TRANSMISSION, REFLECTION, AND SECOND-HARMONIC GENERATION IN A NONLINEAR WAVEGUIDE*

ROBERTO CAMASSA†, ALP FINDIKOGLU‡, AND GRANT LYTHE§

Abstract. We present an experimental, analytical, and numerical investigation of the passage of electromagnetic signals through a device with voltage-dependent differential capacitance. This dependence gives rise to the device's nonlinear response, which can then be tuned by an externally applied static electric field. The system is modeled with a wave equation for the current and the charge density with continuity conditions at the boundaries between two linear regions and the nonlinear medium they sandwich. We derive asymptotic formulae for transmission and reflection coefficients of a monochromatic signal and its nonlinearity-induced second harmonics. Predictions based on this analysis are then compared with numerical and experimental results, across a range of parameter values, including those tuning the nonlinearity by means of an imposed voltage. The experiments are carried out at microwave frequencies using 1cm^2 devices consisting of a superconducting thin film meandering waveguide on a nonlinear dielectric substrate.

Key words. transmission and reflection, tunable nonlinearity, finite length nonlinear medium, second harmonic, differential capacitance, boundaries, method of characteristics, noise, numerical solution

1. Introduction.

In this paper we study transmission, reflection, and generation of harmonics when an electromagnetic signal passes through a finite-length region, which represents a nonlinear medium coupled via realistic boundary conditions to its environment. Our theory is developed with actual experimental devices in mind, but it is applicable to any system where waves pass through a medium with voltage-dependent differential capacitance; i.e., the charge does not simply increase linearly with voltage [1] and where losses are not so strong as to overwhelm nonlinear effects. Of particular interest in this class of media is the consequence that the functional form of nonlinearity is tunable: the device response can be controlled with an external bias voltage, which enables exploration of dynamical behaviors characteristic of quadratic and cubic nonlinear media within the same apparatus [2, 3, 4, 5, 6, 7, 8, 9, 10, 11].

The experimental data we collect are obtained by sending electromagnetic signals along an 8cm length meandering waveguide consisting of superconducting electrodes on the surface of a 10mm × 10mm × 0.5mm nonlinear dielectric crystal of strontium titanate [10, 11, 12, 13, 14, 15]. Electromagnetic waves in the waveguide with wave-

lengths of a few cm have frequencies of a few hundred MHz (microwaves). We model this experimental setup with a wave equation coupling the evolution of voltage and current through a distributed capacitance that depends on voltage and temperature throughout the nonlinear region. Section 2 formulates this model in its nondimensional form used for analytical and numerical studies. After introducing the nonlinear wave equation and the definition of differential capacitance, we express it in terms of its characteristic variables and the corresponding Riemann invariants [16]. Because of the boundary conditions, this form cannot be immediately used to provide closed form solutions. We then proceed by carrying out an asymptotic expansion in these variables in the limit of low-amplitude incident signals, through a corresponding expansion of the boundary conditions. The analysis is simplified by the absence of dispersion and dissipation in the nonlinear wave equation and produces closed form expressions for the nonlinear contributions to experimentally measurable quantities such as transmission and reflection coefficients.

In section 3, we study the concrete case of a sinusoidal input from the left of the region. In the weakly nonlinear regime, we carry out an asymptotic expansion of the characteristics solution in the parameter a/v^*, where a is the amplitude of the input signal and v^* is the characteristic voltage associated with the variation of the differential capacitance in the nonlinear central region. The calculation of the second-harmonic generated signal is given in some detail in section 3 and Appendix A, since this establishes a basis for further research on this class of system. The analysis yields explicit formulae that characterize the frequency-doubling response caused by nonlinearity.

Section 4 reports on numerical simulations of the governing equations: two coupled PDEs for the charge and current fields in three regions. The charge and current fields are updated in such a way as to keep current and voltage continuous across the boundaries, even though the charge-voltage relationship has a discontinuity. Sinusoidal signals and noise, band-limited or white, are continuously input from the left. Fourier transforms of numerical time series in the steady state, at points in the left and right regions, are used to evaluate the transmitted and reflected signals. We find good quantitative agreement with analytical results. In particular, we are able to predict the amplitude of the second harmonic generated by the nonlinearity.

In section 5 we compare the analytical and numerical results with experimental data. These are collected for microwave signals and noise passing through a compact device that operates at temperatures that are easily attained using liquid nitrogen or helium and whose response can be tuned with a bias voltage of a few volts. The waveguide is a patterned superconducting thin film; because its lateral dimensions are much smaller than the wavelengths of the input signals, wave propagation is effectively one-dimensional. The source of the nonlinearity is the nonlinear dielectric substrate that the superconducting waveguide rests on [19, 20, 21]. We find very good agreement with all the major measurable quantities of interest, while qualitative agreement is achieved when effects neglected by our model, but known to become relevant in certain regimes (like high frequencies), come into play.

2. The governing equations. The dynamics of wave propagation along the transmission line is described by the wave equation for the current $i(x,t)$ (Coulomb s^{-1}) and the charge density $q(x,t)$ (Coulomb m^{-1})

$$\frac{\partial q(x,t)}{\partial t} = -\frac{\partial i(x,t)}{\partial x},$$

$$L\frac{\partial i(x,t)}{\partial t} = -\frac{\partial v(x,t)}{\partial x}, \tag{2.1}$$

where L is the inductance per unit length. A relationship between $q(x,t)$ and the voltage $v(x,t)$ is needed to close the set of equations (2.1). Let

$$q(x,t) = \mathcal{Q}(v(x,t)). \tag{2.2}$$

The "differential capacitance" [1] is the derivative of $\mathcal{Q}(v)$:

$$C_{\rm d}(v) = \frac{{\rm d}\mathcal{Q}(v)}{{\rm d}v}. \tag{2.3}$$

In a linear medium $q(x,t) = Cv(x,t)$, where C is constant. Then the differential capacitance is the constant C and the wave equation (2.1) is linear:

$$\frac{\partial^2}{\partial t^2}v(x,t) = (LC)^{-1}\frac{\partial^2}{\partial x^2}v(x,t). \tag{2.4}$$

The nonlinear wave equation we study in this work can be written as

$$LC_{\rm d}(v(x,t))\frac{\partial^2}{\partial t^2}v(x,t) + L\frac{\partial C_{\rm d}(v(x,t))}{\partial v}\frac{\partial v(x,t)}{\partial t} = \frac{\partial^2}{\partial x^2}v(x,t). \tag{2.5}$$

Motivated by the configuration of the experiments and by analogy with classical transmission-reflection problems, we study the propagation of waves through a nonlinear region (region II, $0 \le x \le l$) sandwiched between two semi-infinite regions (region I, $-\infty < x < 0$ and region III, $l < x < \infty$) where the wave equation is linear. Current and voltage are continuous at the boundaries. The situation is illustrated in Figure 2.1.

We shall assume that the relationship (2.2) is such that we can define its inverse: $v(x,t) = \mathcal{Q}^{-1}(q(x,t))$. The inductance and differential capacitances per unit length are as follows:

$$L = \begin{cases} L_{\rm I}, \\ \\ L_{\rm II}, \end{cases} \qquad C_{\rm d}(v) = \begin{cases} C_{\rm I}, & \text{regions I and III,} \\ \\ C_{\rm m}(v), & \text{region II,} \end{cases} \tag{2.6}$$

where $L_{\rm I}$, $L_{\rm II}$, and $C_{\rm I}$ are constants. We assume that $C_{\rm m}(v)$ is a positive even function with maximum at $v = 0$. See Figure 2.2. Since $C'_{\rm m}(0) = 0$ and $C''_{\rm m}(0) < 0$ we define the characteristic voltage associated with the differential capacitance curve by

$$v^* = \left(\frac{2C_{\rm m}(0)}{|C''_{\rm m}(0)|}\right)^{\frac{1}{2}}. \tag{2.7}$$

A constant "bias" voltage $v_{\rm b}$ is applied across the three regions. The voltage at time t and position x is thus the sum of $v_{\rm b}$ and the time-dependent voltages due to the input signals and their interactions. The input signals consist of one or more sinusoidal signals and broadband noise. Noise effects are interesting in their own right [11], but in this paper we shall use noise input as a technique to explore simultaneously the response at numerous frequencies.

In section 3 we consider the case where the input signal (the right-going wavetrain in region I) is given by $v_{\rm in} = a\cos(2\pi f(t - x/u))$. Our analysis is based on the

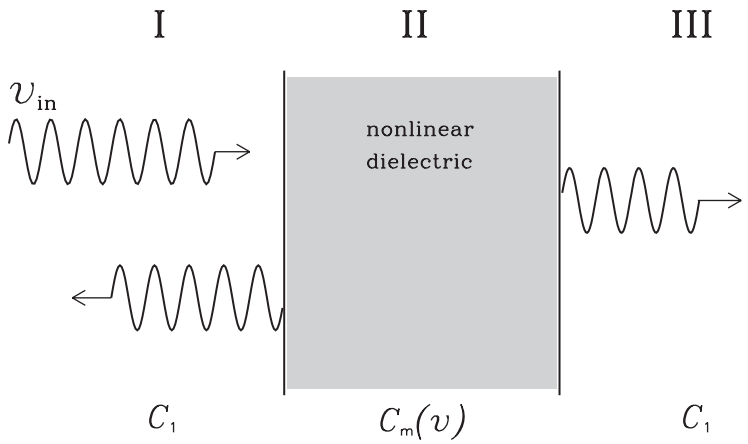

FIG. 2.1. *Schematic diagram for solution of the nonlinear wave equation in three one-dimensional regions. A constant bias voltage v_b is applied across all three regions and the right-going wavetrain in region* I *is the input signal, v_{in}. The late-time solution has the form of an incident and reflected wavetrain in region* I *and a transmitted wavetrain in region* III.

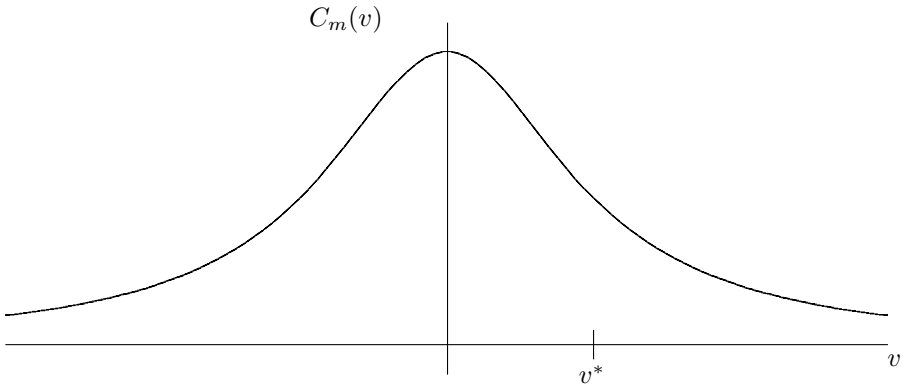

FIG. 2.2. *A typical graph of differential capacitance versus voltage. The voltage v^* is defined in* (2.7).

assumption that $a/v^* \ll 1$. The bias voltage is not assumed small but is fixed for any one experimental or numerical run. Thus the voltage values attained in any one experiment are in a small interval of the differential capacitance curve, but the full catalogue of nonlinear behaviors can be explored by performing runs at various values of the bias voltage.

We define the dimensionless fields

$$
\begin{aligned}
V(x,t) &= \frac{v(x,t)}{v^*}, \\
Q(x,t) &= \frac{q(x,t)}{C_{\text{II}} v^*}, \\
I(x,t) &= \left(\frac{L_{\text{II}}}{C_{\text{II}}}\right)^{\frac{1}{2}} \frac{i(x,t)}{v^*},
\end{aligned}
\tag{2.8}
$$

where

$$C_{\rm II} = C_{\rm m}(0). \tag{2.9}$$

In these variables, (2.1) is

$$\frac{\partial}{\partial t}\begin{pmatrix} Q(x,t) \\ I(x,t) \end{pmatrix} = -\left(L_{\rm II}C_{\rm II}\right)^{-\frac{1}{2}} \frac{\partial}{\partial x}\begin{pmatrix} I(x,t) \\ V(x,t) \end{pmatrix}, \tag{2.10}$$

where $V(x,t)$ is given as a function of $Q(x,t)$ by

$$V(x,t) = \begin{cases} \dfrac{L_{\rm II}C_{\rm II}}{L_{\rm I}C_{\rm I}}\, Q(x,t), & \text{regions I and III,} \\ \dfrac{1}{v^*}\mathcal{Q}^{-1}(C_{\rm II}v^*Q(x,t)), & \text{region II.} \end{cases}$$

We also nondimensionalize space and time by dividing by the length l of the waveguide and the transit time at the velocity of light in a vacuum, c:

$$X = \frac{x}{l}, \qquad T = t\frac{c}{l}. \tag{2.11}$$

So region I is $-\infty < X < 0$, region II is $0 \le X \le 1$, and region III is $1 < X < \infty$. Then (2.10) becomes

$$\frac{\partial}{\partial T}\begin{pmatrix} Q(X,T) \\ I(X,T) \end{pmatrix} = -U\frac{\partial}{\partial X}\begin{pmatrix} I(X,T) \\ V(X,T) \end{pmatrix}, \tag{2.12}$$

where

$$U = \frac{1}{c}\left(L_{\rm II}C_{\rm II}\right)^{-\frac{1}{2}}. \tag{2.13}$$

The propagation speed of small-amplitude signals in region II, $u_{\rm m}(v_{\rm b})$, is

$$u_{\rm m}(v_{\rm b}) = \left(L_{\rm II}C_{\rm m}(v_{\rm b})\right)^{-\frac{1}{2}}; \tag{2.14}$$

the constant $U = u_{\rm m}(0)/c$ is the dimensionless speed at zero bias. In our numerical work, we solve the nonlinear PDEs in the form (2.12).

Our analytical work, using the method of characteristics, proceeds by rewriting (2.12), using

$$\frac{{\rm d}Q}{{\rm d}T} = \frac{{\rm d}Q}{{\rm d}V}\frac{{\rm d}V}{{\rm d}T}, \tag{2.15}$$

in the form

$$\frac{\partial}{\partial X}\begin{pmatrix} I \\ V \end{pmatrix} = -U^{-1}\begin{pmatrix} 0 & G(V) \\ 1 & 0 \end{pmatrix}\frac{\partial}{\partial T}\begin{pmatrix} I \\ V \end{pmatrix}, \tag{2.16}$$

where the arguments (X,T) for the fields V and I have been suppressed and

$$G(V) = \begin{cases} G_{\rm l}, & \text{regions I and III,} \\ G_{\rm n}(V), & \text{region II,} \end{cases}$$

where

$$G_{\mathrm{l}} = \frac{L_{\mathrm{I}} C_{\mathrm{I}}}{L_{\mathrm{II}} C_{\mathrm{II}}}, \tag{2.17}$$

a constant, and

$$G_{\mathrm{n}}(V) = \frac{C_{\mathrm{m}}(v^* V)}{C_{\mathrm{II}}}. \tag{2.18}$$

As $V \to 0$, $G_{\mathrm{n}}(V) \to 1 - V^2 + \mathcal{O}(V^4)$.

In order to use the method of characteristics [16] in region II, we introduce the fields $\Gamma_+(X,T)$ and $\Gamma_-(X,T)$, defined as

$$\Gamma_\pm = H(V) \pm I, \tag{2.19}$$

where

$$H'(V) = (G_{\mathrm{n}}(V))^{\frac{1}{2}}. \tag{2.20}$$

The fields $\Gamma_\pm(X,T)$ are constants on two characteristic curves in the (X,T)-plane defined by the solutions $T_\pm(X)$ of the equations

$$\frac{\mathrm{d}T_\pm}{\mathrm{d}X} = \pm U^{-1}(G_{\mathrm{n}}(V(X,T_+)))^{\frac{1}{2}}. \tag{2.21}$$

We shall impose conservation of the fields $\Gamma_\pm(X,T)$ along characteristics using "initial times functions": given that a characteristic curve passes through $X = 1$ at time S, the time at which it passes through $X = 0$ is

$$\tau_\pm(S) = T_\pm(0)|_{T(1)=S}. \tag{2.22}$$

Then

$$\Gamma_\pm(0, \tau_\pm(S)) = \Gamma_\pm(1, S). \tag{2.23}$$

See Figure 2.3. At the boundary between region I and region II, $X = 0$, we denote

$$\begin{aligned} V(0,T) &= V_{\mathrm{I}}(T), \\ I(0,T) &= I_{\mathrm{I}}(T). \end{aligned} \tag{2.24}$$

At the boundary between region II and region III, $X = 1$, we denote

$$\begin{aligned} V(1,T) &= V_{\mathrm{III}}(T), \\ I(1,T) &= I_{\mathrm{III}}(T). \end{aligned} \tag{2.25}$$

The conditions (2.23) can be rewritten

$$H(V_{\mathrm{I}}(\tau_\pm(S))) \pm I_{\mathrm{I}}(\tau_\pm(S)) = H(V_{\mathrm{III}}(S)) \pm I_{\mathrm{III}}(S). \tag{2.26}$$

In section 3, we evaluate the transmitted signal as a function of the input signal using (2.26).

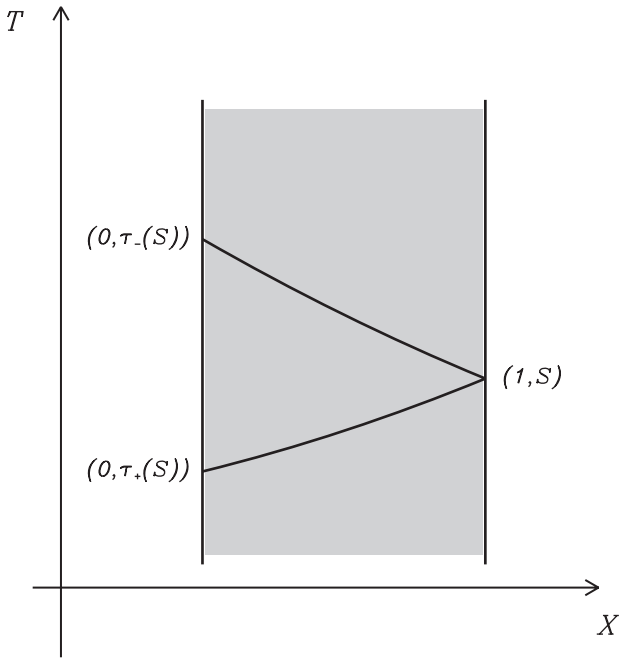

FIG. 2.3. *The "initial times" functions. The two characteristic curves that cross at* $(1, S)$ *follow paths that intersect* $X = 0$ *at times* $\tau_+(S)$ *and* $\tau_-(S)$.

3. Transmission, reflection, and harmonic generation: Analytical results. Let the input signal be sinusoidal with amplitude a at frequency f, that is,

$$v_{\text{in}}(x,t) = a\cos(2\pi f(t - x/u)), \tag{3.1}$$

where $u = (L_{\text{I}}C_{\text{I}})^{-\frac{1}{2}}$. We nondimensionalize the input amplitude and bias voltage,

$$A = \frac{a}{v^*} \qquad \text{and} \qquad V_{\text{b}} = \frac{v_{\text{b}}}{v^*}, \tag{3.2}$$

where v^* is defined in (2.7). The solution of (2.16) can be expanded as

$$V(X,T) = V_{\text{b}} + AV^{(0)}(X,T) + A^2V^{(1)}(X,T) + \mathcal{O}(A^3). \tag{3.3}$$

Thus

$$V_{\text{I}}(T) = V(0,T) = V_{\text{b}} + AV_{\text{I}}^{(0)}(T) + A^2V_{\text{I}}^{(1)}(T) + \mathcal{O}(A^3); \tag{3.4}$$

$I_{\text{I}}(T)$, $V_{\text{III}}(T)$ and $I_{\text{III}}(T)$ will be written in a similar way.

The function $H(V(X,T))$ is expanded as

$$\begin{aligned} H(V(X,T)) &= H(V_{\text{b}}) + H'(V_{\text{b}})(V(X,T) - V_{\text{b}}) + \frac{1}{2}H''(V_{\text{b}})(V(X,T) - V_{\text{b}})^2 + \mathcal{O}(A^3) \\ &= H(V_{\text{b}}) + G_{\text{n}}(V_{\text{b}})^{\frac{1}{2}}\Bigg(AV^{(0)}(X,T) \\ &\quad + A^2V^{(1)}(X,T) + \frac{1}{4}A^2\frac{G_{\text{n}}'(V_{\text{b}})}{G_{\text{n}}(V_{\text{b}})}(V^{(0)}(X,T))^2\Bigg) \\ &\quad + \mathcal{O}(A^3), \end{aligned}$$

and the characteristic curves and initial times functions as

$$T_\pm(X) = T_\pm^{(0)}(X) + AT_\pm^{(1)}(X) + \mathcal{O}(A^2) \tag{3.5}$$

and

$$\tau_\pm(S) = \tau_\pm^{(0)}(S) + A\tau_\pm^{(1)}(S) + \mathcal{O}(A^2). \tag{3.6}$$

Finally, the equality (2.26) is expanded as

$$\begin{aligned} &G_{\rm n}(V_{\rm b})^{\frac{1}{2}}\Big[AV_{\rm I}^{(0)}(\tau_\pm^{(0)}(S) + A\tau_\pm^{(1)}(S)) \\ &\qquad +A^2\left(V_{\rm I}^{(1)}(\tau_\pm^{(0)}(S)) + \frac{1}{4}\frac{G_{\rm n}'(V_{\rm b})}{G_{\rm n}(V_{\rm b})}V_{\rm I}^{(0)}(\tau_\pm^{(0)}(S))^2\right)\Big] \\ &\qquad \pm\left[AI_{\rm I}^{(0)}(\tau_\pm^{(0)}(S) + A\tau_\pm^{(1)}(S)) + A^2 I_{\rm I}^{(1)}(\tau_\pm^{(0)}(S))\right] \\ &= G_{\rm n}(V_{\rm b})^{\frac{1}{2}}\left[AV_{\rm III}^{(0)}(S) + A^2\left(V_{\rm III}^{(1)}(S) + \frac{1}{4}\frac{G_{\rm n}'(V_{\rm b})}{G_{\rm n}(V_{\rm b})}V_{\rm III}^{(0)}(S)^2\right)\right] \\ &\qquad \pm\left[AI_{\rm III}^{(0)}(S) + A^2 I_{\rm III}^{(1)}(S)\right] + \mathcal{O}(A^3). \end{aligned} \tag{3.7}$$

In section 3.1, we shall impose (3.7), keeping only terms proportional to A. The result is the classical transmission-reflection relation for finite-length linear media: perfect transmission is found at frequencies such that the length of region II is a multiple of half the wavelength of the input sinusoid. In section 3.2, we shall also keep terms proportional to A^2 in (3.7).

3.1. Lowest order. To order A, the characteristic curves (2.21) and (2.21) are straight lines:

$$T_\pm^{(0)}(X) = T_\pm^{(0)}(0) \pm \frac{X}{U_{\rm m}}, \tag{3.8}$$

where the normalized speed of propagation in region II is

$$U_{\rm m} = G_{\rm n}(V_{\rm b})^{-\frac{1}{2}}U = \frac{1}{c}\left(L_{\rm II}C_{\rm m}(V_{\rm b})\right)^{-\frac{1}{2}}. \tag{3.9}$$

Thus the initial times functions at order A are simply

$$\tau_\pm^{(0)}(S) = S \mp U_{\rm m}^{-1}. \tag{3.10}$$

To order A, the invariant functions along the characteristics are

$$\Gamma_\pm^{(0)}(X,T) = G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V^{(0)}(X,T) \pm I^{(0)}(X,T) \tag{3.11}$$

and the condition (2.26) is

$$G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V_{\rm I}^{(0)}\left(S \mp U_{\rm m}^{-1}\right) \pm I_{\rm I}^{(0)}\left(S \mp U_{\rm m}^{-1}\right) = G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V_{\rm III}^{(0)}(S) \pm I_{\rm III}^{(0)}(S). \tag{3.12}$$

Notice that (3.8) and (3.12) apply to the following linear wave equation:

$$\frac{\partial}{\partial X}\begin{pmatrix} I^{(0)} \\ V^{(0)}\end{pmatrix} = -U^{-1}\begin{pmatrix} 0 & G(V_{\rm b}) \\ 1 & 0\end{pmatrix}\frac{\partial}{\partial T}\begin{pmatrix} I^{(0)} \\ V^{(0)}\end{pmatrix}. \tag{3.13}$$

The function $G(V_{\rm b})$ is piecewise constant, so the speed of propagation in region II depends on bias voltage.

With a continuous sinusoidal input, (3.1), the solution of (3.13) after a transient has the form of an incident and reflected wavetrain in region I and a transmitted wavetrain in region III. In region I, as $T \to \infty$, let

$$V^{(0)}(X,T) = \frac{1}{2}\left(\exp\left(\mathrm{i}\Omega\left(T - \frac{X}{U_{\rm I}}\right)\right) + \mathcal{R}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T + \frac{X}{U_{\rm I}}\right)\right) + \text{c.c.}\right)$$

(3.14) and

$$I^{(0)}(X,T) = \left(\frac{L_{\rm II}C_{\rm I}}{L_{\rm I}C_{\rm II}}\right)^{\frac{1}{2}}\frac{1}{2}\left(\exp\left(\mathrm{i}\Omega\left(T - \frac{X}{U_{\rm I}}\right)\right) - \mathcal{R}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T + \frac{X}{U_{\rm I}}\right)\right) + \text{c.c.}\right),$$

where c.c. indicates complex conjugate and we have used the freedom to set the origin of T. The normalized speed of propagation in region I is

$$U_{\rm I} = \frac{1}{c}\left(L_{\rm I}C_{\rm I}\right)^{-\frac{1}{2}}, \tag{3.15}$$

and the normalized signal frequency is

$$\Omega = 2\pi f\frac{l}{c}. \tag{3.16}$$

Similarly, in region III, let

$$V^{(0)}(X,T) = \frac{1}{2}\left(\mathcal{T}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T - \frac{(X-1)}{U_{\rm I}}\right)\right) + \text{c.c.}\right)$$

(3.17) and

$$I^{(0)}(X,T) = \left(\frac{L_{\rm II}C_{\rm I}}{L_{\rm I}C_{\rm II}}\right)^{\frac{1}{2}}\frac{1}{2}\left(\mathcal{T}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\Big(T - \frac{(X-1)}{U_{\rm I}}\Big)\right) + \text{c.c.}\right).$$

Notice that the phase at $X = 1$ is absorbed into $\mathcal{T}^{(0)}(\Omega)$.

The lowest-order transmission and reflection coefficients $\mathcal{T}^{(0)}(\Omega)$ and $\mathcal{R}^{(0)}(\Omega)$ are found by imposing the condition (3.12). Using (3.10), (3.14), and (3.17) gives explicit expressions for the functions $V_{\rm I}^{(0)}(T)$, $I_{\rm I}^{(0)}(T)$, $V_{\rm III}^{(0)}(T)$, and $I_{\rm III}^{(0)}(T)$ introduced in (2.24) and (2.25). Thus (3.12) is

$$1 + \mathcal{R}^{(0)}(\Omega) \pm \beta^{\frac{1}{2}}\left(1 - \mathcal{R}^{(0)}(\Omega)\right) = \mathrm{e}^{\pm\mathrm{i}\Omega U_{\rm m}^{-1}}\mathcal{T}^{(0)}(\Omega)\left(1 \pm \beta^{\frac{1}{2}}\right), \tag{3.18}$$

where

$$\beta = \frac{L_{\rm II}C_{\rm I}}{L_{\rm I}C_{\rm m}(v_{\rm b})} = \frac{L_{\rm II}C_{\rm I}}{L_{\rm I}C_{\rm II}}\frac{1}{G_{\rm n}(V_{\rm b})}. \tag{3.19}$$

In the experimental system $\beta \ll 1$ because the impedance in region II is higher than that in regions I and III.

The pair of equations (3.18) can be solved to yield

$$\mathcal{R}^{(0)}(\Omega) = -\frac{(1-\beta)\sin(\frac{\Omega}{U_{\rm m}})}{(1+\beta)\sin(\frac{\Omega}{U_{\rm m}}) - 2\mathrm{i}\beta^{\frac{1}{2}}\cos(\frac{\Omega}{U_{\rm m}})}$$

$$= -\frac{(1-\beta^2)\sin^2(\frac{\Omega}{U_\mathrm{m}}) - 2\mathrm{i}\beta^{\frac{1}{2}}(1-\beta)\sin(\frac{\Omega}{U_\mathrm{m}})\cos(\frac{\Omega}{U_\mathrm{m}})}{(1+\beta)^2\sin^2(\frac{\Omega}{U_\mathrm{m}}) + 4\beta\cos^2(\frac{\Omega}{U_\mathrm{m}})}, \tag{3.20}$$

$$\mathcal{T}^{(0)}(\Omega) = -\frac{2\mathrm{i}\beta^{\frac{1}{2}}}{(1+\beta)\sin(\frac{\Omega}{U_\mathrm{m}}) - 2\mathrm{i}\beta^{\frac{1}{2}}\cos(\frac{\Omega}{U_\mathrm{m}})}$$

$$= -\frac{4\beta\cos(\frac{\Omega}{U_\mathrm{m}}) + 2\mathrm{i}\beta^{\frac{1}{2}}(1+\beta)\sin(\frac{\Omega}{U_\mathrm{m}})}{(1+\beta)^2\sin^2(\frac{\Omega}{U_\mathrm{m}}) + 4\beta\cos^2(\frac{\Omega}{U_\mathrm{m}})}\,. \tag{3.21}$$

These coefficients, also found in the quantum-mechanical problem of a potential step [17], satisfy the energy constraint $|\mathcal{R}^{(0)}(\Omega)|^2 + |\mathcal{T}^{(0)}(\Omega)|^2 = 1$. Perfect transmission, i.e., $|\mathcal{T}^{(0)}(\Omega)| = 1$, is found at resonant frequencies Ω satisfying

$$\sin\left(\frac{\Omega}{U_\mathrm{m}}\right) = 0. \tag{3.22}$$

3.2. Next order. In order to impose the equality (3.7) to order A^2 we write

$$\begin{aligned} &AV_\mathrm{I}^{(0)}(\tau_\pm^{(0)}(S) + A\tau_\pm^{(1)}(S)) \\ &= AV_\mathrm{I}^{(0)}(S \pm U_\mathrm{m}^{-1}) + A^2V_\mathrm{I}'(S \pm U_\mathrm{m}^{-1})\tau_\pm^{(1)}(S) + \mathcal{O}(A^3), \end{aligned} \tag{3.23}$$

where $V_\mathrm{I}'(T) = \frac{\mathrm{d}}{\mathrm{d}T}V_\mathrm{I}^{(0)}(T)$. The current $I_\mathrm{I}^{(0)}(\tau_\pm^{(0)}(S) + A\tau_\pm^{(1)}(S))$ is expanded in the same way. To find the solution at order A^2, we therefore need an explicit form for the initial times function to order A. The relationship that gives the initial times for the two characteristics that cross at $(1, S)$ is

$$\begin{aligned} S &= \tau_\pm(S) \pm \frac{1}{U}\int_0^1 (G_\mathrm{n}(V(X, T_\pm(X)))^{\frac{1}{2}}\,\mathrm{d}X \\ &= \tau_\pm^{(0)}(S) + A\tau_\pm^{(1)}(S) \\ &\quad \pm \frac{1}{U_\mathrm{m}}\int_0^1 \left(1 + \frac{1}{2}\frac{G_\mathrm{n}'(V_\mathrm{b})}{G_\mathrm{n}(V_\mathrm{b})}AV^{(0)}(X, T_\pm^{(0)}(X))\right)\mathrm{d}X + \cdots. \end{aligned} \tag{3.24}$$

Using (3.10) yields

$$\tau_\pm^{(1)}(S) = \mp\frac{1}{2}U_\mathrm{m}^{-1}\frac{G_\mathrm{n}'(V_\mathrm{b})}{G_\mathrm{n}(V_\mathrm{b})}\int_0^1 V^{(0)}(X, T_\pm^{(0)}(X))\mathrm{d}X. \tag{3.25}$$

In Appendix A, we construct the explicit form of $V^{(0)}(X, T_\pm^{(0)})$ and perform the integral in (3.25), leading to the expansion (A.8) of (3.7) to order A^2.

The only sinusoidal terms on the right-hand side of (A.8) have frequency 2Ω, so there is a transmitted second-harmonic signal with amplitude proportional to the square of the input amplitude [11]. We therefore let the nonconstant terms of order A^2 in the expansion (3.4) be

$$V_\mathrm{I}^{(1)}(T) = \frac{1}{2}\left[\mathcal{R}^{(1)}(\Omega)\,\mathrm{e}^{2\,\mathrm{i}\Omega T} + \mathrm{c.c.}\right], \quad I_\mathrm{I}^{(1)}(T) = -\left(\frac{L_\mathrm{II}C_\mathrm{I}}{L_\mathrm{I}C_\mathrm{II}}\right)^{\frac{1}{2}}\frac{1}{2}\left[\mathcal{R}^{(1)}(\Omega)\,\mathrm{e}^{2\,\mathrm{i}\Omega T} + \mathrm{c.c.}\right],$$

$$V_\mathrm{III}^{(1)}(T) = \frac{1}{2}\left[\mathcal{T}^{(1)}(\Omega)\,\mathrm{e}^{2\,\mathrm{i}\Omega T} + \mathrm{c.c.}\right], \quad I_\mathrm{III}^{(1)}(T) = \left(\frac{L_\mathrm{II}C_\mathrm{I}}{L_\mathrm{I}C_\mathrm{II}}\right)^{\frac{1}{2}}\frac{1}{2}\left[\mathcal{T}^{(1)}(\Omega)\,\mathrm{e}^{2\,\mathrm{i}\Omega T} + \mathrm{c.c.}\right].$$

Then (A.8) becomes

$$
\begin{aligned}
&(1\pm\beta^{\frac12})\mathcal{T}^{(1)}(\Omega)-(1\mp\beta^{\frac12})\mathcal{R}^{(1)}(\Omega)\mathrm{e}^{\mp 2\mathrm{i}\Omega U_{\mathrm{m}}^{-1}}\\
&=\frac18\,\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\mathcal{T}^{(0)}(\Omega)^2\Bigg[\left(\cos\frac{\Omega}{U_{\mathrm{m}}}-\mathrm{i}\beta^{\frac12}\sin\frac{\Omega}{U_{\mathrm{m}}}\right)^2\mathrm{e}^{\mp 2\mathrm{i}\Omega U_{\mathrm{m}}^{-1}}-1\\
&\mp\ \mathrm{i}\left((1\pm\beta^{\frac12})^2\frac{\Omega}{U_{\mathrm{m}}}+(1-\beta)\frac12\left(\sin\left(2\frac{\Omega}{U_{\mathrm{m}}}\right)\pm\mathrm{i}\left(1-\cos\left(2\frac{\Omega}{U_{\mathrm{m}}}\right)\right)\right)\right)\Bigg].
\end{aligned}
\tag{3.26}
$$

Explicit expressions for $\mathcal{T}^{(1)}(\Omega)$ and $\mathcal{R}^{(1)}(\Omega)$ can now be obtained by inverting the pair of complex equations (3.26). The result simplifies considerably at *resonant frequencies*, (3.22), when (3.26) reduces to

$$
(1\pm\beta^{\frac12})\mathcal{T}^{(1)}(\Omega)-(1\mp\beta^{\frac12})\mathcal{R}^{(1)}(\Omega)=\mp\,\mathrm{i}(1\pm\beta^{\frac12})^2\frac18\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\frac{\Omega}{U_{\mathrm{m}}}.
\tag{3.27}
$$

The solution of (3.27) is

$$
\mathcal{T}^{(1)}(\Omega)=-\frac{1}{16}\,\frac{\mathrm{i}}{\beta^{\frac12}}\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\frac{\Omega}{U_{\mathrm{m}}}(1+3\beta),
\tag{3.28}
$$

$$
\mathcal{R}^{(1)}(\Omega)=-\frac{1}{16}\,\frac{\mathrm{i}}{\beta^{\frac12}}\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\frac{\Omega}{U_{\mathrm{m}}}(1-\beta).
\tag{3.29}
$$

Note that $G'(0)=0$ and $G'(V)<0$ when $V\neq 0$. A relatively simple form is also found in the limit $\frac{\Omega}{U_{\mathrm{m}}}\gg 1$, where

$$
\begin{aligned}
&(1\pm\beta^{\frac12})\mathcal{T}^{(1)}(\Omega)-(1\mp\beta^{\frac12})\mathcal{R}^{(1)}(\Omega)\mathrm{e}^{\mp 2\mathrm{i}\Omega U_{\mathrm{m}}^{-1}}\\
&\qquad=\mp\mathcal{T}^{(0)}(\Omega)^2\mathrm{i}(1\pm\beta^{\frac12})^2\frac18\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\frac{\Omega}{U_{\mathrm{m}}}\,.
\end{aligned}
\tag{3.30}
$$

The solution of the system (3.30) is

$$
\begin{aligned}
\mathcal{T}^{(1)}(\Omega)&=-\frac{\mathrm{i}}{8}\,\mathcal{T}^{(0)}(\Omega)^2\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\frac{\Omega}{U_{\mathrm{m}}}\frac{(1+3\beta)\cos 2\frac{\Omega}{U_{\mathrm{m}}}+\mathrm{i}(3\beta^{\frac12}+\beta^{\frac32})\sin 2\frac{\Omega}{U_{\mathrm{m}}}}{2\beta^{\frac12}\cos 2\frac{\Omega}{U_{\mathrm{m}}}+\mathrm{i}(1+\beta)\sin 2\frac{\Omega}{U_{\mathrm{m}}}}\ ,\\
\mathcal{R}^{(1)}(\Omega)&=-\frac{\mathrm{i}}{8}\,\mathcal{T}^{(0)}(\Omega)^2\frac{G_{\mathrm{n}}'(V_{\mathrm{b}})}{G_{\mathrm{n}}(V_{\mathrm{b}})}\frac{\Omega}{U_{\mathrm{m}}}\frac{1-\beta}{2\beta^{\frac12}\cos 2\frac{\Omega}{U_{\mathrm{m}}}+\mathrm{i}(1+\beta)\sin 2\frac{\Omega}{U_{\mathrm{m}}}}\ .
\end{aligned}
\tag{3.31}
$$

At the nth resonance, $\frac{\Omega}{U_{\mathrm{m}}}=n\pi$, so (3.31) is a rather good approximation in typical experimental situations where $n\geq 4$.

The factors on the right-hand side of (3.31) have simple interpretations. The factor $\mathcal{T}^{(0)}(\Omega)^2$ means that the amplitude of the second harmonic is maximized when the frequency of the input signal is at resonance. The factor $G_{\mathrm{n}}'(V_{\mathrm{b}})/G_{\mathrm{n}}(V_{\mathrm{b}})$ gives the explicit dependence on bias voltage; because $G_{\mathrm{n}}'(0)=0$ there is no second-harmonic generation at order A^2 for zero bias. The factor $\Omega=2\pi fl/c$ means that the second-harmonic amplitude is proportional to the "effective length" of the waveguide, the number of wavelengths over which the nonlinearity has time to act. The final factor involving transcendental functions is complicated. However, it can be seen that the

dependence on $2\Omega/U_{\rm m}$ will produce secondary maxima in the second-harmonic amplitude at frequencies halfway between resonances of the input signal. Finally, we remark that the constant terms (zero-frequency "DC-component") of amplitude A^2, also generated by the quadratic component of nonlinearity, can always be absorbed into the bias voltage, and hence their effects are already accounted for by V_b-variations.

4. Comparison with numerical solutions. The response of a finite-length nonlinear device was modeled by dividing the space into three one-dimensional regions. In the central region (region II) the wave equation, two coupled PDEs for the charge and current fields (2.12), is nonlinear. The numerical runs described in this section used values of the capacitances and inductances, length of region II, and input frequencies, chosen to be similar to those found in the experiments described in section 5 below [23].

In the interior of each region, timestepping is performed according to the Lax–Wendroff method described in section B.1. At the boundaries between region I and II and between regions II and III, we impose continuity of voltage and current. In section B.2 we describe how this is made consistent with the different relations between charge and voltage functions that hold to the left and to the right of the boundary. In the numerics, we can examine the whole configuration of current and charge at any time. An example numerical configuration (a"snapshot" at one instant of time) is shown in Figure 4.1.

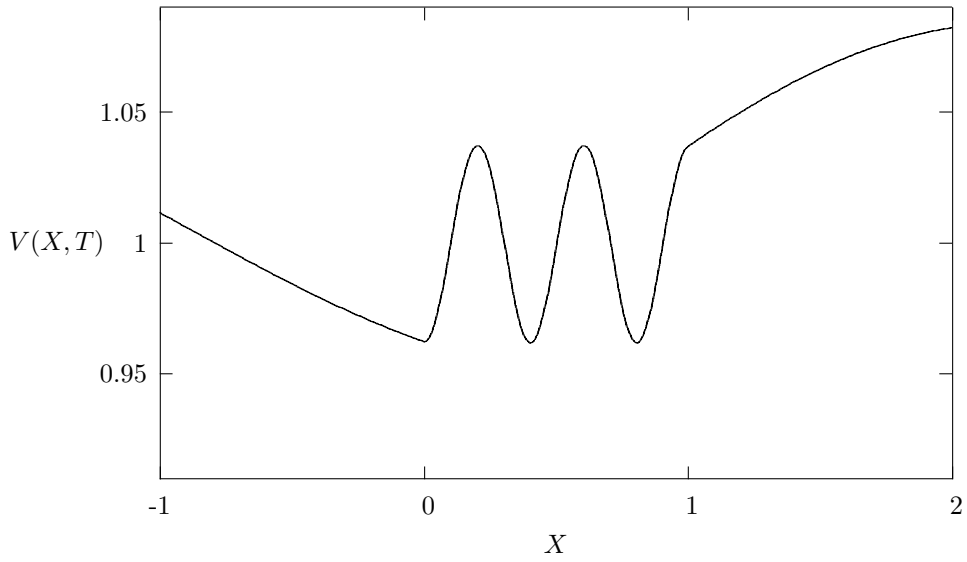

FIG. 4.1. *Numerical voltage field as a function of* X *for* $T = 1000$. *In regions* I *and* III *(*$X < 0$ *and* $X > 1$*), the wave equation is linear; in region* II *(*$0 \le X \le 1$*), the wave equation is nonlinear. A sinusoidal signal was input at* $f = 250$MHz *with* $a = 0.1$V. *The parameters are* $L_{\rm I}C_{\rm I}c^2 = 9$, $L_{\rm II}C_{\rm II}c^2 = 2500$, *and* $l = 6$cm, $v_{\rm b} = 1$V, *and* $v^* = 10$V. *The partial differential equations* (2.12) *were solved with* $\Delta X = 0.001$ *and* $\Delta T = 0.001$.

Regions I and III, semi-infinite in the PDE (2.12), are of finite length in the numerical scheme. In region I, which stretches from $X = -L$ to $X = 0$, there is a prescribed input signal; the update employed at the leftmost extremity for producing it is derived in section B.3. Fourier transforms of numerical time series at points in

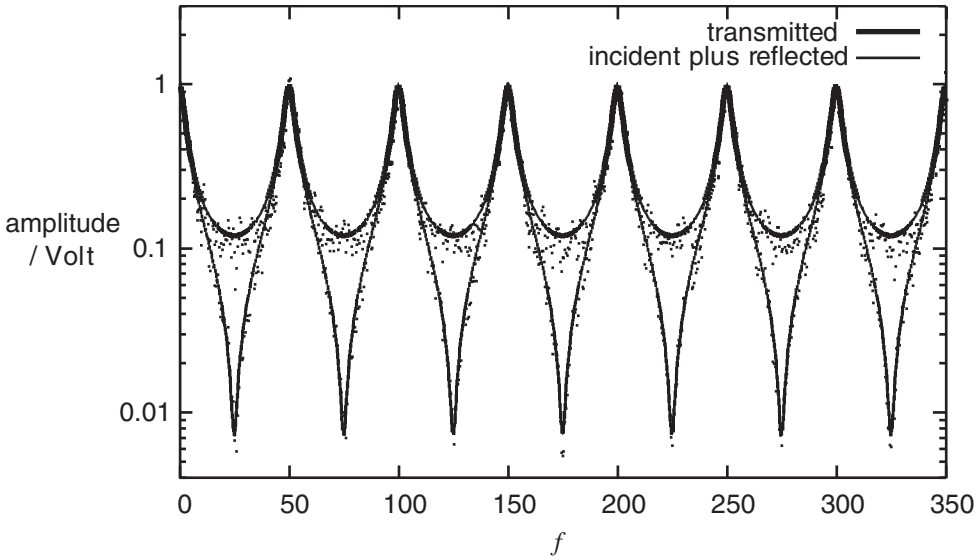

FIG. 4.2. *The solid lines are modulus of the transmission coefficient* $\mathcal{T}^{(0)}(\Omega)$ *and of* $1+\mathcal{R}^{(0)}(\Omega)$ *as a function of frequency at* (3.21). *The dots are the Fourier transforms of numerical time series with white noise input.*

regions I and III are used to evaluate the transmitted and reflected signals. Sinusoidal input signals may be accompanied by noise, either white or with constant power in a window of frequencies. The latter "band-limited" noise is generated either by filtering white noise or by explicitly constructing a signal as a sum of Fourier components with constant power in the frequency window.

Our analytical and numerical methods are not altered by changes in the form of the function $C(V)$, assuming that it is a positive even function with maximum at 0. In the numerical runs producing the results displayed in Figures 4.1–4.5, we used the following form:

$$C_{\rm m}(v) = C_{\rm II}\left(1+\left(\frac{v}{v^*}\right)^2\right)^{-1}, \tag{4.1}$$

giving the convenient explicit form $V(x,t) = \tan(Q(x,t))$ in region II and

$$G_{\rm n}(V) = \frac{1}{1+V^2}. \tag{4.2}$$

The parameter values used in the numerical runs reported in this section were as follows. The length of region II was taken to be $l = 6$cm and the characteristic voltage $v^* = 10$V. The L and C constants in the regions were given by $L_{\rm I}C_{\rm I}c^2 = 9$, $L_{\rm II}C_{\rm II}c^2 = 2500$. Thus the speed of light in regions I and III was one third of that in a vacuum, c. The corresponding speed in region II and the factor β are bias-dependent; at zero bias the speed was $c/50$ and $\beta = 0.0036$.

The results of one numerical experiment are shown in Figure 4.2. The input was broadband white noise with small amplitude, so that all frequencies have equal average amplitude in the input. The solid lines are the predictions obtained from (3.21). Assuming a flat input spectrum, we obtain the transmission coefficient $\mathcal{T}^{(0)}(\Omega)$ as the Fourier transform of the time series in region III, showing resonances when

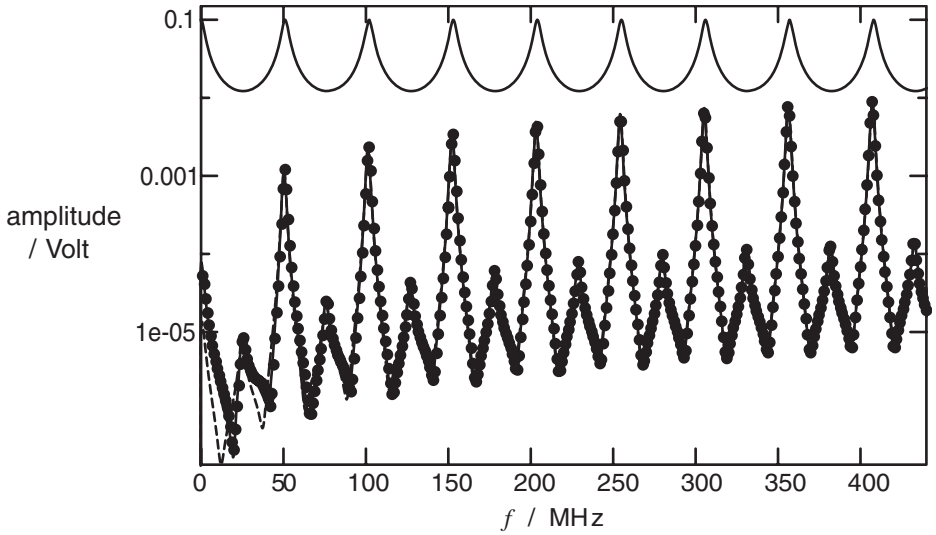

FIG. 4.3. *Transmission and second-harmonic generation as a function of input frequency. The transmitted amplitudes at f and $2f$ are shown on a logarithmic scale. Numerical results are shown as solid circles and analytical results as lines. In particular, the dashed line corresponds to the high frequency limit* (3.31)*, and, as seen, it becomes accurate past frequencies of about* 50MHz.

Ω/U_m was a multiple of π. (With $l = 6$cm, resonant frequencies are at multiples of 50MHz.) The numerical results, shown as dots, fluctuate about the theoretical line as expected. In region I, the time-dependent voltage is the sum of incident and reflected signals; the Fourier amplitude in this case, shown in the figure, is $1 + \mathcal{R}^{(0)}(\Omega)$. At resonant frequencies (3.22), there is perfect transmission and $\mathcal{R}^{(0)}(\Omega) = 0$. Halfway between resonant frequencies, at frequencies satisfying $\sin\left(\frac{\Omega}{U_{\rm m}}\right) = \pm 1$, we find minimum transmission

$$|\mathcal{T}^{(0)}(\Omega)|^2_{\rm min} = \frac{4\beta}{(1+\beta)^2} \tag{4.3}$$

and

$$\mathcal{R}^{(0)}(\Omega) = -\frac{1-\beta}{1+\beta} = -1 + 2\beta + \mathcal{O}(\beta^2); \tag{4.4}$$

at these frequencies $\mathcal{R}^{(0)}(\Omega) \simeq -1$, and the reflected and incident signals almost cancel each other out. This feature is clearly visible in the numerical results. No nonlinear effects are displayed in Figure 4.2, but the run serves as a stringent check on the numerical algorithm over several orders of magnitude in voltage.

The effect of the nonlinearity in generating an output at twice the input frequency is shown in Figure 4.3, which summarizes the results of a series of numerical runs, each with a single sinusoidal input. The input amplitude $a = 0.1$V was fixed, and all runs were performed with bias voltage $v_{\rm b} = 2.01$; the frequency f of the input signal was changed from run to run. At the chosen bias voltage, resonant frequencies are multiples of 51MHz. The figure shows the transmitted amplitude at frequencies f and $2f$, along with the analytical predictions. The amplitude at f is given by (3.21). The prediction at $2f$, obtained by inverting (3.26), is remarkably accurate over many orders of magnitude in the transmitted amplitude. The asymptotic formula for high

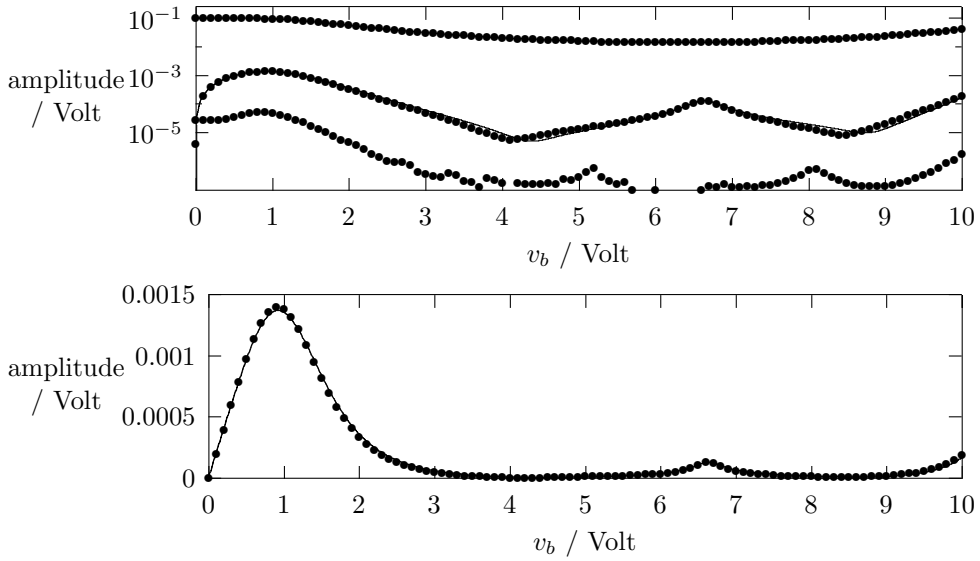

FIG. 4.4. *Transmission and harmonic generation as a function of bias voltage. In the upper graph the output amplitudes at f, $2f$, and $3f$ are shown on a logarithmic scale. In the lower graph the amplitude at $2f$ is shown on a linear scale. Numerical results are shown as solid circles. The solid lines use* (3.21) *and* (3.26). *The dotted line, using* (3.31), *differs visibly from* (3.26) *only at low frequencies. In each case $f = 150$MHz and $a = 0.1$V.*

frequency (3.31), shown in this figure as a dashed line, is indistinguishable from the full inversion of (3.26) and the numerical data past frequencies of about 50MHz.

The features of the second-harmonic amplitude predicted by (3.31) are clearly evident in the numerical results. The amplitude of the second harmonic is maximized when the frequency of the input signal is at resonance. Local maxima of the second-harmonic amplitude are also found at frequencies halfway between resonances of the input signal. The height of the maxima coinciding with the nth resonance is proportional to n because the second-harmonic amplitude is proportional to Ω.

A similar series of runs was used to produce Figure 4.4, this time with all parameters except bias voltage held fixed. The input frequency is chosen to be at resonance at zero bias. The top graph shows the transmitted amplitude at f, $2f$, and $3f$ on a logarithmic scale. (We have not attempted to calculate the $3f$ amplitude but conjecture that it is proportional to $C''(V_\mathrm{b})$, and hence nonzero at $V_\mathrm{b} = 0$.) In the lower graph we plot the transmitted second-harmonic ($2f$) amplitude and the approximation (3.31) on a linear scale. At zero bias voltage, it is zero at order A^2 because $C'(0) = 0$. The second-harmonic amplitude at first increases with bias voltage, and then decreases as the bias voltage is further increased, as the resonant frequency is shifted away from the input frequency. For sufficiently large bias voltage, the shift in resonant frequencies is such that the input frequency can once again be at resonance.

The convenient analytical forms (3.31), for the amplitudes and phases of the transmitted and reflected second harmonic at order A^2, give several intriguing possibilities if the input signal consists of two or more sinusoids. For example, in addition to a sinusoidal input at frequency f, another at frequency $2f$ can be chosen so that the total transmission at $2f$ is zero to order A^2 by cancellation of the second harmonic produced by the nonlinearity with the transmitted signal at $2f$. This cancellation

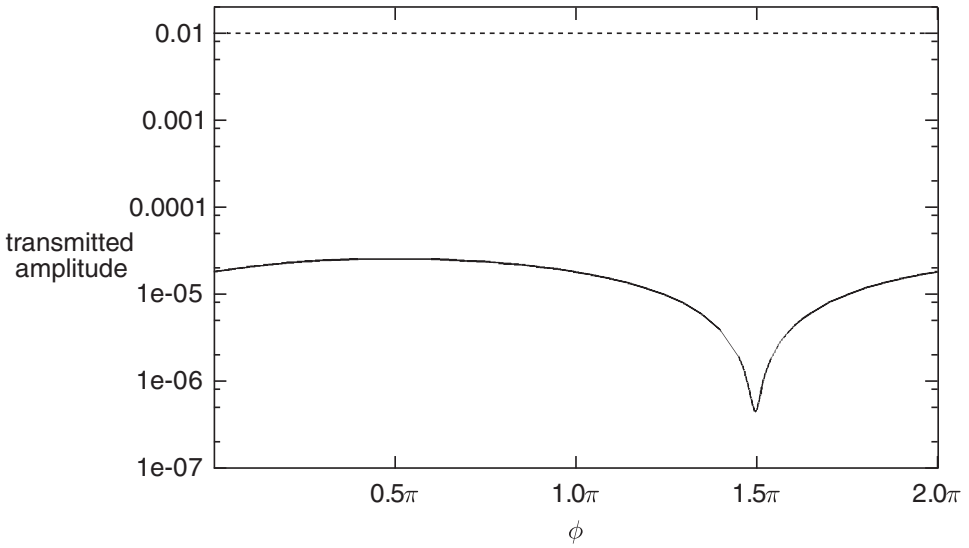

FIG. 4.5. *Transmitted amplitude at f (dashed) and $2f$ (solid) versus phase ϕ, logarithmic scale. The input signal is given by* (4.5)*, with the amplitude b chosen to be equal to that of the second harmonic generated by the nonlinearity from the input at frequency f with amplitude a. The parameters are $f = 51$MHz and $a = 0.01$.*

can be produced for any input frequency and will be explored further below in the case where f is a resonant frequency. Alternatively, for an input frequency slightly off resonance, it is possible to choose a combination such that the *reflected* signal is free of harmonics to order A^2.

In Figure 4.5 we show the transmitted amplitude at f and $2f$, as a function of the phase ϕ, when the input signal is given by

$$v_{\text{in}} = a\cos(2\pi f t) + b\cos(4\pi f t + \phi), \tag{4.5}$$

where f is chosen to be the lowest resonant frequency at a nonzero bias voltage. At lowest order, the transmitted signal is equal to the input signal, since $2f$ is also a resonant frequency. There is another source of transmitted power at $2f$, the generated second-harmonic signal with amplitude, given by (3.28), proportional to a^2/v^*. We choose b in (4.5) to be equal to that amplitude. (With the parameters in Figure 4.5, $|\mathcal{T}^{(1)}(\Omega)| \simeq 1.3$, so $b = |\mathcal{T}^{(1)}(\Omega)|a^2/v^* \simeq 0.000013$.) According to (3.28), the phase of the generated $2f$ signal is $\frac{1}{2}\pi$. Thus when $\phi = -\frac{1}{2}\pi$, the generated and directly transmitted outputs have equal amplitude and opposite phase; the result is to eliminate the total transmitted $2f$ signal to order A^2. (Also shown in Figure 4.5, as a dashed line, is the transmitted amplitude at f, which is independent of ϕ and indistinguishable from the input amplitude.)

The procedure of producing a pure transmitted signal with frequency f from a mixed input can in principle be carried to nth order, using an input signal with amplitudes and phases chosen to eliminate n multiples of f from the transmitted signal. The result would be a unique multifrequency input that gives a pure single frequency transmitted signal through a given device. This uniqueness property, and its dependence on the external bias field, might have encoding implications in signal transmission protocols.

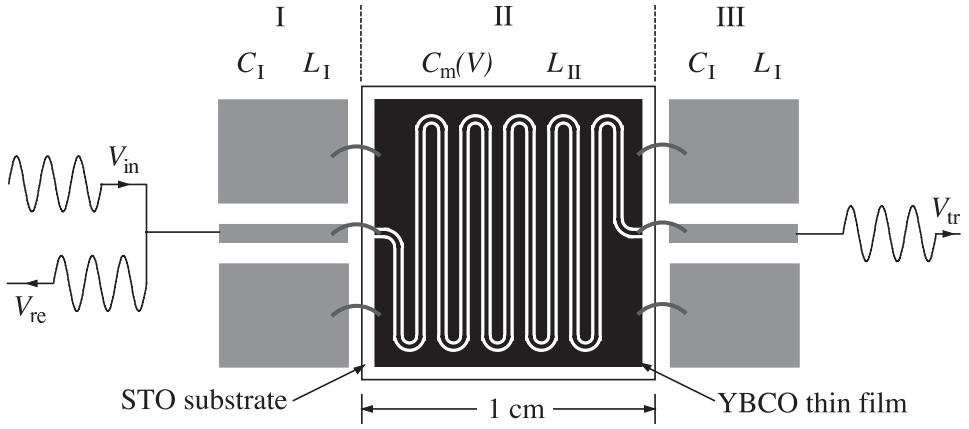

FIG. 5.1. *Device top view and schematic diagram. The input circuitry, device, and output circuitry are modeled as regions* I, II, *and* III. *The time-dependent voltage in region* I *is a sum of the incident and reflected sinusoidal signals,* $V_{\rm in}$ *and* $V_{\rm re}$. *In the central region, region* II, *the wave equation is nonlinear. Signals travel along the meandering waveguide patterned into a superconducting thin film. The transmitted signal in region* III, $V_{\rm tr}$, *is measured and analyzed.*

5. Comparison with an experimental system. In this section we report on experimental results. Microwave signals and noise were passed through a small device whose properties depend on operating temperature and applied voltage. A schematic diagram is shown in Figure 5.1. The devices are 1cm × 1cm × 0.5mm, consisting of 0.4μm-thick superconducting $YBa_2Cu_3O_7$ (YBCO) film on single-crystal substrates [22]. They are manufactured with two parallel meandering gaps (width 15μm) patterned into the superconducting thin film. The result is a waveguide with a narrow meandering centerline (length $l \simeq$ 8cm and width 20μm) and two groundplanes (the rest of the superconducting film).

A constant voltage difference, the "bias" voltage, is maintained between the centerline and the groundplane. Because the lateral dimensions of the waveguide are much smaller than the wavelengths of the input signals, wave propagation is effectively one-dimensional. In the superconducting state, below the transition temperature $T_{\rm c} \simeq 85K$, resistive losses of the YBCO film are negligible. Working temperatures were in the range 20K–60K. The source of the nonlinearity in the experiment is the substrate that the superconducting waveguide rests on, a single crystal of strontium titanate, $SrTiO_3$ (STO), with large permittivity. Due to the nonlinear dielectric properties of STO [19, 20], the shunt capacitance per unit length of the waveguide depends on temperature and on voltage. The resulting voltage-dependent differential capacitance produces behavior that combines resonance effects with harmonic generation and frequency mixing. More details can be found in [3], [10], and [11].

Our quantitative studies begin with a measurement of the differential capacitance as a function of temperature and voltage. We assume that the inductance per unit length, $L_{\rm II}$, is unaffected by changes in temperature and voltage. (The value $L_{\rm II} = 505.7$pH/mm is deduced from measurements of the capacitance and resonant frequencies of the devices [11].) Measurement of the differential capacitance is conveniently carried out using a small-amplitude broadband noise input at various temperatures and bias voltages. The dominant feature of the transmitted spectrum is a series of maxima at resonant frequencies. The resonant frequencies at bias voltage $v_{\rm b}$

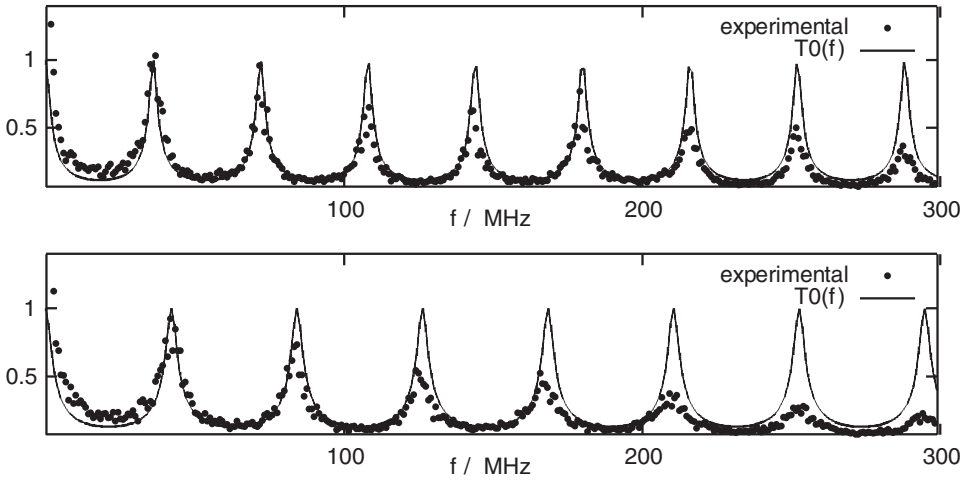

FIG. 5.2. *Experimental and theoretical results: Transmission versus frequency. The experimental results were obtained at operating temperature* 40K. *In the upper graph, bias voltage* $= 0$. *In the lower graph, bias voltage* $= 10$V. *The solid lines are the theoretical curve* (3.21) *for linear lossless transmission. The parameters are* $L_{\rm I}C_{\rm I}/L_{\rm II}C_{\rm II} = 9/2500$ *and* $l = 7.8$cm. *The positions of the resonance peaks are well predicted, but successive experimental peaks are of reduced height due to losses in the device.*

are $f_n(v_{\rm b})$, where

$$f_n(v_{\rm b}) = \frac{n}{2}\frac{u_{\rm m}(v_{\rm b})}{l}, \qquad n = 0, 1, 2, \ldots, \tag{5.1}$$

and the propagation speed for small-amplitude signals, $u_{\rm m}(v_{\rm b})$, is given by (2.14): $u_{\rm m}(v_{\rm b}) = (L_{\rm II}C_{\rm m}(v_{\rm b}))^{-\frac{1}{2}}$.

Experimental results for the transmitted signal as a function of input frequency are shown in Figure 5.2. The input in each case was broadband white noise and the operating temperature was 40K. Because $C_{\rm m}(v_{\rm b})$ is a decreasing function on $v_{\rm b}$, the distance between resonant peaks increases when a bias voltage is applied. The theoretical curve accurately gives the position of the resonant peaks in transmission but does not predict their decreasing height as a function of frequency. The reason is that the model PDEs (2.12) do not include losses whose effect is to reduce transmission by a factor that increases with frequency.

The decreasing height of resonant peaks does not prevent us from accurately determining their position. Using (2.14) determines the differential capacitance as a function of voltage; $C_{\rm m}(v_{\rm b})$ is related to the frequency f_n of the nth peak in the transmission versus frequency curve by

$$L_{\rm II}C_{\rm m}(v_{\rm b}) = \left(\frac{n}{2}\frac{1}{l}\right)^2 f_n^{-2}(v_{\rm b}). \tag{5.2}$$

The upper plot in Figure 5.3 is the position of the third resonance as a function of bias voltage at operating temperature 40K. The function used to obtain the fit shown as a solid line is

$$f(v_{\rm b}) = f(0) + c_1 v_{\rm b}\tanh(c_2 v_{\rm b}), \tag{5.3}$$

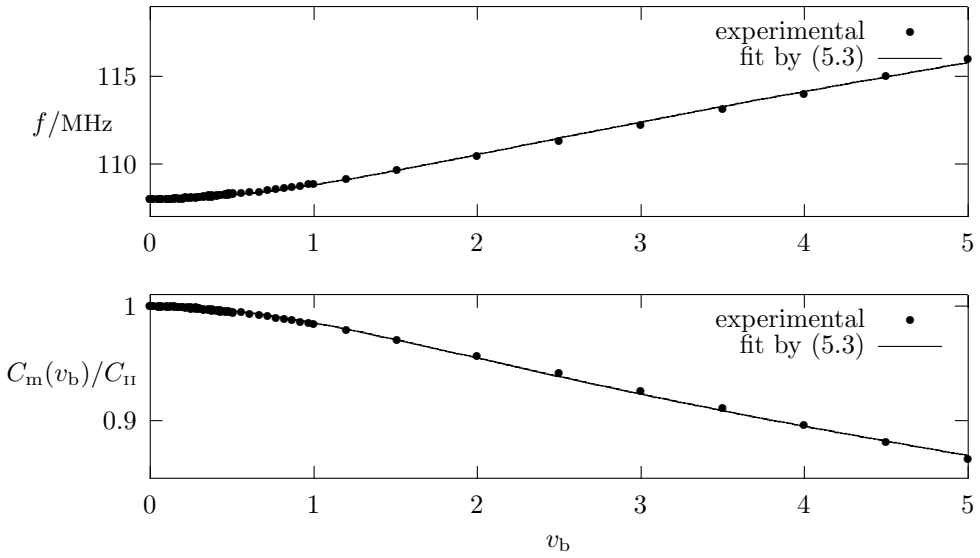

FIG. 5.3. *Experimental results at operating temperature* 40K *and best fit using* (5.3). *Upper graph: Frequency at the* $n = 3$ *peak as a function of bias voltage. Lower graph: Differential capacitance as a function of bias voltage divided by* $C_{\rm II} = C_{\rm m}(0)$.

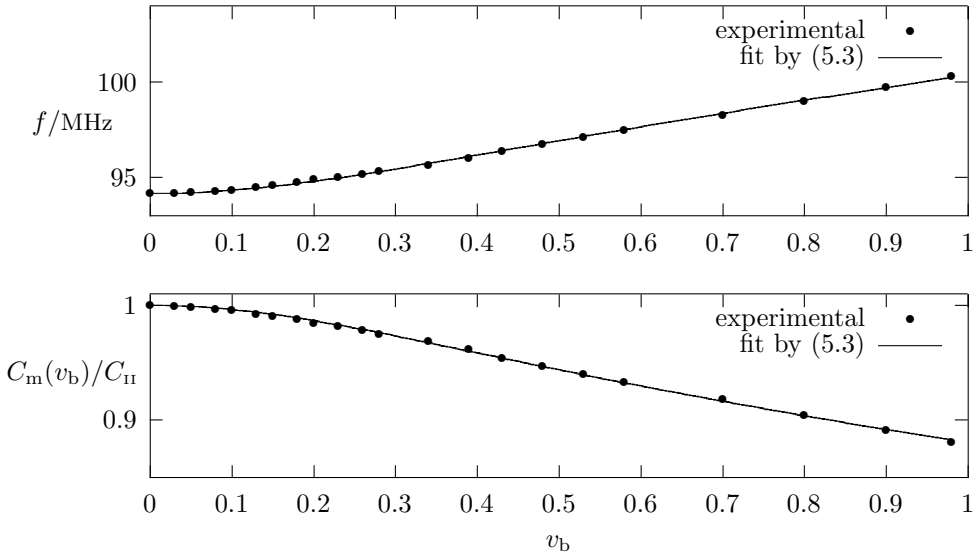

FIG. 5.4. *Experimental results at operating temperature* 20K *and best fit using* (5.3). *Upper graph: Frequency at the* $n = 4$ *peak as a function of bias voltage. Lower graph: Differential capacitance as a function of bias voltage divided by* $C_{\rm II} = C_{\rm m}(0)$.

where the two parameters c_1 and c_2 are adjusted once to obtain a fit through all the experimental points. The lower plot in Figure 5.3 is the ratio $C_{\rm m}(v_{\rm b})/C_{\rm II}$, deduced from the upper curve using (5.2). In Figure 5.4, similar results are shown for operating temperature 20K. At this lower temperature, differential capacitance is a more rapidly varying function of bias voltage. As the graphs in Figure 5.4 show, the functional

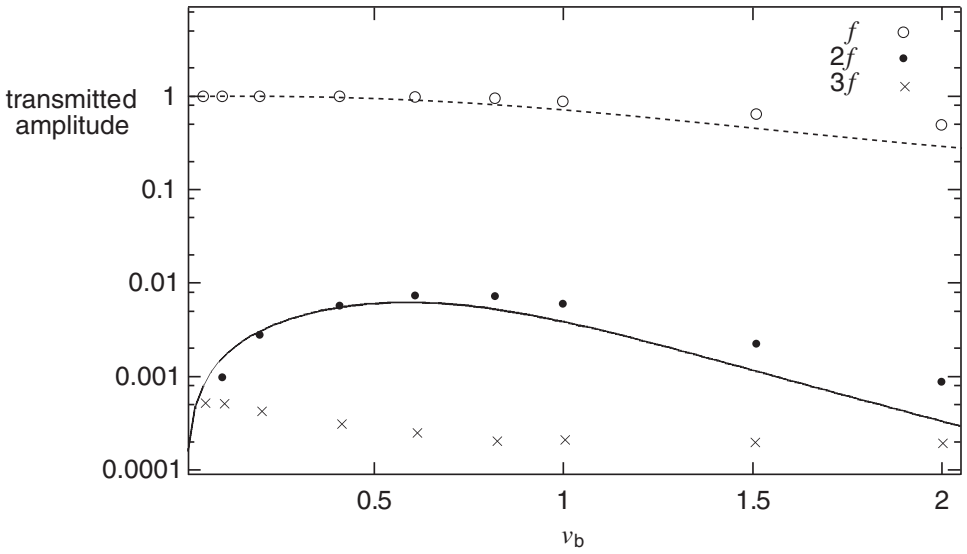

FIG. 5.5. *Experimental results and theoretical curves: Transmitted amplitudes at f (empty circles), $2f$ (filled circles), and $3f$ (crosses) versus bias. The input is of fixed amplitude and frequency $f = 215$MHz. The lines are the theoretical curves using asymptotic analysis of the lossless nonlinear PDE* (2.12). *The dashed line is the transmission coefficient from the linear equation. The solid line shows the order A^2 second-harmonic amplitude* (3.31).

form (5.3) appears quite suitable for the purpose of modeling the medium's nonlinear response within the range of voltage amplitudes we have considered.

Figure 5.5 summarizes experimental data taken at 40K using an input signal of fixed amplitude at $f = 215$MHz. The frequency is chosen to be at the sixth resonance peak for zero bias voltage. The upper part of the plot shows the transmitted amplitude at f, normalized to its value at zero bias. As bias voltage increases away from zero, there is a shift in the resonance frequency (compare Figure 5.2) so that the input frequency is no longer a resonant frequency and the transmitted power decreases. The decrease is less rapid in the experiment (empty circles) than in the theoretical curve (dotted line) because losses have the effect of widening (as well as reducing the height of) resonant peaks. Dielectric losses are also known to decrease with bias voltage [22, 24]. The solid line and filled circles show the transmitted amplitude at $2f$ as a function of bias. The reason for the initial rapid increase with bias is that the amplitude of the second-harmonic signal is proportional to $C'_{\rm m}(v_{\rm b})$ and $C'_{\rm m}(0) = 0$. The subsequent decline is due to the decrease of the transmitted power at frequency f (compare (3.31)). Also shown is the third-harmonic power, which has a nonzero value at zero bias voltage and then decreases slowly [11].

6. Conclusion. A few points emerge from our side-by-side modeling and experimental investigation of electromagnetic propagation in a class of nonlinear waveguides. First, our simple voltage-current model seems to capture most of the physical features of the experimental device, including the tunable nonlinearity via an externally applied electric field. We find quantitative agreement with most measurable quantities. Some effects we neglect, such as dissipation, do show up in the data, but at least for the experimental regimes we have focused on, they can be considered secondary.

Second, transmission of sinusoidal signals through a linear medium is maximized

when the length of the region is equal to a multiple of half the wavelength. This remains the dominant feature in transmission through the nonlinear region we studied, because the signal amplitude is small enough and the nonlinear region is short enough that nonlinear and dispersive effects have a subdominant role. The main effect of the nonlinearity is to produce a second-harmonic output, with amplitude that is well predicted by an expansion that assumes that the input signal is sufficiently weak. The explicit and, especially near resonance, relatively simple formulae we have derived using an asymptotic approach perform well against both numerical solutions of our model equation and experimental results, thus giving us confidence that the theoretical building blocks we have established can be used in other studies of this class of materials.

Third, the numerical simulations in which we mix the input signal with a second harmonic show that it is possible to achieve transparency (or total reflection) at second order in the input amplitude. In principle the expansion we have set up could be carried out to higher orders, thus eliminating all higher harmonics from the transmitted signal. Such transparency, and its dependence on the external bias field, might be exploited for technological applications such as signal transmission protocols.

The main difference between our system and optical systems [25] is the absence of frequency dispersion. Future work will apply and extend the tools we have developed in this paper to study arrays of similar devices, where the longer effective length will permit nonlinear pulses of permanent form (or "solitons") because of the dispersive effects that such configurations generate. Distributed (or spatially extended) nonlinear arrays have intrinsic broadband capability (at least several hundred GHz) in contrast to electronic circuits based on discrete elements and high-dimensional complexity, governed by PDEs or coupled ODEs, in contrast to low-dimensional systems whose dynamics are governed by ODEs. Thus, distributed nonlinear arrays have the potential to handle wider data bandwidth at a high level of security in communication.

Appendix A. The initial times function.

In this appendix we find the explicit lowest-order solution for the voltage in region II, evaluate the integral (3.25) that gives the initial times function, and explicitly expand (3.7) to order A^2.

Consider a point (T, X) in region II. It is the intersection of the two characteristics that intersect $X = 0$ at $(T_\pm(0), 0)$, where

$$T_\pm^{(0)}(0) = T \mp \frac{X}{U_{\rm m}}\,. \tag{A.1}$$

Now the solution is constructed using

$$V^{(0)}(X,T) = (2G_{\rm n}(V_{\rm b})^{\frac{1}{2}})^{-1}\left(\Gamma_+^{(0)}(X,T) + \Gamma_-^{(0)}(X,T)\right). \tag{A.2}$$

Using the property of the characteristics, $\Gamma_\pm(X,T) = \Gamma_\pm(0, T_\pm(0))$, and the explicit forms,

$$V_{\rm I}^{(0)}(T) = \frac{1}{2}\left((1+\mathcal{R}^{(0)}(\Omega))\mathrm{e}^{\mathrm{i}\Omega T} + \text{c.c.}\right),$$

$$I_{\rm I}^{(0)}(T) = \left(\frac{L_{\rm II}C_{\rm I}}{L_{\rm I}C_{\rm II}}\right)^{\frac{1}{2}}\frac{1}{2}\left((1-\mathcal{R}^{(0)}(\Omega))\mathrm{e}^{\mathrm{i}\Omega T} + \text{c.c.}\right),$$

$$V_{\rm III}^{(0)}(T) = \frac{1}{2}\left(\mathcal{T}^{(0)}(\Omega)\mathrm{e}^{\mathrm{i}\Omega T} + \text{c.c.}\right),$$

$$I^{(0)}_{\rm III}(T) = \left(\frac{L_{\rm II}C_{\rm I}}{L_{\rm I}C_{\rm II}}\right)^{\frac{1}{2}} \frac{1}{2}\left(\mathcal{T}^{(0)}(\Omega)\mathrm{e}^{\mathrm{i}\Omega T} + \text{c.c.}\right), \tag{A.3}$$

we obtain

$$\begin{aligned}
V^{(0)}(X,T) &= G_{\rm n}(V_{\rm b})^{-\frac{1}{2}}\frac{1}{2}\Bigg[G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V_{\rm I}^{(0)}\left(T-\frac{X}{U_{\rm m}}\right) + I_{\rm I}^{(0)}\left(T-\frac{X}{U_{\rm m}}\right) \\
&\qquad + G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V_{\rm I}^{(0)}\left(T+\frac{X}{U_{\rm m}}\right) - I_{\rm I}^{(0)}\left(T+\frac{X}{U_{\rm m}}\right)\Bigg] \\
&= \frac{1}{2}\Bigg[\exp\left(\mathrm{i}\Omega\left(T-\frac{X}{U_{\rm m}}\right)\right) + \mathcal{R}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T-\frac{X}{U_{\rm m}}\right)\right) \\
&\quad +\beta^{\frac{1}{2}}\left(\exp\left(\mathrm{i}\Omega\left(T-\frac{X}{U_{\rm m}}\right)\right) - \mathcal{R}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T-\frac{X}{U_{\rm m}}\right)\right)\right) \\
&\quad + \exp\left(\mathrm{i}\Omega\left(T+\frac{X}{U_{\rm m}}\right)\right) + \mathcal{R}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T+\frac{X}{U_{\rm m}}\right)\right) \\
&\quad -\beta^{\frac{1}{2}}\left(\exp\left(\mathrm{i}\Omega\left(T+\frac{X}{U_{\rm m}}\right)\right) - \mathcal{R}^{(0)}(\Omega)\exp\left(\mathrm{i}\Omega\left(T+\frac{X}{U_{\rm m}}\right)\right)\right) + \text{c.c.}\Bigg] \\
&= \frac{1}{2}\Bigg[\mathrm{e}^{\mathrm{i}\Omega T}\Bigg((1+\mathcal{R}^{(0)}(\Omega))\cos\left(\frac{\Omega}{U_{\rm m}}X\right) \\
&\quad - \mathrm{i}\beta^{\frac{1}{2}}(1-\mathcal{R}^{(0)}(\Omega))\sin\left(\frac{\Omega}{U_{\rm m}}X\right)\Bigg) + \text{c.c.}\Bigg].
\end{aligned}$$

Thus

$$\begin{aligned}
V^{(0)}(X,T) &= |1+\mathcal{R}^{(0)}(\Omega)|\cos\left(\frac{\Omega}{U_{\rm m}}X\right)\cos(\Omega T+\phi_1) \\
&\quad - \beta^{\frac{1}{2}}|1-\mathcal{R}^{(0)}(\Omega)|\sin\left(\frac{\Omega}{U_{\rm m}}X\right)\sin(\Omega T+\phi_2)\,,
\end{aligned} \tag{A.4}$$

where $\phi_1 = \arg(1+\mathcal{R}^{(0)}(\Omega))$ and $\phi_2 = \arg(1-\mathcal{R}^{(0)}(\Omega))$. In the case of resonance, $\Omega = U_{\rm m}\, n\pi$, $\mathcal{R}^{(0)}(\Omega) = 0$, and the solution in region II is simply

$$V(X,T) = V_{\rm b} + A\left(\cos(n\pi X)\cos(\Omega T) - \beta^{\frac{1}{2}}\sin(n\pi X)\sin(\Omega T)\right). \tag{A.5}$$

To evaluate the integral in (3.25), we need the quantity $V^{(0)}(X, T^{(0)}_{\pm}(X))$. Inserting

$$T^{(0)}_{\pm}(X) = S \mp \frac{1-X}{U_{\rm m}} \tag{A.6}$$

and using (3.18) gives

$$V^{(0)}(X,T^{(0)}_{\pm}(X)) = \frac{1}{4}\Bigg[\mathrm{e}^{\mathrm{i}\Omega(S\mp U_{\rm m}^{-1})}\Bigg(1+\mathcal{R}^{(0)}(\Omega) \pm \beta^{\frac{1}{2}}(1-\mathcal{R}^{(0)}(\Omega))$$

$$+\left(\cos\left(2\frac{\Omega}{U_{\rm m}}X\right)\pm\ {\rm i}\,\sin\left(2\frac{\Omega}{U_{\rm m}}X\right)\right)\left(1+\mathcal{R}^{(0)}(\Omega)\mp\beta^{\frac{1}{2}}(1-\mathcal{R}^{(0)}(\Omega))\right)\Bigg)+{\rm c.c.}\Bigg]$$

$$=\frac{1}{4}\left[{\rm e}^{{\rm i}\Omega S}\mathcal{T}^{(0)}(\Omega)\Big(1\pm\beta^{\frac{1}{2}}+(1\mp\beta^{\frac{1}{2}}){\rm e}^{\mp 2{\rm i}\frac{\Omega}{U_{\rm m}}}\Big(\cos\left(2\frac{\Omega}{U_{\rm m}}X\right)\pm{\rm i}\sin\left(2\frac{\Omega}{U_{\rm m}}X\right)\Big)\Big)+{\rm c.c.}\right].$$

Thus, the next-to-lowest order term in the initial times function is explicitly

$$\tau_{\pm}^{(1)}(S)=\mp U_{\rm m}^{-1}\frac{1}{8}\frac{G_{\rm n}'(V_{\rm b})}{G_{\rm n}(V_{\rm b})}\Bigg[{\rm e}^{{\rm i}\Omega S}\mathcal{T}^{(0)}(\Omega)\Bigg(1\pm\beta^{\frac{1}{2}}$$

$$+\frac{1}{2}\frac{U_{\rm m}}{\Omega}(1\mp\beta^{\frac{1}{2}}){\rm e}^{\mp 2{\rm i}\frac{\Omega}{U_{\rm m}}}\left(\sin\left(2\frac{\Omega}{U_{\rm m}}\right)\pm{\rm i}\mp{\rm i}\cos\left(2\frac{\Omega}{U_{\rm m}}\right)\right)\Bigg)+{\rm c.c.}\Bigg]. \tag{A.7}$$

The full expression for (3.7), up to order A^2 with (3.14) and (3.17), is

$$\begin{aligned}
&AG_{\rm n}(V_{\rm b})^{\frac{1}{2}}\left(1\pm\beta^{\frac{1}{2}}\right)\frac{1}{2}\left(\mathcal{T}^{(0)}(\Omega){\rm e}^{{\rm i}\Omega S}+{\rm c.c.}\right)\\
&+\ A^2G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V_{\rm III}^{(1)}(S)\pm A^2I_{\rm III}^{(1)}(S)\\
&+\ A^2G_{\rm n}(V_{\rm b})^{\frac{1}{2}}\frac{1}{8}\frac{G_{\rm n}'(V_{\rm b})}{G_{\rm n}(V_{\rm b})}\left(|\mathcal{T}^{(0)}(\Omega)|^2+\frac{1}{2}(\mathcal{T}^{(0)}(\Omega)^2{\rm e}^{2{\rm i}\Omega S}+{\rm c.c.})\right)\\
&=AG_{\rm n}(V_{\rm b})^{\frac{1}{2}}\frac{1}{2}\left[{\rm e}^{{\rm i}\Omega(S\mp U_{\rm m}^{-1})}\left(1+\mathcal{R}^{(0)}(\Omega)\pm\beta^{\frac{1}{2}}(1-\mathcal{R}^{(0)}(\Omega))\right)+{\rm c.c.}\right]\\
&+\ A^2G_{\rm n}(V_{\rm b})^{\frac{1}{2}}V_{\rm I}^{(1)}(S\mp U_{\rm m}^{-1})\pm A^2I_{\rm I}^{(1)}(S\mp U_{\rm m}^{-1})\\
&+\ A^2G_{\rm n}(V_{\rm b})^{\frac{1}{2}}\frac{1}{8}\frac{G_{\rm n}'(V_{\rm b})}{G_{\rm n}(V_{\rm b})}\left(|1+\mathcal{R}^{(0)}(\Omega)|^2+\frac{1}{2}\left[(1+\mathcal{R}^{(0)}(\Omega))^2\,{\rm e}^{2{\rm i}\Omega(S\mp U_{\rm m}^{-1})}+{\rm c.c.}\right]\right)\\
&+\ A^2G_{\rm n}(V_{\rm b})^{\frac{1}{2}}\frac{1}{2}\Omega\left[{\rm i}{\rm e}^{{\rm i}\Omega(S\mp U_{\rm m}^{-1})}\left(1+\mathcal{R}^{(0)}(\Omega)\pm\beta^{\frac{1}{2}}(1-\mathcal{R}^{(0)}(\Omega))\right)+{\rm c.c.}\right]\tau_{\pm}^{(1)}(S).
\end{aligned}$$

To order A we regain (3.18). With (A.7), we obtain the following expression for (3.7) at order A^2:

$$\begin{aligned}
&V_{\rm III}^{(1)}(S)\pm G_{\rm n}(V_{\rm b})^{-\frac{1}{2}}I_{\rm III}^{(1)}(S)-V_{\rm I}^{(1)}(S\mp U_{\rm m}^{-1})\mp G_{\rm n}(V_{\rm b})^{-\frac{1}{2}}I_{\rm I}^{(1)}(S\mp U_{\rm m}^{-1})\\
=&\frac{1}{16}\frac{G_{\rm n}'(V_{\rm b})}{G_{\rm n}(V_{\rm b})}\Bigg[\Bigg(-|\mathcal{T}^{(0)}(\Omega)|^2-\mathcal{T}^{(0)}(\Omega)^2\,{\rm e}^{2{\rm i}\Omega S}+|\mathcal{T}^{(0)}(\Omega)|^2\left(\cos^2\frac{\Omega}{U_{\rm m}}+\beta\sin^2\frac{\Omega}{U_{\rm m}}\right)\\
&+\mathcal{T}^{(0)}(\Omega)^2\left(\cos^2\frac{\Omega}{U_{\rm m}}-{\rm i}\beta^{\frac{1}{2}}\sin^2\frac{\Omega}{U_{\rm m}}\right)^2{\rm e}^{2{\rm i}\Omega(S\mp U_{\rm m}^{-1})}+{\rm c.c.}\Bigg)\\
&\mp\frac{\Omega}{U_{\rm m}}(1\pm\beta^{\frac{1}{2}})\Bigg(\Bigg(1\pm\beta^{\frac{1}{2}}+\frac{1}{2}\frac{U_{\rm m}}{\Omega}\Big(\sin\left(2\frac{\Omega}{U_{\rm m}}\right)\\
&\pm{\rm i}\left(1-\cos\left(2\frac{\Omega}{U_{\rm m}}\right)\right)\Big)\Bigg){\rm i}\mathcal{T}^{(0)}(\Omega)^2{\rm e}^{2{\rm i}\Omega S}+{\rm c.c.}\Bigg)\Bigg].
\end{aligned} \tag{A.8}$$

Appendix B. Numerical techniques.

B.1. Lax–Wendroff finite-difference method. The fields Q and I are updated on a grid with spacing ΔX. In the first-order Lax–Wendroff method, the values at $T + \Delta T$ are obtained from those at T using [18]:

$$\begin{aligned} Q(X, T+\Delta T) = &\frac{1}{2}\left(Q(X+\Delta X, T) + Q(X, T)\right) \\ &-\frac{1}{2}U\frac{\Delta T}{\Delta X}\left(I(X+\Delta X, T) - I(X-\Delta X, T)\right), \end{aligned} \tag{B.1}$$

$$\begin{aligned} I(X, T+\Delta T) = &\frac{1}{2}\left(I(X+\Delta X, T) + I(X, T)\right) \\ &-\frac{1}{2}U\frac{\Delta T}{\Delta X}\left(\mathcal{V}(Q(X+\Delta X, T)) - \mathcal{V}(Q(X-\Delta X, T))\right). \end{aligned} \tag{B.2}$$

We use the following second-order adaptation [18]:

$$\begin{aligned} Q(X, T+\Delta T) = &Q(X, T) - \frac{1}{2}U\frac{\Delta T}{\Delta X}\left(I(X+\Delta X, T) - I(X-\Delta X, T)\right) \\ &+\frac{1}{2}\left(U\frac{\Delta T}{\Delta X}\right)^2\left(\mathcal{V}(Q(X+\Delta X, T)) + \mathcal{V}(Q(X-\Delta X, T))\right), \end{aligned} \tag{B.3}$$

$$\begin{aligned} I(X, T+\Delta T) = I(X, T) - U\frac{\Delta T}{\Delta X}\Bigg[&\mathcal{V}\Bigg(\frac{1}{2}(Q(X+\Delta X, T) + Q(X, T)) \\ &-\frac{1}{2}U\frac{\Delta T}{\Delta X}(I(X+\Delta X, T) - I(X, T))\Bigg) \\ -&\mathcal{V}\Bigg(\frac{1}{2}(Q(X, T) + Q(X-\Delta X, T)) \\ &-\frac{1}{2}U\frac{\Delta T}{\Delta X}(I(X, T) - I(X-\Delta X, T))\Bigg)\Bigg]. \end{aligned} \tag{B.4}$$

B.2. Discretized boundary conditions. At the interface between different media it is important to implement numerical boundary conditions that are of the same order of the scheme and do not produce artificial reflections [26]. Consider the boundary between regions I and II. Let $Q_1(n\Delta X, T)$ and $I_1(n\Delta X, T)$ be the values of the last point in region I; let $Q_2(0, T)$ and $I_2(0, T)$ be the values of the first point in region II. We cannot immediately implement the Lax–Wendroff scheme because the neighboring points to the boundary points are in different regions, where the equation of motion takes different forms: $\mathcal{V}(Q) = V_{\rm l}(Q)$ and $\mathcal{V}(Q) = V_{\rm n}(Q)$.

Because $Q_1(n\Delta x, T)$ and $Q_2(0, T)$ correspond to the same position,

$$I_1(n\Delta x, T) = I_2(0, T) \qquad \text{and} \quad V_{\rm l}(Q_1(n\Delta x, T)) = V_{\rm n}(Q_2(0, T)), \tag{B.5}$$

with $V_{\rm l}$ and $V_{\rm n}$ as defined in (2.11). As (B.5) is true for any T, we also have the equalities

$$\frac{\partial}{\partial T} I_1(n\Delta x, T) = \frac{\partial}{\partial T} I_2(0, T) \tag{B.6}$$

and

$$\frac{\partial}{\partial T}V_{\rm l}(Q_1(n\Delta x,T)) = \frac{\partial}{\partial T}V_{\rm n}(Q_2(0,T)). \tag{B.7}$$

Therefore, from the equation of motion (2.12),

$$\frac{\partial}{\partial X}V_{\rm l}(Q_1(n\Delta x,T)) = \frac{\partial}{\partial X}V_{\rm n}(Q_2(0,T)) \tag{B.8}$$

and

$$V_{\rm l}'(Q_1(n\Delta x,T))\frac{\partial}{\partial X}I_1(n\Delta x,T) = V_{\rm n}'(Q_2(0,T))\frac{\partial}{\partial X}I_2(0,T), \tag{B.9}$$

where

$$V_{\rm l}'(Q) = \frac{\partial}{\partial Q}V_{\rm l}(Q), \qquad V_{\rm n}'(Q) = \frac{\partial}{\partial Q}V_{\rm n}(Q). \tag{B.10}$$

The discrete approximation to the partial derivatives on the right-hand side of (B.9) is

$$\frac{\partial}{\partial X}I_1(n\Delta x,T) = (2\Delta x)^{-1}\left(3I_1(n\Delta x) - 4I_1((n-1)\Delta x) + I_1((n-2)\Delta x)\right), \tag{B.11}$$

$$\frac{\partial}{\partial X}I_2(0,T) = (2\Delta x)^{-1}\left(-3I_2(0) + 4I_2(\Delta x) - I_2(2\Delta x)\right); \tag{B.12}$$

the derivatives in (B.8) are evaluated similarly. The discretized version of (B.8)–(B.9) is therefore

$$\begin{aligned} V_{\rm l}(Q_1(n\Delta x,T)) &= V_{\rm n}(Q_2(0,T)) \\ &= \frac{1}{6}\Big(4V_{\rm l}(Q_1((n-1)\Delta x,T)) - V_{\rm l}(Q_1((n-2)\Delta x,T)) \\ &\quad + 4V_{\rm n}(Q_2(\Delta x,T)) - V_{\rm n}(Q_2(2\Delta x,T))\Big), \end{aligned}$$

$$\begin{aligned} I_1(n\Delta x,T) &= I_2(0,T) \\ &= \frac{1}{3}\left(1 + \frac{V_{\rm n}'(Q_2(0,T))}{V_{\rm l}'(Q_1(n\Delta x,T))}\right)^{-1}\left(4I_1((n-1)\Delta x) - I_1((n-2)\Delta x)\right. \\ &\quad \left. + \frac{V_{\rm n}'(Q_2(0,T))}{V_{\rm l}'(Q_1(n\Delta x,T))}(4I_2(\Delta x) - I_2(2\Delta x))\right). \end{aligned}$$

B.3. Input signal. At the left-hand extremity of region I, $X = -L$, the solution of the field equation (2.12) can be written as a superposition of two fields: a prescribed incident wave $Q_{\rm in}(X - cT)$, $I_{\rm in}(X - cT)$, and an (unknown) outgoing wave $Q_{\rm out}(X + cT)$, $I_{\rm out}(X + cT)$ ($c > 0$). Thus, the incoming field satisfies the unidirectional wave equation

$$\frac{\partial}{\partial T}\begin{pmatrix} Q_{\rm in} \\ I_{\rm in} \end{pmatrix} = -c\frac{\partial}{\partial X}\begin{pmatrix} Q_{\rm in} \\ I_{\rm in} \end{pmatrix}, \tag{B.13}$$

while the outgoing field satisfies

$$\frac{\partial}{\partial T}\begin{pmatrix} Q_{\text{out}} \\ I_{\text{out}} \end{pmatrix} = +c\frac{\partial}{\partial X}\begin{pmatrix} Q_{\text{out}} \\ I_{\text{out}} \end{pmatrix}. \tag{B.14}$$

Hence, for the total field $Q(X,T)$, $I(X,T)$,

$$\begin{aligned}\frac{\partial}{\partial T}\begin{pmatrix} Q \\ I \end{pmatrix} &= \frac{\partial}{\partial T}\begin{pmatrix} Q_{\text{in}} \\ I_{\text{in}} \end{pmatrix} + \frac{\partial}{\partial T}\begin{pmatrix} Q_{\text{out}} \\ I_{\text{out}} \end{pmatrix} \\ &= \frac{\partial}{\partial T}\begin{pmatrix} Q_{\text{in}} \\ I_{\text{in}} \end{pmatrix} + c\frac{\partial}{\partial X}\begin{pmatrix} Q_{\text{out}} \\ I_{\text{out}} \end{pmatrix} \\ &= \frac{\partial}{\partial T}\begin{pmatrix} Q_{\text{in}} \\ I_{\text{in}} \end{pmatrix} + c\frac{\partial}{\partial X}\begin{pmatrix} Q - Q_{\text{in}} \\ I - I_{\text{in}} \end{pmatrix}. \end{aligned} \tag{B.15}$$

Using (B.13), the governing equation of the total field in the left linear region can then be rewritten as

$$\frac{\partial}{\partial T}\begin{pmatrix} Q \\ I \end{pmatrix} = 2\frac{\partial}{\partial T}\begin{pmatrix} Q_{\text{in}} \\ I_{\text{in}} \end{pmatrix} + c\frac{\partial}{\partial X}\begin{pmatrix} Q \\ I \end{pmatrix}; \tag{B.16}$$

this is used with one-sided spatial derivatives to construct the field at $X = -L$ from the knowledge of the field at the previous time step.

For example, consider a sinusoidal input signal, as in (3.1). Then, using (3.2),

$$V_{\text{in}}(X,T) = A\cos(\Omega(T - X/U_{\text{I}})). \tag{B.17}$$

The incident Q and I fields are given by

$$Q_{\text{in}}(X,T) = \frac{C_{\text{I}}}{C_{\text{II}}}A\cos\left(\Omega\left(T - \frac{X}{U_{\text{I}}}\right)\right), \tag{B.18}$$

$$I_{\text{in}}(X,T) = \left(\frac{L_{\text{II}}C_{\text{I}}}{L_{\text{I}}C_{\text{II}}}\right)^{\frac{1}{2}} A\cos\left(\Omega\left(T - \frac{X}{U_{\text{I}}}\right)\right). \tag{B.19}$$

Thus the (lowest-order) increments at the left extremity of region I are

$$\begin{aligned} Q_1(-L, T+\Delta T) = Q_1(-L,T) + \Delta T\Big(&2\frac{\mathrm{d}}{\mathrm{d}t}Q_{\text{in}}(-L,T) \\ &- U_{\text{I}}(2\Delta x)^{-1}\big(3Q_1(0) - 4Q_1(-L+\Delta x) + Q_1(-L+2\Delta x)\big)\Big), \\ I_1(-L, T+\Delta T) = I_1(-L,T) + \Delta T\Big(&2\frac{\mathrm{d}}{\mathrm{d}t}I_{\text{in}}(-L,T) \\ &- U_{\text{I}}(2\Delta x)^{-1}\big(3I_1(0) - 4I_1(-L+\Delta x) + I_1(-L+2\Delta x)\big)\Big). \end{aligned}$$

(SEMI)CLASSICAL LIMIT OF THE HARTREE EQUATION WITH HARMONIC POTENTIAL*

RÉMI CARLES†, NORBERT J. MAUSER‡, AND HANS PETER STIMMING§

Abstract. Nonlinear Schrödinger equations (NLS) of the Hartree type occur in the modeling of quantum semiconductor devices. Their "semiclassical" limit of vanishing (scaled) Planck constant is both a mathematical challenge and practically relevant when coupling quantum models to classical models. With the aim of describing the semiclassical limit of the three-dimensional (3D) Schrödinger–Poisson system with an additional harmonic potential, we study some semiclassical limits of the Hartree equation with harmonic potential in space dimension $n \geq 2$. The harmonic potential is confining and causes focusing periodically in time. We prove asymptotics in several cases, showing different possible nonlinear phenomena according to the interplay of the size of the initial data and the power of the Hartree potential. In the case of the 3D Schrödinger–Poisson system with harmonic potential, we can give only a formal computation since the need for modified scattering operators for this long-range scattering case goes beyond current theory.

We also deal with the case of an additional "local" nonlinearity given by a power of the local density—a model that is relevant when incorporating the Pauli principle in the simplest model given by the "Schrödinger–Poisson-Xα equation." Further we discuss the connection of our WKB-based analysis to the Wigner function approach to semiclassical limits.

Key words. Schrödinger–Poisson, Hartree equation, semiclassical limit, harmonic potential

DOI. 10.1137/040609732

1. Introduction.

Nonlinear Schrödinger equations (NLS) are important both for many different applications and as a source of rich mathematical theory, with several hard challenges still open. The NLS in the most common meaning contains a "local" nonlinearity given by a power of the local density, in particular the (de)focusing "cubic" NLS which arises, e.g., in nonlinear optics or for Bose–Einstein condensates. In one dimension this NLS is an integrable system, and the "semiclassical limit" ("high wave number limit") can be performed by methods of inverse scattering (see, e.g., [20] and [22] for results on the defocusing and focusing cases). A class of NLS with a "nonlocal" nonlinearity that we call "Hartree type" occurs in the modeling of quantum semiconductor devices. Their "semiclassical" limit of vanishing (scaled) Planck constant is both a mathematical challenge and practically relevant when coupling quantum models to classical models.

Incorporating the Pauli principle for fermions in the simplest possible model yields the case of a Hartree equation with an additional "local" nonlinearity given by a power of the local density, the "Schrödinger–Poisson-Xα equation" (see [25]).

In this paper we deal with the "semiclassical limit" of nonlinear Schrödinger equations of Hartree type, with a harmonic potential and a "weak" nonlinearity which is a convolution of the density with a more or less singular potential.

In three space dimensions, for the case where we convolute with the Newtonian potential $1/|x|$, the Hartree equation is the Schrödinger–Poisson system with harmonic potential:

$$\left\{\begin{array}{r} i\varepsilon\partial_t \mathrm{u}^\varepsilon + \frac{1}{2}\varepsilon^2\Delta \mathrm{u}^\varepsilon = \frac{|x|^2}{2}\mathrm{u}^\varepsilon + V(x)\mathrm{u}^\varepsilon\,, \\ \Delta V = |\mathrm{u}^\varepsilon|^2\,, \\ \mathrm{u}^\varepsilon_{|t=0} = \mathrm{u}^\varepsilon_0\,, \end{array}\right. \tag{1.1}$$

with $x \in \mathbb{R}^3$.

This equation typically arises if we consider the quantum mechanical time evolution of electrons in the mean field approximation of the many body effects, modeled by the Poisson equation, with a confinement modeled by the quadratic potential of the harmonic oscillator.

The limit $\varepsilon \to 0$ in such a quantum model corresponds to a "classical limit" of vanishing Planck constant $\hbar = \varepsilon \to 0$. We adopt the term "semiclassical limit" for what should properly be called "classical limit" (see the discussion in [31]), the term "semiclassical" being actually more appropriate for the situation of the homogenization limit from a Schrödinger equation with periodic potential (see, e.g., [2]).

The problem of the mathematically rigorous "classical limit" of the Schrödinger–Poisson system is highly nontrivial. First results of weak limits $\varepsilon \to 0$ to the Vlasov–Poisson system were given in [23] and [24] using Wigner transform techniques for the "mixed state case," where additional strong assumptions on the initial data can be imposed (which are necessary to guarantee a uniform L^2 bound on the Wigner function). In [31] this assumption was removed for the 1D case, and the classical limit for the "pure state" case was performed, where the notorious problem of nonuniqueness of the Vlasov–Poisson system with measure valued initial data reappeared. For an overview of this kind of "semiclassical limits" of Hartree equations see [26]. For an introduction to Wigner transforms and their comparison to WKB methods for the linear case see [11] and [29].

Up to a constant, (1.1) is equivalent to the Hartree equation

$$i\varepsilon\partial_t \mathrm{u}^\varepsilon + \frac{1}{2}\varepsilon^2\Delta \mathrm{u}^\varepsilon = \frac{|x|^2}{2}\mathrm{u}^\varepsilon + \left(|x|^{-1} * |\mathrm{u}^\varepsilon|^2\right)\mathrm{u}^\varepsilon, \quad \mathrm{u}^\varepsilon_{|t=0} = \mathrm{u}^\varepsilon_0\,. \tag{1.2}$$

We restrict our attention to small data cases with $\mathrm{u}^\varepsilon_0 = \varepsilon^{\alpha/2} f$, where f is independent of ε and $\alpha \geq 1$.

Notice that we can allow for more general data with initial plane oscillations,

$$\mathbf{u}^\varepsilon_{|t=0} = \varepsilon^{\alpha/2} f(x) e^{i\frac{x\cdot\xi_0}{\varepsilon}} \quad \text{for} \quad \xi_0 \in \mathbb{R}^3, \tag{1.3}$$

since the change of variables given in [6],

$$\mathbf{u}^\varepsilon(t,x) = \mathrm{u}^\varepsilon(t, x - \xi_0 \sin t) e^{i\left(x - \frac{\xi_0}{2}\sin t\right).\xi_0 \cos t/\varepsilon}\,, \tag{1.4}$$

yields the solution of (1.2). This change of variable could also be used in (1.6) below, and hence our results also hold for the more general ε-dependent class of data (1.3).

Note that "small data" can be equivalently written as "small nonlinearity," since with the change of the unknown $u^\varepsilon = \varepsilon^{-\alpha/2}\mathtt{u}^\varepsilon$, (1.2) becomes

$$i\varepsilon\partial_t u^\varepsilon + \frac{1}{2}\varepsilon^2\Delta u^\varepsilon = \frac{|x|^2}{2}u^\varepsilon + \varepsilon^\alpha\left(|x|^{-1} * |u^\varepsilon|^2\right)u^\varepsilon, \quad u^\varepsilon_{|t=0} = f\,. \tag{1.5}$$

We will consider the more general "semiclassical Hartree equation"

$$i\varepsilon\partial_t u^\varepsilon + \frac{1}{2}\varepsilon^2\Delta u^\varepsilon = \frac{|x|^2}{2}u^\varepsilon + \varepsilon^\alpha\left(|x|^{-\gamma} * |u^\varepsilon|^2\right)u^\varepsilon, \quad u^\varepsilon_{|t=0} = f\,, \tag{1.6}$$

with $\gamma > 0$, $\alpha \geq 1$, and $x \in \mathbb{R}^n$, where the space dimension $n \geq 2$ may be different from 3.

The first point to notice is that in the linear case, the harmonic potential causes focusing at the origin (resp., at $(-1)^k\xi_0$ in the case (1.4)) at times $t = \pi/2 + k\pi$ for any $k \in \mathbb{N}$. The solution $u^\varepsilon_{\rm free}$ of the linear equation

$$i\varepsilon\partial_t u^\varepsilon_{\rm free} + \frac{1}{2}\varepsilon^2\Delta u^\varepsilon_{\rm free} = \frac{|x|^2}{2}u^\varepsilon_{\rm free}, \quad u^\varepsilon_{\rm free|t=0} = f\,, \tag{1.7}$$

is initially of size $\mathcal{O}(1)$. At time $t = \pi/2$, the solution focuses at the origin and is of order $\mathcal{O}(\varepsilon^{-n/2})$; it is of order $\mathcal{O}(1)$ for $t = \pi$, and so on (for a more precise analysis, see [6]). This phenomenon is easy to read from Mehler's formula (see, e.g., [10, 18]): for $0 < t < \pi$, we have

$$u^\varepsilon_{\rm free}(t,x) = \frac{e^{-in\frac{\pi}{4}}}{(2\pi\varepsilon\sin t)^{n/2}}\int_{\mathbb{R}^n} e^{\frac{i}{\varepsilon\sin t}\left(\frac{x^2+y^2}{2}\cos t - x\cdot y\right)} f(y)dy\,. \tag{1.8}$$

Essentially, one can apply a stationary phase formula for $t \in]0,\pi/2[\,\cup\,]\pi/2,\pi[$ ($u^\varepsilon_{\rm free}$ is $\mathcal{O}(1)$), while it is not possible at $t = \pi/2$ ($u^\varepsilon_{\rm free}$ is $\mathcal{O}(\varepsilon^{-n/2})$). Following the same approach as in [3], we get the following distinctions.

	$\alpha > \gamma$	$\alpha = \gamma$
$\alpha > 1$	linear WKB, linear focus	linear WKB, nonlinear focus
$\alpha = 1$	nonlinear WKB, linear focus	nonlinear WKB, nonlinear focus

The expression "linear WKB" means that the nonlinear Hartree interaction term is negligible away from the focus (when the WKB approximation is valid); "linear focus" means that the nonlinearity is negligible near the focus; the WKB regime (resp., the focus) is "nonlinear" when the Hartree term has a leading order influence away from (resp., in the neighborhood of) the focus, in the limit $\varepsilon \to 0$. This terminology follows [19].

We did not obtain a rigorous description of the case $\alpha = \gamma = 1$, which corresponds to the Schrödinger–Poisson system (1.1) when $n = 3$. This problem seems out of reach for the methods currently available in this field. On the other hand, we study rigorously the other three cases in an exhaustive way.

