ and $\dot{\varphi}_\epsilon$ (as well as other associated derivatives) are undefined. The asymptotic analysis performed here shows that, at such a defect, the normal configurational force balance for uniformity surfaces yields directly information that arises only indirectly—as a solvability condition imposed by the Fredholm alternative—from the evolution equation for φ_ϵ. In this sense, we view the asymptotically derived interfacial evolution equation as a statement of normal configurational force balance for the interface.

Our asymptotic derivations of the evolution equation (1.2) are predicated on (10.8) and (10.14). We interpret (10.8) and (10.14) as *constitutive connections* between the theories at hand, connections that guarantee that the phase-field theory corresponds asymptotically to the sharp-interface theory.

11. Generalization. To obtain the general evolution equation (1.1) from the phase-field theory, we first modify the constitutive equations (6.1) and (6.6), determining the free-energy density and the kinetic modulus to be

$$\psi = f(\varphi) + \Psi_\alpha(1 - g(\varphi)) + \Psi_\beta g(\varphi) + \frac{1}{2}\lambda(\mathbf{n})|\nabla\varphi|^2 \tag{11.1}$$

and

$$\beta(\varphi, \nabla\varphi, \dot{\varphi}) = B(\mathbf{n}, V) > 0, \tag{11.2}$$

with $\mathbf{n}$ and V as defined in (4.2) and (4.3).

Scaling as in section 7, we arrive at the evolution equation

$$\epsilon B(\mathbf{n}_\epsilon, V_\epsilon)\dot{\varphi}_\epsilon = \epsilon \mathrm{div}\left\{|\nabla\varphi_\epsilon|\left(\lambda(\mathbf{n}_\epsilon)\mathbf{n}_\epsilon + \frac{1}{2}\frac{\partial\lambda(\mathbf{n}_\epsilon)}{\partial\mathbf{n}_\epsilon}\right)\right\} - \epsilon^{-1}f'(\varphi_\epsilon) - [\![\Psi]\!]g'(\varphi_\epsilon) \tag{11.3}$$

and the normal configurational force balance for uniformity surfaces

$$\begin{aligned}\epsilon|\nabla\varphi_\epsilon|^2 B(\mathbf{n}_\epsilon, V_\epsilon)V_\epsilon &= \left\{\epsilon^{-1}f(\varphi_\epsilon) + \frac{1}{2}\epsilon\lambda(\mathbf{n}_\epsilon)|\nabla\varphi_\epsilon|^2\right\}K_\epsilon \\ &\quad + \mathrm{div}\left\{\left\{\epsilon^{-1}f(\varphi_\epsilon) - \frac{1}{2}\epsilon\lambda(\mathbf{n}_\epsilon)|\nabla\varphi_\epsilon|^2\right\}\mathbf{n}_\epsilon - \frac{1}{2}\epsilon|\nabla\varphi_\epsilon|^2\frac{\partial\lambda(\mathbf{n}_\epsilon)}{\partial\mathbf{n}_\epsilon}\right\} + [\![\Psi]\!]\mathbf{n}\cdot\nabla g(\varphi_\epsilon),\end{aligned} \tag{11.4}$$

which generalize (7.6) and (7.7).

The results for the bulk regions are unchanged from those presented in section 9. To study the layer, we follow the approach taken in section 10.4. Specifically, at $O(\epsilon^{-2})$, (11.4) yields

$$\overline{\left\{\tfrac{1}{2}\lambda(\mathbf{n})|\acute{\varphi}_0^{\mathrm{in}}|^2 - f(\varphi_0^{\mathrm{in}})\right\}} = 0. \tag{11.5}$$

Further, the matching conditions (8.9) and the bulk results (9.1) yield, as before, the far-field conditions (10.4) and (10.5). Combining (11.5), (10.4), and (10.5), we arrive at the first integral

$$\frac{1}{2}\lambda(\mathbf{n})|\acute{\varphi}_0^{\mathrm{in}}|^2 = f(\varphi_0^{\mathrm{in}}) \tag{11.6}$$

and find, in view of the properties of f, that once again, as a function of r, $\varphi_0^{\rm in}$ must be square-integrable on $(-\infty,+\infty)$. This leads to a generalization

$$\int_{-\infty}^{+\infty}\sqrt{\lambda(\mathbf{n})}|\varphi_0^{\rm in}(r,\cdot,\cdot)|^2\,dr=\int_{\varphi_\alpha}^{\varphi_\beta}\sqrt{2f(\varphi)}\,d\varphi \tag{11.7}$$

of (10.7).

We next introduce analogues

$$\hat{\psi}_{\mathcal{S}}(\mathbf{n})=\sqrt{\lambda(\mathbf{n})}\int_{\varphi_\alpha}^{\varphi_\beta}\sqrt{2f(\varphi)}\,d\varphi \tag{11.8}$$

and

$$b_{\mathcal{S}}(\mathbf{n},V_{\mathcal{S}})=\frac{B(\mathbf{n},V_{\mathcal{S}})}{\sqrt{\lambda(\mathbf{n})}}\int_{\varphi_\alpha}^{\varphi_\beta}\sqrt{2f(\varphi)}\,d\varphi=\frac{B(\mathbf{n},V_{\mathcal{S}})\hat{\psi}_{\mathcal{S}}(\mathbf{n})}{\lambda(\mathbf{n})} \tag{11.9}$$

of the constitutive connections (10.8) and (10.14). Direct consequences of (11.7) and (11.8) are the identities

$$\begin{cases}\displaystyle\int_{-\infty}^{+\infty}\lambda(\mathbf{n})|\varphi_0^{\rm in}(r,\cdot,\cdot)|^2\,dr=\hat{\psi}_{\mathcal{S}}(\mathbf{n}),\\[2ex]\displaystyle\int_{-\infty}^{+\infty}\frac{\partial\lambda(\mathbf{n})}{\partial\mathbf{n}}|\varphi_0^{\rm in}(r,\cdot,\cdot)|^2\,dr=2\frac{\partial\hat{\psi}_{\mathcal{S}}(\mathbf{n})}{\partial\mathbf{n}}.\end{cases} \tag{11.10}$$

Finally, proceeding as in section 10.4, (11.4) yields at $O(\epsilon^{-1})$

$$\begin{aligned}|\varphi_0^{\rm in}|^2B(\mathbf{n},V_{\mathcal{S}})V_{\mathcal{S}}&=|\varphi_0^{\rm in}|^2\lambda(\mathbf{n})K_{\mathcal{S}}-\operatorname{div}_{\mathcal{S}}\left\{\frac{1}{2}|\varphi_0^{\rm in}|^2\frac{\partial\lambda(\mathbf{n})}{\partial\mathbf{n}}\right\}\\&\quad+\overline{\left\{f'(\varphi_0^{\rm in})\varphi_1^{\rm in}-\varphi_0^{\rm in}\varphi_1^{\rm in}\lambda(\mathbf{n})-\frac{1}{2}\varphi_0^{\rm in}\nabla\varphi_0^{\rm in}\cdot\frac{\partial\lambda(\mathbf{n})}{\partial\mathbf{n}}\right\}}+[\![\Psi]\!]\overline{g(\varphi_0^{\rm in})};\end{aligned} \tag{11.11}$$

by integrating (11.11) over r from $r=-\infty$ to $r=+\infty$ and utilizing the constitutive connections (11.8) and (11.9), the boundary and far-field conditions (10.4) and (10.5), and properties of f and g, we obtain

$$\hat{b}_{\mathcal{S}}(\mathbf{n},V_{\mathcal{S}})V_{\mathcal{S}}=\left\{\hat{\psi}_{\mathcal{S}}(\mathbf{n})\mathbf{P}+\frac{\partial^2\hat{\psi}_{\mathcal{S}}(\mathbf{n})}{\partial\mathbf{n}^2}\right\}\cdot\mathbf{L}+[\![\Psi]\!], \tag{11.12}$$

which, on performing a suitable redimensionalization, is precisely the general interfacial evolution equation (1.1) of the sharp-interface theory.

12. Discussion. Our results are predicated on the provision of constitutive equations within the phase-field theory and, moreover, upon stipulated connections (11.8) and (11.9) between those constitutive equations and the constitutive equations of the sharp-interface theory. However, because the framework of the phase-field theory is a dynamical one that allows for dissipation, the results of our analysis are more broadly applicable than any alternative based on variational methods.

By restricting our attention to a setting where the standard force balance is irrelevant, we leave open the possibility that, once the constraint of rigidity is relaxed

and the standard stress is no longer indeterminate, the standard force balance might somehow give rise to the interfacial configurational force balance and, thus, to a law governing the evolution of the interface. However, such an outcome would be at odds with the implications of variationally based descriptions. Indeed, in considering phase interfaces within the context of the theory of finite elastostatics, Podio-Guidugli [30] shows that, while both the bulk configurational force balance and the tangential component of the interfacial configurational force balance are implied consequences of standard force balance, the normal component of the interfacial configurational force balance is independent. Moreover, asymptotic analyses of phase-field theories that account for deformation (Fried and Grach [11]; Fried and Gurtin [14]) demonstrate that the supplemental evolution equation of the sharp-interface theory arises not from the deformational force balance but, as in the simple theory considered here, either "indirectly" from the evolution equation for the phase field or "directly" from the associated configurational force balance.

ON THE FUNDAMENTAL DIAGRAM OF TRAFFIC FLOW*

FLORIAN SIEBEL† AND WOLFRAM MAUSER†

Abstract. We present a new fluid-dynamical model of traffic flow. This model generalizes the model of Aw and Rascle [*SIAM J. Appl. Math.*, 60 (2000), pp. 916–938] and Greenberg [*SIAM J. Appl. Math.*, 62 (2001), pp. 729–745] by prescribing a more general source term to the velocity equation. This source term can be physically motivated by experimental data, when taking into account relaxation and reaction time. In particular, the new model has a (linearly) unstable regime as observed in traffic dynamics. We develop a numerical code that solves the corresponding system of balance laws. Applying our code to a wide variety of initial data, we find the observed inverse-λ shape of the fundamental diagram of traffic flow.

Key words. macroscopic traffic model, instability, system of balance laws, high-resolution shock-capturing schemes

1. Introduction.

After two-equation models of traffic flow were seriously criticized by Daganzo [5], the main focus of the traffic community shifted toward microscopic models of traffic flow. However, the criticism has been overcome; see, e.g., [26, 11]. By replacing the space derivate in old two-equation models by the convective derivative, Aw and Rascle [2] and Greenberg [8] deduced a two-equation model which solves all inconsistencies of the earlier models, as they showed with a detailed mathematical analysis and numerical simulations. In particular, in their model (which we call the ARG model), no information travels faster than the vehicle velocity; i.e., in general drivers do not react to the traffic situation behind them. Moreover, the velocity is always nonnegative. In the ARG model, traffic flow is described by the following system of balance laws determining the density $\rho = \rho(t,x)$ and velocity $v = v(t,x)$ of cars:

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho v)}{\partial x} = 0, \tag{1.1}$$

$$\frac{\partial (\rho (v - u(\rho)))}{\partial t} + \frac{\partial (\rho v (v - u(\rho)))}{\partial x} = \frac{\rho (u(\rho) - v)}{T}. \tag{1.2}$$

As usual, (t,x) denote the time and space variables. $u(\rho)$ denotes the *equilibrium velocity*, which fulfills the following conditions:

$$u'(\rho) < 0 \quad \text{for } 0 \le \rho \le \rho_m, \tag{1.3}$$

$$\frac{d^2(\rho u(\rho))}{d\rho^2} < 0 \quad \text{for } 0 \le \rho \le \rho_m, \tag{1.4}$$

with the maximum vehicle density ρ_m. $T > 0$ is an additional parameter, the *relaxation time*. In the formal limit $T \to 0$ the ARG model reduces to the classic Lighthill–Whitham–Richards model [16, 19, 25]. For smooth solutions, the ARG model can be

†Department of Earth and Environmental Sciences, University of Munich, Luisenstraße 37, D-80333 Munich, Germany (f.siebel@iggf.geo.uni-muenchen.de, w.mauser@iggf.geo.uni-muenchen.de).

rewritten as

$$\frac{\partial \rho}{\partial t} + v\frac{\partial \rho}{\partial x} + \rho\frac{\partial v}{\partial x} = 0, \tag{1.5}$$

$$\frac{\partial v}{\partial t} + (v + \rho u'(\rho))\frac{\partial v}{\partial x} = \frac{u(\rho) - v}{T}. \tag{1.6}$$

In our opinion the ARG model still has a drawback; i.e., it cannot explain the growth of structures and the general behavior for congested traffic, as observed in traffic dynamics (see, e.g., [20, 10, 12]). To see this, we consider a linear stability analysis around the equilibrium solution $\rho(t,x) = \rho_0$, $v(t,x) = u(\rho_0)$, i.e.,

$$\rho(t,x) = \rho_0 + \tilde{\rho}\exp(ikx + \omega(k)t), \tag{1.7}$$

$$v(t,x) = u(\rho_0) + \tilde{v}\exp(ikx + \omega(k)t). \tag{1.8}$$

Substituting this ansatz into system (1.5)–(1.6) we obtain

$$\begin{pmatrix} \omega + iku & ik\rho_0 \\ -\frac{u'}{T} & \omega + \frac{1}{T} + ik(u + \rho_0 u') \end{pmatrix} \begin{pmatrix} \tilde{\rho} \\ \tilde{v} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{1.9}$$

Nontrivial solutions of this linear system exist if and only if

$$(\omega + iku)\Big(\omega + \frac{1}{T} + ik(u + \rho_0 u')\Big) + ik\frac{\rho_0 u'}{T} = 0 \tag{1.10}$$

or, equivalently, for

$$\omega_1 = -ik(u + \rho_0 u'), \tag{1.11}$$

$$\omega_2 = -\frac{1}{T} - iku. \tag{1.12}$$

For the stability properties, the real parts of the above solutions are important; i.e.,

$$Re(\omega_1) = 0, \tag{1.13}$$

$$Re(\omega_2) = -\frac{1}{T}. \tag{1.14}$$

For $T > 0$ both real parts are nonpositive, which means that the ARG model is linearly stable, and the velocity v relaxes to the equilibrium velocity u in the entire region $0 \le \rho \le \rho_m$. This is clearly in contrast to observations, where a wide range of states in the fundamental diagram, the relation between vehicle flux and the density, are observed for congested traffic flow. To correct this defect, Greenberg, Klar, and Rascle developed an extended model with two equilibrium velocities [9]. In the present paper, we propose an alternative model, which takes into account the reaction times of drivers (as well as mechanical restrictions).

We give a physical argument for our new model and define it in section 2. Section 3 presents the methods used for numerically solving the model equations. Section 4 describes tests to validate our numerical algorithm, before we finally discuss the numerical results on the fundamental diagram obtained with our model in section 5.

2. A heuristic derivation of the new model. Before we turn to the new model, let us first give a simple derivation of the ARG model. Note that the model was mathematically derived from a car-following theory in [1]. Suppose that in the

reference frame of individual drivers, drivers adjust their speed v in such a way that they asymptotically approach the equilibrium velocity u; i.e.,

$$\frac{d(v-u)}{dt} = \frac{u-v}{T}. \tag{2.1}$$

Here, $T = \text{const} > 0$ is the relaxation time. In comparison to optimal velocity models (see, e.g., [3]) the equilibrium velocity term on the left has been added which vanishes for $u = \text{const}$. It is easy to verify that the analytical solution of the ordinary differential equation (2.1) reads

$$v(t) = u(t) + (v(0) - u(0)) \exp\left(-\frac{t}{T}\right). \tag{2.2}$$

In the coordinate system of the road, (2.1) translates to

$$\frac{\partial(v-u)}{\partial t} + v\frac{\partial(v-u)}{\partial x} = \frac{u-v}{T}. \tag{2.3}$$

Moreover, since

$$-\left(\frac{\partial u}{\partial t} + v\frac{\partial u}{\partial x}\right) = -u'\left(\frac{\partial \rho}{\partial t} + v\frac{\partial \rho}{\partial x}\right) = \rho u'\frac{\partial v}{\partial x}, \tag{2.4}$$

where we have used the continuity equation (1.5) for the last equality, we recover the velocity equation of the ARG model (1.6). From this derivation, it is obvious that drivers instantaneously react to the current traffic situation.

We therefore tried to generalize (2.1) and took the reaction time of drivers $\tau > 0$ into account:

$$\frac{dv}{dt}(t,x) - \frac{du}{dt}(\rho(t-\tau, x-v\tau)) = \frac{u(\rho(t-\tau,x-v\tau)) - v(t-\tau,x-v\tau)}{T}. \tag{2.5}$$

Using a Taylor series expansion in τ and keeping only terms up to order 0 in τ and T, i.e.,

$$\frac{du}{dt}(\rho(t-\tau,x-v\tau)) = \frac{\partial u(\rho(t,x))}{\partial t} + v\frac{\partial u(\rho(t,x))}{\partial x} + O^1(\tau,T), \tag{2.6}$$

$$u(\rho(t-\tau,x-v\tau)) = u(\rho(t,x)) - \tau u'(\rho(t,x))\left(\frac{\partial \rho}{\partial t} + v\frac{\partial \rho}{\partial x}\right) + O^2(\tau,T)$$

$$= u + \rho u'\frac{\partial v}{\partial x}\tau + O^2(\tau,T), \tag{2.7}$$

$$v(t-\tau,x-v\tau) = v(t,x) - \tau\left(\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial x}\right) + O^2(\tau,T), \tag{2.8}$$

we find

$$\frac{\partial v}{\partial t} + (v + \rho u'(\rho))\frac{\partial v}{\partial x} = \frac{u(\rho) - v}{T - \tau}. \tag{2.9}$$

This equation is identical to the velocity equation of the ARG model (1.6), except that the relaxation time T has been replaced by $T - \tau$. In particular it follows from the stability analysis of the ARG model that for $\tau > T$ the new system is (linearly) unstable.

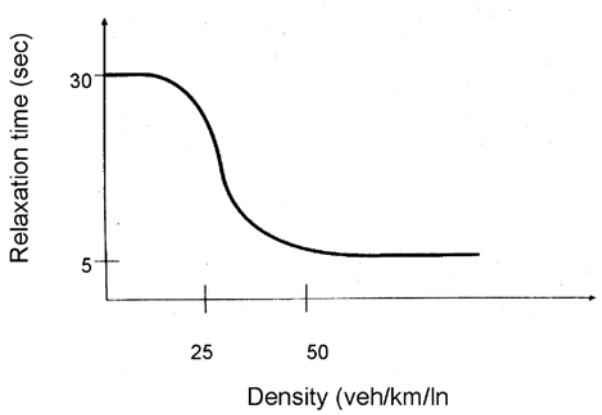

FIG. 1. *Dependence of the relaxation time $\tilde{T}$ on the vehicle density per lane. Reprinted with permission from* [14].

Before we look at the experimental data on the relaxation and reaction times, we remark that it is tempting to include an anticipation length in the model, as, e.g., in [23, 17]. This approach has not been followed here for two reasons: First, the ARG model already includes anticipatory elements, as noted by [8]. Second, including the anticipation length in the above derivation yields a system that does not guarantee that the maximum speed at which information travels is bounded from above by the velocity of cars, and is therefore unrealistic.

For the reaction time τ, which includes the human perception time as well as the time it takes to realize the reaction (hence τ is also called perception-reaction time), typical values [13] are of the order

$$\tau \approx 0.5 \,..\, 2 \text{ s}. \tag{2.10}$$

Figure 1 shows experimental results for the relaxation time $\tilde{T}$ taken from [14]. However, these values have to be interpreted with care and cannot be translated directly to our model context. To see this, we note that the relaxation time $\tilde{T}$ is determined for the ansatz $v(t+\tilde{T}, x) = u(\rho(t, x+\Delta x))$. In this expression, $x+\Delta x$ denotes the anticipated location, where according to [14], $\Delta x = -\tilde{T} c_0^2(\rho) u'(\rho)^{-1} \rho^{-1}$, with an anticipation coefficient $c_0^2(\rho)$ corresponding to the standard deviation of the vehicular speed distribution, which for simplicity is often set to a constant value. In this approach, the drivers have fully adjusted their velocities to the equilibrium velocity u after the relaxation time $\tilde{T}$. Here, according to (2.1) and (2.2), the equilibrium velocity in general will never be reached exactly. Instead, if we require that $|v(t) - u(t)| < |v(0) - u(0)|/1000$, we find that $t > 6.908\, T \approx \tilde{T}$. Hence it seems reasonable to set

$$\tilde{T} \approx 5 \,..\, 10\, T. \tag{2.11}$$

With typical values $\tau = 1$ s and $\tilde{T} = 7.5\, T$, we indeed find that $T - \tau < 0$ for about $\rho > 40$ [1/km/lane]. It was also pointed out in [14] that for large densities the relaxation time $\tilde{T}$ increases, which we interpret as $T - \tau \geq 0$ for $\rho \approx \rho_m$. We remark that the precise form in which the reaction time and anticipation effects are included in the traffic equations differs for different traffic models; see, e.g., [17, 6, 18].

One could try to repeat the derivation leading to (2.9) for a general relaxation time $T = T(\rho, v)$. Note that the above derivation is valid only for a constant relaxation time. Moreover, it involves only the leading term of a Taylor series expansion. We therefore decided to generalize the velocity equation of the ARG model in the following way:

$$\frac{\partial v}{\partial t} + (v + \rho u'(\rho))\frac{\partial v}{\partial x} = \beta(\rho, v)(u(\rho) - v). \tag{2.12}$$

Note that we do not require $v \leq u$ as in Greenberg [8]. From the experimental data and the argument put forward before (note that the sign of β determines whether the traffic flow is linearly stable or not), we require

$$\beta(\rho, v) < 0 \quad \text{for } 0 < \rho_1 < \rho < \rho_2 \leq \rho_m,\ v = u(\rho), \tag{2.13}$$

$$\lim_{\rho \to 0, \rho_m} \beta(\rho, v) \geq 0, \tag{2.14}$$

$$\lim_{v \to 0, u_m = u(0)} \beta(\rho, v) \geq 0. \tag{2.15}$$

The last condition is necessary, as the system would otherwise be driven to negative or arbitrarily large vehicle velocities, which is clearly unrealistic. Throughout this paper we use a functional form

$$\beta(\rho, v) = \begin{cases} \frac{a_c}{u - v} & \text{if } \tilde{\beta}(\rho, v)(u - v) - a_c \geq 0, \\ \frac{d_c}{u - v} & \text{if } \tilde{\beta}(\rho, v)(u - v) - d_c \leq 0, \\ \tilde{\beta}(\rho, v) & \text{else,} \end{cases} \tag{2.16}$$

where the function $\tilde{\beta}(\rho, v)$ is defined as

$$\tilde{\beta} = \frac{1}{\hat{T}}\left(1 + \alpha\frac{|u - v|}{u_m} + \frac{1}{\rho_1 \rho_2}(-(\rho_1 + \rho_2)\rho + \rho^2)\right). \tag{2.17}$$

For $v = u(\rho)$, the function $\tilde{\beta}$ reduces to a parabola with zeros ρ_1 and ρ_2 in accordance with conditions (2.13) and (2.14). The term involving the velocity is added in order to fulfill condition (2.15). In the following we specify the free functions and parameters for a two-lane highway. For the choice of the velocity-density relation of Cremer [4],

$$u(\rho) = u_m\left(1 - \left(\frac{\rho}{\rho_m}\right)^{n_1}\right)^{n_2}, \tag{2.18}$$

and the parameters $\rho_m = 300$ [1/km], $u_m = 140$ km/h, $n_1 = 0.35$, $n_2 = 1$ (note that with these parameters, the equilibrium velocity of Cremer (2.18) fulfills the conditions (1.3) and (1.4)), $\hat{T} = 1$ s, $\alpha = 12$, $\rho_1 = 70$ [1/km], and $\rho_2 = 270$ [1/km], the function $\tilde{\beta}(\rho, v)$ already fulfills all requirements (2.13)–(2.15). However, due to mechanical restrictions, the maximum acceleration a_c and deceleration d_c give stronger limitations, i.e.,

$$\frac{dv}{dt} \leq a_c \qquad \text{and} \qquad \frac{dv}{dt} \geq d_c \tag{2.19}$$

with typical values $a_c = 2$ m/s^2 and $d_c = -5$ m/s^2. Since the resulting system is not strictly hyperbolic for equality in (2.19), which is problematic for a numerical solution, we prescribe the limitations on

$$\frac{d(v - u)}{dt} \leq a_c \qquad \text{and} \qquad \frac{d(v - u)}{dt} \geq d_c, \tag{2.20}$$

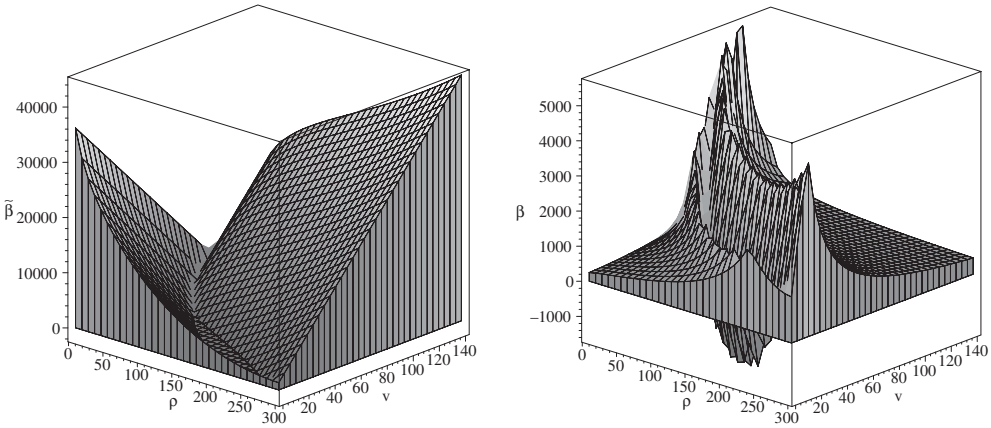

FIG. 2. *Functions $\tilde{\beta}(\rho, v)$ (left panel) and $\beta(\rho, v)$ (right panel) defined in* (2.17) *and* (2.16). *We used units* $[\rho] = 1/\text{km}, [v] = \text{km/h}$, *and* $[\tilde{\beta}] = [\beta] = 1/\text{h}$. *The function $\tilde{\beta}(\rho, v)$ reaches very large values leading to unrealistic accelerations and decelerations according to* (2.12). *For the function $\beta(\rho, v)$ mechanical restrictions were taken into account, which change the functional shape but not the sign.*

which then leads to the functional form (2.16). We plot the functions $\tilde{\beta}(\rho, v)$ and $\beta(\rho, v)$ for the mentioned parameter values in Figure 2. We stress that the above functions describe reality only qualitatively. For realistic simulations of traffic flow, experimental data are required to determine $\beta(\rho, v)$.

In the new model, traffic flow is described by the system of balance laws

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho v)}{\partial x} = 0, \tag{2.21}$$

$$\frac{\partial(\rho(v - u(\rho)))}{\partial t} + \frac{\partial(\rho v(v - u(\rho)))}{\partial x} = \beta\rho(u - v) \tag{2.22}$$

or, equivalently, for smooth solutions by (1.5) and (2.12). As the corresponding system of the ARG model, the new system is strictly hyperbolic for $0 < \rho \leq \rho_m$.

3. The numerical implementation. Writing traffic flow as a system of balance laws in (2.21) and (2.22) is very adequate for numerical purposes, as it allows the application of well-established hydrodynamic methods for the numerical solution. We use a high-resolution shock-capturing scheme with an approximate Riemann solver for the numerical solution (see, e.g., [15]).

We rewrite (2.21) and (2.22) in the form

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = S(U), \tag{3.1}$$

where

$$U = \begin{pmatrix} \rho \\ \rho(v - u) \end{pmatrix} = \begin{pmatrix} U_1 \\ U_2 \end{pmatrix}, \tag{3.2}$$

$$F(U) = \begin{pmatrix} \rho v \\ \rho v(v - u) \end{pmatrix} = \begin{pmatrix} U_2 + U_1 u(U_1) \\ \frac{U_2^2}{U_1} + U_2 u(U_1) \end{pmatrix}, \tag{3.3}$$

$$S(U) = \begin{pmatrix} 0 \\ \beta\rho(u - v) \end{pmatrix}. \tag{3.4}$$

We use the second-order reconstruction scheme of van Leer [24] to reconstruct quantities at cell interfaces. At cell i with cell center at the location $x_i = x_0 + i\Delta x$ the update in time from t^n to t^{n+1} is performed according to a conservative algorithm

$$U_i^{n+1} = U_i^n - \frac{\Delta t}{\Delta x}(\hat{F}_{i+\frac{1}{2}} - \hat{F}_{i-\frac{1}{2}}) + \Delta t S_i, \tag{3.5}$$

where $U_i^n = U(t^n, x_i)$ and $\Delta t = t^{n+1} - t^n$. To obtain a higher order of convergence, we use the third-order scheme of Shu and Osher [21]. The numerical fluxes $\hat{F}$ are determined according to the flux formula of Marquina [7], which reads

$$\hat{F} = \frac{1}{2}(F^R + F^L - \Delta q). \tag{3.6}$$

Here, the superscripts R and L denote the reconstructed values on the right and left of a cell interface. The numerical viscosity term takes the form

$$\Delta q = \mathbf{R}^R |\Lambda|_{\max} \mathbf{L}^R U^R - \mathbf{R}^L |\Lambda|_{max} \mathbf{L}^L U^L. \tag{3.7}$$

The matrix $|\Lambda|_{\max}$ involves the characteristic speeds

$$|\Lambda|_{\max} = \begin{pmatrix} \max(|\lambda_1^R|, |\lambda_1^L|) & 0 \\ 0 & \max(|\lambda_2^R|, |\lambda_2^L|) \end{pmatrix}, \tag{3.8}$$

where the characteristic speeds read explicitly as

$$\lambda_1 = v + \rho u', \tag{3.9}$$

$$\lambda_2 = v. \tag{3.10}$$

$\mathbf{R}$ and $\mathbf{L}$ are the matrices of the right and left eigenvectors of the matrix

$$\frac{\partial F}{\partial U} = \begin{pmatrix} u + \rho u' & 1 \\ -(v-u)^2 + \rho(v-u)u' & 2v - u \end{pmatrix}. \tag{3.11}$$

Explicitly,

$$\mathbf{R} = \begin{pmatrix} 1 & 1 \\ v - u & v - u - \rho u' \end{pmatrix}, \tag{3.12}$$

$$\mathbf{L} = \frac{1}{\rho u'} \begin{pmatrix} u - v + \rho u' & 1 \\ v - u & -1 \end{pmatrix}. \tag{3.13}$$

4. Code tests. We checked that our numerical algorithm is convergent. Moreover, the density equation (2.21) is a strict conservation law. Prescribing periodic boundary conditions as in section 5, the total number of cars included in the numerical domain Ω should therefore be constant; i.e.,

$$\int_\Omega \rho \, dx = \text{const}. \tag{4.1}$$

We checked that our numerical code fulfills (4.1) up to machine precision (see also the corresponding results for a network simulation based on the Lighthill–Whitham theory in [22]).

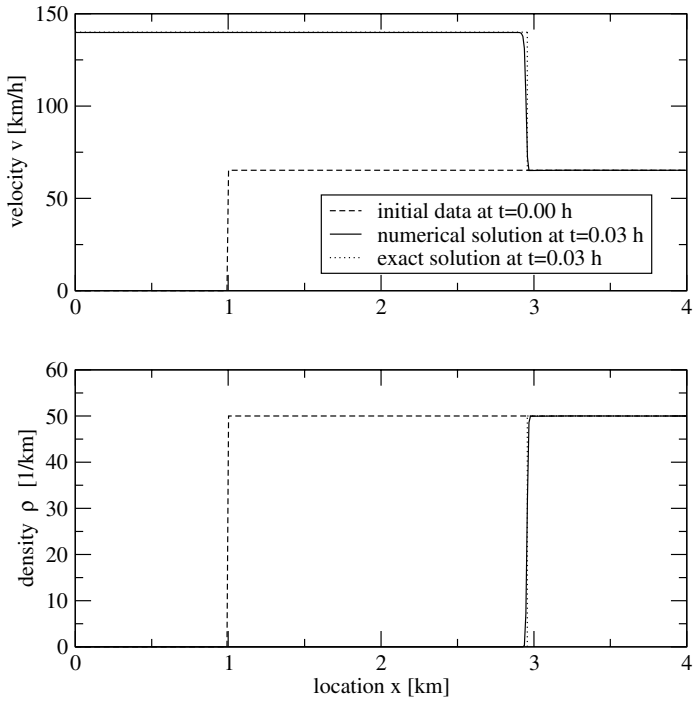

FIG. 3. *Numerical solution for a Riemann problem of Aw and Rascle* [2]. *The numerical solution at time* $t = 0.03$ h *(solid line) for the initial data (dashed line) reproduces the exact solution (dotted line).*

Finally, Aw and Rascle presented in their paper the exact solution of a Riemann problem, for which old two-equation models fail to describe the correct behavior (see [2, Figure 5.4]). This Riemann problem consists of the following initial data:

$$\rho = \begin{cases} 0 & \text{if } x < 1 \text{ km}, \\ \rho_+ & \text{if } x \geq 1 \text{ km}, \end{cases} \tag{4.2}$$

$$v = \begin{cases} 0 & \text{if } x < 1 \text{ km}, \\ v_+ & \text{if } x \geq 1 \text{ km}. \end{cases} \tag{4.3}$$

The exact solution to the homogeneous system consists of the constant state on the right (ρ_+, v_+) moving to the right with velocity v_+, leaving behind a vacuum. If we choose $v_+ = u(\rho_+)$, this exact solution will carry over to our inhomogeneous system. Figure 3 displays our numerical solution for a choice $\rho_+ = 50$ [1/km]. For numerical reasons, we prescribe a density $\rho = 10^{-6}$ [1/km] for $x < 1$ km. Note that our numerical algorithm resolves the steep gradient within only a few grid cells, at the same time reproducing the correct velocity at which the constant state moves to the right. Moreover, the velocity relaxes to the equilibrium velocity behind the constant state (ρ_+, v_+).

5. Results on the fundamental diagram. For the results presented in this section we restrict the calculation to a 7 km long section of a (two-lane) highway with periodic boundary conditions. On this section of the highway, we start our simulations

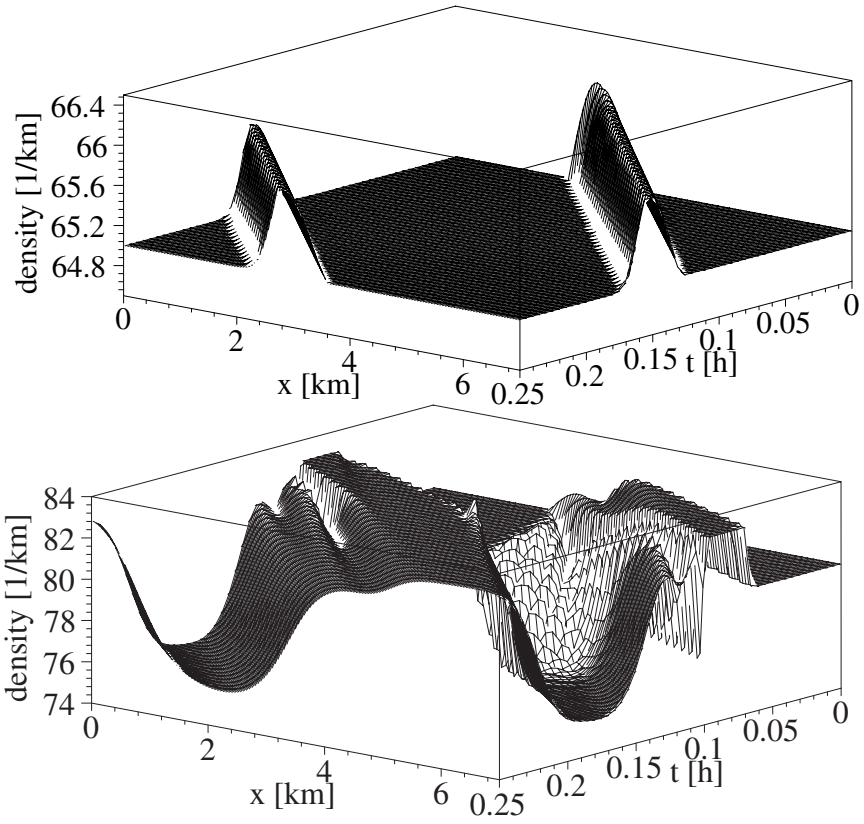

FIG. 4. *Time evolution of the density for stable and unstable initial data. We prescribe an equilibrium density* $\rho_0 = 65$ [1/km] *and* $\rho_0 = 80$ [1/km]*, respectively, and in addition a sinusoidal density perturbation. For the unstable data, the initial perturbation located at* $x = 2.5$ [km] *is amplified and finally two clusters form.*

with constant equilibrium data $\rho = \rho_0$, $v = u(\rho_0)$ and, in addition, between kilometers 2 and 3 a sinusoidal density perturbation

$$\Delta\rho = \sin(\pi x) \quad \text{for } 2 < x < 3 \text{ km}. \tag{5.1}$$

For all numerical results presented we used a resolution of 50 m. Figure 4 shows the evolution of these data for parameters $\rho_0 = 65$[1/km] and $\rho_0 = 80$[1/km]. Whereas the amplitude of the perturbation is gradually damped with time for the stable initial data $\rho_0 = 65$[1/km], the amplitude of the perturbation increases for the unstable initial data $\rho_0 = 80$ [1/km]. Moreover, the perturbation travels with a larger velocity downstream in the first case. For the unstable situation, two clusters are forming. We plot the corresponding time evolutions of the velocity in Figure 5.

To obtain a more general picture we varied the initial density in the entire density regime and analyzed the resulting flow-density relation as a function of time. More precisely, we used initial values for the equilibrium data $\rho_0 = 2, 4, \ldots, 298$ and read off the resulting values for the density ρ and the flux function ρv at five equidistantly distributed cross sections of the highway. Figure 6 shows the results for evolution times $t = 0.00$ h (initial data), $t = 0.05$ h, $t = 0.10$ h, $t = 0.15$ h, $t = 0.20$ h, and $t = 0.25$ h. For the initial data, the flow-density curve closely corresponds to the

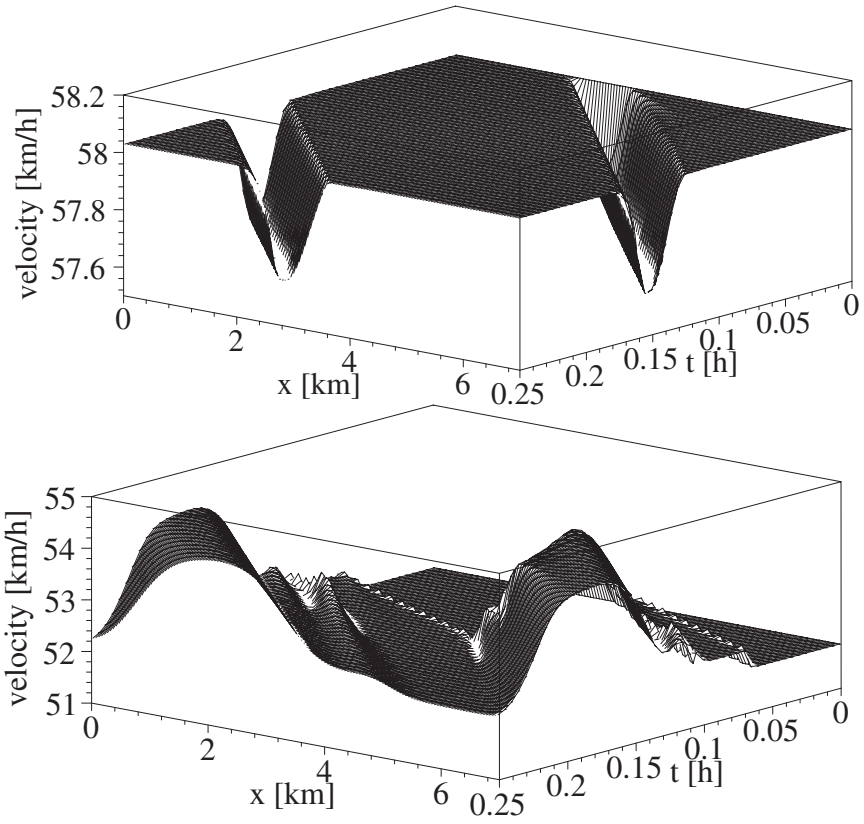

FIG. 5. *Time evolution of the velocity for stable ($\rho_0 = 65$ [1/km]) and unstable initial data ($\rho_0 = 80$ [1/km]) with initial density perturbation.*

equilibrium flow density, the initial perturbation (5.1) being negligible for the visual output. After an evolution time $t = 0.05$ h, the equilibrium flow-density curve is still visible, but in the unstable regime for densities $70 < \rho < 270$ [1/km] two new flow-density curves start to appear. In the evolution further in time, the equilibrium density curve vanishes. Instead the two new branches produce an inverse-λ shape.

6. Conclusion and outlook. We generalized the traffic model of Aw, Rascle, and Greenberg by prescribing a more general source term to the velocity equation and developed a new numerical code to solve the resulting system of balance laws. In total, our (numerical) results show the following:

- The new model can explain the large variance of the measured values of the fundamental diagram in the congested regime, which corresponds to fluctuations between two branches in the unstable density regime. Moreover, due to the stability properties, the model predicts oscillations in the relative velocity of cars in the congested regime, as they are found in experimental data. At the same time, it reproduces the small variance of velocities for free traffic flow and can explain the appearance of wide traffic jams.
- Macroscopic traffic models have often used an equilibrium velocity $u(\rho)$, for which $\frac{d(\rho u(\rho))}{d\rho^2} > 0$ in the congested regime, in order to account for the values of traffic flow at the maximum (the tip of the inverted λ). According to

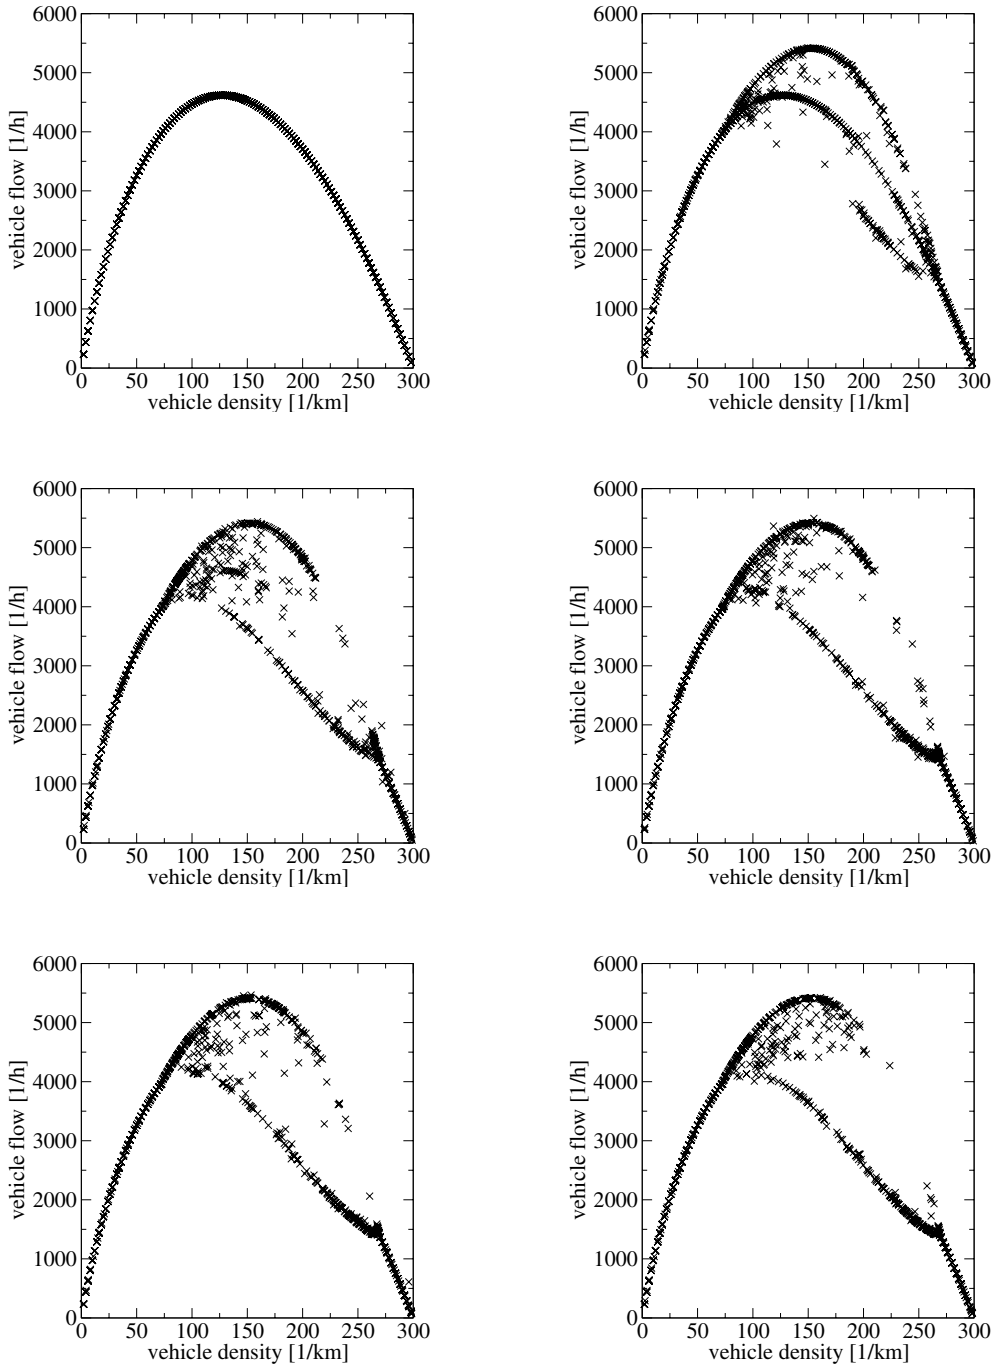

FIG. 6. *Fundamental diagram for the initial data ($t = 0.00$ h) (top left), for $t = 0.05$ h (top right), for $t = 0.10$ h (middle left), for $t = 0.15$ h (middle right), for $t = 0.20$ h (bottom left), and for $t = 0.25$ h (bottom right). At intermediate densities, our traffic model is linearly unstable; the representative points in the fundamental diagram are shifted toward two branches, which gives the visual impression of an inverted λ.*

our study, this is not necessary, as the high values for the fluxes can be explained with overcritical solutions and an equilibrium velocity function with $\frac{d(\rho u(\rho))}{d\rho^2} < 0$ everywhere.

The new model, which is a deterministic and effective one-lane model, has the capacity to reproduce many features observed in traffic dynamics. In the present work, the form of the function β in Figure 2 was motivated by a physical argument, but the quantitative details were determined rather ad hoc. However, we found that the fundamental diagram in the unstable region (e.g., the tip of the inverted λ) depends on the particular form of β. Hence one should try to determine the function β from experimental data of the fundamental diagram. In our opinion, the presented algorithm is adequate for use in network simulations of traffic flow.

THE EFFECT OF CONTACT LINES ON THE RAYLEIGH INSTABILITY WITH ANISOTROPIC SURFACE ENERGY*

K. F. GURSKI†, G. B. MCFADDEN‡, AND M. J. MIKSIS§

Abstract. We determine the linear stability of a rod or wire on a substrate subject to capillary forces arising from an anisotropic surface energy for a range of contact angles between $-\pi/2$ and $\pi/2$. The unperturbed rod is assumed to have infinite length with a uniform cross-section given by a portion of the two-dimensional equilibrium shape. We examine the effect of surface perturbations on the total energy. The stability of the equilibrium interface is reduced to determining the eigenvalues of a coupled system of ordinary differential equations. This system is solved both asymptotically and numerically for several types of anisotropic surface energies. We find that, in general, the presence of the substrate tends to stabilize the rod.

Key words. Rayleigh instability, contact lines, anisotropic surface energy, quantum wires, nanowires, Plateau

1. Introduction.

While stability studies of cylindrical rods have a long history, they are still a subject of current interest. For example, nanowires (alternatively called nanorods or quantum wires) are nanoscale crystal structures that are formed by deposition on a substrate, typically with a high lattice-mismatch that tends to produce aligned crystals on the substrate. The processing parameters that govern the growth and stability of the wires are of intense interest. Here we focus on two important issues surrounding nanowire stability: anisotropic surface tension and the contact angle between the rod and substrate.

The analysis of capillary driven instabilities spurring cylindrical rods to break up into droplets was initiated in 1873 by Plateau [27], who showed that breakup will occur when the rod, with isotropic surface energy, is subject to axisymmetric perturbations whose wavelength exceeds the circumference of the cylinder. Lord Rayleigh [28] determined that the length scale of the instability is controlled by the perturbations having the fastest temporal growth rate. The tendency for preferential beading has subsequently become known as the Rayleigh instability. A nice review by Michael may be found in [22]. Molares et al. [23] recently performed an experimental demonstration using the Rayleigh instability of a nanowire to produce long chains of nanospheres.

The surface energy of a liquid-solid or vapor-solid interface is generally anisotropic due to the underlying crystal lattice and depends on the orientation of the local normal

vector at each point of the interface [12, 25, 30]. As a first step in applying the analysis of Plateau to a nanowire, the effects of the substrate may be ignored, and the stability of the isolated rod determined strictly by the consideration of anisotropic surface energy. The experimental studies of Kondo and Takayanagi [18] show an apparent stability of elongated nanowires that are grown in a bridge configuration, in contrast to the expected nanoislands or quantum dots predicted by the Rayleigh instability for the isotropic case.

Cahn [2] studied the effect of anisotropic surface energy on the Rayleigh instability for isolated rods with circular cross-sections that are subject to axisymmetric perturbations; the underlying surface free energy was assumed to have transverse isotropy, resulting in closed-form solutions to the stability problem. Glaeser and Stölken [9, 32] extended Cahn's analysis and evaluated the effect of the axisymmetric surface energy anisotropy on evolution kinetics. Gurski and McFadden [10] considered general anisotropic surface energies by computing the second variation of the surface free energy of a freestanding rod whose cross-section is smooth and given by a two-dimensional equilibrium shape. The analysis was applied to examples with uniaxial or cubic anisotropy, which illustrated that anisotropic surface energy plays a significant role in establishing the stability of the rod. It was found that both the magnitude and sign of the anisotropy determine whether the contribution stabilizes or destabilizes the system relative to the case of isotropic surface energy.

Previous theoretical studies of the relationship between the morphological instability of a cylinder that is in contact with a substrate have concentrated on cylinders with isotropic surface energy. McCallum et al. [19] investigated the linear instability of a line of film on a substrate. The unperturbed film state was a cylinder of infinite length with a cross-sectional shape of a segment of a circle. Mass was allowed to flow by diffusion along the film surface. The results of the study found that the substrate presence was a stabilizing influence. Roy and Schwartz [31] studied the stability of liquid ridges on a substrate in the absence of gravity. In this problem the liquid region had a boundary composed of a free surface with a circular arc for a cross-section and a solid cylindrical substrate of arbitrary shape. Their results show that when a particular relationship between the curvatures of the liquid and solid interfaces and the contact angle is satisfied, the infinite liquid ridge is stable with respect to sinuous transverse modes, unlike an infinite cylindrical jet.

For an isotropic surface energy, the base state of the system is relatively simple to describe: the cross-section of the ridge is a circular arc that is determined by the equilibrium contact angles with the substrate. With surface tension anisotropy, the situation is more complicated in several respects. The axis of the nanowire relative to its underlying crystalline axes is a variable to be considered. Once the preferred orientation of the wire axis is established and the wire is assumed to be in contact with the substrate, there remains a geometrical degree of freedom represented by a rotation of the wire about its axis. This rotation exposes different sets of orientations on the crystal-vapor interface, which in turn affects the total energy of the system. Therefore, before the stability to axial perturbations of a nanowire on a substrate is addressed, the selection of the orientation of the wire relative to the substrate must be considered.

During the deposition process, various wire orientations are observed experimentally, depending on the processing conditions and the composition of the deposited crystal and substrate [6, 7, 8, 24, 26, 29]. In particular, for a given set of material parameters, it is argued that the observed orientations depend on kinetics of the (nonequilibrium) deposition process as well as on the effects of surface energy and

surface stress of the crystal-substrate interface [4, 5, 6, 11, 15]. In our simplified model, we consider an inert (nondeforming) substrate with an isotropic crystal-substrate surface energy and ignore kinetic effects by focusing on equilibrium states.

Even with these simplifying assumptions, the identification of the lowest energy orientation of a nanowire on a substrate is more complicated than the simpler problem of determining the lowest energy crystalline orientation of a planar epitaxial layer deposited on a substrate [5, 15, 29], since a nonfacetted nanowire contains a range of crystal-vapor surface orientations instead of the single orientation of a planar film. Within our model, we are able to investigate the low energy orientations of the nanowire on a substrate and perform a stability analysis to axial perturbations (Rayleigh instability).

Our results depend in detail on the anisotropy of the crystal-vapor surface energy. Experimental measurements of this anisotropy for metallic systems are uncommon, although there has been considerable progress recently in atomic-scale simulations of the surface energy anisotropy, specifically for crystal-melt interfaces [1, 14]. Here we adopt a simple one-parameter model for the surface energy anisotropy of the cubic material with a form that is often used to fit the simulation results [1, 14].

In this paper we examine how both the anisotropy of the surface energy of the wire and the interaction of the rod with a substrate affect the stability of the rod. As in the work of Roy and Schwartz [31] on the stability of liquid ridges, we use a variational approach using an energy functional and constant volume condition. Using general anisotropic surface energies, we derive an associated eigenproblem. The eigenproblem is described by a pair of coupled second-order ordinary differential equations with periodic boundary conditions along the axis of the rod and boundary conditions arising from the contact angles between the rod and substrate. We consider the effects of the overall orientation of the crystal relative to the substrate and examine a range of contact angles. The substrate is assumed to be rigid with an isotropic surface energy. We apply the analysis to a number of examples, including the case of a cubic material, and compute the stability of the rod to perturbations when the axis of the rod is aligned parallel to the high symmetry orientations [001], [011], and [111]. When the anisotropy is sufficiently small, the stability of the rod can be computed approximately with asymptotics. For larger levels of anisotropy, the solution is computed numerically.

2. The model. We consider the stability of an infinite rod deposited on a planar substrate below a vapor phase. The rod extends uniformly in the z direction of a Cartesian coordinate system (x, y, z) with the y direction normal to the plane of the substrate. The cross-section of the rod is uniform in z and defined by a two-dimensional equilibrium shape which is determined by surface energy considerations and the angle of contact between crystal and substrate. The vapor-substrate surface energy is denoted by γ_V and the crystal-substrate surface energy is denoted by γ_S. In this model we assume that both γ_V and γ_S are isotropic (constants that are independent of orientation).

Since we will be considering the stability of the rod under an arbitrary shape perturbation, we need to consider the three-dimensional crystal-vapor surface energy for general orientations. The crystal-vapor surface energy will be expressed in terms of the local normal vector to the crystal-vapor interface written in terms of spherical coordinates (ρ, θ, ϕ) in which z is the polar axis, $\rho = \sqrt{x^2 + y^2 + z^2}$ is the radius, θ the polar angle, and ϕ the azimuthal angle as shown in Figure 2.1. The crystal-vapor surface energy is assumed to be anisotropic (orientation-dependent) and is denoted by $\gamma = \gamma(\phi, \theta)$. The unit normal to the unperturbed rod lies in the plane

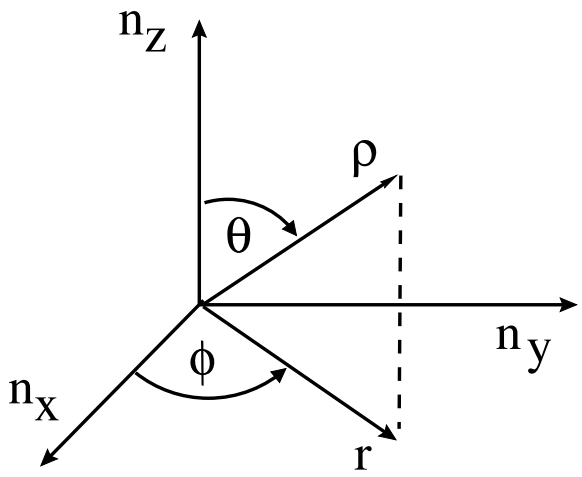

FIG. 2.1. *Schematic diagram of the spherical coordinate system* (ρ, θ, ϕ) *used for the definition of the surface energy* $\gamma(\phi, \theta)$.

$\theta = \pi/2$ and is given by $\hat{\rho}(\phi, \theta = \pi/2) = \hat{r}(\phi) = (\cos\phi, \sin\phi, 0)$, with $\hat{\theta} = -\hat{z}$ and $\hat{\phi}(\phi, \theta = \pi/2) = (-\sin\phi, \cos\phi, 0)$. The axis of the unperturbed rod is parallel to the plane of constant y which represents the substrate. Variables with hats are unit vectors in their corresponding directions.

We restrict our consideration to differentiable surface energies with anisotropies that are mild enough that the surface of the rod is smooth and does not exhibit any missing orientations.

2.1. Three-dimensional surface energy: General formulation. In order to examine the stability of the rod using a variational approach, we will need the general energy functional. This formula and the constant volume condition will be perturbed about the equilibrium rod. The higher order terms in this perturbation expansion will produce a condition for stability. Simply put, for constant volume, if the perturbation increases the energy, the equilibrium state is stable; otherwise it is unstable. This approach parallels the method used by Gurski and McFadden [10], who study the stability of a free rod, but here it is necessary to account for the presence of the substrate.

We will consider the stability of the rod to small amplitude disturbances in the z direction of wavelength $\lambda = 2\pi/k$, where k is the axial wave number. Hence, only the energy and the volume of a portion of the rod of length λ need to be determined. The effect of the substrate on the stability of the rod is local, so only a finite section of the substrate large enough to contain the perturbed rod needs to be examined. In particular, we will consider a rectangular section of the substrate of length λ in the z direction and width $2L_R$ in the x direction.

The total energy of our rod-substrate system, E, can be written as

$$E = E_{CV} + E_{VS} + E_{CS}, \tag{2.1}$$

where E_{CV} is the energy of the crystal-vapor interface, E_{VS} is the energy of the vapor-substrate system, and E_{CS} is the energy of the crystal-substrate system. Letting A_{CS} be the surface area of the crystal-substrate interface, we have that $E_{CS} = \gamma_S A_{CS}$ and $E_{VS} = \gamma_V(2\lambda L_R - A_{CS})$.

The energy of the crystal-vapor interface, E_{CV}, is equal to the surface integral of γ along this interface. If γ is constant, the energy equals γ times the surface area of the crystal-vapor interface. We wish to consider the anisotropic case, so the integral will depend on the orientation of the unit normal to the interface. To compute the associated surface integral, it is helpful to introduce some notation. Let $\vec{X} = \vec{X}(u, v)$ be the position vector of a point along the surface of the rod, where u and v denote surface coordinates. The normal vector field to the rod interface is given by $\vec{P} = \vec{X}_u \times \vec{X}_v$.

Following Gurski and McFadden [10], it is convenient to introduce a generalized surface energy function defined by

$$\Gamma(\vec{P}) = |\vec{P}|\gamma(\Phi, \Theta), \tag{2.2}$$

where

$$\Theta = \tan^{-1}\left(\sqrt{P_x^2 + P_y^2}/P_z\right), \qquad \Phi = \tan^{-1}\left(P_y/P_x\right) \tag{2.3}$$

are the corresponding spherical angles based on the normal vector $\vec{P}$.

A formula for the surface energy can now be obtained by noting that $\gamma(\Phi, \Theta)dA = \Gamma(\vec{P})du\,dv$. The surface energy E_{CV} can therefore be written as

$$E_{CV} = \int\int \Gamma(\vec{P})du\,dv. \tag{2.4}$$

The total energy E is then obtained by substituting (2.4) into (2.1).

It should be noted that the generalized surface energy Γ is closely related to the three-dimensional Cahn–Hoffmann vector [3, 13], $\xi = \nabla\left[\rho\gamma(\phi, \theta)\right]$; in fact,

$$\xi_j(\vec{P}) = \frac{\partial\Gamma(\vec{P})}{\partial P_j}. \tag{2.5}$$

The dimensionless three-dimensional equilibrium shape of a solid particle in a vapor is given by $\vec{\xi}(\phi, \theta)$ for $0 \le \phi \le 2\pi$ and $0 \le \theta \le \pi$, and its normal is $\hat{\rho}(\phi, \theta)$. In the plane $\theta = \pi/2$, this relation reduces to

$$\vec{\xi}(\phi, \pi/2) = \gamma(\phi, \pi/2)\,\hat{r}(\phi) + \gamma_\phi(\phi, \pi/2)\,\hat{\phi}(\phi) - \gamma_\theta(\phi, \pi/2)\,\hat{z}, \tag{2.6}$$

where we have used $\hat{r}(\phi) = (\cos\phi, \sin\phi, 0)$, $\hat{\phi}(\phi) = (-\sin\phi, \cos\phi, 0)$, and $\hat{\theta} = -\hat{z}$ in the plane $\theta = \pi/2$. Note that here partial derivatives are denoted by subscripts, e.g., $\gamma_\phi = \partial\gamma/\partial\phi$. If $\gamma_\theta(\phi, \pi/2) = 0$, then the two-dimensional equilibrium shape defined by (2.6) is characterized by a constant weighted mean curvature $[\gamma + \gamma_{\phi\phi}]\,\mathcal{K}$ [33]. Missing orientations can occur if $\gamma + \gamma_{\phi\phi} < 0$ [35]; here we will assume $\gamma + \gamma_{\phi\phi} > 0$. If $\gamma_\theta(\phi, \pi/2) \neq 0$, then the curve $\vec{\xi}(\phi, \pi/2)$ is out of the plane $z = 0$, but its projection onto the plane represents the two-dimensional equilibrium shape corresponding to $\gamma = \gamma(\phi)$. These two-dimensional shapes define the cross-sections of our rod. We will choose the surface coordinates $(u, v) = (\phi, z)$, which is a natural choice for studying the stability of the equilibrium rod along a substrate to small perturbations.

2.2. The equilibrium rod. The cross-section of the unperturbed rod is a portion of a two-dimensional equilibrium shape parameterized by the vector $\vec{X}^{(0)}(\phi) = (X^{(0)}(\phi), Y^{(0)}(\phi))$, where

$$X^{(0)}(\phi) = \frac{\ell}{\gamma_0}\left[\gamma\left(\phi, \frac{\pi}{2}\right)\cos\phi - \gamma_\phi\left(\phi, \frac{\pi}{2}\right)\sin\phi\right] \tag{2.7}$$

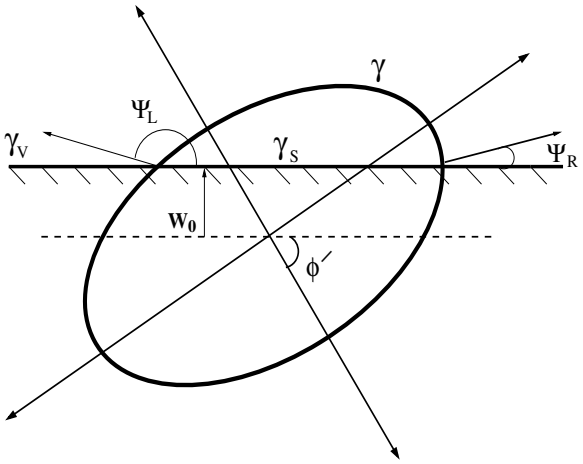

FIG. 2.2. *Ellipse rotated an angle of ϕ' about the original axes. Contact angles between the ellipse and substrate are ψ_R and ψ_L.*

and

$$Y^{(0)}(\phi) = \frac{\ell}{\gamma_0}\left[\gamma\left(\phi, \frac{\pi}{2}\right)\sin\phi + \gamma_\phi\left(\phi, \frac{\pi}{2}\right)\cos\phi\right] \tag{2.8}$$

for $\psi_R \le \phi \le \psi_L$, where $\gamma(\phi,\theta)$ is the surface energy, ℓ is a characteristic length scale, and γ_0 is a characteristic surface energy (see, e.g., [35]). Anticipating the subsequent perturbation expansion, we associate variables having a superscript (0) with the equilibrium rod. The rod is in contact with the substrate over the range $X^{(0)}(\psi_L) \le x \le X^{(0)}(\psi_R)$, and the surface of the substrate in this coordinate system is $y = W_0 = Y^{(0)}(\psi_R) = Y^{(0)}(\psi_L)$. The contact angle that the rod makes with the substrate thus is described by ψ_R and ψ_L, as illustrated in Figure 2.2. Winterbottom [36] (see also [3]) shows that the conditions for equilibrium at the contact line are satisfied for the choice $W_0 = (\ell/\gamma_0)[\gamma_V - \gamma_S]$; we also derive this result below in the course of the energy minimization. Unless otherwise noted, we will henceforth assume that all variables are dimensionless, based on the units of length ℓ and energy γ_0.

3. Stability under perturbations. We determine the stability of the rod by computing the total energy of a volume-preserving perturbation to the rod. The unperturbed interface can be written in the form $\vec{X}^{(0)}(\phi) + z\,\hat{z}$. As in our previous development (see [10]), we then consider a perturbed interface of the form

$$\vec{X}(\phi, z) = \vec{X}^{(0)}(\phi) + z\,\hat{z} + \epsilon h(\phi, z)\hat{r}(\phi) + \frac{\epsilon^2}{2}h_2\hat{r}(\phi) + \cdots, \tag{3.1}$$

where ϵ is a small parameter, $h(\phi, z)$ is the height of the perturbation along the normal $\hat{r}$ to the unperturbed shape, and the constant h_2 is a second-order shape correction introduced to satisfy the volume constraint at $O(\epsilon^2)$. The domain of ϕ is given by $\psi_R(z) \le \phi \le \psi_L(z)$. Note that the contact angles depend on both z and ϵ since the contact angles are determined by the boundary conditions at the contact point. In particular, we will assume that ψ_i has a regular expansion in ϵ of the form

$$\psi_i(z) = \psi_i^{(0)} + \epsilon\psi_i^{(1)}(z) + \frac{\epsilon^2}{2}\psi_i^{(2)}(z) + \cdots \tag{3.2}$$

for $i = L, R$. At the substrate we have

$$Y(\psi_i, z) = W_0, \tag{3.3}$$

so that at leading order we have

$$W_0 = Y^{(0)}(\psi_i^{(0)}) = \gamma(\psi_i^{(0)}, \pi/2)\sin\psi_i^{(0)} + \gamma_\phi(\psi_i^{(0)}, \pi/2)\cos\psi_i^{(0)} \tag{3.4}$$

for $i = L, R$. The case $W_0 = 0$, $\psi_R^{(0)} = 0$, $\psi_L^{(0)} = \pi$ represents a contact line at the orientation of an equatorial plane of symmetry of the equilibrium shape and also corresponds to the upper half of a freely suspended rod [10].

At the contact line the variables X, Y, h, and ψ are related through (3.1)–(3.3). Expanding (3.3) to first order yields

$$Y_\phi^{(0)}(\psi_i^{(0)})\psi_i^{(1)} + Y^{(1)}(\psi_i^{(0)}, z) = 0, \tag{3.5}$$

where from (3.1) the first-order shape change is given by

$$X^{(1)}(\phi, z) = h(\phi, z)\cos\phi, \quad Y^{(1)}(\phi, z) = h(\phi, z)\sin\phi. \tag{3.6}$$

Since $X_\phi^{(0)}(\psi_i^{(0)}) = -(\gamma+\gamma_{\phi\phi})\sin\psi_i^{(0)}$ and $Y_\phi^{(0)}(\psi_i^{(0)}) = (\gamma+\gamma_{\phi\phi})\cos\psi_i^{(0)}$, (3.5) yields

$$\psi_i^{(1)}(z) = \frac{-h(\psi_i^{(0)}, z)\sin\psi_i^{(0)}}{(\gamma + \gamma_{\phi\phi})\cos\psi_i^{(0)}}, \tag{3.7}$$

which relates h and $\psi^{(1)}$ at the contact line.

The geometry of the perturbed rod is determined by the two tangent vectors $\vec{X}_\phi$ and $\vec{X}_z$, and their cross product, $\vec{P} = \vec{X}_\phi \times \vec{X}_z$, which is normal to the interface. The area element on the interface is given by $dA = |\vec{P}|\, d\phi\, dz$. Evaluating the tangent vectors by using (3.1) and taking their cross product, we find that the interface normal has the expansion

$$\vec{P}(\phi, z) = \vec{P}^{(0)}(\phi) + \epsilon\vec{P}^{(1)}(\phi, z) + \frac{\epsilon^2}{2}\vec{P}^{(2)}(\phi, z) + O(\epsilon^3), \tag{3.8}$$

where

$$\vec{P}^{(0)} = (\gamma + \gamma_{\phi\phi})\,\hat{r}, \tag{3.9}$$

$$\vec{P}^{(1)} = h\,\hat{r} - h_\phi\,\hat{\phi} - (\gamma + \gamma_{\phi\phi})\,h_z\,\hat{z}, \tag{3.10}$$

$$\vec{P}^{(2)} = h_2\,\hat{r} - 2hh_z\,\hat{z}. \tag{3.11}$$

3.1. Volume. The shape perturbation (3.1) is required to preserve the volume of the rod over a given length with a period of the perturbation equal to $\lambda = 2\pi/k$. As in Gurski and McFadden [10], we can write the volume as a surface integral by using the divergence theorem. Then using the expansion (3.1), we find that to $O(\epsilon^2)$ the volume is given by

$$\begin{aligned} V &= \frac{1}{2}\int\int\int \nabla\cdot(x, y, 0)\, dV \\ &= \frac{1}{2}\int_0^{2\pi/k}\int_{\psi_R(z)}^{\psi_L(z)} \vec{P}(\phi, z)\cdot[\vec{X}(\phi, z) - z\,\hat{z}]\, d\phi\, dz \end{aligned} \tag{3.12}$$

$$
\begin{aligned}
&-\frac{1}{2}\int_0^{2\pi/k} W_0\left[X(\psi_R(z),z)-X(\psi_L(z),z)\right]\,dz \\
&=\frac{1}{2}\int_0^{2\pi/k}\int_{\psi_R(z)}^{\psi_L(z)}\left\{\left[\gamma+\epsilon h+\frac{\epsilon^2}{2}h_2\right]\left[(\gamma+\gamma_{\phi\phi})+\epsilon h+\frac{\epsilon^2}{2}h_2\right]-\epsilon\gamma_\phi h_\phi\right\}d\phi\,dz \\
&\quad-\frac{1}{2}\int_0^{2\pi/k} W_0\left[X(\psi_R(z),z)-X(\psi_L(z),z)\right]\,dz.
\end{aligned}
$$

Expanding in ϵ then gives

$$V = V^{(0)} + \epsilon V^{(1)} + \frac{\epsilon^2}{2}V^{(2)} + O(\epsilon^3) + \cdots, \tag{3.13}$$

where

$$V^{(0)} = \frac{\lambda}{2}\int_{\psi_R^{(0)}}^{\psi_L^{(0)}} \gamma\left(\gamma+\gamma_{\phi\phi}\right)\,d\phi - \frac{\lambda}{2}W_0[X^{(0)}(\psi_R^{(0)}) - X^{(0)}(\psi_L^{(0)})], \tag{3.14}$$

$$V^{(1)} = \int_0^{2\pi/k}\int_{\psi_R^{(0)}}^{\psi_L^{(0)}} h\left(\gamma+\gamma_{\phi\phi}\right)\,d\phi\,dz, \tag{3.15}$$

$$V^{(2)} = \int_0^{2\pi/k}\int_{\psi_R^{(0)}}^{\psi_L^{(0)}} \left\{h^2 + h_2\left(\gamma+\gamma_{\phi\phi}\right)\right\}d\phi\,dz - \int_0^{2\pi/k} h^2\tan\phi\Big|_{\psi_R^{(0)}}^{\psi_L^{(0)}}\,dz. \tag{3.16}$$

A perturbation $h(\phi,z)$ that is periodic in z with mean zero makes $V^{(1)}=0$, and the condition $V^{(2)}=0$ then determines the appropriate value of the constant h_2. A perturbation $h(\phi)$ that is independent of z does not automatically make $V^{(1)}=0$. This represents a special case for the stability calculation that is treated in the appendix.

3.2. Energy. The stability of the rod is determined by expanding the total energy through $O(\epsilon^2)$ for $|\epsilon| \ll 1$, and, for a given volume, examining whether the shape perturbation, constrained to maintain constant volume of the rod, raises or lowers the energy of the rod. Since the rod is assumed to be infinite in the z direction, an analysis in terms of Fourier components allows us to consider shape perturbations that are periodic in z. The contact angle is now a function of z as well, $\psi_i = \psi_i(z)$ for both $i = L, R$, and the energy E in the region $-L < x < L$ and $0 < z < 2\pi/k$ from (2.1) is given by

$$
\begin{aligned}
E = &\int_0^{2\pi/k} dz \int_{\psi_R(z)}^{\psi_L(z)} \Gamma(\vec{P}(\phi,z))\,d\phi + \frac{4\pi\gamma_V L_R}{k} \\
&-(\gamma_V-\gamma_S)\int_0^{2\pi/k}\left[X(\psi_R(z),z)-X(\psi_L(z),z)\right]dz.
\end{aligned} \tag{3.17}
$$

Expanding in powers of ϵ, we find

$$E = E^{(0)} + \epsilon E^{(1)} + \frac{\epsilon^2}{2}E^{(2)} + O(\epsilon^3), \tag{3.18}$$

where

$$E^{(0)} = \int_0^{2\pi/k} dz \int_{\psi_R^{(0)}}^{\psi_L^{(0)}} \gamma\left(\gamma + \gamma_{\phi\phi}\right)\, d\phi + \frac{4\pi\gamma_V L}{k} + \left(\gamma_V - \gamma_S\right) \int_0^{2\pi/k} \left(\gamma\cos\phi - \gamma_\phi \sin\phi\right) \Big|_{\psi_R^{(0)}}^{\psi_L^{(0)}} dz. \tag{3.19}$$

The first variation of the energy is

$$\frac{E^{(1)}}{2} = \int_0^{2\pi/k} dz \int_{\psi_R^{(0)}}^{\psi_L^{(0)}} \left\{(\gamma + \gamma_{\phi\phi})h + \gamma_\theta\left(\gamma + \gamma_{\phi\phi}\right) h_z\right\} d\phi - \int_0^{2\pi/k} dz \left(\frac{h(\phi, z)}{\cos\phi}\left\{[\gamma_S - \gamma_V] + [\gamma\sin\phi + \gamma_\phi\cos\phi]\right\}\right) \Big|_{\psi_R^{(0)}}^{\psi_L^{(0)}}, \tag{3.20}$$

where we used (3.7) to simplify the second integral.

The second variational term is

$$\begin{aligned}\frac{E^{(2)}}{2} = &\int_0^{2\pi/k} dz \int_{\psi_R^{(0)}}^{\psi_L^{(0)}} \left[h_\phi^2 + (\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta})h_z^2 - 2\gamma_{\phi\theta}h_\phi h_z + \gamma h_2 + 2\gamma_\theta h h_z\right] d\phi \\ &+ \int_0^{2\pi/k} \left\{\left[h_2\gamma_\phi(\psi_L^{(0)}) - 2\gamma_\theta(\psi_L^{(0)})h(\psi_L^{(0)}, z)h_z(\psi_L^{(0)}, z)\tan\psi_L^{(0)}\right]\right. \\ &\left. - \left[h_2\gamma_\phi(\psi_R^{(0)}) - 2\gamma_\theta(\psi_R^{(0)})h(\psi_R^{(0)}, z)h_z(\psi_R^{(0)}, z)\tan\psi_R^{(0)}\right]\right\} dz.\end{aligned} \tag{3.21}$$

3.3. Three-dimensional eigenvalue problem. Our choice of $h(\phi, z)$ makes the integral of the sum of the second and fourth terms in (3.21) identically zero. Eliminating h_2 from (3.21) by using the volume condition, $V^{(2)} = 0$ in (3.16), and integrating by parts, we find that

$$\begin{aligned}\frac{E^{(2)}}{2} = &-\int_0^{2\pi/k} dz \int_{\psi_R^{(0)}}^{\psi_L^{(0)}} h\mathcal{L}h\, d\phi \\ &+ \int_0^{2\pi/k} \left\{\left[h(\psi_L^{(0)}, z)\tan\psi_L^{(0)} + h_\phi(\psi_L^{(0)}, z) - \gamma_{\theta\phi}(\psi_L^{(0)})h_z(\psi_L^{(0)}, z)\right]h(\psi_L^{(0)}, z)\right. \\ &\left. - \left[h(\psi_R^{(0)}, z)\tan\psi_R^{(0)} + h_\phi(\psi_R^{(0)}, z) - \gamma_{\theta\phi}(\psi_R^{(0)})h_z(\psi_R^{(0)}, z)\right]h(\psi_R^{(0)}, z)\right\} dz,\end{aligned} \tag{3.22}$$

where

$$\mathcal{L}h = h_{\phi\phi} + (\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta})h_{zz} - \gamma_{\phi\theta}h_{\phi z} - \left(\gamma_{\theta\phi}h_z\right)_\phi + h. \tag{3.23}$$

Recall that the aim of this calculation is to determine perturbations h such that $E^{(2)} > 0$. This condition can be satisfied if the eigenvalue problem

$$\mathcal{L}h = \mu h \tag{3.24}$$

with boundary conditions

$$h(\psi_i^{(0)}, z)\sin\psi_i^{(0)} + h_\phi(\psi_i^{(0)}, z)\cos\psi_i^{(0)} - \gamma_{\theta\phi}(\psi_i^{(0)})h_z(\psi_i^{(0)}, z)\cos\psi_i^{(0)} = 0 \tag{3.25}$$

for $i = L, R$ has only negative eigenvalues μ. The differential operator $\mathcal{L}$ is identical to that for the isolated rod as given in [10], but instead of periodicity in ϕ we now have boundary conditions that apply at $\psi_R^{(0)}$ and $\psi_L^{(0)}$.

Assuming a discrete set of eigenvalues μ_n and eigenfunctions h_n, for $n = 0, 1, 2, \ldots$, we can rewrite the eigenvalue problem (3.24)–(3.25) as

$$\partial_{\phi\phi}h_n + (\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta})\partial_{zz}h_n - \gamma_{\phi\theta}\partial_{\phi z}h_n - (\gamma_{\theta\phi}\partial_z h_n)_\phi + h_n = \mu_n h_n, \tag{3.26}$$

where the eigenfunctions h_n satisfy the boundary conditions given by (3.25) for $i = L, R$. Note that (3.26) must also satisfy periodicity in the z direction, which can be satisfied by assuming the solution has the form $h_n(\phi, z) = H_n(\phi)\sin kz + G_n(\phi)\cos kz$. Substituting this into (3.26) implies

$$\frac{d^2H_n}{d\phi^2} + (1 - k^2(\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta}))H_n + k\gamma_{\phi\theta}\frac{dG_n}{d\phi} + k\left(\gamma_{\theta\phi}G_n\right)_\phi = \mu_n H_n, \tag{3.27}$$

$$\frac{d^2G_n}{d\phi^2} + (1 - k^2(\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta}))G_n - k\gamma_{\phi\theta}\frac{dH_n}{d\phi} - k\left(\gamma_{\theta\phi}H_n\right)_\phi = \mu_n G_n \tag{3.28}$$

with the boundary conditions

$$H_n \sin\psi_i^{(0)} + \frac{dH_n}{d\phi}\cos\psi_i^{(0)} + k\gamma_{\theta\phi}(\psi_i^{(0)})G_n\cos\psi_i^{(0)} = 0, \tag{3.29}$$

$$G_n \sin\psi_i^{(0)} + \frac{dG_n}{d\phi}\cos\psi_i^{(0)} - k\gamma_{\theta\phi}(\psi_i^{(0)})H_n\cos\psi_i^{(0)} = 0 \tag{3.30}$$

for $i = L, R$. This coupled system of equations must be solved to determine the eigenfunctions and eigenvalues. Note that if γ is independent of θ, the equations decouple.

4. Rotation and contact angles. In the next two sections we consider two related aspects of the stability of a two-dimensional rod on a substrate. We first consider the preferred, low energy orientations of the two-dimensional rod neglecting axial perturbations. For this evaluation, we fix the rod axis that lies parallel to the substrate and compute the energy of the system as the rod is rotated about this axis. Given the specification of the axis of the rod, we assume that preferred orientations correspond to minima of the energy as a function of the rotation angle. Once the low energy orientations are determined, we go on to consider the further effect of axial perturbations on the stability of rods aligned in the preferred orientation.

4.1. Ellipse. Consider the special case of a rod whose cross-section is given by a two-dimensional ellipse,

$$\frac{x^2}{a_x^2} + \frac{y^2}{a_y^2} = 1. \tag{4.1}$$

The major and minor axes of the ellipse are then rotated with respect to the x-axis by an angle ϕ', as shown in Figure 2.2. The corresponding surface free energy γ is given by

$$\gamma(\phi) = \sqrt{a_x^2\cos^2(\phi + \phi') + a_y^2\sin^2(\phi + \phi')}. \tag{4.2}$$

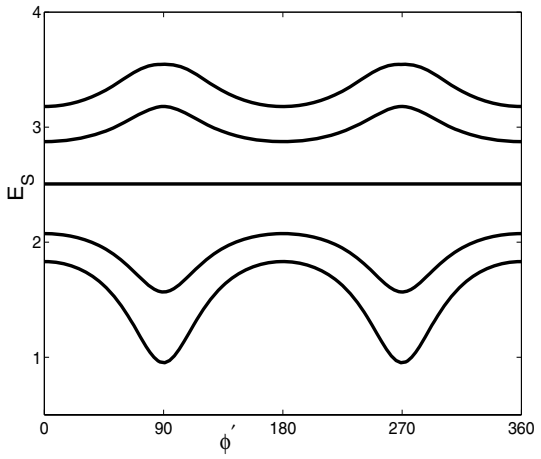

FIG. 4.1. *Scaled energy versus rotation angle for the ellipse. From the top at* $\phi' = 0$ *the curves correspond to* $\tilde{W}_0 = -1.0, -0.5, 0, 0.5, 0.75$.

The surface of the substrate is the plane $y = W_0 = (\gamma_V - \gamma_S)$, and the ellipse makes contact with the substrate with two angles ψ_R and ψ_L, which are roots of the equation

$$0 = W_0 - [\gamma(\phi)\sin\phi + \gamma_\phi(\phi)\cos\phi]. \tag{4.3}$$

If ϕ' is zero or $\pi/2$, then $\psi_L = \pi - \psi_R$.

First, let us consider how the energy depends on the angle of rotation ϕ' and the parameter W_0. Since the volume of a rod with an elliptical cross-section will vary as W_0 varies, we must find a normalization for the energy

$$E = \lambda \int_{\psi_R}^{\psi_L} \gamma\,(\gamma + \gamma_{\phi\phi})\; d\phi - \lambda W_0\,(X(\psi_R) - X(\psi_L)) + 2\lambda L\gamma_V. \tag{4.4}$$

The corresponding formula for the volume of the rod is

$$V = \frac{\lambda}{2} \int_{-\pi/2}^{3\pi/2} \gamma\,(\gamma + \gamma_{\phi\phi})\; d\phi - \lambda \int_{\psi_L}^{\psi_R+2\pi} (W_0 - Y)\; \frac{\partial X(\phi)}{\partial \phi}\, d\phi. \tag{4.5}$$

Using these definitions, we can define a normalized energy E_S as

$$E_S = \frac{E - 2L\gamma_V}{\sqrt{2V\lambda}} = \frac{\int_{\psi_R}^{\psi_L} \gamma\,(\gamma + \gamma_{\phi\phi})\; d\phi - W_0\,(X(\psi_R) - X(\psi_L))}{\sqrt{\int_{-\pi/2}^{3\pi/2} \gamma\,(\gamma + \gamma_{\phi\phi})\; d\phi - 2\int_{\psi_L}^{\psi_R+2\pi} (W_0 - Y)\; \frac{\partial X(\phi)}{\partial \phi}\, d\phi}}. \tag{4.6}$$

For our numerical calculations we set $a_x = 1$, $a_y = 2$. Figure 4.1 shows that when $W_0 > 0$, the lowest scaled energy E_S is attained when $\phi' = 90$ (i.e., the major axis is horizontal) and the highest scaled energy is reached when $\phi' = 0$ degrees (i.e., the major axis is vertical). Since $W_0 = \gamma_V - \gamma_S > 0$, the lowest energy state of the ellipse will be where contact between the crystal and the substrate is maximized and where contact between the substrate and vapor is minimized, i.e., when the semimajor axis is horizontal. The scaled energy is independent of ϕ' when W_0 is zero, showing that when $\gamma_V = \gamma_S$, there is no preferred rod orientation. When W_0 is negative, the scaled energy is higher at $\phi' = 90$ degrees and lower at $\phi' = 0$ degrees as the crystal orients itself to minimize the crystal-substrate interface.

4.2. Cubic materials. A simple model of the surface energy anisotropy for a cubic material is given by the dimensionless expression [20]

$$\gamma(n'_x, n'_y, n'_z) = \left\{1 + 4\epsilon_4([n'_x]^4 + [n'_y]^4 + [n'_z]^4)\right\}, \tag{4.7}$$

where we employ a primed coordinate system that is attached to the crystal axes. We will consider rod directions z that coincide with the high symmetry orientations [001], a fourfold axis; [011], a twofold axis; and [111], a threefold axis. We will use appropriate preliminary rotations of the crystal axes in each case to bring these axes into alignment with the z-axis of the rod, which will be fixed in the unprimed coordinate system.

The shapes are smooth for $-1/18 < \epsilon_4 < 1/12$ (see [20]). For $\epsilon_4 < 0$ the shapes resemble rounded cubes, with [110] edges first forming at $\epsilon_4 = -1/18 \approx -0.0556$. As ϵ_4 decreases below $-1/18$, the edges extend toward the [111] directions, merging to form a corner for $\epsilon_4 = -5/68 \approx -0.07735$. For $\epsilon_4 > 0$ the shapes are octahedral, with [100] corners first forming at $\epsilon_4 = 1/12 \approx 0.0833$.

4.2.1. Rod axis parallel to [001] orientation. If the axis of the rod is aligned with the [001] orientation of the crystal, the dimensionless surface energy resulting from (4.7) is given by [16, 17, 21]

$$\gamma(\phi, \theta) = 1 + \epsilon_4 \left[4\cos^4\theta + \sin^4\theta\,(3 + \cos 4\phi)\right]. \tag{4.8}$$

In the plane $\theta = \pi/2$,

$$\gamma = (1 + 3\epsilon_4) + \epsilon_4 \cos 4\phi. \tag{4.9}$$

If we allow the crystal to rotate on the substrate, we must include the effect of the rotation angle ϕ',

$$\gamma = (1 + 3\epsilon_4) + \epsilon_4 \cos 4\,(\phi + \phi'). \tag{4.10}$$

We can determine the scaled energies using (4.6). Results are shown in Figure 4.2 for several values of ϵ_4 in the range of -0.0556 to 0.0833. The two extreme heights of $W_0 = \pm W_M$, where

$$W_M = \min\left(0.95\sqrt{X(0)^2 + Y(0)^2}, 0.95\sqrt{X(\pi/2)^2 + Y(\pi/2)^2}\right), \tag{4.11}$$

are shown. When W_0 is near $-W_M$, i.e., the origin of the coordinate system is nearly at a maximum height above the substrate surface, the effects of rotation are very slight, with maxima at $\phi' = 0$, 90, 180, 270, and 360 degrees for negative ϵ_4. When ϵ_4 is positive, these maxima switch to minima. The plot of the scaled energy versus angle of rotation for $\epsilon_4 = -0.0556$ has the largest oscillations with an amplitude of 0.001. The fourfold symmetry of the [001] oriented crystal is responsible for the 90 degree spacing. When W_0 is near W_M, the location of the maxima and minima reverse with respect to their locations at $W_0 = -W_M$, and the effect of the rotation becomes more pronounced.

4.2.2. Rod axis parallel to [011] orientation. If the axis of the rod is aligned with the [011] orientation of the crystal, then an appropriate rotation of the crystal axes relative to the rod axis is given by [20]

$$\begin{pmatrix} n'_x \\ n'_y \\ n'_z \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1/\sqrt{2} & 1/\sqrt{2} \\ 0 & -1/\sqrt{2} & 1/\sqrt{2} \end{pmatrix} \begin{pmatrix} n_x \\ n_y \\ n_z \end{pmatrix}. \tag{4.12}$$

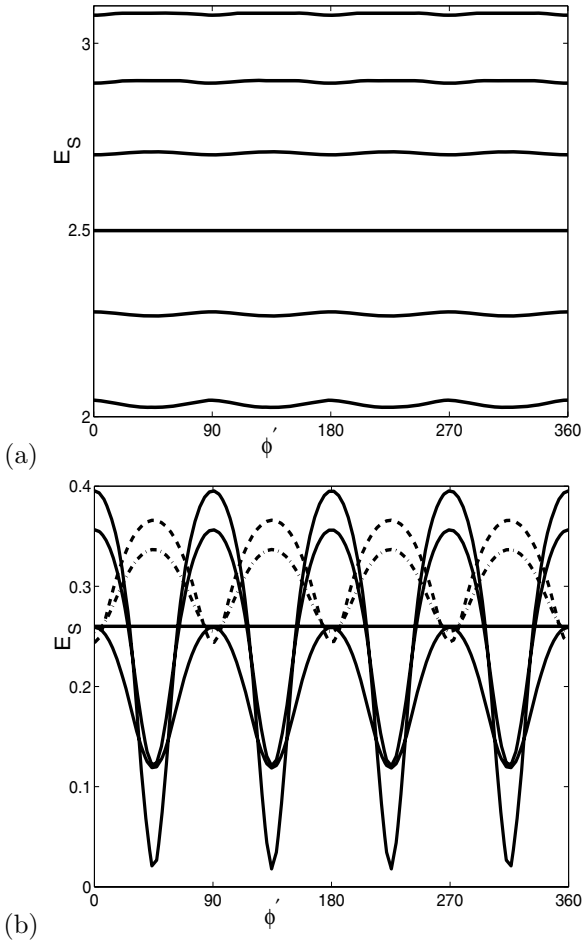

FIG. 4.2. *Scaled energy versus ϕ' for the* [001] *cubic orientation.* (a) *From the bottom, the curves are* $\epsilon_4 = -0.0556,\ -0.02778,\ 0.0,\ 0.02778,\ 0.0556,\ 0.0833$. $W_0 = -W_M$. (b) *From the top, the two dashed curves are* $\epsilon_4 = -0.0556$ *and* -0.02778, *and the solid curves are* $\epsilon_4 = 0.0,\ 0.02778,\ 0.0556,\ 0.0833$. $W_0 = W_M$.

This rotation gives

$$\gamma = 1 + 4\epsilon_4 \left(n_x^4 + \frac{n_y^4}{2} + \frac{n_z^4}{2} + 3n_y^2 n_z^2 \right), \tag{4.13}$$

which reduces to

$$\gamma = 1 + 2\epsilon_4 \left(\cos^4\theta + 6\cos^2\theta \sin^2\theta \sin^2\phi + 2\sin^4\theta \cos^4\phi + \sin^4\theta \sin^4\phi \right). \tag{4.14}$$

When $\theta = \pi/2$ and rotation of the crystal about the substrate is included, then

$$\gamma = 1 + \epsilon_4 \left[\frac{9}{4} + \cos 2(\phi + \phi') + \frac{3}{4} \cos 4(\phi + \phi') \right]. \tag{4.15}$$

The rod is smooth for $-5/68 \le \epsilon_4 \le 1/12$, which is a larger range than the [001] case.

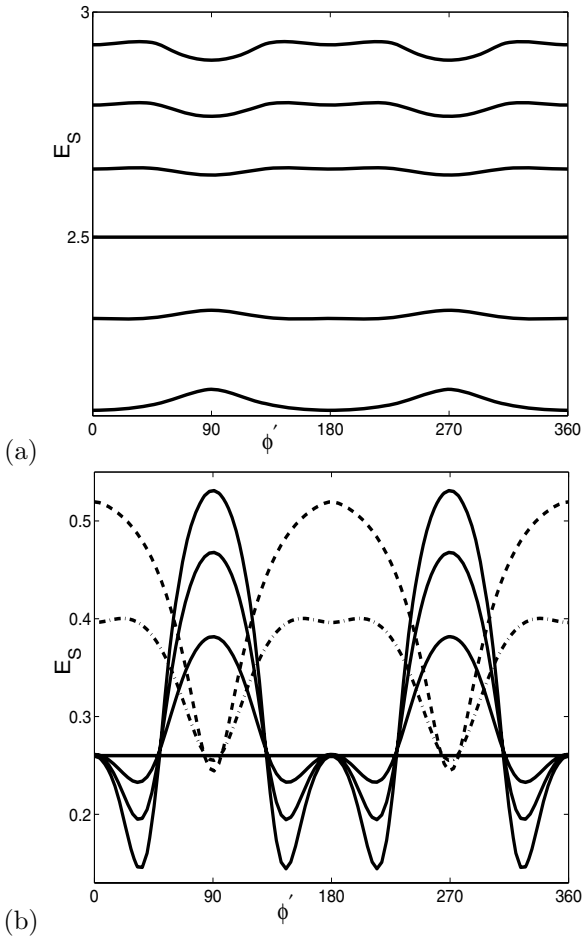

FIG. 4.3. *Scaled energy versus θ' for the* [011] *cubic orientation.* (a) *From the bottom, the curves are* $\epsilon_4 = -0.0556, -0.02778, 0.0, 0.02778, 0.0556, 0.0833$. $\tilde{W}_0 = -W_{M'}$. (b) *At* $\theta' = 0$ *from the bottom, the two dashed curves correspond to* $\epsilon_4 = -0.0556$ *and* -0.02778*, and the solid curves correspond to* $\epsilon_4 = 0.0, 0.02778, 0.0556, 0.0833$. $\tilde{W}_0 = W_M$.

We can determine the scaled energies using (4.6). Results are shown in Figure 4.3 for several values of ϵ_4 in the range of -0.0556 to 0.0833 for the two extreme heights of $W_0 = \pm W_M$. The twofold symmetry of the [011] crystal is apparent in the spacing of maxima and minima shown in Figure 4.3. When ϵ_4 is negative, the minima (maxima) are located at 0, 180, and 360 degrees for $W_0 = -W_M(+W_M)$. When ϵ_4 is positive, the minima are located at 90 and 270 degrees for $W_0 = -W_M$. At $W_0 = W_M$, maxima are maintained at 90 and 270 degrees for positive ϵ_4. We see that secondary local maxima form at $\phi' = 0$, 180, 360 for positive ϵ_4 at $W_0 = W_M$.

4.2.3. Rod axis parallel to [111] orientation. If the axis of the rod is aligned with the [111] orientation of the crystal, then an appropriate rotation of the crystal axes relative to the rod axis is given by [20]

$$\begin{pmatrix} n'_x \\ n'_y \\ n'_z \end{pmatrix} = \begin{pmatrix} \sqrt{2}/\sqrt{3} & 0 & 1/\sqrt{3} \\ -1/\sqrt{6} & 1/\sqrt{2} & 1/\sqrt{3} \\ -1/\sqrt{6} & -1/\sqrt{2} & 1/\sqrt{3} \end{pmatrix} \begin{pmatrix} n_x \\ n_y \\ n_z \end{pmatrix}. \tag{4.16}$$

This leads to the form

$$\gamma = 1 + 4\epsilon_4\left(\frac{n_x^4}{2} + \frac{n_y^4}{2} + \frac{n_z^4}{3} + n_x^2 n_y^2 + 2n_x^2 n_z^2 + 2n_y^2 n_z^2 + \frac{2\sqrt{2}}{3} n_x^3 n_z - 2\sqrt{2} n_x n_y^2 n_z\right), \tag{4.17}$$

which reduces to

$$\gamma = 1 + 4\epsilon_4\left(\frac{1}{3}\cos^4\theta + 2\cos^2\theta\sin^2\theta + \frac{1}{2}\sin^4\theta + \frac{2\sqrt{2}}{3}\cos\theta\sin^3\theta\cos 3\phi\right). \tag{4.18}$$

Although the [111] orientation is not isotropic, in the $\theta = \pi/2$ plane,

$$\gamma = 1 + 2\epsilon_4. \tag{4.19}$$

Therefore, the effect of the ϕ dependence is lost and the surface energy for the [111] orientation is unchanged by a rotation of ϕ' about the substrate.

5. Linear stability calculations. Next we investigate the linear stability of the system by examining the eigenvalue problem associated with diagonalizing the second variation of the energy for a fixed orientation of the rod on the substrate. We consider a number of examples, including an ellipsoidal surface energy anisotropy and several variants of cubic anisotropy. The three-dimensional study includes both numerical and asymptotic results. A discussion on the effect of rotation on stability is covered in the appendix.

5.1. Ellipsoidal anisotropy. We first discuss an anisotropic surface energy that leads to an ellipsoidal equilibrium shape described by

$$\frac{x^2}{a_x^2} + \frac{y^2}{a_y^2} + \frac{z^2}{a_z^2} = 1. \tag{5.1}$$

We consider an axisymmetric shape with $a_x = a_y = 1$. The corresponding surface free energy is given by $\gamma(\phi,\theta) = \sqrt{\sin^2\theta + a_z^2\cos^2\theta}$, and in the plane $\theta = \pi/2$ we have $\gamma = 1$, $\gamma_{\phi\phi} = 0$, $\gamma_{\theta\phi} = 0$, and $\gamma_{\theta\theta} = a_z^2 - 1$. The eigenvalue problem (3.27)–(3.28) decouples, leading to the single equation

$$\frac{\partial^2 H_n}{\partial\phi^2} + (1 - K^2)H_n = \mu_n H_n, \tag{5.2}$$

where $K = a_z k$. The boundary conditions for $i = L, R$ are

$$H_n(\psi_i^{(0)})\sin\psi_i^{(0)} + H_{n\phi}(\psi_i^{(0)})\cos\psi_i^{(0)} = 0. \tag{5.3}$$

We solve this problem numerically using a pseudospectral Chebyshev method for a range of contact angles determined by solutions to (4.3), where $-1 \le W_0 \le 1$. To eliminate the change in length scale with the contact angle, we define $\kappa = KR_e$ as the dimensionless axial wave number based on the effective radius of the cross-section.

In Figure 5.1(a) we show the most unstable mode μ_0 for a range of contact angles ψ_R as a function of κ. The results indicate that the ellipsoid is stabilized with respect to long wavelengths for large ψ_R. In Figure 5.1(b) we plot the square of the critical wavenumber κ_C, which corresponds to the transition between stable and unstable behavior, as a function of the contact angle ψ_R.