In section 3, we prove that the Hartree term has no influence at leading order when $\alpha > \gamma = 1$. Back to (1.2), this shows that initial data of size $\varepsilon^{\alpha/2}$ with $\alpha > 1$ yield a linearizable solution. The expected critical size is $\sqrt{\varepsilon}$; this heuristic is reinforced by the next three sections.

In section 4, we study the case $\alpha = 1 > \gamma$. We prove that the nonlinear term must be taken into account to describe the solution u^ε. It is so through a slowly oscillating phase term. On the other hand, no nonlinear effect occurs at leading order near the focus.

In section 5, we show that when $\alpha = \gamma > 1$, nonlinear effects occur at leading order at the foci, while they are negligible elsewhere. This phenomenon is the same as in [6] for the nonlinear Schrödinger equation; each focus crossing is described in terms of the scattering operator associated to the Hartree equation

$$i\partial_t \psi + \frac{1}{2}\Delta\psi = \left(|x|^{-\gamma} * |\psi|^2\right)\psi\,. \tag{1.9}$$

In section 6, we perform a formal computation suggested by the results of sections 4 and 5. This can be seen as further evidence that nonlinear effects are always relevant in the case $\alpha = \gamma = 1$, along with a precise idea of the nature of these nonlinear effects, which we expect to be true. We add a brief discussion of the case of an additional local nonlinearity in the equation and some remarks on the Wigner measures in view of the ill-posedness results of [5].

This program is very similar to the one achieved in [3]. We want to underscore at least two important differences. First, we have to adapt the notion of oscillatory integral to incorporate the presence of the harmonic potential (see section 4.1). Second, the power-like nonlinearity treated in [3] is replaced by a Hartree-type nonlinearity. This yields different and less technical proofs (we do not use Strichartz estimates in sections 3 and 4) and makes a more complete description of the above table possible; the case "nonlinear WKB, linear focus" was treated very partially in [3] due to the lack of regularity of the map $z \mapsto |z|^{2\sigma}z$ for small $\sigma > 0$. This technical difficulty does not occur in the present case, and the main result of section 4 (Proposition 4.1) is proved with no restriction.

The content of this article is as explained above, plus a paragraph dedicated to a quick review of the facts we will need about the Cauchy problem (1.6) (see section 2).

We will use the following notation throughout this paper.

Notation. If $(a^\varepsilon)_{\varepsilon\in]0,1]}$ and $(b^\varepsilon)_{\varepsilon\in]0,1]}$ are two families of numbers, we write

$$a^\varepsilon \lesssim b^\varepsilon$$

if there exists C independent of $\varepsilon \in]0,1]$ such that for any $\varepsilon \in]0,1]$, $a^\varepsilon \leq Cb^\varepsilon$.

2. The Cauchy problem. Before studying semiclassical limits, we recall some known facts about the initial value problem (1.6). We will always assume that the initial datum f is in the space Σ defined by

$$\Sigma := \left\{\phi \in H^1(\mathbb{R}^n)\ ;\ \|\phi\|_\Sigma := \|\phi\|_{L^2} + \|x\phi\|_{L^2} + \|\nabla\phi\|_{L^2} < +\infty\right\}.$$

This space is natural in the case of Schrödinger equations with harmonic potential, since Σ is the domain of $\sqrt{-\Delta + |x|^2}$ (see, for instance, [27]). Local existence results for (1.6) follow, for instance, from Strichartz inequalities (one can do without these inequalities; see [27]). Global existence results then stem from conservation laws (see (2.3) below). From Mehler's formula (1.8), Strichartz type estimates are available for

$$e^{-i\frac{t}{2\varepsilon}(-\varepsilon^2\Delta + x^2)} =: \mathcal{U}^\varepsilon(t)\,.$$

DEFINITION 2.1. *Let $n \geq 2$. A pair (q,r) is* admissible *if $2 \leq r < \frac{2n}{n-2}$ (resp., $2 \leq r < \infty$ if $n = 2$) and*

$$\frac{2}{q} = \delta(r) \equiv n\left(\frac{1}{2} - \frac{1}{r}\right).$$

Following [6], we have the following scaled Strichartz inequalities.

PROPOSITION 2.2. *Let I be a* finite *time interval.*

(1) *For any admissible pair (q,r), there exists $C_r(I)$ such that*

$$\varepsilon^{\frac{1}{q}} \left\|\mathcal{U}^\varepsilon(t)\phi\right\|_{L^q(I;L^r)} \leq C_r(I)\|\phi\|_{L^2}\,. \tag{2.1}$$

(2) *For any admissible pairs (q_1,r_1) and (q_2,r_2), there exists $C_{r_1,r_2}(I)$ such that*

$$\varepsilon^{\frac{1}{q_1}+\frac{1}{q_2}} \left\|\int_{I\cap\{s\leq t\}} \mathcal{U}^\varepsilon(t-s)F(s)ds\right\|_{L^{q_1}(I;L^{r_1})} \leq C_{r_1,r_2}(I)\left\|F\right\|_{L^{q_2'}(I;L^{r_2'})}\,. \tag{2.2}$$

The above constants are independent of ε.

The main result of this section follows from [7, 12]. Denote

$$Y(I) = \{\phi \in C(I,\Sigma)\ ;\ \phi,\, |x|\phi,\, \nabla_x\phi \in L^q_{\rm loc}(I,L^r_x)\ \forall (q,r) \text{ admissible}\}\,.$$

PROPOSITION 2.3. *Fix $\varepsilon \in]0,1]$ and let $f \in \Sigma$. Then (1.6) has a unique solution $u^\varepsilon \in Y(\mathbb{R})$. Moreover, the following quantities are independent of time:*

$$\begin{aligned} &\textit{Mass: } \|u^\varepsilon(t)\|_{L^2}\,,\\ &\textit{Energy: } \frac{1}{2}\|\varepsilon\nabla_x u^\varepsilon(t)\|_{L^2}^2 + \frac{1}{2}\|xu^\varepsilon(t)\|_{L^2}^2 + \varepsilon\int_{\mathbb{R}^n}\left(|x|^{-\gamma} * |u^\varepsilon|^2\right)|u^\varepsilon(t,x)|^2dx. \end{aligned} \tag{2.3}$$

It was noticed in [6] that this result can be retrieved very simply thanks to the following lemma, which we will use to prove asymptotics.

LEMMA 2.4 (see [6]). *Define the operators*

$$J^\varepsilon(t) = \frac{x}{\varepsilon}\sin t - i\cos t\nabla_x, \qquad H^\varepsilon(t) = x\cos t + i\varepsilon\sin t\nabla_x\,. \tag{2.4}$$

J^ε and H^ε satisfy the following properties.

- *They are Heisenberg observables:*

$$J^\varepsilon(t) = -i\,\mathcal{U}^\varepsilon(t)\nabla_x\mathcal{U}^\varepsilon(-t), \qquad H^\varepsilon(t) = \mathcal{U}^\varepsilon(t)x\,\mathcal{U}^\varepsilon(-t)\,. \tag{2.5}$$

- *The commutation relation:*

$$\left[J^\varepsilon(t), i\varepsilon\partial_t + \frac{\varepsilon^2}{2}\Delta - \frac{|x|^2}{2}\right] = \left[H^\varepsilon(t), i\varepsilon\partial_t + \frac{\varepsilon^2}{2}\Delta - \frac{|x|^2}{2}\right] = 0\,. \tag{2.6}$$

- *Denote $M^\varepsilon(t) = e^{-i\frac{x^2}{2\varepsilon}\tan t}$ and $Q^\varepsilon(t) = e^{i\frac{x^2}{2\varepsilon}\cot t}$; then*

$$J^\varepsilon(t) = -i\cos t\, M^\varepsilon(t)\nabla_x M^\varepsilon(-t), \qquad H^\varepsilon(t) = i\varepsilon\sin t\, Q^\varepsilon(t)\nabla_x Q^\varepsilon(-t)\,. \tag{2.7}$$

- *The modified Sobolev inequalities. Let $2 \leq r \leq \frac{2n}{n-2}$ ($2 \leq r < \infty$ if $n = 2$); there exists C_r independent of ε such that, for any $\phi \in \Sigma$,*

$$\begin{aligned} \|\phi\|_{L^r} &\leq C_r|\cos t|^{-\delta(r)}\|\phi\|_{L^2}^{1-\delta(r)}\|J^\varepsilon(t)\phi)\|_{L^2}^{\delta(r)}\,,\\ \|\phi\|_{L^r} &\leq C_r|\varepsilon\sin t|^{-\delta(r)}\|\phi\|_{L^2}^{1-\delta(r)}\|H^\varepsilon(t)\phi\|_{L^2}^{\delta(r)}\,. \end{aligned} \tag{2.8}$$

- *Action on nonlinear Hartree term: for $\phi = \phi(t,x)$,*

$$J^\varepsilon(t)\left(\left(|x|^{-\gamma} * |\phi|^2\right)\phi\right) = \left(|x|^{-\gamma} * |\phi|^2\right) J^\varepsilon(t)\phi + 2\,\mathrm{Re}\left(|x|^{-\gamma} * \left(\overline{\phi} J^\varepsilon(t)\phi\right)\right)\phi\,. \tag{2.9}$$

The same holds for $H^\varepsilon(t)$.

Remark 2.5. Property (2.6) follows from (2.5), which is the way J^ε and H^ε appear in the linear theory (see, e.g., [30, p. 108]). Property (2.8) is a consequence of Gagliardo–Nirenberg inequalities and (2.7). Finally, (2.9) stems from (2.7).

3. "Very weak nonlinearity" case. In this section, we study the semiclassical limit of u^ε when $\gamma = 1$ *and* $\alpha > 1$, which is equivalent to "very small" data in our context (cf. (1.2)). This case includes the 3D Schrödinger–Poisson equation with "very small data." We prove that the Hartree term plays no role at leading order.

PROPOSITION 3.1. *Let $f \in \Sigma$, $n \geq 2$, and assume $\alpha > \gamma = 1$. Then for any $T > 0$,*

$$\|u^\varepsilon - u^\varepsilon_{\mathrm{free}}\|_{L^\infty([0,T];L^2)} = \mathcal{O}\left(\varepsilon^{\alpha-1}\ln\frac{1}{\varepsilon}\right) \quad \text{as } \varepsilon \to 0\,,$$

and for any $\delta > 0$ ($\alpha - 1 - \delta > 0$),

$$\|A^\varepsilon(t)\,(u^\varepsilon - u^\varepsilon_{\mathrm{free}})\|_{L^\infty([0,T];L^2)} = \mathcal{O}\left(\varepsilon^{\alpha-1-\delta}\right) \quad \text{as } \varepsilon \to 0\,,$$

where A^ε is either of the operators J^ε or H^ε, and $u^\varepsilon_{\mathrm{free}}$ is the solution of (1.7).

Remark 3.2. Using modified Sobolev inequalities (2.8), we can deduce L^p estimates for $u^\varepsilon - u^\varepsilon_{\mathrm{free}}$ for $2 \leq p \leq 2n/(n-2)$ ($2 \leq p < \infty$ if $n = 2$) from the above result.

Remark 3.3. We could probably get the logarithmic estimate for the second part of the statement as well, using Strichartz estimates. The proof given below is not technically involved and suffices for our purpose; we do not seek sharp results.

Proof. Denote $w^\varepsilon = u^\varepsilon - u^\varepsilon_{\mathrm{free}}$. It solves the initial value problem

$$i\varepsilon\partial_t w^\varepsilon + \frac{1}{2}\varepsilon^2\Delta w^\varepsilon = \frac{|x|^2}{2}w^\varepsilon + \varepsilon^\alpha\left(|x|^{-1} * |u^\varepsilon|^2\right)u^\varepsilon, \qquad w^\varepsilon_{|t=0} = 0\,.$$

Standard energy estimates for Schrödinger equations yield

$$\varepsilon\partial_t\|w^\varepsilon(t)\|_{L^2} \lesssim \varepsilon^\alpha\left\|\left(|x|^{-1} * |u^\varepsilon|^2\right)u^\varepsilon\right\|_{L^2}\,. \tag{3.1}$$

From Hölder's inequality, we have

$$\left\|\left(|x|^{-1} * |u^\varepsilon|^2\right)u^\varepsilon\right\|_{L^2} \leq \left\||x|^{-1} * |u^\varepsilon|^2\right\|_{L^r}\|u^\varepsilon\|_{L^k} \quad \text{for } \frac{1}{r} + \frac{1}{k} = \frac{1}{2}\,. \tag{3.2}$$

From the Hardy–Littlewood–Sobolev inequality,

$$\left\||x|^{-1} * |u^\varepsilon(t)|^2\right\|_{L^r} \lesssim \|u^\varepsilon(t)\|^2_{L^p} \quad \text{for } 1 < r, \frac{p}{2} < \infty \text{ and } 1 + \frac{1}{r} = \frac{2}{p} + \frac{1}{n}\,. \tag{3.3}$$

Therefore, (3.1) yields

$$\varepsilon\partial_t\|w^\varepsilon(t)\|_{L^2} \lesssim \varepsilon^\alpha\|u^\varepsilon(t)\|^2_{L^p}\|u^\varepsilon(t)\|_{L^k}\,, \tag{3.4}$$

where p and k satisfy the properties stated in (3.2) and (3.3). For $k = 2$, $r = \infty$, and $p = 2n/(n-1)$, the algebraic identities stated in (3.2) and (3.3) are satisfied. Now

since the conditions $1 < r < \infty$ and $1 < p/2 < \infty$ are open, a continuity argument shows that we can find p and k satisfying all the properties stated in (3.2) and (3.3). Notice that they imply the relation $2\delta(p) + \delta(k) = 1$ and hence $\delta(p)$, $\delta(k) < 1$; this allows us to use weighted Gagliardo–Nirenberg inequalities.

We have $w^\varepsilon_{|t=0} = 0$, and from Proposition 2.3, $w^\varepsilon \in C(\mathbb{R}_+; \Sigma)$. Therefore, there exists $t^\varepsilon > 0$ such that

$$\|J^\varepsilon(t) w^\varepsilon\|_{L^2} \leq 1 \tag{3.5}$$

for $0 \leq t \leq t^\varepsilon$. The argument of the proof then follows [28] (see also [6]). Recall that from (2.5), $\|J^\varepsilon(t) u^\varepsilon_{\rm free}\|_{L^2} = \|\nabla f\|_{L^2}$.

Because of (2.6), $J^\varepsilon u^\varepsilon_{\rm free}$ solves the linear Schrödinger equation with harmonic potential, and $\|J^\varepsilon(t) u^\varepsilon_{\rm free}\|_{L^2} \equiv \|\nabla f\|_{L^2}$. So long as (3.5) holds, we have, from (2.8),

$$\|u^\varepsilon(t)\|_{L^p} \leq \frac{C_0}{|\cos t|^{\delta(p)}}, \qquad \|u^\varepsilon(t)\|_{L^k} \leq \frac{C_0}{|\cos t|^{\delta(k)}}$$

for some C_0 independent of ε and t. Then (3.4) yields

$$\varepsilon \partial_t \|w^\varepsilon(t)\|_{L^2} \lesssim \frac{\varepsilon^\alpha}{|\cos t|^{2\delta(p)+\delta(k)}} = \frac{\varepsilon^\alpha}{|\cos t|}\,.$$

Integration in time on $[0,t]$ yields, so long as (3.5) holds,

$$\|w^\varepsilon\|_{L^\infty([0,t];L^2)} \lesssim \varepsilon^{\alpha-1} \int_0^t \frac{d\tau}{|\cos\tau|}\,.$$

For $t < \pi/2$, we get, so long as (3.5) holds,

$$\|w^\varepsilon\|_{L^\infty([0,t];L^2)} \lesssim \varepsilon^{\alpha-1} \left|\ln\left(\frac{\pi}{2} - t\right)\right|\,.$$

From (2.6), $J^\varepsilon(t) w^\varepsilon$ solves

$$i\varepsilon\partial_t J^\varepsilon w^\varepsilon + \frac{1}{2}\varepsilon^2 \Delta J^\varepsilon w^\varepsilon = \frac{|x|^2}{2} J^\varepsilon w^\varepsilon + \varepsilon^\alpha J^\varepsilon \left(\left(|x|^{-1} * |u^\varepsilon|^2\right) u^\varepsilon\right), \qquad J^\varepsilon w^\varepsilon_{|t=0} = 0\,.$$

By use of (2.9), the energy estimate for $J^\varepsilon w^\varepsilon$ yields

$$\begin{aligned}\varepsilon\partial_t \|J^\varepsilon(t) w^\varepsilon\|_{L^2} &\lesssim \varepsilon^\alpha \left(\left\|\left(|x|^{-1} * |u^\varepsilon|^2\right) J^\varepsilon(t) u^\varepsilon\right\|_{L^2} + \left\||x|^{-1} * (\overline{u^\varepsilon} J^\varepsilon u^\varepsilon)\cdot u^\varepsilon\right\|_{L^2}\right)\\ &\lesssim \varepsilon^\alpha \left(\left\||x|^{-1} * |u^\varepsilon|^2\right\|_{L^\infty} \|J^\varepsilon(t) u^\varepsilon\|_{L^2} + \left\||x|^{-1} * (\overline{u^\varepsilon} J^\varepsilon u^\varepsilon)\cdot u^\varepsilon\right\|_{L^2}\right).\end{aligned}$$

For the first term of the right-hand side, use the easy estimate

$$\left\||x|^{-1} * f\right\| \lesssim \|f\|_{L^{(n^-)'}} + \|f\|_{L^{(n^+)'}},$$

where n^- (resp., n^+) stands for $n - \eta$ (resp., $n + \eta$) for any small $\eta > 0$. We have

$$\left\||x|^{-1} * |u^\varepsilon|^2\right\|_{L^\infty} \lesssim \|u^\varepsilon(t)\|^2_{L^{\kappa^-}} + \|u^\varepsilon(t)\|^2_{L^{\kappa^+}}\,, \quad \text{with} \quad \kappa = \frac{2n}{n-1}\,.$$

It is at this stage that we lose the logarithmic rate (we cannot use Hardy–Littlewood–Sobolev inequality when an exponent is infinite): using Strichartz estimates (see section 5), we believe that we could recover that rate, with a more technically involved proof.

For the second term, we proceed as in the beginning of the proof. From Hölder's inequality,

$$\left\| \left(|x|^{-1} * \overline{u^\varepsilon} J^\varepsilon u^\varepsilon \right) \cdot u^\varepsilon \right\|_{L^2} \leq \left\| |x|^{-1} * (\overline{u^\varepsilon} J^\varepsilon u^\varepsilon) \right\|_{L^r} \|u^\varepsilon\|_{L^\sigma} , \text{ with } \frac{1}{r} + \frac{1}{\sigma} = \frac{1}{2} \cdot \tag{3.6}$$

From the Hardy–Littlewood–Sobolev inequality, this is estimated, up to a constant, by

$$\|\overline{u^\varepsilon} J^\varepsilon u^\varepsilon\|_{L^p} \|u^\varepsilon\|_{L^\sigma} , \text{ with } 1 + \frac{1}{r} = \frac{1}{p} + \frac{1}{n} \text{ for } 1 < r, p < \infty . \tag{3.7}$$

Use of Hölder's inequality again yields an estimate by

$$\|u^\varepsilon\|_{L^k} \|J^\varepsilon u^\varepsilon\|_{L^2} \|u^\varepsilon\|_{L^\sigma} , \text{ with } \frac{1}{p} = \frac{1}{2} + \frac{1}{k} \cdot \tag{3.8}$$

Take $r = n$, $\sigma = 2n/(n-2)$, $k = 2$, and $p = 1$; the algebraic identities from (3.6), (3.7), and (3.8) are satisfied, but not the bound $p > 1$. Decreasing σ slightly increases p (take σ large but finite when $n = 2$), so we can find indices satisfying (3.6), (3.7), and (3.8) by a continuity argument. Note that they satisfy $\delta(k) + \delta(\sigma) = 1$, and each term is positive.

Gathering all these estimates together we get the energy estimate

$$\varepsilon \partial_t \|J^\varepsilon(t) w^\varepsilon\|_{L^2} \lesssim \varepsilon^\alpha \left(\|u^\varepsilon(t)\|^2_{L^{\kappa^-}} + \|u^\varepsilon(t)\|^2_{L^{\kappa^+}} + \|u^\varepsilon\|_{L^k} \|u^\varepsilon\|_{L^\sigma} \right) \|J^\varepsilon(t) u^\varepsilon\|_{L^2} .$$

So long as (3.5) holds, we deduce from (2.8) that

$$\begin{aligned} \varepsilon \partial_t \|J^\varepsilon(t) w^\varepsilon\|_{L^2} &\lesssim \varepsilon^\alpha \left(\frac{1}{|\cos t|^{2\delta(\kappa^-)}} + \frac{1}{|\cos t|^{2\delta(\kappa^+)}} + \frac{1}{|\cos t|^{\delta(k)+\delta(\sigma)}} \right) \\ &\lesssim \varepsilon^\alpha \left(\frac{1}{|\cos t|^{2\delta(\kappa^+)}} + \frac{1}{|\cos t|} \right) \lesssim \frac{\varepsilon^\alpha}{|\cos t|^{1^+}} . \end{aligned}$$

Integrate this, so long as (3.5) holds:

$$\|J^\varepsilon w^\varepsilon\|_{L^\infty([0,t];L^2)} \lesssim \varepsilon^{\alpha-1} \left(\frac{\pi}{2} - t \right)^{0^-} .$$

Fix $\delta, \Lambda > 0$. So long as (3.5) holds, we infer, for $t \leq \pi/2 - \Lambda\varepsilon$,

$$\|J^\varepsilon w^\varepsilon\|_{L^\infty([0,t];L^2)} \lesssim \varepsilon^{\alpha-1} (\Lambda\varepsilon)^{-\delta} .$$

Therefore, there exists $\varepsilon_\Lambda > 0$ such that, for $0 < \varepsilon \leq \varepsilon_\Lambda$, (3.5) holds up to time $\pi/2 - \Lambda\varepsilon$, with the estimates

$$\|w^\varepsilon\|_{L^\infty([0,\pi/2-\Lambda\varepsilon];L^2)} \lesssim \varepsilon^{\alpha-1} \ln \frac{1}{\varepsilon}, \qquad \|J^\varepsilon w^\varepsilon\|_{L^\infty([0,\pi/2-\Lambda\varepsilon];L^2)} \lesssim \varepsilon^{\alpha-1-\delta} . \tag{3.9}$$

An estimate similar to that of $J^\varepsilon w^\varepsilon$ then follows for $H^\varepsilon w^\varepsilon$, since from the conservation laws (2.3), $\|H^\varepsilon(t) u^\varepsilon\|_{L^2} \lesssim \|f\|_\Sigma$.

Denote $I^\varepsilon_\Lambda = [\pi/2 - \Lambda\varepsilon, \pi/2 + \Lambda\varepsilon]$. Mimicking the above computations, we have

$$\|w^\varepsilon\|_{L^\infty(I^\varepsilon_\Lambda;L^2)} \lesssim \left\| w^\varepsilon \left(\frac{\pi}{2} - \Lambda\varepsilon \right) \right\|_{L^2} + \varepsilon^{\alpha-1} \int_{I^\varepsilon_\Lambda} \|u^\varepsilon(\tau)\|^2_{L^p} \|u^\varepsilon(\tau)\|_{L^k} d\tau ,$$

where p and k satisfy (3.2) and (3.3). Recall that they satisfy $2\delta(p)+\delta(k)=1$. Using the conservations of mass and energy (2.3), along with Gagliardo–Nirenberg inequalities, we have, for any t,

$$\|u^\varepsilon(t)\|_{L^p}\lesssim \varepsilon^{-\delta(p)}, \qquad \|u^\varepsilon(t)\|_{L^k}\lesssim \varepsilon^{-\delta(k)}\,.$$

We deduce

$$\|w^\varepsilon\|_{L^\infty(I^\varepsilon_\Lambda;L^2)}\lesssim \left\|w^\varepsilon\left(\frac{\pi}{2}-\Lambda\varepsilon\right)\right\|_{L^2}+\varepsilon^{\alpha-1}\varepsilon^{-2\delta(p)-\delta(k)}\left|I^\varepsilon_\Lambda\right|\lesssim \varepsilon^{\alpha-1}\ln\frac{1}{\varepsilon}+\Lambda\varepsilon^{\alpha-1}\,.$$

The same method yields, since (2.3) shows that $\|H^\varepsilon(t)u^\varepsilon\|_{L^2}\lesssim\|f\|_\Sigma$,

$$\|H^\varepsilon w^\varepsilon\|_{L^\infty(I^\varepsilon_\Lambda;L^2)}\lesssim \varepsilon^{\alpha-1-\delta}\quad \text{for any } \delta>0\,.$$

To treat the case of $J^\varepsilon w^\varepsilon$, introduce

$$z_\varepsilon(t)=\sup_{\frac{\pi}{2}-\Lambda\varepsilon\le\tau\le t}\|J^\varepsilon(\tau)w^\varepsilon\|_{L^2}\,.$$

Proceeding as above, we have

$$\begin{aligned} z_\varepsilon(t)&\lesssim \left\|J^\varepsilon\left(\frac{\pi}{2}-\Lambda\varepsilon\right)w^\varepsilon\right\|_{L^2}+\varepsilon^{\alpha-1}\int_{\frac{\pi}{2}-\Lambda\varepsilon}^t\left\|J^\varepsilon(\tau)\left(|x|^{-1}*|u^\varepsilon|^2u^\varepsilon\right)\right\|_{L^2}d\tau\\ &\lesssim \varepsilon^{\alpha-1^+}+\varepsilon^{\alpha-1}\int_{\frac{\pi}{2}-\Lambda\varepsilon}^t\varepsilon^{-1^+}\left(z_\varepsilon(\tau)+\|J^\varepsilon(\tau)u^\varepsilon_{\rm free}\|_{L^2}\right)d\tau\,. \end{aligned} \tag{3.10}$$

We can then apply the Gronwall lemma (recall that $\|J^\varepsilon(\tau)u^\varepsilon_{\rm free}\|_{L^2}\equiv\|\nabla f\|_{L^2}$):

$$z_\varepsilon(t)\lesssim\varepsilon^{\alpha-1^+}.$$

Gathering this information we get, for any $\delta>0$,

$$\begin{aligned} \|w^\varepsilon\|_{L^\infty(I^\varepsilon_\Lambda;L^2)}&\lesssim\varepsilon^{\alpha-1}\ln\frac{1}{\varepsilon}\,,\\ \|J^\varepsilon w^\varepsilon\|_{L^\infty(I^\varepsilon_\Lambda;L^2)}+\|H^\varepsilon w^\varepsilon\|_{L^\infty(I^\varepsilon_\Lambda;L^2)}&\lesssim\varepsilon^{\alpha-1-\delta}\,. \end{aligned}$$

For $t\in[\pi/2+\varepsilon,\pi]$, we can use the same proof as for $t\in[0,\pi/2-\varepsilon]$ to obtain

$$\begin{aligned} \|w^\varepsilon\|_{L^\infty([0,\pi];L^2)}&\lesssim\varepsilon^{\alpha-1}\ln\frac{1}{\varepsilon}\,,\\ \|J^\varepsilon w^\varepsilon\|_{L^\infty([0,\pi];L^2)}+\|H^\varepsilon w^\varepsilon\|_{L^\infty([0,\pi];L^2)}&\lesssim\varepsilon^{\alpha-1-\delta}\,. \end{aligned}$$

Repetition of the same argument a finite number of times covers any given time interval $[0,T]$ and completes the proof of Proposition 3.1. □

4. Nonlinear propagation and linear focus. In this paragraph, we assume $\alpha=1$ and $\gamma<1$. We define

$$g(t,x)=-\left(|x|^{-\gamma}*|f|^2\right)(x)\int_0^t\frac{d\tau}{|\cos\tau|^\gamma}\,. \tag{4.1}$$

This function is well defined for any t, since $\gamma<1$. We will see later how this function appears.

PROPOSITION 4.1. *Let $n \geq 2$, $f \in \Sigma$, and assume $\gamma < \alpha = 1$. Let A^ε be one of the operators Id, J^ε, or H^ε.*

- *For $0 \leq t < \pi/2$, the following asymptotic relation holds:*

$$\sup_{0\leq\tau\leq t} \left\| A^\varepsilon(\tau) \left(u^\varepsilon(\tau,x) - \frac{1}{(\cos\tau)^{n/2}} f\left(\frac{x}{\cos\tau}\right) e^{-i\frac{x^2}{2\varepsilon}\tan\tau + ig\left(\tau,\frac{x}{\cos\tau}\right)} \right) \right\|_{L^2_x} \underset{\varepsilon\to 0}{\longrightarrow} 0\,.$$

- *For $\pi/2 < t \leq \pi$,*

$$\sup_{t\leq\tau\leq\pi} \left\| A^\varepsilon(\tau) \left(u^\varepsilon(\tau,x) - \frac{e^{-in\frac{\pi}{2}}}{(\cos\tau)^{n/2}} f\left(\frac{x}{\cos\tau}\right) e^{-i\frac{x^2}{2\varepsilon}\tan\tau + ig\left(\tau,\frac{x}{\cos\tau}\right)} \right) \right\|_{L^2_x} \underset{\varepsilon\to 0}{\longrightarrow} 0\,.$$

- *For $t = \pi/2$,*

$$\left\| B^\varepsilon \left(u^\varepsilon\left(\frac{\pi}{2}\right) - \frac{1}{\varepsilon^{n/2}} \mathcal{F}\left(f e^{ig\left(\frac{\pi}{2}\right)} \right)\left(\frac{\cdot}{\varepsilon}\right) \right) \right\|_{L^2} \underset{\varepsilon\to 0}{\longrightarrow} 0\,,$$

where B^ε is one of the operators Id, $\frac{x}{\varepsilon}$, or $\varepsilon\nabla_x$, and the Fourier transform is defined by

$$\mathcal{F}\phi(\xi) = \widehat{\phi(\xi)} = \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} e^{-ix\cdot\xi}\phi(x)dx\,. \tag{4.2}$$

Remark 4.2. We can also prove estimates for arbitrarily large time intervals, with the same proof as below.

Remark 4.3. The difference between the asymptotic behavior before and after the focus is measured only by the Maslov index, through the phase shift $e^{-in\pi/2}$; no nonlinear phenomenon occurs at leading order near the focus. On the other hand, nonlinear effects are relevant outside the focus, as shown by the presence of g.

4.1. Oscillatory integrals. The main tool for proving Proposition 4.1 is the same as in linear cases ([9]; see also [21, 3] for applications in nonlinear settings); we represent the solution u^ε as an oscillatory integral. Recall that $u^\varepsilon \in C(\mathbb{R};\Sigma)$ and that $e^{-i\frac{t}{2\varepsilon}(-\varepsilon^2\Delta + x^2)} = \mathcal{U}^\varepsilon(t)$ is a unitary group on L^2. Define a^ε by

$$a^\varepsilon(t,x) = \mathcal{U}^\varepsilon(-t)u^\varepsilon(t,x)\,. \tag{4.3}$$

We first seek a limit as $\varepsilon \to 0$ for a^ε before the focus. This is suggested by a formal computation as in [4] and by the following lemma.

LEMMA 4.4. *For $t \in [0,\pi/2[\,\cup\,]\pi/2,\pi]$, define $\mathtt{V}^\varepsilon$ by*

$$\mathtt{V}^\varepsilon(t)\phi(x) = \begin{cases} \dfrac{1}{(\cos t)^{n/2}}\phi\left(\dfrac{x}{\cos t}\right) e^{-i\frac{x^2}{2\varepsilon}\tan t} & \text{if } 0 \leq t < \pi/2\,, \\ \dfrac{e^{-in\pi/2}}{|\cos t|^{n/2}}\phi\left(\dfrac{x}{\cos t}\right) e^{-i\frac{x^2}{2\varepsilon}\tan t} & \text{if } \pi/2 < t \leq \pi\,. \end{cases} \tag{4.4}$$

For any $\phi \in H^1(\mathbb{R}^n)$, any $\theta \in]0,1/2]$, and any $t \in [0,\pi/2[\,\cup\,]\pi/2,\pi]$,

$$\|\mathcal{U}^\varepsilon(t)\phi - \mathtt{V}^\varepsilon(t)\phi\|_{L^2} \leq 2|\varepsilon\tan t|^\theta \|\phi\|_{H^1}\,.$$

Proof. Notice that from Mehler's formula (1.8), we can write, for $0 < t < \pi$,

$$\mathcal{U}^\varepsilon(t) = \mathcal{M}^\varepsilon_t \mathtt{D}^\varepsilon_t \mathcal{F} \mathcal{M}^\varepsilon_t, \quad \text{where} \quad \mathcal{M}^\varepsilon_t(x) = e^{-i\frac{x^2}{2\varepsilon\tan t}}\,,\ \mathtt{D}^\varepsilon_t\phi(x) = \frac{1}{(i\varepsilon\sin t)^{n/2}}\phi\left(\frac{x}{\sin t}\right),$$

and the Fourier transform is defined by (4.2). We infer

$$\|\mathcal{U}^\varepsilon(t)\phi - \mathtt{V}^\varepsilon(t)\phi\|_{L^2} = \left\| \frac{1}{(2i\pi\tan t)^{n/2}} \int e^{i\frac{|x-y|^2}{2\varepsilon\tan t}} f(y)dy - f(x) \right\|_{L^2}.$$

From the Parseval formula,

$$\frac{1}{(2i\pi\tan t)^{n/2}} \int e^{i\frac{|x-y|^2}{2\varepsilon\tan t}} f(y)dy = \frac{1}{(2\pi)^{n/2}} \int e^{-i\varepsilon\tan t\frac{\xi^2}{2}+ix\cdot\xi} \mathcal{F}f(\xi)d\xi\,;$$

therefore

$$\begin{aligned}\|\mathcal{U}^\varepsilon(t)\phi - \mathtt{V}^\varepsilon(t)\phi\|_{L^2} &= \frac{1}{(2\pi)^{n/2}} \left\| \int \left(e^{-i\varepsilon\tan t\frac{\xi^2}{2}} - 1 \right) e^{ix\cdot\xi} \mathcal{F}f(\xi)d\xi \right\|_{L^2} \\ &= \left\| \left(e^{-i\varepsilon\tan t\frac{\xi^2}{2}} - 1 \right) \mathcal{F}f(\xi) \right\|_{L^2}\end{aligned}$$

from the Plancherel formula. The lemma then follows from the estimate $|e^{is} - 1| \leq 2|s|^\theta$ for $0 \leq \theta \leq 1/2$. □

From Duhamel's principle, we have

$$u^\varepsilon(t) = \mathcal{U}^\varepsilon(t)f - i\int_0^t \mathcal{U}^\varepsilon(t-s) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon \right)(s)ds\,.$$

Using (4.3), we deduce

$$\partial_t a^\varepsilon(t) = -i\mathcal{U}^\varepsilon(-t) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon \right)(t)\,. \tag{4.5}$$

Now the formal computation begins. Assume $a^\varepsilon \to a$ as $\varepsilon \to 0$, in some suitable sense. Then $u^\varepsilon(t) \sim \mathcal{U}^\varepsilon(t)a(t)$, and from Lemma 4.4,

$$u^\varepsilon(t,x) \underset{\varepsilon\to 0}{\sim} \frac{1}{(\cos t)^{n/2}} a\left(t, \frac{x}{\cos t}\right) e^{-i\frac{x^2}{2\varepsilon}\tan t} \quad \text{for} \quad 0 \leq t < \pi/2\,.$$

Plugging this into (4.5) and using Lemma 4.4 again (with $\mathcal{U}^\varepsilon(-t)$ instead of $\mathcal{U}^\varepsilon(t)$, the result still holds), we find

$$\partial_t a(t,x) = \frac{-i}{|\cos t|^\gamma} \left(|x|^{-\gamma} * |a|^2 \right) a(t,x)\,.$$

Recall that $a_{|t=0} = u^\varepsilon_{|t=0} = f$ and notice that from the above ordinary differential equation, $\partial_t|a|^2 = 0$; we have $a(t,x) = f(x)e^{ig(t,x)}$, where

$$\partial_t g(t,x) = \frac{-1}{|\cos t|^\gamma} \left(|x|^{-\gamma} * |f|^2 \right)(x), \qquad g_{|t=0} = 0\,.$$

Integration of this equation yields the definition of $g(t,x)$ given in (4.1).

Proposition 4.1 stems from the more precise following proposition, Lemma 4.4, and a density argument. In view of a rigorous justification, denote

$$b^\varepsilon(t,x) = a^\varepsilon(t,x)e^{-ig(t,x)} = e^{-ig(t,x)}\mathcal{U}^\varepsilon(-t)u^\varepsilon(t,x)\,. \tag{4.6}$$

Proposition 4.5. *Let $f \in \Sigma \cap H^2(\mathbb{R}^n)$. Fix $\delta > 0$. There exists C_δ such that*

$$\sup_{0\leq t\leq\pi} \|b^\varepsilon(t) - f\|_\Sigma \leq \int_0^\pi \|\partial_t b^\varepsilon(t)\|_\Sigma dt \leq C_\delta \varepsilon^{1-\gamma-\delta}\,.$$

The first inequality is trivial. We prove the second one in three steps:

(i) On $[0, \pi/2 - \Lambda\varepsilon]$ for any $\Lambda > 0$, with a constant depending on δ and Λ;
(ii) On $[\pi/2 - \Lambda\varepsilon, \pi/2 + \Lambda\varepsilon]$, with a constant depending on δ and Λ;
(iii) On $[\pi/2 + \Lambda\varepsilon, \pi]$, with a constant depending on δ and Λ.

As in section 3, the parameter $\Lambda > 0$ is arbitrary, while it has to be large in the case $\alpha = \gamma > 1$ (see section 5 and [6]). This situation is typical for a case where the focus is "linear."

4.2. Asymptotic behavior before the focus. Fix $\Lambda, \delta > 0$. We prove that there exists $C_{\Lambda,\delta}$ such that

$$\int_0^{\frac{\pi}{2}-\Lambda\varepsilon} \|\partial_t b^\varepsilon(t)\|_\Sigma dt \leq C_{\Lambda,\delta}\varepsilon^{1-\gamma-\delta}\,. \tag{4.7}$$

Denote

$$y_\varepsilon(t) = \int_0^t \|\partial_t b^\varepsilon(\tau)\|_{H^1} d\tau\,.$$

From (4.5) and the definition (4.6),

$$\begin{aligned}\|\partial_t b^\varepsilon(t)\|_{L^2} &= \left\| \mathcal{U}^\varepsilon(-t)\left(\left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon\right)(t) - \frac{1}{|\cos t|^\gamma}\left(|x|^{-\gamma} * |f|^2\right) a^\varepsilon(t)\right\|_{L^2} \\ &= \left\| \left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon(t) - \frac{1}{|\cos t|^\gamma}\mathcal{U}^\varepsilon(t)\left(\left(|x|^{-\gamma} * |f|^2\right) a^\varepsilon\right)(t)\right\|_{L^2}\,. \end{aligned} \tag{4.8}$$

Lemma 4.4 suggests that we can replace $\mathcal{U}^\varepsilon$ with $\mathtt{V}^\varepsilon$ in the last expression, up to a controllable error. Before going into further details, we prove two lemmas which will be of constant use in the proof of Proposition 4.5.

LEMMA 4.6. *Assume $\gamma < 1$, and let $0 < \delta < 2(1-\gamma)$. There exist p and q with*

$$2\delta(2p') = \gamma + \frac{\delta}{2}\big(< 1\big)\ ,\ p < \frac{n}{\gamma}, \qquad \delta(2q') = \frac{\gamma+1}{2} + \frac{\delta}{4}\big(<1\big),\ q < \frac{n}{\gamma+1}\,,$$

and such that there exists C such that for any $\phi \in C_c^\infty(\mathbb{R}^n)$,

$$\begin{aligned}\left\||x|^{-\gamma} * \phi\right\|_{L^\infty} &\leq C\left(\|\phi\|_{L^1} + \|\phi\|_{L^{p'}}\right), \\ \left\|\nabla\left(|x|^{-\gamma} * \phi\right)\right\|_{L^\infty} &\leq C\left(\|\phi\|_{L^1} + \|\phi\|_{L^{q'}}\right).\end{aligned}$$

Proof. We have $2\delta(2p') = \gamma$ when $p = n/\gamma$, and $\delta(2q') = \frac{\gamma+1}{2}$ when $q = n/(\gamma+1)$. Therefore $p < n/\gamma$ and $q < n/(\gamma+1)$ if $2\delta(2p') = \gamma + \delta/2$ and $\delta(2q') = \frac{\gamma+1}{2} + \frac{\delta}{4}$.

Let $\chi \in C_c^\infty(\mathbb{R}_+, [0,1])$ with $\chi \equiv 1$ on $[0,1]$. We have

$$\begin{aligned}\||x|^{-\gamma} * \phi\|_{L^\infty} &\leq \left\|\left(\chi|x|^{-\gamma}\right) * \phi\right\|_{L^\infty} + \left\|\left((1-\chi)|x|^{-\gamma}\right) * \phi\right\|_{L^\infty} \\ &\leq \left\|\chi|x|^{-\gamma}\right\|_{L^p}\|\phi\|_{L^{p'}} + \|(1-\chi)|x|^{-\gamma}\|_{L^\infty}\|\phi\|_{L^1} \\ &\leq C\left(\|\phi\|_{L^{p'}} + \|\phi\|_{L^1}\right),\end{aligned}$$

where we have used $x \mapsto |x|^{-\gamma} \in L^p_{\mathrm{loc}}(\mathbb{R}^n)$ because $p < n/\gamma$. The other estimate is similar, since $\nabla|x|^{-\gamma} = \mathcal{O}(|x|^{-\gamma-1})$. ∎

LEMMA 4.7. *Let $\gamma < 1$ and $f \in \Sigma \cap H^2(\mathbb{R}^n)$. Recall that g is defined by* (4.1). *We have*

$$|x|^{-\gamma} * |f|^2 \in W^{2,\infty};\ g \in L^\infty_{\mathrm{loc}}(\mathbb{R}; W^{2,\infty});\ fe^{ig}, \left(|x|^{-\gamma} * |f|^2\right) fe^{ig} \in L^\infty_{\mathrm{loc}}(\mathbb{R}; H^2)\,.$$

Proof. From Lemma 4.6 and Sobolev embeddings,

$$\begin{aligned}
\left\| |x|^{-\gamma} * |f|^2 \right\|_{L^\infty} &\lesssim \|f\|_{L^2}^2 + \|f\|_{L^{2p'}}^2 \lesssim \|f\|_{H^1}^2 \,, \\
\left\| \nabla |x|^{-\gamma} * |f|^2 \right\|_{L^\infty} &\lesssim \|f\|_{L^2}^2 + \|f\|_{L^{2q'}}^2 \lesssim \|f\|_{H^1}^2 \,, \\
\left\| \nabla^2 |x|^{-\gamma} * |f|^2 \right\|_{L^\infty} &\lesssim \left\| \nabla |x|^{-\gamma} * \left(\nabla |f|^2 \right) \right\|_{L^\infty} \\
&\lesssim \|f\|_{L^2} \|\nabla f\|_{L^2} + \|f\|_{L^{2q'}} \|\nabla f\|_{L^{2q'}} \lesssim \|f\|_{H^2}^2 \,.
\end{aligned}$$

Since $t \mapsto |\cos t|^{-\gamma} \in L^1_{\rm loc}(\mathbb{R})$, we infer that $g \in L^\infty_{\rm loc}(\mathbb{R}; W^{2,\infty})$. The last two properties follow easily. ∎

We can now replace $\mathcal{U}^\varepsilon$ with $\mathtt{V}^\varepsilon$ in (4.8), up to the following error. From Lemmas 4.4, 4.6, and 4.7,

$$\begin{aligned}
\left\| \left(\mathcal{U}^\varepsilon(t) - \mathtt{V}^\varepsilon(t) \right) \left(\left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon \right)(t) \right\|_{L^2} &\lesssim |\varepsilon \tan t|^\theta \left\| \left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon(t) \right\|_{H^1} \\
&\lesssim |\varepsilon \tan t|^\theta \left\| |x|^{-\gamma} * |f|^2 \right\|_{W^{1,\infty}} \left\| a^\varepsilon(t) \right\|_{H^1} \\
&\lesssim |\varepsilon \tan t|^\theta \left(\left\| a^\varepsilon(t) \right\|_{L^2} + \left\| \nabla_x a^\varepsilon(t) \right\|_{L^2} \right) \\
&\lesssim |\varepsilon \tan t|^\theta \left(\|f\|_{L^2} + \left\| \nabla_x \left(b^\varepsilon e^{ig} \right) \right\|_{L^2} \right) \\
&\lesssim |\varepsilon \tan t|^\theta \left(1 + \left\| \nabla_x b^\varepsilon(t) \right\|_{L^2} \right) \\
&\lesssim |\varepsilon \tan t|^\theta \left(1 + \left\| \nabla_x \left(b^\varepsilon(t) - f \right) \right\|_{L^2} \right) \\
&\lesssim |\varepsilon \tan t|^\theta \left(1 + \int_0^t \left\| \partial_t b^\varepsilon(\tau) \right\|_{H^1} d\tau \right)
\end{aligned}$$

for $0 < \theta \le 1/2$ to be fixed later. Plugging this estimate into (4.8) we find

$$\begin{aligned}
\left\| \partial_t b^\varepsilon(t) \right\|_{L^2} \lesssim & \left\| \left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon(t) - \frac{1}{|\cos t|^\gamma} \mathtt{V}^\varepsilon(t) \left(\left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon \right)(t) \right\|_{L^2} \\
& + \frac{|\varepsilon \tan t|^\theta}{|\cos t|^\gamma} \left(1 + y_\varepsilon(t) \right) .
\end{aligned} \tag{4.9}$$

We check that

$$\frac{1}{|\cos t|^\gamma} \mathtt{V}^\varepsilon(t) \left(\left(|x|^{-\gamma} * |f|^2 \right) \phi \right) = \left(|x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right) \mathtt{V}^\varepsilon(t) \phi \,. \tag{4.10}$$

Since we expect $\mathtt{V}^\varepsilon(t) a^\varepsilon(t)$ to be close to $\mathcal{U}^\varepsilon(t) a^\varepsilon(t) = u^\varepsilon(t)$ as $\varepsilon \to 0$, we estimate the difference

$$\begin{aligned}
& \left\| \left(|x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right) \left(\mathtt{V}^\varepsilon(t) a^\varepsilon(t) - \mathcal{U}^\varepsilon(t) a^\varepsilon(t) \right) \right\|_{L^2} \\
& \qquad \lesssim \left\| |x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right\|_{L^\infty} \left\| \left(\mathtt{V}^\varepsilon(t) - \mathcal{U}^\varepsilon(t) \right) \left(b^\varepsilon e^{ig} \right) \right\|_{L^2} \\
& \qquad \lesssim \left(\|\mathtt{V}^\varepsilon(t) f\|_{L^2}^2 + \|\mathtt{V}^\varepsilon(t) f\|_{L^{2p'}}^2 \right) (\varepsilon \tan t)^\theta \left\| b^\varepsilon(t) e^{ig(t)} \right\|_{H^1} \\
& \qquad \lesssim \left(1 + |\cos t|^{-2\delta(2p')} \right) |\varepsilon \tan t|^\theta \left(\|b^\varepsilon(t) - f\|_{H^1} + \|f\|_{H^1} \right)
\end{aligned}$$

using the modified Sobolev inequality (2.8). Since $2\delta(2p') = \frac{n}{p} > \gamma$, we infer from (4.9) that

$$\begin{aligned}
\left\| \partial_t b^\varepsilon(t) \right\|_{L^2} \lesssim \; & \frac{|\varepsilon \tan t|^\theta}{|\cos t|^{2\delta(2p')}} \left(1 + y_\varepsilon(t) \right) \\
& + \left\| \left(|x|^{-\gamma} * \left(|u^\varepsilon(t)|^2 - |\mathtt{V}^\varepsilon(t) f|^2 \right) \right) u^\varepsilon(t) \right\|_{L^2} .
\end{aligned} \tag{4.11}$$

From Lemma 4.6, the last term is estimated, up to a constant, by

$$\begin{aligned}
&\left\||u^\varepsilon(t)|^2-|\mathtt{V}^\varepsilon(t)f|^2\right\|_{L^1}+\left\||u^\varepsilon(t)|^2-|\mathtt{V}^\varepsilon(t)f|^2\right\|_{L^{p'}}\\
&\lesssim \left\|u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^2}\left(\|u^\varepsilon(t)\|_{L^2}+\left\|\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^2}\right)\\
&\quad+\left\|u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^{2p'}}\left(\|u^\varepsilon(t)\|_{L^{2p'}}+\left\|\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^{2p'}}\right).
\end{aligned}\tag{4.12}$$

For the first term of the right-hand side, we have, since $\mathcal{U}^\varepsilon$ is unitary on L^2,

$$\begin{aligned}
\left\|\mathcal{U}^\varepsilon(t)\left(b^\varepsilon e^{ig}\right)-\mathtt{V}^\varepsilon(t)\left(fe^{ig}\right)\right\|_{L^2}&\lesssim \|b^\varepsilon(t)-f\|_{L^2}+\left\|(\mathcal{U}^\varepsilon(t)-\mathtt{V}^\varepsilon(t))\left(fe^{ig(t)}\right)\right\|_{L^2}\\
&\lesssim y_\varepsilon(t)+|\varepsilon\tan t|^\theta\left\|fe^{ig(t)}\right\|_{H^1}.
\end{aligned}$$

In addition, notice that $\|u^\varepsilon(t)\|_{L^2}=\|\mathtt{V}^\varepsilon(t)f\|_{L^2}=\|f\|_{L^2}$. The second term is estimated thanks to the modified Gagliardo–Nirenberg inequality (2.8):

$$\begin{aligned}
\left\|u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^{2p'}}&\lesssim|\cos t|^{-\delta(2p')}\left\|u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^2}^{1-\delta(2p')}\\
&\quad\times\left\|J^\varepsilon(t)\left(u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right)\right\|_{L^2}^{\delta(2p')}.
\end{aligned}$$

The first L^2-norm was estimated just above. For the second one, notice that

$$J^\varepsilon(t)\mathcal{U}^\varepsilon(t)=-i\,\mathcal{U}^\varepsilon(t)\nabla_x,\qquad J^\varepsilon(t)\mathtt{V}^\varepsilon(t)=-i\,\mathtt{V}^\varepsilon(t)\nabla_x;$$

therefore

$$\begin{aligned}
\left\|J^\varepsilon(t)\Big(u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\Big(fe^{ig(t)}\Big)\Big)\right\|_{L^2}&\lesssim\left\|\mathcal{U}^\varepsilon(t)\nabla\left(b^\varepsilon(t)e^{ig(t)}\right)-\mathtt{V}^\varepsilon(t)\nabla\left(fe^{ig(t)}\right)\right\|_{L^2}\\
&\lesssim\left\|\nabla\left(b^\varepsilon(t)e^{ig(t)}-fe^{ig(t)}\right)\right\|_{L^2}+\left\|(\mathcal{U}^\varepsilon(t)-\mathtt{V}^\varepsilon(t))\,\nabla\left(fe^{ig(t)}\right)\right\|_{L^2}\\
&\lesssim y_\varepsilon(t)+|\varepsilon\tan t|^\theta,
\end{aligned}$$

where we have used Lemmas 4.4 and 4.7. We infer that

$$\left\|u^\varepsilon(t)-\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^{2p'}}\lesssim|\cos t|^{-\delta(2p')}\left(y_\varepsilon(t)+|\varepsilon\tan t|^\theta\right).$$

We have explicitly

$$\left\|\mathtt{V}^\varepsilon(t)\left(fe^{ig(t)}\right)\right\|_{L^{2p'}}=|\cos t|^{-\delta(2p')}\|f\|_{L^{2p'}}\lesssim|\cos t|^{-\delta(2p')}.$$

Proceeding as above, we have

$$\|u^\varepsilon(t)\|_{L^{2p'}}\lesssim|\cos t|^{-\delta(2p')}\|u^\varepsilon\|_{L^2}^{1-\delta(2p')}\|J^\varepsilon(t)u^\varepsilon\|_{L^2}^{\delta(2p')},$$

with $\|J^\varepsilon(t)u^\varepsilon\|_{L^2}\lesssim\|b^\varepsilon(t)-f\|_{H^1}+\|f\|_{H^1}$. These estimates will eventually lead to an inequality of the form $y_\varepsilon'(t)\le a(t)y_\varepsilon(t)+b(t)y_\varepsilon(t)^\kappa+c(t)$ for some $\kappa>1$. To avoid that situation, we proceed as in section 3; there exists $t^\varepsilon>0$ such that

$$\|b^\varepsilon(t)\|_{H^1}\le 2\|f\|_{H^1}\tag{4.13}$$

for $t \in [0, t^\varepsilon]$. So long as (4.13) holds, we have from the above estimates

$$\|\partial_t b^\varepsilon(t)\|_{L^2} \lesssim |\cos t|^{-2\delta(2p')} \left(y_\varepsilon(t) + |\varepsilon \tan t|^\theta\right). \tag{4.14}$$

To prove that (4.13) holds up to time $\pi/2 - \Lambda\varepsilon$ for $0 < \varepsilon \leq \varepsilon_\Lambda$ along with the error estimate (4.7), we estimate the L^2-norm of $\nabla_x \partial_t b^\varepsilon$. From (4.5) and (4.6),

$$\begin{aligned}\nabla_x \partial_t b^\varepsilon(t) &= -i\nabla_x g(t) \partial_t b^\varepsilon(t) \\ &-ie^{-ig(t)} \nabla_x \left(\mathcal{U}^\varepsilon(-t) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon \right)(t) - \frac{1}{|\cos t|^\gamma} \left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon(t) \right).\end{aligned}$$

The first term is controlled thanks to Lemma 4.7 and (4.14). For the other term, we notice that since $\mathcal{U}^\varepsilon$ is unitary on L^2, from (2.5) its L^2-norm is equal to

$$\left\| J^\varepsilon(t) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon \right)(t) + \frac{i}{|\cos t|^\gamma} \mathcal{U}^\varepsilon(t) \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon(t) \right) \right\|_{L^2}.$$

We proceed as before: we first replace $\mathcal{U}^\varepsilon$ with $\mathtt{V}^\varepsilon$ in the last term, up to an error of $|\cos t|^{-\gamma}$ times:

$$\begin{aligned}&\left\| (\mathcal{U}^\varepsilon(t) - \mathtt{V}^\varepsilon(t)) \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon \right) \right\|_{L^2} \lesssim \\ &\qquad \lesssim \left\| (\mathcal{U}^\varepsilon(t) - \mathtt{V}^\varepsilon(t)) \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) (b^\varepsilon - f) e^{ig} \right) \right\|_{L^2} \\ &\qquad\quad + \left\| (\mathcal{U}^\varepsilon(t) - \mathtt{V}^\varepsilon(t)) \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) f e^{ig} \right) \right\|_{L^2}.\end{aligned}$$

For the first term, we do not use Lemma 4.4, but roughly the fact that $\mathcal{U}^\varepsilon$ and $\mathtt{V}^\varepsilon$ are unitary on L^2. It is not larger than

$$2 \left\| \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) (b^\varepsilon - f) e^{ig} \right) \right\|_{L^2} \lesssim \|b^\varepsilon(t) - f\|_{H^1},$$

from Lemma 4.7. The second term is controlled thanks to Lemmas 4.4 and 4.7:

$$\left\| (\mathcal{U}^\varepsilon(t) - \mathtt{V}^\varepsilon(t)) \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) f e^{ig} \right) \right\|_{L^2} \lesssim |\varepsilon \tan t|^\theta.$$

We now have, so long as (4.13) holds,

$$\begin{aligned}&\|\partial_t b^\varepsilon(t)\|_{H^1} \lesssim |\cos t|^{-2\delta(2p')} \left(y_\varepsilon(t) + |\varepsilon \tan t|^\theta \right) \\ &+ \left\| J^\varepsilon(t) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon \right) + \frac{i}{|\cos t|^\gamma} \mathtt{V}^\varepsilon(t) \nabla_x \left(\left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon(t) \right) \right\|_{L^2}.\end{aligned} \tag{4.15}$$

Using the identity $J^\varepsilon(t) \mathtt{V}^\varepsilon(t) = -i\, \mathtt{V}^\varepsilon(t) \nabla_x$ and (4.10), we have to estimate

$$\begin{aligned}&\left\| J^\varepsilon(t) \left(\left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon \right) - \frac{1}{|\cos t|^\gamma} \mathtt{V}^\varepsilon(t) \left(\left(|x|^{-\gamma} * |f|^2 \right) a^\varepsilon(t) \right) \right) \right\|_{L^2} \\ &= \left\| J^\varepsilon(t) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon - \left(|x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right) \mathtt{V}^\varepsilon(t) a^\varepsilon \right) \right\|_{L^2} \\ &\lesssim \left\| \left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) J^\varepsilon(t) u^\varepsilon - \left(|x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right) J^\varepsilon(t) \mathtt{V}^\varepsilon(t) a^\varepsilon \right\|_{L^2} \\ &\quad + |\cos t| \left\| \nabla_x \left(|x|^{-\gamma} * |u^\varepsilon|^2 \right) u^\varepsilon - \nabla_x \left(|x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right) \mathtt{V}^\varepsilon(t) a^\varepsilon \right\|_{L^2}.\end{aligned} \tag{4.16}$$

We replace $\mathtt{V}^\varepsilon$ with $\mathcal{U}^\varepsilon$ in the first term of the right-hand side, up to the error

$$\begin{aligned}&\left\| \left(|x|^{-\gamma} * |\mathtt{V}^\varepsilon(t) f|^2 \right) J^\varepsilon(t) \left(\mathtt{V}^\varepsilon(t) - \mathcal{U}^\varepsilon(t) \right) a^\varepsilon \right\|_{L^2} \\ &\qquad \lesssim \left(\|\mathtt{V}^\varepsilon(t) f\|_{L^2}^2 + \|\mathtt{V}^\varepsilon(t) f\|_{L^{2p'}}^2 \right) \|(\mathtt{V}^\varepsilon(t) - \mathcal{U}^\varepsilon(t)) \nabla_x a^\varepsilon\|_{L^2} \\ &\qquad \lesssim |\cos t|^{-2\delta(2p')} \left\| (\mathtt{V}^\varepsilon(t) - \mathcal{U}^\varepsilon(t)) \nabla_x \left((b^\varepsilon - f) e^{ig} \right) \right\|_{L^2} \\ &\qquad\quad + |\cos t|^{-2\delta(2p')} \left\| (\mathtt{V}^\varepsilon(t) - \mathcal{U}^\varepsilon(t)) \nabla_x \left(f e^{ig} \right) \right\|_{L^2} \\ &\qquad \lesssim |\cos t|^{-2\delta(2p')} \left(\|b^\varepsilon(t) - f\|_{H^1} + |\varepsilon \tan t|^\theta \right),\end{aligned}$$

from the above computation. Therefore, the first term of the right-hand side of (4.16) is estimated by

$$|\cos t|^{-2\delta(2p')}\left(y_\varepsilon(t)+|\varepsilon\tan t|^\theta\right)+\left\|\left(|x|^{-\gamma}*\left(|u^\varepsilon|^2-|\mathtt{V}^\varepsilon(t)f|^2\right)\right)J^\varepsilon(t)u^\varepsilon\right\|_{L^2}\,.$$

So long as (4.13) holds, $\|J^\varepsilon(t)u^\varepsilon\|_{L^2}\lesssim 1$, and the last term is estimated by

$$\left\||x|^{-\gamma}*\left(|u^\varepsilon|^2-|\mathtt{V}^\varepsilon(t)f|^2\right)\right\|_{L^\infty}\,,$$

which already appeared above and was estimated in (4.12). We are left with the second term of the right-hand side of (4.16). Using Lemma 4.6 with q instead of p now, we see

$$\begin{aligned}\left\|\nabla_x\left(|x|^{-\gamma}*|\mathtt{V}^\varepsilon(t)f|^2\right)\left(\mathtt{V}^\varepsilon(t)-\mathcal{U}^\varepsilon(t)\right)a^\varepsilon\right\|_{L^2}&\lesssim\\ &\lesssim\left(\|\mathtt{V}^\varepsilon(t)f\|_{L^2}^2+\|\mathtt{V}^\varepsilon(t)f\|_{L^{2q'}}^2\right)\|(\mathtt{V}^\varepsilon(t)-\mathcal{U}^\varepsilon(t))\,a^\varepsilon\|_{L^2}\\ &\lesssim|\cos t|^{-2\delta(2q')}\left(y_\varepsilon(t)+|\varepsilon\tan t|^\theta\right)\,.\end{aligned}$$

The final term to estimate is

$$\begin{aligned}\left\|\nabla_x\left(|x|^{-\gamma}*\left(|u^\varepsilon|^2-|\mathtt{V}^\varepsilon(t)f|^2\right)\right)u^\varepsilon\right\|_{L^2}\lesssim&\left\||u^\varepsilon|^2-|\mathtt{V}^\varepsilon(t)f|^2\right\|_{L^1}\\ &+\left\||u^\varepsilon|^2-|\mathtt{V}^\varepsilon(t)f|^2\right\|_{L^{q'}}\,.\end{aligned}$$

The right-hand side was already estimated in (4.12) with p instead of q. We finally have, so long as (4.13) holds,

$$y'(t)\lesssim\left(|\cos t|^{-2\delta(2p')}+|\cos t|^{1-2\delta(2p')}\right)\left(y_\varepsilon(t)+|\varepsilon\tan t|^\theta\right).$$

Now recall that given $\delta>0$, $\delta(2p')$ and $\delta(2q')$ are explicit; hence

$$y'(t)\lesssim|\cos t|^{-\gamma-\frac{\delta}{2}}\left(y_\varepsilon(t)+|\varepsilon\tan t|^\theta\right).$$

It is now time to fix θ. In view of (4.7), it is natural to take $\theta=1-\gamma-\delta$. This yields, so long as (4.13) holds,

$$y_\varepsilon'(t)\lesssim|\cos t|^{-\gamma-\frac{\delta}{2}}\left(y_\varepsilon(t)+|\varepsilon\tan t|^{1-\gamma-\delta}\right)\lesssim|\cos t|^{-\gamma-\frac{\delta}{2}}y_\varepsilon(t)+\frac{\varepsilon^{1-\gamma-\delta}}{|\cos t|^{1-\frac{\delta}{2}}}\,. \tag{4.17}$$

The maps $t\mapsto|\cos t|^{-\gamma-\frac{\delta}{2}}$ and $t\mapsto|\cos t|^{-1+\frac{\delta}{2}}$ are locally integrable (we can assume $\gamma+\delta/2<1-\delta/2$; otherwise (4.7) is of no interest). From the Gronwall lemma, so long as (4.13) holds, we infer

$$y_\varepsilon(t)\lesssim\varepsilon^{1-\gamma-\delta}\,. \tag{4.18}$$

Therefore, there exists $\varepsilon_\Lambda>0$ such that for $0<\varepsilon\leq\varepsilon_\Lambda$, (4.13) holds up to time $\pi/2-\Lambda\varepsilon$, with (4.18). The estimate for $x\partial_t b^\varepsilon$ then is easy, and we leave out this part; this proves (4.7).

Remark 4.8. One might believe that we could deduce Proposition 4.5 in one shot from (4.17) and wonder why we split the proof into three steps. The reason is that we cannot apply Lemma 4.4 (which was used to get (4.17)) near $t=\pi/2$. On the other hand, we will see below that computations near $t=\pi/2$ are far simpler.

4.3. Near the focus and beyond. Keep $\Lambda, \delta > 0$ fixed. We prove that there exists $C_{\Lambda,\delta}$ such that

$$\int_{\frac{\pi}{2}-\Lambda\varepsilon}^{\frac{\pi}{2}+\Lambda\varepsilon} \|\partial_t b^\varepsilon(t)\|_\Sigma dt \leq C_{\Lambda,\delta}\varepsilon^{1-\gamma-\delta}\,. \tag{4.19}$$

A rough estimate in (4.8) yields

$$\begin{aligned}\|\partial_t b^\varepsilon(t)\|_{L^2} &\lesssim \left\|\left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon(t)\right\|_{L^2} + \frac{1}{|\cos t|^\gamma}\left\|\left(|x|^{-\gamma} * |f|^2\right) a^\varepsilon(t)\right\|_{L^2} \\ &\lesssim \left(\|u^\varepsilon(t)\|_{L^2}^2 + \|u^\varepsilon(t)\|_{L^{2p'}}^2\right)\|u^\varepsilon(t)\|_{L^2} + \frac{1}{|\cos t|^\gamma}\|u^\varepsilon(t)\|_{L^2}\,.\end{aligned} \tag{4.20}$$

The conservation of mass yields $\|u^\varepsilon(t)\|_{L^2} = \|f\|_{L^2}$. The conservations of mass and energy (2.3) yield, along with Gagliardo–Nirenberg inequalities,

$$\|u^\varepsilon(t)\|_{L^{2p'}} \lesssim \varepsilon^{-\delta(2p')}\,.$$

Using this estimate (which is sharp near the focus and only near the focus) and integrating (4.20), we get

$$\begin{aligned}\int_{\frac{\pi}{2}-\Lambda\varepsilon}^{\frac{\pi}{2}+\Lambda\varepsilon} \|\partial_t b^\varepsilon(t)\|_{L^2} dt &\lesssim \Lambda\varepsilon^{1-2\delta(2p')} + \int_{\frac{\pi}{2}-\Lambda\varepsilon}^{\frac{\pi}{2}+\Lambda\varepsilon} \frac{dt}{|\cos t|^\gamma} \\ &\lesssim \varepsilon^{1-\gamma-\frac{\delta}{2}} + \varepsilon^{1-\gamma}\,.\end{aligned}$$

The term $\|x\partial_t b^\varepsilon(t)\|_{L^2}$ is estimated the same way, since the conservation of energy yields an a priori bound for $H^\varepsilon u^\varepsilon$. For $\|\nabla_x \partial_t b^\varepsilon(t)\|_{L^2}$, we proceed as in section 3, (3.10) to get an estimate from the Gronwall lemma; the details are left to the reader.

Finally, one can prove that there exists $C_{\Lambda,\delta}$ such that

$$\int_{\frac{\pi}{2}+\Lambda\varepsilon}^{\pi} \|\partial_t b^\varepsilon(t)\|_\Sigma dt \leq C_{\Lambda,\delta}\varepsilon^{1-\gamma-\delta}$$

by mimicking the computations performed in section 4.2, and the proof of Proposition 4.5 is complete.

5. Linear propagation and nonlinear focus. We now consider the case where $\alpha = \gamma > 1$ in (1.6). Our results are similar to those of [6]. Before stating the main result, we recall some points of the scattering theory for (1.9).

PROPOSITION 5.1 (see [13, 17]). *Assume $\psi_- \in \Sigma$ and $1 < \gamma < \min(4, n)$. If $\gamma > 4/3$ or if $\|\psi_-\|_\Sigma$ is sufficiently small, then we have the following:*

- *There exists a unique $\psi \in C(\mathbb{R}_t, \Sigma)$ which is solution to (1.9), such that*

$$\lim_{t\to-\infty} \|\psi_- - \mathtt{U}(-t)\psi(t)\|_\Sigma = 0\,, \quad \text{where } \mathtt{U}(t) = e^{i\frac{t}{2}\Delta}\,.$$

- *There exists a unique $\psi_+ \in \Sigma$ such that*

$$\lim_{t\to+\infty} \|\psi_+ - \mathtt{U}(-t)\psi(t)\|_\Sigma = 0\,.$$

The scattering operator is defined as the map $S\colon \psi_- \mapsto \psi_+$.

Our main result in this section follows.

PROPOSITION 5.2. *Suppose* $n \geq 2$. *Let* $f \in \Sigma$, $1 < \gamma = \alpha < \min(4, n)$, *and* $k \in \mathbb{N}$. *Assume either* $\gamma > 4/3$ *or* $\|f\|_\Sigma$ *is sufficiently small. Then the asymptotic behavior of* u^ε *for* $\pi/2 + (k-1)\pi < a \leq b < \pi/2 + k\pi$ *is given by*

$$\sup_{a\leq t\leq b} \left\| A^\varepsilon(t) \left(u^\varepsilon(t,x) - \frac{e^{-ink\frac{\pi}{2}}}{|\cos t|^{n/2}} \left(\mathcal{F}\circ S^k \circ \mathcal{F}^{-1}\right) f\left(\frac{x}{\cos t}\right) e^{-i\frac{x^2}{2\varepsilon}\tan t} \right) \right\|_{L^2_x} \underset{\varepsilon\to 0}{\longrightarrow} 0\,,$$

where A^ε *is one of the operators* Id, J^ε, *or* H^ε, *and* S^k *denotes the* k*th iterate of* S *(which is well defined under our assumptions on* f*). At the foci,*

$$\left\| B^\varepsilon \left(u^\varepsilon\left(\frac{\pi}{2} + k\pi\right) - \frac{e^{-ink\frac{\pi}{2}}}{\varepsilon^{n/2}} \left(\mathcal{F}\circ S^k\right) f\left(\frac{\cdot}{\varepsilon}\right) \right) \right\|_{L^2} \underset{\varepsilon\to 0}{\longrightarrow} 0\,,$$

where B^ε *is one of the operators* Id, $\frac{x}{\varepsilon}$, *or* $\varepsilon\nabla_x$.

With Lemma 4.4 in mind, this shows that nonlinear effects are negligible away from foci, while they have an influence at leading order near the foci: each caustic crossing is described in average by the nonlinear scattering operator S (the phase shift $e^{-ink\frac{\pi}{2}}$ is the Maslov index, present in the linear case [9]).

The proof of Proposition 5.2 is very similar to the one in [6], which relies on (scaled) Strichartz estimates. We will refrain from repeating everything in detail and limit ourselves to proving the main technical proposition and presenting an outline for the rest of the proof. One main difference compared to the problem in [6] is the action of the operators $J^\varepsilon(t)$, $H^\varepsilon(t)$ on the Hartree nonlinearity as described by (2.9).

We start by reformulating (1.6) by Duhamel's formula:

$$\begin{aligned} u^\varepsilon(t) = \mathcal{U}^\varepsilon(t-t_0)u_0^\varepsilon - i\varepsilon^{\gamma-1}\int_{t_0}^t \mathcal{U}^\varepsilon(t-s)F^\varepsilon(u^\varepsilon)(s)ds \\ - i\varepsilon^{-1}\int_{t_0}^t \mathcal{U}^\varepsilon(t-s)h^\varepsilon(s)ds. \end{aligned} \tag{5.1}$$

This equation generalizes (1.6) to the case of an additional source term and a general nonlinear term F^ε. The main technical result which is used throughout the proof of Proposition 5.2 is as follows.

PROPOSITION 5.3. *Let* $t_1 > t_0$, *with* $|t_1 - t_0| \leq \pi$. *Let* $q, r, s, k \in [1, \infty]$ *be such that*

$$\begin{cases} \text{(a)} \quad \dfrac{1}{r'} = \dfrac{1}{r} + \dfrac{2}{s} + \dfrac{\gamma}{n} - 1 \quad \textit{and} \quad s < \dfrac{2n}{n-\gamma}, \\ \text{(b)} \quad \dfrac{1}{q'} = \dfrac{1}{q} + \dfrac{2}{k}, \\ \text{(c)} \quad (q,r) \textit{ is an admissible pair}, \\ \text{(d)} \quad 0 < \dfrac{1}{k} < \delta(s) < 1\,. \end{cases} \tag{5.2}$$

Assume that there exists a constant C *independent of* t *and* ε *such that for* $t_0 \leq t \leq t_1$,

$$\|F^\varepsilon(u^\varepsilon)(t)\|_{L^{r'}_x} \leq \frac{C}{(|\cos t| + \varepsilon)^{2\delta(s)}} \|u^\varepsilon(t)\|_{L^r_x}, \tag{5.3}$$

and define

$$A^\varepsilon(t_0,t_1) := \left(\int_{t_0}^{t_1} \frac{dt}{(|\cos t| + \varepsilon)^{k\delta(s)}} \right)^{2/k}.$$

Then there exists C^* independent of ε, t_0, and t_1 such that for any admissible pair (ρ,σ),

$$\begin{aligned} \|u^\varepsilon\|_{L^q(t_0,t_1;L^r)} \le{}& C^*\varepsilon^{-1/q}\|u_0^\varepsilon\|_{L^2} + C_{q,\rho}\varepsilon^{-1-\frac{1}{q}-\frac{1}{\rho}}\|h^\varepsilon\|_{L^{\rho'}(t_0,t_1;L^{\sigma'})} \\ &+ C^*\varepsilon^{2\left(\delta(s)-\frac{1}{k}\right)}A^\varepsilon(t_0,t_1)\|u^\varepsilon\|_{L^q(t_0,t_1;L^r)}. \end{aligned} \tag{5.4}$$

Mostly the following corollary is applied.

COROLLARY 5.4. *Suppose the assumptions of Proposition* 5.3 *are satisfied. Assume moreover that $C^*\varepsilon^{2\left(\delta(s)-\frac{1}{k}\right)}A^\varepsilon(t_0,t_1) \le 1/2$, which holds in either of the following two cases:*

- *$0 \le t_0 \le t_1 \le \frac{\pi}{2} - \Lambda\varepsilon$, with $\Lambda \ge \Lambda_0$ sufficiently large,*
- *$t_0, t_1 \in [\frac{\pi}{2} - \Lambda\varepsilon, \frac{\pi}{2} + \Lambda\varepsilon]$, with $\frac{t_1-t_0}{\varepsilon} \le \eta$ sufficiently small.*

Then

$$\|u^\varepsilon\|_{L^\infty(t_0,t_1;L^2)} \le C\|u_0^\varepsilon\|_{L^2} + C_{q,\rho}\varepsilon^{-1-\frac{1}{\rho}}\|h^\varepsilon\|_{L^{\rho'}(t_0,t_1;L^{\sigma'})}. \tag{5.5}$$

To prove Proposition 5.3, we first prove the following algebraic lemma.

LEMMA 5.5. *Let $n \ge 2$, and assume $1 < \gamma < \min(4,n)$. Then there exist $q,r,s,k \in [1,\infty]$ satisfying the conditions* (5.2).

Proof. Note that (a) is equivalent to demanding $\gamma/2 = \delta(r)+\delta(s)$ and $\gamma/2 > \delta(s)$.

Case $\gamma \le 2$. Suppose $\gamma/2 = \delta(s)$. Then by the first half of (a), $\delta(r) = 0$, and $(q,r) = (\infty,2)$ by (c). With $k = 2$, (b) and (d) are satisfied. Now choose s such that $1/2 < \delta(s) < \gamma/2$, but close enough to $\gamma/2$ for (5.2) still to be valid by continuity (for example, $\delta(s) = \frac{1}{2} + \frac{1}{2}(\frac{\gamma}{2} - \frac{1}{2})$). Then (5.2) is satisfied.

Case $\gamma > 2$. In this case take s such that $\delta(s) = 1$, e.g., $s = \frac{2n}{n-2}$. Up to a continuity argument as in the previous case, $\delta(s) < 1$, and (5.2) is satisfied. ∎

Proof of Proposition 5.3. Application of the (scaled) Strichartz estimates (Proposition 2.2) to (5.1) yields

$$\begin{aligned} \|u^\varepsilon\|_{L^q(t_0,t_1;L^r)} \le{}& C\varepsilon^{-1/q}\|u_0^\varepsilon\|_{L^2} + C_{q,\rho}\varepsilon^{-1-\frac{1}{q}-\frac{1}{\rho}}\|h^\varepsilon\|_{L^{\rho'}(t_0,t_1;L^{\sigma'})} \\ &+ C\varepsilon^{\gamma-1-\frac{2}{q}}\|F^\varepsilon(u^\varepsilon)\|_{L^{q'}(t_0,t_1;L^{r'})}. \end{aligned}$$

Then by the assumptions on $F^\varepsilon(u^\varepsilon)$, after an application of Hölder inequality in time, the statement follows. ∎

Proof of Corollary 5.4. The additional assumption implies that the last term in (5.4) can be absorbed by the left-hand side, and we get

$$\|u^\varepsilon\|_{L^q(t_0,t_1;L^r)} \le C\varepsilon^{-1/q}\|u_0^\varepsilon\|_{L^2} + C\varepsilon^{-1-\frac{1}{q}-\frac{1}{\rho}}\|h^\varepsilon\|_{L^{\rho'}(t_0,t_1;L^{\sigma'})}. \tag{5.6}$$

Another application of Strichartz estimates to (5.1), with indices $(\infty,2)$ on the left and (ρ,σ), respectively (q,r), on the right, yields

$$\begin{aligned} \|u^\varepsilon\|_{L^\infty(t_0,t_1;L^2)} \le{}& C\|u_0^\varepsilon\|_{L^2} + C\varepsilon^{-1-\frac{1}{\rho}}\|h^\varepsilon\|_{L^{\rho'}(t_0,t_1;L^{\sigma'})} \\ &+ C\varepsilon^{\gamma-1-\frac{1}{q}}\|F^\varepsilon(u^\varepsilon)\|_{L^{q'}(t_0,t_1;L^{r'})}. \end{aligned}$$

As before,

$$\begin{aligned}\varepsilon^{\gamma-1-\frac{1}{q}}\|F^\varepsilon(u^\varepsilon)\|_{L^{q'}(t_0,t_1;L^{r'})} &\leq C\varepsilon^{\frac{1}{q}}\varepsilon^{2\left(\delta(s)-\frac{1}{k}\right)}A^\varepsilon(t_0,t_1)\|u^\varepsilon\|_{L^q(t_0,t_1;L^r)}\\ &\leq C\varepsilon^{\frac{1}{q}}\|u^\varepsilon\|_{L^q(t_0,t_1;L^r)},\end{aligned}$$

and the statement now follows from (5.6). □

The proof of Proposition 5.2 consists of three parts: the propagation before the focus, the matching between the two regimes, and proof that near the focus, the harmonic potential is negligible. In all parts the main tool used to derive the major statements is Proposition 5.3. Since the proof is very similar to the one in [6], we do not repeat everything in detail but give a detailed proof only for the first part to show how the methods of [6] are applied.

We now show the proof for the propagation before the focus, that is, the approximation of $u^\varepsilon(t)$ by $u^\varepsilon_{\rm free}(t)$ for $0\leq t\leq \frac{\pi}{2}-\Lambda\varepsilon$, in the limit $\Lambda\to+\infty$. We prove that

$$\limsup_{\varepsilon\to 0}\sup_{0\leq t\leq\frac{\pi}{2}-\Lambda\varepsilon}\left\|A^\varepsilon(t)\left(u^\varepsilon(t,x)-u^\varepsilon_{\rm free}(t,x)\right)\right\|_{L^2_x}\underset{\Lambda\to+\infty}{\longrightarrow}0\,,$$

with $A^\varepsilon(t)$ being one of the operators Id, J^ε, or H^ε.

Define the remainder $w^\varepsilon=u^\varepsilon-u^\varepsilon_{\rm free}$. It solves

$$\begin{cases} i\varepsilon\partial_t w^\varepsilon+\dfrac{1}{2}\varepsilon^2\Delta w^\varepsilon=V(x)w^\varepsilon+\varepsilon^\gamma\left(|x|^{-\gamma}*|u^\varepsilon|^2\right)u^\varepsilon\,,\\ w^\varepsilon_{|t=0}=0\,.\end{cases}$$

From Duhamel's principle, this can be written as

$$w^\varepsilon(t)=\mathcal{U}^\varepsilon(t)r^\varepsilon-i\varepsilon^{\gamma-1}\int_0^t\mathcal{U}^\varepsilon(t-s)\left(|x|^{-\gamma}*|u^\varepsilon|^2\right)u^\varepsilon(s)ds. \tag{5.7}$$

Since $u^\varepsilon_{\rm free}$ solves the linear equation (1.7), so does $J^\varepsilon(t)u^\varepsilon_{\rm free}$ from (2.6), and

$$\|u^\varepsilon_{\rm free}(t)\|_{L^2}=\|f\|_{L^2},\qquad \|J^\varepsilon(t)u^\varepsilon_{\rm free}\|_{L^2}=\|\nabla f\|_{L^2}.$$

From the Sobolev inequality (2.8),

$$\|u^\varepsilon_{\rm free}(t)\|_{L^s}\leq\frac{C}{|\cos t|^{\delta(s)}}\|f\|_{L^2}^{1-\delta(s)}\|\nabla f\|_{L^2}^{\delta(s)}$$

for any $s\in[2,\frac{2n}{n-2}[$. Therefore there exists C_0 such that

$$\|u^\varepsilon_{\rm free}(t)\|_{L^s}\leq\frac{C_0}{|\cos t|^{\delta(s)}}\ . \tag{5.8}$$

From Proposition 2.3, for fixed $\varepsilon>0$, $u^\varepsilon\in C(\mathbb{R},\Sigma)$, and the same obviously holds for $u^\varepsilon_{\rm free}$. Therefore, $w^\varepsilon\in C(\mathbb{R},\Sigma)$, and there exists $t^\varepsilon>0$ such that

$$\|w^\varepsilon(t)\|_{L^s}\leq\frac{C_0}{|\cos t|^{\delta(s)}} \tag{5.9}$$

for any $t\in[0,t^\varepsilon]$. So long as (5.9) holds, we have

$$\|u^\varepsilon(t)\|_{L^s}\leq\frac{2C_0}{|\cos t|^{\delta(s)}},$$

and we can apply Proposition 5.3.

Take $h^\varepsilon = \varepsilon^\gamma \left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon_{\rm free}$ and $F^\varepsilon(w^\varepsilon) = \left(|x|^{-\gamma} * |u^\varepsilon|^2\right) w^\varepsilon$ and let $q, k, r, s \in [1, \infty]$ satisfy the assumptions of Proposition 5.3. Now by Hölder's inequality,

$$\|F^\varepsilon(w^\varepsilon)(t)\|_{L^{r'}} \leq \left\||x|^{-\gamma} * |u^\varepsilon(t)|^2\right\|_{L^\beta} \|w^\varepsilon(t)\|_{L^r},$$

with β such that $\frac{1}{r'} = \frac{1}{r} + \frac{1}{\beta}$. By the Hardy–Littlewood–Sobolev inequality and the above estimate,

$$\begin{aligned}\|F^\varepsilon(w^\varepsilon)(t)\|_{L^{r'}} &\lesssim \|u^\varepsilon(t)\|^2_{L^s} \|w^\varepsilon(t)\|_{L^r} \\ &\lesssim \frac{(2C_0)^2}{|\cos t|^{2\delta(s)}} \|w^\varepsilon(t)\|_{L^r}.\end{aligned}$$

Note that the second statement of (5.2)(a) ensures that $s, \beta \in (1, \infty)$ so the Hardy–Littlewood–Sobolev inequality is applicable here. Assume (5.9) holds for $0 \leq t \leq T^\varepsilon$. If $0 \leq t \leq T^\varepsilon \leq \frac{\pi}{2} - \Lambda\varepsilon$, then $\varepsilon \lesssim \cos t$, and the above estimate shows that F^ε satisfies assumption (5.3).

From Corollary 5.4, if Λ is sufficiently large, we get for $0 \leq t \leq T^\varepsilon \leq \frac{\pi}{2} - \Lambda\varepsilon$

$$\|w^\varepsilon\|_{L^\infty(0,T;L^2)} \leq C_\sigma \varepsilon^{\gamma - 1 - \frac{1}{\rho}} \left\|(|x|^{-\gamma} * |u^\varepsilon|^2) u^\varepsilon_{\rm free}\right\|_{L^{\rho'}(0,T;L^{\sigma'})}$$

for any admissible (ρ, σ). Now take $(\rho, \sigma) = (q, r)$ and proceed as above in space and apply Hölder inequality in time:

$$\left\|\left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon_{\rm free}\right\|_{L^{q'}(0,T;L^{r'})} \leq C_{\gamma,n} \|u^\varepsilon\|^2_{L^k(0,T;L^s)} \|u^\varepsilon_{\rm free}\|_{L^q(0,T;L^r)}.$$

The first term of the right-hand side is estimated through (5.8) and (5.9):

$$\|u^\varepsilon\|^2_{L^k(0,T;L^s)} \leq \frac{C}{\left(\frac{\pi}{2} - T\right)^{2(\delta(s) - 1/k)}}.$$

The last term is estimated the same way, for (5.8) still holds when replacing s with r:

$$\|u^\varepsilon_{\rm free}\|_{L^q(0,T;L^r)} \leq \frac{C}{\left(\frac{\pi}{2} - T\right)^{\delta(r) - 1/q}}.$$

We infer

$$\left\|\left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon_{\rm free}\right\|_{L^{q'}(0,T;L^{r'})} \leq \frac{C}{\left(\frac{\pi}{2} - T\right)^{\gamma - 1 - \frac{1}{q}}};$$

thus

$$\|w^\varepsilon\|_{L^\infty(0,T;L^2)} \leq C \left(\frac{\varepsilon}{\frac{\pi}{2} - T}\right)^{\gamma - 1 - \frac{1}{q}}. \tag{5.10}$$

Now apply the operator J^ε to (5.7). This yields, since J^ε and $\mathcal{U}^\varepsilon$ commute,

$$J^\varepsilon(t) w^\varepsilon = \mathcal{U}^\varepsilon(t) J^\varepsilon(0) r^\varepsilon - i\varepsilon^{\gamma - 1} \int_0^t \mathcal{U}^\varepsilon(t - s) J^\varepsilon(s) \left(\left(|x|^{-\gamma} * |u^\varepsilon|^2\right) u^\varepsilon\right)(s) ds.$$

The action of J^ε on the nonlinear term is described by (2.9). In order to apply Proposition 5.3 as before, we now take

$$h^\varepsilon = \varepsilon^{\gamma-1}\left(|x|^{-\gamma} * |u^\varepsilon|^2\right) J^\varepsilon(t) u^\varepsilon_{\rm free} + \varepsilon^{\gamma-1}\ 2{\rm Re}\Big(|x|^{-\gamma} * (\overline{u^\varepsilon} J^\varepsilon(t) u^\varepsilon_{\rm free})\Big) u^\varepsilon$$

and

$$F^\varepsilon(w^\varepsilon) = \left(|x|^{-\gamma} * |u^\varepsilon|^2\right) J^\varepsilon(t) w^\varepsilon + \ 2{\rm Re}\Big(|x|^{-\gamma} * (\overline{u^\varepsilon} J^\varepsilon(t) w^\varepsilon)\Big) u^\varepsilon\,. \tag{5.11}$$

The first term on the right-hand side of (5.11) leads to an equation which is very similar to (5.7), with w^ε replaced by $J^\varepsilon w^\varepsilon$, and is treated by the same computations as above. For the second term, we estimate by Hölder, by the Hardy–Littlewood–Sobolev inequality, and then again by Hölder:

$$\begin{aligned}\left\|2{\rm Re}\Big(|x|^{-\gamma} * (\overline{u^\varepsilon} J^\varepsilon(t) w^\varepsilon)\Big) u^\varepsilon\right\|_{L^{r'}} &\lesssim \||x|^{-\gamma} * (\overline{u^\varepsilon} J^\varepsilon(t) w^\varepsilon)\,\|_{L^{\beta_1}} \|u^\varepsilon(t)\|_{L^s} \\ &\lesssim \|u^\varepsilon(t)\|_{L^s} \|J^\varepsilon(t) w^\varepsilon(t)\|_{L^r} \|u^\varepsilon(t)\|_{L^s},\end{aligned}$$

with r, s as stated in (5.2) and $\frac{1}{r'} = \frac{1}{\beta_1} + \frac{1}{s}$. Here the condition to use the Hardy–Littlewood–Sobolev inequality is $\gamma > \delta(r) + \delta(s)$, which is always satisfied by (5.2). By applying (5.9) now we continue to estimate:

$$\leq \frac{(2C_0)^2}{(|\cos t|)^{2\delta(s)}} \|J^\varepsilon(t) w^\varepsilon(t)\|_{L^r}\,.$$

Then we apply, as before, Proposition 5.3 and estimate the term for h^ε as above, to obtain

$$\|J^\varepsilon w^\varepsilon\|_{L^\infty(0,T;L^2)} \leq C\|\nabla r^\varepsilon\|_{L^2} + C\left(\frac{\varepsilon}{\frac{\pi}{2} - T}\right)^{\gamma-1-\frac{1}{q}}. \tag{5.12}$$

Combining (5.10) and (5.12) along with (2.8), we see that

$$\forall t \in [0,T], \quad \|w^\varepsilon(t)\|_{L^s} \leq \frac{C}{|\cos t|^{\delta(s)}}\left(\|r^\varepsilon\|_{H^1} + \left(\frac{\varepsilon}{\frac{\pi}{2} - t}\right)^{\gamma-1-\frac{1}{q}}\right).$$

Therefore, choosing ε sufficiently small and Λ sufficiently large, we deduce that we can take $T = \frac{\pi}{2} - \Lambda\varepsilon$. With the result of Lemma 4.4 on the limit of $u^\varepsilon_{\rm free}$, this yields Proposition 5.2, away from the focus, for $A^\varepsilon = Id$ and J^ε. The case $A^\varepsilon = H^\varepsilon$ on this time interval is now straightforward.

The remaining parts of the proof for Proposition 5.2 are done as in [6] with the method changed as in the part shown above. It remains to show that the approximations in the two different regimes match at $t_* = \frac{\pi}{2} - \Lambda\varepsilon$ and that the influence of the harmonic potential is small near the focus so that the propagation there is given by

$$v^\varepsilon(t,x) = \frac{1}{\varepsilon^{n/2}}\ \psi\left(\frac{t - \frac{\pi}{2}}{\varepsilon}, \frac{x}{\varepsilon}\right), \tag{5.13}$$

where ψ is the solution of (1.9) subject to the following initial condition at $t = -\infty$:

$$\mathtt{U}(-t)\psi(t)\big|_{t=-\infty} = e^{i\frac{n\pi}{4}}\widehat{f}.$$

This solution exists according to Proposition 5.1.

Then the following asymptotic relation is proven:

$$\limsup_{\varepsilon\to 0} \sup_{\frac{\pi}{2}-\Lambda\varepsilon\le t\le\frac{\pi}{2}+\Lambda\varepsilon} \left\| A^\varepsilon(t)\left(u^\varepsilon(t,x)-v^\varepsilon(t,x)\right)\right\|_{L^2_x} \underset{\Lambda\to+\infty}{\longrightarrow} 0\,,$$

with $A^\varepsilon(t)$ being one of the operators Id, J^ε, or H^ε. Since these parts are quite similar to the treatment in [6], we do not repeat them.

After the crossing of the first focus, the solution is again propagated linearly, and at subsequent focusing points this process is iterated.

6. Formal computations and discussion.

6.1. The case $\alpha = \gamma = 1$ (in 3D: Schrödinger–Poisson). We saw in section 5 that when $\alpha = \gamma > 1$, the nonlinear term in (1.6) has a leading order influence near the foci and only in these regions. On the other hand, if $\alpha = 1$ and $\gamma < 1$, section 4 shows that the Hartree term cannot be neglected away from the foci. These two cases suggest that when $\alpha = \gamma = 1$, the nonlinear influence is relevant everywhere. The aim of this final section is to give convincing arguments that this is the case.

For the influence near the foci, we need the scattering theory for (1.9) at $\gamma = 1$. In this long-range scattering case, modified scattering operators are needed instead of the ones described in Proposition 5.1. Hayashi and Naumkin [16] obtained an asymptotic completeness result for $n \ge 2$ with smoothness assumptions which are applicable to our situation. On the other hand, they could not obtain wave operators. Ginibre and Velo [14, 15] obtained modified wave operators for (1.9) with $\gamma = 1$ using Gevrey spaces by a technically involved method. A drawback of both results is that they include a loss in regularity.

To show how the long-range scattering theory fits into our framework we report (a particular case of) the result of Hayashi and Naumkin [16].

PROPOSITION 6.1 (see [16]). *Assume $n = 3$, $\varphi \in \Sigma$, and $\delta = \|\varphi\|_\Sigma$ is sufficiently small. Let $\psi \in C(\mathbb{R}, \Sigma)$ be the solution of (1.9) with $\psi_{t=0} = \varphi$. Then there exists a unique function $\psi_+ \in H^{\sigma,0} \cap H^{0,\sigma}$, $\frac{1}{2} < \sigma < 1$, such that*

$$\left\|\psi(t) - \exp\left(i\left(|x|^{-1} * |\widehat{\psi_+}|^2\right)\left(\frac{x}{t}\right)\log|t|\right)\mathtt{U}(t)\psi_+\right\|_{L^2} \underset{t\to+\infty}{\longrightarrow} 0\,,$$

where $H^{\alpha,\beta} = \{\phi \in \mathcal{S}' \mid \|(1+|x|^2)^{\beta/2}(1+\Delta)^{\alpha/2}\phi\|_{L^2} < \infty\}$.

To summarize very roughly, the results in [14, 15] consist of showing that given some ψ_+ (or ψ_- for an asymptotic behavior for $t \to -\infty$), one can find ψ solving (1.9) such that the above asymptotic relation holds.

Analogously to the treatment of long-range scattering in [4], one can now define $g^\varepsilon(t,x) := \left(|x|^{-1} * |f|^2\right)(x)\log(\frac{\cos t}{\varepsilon})$ (compare with (4.1)) and add the phase $g^\varepsilon\big|_{t=0}$ to the initial data in (1.6). This yields

$$u^\varepsilon\big|_{t=0} = f(x)e^{-i\left(|x|^{-1}*|f|^2\right)(x)\log\varepsilon}\,.$$

Using the modified scattering operators from the results of [14, 15] we get, at least formally, for $0 \le t < \pi/2$,

$$u^\varepsilon(t,x) \sim \frac{1}{(\cos t)^{3/2}} f\left(\frac{x}{\cos t}\right) e^{-i\frac{x^2}{2\varepsilon}\tan t + ig^\varepsilon\left(t,\frac{x}{\cos t}\right)} \quad \text{as } \varepsilon \to 0\,.$$

This asymptotic relation also stems from the same computations as those performed in section 4.1. Notice that the matching for $|t-\frac{\pi}{2}| = \mathcal{O}(\varepsilon)$ is similar to the one in [6], except that we now have to take the presence of g^ε into account. This is where changing the integration from 0 to t in (4.1) into the above definition of g^ε makes the matching possible. Indeed, for $|t-\frac{\pi}{2}| = \mathcal{O}(\varepsilon)$, we compare u^ε with the function v^ε given by (5.13), where ψ is now the solution given by the long-range wave operators constructed in [14, 15]. To make this statement more precise and the link between (4.1) and the definition of g^ε more explicit, notice that we have, as $t \to \frac{\pi}{2}$,

$$\begin{aligned} g^\varepsilon\left(t, \frac{x}{\cos t}\right) &\sim \left(|x|^{-1} * |f|^2\right)\left(\frac{x}{\frac{\pi}{2}-t}\right) \log\left(\frac{\frac{\pi}{2}-t}{\varepsilon}\right) \quad \text{(phase shift for } v^\varepsilon\text{)} \\ &\sim -\left(|x|^{-1} * |f|^2\right)\left(\frac{x}{\cos t}\right) \int_{\arccos \varepsilon}^{t} \frac{d\tau}{\cos \tau} \quad \text{(compare with (4.1))}\,. \end{aligned}$$

The effects of the nonlinearity show up in g^ε. Using the scaling (5.13) we can then (formally) continue with Proposition 6.1: for $\pi/2 < t < 3\pi/2$,

$$u^\varepsilon(t,x) \sim \frac{e^{-i\frac{3\pi}{2}}}{|\cos t|^{3/2}} \left(\mathcal{F}\circ\widetilde{S}\circ\mathcal{F}^{-1}\right) f\left(\frac{x}{\cos t}\right) e^{-i\frac{x^2}{2\varepsilon}\tan t + i h^\varepsilon\left(t, \frac{x}{\cos t}\right)} \quad \text{as } \varepsilon \to 0\,,$$

where $\widetilde{S}$ is the map $\widetilde{S} : \psi_- \mapsto \psi_+$, where ψ_- is the asymptotic state of the result of [14], which yields some solution ψ to (1.9), and ψ_+ is provided by Proposition 6.1. h^ε is given by

$$h^\varepsilon(t,x) := -\left(|x|^{-1} * |\mathcal{F}\circ\widetilde{S}\circ\mathcal{F}^{-1} f|^2\right)(x) \log\left(\frac{|\cos t|}{\varepsilon}\right).$$

The action of $\mathcal{F}\circ\widetilde{S}\circ\mathcal{F}^{-1}$ on f accounts for nonlinear effects taking place at the focus, and the term h^ε accounts for nonlinear effects after the focus. So the influence of the nonlinearity will be relevant at all times.

The impossibility of defining a scattering operator for this case is one of the reasons this argument is only formal.

Remark 6.2. A rigorous result could be obtained with the same approach as in [3]. It would consist of studying the system of *linear* equations with a *nonlinear* coupling,

$$\begin{cases} i\varepsilon\partial_t \mathbf{u}^\varepsilon + \frac{1}{2}\varepsilon^2 \Delta \mathbf{u}^\varepsilon = \frac{|x|^2}{2}\mathbf{u}^\varepsilon\,, \\ i\varepsilon\partial_t u^\varepsilon + \frac{1}{2}\varepsilon^2 \Delta u^\varepsilon = \frac{|x|^2}{2} u^\varepsilon + \varepsilon\left(|x|^{-1} * |\mathbf{u}^\varepsilon|^2\right) u^\varepsilon\,. \end{cases}$$

The first equation is solved explicitly thanks to Mehler's formula, and the second is a linear Schrödinger equation with a harmonic potential and a time-dependent perturbation. With the oscillatory integral used in section 4, and adapting the results of [8], one could prove similar asymptotic relations to those stated above.

6.2. The case of an additional local strong nonlinearity. We now consider (1.6) with an additional nonlinear term that is a multiplication operator with a power of the density $|\mathfrak{u}^\varepsilon|^2$.

Such equations arise in the modeling of effective one-particle Schrödinger equations where "exchange terms" like in the Hartree–Fock equation are simplified to

functionals of the local densities, i.e., time-dependent density functional theory, with the Schrödinger–Poisson-Xα equation as the simplest of such models (see [25] and [1] for a heuristic derivation and numerical simulations). Note that the additional "local" term has the opposite sign from the Hartree term (corresponding to the physical fact that the "exchange-correlation hole" weakens the direct Coulomb interaction).

We will hence consider the following class of semiclassical Hartree equations:

$$i\varepsilon\partial_t u^\varepsilon + \frac{1}{2}\varepsilon^2\Delta u^\varepsilon = \frac{|x|^2}{2}u^\varepsilon + \varepsilon^\alpha\left(|x|^{-\gamma} * |u^\varepsilon|^2\right)u^\varepsilon - \varepsilon^\beta|u^\varepsilon|^{2\sigma}u^\varepsilon, \tag{6.1}$$

with $\alpha \geq 1$, $\beta \geq 1$, $\gamma > 0$ for $x \in \mathbb{R}^n$ and with a σ that is subcritical with respect to finite time blow-up, i.e., $\frac{2}{n} > \sigma > 0$.

We can now discern the influence of the two nonlinear terms in the classical limit in terms of

- the size of the scaling exponents α, β with respect to the critical value;
- the relation between the scaling and the "strength" of the nonlinearities determined respectively by γ and σ.

If we take $\alpha > 1$ and $\beta > 1$, by [6] and section 5 we find that the classical limit is given by the linear propagation as long as no focusing occurs. At the focus, the relevant discrimination is $\sigma = \beta/n$ or $< \beta/n$ for the power nonlinearity and $\gamma = \alpha$ or $< \alpha$ for the Hartree term. If $\sigma = \beta/n$ and $\gamma < \alpha$, the crossing of the focus will be described by the scattering operator for NLS (when it is defined); if, on the other hand, $\sigma < \beta/n$ and $\gamma = \alpha$ (and the assumptions of Proposition 5.1 are satisfied), focus crossing will be determined by the scattering operator of Proposition 5.1. If both nonlinearities are at the critical strength ($\sigma = \beta/n$ and $\gamma = \alpha$), then both will have an influence in crossing the caustic. If, on the other hand, both $\sigma < \beta/n$ and $\gamma < \alpha$, the nonlinear influence will be negligible everywhere.

If at least one of the scaling exponents α and β is equal to 1 and, at the same time, both $\sigma < \beta/n$ and $\gamma < \alpha$, the corresponding nonlinear term will be relevant in the WKB propagation before the focusing. At the focus, the nonlinear terms will not be relevant and the crossing of the focus will be as in Proposition 4.1. If $\sigma = \beta/n$ and $\gamma = \alpha$, then there will be a nonlinear influence everywhere and long-range scattering for NLS and/or Hartree has to be taken into account.

The influence of the nonlinear action for the single power NLS and the Hartree equation is summed up in two tables; for Hartree the table is given in the introduction, and for the single power nonlinear Schrödinger equation it is stated in [3]. The behavior of (6.1) can be described by independently superposing these two tables. The following table is an extract from that superposition:

	$\alpha > \gamma$ *and* $\beta > \sigma n$	$\alpha = \gamma$ *or* $\beta = \sigma n$
$\alpha > 1$ *and* $\beta > 1$	linear WKB, linear focus	linear WKB, nonlinear focus
$\alpha = 1$ *or* $\beta = 1$	nonlinear WKB, linear focus	nonlinear WKB, nonlinear focus

Here, "nonlinear WKB," respectively, "nonlinear focus," stands for an influence from at least one of the nonlinear terms away from the focus or close to the focus.

6.3. Wigner measures. We already mentioned, in the introduction, the work of Zhang, Zheng, and Mauser [31], where the (semi)classical limit of the Schrödinger–Poisson equation with no smallness assumption (on the initial data or the nonlinearity)

is studied by means of Wigner measures. Wigner measures have proven to be efficient tools for linear semiclassical problems and for homogenization limits; see [26] for an overview on Wigner measure limits of Hartree equations. Wigner measures have the merit that in phase space the caustics of physical space are somewhat unfolded and that generally, results globally in time are possible.

In [5], the Wigner measure of the nonlinear Schrödinger equation with power-like nonlinearity studied in [3] is investigated. It is shown that the Wigner measure leads to an ill-posed problem whenever nonlinear effects at the focal points come into play. In other words, the Wigner measure can be valid only as long as no caustic appears. We briefly discuss the Wigner measures of (1.6) in view of these results.

The Wigner measure of the family $(u^\varepsilon(t))_{0<\varepsilon\leq 1}$, which is bounded in L^2, is the weak limit under $\varepsilon \to 0$ (up to an extraction) of its Wigner transform,

$$W^\varepsilon(u^\varepsilon)(t,x,\xi) = \frac{1}{(2\pi)^n}\int u^\varepsilon\left(t, x-\frac{v\varepsilon}{2}\right)\overline{u^\varepsilon}\left(t,x+\frac{v\varepsilon}{2}\right)e^{i\xi\cdot v}dv.$$

This limit is a positive radon measure μ and is in general not a unique limit.

– *Linear case:* Case $\alpha > \gamma$, $\alpha > 1$.
By the result of Proposition 3.1 and the asymptotic behavior of $u_{\rm free}$ in Lemma 4.4, the Wigner measure μ^- for $t < \pi/2$ of the family $(u^\varepsilon(t))_{0<\varepsilon\leq 1}$ is

$$\mu^-(t,x,\xi) = \frac{1}{|\cos t|^n}\left|f\left(\frac{x}{\cos t}\right)\right|^2 dx\otimes\delta_{\xi = x\tan t}.$$

For $\pi/2 < t < \pi$, the Wigner measure of $(u^\varepsilon(t))_{0<\varepsilon\leq 1}$ (denoted by μ^+) is the same: $\mu^+(t,x,\xi) = \mu^-(t,x,\xi)$. At $t = \pi/2$, the limits from above and below are

$$\lim_{t\to\pi/2^-}\mu^-(t,x,\xi) = \lim_{t\to\pi/2^+}\mu^+(t,x,\xi) = |f(\xi)|^2 d\xi\otimes\delta(x).$$

– *Nonlinear WKB, linear focus:* Case $\gamma < \alpha = 1$.
The asymptotic behavior of u^ε is stated in Proposition 4.1. The additional phase term g is of order 1 and does not change the Wigner measure of $(u^\varepsilon(t))_{0<\varepsilon\leq 1}$, so in this case μ^- and μ^+ are the same as in the previous case; the Wigner measure does not "see" the nonlinear effect g.

– *Linear WKB, nonlinear focus:* Case $\gamma = \alpha > 1$.
The asymptotic relations of Proposition 5.2 involve, for $t \geq \pi/2$, the scattering operator associated with the unscaled equation (1.9). For $t < \pi/2$, the Wigner measure of $(u^\varepsilon(t))_{0<\varepsilon\leq 1}$ is still the same as above, but for $\pi/2 < t < \pi$, we have

$$\mu^+(t,x,\xi) = \frac{1}{|\cos t|^n}\left|\mathcal{F}\circ S\circ\mathcal{F}^{-1}f\left(\frac{x}{\cos t}\right)\right|^2 dx\otimes\delta_{\xi = x\tan t},$$

where S is the scattering operator for (1.9) and $\mathcal{F}$ is the Fourier transform.

– *Nonlinear WKB, nonlinear focus:* Case $\gamma = \alpha = 1$.
The asymptotic behavior for this case of (the formal computation) Proposition 6.1 includes an additional phase term which is of order $\log\varepsilon$ and a modification of the initial data of the same order of magnitude. Both do not alter the Wigner measure, since they are dominated by the scaling of the Wigner transform, and thus the Wigner measure is the same as in the previous case.

For the last two cases, the limits at $t = \pi/2$ are

$$\begin{aligned}\lim_{t\to\pi/2^-}\mu^-(t,x,\xi) &= |f(\xi)|^2 d\xi\otimes\delta(x),\\ \lim_{t\to\pi/2^+}\mu^+(t,x,\xi) &= |\mathcal{F}\circ S\circ\mathcal{F}^{-1}f(\xi)|^2 d\xi\otimes\delta(x).\end{aligned} \tag{6.2}$$

The idea of [5] is to find now two profiles f_1 and f_2 for which $|f_1|^2 \equiv |f_2|^2$, but at the same time $|\mathcal{F} \circ S \circ \mathcal{F}^{-1} f_1|^2 \not\equiv |\mathcal{F} \circ S \circ \mathcal{F}^{-1} f_2|^2$. Then the Wigner measures of the corresponding families $(u_j^\varepsilon(t))_{0<\varepsilon\leq 1}$, $j = 1, 2$, will be equal up to the focus but different after the focus, i.e., $\mu_1^- = \mu_2^-$ but $\mu_1^+ \neq \mu_2^+$. So after the caustic point the Wigner measure will not be unique anymore in the case where the nonlinearity is relevant at the focus. These profiles were constructed using an expansion of S around the origin. Since our problem is very similar to the one studied there, we expect a similar result to hold for (1.6), i.e., we expect the Wigner measure to lead to an ill-posed problem if there is a nonlinear influence at the caustic.

In view of the result of [31], note that the nonuniqueness of the weak solutions for Vlasov–Poisson with measures as initial data and the nonuniqueness of the Wigner measure of a given ε-dependent family of solutions coincide, such that there is no contradiction with the global and unique semiclassical limits of the Hartree-type equations obtained here.

Acknowledgment. This work was completed while the first author was on leave at IRMAR (University of Rennes). He would like to thank this institution for its hospitality.

WEAKLY INTERACTING PULSES IN SYNAPTICALLY COUPLED NEURAL MEDIA*

PAUL C. BRESSLOFF†

Abstract. We use singular perturbation theory to analyze the dynamics of N weakly interacting pulses in a one-dimensional synaptically coupled neuronal network. The network is modeled in terms of a nonlocal integro-differential equation, in which the integral kernel represents the spatial distribution of synaptic weights, and the output activity of a neuron is taken to be a mean firing rate. We derive a set of N coupled ordinary differential equations (ODEs) for the dynamics of individual pulses, establishing a direct relationship between the explicit form of the pulse interactions and the structure of the long-range synaptic coupling. The system of ODEs is used to explore the existence and stability of stationary N-pulses and traveling wave trains.

Key words. neural networks, localized spiral patterns, traveling pulses, integro-differential equations

AMS subject classification. 92C20

DOI. 10.1137/040616371

1. Introduction.

Synaptically coupled neuronal networks provide an important example of spatially extended excitable systems with nonlocal interactions. The network dynamics is usually modeled in terms of an integro-differential equation, in which the integral kernel represents the spatial distribution of synaptic weights and the output activity of a neuron is taken to be a mean firing rate [41, 12]. As in the case of nonlinear PDE models of diffusively coupled excitable systems [23], neuronal networks can exhibit a variety of coherent pulse-like structures including both stationary and traveling solitary pulses. Traveling pulses tend to occur when synaptic connections are predominantly excitatory and there is some form of slow local adaptation or recovery [34, 7], whereas stationary pulses occur in the presence of lateral inhibition [1, 35, 40]. Analogous solutions are found in integrate-and-fire networks, where the output of a neuron is taken to be a sequence of spikes rather than a firing rate [13, 4, 24]. The formation of localized activity states can be used to model a number of neurobiological phenomena. For example, traveling pulses have been observed in disinhibited slice preparations [6, 20, 42] using voltage-sensitive dyes and multiple electrodes. An individual pulse is generated by a brief current stimulus, whereas a train of pulses occurs in the case of repeated stimulation. A second example is given by a delayed response task, in which an animal is required to retain information about a sensory cue across a delay period between the stimulus and behavioral response. Physiological recordings in prefrontal cortex have shown that spatially localized groups of neurons fire during the recall task and then stop firing once the task has finished [18, 39]. Thus persistent localized states of activity are thought to be neural correlates of spatial working memory. An interesting question then concerns the nature of the interactions between multiple regions of localized activity induced by more complex stimuli.

Although there are an increasing number of studies regarding the behavior of solitary pulses in excitable neural media, there is relatively little known about multipulse

solutions. One approach to studying stationary N-pulse solutions in rate models is to convert the integro-differential equation into a corresponding fourth-order PDE by an appropriate choice of weight distribution, and then to search for global homoclinic connections [25, 26, 7] or bifurcations from single-pulse solutions [27]. This approach has established, for example, that stable N-pulse solutions can occur when lateral inhibition is modulated by a spatially oscillating component.

In this paper we analyze multipulse solutions of a one-dimensional neuronal network with a Heaviside firing rate function, under the assumption that the individual pulses are well separated so that their mutual interactions are weak. We use singular perturbation theory to derive equations of motion for the pulse positions, in order to investigate the existence and stability of stationary and traveling N-pulse solutions. Our analysis provides a nontrivial extension of previous studies of weakly interacting pulses in nonlinear PDE models of diffusively coupled excitable media and fluids [9, 10, 2, 3, 37, 33]. First, it applies to a nonlocal integro-differential equation that cannot be reduced to a finite-order PDE except for very specific choices of the synaptic weight distribution. Second, using a Heaviside firing rate function, it is possible to obtain exact solutions for single-pulse profiles and to carry out explicit calculations in the derivation of the dynamical equations for weakly interacting pulses. Third, and most significantly from a biological perspective, there is a direct relationship between the nature of the pulse interactions and the form of the long-range synaptic coupling.

We focus in this paper on three distinct but related models that correspond to three distinct experimental paradigms. In section 2, we analyze stationary pulses in a network with symmetric lateral inhibition, which can be interpreted as a simple model of persistent working memory. Assuming that the weights decay exponentially at large distances, the corresponding single-pulse profile also decays exponentially so that widely separated pulses interact weakly. Using singular perturbation theory, we show how the existence and stability of stationary N-pulses reduces to the problem of finding fixed points of a set of N coupled ODEs describing the motion of individual pulses. This is considerably simpler than looking for multipulse solutions of the full nonlocal equation [25, 26, 7]. Consistent with these other studies, we find that in the presence of pure lateral inhibition well separated pulses repel each other, so that a stable N-pulse solution cannot exist. On the other hand, in the case of a spatially decaying oscillatory weight distribution, stable N-pulses can occur. In section 3, we extend our analysis to the case of a network with asymmetric lateral inhibition, which has been proposed as a model of direction selective neurons in visual cortex [38, 30, 32, 43]. Localized activity pulses now tend to propagate unidirectionally rather than remain stationary. Extending the analysis of section 2 by working in the moving frame of a single traveling pulse, we derive the corresponding system of ODEs for N weakly interacting traveling pulses. These equations are then used to explore the existence and stability of traveling wave trains, with the separation between successive pulses characterized by a lattice map [10]. In the case of spatially oscillatory weights, such a map could potentially exhibit both regular and chaotic behavior. In section 4, we consider an excitatory network with an additional adaptation variable, which has been used to model wave propagation in disinhibited cortical slices [34]. In contrast to the asymmetric lateral inhibition network, waves can now travel in both directions. The resulting system of ODEs for N interacting pulses is identical in form to the previous case, but the asymptotic behavior of a single pulse profile is different. In particular, the leading edge of the pulse decays much more rapidly than the trailing edge, which also typically holds for traveling pulses in diffusively coupled excitable systems [23]. This difference in decay rates can be used to reduce the dynamics to a

kinematic form [11, 33].

2. Stationary pulses in symmetric lateral inhibition networks. Let $u(x,t)$ represent the local activity of a population of neurons at position $x \in \mathbf{R}$ in a one-dimensional neuronal network. Suppose that u evolves according to the integro-differential equation

$$\tau_m \frac{\partial u(x,t)}{\partial t} = -u(x,t) + \int_{-\infty}^{\infty} w(x-x')H[u(x',t)-\kappa]dx', \tag{2.1}$$

where τ_m is a membrane or synaptic time constant, κ is a threshold, $H(u)$ denotes the output firing rate, and $w(x-x')$ is the strength of connections from neurons at x' to neurons at x. We assume that w is a continuous function satisfying $w(-x) = w(x)$ and $\int_{-\infty}^{\infty} w(x) < \infty$. The nonlinearity H is taken to be the Heaviside function

$$H[u] = \begin{cases} 0 & \text{if } u \le 0, \\ 1 & \text{if } u > 0. \end{cases} \tag{2.2}$$

In the following we treat length and time in dimensionless units. First, we set $\tau_m = 1$ so that the unit of time is of the order 10msec. Second, the range of the synaptic coupling introduces a fundamental length scale, which we use to set the unit of length to be of the order 200μm.

Equation (2.1) was first analyzed in detail by Amari [1], who showed that there exist stationary solitary pulse solutions when the weight distribution $w(x)$ is given by a Mexican hat function:

(i) $w(x) > 0$ for $x \in [0, x_0)$ with $w(x_0) = 0$,
(ii) $w(x) < 0$ for $x \in (x_0, \infty)$,
(iii) $w(x)$ is decreasing on $[0, x_0]$,
(iv) $w(x)$ has a unique minimum on $\mathbf{R}^+$ at $x = x_1$ with $x_1 > x_0$ and $w(x)$ strictly increasing on (x_1, ∞).

More recently, it has been established that (2.1) can also support stable stationary N-pulse solutions, provided that the weight distribution has additional zeros, which would occur if there were an oscillatory modulation of the long-range connections [25, 26, 27]. We will refer to any network that has long-range inhibition (possibly alternating with long-range excitation) as a lateral inhibition network. In this section we use singular perturbation theory to analyze the dynamics of N-pulse solutions of (2.1), under the assumption that the interactions between pulses are weak. We show that in the case of a Mexican hat weight distribution, the pulses mutually repel each other so that stable N-pulse solutions cannot occur. On the other hand, when the weight distribution consists of decaying spatial oscillations, there exist configurations of the pulse locations (up to a global translation) corresponding to stable N-pulse bound states. This result is consistent with the findings of Laing et al. [25] and Laing and Tray [26, 27].

2.1. Stationary solitary pulses. Suppose that $U(x)$ is a stationary solution of (2.1): $u(x,t) = U(x)$ with

$$U(x) = \int_{-\infty}^{\infty} w(x-x')H[U(x')-\kappa]dx'. \tag{2.3}$$

Let $\mathcal{M}[U] = \{x | U(x) > \kappa\}$ be the region over which the activity U is excited (superthreshold). Equation (2.3) can then be rewritten as

$$U(x) = \int_{\mathcal{M}[U]} w(x-x')dx'. \tag{2.4}$$

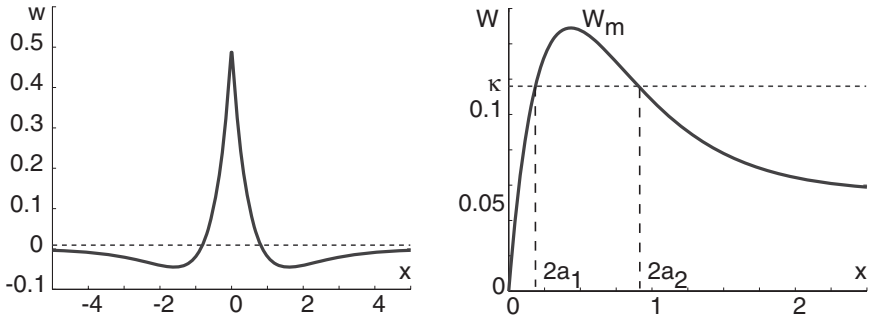

FIG. 2.1. *Construction of stationary pulses for a Mexican hat weight distribution.* (a) *Plot of* $w(x)$ *given by the difference-of-exponentials* (2.8) *with* $\sigma_E = 1.8, \sigma_I = 1.0$, *and* $\Gamma = 0.5$. (b) *Plot of corresponding function* $W(x)$. *Horizontal line shows the threshold* κ *whose intersections with* $W(2a)$ *determine the allowed pulse widths.*

We define a single pulse solution of width $2a$ to be one that is excited over the interval $(-a, a)$; any pulse solution can be arbitrarily translated so that it is centered at the origin. If we set

$$W(x) = \int_0^x w(y)dy, \tag{2.5}$$

then (2.4) reduces to the form

$$U(x) = W(a + x) - W(x - a). \tag{2.6}$$

Note that $W(0) = 0$ and $W(-x) = -W(x)$. Since $U(\pm a) = \kappa$, we obtain the following necessary condition for the existence of a stationary pulse of width $2a$:

$$W(2a) = \kappa. \tag{2.7}$$

Amari [1] showed that in the case of a Mexican hat weight distribution this condition is also sufficient. He also established that a stationary pulse is stable, provided that $W'(a) \equiv w(a) < 0$; otherwise it is unstable.

The stable and unstable pulses can be determined graphically, as illustrated in Figure 2.1 for a Mexican hat function w given by the difference-of-exponentials

$$w(x) = \mathrm{e}^{-\sigma_E|x|} - \Gamma \mathrm{e}^{-\sigma_I|x|}, \tag{2.8}$$

with $\sigma_E > \sigma_I > 0$ and $0 < \Gamma < 1$. Here σ_E^{-1} and σ_I^{-1} determine the range of excitatory and inhibitory synaptic coupling, respectively. If one neglects long-range horizontal connections (see below), then such coupling tends to extend up to around 0.8mm in cortex [29]. Integrating (2.8), we have

$$W(x) = \frac{1}{\sigma_E}\left[1 - \mathrm{e}^{-\sigma_E x}\right] - \frac{\Gamma}{\sigma_I}\left[1 - \mathrm{e}^{-\sigma_I x}\right] \tag{2.9}$$

for $x \geq 0$. The existence of single-pulse solutions depends on the relative sizes of W_m, W_∞, and κ, where

$$W_m = \max_{x>0} W(x), \quad W_\infty = \lim_{x\to\infty} W(x) = \frac{1}{\sigma_E} - \frac{\Gamma}{\sigma_I}. \tag{2.10}$$

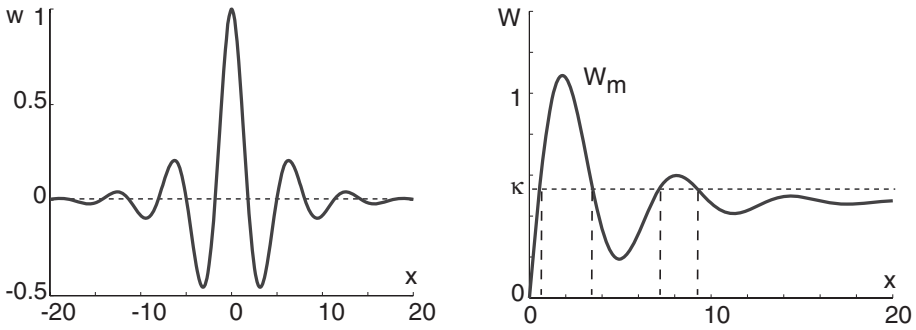

FIG. 2.2. *Construction of a stationary pulse for a spatially decaying oscillatory weight distribution.* (a) *Plot of* $w(x)$ *given by* (2.11) *with* $\sigma = 0.25$. (b) *Plot of corresponding function* $W(x)$. *The horizontal line shows the threshold* κ *whose intersections with* $W(2a)$ *determine the allowed pulse widths.*

If $0 < W_\infty < \kappa < W_m$, then there exists an unstable pulse of width a_1 and a stable pulse of width a_2 with $a_2 > a_1$, whereas there is only an unstable pulse when $0 < \kappa < W_\infty$. In the latter case the network is in a bistable regime, where the unstable pulse acts as a separatrix between a stable uniform resting state ($U \equiv 0$) and a traveling front. If $W_\infty < \kappa < 0 < W_m$, then there is a stable pulse but no unstable pulse. Outside these parameter regimes there are no pulses.

In Figure 2.2, we illustrate the corresponding graphical construction for a spatially decaying oscillatory weight distribution of the form [25]

$$w(x) = \mathrm{e}^{-\sigma|x|}\left[\cos(x) + \sigma \sin|x|\right]. \tag{2.11}$$

Integrating (2.11), we have

$$W(x) = \frac{2\sigma}{1+\sigma^2}\left[1 - \mathrm{e}^{-\sigma x}\cos(x)\right] + \frac{1-\sigma^2}{1+\sigma^2}\mathrm{e}^{-\sigma x}\sin(x), \quad x \geq 0, \tag{2.12}$$

with $W(-x) = -W(x)$. It can be seen from Figure 2.2 that, as κ is reduced below W_m, an increasing number of stable/unstable pairs of pulses are generated, assuming that condition (2.7) is sufficient to ensure $U(x) > \kappa$ for $|x| < a$ and $U(x) < \kappa$ for $|x| > a$. This has not been proven analytically for the weight distribution (2.11), although the existence of stable pulses has been confirmed numerically by Laing et al. [25]. These authors have also suggested that an anatomical substrate for the oscillatory weight distribution (2.11) might be the long-range horizontal connections found in superficial layers of cortex. Such connections extend several millimeters across cortex and are broken into discrete patches with a very regular size and spacing [36, 19, 28]. Although the horizontal connections arise almost exclusively from excitatory neurons, 20% of them terminate on interneurons that can generate significant inhibition [31]. Whether the horizontal connections have a net inhibitory or excitatory effect does not appear to be a simple function of cortical separation, however, since it also depends on the local level of activity of neurons innervated by the long-range connections [29]. Therefore, certain care has to be taken in the biological interpretation of the weight distribution (2.11).

2.2. Singular perturbation theory. Suppose that (2.1) has a stable stationary pulse solution $U(x)$ of width $2a$ centered at the origin such that in the large-$|x|$ limit,

the activity of the pulse decays exponentially, $|U(x)| \sim \mathrm{e}^{-\rho|x|}$. For example, $\rho = \sigma_I$ in the case of the Mexican hat function (2.8), and $\rho = \sigma$ in the case of the spatially decaying oscillatory function (2.11). This suggests that if two or more such pulses are placed on the real line such that the characteristic separation d between the centers of any two pulses satisfies $\mathrm{e}^{-\rho d} = \varepsilon \ll 1$, then the interactions between the pulses will be weak. In the weakly interacting regime, we can carry out a perturbation analysis of the dynamics along lines analogous to those used by Elphick, Meron, and Spiegel [10] by treating ε as a small parameter.

Following [10], we look for an N-pulse solution with individual pulses having centers at $x_n = nd + \phi_n(\tau)$, where $\phi_n(\tau)$ is a slowly varying phase and $\tau = \varepsilon t$. That is, we consider a train of pulses

$$u(x,\tau) = \sum_{n=1}^{N} U(x - nd - \phi_n(\tau)) + \varepsilon R(x,\tau). \tag{2.13}$$

The remainder term εR takes into account the fact that a superposition of widely separated pulses cannot be an exact solution, even when we allow for slowly drifting phases ϕ_n. Substituting (2.13) into (2.1) with $\partial_t \to \partial_t + \varepsilon\partial_\tau$, and using (2.3), gives

$$\varepsilon^2\partial_\tau R - \varepsilon\sum_{n=1}^{N}\dot{\phi}_n U_n' = -\varepsilon R + w * H\left(\sum_{n=1}^{N} U_n + \varepsilon R - \kappa\right) - w * \sum_{n=1}^{N} H(U_n - \kappa), \tag{2.14}$$

where $U_n(x) = U(x - nd - \phi_n(\tau))$ and $w * g$ denotes the convolution

$$w * g = \int_{-\infty}^{\infty} w(x - x')g(x')dx'. \tag{2.15}$$

We now carry out a perturbation expansion in ε by formally Taylor expanding with respect to εR inside the convolution integral:

$$w * H\left(\sum_{n=1}^{N} U_n - \kappa + \varepsilon R\right) = w * \left[H\left(\sum_{n=1}^{N} U_n - \kappa\right) + \varepsilon\delta\left(\sum_{n=1}^{N} U_n - \kappa\right) R + \mathcal{O}\left(\varepsilon^2\right)\right], \tag{2.16}$$

where δ is the Dirac delta function. This formal series expansion can be interpreted along the following lines. First, we assume that in the case of widely separated pulses, the multibump function $V \equiv \sum_n U_n(x)$ has N pairs of threshold crossing points $x_m^{\pm} \approx x_m \pm a$ such that $V(x) > \kappa$ for $x_m^- < x < x_m^+$, $V(x_m^{\pm}) = \kappa$ and $V(x) < \kappa$ otherwise. It follows that

$$\delta(V(x) - \kappa) = \sum_{m=1}^{N}\left[\frac{\delta(x - x_m^+)}{|V'(x_m^+)|} + \frac{\delta(x - x_m^-)}{|V'(x_m^-)|}\right]. \tag{2.17}$$

Similarly, the function $V + \varepsilon R$ is assumed to have threshold crossing points at $x_m^{\pm} + \varepsilon\Delta_m^{\pm}$. The convolution integral then has the explicit form

$$\begin{aligned} w * H\left(\sum_{n=1}^{N} U_n - \kappa + \varepsilon R\right)(x) &= \sum_{n=1}^{N}\int_{x_n^- + \varepsilon\Delta_n^-}^{x_n^+ + \varepsilon\Delta_n^+} w(x - x')dx' \\ &= \sum_{n=1}^{N}\int_{x_n^-}^{x_n^+} w(x - x')dx' \\ &\quad + \varepsilon\left[w(x - x_n^+)\Delta_n^+ - w(x - x_n^-)\Delta_n^-\right] + \mathcal{O}(\varepsilon^2), \end{aligned} \tag{2.18}$$

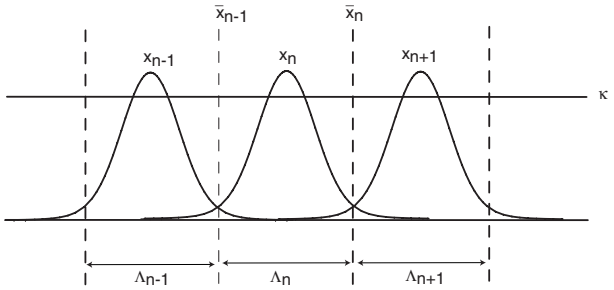

FIG. 2.3. *Illustrative sketch of a multibump solution in which the nth activity bump (region above threshold κ) is localized within the domain Λ_n. In a neighborhood of the mth activity bump we assume that $U_n(x) \sim \varepsilon^{|m-n|}$ for $m \neq n$, where $U_n(x) = U(x - x_n)$ and x_n is the center of the nth bump.*

where we have Taylor expanded with respect to the perturbations $\varepsilon\Delta_m^{\pm}$ in the locations of the activity bump boundaries. Substituting (2.17) into (2.16) shows that the latter is equivalent to (2.18) with $\Delta_m^+ = R(x_m^+)/|V'(x_m^+)|$ and $\Delta_m^- = -R(x_m^-)/|V'(x_m^-)|$.

Substituting (2.16) into (2.14) and collecting first-order terms in ε leads to the following inhomogeneous equation for R:

$$\widehat{L}R = \sum_{n=1}^{N} \dot{\phi}_n U_n' + \frac{1}{\varepsilon} w * \left[H\left(\sum_{n=1}^{N} U_n - \kappa \right) - \sum_{n=1}^{N} H(U_n - \kappa) \right], \tag{2.19}$$

where $\widehat{L}$ is the linear operator

$$\widehat{L}\psi = \psi - w * \left(\delta\left(\sum_{n=1}^{N} U_n - \kappa \right) \psi \right) \tag{2.20}$$

for any function $\psi \in L^2(\mathbf{R})$. We now show that the term in square brackets on the right-hand side of (2.19) is $\mathcal{O}(\varepsilon)$. First, partition the real line into nonoverlapping domains such that the mth activity bump lies entirely in the domain Λ_m, as illustrated in Figure 2.3. More specifically, take $\mathbf{R} = \cup_{m=1}^{N} \Lambda_m$ with $\Lambda_m = [\bar{x}_{m-1}, \bar{x}_m)$ for $m = 2, \ldots, N-1$, $\Lambda_1 = (-\infty, \bar{x}_1)$, and $\Lambda_N = (\bar{x}_{N-1}, \infty)$. Here $\bar{x}_m = (x_{m+1} - x_m)/2$ is the midpoint between neighboring bumps. The characteristic pulse separation d is assumed to be sufficiently large such that $U_n(x) \sim \varepsilon^{|m-n|}$ in a neighborhood of the mth activity bump for $m \neq n$. The given partition then allows us to carry out a formal perturbation expansion along lines similar to (2.16):

$$\begin{aligned}
&\int_{-\infty}^{\infty} w(x - x') H\left(\sum_n U_n(x') - \kappa \right) dx' = \sum_{m=-\infty}^{\infty} \int_{\Lambda_m} w(x - x') H\left(\sum_n U_n(x') - \kappa \right) dx' \\
&= \sum_{m=-\infty}^{\infty} \int_{\Lambda_m} w(x - x') H\left(U_m(x') + \sum_{n \neq m} U_n(x') - \kappa \right) dx' \\
&= \sum_{m=-\infty}^{\infty} \int_{\Lambda_m} w(x - x') \left(H(U_m(x') - \kappa) + \delta(U_m(x') - \kappa) \sum_{n=m\pm1} U_n(x') + \mathcal{O}(\varepsilon^2) \right) dx'.
\end{aligned} \tag{2.21}$$

Only nearest neighbor bumps contribute to the $\mathcal{O}(\varepsilon)$ term. The delta function $\delta(U_m(x)-\kappa)$ can be simplified using the threshold condition $U_m(\pm a+x_m)=\kappa$:

$$\delta(U_m(x)-\kappa)=\frac{\delta(x-a-x_m)}{|U'(a)|}+\frac{\delta(x+a-x_m)}{|U'(-a)|}. \tag{2.22}$$

Since $U_m(x)<\kappa$ for all $x\notin\Lambda_m$, we can replace the integral domain Λ_m in each of the integrals in (2.21) by the whole real line $(-\infty,\infty)$. Thus we find

$$w*H\left(\sum_{n=1}^{N}U_n-\kappa\right)=w*\left[\sum_{n=1}^{N}H(U_n-\kappa)+\sum_{n=1}^{N}\delta(U_n-\kappa)[U_{n+1}+U_{n-1}]+\mathcal{O}(\varepsilon^2)\right] \tag{2.23}$$

with $U_{N+1},U_0\equiv 0$.

In order for the above perturbation expansion to be valid, we require that the correction term R be finite everywhere. Following Elphick, Meran, and Spiegel [10], we will show how this implies a set of solvability conditions on (2.19), which in turn determine the leading-order dynamics of the phases ϕ_n or, equivalently, the pulse positions x_n. In order to gain insights into the analytical properties of the linear operator $\widehat{L}$ it is useful to consider the simpler operator $\widehat{L}_n$, where

$$\widehat{L}_n\psi=\psi-w*[\delta(U_n-\kappa)\psi]. \tag{2.24}$$

The latter has zero as an eigenvalue with corresponding eigenfunction $Q=U_n'$, which can be seen by differentiating (2.3). Therefore, the eigenvalue equation $\widehat{L}Q=\lambda Q$ has approximate solutions of the form $Q=\sum_{i=1}^{N}c_nU_n'$, where c_n are constants, with associated eigenvalues $\lambda=\mathcal{O}(\varepsilon)$. Assuming the standard inner product of functions P,Q on $\mathbf{R}$,

$$\langle P|Q\rangle=\int_{-\infty}^{\infty}P(x)Q(x)dx, \tag{2.25}$$

we define the adjoint operator $\widehat{L}^\dagger$ according to

$$\langle P|\widehat{L}Q\rangle=\langle\widehat{L}^\dagger P|Q\rangle, \tag{2.26}$$

so that

$$\widehat{L}^\dagger\psi=\psi-\delta\left(\sum_{n=1}^{N}U_n-\kappa\right)w*\psi. \tag{2.27}$$

The existence of N null vectors of $\widehat{L}_n$ suggests that its adjoint should also have N null vectors, which can then be used to construct eigenfunctions of $\widehat{L}^\dagger$ with $\mathcal{O}(\varepsilon)$ eigenvalues. However, since the operator $\widehat{L}_n$ is not self-adjoint, one cannot assume a priori that it has index zero. The situation is further complicated by the fact that $\widehat{L}^\dagger$ involves distributions. Therefore, we will proceed by searching for weak solutions P of the equation

$$\langle\widehat{L}^\dagger P|Q\rangle=\mathcal{O}(\varepsilon) \tag{2.28}$$

for any bounded function Q.

Comparison of (2.17) and (2.22) shows that in the weakly interacting regime,

$$\int \psi(x)\delta\left(\sum_n U_n(x)-\kappa\right)dx = \int \psi(x)\sum_{n=1}^{N}\delta\left(U_n(x)-\kappa\right)dx+\mathcal{O}(\varepsilon) \tag{2.29}$$

for arbitrary ψ. This leads to the formal decomposition of the adjoint operator given by

$$\widehat{L}^{\dagger}\psi = \widehat{L}_n^{\dagger}\psi - \sum_{j\neq n}\delta(U_j-\kappa)w*\psi+\mathcal{O}(\varepsilon) \tag{2.30}$$

for any $n=1,\ldots,N$, with $\delta(U_n-\kappa)$ satisfying (2.22). Without loss of generality, set $x_0=0$ and look for solutions of $\widehat{L}_0^{\dagger}\mathcal{P}=0$, which can be written as

$$\mathcal{P}(x) = \left[\frac{\delta(x+a)}{U'(-a)}+\frac{\delta(x-a)}{|U'(a)|}\right]\int_{-\infty}^{\infty} w(x-x')\mathcal{P}(x')dx'. \tag{2.31}$$

The formal solution is $\mathcal{P}(x)=p_1\delta(x-a)-p_2\delta(x+a)$, with coefficients p_1,p_2 satisfying the pair of algebraic equations

$$p_1 = \frac{1}{|U'(a)|}\left[p_1w(0)-p_2w(2a)\right],$$

$$p_2 = -\frac{1}{U'(-a)}\left[p_1w(2a)-p_2w(0)\right].$$

Differentiating (2.6) shows that

$$U'(-a) = -U'(a) = w(0)-w(2a), \tag{2.32}$$

and hence $p_1=p_2$. This establishes that $\widehat{L}_0^{\dagger}$ has the null vector

$$\mathcal{P}(x) = \delta(x-a)-\delta(x+a). \tag{2.33}$$

From translation symmetry, it follows that $\widehat{L}_n^{\dagger}$ has the null vector $P_n(x)$, where

$$P_n(x) \equiv \mathcal{P}(x-x_n). \tag{2.34}$$

Hence, using the decomposition (2.30) and the result $\widehat{L}_n^{\dagger}P_n=0$, we have

$$\langle \widehat{L}^{\dagger}P_n|Q\rangle = -\sum_{j\neq n}\langle\delta(U_j-\kappa)w*P_n|Q\rangle+\mathcal{O}(\varepsilon) \tag{2.35}$$

for any bounded function Q. Since $w(x)$ decays as $\mathrm{e}^{-\rho|x|}$ for large $|x|$, we see that $w(x_n-x_j)\sim\varepsilon^{|n-j|}$ for $n\neq j$, so that the inner product on the right-hand side of (2.35) is also $\mathcal{O}(\varepsilon)$. We conclude that (2.28) has the set of solutions P_n, $n=1,\ldots,N$. Interestingly, these solutions are independent of the choice of weight function w.

We now take the inner product of (2.19) with respect to P_m and use (2.23). Keeping only leading-order terms in ε then yields the following solvability condition:

$$\dot{\phi}_m\left\langle P_m\,|U_m'\right\rangle + \frac{1}{\varepsilon}\left\langle P_m\,|w*\delta(U_m-\kappa)[U_{m+1}+U_{m-1}]\right\rangle = \mathcal{O}(\varepsilon). \tag{2.36}$$

Substituting (2.33) into (2.36) and using (2.22), (2.32) shows that

$$\langle P_m\,|w*\delta(U_m-\kappa)[U_{m+1}+U_{m-1}]\rangle = U(a+x_m-x_{m+1})+U(a+x_m-x_{m-1}) - U(-a+x_m-x_{m+1})-U(-a+x_m-x_{m-1})$$

(2.37)

and

$$\langle P_m\,|U_m'\rangle = [U_m'(a+x_m)-U_m'(-a+x_m)] = -2|U'(a)|. \tag{2.38}$$

We thus obtain the following system of differential equations for the pulse positions $x_m(t) = md + \phi_m(\varepsilon t)$:

$$\begin{aligned} &\dot{x}_m = f(x_{m+1}-x_m) - f(x_m - x_{m-1}), \quad 1 < m < N, \\ &\dot{x}_1 = f(x_2-x_1), \quad \dot{x}_N = -f(x_N - x_{N-1}) \end{aligned} \tag{2.39}$$

with

$$f(x) = \frac{1}{2|U'(a)|}\left[U(x-a)-U(x+a)\right]. \tag{2.40}$$

2.3. Stationary *N*-pulses. Equations (2.6) and (2.40) show that the explicit form of the interaction function $f(x)$ for large x is determined by the asymptotic behavior of the weight distribution w. In the case of the Mexican hat function (2.8), equations (2.6), (2.9), and (2.40) imply that for large x

$$f(x) = -\frac{\Gamma\cosh(\sigma_I a)}{\sigma_I|U'(a)|}\left[\mathrm{e}^{-\sigma_I(x-a)} - \mathrm{e}^{-\sigma_I(x+a)}\right] = -Ae^{-\sigma_I x} \tag{2.41}$$

with

$$A = \frac{\Gamma\sinh(2\sigma_I a)}{\sigma_I|U'(a)|} > 0. \tag{2.42}$$

Similarly, in the case of a spatially decaying oscillatory function (2.11), we find that for large x,

$$f(x) = \frac{2\mathrm{e}^{-\sigma x}}{(1+\sigma^2)|U'(a)|}\left[A_1(a,\sigma)\cos(x) + A_2(a,\sigma)\sin(x)\right] \tag{2.43}$$

with

$$A_1(a,\sigma) = (1-\sigma^2)\sinh(\sigma a)\sin(a) + 2\sigma\cosh(\sigma a)\cos(a) - 2\sigma, \tag{2.44}$$

$$A_2(a,\sigma) = 2\sigma\sinh(\sigma a)\sin(a) - (1-\sigma^2)\cosh(\sigma a)\cos(a) + 1 - \sigma^2. \tag{2.45}$$

The function f can be written in the more compact form

$$f(x) = B\mathrm{e}^{-\sigma x}\cos(x-\Phi) \tag{2.46}$$

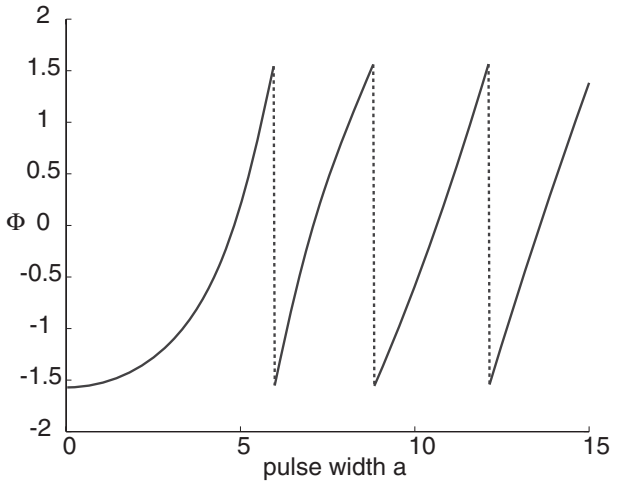

FIG. 2.4. *Plot of phase separation* Φ *for a pair of pulses as a function of pulse width* a *in the case of the spatially decaying oscillatory weight distribution* (2.11) *with* $\sigma = 0.25$.

with

$$\Phi = \tan^{-1}\frac{A_2}{A_1}, \quad B = \frac{2\sqrt{A_1^2 + A_2^2}}{(1+\sigma^2)|U'(a)|}. \tag{2.47}$$

The dependence of the phase Φ on pulse width for fixed decay rate σ is shown in Figure 2.4. Note that for $\sigma a \gg 1$ we have $\Phi \approx a - \phi$ with $\tan\phi = (1-\sigma^2)/2\sigma$.

The existence and stability of stationary N-pulse solutions can now be investigated in terms of the fixed point solutions of (2.39) for a given weight distribution. Let us first consider a pair of pulses, whose positions satisfy the pair of equations

$$\dot{x}_1 = f(x_2 - x_1), \quad \dot{x}_2 = -f(x_2 - x_1). \tag{2.48}$$

Defining the separation variable $\Delta = x_2 - x_1$, we have

$$\dot{\Delta} = -2f(\Delta). \tag{2.49}$$

It immediately follows from (2.41) that mutual interactions between pulses are repulsive for a Mexican hat weight function, since $f(\Delta) < 0$ for all Δ. Hence, the pulses repel each other and cannot form a bound 2-pulse state. A similar result holds for more than two pulses. Note that Amari [1] originally suggested that pulses were attractive at short distances, repulsive at intermediate distances, and neutral at sufficiently large distances. Our analysis suggests that repulsion actually persists to arbitrarily large distances, but that the rate of separation is slow since $f(\Delta) \sim \mathrm{e}^{-\sigma_I \Delta} \ll 1$. Following the results of Laing and colleagues [25, 27] and analogous results for PDEs [2], one expects a stable N-pulse solution to exist when the weights have an oscillatory tail. This is easily seen in the case for a pair of pulses by substituting (2.46) into (2.49):

$$\dot{\Delta} = -2B\mathrm{e}^{-\sigma\Delta}\cos(\Delta - \Phi). \tag{2.50}$$

Such an equation has a countable set of stable/unstable pairs of fixed point solutions: $\Delta = \Delta_\pm(p) = \Phi \pm \pi/2 + 2\pi p$ for integers $p \gg 1$ (so that pulses are well separated) with $\Delta_-(p)$ stable and $\Delta_+(p)$ unstable.

Higher-order N-pulse solutions can be constructed by taking the separations $\Delta_m = x_m - x_{m-1}$ to be zeros of f for all $m = 2, \ldots, N$. Stability is determined by the eigenvalues of the tridiagonal matrix

$$\mathbf{A}_N = \begin{pmatrix} -2f'(\Delta_2) & f'(\Delta_3) & 0 & \ldots & 0 \\ f'(\Delta_2) & -2f'(\Delta_3) & f'(\Delta_4) & 0 & \ldots \\ 0 & f'(\Delta_3) & -2f'(\Delta_4) & f'(\Delta_5) & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \ldots & 0 & f'(\Delta_{N-1}) & -2f'(\Delta_N) \end{pmatrix}. \tag{2.51}$$

Note that the matrix coefficients satisfy $a_{i,i+1} = a_{i+1,i} > 0$ for all i so that the eigenvalues are all real and simple. Moreover, by the Gerschgorin disk theorem (see [22]), the eigenvalues of $\mathbf{A}_N$ are contained in the union of disks defined according to $\cup_i \{|\lambda - a_{ii}| \leq \sum_{j \neq i} |a_{ij}|\}$. Consider the simplest case in which all pulse spacings are equal, $\Delta_m = \Delta$ for all $m = 2, \ldots, N$. We then obtain the pair of conditions

$$|\lambda + 2f'(\Delta)| \leq f'(\Delta), \quad |\lambda + 2f'(\Delta)| \leq 2f'(\Delta). \tag{2.52}$$

These are circles contained within the left-half complex plane, provided that $f'(\Delta) > 0$. One can also show that there are no zero eigenvalues by noting that in the uniform case the determinant $D_N = \det[\mathbf{A}_N - \lambda \mathbf{I}]$ satisfies the iterative equation

$$D_m(\lambda) = (-2f'(\Delta) - \lambda) D_{m-1} - f'(\Delta)^2 D_{m-2}, \quad 2 \leq m \leq N, \tag{2.53}$$

with $D_1 = 1$ and $D_0 = 0$. This has the solution

$$D_N(\lambda) = \frac{\Lambda_+^N - \Lambda_-^N}{\Lambda_+ - \Lambda_-}, \tag{2.54}$$

where

$$\Lambda_\pm = \frac{1}{2}\left(-2f' - \lambda \pm \sqrt{\lambda^2 + 4f'\lambda}\right). \tag{2.55}$$

Since $D_N(0) \neq 0$, it follows that zero is not an eigenvalue. Therefore, there exists a stable uniformly spaced stationary N-pulse solution if $f(\Delta) = 0$ and $f'(\Delta) > 0$.

One can also analyze the stationary states of N pulses arranged on a ring of length L. Now the dynamics is described by the cyclic system of ODEs

$$\dot{x}_m = f(x_{m+1} - x_m) - f(x_m - x_{m-1}), \quad m = 1, \ldots, N, \tag{2.56}$$

with $x_0 = x_N$ and $x_{N+1} = x_0$. The evenly spaced solution $\Delta = L/N$ is automatically a fixed point of the dynamics, and its stability can be determined by linearizing (2.56) with $x_m = m\Delta + \theta_m$:

$$\dot{\theta}_m = -f'(\Delta)\left[2\theta_m - \theta_{m-1} - \theta_{m+1}\right]. \tag{2.57}$$

This has eigensolutions of the form $\theta_m(t) = \mathrm{e}^{\lambda(k)t}\mathrm{e}^{imk}$ with wavenumber $k = 2\pi p/N$ for $p = 1, \ldots, N$ and

$$\lambda(k) = -2f'(\Delta)[1 - \cos(k)]. \tag{2.58}$$

The zero eigenvalue at $k = 0$ reflects the translation invariance of the system. Hence, the N-pulse solution on the ring is (marginally) stable if $f'(\Delta) > 0$; otherwise it is

unstable. It then follows from (2.41) and (2.46) that a ring network with a Mexican hat weight distribution supports stable N-pulse solutions independently of the length L of the ring, whereas a spatially decaying oscillatory distribution supports such a solution only for certain ranges of L. This example illustrates how the existence and stability of multipulse solutions depends on the topology of the network as well as its weight distribution.

3. Traveling pulses in asymmetric lateral inhibition networks. In section 2 we considered a lateral inhibition network with a weight distribution that is symmetric, $w(-x) = w(x)$. Although this is usually a reasonable modeling assumption regarding the large-scale anatomy of cortical circuits, there are some examples of more specialized circuits where lateral inhibition may be asymmetric. In particular, asymmetric coupling has been suggested as providing a possible mechanism for direction selective neurons in the visual cortex [38, 30, 32, 43]. Networks with asymmetric lateral inhibition support unidirectional wave propagation rather than stationary activity pulses. If a moving external stimulus is presented to a one-dimensional network, then a superthreshold response is elicited only if the velocity of the stimulus approximately matches the direction and speed of the intrinsic waves. Here we extend the singular perturbation theory of stationary pulses in order to investigate traveling N-pulse solutions of (2.1) in the case of asymmetric lateral inhibition.

3.1. Traveling solitary pulses. Suppose that (2.1) with asymmetric w has a right-moving traveling pulse solution of the form $u(x,t) = U(x-ct)$, $c > 0$, where $U(\pm\infty) = 0$ and $U(-a) = U(0) = \kappa$. Substituting into (2.1) with $\xi = x - ct$ gives

$$\begin{aligned} -c\partial_\xi U(\xi) + U(\xi) &= \int_{-\infty}^{\infty} w(\xi - \xi')H(U(\xi') - \kappa)d\xi' \\ &= W(\xi + a) - W(\xi), \end{aligned} \tag{3.1}$$

with W defined by (2.5). Multiplying both sides of (3.1) by the integrating factor $-c^{-1}\mathrm{e}^{-\xi/c}$ and integrating from $-a$ to ξ using the threshold condition $U(-a) = \kappa$ leads to the result

$$U(\xi) = \mathrm{e}^{\xi/c}\left[\kappa\mathrm{e}^{a/c} - \frac{1}{c}\int_{-a}^{\xi}[W(\xi' + a) - W(\xi')]\mathrm{e}^{-\xi'/c}d\xi'\right]. \tag{3.2}$$

Finiteness of the solution in the limit $\xi \to \infty$ requires that the term in square brackets vanish. Hence, we can rewrite the solution for $U(\xi)$ as

$$U(\xi) = \frac{1}{c}\int_0^{\infty}(W(\xi' + \xi + a) - W(\xi' + \xi))\mathrm{e}^{-\xi'/c}d\xi'. \tag{3.3}$$

Enforcing the threshold conditions $U(0) = \kappa$ and $U(-a) = \kappa$ then generates a pair of equations that determine existence curves relating the speed c to the pulse width a for a given threshold κ.

A typical way to model asymmetric lateral inhibition is to take $w(x) = w_0(x - x_0)$ with w_0 a symmetric weight distribution such as a Mexican hat function. If $x_0 > 0$, then short-range coupling is predominantly excitatory to the right and inhibitory to the left, which leads to right-propagating waves, as illustrated in Figure 3.1. The function $W(x)$ of (2.9) may be expressed in terms of w_0 as

$$W(x) = W_0(x - x_0) + W_0(x_0), \quad W_0(x) = \int_0^x w_0(y)dy, \tag{3.4}$$

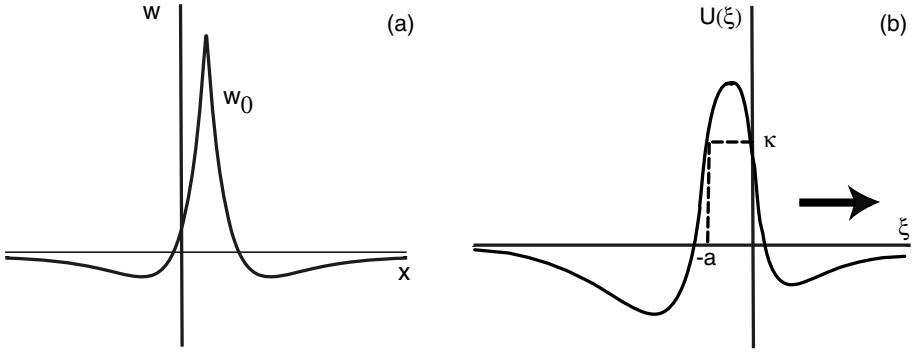

FIG. 3.1. (a) *Shifted weight distribution* $w(x) = w(x - x_0)$ *in the case of asymmetric lateral inhibition.* (b) *Illustration of a right-moving traveling pulse of width* a.

so that the wave profile becomes

$$U(\xi) = \frac{1}{c}\int_0^\infty (W_0(\xi' + \xi + a - x_0) - W_0(\xi' + \xi - x_0))\mathrm{e}^{-\xi'/c}d\xi'. \tag{3.5}$$

Equation (3.5) can be used to determine the asymptotic behavior of the solitary pulse for any exponentially decaying weight distribution. In particular, suppose that

$$w_0(x) = \mathrm{e}^{-\sigma|x|}g(x),$$

with $g(x)$ bounded for all x and $\lim_{x\to\pm\infty} g(x) = g_{\pm\infty}$. If $\xi > x_0$, then there is a common factor of $\mathrm{e}^{-\sigma\xi}$ on the right-hand side of (3.5), which can be taken outside the integral. Hence, in the limit $\xi \to \infty$,

$$U(\xi) \sim \frac{g_\infty}{c}\int_0^\infty (\mathrm{e}^{-\sigma(\xi'+\xi+a-x_0)} - \mathrm{e}^{-\sigma(\xi'+\xi-x_0)})\mathrm{e}^{-\xi'/c}d\xi' \sim -\mathrm{e}^{-\sigma\xi}. \tag{3.6}$$

On the other hand, when $\xi < x_0$, we have to partition the integral of (3.5) into the separate domains $\xi' > \xi + x_0$, $\xi + x_0 - a < \xi' < \xi + x_0$, and $\xi' < \xi + x_0 - a$ so that in the limit $\xi \to -\infty$,

$$U(\xi) \sim -\left[U_1\mathrm{e}^{\sigma\xi} + U_2\mathrm{e}^{\xi/c}\right]. \tag{3.7}$$

Therefore, the leading edge of the pulse profile decays at the rate σ determined by the weight distribution w_0, whereas the trailing edge decays at the rates σ and c^{-1}. The activity profile $U(\xi)$ of both the leading and trailing edges is negative due to the effects of inhibition; see Figure 3.1b. If $g(x)$ is taken to be an oscillatory function, then the asymptotic terms $\mathrm{e}^{-\sigma|\xi|}$ will also be oscillatory.

In Figure 3.2 we show existence curves for a traveling pulse of width a and speed c with w_0 given by the difference-of-exponentials (2.8). The pulse profile is given by $U(\xi) = U_{\sigma_E}(\xi) - \Gamma U_{\sigma_I}(\xi)$ with

$$\sigma U_\sigma(\xi) = \frac{\mathrm{e}^{-(\xi-x_0)\sigma}}{c\sigma+1} - \frac{\mathrm{e}^{-(\xi+a-x_0)\sigma}}{c\sigma+1}$$

for $\xi > x_0$,

$$\sigma U_\sigma(\xi) = 2 - \frac{\mathrm{e}^{-(\xi+a-x_0)\sigma}}{c\sigma+1} - \left[\left(\frac{2c^2\sigma^2}{c^2\sigma^2-1}\right)\mathrm{e}^{-(x_0-\xi)/c} - \frac{\mathrm{e}^{-(x_0-\xi)\sigma}}{c\sigma-1}\right]$$

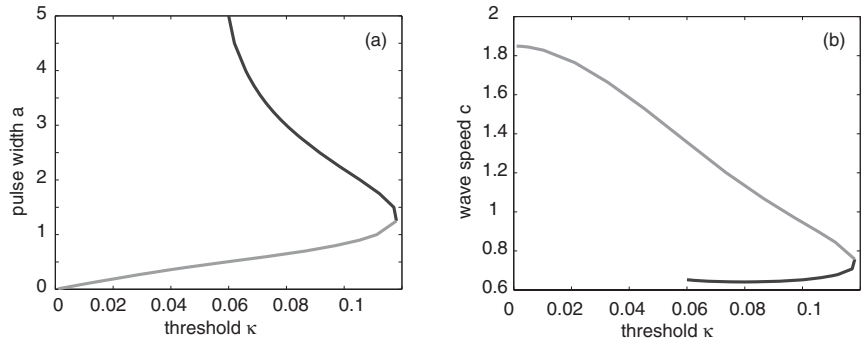

FIG. 3.2. *Existence of right-moving traveling pulses in the case of a shifted weight distribution* $w(x) = w_0(x - x_0)$ *with* $w_0(x)$ *given by the difference-of-exponentials* (2.8) *for* $\sigma_E = 1.8, \sigma_I = 1.0, \Gamma = 0.5$, *and* $x_0 = 0.5$. (a) *Plot of pulse width* a *against threshold* κ. (b) *Plot of wave speed* c *against threshold* κ. *Black (gray) curves denote stable (unstable) branches.*

for $x_0 - a < \xi < x_0$, and

$$\sigma U_\sigma(\xi) = \left[\left(\frac{2c^2\sigma^2}{c^2\sigma^2 - 1}\right) \mathrm{e}^{-(x_0-\xi-a)/c} - \frac{\mathrm{e}^{-(x_0-\xi-a)\sigma}}{c\sigma - 1}\right] - \left[\left(\frac{2c^2\sigma^2}{c^2\sigma^2 - 1}\right) \mathrm{e}^{-(x_0-\xi)/c} - \frac{\mathrm{e}^{-(x_0-\xi)\sigma}}{c\sigma - 1}\right]$$

for $\xi < x_0 - a$. Note that there are two existence branches corresponding, respectively, to narrow fast waves and wide slow waves. Given that wide pulses are stable in the stationary case (see Figure 2.1), we expect the slow branch to be stable, as can be confirmed numerically. This should be contrasted with traveling pulses in excitatory networks, where the fast branch is stable (see section 4). For the parameter values chosen in Figure 3.2, a stable pulse has a speed lying within the interval $0.6 < c < 0.8$ so that $\sigma_I < c^{-1} < \sigma_E$. Thus the dominant rate of decay for both the leading and trailing edges is σ_I. Note that if the units of length and time are taken to be 200μm and 10ms, respectively, then $c = 1$ corresponds to a wave speed of $2\mathrm{cms}^{-1}$, which is consistent with the range of speeds observed experimentally in cortical slices [20].

3.2. Singular perturbation theory. Suppose that there is a set of well separated exponentially decaying right-moving pulses. Following Elphick, Meron, and Spiegel [10], we now extend the singular perturbation theory of stationary pulses by working in the moving frame $\xi = x - ct$, where c is the speed of an isolated pulse. That is, we search for a traveling N-pulse solution with individual pulses having centers at $\xi_n = nd + \phi_n(\tau)$, where $\tau = \varepsilon t$ and $\varepsilon = \mathrm{e}^{-\rho d}$ with $\rho = \min\{\sigma, c^{-1}\}$:

$$u(\xi, \tau) = \sum_{n=1}^{N} U(\xi - nd - \phi_n(\tau)) + \varepsilon R(\xi, \tau). \tag{3.8}$$

Substituting (3.8) into (2.1) with $\partial_t \to \partial_t + \varepsilon\partial_\tau$, and performing an expansion in ε along lines identical to those of section 2, leads to the inhomogeneous equation (2.19), with the modified linear operator

$$\widehat{L}\psi = \psi - c\partial_\xi\psi - w * \left[\delta\left(\sum_{n=1}^{N} U_n - \kappa\right)\psi\right]. \tag{3.9}$$

The corresponding adjoint operator is now

$$\widehat{L}^{\dagger}\psi = \psi + c\partial_{\xi}\psi - \delta\left(\sum_{n=1}^{N} U_n - \kappa\right) w^T * \psi, \tag{3.10}$$

where $w^T(\xi) = w(-\xi) \neq w(\xi)$, since w is asymmetric. By differentiating (3.1), it can be seen that for largely separated pulses the functions U_n' are $\mathcal{O}(\varepsilon)$ null vectors of the operator $\widehat{L}$. This motivates us to seek $\mathcal{O}(\varepsilon)$ null vectors of the adjoint operator (3.10).

Proceeding along lines identical to those of section 2, we first decompose $\widehat{L}^{\dagger}$ according to (2.30) with

$$\widehat{L}_n^{\dagger}\psi = \psi + c\partial_{\xi}\psi - \delta(U_n - \kappa)w^T * \psi \tag{3.11}$$

and

$$\delta(U_n - \kappa) = \frac{\delta(\xi + a)}{U'(-a)} + \frac{\delta(\xi)}{|U'(0)|}. \tag{3.12}$$

We then look for null vectors $\mathcal{P}$ of $\widehat{L}_0^{\dagger}$ with $\xi_0 = 0$:

$$\mathcal{P}(\xi) + c\partial_{\xi}\mathcal{P}(\xi) = \left[\frac{\delta(\xi + a)}{U'(-a)} + \frac{\delta(\xi)}{|U'(0)|}\right] \int_{-\infty}^{\infty} w(\xi' - \xi)\mathcal{P}(\xi')d\xi'. \tag{3.13}$$

This has the formal solution

$$\mathcal{P}(\xi) = p_1 H(\xi + a)\mathrm{e}^{-(\xi+a)/c} - p_2 H(\xi)\mathrm{e}^{-\xi/c}, \tag{3.14}$$

with

$$p_1 c = \frac{1}{U'(-a)}\left[p_1 \int_0^{\infty} w(\xi)\mathrm{e}^{-\xi/c}d\xi - p_2 \int_0^{\infty} w(\xi + a)\mathrm{e}^{-\xi/c}d\xi\right]$$

and

$$p_2 c = -\frac{1}{|U'(0)|}\left[p_1 \int_0^{\infty} w(\xi - a)\mathrm{e}^{-\xi/c}d\xi - p_2 \int_0^{\infty} w(\xi)\mathrm{e}^{-\xi/c}d\xi\right].$$

Up to a scalar multiplication, the pair of algebraic equations for the coefficients p_1, p_2 has the solution

$$p_1 = \int_0^{\infty} w(\xi + a)\mathrm{e}^{-\xi/c}d\xi, \qquad p_2 = \int_0^{\infty} w(\xi - a)\mathrm{e}^{-\xi/c}d\xi. \tag{3.15}$$

In order to prove this, differentiate (3.3) with respect to ξ using (2.5):

$$U'(\xi) = \frac{1}{c}\int_0^{\infty} (w(\xi' + \xi + a) - w(\xi' + \xi))\mathrm{e}^{-\xi'/c}d\xi'. \tag{3.16}$$

Setting $\xi = 0$ and $\xi = -a$ then leads to the following equations for $U'(-a)$ and $|U'(0)|$:

$$\begin{aligned} U'(-a) &= \frac{1}{c}\int_0^{\infty} [w(\xi) - w(\xi - a)]\,\mathrm{e}^{-\xi/c}d\xi, \\ |U'(0)| &= \frac{1}{c}\int_0^{\infty} [w(\xi) - w(\xi + a)]\,\mathrm{e}^{-\xi/c}d\xi. \end{aligned} \tag{3.17}$$

It is now straightforward to verify (3.15).

Following the same arguments as section 2, we conclude that (2.28) has solutions of the form $P_n(\xi) = \mathcal{P}(\xi - \xi_n)$, with $\mathcal{P}$ given by (3.14) and (3.15). A dynamical equation for the pulse positions ξ_n can then be derived by taking the inner product of (2.19) with P_n, which yields an equation of the form (2.36). Substituting (3.14) and (3.12) into (2.36), we find that

$$\begin{aligned}\langle P_m \,|w * \delta(U_m - \kappa)[U_{m+1} + U_{m-1}]\rangle \\ = p_1 c\,(U(-a + \xi_m - \xi_{m+1}) + U(-a + \xi_m - \xi_{m-1})) \\ - p_2 c(U(\xi_m - \xi_{m+1}) + U(\xi_m - \xi_{m-1})),\end{aligned} \tag{3.18}$$

and $\langle P_m | U'_m \rangle = \langle \mathcal{P} | U' \rangle = K$, where

$$K = p_1 \int_0^\infty \mathrm{e}^{-\xi/c} U'(\xi - a) d\xi - p_2 \int_0^\infty \mathrm{e}^{-\xi/c} U'(\xi) d\xi. \tag{3.19}$$

Hence, (2.36) reduces to the form

$$\dot{\xi}_m = f_R(\xi_{m+1} - \xi_m) + f_L(\xi_m - \xi_{m-1}), \tag{3.20}$$

for $\xi_m(t) = nd + \phi_m(\varepsilon t)$, with

$$f_R(\xi) = \frac{c}{K}\left[p_2 U(-\xi) - p_1 U(-\xi - a)\right], \qquad f_L(\xi) = \frac{c}{K}\left[p_2 U(\xi) - p_1 U(\xi - a)\right], \tag{3.21}$$

and $U(\xi)$ determined from the underlying weight distribution according to (3.5).

3.3. Traveling wave trains. Lattice equations of the form (3.20) have been studied in considerable detail within the context of diffusive excitable systems and fluids [10, 2, 37]. Here we illustrate some of the basic results by explicitly calculating the interaction functions f_L, f_R. We define a traveling wave train as an N-pulse solution of (3.20) in which $\dot{\xi}_m = \delta c$ independently of m, where δc is a constant velocity in the frame of an isolated pulse. The spacings between pulses are then fixed, and we obtain the so-called pattern map [10]

$$\delta c = f_R(\Delta_{m+1}) + f_L(\Delta_m), \quad \Delta_m = \xi_m - \xi_{m-1}. \tag{3.22}$$

As a further simplification, we impose periodic boundary conditions by taking the pulses to be moving on a ring of length L with $\xi_0 = \xi_N$ and $\xi_{N+1} = \xi_0$. The simplest solution of (3.22) is then the fixed point $\Delta_m = \Delta = L/N$ for all m. The fixed point equation $\delta c = f_R(\Delta) + f_L(\Delta)$ determines the relationship between the total speed of the wave train $c + \delta c$ and the uniform spacing Δ between neighboring pulses. Linearizing (3.20) about the uniformly spaced wave train by setting $\xi_m = m\Delta + \delta c t + \theta_m$ gives

$$\dot{\theta}_m = f'_R(\Delta)\left[\alpha\theta_{m-1} - (1 + \alpha)\theta_m + \theta_{m+1}\right] \tag{3.23}$$

with $\alpha = -f'_L(\Delta)/f'_R(\Delta)$. This has eigensolutions of the form $\theta_m(t) = \mathrm{e}^{\lambda(k)t}\mathrm{e}^{imk}$

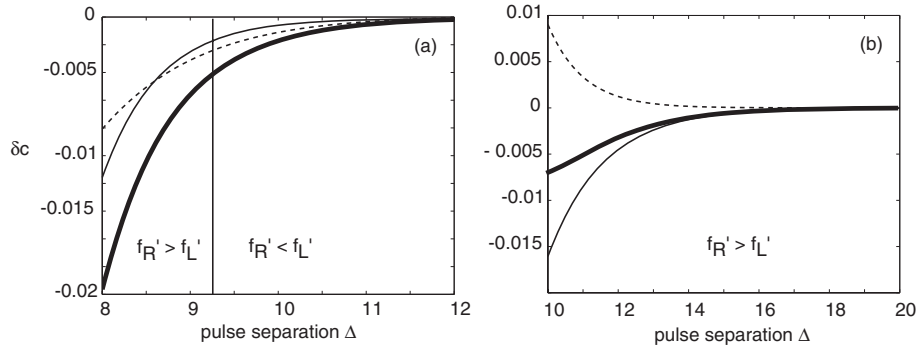

FIG. 3.3. *Plot of $\delta c = f_L(\Delta) + f_R(\Delta)$ against Δ (thick curves) in the case of a shifted weight distribution $w(x) = w_0(x - x_0)$, with $w_0(x)$ given by the difference-of-exponentials* (2.8) *for $\sigma_E = 1.8, \sigma_I = 1.0, \Gamma = 0.5$. Also shown are the plots of $f_L(\Delta)$ (dashed curves) and $f_R(\Delta)$ (thin curves).* (a) *$x_0 = 0.5$, $a = 5$, and $c = 0.65$.* (b) *$x_0 = 1$, $a = 4$, and $c = 1.58$. In both cases, the pulse width and speed of an isolated pulse are chosen to lie on the stable existence branch.*

with wavenumber $k = 2\pi p/N$ for $p = 1, \ldots, N$ and

$$\lambda(k) = -f_R'(\Delta)\left[(1+\alpha)(1-\cos(k)) \pm i(1-\alpha)\sin(k)\right]. \tag{3.24}$$

The condition for (marginal) stability of the uniformly spaced wave train is thus $f_R'(\Delta) > f_L'(\Delta)$. For the sake of illustration, consider the case of an asymmetric Mexican hat weight distribution $w(x) = w_0(x - x_0)$, with w_0 given by the difference-of-exponentials (2.8). Let the unperturbed pulse width a and speed c correspond to a solitary wave on the stable slow branch; see Figure 3.2. Two examples of dispersion curves δc versus Δ are shown in Figure 3.3. In (a), one sees that there exists a finite range of separations Δ for which $f_R'(\Delta) > f_L'(\Delta)$, corresponding to a finite band of stable wave trains. Similarly, (b) shows an example of a semi-infinite band of stable wave trains. In both examples, a given wave train moves more slowly than an isolated pulse, since $\delta c = f_L(\Delta) + f_R(\Delta) < 0$. Which wave train is actually selected will depend on initial conditions.

Suppose that we now allow for the possibility of an oscillatory weight distribution such as (2.11). If $\sigma_I < c^{-1}$, then the leading and trailing edges both consist of exponentially decaying spatial oscillations, so that for widely separated pulses the lattice dynamics takes the form

$$\begin{aligned}\dot{\xi}_m = {} & A_R \mathrm{e}^{-\sigma(\xi_{m+1}-\xi_m)} \cos(\omega(\xi_{m+1}-\xi_m) - \Phi_R) \\ & + A_L \mathrm{e}^{-\sigma(\xi_m - \xi_{m-1})} \cos(\omega(\xi_m - \xi_{m-1}) - \Phi_L).\end{aligned} \tag{3.25}$$

In the case of oscillatory interaction functions, the associated pattern map (3.22) can generate nontrivial sequences of pulse intervals $\{\ldots \Delta_{m-1}, \Delta_m, \Delta_{m+1}, \ldots\}$, including possibly chaotic sequences [17]. From a dynamical systems perspective, such wave trains can be reinterpreted in terms of nearly homoclinic orbits [2].

4. Traveling pulses in excitatory networks with adaptation. As our final example, let us return to the case of a symmetric weight distribution w, but now take w to be purely excitatory, as in the case of a disinhibited cortical slice [34]. In the absence of lateral inhibition, the scalar equation (2.1) no longer supports localized persistent states of activity but does exhibit traveling front solutions. In order to

obtain traveling localized pulses, it is necessary to introduce some form of adaptation. Therefore, following Pinto and Ermentrout [34], we extend the basic Amari model by considering the following system of equations:

$$\begin{aligned} \frac{\partial u(x,t)}{\partial t} &= -u(x,t) + \int_{-\infty}^{\infty} w(x-x')H(u(x',t)-\kappa)dx' - \beta v(x,t), \\ \frac{\partial v(x,t)}{\partial t} &= \gamma[-v(x,t)+u(x,t)], \end{aligned} \tag{4.1}$$

where $v(x,t)$ represents some form of negative feedback mechanism such as spike frequency adaptation or synaptic depression, with β, γ determining the relative strength and rate of feedback. We will extend the singular perturbation theory of section 3 in order to investigate traveling N-pulse solutions of (4.1) in the case of a positive exponentially decaying weight distribution w.

4.1. Traveling solitary pulses. In contrast to the asymmetric lateral inhibition network of section 3, the excitatory network given by (4.1) supports bidirectional wave propagation. Without loss of generality, let us consider a right-moving traveling pulse solution of the form $(u(x,t), v(x,t)) = (U(x-ct), V(x-ct))$ with $U(\pm\infty), V(\pm\infty) = 0$ and $U(-a) = U(0) = \kappa$. Substituting into (4.1) with $\xi = x - ct$ gives

$$\begin{aligned} -c\partial_\xi U(\xi) + U(\xi) + \beta V(\xi) &= \int_{-\infty}^{\infty} w(\xi-\xi')H(U(\xi')-\kappa)d\xi', \\ -c\partial_\xi V(\xi) + \gamma[V(\xi)-U(\xi)] &= 0. \end{aligned} \tag{4.2}$$

It is useful to rewrite (4.2) in the matrix form

$$\begin{pmatrix} 1 & \beta \\ -\gamma & \gamma \end{pmatrix} \begin{pmatrix} U \\ V \end{pmatrix} - c\partial_\xi \begin{pmatrix} U \\ V \end{pmatrix} = [W(\xi+a) - W(\xi)] \begin{pmatrix} 1 \\ 0 \end{pmatrix}. \tag{4.3}$$

We proceed by diagonalizing the left-hand side of (4.3) using the right eigenvectors $\mathbf{v}$ of the matrix

$$\mathbf{M} = \begin{pmatrix} 1 & \beta \\ -\gamma & \gamma \end{pmatrix}. \tag{4.4}$$

These are given by

$$\mathbf{v}_\pm = \begin{pmatrix} \gamma - \lambda_\pm \\ \gamma \end{pmatrix}, \tag{4.5}$$

with corresponding eigenvalues

$$\lambda_\pm = \frac{1}{2}\left[1 + \gamma \pm \sqrt{(1+\gamma)^2 - 4\gamma(1+\beta)}\right]. \tag{4.6}$$

Note that $\mathbf{v}_\pm e^{\lambda_\pm \xi/c}$ are the corresponding null vectors of the linear operator on the left-hand side of (4.3); that is, they generate the complementary solution. Performing the transformation

$$\begin{pmatrix} \widetilde{U} \\ \widetilde{V} \end{pmatrix} = \mathbf{T}^{-1} \begin{pmatrix} U \\ V \end{pmatrix}, \quad \mathbf{T} = \begin{pmatrix} \mathbf{v}_+ & \mathbf{v}_- \end{pmatrix}, \tag{4.7}$$

then gives the pair of equations

$$-c\partial_\xi \widetilde{U} + \lambda_+ \widetilde{U} = \eta_+[W(\xi+a) - W(\xi)],$$
$$-c\partial_\xi \widetilde{V} + \lambda_- \widetilde{V} = \eta_-[W(\xi+a) - W(\xi)], \tag{4.8}$$

with $\eta_\pm = \mp 1/(\lambda_+ - \lambda_-)$. Integrating the equation for $\widetilde{U}$ from $-a$ to ∞, we have

$$\widetilde{U}(\xi) = \mathrm{e}^{\lambda_+\xi/c}\left[\widetilde{U}(-a)\mathrm{e}^{a\lambda_+/c} - \frac{\eta_+}{c}\int_{-a}^{\xi} \mathrm{e}^{-\lambda_+\xi'/c}[W(\xi'+a) - W(\xi')]d\xi'\right]. \tag{4.9}$$

Finiteness of $\widetilde{U}$ in the limit $\xi \to \infty$ requires that the term in square brackets cancel. Hence, we can eliminate $\widetilde{U}(-a)$ to obtain the result

$$\widetilde{U}(\xi) = \frac{\eta_+}{c}\int_0^\infty \mathrm{e}^{-\lambda_+\xi'/c}[W(\xi'+\xi+a) - W(\xi'+\xi)]d\xi'. \tag{4.10}$$

Similarly,

$$\widetilde{V}(\xi) = \frac{\eta_-}{c}\int_0^\infty \mathrm{e}^{-\lambda_-\xi'/c}[W(\xi'+\xi+a) - W(\xi'+\xi)]d\xi'. \tag{4.11}$$

Performing the inverse transformation $U = (\gamma - \lambda_+)\widetilde{U} + (\gamma - \lambda_-)\widetilde{V}$, we have

$$U(\xi) = \frac{1}{c}\int_0^\infty \left[\chi_+\mathrm{e}^{-\lambda_+\xi'/c} + \chi_-\mathrm{e}^{-\lambda_-\xi'/c}\right][W(\xi'+\xi+a) - W(\xi'+\xi)]d\xi', \tag{4.12}$$

with $\chi_\pm = (\gamma - \lambda_\pm)\eta_\pm$. Using $\lambda_+ + \lambda_- = 1 + \gamma$, we can rewrite $\chi_\pm$ as

$$\chi_+ = \frac{1-\lambda_-}{\lambda_+ - \lambda_-}, \qquad \chi_- = \frac{\lambda_+ - 1}{\lambda_+ - \lambda_-}. \tag{4.13}$$

The threshold conditions $U(-a) = \kappa$ and $U(0) = \kappa$ then yield a pair of equations whose solutions determine existence curves relating the speed c and width a of a pulse to the threshold κ [34].

For the sake of illustration, let w be given by the exponential function (2.8) with $\Gamma = 0$ and $\sigma_E = \sigma$; that is, $w(x) = \mathrm{e}^{-\sigma|x|}$. In the domain $\xi > 0$, there is a common factor of $\mathrm{e}^{-\sigma\xi}$ in the integrand of (4.12) so that $U(\xi) = \kappa\mathrm{e}^{-\sigma\xi}$ for $\xi > 0$, provided that

$$\kappa = \frac{(c\sigma + \gamma)(1 - \mathrm{e}^{-a\sigma})}{c^2\sigma^2 + c\sigma(1+\gamma) + \gamma(1+\beta)}. \tag{4.14}$$

On the other hand, when $\xi < 0$, one has to partition the integral of (4.12) into the separate domains $\xi' > |\xi|$, $|\xi| - a < \xi' < |\xi|$, and $\xi' < |\xi| - a$. This then determines the second threshold condition as well as the asymptotic behavior of $U(\xi)$ in the limit $\xi \to -\infty$:

$$U(\xi) = U_+\mathrm{e}^{\lambda_+\xi/c} + U_-\mathrm{e}^{\lambda_-\xi/c} + U_0\mathrm{e}^{\sigma\xi}, \tag{4.15}$$

where the amplitudes $U_\pm$ and U_0 can be determined from matching conditions at the threshold crossing points [34, 15]. Note that the leading edge of the pulse is positive, whereas the trailing edge is negative due to the effects of adaptation. One finds that for sufficiently slow negative feedback (small γ) and large β there exist two pulse solutions, one narrow and slow and the other wide and fast. This is illustrated in Figure 4.1. Numerically, the fast solution is found to be stable [34]. Its stability can also be established analytically using Evans function techniques [44, 8, 16].

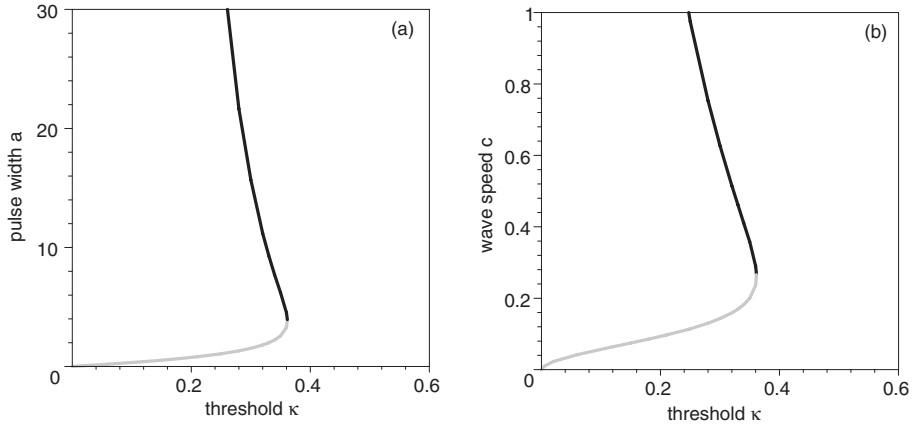

FIG. 4.1. *Existence of right-moving traveling pulses in the case of the excitatory network* (4.1) *for an exponential weight distribution with* $w(x) = e^{-\sigma|x|}$. *Here* $\sigma = 1, \gamma = 0.01$, *and* $\beta = 2.5$. (a) *Plot of pulse width* a *against threshold* κ. (b) *Plot of wave speed* c *against threshold* κ. *Stable (unstable) branches indicated by black (gray) curves.*

4.2. Singular perturbation theory. Suppose that (4.1) has a stable right-moving pulse solution $U(\xi)$ of width a and speed c. Following the model set by section 3, we search for a traveling N-pulse solution with individual pulses having centers at $\xi_n = nd + \phi_n(\tau)$, where $\tau = \varepsilon t$ and $\varepsilon = \mathrm{e}^{-\rho d}$ with $\rho = \min\{c^{-1}\lambda_{\pm}, \sigma\}$:

$$
\begin{aligned}
u(\xi,\tau) &= \sum_{n=1}^{N} U(\xi - nd - \phi_n(\tau)) + \varepsilon R(\xi,\tau),\\
v(\xi,\tau) &= \sum_{n=1}^{N} V(\xi - nd - \phi_n(\tau)) + \varepsilon \overline{R}(\xi,\tau).
\end{aligned}
\tag{4.16}
$$

Substituting (4.16) into (4.1) with $\partial_t \to \partial_t + \varepsilon\partial_\tau$, and using (4.2), gives

$$
\begin{aligned}
&-c\varepsilon\partial_\xi R + \varepsilon^2\partial_\tau R - \varepsilon\sum_{n=1}^{N}\dot{\phi}_n U_n'\\
&\qquad = -\varepsilon(R + \beta\overline{R}) + w * H\left(\sum_{n=1}^{N} U_n + \varepsilon R - \kappa\right) - w * \sum_{n=1}^{N} H(U_n - \kappa),\\
&-c\varepsilon\partial_\xi \overline{R} + \varepsilon^2\partial_\tau \overline{R} - \varepsilon\sum_{n=1}^{N}\dot{\phi}_n V_n' = -\varepsilon\gamma(\overline{R} - R).
\end{aligned}
\tag{4.17}
$$

Performing an expansion to $\mathcal{O}(\varepsilon)$ along lines identical to section 2 leads to the inhomogeneous equation

$$
\widehat{L}\begin{pmatrix} R \\ \overline{R} \end{pmatrix} = \sum_{n=1}^{N}\dot{\phi}_n\begin{pmatrix} U_n' \\ V_n' \end{pmatrix} + \frac{1}{\varepsilon} w * \left[H\left(\sum_{n=1}^{N} U_n - \kappa\right) - \sum_{n=1}^{N} H(U_n - \kappa)\right]\begin{pmatrix} 1 \\ 0 \end{pmatrix},
\tag{4.18}
$$

with the linear operator $\widehat{L}$ given by

$$\widehat{L}\psi = \begin{pmatrix} 1 & \beta \\ -\gamma & \gamma \end{pmatrix} \psi - c\partial_\xi \psi - w * \left[\delta \left(\sum_{n=1}^{N} U_n - \kappa \right) \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \psi \right], \tag{4.19}$$

where ψ now denotes a two-vector rather than a scalar. Differentiating (4.2) and using arguments similar to those of section 2, it is straightforward to show that $\widehat{L}(U_n', V_n')^{tr} = \mathcal{O}(\varepsilon)$ for all $n = 1, \ldots, N$. This again motivates us to seek $\mathcal{O}(\varepsilon)$ null vectors of the adjoint operator.

In order to determine the corresponding solvability conditions on (4.18), we seek weak solutions $(P, \overline{P})$ of the equation

$$\left\langle \widehat{L}^\dagger \begin{pmatrix} P \\ \overline{P} \end{pmatrix} \middle| \begin{pmatrix} Q \\ \overline{Q} \end{pmatrix} \right\rangle = \mathcal{O}(\varepsilon) \tag{4.20}$$

for arbitrary bounded functions $Q, \overline{Q}$, where $\widehat{L}^\dagger$ is the adjoint operator

$$\widehat{L}^\dagger \psi = \begin{pmatrix} 1 & -\gamma \\ \beta & \gamma \end{pmatrix} \psi + c\partial_\xi \psi - \delta \left(\sum_{n=1}^{N} U_n - \kappa \right) w * \left[\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \psi \right]. \tag{4.21}$$

The inner product is defined by first taking the dot product of the two vectors and then integrating over $\mathbf{R}$. Using the perturbation expansion (2.29) with $\delta(U_n - \kappa)$ given by (3.12), we obtain the following formal decomposition:

$$\widehat{L}^\dagger \psi = \widehat{L}_n^\dagger \psi - \sum_{j \neq n} \delta(U_j - \kappa) w * \left[\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \psi \right] + \mathcal{O}(\varepsilon) \tag{4.22}$$

for any $n = 1, \ldots, N$, with

$$\widehat{L}_n^\dagger \psi = \begin{pmatrix} 1 & -\gamma \\ \beta & \gamma \end{pmatrix} \psi + c\partial_\xi \psi - \delta(U_n - \kappa) w * \left[\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \psi \right]. \tag{4.23}$$

We now look for null vectors of $\widehat{L}_0^\dagger$ with $\xi_0 = 0$. We proceed by partially diagonalizing $\widehat{L}_0^\dagger$ using the left eigenvectors $\widetilde{\mathbf{v}}$ of the matrix $\mathbf{M}$ (see (4.4)):

$$\widetilde{\mathbf{v}}_\pm = \begin{pmatrix} \gamma \\ 1 - \lambda_\pm \end{pmatrix}. \tag{4.24}$$

Introducing the transformation

$$\begin{pmatrix} \mathcal{Q} \\ \overline{\mathcal{Q}} \end{pmatrix} = \widetilde{\mathbf{T}}^{-1} \begin{pmatrix} \mathcal{P} \\ \overline{\mathcal{P}} \end{pmatrix}, \quad \widetilde{\mathbf{T}} = \begin{pmatrix} \widetilde{\mathbf{v}}_+ & \widetilde{\mathbf{v}}_- \end{pmatrix}, \tag{4.25}$$

then leads to the following pair of equations:

$$c\partial_\xi \mathcal{Q} + \lambda_+ \mathcal{Q} = \chi_+ \delta(U - \kappa) w * [\mathcal{Q} + \overline{\mathcal{Q}}], \tag{4.26}$$

$$c\partial_\xi \overline{\mathcal{Q}} + \lambda_- \overline{\mathcal{Q}} = \chi_- \delta(U - \kappa) w * [\mathcal{Q} + \overline{\mathcal{Q}}], \tag{4.27}$$

with $\chi_\pm$ defined by (4.13). Using an analysis similar to that of section 3, we obtain the solution

$$\begin{aligned} \mathcal{Q}(\xi) &= \chi_+ \left[p_1 H(\xi + a) \mathrm{e}^{-\lambda_+(\xi+a)/c} - p_2 H(\xi) \mathrm{e}^{-\lambda_+ \xi/c} \right], \\ \overline{\mathcal{Q}}(\xi) &= \chi_- \left[p_1 H(\xi + a) \mathrm{e}^{-\lambda_-(\xi+a)/c} - p_2 H(\xi) \mathrm{e}^{-\lambda_- \xi/c} \right], \end{aligned} \tag{4.28}$$

with p_1, p_2 given by (3.15) and $U'(0), U'(-a)$ satisfying the self-consistency conditions

$$c = \frac{1}{U'(-a)} \int_0^\infty [w(\xi) - w(\xi - a)] \left[\chi_+ \mathrm{e}^{-\lambda_+ \xi/c} + \chi_- \mathrm{e}^{-\lambda_- \xi/c}\right] d\xi,$$

$$c = \frac{1}{U'(0)} \int_0^\infty [w(\xi + a) - w(\xi)] \left[\chi_+ \mathrm{e}^{-\lambda_+ \xi/c} + \chi_- \mathrm{e}^{-\lambda_- \xi/c}\right] d\xi. \tag{4.29}$$

The latter follow immediately from differentiating (4.12) and setting $\xi = 0, -a$. Finally, we perform the inverse transformation on $\mathcal{Q}, \overline{\mathcal{Q}}$ to obtain $\mathcal{P}, \overline{\mathcal{P}}$:

$$\begin{pmatrix} \mathcal{P}(\xi) \\ \overline{\mathcal{P}}(\xi) \end{pmatrix} = \chi_+ \begin{pmatrix} \gamma \\ 1 - \lambda_+ \end{pmatrix} \left[p_1 H(\xi + a) \mathrm{e}^{-\lambda_+(\xi+a)/c} - p_2 H(\xi) \mathrm{e}^{-\lambda_+ \xi/c}\right] + \chi_- \begin{pmatrix} \gamma \\ 1 - \lambda_- \end{pmatrix} \left[p_1 H(\xi + a) \mathrm{e}^{-\lambda_-(\xi+a)/c} - p_2 H(\xi) \mathrm{e}^{-\lambda_- \xi/c}\right]. \tag{4.30}$$

From translation symmetry, it follows that $\widehat{L}_n^\dagger$ has the null vector $(P_n, \overline{P}_n)$ with

$$P_n(\xi) = \mathcal{P}(\xi - \xi_n), \quad \overline{P}_n(\xi) = \overline{\mathcal{P}}(\xi - \xi_n). \tag{4.31}$$

Hence, applying the decomposition (4.22), we see that

$$\left\langle \widehat{L}^\dagger \begin{pmatrix} P_n \\ \overline{P}_n \end{pmatrix} \middle| \begin{pmatrix} Q \\ \overline{Q} \end{pmatrix} \right\rangle = -\sum_{j \neq n} \langle \delta(U_j - \kappa) w * P_n | Q \rangle + \mathcal{O}(\varepsilon). \tag{4.32}$$

Equations (4.30) and (4.31) imply that $P_n, \overline{P}_n$ are zero for $\xi < \xi_n - a$ and exponentially decaying for $\xi > \xi_n - a$. Evaluating the inner product on the right-hand side of (4.32) establishes that it is also $\mathcal{O}(\varepsilon)$. We conclude that (4.20) has the set of solutions $(P_n, \overline{P}_n)$, $n = 1, \ldots, N$. We now take the inner product of (4.18) with respect to the vector $(P_m, \overline{P}_m)$ for some integer $m, m = 1, \ldots, N$, and use (2.23):

$$\dot{\phi}_m \left\langle \begin{pmatrix} P_m \\ \overline{P}_m \end{pmatrix} \middle| \begin{pmatrix} U_m' \\ V_m' \end{pmatrix} \right\rangle + \frac{1}{\varepsilon} \langle P_m | w * \delta(U_m - \kappa)[U_{m+1} + U_{m-1}] \rangle = \mathcal{O}(\varepsilon). \tag{4.33}$$

Evaluating the various inner products using (4.30) and (3.12) leads to the same (3.20) and (3.21) as the scalar case, with

$$K = \gamma^{-1} \left\langle \begin{pmatrix} \mathcal{P} \\ \overline{\mathcal{P}} \end{pmatrix} \middle| \begin{pmatrix} U' \\ V' \end{pmatrix} \right\rangle. \tag{4.34}$$

However, there is a significant difference in the asymptotic behavior of the interaction functions f_L, f_R when compared to the scalar case. This is due to the fact that adaptation is slow ($\gamma \ll 1$) so that $\lambda_- \approx 0$, and thus the leading edge decays much faster than the trailing edge; see (4.6) and (4.15). Hence, we can neglect the interaction term f_L in (3.20) to obtain

$$\dot{\xi}_m = f_R(\xi_{m+1} - \xi_m) \tag{4.35}$$

with $f_R(\Delta) \sim -\mathrm{e}^{-\lambda_- \Delta/c}$. In this case the dynamics of the pulse position ξ_m depends only on the distance to the proceeding pulse $\Delta_m = \xi_{m+1} - \xi_m$ and can thus be reformulated within a kinematic framework [11, 33]. This is based on the observation that the function f_R directly determines the dispersion relation between the speed C and the pulse separation Δ of a uniformly spaced wave train, $C(\Delta) = f_R(\Delta) + c$. Thus

$$\dot{\xi_m} = C(\Delta_m) - c. \tag{4.36}$$

The condition for stability of a uniform wave train on a ring is then $f_R'(\Delta) > 0$.

5. Discussion. In this paper we have used perturbation methods to develop a theory of weakly interacting pulses in one-dimensional neuronal networks. We have shown how the pulse interactions explicitly depend on the form of the long-range synaptic coupling, and investigated how this determines the existence and stability of multipulse solutions. For simplicity, we have assumed throughout that the network is homogeneous: the coupling depends only on the distance between interacting elements in the network, and external inputs have been ignored. In a recent series of papers, we have shown that introducing a localized inhomogeneous input can generate oscillatory coherent states in the form of standing and traveling breathing pulses [5, 15, 16]. It would be interesting to develop a theory of weakly interacting breathers and to determine under what conditions long-range synaptic coupling can provide a mechanism for synchronizing the oscillations between breathers. This would provide an alternative way of thinking about stimulus-induced coherent oscillations in cortex, which are observed *in vivo* during periods of sensory processing [21, 14].

BLOCKING PROBABILITIES FOR AN UNDERLOADED OR OVERLOADED LINK WITH TRUNK RESERVATION*

CHARLES KNESSL† AND JOHN A. MORRISON‡

Abstract. A single link in a circuit-switched network is considered. The link has C circuits, R of which are reserved for the primary traffic. Offered calls arrive in independent Poisson streams with mean rates λ and ν for the primary and secondary traffic, respectively, and corresponding independent and exponentially distributed holding times with means 1 and $1/\kappa$. Both primary and secondary calls require 1 circuit. A primary call is blocked on arrival if all C circuits are busy, whereas a secondary call is blocked if more than $C - R - 1$ circuits are busy. Blocked calls are lost to the link. It is assumed that $R = O(1)$ and $\lambda \gg 1$, $\nu = O(\lambda)$ and $C = O(\lambda)$, and that the link is either underloaded, corresponding to $\lambda + \nu/\kappa < C$, or overloaded, corresponding to $\lambda + \nu/\kappa > C$. Asymptotic approximations to the blocking probabilities B_1 and B_2 of the primary and secondary calls, respectively, are derived. Numerical results are presented to illustrate the accuracy of the approximations.

Key words. queueing, blocking, trunk reservation, asymptotics

DOI. 10.1137/S0036139903426599

1. Introduction.

The concept of trunk reservation is of fundamental importance in circuit-switched communication networks. On any link of the network, which has a fixed number of circuits, some of them may be reserved for the primary traffic which is offered directly to the link. Secondary traffic, which is rerouted because of a busy link on its direct route, is accepted on an alternate link only if there are enough unreserved links available. State-dependent routing on symmetric loss networks with trunk reservation has been investigated by Mitra, Gibbens, and Huang [4], [5] and Mitra and Gibbens [3]. Basic to the investigations is an analysis of a single link. The network is then analyzed by means of fixed point approximations [1], [2] which are based on the assumption that each link acts independently; the traffic streams which are Poisson when offered to the network remain Poisson when offered to the links by virtue of this assumption.

The investigation of a single link with trunk reservation is also of interest when integrated traffic is considered. Thus, some classes of traffic may have less stringent blocking requirements than others, e.g., voice as compared to data. It is crucial for practical applications to investigate the effect of trunk reservation on the blocking probabilities, since this is a prime quality of service (QoS) requirement. In this paper we obtain asymptotic approximations to these probabilities for two classes under appropriate traffic conditions. The approximations provide insight into the effect of trunk reservation, and they are easily evaluated numerically.

A different aspect has been considered by Hunt and Laws [7] who investigated control policies for a single link in heavy traffic. They allowed for several classes of traffic with different capacity requirements, which earn different rewards for being accepted, rather than blocked and lost. The goal is to maximize the expected reward per unit time. They show that the optimal policy for accepting or rejecting calls offered to the link is of (generalized) trunk reservation from. However, their results do not provide a concrete guideline for setting trunk reservation parameters, but they do suggest an insensitivity to the value of such parameters.

In this paper we consider a single link with C circuits, R of which are reserved for the primary traffic. The offered calls arrive in independent Poisson streams with mean rates λ and ν for the primary and secondary traffic, respectively, and corresponding independent and exponentially distributed holding times with means 1 and $1/\kappa$. Both primary and secondary calls require 1 circuit. A primary call is blocked on arrival if all C circuits are busy, whereas a secondary call is blocked if more than $C-R-1$ circuits are busy. Blocked calls are lost to the link.

When $\kappa = 1$, the single link corresponds to the one investigated by Mitra and Gibbens [3]. Exact expressions for the blocking probabilities B_1 and B_2 of the primary and secondary calls, respectively, may be obtained. Mitra and Gibbens [3] derived asymptotic approximations to B_1 and B_2 under the assumptions $\lambda \gg 1$, $C-\lambda = O(\sqrt{\lambda}\,)$, $R = O(\sqrt{\lambda}\,)$, and $\nu = O(\sqrt{\lambda}\,)$. Since $C-\lambda-\nu/\kappa = O(\sqrt{\lambda}\,)$, the link is critically loaded. Morrison [6] investigated the single link when $\kappa \neq 1$, for which no exact solution is known, by means of singular perturbation techniques. For $\nu = \gamma\sqrt{\lambda}$, he derived the first two terms in the power series expansion in γ of the leading term in the asymptotic approximations to B_1 and B_2. For $R = O(1)$ and $\nu = O(\sqrt{\lambda}\,)$, Morrison [6] obtained explicit expressions for B_1 and B_2.

In this paper we consider $R = O(1)$ and the asymptotic regime $\lambda \gg 1$, $\nu = O(\lambda)$, and $C = O(\lambda)$ for both an underloaded link, corresponding to $\lambda+\nu/\kappa < C$, and for an overloaded link, corresponding to $\lambda+\nu/\kappa > C$. It is assumed that $(\lambda+\nu/\kappa-C)/\lambda$ is not small. The leading term in the asymptotic approximations to B_1 and B_2 is derived. Numerical results are presented to illustrate the accuracy of the approximations.

The paper is organized as follows. In section 2 the problem is formulated, and the asymptotic regime is introduced. An underloaded link is investigated in section 3, and an overloaded one in section 4. The leading term in the lowest order asymptotic approximation to the joint steady-state distribution of the number of primary and secondary calls is investigated for an overloaded link in section 5. Numerical results are presented in section 6. In section 7 we discuss in more detail the ranges of validity of the asymptotic approximations.

2. Formulation. For the model described in the previous section, let $p(n_1, n_2)$ denote the steady-state probability that n_1 primary and n_2 secondary calls are in progress, and let $I(\cdot)$ be the indicator function. Then, by standard arguments,

$$\begin{aligned}
&[\lambda I(n_1+n_2+1 \le C) + \nu I(n_1+n_2+1 \le C-R) + n_1 + \kappa n_2]p(n_1,n_2)\\
&= \lambda I(n_1 \ge 1)p(n_1-1,n_2) + \nu I(n_1+n_2 \le C-R)I(n_2 \ge 1)p(n_1,n_2-1)\\
&\quad + I(n_1+n_2+1 \le C)(n_1+1)p(n_1+1,n_2)\\
&\quad + \kappa I(n_1+n_2+1 \le C)I(n_2+1 \le C-R)(n_2+1)p(n_1,n_2+1),\\
&\qquad n_1 \ge 0, \quad 0 \le n_2 \le C-R, \quad n_1+n_2 \le C. \qquad (2.1)
\end{aligned}$$

The normalization condition is

$$\sum_{n_2=0}^{C-R}\sum_{n_1=0}^{C-n_2} p(n_1,n_2)=1. \tag{2.2}$$

The terms on the right-hand side of (2.1) correspond to different transitions that leave the system with n_1 primary and n_2 secondary customers. The first term corresponds to a primary arrival, the second to a secondary arrival, the third to a primary departure, and the fourth to a secondary departure. The indicator functions show when such a transition is possible; their use allows us to avoid writing down a large number of "boundary equations."

The blocking probabilities B_1 and B_2 of the primary and secondary calls, respectively, are

$$B_1=\sum_{n_1=R}^{C} p(n_1,C-n_1),\quad B_2=\sum_{\ell=0}^{R}\sum_{n_1=\ell}^{C-R+\ell} p(n_1,C-R+\ell-n_1). \tag{2.3}$$

We let

$$n_1=m,\quad n_1+n_2=C-R+\ell,\quad p(n_1,n_2)=P_\ell(m). \tag{2.4}$$

Then, from (2.1)–(2.3), we obtain

$$\begin{aligned}&[\lambda I(\ell\le R-1)+\nu I(\ell\le -1)+m+\kappa(C-R+\ell-m)]P_\ell(m)\\&=\lambda I(m\ge 1)P_{\ell-1}(m-1)+\nu I(\ell\ge 0)I(C-R+\ell-m\ge 1)P_{\ell-1}(m)\\&+I(\ell\le R-1)[(m+1)P_{\ell+1}(m+1)+\kappa I(m\ge \ell+1)(C-R+\ell-m+1)P_{\ell+1}(m)],\end{aligned}$$

$$0\le m\le C,\quad R-C+m\le \ell\le R,\quad R\ge 0, \tag{2.5}$$

$$\sum_{\ell=R-C}^{R}\sum_{m=\max(\ell,0)}^{C-R+\ell} P_\ell(m)=1, \tag{2.6}$$

and

$$B_1=\sum_{m=R}^{C} P_R(m),\quad B_2=\sum_{\ell=0}^{R}\sum_{m=\ell}^{C-R+\ell} P_\ell(m). \tag{2.7}$$

We consider the asymptotic regime in which

$$C-R=\frac{\sigma\lambda}{\kappa},\quad \nu=(\rho-\kappa)\lambda>0,\quad \lambda\gg 1,\quad R=O(1), \tag{2.8}$$

and let

$$m=\zeta\lambda+x\sqrt{\lambda},\quad P_\ell(m)=p_\ell(x),\qquad x=O(1),\quad \ell=O(1), \tag{2.9}$$

where ζ is to be determined, with $0<\zeta<\sigma/\kappa$. Then (2.5) becomes

$$\begin{aligned}&[\lambda I(\ell\le R-1)+(\rho-\kappa)\lambda I(\ell\le -1)+(1-\kappa)(\zeta\lambda+x\sqrt{\lambda}\,)+\sigma\lambda+\kappa\ell]p_\ell(x)\\&=\lambda p_{\ell-1}\left(x-\frac{1}{\sqrt{\lambda}}\right)+(\rho-\kappa)\lambda I(\ell\le 0)p_{\ell-1}(x)\\&\quad+I(\ell\le R-1)\left\{\left(\zeta\lambda+x\sqrt{\lambda}+1\right)p_{\ell+1}\left(x+\frac{1}{\sqrt{\lambda}}\right)\right.\\&\qquad\left.+[(\sigma-\kappa\zeta)\lambda-\kappa x\sqrt{\lambda}+\kappa(\ell+1)]p_{\ell+1}(x)\right\},\quad \ell\le R.\end{aligned} \tag{2.10}$$

We assume that

$$p_\ell(x) = A(\lambda)\left[p_\ell^{(0)}(x) + \frac{1}{\sqrt{\lambda}}p_\ell^{(1)}(x) + O\left(\frac{1}{\lambda}\right)\right]. \tag{2.11}$$

Then, from (2.10), we obtain at the first two orders

$$\begin{aligned}&[I(\ell \le R-1) + (\rho-\kappa)I(\ell \le -1) + \sigma + \zeta - \kappa\zeta]p_\ell^{(0)}(x)\\ &= [1 + (\rho-\kappa)I(\ell \le 0)]p_{\ell-1}^{(0)}(x) + I(\ell \le R-1)(\sigma+\zeta-\kappa\zeta)p_{\ell+1}^{(0)}(x), \quad \ell \le R,\end{aligned} \tag{2.12}$$

and

$$\begin{aligned}&[I(\ell \le R-1) + (\rho-\kappa)I(\ell \le -1) + \sigma + \zeta - \kappa\zeta]p_\ell^{(1)}(x) + (1-\kappa)xp_\ell^{(0)}(x)\\ &= [1 + (\rho-\kappa)I(\ell \le 0)]p_{\ell-1}^{(1)}(x) - \frac{dp_{\ell-1}^{(0)}}{dx}\\ &\quad + I(\ell \le R-1)\left[(\sigma+\zeta-\kappa\zeta)p_{\ell+1}^{(1)}(x) + (1-\kappa)xp_{\ell+1}^{(0)}(x) + \zeta\frac{dp_{\ell+1}^{(0)}}{dx}\right], \quad \ell \le R.\end{aligned} \tag{2.13}$$

It will be shown that $p_\ell^{(0)}(x)$, $0 \le \ell \le R$, is proportional to $\exp(-\beta x^2)$, where $\beta > 0$. Hence, from (2.7), (2.9), and (2.11), the blocking probabilities are asymptotically given by

$$B_1 \sim \sqrt{\lambda}A(\lambda)\int_{-\infty}^{\infty} p_R^{(0)}(x)dx, \qquad B_2 \sim \sqrt{\lambda}A(\lambda)\sum_{\ell=0}^{R}\int_{-\infty}^{\infty} p_\ell^{(0)}(x)dx. \tag{2.14}$$

The constant $A(\lambda)$ will be ultimately determined by the normalization condition (2.6).

3. Underloaded link. We here consider the case $\rho < \sigma$, so that $\lambda + \nu/\kappa < C - R$, and the link is underloaded. In the interior of the admissible region, $p(n_1, n_2)$ is given asymptotically by the solution corresponding to $C = \infty$, since the blocking probabilities will be exponentially small. Hence,

$$p(n_1, n_2) \sim e^{-\lambda}e^{-\nu/\kappa}\frac{\lambda^{n_1}(\nu/\kappa)^{n_2}}{n_1!n_2!}, \qquad 0 \le n_1 + n_2 \ll C - R. \tag{3.1}$$

The precise range of validity of (3.1) is discussed in section 7. If we use Stirling's formula, we find that $p(n_1, n_2)$ attains its maximum for $n_1 \sim \lambda$, $n_2 \sim \nu/\kappa$. Also, for $n_1 \sim \zeta\lambda$ and $n_1 + n_2 = \sigma\lambda/\kappa$, we find that $p(n_1, n_2)$ attains its maximum for $\zeta = \sigma/\rho$, which is the appropriate choice for ζ in (2.9). For

$$n_1 = \frac{\sigma\lambda}{\rho} + x\sqrt{\lambda}, \qquad n_1 + n_2 = \frac{\sigma\lambda}{\kappa} + \ell, \tag{3.2}$$

we obtain from (3.1)

$$p_\ell(x) \sim A(\lambda)\left(\frac{\rho}{\sigma}\right)^\ell \exp\left[-\frac{\rho^2x^2}{2\sigma(\rho-\kappa)}\right], \qquad -\ell \gg 1, \ \frac{-\ell}{\sqrt{\lambda}} \ll 1, \tag{3.3}$$

where

$$A(\lambda) = \frac{e^{(\sigma-\rho)\lambda/\kappa}\left(\frac{\rho}{\sigma}\right)^{\frac{\sigma\lambda}{\kappa}+1}}{2\pi\lambda\sqrt{\frac{\rho}{\kappa}-1}}. \tag{3.4}$$

From (2.12), with $\zeta = \sigma/\rho$, we have

$$\left(1+\frac{\sigma}{\rho}\right) p_\ell^{(0)}(x) = p_{\ell-1}^{(0)}(x) + \frac{\sigma}{\rho} p_{\ell+1}^{(0)}(x), \qquad \ell \le -1. \tag{3.5}$$

Hence, matching with the interior solution (3.3) for $-\ell \gg 1$ and noting that $\rho < \sigma$, we obtain

$$p_\ell^{(0)}(x) = \left(\frac{\rho}{\sigma}\right)^\ell \exp\left[-\frac{\rho^2 x^2}{2\sigma(\rho-\kappa)}\right] + H_0(x), \qquad \ell \le 0. \tag{3.6}$$

Here $H_0(x)$ is to be determined shortly. If $R \ge 1$, then, from (2.12) with $\zeta = \sigma/\rho$, we have

$$\begin{aligned} &\left[I(\ell \le R-1) + \frac{\sigma}{\rho}(1+\rho-\kappa)\right] p_\ell^{(0)}(x) \\ &= p_{\ell-1}^{(0)}(x) + I(\ell \le R-1)\frac{\sigma}{\rho}(1+\rho-\kappa) p_{\ell+1}^{(0)}(x), \qquad 1 \le \ell \le R. \end{aligned} \tag{3.7}$$

Hence,

$$p_\ell^{(0)}(x) = \widetilde{a}^\ell F_0(x), \qquad 0 \le \ell \le R, \tag{3.8}$$

where

$$\widetilde{a} = \frac{\rho}{\sigma(1+\rho-\kappa)} < 1, \tag{3.9}$$

since $\kappa < \rho < \sigma$.

It follows from (3.6) and (3.8), by continuity at $\ell = 0$, that

$$F_0(x) = \exp\left[-\frac{\rho^2 x^2}{2\sigma(\rho-\kappa)}\right] + H_0(x). \tag{3.10}$$

But, from (2.12) with $\zeta = \sigma/\rho$,

$$\begin{aligned} &\left[I(R \ge 1) + \frac{\sigma}{\rho}(1+\rho-\kappa)\right] p_0^{(0)}(x) \\ &= (1+\rho-\kappa) p_{-1}^{(0)}(x) + I(R \ge 1)\frac{\sigma}{\rho}(1+\rho-\kappa) p_1^{(0)}(x). \end{aligned} \tag{3.11}$$

Hence, from (3.6) and (3.8)–(3.11), since $\rho < \sigma$, we obtain $H_0(x) = 0$, and

$$p_\ell^{(0)}(x) = \widetilde{a}^\ell \exp\left[-\frac{\rho^2 x^2}{2\sigma(\rho-\kappa)}\right], \qquad 0 \le \ell \le R. \tag{3.12}$$

From (2.14), (3.4), and (3.12), we obtain the asymptotic approximations to the blocking probabilities,

$$\begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \sim \sqrt{\frac{\kappa}{2\pi\sigma\lambda}} e^{(\sigma-\rho)\lambda/\kappa} \left(\frac{\rho}{\sigma}\right)^{\sigma\lambda/\kappa} \begin{bmatrix} \widetilde{a}^R \\ \frac{(1-\widetilde{a}^{R+1})}{(1-\widetilde{a})} \end{bmatrix}, \tag{3.13}$$

and $\widetilde{a}$ is given by (3.9). We note that B_1 and B_2 become exponentially small as $\lambda \to \infty$.

We now illustrate the matching of this result for an underloaded link with the one for a critically loaded link [6] when $R = O(1)$. In the notation of [6], $C - R = \lambda - \beta\sqrt{\lambda}$ and $\nu = \gamma\sqrt{\lambda}$. We let

$$\omega = \beta + \frac{\gamma}{\kappa}, \quad -\omega \gg 1, \ -\frac{\omega}{\sqrt{\lambda}} \ll 1. \tag{3.14}$$

Then, from (2.8), we have

$$\sigma = \kappa + \frac{\gamma - \kappa\omega}{\sqrt{\lambda}}, \qquad \rho = \kappa + \frac{\gamma}{\sqrt{\lambda}}. \tag{3.15}$$

Hence,

$$\frac{\sigma}{\kappa} \sim 1, \quad 1 - \frac{\rho}{\sigma} \sim -\frac{\omega}{\sqrt{\lambda}}, \quad \frac{\lambda\sigma}{\kappa}\left[1 - \frac{\rho}{\sigma} + \log\left(\frac{\rho}{\sigma}\right)\right] \sim -\frac{\omega^2}{2}. \tag{3.16}$$

Also, from (3.9), $\widetilde{a} \sim 1$ so that $\widetilde{a}^R \sim 1$ and $(1 - \widetilde{a}^{R+1})/(1 - \widetilde{a}) \sim R + 1$, and from (3.13) we obtain

$$\begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \sim \frac{e^{-\omega^2/2}}{\sqrt{2\pi\lambda}} \begin{bmatrix} 1 \\ R+1 \end{bmatrix}. \tag{3.17}$$

But, from (7.16)–(7.18) in [6], with $t = 1$,

$$\begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \sim \frac{1}{W_0(\omega)\sqrt{\lambda}} \begin{bmatrix} 1 \\ R+1 \end{bmatrix}, \tag{3.18}$$

where

$$W_0(\omega) = e^{\omega^2/2} \int_\omega^\infty e^{-u^2/2} du \sim \sqrt{2\pi} e^{\omega^2/2}, \qquad -\omega \gg 1. \tag{3.19}$$

Hence the results match asymptotically.

To summarize, we have obtained the blocking probabilities for the underloaded case; cf. (3.13) with (3.9) and (2.8). The joint probability distribution is given, asymptotically, by (3.3) with (3.2) and (3.4) for $\ell < 0$, and by (3.12) with (2.11) for $0 \le \ell \le R$.

4. Overloaded link. We now consider the case

$$\rho > \max(\kappa, \sigma) > 0, \tag{4.1}$$

so that $\lambda + \nu/\kappa > \sigma\lambda/\kappa = C - R$, and the link is overloaded. We note that the link is underloaded or overloaded, by the primary traffic alone, according as $\sigma > \kappa$ or $\sigma < \kappa$, respectively. If $R \ge 1$, then, from (2.12), we have

$$\begin{aligned} &[I(\ell \le R-1) + \sigma + \zeta - \kappa\zeta] p_\ell^{(0)}(x) \\ &= p_{\ell-1}^{(0)}(x) + I(\ell \le R-1)(\sigma + \zeta - \kappa\zeta) p_{\ell+1}^{(0)}(x), \qquad 1 \le \ell \le R. \end{aligned} \tag{4.2}$$

We let

$$a = \frac{1}{(\sigma + \zeta - \kappa\zeta)} > 0, \tag{4.3}$$

since $0 < \zeta < \sigma/\kappa$. It follows from (4.2) that

$$p_\ell^{(0)}(x) = a^\ell F_0(x), \qquad 0 \le \ell \le R, \tag{4.4}$$

where $F_0(x)$ is to be determined.

From (2.12), we have

$$\begin{aligned} &[1+\rho+\sigma-\kappa+(1-\kappa)\zeta]p_\ell^{(0)}(x) \\ &= (1+\rho-\kappa)p_{\ell-1}^{(0)}(x) + (\sigma+\zeta-\kappa\zeta)p_{\ell+1}^{(0)}(x), \qquad \ell \le -1. \end{aligned} \tag{4.5}$$

We let

$$b = \frac{(1+\rho-\kappa)}{(\sigma+\zeta-\kappa\zeta)} > a, \tag{4.6}$$

from (4.3), since $\rho > \kappa$. We will show that $b > 1$. Then, the solution of (4.5) which decreases geometrically as $-\ell$ increases is

$$p_\ell^{(0)}(x) = b^\ell F_0(x), \qquad \ell \le 0. \tag{4.7}$$

If we sum on ℓ in (2.10), neglect exponentially small terms, and expand $p_{\ell-1}(x - 1/\sqrt{\lambda}\,)$ and $p_{\ell+1}(x + 1/\sqrt{\lambda}\,)$ in powers of $1/\sqrt{\lambda}$, we obtain

$$\begin{aligned} &\sum_{\ell=-\infty}^{R}\left[\sqrt{\lambda}\zeta\frac{dp_\ell}{dx} + \frac{\zeta}{2}\frac{d^2p_\ell}{dx^2} + x\frac{dp_\ell}{dx} + p_\ell(x)\right] \\ &= \sum_{\ell=-\infty}^{R-1}\left(\sqrt{\lambda}\frac{dp_\ell}{dx} - \frac{1}{2}\frac{d^2p_\ell}{dx^2}\right) + O\left(\frac{1}{\sqrt{\lambda}}\right). \end{aligned} \tag{4.8}$$

Hence, from (2.11), we have

$$\zeta\sum_{\ell=-\infty}^{R}\frac{dp_\ell^{(0)}}{dx} = \sum_{\ell=-\infty}^{R-1}\frac{dp_\ell^{(0)}}{dx}. \tag{4.9}$$

It follows from (4.4) and (4.7) that

$$h(\zeta) \equiv \zeta\left[\frac{1}{(b-1)} + \frac{(1-a^{R+1})}{(1-a)}\right] - \left[\frac{1}{(b-1)} + \frac{(1-a^R)}{(1-a)}\right] = 0, \tag{4.10}$$

where a and b are functions of ζ, as given by (4.3) and (4.6). The limiting values as $a \to 1$ are to be taken in (4.10) if $a = 1$.

In Appendix A we show that there is a solution of (4.10) with $b > 1$ and $0 < \zeta\sigma/\kappa$. In fact, $0 < \zeta < \min(1, \sigma/\kappa)$ if $\sigma < 1 + \rho - \kappa$, and $0 \le \zeta^* < \zeta < \min(1, \sigma/\kappa)$ if $\sigma \ge 1 + \rho - \kappa$, which implies $\kappa > 1$, where

$$\zeta^* = \frac{(\kappa+\sigma-1-\rho)}{(\kappa-1)}. \tag{4.11}$$

Moreover, in the next section, we show that $F_0(x)$ is proportional to $\exp(-\gamma x^2/2)$, where $\gamma > 0$, and without loss of generality we may take $\int_{-\infty}^{\infty} F_0(x)dx = 1$. Then, from (2.6), (2.9), (2.11), (4.4), and (4.7), we obtain

$$1 \sim \sqrt{\lambda}A(\lambda)\sum_{\ell=-\infty}^{R} p_\ell^{(0)}(x)dx = \sqrt{\lambda}A(\lambda)\left[\frac{1}{(b-1)} + \frac{(1-a^{R+1})}{(1-a)}\right]. \tag{4.12}$$

Hence, from (2.14), the blocking probabilities are asymptotically given by

$$\begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \sim \left[\frac{1}{(b-1)} + \frac{(1-a^{R+1})}{(1-a)}\right]^{-1} \begin{bmatrix} a^R \\ \frac{(1-a^{R+1})}{(1-a)} \end{bmatrix}, \tag{4.13}$$

where a and b are given by (4.3) and (4.6).

We now illustrate the matching of this result for an overloaded link with the one for a critically loaded link [6] when $R = O(1)$. Now ω, as defined in (3.14), satisfies $\omega \gg 1$ and $\omega/\sqrt{\lambda} \ll 1$. With $\zeta \sim 1 - \delta/\sqrt{\lambda}$, it follows from (4.3) and (4.6) that

$$a - 1 \sim \frac{1}{\sqrt{\lambda}} \left[\kappa\omega - \gamma + (1-\kappa)\delta\right], \qquad b - 1 \sim \frac{1}{\sqrt{\lambda}} \left[\kappa\omega + (1-\kappa)\delta\right]. \tag{4.14}$$

After some straightforward algebra, it is found from (4.10) that $\delta = \omega$. Hence $a \sim 1$, $b - 1 \sim \omega/\sqrt{\lambda}$, and (4.13) implies that

$$\begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \sim \frac{\omega}{\sqrt{\lambda}} \begin{bmatrix} 1 \\ R+1 \end{bmatrix}. \tag{4.15}$$

However,

$$W_0(\omega) = \int_0^\infty e^{-v^2/2} e^{-\omega v} dv = \frac{1}{\omega} \int_0^\infty \exp\left[-\frac{\eta^2}{2\omega^2}\right] e^{-\eta} d\eta \sim \frac{1}{\omega}, \qquad \omega \ll 1, \tag{4.16}$$

and (4.15) is consistent with (3.18).