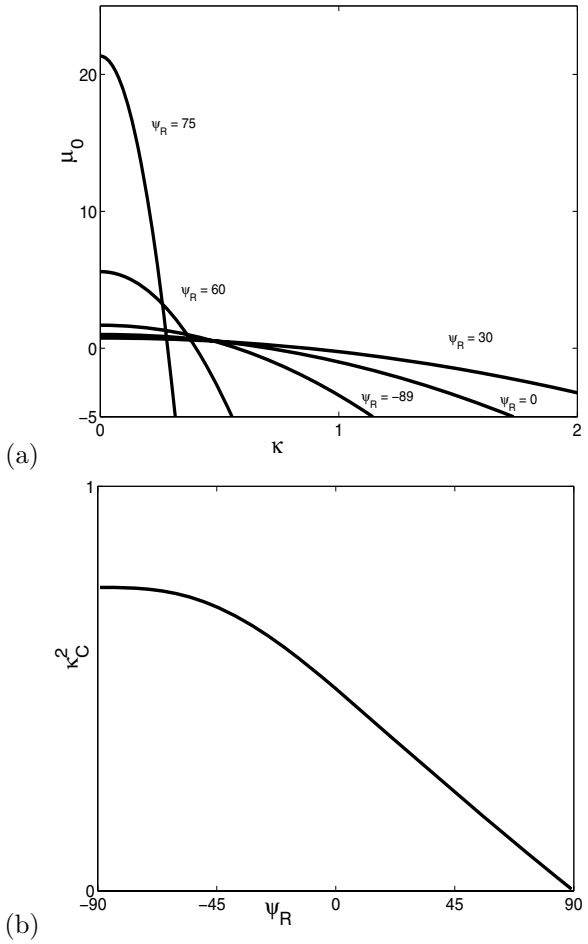

FIG. 5.1. (a) *Eigenvalues for $n = 0$ versus $\kappa = R_e K$ for the ellipsoid case. From the lower curve at $\kappa = 0$: $\psi_R^{(0)} = -89, 0, 30, 60, 75$ degrees.* (b) *The square of the rescaled wave number, κ_C^2, versus ψ_R for the ellipsoid.*

5.2. Cubic materials. For numerical determination of the eigenvalues we used a pseudospectral Chebyshev discretization of the (3.27), (3.28) with boundary conditions from (3.25) for contact angles, where $-\pi \leq \psi_R \leq \pi$. For this problem we may choose a value ψ_R, thereby fixing the value of W_0. If we restrict ψ_R between $-\pi/2$ and $\pi/2$, then ψ_L is the solution to

$$W_0 - (\gamma(\phi)\sin\phi + \gamma_\phi(\phi)\cos\phi) = 0 \tag{5.4}$$

for a value of ϕ between $\pi/2$ and $3\pi/2$. Therefore, fixing the value of ψ_R determines the value of ψ_L.

Since γ varies with respect to ϵ_4 for each of the three high symmetry cubic orientations [001], [011], and [111], we must determine the effective radius of the cross-section R_e. To eliminate the change in length scale with ϵ_4, we set $\kappa = kR_e$, which is the dimensionless axial wave number based on the effective radius of the cross-section.

In addition, we performed an asymptotic expansion of the problem with a plane of symmetry at $\phi = \pi/2$, i.e., when $\psi_L = \pi - \psi_R$. The results for the numerical cal-

culation will be compared to the results for the asymptotic expansion in the following sections.

5.2.1. Rod axis parallel to [001] orientation. The dimensionless surface energy is given by (4.8) for the [001] orientation. In the plane $\theta = \pi/2$, we then have $\gamma_{\theta\phi} = 0$, and

$$\gamma = (1 + 3\epsilon_4) + \epsilon_4 \cos 4\phi, \tag{5.5}$$

$$(\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta}) = \left(1 - 6\epsilon_4 - \frac{9}{2}\epsilon_4^2\right) - (18\epsilon_4 - 126\epsilon_4^2)\cos 4\phi + \frac{45}{2}\epsilon_4^2 \cos 8\phi. \tag{5.6}$$

The rod is smooth for $-1/18 \le \epsilon_4 \le 1/12$.

For this orientation, $\gamma_{\theta\phi}(\phi, \pi/2)$ vanishes, leading to a decoupling of (3.27), (3.28) that leaves a single equation,

$$\frac{\partial H_n}{\partial_{\phi\phi}} + \left(1 - k^2\left[1 + \epsilon_4 A_1(\phi) + \epsilon_4^2 A_2(\phi)\right]\right) H_n = \mu_n H_n, \tag{5.7}$$

where

$$A_1 = -6[1 + 3\cos 4\phi], \quad A_2 = -\frac{9}{2}[1 - 28\cos 4\phi - 5\cos 8\phi]. \tag{5.8}$$

For the asymptotics, we assume a symmetry condition about $\phi = \pi/2$. If $-\pi/2 \le \psi_R \le \pi/2$, then $\psi_L = \pi - \psi_R$. Then the boundary conditions become

$$H_n(\psi_R)\sin\psi_R + H_{n\phi}(\psi_R)\cos\psi_R = 0, \tag{5.9}$$

$$H_{n\phi}(\pi/2) = 0. \tag{5.10}$$

We take the simple expansions of H_n and μ_n in terms of small ϵ_4:

$$H_n(\phi) = H_n^{(0)}(\phi) + \epsilon_4 H_n^{(1)}(\phi) + O\left(\epsilon_4^2\right), \tag{5.11}$$

$$\mu_n = \mu_n^{(0)} + \epsilon_4 \mu_n^{(1)} + O(\epsilon_4^2). \tag{5.12}$$

The formal asymptotic expansion gives

$$H_n(\phi) = C_1 \cos\beta_n(\pi/2 - \phi) + O(\epsilon_4), \tag{5.13}$$

$$\mu_n = 1 - k^2 - \beta_n^2 + \epsilon_4\left\{6k^2 - \frac{9k^2\beta_n}{(\eta_n + \sin\eta_n)}\left[\sin 4\psi_R^{(0)} + \frac{\sin(4\psi_R^{(0)} - \eta_n)}{(\beta_n + 2)} - \frac{\sin(4\psi_R^{(0)} + \eta_n)}{(\beta_n - 2)}\right]\right\} + O(\epsilon_4^2), \tag{5.14}$$

where $\eta_n = 2\beta_n(\pi/2 - \psi_R^{(0)})$ and the value of β_n must satisfy

$$\cos\beta_n(\pi/2 - \psi_R)\sin\psi_R + \beta_n \sin\beta_n(\pi/2 - \psi_R)\cos(\psi_R) = 0.$$

In Figure 5.2, the first two terms of the asymptotic expansion for the most unstable mode, μ_0, are compared against the numerical value for several choices of contact angle, $\psi_R^{(0)}$, for $\epsilon_4 = 0.20$. The asymptotic results, shown by the dashed curves, are

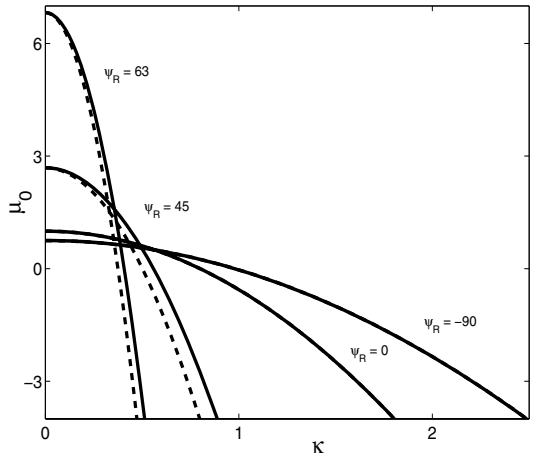

FIG. 5.2. *Eigenvalues for $n = 0$ versus the rescaled wave number $\kappa = R_e k$ for the* [001] *orientation. Reading from the solid lower curve to the solid upper curve at $\kappa = 0$, the corresponding values of ψ_R are $-90, 0, 45, 63$ degrees as indicated. The solid curve represents the numerical solution, and the dashed curve represents the asymptotic solution for $\epsilon_4 = 0.020$.*

close to the numerical results represented by the solid curves. These results show that the larger contact angles are more stable with respect to large dimensionless axial wave numbers. In addition, the [001] orientation is more stable with respect to the isotropic case for negative ϵ_4 and destabilized for positive ϵ_4. The $\psi_R = 0$ case corresponds to the free rod discussed in [10].

The corresponding critical wave number κ_C, defined where μ_0 is zero, as a function of ϵ_4 has the form $\kappa_C = R_e k$. If we define $\sigma_n^{(1)} = k^2\tau$, then the critical dimensionless wave number is as follows:

$$\kappa_C^2 = R_e^2(1 - \beta_n^2)(1 + \epsilon_4\tau) + O(\epsilon_4^2). \tag{5.15}$$

Figure 5.3 shows the results for the square of the rescaled critical wave number versus the contact angle ψ_R. The isotropic case, where ϵ_4 is zero, matches the results found in McCallum et al. [19] for the isotropic rod in contact with a substrate. It is clear from Figure 5.3 that the negative values of ϵ_4 stabilize the rod for all contact angles with respect to the isotropic rod, while the positive values of ϵ_4 destabilize the rod. This behavior also was observed for the freestanding rod [10].

5.2.2. Rod axis parallel to [011] orientation. The dimensionless surface energy, γ, for the [011] orientation is given by (4.15). In the plane $\theta = \pi/2$, we then have $\gamma_{\theta\phi} = 0$, and

$$\gamma = \left(1 + \frac{9}{4}\epsilon_4\right) + \epsilon_4 \cos 2\phi + \frac{3}{4}\epsilon_4 \cos 4\phi, \tag{5.16}$$

(5.17)

$$\begin{aligned}(\gamma + \gamma_{\phi\phi})\,(\gamma + \gamma_{\theta\theta}) = \Big(&1 + \frac{3}{2}\epsilon_4[5 - 12\cos 2\phi - 9\cos 4\phi] \\ &+ \frac{9}{32}\epsilon_4^2[167 + 136\cos 2\phi - 148\cos 4\phi + 312\cos 6\phi + 45\cos 8\phi]\Big).\end{aligned}$$

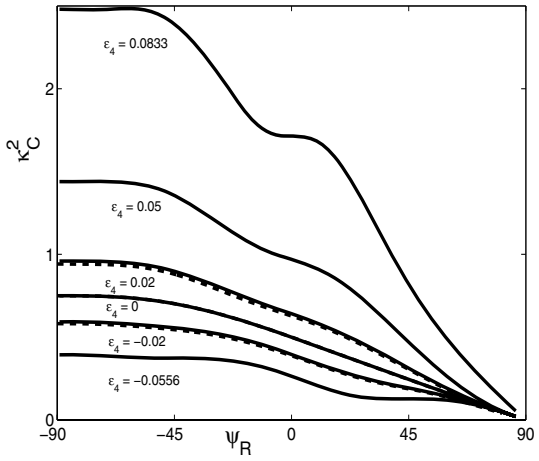

FIG. 5.3. *The square of the critical rescaled wavenumber, κ_C^2, versus ψ_R for the* [001] *orientation for* $\epsilon_4 = -0.0556, -0.02, 0, 0.02, 0.05, 0.0833$. *The solid curves represent the numerical solutions and the dashed curves the asymptotic solutions. The asymptotic solutions are given only for* $\epsilon_4 = -0.02, 0.0.02$.

The asymptotic expansion for the [011] orientation is similar to the [001] orientation. Therefore, we merely state the results for the first two terms of the eigenvalue expansion:

$$\mu_n^{(0)} = 1 - k^2 - \beta_n^2, \tag{5.18}$$

$$\begin{aligned}\mu_n^{(1)} = -\frac{15}{2}k^2 - \frac{9k^2\beta_n}{(\eta_n + \sin\eta_n)}\Bigg[&2\sin 2\psi_R^{(0)} + \frac{3}{4}\sin 4\psi_R^{(0)} \\ &-\left(\frac{2\sin 2\psi_R^{(0)}}{\beta_n^2 - 1} + \frac{3\sin 4\psi_R^{(0)}}{\beta_n^2 - 4}\right)\cos\eta_n \\ &-\left(\frac{2\beta_n\cos 2\psi_R^{(0)}}{\beta_n^2 - 1} + \frac{3\beta_n\cos 4\psi_R^{(0)}}{2(\beta_n^2 - 4)}\right)\sin\eta_n\Bigg],\end{aligned} \tag{5.19}$$

where η_n and β_n are as defined for the [001] orientation. Figure 5.4(a) shows numerical results for the range $-0.05 \le \epsilon_4 \le 0.08$ and the asymptotic results for $\epsilon_4 = -0.02, 0, 0.02$. The extreme ends of the smooth ϵ_4 range present some numerical difficulties and are therefore not shown. Likewise the extreme case, where ψ_R is approaching 90 degrees and the cross-sectional area of the rod is approaching zero, prevents us from calculating over the entire range of ψ_R. The curve $\epsilon_4 = 0$ corresponds to the isotropic case. The substrate acts as a stabilizing influence on the rod; even the negative ϵ_4 case, while less stable than the positive ϵ_4 case, is less unstable than it is for a freestanding rod. The large wave number instability associated with negative values of $(\gamma + \gamma_{\theta\theta})$ seen in the freestanding rod [10] when ϵ_4 is in the range $-5/68 \le \epsilon_4 \le -1/18$ is possibly related to the growing κ_C^2 values observed for $\epsilon_4 = -0.05$ over a positive range of ψ_R.

5.2.3. Rod axis parallel to [111] orientation. If the axis of the rod is aligned with the [111] orientation of the crystal axes relative to the rod axis, then γ is given by the following in the plane $\theta = \pi/2$:

$$\gamma = 1 + 2\epsilon_4, \tag{5.20}$$

$$(\gamma + \gamma_{\phi\phi})(\gamma + \gamma_{\theta\theta}) = 1 + 12\epsilon_4 + 20\epsilon_4^2. \tag{5.21}$$

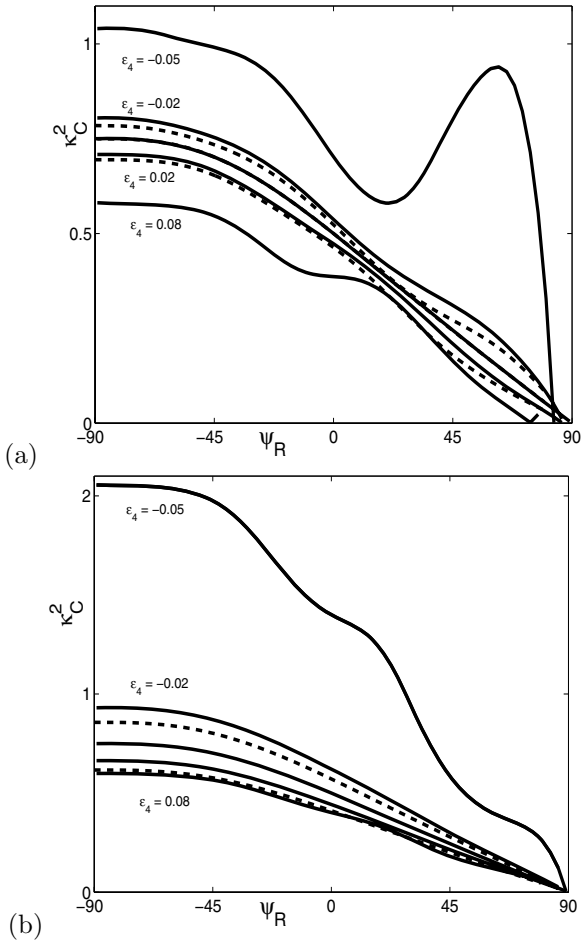

FIG. 5.4. *The square of the critical rescaled wave number, κ_C^2, versus ψ_R for $\epsilon_4 = -0.05, -0.02, 0, 0.02, 0.08$ for* (a) *the* [011] *orientation and* (b) *the* [111] *orientation. The solid curves represent the numerical solutions, and the dashed curves represent the asymptotic solutions. The asymptotic solutions are given only for $\epsilon_4 = -0.02, 0.0.02$.*

The asymptotic expansion for this orientation differs from the expansions for the [001] and [011] orientations since in the [111] orientation (3.27) and (3.28) are coupled through the nonzero term

$$\gamma_{\theta\phi} = 8\sqrt{2}\epsilon_4 \sin 3\phi. \tag{5.22}$$

The zeroth-order conditions and results are the same as those for the [001] and [011] orientations, as expected, so only the details for the first-order terms are shown here. We begin with the equations that must be solved to determine $\mu_n^{(1)}$:

$$\begin{aligned} &- H_{n\phi}^{(1)}(\psi_0)u(\psi_0) + H_n^{(1)}(\psi_0)u_\phi(\psi_0) \\ &- \int_{\psi_R^{(0)}}^{\pi/2} [(\mu_n^{(1)} + 12k^2)H_n^{(0)} - k\gamma_{\theta\phi}(\phi)G_{n\phi}^{(0)} - k(\gamma_{\theta\phi}(\phi)G_n^{(0)})_\phi]u\, d\phi = 0 \end{aligned} \tag{5.23}$$

and

$$-G^{(1)}_{n\phi}(\psi^{(0)}_R)u(\psi^{(0)}_R)+G^{(1)}_{n}(\psi^{(0)}_R)u_\phi(\psi^{(0)}_R) - \int_{\psi^{(0)}_R}^{\pi/2}[(\mu^{(1)}_n+12k^2)G^{(0)}_n+k\gamma_{\theta\phi}(\phi)H^{(0)}_{n\phi}+k(\gamma_{\theta\phi}(\phi)H^{(0)}_n)_\phi]u\,d\phi=0 \tag{5.24}$$

with the boundary conditions

$$H^{(1)}_{n\phi}(\pi/2)=0, \tag{5.25}$$

$$G^{(1)}_{n\phi}(\pi/2)=0, \tag{5.26}$$

$$H^{(1)}_n(\psi^{(0)}_R)\sin\psi^{(0)}_R+H^{(1)}_{n\phi}(\psi^{(0)}_R)\cos\psi^{(0)}_R+k\gamma_{\theta\phi}(\psi^{(0)}_R)G^{(0)}_n\cos\psi^{(0)}_R=0, \tag{5.27}$$

$$G^{(1)}_n(\psi^{(0)}_R)\sin\psi^{(0)}_R+G^{(1)}_{n\phi}(\psi^{(0)}_R)\cos\psi^{(0)}_R-k\gamma_{\theta\phi}(\psi^{(0)}_R)H^{(0)}_n\cos\psi^{(0)}_R=0. \tag{5.28}$$

Concentrating on (5.23), one sees that the equation can be rewritten as

$$-\big(H^{(1)}_{n\phi}(\psi^{(0)}_R)+k\gamma_{\theta\phi}(\psi^{(0)}_R)G^{(0)}_n(\psi^{(0)}_R)\big)u(\psi^{(0)}_R)+H^{(1)}_n(\psi^{(0)}_R)u_\phi(\psi^{(0)}_R) -(\mu^{(1)}_n+12k^2)\int_{\psi^{(0)}_R}^{\pi/2}H^{(0)}_n u\,d\phi+k\int_{\psi^{(0)}_R}^{\pi/2}[\gamma_{\theta\phi}(\phi)G^{(0)}_{n\phi}u(\phi)-\gamma_{\theta\phi}(\phi)G^{(0)}_n u_\phi(\phi)]\,d\phi=0. \tag{5.29}$$

The boundary terms vanish since the operator is self-adjoint. In addition, since $G^{(0)}_n(\phi)$ and $u(\phi)$ differ only by a constant, the second integral vanishes as well. Thus one finds that

$$\mu^{(1)}_n=-12k^2. \tag{5.30}$$

Applying similar logic to (5.24), one finds the same result.

The numerical results for the [111] orientation for $-0.05\le\epsilon_4\le 0.08$ and the asymptotic results for $\epsilon_4=-0.02,0,0.02$ are shown in Figure 5.4(b). The extreme ends of the smooth ϵ_4 range present some numerical difficulties and are therefore not shown. Figure 5.4(b) shows that for nonnegative ϵ_4, the substrate is a stabilizing presence, but even this added stability is unable to overcome the instability associated with positive values of ϵ_4.

6. Conclusion. We have examined rotation effects and the linear stability of a rod on a substrate, in which the rod has a uniform cross-section given by a two-dimensional equilibrium shape. This work extends our previous treatment of a free-standing rod, where the stability analysis produces an associated eigenvalue problem with periodic boundary conditions. The effect of the rod making contact with the substrate involves instead mixed boundary conditions for the eigenvalue problem. The eigenvalues are determined numerically with asymptotic solutions given for the limiting case of small anisotropy. The eigenproblem is a coupled pair of second-order ordinary differential equations with coefficients that are periodic along the axis of the rod and depend on the second derivatives with respect to the orientation variables. We assumed a weak anisotropic surface energy to eliminate missing orientations on the rod.

As was found in our previous exploration of the freestanding anisotropic rod, the magnitude and the sign of the anisotropy determine the relative stability in comparison to the isotropic case. The overall effect of the substrate is stabilizing to the anisotropic rod. In general, as the contact angle ψ_R tends to 90 degrees, the rod on the substrate becomes more stable, which is analogous to the stability of a

three-dimensional planar film, where the anisotropy is not strong enough to make the problem ill-posed. In particular, the rod on a substrate with any of the high symmetry cubic orientations maintains the same relationship as the freestanding rods as to whether or not a positive or negative anisotropy enhances or diminishes stability. When the contact angle ψ_R between the rod and the substrate approaches -90 degrees, the stability does not revert to that of the freestanding rod. In this limiting case, the rods are pinned to the surface at one point, and this single point of contact increases the stability of the rod with respect to the unpinned case. This effect was also seen by McCallum et al. [19] for the isotropic rod.

We have considered the effect of rotation on the stability of a two-dimensional rod whose cross-section is either elliptical or a shape determined by one of the three high symmetry cubic orientations. In order to describe these cross-sections, the coordinate system is fixed to the center of the rod, thereby defining a substrate height above this center. When the major axis of the ellipse is horizontal, the ellipse is most stable with a positive substrate height (see Figure 2.2) and is least stable with a negative substrate height. For this elliptical case, the observation is consistent with the remark above that contact angles near 90 degrees are more stable than contact angles near -90 degrees. But the observation concerning substrate height applies to more general cases. In particular, the stability of rods whose cross-sections are determined by high symmetry cubic orientations mimic this reversal of stability when the substrate height is at a maximum over the coordinate axes in comparison to a minimum. Similar to the linear stability results, the stability under rotation of these rods with the [001] and [011] cubic orientations depends greatly on the sign and magnitude of the anisotropy. Negative anisotropy corresponds to a rod with a cross-section of a rounded cube; positive anisotropy corresponds to a rod with a smoothed octahedral cross-section. In general we observe that for the [001] cubic orientation, the more negative the anisotropy, the more unstable the rod. The situation is reversed for the [011] and [111] cubic orientations.

The two- or fourfold symmetry of the orientations is reflected in the effect of rotation of the rods on the stability. The stability of the rod with the [111] cubic orientation is found to be unchanged by rotation.

These results may be potentially useful in the manufacture of stable long rods or wires with an axis oriented along the high symmetry orientations [001], [011], and [111].

Appendix. The effect of rotations on perturbation stability. In this section we discuss the effect of rotating a crystal on the second variational energy of the contact line problem. We start with a study of the two-dimensional shapes from sections 4.1 and 4.2: an ellipse and three two-dimensional cubic crystals in high symmetry orientations. For the ellipse, the major and minor axes are rotated with respect to the x-axis at an angle of ϕ'. Additionally, the substrate may be moved upwards from the original x-axis at a distance of W_0. In this particular case the effect of W_0 will be seen indirectly, as it does not appear explicitly in the relevant equations. However, W_0 determines the contact angles ψ_R and ψ_L that the crystal makes with the substrate.

In two dimensions the stability problem (i.e., the second variation of the energy) reduces to the following:

$$\frac{E^{(2)}}{2} = -\int_{\psi_R^{(0)}}^{\psi_L^{(0)}} [h_{\phi\phi}(\phi) + h(\phi)]h(\phi)\, d\phi \tag{A.1}$$

with the boundary conditions

$$h(\psi_i^{(0)})\sin\psi_i^{(0)} + h_\phi(\psi_i^{(0)})\cos\psi_i^{(0)} = 0 \tag{A.2}$$

for $i = L, R$, subject to the constraints where

$$\int_{\psi_R^{(0)}}^{\psi_L^{(0)}} h(\phi)\left[\gamma(\phi+\phi') + \gamma_{\phi\phi}(\phi+\phi')\right] d\phi = 0, \tag{A.3}$$

and where

$$\int_{\psi_R^{(0)}}^{\psi_L^{(0)}} h^2(\phi)\, d\phi \tag{A.4}$$

is minimized.

Therefore we can formulate the problem as

$$h_{\phi\phi}(\phi) + h(\phi) = \mu\, h(\phi) + \tau\, \left[\gamma(\phi+\phi') + \gamma_{\phi\phi}(\phi+\phi')\right] \tag{A.5}$$

with the boundary conditions given as above in (A.2). We solve this problem using two different numerical techniques. The first uses a pseudospectral Chebyshev calculation [34] to determine a basis of eigenvectors for the problem

$$h_{\phi\phi}(\phi) + h(\phi) = \mu\, h(\phi), \tag{A.6}$$

subject to the boundary conditions, that are orthogonal to the vector

$$\gamma(\phi+\phi') + \gamma_{\phi\phi}(\phi+\phi'). \tag{A.7}$$

In addition, we can solve (A.2), (A.5) with a double shooting method.

The unstable eigenmodes are those where $\mu_n > 0$. We find that the largest eigenvalue, μ_0, is zero to numerical accuracy for all cases, indicating that none of the modes are unstable. Analytically we can obtain some insight by noting that (A.6) admits solutions of the form

$$-n^2 + 1 = \mu_n, \tag{A.8}$$

$$h_n(\phi) = A_n \sin(n\phi) + B_n \cos(n\phi). \tag{A.9}$$

Note that μ_n is negative for $n \geq 2$, resulting in stable shape perturbations. The boundary conditions show that if $n = 0$, then $h_0 = 0$. The next allowed n is $n = 1$, which gives $\mu_1 = 0$ and $h_1 = B_1 \cos\phi$, an allowable solution. This is an eigenmode as long as it satisfies the orthogonality constraint given in (A.3).

THE EXIT PROBLEM IN A NONLINEAR SYSTEM DRIVEN BY $1/f$ NOISE: THE DELAY LOCKED LOOP*

S. LANDIS†, B. Z. BOBROVSKY†, AND Z. SCHUSS‡

Abstract. The frequency generated by high frequency oscillators contains a small but significant noise component known as phase noise, also known as oscillator noise or phase jitter. The phase noise belongs to the family of stochastic processes with spectra $1/f^\alpha$, which exhibits scale invariance (or self-similarity) and a long-term correlation structure that decays polynomially in time. Both the phase and thermal noises cause errors in receivers that contain the oscillators. In particular, they cause losses of lock in phase tracking systems such as the phase locked loop in coherent systems, which include cellular phones, global positioning systems (GPS), and radar (e.g., synthetic aperture radar (SAR)), and in the delay locked loop (DLL), which is an important component of code division multiple access receivers and interface to modern memory modules, such as double data rate synchronous dynamic random access memory. The mean time to lose lock (MTLL) is well known to be an important design objective for various tracking loops. The evaluation of the MTLL is known in the mathematical literature as the exit problem for a dynamical system driven by noise, which is the problem of calculating the mean time for the noisy trajectories to reach the boundary of the domain of attraction of a stable point of the noiseless dynamics. In this paper we develop an analytic approach to the evaluation of the leading order term for MTLL of a second order DLL, due to both the non-Markovian $1/f^\alpha$ noise and to thermal white noise. The method is applicable to more general systems driven by a wide class of phase noises. The keys to the solution of this exit problem are the construction of a series of higher order Markovian processes that converge to the non-Markovian $1/f^\alpha$ noise and the asymptotic solution to a multidimensional elliptic boundary value problem that the mean first passage time (MFPT) satisfies.

Key words. exit problem, phase noise, fractional Brownian motion, loss of lock, delay locked loop, mean time to lose lock, phase locked loop, $1/f$ noise

1. Introduction.

In communication theory random signals are often described as the output of a dynamical system driven by noise [1]. Various types of noise are used to model different signals, including white noise, colored noise, shot noise, and so on. When the signal is carried by the phase of the wave, such as in phase modulation (PM), frequency modulation (FM), and various keying modulations [1], [2], as well as in global positioning systems (GPS) and other signal tracking systems, the main component that generates the signal is an oscillator [3]. The frequency generated by high frequency oscillators is not very stable; it drifts randomly and contains a small but significant noise component known as *phase noise*. Both the random drift and thermal noise cause errors in the receivers of these signals. In particular, they cause losses of lock in phase tracking systems such as the phase locked loop (PLL) in coherent systems [1], [2], [4], which include cellular phones [3], GPS [5], and radar (e.g., synthetic aperture radar (SAR)) [6], and in the delay locked loop (DLL) [7], [8], which is an important component of code division multiple access (CDMA) receivers [3], GPS, and interface to modern memory modules such as double data rate synchronous

dynamic random access memory (DDR SDRAM) [9]. The mean time to lose lock (MTLL) is well known to be an important design objective for various tracking loops [2], [4].

Phase noise, also known as oscillator noise or phase jitter, is a well-known problem that does not yet have a full physical model (a recent example of a physical model is found in [10]) or extensive tools for mathematical manipulation. The phase drift and noise may be due to impurities, imperfections, thermal fluctuations, and other factors in the oscillator's crystal. The phase noise is usually described as having four parts [3]: the first is "frequency flicker" with power spectrum $1/f^3$; the second is "flat frequency" with power spectrum $1/f^2$; the third is "phase flicker" with power spectrum of the form $1/f$; and finally, the fourth is a "flat spectrum" phase. Often a white noise term is added to represent thermal noise. This thermal noise should not be confused with the "flat spectrum" part of the phase noise. The family of stochastic processes with spectra $1/f^\alpha$ is of growing interest in many fields of research due to the wide variety of data for which they are inherently suited [11], [12]. This family of processes exhibits scale invariance (or self-similarity) and a long-term correlation structure that decays polynomially in time rather than exponentially, as is the case for the well-studied family of autoregressive moving average (ARMA) processes [13]. The long-term correlation structure of $1/f$ noise is due to the absence of a low frequency cutoff in the spectrum, which results in nonstationarity. This means that an approximation that has a low frequency cutoff (flattening of the spectrum below a certain frequency) has a finite correlation structure. Furthermore, "ideal" $1/f$ Gaussian noise cannot exist since the single-time variance of the process is not finite. A model that has a low frequency cutoff, as in our case, can be Gaussian. A considerable body of work has been devoted to $1/f^\alpha$ processes (see [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], and references therein). An approximation to $1/f$ noise by an output of a linear system of first order stochastic differential equations, driven by a vector of white noises, is given in [23]. The structure of this model is similar to that of the present one but is derived from different considerations. The model in [23] is based on a physical description of diffusion and transport that leads to $1/f$ spectrum. In contrast, our model is based on a purely mathematical construction and can be generated for any $1/f^\alpha$ spectrum and, in general, for a wide class of spectra. Further, our model is constructed as the output of a system driven by a single noise source, whereas Milotti's model is driven by many noise sources. Our construction may be more appropriate for linear estimation problems driven by $1/f$ noise because in the absence of observation noise, completely accurate reconstruction of the state of the system is possible only if the rank of the observed variable is not lower than the rank of the noise driving the system [24]. Both models can be used for the calculation of the mean first passage time (MFPT) because they are based on a system of first order stochastic differential equations driven by white noise.

The MTLL of coherent and noncoherent pseudonoise code tracking loops, due to white (e.g., thermal) noise, has been studied extensively in the literature [7], [8]. A more analytic approach to the second order DLL was given in [25], where an asymptotic expansion of the solution for the MTLL was derived using singular perturbation theory. The MTLL in systems driven by $1/f$ noise, or more specifically, the effects of phase noise on a DLL, has not been solved analytically in the literature to date, although its existence and significance are well known [3]. Our aim in the specific application considered in this paper is to develop an analytic approach to the evaluation of the leading order term for the MTLL of a second order DLL due to both phase and thermal white noise. It should be noted that in this article we calculate

the asymptotic rate at which the MTLL grows exponentially when the dimensionless noise strength tends to zero. The result is a single leading order term in an asymptotic expansion.

The evaluation of the MTLL is known in the mathematical literature as the *exit problem* for a dynamical system driven by noise [26], which is the problem of calculating the mean time for the noisy trajectories to reach the boundary of the domain of attraction of a stable point of the noiseless dynamics. The problem has been extensively studied for the case of Itô dynamics driven by small white noise (see the comprehensive review [27]). The key to the calculation of the MFPT to the boundary is the construction of an asymptotic solution to a boundary value problem for the elliptic partial differential equation that the MFPT satisfies.

When the noise is non-Markovian or cannot be imbedded in a higher order Markovian process, the calculation of the MFPT is complicated by the absence of differential or integral equations that the MFPT satisfies. To circumvent this difficulty, methods have been developed to approximate the noise by a Markov process, e.g., by an output of a finite-dimensional Itô system. The MFPT is then calculated for the approximating Itô system, and convergence is shown as the order of approximation increases [28]. This procedure requires the development of an asymptotic method for the calculation of the MFPT in Itô systems of high dimension.

Our approach is based on constructing a convergent sequence of rational approximations to $1/f$ (see [28] and references therein). The approximate $1/f$ noise is a component of a higher dimensional (Markovian) diffusion process. We construct a sequence of approximations to the noise by multidimensional diffusion processes, whose power spectral densities are obtained by truncating the continued fraction expansion of the Laplace transform of the function $1/\sqrt{s}$ about $s = 1$. The resulting approximation to the $1/f$ noise is represented by a set of first order linear Itô equations. The resulting rational spectra approximate $1/f$ in finite intervals without ripples. The width of these intervals can be increased arbitrarily by increasing the degree of the truncation. Our model is amenable to asymptotic analysis of the exit problem for high-dimensional diffusion processes. We develop a multidimensional singular perturbation theory for the solution of the exit problem for multidimensional diffusion processes and apply it to the calculation of the leading order term of MTLL in a DLL with an approximate $1/f^3$ phase noise. The dynamics of the delay estimator error is driven by the derivative of the phase noise, which for $1/f^3$ is $1/f$ noise. It is shown that truncation of the model for the phase noise results in a convergent sequence of approximations for the first approximation of the MTLL (the exponential growth rate).

Our main result is the calculation of the leading order term for the MTLL in a specific second order DLL loop under the combined influence of $1/f^3$ phase noise and additive thermal white noise. Specifically, we find explicit asymptotic expressions for the MTLL for Markovian approximations to the phase noise. The calculations indicate that as the degree of approximation increases, the MTLL converges to a finite limit. Actually, no significant change in the MTLL is observed after truncation of the phase noise model at order 10. From a practical point of view it is most important to optimize the system at a low carrier-to-noise ratio (CNR), because this is where the system will stop operating. It turns out that as CNR decreases, the needed order of truncation decreases. We also show that the filter can be optimized for maximal MTLL when both composite phase and thermal white noise drive the system.

2. The leading order term for the MTLL problem for a second order DLL with approximated $1/f^3$ phase noise. The baseband equivalent model for

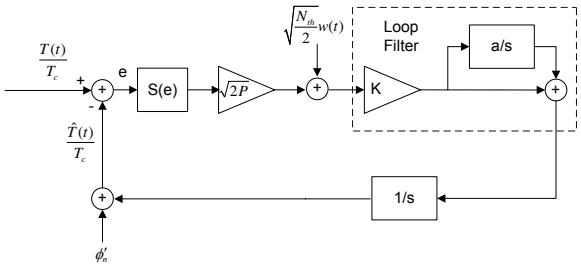

FIG. 1. *Baseband equivalent model for nonlinear DLL.*

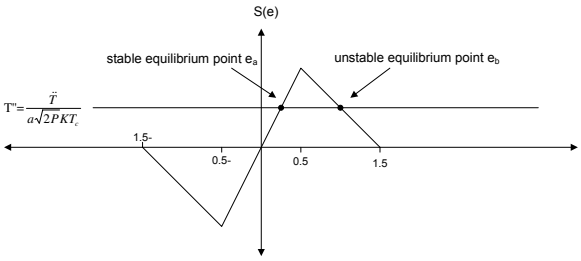

FIG. 2. *S-curve for early-late DLL problem and the corresponding equilibrium points.*

the second order nonlinear early-late DLL shown in Figure 1 [29] has normalized channel propagation delay $T(t)/T_c$, total power of received signal P, gains K and a that define the loop's filter, and phase noise $\tilde{\phi}_n$ with power spectrum

$$S_{\tilde{\phi}_n\tilde{\phi}_n}(f) = \frac{N_{ph}}{2\,|2\pi f|^3}. \tag{2.1}$$

The loop filter used is of proportional integration type [30] with a zero at $s = -a$. The parameter $K[\sqrt{\text{Hz}}]$ determines the loop's gain, and the dimensionless parameter $a \neq 0$ stabilizes the loop. This type of loop can handle relative velocity $\dot{T}$ without a steady state error, and relative acceleration $\ddot{T}$ with a steady state error. The piecewise linear S-curve for the early-late DLL used in spread spectrum synchronization of long PN (pseudonoise) sequences is given by [29] (see Figure 2)

$$S(e) = \begin{cases} 2e, & |e| \le \frac{1}{2}, \\ 1.5 - e, & \frac{1}{2} < |e| < \frac{3}{2}, \\ -1.5 - e, & -\frac{3}{2} < |e| < -\frac{1}{2}, \\ 0 & \text{otherwise.} \end{cases}$$

The resulting equations describing the system are

$$e = \frac{T}{T_c} + \tilde{\phi}_n - \frac{\hat{T}}{T_c}, \tag{2.2}$$

$$\dot{z} = aK\sqrt{2P}S(e) + K\sqrt{\frac{N_{th}}{2}}\,\dot{w}(t),$$

$$\frac{\dot{\hat{T}}}{T_c} = z + K\sqrt{2P}S(e) + K\sqrt{\frac{N_{th}}{2}}\,\dot{w}(t),$$

where e is the delay estimation error, $\dot{z}$ is the output of the loop filter, and the last equation is the output of the integrator. Here $w(t)$ is the standard Wiener process (Brownian motion), whose "derivative" $\dot{w}(t)$ is standard δ-correlated Gaussian white noise [26], independent of $\nu(t)$.

Differentiating e and setting $\tilde{z} = z - \frac{\dot{T}}{T_c}$, equations (2.2) become

$$\begin{aligned}
\dot{e} &= -\tilde{z} - K\sqrt{2P}S(e) + \dot{\tilde{\phi}}_n - K\sqrt{\frac{N_{th}}{2}}\,\dot{w}(t),\\
\dot{\tilde{z}} &= aK\sqrt{2P}S(e) - \frac{\ddot{T}}{T_C} + K\sqrt{\frac{N_{th}}{2}}\,\dot{w}(t).
\end{aligned} \tag{2.3}$$

The spectral power density (2.1) indicates that the new noise process $\phi_n = \dot{\tilde{\phi}}_n$ is well defined and that its power spectral density function is given by $S_{\phi_n\phi_n}(f) = \frac{N_{ph}}{2|2\pi f|}$.

Next, we construct an approximate $1/f$ Gaussian noise by passing white Gaussian noise through a filter, whose response in the Laplace domain is [20]

$$H(s) = \frac{1}{\sqrt{s}}. \tag{2.4}$$

This filter cannot be realized as a Markovian process in a straightforward fashion, and therefore the standard tools of Markov processes are not available for the study of the effects of the $1/f$ noise in dynamical systems. We construct a sequence of rational approximations to (2.4) by truncating its continued fraction representation in a fashion similar to that used in [28] and references therein. Although (2.4) is not an analytic function near the origin, it is analytic at any nonzero s such as $s = \omega_0 > 0$, so it has the continued fraction representation

$$\frac{1}{\sqrt{\tilde{s}+\omega_0}} = \cfrac{1}{1+\cfrac{1}{\cfrac{2\omega_0}{\tilde{s}}+\cfrac{1}{2+\cfrac{1}{\cfrac{2\omega_0}{\tilde{s}}+\cfrac{1}{2+\ddots}}}}}, \tag{2.5}$$

where $\tilde{s} = \omega_0(s-1)$. Thus (2.4) is

$$H(s) = \cfrac{1}{1+\cfrac{1}{\cfrac{2}{s-1}+\cfrac{1}{2+\cfrac{1}{\cfrac{2}{s-1}+\cfrac{1}{2+\ddots}}}}}, \tag{2.6}$$

which converges for $|s-\omega_0| < \omega_0$. Next, we define an approximate $1/f$ noise through the Laplace transform relation

$$\Phi_n(s) = H(s)V(s), \tag{2.7}$$

where the power spectral density of a white Gaussian process is given by

$$S_{vv}(f) = N_{ph}. \tag{2.8}$$

Truncating the continued fraction and using (2.6), (2.7), we obtain the system of $2N$ equations

$$\begin{aligned}
V(s) &= \Phi_n(s) + Y_1(s), \quad \Phi_n(s) = \frac{2}{s-1}Y_1(s) + Y_2(s),\\
Y_1(s) &= 2Y_2(s) + Y_3(s), \quad Y_2(s) = \frac{2}{s-1}Y_3(s) + Y_4(s),\\
Y_3(s) &= 2Y_4(s) + Y_5(s), \quad Y_4(s) = \frac{2}{s-1}Y_5(s) + Y_6(s),\\
&\vdots \qquad\qquad\qquad\quad \vdots\\
Y_{2N-3}(s) &= 2Y_{2N-2}(s) + Y_{2N-1}(s), \quad Y_{2N-2}(s) = \frac{2}{s-1}Y_{2N-1}(s) + Y_{2N}(s),\\
2Y_{2N-1}(s) &= 4Y_{2N}(s) + (s-1)Y_{2N},
\end{aligned} \tag{2.9}$$

where N denotes the order of approximation to the $1/f$ noise.

We note that all the state variables $Y_{2j+1}(s)$ in (2.9) can be eliminated by a linear transformation. To transform the system (2.9) into the time domain, we denote by $\nu(t)$ a standard Gaussian white noise and denote the state variables in the time domain by lowercase letters. Then (2.9) is transformed into the Itô system

$$\begin{aligned}
\dot{y}_{2N}(t) &= y_{2N}(t) - y_{2N}(0) + 2\left[\nu(t) - \phi_n(t) - 2\sum_{k=1}^{N} y_{2k}(t)\right],\\
\dot{y}_{2N-2}(t) &= y_{2N-2}(t) - y_{2N-2}(0) - 4y_{2N}(t) + 4\left[\nu(t) - \phi_n(t) - 2\sum_{k=1}^{N-1} y_{2k}(t)\right],\\
\dot{y}_{2N-4}(t) &= y_{2N-4}(t) - y_{2N-4}(0) - 4y_{2N}(t) - 8y_{2N-2}(t)\\
&\quad + 6\left[\nu(t) - \phi_n(t) - 2\sum_{k=1}^{N-2} y_{2k}(t)\right],\\
&\vdots\\
\dot{y}_2(t) &= y_2(t) - y_2(0) - 4\sum_{m=1}^{N-1} m y_{2(N-m+1)}(t) + 2N\left[\nu(t) - \phi_n(t) - 2y_2(t)\right],\\
\dot{\phi}_n(t) &= -(2N+1)\phi_n(t) - \phi_n(0) - 4\sum_{m=1}^{N} m y_{2(N-m+1)}(t) + 2(N+1)\nu(t).
\end{aligned} \tag{2.10}$$

Thus the Nth approximation to the $1/f$ noise process is an output of a Markovian system of $N+1$ linear stochastic differential equations of Itô type [26]. Finally, since

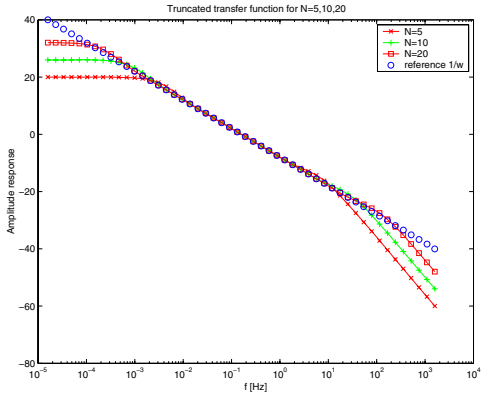

FIG. 3. *Frequency response of continued fraction approximations of* $1/\omega$ *with* ω_0=1, *truncated at* $N = 5$ *(red* $\times$*'s),* $N = 10$ *(green), and* $N = 20$ *(red squares). The reference* $1/\omega$ *is blue circles.*

the expected value of the $1/f$ noise process is zero, we find the initial conditions by taking the expectation of (2.10)

$$\phi_n(0) = y_2(0) = y_4(0) = \cdots = y_{2N}(0) = 0. \tag{2.11}$$

An interesting feature of our model is that for $N = 0$, (2.10) becomes an Ornstein–Uhlenbeck process. This type of process is commonly used for colored Gaussian noise models. In Figure 3 the frequency response [31] of the truncated transfer function $H(s)$ (2.6) is given for the approximation of $1/\omega$, where $\omega = 2\pi f$, with $N = 5$, $N = 10$, and $N = 20$, to show how the range of validity of the approximation expands with increasing N, and that the approximation is without ripples.

Thus, using (2.3), (2.10), we obtain the system

$$\begin{aligned}
\dot{e}(t) &= -\tilde{z}(t) - K\sqrt{2P}S(e(t)) + \phi_n(t) - K\sqrt{\frac{N_{th}}{2}}\,\dot{w}(t), \qquad (2.12)\\
\dot{\tilde{z}}(t) &= aK\sqrt{2P}S(e(t)) - \frac{\ddot{T}}{T_C} + K\sqrt{\frac{N_{th}}{2}}\,\dot{w}(t),\\
\dot{y}_{2N}(t) &= y_{2N}(t) + 2\left[\sqrt{\frac{N_{ph}}{2}}\,\nu(t) - \phi_n(t) - 2\sum_{k=1}^{N} y_{2k}(t)\right],\\
\dot{y}_{2N-2}(t) &= y_{2N-2}(t) - 4y_{2N}(t) + 4\left[\sqrt{\frac{N_{ph}}{2}}\,\nu(t) - \phi_n(t) - 2\sum_{k=1}^{N-1} y_{2k}(t)\right],\\
\dot{y}_{2N-4}(t) &= y_{2N-4}(t) - 4y_{2N}(t) - 8y_{2N-2} + 6\left[\sqrt{\frac{N_{ph}}{2}}\,\nu(t) - \phi_n(t) - 2\sum_{k=1}^{N-2} y_{2k}(t)\right],\\
&\vdots\\
\dot{y}_2(t) &= y_2(t) - 4\sum_{m=1}^{N-1} m y_{2(N-m+1)} + 2N\left[\sqrt{\frac{N_{ph}}{2}}\,\nu(t) - \phi_n(t) - 2y_2(t)\right],
\end{aligned}$$

$$\dot{\phi}_n(t) = -(2N+1)\phi_n(t) - 4\sum_{m=1}^{N} m y_{2(N-m+1)}(t) + 2(N+1)\sqrt{\frac{N_{ph}}{2}}\,\nu(t).$$

Next, we normalize the equations so that the noise term converges to zero as the CNR term P/N_{ph} increases to infinity. The CNR, measured in Hz, is a well-accepted engineering quantity [5]. We introduce dimensionless time and define the auxiliary variables

$$\tilde{t} = \sqrt{2P}Kt, \quad \beta = \frac{\tilde{z}}{a}, \quad T'' = \frac{\ddot{T}}{a\sqrt{2P}KT_c} \tag{2.13}$$

to convert to the nondimensional system

$$\begin{aligned}
\dot{e}\left(\tilde{t}\right) &= -\frac{a}{\sqrt{2P}K}\beta\left(\tilde{t}\right) - S\left(e\left(\tilde{t}\right)\right) + \frac{\phi_n\left(\tilde{t}\right)}{\sqrt{2P}K} - \sqrt{\frac{KN_{th}}{2\sqrt{2P}}}\,\dot{w}(\tilde{t}),\\
\dot{\beta}\left(\tilde{t}\right) &= S\left(e\left(\tilde{t}\right)\right) - T'' + \sqrt{\frac{KN_{th}}{2\sqrt{2P}}}\,\dot{w}(\tilde{t}),\\
\dot{y}_{2N}\left(\tilde{t}\right) &= \frac{1}{K\sqrt{2P}}\left\{y_{2N}\left(\tilde{t}\right) + 2\left[-\phi_n\left(\tilde{t}\right) - 2\sum_{k=1}^{N} y_{2k}\left(\tilde{t}\right)\right]\right\} + 2\sqrt{\rho}\,\nu\left(\tilde{t}\right),\\
\dot{y}_{2N-2}\left(\tilde{t}\right) &= \frac{1}{K\sqrt{2P}}\left\{y_{2N-2}\left(\tilde{t}\right) - 4y_{2N}\left(\tilde{t}\right) + 4\left[-\phi_n\left(\tilde{t}\right) - 2\sum_{k=1}^{N-1} y_{2k}\left(\tilde{t}\right)\right]\right\}\\
&\quad + 4\sqrt{\rho}\,\nu\left(\tilde{t}\right),\\
\dot{y}_{2N-4}\left(\tilde{t}\right) &= \frac{1}{K\sqrt{2P}}\left\{y_{2N-4}\left(\tilde{t}\right) - 4y_{2N}\left(\tilde{t}\right) - 8y_{2N-2}\left(\tilde{t}\right) + 6\left[-\phi_n\left(\tilde{t}\right) - 2\sum_{k=1}^{N-2} y_{2k}\left(\tilde{t}\right)\right]\right\}\\
&\quad + 6\sqrt{\rho}\,\nu\left(\tilde{t}\right),\\
&\vdots\\
\dot{y}_2\left(\tilde{t}\right) &= \frac{1}{K\sqrt{2P}}\left\{y_2\left(\tilde{t}\right) - 4\sum_{m=1}^{N-1} m y_{2(N-m+1)}\left(\tilde{t}\right) + 2N\left[-\phi_n\left(\tilde{t}\right) - 2y_2\left(\tilde{t}\right)\right]\right\}\\
&\quad + 2N\sqrt{\rho}\,\nu\left(\tilde{t}\right),\\
\dot{\phi}_n\left(\tilde{t}\right) &= \frac{1}{K\sqrt{2P}}\left\{-(2N+1)\phi_n\left(\tilde{t}\right) - 4\sum_{m=1}^{N} m y_{2(N-m+1)}\left(\tilde{t}\right)\right\} + 2(N+1)\sqrt{\rho}\,\nu\left(\tilde{t}\right),
\end{aligned} \tag{2.14}$$

where the dimensionless noise level is given by $\rho = \frac{N_{ph}}{2K\sqrt{2P}}$. For small values of ρ the system (2.14) can be viewed as a small stochastic perturbation of a nonlinear dynamical system that has a stable equilibrium at the point

$$e_a = \frac{T''}{2}, \quad \beta_a = -\frac{\ddot{T}}{T_c a^2}, \quad \phi_{n,a} = 0, \quad y_{2i,a} = 0, \quad 1 \le i \le N, \tag{2.15}$$

and an unstable equilibrium point at

$$e_b = \frac{3}{2} - |T''|, \quad \beta_b = -\frac{\ddot{T}}{T_c a^2}, \quad \phi_{n,b} = 0, \quad y_{2i,b} = 0, \quad 1 \le i \le N, \tag{2.16}$$

which we refer to as the *saddle point*.

The stable equilibrium point (2.15) of the system (2.14) has a domain of attraction D. This means that any noiseless trajectory of (2.14) starting in D converges to the stable equilibrium point (2.15). The boundary of the region D is denoted ∂D. As long as a trajectory of the stochastic system (2.14) remains in D, the DLL is said to be in a locked state. Upon exiting the region D through the boundary ∂D, the DLL is said to have lost lock. The exact description of the boundary ∂D is complex and is omitted here; however, in the limit of weak noise, the exit from D occurs in the immediate neighborhood of the saddle point. Thus the calculation of the MTLL is the classical exit problem of a dynamical system from the domain of attraction of a stable point under the influence of small noise [26].

We denote a trajectory of (2.14) by

$$\boldsymbol{x}^T(t) = [e(t),\ \beta(t),\ y_{2N}(t),\ y_{2N-2}(t),\ \ldots,\ y_2(t),\ \phi_n(t)]\,.$$

For each trajectory of (2.14) that starts in D, we denote by τ_D the first time it reaches the boundary ∂D (the first passage time to the boundary),

$$\tau_D = \inf\{t \geq 0 \,|\, \boldsymbol{x}(t) \in \partial D,\, \boldsymbol{x}(0) \in D\}\,, \tag{2.17}$$

and its conditional expectation

$$\bar{\tau}_D(\boldsymbol{x}) = E[\tau_D \,|\, \boldsymbol{x}(0) = \boldsymbol{x}].$$

The MTLL is defined as

$$\bar{t}_L(\boldsymbol{x}) = 2\bar{\tau}_D(\boldsymbol{x}) \tag{2.18}$$

because once on ∂D, a trajectory is equally likely to return to D immediately or to leave D for a long time [32]. In the case of small ρ an analytic approximation to the MTLL can be obtained, as described below.

3. Review of the multidimensional exit problem for diffusions. The approximation scheme used in the previous section reduces the loss of lock problem for a DLL with $1/f^3$ phase noise to the classical problem of escape of a multidimensional diffusion process from the domain of attraction of an attractor [26], [32], [33], [34], [35]. In the following, we outline a singular perturbation method for constructing an asymptotic approximation to the solution of the Fokker–Planck equation (FPE) and to the escape problem in high dimensions.

Consider the autonomous multidimensional system

$$\frac{d\boldsymbol{x}}{dt} = \boldsymbol{a}(\boldsymbol{x}) + \sqrt{2\varepsilon}\,\boldsymbol{b}(\boldsymbol{x})\boldsymbol{\nu}(t), \tag{3.1}$$

$$\boldsymbol{x}(0) = \boldsymbol{x} \tag{3.2}$$

in a domain D in $\boldsymbol{R}^n$ for piecewise smooth flows (vector fields) $\boldsymbol{a}(\boldsymbol{x})$ and an $n \times m$ noise matrix $\boldsymbol{b}(\boldsymbol{x})$. Here $\boldsymbol{\nu}(t)$ is a vector of m independent standard Gaussian white noises [26]. We assume that the noiseless dynamics

$$\dot{\boldsymbol{x}} = \boldsymbol{a}(\boldsymbol{x}) \tag{3.3}$$

has a unique critical point $\boldsymbol{x}_0$ in D and that it is a global attractor in D. This means that

$$\boldsymbol{a}(\boldsymbol{x}_0) = \boldsymbol{0},$$

and we assume that the eigenvalues of the matrix

$$\boldsymbol{A} = \left\{ \frac{\partial a^i(\boldsymbol{x}_0)}{\partial x^j} \right\}_{i,j=1}^{n} \tag{3.4}$$

of the linearized system

$$\dot{\boldsymbol{z}} = \boldsymbol{A}\boldsymbol{z} \tag{3.5}$$

have negative real parts. Thus the trajectories of the system (3.3) that start in D cannot reach the boundary ∂D.

The FPE for the stationary probability density function $p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x})$ of the solution $\boldsymbol{x}(t, \varepsilon)$ of (3.1), (3.2), with a source at $\boldsymbol{x}$ and absorption in ∂D, is [34]

$$-\sum_{i=1}^{n} \frac{\partial}{\partial y^i} \left[a^i(\boldsymbol{y}) p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x}) \right] + \sum_{i,j=1}^{n} \varepsilon \frac{\partial^2}{\partial y^i \partial y^j} \left[\sigma^{i,j}(\boldsymbol{y}) p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x}) \right] = -\delta(\boldsymbol{y} - \boldsymbol{x}) \tag{3.6}$$

with the boundary condition

$$p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x}) \,|\, _{\boldsymbol{x} \in D, \boldsymbol{y} \in \partial D} = 0,$$

where

$$\boldsymbol{\sigma}(\boldsymbol{y}) = \boldsymbol{b}(\boldsymbol{y}) \boldsymbol{b}^T(\boldsymbol{y}).$$

The function $p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x})$ develops singularities in the domain and on its boundary as $\varepsilon \to 0$. We resolve these singularities by constructing an approximate solution that contains all the singularities of $p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x})$ at $\varepsilon = 0$. First, we transform the FPE (3.6) by seeking a solution in the WKB form

$$p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x}) = K_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x}) \exp\left\{ -\frac{\Psi(\boldsymbol{y})}{\varepsilon} \right\}, \tag{3.7}$$

where $K_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x})$ has an asymptotic series expansion in powers of ε for $\boldsymbol{x}$ in the domain and $\Psi(\boldsymbol{y})$ is a regular function. The asymptotic approximation to the MFPT for small ε is given by

$$\bar{\tau}(\boldsymbol{x}) = C(\varepsilon) \exp\left\{ \frac{\hat{\Psi}}{\varepsilon} \right\} (1 + o(1)), \tag{3.8}$$

where $C(\varepsilon)$ has an asymptotic series expansion in powers of ε and $\hat{\Psi}$ is the minimum of the eikonal function $\Psi(\boldsymbol{x})$ on the boundary of the domain of attraction of the stable equilibrium point $\boldsymbol{x}_0$. Equation (3.8) indicates that to leading order $\bar{\tau}(\boldsymbol{x})$ is independent of $\boldsymbol{x}$.

The essential singularity of $p_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x})$ inside D is captured by the exponential term in (3.7) and that on ∂D by the preexponential factor $K_\varepsilon(\boldsymbol{y} \,|\, \boldsymbol{x})$. Substituting (3.7)

in (3.6) and collecting like powers of ε, we obtain at the leading order the first order *eikonal equation*

$$\sum_{i,j=1}^{n} \sigma^{i,j}(\boldsymbol{y}) \frac{\partial \Psi(\boldsymbol{y})}{\partial y^i} \frac{\partial \Psi(\boldsymbol{y})}{\partial y^j} + \sum_{i=1}^{n} a^i(\boldsymbol{y}) \frac{\partial \Psi(\boldsymbol{y})}{\partial y^i} = 0. \tag{3.9}$$

The eikonal equation has the form of a Hamilton–Jacobi equation [37] and is solved by the method of characteristics [38], [39]. Setting $\boldsymbol{p} = \nabla \Psi(\boldsymbol{x})$, (3.9) becomes

$$\sum_{i,j=1}^{n} \sigma^{i,j}(\boldsymbol{x}) p^i p^j + \sum_{i=1}^{n} a^i(\boldsymbol{x}) p^i = 0,$$

and the characteristic equations (or rays [33]) are the solutions of

$$\frac{d\boldsymbol{x}}{ds} = 2\boldsymbol{\sigma}(\boldsymbol{x})\boldsymbol{p} + \boldsymbol{a}(\boldsymbol{x}), \tag{3.10}$$

$$\frac{d\boldsymbol{p}}{ds} = -\nabla_{\boldsymbol{x}} \boldsymbol{p}^T \boldsymbol{\sigma}(\boldsymbol{x})\boldsymbol{p} - \nabla_{\boldsymbol{x}} \boldsymbol{a}^T(\boldsymbol{x})\boldsymbol{p}, \tag{3.11}$$

$$\frac{d\Psi}{ds} = \boldsymbol{p}^T \boldsymbol{\sigma}(\boldsymbol{x})\boldsymbol{p}. \tag{3.12}$$

Since the rays that begin near the attractor $(\boldsymbol{x}_0, \boldsymbol{0})$ diverge, we can cover the domain of attraction of $(\boldsymbol{x}_0, \boldsymbol{0})$ with rays emanating from a small neighborhood of $(\boldsymbol{x}_0, \boldsymbol{0})$. To integrate the characteristic equations (3.10), (3.11), initial conditions can be imposed near the attractor $(\boldsymbol{x}_0, \boldsymbol{0})$ by constructing $\Psi(\boldsymbol{x})$ in the form of a power series. The truncation of the power series near the attractor provides an approximation to $\Psi(\boldsymbol{x})$ and to $\boldsymbol{p} = \nabla \Psi(\boldsymbol{x})$, whose error can be made arbitrarily small. Expanding the functions $\Psi(\boldsymbol{x})$, $\boldsymbol{a}(\boldsymbol{x})$, and $\boldsymbol{\sigma}(\boldsymbol{x})$ in powers of $\boldsymbol{z} = \boldsymbol{x} - \boldsymbol{x}_0$, we find from the eikonal equation (3.9) that $\nabla \Psi(\boldsymbol{x}_0) = \boldsymbol{0}$, so that the power series expansion of $\Psi(\boldsymbol{x})$ begins as a quadratic form

$$\Psi(\boldsymbol{x}) = \frac{1}{2} \boldsymbol{x}^T \boldsymbol{Q} \boldsymbol{x} + o\left(|\boldsymbol{x}|^2\right) \tag{3.13}$$

and $\boldsymbol{Q}$ is the solution of the Riccati equation [36]

$$2\boldsymbol{Q}\boldsymbol{\sigma}(\boldsymbol{x}_0)\boldsymbol{Q} + \boldsymbol{Q}\boldsymbol{A} + \boldsymbol{A}^T\boldsymbol{Q} = \boldsymbol{0}. \tag{3.14}$$

Obviously, the first term in the power series expansion of $\boldsymbol{p}$ is given by

$$\boldsymbol{p} = \boldsymbol{Q}\boldsymbol{x} + O\left(|\boldsymbol{x}|^2\right). \tag{3.15}$$

Taking the contour

$$\frac{1}{2} \boldsymbol{x}^T \boldsymbol{Q} \boldsymbol{x} = \delta, \tag{3.16}$$

for some small positive δ, as the initial surface for the system (3.10)–(3.12) and using the approximate initial values $\Psi(\boldsymbol{x}) = \delta$ and (3.15) at each point of the surface, we can integrate the system (3.10)–(3.12) analytically or numerically. Once the domain D is covered with characteristics, the approximate value of $\Psi(\boldsymbol{x})$ can be determined

at each point $\boldsymbol{x} \in D$ as the value of the solution $\Psi(s)$ of (3.12) at s, such that the solution of (3.10) satisfies

$$\boldsymbol{x}(s) = \boldsymbol{x}. \tag{3.17}$$

The initial condition on the surface (3.16) determines the unique trajectory of the system (3.10)–(3.12) that satisfies (3.17) for some s. It can be found numerically by the method of shooting.

4. The exit problem for the DLL. The eikonal equation (3.9) corresponding to the stochastic system (2.14) is given by

(4.1)

$$\begin{aligned} H = &\left(-\frac{a}{\sqrt{2P}K}\beta - S(e) + \frac{\phi_n}{\sqrt{2P}K}\right)\frac{\partial\Psi}{\partial e} + \left(S(e) - \frac{T''}{2}\right)\frac{\partial\Psi}{\partial\beta} \\ &+ \frac{1}{\sqrt{2P}K}\sum_{i=1}^{N}\left(y_{2i} - 4\sum_{l=1}^{N-i} l y_{2(N-l+1)} + 2(N-i+1)\left(-\phi_n - 2\sum_{l=1}^{i} y_{2l}\right)\right)\frac{\partial\Psi}{\partial y_{2i}} \\ &+ \frac{1}{\sqrt{2P}K}\left(-(2N+1)\phi_n - 4\sum_{l=1}^{N} l y_{2(N-l+1)}\right)\frac{\partial\Psi}{\partial\phi_n} \\ &+ \left(\sum_{l=1}^{N} 2(N-l+1)\frac{\partial\Psi}{\partial y_{2l}} + 2(N+1)\frac{\partial\Psi}{\partial\phi_n}\right)^2 + \left(-K\sqrt{\frac{N_{th}}{N_{ph}}}\frac{\partial\Psi}{\partial e} + K\sqrt{\frac{N_{th}}{N_{ph}}}\frac{\partial\Psi}{\partial\beta}\right)^2 \\ &= 0. \end{aligned}$$

The solution in the slab $-1/2 \le e \le 1/2$, corresponding to the linear part of the S-curve (see Figure 2), is the quadratic form (3.13), determined by the solution to Lyapunov's (Riccati's) equation (3.14). The system in the linear region can be written as

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{A}\boldsymbol{x}(t) + \boldsymbol{B}\boldsymbol{\nu}(t), \tag{4.2}$$

where $\boldsymbol{\nu}(t)$ is a standard Gaussian white noise vector composed of the uncorrelated white noises $w(t)$ and $\nu(t)$ in (2.14) and the matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are given by

$$\boldsymbol{A} = \frac{1}{\sqrt{2P}K} \times \begin{bmatrix} -2\sqrt{2P}K & -a & 0 & 0 & 0 & 0 & \cdots & 0 & -1 \\ 2\sqrt{2P}K & 0 & 0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & -3 & -4 & -4 & -4 & \cdots & -4 & -2 \\ 0 & 0 & -4 & -7 & -8 & -8 & \cdots & -8 & -4 \\ 0 & 0 & -4 & -8 & -11 & -12 & \cdots & -12 & -6 \\ \vdots & & & & & & & & \\ 0 & 0 & -4 & -8 & -12 & \cdots & -4(N-1) & -4N-1 & -2N \\ 0 & 0 & -4 & -8 & -12 & -16 & \cdots & -4N & -2N-1 \end{bmatrix}$$

and

$$\boldsymbol{B}^T = \sqrt{\frac{N_{ph}}{2K\sqrt{2P}}} \begin{bmatrix} -K\sqrt{\frac{N_{th}}{N_{ph}}} & K\sqrt{\frac{N_{th}}{N_{ph}}} & 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 2 & 4 & \cdots & 2N & 2(N+1) \end{bmatrix},$$

respectively. The explicit solution of (3.14) can be obtained by using standard symbolic mathematical packages such as Maple or Mathematica.

To solve (4.1) outside the strip $|e| < 1/2$, we use the method of characteristics, as described in section 3 above. We define the components of the vector $\boldsymbol{p}$ by the equations

$$p = \frac{\partial \Psi}{\partial e}, \quad q = \frac{\partial \Psi}{\partial \beta}, \quad \alpha_1 = \frac{\partial \Psi}{\partial y_2}, \quad \alpha_2 = \frac{\partial \Psi}{\partial y_4}, \quad \ldots, \quad \alpha_N = \frac{\partial \Psi}{\partial y_{2N}}, \quad r = \frac{\partial \Psi}{\partial \phi_n}.$$

Now, taking the total derivative of H with respect to time, we get

$$\begin{aligned} \frac{dH}{dt} = 0 = {} & \frac{\partial H}{\partial e}\frac{de}{dt} + \frac{\partial H}{\partial \beta}\frac{d\beta}{dt} + \frac{\partial H}{\partial \phi_n}\frac{d\phi_n}{dt} \\ & + \sum_{i=1}^{N} \frac{\partial H}{\partial y_{2i}}\frac{dy_{2i}}{dt} + \frac{\partial H}{\partial p}\frac{dp}{dt} + \frac{\partial H}{\partial q}\frac{dq}{dt} + \frac{\partial H}{\partial r}\frac{dr}{dt} + \sum_{i=1}^{N} \frac{\partial H}{\partial \alpha_i}\frac{d\alpha_i}{dt}. \end{aligned} \tag{4.3}$$

The characteristic equations (3.10)–(3.12) are given by

$$\begin{aligned} & \frac{de}{dt} = \frac{\partial H}{\partial p}, \quad \frac{dp}{dt} = -\frac{\partial H}{\partial e}, \quad \frac{d\beta}{dt} = \frac{\partial H}{\partial q}, \quad \frac{dq}{dt} = -\frac{\partial H}{\partial \beta}, \\ & \frac{dy_2}{dt} = \frac{\partial H}{\partial \alpha_1}, \quad \frac{d\alpha_1}{dt} = -\frac{\partial H}{\partial y_2}, \quad \frac{dy_4}{dt} = \frac{\partial H}{\partial \alpha_2}, \quad \frac{d\alpha_2}{dt} = -\frac{\partial H}{\partial y_4}, \\ & \qquad \vdots \\ & \frac{dy_{2N}}{dt} = \frac{\partial H}{\partial \alpha_N}, \quad \frac{d\alpha_N}{dt} = -\frac{\partial H}{\partial y_{2N}}, \quad \frac{d\phi_n}{dt} = \frac{\partial H}{\partial r}, \quad \frac{dr}{dt} = -\frac{\partial H}{\partial \phi_n}. \end{aligned} \tag{4.4}$$

Inserting (4.1) and (4.3) into (4.4), we get

$$\begin{aligned} \frac{de}{dt} = {} & -\frac{a}{K\sqrt{2P}}\beta - S(e) + \frac{\phi_n}{K\sqrt{2P}} - 2K^2\frac{N_{th}}{N_{ph}}(-p+q), \\ \frac{d\beta}{dt} = {} & S(e) - T'' + 2K^2\frac{N_{th}}{N_{ph}}(-p+q), \\ \frac{dy_{2i}}{dt} = {} & \frac{1}{K\sqrt{2P}}\left\{ y_{2i} - 4\sum_{l=1}^{N-i} l y_{2(N-l+1)} - 2(N-i+1)\left(\phi_n + 2\sum_{l=1}^{i} y_{2l}\right)\right\} \\ & + 4(N-i+1)\left(\sum_{l=1}^{N} 2(N-l+1)\alpha_l + 2(N+1)r\right) \quad \text{for all } 1 \le i \le N, \end{aligned} \tag{4.5}$$

$$\frac{d\phi_n}{dt} = \frac{1}{K\sqrt{2P}}\left\{-(2N+1)\,\phi_n - \sum_{l=1}^{N} 4l y_{2(N-l+1)}\right\}$$
$$+ 4(N+1)\left(\sum_{l=1}^{N} 2(N-l+1)\alpha_l + 2(N+1)\,r\right),$$
$$\frac{dp}{dt} = (p-q)\,S'(e),$$
$$\frac{dq}{dt} = \frac{a}{K\sqrt{2P}}p$$

and

$$\frac{d\alpha_i}{dt} = -\frac{1}{K\sqrt{2P}}\left\{\alpha_i - 4\sum_{l=i+1}^{N}(N-l+1)\,\alpha_l - 4(N-i+1)\sum_{l=1}^{i}\alpha_i\right\}$$
$$+ \frac{r}{K\sqrt{2P}}4(N-i+1) \quad \text{for all } 1 \le i \le N,$$
$$\frac{dr}{dt} = -\frac{p}{K\sqrt{2P}} + \frac{1}{K\sqrt{2P}}\sum_{i=1}^{N} 2(N-i+1)\,\alpha_i + \frac{r}{K\sqrt{2P}}(2N+1).$$

To complete the solution of (4.1), we must show that $H = 0$ for at least one point. Taking the total derivative $\frac{d\Psi}{dt}$ along a characteristic, and using (4.1) and (4.5), we get

$$\frac{d\Psi}{dt} = \frac{\partial\Psi}{\partial e}\frac{de}{dt} + \frac{\partial\Psi}{\partial\beta}\frac{d\beta}{dt} + \frac{\partial\Psi}{\partial\phi_n}\frac{d\phi_n}{dt} + \sum_{i=1}^{N}\frac{\partial\Psi}{\partial y_{2i}}\frac{dy_{2i}}{dt} \tag{4.6}$$
$$= H + \sum_{i=1}^{N} 2(N-i+1)\,\alpha_i\left(\sum_{l=1}^{N} 2(N-l+1)\,\alpha_l + 2(N+1)\,r\right)$$
$$+ 2(N+1)\left(\sum_{l=1}^{N} 2(N-l+1)\,\alpha_l + 2(N+1)\,r\right) r$$
$$= H + \left(\sum_{l=1}^{N} 2(N-l+1)\,\alpha_l + 2(N+1)\,r\right)^2.$$

Thus, $H = 0$ if

$$\frac{d\Psi}{dt} = \left(\sum_{l=1}^{N} 2(N-l+1)\,\alpha_l + 2(N+1)\,r\right)^2 + K^2\frac{N_{th}}{N_{ph}}(-p+q)^2. \tag{4.7}$$

Equations (4.5) and (4.7) represent the solution of (4.1) on each characteristic curve. The boundary ∂D is spanned by characteristic curves that converge to the saddle point, and Ψ decreases on each characteristic to its value $\hat{\Psi}$ at the saddle point [26].

5. The MTLL in a second order DLL with $1/f^3$ phase noise. The S-curve $S(e)$ for a DLL is given in Figure 2. The stable equilibrium point of the system, in the

absence of relative motion between the transmitter and the receiver, is the point where the S-curve vanishes with positive slope, and the two unstable equilibrium points (the saddle points) are the points where it vanishes with negative slopes. In case there is relative motion with constant acceleration $\ddot{T}$ (see (2.13)), the equilibrium points of the dynamics (2.14) are the points where the S-curve intersects the line $S = T''$ (see Figure 2). For $\ddot{T} \neq 0$ there are one stable equilibrium point and one unstable equilibrium point, given by (2.15) and (2.16), respectively.

The minimum value $\hat{\Psi}$ determines the leading order term (or small ρ exponential growth rate) of the MTLL (see (3.8)), so we have to determine it by finding the characteristic that hits the saddle point and the limiting value of Ψ there. To this end, we start the characteristic on the hyperplane $e = 1/2$, where Ψ is given explicitly by (3.13). Since the characteristic equations are linear in the half-space to the right of the hyperplane $e = 1/2$, all characteristics diverge exponentially fast, except one that corresponds to the only negative eigenvalue of the system matrix (see below). Thus, the starting point of the desired characteristic is the column corresponding to this eigenvalue in the matrix that reduces the system matrix into its Jordan canonical form.

Specifically, we observe in (4.5) and (4.7) that the quasi-potential Ψ is dependent only on the variables $\{p, q, \boldsymbol{\alpha}, r\}$. We define the state vector

$$\boldsymbol{v} = \{p, q, \boldsymbol{\alpha}, r\}^T. \tag{5.1}$$

In the strip $|e| < 1/2$ the S-curve is linear so that the system (4.5) is linear, and with the notation (5.1) it can be written as

$$\dot{\boldsymbol{v}} = \boldsymbol{M}\boldsymbol{v}. \tag{5.2}$$

Since we are looking for the minimum $\hat{\Psi} = \Psi(\boldsymbol{x}_b)$, and $\boldsymbol{x}_b$ is the saddle point of the system (2.14), we need only find the starting point of the characteristic that hits the saddle point (2.16). In the linear strip $|e| < 1/2$ we can use (3.13) and start shooting characteristic trajectories (4.4) from the hyperplane $e = 1/2$. For clarity, we explain the method for finding $\hat{\Psi}$ by considering the simplest case of a noise approximation of order $N = 1$, loop parameters $P = 1/2$, $K = a = 1$, and without thermal noise ($N_{th} = 0$). For these parameters the value of $\Psi(\boldsymbol{x})$ in the linear domain $|e| < 1/2$ is given by

$$\begin{aligned}\Psi(\boldsymbol{x}) = \frac{1}{64}\Bigg\{ & -424\phi_n e + 1408 y_2\beta + 832 y_2 e - 704 y_2\phi_n + 900\beta\frac{\ddot{T}}{T_c} \\ & + 388 e\frac{\ddot{T}}{T_c} + 784 e\beta - 436\phi_n\frac{\ddot{T}}{T_c} - 648\phi_n\beta + 992 y_2\frac{\ddot{T}}{T_c} + 646\beta^2 + 792 y_2^2 \\ & + 170\phi_n^2 + 396 e^2 + 353\left(\frac{\ddot{T}}{T_c}\right)^2\Bigg\}.\end{aligned} \tag{5.3}$$

The coordinate of the point on the hyperplane $e = 1/2$, where the shooting begins, is denoted by $\boldsymbol{v}_0$. It is chosen as the coordinate $(\beta_0, \boldsymbol{y}_0, \phi_{n,0})$ of a point on the unique stable characteristic trajectory of (5.2). We write (5.2) in the linear domain $e \geq 1/2$ as the linear system

$$\dot{\boldsymbol{u}} = \boldsymbol{\Lambda}\boldsymbol{u}, \tag{5.4}$$

where $\boldsymbol{\Lambda}$ is diagonal with the eigenvalues of $\boldsymbol{M}$ on its diagonal. We can write

$$\boldsymbol{v} = \boldsymbol{P}\boldsymbol{u}, \quad \boldsymbol{\Lambda} = \boldsymbol{P}^{-1}\boldsymbol{M}\boldsymbol{P}. \tag{5.5}$$

The columns of $\boldsymbol{P}$ are the eigenvectors of the matrix $\boldsymbol{M}$ with respect to the eigenvalues on the diagonal $\boldsymbol{\Lambda}$. The matrix $\boldsymbol{M}$ has only one negative eigenvalue,

$$\lambda_1 = -\frac{1}{2} - \frac{\sqrt{5}}{2}, \tag{5.6}$$

and thus only the eigenvector corresponding to that eigenvalue leads to a stable solution of (5.4). Assuming that the negative eigenvalue is the first element in $\boldsymbol{\Lambda}$, we need only take the first element in $\boldsymbol{u}$, replacing the others by zeros.

The initial values are defined by

$$p_0 = \frac{\partial \Psi(1/2,\, \beta_0, \boldsymbol{y}_0, \phi_{n,0})}{\partial e}, \quad q_0 = \frac{\partial \Psi(1/2,\, \beta_0, \boldsymbol{y}_0, \phi_{n,0})}{\partial z}, \tag{5.7}$$

$$r_0 = \frac{\partial \Psi(1/2,\, \beta_0, \boldsymbol{y}_0, \phi_{n,0})}{\partial r}, \quad \boldsymbol{\alpha}_{i,0} = \frac{\partial \Psi(1/2,\, \beta_0, \boldsymbol{y}_0, \phi_{n,0})}{\partial y_{2i}} \quad \text{for all } 1 \le i \le N.$$

Using (5.3), (5.6), and (5.7), we get

$$p_0 = -\left(\frac{11}{8} + \frac{7}{8}\sqrt{5}\right) u_{1,0}, \quad q_0 = \left(\frac{3}{2} + \frac{\sqrt{5}}{4}\right) u_{1,0},$$

$$r_0 = -\left(\frac{7}{8} + \frac{\sqrt{5}}{8}\right) u_{1,0}, \quad \alpha_{1,0} = u_{1,0}. \tag{5.8}$$

It follows from (5.4) that $u_1 = u_{1,0} \exp\{\lambda_1 \tilde{t}\}$. Now, we can solve for the initial conditions $(\beta_0, y_0, \phi_{n,0})$ from equations (5.3), (5.7), and (5.8). Having found the initial conditions, we can proceed to integrate (4.7) to find the minimal value $\hat{\Psi}$ on ∂D,

$$\hat{\Psi} = \Psi(1/2,\, \beta_0, \boldsymbol{y}_0, \phi_{n,0}) + 4 \int_0^\infty \left\{ \sum_{l=1}^{N} (N - l + 1)\alpha_l(t) + (N+1) r(t) \right\}^2 dt, \tag{5.9}$$

where $\alpha_l(t)$ and $r(t)$ are calculated on the characteristic that starts at $(1/2,\, \beta_0,\, \boldsymbol{y}_0,\, \phi_{n,0})$. For the case of zero acceleration between transmitter and receiver, i.e., $\ddot{T}/T_c = 0$, we get $\hat{\Psi} = 0.9120$. The analogous computation for Nth order approximations can be done by solving the Lyapunov equation numerically or symbolically (e.g., with Maple or Mathematica), finding the negative eigenvalue, and determining the matrix $\boldsymbol{P}$. This was done with the results in Table 1. As can be seen in Table 1, the minimum value $\hat{\Psi}$ changes very slightly for $N \ge 5$. Thus, approximation of order $N = 5$ for the noise is sufficient for the calculation of the MTLL of 100–1000 seconds. This range of values of the MTLL is chosen because for MTLL less than 100 seconds the leading order approximation is insufficient. The problem of optimizing the MTLL is most critical at low CNR, where the majority of losses of lock occur and the MTLL is still below 1000 seconds. The MTLL increases exponentially with the CNR, so higher accuracy of $\hat{\Psi}$ is needed. Long MTLLs are of less interest in the optimization process. The range of validity of the leading order approximation is for values of the CNR

TABLE 1
$\hat{\Psi}$ *and MTLL for different* N.

that result in $\rho \ll \hat{\Psi}$. We have disregarded the preexponential factor in (3.8) because the main contribution to the MTLL comes from the exponential term. Furthermore, since we assume a constant prefactor, the results of the simulations might be slightly displaced from the theoretical line. The prefactor can be resolved by simulations for small MTLL and then applied to large MTLL, where simulations are impractical. Our derivation results in a single quantity in an asymptotic expansion. This result is the exponential growth rate of MTLL as the dimensionless noise strength ρ tends to zero.

This can be understood as follows. The loop's noise equivalent bandwidth is 1/2Hz, which is much smaller than the region of validity of the truncated continued fraction approximation to $1/f$. Furthermore, for MTLL of the order of 100–1000 seconds, the corresponding frequency range is $10^{-3}\text{Hz} \leq f \leq 10^{-2}\text{Hz}$. Since the region of validity of the approximation for $N = 5$ is in the range $10^{-3}\text{Hz} \leq f \leq 10\text{Hz}$ (Figure 3), it is understandable that using the approximation for the $1/f$ noise with $N = 5$ results in an accurate value of $\hat{\Psi}$, which in turn accurately approximates the exponential growth rate of the MTLL.

In general one would expect that as more phase noise enters the DLL, the MTLL will become smaller. In Figure 3 we see that as the approximation order becomes larger, more energy enters at very low and very high frequencies. However, we see in Table 1 that $\hat{\Psi}$ actually increases monotonically for $N \geq 2$. The answer to this paradox can be solved by taking a closer look at the transfer function of our $1/f$ approximation. Before flattening out below a certain low frequency, the transfer function displays a "knee" that is above the $1/f$ curve. Further, for a specific MTLL only frequencies larger than 1/MTLL need be considered and only frequencies smaller than the loop's bandwidth should be accounted for. In this frequency band the noise entering the loop actually decreases as the phase noise approximation order is increased, since the "knee" moves to lower frequencies that are irrelevant to the problem at hand. For example, let us consider an MTLL of 100 seconds. The frequency band in question is $0.01 \leq f \leq 0.5$. In Table 2 the energy in the $0.01 \leq f \leq 0.5$ frequency band is given for different approximation orders N. Since for $N < 6$ the "knee" is above $f = 0.01$Hz, the decrease in energy for increasing N explains the increasing $\hat{\Psi}$. From Table 1 we learn that for $N \geq 6$ the changes in $\hat{\Psi}$ result in an insignificant rise in MTLL. In fact, the difference between MTLL for CNR that gives MTLL of 100 seconds for approximation order $N = 6$ and MTLL given for approximation order $N = 30$ with the same CNR is less than 0.1%.

Next we present Monte-Carlo results of the MTLL for approximation of order $N = 5$ compared to the analytic MTLL calculated above for that order of approximation

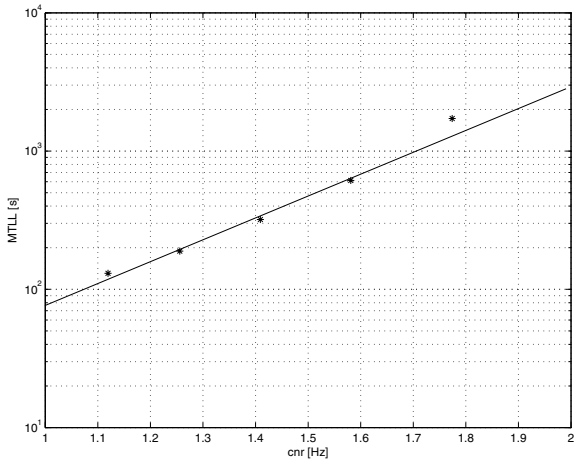

FIG. 4. *The MTLL of a second order DLL under the influence of* $1/f^3$ *noise approximation of order* $N = 5$. *The loop parameters were taken as* $P = 1/2, a = K = 1$. *The solid line is the derived analytic leading order of the MTLL, and the asterisks denote the Monte-Carlo results (each asterisk represents the mean result of* 50 *trials).*

(see Figure 4). Furthermore, Monte-Carlo results of the MTLL under the influence of exact $1/f$ discrete noise generated according to [20] are presented along with the results of the MTLL under the influence of $1/f$ noise approximation with $N = 20$ in Figure 5.

Figures 4 and 5 show that the analytic calculation of the leading order term of the MTLL results in a model that fits well the Monte-Carlo results. Furthermore, the similarity of the analytic calculation of the leading order term of the MTLL to those calculated via Monte-Carlo trials under the influence of exact discrete $1/f$ proves that the truncation of our model with the appropriate N provides very accurate results for the calculation of the MTLL for the second order DLL. The dependence of the loop's parameters on the power P can be eliminated by a proper AGC (automatic gain control) loop.

6. Discussion and conclusions. First, we apply the results to the optimization of the loop's parameters by finding the values of a and K that yield the maximum $\hat{\Psi}$. In our case it turns out that the best result is obtained in the limit $K \to \infty$. This can be easily derived analytically and is quite predictable from (2.14). In a real system

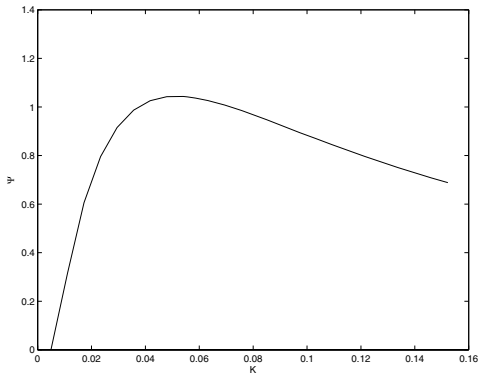

FIG. 6. *Optimizing for loop filter parameter* K *for* $a = 100$.

with additive channel thermal noise, increasing K will increase the thermal noise entering the loop, thus limiting the profitability of increasing K. We also analyzed the case with additive thermal noise by choosing $N_{th} = \frac{N_{ph}}{10}$, $P = \frac{1}{2}$, and $\ddot{T} = 0.5$. It is clear from (2.14) that for the system to remain stable the condition $aK \geq \frac{\ddot{T}}{\sqrt{2P}T_c}$ has to be satisfied, which simplifies in our case to $aK \geq \frac{1}{2}$. It turns out that for every a there is a $K_{opt}(a)$ that maximizes $\hat{\Psi}$. We found that $\hat{\Psi}$ increases monotonically as a increases, but only to a very slight extent, e.g., beyond $a = 100$. In a real system the loop filter coefficients cannot be chosen arbitrarily large, and thus a has to be chosen as large as possible for any given realizable K. Finally, a graph showing $\hat{\Psi}$ for $a = 100$ is given in Figure 6.

In summary, we give here the first analytic approach to the determination of the effects of $1/f^3$ noise on the leading order term for the MTLL of a second order DLL. The analytic derivation of the leading term in a small noise expansion of the MTLL makes it possible to find the loop parameters that maximize the leading order term

of the MTLL. The concept outlined in this paper can be further applied to other tracking loops, such as the commonly used PLL. It sets the foundation for a more complete analysis, to be explored in a future investigation of a comprehensive model that includes additional elements of phase noise ($1/f^2$, $1/f$, and flat segment).

MOMENTS OF THE INVERSE SCATTERING OPERATOR OF THE BOLTZMANN EQUATION: THEORY AND APPLICATIONS*

S. C. BRUGGER†, A. SCHENK†, AND W. FICHTNER†

Abstract. In this paper useful physical objects called moments of the inverse scattering operator (MISO) of the Boltzmann equation (BE) are studied. The existence and uniqueness of the MISO is proven and a simple, generally valid, iterative scheme to actually compute those objects is given. The applications of the MISO extend from the computation of the solution for the space-homogeneous BE for small electric and magnetic fields to the exact computation of any transport parameter. This can be done for all moments of the space-inhomogeneous BE and for arbitrary electric and magnetic field intensities. The concept of MISO offers an elegant way to avoid the relaxation time approximation (RTA) every time it comes into play, not only theoretically but also in practical computations.

Key words. Boltzmann equation, transport model, beyond the relaxation time approximation, inverse scattering operator, semiconductor

1. Introduction.

In contemporary semiconductor device simulation two approaches are common: For industrial application the so-called transport models (TMs) are widely used to compute terminal currents and to perform small signal and noise analysis. On the research side, one prefers, when possible, to directly solve the space-inhomogeneous Boltzmann equation (BE) either using Monte Carlo (MC) methods or directly. The two methods often lead to different results. When trying to understand the origin of these discrepancies, one is immediately confronted with the relaxation time approximation (RTA). The RTA has been used to derive the TMs from the BE as a standard method mainly due to the lack of alternative ways to treat the problem. In the case of device simulation, it is impossible to validate the correctness of the RTA because there is no general method for directly comparing it with exact solutions.

The aim of this paper is to develop a method that avoids the RTA. It will allow, among others, the exact computation of transport parameters and noise sources for any moment of the BE using the MC method. The key feature in this formalism is the derivation and computation of moments of the inverse scattering operator (MISO). Although the formalism was primarily developed to be applied to semiconductors, it can also be used to analyze any open system described by a BE (linear or not).

The paper is organized in four sections. First, we recall the approximations in deriving a TM and point out how the knowledge of the MISO enables us to locally compare *term by term* the TM with the outcome of an MC simulation, i.e., with the solution of the BE. In section 3, we will outline the sufficient mathematical conditions under which the MISO exist, and we will present a natural way to compute them. In section 4, five useful applications are presented. First, the MISO are used to compute the solution of the space-homogeneous BE for small electric and magnetic fields. Then, transport parameters, Hall factors, and relaxation times (RTs) are computed in a very general way. At the end of the section, an exact expression is derived for

the correlation functions of the Langevin noise sources for arbitrary moments of the space-homogeneous nondegenerate BE. Finally, section 5 gives conclusions and a brief outlook on future work.

2. Direct comparison of TMs with the BE.

2.1. Derivation of TMs from the BE. The first step in the derivation of any TM from the BE

$$\partial_t f + \vec{v}\cdot\nabla_{\mathbf{r}} f - \frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}} f = Sf \tag{2.1}$$

is to introduce some kind of RT τ, which ideally should contain all information about the scattering operator (SO) S:

$$\partial_t f + \vec{v}\cdot\nabla_{\mathbf{r}} f - \frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}} f = \frac{f - \frac{n}{n_{eq}} f_{eq}}{\tau(f,\vec{r},t,\vec{k},\vec{E})}. \tag{2.2}$$

The function τ may depend on moments of the distribution function f, the position in real space $\vec{r}$, the momentum $\vec{k}$, the time t, and the electric field $\vec{E}$. Multiplying both sides of (2.2) by τ results in

$$\begin{aligned}\tau(f,\vec{r},t,\vec{k},\vec{E})\partial_t f + \tau(f,\vec{r},t,\vec{k},\vec{E})\vec{v}\cdot\nabla_{\mathbf{r}} f \\ -\tau(f,\vec{r},t,\vec{k},\vec{E})\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}} f = f - \frac{n}{n_{eq}} f_{eq}.\end{aligned} \tag{2.3}$$

In (2.1)–(2.3), f_{eq} denotes the Boltzmann distribution function normalized to one ($\int_{Bz} f_{eq}^2(\vec{k})\mathrm{d}^3k = 1$) and $n := \int_{Bz} f(\vec{k})\mathrm{d}^3k$, $n_{eq} := \int_{Bz} f_{eq}(\vec{k})\mathrm{d}^3k$, with Bz the Brillouin zone. The symbol n_{eq} is used here for convenience, although the actual equilibrium density differs from n_{eq} by a constant due to the normalization condition.

To be able to compare (2.2) and (2.3) with the exact BE (2.1), one has to invert the SO (2.4):

$$\begin{aligned}\int S^{-1}(\vec{k},\vec{k}')\partial_t f(\vec{k}')d^3k' + \int S^{-1}(\vec{k},\vec{k}')\vec{v}(\vec{k}')\cdot\nabla_{\mathbf{r}} f(\vec{k}')d^3k' \\ - \int S^{-1}(\vec{k},\vec{k}')\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}'} f(\vec{k}')d^3k' = f(\vec{k}) - \frac{n}{n_{eq}} f_{eq}(\vec{k}).\end{aligned} \tag{2.4}$$

Note that $S^{-1}\circ S \neq \mathbb{1}$! This crucial statement will be explained in detail in section 3.

RTs are introduced because the original BE (2.1) causes a major problem when one wants to derive a transport equation: The distribution function f does not appear isolated in the equation. The only term in which f is isolated is $\partial_t f$, which is the partial derivative of f by the time, which is not an equation for f. By introducing an RT τ, f appears isolated on the rhs of the equation. This is the main reason why RTs are introduced. To do the same in an exact way, the simplest possibility is to reverse the SO. This is the only possibility for expressing in an exact mathematical way what the RTA tries to achieve on a heuristic basis. In (2.2), the term $-\frac{n}{n_{eq}} f_{eq}$ was introduced phenomenologically to express the fact that at thermodynamic equilibrium the collision term disappears. The mathematical reason is, however, that the SO S has an eigenvector with eigenvalue 0, which is the equilibrium distribution f_{eq} in the case of Boltzmann statistics. Therefore, (2.4) is the rigorous mathematical formulation of what was done approximately and heuristically by introducing an RT.

The second step is to build a moment of interest of (2.3) by multiplying (2.3) by a function $g(\vec{k})$ and integrating over the momentum space,

$$\begin{aligned}(2.5)\quad &\int_{Bz}\Big[g(\vec{k})\tau(f(\vec{k},\vec{r}))\partial_t f(\vec{k},\vec{r})\Big]\mathrm{d}^3k+\int_{Bz}\Big[g(\vec{k})\tau(f(\vec{k},\vec{r}))\vec{v}(\vec{k})\cdot\nabla_{\mathbf{r}}f(\vec{k},\vec{r})\Big]\mathrm{d}^3k\\ &-\int_{Bz}\Big[g(\vec{k})\tau(f(\vec{k},\vec{r}))\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}}f(\vec{k},\vec{r})\Big]\mathrm{d}^3k=\int_{Bz}g(\vec{k})\left[f(\vec{k},\vec{r})-\frac{n}{n_{eq}}f_{eq}(\vec{k},\vec{r})\right]\mathrm{d}^3k,\end{aligned}$$

where $g(\vec{k})$ is a function in which we are interested. $g(\vec{k})$ could be, e.g., a power of the velocity.

Building moments in a similar fashion with (2.4) leads to

$$\begin{aligned}(2.6)\quad &\int_{Bz}\int_{Bz}\Big[g(\vec{k})S^{-1}(\vec{k},\vec{k}_1,\vec{r})\partial_t f(\vec{k}_1,\vec{r})\Big]\mathrm{d}^3k_1\mathrm{d}^3k\\ &\qquad+\int_{Bz}\int_{Bz}\Big[g(\vec{k})S^{-1}(\vec{k},\vec{k}_1,\vec{r})\vec{v}(\vec{k}_1)\cdot\nabla_{\mathbf{r}}f(\vec{k}_1,\vec{r})\Big]\mathrm{d}^3k_1\mathrm{d}^3k\\ &\qquad-\int_{Bz}\int_{Bz}\Big[g(\vec{k})S^{-1}(\vec{k},\vec{k}_1,\vec{r})\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k_1}}f(\vec{k}_1,\vec{r})\Big]\mathrm{d}^3k_1\mathrm{d}^3k\\ &:=\int_{Bz}S_g^{-1}(\vec{k}_1,\vec{r})\partial_t f(\vec{k}_1,\vec{r})\mathrm{d}^3k_1+\int_{Bz}S_g^{-1}(\vec{k}_1,\vec{r})\vec{v}(\vec{k}_1)\cdot\nabla_{\mathbf{r}}f(\vec{k}_1,\vec{r})\mathrm{d}^3k_1\\ &-\int_{Bz}S_g^{-1}(\vec{k}_1,\vec{r})\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k_1}}f(\vec{k}_1,\vec{r})\mathrm{d}^3k_1=\int_{Bz}g(\vec{k})\left[f(\vec{k},\vec{r})-\frac{n}{n_{eq}}f_{eq}(\vec{k},\vec{r})\right]\mathrm{d}^3k,\end{aligned}$$

where

$$(2.7)\qquad S_g^{-1}(\vec{k}_1,\vec{r})=\int_{Bz}g(\vec{k})S^{-1}(\vec{k},\vec{k}_1,\vec{r})\mathrm{d}^3k$$

is a moment of the inverse scattering operator (ISO) in (2.5).

The third step is to perform a partial integration of the **k**-gradient term in (2.5) and to neglect the boundary term

$$(2.8)\qquad \int_{Bz}g(\vec{k})\tau(f(\vec{k},\vec{r}))\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}}f(\vec{k},\vec{r})\mathrm{d}^3k\simeq-\frac{q}{\hbar}\vec{E}\cdot\int_{Bz}\nabla_{\mathbf{k}}(g(\vec{k})\tau(f(\vec{k},\vec{r})))f(\vec{k},\vec{r})\mathrm{d}^3k.$$

Because the function $S_g^{-1}(\vec{k}_1,\vec{r})$ can be discontinuous in some points (for some silicon MC models, this happens on the boundary surfaces between two valleys), we cannot exactly transform the **k**-gradient term of (2.6) as in (2.8). Instead we have to decompose the domain Bz into subdomains, where the function $S_g^{-1}(\vec{k}_1,\vec{r})$ is continuous, and keep all the boundary terms, which in general will not disappear, as follows:

$$\begin{aligned}(2.9)\quad &\sum_i\int_{Bz_i}S_g^{-1}(\vec{k},\vec{r})\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}}f(\vec{k},\vec{r})\mathrm{d}^3k\\ &=-\frac{q}{\hbar}\vec{E}\cdot\sum_i\int_{Bz_i}\nabla_{\mathbf{k}}(S_g^{-1}(\vec{k},\vec{r}))f(\vec{k},\vec{r})\mathrm{d}^3k+\frac{q}{\hbar}\vec{E}\cdot\sum_i\oint_{\partial Bz_i}S_g^{-1}(\vec{k},\vec{r})f(\vec{k},\vec{r})\vec{n}\mathrm{da},\end{aligned}$$

where $\bigcup_i Bz_i=Bz$.

The boundary term $\sum_i\oint_{\partial Bz_i}S_g^{-1}(\vec{k},\vec{r})f(\vec{k},\vec{r})\vec{n}\mathrm{d}a$ does not vanish. To our knowledge it has never been investigated numerically whether this term is negligible for all

moments and for all field strengths of practical interest, e.g., for bulk silicon. We will therefore keep this term in our numerical analysis.

To derive common TMs, only a small number of functions g is relevant. For the drift-diffusion (DD) model, only the moment corresponding to $g_1 = \vec{v}$ is needed. The hydrodynamic model is obtained by considering the moments $g_1 = \vec{v}$, $g_2 = \epsilon$ (where $\epsilon(\vec{k})$ is the energy) or $||v||^2$ and $g_3 = \tau g_2 \vec{v}$. Finally, for the so-called six moments method (see [6]), the additional moments $g_4 = \epsilon^2$ and $g_5 = \tau g_4 \vec{v}$ are considered. These moments equations, together with the Poisson equation and the current continuity equation (the contraction of the BE with the constant function 1), constitute a TM that should approximate the solution to the BE coupled with the Poisson equation. These equations are usually parametrized using the electrostatic potential, the particle density(ies), and the mean value of g_2 and g_4. To close this system, further steps are needed: The g_3 (resp., g_5) moment is inserted into the $\nabla_{\mathbf{r}}$ term of the g_2 (resp., g_4) moment and approximations are done, such as the use of the Einstein relation, the replacement of tensorial transport coefficients by scalars, and the use of a closure relation for the last moment (see, e.g., [13], [3], [1], [12]). Finally, all expressions still unknown are called transport coefficients and computed using a model (analytical and/or bulk MC simulation) and parametrized by the functions listed above.

2.2. Transport parameters. In order to illustrate potential applications of the outlined concept, we directly compare the moments of well-known macroscopic TMs, such as the DD model and the energy-balance (EB) model (see, e.g., [12, Chap. 1.1.3]), with the corresponding terms from the BE containing the exact ISO. The equation for the current in the DD model reads

$$\tau_p \partial_t(\langle \vec{v} \rangle) - \mu n \vec{E} - D \nabla_{\mathbf{r}} n = \langle \vec{v} \rangle =: -\frac{\vec{J}}{q}, \tag{2.10}$$

where τ_p is the momentum RT, μ the mobility tensor, D the diffusivity tensor, n the density, and $\langle \vec{v} \rangle := \int_{Bz} \vec{v} f \mathrm{d}^3 k$ ($\langle \vec{v} \rangle / n$ is the mean velocity).

If we compare term by term the lhs of (2.10) with the lhs of (2.6), we find the following conditions for the DD model to be exact:

$$\tau_p \partial_t(\langle v_i \rangle) \stackrel{!}{=} \int_{Bz} S_{v_i}^{-1}(\vec{k}_1, \vec{r}) \partial_t f(\vec{k}_1, \vec{r}) \mathrm{d}^3 k_1, \quad i = 1, \ldots, 3, \tag{2.11}$$

$$\left(\mu n \vec{E}\right)_i \stackrel{!}{=} -\frac{q}{\hbar} \vec{E} \cdot \int_{Bz} \nabla_{\mathbf{k}} (S_{v_i}^{-1}(\vec{k}, \vec{r})) f(\vec{k}, \vec{r}) \mathrm{d}^3 k + \frac{q}{\hbar} \vec{E} \cdot \sum_j \oint_{\partial Bz_j} S_{v_i}^{-1}(\vec{k}, \vec{r}) f(\vec{k}, \vec{r}) \vec{n} \mathrm{d}a, \quad i = 1, \ldots, 3, \tag{2.12}$$

$$(-D \nabla_{\mathbf{r}} n)_i \stackrel{!}{=} \int_{Bz} S_{v_i}^{-1}(\vec{k}_1, \vec{r}) \vec{v}(\vec{k}_1) \cdot \nabla_{\mathbf{r}} f(\vec{k}_1, \vec{r}) \mathrm{d}^3 k_1, \quad \mathrm{i} = 1, \ldots, 3, \quad \langle v_i \rangle_{eq} = 0. \tag{2.13}$$

Note that (2.13) gives a natural definition of the mobility tensor

$$(\mu)_{ij} := -\frac{q}{n\hbar} \int_{Bz} \partial_{k_j} (S_{v_i}^{-1}(\vec{k}, \vec{r})) f(\vec{k}, \vec{r}) \mathrm{d}^3 k + \frac{q}{n\hbar} \sum_l \oint_{\partial Bz_l} S_{v_i}^{-1}(\vec{k}, \vec{r}) f(\vec{k}, \vec{r}) (\vec{n} \mathrm{d}a)_j, \quad i = 1, \ldots, 3. \tag{2.14}$$

The corresponding equations for the EB model are

$$\tau_p \partial_t(\langle \vec{v} \rangle) - \mu n \vec{E} - \mu n \nabla_{\mathbf{r}} \left(\frac{k_B}{q} \frac{\langle T \rangle}{n} \right) - D' \nabla_{\mathbf{r}} n = \langle \vec{v} \rangle \,, \tag{2.15}$$

$$\frac{3}{2} k_B \left(\langle T \rangle - n \underbrace{\frac{\langle T \rangle_{eq}}{n_{eq}}}_{:=T_{eq}} \right) = -\tau_E q \langle \vec{v} \rangle \cdot \vec{E} - \tau_E \nabla_{\mathbf{r}} \left[-\kappa_n \nabla_{\mathbf{r}} \left(\frac{\langle T \rangle}{n} \right) + \frac{5 k_B}{2} \frac{\langle T \rangle \langle \vec{v} \rangle}{n} \right], \tag{2.16}$$

where τ_E is the energy RT, κ_n the heat conduction coefficient, $\langle T \rangle_{eq} / n_{eq}$ the temperature in thermodynamic equilibrium, $D' := \frac{k_B}{q} \frac{\langle T \rangle}{n} \mu$, and $\langle T \rangle := \frac{m}{3 k_B} \cdot \mathrm{Tr}(\int_{Bz} (\vec{v} \otimes \vec{v}) f \mathrm{d}^3 k)$. If we compare (2.15) and (2.16) with (2.6), we find the following conditions for the EB model to be exact:

$$-\mu \left(\nabla_{\mathbf{r}} \left(\frac{k_B \langle T \rangle}{q} \right) \right)_i \stackrel{!}{=} \int_{Bz} S^{-1}_{v_i}(\vec{k}_1, \vec{r}) \vec{v}(\vec{k}_1) \cdot \nabla_{\mathbf{r}} f(\vec{k}_1, \vec{r}) \mathrm{d}^3 k_1, \quad i = 1, \ldots, 3, \tag{2.17}$$

$$\begin{aligned} \tau_E q \langle \vec{v} \rangle \cdot \vec{E} \stackrel{!}{=} & -\frac{1}{2} m \sum_{i=1}^{3} \frac{q}{\hbar} \vec{E} \cdot \int_{Bz} \nabla_{\mathbf{k}} (S^{-1}_{v_i v_i}(\vec{k}, \vec{r})) f(\vec{k}, \vec{r}) \mathrm{d}^3 k \\ & + \frac{1}{2} m \sum_{i=1}^{3} \frac{q}{\hbar} \vec{E} \cdot \sum_j \oint_{\partial Bz_j} S^{-1}_{v_i v_i}(\vec{k}, \vec{r}) f(\vec{k}, \vec{r}) \vec{n} \mathrm{d}a, \end{aligned} \tag{2.18}$$

$$-\tau_E \nabla_{\mathbf{r}} \left[-\kappa_n \nabla_{\mathbf{r}} \left(\frac{\langle T \rangle}{n} \right) + \frac{5 k_B}{2} \frac{\langle T \rangle \langle \vec{v} \rangle}{n} \right] \stackrel{!}{=} \frac{1}{2} m \sum_{i=1}^{3} \int_{Bz} S^{-1}_{v_i v_i}(\vec{k}_1, \vec{r}) \vec{v}(\vec{k}_1) \cdot \nabla_{\mathbf{r}} f(\vec{k}_1, \vec{r}) \mathrm{d}^3 k_1. \tag{2.19}$$

Although the terms in the rhs of (2.11)–(2.13) and (2.17)–(2.19) look rather cumbersome, this is not the case. As soon as we know $S_g^{-1}(\vec{k}, \vec{r})$ for all required g, we can easily compute such terms for a given device with an MC simulation and then locally compare with the terms of the TM. It should be noted that by construction the following holds: If the transport coefficients computed by the MC method are reinserted into the TMs as a function of position only (not as a function of the density or the mean energy), then the TMs will exactly reproduce the MC density and the MC current density in the case of the DD and EB models, as well as the MC energy current density in the case of the EB model. Another way to verify this statement is to reinsert electric field, density, and mean energy from the MC solution of the BE into the TMs that contain the exact transport coefficients, and to observe that they indeed solve these equations. Therefore, the restrictions imposed on these TMs to be valid (restrictions arising from the models for the transport coefficients) become obsolete as soon as the exact expressions (2.11)–(2.13) and (2.17)–(2.19) are used.

Based on this motivation for the computation of MISO, we show how to actually compute them in a general way.

3. Existence and computation of the MISO.

3.1. Derivation of an equation for the MISO. We start with the general form of the BE,

$$\partial_t f(\vec{r},t,\vec{k},b) + \dot{\vec{r}}\cdot\nabla_{\mathbf{r}} f(\vec{r},t,\vec{k},b) + \dot{\vec{k}}\cdot\nabla_{\mathbf{k}} f(\vec{r},t,\vec{k},b) \tag{3.1}$$
$$= \sum_{b_0}\int_{V_{b_0}} f(\vec{r},t,\vec{k}_0,b_0)w(\vec{r},t)(\vec{k}_0,b_0|\vec{k},b)\mathrm{d}^3k_0 - \sum_{b_0}\int_{V_{b_0}} f(\vec{r},t,\vec{k},b)w(\vec{r},t)(\vec{k},b|\vec{k}_0,b_0)\mathrm{d}^3k_0,$$

where $\vec{r}$ is the position in space, $\vec{k}$ the position in k-space, b a band-valley index, V_b the k-space of band-valley b, and $w(\vec{r},t)(\vec{k},b|\vec{k}_0,b_0)$ is the scattering rate from point $(\vec{k},b)$ to $(\vec{k}_0,b_0)$ (at time t and space position $\vec{r}$, respectively). Note that the Pauli blocking factors $(1-f)$ are included in the scattering rates w. Since $0<1-f\leq 1$, they will never increase the magnitude of w. This will be of some importance below. In the following we will work under the assumption that the V_b are compact pairwise disjoint subsets of $\mathbb{R}^3$, and $w(\vec{r},t)(\vec{k},b|\vec{k}_0,b_0) : V_b \times V_{b_0} \to \mathbb{R}$ is a continuous function of $\vec{k}$ and $\vec{k}_0$. We define $K := \bigcup_{i=0}^{N} V_{b_i}$.

The scattering operator S is defined as

$$S(\vec{r},t)(\vec{k},b|\vec{k}_0,b_0) := w(\vec{r},t)(\vec{k}_0,b_0|\vec{k},b) - \delta^3(\vec{k}-\vec{k}_0)\delta_{b,b_0}W_{tot}(\vec{r},t)(\vec{k},b), \tag{3.2}$$

with $W_{tot}(\vec{r},t)(\vec{k},b) := \sum_{b'}\int_{V_{b'}} w(\vec{r},t)(\vec{k},b|\vec{k}',b')\,\mathrm{d}^3k' > 0$.

By definition, $w(\vec{r},t)(\vec{k}_0,b_0|\vec{k},b)$ is a bound continuous compact operator on the Banach space $C^0(K)$ with $||\cdot||_\infty$ (see, e.g., [14, p. 70]).

In the remainder, the argument $(\vec{r},t)$ will be omitted, and the Dirac notation sometimes will be used for better readability (e.g., $|f\rangle := f$). We will also sometimes use the "$\circ$" notation

$$(A\circ B)(\vec{k},b|\vec{k}_1,b_1) := \sum_{b_0}\int_{V_{b_0}} A(\vec{k},b|\vec{k}_0,b_0)B(\vec{k}_0,b_0|\vec{k}_1,b_1)\mathrm{d}^3k_0 \tag{3.3}$$

to avoid confusion. Using the Dirac notation, the lhs of (3.1) can be written as

$$S|f\rangle := \sum_{b_0}\int_{V_{b_0}} S(\vec{k},b|\vec{k}_0,b_0)f(\vec{k}_0,b_0)\mathrm{d}^3k_0 \tag{3.4}$$
$$= \sum_{b_0}\int_{V_{b_0}} \Big(f(\vec{k}_0,b_0)w(\vec{k}_0,b_0|\vec{k},b) - f(\vec{k},b)w(\vec{k},b|\vec{k}_0,b_0)\Big)\mathrm{d}^3k_0.$$

Now we want to define an inverse operator H for the SO, i.e., an ISO. First of all, one cannot define the ISO naively as $H\circ S|f\rangle = |f\rangle$ for all $f\in C^0(K)$, because S has an eigenvector with eigenvalue 0 (indeed only one, as we will show later), namely, the Boltzmann function f_{eq}.[1] Therefore, we have to invert the SO on the space $Ker^\perp$ perpendicular to its kernel $Ker := \{\lambda|f_{eq}\rangle \mid \lambda\in\mathbb{R}\}$. To do so, we define explicitly

$$Ker^\perp := \{P_{f_{eq}}|g\rangle \mid g\in C^0(K)\}, \tag{3.5}$$

[1] Also in the case of degenerate systems and/or systems with two-particle scattering (e.g., e-e collisions) the eigenvector with eigenvalue 0 exists and is unique, but it will depend on the solution f of the BE, because the scattering operator S depends on f. This will not impact the validity of our approach.

where

$$P_{f_{eq}} := \mathbb{1} - |f_{eq}\rangle\langle f_{eq}|, \tag{3.6}$$

f_{eq} is chosen such that

$$\langle f_{eq}|f_{eq}\rangle = 1, \tag{3.7}$$

and the scalar product is given by

$$\langle f|g\rangle := \sum_b \int_{V_b} f(\vec{k},b)g(\vec{k},b)\mathrm{d}^3k. \tag{3.8}$$

A trivial but important property of S is

$$S|g\rangle = S \circ P_{f_{eq}}|g\rangle. \tag{3.9}$$

Now, the ISO H, if it exists on $Ker^{\perp}$, can be unequivocally defined on $C^0(K)$ based on the properties it must fulfill:

1. $H \circ S|g\rangle \stackrel{!}{=} |g\rangle$ for all $g \in Ker^{\perp}$,
2. $H|f_1\rangle = 0$,

with $f_1(\vec{k},b) := \frac{1}{\sqrt{\sum_{b'}|V_{b'}|}} = \text{const}$, where $|V_{b'}|$ is the volume of $V_{b'}$. Using (3.9), condition 1 can be rewritten as

$$H \circ S|g\rangle = H \circ S \circ P_{f_{eq}}|g\rangle \stackrel{!}{=} P_{f_{eq}}|g\rangle \;\; \forall g \in C^0(K). \tag{3.10}$$

The appropriateness of condition 2 will now be explained in detail. First, note that $S^T|f_1\rangle = 0$ ($\langle f_1|S = 0$) by definition of W_{tot}. Without condition 2 we could define an infinite number of ISOs, because if H satisfies condition 1, then $H + |v\rangle\langle f_1|$ fulfills the same condition for any $|v\rangle$. Let H^* be an ISO fulfilling condition 1, and $|h^*\rangle := H^*|f_1\rangle$. We can always rewrite H^* as $H^* = H^{\perp} + |h^*\rangle\langle f_1|$, where $H^{\perp} := H^* - |h^*\rangle\langle f_1|$. (Note here that because $H^{\perp}$ fulfills conditions 1 and 2, it is unambiguously defined and, therefore, independent of H^*.) By multiplying (3.1) by $\langle f_1|$ we obtain $\partial_t n + \nabla_{\mathbf{r}}\langle\dot{\vec{r}}\rangle = 0$, which is nothing but the current continuity equation. (In the case of semiconductors, the boundary term $\oint_{\partial V_{b_0}} f\dot{\vec{k}} \cdot \vec{n}\mathrm{d}a$ always disappears due to the inversion symmetry of the V_{b_0}.) Thus, by multiplying (3.1) by H^* and using (3.10), we obtain

$$\begin{aligned} H^*\partial_t|f\rangle + H^*\dot{\vec{r}}\cdot\nabla_{\mathbf{r}}|f\rangle + H^*\dot{\vec{k}}\cdot\nabla_{\mathbf{k}}|f\rangle &= |f\rangle - \langle f|f_{eq}\rangle\,|f_{eq}\rangle \\ &= H^{\perp}\partial_t|f\rangle + H^{\perp}\dot{\vec{r}}\cdot\nabla_{\mathbf{r}}|f\rangle + H^{\perp}\dot{\vec{k}}\cdot\nabla_{\mathbf{k}}|f\rangle. \end{aligned} \tag{3.11}$$

The last equation shows that $H^{\perp}$ already contains the full physical information, and that it is reasonable to define $H := H^{\perp}$, i.e., $H|f_1\rangle = 0$.

We can now write an equation for the ISO:

$$H \circ S|g\rangle \stackrel{!}{=} |g\rangle - |f_{eq}\rangle\,\langle f_{eq}|g\rangle \;\; \forall g, \tag{3.12}$$

and finally write the operator equations for H:

$$H \circ S \stackrel{!}{=} \delta^3(\vec{k} - \vec{k}_0)\delta_{b,b_0} - f_{eq}(\vec{k},b)f_{eq}(\vec{k}_0,b_0) = \mathbb{1} - |f_{eq}\rangle\langle f_{eq}|, \tag{3.13}$$

$$H|f_1\rangle \stackrel{!}{=} 0. \tag{3.14}$$

Next we have to solve for (3.13), (3.14). From (3.2) and (3.13) we obtain

$$H \circ S = \sum_{b_2} \int_{V_{b_2}} H(\vec{k}, b|\vec{k}_2, b_2) w(\vec{k}_0, b_0|\vec{k}_2, b_2) \mathrm{d}^3 k_2 - W_{tot}(\vec{k}_0, b_0) H(\vec{k}, b|\vec{k}_0, b_0) \stackrel{!}{=} \delta^3(\vec{k} - \vec{k}_0)\delta_{b,b_0} - f_{eq}(\vec{k}, b) f_{eq}(\vec{k}_0, b_0). \tag{3.15}$$

By rearranging the terms, this equation can be written as

$$H(\vec{k}, b|\vec{k}_0, b_0) = \sum_{b_2} \int_{V_{b_2}} H(\vec{k}, b|\vec{k}_2, b_2) \frac{w(\vec{k}_0, b_0|\vec{k}_2, b_2)}{W_{tot}(\vec{k}_0, b_0)} \mathrm{d}^3 k_2 - \frac{\delta^3(\vec{k} - \vec{k}_0)\delta_{b,b_0}}{W_{tot}(\vec{k}_0, b_0)} + f_{eq}(\vec{k}, b) \frac{f_{eq}(\vec{k}_0, b_0)}{W_{tot}(\vec{k}_0, b_0)} . \tag{3.16}$$

Now remember that we are interested only in MISO,

$$H_g(\vec{k}_0, b_0) := \sum_{b} \int_{V_b} g(\vec{k}, b) H(\vec{k}, b|\vec{k}_0, b_0) \mathrm{d}^3 k = \langle g|H, \tag{3.17}$$

for which we can rewrite (3.16) as

$$|H_g\rangle := H_g(\vec{k}_0, b_0) = \sum_{b_2} \int_{V_{b_2}} H_g(\vec{k}_2, b_2) \frac{w(\vec{k}_0, b_0|\vec{k}_2, b_2)}{W_{tot}(\vec{k}_0, b_0)} \mathrm{d}^3 k_2 - \left(\frac{g(\vec{k}_0, b_0) - \langle g \rangle_{eq} f_{eq}(\vec{k}_0, b_0)}{W_{tot}(\vec{k}_0, b_0)} \right), \tag{3.18}$$

where $\langle g \rangle_{eq} := \langle f_{eq}|g \rangle$.

If we define

$$A(\vec{k}_0, b_0|\vec{k}_2, b_2) := \frac{w(\vec{k}_0, b_0|\vec{k}_2, b_2)}{W_{tot}(\vec{k}_0, b_0)},$$

$$A^T(\vec{k}_0, b_0|\vec{k}_2, b_2) := \frac{w(\vec{k}_2, b_2|\vec{k}_0, b_0)}{W_{tot}(\vec{k}_2, b_2)},$$

$$|l_g\rangle := l_g(\vec{k}_0, b_0) := \left(\frac{g(\vec{k}_0, b_0) - \langle g \rangle_{eq} f_{eq}(\vec{k}_0, b_0)}{W_{tot}(\vec{k}_0, b_0)} \right), \tag{3.19}$$

we can express (3.18) as

$$|H_g\rangle = A|H_g\rangle - |l_g\rangle \tag{3.20}$$

and (3.14) as

$$\langle H_g|f_1\rangle = 0. \tag{3.21}$$

Note that

$$S(\vec{k}|\vec{k}_0) = (A^T(\vec{k}|\vec{k}_0) - \mathbb{1}) W_{tot}(\vec{k}_0). \tag{3.22}$$

So far we found that if, for a given g, there exists one and only one solution to (3.20) and (3.21), then this solution will have the properties we are looking for.

3.2. Computation of the solution. One could think that by iteratively inserting the lhs of (3.20) into the rhs, we could solve the problem, i.e.,

$$|H_g\rangle = A^n|H_g\rangle - \sum_{k=0}^{n-1} A^k|l_g\rangle. \tag{3.23}$$

However, the way to solve (3.20) is somewhat more involved.

Before we go to the solution we discuss an additional condition we have to impose on A. The term $A(k,b|k_0,b_0)$ is nothing but the probability for a particle to end in (k_0,b_0) after one scattering event, having started in (k,b). $A^m(k,b|k_0,b_0)$ is then the probability of going to (k_0,b_0) after m scattering events. In the following we will work under the assumption that there exists an $M \in \mathbb{N}$ such that $A^M(k,b|k_0,b_0) > 0$ for all $(k,b),(k_0,b_0)$. It means that it is possible, starting from any (k,b), to reach any (k_0,b_0) after M scattering events. Under this assumption, A^M is a strong positive compact operator.

PROPOSITION 3.1. *The first Krein–Rutman theorem* [9] *ensures the existence and uniqueness of a stationary solution in thermodynamic equilibrium* $(\exists! f \in C^0(K) \mid S|f\rangle = 0)$.

Proof. We first prove $r(A^M) = 1$. By construction, $||A|| := \sup_{x\in C^0(K)\setminus\{0\}} \frac{||Ax||_\infty}{||x||_\infty} \leqslant 1$, and $A|f_1\rangle = |f_1\rangle$. Therefore, $r(A) \geqslant 1$, and because by definition $r(A) \leqslant ||A||$, we find $\sqrt[M]{r(A^M)} = r(A) = ||A|| = 1$. The first Krein–Rutman theorem ensures that there is only one strict positive function $u \in C^0(K)$ such that $A^M u = r(A^M)u = u$. Of course this function is nothing but f_1. Now we are interested in $(A^T)^M$. By construction, $(A^T)^M$ is a strong positive compact operator. Using again the Krein–Rutman theorem we find a unique v with $0 < v \in C^0(K)$ such that $(A^T)^M v = r((A^T)^M)v$. Because $u > 0$ and $v > 0$, we find $0 < \langle u|v\rangle = \langle A^M u|v\rangle = \langle u|(A^T)^M v\rangle = r((A^T)^M)\langle u|v\rangle$. Thus, $r((A^T)^M) = 1$ and $(A^T)^M v = v$. Then, because $(A^T)^{M+1} v = A^T v \iff A^T v = c * v$ with c real and $c^M = 1$, $A^T v = v$. Using (3.22) gives $S f_{eq} = 0$ with $f_{eq} := \frac{v}{W_{tot}}$. The function f_{eq} is the only solution. ∎

To solve (3.20), we construct a sub-Banach space $Q \subset C^0(K)$, where the solution is unique. Using two important properties of A,

1. $A|f_1\rangle = |f_1\rangle$ by definition of W_{tot},
2. $A^T|W_{tot} f_{eq}\rangle = |W_{tot} f_{eq}\rangle$ because $S|f_{eq}\rangle = 0$,

we can define

$$P_L := \mathbb{1} - \frac{|f_1\rangle\langle f_{eq} W_{tot}|}{\langle f_1|f_{eq} W_{tot}\rangle}, \tag{3.24}$$

which has the following important properties:

$$P_L^2 = P_L, \tag{3.25}$$

$$P_L \circ A = A \circ P_L = P_L \circ A \circ P_L. \tag{3.26}$$

Using P_L, we define the space $Q := \{P_L x | x \in C^0(K)\}$. Because $W_{tot} f_{eq}$ and f_1 are continuous functions, Q is a Banach space.

PROPOSITION 3.2. *A is a linear compact operator on Q.*

Proof. Let $x \in Q$. By definition of Q and property (3.25), $P_L x = x$. Therefore, using property (3.26), $Ax = A \circ P_L x = P_L \circ Ax \in Q$. ∎

Note that $|l_g\rangle \in Q$ because

$$\langle f_{eq} W_{tot} | l_g \rangle = 0. \tag{3.27}$$

By multiplying (3.20) by P_L we reformulate the problem on Q:

$$P_L |H_g\rangle = P_L \circ A \circ P_L |H_g\rangle - |l_g\rangle. \tag{3.28}$$

Defining $|H_g^\perp\rangle := P_L |H_g\rangle$ we obtain

$$(\mathbb{1} - A)|H_g^\perp\rangle = -|l_g\rangle. \tag{3.29}$$

PROPOSITION 3.3. *$(\mathbb{1} - A^M)$ is invertible on Q, and, therefore, $(\mathbb{1} - A)$ is also invertible on Q.*

Proof. We first prove $||A^M||_\infty < 1$ on Q. Let x be in Q. x is a continuous function and $\langle f_{eq} W_{tot} | x \rangle = 0$ because $\langle f_{eq} W_{tot} | P_L = 0$. By definition, $f_{eq} W_{tot}$ is a strict positive function, and therefore x must have a positive part and a negative part. We define $x_+(k) := x(k)$ if $x(k) \geqslant 0$, $x_+(k) = 0$ else, and $x_-(k) := x(k)$ if $x(k) < 0$, $x_-(k) = 0$ else. By definition, $x(k) = x_+(k) + x_-(k)$ for all $k \in K$. Without loss of generality, $||x||_\infty = ||x_+||_\infty$. Then, remembering that A^M is strictly positive, we have $|A^M x| = |\,|A^M x_+| - |A^M x_-|\,| < |A^M x_+| \leqslant ||x_+||_\infty$. Therefore, $||A^M||_\infty < 1$. It means that $(\mathbb{1} - A^M)$ has an inverse on Q that can be written as a Neumann series: $(\mathbb{1} - A^M)^{-1} = \sum_{i=0}^\infty A^{M^i}$. Rewriting $(\mathbb{1} - A^M)$ as $(\mathbb{1} - A) \circ \sum_{j=0}^{M-1} A^j$ and multiplying by $(\mathbb{1} - A^M)^{-1}$, we find $\mathbb{1} = \sum_{i=0}^\infty A^{M^i} \circ (\mathbb{1} - A) \circ \sum_{j=0}^{M-1} A^j = (\mathbb{1} - A) \circ \sum_{i=0}^\infty A^{M^i} \circ \sum_{j=0}^{M-1} A^j$. Thus, clearly $(\mathbb{1} - A)^{-1} = \sum_{i=0}^\infty A^{M^i} \circ \sum_{j=0}^{M-1} A^j = \sum_{i=0}^\infty A^i$. ∎

Multiplying (3.29) by $(\mathbb{1} - A)^{-1}$ gives the solution we were looking for:

$$|H_g^\perp\rangle = -\sum_{i=0}^\infty A^i |l_g\rangle. \tag{3.30}$$

Thus, problem (3.20) has a unique solution on Q, but infinitely many of the form $H_g^\lambda := H_g^\perp + \lambda |f_1\rangle$, $\lambda \in \mathbb{R}$, on $C^0(K)$. In (3.21) we imposed the condition $\langle H_g | f_1 \rangle = 0$ to obtain a unique solution. The only H_g^λ fulfilling this condition is $H_g^{\lambda_g}$ with

$$\lambda_g := -\langle f_1 | H_g^\perp \rangle, \tag{3.31}$$

which is the unique solution we are looking for.

Equation (3.30) represents an iterative method for computing $H_g^\perp$, i.e., for finding an exact solution of (3.13), (3.14) for any $g \in C^0(K)$.

As $\langle H_g | = \langle g | H$ exists for all $g \in C^0(K)$, H also exists and is unique. Thus, (3.13) together with (3.14) also has a unique solution.

3.3. Connection between H and S^{-1}. We show the connection between H and S^{-1}, as well as between H_g and S_g^{-1}. If we let the operator H act on both sides of (3.1), we find with (3.13)

$$H \partial_t |f\rangle + H \dot{\vec{r}} \cdot \nabla_{\mathbf{r}} |f\rangle + H \dot{\vec{k}} \cdot \nabla_{\mathbf{k}} |f\rangle = |f\rangle - \langle f | f_{eq} \rangle \, |f_{eq}\rangle. \tag{3.32}$$

We want to dispose of the term $\langle f | f_{eq} \rangle$ and replace it with a term containing the density. By computing the 0th moment of (3.32), we obtain

$$\begin{aligned} &\langle H_1 | \partial_t | f \rangle + \langle H_1 | \dot{\vec{r}} \cdot \nabla_{\mathbf{r}} | f \rangle + \langle H_1 | \dot{\vec{k}} \cdot \nabla_{\mathbf{k}} | f \rangle = n - \langle f | f_{eq} \rangle \, n_{eq} \\ &\quad \Leftrightarrow \langle f | f_{eq} \rangle = \frac{n}{n_{eq}} - \frac{1}{n_{eq}} \langle H_1 | \partial_t | f \rangle - \frac{1}{n_{eq}} \langle H_1 | \dot{\vec{r}} \cdot \nabla_{\mathbf{r}} | f \rangle - \frac{1}{n_{eq}} \langle H_1 | \dot{\vec{k}} \cdot \nabla_{\mathbf{k}} | f \rangle, \end{aligned} \tag{3.33}$$

where $H_1(\vec{k}_0, b_0) := \sum_b \int_{V_b} H(\vec{k}, b|\vec{k}_0, b_0)\mathrm{d}^3k$ and $n_{eq} := \sum_b \int_{V_b} f_{eq}(\vec{k}, b)\mathrm{d}^3k$. Inserting (3.33) into (3.32) results in

(3.34)
$$\left(H - \frac{|f_{eq}\rangle\langle H_1|}{n_{eq}}\right)\partial_t|f\rangle + \left(H - \frac{|f_{eq}\rangle\langle H_1|}{n_{eq}}\right)\dot{\vec{r}}\cdot\nabla_{\mathbf{r}}|f\rangle + \left(H - \frac{|f_{eq}\rangle\langle H_1|}{n_{eq}}\right)\dot{\vec{k}}\cdot\nabla_{\mathbf{k}}|f\rangle = |f\rangle - |f_{eq}\rangle\frac{n}{n_{eq}}.$$

With the definition $S^{-1}(\vec{k}, b|\vec{k}_0, b_0) := H(\vec{k}, b|\vec{k}_0, b_0) - f_{eq}(\vec{k}, b)H_1(\vec{k}_0, b_0)/n_{eq}$ we find (2.4). Finally, one obtains for the g-moment

$$S_g^{-1}(\vec{k}_0, b_0) := H_g(\vec{k}_0, b_0) - \frac{\langle g\rangle_{eq}\, H_1(\vec{k}_0, b_0)}{n_{eq}}. \tag{3.35}$$

Note that $S_g^{-1}(\vec{k}_0, b_0)$ fulfills by definition the equations

$$AS_g^{-1} = S_g^{-1}(\vec{k}, b) + \left(\frac{g(\vec{k}, b) - \frac{\langle g\rangle_{eq}}{n_{eq}}}{W_{tot}(\vec{k}, b)}\right) \Leftrightarrow |S_g^{-1}\rangle = A|S_g^{-1}\rangle - |h_g\rangle, \tag{3.36}$$

$$\langle S_g^{-1}|f_1\rangle = 0, \tag{3.37}$$

where $h_g(\vec{k}, b) := (g(\vec{k}, b) - \frac{\langle g\rangle_{eq}}{n_{eq}})/W_{tot}(\vec{k}, b)$ (compare with (3.20) and (3.21)).

The proof of the existence and of the uniqueness of S_g^{-1} up to a constant is herewith completed.

Putting (3.30) and (3.35) together leads to

(3.38)
$$\left|S_g^{-1}\right\rangle = -\left(\mathbb{1} - |f_1\rangle\langle f_1|\right)\circ\sum_{i=0}^{\infty}\left(P_L\circ A\circ P_L\right)^i|h_g\rangle = -\left(\mathbb{1} - |f_1\rangle\langle f_1|\right)\circ\sum_{i=0}^{\infty}A^i|h_g\rangle,$$

which is an iterative method for computing S_g^{-1} for any given operator S and function g.

3.4. The Dirac delta distribution. Before going to the applications we would like to discuss the hypothesis on $w(\vec{k}, b|\vec{k}', b')$. At the beginning of this section we chose $w(\vec{k}, b|\vec{k}', b')$ to be a continuous function of its arguments $\vec{k}$ and $\vec{k}'$. In many "physical" models, however, the function $w(\vec{k}, b|\vec{k}', b')$ is replaced with a distribution (usually a sum of Dirac's delta "functions" of a continuous function of $\vec{k}$ and $\vec{k}'$). In the following we argue against delta distributions (functions) based on the concept of regularization of the delta distribution. A function belonging to a family of continuous functions $\delta_\gamma(\varepsilon)$ depending on a continuous parameter γ is called a *regularization of the delta function* iff $\lim_{\gamma\to\infty}\int_{-\infty}^{\infty}\delta_\gamma(\varepsilon)f(\varepsilon)d\varepsilon = f(0)$ for all continuous functions of the energy $f(\varepsilon)$, and $\int_{-\infty}^{\infty}\delta_\gamma(\varepsilon)d\varepsilon = 1$ for all γ. Now, remember that the delta distributions contained in the usual scattering rates arise from Fermi's golden rule, i.e., from the regularization $\delta_\gamma^{(F)}(\varepsilon) := (\sin(\varepsilon\gamma)^2)/(\gamma\pi\varepsilon^2)$. Replacing in the scattering rate w the delta distributions with $\delta_\gamma^{(F)}(\varepsilon)$ for any $\gamma < \infty$, the hypotheses on w are again fulfilled. This fact can be interpreted physically, mathematically, and numerically.

Physically, a simple argument can be found for why γ should be smaller than ∞: From the Heisenberg uncertainty principle there is no exact energy conservation in a finite amount of time. Thus, the delta distribution is just a useful approximation. Mathematically, the situation is quite different if one considers the limit $\gamma \to \infty$ before or after computing the MISO. Taking the limit before the computation of the MISO leads to an operator A, which is not compact and, even worse, leads to infinitely many solutions to the BE at thermodynamic equilibrium (see [11]). Taking the limit after the computation of the MISO trivially leads to a single well-defined solution for each $g \in C^0(K)$. Numerically, a computer using double arithmetic cannot digitize the difference between a delta distribution and, e.g., the regularization $\delta_\gamma^{(a)}(\varepsilon)$ such that $\mathrm{supp}(\delta_\gamma^{(a)}) = [-\gamma^{-1}, \gamma^{-1}]$ and $\gamma > 10^{307}$. This means that when solving the BE on a computer, one is actually working with a delta distribution. For these reasons we conclude that a delta distribution contained in the scattering rates can and should be replaced with a well-chosen regularization. Metaphorically speaking, delta distributions give birth to operators which are a bit like monsters (due to their noncompactness) and, although they are interesting objects from a mathematical point of view (see, e.g., [2] and [11]), they create artificial problems from a physical point of view.

4. Applications.

4.1. Introduction. The knowledge of the MISO and of the solution f of the BE is necessary and sufficient to compute all transport parameters next to and far from thermodynamic equilibrium. In this section, five important applications are presented.

4.2. Low-field solution to the BE. The space-homogeneous, stationary BE

$$-\frac{q}{\hbar}\vec{E}\cdot\nabla_{\mathbf{k}}|f\rangle - q(\vec{v}\wedge\vec{B})\cdot\nabla_{\mathbf{k}}|f\rangle = S|f\rangle \tag{4.1}$$

can be solved for small electric and magnetic fields using the ansatz (see, e.g., [10])

$$f(\vec{k}) = f_{eq}(\varepsilon(\vec{k})) + q\frac{\partial f_{eq}}{\partial\varepsilon}(\varepsilon(\vec{k}))\vec{E}\cdot\vec{\Lambda}^a(\vec{k}) + q\frac{\partial f_{eq}}{\partial\varepsilon}(\varepsilon(\vec{k}))(\vec{v}\wedge\vec{B})\cdot\vec{\Lambda}^b(\vec{k}). \tag{4.2}$$

Inserting (4.2) into (4.1) and taking into account only the first order terms in the magnetic and electric fields leads to

$$(\vec{v}\wedge\vec{B})\cdot\vec{\Lambda}^b = 0, \tag{4.3}$$

because $(\vec{v}\wedge\vec{B})\cdot\vec{v} = 0$, and

$$\langle(1-f_{eq})(\vec{v})_i| = -\langle(\vec{\Lambda}^a)_i)|S. \tag{4.4}$$

It is important that (4.4) be derived only by using the principle of detailed balance. The solution to (4.4) is trivially

$$(\vec{\Lambda}^a)_i(\vec{k}) = -S^{-1}_{(1-f_{eq})v_i}(\vec{k}). \tag{4.5}$$

Therefore, the solution to the low-field BE is

$$f(\vec{k}) = f_{eq}\left(1 + \frac{q}{k_BT}(1-f_{eq})\vec{E}\cdot S^{-1}_{(1-f_{eq})\vec{v}}\right) \tag{4.6}$$

in the case of Fermi–Dirac statistics, and

$$f(\vec{k}) = f_{eq}\left(1 + \frac{q}{k_B T}\vec{E}\cdot S_{\vec{v}}^{-1}\right) \tag{4.7}$$

in the case of Boltzmann statistics.

In the low-field case the solution of the BE is therefore determined only by the equilibrium distribution f_{eq} and by $S^{-1}_{(1-f_{eq})\vec{v}}$ (resp., $S_{\vec{v}}^{-1}$).

4.3. Transport parameters. As already mentioned in section 2, tensorial transport parameters can be exactly computed using MISO. For example, the mobility is given by

$$\mu_{ij} := \frac{q}{n\hbar}\int_K S^{-1}_{v_i}\partial_{k_j} f d^3k \tag{4.8}$$

and the diffusivity tensor by

$$D_{ij} := -\frac{1}{n}\int_K S^{-1}_{v_i} v_j f d^3k. \tag{4.9}$$

Note that in the case of Boltzmann statistics, setting $f = f_{eq}$ in (4.8) and (4.9) yields the well-known Einstein relation for all components of the tensors

$$\frac{k_B T}{q}\mu_{ij} = D_{ij}. \tag{4.10}$$

These transport coefficients are exact and unique. Their definition does not require any restrictions except those already contained in the BE. If they are used in the associated TM, its solution will reproduce the corresponding moment(s) of the BE. In two and three dimensions this is, to the authors' knowledge, the first generally valid scheme ever described which can be used to compute tensorial transport coefficients for all possible geometries and configurations.

A straightforward application is the customization of the model for the transport coefficients for a given device. Using (4.8) and (4.9), transport coefficients can be computed in a device for different bias points (using, e.g., the MC method), especially in the parts of the device where the usual bulk models for the transport coefficients are no longer valid. Then, a customized model for the device can be extracted by choosing a proper local parametrization. In the case of the DD model the transport coefficients can be parametrized using, e.g., the local electric field or the local current density. This custom model will be, of course, valid only for the considered device, but nevertheless, it will enable us to compute the direct current (DC), alternating current (AC), and noise characteristics of the device in a much simpler way than by directly working with the BE.

4.4. Hall factor. When a constant voltage is applied between A and B (see Figure 4.1), and a constant magnetic field $B_{z'}$ is present in the z' direction, then two Hall factors can be defined,

$$R_H := \frac{V_{21}}{d_1 J_{x'} B_{z'}}, \tag{4.11}$$

$$R_H^* := \frac{V_{43}}{d_2 J_{x'} B_{z'}}, \tag{4.12}$$

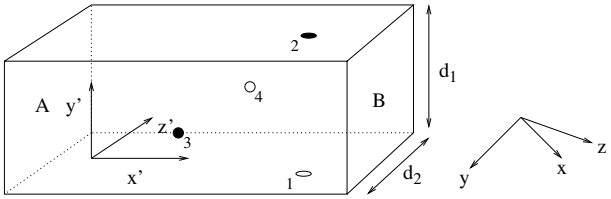

FIG. 4.1. *Piece of bulk material.*

where V_{21} is the voltage between the points 1 and 2, V_{43} is the voltage between the points 3 and 4, and $J_{x'}$ is the current density in x'-direction. Under the assumption that the electric fields $E_{y'}$ in the y'-direction and $E_{z'}$ in the z'-direction are constant, the definitions can be rewritten as

$$R_H := \frac{E_{y'}}{J_{x'} B_{z'}}, \tag{4.13}$$

$$R_H^* := \frac{E_{z'}}{J_{x'} B_{z'}}. \tag{4.14}$$

To obtain expressions for R_H and R_H^*, the current density equation in the space-homogeneous case can be written as

$$\frac{\vec{J}}{nq} = \mu \vec{E} + \alpha \vec{B}, \tag{4.15}$$

where μ is defined in (4.8), and α is defined as

$$\alpha_{ij} := \frac{1}{n} \int_K S_{v_i}^{-1} \left(\vec{v} \wedge \nabla_{\mathbf{k}} f\right)_j d^3k. \tag{4.16}$$

For better readability, only the case of Boltzmann statistics will be considered.

In the low-field case, f can be replaced with (4.7), leading to

$$\alpha_{ij} = \frac{1}{n} \frac{q}{k_B T} \int_K S_{v_i}^{-1} \left(\vec{v} \wedge \nabla_{\mathbf{k}} (f_{eq} \vec{E} S_{\vec{v}}^{-1})\right)_j d^3k, \tag{4.17}$$

where the field-independent term disappeared because $\vec{v} \wedge \vec{v} = 0$. Taking advantage of the linearity of (4.17) in $\vec{E}$, (4.15) can be rewritten as

$$\frac{\vec{J}}{nq} = \mu \vec{E} + B_x \gamma_x \vec{E} + B_y \gamma_y \vec{E} + B_z \gamma_z \vec{E}, \tag{4.18}$$

with

$$(\gamma_l)_{ij} := \frac{1}{n} \frac{q}{k_B T} \int_K S_{v_i}^{-1} \left(\vec{v} \wedge \nabla_{\mathbf{k}} (f_{eq} S_{v_j}^{-1})\right)_l d^3k. \tag{4.19}$$

Therefore,

$$\vec{E} = \left(\mu + B_x \gamma_x + B_y \gamma_y + B_z \gamma_z\right)^{-1} \frac{\vec{J}}{nq}. \tag{4.20}$$

If R is the matrix that transforms the (x, y, z)-coordinate system into the (x', y', z')-coordinate system, then the Hall factors can be written as

$$R_H = \frac{\left(R\left(\mu + B_x\gamma_x + B_y\gamma_y + B_z\gamma_z\right)^{-1} R^{-1}\right)_{yx}}{qnB_{z'}}, \tag{4.21}$$

$$R_H^* = \frac{\left(R\left(\mu + B_x\gamma_x + B_y\gamma_y + B_z\gamma_z\right)^{-1} R^{-1}\right)_{zx}}{qnB_{z'}}. \tag{4.22}$$

Equation (4.21) is more general than the formula given in [7] and reduces to the formula given in [10] in special cases. In the case of unstrained bulk silicon, e.g., because of the symmetries of the crystal, (4.18) takes the form

$$\frac{\vec{J}}{n_{eq}q} = \mu_{eq}\vec{E} - \gamma_{eq}\vec{B} \wedge \vec{E}, \tag{4.23}$$

where

$$\mu_{eq} := \frac{q}{n_{eq}\hbar}\int_K S_{v_x}^{-1}\partial_{k_x} f_{eq} d^3k, \tag{4.24}$$

$$\gamma_{eq} := \frac{1}{n_{eq}}\frac{q}{k_B T}\int_K S_{v_x}^{-1}\left(\vec{v} \wedge \nabla_{\mathbf{k}}(f_{eq}S_{v_y}^{-1})\right)_z d^3k. \tag{4.25}$$

The Hall factors are then

$$R_H = \frac{1}{qn_{eq}}\frac{\gamma_{eq}}{\mu_{eq}^2 + \gamma_{eq}^2 B_{z'}^2}, \tag{4.26}$$

$$R_H^* = 0, \tag{4.27}$$

where R_H and R_H^* are independent of the transformation matrix R, i.e., of the crystal orientation.

4.5. RTs. The RT for the g-moments of the space-homogeneous BE is usually computed using the formula (see [8, p. 136])

$$\tau_g = -\frac{\langle g|f - f_{eq}\rangle}{\langle g|S|f\rangle}. \tag{4.28}$$

At least in all semiconductors (strained and unstrained), (4.28) is fully inappropriate, because in the low-field limit (4.28) reduces to the singular expression $\frac{0}{0}$ in the case of even functions g, such as, e.g., ε, ε^2, v^2, and v^4. To solve this problem, the alternative expression

$$\tau_g = -\frac{\vec{n} \cdot \int (\nabla_{\mathbf{k}} f) S_g^{-1} d^3k}{\vec{n} \cdot \int (\nabla_{\mathbf{k}} f) g d^3k} \tag{4.29}$$

can be used, where $\vec{n}$ is the vector pointing in the direction of the electric field. Equation (4.29) never becomes singular in the limit of vanishingly small electric fields.

An extensive application of this theory to silicon can be found in [4].

4.6. Langevin noise sources. We are interested in the BE with an additional Langevin term, the so-called "Boltzmann–Langevin" equation (BLE)

$$\partial_t f(\vec{r},t,\vec{k},b) + \dot{\vec{r}}\cdot\nabla_{\mathbf{r}} f(\vec{r},t,\vec{k},b) + \dot{\vec{k}}\cdot\nabla_{\mathbf{k}} f(\vec{r},t,\vec{k},b) = Sf + \delta s(\vec{r},t,\vec{k},b). \tag{4.30}$$

The BE describes the average state of an infinite number of systems with identical initial conditions, whereas the BLE describes the evolution of one of these systems. The Langevin source term is responsible for the deviation from the average state.

By multiplying (4.30) by S_g^{-1}, we obtain

$$\langle S_g^{-1}|\partial_t f\rangle + \langle S_g^{-1}|\dot{\vec{r}}\cdot\nabla_{\mathbf{r}} f\rangle + \langle S_g^{-1}|\dot{\vec{k}}\cdot\nabla_{\mathbf{k}} f\rangle = \langle g\rangle - \langle g\rangle_{eq}\frac{n}{n_{eq}} + \langle S_g^{-1}|\delta s\rangle. \tag{4.31}$$

We want to derive an expression for the Fourier transform of correlation functions of $\langle S_g^{-1}|\delta s\rangle$ around a stationary state for the homogeneous BLE with constant density n; i.e., we want to compute

$$C_{gg'}(\omega) := \int_{-\infty}^{\infty} \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} (\langle S_g^{-1}|\delta s\rangle)(t)(\langle S_{g'}^{-1}|\delta s\rangle)(t+s)dt e^{-i\omega s}ds \text{ for constant } n. \tag{4.32}$$

We define the correlation function

$$C(\omega)(\vec{k},b|\vec{k}_0,b_0) := \int_{-\infty}^{\infty} \lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} \delta s(t)(\vec{k},b)\delta s(t+s)(\vec{k}_0,b_0)dt e^{-i\omega s}ds. \tag{4.33}$$

Note that

$$C_{gg'}(\omega) = \sum_{b,b_0}\int_{V_b}\int_{V_{b_0}} S_g^{-1}(\vec{k},b)S_{g'}^{-1}(\vec{k}_0,b_0)C(\omega)(\vec{k},b|\vec{k}_0,b_0)\mathrm{d}^3k\mathrm{d}^3k_0. \tag{4.34}$$

We know from [5, eq. (1.55a), p. 21], that for a homogeneous nondegenerate system with given density, we obtain

$$\begin{aligned} C(\omega)(\vec{k},b|\vec{k}_0,b_0) &= \delta^3(\vec{k}-\vec{k}_0)\delta_{b,b_0}\sum_{b_1}\int_{V_{b_1}} w(\vec{k},b|\vec{k}_1,b_1)f(\vec{k},b)\mathrm{d}^3k_1 \\ &+ \delta^3(\vec{k}-\vec{k}_0)\delta_{b,b_0}\sum_{b_1}\int_{V_{b_1}} w(\vec{k}_1,b_1|\vec{k},b)f(\vec{k}_1,b_1)\mathrm{d}^3k_1 \\ &\quad - w(\vec{k}_0,b_0|\vec{k},b)f(\vec{k}_0,b_0) - w(\vec{k},b|\vec{k}_0,b_0)f(\vec{k},b), \end{aligned} \tag{4.35}$$

where $f(\vec{k},b)$ is the stationary homogeneous solution to (3.1).[2]

By plugging (4.35) into (4.34) and rearranging terms, we obtain

$$C_{gg'}(\omega) = \sum_b\int_{V_b} K_{gg'}(\vec{k},b)f(\vec{k},b)\mathrm{d}^3k = \langle K_{gg'}\rangle, \tag{4.36}$$

[2]In the case of particle-particle scattering the corresponding additional contribution to the correlation function has to be added (see [5, eq. (1.55b), p. 21]).

where

$$K_{gg'}(\vec{k},b) := \sum_{b_0} \int_{V_{b_0}} w(\vec{k},b|\vec{k}_0,b_0) \begin{bmatrix} S_g^{-1}(\vec{k},b)S_{g'}^{-1}(\vec{k},b) \\ -S_g^{-1}(\vec{k},b)S_{g'}^{-1}(\vec{k}_0,b_0) \\ -S_g^{-1}(\vec{k}_0,b_0)S_{g'}^{-1}(\vec{k},b) \\ +S_g^{-1}(\vec{k}_0,b_0)S_{g'}^{-1}(\vec{k}_0,b_0) \end{bmatrix} \mathrm{d}^3k_0. \tag{4.37}$$

Note that (4.37) is invariant under the transformation $S_g^{-1}(\vec{k},b) \to S_g^{-1}(\vec{k},b) + \alpha_g f_1$. Therefore, $C_{gg'}(\omega)$ is independent of condition (3.14), as it should be.

Thus, the function $C_{gg'}(\omega)$ is nothing but the expectancy of $K_{gg'}$. Since we can compute $K_{gg'}$, we can also compute $\langle K_{gg'} \rangle$ in a very efficient way with an MC simulation. We call $C_{gg'}(\omega)$ the Langevin noise source of the functions g, g'. It describes white noise because it does not depend on ω.

5. Conclusion. The formalism developed in section 3 cannot only be used for studying interesting systems like strained semiconductors, where the SO is fully dependent on the band-valley index, but also for studying electron-hole systems. To do so we have only to formally replace the distribution function f_h of the holes in the valence bands by $f_e := 1 - f_h$, i.e., the distribution function for the electrons in the valence bands.

We have described a method based on exact S_g^{-1} moments of the inverse scattering operator (MISO) of the Boltzmann equation (BE). This formalism is therefore free of any relaxation time approximation (RTA). We have shown under what sufficient conditions the S_g^{-1} exist, and we gave an explicit algorithm to compute them.

We have demonstrated that the knowledge of the S_g^{-1} enables the exact computation of transport parameters, correlation functions, and Langevin noise sources. Moreover, the important assumptions underlying the transport models (TMs) and method such as, e.g., the impedance field method (IFM) can be critically examined by our approach.

In forthcoming papers, we will give a general discretization scheme to numerically compute any MISO and extend the method to time-dependent scattering operators (SOs).

Acknowledgments. The authors would like to thank Dr. F. Geelhaar, Dr. B. Schmithüsen, Priv.-Doz. Dr. F. M. Bufler, and T. Bühler of the ETH Zurich for helpful discussions.

ON WEAK PLANE COUETTE AND POISEUILLE FLOWS OF RIGID ROD AND PLATELET ENSEMBLES*

ZHENLU CUI†, M. GREGORY FOREST‡, QI WANG§, AND HONG ZHOU¶

Abstract. Films and molds of nematic polymer materials are notorious for heterogeneity in the orientational distribution of the rigid rod or platelet macromolecules. Predictive tools for structure length scales generated by shear-dominated processing are vitally important: both during processing because of flow feedback phenomena such as shear thinning or thickening, and postprocessing since gradients in the rod or platelet ensemble translate to nonuniform composite properties and to residual stresses in the material. These issues motivate our analysis of two prototypes for planar shear processing: drag-driven Couette and pressure-driven Poiseuille flows. Hydrodynamic theories for high aspect ratio rod and platelet macromolecules in viscous solvents are well developed, which we apply in this paper to model the coupling between short-range excluded volume interactions, anisotropic distortional elasticity (unequal elasticity constants), wall anchoring conditions, and hydrodynamics. The goal of this paper is to generalize scaling properties of steady flow molecular structures in slow Couette flows with equal elasticity constants [M. G. Forest et al., *J. Rheol.*, 48 (2004), pp. 175–192] in several ways: to contrast isotropic and anisotropic elasticity; to compare Couette versus Poiseuille flow; and to consider dynamics and stability of these steady states within the asymptotic model equations.

1. Introduction.

Shear dominated flows of nematic liquid crystal polymers (NLCPs) generate anisotropy and spatial heterogeneity in the orientational distribution of the rigid rod or platelet ensemble. These phenomena are well documented in light scattering textures [9, 1, 24, 25, 31]. A characterization of the lengthscales in the molecular distribution responsible for the scattering patterns, and whether they are due to changes in the direction of peak orientation (nematic elasticity) or due to focusing and defocusing of the orientational distribution (molecular elasticity), are the subject of numerous modeling and computational studies (cf. [32, 30, 21, 29]). Molecular orientation features in different flow regimes are of extreme importance for materials design, as they impart anisotropic and nonuniform material properties [34, 18, 19]. Another issue typical of non-Newtonian fluids is flow feedback, where

elastic stresses alter apparent viscosity. This paper is a continuation of our systematic studies of mesostructures, both from free space elasticity patterns absent of external fields and boundary anchoring conditions [11, 12], and from planar Couette cells moving at prescribed slow speeds [13, 14]. We defer to these articles, where a detailed account of analytical results on continuum Leslie–Ericksen–Frank (LEF) models is given, notably by [26, 4, 5, 7, 27, 23, 28].

In [14], the authors considered a Doi–Marrucci–Greco (DMG) mesoscopic orientation tensor model, allowing a full coupling between flow structure, director (nematic) and order parameter (molecular) distortions, and with imposed plate motion and molecular anchoring conditions. The model has been benchmarked in the longwave, monodomain regime with resolved simulations of the Doi kinetic theory [15, 16]. Indeed, the motivation for an analytical study of structure properties is to provide guidance for structure simulations of mesoscopic [17] and kinetic [15, 16] models, where the parameter space is too large to assimilate any kind of collapse of the numerical data through scaling laws.

In this paper, we extend our previous asymptotic scaling analysis in several ways. First, we consider a more general physical model to admit anisotropic distortional elasticity (unequal bend, splay, twist elasticity constants). The second-moment orientation model is derived from a recent generalization of the Doi–Hess–Marrucci–Greco kinetic theory [33] and guides our numerical studies [15, 16], for which there are no preceding numerical or analytical results. Second, the asymptotic analysis is extended from plate-driven Couette cell properties to pressure-driven Poiseuille flows. The boundary conditions consist of molecular orientational anchoring conditions at solid walls, where the degree of order is set by the concentration of the nematic liquid and the principal orientation axis is a free parameter, together with no-slip conditions for the velocity field. We further assume an in-plane orientation tensor (restricting the principal orientation axes of the molecular distribution to the flow-flow gradient plane), and posit that the velocity field varies only transverse to the primary flow direction. These assumptions are not easily lifted, in that the fortuitous diagonalization of the flow-nematic steady balance equations is apparently lost for higher dimensional orientational and spatial degrees of freedom. Finally, we extend the asymptotic analysis to time-dependent model equations.

From this formulation, we develop a formal asymptotic analysis in the slow-plate (so-called small Deborah number) and weak pressure gradient limits, which yield exactly solvable, steady flow-nematic model equations. From the explicit solutions, lengthscale selection criteria and scaling properties become explicit, parameterized in terms of *molecular parameters* (nematic concentration N, molecule aspect ratio r, persistence length $\mathcal{L}$ of distortional elasticity, persistence length L of the anisotropic distortional elasticity) [33], and *experimental conditions* (gap width ($2h$), plate speeds $\pm v_0$ for plane Couette flows and pressure gradient $\frac{\partial p}{\partial x}$ for the plane Poiseuille flow, and plate anchoring conditions on the molecular field). From the time-dependence in the asymptotic equations, we explore transient solutions at the first and second order in the asymptotic scheme to infer stability of the steady states within the asymptotic balance equations. We first consider plane Couette flow, followed in the next section by plane Poiseuille flow.

2. Spatial structures and their stability in plane Couette flows. We consider plane Couette flow between two parallel plates located at $y = \pm h$ and moving with velocity $\mathbf{v} = (\pm v_0, 0, 0)$, respectively, in Cartesian coordinates (x, y, z). Figure 1 depicts the cross section of the flow geometry on the (x, y) plane.

Here we consider flow-orientation interactions in weak plane Couette flow, char-

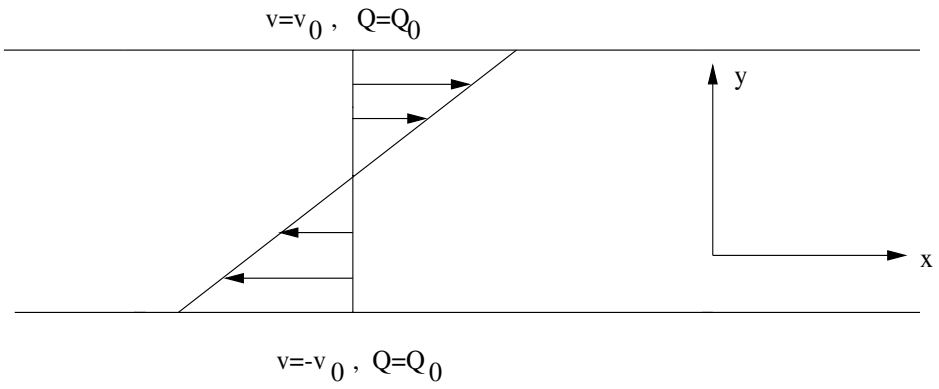

FIG. 1. *Geometry of plane Couette flow. The gap width in the shear cell is* $2h$. *The LCP in the cell is sheared by moving the upper plate with a constant speed* v_0 *and the lower one with the same speed in the opposite direction. At the bounding surfaces, the orientation tensor is equal to its equilibrium value.*

acterized by a small effective or averaged shear rate. We nondimensionalize using the gap half-width (h) between the shearing plates and the nematic polymer mean relaxation time $t_0 = \frac{1}{D_r^0}$, where D_r^0 is the rotary diffusivity for the rigid rod or platelet [33]. We denote the position vector by $\mathbf{x}$, the velocity by $\mathbf{v}$, the extra stress tensor by τ, and the pressure by p, respectively. The dimensionless flow and stress variables are defined by:

$$\tilde{\mathbf{v}} = \frac{t_0}{h}\mathbf{v}, \quad \tilde{\mathbf{x}} = \frac{1}{h}\mathbf{x}, \quad \tilde{t} = \frac{t}{t_0}, \quad \tilde{\tau} = \frac{h^2}{f_0}\tau, \quad \tilde{p} = \frac{h^2}{f_0}p, \tag{1}$$

where $f_0 = \rho h^4/t_0^2$ is a mesophase bulk force and ρ is the nematic polymer (NLCP) density. Let c be the NLCP number density, k the Boltzmann constant, T absolute temperature, N a dimensionless concentration, η_s the solvent viscosity, and $\zeta_i, i = 1, 2, 3$ three friction coefficients related to NLCP-solvent interactions. $\mathcal{L}$ measures the range of isotropic elastic interaction while L does so for the anisotropic elastic interaction [33]. The following eight dimensionless parameters arise:

$$Re = \frac{\rho h^2}{t_0 \eta_s}, \quad \alpha = \frac{3ckTt_0^2}{h^2\rho}, \quad Er = \frac{8h^2}{N\mathcal{L}^2}, \quad \mu_i = \frac{3ckT\zeta_i t_0}{h^2\rho}, \quad i = 1, 2, 3, \quad \theta = \frac{L^2}{\mathcal{L}^2}. \tag{2}$$

α measures the strength of elastic energy relative to kinetic energy; Re is the solvent Reynolds number; Er is the Ericksen number which measures the relative strength of the short-range nematic potential and the isotropic distortional elasticity potential; θ measures the degree of anisotropy in the distortional elasticity, with values limited to $[-1, \infty)$; $1/\mu_i, i = 1, 2, 3$ are three nematic Reynolds numbers. We drop the tilde ˜ on all variables from now on so that all equations and figures in the following correspond to normalized variables, length, and time scales.

The dimensionless forms of the balance of linear momentum, stress constitutive equation, and the continuity equation (dimensional forms are in [33]) take the following form.

Linear momentum balance:

$$\frac{d}{dt}\mathbf{v} = \nabla \cdot (-p\mathbf{I} + \tau), \tag{3}$$

where external forces are neglected.

Continuity equation:

$$\nabla \cdot \mathbf{v} = 0. \tag{4}$$

Constitutive equation for the extra stress:

$$\begin{aligned}
\tau = {} & 2\eta\mathbf{D} + a\alpha[\mathbf{M} - \tfrac{\mathbf{I}}{3} - \tfrac{N}{2}((\mathbf{I} + \tfrac{1}{3NEr}\Delta)\mathbf{M}\cdot\mathbf{M} + \mathbf{M}\cdot(\mathbf{I} + \tfrac{1}{3NEr}\Delta)\mathbf{M} \\
& -2(\mathbf{I} + \tfrac{1}{3NEr}\Delta)\mathbf{M} : \mathbf{M}_4)] - \tfrac{\alpha}{6Er}(\Delta\mathbf{M}\cdot\mathbf{M} - \mathbf{M}\cdot\Delta\mathbf{M}) - \tfrac{\alpha}{12Er}[\nabla\mathbf{M} : \nabla\mathbf{M} \\
& -(\nabla\nabla\mathbf{M}) : \mathbf{M}] + \tfrac{a\alpha\theta}{12Er}[4\mathbf{M}_6 :: \nabla\nabla\mathbf{M} + 2\mathbf{M}_4\nabla\nabla :: \mathbf{M}_4 - \nabla\nabla\mathbf{M}\dddot{:}\mathbf{M}_4 - (\nabla\nabla\mathbf{M}\dddot{:}\mathbf{M}_4)^T \\
& -\mathbf{M}_4\dddot{:}\nabla\nabla\mathbf{M} - (\mathbf{M}_4\dddot{:}\nabla\nabla\mathbf{M})^T - (\mathbf{M}\nabla\nabla\dddot{:}\mathbf{M}_4)^T - \mathbf{M}\nabla\nabla\dddot{:}\mathbf{M}_4] - \tfrac{\alpha\theta}{12Er}[\nabla\nabla\mathbf{M}\dddot{:}\mathbf{M}_4 \\
& -(\nabla\nabla\mathbf{M}\dddot{:}\mathbf{M}_4)^T - \mathbf{M}_4\dddot{:}\nabla\nabla\mathbf{M} + (\mathbf{M}_4\dddot{:}\nabla\nabla\mathbf{M})^T - \mathbf{M}\nabla\nabla\dddot{:}\mathbf{M}_4 + (\mathbf{M}\nabla\nabla\dddot{:}\mathbf{M}_4)^T] \\
& +[\mu_1(a)(\mathbf{D}\mathbf{M} + \mathbf{M}\mathbf{D}) + \mu_2(a)\mathbf{D} : \mathbf{M}_4],
\end{aligned} \tag{5}$$

where $\mathbf{M}$ is the second moment of the orientational probability density function of the kinetic theory (called the structure tensor), $\mathbf{M}_4$ and $\mathbf{M}_6$ are the fourth and sixth moment of the probability density function, respectively, $\eta = 1/Re + \frac{1}{2}\mu_3(a)$ and $a = \frac{r^2+1}{r^2-1}$ parameterizes the aspect ratio r of the spheroidal molecules, where $0 < a \le 1$ corresponds to a rod-like molecule and $-1 \le a < 0$ for platelets [33].

The boundary conditions on velocity $\mathbf{v}$ are scaled to

$$\mathbf{v}|_{y=\pm 1} = (\pm De, 0, 0), \tag{6}$$

where

$$De = \frac{t_0 v_0}{h}, \tag{7}$$

the *Deborah number*, is the ratio of the relaxation time relative to the time scale set by the moving plates in the shear experiment. Weak shear is defined by a small value of De indicating the time scale set by the shear experiment is much larger than the molecular relaxation time scale. Following previous studies [8, 11, 12], we assume strong molecular anchoring at the plates given by the quiescent nematic equilibrium of the orientation tensor (the deviatoric part of the structure tensor) $\mathbf{Q}_0 = \mathbf{M}_0 - \frac{\mathbf{I}}{3} = s_0(\mathbf{nn} - \frac{\mathbf{I}}{3})$. The rest state equilibrium of $\mathbf{Q}$ at sufficiently high concentrations is a uniaxial nematic phase, with unique order parameter,

$$s_0 = \frac{1}{4}\left[1 + 3\sqrt{1 - \frac{8}{3N}}\right]. \tag{8}$$

The uniaxial director $\mathbf{n}$ is arbitrary for quiescent phases; this degeneracy is broken experimentally by mechanical or chemical plate preparations. We model a uniform plate anchoring condition, either parallel to the flow direction, called tangential anchoring, or perpendicular to the shearing plates, called normal (or homeotropic) anchoring.

The time evolution equation of $\mathbf{M}$ (in dimensionless form) is given by [33]:

$$
(9)\quad \begin{cases} \frac{d}{dt}\mathbf{M} - \Omega\cdot\mathbf{M} + \mathbf{M}\cdot\Omega - a[\mathbf{D}\cdot\mathbf{M} + \mathbf{M}\cdot\mathbf{D}] = -2a\mathbf{D} : \mathbf{M}_4 \\ -6[\mathbf{Q} - N(\mathbf{M}\cdot\mathbf{M} - \mathbf{M} : \mathbf{M}_4)] + \frac{1}{Er}[\Delta\mathbf{M}\cdot\mathbf{M} + \mathbf{M}\cdot\Delta\mathbf{M} - 2\Delta\mathbf{M} : \mathbf{M}_4] \\ +\frac{\theta}{2Er}[(\nabla\nabla\mathbf{M})\dddot{:}\mathbf{M}_4 + ((\nabla\nabla\mathbf{M})\dddot{:}\mathbf{M}_4)^T + \mathbf{M}_4\dddot{:}\nabla\nabla\mathbf{M} + (\mathbf{M}_4\dddot{:}\nabla\nabla\mathbf{M})^T \\ +\mathbf{M}\nabla\nabla\dddot{:}\mathbf{M}_4 + (\mathbf{M}\nabla\nabla\dddot{:}\mathbf{M}_4)^T - 4\mathbf{M}_6 :: \nabla\nabla\mathbf{M} - 2\mathbf{M}_4\nabla\nabla :: \mathbf{M}_4]. \end{cases}
$$

In order to arrive at a closed system of governing equations at the level of second order tensors, we approximate fourth ($\mathbf{M}_4$)and sixth ($\mathbf{M}_6$) order tensors in the above governing system of equations using the following simple closure rules:

$$
(10)\qquad \mathbf{M}_4 \approx \mathbf{MM}, \qquad \mathbf{M}_6 \approx \mathbf{MMM}.
$$

These simple closure approximations respect the traceless property of the orientational dynamic equation, and have been shown to yield a good approximation of kinetic theory in the dynamics of monodomains at the nematic concentrations of interest here [10, 15, 16]. These closures are exact when the molecules are aligned perfectly.

We remark that the distortional elastic free energy reduces to the Oseen–Frank energy after the closure approximation, in which the three Frank elastic constants are given by

$$
(11)\qquad k_1 = k_2 = \tfrac{2kT}{Er}s^2(1 + \tfrac{\theta}{3}(1 - s)), \qquad k_3 = \tfrac{2kT}{Er}s^2(1 + \tfrac{\theta}{6}(1 + 4s)).
$$

For rod-like NLCPs,

$$
(12)\qquad 0 < k_1 = k_2 < k_3;
$$

whereas for discotic NLCPs (platelets),

$$
(13)\qquad 0 < k_3 < k_1 = k_2.
$$

2.1. Asymptotic solutions in weak plane Couette flows. We seek asymptotic solutions of the governing system of equations with the boundary conditions given by (6) and (8). We employ a biaxial representation of the orientation tensor [11]

$$
(14)\qquad \mathbf{Q} = s\left(\mathbf{nn} - \frac{1}{3}\mathbf{I}\right) + \beta\left(\mathbf{n}^\perp\mathbf{n}^\perp - \frac{1}{3}\mathbf{I}\right),
$$

where (s, β) are two order parameters measuring the birefringence relative to the optical axes (also called directors) $\mathbf{n}$ and $\mathbf{n}^\perp$ confined to the shearing plane (x, y) and parameterized by a director angle ψ,

$$
(15)\qquad \mathbf{n} = (\cos\psi, \sin\psi, 0), \qquad \mathbf{n}^\perp = (-\sin\psi, \cos\psi, 0),
$$

and $\mathbf{I}$ is the 3×3 identity matrix. We propose the solution ansatz

$$
(16)\qquad v_x = \sum_{k=1}^{\infty} De^k v_x^{(k)}, \qquad (\bullet) = \sum_{k=0}^{\infty} (\bullet)_k De^k, \qquad \psi = \psi_0 + \sum_{k=1}^{\infty} \psi^{(k)} De^k,
$$

where $(\bullet)$ represents the order parameters s, β, respectively. The solution is sensitive to the choice of boundary conditions, so we present tangential ($\psi_0 = 0$) and normal ($\psi_0 = \frac{\pi}{2}$) anchoring conditions separately.

2.2. Tangential anchoring ($\psi_0 = 0$). First, we note that

$$v_x^{(2k)} = \psi^{(2k)} = s_{2k-1} = \beta_{2k-1} = 0, \qquad k = 1, \dots, \infty, \tag{17}$$

demanded by the boundary conditions and the governing equations at the respective orders. This also applies to the case of normal anchoring, but not to tilted anchoring ($\psi_0 \neq 0, \frac{\pi}{2}$) [14]. The governing equations at order $O(1)$ give the equilibrium solution of $\mathbf{Q}$ consistent with the boundary anchoring condition; the equations at order $O(De)$ are obtained by solving the following equations for $\psi^{(1)}$ and $v_x^{(1)}$:

$$\begin{aligned} \frac{\partial \psi^{(1)}}{\partial t} &= A\frac{\partial^2 \psi^{(1)}}{\partial y^2} + B\frac{\partial v_x^{(1)}}{\partial y}, \\ \frac{\partial v_x^{(1)}}{\partial t} &= \frac{\partial \tau_{xy}}{\partial y}, \\ \tau_{xy} &= C\frac{\partial^2 \psi^{(1)}}{\partial y^2} + D\frac{\partial v_x^{(1)}}{\partial y}, \end{aligned} \tag{18}$$

where

$$\begin{aligned} &A = \tfrac{1}{9Er}(s_0+2)(3+\theta(1-s_0)), \qquad B = \tfrac{1}{2}(\lambda_L - 1), \\ &C = -\tfrac{\alpha s_0^2}{18Er}[\theta(1-s_0)\lambda_L + 3(\lambda_L - 1)], \qquad D = \tfrac{1}{3}(\mu_1 s_0 + 3\eta), \end{aligned} \tag{19}$$

where the "tumbling parameter" λ_L is defined by

$$\lambda_L = \frac{a(2+s_0)}{3s_0}; \tag{20}$$

$|\lambda_L| > 1$ corresponds to flow aligning and $|\lambda_L| < 1$ yields director tumbling in monodomain shear flows ($Er \to \infty$) [14].

2.2.1. Steady state features of the major director $\psi^{(1)}$ and primary flow $v_x^{(1)}$. The nonzero leading order steady solution for the velocity, order parameters s and β, and the director angle ψ can be solved explicitly:

$$v_x^{(1)}(y) = y, \quad s_0 = s_0, \quad \beta_0 = 0, \quad \psi^{(1)}(y) = MEr(y^2 - 1), \tag{21}$$

$$M = \tfrac{9}{4(s_0+2)(3+(1-s_0)\theta)}(1 - \lambda_L). \tag{22}$$

Note that, as in the isotropic elasticity limit [14], these solvability conditions imply simple shear flow at leading order in De, and yield that the orientational distribution is dominated by nematic (director) distortions. The prefactor (22) yields that the winding number of the major director between the plates is proportional to the Ericksen number, as with the isotropic elasticity limit [14]. The formula (22) yields the scaling law for elastic distortions which are nonuniform across the gap with length-scale proportional to M^{-1}, which in turn is proscribed by three material parameters: (a, N, θ). For fixed (a, N), $|M|$ decreases as θ increases ($\theta \in [-1, \infty)$). We summarize the dependence of M on θ for given material parameters (a, N) as follows:

- The sign of M governs the "chirality" of nematic distortion, or direction of director rotation from the plates. M is negative for flow-aligning rods ($a > 0, \lambda_L > 1$) and positive for tumbling rods ($a > 0, 0 < \lambda_L < 1$) and discs or platelets ($a < 0$). $|M|$ decreases with respect to all $\theta \in [-1, \infty)$.

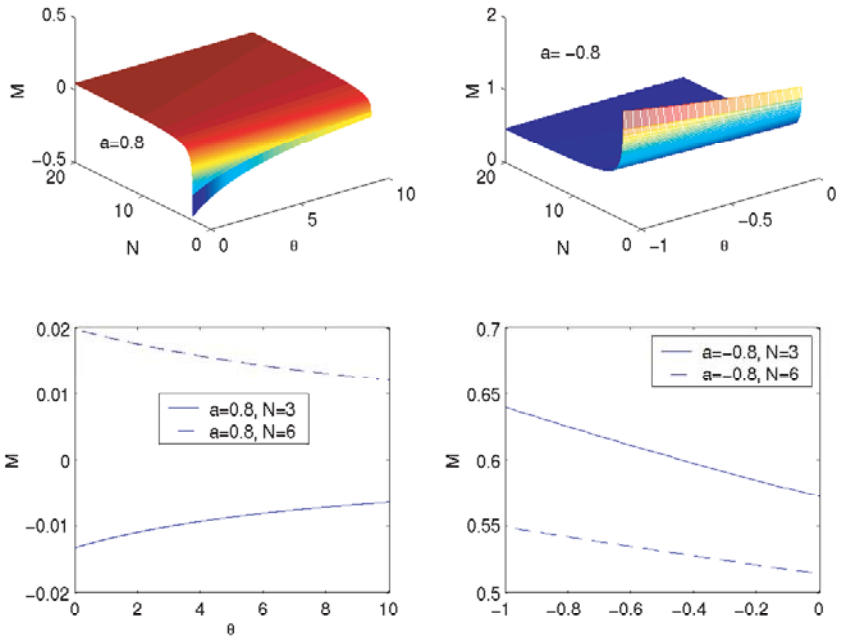

FIG. 2. *M as a function of N and θ with tangentially anchored boundary conditions in weak Couette flow: The top left panel is for rods, with $a = 0.8$, whereas the top right panel is for platelets, with $a = -0.8$. The bottom panels show M for two distinct concentrations of rods (left) and platelets (right).*

- Physically, the director angle winds counterclockwise for rods in the flow-aligning regime $\lambda_L > 1$ from the lower plate to the midplane, then unwinds from the midplane to the upper plane; the orientation reverses for rods in the tumbling regime and for platelets in all regimes.
- At fixed Ericksen number, anisotropic elasticity tends to reduce the magnitude of the director winding for rods while enhancing director distortion for platelets.

Figure 2 depicts M as a function of (N, θ) two values of a corresponding to rods ($a = 0.8$) and platelets ($a = -0.8$). Next, we consider a limited notion of stability of this steady-state structure, by studying transients of the first order governing system of equations in the presence of superimposed spatial disturbances.

2.2.2. Transient behavior of $(v_x^{(1)}, \psi^{(1)})$ near steady states. The transient solution for $v_x^{(1)}$ and $\psi^{(1)}$ (the difference between the time-dependent solution and the steady state) obeys the same homogeneous linear partial differential equations but satisfies a zero boundary condition. Its behavior dictates the stability of the steady state within the asymptotic balance model: the steady state is asymptotically stable if the transient solution vanishes as $t \to \infty$.

PROPOSITION 1. *The steady solution* (21, 22) *of system* (18) *is stable for $AD - BC > 0$ and unstable for $AD - BC < 0$ with respect to zero boundary conditions on $v_x^{(1)}$ and $\phi^{(1)}$.*

Proof. We first consider the case of $BC \neq 0$ and prove the steady solution is stable provided $AD - BC > 0$. In the following proof, we drop the superscripts on ψ and v_x. Extending $(18)_1$ to the boundary and accounting for the boundary condition $\psi(-1,t) = \psi(1,t) = 0$, we have

$$(A\tfrac{\partial^2\psi}{\partial y^2} + B\tfrac{\partial v_x}{\partial y})|_{y=\pm 1} = 0. \tag{23}$$

We introduce a nonnegative functional

$$I(t) = \int_{-1}^{1} [\delta_1 \psi_y^2 + \delta_2 v_x^2] dy \tag{24}$$

with $\delta_1 > 0$ and $\delta_2 > 0$. We note that $A > 0$ and $D > 0$ from (19). ∎

Case 1. $BC < 0$. Choosing $\delta_1 = |C|$ and $\delta_2 = |B|$ and integrating by parts, the time derivative of the nonnegative functional can be estimated:

$$\begin{aligned} \frac{dI(t)}{dt} &= -2\int_{-1}^{1} [\delta_1 A\psi_{yy}^2 + (\delta_1 B + \delta_2 C)\psi_{yy} v_{x,y} + \delta_2 D v_{x,y}^2] dy \\ &= -2\int_{-1}^{1} [|C| A\psi_{yy}^2 + |B| D v_{x,y}^2] dy < 0. \end{aligned} \tag{25}$$

This shows that the steady solution of the system is stable.

Case 2. Choose $\delta_1 = \max(\frac{C^2}{AD}, 1) \geq 1, \delta_2 = \max(\frac{B^2}{AD}, 1) \geq 1$. We have

$$\begin{aligned} \frac{dI(t)}{dt} &= 2\int_{-1}^{1} [\delta_1 \psi_y \psi_{ty} + \delta_2 v_x v_{xt}] dy \\ &= -2\int_{-1}^{1} [\delta_1 A\psi_{yy}^2 + (\delta_1 B + \delta_2 C)\psi_{yy} v_{x,y} + \delta_2 D v_{x,y}^2] dy. \end{aligned} \tag{26}$$

The integrand is quadratic and the discriminant is

$$\begin{aligned} &(\delta_1 B + \delta_2 C)^2 - 4\delta_1 A \delta_2 D \\ &= \delta_1 AD\left(\frac{B^2}{AD}\delta_1 - \delta_2\right) + \delta_2 AD\left(\frac{C^2}{AD}\delta_2 - \delta_1\right) - 2\delta_1\delta_2(AD - BC) \\ &= \delta_1 AD\left[\frac{B^2}{AD}\max\left(\frac{C^2}{AD}, 1\right) - \max\left(\frac{B^2}{AD}, 1\right)\right] \\ &\quad + \delta_2 AD\left[\frac{C^2}{AD}\max\left(\frac{B^2}{AD}, 1\right) - \max\left(\frac{C^2}{AD}, 1\right)\right] \\ &-2\delta_1\delta_2(AD - BC) < -2\delta_1\delta_2(AD - BC) < 0. \end{aligned} \tag{27}$$

The first inequality is based on $\frac{B^2C^2}{(AD)^2} < 1$ because of $AD - BC > 0$ and $BC > 0$. Since $\delta_1 A > 0$, the integrand is always positive; thus $\frac{dI(t)}{dt} < 0$. Hence the steady solution of the system is stable.

The proof for $BC = 0$ is far simpler and omitted. To prove instability when $AD - BC < 0$, we only need to find one unstable mode. Let $\phi(y,t) = \psi_y(y,t)$; the system (18) with the boundary condition becomes

$$\begin{aligned} &\phi_t = A\phi_{yy} + Bv_{x,yy}, \\ &v_{x,t} = C\phi_{yy} + Dv_{x,yy}, \\ &(A\phi_y + Bv_{x,y})|_{y=\pm 1} = 0, \quad v_x(1,t) = 1, \quad v_x(-1,t) = -1. \end{aligned} \tag{28}$$

To find an unstable mode, we seek normal modes of the form

$$\begin{pmatrix} \phi \\ v_x \end{pmatrix} = e^{\gamma t} \begin{pmatrix} \tilde{\phi}(y) \\ \tilde{v_x}(y) \end{pmatrix} \tag{29}$$

and consider the resultant eigenvalue problem

$$P \begin{pmatrix} \tilde{\phi} \\ \tilde{v_x} \end{pmatrix}_{yy} = \gamma \begin{pmatrix} \tilde{\phi} \\ \tilde{v_x} \end{pmatrix}, \qquad P = \begin{pmatrix} A & B \\ C & D \end{pmatrix}, \tag{30}$$

where γ is the growth rate. The steady solution is unstable if $\gamma > 0$.

The matrix P has two distinct eigenvalues given by

$$r_1 = \frac{A+D-\sqrt{(A+D)^2-4(AD-BC)}}{2} < 0, \qquad r_2 = \frac{A+D+\sqrt{(A+D)^2-4(AD-BC)}}{2} > 0. \tag{31}$$

Let $\xi = \arctan \frac{A-r_1}{B}$, then

$$\begin{pmatrix} \tilde{\phi} \\ \tilde{v_x} \end{pmatrix} = \begin{pmatrix} \cos\xi & \sin\xi \\ -\sin\xi & \cos\xi \end{pmatrix} \begin{pmatrix} \cos\xi \dfrac{\sin\sqrt{\frac{\gamma}{-r_1}}y}{\sin\sqrt{\frac{\gamma}{-r_1}}} \\ \sin\xi \dfrac{\sinh\sqrt{\frac{\gamma}{r_2}}y}{\sinh\sqrt{\frac{\gamma}{r_2}}} \end{pmatrix} \tag{32}$$

is a solution of (28) satisfying $v_x(1,t) = v_x(-1,t) = 0$ and γ is determined by $(A\phi_y + Bv_{x,y})|_{y=\pm 1} = 0$, which yields

$$(A - r_1)(1 + \tfrac{A(A-r_1)}{B^2}) \coth\sqrt{\tfrac{\gamma}{r_2}} - \sqrt{-r_1 r_2}\cot\sqrt{\tfrac{\gamma}{-r_1}} = 0. \tag{33}$$

As $\gamma \to +\infty$, the first term goes to a finite value while the second one is periodic and varies between $-\infty$ and $+\infty$ within one period. Consequently, the equation has infinitely many positive solutions for γ, which completes the proof, and indicates that the diagnostic $AD - BC$ signals catastrophic instability when it is negative.

We note that for discs ($a < 0$) and flow-aligning rods ($a > 0, \lambda_L > 1$),

$$\begin{aligned} AD - BC = \tfrac{1}{27Er}[&3(2+s_0)(\mu_1 s_0 + 3\eta) + \tfrac{\alpha}{4}((\lambda_L - 1)3s_0)^2 \\ &+\theta(1-s_0)(2+s_0)(\tfrac{\alpha}{12}a((\lambda_L-1)3s_0) + \mu_1 s_0 + 3\eta)] > 0. \end{aligned} \tag{34}$$

Hence, the steady state is always stable for discotic LCPs and flow-aligning rods, and may be unstable only for tumbling rods ($0 < a, 0 < \lambda_L < 1$).

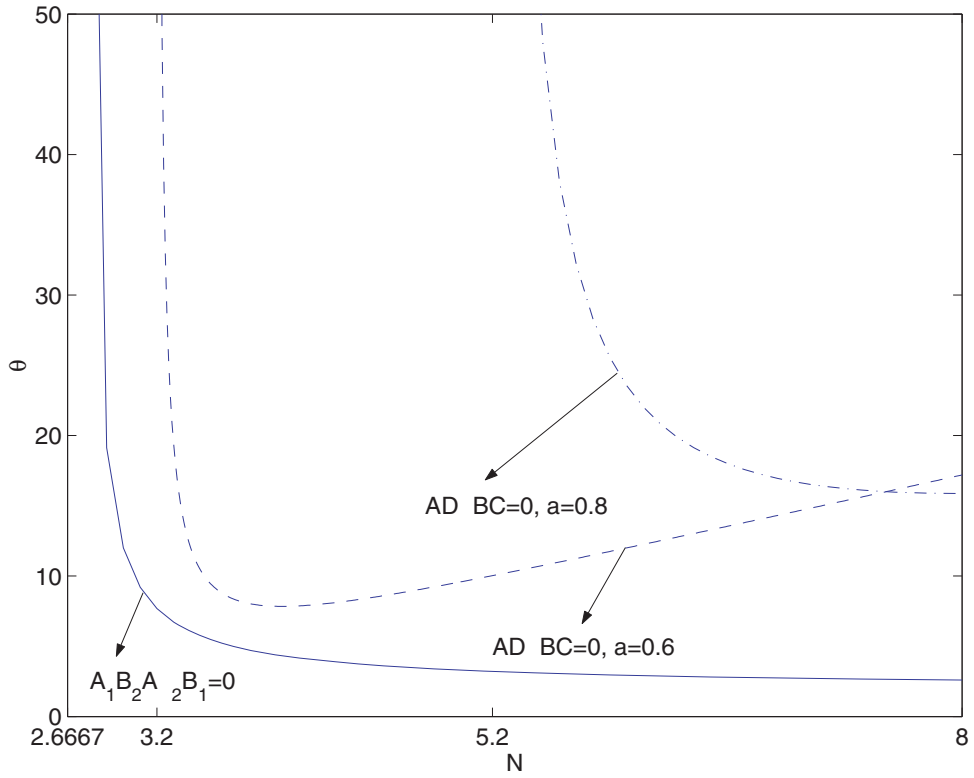

FIG. 3. *The neutral stability curves defined by* $A_1B_2 - A_2B_1 = 0$ *and* $AD - BC = 0$ *with tangentially anchored boundary conditions in weak shear. The arrows point to the positive directions of the discriminant. The systems for* (s_2, β_2) *and* $(\psi^{(1)}, v_x^{(1)})$ *are stable when the discriminant is positive, respectively, unstable otherwise. The parameter values are* $Er = 100, \alpha = 1, \mu_1 = 0.001$ *and* $\eta = 0.002$.

The neutral stability curve ($AD - BC = 0$) depends on the values of the parameters $(\theta, a, N, \alpha, \mu_1, \eta)$. From (34), $AD - BC > 0$ can be translated into two separate constraints on the energy parameter α and θ,

$$\begin{aligned} &\alpha \le \alpha_c = \tfrac{4(\mu_1 s_0 + 3\eta)}{a(1-\lambda_L)s_0}; \text{ or} \\ &\alpha > \alpha_c \quad \text{and} \quad \theta < \theta_c = \tfrac{3(2+s_0)(\mu_1 s_0 + 3\eta) + \frac{\alpha}{4}((\lambda_L - 1)3s_0)^2}{(1-s_0)(2+s_0)(\frac{\alpha}{12}a((1-\lambda_L)3s_0) - \mu_1 s_0 + 3\eta)}. \end{aligned} \tag{35}$$

Figure 3 depicts the stability transition curve in the parameter space (N, θ) at a few selected values of other parameters. We observe that the values of N, θ that yield instability tend to be large and out of the practical range for nematic polymer materials. We also note that the flow-aligning region and the stable region versus (N, θ) both grow significantly as the shape parameter a increases, i.e., as the aspect ratio becomes more extreme. The instability region vanishes as $a \to \frac{3s_0}{2+s_0}$. The stable region also grows as $\mu_1/\alpha, \eta/\alpha$ increase.

We summarize this more precise statement of Proposition 1 in the following corollary.

COROLLARY 1. *The steady asymptotic solution* (21, 22) *is asymptotically stable within the leading order balance equations if either of conditions* (35) *is satisfied. If*

$\alpha > \alpha_c$ and $\theta > \theta_c$, where α_c, θ_c are defined in (35)*, the steady solution is unstable and the leading order system of equations is ill-posed.*

2.2.3. Steady state features of the order parameters s_2 and β_2 at $O(De^2)$. The order parameters (s, β) vanish at leading order in De, with order $O(De^2)$ behavior governed by the equations

$$\begin{aligned}
\frac{\partial s_2}{\partial t} &= \frac{-1}{9Er}\Big(A_1\frac{\partial^2 s_2}{\partial y^2} + B_1\frac{\partial^2 \beta_2}{\partial y^2} + C_1 s_2 + D_1\beta_2 + E_1\big(\frac{\partial \psi^{(1)}}{\partial y}\big)^2 + \\
&F_1\psi_1\frac{\partial^2 \psi^{(1)}}{\partial y^2} + G_1\psi^{(1)}\frac{\partial v_x^{(1)}}{\partial y}\Big) + 2s_0\psi^{(1)}\frac{\partial \psi^{(1)}}{\partial t}, \\
\frac{\partial \beta_2}{\partial t} &= \frac{-1}{9Er}\Big(A_2\frac{\partial^2 s_2}{\partial y^2} + B_2\frac{\partial^2 \beta_2}{\partial y^2} + C_2 s_2 + D_2\beta_2 + E_2\big(\frac{\partial \psi^{(1)}}{\partial y}\big)^2 + \\
&F_2\psi^{(1)}\frac{\partial^2 \psi^{(1)}}{\partial y^2} + G_2\psi^{(1)}\frac{\partial v_x^{(1)}}{\partial y}\Big) - 2s_0\psi^{(1)}\frac{\partial \psi^{(1)}}{\partial t},
\end{aligned} \tag{36}$$

where the coefficients are lengthy and provided in Appendix A. This system of equations is linear in (s_2, β_2) but driven by nonlinear functions of $v_x^{(1)}$ and $\psi^{(1)}$.

The steady solution, with Λ and Γ defined in the appendix, is

$$\begin{aligned}
\beta_2(y) &= K_1\Big(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\Big) + K_2\Big(\frac{\cosh(\sqrt{Er}\Gamma y)}{\cosh(\sqrt{Er}\Gamma)} - 1\Big) + R_1 Er(y^2 - 1), \\
s_2(y) &= K_3\Big(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\Big) + K_4\Big(\frac{\cosh(\sqrt{Er}\Gamma y)}{\cosh(\sqrt{Er}\Gamma)} - 1\Big) + S_1 Er(y^2 - 1),
\end{aligned} \tag{37}$$

where the coefficients are given in Appendix B.

We denote $\lambda^2 = 1/(Er\Lambda)$ and $\mu^2 = 1/(Er\Gamma)$; λ^2 is always positive and concave up as a function of θ, whereas μ^2 is monotonically decreasing and may change sign as θ varies. For example, μ^2 goes through zero at a critical degree of anisotropy $\theta_c = 2.93$ for $N = 6$. For $\theta > \theta_c$, the steady state becomes highly oscillatory; we show in the study of transient solutions that this behavior coincides with the onset of ill-posedness in the governing system of equations. The behavior of θ_c versus concentration N can be gleaned from Figure 3.

Since the dominating terms in the order parameters near $y = \pm 1$ are

$$\frac{e^{\sqrt{Er}\Lambda y}}{e^{\sqrt{Er}\Lambda}}, \qquad \frac{e^{\sqrt{Er}\Gamma y}}{e^{\sqrt{Er}\Gamma}}, \tag{38}$$

the order parameters have a boundary layer near the wall, whose width is proportional to

$$\frac{1}{\sqrt{Er}\Lambda}, \qquad \frac{1}{\sqrt{Er}\Gamma}, \tag{39}$$

respectively. These are the penetration depths of the wall layer for tangential anchoring, which agrees with the asymptotic analysis of the DMG model [14] in the single elastic constant limit. One finds the order parameters are coupled with anisotropic elasticity, i.e., the orientational distribution is strongly biaxial (birefringent in any plane). For both rods and discs, by comparing the two exponential terms in β_2 and s_2, we notice that the boundary layer in s_2 is governed by $\frac{1}{\sqrt{Er}\Lambda}$, whereas in β_2 by $\frac{1}{\sqrt{Er}\Gamma}$, so that their scaling behavior is incommensurate with the leading order wall layer scaling.

TABLE 1

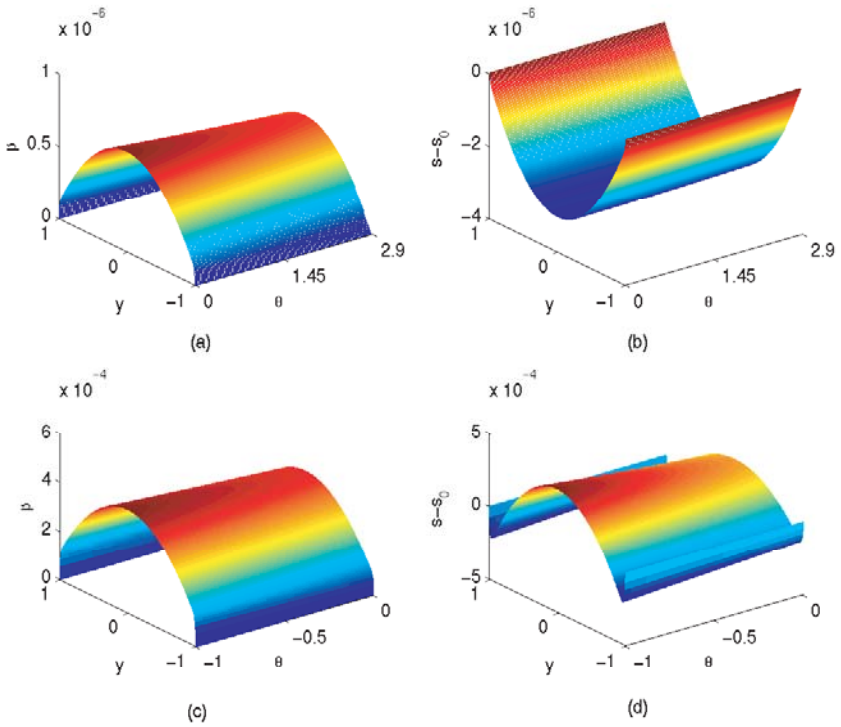

FIG. 4. *The steady-state asymptotic solutions β (left column) and $s - s_0$ (right column) in the tumbling regime as functions of (θ, y) with tangentially anchored boundary conditions in weak Couette flows.* (a) *and* (b) *depict the solution for rods with parameter values* $a = 0.8, N = 6, De = 0.01, Er = 100$. (c) *and* (d) *depict the solution for discs with parameter values* $a = -0.8, N = 6, De = 0.01, Er = 100$.

Table 1 tabulates the general behavior of the steady states in the regime of flow-aligning and tumbling for both rods and discs, in which FA stands for flow-aligning, T denotes tumbling, and BL denotes a boundary layer. The concavity switching phenomenon between tumbling and flow-aligning materials, noted in [14], is observed in both rods and discs. The steady states are in general insensitive to changes in θ. In addition, the order parameter correction s_2 goes through a similar transition for rods versus discs, whereas β has the same concavity; this is another indication of strong biaxiality for anisotropic elasticity. Figure 4 depicts a typical steady state asymptotic solution of (s_2, β_2) for tumbling rods $(a = 0.8)$ and tumbling discs $(a = -0.8)$.

2.2.4. Transient behavior of (s_2, β_2) near steady states. The transient behavior of the order parameters s_2 and β_2 obey:

$$\begin{aligned}\frac{\partial \tilde{s_2}}{\partial t} &= \frac{-1}{9Er}\left(A_1\frac{\partial^2 \tilde{s_2}}{\partial y^2} + B_1\frac{\partial^2 \tilde{\beta}_2}{\partial y^2} + C_1\tilde{s_2} + D_1\tilde{\beta}_2\right),\\ \frac{\partial \tilde{\beta}_2}{\partial t} &= \frac{-1}{9Er}\left(A_2\frac{\partial^2 \tilde{s_2}}{\partial y^2} + B_2\frac{\partial^2 \tilde{\beta}_2}{\partial y^2} + C_2\tilde{s_2} + D_2\tilde{\beta}_2\right),\end{aligned} \tag{40}$$

with zero boundary conditions.

After tedious but straightforward Fourier analysis, the growth ($\sigma' > 0$) or decay ($\sigma' < 0$) of solutions $\tilde{s_2}(y,t)$ and $\tilde{\beta}_2(y,t)$, due to the time-dependent factor $e^{\sigma' t}$, is determined by $sgn(\sigma')$

$$\sigma'_{\pm} = -\tfrac{1}{2}[C_1 + D_2 - A_1k^2 - B_2k^2 \pm$$

$$\sqrt{(C_1 + D_2 - A_1k^2 - B_2k^2)^2 - 4((A_2k^2 - C_2)(D_1 - B_1k^2) + (C_1 - A_1k^2)(D_2 - B_2k^2))}]. \tag{41}$$

We now analyze $sgn(\sigma'_{\pm})$ to deduce stability. For long waves ($|k| << 1$), asymptotic formulae can be derived:

$$\sigma'_{\pm} \sim -\frac{1}{2}[C_1 + D_2 \pm \sqrt{(C_1 + D_2)^2 + 4(C_2D_1 - C_1D_2)}]. \tag{42}$$

Using the formulae in Appendix B, $C_1, D_2 > 0, C_2 = 0$, which implies $\sigma'_{\pm} < 0$. On the other hand, the growth rate for short waves ($|k| >> 1$) is dominated by

$$\sigma'_{\pm} \sim \frac{1}{2}[A_1 + B_2 \pm \sqrt{(A_1 + B_2)^2 + 4(A_2B_1 - A_1B_2)}]k^2. \tag{43}$$

We find $\sigma'_{\pm} < 0$ only for sufficiently small $|\theta|$. Otherwise, $A_1B_2 - A_2B_1$ may be negative, leading to a positive growth rate proportional to k^2, an ill-posed behavior. The transition to ill-posedness, $A_1B_2 - A_2B_1 = 0$, simplifies dramatically to the condition $\theta = \frac{6}{5s_0-2}$, where s_0 is given in (8). This neutral stability curve is plotted in Figure 3.

PROPOSITION 2. *The steady state solution* (s_2, β_2) *of* (36) *is catastrophically unstable if and only if the degree of anisotropic elasticity satisfies*

$$\theta > \frac{6}{5s_0 - 2}. \tag{44}$$

2.2.5. Rheological features of steady structures. The shear viscosity (shear stress divided by local shear rate) at the plates is identical to the averaged shear viscosity over the shear cell; it is a nonzero constant at $O(De)$, given by

$$\eta_{wall} = \frac{\tau_{xy}}{\frac{dv_x^{(1)}}{dy}} = \frac{\alpha a^2(1-\frac{1}{\lambda_L})[\theta(1-s_0)+3(1-\frac{1}{\lambda_L})]}{36(3+\theta(1-s_0))} + \tfrac{1}{3}(\mu_1 s_0 + 3\eta). \tag{45}$$

It can be readily shown that η_{wall} is a slowly varying, decreasing function of the degree of anisotropic elasticity θ for tumbling rods and all platelet nematic liquids; however, η_{wall} increases versus θ for flow-aligning rods. Nonzero first normal stress difference N_1 and second normal stress difference N_2 show up at order $O(De^2)$ and

are given in Appendix C. These non-Newtonian effects are measurable physically, e.g., $N_1 > 0$ corresponds to pushing the parallel plates apart and $N_1 < 0$ corresponds to pulling the plates together. N_1 is a linear combination of α and μ_2 and N_2 is a linear combination of α and $\mu_1 + \mu_2$. At walls, the terms containing $\mu_{1,2}$ drop out so that N_1 and N_2 are proportional to α:

$$\begin{aligned}
N_1 = [&\tfrac{G}{54Er}(K_3\lambda^2 + K_4\mu^2 + 2\,S) \\
&+\tfrac{(-4a\theta+3s_0+16a\theta s_0^3-12a+12as_0^2-12a\theta s_0)}{108Er}\left(K_1\lambda^2 + K_2\mu^2 + 2\,R\right) \\
&+\tfrac{4K^2 s_0}{27Er}(-4a\theta {s_0}^2 - 4a\theta + 24a\theta {s_0}^3 - 6as_0 + 9s_0 + 18a{s_0}^2 - 12a - 16a\theta s_0)]\alpha, \\
N_2 = [&-\tfrac{G}{54Er}(K_3\lambda^2 + K_4\mu^2 + 2\,S) \\
&+\tfrac{(8a\theta+12a-3+8as_0-16as_0^2-12s_0)s_0}{108Er}\left(K_1\lambda^2 + K_2\mu^2 + 2\,R\right) \\
&+\tfrac{4K^2 as_0}{27Er}(8\theta {s_0}^2 + 2\theta - 24\theta {s_0}^3 + 12s_0 - 9s_0 - 18a{s_0}^2 + 6 + 14\theta s_0)]\alpha,
\end{aligned} \tag{46}$$

where G, K, R, S, λ, μ and $K_i (i = 1, 2, 3, 4)$ are given in Appendix C.