To summarize, we have obtained the blocking probabilities for the overloaded case; cf. (4.13) with (4.3), (4.6), and (4.10). The joint probability distribution is given, asymptotically, by (4.4) and (4.7), with (2.4), (2.9), (2.11), and (4.12), with $F_0(x)$ being the Gaussian defined below (4.11).

5. Lowest order function. We here derive an equation for $F_0(x)$, which appears in (4.4) and (4.7). We emphasize that it is crucial to show that $F_0(x)$ is exponentially small for $x \to \pm\infty$, so that (2.14) and (4.12) hold. From (2.13), (4.6), and (4.7), we obtain

$$\begin{aligned} &(1+\rho-\kappa)\left[\frac{1}{b} p_{\ell+1}^{(1)}(x) - \left(1 + \frac{1}{b}\right) p_\ell^{(1)}(x) + p_{\ell-1}^{(1)}(x)\right] \\ &= b^{\ell-1}[b(1-b)(1-\kappa)xF_0(x) + (1-\zeta b^2)F_0'(x)], \qquad \ell \le -1, \end{aligned} \tag{5.1}$$

where the prime denotes derivative. The solution, which becomes small for large values of $-\ell$, is

$$p_\ell^{(1)}(x) = b^\ell \left\{F_1(x) - \frac{\ell}{(1+\rho-\kappa)} \left[b(1-\kappa)xF_0(x) + \frac{(\zeta b^2 - 1)}{(b-1)} F_0'(x)\right]\right\}, \quad \ell \le 0, \tag{5.2}$$

where $F_1(x)$ is not determined.

If $R \ge 1$, then, from (2.13), (4.3), and (4.4), we have

$$\begin{aligned} &I(\ell \le R-1)\frac{1}{a} p_{\ell+1}^{(1)}(x) - \left[I(\ell \le R-1) + \frac{1}{a}\right] p_\ell^{(1)}(x) + p_{\ell-1}^{(1)}(x) \\ &= a^{\ell-1}[a(1-\kappa)xF_0(x) + F_0'(x)] \\ &\quad - I(\ell \le R-1)a^{\ell+1}[(1-\kappa)xF_0(x) + \zeta F_0'(x)], \qquad 1 \le \ell \le R. \end{aligned} \tag{5.3}$$

Since $p_0^{(1)}(x) = F_1(x)$, it is found that, for $a \neq 1$,

$$p_\ell^{(1)}(x) = a^\ell \left\{ F_1(x) - \ell \left[a(1-\kappa)xF_0(x) + \frac{(1-\zeta a^2)}{(1-a)} F_0'(x) \right] \right\}$$

$$+ a^{R+1} \frac{(1-a^\ell)}{(1-a)^2}(1-a\zeta)F_0'(x), \qquad 0 \leq \ell \leq R. \tag{5.4}$$

The expression in (5.4) remains finite as $a \to 1$, so that the result for $a = 1$ may be obtained in this limit. Consequently, we subsequently assume that $a \neq 1$.

If we let $\ell = 0$ in (2.13), then

$$[I(R \geq 1) + \sigma + \zeta - \kappa\zeta]p_0^{(1)}(x) + (1-\kappa)xp_0^{(0)}(x)$$
$$= (1 + \rho - \kappa)p_{-1}^{(1)}(x) - \frac{dp_{-1}^{(0)}}{dx}$$
$$+ I(R \geq 1) \left[(\sigma + \zeta - \kappa\zeta)p_1^{(1)}(x) + (1-\kappa)xp_1^{(0)}(x) + \zeta \frac{dp_1^{(0)}}{dx} \right]. \tag{5.5}$$

It may be verified from (4.3), (4.4), (4.6), (4.7), (5.2), and (5.4) that this equation is satisfied in view of (4.10), which follows from (4.9).

Next, from (2.11), (4.8), and (4.9), we obtain

$$\sum_{\ell=-\infty}^{R} \left[\zeta \frac{dp_\ell^{(1)}}{dx} + \frac{\zeta}{2} \frac{d^2 p_\ell^{(0)}}{dx^2} + x \frac{dp_\ell^{(0)}}{dx} + p_\ell^{(0)}(x) \right]$$
$$= \sum_{\ell=-\infty}^{R-1} \left[\frac{dp_\ell^{(1)}}{dx} - \frac{1}{2} \frac{d^2 p_\ell^{(0)}}{dx^2} \right]. \tag{5.6}$$

We define

$$\Omega \equiv \frac{(\zeta b^2 - 1)(1-\zeta)}{(1+\rho-\kappa)(b-1)} \sum_{\ell=-\infty}^{-1} \ell b^\ell + \frac{(1-\zeta a^2)}{(1-a)} \left(\sum_{\ell=0}^{R-1} \ell a^\ell - \zeta \sum_{\ell=0}^{R} \ell a^\ell \right)$$
$$+ \frac{(\zeta a - 1)}{(1-a)^2} a^{R+1} \left[\zeta \sum_{\ell=0}^{R} (a^\ell - 1) - \sum_{\ell=0}^{R-1} (a^\ell - 1) \right] + \zeta \left(\sum_{\ell=-\infty}^{-1} b^\ell + \sum_{\ell=0}^{R} a^\ell \right) \tag{5.7}$$

and

$$\Gamma \equiv \frac{b(1-\kappa)(1-\zeta)}{(1+\rho-\kappa)} \sum_{\ell=-\infty}^{-1} \ell b^\ell + a(1-\kappa) \left(\sum_{\ell=0}^{R-1} \ell a^\ell - \zeta \sum_{\ell=0}^{R} \ell a^\ell \right)$$
$$+ \sum_{\ell=-\infty}^{-1} b^\ell + \sum_{\ell=0}^{R} a^\ell. \tag{5.8}$$

Then from (4.4), (4.7), (5.2), (5.4), and (5.6) we obtain

$$\Omega F_0''(x) + \Gamma[xF_0'(x) + F_0(x)] = 0. \tag{5.9}$$

In Appendices B and C we use (4.10) to express ζ, and hence Ω and Γ, in terms of a and b. Then, using the facts that $b > a > 0$ and $b > 1$, it is shown that $\Omega > 0$ and $\Gamma > 0$. Hence $F_0(x)$ is proportional to $\exp(-\gamma x^2/2)$, where $\gamma = \Gamma/\Omega > 0$. This establishes the validity of the asymptotic approximation (4.13) to the blocking probabilities.

6. Numerical results. We present numerical results for the blocking probabilities B_1 and B_2 of the primary and secondary calls, respectively. Exact results may be obtained from (2.3) by numerically solving the recursion (2.1) for the joint steady-state probability $p(n_1, n_2)$ of the numbers of primary and secondary calls, subject to the normalization condition (2.2). However, this is feasible for values of C, the number of circuits in the link, up to about 50. If the mean holding times of the primary and secondary calls are equal, so that $\kappa = 1$, then the distribution of the total number of calls, and hence B_1 and B_2, may be calculated from a well-known single recursion for values of C up to at least 1000.

Asymptotic approximations to B_1 and B_2 were derived under the assumptions in (2.8), where λ and ν are the mean arrival rates of the primary and secondary calls, respectively, with corresponding mean holding times 1 and $1/\kappa$, and R circuits are reserved for the prime calls. In the case of an underloaded link, corresponding to $\lambda + \nu/\kappa = \rho\lambda/\kappa < \sigma\lambda/\kappa = C - R$, the approximations to B_1 and B_2 are given by (3.13), where $\tilde{a}$ is given by (3.9). In the case of an underloaded link, corresponding to $\lambda + \nu/\kappa > C - R$, so that $\rho > \sigma$, the approximations to B_1 and B_2 are given by (4.13), where a and b are given by (4.3) and (4.6), and ζ is a solution of (4.10) with $b > 1$ and $0 < \zeta < \min(1, \sigma/\kappa)$. We have assumed that $\lambda \gg 1$ and $R = O(1)$. It follows from (4.4) and (5.4) that for the asymptotic expansion (2.11) to be valid we need $R/\sqrt{\lambda} \ll 1$. Consideration of the first order correction term in (2.11) for an underloaded link leads to the same restriction.

In Table 1 we compare the asymptotic approximations to B_1 and B_2 and the exact values for an underloaded link, with $R = 5,\ \kappa = 1$, and $\lambda = 0.4C = \nu$, for different values of C. The analogous comparisons are made in Table 2 for an overloaded link, with $R = 5, \kappa = 1$, and $\lambda = 0.6C = \nu$. It is seen that the approximations improve as C increases. In Tables 3 and 4 the comparisons are made for $R = 2$ and $\kappa = 2$ and $1/2$, for an underloaded link with $\lambda = 0.2C = \nu/\kappa$, and for an overloaded link with $\lambda = 0.8C = \nu/\kappa$. In Tables 5 and 6 the comparisons are made for $R = 2,\ \kappa = 1$, and $\lambda/\nu = 1, 1/3$, and 3, for an underloaded link with $\lambda + \nu = 0.8C$, and for an overloaded link with $\lambda + \nu = 1.6C$. Again, the approximations improve as C increases.

7. Discussion. Finally, we discuss the range of validity of our asymptotic approximations to $p(n_1, n_2)$ and also indicate how to obtain results of a more "global" nature. We view the domain of the difference equation (2.1) as consisting of the union of the lattice triangle $T = \{(n_1, n_2) : n_1 \geq 0, n_2 \geq 0, n_1 + n_2 \leq C - R\}$ and the oblique strip $S = \{(n_1, n_2) : 0 \leq n_2 \leq C - R, C - R - n_2 \leq n_1 \leq C - n_2\}$. We refer to $\mathcal{I} = T \cap S = \{(n_1, n_2) : n_1 + n_2 = C - R, n_1 \geq 0, n_2 \geq 0\}$ as an "interface."

The boundary segment $\mathcal{B} = \{(n_1, n_2) : n_1 + n_2 = C, 0 \le n_2 \le C - R\}$ also plays an important role in the analysis.

If we view the problem (2.1) on a coarse spatial scale with $(\xi, \eta) = C^{-1}(n_1, n_2)$, then the differences become small in the new variables, and the domain is approximately

$$\{(\xi, \eta) : \xi \ge 0, \eta \ge 0, \xi + \eta \le 1\}.$$

For $C \to \infty$ with $R = O(1)$ the interface $\mathcal{I}$ and boundary $\mathcal{B}$ are close to (within $O(C^{-1})$ of) one another. The scaling (2.9) corresponds to a small neighborhood of the point $(\xi, \eta) = (\zeta_1, 1 - \zeta_1)$, where $\zeta_1 = \zeta\lambda/C = O(1)$. This is the region where most of the probability mass concentrates, and analysis of this range is sufficient for obtaining asymptotically the blocking probabilities in (2.14).

To obtain results for $p(n_1, n_2)$ that have a wider range of validity, we can consider the scale $\ell = C - R - n_1 - n_2 = O(1)$ with $\xi \in (0, 1)$. For the overloaded case we can use a WKB-type expansion of the form

$$p(n_1, n_2) = \frac{1}{\sqrt{C}} e^{C\phi(\xi;R)} \left[A_\ell(\xi; R) + \frac{1}{C} A_\ell^{(1)}(\xi; R) + O(C^{-2}) \right]. \tag{7.1}$$

Using (7.1) in (a scaled form of) (2.1) and (2.5), the derivative of the function ϕ can be characterized as a root of a transcendental equation. More precisely, $e^{\phi'}$ can be obtained as an algebraic function of ξ. By expanding (7.1) about $\xi = \zeta_1$, we find that $\phi(\zeta_1; R) = \phi'(\zeta_1; R) = 0$, and near $\xi = \zeta_1$, (7.1) reduces to the form we obtained in section 4. The exponential factor in (7.1) becomes proportional to the Gaussian factor $F_0(x)$, and $A_\ell(\zeta_1; R)$ yields the geometric factors a^ℓ in (4.4) and b^ℓ in (4.7). However, for some parameter ranges within the overloaded case, the function $A_\ell(\xi)$ may, for certain $\xi \in (0, 1)$, become negative and/or not decay for $\ell \to -\infty$. Thus (7.1) will be valid for ξ only in some subset of the unit interval $[0, 1]$. However, it can be shown that ζ_1 is always contained in this subinterval.

We can obtain results even more global than (7.1) by considering the problem on the (ξ, η) scale. Then employing a geometrical optics expansion of the form

$$p(n_1, n_2) = \frac{1}{\sqrt{C}} e^{C\Phi(\xi,\eta)} \left[K(\xi, \eta) + \frac{1}{C} K^{(1)}(\xi, \eta) + O(C^{-2}) \right] \tag{7.2}$$

will yield PDEs satisfied by Φ and K. Solving the PDE for Φ subject to the condition $\Phi(\xi, 1-\xi) = \phi(\xi)$ will determine the solution in either the entire triangular domain or some subset thereof. In the latter case the expansion (7.2) would need to be modified, and different boundary conditions used to determine $\Phi(\xi, \eta)$ in the complementary subset(s). In general, obtaining a complete set of results on the (ξ, η) scale is likely to lead to consideration of several subregions of the basic triangle.

For the underloaded case ($\lambda + \nu/\kappa < C$) we can first consider the problem on the (ξ, η) scale. Employing an expansion of the type (7.2), with the initial factor $1/\sqrt{C}$ replaced by $1/C$, we again find that Φ satisfies a nonlinear PDE. Solving this by the method of characteristics (ray method) and using the characteristic curves that start from the equilibrium point $(\xi, \eta) = C^{-1}(\lambda, \nu/\kappa)$, we can regain the asymptotic expansion of $\log[p(n_1, n_2)]$ in (3.1). Note that $p(n_1, n_2)$ is maximal near this equilibrium point. The range of validity of this expansion is determined by the portion of the triangle $\xi + \eta < 1$ that is filled by the rays. When $\kappa = 1$, this can be shown to be the entire triangle, but in general for $\kappa \neq 1$ the rays will not fill the entire triangle, and thus have a "shadow region." In the shadow the product form expression in (3.1) is not the appropriate approximation to $p(n_1, n_2)$, and an entirely separate analysis is needed. However, we can show that the point $(\xi, \eta) = (\lambda\kappa, \nu)/(\nu + \lambda\kappa)$ always lies in the region illuminated by the rays from the equilibrium, and our analysis used (3.1) only near this point (cf. (3.2)).

This brief discussion shows that obtaining more global results for $p(n_1, n_2)$, with the scaling (2.8), is nontrivial and would require considerably more analysis. We are also presently investigating the case of critical loading, where $\lambda + \nu/\kappa = C + O(\sqrt{C})$. This analysis will likely lead to a two-dimensional diffusion approximation. Another interesting asymptotic limit is to have $R \to \infty$ with $R/C = r = O(1)$. Then even on the coarse (ξ, η) scale, both the triangle T (with $\xi + \eta < 1 - r$) and the oblique strip S (with $1 - r < \xi + \eta < 1, 0 < \eta < 1 - r$) have nonvanishing volume. The clearer separation between the interface $\mathcal{I}$ and boundary $\mathcal{B}$ may actually simplify the asymptotic analysis, over that with the present assumption $R = O(1)$.

Appendix A. We here establish that there is a solution of (4.10) with $b > 1$ and $0 < \zeta < \sigma/\kappa$, where a and b are functions of ζ, as given by (4.3) and (4.6), and (4.1) holds. We let

$$f(\zeta) = \sigma + \zeta - \kappa\zeta > 0, \qquad 0 \leq \zeta \leq \frac{\sigma}{\kappa}. \tag{A.1}$$

From (4.3) and (4.6), we have

$$a(\zeta) = \frac{1}{f(\zeta)}, \qquad b(\zeta) = \frac{(1 + \rho - \kappa)}{f(\zeta)}. \tag{A.2}$$

If $\sigma/\kappa > 1$, then $b(1) > 1$ since $\rho > \sigma$, and $a(1) > 0$, so that $h(1) > 0$. If $\sigma/\kappa \leq 1$, then $b(\sigma/\kappa) = \kappa(1 + \rho - \kappa)/\sigma > 1$ since $\rho > \kappa$. Also, $h(\sigma/\kappa) = (\rho - \kappa)/(b - 1) > 0$. Hence,

$$h\left(\min\left(1, \frac{\sigma}{\kappa}\right)\right) > 0. \tag{A.3}$$

There are two cases to consider.

Case 1. $\sigma < 1 + \rho - \kappa$. Then $b(0) = (1 + \rho - \kappa)/\sigma > 1$, and $b(\zeta) > 1$ for $0 \le \zeta \le \min(1, \sigma/\kappa)$. However, $h(0) < 0$. Hence, from (A.3), $0 < \zeta < \min(1, \sigma/\kappa)$.

Case 2. $\sigma \ge 1 + \rho - \kappa$. Then $\kappa > 1$, since $\rho > \sigma$, and $b(\zeta^*) = 1$, where $\zeta^* < 1$ is given by (4.11). However,

$$\frac{\sigma}{\kappa} - \zeta^* = \frac{[\kappa(\rho - \kappa) + (\kappa - \sigma)]}{\kappa(\kappa - 1)}. \tag{A.4}$$

Hence, if $\sigma \le \kappa$, then $\zeta^* < \sigma/\kappa$, and so $0 \le \zeta^* < \min(1, \sigma/\kappa)$. If follows that $b(\zeta) > 1$ for $\zeta^* < \zeta \le \min(1, \sigma/\kappa)$. Moreover, $b(\zeta) \to 1+$ as $\zeta \to \zeta^*+$, so that $h(\zeta) \to -\infty$ as $\zeta \to \zeta^*+$. Hence, from (A.3), $\zeta^* < \zeta < \min(1, \sigma/\kappa)$.

Appendix B. We here show that $\Omega > 0$, where Ω is given by (5.7). Now,

$$\sum_{\ell=-\infty}^{-1} b^\ell = \frac{1}{(b-1)}, \qquad \sum_{\ell=-\infty}^{-1} \ell b^\ell = -\frac{b}{(b-1)^2}, \tag{B.1}$$

and, for $a \ne 1$,

$$\sum_{\ell=0}^{R-1} a^\ell = \frac{(1-a^R)}{(1-a)}, \qquad \sum_{\ell=0}^{R-1} \ell a^\ell = a\left[\frac{(1-a^R)}{(1-a)^2} - \frac{Ra^{R-1}}{(1-a)}\right]. \tag{B.2}$$

Also, from (4.3) and (4.6),

$$b = (1 + \rho - \kappa)a. \tag{B.3}$$

If we use (4.10) to express ζ in terms of a and b, then after some straightforward algebra, it is found that

$$\left[\frac{1}{(b-1)} + \frac{(1-a^{R+1})}{(1-a)}\right]^2 \Omega = c_0(a) + \frac{c_1(a)}{(b-1)} + \frac{c_2(a)}{(b-1)^2} + \frac{c_3(a)}{(b-1)^3}, \tag{B.4}$$

where

$$\begin{aligned} c_0(a) = {} & \frac{a^R}{(1-a)^2}(1 + a - a^{R+1})\left[\frac{a(1-a^R)}{(1-a)} - R\right] \\ & + \frac{a^{R+1}}{(1-a)^2}\left[\frac{(1-a^R)}{(1-a)} - Ra^R\right] + \frac{(1-a^R)(1-a^{R+1})^2}{(1-a)^3}, \end{aligned} \tag{B.5}$$

$$\begin{aligned} c_1(a) = {} & -a^{R+1}\frac{(1-a^R)}{(1-a)} + a^{R+1}(1+a)\frac{(1-a^R)}{(1-a)^2} - Ra^R\frac{(2+2a-a^{R+1})}{(1-a)} \\ & + \frac{a^{R+1}}{(1-a)}\left[\frac{2(1-a^R)}{(1-a)} - Ra^R\right] + \frac{(1-a^{R+1})}{(1-a)^2}(3 - 2a^R - a^{R+1}), \end{aligned} \tag{B.6}$$

$$\begin{aligned} c_2(a) = {} & -a^{R+1}\frac{(3-a-2a^R)}{(1-a)} - R(1+a)a^R \\ & + a^{R+1}\frac{(1-a^R)}{(1-a)} + \frac{(3-a^R-2a^{R+1})}{(1-a)}, \end{aligned} \tag{B.7}$$

and

$$c_3(a) = 1 + a^{R+1}(a^R - 2) = (1 - a^{R+1})^2 + (1 - a)a^{2R+1}. \tag{B.8}$$

After simplification in (B.5), we obtain

$$c_0(a) = (1 + a^{R+2})\frac{(1 - a^R)}{(1 - a)^3} - \frac{R(1 + a)a^R}{(1 - a)^2}. \tag{B.9}$$

Then, from (B.6) and (B.7), it is found that

$$c_1(a) = 2(1 - a)c_0(a) + \frac{(1 - a^{R+1})^2}{(1 - a)^2} \tag{B.10}$$

and

$$c_2(a) = (1 - a)^2 c_0(a) + a^{2R+1} + \frac{2(1 - a^{R+1})^2}{(1 - a)}. \tag{B.11}$$

Hence, from (B.4), (B.8), (B.10), and (B.11), we have

$$\begin{aligned}&\left[\frac{1}{(b - 1)} + \frac{(1 - a^{R+1})}{(1 - a)}\right]^2 \Omega \\ &= \frac{(b - a)}{(b - 1)^3}\left[(b - a)(b - 1)c_0(a) + (b - a)\frac{(1 - a^{R+1})^2}{(1 - a)^2} + a^{2R+1}\right].\end{aligned} \tag{B.12}$$

However,

$$\sum_{\ell=0}^{R} \ell a^{R-\ell} = \sum_{\ell=0}^{R} (R - \ell)a^\ell = \frac{R}{(1 - a)} - \frac{a(1 - a^R)}{(1 - a)^2}, \tag{B.13}$$

from (B.2). Hence, from (B.9),

$$c_0(a) = \frac{1}{(1 - a)}\sum_{\ell=0}^{R} \ell(a^{\ell-1} - a^{2R-\ell+1}) = \sum_{\ell=0}^{R} \ell a^{\ell-1} \sum_{m=0}^{2R+1-2\ell} a^m \geq 0, \tag{B.14}$$

since $a > 0$ from (4.3). But $b > 1$ and $b > a$ from (4.6). It follows from (B.12) and (B.14) that $\Omega > 0$.

Appendix C. We here show that $\Gamma > 0$, where Γ is given by (5.8). If we use (4.10) to express ζ in terms of a and b, then it is found that

$$\begin{aligned}&\left[\frac{1}{(b - 1)} + \frac{(1 - a^{R+1})}{(1 - a)}\right]\Gamma = \left[\frac{1}{(b - 1)} + \frac{(1 - a^{R+1})}{(1 - a)}\right]^2 \\ &+ (1 - \kappa)a^{R+1}\left[\frac{a(1 - a^R)}{(1 - a)^2} - \frac{R}{(1 - a)} - \frac{b}{(b - 1)^2} - \frac{R}{(b - 1)}\right].\end{aligned} \tag{C.1}$$

Now,

$$\frac{1}{(b - 1)} + \frac{(1 - a^{R+1})}{(1 - a)} = \frac{1}{(b - 1)}\left[(b - a)\frac{(1 - a^R)}{(1 - a)} + a^R b\right]. \tag{C.2}$$

We let

$$f(a,b) = b + R(b-1) + \left[\frac{R}{(1-a)} - \frac{a(1-a^R)}{(1-a)^2}\right](b-1)^2 \tag{C.3}$$

and

$$g(a,b) = \left[(b-a)\frac{(1-a^R)}{(1-a)} + a^R b\right]^2 - a^{R+1} f(a,b). \tag{C.4}$$

Then,

$$(b-1)^2\left[\frac{1}{(b-1)} + \frac{(1-a^{R+1})}{(1-a)}\right]\Gamma = \kappa a^{R+1} f(a,b) + g(a,b). \tag{C.5}$$

Since $a > 0$ and $b > 1$, it follows from (B.13) and (C.3) that $f(a,b) > 0$. We may express $f(a,b)$ in the form

$$f(a,b) = \frac{R(b-a)(b-1)}{(1-a)} + \frac{(1-a^R)}{(1-a)^2}(b-a)(1-ab) + a^R b. \tag{C.6}$$

From (C.4), after some algebra, it is found that

$$g(a,b) = (b-a)[\ell(a)(b-a) + (R+1)a^{R+1}], \tag{C.7}$$

where

$$\ell(a) = \frac{(1-a^{R+1})^2}{(1-a)^2} - a^{R+1}\left[\frac{R}{(1-a)} - \frac{a(1-a^R)}{(1-a)^2}\right]. \tag{C.8}$$

Hence, from (B.13),

$$\ell(a) = \sum_{r=0}^{R} a^r \sum_{s=0}^{R} a^s - \sum_{\ell=0}^{R} \ell a^{2R-\ell+1} = \sum_{n=0}^{R} (n+1)a^n > 0, \tag{C.9}$$

since $a > 0$. However, $b > a$, and it follows from (C.7) that $g(a,b) > 0$. Finally, since $\kappa > 0$ and $f(a,b) > 0$, we obtain $\Gamma > 0$.

Acknowledgment. The authors would like to thank the referees for their helpful suggestions for improving the presentation.

NONADIABATIC CORRECTIONS TO THE HANNAY–BERRY PHASE*

SEAN B. ANDERSSON†

Abstract. The effect of the Coriolis force on a moving system can be described as a holonomy with respect to a particular connection known as the Cartan–Hannay–Berry connection. The resulting geometric phase is called the Hannay–Berry phase, and it provides direct information about the imposed motion on the system. This approach assumes that the imposed motion is adiabatic. In this paper we describe the use of Hamiltonian perturbation theory to develop nonadiabatic corrections to the Hannay–Berry phase for a moving system. The technique is illustrated by applying it to a rotating free-floating spring-jointed equal-sided four-bar mechanism.

Key words. geometric phases, perturbations, systems with slow and fast motions, averaging of perturbations

1. Introduction.

When a system undergoes an imposed motion, the external forces can alter the natural dynamics. A simple example is the Foucault pendulum, where the rotation of the Earth causes a precession of the swing plane of the pendulum. Classically the effect of the external forces is captured by introducing fictitious forces (the centrifugal, Coriolis, and Euler forces) into the moving system (see, e.g., [26]). When the rate of the imposed motion is slow with respect to the time scale of the nominal dynamics, that is, with respect to the dynamics in the absence of any external forces, one does not expect the imposed motion to fundamentally alter the behavior of the system. (This is essentially a statement of the averaging principle. It should be kept in mind that this principle is simply one of physical intuition and not a theorem. See [6] for further comments.) For the Foucault pendulum, the rotation of the Earth slowly shifts the swing plane; on short time scales the motion of the bob is well approximated by ignoring the effects of the imposed rotation. (See [2] for a historical narrative of Foucault and the pendulum experiment.)

An effect analogous to the precession of the swing plane of the Foucault pendulum due to the Coriolis force has been observed in many other rotating dynamical systems including rotating vibrating beams [18], tuning forks [27], and shells [10]. Vibratory gyroscopes take advantage of the effect to sense the imposed rotation, and a wide variety of designs have been proposed and built [24]. Most modern analyses of slowly rotating systems are linear in nature and view the Coriolis force as providing a coupling between two vibratory modes of the system (see, e.g., [30]). However, it is desirable to have a method which, at least in principle, can be extended to a nonlinear theory and which provides a unified setting for understanding a variety of systems in which

the Coriolis force plays a role. A technique developed by Marsden, Montgomery, and Ratiu, known as the moving systems approach, provides such a method [25]. The moving systems approach descends from the classical work of Cartan [11] and describes the effect of the Coriolis force as a geometric phase (holonomy) with respect to a particular Ehresmann connection known as the Cartan–Hannay–Berry connection. Research on geometric phases in physical systems was spurred by the work of Berry in the early 1980s on the geometric shift of the phase in a quantum system as a result of an adiabatic variation of a parameter-dependent Hamiltonian [7]. In previous work we have applied the moving systems approach to show that the Hannay–Berry phase in a rotating equal-sided four-bar mechanism is zero [4] and to show that the precession of the nodal points in a rotating vibrating ring can be understood as a Hannay–Berry phase [3].

Inherent in the moving systems approach is an assumption of adiabaticity; that is, it is assumed that the imposed motion is infinitely slow. In practice, of course, while the imposed motion may be extremely slow with respect to the nominal dynamics of the system, it is not infinitely slow, and neglecting this fact introduces some error. By accounting for the nonadiabatic nature of the imposed motion, more accurate models of the resulting response of the system can be developed.

Since Berry's original work on geometric phases in quantum systems, various techniques have been proposed to account for the finite rate of change of the parameters in the Hamiltonian. Berry developed an iterative scheme in which the geometric phase at each step is incorporated into the nominal dynamics [8], while other authors have showed that the Berry phase can be viewed as the first-order term in a perturbation expansion of the system [15, 33]. This work has been applied to systems such as nuclear quadrupole resonance [34], hysteresis loops in manganese acetate crystals [16], and magnetic resonance [19]. A few authors have also considered the effect of the finite rate of change of the parameters on the Hannay angles, the geometric phase in classical integrable systems. Bhattacharjee and Sen used a perturbative method [9], which was later compared by Gjaja and Bhattacharjee to a classical analogue of the iterative scheme of Berry [20].

In this work we consider a perturbative approach to account for the nonadiabatic nature of the imposed motion. However, classical perturbation techniques ignore the underlying geometric structure of the Hamiltonian system to which the moving systems method applies. We will show that the averaged Hamiltonian which gives rise to the Hannay–Berry phase Poisson commutes with the nominal Hamiltonian, using the canonical Poisson bracket on the phase space. This leads us to Hamiltonian perturbation theory and Hamiltonian normal forms. We note that when not considering the imposed motion as a small perturbation from the nominal system, the effect of the external forces is often incorporated into an amended potential (see, e.g., [26]). Here we wish to develop a technique which takes advantage of the fact that the imposed motion is slow when describing the resulting system dynamics. If the original system is integrable, then the techniques developed here are similar to a perturbation expansion in the action-angle variables as in [23].

In the next section we briefly recall the moving system approach, and in section 3 give a short introduction to Hamiltonian normal form theory. In section 4 the theory of normal forms is applied to the moving systems approach to develop higher-order corrections. The technique is illustrated in section 5 by applying it to a spring-jointed equal-sided four-bar mechanism, where we show that the effect of an imposed rotation is zero to second order.

2. The moving systems approach. Inspired by classical examples such as the Foucault pendulum and the ball in a hoop, one is naturally led to consider the effect in the phase space of a mechanical system as a parameter is slowly varied along a closed loop in parameter space. Well-known examples in quantum physics, optics, and other settings [7, 31, 35] reveal that the essential calculation is a geometric one and is in fact captured by the holonomy of a connection on a fiber bundle. (For background material on fiber bundles, connections, and holonomy see [17, 28].)

Marsden, Montgomery, and Ratiu have developed an approach to moving systems using the tools of Ehresmann connections on fiber bundles [25]. Here we provide a brief review of their approach. Let S be a Riemannian manifold, and let M be the space of embeddings of a manifold Q into S. We think of S as the ambient space in which Q is being moved and of Q as the configuration space for a system of interest. A tangent vector to M at m is a map $u_m : Q \to TS$ such that $u_m(q) \in T_{m(q)}S$. Given a tangent vector $u_m(q)$, one can construct a tangent vector to T_qQ as follows. Relative to the metric on S, orthogonally project $u_m(q)$ to $T_{m(q)}m(Q) \subset (T_qm)(T_qQ)$, denote this vector $u_m^T(q)$, and then pull-back $u_m^T(q)$ by Tm^{-1} to T_qQ. This natural construction defines an Ehresmann connection on the product bundle $\pi : Q \times M \to M$ as follows.

Definition 2.1 (see [25]). *The* Cartan connection *on $\pi : Q \times M \to M$ is given by the vertical-valued one-form γ_c defined by*

$$\gamma_c(q, m)(v_q, u_m) = (v_q + (T^{-1}m \circ u_m^T)q, 0). \tag{2.1}$$

The Cartan connection induces a connection on $\rho : T^*Q \times M \to M$ as follows.

Definition 2.2 (see [25]). *The* induced Cartan connection *on $\rho : T^*Q \times M \to M$ is given by the vertical-valued one-form γ_o defined by*

$$\gamma_o(\alpha_q, m)(U_{\alpha_q}, u_m) = \left(U_{\alpha_q} + X_{\mathcal{P}(u_m)}(\alpha_q), 0\right), \tag{2.2}$$

where $\mathcal{P}(u_m)$ is the function defined by

$$(\mathcal{P}(u_m))\,\alpha_q = \alpha_q \cdot (T^{-1}m \circ u_m^T)(q) \tag{2.3}$$

and $X_{\mathcal{P}(u_m)}$ is the Hamiltonian vector field of $\mathcal{P}(u_m)$.

To separate the effects of the imposed motion on the system (as defined by the embeddings m_t) from the nominal dynamics (when the imposed motion is zero) we assume we are given a left action of a compact Lie group G on T^*Q with respect to which we can define an average and then make the following definition.

Definition 2.3 (see [25]). *The* Cartan–Hannay–Berry connection *on $\rho : T^*Q \times M \to M$ is given by the vertical-valued one-form γ defined by*

$$\gamma(\alpha_q, m)(U_{\alpha_q}, u_m) = \left(U_{\alpha_q} + X_{\langle \mathcal{P}(u_m)\rangle}(\alpha_q), 0\right), \tag{2.4}$$

where $\langle\cdot\rangle$ denotes the average with respect to the action of the Lie group G.

In [25] Marsden, Montgomery, and Ratiu show that this is an Ehresmann connection. The horizontal lift of a vector field Z on M relative to γ is

$$(\mathrm{hor}\, Z)(\alpha_q, m) = \left(-X_{\langle \mathcal{P}(Z(m))\rangle}(\alpha_q), Z(m)\right). \tag{2.5}$$

Definition 2.4 (see [25]). *The holonomy of the Cartan–Hannay–Berry connection is called the* Hannay–Berry phase *for a moving system.*

2.1. The adiabatic assumption. The Hannay–Berry phase captures the effects of the imposed motion on a system under the assumption that this imposed motion is slow with respect to the nominal dynamics. To better understand this adiabatic assumption, we consider the following system (as in [26]). If a particle in Q is following a curve $q(t)$ and if Q is in turn being moved in the ambient space S by superposing the motion m_t, then the path of the particle in S is given by $m_t(q(t))$. The velocity in S is then

$$T_{q(t)}m_t\dot{q}(t) + \mathcal{Z}_t(m_t(q(t))), \tag{2.6}$$

where $\mathcal{Z}_t(m_t(q)) = \frac{d}{dt}m_t(q)$ (with q viewed as fixed). The standard Lagrangian is given by the kinetic energy minus the potential energy,

$$L(q,v) = \frac{1}{2}\|T_{q(t)}m_t v + \mathcal{Z}_t(m_t(q))\|^2 - V(q) - U(m_t(q)). \tag{2.7}$$

Here V is a given potential on Q, and U is a given potential on S. To compute the associated Hamiltonian we take the Legendre transform. Taking the derivative of L with respect to v in the direction w yields

$$\frac{\partial L}{\partial v}\cdot w = p\cdot w = \langle T_{q(t)}m_t v + \mathcal{Z}_t(m_t(q(t)))^T, T_{q(t)}m_t w\rangle_{m_t(q(t))},$$

where $p\cdot w$ is the natural pairing between the covector $p\in T^*_{q(t)}Q$ and the vector $w\in T_{q(t)}Q$, $\langle\cdot,\cdot\rangle_{m_t(q(t))}$ denotes the metric inner product on S at the point $m_t(q(t))$, and ^{T} denotes the orthogonal projection to $Tm_t(Q)$ using the metric of S at $m_t(q(t))$. Q inherits a metric from S such that m_t is an isometry for each t. Thus

$$\begin{aligned} p\cdot w &= \left\langle v + \left(T_{q(t)}m_t\right)^{-1}\mathcal{Z}_t^T(m_t(q(t)))^T, w\right\rangle_{q(t)} \\ \Rightarrow p &= \left(v + \left(T_{q(t)}m_t\right)^{-1}\mathcal{Z}_t^T(m_t(q(t)))^T\right)^\flat \triangleq (v+Z_t)^\flat, \end{aligned} \tag{2.8}$$

where we have defined the tangent vector Z_t. Here $\flat : T_qQ \to T_q^*Q$ is the map defined by

$$z^\flat\cdot w = \langle z, w\rangle_q \quad \forall w\in T_qQ. \tag{2.9}$$

The Hamiltonian for the moving system is given by

$$H(q,p) = \frac{1}{2}\|p\|^2 - \mathcal{P}(Z_t) - \frac{1}{2}\|\mathcal{Z}_t^\perp\|^2 + V(q) + U(m_t(q)), \tag{2.10}$$

where $\mathcal{Z}_t^\perp = \mathcal{Z}_t - \mathcal{Z}_t^T$ is the orthogonal complement of $\mathcal{Z}_t$ and $\mathcal{P}(Z_t)$ is the function on T^*Q (defined in (2.3)) given by

$$\mathcal{P}(Z_t)(q,p) = p\cdot Z_t(q).$$

The nominal Hamiltonian H_0 is defined by setting $\mathcal{Z}_t = 0$ and $U = 0$. The term $\mathcal{P}(Z_t)$ captures what are classically referred to as the Coriolis terms, and $\|\mathcal{Z}_t^\perp\|^2$ captures the centrifugal terms.

Recall now that we have a compact Lie group G acting on T^*Q on the left. We assume that the group action leaves the nominal Hamiltonian invariant. Applying the corresponding average, we obtain

$$\langle H\rangle(q,p) = \frac{1}{2}\|p\|^2 - \langle\mathcal{P}(Z_t)\rangle - \frac{1}{2}\langle\|\mathcal{Z}_t^\perp\|^2\rangle + V(q) + \langle U(m_t(q))\rangle. \tag{2.11}$$

Invoking the adiabatic assumption, we discard $\langle \|\mathcal{Z}_t^{\perp}\|^2 \rangle$ since it is small with respect to the other terms in the averaged Hamiltonian. After discarding the centrifugal terms, the dynamics of the Hamiltonian system are governed by the Hamiltonian vector field

$$X_{\langle H \rangle} = X_{H_0} - X_{\langle \mathcal{P}(Z_t) \rangle} + X_{\langle U \circ m_t \rangle}. \tag{2.12}$$

The second term captures the effect of the imposed motion in the adiabatic limit and is precisely the term given by the horizontal lift of the vector field $\mathcal{Z}_t$ with respect to the Cartan–Hannay–Berry connection as defined in (2.5).

2.2. Geometric character of the Hannay–Berry phase. The effect of the vector field $X_{\langle \mathcal{P}(Z_t) \rangle}$ is geometric in nature. By this we mean that the resulting change in the system is independent of the parametrization of the curve followed in the base space M; i.e., the effect depends only on the loop itself and not on how it is traversed. To see this explicitly, recall that the vector field $-X_{\langle \mathcal{P}(Z_t) \rangle}$ is the horizontal lift of a vector field $\mathcal{Z}_t$ on the base space M to the fiber T^*Q with respect to the Cartan–Hannay–Berry connection and is thus a linear map of $\mathcal{Z}_t$. Denoting points in T^*Q by z, the ordinary differential equation defining the Hannay–Berry phase may be expressed as

$$\frac{dz}{dt} = -X_{\langle \mathcal{P}(Z_t) \rangle} = D(z)\mathcal{Z}_t. \tag{2.13}$$

In coordinates, $D(z)$ is a matrix taking tangent vectors on M to tangent vectors on T^*Q. We now change the time parametrization by taking $t \mapsto \tau(t)$ with $\frac{d\tau}{dt}$ strictly positive. Under this new parametrization, the vector field $\mathcal{Z}_t$ is scaled by $\frac{d\tau}{dt}$, and thus

$$\frac{dz}{dt} = \frac{dz}{d\tau}\frac{d\tau}{dt} = D(z)\left(\frac{d\tau}{dt}\right)\mathcal{Z}_\tau. \tag{2.14}$$

We then have

$$\frac{dz}{d\tau} = D(z)\mathcal{Z}_\tau, \tag{2.15}$$

which has the same form as the differential equation in the original parametrization.

3. Hamiltonian normal forms. The theory of Hamiltonian normal forms (or Hamiltonian perturbation theory) is a generalization of Lie perturbation techniques (see, e.g., [12]), which in turn is built upon the perturbation methods developed by Poincaré and von Ziepel (see [5] for historical comments). In this section we provide a brief description of the theory and refer the reader to [13, 14] for more details and further references.

Recall the definition of a Poisson manifold.

DEFINITION 3.1. *A* Poisson manifold *is a smooth manifold M together with a $\mathbb{R}$-bilinear map on $C^\infty(M)$,*

$$\{\cdot,\cdot\} : C^\infty(M) \times C^\infty(M) \to C^\infty(M),$$

which for all $f, g, h \in C^\infty(M)$ satisfies

(i) *skew symmetry:* $\{f, g\} = -\{g, f\}$,
(ii) *Leibniz identity:* $\{f, gh\} = \{f, g\}h + g\{f, h\}$,
(iii) *Jacobi identity:* $\{f, \{g, h\}\} + \{g, \{h, f\}\} + \{h, \{f, g\}\} = 0$.

Consider a Poisson manifold $(M, \{\cdot,\cdot\})$. Let $\mathcal{F}(M)$ be the vector space of formal power series in ϵ with coefficients in $C^\infty(M)$. That is,

$$\mathcal{F}(M) = \left\{ f_\epsilon \in C^\infty(M) \,\middle|\, f_\epsilon = \sum_{i=0}^{\infty} \epsilon^i f_i,\ f_i \in C^\infty(M) \right\}. \tag{3.1}$$

Let $\mathrm{ad}_f g = \{g, f\}$ and define $\mathrm{ad}_f^0 g = g$. Recursively define ad_f^i by

$$\mathrm{ad}_f^i g = \{\mathrm{ad}_f^{i-1} g, f\}. \tag{3.2}$$

DEFINITION 3.2. *The* Lie series *of f is the formal power series*

$$\phi_\epsilon^f = \exp(\epsilon \mathrm{ad}_f) = \sum_{i=0}^{\infty} \frac{\epsilon^i}{i!} \mathrm{ad}_f^i. \tag{3.3}$$

Here ϕ_ϵ^f is the formal flow of the Hamiltonian vector field X_f with ϵ as the time parameter.

DEFINITION 3.3. *For $f \in \mathcal{F}(M)$, X_f is said to have* periodic flow *if there exists a positive, smooth function T on M such that for all $m \in M$ and for all $g \in \mathcal{F}(M)$, $((\phi_T^f)^*(g))(m) = g(m)$.*

DEFINITION 3.4. *Consider $H \in \mathcal{F}(M)$ and suppose X_{H_0} has periodic flow. H is said to be in* normal form with respect to H_0 *if $\{H_0, H_i\} = 0$ for $i = 1, 2, \ldots$ and in* normal form up to order n with respect to H_0 *if $\{H_0, H_i\} = 0$, $i = 1, 2, \ldots, n$.*

To bring a Hamiltonian into normal form we will use a formal change of coordinates of the form ϕ_ϵ^f for some appropriate $f \in \mathcal{F}(m)$. The following lemma from [14] shows how the Hamiltonian is modified under such a change of coordinates.

LEMMA 3.5 (see [14]). *Let $H, f \in \mathcal{F}(M)$. If ϕ_ϵ^f is the flow of X_f, then*

$$\left(\phi_\epsilon^f\right)^* H = \exp(\epsilon \mathrm{ad}_f) H. \tag{3.4}$$

The use of (3.3) in (3.4) yields

$$\begin{aligned} \left(\phi_\epsilon^f\right)^* H &= \sum_{i=0}^{\infty} \frac{\epsilon^i}{i!} \mathrm{ad}_f^i \left(\sum_{j=0}^{\infty} \epsilon^j H_j \right) \\ &= H_0 + \epsilon(H_1 + \mathrm{ad}_f H_0) + \epsilon^2 \left(H_2 + \mathrm{ad}_f H_1 + \frac{1}{2} \mathrm{ad}_f^2 H_0 \right) + O(\epsilon^3). \end{aligned} \tag{3.5}$$

To bring H into first-order normal form, we seek a function $f \in \mathcal{F}(M)$ such that

$$\{H_0, H_1 + \mathrm{ad}_f H_0\} = 0. \tag{3.6}$$

To find this function we use the following lemma from [13].

LEMMA 3.6 (see [13]). *If X_{H_0} has periodic flow on M, then*

$$C^\infty(M) = \ker\left(\mathrm{ad}_{H_0}\right) \oplus \mathrm{im}\left(\mathrm{ad}_{H_0}\right). \tag{3.7}$$

Let $\langle\cdot\rangle$ denote the average over the orbits of H_0; i.e., for $g \in C^\infty(M)$

$$\langle g \rangle = \frac{1}{T} \int_0^T \left(\phi_t^{H_0}\right)^* g \, dt. \tag{3.8}$$

To use Lemma 3.6 we first show the following.

LEMMA 3.7. *Let $g \in C^\infty(M)$. Then $\langle g \rangle \in \ker(\mathrm{ad}_{H_0})$.*

Proof. The equation $\mathrm{ad}_{H_0}\langle g\rangle = \rho$ is equivalent to the dynamical system

$$\frac{d}{dt}\left(\phi_t^{H_0}\right)^* \langle g\rangle = \left(\phi_t^{H_0}\right)^* \rho$$

(see, e.g., Proposition 10.2.3 of [26]). We show that $\rho = 0$. The use of the definition of the average of g yields

$$\begin{aligned}
\frac{d}{dt}\left(\phi_t^{H_0}\right)^* \langle g\rangle &= \frac{d}{dt}\left(\phi_t^{H_0}\right)^* \frac{1}{T}\int_0^T \left(\phi_\tau^{H_0}\right)^* g\, d\tau \\
&= \frac{1}{T}\frac{d}{dt}\int_0^T \left(\phi_{t+\tau}^{H_0}\right)^* g\, d\tau \\
&= \frac{1}{T}\frac{d}{dt}\int_t^{T+t} \left(\phi_\sigma^{H_0}\right)^* g\, d\sigma \\
&= \frac{1}{T}\left(\left(\phi_{T+t}^{H_0}\right)^* g - \left(\phi_t^{H_0}\right)^* g\right) \\
&= \frac{1}{T}\left(\left(\phi_t^{H_0}\right)^* g - \left(\phi_t^{H_0}\right)^* g\right) \\
&= 0.
\end{aligned}$$

Therefore $\mathrm{ad}_{H_0}\langle g\rangle = 0$. □

To put the Hamiltonian into normal form to first order we write

$$H_1 = \langle H_1\rangle + (H_1 - \langle H_1\rangle) \tag{3.9}$$

and then substitute (3.9) into (3.6). Thus

$$\begin{aligned}
0 &= \{H_0, \langle H_1\rangle + (H_1 - \langle H_1\rangle) + \mathrm{ad}_f H_0\} \\
&= \{H_0, \langle H_1\rangle\} + \{H_0, (H_1 - \langle H_1\rangle) + \mathrm{ad}_f H_0\} \\
&= \{H_0, (H_1 - \langle H_1\rangle) + \mathrm{ad}_f H_0\}, \qquad (3.10)
\end{aligned}$$

where the last step follows from the fact that, from 3.7, $\langle H_1\rangle \in \ker(\mathrm{ad}_{H_0})$. We then seek a solution to the *homological equation*

$$\mathrm{ad}_f H_0 = -(H_1 - \langle H_1\rangle), \tag{3.11}$$

where f is the unknown function.

PROPOSITION 3.8 (see [13]). *The solution to* (3.11) *is given by*

$$f = \frac{1}{T}\int_0^T t\left(\phi_t^{H_0}\right)^* (H_1 - \langle H_1\rangle)\, dt. \tag{3.12}$$

Proof. Let $g = -\mathrm{ad}_f H_0 = \mathrm{ad}_{H_0} f$. This is equivalent to the dynamical system

$$\frac{d}{dt}\left(\phi_t^{H_0}\right)^* f = \left(\phi_t^{H_0}\right)^* g.$$

We show that $g = H_1 - \langle H_1 \rangle$ by direct substitution. Thus

$$\begin{aligned}
\frac{d}{dt}\left(\phi_t^{H_0}\right)^* f &= \frac{d}{dt}\left(\frac{1}{T}\int_0^T \tau \left(\phi_\tau^{H_0}\right)^* (H_1 - \langle H_1\rangle) d\tau\right) \\
&= \frac{1}{T}\frac{d}{dt}\int_0^T \tau \left(\phi_{t+\tau}^{H_0}\right)^* (H_1 - \langle H_1\rangle) d\tau \\
&= \frac{1}{T}\frac{d}{dt}\int_t^{t+T} (\sigma - t)\left(\phi_\sigma^{H_0}\right)^* (H_1 - \langle H_1\rangle) d\sigma \\
&= \frac{1}{T}\left(T\left(\phi_{t+T}^{H_0}\right)^* (H_1 - \langle H_1\rangle) - \int_t^{t+T} \left(\phi_\sigma^{H_0}\right)^* (H_1 - \langle H_1\rangle) d\sigma\right) \\
&= \left(\phi_{t+T}^{H_0}\right)^* (H_1 - \langle H_1\rangle) - \frac{1}{T}\int_t^{t+T} \left(\phi_\sigma^{H_0}\right)^* H_1 d\sigma + \langle H_1\rangle \\
&= \left(\phi_{t+T}^{H_0}\right)^* (H_1 - \langle H_1\rangle) - \langle H_1\rangle + \langle H_1\rangle \\
&= \left(\phi_t^{H_0}\right)^* (H_1 - \langle H_1\rangle).
\end{aligned}$$

Therefore $g = (H_1 - \langle H_1\rangle)$. From this the proposition follows. □

With this choice of f, the Hamiltonian in (3.4) becomes

$$\exp(\epsilon \mathrm{ad}_f) H = H_0 + \epsilon\langle H_1\rangle + \epsilon^2\left(H_2 + \mathrm{ad}_f H_1 + \frac{1}{2}\mathrm{ad}_f^2 H_0\right) + O(\epsilon^3), \tag{3.13}$$

which is in first-order normal form. Notice that if we wish to bring the Hamiltonian into normal form only up to first order, then there is no need to explicitly calculate the generating function f.

To bring the function into normal form up to second order we repeat the process, now on the once transformed Hamiltonian. This time we seek a generating function of the form ϵg. Application of the corresponding change of coordinates results in

$$\begin{aligned}
&\exp(\epsilon \mathrm{ad}_{\epsilon g})\left(\exp(\epsilon \mathrm{ad}_f) H\right) = \sum_{i=0}^{\infty} \frac{\epsilon^i}{i!}\mathrm{ad}_{\epsilon g}^i \left(\exp(\epsilon \mathrm{ad}_f) H\right) \\
&\quad = H_0 + \epsilon\langle H_1\rangle + \epsilon^2\left(H_2 + \mathrm{ad}_f H_1 + \frac{1}{2}\mathrm{ad}_f^2 H_0 + \mathrm{ad}_g H_0\right) + O(\epsilon^3).
\end{aligned} \tag{3.14}$$

The homological equation which needs to be solved is

$$\mathrm{ad}_g H_0 = -\left(H_2 + \mathrm{ad}_f H_1 + \frac{1}{2}\mathrm{ad}_f^2 H_0 - \left(\langle H_2\rangle + \langle \mathrm{ad}_f H_1\rangle + \left\langle \frac{1}{2}\mathrm{ad}_f^2 H_0\right\rangle\right)\right). \tag{3.15}$$

From Proposition 3.8, the solution to this equation is

$$\begin{aligned}
g = \frac{1}{T}\int_0^T t\left(\phi_t^{H_0}\right)^* \Big[&H_2 - \langle H_2\rangle + \mathrm{ad}_f H_1 - \langle \mathrm{ad}_f H_1\rangle \\
&+ \frac{1}{2}\left(\mathrm{ad}_f^2 H_0 - \langle \mathrm{ad}_f^2 H_0\rangle\right)\Big] dt.
\end{aligned} \tag{3.16}$$

With this choice our transformed Hamiltonian becomes

$$\begin{aligned}
&\exp(\epsilon \mathrm{ad}_{\epsilon g})\left(\exp(\epsilon \mathrm{ad}_f) H\right) \\
&\quad = H_0 + \epsilon\langle H_1\rangle + \epsilon^2\left(\langle H_2\rangle + \langle \mathrm{ad}_f H_1\rangle + \frac{1}{2}\langle \mathrm{ad}_f^2 H_0\rangle\right) + O(\epsilon^3).
\end{aligned} \tag{3.17}$$

The Hamiltonian can be placed into normal form up to arbitrary order n by repeating this process.

In practice one places the system into normal form up to some desired order and then truncates the higher-order terms. The truncated Hamiltonian gives an approximation to the original system. Since the coefficients of ϵ^i in the transformed Hamiltonian all commute with H_0 for $i = 1, 2, \ldots, n$, the flow of the corresponding Hamiltonian vector field of the higher-order terms also commutes with the flow of the nominal system. Thus for a Hamiltonian in first-order normal form we have

$$\phi_t^{H_0+\epsilon\langle H_1\rangle}(m) = \phi_t^{\epsilon\langle H_1\rangle} \circ \phi_t^{H_0}(m), \qquad m \in M, \tag{3.18}$$

and the first-order terms give rise naturally to a first-order correcting symplectic map given by the flow of the Hamiltonian system $\epsilon\langle H_1\rangle$. For systems in higher-order normal form, however, while the functions at each order do Poisson commute with H_0, they do not in general commute with each other, and thus a system in nth-order normal form defines a single nth-order correcting symplectic map.

4. Normal forms and the Hannay–Berry phase. In the setting of the moving systems approach the Poisson manifold is T^*Q together with the canonical Poisson bracket defined by

$$\{f, g\} = \sum_{i=1}^{n} \frac{\partial f}{\partial q^i}\frac{\partial g}{\partial p_i} - \frac{\partial f}{\partial p_i}\frac{\partial g}{\partial q^i}, \quad f, g \in C^\infty(M). \tag{4.1}$$

To apply Hamiltonian normal form theory we make a few additional assumptions on the Hamiltonian of a moving system, (2.10). We first assume that the potential U on S is constant and drop it from the Hamiltonian. Next we assume that $\mathcal{Z}_t(m_t(q))$ can be written in the form

$$\mathcal{Z}_t(m_t(q)) = \epsilon\hat{\mathcal{Z}}_t(m_t(q)) \tag{4.2}$$

for some parameter ϵ. For example, if M is a Riemannian manifold and $\mathcal{Z}_t$ is a constant magnitude vector field, then we may take $\epsilon = \|\mathcal{Z}_t\|$ and $\hat{\mathcal{Z}}_t = \frac{\mathcal{Z}_t}{\|\mathcal{Z}_t\|}$. If $\|\mathcal{Z}_t\|$ is not constant, then one could take ϵ to be the average magnitude of $\|\mathcal{Z}_t\|$ over the loop in M starting at the given initial condition. However, the form of $\mathcal{Z}_t$ in (4.2) is often natural to the problem, and in general $\hat{\mathcal{Z}}_t$ is not a unit vector. Under these assumptions the Hamiltonian can be written as

$$H(q, p) = H_0(q, p) + \epsilon H_1(q, p) + \epsilon^2 H_2(q, p), \tag{4.3}$$

where

$$H_0(q, p) = \frac{1}{2}\|p\|^2 + V(q), \tag{4.4}$$

$$H_1(q, p) = -\mathcal{P}(\hat{Z}_t), \tag{4.5}$$

$$H_2(q, p) = -\frac{1}{2}\|\hat{\mathcal{Z}}_t^{\perp}\|^2. \tag{4.6}$$

Finally we assume that H_0 has periodic flow with period T. We then have a natural action of S^1 on T^*Q, given by $\phi_t^{H_0}$, the flow of X_{H_0}. Let $\langle\cdot\rangle$ denote the average with respect to this group action; i.e., for a smooth function f on T^*Q we have

$$\langle f\rangle = \frac{1}{T}\int_0^T \left(\phi_t^{H_0}\right)^* f\, dt. \tag{4.7}$$

In general, the parameter ϵ captures the rate of the imposed motion on the system. In the adiabatic limit, then, ϵ goes to zero and the terms in ϵ^2 are negligible. (Note that the terms in ϵ are not negligible in the adiabatic limit since the time parametrization of the (slow) imposed motion scales as $\frac{1}{\epsilon}$. See section 2.2.) In what follows we are interested in relaxing the adiabatic condition; i.e., we assume that while ϵ is small, the terms in ϵ^2 are not negligible. The truncated Hamiltonian defined by

$$\langle H\rangle^{(1)}(q,p) = H_0(q,p) + \epsilon\langle H_1\rangle(q,p) = H_0(q,p) - \epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle \tag{4.8}$$

is in first-order normal form. The flow of the system to first order is then given by

$$\phi_t^{H_0-\epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle}(q,p) = \phi_t^{-\epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle} \circ \phi_t^{H_0}(q,p), \tag{4.9}$$

and the flow of $-\langle \mathcal{P}(\hat{Z}_t)\rangle$ defines the correcting symplectic map to first order. Thus, in the setting where the group action on T^*Q is given by the flow of the nominal dynamics, the Hannay–Berry phase is the first-order correction at the completion of a closed loop in parameter space.

To find a more accurate expression we express the Hamiltonian in normal form to a higher order before truncating. Let G be the generator of a change of coordinates bringing the original Hamiltonian into first-order normal form. From Proposition 3.8 and the form of H_1 in (4.5), G is given by

$$G = \frac{1}{T}\int_0^T t\left(\phi_t^{H_0}\right)^*\left[\langle \mathcal{P}(\hat{Z}_t)\rangle - \mathcal{P}(\hat{Z}_t)\right]dt. \tag{4.10}$$

From (3.17) and the form of H_2 in (4.6), the second-order truncated normal form is

$$\begin{aligned}\langle H\rangle^{(2)}(q,p) &= H_0(q,p) - \epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle \\ &\quad -\epsilon^2\left(\frac{1}{2}\langle\|\hat{\mathcal{Z}}_t^{\perp}\|^2\rangle + \langle \mathrm{ad}_G\mathcal{P}(\hat{Z}_t)\rangle - \frac{1}{2}\langle \mathrm{ad}_G^2 H_0\rangle\right).\end{aligned} \tag{4.11}$$

Notice that the terms at second order in the Hamiltonian not only account for the average effect of the centrifugal force but also include additional terms involving the first-order change of coordinates. The flow of the system to second order is

$$\begin{aligned}&\phi_t^{H_0-\epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle-\epsilon^2\left(\frac{1}{2}\langle\|\hat{\mathcal{Z}}_t^{\perp}\|^2\rangle+\langle \mathrm{ad}_G\mathcal{P}(\hat{Z}_t)\rangle-\frac{1}{2}\langle \mathrm{ad}_G^2 H_0\rangle\right)}(q,p) \\ &= \phi_t^{-\epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle-\epsilon^2\left(\frac{1}{2}\langle\|\hat{\mathcal{Z}}_t^{\perp}\|^2\rangle+\langle \mathrm{ad}_G\mathcal{P}(\hat{Z}_t)\rangle-\frac{1}{2}\langle \mathrm{ad}_G^2 H_0\rangle\right)} \circ \phi_t^{H_0}(q,p),\end{aligned} \tag{4.12}$$

and this in general defines a correcting symplectic map to second order. If in addition the terms in ϵ Poisson commute with the terms in ϵ^2, then the second-order terms define a second-order correcting symplectic map. In this case the three Hamiltonian systems can be solved independently and their flows composed to obtain the second-order solution. This is captured in the following lemma.

LEMMA 4.1. *If*

$$\left\{\langle \mathcal{P}(\hat{Z}_t)\rangle, \frac{1}{2}\langle\|\hat{\mathcal{Z}}_t^{\perp}\|^2\rangle + \langle \mathrm{ad}_G\mathcal{P}(\hat{Z}_t)\rangle - \frac{1}{2}\langle \mathrm{ad}_G^2 H_0\rangle\right\} = 0, \tag{4.13}$$

then

$$\begin{aligned}&\phi_t^{H_0-\epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle-\epsilon^2\left(\frac{1}{2}\langle\|\hat{\mathcal{Z}}_t^{\perp}\|^2\rangle+\langle \mathrm{ad}_G\mathcal{P}(\hat{Z}_t)\rangle-\frac{1}{2}\langle \mathrm{ad}_G^2 H_0\rangle\right)}(q,p) \\ &= \phi_t^{-\epsilon^2\left(\frac{1}{2}\langle\|\hat{\mathcal{Z}}_t^{\perp}\|^2\rangle+\langle \mathrm{ad}_G\mathcal{P}(\hat{Z}_t)\rangle-\frac{1}{2}\langle \mathrm{ad}_G^2 H_0\rangle\right)} \circ \phi_t^{-\epsilon\langle \mathcal{P}(\hat{Z}_t)\rangle} \circ \phi_t^{H_0}(q,p).\end{aligned} \tag{4.14}$$

Proof. The proof is immediate by the assumption of the Poisson commutativity of the functions. ∎

4.1. Time-dependence of nonadiabatic corrections. In section 2.2 we showed that the Hannay–Berry phase is a geometric phenomenon by showing that the corresponding ordinary differential equation is independent of the time parametrization. We now show that the terms in ϵ^2 in the moving systems Hamiltonian do not result in a geometric effect. Consider (4.11). For simplicity assume that the generating function for the change of coordinates is $G = 0$ and that $\{\langle H_1\rangle, \langle H_2\rangle\} = 0$ so that we can calculate the effect on the system from these two terms separately. Denote points in T^*Q by z. Noticing that $X_{\langle \|\mathcal{Z}^\perp\|^2\rangle}$ is a quadratic form in the vector field $\mathcal{Z}$ on the base space, we define

$$Y(\mathcal{Z}_t, z) = -X_{\langle \|\mathcal{Z}_t^\perp|^2\rangle}, \tag{4.15}$$

where $Y(a\mathcal{Z}_t, z) = a^2 Y(\mathcal{Z}_t, z)$. The corresponding ordinary differential equation is

$$\dot{z} = Y(\mathcal{Z}_t, z). \tag{4.16}$$

We now change the time parametrization (as in section 2.2) by taking $t \mapsto \tau(t)$ with $\frac{d\tau}{dt}$ strictly positive. Under this parametrization, the vector field $\mathcal{Z}_t$ is scaled by $\frac{d\tau}{dt}$ and thus

$$\frac{dz}{dt} = \frac{dz}{d\tau}\frac{d\tau}{dt} = Y\left(\frac{d\tau}{dt}\mathcal{Z}_\tau, z\right) = \left(\frac{d\tau}{dt}\right)^2 Y(\mathcal{Z}_\tau, z). \tag{4.17}$$

From this we have

$$\frac{dz}{d\tau} = \frac{d\tau}{dt} Y(\mathcal{Z}_\tau, z), \tag{4.18}$$

which shows the dependence on the time parametrization.

5. The equal-sided spring-jointed free-floating four-bar mechanism. In this section we apply the method developed in section 4 to an equal-sided spring-jointed free-floating four-bar mechanism which is being rotated about its center of mass. The study of the four-bar mechanism has a long history, dating at least back to the work of Grashof in the mid-nineteenth century [22]. (See also [29] and references therein.) Building upon an analysis of four-bar linkages due to Yang and Krishnaprasad [37], this system is analyzed in [4, 3] using the moving system approach, and it is shown that the Hannay–Berry phase is zero. After briefly recalling this result, we will show that the second-order effects of the imposed rotation are also zero.

Consider an equal-sided four-bar mechanism as shown in Figure 5.1. By a "bar" we mean a planar rigid body on which the center of mass and pin joints are arbitrarily located. The identical bars are labeled sequentially from 0 to 3, and on each a body-fixed frame is defined such that its origin is at the body center of mass and the x-axis is parallel to the line connecting the pin joints. The positive direction of the x-axis of the ith bar is defined to be towards the $(i+1)$th bar for $i = 0, 1, 2, 3$, where we adopt

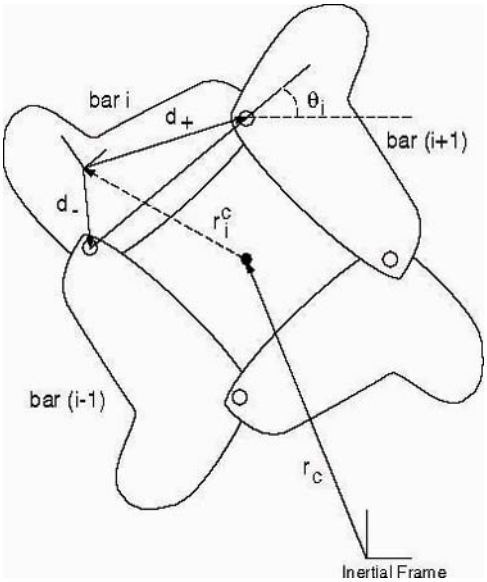

FIG. 5.1. *Equal-sided four-bar mechanism.*

the convention of modulo four addition for subscripts. We define the following:

- $\mathbf{d}_+$ the vector from the body center of mass of the ith bar to the pin joint with the $(i+1)$th bar,
- $\mathbf{d}_-$ the vector from the body center of mass of the ith bar to the pin joint with the $(i-1)$th bar,
- l the length of each bar $\|\mathbf{d}_+ - \mathbf{d}_-\|$, where $\|\cdot\|$ is the standard Euclidean norm,
- $\mathbf{r}_i^c$ the vector from the system center of mass to the ith body center of mass,
- $\mathbf{r}_c$ the vector from the origin of the inertial system to the system center of mass,
- θ_i the angle between the ith bar frame and the inertial frame,
- $\theta_{i,j}$ the angle $\theta_i - \theta_j$ between the ith and jth bars,
- I, m the moment of inertia and mass of each bar.

From Figure 5.1 we have that

$$r_{i+1}^c = r_i^c + R(\theta_i)\mathbf{d}_+ - R(\theta_{i+1})\mathbf{d}_-, \quad i = 0, 1, 2, 3, \tag{5.1}$$

where $R(\theta_i)$ is the rotation matrix given by

$$R(\theta_i) = \begin{pmatrix} \cos(\theta_i) & -\sin(\theta_i) \\ \sin(\theta_i) & \cos(\theta_i) \end{pmatrix}.$$

We use (5.1) recursively to define the loop closure constraint

$$F(r) = \sum_{i=0}^{3} R(\theta_i)(\mathbf{d}_+ - \mathbf{d}_-) = 0. \tag{5.2}$$

In [32] it is shown that the configuration space for a free-floating four-link open chain is $\mathcal{R} = \mathbb{R}^2 \times S^1 \times S^1 \times S^1 \times S^1$. The configuration space for a general four-bar mechanism is thus $S_{\text{gen}} = \{r \in \mathcal{R} | F(r) = 0\}$. For a four-bar mechanism with identical bars it can be shown that if the system is not allowed to pass through any singularities (joint angles of 0 or 2π), then the configuration space $S = \{r \in \mathcal{R} | F(r) = 0, \theta_{i+1,i} \neq 0, \pi\}$ is a smooth submanifold of $\mathcal{R}$ [3].

While in the general four-bar mechanism the relations between the angles θ_i can be quite complicated (see, for example, [29]), they have a particularly simple form for the equal-sided case, namely

$$\theta_2 = \theta_0 + \pi, \qquad \theta_3 = \theta_0 - \pi, \tag{5.3}$$

which leads to the following equalities:

$$\theta_{32} = \theta_{10}, \quad \theta_{21} = \theta_{03} = \pi - \theta_{10}, \quad \theta_{13} = \theta_{20} = \pi. \tag{5.4}$$

For the free-floating equal-sided four-bar linkage the configuration is completely specified by the choice of one global angle and one joint angle. We arbitrarily choose θ_0 and θ_{10}. After removing the singular points $\theta_{10} = 0, \pi$, the configuration space is given by $S^1 \times \{(0, \pi) \cup (0, -\pi)\}$. Since the joint angle is not allowed to pass through the singular points, we may arbitrarily choose either one of the connected components of this space to describe the configuration of our system, with the additional requirement that the initial condition lie in the component we have chosen. Without loss of generality, then, we take $S = S^1 \times (0, \pi)$ as the configuration space of the free-floating equal-sided four-bar mechanism.

The total kinetic energy of the system in the center of mass frame is given by

$$T = \frac{1}{2} I \sum_{i=0}^{3} \omega_i^2 + \frac{1}{2} m \sum_{i=0}^{3} \|\dot{r}_i^c\|^2. \tag{5.5}$$

Following [37], this can be written

$$T = \frac{1}{2} \langle \tilde{\omega}, \tilde{M} \tilde{\omega} \rangle, \tag{5.6}$$

where $\tilde{\omega} = (\omega_0, \omega_1, \omega_2, \omega_3)'$ and $\tilde{M}$ is a 4×4 symmetric matrix whose elements for the equal-sided four-bar system are

$$\tilde{M}_{ii} = I + \frac{3m}{8} \left(\|\mathbf{d}_+\|^2 + \|\mathbf{d}_-\|^2 \right), \tag{5.7}$$

$$\tilde{M}_{i,i+1} = \frac{m}{8} \left(\mathbf{d}'_- R_{i+1,i} \mathbf{d}_+ - 3 \mathbf{d}'_+ R_{i+1,i} \mathbf{d}_- \right), \tag{5.8}$$

$$\tilde{M}_{i,i+2} = -\frac{m}{8} \left(\mathbf{d}'_+ R_{i+2,i} \mathbf{d}_+ + \mathbf{d}'_- R_{i+2,i} \mathbf{d}_- \right), \tag{5.9}$$

where $'$ indicates transpose and $R_{i,j} = R(\theta_i - \theta_j)$. From (5.3) we have

$$\begin{pmatrix} \omega_2 \\ \omega_3 \end{pmatrix} = \begin{pmatrix} \omega_0 \\ \omega_1 \end{pmatrix}, \tag{5.10}$$

where $\omega_i = \dot{\theta}_i$. Let $\mathbb{I}$ denote the identity matrix. Define

$$M = \begin{pmatrix} \mathbb{I} & \mathbb{I} \end{pmatrix} \tilde{M} \begin{pmatrix} \mathbb{I} \\ \mathbb{I} \end{pmatrix}. \tag{5.11}$$

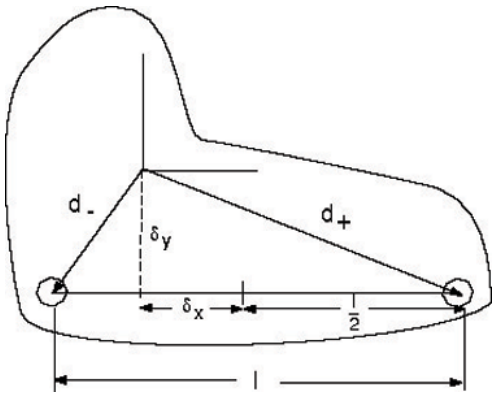

FIG. 5.2. *Single bar diagram.*

Then

$$T = \frac{1}{2} \begin{pmatrix} \omega_0 & \omega_1 \end{pmatrix} M \begin{pmatrix} \omega_0 \\ \omega_1 \end{pmatrix}. \tag{5.12}$$

M is symmetric. It depends only on the joint angles and thus, given the relations (5.4), it depends only on θ_{10}. We would like to express the entries in this matrix in terms of the parameters of the four-bar linkage. From (5.4), (5.7), (5.9), and (5.11), we have

$$M_{00} = 2I + m(\|\mathbf{d}_+\|^2 + \|\mathbf{d}_-\|^2), \tag{5.13}$$

$$M_{11} = M_{00}. \tag{5.14}$$

From (5.4), (5.8), and (5.11) we have

$$M_{10} = \frac{m}{4} \left(\mathbf{d}'_- R_{1,0} \mathbf{d}_+ - 3\mathbf{d}'_+ R_{1,0} \mathbf{d}_- + \mathbf{d}'_- R_{\pi-\theta_{10}} \mathbf{d}_+ - 3\mathbf{d}'_+ R_{\pi-\theta_{10}} \mathbf{d}_- \right).$$

Since

$$R_{\pi-\theta_{10}} = \begin{pmatrix} -\cos(\theta_{10}) & -\sin(\theta_{10}) \\ \sin(\theta_{10}) & -\cos(\theta_{10}) \end{pmatrix} = -R_{0,1}, \tag{5.15}$$

this may be rewritten as

$$M_{10} = m \left(\mathbf{d}'_- R_{1,0} \mathbf{d}_+ - \mathbf{d}'_+ R_{1,0} \mathbf{d}_- \right) = 2m(d^1_+ d^2_- - d^2_+ d^1_-) \sin(\theta_{10}), \tag{5.16}$$

where $d^j_\pm$ is the jth component of $d_\pm$.

Consider the diagram of a single bar shown in Figure 5.2. From the figure we have

$$\mathbf{d}_+ = \begin{pmatrix} \frac{l}{2} + \delta_x \\ \delta_y \end{pmatrix}, \qquad \mathbf{d}_- = \begin{pmatrix} -(\frac{l}{2} - \delta_x) \\ \delta_y \end{pmatrix}.$$

Thus

$$d^1_+ d^2_- - d^2_+ d^1_- = \left(\frac{l}{2} + \delta_x \right) (\delta_y) + (\delta_y) \left(\frac{l}{2} - \delta_x \right) = l\delta_y,$$

and so

$$M_{10} = 2ml\delta_y \sin(\theta_{10}). \tag{5.17}$$

The kinetic energy defines a Riemannian metric K on S given by

$$K(\theta_{10})(X, W) = X'\hat{M}(\theta_{10})W, \quad X, W \in T_{(\theta_0,\theta_{10})}S. \tag{5.18}$$

Each joint is equipped with an identical spring. Let the spring potential for each be given by $V_s(\theta_{i+1,i})$, $i = 0, 1, 2, 3$, with V_s twice continuously differentiable. The total potential energy is then

$$V(\theta_0, \theta_{10}) = 2(V_s(\theta_{10}) + V_s(\pi - \theta_{10})) \stackrel{\triangle}{=} V(\theta_{10}), \tag{5.19}$$

where the relations in (5.4) have been used to simplify the expression. We assume that the potential energy is such that there exists $\alpha \in \{0, \pi\}$ such that

$$\left.\frac{\partial V}{\partial \theta_{10}}\right|_\alpha = 0, \qquad \left.\frac{\partial^2 V}{\partial \theta_{10}^2}\right|_\alpha > 0, \tag{5.20}$$

and without loss of generality we take $V(\alpha) = 0$. The standard Lagrangian is then given by

$$L(\theta_{10}, \omega_{10}) = \frac{1}{2} \begin{pmatrix} \omega_0 & \omega_{10} \end{pmatrix} \hat{M}(\theta_{10}) \begin{pmatrix} \omega_0 \\ \omega_{10} \end{pmatrix} - V(\theta_{10}). \tag{5.21}$$

Consider now the following action Φ_g of the Lie group S^1 on S:

$$\Phi_g(\theta_0, \theta_{10}) = (\theta_0 + g, \theta_{10}). \tag{5.22}$$

The quadruple (S, K, V, S^1) is a simple mechanical system with symmetry, where the action of S^1 on S is given by (5.22). (For a definition and discussion of simple mechanical systems with symmetry, see [1].) Since the action is both free and proper, the reduced space is a manifold. Recall that we defined $S = S^1 \times (0, \pi)$; the reduced (or shape) space is then $Q = (0, \pi)$ with the coordinate θ_{10}.

In the language of the moving systems approach, Q is the configuration space and S is the ambient space. To slowly rotate the mechanism set $\theta_0 = \Omega t + \hat{\theta}_0$ for some fixed initial offset $\hat{\theta}_0$. (Note that θ_0 and $\theta_0 + 2\pi$ are identified.) The imposed motion on the four-bar system is captured by the parametrized family of embeddings from Q into S given by

$$m_t(\theta_{10}) = \begin{pmatrix} \Omega t + \hat{\theta}_0 \\ \theta_{10} \end{pmatrix}. \tag{5.23}$$

5.1. The nominal dynamics. To apply the method developed in section 4 the dynamics of the system in the absence of any imposed motion must be periodic. Consider the nominal Lagrangian for the four-bar mechanism, defined by setting $\Omega = 0$ in (5.21):

$$L_0(\theta_{10}, \omega_{10}) = \frac{M_{11}}{2}\omega_{10}^2 - V(\theta_{10}). \tag{5.24}$$

Applying the Legendre transform, the conjugate momentum is found to be

$$p_{10} = M_{11}\omega_{10},$$

and thus the Hamiltonian for the nominal system is

$$H_0(\theta_{10}, p_{10}) = \frac{p_{10}^2}{2M_{11}} + V(\theta_{10}). \tag{5.25}$$

The nominal dynamics is

$$\dot{\theta}_{10} = \frac{p_{10}}{M_{11}}, \quad \dot{p}_{10} = -\frac{\partial V}{\partial \theta_{10}}. \tag{5.26}$$

From (5.20) and (5.26), we see that there is an equilibrium point at $(\theta_{10} = \alpha, p_{10} = 0)$. The existence of periodic solutions near this equilibrium point can be assured by appealing to the following theorem by Weinstein.

THEOREM 5.1 (see [36]). *Consider $H : \mathbb{R}^{2n} \to \mathbb{R}$. If H is twice continuously differentiable near an equilibrium point z and the Hessian matrix at the equilibrium point is positive definite, then for sufficiently small ϵ any energy surface $H(z) = H(0) + \epsilon^2$ contains at least n periodic orbits of the associated Hamiltonian system.*

The Hessian matrix of the nominal system, evaluated at the equilibrium $(\alpha, 0)$, is

$$\left(\begin{array}{cc} \frac{\partial^2 H}{\partial \theta_{10}^2} & 0 \\ 0 & \frac{\partial^2 H}{\partial p_{10}^2} \end{array} \right) \Bigg|_{(\alpha,0)} = \left(\begin{array}{cc} \frac{\partial^2 V}{\partial \theta_{10}^2} & 0 \\ 0 & M_{11}^{-1} \end{array} \right) \Bigg|_{(\alpha,0)}. \tag{5.27}$$

M is positive definite by its construction, and so $M_{11} > 0$. Combining this with the assumption in (5.20), we see that the Hessian matrix of the Hamiltonian at the equilibrium point is positive definite, and therefore by Theorem (5.1) there is a periodic solution around the equilibrium if the energy is sufficiently small.

Since this is a one-degree-of-freedom system, it is integrable, and thus there exist action-angle coordinates (J, ψ) [6]. These coordinates will prove particularly convenient for evaluating both the Hannay–Berry phase and the higher-order corrections. Let $\Gamma(h)$ be the trajectory in phase space corresponding to the energy h. Then

$$J = \frac{1}{2\pi} \oint_{\Gamma(h)} p_{10} d\theta_{10}. \tag{5.28}$$

The trajectory $\Gamma(h)$, and thus the action, depends on the form of $V(\theta_{10})$. We can write in general

$$\begin{array}{ll} J = g_1(\theta_{10}, p_{10}), & \theta_{10} = f_1(J, \psi), \\ \psi = g_2(\theta_{10}, p_{10}), & p_{10} = f_2(J, \psi). \end{array} \tag{5.29}$$

For the remainder of this paper we will assume that the initial conditions are such that the periodic solutions of the nominal system are of small amplitude. The expansion of $V(\theta_{10})$ about the equilibrium point $(\alpha, 0)$ yields

$$V(\theta_{10}) = \frac{1}{2} \left. \frac{\partial^2 V}{\partial \theta_{10}^2} \right|_{\alpha} (\theta_{10} - \alpha)^2 + O((\theta_{10} - \alpha)^3). \tag{5.30}$$

In the small angle limit the potential is taken only to second order. Since the springs on each bar are identical, this is equivalent to taking

$$V_s(\theta_{10}) = \frac{k_s}{2} (\theta_{10} - \alpha_s)^2 \tag{5.31}$$

for the potential of each spring. Here $\alpha_s \in S^1$. From (5.19) the total potential is

$$V(\theta_{10}) = k_s \left[(\theta_{10} - \alpha_s)^2 + (\pi - \theta_{10} - \alpha_s)^2 \right]. \tag{5.32}$$

The equilibrium point α is given by setting the derivative of V with respect to θ_{10} to zero. This yields

$$0 = \left. \frac{\partial V}{\partial \theta_{10}} \right|_{\theta_{10}=\alpha} = 2k_s \left(2\alpha - \pi \right) \tag{5.33}$$

and thus $\alpha = \frac{\pi}{2}$. The second derivative of V with respect to θ_{10} is

$$\frac{\partial^2 V}{\partial \theta_{10}^2} = 4k_s \triangleq k. \tag{5.34}$$

With this choice of spring potential the nominal Hamiltonian is given by

$$H_0 = \frac{p_{10}^2}{2M_{11}} + \frac{k}{2}(\theta_{10} - \alpha)^2. \tag{5.35}$$

This is the Hamiltonian for a harmonic oscillator. From [6] the angle variable is the phase of the oscillation, and the action is

$$J = \frac{h}{\omega}, \tag{5.36}$$

where $\omega = \sqrt{\frac{k}{M_{11}}}$ is the frequency of oscillation and h is the energy corresponding to a given initial condition. From (5.35) and (5.36)

$$J = \frac{p_{10}^2 + kM_{11}(\theta_{10} - \alpha)^2}{2\sqrt{kM_{11}}}. \tag{5.37}$$

Therefore

$$\theta_{10} = \alpha + \left[\frac{2J}{\sqrt{kM_{11}}} \right]^{\frac{1}{2}} \cos\psi = f_1(J, \psi), \tag{5.38}$$

$$p_{10} = -\left[2J\sqrt{kM_{11}} \right]^{\frac{1}{2}} \sin\psi = f_2(J, \psi). \tag{5.39}$$

The use of (5.38), (5.39) in (5.35) yields

$$H_0(\theta_{10}, p_{10}) = H_0(J) = \sqrt{\frac{k}{M_{11}}} J, \tag{5.40}$$

leading to the following dynamics in the action-angle variables.

$$\dot{\psi} = \sqrt{\frac{k}{M_{11}}}, \quad \dot{J} = 0. \tag{5.41}$$

The average $\langle \cdot \rangle$ is then the average over one cycle of the angle variable ψ.

5.2. The Hannay–Berry phase of the four-bar linkage. Recall that the Hannay–Berry phase is the holonomy of the Cartan–Hannay–Berry connection and is determined by solving the Hamiltonian system associated to the averaged momentum function defined in (2.3). From (5.23), the velocity vector of the motion in S is

$$\frac{d}{dt}\left(m_t(\theta_{10})\right) = \begin{pmatrix} 0 \\ \omega_{10} \end{pmatrix} + \begin{pmatrix} \Omega \\ 0 \end{pmatrix},$$

and thus the tangent vector which must be projected to $T_{m_t(q)}m_t(Q)$ is

$$\mathcal{Z} \triangleq \mathcal{Z}_t(m_t(q(t))) = \begin{pmatrix} \Omega \\ 0 \end{pmatrix}. \tag{5.42}$$

The projection of $\mathcal{Z}$ to $T_{m_t(q)}m_t(Q)$ with respect to the kinetic energy metric on S is given by $\mathcal{Z}^T = \mathcal{Z} - \mathcal{Z}^\perp$, where $\mathcal{Z}^\perp$ satisfies the orthogonality condition

$$K(\theta_{10})(\mathcal{Z}^\perp, X) = 0 \quad \forall X \in T_{m_t(q)}m_t(Q).$$

Application of the orthogonality condition yields

$$\mathcal{Z}^\perp = \begin{pmatrix} \Omega \\ -\Omega\left[\frac{M_{10}(\theta_{10})+M_{11}}{M_{11}}\right] \end{pmatrix} \tag{5.43}$$

and thus

$$\mathcal{Z}^T = \begin{pmatrix} 0 \\ \Omega\left[\frac{M_{10}(\theta_{10})+M_{11}}{M_{11}}\right] \end{pmatrix}. \tag{5.44}$$

The pull-back of $\mathcal{Z}^T$ to T_qQ by $[Tm]^{-1}$ is given by projection onto the second factor,

$$Z \triangleq [Tm]^{-1}\,\mathcal{Z}^T = \Omega\left[\frac{M_{10}(\theta_{10}) + M_{11}}{M_{11}}\right]. \tag{5.45}$$

The function $\mathcal{P}(Z)$ is then (following (2.3))

$$\begin{aligned}\mathcal{P}(Z)(J,\psi) &= \Omega\left[\frac{M_{10}(\theta_{10}(J,\psi)) + M_{11}}{M_{11}}\right] p_{10}(J,\psi) \\ &= -\Omega\left[1 + \frac{2ml\delta_y}{M_{11}}\sin\left(\alpha + \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\cos\psi\right)\right]\left[2J\sqrt{kM_{11}}\right]^{\frac{1}{2}}\sin\psi, \end{aligned} \tag{5.46}$$

where we have expressed the function in terms of the action-angle coordinates given by (5.38), (5.39) and substituted for M_{10} using (5.17).

The flow of the nominal system induces an S^1 action on T^*Q, and the average with respect to this action is simply the average over one cycle of the angle coordinate ψ. Thus the Hamiltonian function defining the lift with respect to the Cartan–Hannay–Berry connection is

$$\begin{aligned}\langle P(Z)\rangle &= \frac{1}{2\pi}\int_0^{2\pi} P(Z)(J,\psi)d\psi \\ &= -\frac{\Omega\left[2J\sqrt{kM_{11}}\right]^{\frac{1}{2}}}{2\pi}\left[\int_0^{2\pi}\sin\psi d\psi + \int_0^{2\pi}\frac{2ml\delta_y}{M_{11}}\sin\left(\alpha + \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\cos\psi\right)\sin\psi d\psi\right] \\ &= -\frac{\Omega\sqrt{kM_{11}}}{2\pi}\left[\frac{2ml\delta_y}{M_{11}}\right]\cos\left(\alpha + \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\cos\psi\right)\Bigg|_0^{2\pi} = 0. \end{aligned} \tag{5.47}$$

Therefore, under the assumption of linear springs, the Hannay–Berry phase for the equal-sided spring-jointed four-bar mechanism is zero.

5.3. Nonadiabatic corrections. From the kinetic energy metric in (5.18) and the form of $\mathcal{Z}^{\perp}$ in (5.43) we have

$$\|\mathcal{Z}^{\perp}\|^2 = \Omega^2 \left[\frac{M_{11}^2 - M_{10}^2(J,\psi)}{M_{11}}\right]. \tag{5.48}$$

Using this and the form of $\mathcal{P}(Z)$ for the four-bar in (5.46), the Hamiltonian for the rotating four-bar may be written as

$$H(J,\psi) = H_0(J) + \Omega H_1(J,\psi) + \Omega^2 H_2(J,\psi), \tag{5.49}$$

where

$$H_0(J) = \sqrt{\frac{k}{M_{11}}}J, \tag{5.50}$$

$$H_1(J,\psi) = \left[\frac{b\sin\left(\alpha + \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\cos\psi\right) + M_{11}}{M_{11}}\right]\left[2J\sqrt{kM_{11}}\right]^{\frac{1}{2}}\sin\psi, \tag{5.51}$$

$$H_2(J,\psi) = -\frac{1}{2}\left[\frac{M_{11}^2 - b^2\sin^2\left(\alpha + \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\cos\psi\right)}{M_{11}}\right], \tag{5.52}$$

where we have defined the constant $b = 2ml\delta_y$ to ease the notation. To find the effect of the imposed rotation to second order we must first find the generating function for the change of coordinates bringing the system into first-order normal form. From Proposition 3.8 we have

$$\begin{aligned} G(J) &= \frac{1}{2\pi}\int_0^{2\pi} \psi\left(H_1(J,\psi) - \langle H_1(J,\psi)\rangle\right)d\psi \\ &= \frac{1}{2\pi}\int_0^{2\pi} \psi\left[\frac{b\sin\left(\alpha + \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\cos\psi\right) + M_{11}}{M_{11}}\right]\left[2J\sqrt{kM_{11}}\right]^{\frac{1}{2}}\sin\psi d\psi, \end{aligned} \tag{5.53}$$

where we have used (5.47). Define

$$c_1(J) = \left[\frac{2J}{\sqrt{kM_{11}}}\right]^{\frac{1}{2}}, \quad c_2(J) = \left[2J\sqrt{kM_{11}}\right]^{\frac{1}{2}}. \tag{5.54}$$

Then

$$G(J) = \frac{c_2(J)b}{2\pi M_{11}}\int_0^{2\pi}\psi\sin\psi\sin(\alpha + c_1(J)\cos\psi)d\psi + \frac{c_2(J)}{2\pi}\int_0^{2\pi}\psi\sin\psi d\psi. \tag{5.55}$$

A simple integration by parts shows that

$$\int_0^{2\pi}\psi\sin\psi d\psi = -2\pi. \tag{5.56}$$

Similarly

$$\begin{aligned}\int_0^{2\pi} \psi \sin\psi \sin(\alpha + c_1(J)\cos\psi) d\psi \\ &= \frac{2\pi}{c_1(J)} \cos(\alpha + c_1(J)) - \frac{1}{c_1(J)} \int_0^{2\pi} \cos(\alpha + c_1(J)\cos\psi) d\psi \\ &= \frac{2\pi}{c_1(J)} \left[\cos(\alpha + c_1(J)) - \cos(\alpha) J_0(c_1(J))\right], \end{aligned} \tag{5.57}$$

where J_0 is a Bessel function of the first kind. Therefore

$$G(J) = \frac{c_2(J) b}{c_1(J)} \left[\cos(\alpha + c_1(J)) - \cos(\alpha) J_0(c_1(J))\right] - c_2(J). \tag{5.58}$$

To determine the second-order terms in the truncated second-order normal form Hamiltonian for a moving system, as in (4.11), we must find the terms $\mathrm{ad}_G^2 H_0$ and $\mathrm{ad}_G H_1$. Using the canonical bracket (4.1), we have

$$\mathrm{ad}_G H_0 = \frac{\partial H_0}{\partial \psi}\frac{\partial G}{\partial J} - \frac{\partial H_0}{\partial J}\frac{\partial G}{\partial \psi} = 0, \tag{5.59}$$

since H_0 and G are each independent of ψ. Thus

$$\mathrm{ad}_G^2 H_0 = 0. \tag{5.60}$$

For the next term we have

$$\mathrm{ad}_G H_1 = \frac{\partial H_1}{\partial \psi}\frac{\partial G}{\partial J} - \frac{\partial H_1}{\partial J}\frac{\partial G}{\partial \psi} = \frac{\partial H_1}{\partial \psi}\frac{\partial G}{\partial J}. \tag{5.61}$$

From the form of G in (5.58) we have

$$\frac{\partial G}{\partial J} = \frac{1}{c_1(J)} \left(b\cos(\alpha) J_1(c_1(J)) - b\sin(\alpha + c_1(J)) - 1\right), \tag{5.62}$$

and from (5.51) we have

$$\begin{aligned}\frac{\partial H_1}{\partial \psi} = c_2(J) \Bigg[\cos\psi \left(\frac{b\sin(\alpha + c_1(J)\cos\psi) + M_{11}}{M_{11}}\right) \\ - \frac{b c_1(J)}{M_{11}} \sin^2\psi \cos(\alpha + c_1(J)\cos\psi)\Bigg]. \end{aligned} \tag{5.63}$$

Since the average $\langle\cdot\rangle$ is over the variable ψ, we simplify the notation by defining

$$A_1 = \frac{c_2(J)}{c_1(J) M_{11}} \left(b\cos\alpha J_1(c_1(J)) - b\sin(\alpha + c_1(J)) - 1\right). \tag{5.64}$$

With this definition we may write

$$\begin{aligned}\mathrm{ad}_G H_1 = A_1 \left[b\cos\psi \sin(\alpha + c_1(J)\cos\psi) + \cos\psi \right. \\ \left. - b c_1(J) \sin^2\psi \cos(\alpha + c_1(J)\cos\psi)\right]. \end{aligned} \tag{5.65}$$

We now calculate $\langle \mathrm{ad}_G H_1 \rangle$. Since the average of $\cos\psi$ over a full cycle of ψ is zero, we have

$$\langle \mathrm{ad}_G H_1 \rangle = A_1 b \langle \cos\psi \sin(\alpha + c_1(J)\cos\psi)\rangle - A_1 b c_1(J) \langle \sin^2\psi \cos(\alpha + c_1(J)\cos\psi)\rangle. \tag{5.66}$$

Using integration by parts, we have

$$\begin{aligned} \langle \sin^2\psi \cos(\alpha + c_1(J)\cos\psi)\rangle &= \frac{1}{2\pi}\int_0^{2\pi} \sin^2\psi \cos(\alpha + c_1(J)\cos\psi) d\psi \\ &= \frac{1}{2\pi c_1(J)}\int_0^{2\pi} \sin(\alpha + c_1(J)\cos\psi)\cos\psi d\psi \\ &= \frac{1}{c_1(J)}\langle \cos\psi \sin(\alpha + c_1(J)\cos\psi)\rangle, \end{aligned} \tag{5.67}$$

and using this result in (5.65) yields

$$\langle \mathrm{ad}_G H_1 \rangle = 0. \tag{5.68}$$

Finally consider

$$\begin{aligned} \langle H_2 \rangle &= -\frac{1}{2}\left\langle \frac{M_{11}^2 - b^2 \sin^2(\alpha + c_1(J)\cos\psi)}{M_{11}} \right\rangle \\ &= -\frac{M_{11}}{2} + \frac{b^2}{2M_{11}}\langle \sin^2(\alpha + c_1(J)\cos\psi)\rangle. \end{aligned} \tag{5.69}$$

Thus the second-order truncated normal-form Hamiltonian for the rotating four-bar is

$$\begin{aligned} H^{(2)} &= H_0 + \Omega^2 \langle H_2 \rangle \\ &= \sqrt{\frac{k}{M_{11}}} J + \frac{b^2\Omega^2}{2M_{11}} \left\langle \sin^2(\alpha + c_1(J)\cos\psi)\right\rangle, \end{aligned} \tag{5.70}$$

where a constant term has been dropped from the Hamiltonian. Since the system is now in second-order normal form, we have for the initial conditions $(\bar{J}, \bar{\psi})$

$$\phi_t^{H^{(2)}}(\bar{J}, \bar{\psi}) = \phi_t^{\Omega^2\langle H_2\rangle} \circ \phi_t^{H_0}(\bar{J}, \bar{\psi}). \tag{5.71}$$

From (5.41) the flow map for the nominal dynamics is

$$\phi_t^{H_0}(\bar{J}, \bar{\psi}) = \left(\bar{J}, \sqrt{\frac{k}{M_{11}}} t + \bar{\psi}\right). \tag{5.72}$$

To determine the flow map for the second-order correction we need to solve the Hamiltonian vector field of $\Omega^2\langle H_2\rangle$. We have

$$\begin{aligned} \dot{\psi} &= \Omega^2 \frac{\partial}{\partial J}\left\langle \sin^2(\alpha + c_1(J)\cos\psi)\right\rangle \\ &= \Omega^2 \left[\frac{2}{J\sqrt{kM_{11}}}\right]^{\frac{1}{2}} \left\langle \sin(\alpha + c_1(J)\cos\psi)\cos(\alpha + c_1(J)\cos\psi)\right\rangle, \end{aligned} \tag{5.73}$$

$$\dot{J} = 0. \tag{5.74}$$

Calculating the average, we find

$$\begin{aligned}
&\langle \sin(\alpha + c_1(J)\cos(\psi))\cos(\alpha + c_1(J)\cos(\psi))\rangle \\
&\quad = \frac{1}{2\pi}\int_0^{2\pi} \sin(\alpha + c_1(J)\cos\psi)\cos(\alpha + c_1(J)\cos\psi)d\psi \\
&\quad = \frac{1}{2\pi}\left[\int_0^{\pi} \sin(\alpha + c_1(J)\cos\psi)\cos(\alpha + c_1(J)\cos\psi)d\psi \right. \\
&\qquad\qquad \left. + \int_{\pi}^{2\pi} \sin(\alpha + c_1(J)\cos\psi)\cos(\alpha + c_1(J)\cos\psi)d\psi\right] \\
&\quad = \frac{1}{2\pi}\left[\int_0^{\pi} \sin(\alpha + c_1(J)\cos\psi)\cos(\alpha + c_1(J)\cos\psi) \right. \\
&\qquad\qquad \left. + \sin(\alpha - c_1(J)\cos\psi)\cos(\alpha - c_1(J)\cos\psi)d\psi\right]. \qquad (5.75)
\end{aligned}$$

The use of the standard sum-angle formulas for sin and cos together with an expansion of the products in (5.75) yields

$$\begin{aligned}
&\frac{1}{2\pi}\left[\int_0^{\pi} \left[\left(\sin\alpha\cos\alpha\cos^2(c_1(J)\cos\psi) - \sin^2\alpha\cos(c_1(J)\cos\psi)\sin(c_1(J)\cos\psi)\right.\right.\right. \\
&\qquad + \cos^2\alpha\cos(c_1(J)\cos\psi)\sin(c_1(J)\cos\psi) - \sin\alpha\cos\alpha\sin^2(c_1(J)\cos\psi)\big) \\
&\qquad + \big(\sin\alpha\cos\alpha\cos^2(c_1(J)\cos\psi) + \sin^2\alpha\cos(c_1(J)\cos\psi)\sin(c_1(J)\cos\psi) \\
&\qquad\quad \left.\left.\left. - \cos^2\alpha\cos(c_1(J)\cos\psi)\sin(c_1(J)\cos\psi) - \cos\alpha\sin\alpha\sin^2(c_1(J)\cos\psi)\big)\right] d\psi\right] \\
&\quad = \frac{\sin\alpha\cos\alpha}{\pi}\int_0^{\pi}\left(\cos^2(c_1(J)\cos\psi) - \sin^2(c_1(J)\cos\psi)\right)d\psi \\
&\quad = \frac{\sin\alpha\cos\alpha}{\pi}\int_0^{\pi}\left(2\cos^2(c_1(J)\cos\psi) - 1\right)d\psi \\
&\quad = \frac{\sin\alpha\cos\alpha}{\pi}\int_0^{\pi}\cos(2c_1(J)\cos\psi)d\psi \\
&\quad = \sin\alpha\cos\alpha J_0(2c_1(J)), \qquad (5.76)
\end{aligned}$$

and thus

$$\dot{\psi} = \frac{\Omega^2 b^2}{2M_{11}}\left[\frac{2}{J\sqrt{kM_{11}}}\right]^{\frac{1}{2}}\sin\alpha\cos\alpha J_0\left(2c_1(J)\right). \qquad (5.77)$$

Recall now that the equilibrium point is $\alpha = \frac{\pi}{2}$. Insertion of this value into (5.77) yields

$$\dot{\psi} = 0. \qquad (5.78)$$

The second-order correction is therefore the identity map, and we have

$$\phi_t^{H^{(2)}}(\bar{J},\bar{\psi}) = \phi_t^{H_0}(\bar{J},\bar{\psi}). \qquad (5.79)$$

Thus to second order the effect of a slow imposed rotation on the four-bar is zero.

6. Conclusions. The approach developed by Marsden, Montgomery, and Ratiu provides a unified setting for understanding the role of the Coriolis force in moving systems. In this work we have extended the method through the use of Hamiltonian normal form theory to account for the nonadiabatic nature of the imposed motion. In particular we have shown that the Hannay–Berry phase can be viewed as arising from a first-order normal form approximation to the moving system. The moving systems approach is then naturally understood as a perturbation approach in the rate of the imposed motion. More accurate models can be determined by carrying the perturbation series out to higher orders. The method was applied to a rotating free-floating spring-jointed equal-sided four-bar mechanism, and it was shown that the effect of the imposed motion is zero to second order.

It is important to note that the approach developed here is perturbative, and it therefore relies on the assumption that the imposed motion, while not adiabatic, is slow with respect to the nominal dynamics. The resulting correction terms are second-order in the rate of the imposed motion, and the technique is thus useful only when extremely accurate modeling of the moving system is required. In addition, the resulting approximation is valid only on the time scale $O(\frac{1}{\epsilon^2})$, where ϵ is the rate of the imposed motion. See [21] for more detailed comments along these lines.

CONVERGENCE OF THE GENERALIZED VOLUME AVERAGING METHOD ON A CONVECTION-DIFFUSION PROBLEM: A SPECTRAL PERSPECTIVE*

C. PIERRE†, F. PLOURABOUÉ‡, AND M. QUINTARD‡

Abstract. This paper proposes a thorough investigation of the convergence of the volume averaging method described by Whitaker [*The Method of Volume Averaging*, Kluwer Academic, Norwell, MA, 1999] as applied to convection-diffusion problems inside a cylinder. A spectral description of volume averaging brings to the fore new perspectives about the mathematical analysis of those approximations. This spectral point of view is complementary with the Lyapunov–Schmidt reduction technique and provides a precise framework for investigating convergence. It is shown for convection-diffusion inside a cylinder that the spectral convergence of the volume averaged description depends on the chosen averaging operator, as well as on the boundary conditions. A remarkable result states that only part of the eigenmodes among the infinite discrete spectrum of the full solution can be captured by averaging methods. This leads to a general convergence theorem (which was already examined with the use of the center manifold theorem [G. N. Mercer and A. J. Roberts, *SIAM J. Appl. Math.*, 50 (1990), pp. 1547–1565] and investigated with Lyapunov–Schmidt reduction techniques [S. Chakraborty and V. Balakotaiah, *Chem. Engrg. Sci.*, 57 (2002), pp. 2545–2564] in similar contexts). Moreover, a necessary and sufficient condition for an eigenvalue to be captured is given. We then investigate specific averaging operators, the convergence of which is found to be exponential.

1. Introduction.

Volume averaging techniques are widely used to model transport problems for which decoupled or separated scales can be identified. The first part of this introduction deals with the potential interest of volume averaging for convection-diffusion problems in different applications. In the second part we discuss the interest and the specificity of volume averaging as compared to other homogenization methods. This general discussion is developed in the paper in a specific case suitable for mathematical treatment: the problem of convection-diffusion in a circular tube.

Convection-diffusion inside a tube would seem to be a simple mathematical problem. It turns out that it is a nontrivial problem, well known in the history of applied mathematics. Starting from Graetz [17] and Lévêque [20] in the stationary case, it has more lately interested Taylor [38] and Aris [1] in the context of its transient nonstationary asymptotic behavior. These seminal works have inspired many others, some of which are discussed in the second part of the introduction when discussing the methodological point of view.

Many research areas such as chemical engineering, biomechanics, and porous media are interested by variants of such a simple generic convection-diffusion problem. For example, when the considered problem involves many tubes inside which con-

vection occurs (such as heat exchangers or microvascular beds), transport equations have been sought in terms of cross-section averaged fields [7, 19, 26, 27, 41]. Recently, the design and optimization of microheater exchangers has stimulated the search for averaged equations governing averaged temperature either at the tube scale or at the scale of the whole exchanger [26, 41]. In the context of heat exchange in biological tissues, averaged descriptions have remained very useful models [28] since the pioneering Pennes model [2, 3, 30]. These investigations suggest that averaged temperature associated with "compartmental" domains such as tissues and blood flow in vessels are interesting quantities to consider in order to model heat exchanges inside bodies. In these cases it is crucial to understand how the microscale flow may be approximated by averaged models because, even if possible, a detailed description of the full stationary problem at the local scale of each tube is not of great interest. In the context of these applications, averaged models have proved to be useful and interesting for applied concerns. Nevertheless, even if the description of averaged quantities is useful in practice for obvious operational reasons, there are still numerous questions concerning the validity and the quality of the approximation given by these ad hoc models. As a matter of fact, even if the model predictions could be *in retrospect* tested numerically, it is always interesting to better understand what their mathematical foundations are. This allows one to better understand their limits and their possible extensions. In this paper, we investigate the model of stationary convection-diffusion inside a tube. This study shows that, in this particular context, an averaged description can capture only large scale features of the exact solution, the convergence of which can be made as precise as necessary.

From a methodological point of view, spatial averaging is at first used as an operational definition of macroscale quantities. From this, macroscale equations may be derived, and the reader is referred to the paper [13] for a review of the different perspectives and points of view. For example, macroscale equations are introduced by many authors from extensive use of irreversible thermodynamics [18] (this approach is also often called mixture theory). In this paper, we are interested in methods that provide a direct, deterministic link, through some *mapping variables*, between the microscale and the macroscale fields. Such a method has been applied to determine macroscale transport equations for porous media applications, as illustrated in [39], while concomitantly a very similar approach has been proposed by Brenner [9]. Many characteristics and assumptions of the cited methods are close to other macroscopization methods, such as homogenization theory [6, 36]. Indeed, the general agreement between both methods has been described for diffusion problems in [8]. The major features may be summarized in the following terms:

- The macroscopic characteristic scales are supposed to be decoupled from the microscopic ones, each level having its own variable description.
- The initial boundary value problem (IBVP) that determines the microscale fields is solved in an approximated manner in terms of the macroscale variables and some mapping variables. The approximation is materialized by microscale problems or *closure problems* that completely define these mapping variables.
- Having solved these microscale problems, the macroscopic mathematical description is essentially dependent on the estimation of macroscopic coefficients or *effective* coefficients that are explicitly given in terms of averages of the mapping variables.

One feature of the considered volume averaging method is, therefore, that some additional hypotheses are needed in order to simplify the original problem and relate

the microscale fields to the macroscale ones. These additional relations, which we called "closure relations," are problem dependent and must be consistent with the assumption made of separated scales. This feature is common to almost all homogenization methods. For example, asymptotic methods are based on regular asymptotic expansions for inner (microscale) and outer (macroscale) variables to be specified, the scaling of which has to be carefully evaluated by order of magnitude analysis of the relevant parameters [23]. Another method involving scales is the time-scale separation between master and slave modes based on center manifold description [33]. This method has been used to provide a general and rigorous treatment of Taylor dispersion [4, 5, 10, 21, 24, 31, 34, 40]. This method shares many features with the one examined in this paper, besides a more general background and different objectives. One important starting point for this method is to use steady state solutions as decomposed into a discrete and infinite set of eigenfunctions. Examining a linear problem, the temporal solution are then linearly decomposed into those stationary eigenmodes, i.e., each stationary eigenmode is associated with a nonstationary one. Among those, the one associated with the trivial zero eigenvalue is called the master mode because it is associated with slow temporal relaxations of interest for long-time asymptotic behavior. The other temporal modes fulfill fast temporal relaxations whose influence on the master mode can be recast into the master equation parameters. The coupling between slave and master modes is obtained from a linear decomposition strictly similar to the above-mentioned "closure relations." These closure relations are derived from a Lyapunov–Schmidt reduction [4, 5] associated with a small parameter which is the product between the Péclet number and the aspect ratio of the considered tube.

The general philosophy of this master/slave time separation method is then much similar to the one applied in this paper on the spatial level. In the case of volume averaged methods, far-field spatial asymptotic behavior (sometimes called "fully developed" spatial variations) is interesting in that it describes the evolution of a simple one-dimensional macroscopic field, without requiring of a precise description of supplementary spatial variations. There is nevertheless one major technical difference with the goal pursued in this paper. In the case of the master/slave time separation method, the invariant manifold theorem gives a nice framework for the validity of such slow/fast mode decomposition close to any trivial zero eigenvalue [24] (because the time scales separation is governed by the ratio of the fast to slow mode eigenvalues). This framework can be easily transposed for spatially decaying modes close to a trivial zero eigenvalue [4]. Those zero eigenvalue macroscopic modes might be interesting, especially when the problem has Neumann boundary conditions. In this case, direct Lyapunov–Schmidt reduction techniques have been used to assess the convergence of averaging models, for example, when chemical reaction occurs within the fluid [11]. In section 5.1.1 we will compare our results with those obtained in [11] that are rediscussed in the third section of [5]. Those zero eigenvalue macroscopic modes are nevertheless less interesting in transfer problems. In that case they are associated with a spatially uniform eigenmode whose contribution to the transfer between the tube wall and the fluid is zero. Other nontrivial spatially decaying eigenmodes should then be sought. This is especially true when boundary conditions are not of Neumann type, so that there is no trivial zero eigenmode. But, in this case, the invariant manifold theorem hardly guarantees the validity and accuracy of a slow/fast scale decoupling. One of the purposes of this paper is to reexamine the conditions for which a macro/micro decoupling is a sensible approach in the case of a simple convection-diffusion problem with general boundary conditions.

In this sense, the presented analysis extends previous works [5, 11] which have used Lyapunov–Schmidt reduction techniques close to a 0 eigenmode. Our analysis considers the approximation of nonzero eigenmodes with non-self-adjoint operators. While restricted to a given convection-diffusion problem, this paper examines the precise conditions for which a part of the exact solution can be captured by an averaged model. One important conclusion, for applications purposes, that is drawn from the proposed analysis is that, depending on the chosen averaging method (more precisely depending on the applied weighting function), the nontrivial, interesting eigenmodes cannot always be captured. It is, therefore, of great interest to know better what causes averaging for convection-diffusion problems to work and why.