Figure 5 depicts N_1 and N_2 for tumbling rods as well as discs as functions of y at some parameter values; Figure 6 shows N_1 and N_2 for flow-aligning rods and discs. Table 3 lists the averaged normal stress differences calculated in four representative cases. We summarize the noticeable features in the stress differences below.

- For flow-aligning rods, $N_1 < 0$ and $N_2 > 0$ across the gap; their signs change in plate boundary layers for small degree θ of elastic anisotropy.
- These properties reverse for flow-aligning or tumbling discs, which may experience sign changes in N_1 and N_2 in the middle of the plate gap for small $|\theta|$.
- For tumbling rods and all discotic NLCPs, $N_1 > 0$ and $N_2 < 0$, with sign changes for rods in the wall boundary layer for large θ, and sign changes for platelets in the midgap at small $|\theta|$.
- The averages across the gap yield $N_1 > 0$ and $N_2 < 0$ for flow-aligning rods, and $N_1 < 0$ and $N_2 > 0$ in all other cases.

2.3. Homeotropic anchoring ($\psi_0 = \frac{\pi}{2}$). The boundary anchoring condition affects only the coefficients of the governing system of partial differential equations at each order. The structure of the equations at $O(De)$ for $(v_x^{(1)}, \psi^{(1)})$ are identical to (18) with the following new coefficients:

$$\begin{aligned}
&A = \tfrac{1}{9Er}(s_0 + 2)(3 + \theta(2s_0 + 1)), \qquad B = -\tfrac{1}{2}(1 + \lambda_L), \\
&C = \tfrac{\alpha s_0}{18Er}[\theta(2s_0 + 1)\lambda_L + 3(\lambda_L + 1)], \qquad D = \tfrac{1}{3}(\mu_1 s_0 + 3\eta).
\end{aligned} \tag{47}$$

The nonzero leading order solution for the order parameters, primary velocity component, and major director angle are

$$s_0 = s_0, \quad \beta_0 = 0, \quad v_x^{(1)}(y) = y, \quad \psi^{(1)}(y) = MEr(y^2 - 1), \tag{48}$$

$$M = \frac{9}{2(s_0 + 2)(3 + \theta(2s_0 + 1))}(1 + \lambda_L). \tag{49}$$

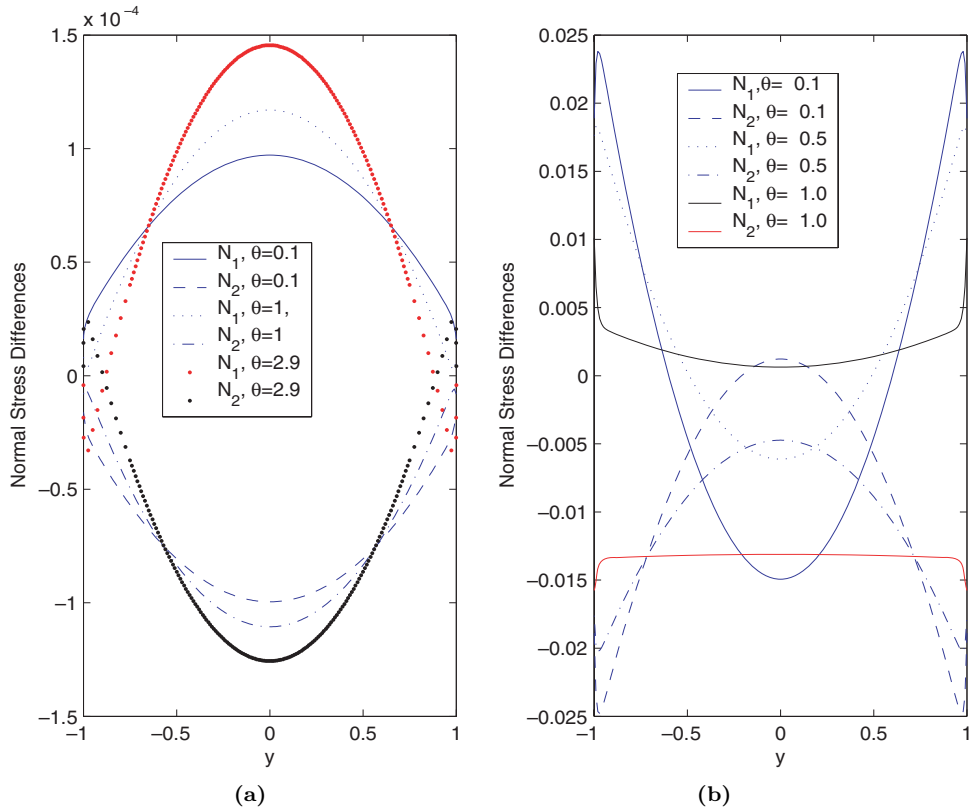

FIG. 5. *The normal stress differences N_1 and N_2 in tumbling regimes as functions of y at selected values of θ with tangentially anchored boundary conditions in weak shear.* (a) *Rods:* $a = 0.8, N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_1 = 0.01, \eta = 0.02$. (b) *Discs:* $a = -0.8, N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_1 = -0.01, \eta = 0.02$.

It is easy to see that $|M|$ decreases with respect to θ; M is negative for flow-aligning discs ($a < 0, \lambda_L < -1$) and positive for all other cases. Thus, directors wind counterclockwise from the lower shearing plate to the midplane, and unwind from the midplane to the upper plate for flow-aligning discs. The winding reverses direction in the other cases.

Analogous to tangential anchoring, *steady states may be catastrophically unstable for discs in the flow-aligning regime $a < 0, \lambda_L < -1$ if $AD - BC < 0$, yet are stable in the other cases, where*

$$AD - BC = \tfrac{1}{27Er}\,[(s+2)(\mu_1 s_0 + 3\eta)(\theta(2s_0+1)+3) + \tfrac{\alpha s_0}{4}(1+\lambda_L)(a\theta(2s_0+1)(s_0+2) + 9s_0(1+\lambda_L))]. \tag{50}$$

PROPOSITION 3. *The steady-state solution is stable so long as*

$$\theta > \theta_c = -\frac{12(s_0+2)(\mu_1 s_0 + 3\eta) + 9\alpha s_0^2(1+\lambda_L)^2}{4(s_0+2)(2s_0+1)(\mu_1 s_0 + 3\eta) + a\alpha s_0(1+\lambda_L)(1+2s_0)(2+s_0)}. \tag{51}$$

The governing system of equations for the order parameters (s, β) at order $O(De^2)$ is of the same form as tangential anchoring, with different coefficients given in Appendix C.

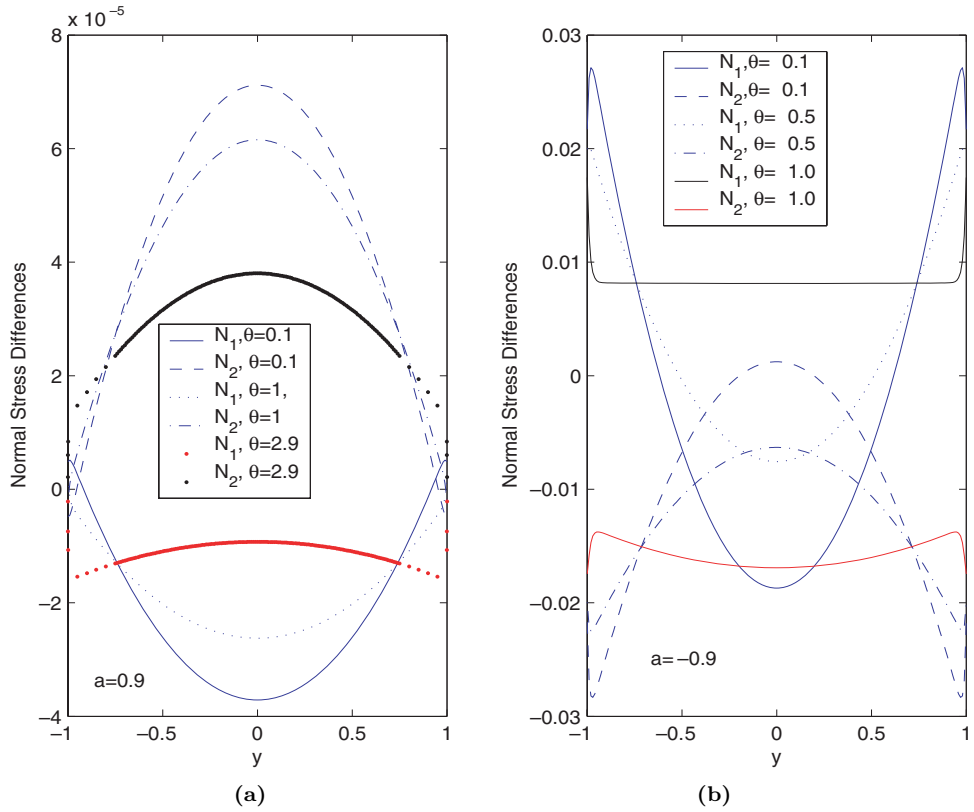

FIG. 6. *The normal stress differences N_1 and N_2 in flowing-aligning regimes as functions of y at selected values of θ with tangentially anchored boundary conditions in weak shear.* (a) *Rods:* $a = 0.9, N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_1 = 0.01, \eta = 0.02$. (b) *Discs:* $a = -0.9, N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_1 = -0.01, \eta = 0.02$.

The steady solutions are

$$\beta_2(y) = K_{11}\left(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\right) + R_2 Er(y^2 - 1),$$
$$s_2(y) = K_{21}\left(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\right) + K_{22}\left(\frac{\cosh(\sqrt{Er}\Gamma y)}{\cosh(\sqrt{Er}\Gamma)} - 1\right) + S_2 Er(y^2 - 1). \tag{52}$$

In this solution, μ^2 (defined earlier) changes sign only as θ varies below a threshold value θ_d for platelets. Again, the change of sign in μ^2 coincides with ill-posedness in the governing system of equations.

Notice that in s_2, there are two cosh terms, whereas there is only one in β_2. For rods, the second term in s_2 dominates in the boundary layer while the first term dominates for discs. Table 2 tabulates features of the steady states. Compared with results above for tangential anchoring, the steady states with normal anchoring are more sensitive to the degree θ of elastic anisotropy. The order parameter variation versus θ decreases for rods and increases for platelets. The solution profiles switch concavity in the boundary layer for flow-aligning versus tumbling discotics, whereas the concavity remains the same for rods. Figure 7 depicts typical steady solutions for tumbling rods and discs.

TABLE 2
Steady-state features of the order parameter morphology for Couette flow with normal anchoring.

	FA/rods	FA/discs	T/rods	T/discs
$s - s_0$	Concave down	Concave down & Concave up in BL	Concave down & Concave up in BL	Concave up & Concave down in BL

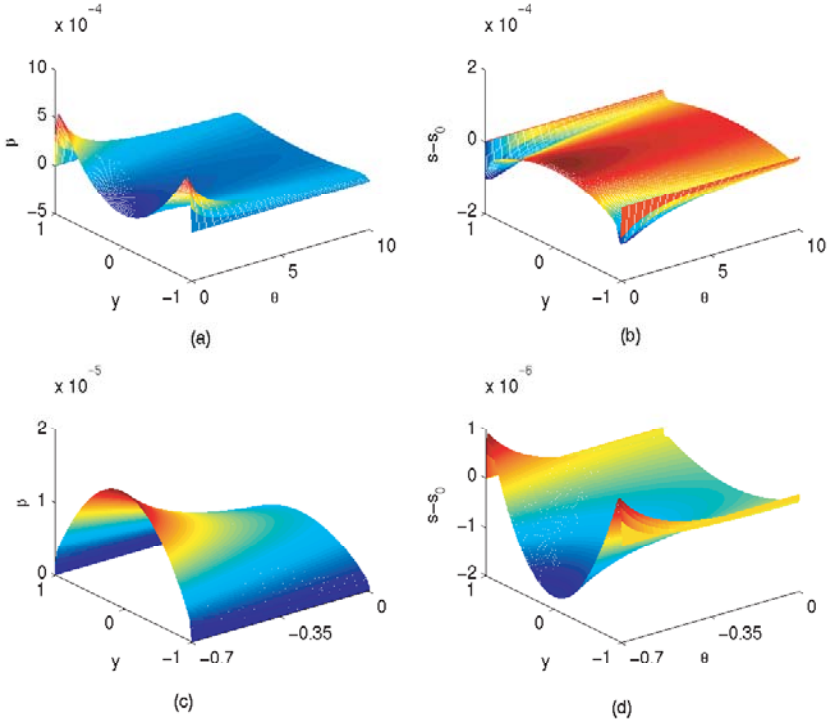

FIG. 7. *The steady-state asymptotic solution as functions of* (θ, y) *in tumbling regime with normally anchored boundary condition in weak shear.* (a) *and* (b) *depict the solution for rods with parameter values* $a = 0.8, N = 6, De = 0.01, Er = 100$. (c) *and* (d) *depict the solution for discs with parameter values* $a = -0.8, N = 6, De = 0.01, Er = 100$.

Again the governing system can become ill-posed. The growth rate formulae for the steady states are identical to (41), but with new coefficients. Notice that the discriminant $A_1B_2 - A_2B_1 = 4(1 - s_0)^2(1 + 2s_0)[3 + \theta(1 + 2s_0)][3 + \theta(1 + 4s_0)]$. For rods, $\theta > 0$ and $A_1B_2 - A_2B_1 > 0$ indicating stability. For discs and $\theta < -\frac{3}{1+4s_0}$, the discriminant is negative so that the steady state is unstable.

PROPOSITION 4. *The system for the two order parameters* (s_2, β_2) *is locally ill-posed if and only if* $\theta < \theta_d$, *where*

$$\theta_d = -\frac{3}{1 + 4s_0}. \tag{53}$$

The shear viscosity at the walls in this case is given by

$$\eta_{wall} = \frac{\tau_{xy}}{\frac{dv_x^{(1)}}{dy}} = \frac{\alpha a^2(1+\frac{1}{\lambda_L})(2\theta(2s_0+1)+3(1+\frac{1}{\lambda_L}))}{36(\theta(2s_0+1)+3)} + \frac{1}{3}(\mu_1 s_0 + 3\eta). \tag{54}$$

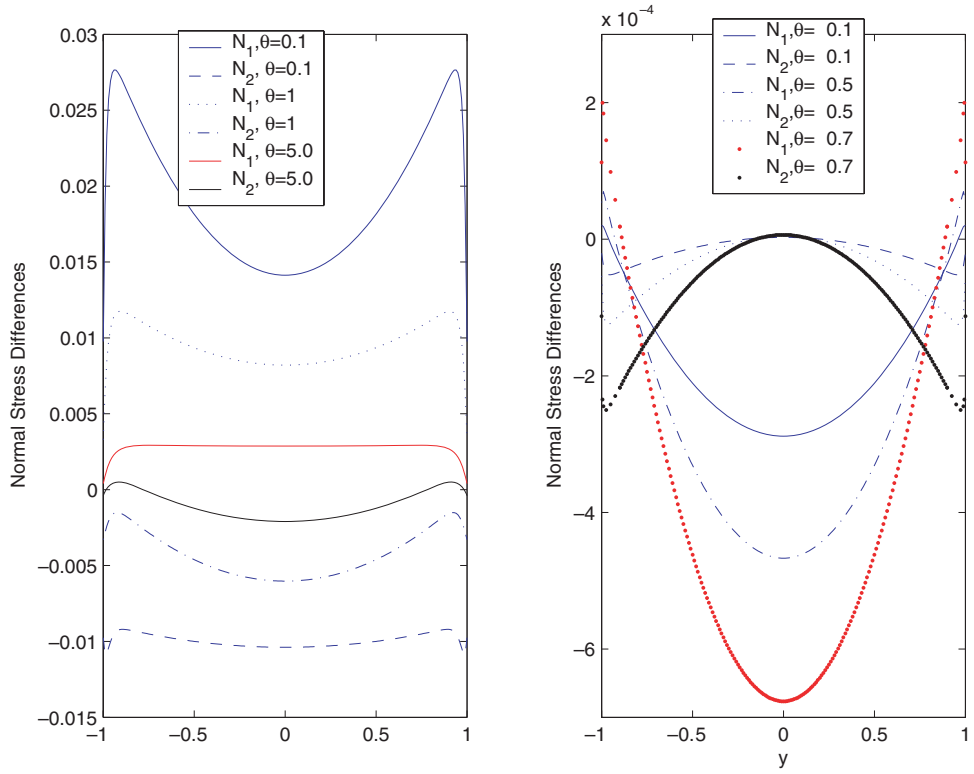

FIG. 8. *The normal stress differences N_1 and N_2 as functions of y in tumbling regime at selected values of θ with normally anchored boundary conditions in weak shear. The parameter values are $a = \pm 0.8, N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_1 = \pm 0.01, \mu_2 = 0.02$ for rods and discs, respectively.*

Similar to the case of tangential anchoring, the viscosity decreases with respect to θ for rods and flow-aligning discs, but increases with respect to θ for tumbling discs. The leading order normal stress differences again show up at $O(De^2)$ and are given in Appendix D.

Figures 8 *and* 9 *depict representative plots of the first and second normal stress differences in tumbling and flow-aligning regimes, respectively, and demonstrate the following properties:*

- *Rods are more sensitive to the variation in degree θ of elastic anisotropy than discs.*
- *For tumbling rods, $N_1 > 0$ and $N_2 < 0$ except there may be a sign change in a boundary layer near the wall at large θ. For tumbling discs, N_1 and N_2 are both negative except that N_1 is positive in a boundary layer near the wall.*
- *The behavior of the normal stress differences does not change much for flow-aligning rods compared with tumbling rods. For flow-aligning discs, $N_1 > 0$ and $N_2 > 0$ except that N_2 is negative in boundary layer near the wall.*
- *The average values across the gap obey $N_1 > 0$ and $N_2 < 0$ for rods, but they may change signs for discs.*

The averaged normal stress differences are tabulated in Table 3.

In summary, the salient predictions from this analysis are:

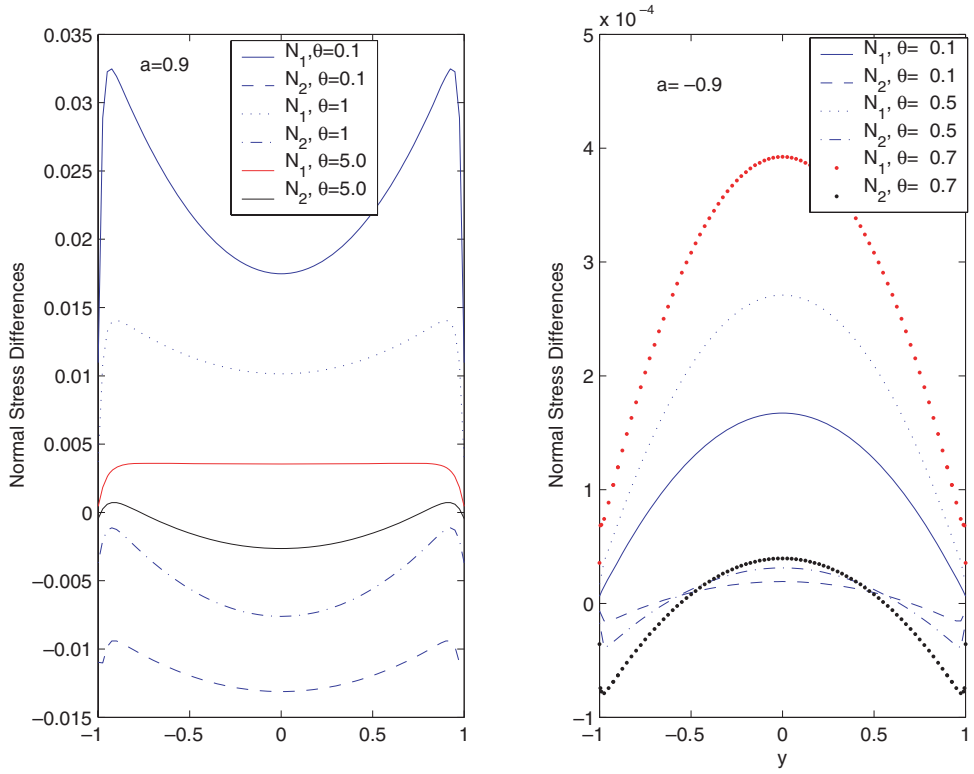

FIG. 9. *The normal stress differences N_1 and N_2 as functions of y in flowing-aligning regime at selected values of θ with normally anchored boundary conditions in weak shear. The parameter values are $a = \pm 0.9, N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_1 = \pm 0.01, \mu_2 = 0.02$ for rods and discs, respectively.*

TABLE 3
The averaged normal stress differences (Couette).

	FA/rods	FA/discs	T/rods	T/discs
Tangential	$N_1 < 0, N_2 > 0$	$N_1 > 0, N_2 < 0$	$N_1 > 0, N_2 < 0$	$N_1 > 0, N_2 < 0$
Normal	$N_1 > 0, N_2 < 0$	$N_1 > 0$	$N_1 > 0, N_2 < 0$	$N_1 < 0, N_2 < 0$

- The major director winds counterclockwise from the bottom to top plates, for both flow-aligning rods in tangential anchoring and flow-aligning discs in homeotropic anchoring. Remarkably, the principal orientation axis rotates clockwise if the nematic polymer tumbles in weak shear rather than flow aligns. The magnitude of winding of the orientation axis, which sets the number of bands of nematic distortion, reduces with the degree of elastic anisotropy θ.
- The order parameters are relatively insensitive to the degree of elastic anisotropy in tangential anchoring, and more sensitive in normal anchoring.
- Ill-posedness may occur within each order of asymptotic equations depending on the values of the parameters, although the full equations are well posed. This transition implies a breakdown in the asymptotic ordering which allows explicit solution and scaling properties, and suggests a physical transition away from these asymptotic structures.

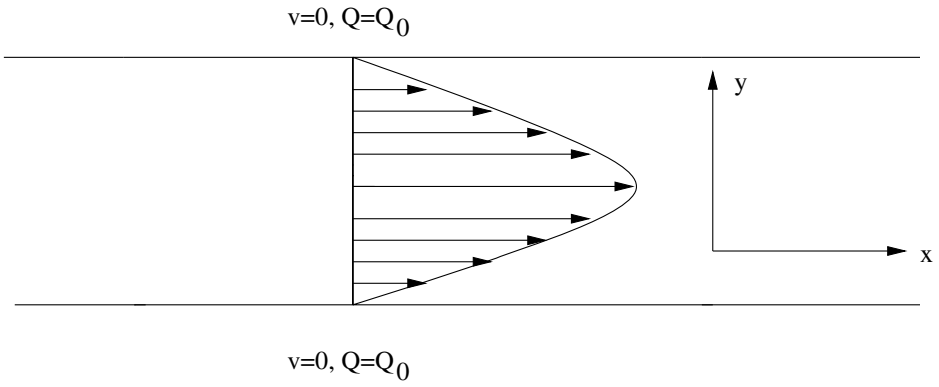

FIG. 10. *The geometry of the plane Poiseuille flow. A pressure gradient* $\frac{\partial p}{\partial x} = -De^2$ *is imposed across the channel. At the bounding surfaces, the orientation tensor is assumed to equal to its equilibrium value.*

- The averaged shear viscosity varies weakly with respect to the strength of anisotropic elasticity.
- The averaged normal stress differences may take on all possible signs depending on the parameter regime.

3. Spatial structures in weak Poiseuille flows. In this section, we study steady structures in the direction of the velocity gradient under an imposed, small pressure gradient $\frac{\partial p}{\partial x}$ in plane Poiseuille flow. Figure 10 depicts the cross section of the plane Poiseuille flow on the (x, y) plane. The boundary condition for the orientation tensor is identical to that used for shear flows while the velocity boundary condition is no-slip $\mathbf{v}(\pm 1) = \mathbf{0}$. As before, we use h and $t_0 = t_n = \frac{1}{D_r}$ as the characteristic length and time scale, respectively. We adopt the same dimensionless symbols used in weak plane Couette and assume $\frac{\partial p}{\partial x} = -\epsilon = -De^2$ in the dimensionless form, where the Deborah number is defined by

$$De = \sqrt{-\frac{\partial p}{\partial x}\frac{t_0^2}{\rho h}}, \qquad \epsilon = De^2. \tag{55}$$

We seek asymptotic solutions in powers of ϵ. The momentum equation yields at order $O(\epsilon)$:

$$\frac{\partial v_x^{(1)}}{\partial t} = -1 + \frac{\partial \tau_{xy}^{(1)}}{\partial y}. \tag{56}$$

The other governing equations are identical to those derived for plane Couette flows. Hence, the transient solution and the stability of steady states are identical to the corresponding problems in plane Couette flows. We will not repeat them here; instead, we only present the asymptotic steady states with respect to the two anchoring conditions.

3.1. Tangential anchoring ($\psi_0 = 0$). The steady solutions up to order $O(\epsilon)$ are

$$s_0 = s_0, \quad \beta_0 = 0, \quad v_x^{(1)}(y) = H_1(1 - y^2), \quad \psi^{(1)}(y) = H_2 Ery(1 - y^2), \tag{57}$$

where H_1 and H_2 are given in Appendix E. The positivity of H_1 coincides with the stability of the steady state, giving rise to a parabolic velocity profile. H_2 is positive for flow aligning rods and negative otherwise in stable steady states. H_2 behaves more or less like the diagnostic M in the plane Couette flow. Notice that $\psi^{(1)}$ is an odd function of y leading to an asymmetric major director pattern, known as a chevron pattern, with respect to the midplane [6, 2, 3].

For flow-aligning rods in stable steady states, H_1 (H_2) decreases (increases) with respect to θ, and increases (decreases) with respect to θ in all other cases. The rotational pattern of the major director (a function of $\psi^{(1)}$) is dictated by λ_L. For flow-aligning rods, $\lambda_L > 1$, the major director rotates counterclockwise from the lower plate to the $\frac{\sqrt{3}}{6}$ of the shear cell and then reverses its rotation to the midplane. The orientation pattern in the top half of the cell is the mirror image of that in the lower half. The rotation reverses for the other cases where $\lambda_L < 1$.

The steady solutions of the order parameters at order $O(\epsilon^2)$ are given by

$$\beta_2(y) = K_{11}\left(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\right) + K_{12}\left(\frac{\cosh(\sqrt{Er}\Gamma y)}{\cosh(\sqrt{Er}\Gamma)} - 1\right) + R_{11}(y^4 - 1) + R_{12}(y^2 - 1),$$

$$s_2(y) = K_{21}\left(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\right) + K_{22}\left(\frac{\cosh(\sqrt{Er}\Gamma y)}{\cosh(\sqrt{Er}\Gamma)} - 1\right) + R_{21}(y^4 - 1) + R_{22}(y^2 - 1), \tag{58}$$

where the coefficients are given in Appendix E. The order parameters behave like a quartic polynomial with respect to y in most part of the cell except at the boundary layers near the plates. The velocity $v_x^{(1)}$, angle variable $\psi^{(1)}$ and the order parameter β_2 are insensitive to the variation of θ. The sensitivity of the order parameter correction s_2 is the most pronounced at $\theta = 0$, i.e., in the one-constant approximation. Figure 11 depicts typical steady solutions for tumbling rods. Table 4 tabulates all the steady state behavior:

- The thickness of the boundary layers in this flow are narrower than those in the weak plane Couette flows, suggesting a mollifying effect of stronger velocity gradients near the walls.
- The two order parameter corrections (at small $|\theta|$) and the angle variable change their signs and concavity in the tumbling versus flow-aligning regime, but only for rods; this predicts a profile concavity flip in the focusing and defocusing of the orientation distribution occurs as rods pass through the flow-aligning to tumbling transition; the profile of β_2 is either W-shaped or M-shaped.
- The velocity profile is concave down.
- The parameter $s - s_0$ is very sensitive around $\theta = 0$ for both rods and discs.
- The angle profile is a rotated-S shape.

Figure 11 depicts typical steady solutions for tumbling discs as functions of (θ, y).

The shear viscosity is given by

$$\eta_{app} = \frac{\tau_{xy}}{\frac{dv_x^{(1)}}{dy}} = -\frac{\alpha H_2 s_0}{18 H_1}\left[a(s_0 + 2)(\theta(1 - s_0) + 3(1 - \tfrac{1}{\lambda_L}))\right] + \tfrac{1}{3}(\mu_1 s_0 + 3\eta), \tag{59}$$

a decreasing function with respect to θ for discs and tumbling rods but an increasing function for flow-aligning rods.

The normal stress differences in this case are given in Appendix E. Unlike weak Couette flows, they are rational functions of μ_1, μ_2 and α. Figures 12 and 13

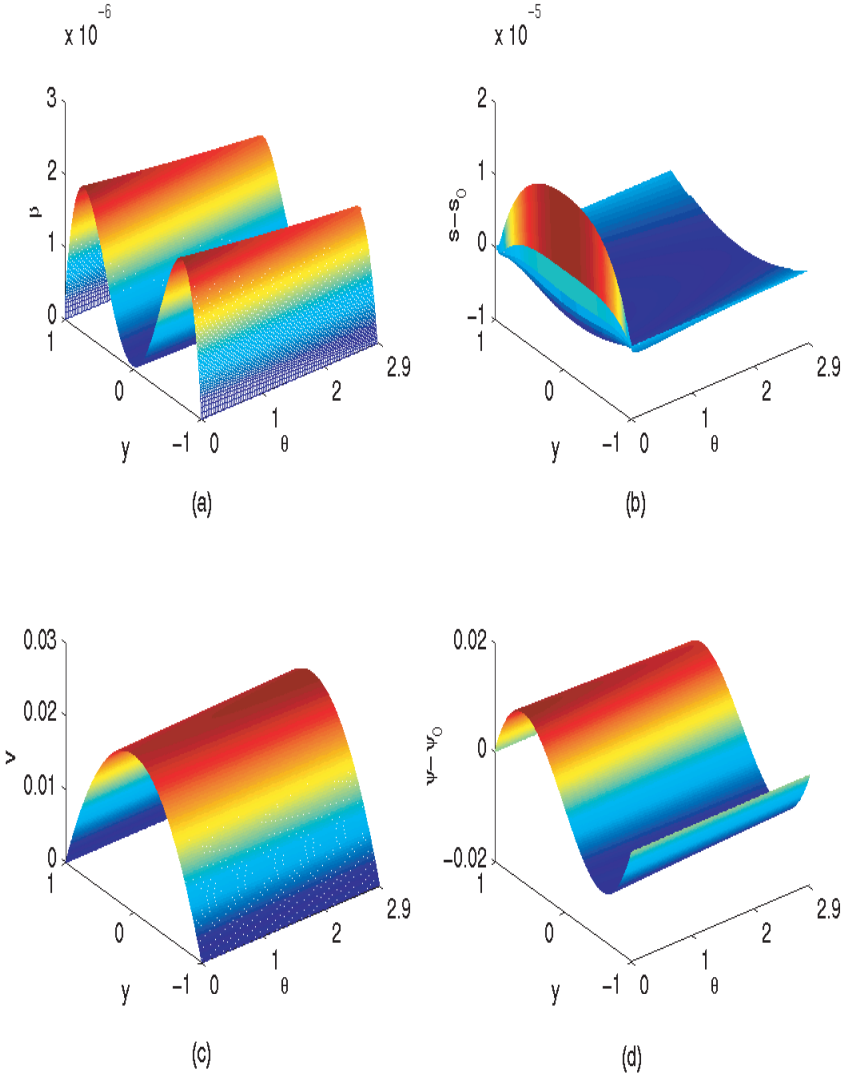

FIG. 11. *Steady solutions of* $\beta, s-s_0, v$ *and* $\psi-\psi_0$ *as functions of* (θ, y) *in the regime of tumbling rods with tangentially anchored boundary conditions in plane Poiseuille flow. The parameter values are* $N = 6, a = 0.8, De = 0.01, Er = 100, \mu_1 = 0.1, \eta = 0.2, \alpha = 10$.

depict some representative plots of the normal stress differences for tumbling and flow-aligning nematics, respectively. In summary, they have the following properties:

- For flow-aligning rods, N_1 is positive and N_2 is negative. The signs are reversed for flow-aligning discs.
- For tumbling rods and discs, N_1 is negative, but N_2 is positive.
- In both stable tumbling and flow-aligning regimes, for rods and discs, the absolute values of N_1 and N_2 increase and decrease, respectively, as α increases.

TABLE 4
Steady states (Poiseuille) in tangential anchoring.

	FA/rods	FA/discs	T/rods	T/discs
$s - s_0$	Concave up	Concave up	Concave down at small θ & Concave up at large θ	Concave up
β	W-shape	M-shape	M-shape	M-shape
$\psi - \psi_0$	S	Rotated-S	Rotated-S	Rotated-S

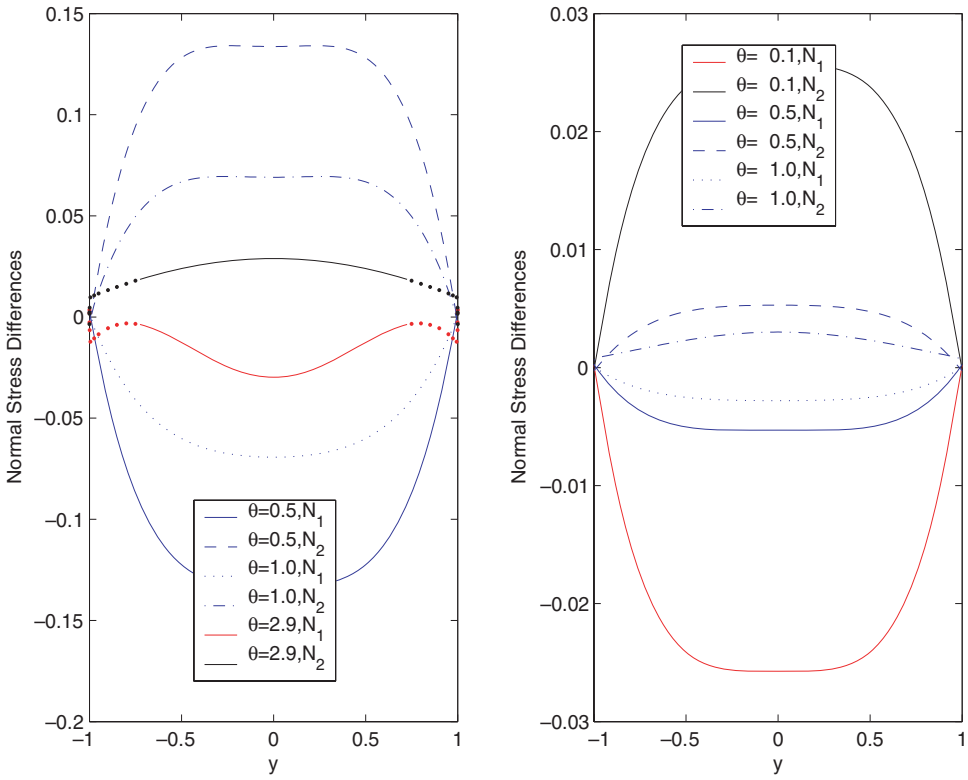

FIG. 12. *The normal stress differences N_1 and N_2 as functions of y in tumbling regime at selected values of θ with tangentially anchored boundary conditions in plane Poiseuille flows. The other parameter values are $N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_2 = 0.02$, for rods $a = 0.8, \mu_1 = 0.01$, and for discs, $a = -0.8, \mu_1 = -0.01$.*

- The gap averages satisfy $N_1 > 0$ and $N_2 < 0$ for flow-aligning rods while $N_1 < 0, N_2 > 0$ in all other regimes.

The behavior of the averaged normal stress differences is tabulated in Table 6.

3.2. Homeotropic anchoring ($\psi = \frac{\pi}{2}$). The steady solutions up to order $O(\epsilon)$ are given by (57) with new H_1 and H_2 given in Appendix F. As in the tangential anchoring case, H_1 is positive in all stable steady states. H_2 is negative for flow-aligning discs and positive otherwise for other stable steady states. For flow-aligning discs in stable steady states, H_1 (H_2) decreases (increases) with respect to θ for flow-aligning discs, yet increases (decreases) with respect to θ for all other stable steady states.

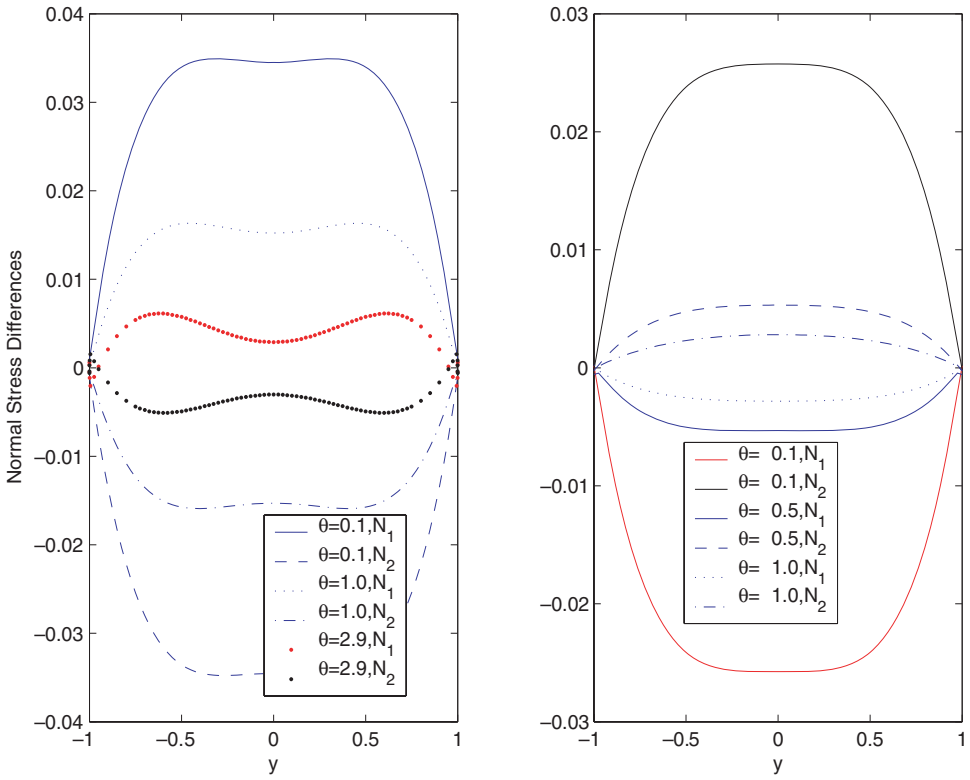

FIG. 13. *The normal stress differences N_1 and N_2 as functions of y in flow-aligning regime at some values of θ with tangentially anchored boundary conditions in plane Poiseuille flows. The other parameter values are $N = 6, De = 0.01, Er = 100, \alpha = 10, \mu_2 = 0.02$, for rods $a = 0.9, \mu_1 = 0.01$, and for discs, $a = -0.9, \mu_1 = -0.01$.*

TABLE 5
Steady states (Poiseuille) in homeotropic anchoring.

	FA/rods	FA/discs	T/rods	T/discs
$s - s_0$	W-shape	M-shape	W-shape	W-shape
β	W-shape	M-shape	W-shape	W-shape
$\psi - \psi_0$	Rotated-S	S	Rotated-S	Rotated-S

The steady solutions of the order parameters at $O(\epsilon^2)$ are

$$\beta_2(y) = K_{11}\left(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\right) + R_1(y^4 - 1) + S_1(y^2 - 1),$$

$$s_2(y) = K_{21}\left(\frac{\cosh(\sqrt{Er}\Lambda y)}{\cosh(\sqrt{Er}\Lambda)} - 1\right) \tag{60}$$

$$+K_{22}\left(\frac{\cosh(\sqrt{Er}\Gamma y)}{\cosh(\sqrt{Er}\Gamma)} - 1\right) + R_2(y^4 - 1) + S_2(y^2 - 1).$$

We summarize the features of stable steady states in Table 5:

- The two order parameters and the angle parameter change their signs and shapes in tumbling and flow-aligning regime for discs but not for rods, indicating the solutions are more sensitive for platelet molecules than for rods.

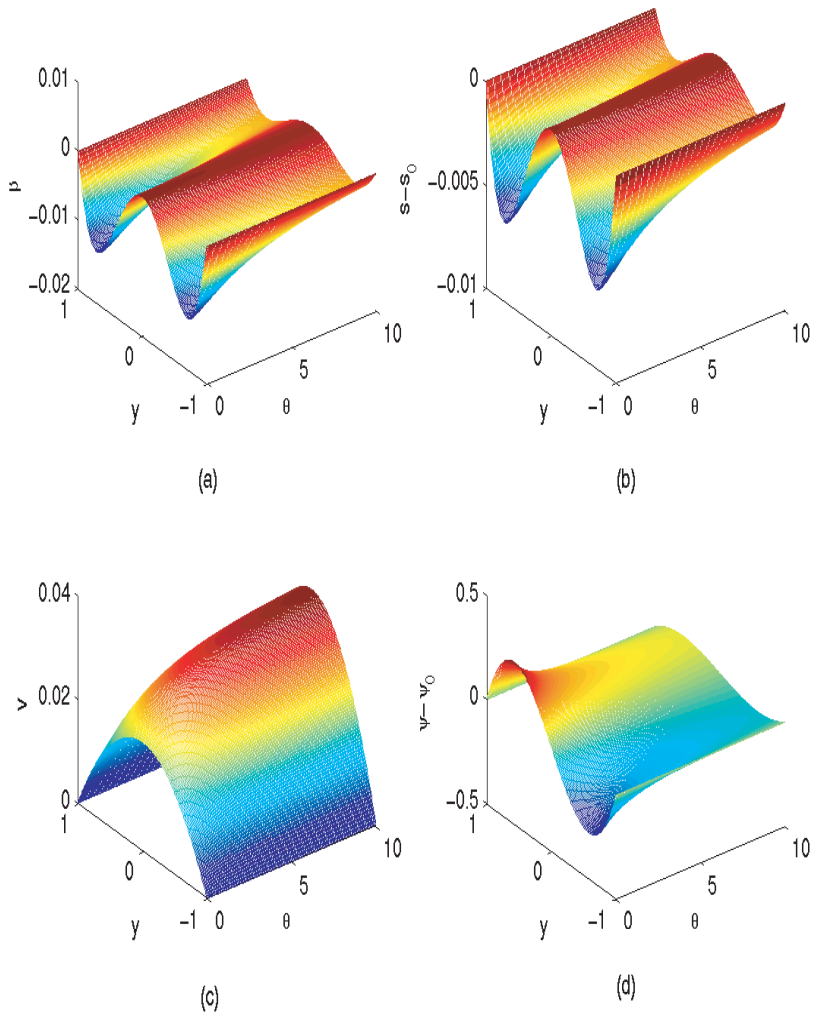

FIG. 14. *Steady solutions* $\beta, s - s_0, v$ *and* $\psi - \psi_0$ *for tumbling rods as functions of* (θ, y) *with normally anchored boundary conditions in plane Poiseuille flows. The parameter values are* $a = 0.8, N = 6, De = 0.01, Er = 100, \mu_1 = 0.01, \eta = 0.02, \alpha = 1$.

- As the anisotropic elasticity enhances, the order parameter variations and the angle variation reduces for rods yet amplifies for discs.
- The velocity profile has fixed concavity in all regimes. As the anisotropic elasticity increases, the velocity increases for rods.
- The orientational variables decrease with respect to θ while the flow variable v increases.
- Again, the thickness of the boundary layers are smaller compared to weak plane Couette flows.

Figure 14 depicts a typical steady solution for tumbling discs as functions of (θ, y).

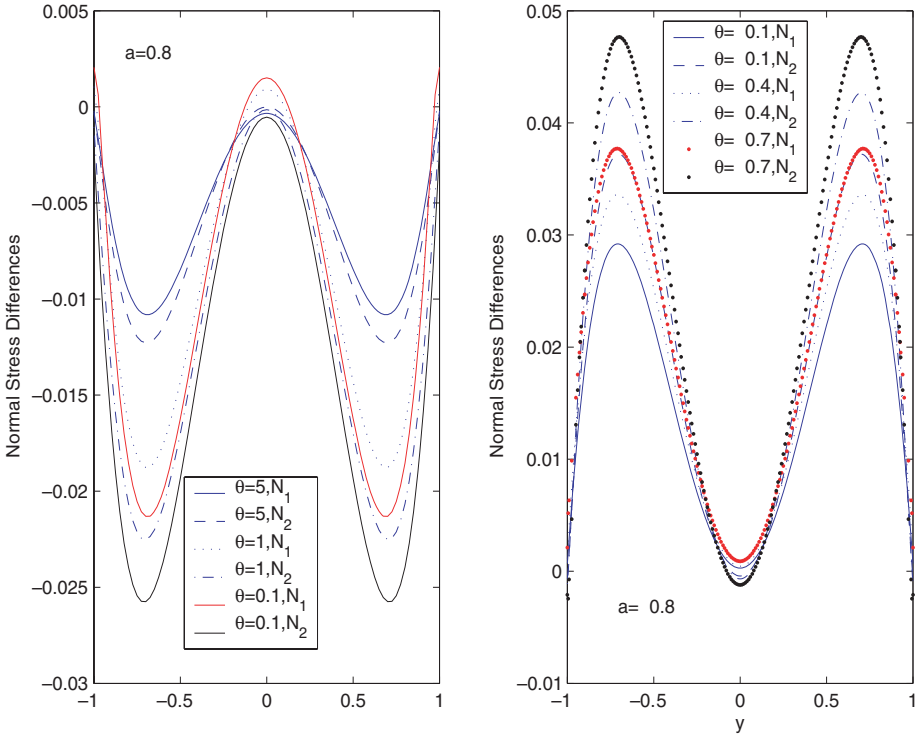

FIG. 15. *The normal stress differences N_1 and N_2 as functions of y in tumbling regime at selected values of θ with normal anchoring boundary conditions in plane Poiseuille flows. The parameter values are $N = 6, De = 0.01, Er = 100, \alpha = 10,$, $a = 0.8, \mu_1 = 0.01, \mu_2 = 0.02$ for rods, and $a = -0.8, \mu_1 = -0.01, \mu_2 = 0.02$ for discs.*

The wall shear viscosity is given by

$$\eta_{wall} = \frac{\tau_{xy}}{\frac{dv_x^{(1)}}{dy}} = \frac{\alpha H_2}{18 Er H_1}(a(2+s_0)(\theta(2s_0+1)+3(1+\tfrac{1}{\lambda_L}))) + \tfrac{1}{3}(\mu_1 s_0 + 3\eta), \tag{61}$$

which decays with respect to θ for all rods and flow-aligning discs, but increases for tumbling discs. The first and second normal stress differences in this case are given in Appendix F. Figures 15 and 16 depict the normal stress differences for flow-aligning and tumbling nematics, respectively. In summary, they exhibit the following features:

- For flow-aligning rods and disks, N_1 and N_2 are negative except for a small region at the midplane, where some of the first normal stress difference may be positive.
- For tumbling rods, N_1 and N_2 are negative. For tumbling discs ($-1 < \lambda_L < 0$), N_1 and N_2 are negative except for a tiny region at the midplane at small θ. For tumbling discs, the behavior reverses completely, i.e., the normal stress differences are positive except for a small region at the midplane.
- In both stable tumbling and flow-aligning regimes, for rods and discs, the absolute values of N_1 and N_2 will decrease and increase as α increases, respectively.
- The gap averages obey $N_1 > 0$ and $N_2 > 0$ for tumbling rods and both become negative in all other regimes.

The behavior of averaged normal stress differences is tabulated in Table 6.

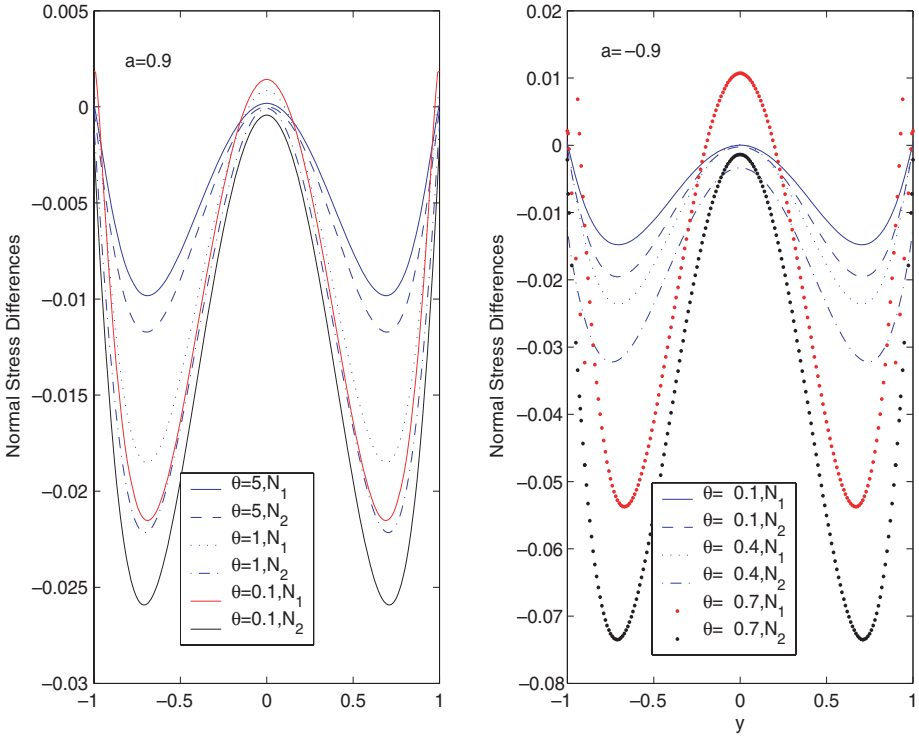

FIG. 16. *The normal stress differences N_1 and N_2 as functions of y in flow-aligning regime at selected values of θ with normal anchoring boundary conditions in plane Poiseuille flows. The parameter values are $N = 6, De = 0.01, Er = 100, \alpha = 10, a = 0.9, \mu_1 = 0.01, \mu_2 = 0.02$ for rods, and $N = 6, De = 0.01, Er = 100, \alpha = 1, a = -0.9, \mu_1 = -0.01, \mu_2 = 0.02$ for discs.*

TABLE 6
The normal stress differences (Poiseuille).

	FA/rods	FA/discs	T/rods	T/discs
Tangential	$N_1 > 0, N_2 > 0$	$N_1 < 0, N_2 > 0$	$N_1 < 0, N_2 > 0$	$N_1 < 0, N_2 > 0$
Normal	$N_1 < 0, N_2 < 0$	$N_1 < 0, N_2 < 0$	$N_1 < 0, N_2 < 0$	$N_1 > 0, N_2 > 0$

4. Conclusion. We have derived explicit asymptotic structures for weakly sheared nematic polymers in both plate-driven and pressure-driven experimental conditions. The goal of this analysis is to predict scaling properties in the orientational distribution of the rigid rod ensemble from the strong elasticity, weak flow regime, which then guide numerical continuation studies of heterogeneous films and molds across a multi-parameter space of material properties and processing conditions. We have explored the effect of anisotropic elasticity for both flow conditions, using a second-moment model for the orientational distribution derived from Doi–Hess–Marrucci–Greco kinetic theory. These results extend previous work of the authors for steady structures with equal elasticity constants in plate-driven flow in several ways: anisotropic elasticity, pressure-driven flows, and transient asymptotic equations followed by stability predictions within the asymptotic ordering of the flow-nematic system. The leading order flow structure is simple linear shear versus Poiseuille profiles for the respective driving conditions, with elastic hydrodynamic feedback contributions characterized at next order. These results confirm the consistency of imposing

the kinematics (and thereby suppressing flow feedback) in special asymptotic parameter regimes, yet also predict breakdown of this decoupling of the momentum equation when either of several conditions is relaxed: weak flow, strong elasticity, or sufficiently isotropic elasticity.

The orientational structures for both flow conditions convey scaling properties of nematic (director dominated) elastic distortions as well as molecular elasticity (dominated by focusing or defocusing of the orientational distribution). The structure scaling laws are similar for plane Couette and Poiseuille flows, with plate boundary layer thicknesses proportional to $1/\sqrt{Er}$ and nonuniform structures spanning the plates with mean lengthscale proportional to $1/Er$. The prefactors of the structures capture the roles of material properties: flow-aligning versus tumbling nematics, degree of anisotropy in the elasticity potential, strength of the short-range nematic potential, and molecular aspect ratio. These subtleties are detailed in the body of the paper, where the amplitude of structure variations, convexity of profiles, and stability of the steady structures all depend strongly on these molecular parameters as well as plate anchoring conditions.

The particular results are less important than the overall insight into the sensitivity, flow-nematic feedback and processing-generated structures on material and device properties. The instability within the asymptotic equations is catastrophic, similar to backward heat flow instabilities, so there is no mistaking the breakdown of these steady profiles in the weak flow model system. The role of anisotropic elasticity is shown to be greater for normal versus tangential plate anchoring, and greater in pressure-driven than plate-driven flows. In Poiseuille flow, the transition to catastrophic instability coincides with a rapidly growing midplane axial velocity, confirming a breakdown in the asymptotic analysis. Finally, anisotropic elasticity is shown to contribute to either shear thinning or shear thickening behavior as other parameters are modified, and signs of normal stress differences (which determine whether the plates are pushed or pulled by the stresses generated between) are likewise sensitive to various material parameters.

DRAW RESONANCE REVISITED*

MICHAEL RENARDY†

Abstract. We consider the problem of isothermal fiber spinning in a Newtonian fluid with no inertia. In particular, we focus on the effect of the downstream boundary condition. For prescribed velocity, it is well known that an instability known as draw resonance occurs at draw ratios in excess of about 20.2. We shall revisit this problem. Using the closed form solution of the differential equation, we shall show that an infinite family of eigenvalues exists and discuss its asymptotics. We also discuss other boundary conditions. If the force in the filament is prescribed, no eigenvalues exist, and the problem is stable at all draw ratios. If the area of the cross section is prescribed downstream, on the other hand, the problem is unstable at any draw ratio. Finally, we discuss the stability when the drawing speed is controlled in response to changes in cross section or force.

Key words. extensional flow, fiber spinning, draw resonance

AMS subject classifications. 76E99

DOI. 10.1137/050634268

1. Formulation of the problem. Fiber spinning is a manufacturing process used in making textile or glass fibers. A highly viscous fluid is extruded vertically from a nozzle. It is then cooled by the ambient air and solidifies. The solidified fiber is then wound on a spool at the end of the spinline.

Many physical effects are potentially significant in the study of this problem: viscosity, inertia, gravity, surface tension, cooling, elasticity, and air drag may all be relevant. In this paper, we focus on the simplest model and study the influence of varying boundary conditions. We assume that the force in the fiber is purely due to viscous effects, and we ignore temperature dependence. We use a one-dimensional model based on slender geometry and cross-sectional averaging. Let $u(x,t)$ denote the axial speed and $A(x,t)$ the area of the cross section. The spinneret is located at $x=0$ and the spool is at $x=L$. The conservation of mass implies that

$$A_t + (uA)_x = 0. \tag{1}$$

If only viscous forces contribute, the tension in the fiber is given by $3\eta A u_x$, where η is the viscosity. The requirement of constant tension in the fiber leads to

$$(Au_x)_x = 0. \tag{2}$$

Boundary conditions in industrial processes are notoriously ill defined. It is customary to assume that A and u are given at the spinneret: $A(0,t)=A_0$, $u(0,t)=u_0$. This of course, is an idealization; in reality there is a transition to an upstream flow, which cannot be described by the one-dimensional model. At the spool, it is sensible to prescribe either the speed or the force with which the fiber is wound. One might also consider control strategies where the flow is monitored and the speed of the spool adjusted to achieve a given objective. Since the goal of the manufacturing process is

a fiber of uniform cross section, a control strategy might aim to keep the cross section constant. We shall consider what happens in the case of perfect success of such a control, i.e., when constant area is imposed as a boundary condition. We shall thus focus on the following three boundary conditions:

1. Prescribed speed: $u(L,t) = u_1$.
2. Prescribed force: $A(L,t)u_x(L,t) = F$, where F denotes the force divided by the elongational viscosity 3η.
3. Prescribed cross section: $A(L,t) = A_1$.

It is easy to see that the problem admits the steady solution

$$u_s(x) = u_0 e^{kx}, \quad A_s(x) = A_0 e^{-kx}, \tag{3}$$

where, respectively,

$$e^{kL} = u_1/u_0, \quad k = F/(A_0 u_0), \quad e^{kL} = A_0/A_1 \tag{4}$$

for the three choices of boundary conditions. The dimensionless quantity $q = e^{kL}$ is called the draw ratio.

2. Linear stability. The stability of the steady solution was first analyzed by Kase, Matsuo, and Yoshimoto [5] and Pearson and Matovich [6]. For subsequent reviews and textbook chapters, see also [2, 7, 9, 10]. We note that much of the literature on draw resonance is concerned with the effect of additional physical mechanism, which are not included in our analysis. Inertia, elasticity, and cooling generally have a stabilizing effect, while surface tension and shear thinning are destabilizing. This paper, on the other hand, will focus purely on the case of Stokes flow and investigate the effect of varying the downstream boundary condition. In the case of prescribed speed, an instability known as draw resonance is found for draw ratios in excess of about 20.2, while no such instability is found for prescribed force. In [8], the case of a linear combination of speed and force is also investigated; as expected, the stability threshold increases from 20.2 to infinity as the relevant coefficient is varied. The case of prescribed cross section does not seem to have been analyzed in the literature. We shall see that this boundary condition leads to instability at all draw ratios.

We linearize at the steady solution and consider exponentially varying perturbations:

$$u(x,t) = u_s(x) + \tilde{u}(x)e^{\lambda t}, \quad A(x,t) = A_s(x) + \tilde{a}(x)e^{\lambda t}. \tag{5}$$

The linearized equations are

$$\lambda\tilde{a} + (u_s\tilde{a} + A_s\tilde{u})_x = 0, \quad (A_s\tilde{u}_x + \tilde{a}(u_s)_x)_x = 0. \tag{6}$$

It is advantageous to make the transformation $z = e^{kx}$. The steady solution then takes the form $u_s(z) = u_0 z$, $A_s(z) = A_0/z$. The linearized equations (6) are transformed to

$$\lambda\tilde{a} + kz(zu_0\tilde{a} + A_0\tilde{u}/z)_z = 0, \quad (A_0\tilde{u}_z + zu_0\tilde{a})_z = 0. \tag{7}$$

We can rewrite these equations in the form

$$\begin{aligned} \frac{\lambda}{ku_0}\frac{\tilde{a}}{A_0} + z\frac{\tilde{a}}{A_0} + z^2\frac{\tilde{a}_z}{A_0} - \frac{\tilde{u}}{u_0 z} + \frac{\tilde{u}_z}{u_0} &= 0, \\ \frac{\tilde{u}_z}{u_0} + z\frac{\tilde{a}}{A_0} &= C_1. \end{aligned} \tag{8}$$

We simplify by setting $\lambda/(ku_0) = \mu$, $\tilde{a}/A_0 = a$, $\tilde{u}/u_0 = u$. This is equivalent to nondimensionalizing the equations by scaling the velocity and area with their steady state values at the spinneret, length along the filament with $1/k$, and time with $1/(ku_0)$. The resulting dimensionless equations are

$$\begin{aligned} \mu a + za + z^2 a_z - \frac{u}{z} + u_z &= 0, \\ u_z + za &= C_1. \end{aligned} \tag{9}$$

We can now solve the second equation for a:

$$a = \frac{C_1 - u_z}{z}. \tag{10}$$

After inserting this into the first equation, we obtain

$$-u + (-\mu + z)u_z + \mu C_1 - z^2 u_{zz} = 0. \tag{11}$$

Clearly, $u = \mu C_1$ is a particular solution, and $u = z - \mu$ is a particular solution of the homogeneous equation. We can then obtain the full solution using the reduction of order method:

$$u(z) = \mu C_1 + (z - \mu)C_2 + C_3(-ze^{\mu/z} + (\mu - z)\mathrm{Ei}(\mu/z)); \tag{12}$$

see also [8]. Here Ei is the exponential integral defined for $z > 0$ by

$$\mathrm{Ei}(x) = \int_{-\infty}^{z} \frac{e^t}{t}\, dt, \tag{13}$$

where the integral is understood in the principal value sense (see Ch. 5 of [1]).

We have the boundary conditions $u(1) = a(1) = 0$ at the spinneret and one of the following three at the take-up point:

1. Fixed speed: $u(q) = 0$.
2. Fixed force: $u_z(q) + qa(q) = 0$.
3. Fixed cross section: $a(q) = 0$.

The requirement of a nontrivial solution leads to the following characteristic equations. For fixed speed,

$$(e^{\mu} - e^{\mu/q})q + (q - \mu)(\mathrm{Ei}(\mu) - \mathrm{Ei}(\mu/q)) = 0. \tag{14}$$

For fixed force,

$$e^{\mu} = 0. \tag{15}$$

For fixed cross section,

$$\mathrm{Ei}(\mu) - \mathrm{Ei}(\mu/q) = 0. \tag{16}$$

3. Remarks on well-posedness. For the case of fixed force, no eigenvalues exist, and indeed it can be shown for this case that any initial disturbance will decay to zero in finite time. To see this, we note that the linearized equations (9) (without the assumption of exponential time dependence) are

$$\begin{aligned} a_t + z^2 a_z - \frac{u}{z} &= 0, \\ u_z + za &= 0. \end{aligned} \tag{17}$$

We can integrate the second of these equations to find

$$u = -\int_1^z ya\,dy. \tag{18}$$

For any given initial data $a(z,0) = a_0(z)$, we can now solve the equation using the iterative procedure

$$\begin{aligned} u^1 &= 0, \\ a_t^n + z^2 a_z^n - \frac{u^n}{z} &= 0, \quad a^n(1,t) = 0, \quad a_n(z,0) = a_0(z), \\ u^{n+1} &= -\int_0^x ya^n\,dy. \end{aligned} \tag{19}$$

It follows by induction that

$$a(z,t) = 0 \tag{20}$$

for $1 < z < Z(t)$, where

$$Z'(t) = Z(t)^2, \quad Z(0) = 1. \tag{21}$$

The solution will thus become identically zero as soon as $Z(t)$ reaches the value q.

For the case of prescribed speed, a rigorous proof of well-posedness and spectrally determined growth can be given along similar lines as [4]. The case of prescribed cross section is somewhat different and will be discussed now. In this case, the linear problem, again without the assumption of exponential time dependence, is

$$\begin{aligned} a_t + za + z^2 a_z - \frac{u}{z} + u_z &= 0, \\ u_z + za &= \phi(t), \end{aligned} \tag{22}$$

where $\phi(t)$ is a function to be determined after the boundary conditions are imposed. We can integrate the second equation to find

$$u(z,t) = -\int_1^z ya(y,t)\,dy + (z-1)\phi(t) \tag{23}$$

and insert this result into the first equation. This yields

$$a_t + z^2 a_z + \frac{1}{z}\int_1^z ya\,dy + \frac{\phi(t)}{z} = 0. \tag{24}$$

We next set $a = b + \gamma/z$, where γ is independent of z, and b satisfies

$$\int_1^q b(z,t)\chi(z)\,dz, \tag{25}$$

with χ to be determined. We shall denote the projections of a onto b and γ/z by P and Q.

We want χ to be such that we also have

$$\int_1^q z^2 b_z \chi(z)\,dz = 0. \tag{26}$$

We note that the boundary condition $a(1,t) = a(q,t) = 0$ leads to $b(1,t) = qb(q,t)$. We now integrate by parts to find

$$\int_1^q z^2 b_z \chi \, dz = -\int_1^q b(z^2\chi)' \, dz + q^2 b(q,t)\chi(q) - b(1,t)\chi(1). \tag{27}$$

We achieve our objective if

$$\frac{d}{dz}(z^2\chi) = K\chi, \quad \chi(1) = q\chi(q) \tag{28}$$

for some constant K. This leads to

$$\chi(z) = \frac{1}{z^2} e^{-K/z}, \quad e^{-K} = \frac{1}{q} e^{-K/q}. \tag{29}$$

With χ thus determined, (24) can be decomposed as follows:

$$\begin{aligned} \gamma_t - \gamma + zQ\left(\frac{1}{z}\int_1^z yb \, dy\right) + \phi(t) &= 0, \\ b_t + z^2 b_z + P\left(\frac{1}{z}\int_1^z yb \, dy\right) &= 0. \end{aligned} \tag{30}$$

The solution procedure is now obvious. We solve the second equation for b with the boundary condition $b(1,t) = qb(q,t)$, and after b is determined, the first equation, and the condition $\gamma(t) = -b(1,t)$, determine $\phi(t)$. Well-posedness and spectral growth are obvious from this reformulation of the equations. We note that the boundary condition for b is a two-point condition rather than an upstream condition. This is reflected in the nature of the eigenspectrum below; the limit of the real part of large eigenvalues will be a finite number rather than $-\infty$.

We note that a general discussion of boundary conditions for the hyperbolic systems arising in viscoelastic flows is given in [3]; in the context of that discussion the Newtonian case is degenerate, even if inertia is included.

4. Asymptotics of large eigenvalues. In this section, we focus on the asymptotic behavior of large eigenvalues. It is instructive to look at this case for a number of reasons. As we shall see, some instabilities can be predicted from the analysis of this limit. The asymptotic formula also gives insights into the qualitative nature of the eigenspectrum; it shows that there are infinitely many eigenvalues and that they line up along a curve and shows what the approximate spacing is.

We begin with the simpler case of fixed cross section.

We use the asymptotic expansion of the exponential integral for large argument [1]:

$$\mathrm{Ei}(\mu) = \pi i \, \mathrm{sgn}(\mathrm{Im}\, \mu) + \frac{e^\mu}{\mu}\left(1 + O\left(\frac{1}{\mu}\right)\right). \tag{31}$$

Using this, we can approximate the characteristic equation by

$$e^\mu = qe^{\mu/q}, \tag{32}$$

which leads to

$$\mu = \frac{q}{q-1}(2n\pi i + \ln q). \tag{33}$$

Since $\ln q/(q-1)$ is positive, we find an infinite family of unstable eigenvalues for any value of q. For $q = 2$ the following table compares the eigenvalues found from the asymptotic formula (33) with exact roots of the characteristic equation found by Newton's method:

n	Result from (33)	Exact eigenvalue
1	$1.38629 + 12.5664i$	1.35405 + 12.42i
2	$1.38629 + 25.1327i$	1.37705 + 25.0552i
3	$1.38629 + 37.6991i$	1.38204 + 37.6467i
4	$1.38629 + 50.2655i$	1.38387 + 50.226i
5	$1.38629 + 62.8319i$	1.38473 + 62.8002i

For the case of fixed speed, we need to carry the approximation of the exponential integral a little further:

$$\mathrm{Ei}(\mu) = \pi i \,\mathrm{sgn}(\mathrm{Im}\,\mu) + \frac{e^\mu}{\mu}\left(1 + \frac{1}{\mu} + \frac{2}{\mu^2} + O\left(\frac{1}{\mu^3}\right)\right). \tag{34}$$

Using this, we obtain the approximate characteristic equation

$$e^{\mu - \mu/q} = -\frac{q^3}{(q-1)\mu^2}. \tag{35}$$

For large $|\mu|$, we obtain the following asymptotic formula for the eigenvalues

$$\mu_n = \frac{q}{q-1}\left(2n\pi i + \ln\left(\frac{q^3}{q-1}\right) - 2\ln\left(2n\pi\frac{q}{q-1}\right)\right). \tag{36}$$

Here n is any integer. For $n \to \infty$, the real parts of these eigenvalues tend to $-\infty$ logarithmically, i.e., they are stable.

Since the asymptotic approximation depends on $|\mu/q|$ being large in addition to $|\mu|$, the first few eigenvalues are predicted poorly if q is large. The following table illustrates this behavior for $q = 20.218$, the value at which onset of draw resonance occurs:

n	μ_n given by (36)	Exact eigenvalue
1	$2.40565 + 6.61013i$	4.66015i
2	$0.947223 + 13.2203i$	$-0.738622 + 11.4532$i
3	$0.094096 + 19.8304i$	$-1.20379 + 18.2453$i
4	$-0.511207 + 26.4405i$	$-1.55854 + 25.0014$i
5	$-0.980716 + 33.0506i$	$-1.85118 + 31.7307$i
10	$-2.43915 + 66.1013i$	$-2.8734 + 65.1607$i
20	$-3.89758 + 132.203i$	$-4.0729 + 131.605$i
50	$-5.82551 + 330.506i$	$-5.86414 + 330.225$i

Another limit which can be approached by asymptotics is that of large draw ratio. If we consider the case $\mu \to \infty$, $q \to \infty$ in (14) with the expectation that $\mu/q \to 0$, the balance of leading order terms yields

$$e^\mu + \ln q = 0, \tag{37}$$

i.e.,

$$\mu_n = (2n-1)i\pi + \ln\ln q. \tag{38}$$

Since q must be really large for $\ln\ln q$ to be considered "large," this approximation is not useful in practice. For $q = 5 * 10^8$, a totally unrealistic value of course, we have

$$i\pi + \ln\ln q = 2.99724 + 3.14159i, \quad 3i\pi + \ln\ln q = 2.99724 + 9.42478i, \tag{39}$$

compared to exact eigenvalues of $2.72203 + 3.471i$ and $2.76567 + 9.63623i$, respectively.

5. Control strategies. In this section, we consider how the onset of draw resonance is affected if we add a control which adjusts the drawing speed in response to observed fluctuations. Since the goal of the manufacturing process is a uniform thread, it seems natural to change the speed in response to fluctuations in the cross-sectional area. This leads to a downstream boundary condition

$$u(q) - \epsilon a(q) \tag{40}$$

to be imposed on (9). Intuitively, we would be tempted to increase the drawing speed when the cross section becomes larger, i.e., $\epsilon > 0$.

The resulting characteristic equation is

$$(e^{\mu} - e^{\mu/q})q + \left(q + \frac{\epsilon}{q} - \mu\right)(\mathrm{Ei}(\mu) - \mathrm{Ei}(\mu/q)) = 0. \tag{41}$$

The asymptotic behavior of the eigenvalues can be discussed by the same methods as above. We obtain

$$\mu_n \sim \frac{q}{q-1}\left(2\pi n i + \ln\left(\frac{\epsilon}{2n\pi q}\right) - \mathrm{sgn}(\epsilon)\frac{i\pi}{2}\right). \tag{42}$$

For large n, these eigenvalues become stable.

Next, we consider the onset value for draw resonance as a function of ϵ. The results are summarized in the following table:

ϵ	Critical draw ratio
0	20.218
10	18.872
20	17.224
30	14.904

Contrary to intuition, the effect of the control is destabililizing, and the critical draw ratio decreases. For negative ϵ, if we just track the eigenvalue that is responsible for draw resonance at $\epsilon = 0$, the critical draw ratio seems to increase:

ϵ	Critical draw ratio
-20000	200.00
-10000	147.10
-5000	109.13
-1000	57.324
-500	44.843
-100	28.536
-50	25.056
-20	22.420
-10	21.3817

It would be wrong to think, however, that we can achieve stability at any draw ratio by choosing ϵ large and negative. In fact, there are new instabilities at low draw ratios when $|\epsilon|$ is large. We can see this by looking at the asymptotic behavior of eigenvalues assuming that both $|\mu|$ and $|\epsilon|$ are large. The result is

$$\mu_n \sim \frac{q}{q-1}\left(2\pi i n + \ln\left(\frac{\epsilon q}{\epsilon + 2\pi i n q(q-1)}\right)\right). \tag{43}$$

For $q = 4$, $\epsilon = -100$, for instance, this formula yields $\mu_1 = 1.54832 + 9.23897i$, while the actual eigenvalue is $1.21466 + 9.25047i$. The instability resulting from this

eigenvalue persists for $q < 8.01516$. We thus have two separate instabilities, one for low draw ratio and another for high draw ratio. The next table shows the first eigenvalue for $\epsilon = -100$ as a function of the draw ratio q (the higher eigenvalues are more stable):

q	First eigenvalue
2	$1.33788 + 12.9402$i
3	$1.40897 + 10.04$i
4	$1.21466 + 9.25047$i
6	$0.579954 + 8.55471$i
8	$0.004134 + 8.08557$i
10	$-0.533251 + 7.66538$i
15	$-1.59346 + 5.79611$i
20	$-0.601555 + 4.77314$i
25	$-0.173004 + 4.58841$i
30	$0.0558642 + 4.49297$i
40	$0.31093 + 4.37887$i

Another control strategy is to monitor the force in the thread and change the drawing speed in response. This leads to the boundary condition

$$u(q) + \epsilon(u'(q) + qa(q)) = 0. \tag{44}$$

This boundary condition was also considered in [8]. The resulting characteristic equation is

$$(e^{\mu} - e^{\mu/q})q + (q - \mu)(\mathrm{Ei}(\mu) - \mathrm{Ei}(\mu/q)) + \epsilon e^{\mu} = 0. \tag{45}$$

The behavior of large eigenvalues becomes

$$\mu_n \sim \frac{q}{q-1}\left(2n\pi i + \ln\left(\frac{q^3}{q+\epsilon-1}\right) - 2\ln\left(2n\pi\frac{q}{q-1}\right)\right). \tag{46}$$

We see from this asymptotic formula that a positive ϵ is stabilizing, as would heuristically be expected. The effect on draw resonance follows the same trend, and the results show no surprises.

ϵ	Critical draw ratio
-5	5.387
-2	16.786
0	20.218
5	26.561
10	31.632
20	40.137
50	60.37
100	87.468

6. Conclusions. We have investigated the simplest model of fiber spinning in a viscous fluid, which includes only viscous forces, neglecting all other effects. In this simple case, the linear stability problem has a closed form solution in terms of an exponential integral, which can be exploited to gain substantial qualitative insight into the behavior of the eigenvalues. The stability of the flow depends crucially on the choice of downstream boundary conditions. If the speed is prescribed, then, as is well known, the flow becomes unstable beyond a critical draw ratio. On the other hand, prescribed force leads to no instabilities, while prescribed cross section leads to instability at all draw ratios. In terms of strategies to control instability, adjustment

of the speed in reaction to changes in cross section has an effect opposite of what is intuitively expected. In addition to changing the threshold for high draw ratio instabilities, such a control also produces new instabilities at low draw ratios.

HILBERT FORMULAS FOR r-ANALYTIC FUNCTIONS IN THE DOMAIN EXTERIOR TO SPINDLE*

MICHAEL ZABARANKIN† AND ANDREI F. ULITKO‡

Abstract. Hilbert formulas for an r-analytic function, defined by a generalized Cauchy–Riemann system in the domain exterior to the contour of a spindle in the meridional cross-section plane, have been derived. The derivation is based on the theory of Riemann boundary-value problems for analytic functions. For numerical calculations, Fourier integrals with Hilbert formulas representing the real and imaginary parts of the r-analytic function have been reduced to the form of regular integrals. The problem of the axially symmetric steady motion of a rigid spindle-shaped body in a Stokes fluid has been solved, and the pressure in the fluid has been expressed analytically based on a Hilbert formula. As an illustration, streamlines about the body, vortex and pressure functions at the contour of the body, and the drag force, exerted on the body by the fluid, have been calculated.

Key words. Hilbert formula, r-analytic function, Riemann boundary-value problem, analytic function, spindle, bipolar coordinates, Fourier integral transform, Lame equation, Stokes equations, pressure, vorticity, drag force

1. Introduction.

This paper derives Hilbert formulas for an r-analytic function in the domain exterior to the contour of a spindle in the meridional cross-section plane and applies these formulas in a hydrodynamic problem of axially symmetric Stokes flow about a rigid spindle-shaped body. So-called r-analytic functions are a special case of pseudoanalytic functions [2, 22] or so-called p-analytic and (p,q)-analytic functions introduced by Polozhii [17]. For a given positive continuously differentiable function $p = p(x,y)$, a p-analytic function $F(x,y) = u(x,y) + i\,v(x,y)$ is defined by the generalized Cauchy–Riemann system

$$\frac{\partial u}{\partial x} = \frac{1}{p}\,\frac{\partial v}{\partial y}, \qquad \frac{\partial u}{\partial y} = -\frac{1}{p}\,\frac{\partial v}{\partial x}, \tag{1}$$

where $i = \sqrt{-1}$. This system is encountered in different areas of mathematical physics, in particular, the theory of elasticity [6, 17, 21], hydrodynamics [21, 28, 30], and quantum mechanics [12].

We consider a special case of system (1) from the linear theory of elasticity and hydrodynamics of Stokes flows. Let $\mathbf{u}$ be the displacement vector of an isotropic elastic medium, characterized by Poisson number $m \in [2, +\infty)$. In the framework of the linear theory of elasticity, equilibrium of the medium is governed by Lame equation

$$2\,\tfrac{m-1}{m-2}\ \operatorname{grad}\operatorname{div}\mathbf{u} - \operatorname{curl}\operatorname{curl}\mathbf{u} = \mathbf{0}. \tag{2}$$

For the vector field, $\mathbf{u}$, divergence, θ, and vorticity, $\boldsymbol{\omega}$, are two fundamental characteristics that we introduce by

$$\theta = -2\,\tfrac{m-1}{m-2}\,\operatorname{div}\mathbf{u}, \tag{3}$$

$$\boldsymbol{\omega} = \operatorname{curl}\mathbf{u}. \tag{4}$$

In the case of $m = 2$ and $\operatorname{div}\mathbf{u} = 0$, the function θ is defined as a finite limit of expression $-2\frac{m-1}{m-2}\operatorname{div}\mathbf{u}$ under $m \to 2$ and $\operatorname{div}\mathbf{u} \to 0$, and Lame equation (2) becomes mathematically identical to the Stokes model for a viscous incompressible fluid under low Reynolds numbers (so-called Stokes fluid). In this case, the displacement vector, $\mathbf{u}$, corresponds to the vector of velocity of fluid particles, and θ corresponds to the pressure $\mathcal{P}$, i.e., $\theta = \mathcal{P}/\rho$, where ρ is the shear viscosity. The Stokes model is given by

$$\begin{cases} \operatorname{curl}(\operatorname{curl}\mathbf{u}) = -\operatorname{grad}\theta, \\ \operatorname{div}\mathbf{u} = 0. \end{cases} \tag{5}$$

This model can also be obtained by linearizing Navier equations with the zero Reynolds number [8].

In terms of θ and $\boldsymbol{\omega}$, Lame equation (2) and the first equation in Stokes model (5) take the form

$$\operatorname{grad}\theta = -\operatorname{curl}\boldsymbol{\omega}. \tag{6}$$

Relations (3), (4), and (6) imply that θ and $\boldsymbol{\omega}$ are harmonic functions. Indeed, $\Delta\,\theta = \operatorname{div}\operatorname{grad}\theta = -\operatorname{div}\operatorname{curl}\boldsymbol{\omega} \equiv 0$, and $\operatorname{curl}\operatorname{curl}\boldsymbol{\omega} = -\operatorname{curl}\operatorname{grad}\theta \equiv \mathbf{0}$, where $\Delta = \nabla^2$ is the harmonic operator. Since $\operatorname{div}\boldsymbol{\omega} \equiv 0$, we have $\Delta\,\boldsymbol{\omega} = \operatorname{grad}\operatorname{div}\boldsymbol{\omega} - \operatorname{curl}\operatorname{curl}\boldsymbol{\omega} = \mathbf{0}$. These relations are used for constructing exact solutions to Lame equation (2) and Stokes model (5); see [21].

In planar problems, the vorticity vector has only one nonzero component. Suppose a problem is considered in the plane xy in the system of cartesian coordinates (x, y, z); then $\boldsymbol{\omega} = (0, 0, \omega_z)$. In this case, (6) reduces to the Cauchy–Riemann system for an analytic function $F = \theta + i\,\omega_z$, and the vector $\mathbf{u}$ is expressed by the Kolosov–Muskhelishvili formulas; see, for example, [21]. In axially symmetric three-dimensional (3-D) problems, the vorticity vector can be represented by a scalar vortex function ω, and (6) reduces to the generalized Cauchy–Riemann system. Let (r, φ, z) be a system of cylindric coordinates with basis $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$, and let axis z determine the axis of symmetry. The axially symmetric case means that the vector $\mathbf{u}$ is independent of angular coordinate φ, and the vorticity vector can be represented by $\boldsymbol{\omega} = \omega\,\mathbf{e}_\varphi$, where ω is the vortex function. Here, θ and ω depend only upon r and z. Equation (6) reduces to a special case of the generalized Cauchy–Riemann system with $p(r, z) = r$, i.e.,

$$\frac{\partial\theta}{\partial r} = \frac{1}{r}\frac{\partial}{\partial z}(r\omega), \qquad \frac{\partial\theta}{\partial z} = -\frac{1}{r}\frac{\partial}{\partial r}(r\omega). \tag{7}$$

Function $F(r, z) = \theta(r, z) + i\,r\,\omega(r, z)$ is called r-analytic if it satisfies system (7). Functions θ and $r\,\omega$ are considered to be real and imaginary parts of the r-analytic function, respectively. Let Δ_k define so-called k-harmonic operator

$$\Delta_k = \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2} - \frac{k^2}{r^2}, \tag{8}$$

where $\Delta \equiv \Delta_0$. System (7) implies that $\theta(r,z)$ and $\omega(r,z)$ are harmonic and 1-harmonic functions, respectively, i.e.,

$$\Delta\,\theta = 0, \qquad \Delta_1\omega = 0. \tag{9}$$

Suppose $\mathcal{D}$ is a bounded domain in the meridional cross-section plane rz with smooth boundary $\partial\mathcal{D}$, and suppose boundary values of functions θ and ω at $\partial\mathcal{D}$ are given. Establishing existence and uniqueness of solutions to (9) is a Dirichlet problem, which is discussed in 3-D potential theory [23]. For the domain exterior to $\mathcal{D}$, a harmonic function vanishing at infinity in 3-D space is uniquely determined by its boundary value at $\partial\mathcal{D}$. For domains determined by the surface of bodies of revolution in the meridional cross-section plane, Polozhii [17] obtained integral representations for p-analytic functions via analytic functions of complex variable and generalized Kolosov–Muskhelishvili formulas for axially symmetric problems of the linear theory of elasticity.

Of special interest is the problem of finding the boundary value of the imaginary part of an r-analytic function via the boundary value of its real part, and vice versa. If harmonic functions θ and ω are represented by integrals with densities that are analytic functions, then the problem reduces to finding corresponding relations between those analytic functions. These relations are called Hilbert formulas. Integral representations for r-analytic functions in domains exterior to the contour of lens, spindle, torus, and two spheres in the meridional cross-section plane are discussed in [21]. In our previous work [28], we obtained Hilbert formulas for the domain exterior to the contour of a spindle by integrating the generalized Cauchy–Riemann system (7) in bipolar coordinates. In this paper we derive Hilbert formulas for the same domain based on the theory of Riemann boundary-value problems for analytic functions. For details of this theory, see [4]. We represent functions θ and ω by Fourier integrals in bipolar coordinates and reduce system (7) to a problem for a meromorphic function on three parallel contours in the infinite strip $|\operatorname{Re}\mu| \le 1$. Further, using conformal mapping, we reformulate this problem as the Riemann boundary-value problem for finding a meromorphic function in the plane with the branch cut along the segment $[-1,1]$. A solution to this problem is represented by a Cauchy integral, and boundary values of this solution at the upper and lower banks of the branch cut are expressed by the Sokhotski formulas [4]. For numerical calculations, representations of r-analytic functions in the form of Fourier integrals with Hilbert formulas reduce to the form of regular integrals. In our previous work [29], we found a nonhomogeneous solution to the problem on three parallel contours using complex Fourier transform. In this paper, we apply the approach of Riemann boundary-value problems to obtaining the nonhomogeneous solution from the class of meromorphic functions with only two simple poles at $\mu = \pm\frac{1}{2}$ in the strip $|\operatorname{Re}\mu| \le 1$ and to analyzing the existence of corresponding nontrivial homogeneous solutions.

Hilbert formulas are applied for finding the pressure function in axially symmetric problems of Stokes flows. As discussed, Lame equation (2) with $m = 2$ corresponds to the model for a Stokes fluid, and θ corresponds to the pressure in the fluid. However, there is a crucial difference in solving Lame equation (2) with $m \in (2,+\infty)$ and Stokes model (5). Namely, if $m \in (2,+\infty)$, and $\mathbf{u}$ is already known, then θ can readily be determined by (3). But relation (3) cannot be used for determining θ in the case of $m = 2$, since $\operatorname{div}\mathbf{u} = 0$. Thus, in axially symmetric problems of Stokes flows, we use Hilbert formulas for r-analytic functions to express θ via ω. As an illustration, we consider the problem of axially symmetric steady motion of a rigid spindle-shaped

body in a Stokes fluid. Stokes [19] was the first to study steady motion of a rigid sphere in a viscous incompressible fluid under low Reynolds numbers. Constructing analytical solutions to similar problems with rigid bodies of axially symmetric shape is mainly based on a stream function approach [8, 13, 14]. There are extensive studies of axially symmetric Stokes flows about spherical cap [3, 21], two spheres [18, 27], torus [5, 7, 11, 16, 20, 21, 26], lens-shaped body [3, 21, 24], and spindle-shaped body [15, 28, 30]. However, analytic formulas for the pressure function in these studies were obtained only for torus [21] and spindle-shaped body [28]. For detailed discussion of these issues, see [21]. In this paper we solve the problem of steady axially symmetric motion of a rigid spindle-shaped body in a Stokes fluid using the stream function that we proposed in [30]. Based on Hilbert formulas, we obtain an analytic expression for the pressure in the fluid, which coincides with that derived in our work [28]. To illustrate obtained results, we calculate streamlines about the body, vortex and pressure functions at the contour of the body, and the drag force exerted on the body by the fluid.

The paper is organized as follows. Section 2 represents an r-analytic function in the domain exterior to the contour of a spindle in the meridional cross-section plane. Section 3 derives Hilbert formulas for r-analytic functions in the framework of the theory of Riemann boundary-value problems for analytic functions. Section 4 reduces Fourier integral representations of r-analytic functions with Hilbert formulas to the form of regular integrals. Section 5 solves the problem of steady axially symmetric motion of a rigid spindle-shaped body in a Stokes fluid. Section 6 obtains analytic expressions for the pressure and drag force exerted on the body. Section 7 concludes the paper. The appendix derives some auxiliary formulas.

2. An r-analytic function in the domain exterior to spindle. Let (r, φ, z) be a system of cylindric coordinates with basis $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$, and let the z-axis be the axis of symmetry. In the meridional cross-section plane rz, bipolar coordinates (ξ, η) are defined by

$$r = c\,\frac{\sin\eta}{\cosh\xi - \cos\eta}\,, \qquad z = c\,\frac{\sinh\xi}{\cosh\xi - \cos\eta}\,, \tag{10}$$

where $-\infty < \xi < +\infty$, $0 \le \eta \le \pi$, and c is a metric parameter of bipolar coordinates. Spindle is an axially symmetric body, whose contour in the plane rz is determined by fixing coordinate η, i.e., $\eta = \eta_0$ (see Figure 1). For example, the surface of the spindle for $\eta_0 = \frac{\pi}{2}$ is sphere.

In the system of bipolar coordinates, derivatives $\frac{\partial}{\partial r}$, $\frac{\partial}{\partial z}$ and the k-harmonic operator Δ_k, defined by (8), take the form

$$\begin{aligned}
\frac{\partial}{\partial r} &= -\frac{1}{c}\left(\sinh\xi\sin\eta\frac{\partial}{\partial\xi} - (\cosh\xi\cos\eta - 1)\frac{\partial}{\partial\eta}\right),\\
\frac{\partial}{\partial z} &= -\frac{1}{c}\left((\cosh\xi\cos\eta - 1)\frac{\partial}{\partial\xi} + \sinh\xi\sin\eta\frac{\partial}{\partial\eta}\right),\\
\Delta_k =& \frac{(\cosh\xi - \cos\eta)^2}{c^2}\\
&\times\left(\frac{\partial^2}{\partial\xi^2} + \frac{\partial^2}{\partial\eta^2} - \frac{\sinh\xi}{\cosh\xi - \cos\eta}\frac{\partial}{\partial\xi} + \left(\cot\eta - \frac{\sin\eta}{\cosh\xi - \cos\eta}\right)\frac{\partial}{\partial\eta} - \frac{k^2}{\sin^2\eta}\right).
\end{aligned} \tag{11}$$

Let $F(r, z) = \theta(r, z) + i\,r\,\omega(r, z)$ be an r-analytic function satisfying system (7). In this case, θ and ω are harmonic and 1-harmonic functions defined by (9). In the

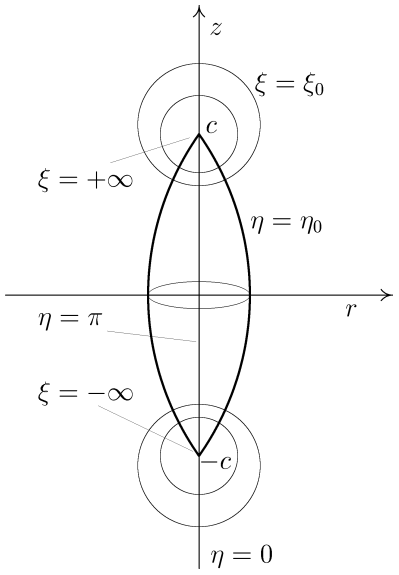

FIG. 1. *Bipolar coordinates and spindle-shaped body.*

domain exterior to the contour of spindle in the plane rz, an arbitrary k-harmonic function is represented by a Fourier integral with respect to variable ξ. Thus, in bipolar coordinates, functions $\theta(\xi,\eta)$ and $\omega(\xi,\eta)$ take the form (see [10])

$$\theta(\xi,\eta)=\frac{1}{2\pi i}\sqrt{\cosh\xi-\cos\eta}\int\limits_{-i\infty}^{+i\infty}X(\mu)\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu,\quad 0\le\eta\le\eta_0, \tag{12}$$

$$\omega(\xi,\eta)=\frac{1}{2\pi i}\sqrt{\cosh\xi-\cos\eta}\int\limits_{-i\infty}^{+i\infty}Y(\mu)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu,\quad 0\le\eta\le\eta_0, \tag{13}$$

where $\mathrm{P}^{(k)}_{-\frac{1}{2}+\mu}(\cos\eta)$ is the associated Legendre function of the first kind of complex index μ; see [1]. For $k=0$, the upper index (k) is omitted. Since $\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)\sim\frac{1}{\sqrt{2\pi\sin\eta}}\,\mathrm{e}^{\eta|\tau|}$ and $\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)\sim\frac{|\tau|}{\sqrt{2\pi\sin\eta}}\,\mathrm{e}^{\eta|\tau|}$ at $\tau\to\pm\infty$, we require functions $X(i\tau)$ and $Y(i\tau)$ in Fourier integrals (12) and (13) to have exponentially fast convergence $C\mathrm{e}^{-\gamma|\tau|}$ at $\tau\to\pm\infty$, where C is a constant, and $\gamma>\eta_0$.

Note that the harmonic functions θ and ω represented by (12) and (13), respectively, vanish at infinity $\sqrt{r^2+z^2}\to\infty$, that is, at $\xi\to 0$ and $\eta\to 0$. This guarantees uniqueness of solutions to a Dirichlet problem for (9) in the domain of consideration.

3. Problem for an analytic function on three parallel contours. Let $\mathcal{M}_{[a,b]}$ be the space of functions that are meromorphic in the strip $a\le\operatorname{Re}\mu\le b$ and have exponentially fast convergence at $|\mu|\to\infty$, i.e., vanish as $C\mathrm{e}^{-\gamma|\tau|}$, where C is a constant, and $\gamma>\eta_0$. Functions from the space $\mathcal{M}_{[a,b]}$ may have simple poles at $\mu=\pm\frac{1}{2}$ only.

Suppose $X(\mu),\,Y(\mu)\in\mathcal{M}_{[-1,1]}$, and $\eta\in[0,\eta_0]$. Under these assumptions, the following relations hold [29]:

(14)
$$\frac{\partial\theta}{\partial r} = \frac{1}{4\pi ic}\sqrt{\cosh\xi-\cos\eta}\int\limits_{-i\infty}^{+i\infty}\left(X(\mu+1)-2X(\mu)+X(\mu-1)\right)\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu,$$

(15)
$$\frac{\partial\omega}{\partial z} = \frac{1}{4\pi ic}\sqrt{\cosh\xi-\cos\eta}\int\limits_{-i\infty}^{+i\infty}\left(\left(\mu+\tfrac{3}{2}\right)Y(\mu+1)-2\mu\,Y(\mu)+\left(\mu-\tfrac{3}{2}\right)Y(\mu-1)\right)\times\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu.$$

The derivation of formulas (14) and (15) is presented in the appendix.

Note that because function $\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)$ has simple zeroes at $\mu=\pm\frac{1}{2}$, functions $X(\mu)$ and $Y(\mu)$ are allowed to have simple poles at $\mu=\pm\frac{1}{2}$. Substituting (14) and (15) into the first equation of system (7), we obtain an equation for $X(\mu)$ and $Y(\mu)$:

(16)
$$X(\mu+1)-2X(\mu)+X(\mu-1)=\left(\mu+\tfrac{3}{2}\right)Y(\mu+1)-2\mu\,Y(\mu)+\left(\mu-\tfrac{3}{2}\right)Y(\mu-1),$$

where $\mu=i\tau$, $\tau\in\mathbb{R}$.

Equation (16) is the problem on three parallel contours for finding either $X(\mu)$ given $Y(\mu)$ at the contour $\operatorname{Re}\mu=0$ or $Y(\mu)$ given $X(\mu)$ at $\operatorname{Re}\mu=0$. The uniqueness of a solution to (16) with respect to either $X(\mu)$ or $Y(\mu)$ reduces to proving that a corresponding homogeneous equation has only trivial solution. We will also show that if $X(\mu)$, $Y(\mu)\in\mathcal{M}_{[-1,1]}$ solve (16), then the function $X(\mu)$ should necessarily satisfy an additional condition $\int_{-i\infty}^{+i\infty}X(\mu)\,d\mu=0$.

3.1. Hilbert formula for the real part of r-analytic function. In this section, we solve (16) with respect to $X(\mu)\in\mathcal{M}_{[-1,1]}$ assuming that $Y(\mu)\in\mathcal{M}_{[-1,1]}$ is given. If $X(\mu)\in\mathcal{M}_{[-1,1]}$ solves (16), then $X(\mu)$ is unique. Indeed, suppose that $X_1(\mu)\in\mathcal{M}_{[-1,1]}$ and $X_2(\mu)\in\mathcal{M}_{[-1,1]}$ both solve (16), and $X_1(\mu)\neq X_2(\mu)$. This means that $X_0(\mu)=X_1(\mu)-X_2(\mu)\in\mathcal{M}_{[-1,1]}$ is a solution to homogeneous equation (16) such that $X_0(\mu)\not\equiv 0$. We prove the following proposition.

PROPOSITION 1 (homogeneous solution $X_0(\mu)$). *The only $X_0(\mu)\in\mathcal{M}_{[-1,1]}$ that solves homogeneous equation* (16)

$$X_0(\mu+1)-2X_0(\mu)+X_0(\mu-1)=0,\quad \operatorname{Re}\mu=0, \tag{17}$$

is zero function, i.e., $X_0(\mu)\equiv 0$.

Proof. Let a function $Z(\mu)$ be defined by

$$Z(\mu)=X_0(\mu)-X_0(\mu-1)\quad\text{and}\quad Z(\mu+1)=X_0(\mu+1)-X_0(\mu);$$

then $Z(\mu)\in\mathcal{M}_{[0,1]}$, and (17) reduces to

$$Z(\mu+1)-Z(\mu)=0,\quad \operatorname{Re}\mu=0. \tag{18}$$

The function

$$z=i\tan(\pi\mu) \tag{19}$$

maps the complex plane μ with the strip $0\le\operatorname{Re}\mu\le 1$ to the complex plane z with the branch cut along the segment $[-1,1]$ (see Figure 2). The line $\mu=i\tau$, $\tau\in\mathbb{R}$,

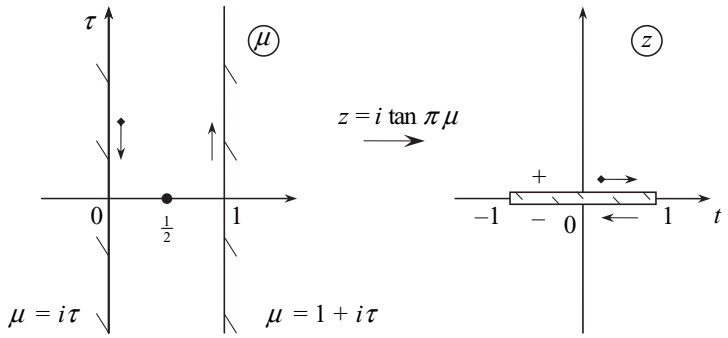

FIG. 2. *Function $z = i\tan(\pi\mu)$ maps the complex plane μ with the strip $0 \le \operatorname{Re}\mu \le 1$ to the complex plane z with the branch cut along the segment $[-1,1]$.*

corresponds to the upper bank of the branch cut, and the line $\mu = 1 + i\tau$, $\tau \in \mathbb{R}$, corresponds to the lower bank of the branch cut with the counterclockwise orientation as shown in Figure 2. The pole at $\mu = \frac{1}{2}$ in the complex plane μ corresponds to the pole at infinity in the complex plane z.

Using conformal mapping (19), we introduce a function $\tilde{Z}(z)$ in the complex plane z such that

$$\tilde{Z}^+(t) = Z(i\tau), \qquad \tilde{Z}^-(t) = Z(i\tau + 1), \qquad \tau \in \mathbb{R},$$

where $\tilde{Z}^+(t)$ and $\tilde{Z}^-(t)$ are boundary values of $\tilde{Z}(z)$ at the upper and lower banks of the branch cut. Problem (18) becomes a Riemann boundary-value problem for finding the function $\tilde{Z}(z)$, analytic in the plane z with the branch cut along the segment $[-1,1]$, such that

$$\tilde{Z}^+(t) = \tilde{Z}^-(t), \quad -1 \le t \le 1.$$

This means that the function $\tilde{Z}(z)$ is analytic in the whole plane z and has the simple pole at infinity. A solution to this problem is given by

$$\tilde{Z}(z) = \tilde{c}_1 z + \tilde{c}_0,$$

where $\tilde{c}_0$ and $\tilde{c}_1$ are constants. However, since $Z(\mu) \in \mathcal{M}_{[0,1]}$, i.e., it vanishes at $|\mu| \to \infty$, the function $\tilde{Z}(z)$ should satisfy $\tilde{Z}(\pm 1) = 0$. Consequently, $\tilde{c}_0 = 0$ and $\tilde{c}_1 = 0$, and we obtain

$$X_0(\mu + 1) - X_0(\mu) = 0, \qquad \operatorname{Re}\mu = 0,$$

for $X_0(\mu) \in \mathcal{M}_{[0,1]}$. This is the same problem as (18). Its only solution is $X_0(\mu) \equiv 0$. Thus, since $\mathcal{M}_{[-1,1]} \subset \mathcal{M}_{[0,1]}$, the only solution to (17) in the space of $\mathcal{M}_{[-1,1]}$ is zero function. □

Consequently, if $X(\mu) \in \mathcal{M}_{[-1,1]}$ solves (16), then it is unique.

THEOREM 1 (Hilbert formula for the real part). *Let the real and imaginary parts of an r-analytic function be represented in bipolar coordinates by Fourier integrals* (12) *and* (13)*, respectively. If $X(\mu) \in \mathcal{M}_{[-1,1]}$ and $Y(\mu) \in \mathcal{M}_{[-1,1]}$, then at the contour $\operatorname{Re}\mu = 0$, the function $X(\mu)$ is represented by the Hilbert formula for the real part of the r-analytic function*

$$X(\mu) = \mu\, Y(\mu) - \frac{i}{2\cos(\pi\mu)} \fint_{-i\infty}^{+i\infty} Y(\nu)\, \frac{\cos(\pi\nu)}{\sin[\pi(\nu - \mu)]}\, d\nu, \qquad \operatorname{Re}\mu = 0, \tag{20}$$

where $⨍$ *means the Cauchy principal value or v.p. (i.e.,* valeur principale*) of a singular integral.*

Proof. For $\operatorname{Re}\mu = 0$, equation (16) may be rewritten as

$$[X(\mu+1) - X(\mu)] - [X(\mu) - X(\mu-1)]$$
$$= \left[\left(\mu+\tfrac{3}{2}\right)Y(\mu+1) - \left(\mu-\tfrac{1}{2}\right)Y(\mu)\right] - \left[\left(\mu+\tfrac{1}{2}\right)Y(\mu) - \left(\mu-\tfrac{3}{2}\right)Y(\mu-1)\right].$$

Introducing a new function $Z(\mu)$ by

$$Z(\mu+1) = [X(\mu+1) - X(\mu)] - \left[\left(\mu+\tfrac{3}{2}\right)Y(\mu+1) - \left(\mu-\tfrac{1}{2}\right)Y(\mu)\right],$$
$$Z(\mu) = [X(\mu) - X(\mu-1)] - \left[\left(\mu+\tfrac{1}{2}\right)Y(\mu) - \left(\mu-\tfrac{3}{2}\right)Y(\mu-1)\right],$$

we reduce (16) to

$$Z(\mu+1) - Z(\mu) = 0, \qquad \operatorname{Re}\mu = 0,$$

for $Z(\mu) \in \mathcal{M}_{[0,1]}$. This is the same problem as (18). Its only solution is $Z(\mu) \equiv 0$. Consequently,

$$X(\mu+1) - X(\mu) = \left(\mu+\tfrac{3}{2}\right)Y(\mu+1) - \left(\mu-\tfrac{1}{2}\right)Y(\mu), \quad \operatorname{Re}\mu = 0, \tag{21}$$
$$X(\mu) - X(\mu-1) = \left(\mu+\tfrac{1}{2}\right)Y(\mu) - \left(\mu-\tfrac{3}{2}\right)Y(\mu-1), \quad \operatorname{Re}\mu = 0. \tag{22}$$

It is sufficient to solve only (21) for $X(\mu) \in \mathcal{M}_{[0,1]}$ given $Y(\mu) \in \mathcal{M}_{[0,1]}$. It can be shown that solutions to (21) and (22) provide the same $X(\mu)$ at $\operatorname{Re}\mu = 0$.

Representing $X(\mu)$ by

$$X(\mu) = \left(\mu+\tfrac{1}{2}\right)Y(\mu) + \hat{X}(\mu), \tag{23}$$

where $\hat{X}(\mu) \in \mathcal{M}_{[0,1]}$ is a new function, we reformulate (21) for $\hat{X}(\mu)$:

$$\hat{X}(\mu+1) - \hat{X}(\mu) = Y(\mu), \quad \operatorname{Re}\mu = 0. \tag{24}$$

Since $\hat{X}(\mu)$ and $Y(\mu)$ have exponentially fast convergence at $|\mu| \to \infty$, we integrate equation (24) at the contour $\operatorname{Re}\mu = 0$ and obtain

$$\operatorname*{Res}_{\mu=\frac{1}{2}} \hat{X}(\mu) = \frac{1}{2\pi i} ⨍_{-i\infty}^{+i\infty} Y(\mu)\, d\mu. \tag{25}$$

Using conformal mapping (19), we introduce functions $\tilde{X}(z)$ and $\tilde{Y}(z)$, meromorphic in the complex plane z, such that

$$\begin{aligned} \tilde{X}^+(t) &= \hat{X}(i\tau), & \tilde{Y}^+(t) &= Y(i\tau), \\ \tilde{X}^-(t) &= \hat{X}(i\tau+1), & \tilde{Y}^-(t) &= Y(i\tau+1), \end{aligned} \qquad \tau \in \mathbb{R},$$

where pairs $\tilde{X}^+(t)$, $\tilde{X}^-(t)$ and $\tilde{Y}^+(t)$, $\tilde{Y}^-(t)$ are boundary values of $\tilde{X}(z)$ and $\tilde{Y}(z)$ at the upper and lower banks of the branch cut, respectively. Note that the pole $\mu = \frac{1}{2}$ in the complex plane μ became the pole at infinity in the complex plane z. Problem (24) reduces to a Riemann boundary-value problem for finding the function

$\tilde{X}(z)$ analytic in the plane z with the branch cut along the segment $[-1,1]$ and having the simple pole at infinity:

$$\tilde{X}^+(t)-\tilde{X}^-(t)=-\tilde{Y}^+(t),\quad -1\le t\le 1. \tag{26}$$

The function $\tilde{X}(z)$ is represented by a Cauchy integral

$$\tilde{X}(z)=-\frac{1}{2\pi i}\oint_{-1}^{1}\frac{\tilde{Y}^+(s)}{s-z}\,ds+\tilde{c}_1 z+\tilde{c}_0,$$

where $\tilde{c}_0$ and $\tilde{c}_1$ are unknown constants. The function $\tilde{Y}^+(s)$ must satisfy Hölder condition, i.e., $|\tilde{Y}^+(t_2)-\tilde{Y}^+(t_1)|\le c'\,|t_2-t_1|^{\lambda}$ for all t_1, $t_2\in[-1,1]$, some $\lambda\in(0,1]$, and nonnegative constant c'. At points $t=\pm1$, it converges to zero not slower than $(1-t^2)^{\frac{\eta_0}{2\pi}}$.

Using the Sokhotski formulas, we obtain

$$\tilde{X}^+(t)=-\frac{1}{2}\tilde{Y}^+(t)-\frac{1}{2\pi i}\oint_{-1}^{1}\frac{\tilde{Y}^+(s)}{s-t}\,ds+\tilde{c}_1 t+\tilde{c}_0. \tag{27}$$

Constants $\tilde{c}_0$ and $\tilde{c}_1$ are found based on the requirement $\tilde{X}^+(\pm1)=0$ and condition $\tilde{Y}^+(t)|_{t\to\pm1}\sim(1-t^2)^{\frac{\eta_0}{2\pi}}$:

$$\tilde{c}_0=-\frac{1}{2\pi i}\oint_{-1}^{1}\frac{s}{1-s^2}\,\tilde{Y}^+(s)\,ds,\qquad \tilde{c}_1=-\frac{1}{2\pi i}\oint_{-1}^{1}\frac{1}{1-s^2}\,\tilde{Y}^+(s)\,ds.$$

Note that $\tilde{c}_1$ satisfies $\tilde{c}_1\operatorname{Res}_{\mu=\frac{1}{2}}[i\tan(\pi\mu)]=\operatorname{Res}_{\mu=\frac{1}{2}}\hat{X}(\mu)$, where $\operatorname{Res}_{\mu=\frac{1}{2}}\hat{X}(\mu)$ is determined by (25). Thus, expression (27) takes the form

$$\tilde{X}^+(t)=-\frac{1}{2}\tilde{Y}^+(t)-\frac{1}{2\pi i}(1-t^2)\oint_{-1}^{1}\frac{\tilde{Y}^+(s)}{1-s^2}\,\frac{ds}{s-t}. \tag{28}$$

Finally, making change of variables $t=i\tan(\pi\mu)$, $\operatorname{Re}\mu=0$, and $s=i\tan(\pi\nu)$, $\operatorname{Re}\nu=0$, in (28), and substituting (28) into (23), we obtain Hilbert formula (20). The change of variables in singular integral (28) is valid because $t'(\mu)=\pi/\cos^2(\pi\mu)$ is a continuous strictly positive function at $\operatorname{Re}\mu=0$ (for details see [4]). □

3.2. Hilbert formula for the imaginary part of *r*-analytic function. Now we solve (16) with respect to $Y(\mu)\in\mathcal{M}_{[-1,1]}$ assuming that $X(\mu)\in\mathcal{M}_{[-1,1]}$ is given. As in the previous case, uniqueness of a solution $Y(\mu)$ to (16) is guaranteed by the fact that the homogeneous equation corresponding to (16) has only trivial solution.

PROPOSITION 2 (homogeneous solution $Y_0(\mu)$). *The only $Y_0(\mu)\in\mathcal{M}_{[-1,1]}$ that solves homogeneous equation*

$$\left(\mu+\tfrac{3}{2}\right)Y_0(\mu+1)-2\mu\,Y_0(\mu)+\left(\mu-\tfrac{3}{2}\right)Y_0(\mu-1)=0,\qquad \operatorname{Re}\mu=0, \tag{29}$$

is zero function, i.e., $Y_0(\mu)\equiv0$.

Proof. Let a function $Z(\mu)$ be defined by

$$Z(\mu+1) = \left(\mu+\tfrac{3}{2}\right) Y_0(\mu+1) - \left(\mu-\tfrac{1}{2}\right) Y_0(\mu),$$
$$Z(\mu) = \left(\mu+\tfrac{1}{2}\right) Y_0(\mu) - \left(\mu-\tfrac{3}{2}\right) Y_0(\mu-1);$$

then $Z(\mu) \in \mathcal{M}_{[0,1]}$, and (29) reduces to $Z(\mu+1) - Z(\mu) = 0$, $\operatorname{Re}\mu = 0$. This problem, being the same as (18), has only zero solution, i.e., $Z(\mu) \equiv 0$. Consequently, for $Y_0(\mu) \in \mathcal{M}_{[0,1]}$ we obtain

$$\left(\mu+\tfrac{3}{2}\right) Y_0(\mu+1) - \left(\mu-\tfrac{1}{2}\right) Y_0(\mu) = 0, \qquad \operatorname{Re}\mu = 0. \tag{30}$$

Multiplying (30) by $\left(\mu+\frac{1}{2}\right)$ and representing $Y_0(\mu) = \frac{1}{\mu^2-\frac{1}{4}}\, Y_1(\mu)$, where $Y_1(\mu)$ is a function analytic in $0 \le \operatorname{Re}\mu \le 1$ and vanishing at $|\mu| \to \infty$, we reduce equation (30) to the problem for function $Y_1(\mu)$: $Y_1(\mu+1) - Y_1(\mu) = 0$, $\operatorname{Re}\mu = 0$. By similar reasoning, we conclude that the only possible solution to this problem is zero function. Thus, since $\mathcal{M}_{[-1,1]} \subset \mathcal{M}_{[0,1]}$, the only solution to (29) in the space of $\mathcal{M}_{[-1,1]}$ is $Y_0(\mu) \equiv 0$. □

This proposition implies that $Y(\mu) \in \mathcal{M}_{[-1,1]}$ solving (16) is unique.

THEOREM 2 (Hilbert formula for the imaginary part). *Let the real and imaginary parts of an r-analytic function be represented in bipolar coordinates by Fourier integrals* (12) *and* (13)*, respectively. If $X(\mu) \in \mathcal{M}_{[-1,1]}$, $Y(\mu) \in \mathcal{M}_{[-1,1]}$, and $\int_{-i\infty}^{+i\infty} X(\mu)\, d\mu = 0$, then at the contour $\operatorname{Re}\mu = 0$, the function $Y(\mu)$ is represented by the Hilbert formula for the imaginary part of the r-analytic function*

$$Y(\mu) = \frac{1}{\mu^2-\frac{1}{4}} \left(\mu\, X(\mu) + \frac{i}{2\cos(\pi\mu)} \fint_{-i\infty}^{+i\infty} X(\nu)\, \frac{\cos(\pi\nu)}{\sin[\pi(\nu-\mu)]}\, d\nu \right), \qquad \operatorname{Re}\mu = 0. \tag{31}$$

Proof. Repeating the same arguments as in the proof of Theorem 1, we obtain (21) and (22), which we now solve with respect to $Y(\mu)$. It can be shown that solutions to (21) and (22) provide the same $Y(\mu)$ at $\operatorname{Re}\mu = 0$. Multiplying (21) by $\left(\mu+\frac{1}{2}\right)$ and representing function $Y(\mu)$ by

$$Y(\mu) = \frac{1}{\mu^2-\frac{1}{4}} \left(\hat{Y}(\mu) + \left(\mu-\tfrac{1}{2}\right) X(\mu) \right), \tag{32}$$

where $\hat{Y}(\mu)$ is analytic in $0 \le \operatorname{Re}\mu \le 1$ and has exponentially fast convergence at $|\mu| \to \infty$, we reduce (21) to

$$\hat{Y}(\mu+1) - \hat{Y}(\mu) = -X(\mu), \quad \operatorname{Re}\mu = 0. \tag{33}$$

This problem is similar to (24). However, while the function $\hat{X}(\mu)$ in (24) has the simple pole at $\mu = \frac{1}{2}$, the function $\hat{Y}(\mu)$ in (33) does not. Consequently, integrating (33) at the contour $\operatorname{Re}\mu = 0$, we obtain $\frac{1}{2\pi i}\int_{-i\infty}^{+i\infty} X(\mu)\, d\mu = 0$. This means that the function $X(\mu)$ should necessarily satisfy this condition.

Using conformal mapping (19), we introduce analytic function $\tilde{X}(z)$ and meromorphic function $\tilde{Y}(z)$ in the complex plane z such that

$$\begin{aligned} &\tilde{Y}^+(t) = \hat{Y}(i\tau), && \tilde{X}^+(t) = X(i\tau), \\ &\tilde{Y}^-(t) = \hat{Y}(i\tau+1), && \tilde{X}^-(t) = X(i\tau+1), \end{aligned} \qquad \tau \in \mathbb{R},$$

where pairs $\tilde{Y}^+(t)$, $\tilde{X}^+(t)$ and $\tilde{Y}^-(t)$, $\tilde{X}^-(t)$ are boundary values of functions $\tilde{Y}(z)$ and $\tilde{X}(z)$ at the upper and lower banks of the branch cut, respectively. Problem (33) reduces to a Riemann boundary-value problem for finding the function $\tilde{Y}(z)$ analytic in the plane z with the branch cut along the segment $[-1,1]$ and bounded at infinity:

$$\tilde{Y}^+(t)-\tilde{Y}^-(t)=\tilde{X}^+(t),\quad -1\le t\le 1. \tag{34}$$

Problem (34) is similar to (26). Thus, a solution to (34) takes the form

$$\tilde{Y}^+(t)=\frac{1}{2}\tilde{X}^+(t)+\frac{1}{2\pi i}\fint_{-1}^{1}\frac{\tilde{X}^+(s)}{s-t}\,ds+\tilde{c}_0, \tag{35}$$

where $\tilde{c}_0$ is a constant. The function $\tilde{X}^+(s)$ must satisfy Hölder condition $|\tilde{X}^+(t_2)-\tilde{X}^+(t_1)|\le c'\,|t_2-t_1|^{\lambda}$ for some $\lambda\in(0,1]$, nonnegative constant c', and all t_1, $t_2\in[-1,1]$. At points $t=\pm1$, it converges to zero not slower than $(1-t^2)^{\frac{\eta_0}{2\pi}}$. Since there is only one constant to satisfy two conditions $\tilde{Y}^+(1)=0$ and $\tilde{Y}^+(-1)=0$, we have

$$\tilde{c}_0=\frac{1}{2\pi i}\fint_{-1}^{1}\frac{s}{1-s^2}\,\tilde{X}^+(s)\,ds,\qquad \frac{1}{2\pi i}\fint_{-1}^{1}\frac{1}{1-s^2}\,\tilde{X}^+(s)\,ds=0,$$

where the second relation is equivalent to $\int_{-i\infty}^{+i\infty}X(\mu)\,d\mu=0$. Thus, expression (35) takes the form

$$\tilde{Y}^+(t)=\frac{1}{2}\tilde{X}^+(t)+\frac{1}{2\pi i}(1-t^2)\fint_{-1}^{1}\frac{\tilde{X}^+(s)}{1-s^2}\,\frac{ds}{s-t}. \tag{36}$$

Finally, making change of variables $t=i\tan(\pi\mu)$, $\operatorname{Re}\mu=0$, and $s=i\tan(\pi\nu)$, $\operatorname{Re}\nu=0$, in (36), and substituting (36) into (32), we obtain Hilbert formula (31). The change of variables in singular integral (36) is valid because $t'(\mu)=\pi/\cos^2(\pi\mu)$ is a continuous strictly positive function at $\operatorname{Re}\mu=0$ (for details see [4]). □

Corollary. Hilbert formula (20) reduces the necessary condition

$$\int_{-i\infty}^{+i\infty}X(\mu)\,d\mu=0$$

to identity, i.e.,

$$\int_{-i\infty}^{+i\infty}\left(\mu\,Y(\mu)-\frac{i}{2\cos(\pi\mu)}\fint_{-i\infty}^{+i\infty}Y(\nu)\frac{\cos(\pi\nu)}{\sin[\pi(\nu-\mu)]}\,d\nu\right)d\mu\equiv 0.$$

Proof. The result follows from the fact that

$$\fint_{-i\infty}^{+i\infty}\frac{d\mu}{\cos(\pi\mu)\,\sin[\pi(\nu-\mu)]}=-2i\,\frac{\nu}{\cos(\pi\nu)},\qquad \operatorname{Re}\nu=0.$$

Conditions for changing the order of integration for singular integrals are discussed in [4]. □

Example. The following two pairs reduce (16) to identity:

$$X(\mu)=\frac{\mu}{\cos(\pi\mu)},\quad Y(\mu)=\frac{1}{\cos(\pi\mu)}\qquad\text{and}\qquad X(\mu)=\frac{\mu^2+\frac{1}{4}}{\cos(\pi\mu)},\quad Y(\mu)=\frac{\mu}{\cos(\pi\mu)}.$$

In each pair, $X(\mu)$ and $Y(\mu)$ are related by Hilbert formulas (20) and (31).

Proof. Verification of Hilbert formulas reduces to the following calculations:

$$\fint_{-i\infty}^{+i\infty}\frac{d\nu}{\sin[\pi(\nu-\mu)]}=0,\qquad \fint_{-i\infty}^{+i\infty}\frac{\nu\,d\nu}{\sin[\pi(\nu-\mu)]}=\frac{i}{2},\qquad \fint_{-i\infty}^{+i\infty}\frac{\nu^2\,d\nu}{\sin[\pi(\nu-\mu)]}=i\mu.$$

Obviously, the condition $\int_{-i\infty}^{+i\infty}X(\mu)\,d\mu=0$ holds: $\int_{-i\infty}^{+i\infty}\frac{\mu}{\cos(\pi\mu)}\,d\mu=0$ and $\int_{-i\infty}^{+i\infty}\frac{(\mu^2+\frac{1}{4})}{\cos(\pi\mu)}\,d\mu=0$, respectively. □

4. Implementation of Fourier integrals with Hilbert formulas. Hilbert formulas (20) and (31) are expressed by singular integrals; consequently, they require special treatment in numerical implementation. In this section, we derive formulas for efficient calculating double integrals in (12) with (20) and (13) with (31).

PROPOSITION 3 (function $\omega(\xi,\eta)$). *If function $Y(\mu)$ is represented at $\operatorname{Re}\mu=0$ by Hilbert formula* (31)*, then the function $\omega(\xi,\eta)$ takes the form*

$$\begin{aligned}\omega(\xi,\eta)=&\frac{1}{2\pi i}\sqrt{\cosh\xi-\cos\eta}\\ &\times\int_{-\infty}^{+\infty}X(i\tau)\left(\frac{\tau}{\tau^2+\frac{1}{4}}\,\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}+G_1(\xi,\eta,\tau)\right)d\tau,\end{aligned}\tag{37}$$

where

(38)

$$G_1(\xi,\eta,\tau)=\begin{cases}\dfrac{i\sqrt{2}}{\pi\sin\eta}\left(\mathrm{e}^{i\xi\tau}\displaystyle\int_0^{\eta}g(\xi,\tau,t)\sqrt{\cos t-\cos\eta}\,dt-2\,h_1(\xi,\eta)\,\sinh\dfrac{\xi}{2}\right),\ \ \xi\neq0,\\ \dfrac{\sqrt{2}}{\pi\sin\eta}\displaystyle\int_0^{\eta}\cot\tfrac{t}{2}\sinh(\tau t)\sqrt{\cos t-\cos\eta}\,dt,\ \ \xi=0,\end{cases}$$

$$g(\xi,\tau,t)=\frac{\sinh\xi\cosh(\tau t)-i\sin t\,\sinh(\tau t)}{\cosh\xi-\cos t},\tag{39}$$

$$h_1(\xi,\eta)=\frac{\pi}{\sqrt{2}}\left(\sqrt{1+\left(\frac{\sin\frac{\eta}{2}}{\sinh\frac{\xi}{2}}\right)^2}-1\right),\quad \xi\neq0.\tag{40}$$

Both integrals in (38) *are regular and can be efficiently calculated by a Gaussian quadrature.*

Proof. Substituting formula (31) into (13), we obtain

(41)

$$\begin{aligned}\omega(\xi,\eta)=&\frac{1}{2\pi i}\sqrt{\cosh\xi-\cos\eta}\int_{-\infty}^{+\infty}\left(\tau X(i\tau)+\frac{1}{2}\fint_{-\infty}^{+\infty}X(i\tau_1)\frac{\cosh(\pi\tau_1)}{\cosh(\pi\tau)}\frac{d\tau_1}{\sinh[\pi(\tau_1-\tau)]}\right)\\ &\times\frac{\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)}{\tau^2+\frac{1}{4}}\,\mathrm{e}^{-i\xi\tau}d\tau.\end{aligned}$$

The inner integral in (41) is singular, but the external integral is regular. Consequently, we do not need the Poincaré–Bertrand formula for changing the order of integration in (41) (see [4]):

$$\begin{aligned}\mathcal{I}_Y(\xi,\eta) &= \frac{1}{2}\int\limits_{-\infty}^{+\infty}\left(\mathop{\not\int}\limits_{-\infty}^{+\infty} X(i\tau_1)\,\frac{\cosh(\pi\tau_1)\,d\tau_1}{\sinh[\pi(\tau_1-\tau)]}\right)\frac{\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)}{\left(\tau^2+\frac{1}{4}\right)\cosh(\pi\tau)}\,\mathrm{e}^{-i\xi\tau}d\tau\\ &= \frac{1}{2}\int\limits_{-\infty}^{+\infty} X(i\tau_1)\cosh(\pi\tau_1)\underbrace{\left(\mathop{\not\int}\limits_{-\infty}^{+\infty}\frac{\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)}{\left(\tau^2+\frac{1}{4}\right)\cosh(\pi\tau)}\,\frac{\mathrm{e}^{-i\xi\tau}\,d\tau}{\sinh[\pi(\tau_1-\tau)]}\right)}_{I_1(\xi,\eta,\tau_1)}d\tau_1.\end{aligned}$$

The inner integral $I_1(\xi,\eta,\tau_1)$ in $\mathcal{I}_Y(\xi,\eta)$ is calculated based on the following representation [1]:

$$\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta) = \frac{2\sqrt{2}}{\pi}\frac{\left(\tau^2+\frac{1}{4}\right)}{\sin\eta}\int\limits_0^\eta \cosh(\tau t)\sqrt{\cos t-\cos\eta}\,dt.$$

We obtain

$$\begin{aligned}I_1(\xi,\eta,\tau_1) &= \frac{2\sqrt{2}}{\pi\sin\eta}\int\limits_0^\eta J_1(\xi,\tau_1,t)\sqrt{\cos t-\cos\eta}\,dt\\ &= \frac{2\sqrt{2}}{\pi\sin\eta}\,\frac{i}{\cosh(\pi\tau_1)}\\ &\quad\times\left(\mathrm{e}^{-i\xi\tau_1}\int\limits_0^\eta g(\xi,\tau_1,t)\,\sqrt{\cos t-\cos\eta}\,dt-2h_1(\xi,\eta)\sinh\tfrac{\xi}{2}\right),\quad \xi\neq 0,\end{aligned}$$

where

$$\begin{aligned}J_1(\xi,\tau_1,t) &= \mathop{\not\int}\limits_{-\infty}^{+\infty}\frac{\cosh(\tau t)}{\cosh(\pi\tau)}\frac{\mathrm{e}^{-i\xi\tau}\,d\tau}{\sinh[\pi(\tau_1-\tau)]}\\ &= \frac{i}{\cosh(\pi\tau_1)}\left(g(\xi,\tau_1,t)\,\mathrm{e}^{-i\xi\tau_1}-\frac{2\sinh\frac{\xi}{2}\cos\frac{t}{2}}{\cosh\xi-\cos t}\right),\end{aligned}\tag{42}$$

$$h_1(\xi,\eta) = \int\limits_0^\eta\frac{\sqrt{\cos t-\cos\eta}}{\cosh\xi-\cos t}\,\cos\tfrac{t}{2}\,dt = \frac{\pi}{\sqrt{2}}\left[\sqrt{1+\left(\frac{\sin\frac{\eta}{2}}{\sinh\frac{\xi}{2}}\right)^2}-1\right],\quad \xi\neq 0,$$

and function $g(\xi,\tau_1,t)$ is determined by (39). For $\xi=0$, expression (42) takes on finite values for all $t\in[0,\eta]$:

$$J_1(0,\tau_1,t) = \frac{\sinh(\tau_1 t)}{\cosh(\pi\tau_1)}\,\cot\tfrac{t}{2}.\tag{43}$$

Thus,

$$I_1(0,\eta,\tau_1) = \frac{2\sqrt{2}}{\pi\sin\eta}\int\limits_0^\eta J_1(0,\tau_1,t)\sqrt{\cos t-\cos\eta}\,dt,$$

and $G_1(\xi,\eta,\tau_1)=\frac{1}{2}\,I_1(\xi,\eta,\tau_1)\cosh(\pi\tau_1)$. □

PROPOSITION 4 (function $\theta(\xi,\eta)$). *If function $X(\mu)$ is represented at $\operatorname{Re}\mu = 0$ by Hilbert formula* (20)*, then the function $\theta(\xi,\eta)$ takes the form*

(44)
$$\theta(\xi,\eta) = -\frac{1}{2\pi i}\sqrt{\cosh\xi - \cos\eta}\int\limits_{-\infty}^{+\infty} Y(i\tau)\left(\tau\,\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau} + G_2(\xi,\eta,\tau)\right)d\tau,$$

where

(45)
$$G_2(\xi,\eta,\tau) = \begin{cases} -\dfrac{2\sqrt{2}\,i}{\pi\sin^2\eta}\displaystyle\int\limits_0^{\eta}\Bigg[g(\xi,\tau,t)\left(\frac{3}{4}\cos t + \frac{1}{4}\cos\eta\right)\sqrt{\cos t - \cos\eta}\,\mathrm{e}^{-i\xi\tau} \\ \qquad\qquad -\dfrac{1}{3}\dfrac{\partial^2}{\partial\xi^2}\left(g(\xi,\tau,t)\,\mathrm{e}^{-i\xi\tau}\right)(\cos t - \cos\eta)^{\frac{3}{2}}\Bigg]dt \\ \qquad\qquad +\dfrac{i}{\sqrt{2}}\dfrac{\operatorname{sign}\xi}{\sqrt{\cosh\xi - \cos\eta}}, \quad \xi \neq 0, \\ -\dfrac{2\sqrt{2}}{\pi\sin^2\eta}\displaystyle\int\limits_0^{\eta}\Bigg[\cot\frac{t}{2}\,\sinh(\tau t)\left(\frac{3}{4}\cos t + \frac{1}{4}\cos\eta - \frac{1}{2}\right) \\ \qquad\qquad +\tau\,\cos^2\left(\dfrac{t}{2}\right)\cosh(\tau t)\Bigg]\sqrt{\cos t - \cos\eta}\,dt, \quad \xi = 0, \end{cases}$$

and $g(\xi,\tau,t)$ is defined by (39)*. Both integrals in* (45) *are regular and can be efficiently calculated by a Gaussian quadrature.*

Proof. Substituting formula (20) into (12), we obtain

(46)
$$\theta(\xi,\eta) = -\frac{1}{2\pi i}\sqrt{\cosh\xi - \cos\eta}\int\limits_{-\infty}^{+\infty}\left(\tau Y(i\tau) - \frac{1}{2}\,\xint-\limits_{-\infty}^{+\infty} Y(i\tau_1)\frac{\cosh(\pi\tau_1)}{\cosh(\pi\tau)}\frac{d\tau_1}{\sinh[\pi(\tau_1-\tau)]}\right) \times \mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}d\tau.$$

Although the inner integral in (46) is singular, the external integral is regular. Consequently, we do not need the Poincaré–Bertrand formula for changing the order of integration in (46) (see [4]):

$$\begin{aligned}\mathcal{I}_X(\xi,\eta) &= \int\limits_{-\infty}^{+\infty}\left(\xint-\limits_{-\infty}^{+\infty} Y(i\tau_1)\,\frac{\cosh(\pi\tau_1)\,d\tau_1}{\sinh[\pi(\tau_1-\tau)]}\right)\frac{\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)}{\cosh(\pi\tau)}\,\mathrm{e}^{-i\xi\tau}d\tau \\ &= \int\limits_{-\infty}^{+\infty} Y(i\tau_1)\cosh(\pi\tau_1)\underbrace{\left(\xint-\limits_{-\infty}^{+\infty}\frac{\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)}{\cosh(\pi\tau)}\frac{\mathrm{e}^{-i\xi\tau}\,d\tau}{\sinh[\pi(\tau_1-\tau)]}\right)}_{I_2(\xi,\eta,\tau_1)}d\tau_1.\end{aligned}$$

The inner integral $I_2(\xi,\eta,\tau_1)$ in $\mathcal{I}_X(\xi,\eta)$ is calculated based on the following representation [1]:

$$\begin{aligned}\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta) =& \frac{4\sqrt{2}}{\pi\sin^2\eta}\int\limits_0^{\eta}\cosh(\tau t)\left(\cos\eta + \tfrac{1}{3}\left(\tau^2 + \tfrac{9}{4}\right)(\cos t - \cos\eta)\right) \\ &\times\sqrt{\cos t - \cos\eta}\,dt.\end{aligned}$$

We have

$$I_2(\xi,\eta,\tau_1) = \frac{4\sqrt{2}}{\pi\sin^2\eta} \times \int\limits_0^\eta \left(J_1(\xi,\tau_1,t)\ \cos\eta\sqrt{\cos t-\cos\eta} + \tfrac{1}{3}J_2(\xi,\tau_1,t)(\cos t-\cos\eta)^{\frac{3}{2}} \right) dt,$$

where the function $J_1(\xi,\tau_1,t)$ is defined by (42), and

$$J_2(\xi,\tau_1,t) = \fint\limits_{-\infty}^{+\infty} \frac{\cosh(\tau t)}{\cosh(\pi\tau)} \frac{\left(\tau^2+\frac{9}{4}\right)\mathrm{e}^{-i\xi\tau}\,d\tau}{\sinh[\pi(\tau_1-\tau)]} = \frac{9}{4}J_1(\xi,\tau_1,t) - \frac{\partial^2}{\partial\xi^2}J_1(\xi,\tau_1,t).$$

Using intermediate calculations

$$\begin{aligned} h_2(\xi,\eta) &= \int\limits_0^\eta \frac{(\cos t-\cos\eta)^{\frac{3}{2}}}{\cosh\xi-\cos t}\ \cos\tfrac{t}{2}\ dt \\ &= (\cosh\xi-\cos\eta)\,h_1(\xi,\eta) - \frac{\pi}{\sqrt{2}}\sin^2(\tfrac{\eta}{2}), \quad \xi\neq 0, \\ \left(2h_1(\xi,\eta)\cos\eta+\tfrac{3}{2}h_2(\xi,\eta)\right)\sinh\tfrac{\xi}{2} &- \frac{2}{3}\frac{\partial^2}{\partial\xi^2}\left(h_2(\xi,\eta)\sinh\tfrac{\xi}{2}\right) \\ &= \frac{\pi}{4}\frac{\sinh\xi}{|\sinh\xi|}\frac{\sin^2\eta}{\sqrt{\cosh\xi-\cos\eta}}, \quad \xi\neq 0, \end{aligned}$$

where the function $h_1(\xi,\eta)$ is defined by (40), we reduce the integral $I_2(\xi,\eta,\tau_1)$ to the form

$$I_2(\xi,\eta,\tau_1) = \frac{1}{\cosh(\pi\tau_1)}\left(R(\xi,\eta,\tau_1,t)\,\mathrm{e}^{-i\xi\tau_1} - \frac{\sqrt{2}\,i\ \operatorname{sign}\xi}{\sqrt{\cosh\xi-\cos\eta}} \right), \quad \xi\neq 0,$$

where

$$\begin{aligned} R(\xi,\eta,\tau_1,t)\,\mathrm{e}^{-i\xi\tau_1} =& \frac{4\sqrt{2}\,i}{\pi\sin^2\eta}\int\limits_0^\eta \Big[g(\xi,\tau_1,t)\left(\tfrac{3}{4}\cos t+\tfrac{1}{4}\cos\eta\right)\sqrt{\cos t-\cos\eta}\,\mathrm{e}^{-i\xi\tau_1} \\ &- \frac{1}{3}\frac{\partial^2}{\partial\xi^2}\left(g(\xi,\tau_1,t)\,\mathrm{e}^{-i\xi\tau_1}\right)(\cos t-\cos\eta)^{\frac{3}{2}} \Big]\, dt, \end{aligned}$$

and function $g(\xi,\tau_1,t)$ is defined by (39). In the case of $\xi=0$, we use (43) to derive expression for $I_2(0,\eta,\tau_1)$:

$$\begin{aligned} I_2(0,\eta,\tau_1) =& \frac{1}{\cosh(\pi\tau_1)}\ \frac{4\sqrt{2}}{\pi\sin^2\eta}\int\limits_0^\eta \Big[\cot\tfrac{t}{2}\ \sinh(\tau_1 t)\left(\tfrac{3}{4}\cos t+\tfrac{1}{4}\cos\eta-\tfrac{1}{2}\right) \\ &+ \tau_1\ \cos^2(\tfrac{t}{2})\ \cosh(\tau_1 t)\Big]\sqrt{\cos t-\cos\eta}\,dt. \end{aligned}$$

Note that the integrand in $I_2(0,\eta,\tau_1)$ takes on finite values for all $t\in[0,\eta]$. Finally, defining $G_2(\xi,\eta,\tau_1) = -\frac{1}{2}\ I_2(\xi,\eta,\tau_1)\cosh(\pi\tau_1)$, we finish the proof of the proposition. □

Remark (function $\theta(\xi,\eta)$). If we represent $\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)$ by

$$\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)=\frac{1}{\pi\sqrt{2}}\cosh(\pi\tau)\int\limits_{-\infty}^{+\infty}\frac{\mathrm{e}^{i\tau t}}{\sqrt{\cosh t+\cos\eta}}\,dt$$

(see [1]), then function (45) takes the form

(47)

$$\begin{aligned}G_2(\xi,\eta,\tau_1)&=-\frac{1}{2\pi\sqrt{2}}\,\cosh(\pi\tau_1)\int\limits_{-\infty}^{+\infty}\frac{1}{\sqrt{\cosh t+\cos\eta}}\left(\int\limits_{-\infty}^{+\infty}\frac{\mathrm{e}^{i\tau(t-\xi)}\,d\tau}{\sinh[\pi(\tau_1-\tau)]}\right)dt\\&=\frac{i}{2\pi\sqrt{2}}\,\cosh(\pi\tau_1)\int\limits_{-\infty}^{+\infty}\frac{\tanh\left(\frac{t-\xi}{2}\right)}{\sqrt{\cosh t+\cos\eta}}\,\mathrm{e}^{i\tau_1(t-\xi)}dt.\end{aligned}$$

Expression (47) is simpler than (45). However, although (47) is a regular integral, it is a Fourier integral on an infinite interval. Consequently, from a computational point of view, representation (45) is preferable.

5. Axially symmetric Stokes flow about a spindle-shaped body. Let us consider axially symmetric steady motion of a rigid spindle-shaped body in a Stokes fluid. In this case, the vector of velocity of fluid particles, $\mathbf{u}$, satisfies Stokes model (5). Suppose that the body moves in the fluid with constant velocity V_0 along its axis of symmetry. Let (r,φ,z) be a system of cylindrical coordinates with basis $(\mathbf{e}_r,\mathbf{e}_\varphi,\mathbf{k})$ such that axis z determines a body's axis of symmetry. Then boundary conditions for $\mathbf{u}$ are determined on the surface S of the body by

$$\mathbf{u}|_S=V_0\,\mathbf{k}. \tag{48}$$

We assume that the velocity $\mathbf{u}$ and the pressure function θ vanish at infinity,

$$\mathbf{u}|_\infty=0,\qquad \theta|_\infty=0. \tag{49}$$

The boundary-value problem (5), (48), and (49) is a classical problem in hydrodynamics of Stokes flows [8]. Since we consider only axially symmetric motion, boundary conditions (48) are reformulated for components of the vector $\mathbf{u}$ in cylindrical coordinates as

$$u_r(r,z)|_{\eta=\eta_0}=0,\qquad u_\varphi(r,z)\equiv 0,\qquad u_z(r,z)|_{\eta=\eta_0}=V_0, \tag{50}$$

where $\eta=\eta_0$ determines the contour of the spindle-shaped body in bipolar coordinates (ξ,η) in the meridional cross-section plane rz (see Figure 1).

The problem of the steady motion of a rigid body in a Stokes fluid is closely related to the problem of the Stokes flow about the body immersed in the viscous fluid [8]. The only difference is that in the latest problem, the body is immersed in the uniform flow, and the velocity of the flow is assumed to be constant at infinity. In this case, the boundary conditions take the form $\tilde{\mathbf{u}}|_S=\mathbf{0}$ and $\tilde{\mathbf{u}}|_\infty=-V_0\,\mathbf{k}$, where $\tilde{\mathbf{u}}$ is the velocity of the Stokes flow in this problem. Obviously, the velocities $\mathbf{u}$ and $\tilde{\mathbf{u}}$ are related by $\tilde{\mathbf{u}}=\mathbf{u}-V_0\,\mathbf{k}$.

5.1. Stream function. A standard approach to solving axially symmetric problems of Stokes flows is to represent the vector $\mathbf{u}$ by a stream function $\Psi(r,z)$ in cylindrical coordinates:

$$\mathbf{u} = -\operatorname{curl}(\Psi \mathbf{e}_\varphi). \tag{51}$$

In component form, (51) is rewritten as

$$u_r(r,z) = \frac{1}{r}\frac{\partial}{\partial z}(r\Psi), \qquad u_\varphi(r,z) \equiv 0, \qquad u_z(r,z) = -\frac{1}{r}\frac{\partial}{\partial r}(r\Psi). \tag{52}$$

The stream function Ψ is different from the stream function, Ψ_P, introduced by Payne and Pell [14] as $u_r = -\frac{1}{r}\frac{\partial \Psi_P}{\partial z}$, $u_z = \frac{1}{r}\frac{\partial \Psi_P}{\partial r}$ in the problem of the Stokes flow about a body immersed in a viscous fluid. If the velocity of the Stokes flow at infinity in Payne and Pell's problem is $-V_0\,\mathbf{k}$, then the stream functions Ψ and Ψ_P are related by $\Psi_P = -\left(r\Psi + \frac{1}{2}V_0 r^2\right)$.

Stokes model (5) and equation (51) imply that the stream function Ψ satisfies

$$(\operatorname{curl})^4(\Psi \mathbf{e}_\varphi) = 0.$$

This relation reduces to a so-called bi-1-harmonic equation

$$\Delta_1^2 \Psi(r,z) = 0, \tag{53}$$

where 1-harmonic operator Δ_1 is defined by (8) for $k=1$. Based on (52), boundary conditions (50) are reformulated as

$$\left(\frac{\partial}{\partial z}(r\Psi)\right)\Big|_{\eta=\eta_0} = 0, \qquad \left(\frac{\partial}{\partial r}(r\Psi)\right)\Big|_{\eta=\eta_0} = -V_0\ r|_{\eta=\eta_0}. \tag{54}$$

Substituting derivatives (11) into (54) and solving system (54) with respect to $(\frac{\partial}{\partial \xi}(r\Psi))|_{\eta=\eta_0}$ and $(\frac{\partial}{\partial \eta}(r\Psi))|_{\eta=\eta_0}$, we obtain

$$\begin{aligned}
\left(\frac{\partial}{\partial \xi}(r\Psi)\right)\Big|_{\eta=\eta_0} &= V_0 c^2 \frac{\sinh\xi \sin^2\eta_0}{(\cosh\xi - \cos\eta_0)^3},\\
\left(\frac{\partial}{\partial \eta}(r\Psi)\right)\Big|_{\eta=\eta_0} &= -V_0 c^2 \sin\eta_0 \frac{(\cosh\xi\cos\eta_0 - 1)}{(\cosh\xi - \cos\eta_0)^3},
\end{aligned} \tag{55}$$

where c is a metric parameter of bipolar coordinates. Integrating the first equation of (55) with respect to ξ, we have

$$\Psi|_{\eta=\eta_0} = -\frac{V_0 c}{2}\frac{\sin\eta_0}{\cosh\xi - \cos\eta_0} + \tilde{c}\,\frac{(\cosh\xi - \cos\eta_0)}{\sin\eta_0},$$

where $\tilde{c}$ is a constant of integration. Assuming that Ψ is bounded at $\xi \to \infty$, we put $\tilde{c} = 0$, and consequently,

$$\Psi|_{\eta=\eta_0} = -\frac{V_0 c}{2}\frac{\sin\eta_0}{\cosh\xi - \cos\eta_0}. \tag{56}$$

Note that for spatial doubly connected bodies, e.g., torus [21], $\tilde{c} \neq 0$. Substituting (56) into the second equation of (55), we obtain

$$\left(\frac{\partial \Psi}{\partial \eta}\right)\Big|_{\eta=\eta_0} = -\frac{V_0 c}{2}\frac{(\cosh\xi\cos\eta_0 - 1)}{(\cosh\xi - \cos\eta_0)^2}. \tag{57}$$

Thus, the boundary-value problem (5), (48), and (49) reduces to finding the stream function Ψ that satisfies bi-1-harmonic equation (53) and boundary conditions (56) and (57).

In our paper [30], we showed that a solution to (53) may be represented by one harmonic function $\Phi_0(r,z)$ and one 1-harmonic function $\Phi_1(r,z)$ in the form

$$\Psi(r,z) = \frac{1}{2}\left(r^2+z^2-c^2\right)\Phi_1(r,z) + r\,\Phi_0(r,z), \tag{58}$$

where

$$\Delta_1\,\Phi_1(r,z) = 0, \qquad \Delta\,\Phi_0(r,z) = 0.$$

In bipolar coordinates (ξ,η), functions Φ_0 and Φ_1 are represented by Fourier integrals:

$$\Phi_1(\xi,\eta) = \frac{1}{2\pi i c^2}\sqrt{\cosh\xi-\cos\eta}\int\limits_{-i\infty}^{+i\infty} A(\mu)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu, \quad \eta\le\eta_0, \tag{59}$$

$$\Phi_0(\xi,\eta) = \frac{1}{2\pi i c}\sqrt{\cosh\xi-\cos\eta}\int\limits_{-i\infty}^{+i\infty} B(\mu)\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu, \quad \eta\le\eta_0, \tag{60}$$

where $A(\mu)$ and $B(\mu)$ are meromorphic functions in the strip $-1\le\operatorname{Re}\mu\le 1$. Representations (58), (60), and (59) reduce the function Ψ to the form

$$\Psi(\xi,\eta) = \frac{1}{2\pi i\sqrt{\cosh\xi-\cos\eta}}\left(\cos\eta\int\limits_{-i\infty}^{+i\infty} A(\mu)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu + \sin\eta\int\limits_{-i\infty}^{+i\infty} B(\mu)\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu\right), \quad \eta\le\eta_0. \tag{61}$$

To express right-hand sides of (56) and (57) by Fourier integrals, we use the relation

$$\frac{(2k-1)!!}{2^k}\frac{\sin^k\eta}{(\cosh\xi+\cos\eta)^{k+\frac{1}{2}}} = \frac{1}{i\sqrt{2}}\int\limits_{b-i\infty}^{b+i\infty}\frac{1}{\cos(\pi\mu)}\,\mathrm{P}^{(k)}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu,$$

where $k\ge 0$, $(2k-1)!! = \prod_{j=1}^{k}(2j-1)$, and $b\in\left(-k-\frac{1}{2},k+\frac{1}{2}\right)$; see [1]. For $k=0$, we define $(-1)!!=1$.

Thus, boundary conditions (56) and (57) reduce to a system of linear equations with respect to functions $A(\mu)$ and $B(\mu)$:

$$\begin{pmatrix} \cos\eta_0\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0) & \sin\eta_0\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta_0) \\ \cos\eta_0\,\mathrm{P}^{(2)}_{-\frac{1}{2}+\mu}(\cos\eta_0)-\sin\eta_0\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0) & \sin\eta_0\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0) \end{pmatrix}\begin{pmatrix} A(\mu) \\ B(\mu)\end{pmatrix} = \frac{\pi c V_0}{\sqrt{2}}\frac{\sin\eta_0}{\cos(\pi\mu)}\begin{pmatrix} -\mathrm{P}_{-\frac{1}{2}+\mu}(-\cos\eta_0) \\ \mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(-\cos\eta_0)\end{pmatrix}. \tag{62}$$

Let $D(\mu)$ denote the determinant of system (62):

$$
\begin{aligned}
D(\mu) &= (1+\cos^2\eta_0)\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta_0)\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0) \\
&\quad + \sin\eta_0\cos\eta_0\left(\left(\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0)\right)^2 + \left(\mu^2-\tfrac{1}{4}\right)\left(\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta_0)\right)^2\right);
\end{aligned}
\tag{63}
$$

then using a relation for the associated Legendre functions

$$
\mathrm{P}_{-\frac{1}{2}+\mu}(-\cos\eta_0)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0)+\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta_0)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(-\cos\eta_0)=\frac{2}{\pi}\frac{\cos(\pi\mu)}{\sin\eta_0}
\tag{64}
$$

(see [1]), we obtain a solution to system (62):

$$
\begin{aligned}
A(\mu) &= -V_0 c\sqrt{2}\,\frac{\sin\eta_0}{D(\mu)}, \\
B(\mu) &= \frac{V_0 c}{\sqrt{2}}\left(\frac{2\cos\eta_0}{D(\mu)}\,\frac{\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta_0)}{\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta_0)}-\frac{\pi}{\cos(\pi\mu)}\,\frac{\mathrm{P}_{-\frac{1}{2}+\mu}(-\cos\eta_0)}{\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta_0)}\right).
\end{aligned}
\tag{65}
$$

Consequently, the velocity vector, $\mathbf{u}$, that solves problem (5), (48), and (49) is expressed analytically by (52), (61), and (65). As an illustration, we calculated streamlines about a rigid spindle-shaped body by solving the equation

$$
r\,\Psi(r,z)+\frac{1}{2}V_0\,r^2=C
\tag{66}
$$

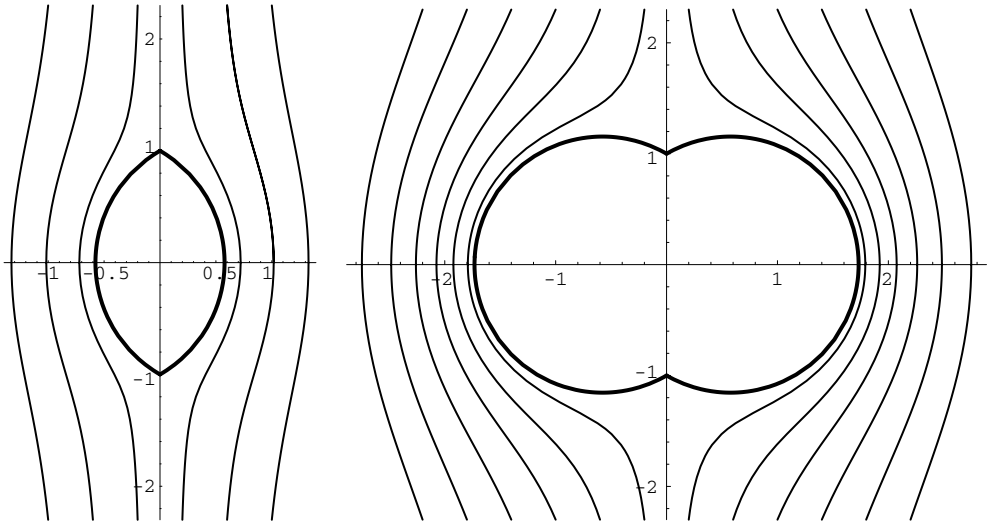
with respect to pairs (r,z) for different values of constant C. It should be noted that (66), in fact, determines streamlines about the body immersed in the uniform Stokes flow with the constant velocity, $-V_0\,\mathbf{k}$, at infinity, while the stream function Ψ corresponds to the motion of the body with the constant velocity $V_0\,\mathbf{k}$. We obtain (66) based on the fact that in terms of Payne and Pell's stream function, Ψ_P, streamlines are defined by Ψ_P = constant, and that Ψ and Ψ_P are related by $\Psi_P = -\left(r\,\Psi+\frac{1}{2}V_0\,r^2\right)$. We used Mathematica 5 to solve (66). Figure 3 shows streamlines about a rigid spindle-shaped body for $\eta_0=\frac{2\pi}{3}$ and $\eta_0=\frac{\pi}{3}$, respectively. Streamlines may also be calculated based on the relation $\frac{dr}{dz}=u_r/\left(u_z-V_0\right)$; see [8].

For the case of sphere, $\eta_0=\frac{\pi}{2}$, the stream function Ψ in cylindrical coordinates takes the form

$$
\Psi=\frac{cV_0}{4}\frac{r}{\sqrt{r^2+z^2}}\left(\frac{c^2}{r^2+z^2}-3\right).
$$

5.2. Analysis of the determinant $D(\mu)$ and functions $A(\mu)$ and $B(\mu)$. Asymptotic behavior of functions (59) and (60) at $\xi\to\infty$ is determined by zeros of determinant (63). The function $D(\mu)$ is even, i.e., $D(-\mu)=D(\mu)$, and equals zero at $\mu=\pm\frac{1}{2}$ and $\mu=\pm\frac{3}{2}$ for all $\eta_0\in(0,\pi)$:

$$
\begin{aligned}
D(\mu)\big|_{\mu\to\pm\frac{1}{2}} &\to -\tfrac{(1-\cos\eta_0)^2}{\sin\eta_0}\left(|\mu|-\tfrac{1}{2}\right), \\
D(\mu)\big|_{\mu\to\pm\frac{3}{2}} &\to -\tfrac{(1-\cos\eta_0)^2}{\sin\eta_0}(1+2\cos\eta_0)\left(|\mu|-\tfrac{3}{2}\right).
\end{aligned}
$$



$\eta_0 = \frac{2\pi}{3}$ $\eta_0 = \frac{\pi}{3}$

FIG. 3. *Streamlines about a rigid spindle-shaped body for* $\eta_0 = \frac{2\pi}{3}$ *and* $\eta_0 = \frac{\pi}{3}$*, respectively.*

TABLE 1
First individual root for $D(\mu)$*.*

η_0	μ_0	η_0	μ_0
$2\pi/12$	$8.564 + i\ 2.614$	$7\pi/12$	1.897
$3\pi/12$	$5.740 + i\ 1.569$	$8\pi/12$	$1.5^{\ddagger}$
$4\pi/12$	$4.341 + i\ 0.960$	$9\pi/12$	1.211
$5\pi/12$	$3.517 + i\ 0.437$	$2.6037^{\S}$	1.000
$9\pi/20^{\dagger}$	$3.345 + i\ 0.000$	$10\pi/12$	0.989
$6\pi/12$	2.5	$11\pi/12$	0.807

† For $\eta_0 \geq 9\pi/20$, the first individual root is real.
‡ Since the root $\frac{3}{2}$ is generic, it becomes the root of multiplicity 2 for $8\pi/12$.
§ For $\eta_0 \geq 2.6037$, the first individual root lies within the strip $-1 \leq \operatorname{Re}\mu \leq 1$.

We call values $\mu = \pm\frac{1}{2}$ and $\mu = \pm\frac{3}{2}$ generic roots of $D(\mu)$. Consequently, functions $A(\mu)$ and $B(\mu)$ have simple poles at $\mu = \pm\frac{1}{2}$ and $\mu = \pm\frac{3}{2}$ with corresponding residues determined by

$$\operatorname*{Res}_{\mu=\pm\frac{1}{2}} A(\mu) = \pm V_0 c\sqrt{2}\left(\tfrac{1+\cos\eta_0}{1-\cos\eta_0}\right), \qquad \operatorname*{Res}_{\mu=\pm\frac{3}{2}} A(\mu) = \mp V_0 c\sqrt{2}\left(\tfrac{1+\cos\eta_0}{1-\cos\eta_0}\right)\tfrac{1}{1+2\cos\eta_0},$$

$$\operatorname*{Res}_{\mu=\pm\frac{1}{2}} B(\mu) = \pm\tfrac{V_0 c}{\sqrt{2}}, \qquad \operatorname*{Res}_{\mu=\pm\frac{3}{2}} B(\mu) = \mp\tfrac{V_0 c}{\sqrt{2}}\tfrac{(1+\cos\eta_0+2\cos^2\eta_0)}{(1-\cos\eta_0)(1+2\cos\eta_0)}.$$

Except for generic roots, the determinant $D(\mu)$ has individual roots for any $\eta_0 \in (0, \pi)$. Table 1 presents the first individual root, μ_0, for different η_0.

Using asymptotic formulas for functions $\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta_0)$ and $\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta_0)$ at $\tau\to\infty$

$$\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta_0)\Big|_{\tau\to\infty}=\frac{\mathrm{e}^{\eta_0|\tau|}}{\sqrt{2\pi\sin\eta_0}}\left(1+\frac{\cot\eta_0}{8\tau}+O\left(\frac{1}{\tau^2}\right)\right),$$
$$\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta_0)\Big|_{\tau\to\infty}=\frac{|\tau|\,\mathrm{e}^{\eta_0|\tau|}}{\sqrt{2\pi\sin\eta_0}}\left(1-\frac{3\cot\eta_0}{8\tau}+O\left(\frac{1}{\tau^2}\right)\right)$$

(see [1]), we determine asymptotic behavior of $D(i\tau)$, $A(i\tau)$, and $B(i\tau)$:

$$D(i\tau)|_{\tau\to\infty}=\frac{\mathrm{e}^{2\eta_0|\tau|}}{2\pi\sin\eta_0}\left(1+O\left(\frac{1}{\tau}\right)\right),$$
$$A(i\tau)|_{\tau\to\infty}=V_0c\,2\pi\sqrt{2}\,(\sin^2\eta_0)\,\mathrm{e}^{-2\eta_0|\tau|}\left(1+O\left(\frac{1}{\tau}\right)\right),$$
$$B(i\tau)|_{\tau\to\infty}=V_0c\,\pi\sqrt{2}\,\sin(2\eta_0)\,|\tau|\,\mathrm{e}^{-2\eta_0|\tau|}\left(1+O\left(\frac{1}{\tau}\right)\right).$$

For the case of sphere, $\eta_0=\frac{\pi}{2}$, functions $D(\mu)$, $A(\mu)$, and $B(\mu)$ take the form

$$D(\mu)=\frac{1}{\pi}\cos(\pi\mu),\qquad A(\mu)=-\frac{V_0c\,\pi\sqrt{2}}{\cos(\pi\mu)},\qquad B(\mu)=-\frac{V_0c\,\pi}{\sqrt{2}}\frac{1}{\cos(\pi\mu)}.$$

6. Hilbert formulas in hydrodynamics of Stokes flows. In this section, we analyze basic hydrodynamic characteristics: vorticity, pressure, and drag force. We use Hilbert formula (20) for analytic representation of the pressure function θ via a vortex function.

6.1. Vorticity and scalar vortex function. The vorticity, $\boldsymbol{\omega}$, is defined by (4). In the case of axially symmetric boundary-value conditions, it may be represented as

$$\boldsymbol{\omega}=-\operatorname{curl}(\operatorname{curl}(\Psi\mathbf{e}_\varphi))=\omega(r,z)\,\mathbf{e}_\varphi,$$

where $\omega(r,z)$ is a scalar vortex function given by

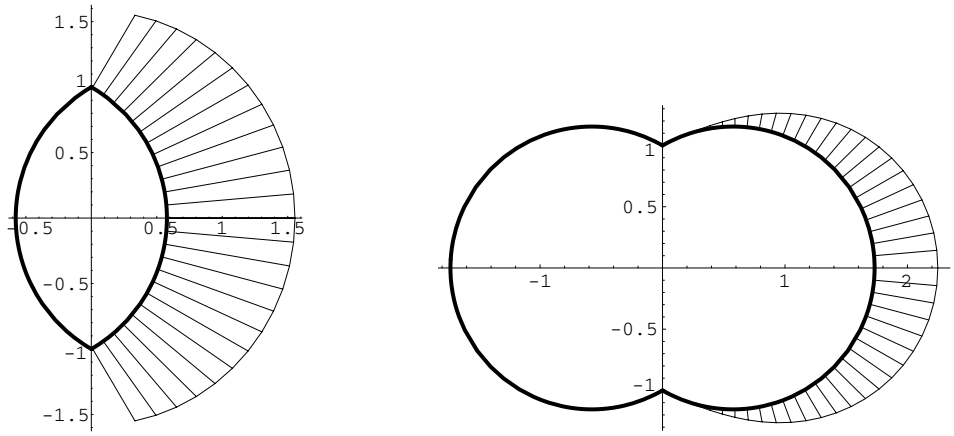
$$\omega(r,z)=\Delta_1\Psi(r,z).$$

Since the stream function Ψ is bi-1-harmonic, the vortex function $\omega(r,z)$ satisfies 1-harmonic equation (9), and in terms of functions Φ_0 and Φ_1, it takes the form

$$\omega(r,z)=2\left(r\frac{\partial}{\partial r}+z\frac{\partial}{\partial z}+\frac{3}{2}\right)\Phi_1+2\frac{\partial\Phi_0}{\partial r}. \tag{67}$$

Consequently, representation of ω by $A(\mu)$ and $B(\mu)$ is straightforward. At the contour $\eta=\eta_0$, the function ω is determined by

$$\omega(\xi,\eta)|_{\eta=\eta_0}=\frac{V_0\sqrt{2}}{\pi ic}\,(\cosh\xi-\cos\eta_0)^{\frac{3}{2}}\int\limits_{-i\infty}^{+i\infty}\frac{1}{D(\mu)}\,\mathrm{P}^{(2)}_{-\frac{1}{2}+\mu}(\cos\eta_0)\,\mathrm{e}^{-\xi\mu}d\mu.$$



$\eta_0 = \frac{2\pi}{3}$ $\eta_0 = \frac{\pi}{3}$

FIG. 4. *Epures for the vortex function,* $\frac{c}{2V_0}\,\omega(\xi,\eta)|_{\eta=\eta_0}$*, at the surface of a rigid spindle-shaped body for* $\eta_0 = \frac{2\pi}{3}$ *and* $\eta_0 = \frac{\pi}{3}$*, respectively. At a particular point on the contour, the value of the function is depicted by the length of the outward normal line if the value is positive and by the length of the inward normal line if the value is negative.*

Figure 4 illustrates behavior of $\frac{c}{2V_0}\,\omega(\xi,\eta)|_{\eta=\eta_0}$ for $\eta_0 = \frac{2\pi}{3}$ and $\eta_0 = \frac{\pi}{3}$. Since in the case of $\eta_0 > \frac{2\pi}{3}$, the determinant $D(\mu)$ has first individual root $\mu_0 < \frac{3}{2}$, the vortex function $\omega(\xi,\eta)|_{\eta=\eta_0}$ diverges at $\xi \to \infty$. For $\eta_0 = \frac{2\pi}{3}$, it takes on a nonzero finite value at $\xi \to \infty$:

$$\lim_{\xi\to\infty} \omega(\xi,\eta)|_{\eta=\eta_0=\frac{2\pi}{3}} = 1.275\,\frac{V_0}{c}.$$

For the case of sphere, $\eta_0 = \frac{\pi}{2}$, the vortex function takes the form

$$\omega(r,z) = \frac{3}{2}\,c\,V_0\frac{r}{(r^2+z^2)^{\frac{3}{2}}}.$$

In this case, if the function ω is represented by Fourier integral (13), then $Y(\mu) = \frac{3\pi}{\sqrt{2}}\frac{V_0}{c}\frac{1}{\cos(\pi\mu)}$.

6.2. Pressure. We associate the function θ in Stokes model (5) with the pressure in a Stokes fluid. In an axially symmetric case, the pressure θ and the vortex function ω are independent of angular coordinate φ and may be considered as real and imaginary parts of an r-analytic function $F(r,z) = \theta(r,z) + i\,r\,\omega(r,z)$ that satisfies the generalized Cauchy–Riemann system (7). Consequently, we may use Hilbert formula (20) to express θ via ω.

PROPOSITION 5 (pressure). *Let the vortex function* ω *be determined by* (67)*. Then for* $\eta_0 < 2.6037$*, the pressure* θ *is a real-valued function represented by*

(68)
$$\theta(\xi,\eta)=\frac{1}{\pi i c^2}\sqrt{\cosh\xi-\cos\eta}\left(\cosh\xi\sin\eta\int\limits_{-\infty}^{+\infty}\tau\,A(i\tau)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}d\tau\right.$$
$$-(\cosh\xi\cos\eta-1)\int\limits_{-\infty}^{+\infty}\tau\,B(i\tau)\,\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}d\tau$$
$$-i\,\sinh\xi\sin\eta\int\limits_{-\infty}^{+\infty}\left(\tfrac{1}{2}A(i\tau)+B(i\tau)\right)\mathrm{P}^{(1)}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}d\tau$$
$$-i\,\sinh\xi\cos\eta\int\limits_{-\infty}^{+\infty}\left(\left(\tau^2+\tfrac{1}{4}\right)A(i\tau)+\tfrac{1}{2}B(i\tau)\right)\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}d\tau$$
$$+\frac{3}{2}\int\limits_{-\infty}^{+\infty}\left[-\tau\,A(i\tau)+\frac{1}{2\cosh(\pi\tau)}\oint\limits_{-\infty}^{+\infty}A(i\tau_1)\frac{\cosh(\pi\tau_1)\,d\tau_1}{\sinh[\pi(\tau_1-\tau)]}\right]$$
$$\left.\times\,\mathrm{P}_{-\frac{1}{2}+i\tau}(\cos\eta)\,\mathrm{e}^{-i\xi\tau}d\mu\right).$$

The double integral in (68) *can be efficiently calculated by* (45).

Proof. Using representation (67) and the fact that $\Delta\,\Phi_0=0$ and $\Delta_1\,\Phi_1=0$, we obtain identities

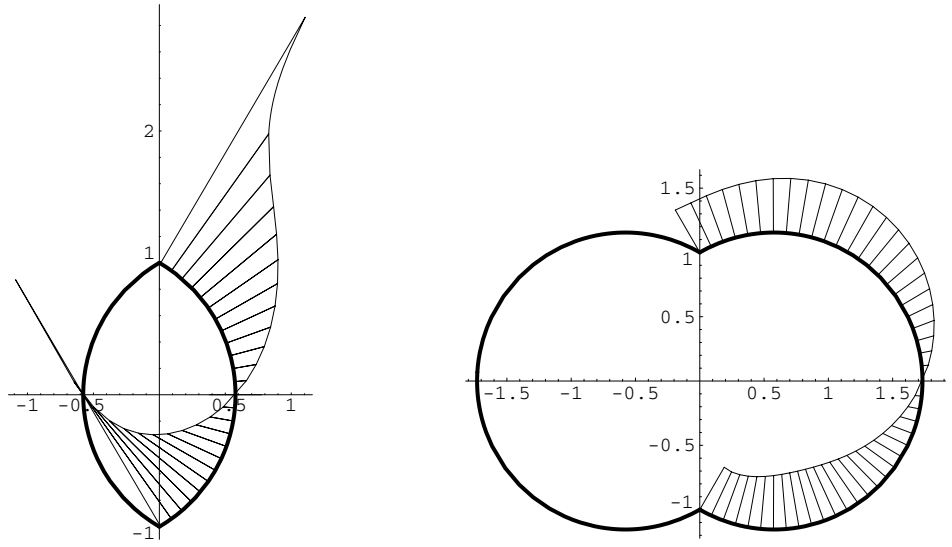
$$\frac{\partial\omega}{\partial z}\equiv 2\,\frac{\partial}{\partial z}\left[\left(r\frac{\partial}{\partial r}+z\frac{\partial}{\partial z}+\frac{3}{2}\right)\Phi_1+\frac{\partial\Phi_0}{\partial r}\right]$$
$$=2\,\frac{\partial}{\partial r}\left[-\frac{z}{r}\frac{\partial}{\partial r}\,(r\,\Phi_1)+r\frac{\partial\Phi_1}{\partial z}+\frac{\partial\Phi_0}{\partial z}\right]+3\,\frac{\partial\Phi_1}{\partial z},$$
$$-\frac{1}{r}\frac{\partial}{\partial r}\,(r\omega)\equiv-\frac{2}{r}\frac{\partial}{\partial r}\left(r\left[\left(r\frac{\partial}{\partial r}+z\frac{\partial}{\partial z}+\frac{3}{2}\right)\Phi_1+\frac{\partial\Phi_0}{\partial r}\right]\right)$$
$$=2\,\frac{\partial}{\partial z}\left[-\frac{z}{r}\frac{\partial}{\partial r}\,(r\,\Phi_1)+r\frac{\partial\Phi_1}{\partial z}+\frac{\partial\Phi_0}{\partial z}\right]-3\,\frac{1}{r}\frac{\partial}{\partial r}\,(r\,\Phi_1).$$

If we represent the pressure function θ by

$$\theta=-2\,\frac{z}{r}\frac{\partial}{\partial r}\,(r\,\Phi_1)+2\,r\frac{\partial\Phi_1}{\partial z}+2\,\frac{\partial\Phi_0}{\partial z}+3\,\tilde{\theta}+\tilde{c},\tag{69}$$

where $\tilde{\theta}=\tilde{\theta}(r,z)$ is a new function, and $\tilde{c}$ is a constant, then system (7) for functions θ and ω reduces to (7) for functions $\tilde{\theta}$ and Φ_1, i.e., $\tilde{F}(r,z)=\tilde{\theta}(r,z)+i\,r\,\Phi_1(r,z)$ is an r-analytic function. In an axially symmetric case, $\theta(-\xi,\eta)=-\theta(\xi,\eta)$, $\Phi_0(-\xi,\eta)=\Phi_0(\xi,\eta)$, $\Phi_1(-\xi,\eta)=\Phi_1(\xi,\eta)$, and $\tilde{\theta}(-\xi,\eta)=-\tilde{\theta}(\xi,\eta)$. Consequently, the left-hand side in (69) is an odd function with respect to ξ, only if $\tilde{c}=0$.

Recall that the function Φ_1 is represented by Fourier integral (59) with the density $A(\mu)$ determined by (65). For $\eta_0<2.6037$, $A(\mu)$ is meromorphic within the strip $-1\le\mathrm{Re}\,\mu\le 1$ with only two simple poles at $\mu=\pm\frac{1}{2}$, i.e., it belongs to the space $\mathcal{M}_{[-1,1]}$. Let $\tilde{\theta}$ be represented by Fourier integral (12) with density $X(\mu)\in\mathcal{M}_{[-1,1]}$. Consequently, functions $A(\mu)$ and $X(\mu)$ satisfy conditions of Theorem 1. We use Hilbert formula (20) to represent $X(i\tau)$ by $A(i\tau)$ and then express (69) in terms of $A(i\tau)$ and $B(i\tau)$, where $\tau\in\mathbb{R}$. ∎



$\eta_0 = \frac{2\pi}{3}$ $\eta_0 = \frac{\pi}{3}$

FIG. 5. *Epures for the pressure function,* $\frac{c}{2V_0}\,\theta(\xi,\eta_0)$*, at the surface of a rigid spindle-shaped body for* $\eta_0 = \frac{2\pi}{3}$ *and* $\eta_0 = \frac{\pi}{3}$*, respectively. At a particular point on the contour, the value of the function is depicted by the length of the outward normal line if the value is positive and by the length of the inward normal line if the value is negative.*

TABLE 2
Function $\frac{c}{V_0}\,\theta(\xi,\eta)|_{\eta=\eta_0}$ *at* $\xi \to +\infty$ *for different* η_0*.*

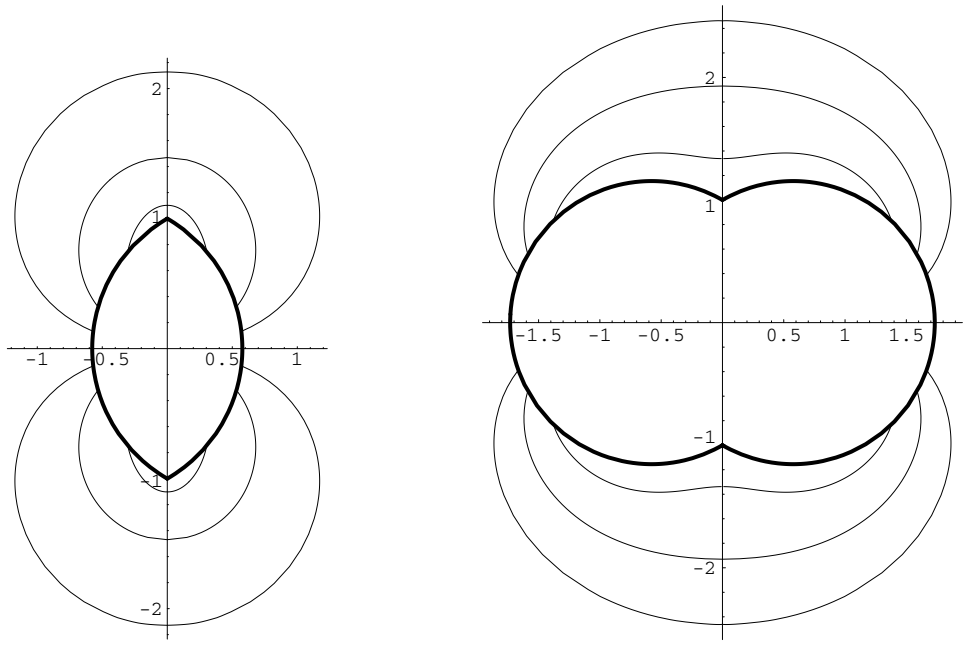
η_0	$\frac{c}{V_0}\,\theta(+\infty,\eta_0)$	η_0	$\frac{c}{V_0}\,\theta(+\infty,\eta_0)$
$\pi/12$	0.164	$5\pi/12$	1.034
$2\pi/12$	0.338	$6\pi/12$	1.5
$3\pi/12$	0.526	$7\pi/12$	2.692
$4\pi/12$	0.746	$8\pi/12$	$+\infty$

As an illustration to (68), epures of the pressure, $\frac{c}{V_0}\,\theta(\xi,\eta)|_{\eta=\eta_0}$, are calculated at the contour of a spindle-shaped body for $\eta_0 = \frac{2\pi}{3}$ and $\eta_0 = \frac{2\pi}{3}$; see Figure 5. For $0 < \eta_0 < \frac{2\pi}{3}$, the function $\theta(\xi,\eta)|_{\eta=\eta_0}$ takes on finite nonzero values at $\xi \to +\infty$:

$$\lim_{\xi\to+\infty}\theta(\xi,\eta)|_{\eta=\eta_0} = \frac{6V_0}{c}\left(-\frac{\cot^2\left(\frac{\eta_0}{2}\right)\cos\eta_0}{1+2\cos\eta_0} + \frac{1}{2\pi}\sin\eta_0\int\limits_0^{+\infty}\frac{d\tau}{D(i\tau)}\right).$$

Table 2 presents values of $\frac{c}{V_0}\,\theta(\xi,\eta)|_{\eta=\eta_0}$ at the tip point, i.e., $\xi \to +\infty$, for different η_0.

Figure 6 shows isobars about a spindle-shaped body for $\eta_0 = \frac{2\pi}{3}$ and $\eta_0 = \frac{2\pi}{3}$. Isobars are determined by equation $\theta(\xi,\eta) = C$ for different values of constant C. To solve this equation numerically, we represented $\theta(\xi,\eta)$ by (68) and used Mathematica 5. An alternative approach for computing isobars is based on the fact that at an isobar the relation $d\theta = \frac{\partial\theta}{\partial r}dr + \frac{\partial\theta}{\partial z}dz = 0$ holds. Consequently, using system (7), we obtain the explicit first-order differential equation $\frac{dz}{dr} = -\frac{\partial\theta}{\partial r}\Big/\frac{\partial\theta}{\partial z} = \frac{\partial\omega}{\partial z}\Big/\frac{1}{r}\frac{\partial}{\partial r}(r\omega)$, which can be solved by the Runge–Kutta method. We compared both approaches with respect to running time and accuracy. In comparison to the alternative approach, solving



$\eta_0 = \frac{2\pi}{3}$ $\eta_0 = \frac{\pi}{3}$

FIG. 6. *Isobars about a rigid spindle-shaped body for* $\eta_0 = \frac{2\pi}{3}$ *and* $\eta_0 = \frac{\pi}{3}$*, respectively.*

$\theta(\xi, \eta) = C$ is faster and more accurate. This proves superiority of the analytical solution based on the Hilbert formula.

For the case of sphere, $\eta_0 = \frac{\pi}{2}$, the pressure function takes the form

$$\theta(r, z) = \frac{3}{2}\, c\, V_0 \frac{z}{(r^2 + z^2)^{\frac{3}{2}}}.$$

In this case, if the function θ is represented by Fourier integral (12), then $X(\mu) = \frac{3\pi}{\sqrt{2}} \frac{V_0}{c} \frac{\mu}{\cos(\pi\mu)}$.

6.3. Drag force. Drag force is the characteristics that attracts most of the attention devoted to problems of motion of rigid bodies in a viscous fluid [8]. Approximate calculation of drag force by means of variational principles is discussed in [9]. We derive an analytical formula for the drag force exerted on a rigid spindle-shaped body using expressions for pressure and vortex functions obtained in previous sections.

PROPOSITION 6 (drag force). *The magnitude of the force exerted by a Stokes fluid on the spindle-shaped body is determined by*

$$F_0 = -4\sqrt{2}\,\rho \int_0^{+\infty} \left(\left(\tau^2 + \tfrac{1}{4}\right) A(i\tau) + 2B(i\tau)\right) d\tau, \tag{70}$$

where ρ *is the shear viscosity, and functions* $A(\mu)$ *and* $B(\mu)$ *are given by* (65).

Proof. Let $\mathbf{n} = n_r \mathbf{e}_r + n_z \mathbf{k}$ be the outer normal to the surface of the body, S, where $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$ is the basis of the system of cylindric coordinates. By definition,

$n_r = \frac{\partial r}{\partial n}$ and $n_z = \frac{\partial z}{\partial n}$. The force, exerted by the fluid at a particular point and acting in the direction $\mathbf{n}$, is given by

$$\frac{1}{2\rho}\mathbf{P}_n = (\mathbf{n}\cdot\operatorname{grad})\,\mathbf{u} + \frac{1}{2}\,[\mathbf{n}\times\operatorname{curl}\mathbf{u}] - \frac{1}{2}\,\theta\,\mathbf{n};$$

see [21]. Since the body moves along its axis of symmetry, the resultant force has only the component in the direction $\mathbf{k}$. Thus, the magnitude of the total drag force is the integral of the projection $\mathbf{P}_n$ onto $(-\mathbf{k})$ over the surface S:

$$\frac{1}{2\rho}F_0 = -\frac{1}{2\rho}\iint\limits_S \mathbf{P}_n\cdot\mathbf{k}\,dS = -\iint\limits_S\left(\left(n_r\frac{\partial}{\partial r}+n_z\frac{\partial}{\partial z}\right)u_z + \frac{1}{2}\,\omega\,n_r - \frac{1}{2}\,\theta\,n_z\right)dS.$$

To simplify this expression, we use representation (52), formula $dS = r\,d\varphi\,ds$, and relations

$$n_r = \frac{\partial z}{\partial s}, \qquad n_z = -\frac{\partial r}{\partial s},$$
$$\frac{\partial}{\partial s} = \frac{1}{h}\frac{\partial}{\partial\xi}, \qquad \frac{\partial}{\partial n} = -\frac{1}{h}\frac{\partial}{\partial\eta},$$

where $ds = h\,d\xi$ is the element of the contour of the surface S in the meridional cross-section plane rz, and $h = \frac{c}{\cosh\xi - \cos\eta_0}$ is the Lame coefficient. Directional derivative $\frac{\partial}{\partial s}$ corresponds to the vector $\mathbf{s}$, which is orthogonal to $\mathbf{n}$ and oriented towards an increase of coordinate ξ. We have

$$\left(n_r\frac{\partial}{\partial r}+n_z\frac{\partial}{\partial z}\right)u_z = -\omega\,n_r + \frac{1}{r}\frac{\partial}{\partial s}\left(r\frac{\partial\Psi}{\partial z}\right)$$

and

$$\iint\limits_S \frac{1}{r}\frac{\partial}{\partial s}\left(r\frac{\partial\Psi}{\partial z}\right)dS = 2\pi\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial\xi}\left(r\frac{\partial\Psi}{\partial z}\right)\Big|_{\eta=\eta_0}d\xi = 2\pi\left(r\frac{\partial\Psi}{\partial z}\right)\Big|_{(\xi,\eta)=(-\infty,\eta_0)}^{(\xi,\eta)=(+\infty,\eta_0)} = 0.$$

Thus, the expression for the total drag force reduces to

$$\frac{1}{2\rho}F_0 = \frac{1}{2}\iint\limits_S(\omega\,n_r + \theta\,n_z)\,dS. \tag{71}$$

Using representations (67) and (69) for functions ω and θ, respectively, we obtain

$$\omega\,n_r + \theta\,n_z = 2\,r\frac{\partial\Phi_1}{\partial n} + 2\,\frac{\partial\Phi_0}{\partial n} + \frac{2}{r}\frac{\partial}{\partial s}(rz\,\Phi_1) + \Phi_1 n_r + 3\,\tilde\theta\,n_z.$$

Note that the integral contribution of the term $\frac{1}{r}\frac{\partial}{\partial s}(rz\,\Phi_1)$ to (71) is zero. Indeed,

$$\iint\limits_S \frac{1}{r}\frac{\partial}{\partial s}(rz\,\Phi_1)\,dS = 2\pi\int\limits_{-\infty}^{+\infty}\frac{\partial}{\partial\xi}(rz\,\Phi_1)\Big|_{\eta=\eta_0}d\xi = 2\pi\,(rz\,\Phi_1)\big|_{(\xi,\eta)=(-\infty,\eta_0)}^{(\xi,\eta)=(+\infty,\eta_0)} = 0.$$

We may avoid the use of Hilbert formulas for expressing $\tilde\theta$. Indeed, representing the generalized Cauchy–Riemann system (7) in terms of $\frac{\partial}{\partial s}$ and $\frac{\partial}{\partial n}$:

$$\frac{\partial\tilde\theta}{\partial n} = \frac{1}{r}\frac{\partial}{\partial s}(r\,\Phi_1), \qquad \frac{\partial\tilde\theta}{\partial s} = -\frac{1}{r}\frac{\partial}{\partial n}(r\,\Phi_1),$$

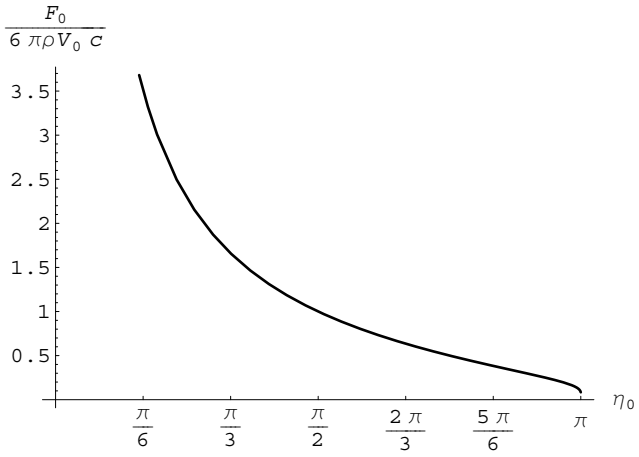


FIG. 7. *Normalized drag force,* $\frac{F_0}{6\pi\rho V_0 c}$*, as a function of* η_0.

we obtain

$$\tilde{\theta}\, n_z = -\frac{1}{2r}\frac{\partial}{\partial s}\left(r^2\tilde{\theta}\right) - \frac{1}{2}\,\frac{\partial}{\partial n}\left(r\,\Phi_1\right),$$

where the integral contribution of the term $\frac{1}{r}\frac{\partial}{\partial s}\left(r^2\tilde{\theta}\right)$ to (71) is zero:

$$\iint\limits_S \frac{1}{r}\frac{\partial}{\partial s}\left(r^2\tilde{\theta}\right) dS = 2\pi \int\limits_{-\infty}^{+\infty} \frac{\partial}{\partial \xi}\left(r^2\tilde{\theta}\right)\Big|_{\eta=\eta_0} d\xi = 2\pi\, \left(r^2\tilde{\theta}\right)\Big|_{(\xi,\eta)=(-\infty,\eta_0)}^{(\xi,\eta)=(+\infty,\eta_0)} = 0.$$

Thus, expression (71) reduces to

$$\frac{1}{2\rho}F_0 = -\frac{\pi}{2}\int\limits_{-\infty}^{+\infty}\left(r^2\,\frac{\partial\Phi_1}{\partial\eta} - \Phi_1\, r\frac{\partial r}{\partial\eta} + 4r\,\frac{\partial\Phi_0}{\partial\eta}\right)\Big|_{\eta=\eta_0} d\xi.$$

Finally, substituting representations (59) and (60) into the last expression and using relation (64), we obtain (70). □

Note that since the derivation of (70) does not use Hilbert formulas, formula (70) holds for all values of $\eta_0 \in (0,\pi)$. Figure 7 illustrates behavior of the normalized drag force $\frac{F_0}{6\pi\rho V_0 c}$ as a function of η_0. Table 3 presents values of $\frac{F_0}{6\pi\rho V_0 c}$ for $\eta_0 = \frac{\pi k}{12}$, $1 \le k \le 12$. In the case of $\eta_0 \to 0$, we have $F_0 \to \infty$.

The drag force may also be calculated as the limit of the stream function at $z = 0$ and $r \to \infty$

$$F_0 = -8\pi\rho \lim_{r\to\infty} \Psi|_{z=0}\,;$$

see [8]. For the stream function given by (61), this expression reduces to (70).

7. Concluding remarks. This paper addresses the problem of obtaining the Hilbert formulas for so-called r-analytic functions in the domain exterior to the contour of a spindle. In the meridional cross-section plane of the spindle, the real and

imaginary parts of the r-analytic function are represented by Fourier integrals with densities $X(\mu)$ and $Y(\mu)$, respectively, and the problem reduces to solving equation (16). To our knowledge, three approaches are available for obtaining the Hilbert formulas:

(1) Integrating system (7) in bipolar coordinates analytically [28],
(2) Solving (16) by complex Fourier transform [28, 29],
(3) Solving (16) in the framework of Riemann boundary-value problems for analytic functions.

In our previous work [28], we obtained Hilbert formulas by integrating the generalized Cauchy–Riemann system (7) under the condition that functions $\theta(\xi,\eta)$ and $\omega(\xi,\eta)$ had the same asymptotic behavior at $\xi \to \infty$. The disadvantage of this approach is that it is relatively complex in the sense of analytical computations and is based on special relations for Legendre functions. In our paper [29], we derived Hilbert formulas using modified Green's functions in the representations of θ and ω. The approach reduced the original problem to the equation similar to (16) and obtained the Hilbert formulas for the modified Green's functions by complex Fourier transform. Although we took into account the fact that the modified Green's functions might have simple poles $\mu = \pm\frac{1}{2}$ in the strip $|\operatorname{Re}\mu| \le 1$, this issue was not linked to specifying the class of functions for $X(\mu)$ and $Y(\mu)$, and as a result, the Hilbert formulas were stated with the accuracy of an additional term associated with homogeneous solutions to (16). In contrast to [29], this paper develops a new approach based on Riemann boundary-value problems to solving (16) for the class of meromorphic functions with two simple poles $\mu = \pm\frac{1}{2}$ in the strip $|\operatorname{Re}\mu| \le 1$ and having exponentially fast convergence at $\tau \to \infty$. The chosen class of meromorphic functions $X(\mu)$ and $Y(\mu)$ is determined by the hydrodynamic problem of the steady motion of a rigid-spindle shaped body in a viscous fluid: the function $A(\mu)$ in (65) has at least two simple poles at $\mu = \pm\frac{1}{2}$ for all values of the parameter η_0. In particular, in the framework of this approach, we show that the homogeneous equations $X(\mu+1) - 2X(\mu) + X(\mu-1) = 0$ and $\left(\mu + \frac{3}{2}\right) Y(\mu+1) - 2\mu\, Y(\mu) + \left(\mu - \frac{3}{2}\right) Y(\mu-1) = 0$ have only trivial solutions from the specified class of meromorphic functions. However, this may not be the case if we consider another class of meromorphic functions. Also, in this work, we derive formulas for efficient calculating Fourier integrals with the Hilbert formulas, i.e., double integrals one of which is singular.

The problem of axially symmetric Stokes flow about a rigid spindle-shaped body was originally considered by Pell and Payne [15]. However, they did not address the issue of determining and analyzing the pressure function. In our paper [30], we solved this hydrodynamic problem using the stream function in the form of (58) and presented the Hilbert formula for θ, obtained by integrating system (7) analytically. However, at the surface of the body, the pressure was calculated by integrating system

(7) numerically. Moreover, the Hilbert formula for the vortex function ω was not presented. This paper closes the gap: it presents both Hilbert formulas for θ and ω, respectively, and calculates isobars and the pressure at the surface using the special representations for the Fourier integrals with Hilbert formulas.

We should note that the class of meromorphic functions with only two simple poles at $\mu = \pm\frac{1}{2}$ in the strip $\mathrm{Re}\,|\mu| \leq 1$ precludes applying the Hilbert formulas for determining the pressure when $\eta_0 \geq 2.6037$, since in this case, the function $A(\mu)$ has other poles in the strip $\mathrm{Re}\,|\mu| \leq 1$; see Table 1. We may show that under some conditions, the Hilbert formulas (20) and (31) will be the same for a class of meromorphic functions $X(\mu)$ and $Y(\mu)$ with more than two simple poles in the strip $\mathrm{Re}\,|\mu| \leq 1$. Consequently, formulas (20) and (31) can be used for all $\eta_0 \in [0, \pi)$. However, addressing this issue calls for a separate publication.

Appendix A. The derivation of formulas (14) and (15). Formula (14) is derived as follows. Using the expression for the derivative $\frac{\partial}{\partial r}$ in (11) and the relation $\frac{\partial}{\partial r}\sqrt{\cosh\xi - \cos\eta} = -\frac{1}{2c}\cosh\xi\sin\eta\sqrt{\cosh\xi - \cos\eta}$, we have

$$\frac{\partial\theta}{\partial r} = \frac{1}{2\pi ic}\sqrt{\cosh\xi - \cos\eta}\left(-\frac{1}{2}\cosh\xi\sin\eta\int\limits_{-i\infty}^{+i\infty} X(\mu)\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu\right.$$
$$+\ \sinh\xi\sin\eta\int\limits_{-i\infty}^{+i\infty}\mu\,X(\mu)\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu$$
$$\left.+\ (\cosh\xi\cos\eta - 1)\int\limits_{-i\infty}^{+i\infty} X(\mu)\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu\right).$$

Next, using the formulas

$$\sin\eta\,\mathrm{P}_{-\frac{1}{2}+\mu}(\cos\eta) = \frac{1}{2\mu}\left(\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta) - \mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\right),$$
$$\cos\eta\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta) = \frac{1}{2\mu}\left(\left(\mu+\tfrac{1}{2}\right)\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta) + \left(\mu-\tfrac{1}{2}\right)\mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\right),$$

we obtain

$$\frac{\partial\theta}{\partial r} = \frac{1}{4\pi ic}\sqrt{\cosh\xi - \cos\eta}\left(\cosh\xi\int\limits_{-i\infty}^{+i\infty} X(\mu)\left(\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta) + \mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\right)\mathrm{e}^{-\xi\mu}d\mu\right.$$
$$+\ \sinh\xi\int\limits_{-i\infty}^{+i\infty} X(\mu)\left(\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta) - \mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\right)\mathrm{e}^{-\xi\mu}d\mu$$
$$\left.-\ 2\int\limits_{-i\infty}^{+i\infty} X(\mu)\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu\right),$$

which reduces to

$$\frac{\partial\theta}{\partial r} = \frac{1}{4\pi i c}\sqrt{\cosh\xi - \cos\eta}\left(\int_{-i\infty}^{+i\infty} X(\mu)\,\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi(\mu-1)}d\mu\right.$$
$$+\int_{-i\infty}^{+i\infty} X(\mu)\,\mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi(\mu+1)}d\mu \tag{72}$$
$$\left.-\,2\int_{-i\infty}^{+i\infty} X(\mu)\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\mathrm{e}^{-\xi\mu}d\mu\right).$$

Assuming $X(\mu)$ to be a meromorphic function with only two simple poles at $\mu = \pm\frac{1}{2}$ in the strip $|\operatorname{Re}\mu| \le 1$, and noticing that functions $\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta)$ and $\mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)$ have nulls at $\mu = \frac{1}{2}$ and $\mu = -\frac{1}{2}$, respectively, we can write

$$\int_{-i\infty}^{+i\infty} X(\mu)\,\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi(\mu-1)}d\mu = \int_{1-i\infty}^{1+i\infty} X(\mu)\,\mathrm{P}^{(1)}_{-\frac{3}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi(\mu-1)}d\mu$$
$$= \int_{-i\infty}^{+i\infty} X(\mu+1)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu,$$

$$\int_{-i\infty}^{+i\infty} X(\mu)\,\mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi(\mu+1)}d\mu = \int_{-1-i\infty}^{-1+i\infty} X(\mu)\,\mathrm{P}^{(1)}_{\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi(\mu+1)}d\mu$$
$$= \int_{-i\infty}^{+i\infty} X(\mu-1)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+\mu}(\cos\eta)\,\mathrm{e}^{-\xi\mu}d\mu.$$

It should be noted that the two equalities above do not hold if the function $X(\mu)$ has other poles in the strip $|\operatorname{Re}\mu| \le 1$. Finally, substituting the last two equalities into expression (72), we obtain formula (14). Formula (15) is derived similarly.

MULTISTABILITY IN RECURRENT NEURAL NETWORKS*

CHANG-YUAN CHENG†, KUANG-HUI LIN†, AND CHIH-WEN SHIH‡

Abstract. Stable stationary solutions correspond to memory capacity in the application of associative memory for neural networks. In this presentation, existence of multiple stable stationary solutions for Hopfield-type neural networks with delay and without delay is investigated. Basins of attraction for these stationary solutions are also estimated. Such a scenario of dynamics is established through formulating parameter conditions based on a geometrical setting. The present theory is demonstrated by two numerical simulations on the Hopfield neural networks with delays.

Key words. neural network, multistability, delay equations

1. Introduction.

The studies of neural networks have attracted considerable multidisciplinary research interest in recent years. The developments for neural network models and the theory for the models are, on the one hand, driven by application motif or inspired by biological neuronal behaviors. On the other hand, the neural network theory has motivated and elicited further progress in dynamical system theory. For example, theory for existence of many stable patterns or chaotic dynamics for systems in phase space of large dimension is in strong demand for neural network applications. The progress in this direction of research has also enriched dynamical system theory [6, 17, 27].

The applications of neural networks range from classifications, associative memory, image processing, and pattern recognition to parallel computation and its ability to solve optimization problems. The theory on the dynamics of the networks has been developed according to the purposes of the applications. In the application to parallel computation and signal processing involving finding the solution of an optimization problem, the existence of a computable solution for all possible initial states is the best situation. Mathematically, this means that the network needs to have a unique equilibrium which is globally attractive. Such a convergent behavior is referred to as "monostability" of a network. On the other hand, when a neural network is employed as an associative memory storage or for pattern recognition, the existence of many equilibria is a necessary feature [7, 11, 16, 21]. The notion of "multistability" of a neural network is used to describe coexistence of multiple stable patterns such as equilibria or periodic orbits. In general, if the dynamics for a system are bounded, the existence of multiple stable patterns is accompanied with coexistence of stable and unstable equilibria or periodic orbits. The existence of unstable equilibria is essential in certain applications of neural network. For example, unstable equilibria are related to digital constraints on selection in winner-take-all problems [32, 33].

Classical recurrent neural networks are usually systems of ordinary differential equations. Recently, neural network systems with delays have also been studied extensively, thanks to the need from practical applications and mathematical interests. In this presentation, we propose an approach to investigate existence of multiple stationary solutions and their stability for recurrent neural networks with delay and without delay. We shall illustrate our approach through the Hopfield-type model.

Hopfield-type neural networks and their various generalizations have been widely studied and applied in various scientific areas. A typical form for such a network is given by

$$C_i \frac{dx_i(t)}{dt} = -\frac{x_i(t)}{R_i} + \sum_{j=1}^{n} T_{ij} g_j(x_j(t-\tau_{ij})) + I_i, \quad i = 1, 2, \ldots, n, \tag{1.1}$$

where $C_i > 0$ and $R_i > 0$ are, respectively, the input capacitance and resistance associated with neuron i; I_i is the constant input; T_{ij} are the connection strengths between neurons; $\tau_{ij} > 0$ are the transmission delays; and $g_i, i = 1, 2, \ldots, n$, are neuron activation functions.

The classical Hopfield-type neural network [16] is system (1.1) without delay, that is, $\tau_{ij} = 0$ for all i, j. For the Hopfield-type neural networks, the theory of unique equilibrium and global convergence to the equilibrium has been extensively studied; cf. [9, 10] for the networks without delays and [5, 13, 19, 23, 24, 29, 30, 31, 34, 35] for the delay cases.

In contrast to these studies, we propose a treatment to explore the existence of multiple stationary solutions for (1.1) through a geometrical formulation on the parameter conditions. Stability of these equilibria for (1.1) with and without delay shall also be investigated. In addition, estimations of basins of attraction for these stable stationary solutions are derived. The stationary equations are identical for system (1.1) with delay and without delay. Thus, confirmation for the existence of equilibrium points is valid for both cases. However, stability of the equilibrium points and dynamical behaviors can be very different for the systems with delay and without delay. It is very interesting to explore such a difference as well as a possible coincidence of behaviors.

The theory for existence of multiple stable patterns has been developed for cellular neural networks [8, 17, 26, 27]. The neurons in such a system are locally connected and no time lags were considered therein. Our approach can be adopted to such a network with delays, as remarked in the later section. There are other interesting studies on delayed neural networks in [1, 2, 12, 22, 25].

This presentation is organized as follows. In section 2, we establish conditions for existence of 3^n equilibria for the Hopfield network. 2^n equilibria among them will be shown to be asymptotically stable for the system without delays, through a linearization analysis. In section 3, we shall verify that under the same conditions, there are 2^n regions in $\mathbb{R}^n$, each containing an equilibrium, which are positively invariant under the flow generated by the system with delays and without delays. Subsequently, it is argued that these 2^n equilibria are asymptotically stable, even in the presence of delays. We also formulate more sufficient conditions for stability of these 2^n equilibria. We extend our theory to more general activation functions, including those with saturations, in section 4. Two numerical simulations on the dynamics of two-neuron networks, which illustrate the present theory, are given in section 5. We summarize our results with a discussion (section 6).

2. Existence of multiple equilibria and their stability. In this section, we shall formulate sufficient conditions for the existence of multiple stationary solutions for Hopfield neural networks with and without delays. Our approach is based on a geometrical observation. The derived parameter conditions are concrete and can be examined easily. We also establish stability criteria of these equilibria for the system without delays, through estimations on the eigenvalues of the linearized system. Stability for the system with delays will be discussed in the next section. After rearranging the parameters, we consider system (1.1) in the following forms: for the network without delay,

$$\frac{dx_i(t)}{dt} = -b_i x_i(t) + \sum_{j=1}^{n} \omega_{ij} g_j(x_j(t)) + J_i, \quad i = 1, 2, \ldots, n, \tag{2.1}$$

and for the network with delays,

$$\frac{dx_i(t)}{dt} = -b_i x_i(t) + \sum_{j=1}^{n} \omega_{ij} g_j(x_j(t - \tau_{ij})) + J_i, \quad i = 1, 2, \ldots, n. \tag{2.2}$$

Herein, $b_i > 0$, $0 < \tau_{ij} \le \tau := \max_{1 \le i,j \le n} \tau_{ij}$. While (2.1) is a system of ordinary differential equations, (2.2) is a system of functional differential equations. The initial condition for (2.2) is

$$x_i(\theta) = \phi_i(\theta), \quad -\tau \le \theta \le 0, \quad i = 1, 2, \ldots, n,$$

and it is usually assumed that $\phi_i \in \mathcal{C}([-\tau, 0], \mathbb{R})$. Let $\ell > 0$. For $\mathbf{x} \in \mathcal{C}([-\tau, \ell], \mathbb{R}^n)$ and $t \in [0, \ell]$, we define

$$\mathbf{x}_t(\theta) = \mathbf{x}(t + \theta), \quad \theta \in [-\tau, 0]. \tag{2.3}$$

Let us denote $\tilde{F} = (\tilde{F}_1, \ldots, \tilde{F}_n)$, where $\tilde{F}_i$ is the right-hand side of (2.2),

$$\tilde{F}_i(\mathbf{x}_t) := -b_i x_i(t) + \sum_{j=1}^{n} \omega_{ij} g_j(x_j(t - \tau_{ij})) + J_i,$$

where $\mathbf{x} = (x_1, \ldots, x_n)$. A function $\mathbf{x} = \mathbf{x}(t)$ is called a solution of (2.2) on $[-\tau, \ell)$ if $\mathbf{x} \in \mathcal{C}([-\tau, \ell), \mathbb{R}^n)$ and $\mathbf{x}_t$ defined as (2.3) lies in the domain of $\tilde{F}$ and satisfies (2.2) for $t \in [0, \ell)$. For a given $\phi \in \mathcal{C}([-\tau, 0], \mathbb{R}^n)$, let us denote by $\mathbf{x}(t; \phi)$ the solution of (2.2) with $\mathbf{x}_0(\theta; \phi) := \mathbf{x}(0 + \theta; \phi) = \phi(\theta)$ for $\theta \in [-\tau, 0]$.