Moreover, there is an additional interest in our analysis for those willing to use averaged models. Macroscale equations, as generally introduced in the literature [39], come from first order terms. The "quality" of the first order approximation is often checked through some comparison with direct simulations, or analytical solutions of the microscale equations, or by developing estimates for the higher order terms. It is often difficult to have a precise quantitative determination of those terms, and the first approach, if available, can offer valuable information. In a preliminary study of the tube problem, it was found that the approximation proposed by [32] would provide a reasonable estimate of the exchange term for the established regime in the case of diffusion/advection in a tube with constant temperature or concentration at the surface [16]. The objective of this paper is to exhibit a higher order analysis of the problem from which convergence proofs can be obtained so that a posteriori conditions are found for the definition of the macroscopic scale.

The paper is organized as follows. The second section reviews a convection-diffusion problem in the stationary case and describes its known solutions. A short review of the results obtained with the volume averaging method is also presented in this section to further document the general context of the study. The third section presents a generalization of the volume averaging method previously used to describe temporal variations [4, 5]. This leads to a precise formulation of the mathematical convergence to any eigenmode. The fourth section presents the convergence proof in a two-step procedure. Some numerical results associated with the the convergence of different averaging operators are presented at the end of this section.

2. General background.

2.1. Convection-diffusion problem. The material exposed in this section closely follows classical steps that may be found in textbooks; see, for instance, [14]. We first present the dimensionless formulation associated with convection-diffusion of a passive scalar inside a cylinder with radial coordinate r made dimensionless by the tube radius R. This passive scalar could be associated, for instance, with some heat or mass transfer problem, and we will refer to it as $T(r, \phi, z)$. Classically, the ratio of convection to diffusion characteristic times is associated with a dimensionless Péclet number $\mathrm{Pe} = \langle v \rangle R/D_m$, where D_m is the diffusion coefficient of the passive tracer in the liquid and $\langle v \rangle$ is the spatially averaged velocity field. The physical problem giving the convection velocity is supposed to be independent of the passive scalar, so that a translation-invariant fully developed flow $v(r)$ settles in the longitudinal direction z along the cylinder principal axis. Making dimensionless the longitudinal direction z by the tube radius R, the stationary governing equation expressing heat- or mass-conservation of the passive scalar $T(r, z)$ reads

$$\Delta T = Pe v(r) \partial_z T \quad \text{with} \quad v(r) \geq 0 \quad \text{analytical in 0}, \tag{2.1}$$

where Δ stands for the Laplace operator, which will be appropriately expressed in cylindrical coordinates. As discussed later, we will be mainly interested in the situation where $Pe \gg 1$. Nevertheless, it is important to note that other definitions of the dimensionless variable in the z direction could be adopted. As a matter of fact, the typical longitudinal variations are linearly increasing with the Péclet number when $Pe \gg 1$, and, furthermore, the longitudinal dimensions of the tube could be much larger than its radius. Hence, many authors [4, 5] prefer to introduce an additional parameter $pe = PeR/L$, where L is some longitudinal characteristic length associated with the axial variations. In this context, many studies such as the classical ones [1, 38] have been interested in the limit of $pe \ll 1$, while $Pe \gg 1$ so that longitudinal diffusion can be neglected in comparison with transverse diffusion. This choice is important when considering the averaged description of (2.1), which should then be written with a small parameter pe instead of a large parameter Pe on the right-hand side. In the following, we will keep using the Péclet number Pe parameter for the problem. Of course, this choice should give equivalent results as those obtained from the use of the small parameter pe, as will be explained in section 5.1.1.

In the case of a Newtonian fluid, the velocity field develops a parabolic Poiseuille flow $v(r) = 2(1 - r^2)$. Because of its particular importance, all the numerical results will be given in this case. However, all the theoretical results obtained in this paper still hold for general nonnegative velocity fields $v(r) \geq 0$ that are analytical in 0. General velocity profiles are of interest for applications associated with non-Newtonian fluid, such as, for example, blood, for which different analytical models have been proposed for the velocity profile in a tube [15]. This can also be useful in the treatment of turbulent dispersion in tubes, for which the Poiseuille solution is replaced by the turbulent average velocity field, following the double averaging procedure in Pedras and Lemos [29].

Because of its relevance to many research areas, this partial differential problem has received much attention. Three basic classes of boundary conditions are naturally associated with this cylindrical geometry: adiabatic Neumann boundary condition $\partial_r T(r = 1, \phi, z) = 0$ (we shall refer to it as $\mathcal{N}$ in the following), constant temperature Dirichlet boundary condition $T(r = 1, \phi, z) = 0$ (we shall refer to it as $\mathcal{D}$ in the following), or mixed Robin boundary condition $\partial_r T(r = 1, \phi, z) + \gamma T(r = 1, \phi, z) = 0$, where $\gamma > 0$ may be called Thiele modulus by reference to the case of heterogeneous reaction (we shall refer to it as $\mathcal{R}$ in the following). Furthermore, the passive scalar reference value is chosen so that, far away from the origin, it reaches its equilibrium state, $T(r, \infty) = 0$. The only missing boundary condition is the initial value of the scalar field at the cylinder origin $z = 0$, $T(r, 0) \equiv T_0(r)$, which has to be specified. It is easy to note that the PDE problem (2.1) is not tensorized, so that it does not independently factorize the radial coordinate r and the longitudinal one z. While very simple, the linear problem (2.1) does not have any explicit general solution. Hence, many authors have been interested in the special limit for which a variable separation can be found. In the limit of a large Péclet number, $Pe \gg 1$, when neglecting the longitudinal diffusion compared to the radial one, (2.1) degenerates to

$$\left(\Delta_c + \frac{1}{r^2}\partial_\phi^2\right) T = Pev(r)\partial_z T, \tag{2.2}$$

where Δ_c stands for the cylindrical part of the Laplace operator $\Delta_c \equiv 1/r\partial_r(r\partial_r)$ and ϕ is the azimuthal angle. It can be shown that such an approximation is $O(1/Pe^2)$, because in this limit, the longitudinal typical variations scale linearly with Pe [14].

Equation (2.2) associated with either Neumann $\mathcal{N}$, Dirichlet $\mathcal{D}$, or Robin $\mathcal{R}$ boundary conditions is then a separable problem for which the PDE degenerates into a Sturm–Liouville ODE problem. Graetz [17] has found that its general solution is associated with the discrete sets L_N, $N \in \mathbb{Z}$, of eigenvalues depending on the boundary condition

$$T(r,\phi,z) = \sum_{N\in\mathbb{Z}} \sum_{l\in L_N} c_{N,l} G_{N,l}(r) e^{iN\phi} e^{\frac{l}{Pe}z}. \tag{2.3}$$

We define the generalized Graetz functions $G_{N,l}$ as the functions of r that satisfy

$$\begin{cases} \left(\Delta_c - \frac{N^2}{r^2}\right) G_{N,l} = l v(r) G_{N,l} \quad \text{with} \quad \mathcal{D} : G_{N,l}(1) = 0, \quad \mathcal{N} : \partial_r G_{N,l}(1) = 0, \\ \dfrac{G_{N,l}(r)}{r^N}(r=0) = 1, \qquad\qquad\qquad\qquad \mathcal{R} : \ G_{N,l}(1) + \gamma \partial_r G_{N,l}(1) = 0. \end{cases} \tag{2.4}$$

For a general—analytical in 0—velocity field $v(r)$ one can use the Frobenius method (cf., e.g., [35]) to see that the equation

$$\left(\Delta_c - \frac{N^2}{r^2}\right) y = l v(r) y,$$

which is singular in 0, has two linearly independent solutions y_1 and y_2; the first one regular in 0 satisfies $y_1(r)/r^N(r=0) \neq 0$, and the second one being singular in 0: $y_2(0) = \pm\infty$. As a result, (2.4) with initial condition $G_{N,l}/r^N(r=0) = 1$ defines a unique function $G_{N,l}$—which we will call the generalized Graetz function—for each $l \in \mathbb{C}$ and $N \in \mathbb{Z}$. Thus the following conditions in (2.4), $G_{N,l}(1) = 0$ for $\mathcal{D}$, $\partial_r G_{N,l}(1) = 0$ for $\mathcal{N}$, or $G_{N,l}(1) + \gamma \partial_r G_{N,l}(1) = 0$ for $\mathcal{R}$, only select among these generalized Graetz functions those satisfying the correct boundary condition.

Historically, the cylindrical Graetz functions $G_{0,l}$ has been associated with a parabolic Poiseuille flow $v(r) = 2(1-r^2)$ and it is usually found in the literature that the function $G_{0,l}$ is the eigenfunction of $\sqrt{-l}$ rather than l. However, this notation will be kept for the sake of simplicity in the rest of the paper, and Appendix A gives a more detailed discussion of Graetz eigenfunctions and their relations with confluent hypergeometric functions—or Kummer's functions.

Because (2.4) defines a self-adjoint Sturm–Liouville problem, the eigenvalues associated either with the Dirichlet, Neumann, or Robin conditions are real. Moreover, the chosen far-field extinction boundary condition $T(r,\infty) = 0$ selects, among those, negative eigenvalues. L_N is, therefore, a discrete set $L_N \subset \mathbb{R}^-$ of ordered eigenvalues $L_N = \{\cdots < l_{i,N} < \cdots < l_{1,N} < l_{0,N} \leq 0\}$. For convenience, we will use specific notation for the sets associated with Dirichlet, Neumann, or Robin boundary conditions, i.e.,

$$\begin{aligned} L_N^{\mathcal{D}} &= \{l \in \mathbb{R}^-, G_{N,l}(1) = 0\}, \qquad L_N^{\mathcal{N}} = \{l \in \mathbb{R}^-, \partial_r G_{N,l}(1) = 0\}, \\ &\text{or} \qquad L_N^{\mathcal{R}} = \{l \in \mathbb{R}^-, G_{N,l}(1) + \gamma \partial_r G_{N,l}(1) = 0\}. \end{aligned} \tag{2.5}$$

Graetz computed the first eigenvalue with two-digit precision in [17]. Tables 2.1 and 2.2 give the numerical estimates of the first three eigenvalues associated with a parabolic flow, Dirichlet and Neumann boundary conditions. More complete and precise computations of the eigenvalues can be found, for example, in [37]. Solution given by (2.3) can be completed by the orthogonality properties of the eigenfunctions,

$$\int_0^{2\pi} \int_0^1 G_{N,l}(r) e^{iN\phi} \overline{G_{N',l'}(r)} e^{-iN'\phi} v(r) r \, dr \, d\phi = 0 \qquad \text{if} \quad N \neq N' \ \text{ or } \ l \neq l', \tag{2.6}$$

$N = 2$	-12.83980600	-41.93087773	-87.08337035
$N = 3$	-26.13743028	-62.80555035	-115.8424000

where the overbar denotes a complex conjugate. Hence, using (2.6), the constant coefficients $c_{N,l}$ in decomposition (2.3) are directly related to the projection of the initial conditions over its corresponding eigenfunction $G_{N,l}$:

$$c_{N,l} = \frac{\displaystyle\int_0^{2\pi}\int_0^1 T_0(r,\phi)\overline{G_{N,l}(r)}e^{-iN\phi}v(r)r\ dr\ d\phi}{\displaystyle 2\pi\int_0^1 |G_{N,l}(r)|^2 v(r)r\ dr}. \tag{2.7}$$

Hence, using the eigenfunctions defined in (2.4) the complete solution of the high Péclet limit of the convection-diffusion problem (2.2) within a tube admits a complete spectral representation. Incidentally, the convergence of this representation is known to be rather slow [37]. This is especially true when describing the solution near the origin $z = 0$. In this limit, even if (2.3) and (2.7) describe the true mathematical solution, the Lévêque [20] asymptotic expansion should be preferred because of its simplicity.

Nevertheless, this spectral representation is very useful when only part of the solution is required, as, for example, for the far-field behavior when $z > Pe/(l_1 - l_0)$ for which the solution exponentially converges to the first eigenfunction. In the following, we will concentrate on the first eigenfunctions and their associated eigenvalues. We will be furthermore interested in the averaged description of the solution. It should be noted that a uniform averaging along the disk section of the cylinder only keeps axisymmetrical modes. A more detailed discussion about nonasymmetrical contributions to the averaged description will be discussed in section 5.1.3. The amplitude decomposition (2.7) nevertheless shows that every axisymmetrical eigenvalue $l_{i,0}$ contributes to uniformly averaged concentration solution. This should be kept in mind in the following because many results associated with averaged descriptions in the literature have neglected contributions from eigenvalue $l_{i,0}$, with $i \geq 1$. In the following, we will, for example, see (what is already obvious from directly averaging solutions (2.3) and (2.7), which lead to no contribution of $l \neq 0$ modes for which $\langle v(r)G_{N,l}\rangle = 0$)

that a uniform averaging does not permit one to capture any decaying eigenvalue associated with the Neumann boundary conditions.

2.2. Weighted volume averaging method. In this section we present an improved version of the volume averaging method introduced in [39] that nevertheless remains closely related to this first method—which we will call the *standard volume averaging method*. The improvement is based on the introduction of weighted averaging operators as proposed in [16] when the standard volume averaging method considers only averaging associated with the Lebesgue measure. The use of weighted averages had been considered long ago for averaging transport equations [12, 13, 22, 25]. The intentions were to correctly regularize the microscale fields with the objective of improving comparison with experiments. It is interesting to note that this paper emphasizes another important and fundamental role of weighted averages more related to the mathematical structure of the operator to be averaged.

2.2.1. Definition and notation. To introduce general weighted averaging operators we first introduce the standard averaging operator $\langle\ \rangle$ corresponding to the Lebesgue measure on each cylinder section for functions with radial symmetry,

$$\langle T\rangle(\phi,z) = 2\int_0^1 T(r,\phi,z)r\,dr,$$

and we now define a general weighted averaging operator $\langle\ \rangle^\star$, sometimes simply denoted $\star$, associated with any normalized weight function $w(r)$—i.e., such that $\langle w\rangle = 1$—in cylindrical coordinates as

$$\langle T\rangle^\star(\phi,z) \equiv T^\star(\phi,z) = \langle Tw\rangle(\phi,z) = 2\int_0^1 T(r,\phi,z)w(r)r\,dr. \tag{2.8}$$

In the next sections of this paper we will examine special cases of weight function w. First, a uniform weight $w = 1$ is associated with the standard volume averaging method [39]. Another interesting case, introduced in the preceding section is "mixing-cup" averaging, where the weight function has a dependence exactly similar to that of the velocity field $w(r) \equiv v(r)/\langle v\rangle$. The resulting averaged temperature is also often called bulk temperature. As mentioned in the previous section, this weight function is interesting considered in this context precisely because it corresponds exactly to the orthogonalization operator associated with the Graetz eigenfunctions, as illustrated in (2.6). In the following, the averaging operator is either defined using a specific weight function yet to be specified w, or, on the contrary, to simplify the notation, a generic $\star$ is used for averaging (2.8). Now, averaging the theoretical solution (2.3) leads to

$$T^\star(\phi,z) = \sum_{N\in\mathbb{Z}}\sum_{l\in L_N} C_{N,l}e^{iN\phi}e^{\frac{l}{Pe}z} \quad \text{with} \quad C_{N,l} = c_{N,l}G^\star_{N,l} \in \mathbb{R}. \tag{2.9}$$

It should be noted that a supplementary average along the azimuthal direction ϕ could be performed. If uniform along ϕ, such an average will only preserve the axisymmetric mode $N = 0$ in (2.9). If the azimuthal averaging is chosen nonuniform along ϕ, then the averaged solution could have contributions from nonaxisymmetric mode $N \neq 0$. In the following, we will be mainly interested in averaging along the radial coordinate. Thus the macroscopic field depends on the azimuthal angle ϕ. The results that are presented for the convergence of averaging models will be discussed for

any azimuthal mode N. Those averaged models could easily been averaged a second time along ϕ to find longitudinally varying averaged equations as finally discussed in section 5.1.3.

As mentioned in the introduction, the volume averaging method is a general technique whose purpose is to find a macroscopic description, i.e., an averaged description of a microscopic field that fulfills some PDE problem, without explicitly solving the complete problem, but solving some simplified version of it. Greek letters will be reserved for quantities associated with the volume averaging predictions. Prediction for the scalar field T is thus denoted Θ. In general, the prediction is decomposed into a macroscopic volume averaging prediction $\Theta^\star$ and some local deviation θ to this macroscopic behavior:

$$\Theta(r,\phi,z) = \Theta^\star(\phi,z) + \theta(r,\phi,z) \ = \sum_{N\in\mathbb{Z}} \left(\Theta_N^\star(z) + \theta_N(r,z)\right) e^{iN\phi} \tag{2.10}$$

with the associated condition $\langle\theta\rangle^\star = 0$. In the upscaling techniques considered in this paper, the derivation is sought generally under the form of a mapping onto the macroscopic variables and derivatives. The averaged of the microscale equation will be discussed in detail later. This macroscale equation can be used to show that $\Theta^\star$ also decomposes into a sum of exponential modes:

$$\Theta^\star(\phi,z) = \sum_{N\in\mathbb{Z}} \Theta_N^\star(z) e^{iN\phi} \tag{2.11}$$

with

$$\Theta_N^\star(z) = \sum_{\lambda\in\Lambda_N} C_{N,\lambda} e^{\frac{\lambda}{Pe}z} \quad \text{with} \quad C_{N,\lambda} = c_{N,\lambda}\Gamma^\star_{N,\lambda} \in \mathbb{R}, \tag{2.12}$$

where the corresponding Greek letters have been used to describe the approximated discrete spectrum Λ_N and its corresponding approximated eigenvalues λ, as well as the corresponding approximated eigenfunction $\Gamma_{N,\lambda}$, approximating $G_{N,l}$ with an approximated amplitude $c_{N,\lambda}$ that will be more explicitly defined in section 4.

The main purpose of section 4 is to find from which conditions it is possible to find intersections between Λ_N and the eigenvalue set L_N (2.5) of the theoretical problem (2.2). It will be found in section 4.1 that *only a part of the spectrum L_N can be approximated by elements of Λ_N*. It will, furthermore, be shown in section 4.2 that elements of Λ_N converges toward these elements of L_N that can be approximated when increasing the order of the averaging method. The rate of convergence is consequently studied in section 4.3.

2.2.2. Weighted volume averaging technique. In this section we present the principal steps of the weighted volume averaging technique. The next section will a posteriori justify the classical assumptions made in this section, from examining the weighted volume averaging method generalized to higher order. We will study here both Neumann and Dirichlet Graetz problems. The case of Dirichlet boundary conditions associated with the Graetz problem has been previously examined in the context of the standard volume averaging technique in [16]. The first step of the method is to average the governing equation (2.2), so that $\langle 2.2\rangle^\star$ is

$$Pe\partial_z \langle v\Theta\rangle^\star = \langle \Delta_c\Theta\rangle^\star + \frac{1}{r^2}\langle\partial_\phi^2\Theta\rangle^\star = \langle \Delta_c\Theta\rangle^\star + \frac{1}{r^2}\partial_\phi^2\langle\Theta\rangle^\star. \tag{2.13}$$

The next step is to use decomposition (2.10) and (2.11) in (2.13), so that a macroscopic equation is defined for $\Theta_N^\star$:

$$\langle \Delta_c \Theta_N \rangle^\star - N^2 \left\langle \frac{\Theta_N}{r^2} \right\rangle^\star = Pe\partial_z \langle v\Theta_N \rangle^\star . \tag{2.14}$$

The completeness of this macroscopic equation necessitates the knowledge of deviation θ_N. The problem associated with the deviation θ_N is now obtained from subtracting (2.14) from (2.2):

$$(v - \langle v \rangle^\star) Pe\partial_z \Theta_N^\star + Pe\partial_z (v\theta_N - \langle v\theta_N \rangle^\star) = \mathcal{L}_N^\star \Theta_N, \tag{2.15}$$

where $\mathcal{L}_N^\star$ stands for the nonlocal differential operator:

$$\begin{aligned} \mathcal{L}_N^\star \Theta_N &= \Delta_N \Theta_N - \langle \Delta_N \Theta_N \rangle^\star, \\ \Delta_N \Theta_N &= \Delta_c \Theta_N - \frac{N^2}{r^2} \Theta_N, \\ \langle \Delta_N \Theta \rangle^\star &= \langle \Delta_c \Theta_N \rangle^\star - N^2 \Big\langle \frac{1}{r^2} \Theta_N \Big\rangle^\star . \end{aligned} \tag{2.16}$$

This operator is neither local nor self-adjoint. It is nevertheless invertible, as shown in Appendix C. The first term of (2.15) is a macroscopic source term that enters in the microscopic problem defined for deviation θ_N. So far, no hypothesis has been made and the above equations are exact. These equations are nevertheless not closed because the coupling between the deviation and the macroscopic field still remains unsolved. Finding this coupling is in fact exactly identical to solving the original problem (2.2), the resolution of which we precisely want to avoid.

Hence, the key step is then to find a suitable hypothesis to close deviation problem (2.14) so that it should depend only on the macroscopic field $\Theta_N^\star$. First, it should be kept in mind that the governing equation (2.2) is linear. As a consequence, it is obvious that the deviation θ_N dependence with the macroscopic field $\Theta_N^\star$ has to be linear here. Such a linear dependence is in fact very generally admitted in most of the application of the method [39] and comes from the assumption of scale separation. Hence, one writes the "closure hypothesis" by introducing the additional closure field or mapping variables $\alpha_{0,1}(r)$ which relates the deviation $\theta_N(r,z)$ to the macroscopic field $\Theta_N^\star(z)$,

$$\theta_N(r,z) = \big(w(r)\alpha_{0,N}(r) - 1\big)\Theta_N^\star(z) + w(r)\alpha_{1,N}(r) Pe\partial_z \Theta_N^\star(z),$$

or, equivalently,

$$\Theta_N(r,z) = \alpha_{0,N}(r)\Theta_N^\star(z) + \alpha_{1,N}(r) Pe\partial_z \Theta_N^\star(z). \tag{2.17}$$

It is clear that additional terms are required to obtain an exact solution, and it is our objective to understand *what has been kept* in such an approximate solution. Using the closure hypothesis (2.17) in (2.15) we obtain

$$\begin{aligned} &(\mathcal{L}_N^\star \alpha_{0,N})\Theta_N^\star + (\mathcal{L}_N^\star \alpha_{1,N} - v(r)\alpha_{0,N} + \langle v\alpha_{0,N} \rangle^\star) Pe\partial_z \Theta_N^\star \\ &\quad -(v(r)\alpha_{1,N} - \langle v\alpha_{1,N} \rangle^\star) Pe^2 \partial_z^2 \Theta_N^\star = 0. \end{aligned}$$

The condition of this equality is that each coefficient multiplying the macroscopic field variations $\Theta^\star, \partial_z\Theta^\star, \partial_z^2\Theta^\star$ is equal to zero. Nevertheless, (2.17) has introduced

a closure hypothesis with only two terms, so that the first two terms should also be considered here self-consistently. This last point is further discussed in the next section. Hence, problems associated with the closure fields $\alpha_{0,N}$ and $\alpha_{1,N}$ are

$$\text{(2.18)}\quad \begin{cases} \left(\mathcal{L}_N^\star \alpha_{0,N}\right)(r) = 0, \\ \alpha_{0,N}^\star = 1, \end{cases} \quad \text{and} \quad \begin{cases} \left(\mathcal{L}_N^\star \alpha_{1,N}\right)(r) = v(r)\alpha_{0,N}(r) - \langle v\alpha_{0,N}\rangle^\star, \\ \alpha_{1,N}^\star = 0 \end{cases}$$

$$\text{with} \quad \alpha_{\mathrm{i},N}(1) = 0 \text{ for } \mathcal{D}, \qquad \partial_r \alpha_{i,N}(1) = 0 \text{ for } \mathcal{N} \quad \text{or}$$

$$\alpha_{i,N}(1) + \gamma \partial_r \alpha_{i,N}(1) = 0 \text{ for } \mathcal{R}, \quad i = 1, 2.$$

These problems can be solved analytically for a Neumann, Dirichlet, or Robin boundary condition, and their resolution is detailed in Appendix C. When introducing these solutions in the macroscopic problem (2.14), one finds the macroscopic problem

$$\text{(2.19)}\qquad K_{0,N}\Theta_N^\star + K_{1,N} Pe \partial_z \Theta_N^\star - \langle v\alpha_{1,N}\rangle Pe^2 \partial_z^2 \Theta_N^\star = 0,$$

which involves the *effective parameters*

$$\text{(2.20)}\qquad K_{0,N} = \langle \Delta_N \alpha_{0,N}\rangle^\star, \quad K_{1,N} = \langle \Delta_N \alpha_{1,N}\rangle^\star - \langle v\alpha_{0,N}\rangle^\star,$$

and the solution for $\Theta_N^\star$ decomposes to a sum of exponential modes with an associated characteristic length Pe/λ, which then defines the set $\Lambda_{1,N}$ of eigenvalues predicted by the volume averaging technique

$$\text{(2.21)}\qquad \Lambda_{1,N} = \{\ \lambda \ / \quad K_{0,N} + K_{1,N}\lambda - \langle v\alpha_{1,N}\rangle \lambda^2 = 0\ \}.$$

2.2.3. Explicit results. This section gives the solutions of problem (2.18), i.e., the mapping variables, and (2.19) obtained for different values of the weighted function w.

- *Standard volume averaging*, $w = 1$, axisymmetric mode $N = 0$.

The solution for the closure function has been found equal to the following:

$$\text{(2.22)}\quad \text{for } \mathcal{D}: \begin{cases} \alpha_{0,0}(r) = 2(1 - r^2), \\ \alpha_{1,0}(r) = \frac{r^6}{9} - \frac{r^4}{2} + \frac{r^2}{2} - \frac{1}{9}; \end{cases} \quad \text{for } \mathcal{N}: \begin{cases} \alpha_{0,0}(r) = 1, \\ \alpha_{1,0}(r) = -\frac{r^4}{8} + \frac{r^2}{4} - \frac{1}{12}. \end{cases}$$

Thus constants $K_{0,0}$ and $K_{1,0}$ can be computed:

$$\text{(2.23)}\qquad \text{for } \mathcal{D}: \begin{cases} K_{0,0} = -16, \\ K_{1,0} = -2; \end{cases} \qquad \text{for } \mathcal{N}: \begin{cases} K_{0,0} = 0, \\ K_{1,0} = -1. \end{cases}$$

These calculations permit us to compute the associated approximated eigenvalues by solving (2.21). As already observed in [16], the resulting Dirichlet eigenvalue $\lambda_{0,0}^{\mathcal{D}} \simeq -3.874877690$ gives a rather good approximation of the Graetz value $l_{0,0}^{\mathcal{D}} \simeq -3.656793458$ up to 6%. On the contrary, the Neumann eigenvalue $l_1^N \simeq -12.839806$ is completely missed by the volume averaging method, which nevertheless gives the trivial solution zero, $l_{0,0}^{\mathcal{N}} = 0$. This trivial solution is of course of great practical interest since it corresponds to the exact solution when the temperature at the origin is constant; it also gives the correct averaged temperature of the far-field solution.

- *Flow averaging*, $w = v/\langle v\rangle = 2(1 - r^2)$, axisymmetric mode $N = 0$.

The solution for the closure function has been found equal to the following:

$$\text{(2.24)}\quad \text{for } \mathcal{D}: \begin{cases} \alpha_{0,0}(r) = \frac{3}{2}(1 - r^2), \\ \alpha_{1,0}(r) = \frac{r^6}{12} - \frac{3r^4}{8} + \frac{57r^2}{160} - \frac{31}{480}; \end{cases} \quad \text{for } \mathcal{N}: \begin{cases} \alpha_{0,0}(r) = 1, \\ \alpha_{1,0}(r) = -\frac{r^4}{8} + \frac{r^2}{4} - \frac{1}{16}. \end{cases}$$

Thus constants $K_{0,0}$, $K_{1,0}$ can be computed:

$$\text{for } \mathcal{D}: \begin{cases} K_{0,0} = -3, \\ K_{1,0} = -\frac{63}{40}; \end{cases} \quad \text{for } \mathcal{N}: \begin{cases} K_{0,0} = 0, \\ K_{1,0} = -1. \end{cases} \tag{2.25}$$

The approximate Dirichlet eigenvalue in this case is found equal to $\lambda^{\mathcal{D}}_{0,0} \simeq -3.809523810$, which is 4% from the theoretical Graetz eigenvalue $l^{\mathcal{D}}_{0,0}$. The Neumann trivial solution $\lambda^{\mathcal{N}}_{0,0} = 0$ is also found and the first Neumann nontrivial eigenvalue $\lambda^{\mathcal{N}}_{1,0}$ is also totally missed in the case of a flow averaging.

The following section investigates the capacity of the method to find the correct answer to the problem while generalizing it by introducing higher order closure hypothesis.

3. Weighted volume averaging method of higher order. The notation and methodological steps in this section are closely following those previously presented in sections 2.2.1 and 2.2.2. More precisely, the solution we are looking for is decomposed as (2.10), and the same exact steps (2.13)–(2.15) are now considered again.

The improvement of the method consists in a generalization of the closure hypothesis (2.17). This is introduced in order to ameliorate the results previously obtained in section 2.2.3, with, for instance, the hope to capture the first nontrivial Neumann eigenvalue $l^{\mathcal{N}}_{1,0}$.

From the property (4.2) of the exact solution that will be studied in section 4.1.1, and from the previously examined closure relation (2.17) let us now introduce a generalized closure relation:

$$\Theta_N(r,z) = \sum_{n=0}^{p} \alpha_{n,N}(r) Pe^n \partial_z^n \Theta^\star_N(z) \tag{3.1}$$

with $p \geq 1$. The case $p = 1$ has been analyzed in section 2.2.2, and we now follow the same steps. Using (3.1) in the deviation equation (2.15) it is found, assuming $\alpha_{-1,N}(r) = 0$, that

$$\begin{aligned} &\sum_{n=0}^{p} (\mathcal{L}^\star_N \alpha_{n,N} - v\alpha_{n-1,N} + \langle v\alpha_{n-1,N}\rangle^\star) Pe^n \partial_z^n \Theta^\star_N(z) \\ &\quad - (v\alpha_{p,N} - \langle v\alpha_{p,N}\rangle^\star) Pe^{p+1} \partial_z^{p+1} \Theta^\star_N(z) = 0. \end{aligned}$$

The condition of this equality gives, at each order, the closure problem associated with the closure functions $\alpha_{n,N}(r)$, whose solvability is left to Appendix C, and which is to be solved recursively:

$$\begin{cases} \mathcal{L}^\star_N \alpha_{n,N} = v(r)\alpha_{n-1,N}(r) - \langle v\alpha_{n-1,N}\rangle^\star & \text{with} \quad \alpha_{-1,N}(r) = 0, \\ \alpha^\star_{0,N} = 1 \quad \text{or} \quad \alpha^\star_{n,N} = 0 & \text{for} \quad n \geq 1, \\ \alpha_{n,N}(1) = 0 & \text{for} \quad \mathcal{D}, \\ \partial_r \alpha_{n,N}(1) = 0 & \text{for} \quad \mathcal{N}. \end{cases} \tag{3.2}$$

The resolution of these problems is detailed in Appendix C.2.

From solving (3.2) it is possible to find the generalized macroscopic closed problem at order p:

$$\sum_{n=0}^{p} K_{n,N} Pe^n \partial_z^n \Theta^\star_N(z) - \langle v\alpha_{p,N}\rangle^\star Pe^{p+1} \partial_z^{p+1} \Theta^\star_N(z) = 0, \tag{3.3}$$

where the macroscopic coefficients $K_{n,N}$ are given by

$$K_{n,N} = \langle \Delta_N \alpha_{n,N} \rangle^\star - \langle v \alpha_{n-1,N} \rangle^\star, \quad K_{n,N} \in \mathbb{R}. \tag{3.4}$$

The predicted solutions of (3.3) then decompose into a sum of exponentials with modes λ/Pe for λ belonging to the set of predicted eigenvalues at order p, $\Lambda_{p,N}$, defined as the zeros set of a $p+1$ order polynomial:

$$\Lambda_{p,N} = \left\{ \lambda \Big/ \sum_{n=0}^{p} K_{n,N} \lambda^n - \langle v \alpha_{p,N} \rangle^\star \lambda^{p+1} = 0 \right\}. \tag{3.5}$$

As previously, $\Lambda_{p,N}$ is independent of Pe, but does depend on the chosen boundary conditions and the order p of the closure relation. This last point naturally leads to the concept of convergence.

DEFINITION 3.1 (convergence of the weighted volume averaging method). *The elements of all sets $\Lambda_{p,N}$ define sequences of predicted eigenvalues: $(\lambda_{i,p})_{p\geq 1, i\geq 0}$, $\lambda_{i,p} \in \Lambda_{p,N}$.*

We shall say that the method is convergent toward some eigenvalue $l_i \in L_N$ of the theoretical problem (2.2) *if there exists a sequence of predicted eigenvalues $(\lambda_{i,p})_{p\geq 1, i\geq 0}$ such that $\lambda_{i,p} \in \Lambda_{p,N}$ and $\lim_{p\to+\infty} \lambda_{i,p} = l_i \in L_N$.*

We will establish the convergence for a characterized part of the spectrum in section 4.3.

4. Convergence analysis. Previous sections have mainly considered the explicit application of the averaging method to Graetz problem. The necessary material and notation being now defined, this section considers the mathematical analysis of the convergence of these averaging methods. This convergence analysis requires two different steps. The first step introduces two necessary conditions over eigenvalues for convergence to hold. The second step gives the proof that these two necessary conditions are sufficient. In the two subsequent sections, the results are derived in a general context, and formally apply to any mode N, as well as any boundary conditions $\mathcal{D}$, $\mathcal{N}$, or $\mathcal{R}$ and any flow $v(r)$. Hence, in order to simplify notation, the analysis does not mention, unless necessary to avoid confusion, which azimuthal mode it refers to, nor the boundary conditions that are considered. Finally, specific situations will be considered in section 4.3 for analyzing the numerical convergence.

4.1. Restricted convergence of weighted averaging methods. We define in the two following sections two sets, the validity—$D^\star_{val}$—and the accessibility—$D^\star_{acc}$—domains, which are disks lying in the complex plane $\mathbb{C}$. As we will see, a necessary condition for the weighted averaging method to converge toward an eigenvalue $l \in L$ is that this eigenvalue belongs to both of these domains.

4.1.1. Validity domain $D^\star_{val}$. The variables of the initial problem (2.2) can be separated so that any solution $T(r,\phi,z)$ may be written as a product of functions of r, ϕ, and z only. Let us first show in this section that the exact solution of the problem can be formally written as a regular asymptotic expansion of the macroscopic field $T^\star(\phi,z)$. First let us decompose T as

$$T(r,\phi,z) = \sum_{N\in\mathbb{Z}} T_N(r,z) e^{iN\phi}. \tag{4.1}$$

The aim of this section is to analyze under which condition the Nth component $T_N(r,z)$ in decomposition (4.1) of the theoretical solution $T(r,\phi,z)$ can be written as

the following expansion of $T_N^\star(z)$:

$$T_N(r,z) = \sum_{n\geq 0} a_n(r) Pe^n \partial_z^n T_N^\star(z) \tag{4.2}$$

(where the index N on the closure functions $a_n(r)$ has been omitted for simplicity) to be compared with the general closure hypothesis (3.1) for $\Theta_N(r,z)$.

Let us recall the form of the original solution (2.3),

$$T_N(r,z) = \sum_{l\in L_N} c_l T_l(r,z) \quad \text{with} \quad c_l \in \mathbb{R}\,, \quad T_l(r,z) = G_{N,l}(r) e^{\frac{l}{Pe}z}, \tag{4.3}$$

so that (4.2) is true for $T_N(r,z)$ if and only if it holds for each function $T_l(r,z)$ standing in the decomposition (4.3) of $T_N(r,z)$. Comparing then the expression for T_l in (4.2) and (4.3), one can see that (4.2) holds for $T_l(r,z)$ if and only if the following equality over the Graetz eigenfunctions G_l holds:

$$\sum_{n\geq 0} a_n(r) l^n = \frac{G_{N,l}(r)}{G_{N,l}^\star}. \tag{4.4}$$

We will prove that both functions $G_{N,l}(r)$ and $G_{N,l}^\star$ are analytical with respect to l, so that the expansion of $G_{N,l}(r)/G_{N,l}^\star$ on the form (4.4) is only possible for l belonging to a disk $D_{val}^\star$ centered on zero whose radius R is equal to the smallest root of $G_l^\star$.

Definition 4.1. *Let us call validity domain the disk* $D_{val}^\star \subset \mathbb{C}$,

$$D_{val}^\star = \big\{l, \quad |l| < R\big\}, \quad \textit{where} \quad R = \inf\big\{|l| \,/\, G_{N,l}^\star = 0\big\},$$

depending only on the averaging operator $\star$ *and on* N.

Now, one can see that the decomposition (4.2) is not true in general. It is true only if all the eigenvalues l standing in the decomposition (4.3) of $T_N(r,z)$ belong to the validity domain $D_{val}^\star$. An important consequence is that a closure formulation (3.1) only makes sense for eigenvalues lying in $D_{val}^\star$. Hence, a necessary—but not sufficient—condition for an eigenvalue $l \in L$ to be predicted by the averaging method is to lie within $D_{val}^\star$. It is also interesting to note that $D_{val}^\star$ depends only on the averaging operator $\star$ and N, but not on the boundary conditions.

We summarize this condition, as well as the definition of the new functions $a_n(r)$, in the following lemma.

Lemma 4.2. *The base functions* $T_l(r,z) = G_{N,l}(r) e^{\frac{l}{Pe}z}$ *for problem* (2.2) *can be written*

$$T_l(r,z) = \sum_{n\geq 0} a_n(r) Pe^n \partial_z^n T_l^\star(z)$$

if and only if $l \in D_{val}^\star$ *defined by*

$$D_{val}^\star = \big\{l/|l| \leq R\big\}, \quad \textit{where} \quad R = \inf\big\{|l|/G_{N,l}^\star = 0\big\},$$

and the functions $a_n(r)$ *are the solution of the recursive scheme*

$$\begin{cases} \Delta_N a_n(r) \;=\; v(r) a_{n-1}(r) & \textit{with} \quad a_{-1}(r) = 0, \\ a_0^\star = 1 \quad \textit{and} \quad a_n^\star = 0 & \textit{for} \quad n \geq 1. \end{cases} \tag{4.5}$$

Proof. In Appendix B we give the proof that the functions $G_{N,l}(r)$, $\partial_r G_{N,l}(r)$, and $\Delta_N G_{N,l}(r)$ are analytical with respect to l on the whole complex plane $\mathbb{C}$. More precisely there exists a set of functions $(q_n(r))_{n\in\mathbb{N}}$ (depending also on N) defined by (B.4) such that for $r \in [0,1]$ and $l \in \mathbb{C}$ one has

$$G_{N,l}(r) = \sum_{n\geq 0} q_n(r) l^n \ , \quad \partial_r G_{N,l}(r) = \sum_{n\geq 0} \partial_r q_n(r) l^n \ , \quad \Delta_N G_{N,l}(r) = \sum_{n\geq 0} \Delta_N q_n(r) l^n.$$

As a result the three functions $\frac{G_{N,l}(r)}{G^\star_{N,l}}$, $\frac{\partial_r G_{N,l}(r)}{G^\star_{N,l}}$, $\frac{\Delta_N G_{N,l}(r)}{G^\star_{N,l}}$ are analytical with respect to l for $l \in D^\star_{val}$ and $r \in [0,1]$ and there exist three sets of functions $(a_n(r))_{n\in\mathbb{N}}$, $(b_n(r))_{n\in\mathbb{N}}$, and $(c_n(r))_{n\in\mathbb{N}}$ such that for $l \in D^\star_{val}$ and $r \in [0,1]$,

$$\frac{G_{N,l}}{G^\star_{N,l}}(r) = \sum_{n\geq 0} a_n(r) l^n \ , \quad \frac{\partial_r G_{N,l}}{G^\star_{N,l}}(r) = \sum_{n\geq 0} b_n(r) l^n \ , \quad \frac{\Delta_N G_{N,l}}{G^\star_{N,l}}(r) = \sum_{n\geq 0} c_n(r) l^n. \tag{4.6}$$

Using the integration theorem on these series one gets

$$b_n(r) = \partial_r a_n(r) \quad \text{and} \quad c_n(r) = \Delta_N a_n(r) \quad \forall\, n \in \mathbb{N},$$

so that

$$\frac{\Delta_N G_{N,l}}{G^\star_{N,l}}(r) = \sum_{n\geq 0} \Delta_N a_n(r) l^n. \tag{4.7}$$

Now the function $\frac{G_{N,l}}{G^\star_{N,l}}(r)$ is the unique solution of the ODE:

$$\Delta_N f = l v(r) f \quad \text{and} \quad f^\star = 1. \tag{4.8}$$

Rewriting (4.8) with (4.6) and (4.7) gives that the functions $(a_n(r))_{n\in\mathbb{N}}$ are exactly given by the recursive scheme (4.5). ∎

4.1.2. Accessibility domain $D^\star_{acc}$. The eigenvalues predicted by the averaging method are the roots of the polynomial equation (3.5). Let us consider—as $p \to \infty$—the limit set of predicted eigenvalues Λ_∞ defined as the zeros set of the series $\sum_{n\geq 0} K_n \lambda^n$:

$$\Lambda_\infty = \left\{ \lambda \Big/ \sum_{n\geq 0} K_n \lambda^n = 0 \right\}, \tag{4.9}$$

where the index N on the macroscopic coefficient, assumed to be fixed, has been omitted. Among the eigenvalues predicted with the averaging method at order p, the only ones that make sense are those approximating some $\lambda \in \Lambda_\infty$, and by increasing the order p of the method one can only improve the computation on these modes $\lambda \in \Lambda_\infty$. As a result, for an eigenvalue $l \in L$ of the theoretical problem (2.2) to be approximated by the averaging method, and for this method to be convergent as $p \to \infty$ to this eigenvalue $l \in L$, it is necessary—but not sufficient—that the series $\sum_{n\geq 0} K_n l^n$ be convergent.

With definition (3.4) of the macroscopic coefficient K_n, the series $\sum_{n\geq 0} K_n l^n$ make sense for $l \in D^\star_{acc}$ defined as follows.

DEFINITION 4.3. *Let us call accessibility domain* $D^\star_{acc} \subset \mathbb{C}$ *the disk of all the complex* $\lambda \in \mathbb{C}$ *such that the series*

$$\sum_{n\geq 0} \alpha_n(r)\lambda^n, \quad \sum_{n\geq 0} \Delta_N\alpha_n(r)\lambda^n, \quad \sum_{n\geq 0} \partial_r\alpha_n(r)\lambda^n \tag{4.10}$$

are convergent for $r \in [0,1]$. *If* $\lambda \in D^\star_{acc}$, *we say that* λ *is accessible by the averaging method.*

Contrary to the validity domain $D^\star_{val}$, the accessibility domain $D^\star_{acc}$ does not depend only on the averaging operator $\star$ and on N, but also on the boundary conditions that influences the computation of functions α_n.

4.1.3. Evaluation of $D^\star_{val}$ and $D^\star_{ac}$. We here focus on the numerical evaluation of the two previously introduced domains $D^\star_{val}$ and $D^\star_{ac}$.

To compute the radius of the validity domain $D^\star_{val}$, we need to compute the smallest root of the function of l, $G^\star_{N,l}$. For this, we give in Appendix B an expansion of the generalized Graetz functions $G_{N,l}(r)$ with the help of a set of functions $q_n(r)$ defined in (B.4): $G_{N,l}(r) = \sum_{n\geq 0} q_n(r)l^n$. The computation of these functions $q_n(r)$ make it possible to compute the radius of $D^\star_{val}$ as the smallest root of the polynomial $\sum_{n\geq 0} q^\star_n l^n$.

To compute the radius of the accessibility domain $D^\star_{acc}$ one needs an upper bound on the three functions $\alpha_n(r)$, $\partial_r\alpha_n(r)$, and $\Delta_N\alpha_n(r)$ for $r \in [0,1]$. Experiments based on the computation of these functions showed that $\Delta_N\alpha_n(r=1)$ is a good upper bound for these functions and the radius of $D^\star_{acc}$ is equal to the convergence radius of the series $\sum_{n\geq 0} \Delta_N\alpha_n(r=1)\lambda^n$.

Radii for $D^\star_{val}$ and $D^\star_{acc}$ for some chosen weight functions $w(r)$ are given in Table 4.1. Comparing Table 4.1 with Tables 2.1 and 2.2 shows that the standard and the flow averaging method can only capture $l^{\mathcal{D}}_{0,0}$ for $\mathcal{D}$ and $l^{\mathcal{N}}_{0,0} = 0$ for $\mathcal{N}$. This result is self-consistent with the computations previously examined in section 2.2.3. To capture the first nontrivial eigenvalue for $\mathcal{N}$ one needs to use other averaging operators. Moreover, it will be shown in section 4.2 that the two necessary conditions introduced in the previous sections are actually sufficient for the convergence to hold. In addition, it will appear that the first nontrivial eigenvalue for $\mathcal{N}$, $l^{\mathcal{N}}_{1,0} \simeq -12.8398060$, and even the second eigenvalue for $\mathcal{D}$, $l^{\mathcal{D}}_{1,0} \simeq -22.30473055$, can be captured when using adapted averaging operators.

4.2. Convergence theorem. We introduced in the previous subsection two necessary conditions associated with any eigenvalue $l \in L$ to be captured by the averaging method. We prove here that these conditions are actually sufficient for the convergence to hold. More precisely, the eigenvalues predicted by the averaging method when $p \to \infty$ are exactly the eigenvalues of the theoretical problem (2.2) that both belong to the validity and accessibility domains.

TABLE 4.1
Radius of $D^\star_{val}$ *and* $D^\star_{acc}$ *for different weights and for* $N = 0$.

$w(r)$	$D^\star_{val}$	$D^\star_{acc}$, $\mathcal{D}$	$D^\star_{acc}$, $\mathcal{N}$
1	7.84	15.899	10.568
$2(1-r^2)$	$-l^{\mathcal{N}}_1 \simeq 12.839$	18.632	12.839
$1/(2r)$	354.75	24.789	14.665
$10(1-r)^3$	>500	29.82	23.33

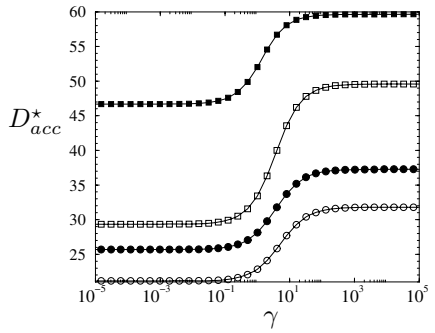

FIG. 4.1. *Computation of the accessibility domain $D^\star_{acc}$ for a Robin boundary condition versus the parameter γ and for $N = 0$. The four weighting functions w considered on Table* 4.1 *have been analyzed. Black circles stands for the flow-averaging method with $w = v/\langle v\rangle$, and white circles for the classical uniform volume averaging $w = 1$. White squares are for $w = 1/(2r)$ and black squares are for $w = 10(1-r)^3$.*

THEOREM 4.4. *Between the set of eigenvalues L of theoretical problem* (2.2) *and the three following sets: the validity domain $D^\star_{val}$ defined in Definition* 4.1*, the limit set of predicted eigenvalues Λ_∞ in* (4.9)*, and the accessibility domain $D^\star_{acc}$ defined in Definition* 4.3*, one has the relation (for any azimuthal mode N, any boundary condition $\mathcal{D}$, $\mathcal{N}$, or $\mathcal{R}$, and any averaging operator $\star$)*

$$\Lambda_\infty \cap D^\star_{val} = L \cap D^\star_{val} \cap D^\star_{acc}, \tag{4.11}$$

which means that the eigenvalues predicted by the averaging method inside $D^\star_{val}$ exactly converge toward the theoretical eigenvalues of (2.2) *being inside $D^\star_{val} \cap D^\star_{acc}$.*

Proof. We recall that we defined in (2.4) the generalized Graetz functions $G_{N,l}(r)$ for each $l \in \mathbb{C}$ and each $N \in \mathbb{Z}$ as the unique solution for the ODE,

$$\Delta_N G_{N,l} = l v(r) G_{N,l}(r), \quad \frac{G_{N,l}(r)}{r^N}(r=1) = 1, \tag{4.12}$$

and that for Neumann, Dirichlet, or Robin boundary conditions, the associated sets of theoretical eigenvalues are given by (2.5).

Using Lemma 4.2, one has that

$$L^{\mathcal{N}} \cap D^\star_{val} = \left\{ l \in \mathbb{C},\ \sum_{n\geq 0} \partial_r a_n(1) l^n = 0 \right\},$$

$$L^{\mathcal{D}} \cap D^\star_{val} = \left\{ l \in \mathbb{C},\ \sum_{n\geq 0} a_n(1) l^n = 0 \right\}, \quad \text{or}$$

$$L^{\mathcal{R}} \cap D^\star_{val} = \left\{ l \in \mathbb{C},\ \sum_{n\geq 0} (a_n(1) + \gamma \partial_r a_n(1)) l^n = 0 \right\},$$

where the functions $(a_n(r))_{n\in\mathbb{N}}$ are those defined by the recursive scheme (4.5). For simplicity, one introduces the quantities A_n defined as follows:

$$\text{for } \mathcal{D} \ :\ A_n = a_n(1); \quad \text{for } \mathcal{N} \ :\ A_n = \partial_r a_n(1); \quad \text{for } \mathcal{R} \ :\ A_n = a_n(1) + \gamma \partial_r a_n(1). \tag{4.13}$$

Thus for $\mathcal{D}$, $\mathcal{N}$, or $\mathcal{R}$ cases one has

$$L \cap D^{\star}_{val} = \left\{ l \in \mathbb{C},\ \sum_{n\geq 0} A_n l^n = 0 \right\}.$$

Let us consider the two functions of l as the sum of the following series in l:

$$A_l = \sum_{n\geq 0} A_n l^n, \qquad K_l = \sum_{n\geq 0} K_n l^n,$$

which are convergent for $l \in D^{\star}_{val} \cap D^{\star}_{acc}$.

Then, to prove (4.11) one exactly has to show that

$$\forall\, l \in D^{\star}_{val} \cap D^{\star}_{acc}\ :\ A_l = 0 \quad \text{if and only if} \quad K_l = 0. \tag{4.14}$$

To prove this, one has to find a relation between A_n and the macroscopic coefficient K_n. For this, one introduces the set of functions $\big(e_n(r)\big)$ associated with the difference between functions $a_n(r)$ and $\alpha_n(r)$ defined in (4.5) and (3.2):

$$e_n(r) = \alpha_n(r) - a_n(r)\ . \tag{4.15}$$

These functions, by subtracting (4.5) from (3.2), are exactly defined by the following recursive scheme:

$$\begin{cases} \Delta_N e_n(r) = K_n + v(r) e_{n-1}(r) & \text{with } e_{-1}(r) = 0, \\ e^{\star}_n = 0, & \\ e_n(1) = -A_n & \text{for } \mathcal{D}, \\ \partial_r e_n(1) = -A_n & \text{for } \mathcal{N}, \\ e_n(1) + \gamma \partial_r e_n(1) = -A_n & \text{for } \mathcal{R}. \end{cases} \tag{4.16}$$

This recursive formula does depend on both macroscopic coefficients K_n and A_n. Let us finally define the macroscopic difference function $E_l(r)$ by

$$E_l(r) = \sum_{n\geq 0} e_n(r) l^n = \sum_{n\geq 0} \alpha_n(r) l^n - \sum_{n\geq 0} a_n(r) l^n,$$

which is well defined for $l \in D^{\star}_{val} \cap D^{\star}_{acc}$.

We search a differential problem satisfied by $E_l(r)$.

Thanks to Lemma 4.9 on $D^{\star}_{val}$ and to Definition 4.3 of $D^{\star}_{val}$, the series

$$\sum_{n\geq 0} a_n(r) l^n, \quad \sum_{n\geq 0} \partial_r a_n(r) l^n, \quad \sum_{n\geq 0} \Delta_N a_n(r) l^n \quad \text{and}$$
$$\sum_{n\geq 0} \alpha_n(r) l^n, \quad \sum_{n\geq 0} \partial_r \alpha_n(r) l^n, \quad \sum_{n\geq 0} \Delta_N \alpha_n(r) l^n$$

converge for all $l \in D^{\star}_{val} \cap D^{\star}_{acc}$ and all $r \in [0,1]$. Then, using the integration theorem and the properties (4.16) of functions $e_n(r)$ one has

$$\forall\, l \in D^{\star}_{val} \cap D^{\star}_{acc} \quad \forall\, r \in [0,1] \quad : \begin{cases} \Delta_N E_l(r) = K_l + v(r) E_l(r), & \\ E^{\star}_l = 0, & \\ E_l(1) = -A_l & \text{for } \mathcal{D}, \\ \partial_r E_l(1) = -A_l & \text{for } \mathcal{N}, \\ E_l(1) + \gamma \partial_r E_l(1) = -A_l & \text{for } \mathcal{R}. \end{cases}$$

K_l or A_l being fixed, this problem has one and only one solution so that A_l is a function of K_l and vice versa. Now, it is easy to check that the solution associated with $A_l = 0$ is $E_l = 0$, which eventually fixes $K_l = 0$. Conversely, and for the same reason, $K_l = 0$ fixes $A_l = 0$. This ensures (4.14), which proves Theorem 4.4. ∎

It is interesting to note that because $E_l = 0$ is the solution associated with a converging eigenvalue $\lambda_\infty \in \Lambda_\infty = l \in L$, the ratio between the predicted eigenfunction and its value at $r = 0$ also converges to the theoretical Graetz eigenfunction. This leads to the following important corollary.

COROLLARY 4.5. *For an eigenvalue $l \in L \cap D^\star_{val} \cap D^\star_{acc}$, with an associated set of approximated eigenvalues $(\lambda_p)_{p\in\mathbb{N}}$ such that $\lim_{p\to\infty} \lambda_p = l$, let us define the approximated eigenfunction Γ_{λ_p} as*

$$\Gamma_{\lambda_p}(r) = \frac{1}{\rho}\sum_{n=0}^{p} \alpha_n(r)\lambda_p^n \quad \textit{with} \quad \rho = \sum_{n=0}^{p} \frac{\alpha_n(r)}{r^N}(r=0)\lambda_p^n; \tag{4.17}$$

then Γ_{λ_p} converges toward the generalized Graetz function $G_{N,l}$,

$$\lim_{p\to\infty} \|\Gamma_{\lambda_p} - G_{N,l}\| = 0. \tag{4.18}$$

Moreover, defining the amplitude c_λ, in the same way as c_l defined in (2.7),

$$c_{\lambda_p} = \frac{\displaystyle\int_0^{2\pi}\int_0^1 T_0(r)\overline{\Gamma_{\lambda_p}(r)}e^{-iN\phi}v(r)r\,dr}{\displaystyle 2\pi\int_0^1 |\Gamma_{\lambda_p}(r)|^2 v(r)r\,dr}; \quad \textit{then} \quad \lim_{p\to\infty} |c_{\lambda_p} - c_l| = 0. \tag{4.19}$$

Hence, not only does Theorem 4.4 give a necessary and sufficient condition for an eigenvalue to converge, but also the eigenmode will converge to the corresponding theoretical solution. We now numerically study the convergence of various eigenmodes for different averaging operator w.

4.3. Convergence evaluation. This section studies the numerical evaluation of the convergence to either the eigenvalue, the eigenfunction, or the eigenmode amplitude for a Poiseuille parabolic velocity profile $v(r) = 2(1 - r^2)$.

We calculate the closure functions α_n from the recursive scheme (3.2), so that the coefficients K_n defined in (3.4) of the eigenvalues polynomial (3.5) can be computed. From the obtained solution leading to $p + 1$ eigenvalues, we select the larger one in $\mathbb{R}^-$. Figure 4.2 displays the relative error of this approximated eigenvalue for different weighting functions w. For the first Dirichlet eigenvalue, Figure 4.2(a) displays exponential convergence rates. Moreover, when comparing the results of Figure 4.2(a) with Table 4.1, it is not surprising to observe that a larger radius of convergence $D^\star_{acc}$ gives rise to a faster convergence rate. As demonstrated in the previous section, the second eigenvalue for the Dirichlet or Neumann boundary condition is not accessible to the standard volume averaging methods—$w = 1$—or the kinematic volume averaging—$w = v/\langle v\rangle$. On the contrary, two other weighting functions w have been proposed in Table 4.1, the convergence of which has been established for the second eigenvalue in the previous section. Figures 4.2(b) and (c) study their convergence on the second eigenvalue in the Dirichlet and Neumann cases. It is interesting to observe on these figures that the convergence rate still looks exponential, even if the convergence rate is much slower than those observed in Figure 4.2(a). More modes should indeed be needed for an acceptable precision to be obtained.

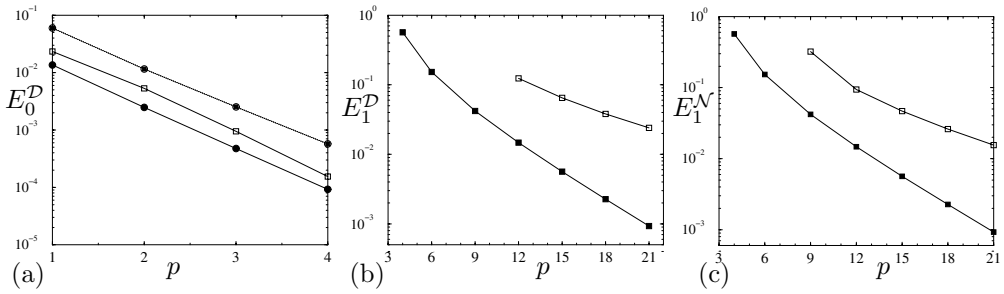

FIG. 4.2. *Relative error for axisymmetrical $N = 0$ eigenvalues $l_{0,0}$ and $l_{0,1}$.* (a) *Relative error $E_0^{\mathcal{D}} = |\lambda_{0,p}^{\mathcal{D}} - l_{0,0}^{\mathcal{D}}|/l_{0,0}^{\mathcal{D}}$ between the predicted eigenvalue and the theoretical one $l_{0,0}^{\mathcal{D}} = -3.656793458$, versus the order p of the approximation. Black circles stand for the flow-averaging method with $w = v/\langle v \rangle$, and white circles for the classical uniform volume averaging $w = 1$. White squares are for $w = 1/(2r)$ and black squares are for $w = 10(1-r)^3$. In every case the convergence is exponential, as indicated by the observed semilog linear behavior.* (b) *We use the same conventions for the second Dirichlet eigenvalue $l_{0,1}^{\mathcal{D}} = -22.30473055$ convergence $E_1^{\mathcal{D}} = |\lambda_{1,p}^{\mathcal{D}} - l_{0,1}^{\mathcal{D}}|/l_{0,1}^{\mathcal{D}}$.* (c) *We use the same conventions for the second Neumann eigenvalue convergence $l_{0,1}^{\mathcal{N}} = -12.8398060$ with $E_1^{\mathcal{N}} = |\lambda_{1,p}^{\mathcal{N}} - l_{0,1}^{\mathcal{N}}|/l_{0,1}^{\mathcal{N}}$.*

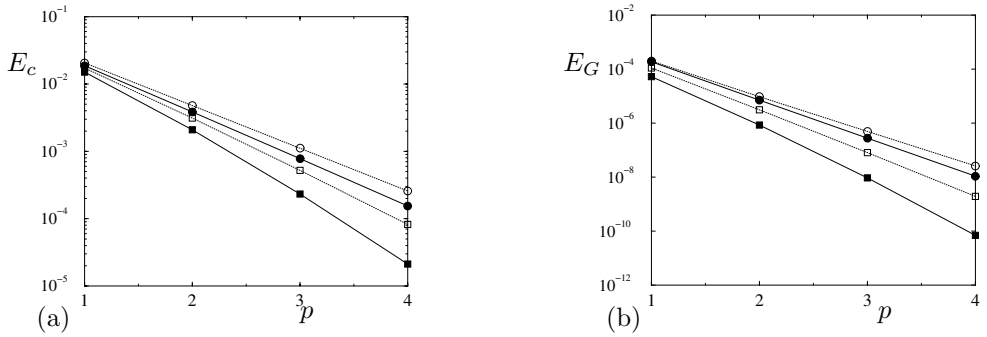

FIG. 4.3. *Relative error for axisymmetrical $N = 0$ eigenmode.* (a) *Relative error $E_c = |c_{\lambda_{0,p}^{\mathcal{D}}} - c_{l_{0,0}^{\mathcal{D}}}|/c_{l_{0,0}^{\mathcal{D}}}$ between the predicted amplitude and its theoretical value associated with a uniform initial temperature $T_0 = 1$ at $z = 0$ for the first Dirichlet eigenmode, versus the order p of the approximation.* (b) *Absolute error $E_G = ||\Gamma_{\lambda_{0,p}^{\mathcal{D}}} - G_{l_{0,0}^{\mathcal{D}}}|| = \langle w(\Gamma_{\lambda_{0,p}^{\mathcal{D}}} - G_{l_{0,0}^{\mathcal{D}}})^2 \rangle$ on the predicted eigenfunction for the first Dirichlet eigenmode.*

Moreover, for finite values of the spectral cut-off p, the second eigenvalue could not always be captured. For example, this can be observed in Figure 4.2(b) in the case of weighting function $w = 10(1-r)^3$, for which the eigenvalue becomes real, so that it is considered to be captured by the approximation for $p \geq 12$ only. This example also illustrates that an empirical test of the convergence is not always successful. If one would have guessed, ignoring the convergence proof, from the computation of the first 10 mapping variables α_p, $p < 10$, that the first eigenvalue computed in Figure 4.2(b) is captured by the weighting function $w = 10(1-r)^3$, it would have found the wrong answer. Figure 4.3 displays the convergence of the amplitude and the eigenfunction defined in Corollary 4.5 for the first Dirichlet mode. It is interesting to note that even the first approximation $p = 1$ that has been detailed in section 2.2.3 permits a rather precise amplitude and eigenmode estimate for every tested weighting function w. The convergence rate displayed on Figure 4.3 is also found to be exponential,

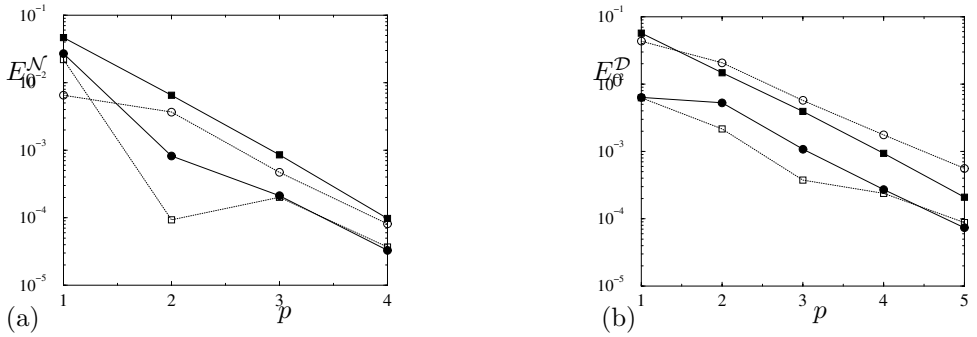

FIG. 4.4. *We use the same conventions as in Figure* 4.2 *for the relative error for nonaxisymmetrical* $N = 1$ *eigenvalues* $l_{1,0}$. (a) *Relative error* $E_0^{\mathcal{N}} = |\lambda_{0,p}^{\mathcal{N}} - l_{1,0}^{\mathcal{N}}|/l_{1,0}^{\mathcal{N}}$ *between the predicted eigenvalue and the theoretical Neumann one* $l_{1,0}^{\mathcal{N}} = -4.160532810$, *versus the order* p *of the approximation.* (b) *We use the same conventions for the first Dirichlet eigenvalue convergence* $l_{1,0}^{\mathcal{D}} = -10.69115115$ *with* $E_0^{\mathcal{D}} = |\lambda_{1,p}^{\mathcal{D}} - l_{1,0}^{\mathcal{D}}|/l_{1,0}^{\mathcal{D}}$.

as already observed for the eigenvalue convergence. This result does not seem very surprising, for the generalized averaging method has many characteristics in common with a spectral discrete method.

Finally, nonaxisymmetrical mode convergence have been investigated. The convergence of the leading order $N = 1$ eigenvalue is represented on Figure 4.4. It is interesting to observe that low order approximation (e.g., $p < 5$) gives rise to a rather precise estimation of this first nonaxisymmetric mode. It should then be noted that for both Neumann and Dirichlet boundary conditions, $|l_{1,0}|$ is smaller than $|l_{0,1}|$. Hence, the better convergence of Figures 4.4(a) and (b) compared to Figures 4.2(b) and (c) can be qualitatively understood. Neumann and Dirichlet situations give lower and upper bounds for the convergence of the more general Robin boundary condition when varying γ from 0 to infinity. Hence, the Robin case should converge the same way as it is observed in the above figures.

5. Discussion and conclusion.

5.1. Discussion. This section discusses the results obtained in the previous sections in the light of previous analysis found in the literature.

5.1.1. Context of the presented analysis. As already mentioned in section 2.1 after defining the convection diffusion problem, (2.1), different characteristic lengths can be chosen for making dimensionless the longitudinal dimension z, and this leads to different Péclet numbers $Pe \gg 1$ or $pe \ll 1$. Any choice should lead to consistent results. When choosing the Péclet number $Pe \gg 1$, it is known that longitudinal variations along z scale linearly with Pe. This result holds as an asymptotic expansion discarding $O(1/Pe^2)$ terms [1], and leads to the simplified constitutive equation (2.2). Balakotaiah and Chang [5] mention that the condition $Pe \gg 6.93$ is necessary for neglecting axial diffusion. The linear scaling of z variations with Pe is described in solution (2.3) and used in the average description of the problem (2.12). From this nondimensionalization choice, it appears that standard [39] "ad hoc" closure relations used in (2.17) and (3.1) do not depend on the Péclet number because each z derivative cancels the corresponding algebraic dependence in Pe. It then appears that closure relations (2.17) and (3.1) are in fact an asymptotic expansion that in-

volves the eigenvalue l of the problem as a small parameter. The validity range of this asymptotic expansion, which should better be described as an analytic expansion of the eigenfunction with the eigenvalue, is investigated in section 4, while in the meantime the "ad hoc"closure relations are a posteriori justified by the convergence proof obtained in the same section. All the validity range results for eigenvalues are obtained independently from the value of the Péclet number, but are valid for $Pe \gg 1$ since the starting constitutive equation (2.2) derives from (2.1) discarding $O(1/Pe^2)$ terms [1].

5.1.2. Comparison with other convergence results. It is now interesting to more clearly compare our analysis with previously obtained convergence results. For example, some convergence criteria have been discussed in the context of center manifold approximations of the convection-diffusion problem (2.1) by Balakotaiah and Chang in [4]. In the case of spatially varying solutions, the solution is projected over Graetz eigenfunctions, and a criterion has been found by summing the expansion series. The convergence criterion can be expressed in the same framework by considering the smallest longitudinal variations associated with a critical λ_c. In the case of Dirichlet boundary conditions, it was found $\lambda_c^{\mathcal{D}} = 13.80$ in [4], whereas $\lambda_c^{\mathcal{N}} = 37.7$ was obtained in the case of Neumann boundary conditions. These values have to be compared with the results in Table 4.1. One has to note, that, in our case, the convergence radius D_{acc} obtained from computing the expansion series is not the only relevant parameter for convergence. D_{val}, which comes from the analyticity condition on the averaged Graetz eigenfunction that we wish to approximate, must also be considered. The convergence radius is the minimum of D_{acc} and D_{val}.

The Lyapunov–Schmidt reduction technique such as used in [5, 11] is also another method that should be compared to our analysis. As mentioned in the introduction, this approximation shares much similarities with ours, and the results are also quite similar. In this case, the considered equation (2.1) is written by making dimensionless the longitudinal direction z by L so that the Péclet number is replaced by the small parameter $pe = PeR/L$, as already indicated in section 2.1. The first step of the Lyapunov–Schmidt reduction approximation is to look for a regular asymptotic expansion solution of (2.1) in terms of the small parameter pe. The solution is then decomposed into two parts similar to (2.10) and (3.1) (but based on a splitting of the linear operator eigenfunctions into "master" eigenfunctions of the kernel of the adjoint operator and "slave" eigenfunctions of the image of the adjoint operator; see, for example, [11]). In the case of the Neumann boundary condition and weighting function $w = 1$, the first closure field solutions that we have obtained are exactly the same as those previously obtained in [5, 11]. More precisely, the first slave mode computed in equation (31) of [11] or equation (3.8) of [5] corresponds to the Neumann solution $\alpha_{1,0}$ found in (2.22). Nevertheless, higher expansion closure fields differ from those of Chakraborty and Balakotaiah [11]. By summing the expansion series, those authors have been able to find a convergence radius for the approximation. Following criteria equation (73) of [11], and the discussion in section 3 of [5], the convergence radius of the Neumann boundary conditions with uniform averaging is $\lambda_c^{\mathcal{N}} = 48 \times 0.288 = 13.8$, which should be compared with the value 10.56 in Table 4.1.

This comparison shows that some of our convergence results are very similar to those previously obtained in the literature with other approaches.

5.1.3. Azimuthal averaging. In this section we discuss the possibility and the interest of azimuthal averaging. First, it should be noted that relation (2.7) gives the amplitude of each nonaxisymmetrical mode of the theoretical solution. If, for example,

an initial condition is chosen with a pulse at a given location (r_0, ϕ_0), i.e., $T_0(r,\phi) = \delta(r-r_0)\delta(\phi-\phi_0)$, then all nonaxisymmetrical modes, $N \neq 0$ will be represented with a weight $c_{N,l} = G_{N,l}(r_0)v(r_0)r_0/\int_0^1 |G_{N,l}(r)|^2 v(r)r\,dr$ because the Fourier transform of the Dirac distribution is uniform. In that case, if one averages the theoretical solution with a uniform weight function along the azimuthal angle ϕ, all nonaxisymmetrical mode,s $N \neq 0$ will not contribute to the averaged concentration because $\langle e^{iN\phi}\rangle_\phi = 0$ for $N \neq 0$. This is not true when using a nonuniform averaging operator w_ϕ along the azimuthal angle ϕ. In this case, there should be some contribution to the averaged concentration coming from nonaxisymmetrical mode $N \neq 0$, summing $c_{N,l}\langle e^{iN\phi}w_\phi\rangle_\phi\langle G_{N,l}\rangle^\star$ contributions.

Some of these nonaxisymmetrical contributions to the true averaged concentration solution could indeed be captured by an averaging method, as shown in the previous sections. Hence, for each nonaxisymmetrical eigenvalue l, one can obtain the appropriate averaging approximation $c_{\lambda_p}\langle e^{iN\phi}w_\phi\rangle_\phi\langle\Gamma_{\lambda_p}\rangle^\star$ of its contribution to the averaged solution.

5.2. Conclusion. This paper analyzes the convergence of volume averaging methods on unidirectional convection-diffusion problems. Neumann, Robin, and Dirichlet boundary conditions have been considered. The last problem is of a great interest in the case of local nonequilibrium conditions, i.e., averaged temperature not equal to the value at the boundary for which approximate solutions are more difficult to obtain.

Concentrating on the stationary solution associated with large Péclet numbers, it has been found that volume averaging methods converge toward the exact solution. A necessary and sufficient condition for this convergence to occur has been found for any unidirectional velocity field, which depends on the averaging operator w. This condition has been obtained in a general form as related to the analytical character of the averaged eigenfunction with the eigenvalue λ. This condition has in fact a general scope, because it is the basis for writing "closure relations" as a power series of the eigenvalue.

It is interesting to note that the convergence also depends, obviously, on the eigenvalue to be captured. In the case of a parabolic velocity profile, the convergence to the Graetz solution has been studied in more detail. In the case of Dirichlet boundary conditions, "natural" operators $w = 1$ or $w = v$ allow the convergence to the first nontrivial eigenvalue. In the case of a Neumann boundary condition, these usual weighting operators do not capture the first nontrivial eigenvalue of the Graetz problem. In this case, it is necessary to use other averaging operators w to get the first spatially decaying mode, some of which have been proposed in this paper.

This result shows that averaging over some spatial volume unavoidably degenerates the space of mathematically accessible solutions. Nevertheless, despite smoothing out the small scales—the large eigenvalues—the averaged solution can lead to an asymptotically exact representation of the large scale structure—the small eigenvalues —of the solution. It is expected that this conclusion could be of some general scope when decreasing the dimension number of a problem by averaging along part of its dimensions.

Moreover, the mathematical proof presented in this paper has been complemented in the case of a parabolic Poiseuille flow by some numerical computation of convergence rates. They have been found to be exponential, as expected from a spectral discrete method. It should also be of some general scope when averaging linear problems. It is interesting to note that the convergence toward nontrivial eigenvalues is

directly related to a correct evaluation of the heat transfer between the fluid and the solid boundary. As a matter of fact it should be kept in mind that the Nusselt number Nu, defined as usual as the dimensionless number associated with the heat (or mass) transfer [14] scales asymptotically, when $z \gg Pe/(l_1 - l_0)$, as $Nu = l_1^2/2$. Hence, convergence toward the eigenvalue of the averaged model is also directly related to a correct evaluation of the asymptotic transfer between the flow and the solid.

Different extensions of this work could be considered. First, a direct transposition of the convergence proof in the case of a plane geometry, with transverse velocity field, should be easily obtained. The quantitative results on the accessibility domain as well as on the convergence accuracy could nevertheless be different in that case. The second extension of interest should be related to more complicated situations associated with a coupling with conduction in some external solid domain.

Appendix A. Graetz functions and Kummer's functions. The generalized Graetz functions are the eigenfunctions of the operator $\frac{1}{1-r^2}\Delta_N$,

$$\frac{1}{1-r^2}\Delta_N \equiv \frac{1}{1-r^2}\left(\partial_r^2 + \frac{1}{r}\partial_r - \frac{N^2}{r^2}\right). \tag{A.1}$$

One wants to solve the self-adjoint Sturm–Liouville problem

$$\frac{1}{1-r^2}\Delta_N f = -\ell^2 f, \tag{A.2}$$

where we have introduced the positive eigenvalue $\ell^2 = -l$ to compare to (2.4). Defining a new function y, from $f(r) = r^N e^{-\frac{\ell}{2}r^2} y(\ell r^2)$, y is then a solution of the hypergeometric equation

$$z\partial_z^2 y + (1 + N - z)\,\partial_z y - \left(\frac{1+N}{2} - \frac{\ell}{4}\right) y = 0. \tag{A.3}$$

In its more general form, the hypergeometric equation reads

$$z\partial_z^2 y + (c - z)\,\partial_z y - ay = 0, \tag{A.4}$$

which possesses two solutions called confluent hypergeometric functions, and when $c = 1$,

- the first one is singular at $z = 0$ and is not considered here;
- the other one is regular, convergent, and denoted $\Phi(a, c, z)$, It is defined by the Kummer's series (with infinite radius of convergence)

$$\Phi(a, c, z) = 1 + \frac{a}{c}z + \frac{a(a+1)}{c(c+1)}\frac{z^2}{2} + \cdots + \frac{a\cdots(a+n-1)}{c\cdots(c+n-1)}\frac{z^n}{n!} + \cdots. \tag{A.5}$$

f is proportional to the Graetz function $G_{N,\ell}$,

$$G_{N,\ell}(r) = r^N e^{-\ell r^2/2}\Phi\left(\frac{1+N}{2} - \frac{\ell}{4}, 1 + N, \ell r^2\right). \tag{A.6}$$

Appendix B. Analyticity in l of the Graetz functions. In this appendix we prove that the generalized Graetz functions defined in (2.4) $G_{N,l}(r)$ are analytical

in l on the whole complex field $\mathbb{C}$. More precisely, for the closure functions $q_{N,n}(r)$ defined in (B.4) one has for each $l \in \mathbb{C}$

$$G_{N,l}(r) = \sum_{n\geq 0} q_{N,n}(r) l^n, \quad \partial_r G_{N,l}(r) = \sum_{n\geq 0} \partial_r q_{N,n}(r) l^n. \tag{B.1}$$

We point out that this result is true for any $N \in \mathbb{Z}$ and for any flow $v(r)$ that is nonnegative and analytical in 0.

We shall prove this result in two steps:

- in section B.1 we prove that (B.1) is true when l belongs to a disk $D \subset \mathbb{C}$ which we characterize;
- in section B.2 we prove that $D = \mathbb{C}$.

We first recall the following definitions:

For a given value $N \in \mathbb{Z}$ of the axisymmetric parameter, the operator Δ_N is defined as

$$\Delta_N \equiv \partial_r^2 + \frac{1}{r}\partial_r - \frac{N^2}{r^2},$$

so that $\Delta_{-N} = \Delta_N$. Hence, we will consider the case $N \geq 0$ only.

The operator Δ_N can be written under a divergence form

$$\Delta_N f = \frac{1}{r^{N+1}} \partial_r \left(r^{2N+1} \partial_r \left(\frac{f}{r^N} \right) \right). \tag{B.2}$$

For each $l \in \mathbb{C}$ the Graetz function $G_{l,N}$ is the only solution for the following ODE:

$$\begin{cases} \Delta_N G_{N,l} = l v(r) G_{N,l}(r), \\ \dfrac{G_{N,l}}{r^N}(0) = 1. \end{cases} \tag{B.3}$$

We define the set of closure functions $q_{N,n}$, for $n \geq 0$, as follows:

$$\begin{cases} \Delta_N q_{N,n} = v(r) q_{N,n-1}(r) \quad \text{with } q_{N,-1} = 0, \\ \dfrac{q_{N,0}}{r^N}(0) = 1 \quad \text{and} \quad \dfrac{q_{N,n}}{r^N}(0) = 0 \quad \text{for} \quad n \geq 1. \end{cases} \tag{B.4}$$

B.1. A criterion for the Graetz function to be analytical in l.

THEOREM B.1. *Let D be the convergence disk of the series*

$$\sum_{n\geq 0} q_{N,n}(1) l^n, \tag{B.5}$$

where the closure functions $q_{N,n}$ are defined in (B.4)*. Then for all $l \in D$,*

$$\begin{gathered} G_{N,l}(r) = \sum_{n\geq 0} q_{N,n}(r) l^n, \quad \partial_r G_{N,l}(r) = \sum_{n\geq 0} \partial_r q_{N,n}(r) l^n, \\ \text{and} \quad \Delta_N G_{N,l}(r) = \sum_{n\geq 0} \Delta_N q_{N,n}(r) l^n. \end{gathered} \tag{B.6}$$

Proof. We begin by proving that for a fixed $l \in D$ the three series $\sum_{n\geq 0} q_{N,n}(r)l^n$, $\sum_{n\geq 0} \partial_r q_{N,n}(r)l^n$, and $\sum_{n\geq 0} \Delta_N q_{N,n}(r)l^n$ are uniformly convergent for $r \in [0,1]$.

First of all the recursive definition (B.4) of the functions $q_{N,n}$ implies that, for all $n \geq 0$, $q_{N,n}(r) = r^N \psi_n(r)$, where ψ_n is a nonnegative, nondecreasing, continuous function on $[0,1]$,

(B.7)
$$q_{N,0} = r^N \quad \text{and} \quad q_{N,n}(r) = r^N \int_0^r \frac{1}{y^{2N+1}} \int_0^y x^{N+1} v(x) q_{N,n-1}(x)\, dx\, dy \quad \text{for} \quad n \geq 1,$$

so that $0 \leq q_{N,n}(r) \leq q_{N,n}(1)$ and the series $\sum_{n\geq 0} q_{N,n}(r)l^n$ is uniformly converging on $[0,1]$ for $l \in D$.

In the same way $\Delta_N q_{N,n}(r) = v(r) q_{N,n-1}(r)$, and so one has $0 \leq \Delta_N q_{N,n}(r) \leq \|v\| q_{N,n-1}(1)$ and the series $\sum_{n\geq 0} \Delta_N q_{N,n}(r)l^n$ is uniformly converging on $[0,1]$ for $l \in D$.

Now one has

$$\begin{aligned} 0 \leq \partial_r q_{N,n}(r) &= N r^{N-1} \int_0^r \frac{1}{y^{2N+1}} \int_0^y x^{N+1} v(x) q_{N,n-1}(x)\, dx\, dy \\ &\quad + \frac{1}{r^{N+1}} \int_0^r x^{N+1} v(x) q_{N,n-1}(x) dx \\ &\leq N r^{N-1} q_{N,n}(1) + \frac{\|v\|}{N+2} r q_{N,n-1}(1) \\ &\leq C \left(q_{N,n}(1) + q_{N,n-1}(1) \right), \end{aligned}$$

where the constant C depends only on N and v so that the series $\sum_{n\geq 0} \partial_r q_{N,n}(r)l^n$ is uniformly converging on $[0,1]$ for $l \in D$.

Now, for a given value $l \in D$ we introduce the two functions defined on $[0,1]$,

$$F(r) = \sum_{n\geq 0} q_{N,n}(r)l^n, \quad H(r) = \sum_{n\geq 0} \Delta_N q_{N,n}(r)l^n,$$

since these are uniformly converging series, and since $\sum_{n\geq 0} \partial_r q_{N,n}(r)l^n$ is also a uniformly converging series for $r \in [0,1]$, one can use the integration theorem, which implies that

$$H(r) = \Delta_N F(r) \quad \text{for } r \in [0,1],$$

and at the same time one has with (B.4) that $H(r) = l v(r) F(r)$ and that $\frac{F}{r^N}(0) = 1$. The unicity of the solutions of (B.3) ensures then that $F(r) = G_{N,l}(r)$, and this ends the proof. ∎

B.2. Analyticity on the whole complex field $\mathbb{C}$.

LEMMA B.2. *The series*

$$\sum_{n\geq 0} q_{N,n}(1)l^n$$

is convergent on the whole complex plane $\mathbb{C}$ *and so* (B.1) *is true for all* $l \in \mathbb{C}$.

Proof. With the integral formulation (B.7) on the closure functions $q_{N,n}$ one has

$$\begin{aligned} q_{N,n+m}(1) &= \int_0^1 \frac{1}{y_1^{2N+1}} \int_0^{y_1} x_1^{N+1} v(x_1) q_{N,n+m-1}(x_1)\, dx_1\, dy_1 \\ &= \int_0^1 \frac{1}{y_1^{2N+1}} \int_0^{y_1} x_1^{2N+1} v(x_1) \cdots \int_0^{x_{m-1}} \frac{1}{y_m^{2N+1}} \\ &\quad \times \int_0^{y_m} x_m^{N+1} v(x_m) q_{N,n}(x_m) dx_m dy_m \cdots dx_1 dy_1, \end{aligned}$$

and since $0 \leq q_{N,n}(r) \leq r^N q_{N,n}(1)$ (see (B.7)), we have

$$\begin{aligned} \frac{q_{N,n+m}(1)}{q_{N,n}(1)} &\leq \int_0^1 \frac{1}{y_1^{2N+1}} \int_0^{y_1} x_1^{2N+1} v(x_1) \cdots \int_0^{x_{m-1}} \frac{1}{y_m^{2N+1}} \\ &\quad \times \int_0^{y_m} x_m^{2N+1} v(x_m) dx_m\, dy_m \cdots dx_1\, dy_1 \\ &\leq \|v\|^m \int_0^1 \frac{1}{y_1^{2N+1}} \int_0^{y_1} x_1^{2N+1} \cdots \int_0^{x_{m-1}} \frac{1}{y_m^{2N+1}} \\ &\quad \times \int_0^{y_m} x_m^{2N+1} dx_m\, dy_m \cdots dx_1\, dy_1, \end{aligned}$$

where $\|v\| = \sup v(r)$.

This upper bound can be computed explicitly,

$$\frac{q_{N,n+m}(1)}{q_{N,n}(1)} \leq \|v\|^m \frac{1}{2(2N+2)} \cdots \frac{1}{2m(2N+2m)} := \alpha_m,$$

and $\alpha_m^{-1/m}$ is a lower bound for the radius of convergence of the series (B.2). One can easily check that

$$\alpha^{-1/m} \geq 2 \frac{2N+2}{\|v\|} (m!)^{1/m},$$

and so $\alpha^{-1/m}$ grows up to infinity. As a result the series (B.2) is convergent on the whole complex plane $\mathbb{C}$. ∎

Appendix C. Invertibility of the operator $\mathcal{L}_N^\star$ and resolution of the closure problems. In this appendix we prove that the closure problems

$$\text{(C.1)} \quad \begin{cases} \mathcal{L}_N^\star \alpha_n = v(r)\alpha_{n-1}(r) - \langle v\alpha_{n-1}\rangle^\star & \text{with } \alpha_{-1}(r) = 0, \\ \alpha_0^\star = 1 \quad \text{or} \qquad \alpha_n^\star = 0 & \text{for } n \geq 1 + \text{boundary condition} \end{cases}$$

for a boundary condition either of a homogeneous Dirichlet, homogeneous Neumann, or Robin type,

$$\text{(C.2)} \qquad \alpha_n(1) = 0, \quad \partial\alpha_n(1) = 0, \quad \text{or} \quad \partial\alpha_n(1) + \gamma\alpha_n(1) = 0,$$

has one and only one bounded solution for each $n \in \mathbb{N}$.

The operator $\mathcal{L}_N^\star$ is defined for $N \in \mathbb{Z}$ and for a normalized averaging operator $\star$ (i.e., such that $\langle 1\rangle^\star = 1$) by

$$\text{(C.3)} \qquad \mathcal{L}_N^\star f = \Delta_N f - \langle \Delta_N f\rangle^\star;$$

for the operator Δ_N,

$$\Delta_N f = \partial_r^2 f + \frac{1}{r}\partial_r f - \frac{N^2}{r^2} f.$$

Because $\Delta_N = \Delta_{-N}$ we will only consider here the proof for $N \geq 0$.

We proceed in two steps: in section C.1 we prove a lemma on the general solution of $\Delta_N f = g$ and in section C.2 we apply that lemma to the problems (C.1) for every boundary condition (C.2).

C.1. A technical lemma.

LEMMA C.1. *Let g be a continuous function defined on $[0,1]$ and such that $g^\star = 0$. Then for all $A \in \mathbb{R}$ the ODE*

$$\Delta_N f - A = g, \tag{C.4}$$

$$f^\star = M \in \mathbb{R} \tag{C.5}$$

has one and only one bounded solution on $[0,1]$.

Moreover, this solution fulfills

$$\langle \Delta_N f \rangle^\star = A$$

and then is a solution of

$$\begin{cases} \mathcal{L}_N^\star f = g, \\ f^\star = M. \end{cases}$$

Proof. We define the function $\psi_1(r)$,

$$\psi_1(r) = -r^N \int_r^1 \frac{1}{y^{2N+1}} \int_0^y x^{N+1} g(x)\, dx\, dy, \tag{C.6}$$

which is well defined since g is continuous in 0 for $N \geq 0$, and the function $\psi_2(r)$,

$$\psi_2(r) = \frac{r^N - r^2}{N^2 - 4} \quad \text{if } N \neq 2 \quad \text{and} \quad \psi_2(r) = \frac{r^2}{4}\ln(r) \quad \text{for } N = 2. \tag{C.7}$$

Any solution of (C.4) is of the form

$$f(r) = \lambda r^N + \mu r^{-N} + A\psi_2(r) + \psi_1(r) \quad \text{if } N \neq 0, \quad \text{or}$$
$$f(r) = \lambda r^N + \mu \ln(r) + A\psi_2(r) + \psi_1(r) \quad \text{if } N = 0.$$

Then all bounded solutions of (C.4) on $[0,1]$ are on the form

$$f(r) = \lambda r^N + A\psi_2(r) + \psi_1(r), \tag{C.8}$$

and (C.5) gives

$$\lambda = \frac{M - A\psi_2^\star - \psi_1^\star}{\langle r^N \rangle^\star}.$$

Thus (C.4) and (C.5) have only one bounded solution.

Since $g^\star = 0$ one also has $\langle r^N \rangle^\star = A$. ∎

C.2. Resolution of the closure problems.

Homogeneous Dirichlet case. We consider the solution f as in (C.8) of (C.4) and (C.5) and search for a value of A such that $f(1) = 0$.

We have

$$f(1) = \frac{M - A\psi_2^\star - \psi_1^\star}{\langle r^N \rangle^\star}. \tag{C.9}$$

So there is only one bounded solution f of (C.4) and (C.5) such that $f(1) = 0$; it is defined as

$$f(r) = \frac{M - A\psi_2^\star - \psi_1^\star}{\langle r^N \rangle^\star} r^N + A\psi_2(r) + \psi_1(r),$$
$$A = \frac{M - \psi_1^\star}{\psi_2^\star},$$

and A is well defined because ψ_2 is negative and so $\psi_2^\star \neq 0$.

Consequently, the closure problems (C.1) for an homogeneous Dirichlet boundary condition are well posed.

Homogeneous Neumann case. We consider the solution f as in (C.8) of (C.4) and (C.5) and search for a value of A such that $\partial_r f(1) = 0$.

By multiplying (C.4) by r^{N+1} and integrating over $[0, 1]$ one gets

$$\partial_r f(1) = N f(1) + \frac{A}{N+2} + \int_0^1 r^{N+1} g(r)\, dr, \tag{C.10}$$

and since

$$f(1) = \frac{M - A\psi_2^\star - \psi_1^\star}{\langle r^N \rangle^\star},$$

there is only one solution defined as

$$f(r) = \frac{M - A\psi_2^\star - \psi_1^\star}{\langle r^N \rangle^\star} r^N + A\psi_2(r) + \psi_1(r),$$
$$A\left(\frac{1}{N+2} - N\frac{\psi_2^\star}{\langle r^N \rangle^\star}\right) = N\frac{\psi_1^\star - M}{\langle r^N \rangle^\star} - \int_0^1 r^{N+1} g(r)\, dr,$$

where A is well defined because ψ_2 is negative and so $\frac{1}{N+2} - N\frac{\psi_2^\star}{\langle r^N \rangle^\star} \neq 0$.

Consequently the closure problems (C.1) for an homogeneous Neumann boundary condition are well posed.

Robin case. We consider the solution f as in (C.8) of (C.4) and (C.5) and search for a value of A such that $\partial_r f(1) + \gamma f(1) = 0$ for $\gamma > 0$.

With (C.9) and (C.10) we have

$$\partial_r f(1) + \gamma f(1) = A\left(\frac{1}{N+2} - (N+\gamma)\frac{\psi_2^\star}{\langle r^N \rangle^\star}\right) - (N+\gamma)\frac{\psi_1^\star - M}{\langle r^N \rangle^\star} + \int_0^1 r^{N+1} g(r)\, dr,$$

and so there is only one solution defined as

$$f(r) = \frac{M - A\psi_2^\star - \psi_1^\star}{\langle r^N \rangle^\star} r^N + A\psi_2(r) + \psi_1(r),$$
$$A\left(\frac{1}{N+2} - (N+\gamma)\frac{\psi_2^\star}{\langle r^N \rangle^\star}\right) = (N+\gamma)\frac{\psi_1^\star - M}{\langle r^N \rangle^\star} - \int_0^1 r^{N+1} g(r)\, dr,$$

where A is well defined for $\gamma \geq 0$.

Consequently the closure problems (C.1) for an homogeneous Neumann boundary condition are well posed.

SHAPE ANALYSIS OF AN ADAPTIVE ELASTIC ROD MODEL*

ISABEL N. FIGUEIREDO†, CARLOS F. LEAL†, AND CECÍLIA S. PINTO‡

Abstract. We analyze the shape semiderivative of the solution to an asymptotic nonlinear adaptive elastic rod model, derived in Figueiredo and Trabucho [*Math. Mech. Solids*, 9 (2004), pp. 331–354], with respect to small perturbations of the cross section. The rod model is defined by generalized Bernoulli–Navier elastic equilibrium equations and an ordinary differential equation with respect to time. Taking advantage of the model's special structure and the regularity of its solution, we compute and completely identify, in an appropriate functional space involving time, the weak shape semiderivative.

Key words. adaptive elasticity, rod, shape derivative

1. Introduction.

In this paper we consider a sensitivity analysis problem in shape optimization: the calculus of the derivative of the solution to an asymptotic nonlinear adaptive elastic rod model, with respect to shape variations of the cross section of the rod. More precisely, for each small parameter $s \in [0, \delta]$ we define a perturbed adaptive elastic rod $\overline{\Omega}_s = \overline{\omega}_s \times [0, L]$. The scalar $L > 0$ is its length, and $\omega_s = \omega + s\,\theta(\omega)$ is a perturbation of a fixed cross section ω, in the direction of the vector field $\theta = (\theta_1, \theta_2)$, that realizes the shape variation. To each rod $\overline{\Omega}_s$ we associate the corresponding unique solution (u^s, d^s) of the asymptotic adaptive elastic rod model, derived in Figueiredo and Trabucho [7]. The purpose of this paper is to compute the limit $(\frac{u^s-u}{s}, \frac{d^s-d}{s})$, when $s \to 0^+$, where (u, d) is the solution's rod model for the case $s = 0$. This limit is the semiderivative of the shape function $J : s \in [0, \delta] \to J(\Omega_s) = (u^s, d^s)$, at $s = 0$ in the direction of the vector field θ (in the sense of Delfour and Zolésio [5, p. 289]), or equivalently, the material derivative of the map J at $s = 0$ (in the sense of Haslinger and Mäkinen [8, p. 111]).

The difficulties that arise in the computation of the limit $(\frac{u^s-u}{s}, \frac{d^s-d}{s})$, when $s \to 0^+$, are caused by the complicated form of the asymptotic adaptive elastic rod model derived in Figueiredo and Trabucho [7]. In fact, this is a simplified adaptive elastic model, proposed for the mathematical modeling of the physiological process of bone remodeling. It couples the generalized Bernoulli–Navier elastic equilibrium equations with an ordinary differential equation with respect to time, which is the remodeling rate equation. This latter equation expresses the process of absorption and deposition of bone material due to external stimulus (cf. Cowin and Hegedus [3] and Hegedus and Cowin [9] for a description of the theory of adaptive elasticity, Cowin and Nachlinger [4] for uniqueness results, and Monnier and Trabucho [10] for existence results of three-dimensional solutions). For each $s \in [0, \delta]$, the pair (u^s, d^s) is the unique solution of this asympotic adaptive elastic rod model, where u^s is the displacement vector field

of the rod $\overline{\Omega}_s$ and d^s is a scalar field that represents the change in volume fraction of the elastic material (from a reference volume fraction) in the rod $\overline{\Omega}_s$. Moreover, u^s is the solution of the generalized Bernoulli–Navier equilibrium equations, and d^s is the solution of the remodeling rate equation. In addition, u^s and d^s are coupled in the model because the material coefficients depend on d^s and the remodeling rate equation depends on u^s.

In spite of this complex structure, we are able to compute the limit $(\frac{u^s-u}{s}, \frac{d^s-d}{s})$ when $s \to 0^+$. There are two main results in this paper, which lead to this limit's computation. The first principal result states that, for each time t, the sequence $(\frac{u^s-u}{s}, \frac{d^s-d}{s})(.,t)$ converges weakly to $(\bar{u}, \bar{d})(.,t)$, when $s \to 0^+$, in an appropriate functional space of Sobolev type. (We denote by (u^s, d^s) the solution of the perturbed rod model, formulated in the unperturbed fixed domain $\overline{\Omega}$, which is the domain of (u, d).) The second main result identifies the weak shape semiderivative denoted by $(\bar{u}, \bar{d})$; it is the unique solution of a nonlinear problem which couples a variational equation (whose solution is $\bar{u}$) and depends on (u, d) and $\bar{d}$, and an ordinary differential equation with respect to time (whose solution is $\bar{d}$) that depends on (u, d) and $\bar{u}$.

The reasonings that we have used to achieve these two results are next summarized. We show that the sequences (u^s, d^s) and $(\frac{u^s-u}{s}, \frac{d^s-d}{s})$ are bounded in appropriate functional spaces, involving time; we use the continuity, the ellipticity, the regularity properties, and the special structure of the asymptotic adaptive elastic rod model. In order to identify the weak shape semiderivative we also apply the weak and/or strong convergence of the sequences $\{u^s\}$ and $\{d^s\}$, when $s \to 0^+$, and again the special structure of the asymptotic adaptive elastic rod model. In particular, due to the form of the remodeling rate equation, we are able to use the integral Gronwall's inequality, which is the key to obtaining the estimates for the sequences $\{d^s\}$ and $\{\frac{d^s-d}{s}\}$ and to identifying the ordinary differential equation with respect to time, whose solution is $\bar{d}$.

Finally let us briefly explain the contents of the paper. After this introduction, in section 2, we describe the problem P_s, which is the asymptotic nonlinear adaptive elastic model for the perturbed rod $\overline{\Omega}_s$; we also prove a regularity property of its solution, and finally we describe the shape problem that we want to solve. In section 3 we reformulate the problem P_s in the unperturbed domain $\overline{\Omega}$; this reformulation is necessary because, in order to compute the limit of the quotient sequence $(\frac{u^s-u}{s}, \frac{d^s-d}{s})$, the vector fields u^s, u, d^s, and d must be defined in the same fixed domain, independent of s. In section 4 we prove that all the sequences $\{u^s\}$, $\{d^s\}$, $\{\frac{u^s-u}{s}\}$, and $\{\frac{d^s-d}{s}\}$ are bounded in appropriate functional spaces involving time; we determine, for each time t, the weak limit of the quotient sequence $(\frac{u^s-u}{s}, \frac{d^s-d}{s})(.,t)$ when $s \to 0^+$; and we identify the weak shape semiderivative (this identification is summarized in theorem 4.11). Finally we present some conclusions and future work.

2. Description of the problem. In this section we first introduce the notation used in this paper; namely, we consider a family of rods $\overline{\Omega}_s = \overline{\omega}_s \times [0, L]$, with length L and cross section ω_s, parameterized by $s \in [0, \delta]$, which is a small parameter. Next, for each s, we describe the adaptive elastic rod model denoted by P_s, derived by Figueiredo and Trabucho [7]. We prove a regularity result for the displacement vector field u_s, the first component of the solution (u_s, d_s) of P_s. Finally, we describe the shape problem under consideration in this paper.

2.1. Notation. Let $\delta > 0$ be a small parameter, and for each $s \in [0, \delta]$ we consider the perturbation I_s of the identity operator I in $\mathbb{R}^2$, defined by $I_s(x_1, x_2) = (I + s\theta)(x_1, x_2) = (x_{s1}, x_{s2})$, for all $(x_1, x_2) \in \mathbb{R}^2$, where $\theta = (\theta_1, \theta_2) : \mathbb{R}^2 \longrightarrow \mathbb{R}^2$ is a

vector field regular enough (at least $\theta \in [W^{2,\infty}(\mathbb{R}^2)]^2$). Let ω be an open, bounded, and connected subset of $\mathbb{R}^2$, with a boundary $\partial\omega$ regular enough. For each $s \in [0,\delta]$ we define $\omega_s = I_s(\omega)$, which is the perturbation of ω in the direction of the vector field θ. We also denote by $\overline{\Omega}_s$ the set occupied by a cylindrical adaptive elastic rod, in its reference configuration, with length $L > 0$ and cross section ω_s, that is, $\overline{\Omega}_s = \overline{\omega}_s \times [0,L] = I_s(\overline{\omega}) \times [0,L] \subset \mathbb{R}^3$. Moreover, we denote by $x_s = (x_{s1}, x_{s2}, x_3)$ a generic element of $\overline{\Omega}_s$ and define the sets $\Gamma_s = \partial\omega_s \times]0,L[$, $\Gamma_{s0} = \overline{\omega}_s \times \{0\}$, $\Gamma_{sL} = \overline{\omega}_s \times \{L\}$, and $\Gamma_{s0,L} = \Gamma_{s0} \cup \Gamma_{sL}$, where $\partial\omega_s$ is the boundary of ω_s. These last four sets represent, respectively, the lateral boundary of the rod $\overline{\Omega}_s$ and its extremities. We assume that, for each $s \in [0,\delta]$, the coordinate system (O, x_{s1}, x_{s2}, x_3) is a principal system of inertia associated with the rod Ω_s. Consequently, axis Ox_3 passes through the centroid of each section $\omega_s \times \{x_3\}$, and we have $\int_{\omega_s} x_{s1}\, d\omega_s = \int_{\omega_s} x_{s2}\, d\omega_s = \int_{\omega_s} x_{s1}x_{s2}\, d\omega_s = 0$. (We observe that the choice of the vector field θ, which realizes the shape variation of the cross section ω, must be admissible with this condition.)

The set $C^m(\overline{\Omega}_s)$ is the space of real functions m times continuously differentiable in $\overline{\Omega}_s$. The spaces $W^{m,q}(\Omega_s)$ and $W^{0,q}(\Omega_s) = L^q(\Omega_s)$ are the usual Sobolev spaces, where q is a real number satisfying $1 \le q \le \infty$ and m is a positive integer. The norms in these Sobolev spaces are denoted by $\|.\|_{W^{m,q}(\Omega_s)}$. The set $\mathcal{R}_s = \{v_s \in \mathbb{R}^3 :\ v_s = a + b \wedge x_s,\ a, b \in \mathbb{R}^3\}$, where $\wedge$ is the exterior product in $\mathbb{R}^3$, is the set of infinitesimal rigid displacements. We denote by $[W^{m,q}(\Omega_s)]^3/\mathcal{R}_s$ the quotient space induced by the set $\mathcal{R}_s$ in the Sobolev space $[W^{m,q}(\Omega_s)]^3$.

Throughout the paper, the Latin indices i, j, k, $l, \ldots$ belong to the set $\{1,2,3\}$; the Greek indices α, β, $\mu, \ldots$ vary in the set $\{1,2\}$; and the summation convention with respect to repeated indices is employed, that is, for example, $a_i b_i = \sum_{i=1}^3 a_i b_i$.

Let $T > 0$ be a real parameter, and denote by t the time variable in the interval $[0,T]$. If V is a topological vectorial space, the set $C^m([0,T];V)$ is the space of functions $g : t \in [0,T] \to g(t) \in V$ such that g is m times continuously differentiable with respect to t. If V is a Banach space, we denote by $\|.\|_{C^m([0,T];V)}$ the usual norm in $C^m([0,T];V)$. Moreover, given a function $g_s(x_s,t)$ defined in $\overline{\Omega}_s \times [0,T]$, we denote by $\dot{g}_s$ its partial derivative with respect to time and by $\partial_{s\alpha} g_s$ and $\partial_3 g_s$ its partial derivatives with respect to $x_{s\alpha}$ and x_3; that is, $\dot{g}_s = \frac{\partial g_s}{\partial t}$, $\partial_{s\alpha} g_s = \frac{\partial g_s}{\partial x_{s\alpha}}$, and $\partial_3 g_s = \frac{\partial g_s}{\partial x_3}$.

2.2. The adaptive elastic rod model. Figueiredo and Trabucho [7] have applied the asymptotic expansion method to the three-dimensional adaptive elasticity model derived by Cowin and Hegedus [3, 9], with the modifications proposed by Monnier and Trabucho [10], for a thin rod whose cross section is a function of a small parameter and for a three-dimensional remodeling rate equation depending nonlinearly or linearly on the strain tensor field (cf. also Trabucho and Viaño [11] for an explanation of the mathematical modeling of rods with the asymptotic expansion method). They have obtained a simplified adaptive elastic rod model, which is designated in what follows by the asymptotic adaptive elastic rod model. This is a system of nonlinear coupled equations, which includes generalized Bernoulli–Navier equilibrium equations and a simplified remodeling rate equation. For any perturbed rod $\overline{\Omega}_s$ (with $s \in [0,\delta]$) and for the case where the original three-dimensional remodeling rate equation depends linearly on the strain tensor field, this system is defined as follows:

$$
\left[\begin{array}{l}
u_s = (u_{s1}, u_{s2}, u_{s3}) : \overline{\Omega}_s \times [0,T] \to \mathbb{R}^3, \quad d_s : \overline{\Omega}_s \times [0,T] \to \mathbb{R}, \\
u_{s\alpha} : [0,L] \times [0,T] \to \mathbb{R}, \\
u_{s3} = \underline{u}_{s3} - x_{s\alpha}\partial_3 u_{s\alpha} \quad \text{and} \quad \underline{u}_{s3} : [0,L] \times [0,T] \to \mathbb{R}, \\
(u_s, d_s) \quad \text{satisfies the following:}
\end{array}\right. \tag{2.1}
$$

$$
\left[\begin{array}{l}
\textit{Equilibrium equations} \text{ in } (0,L)\times(0,T)\\

d_s(x_s,0) = \hat{d}_s(x_s) & \text{in} \quad \overline{\Omega}_s.
\end{array}\right. \tag{2.4}
$$

The unknowns of the model (2.1)–(2.4) are the displacement vector field $u_s(x_s,t)$, corresponding to the displacement of the point x_s of the rod $\overline{\Omega}_s$ at time t, and the measure of change in volume fraction of the elastic material (from the reference volume fraction ξ_{s0}) $d_s(x_s,t)$ at (x_s,t). In particular, $e_{33}(u_s) = \partial_3 u_{s3} = \partial_3\underline{u}_{s3} - x_{s\alpha}\partial_{33}u_{s\alpha}$ is an element of the linear strain tensor field $(e_{ij}(u_s))$, which depends on u_s.

On the other hand, the data of the model (2.1)–(2.4) are the following: the open set $\Omega_s\times(0,T)$; the density $\gamma_s = \gamma$ of the full elastic material, which is supposed to be a constant independent of s; the reference volume fraction of the elastic material ξ_{s0}, which belongs to $C^1(\overline{\Omega}_s)$ for each s; the body load $f_s = (f_{si})$ such that $f_{si}\in C^1([0,T])$ and depends only on t; the normal tractions on the boundary $g_s = (g_{si})$ and $h_s = (h_{si})$; the initial value of the change in volume fraction $\hat{d}_s$, which belongs to $C^0(\overline{\Omega}_s)$; the truncation operator $\mathcal{P}_\eta(.)$; and the coefficients $l_s(d_s)$, $e_{s\alpha}(d_s)$, $h_{s\alpha\beta}(d_s)$, $c(d_s)$, $a(d_s)$, $A_{\alpha\beta}(d_s)$, $A_{33}(d_s)$, $b_{\alpha\beta33}(d_s)$, and $b_{3333}(d_s)$, which are all material coefficients depending upon the change in volume fraction d_s.

On these data we also suppose further conditions, which we will describe next. We assume that, for each $s\in[0,\delta]$, $0<\xi_{s0}^{min}\le\xi_{s0}(x_s)\le\xi_{s0}^{max}<1$ and the normal tractions verify

$$
g_{si}\in C^1([0,T];W^{1-1/p,p}(\Gamma_s)), \quad h_{si}\in C^1([0,T];W^{1-1/p,p}(\Gamma_{s0}\cup\Gamma_{sL})), \tag{2.5}
$$

with $p>3$. In addition, we assume that the resultant of the system of applied forces is null for rigid displacements; this means that, for any $v_s = (v_{si})$ in $\mathcal{R}_s$ and for all $t\in[0,T]$,

$$
\int_{\Omega_s}\gamma(\xi_{s0}+\mathcal{P}_\eta(d_s))f_{si}v_{si}dx_s + \int_{\Gamma_s} g_{si}v_{si}d\Gamma_s + \int_{\Gamma_{s0,L}} h_{si}v_{si}d\Gamma_{s0,L} = 0. \tag{2.6}
$$

The truncation operator $\mathcal{P}_\eta$ is of class C^1 and satisfies $0 < \frac{\eta}{2} \leq (\xi_{s0} + \mathcal{P}_\eta(d_s))(x_s) \leq 1$ for all $x_s \in \overline{\Omega}_s$, where $\eta > 0$ is a small parameter.

The coefficients $b_{\alpha\beta 33}(d_s)$ and $b_{3333}(d_s)$ are continuously differentiable with respect to d_s and are elements of the matrix $(b_{ijkl}(d_s))$, which is the inverse of the matrix defined by the three-dimensional elastic coefficients $(c_{ijkl}(d_s))$ of the rod $\overline{\Omega}_s$, that depend on d_s through truncation and mollification (cf. formulas (47)–(48), Figueiredo and Trabucho [7]). The coefficients $A_{\alpha\beta}(d_s)$, $A_{33}(d_s)$, $c(d_s)$, and $a(d_s)$ are remodeling rate coefficients and are continuously differentiable with respect to d_s.