The activation functions g_j usually have sigmoidal configuration or are nondecreasing with saturations. Herein, we consider the typical logistic or Fermi function: for all $j = 1, 2, \ldots, n$,

$$g_j(\xi) = g(\xi) := \frac{1}{1 + e^{-\xi/\varepsilon}}, \quad \varepsilon > 0. \tag{2.4}$$

One may also adopt $g_j(\xi) = 1/(1 + e^{-\xi/\varepsilon_j})$, $\varepsilon_j > 0$, or other output functions, as discussed in section 4. Note that the stationary equations for systems (2.1) and (2.2) are identical; namely,

$$F_i(\mathbf{x}) := -b_i x_i + \sum_{j=1}^{n} \omega_{ij} g_j(x_j) + J_i = 0, \quad i = 1, 2, \ldots, n, \tag{2.5}$$

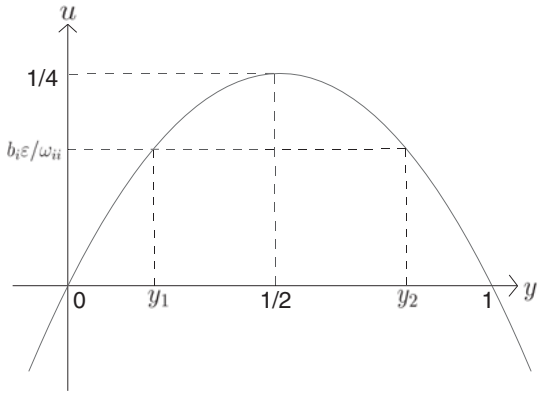

FIG. 1. *The graph for function* $u(y) = y - y^2$ *and* $y_1 = g(p_i)$, $y_2 = g(q_i)$.

where $\mathbf{x} = (x_1, \ldots, x_n)$. For our formulation in the following discussions, we introduce a single neuron analogue (no interaction among neurons),

$$\frac{d\xi}{dt} = f_i(\xi) := -b_i\xi + \omega_{ii}g(\xi) + J_i, \quad \xi \in \mathbb{R}.$$

Let us propose the first parameter condition:

$$(\mathrm{H}_1)\colon 0 < \frac{b_i\varepsilon}{\omega_{ii}} < \frac{1}{4}, \quad i = 1, 2, \ldots, n.$$

LEMMA 2.1. *Under condition* (H_1)*, there exist two points* p_i *and* q_i *with* $p_i < 0 < q_i$ *such that* $f_i'(p_i) = 0$, $f_i'(q_i) = 0$ *for* $i = 1, 2, \ldots, n$.

Proof. We compute that

$$g'(\xi) = \frac{1}{\varepsilon}(1 + e^{-\xi/\varepsilon})^{-2}e^{-\xi/\varepsilon}. \tag{2.6}$$

Note that g is strictly increasing and that the graph of function $g'(\xi)$ is concave down and has its maximal value at $\xi = 0$. We let $y = g(\xi)$, $\xi \in \mathbb{R}$. Then $y \in (0, 1)$ and $g(0) = 1/2$. It follows from (2.6) that

$$g'(\xi) = \frac{1}{\varepsilon}y^2\left(\frac{1}{y} - 1\right) = \frac{1}{\varepsilon}(y - y^2).$$

On the other hand, for each i, since $f_i'(\xi) = -b_i + \omega_{ii}g'(\xi)$, we have $f_i'(\xi) = 0$ if and only if $b_i = \omega_{ii}g'(\xi)$; equivalently,

$$\frac{b_i\varepsilon}{\omega_{ii}} = y - y^2.$$

From the configuration in Figure 1, it follows that, for each i, there exist two points p_i, q_i, $p_i < 0 < q_i$, such that $f_i'(p_i) = f_i'(q_i) = 0$ if the parameter condition $0 < b_i\varepsilon/\omega_{ii} < 1/4$ holds. This completes the proof. ∎

Note that condition (H_1) implies $\omega_{ii} > 0$ for all $i = 1, 2, \ldots, n$, since each b_i is already assumed to be a positive constant. We define, for $i = 1, 2, \ldots, n$,

$$\hat{f}_i(\xi) = -b_i\xi + \omega_{ii}g(\xi) + k_i^+,$$
$$\check{f}_i(\xi) = -b_i\xi + \omega_{ii}g(\xi) + k_i^-,$$

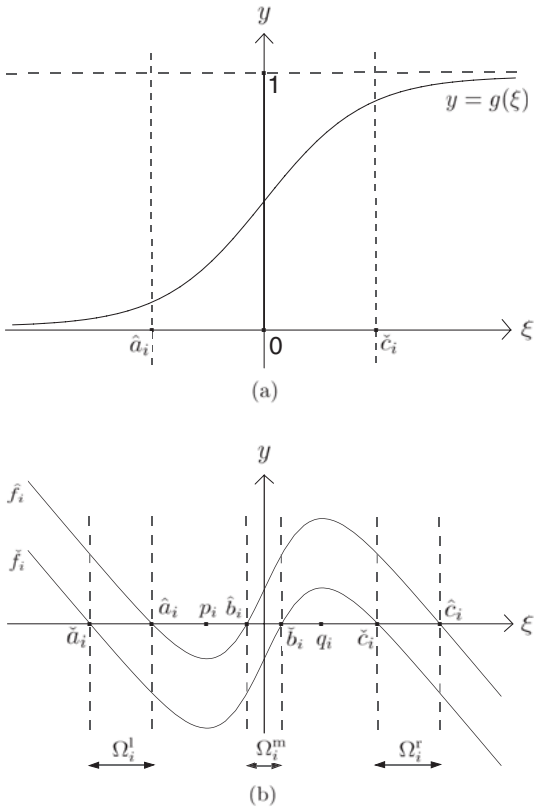

FIG. 2. (a) *The graph of g with* $\varepsilon = 0.5$*;* (b) *Configurations for* $\hat{f}_i$ *and* $\check{f}_i$.

where

$$k_i^+ := \sum_{j=1, j\neq i}^{n} |\omega_{ij}| + J_i, \;\; k_i^- := -\sum_{j=1, j\neq i}^{n} |\omega_{ij}| + J_i.$$

It follows that

$$\check{f}_i(x_i) \leq F_i(\mathbf{x}) \leq \hat{f}_i(x_i) \tag{2.7}$$

for all $\mathbf{x} = (x_1, \ldots, x_n)$ and $i = 1, 2, \ldots, n$, since $0 \leq g_j \leq 1$ for all j.

We consider the second parameter condition which is concerned with the existence of multiple equilibria for (2.1) and (2.2):

$$(\mathrm{H}_2)\text{: } \hat{f}_i(p_i) < 0, \quad \check{f}_i(q_i) > 0, \quad i = 1, 2, \ldots, n.$$

The configuration that motivates (H_2) is depicted in Figure 2. Such a configuration is due to the characteristics of the output function g. Under assumptions (H_1) and (H_2), there exist points $\hat{a}_i, \hat{b}_i, \hat{c}_i$ with $\hat{a}_i < \hat{b}_i < \hat{c}_i$ such that $\hat{f}_i(\hat{a}_i) = \hat{f}_i(\hat{b}_i) = \hat{f}_i(\hat{c}_i) = 0$ as well as points $\check{a}_i, \check{b}_i, \check{c}_i$ with $\check{a}_i < \check{b}_i < \check{c}_i$ such that $\check{f}_i(\check{a}_i) = \check{f}_i(\check{b}_i) = \check{f}_i(\check{c}_i) = 0$.

THEOREM 2.2. *Under* (H_1) *and* (H_2)*, there exist* 3^n *equilibria for systems* (2.1) *and* (2.2).

Proof. The equilibria of systems (2.1) and (2.2) are zeros of (2.5). Under conditions (H_1) and (H_2), the graphs of $\hat{f}_i$ and $\check{f}_i$ defined above are as depicted in Figure

2. According to the configurations, there are 3^n disjoint closed regions in $\mathbb{R}^n$. Set $\Omega^\alpha = \{(x_1, x_2, \ldots, x_n) \in \mathbb{R}^n \mid x_i \in \Omega_i^{\alpha_i}\}$ with $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_n)$, and $\alpha_i =$ "l," "m," or "r," where

$$\begin{aligned} &\Omega_i^{\mathrm{l}} := \{x \in \mathbb{R} |\ \check{a}_i \le x \le \hat{a}_i\}, \quad \Omega_i^{\mathrm{m}} := \{x \in \mathbb{R} |\ \hat{b}_i \le x \le \check{b}_i\}, \\ &\Omega_i^{\mathrm{r}} := \{x \in \mathbb{R} |\ \check{c}_i \le x \le \hat{c}_i\}. \end{aligned} \tag{2.8}$$

Herein, "l," "m," and "r" mean, respectively, "left," "middle," and "right." Consider any fixed one of these regions Ω^α. For a given $\tilde{\mathbf{x}} = (\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_n) \in \Omega^\alpha$, we solve

$$h_i(x_i) := -b_i x_i + \omega_{ii} g(x_i) + \sum_{j=1, j\neq i}^{n} \omega_{ij} g(\tilde{x}_j) + J_i = 0$$

for x_i, $i = 1, 2, \ldots, n$. According to an estimate similar to (2.7), the graph of h_i lies between the graphs of $\hat{f}_i$ and $\check{f}_i$. In fact, the graph of h_i is a vertical shift of the graph of $\hat{f}_i$ or $\check{f}_i$. Thus, one can always find three solutions, and each of them lies in one of the regions in (2.8) for each i. Let us pick the one lying in $\Omega_i^{\alpha_i}$ and set it as $\underline{x}_i$ for each i. We define a mapping $\mathbf{H}_\alpha : \Omega^\alpha \to \Omega^\alpha$ by $\mathbf{H}_\alpha(\tilde{\mathbf{x}}) = \underline{\mathbf{x}} = (\underline{x}_1, \underline{x}_2, \ldots, \underline{x}_n)$. Restated, we set

$$\begin{aligned} \underline{x}_i &= (h_i|_{\Omega_i^{\mathrm{l}}})^{-1}(0) \text{ if } \alpha_i = \text{"l,"} \\ \underline{x}_i &= (h_i|_{\Omega_i^{\mathrm{m}}})^{-1}(0) \text{ if } \alpha_i = \text{"m,"} \\ \underline{x}_i &= (h_i|_{\Omega_i^{\mathrm{r}}})^{-1}(0) \text{ if } \alpha_i = \text{"r."} \end{aligned}$$

Since g is continuous and h_i is a vertical shift of function $\xi \mapsto -b_i\xi + \omega_{ii} g(\xi)$ by the quantity $\sum_{j=1, j\neq i}^{n} \omega_{ij} g(\tilde{x}_j) + J_i$, the map $\mathbf{H}_\alpha$ is continuous. It follows from Brouwer's fixed point theorem that there exists one fixed point $\bar{\mathbf{x}} = (\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n)$ of $\mathbf{H}_\alpha$ in Ω^α which is also a zero of the function F, where $F = (F_1, F_2, \ldots, F_n)$. Consequently, there exist 3^n zeros of F, hence 3^n equilibria for systems (2.1) and (2.2), and each of them lies in one of the 3^n regions Ω^α. This completes the proof. □

We consider the following criterion concerning stability of the equilibria:

(2.9)

$$(\mathrm{H}_3)\colon -b_i + \sum_{j=1}^{n} |\omega_{ij}| g'(\eta_j) < 0, \quad g'(\eta_j) := \max\{g'(x_j) \mid x_j = \check{c}_j, \hat{a}_j\}, \quad i = 1, 2, \ldots, n.$$

A simplified yet more restrictive version for condition (H_3) is that for $i = 1, 2, \ldots, n$,

$$b_i > g'(\eta) \sum_{j=1}^{n} |\omega_{ij}| \text{ with } g'(\eta) := \max\{g'(x_j) \mid x_j = \check{c}_j, \hat{a}_j, j = 1, 2, \ldots, n\}. \tag{2.10}$$

THEOREM 2.3. *Under conditions* (H_1), (H_2), *and* (H_3), *there exist* 2^n *asymptotically stable equilibria for the Hopfield neural networks without delay* (2.1).

Proof. Among the 3^n equilibria in Theorem 2.2, we consider those $\bar{\mathbf{x}} = (\bar{x}_1, \ldots, \bar{x}_n)$ with $\bar{x}_i \in \Omega_i^{\mathrm{l}}$ or Ω_i^{r} for each i. The linearized system of (2.1) at equilibrium $\bar{\mathbf{x}}$ is

$$\frac{dy_i}{dt} = -b_i y_i + \sum_{j=1}^{n} \omega_{ij} g_j'(\overline{x}_j) y_j, \quad i = 1, 2, \ldots, n.$$

Restated, $\dot{\mathbf{y}} = A\mathbf{y}$, where $DF(\bar{\mathbf{x}}) =: A = [a_{ij}]_{n\times n}$ with

$$[a_{ij}] = \begin{pmatrix} -b_1 + \omega_{11}g'(\bar{x}_1) & \omega_{12}g'(\bar{x}_2) & \cdots & \omega_{1n}g'(\bar{x}_n) \\ \omega_{21}g'(\bar{x}_1) & -b_2 + \omega_{22}g'(\bar{x}_2) & & \omega_{2n}g'(\bar{x}_n) \\ \vdots & \vdots & \ddots & \vdots \\ \omega_{n1}g'(\bar{x}_1) & \omega_{n2}g'(\bar{x}_2) & \cdots & -b_n + \omega_{nn}g'(\bar{x}_n) \end{pmatrix}.$$

Let

$$r_i = \sum_{j=1,j\neq i}^{n} |a_{ij}| = \sum_{j=1,j\neq i}^{n} |\omega_{ij}g'(\bar{x}_j)| = \sum_{j=1,j\neq i}^{n} |\omega_{ij}|g'(\bar{x}_j), \quad i = 1, 2, \ldots, n.$$

According to Gerschgorin's theorem,

$$\lambda_k \in \bigcup_{i=1}^{n} B(a_{ii}, r_i)$$

for all $k = 1, 2, \ldots, n$, where λ_k are the eigenvalues of A and $B(a_{ii}, r_i) := \{\zeta \in \mathbb{C} \mid |\zeta - a_{ii}| < r_i\}$. Hence, for each k, there exists some $i = i(k)$ such that

$$\mathrm{Re}(\lambda_k) < -b_i + \omega_{ii}g'(\bar{x}_i) + \sum_{j=1,j\neq i}^{n} |\omega_{ij}|g'(\bar{x}_j).$$

Notice that for each j, $g'(\xi) \le g'(\check{c}_j)$ (resp., $g'(\xi) \le g'(\hat{a}_j)$) if $\xi \ge \check{c}_j$ (resp., $\xi \le \hat{a}_j$). Since $\bar{\mathbf{x}}$ is such that $\bar{x}_j \in \Omega_j^{\mathrm{l}}$ or Ω_j^{r}, we have $\bar{x}_j \ge \check{c}_j$ or $\bar{x}_j \le \hat{a}_j$ for all $j = 1, 2, \ldots, n$. It follows that $\mathrm{Re}(\lambda_k) < 0$ by (2.9). Thus, under (H_3), all the eigenvalues of A have negative real parts. Therefore, there are 2^n asymptotically stable equilibria for system (2.1). The proof is completed. □

We certainly can replace condition (H_3) by weaker ones, such as an individual condition for each equilibrium. Let $\bar{\mathbf{x}}$ be an equilibrium lying in Ω^α with $\alpha = (\alpha_1, \ldots, \alpha_n)$ and $\alpha_i =$ "r" or $\alpha_i =$ "l," that is, $\bar{x}_i \in \Omega_i^{\mathrm{l}}$ or Ω_i^{r}, for each i. For such an equilibrium we consider, for $i = 1, 2, \ldots, n$,

$$b_i > \omega_{ii}g'(\xi_i) + \sum_{j=1,j\neq i}^{n} |\omega_{ij}|g'(\xi_j), \quad \xi_k = \check{c}_k \text{ if } \alpha_k = \text{"r,"} \quad \xi_k = \hat{a}_k \text{ if } \alpha_k = \text{"l,"} \quad k = 1, \ldots, n.$$

Such conditions are obviously much more tedious than (H_3).

3. Stability of equilibria and the basins of attraction. We plan to investigate the stability of equilibrium for system (2.2), that is, with delays. We shall also explore the basins of attraction for the asymptotically stable equilibria, for both systems (2.1) and (2.2), in this section.

Note that the function $\xi \mapsto [\omega_{ii} + \sum_{j=1,j\neq i}^{n} |\omega_{ij}|]g'(\xi)$ is continuous for all $i = 1, 2, \ldots, n$. From (2.9) and $\omega_{ii} > 0$, it follows that there exists a positive constant ϵ_0 such that

$$b_i > \max\left\{ \left[\omega_{ii} + \sum_{j=1,j\neq i}^{n} |\omega_{ij}| \right] g'(\xi) : \xi = \hat{a}_i + \epsilon_0, \check{c}_i - \epsilon_0 \right\}, \ i = 1, 2, \ldots, n. \tag{3.1}$$

Herein, we choose ϵ_0 such that $\epsilon_0 < \min\{|\hat{a}_i - p_i|, |\check{c}_i - q_i|\}$ for all $i = 1, 2, \ldots, n$. For system (2.1), we consider the following 2^n subsets of $\mathbb{R}^n$. Let $\alpha = (\alpha_1, \ldots, \alpha_n)$ with $\alpha_i =$ "l" or "r," and set

$$\tilde{\Omega}^\alpha = \{(x_1, x_2, \ldots, x_n) \mid x_i \in \tilde{\Omega}_i^{\mathrm{l}} \text{ if } \alpha_i = \text{"l,"}\ x_i \in \tilde{\Omega}_i^{\mathrm{r}} \text{ if } \alpha_i = \text{"r"}\}, \tag{3.2}$$

where $\tilde{\Omega}_i^{\mathrm{l}} := \{\xi \in \mathbb{R} \mid \xi \le \hat{a}_i + \epsilon_0\}$, $\tilde{\Omega}_i^{\mathrm{r}} := \{\xi \in \mathbb{R} \mid \xi \ge \check{c}_i - \epsilon_0\}$. For system (2.2), we consider the following 2^n subsets of $\mathcal{C}([-\tau, 0], \mathbb{R}^n)$. Let $\alpha = (\alpha_1, \ldots, \alpha_n)$ with $\alpha_i =$ "l" or "r," and set

$$\Lambda^\alpha = \{\varphi = (\varphi_1, \varphi_2, \ldots, \varphi_n) \mid \varphi_i \in \Lambda_i^{\mathrm{l}} \text{ if } \alpha_i = \text{"l,"}\ \varphi_i \in \Lambda_i^{\mathrm{r}} \text{ if } \alpha_i = \text{"r"}\}, \tag{3.3}$$

where

$$\Lambda_i^{\mathrm{l}} := \{\varphi_i \in \mathcal{C}([-\tau, 0], \mathbb{R}) \mid \varphi_i(\theta) \le \hat{a}_i + \epsilon_0 \text{ for all } \theta \in [-\tau, 0]\},$$
$$\Lambda_i^{\mathrm{r}} := \{\varphi_i \in \mathcal{C}([-\tau, 0], \mathbb{R}) \mid \varphi_i(\theta) \ge \check{c}_i - \epsilon_0 \text{ for all } \theta \in [-\tau, 0]\}.$$

THEOREM 3.1. *Assume that* (H_1) *and* (H_2) *hold. Then each* $\tilde{\Omega}^\alpha$ *and each* Λ^α *are positively invariant with respect to the solution flow generated by systems* (2.1) *and* (2.2)*, respectively.*

Proof. We prove only the delay case, i.e., system (2.2). Consider any one of the 2^n sets Λ^α. For any initial condition $\phi = (\phi_1, \phi_2, \ldots, \phi_n) \in \Lambda^\alpha$, we claim that the solution $\mathbf{x}(t; \phi)$ remains in Λ^α for all $t \ge 0$. If this is not true, there exists a component $x_i(t)$ of $\mathbf{x}(t; \phi)$ which is the first (or one of the first) escaping from Λ_i^{l} or Λ_i^{r}. Restated, there exist some i and $t_1 > 0$ such that either $x_i(t_1) = \check{c}_i - \epsilon_0$, $\frac{dx_i}{dt}(t_1) \le 0$, and $x_i(t) \ge \check{c}_i - \epsilon_0$ for $-\tau \le t \le t_1$ or $x_i(t_1) = \hat{a}_i + \epsilon_0$, $\frac{dx_i}{dt}(t_1) \ge 0$, and $x_i(t) \le \hat{a}_i + \epsilon_0$ for $-\tau \le t \le t_1$. For the first case $x_i(t_1) = \check{c}_i - \epsilon_0$ and $\frac{dx_i}{dt}(t_1) \le 0$, we derive from (2.2) that

$$\frac{dx_i}{dt}(t_1) = -b_i(\check{c}_i - \epsilon_0) + \omega_{ii} g(x_i(t_1 - \tau_{ii})) + \sum_{j=1, j\ne i}^{n} \omega_{ij} g(x_j(t_1 - \tau_{ij})) + J_i \le 0. \tag{3.4}$$

On the other hand, recalling (H_2) and previous descriptions of $\check{c}_i$ and ϵ_0, we have $\check{f}_i(\check{c}_i - \epsilon_0) > 0$ which gives

$$\begin{aligned} &-b_i(\check{c}_i - \epsilon_0) + \omega_{ii} g(\check{c}_i - \epsilon_0) + k_i^- \\ &= -b_i(\check{c}_i - \epsilon_0) + \omega_{ii} g(\check{c}_i - \epsilon_0) - \sum_{j=1, j\ne i}^{n} |\omega_{ij}| + J_i > 0. \end{aligned} \tag{3.5}$$

Notice that t_1 is the first time for x_i to escape from Λ_i^{r}. We have $g(x_i(t_1 - \tau_{ii})) \ge g(\check{c}_i - \epsilon_0)$, by the monotonicity of function g. In addition, by $\omega_{ii} > 0$ and $|g(\cdot)| \le 1$, we obtain from (3.5) that

$$\begin{aligned} &-b_i(\check{c}_i - \epsilon_0) + \omega_{ii} g(x_i(t_1 - \tau_{ii})) + \sum_{j=1, j\ne i}^{n} \omega_{ij} g(x_j(t_1 - \tau_{ij})) + J_i \\ &\ge -b_i(\check{c}_i - \epsilon_0) + \omega_{ii} g(\check{c}_i - \epsilon_0) - \sum_{j=1, j\ne i}^{n} |\omega_{ij}| + J_i > 0, \end{aligned}$$

which contradicts (3.4). Hence, $x_i(t) \geq \check{c}_i - \epsilon_0$ for all $t > 0$. Similar arguments can be employed to show that $x_i(t) \leq \hat{a}_i + \epsilon_0$ for all $t > 0$ for the situation that $x_i(t_1) = \hat{a}_i + \epsilon_0$ and $\frac{dx_i}{dt}(t_1) \geq 0$. Therefore, Λ^α is positively invariant under the flow generated by system (2.2). The assertion for system (2.1) can be justified similarly. □

THEOREM 3.2. *Under conditions* (H_1), (H_2), *and* (H_3), *there exist* 2^n *exponentially stable equilibria for system* (2.2).

Proof. Consider an equilibrium $\bar{\mathbf{x}} = (\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n) \in \Omega^\alpha$ for some $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_n)$, with $\alpha_i =$ "l" or "r," obtained in Theorem 2.2. We consider the single-variable functions $G_i(\cdot)$, defined by

$$G_i(\zeta) = b_i - \zeta - \sum_{j=1}^{n} |\omega_{ij}| g'(\xi_j) e^{\zeta \tau_{ij}},$$

where $\xi_j = \hat{a}_j + \epsilon_0$ (resp., $\check{c}_j - \epsilon_0$) if $\alpha_j =$ "l" (resp., "r"). Then, $G_i(0) > 0$ from (3.1) or (H_3). Moreover, there exists a constant $\mu > 0$ such that $G_i(\mu) > 0$ for $i = 1, 2, \ldots, n$, due to continuity of G_i. Let $\mathbf{x}(t) = \mathbf{x}(t; \phi)$ be the solution to (2.2) with initial condition $\phi \in \Lambda^\alpha$ defined in (3.3). Under the translation $\mathbf{y}(t) = \mathbf{x}(t) - \bar{\mathbf{x}}$, system (2.2) becomes

$$\frac{dy_i(t)}{dt} = -b_i y_i(t) + \sum_{j=1}^{n} \omega_{ij} [g(x_j(t - \tau_{ij})) - g(\bar{x}_j)], \tag{3.6}$$

where $\mathbf{y} = (y_1, \ldots, y_n)$. Now, consider functions $z_i(\cdot)$ defined by

$$z_i(t) = e^{\mu t} |y_i(t)|, \quad i = 1, 2, \ldots, n. \tag{3.7}$$

The domain of definition for $z_i(\cdot)$ is identical to the interval of existence for $y_i(\cdot)$. We shall see in the following computations that the domain can be extended to $[-\tau, \infty)$. Let $\delta > 1$ be an arbitrary real number and let

$$K := \max_{1 \leq i \leq n} \left\{ \sup_{\theta \in [-\tau, 0]} |x_i(\theta) - \bar{x}_i| \right\} > 0. \tag{3.8}$$

It follows from (3.7) and (3.8) that $z_i(t) < K\delta$ for $t \in [-\tau, 0]$ and all $i = 1, 2, \ldots, n$. Next, we claim that

$$z_i(t) < K\delta \quad \text{for all } t > 0,\ i = 1, 2, \ldots, n. \tag{3.9}$$

Suppose this is not the case. Then there are an $i \in \{1, 2, \ldots, n\}$ (say $i = k$) and a $t_1 > 0$ for the first time such that

$$\begin{aligned} z_i(t) &\leq K\delta, \quad t \in [-\tau, t_1], \quad i = 1, 2, \ldots, n,\ i \neq k, \\ z_k(t) &< K\delta, \quad t \in [-\tau, t_1), \\ z_k(t_1) &= K\delta \quad \text{with } \frac{d}{dt} z_k(t_1) \geq 0. \end{aligned}$$

Note that $z_k(t_1) = K\delta > 0$ implies $y_k(t_1) \neq 0$. Hence $|y_k(t)|$ and $z_k(t)$ are differentiable at $t = t_1$. From (3.6), we derive that

$$\frac{d}{dt} |y_k(t_1)| \leq -b_k |y_k(t_1)| + \sum_{j=1}^{n} |\omega_{kj}| g'(\varsigma_j) |y_j(t_1 - \tau_{kj})| \tag{3.10}$$

for some ς_j between $x_j(t_1-\tau_{kj})$ and $\bar{x}_j$. Hence, from (3.7) and (3.10),

$$\begin{aligned}\frac{dz_k(t_1)}{dt} &\le \mu e^{\mu t_1}|y_k(t_1)| + e^{\mu t_1}\left[-b_k|y_k(t_1)| + \sum_{j=1}^{n}|\omega_{kj}|g'(\varsigma_j)|y_j(t_1-\tau_{kj})|\right]\\ &\le \mu z_k(t_1) - b_k z_k(t_1) + \sum_{j=1}^{n}|\omega_{kj}|g'(\varsigma_j)e^{\mu\tau_{kj}}z_j(t_1-\tau_{kj})\\ &\le -(b_k-\mu)z_k(t_1) + \sum_{j=1}^{n}|\omega_{kj}|g'(\xi_j)e^{\mu\tau_{kj}}\left[\sup_{\theta\in[t_1-\tau,t_1]}z_j(\theta)\right], \qquad (3.11)\end{aligned}$$

where $\xi_j = \hat{a}_j + \epsilon_0$ (resp., $\check{c}_j - \epsilon_0$) if $\alpha_j =$ "l" (resp., "r"). Herein, the invariance property of Λ^α in Theorem 3.1 has been applied. Due to $G_i(\mu) > 0$, we obtain

$$\begin{aligned}0 \le \frac{dz_k(t_1)}{dt} &\le -(b_k-\mu)z_k(t_1) + \sum_{j=1}^{n}|\omega_{kj}|g'(\xi_j)e^{\mu\tau_{kj}}\left[\sup_{\theta\in[t_1-\tau,t_1]}z_j(\theta)\right]\\ &< -\left\{b_i - \mu - \sum_{j=1}^{n}|\omega_{ij}|g'(\xi_j)e^{\mu\tau_{kj}}\right\}K\delta\\ &< 0, \qquad (3.12)\end{aligned}$$

which is a contradiction. Hence the claim (3.9) holds. Since $\delta > 1$ is arbitrary, by allowing $\delta \to 1^+$, we have $z_i(t) \le K$ for all $t > 0$, $i = 1, 2, \ldots, n$. We then use (3.7) and (3.8) to obtain

$$|x_i(t) - \bar{x}_i| \le e^{-\mu t}\max_{1\le j\le n}\left(\sup_{\theta\in[-\tau,0]}|x_j(\theta) - \bar{x}_j|\right)$$

for $t > 0$ and all $i = 1, 2, \ldots, n$. Therefore, $\mathbf{x}(t)$ is exponentially convergent to $\bar{\mathbf{x}}$. This completes the proof. □

In the following, we employ the theory of the local Lyapunov functional [15] and the Halanay-type inequality [4, 14] to establish other sufficient conditions for asymptotic stability and exponential stability for the equilibria of system (2.2).

THEOREM 3.3. *There exist 2^n asymptotically stable equilibria for system* (2.2) *under conditions* (H_1) *and* (H_2) *and one of the following conditions:*

(H_4): $2b_i > \sum_{j=1}^{n}|\omega_{ij}| + [g'(\eta_i)]^2\sum_{j=1}^{n}|\omega_{ji}|$ for $\eta_i = \hat{a}_i$ and $\check{c}_i$, $i = 1, 2, \ldots, n$,

(H_5): $\min_{1\le i\le n}\left[2b_i - \sum_{j=1}^{n}|\omega_{ij}|g'(\xi_j)\right] > \max_{1\le i\le n}\left[\sum_{j=1}^{n}|\omega_{ji}|g'(\eta_i)\right]$ for $\xi_j = \hat{a}_j$ and $\check{c}_j$, $\eta_i = \hat{a}_i$ and $\check{c}_i$.

Proof. Similarly to (3.1), there exists $\epsilon_0 > 0$ such that (H_4) holds for $\eta_i = \hat{a}_i + \epsilon_0$, $\check{c}_i - \epsilon_0$, and (H_5) holds for $\xi_j = \hat{a}_j + \epsilon_0$, $\check{c}_j - \epsilon_0$, $\eta_i = \hat{a}_i + \epsilon_0$, $\check{c}_i - \epsilon_0$, $i = 1, 2, \ldots, n$, by continuity of g'. We thus define Λ^α as in (3.3). The following computations are reserved for solutions lying entirely within each of the 2^n positively invariant regions Λ^α.

(i) We employ the following Lyapunov functional:

$$V(\mathbf{y})(t) = \sum_{i=1}^{n} y_i^2(t) + \sum_{i=1}^{n}\sum_{j=1}^{n} |\omega_{ij}| \int_{t-\tau_{ij}}^{t} [g(x_j(s)) - g(\overline{x}_j)]^2 ds,$$

where $\mathbf{y}(t) = \mathbf{x}(t) - \overline{\mathbf{x}}$. By recalling (3.6) and using (H_4), we derive

$$\begin{aligned}
\frac{dV(\mathbf{y})(t)}{dt} &= 2\sum_{i=1}^{n} y_i(t) \left\{ -b_i y_i(t) + \sum_{j=1}^{n} \omega_{ij}[g(x_j(t-\tau_{ij})) - g(\overline{x}_j)] \right\} \\
&\quad + \sum_{i=1}^{n}\sum_{j=1}^{n} |\omega_{ij}|[g(x_j(t)) - g(\overline{x}_j)]^2 - \sum_{i=1}^{n}\sum_{j=1}^{n} |\omega_{ij}|[g(x_j(t-\tau_{ij})) - g(\overline{x}_j)]^2 \\
&\le -2\sum_{i=1}^{n} b_i y_i^2(t) + \sum_{i=1}^{n}\sum_{j=1}^{n} |\omega_{ij}| y_i^2(t) + \sum_{i=1}^{n}\sum_{j=1}^{n} |\omega_{ij}|[g'(\eta_j)]^2 y_j^2(t) \\
&= \sum_{i=1}^{n} \left\{ -2b_i + \sum_{j=1}^{n} |\omega_{ij}| + [g'(\eta_i)]^2 \sum_{j=1}^{n} |\omega_{ji}| \right\} y_i^2(t) < 0.
\end{aligned}$$

We thus conclude the asymptotic stability for equilibrium $\bar{\mathbf{x}}$ via applying the theory of the local Lyapunov functional; cf. [15].

(ii) Recall (3.6), and let

$$W(\mathbf{y})(t) = \frac{1}{2}\sum_{i=1}^{n} y_i^2(t). \tag{3.13}$$

Then,

$$\begin{aligned}
\frac{dW(\mathbf{y})(t)}{dt} &= \sum_{i=1}^{n} y_i(t) \left\{ -b_i y_i(t) + \sum_{j=1}^{n} \omega_{ij}[g(x_j(t-\tau_{ij})) - g(\overline{x}_j)] \right\} \\
&\le \sum_{i=1}^{n} \left\{ -b_i y_i^2(t) + \frac{1}{2}\sum_{j=1}^{n} |\omega_{ij}| g'(\varsigma_j)[y_i^2(t) + y_j^2(t-\tau_{ij})] \right\} \\
&\le -\sum_{i=1}^{n} \left[b_i - \frac{1}{2}\sum_{j=1}^{n} |\omega_{ij}| g'(\xi_j) \right] y_i^2(t) \\
&\quad + \frac{1}{2} \left[\max_{1\le i\le n} \sum_{j=1}^{n} |\omega_{ji}| g'(\eta_i) \right] \sum_{i=1}^{n} \sup_{t-\tau\le s\le t} y_i^2(s) \\
&\le -\beta W(\mathbf{y})(t) + \zeta \sup_{t-\tau\le s\le t} W(\mathbf{y})(s),
\end{aligned}$$

where

$$\begin{aligned}
\beta &:= \min_{1\le i\le n} \left\{ 2b_i - \sum_{j=1}^{n} |\omega_{ij}| g'(\xi_j), \xi_j = \hat{a}_j + \epsilon_0,\ \check{c}_j - \epsilon_0 \right\}, \\
\zeta &:= \max_{1\le i\le n} \left\{ \sum_{j=1}^{n} |\omega_{ji}| g'(\eta_i), \eta_i = \hat{a}_i + \epsilon_0,\ \check{c}_i - \epsilon_0 \right\}.
\end{aligned}$$

By (H_5), we have $\beta > \zeta > 0$. By using the Halanay inequality, we obtain that

$$W(\mathbf{y})(t) \le \left(\sup_{-\tau \le s \le 0} W(\mathbf{y})(s) \right) e^{-\gamma t} \tag{3.14}$$

for all $t \ge 0$, where γ is the unique solution of $\gamma = \beta - \zeta e^{\gamma \tau}$. It follows that

$$\frac{1}{2} \sum_{i=1}^{n} y_i^2(t) \le \left[\sup_{-\tau \le s \le 0} \left(\frac{1}{2} \sum_{i=1}^{n} y_i^2(s) \right) \right] e^{-\gamma t}. \tag{3.15}$$

Hence, the equilibrium $\bar{\mathbf{x}}$ is asymptotically stable. □

COROLLARY 3.4. *Under conditions* (H_1), (H_2), *and* (H_5), *there exist* 2^n *exponentially stable equilibria for system* (2.2).

We observe from (2.1) and (2.2) that for every i,

$$F_i(\mathbf{x}),\ \tilde{F}_i(\mathbf{x}_t) < 0 \text{ whenever } x_i > 0 \text{ is sufficiently large,}$$
$$F_i(\mathbf{x}),\ \tilde{F}_i(\mathbf{x}_t) > 0 \text{ whenever } x_i < 0 \text{ and } |x_i| \text{ is sufficiently large,}$$

since $b_i > 0$ and $\sum_{j=1}^{n} \omega_{ij} g_j(x_j(t)) + J_i$ and $\sum_{j=1}^{n} \omega_{ij} g_j(x_j(t - \tau_{ij})) + J_i$ are bounded for any $\mathbf{x}$ and $\mathbf{x}_t$. Therefore, it can be concluded that every solution of (2.1) and (2.2) is bounded in forward time.

4. Further extension. We shall extend our studies in sections 2 and 3 to more general activation functions in this section.

4.1. Activation functions in general form. Let us consider the activation functions $\{g_i(\cdot)\}_1^n$ which are $\mathcal{C}^2$ and satisfy

$$(C): \begin{cases} u_i \le g_i(\xi) \le v_i, & g_i'(\xi) > 0, \\ (\xi - \sigma_i) g_i''(\xi) < 0 & \text{for all } \xi \in \mathbb{R}, \end{cases}$$

$i = 1, 2, \ldots, n$. Herein, u_i, v_i, and σ_i are constants with $u_i < v_i$, $i = 1, 2, \ldots, n$. Under these circumstances, (H_1) can be modified to

$$(H_1'):\ 0 = \inf_{\xi \in \mathbb{R}} g_i'(\xi) < \frac{b_i}{\omega_{ii}} < \max_{\xi \in \mathbb{R}} g_i'(\xi)\ (= g_i'(\sigma_i)),\ i = 1, 2, \ldots, n.$$

As in section 2, we define

$$f_i(\xi) = -b_i \xi + \omega_{ii} g_i(\xi) + J_i.$$

LEMMA 4.1. *For* g_i *in the class* (C), *under condition* (H_1'), *there exist constants* $\{p_i\}_1^n$ *and* $\{q_i\}_1^n$ *with* $p_i < \sigma_i < q_i$ *such that* $f_i'(p_i) = f_i'(q_i) = 0$ *for each* $i = 1, 2, \ldots, n$.

We define

$$\hat{f}_i(\xi) = -b_i \xi + \omega_{ii} g_i(\xi) + k_i^+, \quad \check{f}_i(\xi) = -b_i \xi + \omega_{ii} g_i(\xi) + k_i^-, \tag{4.1}$$

where

$$k_i^+ := \sum_{j=1, j \ne i}^{n} \rho_j |\omega_{ij}| + J_i, \quad k_i^- := -\sum_{j=1, j \ne i}^{n} \rho_j |\omega_{ij}| + J_i \tag{4.2}$$

with $\rho_j = \max\{|u_j|, |v_j|\}$. We locate the points $\hat{a}_i < \hat{b}_i < \hat{c}_i$ and $\check{a}_i < \check{b}_i < \check{c}_i$, where $\hat{f}_i(\hat{a}_i) = \hat{f}_i(\hat{b}_i) = \hat{f}_i(\hat{c}_i) = 0$ and $\check{f}_i(\check{a}_i) = \check{f}_i(\check{b}_i) = \check{f}_i(\check{c}_i) = 0$.

Let $\eta \in \mathbb{R}$ and $k \in \{1, \dots, n\}$ be such that $g_k'(\eta) = \max\{g_i'(\xi) : \xi = \hat{a}_i, \check{c}_i, i = 1, 2, \dots, n\}$. Consider

$$(\mathrm{H}_3'): \; b_i > g_k'(\eta) \left[\omega_{ii} + \sum_{j=1, j\neq i}^{n} |\omega_{ij}| \right], \quad i = 1, 2, \dots, n.$$

THEOREM 4.2. *Let g_i be in the class* (C). *Under conditions* (H_1'), (H_2), *and* (H_3'), *there exist 3^n equilibria for systems* (2.1) *and* (2.2) *with 2^n among them being exponentially stable.*

4.2. Saturated activation functions. In this subsection, we investigate systems (2.1), (2.2) with saturated activation functions. In particular, we consider the following continuous functions:

$$g_i(\xi) = \begin{cases} u_i & \text{if } -\infty < \xi \le p_i, \\ \text{increasing} & \text{if } p_i \le \xi \le q_i, \\ v_i & \text{if } q_i \le \xi < \infty, \end{cases}$$

where p_i, q_i are constants with $p_i < q_i$ for $i = 1, 2, \dots, n$. Such a class of functions includes the piecewise linear function with saturations:

$$g_i(\xi) = \begin{cases} u_i & \text{if } -\infty < \xi \le p_i, \\ u_i + \frac{v_i - u_i}{q_i - p_i}(\xi - p_i) & \text{if } p_i \le \xi \le q_i, \\ v_i & \text{if } q_i \le \xi < \infty \end{cases}$$

for each i. Typical graphs for these functions are depicted in Figures 3(a) and (c). With such activation functions, existence of multiple equilibria for (2.1) and (2.2) can be obtained under condition

$$(\mathrm{H}_\mathrm{s}): b_i > 0, -b_i p_i + \omega_{ii} u_i + k_i^+ < 0, \quad -b_i q_i + \omega_{ii} v_i + k_i^- > 0, \quad i = 1, 2, \dots, n,$$

where k_i^+, k_i^- are defined as in (4.2). We define $\hat{f}_i, \check{f}_i$ as in (4.1). The graphs of $\hat{f}_i$ and $\check{f}_i$ are depicted in Figures 3(b) and (d). Under condition (H_s), we also locate the points $\hat{a}_i < \hat{b}_i < \hat{c}_i$ and $\check{a}_i < \check{b}_i < \check{c}_i$, where $\hat{f}_i(\hat{a}_i) = \hat{f}_i(\hat{b}_i) = \hat{f}_i(\hat{c}_i) = 0$ and $\check{f}_i(\check{a}_i) = \check{f}_i(\check{b}_i) = \check{f}_i(\check{c}_i) = 0$.

Note that we do not need differentiability at corner points p_i, q_i of g_i in our analysis; moreover, $g_i'(\xi) = 0$ for $\xi < p_i$ and $\xi > q_i$. Thus, (H_3) is already satisfied if $b_i > 0$ for $i = 1, 2, \dots, n$. With these formulations, we can derive that there exist 3^n equilibria for systems (2.1) and (2.2), and that 2^n of them are exponentially stable under condition (H_s).

4.3. Unbounded activation functions. Our theory can also be extended to certain unbounded activation functions with controlled slopes, for example, the activation functions g_i with bounded slopes in Figure 4. Herein, we require that the slopes m_i^r of the right- and m_i^l of the left-hand parts of g_i satisfy $b_i > \omega_{ii} m_i^\mathrm{r}$, $b_i > \omega_{ii} m_i^\mathrm{l}$ for $i = 1, \dots, n$.

5. Numerical illustrations. In this section, we present two examples (with delays) to illustrate our theory.

Example 5.1. Consider the two-dimensional neural network

$$\frac{dx_1(t)}{dt} = -x_1(t) + 18g_1(x_1(t-10)) + 5g_2(x_2(t-10)) - 9,$$
$$\frac{dx_2(t)}{dt} = -3x_2(t) + 5g_1(x_1(t-10)) + 30g_2(x_2(t-10)) - 15,$$

TABLE 1
Local extreme points and zeros of $\hat{f}_1, \check{f}_1, \hat{f}_2, \check{f}_2$.

$\hat{a}_1 = -3.993889$	$p_1 = -1.762747$	$\hat{b}_1 = -0.757751$	q_1=1.762747	$\hat{c}_1$=14
$\check{a}_1 = -14$		$\check{b}_1$=0.757751		$\check{c}_1$=3.993889
$\hat{a}_2 = -3.320288$	$p_2 = -1.443635$	$\hat{b}_2 = -0.452309$	q_2=1.443635	$\hat{c}_2$=6.666650
$\check{a}_2 = -6.666650$		$\check{b}_2$=0.452309		$\check{c}_2$=3.320288

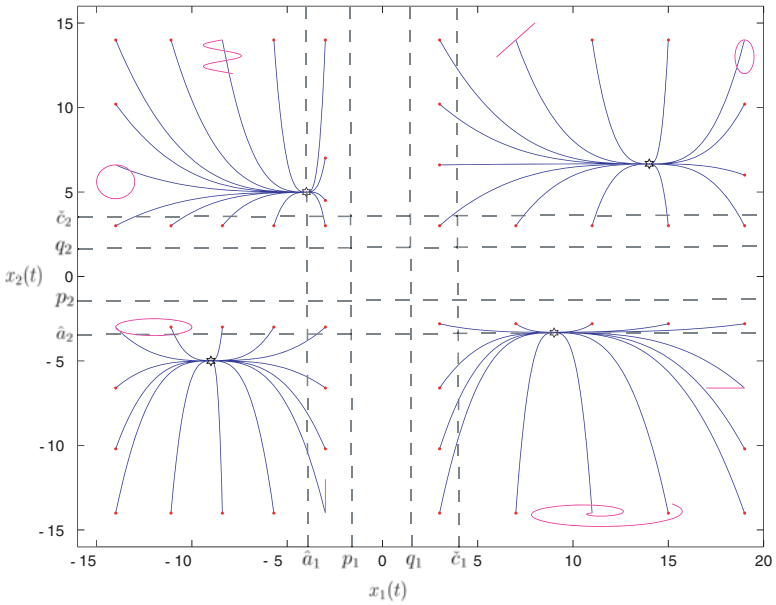

FIG. 5. *Illustrations for the dynamics in Example* 5.1.

where $g_1(x) = g_2(x) = g(x)$ in (2.4) with $\varepsilon = 0.5$. A computation gives

$$\hat{f}_1(x_1) = -x_1 + 18g(x_1) - 4, \quad \check{f}_1(x_1) = -x_1 + 18g(x_1) - 14,$$
$$\hat{f}_2(x_2) = -3x_2 + 30g(x_2) - 10, \quad \check{f}_2(x_2) = -3x_2 + 30g(x_2) - 20.$$

Herein, the parameters satisfy our conditions in Theorem 3.2:

$$\text{Condition } (\mathrm{H}_1)\text{: } 0 < \frac{b_1\varepsilon}{\omega_{11}} = \frac{1}{36} < \frac{1}{4}, \quad 0 < \frac{b_2\varepsilon}{\omega_{22}} = \frac{1}{20} < \frac{1}{4}.$$
$$\text{Condition } (\mathrm{H}_2)\text{: } \hat{f}_1(p_1) = -1.722534 < 0, \quad \check{f}_1(q_1) = 1.722534 > 0,$$
$$\hat{f}_2(p_2) = -4.085501 < 0, \quad \check{f}_2(q_2) = 4.085501 > 0.$$
$$\text{Condition } (\mathrm{H}_3)\text{: } b_1 = 1 > 0.025246 = \omega_{11}g'(\eta_1) + |\omega_{12}|g'(\eta_2),$$
$$b_2 = 3 > 0.081566 = |\omega_{21}|g'(\eta_1) + \omega_{22}g'(\eta_2),$$

where $\eta_1 = \pm 3.993889$, $\eta_2 = \pm 3.320288$ are defined in (2.9). Local extreme points and zeros of $\hat{f}_1, \check{f}_1, \hat{f}_2, \check{f}_2$ are listed in Table 1. The dynamics of this system are illustrated in Figure 5, where evolutions of 56 initial conditions have been tracked. The constant initial conditions are plotted in red dots, and the time-dependent initial conditions are plotted in purple curves. The evolutions of components $x_1(t)$ and $x_2(t)$ are depicted

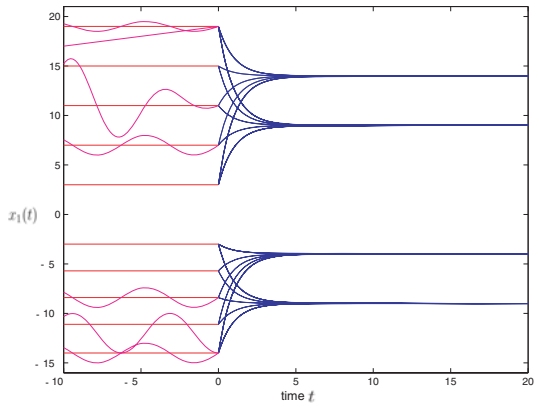

FIG. 6. *Evolution of state variable* $x_1(t)$ *in Example* 5.1.

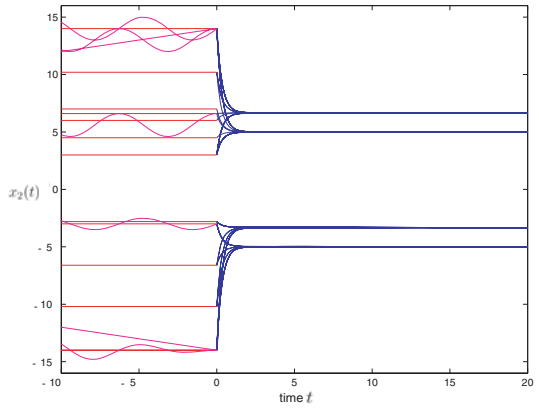

FIG. 7. *Evolution of state variable* $x_2(t)$ *in Example* 5.1.

in Figures 6 and 7, respectively. There are four exponentially stable equilibria in the system, as confirmed by our theory. The simulations demonstrate the convergence to these four equilibria from initial functions ϕ lying in the basin of the respective equilibrium.

Example 5.2. In this example, we simulate the neural network

$$\frac{dx_1(t)}{dt} = -x_1(t) + 18g_1(x_1(t-10)) + 11g_2(x_2(t-10)) + 1,$$
$$\frac{dx_2(t)}{dt} = -3x_2(t) + 11g_1(x_1(t-10)) + 30g_2(x_2(t-10)) + 4$$

with the output function $g_i(\xi) = h(\xi)$, where

$$h(\xi) = \frac{1}{2}(|\xi + 1| - |\xi - 1|), \tag{5.1}$$

for each i. The parameters also satisfy the conditions in our formulations with such an output function. We demonstrate the dynamics as well as evolutions of components $x_1(t)$, $x_2(t)$ for the system in Figures 8, 9, and 10, respectively.

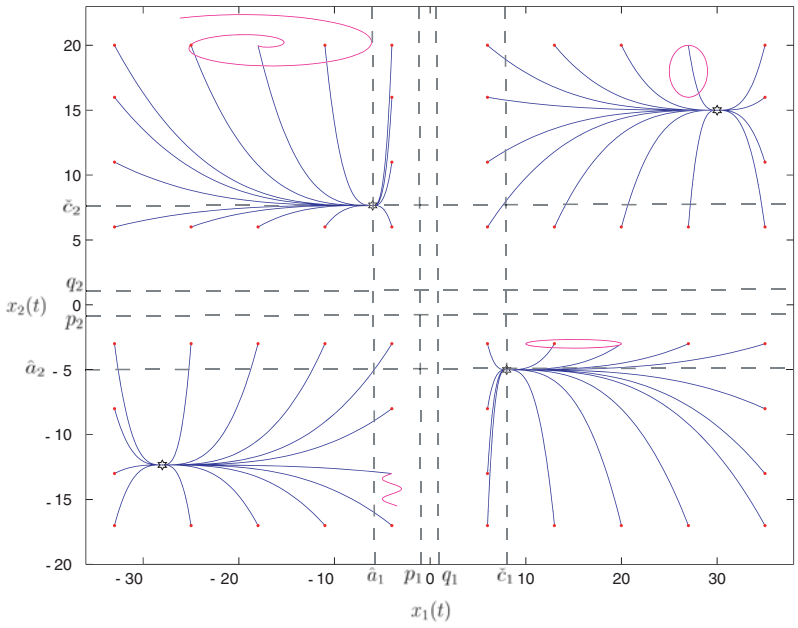

FIG. 8. *Illustrations for the dynamics in Example* 5.2.

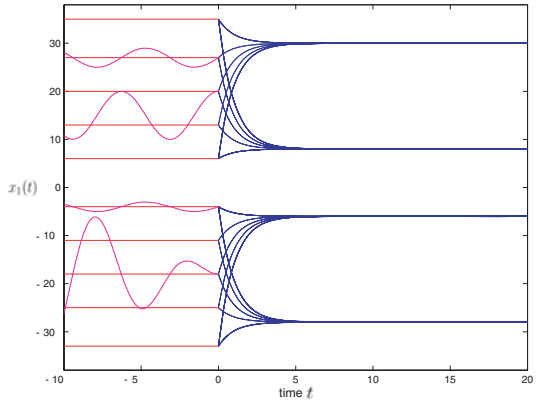

FIG. 9. *Evolution of state variable* $x_1(t)$ *in Example* 5.2.

6. Discussions. Our approach can also be adapted to the cellular neural networks with delays. The cellular neural networks (CNNs) were introduced by Chua and Yang [8] in 1988. A model called delayed cellular neural network [24] is given by

$$\frac{dx_i(t)}{dt} = -x_i(t) + \sum_{j\in N_r(i)} a_{ij}h(x_j(t)) + \sum_{j\in N_r(i)} b_{ij}h(x_j(t-\tau)) + J_i, \tag{6.1}$$

where $N_r(i) = \{i-1, i, i+1\}$ if $r = 1$. The standard activation function for such a network is the piecewise linear h defined in (5.1). Notably, (6.1) is a system of CNNs with cells coupled in the one-dimensional manner, and its local coupling structure is expressed in the equations. Global exponential stability of a single equilibrium for

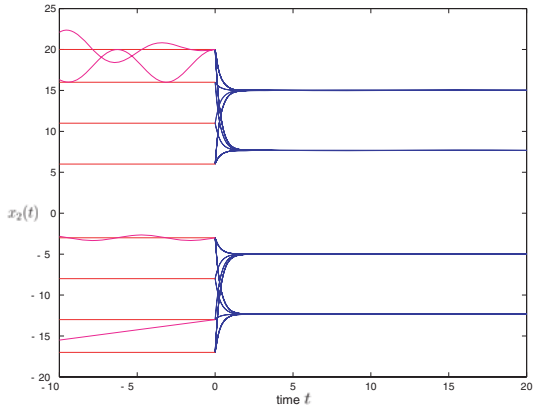

FIG. 10. *Evolution of state variable* $x_2(t)$ *in Example* 5.2.

(6.1) has been studied by many researchers, for instance, the authors of [3, 20]. The CNNs can be built by multidimensional couplings among cells. Since there are finitely many cells at most, the CNNs can always be rewritten in a one-dimensional coupling form by renaming the indices [28]. It can then be written in a form similar to (1.1). Such an arrangement, however, destroys the local connection representation. While previous studies on multistability for the CNNs without delays [17, 26, 27] employed the structure of local connections among cells of CNNs, our approach does not rely on such a structure. Moreover, our theory generalized the multistability to the CNNs with delays (6.1).

In this investigation, we have obtained existence of 2^n stable stationary solutions for recurrent neural networks comprised of n neurons, with delays and without delays. The theory is primarily based upon an observation on the structures of the equations. It is thus rather general and can be applied to at least the Hopfield-type neural networks and the cellular neural networks. The analysis is valid for the networks with various activation functions, including the typical sigmoidal ones and the saturated linear ones, as well as some unbounded activation functions. In fact, our formulation depends on the configuration of the activation functions instead of the precise form of the functions. The theorems thus developed are pertinent in neural network theory.

Stable periodic orbits and limit cycle attractors are also important for memory storage and other neural activities. By similar analysis, we can also establish existence of multiple limit cycles for systems (1.1) and (6.1) with periodic inputs $J_i = J_i(t) = J_i(t + T)$. The result will be reported in another article. The approach in this presentation can be adopted to discrete-time neural networks as well.

The major discussions on neural networks have been centered around monostability, in an abundance of articles in the areas of physics, information sciences, electrical engineering, and mathematics. Multistability in neural networks is, however, essential in numerous applications such as content-addressable memory storage and pattern recognition. Recently, further application potentials of multistability have been found in decision making, digital selection, and analogy amplification [18].

We have exploited further interesting structures of Hopfield-type neural networks in this study. Our investigations have provided computable parameter conditions for multistable dynamics in the recurrent neural networks and are expected to contribute toward practical applications.

Acknowledgment. The authors are grateful to the reviewers for their suggestions on improving the presentation.

MULTIPLE EQUILIBRIA IN COMPLEX CHEMICAL REACTION NETWORKS: II. THE SPECIES-REACTION GRAPH*

GHEORGHE CRACIUN† AND MARTIN FEINBERG‡

Abstract. For mass action kinetics, the capacity for multiple equilibria in an isothermal homogeneous continuous flow stirred tank reactor is determined by the structure of the underlying network of chemical reactions. We suggest a new graph-theoretical method for discriminating between complex reaction networks that can admit multiple equilibria and those that cannot. In particular, we associate with each network a species-reaction graph, which is similar to reaction network representations drawn by biochemists, and we show that, if the graph satisfies certain weak conditions, the differential equations corresponding to the network cannot admit multiple equilibria *no matter what values the rate constants take*. Because these conditions are very mild, they amount to powerful (and quite delicate) necessary conditions that a network must satisfy if it is to have the capacity to engender multiple equilibria. Broad qualitative results of this kind are especially apt, for individual reaction rate constants are rarely known fully for complex reaction networks (if they are known at all). Some concluding remarks address connections to biology.

Key words. equilibrium points, chemical reaction networks, mass action kinetics, SR graph

1. Introduction.

The purpose of this article is to provide theory for distinguishing between complex chemical reaction networks that have the capacity to admit multiple positive equilibria and those that do not. In particular, we shall be interested in networks governed by mass action kinetics and operating in the context of what chemical engineers call the continuous flow stirred tank reactor (CFSTR [1]). Models in cell biology sometimes invoke pictures and mathematics reminiscent of CFSTRs [9, 12, 17, 14], so it not unreasonable to expect that theory presented here might ultimately provide insight that is useful in biological applications. Indeed, in biology one rarely has detailed knowledge of reaction rate constants; at the outset, then, it is especially appropriate to seek a *qualitative* understanding of the relationship between reaction network structure and the capacity for various kinds of behavior (e.g., bistability). As we indicated in the first article of this series [4], the connection between the two is quite delicate. The theory offered here is intended to render the relationship between reaction network structure and behavior more concrete.

Our principal results will serve to describe very large classes of networks, including highly complex ones, that cannot give rise to multiple steady states regardless of parameter values. These results provide very strong necessary conditions that a network must satisfy if it is to have the capacity to give rise, for example, to bistable behavior.

Denial of the capacity of a reaction network to admit multiple equilibria follows from inspection of what we call the Species-Reaction Graph (or SR graph [3]) for the network, which is similar to the reaction diagram often drawn by biochemists. Properties of the SR graph and results about it are similar to those in earlier work [8, 15, 16] on properties of a related graph, called the Species-Complex-Linkage Graph (or SCL graph). However, the newer results presented here are substantially more generous in the information they give. Inspection of the SR graph often tells one very quickly that the network under study is, in the sense of a previous article [4], *injective*, which in turn implies that multiple positive equilibria are impossible. That is, inspection of the SR graph for a reaction network will often tell one that the complex nonlinear system of differential equations associated with the network cannot admit multiple positive equilibria, no matter what values the (generally unknown) parameter values might take.

Our aim in this introductory section is to present, in an informal way, the main theorem of this article, largely motivated by a single example. More formal definitions are given in section 2, which will prepare the groundwork for proofs.

A CFSTR consists of a perfectly stirred vessel along with two streams, a feed stream that carries reactants to the vessel and an outflow stream that leaves the vessel, carrying away mixture having the same instantaneous composition as that within the vessel. Hereafter we suppose that the mixtures involved are liquids, all of which have the same time-invariant density, that the mixture within the vessel is maintained at a fixed temperature, and that the feed and outflow streams have the same volumetric flow rate, g (volume/time). For the purposes of an example, we will suppose that (1.1) is a network of chemical reactions among species A, B, M, N, R, X, Y, and Z:

$$A + M \rightleftharpoons X, \quad B + N \rightleftharpoons Y \to 2A + N, \quad B + X \rightleftharpoons Z \to R + M. \tag{1.1}$$

By virtue of the occurrence of chemical reactions, the molar concentrations of the various species within the vessel will generally depend on time. These we denote by $c_A(t), c_B(t), \ldots, c_Z(t)$, which, by supposition, are identical to the species concentrations in the outflow stream. We denote by $c_A^f, c_B^f, \ldots, c_Z^f$ the (fixed) concentrations of the species in the feed stream. We assume hereafter that the rates of the chemical reactions are governed by mass action kinetics [4, 6, 7, 10, 11]. In this case, the system of differential equations associated with network (1.1) is the following:

$$\begin{aligned}
\dot{c}_A &= (g/V)(c_A^f - c_A) - k_{A+M\to X}c_Ac_M + k_{X\to A+M}c_X + 2k_{Y\to 2A+N}c_Y,\\
\dot{c}_B &= (g/V)(c_B^f - c_B) - k_{B+X\to Z}c_Bc_X + k_{Z\to B+X}c_Z + k_{Y\to B+N}c_Y\\
&\quad - k_{B+N\to Y}c_Bc_N,\\
\dot{c}_M &= (g/V)(c_M^f - c_M) - k_{A+M\to X}c_Ac_M + k_{X\to A+M}c_X + k_{Z\to R+M}c_Z,\\
\dot{c}_N &= (g/V)(c_N^f - c_N) - k_{B+N\to Y}c_Bc_N + k_{Y\to B+N}c_Y + k_{Y\to 2A+N}c_Y,\\
\dot{c}_R &= (g/V)(c_R^f - c_R) + k_{Z\to R+M}c_Z,\\
\dot{c}_X &= (g/V)(c_X^f - c_X) - k_{X\to A+M}c_X + k_{A+M\to X}c_Ac_M - k_{B+X\to Z}c_Bc_X\\
&\quad + k_{Z\to B+X}c_Z,\\
\dot{c}_Y &= (g/V)(c_Y^f - c_Y) - k_{Y\to B+N}c_Y + k_{B+N\to Y}c_Bc_N - k_{Y\to 2A+N}c_Y,\\
\dot{c}_Z &= (g/V)(c_Z^f - c_Z) + k_{B+X\to Z}c_Bc_X - k_{Z\to B+X}c_Z - k_{Z\to R+M}c_Z,
\end{aligned} \tag{1.2}$$

where g is the volumetric flow rate (volume/time), V is the reactor volume, $k_{A+M\to X}$ is the rate constant of the reaction $A + M \to X$, $k_{X\to A+M}$ is the rate constant of the

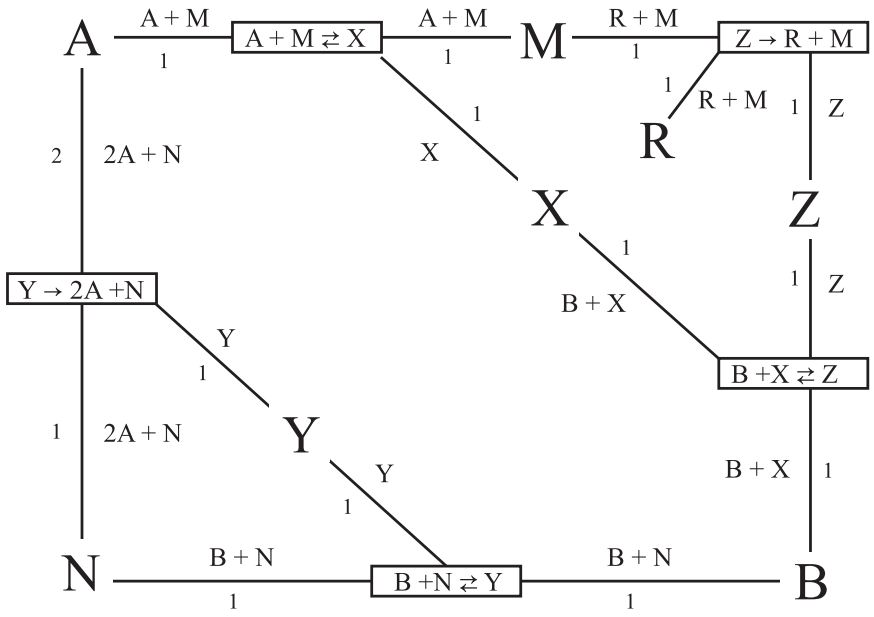

FIG. 1.1. *The SR graph* Γ *of the reaction network* (1.1).

reaction $X \to A + M$, and so on. See [4, 6] for a detailed explanation of how, given a reaction network, we obtain such a system of differential equations.

We say that the reaction network (1.1) *has the capacity for multiple positive equilibria* if there exist some positive flow rate g, positive volume V, nonnegative feed concentrations $c_A^f, \ldots, c_Z^f$, and positive rate constants $k_{A+M\to X}, \ldots, k_{Z\to R+M}$ such that the system of differential equations (1.2) has two or more distinct equilibria at which the species concentrations are positive.

In preparation for a description of how to draw the SR graph for a reaction network, we need a little vocabulary: By the *complexes* [10] of a reaction network we mean the objects at the heads and tails of the reaction arrows. Thus, the complexes of network (1.1) are $A + B$, X, $B + N$, Y, $2A + N$, $B + X$, Z, and $R + M$.

The SR graph for a reaction network has two kinds of nodes: *species nodes* and *reaction nodes*. There is a species node for each species in the network (A, B, M, N, R, Y, and Z in (1.1)). Moreover, there is a reaction node for each reaction or reversible reaction pair in the network. That is, reversible reactions such as $A + M \rightleftharpoons X$ share the same node. *Edges* join species nodes to reaction nodes as follows: If a species (such as A) appears in a complex (such as $A + M$) at the head or tail of a reaction (such as $A + M \rightleftharpoons X$), then an (unoriented) edge joins the species node to the reaction node and is *labeled* with the name of the complex in which that species appears. (Thus, for example, an edge would join the species node corresponding to A to the reaction node corresponding to $A + M \rightleftharpoons X$, and the edge would be labeled $A + M$.) The SR graph for network (1.1) is shown in Figure 1.1.

We now need to define some features of SR graphs that are especially relevant to our problem. Pairs of edges that meet at a reaction node and have the same complex label are called *c-pairs* (complex pairs). For example, the two edges labeled $A + M$ that meet at the reaction node $A + M \rightleftharpoons X$ in Figure 1.1 form a c-pair.

Notice that *cycles* might appear in the SR graph. Cycles that contain an odd

number of c-pairs are called *o-cycles* (odd cycles). For example, the outer cycle in Figure 1.1 is an o-cycle, since it contains three c-pairs, centered at the reaction nodes $A + M \rightleftharpoons X$, $B + N \rightleftharpoons Y$, and $Y \to 2A + N$. Cycles that contain an even number of c-pairs are called *e-cycles* (even cycles). In particular, cycles that contain no c-pairs are e-cycles.

The *stoichiometric coefficient* of an edge is the coefficient of the species adjacent to that edge in the complex label of the edge. For the reader's convenience, we have labeled each edge of the SR graph in Figure 1.1 with its stoichiometric coefficient. For example, the stoichiometric coefficient of the edge from A to $A + M \rightleftharpoons X$ in Figure 1.1 is 1, and the stoichiometric coefficient of the edge from A to $Y \to 2A + N$ is 2. Cycles for which alternately multiplying and dividing the stoichiometric coefficients along the cycle gives the final result 1 are called *s-cycles* (stoichiometric cycles). For example, for the outer cycle that begins at A and visits N, B, Z M, the stoichiometric coefficients along the cycle are $2, 1, 1, 1, 1, 1, 1, 1, 1$ (see Figure 1.1). Then, by alternately multiplying and dividing the stoichiometric coefficients along the cycle, we get $2 \cdot 1^{-1} \cdot 1 \cdot 1^{-1} \cdot 1 \cdot 1^{-1} \cdot 1 \cdot 1^{-1} \cdot 1 \cdot 1^{-1} = 2$, and thus this cycle is not an s-cycle. On the other hand, for the cycle that visits N, Y we get $1 \cdot 1^{-1} \cdot 1 \cdot 1^{-1} = 1$, and thus this cycle is an s-cycle.

We say that two cycles in the SR graph *have a species-to-reaction (S-to-R) intersection* if the common edges of the two cycles constitute a path that begins at a species node and ends at a reaction node, or if they constitute a disjoint union of such paths.

For example, the common edges of the cycle that visits N, Y with the cycle that visits A, X, B, Y in Figure 1.1 form a path that begins at a reaction node and ends at a reaction node, and so they do *not* have an S-to-R intersection.

Then the main result of this article is the following.

THEOREM 1.1. *Consider a reaction network such that in its SR graph*

(i) *each cycle is an o-cycle or an s-cycle,*

(ii) *no two e-cycles have an S-to-R intersection.*

Then, taken with mass action kinetics, the reaction network does not have the capacity for multiple positive equilibria.

In particular, the theorem above implies that the reaction network (1.1) does not have the capacity for multiple equilibria. Indeed, all cycles in the SR graph of (1.1) are o-cycles, except for two cycles (the cycle that visits N, Y and the cycle that visits M, Z, X), which are s-cycles, and so condition (i) is satisfied. Also, these two e-cycles do not have an S-to-R intersection, so condition (ii) is satisfied. On the other hand, previous results in [8, 15, 16] give no information about network (1.1).

In general, if there are no cycles in the SR graph, or if all cycles are o-cycles, then conditions (i) and (ii) are satisfied. Or, if all stoichiometric coefficients in a network are one, then all cycles are s-cycles, and so condition (i) is satisfied. Also, if no species node is adjacent to three or more reaction nodes, then no two cycles have an S-to-R intersection, and so condition (ii) is satisfied. Note then that for some reaction networks it is not even necessary to draw the SR graph in order to conclude that they do not have the capacity for multiple equilibria: If all the stoichiometric coefficients are one and no species appears in three or more reactions, then the reaction network does not have the capacity for multiple equilibria. For example, if we replace $2A + N$ by $A + N$ in (1.1), then the new reaction network has all stoichiometric coefficients equal to one, and no species appears in three or more reactions. Therefore, without having to draw its SR graph, it follows that this new reaction network does not have the capacity for multiple equilibria.

In the next section we begin our proof of Theorem 1.1. In particular, we will eventually want to connect the SR graph to network *injectivity*, an idea introduced in [4].

2. Reaction networks and injectivity. Let us first give a precise definition of a reaction network in terms of the set of species, the set of complexes, and the set of reactions. Recall that the *complexes* of a reaction network are to be understood as the objects at the head or tail of reaction arrows. We denote by $\mathbb{R}$ the set of real numbers, by $\mathbb{R}_+$ the set of positive numbers, and by $\bar{\mathbb{R}}_+$ the set of nonnegative numbers. Also, given a set I, we denote by $\mathbb{R}^I$ the vector space of formal linear combinations $\sum_{i\in I}\lambda_i i$, generated by the elements of $i \in I$, with coefficients $\lambda_i \in \mathbb{R}$. By $\bar{\mathbb{R}}^I_+$ we mean the members of $\mathbb{R}^I$ with $\lambda_i \geq 0$ for all $i \in I$. By $\mathbb{R}^I_+$ we mean the members of $\mathbb{R}^I$ with $\lambda_i > 0$ for all $i \in I$. By the *support* of an element $x \in \mathbb{R}^I_+$ we mean the set $\operatorname{supp}(x) = \{i \in I :\ x_i \neq 0\}$.

As in [4], we can regard a chemical reaction network as an abstract structure given by the following definition.

DEFINITION 2.1 (see [6, 7]). *A* chemical reaction network $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$ *consists of three finite sets:*

(i) *a set* $\mathscr{S}$ *of* species *of the network,*
(ii) *a set* $\mathscr{C} \subset \bar{\mathbb{R}}^{\mathscr{S}}_+$ *of* complexes *of the network,*
(iii) *a set* $\mathscr{R} \subset \mathscr{C} \times \mathscr{C}$ *of* reactions*, with the following properties:*
  (a) $(y, y) \notin \mathscr{R}$ *for any* $y \in \mathscr{C}$*,*
  (b) *for each* $y \in \mathscr{C}$ *there exists* $y' \in \mathscr{C}$ *such that* $(y, y') \in \mathscr{R}$ *or such that* $(y', y) \in \mathscr{R}$*.*

We write the more suggestive $y \to y'$ in place of (y, y') when (y, y') is a member of $\mathscr{R}$. Also, if $\{y \to y',\ y' \to y\} \subset \mathscr{R}$, we will denote the set $\{y \to y',\ y' \to y\}$ by the more suggestive $y \rightleftharpoons y'$ and will say that $y \rightleftharpoons y'$ is a *reversible reaction.* If $y \to y' \in \mathscr{R}$ and $y' \to y \notin \mathscr{R}$, we say that $y \to y'$ is an *irreversible reaction.* For example, consider the reaction network

$$A + B \rightleftharpoons C, \qquad A \to 2B. \tag{2.1}$$

In this case $\mathscr{S} = \{A, B, C\}$, $\mathscr{C} = \{A + B, C, A, 2B\}$, $\mathscr{R} = \{A + B \to C,\ C \to A + B,\ A \to 2B\}$.

DEFINITION 2.2. *By a* mass action system *we mean a reaction network* $(\mathscr{S}, \mathscr{C}, \mathscr{R})$ *taken together with an element* $k \in \mathbb{R}^{\mathscr{R}}_+$*. The number* $k_{y\to y'}$ *is the* rate constant *for the reaction* $y \to y'$*.*

In the next definition we use the following notation: for two vectors in $\bar{\mathbb{R}}^{\mathscr{S}}_+$, say $u = \sum_{s\in\mathscr{S}} u_s s$ and $v = \sum_{s\in\mathscr{S}} v_s s$, we denote by u^v the product $\prod_{s\in\mathscr{S}}(u_s)^{v_s}$. Here we use the convention that $0^0 = 1$.

Our aim now is to write the differential equation that, for a mass action system, governs the evolution of composition vector $c \in \bar{\mathbb{R}}^{\mathscr{S}}_+$.

DEFINITION 2.3. *For a mass action system* $(\mathscr{S}, \mathscr{C}, \mathscr{R}, k)$ *the associated differential equation is*

$$\dot{c} = \sum_{y\to y'\in\mathscr{R}} k_{y\to y'} c^y (y' - y). \tag{2.2}$$

In components, the differential equations associated with a mass action system derived from network (2.1) are

$$\begin{aligned}\dot{c}_A &= -k_{A+B\to C}c_Ac_B - k_{A\to 2B}c_A + k_{C\to A+B}c_C,\\ \dot{c}_B &= -k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C + 2k_{A\to 2B}c_A,\\ \dot{c}_C &= k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C.\end{aligned} \tag{2.3}$$

Note that these are not the differential equations one would write for a CFSTR, for they take no account of the effects of the feed and outflow streams. The appropriate CFSTR differential equations are

$$\begin{aligned}\dot{c}_A &= (g/V)(c_A^f - c_A) - k_{A+B\to C}c_Ac_B - k_{A\to 2B}c_A + k_{C\to A+B}c_C,\\ \dot{c}_B &= (g/V)(c_B^f - c_B) - k_{A+B\to C}c_Ac_B + k_{C\to A+B}c_C + 2k_{A\to 2B}c_A,\\ \dot{c}_C &= (g/V)(c_C^f - c_C) + k_{A+B\to C}c_Ac_B - k_{C\to A+B}c_C.\end{aligned} \tag{2.4}$$

As we indicated in [4], however, the appropriate CFSTR equations *do* derive from a mass action system associated with the augmented network

$$A + B \rightleftharpoons C,\ A \to 2B,\ 0 \to A,\ 0 \to B,\ 0 \to C,\ A \to 0,\ B \to 0,\ C \to 0. \tag{2.5}$$

Here 0 is the *zero complex*, which is understood to be the zero vector of $\bar{\mathbb{R}}_+^{\mathscr{S}}$. As explained in [4], the added *outflow reactions* $A \to 0$, $B \to 0$, and $C \to 0$ serve to model the contributions of the outflow stream to the CFSTR differential equations (taking each rate constant to be g/V), while the *feed reactions* $0 \to A$, $0 \to B$, and $0 \to C$ serve to model the contributions of the feed stream (taking the rate constants to be, respectively, gc_A^f/V, gc_B^f/V, and gc_C^f/V).

In general, to obtain the augmented network, one adds to the network of true chemical reactions an outflow reaction $s \to 0$ for each $s \in \mathscr{S}$, and a feed reaction $0 \to s$ for each species s deemed to be in the feed stream. *Hereafter, when we speak of a reaction network $(\mathscr{S},\mathscr{C},\mathscr{R})$, it will be understood that we have in mind the augmented network constructed to generate the CFSTR differential equations. In particular, the full set of reactions $\mathscr{R}$ will contain the "true" set of chemical reactions (denoted $\mathscr{R}_t$) and a reaction $s \to 0$ for each $s \in \mathscr{S}$.*

DEFINITION 2.4. *A reaction network $(\mathscr{S},\mathscr{C},\mathscr{R})$* has the capacity to admit multiple positive equilibria *if there is a $k \in \mathbb{R}_+^{\mathscr{R}}$ such that, for the mass action system $(\mathscr{S},\mathscr{C},\mathscr{R},k)$, the associated differential equation admits two distinct equilibria in $\mathbb{R}_+^{\mathscr{S}}$.*

Remark. Our aim will be to describe networks that do *not* have the capacity for multiple positive equilibria. For our study of classical CFSTRs this is apparently a little more than we need: In Definition 2.4, we permit the rate constants associated with the outflow reactions (i.e., reactions of the form $s \to 0$ for all $s \in \mathscr{S}$) to take arbitrary positive values, while for the classical CFSTRs such rate constants should all be identical (and equal to g/V).

We are interested in what we call *injective* reaction networks because *injective reaction networks do not have the capacity for multiple positive equilibria* (see [4]). The characterization of injectivity we use here is the one given by Theorem 3.3 in [4].

DEFINITION 2.5. *A reaction network $\mathcal{N} = (\mathscr{S},\mathscr{C},\mathscr{R})$ with n species is* injective *if*

$$\det(y_1,\dots,y_n)\det(y_1 - y_1',\dots,y_n - y_n') \geq 0$$

for all choices of reactions[1] *$y_1 \to y_1',\dots,y_n \to y_n'$ in $\mathscr{R}$.*

[1] Some of these reactions could be feed or outflow reactions.

Therefore, we need to study the relationship between the signs of $\det(y_1, \dots, y_n)$ and $\det(y_1 - y_1', \dots, y_n - y_n')$. For this, our main tool will be the SR graph.

3. The SR graph.

DEFINITION 3.1. *Consider some reaction network* $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$. *The* SR graph $\Gamma_{\mathcal{N}}$ *of* $\mathcal{N}$ *is an unoriented graph defined as follows. Each node of* $\Gamma_{\mathcal{N}}$ *is either a* species node *or a* reaction node. *There is one species node for each species in* $\mathscr{S}$. *There is one reaction node for each reversible reaction in* $\mathscr{R}_t$, *and there is one reaction node for each irreversible reaction in* $\mathscr{R}_t$.[2] *Each edge in the graph* $\Gamma_{\mathcal{N}}$ *connects a species node to a reaction node (so* $\Gamma_{\mathcal{N}}$ *is a bipartite graph) according to the following prescription: Consider a species node* s *and a reaction node* r *given by* $y \to y'$ *or* $y \rightleftharpoons y'$. *If* $s \in \operatorname{supp}(y)$, *then there is an edge between* s *and* r *and we* label *it with the complex* y. *Similarly, if* $s \in \operatorname{supp}(y')$, *then there is an edge*[3] *between* s *and* r *and we* label *it with the complex* y'.

For example, for the reaction network (2.1) there are three species nodes and two reaction nodes, and we get the SR graph in Figure 3.1.

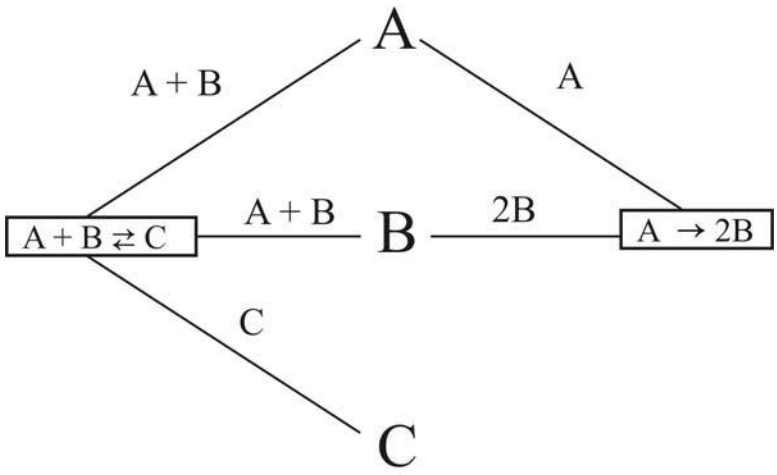

FIG. 3.1. *The SR graph of reaction network* (2.1).

In an SR graph there are some configurations of edges and cycles that are especially important to us. The following definition describes them.

DEFINITION 3.2. *Consider the SR graph* $\Gamma_{\mathcal{N}}$ *of some reaction network* $\mathcal{N}$. *A pair of edges in* $\Gamma_{\mathcal{N}}$ *that meet at a reaction node and have the same complex label is called a* c-pair. *A cycle that contains an odd number of c-pairs is called an* o-cycle. *A cycle that contains an even number of c-pairs is called an* e-cycle. *The* stoichiometric coefficient *of an edge is the coefficient of the species adjacent to that edge in the complex label of the edge. An* s-cycle *is one for which, if we alternately multiply and divide the stoichiometric coefficients of edges along the cycle, we get the final result* 1. *An* S-to-R chain *in an SR graph is a simple path from a species node*

[2]Recall that $\mathscr{R}_t$ is the set of true chemical reactions—that is, the set of reactions before the addition of reactions such as $s \to 0$ or $0 \to s$.

[3]If s is contained in both $\operatorname{supp}(y)$ and $\operatorname{supp}(y')$ (as in $A + B \to 2A$), then there are two edges joining the species node s to the reaction node $y \to y'$, one carrying the label y and the other carrying the label y'.

to a reaction node. We say that two cycles in $\Gamma_{\mathcal{N}}$ have an S-to-R intersection *if their common edges constitute an S-to-R chain or a disjoint union of two or more S-to-R chains.*

Recall that we gave another example of an SR graph in section 1.

4. The OSR graph. In this section we define the *oriented species-reaction graph (OSR graph)*, which will be the main tool for proving the results in the rest of this article. For this and the next section, we consider a fixed reaction network $\mathcal{N} = (\mathscr{S}, \mathscr{C}, \mathscr{R})$. Recall that any complex y in $\mathscr{C}$ is a linear combination $y = \sum_{s\in\mathscr{S}} y_s s$, where $y_s \geq 0$ for all $s \in \mathscr{S}$. Recall too that the *support* of y is defined by $\text{supp}(y) = \{s \in \mathscr{S} : y_s > 0\}$. In view of our interest in network injectivity (Definition 2.5), we consider a fixed ordered set of reactions[4] $R = \{y_1 \to y_1', \ldots, y_n \to y_n'\} \subset \mathscr{R}$, where n is the number of species for the network $\mathcal{N}$. *We seek to determine the conditions under which the product*

$$\det(y_1, \ldots, y_n) \det(y_1 - y_1', \ldots, y_n - y_n')$$

is positive when it is not zero. Hereafter, then, we assume that, for the ordered set of reactions R under consideration, the product above is not zero.

In this case the complexes $y_1, \ldots, y_n$ are linearly independent vectors. Then it is not difficult to see that one can make a bijective association between the n species of the network $\mathcal{N}$ and the n complexes $y_1, \ldots, y_n$, which associates with each complex a particular species in its support. In other words, there exists a (not necessarily unique) bijection $f : \{y_1, \ldots, y_n\} \to \mathscr{S}$ such that $f(y_i) \in \text{supp}(y_i)$, $i = 1, 2, \ldots, n$.

Hereafter, we choose one such bijection and denote by e_i the species $f(y_i)$. Thus, the set of species of the network $\mathcal{N}$ becomes $\{e_1, \ldots, e_n\}$, and we have $e_i \in \text{supp}(y_i)$, $i = 1, 2, \ldots, n$. For the sake of concreteness, we suppose that the determinant function is such that $\det(e_1, \ldots, e_n) > 0$. (In what follows, some readers might wish to associate $\{e_1, \ldots, e_n\}$ with the standard basis of $\mathbb{R}^n$, in which case the complexes $y_1, \ldots, y_n$ would be associated with vectors in $\mathbb{R}^n$.)

DEFINITION 4.1. *The* OSR graph of R *is an oriented graph* $\mathcal{G}_R$*, defined as follows. The set of nodes of* $\mathcal{G}_R$ *is* $\mathscr{S} \cup (R \cap \mathscr{R}_t)$*. The nodes in* $\mathscr{S}$ *are called* species nodes*, and the nodes in* $R \cap \mathscr{R}_t$ *are called* reaction nodes*. Each (oriented) edge in the graph* $\mathcal{G}_R$ *connects a species node to a reaction node or a reaction node to a species node in the following way. Consider some true reaction* $y_j \to y_j'$*. There is exactly one incoming edge toward the node* $y_j \to y_j'$ *in* $\mathcal{G}_R$*, and it comes from the node of the species* e_j*. We label this edge with the complex* y_j*. There is one outgoing edge from the reaction node* $y_j \to y_j'$ *toward each species node* $e_i \in \text{supp}(y_j)$*, except for* e_j*. We label these edges with the complex* y_j *as well. There is one outgoing edge from the reaction node* $y_j \to y_j'$ *toward each species node* $e_i \in \text{supp}(y_j')$*. We label these edges with the complex* y_j'*.*

For example, if in the reaction network (2.1) we choose the reactions that make up the set R to be $y_1 \to y_1' = A \to 2B$, $y_2 \to y_2' = A + B \to C$, $y_3 \to y_3' = C \to 0$ and we identify A, B, C with e_1, e_2, e_3, then we get the OSR graph in Figure 4.1.

Since the OSR graph is defined similarly to the SR graph, we can also refer to s-cycles, o-cycles, and e-cycles in the OSR graph, their definitions being analogous to those in the SR graph. However, whenever we mention a cycle in an OSR graph, that cycle *will have to be an oriented cycle.* In particular, the s-cycles, o-cycles, and e-cycles in an OSR graph have to be oriented cycles, and a c-pair has to be an oriented

[4]Some of these reactions might be outflow reactions.

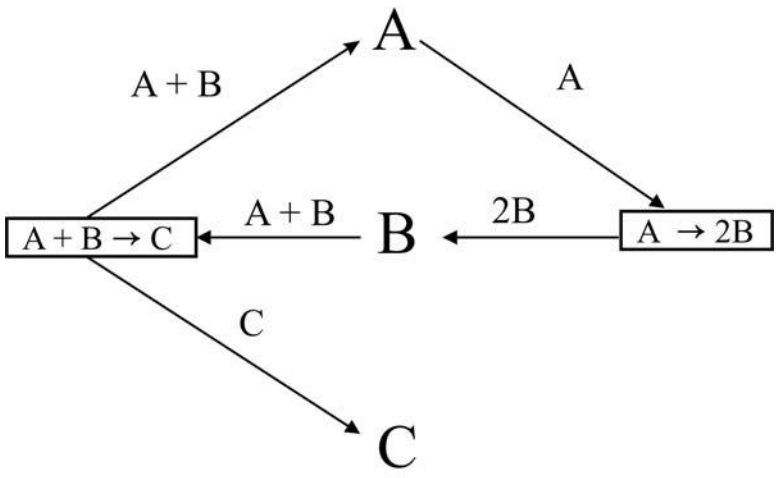

FIG. 4.1. *An OSR graph for some reactions in* (2.1).

pair of edges as well (i.e., one of the two adjacent edges that form a c-pair should point toward their common reaction vertex, and the other should point away from their common reaction vertex).

Remark. Note that each (oriented) edge in the OSR graph $\mathcal{G}_R$, connecting some species node and some reaction node, corresponds uniquely to some (unoriented) edge in the SR graph $\Gamma_{\mathcal{N}}$ of $\mathcal{N}$ connecting the same species node to the corresponding reaction node in $\Gamma_{\mathcal{N}}$, and has the same complex label. In other words, the OSR graph $\mathcal{G}_R$ is an (oriented) subgraph of the SR graph $\Gamma_{\mathcal{N}}$.

Remark. Suppose that R contains only outflow reactions, i.e., $R = \{A_1 \to 0, \ldots, A_n \to 0\}$. Then the OSR graph G_R has n species vertices, has *no reaction vertices*, and has *no edges*.

5. Properties of the OSR graph. To be able to formulate properties of the OSR graph we first need to introduce more definitions and notation.

Note that, for each $y_i \to y_i' \in R$, the complex y_i has a decomposition of the form

$$y_i = \sum_{e_k \in \mathrm{supp}(y_i)} y_{ik} e_k,$$

which defines numbers $y_{ik} > 0$. In particular, recall that $e_i \in \mathrm{supp}(y_i)$; i.e., we obtain $y_{ii} > 0$.

In view of Definition 2.5, we will now define a special multilinear expansion of $\det(y_1 - y_1', \ldots, y_n - y_n')$. For each $y_i \to y_i' \in R$ the vector $y_i - y_i'$ has a decomposition of the form

$$y_i - y_i' = \sum_{e_k \in \mathrm{supp}(y_i)} y_{ik} e_k - \sum_{e_k \in \mathrm{supp}(y_i')} y_{ik}' e_k,$$

where $y_{ik} > 0$ were mentioned above. We want now to consider the multilinear expansion of $\det(y_1 - y_1', \ldots, y_n - y_n')$ obtained by expanding each $y_i - y_i'$ in terms of the basis elements $e_1, \ldots, e_n$, with one exception: If $\mathrm{supp}(y_i) \cap \mathrm{supp}(y_i') \neq \emptyset$ for some i (as in a reaction of the form $A + B \to 2A$), we *do not* want to confuse

the contribution of y_i with the contribution of y'_i. For this reason, we represent the multilinear expansion of $\det(y_1 - y'_1, \ldots, y_n - y'_n)$ as the sum of all terms of the form

$$\det(\delta_{1k_1} e_{k_1}, \ldots, \delta_{nk_n} e_{k_n}),$$

where $e_{k_1} \in \mathrm{supp}(y_1) \cup \mathrm{supp}(y'_1), \ldots, e_{k_n} \in \mathrm{supp}(y_n) \cup \mathrm{supp}(y'_n)$, and

$$\delta_{ik_i} = \begin{cases} y_{ik_i} & \text{if } e_{k_i} \in \mathrm{supp}(y_i) \backslash \mathrm{supp}(y'_i), \\ -y'_{ik_i} & \text{if } e_{k_i} \in \mathrm{supp}(y'_i) \backslash \mathrm{supp}(y_i), \\ \text{either } y_{ik_i} \text{ or } -y'_{ik_i} & \text{if } e_{k_i} \in \mathrm{supp}(y_i) \cap \mathrm{supp}(y'_i). \end{cases}$$

DEFINITION 5.1. *By a* term in the expansion of the determinant $\det(y_1 - y'_1, \ldots, y_n - y'_n)$ *we mean a term in the multilinear expansion of* $\det(y_1 - y'_1, \ldots, y_n - y'_n)$ *described above.*

Note that a term might have the value zero. We will describe an important relationship between *nonzero* terms in the expansion of $\det(y_1 - y'_1, \ldots, y_n - y'_n)$ and the graph $\mathcal{G}_R$. Let us denote by Δ the term $\det(y_{11}e_1, \ldots, y_{nn}e_n)$. Of course, Δ is a (nonzero) term in the expansion of $\det(y_1 - y'_1, \ldots, y_n - y'_n)$ in the sense of the previous definition. Suppose that there is an edge ε in $\mathcal{G}_R$ from the reaction node $y_i \to y'_i$ to some species node e_k and having the complex label y_i. Let us denote by Δ_ε the result of replacing $y_{ii}e_i$ by $y_{ik}e_k$ in Δ and leaving everything else unchanged. Note that, according to the definition above, Δ_ε *is a (zero-valued) term in the expansion of* $\det(y_1 - y'_1, \ldots, y_n - y'_n)$. Similarly, suppose there is an edge ε' in $\mathcal{G}_R$ from the reaction node $y_i \to y'_i$ to some species node e_k and having the complex label y'_i. Let us denote by $\Delta_{\varepsilon'}$ the result of replacing $y_{ii}e_i$ by $-y'_{ik}e_k$ in Δ and leaving everything else unchanged. According to the definition above, $\Delta_{\varepsilon'}$ *is also a (zero-valued) term in the expansion of* $\det(y_1 - y'_1, \ldots, y_n - y'_n)$.

If L is a cycle in $\mathcal{G}_R$, let us denote by Δ_L the term resulting from making replacements in Δ as above, simultaneously for all edges in L that go from a reaction node to a species node. (See the example after the proof of the following lemma.) Then Δ_L is also a (nonzero) term in the expansion of $\det(y_1 - y'_1, \ldots, y_n - y'_n)$. If $\mathcal{L}$ is a set of disjoint cycles in $\mathcal{G}_R$, let us denote by $\Delta_\mathcal{L}$ the term resulting from making replacements in Δ as above, simultaneously for all edges in $\mathcal{L}$ that go from a reaction node to a species node. Then $\Delta_\mathcal{L}$ is also a (nonzero) term in the expansion of $\det(y_1 - y'_1, \ldots, y_n - y'_n)$. Lemma 5.1 will show that all nonzero terms in the expansion of $\det(y_1 - y'_1, \ldots, y_n - y'_n)$ are of the form $\Delta_\mathcal{L}$ for some set $\mathcal{L}$ of disjoint cycles in $\mathcal{G}_R$.

The case of $\det(y_1, \ldots, y_n)$ is similar, but simpler. We have

$$\det(y_1, \ldots, y_n) = \sum_{e_{k_1} \in \mathrm{supp}(y_1), \ldots, e_{k_n} \in \mathrm{supp}(y_n)} \det(y_{1k_1} e_{k_1}, \ldots, y_{nk_n} e_{k_n}),$$

and we state the following definition.

DEFINITION 5.2. *By a* term in the expansion of the determinant $\det(y_1, \ldots, y_n)$ *we mean a term in the multilinear expansion of* $\det(y_1, \ldots, y_n)$ *above.*

Note now that, according to the two definitions above, each term in the expansion of the determinant $\det(y_1, \ldots, y_n)$ is also a term in the expansion of the determinant $\det(y_1 - y'_1, \ldots, y_n - y'_n)$. Note also that Δ_ε defined as above is a term in the expansion of $\det(y_1, \ldots, y_n)$, since the complex label of ε is y_i, while $\Delta_{\varepsilon'}$ defined as above will not be a term in the expansion of $\det(y_1, \ldots, y_n)$, since the complex label of ε' is y'_i. Let us refer to edges similar to ε' as *product edges*. In other words, an edge ε' is a "product edge" if it is oriented from a reaction node $y_i \to y'_i$ to a species node, and

the complex label of the edge ε' is y'_i. Then, if a cycle L in $\mathcal{G}_R$ contains no product edges, Δ_L is also a (nonzero) term in the expansion of $\det(y_1, \dots, y_n)$. Similarly, if $\mathcal{L}$ is a set of disjoint cycles in $\mathcal{G}_R$ that contain no product edges, then $\Delta_{\mathcal{L}}$ is also a (nonzero) term in the expansion of $\det(y_1, \dots, y_n)$.

The following lemma associates with each nonzero term in the expansion of $\det(y_1 - y'_1, \dots, y_n - y'_n)$ a set of mutually disjoint cycles in the OSR graph $\mathcal{G}_R$, in a bijective way (also note the example after the proof).

LEMMA 5.1. *There is a bijective correspondence that associates with each nonzero term Δ_* in the expansion of $\det(y_1 - y'_1, \dots, y_n - y'_n)$ a set $\mathcal{L}$ of disjoint cycles in $\mathcal{G}_R$ such that $\Delta_* = \Delta_{\mathcal{L}}$. In particular, if $\mathbf{L}$ is the collection of all sets of mutually disjoint cycles in $\mathcal{G}_R$, we have*

$$\det(y_1 - y'_1, \dots, y_n - y'_n) = \sum_{\mathcal{L} \in \mathbf{L}} \Delta_{\mathcal{L}}.$$

Proof. Consider some nonzero term $\Delta_* = \det(\delta_{1k_1} e_{k_1}, \dots, \delta_{nk_n} e_{k_n})$ in the expansion of $\det(y_1 - y'_1, \dots, y_n - y'_n)$. Then $(k_1, k_2, \dots, k_n)$ is a permutation of the set $\{1, 2, \dots, n\}$. We denote this permutation by σ, i.e., $\sigma(i) = k_i$, $i = 1, \dots, na$. Recall that if $e_k \in \operatorname{supp}(y_i) \cup \operatorname{supp}(y'_i)$ and $i \neq k$, then there is an edge in $\mathcal{G}_R$ from the reaction node $y_i \to y'_i$ to the species node e_k. Also, recall that for any i there is an edge in $\mathcal{G}_R$ from the species node e_i to the reaction node $y_i \to y'_i$.

Suppose that the permutation σ has a cycle of length two, $\mathcal{C} = (ij)$, $i \neq j$. In this case $\delta_{ij} \neq 0$ and $\delta_{ji} \neq 0$. Then $e_j \in \operatorname{supp}(y_i) \cup \operatorname{supp}(y'_i)$ and $i \neq j$, so there is an edge in $\mathcal{G}_R$ from the reaction node $y_i \to y'_i$ to the species node e_j. Also, $e_i \in \operatorname{supp}(y_j) \cup \operatorname{supp}(y'_j)$ and $j \neq i$, so there is an edge in $\mathcal{G}_R$ from the reaction node $y_j \to y'_j$ to the species node e_i. These two edges together with the edge from e_i to $y_i \to y'_i$ and the edge from e_j to $y_j \to y'_j$ form an (oriented) cycle $L_{\mathcal{C}}$ of length four in $\mathcal{G}_R$. Also, note that $\Delta_{L_{\mathcal{C}}}$ is the same as Δ_* at its ith and jth entries. Similarly, with any other cycle $\mathcal{C}$ of σ of length k we associate an (oriented) cycle of length $2k$ in $\mathcal{G}_R$.

Then it is not difficult to see that we have $\Delta_* = \Delta_{\mathcal{L}}$, where $\mathcal{L}$ is the set of all cycles $L_{\mathcal{C}}$ with $\mathcal{C}$ a cycle of σ.

Finally, note that if we begin from some set $\mathcal{L}$ of disjoint cycles in $\mathcal{G}_R$, construct the term $\Delta_{\mathcal{L}}$, and then construct a set $\tilde{\mathcal{L}}$ of disjoint cycles in $\mathcal{G}_R$ from the term $\Delta_{\mathcal{L}}$, as described above, then $\mathcal{L} = \tilde{\mathcal{L}}$. This shows that the correspondence described above is bijective. ∎

Example. Consider the ordered set of five reactions

$$2A \to B, \quad A + B \to C, \quad C + D \to B + E, \quad D \to 2C, \quad E \to 0. \tag{5.1}$$

We identify the species sequence A, B, C, D, E with e_1, e_2, e_3, e_4, e_5. The corresponding OSR graph appears in Figure 5.1.

There are three oriented cycles: l_1, which passes through the species nodes A and B; l_2, which passes through the species nodes B and C; and l_3, which passes through the species nodes C and D.

We have $\det(y_1 - y'_1, \dots, y_5 - y'_5) = \det(2e_1 - e_2, e_1 + e_2 - e_3, e_3 + e_4 - e_2 - e_5, e_4 - 2e_3, e_5)$. The term $\det(y_{11}e_1, \dots, y_{nn}e_n)$ in the multilinear expansion of $\det(y_1 - y'_1, \dots, y_5 - y'_5)$ is in this case $\det(2e_1, e_2, e_3, e_4, e_5)$. This term equals $\Delta_\emptyset$; i.e., it corresponds to the set $\mathcal{L}$ of disjoint cycles being the empty set.

We will now check that there is a one-to-one correspondence between all other nonzero terms in the multilinear expansion of $\det(y_1 - y'_1, \dots, y_5 - y'_5)$ and nonempty sets of disjoint cycles in the OSR graph.

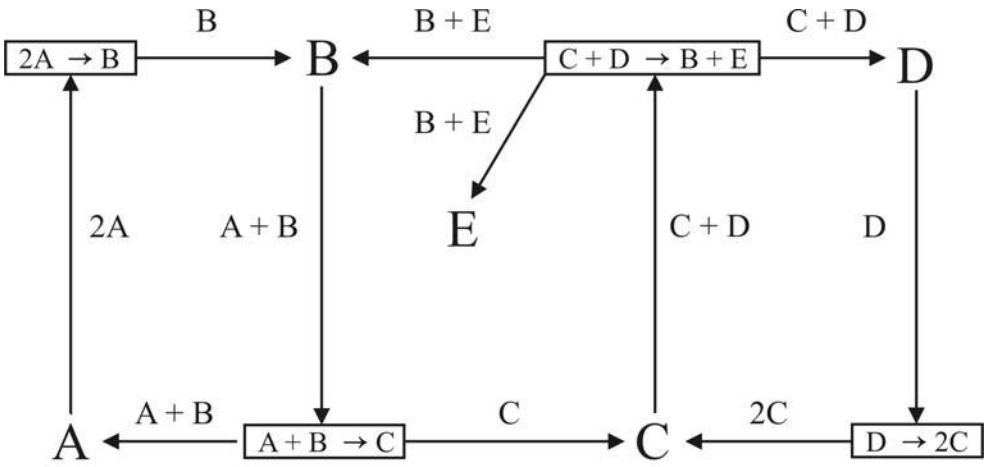

FIG. 5.1. *An OSR graph for the set of reactions* (5.1).

The cycle l_1 corresponds to replacing $2e_1$ in $\det(2e_1, e_2, e_3, e_4, e_5)$ by $-e_2$, and replacing e_2 in $\det(2e_1, e_2, e_3, e_4, e_5)$ by e_1, since the cycle l_1 visits the species node B after leaving A and visits the species node A after leaving B. The corresponding term in the multilinear expansion of $\det(y_1 - y_1', \ldots, y_5 - y_5')$ is therefore $\det(-e_2, e_1, e_3, e_4, e_5)$. Similarly, the cycle l_2 corresponds to replacing e_2 in $\det(2e_1, e_2, e_3, e_4, e_5)$ by $-e_3$, and replacing e_3 in $\det(2e_1, e_2, e_3, e_4, e_5)$ by $-e_2$, since the cycle l_2 visits the species node C after leaving B and visits the species node B after leaving C. The corresponding term in the multilinear expansion of $\det(y_1 - y_1', \ldots, y_5 - y_5')$ is therefore $\det(2e_1, -e_3, -e_2, e_4, e_5)$. Similarly, the cycle l_3 corresponds to the term $\det(2e_1, e_2, e_4, -2e_3, e_5)$. There is one more nonzero term in the expansion of $\det(y_1 - y_1', \ldots, y_5 - y_5')$. This term is $\det(-e_2, e_1, e_4, -2e_3, e_5)$, and it corresponds to the set $\{l_1, l_3\}$ of disjoint cycles.

To formulate an analogous lemma for $\det(y_1, \ldots, y_n)$ let us denote by $\mathbf{L}_{np}$ the collection of all sets of mutually disjoint cycles in $\mathcal{G}_R$ that have no product edges. Then we have the following result.

LEMMA 5.2. *There is a bijective correspondence that associates with each nonzero term* Δ_* *in the expansion of* $\det(y_1, \ldots, y_n)$ *a set* $\mathcal{L} \in \mathbf{L}_{np}$ *such that* $\Delta_* = \Delta_{\mathcal{L}_{np}}$. *In particular, we have*

$$\det(y_1, \ldots, y_n) = \sum_{\mathcal{L} \in \mathbf{L}_{np}} \Delta_{\mathcal{L}}.$$

Proof. The proof here is analogous to that of the previous lemma. ∎

Let us now look more closely at the connection between the SR graph and the OSR graph, as follows.

LEMMA 5.3. *If two (oriented) cycles* l_1 *and* l_2 *in* $\mathcal{G}_R$ *have a common vertex, then their (unoriented) versions* l_1^{SR} *and* l_2^{SR} *in* $\Gamma_{\mathcal{N}}$ *have an S-to-R intersection.*

Proof. Suppose that l_1 and l_2 have a species node s in common. Since they are oriented cycles, each one of them has to contain an outgoing edge from s. However, there is a unique outgoing edge adjacent to s in $\mathcal{G}_R$. Therefore that edge is common to the two cycles, and the corresponding edge in $\Gamma_{\mathcal{N}}$ is common to l_1^{SR} and l_2^{SR}. Analogously, if l_1 and l_2 have a reaction node r in common, each one of them has to

contain the unique incoming edge adjacent to r in $\mathcal{G}_R$. This shows that l_1^{SR} and l_2^{SR} have at least one edge in common.

Suppose now that we travel along the two cycles l_1 and l_2 in $\mathcal{G}_R$, beginning from some common edge and following the orientation of that edge. The first node where the two cycles separate from each other has to be a reaction node, since all species nodes have just one outgoing edge in $\mathcal{G}_R$. On the other hand, if we travel along the two cycles l_1 and l_2 in $\mathcal{G}_R$, beginning from some common edge, in the direction opposite to the orientation of that edge, then the first node where the two cycles separate from each other has to be a species node, since all reaction nodes have just one incoming edge in $\mathcal{G}_R$. In conclusion, the common edges of l_1^{SR} and l_2^{SR} form one or more S-to-R chains (see Definition 3.2); i.e., l_1^{SR} and l_2^{SR} have an S-to-R intersection. □

Before we can prove our main result we have to prove a few lemmas about special types of cycles in OSR graphs.

LEMMA 5.4. *Consider a set $\mathcal{L}$ of disjoint o-cycles in $\mathcal{G}_R$. Then $\Delta_{\mathcal{L}} > 0$.*

Proof. If $\mathcal{L} = \emptyset$, we have $\Delta_\emptyset = \det(y_{11}e_1, \dots, y_{nn}e_n) > 0$. Consider now the case when $\mathcal{L}$ contains exactly one cycle l. Denote by $e_{i_1}, e_{i_2}, \dots, e_{i_k}, e_{i_1}$ (in this order) the species vertices visited by the oriented cycle l. Then the term $\Delta_{\{l\}}$ is the same as $\det(y_{11}e_1, \dots, y_{nn}e_n)$ *except* that the entry $y_{i_1 i_1}e_{i_1}$ in $\det(y_{11}e_1, \dots, y_{nn}e_n)$ is replaced by $\delta_{i_1 i_2}e_{i_2}$, the entry $y_{i_2 i_2}e_{i_2}$ is replaced by $\delta_{i_2 i_3}e_{i_3}$, and so on, until the entry $y_{i_k i_k}e_{i_k}$ is replaced by $\delta_{i_k i_1}e_{i_1}$.

Since all $y_{ii} > 0$ it follows that the sign of $\Delta_{\{l\}}$ equals the sign of the cyclic permutation $(i_1 i_2 \dots i_k)$ times the sign of the product $\delta_{i_1 i_2}\delta_{i_2 i_3} \dots \delta_{i_k i_1}$. According to the standard decomposition of a cyclic permutation into a product of transpositions[5] the sign of the cyclic permutation $(i_1 i_2 \dots i_k)$ is $(-1)^{k-1}$. On the other hand, note that if the edge of l from the reaction node $y_{i_j} \to y'_{i_j}$ to the species node $e_{i_{j+1}}$ has the complex label y_{i_j}, then $\delta_{i_j i_{j+1}}$ is positive, and if the edge of l from the reaction node $y_{i_j} \to y'_{i_j}$ to the species node $e_{i_{j+1}}$ has the complex label y'_{i_j}, then $\delta_{i_j i_{j+1}}$ is negative.[6] Recall that the other edge of l adjacent to $y_{i_j} \to y'_{i_j}$ has to have the complex label y_{i_j}. In conclusion, the number of *positive* $\delta_{i_j i_{j+1}}$'s equals the number of *c-pairs* along l. However, according to the hypothesis, l has an odd number of c-pairs, say $2p+1$. Then the sign of the product $\delta_{i_1 i_2}\delta_{i_2 i_3} \dots \delta_{i_k i_1}$ is $(-1)^{k-2p-1}$, which implies that the sign of $\Delta_{\{l\}}$ is $(-1)^{k-1}(-1)^{k-2p-1}$, i.e., $\Delta_{\{l\}} > 0$.

For arbitrary $\mathcal{L}$ let us notice that since the cycles in $\mathcal{L}$ are mutually disjoint it follows that $\Delta_{\mathcal{L}}$ can be written as a product of determinants, one for each cycle in $\mathcal{L}$, and the considerations above apply for each one of these determinants. Then $\Delta_{\mathcal{L}} > 0$. □

LEMMA 5.5. *Suppose that l is an e-cycle and an s-cycle in $\mathcal{G}_R$, and $\mathcal{L}$ is a set of cycles in $\mathcal{G}_R$ that are disjoint from each other and disjoint from l. Then $\Delta_{\mathcal{L}} + \Delta_{\mathcal{L}\cup\{l\}} = 0$.*

Proof. Case 1. Suppose that the set $\mathcal{L}$ is empty. We have $\Delta_\emptyset = \det(y_{11}e_1, \dots, y_{nn}e_n)$. As in the proof of the previous lemma, the term $\Delta_{\{l\}}$ is the same as $\det(y_{11}e_1, \dots, y_{nn}e_n)$ *except* that the entry $y_{i_1 i_1}e_{i_1}$ in $\det(y_{11}e_1, \dots, y_{nn}e_n)$ is replaced by $\delta_{i_1 i_2}e_{i_2}$, the entry $y_{i_2 i_2}e_{i_2}$ is replaced by $\delta_{i_2 i_3}e_{i_3}$, and so on, until the entry $y_{i_k i_k}e_{i_k}$ is replaced by $\delta_{i_k i_1}e_{i_1}$. Note that the stoichiometric coefficient of the edge of l from the species node e_{i_j} to the reaction node $y_{i_j} \to y'_{i_j}$ is $y_{i_j i_j}$, and the stoichiometric coefficient of the edge of l from the reaction node $y_{i_j} \to y'_{i_j}$ to the species node $e_{i_{j+1}}$ is $\delta_{i_j i_{j+1}}$. Therefore if we alternately multiply and divide the stoichiometric coefficients

[5] I.e., the decomposition $(i_1 i_2 \dots i_k) = (i_1 i_2)(i_2 i_3) \dots (i_{k-1} i_k)$.

[6] Here we are using cyclic notation: By $\delta_{i_k i_{k+1}}$ we mean $\delta_{i_k i_1}$, and by $e_{i_{k+1}}$ we mean e_{i_1}.

of the edges along the cycle l, we get

$$(y_{i_1 i_1}/\delta_{i_1 i_2})(y_{i_2 i_2}/\delta_{i_2 i_3})\dots(y_{i_{k-1} i_{k-1}}/\delta_{i_{k-1} i_k})(y_{i_k i_k}/\delta_{i_k i_1}).$$

Since l is an s-cycle the product above equals 1, and we obtain $y_{i_1} y_{i_2} \dots y_{i_k} = \delta_{i_1}\delta_{i_2}\dots\delta_{i_k}$. Then the absolute value of $\Delta_{\{l\}}$ is the same as the absolute value of $\det(y_{11}e_1, \dots, y_{nn}e_n)$. Since l is an e-cycle we reason as in the proof of the previous lemma to conclude that $\Delta_{\{l\}}$ is negative. Then

$$\Delta_\emptyset + \Delta_{\{l\}} = \det(y_{11}e_1, \dots, y_{nn}e_n) + \Delta_{\{l\}} = 0.$$

Case 2. Suppose that $\mathcal{L}$ contains at least one cycle. Since l is disjoint from all cycles in $\mathcal{L}$, we can argue exactly as in Case 1 that $\Delta_\mathcal{L}$ and $\Delta_{\mathcal{L}\cup\{l\}}$ have the same absolute value and different signs. □

6. The main result. We can now prove the following theorem.

THEOREM 6.1. *Consider some reaction network $\mathcal{N}$ such that in its SR graph $\Gamma_\mathcal{N}$ all cycles are o-cycles or s-cycles, and no two e-cycles have an S-to-R intersection. Then the reaction network $\mathcal{N}$ is injective.*

Proof. Consider some set $R = \{y_1 \to y_1', \dots, y_n \to y_n'\}$ of n reactions in $\mathcal{N}$ such that $\det(y_1, \dots, y_n)\det(y_1 - y_1', \dots, y_n - y_n') \neq 0$. We want to show that

$$\det(y_1, \dots, y_n)\det(y_1 - y_1', \dots, y_n - y_n') > 0.$$

By reordering the basis vectors e_i, we can suppose that $e_i \in \mathrm{supp}(y_i)$; i.e., the set R obeys the conditions imposed in the previous sections. (We are using here the "standard" determinant, for which $\det(e_1, \dots, e_n) > 0$.)

We will show first that $\det(y_1 - y_1', \dots, y_n - y_n') > 0$. Recall from Lemma 5.1 that the determinant can be calculated as a sum of terms, one for each member of the class $\mathbf{L}$ of all possible sets (including the empty set) of disjoint cycles taken from the OSR graph $\mathcal{G}_R$:

$$\det(y_1 - y_1', \dots, y_n - y_n') = \sum_{\mathcal{L}\in\mathbf{L}} \Delta_\mathcal{L}. \tag{6.1}$$

Let $\{\mathcal{O}_1, \dots, \mathcal{O}_p\}$ be the collection of all possible sets (including the empty set) of disjoint o-cycles that can be taken from $\mathcal{G}_R$. We partition the class $\mathbf{L}$ of all possible sets of disjoint cycles into p subclasses $\{\mathbf{L}_1, \mathbf{L}_2, \dots, \mathbf{L}_p\}$, according to the particular subset of o-cycles that each cycle-set in $\mathbf{L}$ contains. That is, $\mathbf{L}_i$ might contain several sets of cycles, but for each set of cycles in $\mathbf{L}_i$ the subset of o-cycles is precisely $\mathcal{O}_i$, $i = 1, \dots, p$. In light of this partition, (6.1) can be rewritten as

$$\det(y_1 - y_1', \dots, y_n - y_n') = \sum_{i=1}^{p} \sum_{\mathcal{L}\in\mathbf{L}_i} \Delta_\mathcal{L}. \tag{6.2}$$

To show that the (presumed nonzero) $\det(y_1 - y_1', \dots, y_n - y_n')$ is in fact positive, it will suffice to show that $\sum_{\mathcal{L}\in\mathbf{L}_i} \Delta_\mathcal{L} \geq 0$ for all $i = 1, \dots, p$.

With this in mind, we consider a particular collection $\mathbf{L}_i$ of disjoint cycle-sets, with $\mathcal{O}_i$ the common subset of o-cycles for each cycle-set in $\mathbf{L}_i$. If no cycle-set in $\mathbf{L}_i$ contains an e-cycle, then, by virtue of Lemma 5.4, $\Delta_\mathcal{L} > 0$ for every $L \in \mathbf{L}_i$. (This is true even if $\mathcal{O}_i$ is empty.) Thus, it remains to consider only the case for which at least one cycle-set in $\mathbf{L}_i$ contains an e-cycle (which, by hypothesis, must be an

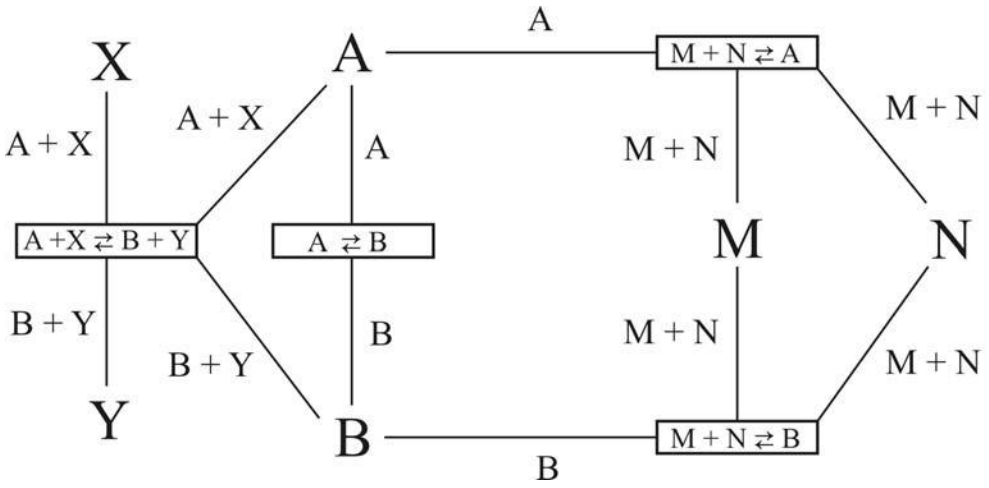

FIG. 6.1. *SR graph for the reaction network* (6.4).

s-cycle). Let l_e be some fixed e-cycle residing in a cycle-set of $\mathbf{L}_i$. Since l_e is disjoint from all members of $\mathcal{O}_i$ and from every other e-cycle (by virtue of the hypothesis and Lemma 5.3), it follows that, for each cycle-set $\mathcal{L} \in \mathbf{L}_i$ that does not have l_e as a member, the cycle-set $\mathcal{L} \cup \{l_e\}$ also belongs to the family $\mathbf{L}_i$. Note that from Lemma 5.5 we have

$$\Delta_{\mathcal{L}} + \Delta_{\mathcal{L}\cup\{l_e\}} = 0. \tag{6.3}$$

By partitioning $\mathbf{L}_i$ into such cycle-set pairs—one member distinguished from the other only by the presence of l_e—we can deduce in this case that $\sum_{\mathcal{L}\in\mathbf{L}_i} \Delta_{\mathcal{L}} = 0$.

The proof that $\det(y_1, \ldots, y_n) > 0$ is virtually identical, except that we consider only cycles containing no product edges. □

Remark. We will say that two cycles have an *orientable S-to-R intersection* if the two cycles have an S-to-R intersection and also have the following additional property: There are directions along the two cycles, consistent on their intersection, such that, for each S-to-R connected component of the intersection of the two cycles, its species end node occurs before its reaction end node. Note then that in Lemma 5.3 one can replace "S-to-R intersection" by "orientable S-to-R intersection." It is then possible to strengthen Theorem 6.1 by replacing "S-to-R intersection" by "orientable S-to-R intersection."

The following example shows a reaction network for which Theorem 6.1 gives no information, but for which this strengthened version of Theorem 6.1 does give information. Consider the reaction network

$$A + X \rightleftharpoons B + Y, \quad A \rightleftharpoons B, \quad M + N \rightleftharpoons A, \quad M + N \rightleftharpoons B. \tag{6.4}$$

The SR graph of this reaction network is shown in Figure 6.1. The middle cycle and the outer cycle are e-cycles that have an S-to-R intersection, but they do not have an orientable S-to-R intersection.

7. Split c-pairs. A different approach to showing that a reaction network does not have the capacity for multiple equilibria was described in [8, 15, 16] and is based on a different graph associated with the reaction network, called the *SCL graph*. That

approach introduced the notion of a *split c-pair*. The same notion of *split c-pair* makes sense for SR graphs as well: We say that two cycles in an SR graph *split a c-pair* if each edge of the c-pair appears in at least one of the two cycles, and if one of the two cycles contains one edge of the c-pair but not the other edge. (The other cycle might contain just the other edge, or both.) We have the following claim.

LEMMA 7.1. *Consider some reaction network $\mathcal{N}$ and its SR graph $\Gamma_{\mathcal{N}}$. Suppose that there are two cycles l_1 and l_2 in $\Gamma_{\mathcal{N}}$ that have an S-to-R intersection. Then l_1 and l_2 split a c-pair.*

Proof. Denote by r the reaction node ending of a component of the intersection of l_1 and l_2. Note that there are exactly three edges of l_1 and l_2 adjacent to the node r, precisely one of which is common to both cycles. Then at least two of these three edges have the same complex label, because there are at most two different complex labels on all edges adjacent to r. These two edges that have the same complex label (say ε_1 and ε_2) form a c-pair. It is not possible that each one of l_1 and l_2 contains both ε_1 and ε_2, since r is the ending of a component of the intersection of l_1 and l_2. On the other hand, each one of l_1 and l_2 has to contain at least one of ε_1 and ε_2, because, of their three edges adjacent to r, only one edge is common to both ε_1 and ε_2. Therefore l_1 and l_2 split a c-pair. □

Then our main result implies a criterion based on split c-pairs, but for the SR graph instead of the SCL graph, as follows.

COROLLARY 7.2. *Consider some reaction network $\mathcal{N}$ such that in its SR graph $\Gamma_{\mathcal{N}}$ all cycles are o-cycles or s-cycles and no two e-cycles split a c-pair. Then the reaction network $\mathcal{N}$ is injective.*

8. Concluding remarks and implications for biology. Theorem 1.1 provides rather easily satisfied conditions for the preclusion of multiple equilibria based on reaction network structure alone. The first condition will be satisfied in the very common situation for which every nonzero stoichiometric coefficient is 1 (in which case every cycle in the SR graph is an s-cycle). Further, violation of the second condition requires not only that there be two cycles in the SR graph but also that there be two even cycles that intersect in a prescribed way. Indeed, Theorem 1.1 goes a long way toward explaining just why, despite the great variety of reaction networks that might arise in nature, there are so few experimental reports in the chemical engineering literature of multiple stationary states in an isothermal homogeneous CFSTR context.

At the same time, we believe that the theorem provides reasons to believe that enzyme-driven biochemical reaction networks, written at the mechanistic mass action level, might be far more prone than others to exhibit multiple equilibria (and particularly bistability [2, 13, 18]). The fact is that enzyme catalysis promotes the presence of cycles in the SR graph, as might be seen by constructing the SR graph for even the simplest possible mechanism of enzyme catalysis:

$$S + E \rightleftharpoons SE \to P + E.$$

Here, E is an enzyme, S is a substrate, P is a product, and SE represents S bound to the enzyme. (The enzyme E serves as a catalyst for the "overall reaction" $S \to P$.) For more intricate enzyme-catalyzed reaction networks, written at the mechanistic level, it is easy to see how an abundance of cycles in the SR graph might arise (so that the second condition of Theorem 1.1 becomes more likely to be violated).

Extensions to biology are somewhat more complicated than might first appear, for the classical CFSTR model as described in this article might not be entirely ap-

propriate in biological settings, not even as a crude metaphor. Even if we think of the stirred reactor vessel as a surrogate for a cell and even if we imagine that substrates and products (S and P in the example above) are transported readily through the cell membrane, it might be inappropriate to suppose that high molecular weight enzyme-related molecules (E and ES in the example) are also transported through the cell membrane. That is, the heavy enzyme-related species might be regarded as "entrapped" within the cell. For the entrapped species picture, the classical homogeneous CFSTR equations, which presume an outflow of all species, might not always be suitable. (Note that this presumption played a substantive role in proofs contained in this paper and in its predecessor [4].)

In some cases, it might be appropriate to imagine that enzymes are synthesized within the cell at constant rate (i.e., constant relative to the rapid time scale of other reactions) and that all enzyme-containing species degrade within the cell at rates proportional to their concentrations. In such cases, the mathematics becomes essentially identical to the mathematics of the classical CFSTR: Constant-rate enzyme synthesis plays the role of a constant enzyme feed rate to the cell, while the degradation of enzyme-containing species replaces the outflow of these species from the cell.

In other cases, when such suppositions of enzyme supply and degradation are deemed inappropriate, the resulting mathematical structure is similar but not identical to that studied in this article; in particular, there are no outflow reactions, such as $E \to 0$ for the enzymatic species. It happens that the absence of these outflows gives rise to surprisingly delicate mathematical questions when one tries to extend the results of Theorem 1.1 to entrapped enzyme models. Indeed, *one must reframe the very question of multiple equilibria to take into account the fact that one is interested only in equilibria consistent with a fixed enzyme supply.*

Nevertheless, there is a sense in which results in this paper and its predecessor [4] carry over to the entrapped species case. Even when the kinetics is not mass action, it can be shown that if a reaction network does not have the capacity for multiple equilibria when all species are in the outflow, then, in the entrapped species case, the network cannot give rise to multiple equilibria that are, in a certain sense, nondegenerate [5].

MULTIPARAMETRIC BIFURCATION ANALYSIS OF A BASIC TWO-STAGE POPULATION MODEL*

S. M. BAER†, B. W. KOOI‡, YU. A. KUZNETSOV§, AND H. R. THIEME¶

Abstract. In this paper we investigate long-term dynamics of the most basic model for stage-structured populations, in which the per capita transition from the juvenile into the adult class is density dependent. The model is represented by an autonomous system of two nonlinear differential equations with four parameters for a single population. We find that the interaction of intra-adult competition and intra-juvenile competition gives rise to multiple attractors, one of which can be oscillatory. A detailed numerical study reveals a rich bifurcation structure for this two-dimensional system, originating from a degenerate Bogdanov–Takens (BT) bifurcation point when one parameter is kept constant. Depending on the value of this fixed parameter, the corresponding triple critical equilibrium has either an elliptic sector or it is a topological focus, which is demonstrated by the numerical normal form analysis. It is shown that the canonical unfolding of the codimension-three BT point reveals the underlying dynamics of the model. Certain new features of this unfolding in the elliptic case, which are important in applications but have been overlooked in available theoretical studies, are established. Various three-, two-, and one-parameter bifurcation diagrams of the model are presented and interpreted in biological terms.

1. Introduction.

Population growth models that include age, stage or body size structure often predict complex population dynamics. The models are rather sophisticated, involving partial or functional differential equations, difference equations, or integral equations [3, 6, 7, 35]. In this paper, we investigate a simple-stage structured model governed by a two-dimensional system of time-autonomous ordinary differential equations. The equations represent the juvenile and adult stage, respectively. We show that this reduced but biologically-based model predicts, qualitatively, complex population dynamics. Of course, the complexity is restricted by the Poincaré–Bendixson theory. Earlier work addressing competition between age stages [21] found that periodic orbits can surround a unique interior equilibrium. Here we show that multiple equilibria are possible, both stable and unstable periodic orbits can exist and even coexist, and homoclinic orbits can occur through the interaction of periodic orbits and multiple equilibria.

The best-known two-dimensional ODE system in population biology is the Lotka–Volterra predator/prey model where the dynamic behavior is simple but structurally

unstable. In an extension of this model, called the Rosenzweig–MacArthur model, the trophic interaction is described by a hyperbolic functional response instead of a linear functional response. If a carrying capacity for the prey is added, stable oscillations can occur, but no more complex dynamics. An extension of the Rosenzweig–MacArthur model was proposed and studied in [1], where the per capita mortality rate of the predators is replaced by a density-dependent mortality rate, and in [40] where the Holling type II functional response is replaced by a nonmonotonic Holling type IV functional response for the predator-prey interaction. These planar systems show rich asymptotic dynamic behavior including global bifurcations and a variety of codimension-two points originating from codimension-three bifurcation points.

We deal with a model for one population with two stages introduced in [21] and further studied in [34, Chapter 11]. The life history of the individuals comprises a juvenile and an adult stage. The population state is the number of juveniles and adults. Juveniles and adults die, while adults reproduce. The transition rate between the two stages, together with the per capita mortality and reproduction rates, form the parameters of the two first-order ordinary differential equations (ODEs) which specify the time derivative of the population state.

We use bifurcation analysis to study the dependence of the long-term dynamic behavior of this system on parameter variation. See [16, 36, 32, 22] for an introduction to bifurcation analysis and [1] for applications to ecosystem models. The structural stability is studied with respect to so-called free or bifurcation parameters. Parameter values at which the asymptotic dynamics change are called bifurcation points; for example, a Hopf bifurcation point represents a transition between constant and time-periodic solutions. Starting at this point one can vary two parameters simultaneously. This is sometimes called a two-parameter bifurcation study. The resulting bifurcation curves separate regions in the two-dimensional parameter space, which differ in qualitative asymptotic behavior. At so-called codimension-two points three or more parameter regions come together. In other words, different types of bifurcation points can originate from or terminate at these points, making these points useful for starting a numerical bifurcation analysis. Codimension-two points can be followed by varying three parameters simultaneously, and so on.

Our stage-structured population model is a two-dimensional system with four parameters. When one parameter is fixed, a degenerate Bogdanov–Takens bifurcation (BT point for short) with a triple critical equilibrium is found. Different types of such degenerate BT points are studied in detail in [2, 12], where three categories of topological types are distinguished: the saddle, the focus, and the elliptic case. We will derive a normal form with terms up to and including fourth order for the codimension-three BT point by using a time reparameterization combined with a smooth transformation that also includes fourth-order terms. This analysis reveals that the elliptic or focus case applies for the two-stage population model depending on the value of the fixed parameter. When this parameter is varied a transition from elliptic to focus codimension-three BT bifurcation is found.

The truncated normal form of the codimension-three BT point in the elliptic case is embedded into an appropriate three-parameter family, and we study its unfolding by performing a numerical bifurcation analysis for the neighborhood of the origin in that three-dimensional parameter space. In the three-dimensional parameter space, two branches of codimension-two BT curves emanate from the codimension-three point. These curves form the intersection of saddle-node and Hopf bifurcation planes. Furthermore, codimension-two Bautin bifurcations as well as codimension-two homoclinic orbits to neutral saddles originate from the codimension-three BT point.

In two-parameter space, codimension-one homoclinic bifurcation curves can originate from BT points. Both saddle, saddle-node and neutral saddle homoclinic orbit bifurcations actually occur. The analysis reveals unexpected similarities between the elliptic and the focus cases, which have been overlooked in earlier theoretical studies.

The normal form analysis results are used to interpret those of the numerical bifurcation analysis study of the full planar two-stage population model and consequently also those reported in [34, Chapter 11].

2. The two-stage population model. The model is introduced in [21] and further motivated in [34, Chapter 11]. The population is split into juveniles (larvae, e.g.) and adults, the numbers of which are denoted by $L(t)$ and $A(t)$, respectively. The system has the form

$$\frac{dL}{dt} = \beta(L,A)A - \mu(L,A)L - f(L,A)L\,, \tag{2.1a}$$

$$\frac{dA}{dt} = f(L,A)L - \alpha(L,A)A\,, \tag{2.1b}$$

where β is the per capita reproduction rate of an average adult individual, μ is the per capita mortality rate of an average juvenile individual (α for the adults) and f the per capita transition rate from the juvenile into the adult stage. In general, these rates can depend on both the densities of juveniles and adults.

Under realistic additional assumptions, all trajectories converge to an equilibrium (not necessarily the same) if $\frac{\partial}{\partial L}[f(L,A)L] \geq 0$ for all $L, A > 0$ [34, Thm. 11.6]. (See [21] for a convergence result under different assumptions.) So there are no complex dynamics if the transition from the juvenile to the adult stage is only weakly affected by intra-juvenile competition. However, we show in this paper that complex behavior may indeed occur if there is both a strong influence on the per capita transition rate by intra-juvenile competition and a strong effect on the per capita birth rate by intra-adult competition. We restrict our consideration to pure intrastage competition, i.e., there is no competition between juveniles and adults. So the juvenile per capita mortality rate depends on the number of juveniles, i.e., $\mu(L)$, and the adult per capita mortality rate $\alpha(A)$ and reproduction rate $\beta(A)$ depend only on the number of adults A. This may occur when juveniles and adults have different habitats. For simplicity, the per capita mortality rates for both juveniles and adults are taken as constants. Time is scaled such that $\alpha = 1$; this means that one time unit equals the expectation of adult life. For convenience we divide the other rates β, μ and f by α, but we do not introduce new variables. As in [21], a Ricker-type function is chosen for the stage transition rate,

$$f(L) = \frac{\mu}{m}e^{-L}. \tag{2.2}$$

The reproduction rate $\beta(A)$ is chosen as

$$\beta(A) = g\big(\frac{m}{\mu}A\big). \tag{2.3}$$

To interpret the parameter m, we consider the expression for the probability of surviving the juvenile stage to become an adult in the absence of competition ($L = 0$):

$$p = \frac{f(0)}{\mu + f(0)} = \frac{1}{1+m}, \tag{2.4}$$

where $f(0)$ is evaluated using (2.2). The numerator $f(0)$ is the per capita transition rate from the juvenile and the adult stage (without competition) and the denominator $\mu + f(0)$ is the total rate at which juveniles leave their stage. For $m = 0$ all juveniles survive to adults, for $m = 1$ half survive, and as $m \to \infty$ the probability of surviving approaches zero.

After introducing the scaled number of adults y as

$$y = \frac{m}{\mu} A, \tag{2.5}$$

the stage-structured population model becomes

$$\frac{dL}{dt} = \frac{\mu}{m}\big[g(y)y - mL - Le^{-L}\big], \tag{2.6a}$$

$$\frac{dy}{dt} = Le^{-L} - y. \tag{2.6b}$$

At equilibrium, (2.6b) gives a fixed relationship between y^* and L^* which is independent of all parameters. Note from (2.6a) that these values are independent of the parameter μ. We assume that the birth rate $g(y)$ is also of Ricker-type:

$$g(y) = e^{(1/b)(a-y)}. \tag{2.7}$$

When not varied, the model parameters have the following reference values $a = 0.43, b = 2.2, m = 0.01$, while $0 \le \mu \le 1.0$.

3. Organizing centers. This section is partially based on [34, section 11.9]. The system (2.6) has been scaled in such a way that the equilibria do not depend on the parameter μ. The origin $(L = 0, y = 0)$ is always an equilibrium.

The parameter m can be expressed as a function of the L-component of the interior equilibria, L^*,

$$m = \big[g(L^*e^{-L^*}) - 1\big]e^{-L^*} =: M(L^*). \tag{3.1}$$

The value

$$m_0 = M(0) = g(0) - 1 = e^{a/b} - 1 \tag{3.2}$$

is the threshold value for the existence of interior equilibria and the stability of the origin. The Jacobian of system (2.6) evaluated at the origin reads

$$\begin{pmatrix} -\frac{\mu}{m}(m+1) & \frac{\mu}{m}g(0) \\ 1 & -1 \end{pmatrix}. \tag{3.3}$$

The determinant of this Jacobian matrix switches its sign at m_0. Hence, m_0 marks a transcritical bifurcation. If $m \ge m_0$, the origin is the only equilibrium and it attracts all solutions starting in the biologically relevant nonnegative quadrant. We therefore restrict our investigation to $m \in (0, m_0)$. Then the origin is a saddle with one part of its unstable manifold lying in the positive quadrant. Moreover the origin is a strong repeller and not part of ω-limit sets of solutions starting in the nonnegative quadrant, except at the origin itself. Further, there exists at least one interior equilibrium.

Whatever the choice of the positive parameters a and b, the function M is strictly decreasing for small $L^* > 0$ and large $L^* > 0$. It can also be shown that the equation $M(L^*) = m$ has at most three interior solutions. This implies that, depending on the

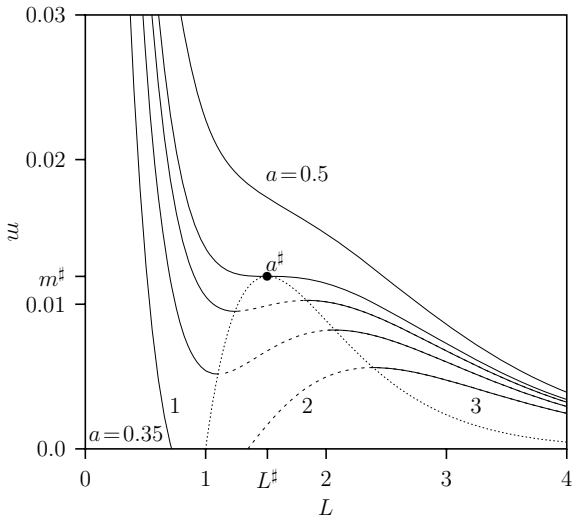

FIG. 3.1. *Graph of the function M for $b = 2.2$ and various values of a. From right to left: $a = 0.5$, $a = a^\sharp = 0.4492276697$, $a = 0.43$, $a = 0.4$, $a = 0.35$. The bullet gives the simultaneous point of inflection and critical point for $a = a^\sharp$. The dotted line connects the critical points where a is varied. The numbers label the branches where equilibrium E_i occurs at branch $i = 1, 2, 3$.*

choice of a and b, M is either strictly decreasing on $[0, \infty)$ or that there are numbers $L_2, L_1 > 0$ such that M is strictly decreasing on $[0, L_1]$ and $[L_2, \infty)$ and strictly increasing on $[L_1, L_2]$. When the transition occurs, the three positive equilibria merge into one *triple* equilibrium, and we have a unique $L^* > 0$ such that $M'(L^*) = 0 = M''(L^*) = 0$. If we fix $b > 0$, we can use this relation to determine the value of a at which the transition occurs, say $a^\sharp$. Then, M is strictly decreasing for $a > a^\sharp$ and has changing monotonicity behavior for $a < a^\sharp$. The value of L at the corresponding equilibrium $L^\sharp = L^*$, which together with (3.1) finally gives $m^\sharp = M(L^*)$ and $y^\sharp = y^* = L^* e^{-L^*}$.

Figure 3.1 shows the graph of the function M for $b = 2.2$ and various values of a. The dotted curve marks points where $M'(L^*) = 0$ when a is varied. This curve cuts the horizontal axis $m = 0 = M(L^*)$ at $L^* = 1$, where $a = a_\sharp = 0.3679$.

For the fixed choice of $a_\sharp < a < a^\sharp$ and $b > 0$, M changes its monotonicity; moreover M is strictly positive on $[0, \infty)$. Let

$$m_0 = M(0) = g(0) - 1, \qquad m_1 = M(L_1), \qquad m_2 = M(L_2). \tag{3.4}$$

The critical points L_1 and L_2 can be determined as the solutions of $M'(L) = 0$ and one finds $m_0 > m_2 > m_1$.

We have the following cases depending on m:

$m = m_1$: There are exactly two interior equilibria and their L-components satisfy $L_1^* = L_1$ and $L_2^\diamond := L_2^* > L_2$.

$m = m_2$: There are exactly two interior equilibria, and their L-components satisfy $L_1^\diamond := L_1^* \in (0, L_1)$ and $L_2^* = L_2$.

Then,

$m \geq m_0$: There is no interior equilibrium.

$m \in (m_2, m_0)$: There is exactly one interior equilibrium and its L-component satisfies $L^* \in (0, L_1^\diamond)$.

$m \in (m_1, m_2)$: There are exactly three interior equilibria and their L-components satisfy $L_1^* \in (L_1^\diamond, L_1)$, $L_2^* \in (L_1, L_2)$, $L_3^* \in (L_2, L_2^\diamond)$.

$m \in (0, m_1)$: There is exactly one interior equilibrium and its L-component satisfies $L^* > L_2^\diamond$.

$m = 0$: There is exactly one interior equilibrium $L^* = 1$.

One can show (see [34, page 173]) that the determinant of the Jacobian matrix of the system (2.6), with $y = Le^{-L}$, has the opposite sign of the derivative of M. Hence, every interior equilibrium with $L^* = L_1$ or $L^* = L_2$ has at least one eigenvalue 0. As we have seen, such equilibria occur if and only if $m = m_1$ or $m = m_2$. It can also be shown (see [34, page 172]) that the trace of the Jacobian matrix evaluated at an interior equilibrium is a linear function of μ. The trace switches its sign from negative to positive at

$$\mu = \phi(L^*) := \frac{g(y^*) - 1}{L^* - g(y^*)}, \qquad y^* = L^* e^{-L^*}. \tag{3.5}$$

At $a = a^\sharp$ we have $L^* = L_1 = L_2 = L^\sharp$ and $m = m_1 = m_2 = m^\sharp$, see Figure 3.1. At this point the determinant and the trace of the Jacobian matrix evaluated at the equilibrium $(L^\sharp, y^\sharp)$ are zero. Therefore, for fixed $b > 0$ and $\mu = \mu^\sharp, m = m^\sharp$, and $a = a^\sharp$, we have a BT point. Moreover, the equilibrium is triple at this point; thus a degenerate BT point occurs.

For $b = 2.2$, we have

$$L^\sharp = 1.513180178,\ y^\sharp = 0.33321523 \tag{3.6}$$

and

$$\mu^\sharp = 0.01179614,\ m^\sharp = 0.01192386945,\ a^\sharp = 0.4492276697. \tag{3.7}$$

4. Normal form analysis. In this section we perform a normal form analysis of the degenerate BT point and study its canonical unfolding.

4.1. Critical normal form. First, we write system (2.1) for fixed $b > 0$ at the critical parameter values (3.7) in a coordinate system where the equilibrium with the coordinates (3.6) is shifted to the origin of the phase plane by the transformation

$$\mathbf{x} = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} L - L^\sharp \\ y - y^\sharp \end{pmatrix}. \tag{4.1}$$

The transformed planar system becomes

$$\dot{\mathbf{x}} = \mathbf{J}\mathbf{x} + \mathbf{F}(\mathbf{x}), \tag{4.2}$$

where $\mathbf{J}$ is the Jacobian matrix evaluated at the equilibrium and $\mathbf{F}(\mathbf{x}) = O(\|\mathbf{x}\|^2)$.

Next we use a similarity transformation to put the linear part in the Jordan canonical form. First we calculate two vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^2$ such that

$$\mathbf{J}^2\mathbf{v} = 0, \quad \mathbf{J}\mathbf{v} = \mathbf{u}, \quad \|\mathbf{u}\| = 1, \tag{4.3}$$

where the vector norm is defined by $\|\mathbf{u}\|^2 = \langle \mathbf{u}, \mathbf{u} \rangle$ and $\langle \mathbf{u}, \mathbf{v} \rangle$ stands for the standard inner product in $\mathbb{R}^2$: $u_1 v_1 + u_2 v_2$. These two vectors (the eigenvector $\mathbf{u}$ and the generalized eigenvector $\mathbf{v}$), are linearly independent and form a basis in the plane. Notice that $\mathbf{v}$ is the eigenvector belonging to the zero eigenvalue of the matrix $\mathbf{J}^2$

($\mathbf{J}$ is nilpotent of index 2, that is, $\mathbf{J}^2\mathbf{v} = \mathbf{0}$ but $\mathbf{J}\mathbf{v} \neq \mathbf{0}$). One can calculate $\mathbf{v}$ as an eigenvector associated with the zero eigenvalue of the squared Jacobian matrix evaluated at the equilibrium point.

The similarity transformation is now defined by

$$\mathbf{x} = \mathbf{U}\mathbf{y}, \tag{4.4}$$

where $\mathbf{U}$ denotes the matrix the columns of which are formed by a normalized eigenvector and a generalized eigenvector. The matrix $\mathbf{U}$ is invertible, since the vectors $\mathbf{u}$ and $\mathbf{v}$ are linearly independent, and we can write

$$\mathbf{y} = \mathbf{U}^{-1}\mathbf{x}. \tag{4.5}$$

Then

$$\mathbf{U}^{-1}\mathbf{J}\mathbf{U} = \mathbf{J}_0 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \tag{4.6}$$

and

$$\dot{\mathbf{y}} = \mathbf{J}_0\mathbf{y} + \mathbf{U}^{-1}\mathbf{F}(\mathbf{U}\mathbf{y}). \tag{4.7}$$

Taylor series expansion of the right-hand side of (4.7) at the equilibrium $\mathbf{y} = \mathbf{0}$ gives

$$\begin{aligned} \frac{dy_1}{dt} &= y_2 + \frac{1}{2}a_{20}y_1^2 + a_{11}y_1y_2 + \frac{1}{2}a_{02}y_2^2 \\ &\quad + \frac{1}{6}a_{30}y_1^3 + \frac{1}{2}a_{21}y_1^2y_2 + \frac{1}{2}a_{12}y_1y_2^2 + \frac{1}{6}a_{03}y_2^3 \\ &\quad + \frac{1}{24}a_{40}y_1^4 + \frac{1}{6}a_{31}y_1^3y_2 + \frac{1}{4}a_{22}y_1^2y_2^2 + \frac{1}{6}a_{13}y_1y_2^3 + \frac{1}{24}a_{04}y_2^4 + O(\|\mathbf{y}\|^5), \end{aligned} \tag{4.8a}$$

$$\begin{aligned} \frac{dy_2}{dt} &= \frac{1}{2}b_{20}y_1^2 + b_{11}y_1y_2 + \frac{1}{2}b_{02}y_2^2 \\ &\quad + \frac{1}{6}b_{30}y_1^3 + \frac{1}{2}b_{21}y_1^2y_2 + \frac{1}{2}b_{12}y_1y_2^2 + \frac{1}{6}b_{03}y_2^3 \\ &\quad + \frac{1}{24}b_{40}y_1^4 + \frac{1}{6}b_{31}y_1^3y_2 + \frac{1}{4}b_{22}y_1^2y_2^2 + \frac{1}{6}b_{13}y_1y_2^3 + \frac{1}{24}b_{04}y_2^4 + O(\|\mathbf{y}\|^5). \end{aligned} \tag{4.8b}$$

The final transformation to the normal form

$$\frac{d\xi}{d\tau} = \eta, \tag{4.9a}$$

$$\frac{d\eta}{d\tau} = A\xi^2 + B\xi\eta + C\xi^3 + D\xi^2\eta + E\xi^4 + F\xi^3\eta + O(\|(\xi,\eta)\|^5) \tag{4.9b}$$

is achieved by a time reparameterization combined with a smooth change of coordinates. In this way it is possible to remove both fourth-order terms from (4.9) (using $BC \neq 0$ as will be verified numerically in our case).

The time reparameterization introduces a new time τ as follows:

$$dt = (1 + \theta_1 y_1 + \theta_2 y_1^2)d\tau, \tag{4.10}$$

where θ_1 and θ_2 are to be defined later. Alternatively one can use $(1+\theta_1 y_1+\theta_2 y_2)$ which leads to the same results. The smooth transformation reads

$$\begin{aligned}\xi = {} & y_1 + \frac{1}{2}g_{20}y_1^2 + g_{11}y_1y_2 + \frac{1}{6}g_{30}y_1^3 + \frac{1}{2}g_{21}y_1^2y_2 + \frac{1}{2}g_{12}y_1y_2^2 \\ & + \frac{1}{24}g_{40}y_1^4 + \frac{1}{6}g_{31}y_1^3y_2 + \frac{1}{4}g_{22}y_1^2y_2^2 + \frac{1}{6}g_{13}y_1y_2^3, \end{aligned} \tag{4.11a}$$

$$\begin{aligned}\eta = {} & y_2 + \frac{1}{2}h_{20}y_1^2 + h_{11}y_1y_2 + \frac{1}{6}h_{30}y_1^3 + \frac{1}{2}h_{21}y_1^2y_2 + \frac{1}{2}h_{12}y_1y_2^2 \\ & + \frac{1}{24}h_{40}y_1^4 + \frac{1}{6}h_{31}y_1^3y_2 + \frac{1}{4}h_{22}y_1^2y_2^2 + \frac{1}{6}h_{13}y_1y_2^3, \end{aligned} \tag{4.11b}$$

where g_{ij} and h_{ij} are unknown coefficients. Differentiating (4.11a) and (4.11b) with respect to τ yields

$$\frac{d\xi}{d\tau} = (1+\theta_1 y_1+\theta_2 y_1^2)\left(\frac{\partial \xi}{\partial y_1}\frac{dy_1}{dt} + \frac{\partial \xi}{\partial y_2}\frac{dy_2}{dt}\right), \tag{4.12a}$$

$$\frac{d\eta}{d\tau} = (1+\theta_1 y_1+\theta_2 y_1^2)\left(\frac{\partial \eta}{\partial y_1}\frac{dy_1}{dt} + \frac{\partial \eta}{\partial y_2}\frac{dy_2}{dt}\right). \tag{4.12b}$$

Substituting (4.8a) and (4.8b) into (4.12a) and (4.12b), and then equating coefficients (4.9a) and (4.9b), gives the equations to find the coefficients $g_{ij}, h_{ij}, \theta_1, \theta_2$ in (4.11) and (4.10), as well as A, B, C, D in (4.9), where θ_1 and θ_2 are used to enforce $E = F = 0$. This gives

$$A = \frac{1}{2}b_{20}, \tag{4.13a}$$

$$B = a_{20} + b_{11}, \tag{4.13b}$$

$$C = \frac{1}{6}b_{30} - \frac{1}{2}a_{20}b_{11}, \tag{4.13c}$$

$$\begin{aligned} D = {} & \frac{1}{2}\,b_{21} + \frac{1}{4}\,b_{02}(b_{11}-a_{20}) + \frac{1}{2}\,b_{11}a_{11} + \frac{1}{2}\,a_{30} + \frac{3(a_{20}+b_{11})}{20(3\,a_{20}b_{11}-b_{30})} \\ & \times \big(b_{40} - 6\,a_{20}b_{21} - 3\,b_{11}b_{02}a_{20} + 3\,b_{02}{a_{20}}^2 \\ & \qquad -4\,b_{11}a_{30} + 6\,b_{30}a_{11} + b_{30}b_{02} - 6\,b_{11}a_{20}a_{11}\big)\,. \end{aligned} \tag{4.13d}$$

Note that the third-order coefficient D in (4.9) depends (via b_{40}) on the fourth-order terms of (4.8).

The Taylor coefficient A in (4.9) equals zero, since $b_{20} = 0$ because the critical equilibrium is triple. This implies that one of the nondegeneracy conditions for a classical codimension-two BT point is violated [22, p. 272]. This leads to a bifurcation point with codimension three (or higher) and could, together with the requirement $\det \mathbf{J} = 0$ and $\operatorname{tr} \mathbf{J} = 0$, be used as defining functions to determine the critical parameter values corresponding to this bifurcation point.

If $CD \neq 0$, then the truncated critical normal form

$$\frac{d\xi}{dt} = \eta, \tag{4.14a}$$

$$\frac{d\eta}{dt} = B\xi\eta + C\xi^3 + D\xi^2\eta \tag{4.14b}$$

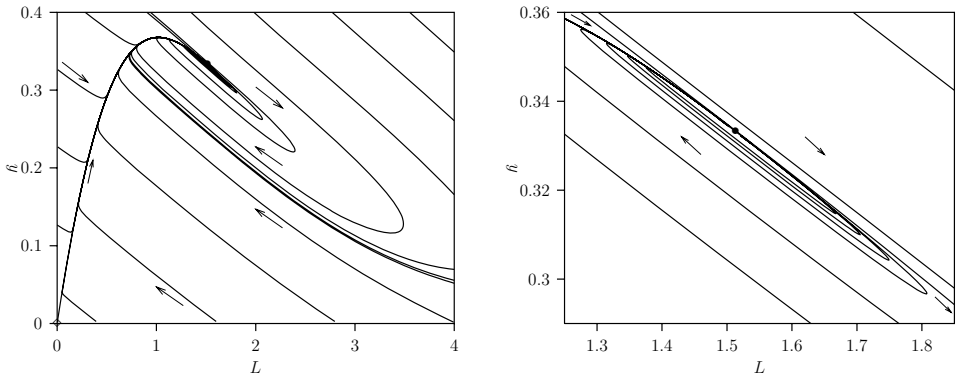

FIG. 4.1. *Phase portrait of* (2.1) *at the critical parameter values with* $b = 2.2$ *(left) and an enlargement of a neighborhood of the critical equilibrium (right), where the elliptic sector is clearly visible.*

can be simplified further by a linear coordinate and time scaling:

$$\frac{d\xi}{dt} = \eta, \tag{4.15a}$$

$$\frac{d\eta}{dt} = \beta\xi\eta + \epsilon_1\xi^3 + \epsilon_2\xi^2\eta, \tag{4.15b}$$

where $\epsilon_1 = \pm 1, \epsilon_2 = \pm 1$, and

$$\beta = \frac{B}{\sqrt{|C|}}.$$

In [2, 12], three topologically different cases are distinguished:

- Saddle case $\epsilon_1 = 1$, any ϵ_2 and β;
- Focus case $\epsilon_1 = -1$ and $0 < \beta < 2\sqrt{2}$;
- Elliptic case $\epsilon_1 = -1$ and $2\sqrt{2} < \beta$.

When $b = 2.2$, the calculated values of the coefficients of the truncated critical normal form (4.14) are $B = 1.0538275511$, $C = -0.110108078$, and $D = -1.23163654$. This gives $\epsilon_1 = -1$ (because $C < 0$), $\epsilon_2 = -1$ (because $D < 0$), and

$$\beta = \frac{B}{\sqrt{-C}} = 3.175849820.$$

We conclude that with $b = 2.2$ the *elliptic case* applies, for $\beta = 3.175849820 > 2\sqrt{2}$. Direct numerical integration of (2.1) at the critical parameter values (3.7) confirms this conclusion (see Figure 4.1).

Calculations showed that in an extended range of parameter values $b > 0$ the parameters C and D defined in (4.14b) are negative, implying $\epsilon_1 = -1$ and $\epsilon_2 = -1$. In Figure 4.2 we give the dependence of β on the parameter b. At $b^\natural = 1.7300228$, where $\beta = 2\sqrt{2}$, there is a transition from the elliptic case to the *focus* case. The phase portrait at the critical parameter values with $b = 1.5$ (when the focus case applies) is depicted in Figure 4.3. Compared with Figure 4.1, where $b = 2.2$, we see that the elliptic sector disappeared.

The transition at $b = b^\natural$ is a bifurcation of codimension four (or higher), which could be considered as the ultimate organizing center in model (2.6). However, in the following we will deal with $b > b^\natural$ corresponding to the elliptic case because it is

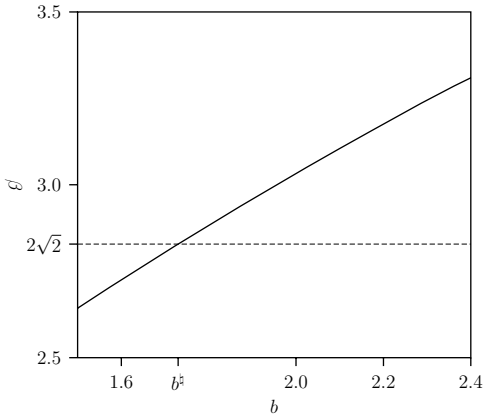

FIG. 4.2. *The coefficient β defined in* (4.15b) *as a function of the parameter b. There is a transition from the elliptic case to the focus case at the codimension-four bifurcation point, where $b = b^\natural = 1.7300228$.*

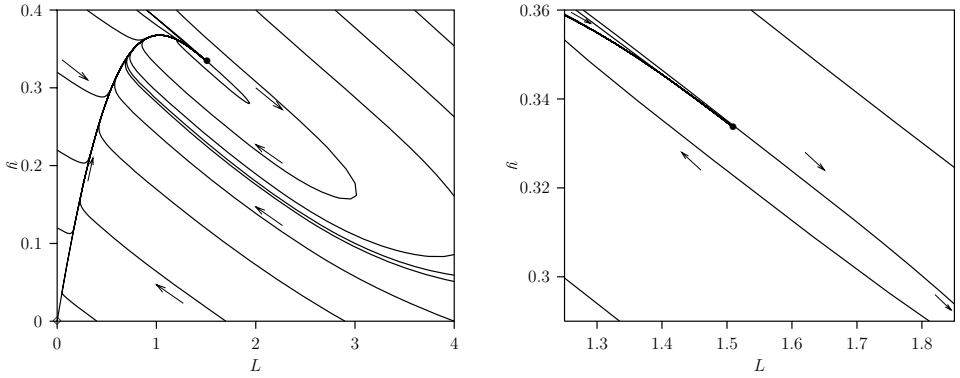

FIG. 4.3. *Phase portrait of* (2.1) *at the critical parameter values with $b = 1.5$ (left) and an enlargement of a neighborhood of the critical equilibrium (right), where no elliptic sector is present.*

the most interesting one. The focus case is discussed extensively in applied literature (for example, in [1, 22] with the analysis of the Rosenzweig–MacArthur predator-prey model having density-dependent mortality rate for the predators, as well as in [13], where an enzyme-catalyzed reaction model is studied). The elliptic case is much less understood, although it has been found in a mathematical model of a reaction of catalytic oxidation in [37].

4.2. Bifurcation diagram of the canonical unfolding. The local bifurcation diagram for the focus and elliptic case has been studied theoretically in [12], where the truncated critical normal form (4.15) is embedded in the following three-parameter family

$$\frac{d\xi}{dt} = \eta, \tag{4.16a}$$

$$\frac{d\eta}{dt} = -\mu_1 - \mu_2\xi + \nu\eta + \beta\xi\eta - \xi^3 - \xi^2\eta, \tag{4.16b}$$

with μ_1, μ_2, and ν serving as the unfolding parameters. Below we reconstruct the

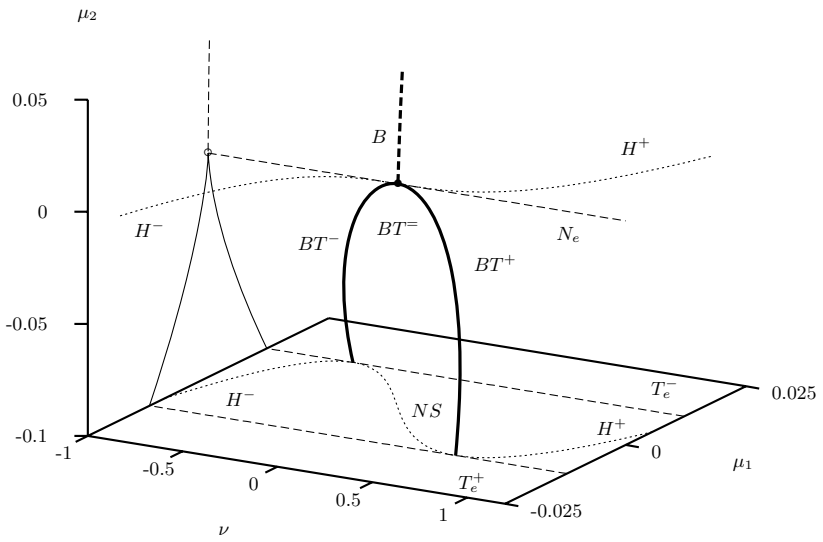

FIG. 4.4. *Three-parameter bifurcation diagram with μ_1, μ_2, and ν as bifurcation parameters for the normal form* (4.16)*, where $\beta = 3.175849820$. Only equilibrium bifurcations are shown. The tangent bifurcation curves $T_e^{\pm}$ (dashed curves) and Hopf $H^{\pm}$ and neutral saddle NS curve (dotted curve) in the (μ_1, ν)-plane for $\mu_2 = -0.1$ are plotted.*

bifurcation diagram of (4.16) in the elliptic case using the same numerical continuation methods as applied in the next section to compute global bifurcation diagrams of (2.1).

The equilibria of (4.16) satisfy $\eta = 0$ and $-\mu_1 - \mu_2\xi - \xi^3 = 0$. Therefore, depending on the parameter values μ_1 and μ_2, there is one or there are three real solutions. For example, when $\mu_1 = 0$, we have $\xi = 0$ and $\xi = \pm\sqrt{-\mu_2}$ besides $\eta = 0$.

In Figure 4.4, a partial three-parameter bifurcation diagram near the codimension-three bifurcation point $\mu_1 = \mu_2 = \nu = 0$ is shown for the normal form (4.16), where $\beta = 3.175849820$ (elliptic case). Two BT curves of different type emanate from the codimension-three point denoted by $BT^=$. Locally attracting limit cycles bifurcate from the first curve which is called a *supercritical Bogdanov–Takens bifurcation curve* and is denoted by BT^-, while repelling limit cycles bifurcate from the curve of second type which is a *subcritical Bogdanov–Takens bifurcation curve*, denoted by BT^+. Another codimension-two bifurcation curve, namely, a cusp curve denoted by N_e in the figure, passes through the point $BT^=$. Finally, from $BT^=$, a codimension-two Bautin (generalized or degenerated Hopf, see [22]) bifurcation curve B emanates. Software packages LOCBIF [18, 22] and CONTENT [25, 15] were used for the numerical continuation of these curves related to equilibrium bifurcations.

Figure 4.5 presents two-parameter slices of the complete bifurcation diagram of (4.16) with $\beta = 3.175849820$ for $\mu_2 = -0.1$ and $\mu_2 = -1$. The left diagram with $\mu_2 = -0.1$ gives a clear picture of the unfolding near the codimension-three BT point. The same diagram (together with corresponding phase portraits) is sketched in Figure 4.6, which we advise to consult while reading the rest of this section. The codimension-two $BT^{\pm}$ points and four saddle-node homoclinic bifurcation points $D_i, i = 1, \ldots, 4$ (analyzed theoretically in [26]) are indicated in all diagrams. These points lie all on the tangent bifurcation curves for equilibria $T_e^{\pm}$. At the supercritical BT^- point, a supercritical Hopf bifurcation curve H^- originates, and similarly a subcritical Hopf bifurcation curve H^+ emanates from the subcritical BT^+. From each BT point, BT^-

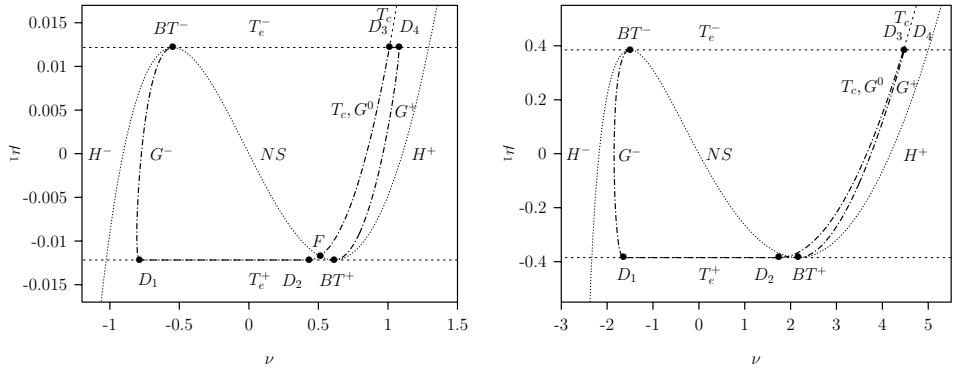

FIG. 4.5. *Two-parameter bifurcation diagrams of* (4.16) *with* μ_1 *and* ν *as bifurcation parameters and* $\mu_2 = -0.1$ *(left) and* $\mu_2 = -1$ *(right) for normal form* (4.16)*, where* $\beta = 3.175849820$*. The labels are explained in the text.*

and BT^+, a global bifurcation curve emanates, indicated by G^+ or G^-, respectively. These are saddle homoclinic bifurcation curves. The homoclinic orbits corresponding to them are "small", i.e., they go around one equilibrium only. There exists another

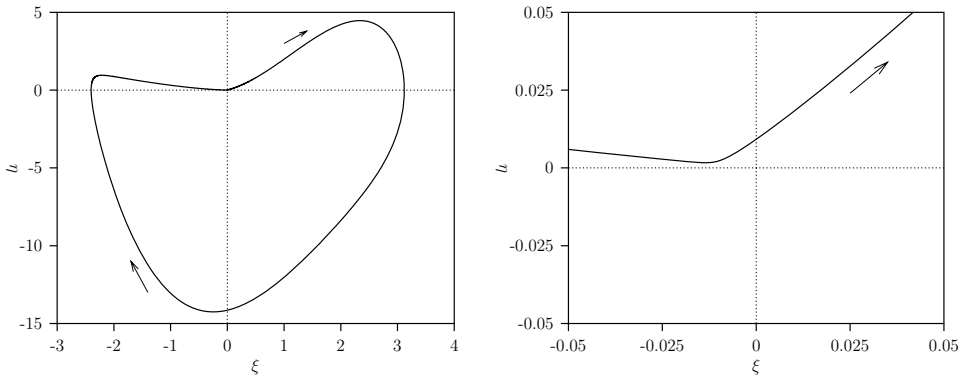

FIG. 4.7. *A nonhyperbolic limit cycle of* (4.16) *at the critical parameter value* $\nu = 0.8458472970$ *corresponding to* T_c *(left) and an enlargement of a neighborhood of the origin, where a saddle equilibrium is located (right). Other parameters are* $\mu_1 = 0, \mu_2 = -0.1, b = 3.175849820$. *We recall that the three equilibria are:* $\eta = 0$ *and* $\xi = 0$ *or* $\xi = \pm\sqrt{0.1}$. *The equilibrium in the origin is a saddle, the left one is stable and the right one unstable.*

saddle homoclinic bifurcation curve, denoted by G^0 in the figure. In contrast with G^+ and G^-, the homoclinic orbit corresponding to G^0 is "big", i.e., it surrounds two equilibria. The homoclinic curves were calculated using the package HOMCONT, a part of AUTO [11]. The implemented theory and numerical procedures are described in [4, 5].

A tangent bifurcation curve for limit cycles T_c, where two limit cycles collide and disappear, crosses the curve T_e^- and ends at a point F in the intersection of the homoclinic curve G^0 and the neutral saddle curve NS connecting the Bogdanov–Takens points BT^- and BT^+. This point F corresponds to a codimension-two "big" homoclinic orbit to a neutral saddle, where the trace of the Jacobian matrix is zero [22]. The tangent bifurcation curve for limit cycles T_c and the homoclinic curve G^0 have an infinite-order contact at F [29]. It should be noted that T_c is indistinguishable from G^0 in Figure 4.5. Between the equilibrium bifurcation curves T_e^+ and T_e^-, the curve T_c is located just above G^0. This can be verified by accurate computations in AUTO or CONTENT with many mesh points (e.g., `NTST=1000`). Figure 4.7 demonstrates that the critical limit cycle corresponding to T_c is located at a small but clearly visible distance from the saddle equilibrium at the origin. This nonhyperbolic limit cycle bifurcates into (outer) stable and (inner) unstable limit cycles, shown in Figure 4.8 for parameter values between the curves T_c and G^0. When we cross the homoclinic bifurcation curve G_0 above point F, the inner unstable limit cycle "collides" with the saddle and disappears via the saddle homoclinic orbit that is unstable from the outside, in accordance with the positive sign of the trace of the Jacobian matrix above the curve NS (see Figure 4.5). Crossing G^0 below F results in the appearance of a stable "big" cycle.

The saddle homoclinic curve G^-, originating at the point BT^-, terminates tangentially at a point D_1 on the bifurcation curve T_e^+. Between the two codimension-two points D_1 and D_2 the saddle-node equilibrium (existing along the tangent bifurcation curve T_e^+) has a smooth homoclinic orbit. On this line segment D_1D_2, the global bifurcation and the local bifurcation occur simultaneously. The homoclinic orbit is asymptotic to a saddle-node rather than to a saddle. In point D_2, the "big" saddle homoclinic curve G^0 departs tangentially from T_e^+. This curve G^0 ends also tangen-

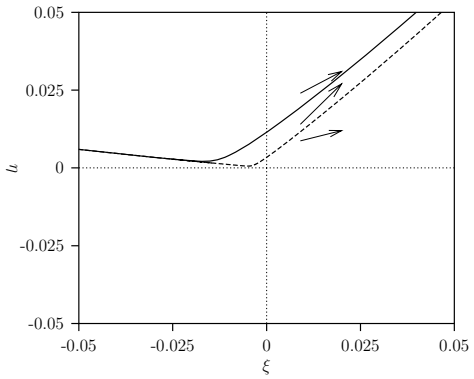

FIG. 4.8. *A stable limit cycle (outer, solid) and an unstable (inner, dashed) limit cycle of* (4.16) *at* $\nu = 0.8458473000$. *The other parameters are* $\mu_1 = 0, \mu_2 = -0.1, b = 3.175849820$.

tially at a codimension-two point D_3 on T_e^-, which is similar to D_2. Another saddle homoclinic curve, G^-, originating at BT^+ on the bifurcation curve T_e^+, terminates tangentially at a point D_4 on T_e^-. In all points D_i, the corresponding homoclinic orbits are nonsmooth at the saddle-node. The right diagram with $\mu_2 = -1$ shows that already in the vicinity of the codimension-three point the two saddle-node homoclinic bifurcation points D_3 and D_4 are also close to each other and hardly distinguishable in Figure 4.5.

4.3. Elliptic versus focus case. The bifurcation diagram of the normal form (4.16) presented in Figure 4.6 differs drastically from the theoretical bifurcation diagram for the elliptic case given in [12, p. 8]. The reason for this discrepancy is that the diagram in [12] concerns phase portraits in a *fixed* small neighborhood (in fact, an elliptic disk) of the origin. Therefore, additional bifurcation curves associated with boundary tangencies appear, while some parts of the global bifurcation curves described above become "invisible," since the corresponding bifurcations happen outside the neighborhood. This approach is absolutely legitimate in theoretical studies, but is of little use in applied analysis, where artificial boundaries have no meaning and global phase portraits in the whole phase plane must be considered. Only such portraits could provide a good understanding of the long-term dynamics of the model.

Figure 4.5 gives such global bifurcation diagrams of the normal form (4.16). It turns out that the two-parameter slices are topologically equivalent to those corresponding to the focus case (see [2, p. 36] or [12, p. 7], where an intersection of bifurcation surfaces with a small sphere centered at the origin in the three-dimensional parameter space is shown). However, the inner limit cycle demonstrates rapid amplitude changes ("canard-like" behavior) near the bifurcation curve T_c. It is this phenomenon that makes the continuation of limit cycles near T_c difficult. One could also observe that, in contrast with the focus case, the "big" homoclinic orbit to the neutral saddle (see point F) does not shrink to the origin of the phase plane, when we approach the codimension-three elliptic BT point in the parameter space. Instead, this homoclinic orbit tends to the boundary of the elliptic sector that has a finite size in (4.16). The similarity between the focus and the elliptic cases implies that the transition between them at $b = b^\natural$, although interesting from a theoretical point of view, is of minor importance in applications, since it does not affect dynamics away from the degenerate BT bifurcation points.

These similarities and differences between the focus and the elliptic cases were overlooked in all theoretical studies. Of course, global phase portraits arising from an elliptic BT case in a specific model could differ from the global bifurcation diagrams of the canonical unfolding (4.16) reported above. However, if other phase objects (equilibria, cycles, etc.) do not interact with the objects bifurcating around the codimension-three BT point, one would encounter the described bifurcation diagrams in his/her system, as it happens in our ecological model (2.1).

5. Bifurcation diagrams of (2.1). To facilitate our understanding of the bifurcation structure, we construct three-, two-, and one-parameter bifurcation diagrams of (2.1) for a representative parameter value $b = 2.2$ (elliptic case). We also show explicitly various homoclinic orbits.

5.1. Three-parameter bifurcation diagram. In Figure 5.1, the three parameters μ, m, a are changed simultaneously. There is a codimension-three point, denoted by $BT^{=}$ at the critical parameter values $(\mu^\sharp, m^\sharp, a^\sharp)$ given by (3.7). The bifurcation pattern resembles that of the normal form (4.16) presented in Figure 4.4. There is now another codimension-two Bautin bifurcation curve B which is not connected to a codimension-three point $BT^{=}$. Varying the fourth parameter b showed that such a connection never occurs in the region of the parameter space of interest in this paper.

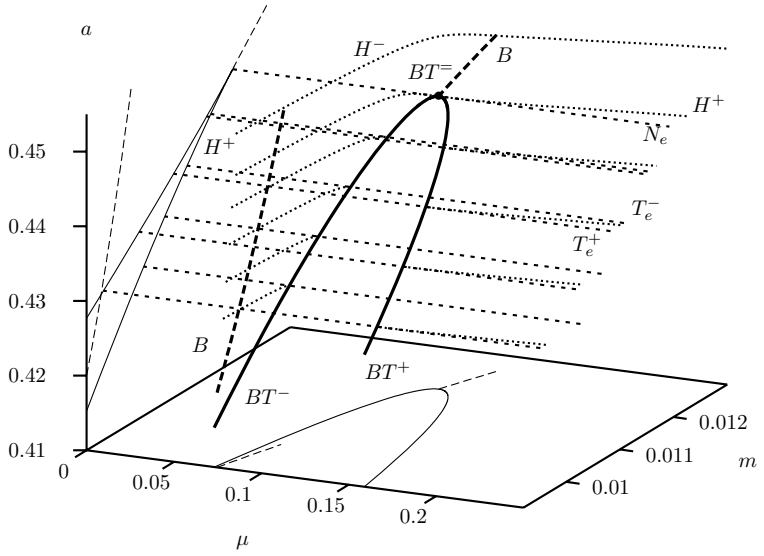

FIG. 5.1. *Three-parameter bifurcation diagram for equilibria of* (2.1) *with* μ, m *and* a *as bifurcation parameters. The codimension-three Bogdanov–Takens point is denoted by* $BT^{=}$. *From this point two codimension-two BT curves,* BT^{-} *and* BT^{+}, *emanate. They are shown along with their projections. The codimension-two Bautin bifurcation curves* B *are long dashed. The Hopf bifurcation curves (dotted) and tangent bifurcation curves (short dashed) are shown for* $a = 0.455$, $a = 0.4492277$, $a = 0.44$ *and* $a = 0.43$. *The curve* N_e *passing through* $BT^{=}$ *is a cusp bifurcation curve for equilibria. The two curves* $T_e^{\pm}$ *for* $a = 0.44$ *are the intersections of the* $a = 0.44$ *plane with the tangent bifurcation surfaces. Similarly the* H^{+} *and* H^{-} *curves from the intersections for the two-dimensional Hopf bifurcation surfaces. For a-values above the point* $BT^{=}$ *these sheets are separated by the codimension-two Bautin bifurcation curves* B. *These sheets are separated for a-values below the point* $BT^{=}$, *where the two codimension-two BT curves,* BT^{-} *and* BT^{+}, *form the end curves of the separated sheets. For smaller* μ*-values there is always a codimension-two Bautin bifurcation curve* B *that separates super- and subcritical Hopf bifurcation surfaces.*

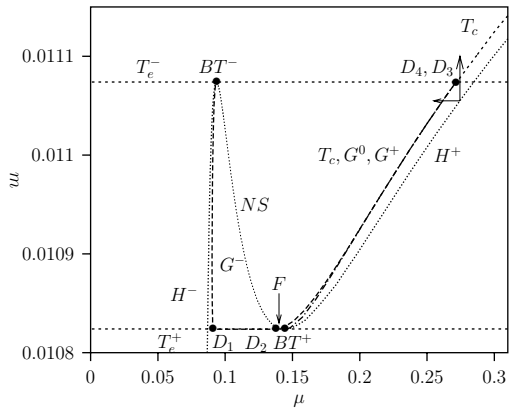

FIG. 5.2. *Two-dimensional bifurcation diagram with μ and m as bifurcation parameters, where $a = 0.44$.*

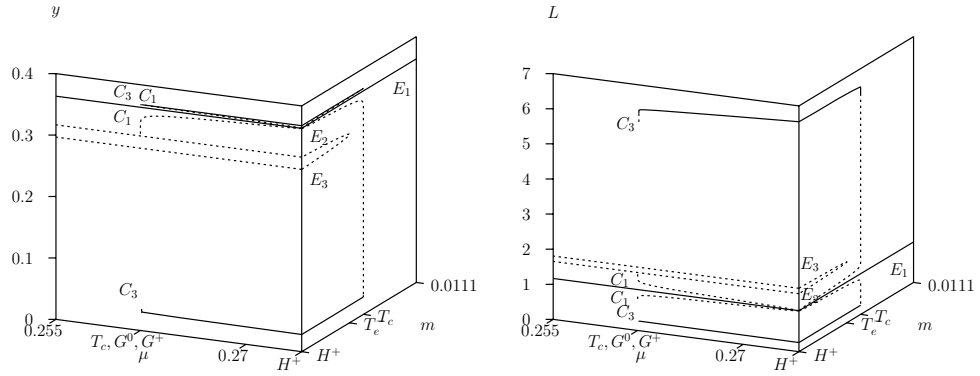

FIG. 5.3. *Combined bifurcation diagrams for region around bifurcation point D_3, where $a = 0.44$. The bottom right vertex, for both y and L, corresponds to the point $\mu = 0.2743923$ and $m = 0.01105501$ on the Hopf bifurcation H^+ in Figure 5.2.*

Codimension-one bifurcation curves for $a = 0.44$ and for the reference value $a = 0.43$ are investigated in the next section using two-parameter bifurcation diagrams.

5.2. Two-parameter bifurcation diagram. The two-parameter bifurcation diagram for $a = 0.44$ in Figure 5.2 strongly resembles that given in Figure 4.5 (right), where $\mu_2 = -1$. The Hopf bifurcation curves H^- (origination to the left in BT^-) and H^+ (origination to the right in BT^+), the neutral-saddle curve NS (between BT^- and BT^+), and the tangent bifurcation curves $T_e^{\pm}$ (straight lines parallel to the ν-axis) as well as the tangent bifurcation curve for limit cycles T_c are shown. Observe that although the parameter value $a = 0.44$ is rather close to $a^\sharp$, the two saddle-node homoclinic bifurcation points D_3 and D_4 are indistinguishable in the figure. In two one-parameter bifurcation diagrams with respect to μ and m combined in Figure 5.3, the extrema of the cycles in the region close to points D_3 and D_4 are plotted. The two homoclinic bifurcations for the cycles C_1 and C_3 are connected via the tangent bifurcation of these cycles at T_c. This explains how the large amplitude cycle C_3 surrounding all three equilibria, E_1, E_2, and E_3, appears. The tangent bifurcation

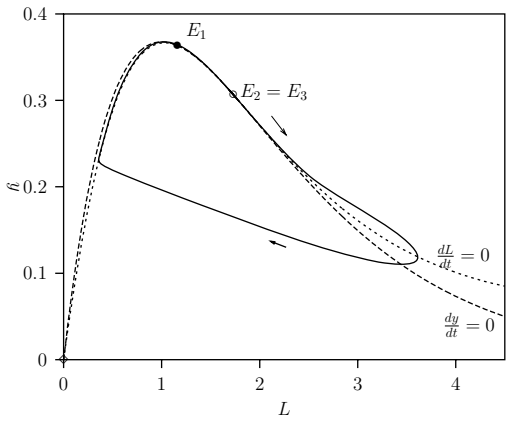

FIG. 5.4. *Phase-plane plot for parameter values between the codimension-two points D_3 and D_4, $\mu = 0.2714740$ and $m = 0.01107377$ for $a = 0.44$. Also the two isoclines are shown. These intersect in the two equilibria, namely, the saddle-node, where two points E_2 and E_3 coincide, and the unstable equilibrium E_1.*

curve T_c for limit cycles goes all the way down to the point F corresponding to the homoclinic orbit to a neutral saddle. Between the lines $T_e^{\pm}$, T_c is very close to the "big" homoclinic curve G^0.

A smooth homoclinic orbit to a saddle-node on the tangent bifurcation curve T_e^- between the points D_3 and D_4 is depicted in Figure 5.4. Also the isoclines are drawn. The homoclinic orbits locally coincide with a center manifold W^c of the saddle-node $E_2 = E_3$ and is therefore smooth. The orbit approaches and leaves the saddle-node via the center manifold, that is, it is tangent to the eigenvector belonging to the zero eigenvalue of the saddle-node on T_e^-. At the points D_3 and D_4 the homoclinic bifurcation curves G^+ and G^0 terminate at the equilibrium tangent bifurcation curve T_e^-, where the equilibria E_3 and E_2 coincide. At these points, the homoclinic orbit to the saddle-node is nonsmooth.

Figure 5.5 shows a two-parameter bifurcation diagram where μ and m are again the bifurcation parameters, while now $a = 0.43$. The two-parameter bifurcation diagram in Figure 5.5 resembles that for $a = 0.44$ given in Figure 5.2 except that there are no points D_3, D_4. If the values of the parameter a are lower, the Hopf bifurcation H^+ does not intersect the curve T_e^-. One can show that H^+ has a horizontal asymptote as $\mu \to \infty$, namely, the line $m = m_\sharp = 0.01026241193$. Furthermore, the curve G^- originating at BT^- and terminating at D_1 follows closely the Hopf bifurcation curve H^-. Figure 5.6 is an expanded view of Figure 5.5 in the region of the the two points D_1 and D_2. The tangent bifurcation curve T_c for limit cycles is indistinguishable from the segment of G^0 located above the point F also in Figure 5.6.

5.3. One-parameter bifurcation diagrams. In Figures 5.7 and 5.8, where $m = 0.01, a = 0.43$, the bifurcation parameter is μ. For all μ-values, there are three interior equilibria, denoted by E_1, E_2 and E_3, the positions of which are independent of μ. For the (scaled) numbers of juveniles and adults at these equilibria, $E_j = (L_j^*, y_j^*)$, we have $L_1^* < L_2^* < L_3^*$ and $y_1^* > y_2^* > y_3^*$, respectively. Hopf bifurcations of E_1 and E_3 occur at H^+ and H^-, respectively, giving rise to limit cycles. Their maximum and minimum values are plotted in the figure, a stable one, denoted by C_3 and generated by the supercritical Hopf bifurcation from the equilibrium E_3 and an unstable one,

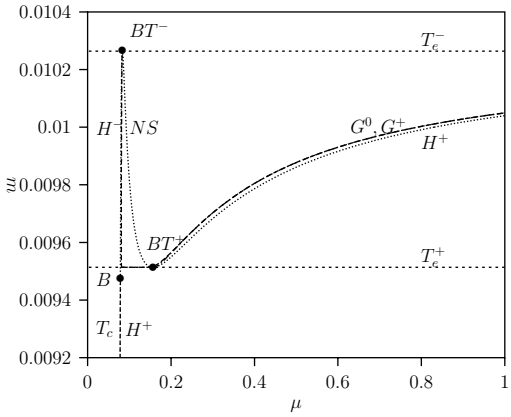

FIG. 5.5. *Two-parameter bifurcation diagram with μ and m as bifurcation parameters, where $a = 0.43$. At the Bogdanov–Takens codimension-two point BT^-, a tangent (T_e^-), supercritical Hopf (H^-) and a homoclinic curve (G^-) meet. Similarly, at the point BT^+, a tangent (T_e^+), subcritical Hopf (H^+) and a homoclinic curve (G^+) meet. At the Bautin codimension-two point B, a tangent bifurcation for the limit cycle T_c originates. For more details, see Figure* 5.6.

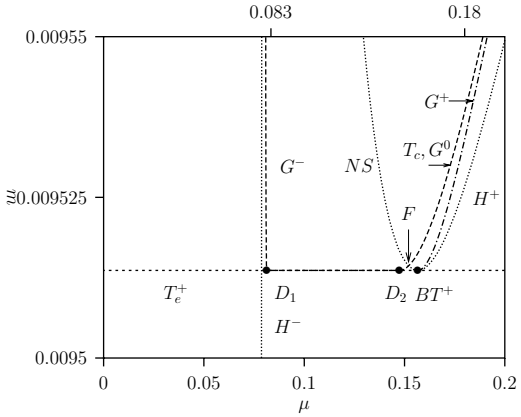

FIG. 5.6. *The Hopf bifurcation curve H^- (dotted) and the tangent bifurcation T_e^+ (short dashed) are shown. Further, the homoclinic bifurcation curve G^- which originates from BT^- (shown in Figure* 5.5*), and the homoclinic bifurcation curve G^+ (dashed-dotted) which originates from BT^+ ($\mu = 0.1566$) together with T_e^+ are shown. Between the codimension-two points D_1 ($\mu = 0.1474$) and D_2 ($\mu = 0.0813$), there is a smooth saddle-node homoclinic orbit. The tangent bifurcation curve T_c for limit cycles is indistinguishable from the segment of the homoclinic curve G^0 located above the point F.*

denoted by C_1 and generated by the subcritical Hopf bifurcation from the equilibrium E_1. For large μ, there is a branch of "big" stable periodic orbits (also denoted by C_3) which surround all three equilibria. This branch also exists for μ values for which the unstable period orbits C_1 surrounding the equilibrium E_1 exist. There are homoclinic orbits at the points where these limit cycles touch the saddle equilibrium E_2.

In Figure 5.9, we show the one-parameter diagram for fixed $\mu = 0.08337$ with m as the bifurcation parameter. The parameter μ has been chosen in such a way that it lies between the μ-coordinates of the codimension-two points D_1 and D_2 in Figure 5.6, where a saddle-node homoclinic bifurcation occurs. In this global bifurcation curve,

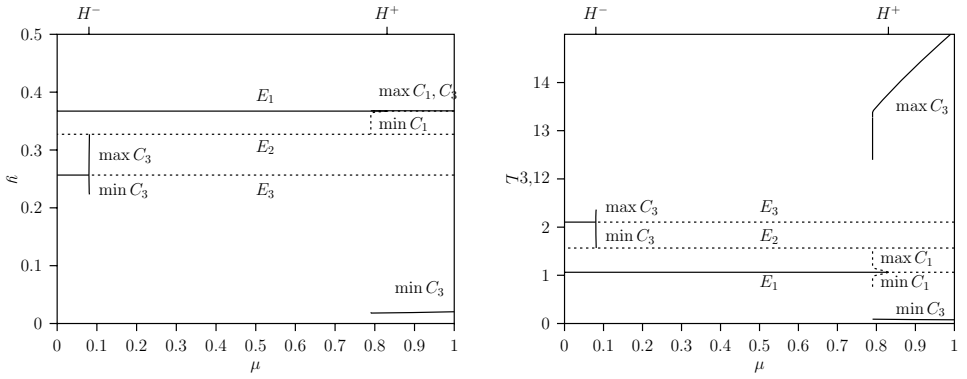

FIG. 5.7. *Bifurcation diagram, where $m = 0.01$ and $a = 0.43$, and μ is the single bifurcation parameter. Stable equilibria are represented by solid lines and unstable equilibria by dashed lines which are horizontal because the y and L equilibrium values are independent of μ. A branch of stable limit cycles C_3 (solid curves) originate through the supercritical Hopf (H^-), and a branch of unstable limit cycles C_1 (dashed curves) through the subcritical Hopf bifurcation (H^+). A homoclinic orbit occurs where these limit cycles touch the saddle equilibrium E_2.*

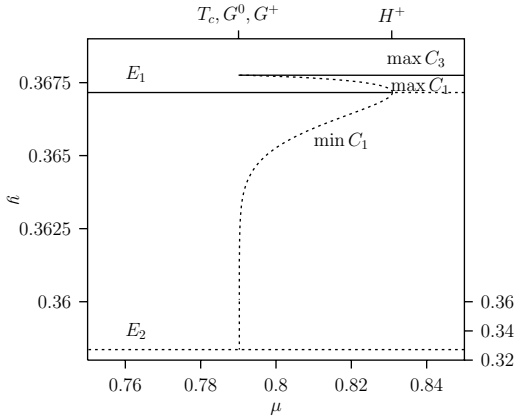

FIG. 5.8. *Detail of Figure 5.7. The solid curve is the maximum of the large amplitude cycle C_3. The dashed curve is the unstable limit cycle C_1 that emanates from the Hopf bifurcation point H^+. In order to get a better plot, the scaling of the y-axis below $y = 0.36$ is changed. The two homoclinic bifurcations G^0 and G^+, as well as the tangent bifurcation T_c of limit cycles, occur at almost the same value of μ.*

also a local tangent bifurcation T_e^+, where the two equilibria E_1 and E_2 coincide, is involved. The time-averages of the limit cycles are plotted. The stable limit cycle C_3 disappears when the average reaches the tangent point at T_e^+. This is explained in Figure 5.10, where the homoclinic orbit in the phase plane is shown for parameter values of m at the saddle-node homoclinic bifurcation. The homoclinic orbit is similar to that shown in Figure 5.4 for a point between the two codimension-two points D_3 and D_4.

A periodic solution $(L(t), y(t))$ near the saddle-node homoclinic orbit stays close to a point where the saddle-node will appear for most of its period, then completes the orbit by making a rapid and large excursion in the phase plane. Hence the time-average for one period is approximately the equilibrium value. This explains why it

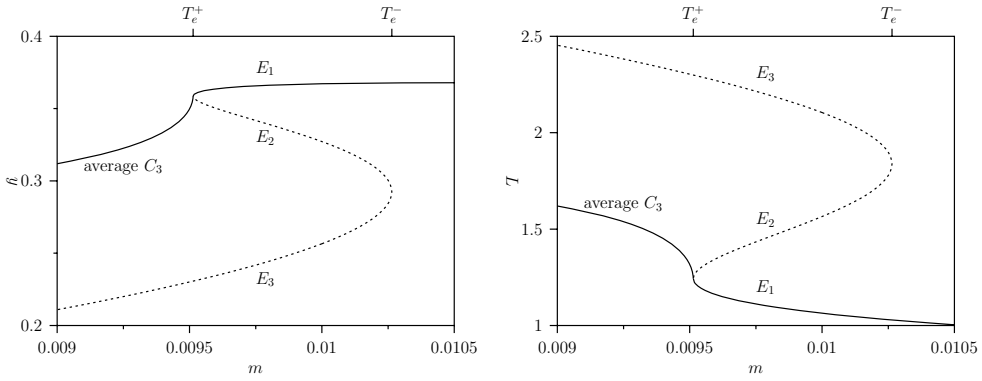

FIG. 5.9. *Bifurcation diagrams for* $y = \frac{\mu}{m}A$ *and* L *with* m *as bifurcation parameter for* $\mu = 0.08336837$ *and* $a = 0.43$. *Stable equilibria (solid curve) and unstable equilibria (dashed curve) as well as the time-averages for the stable limit cycle (solid curve) are plotted. Stable limit cycles originate in the supercritical Hopf* (H^-) *bifurcation shown in Figures* 5.5 *and* 5.6. *These cycles terminate at a smooth saddle-node homoclinic orbit.*

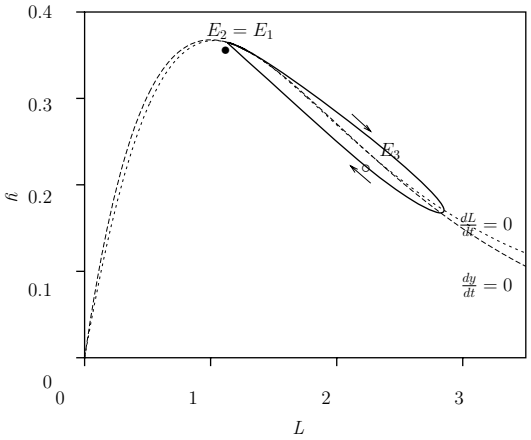

FIG. 5.10. *Phase portrait for* $\mu = 0.083$, $a = 0.43$ *and* $m = 0.009513629$. *The smooth homoclinic orbit to the saddle-node equilibrium* $E_1 = E_2$ *coincides locally with a center manifold of this point. Also, the unstable equilibrium* E_3 *inside the homoclinic orbit and two isoclines are shown.*

is advantageous to plot the time-averages in addition to the maximum and minimum values. Observe that y becomes small during the excursion but this occurs over a relatively (the period T goes to infinity) short time interval. Note that the unstable manifold of the saddle E_2 can go to E_1 directly or via a "big" loop around E_3 similar to the saddle-node homoclinic orbit shown in Figure 5.10.

Figure 5.11 is a one-parameter diagram, where m is the bifurcation parameter for $\mu = 1.0$ and $a = 0.43$. It shows how the three interior equilibria are connected. There are two tangent bifurcations $T_e^{\pm}$, where two equilibria coincide. A subcritical Hopf bifurcation of E_1 occurs at H^+, generating a branch of unstable limit cycles, denoted by C_1, while a supercritical Hopf bifurcation of E_3 occurs at H^-, generating a branch of stable limit cycles, denoted by C_3. The maximum and minimum values for both branches have been plotted in the figure. Varying m, this unstable limit cycle touches the saddle E_2 in a homoclinic orbit.

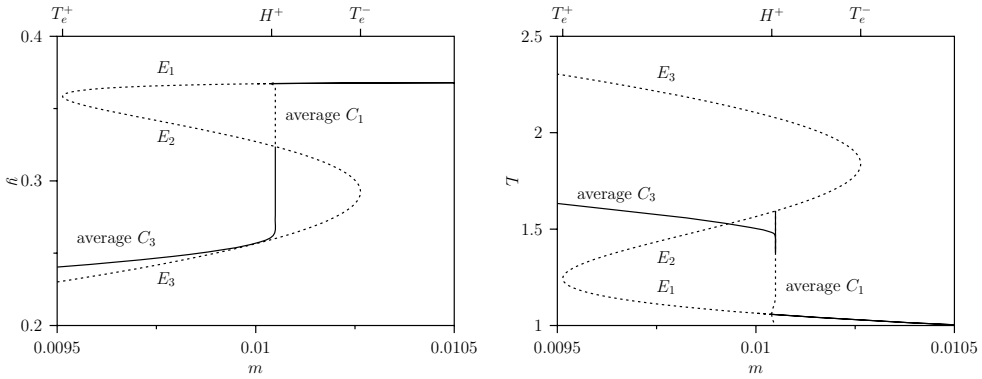

FIG. 5.11. *Bifurcation diagrams for $y = \frac{\mu}{m}A$ and L with m as bifurcation parameter, where $\mu = 1.0$ and $a = 0.43$. Stable equilibria (solid curve) and unstable equilibria (dashed curve) as well as the time-averages for the stable limit cycles (solid curve) and for the unstable limit cycles (dashed curve) are plotted.*

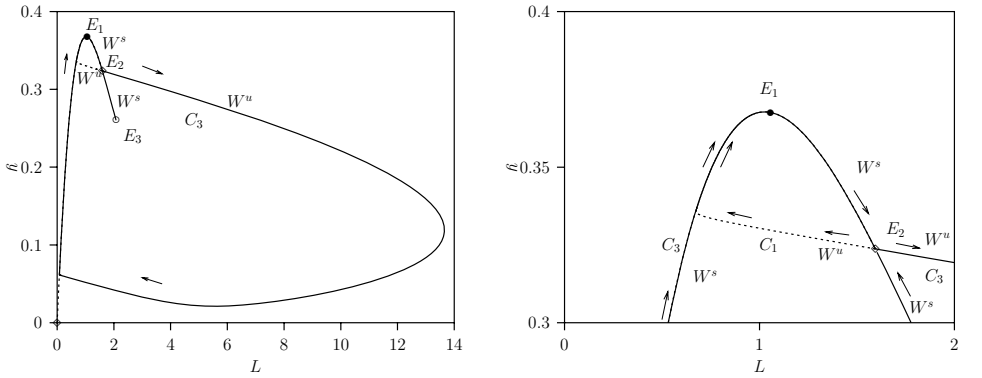

FIG. 5.12. *Two homoclinic orbits and time-evolution for $\mu = 1.0$ and $a = 0.43$, where $m = 0.01004953$ and $m = 0.01004952$ for large amplitude and small amplitude orbits, respectively. The right figure is an expanded view of the left figure. The stable W^s and unstable W^u manifolds of the saddle point indicated by a $\diamond$ are shown. The stable focus E_1 is indicated by a bullet and the source E_3 by a circle. Here the flow direction is indicated by arrows for the stable homoclinic orbit C_3 at the outside and for the unstable homoclinic orbit C_1 at the inside.*

Furthermore, the average values for the limit cycle C_3 are plotted. The unstable cycle C_3 originates in the supercritical Hopf bifurcation H^- of equilibrium E_3. Both average curves touch the saddle curve E_2. The average curve as a function of m for the stable limit cycles C_3 is very steep close to the bifurcation point. The average L-values first decrease before increasing up to the saddle-point value. This is most clear from the graphs $y(m)$ and $L(m)$. Actually, the cycle C_3 becomes unstable via a tangent limit cycle bifurcation not show in the figure. Both homoclinic bifurcations occur in very close proximity.

Figure 5.12 shows approximations of these two homoclinic orbits, one "big" (solid) C_3 and one "small" (dashed) C_1. The period of the plotted limit cycles is very large, indicating a homoclinic orbit. There are two rather sharp bends in the "big" homoclinic orbit. The top one is close to the saddle point as expected. The lower bend is associated with the zero equilibrium $(L = 0, y = 0)$ which is a saddle point for the parameter values used. Both orbits pass the stable focus E_1 closely.

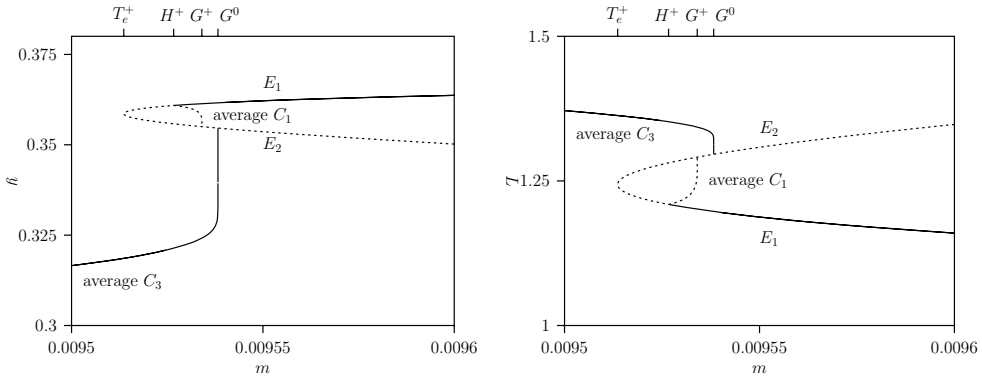

FIG. 5.13. *Bifurcation diagrams for $y = \frac{\mu}{m}A$ and L with m as bifurcation parameter, where $\mu = 0.18$ and $a = 0.43$. Stable equilibria (solid curve) and unstable equilibria (dashed curve) as well as the time-averages for the stable limit cycle (solid curve) and for the unstable limit cycle (dashed curve) are plotted.*

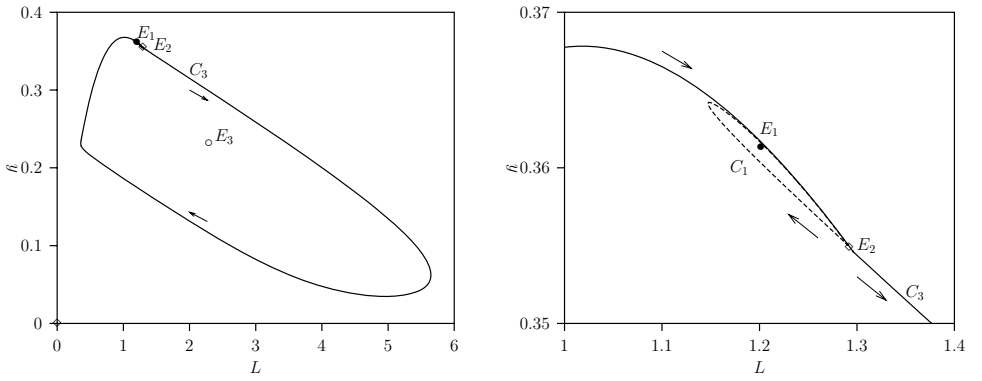

FIG. 5.14. *Phase portrait for $\mu = 0.18$ and $a = 0.43$. Left: Where $m = 0.009534053$, there is a "big" homoclinic orbit C_3. Right: An expanded view of the homoclinic orbit C_3 (solid curve) close to saddle E_2. For $m = 0.009538250$, in the same plot the "small" homoclinic orbit C_1 (dashed curve) is shown.*

In order to get more detailed information on the dynamics close to the homoclinic orbits, we study the one-parameter diagram for fixed $\mu = 0.18$, where m is varied (see also Figure 5.6).

In Figure 5.13, the average values of the variables for the limit cycles are plotted together with their equilibrium values. For m values below the Hopf bifurcation H^+, the large amplitude stable limit cycles, whose averaged values form the curve C_3, are globally attracting. For m values above the curve H^+, the unstable limit cycles C_1 which emanate from E_1 at the Hopf bifurcation H^+ are separating boundaries. Starting outside the limit cycle results in convergence to the stable limit cycle C_3, but starting inside the limit cycle gives convergence to the stable equilibrium E_1. Increasing m, this bistability persists until the unstable limit cycle (averaged C_1) disappears abruptly at the global bifurcation G^+ via the homoclinic orbit shown in Figure 5.14. For parameter values m above G^+, there is still bistability of the stable equilibrium E_1 and the stable limit cycle C_3, but now the stable manifold of the saddle equilibrium E_2 acts as the separatrix.