Moreover, $b_{\alpha\beta 33}(d_s)$ and $b_{3333}(d_s)$ belong to the space $C^1([0,T]; C^1(\mathbb{R}^3))$ when $d_s \in C^1([0,T]; C^0(\overline{\Omega}_s))$ (cf. Monnier and Trabucho [10, p. 542] and also formulas (47)–(48) of Figueiredo and Trabucho [7]). In addition we also assume that there exist strictly positive constants C_1, C_2, C_3, C_4, C_5, and C_6 independent of s and t such that for any $(x_s, t) \in \overline{\Omega}_s \times [0,T]$

$$0 < C_1 \leq \frac{1}{b_{3333}(d_s)} \leq C_2 \quad \forall s \in [0,\delta], \tag{2.7}$$

$$|c(d_s)| \leq C_3,\ |a(d_s)| \leq C_4,\ |c'(d_s)| \leq C_5,\ |a'(d_s)| \leq C_6 \quad \forall s \in [0,\delta], \tag{2.8}$$

where $c'(.)$ and $a'(.)$ are the derivatives of the scalar functions $c(.)$ and $a(.)$. We remark that the assumption (2.7) is a direct consequence of the definition of b_{3333}, and also a consequence of [10, Lemma 1, p. 542]. The assumption (2.8) can be proven using exactly the same arguments of this Lemma 1, supposing that $c(d_s)$ and $a(d_s)$ depend on d_s through truncation and mollification.

The coefficients $l_s(d_s)$, $e_{s\alpha}(d_s)$, and $h_{s\alpha\beta}(d_s)$, which depend on $b_{3333}(d_s)$ (cf. formula (49), Figueiredo and Trabucho [7]), are functions of x_3 and t, and are defined by

$$l_s = \int_{\omega_s} \frac{1}{b_{3333}(d_s)} d\omega_s, \quad e_{s\alpha} = \int_{\omega_s} \frac{x_{s\alpha}}{b_{3333}(d_s)} d\omega_s, \quad h_{s\alpha\beta} = \int_{\omega_s} \frac{x_{s\alpha}x_{s\beta}}{b_{3333}(d_s)} d\omega_s. \tag{2.9}$$

The variational formulation of the equilibrium equations (2.2) is obtained by multiplying the first equilibrium equation (2.2) by $\underline{v}_{s3} \in W^{1,2}(0,L)$ and the second and third equilibrium equations by $x_{s1}\, v_{s1}$ and $x_{s2}\, v_{s2}$, respectively, with $v_{s\beta} \in W^{2,2}(0,L)$, for $\beta = 1, 2$, and subsequently integrating in $(0,L)$ and using the boundary conditions (2.3). Thus, the asymptotic adaptive elastic rod model (2.1)–(2.4) is equivalent to the following nonlinear (variational and differential) system (P_s) (cf. formula (56) of Figueiredo and Trabucho [7]):

$$(\mathrm{P}_s) \quad \left[\begin{array}{l} \text{Find} \quad u_s : \overline{\Omega}_s \times [0,T] \to \mathbb{R}^3 \quad \text{and} \quad d_s : \overline{\Omega}_s \times [0,T] \to \mathbb{R} : \\ u_s(.,t) \in V(\Omega_s)/\mathcal{R}_s, \\ a_s(u_s, v_s) = L_s(v_s) \qquad \forall v_s \in V(\Omega_s)/\mathcal{R}_s, \\ \dot{d}_s = c(d_s) e_{33}(u_s) + a(d_s) \quad \text{in} \quad \Omega_s \times (0,T), \\ d_s(x_s, 0) = \hat{d}_s(x_s) \quad \text{in} \quad \overline{\Omega}_s. \end{array}\right.$$

The space $V(\Omega_s) = \{v_s \in [W^{1,2}(\Omega_s)]^3 :\ e_{\alpha\beta}(v_s) = e_{3\beta}(v_s) = 0\}$ is identified with

$$\begin{aligned} \Big\{ v_s = (v_{s1}, v_{s2}, v_{s3}) \in [W^{2,2}(0,L)]^2 \times W^{1,2}(\Omega_s) :\quad & v_{s\alpha}(x_s) = v_{s\alpha}(x_3), \\ & v_{s3}(x_s) = \underline{v}_{s3}(x_3) - x_{s\alpha}\partial_3 v_{s\alpha}(x_3), \quad \underline{v}_{s3} \in W^{1,2}(0,L) \Big\}, \end{aligned} \tag{2.10}$$

and the quotient space $V(\Omega_s)/\mathcal{R}_s$ is the following set:

$$\Big\{v_s = z_s + a + b \wedge x_s : \;\; z_s \in V(\Omega_s),\; a \in \mathbb{R}^3,\;\; b = (b_1, b_2, 0) \in \mathbb{R}^3\Big\}. \tag{2.11}$$

The bilinear form $a_s(.,.)$, depending on the unknown d_s, is defined in $V(\Omega_s)/\mathcal{R}_s$ by

$$a_s(z_s, v_s) = \int_{\Omega_s} \frac{1}{b_{3333}(d_s)} e_{33}(z_s) e_{33}(v_s) d\Omega_s \quad \forall z_s,\; v_s \in V(\Omega_s)/\mathcal{R}_s, \tag{2.12}$$

and $L_s(.)$ is a linear form also defined in $V(\Omega_s)/\mathcal{R}_s$ such that $L_s(v_s)$ is equal to

$$\int_{\Omega_s} \gamma(\xi_{s0} + P_\eta(d_s))\, f_{si}\, v_{si}\, d\Omega_s + \int_{\Gamma_s} g_{si}\, v_{si}\, d\Gamma_s + \int_{\Gamma_{s0,L}} h_{si}\, v_{si}\, d\Gamma_{s0,L}. \tag{2.13}$$

We remark that in (2.11) we must have $b_3 = 0$, because otherwise the quotient space $V(\Omega_s)/\mathcal{R}_s$ would not be contained in $V(\Omega_s)$. In fact, developing $v_s = z_s + a + b \wedge x_s$, we have for the first component $v_{s1} = z_{s1} + a_1 + b_2 x_3 - b_3 x_{s2}$, for the second component $v_{s2} = z_{s2} + a_2 - b_1 x_3 + b_3 x_{s1}$, and finally for the third component $v_{s3} = \underline{z}_{s3} - x_{s\alpha}\partial_3 z_{s\alpha} + a_3 + b_1 x_{s2} - b_2 x_{s1}$. Therefore if $b_3 \neq 0$, then $v_s \notin V(\Omega_s)$, and if $b_3 = 0$, then $(b_1, b_2, 0) \wedge x_s = \big(b_2 x_3, -b_1 x_3, b_1 x_{s2} - b_2 x_{s1}\big)$ and we obtain $v_{s1} = z_{s1} + a_1 + b_2 x_3$, which depends only on x_3, $v_{s2} = z_{s2} + a_2 - b_1 x_3$, which depends only on x_3, and $v_{s3} = \underline{v}_{s3} - x_{s\alpha}\partial_3 v_{s\alpha}$ with $\underline{v}_{s3} = \underline{z}_{s3} + a_3$, which depends only on x_3.

By the following Korn-type inequality in the quotient space $V(\Omega_s)/\mathcal{R}_s$ (cf. Ciarlet [1] or Valent [12]) we have

$$\exists c > 0 : \quad \|v_s\|^2_{[W^{1,2}(\Omega_s)]^3} \leq c \|e_{33}(v_s)\|^2_{L^2(\Omega_s)}, \tag{2.14}$$

where

$$\|e_{33}(v_s)\|^2_{L^2(\Omega_s)} = c_s \|\partial_3 \underline{v}_{s3}\|^2_{L^2(0,L)} + \left(\int_{\omega_s} x^2_{s\alpha} d\omega_s\right) \|\partial_{33} v_{s\alpha}\|^2_{L^2(0,L)}, \tag{2.15}$$

with $c_s = [\mathrm{meas}(\omega_s)]^{\frac{1}{2}}$, since $e_{33}(v_s) = \partial_3 v_{s3} = \partial_3 \underline{v}_{s3} - x_{s\alpha}\partial_{33} v_{s\alpha}$. Hence, we conclude that $\|e_{33}(.)\|_{L^2(\Omega_s)}$ is a norm in the space $V(\Omega_s)/\mathcal{R}_s$, equivalent to the usual norm induced in the quotient space by $\|.\|_{[W^{1,2}(\Omega_s)]^3}$. Moreover, $V(\Omega_s)/\mathcal{R}_s$ is a Hilbert space with the norm $\|e_{33}(.)\|_{L^2(\Omega_s)}$, and the bilinear form $a_s(.,.)$ is elliptic in $V(\Omega_s)/\mathcal{R}_s$. In fact, there exists a constant $C > 0$ such that

$$\begin{cases} a_s(v_s, v_s) = \int_{\Omega_s} \frac{1}{b_{3333}(d_s)}\, e_{33}(v_s)\, e_{33}(v_s)\, d\Omega_s \geq C_1 \|e_{33}(v_s)\|^2_{L^2(\Omega_s)} \\ = C_1 \|v_s\|^2_{V(\Omega_s)/\mathcal{R}_s} \geq C \|v_s\|^2_{[W^{1,2}(\Omega_s)]^3} \quad \forall v_s \in V(\Omega_s)/\mathcal{R}_s, \end{cases} \tag{2.16}$$

where C_1 is the constant defined in condition (2.7).

For each $s \in [0, \delta]$, there exists a unique pair (u_s, d_s) solution of the asymptotic adaptive elastic rod model P_s, which verifies $u_s \in C^1([0,T]; V(\Omega_s)/\mathcal{R}_s)$ and $d_s \in C^1([0,T]; C^0(\overline{\Omega}_s))$ (cf. Theorem 6, Figueiredo and Trabucho [7]). The next theorem states a regularity result, concerning the component solution u_s, that will be important in section 4. In order to prove it, we introduce the following notation:

$$\begin{aligned} & z_{s3} = l_s \partial_3 \underline{u}_{s3} - e_{s\alpha}\partial_{33} u_{s\alpha}, \quad z_{s\beta} = h_{s\alpha\beta}\partial_{33} u_{s\alpha} - e_{s\beta}\partial_3 \underline{u}_{s3}, \\ & F_{s3} = \int_{\omega_s} \gamma(\xi_{s0} + P_\eta(d_s))\, f_{s3}\, d\omega_s + \int_{\partial\omega_s} g_{s3}\, d\partial\omega_s, \\ & F_{s\beta} = \begin{cases} \int_{\omega_s} \gamma(\xi_{s0} + P_\eta(d_s))\, f_{s\beta}\, d\omega_s + \int_{\partial\omega_s} g_{s\beta}\, d\partial\omega_s \\ \quad + \int_{\omega_s} x_{s\beta}\, \partial_3[\gamma(\xi_{s0} + P_\eta(d_s))\, f_{s3}]\, d\omega_s + \int_{\partial\omega_s} x_{s\beta}\, \partial_3 g_{s3}\, d\partial\omega_s, \end{cases} \end{aligned} \tag{2.17}$$

where $z_{si} \in C^1([0,T];L^2(0,L))$, $F_{si} \in C^1([0,T];L^2(0,L))$, for $i = 1,2,3$, and the matrix M_s,

$$M_s = \begin{bmatrix} l_s & -e_{s1} & -e_{s2} \\ -e_{s1} & h_{s11} & h_{s12} \\ -e_{s2} & h_{s21} & h_{s22} \end{bmatrix} \in C^1\big([0,T];[C^1(\mathbb{R}^3)]^9\big). \tag{2.18}$$

THEOREM 2.1 (regularity of u_s). *Let (u_s, d_s) be the unique solution of problem (P_s). We assume that the determinant of matrix M_s is not zero, $\det M_s \neq 0$ (for example, if $b_{3333}(d^s) = c$, where c is a constant, then $\det M_s > 0$). Then, for each $t \in [0,T]$, $u_{s\beta}(.,t) \in W^{3,2}(0,L)$, $\underline{u}_{s3}(.,t) \in W^{2,2}(0,L)$, and consequently $u_s(.,t) \in [W^{2,2}(\Omega_s)]^3$.*

Proof. We first remark that the equilibrium equations (2.2) can be written in the form

$$-\partial_3 z_{s3} = F_{s3}, \qquad \partial_{33} z_{s\beta} = F_{s\beta}, \quad \text{for } \beta = 1,2, \tag{2.19}$$

and for each t, $F_{s3}(.,t)$ and $F_{s\beta}(.,t)$ belong to the space $L^2(0,L)$.

Since $z_{s3}(.,t)$ belongs to $L^2(0,L)$, and because of the first equilibrium equation in (2.19), $\partial_3 z_{s3}(.,t)$ also belongs to $L^2(0,L)$, so we conclude that, for each t, $z_{s3}(.,t) \in W^{1,2}(0,L)$. For each t, $z_{s\beta}(.,t) \in L^2(0,L)$ and consequently $\partial_3 z_{s\beta}(.,t) \in [W^{1,2}(0,L)]'$, where $[W^{1,2}(0,L)]'$ is the dual of $W^{1,2}(0,L)$. But from the second equilibrium equation in (2.19) we have that $\partial_{33} z_{s\beta}(.,t) \in L^2(0,L)$ and also $\partial_{33} z_{s\beta}(.,t) \in [W^{1,2}(0,L)]'$ because $L^2(0,L) \subset [W^{1,2}(0,L)]'$. Thus, as a consequence of a lemma of Lions (cf. Ciarlet [2, p. 39]) we have $\partial_3 z_{s\beta}(.,t) \in L^2(0,L)$. Hence the elements $z_{s\beta}(.,t)$, $\partial_3 z_{s\beta}(.,t)$, and $\partial_{33} z_{s\beta}(.,t)$ belong to the space $L^2(0,L)$, which means that $z_{s\beta}(.,t) \in W^{2,2}(0,L)$.

Therefore, assembling these properties, we obtain for each t and for $\beta = 1,2$

$$z_{s3}(.,t) = p_{s3}(.,t) \in W^{1,2}(0,L), \qquad z_{s\beta}(.,t) = p_{s\beta}(.,t) \in W^{2,2}(0,L), \tag{2.20}$$

where p_{si} is a primitive of F_{si}, in the distribution's sense in $W^{1,2}(0,L)$, for $i = 1,2,3$. Replacing z_{si} by its definition (2.17), the system (2.20) is equivalent to the following system:

$$\begin{bmatrix} l_s & -e_{s1} & -e_{s2} \\ -e_{s1} & h_{s11} & h_{s12} \\ -e_{s2} & h_{s21} & h_{s22} \end{bmatrix} \begin{bmatrix} \partial_3 \underline{u}_{s3} \\ \partial_{33} u_{s1} \\ \partial_{33} u_{s2} \end{bmatrix} = \begin{bmatrix} p_{s3} \\ p_{s1} \\ p_{s2} \end{bmatrix}. \tag{2.21}$$

With the assumption $\det M_s \neq 0$, we clearly obtain, by solving (2.21), that

$$\partial_3 \underline{u}_{s3}(.,t) \in W^{1,2}(0,L), \qquad \partial_{33} u_{s\beta}(.,t) \in W^{1,2}(0,L), \quad \text{for } \beta = 1,2. \tag{2.22}$$

We remark that the regularity indicated in (2.22) depends also on the regularity of the elements of M_s that belong to the space $C^1([0,T];C^1(\mathbb{R}^3))$.

Thus we conclude that the components $u_{s\beta}(.,t) \in W^{3,2}(0,L)$, for $\beta = 1,2$ and $\underline{u}_{s3}(.,t) \in W^{2,2}(0,L)$, and consequently, because $u_s = (u_{s1}, u_{s2}, \underline{u}_{s3} - x_{s\beta}\partial_3 u_{s\beta})$, we have $u_s(.,t) \in [W^{2,2}(\Omega_s)]^3$. ∎

2.3. The shape problem. We now consider the shape map J defined by

$$\begin{array}{rccl} J: & [0,\delta] & \longrightarrow & C^1([0,T];V(\Omega_s)/\mathcal{R}_s) \times C^1([0,T];C^0(\overline{\Omega}_s)) \\ & s & \longrightarrow & J(\Omega_s) = (u_s, d_s), \end{array} \tag{2.23}$$

where (u_s, d_s) is the unique solution of the nonlinear asymptotic adaptive rod model P_s (cf. (P_s)), defined in the perturbed rod Ω_s. As remarked before, the unknowns u_s and d_s are coupled in the model P_s and depend on (x_s, t).

We recall that $I_s(\omega)$ is a shape perturbation of the cross section ω of the rod $\overline{\Omega} = \overline{\omega} \times [0, L]$, so $\overline{\Omega}_s$ is a shape perturbation of the rod $\overline{\Omega}$; that is, $\overline{\Omega}_s = I_s(\overline{\omega}) \times [0, L] = (I + s\,\theta)(\overline{\omega}) \times [0, L]$ and $\overline{\Omega} = \overline{\omega} \times [0, L] = I_0(\overline{\omega}) \times [0, L] = \overline{\Omega}_0$.

The aim of this paper is to compute the shape semiderivative $dJ(\Omega; \theta)$ at $s = 0$ in the direction of the vector field θ. This semiderivative is defined by (cf. Delfour and Zolésio [5, p. 289])

$$dJ(\Omega;\theta) = \lim_{s\to 0^+} \frac{J(\Omega_s) - J(\Omega)}{s} = \left(\lim_{s\to 0^+} \frac{u_s - u}{s},\ \lim_{s\to 0^+} \frac{d_s - d}{s} \right), \tag{2.24}$$

where (u, d) is the solution of problem (P_s) but for the unperturbed rod $\overline{\Omega}_0 = \overline{\Omega} = \overline{\omega} \times [0, L]$. We also remark that the semiderivative $dJ(\Omega; \theta)$ is equivalent to the definition of the material derivative of the map J at $s = 0$, in the sense of Haslinger and Mäkinen [8, p. 111].

As explained in section 4, Theorem 4.11, it is possible to compute and to identify, in a weak sense and in an appropriate product space, this shape semiderivative.

3. Equivalent formulation of the adaptive rod model. In order to be able to calculate the shape semiderivative (2.24) we must reformulate, for each s, the problem P_s (cf. (P_s)) in the domain $\overline{\Omega} \times [0, T]$, independent of s. Therefore we first formulate in Ω all the forms involved in the definition of problem P_s. Afterwards, we describe the resulting rod model, denoted by P^s (with upper index s) and formulated in the fixed domain $\overline{\Omega} \times [0, T]$, that is equivalent to P_s (with lower index s).

3.1. Reformulation of the forms defining $\mathbf{P_s}$. We define the map

$$Q_s(x_1, x_2, x_3) = \big(x_1 + s\theta_1(x_1, x_2), x_2 + s\theta_2(x_1, x_2), x_3\big), \tag{3.1}$$

which verifies

$$\Omega_s = Q_s(\Omega) \quad \text{and} \quad \det \nabla Q_s = 1 + s \operatorname{div} \theta + s^2 \det \nabla\theta, \tag{3.2}$$

where the matrices ∇Q_s and $\nabla\theta$ are the gradients of Q_s and θ, respectively, and $\operatorname{div}\theta = \partial_\alpha \theta_\alpha$ is the divergence of θ.

To each function v_s defined in Ω_s we associate the corresponding function v^s (with upper index s) defined on Ω by $v^s = v_s \circ Q_s$. Hence, for any $v_s \in V(\Omega_s)/\mathcal{R}_s$, the correspondent v^s is in $V(\Omega)/\mathcal{R}$ (whose definition is (2.11), with $s = 0$). Moreover,

$$\begin{aligned} e_{33}(v_s) &= \partial_3 \underline{v}_{s3} - x_{s\alpha}\partial_{33} v_{s\alpha} = \partial_3 \underline{v}_{s3} - (x_\alpha + s\,\theta_\alpha)\partial_{33} v^s_\alpha \\ &= \partial_3 \underline{v}^s_3 - x_\alpha \partial_{33} v^s_\alpha - s\,\theta_\alpha \partial_{33} v^s_\alpha = e_{33}(v^s) - s\,\theta_\alpha \partial_{33} v^s_\alpha. \end{aligned} \tag{3.3}$$

Using (3.2)–(3.3) and the change of variables formula for domain and boundary integrals (cf. Delfour and Zolésio [5, pp. 351–353]), we get the next expression for $a_s(u_s, v_s)$,

$$\int_\Omega \frac{1}{b_{3333}(d^s)} \big(e_{33}(u^s) - s\,\theta_\alpha \partial_{33} u^s_\alpha\big)\big(e_{33}(v^s) - s\,\theta_\alpha \partial_{33} v^s_\alpha\big)\, \det \nabla Q_s d\Omega, \tag{3.4}$$

and for $L_s(v_s)$ the expression

$$(3.5)\qquad \begin{cases} \int_\Omega \gamma(\xi_0^s + P_\eta(d^s))\, f_i^s\, v_i^s\, (\det \nabla Q_s)\, d\Omega + \int_\Gamma g_i^s\, v_i^s\, |(Cof\, \nabla Q_s)^T n|_{\mathbb{R}^3}\, d\Gamma \\ \qquad + \int_{\Gamma_0 \cup \Gamma_L} h_i^s\, v_i^s\, |(Cof\, \nabla Q_s)^T n|_{\mathbb{R}^3}\, d(\Gamma_0 \cup \Gamma_L). \end{cases}$$

In (3.5), $|.|_{\mathbb{R}^3}$ is the Euclidean norm in $\mathbb{R}^3$, $n = (n_1, n_2, n_3)$ is the unit outer normal vector along the boundary $\partial\Omega$ of Ω, and $(Cof\, \nabla Q_s)^T$ is the transpose of the cofactor matrix of ∇Q_s, that is, $(Cof\, \nabla Q_s)^T = (\det \nabla Q_s)(\nabla Q_s)^{-T}$, whose definition depends only on s and the partial derivatives of θ. Developing (3.4)–(3.5), we obtain the following decomposition for the equation $a_s(u_s, v_s) = L_s(v_s)$:

(3.6)
$$\left[\begin{array}{l} a_0^s(u^s, v^s) + s a_1^s(u^s, v^s) + s^2 a_2^s(u^s, v^s) + s^3 a_3^s(u^s, v^s) + s^4 a_4^s(u^s, v^s) \\ \\ = \left\{ \begin{array}{l} F_0^s(v^s) + G_0^s(v^s) + H_0^s(v^s) + s\left(F_1^s(v^s) + G_1^s(v^s) + H_1^s(v^s)\right) \\ + s^2\left(F_2^s(v^s) + G_2^s(v^s) + H_2^s(v^s)\right) + s^3\left(F_3^s(v^s) + G_3^s(v^s) + H_3^s(v^s)\right). \end{array} \right. \end{array} \right.$$

The bilinear forms $a_i^s(.,.)$ for $i = 0, 1, 2, 3, 4$ depend on θ and d^s and are defined by the formulas

$$a_0^s(u, v) = \int_\Omega \frac{1}{b_{3333}(d^s)} e_{33}(u) e_{33}(v) d\Omega,$$

$$a_1^s(u, v) = \left\{ \begin{array}{l} \displaystyle\int_\Omega \frac{1}{b_{3333}}(d^s)\Big[- \theta_\alpha\big(e_{33}(u)\partial_{33} v_\alpha + e_{33}(v)\partial_{33} u_\alpha\big) \\ \qquad\qquad + e_{33}(u) e_{33}(v) \mathrm{div}\, \theta\Big] d\Omega, \end{array} \right.$$

$$(3.7)\qquad a_2^s(u, v) = \left\{ \begin{array}{l} \displaystyle\int_\Omega \frac{1}{b_{3333}(d^s)}\Big[e_{33}(u) e_{33}(v) \det \nabla\theta + \theta_\alpha\, \theta_\beta\, \partial_{33} u_\alpha\, \partial_{33} v_\beta \\ \qquad\qquad - (\mathrm{div}\, \theta)\, \theta_\alpha\big(e_{33}(u)\partial_{33} v_\alpha + e_{33}(v)\partial_{33} u_\alpha\big)\Big] d\Omega, \end{array} \right.$$

$$a_3^s(u, v) = \left\{ \begin{array}{l} \displaystyle\int_\Omega \frac{1}{b_{3333}}(d^s)\Big[\theta_\alpha \theta_\beta \partial_{33} u_\alpha \partial_{33} v_\beta\, \mathrm{div}\, \theta \\ \qquad\qquad - (\det \nabla\theta)\, \theta_\alpha\big(e_{33}(u)\partial_{33} v_\alpha + e_{33}(v)\partial_{33} u_\alpha\big)\Big] d\Omega, \end{array} \right.$$

$$a_4^s(u, v) = \int_\Omega \frac{1}{b_{3333}(d^s)}\Big[\theta_\alpha\, \theta_\beta\, \partial_{33} u_\alpha\, \partial_{33} v_\beta\, \det \nabla\theta\Big] d\Omega$$

for any pair (u, v) in the space $V(\Omega)/\mathcal{R}$. The linear forms F_0^s, F_1^s, F_2^s, and F_3^s depend on θ and d^s and are also defined in the same quotient space $V(\Omega)/\mathcal{R}$ by the following expressions:

$$(3.8)\qquad \begin{array}{l} F_0^s(v) = \displaystyle\int_\Omega \gamma(\xi_0^s + P_\eta(d^s))\, (f_\alpha^s\, v_\alpha + f_3^s\, \underline{v}_3)\, d\Omega, \\ F_1^s(v) = \displaystyle\int_\Omega \gamma(\xi_0^s + P_\eta(d^s))\, \Big[(f_\alpha^s\, v_\alpha + f_3^s\, \underline{v}_3)\, \mathrm{div}\, \theta - f_3^s\, \theta_\alpha\, \partial_3 v_\alpha\Big]\, d\Omega, \\ F_2^s(v) = \displaystyle\int_\Omega \gamma(\xi_0^s + P_\eta(d^s))\, \Big[(f_\alpha^s\, v_\alpha + f_3^s\, \underline{v}_3)\, \det \nabla\theta - f_3^s\, \theta_\alpha\, \partial_3 v_\alpha\, \mathrm{div}\, \theta\Big]\, d\Omega, \\ F_3^s(v) = -\displaystyle\int_\Omega \gamma(\xi_0^s + P_\eta(d^s))\, f_3^s\, \theta_\alpha\, \partial_3 v_\alpha\, \det \nabla\theta\, d\Omega. \end{array}$$

The linear forms G_0^s, G_1^s, G_2^s, G_3^s and H_0^s, H_1^s, H_2^s, H_3^s result from the change of variable in the boundary integrals (defined in Γ_s and in $\Gamma_{s0} \cup \Gamma_{sL}$, respectively) and depend on θ and n (the unit outer normal vector) but are independent of d^s. These forms are defined by the following expressions, for any v in the space $V(\Omega)/\mathcal{R}$:

$$
\begin{aligned}
G_0^s(v) &= \int_\Gamma \left(g_\alpha^s\, v_\alpha + g_3^s\, \underline{v}_3\right) d\Gamma,\\
G_1^s(v) &= \int_\Gamma \Big[(g_\alpha^s\, v_\alpha + g_3^s\, \underline{v}_3)\, G_1(\theta,n) - g_3^s\, \theta_\alpha\, \partial_3 v_\alpha\Big]\, d\Gamma,\\
G_2^s(v) &= \int_\Gamma \Big[(g_\alpha^s\, v_\alpha + g_3^s\, \underline{v}_3)\, G_2(\theta,n) - g_3^s\, \theta_\alpha\, \partial_3 v_\alpha\, G_1(\theta,n)\Big]\, d\Gamma,\\
G_3^s(v) &= -\int_\Gamma g_3^s\, \theta_\alpha\, \partial_3 v_\alpha\, G_3(\theta,n)\, d\Gamma,
\end{aligned}
\tag{3.9}
$$

where $G_1(\theta,n)$, $G_2(\theta,n)$, and $G_3(\theta,n)$ are bounded scalar functions of θ and n and

$$
\begin{aligned}
H_0^s(v) &= \int_{\Gamma_0\cup\Gamma_L} \left(h_\alpha^s\, v_\alpha + h_3^s\, \underline{v}_3\right) d(\Gamma_0 \cup \Gamma_L),\\
H_1^s(v) &= \int_{\Gamma_0\cup\Gamma_L} \Big[(h_\alpha^s\, v_\alpha + h_3^s\, \underline{v}_3)\, H_1(\theta) - h_3^s\, \theta_\alpha\, \partial_3 v_\alpha\Big]\, d(\Gamma_0 \cup \Gamma_L),\\
H_2^s(v) &= \int_{\Gamma_0\cup\Gamma_L} \Big[(h_\alpha^s\, v_\alpha + h_3^s\, \underline{v}_3)\, H_2(\theta) - h_3^s\, \theta_\alpha\, \partial_3 v_\alpha\, H_1(\theta)\Big]\, d(\Gamma_0 \cup \Gamma_L),\\
H_3^s(v) &= -\int_{\Gamma_0\cup\Gamma_L} h_3^s\, \theta_\alpha\, \partial_3 v_\alpha\, H_2(\theta)\, d(\Gamma_0 \cup \Gamma_L),
\end{aligned}
\tag{3.10}
$$

where $H_1(\theta)$ and $H_2(\theta)$ are bounded scalar functions of θ.

3.2. The problem $\mathbf{P_s}$ formulated in $\overline{\Omega} \times [0, T]$. As a direct consequence of (3.6) we can formulate, for each $s \in [0, \delta]$, the problem (P_s) in the fixed domain $\overline{\Omega} \times [0, T]$, as explained in the following theorem. The new equivalent problem is denoted by (P^s), with upper index s.

THEOREM 3.1 (problem (P^s)). *For each $s \in [0, \delta]$, we assume that $d^s(x, 0) = \hat{d}(x)$ in $\overline{\Omega}$, and $\hat{d}$ is independent of s. Then, the problem (P^s), for $s \neq 0$, is equivalent to the following problem (P^s) posed in the domain $\overline{\Omega} \times [0, T]$ independent of s:*

$$
\left[\begin{array}{l}
\text{Find } u^s : \overline{\Omega} \times [0,T] \to \mathbb{R}^3 \quad \text{and} \quad d^s : \overline{\Omega} \times [0,T] \to \mathbb{R} \quad \text{such that}\\
u^s(.,t) \in V(\Omega)/\mathcal{R},\\
\left[\begin{array}{l}
a_0^s(u^s,v) + s\, a_1^s(u^s,v) + s^2\, a_2^s(u^s,v) + s^3\, a_3^s(u^s,v) + s^4\, a_4^s(u^s,v)\\
= F_0^s(v) + sF_1^s(v) + s^2\, F_2^s(v) + s^3\, F_3^s(v)\\
\quad + G_0^s(v) + s\, G_1^s(v) + s^2\, G_2^s(v) + s^3\, G_3^s(v)\\
\qquad + H_0^s(v) + s\, H_1^s(v) + s^2\, H_2^s(v) + s^3\, H_3^s(v) \qquad \forall v \in V(\Omega)/\mathcal{R},
\end{array}\right.\\
\dot{d}^s = c(d^s) e_{33}(u^s) + a(d^s) - s\, c(d^s) \theta_\alpha \partial_{33} u_\alpha^s \quad \text{in} \quad \Omega \times (0,T),\\
d^s(x,0) = \hat{d}(x) \quad \text{in} \quad \overline{\Omega},
\end{array}\right.
\tag{3.11}
$$

where the sets $V(\Omega)$ and $V(\Omega)/\mathcal{R}$ are defined by (2.10) *and* (2.11), *for $s = 0$. We also denote by (u, d) the unique solution of problem (P^s) for $s = 0$; that is, (u, d) is*

the solution of the following problem (P^0) (*cf.* (P_s), *for the case* $s = 0$), *formulated in* $\overline{\Omega} \times [0,T]$:

$$
\left\lfloor
\begin{array}{l}
\text{Find } u : \overline{\Omega} \times [0,T] \to \mathbb{R}^3 \quad \text{and} \quad d : \overline{\Omega} \times [0,T] \to \mathbb{R} \quad \text{such that} \\
u(.,t) \in V(\Omega)/\mathcal{R}, \\
a_0(u,v) = L_0(v) \equiv F_0(v) + G_0(v) + H_0(v) \qquad \forall v \in V(\Omega)/\mathcal{R}, \\
\dot{d} = c(d) e_{33}(u) + a(d) \quad \text{in} \quad \Omega \times (0,T), \\
d(x,0) = \hat{d}(x) \quad \text{in} \quad \overline{\Omega},
\end{array}
\right. \tag{3.12}
$$

where $a_0(.,.)$, $F_0(.)$, $G_0(.)$, *and* $H_0(.)$ *are independent of* s *and are defined by*

$$
\begin{aligned}
a_0(z,v) &= \int_\Omega \frac{1}{b_{3333}(d)}\, e_{33}(z)\, e_{33}(v)\, d\Omega \quad (a_0(.,.) \text{ depends on } d), \\
F_0(v) &= \int_\Omega \gamma(\xi_0 + P_\eta(d))\, (f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, d\Omega \quad (F_0(.) \text{ depends on } d), \\
G_0(v) &= \int_\Gamma \big(g_\alpha\, v_\alpha + g_3\, \underline{v}_3\big)\, d\Gamma, \\
H_0(v) &= \int_{\Gamma_0 \cup \Gamma_L} \big(h_\alpha\ v_\alpha + h_3\, \underline{v}_3\big)\, d(\Gamma_0 \cup \Gamma_L) \quad \forall z,\, v \in V(\Omega)/\mathcal{R}.
\end{aligned} \tag{3.13}
$$

4. Calculus and identification of the shape semiderivative. In this section we first present some preliminary estimates, which prove that the sequences $\{(u^s, d^s)\}$, $\{e_{33}(u^s)\}$, and $\{(\frac{u^s-u}{s}, \frac{d^s-d}{s})\}$ are bounded, independently of s, in appropriate functional spaces involving time. These results guarantee the existence, for each t, of a pair $(\bar{u}, \bar{d})(.,t)$, which is the weak limit of a subsequence of $\{(\frac{u^s-u}{s}, \frac{d^s-d}{s})(.,t)\}$ when $s \to 0^+$. Moreover, using the regularity of u^s, we also show that the sequences $\{e_{33}(u^s - u)\}$ and $\{d^s - d\}$ converge strongly to 0, in $C^0([0,T]; C^0(\overline{\Omega}))$, when $s \to 0^+$. These two strong convergences and the preliminary estimates are the key results that enable us to prove that the weak shape semiderivative $(\bar{u}, \bar{d})$ exists and is the unique solution of a nonlinear problem.

4.1. Preliminary estimates. We present several estimates that are needed for the identification of the shape semiderivative.

THEOREM 4.1 (first estimates for the sequences u^s and d^s). *We suppose that the conditions* (2.7)–(2.8) *are verified and* $\hat{d}(x) \in L^2(\Omega)$; *then*

$$
\exists c_1 > 0 : \quad \|u^s\|_{C^0([0,T];V(\Omega)/\mathcal{R})} \le c_1 \quad \forall s \in [0,\delta], \tag{4.1}
$$

$$
\exists c_2 > 0 : \quad \|d^s\|_{C^0([0,T];L^2(\Omega))} \le c_2 \quad \forall s \in [0,\delta], \tag{4.2}
$$

where c_1 *and* c_2 *are constants independent of* s.

Proof. The pair (u^s, d^s) is the solution of problem (P^s) (cf. (3.11)); thus for each time t,

$$
a_0^s(u^s, u^s) = L^s(u^s) - \sum_{i=1}^{4} s^i\, a_i^s(u^s, u^s). \tag{4.3}
$$

By the ellipticity of $a_0^s(.,.)$ in $V(\Omega)/\mathcal{R}$ (cf. (2.16)) we have for each t

$$a_0^s(u^s,u^s) \geq c\,\|u^s(.,t)\|^2_{V(\Omega)/\mathcal{R}}, \tag{4.4}$$

where c is a constant independent of s and t. From (2.15), for $s=0$, we obtain

$$\begin{aligned} &\|\partial_3 \underline{u}_3^s(.,t)\|_{L^2(0,L)} \leq \|e_{33}(u^s(.,t))\|_{L^2(\Omega)} = \|u^s(.,t)\|_{V(\Omega)/\mathcal{R}},\\ &\|\partial_{33} u_\alpha^s(.,t)\|_{L^2(0,L)} \leq c\,\|e_{33}(u^s(.,t))\|_{L^2(\Omega)} = c\,\|u^s(.,t)\|_{V(\Omega)/\mathcal{R}}, \end{aligned} \tag{4.5}$$

where c is a constant independent of s and t. Thus using (4.5), we easily check that $a_i^s(.,.)$, for $i=1,2,3,4$, are continuous bilinear forms that verify, for each t,

$$a_i^s(u^s,u^s) \leq c_i\,\|u^s(.,t)\|^2_{V(\Omega)/\mathcal{R}} \tag{4.6}$$

with c_i strictly positive constants, independent of s and t, and depending on θ. Using the definition of the linear form $L^s(.)$ and (4.5), we also have, for each t,

$$L^s(u^s) \leq c_L\,\|u^s(.,t)\|_{V(\Omega)/\mathcal{R}}, \tag{4.7}$$

where c_L is another strictly positive constant independent of s and t. So applying (4.4), (4.6), and (4.7), we conclude that, for each time t,

$$\left(c - \sum_{i=1}^{4} s^i\,c_i\right)\,\|u^s(.,t)\|^2_{V(\Omega)/\mathcal{R}} \leq c_L\,\|u^s(.,t)\|_{V(\Omega)/\mathcal{R}}, \tag{4.8}$$

and we obtain the estimate (4.1), since s is a very small parameter.

Taking now the integral in time in the remodeling rate equation of problem (3.11), we get

$$d^s(x,t) = \int_0^t \Big[c(d^s)e_{33}(u^s) + a(d^s) - s\,c(d^s)\theta_\alpha \partial_{33} u_\alpha^s\Big]\,dr + \hat{d}(x). \tag{4.9}$$

But as the material and remodeling coefficients $c(d^s)$ and $a(d^s)$ appearing in (4.9) are bounded (cf. (2.8)), we deduce that

$$\|d^s(.,t)\|_{L^2(\Omega)} \leq \int_0^T \Big[c_1\,\|u^s(.,r)\|_{V(\Omega)/\mathcal{R}} + c_2\Big]\,dr + \|\hat{d}(x)\|_{L^2(\Omega)}, \tag{4.10}$$

with c_1 and c_2 two strictly positive constants independent of s. Therefore and because of (4.1) we have the inequality (4.2). □

THEOREM 4.2 (second estimate for the sequence u^s). *We assume that the hypotheses of Theorem* 2.1 *are satisfied, and* $\frac{1}{b_{3333}(d^s)} = b + \mathcal{O}(s)$, *where* $b:\mathbb{R}\to\mathbb{R}$ *is a scalar function independent of* s, $0<|b|\leq c$ *with* $c>0$ *a constant, and* $\mathcal{O}(s)$ *is a term of order* s *(cf. Monnier and Trabucho* [10, formulas (6) and (2)], *for a justification of this latter condition on the material coefficient* $b_{3333}(d^s)$*). Then*

$$\exists c_1>0: \quad \|u^s\|_{C^0([0,T];W^{2,2}(\Omega))} \leq c_1, \tag{4.11}$$

$$\exists c_2>0: \quad \|e_{33}(u^s)\|_{C^0([0,T];C^0(\overline{\Omega}))} \leq c_2, \tag{4.12}$$

where c_1 *and* c_2 *are constants independent of* $s\in[0,\delta]$.

Proof. Using (2.21)–(2.22) (in the proof of Theorem 2.1), we infer that, for each t, $\|u^s(.,t)\|_{W^{2,2}(\Omega)} \leq C(M^s; p_i^s)$, where $M^s = M_s \circ Q_s$, $p_i^s = p_{si} \circ Q_s$, and $C(M^s; p_i^s)$ is a strictly positive constant depending on the $W^{1,2}(0,L)$ norms of the elements of M^s and p_i^s. As p_i^s are data of the problem, related to the forces (cf. (2.20)), for $i = 1, 2, 3$, and due to the definition of M^s and the additional hypothesis for $\frac{1}{b_{3333}(d^s)}$, we easily deduce that there exists a constant $c > 0$, independent of s and t, such that $C(M^s; p_i^s) \leq c$ for all $s \in [0, \delta]$, and therefore we have (4.11).

Also from the regularity Theorem 2.1 we have, for each t,

$$e_{33}(u^s)(.,t) = \partial_3 \underline{u}_3^s(.,t) - x_\alpha \partial_{33} u_\alpha^s(.,t) \in W^{1,2}(\Omega) \cap C^0(\overline{\Omega}) \tag{4.13}$$

because $\partial_3 \underline{u}_3^s(.,t)$ and $\partial_{33} u_\alpha^s(.,t)$ belong to $W^{1,2}(0,L)$, which is compactly embedded in the space $C^0([0,L])$. Hence we get

$$\|e_{33}(u^s)(.,t)\|_{C^0(\overline{\Omega})} \leq c_1 \|e_{33}(u^s)(.,t)\|_{W^{1,2}(\Omega)} \leq c_2 \|u^s(.,t)\|_{W^{2,2}(\Omega)} \leq c_3, \tag{4.14}$$

where c_1, c_2, and c_3 are constants independent of s and t, and consequently we have (4.12). □

THEOREM 4.3 (estimate for the sequence $\frac{u^s-u}{s}$). *Let (u^s, d^s) and (u, d) be the solutions of problems* (P^s) *(cf.* (3.11)*) and* (P^0) *(cf.* (3.12)*), respectively. We assume that conditions* (2.7)–(2.8) *are verified, and, for each s, $\xi_0^s = \xi_0$, $f_i^s = f_i$, $g_i^s = g_i$, $h_i^s = h_i$, where ξ_0, f_i, g_i, and h_i are independent of s. Then,*

$$\left\| \frac{u^s - u}{s} \right\|_{C^0([0,T];V(\Omega)/\mathcal{R})} \leq c_1 \left\| \frac{d^s - d}{s} \right\|_{C^0([0,T];L^2(\Omega))} + c_2, \tag{4.15}$$

where c_1 and c_2 are strictly positive constants independent of s and t.

Proof. In this proof we sometimes write u^s instead of $u^s(.,t)$ in order to simplify the notations. For each $t \in [0,T]$, we have

$$\frac{1}{s}[a^s(u^s, v) - a_0(u, v)] = \frac{L^s(v) - L_0(v)}{s} \qquad \forall v \in V(\Omega)/\mathcal{R}. \tag{4.16}$$

Developing this last equation for the choice $v = \frac{u^s-u}{s}$, we obtain that, for each t,

$$\left[\begin{array}{l} a_0^s(\frac{u^s-u}{s}, \frac{u^s-u}{s}) = \frac{1}{s}\Big[F_0^s(\frac{u^s-u}{s}) - F_0(\frac{u^s-u}{s})\Big] - s^3\, a_4^s(u^s, \frac{u^s-u}{s}) \\ - \int_\Omega \frac{b_{3333}(d) - b_{3333}(d^s)}{s} \big(b_{3333}(d^s)\, b_{3333}(d)\big)^{-1} e_{33}(u) e_{33}(\frac{u^s-u}{s})\, d\Omega \\ + \frac{1}{s}\Big[G_0^s(\frac{u^s-u}{s}) - G_0(\frac{u^s-u}{s}) + H_0^s(\frac{u^s-u}{s}) - H_0(\frac{u^s-u}{s})\Big] \\ - a_1^s(u^s, \frac{u^s-u}{s}) + F_1^s(\frac{u^s-u}{s}) + G_1^s(\frac{u^s-u}{s}) + H_1^s(\frac{u^s-u}{s}) \\ + s\Big[- a_2^s(u^s, \frac{u^s-u}{s}) + F_2^s(\frac{u^s-u}{s}) + G_2^s(\frac{u^s-u}{s}) + H_2^s(\frac{u^s-u}{s})\Big] \\ + s^2\Big[- a_3^s(u^s, \frac{u^s-u}{s}) + F_3^s(\frac{u^s-u}{s}) + G_3^s(\frac{u^s-u}{s}) + H_3^s(\frac{u^s-u}{s})\Big]. \end{array}\right. \tag{4.17}$$

Using this last equation, the ellipticity of $a_0^s(.,.)$, and the properties of continuity of all the other remaining terms in (4.17), we obtain the estimate (4.15). We next explain these calculations in detail, analyzing (4.17) for each t.

Because of condition (2.7), we have for each t,

$$\left| a_0^s\left(\frac{u^s-u}{s}, \frac{u^s-u}{s}\right)\right| \geq c \left\| \frac{u^s-u}{s}(.,t) \right\|^2_{V(\Omega)/\mathcal{R}}, \tag{4.18}$$

where c is a strictly positive constant independent of s and t. Using the definitions of $a_i^s(.,.)$ and the estimate (4.1), we obviously obtain

$$\left| a_i^s\left(u^s, \frac{u^s-u}{s}\right)\right| \leq c_{a_i} \left|\left| \frac{u^s-u}{s}(.,t)\right|\right|_{V(\Omega)/\mathcal{R}}, \tag{4.19}$$

where c_{a_i}, for $i = 1,2,3,4$, are strictly positive constants independent of s and t. Considering now the definitions of the forms F_i^s, G_i^s, and H_i^s, associated with the applied forces, we easily check that, for each t,

$$F_i^s\left(\frac{u^s-u}{s}\right) + G_i^s\left(\frac{u^s-u}{s}\right) + H_i^s\left(\frac{u^s-u}{s}\right) \leq c_i \left|\left| \frac{u^s-u}{s}(.,t)\right|\right|_{V(\Omega)/\mathcal{R}}, \tag{4.20}$$

where c_i are strictly positive constants independent of s and t, for $i = 1,2,3$. In addition we also have, for each t, $G_0^s(\frac{u^s-u}{s}) = G_0(\frac{u^s-u}{s})$ and $H_0^s(\frac{u^s-u}{s}) = H_0(\frac{u^s-u}{s})$. Using the mean value theorem for the operator P_η, we deduce

$$\left[\begin{array}{l} \left|\frac{1}{s}\Big[F_0^s(\frac{u^s-u}{s}) - F_0(\frac{u^s-u}{s})\Big]\right| \\ \quad \leq \int_\Omega \gamma\, |\frac{P_\eta(d^s)-P_\eta(d)}{d^s-d}|\, |\frac{d^s-d}{s}|\, |f_\alpha\, \frac{u_\alpha^s-u_\alpha}{s} + f_3\, \frac{u_3^s-u_3}{s}|\, d\Omega \\ \quad\quad \leq c_0\, \|\frac{d^s-d}{s}(.,t)\|_{L^2(\Omega))}\, \|\frac{u^s-u}{s}(.,t)\|_{V(\Omega)/\mathcal{R}}, \end{array}\right. \tag{4.21}$$

where c_0 is a strictly positive constant independent of s and t. Finally, using the mean value theorem for the material coefficient $b_{3333}(.)$, the estimate (4.12) for $s = 0$, and condition (2.7), we get

$$\left[\begin{array}{l} \Big|\int_\Omega \frac{b_{3333}(d)-b_{3333}(d^s)}{s}\big(b_{3333}(d^s)\, b_{3333}(d)\big)^{-1} e_{33}(u) e_{33}(\frac{u^s-u}{s})\, d\Omega\Big| \\ = \Big|\int_\Omega \frac{b_{3333}(d)-b_{3333}(d^s)}{d^s-d}\, \frac{d^s-d}{s}\big(b_{3333}(d^s)\, b_{3333}(d)\big)^{-1} e_{33}(u) e_{33}(\frac{u^s-u}{s})\, d\Omega\Big| \\ \quad\quad \leq c_b\, \|\frac{d^s-d}{s}(.,t)\|_{L^2(\Omega)}\, \|\frac{u^s-u}{s}(.,t)\|_{V(\Omega)/\mathcal{R}}, \end{array}\right. \tag{4.22}$$

where c_b is a strictly positive constant independent of s and t. Therefore using (4.17) and the estimates (4.18)–(4.22), we have, for each t,

$$\left\{\begin{array}{l} c\, \|\frac{u^s-u}{s}(.,t)\|^2_{V(\Omega)/\mathcal{R}} \\ \leq c_1\, \|\frac{d^s-d}{s}(.,t)\|_{L^2(\Omega)}\, \|\frac{u^s-u}{s}(.,t)\|_{V(\Omega)/\mathcal{R}} + c_2\, \|\frac{u^s-u}{s}(.,t)\|_{V(\Omega)/\mathcal{R}}, \end{array}\right. \tag{4.23}$$

where c, c_1, and c_2 are strictly positive constants independent of s and t. The proof is finished, dividing (4.23) by $c\, \|\frac{u^s-u}{s}(.,t)\|_{V(\Omega)/\mathcal{R}}$. ∎

THEOREM 4.4 (estimate for the sequence $\frac{d^s-d}{s}$). *Let (u^s, d^s) and (u, d) be the solutions of problems* (3.11) *and* (3.12)*, respectively. We assume that the hypotheses of Theorem* 4.3 *are satisfied. Then*

$$\left|\left| \frac{d^s-d}{s}\right|\right|_{C^0([0,T];L^2(\Omega))} \leq c, \tag{4.24}$$

where c is a strictly positive constant independent of s and t.

Proof. Subtracting the remodeling rate equations of problems (P^s) and (P^0) (cf. (3.11) and (3.12)), taking the integral in time between 0 and t and then the

$L^2(\Omega)$ norm, using the conditions (2.7)–(2.8) and the mean value theorem for the terms $c(d^s) - c(d)$ and $a(d^s) - a(d)$, we obtain, for each t, the estimate

$$\left\{\begin{array}{l} \|(d^s - d)(.,t)\|_{L^2(\Omega)} \\ \leq \int_0^t \Big[c_1 \, \|e_{33}(u^s - u)(.,r)\|_{L^2(\Omega)} + s\, c_4 \, \|\partial_{33} u^s_\alpha(.,r)\|_{L^2(\Omega)} \\ \qquad + \big(c_2 \, \|e_{33}(u)(.,r)\|_{C^0(\overline{\Omega})} + c_3\big) \, \|(d^s - d)(.,r)\|_{L^2(\Omega)}\Big] \, dr, \end{array}\right. \tag{4.25}$$

where c_1, c_2, c_3, and c_4 are strictly positive constants independent of s and t. However,

$$\begin{aligned} &\|e_{33}(u^s - u)(.,t)\|_{L^2(\Omega)} = \|(u^s - u)(.,t)\|_{V(\Omega)/\mathcal{R}}, \\ &\|e_{33}(u)(.,t)\|_{C^0(\overline{\Omega})} \leq c_2, \\ &\|\partial_{33} u^s_\alpha(.,t)\|_{L^2(\Omega)} \leq c_0 \|e_{33} u^s(.,t)\|_{L^2(\Omega)} = c_0 \|u^s(.,t)\|_{V(\Omega)/\mathcal{R}} \leq c, \end{aligned} \tag{4.26}$$

where c_2 is the constant defined in (4.12) for the case $s = 0$, c_0 is defined in (4.5), and c is a constant depending on the constant defined in (4.1); these three constants are independent of s and t. So, dividing (4.25) by s, we have from (4.25)–(4.26) and Theorem 4.3

$$\left|\left|\frac{d^s - d}{s}(.,t)\right|\right|_{L^2(\Omega)} \leq c_5 + \int_0^t c_6 \, \left|\left|\frac{d^s - d}{s}(.,r)\right|\right|_{L^2(\Omega)} dr, \tag{4.27}$$

where c_5 and c_6 are strictly positive constants independent of s and t. Then, applying the integral Gronwall inequality (cf. Evans [6, p. 625]),

$$\left|\left|\frac{d^s - d}{s}(.,t)\right|\right|_{L^2(\Omega)} \leq c_5 \, (1 + t \, c_6 \, e^{c_6 \, t}) \qquad \forall t \in [0,T], \tag{4.28}$$

which implies (4.24). □

COROLLARY 4.5. *With the hypotheses of Theorem* 4.3*,*

$$\exists c > 0 : \qquad \left|\left|\frac{u^s - u}{s}\right|\right|_{C^0([0,T];V(\Omega)/\mathcal{R})} \leq c, \tag{4.29}$$

where c is independent of s and t.

Thus we conclude that the solutions (u^s, d^s) and (u, d), of problems (P^s) and (P^0), verify for all $s \in [0, \delta]$

$$\left|\left|\frac{u^s - u}{s}\right|\right|_{C^0([0,T];V(\Omega)/\mathcal{R})} \leq c_1 \quad \text{and} \quad \left|\left|\frac{d^s - d}{s}\right|\right|_{C^0([0,T];L^2(\Omega))} \leq c_2, \tag{4.30}$$

where c_1 and c_2 are strictly positive constants independent of s. As a consequence of this property we state the following theorem.

THEOREM 4.6 (weak limits of the quotient sequences). *Let (u^s, d^s) and (u, d) be the solutions of problems (P^s) and (P^0), and assume that the hypotheses of Theorem* 4.3 *are verified. Then, for each t, there exists a subsequence of $\{(u^s, d^s)(.,t)\}$, also denoted by $\{(u^s, d^s)(.,t)\}$, and elements $\bar{u}(.,t) \in V(\Omega)/\mathcal{R}$ and $\bar{d}(.,t) \in L^2(\Omega)$ such*

that, when the parameter $s \to 0^+$,

$$\frac{u^s - u}{s}(.,t) \rightharpoonup \bar{u}(.,t) \quad \textit{weakly in} \quad V(\Omega)/\mathcal{R}, \tag{4.31}$$

$$e_{33}\left(\frac{u^s - u}{s}\right)(.,t) \rightharpoonup e_{33}(\bar{u})(.,t) \quad \textit{weakly in} \quad L^2(\Omega), \tag{4.32}$$

$$\frac{d^s - d}{s}(.,t) \rightharpoonup \bar{d}(.,t) \quad \textit{weakly in} \quad L^2(\Omega). \tag{4.33}$$

Therefore, when $s \to 0^+$, $(u^s - u)(.,t)$ *converges strongly to* 0 *in* $V(\Omega)/\mathcal{R}$, *and the sequences* $e_{33}(u^s - u)(.,t)$ *and* $(d^s - d)(.,t)$ *converge strongly to* 0 *in* $L^2(\Omega)$.

We conclude this section with a convergence result concerning the sequences $\{u^s\}$ and $e_{33}(u^s)$, and a corollary about the convergence of $\{d^s\}$, which will be useful in subsection 4.2.

THEOREM 4.7 (strong limit of $e_{33}(u^s)$). *Let* (u^s, d^s) *and* (u, d) *be the solutions of problems* (P^s) *and* (P^0) *and assume that the hypotheses of Theorems* 2.1, 4.2, *and* 4.3 *are verified. Then there exists a subsequence of* $\{u^s\}$, *also denoted by* $\{u^s\}$, *that verifies the following convergence, when the parameter* $s \to 0^+$:

$$e_{33}(u^s - u) \longrightarrow 0 \quad \textit{strongly in} \quad C^0([0,T]; C^0(\overline{\Omega})). \tag{4.34}$$

Proof. Recalling the definition of $u^s - u$ and its regularity (cf. Theorem 2.1), we have, for each t, $(u^s_\alpha - u_\alpha)(.,t) \in W^{3,2}(0,L)$ for $\alpha = 1, 2$ and $(\underline{u}^s_3 - \underline{u}_3)(.,t) \in W^{2,2}(0,L)$. The calculus of $e_{33}(u^s - u)$ gives

$$e_{33}(u^s - u) = \partial_3(u^s_3 - u_3) = \partial_3(\underline{u}^s_3 - \underline{u}_3) - x_\alpha \partial_{33}(u^s_\alpha - u_\alpha), \tag{4.35}$$

where $[\partial_3(\underline{u}^s_3 - \underline{u}_3)](.,t) \in W^{1,2}(0,L)$ and $[\partial_{33}(u^s_\alpha - u_\alpha)](.,t) \in W^{1,2}(0,L)$, for $\alpha = 1, 2$. But, because of the strong convergence of $e_{33}(u^s - u)(.,t)$ to 0 in $L^2(\Omega)$ (cf. Theorem 4.6), and applying the definition of $\|e_{33}(u^s - u)(.,t)\|_{L^2(\Omega)}$ (cf. (2.15)), we conclude immediately that, for each t, $\partial_3(\underline{u}^s_3 - \underline{u}_3)(.,t)$ and $\partial_{33}(u^s_\alpha - u_\alpha)(.,t)$ converge strongly to 0 in $L^2(0,L)$. On the other hand, we get directly from (4.11)

$$\begin{cases} \|e_{33}(u^s - u)\|_{C^0([0,T];W^{1,2}(\Omega))} \le \|u^s - u\|_{C^0([0,T];W^{2,2}(\Omega))} \\ \qquad \le \|u^s\|_{C^0([0,T];W^{2,2}(\Omega))} + \|u\|_{C^0([0,T];W^{2,2}(\Omega))} \le c, \end{cases} \tag{4.36}$$

where c is a constant independent of s. Therefore the sequences $\partial_3(\underline{u}^s_3 - \underline{u}_3)$ and $\partial_{33}(u^s_\alpha - u_\alpha)$ are bounded in $C^0([0,T]; W^{1,2}(0,L))$, and consequently, we obtain that $\partial_3(\underline{u}^s_3 - \underline{u}_3)(.,t)$ and $\partial_{33}(u^s_\alpha - u_\alpha)(.,t)$ weakly converge to 0, in $W^{1,2}(0,L)$ when $s \to 0^+$. But as the space $W^{1,2}(0,L)$ is compactly embedded in $C^0([0,L])$, we have that $\partial_3(\underline{u}^s_3 - \underline{u}_3)(.,t)$ and $\partial_{33}(u^s_\alpha - u_\alpha)(.,t)$ strongly converge to 0 in $C^0([0,L])$ when $s \to 0^+$. This implies the strong convergence of $e_{33}(u^s - u)$ to 0 in $C^0([0,T]; C^0(\overline{\Omega}))$. ∎

COROLLARY 4.8 (strong limit of d^s). *Let* (u^s, d^s) *and* (u, d) *be the solutions of problems* (P^s) *and* (P^0), *and assume the same hypotheses of Theorem* 4.7. *Then there exists a constant* $c > 0$ *independent of* s *such that when* $s \to 0^+$

$$d^s - d \longrightarrow 0 \quad \textit{strongly in} \quad C^0([0,T]; C^0(\overline{\Omega})). \tag{4.37}$$

Proof. Using exactly the same arguments as in the beginning of the proof of Theorem 4.4,

$$|(d^s-d)(x,t)| \le \int_0^t \Big[c_1|e_{33}(u^s-u)(x,r)| + c_2|(d^s-d)(x,r)| + sc_3\Big]dr, \tag{4.38}$$

where the constants c_i, for $i=1,2,3$, are strictly positive constants independent of s and t, and consequently

$$\begin{cases} |(d^s-d)(x,t)| \le \int_0^t c_2\,|(d^s-d)(x,r)|\,dr \\ \qquad + \underbrace{T\Big[c_1\,\|e_{33}(u^s-u)\|_{C^0([0,T];C^0(\overline{\Omega}))} + s\,c_3\Big]}_{\varphi^s}. \end{cases} \tag{4.39}$$

Because of the strong convergence (4.34), the scalar $\varphi^s \to 0$ when $s \to 0^+$. Then we obtain the convergence (4.37), applying to (4.39) the integral Gronwall inequality (cf. Evans [6, p. 625]). ∎

4.2. Shape semiderivatives. The objective of this section is to identify, for each t, the weak limits $\bar{u}(.,t)$ and $\bar{d}(.,t)$ of the sequences $\{\frac{u^s-u}{s}(.,t)\}$ and $\{\frac{d^s-d}{s}(.,t)\}$, defined in (4.31) and (4.33). The procedure is the following: we subtract and divide by s the equilibrium variational equations and the remodeling rate equations in problems (P^s) and (P^0), and then we take the limit, when the parameter $s \to 0^+$. We conclude that, for each t, the pair $(\bar{u}(.,t), \bar{d}(.,t))$ is the solution of another nonlinear problem. Finally we end up proving that $(\bar{u},\bar{d})$ is the unique solution of this latter problem in the space $C^1([0,T];V(\Omega)/\mathcal{R}) \times C^1([0,T];C^0(\overline{\Omega}))$.

4.2.1. Weak limit $\bar{\mathbf{u}}(.,\mathbf{t})$. Subtracting and dividing by s the two equilibrium variational equations of problems (P^s) and (P^0), we obtain, for each $t \in [0,T]$ (cf. (4.16)–(4.17)),

$$\begin{cases} \int_\Omega \frac{1}{b_{3333}(d^s)} e_{33}(\frac{u^s-u}{s}) e_{33}(v)d\Omega \\ + \int_\Omega \frac{b_{3333}(d)-b_{3333}(d^s)}{s}\big(b_{3333}(d^s)\,b_{3333}(d)\big)^{-1} e_{33}(u)e_{33}(v)\,d\Omega \\ + a_1^s(u^s,v) - F_1^s(v) - G_1^s(v) - H_1^s(v) \\ = \frac{1}{s}\big[F_0^s(v) - F_0(v) + G_0^s(v) - G_0(v) + H_0^s(v) - H_0(v)\big] \\ + s\,\big[-a_2^s(u^s,v) + F_2^s(v) + G_2^s(v) + H_2^s(v)\big] \\ + s^2\,\big[-a_3^s(v) + F_3^s(v) + G_3^s(v) + H_3^s(v)\big] - s^3\,a_4^s(u^s,v). \end{cases} \tag{4.40}$$

Computing now for each t the limit of each term of (4.40), we obtain the following theorem.

THEOREM 4.9 (identification of $\bar{u}(.,t)$). *We assume the hypotheses of Theorems* 2.1, 4.2, *and* 4.3. *Then the weak limit* $\bar{u}(.,t)$ *of the sequence* $\{\frac{u^s-u}{s}\}(.,t)$ *verifies the following variational equation for each* $t \in [0,T]$:

$$B(\bar{u},v) = S(v) \qquad \forall v \in V(\Omega)/\mathcal{R}. \tag{4.41}$$

The linear form $S(.)$ is defined in $V(\Omega)/\mathcal{R}$ by

$$
\left\{
\begin{array}{l}
S(v) = \int_\Omega b'_{3333}(d)\, b_{3333}(d)^{-2}\, \bar{d}\, e_{33}(u)\, e_{33}(v)\, d\Omega \\
- \int_\Omega \frac{1}{b_{3333}(d)} \big[- \theta_\alpha \big(e_{33}(u) \partial_{33} v_\alpha + e_{33}(v) \partial_{33} u_\alpha \big) \\
\qquad\qquad + e_{33}(u) e_{33}(v) \mathrm{div}\, \theta \big] d\Omega \\
+ \int_\Omega \gamma\, \bar{d}\, P'_\eta(d)\, (f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, d\Omega \\
+ \int_\Omega \gamma (\xi_0 + P_\eta(d)) \left[(f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, \mathrm{div}\, \theta - f_3\, \theta_\alpha\, \partial_3 v_\alpha \right] d\Omega \\
+ \int_\Gamma \left[(g_\alpha\, v_\alpha + g_3\, \underline{v}_3)\, G_1(\theta, n) - g_3\, \theta_\alpha\, \partial_3 v_\alpha \right] d\Gamma \\
+ \int_{\Gamma_0 \cup \Gamma_L} \left[(h_\alpha\, v_\alpha + h_3\, \underline{v}_3)\, H_1(\theta) - h_3\, \theta_\alpha\, \partial_3 v_\alpha \right] d\Gamma_0 \cup \Gamma_L,
\end{array}
\right. \tag{4.42}
$$

with $b'_{3333}(.)$ and $P'_\eta(.)$ the first derivatives of the scalar functions $b_{3333}(.)$ and $P_\eta(.)$, respectively. The bilinear form $B(.,.)$ is defined by

$$
B(z, v) = \int_\Omega \frac{1}{b_{3333}(d)}\, e_{33}(z)\, e_{33}(v)\, d\Omega \qquad \forall z,\ v \in V(\Omega)/\mathcal{R}. \tag{4.43}
$$

Proof. We give a sketch of the computation of the limits in (4.40), for each t.

The first term in (4.40) verifies, when $s \to 0^+$,

$$
\int_\Omega \frac{1}{b_{3333}(d^s)} e_{33} \left(\frac{u^s - u}{s} \right) e_{33}(v) d\Omega \ \longrightarrow\ \int_\Omega \frac{1}{b_{3333}(d)} e_{33}(\bar{u}) e_{33}(v) d\Omega, \tag{4.44}
$$

because the sequence $e_{33}(\frac{u^s - u}{s})(.,t)$ weakly converges to $e_{33}(\bar{u})(.,t)$ in $L^2(\Omega)$ (cf. (4.32)), and $\frac{e_{33}(v)}{b_{3333}(d^s)}$ converges strongly to $\frac{e_{33}(v)}{b_{3333}(d)}$ in $L^2(\Omega)$, due to the condition (2.7), the mean value theorem for the function $\frac{1}{b_{3333}(.)}$, and the strong convergence of d^s to d in $C^0([0,T]; C^0(\overline{\Omega}))$ (cf. (4.37)).

The second term in (4.40) converges to

$$
- \int_\Omega b'_{3333}(d)\, b_{3333}(d)^{-2}\, \bar{d}\, e_{33}(u)\, e_{33}(v)\, d\Omega, \tag{4.45}
$$

when $s \to 0^+$, because of condition (2.7), the mean value theorem for the function $b_{3333}(.)$, the condition (4.12) for the case $s = 0$, the strong convergence of d_s to d in $C^0([0,T]; C^0(\overline{\Omega}))$ (cf. Corollary 4.8, formula (4.37)), and the weak convergence of $\frac{d^s - d}{s}(.,t)$ to $\bar{d}(.,t)$ in $L^2(\Omega)$.

For the third term in (4.40), we have that $a_1^s(u^s, v)$ converges to

$$
\int_\Omega \frac{1}{b_{3333}(d)} \Big[- \theta_\alpha \big(e_{33}(u) \partial_{33} v_\alpha + e_{33}(v) \partial_{33} u_\alpha \big) + e_{33}(u) e_{33}(v) \mathrm{div}\, \theta \Big] d\Omega \tag{4.46}
$$

when $s \to 0^+$, and $F_1^s(v) + G_1^s(v) + H_1^s(v)$ converges to

$$
\left\{
\begin{array}{l}
\int_\Omega \gamma (\xi_0 + P_\eta(d)) \Big[(f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, \mathrm{div}\, \theta - f_3\, \theta_\alpha\, \partial_3 v_\alpha \Big] d\Omega \\
+ \int_\Gamma \Big[(g_\alpha\, v_\alpha + g_3\, \underline{v}_3)\, G_1(\theta, n) - g_3\, \theta_\alpha\, \partial_3 v_\alpha \Big] d\Gamma \\
+ \int_{\Gamma_0 \cup \Gamma_L} \Big[(h_\alpha\, v_\alpha + h_3\, \underline{v}_3)\, H_1(\theta) - h_3\, \theta_\alpha\, \partial_3 v_\alpha \Big] d\Gamma_0 \cup \Gamma_L.
\end{array}
\right. \tag{4.47}
$$

To prove (4.46) we remark that, when $s \to 0^+$, $\|\big(e_{33}(u^s) - e_{33}(u)\big)(.,t)\|_{L^2(\Omega)}$ and $\|(d^s - d)(.,t)\|_{L^2(\Omega)}$ converge to 0 (cf. Theorem 4.6). To obtain (4.47) we apply the definitions of the forms F_1^s, G_1^s, H_1^s and the strong convergence of $P_\eta(d^s)$ to $P_\eta(d)$, when $s \to 0^+$, in the space $C^0([0,T]; C^0(\overline{\Omega}))$.

The fourth term in (4.40) converges to

$$\int_\Omega \gamma\, \bar{d}\, P'_\eta(d)\, (f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, d\Omega \tag{4.48}$$

when $s \to 0^+$. In fact, we have $G_0^s(v) = G_0(v)$ and $H_0^s(v) = H_0(v)$, and

$$\left\{ \begin{array}{l} \frac{1}{s}\Big[F_0^s(v) - F_0(v)\Big] - \int_\Omega \gamma\, \bar{d}\, P'_\eta(d)\, (f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, d\Omega \\ = \int_\Omega \gamma \Big[\frac{P_\eta(d^s) - P_\eta(d)}{d^s - d} \Big(\frac{d^s - d}{s} - \bar{d} \Big) \\ \qquad\qquad + \Big(\frac{P_\eta(d^s) - P_\eta(d)}{d^s - d} - P'_\eta(d) \Big) \bar{d} \Big] (f_\alpha\, v_\alpha + f_3\, \underline{v}_3)\, d\Omega. \end{array} \right. \tag{4.49}$$

When $s \to 0^+$, $\gamma\, \frac{P_\eta(d^s) - P_\eta(d)}{d^s - d}$ converges strongly to $\gamma\, P'_\eta(d)$ in $C^0([0,T]; C^0(\overline{\Omega}))$, and, for each t, $\frac{d^s - d}{s}$ converges weakly to $\bar{d}$ in $L^2(\Omega)$ (cf. Theorem 4.6, formula (4.33)), and $\bar{d}\,(f_\alpha\, v_\alpha + f_3\, \underline{u}_3)$ belongs to $L^1(\Omega)$. Thus (4.49) converges to 0, for each t, when $s \to 0^+$.

Finally the last two terms in (4.40) converge to 0 when $s \to 0^+$, because those are composed of bounded terms multiplied by a positive power of s. ∎

4.2.2. Weak limit $\bar{\mathbf{d}}(.,\mathbf{t})$. By subtracting and dividing by s the remodeling rate equations of problems (P^s) and (P^0), and integrating in time between 0 and t, we obtain the following theorem.

THEOREM 4.10 (identification of $\bar{d}(.,t)$). *We assume that the hypotheses of Theorems* 2.1, 4.2, *and* 4.3 *are verified. For each t, the weak limit $\bar{d}(.,t)$ of the sequence $\{\frac{d^s - d}{s}(.,t)\}$ is the solution of the following ordinary differential equation with respect to time:*

$$\left\{ \begin{array}{l} \dot{\bar{d}} = c(d) e_{33}(\bar{u}) + \bar{d}\,[c'(d)\, e_{33}(u) + a'(d)] - c(d)\, \theta_\alpha \partial_{33} u_\alpha, \\ \bar{d}(x,0) = 0. \end{array} \right. \tag{4.50}$$

Proof. For any $v \in L^2(\Omega)$ and for each t, we have

$$\left\{ \begin{array}{l} \int_\Omega \frac{d^s - d}{s}\, v\, d\Omega = \int_0^t \Big(\int_\Omega \Big[c(d^s)\, e_{33}(\frac{u^s - u}{s}) + \frac{c(d^s) - c(d)}{s}\, e_{33}(u) \\ \qquad\qquad + \frac{a(d^s) - a(d)}{s} - c(d^s) \theta_\alpha \partial_{33} u_\alpha^s \Big]\, v\, d\Omega \Big)\, dr. \end{array} \right. \tag{4.51}$$

On the other hand, for each t, and when $s \to 0^+$, $c(d^s)$ converges strongly to $c(d)$ in $C^0(\overline{\Omega})$, $e_{33}(\frac{u^s - u}{s})$ converges weakly to $e_{33}(\bar{u})$ in $L^2(\Omega)$, $\frac{c(d^s) - c(d)}{s}\, e_{33}(u)$ converges weakly to $\bar{d}\, c'(d)\, e_{33}(u)$ in $L^2(\Omega)$, $\frac{a(d^s) - a(d)}{s}$ converges weakly to $\bar{d}\, a'(d)$ in $L^2(\Omega)$, and $\partial_{33} u_\alpha^s$ converges strongly to $\partial_{33} u_\alpha$ in $L^2(\Omega)$. Hence, we have that, for each t and when $s \to 0^+$, the sequence $\int_\Omega \frac{d^s - d}{s}\, v\, d\Omega$ converges to

$$\int_\Omega \left(\int_0^t \Big[c(d) e_{33}(\bar{u}) + \bar{d}\, c'(d)\, e_{33}(u) + \bar{d}\, a'(d) - c(d)\, \theta_\alpha \partial_{33} u_\alpha \Big]\, dr \right) v\, d\Omega. \tag{4.52}$$

But by (4.33), $\frac{d^s - d}{s}(.,t)$ converges weakly to $\bar{d}(.,t)$ in $L^2(\Omega)$ when $s \to 0^+$. Therefore $\bar{d}(.,t)$ must verify (4.50), since the weak limit is unique. ∎

4.2.3. Final identification result. Assembling the results of Theorems 4.9 and 4.10, we have the next theorem, which completely identifies, for each t, the (weak) shape semiderivatives $\bar{u}(.,t)$ and $\bar{d}(.,t)$.

THEOREM 4.11. *We assume that the hypotheses of Theorems* 2.1, 4.2, *and* 4.3 *are verified. For each* $t \in [0,T]$, *the weak limit* $(\bar{u},\bar{d})(.,t)$ *is an element of the space* $(V(\Omega)/\mathcal{R}) \times L^2(\Omega)$ *and is the solution of the following nonlinear problem* $(\bar{\mathrm{P}})$:

$$
\left[\begin{array}{l}
\text{Find } \bar{u} : \overline{\Omega} \times [0,T] \to \mathbb{R}^3 \quad \text{and} \quad \bar{d} : \overline{\Omega} \times [0,T] \to \mathbb{R} \quad \text{such that} \\
\bar{u}(.,t) \in V(\Omega)/\mathcal{R}, \\
B(\bar{u},v) = S(v) \qquad \forall v \in V(\Omega)/\mathcal{R}, \\
\dot{\bar{d}} = c(d) e_{33}(\bar{u}) + \bar{d}\,[c'(d)\, e_{33}(u) + a'(d)] - c(d)\,\theta_\alpha \partial_{33} u_\alpha \quad \text{in } \ \Omega \times (0,T), \\
\bar{d}(x,0) = 0 \quad \text{in} \quad \overline{\Omega},
\end{array}\right. \tag{4.53}
$$

where the linear form $S(.)$ *and the bilinear form* $B(.,.)$ *are defined by* (4.42) *and* (4.43), *respectively. We observe that* $S(.)$ *depends on* (u,d), *which is the solution of problem* (P^0), *and also on* $\bar{d}$. *The bilinear form* $B(.,.)$ *depends on* d, *that is, the measure of change in volume fraction of the elastic material of problem* (P^0). *Moreover, there exists a unique solution* $(\bar{u},\bar{d})$ *of problem* $(\bar{\mathrm{P}})$ *such that* $\bar{u} \in C^1([0,T]; V(\Omega)/\mathcal{R})$ *and* $\bar{d} \in C^1([0,T]; C^0(\overline{\Omega}))$. *Consequently, for each* t, *the entire sequence* $\{(\frac{u^s-u}{s}, \frac{d^s-d}{s})(.,t)\}$ *weakly converges to* $(\bar{u},\bar{d})(.,t)$ *in the space* $V(\Omega)/\mathcal{R} \times L^2(\Omega)$ *when* $s \to 0^+$. *Thus, there exists the weak shape semiderivative of the shape map* $J(\Omega_s) = (u^s, d^s)$ *at* $s = 0$ *in the direction of the vector field* θ (*cf.* (2.24)), *and it is perfectly defined, for each* t, *by* $dJ(\Omega;\theta)(.,t) = (\bar{u},\bar{d})(.,t)$, *where* $(\bar{u},\bar{d}) \in C^1([0,T]; V(\Omega)/\mathcal{R}) \times C^1([0,T]; C^0(\overline{\Omega}))$ *is the unique solution of problem* $(\bar{\mathrm{P}})$.

Proof. The arguments used to prove the existence and uniqueness of the solution $(\bar{u},\bar{d})$ to problem $(\bar{\mathrm{P}})$, in the space $C^1([0,T]; V(\Omega)/\mathcal{R}) \times C^1([0,T]; C^0(\overline{\Omega}))$, are analogous to those utilized in the proof of existence and uniqueness of the solution to problem $(\mathrm{P_s})$ (cf. Figueiredo and Trabucho [7]) and rely on the Schauder fixed point theorem. □

5. Conclusions and future work. In this paper we have considered the family $\overline{\Omega}_s$ of perturbed thin rods, for $s \in [0,\delta]$, and the corresponding family of solutions (u^s, d^s) of the nonlinear asymptotic adaptive elastic model, derived in Figueiredo and Trabucho [7]. We have proved that, for each t, the sequence $(\frac{u^s-u}{s}, \frac{d^s-d}{s})(.,t)$ converges weakly to $(\bar{u},\bar{d})(.,t)$ in the space $(V(\Omega)/\mathcal{R}) \times L^2(\Omega)$ when $s \to 0^+$. Consequently, for each t, $(\bar{u},\bar{d})(.,t)$ is the weak shape semiderivative of the function $J(\Omega_s) = (u^s, d^s)$ at $s = 0$ in the direction of the vector field θ. Moreover, we have showed that the pair $(\bar{u},\bar{d})$ is the unique solution of another nonlinear problem that couples a variational equation, depending on (u,d) and $\bar{d}$, and an ordinary differential equation with respect to time, depending on (u,d) and $\bar{u}$. We intend to apply this methodology to analyze the weak shape semiderivative of the solution to the nonlinear adaptive elastic asymptotic model (2.1)–(2.4), but for the case where the remodeling rate equation (2.4) depends nonlinearly on $e_{33}(u_s)$ (cf. Figueiredo and Trabucho [7]). We think that this nonlinear term may generate some difficulties in proving that the sequence $\{\frac{d^s-d}{s}\}$ is bounded, independently of s, and subsequently in the identification of the shape semiderivative.

MAGNETIC SHAPING OF A LIQUID METAL COLUMN AND DEFORMATION OF A BUBBLE IN A VORTEX FLOW*

M. G. BLYTH† AND J.-M. VANDEN-BROECK†

Abstract. Two different physical problems are considered: the magnetic shaping of a liquid metal column and the distortion of a bubble in a corner vortex flow. It is shown that the two problems can be modeled with a virtually identical set of equations. These equations are solved numerically using a conformal mapping and a series truncation method, which permits fast and efficient computation of the bubble or column shapes. It is found that the two problems exhibit different limiting configurations. For the bubble problem, the deformation becomes more severe as the vortex moves further into the corner until eventually the free surface makes contact with the walls. For the magnetic shaping problem, columns approach a limiting configuration featuring either a finite number of cusps or a fixed number of trapped bubbles along the perimeter. The division between these two different behaviors is explained by means of an exact solution for zero surface tension.

Key words. bubble, magnetic field, conformal mapping, series truncation

1. Introduction.

This paper is concerned with two apparently unrelated problems. The first problem is the magnetic shaping of a liquid metal column. It is motivated by the process of continuous casting in the metallurgical industry in which a free-falling vertical column of liquid metal is shaped by an electromagnetic field. This avoids any surface imperfections which might be introduced by a mold. Experimental work on magnetic shaping has been performed by Etay [7] and Etay, Gagnoud, and Garnier [8]. It appears to have been first analyzed mathematically by Shercliff [14]. The second problem is the deformation of a two-dimensional bubble in a vortex flow. It is relevant to applications where mixing of fluids or cleaning of unwanted bubbles from an apparatus is important. We show that these two problems can be modeled by almost the same equations. The only difference is a sign in the dynamic boundary condition. We solve these equations numerically, recover previous solutions, and compute new ones. Our method is relatively simple and, for the magnetic problem, for example, can be extended to any number of arbitrarily placed conductors.

The problem of computing the shape and evolution of a bubble under a prescribed set of flow conditions has occupied many workers over the years. In this article, we concentrate on the computation of bubble shapes in steady flow. Unsteady calculations have been performed, for example, by Baker and Moore [1] for a gas bubble rising in an inviscid liquid.

Inviscid models have been applied extensively in the literature to computing bubble shapes. McLeod [10] obtained an exact solution describing uniform flow past a two-dimensional bubble in a special case. Further numerical results were obtained by Vanden-Broeck and Keller [17]. Asymptotic results for the same problem were

presented by Shankar [13], and some analytical results were given by Tanveer [15]. Miksis, Vanden-Broeck, and Keller [11] found numerical solutions for uniform flow past axisymmetric bubbles.

Vanden-Broeck and Keller [18] examined straining flow past a bubble in a right-angled corner using boundary integral methods. Ozugurlu and Vanden-Broeck [12] used a series truncation method to extend these results to flow in a corner of arbitrary angle. In both of these papers, bubble shapes were computed numerically for a range of parameter values, and it was shown that in extreme cases, a configuration is reached featuring smaller, trapped bubbles along the free surface. In the present article, we extend these results to the case when the flow is driven by a line vortex positioned at a finite distance from the corner. Our aim is to compute the prevailing bubble shape, which is unknown in advance. Gravity is neglected and the bubble shape is determined by the ambient flow and by surface tension effects. We use a conformal mapping to transform the flow domain into the unit circle, and then use a series truncation method to compute the bubble shape numerically. The series truncation method has been applied previously to calculate free surface flows by Vanden-Broeck [16], Dias and Vanden-Broeck [6], Vanden-Broeck and Miloh [19], Blyth and Vanden-Broeck [2], and others. When the vortex is moved to infinity, our results reduce exactly to those obtained by Ozugurlu and Vanden-Broeck [12].

As mentioned earlier, the vortex problem and the magnetic shaping problem are intimately related mathematically. Therefore we are able to use the same numerical technique to compute liquid column shapes with little amendment to the analysis. In this way, we are able to recompute and extend the results of Shercliff using a somewhat simplified and more convenient approach.

The layout of the paper is as follows. In section 2, we formulate the two physical problems. In section 3 we describe the conformal mapping and present the numerical method. In section 4 we present our numerical results. Our conclusions are summarized in section 5.

2. Problem formulation. In this section, we present the mathematical formulations for corner vortex flow past a bubble and magnetic shaping of a liquid metal column by an arrangement of electrical conductors. The mathematical details are almost the same.

2.1. Vortex flow past a bubble. First, we consider inviscid, incompressible flow into a corner of general angle α with a trapped air bubble at the apex, as is sketched in Figure 1. Our interest lies in computing the shape of the bubble, which is unknown in advance. The flow in the corner is driven by a line vortex whose intensity and position control the shape of the bubble. We define the vortex circulation by Γ. The vortex lies at some point along the bisector, $y = \tan(\alpha/2)\, x$, at a distance d from the origin. Consequently, the flow is symmetric about this line. The contact angle, β, is a free parameter.

At the surface of the bubble, the fluid pressure undergoes a jump whose magnitude is dictated by the Laplace–Young equation,

$$p_S - p_B = \kappa T. \tag{2.1}$$

Here, p_S is the fluid pressure at the surface of the bubble, p_B is the constant pressure in the bubble, κ is the surface curvature reckoned to be negative when the bubble encloses a convex region (see Figure 1), and T is the constant surface tension. Applying

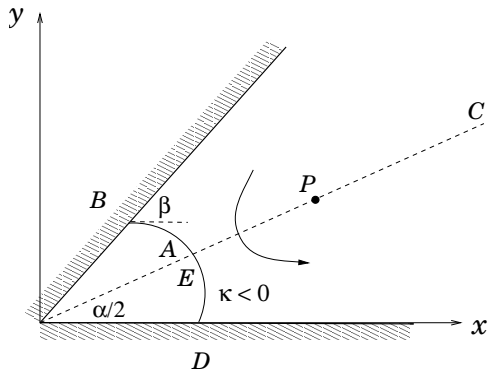

FIG. 1. *Sketch of the corner flow with a trapped air bubble at the vertex. The contact angle between the bubble and the wall is β. The flow is driven by a vortex with circulation Γ at point P which lies along the bisector, shown as a broken line. The point C lies at infinity. The arrow indicates the direction of flow.*

Bernoulli's equation on the bubble surface and invoking condition (2.1), we have

$$\frac{1}{2}q^2 + \frac{T\kappa}{\rho} = \mathcal{B}, \tag{2.2}$$

where q is the fluid speed, ρ is the fluid density, and $\mathcal{B}$ is a constant. If L is a suitable lengthscale, so that Γ/L represents a characteristic velocity scale, then a routine analysis of (2.2) reveals the importance of two dimensionless groups, one involving the surface tension, and the other involving the distance of the vortex from the origin. For example, these might be defined as

$$\frac{Td}{\rho\Gamma^2}, \qquad \frac{\mathcal{B}d^2}{\Gamma^2}. \tag{2.3}$$

The flow outside of the bubble satisfies Laplace's equation, subject to the no-normal flow condition at the walls,

$$v = 0 \quad \text{on} \quad y = 0, \qquad v/u = \tan\alpha \quad \text{on} \quad y = x\tan\alpha, \tag{2.4}$$

where u and v are the x and y components of the velocity, respectively. The dynamic condition (2.2) applies at the bubble surface.

2.2. Magnetic shaping of a liquid metal column. Next, we consider a two-dimensional column of liquid metal surrounded by an even number of wire conductors carrying high-frequency electrical current, as discussed by Shercliff [14]. The conductors are positioned at equally spaced intervals around a circle of radius d centered at the origin. Gravity is neglected. Any stirring effects in the liquid metal are ignored and the problem is treated as quasi-steady. Under this assumption, the magnetic field generated by the current-carrying wires competes with surface tension to shape the molten column. Our goal is to compute the shape of the free surface, which is unknown in advance. The column shape is assumed to be rotationally symmetric according to the number of conductors present. For this reason, the contact angle, β, is taken to be equal to $\pi/2$.

The magnetic field may be described in terms of a potential function satisfying Laplace's equation in the region exterior to the metal column. At the free surface,

the appropriate boundary condition is (see, e.g., Shercliff [14])

$$\frac{B^2}{2\mu_0} - T\,\kappa = p, \tag{2.5}$$

where B is the magnitude of the magnetic field at the surface, μ_0 is the permeability of free space, T is the surface tension, κ is the surface curvature defined as in section 2.1, and p is the uniform pressure in the liquid metal. For simplicity, we recast (2.5) in the notation of section 2.1, writing it instead as

$$\frac{1}{2}q^2 - \frac{T\kappa}{\rho} = \mathcal{E}, \tag{2.6}$$

where $q = B$, $\rho = 1/\mu_0$, and $\mathcal{E} = \mu_0 p$ is a constant. Clearly, the only difference between (2.6) and the free surface condition for the vortex flow (2.2) is the sign on the second term. Together with the fact that both problems are governed by Laplace's equation within the domain of interest, we see that, despite describing wholly different physical phenomena, the two problems are virtually identical mathematically. The solution to both of these problems is considered in the next section.

We note that there are other problems which are closely related to the current work. These include the equilibrium configuration of a charged surface of liquid metal (see Zubarev [20] and Zubarev et al. [21]) and the circulation-induced shape deformation of drops and bubbles (see, e.g., Crowdy [5], [4] and Blyth and Vanden-Broeck [3]). The boundary conditions derived by Zubarev [20] imply that our vortex flow also models the deformation of the surface of a liquid metal due to an arrangement of charges symmetrically distributed around it.

3. Conformal mapping and numerical solution. In the first problem, discussed in section 2.1, the aim is to compute the shape of the bubble for a vortex of given strength and position. In the second problem, discussed in section 2.2, the aim is to compute the shape of the liquid metal column when surrounded by a prescribed number of conductors carrying a fixed current. We have shown that these two problems are virtually mathematically equivalent, save for a difference in sign in the free surface boundary conditions (2.2) and (2.6). Both problems can be solved numerically using a series truncation method to be described in this section.

To prepare the ground, we first map the flow domain onto the unit circle in a transformed plane. To do this, we introduce the complex potential $f(z) = \phi + \mathrm{i}\psi$, where $\phi(x, y)$, $\psi(x, y)$ are the velocity potential and streamfunction, respectively, and $z = x + \mathrm{i}y$. Treating ϕ and ψ as independent coordinates, the domain of interest is illustrated in Figure 2. Note that ϕ varies between $-\Gamma/2$ and $\Gamma/2$ and takes the a priori unknown value of γ at the two contact points B and D. The parameter Γ is either a measure of the vortex strength or the current in the conductors. The mapping from the complex f plane into the unit circle in the target t plane is achieved by the transformation

$$-\frac{2\pi\mathrm{i}f}{\Gamma} = \log\left[\frac{\mathrm{i}(t^2+1) + 2\lambda t}{\mathrm{i}(t^2+1) - 2\lambda t}\right], \tag{3.1}$$

where λ is a positive constant given by

$$\lambda = \tan\left(\frac{\pi\gamma}{\Gamma}\right). \tag{3.2}$$

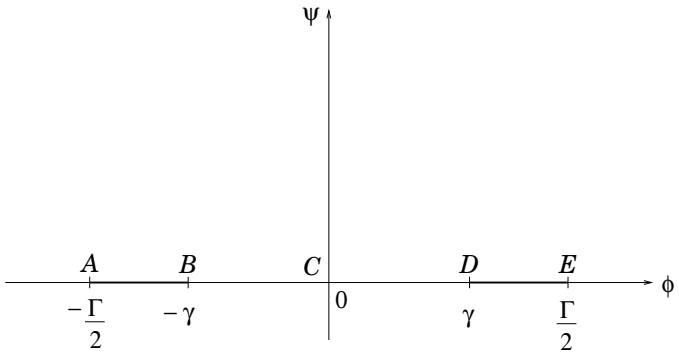

FIG. 2. *The flow domain in the complex f plane. The bubble surface is highlighted by the thick lines.*

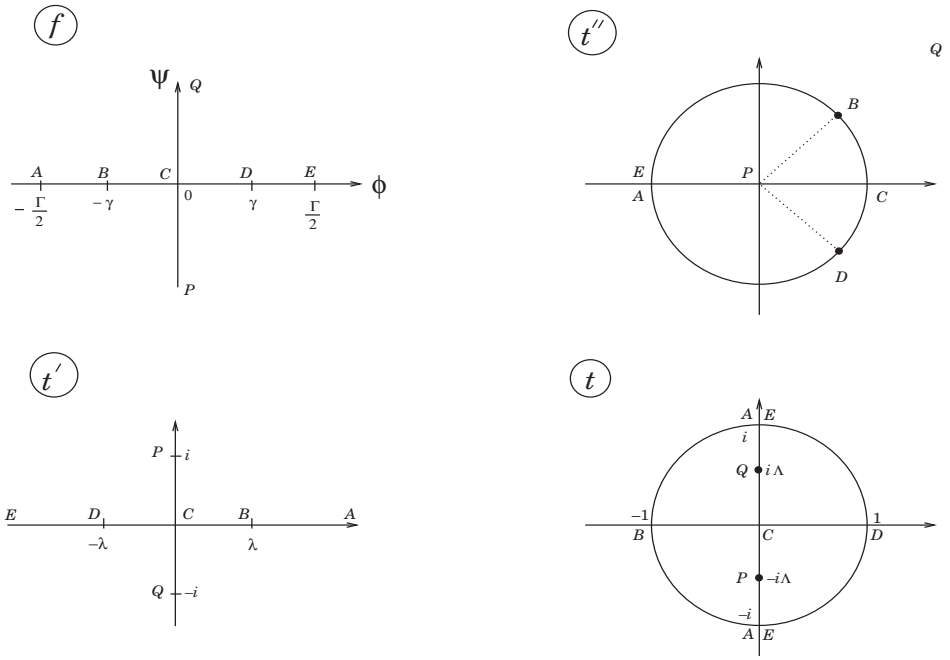

FIG. 3. *The conformal mapping from the f to the t plane via the intermediate t'' and t' planes. The succession of mappings is given by $t'' = \exp(-2\mathrm{i}\pi f/\Gamma)$, $t'' = (\mathrm{i}-t')/(\mathrm{i}+t')$, and $-2\lambda/t' = t+1/t$.*

Moving the corner vortex to infinity corresponds to the double limit $\lambda \to \infty$ and $\Gamma \to \infty$. In this case, $\Lambda \to 0$ and point P collapses onto point C. Moreover, $\gamma \to \Gamma/2$. Writing $b = \Gamma/2 - \gamma$, for constant b, and introducing the shifted complex potential $g = f - \Gamma/2$, we obtain the limiting behavior of the mapping (3.1),

$$\frac{g}{b} \sim -\frac{1+t^2}{2t}, \tag{3.3}$$

which is precisely the mapping used by Ozugurlu and Vanden-Broeck [12] when considering corner flow driven by a vortex at infinity.

The mapping from the f to the t plane is more clearly understood by introducing two intermediate planes, as is shown in Figure 3. For the magnetic shaping problem,

there are $2n$ conductors positioned symmetrically on a circle of radius d at $z = z_k$ and $z = z_k^*$, where

$$z_k = d \exp\left\{ \mathrm{i} \left(k - \frac{1}{2} \right) \frac{\pi}{n} \right\}$$

for $k = 1, \ldots, n$. The current carried by the conductors alternates in sign from one to the other so that as $z \to z_k$, the stream function $\psi \to (-1)^k \infty$. These limits are represented by the points P and Q in Figure 3.

The complex velocity is defined by

$$\zeta \equiv \frac{\mathrm{d}f}{\mathrm{d}z} = u - \mathrm{i}v. \tag{3.4}$$

Taking the limit as $z \to \infty$, we note the behavior of the complex velocity near the origin in the transformed plane,

$$\zeta \sim O\Big(t^{\frac{n+1}{n}} \Big) \quad \text{as} \quad t \to 0. \tag{3.5}$$

Consistent with the local flow at the contact points B and D shown in Figure 1, the complex velocity has the following singular behavior in the t plane:

$$\zeta \sim O\Big((1 - t^2)^{2(1-\beta/\pi)} \Big) \quad \text{as} \quad t \to \pm 1. \tag{3.6}$$

As shown in Figure 3, the points P and Q are mapped onto the points $t = -\mathrm{i}\Lambda$ and $t = \mathrm{i}\Lambda$, respectively, where

$$\Lambda = -\lambda + \sqrt{\lambda^2 + 1}. \tag{3.7}$$

Accordingly, the complex velocity has the local structure,

$$\zeta \sim O\Big((t^2 + \Lambda)^{-1} \Big) \quad \text{as} \quad t \to \pm \mathrm{i}\Lambda. \tag{3.8}$$

Our aim is to construct a function inside the unit circle in the transformed plane, which is analytic except at the singularities just discussed. To this end, we expand the complex velocity in an infinite series, writing

$$\zeta = t^{1/n} \, \frac{(1 - t^2)^{2(1-\beta/\pi)}}{(t^2 + \Lambda)} \, S(t), \qquad S(t) = \sum_{k=1}^{\infty} a_k t^k, \tag{3.9}$$

where the a_k are unknown, real coefficients. It will be noted that, while the magnetic shaping problem requires n to be an integer, no such restriction is necessary for the vortex problem. In the latter case, where the corner angle $\alpha = \pi/n$, n may be taken to be any positive real number. In the limit when the vortex tends to infinity studied above, the complex velocity given in (3.9) has the leading order behavior, $\zeta \sim a_1 \, t^{(1/n)-1} \, (1 - t^2)^{2(1-\beta/\pi)}$, in agreement with the analysis of Ozugurlu and Vanden-Broeck [12].

Since the coefficients, a_k, in (3.9) are real, the boundary conditions (2.4) are satisfied automatically and it only remains to enforce the dynamic condition (2.2). In practice, the infinite series is terminated after M terms, leaving M unknown coefficients $a_1, \ldots, a_M$. These are determined numerically by placing M collocation

points along AB and DE which comprise the free surface. Writing $t = \mathrm{e}^{\mathrm{i}\,\sigma}$, where $0 < \sigma < \pi$, we select the M points $\sigma_k = (k - 1/2)h$ for $k = 1, \ldots, M$, where the step length $h = \pi/M$. Noting the identity,

$$\frac{\partial x}{\partial \phi} + \mathrm{i}\,\frac{\partial y}{\partial \phi} = \frac{1}{u - \mathrm{i}v} = \frac{u + \mathrm{i}v}{u^2 + v^2}, \tag{3.10}$$

we may write the curvature in the convenient form

$$\kappa = \frac{vu' - uv'}{\sqrt{u^2 + v^2}}\,\frac{\partial \sigma}{\partial \phi}, \tag{3.11}$$

where a prime denotes partial differentiation with respect to σ. According to the mapping (3.1),

$$\frac{\partial \sigma}{\partial \phi} = \frac{\pi}{\Gamma}\,\frac{\lambda^2 + \cos^2\sigma}{\lambda \sin\sigma} \tag{3.12}$$

on the unit circle. Substituting (3.11) and (3.12) into the dynamic condition (2.2) and applying the result at each of the collocation points, we derive M nonlinear algebraic equations for the M unknowns $a_1, \ldots, a_M$. These equations are solved numerically using Newton's method. Once the coefficients are known, the shapes are constructed by integrating the identity (3.10). The position of the vortex is given by $z_v = z_A + Z$, where z_A is the position of the midpoint, A, on the bubble surface, and Z is given by

$$Z = \frac{2}{\pi}\lambda\Gamma\,\mathrm{i}\int_1^{\Lambda} \frac{(1 + s^2)^{(\frac{2\beta}{\pi} - 1)}}{(-\mathrm{i}s)^{\frac{1+n}{n}}(s^2 - \hat{\Lambda}^2)S(-is)}\,\mathrm{d}s, \tag{3.13}$$

where $\hat{\Lambda} = \lambda + \sqrt{\lambda^2 + 1}$.

Solutions with a cusp at some point along their perimeter can be described by a simple, exact solution for a free surface with zero surface tension and $\beta = \pi$. According to (2.2), such solutions have constant velocity on the bubble surface. They can be constructed by taking $a_1 = U$, $a_2 = 0$, $a_3 = U\Lambda^2$, and $a_k = 0$ for all $k \geq 4$ in (3.9). This guarantees that $|\zeta| = U$, a constant, on the bubble surface $|t| = 1$. Successful comparison is made below between this exact solution and numerically computed cusp solutions for the magnetic shaping problem.

4. Results. We present results for each of the two different physical problems in turn. For the vortex problem, the contact angle, β, is a free parameter. For the metal column shaping problem, β is equal to $\pi/2$. All solutions were computed using the method described in section 3. In most cases, we took $M = 150$ collocation points along the free surface. This was found to be sufficient to accurately resolve the bubble and liquid metal column shapes. In exceptional cases, we needed to take $M = 200$ to obtain an accurate solution. An example set of coefficients for a sample calculation is presented below.

We begin by presenting results for corner flow past a bubble. To define dimensionless variables, we set $T = \rho = \Gamma = 1$. This leaves a two-parameter family of solutions obtained by varying γ and $\mathcal{B}$. In Figure 4(a), we show a number of bubble shapes with contact angle $\beta = \pi/2$ for the case $\mathcal{B} = 1$ and for various values of γ. The vortex is indicated by a solid disk for each bubble shape. As γ is reduced, the vortex moves towards the origin, forcing the bubble towards the walls until it eventually makes contact at $\gamma = 0.149$. Beyond this point, the free surface intersects the

walls and any physical meaning is lost. For the last case, $\gamma = 0.149$, the coefficients a_k in (3.9) are given by $a_1 = -2.163$, $a_3 = -1.038$, $a_5 = 0.3103$, ..., $a_{11} = -0.01918$, ..., $a_{21} = -6.375 \times 10^{-4}$, ..., $a_{41} = -3.748 \times 10^{-5}$, ..., $a_{61} = -1.2561 \times 10^{-6}$, ..., $a_{81} = -5.75 \times 10^{-8}$. All of the even coefficients are zero. Bubble shapes under the same conditions but with a contact angle of $\beta = \pi/4$ for various values of γ are shown in Figure 4(b). We note that fixing γ and varying the Bernoulli constant $\mathcal{B}$ produces little qualitative difference in the bubble shapes.

Free surface shapes inside a corner of angle $\alpha = \pi/3$ are displayed in Figure 5(a) for the contact angle $\beta = \pi/2$. As γ increases, the vortex moves further into the corner until contact is made between the free surface and the walls. For the contact angle $\beta = \pi$, considered in Figure 5(b), intersection between the bubble and the walls tends to occur much closer to the contact points. As γ increases and the vortex moves a long distance from the corner, the free surface tends to a circular arc, except in small regions close to the walls, where the bubble meets the wall tangentially. The circular arc is the expected shape for a bubble in a stagnant fluid. It is shown as a broken line in Figure 5(b).

Results for flow past a bubble adhering to a plane wall are displayed in Figure 6 for $\mathcal{B} = 0.5$. As γ decreases and the vortex moves towards the wall, the bubble is squashed downwards until its midpoint touches the wall at $\gamma = 0.247$. Beyond this value, the free surface intersects the wall, preventing physical interpretation. As γ increases and the vortex moves away from the wall, the bubble expands and eventually acquires the semicircular shape expected for an attached bubble residing in a quiescent fluid. If, simultaneously, the vortex strength tends to infinity, we obtain uniform flow past a bubble on a flat wall, as discussed by Vanden-Broeck and Keller [17].

We now turn to the liquid metal column shaping problem. We start by recomputing some of Shercliff's results using our simplified conformal mapping. First, we nondimensionalize (2.6), writing $q = B_s q^*$, where B_s is a reference magnetic field strength, and $\kappa = \kappa^*/L$, where L is a reference length. Dropping the asterisks for

convenience, (2.6) becomes

$$\frac{1}{2}q^2 - \frac{\kappa}{2ak} = \frac{1}{2a}, \tag{4.1}$$

where

$$a = \frac{B_s^2}{2\mathcal{E}}, \qquad k = \frac{\rho\mathcal{E}L}{T} \tag{4.2}$$

are the same as Shercliff's dimensionless parameters a and k. Shercliff's parameter, α, to be written here as α_S, is related to our parameter γ by $\alpha_S = \Gamma/2 - \gamma$, where Γ

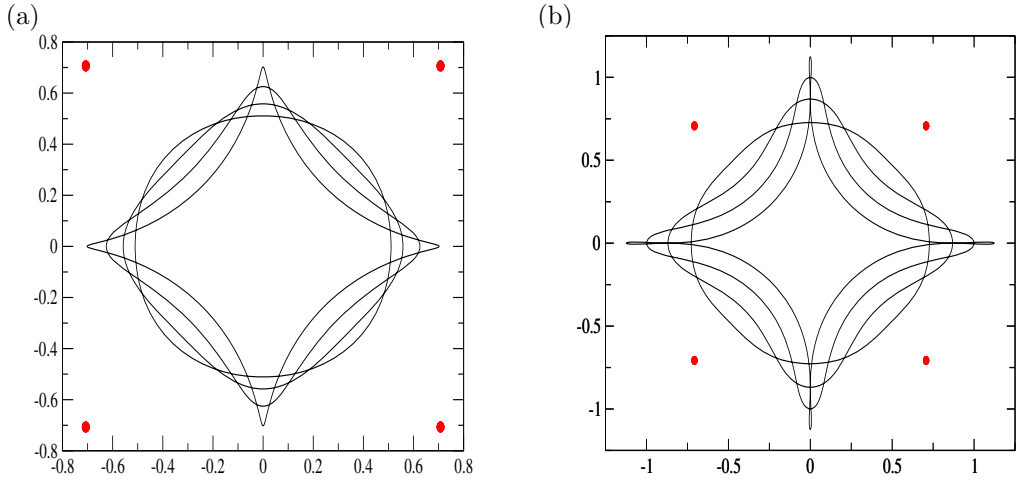

FIG. 7. *Column shapes for four conductors for* (a) $\sin\alpha_S = 0.5$ *and* $a = 1$, 10, 100, 10000, *and* (b) $\sin\alpha_S = 0.8$ *and* $a = 2.5$, 25, 250, 25000. *The largest value of* a *corresponds to the limiting shape exhibiting a cusp and a trapped bubble, respectively. In both figures, the shapes are scaled so that the conductors, shown as four solid dots, are always a unit distance from the origin.*

now represents the dimensionless circulation. To conform with Shercliff's results, we take $k = 0.5$ and $\Gamma = \pi$ throughout.

In Figure 7, we plot column shapes for a number of values of a for the two cases $\sin(\alpha_S) = 0.5$ and $\sin(\alpha_S) = 0.8$, corresponding to Shercliff's Figures 12 and 13. As a increases, the shapes in Figure 7(a) tend to a limiting cusped configuration, while those in Figure 7(b) approach a shape with trapped bubbles along the perimeter. The critical value dividing these two characteristic limits is provided by Shercliff as $\sin\alpha_S = 0.66$. In either the subcritical or supercritical case, the limiting configuration is easily obtained as the exact solution for zero surface tension discussed at the end of section 3. To confirm this statement, we temporarily drop the current nondimensionalization and, in Figure 8(a), present the numerical solution for the case $\mathcal{E} = \rho = 1$ and $T = 10^{-6}$ with contact angle $\beta = \pi/2$. According to (2.6), the surface velocity is approximately $\sqrt{2}$ except near the cusps, where the curvature is large. The exact cusp solution with $U = \sqrt{2}$ is shown as the broken line in Figure 8(a). The agreement between the two curves is excellent. A close-up view in Figure 8(b) illustrates the true cusplike nature of the exact solution in contrast to the sharp turning of the numerical solution.

The effect on the cusp shape of increasing α_S is shown in Figure 9. As α_S is raised, the cusps eventually intersect themselves. The first intersection occurs at the critical value $\sin\alpha_{S_c} = 0.66$, which is in excellent agreement with Shercliff's prediction. Typical subcritical and supercritical profiles are shown in the figure. The behavior of the exact cusp solutions suggests that, as a increases, metal columns for which $\alpha_S < \alpha_{S_c}$ will approach a limiting physical shape exhibiting trapped bubbles, and those for which $\alpha_S > \alpha_{S_c}$ will approach a cusped configuration. These predictions are confirmed by the shapes shown in Figure 7. A magnified view of one of the trapped bubbles seen in Figure 7(a) is shown in Figure 10(a). The shape eventually intersects itself when a is increased further, as can be seen in Figure 10(b).

Shercliff presented results for only four conductors. Our numerical method allows us to compute shapes for any even number of conductors. By way of illustration, we

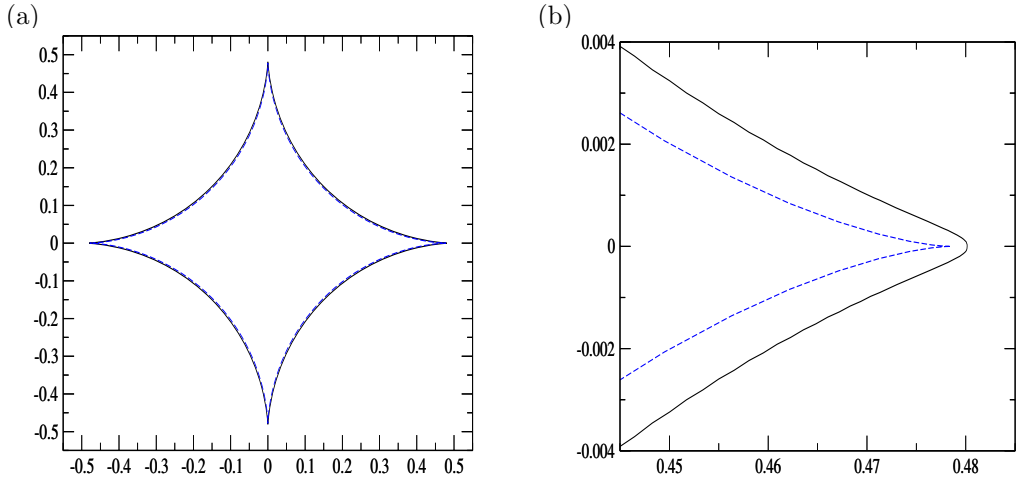

FIG. 8. $\sin\alpha_S = 0.5$: (a) *Numerical solution with* $\beta = \pi/2$ *and* $\mathcal{E} = \rho = 1$, $T = 10^{-6}$, *shown as a solid line, compared with the exact cusp solution with* $\beta = \pi$ *and* $U = \sqrt{2}$, *shown as a broken line.* (b) *Close up of* (a) *near the cusp.*

show in Figure 11 the various column shapes produced by six regularly placed conductors. Computing the exact cusp solution for zero surface tension as described above, we find the critical value $\sin\alpha_S = 0.75$. Subcritical values correspond to limiting cusp solutions appropriate to Figure 11(a), and supercritical values correspond to shapes with trapped bubbles appropriate to Figure 11(b).

5. Summary. We have considered the free surface shapes adopted by a bubble in a vortex corner flow or by a column of liquid metal surrounded by an even number of conductors, and have noted the near mathematical equivalence between these two problems. In both cases, our approach has been to use a conformal map to transform the domain of interest into the unit circle. In the process, the kinematic condition on the walls in the case of the vortex flow, or the symmetry conditions in the case of the

metal column, were satisfied automatically, and the free surface condition was satisfied by expanding in a convergent power series, which was truncated to permit numerical computation. For the magnetic shaping problem, our approach has considerably simplified the analysis used by Shercliff to compute the various shapes.

For both problems, we have presented a variety of shapes over a range of conditions and have demonstrated the limiting configurations featuring either cusps or trapped bubbles along the free surface perimeter. Moreover, we have constructed exact zero surface tension cusp solutions and have shown that as one parameter is varied, these solutions begin to intersect themselves. The critical value at which this self-intersection occurs corresponds to the division between limiting cusp and trapped

bubble solutions of the free surfaces with surface tension present. Below the critical value, the bubble shapes approach a cusped configuration; above it, the free surfaces tend to a shape with trapped bubbles along its perimeter.

The issue of the stability of the configurations computed in this paper is left as a topic for future work. Stability calculations for related problems involving liquid metals have been performed by Felici [9].