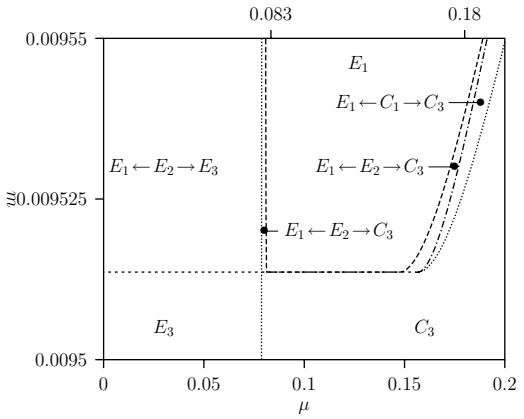

FIG. 5.15. *Attractors in some regions of the two-parameter bifurcation diagram shown in Figure 5.6.* $E_1 \leftarrow E_2 \rightarrow E_3$ *means bistability of the two equilibria* E_1 *and* E_3 *and the stable manifold of the saddle* E_2 *is the separatrix.*

In Figure 5.15 several attractors for typical points in the two-parameter bifurcation diagram Figure 5.6 are indicated. The regimes are all separated by codimension-one curves as shown in Figure 5.6. For small μ values, there is bistability of the two equilibria E_1 and E_3 and the stable manifold of the saddle E_2 is the separatrix. This region is labeled $E_1 \leftarrow E_2 \rightarrow E_3$. For larger μ values there is bistability of the equilibrium E_1 and the limit cycle C_3, while the stable manifold of either the saddle E_2 ($E_1 \leftarrow E_2 \rightarrow C_3$) or the unstable limit cycle C_1 ($E_1 \leftarrow C_1 \rightarrow C_3$) is a separatrix. Note that C_3 can surround either just E_3 or all three equilibria, E_1, E_2, and E_3.

6. Discussion. We have considered the most basic model for stage-structured populations in which per capita transition from the juvenile into the adult class is density dependent, namely, a system of two ordinary differential equations. This model was originally suggested in [21]. Birth pulses have been added in [33], but we are only interested in the time-autonomous case here. Alternative more sophisticated models involve differential-delay equations with density-dependent delays [17], transport equations with density-dependent speed [27, 8], difference equations [3, 6, 7], and integral equations with density-dependent transition kernels [10]. We refer to [20] for a review of the different model formulations and their relationships. While more complex models also exhibit more complex behavior than simple models, the complex behavior may be more difficult to detect and track due to the large number of parameters and initial conditions inherent in such systems.

In [21], periodic orbits were found which surround a unique interior equilibrium. Up to three interior equilibria, two of which can undergo Hopf bifurcation, were discovered in [34, sect. 11]. In order to determine more systematically the dynamics of our planar system (2.6), we have performed a four-parameter bifurcation analysis under the assumption of pure intrastage competition. To report our results, we fix a representative value of parameter b that characterizes the birth rate of adults and then presents the three-parameter bifurcation diagrams. These are the three parameters which we have varied. The parameter a is related to the average number of offspring produced by one typical adult if there is no competition. The parameter μ represents the per capita mortality rate of juveniles. The parameter m has no direct interpretation, but $p_0 = \frac{1}{1+m}$ is the probability of surviving the juvenile stage under

no competition. The parameter a determines the shape of a function M involved in the equation $M(L^*) = m$ which determines the juvenile coordinate L^* of an interior equilibrium. Depending on a, M can be either strictly monotone decreasing in $L^* \geq 0$ or decreasing for small L^*, increasing for intermediate L^*, and decreasing again for large L^*. The $a = a^\sharp$ value at which M undergoes the transition is the a-coordinate of a codimension-three BT bifurcation point which is the organizing center of our three-parameter bifurcation diagrams. There exists a unique $L^* > 0$ such that $M'(L^*) = M''(L^*) = 0$. L^* is the juvenile coordinate of a saddle-node. $m = M(L^*)$ is the m coordinate of the degenerate BT point. Its μ-coordinate is determined by making 0 a double eigenvalue of the Jacobian matrix. This leads to the following procedure for calculating the position of the codimension-three BT bifurcation point. When b is fixed, there are five unknowns, namely, two equilibrium values for the state variables, $L^\sharp, y^\sharp$ and three parameters $a^\sharp, m^\sharp, \mu^\sharp$. There are two equilibrium equations (right-hand sides of (2.6) zero), the requirements that the determinant and trace of the Jacobian matrix evaluated at the equilibrium point are zero and the additional requirement that $M''(L^\sharp) = 0$. The first four are necessary for a codimension-two BT point, while the latter is satisfied at a codimension-three BT point. Surprisingly, the latter condition is a geometrical one (the position of the inflection point of a function $M(L^*)$ defined in (3.1)). The function $M(L^*)$ is the expression for a parameter, m, derived from the equilibrium equation for one state variable, L, where the solution of the other state variable, $y^*(L^*)$, from the second equilibrium equation is substituted. We use the fact that $M(L^*)$ and $y^*(L^*)$ formulations are explicit as is the case with the population model (2.6). Commonly it is the requirement that one coefficient of a higher-order term of a Taylor series expansion equals zero (see [22, p. 272] for details). In this paper we established existence of a codimension-three BT bifurcation in our model and have verified its nondegeneracy by computing its normal form numerically.

The normal form is computed using a preliminary linear transformation to simplify the linear terms, in this case to put the linear part in the Jordan canonical form. In [22, 23] this step is omitted by using a representation of any vector in the state space as a linear combination of the eigenvector and the adjoint eigenvector. That method is appropriate for higher-order dynamics systems where normalization on the center manifold is needed [24]. The nonlinear smooth transformation in this paper is combined with a time reparameterization. This facilitates the removal of all fourth-order terms in the Taylor series expansion. Therefore the expression for the coefficient D of the $\xi^2\eta$ term given by (4.13d) differs from the classical expression [19], where only third-order terms are taken into account. The expressions (4.13) agree with those reported in [14]. In this way, we have computed the relevant normal form coefficients and established that the critical equilibrium at the codimension-three BT point is triple and has an elliptic sector for $b > b^\natural = 1.7300228$. Apparently, this case has never been observed in ecological modeling. At $b = b^\natural$, a transition from the elliptic codimension-three BT to the focus codimension-three BT point occurs.

Using known theoretical results [2, 12], we have concluded that two BT codimension-two curves emanate from the codimension-three BT point. Along these curves a Hopf bifurcation surface, as well as a tangent bifurcation and a homoclinic orbit surface, meet. There is also a codimension-two Bautin bifurcation curve B in the Hopf bifurcation surface, where the supercritical Hopf bifurcation becomes subcritical or vice versa. This happens in a parameter region where only one interior equilibrium exists. In Bautin bifurcation points, a surface of tangent bifurcations of limit cycles originates.

Our numerical analysis of the global bifurcation diagram of the canonical unfolding of the normal form, Figure 4.5, has revealed other global bifurcation curves. On codimension-two bifurcation curves D_i, transitions of the homoclinic orbit to a saddle-node homoclinic orbit occur. There is also a bifurcation surface G^0 corresponding to a "big" homoclinic orbit to the saddle that surrounds two equilibria. In this surface, a line F of codimension-two homoclinic orbits to a neutral saddle exists. Figure 5.2 resembles that of the Bazykin's predator-prey model [1, Fig. 3.5.3] and [22, Fig. 8.10], despite the fact that the degenerate BT point is here of the elliptic type while in Bazykin's model it is of the focus type. The diagrams given in [12] for both types differ a lot on first sight. However, in [12] additional bifurcation curves associated with boundary tangencies are reported. In this paper, we do not have such artificial bifurcations, since we do not restrict our attention to a small neighborhood of the critical equilibrium. Instead, we consider global phase portraits, which allows us to obtain a better understanding of the long-term dynamic behavior of the model. It should be stressed that without a preliminary analysis of the canonical unfolding (4.16) it would have been practically impossible to understand the numerical continuation results for (2.6).

A large-time solution behavior of similar complexity has been found for certain planar predator-prey systems [1, 22, 38, 31, 39] and epidemic models [30]. Predator-prey and host-parasite systems involve two species which influence each other in opposite ways with one suffering while benefiting the other. The predator-prey models which show complex behavior take into account competition among prey and predator competition for prey. Our model involves two stages of one species which compete among themselves but influence each other positively because we assume pure intra-stage competition. (Adding interstage competition actually counteracts the complexity.) Mathematically, this is reflected in the fact that the nonlinear terms in our system only depend on one variable each, whereas predator-prey and epidemic models always have nonlinear terms which involve both variables. In this paper, we find complex behavior in a class of planar systems that is different from predator-prey models both biologically and mathematically.

The complex behavior only occurs in a small parameter region (see [34, Chapter 11] for a discussion of other parameter ranges). In this parameter region, the per capita mortality rate of juveniles is smaller than the one of adults ($\mu \leq 1 = \alpha$), and almost every juvenile makes it into the adult stage if there is no competition (the small values of m result in $p_0 \approx 1$). This would hold for species where the juveniles are less prone to enemies than the adults, and the juvenile stage is very short if there are plenty of resources available. We expect that the complex behavior can be observed in a larger parameter region if more sophisticated nonlinearities than the classical Ricker function are chosen to model the competition among juveniles and adults. A thorough understanding of the basic stage-structured model is important because its simplicity makes it a useful building block in models for several species. Recently it has been used (extended by an intermediate stage of subadult individuals) to explain emergent Allee effects in predators that feed on structured prey populations [9].

The results show that despite the low dimension of the system, the dependence of the resulting long-term dynamics on parameter values can be rather complex. The rich behavior of our model is caused by the interaction of intra-adult competition and intra-juvenile competition. None of the two alone can generate multiple positive attractors. It is essential that the intra-juvenile competition does not only affect juvenile mortality, but also juvenile maturation (the per capita transition rate). A

density-dependent per capita juvenile mortality rate alone, even if combined with a density-dependent per capita birth rate, can neither generate Hopf bifurcation nor multiple interior equilibria. This feature seems to be related to the fact that in our ODE model the length of the juvenile period is exponentially distributed. If the length of the juvenile period is the same for all individuals (at least for those that are born at the same time), then a density-dependent per capita birth rate can lead to periodic solutions without any other nonlinear model ingredients [21, 28].

Acknowledgments. B.W.K. would like to thank Martin Boer for valuable discussions.

ON THE EVOLUTION OF DISPERSAL IN PATCHY LANDSCAPES*

STEPHEN KIRKLAND†, CHI-KWONG LI‡, AND SEBASTIAN J. SCHREIBER‡

Abstract. To better understand the evolution of dispersal in spatially heterogeneous landscapes, we study difference equation models of populations that reproduce and disperse in a landscape consisting of k patches. The connectivity of the patches and costs of dispersal are determined by a $k \times k$ column substochastic matrix S, where S_{ij} represents the fraction of dispersing individuals from patch j that end up in patch i. Given S, a dispersal strategy is a $k \times 1$ vector whose ith entry gives the probability p_i that individuals disperse from patch i. If all of the p_i's are the same, then the dispersal strategy is called unconditional; otherwise it is called conditional. For two competing populations of unconditional dispersers, we prove that the slower dispersing population (i.e., the population with the smaller dispersal probability) displaces the faster dispersing population. Alternatively, for populations of conditional dispersers without any dispersal costs (i.e., S is column stochastic and all patches can support a population), we prove that there is a one parameter family of strategies that resists invasion attempts by all other strategies.

Key words. population dynamics, evolution of dispersal, monotone dynamics

1. Introduction.

Plants and animals often live in landscapes where environmental conditions vary from patch to patch. Within patches, these environmental conditions may include abiotic factors such as light, space, and nutrient availability or biotic factors such as prey, competitors, and predators. Since the fecundity and survivorship of an individual depends on these factors, an organism may decrease or increase its fitness by dispersing across the environment. Depending on their physiology and their ability to accumulate information about the environment, plants and animals can exhibit two modes of dispersals and a variety of dispersal strategies. Plants and animals can be active dispersers that move by their own energy or passive dispersers that are moved by wind, water, or other animals. Passive dispersers alter their dispersal rates by varying the likelihood of dispersing and the time spent dispersing [20]. Dispersal strategies can vary from unconditional strategies in which the probability of dispersing from a patch is independent of the local environmental conditions to conditional strategies in which the likelihood of dispersing depends on local environmental factors. Understanding how natural selection acts on these different modes and strategies of dispersal has been the focus of much theoretical work [2, 5, 8, 10, 12, 15, 16, 17]. For instance, using coupled ordinary differential equation models for populations passively dispersing between two patches, Holt [8] showed that slower dispersing populations could always invade equilibria determined by faster

dispersing populations. Hastings [5] and Dockery et al. [2] considered evolution of dispersal in continuous space using reaction diffusion equations. Dockery et al. proved that for two competing populations differing only in their diffusion constant, the population with the larger diffusion constant is excluded. In contrast, McPeek and Holt [17] using a two patch model consisting of coupled difference equations found that "dispersal between patches can be favored in spatially varying but temporally constant environment, if organisms can express conditional dispersal strategies."

In this article, we consider the evolution of conditional and unconditional dispersers for a general class of multipatch difference equations. For these difference equations, individuals in each patch disperse with some probability. When these probabilities are independent of location, the population exhibits an unconditional dispersal strategy; otherwise it exhibits a conditional dispersal strategy. For dispersing individuals, the nature of the landscape determines the likelihood S_{ji} that a disperser from patch i ends up in patch j. Unlike previous studies of the evolution of unconditional and conditional dispersal [2, 5, 8, 17], we allow for an arbitrary number of patches and place no symmetry conditions on S. For active dispersers, asymmetries in S may correspond to geographical and ecological barriers that inhibit movement from one patch to another. For passive dispersers, these asymmetries may correspond to asymmetries in the abiotic or biotic currents in which they drift.

Our main goal is to determine what types of theorems can be proved about the evolution of dispersal for this general class of difference equation models. To achieve these goals, the remainder of the article is structured as follows. In section 2, we introduce the models. Under monotonicity assumptions about the growth rates, we prove that either populations playing a single dispersal strategy go extinct for all initial conditions or approach a positive fixed point for all positive initial conditions. We also introduce models of competing populations that differ only in their dispersal ability and prove a result about invasiveness. In section 3, we prove that for two competing populations of unconditional dispersers, the slower dispersing population displaces the faster dispersing population. The proof relies heavily on proving, in section 4, monotonicity of the principal eigenvalue for a one-parameter family of nonnegative matrices. In section 5, we prove that, provided there is no cost to dispersal and all patches can support a population, there is a one-parameter family of conditional dispersal strategies that resists invasion from other types of dispersal strategies. Numerical simulations suggest that these strategies can displace all other strategies, and we prove that these strategies can weakly coexist. In section 6, we discuss our findings and suggest directions for future research.

2. The models and basic results. Consider a population exhibiting discrete reproductive and dispersal events and living in an environment consisting of k patches. The vector of population densities is given by $x = (x_1, \ldots, x_k)^T \in \mathbf{R}_+^k$, where $\mathbf{R}_+^k$ is the nonnegative cone of $\mathbf{R}^k$. To describe reproduction and survival in each patch, let $\lambda_i : \mathbf{R}_+ \to \mathbf{R}_+$ denote the per-capita growth rate of the population in the ith patch as a function of the population density in the ith patch. For these per-capita growth rates we make the following assumptions.

A1: λ_i are positive continuous decreasing functions.

A2: $\lim_{x_i \to \infty} \lambda_i(x_i) < 1$.

A3: $x_i \mapsto x_i \lambda_i(x_i)$ is increasing.

Assumption A1 corresponds to the population exhibiting increasing levels of intra specific competition or interference as population densities increase. Assumption A2 implies that at high densities the population tends to decrease in size. Assumption A3

implies that the population does not exhibit overcompensating density dependence: higher densities in the current generation yield higher densities in the next generation. Many models in the population ecology literature satisfy these three assumptions. For instance, see the Beverton–Holt model [1] in which $\lambda_i(x_i) = \frac{a_i}{1+b_i x_i}$ and the Ivlev model [14] in which $\lambda_i(x_i) = a_i(1 - \exp(-b\, x_i))$.

To describe dispersal between patches, we assume that each individual in patch i disperses with a probability p_i and S_{ji} is the probability that a dispersing individual from patch i arrives in patch j. About the matrix S we make the following assumption.

A4: S is a $k \times k$ primitive column substochastic matrix.

S can be column stochastic if all dispersing individuals migrate successfully or substochastic if some dispersing individuals experience mortality. The primitive assumption ensures that individuals (possibly after several generations) can move from any patch to any patch. S characterizes how connected the landscape is for dispersing individuals. For example, for a fully connected metapopulation, S could be the matrix whose entries all equal $\frac{1}{k}$; i.e., an individual is equally likely to end up in any patch after dispersing. Alternatively, in a landscape with a one-dimensional lattice structure with individuals able only to move to neighboring patches in one time step S is a column substochastic tridiagonal matrix that is primitive, provided it has a positive entry on the diagonal. From these p and S, the following matrix describes how the population redistributes itself across the environment in one time step:

$$S_p = I - \operatorname{diag}(p) + S \operatorname{diag}(p),$$

where $\operatorname{diag}(p)$ denotes a diagonal matrix with diagonal entries $p_1, \ldots, p_k$.

If a census of the population is taken before reproduction and after dispersal, then the dynamics of the population are given by

$$x' = S_p \Lambda(x) x =: F(x), \tag{1}$$

where x' denotes the population state in the next time step and $\Lambda(x)$ is the $k \times k$ diagonal matrix whose ith diagonal entry equals $\lambda_i(x_i)$.

Our first result characterizes the global dynamics of (1). To state this result, let $F^n(x)$ denote F composed with itself n times. Given $x, y \in \mathbf{R}^k_+$, we write $x \geq y$ if $x_i \geq y_i$ for all $1 \leq i \leq k$, $x > y$ if $x \geq y$ and $x \neq y$, and $x \gg y$ if $x_i > y_i$ for all $1 \leq i \leq k$. For a matrix A, let $r(A)$ denote the spectral radius of A.

THEOREM 2.1. *Assume that Assumptions* A1–A4 *hold and* $p \in (0,1]^k$. *If* $r(S_p \Lambda(0)) \leq 1$, *then*

$$\lim_{n\to\infty} F^n(x) = 0$$

for all $x \geq 0$. *Alternatively, if* $r(S_p\Lambda(0)) > 1$, *then there exists a fixed point* $\hat{x} \gg 0$ *for* F *such that*

$$\lim_{n\to\infty} F^n(x) = \hat{x}$$

for all $x > 0$.

Proof. Let $A(x) = S_p\Lambda(x)$. Assumptions A1, A4, and $p \gg 0$ imply that $A(x)$ is primitive for all $x \geq 0$. Assumption A3 implies that $F(x) \geq F(y)$ (resp., $F(x) > F(y)$, $F(x) \gg F(y)$) whenever $x \geq y$ (resp., $x > y$, $x \gg y$). In other words, F is a strongly monotone map.

Suppose that $r(A(0)) \leq 1$. Let $w^T \gg 0$ be a left Perron vector of $A(0)$, i.e., $r(A(0))w^T = w^T A(0)$. Define the function $L : \mathbf{R}^k_+ \to \mathbf{R}_+$ by $L(x) = w^T x$. For $x > 0$, Assumption A1 implies that $w^T A(0) \gg w^T A(x)$. Hence, for any $x > 0$,

$$\begin{aligned} L(F(x)) &= w^T A(F(x))x \\ &= w^T A(0)x + w^T(A(F(x)) - A(0))x \\ &< r(A(0))w^T x \leq L(x). \end{aligned}$$

Since L is strictly decreasing along nonzero orbits of F, $L(0) = 0$, and $L(x) > 0$ for $x > 0$, it follows that $\lim_{n\to\infty} F^n(x) = 0$ for all $x \geq 0$.

Suppose $r(A(0)) > 1$. First, we show that there exists a positive fixed point $\hat{x}$. Let $v \gg 0$ be a right Perron eigenvector for $A(0)$, i.e., $A(0)v = r(A(0))v$. Since $A(0)v \gg v$, continuity of $A(x)$ implies that there exists $\epsilon > 0$ such that $A(y)y \gg y$, where $y = \epsilon v$. Since $F(x) \gg F(y)$ whenever $x \gg y$, induction implies $y \ll F(y) \ll F^2(y) \ll F^3(y) \ll \cdots$. Assumption A2 implies that the increasing sequence $F^n(y)$ is bounded. Hence, there exists $\hat{x}$ such that $\lim_{n\to\infty} F^n(y) = \hat{x}$. Continuity of F implies that $F(\hat{x}) = \hat{x}$. Second, we show that $\lim_{n\to\infty} F^n(x) = \hat{x}$ whenever $\hat{x} > x > 0$. In particular, $\hat{x}$ is a unique positive fixed point. Let w^T be the left Perron eigenvector of $A(\hat{x})$ that satisfies $w^T\hat{x} = 1$. Since $\hat{x}$ is a positive fixed point, $r(A(\hat{x})) = 1$. Define $L : \mathbf{R}^k_+ \to \mathbf{R}_+$ by $L(x) = w^T x$. Let $\hat{x} > x > 0$. Then $\hat{x} > F(x) > 0$ and

$$\begin{aligned} L(F(x)) &= w^T A(F(x))x \\ &= w^T A(\hat{x})x + w^T(A(F(x)) - A(\hat{x}))x \\ &> r(A(\hat{x}))w^T x = L(x). \end{aligned}$$

Hence, $L(x), L(F(x)), L(F^2(x)), \ldots$ is a positive increasing sequence bounded above by $L(\hat{x}) = 1$. Since $L(x) < 1$ for all $x < \hat{x}$, it follows that $\lim_{n\to\infty} F^n(x) = \hat{x}$ for all $0 < x < \hat{x}$. Third, it can be shown similarly that $\lim_{n\to\infty} F^n(x) = \hat{x}$ for all $x > \hat{x}$. Fourth, consider any $x \gg 0$. Choose $\overline{x} > x$ such that $\overline{x} > \hat{x}$ and choose $\underline{x} < x$ such that $0 < \underline{x} < \hat{x}$. Since $F^n(\underline{x}) < F^n(x) < F^n(\overline{x})$ for all n and $\lim_{n\to\infty} F^n(\underline{x}) = \lim_{n\to\infty} F^n(\overline{x}) = \hat{x}$, continuity of F implies that $\lim_{n\to\infty} F^n(x) = \hat{x}$. Finally, consider any $x > 0$. Assumptions A3–A4 imply that there exists $n \geq 1$ such that $F^n(x) \gg 0$. Hence, $\lim_{n\to\infty} F^n(x) = \hat{x}$. □

To understand the evolution of dispersal, we shall consider two populations that differ only in their dispersal ability. Let $x, y \in \mathbf{R}^k_+$ denote the vector of densities of the two populations and $p, \widetilde{p}$ denote their dispersal strategies. Since the populations differ only in their dispersal abilities, their dynamics are given by

$$\begin{aligned} x' &= S_p\Lambda(x+y)x =: G_1(x,y), \\ y' &= S_{\widetilde{p}}\Lambda(x+y)y =: G_2(x,y). \end{aligned} \tag{2}$$

From Assumption A2 it follows that (2) is dissipative i.e., there exists a compact set K such that for any $(x, y) \geq (0, 0)$, $G^n(x, y) \in K$ for n sufficiently large. Regarding the dynamics of (2) near equilibria, we need the following result about invasiveness. Since we have not assumed that $G(x, y)$ is continuously differentiable, this result does not follow immediately from the standard unstable manifold theory.

PROPOSITION 2.2. *Assume that $p, \widetilde{p} \in (0,1]^k$, S and Λ satisfy Assumptions* A1–A4, *and $r(S_p\Lambda(0)) > 1$. Let $\hat{x} \gg 0$ be the fixed point satisfying $G_1(\hat{x}, 0) = (\hat{x}, 0)$. If $r(S_{\widetilde{p}}\Lambda(\hat{x})) > 1$, then there exists a neighborhood $U \subset \mathbf{R}^k_+ \times \mathbf{R}^k_+$ of $(\hat{x}, 0)$ such that for any $(x, y) \in U$ with $y > 0$, $G^n(x, y) \notin U$ for some $n \geq 1$.*

Proof. Let $A(x) = S_{\widetilde{p}}\Lambda(x)$. Assume that $r(A(\hat{x})) > 1$. Let $w^T \gg 0$ be a left Perron eigenvector of $A(\hat{x})$. Since $w^T A(\hat{x}) \gg w^T$, continuity of $x \mapsto A(x)$ implies that there exists a compact neighborhood $U \subset \mathbf{R}^k_+ \times \mathbf{R}^k_+$ of $(\hat{x}, 0)$ and $c > 1$ such that $w^T A(x + y) \gg cw^T$ for all $(x, y) \in U$. Define $L : \mathbf{R}^k_+ \times \mathbf{R}^k_+ \to \mathbf{R}_+$ by $L(x, y) = w^T y$. Let (x, y) be in U with $y > 0$. We have $L(G(x, y)) = w^T A_{\widetilde{p}}(x + y)y > cL(x, y)$. Hence, if $(x, y), \ldots, G^n(x, y) \in U$, then $L(G^n(x, y)) > c^n w^T y$. Since U is compact and $y > 0$, it follows that there exists $n \geq 1$ such that $G^n(x, y) \notin U$. ∎

3. The slower unconditional disperser wins. In this section, we consider only an unconditional dispersal strategy p: a strategy that satisfies $p_1 = \cdots = p_k$ for some common value d. Equivalently, $p = d\,\mathbf{1}$, where $\mathbf{1} = (1, \ldots, 1)$. Our key result is the following theorem concerning the monotonicity of the dominant eigenvalue with respect to the parameter d.

THEOREM 3.1. *Let S be an irreducible column substochastic matrix and Λ be a diagonal matrix. If Λ is not a scalar matrix, then $d \mapsto r(((1 - d)I + dS)\Lambda)$ is decreasing on $[0, 1]$.*

The proof of Theorem 3.1 is given in section 4, where we also characterize the function $d \mapsto r(S_{d\mathbf{1}})$ when S is reducible. The following corollary follows immediately from Theorems 2.1 and 3.1.

COROLLARY 3.2. *Assume that F, S, and $\Lambda(x)$ satisfy Assumptions* A1–A4 *and $p = d\,\mathbf{1}$. Then there exists $d^* \geq 0$ such that we have the following.*

Persistence: *If $d \in [0, d^*)$, then there exists $\hat{x} \gg 0$ satisfying $\lim_{n\to\infty} F^n(x) = \hat{x}$ for all $x \gg 0$.*

Extinction: *If $d \in [d^*, 1]$, then $\lim_{n\to\infty} F^n(x) = 0$ for all $x \geq 0$.*

Moreover, $d^* = 0$ if $\max_i \lambda_i(0) \leq 1$, $d^* \in (0, 1)$ if $\max_i \lambda_i(0) > 1$ and $r(S\Lambda(0)) < 1$, and $d^* \geq 1$ if $r(S\Lambda(0)) \geq 1$.

Corollary 3.2 implies that whenever $r(S\Lambda(0)) < 1$, unconditional dispersers have a critical dispersal rate below which the population persists and above which the population is deterministically driven to extinction.

To characterize the dynamics of competing unconditional dispersers, we need an additional assumption on (2) to avoid degenerate cases. Let $v \gg 0$ be a right Perron eigenvector of S, i.e., $Sv = r(S)v$. We make the following assumption.

A5: $\Lambda(tv)$ is not a scalar matrix for any $t \geq 0$.

This assumption assures that the model exhibits a minimal amount of spatial heterogeneity in the per-capita growth rates at fixed points.

THEOREM 3.3. *Let $G = (G_1, G_2)$ satisfy Assumptions* A1–A5. *Assume that $p = d\mathbf{1}$, and $\widetilde{p} = \widetilde{d}\mathbf{1}$, where $0 < d < \widetilde{d} \leq 1$. If $r(S_p\Lambda(0)) > 1$, then for all $x > 0$ and $y \geq 0$,*

$$\lim_{n\to\infty} G^n(x, y) = (\hat{x}, 0),$$

where $\hat{x}$ is the positive fixed point of $x \mapsto G_1(x, 0)$.

Theorem 3.3 implies that the slower disperser always displaces the faster disperser. This occurs despite the fact that the faster disperser is initially able to establish itself more rapidly, as illustrated in Figures 1 and 2.

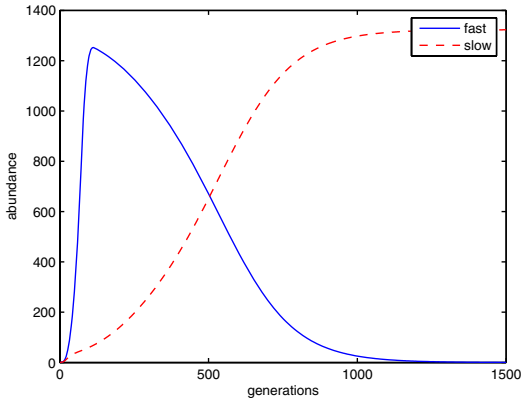

FIG. 1. *A simulation of* (2) *with* $k = 50 \times 50$ *(i.e., a two-dimensional spatial grid),* $\lambda_i(x_i) = \frac{a_i}{1+x_i}$ *with* a_i *randomly chosen from* $[1, 2]$*,* $d = 0.2$*,* $\widetilde{d} = 0.3$*, and* S *given by movement with equal likelihood to east, west, north, and south, and periodic boundary conditions. The initial condition corresponds to a density one of both populations in the center patch. The dotted and solid curves correspond to the abundances of the slower and faster dispersing populations, respectively.*

Proof. The proof of this theorem relies on a result of Hsu, Smith, and Waltman [11, Theorem A] and Theorems 2.1 and 3.1. Let $A_d(x) = S_{d\mathbf{1}}(x)$. We start the proof with an important implication of Assumption A5. Suppose (x, y) satisfies $G(x, y) = (x, y)$. We claim that $\Lambda(x + y)$ is not a scalar matrix. Indeed, suppose to the contrary that $\Lambda(x + y) = tI$ for some $t > 0$. Then

$$x = S_p\Lambda(x+y)x = (1-d)tx + dtSx,$$
$$y = S_{\widetilde{p}}\Lambda(x+y)y = (1-\widetilde{d})ty + \widetilde{d}tSy.$$

Consequently, x and y (and hence $x+y$) are scalar multiples of v. Since this contradicts Assumption A5, $\Lambda(x + y)$ is not a scalar matrix for any fixed point (x, y) of G.

Assuming that $r(A_d(0)) > 1$, Theorem 2.1 implies that $x \mapsto G_1(x, 0)$ has a unique positive fixed point $\hat{x}$ that is globally stable. We prove the theorem in two cases. In the first case, assume that $r(A_{\widetilde{d}}(0)) > 1$. Theorem 2.1 implies that there is a unique $\hat{y} \gg 0$ such that $G(0, \hat{y}) = (0, \hat{y})$ and $\lim_{n\to\infty} G^n(0, y) = (0, \hat{y})$ whenever $y \gg 0$. To employ Theorem A in [11] we need to verify two things: G has no positive fixed point and $(0, \hat{y})$ is unstable. First, suppose to the contrary there exists $x \gg 0$ and $y \gg 0$ such that $G(x, y) = (x, y)$. Then $x = A_d(x + y)x$, $y = A_{\widetilde{d}}(x + y)y$, and $r(A_d(x + y)) = 1$. Since $\Lambda(x + y)$ is not a scalar matrix, Theorem 3.1 implies that $1 = r(A_d(x + y)) > r(A_{\widetilde{d}}(x + y)) = 1$. Hence, there can be no positive fixed point. Second, to show that $(0, \hat{y})$ is unstable, we use Theorem 3.1, which implies that $1 = r(A_{\widetilde{d}}(\hat{y})) < r(A_p(\hat{y}))$, and apply Proposition 2.2. Applying Theorem A of [11] implies that $\lim_{n\to\infty} G^n(x, y) = (\hat{x}, 0)$ whenever $x \gg 0$ and $y \gg 0$.

Suppose that $r(A_{\widetilde{d}}(0)) \leq 1$. Let $w^T \gg 0$ be a left Perron vector of $A_{\widetilde{d}}(0)$. Define the function $L : \mathbf{R}^k_+ \to \mathbf{R}_+$ by $L(y) = w^T y$. Let $\pi(x, y) = y$. Since $L(G^n(x, y))$ is strictly decreasing whenever $y > 0$, $L(0) = 0$, and $L(y) > 0$ for $y > 0$, it follows that $\lim_{n\to\infty} \pi(G^n(x, y)) = 0$ for all $x \geq 0$. Hence, for any $(x, y) \in \mathbf{R}^k_+ \times \mathbf{R}^k_+$, the limit points of $G^n(x, y)$ as $n \to \infty$ lie in $\mathbf{R}^k_+ \times \{0\}$. By Theorem 1.8 in [18], the closure of these limit points form a connected chain recurrent set (see [18] for the definition). Since the only connected chain recurrent sets in $\mathbf{R}^k_+ \times \{0\}$ are $(0, 0)$ and $(\hat{x}, 0)$, instability of $(0, 0)$ implies that $\lim_{n\to\infty} G^n(x, y) = (\hat{x}, 0)$ whenever $x > 0$. ∎

4. Proof of Theorem 3.1. We begin with the following preliminary result.

LEMMA 4.1. *Let v and w^T be positive k-vectors so that $w^T v = 1$. Let $\mathbf{P}$ be the polytope of nonnegative matrices A such that $w^T A = w^T$ and $Av = v$. For each $A \in \mathbf{P}$, let D_A denote the diagonal matrix of column sums of A. Then*

$$\min\{w^T D_A v | A \in \mathbf{P}\} = 1.$$

A matrix $A \in \mathbf{P}$ attains the minimum value for $w^T D_A v$ if and only if $D_A = I$.

Proof. Without loss of generality, assume that $w^T = (w_1, \ldots, w_k)$ is such that $w_1 \leq \cdots \leq w_k$. Note also that if all of the entries in w^T are equal, then each matrix in $\mathbf{P}$ is a column stochastic matrix, and the statement of the lemma follows immediately. We suppose henceforth that w^T has at least two distinct entries.

Suppose that $A \in \mathbf{P}$ and that there are indices i, j, p, q satisfying the following conditions:

$$w_i < w_j, w_p < w_q, \quad \text{and} \quad a_{ip}, a_{jq} > 0. \tag{3}$$

We claim that in this case, the matrix A does not satisfy

$$w^T D_A v \leq w^T D_B v \quad \text{for all } B \in \mathbf{P}. \tag{4}$$

To see the claim, note that from (3), it follows that for sufficiently small $\epsilon > 0$, the matrix

$$\hat{A} = A + \epsilon(-e_i/w_i + e_j/w_j)(e_p/v_p - e_q/v_q)^T$$

is nonnegative, and satisfies $w^T\hat{A} = w^T$ and $\hat{A}v = v$, so that $\hat{A} \in \mathbf{P}$. Further,

$$D_{\hat{A}} = D_A + \epsilon\frac{w_j - w_i}{w_i w_j}\,\mathrm{diag}\left(\frac{-e_p}{v_p} + \frac{e_q}{v_q}\right),$$

so that

$$w^T D_{\hat{A}} v = w^T D_A v - \epsilon\frac{(w_j - w_i)(w_p - w_q)}{w_i w_j} < w^T D_A v.$$

Thus $w^T D_A v$ does not yield the minimum, as claimed.

Suppose the minimum entry in w is repeated a times, i.e., $w_1 = \cdots = w_a < w_{a+1}$. Partition out the first a entries of w^T, to write w^T as $[w_1\mathbf{1}^T|\tilde{w}^T]$, and partition v conformally as

$$v = \left[\frac{\hat{v}}{\tilde{v}}\right].$$

Let $A \in \mathbf{P}$ satisfy (4). Suppose first that there are indices i and p with $1 \leq i \leq a$ and $a+1 \leq p$, such that $a_{ip} > 0$. Since A is a minimizer, we see from the claim above that for any indices j, q with $j \geq a+1$ and $1 \leq q \leq a$, we must have $a_{jq} = 0$. But then A has the form

$$A = \left[\begin{array}{c|c} A_1 & X \\ \hline 0 & A_2 \end{array}\right],$$

where A_1 is $a \times a$. From the facts that $w^T A = w^T$ and that the first a entries of w^T are equal and the partitioned form for A, we find that $\mathbf{1}^T A_1 = \mathbf{1}^T$. Also, $A_1\hat{v} + X\tilde{v} = \hat{v}$, so that $\mathbf{1}^T(A_1\hat{v} + X\tilde{v}) = \mathbf{1}^T\hat{v}$. Since $\mathbf{1}^T A_1 = \mathbf{1}^T$, we conclude that $X = 0$, a contradiction.

Consequently, we conclude that for any indices i and p with $1 \leq i \leq a$ and $a+1 \leq p$, we must have $a_{ip} = 0$. Thus we see that A has the form

$$A = \left[\begin{array}{c|c} A_1 & 0 \\ \hline Y & A_2 \end{array}\right],$$

where A_1 is $a \times a$ and $A_1\hat{v} = \hat{v}$. Using the fact that $w^T A = w^T$, we thus find that $w_1\mathbf{1}^T A_1 + \tilde{w}^T Y = w_1\mathbf{1}^T$. Hence we have $w_1\mathbf{1}^T A_1\hat{v} + \tilde{w}^T Y\hat{v} = w_1\mathbf{1}^T\hat{v}$, from which we deduce that $Y = 0$.

We conclude that if $A \in \mathbf{P}$ satisfies (4), then A can be written as

$$\left[\begin{array}{c|c} A_1 & 0 \\ \hline 0 & A_2 \end{array}\right],$$

where A_1 is column stochastic. The lemma is now readily established by a deflation argument. ∎

Our next result lends some insight into the irreducible case.

LEMMA 4.2. *Suppose that A is an irreducible nonnegative matrix, and let D_A be the diagonal matrix of column sums of A. Let Λ be a diagonal matrix such that $\Lambda \geq D_A$. For each $d \in [0,1]$ let $h(d) = r((1-d)\Lambda + dA)$. Then for any $d \in (0,1), h'(d) \leq 0$, with equality holding if and only if $\Lambda = D_A = aI$ for some $a > 0$. In that case, $h(d) = r(A) = a$ for each $d \in [0,1]$.*

Proof. Throughout, we suppose without loss of generality that $r(A) = 1$.

First, suppose that A is a primitive matrix; we claim that in this case, $h'(1) \leq 0$ with equality holding if and only if $\Lambda = D_A = I$. Let v be a right Perron vector for A. Since A is primitive, its spectral radius is a simple eigenvalue that strictly dominates the modulus of any other eigenvalue; it follows that in a sufficiently small neighborhood of 1, $h(d)$ is an eigenvalue of $(1-d)\Lambda + dA$ that is differentiable in d. For d in such a neighborhood of 1, let $w(d)^T$ be a left $h(d)$-eigenvector of $(1-d)\Lambda + dA$, normalized so that $w(d)^T v = 1$. Since $Av = v$, we have

$$\begin{aligned} h(d) &= w(d)^T((1-d)\Lambda + dA)v \\ &= (d-1)(w(d)^T(A-\Lambda)v) + w(d)^T Av \\ &= (d-1)(1 - w(d)^T \Lambda v) + 1. \end{aligned}$$

Since $\lim_{d\to 1} w(d)^T = w^T$, it follows that

$$\begin{aligned} \lim_{d\to 1} \frac{h(d)-h(1)}{d-1} &= \lim_{d\to 1}(1 - w(d)^T \Lambda v) = 1 - w^T \Lambda v \\ &= -(w^T D_A v - 1) - (w^T(\Lambda - D_A)v). \end{aligned}$$

Since $\Lambda \geq D_A$, we have $w^T(\Lambda - D_A)v \geq 0$, and by Lemma 4.1, we have $w^T D_A v - 1 \geq 0$, so certainly $h'(1) \leq 0$. Further, we see that $h'(1) = 0$ if and only if $w^T D_A v = 1$ and $w^T(\Lambda - D_A)v = 0$. It now follows from Lemma 4.1 that the former holds if and only if $D_A = I$, and since w^T and v are positive vectors, we see that the latter holds if and only if $\Lambda = D_A$. This completes the proof of the claim.

Next, suppose that A is an irreducible nonnegative matrix, and fix $d \in (0,1)$. Observe that the matrix $B = (1-d)\Lambda + dA$ is primitive and that $\Lambda \geq D_B$. For each $c \in [0,1]$, let $k(c) = r((1-c)\Lambda + cB)$, and note that $k(c) = h(cd)$. Applying the claim above to the function k, we see that $k'(1) \leq 0$, with equality holding if and only if $\Lambda = D_B = I$. But from the chain rule, we find that $k'(1) = dh'(d)$, so that $h'(d) \leq 0$, with equality if and only if $\Lambda = D_B = I$. That last condition is readily seen to be equivalent to $\Lambda = D_A = I$.

Finally, we note that if $\Lambda = D_A = I$, it is straightforward to see that for each $d \in [0,1]$, the matrix $(1-d)\Lambda + dA$ is column stochastic, so that $h(d) = 1 = r(A)$ for all such d. ∎

The following, which evidently yields Theorem 3.1 immediately, follows from Lemma 4.2.

COROLLARY 4.3. *Suppose that A is an irreducible nonnegative matrix, and let D_A be the diagonal matrix of column sums of A. Let Λ be a diagonal matrix such that $\Lambda \geq D_A$. For each $d \in [0,1]$ let $h(d) = r((1-d)\Lambda + dA)$. Then either*

(a) *$h(d)$ is a strictly decreasing function of $d \in [0,1]$ or*

(b) *for some $a > 0, \Lambda = D_A = aI$ and $h(d) = a$ for each $d \in [0,1]$.*

We have the following generalization of Corollary 4.3.

THEOREM 4.4. *Let S be a column substochastic matrix and Λ be a diagonal matrix with positive diagonal entries. Define the function $f(d) = r(((1-d)I + dS)\Lambda)$ for $d \in [0,1]$. Then there is a $\hat{d} \in [0,1]$ such that f is strictly decreasing on $[0,\hat{d}]$ and f is constant on $[\hat{d},1]$. Specifically, let P be a permutation matrix such that*

$$P^T S P = \left[\begin{array}{cccc|c} S_1 & 0 & \dots & 0 & X_1 \\ 0 & S_2 & \dots & 0 & X_2 \\ \vdots & & \ddots & \vdots & \vdots \\ 0 & \dots & 0 & S_k & X_k \\ \hline 0 & 0 & \dots & 0 & S_{k+1} \end{array}\right], \quad \textit{and} \quad P^T \Lambda P = \begin{bmatrix} \Lambda_1 & & & \\ & \Lambda_2 & & \\ & & \ddots & \\ & & & \Lambda_{k+1} \end{bmatrix},$$

where (i) *$P^T S P$ and $P^T \Lambda P$ are partitioned conformally,* (ii) *for each $i = 1, \dots, k$, S_i is an irreducible column stochastic matrix, and* (iii) *S_{k+1} is a column substochastic matrix such that $r(S_{k+1}) < 1$. (Note that such a permutation matrix P exists and that one part of this partitioning of $P^T S P$ may be vacuous.) Let $r(\Lambda) = \rho$. Exactly one of the following cases holds.*

(a) *For some $i = 1, \dots, k$, $\Lambda_i = \rho I$. In this case, $f(d) = \rho$ for all $d \in [0,1]$.*

(b) *There is an index $i_0 = 1, \dots, k$ and an $a < \rho$ such that $\Lambda_{i_0} = aI$ and in addition, for each $j = 1, \dots, k+1$, we have that either $r(S_j \Lambda_j) < a$ or $r(((1-d)I + dS_j)\Lambda_j) = a$ for all $d \in [0,1]$. In this case, there is a $\hat{d} \in (0,1)$ such that $f(d)$ is a strictly decreasing function of d for $d \in [0,\hat{d}]$, while for each $d \in [\hat{d},1]$, $f(d) = a$.*

(c) *If $\Lambda_i \neq \rho I$ for $i = 1, \dots, k$ and there is no index i_0 and value a satisfying the hypotheses of* (b)*, then $f(d)$ is strictly decreasing for $d \in [0,1]$.*

Proof. Throughout, we assume without loss of generality that $\rho = 1$. First, note that $f(d) = \max\{r(((1-d)I + dS_i)\Lambda_i) : i = 1, \dots, k+1\}$. Further, since $r(S_{k+1}) < 1$ it follows that no principal submatrix of S_{k+1} (including the entire matrix S_{k+1} itself) can have all of its column sums equal to 1; we then deduce from Corollary 4.3 that $r(((1-d)I + S_{k+1})\Lambda_{k+1})$ is strictly decreasing as a function of $d \in [0,1]$. Note further that if none of $\Lambda_1, \dots, \Lambda_k$ is a scalar matrix, then for each $i = 1, \dots, k$ the function $r(((1-d)I + dS_i)\Lambda_i)$ is strictly decreasing in d, from which we conclude that $f(d)$ is strictly decreasing.

Suppose next that for some $i = 1, \dots, k$, we have $\Lambda_i = I$. From Corollary 4.3 we see that $r(((1-d)I + dS_i)\Lambda_i) = 1$ for all $d \in [0,1]$, and we conclude readily that $f(d) = 1$ for all $d \in [0,1]$.

It remains only to consider the case that $\Lambda_i \neq I$ for $i = 1, \dots, k$ but that for one or more indices $i = 1, \dots, k$, Λ_i is a scalar matrix. For concreteness, we suppose that $\Lambda_i = a_i I$ for $i = 1, \dots, j$ and that for $i = j+1, \dots, k$, Λ_i is not a multiple of the identity matrix. Again without loss of generality, we can assume that $1 > a_1 \geq \cdots \geq a_j$. In this situation, we find that for each $i = 1, \dots, j$, $r(((1-d)I + dS_i)\Lambda_i) = a_i$, while for each $i = j+1, \dots, k+1$, $r(((1-d)I + dS_i)\Lambda_i)$ is a strictly decreasing function of d. It follows from the above considerations that $f(d) = \max\{a_1, r(((1-d)I + dS_{j+1})\Lambda_{j+1}), \dots, r(((1-d)I + dS_{k+1})\Lambda_{k+1})\}$.

Evidently two cases arise: either $\max\{r(S_{j+1}\Lambda_{j+1}), \dots, r(S_{k+1}\Lambda_{k+1})\} \geq a_1$ or $\max\{r(S_{j+1}\Lambda_{j+1}), \dots, r(S_{k+1}\Lambda_{k+1})\} < a_1$. In the former case we see that in fact $f(d) = \max\{r(((1-d)I + dS_{j+1})\Lambda_{j+1}), \dots, r(((1-d)I + dS_{k+1})\Lambda_{k+1})\}$ for all $d \in [0,1]$, from which we conclude that f is strictly decreasing in d. Now suppose that the latter

case holds. Since $a_1 < 1$, we see that when d is near to 0, $f(d) = \max\{r(((1-d)I + dS_{j+1})\Lambda_{j+1}), \ldots, r(((1-d)I + dS_{k+1})\Lambda_{k+1})\} > a_1$. Thus, from the intermediate value theorem it follows that there is a value $\hat{d} \in (0,1)$ such that $\max\{r(((1-d)I + dS_{j+1})\Lambda_{j+1}), \ldots, r(((1-d)I + dS_{k+1})\Lambda_{k+1})\} \geq a_1$ for $d \in [0, \hat{d}]$ and $\max\{r(((1-d)I + dS_{j+1})\Lambda_{j+1}), \ldots, r(((1-d)I + dS_{k+1})\Lambda_{k+1})\} < a_1$ for $d \in [\hat{d}, 1]$. It now follows that $f(d)$ is strictly decreasing for $d \in [0, \hat{d}]$ and $f(d) = a_1$ for $d \in [\hat{d}, 1]$. □

5. Competing conditional dispersers. In this section, we extend our study to conditional dispersers in which p need not be a constant vector. The following theorem coupled with Proposition 2.2 indicates which dispersal strategies are subject to invasion by other dispersal strategies.

THEOREM 5.1. *Assume that $\Lambda(x)$ and S satisfy Assumptions* A1–A4, *$p \in (0,1]^k$, and $r(S_p\Lambda(0)) > 1$. Let $\hat{x} \gg 0$ be the unique positive fixed point of F, and let $v \gg 0$ be a right Perron vector for S. Then $r(S_{\widetilde{p}}\Lambda(\hat{x})) \leq 1$ for all $\widetilde{p} \in (0,1]^k$ if and only if $\lambda_i(0) > 1$ for all i, S is column stochastic, and*

$$p = t\left(\Lambda^{-1}(I)\right)^{-1} v \tag{5}$$

for some $t \in (0, 1/\max\{\Lambda^{-1}(I)^{-1}v\}]$. Moreover, if p is given by (5), *then $\Lambda(\hat{x}) = I$.*

In our proof of Theorem 5.1, we show that if either S is strictly substochastic or p is not given by (5), then there are strategies $\widetilde{p}$ arbitrarily close to p that can invade, i.e., $r(S_{\widetilde{p}}\Lambda(\hat{x})) > 1$. When S is stochastic and p is given by (5), we also show that $\Lambda(\hat{x}) = I$ and, consequently, $r(S_{\widetilde{d}}\Lambda(\hat{x})) = 1$ for all $\widetilde{p} \in [0,1]^k$. The populations playing one of these strategies exhibit an *ideal-free distribution at equilibrium* [3]; i.e., the per-capita fitness in all occupied patches are equal. Theorem 5.1 suggests the possibility that strategies of the form (5) can displace all other strategies. By [11, Theorem A] a sufficient condition for this displacement is verifying that (5) can invade any strategy $\widetilde{p}$ not given by (5) and cannot coexist at equilibrium with strategy $\widetilde{d}$. This turns out not to be true in general. For example, let $\lambda_i(x_i)$ with $i = 1, 2$ be functions such that $\lambda_1(1.2) = \lambda_2(1) = 1$, $\lambda_1(1.19) = \frac{20}{9+\sqrt{41}} \approx 1.29844$, $\lambda_2(9.52/(3+\sqrt{41})) = \frac{10}{9+\sqrt{41}} \approx 0.642919$, where $9.52/(3+\sqrt{41}) \approx 1.01234$, and Assumptions A1–A3 are satisfied. Define

$$S = \begin{pmatrix} 0.5 & 0.6 \\ 0.5 & 0.4 \end{pmatrix},$$

which has right Perron vector

$$v = \begin{pmatrix} 1 \\ 5/6 \end{pmatrix}.$$

Then $p = \mathbf{1}$ is a strategy of the form (5). Define

$$\widetilde{p} = \begin{pmatrix} 0.8 \\ 2/3 \end{pmatrix}.$$

The unique positive fixed point of $y \mapsto S_{\widetilde{p}}\Lambda(y)y = G(0,y)$ is by construction given by

$$\hat{y} = \begin{pmatrix} 1.19 \\ \frac{9.52}{3+\sqrt{41}} \end{pmatrix}.$$

Since a computation reveals that

$$r(S\Lambda(\widehat{y})) = 0.993735\ldots < 1 = r(S_{\widetilde{d}}\Lambda(\widehat{y})),$$

the strategy $p = \mathbf{1}$ cannot invade and displace the strategy $\widetilde{p}$. Hence, for a general $\Lambda(x)$, we cannot expect that strategies of the form (5) will displace all other strategies. However, extensive simulations with the Beverton–Holt growth functions (i.e., $\lambda_i(x_i) = \frac{a_i}{1+b_i x_i}$) suggest that the strategies given by (5) can displace any other strategy (see Figure 3). Thus we make the following conjecture.

CONJECTURE 5.1. *If $\lambda_i(x_i) = \frac{a_i}{1+b_i x_i}$, S is primitive and column stochastic, p is given by* (5)*, $\widetilde{p}$ is not given by* (5)*, and $r(S_p\Lambda(0)) > 1$, then*

$$\lim_{n\to\infty} G^n(x,y) = (\hat{x}, 0)$$

whenever $x > 0$.

Proof of Theorem 5.1 The key proposition (which gives us more than we need) is the following.

PROPOSITION 5.2. *Suppose that A is an irreducible nonnegative matrix with column sums c_i such that $c_1 = \min_i c_i < \max_i c_i = c_k$. If $\widetilde{A}$ is a nonnegative matrix obtained from A by changing its first column from*

$$\begin{pmatrix} a_{11} \\ \cdot \\ \vdots \\ a_{k1} \end{pmatrix} \quad \text{to} \quad \begin{pmatrix} a_{11} \\ \cdot \\ \vdots \\ a_{k1} \end{pmatrix} + \gamma \begin{pmatrix} -\sum_{i=2}^{k} a_{i1} \\ a_{21} \\ \cdots \\ a_{k1} \end{pmatrix}$$

for some positive $\gamma > 0$, then $r(A) < r(\tilde{A})$. Alternatively, if $\hat{A}$ is a nonnegative matrix obtained from A by changing its last column from

$$\begin{pmatrix} a_{1k} \\ \cdot \\ \vdots \\ a_{kk} \end{pmatrix} \quad \text{to} \quad \begin{pmatrix} a_{1k} \\ \cdot \\ \vdots \\ a_{kk} \end{pmatrix} - \gamma \begin{pmatrix} -\sum_{i=2}^{k} a_{ik} \\ a_{2k} \\ \cdots \\ a_{kk} \end{pmatrix}$$

for some $\gamma \in (0,1]$, then $r(A) > r(\hat{A})$.

Proof. Note that $c_k > r(A) > c_1$. Let w^T be the left Perron vector for A such that $w_1 = 1$, and let $\tilde{v}$ be the right Perron vector for $\tilde{A}$ normalized so that $w^T\tilde{v} = 1$. Observe that for any γ such that $\tilde{A}$ is nonnegative, $\tilde{A}$ is irreducible and, consequently, v is a positive vector. Set $W = \operatorname{diag}(w_1, \ldots, w_n)$. Then WAW^{-1} has all the column sums equal to $r(A)$. Consider the first column of WAW^{-1}. We see that

$$a_{11} + \sum_{i=2}^{k} w_i a_{i1} = r(A) > c_1 = \sum_{i=1}^{k} a_{i1}.$$

Thus,

$$\sum_{i=2}^{k} w_i a_{i1} > \sum_{i=2}^{k} a_{i1}.$$

It follows that $r(\tilde{A}) = w^T\tilde{A}\tilde{v} = w^TA\tilde{v} + \gamma\tilde{v}_1(-\sum_{i=2}^{k} a_{i1} + \sum_{i=2}^{k} w_i a_{i1}) > w^TA\tilde{v} = r(A)$.

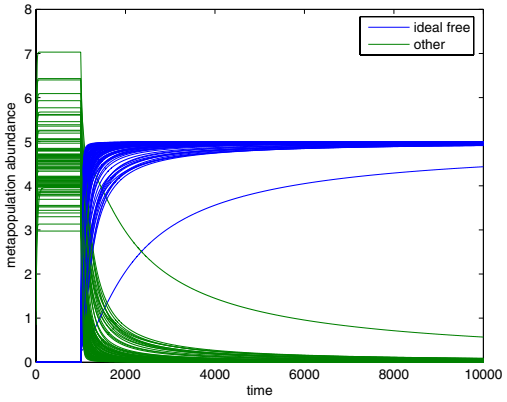

FIG. 3. *One hundred realizations of an ideal-free disperser competing against a random dispersal strategy. In the simulations,* $k = 10$ *and* $\lambda_i(x_i) = \frac{a_i}{1+b_i x_i}$. *For each simulation, the values of* a_i *are randomly selected from the interval* $[1, 2]$, p *is defined by* (5), *where* t *is randomly selected from the interval* $[0, \max(\Lambda^{-1}(I))^{-1} v]$, *and* $\widetilde{p}$ *is randomly selected from* $[0, 1]^{10}$. *To normalize the local population abundances to a value of* 1, *in each simulation* b_i *is set equal to* $\frac{1}{a_i - 1}$.

A similar argument applies to the matrix $\hat{A}$ when $\gamma < 1$, while if $\gamma = 1$, we see that the first column of $\hat{A}$ is $c_k e_k$ and $r(\hat{A}) \geq c_k > r(A)$. □

Now assume $p \in (0, 1]^k$, $r(S_p \Lambda(0)) > 1$, $\hat{x} \gg 0$ is the unique positive fixed point of F, and $v \gg 0$ is a right Perron vector for S. Let $A = S_p \Lambda(\hat{x})$. We begin by showing that $r(S_{\widetilde{p}} \Lambda(\hat{x})) \leq 1$ for all $\widetilde{p} \in [0, 1]^k$ implies that S is stochastic and p is given by (5). First, we show that A must have constant column sums c_i. Suppose to the contrary that there exists $1 \leq j \leq k$ such that $c_j = \max_i c_i > \min_i c_i$. Let $\widetilde{p}$ be any strategy where $\widetilde{p}_i = p_i$ for $i \neq j$ and $\widetilde{p}_j \in (0, p_j)$. Then $S_{\widetilde{p}} \Lambda(\hat{x})$ is given by replacing the jth column of A by a column which is

$$\geq \begin{pmatrix} a_{1j} \\ \cdot \\ \vdots \\ a_{kj} \end{pmatrix} - \gamma \begin{pmatrix} -\sum_{i=2}^{k} a_{ij} \\ a_{2j} \\ \cdots \\ a_{kj} \end{pmatrix},$$

where $\gamma = 1 - \frac{\widetilde{p}_j}{p_j} > 0$. Proposition 5.2 implies that $r(S_{\widetilde{p}} \Lambda(\hat{x})) > r(A) = 1$, contrary to our assumption about p. Therefore A must have constant column sums $c = c_1 = \cdots = c_k$. Second, suppose to the contrary that S is substochastic. Let $\widetilde{p}$ be any strategy where $\widetilde{p}_i \in (0, p_i)$. Since S is substochastic, every column sum $S_{\widetilde{p}} \Lambda(\hat{x})$ is greater than or equal to c and at least one column sum is strictly greater than c. Hence, $r(S_{\widetilde{p}} \Lambda(\hat{x})) > r(A) = 1$, contrary to our assumption about p. Therefore, S is stochastic. Finally, since S is stochastic, it follows that $c = 1$ and $\Lambda(\hat{x}) = I$. Since $\hat{x} \gg 0$, we have $\lambda_i(0) > 1$ and $\hat{x}_i = \lambda_i^{-1}(1)$ for all i. Since $\hat{x}$ is a fixed point, we get that $\hat{x} = (I - \operatorname{diag}(p) + S \operatorname{diag}(p))\hat{x}$. Equivalently, $S \operatorname{diag}(p)\hat{x} = \operatorname{diag}(p)\hat{x}$. Hence, $\operatorname{diag}(p)\hat{x} \gg 0$ is a right Perron vector for S and p is given by (5).

Now suppose that S is stochastic and p is given by (5). Then $\Lambda(\hat{x}) = I$ and $r(S_{\widetilde{p}} \Lambda(\hat{x})) = r(S_{\widetilde{p}}) = 1$ for all $\widetilde{p} \in [0, 1]^k$. □

Conjecture 5.1 suggests that for populations with Beverton–Holt local dynamics, the evolution of conditional dispersers will favor strategies on the ray defined by (5).

Hence, it is natural to ask what happens when two strategies on this ray compete against one another.

PROPOSITION 5.3. *Assume that* $\Lambda(x)$ *and* S *satisfy Assumptions* A1–A4, $\lambda_i(0) > 1$ *for all* i, *and* S *is stochastic. Let* p *and* $\widetilde{p}$ *be strategies given by* (5) *with* $t = d$ *and* $t = \widetilde{d}$, *where* $0 < d < \widetilde{d} \le 1/\max\{\left(\Lambda^{-1}(I)\right)^{-1} v\}$. *Then the set of fixed points of* G *are* $(0,0)$ *and*

$$L = \{(\alpha\hat{x}, (1-\alpha)\hat{x} : \alpha \in [0,1]\},$$

where $\hat{x} = \Lambda^{-1}(I)\mathbf{1}$. *Moreover, if* $\Lambda(x)$ *is continuously differentiable with* $\lambda_i'(x_i) < 0$ *for all* i, *and* $\frac{d}{dx_i} x_i \lambda_i(x_i) > 0$ *for all* i, *then there exists a neighborhood* $U \subset \mathbf{R}_+^k \times \mathbf{R}_+^k$ *of* L *and a homeomorphism* $h : [0,1] \times D \to U$ *with* $D = \{z \in \mathbf{R}^{2k-1} : \|z\| < 1\}$ *such that* $h(\alpha, 0) = \alpha\hat{x} + (1-\alpha)\hat{x}$, $h(0, D) = \{(0, y) \in U\}$, $h(1, D) = \{(x, 0) \in U\}$, *and* $\lim_{n\to\infty} G^n(x,y) = (\alpha\hat{x}, (1-\alpha)\hat{x})$ *for all* $(x,y) \in h(\{\alpha\} \times D)$.

Proof. By the change of variables $x \mapsto \Lambda^{-1}(I)^{-1}\mathrm{diag}\,(v)x$, we can assume without any loss of generality that $p = d\mathbf{1}$ and $\widetilde{p} = \widetilde{d}\mathbf{1}$. Thus, a point $(x,y) > 0$ is a fixed point of G if and only if

$$\begin{aligned}((1-d)I + dS)\Lambda(x+y)x &= x,\\ ((1-\widetilde{d})I + \widetilde{d}S)\Lambda(x+y)y &= y.\end{aligned}$$

Since $r(((1-d)I + dS)\Lambda(x+y))) = r((1-\widetilde{d})I + \widetilde{d}S)\Lambda(x+y)) = 1$ and $d \neq \widetilde{d}$, Theorem 3.1 implies that $\Lambda(x+y) = I$. Therefore, (x,y) needs to satisfy $x + y = \Lambda^{-1}(I)\mathbf{1}$, $Sdx = dx$, and $S\widetilde{d}y = \widetilde{d}y$. Since S is primitive, we get that x must be a scalar multiple of y. Hence, the fixed points of G are given by $(0,0)$ and L.

Now assume that $x \mapsto \Lambda(x)$ is continuously differentiable, $\lambda_i'(x) < 0$ for all i, and $\frac{d}{dx_i} x_i \lambda_i(x_i) > 0$ for all i. We will show that L is a normally hyperbolic attractor in the sense of Hirsch, Pugh, and Shub [7]. Let $(x,y) \in L$. We have

$$DG(x,y) = \begin{pmatrix} S_d(\Lambda'(x+y)\mathrm{diag}\,(x) + \Lambda(x+y)) & S_d\Lambda'(x+y)\mathrm{diag}\,(x) \\ S_d\Lambda'(x+y)\mathrm{diag}\,(y) & S_d(\Lambda'(x+y)\mathrm{diag}\,(y) + \Lambda(x+y)) \end{pmatrix}.$$

Since $0 < \lambda_i'(x_i+y_i)(x_i+y_i) + \lambda_i(x_i+y_i) < \lambda_i'(x_i+y_i)x_i + \lambda_i(x_i+y_i)$ for all i, the diagonal blocks, $S_d(\Lambda'(x+y)\mathrm{diag}\,(x) + \Lambda(x+y))$ and $S_d(\Lambda'(x+y)\mathrm{diag}\,(y) + \Lambda(x+y))$ of $DG(x,y)$, are nonnegative primitive matrices. Since $\lambda_i'(x_i+y_i) < 0$ for all i, the off-diagonal blocks, $S_d\Lambda'(x+y)\mathrm{diag}\,(x)$ and $S_d\Lambda'(x+y)\mathrm{diag}\,(y)$, of $DG(x,y)$ are negative scalar multiples of primitive matrices. Hence, $DG(x,y)$ is a primitive matrix with respect to the competitive ordering on $\mathbf{R}_+^k \times \mathbf{R}_+^k$; i.e., $(\tilde{x}, \tilde{y}) \ge_K (x,y)$ if $\tilde{x} \ge x$ and $\tilde{y} \le y$. Since L is a line of fixed points, $DG(x,y)$ has an eigenvalue of one associated with the eigenvector $(\Lambda^{-1}(I)\mathbf{1}, -\Lambda^{-1}(I)\mathbf{1})$. The Perron–Frobenius theorem implies that all the other eigenvalues of $DG(x,y)$ are strictly less than one in absolute value. Hence, L is a normally hyperbolic one-dimensional attractor. Theorem 4.1 of [7] implies that there is a neighborhood $U \subset \mathbf{R}_+^k \times \mathbf{R}_+^k$ of L and a homeomorphism $h : [0,1] \times D \to U$ with $D = \{z \in \mathbf{R}^{2k-1} : \|z\| < 1\}$ such that $h(\alpha, 0) = \alpha\hat{x} + (1-\alpha)\hat{x}$, $h(0, D) = \{(0, y) \in U\}$, $h(1, D) = \{(x, 0) \in U\}$, and $\lim_{n\to\infty} G^n(x,y) = (\alpha\hat{x}, (1-\alpha)\hat{x})$ for all $(x,y) \in h(\{\alpha\} \times D)$. ∎

Proposition 5.3 implies that once a "resident" population playing a strategy of the form (5) has established itself, a "mutant" strategy of the form (5) can invade only in a weak sense: if the mutants enter at low density, deterministically they will converge to an equilibrium with a low mutant density. After the invasion, one would

expect that demographic or environmental stochasticity would with greater likelihood result in the displacement of the mutants. Hence, once a strategy of the form (5) has established itself, it is likely to resist invasion attempts from other strategies of the form (5). Proposition 5.3 also suggests the following conjecture, which is supported by simulations using the Beverton–Holt growth function.

CONJECTURE 5.2. *Under the conditions of Proposition* 5.3*, for every* $(x, y) > 0$ *there exists* $\alpha \in [0, 1]$ *such that*

$$\lim_{n\to\infty} G^n(x, y) = (\alpha\Lambda^{-1}(I)\mathbf{1}, (1-\alpha)\Lambda^{-1}(I)\mathbf{1}).$$

6. Discussion. For organisms that disperse unconditionally, we proved that a slower dispersing population competitively excludes a faster dispersing population. Similar results have been proven for reaction diffusion equations where the dispersal kernel is self-adjoint [2], observed in a partial analysis of two patch differential equations [8] and illustrated with simulations of two patch difference equations [17]. Our proofs apply to difference equations with an arbitrary number of patches and without any symmetry assumptions about the dispersal matrix S. Since geographical and ecological barriers often create asymmetries in the movement patterns of active dispersers and create asymmetries in abiotic and biotic currents that carry passive dispersers, accounting for these asymmetries is crucial and results in a significantly more difficult mathematical problem than the symmetric case. Theorem 3.1 provides the solution to this problem by proving for any given environmental condition (i.e., the choice of Λ and S), the principal eigenvalue for the growth dispersal matrix is a decreasing function of the dispersal rate. Hence, under all environmental conditions, populations that disperse more slowly spectrally dominate populations that disperse more quickly. Despite this spectral dominance, simulations (e.g., Figure 1) illustrate that for appropriate initial conditions, faster dispersers can be numerically dominant as they initially spread across a landscape. This initial phase of numerical dominance has empirical support in studies of northern range limits of butterflies: dispersal rates increase as species move north to newly formed favorable habitat [6]. Presumably over a long period of time, selection will favor slower dispersal rates commensurate with their ancestral rates of movement (R. Holt, *personal communication*). However, since all initial conditions do not lead to an initial phase of numerical dominance for the faster dispersers (e.g., if the initial condition is a Perron vector for the slower disperser), we still require a detailed understanding of how the local intrinsic rates of growth, the dispersal matrix, and initial conditions determine whether the faster or slower disperser is numerically dominant in the initial phase of establishment.

For conditional dispersers experiencing no dispersal costs (i.e., S is column stochastic and $\lambda_i(0) > 1$ for all i), we provide proofs that generalize previous findings in two patch models [9, 17]. We prove that all dispersal strategies outside of a one-parameter family are not evolutionarily stable: when a population adopts one of these strategies, there are nearby strategies that can invade. For populations playing strategies in this exceptional one-parameter family, the populations exhibit an ideal-free distribution at equilibrium: the per-capita growth rate is constant across the landscape [3]. Contrary to prior expectations [17], we show that are growth functions for which these ideal-free strategies cannot displace all other strategies. However, numerical simulations with the biologically plausible Beverton–Holt growth functions suggest that populations playing these ideal-free strategies can displace populations playing any other strategy. Moreover, when a population at equilibrium plays an ideal-free strategy, we prove that a population playing another ideal-free strategy cannot increase from being rare

and, consequently, is likely to be driven to extinction by stochastic forces. For populations playing these ideal-free strategies, the dispersal likelihood in a patch is inversely proportional to the equilibrium abundance in a patch. Hence, enriching one patch may result in the evolution of lower dispersal rates in that patch. Conversely, habitat degradation of a patch may result in the evolution of higher dispersal rates in that patch. These predictions about ideal-free strategies, however, have to be viewed with caution, as they are sensitive to the assumption of no dispersal costs. The inclusion of the slightest dispersal costs destroys this one-parameter family of evolutionary stable strategies and leaves only the nondispersal strategy as a candidate for an evolutionary stable strategy.

Our models make several simplifying assumptions, and relaxing these assumptions provides several mathematical problems of biological interest. Most importantly, our models do not include temporal heterogeneity, which is an important ingredient in the evolution of dispersal [17]. Temporal heterogeneity can be generated exogenously or endogenously and when combined with spatial heterogeneity can promote the evolution of faster dispersers [10, 13, 17]. For instance, Hutson, Mischaikow, and Poláčik [13] proved that a faster disperser can displace or coexist with a slower disperser for periodically forced reaction diffusion equations. Whether similar results can be proven for periodic or, more generally, random difference equations requires answering mathematically challenging questions about spectral properties of periodic and random products of nonnegative matrices. Similar challenges arise when replacing increasing growth functions with unimodal growth functions [4, 10, 19] that can generate temporal heterogeneity via periodic and chaotic population dynamics.

Acknowledgments. The authors thank participants of the William and Mary "matrices in biology sessions" for their valuable feedback on this evolving work. In particular, we thank Greg Smith and Marco Huertas for finding counterexamples to an earlier conjectured form of Theorem 3.1. We also thank Bob Holt, Vivian Hutson, Konstantin Mischaikow, and an anonymous referee for their encouraging comments and helpful suggestions.

VARIABLE EXPONENT, LINEAR GROWTH FUNCTIONALS IN IMAGE RESTORATION*

YUNMEI CHEN†, STACEY LEVINE‡, AND MURALI RAO†

Abstract. We study a functional with variable exponent, $1 \leq p(x) \leq 2$, which provides a model for image denoising, enhancement, and restoration. The diffusion resulting from the proposed model is a combination of total variation (TV)-based regularization and Gaussian smoothing. The existence, uniqueness, and long-time behavior of the proposed model are established. Experimental results illustrate the effectiveness of the model in image restoration.

Key words. image restoration, linear growth functionals, variable exponent, BV-space, Dirichlet boundary condition

1. Introduction.

1.1. Background. In this paper we propose a new model for image restoration. In the version we address, an image, u, is recovered from an observed, noisy image, I, where the two are related by $I = u + noise$. The proposed model incorporates the strengths of the various types of diffusion arising from the minimization problem

$$\min \int_\Omega |Du|^p + \frac{\lambda}{2}(u - I)^2 \tag{1.1}$$

for $1 \leq p \leq 2$ ($\lambda \geq 0$, and Ω is an open, bounded subset of $\mathbb{R}^n$ with Lipschitz boundary). Specifically, we exploit the benefits of isotropic diffusion ($p = 2$), total variation (TV)-based diffusion ($p = 1$), and more general anisotropic diffusion ($1 < p < 2$).

TV minimization, $p = 1$. TV-based regularization, $p = 1$, as first proposed by Rudin, Osher, and Fatemi [31], does an excellent job of preserving edges while reconstructing images. Mathematically this is reasonable, since it is natural to study solutions of this problem in the space of functions of bounded variation, $BV(\Omega)$, allowing for discontinuities which are necessary for edge reconstruction. This phenomenon can also be explained physically, since the resulting diffusion is strictly orthogonal to the gradient of the image. The TV model has been studied extensively (see, e.g., [1, 15]) and has proved to be an invaluable tool for preserving sharp edges.

Given the success of TV-based diffusion, various modifications have been introduced. For instance, Strong and Chan [32] proposed the adaptive total variation model

$$\min \int_\Omega \alpha(x)|\nabla u|$$

in which they introduce a control factor, $\alpha(x)$, which slows the diffusion at likely edges. This controls the *speed* of the diffusion and has demonstrated good results, as it aids in noise reduction. It is also good at reconstructing edges, since the *type* of diffusion (strictly orthogonal to the image gradient) is the same as that of the original TV model.

TV-based denoising favors solutions that are piecewise constant. This sometimes causes a *staircasing* effect in which noisy smooth regions are processed into piecewise constant regions (see Figure 5.1), a phenomenon long observed in the literature; see, e.g., [9, 15, 20, 28, 30, 34, 36]. Not only do "blocky" solutions fail to satisfy the ubiquitous "eyeball norm," but they can also develop "false edges," which can mislead a human or computer into identifying erroneous features not present in the true image.

Minimization problem (1.1) with $1 < p \leq 2$. On the other hand, one can explore different *types* of diffusion arising from (1.1). Choosing $p = 2$ results in isotropic diffusion, which solves the staircasing problem but alone is not good for image reconstruction since it has no mechanism for preserving edges. Different values of $1 < p < 2$ result in anisotropic diffusion, which is somewhere between TV-based and isotropic smoothing. This type of diffusion can be effective in reconstructing piecewise smooth regions. However, a fixed value of $1 < p < 2$ may not allow for discontinuities, thus obliterating edges. This was shown to be true in the discrete case [28].

Combination of TV-based and isotropic diffusion. Given the strengths of (1.1) for different values of p, it seems worthwhile to investigate a model which could self-adjust in order to reap the benefits of each type of diffusion. To this end, Chambolle and Lions [15] proposed minimizing the following energy functional, which combines isotropic and TV-based diffusion:

$$\min_{u \in BV(\Omega)} \frac{1}{2\beta} \int_{|\nabla u| \leq \beta} |\nabla u|^2 + \int_{|\nabla u| > \beta} |\nabla u| - \frac{\beta}{2}. \tag{1.2}$$

In this model, the diffusion is strictly perpendicular to the gradient, where $|\nabla u| > \beta$, that is, where edges are most likely present, and isotropic where $|\nabla u| \leq \beta$. This model is successful in restoring images in which homogeneous regions are separated by distinct edges; however, if the image intensities representing objects are nonuniform, or if an image is highly degraded, this model may become sensitive to the threshold, β (see Figures 5.2, 5.3, and 5.4). In this case, one might want more flexibility when choosing both the direction and speed of diffusion.

Blomgren et al. [9] proposed the minimization problem

$$\min \int_\Omega |\nabla u|^{p(|\nabla u|)} dx,$$

where $\lim_{s \to 0} p(s) = 2$, $\lim_{s \to \infty} p(s) = 1$, and p is monotonically decreasing. This model should reap the benefits of both isotropic and TV-based diffusion, as well as a combination of the two. However, it is difficult to study mathematically since the lower semicontinuity of the functional is not readily evident.

1.2. Functionals with variable exponent $1 \leq p(x) \leq 2$. The model proposed in this paper capitalizes on the strengths of (1.1) for the different values of $1 \leq p \leq 2$. It ensures TV-based diffusion ($p \equiv 1$) along edges and Gaussian smoothing ($p \equiv 2$) in homogeneous regions. Furthermore, it employs anisotropic diffusion ($1 < p < 2$) in regions which may be piecewise smooth or in which the difference between noise and edges is difficult to distinguish. We let $p = p(x)$ depend on the location, x, in the image. This way, the direction and speed of diffusion at each location depend on the local behavior. Moreover, our choice of exponent yields a model which we can show is theoretically sound.

To this end, the proposed model is as follows:

$$\min_{u \in BV \cap L^2(\Omega)} \int_\Omega \phi(x, Du) + \frac{\lambda}{2}(u - I)^2, \tag{1.3}$$

where

$$\phi(x, r) := \begin{cases} \frac{1}{q(x)}|r|^{q(x)}, & |r| \leq \beta, \\ |r| - \frac{\beta q(x) - \beta^{q(x)}}{q(x)}, & |r| > \beta, \end{cases} \tag{1.4}$$

where $\beta > 0$ is fixed and $1 < \alpha \leq q(x) \leq 2$. For instance, one can choose

$$q(x) = 1 + \frac{1}{1 + k|\nabla G_\sigma * I(x)|^2}, \tag{1.5}$$

where $G_\sigma(x) = \frac{1}{\sigma}\exp(-|x|^2/4\sigma^2)$ is the Gaussian filter and $k > 0$ and $\sigma > 0$ are fixed parameters.

The main benefit of (1.3)–(1.4) is the manner in which it accommodates the local image information. Where the gradient is sufficiently large (i.e., at likely edges), only TV-based diffusion will be used. Where the gradient is close to zero (i.e., in homogeneous regions), the model is isotropic. At all other locations, the filtering is somewhere between Gaussian and TV-based diffusion. Specifically, the type of anisotropy at these ambiguous regions varies according to the strength of the gradient. This enables the model to have a much lower dependence on the threshold (see Figures 5.2, 5.3, 5.4, and 5.5).

For several reasons, we've chosen here to prove the well-posedness of the Dirichlet boundary value problem

$$\min_{u \in BV_g \cap L^2(\Omega)} \int_\Omega \phi(x, Du) + \frac{\lambda}{2}(u - I)^2, \tag{1.6}$$

where

$$BV_g(\Omega) := \{u \in BV(\Omega) | u = g \text{ on } \partial\Omega\}, \tag{1.7}$$

and its associated flow

$$\dot{u} - \operatorname{div}(\phi_r(x, Du)) + \lambda(u - I) = 0 \quad \text{in } \Omega^T, \tag{1.8}$$

$$u(x, t) = g(x) \quad \text{on } \partial\Omega^T, \tag{1.9}$$

$$u(0) = I \quad \text{in } \Omega, \tag{1.10}$$

where

$$\Omega^T := \Omega \times [0, T] \quad \text{and} \quad \partial\Omega^T := \partial\Omega \times [0, T]. \tag{1.11}$$

First, the theory is more interesting and challenging mathematically than (1.3). Second, all of the techniques used to study (1.6) also directly solve (1.3). Finally, the Dirichlet problem (1.6) also has direct application in image processing, as it can be used for image interpolation [13, 27], also referred to as noise-free image inpainting [8, 17, 18].

For a special case of (4), where $q(x) \equiv 2$, i.e., $\phi(r) := |r| - \frac{1}{2}$ when $|r| > 1$ and $\phi(r) := \frac{1}{2}|r|^2$ when $|r| \leq 1$, the existence, uniqueness, and long-time behavior of solutions of (1.6) and its related flow were studied by Zhou [37]. Later, these results were extended to general convex linear-growth functionals, $\phi = \phi(Du)$, by Hardt and Zhou [23]. In this paper we study the more general case, where the functional has a variable exponent and where $\phi = \phi(x, Du)$. We use a different approximate functional than [37], so different estimates are required. Our analysis is also based on techniques introduced in [19]; however, our energy functional requires alternate techniques to establish lower semicontinuity and to pass to the limit from the approximate solution. More related work on linear-growth functionals and their flows can be found in [2, 3, 4, 5, 6, 7, 12, 14, 33]. We also refer the reader to the work in [15, 16, 26, 35] for an alternate variational approach for reducing staircasing by minimizing second order functionals.

The paper is organized as follows. In section 2 we establish some important properties of $\phi(x, Du)$. In section 3 we prove the existence and uniqueness of the solution of minimization problem (1.6). In section 4 we study the associated evolution problem (1.8)–(1.10). Specifically, we define the notion of a weak solution of (1.8)–(1.10), derive estimates for the solution of an approximating problem, prove existence and uniqueness of the solution of (1.8)–(1.10), and discuss the behavior of the solution as $t \to \infty$. In section 5 we provide our numerical algorithm and experimental results to illustrate the effectiveness of our model in image restoration.

2. Properties of ϕ. Recall that for $u \in BV(\Omega)$,

$$Du = \nabla u \cdot \mathcal{L}^n + D^s u$$

is a Radon measure, where ∇u is the density of the absolutely continuous part of Du with respect to the n-dimensional Lebesgue measure, $\mathcal{L}^n$, and $D^s u$ is the singular part (see [21]).

DEFINITION 2.1. *For $v \in BV(\Omega)$, define*

$$\int_\Omega \phi(x, Dv) := \int_\Omega \phi(x, \nabla v)dx + \int_\Omega |D^s v|,$$

where ϕ is defined as in (1.4). *Furthermore, denote*

$$\Phi_\lambda(v) := \int_\Omega \phi(x, Dv) + \frac{\lambda}{2}\int_\Omega |v - I|^2 dx, \tag{2.1}$$

$$\Phi_g(v) := \int_\Omega \phi(x, Dv) + \int_{\partial\Omega} |v - g| d\mathcal{H}^{n-1}, \tag{2.2}$$

and

$$\Phi_{\lambda,g}(v) := \int_\Omega \phi(x, Dv) + \frac{\lambda}{2}\int_\Omega |v - I|^2 dx + \int_{\partial\Omega} |v - g| d\mathcal{H}^{n-1}. \tag{2.3}$$

Remark 2.2. For simplicity, we assume that the threshold $\beta = 1$ in (1.4) for all of our theoretical results.

Similarly to the idea of [10, 11], we can establish lower semicontinuity of the functional Φ_g. For the convenience of the reader, we include the proof below.

LEMMA 2.3. *Using the notation in Definition* 2.1,

$$\Phi_g(u) = \widetilde{\Phi}_g(u) \tag{2.4}$$

for all $u \in BV(\Omega)$, *where*

$$\widetilde{\Phi}_g(u) := \sup_{\substack{\psi \in C^1(\overline{\Omega}, \mathbb{R}^n) \\ |\psi| \leq 1}} \int_\Omega -u \mathrm{div}\psi - \frac{q(x)-1}{q(x)} |\psi|^{\frac{q(x)}{q(x)-1}} dx + \int_{\partial\Omega} \psi \cdot n g d\mathcal{H}^{n-1}.$$

Furthermore, $\Phi_g(u)$ *is lower semicontinuous on* $L^1(\Omega)$*; that is, if* $u_j, u \in BV(\Omega)$ *satisfy* $u_j \to u$ in $L^1(\Omega)$ *as* $j \to \infty$, *then* $\Phi_g(u) \leq \liminf_{j\to\infty} \Phi_g(u_j)$.

Proof. For each $\psi \in C^1(\overline{\Omega}, \mathbb{R}^n)$, the map $u \to \int_\Omega -u \mathrm{div}\psi - \frac{q(x)-1}{q(x)} |\psi|^{\frac{q(x)}{q(x)-1}} dx + \int_{\partial\Omega} \psi \cdot n g d\mathcal{H}^{n-1}$ is continuous and affine on $L^1(\Omega)$. Therefore, $\widetilde{\Phi}_g(u)$ is convex and lower semicontinuous on $L^1(\Omega)$ and the domain of $\widetilde{\Phi}_g(u)$, $\{u \,|\, \widetilde{\Phi}_g(u) < \infty\}$, is precisely $BV(\Omega)$.

We now show that $\Phi_g(u) = \widetilde{\Phi}_g(u)$. For $u \in BV(\Omega)$, we have that for each $\psi \in C^1(\overline{\Omega}, \mathbb{R}^n)$,

$$-\int_\Omega u \mathrm{div}\psi dx = \int_\Omega \nabla u \cdot \psi dx + \int_\Omega D^s u \cdot \psi - \int_{\partial\Omega} u\psi \cdot n d\mathcal{H}^{n-1}.$$

Therefore, since the measures dx, $D^s u$, and $d\mathcal{H}^{n-1}$ are mutually singular, standard arguments show that

$$\widetilde{\Phi}_g(u) = \sup_{\substack{\psi \in C^1(\overline{\Omega}, \mathbb{R}^n) \\ |\psi| \leq 1}} \int_\Omega \nabla u \cdot \psi - \frac{q(x)-1}{q(x)} |\psi|^{\frac{q(x)}{q(x)-1}} dx + \int_\Omega |D^s u| + \int_{\partial\Omega} |u - g| d\mathcal{H}^{n-1}.$$

The proof is then complete once we establish that

$$\int \phi(x, \nabla u) dx = \sup_{\substack{\psi \in C^1(\overline{\Omega}, \mathbb{R}^n) \\ |\psi| \leq 1}} \int \nabla u \cdot \psi - \frac{q(x)-1}{q(x)} |\psi|^{\frac{q(x)}{q(x)-1}} dx. \tag{2.5}$$

Since any $\rho \in L^\infty(\Omega, \mathbb{R}^n)$ can be approximated in measure by $\psi \in C^1(\overline{\Omega}, \mathbb{R}^n)$, we have that

(2.6)

$$\sup_{\substack{\psi \in C^1(\overline{\Omega}, \mathbb{R}^n) \\ |\psi| \leq 1}} \int_\Omega \nabla u \cdot \psi - \frac{q(x)-1}{q(x)} |\psi|^{\frac{q(x)}{q(x)-1}} dx = \sup_{\substack{\rho \in L^\infty(\Omega, \mathbb{R}^n) \\ |\rho| \leq 1}} \int_\Omega \nabla u \cdot \rho - \frac{q(x)-1}{q(x)} |\rho|^{\frac{q(x)}{q(x)-1}} dx.$$

Choosing $\rho(x) = 1_{\{|\nabla u| \leq 1\}} |\nabla u|^{q(x)-1} \frac{\nabla u}{|\nabla u|} + 1_{\{|\nabla u| > 1\}} \frac{\nabla u}{|\nabla u|}$, where 1_E is the indicator function on E, we see that the right-hand side of (2.6) is

(2.7)

$$\geq \int_\Omega \frac{1}{q(x)} |\nabla u|^{q(x)} 1_{\{|\nabla u| \leq 1\}} + \left[|\nabla u| - \frac{q(x)-1}{q(x)} \right] 1_{\{|\nabla u| > 1\}} dx = \int_\Omega \phi(x, \nabla u) dx.$$

To show equality in (2.5), we proceed as follows. For any $\rho \in L^\infty(\Omega, \mathbb{R}^n)$, since $q(x) > 1$ we have that for almost all x, $\nabla u(x) \cdot \rho(x) \leq \frac{1}{q(x)}|\nabla u|^{q(x)} + \frac{q(x)-1}{q(x)}|\rho(x)|^{\frac{q(x)}{q(x)-1}}$. In particular, if $|\nabla u| \leq 1$,

$$\nabla u(x) \cdot \rho(x) - \frac{q(x)-1}{q(x)}|\rho(x)|^{\frac{q(x)}{q(x)-1}} \leq \frac{1}{q(x)}|\nabla u|^{q(x)}. \tag{2.8}$$

On the other hand, if $|\nabla u| > 1$ and $|\rho| \leq 1$, then since $q(x) > 1$ for almost all x, we have that $\nabla u \cdot \rho = |\nabla u|\frac{\nabla u}{|\nabla u|} \cdot \rho \leq |\nabla u|[\frac{1}{q(x)} + \frac{q(x)-1}{q(x)}|\rho|^{\frac{q(x)}{q(x)-1}}]$, and thus

$$\begin{aligned} \nabla u \cdot \rho - \frac{q(x)-1}{q(x)}|\rho|^{\frac{q(x)}{q(x)-1}} &\leq \frac{1}{q(x)}|\nabla u| + (|\nabla u| - 1)\frac{q(x)-1}{q(x)}|\rho|^{\frac{q(x)}{q(x)-1}} \\ &\leq |\nabla u| - \frac{q(x)-1}{q(x)}. \end{aligned} \tag{2.9}$$

Combining (2.6), (2.7), (2.8), and (2.9), we have that

$$\sup_{\substack{\psi \in C^1(\overline{\Omega}, \mathbb{R}^n) \\ |\psi| \leq 1}} \int_\Omega \nabla u \cdot \psi - \frac{q(x)-1}{q(x)}|\psi|^{\frac{q(x)}{q(x)-1}} dx = \int_\Omega \phi(x, \nabla u) dx,$$

and thus for all $u \in BV(\Omega)$, $\widetilde{\Phi}_g(u) = \Phi_g(u)$, where Φ_g is defined as in (2.2). ∎

LEMMA 2.4. *Suppose $\Omega \subset \mathbb{R}^n$ is open, bounded, and has Lipschitz boundary, and let $w \in BV \cap L^2(\Omega)$. Then for each $\delta > 0$, there exists $\tilde{w}_\delta \in C^\infty \cap H^1(\Omega)$ such that*

$$\|\tilde{w}_\delta - w\|_{L^2(\Omega)} \leq \delta \tag{2.10}$$

and

$$\Phi_{\lambda,g}(\tilde{w}_\delta) \leq \Phi_{\lambda,g}(w) + \delta. \tag{2.11}$$

Furthermore, if we also assume that $Trw = TrG$ on $\partial\Omega$ for some $G \in H^1(\Omega)$, then for each $\delta > 0$, there exists $w_\delta \in H^1(\Omega)$ satisfying

$$Trw_\delta = Trw \quad \text{on } \partial\Omega, \tag{2.12}$$

$$w_\delta \to w \quad \text{strongly in } L^2(\Omega) \quad \text{as } \delta \to 0, \tag{2.13}$$

and

$$\Phi_{\lambda,g}(w_\delta) \leq \Phi_{\lambda,g}(w) + \delta, \tag{2.14}$$

where TrG is the trace of G on $\partial\Omega$.

Proof. Fix $w \in BV \cap L^2(\Omega)$. Using Lemma 2.3 and a slight modification of the proof of Theorem 1.17 and Remark 1.18 in [22], there exists a sequence $\{w_j\}$ in $C^\infty \cap H^1(\Omega)$ such that

$$Trw_j = Trw \quad \text{on } \partial\Omega, \tag{2.15}$$

$$w_j \to w \quad \text{in } L^2(\Omega), \tag{2.16}$$

and

$$\lim_{j\to\infty} \Phi_g(w_j) = \Phi_g(w). \tag{2.17}$$

Therefore, for each $\delta > 0$ there exists a function $\tilde{w}_\delta \in C^\infty \cap H^1(\Omega)$ such that (2.10) and (2.11) hold.

Now suppose also that $Trw = TrG$ on $\partial\Omega$. Then by (2.15), $\tilde{w}_\delta - G \in W_0^{1,1}(\Omega)$, and thus there exists a function $h_\delta \in C_c^\infty(\Omega)$ such that

$$\|\tilde{w}_\delta - G - h_\delta\|_{W^{1,1}(\Omega)} + \|\tilde{w}_\delta - G - h_\delta\|_{L^2(\Omega)} \leq \delta. \tag{2.18}$$

Let $w_\delta = G + h_\delta \in H^1(\Omega)$. Then we have that

$$Trw_\delta = Trw \quad \text{on } \partial\Omega,$$

$$w_\delta \to w \quad \text{in } L^2(\Omega) \quad \text{as } \delta \to 0,$$

and

$$\Phi_{\lambda,g}(w_\delta) \leq \Phi_{\lambda,g}(w) + \delta.$$

The proof is complete. ∎

Remark 2.5. If $w \in BV \cap L^\infty(\Omega)$, then there exist $w_\delta \in H^1 \cap L^\infty(\Omega)$ such that, in addition to (2.12)–(2.14), we also have that

$$\|w_\delta\|_{L^\infty(\Omega)} \leq C(\Omega)\|w\|_{L^\infty(\Omega)}. \tag{2.19}$$

3. The minimization problem. In this section we study the existence and uniqueness of the solution to minimization problem (1.6). In general, as discussed in [23, 25, 37], there may not exist a minimizer of $\Phi_\lambda(v)$ (see (2.1)), since the limit of the minimizing sequence may not take the boundary value g. However, we can prove the existence of a unique minimizer for a weaker form of (1.6), where we consider the minimization problem using the *relaxed energy*, $\Phi_{\lambda,g}(v)$, defined in (2.3). To this end, we define a pseudosolution of (1.6) as follows.

DEFINITION 3.1. *A function $u \in BV \cap L^2(\Omega)$ is a pseudosolution of* (1.6) *if it is a solution of*

$$\min_{v \in BV \cap L^2(\Omega)} \Phi_{\lambda,g}(v), \tag{3.1}$$

where $\Phi_{\lambda,g}(v)$ is defined in (2.3).

First, we show that there exists a pseudosolution of (1.6), that is, a solution of (3.1), in Theorem 3.2. In Theorem 3.5 we provide the motivation for using the notion of pseudosolution in Definition 3.1.

THEOREM 3.2. *Suppose $I \in BV \cap L^2(\Omega)$, $g = TrG$ for some function $G \in BV(\Omega)$ with $I = g$ on $\partial\Omega$, and Ω is an open bounded subset of $\mathbb{R}^n$ with Lipschitz boundary. Then there exists a unique pseudosolution of* (1.6) *as given in Definition* 3.1.

Proof. Let $\{u_n\}$ be a minimizing sequence of (3.1) in $BV \cap L^2(\Omega)$. Since $\{u_n\}$ is bounded in $BV(\Omega)$ and $L^2(\Omega)$, using the compactness of $BV(\Omega)$ and the weak compactness of $L^2(\Omega)$, we see that there exists a subsequence $\{u_{n_k}\}$ of $\{u_n\}$ and a function $u \in BV \cap L^2(\Omega)$ satisfying

$$u_{n_k} \to u \quad \text{strongly in } L^1(\Omega), \tag{3.2}$$

$$u_{n_k} \rightharpoonup u \quad \text{weakly in } L^2(\Omega). \tag{3.3}$$

By (3.2), (3.3), Lemma 2.3, and the weak lower semicontinuity of the L^2-norm, we have that

$$\Phi_{\lambda,g}(u) \le \liminf_{k\to\infty} \Phi_{\lambda,g}(u_{n_k}) = \inf_{BV\cap L^2(\Omega)} \Phi_{\lambda,g}(v).$$

Hence, u is a solution of the minimization problem. Uniqueness follows from the strict convexity of $\Phi_{\lambda,g}(v)$ in v. □

To better understand the relationship between (1.6) and (3.1), we need the following two lemmas. For $\beta > 0$, let

$$d_\beta(x) = \min\left(\frac{d(x)}{\beta}, 1\right), \tag{3.4}$$

where $d(x)$ is the distance of the point x to the boundary of Ω.

LEMMA 3.3 (*Theorem A.1 of* [19]). *For each $v \in BV \cap L^\infty(\Omega)$, the vector measures $v\nabla d_\beta$ converge weakly to $-v\gamma d\mathcal{H}^{n-1}$ as $\beta \to 0$, where γ is the unit outward normal to $\partial\Omega$, and*

$$\lim_{\beta\to 0} \int_\Omega |v||\nabla d_\beta| = \int_{\partial\Omega} |v| d\mathcal{H}^{n-1}.$$

LEMMA 3.4. *Let $G \in W^{1,1} \cap L^\infty(\Omega)$. Then for any $v \in BV \cap L^\infty(\Omega)$, there exists a sequence $\{v_\beta\}$ in $BV \cap L^\infty(\Omega)$ such that*

$$\begin{aligned} Trv_\beta &= TrG \quad \text{in } L^1(\partial\Omega), \\ v_\beta &\to v \quad \text{in } L^2(\Omega) \quad \text{as } \beta \to 0, \end{aligned}$$

and

$$\lim_{\beta\to 0} \Phi_g(v_\beta) = \Phi_g(v).$$

Proof. For $\beta > 0$, define $d_\beta(x)$ as in (3.4). Since $d(x) \in W^{1,\infty}(\Omega)$ and $|\nabla d| = 1$, we have that

$$|\nabla d_\beta| = \frac{1}{\beta} \text{ if } d(x) < \beta \quad \text{and} \quad |\nabla d_\beta| = 0 \text{ if } d(x) \ge \beta. \tag{3.5}$$

Fix $v \in BV \cap L^\infty(\Omega)$ and let $v_\beta = d_\beta v + (1 - d_\beta)G$ for $(x,t) \in \Omega$. Then

$$\begin{gathered} v_\beta \in BV \cap L^\infty(\Omega) \text{ with } Trv_\beta = TrG \text{ in } L^1(\partial\Omega), \\ v_\beta \to v \text{ in } L^2(\Omega). \end{gathered}$$

By Lemma 2.3, $\liminf_{\beta\to 0} \Phi_g(v_\beta) \ge \Phi_g(v)$, and thus it remains only to show that

$$\lim_{\beta\to 0} \Phi_g(v_\beta) \le \Phi_g(v). \tag{3.6}$$

Writing $\Phi_g = \widetilde{\Phi}_g$ (Lemma 2.3), since $D^s v_\beta = d_\beta D^s v$ and $Trv_\beta = TrG$ in $L^1(\partial\Omega)$ we have that

$$\begin{aligned} \widetilde{\Phi}_g(v_\beta) = \sup_{\substack{\psi\in C^1(\overline{\Omega},\mathbb{R}^n) \\ |\psi|\le 1}} \Bigg[&\int_\Omega \{(v-G)\nabla d_\beta + d_\beta \nabla v + (1-d_\beta)\nabla G\}\cdot\psi \\ &- \frac{q(x)-1}{q(x)} |\psi|^{\frac{q(x)}{q(x)-1}} dx + \int_\Omega d_\beta D^s v \cdot \psi \Bigg]. \end{aligned}$$

Therefore, by (2.5)

$$\begin{aligned}\widetilde{\Phi}(v_\beta) &\le \sup_{\substack{\psi\in C^1(\overline{\Omega},\mathbb{R}^n)\\ |\psi|\le 1}} \left[\int_\Omega \nabla v\cdot\psi - \frac{q(x)-1}{q(x)}|\psi|^{\frac{q(x)}{q(x)-1}}dx\right] \\ &\quad + \int_\Omega |v-G||\nabla d_\beta|dx + \int_\Omega (1-d_\beta)(|\nabla v|+|\nabla G|)dx + \int_\Omega d_\beta|D^s v| \\ &= \int_\Omega \phi(x,\nabla v) + \int_\Omega |v-G||\nabla d_\beta|dx + \int_\Omega (1-d_\beta)(|\nabla v|+|\nabla G|)dx + \int_\Omega d_\beta|D^s v|.\end{aligned}$$

By Lemma 3.3, as $\beta\to 0$,

$$\int_\Omega |v-G||\nabla d_\beta|dx \to \int_{\partial\Omega} |v-G|d\mathcal{H}^{n-1}.$$

Furthermore, the Lebesgue dominated convergence theorem gives us that

$$\int_\Omega (1-d_\beta)(|\nabla v|+|\nabla G|)dx \to 0 \quad \text{and} \quad \int_\Omega d_\beta|D^s v| \to \int_\Omega |D^s v|.$$

Therefore, (3.6) holds and the lemma is proved. ∎

THEOREM 3.5. *We have that*

$$\inf_{v\in BV_g\cap L^2(\Omega)} \Phi_\lambda(v) = \min_{v\in BV\cap L^2(\Omega)} \Phi_{\lambda,g}(v), \tag{3.7}$$

where Φ_λ *and* $\Phi_{\lambda,g}$ *are as defined in* (2.1) *and* (2.3)*, respectively, and* BV_g *is as defined in* (1.7).

Proof. Since $BV_g(\Omega)\subset BV(\Omega)$,

$$\inf_{v\in BV\cap L^2(\Omega)} \Phi_{\lambda,g}(v) \le \inf_{v\in BV_g\cap L^2(\Omega)} \Phi_{\lambda,g}(v) = \inf_{v\in BV_g\cap L^2(\Omega)} \Phi_\lambda(v).$$

To see the reverse, let $u\in BV\cap L^2(\Omega)$ be the solution of (3.1). By Lemma 3.4, there exist $v_\beta\in BV_g\cap L^\infty(\Omega)$ such that

$$\Phi_\lambda(v_\beta) = \Phi_{\lambda,g}(v_\beta) \xrightarrow{\beta\to 0} \Phi_{\lambda,g}(u) = \min_{v\in BV\cap L^2(\Omega)} \Phi_{\lambda,g}(v),$$

and thus

$$\inf_{v\in BV_g\cap L^2(\Omega)} \Phi_\lambda(v) \le \min_{v\in BV\cap L^2(\Omega)} \Phi_{\lambda,g}(v).$$

Thus, the theorem holds. ∎

4. The flow related to minimization problem (3.1).