AN APPROXIMATE METHOD FOR SCATTERING BY THIN STRUCTURES*

S. MOSKOW†, F. SANTOSA‡, AND J. ZHANG‡

Abstract. Scattering of waves by a thin structure is considered in this work. The Helmholtz equation with variable coefficient models the wave phenomena. The scatterer is assumed to have a high index of refraction while at the same time it is very small in one of the dimensions. We show that if the index scales as $O(1/h)$, where h is the thickness of the scatterer, then an approximate solution, based on perturbation analysis, can be obtained. The approximate solution consists of a leading order term plus a corrector, each of which solves an integral equation in two dimensions for a three-dimensional problem. We provide error analysis on the approximation. The approximate method can be viewed as an efficient computational approach since it can potentially greatly simplify scattering calculations. Numerical results provide an assessment of the accuracy of the approximate solution.

Key words. scattering, Helmholtz equation, approximate solution, asymptotics, error estimates

1. Introduction.

The problem under investigation arises in the study of photonic band gap (PBG) structures. Optical devices that exploit photonic band gap phenomena to guide and manipulate light are expected to play an important role in optical communication networks and optical computing. Thin-film or membrane devices are particularly attractive because of the relative ease with which they can be made.

A typical thin-film device is made of a material with a high index of refraction. The high index is needed to confine light within the structure. To manipulate light within the structure, holes are drilled into film. Typical structures under study can be found in several recent papers [3, 5, 6].

In order to simulate how light behaves in such a structure, it is necessary to solve the wave equation. In most studies, the structure is surrounded by air. Thus, the domain in which the wave equation must be solved will be all of $\mathbb{R}^3$. The thin film structure can be modeled by prescribing index of refraction to a subdomain of $\mathbb{R}^3$.

The classical approach to performing the required simulation of wave propagation in such a complicated structure is the finite-difference time-domain (FDTD) method [2], with absorbing boundary conditions. While the computation proceeds in a straightforward manner, it is very time consuming.

In this paper, we propose an approximate method to solve the scattering problem. The method starts with the time-harmonic wave equations and applies a perturbation approach based on an identified small parameter. The advantage of our method is that it reduces the complexity of the computation by one dimension. The Lippmann–Schwinger formulation of the scattering problem will involve a three-dimensional

(3-D) (volume) integral equation. Our method simplifies the calculation to solving a sequence of two-dimensional (2-D) integral equations.

The present work addresses only the case of the scalar wave equation. Maxwell's equation, which is the correct model for the propagation phenomena, will be treated in a separate, future work.

This paper is organized as follows. We give a description of the problem we wish to solve in the next section. The perturbation approach is presented in section 3. Justification of the approximate method follows in sections 4 and 5. Section 6 contains numerical examples in two dimensions. The paper closes with a discussion.

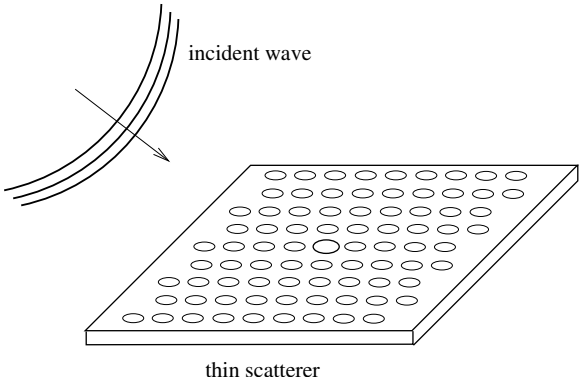

FIG. 2.1. *Scattering by a thin structure.*

2. Problem statement. The situation we are attempting to model is depicted in Figure 2.1. The propagation of waves is modeled by the Helmholtz equation

$$\Delta u + k^2 \epsilon(x,z) u = 0, \tag{2.1}$$

where $x = (x_1, x_2) \in \mathbb{R}^2$ and $z \in \mathbb{R}$. In (2.1) we call $\epsilon(x,z)$ the dielectric constant (an abuse in terminology), which will be set to unity in air and to some value in the structure. The field $u(x,z)$ is of normalized real frequency k and comprises two components:

$$u(x,z) = u_{\mathrm{i}}(x,z) + u_{\mathrm{s}}(x,z),$$

where the incident wave u_{i} is given, and the scattered field u_{s} satisfies the Sommerfeld radiation conditions

$$\frac{\partial u_{\mathrm{s}}}{\partial r} - iku_{\mathrm{s}} = O\left(\frac{1}{r^2}\right) \quad \text{for } r = \sqrt{|x|^2 + z^2} \to \infty.$$

The thin structure is incorporated into the definition of $\epsilon(x,z)$. Let $\Omega \times (-h/2, h/2)$ be the region occupied by the thin structure, where Ω is a bounded domain in $\mathbb{R}^2$. Then the dielectric constant is defined by

$$\epsilon(x,z) = \begin{cases} 1 & \text{for} \quad |z| > h/2, \\ \epsilon_0(x)/h & \text{for} \quad |z| < h/2, x \in \Omega, \\ 1 & \text{for} \quad |z| < h/2, x \notin \Omega. \end{cases} \tag{2.2}$$

Thus, we have assumed that $\epsilon_0(x)$ is supported in Ω.

The problem we wish to solve is to find the scattered field $u_{\rm s}(x,z)$ given a thin structure (2.2) and an incident field $u_{\rm i}(x,z)$. For the purpose of simulating waves in PBG structures, the total field $u(x,z)$ for (x,z) in the thin structure, $\Omega\times(-h/2,h/2)$, is of great interest.

3. Perturbation approach. One can rewrite the problem for $u(x,z)$ in (2.1) as an integral equation [1] by observing that since

$$\Delta u_{\rm i}+k^2u_{\rm i}=0,$$

we have that

$$\Delta u_{\rm s}+k^2u_{\rm s}=k^2(1-\epsilon)u.$$

If $G(x,z,x',z')$ is the free space Green's function for the Helmholtz equation in $\mathbb{R}^3$, i.e., G satisfies

$$(\Delta_{(x',z')}+k^2)G=\delta_{(x,z)}$$

in $\mathbb{R}^3$ with the Summerfeld radiation condition, then by using integration by parts and the decay at infinity, we get

$$u_{\rm s}(x,z)=k^2\int_\Omega\int_{-h/2}^{h/2}\left(1-\frac{\epsilon_0(x')}{h}\right)G(x,z,x',z')u(x',z')dz'dx'.$$

Hence we have that the field satisfies the well-known Lippmann–Schwinger integral equation

$$u(x,z)=u_{\rm i}(x,z)+k^2\int_\Omega\int_{-h/2}^{h/2}\left(1-\frac{\epsilon_0(x')}{h}\right)G(x,z,x',z')u(x',z')dz'dx'. \tag{3.1}$$

We note that $G(x,z,x',z')$ is given by

$$G(x,z,x',z')=\frac{1}{4\pi}\frac{e^{ik\sqrt{|x-x'|^2+|z-z'|^2}}}{\sqrt{|x-x'|^2+|z-z'|^2}}.$$

See [1] for the full proof of equivalence. To solve for the field, we need to view (3.1) as an integral equation satisfied by $u(x,z)$ for $(x,z)\in\Omega\times(-h/2,h/2)$. Once we have found $u(x,z)$ for (x,z) in the thin domain, we can then use (3.1) as a way to compute the field outside the thin domain. Therefore, our first step will be to find an asymptotic approximation for u inside the thin region.

To find a first order approximation, we will scale the variable in the z direction, $z=h\zeta$, so that the integral equation is now

$$u(x,\zeta)=u_{\rm i}(x,h\zeta)+k^2\int_\Omega\int_{-1/2}^{1/2}\left(1-\frac{\epsilon_0(x')}{h}\right)G(x,h\zeta,x',h\zeta')u(x',\zeta')hd\zeta'dx', \tag{3.2}$$
$$(x,\zeta)\in\Omega\times(-1/2,1/2).$$

Formally, we assume a perturbation series ansatz

$$u(x,\zeta)=u_0(x)+hu_1(x,\zeta)+\cdots,\quad (x,\zeta)\in\Omega\times[-1/2,1/2]. \tag{3.3}$$

The goal is now to obtain equations by which $u_0(x,z)$ and $u_1(x,z)$ can be found.

Substituting (3.3) into (3.2), we see that

$$u_0(x) + hu_1(x,\zeta) + \cdots = u_{\mathrm{i}}(x,0) + h\frac{\partial u_{\mathrm{i}}}{\partial z}(x,0) + O(h^2) + k^2 \int_\Omega \int_{-1/2}^{1/2} (h - \epsilon_0(x')) G(x, h\zeta, x', h\zeta') \left[u_0(x') + hu_1(x',\zeta') + \cdots\right] d\zeta' dx'. \tag{3.4}$$

The classical way to find u_0 and u_1 is to equate like powers of h on both sides of (3.4). However, the situation is complicated by the fact that $G(x,z,x',z')$ is singular.

We make the observation that if the integral

$$\int_{-1/2}^{1/2} G(x, h\zeta, x', h\zeta') d\zeta'$$

converges as $h \to 0$ to

$$G(x,0,x',0),$$

then, setting equal like powers of h in (3.4), we see that $u_0(x)$ satisfies the integral equation

$$u_0(x) = u_{\mathrm{i}}(x,0) - k^2 \int_\Omega \epsilon_0(x') G(x,0,x',0) u_0(x') dx'. \tag{3.5}$$

We will justify this step in the next section and show that $u_1(x,z)$ can be calculated, as well as justified, in section 5.

Once we have solved for $u_0(x)$ and $u_1(x,z)$, we can insert them in the right-hand side of (3.1) to obtain an approximation of the field for all points outside the thin domain. Note that the equation for u_0 and, as we shall see, that for u_1 are 2-D integral equations. Therefore, in terms of computational cost we have reduced the dimension of the problem by one.

4. Justification for the first term. Now we provide a rigorous error estimate for the approximation (3.5) derived above. The solution $u(x,z)$ satisfies

$$u(x,z) = u_{\mathrm{i}}(x,z) + k^2 \int_\Omega \int_{-h/2}^{h/2} \left(1 - \frac{\epsilon_0(x')}{h}\right) G(x,z,x',z') u(x',z') dz' dx'. \tag{4.1}$$

The candidate for an approximation to u on the thin strip to substitute into (3.1) is $u_0(x)$, the solution to the lower dimensional problem:

$$u_0(x) = u_{\mathrm{i}}(x,0) - k^2 \int_\Omega \epsilon_0(x') G(x,0,x',0) u_0(x') dx'. \tag{4.2}$$

To show this is a good approximation, let

$$\zeta = z/h \quad \text{and} \quad \tilde{u}(x,\zeta) = u(x,z),$$

so that

$$\tilde{u}(x,\zeta) = u_{\mathrm{i}}(x,h\zeta) + k^2 \int_\Omega \int_{-1/2}^{1/2} (h - \epsilon_0(x')) G(x, h\zeta, x', h\zeta') \tilde{u}(x',\zeta') d\zeta' dx'. \tag{4.3}$$

For convenience define S to be the scaled strip

$$S = \Omega \times (-1/2, 1/2).$$

We will show the following uniform norm estimate.

PROPOSITION 1. *There exists a constant C independent of h (but depending on k) such that*

$$\|u_0(x) - \tilde{u}(x,\zeta)\|_{L^\infty(S)} \leq Ch.$$

Using (4.2) and (4.3) and interchanging the order of integration, we can write

$$\tilde{u}(x,\zeta) - u_0(x) = u_{\mathrm{i}}(x,h\zeta) - u_{\mathrm{i}}(x,0) + hk^2 \int_\Omega \int_{-1/2}^{1/2} G(x,h\zeta,x',h\zeta')\tilde{u}(x',\zeta')d\zeta' dx'$$
$$+ k^2 \int_{-1/2}^{1/2} \int_\Omega \epsilon_0(x') \left[G(x,0,x',0)u_0(x') - G(x,h\zeta,x',h\zeta')\tilde{u}(x',\zeta')\right] dx' d\zeta'.$$

We add and subtract appropriate terms to obtain

$$\tilde{u}(x,\zeta) - u_0(x) = u_{\mathrm{i}}(x,h\zeta) - u_{\mathrm{i}}(x,0) + hk^2 \int_\Omega \int_{-1/2}^{1/2} G(x,h\zeta,x',h\zeta')\tilde{u}(x',\zeta')d\zeta' dx'$$
$$+ k^2 \int_{-1/2}^{1/2} \int_\Omega \epsilon_0(x')\tilde{u}(x',\zeta') \left[G(x,0,x',0) - G(x,h\zeta,x',h\zeta')\right] dx' d\zeta'$$
$$+ k^2 \int_{-1/2}^{1/2} \int_\Omega \epsilon_0(x') G(x,0,x',0) \left[u_0(x') - \tilde{u}(x',\zeta')\right] dx' d\zeta'.$$

For a given $\epsilon_0 \in L^\infty(\Omega)$ which is also piecewise continuous, define the integral operator

$$T : L^2(S) \to L^2(S)$$

by

$$T(f) = \int_{-1/2}^{1/2} \int_\Omega \epsilon_0(x') G(x,0,x',0) f(x',\zeta') dx' d\zeta'.$$

By an abuse of notation, we will also use T to denote the same integral operator on the space of continuous functions, $C^0(\overline{S})$, equipped with the L^∞ norm:

$$T : C^0(\overline{S}) \to C^0(\overline{S}).$$

(Note that $T(f)$ will always be independent of ζ, so the range of T is really only functions on Ω.) Then $\tilde{u} - u_0$ satisfies

$$(I + k^2 T)(\tilde{u} - u_0) = u_{\mathrm{i}}(x,h\zeta) - u_{\mathrm{i}}(x,0) + hk^2 \int_\Omega \int_{-1/2}^{1/2} G(x,h\zeta,x',h\zeta')\tilde{u}(x',\zeta')d\zeta' dx'$$
$$+ k^2 \int_{-1/2}^{1/2} \int_\Omega \epsilon_0(x')\tilde{u}(x',\zeta') \left[G(x,0,x',0) - G(x,h\zeta,x',h\zeta')\right] dx' d\zeta'. \tag{4.4}$$

The lemmas that follow are used to bound the right-hand side of (4.4) and to show that we can invert $(I + k^2 T)$.

LEMMA 1. *There exists a constant C independent of h and ζ' but depending on k such that*

$$\sup_{(x,\zeta)\in S}\int_\Omega |G(x,0,x',0)-G(x,h\zeta,x',h\zeta')|dx' \le Ch.$$

Proof. The difference of these Green's functions can be written as

$$\begin{aligned}
&G(x,0,x',0)-G(x,h\zeta,x',h\zeta')\\
&=\frac{1}{4\pi}\frac{e^{ik|x-x'|}}{|x-x'|}-\frac{1}{4\pi}\frac{e^{ik\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\\
&=\frac{1}{4\pi}e^{ik|x-x'|}\left[\frac{1}{|x-x'|}-\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\right]\\
&\qquad+\frac{1}{4\pi}\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\left[e^{ik|x-x'|}-e^{ik\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\right].
\end{aligned}\tag{4.5}$$

We first work on the second term on the right-hand side of (4.5). Since we know that for $(x,\zeta)\in S$,

$$\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}-|x-x'|\le h,$$

there exists a constant C independent of h and ζ' but depending on (real) k such that

$$|e^{ik|x-x'|}-e^{ik\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}|\le Ch.\tag{4.6}$$

Since

$$\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\le\frac{1}{|x-x'|},$$

which is integrable with respect to x' on Ω, we have that

$$\int_\Omega\frac{dx'}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}$$

is bounded independently of h, ζ', and $(x,z)\in S$. This along with (4.6) gives that we can choose C independent of h, ζ', and $(x,\zeta)\in S$ such that

$$\int_\Omega\frac{1}{4\pi}\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}|e^{ik|x-x'|}-e^{ik\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}|dx'\le Ch.$$

The integral of the first term on the right-hand side of (4.5) can be bounded as follows:

$$\begin{aligned}
&\int_\Omega\left|\frac{1}{4\pi}e^{ik|x-x'|}\left[\frac{1}{|x-x'|}-\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\right]\right|dx'\\
&\le\int_\Omega\left|\frac{1}{|x-x'|}-\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\right|dx'\\
&=\int_\Omega\left(\frac{1}{|x-x'|}-\frac{1}{\sqrt{|x-x'|^2+h^2|\zeta-\zeta'|^2}}\right)dx'
\end{aligned}$$

since the integrand is nonnegative. Now choose R large enough so that if $B_R(x)$ is the ball of radius R centered at x in $\mathbb{R}^2$,

$$\Omega \subset B_R(x)$$

for all $x \in \Omega$. Then the above is bounded by

$$\int_{B_R(x)} \left(\frac{1}{|x-x'|} - \frac{1}{\sqrt{|x-x'|^2 + h^2|\zeta-\zeta'|^2}} \right) dx'.$$

Change to polar coordinates centered at x with

$$r = |x-x'|.$$

The integral transforms to

$$\begin{aligned} &2\pi \int_0^R \left(\frac{1}{r} - \frac{1}{\sqrt{r^2 + h^2|\zeta-\zeta'|^2}} \right) r dr \\ &= 2\pi \left[R - \sqrt{R^2 + h^2|\zeta-\zeta'|^2} + h|\zeta-\zeta'| \right] \end{aligned}$$

by direct calculation. This is then $O(h)$, where the constant is independent of $(x,\zeta) \in S$ and $\zeta' \in (-1/2, 1/2)$. This, combined with the bounds on the first integral, proves the lemma. □

Recall that our scaled domain S is given as

$$S = \Omega \times (-1/2, 1/2).$$

LEMMA 2. *Let $\epsilon_0(x)$ be piecewise continuous on Ω. Then the operator $T : L^2(S) \to L^2(S)$ given by*

$$(Tf)(x) = \int_S \epsilon_0(x') G(x,0,x',0) f(x',\zeta') dx' d\zeta',$$

where

$$G(x,0,x',0) = \frac{1}{4\pi} \frac{e^{ik|x-x'|}}{|x-x'|},$$

is compact. Moreover, if we view T on the Banach space of continuous functions,

$$T : C^0(\overline{S}) \to C^0(\overline{S}),$$

it is also a compact operator. Furthermore, $(I + k^2 T)$ is continuously invertible on both $L^2(S)$ and $C^0(\overline{S})$.

Proof. Since ϵ_0 is piecewise continuous, the kernel $\epsilon_0(x')G(x,0,x',0)$ is a finite sum of weakly singular kernels. Hence the fact that T is a compact operator on $C^0(\overline{S})$ follows from Theorem 1.11 of [1]. To show T is compact on $L^2(S)$, we will show that for any sequence $\{f_n\}$ such that $\|f_n\|_{L^2(S)} < M$ and $f_n \rightharpoonup 0$, the sequence $Tf_n \to 0$ in $L^2(S)$. Let

$$D := \{(x-x', \zeta-\zeta') \; ; \; (x,\zeta), (x',\zeta') \in S\}$$

and define

$$g(y,\eta) := e^{ik|y|}/|y| \text{ for } (y,\eta) \in D.$$

Then since $g \in L^1(D)$, there exists

$$g_m \in C^\infty(D) \quad \text{such that} \quad \|g - g_m\|_{L^1(D)} \to 0 \quad \text{as} \quad m \to \infty.$$

In the estimates that follow we use a standard result (see, for example, [7]). If $g \in L^1(D)$ and $f \in L^p(S)$ $(1 < p < \infty)$, then $(g * f) \in L^p(S)$ and

$$\|g * f\|_{L^p(S)} \le \|g\|_{L^1(D)} \|f\|_{L^p(S)}. \tag{4.7}$$

Now consider

$$\begin{aligned}
\|Tf_n\|^2_{L^2(S)} &= \int_S \left[\int_S \epsilon_0(x') G(x,0,x',0) f_n(x',\zeta') dx' d\zeta' \right]^2 dx d\zeta \\
&= \frac{1}{4\pi} \int_S \left[\int_S \epsilon_0(x') g(x-x',\zeta-\zeta') f_n(x',\zeta') dx' d\zeta' \right]^2 dx d\zeta.
\end{aligned}$$

Let $M_\epsilon = \|\epsilon_0\|_\infty$. By adding and subtracting g_m, we can bound the above by

$$\begin{aligned}
&\frac{M_\epsilon^2}{4\pi} \int_S \left[|g_m * f_n| + |(g - g_m) * f_n| \right]^2 dx d\zeta \\
&\le \frac{M_\epsilon^2}{2\pi} (\| g_m * f_n \|^2_{L^2(S)} + \| (g - g_m) * f_n \|^2_{L^2(S)}) \\
&\le \frac{M_\epsilon^2}{2\pi} (\| g_m * f_n \|^2_{L^2(S)} + \|g - g_m\|^2_{L^1(D)} M^2), \qquad (4.8)
\end{aligned}$$

with the last inequality obtained by using (4.7) with $p = 2$. Also, since

$$|g_m * f_n| \le \|g_m\|_{L^\infty(D)} \|f_n\|_{L^1(S)}$$

and $\|f_n\|_{L^1(S)}$ is bounded, by the Lebesgue dominated convergence theorem,

$$\lim_{n\to\infty} \|g_m * f_n\|_{L^2(S)} = \| \lim_{n\to\infty} (g_m * f_n) \|_{L^2(S)} = 0$$

since $\{f_n\}$ goes to zero weakly. For any given $\varepsilon > 0$, choose m large enough so that

$$\|g - g_m\|^2_{L^1(D)} M^2 < \varepsilon.$$

Then for this m we can choose n large enough that

$$\| g_m * f_n \|^2_{L^2(S)} < \varepsilon$$

also. Hence from (4.8)

$$\|Tf_n\|^2_{L^2(S)} \le C\varepsilon.$$

Therefore, $\lim_{n\to\infty} \|Tf_n\|^2_{L^2(S)} = 0$, and hence T is compact on $L^2(S)$.

Now, by the Fredholm theory (Corollary 1.17 of [1]), $I + k^2 T$ is invertible if $(I + k^2 T) f = 0$ has only the zero solution. The following argument holds on the Banach space X for both $X = L^2(S)$ and $X = C^0(\overline{S})$. Let $f \in X$ be a solution to

$(I + k^2T)f = 0$. Since for any $f \in X$, Tf depends only on $x \in \Omega$, the solution f satisfies

$$f = -k^2 Tf$$

and hence also depends only on x. Let

$$w(x,z) = \int_\Omega \epsilon_0(x') G(x,z,x',0) f(x') dx'.$$

By a slight abuse of notation, in what follows we will use Ω to denote $\Omega \times \{0\}$. Using the equation for G, its conditions at infinity, and standard arguments of single layer potential theory [4],

(a) $(\triangle + k^2)w(x,z) = 0$ in $\mathbb{R}^3 \setminus \Omega$,
(b) w satisfies the radiation condition,
(c) $[w]_\Omega = 0$,
(d) $\left[\frac{\partial w}{\partial z}\right]_\Omega = \epsilon_0 f$,

where $[\cdot]$ denotes the jump across Ω, i.e.,

$$[g] = \lim_{z \to 0^+} g(x,z) - \lim_{z \to 0^-} g(x,z).$$

Let B_R be any ball in $\mathbb{R}^3$ containing Ω, multiply through by $\overline{w}$, and integrate by parts to get

$$\int_{B_R \setminus \Omega} |\nabla w|^2 - k^2 \int_{B_R \setminus \Omega} |w|^2 - \int_{\partial B_R} \overline{w} \frac{\partial w}{\partial \nu} - \int_\Omega \overline{w} \left[\frac{\partial w}{\partial z}\right]_\Omega = 0.$$

Since $(I + k^2T)f = 0$, we conclude that $f = -k^2 w$ on Ω. Substituting this and property (d) in the identity above, we get

$$\int_{B_R \setminus \Omega} |\nabla w|^2 - k^2 \int_{B_R \setminus \Omega} |w|^2 - \int_{\partial B_R} \overline{w} \frac{\partial w}{\partial \nu} + \frac{1}{k^2} \int_\Omega \epsilon_0 |f|^2 = 0.$$

Hence

$$\operatorname{Im} \int_{\partial B_R} \overline{w} \frac{\partial w}{\partial \nu} = 0.$$

We can now use the Rellich lemma (see Theorem 3.12 of [1]) on any domain $U \in \mathbb{R}^3$ arbitrarily close to Ω to obtain $w = 0$ in $B_R \setminus U$. Hence $w = 0$ on $\mathbb{R}^3 \setminus \Omega$. Thus the jump $\left[\frac{\partial w}{\partial z}\right]_\Omega = 0$. By property (d), we can conclude that $f = 0$. □

Note an immediate corollary of the above lemma is that u_0 exists, is unique, and is in $C^0(\overline{S})$.

Proof of Proposition 1. Note that for each fixed h, the right-hand side of (4.4) is a continuous function. We take a Taylor expansion of the smooth incident wave $u_{\mathbf{i}}$ for the first term. We then invoke Lemma 1 for the third term to obtain the bound

$$\|(I + k^2T)(\tilde{u} - u_0)\|_{L^\infty(S)} \leq h\|u_{\mathbf{i}}\|_{C^1(S)} + C_1 h \|\tilde{u}\|_{L^\infty(S)} + C_2 h \|\tilde{u}\|_{L^\infty(S)}.$$

By the boundedness of $(I + k^2T)^{-1}$, we have that

$$\begin{aligned} \|\tilde{u} - u_0\|_{L^\infty(S)} &\leq C_3 h \|u_{\mathbf{i}}\|_{C^1(S)} + C_4 h \|\tilde{u}\|_{L^\infty(S)} \\ &\leq C_3 h \|u_{\mathbf{i}}\|_{C^1(S)} + C_4 h \|\tilde{u} - u_0\|_{L^\infty(S)} + C_4 h \|u_0\|_{L^\infty(S)}. \end{aligned}$$

Since we know u_0 is continuous and u_{i} is bounded in C^1, we have that there exists a C_5 independent of h such that

$$(1 - C_4 h)\|\tilde{u} - u_0\|_{L^\infty(S)} \leq C_5 h,$$

from which the result follows for h small enough. □

5. The next term and its justification. First we find formally an equation for u_1, the next term in the expansion. We begin with the ansatz and Taylor expansion

$$\tilde{u}(x,\zeta) = u_0(x) + h u_1(x,\zeta) + O(h^2),$$

$$u_{\mathrm{i}}(x, h\zeta) = u_{\mathrm{i}}(x,0) + h\zeta \frac{\partial u_{\mathrm{i}}}{\partial z}(x,0) + O(h^2),$$

and, in order to obtain some sort of expansion for G, we consider the function v_h,

$$v_h(x,z) = \int_S \epsilon_0(x') G(x,z,x',h\zeta') u_0(x') d\zeta' dx'.$$

From Lemma 1, it seems that as $h \to 0$, $v_h(x,h\zeta)$ should converge $O(h)$ to $v_0(x)$, where

$$v_0(x) = \int_\Omega \epsilon_0(x') G(x,0,x',0) u_0(x') dx'.$$

So it seems reasonable to define

$$v_1(x,\zeta) = \lim_{h\to 0} \frac{v_h(x,h\zeta) - v_0(x)}{h},$$

so that if the limit exists, we have

$$v_h(x,h\zeta) = v_0(x) + h v_1(x,\zeta) + o(h).$$

Insert these expansions into (4.3) and match like powers of h. The $O(1)$ terms give the equation for u_0. The terms of $O(h)$ yield

$$\begin{aligned} u_1(x,\zeta) = \zeta \frac{\partial u_{\mathrm{i}}}{\partial z}(x,0) - k^2 \int_\Omega \int_{-1/2}^{1/2} \epsilon_0(x') G(x,0,x',0) u_1(x,\zeta') d\zeta' dx' \\ + k^2 \int_\Omega \int_{-1/2}^{1/2} G(x,0,x',0) u_0(x') d\zeta' dx' - k^2 v_1(x,\zeta). \end{aligned}$$

We use the definition of the operator T defined in the last section to obtain

$$\begin{aligned} u_1(x,\zeta) = -k^2 T u_1 + \zeta \frac{\partial u_{\mathrm{i}}}{\partial z}(x,0) - k^2 v_1(x,\zeta) \\ + k^2 \int_\Omega G(x,0,x',0) u_0(x') dx'. \end{aligned} \tag{5.1}$$

To complete our definition of u_1 we need to find an expression for $v_1(x,\zeta)$.

LEMMA 3. *Given any fixed $(x,\zeta) \in S$ and any ρ small enough such that the 2-D ball around x of radius ρ, $B_{x,\rho}$, is contained in Ω, then*

$$\lim_{h\to 0} \frac{1}{h} \int_{-\frac{1}{2}}^{\frac{1}{2}} \int_{B_{x,\rho}} [G(x,h\zeta,x',h\zeta') - G(x,0,x',0)] dx' d\zeta' = -\frac{1}{2}\left(\zeta^2 + \frac{1}{4}\right).$$

Proof. Before dividing by h, the integral above can be written as

$$\begin{aligned} I &= \frac{2\pi}{4\pi}\int_{-\frac{1}{2}}^{\frac{1}{2}}\int_0^{\rho}\left(\frac{e^{ik\sqrt{r^2+h^2(\zeta-\zeta')^2}}}{\sqrt{r^2+h^2(\zeta-\zeta')^2}}-\frac{e^{ikr}}{r}\right)rdrd\zeta' \\ &= \frac{1}{2}\int_{-\frac{1}{2}}^{\frac{1}{2}}\frac{1}{ik}\left(e^{ik\sqrt{\rho^2+h^2(\zeta-\zeta')^2}}-e^{ik\rho}\right)d\zeta'-\frac{1}{2}\int_{-\frac{1}{2}}^{\frac{1}{2}}\frac{1}{ik}\left(e^{ik|h(\zeta-\zeta')|}-1\right)d\zeta' \\ &= I_1+I_2. \end{aligned}$$

Since

$$\frac{\partial}{\partial h}\left(e^{ik\sqrt{\rho^2+h^2(\zeta-\zeta')^2}}\right)$$

is integrable, one can compute

$$\lim_{h\to 0^+}\frac{1}{h}I_1=\lim_{h\to 0^+}\frac{1}{2}\int_{-\frac{1}{2}}^{\frac{1}{2}}\frac{1}{ik}\frac{\partial}{\partial h}\left(e^{ik\sqrt{\rho^2+h^2(\zeta-\zeta')^2}}\right)d\zeta'=0.$$

The second term,

$$\lim_{h\to 0^+}\frac{1}{h}I_2=-\frac{1}{2}\int_{-\frac{1}{2}}^{\frac{1}{2}}|(\zeta-\zeta')|d\zeta'=-\frac{1}{2}\left(\zeta^2+\frac{1}{4}\right). \qquad \square$$

Note that in the previous lemma, although the limit holds pointwise, it is not uniform as x approaches the boundary of Ω. It is this observation that will lead to a boundary correction which we will examine in a forthcoming paper. For shorthand, in what follows we use the notation

$$G=G(x,h\zeta,x',h\zeta') \quad \text{and} \quad G_0=G(x,0,x',0).$$

PROPOSITION 2. *For any $g\in L^\infty(\Omega)$ such that $g\in C^0(B_{x,\rho})$ for some ρ small enough,*

$$\lim_{h\to 0}\frac{1}{h}\int_S g(x')[G-G_0]dx'd\zeta'=-\frac{1}{2}g(x)\left(\zeta^2+\frac{1}{4}\right).$$

Proof. For any small $\varepsilon>0$, choose ρ small enough so that

$$|g(x')-g(x)|<\varepsilon$$

for any $x',x\in B_{x,\rho}$. Consider

$$\begin{aligned}\int_S g(x')[G-G_0]dx'd\zeta' &= \int_{-\frac{1}{2}}^{\frac{1}{2}}\int_{\Omega\setminus B_{x,\rho}}[G-G_0]g(x')dx'd\zeta' \\ &\quad + \int_{-\frac{1}{2}}^{\frac{1}{2}}\int_{B_{x,\rho}}[G-G_0]g(x')dx'd\zeta' \\ &= \int_{-\frac{1}{2}}^{\frac{1}{2}}\int_{\Omega\setminus B_{x,\rho}}[G-G_0]g(x')dx'd\zeta' \\ &\quad + g(x)\int_{-\frac{1}{2}}^{\frac{1}{2}}\int_{B_{x,\rho}}[G-G_0]dx'd\zeta' \\ &\quad + \int_{-\frac{1}{2}}^{\frac{1}{2}}\int_{B_{x,\rho}}[G-G_0][g(x')-g(x)]dx'd\zeta' \\ &= I_1+I_2+I_3.\end{aligned}$$

We first examine I_1. For fixed ρ, we are away from the singularity and can expand the integrand. Define

$$h(y)=\frac{e^{\sqrt{y}}}{\sqrt{y}}.$$

By the mean value theorem, for $y>0$,

$$|h(y+\delta)-h(y)|\le\delta\sup_{[y,y+\delta]}|h'|. \tag{5.2}$$

Note that here,

$$h'(y)=\frac{e^{\sqrt{y}}}{2}\left[\frac{1}{y}-\frac{1}{y^{3/2}}\right].$$

Apply (5.2) with

$$y=|x-x'|^2$$

and

$$\delta=h^2|\zeta-\zeta'|^2.$$

This yields

$$|G-G_0|\le Ch^2\left[\frac{1}{\rho^2}-\frac{1}{\rho^3}\right],$$

where C is independent of h, x', and ζ'. Since $g\in L^\infty$ and ρ is fixed,

$$\lim_{h\to0}\frac{1}{h}I_1=0.$$

By Lemma 3,

$$\lim_{h\to0}\frac{1}{h}I_2=-\frac{1}{2}g(x)\left(\zeta^2+\frac{1}{4}\right).$$

For the last term,

$$\begin{aligned}\frac{1}{h}|I_3| &\le \left\|\frac{G-G_0}{h}\right\|_{L^1(S)} \|g(x')-g(x)\|_{L^\infty(B_{x,\rho})} \\ &\le C\varepsilon\end{aligned}$$

by Lemma 1 and our choice of ρ. From the limits above, we can choose h small enough that

$$\left|\frac{1}{h}\int_S g(x')[G-G_0]dx'd\zeta' + \frac{1}{2}g(x)\left(\zeta^2+\frac{1}{4}\right)\right| \le C\varepsilon+\varepsilon$$

from which the result follows. □

Note that u_0 is continuous from Lemma 2. By setting $g(x) = \epsilon_0(x)u_0(x)$ in Proposition 2, we have that

$$v_1(x) = -\frac{1}{2}\epsilon_0(x)u_0(x)\left(\zeta^2+\frac{1}{4}\right)$$

pointwise almost everywhere in Ω, assuming $\epsilon_0(x)$ is piecewise continuous. Using (5.1), this means that u_1 satisfies

$$\begin{aligned}u_1(x,\zeta) = \zeta\frac{\partial u_{\mathrm{i}}}{\partial z}(x,0) - k^2\int_S \epsilon_0(x')u_1(x',\zeta')G_0 d\zeta' dx' \\ + k^2\int_\Omega u_0(x')G_0dx' + \frac{1}{2}k^2\left(\zeta^2+\frac{1}{4}\right)u_0(x)\epsilon_0(x).\end{aligned} \tag{5.3}$$

To compute a simpler expression for u_1, we first note that from the symmetry of the integral with respect to ζ' we have

$$T\left(\zeta\frac{\partial u_{\mathrm{i}}}{\partial z}(x,0)\right) \equiv 0.$$

Hence $u_1(x,\zeta)$ has the form

$$u_1(x,\zeta) = \hat{u}_1(x) + \zeta\frac{\partial u_{\mathrm{i}}}{\partial z}(x,0) + \frac{1}{2}\zeta^2k^2u_0(x)\epsilon_0(x), \tag{5.4}$$

where $\hat{u}_1(x)$ is the solution to the lower dimensional integral equation

$$\begin{aligned}(I+k^2T)\hat{u}_1(x) = k^2\int_\Omega G(x,0,x',0)u_0(x')dx' \\ -\frac{k^4}{24}\int_\Omega G(x,0,x',0)\epsilon_0^2(x')u_0(x')dx' + \frac{1}{8}k^2u_0(x)\epsilon_0(x).\end{aligned} \tag{5.5}$$

One can verify this by taking $(I+k^2T)$ of both sides of (5.4) and using (5.3) to eliminate u_1. We show the following convergence estimate.

PROPOSITION 3. *Suppose that $\epsilon_0(x)$ is piecewise continuous. Let $\tilde{u}(x,\zeta), u_0(x)$, and $u_1(x,\zeta)$ be given by* (4.3), (4.2), (5.4), *and* (5.5), *respectively. Then as $h \to 0$,*

$$\|\tilde{u} - (u_0 + hu_1)\|_{L^2(S)} = o(h).$$

Proof. Define the error by

$$e = \tilde{u} - (u_0 + hu_1).$$

Then, by using the integral equations for each term we obtain

$$\begin{aligned} e &= u_{\mathrm{i}}(x, h\zeta) + k^2 h \int_S G(x, h\zeta, x', h\zeta')\tilde{u}(x', \zeta')d\zeta' dx' \\ &- k^2 \int_S \epsilon_0(x')G(x, h\zeta, x', h\zeta')\tilde{u}(x', \zeta')d\zeta' dx' - u_{\mathrm{i}}(x, 0) + k^2 T u_0 \\ &- h\zeta \frac{\partial u_{\mathrm{i}}}{\partial z}(x, 0) + hk^2 T u_1 - hk^2 \int_\Omega u_0(x')G(x, 0, x', 0)dx' - \frac{h}{2}k^2 \left(\zeta^2 + \frac{1}{4}\right) u_0(x)\epsilon_0(x). \end{aligned}$$

By adding $k^2 Te$ to both sides and rearranging terms,

$$\begin{aligned} (I + k^2 T)e = u_{\mathrm{i}} &- \left[u_{\mathrm{i}}(x, 0) + h\zeta \frac{\partial u_{\mathrm{i}}}{\partial z}(x, 0)\right] \\ &+ k^2 h \int_S G(x, h\zeta, x', h\zeta')\tilde{u}(x', \zeta')d\zeta' dx' - hk^2 \int_\Omega u_0(x')G(x, 0, x', 0)dx' \\ &+ k^2 \int_S \epsilon_0(x')u_0(x')[G_0 - G]dx' d\zeta' - h\frac{k^2}{2}\left(\zeta^2 + \frac{1}{4}\right) u_0(x)\epsilon_0(x) \\ &+ k^2 \int_S \epsilon_0(x')[G_0 - G](\tilde{u}(x', \zeta') - u_0(x'))d\zeta' dx'. \end{aligned}$$

We will refer to each set of expressions on each line on the right-hand side of the above as $term_1$, $term_2$, $term_3$, and $term_4$. Now, $term_1$ is clearly $O(h^2)$ in L^2 by a Taylor expansion of u_{i}. In $term_2$, we can use Lemma 1 to approximate G by G_0 and commit an error of $O(h)$. Hence $term_2$ becomes

$$hk^2 T\left(\frac{\tilde{u} - u_0}{\epsilon_0}\right) + o(h),$$

which from Proposition 1 and the boundedness of T is $o(h)$ in $L^2(S)$. Consider $term_3/h$. By Proposition 2 and the fact that $g = \epsilon_0 u_0$ is piecewise continuous, this ratio approaches zero pointwise almost everywhere. So,

$$\left\{\left(\frac{term_3}{h}\right)^2\right\}$$

is a sequence of functions converging pointwise almost everywhere to zero, and by Lemma 1, they are uniformly bounded on a bounded domain (and hence in L^1). The Lebesgue dominated convergence theorem therefore yields $term_3/h \to 0$ in $L^2(S)$. Finally, for $term_4$, we can again use Proposition 2 with $g = \epsilon_0(\tilde{u} - u_0)$ to obtain

$$term_4 = h\frac{k^2}{2}\left(\zeta^2 + \frac{1}{4}\right)\epsilon_0(x)(\tilde{u}(x) - u_0(x)) + o(h),$$

which is $o(h)$ in $L^2(S)$ by Proposition 1. We have now shown that

$$\|(I + k^2 T)e\|_{L^2(S)} = o(h).$$

The result follows from Lemma 2. ∎

6. Numerical results. In this section we will show some numerical results. Our goal is to demonstrate the properties of the approximation method, and in order to reduce the computational complexity, we consider 2-D scattering. We will compare results obtained using the approximate method with those obtained by solving the full Lippmann–Schwinger equation numerically.

In two dimensions, we reduce the region Ω to a line segment $\Omega = [-L, L]$. Of course, more general regions consisting of multiple line segments can be considered. The fundamental solution in two dimensions is

$$G(x, \zeta, x', \zeta') = \frac{i}{4} H_0^{(1)} \left(k|(x, \zeta) - (x', \zeta')| \right),$$

where $H_0^{(1)}$ is a Hankel function of the first kind. One can justify that the formula for u_0 is the same as in the 3-D case. The equation satisfied by u_1 hinges on Lemma 3. The result of Lemma 3 applies to the 2-D case without modification. This can be shown by direct calculation. Therefore, the equations for u_0 and u_1 are again (3.5) and (5.4)–(5.5), with the Green's function replaced by the above 2-D version.

In order to obtain solutions to which we compare our approximate solutions, we will solve a 2-D scattering problem. The equation we need to solve is the 2-D version of (3.1). We use piecewise bilinear functions to approximate the exact solution u and discretize the integral equation (3.1) to solve for u. Of particular interest is the solution $u(x, z)$ in the scatterer $S = \Omega \times [-h/2, h/2]$.

We will solve for the approximate solutions $u_0(x)$ using (3.5), and $u_1(x, z)$ using (5.4)–(5.5). To accomplish this, we discretize the integral equations using piecewise linear representations of $u_0(x)$ and $\hat{u}_1$.

The length of the scatterer is $L = 5$, and the thickness is $h = 0.1$. In solving the 2-D problem, we choose a mesh size of 0.02 in the direction of the membrane and 0.025 across its thickness. When solving for u_0 and $\hat{u}_1$, we discretize the interval with mesh size 0.02.

We will solve the scattering problem for three wave numbers, $k = 4$, 8, and 12. We choose the incident wave to be a plane wave of the form

$$u_{\mathrm{i}} = \exp ik(x \cos\theta + z \sin\theta).$$

The wavelengths in the scatterer under these conditions are computed and summarized in Table 6.1. Therefore, one can compare the wavelength with the scatterer thickness $h = 0.1$. For example, at $k = 8$ the thickness is approximately 1/4 the wavelength when $\epsilon = 3$ and approximately 1/3 the wavelength when $\epsilon = 9$.

TABLE 6.1
Wavelength in the scatterer as a function of wave number k and dielectric constant ϵ.

k	$\epsilon = 3$	$\epsilon = 9$
4	0.91	0.52
8	0.45	0.26
12	0.30	0.17

We are particularly interested in the accuracy of the solution on the scatterer itself. In the first experiment, we solve the scattering problem with $k = 8$ with incident wave hitting a uniform scatterer at -45° degrees. For dielectric constant $\epsilon = 3$, the results are shown in Figure 6.1. This is a good situation as the wavelength in the scatterer is more than 4 times the thickness. The error, as can be seen in the figure, is quite small, with the largest disagreement occurring at the bottom of the

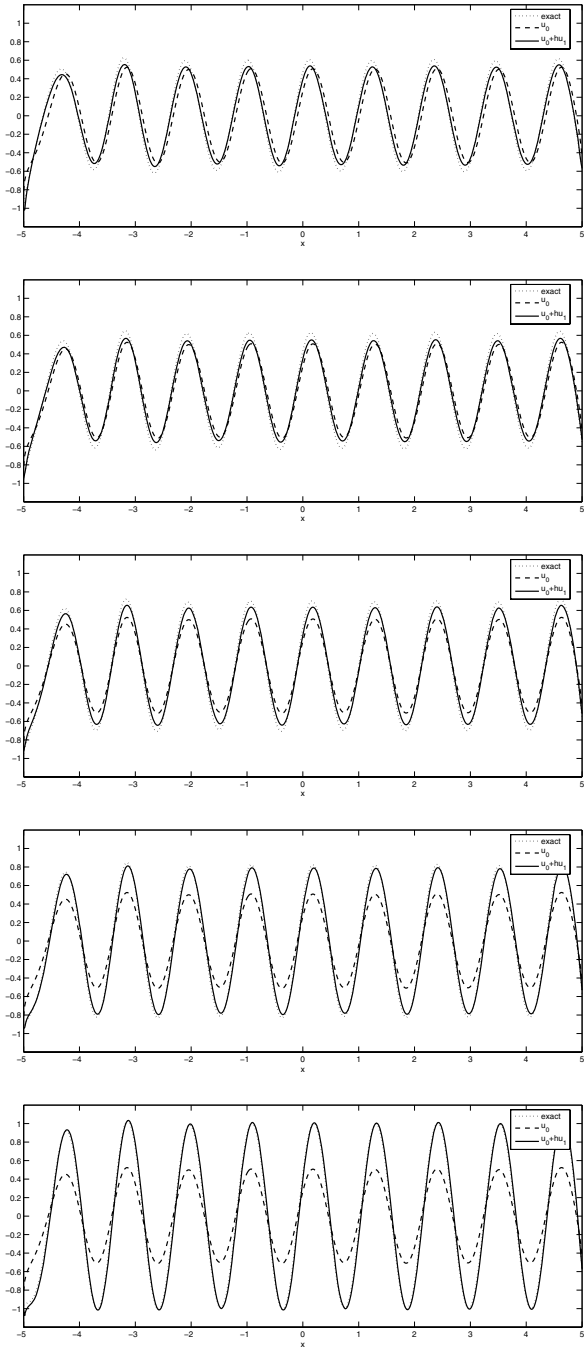

FIG. 6.1. *Top to bottom: real part of* $u(x,z)$ *for* $\epsilon = 3$ *at* $z = -0.05, -0.025, 0, 0.025, 0.05$. *Shown in dots are the exact solutions, and in solid, the approximation* $u_0 + hu_1$. *Also, shown in dashes is the leading order approximation* u_0.

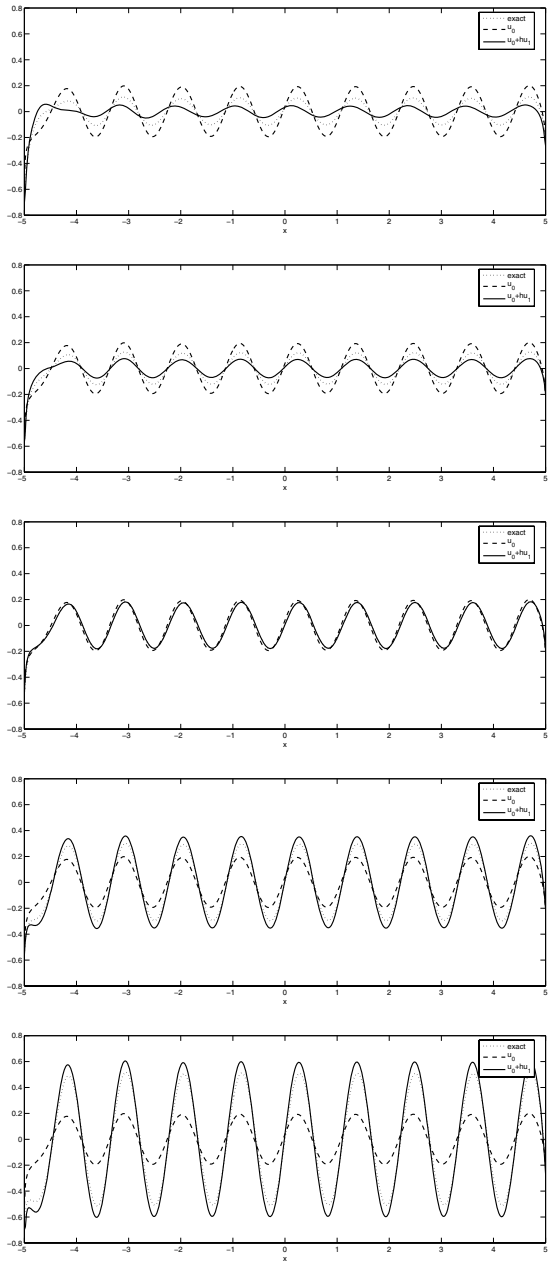

FIG. 6.2. *Top to bottom: real part of* $u(x,z)$ *when* $\epsilon = 9$ *at* $z = -0.05, -0.025, 0, 0.025, 0.05$.

scatterer. There is also some discrepancy at the leading and trailing edges of the scatterer since we have not accounted for the boundary layer.

When the dielectric constant ϵ is 9, the approximation deteriorates. Under this condition, the wavelength is only 2.6 times bigger than the thickness of the scatterer. While the corrector u_1 does improve over the leading order approximation u_0, the error is still quite noticeable. The results are shown in Figure 6.2.

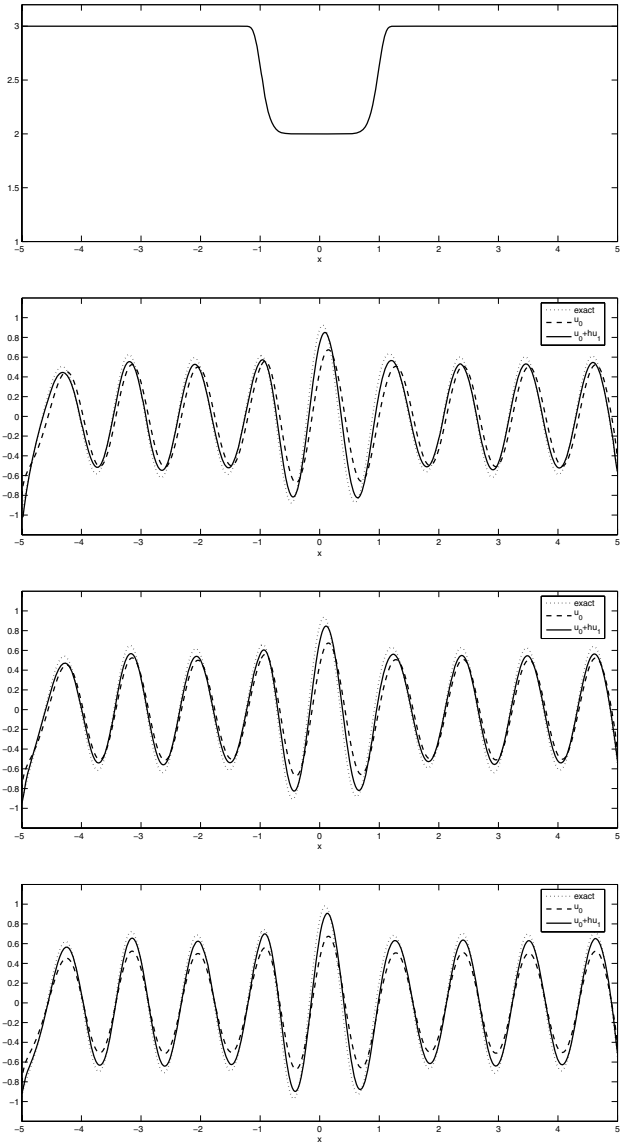

FIG. 6.3. *Top to bottom: the function $\epsilon(x)$, followed by the real part of $u(x,z)$ at $z = -0.05, -0.025, 0$.*

A final example is given when ϵ is x dependent. The distribution of $\epsilon(x)$ is shown in Figure 6.3, together with the solution at various z-values.

Next we calculate the relative L^2 error of the approximation. The L^2 norm is calculated by taking the values of a function at the node points of the regular mesh and interpolating with bilinear splines to obtain an estimate of the function. The interpolated function is then squared and integrated over the domain. The results of the calculations are displayed in Table 6.2. When $\epsilon = 3$, the error increases as a function of k. This is to be expected as the wavelength in the scatterer becomes smaller in comparison to the thickness. When $\epsilon = 9$, the errors follow the same trend

TABLE 6.2
Relative L^2 error of the approximation $u_0 + hu_1$.

	k	Angle of incidence 45°	Normal incidence
$\epsilon = 3$	4	0.0614	0.0529
	8	0.1065	0.1129
	12	0.1413	0.1614
$\epsilon = 9$	4	0.0226	0.0248
	8	0.2058	0.2146
	12	0.6332	0.6567

as k is increased. However, notice that the error is actually smaller for $k = 4$ when $\epsilon = 9$ than when $\epsilon = 3$.

According to our estimates, for a fixed k, as we decrease h and scale ϵ as $1/h$, the error should decrease according to $o(h)$. The numerical examples presented here are meant to give an indication of the accuracy of our approximation.

7. Discussion. In this work, we developed an approximate method for solving a scattering problem where the scatterer is thin. We assume that the dielectric constant of the scatterer scales as $1/h$, where h is the thickness of the scatterer. We formulate the scattering problem using the Lippmann–Schwinger equation. Solution to this equation is approximated by a series in h. Both the leading order solution and the first order corrector can be found by solving an integral equation involving one fewer spatial variable than the original problem. This could lead to substantial savings in realistic computations.

We show that the leading order approximation is $O(h)$ accurate, while the approximation including the first order corrector is $o(h)$ accurate. Boundary layer correctors will be needed to improve the approximation. Finally, we present numerical examples that provide some quantitative assessment of the accuracy of the approximation.

Acknowledgments. The authors are grateful to Habib Ammari, Jay Gopalakrishnan, and Murali Rao for helpful discussions on this work. In particular, we thank Habib Ammari for his clever suggestion which led to the simpler uniqueness proof in Lemma 2.

AMERICAN OPTIONS WITH LOOKBACK PAYOFF*

MIN DAI† AND YUE KUEN KWOK‡

Abstract. We examine the early exercise policies and pricing behaviors of one-asset American options with lookback payoff structures. The classes of option models considered include floating strike lookback options, Russian options, fixed strike lookback options, and the pricing model of the dynamic protection fund. For each class of the American lookback options, we analyze the optimal stopping region, in particular the asymptotic behavior at times close to expiration and at infinite time to expiration. The interrelations between the price functions of these American lookback options are explored. The mathematical technique of analyzing the exercise boundary curves of lookback options at infinitesimally small asset values is also applied to the American two-asset minimum put option model.

1. Introduction.

In this paper, we consider the theoretical analysis of the optimal exercise policies of an American option with lookback payoff. An American lookback option involves the combination of two exotic features: the early exercise feature and the lookback feature. Like other American option models, the analysis of an American lookback option requires the solution of a free boundary value problem. The solution procedure involves the determination of the free exercise boundary that separates the stopping region and the continuation region. The analysis is further complicated by the presence of the path-dependent lookback state variable. For floating strike lookback options, the analysis is easier since the dimensionality of the pricing model can be reduced through homogeneity of the price function. This is achieved by taking the asset price as the numeraire. However, for American fixed strike lookback options, the exercise boundary is a two-dimensional curve in the state space described by the asset price and the lookback state variable.

Several earlier papers on American lookback options concentrated on the analysis of the Russian option [7, 17, 18], which is essentially a perpetual zero-strike fixed strike lookback call option. There have been only a few papers which have analyzed the optimal exercise behaviors of finite time American lookback options. Yu, Kwok, and Wu [22] developed finite difference algorithms to compute the exercise boundaries of both American fixed strike and floating strike lookback options. In their two papers [15, 16], Lai and Lim proposed the Bernoulli walk approach to compute the price functions and optimal exercise boundaries of American fixed strike and floating strike lookback options. They also obtained analytic price formulas for American lookback options using a decomposition, which expresses the price as the sum of the corresponding European value and an early exercise premium. Kwok [4] analyzed the exercise policies of American floating strike lookback options with quanto payoff. These quanto options involve an underlying foreign currency asset, but the payoffs are denominated in domestic currency.

We would like to provide a more comprehensive and thorough analysis of the exercise behaviors of the commonly traded American lookback options. Our analysis framework relies more on the partial differential equation approach, as opposed to the usual stochastic approach in most earlier works (say, [14, 15]). For the sake of completeness, we attempt to provide a comprehensive list of analytic properties of the exercise boundaries and stopping regions of the lookback option models. The classes of American lookback option models considered in this paper include the floating strike and fixed strike lookback call and put options, Russian options, and the pricing model of the dynamic protection fund. We analyze the exercise boundary of each class of lookback options, in particular the asymptotic behavior at times close to expiration and at infinite time to expiration. The interrelations between the price functions of these American lookback options are explored. We observe that our mathematical technique developed for analyzing the exercise boundary at infinitesimally small asset values for lookback options can be extended to the American two-asset minimum put option model. For all types of American lookback options considered in this paper, we performed numerical calculations to compute the corresponding exercise boundaries. These plots of exercise boundaries serve as the verification for all results derived from the theoretical studies of the optimal exercise policies.

2. Floating strike lookback options. In this section, we explore some analytic properties of the price functions and optimal exercise policies of the American floating strike lookback options. The usual assumptions of the Black–Scholes option pricing framework are adopted in this paper. Let S denote the price of the underlying asset of the lookback option, whose stochastic dynamics under the risk neutral measure is governed by

$$\frac{dS}{S} = (r - q)dt + \sigma\, dZ, \tag{2.1}$$

where t is the calendar time, r is the riskless interest rate, σ and q are the volatility and dividend yield of S, respectively, and Z is the standard Wiener process. We write τ as the time to expiry, $0 \le \tau < \infty$. Let m and M denote the realized minimum value and realized maximum value, respectively, of the asset price over the lookback monitoring period (continuous monitoring is assumed) up to the current time. The payoff functions of the American floating strike lookback call and lookback put are taken to be

$$(\alpha S - m)^+ \quad \text{and} \quad (M - \alpha S)^+,$$

respectively, where α is a positive parameter value, $0 < \alpha < \infty$, and $x^+ = \max(x, 0)$. When $\alpha = 1$, we recover the usual lookback payoffs. While lookback options are less attractive to investors due to their high option premium, the parameter α allows flexible adjustment of the resulting option premium. For example, we may take α to be less (greater) than one in the floating strike call (put) payoff so as to achieve option premium reduction. Furthermore, the addition of the parameter α in the pricing model facilitates our asymptotic analysis of the exercise boundary curves at the limit of infinitesimally small asset values.

2.1. American floating strike lookback call. Let $C_{f\ell}(S,m,\tau)$ denote the price function of an American floating strike lookback call with payoff $(\alpha S - m)^+$. The linear complementarity formulation that governs $C_{f\ell}(S,m,\tau)$ is given by (see [12] and [21])

$$\begin{aligned} &\frac{\partial C_{f\ell}}{\partial \tau} - \mathcal{L} C_{f\ell} \geq 0, \quad C_{f\ell} \geq \alpha S - m, \\ &\left(\frac{\partial C_{f\ell}}{\partial \tau} - \mathcal{L} C_{f\ell}\right)[C_{f\ell} - (\alpha S - m)] = 0, \quad S > m > 0, \quad \tau > 0, \end{aligned} \tag{2.2}$$

with auxiliary conditions

$$\begin{aligned} &\left.\frac{\partial C_{f\ell}}{\partial m}\right|_{S=m} = 0, \\ &C_{f\ell}(S,m,0) = (\alpha S - m)^+. \end{aligned} \tag{2.3}$$

The operator $\mathcal{L}$ is defined by

$$\mathcal{L} = \frac{\sigma^2}{2} S^2 \frac{\partial^2}{\partial S^2} + (r-q) S \frac{\partial}{\partial S} - r.$$

Note that the payoff upon early exercise is guaranteed to be positive so that we can replace the payoff function $(\alpha S - m)^+$ by $\alpha S - m$. However, we cannot do so for the terminal payoff at $\tau = 0$. The dimension of the above formulation can be reduced by one if we define the following transformation of variables:

$$\eta = \frac{m}{S} \quad \text{and} \quad \widetilde{C_{f\ell}}(\eta,\tau) = \frac{C_{f\ell}(S,m,\tau)}{S}. \tag{2.4}$$

This is equivalent to taking S as the numeraire. The new linear complementarity formulation for $\widetilde{C_{f\ell}}(\eta,\tau)$ is given by

$$\begin{aligned} &\frac{\partial \widetilde{C_{f\ell}}}{\partial \tau} - \widetilde{\mathcal{L}}\, \widetilde{C_{f\ell}} \geq 0, \quad \widetilde{C_{f\ell}} \geq \alpha - \eta, \\ &\left(\frac{\partial \widetilde{C_{f\ell}}}{\partial \tau} - \widetilde{\mathcal{L}}\, \widetilde{C_{f\ell}}\right)[\widetilde{C_{f\ell}} - (\alpha - \eta)] = 0, \quad 0 < \eta < 1, \quad \tau > 0, \end{aligned} \tag{2.5}$$

with auxiliary conditions

$$\begin{aligned} &\left.\frac{\partial \widetilde{C_{f\ell}}}{\partial \eta}\right|_{\eta=1} = 0, \\ &\widetilde{C_{f\ell}}(\eta,0) = (\alpha - \eta)^+, \end{aligned} \tag{2.6}$$

where the operator $\widetilde{\mathcal{L}}$ is given by

$$\widetilde{\mathcal{L}} = \frac{\sigma^2}{2} \eta^2 \frac{\partial^2}{\partial \eta^2} + (q-r)\eta \frac{\partial}{\partial \eta} - q.$$

Remark. The normal reflection condition in (2.6) plays a crucial role in distinguishing the optimal exercise policies of American lookback options from the usual American options. The auxiliary condition is derived from the observation that the

lookback option value is insensitive to the running extremum value when the current asset value equals the extremum value. This is because the probability that the current extremum value remains to be the realized extremum value at maturity is essentially zero when the current asset value and running extremum value are equal (see [10]). In a more recent work, Peskir [17] presented a proof on the normal reflection condition for the finite time Russian option. A similar proof can be mimicked for an American lookback option with a more general lookback payoff.

The holder optimally exercises the lookback call whenever S reaches a sufficiently high level. In terms of η, the holder chooses to exercise when $\eta \leq \eta^*$, where the threshold η^* has dependence on τ. The domain of the pricing model can be divided into two regions: the stopping region $\mathcal{S} = \{(\eta, \tau) : 0 < \eta \leq \eta^*(\tau),\ 0 < \tau < \infty\}$, inside which it is optimal to exercise the option, and the continuation region $\mathcal{S}^C = \{(\eta, \tau) : \eta^*(\tau) < \eta \leq 1,\ 0 \leq \tau < \infty\}$, inside which it is optimal to continue to hold the option. Upon exercise, we have $\widetilde{C}_{f\ell} = \alpha - \eta$ so that the stopping region is defined by

$$\mathcal{S} = \{(\eta, \tau) : 0 < \eta \leq 1,\ 0 \leq \tau < \infty, \text{ and } \widetilde{C}_{f\ell}(\eta, \tau) = \alpha - \eta\}.$$

The analysis of the optimal exercise policies amounts to the analysis of the analytic properties of $\eta^*(\tau)$ that separate the continuation and stopping regions. Some of the analytic properties of $\eta^*(\tau)$ are summarized in Proposition 2.1.

PROPOSITION 2.1. *The exercise boundary $\eta^*(\tau; \alpha)$ of the American floating strike lookback call option observes the following properties:*

(i) *Suppose $(\eta, \tau) \in \mathcal{S}^C$; then $(\lambda_1 \eta, \lambda_2 \tau) \in \mathcal{S}^C$ for all $\lambda_1 \geq 1$, $\lambda_2 \geq 1$.*

(ii) *The line $\eta = 1$ always lies inside $\mathcal{S}^C$ for a finite value of α.*

(iii) *The behavior of $\eta^*(\tau; \alpha)$ near expiry, $\tau \to 0^+$, is given by*

$$\eta^*(0^+; \alpha) = \min\left(1, \alpha, \frac{q}{r}\alpha\right).$$

When $q > 0$, $\eta^*(0^+; \alpha)$ is guaranteed to be positive so that there exists at least a line segment, $\tau = 0$, where $0 < \eta < \eta^*(0^+; \alpha)$, in the stopping region. Property (ii) reveals that the line $\eta = 1$ lies in the continuation region. Hence, we can conclude that both the continuation and stopping regions exist in the η-τ plane. Further, by virtue of (i), the free boundary $\eta^*(\tau; \alpha)$ that separates the stopping and continuation regions can be deduced to be monotonically decreasing with respect to τ. In conclusion, for $q > 0$, there exists the monotonic free boundary $\eta^*(\tau; \alpha)$ such that $\widetilde{C}_{f\ell} = \alpha - \eta$ for $\eta \leq \eta^*(\tau; \alpha)$, $\tau > 0$. The details of the proof of Proposition 2.1 are presented in Appendix A. Further asymptotic properties of $\eta^*(\tau; \alpha)$ with respect to $\tau \to \infty$ and $\alpha \to \infty$ are stated in Proposition 2.2.

PROPOSITION 2.2. *When $q > 0$, the asymptotic behaviors at $\tau \to \infty$ and $\alpha \to \infty$ of the exercise boundary $\eta^*(\tau; \alpha)$ of the American floating strike lookback call option are summarized as follows.*

(i) *Write $\eta^*_\infty(\alpha)$ as $\lim_{\tau \to \infty} \eta^*(\tau; \alpha)$; $\eta^*_\infty(\alpha)$ is given by the solution of the root inside the interval $(0, 1)$ of the following algebraic equation:*

$$(\eta^*_\infty)^{\lambda_+ - \lambda_-} = \frac{\lambda_+}{\lambda_-} \frac{(1 - \lambda_-)\eta^*_\infty + \lambda_- \alpha}{(1 - \lambda_+)\eta^*_\infty + \lambda_+ \alpha},$$

where

$$\lambda_\pm = \frac{r - q}{\sigma^2} + \frac{1}{2} \pm \sqrt{\left(\frac{r - q}{\sigma^2} + \frac{1}{2}\right)^2 + \frac{2q}{\sigma^2}}.$$

(ii) $\lim_{\alpha \to \infty} \eta^*(\tau; \alpha) = 1$ *for all τ.*

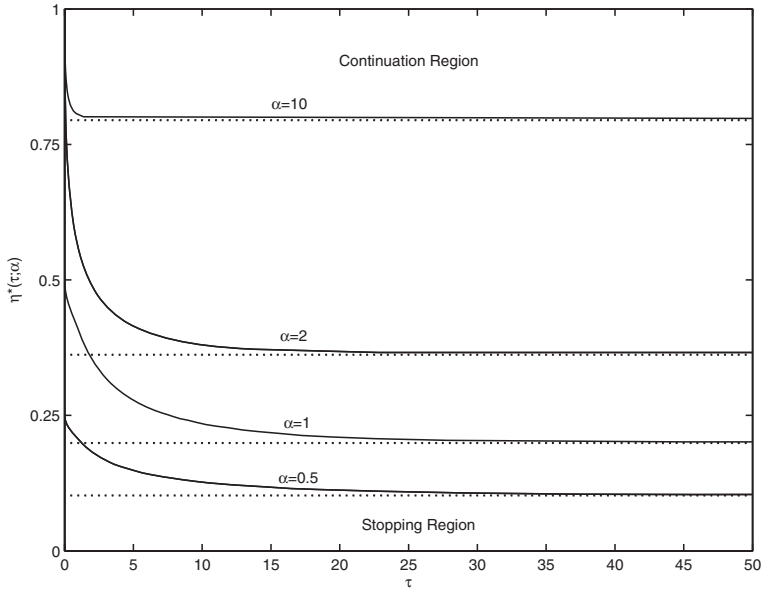

FIG. 1. *The critical threshold $\eta^*(\tau;\alpha)$ of the American floating strike lookback call option is plotted against τ for different values of α. The parameter values of the pricing model are $r = 0.04$, $q = 0.02$, and $\sigma = 0.3$.*

The proof of Proposition 2.2 is presented in Appendix B. From the monotonic decreasing property of $\eta^*(\tau;\alpha)$ with respect to τ and the finiteness property of $\eta^*_\infty(\alpha)$ for $q > 0$, we infer that $\eta^*(\tau;\alpha) > 0$ exists for all τ when $q > 0$. When $\alpha \to \infty$, the continuation region vanishes.

When the underlying asset is non–dividend-paying, $q = 0$, we have $\eta^*(0^+;\alpha) = 0$. Furthermore, since $\eta^*(\tau;\alpha)$ is monotonically decreasing with respect to τ, we deduce that $\eta^*(\tau;\alpha) = 0$ for $\tau > 0$. That is, the stopping region does not exist when $q = 0$. Interpreted in a financial sense, it is never optimal to exercise the American floating strike lookback call at any asset price level if the underlying asset is non–dividend-paying. Such a result agrees intuitively with a similar result of the usual American call.

Figure 1 shows the plot of $\eta^*(\tau;\alpha)$ against τ at varying values of α. The parameter values used in the calculations are $r = 0.04$, $q = 0.02$, and $\sigma = 0.3$. The monotonicity properties of $\eta^*(\tau;\alpha)$ with respect to τ and α and the asymptotic behaviors at $\tau \to 0^+$ and $\tau \to \infty$ as shown in the plots do agree with the results stated in Propositions 2.1 and 2.2. Our calculations give the following asymptotic values for $\eta^*(\tau;\alpha)$:

$$\begin{aligned} &\eta^*(0^+;0.5) = 0.25, \qquad &&\eta^*(\infty;0.5) = 0.1023,\\ &\eta^*(0^+;1) = 0.5, &&\eta^*(\infty;1) = 0.1988,\\ &\eta^*(0^+;2) = 1, &&\eta^*(\infty;2) = 0.3617,\\ &\eta^*(0^+;10) = 1, &&\eta^*(\infty;10) = 0.7947. \end{aligned}$$

2.2. American floating strike lookback put. Let $P_{f\ell}(S, M, \tau)$ denote the price function of an American floating strike lookback put with payoff $(M - \alpha S)^+$. The Russian option is the perpetual version of the American floating strike lookback

put with $\alpha = 0$. In a similar manner, we use S as the numeraire and define

$$\xi = \frac{M}{S} \quad \text{and} \quad \widetilde{P_{f\ell}}(\xi, \tau) = \frac{P_{f\ell}(S, M, \tau)}{S}. \tag{2.7}$$

The linear complementarity formulation for $\widetilde{P_{f\ell}}(\xi, \tau)$ is given by

$$\begin{aligned} &\frac{\partial \widetilde{P_{f\ell}}}{\partial \tau} - \widetilde{\mathcal{L}}\, \widetilde{P_{f\ell}} \geq 0, \quad \widetilde{P_{f\ell}} \geq \xi - \alpha, \\ &\left(\frac{\partial \widetilde{P_{f\ell}}}{\partial \tau} - \widetilde{\mathcal{L}}\, \widetilde{P_{f\ell}} \right) [\widetilde{P_{f\ell}} - (\xi - \alpha)] = 0, \quad 1 < \xi < \infty, \quad \tau > 0, \end{aligned} \tag{2.8}$$

with auxiliary conditions

$$\begin{aligned} &\left. \frac{\partial \widetilde{P_{f\ell}}}{\partial \xi} \right|_{\xi=1} = 0, \\ &\widetilde{P_{f\ell}}(\xi, 0) = (\xi - \alpha)^+. \end{aligned} \tag{2.9}$$

Similarly, we have the free boundary $\xi^*(\tau)$ that separates the stopping region $\{(\xi, \tau) : \xi \geq \xi^*(\tau),\ 0 \leq \tau < \infty\}$ and the continuation region $\{(\xi, \tau) : 1 \leq \xi < \xi^*(\tau),\ 0 \leq \tau < \infty\}$. The analytic properties of $\xi^*(\tau)$ are summarized in Proposition 2.3.

PROPOSITION 2.3. *The free boundary $\xi^*(\tau; \alpha)$ observes the following properties:*

(i) *$\xi^*(\tau; \alpha)$ is monotonically increasing with respect to τ and α.*

(ii) *The behavior of $\xi^*(\tau; \alpha)$ near expiry, $\tau \to 0^+$, is given by*

$$\xi^*(0^+; \alpha) = \max\left(1, \alpha, \frac{q}{r}\alpha\right).$$

(iii) *Write $\xi^*_\infty(\alpha)$ as $\lim_{\tau \to \infty} \xi^*(\tau; \alpha)$; $\xi^*_\infty(\alpha)$ is given by the solution of the root inside the interval $(1, \infty)$ of the following algebraic equation:*

$$(\xi^*_\infty)^{\lambda_+ - \lambda_-} = \frac{\lambda_+}{\lambda_-} \frac{(1 - \lambda_-)\xi^*_\infty + \lambda_- \alpha}{(1 - \lambda_+)\xi^*_\infty + \lambda_+ \alpha}.$$

In particular, when $q = 0$, we have

$$\xi^*_\infty(\alpha) = \infty.$$

As a remark, it is well known that it is never optimal to exercise a Russian option when the underlying asset is non–dividend-paying [18]. The above result shows that such an optimal exercise policy holds even for a nonzero value of α (a Russian option is the special case of $\alpha = 0$).

The ideas behind the proof of Proposition 2.3 are similar to those used in proving Propositions 2.1 and 2.2. In Figure 2, we show the plot of $\xi^*(\tau; \alpha)$ against τ with different values of α. The parameter values used in the calculations are $r = 0.02$, $q = 0.04$, and $\sigma = 0.3$. We obtained the following asymptotic values for $\xi^*(\tau; \alpha)$:

$$\begin{aligned} &\xi^*(0^+; 0) = 1, && \xi^*(\infty; 0) = 3.4939, \\ &\xi^*(0^+; 0.5) = 1, && \xi^*(\infty; 0.5) = 4.8536, \\ &\xi^*(0^+; 1) = 2, && \xi^*(\infty; 1) = 6.6068, \\ &\xi^*(0^+; 2) = 4, && \xi^*(\infty; 2) = 10.7613. \end{aligned}$$

The monotonic behaviors of $\xi^*(\tau; \alpha)$ as exhibited by the plots in Figure 2 are consistent with the results stated in Proposition 2.3.

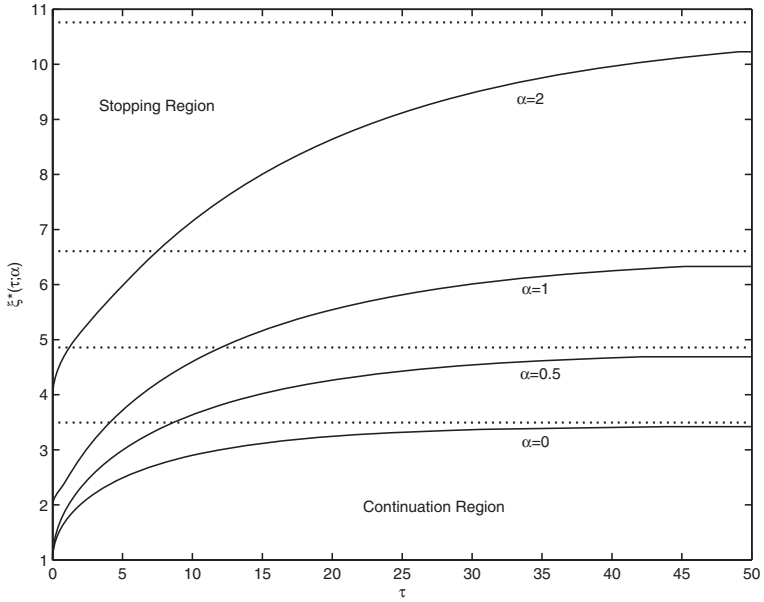

FIG. 2. *The critical threshold* $\xi^*(\tau;\alpha)$ *of the American floating strike lookback put option is plotted against* τ *for different values of* α. *The parameter values of the pricing model are* $r = 0.02$, $q = 0.04$, *and* $\sigma = 0.3$.

3. Fixed strike lookback options. We now consider the pricing behaviors and optimal exercise policies of American fixed strike lookback options, where the payoff involves the strike price K and either realized maximum value M or realized minimum value m. The payoff functions of the American fixed strike lookback call and lookback put are given by

$$(M-K)^+ \quad \text{and} \quad (K-m)^+,$$

respectively. We also consider the American option model with lookback payoff of the form

$$\max(M, K),$$

which is related to the pricing model of the dynamic protection fund with early withdrawal right [8, 11]. According to the guarantee clause, the fund holder acquires more units of the fund from the fund sponsor whenever the fund value falls below the guaranteed protection floor. The early withdrawal right embedded in the protection fund resembles the early exercise right of an American option. When we set $K = 0$ in the payoff $\max(M, K)$, the option model becomes the finite-time Russian option.

It is tempting to seek possible fixed-floating symmetry relations between American lookback call and put options that are similar to those obtained by Detemple [6] for usual American options. While it is possible to obtain symmetry relations between the grant-date price functions of European lookback options (with no dependence on the running extremum value), such relations do not hold for the in-progress counterparts. We do not expect to have nice fixed-floating symmetry relations between the price functions of in-progress American lookback options.

3.1. American fixed strike lookback call. Let $C_{fix}(S, M, \tau; K)$ denote the price function of an American fixed strike lookback call with payoff $(M-K)^+$. The linear complementarity formulation that governs $C_{fix}(S, M, \tau; K)$ is given by

$$\begin{aligned} &\frac{\partial C_{fix}}{\partial \tau} - \mathcal{L}C_{fix} \geq 0, \quad C_{fix} \geq (M-K), \\ &\left(\frac{\partial C_{fix}}{\partial \tau} - \mathcal{L}C_{fix}\right)[C_{fix} - (M-K)] = 0, \quad 0 < S < M, \quad \tau > 0, \end{aligned} \tag{3.1}$$

with auxiliary conditions

$$\begin{aligned} &\left.\frac{\partial C_{fix}}{\partial M}\right|_{S=M} = 0, \\ &C_{fix}(S, M, 0) = (M-K)^+. \end{aligned} \tag{3.2}$$

Let $\mathcal{S}(K)$ denote the stopping region of the American fixed strike lookback call with strike price K. Inside $\mathcal{S}(K)$, the price function equals the exercise payoff; that is,

$$\mathcal{S}(K) = \{(S, M, \tau) \in \{0 < S \leq M\} \times (0, \infty) : C_{fix}(S, M, \tau) = (M-K)^+\}.$$

Propositions 3.1–3.2 summarize the characterization of the optimal exercise policy of the American fixed strike lookback call and the analytic properties of the stopping region.

PROPOSITION 3.1. *The stopping region $\mathcal{S}(K)$ and the price function $C_{fix}(S, M, \tau; K)$ of the American fixed strike lookback call observe the following properties:*

(i) $C_{fix}(S, M, \tau; K_2) - C_{fix}(S, M, \tau; K_1) \leq K_1 - K_2$ *if* $K_1 > K_2$.
(ii) $\mathcal{S}(K_1) \subset \mathcal{S}(K_2)$ *if* $K_1 > K_2$.
(iii) *Suppose* $(S, M, \tau) \in \mathcal{S}(K)$ *and* $0 < \lambda_1 \leq 1$, $\lambda_2 \geq 1$, $0 < \lambda_3 \leq 1$; *we have*

$$(\lambda_1 S, \lambda_2 M, \lambda_3 \tau) \in \mathcal{S}(K).$$

The proof of Proposition 3.1 is presented in Appendix C. In Figure 3, we plot the exercise boundary that separates the stopping region and the continuation region in the S-M plane and use $M^*(S, \tau; K)$ to denote the exercise boundary. Such representation reveals the dependence of the critical realized maximum value M^* on S, τ, and K. By virtue of (iii) in Proposition 3.1, we deduce that the stopping region lies to the upper left-hand side of the exercise boundary in the S-M plane. Hence, we may rewrite $\mathcal{S}(K)$ in the following alternative form:

$$\mathcal{S}(K) = \{(S, M, \tau) \in \{0 < S \leq M\} \times (0, \infty) : \quad M > M^*(S, \tau)\}.$$

Further properties of $M^*(S, \tau; K)$ are summarized in Proposition 3.2.

PROPOSITION 3.2. *Let $M^*(S, \tau; K)$ denote the exercise boundary of the American fixed strike lookback call in the S-M plane; then $M^*(S, \tau; K)$ observes the following properties:*

(i) $\lim_{\tau \to 0^+} M^*(S, \tau; K) = K$ *for all* S.
(ii) $M^*(S, \tau; K)$ *is monotonically increasing with respect to* S *and* τ.
(iii) $\lim_{S \to 0^+} M^*(S, \tau; K) = K$ *for all* τ.
(iv) *When* $K = 0$, $M^*(S, \tau; 0)$ *is a linear function of* S. *Furthermore,* $\frac{M^*(S,\tau;0)}{S}$ *is a monotonically increasing function of* τ *and*

$$\lim_{S \to \infty} \frac{M^*(S, \tau; K)}{S} = \frac{M^*(S, \tau; 0)}{S} \quad \text{for} \quad K > 0. \tag{3.3}$$

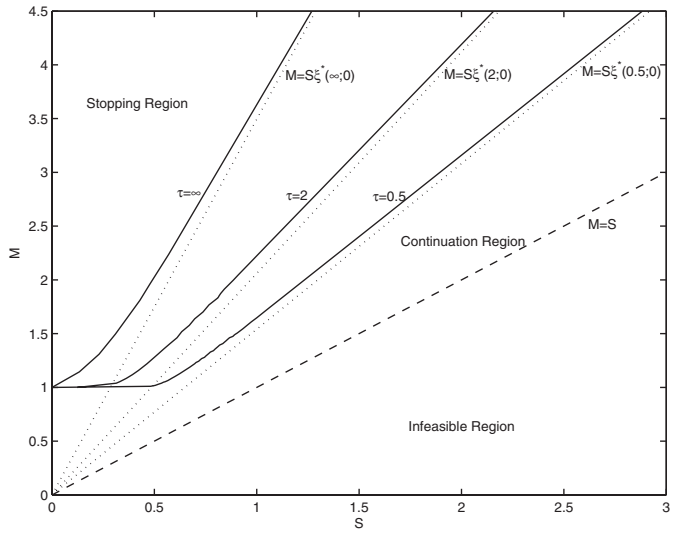

FIG. 3. *The exercise boundaries (solid curves) of the American fixed strike lookback call option with varying values of maturity τ are plotted in the S-M plane. At a given τ, the stopping region is lying to the left of and above the corresponding exercise boundary. The dotted lines are asymptotic lines of the exercise boundaries, corresponding to the exercise boundaries of the zero-strike counterparts. The stopping region of the Russian option lies to the left of the dotted line $M = S\xi^*(\infty; 0)$. The parameter values used in the calculations are $K = 1$, $r = 0.02$, $q = 0.04$, and $\sigma = 0.3$.*

Part (i) gives the zeroth order asymptotic expansion of $M^*(S, \tau; K)$ as $\tau \to 0^+$ (see [15] for a higher order asymptotic expansion of $M^*(S, \tau; K)$ as $\tau \to 0^+$). One can prove part (i) by following an approach similar to that of (iii) in Proposition 2.1. Part (ii) is a corollary of part (iii) in Proposition 3.1. The proofs of parts (iii) and (iv) in Proposition 3.2 are presented in Appendix D.

In Figure 3, we show the plot of the exercise boundaries of the American fixed strike lookback call option with varying values of maturity τ in the S-M plane. The parameter values used in the calculations are $K = 1$, $r = 0.02$, $q = 0.04$, and $\sigma = 0.3$. The exercise boundary corresponding to the zero-strike lookback call is a straight line, the slope of which depends on τ. By virtue of (3.3), the exercise boundaries for the nonzero-strike lookback call options tend to those of their zero-strike counterparts as $S \to \infty$. Note that $M^*(S, \tau; 0)/S = \xi^*(\tau; 0)$, where $\xi^*(\tau; \alpha)$ denotes the exercise boundary in the pricing model for $\widetilde{P_{f\ell}}(\xi, \tau)$ (see (2.8), (2.9)). Our calculations give the following numerical values for $\xi^*(\tau; 0)$:

$$\begin{aligned} \xi^*(\infty; 0) &= 3.4939, \\ \xi^*(2; 0) &= 2.0300, \\ \xi^*(0.5; 0) &= 1.5450. \end{aligned}$$

The finite-time Russian option is seen to be identical to the zero-strike American fixed strike lookback call. Let $V_{Rus}(S, M, \tau)$ denote the price function of the finite-time Russian option so that

$$V_{Rus}(S, M, \tau) = C_{fix}(S, M, \tau; 0). \tag{3.4}$$

Since K does not appear in the price function $V_{Rus}(S, M, \tau)$, the asset value S can

be used as a numeraire. We may write

$$\widetilde{V}_{Rus}(\xi,\tau) = \frac{V_{Rus}(S,M,\tau)}{S}, \quad \text{where} \quad \xi = \frac{M}{S}. \tag{3.5}$$

This explains why $M^*(S,\tau;0)/S$ becomes independent of S. More detailed theoretical analysis of the price function $V_{Rus}(S,M,\tau)$ can be found in Peskir's paper [17].

The exercise boundaries plotted in Figure 3 do agree with our financial intuition about the optimal early exercise policies of the American fixed strike lookback call options. If $S \to 0^+$ or $\tau \to 0^+$, the chance of achieving a higher realized maximum value M becomes vanishingly small, so it becomes optimal to exercise even when M reaches the level K. When the asset price is very high, $M^*(S,\tau;K)$ becomes almost insensitive to the strike price K, since the value K has only a small effect on the exercise payoff. Hence, when $S \to \infty$, the asymptotic behavior of $M^*(S,\tau;K)$ as stated in (3.3) is observed.

3.2. American fixed strike lookback put. Consider an American fixed strike lookback put with payoff $(K-m)^+$; the linear complementarity formulation that governs its price function $P_{fix}(S,m,\tau)$ is given by

$$\begin{aligned} &\frac{\partial P_{fix}}{\partial \tau} - \mathcal{L}P_{fix} \geq 0, \qquad P_{fix} \geq (K-m), \\ &\left(\frac{\partial P_{fix}}{\partial \tau} - \mathcal{L}P_{fix}\right)[P_{fix} - (K-m)] = 0, \qquad 0 < m < S, \quad \tau > 0, \end{aligned} \tag{3.6}$$

with auxiliary conditions

$$\begin{aligned} &\left.\frac{\partial P_{fix}}{\partial m}\right|_{S=m} = 0, \\ &P_{fix}(S,m,0) = (K-m)^+. \end{aligned} \tag{3.7}$$

In a similar manner, we let $m^*(S,\tau;K)$ denote the exercise boundary that separates the stopping region and the continuation region in the S-m plane. The analytic properties of $m^*(S,\tau;K)$ are summarized in Proposition 3.3.

PROPOSITION 3.3. *The exercise boundary $m^*(S,\tau;K)$ of the American fixed strike lookback put satisfies the following properties:*

(i) $\lim_{\tau\to 0^+} m^*(S,\tau;K) = K$ *for all* S.
(ii) $m^*(S,\tau;K)$ *is monotonically increasing with respect to* S.
(iii) $\lim_{S\to\infty} m^*(0,\tau;K) = K$ *for all* τ.
(iv) $\lim_{S\to 0^+} \frac{m^*(S,\tau;K)}{S} = 1$ *for all* τ.

Parts (i)–(iii) in Proposition 3.3 can be proved by using arguments similar to those used in proving parts (i)–(iii) in Proposition 3.2. The proof of (iv) in Proposition 3.3 is interesting and challenging. It relies on the asymptotic result on $\eta^*(\tau;\alpha)$ as stated in (ii) in Proposition 2.2 (see Appendix E for details).

Figure 4 shows the plot of the exercise boundaries $m^*(S,\tau;K)$ of the American fixed strike lookback put with varying values of maturity τ in the S-m plane. The parameter values used in the calculations are $K = 1$, $r = 0.04$, $q = 0.02$, and $\sigma = 0.3$. According to (iii) and (iv) in Proposition 3.3, the exercise boundaries are seen to tend asymptotically to $m = K$ as $S \to \infty$ and to $m = S$ as $S \to 0^+$.

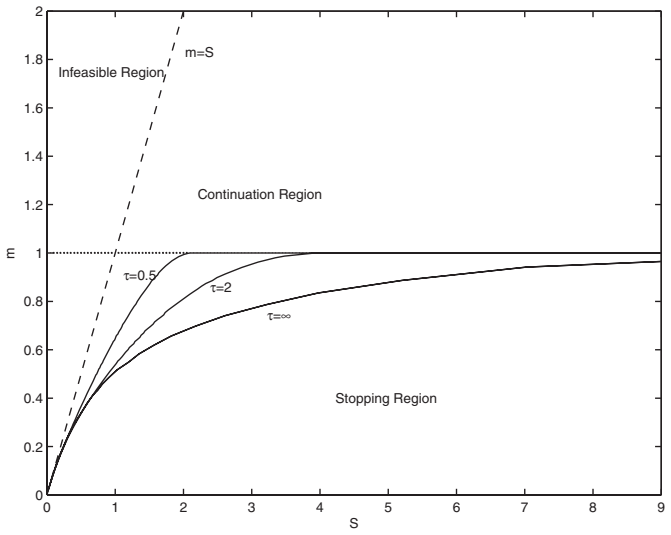

FIG. 4. *The exercise boundaries of the American fixed strike lookback put option with varying values of maturity τ are plotted in the S-m plane. All exercise boundaries tend to the oblique asymptotic line $m = S$ as $S \to 0^+$, and to the horizontal asymptotic line $m = K$ as $S \to \infty$. The parameter values used in the calculations are $K = 1$, $r = 0.04$, $q = 0.02$, and $\sigma = 0.3$.*

3.3. American lookback option with payoff $\max(M, K)$. Let $V_M(S, M, \tau)$ denote the price function of the American option with lookback payoff $\max(M, K)$. First, we argue from financial intuition that $V_M(S, M, \tau)$ should be insensitive to the *current* realized maximum value of asset price M when $M < K$; that is,

$$\frac{\partial V_M}{\partial M} = 0 \quad \text{for} \quad M < K. \tag{3.8}$$

The option payoff is given by K if the *future* realized maximum value of the asset price is less than or equal to K; otherwise, the payoff equals the future realized maximum value. In either case, the current realized maximum value M does not enter into the payoff function. Hence, $V_M(S, M, \tau)$ does have dependence on M when $M < K$. On the other hand, when $M \geq K$, the future realized maximum value is always greater than or equal to K, so the payoff is simply given by M. This is the same payoff as that of the finite-time Russian option. Hence, we have

$$V_M(S, M, \tau) = V_{Rus}(S, M, \tau) \quad \text{for} \quad M \geq K. \tag{3.9}$$

By virtue of the continuity property of the price function $V_M(S, M, \tau)$ with respect to M, we then have

$$V_M(S, M, \tau) = \begin{cases} V_{Rus}(S, M, \tau) & \text{for } M \geq K, \\ V_{Rus}(S, K, \tau) & \text{for } M < K. \end{cases} \tag{3.10}$$

For $M \geq K$, V_M and V_{Rus} should share the same optimal exercise policy. At $M = K$, the exercise boundary of the finite-time Russian option is given by $S = K/\xi^*(\tau; 0)$. Hence, for $M < K$, the American option with payoff $\max(M, K)$ will be exercised optimally when $S \leq K/\xi^*(\tau; 0)$ and unexercised otherwise.

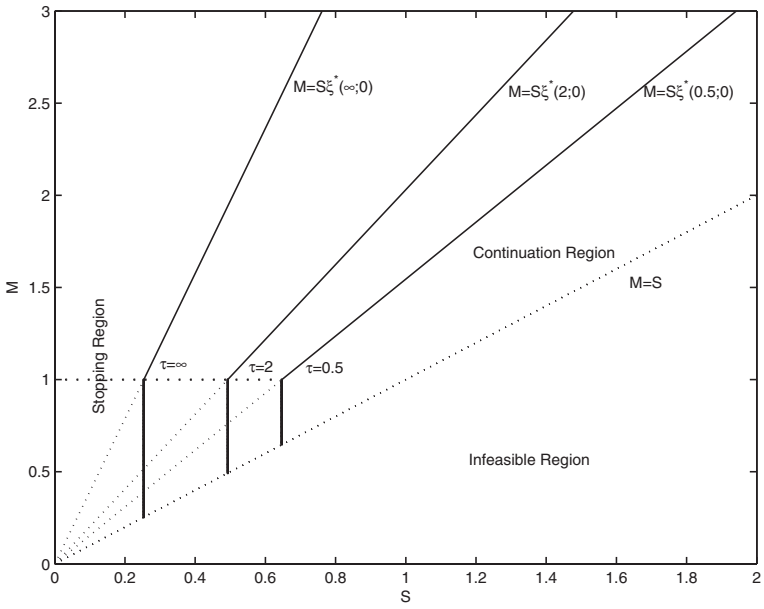

FIG. 5. *The exercise boundaries of the American option with payoff function* $\max(M, K)$ *with varying values of maturity* τ *are plotted in the S-M plane. The parameter values used in the calculations are* $K = 1$, $r = 0.02$, $q = 0.04$, *and* $\sigma = 0.3$.

In Figure 5, we plot the stopping region and the continuation region in the S-M plane of the American option with payoff $\max(M, K)$. The set of parameter values used in the calculations is $K = 1$, $r = 0.02$, $q = 0.04$, and $\sigma = 0.3$. When $M \geq K$, the stopping region and the continuation region for a fixed value of τ are separated by the oblique line $M = S\xi^*(\tau; 0)$. On the other hand, when $M < K$, the exercise boundary becomes the vertical line $S = K/\xi^*(\tau; 0)$.

3.4. A related two-asset American option model. As a slight departure from the option models with lookback payoff structures, we consider the optimal exercise policies of a two-asset American option with a put payoff on the minimum of two asset values. There have been several comprehensive papers that analyze the early exercise policies of two-asset American options [2, 5, 9, 13, 14, 19, 20]. We would like to demonstrate that the mathematical technique of analyzing the exercise boundaries of the American fixed strike lookback put option at $S \to 0^+$ can be adopted to resolve the mystery of the asymptotic behaviors of the exercise boundaries of the two-asset American minimum put option at infinitesimally small asset values.

Let S_1 and S_2 denote the prices of the two underlying assets, whose dynamics under the risk neutral measure is governed by

$$\frac{dS_i}{S_i} = (r - q_i)dt + \sigma_i \, dZ_i, \qquad i = 1, 2, \tag{3.11}$$

where $dZ_1 \, dZ_2 = \rho \, dt$, ρ is the correlation coefficient between the two Wiener processes dZ_1 and dZ_2. The exercise payoff is given by $(K - \min(S_1, S_2))^+$, where K is the strike price. Let $P_{min}(S_1, S_2, \tau; K)$ denote the price function of this two-asset American minimum put option. Let $\mathcal{S}_2(K)$ denote the continuation region in the S_1-S_2 plane, with dependence on K. The linear complementarity formulation for $P_{min}(S_1, S_2, \tau; K)$

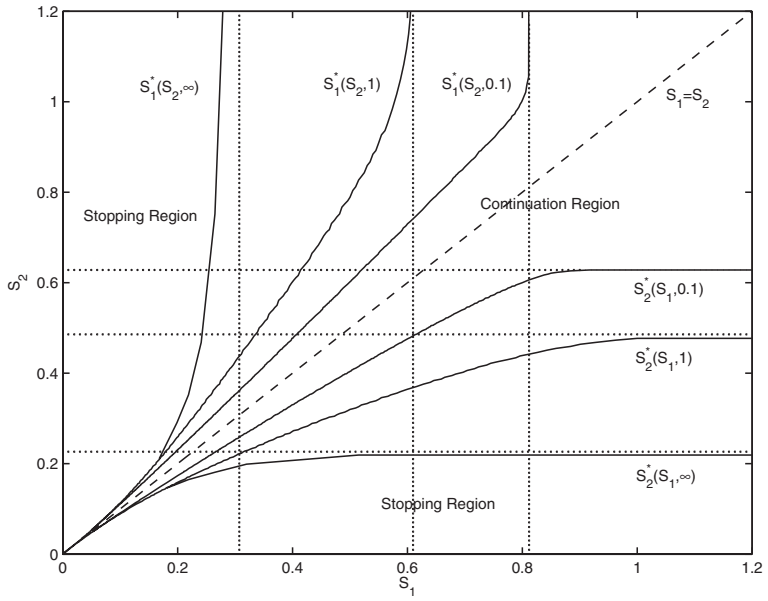

FIG. 6. *The exercise boundaries of the two-asset American minimum put option with varying values of maturity τ are plotted in the S_1-S_2 plane. The continuation region is bounded between the two branches of the exercise boundaries. The parameter values used in the calculations are $K = 1$, $r = 0.02$, $q_1 = 0$, $q_2 = 0.03$, $\sigma_1 = \sigma_2 = 0.3$, and $\rho = 0.5$.*

is given by

$$\begin{aligned} &\frac{\partial P_{min}}{\partial \tau} - \mathcal{L}_2 P_{min} \geq 0, \qquad P_{min} \geq (K - \min(S_1, S_2))^+, \\ &\left[\frac{\partial P_{min}}{\partial \tau} - \mathcal{L}_2 P_{min}\right] [P_{min} - (K - \min(S_1, S_2))^+] = 0, \\ &\qquad\qquad 0 < S_1 < \infty, \quad 0 < S_2 < \infty, \quad \tau > 0. \end{aligned} \tag{3.12}$$

The operator $\mathcal{L}_2$ is defined by

$$\begin{aligned} \mathcal{L}_2 = &\frac{\sigma_1^2}{2} S_1^2 \frac{\partial^2}{\partial S_1^2} + \rho \sigma_1 \sigma_2 S_1 S_2 \frac{\partial^2}{\partial S_1 \partial S_2} + \frac{\sigma_2^2}{2} S_2^2 \frac{\partial^2}{\partial S_2^2} \\ &+ (r - q_1) S_1 \frac{\partial}{\partial S_1} + (r - q_2) S_2 \frac{\partial}{\partial S_2} - r. \end{aligned} \tag{3.13}$$

In Figure 6, we show the plot of the exercise boundaries of the two-asset American minimum put option in the S_1-S_2 plane. The following set of parameter values is used in the calculations: $K = 1$, $r = 0.02$, $q_1 = 0$, $q_2 = 0.03$, $\sigma_1 = \sigma_2 = 0.3$, and $\rho = 0.5$. The whole line $S_1 = S_2$ always lies in the continuation region. The continuation region is bounded by the two branches of the exercise boundaries. In the region $S_1 > S_2$, we let $S_2^*(S_1, \tau)$ denote the exercise boundary at time to expiry τ. We observe that the curve $S_2^*(S_1, \tau)$ tends to the line $S_1 = S_2$ as $S_1 \to 0^+$ and tends to some asymptotic limit as $S_1 \to \infty$. Similar phenomena occur in the region $S_2 > S_1$, where the exercise boundary at time to expiry τ is represented by $S_1^*(S_2, \tau)$. For the

above set of parameter values chosen for the option model, we obtain

$$\lim_{S_1\to\infty} S_2^*(S_1,0.1)=0.6277,\quad \lim_{S_1\to\infty} S_2^*(S_1,1)=0.4855,\quad \lim_{S_1\to\infty} S_2^*(S_1,\infty)=0.2268,$$
$$\lim_{S_2\to\infty} S_1^*(S_2,0.1)=0.8118,\quad \lim_{S_2\to\infty} S_1^*(S_2,1)=0.6100,\quad \lim_{S_2\to\infty} S_1^*(S_2,\infty)=0.3077.$$

Some of the analytic properties of the exercise boundaries $S_1^*(S_2,\tau)$ and $S_2^*(S_1,\tau)$ are summarized in Proposition 3.4.

PROPOSITION 3.4. *Let $S_1^*(S_2,\tau)$ and $S_2^*(S_1,\tau)$ denote the exercise boundaries at time to expiry τ in the two respective regions, $S_2 > S_1$ and $S_1 > S_2$, in the S_1-S_2 plane of the two-asset American minimum put option. The exercise boundaries and the continuation region observe the following properties:*

(i) *Let $S_{1,P}^*(\tau)$ and $S_{2,P}^*(\tau)$ denote the exercise boundary of the one-asset American put option with the underlying asset S_1 and S_2, respectively. We have*

$$\lim_{S_2\to\infty} S_1^*(S_2,\tau)=S_{1,P}^*(\tau)\quad \textit{and}\quad \lim_{S_1\to\infty} S_2^*(S_1,\tau)=S_{2,P}^*(\tau).$$

(ii) *Both $S_1^*(S_2,\tau)$ and $S_2^*(S_1,\tau)$ are monotonically decreasing with respect to time to expiry and monotonically increasing with respect to the asset price level.*

(iii) *The whole line $S_1=S_2$ is contained completely inside the continuation region.*

(iv) *At infinitesimally small asset values, we have*

$$\lim_{S_1\to 0^+}\frac{S_2^*(S_1,\tau)}{S_1}=1\quad \textit{and}\quad \lim_{S_2\to 0^+}\frac{S_1^*(S_2,\tau)}{S_2}=1\quad \textit{for all } \tau. \tag{3.14}$$

All exercise boundaries tend asymptotically to the line $S_1=S_2$ as S_1 and S_2 both tend to zero.

The intuition behind the asymptotic properties stated in part (i) of Proposition 3.4 is quite obvious. When $S_1\to\infty$, $P_{min}(S_1,S_2,\tau;K)\longrightarrow P(S_2,\tau;K)$, where $P(S_2,\tau;K)$ denotes the price function of the one-asset American put option with underlying asset S_2. We would expect that both option models follow the same optimal exercise strategy, thus leading to the asymptotic properties stated in (i). The proof of these asymptotic properties can be pursued by following similar arguments used in the proof of Proposition 4.8 in Villeneuve's paper [20]. Also, the monotonicity properties of $S_1^*(S_2,\tau)$ and $S_2^*(S_1,\tau)$ have been discussed in other papers (say [2] and [20]). Property (iii) states that when $S_1=S_2$, it is never optimal to exercise the two-asset American minimum put option. This optimal exercise policy is similar to that of the two-asset American maximum call option. The proof of (iii) can follow an argument similar to that presented by Detemple, Feng, and Tian [5] on the American maximum call option. The proof of the asymptotic behavior of the exercise boundaries at $S_1\to 0$ and $S_2\to 0$ requires specifically the technique developed in the proof of property (iii) in Proposition 3.3. The proof of part (iv) of Proposition 3.4 is presented in Appendix F.

4. Conclusion. This paper demonstrates the richness of the optimal exercise behaviors adopted by holders of the American options with payoff structures involving lookback state variables. The analysis of the optimal exercise policies of an American lookback option is complicated by the presence of an additional lookback state variable. For fixed strike lookback options, we characterize the exercise behaviors by analyzing the analytic properties of the stopping region and continuation region in

the two-dimensional state space (asset price and lookback state variable). For floating strike lookback options, the dimension of the pricing model can be reduced by one if the asset price is used as the numeraire. We reveal the close relationship between the price functions of the finite-time Russian option and the dynamic protection fund with withdrawal right. For the American put option on the minimum value of two assets, the exercise region consists of two branches of exercise surfaces. Compared to earlier works, our analyses provide a more comprehensive understanding of the optimal exercise policies of commonly traded American lookback options. In particular, we provide a more precise description of the asymptotic behaviors of the exercise boundaries. All the optimal exercise policies of American lookback options derived from our theoretical studies have been verified by plots of the exercise boundaries obtained via numerical calculations.

Appendix A. Proof of Proposition 2.1.

(i) First, we show that if $(\eta, \tau) \in \mathcal{S}^C$, then $(\eta, \lambda_2\tau) \in \mathcal{S}^C$ for $\lambda_2 \geq 1$. By applying the comparison principle, one can show that $\frac{\partial \widetilde{C}_{f\ell}}{\partial \tau} > 0$. This is consistent with the financial intuition that the price function of any American option is an increasing function of τ. Suppose (η, τ) lies in the continuation region; then $\widetilde{C}_{f\ell}(\eta, \tau) > \alpha - \eta$. By virtue of $\frac{\partial \widetilde{C}_{f\ell}}{\partial \tau} > 0$, we deduce that $\widetilde{C}_{f\ell}(\eta, \lambda_2\tau) > \alpha - \eta$ for $\lambda_2 \geq 1$. Hence, $(\eta, \lambda_2\tau)$ also lies in the continuation region.

Next, we show that if $(\eta, \tau) \in \mathcal{S}^C$, then $(\lambda_1\eta, \tau) \in \mathcal{S}^C$ for $\lambda_1 \geq 1$. It suffices to show that

$$\frac{\partial}{\partial \eta}[\widetilde{C}_{f\ell}(\eta, \tau) - (\alpha - \eta)] \geq 0. \tag{A.1}$$

We write $U(\eta, \tau) = \widetilde{C}_{f\ell}(\eta, \tau) - (\alpha - \eta)$; then the linear complementarity formulation for $U(\eta, \tau)$ is given by

$$\frac{\partial U}{\partial \tau} - \widetilde{\mathcal{L}} U \geq r\eta - q\alpha, \quad U \geq 0,$$
$$\left(\frac{\partial U}{\partial \tau} - \widetilde{\mathcal{L}} U\right) U = 0, \quad 0 < \eta < 1, \quad \tau > 0,$$

with auxiliary conditions

$$\left.\frac{\partial U}{\partial \eta}\right|_{\eta=1} = 1 \quad \text{and} \quad U(\eta, 0) = (\eta - \alpha)^+.$$

Both the initial condition $(\eta - \alpha)^+$ and the nonhomogeneous term $r\eta - q\alpha$ are increasing functions of η, and $\frac{\partial U}{\partial \eta}|_{\eta=1} > 0$. By virtue of the comparison principle, we deduce that $\frac{\partial U}{\partial \eta} \geq 0$. □

(ii) We prove by contradiction. Suppose there exists $\tau_0 > 0$ such that $(1, \tau_0) \in S$; by applying (A.1), we can show that $(\eta, \tau_0) \in S$ for $\eta < 1$. We then have

$$\widetilde{C}_{f\ell}(\eta, \tau_0) = \alpha - \eta, \quad \eta < 1.$$

This implies

$$\frac{\partial \widetilde{C}_{f\ell}}{\partial \eta} = -1 \quad \text{at} \quad (1, \tau_0),$$

which contradicts the Neumann boundary condition stated in (2.6). □

(iii) A necessary condition for (η, τ) to lie inside $\mathcal{S}$ is given by

$$\left(\frac{\partial}{\partial \tau} - \widetilde{\mathcal{L}}\right)(\alpha - \eta) = \alpha q - r\eta \geq 0;$$

that is, $\eta \leq \frac{q}{r}\alpha$. Hence, we should have $\eta^*(0^+) \leq \frac{q}{r}\alpha$. Since the exercise payoff must be nonnegative, another necessary condition is given by $\eta \leq \alpha$. Finally, the feasible region for η is $\{\eta : \eta \leq 1\}$. Combining all three necessary conditions, we should have

$$\eta^*(0^+) \leq \min\left(1, \alpha, \frac{q}{r}\alpha\right).$$

Suppose $\eta^*(0^+) < \min(1, \alpha, \frac{q}{r}\alpha)$; then for $\eta \in (\eta^*(0^+), \min(1, \alpha, \frac{q}{r}\alpha))$, we have

$$\left.\frac{\partial \widetilde{C}_{f\ell}}{\partial \tau}\right|_{\tau=0} = \left.\widetilde{\mathcal{L}}\widetilde{C}_{f\ell}\right|_{\tau=0} = \widetilde{\mathcal{L}}(\alpha - \eta) = r\eta - \alpha q < 0.$$

This contradicts $\frac{\partial \widetilde{C}_{f\ell}}{\partial \tau} \geq 0$ for all τ. Hence, we obtain

$$\eta^*(0^+) = \min\left(1, \alpha, \frac{q}{r}\alpha\right). \qquad \square$$

Appendix B. Proof of Proposition 2.2.

(i) Write $\eta^*_\infty(\alpha) = \lim_{\tau\to\infty} \eta^*(\tau; \alpha)$ and $\widetilde{C_{f\ell}}^{\infty}(\eta) = \lim_{\tau\to\infty} \widetilde{C_{f\ell}}(\eta, \tau)$; then $\widetilde{C_{f\ell}}^{\infty}(\eta)$ satisfies the following differential equation:

$$\widetilde{\mathcal{L}}\ \widetilde{C_{f\ell}}^{\infty} = 0, \quad \eta^*_\infty < \eta < 1,$$

subject to the auxiliary conditions

$$\widetilde{C_{f\ell}}^{\infty}(\eta^*_\infty) = \alpha - \eta^*_\infty, \quad \frac{\partial \widetilde{C_{f\ell}}}{\partial \eta}(\eta^*_\infty) = -1, \quad \frac{\partial \widetilde{C_{f\ell}}}{\partial \eta}(1) = 0.$$

The general solution to $\widetilde{C_{f\ell}}^{\infty}(\eta)$ is given by

$$\widetilde{C_{f\ell}}^{\infty}(\eta) = A_1\eta^{\lambda_+} + A_2\eta^{\lambda_-}, \quad \eta^*_\infty < \eta < 1.$$

Applying the auxiliary conditions, we obtain

$$A_1 = \frac{(1-\lambda_-)\eta^*_\infty + \lambda_-\alpha}{(\lambda_- - \lambda_+)(\eta^*_\infty)^{\lambda_+}} \quad \text{and} \quad A_2 = \frac{(1-\lambda_+)\eta^*_\infty + \lambda_+\alpha}{(\lambda_+ - \lambda_-)(\eta^*_\infty)^{\lambda_-}},$$

and η^*_∞ satisfies the nonlinear algebraic equation

$$(\eta^*_\infty)^{\lambda_+ - \lambda_-} = \frac{\lambda_+}{\lambda_-}\frac{(1-\lambda_-)\eta^*_\infty + \lambda_-\alpha}{(1-\lambda_+)\eta^*_\infty + \lambda_+\alpha}. \tag{B.1}$$

The above algebraic equation has two roots; one lies in $(0, 1)$, and the other lies in $(1, \infty)$ (the proof of these properties is found in [3]). Here, η^*_∞ corresponds to the root in $(0, 1)$. Hence, the results in part (i) are established. $\square$

(ii) When $\alpha \to \infty$, the nonlinear algebraic equation (B.1) reduces to

$$(\eta^*_\infty)^{\lambda_+ - \lambda_-} = 1$$

so that the solution for η^*_∞ becomes 1. Also, $\eta^*(0^+) = 1$ when α becomes sufficiently large. Since $\eta^*(\tau)$ is monotonically decreasing with respect to τ, and $\eta^*(0^+) = \eta^*(\infty) = 1$ as $\alpha \to \infty$, we can deduce that

$$\lim_{\alpha \to \infty} \eta^*(\tau; \alpha) = 1 \quad \text{for all } \tau. \qquad \square$$

Appendix C. Proof of Proposition 3.1.

(i) Define the function $V(S, M, \tau; K) = C_{fix}(S, M, \tau; K) + K$. Similar to (3.1)–(3.2), the linear complementarity formulation for $V(S, M, \tau; K)$ is given by

$$\frac{\partial V}{\partial \tau} - \mathcal{L}V \geq rK, \quad V \geq \max(M, K),$$
$$\left[\frac{\partial V}{\partial \tau} - \mathcal{L}V - rK\right][V - \max(M, K)] = 0,$$

with auxiliary conditions

$$\left.\frac{\partial V}{\partial M}\right|_{S=M} = 0 \quad \text{and} \quad V(S, M, 0; K) = \max(M, K).$$

By virtue of the comparison principle, we have

$$V(S, M, \tau; K_1) \geq V(S, M, \tau; K_2) \quad \text{if} \quad K_1 > K_2,$$

and hence the result. $\square$

(ii) From (i), for $K_1 > K_2$ we have

$$C_{fix}(S, M, \tau; K_1) - (M - K_1) \geq C_{fix}(S, M, \tau; K_2) - (M - K_2). \tag{C.1}$$

Suppose $(S, M, \tau) \in \mathcal{S}^C(K_2)$, where $\mathcal{S}^C(K_2)$ denotes the continuation region. In the continuation region, the option value is strictly greater than the exercise payoff so that

$$C_{fix}(S, M, \tau; K_2) > M - K_2.$$

Combining this with inequality (C.1), we can deduce

$$C_{fix}(S, M, \tau; K_1) > M - K_1,$$

so that $(S, M, \tau) \in \mathcal{S}^C(K_1)$. Hence, we establish $\mathcal{S}^C(K_2) \subset \mathcal{S}^C(K_1)$, and thus $\mathcal{S}(K_1) \subset \mathcal{S}(K_2)$. $\square$

(iii) Since $C_{fix}(S, M, \tau)$ is monotonically increasing with respect to both S and τ and the exercise payoff is independent of S and τ, we deduce that if $(S, M, \tau) \in \mathcal{S}(K)$, then

$$(\lambda_1 S, M, \lambda_3 \tau) \in \mathcal{S}(K) \quad \text{for all} \quad 0 < \lambda_1 \leq 1 \text{ and } 0 < \lambda_3 \leq 1.$$

Next, we would like to show that $(S, M, \tau) \in \mathcal{S}(K)$ would imply $(S, \lambda_2 M, \tau) \in \mathcal{S}(K)$ for all $\lambda_2 \geq 1$. Suppose $(S, M, \tau) \in \mathcal{S}(K)$; then $(S/\lambda_2, M, \tau) \in \mathcal{S}(K)$

for $\lambda_2 \geq 1$. Furthermore, by virtue of the linear homogeneity property of the price function and the result in (i), we obtain

$$\begin{aligned} C_{fix}(S, \lambda_2 M, \tau; K) &= \lambda_2 C_{fix}\left(\frac{S}{\lambda_2}, M, \tau; \frac{K}{\lambda_2}\right) \\ &\leq \lambda_2 \left[C_{fix}\left(\frac{S}{\lambda_2}, M, \tau; K\right) + \left(1 - \frac{1}{\lambda_2}\right) K\right] \\ &= \lambda_2 \left[M - K + \left(1 - \frac{1}{\lambda_2}\right) K\right] = \lambda_2 M - K. \end{aligned}$$

On the other hand, the option value $C_{fix}(S, \lambda_2 M, \tau; K)$ cannot fall below the exercise payoff $\lambda_2 M - K$. Combining the results, we then have

$$C_{fix}(S, \lambda_2 M, \tau; K) = \lambda_2 M - K;$$

that is, $(S, \lambda_2 M, \tau) \in \mathcal{S}(K)$. Hence, we obtain the desired result. □

Appendix D. Proof of Proposition 3.2.

(iii) It is clear that $M^*(0^+, \tau; K) \geq K$. From the monotonic increasing property of $M^*(S, \tau; K)$ with respect to S, suppose we can show that the line $M = M_0$ lies in the stopping region in the S-M plane for any $M_0 > K$; then one can deduce that $M^*(S, \tau; K) \to K$ as $S \to 0^+$. This is because the minimum value of $M^*(S, \tau; K)$ is achieved when S is approaching zero from above, and this minimum value is K. We write $U_{fix}(S, \tau) = C_{fix}(S, M_0, \tau) - (M_0 - K)$. The linear complementarity formulation of $U_{fix}(S, \tau)$ is given by

$$\begin{aligned} &\left(\frac{\partial}{\partial \tau} - \mathcal{L}\right) U_{fix} \geq -r(M_0 - K), \quad U_{fix} \geq 0, \\ &\left[\left(\frac{\partial}{\partial \tau} - \mathcal{L}\right) U_{fix}\right] U_{fix} = 0 \end{aligned}$$

with initial condition $U_{fix}(S, 0) = 0$. Since the right-hand term $-r(M_0 - K)$ is always negative and the initial value has compact support, we apply the theorem by Brezis and Friedman [1] that the solution $U_{fix}(S, \tau)$ has compact support, too. The stopping region is nonempty; that is, there exists (S, τ) such that $C_{fix}(S, M_0, \tau) = M_0 - K$ for any $M_0 > K$. Hence, the line $M = M_0 \in \mathcal{S}(K)$ for any $M_0 > K$. □

(iv) When $K = 0$, the American fixed strike lookback call is the same as the American floating strike lookback put (with $\alpha = 0$ in (2.8)). The monotonically increasing property of $\xi^*(\tau) = M^*(S, \tau; 0)/S$ follows directly from Proposition 2.3(i).

For $K > 0$, by virtue of the linear homogeneity property of $M^*(S, \tau; K)$, we obtain

$$\begin{aligned} \lim_{S \to \infty} \frac{M^*(S, \tau; K)}{S} &= \lim_{S \to \infty} \frac{M^*\left(\frac{S}{K}, \tau; 1\right)}{\frac{S}{K}} = \lim_{K \to 0} \frac{M^*\left(\frac{S}{K}, \tau; 1\right)}{\frac{S}{K}} \\ &= \lim_{K \to 0} \frac{M^*(S, \tau; K)}{S} = \frac{M^*(S, \tau; 0)}{S}. \end{aligned}$$

□

Appendix E. Proof of Proposition 3.3.

(iv) First, we consider the proof with $q > 0$, whose arguments rely on the existence of $\eta^*(\tau;\alpha)$. Since $\eta^*(\tau;\alpha)$ does not exist when $q = 0$, we will deal with the special case of zero dividend separately later. For $\alpha \geq 1$, we observe that

$$(K-m)^+ \leq (K-\alpha S)^+ + \alpha S - m$$

so that

$$P_{fix}(S,m,\tau;K) \leq \alpha P\left(S,\tau;\frac{K}{\alpha}\right) + C_{f\ell}(S,m,\tau;\alpha), \tag{E.1}$$

where $P(S,\tau;\frac{K}{\alpha})$ denotes the price function of the American vanilla put option with strike price $\frac{K}{\alpha}$. Let $S_P^*(\tau;\frac{K}{\alpha})$ be the critical asset price of the American vanilla put with payoff $(\frac{K}{\alpha}-S)^+$. Consider the point $(\widehat{S},\widehat{m})$ in the S-m plane which lies inside the region

$$R_\alpha = \left\{(S,m): \quad m \leq S\eta^*(\tau;\alpha) \quad \text{and} \quad S \leq S_P^*\left(\tau;\frac{K}{\alpha}\right)\right\}.$$

$(\widehat{S},\widehat{m})$ lies in the corresponding stopping region of both the American floating strike call and the American vanilla put. We then have

$$P\left(\widehat{S},\tau;\frac{K}{\alpha}\right) = \frac{K}{\alpha} - \widehat{S} \quad \text{and} \quad C_{f\ell}(\widehat{S},\widehat{m},\tau;\alpha) = \alpha\widehat{S} - \widehat{m}. \tag{E.2}$$

Now, we argue that $(\widehat{S},\widehat{m})$ also lies in the stopping region of the American fixed strike put. To establish the claim, it suffices to show that

$$P_{fix}(\widehat{S},\widehat{m},\tau;K) = K - \widehat{m}. \tag{E.3}$$

Combining the results in (E.1) and (E.2), we obtain $P_{fix}(\widehat{S},\widehat{m},\tau;K) \leq K-\widehat{m}$. Since the option value of the American fixed strike put cannot fall below its exercise payoff, the result in (E.3) is then established.

Next, we take the limit $\alpha \to \infty$ and observe that

$$\lim_{\alpha\to\infty} \eta^*(\tau;\alpha) = 1 \quad \text{and} \quad \lim_{\alpha\to\infty} S_P^*\left(\tau;\frac{K}{\alpha}\right) = 0$$

for all τ. As $\alpha \to \infty$, R_α shrinks to an infinitesimally small triangular wedge with the oblique side $S = m$. Hence, we can deduce that as $S \to 0^+$ and for all values of τ, all the exercise boundaries $m^*(S,\tau;K)$ tend to the oblique asymptotic line $S = m$.

Finally, we consider the case where $q = 0$. We add the parameter q in the price function $P_{fix}(S,m,\tau;K,q)$ and exercise boundary $m^*(S,\tau;q)$, and write the corresponding stopping region as $\mathcal{S}(q)$ with dependence on q. From the pricing property

$$P_{fix}(S,m,\tau;K,0) \leq P_{fix}(S,m,\tau;K,q),$$

we deduce that

$$\mathcal{S}(q) \subset \mathcal{S}(0), \quad q > 0.$$

Hence, we have $m^*(S,\tau;0) \geq m^*(S,\tau;q)$ so that

$$\frac{m^*(S,\tau;q)}{S} \leq \frac{m^*(S,\tau;0)}{S} \leq 1, \quad q > 0.$$

Since we have established that $\frac{m^*(S,\tau;q)}{S} \to 1$ as $S \to 0$, it follows that $\lim_{S\to 0^+} \frac{m^*(S,\tau;0)}{S} = 1$. □

Appendix F. Proof of Proposition 3.4.

(iii) We show only the proof of

$$\lim_{S_1\to 0^+} \frac{S_2^*(S_1,\tau)}{S_1} = 1.$$

The proof of the other limiting property in (3.14) can be pursued in a similar manner. Following an approach similar to that in Appendix E, we employ the inequality

$$(K - \min(S_1,S_2))^+ \leq (K-\alpha S_2)^+ + (\alpha S_2 - \min(S_1,S_2))^+ \tag{F.1}$$

and examine the stopping region $\widehat{\mathcal{S}}_\alpha$ of the American two-asset option with payoff $(\alpha S_2 - \min(S_1,S_2))^+$. Also, we let $S_{2,P}^*$ be the critical asset price of the American put with payoff $(\frac{K}{\alpha} - S_2)^+$. By applying inequality (F.1) and following an argument similar to that presented in Appendix E, one can show that the stopping region of the two-asset American minimum put option is contained inside

$$\overline{R}_\alpha = \left\{(S_1,S_2) : (S_1,S_2) \in \widehat{\mathcal{S}}_\alpha \quad \text{and} \quad S_2 \leq S_{2,P}^*\left(\tau; \frac{K}{\alpha}\right)\right\}.$$

The asymptotic behavior of $S_2^*(S_1,\tau)$ at infinitesimally small values of S_1 is established once we can show that the boundaries of $\overline{R}_\alpha$ are bounded by the line $S_1 = S_2$ as $\alpha \to \infty$.

Let V_α denote the price function of the American two-asset option with payoff $(\alpha S_2 - \min(S_1,S_2))^+$, $\alpha \geq 1$. We let $x = S_1/S_2$ and define $W_\alpha = V_\alpha/S_2$. The exercise boundary of the American option model $W_\alpha(x,\tau)$ has two branches; let them be denoted by $x_h^*(\tau)$ and $x_\ell^*(\tau)$. The continuation region is represented by $\{(x,\tau) : x_\ell^*(\tau) < x < x_h^*(\tau),\ 0 \leq \tau < \infty\}$. The linear complementarity formulation of $W_\alpha(x,\tau)$ is given by

$$\frac{\partial W_\alpha}{\partial \tau} - \frac{1}{2}(\sigma_1^2 - 2\rho\sigma_1\sigma_2 + \sigma_2^2)x^2\frac{\partial^2 W_\alpha}{\partial x^2} - (q_2 - q_1)x\frac{\partial W_\alpha}{\partial x} + q_2 W_\alpha = 0,$$
$$x_\ell^*(\tau) < x < x_h^*(\tau), \quad \tau > 0,$$

with auxiliary conditions

$$W_\alpha(x_\ell^*,\tau) = \alpha - x_\ell^*, \qquad \frac{\partial W_\alpha}{\partial x}(x_\ell^*,\tau) = -1,$$
$$W_\alpha(x_h^*,\tau) = \alpha - 1, \qquad \frac{\partial W_\alpha}{\partial x}(x_h^*,\tau) = 0,$$
$$W_\alpha(x,0) = \begin{cases} \alpha - x & \text{if } x \leq 1, \\ \alpha - 1 & \text{if } x > 1. \end{cases}$$

For $q_2 > 0$, one can show that $x_\ell^*(\tau)$ and $x_h^*(\tau)$ are monotonic functions of τ. Also, $x_\ell^*(0^+) = x_h^*(0^+) = 1$ when $\alpha > \frac{q_1}{q_2}$. Similarly to property (ii) in Proposition 2.2, we would like to establish the asymptotic results

$$\lim_{\alpha\to\infty} x_\ell^*(\tau;\alpha) = 1 \quad \text{and} \quad \lim_{\alpha\to\infty} x_h^*(\tau;\alpha) = 1 \tag{F.2}$$

so that the boundary of $\overline{R}_\alpha$ will be bounded by $S_1 = S_2$ as $\alpha \to \infty$. By virtue of the monotonicity properties of $x_\ell^*(\tau)$ and $x_h^*(\tau)$ with respect to τ, the asymptotic properties in (F.2) are valid if we can show that

$$\lim_{\alpha\to\infty} x_\ell^*(\infty;\alpha) = 1 \quad \text{and} \quad \lim_{\alpha\to\infty} x_h^*(\infty;\alpha) = 1. \tag{F.3}$$

When $q_2 = 0$, $x_\ell^*(\tau)$ does not exist, but $\lim_{\alpha\to\infty} x_h^*(\tau;\alpha) = 1$ remains valid. The arguments in the proof presented below have to be modified slightly for this degenerate case.

The proof of (F.3) requires the solution of $W_\alpha^\infty(x)$, the perpetual limit of $W_\alpha(x,\tau)$. The governing equation for $W_\alpha^\infty(x)$ is given by

$$\frac{1}{2}(\sigma_1^2 - 2\rho\sigma_1\sigma_2 + \sigma_2^2)x^2\frac{d^2W_\alpha^\infty}{dx^2} + (q_2 - q_1)x\frac{dW_\alpha^\infty}{dx} - q_2 W_\alpha^\infty = 0, \qquad x_\ell^*(\infty) < x < x_h^*(\infty),$$

with auxiliary conditions

$$W_\alpha^\infty(x_\ell^*(\infty)) = \alpha - x_\ell^*(\infty), \qquad \frac{dW_\alpha^\infty}{dx}(x_\ell^*(\infty)) = -1,$$
$$W_\alpha^\infty(x_h^*(\infty)) = \alpha - 1, \qquad \frac{dW_\alpha^\infty}{dx}(x_h^*(\infty)) = 0.$$

By following an approach similar to that in Appendix B, we can show that

$$\lim_{\alpha\to\infty} \frac{x_h^*(\infty;\alpha)}{x_\ell^*(\infty;\alpha)} = 1,$$

and hence the relations in (F.3) are established. □

VOLUME OF SUSPENSION THAT FLOWS THROUGH A SMALL ORIFICE BEFORE IT CLOGS*

GUILLERMO H. GOLDSZTEIN†

Abstract. We consider the following experiment. A container is filled with a suspension consisting of particles immersed in an incompressible liquid. An opening is made on the container wall and the suspension flows through the opening. We develop a mathematical model to compute the expected volume of suspension extracted before particles clog the opening. Our studies are relevant to the understanding of clogging of pore throats in porous media, which plays an important role in geomaterials, biological systems, and industrial applications.

Key words. clogging, suspension flow, porous media, mathematical modeling

1. Introduction.

The migration of fines, i.e., small particles, in porous media plays an important role in several engineering applications including oil production, soil erosion, ground water pollution, and the operation of filter beds. Accordingly, this topic is an active area of research in a number of disciplines including petroleum, geotechnical, chemical, environmental, and hydraulic engineering (see [6]).

Soil mass is an example of a porous medium. The particles that hold the material together form what is known as the load carrying skeleton. Fines are small particles that do not form part of the load-carrying skeleton. Rocks are other examples of porous media with fines present in them. A typical size of these fines, which can be of inorganic, organic, or biological nature, is 1 μm, and they may have an electric surface charge. If liquid flows through the porous medium, fines attached to pore surfaces may be released due to hydrodynamic forces. These fines will move with the flow and be retained at other locations or exit the porous medium. The sites that retain fines are usually pore constrictions or pore throats. If several migrating particles reach a small pore throat simultaneously, the particles may clog the pore throat. More detailed discussions on the physical phenomena that lead to clogging can be found in [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14].

If fines get captured, the porous medium may become plugged. On the other hand, when fines exit the medium, the porous medium may erode, which may result in structural failure. Examples where these phenomena have important consequences include the following: the extraction of petroleum, where plugging is an undesirable effect—if the well completely clogs, it can no longer be used; the containment of contaminants—plugging may help in this situation; the failure of earthen dams and roads, which can be caused by the erosion that results from particle migration.

In this paper we study the following simple experiment that models aspects of clogging at a single pore throat. A container is filled with a suspension made of an incompressible liquid and spherical particles. A circular opening is made in the container wall through which the suspension flows. The particles may or may not clog

the opening. Our goal is to predict the volume of fluid extracted before clogging (if clogging does occur). The experiment described is illustrated in Figure 1.1.

The mathematical modeling of migration of fines in porous media is a complex task that is in its infancy (see [6]). The objective of this paper is to provide a step toward the more ambitious goal of developing reliable models for studying more complex problems where migration of fines in porous media plays an important role.

The rest of the paper proceeds as follows. In section 2 we make our physical assumptions and describe our mathematical model. In section 3 we describe a numerical algorithm to obtain solutions of the model. In section 4 we derive an upper bound on the volume extracted before clogging, and in section 5 we obtain a lower bound. The paper ends in section 6 with examples and conclusions.

2. The model. Our model relies on the following approximations. The liquid is incompressible. The flow is not disturbed by the presence of particles. The center of each particle flows with the same velocity as the fluid. Before the opening is made, the center of each particle is randomly placed inside the container with a uniform probability distribution in space.

Note that the initial location of the centers of the particles are independent random variables, and thus we allow particles to overlap.

For each point x in the container, we denote by $F(x)$ the volume of fluid extracted by the time the element of fluid initially at x reaches the opening. The left-hand image in Figure 2.1 shows a two-dimensional sketch of level sets of the function F. (The actual level sets of F are surfaces within the three-dimensional container.) Due to the incompressibility of the fluid, the region enclosed by the level sets $\{x : F(x) = V+\Delta V\}$ and $\{x : F(x) = V\}$ has volume ΔV.

We denote by A the area of the orifice and by v the volume fraction of particles (i.e., the volume occupied by the particles divided by the volume of the suspension). All the particles have the same radius r.

To motivate our criteria for clogging, assume that the fluid velocity is constant in space across the opening and out of the container. Once the volume of suspension initially in $\{x : V < F(x) \leq V + rA\}$ leaves the container, it forms a cylinder with height r (see the right-hand image in Figure 2.1). Since the centers of particles flow with the fluid, the number of centers of particles that belong to this cylinder is equal to the number of centers of particles initially placed in $\{x : V < F(x) \leq V + rA\}$. We

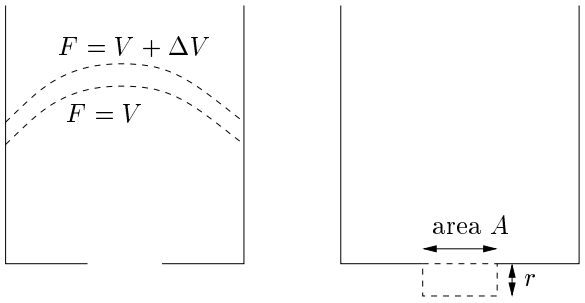

FIG. 2.1. *The left-hand image is a two-dimensional sketch of level sets of F. The region enclosed by the dashed lines is $\{x : V < F(x) \leq V + \Delta V\}$. The right-hand image is a two-dimensional sketch of the three-dimensional cylinder (enclosed by dashed lines) which is formed by the suspension initially in $\{x : V < F(x) \leq V + rA\}$ as soon as it leaves the container.*

denote this number by $k(V)$, i.e.,

$$k(V) = \text{ number of particles initially placed in } \{x : V < F(x) \leq V + rA\}. \tag{2.1}$$

Note that the particles whose centers belong to the dashed cylinder of Figure 2.1 arrive *almost simultaneously* at the opening. Thus, we propose that clogging occurs when $k(V)$, the number of particles arriving almost simultaneously at the opening, exceeds a threshold $k_{\max}$ for the first time. Thus, if the opening clogs, the volume of fluid that is extracted before clogging is

$$V^\star = \min_{\{V : V \geq 0 \text{ and } k(V) > k_{\max}\}} V. \tag{2.2}$$

We define λ to be the ratio of the volume of the dashed cylinder of Figure 2.1 and the volume of a particle, i.e.,

$$\lambda = \frac{3A}{4\pi r^2}. \tag{2.3}$$

Since the number of centers of particles that can belong to the cylinder under the condition that the particles do not overlap increases linearly with λ, we assume that $k_{\max}$ is of the form

$$k_{\max} = \gamma\lambda, \tag{2.4}$$

where γ is a material parameter to be experimentally determined. Given a realization of initial distribution of centers of particles inside the container, (2.1)–(2.4) determine the extracted volume $V^\star$.

3. Algorithm to compute the extracted volume. Assume that the suspension has volume $\mathcal{V}$ and contains a large but finite number N of particles. Then, the volume fraction of particles is $v = N4\pi r^3/(3\mathcal{V})$. The initial location of the center of each particle is a random variable with uniform probability distribution. This fact along with the incompressibility of the fluid implies that the volume extracted by the time a center of a particle reaches the opening is also a random variable with uniform probability distribution. As a consequence, if V_i is the volume extracted when the ith particle reaches the opening, these volumes V_i are the result of ordering N

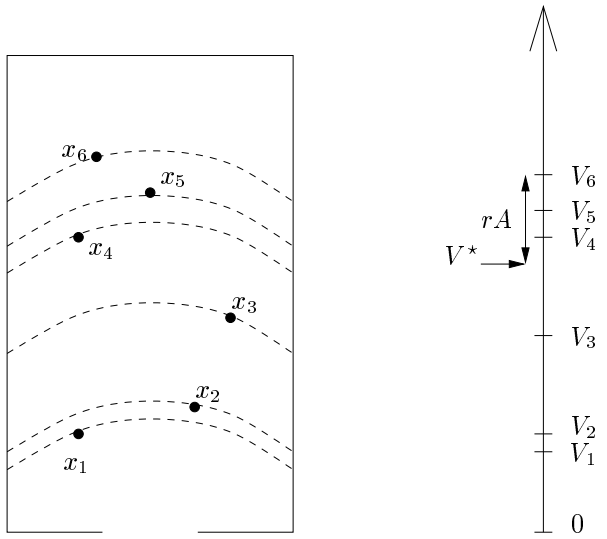

FIG. 3.1. *The initial location of the center of the ith particle to reach the opening is x_i. The dashed lines are the level sets of F. $V_i = F(x_i)$ is the volume extracted when the center of the ith particle reaches the opening. $V^\star$ is the volume extracted before clogging.*

numbers selected independently with uniform probability distribution in the interval $[0, \mathcal{V}]$. This is illustrated in Figure 3.1.

Our criterion for clogging (described in section 2) is illustrated in Figure 3.1. If we place a segment of length rA on top of the vertical volume axis of Figure 3.1 with the left end at 0, then move the segment in the upward direction, and stop as soon as the segment covers more than $k_{\max}$ particles simultaneously, the location of the lower end of the segment is the extracted volume $V^\star$.

The above paragraph can be precisely described as follows. For each i we define n_i to be the largest integer such that $V_{i-n_i+1} > V_i - rA$ subjected to the restriction $n_i \le i$. If there exists $i \in [1, N]$ such that $n_i > k_{\max}$, clogging occurs. Assuming that this is the case, let $i^\star = \min\{i : n_i > k_{\max}\}$. Then

$$V^\star = \begin{cases} 0 & \text{if } V_{i^\star} < rA, \\ V_{i^\star} - rA & \text{if } V_{i^\star} \ge rA. \end{cases} \tag{3.1}$$

The present discussion leads to the following algorithm to compute $V^\star$ for a given realization:

$i \leftarrow 1$
$n \leftarrow 1$
While $n \le k_{\max}$ and $i < N$
    $i \leftarrow i + 1$
    $n \leftarrow n + 1$
    While $V_{i-n+1} \le V_i - rA$
        $n \leftarrow n - 1$
    end
end
If $i = N$ and $n \le k_{\max}$ then
    "No clogging"

else
$V^\star \leftarrow \max\{0, V_i - rA\}$
end

The expected volume extracted before clogging, $E(V^\star)$, is computed by averaging the values of $V^\star$ obtained for a large number of different realizations. Note that the complexity of this algorithm in $O(N)$.

4. Upper bound on the expected extracted volume of suspension before clogging. Given a realization, the extracted volume before clogging $V^\star$, assuming that clogging does occur, is the minimum of the function $f(V) = V$ over the set $\{V : V \geq 0 \text{ and } k(V) > k_{\max}\}$ (see (2.2)). We define U to be the minimum of the same function $f(V) = V$ over a smaller set. More precisely,

$$U = \min_{\{V : V = irA,\ i \text{ integer},\ i \geq 0,\ k(V) > k_{\max}\}} V. \tag{4.1}$$

Since U and $V^\star$ are the minimum of the same function $f(V) = V$, but the set where f is minimized to obtain U is a subset of the set where f is minimized to obtain $V^\star$, we have

$$V^\star \leq U. \tag{4.2}$$

Thus, $E(V^\star)$ and $E(U)$, the expected values of $V^\star$ and U, respectively, satisfy

$$E(V^\star) \leq E(U). \tag{4.3}$$

In Appendix A we show that, if $rA \ll \mathcal{V}$ ($\mathcal{V}$ is the initial volume of the suspension),

$$E(U) = \frac{\mu}{1-\mu} rA, \quad \text{where} \quad \mu = e^{-\lambda v} \sum_{i=0}^{k_{\max}} \frac{(\lambda v)^i}{i!}, \tag{4.4}$$

where we recall that v is the volume fraction of the particles and λ was defined in (2.3). In particular, we also show in Appendix B that, in the parameter regime $\lambda v \ll 1$, we have

$$E(U) \simeq \frac{([k_{\max}] + 1)!}{(\lambda v)^{[k_{\max}]+1}} rA, \tag{4.5}$$

where $[k_{\max}]$ is the integral part of $k_{\max}$, i.e., the largest integer that is not greater than $k_{\max}$.

5. Lower bound on the expected extracted volume of suspension before clogging. Let M be the positive integer that satisfies

$$(M-1)rA \leq V^\star < MrA. \tag{5.1}$$

The sets $\{x : (M-1)rA < F(x) \leq MrA\}$ and $\{x : MrA < F(x) \leq (M+1)rA\}$ are disjoint, and their union contains $\{x : V^\star < F(x) \leq V^\star + rA\}$. Thus, since the number of particle centers initially placed in $\{x : V^\star < F(x) \leq V^\star + rA\}$ is larger than $k_{\max}$, the number of particle centers initially placed in one of the sets $\{x : (M-1)rA < F(x) \leq MrA\}$ or $\{x : MrA < F(x) \leq (M+1)rA\}$ is larger than $k_{\max}/2$. In other words, $\max\{k((M-1)rA), k(MrA)\} > k_{\max}/2$.

We define

$$L = \min_{\{V:V=irA,\ i \text{ integer},\ i\geq 0,\ k(V)>k_{\max}/2\}} V. \tag{5.2}$$

Given the above discussion, we have that $L \leq MrA$. Thus, (5.1) implies

$$L - rA \leq V^\star \tag{5.3}$$

and thus

$$E(L) - rA \leq E(V^\star), \tag{5.4}$$

where, as in the previous section, $E(.)$ denotes the expected value of the expression between brackets.

Following the same arguments to compute the upper bound, we obtain that, in the regime $rA \ll \mathcal{V}$,

$$E(L) = \frac{\eta}{1-\eta} rA, \quad \text{where} \quad \eta = e^{-\lambda v} \sum_{i=0}^{k_{\max}/2} \frac{(\lambda v)^i}{i!}. \tag{5.5}$$

In particular, in the parameter regime $\lambda v \ll 1$, we have

$$E(L) \simeq \frac{([k_{\max}/2]+1)!}{(\lambda v)^{[k_{\max}/2]+1}} rA \tag{5.6}$$

(as before [.] is the integral part of the argument).

6. Examples and conclusions. As an illustrative example, in Figure 6.1 we show a plot of the expected extracted volume $E(V^\star)$ and the upper and lower bounds $E(U)$ and $E(L) - rA$ versus the volume fraction v. The parameter values chosen are $\lambda = 3$ and $\gamma = 1$ (and thus, $k_{\max} = \lambda$). The expected extracted volumes were

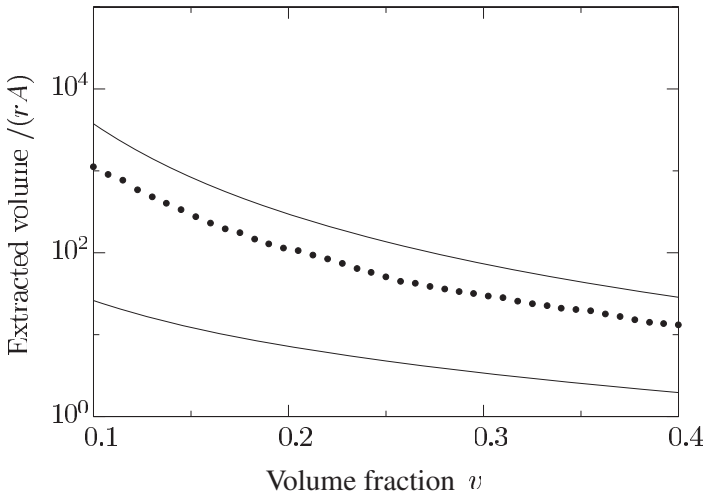

FIG. 6.1. *Normalized expected extracted volume $E(V^\star)/(rA)$ (dotted line), normalized upper bound $E(U)/(rA)$ (upper solid line), and normalized lower bound $(E(L) - rA)/(rA)$ (lower solid line) versus volume fraction v (for $\lambda = 3$ and $\gamma = 1$).*

numerically computed with the method described in this paper. Note that, for a circular opening, $\lambda = 3$ when the radius of the orifice is twice the radius of the particles.

We have developed and analyzed a simple mathematical model to predict the volume of suspension extracted through a small orifice before it clogs. Our model leads to a simple and efficient numerical algorithm as well as analytic expressions for lower and upper bounds on the volume extracted. From the expressions of the bounds, our model reflects the sensitivity of the volume extracted to two key parameters: the volume fraction of particles, v, and λ, which reflects the ratio between the size of the orifice and the size of the particles.

A next step will be to validate the model (or relax some of the physical assumptions made) by comparing the predictions with experimental measurements. After the necessary adjustments, a more ambitious goal is to use the results obtained here as a building block to address more complex problems. These issues will be pursued in the future.

Appendix A. The expected value of the upper bound. To compute the upper bound on the expected volume of suspension extracted before clogging, we need the observations that we describe next. As in the rest of this paper, N is the number of particles initially placed in the container and $\mathcal{V}$ is the initial volume of the suspension.

OBSERVATION 1. *Let Ω be a region inside the container, and let $|\Omega|$ be its volume. The probability that the centers of exactly i of the N particles were initially placed in Ω is*

$$p(i,|\Omega|) = \frac{N!}{i!(N-i)!}\left(\frac{|\Omega|}{\mathcal{V}}\right)^i\left(1-\frac{|\Omega|}{\mathcal{V}}\right)^{N-i}. \tag{A.1}$$

In particular, this probability depends only on i, N, and the volume of Ω. Moreover, the asymptotic value $p(i,|\Omega|)$ in the regime $N \gg i$ and $\mathcal{V} \gg |\Omega|$ is

$$p(i,|\Omega|) \simeq \frac{1}{i!}\left(\frac{N|\Omega|}{\mathcal{V}}\right)^i e^{-\frac{N|\Omega|}{\mathcal{V}}}. \tag{A.2}$$

In particular, if $|\Omega| = rA$,

$$p(i,rA) \simeq \frac{1}{i!}(\lambda v)^i e^{-\lambda v} \tag{A.3}$$

(where v is the volume fraction of the particles and λ was defined in (2.3)).

This observation results from the fact that the centers of the particles are placed in the container randomly with uniform probability distribution, from basic probability arguments (see any probability text book), and from the equality $rAN = \lambda v\mathcal{V}$.

We use the standard notation $P(z)$ for the probability that the event z is true.

OBSERVATION 2. *If i is an integer that satisfies $i \ll N$, and if $rA \ll \mathcal{V}$, then for any $0 \le V \le \mathcal{V} - rA$ we have*

$$P(k(V) = i) \simeq \frac{1}{i!}(\lambda v)^i e^{-\lambda v}. \tag{A.4}$$

Note, in particular, that $P(k(V) = i)$ is independent of V.

This observation results from the definition of the function $k = k(V)$ (see (2.1)), the fact that the volume of the set $\{x : V < F(x) \le V + rA\}$ is rA, and equation (A.3).

OBSERVATION 3. *Let Ω_1 and Ω_2 be two disjoint regions inside the container. Assume that $\mathcal{V} \gg \max\{|\Omega_1|, |\Omega_2|\}$. Let i_1 and i_2 be two nonnegative integers that satisfy $N \gg \max\{i_1, i_2\}$. The probability of having placed exactly i_1 centers of particles in Ω_1 and i_2 centers of particles in Ω_2 is asymptotically equal to $p(i_1, |\Omega_1|)p(i_2, |\Omega_2|)$.*

The validity of this observation is a consequence of the fact that the placements of exactly i_1 centers of particles in Ω_1 and i_2 centers of particles in Ω_2 are asymptotically independent events in the regime $N \gg \max\{i_1, i_2\}$ and $\mathcal{V} \gg \max\{|\Omega_1|, |\Omega_2|\}$.

OBSERVATION 4. *Let i and j be two different nonnegative integers, $i \neq j$. The random variables $k(irA)$ and $k(jrA)$ are asymptotically independent.*

This observation results from the definition of the function $k = k(V)$, the fact that the sets $\{x : jrA < F(x) \leq (j+1)rA\}$ and $\{x : irA < F(x) \leq (i+1)rA\}$ are disjoint, and Observation 3.

Let m be a nonnegative integer. From the definition of U (see (4.1)), we have $U = mrA$ if $k(jrA) \leq k_{\max}$ for $0 \leq j < m$ and $k(mrA) > k_{\max}$. Thus,

$$P(U = mrA) = P(k(jrA) \leq k_{\max} \text{ for } j < m \text{ and } k(mrA) > k_{\max}). \tag{A.5}$$

Given Observation 4, the $m+1$ events $k(jrA) \leq k_{\max}$ (for $0 \leq j < m$) and $k(mrA) > k_{\max}$ are asymptotically independent (more precisely, in the parameter regime $mk_{\max} \ll N$). Thus, (A.5) reduces to

$$P(U = mrA) \simeq P(k(mrA) > k_{\max}) \prod_{j=0}^{m-1} P(k(jrA) \leq k_{\max}). \tag{A.6}$$

From Observation 2 and the definition of the parameter μ in (4.4), we have that

$$P(k(jrA) \leq k_{\max}) \simeq \mu \quad \text{and} \quad P(k(mrA) > k_{\max}) \simeq 1 - \mu. \tag{A.7}$$

Equations (A.6) and (A.7) imply that

$$P(U = mrA) \simeq (1-\mu)\mu^m, \tag{A.8}$$

and thus, in the parameter regime $N \gg k_{\max}$, the expected value of U is

$$E(U) \simeq \sum_{m=0}^{\infty} mrAP(U = mrA) \simeq rA \sum_{m=0}^{\infty} m(1-\mu)\mu^m = \frac{\mu}{1-\mu} rA, \tag{A.9}$$

which shows the validity of (4.4).

Appendix B. The upper bound in the regime $\lambda v \ll 1$. Given the definition of μ (see (4.4)), we have

$$e^{\lambda v}(1-\mu) = e^{\lambda v} - \sum_{i=0}^{k_{\max}} \frac{(\lambda v)^i}{i!} = \sum_{i=0}^{\infty} \frac{(\lambda v)^i}{i!} - \sum_{i=0}^{k_{\max}} \frac{(\lambda v)^i}{i!} = \sum_{i=[k_{\max}]+1}^{\infty} \frac{(\lambda v)^i}{i!}. \tag{B.1}$$

Thus, we have

$$1 - \mu = e^{-\lambda v} \frac{(\lambda v)^{[k_{\max}]+1}}{([k_{\max}]+1)!} \qquad \text{if} \quad \lambda v \ll 1. \tag{B.2}$$

Since we clearly have

$$\mu = e^{-\lambda v} \quad \text{if} \quad \lambda v \ll 1, \tag{B.3}$$

the validity of (4.5) follows.

Acknowledgments. The author thanks Professor Santamarina for introducing the author to this area of research and for stimulating discussions. This work was motivated by experiments of Santamarina's research group.

EXISTENCE AND STABILITY OF TRAVELING WAVES IN BUFFERED SYSTEMS*

JE-CHIANG TSAI† AND JAMES SNEYD‡

Abstract. We study wave propagation in the buffered bistable equation, i.e., the bistable equation where the diffusing species reacts with immobile buffers that restrict its diffusion. Such a model describes wave front propagation in excitable systems where the diffusing species is buffered; in particular, the study of the propagation of waves of increased calcium concentration in a variety of cell types depends directly upon the analysis of such buffered excitability. However, despite the biological importance of these types of equations, there have been almost no analytical studies of their properties.

Here, we study the question of whether or not the inclusion of multiple buffers can eliminate propagated waves. First, we prove that a unique (up to translation) traveling wave front exists. Moreover, the wave speed is also unique. Then we prove that this traveling wave front is stable, i.e., that any initial condition which vaguely resembles a traveling wave front (in a way we make precise) evolves to the unique wave front.

We thus prove that multiple stationary buffers cannot prevent the existence of a traveling wave front in the buffered bistable equation and may not eliminate stable wave fronts. This suggests (although we do not prove) that the same result is true for more complex and realistic models of calcium wave propagation, a result of direct physiological relevance.

Key words. calcium, reaction-diffusion equations, traveling wave, bistable equation, FitzHugh–Nagumo equations, stability

1. Introduction.

Wave propagation in excitable systems has been the subject of a vast number of mathematical studies over the last 50 years. The basic mathematical theory can be used to describe wave propagation in a wide array of biological and chemical systems, from action potentials in neurons to chemical waves in the Belousov–Zhabotinskii reaction to combustion waves [4, 9, 24, 26].

One of the more recent applications of the theory has been to the study of waves of increased calcium concentration that travel both within and between cells. Such waves are observed in a wide array of cell types [19, 24]. Although their precise physiological function is not always clear, it is widely accepted that they are an important way in which cells can transmit an intracellular signal or coordinate the behavior of a large number of cells. They have thus been studied extensively, both by experimentalists and theoreticians.

As a general rule, models for calcium waves have been based on reaction-diffusion mechanisms. Thus, if we let u denote the concentration of free cytosolic calcium, a

typical model for intracellular calcium waves can be expressed in the following generic form:

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial x^2} + f(u), \tag{1.1}$$

where $D > 0$ is the diffusion coefficient of the free calcium and $f(u)$ describes the kinetics of calcium transport into and out of the cytosol. For typical examples, the reader is referred to Sneyd, Keizer, and Sanderson [24].

Despite the complexity of all realistic models of calcium wave propagation, simpler models still play a useful role. Although the FitzHugh–Nagumo (FHN) model was originally designed as a simple model of an action potential, the mathematical similarities between action potential propagation and calcium wave propagation mean that one may gain much understanding of the mechanisms underlying calcium waves from a study of these earlier, simple models. Even simpler models, such as the bistable equation, are also useful, despite their almost complete lack of physiological details. Such, of course, is the power of a mathematical model, to abstract the general from the particular, so that one is not restricted to always dealing with special cases.

However, despite the important similarities with other excitable systems, the study of calcium waves has some crucial differences, the most important of which, at first glance, is the existence of calcium buffers. A large fraction of cytosolic calcium (at least 99%) is bound to large proteins that act as calcium buffers. Not only do these buffers restrict the diffusion of free calcium, they also affect the kinetics of calcium release and uptake, and thus they would be expected to have an important effect on the properties of traveling calcium waves. Terms describing buffering do not occur in simpler excitable models such as FHN, nor even in more complex models such as Hodgkin–Huxley. Thus their effect on wave propagation is not at all well understood. Despite this, there have been few analytic investigations of the effects of buffers on traveling waves.

A simple way to model buffering is to assume that calcium (Ca^{2+}) reacts with buffers according to the following reaction scheme:

$$Ca^{2+} + B_i \rightleftharpoons CaB_i, \quad i = 1, \ldots, n, \tag{1.2}$$

where B_i denotes the ith buffer in its unbound form, and CaB_i denotes the ith buffer that is bound to calcium. Let v_i denote the concentration $[B_i]$ of the ith buffer and b_0^i denote the total amount of the ith buffer. Also note that $b_0^i = [B_i] + [CaB_i]$. We shall assume that b_0^i is a constant. It follows that the rate of change of u due to buffering is given by

$$\frac{du}{dt} = \sum_{i=1}^{n} [k_-^i (b_0^i - v_i) - k_+^i u v_i], \tag{1.3}$$

where k_+^i and k_-^i denote the forward and reverse rate constants of the ith reaction (1.2), respectively. Hence if we assume that all of the buffers are stationary, then we have the buffered reaction-diffusion system

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial x^2} + f(u) + \sum_{i=1}^{n} [k_-^i (b_0^i - v_i) - k_+^i u v_i], \tag{1.4}$$

$$\frac{\partial v_i}{\partial t} = k_-^i (b_0^i - v_i) - k_+^i u v_i, \ (x,t) \in \mathbf{R} \times (0, +\infty), \tag{1.5}$$

with the initial data

$$u(x,0)=\phi(x),\quad v_i(x,0)=\psi_i(x),\ x\in\mathbf{R},\quad \text{for}\ \ i=1,\dots,n. \tag{1.6}$$

Although there are many different types of calcium buffers, each with widely different rate constants, reasonable values for a typical endogenous buffer are $k_+ = 50\ \mu\text{M}^{-1}\text{s}^{-1}$, $k_- = 500\ \text{s}^{-1}$, and $b_0 = 100\ \mu\text{M}$. Typical exogeneous buffers (i.e., ones added experimentally) are BAPTA ($k_+ = 600\ \mu\text{M}^{-1}\text{s}^{-1}$ and $k_- = 100\ \text{s}^{-1}$) or EGTA ($k_+ = 1.5\ \mu\text{M}^{-1}\text{s}^{-1}$ and $k_- = 0.3\ \text{s}^{-1}$). Because BAPTA and EGTA are added exogeneously, their total concentration (b_0) can take any desired value.

There have been a large number of purely numerical studies including calcium buffers (see, for instance, [3, 8, 16, 20]). However, numerical studies suffer from the disadvantage that one can never know how much the results are dependent solely on the particular values chosen for the parameters. It is far preferable to obtain analytical results, applicable to as wide an array of buffers as possible, so that the effects of buffers on calcium dynamics can be understood in the most general possible context.

Some of the early analytical work on buffers was that of Wagner and Keizer [27], who showed that if the buffer is assumed to have fast kinetics (relative to the other reactions in the model), the full buffered model could be reduced to a single equation for the diffusion of calcium, an equation in which the effective diffusion coefficient of calcium was now dependent on the calcium concentration. This is the so-called rapid buffering approximation (RBA). This early work was extended, and put into a more direct experimental context, by Naraghi and Neher [13], Naraghi, Muller, and Neher [14], and Neher [15]. The RBA was also used as the basis of analytical investigations of profiles around the mouth of an open calcium channel [21] and was later derived as one case in a more general asymptotic expansion of the full equation [22].

However, these previous studies left open the question of whether or not multiple buffers, not necessarily fast ones, could eliminate wave propagation. Of course, in the limit of infinitely slow buffers, the answer is intuitively clear; if the wave exists in the absence of buffers, then it will exist in the presence of an infinitely slow buffer. Conversely, Sneyd, Dale, and Duffy [25] showed that if the buffer is infinitely fast, then waves cannot be eliminated by the buffers. However, nothing was known about the intermediate cases when the buffer is neither infinitely fast nor infinitely slow. It is all these intermediate cases that we address here. They are, of course, vastly more difficult. Previous studies also neglected to study the stability of the buffered waves, something we also address here.

As in previous studies [25] we shall study only the buffered bistable equation here, i.e., when the reaction function f takes the particularly simple form,

$$f(u)=u(u-a)(1-u),$$

for some constant $a>0$. A more realistic model of calcium wave propagation would include a recovery variable, as in the FHN equations. However, if recovery is slow, the bistable equation provides a good description of the traveling wave in the FHN equations, and thus our results are also applicable to traveling waves in the FHN equations. This is confirmed numerically in Sneyd, Dale, and Duffy [25]. A similar analysis of a realistic model of calcium waves of much greater complexity is simply not possible at this stage. Nevertheless, as discussed above, previous work suggests that results for the FHN model carry over to more complex calcium wave models.

Description of results. Our results here can be summarized concisely:

1. A unique wave front solution exists (as long as it exists in the absence of buffers). Moreover, the wave speed is also unique.
2. Furthermore, if some technical constraints are made on the initial values, then this unique wave front is also stable with respect to this class of initial values.

Thus, our results complete the picture of how stationary buffers affect wave existence in the bistable equation.

In order to state our results more precisely, we give the definition of a traveling wave solution of (1.4)–(1.5). First, for each solution $(u, \mathbf{v}) = (u, v_1, \dots, v_n)$ of (1.4)–(1.6), we introduce the moving coordinate $z = x - ct$ and set $\tilde{u}(z,t) = u(z+ct,t)$ and $\tilde{v}_i(z,t) = v_i(z+ct,t)$, $i = 1, \dots, n$, where c is a negative constant (wave speed). Then $\tilde{u}$ and $\tilde{v}_i$ satisfy the following system:

$$\frac{\partial \tilde{u}}{\partial t} = D\frac{\partial^2 \tilde{u}}{\partial z^2} + c\frac{\partial \tilde{u}}{\partial z} + f(\tilde{u}) + \sum_{i=1}^{n}[k_-^i(b_0^i - \tilde{v}_i) - k_+^i \tilde{u}\tilde{v}_i], \tag{1.7}$$

$$\frac{\partial \tilde{v}_i}{\partial t} = c\frac{\partial \tilde{v}_i}{\partial z} + k_-^i(b_0^i - \tilde{v}_i) - k_+^i \tilde{u}\tilde{v}_i,\ (z,t) \in \mathbf{R} \times (0, +\infty), \tag{1.8}$$

with the initial data

$$\tilde{u}(z,0) = \phi(z) \ \text{ and } \ \tilde{v}_i(z,0) = \psi_i(z),\ z \in \mathbf{R}, \ \text{ for } \ i = 1, \dots, n. \tag{1.9}$$

Then a set of nonnegative functions $(\mathcal{U}(\xi), \mathbf{\Pi}(\xi)) = (\mathcal{U}(\xi), \Pi_1(\xi), \dots, \Pi_n(\xi)) \in \mathbf{C}^2(\mathbf{R}) \times \mathbf{C}^1(\mathbf{R}) \times \cdots \times \mathbf{C}^1(\mathbf{R})$ are said to be a traveling wave solution of (1.4)–(1.5) with wave speed c if they satisfy

$$D\ddot{\mathcal{U}} + c\dot{\mathcal{U}} + f(\mathcal{U}) + \sum_{i=1}^{n}[k_-^i(b_0^i - \Pi_i) - k_+^i \mathcal{U}\Pi_i] = 0,$$
$$c\dot{\Pi}_i + k_-^i(b_0^i - \Pi_i) - k_+^i \mathcal{U}\Pi_i = 0, \ \ \xi = x - ct \in \mathbf{R},\ i = 1, \dots, n,$$

with the boundary conditions

$$(\mathcal{U}(+\infty), \Pi_1(+\infty), \dots, \Pi_n(+\infty)) = (1, k_-^1 b_0^1/(k_+^1 + k_-^1), \dots, k_-^n b_0^n/(k_+^n + k_-^n))$$

and

$$(\mathcal{U}(-\infty), \Pi_1(-\infty), \dots, \Pi_n(-\infty)) = (0, b_0^1, \dots, b_0^n),$$

where $\cdot$ denotes $d/d\xi$. Note that this definition implies that a traveling wave solution $(\mathcal{U}(\xi), \mathbf{\Pi}(\xi))$ of (1.4)–(1.5) with wave speed c is a steady state solution of (1.7)–(1.8). Also note that, physiologically, the concentration of the ith buffer v_i shall decrease from b_0^i to some constant concentration as time evolves for $i = 1, \dots, n$. Thus we impose such boundary conditions.

It is well known that traveling waves with negative speed in the bistable equation exist only when $a \in (0, 1/2)$ or, more generally, when $\int_0^1 f(u)du > 0$ (see Fife and McLeod [5] and Britton [2]). Moreover, the wave speed is unique. On the other hand, it is interesting to point out that we can prove that given $a \in (0, 1/2)$, then there exists a unique $c := c(a) < 0$ such that a unique (up to translation) traveling wave solution $(\mathcal{U}, \mathbf{\Pi})$ of our buffered bistable equations (1.4)–(1.5) with wave speed c exists. Moreover, $(\mathcal{U}, \mathbf{\Pi})$ satisfies that $\dot{\mathcal{U}} > 0$ and $\dot{\Pi}_i < 0$, $i = 1, \dots, n$, on $\mathbf{R}$. Furthermore,

a traveling wave solution $(\mathcal{U}, \mathbf{\Pi})$ of (1.4)–(1.5) with negative wave speed, such that $\dot{\mathcal{U}} > 0$ and $\dot{\Pi}_i < 0$, $i = 1, \ldots, n$, on $\mathbf{R}$, exists only if $a \in (0, 1/2)$. Comparing this result with the unbuffered equation (1.1), we may conclude that stationary buffers cannot eliminate wave activity. Throughout the remainder of this section, $(\mathcal{U}, \mathbf{\Pi})$ will denote such a unique traveling wave solution of (1.4)–(1.5) with speed c and $\mathcal{U}(0) = 1/2$.

Regarding the stability of this traveling wave solution of (1.4)–(1.5), we need to put some technical constraint on the initial values. More precisely, let $a \in (0, 1/2)$ hold and $(\tilde{u}, \tilde{\mathbf{v}})$ be the solution of (1.7)–(1.8) with the initial condition $(\phi, \psi_1, \ldots, \psi_n)$, which satisfies the following conditions:

(1) ϕ and ψ_i are sufficiently smooth, and $\phi' \geq 0$, $\psi_i' \leq 0$ on $\mathbf{R}$ for $i = 1, \ldots, n$;
(2) $\sup_{z\in\mathbf{R}} |\phi(z)| + \sup_{z\in\mathbf{R}} |\phi'(z)| + \sup_{z\in\mathbf{R}} |\phi''(z)| + \sup_{z\in\mathbf{R}} |\phi'''(z)| < +\infty$;
(3) $1 - \phi_2 > 0$, $\psi_{2i} - k_-^i b_0^i/(k_+^i + k_-^i) > 0$, $\phi_0 > 0$, and $b_0^i - \psi_{0i} > 0$ are sufficiently small for $i = 1, \ldots, n$;
(4) $\tilde{u}_t(z, 0) \geq 0$ and $\tilde{v}_{i,t}(z, 0) \leq 0$ for all $z \in \mathbf{R}$ and $i = 1, \ldots, n$,

where

(1.10)
$$\phi_2 = \lim_{z\to+\infty} \phi(z),\ \psi_{2i} = \lim_{z\to+\infty} \psi_i(z),\ \phi_0 = \lim_{z\to-\infty} \phi(z),\ \text{ and }\ \psi_{0i} = \lim_{z\to-\infty} \psi_i(z);$$

then there exists $z_0 \in \mathbf{R}$ such that

$$\lim_{t\to+\infty} |\tilde{u}(z, t) - \mathcal{U}(z - z_0)| = 0,\ \ \lim_{t\to+\infty} |\tilde{v}_i(z, t) - \Pi_i(z - z_0)| = 0,\ i = 1, \ldots, n,$$

uniformly with respect to $z \in \mathbf{R}$. Roughly speaking, this implies that a solution of (1.4)–(1.5) which vaguely resembles a traveling front $(\mathcal{U}, \Pi_1, \ldots, \Pi_n)$ at initial time will develop into a translate of such a traveling front as $t \to +\infty$. Therefore, we may conclude that, physiologically, a unique stable traveling wave front exists, as long as it exists in the absence of buffers. Finally, we will consider the case for mobile buffers in the future.

We will modify the method of Klaasen and Troy [10] (also see Hastings [7] and Fife and McLeod [5]) to prove our results. However, note that the assumptions made on the reaction terms in [10] are different from the one here. This paper is organized as follows. In section 2, we first give some preliminary results. In section 3, we will adapt the method of [10, 7] to prove the existence and uniqueness of a traveling wave solution of (1.4)–(1.5), and the uniqueness of wave speed is also considered. In section 4, some theorems on partial differential equations and the results of stability for our traveling wave solution will be stated, and then we will modify the method of [10, 5] to prove the theorem of stability for our traveling wave solution of (1.4)–(1.5). Finally, the proofs of some technical lemmas are deferred to the appendix.

2. Preliminaries. First, for ease of use we set up some notation.

DEFINITION 1.

(1) $\gamma_i(u) := k_+^i u + k_-^i$ *and* $k_i(u) := k_-^i b_0^i/(k_+^i u + k_-^i)$ *for* $i = 1, \ldots, n$.
(2) $F(u, \mathbf{v}) := u(u-a)(1-u) + \sum_{i=1}^n [k_-^i b_0^i - (k_+^i u + k_-^i) v_i]$, *where* $\mathbf{v} = (v_1, \ldots, v_n)$.
(3) $G_i(u, \mathbf{v}) := k_-^i b_0^i - (k_+^i u + k_-^i) v_i = \gamma_i(u)(k_i(u) - v_i)$, *where* $\mathbf{v} = (v_1, \ldots, v_n)$ *for* $i = 1, \ldots, n$.
(4) $a_0 = 0$, $a_1 = a$, *and* $a_2 = 1$.
(5) $\pi_0 = (a_0, 0, \mathbf{b_0})^t = (a_0, 0, b_0^1, \ldots, b_0^n)^t = (0, 0, b_0^1, \ldots, b_0^n)^t$,
$\pi_1 = (a_1, 0, \mathbf{b_1})^t = (a_1, 0, b_1^1, \ldots, b_1^n)^t = (a, 0, k_-^1 b_0^1/(k_+^1 a + k_-^1), \ldots, k_-^n b_0^n/(k_+^n a + k_-^n))^t$,
and

$\pi_2 = (a_2, 0, \mathbf{b_2})^t = (a_2, 0, b_2^1, \ldots, b_2^n)^t = (1, 0, k_-^1 b_0^1/(k_+^1 + k_-^1), \ldots, k_-^n b_0^n/(k_+^n + k_-^n))^t$, *where the* t *denotes transposition of a vector.*

(6) *For two vectors* $\mathbf{c} = (c_1, \ldots, c_n)$ *and* $\mathbf{d} = (d_1, \ldots, d_n)$, *the symbol* $\mathbf{c} < \mathbf{d}$ *means* $c_i < d_i$ *for* $i = 1, \ldots, n$, *and* $\mathbf{c} \leq \mathbf{d}$ *means* $c_i \leq d_i$ *for* $i = 1, \ldots, n$.

(7) $\mathbf{R}^+$ *stands for the set of all of the positive real numbers.*

In terms of this notation, we can rewrite (1.4)–(1.5) as the following system:

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial x^2} + u(u-a)(1-u) + \sum_{i=1}^{n} \gamma_i(u)(k_i(u) - v_i), \tag{2.1}$$

$$\frac{\partial v_i}{\partial t} = \gamma_i(u)(k_i(u) - v_i),\ i = 1, \ldots, n. \tag{2.2}$$

The following lemma follows from the associated definitions and a simple calculation.

LEMMA 2.1.

(1) F *and* G_i *are analytic on* $[0,1] \times [0, \infty)$, *and* $\gamma_i(u)$, $k_i(u)$ *are analytic and positive on* $[0,1]$ *for* $i = 1, \ldots, n$.

(2) $F_u(u, \mathbf{v}) = u(2-3u) + a(2u-1) - \sum_{i=1}^n k_+^i v_i$, $F_{v_i}(u, \mathbf{v}) = -\gamma_i(u) < 0$, $G_{i,u}(u, \mathbf{v}) = -k_+^i v_i \leq 0$, *and* $G_{i,v_i}(u, \mathbf{v}) = -\gamma_i(u) < 0$ *for all* $(u, \mathbf{v}) \in [0,1] \times [0, \infty)^n$.

(3) *If* $a \in (0, 1/2)$, *then* $\int_{a_0}^{a_2} F(u, k_1(u), k_2(u), \ldots, k_n(u))du > 0$.

3. Existence and uniqueness of the traveling wave solution.

3.1. Outline of the proof. First, we set up our problem. Namely, we shall look for a traveling wave solution of (2.1)–(2.2) in the form $u = \mathcal{U}(\xi), v_i = \Pi_i(\xi), i = 1, \ldots, n$, with $\xi = x - ct$. Therefore, $(\mathcal{U}, \mathbf{\Pi})$ satisfies

$$\ddot{\mathcal{U}} = (-c\dot{\mathcal{U}} - F(\mathcal{U}, \mathbf{\Pi}))/D, \tag{3.1}$$

$$\dot{\Pi}_i = -G_i(\mathcal{U}, \mathbf{\Pi})/c,\ i = 1, \ldots, n, \tag{3.2}$$

with the boundary conditions

$$(\mathcal{U}(-\infty), \dot{\mathcal{U}}(-\infty), \mathbf{\Pi}(-\infty)) = (a_0, 0, \mathbf{b_0}) \tag{3.3}$$

and

$$(\mathcal{U}(+\infty), \dot{\mathcal{U}}(+\infty), \mathbf{\Pi}(+\infty)) = (a_2, 0, \mathbf{b_2}), \tag{3.4}$$

where $\mathbf{\Pi} = (\Pi_1, \ldots, \Pi_n)$ and $\cdot = d/d\xi$.

By setting $\tau = (-\xi)/c$, $' = d/d\tau$, $\theta = c^2/D$, and $\mathcal{U}' = \mathcal{Z}$, we can rewrite the above problem as the following first-order system of differential equations:

$$\mathcal{U}' = \mathcal{Z}, \tag{3.5}$$

$$\mathcal{Z}' = \theta(\mathcal{Z} - F(\mathcal{U}, \mathbf{\Pi})), \tag{3.6}$$

$$\Pi_i' = G_i(\mathcal{U}, \mathbf{\Pi}),\ i = 1, \ldots, n, \tag{3.7}$$

with the boundary conditions

$$(\mathcal{U}(-\infty), \mathcal{Z}(-\infty), \mathbf{\Pi}(-\infty)) = (a_0, 0, \mathbf{b_0}) \tag{3.8}$$

and

$$(\mathcal{U}(+\infty), \mathcal{Z}(+\infty), \mathbf{\Pi}(+\infty)) = (a_2, 0, \mathbf{b_2}). \tag{3.9}$$

Therefore, in order to solve the problem of existence of traveling wave solutions of (2.1)–(2.2), it suffices to consider the problem (3.5)–(3.9). Note that from the definitions of F and G_i, $i = 1, \dots, n$, it follows that (3.5)–(3.7) have three equilibrium solutions: π_0, π_1, and π_2.

Our strategy is to use the shooting method. We briefly describe the procedure as follows. First, we let $(\mathcal{U}_\theta, \mathcal{Z}_\theta, \mathbf{\Pi}_\theta)$ denote a solution of (3.5)–(3.8) and $(-\infty, T_\theta)$ be the corresponding maximal existence interval of $(\mathcal{U}_\theta, \mathcal{Z}_\theta, \mathbf{\Pi}_\theta)$ (we will omit the subscript θ in the following subsections if there is no ambiguity). Thus our goal is to choose suitable θ to make $(\mathcal{U}_\theta, \mathcal{Z}_\theta, \mathbf{\Pi}_\theta)$ satisfy (3.9). In section 3.2, we will analyze the behavior of $(\mathcal{U}_\theta, \mathcal{Z}_\theta, \mathbf{\Pi}_\theta)$ around $\tau = -\infty$ (see Lemma 3.1) and obtain the uniqueness (up to translation) of the traveling wave solution of (2.1)–(2.2) with given negative wave speed c if it exists. Next, in section 3.3, we will prove two technical lemmas and use one of them to prove a necessary condition for the existence of a monotone traveling wave solution of (2.1)–(2.2) with negative wave speed. Then, in section 3.4, we will give a proof of the existence of the traveling wave solution of (2.1)–(2.2). Roughly speaking, we will consider the following two sets:

$$\mathcal{P}_1 = \{\theta > 0 \mid \mathcal{U}'_\theta > 0 \text{ on } (-\infty, \hat{\tau}] \text{ and } \mathcal{U}_\theta(\hat{\tau}) = a_2 \text{ for some finite } \hat{\tau}\}$$

and

$$\mathcal{P}_2 = \{\theta > 0 \mid \mathcal{U}'_\theta(\tau) = 0 \text{ for some } \tau \in \mathbf{R} \text{ and } \mathcal{U}_\theta(\tau) \in (a_1, a_2]\}.$$

Then we will show that $\mathcal{P}_1$ is open and contains $(\theta_1, +\infty)$ for some $\theta_1 > 0$ (see Step 2 in the proof of Lemma 3.5) and that $\mathcal{P}_2$ is open and contains $(0, \theta_2)$ for some $\theta_2 > 0$ (see Step 3 in the proof of Lemma 3.5). Therefore, $\theta^* := \sup \mathcal{P}_2$ exists and $\theta^* \in \mathbf{R}^+ \setminus (P_1 \cup P_2)$, and so $(\mathcal{U}_{\theta^*}, \mathbf{\Pi}_{\theta^*})$ is our desired solution (see Step 4 in the proof of Lemma 3.5).

Finally, we will use the comparison method to prove the uniqueness of the wave speed of the traveling wave front in section 3.5.

3.2. The behavior of $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ around $\tau = -\infty$. Linearizing (3.5)–(3.7) around the constant solution π_0, we obtain the equation $d\mathbf{X}/d\tau = A_0\mathbf{X}$, where $\mathbf{X} = (\mathcal{U} - a_0, \mathcal{Z}, \Pi_1 - b_0^1, \dots, \Pi_n - b_0^n)^t$,

$$A_0 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ -\theta F_u & \theta & -\theta F_{v_1} & \cdots & -\theta F_{v_n} \\ G_{1,u} & 0 & G_{1,v_1} & \cdots & G_{1,v_n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ G_{n,u} & 0 & G_{n,v_1} & \cdots & G_{n,v_n} \end{bmatrix} \quad \text{with } G_{i,v_j} = \partial G_i/\partial v_j, \tag{3.10}$$

and all the values are evaluated at $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi}) = \pi_0$. Thus the associated characteristic polynomial with A_0 is

$$p_n(\lambda) = \det \begin{bmatrix} -\lambda & 1 & 0 & \cdots & 0 \\ -\theta F_u & \theta - \lambda & -\theta F_{v_1} & \cdots & -\theta F_{v_n} \\ G_{1,u} & 0 & G_{1,v_1} - \lambda & \cdots & G_{1,v_n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ G_{n,u} & 0 & G_{n,v_1} & \cdots & G_{n,v_n} - \lambda \end{bmatrix}. \tag{3.11}$$

Note that $\partial G_i/\partial v_j = 0$ if $i \neq j$ and $G_{i,v_i}(a_0, \mathbf{b_0}) = -k_-^i$ for $i = 1, \dots, n$. Then, by Lemma 5.1 in the appendix, we may assume that the eigenvalues $\lambda_1, \dots, \lambda_{n+2}$ of A_0 satisfy $\lambda_{n+2} < \cdots < \lambda_2 < 0 < \lambda_1$ (some of the negative ones may be equal).

Let $\bar{\mathbf{X}}$ be an eigenvector of A_0 corresponding to λ_1. Then there is a nonconstant solution Γ of (3.5)–(3.7) which tends to π_0 as $\tau \to -\infty$ and whose tangent vector at $\tau = -\infty$ is the eigenvector $\bar{\mathbf{X}}$ or $-\bar{\mathbf{X}}$. Set $\bar{\mathbf{X}} = (X_1, \ldots, X_{n+2})$. From the equation $A_0\bar{\mathbf{X}} = \lambda_1\bar{\mathbf{X}}$ it follows that

$$X_2 = \lambda_1 X_1, \tag{3.12}$$

$$-\theta(F_u(a_0, \mathbf{b_0})X_1 + \sum_{i=1}^{n} F_{v_i}(a_0, \mathbf{b_0})X_{i+2}) = (\lambda_1 - \theta)X_2, \tag{3.13}$$

$$G_{i,u}(a_0, \mathbf{b_0})X_1 = (\lambda_1 - G_{i,v_i}(a_0, \mathbf{b_0}))X_{i+2} \tag{3.14}$$

for $i = 1, \ldots, n$. Noting that $\lambda_1 > 0$, $G_{i,v_i}(a_0, \mathbf{b_0}) = -k_-^i < 0$, and using (3.12) and (3.14), we can assume that $X_1 > 0$ and $X_2 > 0$. Moreover, from $\lambda_1 > 0$, $G_{i,u}(a_0, \mathbf{b_0}) = -k_+^i b_0^i < 0$, $G_{i,v_i}(a_0, \mathbf{b_0}) = -k_-^i < 0$, and (3.14), it follows that $X_{i+2} < 0$ for $i = 1, \ldots, n$.

In the remainder of this section, we assume that a solution $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ of (3.5)–(3.8) satisfies the condition that the tangent vector $\bar{\mathbf{X}}$ to $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ at $\tau = -\infty$ has the properties as discussed above. Hence near $\tau = -\infty$, $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ satisfies $\mathcal{U} > a_0$, $\mathcal{Z} = \mathcal{U}' > 0$, and $\Pi_i' < 0$ for $i = 1, \ldots, n$. From this it follows that the following definition is well defined.

DEFINITION 2. *Let $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ be a solution of* (3.5)–(3.8). *Let $\tau_0 = \tau_0(\theta)$ be the first zero of $\mathcal{U}'$ if it exists; and set $\tau_0 = T$ if $\mathcal{U}' > 0$ on $(-\infty, T)$. We also set $\bar{u} = \mathcal{U}(\tau_0)$ ($\bar{u}$ may be $+\infty$).*

Furthermore, by this definition and the above discussion, we have the following lemma.

LEMMA 3.1. *Let $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ be a solution of* (3.5)–(3.8). *Then $\mathcal{U} > 0$ and $\mathcal{U}' > 0$ on $(-\infty, \tau_0)$, and a traveling wave solution of* (2.1)–(2.2) *for given negative speed c is unique (up to translation) if it exists.*

3.3. Two auxiliary lemmas and a necessary condition. First, we will make a transformation for (3.5)–(3.7) which is useful for our discussion. Since $\mathcal{U}' > 0$ on $(-\infty, \tau_0)$, we can express $\mathcal{Z}$ and Π_i, $i = 1, \ldots, n$, as functions of $\mathcal{U}$ for $\mathcal{U} \in (a_0, \bar{u})$. Let $Z(\mathcal{U}) = \mathcal{Z}(\tau(\mathcal{U}))$ and $V_i(\mathcal{U}) = \Pi_i(\tau(\mathcal{U}))$, $i = 1, \ldots, n$, for $\mathcal{U} \in (a_0, \bar{u})$. Set $\mathbf{V} = (V_1, \ldots, V_n)$. Then Z and V_i satisfy the following equations:

$$Z' := \frac{dZ}{d\mathcal{U}} = \theta\left(1 - \frac{F(\mathcal{U}, \mathbf{V})}{Z}\right), \tag{3.15}$$

$$V_i' := \frac{dV_i}{d\mathcal{U}} = \frac{G_i(\mathcal{U}, \mathbf{V})}{Z},\ i = 1, \ldots, n, \tag{3.16}$$

for $\mathcal{U} \in (a_0, \bar{u})$ with the initial conditions

$$Z(a_0) = 0,\ \ V_i(a_0) = b_0^i \ \text{ for } \ i = 1, \ldots, n. \tag{3.17}$$

Note that $Z(u) > 0$ for $u \in (a_0, \bar{u})$ and $Z(\bar{u}) = 0$ if $\bar{u}$ is finite.

LEMMA 3.2. *Let $(\mathcal{U}, \mathcal{Z}, \mathbf{\Pi})$ be a solution of* (3.5)–(3.8). *Then $k_i(\mathcal{U}) < V_i(\mathcal{U}) < b_0^i$ for all $\mathcal{U} \in (a_0, \bar{u})$ and $i = 1, \ldots, n$. Moreover, $\Pi_i'(\tau) < 0$ for all $\tau \in (-\infty, \tau_0)$ and $i = 1, \ldots, n$.*

Proof. Fix $i \in \{1, \ldots, n\}$. Noting that $\Pi_i' < 0$ near $\tau = -\infty$, $\mathcal{U}(\tau) > 0$ for $\tau \in (-\infty, \tau_0)$ and using (3.7), we have $V_i(\mathcal{U}) > k_i(\mathcal{U})$ for all $\mathcal{U} \in (a_0, u_3)$ for some $u_3 \in (a_0, \bar{u}]$. If $u_3 < \bar{u}$ and $V_i(u_3) = k_i(u_3)$, then $V_i'(u_3) \le k_i'(u_3) < 0$, where we

have used the fact that k_i is decreasing on $\mathbf{R}$. On the other hand, by (3.16) we have $V_i'(u_3) = 0$, a contradiction. Therefore, $V_i(\mathcal{U}) > k_i(\mathcal{U})$ for all $\mathcal{U} \in (a_0, \bar{u})$. Combining this with Lemma 3.1, we have $V_i' < 0$ on $(a_0, \bar{u})$, and so $\Pi_i' < 0$ on $(-\infty, \tau_0)$. Moreover, from $V_i(a_0) = b_0^i$ it follows that $V_i(\mathcal{U}) < b_0^i$ for all $\mathcal{U} \in (a_0, \bar{u})$. This completes the proof. ∎

In the next lemma, we will show that $a \in (0, 1/2)$ is a necessary condition for the existence of a monotone traveling wave solution of (2.1)–(2.2) with negative wave speed.

LEMMA 3.3 (necessary condition). *Let $a > 0$, and suppose that* (3.1)–(3.2) *with the boundary conditions* (3.3)–(3.4) *and $c < 0$ has a solution $(\mathcal{U}, \mathbf{\Pi})$ with $\dot{\mathcal{U}} > 0$ on $\mathbf{R}$. Then we have $a \in (0, 1/2)$.*

Proof. Rewrite (3.1)–(3.2) as the following:

$$\begin{aligned} -D\ddot{\mathcal{U}} &= c\dot{\mathcal{U}} + F(\mathcal{U}, \mathbf{\Pi}), \\ 0 &= c\dot{\Pi}_i + G_i(\mathcal{U}, \mathbf{\Pi}),\ i = 1, \dots, n. \end{aligned}$$

Then multiplying these two equations by $\dot{\mathcal{U}}$, integrating from $-\infty$ to $+\infty$, and summing the second equation from $i = 1$ to n, and then subtracting the first equation from the resulting second one, we get

$$-c\left(\int_{-\infty}^{+\infty} \dot{\mathcal{U}}^2(\xi)d\xi - \sum_{i=1}^{n}\int_{-\infty}^{+\infty} \dot{\mathcal{U}}(\xi)\dot{\Pi}_i(\xi)d\xi\right) = \int_{a_0}^{a_2} u(u-a)(1-u)du.$$

By Lemma 3.2, $\dot{\Pi}_i(\xi) = (-1/c)\Pi_i'(\tau) < 0$ on $\mathbf{R}$ for $i = 1, \dots, n$. Thus the left-hand side of the above equation is positive. From this and Lemma 2.1 it follows that $a \in (0, 1/2)$. Hence the proof is completed. ∎

LEMMA 3.4. *There exists no solution $(\mathcal{U}, \mathbf{\Pi})$ of* (3.5)–(3.7) *with the condition* (3.8) *satisfying that $\mathcal{U}(\tau_0) = a_2$, $\mathcal{U}'(\tau_0) = 0$ and $\mathcal{U}''(\tau_0) \le 0$ for some finite τ_0.*

Proof. Suppose that there is such a solution. Thus either $\mathcal{U}''(\tau_0) = 0$ or $\mathcal{U}''(\tau_0) < 0$. In the first case, it follows from Lemma 3.2 that $\Pi_i'(\tau_0) \le 0$ for $i = 1, \dots, n$. Therefore, noting the fact that if the sum of a sequence of nonnegative numbers is zero, then every number in this sequence must be zero, using (3.6)–(3.7), and the definitions of F and G_i, $i = 1, \dots, n$, it follows that $\Pi_i'(\tau_0) = 0$ for $i = 1, \dots, n$, a contradiction to the uniqueness theorem for the differential equations. For the latter case, by (3.6)–(3.7) again and a similar argument as the above, we have $\Pi_{i_0}'(\tau_0) > 0$ for some $i_0 \in \{1, \dots, n\}$, a contradiction to Lemma 3.2. This completes the proof. ∎

3.4. Final proof. Now we are ready to prove the existence of a traveling wave solution of (2.1)–(2.2) under the assumption $a \in (0, 1/2)$. The proof consists of four steps.

LEMMA 3.5. *If $a \in (0, 1/2)$, then there exists $c := c(a) < 0$ such that there is a unique solution (up to translation) $(\mathcal{U}(\tau), \mathcal{Z}(\tau), \mathbf{\Pi}(\tau))$ of* (3.5)–(3.9) *satisfying that $\mathcal{U}' > 0$ and $\Pi_i' < 0$, $i = 1, \dots, n$, on $\mathbf{R}$.*

Proof. Step 1. *We claim that $\bar{u} > a_1$, $Z(a_1) \ge \theta(a_1 - a_0)$, and $V_i(a_1) > k_i(a_1)$ for $i = 1, \dots, n$.* Indeed, by Lemma 3.2 and Lemma 3.1 we have $V_i' < 0$ and $G_i(\mathcal{U}, \mathbf{V}(\mathcal{U})) < 0$ for all $\mathcal{U} \in (a_0, \bar{u})$ and $i = 1, \dots, n$. Also note that $f(u) < 0$ for $u \in (a_0, a_1)$. Combining these two facts with the definitions of F and G_i, $i = 1, \dots, n$, we obtain that $F(\mathcal{U}, \mathbf{V}(\mathcal{U})) < 0$ and $G_i(\mathcal{U}, \mathbf{V}(\mathcal{U})) < 0$ for all $\mathcal{U} \in (a_0, \min\{\bar{u}, a_1\})$ and $i = 1, \dots, n$. Thus if $\bar{u} \le a_1$, then from (3.15) it follows that $Z' \ge \theta$ on $(a_0, \bar{u})$. This

implies that $Z(\bar{u}) > 0$, a contradiction. Therefore, we have $\bar{u} > a_1$. Moreover, noting that $F(\mathcal{U}, \mathbf{V}(\mathcal{U})) < 0$ and $Z > 0$ on $(a_0, a_1]$, and using (3.15) again, it follows that $Z' \geq \theta$ on $(a_0, a_1]$. Hence $Z(a_1) \geq \theta(a_1 - a_0)$ and $V_i(a_1) > k_i(a_1)$ for $i = 1, \ldots, n$.

Step 2. *We claim that if θ is sufficiently large, then there exists a finite $\hat{\tau}$ such that $\mathcal{U}' > 0$ on $(-\infty, \hat{\tau}]$ and $\mathcal{U}(\hat{\tau}) = a_2$.* By Lemma 3.2, we have $k_i(\mathcal{U}) < V_i(\mathcal{U}) < b_0^i$ for all $\mathcal{U} \in (a_0, \bar{u})$ and $i = 1, \ldots, n$. Let

$$B = \sup\{|\, F(\mathcal{U}, \mathbf{V}) \,|\, |\, a_0 \leq \mathcal{U} \leq a_2, k_i(\mathcal{U}) \leq V_i \leq b_0^i, i = 1, \ldots, n\}.$$

Choose θ_0 such that $\theta_0 > 4B/(a_1 - a_0)$. Then we claim that $\bar{u} > a_2$ for all $\theta > \theta_0$. Suppose that the claim does not hold for some $\tilde{\theta} > \theta_0$. Let $(Z_{\tilde{\theta}}, V_{\tilde{\theta},1}, \ldots, V_{\tilde{\theta},n})$ be the corresponding solution of (3.15)–(3.17). Then, since $Z_{\tilde{\theta}}(a_1) \geq \tilde{\theta}(a_1 - a_0)$ by Step 1, we have $Z_{\tilde{\theta}}(\mathcal{U}) > \tilde{\theta}(a_1 - a_0)/2$ for all $\mathcal{U} \in [a_1, \hat{u})$ for some $\hat{u} \in (a_1, a_2)$ and $Z_{\tilde{\theta}}(\hat{u}) = \tilde{\theta}(a_1 - a_0)/2$. On the other hand, from (3.15) it follows that

$$\begin{aligned} Z'_{\tilde{\theta}}(\mathcal{U}) &= \tilde{\theta}\left(1 - \frac{F(\mathcal{U}, \mathbf{V}_{\tilde{\theta}})}{Z_{\tilde{\theta}}}\right) \\ &\geq \tilde{\theta}(1 - B/[\tilde{\theta}(a_1 - a_0)/2]) \\ &> \tilde{\theta}/2 \end{aligned}$$

for all $\mathcal{U} \in [a_1, \hat{u}]$. This implies that $Z_{\tilde{\theta}}(\mathcal{U}) \geq \tilde{\theta}(a_1 - a_0)$ for all $\mathcal{U} \in [a_1, \hat{u}]$, a contradiction. Therefore, if $\theta > \theta_0$, we have $\bar{u} > a_2$, and so $Z(\mathcal{U}) > 0$ for all $\mathcal{U} \in (a_0, a_2]$. Hence there exists a finite $\hat{\tau}$ such that $\mathcal{U}' > 0$ on $(-\infty, \hat{\tau}]$ and $\mathcal{U}(\hat{\tau}) = a_2$. Moreover, if we let $(\mathcal{U}_\theta, \mathcal{Z}_\theta, \mathbf{\Pi}_\theta)$ be a solution of (3.5)–(3.8) and

$$\mathcal{P}_1 = \{\theta > 0 \mid \mathcal{U}'_\theta > 0 \text{ on } (-\infty, \hat{\tau}] \text{ and } \mathcal{U}_\theta(\hat{\tau}) = a_2 \text{ for some finite } \hat{\tau}\},$$

then $\mathcal{P}_1$ is nonempty. Furthermore, $\mathcal{P}_1$ is open by continuous dependence on the parameter θ.

Step 3. *We show that for sufficiently small $\theta > 0$, there is a finite τ_0 with $\mathcal{U}'_\theta(\tau_0) = 0$ and $\mathcal{U}_\theta(\tau_0) \in (a_1, a_2)$.* If not, then there exists a sequence $\{\theta_i\}_{i \in \mathbf{N}}$ with $\lim_{i \to \infty} \theta_i = 0$ such that the corresponding solutions $(\mathcal{U}_i, \mathbf{\Pi}_i)$ of (3.5)–(3.8) satisfy that $\mathcal{U}'_i > 0$ on $(-\infty, \hat{\tau}_i)$ and $\mathcal{U}_i(\hat{\tau}_i) = a_2$ for some $\hat{\tau}_i$ ($\hat{\tau}_i$ may be infinite). Let $\mathbf{V}_i = (V_{i,1}, \ldots, V_{i,n})$. Multiplying (3.15) with Z_i and integrating from a_0 to $\mathcal{U}$, we obtain

$$\frac{Z_i(\mathcal{U})^2}{2} = \theta_i \int_{a_0}^{\mathcal{U}} (Z_i(t) - F(t, \mathbf{V}_i(t)))dt \tag{3.18}$$

for all $\mathcal{U} \in [a_0, a_2]$. By Lemma 3.2, we have $k_j(\mathcal{U}) \leq V_{i,j}(\mathcal{U}) \leq b_0^j$ for all $\mathcal{U} \in [a_0, a_2]$ and $j = 1, \ldots, n$. Note that $Z_i(\mathcal{U}) > 0$ for all $\mathcal{U} \in (a_0, a_2)$. Thus if we let $A_i = \sup_{a_0 \leq \mathcal{U} \leq a_2} Z_i(\mathcal{U})$, then it follows from (3.18) that $A_i^2/2 \leq \theta_i(A_i(a_2 - a_0) + B(a_2 - a_0))$, and so

$$\lim_{i \to \infty} A_i = 0. \tag{3.19}$$

Solving (3.16) with integration by parts, we obtain that

$$V_{i,j}(\mathcal{U}) = k_j(\mathcal{U}) - \int_{a_0}^{\mathcal{U}} k'_j(t) \exp\left[-\int_t^{\mathcal{U}} (\gamma_j(s)/Z_i(s))ds\right] dt$$

for all $\mathcal{U} \in [a_0, a_2]$ and $j = 1, \dots, n$. Thus it follows from (3.19) that

$$\lim_{i\to\infty} V_{i,j}(\mathcal{U}) = k_j(\mathcal{U}) \tag{3.20}$$

uniformly for $\mathcal{U} \in [a_0, a_2]$ and $j = 1, \dots, n$. From (3.18) it follows that

$$\int_{a_0}^{a_2} F(t, \mathbf{V}_i(t))dt \le \int_{a_0}^{a_2} Z_i(t)dt. \tag{3.21}$$

Letting $i \to \infty$ in (3.21), using (3.19) and (3.20), we obtain that

$$\int_{a_0}^{a_2} F(s, k_1(t), \dots, k_n(t))dt \le 0,$$

a contradiction to Lemma 2.1.

Step 4. *We reach the conclusion.* Let $(\mathcal{U}_\theta, \mathcal{Z}_\theta, \mathbf{\Pi}_\theta)$ be a solution of (3.5)–(3.8) and

$$\mathcal{P}_2 = \{\theta > 0 \mid \mathcal{U}'_\theta(\tau) = 0 \text{ for some } \tau \in \mathbf{R} \text{ and } \mathcal{U}_\theta(\tau) \in (a_1, a_2]\}.$$

Thus $\mathcal{P}_2$ is nonempty by Step 3. For each $\theta \in \mathcal{P}_2$, recall that $\tau_0 = \tau_0(\theta)$ denotes the first zero of $\mathcal{U}'_\theta$. Then we have $\mathcal{U}''_\theta(\tau_0) \le 0$. Moreover, by Lemma 3.4 and Step 1, we have $\mathcal{U}_\theta(\tau_0) \in (a_1, a_2)$. Next we claim that $\mathcal{U}''_\theta(\tau_0) < 0$. If not, then $\mathcal{U}''_\theta(\tau_0) = 0$. By (3.5)–(3.6), we have $F(\mathcal{U}_\theta(\tau_0), \mathbf{\Pi}_\theta(\tau_0)) = 0$. Also recall from Lemma 3.2 that $\Pi'_{\theta,i}(\tau_0) \le 0$ for $i = 1, \dots, n$. Combining these two facts with the fact that $f(u) > 0$ for $u \in (a_1, a_2)$, we obtain that $\Pi'_{\theta,i_0}(\tau_0) < 0$ for some $i_0 \in \{1, \dots, n\}$. From this, (3.6), and part (2) of Lemma 2.1 it follows that $\mathcal{U}'''_\theta(\tau_0) = -\theta \sum_{i=1}^n F_{v_i}(\mathcal{U}_\theta(\tau_0), \mathbf{\Pi}_\theta(\tau_0))\Pi'_{\theta,i}(\tau_0) < 0$, a contradiction to the definition of τ_0. Thus we have $\mathcal{U}''_\theta(\tau_0) < 0$, and this implies that $\mathcal{P}_2$ is open.

By Step 2 and the above discussion, $\mathcal{P}_2$ is nonempty, open, and bounded above. Therefore $\theta^* := \sup \mathcal{P}_2$ exists and $\theta^* \in \mathbf{R}^+ \setminus (P_1 \cup P_2)$. Let $(\mathcal{U}_{\theta^*}, \Pi_{\theta^*,1}, \dots, \Pi_{\theta^*,n})$ be the corresponding solution of (3.5)–(3.8). Then $\mathcal{U}'_{\theta^*} > 0$ on $\mathbf{R}$ and $\mathcal{U}_{\theta^*}(\tau) \to a_2$ as $\tau \to +\infty$. Moreover, by Lemma 3.2 we have $\Pi'_{\theta^*,i} < 0$ on $\mathbf{R}$ for $i = 1, \dots, n$. Now we claim that $\Pi_{\theta^*,i}(\tau) \to b_2^i$ as $\tau \to +\infty$ for $i = 1, \dots, n$. Indeed, fix $i \in \{1, \dots, n\}$; using Lemma 3.2 and noting that $\mathcal{U}_{\theta^*} \in (a_0, a_2)$ on $\mathbf{R}$, we have $\Pi_{\theta^*,i} \in (b_2^i, b_0^i)$ on $\mathbf{R}$. Using this fact and noting that $\Pi'_{\theta^*,i} < 0$ on $\mathbf{R}$, it follows that there exists $l \in [b_2^i, b_0^i)$ such that $\Pi_{\theta^*,i}(\tau) \to l$ as $\tau \to +\infty$. Hence we can choose a sequence $s_1 < s_2 < \cdots < s_m < \cdots$ with $s_m \to +\infty$ as $m \to +\infty$ satisfying that $\mathcal{U}_{\theta^*}(s_m) \to a_2$, $\Pi_{\theta^*,i}(s_m) \to l$, and $\Pi'_{\theta^*,i}(s_m) \to 0$ as $m \to +\infty$. From this and (3.7) it follows that $l = b_2^i$. Hence the proof is completed. □

Finally, combining Lemma 3.3 with Lemma 3.5, we obtain the following theorem.

THEOREM 1. *There exists $c := c(a) < 0$ such that a unique (up to translation) traveling wave solution $(\mathcal{U}, \mathbf{\Pi})$ of our buffered bistable equations* (1.4)–(1.5) *with wave speed c, such that $\dot{\mathcal{U}} > 0$ and $\ddot{\Pi}_i < 0$, $i = 1, \dots, n$, on $\mathbf{R}$, exists if and only if $a \in (0, 1/2)$.*

3.5. Uniqueness of wave speed. In this subsection, we will concern ourselves with the uniqueness of wave speed. First, throughout the remainder of this section, $(\mathcal{U}, \mathbf{\Pi})$ will denote such a unique traveling wave solution of (1.4)–(1.5) with speed c and $\mathcal{U}(0) = 1/2$, which is described in Theorem 1. Since the proof is based on the use of supersolution (subsolution) of (2.1)–(2.2) and the comparison principle, we state the definition of supersolution (subsolution) as follows.

DEFINITION 3. *A set of bounded functions* $(u, \mathbf{v})$ *is called a subsolution of* (2.1)–(2.2) *in* $\mathbf{R}\times\mathbf{R}^+$, *if* $u, v_i \in C^{2,1}(\mathbf{R}\times\mathbf{R}^+)$ *and* $C^{1,1}(\mathbf{R}\times\mathbf{R}^+)$, *respectively, and* $(u, \mathbf{v})$ *satisfies that* $u_t - Du_{xx} \le F(u, \mathbf{v})$, $v_{i,t} \ge G_i(u, \mathbf{v})$, *and*

$$u \ge -\min_{j=1,\dots,n}\{k_-^j/(2k_+^j)\}, \quad v_i(z,t) \ge b_2^i/2 \tag{3.22}$$

on $\mathbf{R}\times\mathbf{R}^+$ *for* $i = 1, \dots, n$. *Supersolution is defined by reversing the inequalities with* (3.22) *held.*

The next lemma is a comparison theorem for the supersolution and subsolution, whose proof is similar to Lemma 5.3 in the appendix.

LEMMA 3.6 (comparison principle). *Let* $(u_1, \mathbf{v}_1)$ *and* $(u_2, \mathbf{v}_2)$ *be the subsolution and supersolution of* (2.1)–(2.2) *on* $\mathbf{R}\times\mathbf{R}^+$, *respectively, with* $u_1(x,0) \le u_2(x,0)$ *and* $\mathbf{v}_2(x,0) \le \mathbf{v}_1(x,0)$ *for all* $x \in \mathbf{R}$. *Then the following statement holds:*

$$u_1(x,t) \le u_2(x,t) \ \text{ and } \ \mathbf{v}_2(x,t) \le \mathbf{v}_1(x,t) \ \text{ for all } \ (x,t) \in \mathbf{R}\times\mathbf{R}^+.$$

Next, from the above lemma (also see the proof of Lemma 5.3 in the appendix), it is easily seen that the following lemma holds.

LEMMA 3.7. *There exist positive constants* d_1, μ_0, *and* k_{0i}, $i = 1, \dots, n$, *which are independent of* $(\mathcal{U}, \mathbf{\Pi})$, *and a positive constant* ν *such that, for any* $d \in (0, d_1]$ *and* $x_0 \in \mathbf{R}$, *the functions* $(w^+, \mathbf{p}^+)$ *and* $(w^-, \mathbf{p}^-)$ *defined by*

$$\begin{aligned} w^{\pm}(x,t) &:= \mathcal{U}(x - ct + x_0 \pm \nu d(1 - e^{-\mu_0 t})) \pm de^{-\mu_0 t}, \\ p_i^{\pm}(x,t) &:= \Pi_i(x - ct + x_0 \pm \nu d(1 - e^{-\mu_0 t})) \mp dk_{0i}e^{-\mu_0 t}, \ i = 1, \dots, n, \end{aligned} \tag{3.23}$$

are a supersolution and a subsolution of (2.1)–(2.2), *respectively.*

Now we are ready to prove the uniqueness of wave speed of a traveling wave front of (2.1)–(2.2).

LEMMA 3.8 (uniqueness). *Given* $a \in (0, 1/2)$, *for any traveling wave solution* $(\tilde{\mathcal{U}}, \tilde{\mathbf{\Pi}})$ *of* (2.1)–(2.2) *with wave speed* $\tilde{c}$ *such that* $\tilde{\mathcal{U}} \in [0,1]$ *and* $\tilde{\mathbf{\Pi}} \in [\mathbf{b_2}, \mathbf{b_0}]$ *on* $\mathbf{R}$, *we have* $\tilde{c} = c$ *and* $(\tilde{\mathcal{U}}(\cdot), \tilde{\mathbf{\Pi}}(\cdot)) = (\mathcal{U}(\cdot + \xi_0), \mathbf{\Pi}(\cdot + \xi_0))$ *for some* $\xi_0 \in \mathbf{R}$.

Proof. We assume that there exists another traveling wave solution $(\tilde{\mathcal{U}}, \tilde{\mathbf{\Pi}})$ of (2.1)–(2.2) with wave speed $\tilde{c}$. Note that $(\tilde{\mathcal{U}}, \tilde{\mathbf{\Pi}})$ is not necessarily monotone. The proof is divided into two steps.

Step 1. *We claim that* $c = \tilde{c}$. We will follow X. Chen's arguments in [1] to prove this claim, where Chen studied the existence, uniqueness, and stability of a single nonlocal equation of the form

$$u_t(x,t) = \mathcal{A}[u(\cdot,t)](x), \ x \in \mathbf{R}, \ t > 0.$$

Since $(\tilde{\mathcal{U}}(\xi), \tilde{\mathbf{\Pi}}(\xi))$ and $(\mathcal{U}(\xi), \mathbf{\Pi}(\xi))$ satisfy the same boundary condition at $\pm\infty$, we can choose a sufficiently large ξ_1 such that the following hold:

$$\mathcal{U}(\cdot - \xi_1) - d_1 < \tilde{\mathcal{U}}(\cdot) \ \text{ and } \ \Pi_i(\cdot - \xi_1) + d_1 k_{0i} > \tilde{\Pi}_i(\cdot) \ \text{ on } \ \mathbf{R} \ \text{ for } \ i = 1, \dots, n. \tag{3.24}$$

By a translation if necessary, we may assume that $\xi_1 = 0$. Next we choose a sufficiently large ξ_2 such that the inequalities

$$\mathcal{U}(\cdot) - d_1 < \tilde{\mathcal{U}}(\cdot) < \mathcal{U}(\cdot + \xi_2) + d_1 \ \text{ and } \ \Pi_i(\cdot + \xi_2) - d_1 k_{0i} < \tilde{\Pi}_i(\cdot) < \Pi_i(\cdot) + d_1 k_{0i}$$

hold on $\mathbf{R}$ for $i = 1, \dots, n$. Using the above inequalities and applying Lemma 3.6 to $(\tilde{\mathcal{U}}(x-\tilde{c}t), \tilde{\mathbf{\Pi}}(x-\tilde{c}t))$ and $(w^{\pm}(x,t), \mathbf{p}^{\pm}(x,t))$ in (3.23) (with $x_0 = 0$ for $(w^-, \mathbf{p}^-)$ and $x_0 = \xi_2$ for $(w^+, \mathbf{p}^+)$), we obtain that

$$\begin{aligned} &\mathcal{U}(x - ct - \nu d_1(1 - e^{-\mu_0 t})) - d_1 e^{-\mu_0 t} \le \tilde{\mathcal{U}}(x - \tilde{c}t) \\ &\qquad\qquad \le \mathcal{U}(x - ct + \xi_2 + \nu d_1(1 - e^{-\mu_0 t})) + d_1 e^{-\mu_0 t} \end{aligned} \tag{3.25}$$

and

$$\begin{aligned} \Pi_i(x - ct + \xi_2 + \nu d_1(1 - e^{-\mu_0 t})) - d_1 k_{0i} e^{-\mu_0 t} &\le \tilde{\Pi}_i(x - \tilde{c}t) \\ &\le \Pi_i(x - ct - \nu d_1(1 - e^{-\mu_0 t})) \\ &\quad + d_1 k_{0i} e^{-\mu_0 t} \end{aligned} \tag{3.26}$$

for all $(x,t) \in \mathbf{R} \times \mathbf{R}^+$ and $i = 1, \dots, n$. Note that $\mathcal{U}(+\infty) = 1$ and that $\tilde{\mathcal{U}} \in [0,1]$ is not identical to the constant 1. Letting $x - \tilde{c}t$ be fixed and $t \to +\infty$ in the first inequality of (3.25), we obtain $c \ge \tilde{c}$. A similar argument for the second inequality of (3.25) leads to the conclusion $c \le \tilde{c}$. Hence, to summarize, we have $c = \tilde{c}$. This proves this claim.

Step 2. *We claim that* $(\mathcal{U}(\cdot), \mathbf{\Pi}(\cdot)) \equiv (\tilde{\mathcal{U}}(\cdot + \xi_0), \tilde{\mathbf{\Pi}}(\cdot + \xi_0))$ *for some* $\xi_0 \in \mathbf{R}$. Indeed, since we have $\tilde{c} = c$ by Step 1, then our claim follows from the final statement of Lemma 3.1. This completes the proof. ∎

Now we can summarize what we have done. Indeed, by Lemma 3.1, Theorem 1, and Lemma 3.8, we obtain the following theorem.

THEOREM 2. *If* $a \in (0, 1/2)$, *then there exists a unique* $c := c(a) < 0$ *such that a unique (up to translation) traveling wave solution* $(\mathcal{U}, \mathbf{\Pi})$ *of our buffered bistable equations* (1.4)–(1.5) *with wave speed* c *exists. Moreover,* $(\mathcal{U}, \mathbf{\Pi})$ *satisfies that* $\dot{\mathcal{U}} > 0$ *and* $\dot{\Pi}_i < 0$, $i = 1, \dots, n$, *on* $\mathbf{R}$. *Furthermore, a traveling wave solution* $(\mathcal{U}, \mathbf{\Pi})$ *of* (1.4)–(1.5) *with negative wave speed, such that* $\dot{\mathcal{U}} > 0$ *and* $\dot{\Pi}_i < 0$, $i = 1, \dots, n$, *on* $\mathbf{R}$, *exists only if* $a \in (0, 1/2)$.

Comparing this result with the unbuffered equation (1.1), we may conclude that stationary buffers cannot eliminate wave activity.

4. The proof of stability of the traveling wave solution.

4.1. Statement of stability of the traveling wave solution. Now we investigate the stability of the traveling wave solution of the problem

$$\frac{\partial u}{\partial t} = D\frac{\partial^2 u}{\partial x^2} + f(u) + \sum_{i=1}^{n} [k_-^i(b_0^i - v_i) - k_+^i u v_i], \tag{4.1}$$

$$\frac{\partial v_i}{\partial t} = k_-^i(b_0^i - v_i) - k_+^i u v_i, \ (x,t) \in \mathbf{R} \times \mathbf{R}^+, \ i = 1, \dots, n, \tag{4.2}$$

with the initial data

$$u(x,0) = \phi(x) \ \text{ and } \ v_i(x,0) = \psi_i(x), \ x \in \mathbf{R}, \ \text{ for } \ i = 1, \dots, n.$$

First, for each solution $(u, \mathbf{v})$ of (4.1)–(4.2), we introduce the moving coordinate $z = x - ct$ and set $\tilde{u}(z,t) = u(z + ct, t)$ and $\tilde{v}_i(z,t) = v_i(z + ct, t)$, $i = 1, \dots, n$, where c is a constant (wave speed). Let $\tilde{\mathbf{v}} = (\tilde{v}_1, \dots, \tilde{v}_n)$. Then $\tilde{u}$ and $\tilde{v}_i$ satisfy the following system:

$$L_1[\tilde{u}, \mathbf{v}] \equiv \tilde{u}_t - D\tilde{u}_{zz} - c\tilde{u}_z = F(\tilde{u}, \tilde{\mathbf{v}}), \tag{4.3}$$

$$L_{2i}[\tilde{u}, \tilde{\mathbf{v}}] \equiv \tilde{v}_{i,t} - c\tilde{v}_{i,z} = G_i(\tilde{u}, \tilde{\mathbf{v}}), \ i = 1, \dots, n, \tag{4.4}$$

with the initial data

$$\tilde{u}(z,0)=\phi(z) \text{ and } \tilde{v}_i(z,0)=\psi_i(z),\ z\in\mathbf{R}, \text{ for } i=1,\dots,n, \tag{4.5}$$

where $\tilde{v}_{i,t}=\partial\tilde{v}_i/\partial t$ and $\tilde{v}_{i,z}=\partial\tilde{v}_i/\partial z$. Hereafter for notational convenience we shall suppress the tilde.

We will briefly discuss the existence of the global solution of (4.3)–(4.5) and its associated properties. Indeed, we assume throughout the remainder of this paper that $\phi(z)$ and $\psi_i(z)$, $i=1,\dots,n$, are sufficiently smooth and satisfy that $a_0\le\phi(z)\le a_2$ and $b_2^i\le\psi_i(z)\le b_0^i$ for all $z\in\mathbf{R}$ and $i=1,\dots,n$. Then a similar argument as in Rauch and Smoller [17] shows that the problem (4.3)–(4.5) has a unique smooth solution $(u(z,t),\mathbf{v}(z,t))$ on $\mathbf{R}\times[0,t_0]$ for some $t_0>0$. Furthermore, we can show that $(u(z,t),\mathbf{v}(z,t))$ is a global solution of (4.3)–(4.5). In fact, we have the following lemma.

LEMMA 4.1 (invariance region). *Let $(u,\mathbf{v})$ be the solution of* (4.3)–(4.5). *Then $(u,\mathbf{v})$ exists for all $t>0$. Moreover, $a_0\le u(z,t)\le a_2$ and $b_2^i\le v_i(z,t)\le b_0^i$ for all $(z,t)\in\mathbf{R}\times\mathbf{R}^+$ and $i=1,\dots,n$.*

Proof. The proof follows from Theorem 14.11 on p. 203 and Corollary 14.9 on p. 202 of Smoller [23]. Also see Redheffer and Walter [18]. The outer normal conditions on the boundary of the set $\{(u,\mathbf{v})\mid a_0\le u\le a_2, b_2^i\le v_i\le b_0^i, i=1,\dots,n\}$ follow from the definitions of F and G_i, $i=1,\dots,n$. □

Recall that for each $D>0$ and $a\in(0,1/2)$, there exists a unique $c<0$ such that there is a unique solution $(\mathcal{U}(z),\ \mathbf{\Pi}(z))$ of the steady state equation

$$D\mathcal{U}_{zz}+c\mathcal{U}_z+F(\mathcal{U},\mathbf{\Pi})=0, \tag{4.6}$$

$$c\Pi_{i,z}+G_i(\mathcal{U},\mathbf{\Pi})=0 \tag{4.7}$$

satisfying that

$$\mathcal{U}(0)=(a_0+a_2)/2,\ \mathcal{U}(-\infty)=a_0,\ \Pi_i(-\infty)=b_0^i,\ \mathcal{U}(+\infty)=a_2,\ \Pi_i(+\infty)=b_2^i \tag{4.8}$$

and that

$$\mathcal{U}'>0,\ \ \Pi_i'<0 \text{ on } \mathbf{R} \text{ for } i=1,\dots,n. \tag{4.9}$$

Thus $(\mathcal{U}(x-ct),\mathbf{\Pi}(x-ct))$ is the unique traveling wave solution of (4.1)–(4.2) with wave speed c, which was shown to exist in section 3. Hereafter, throughout the remainder of this paper, $(\mathcal{U},\mathbf{\Pi})$ will denote such a unique solution of (4.6)–(4.9).

Now we formulate the theorem about the stability of the traveling wave solution of (4.1)–(4.2) which will be shown later.

THEOREM 3. *Let $a\in(0,1/2)$ and $(u,\mathbf{v})$ be the solution of* (4.3)–(4.5) *satisfying the following conditions:*

(1) *ϕ and ψ_i are sufficiently smooth, and $\phi'\ge0$, $\psi_i'\le0$ on $\mathbf{R}$ for $i=1,\dots,n$;*
(2) *$\sup_{z\in\mathbf{R}}|\phi(z)|+\sup_{z\in\mathbf{R}}|\phi'(z)|+\sup_{z\in\mathbf{R}}|\phi''(z)|+\sup_{z\in\mathbf{R}}|\phi'''(z)|<+\infty$;*
(3) *$a_2-\phi_2>0$, $\psi_{2i}-b_2^i>0$, $\phi_0-a_0>0$, and $b_0^i-\psi_{0i}>0$ are sufficiently small for $i=1,\dots,n$, where ϕ_2, ψ_{2i}, ϕ_0, and ψ_{0i} are defined by* (1.10);
(4) *$u_t(z,0)\ge0$ and $v_{i,t}(z,0)\le0$ for all $z\in\mathbf{R}$ and $i=1,\dots,n$;*

then there exists $z_0\in\mathbf{R}$ such that

$$\lim_{t\to+\infty}|u(z,t)-\mathcal{U}(z-z_0)|=0,\ \ \lim_{t\to+\infty}|v_i(z,t)-\Pi_i(z-z_0)|=0,\ i=1,\dots,n,$$

uniformly with respect to $z\in\mathbf{R}$.

4.2. Outline of the proof of Theorem 3. Since the proof of Theorem 3 is lengthy, we outline our proof as follows.

The plan of the proof follows Fife [4]. First, we need the following compactness lemma, whose proof can be found in the appendix.

LEMMA 4.2. *Let* $(u, \mathbf{v})$ *be the solution of* (4.3)–(4.5). *Then, under the assumption of Theorem* 3, $\{u(\cdot,t) \mid t \geq t_0 > 0\}$ *and* $\{v_i(\cdot,t) \mid t \geq t_0 > 0\}$, $i = 1, \ldots, n$, *are relatively compact, considered as subsets of* $C^2(\mathbf{R})$ *and* $C^1(\mathbf{R})$, *respectively, for each* $t_0 > 0$.

Once we have Lemma 4.2, it follows that there exist a sequence of $\{t_p\}$ with $\lim_{p\to+\infty} t_p = +\infty$ and a set of functions $(\hat{u}(z), \hat{\mathbf{v}}(z)) = (\hat{u}(z), \hat{v}_1(z), \ldots, \hat{v}_n(z)) \in C^2(\mathbf{R}) \times C^1(\mathbf{R}) \times \cdots \times C^1(\mathbf{R})$ such that

$$(u(z,t_p), \mathbf{v}(z,t_p)) \to (\hat{u}(z), \hat{\mathbf{v}}(z))$$

as $p \to +\infty$ uniformly in z, together with their associated partial derivatives. Then what is left for us to show are the following two questions.

(1) $(\hat{u}, \hat{\mathbf{v}})$ is a traveling wave front of (4.1)–(4.2) (this also implies that $(\hat{u}(\cdot), \hat{\mathbf{v}}(\cdot)) \equiv (\mathcal{U}(\cdot - z_0), \mathbf{\Pi}(\cdot - z_0))$ for some $z_0 \in \mathbf{R}$ since $(\mathcal{U}, \mathbf{\Pi})$ is unique up to translation), and

(2) the convergence of $(u, \mathbf{v})$ to $(\hat{u}, \hat{\mathbf{v}})$ is more than just along a sequence of t-values.

To answer the first question, we will make use of a Lyapunov function, which is an extension of the one in [10, 5] (see section 4.3). Regarding the second question, we will use Lemma 5.6 (local stability), which says that once u, v_i come close to $\mathcal{U}, \Pi_i$, it remains close; i.e., we have the following:

$$u(z,t) \to \mathcal{U}(z - z_0) \ \text{ and } \ v_i(z,t) \to \Pi_i(z - z_0) \ \text{ as } t \to +\infty$$

uniformly in z, together with their associated partial derivatives for $i = 1, \ldots, n$. We shall prove the first question and Lemma 5.6 in section 4.3 and the appendix, respectively.

4.3. Proof. Now we can reach the conclusion of Theorem 3. The proof will be divided into five steps. Steps 1–4 contain the associated properties of the Lyapunov function, and Step 5 will finish our treatment of the stability of the traveling wave solution. We also need two technical lemmas, i.e., Lemmas 5.4 and 5.5, whose proofs are deferred to the appendix.

Proof.

Step 1. *Construction of auxiliary functions.* First, we will truncate $(u, \mathbf{v})$ for large z and t. In fact, let $\eta > 0$ satisfy $|\kappa_j|\eta - \mu < 0$, where κ_j, μ are defined in Lemma 5.5 for $j = 1, 2$. Define the functions $\bar{u}(z,t)$ and $\bar{v}_i(z,t)$ by

$$\bar{u}(z,t) = \begin{cases} a_0 & \text{for } z \leq -\eta t - 1, \\ u(z,t) & \text{for } |z| \leq \eta t, \\ a_2 & \text{for } z \geq \eta t + 1 \end{cases}$$

and

$$\bar{v}_i(z,t) = \begin{cases} b_0^i & \text{for } z \leq -\eta t - 1, \\ v_i(z,t) & \text{for } |z| \leq \eta t, \\ b_2^i & \text{for } z \geq \eta t + 1 \end{cases}$$

for $i = 1, \dots, n$. From (5.13) and (5.14) defined in Lemma 5.5, it follows that $\bar{u}$ and $\bar{v}_i$ may be smoothed so that $\bar{u}(z,t)$ and $\bar{v}_i(z,t)$ also satisfy (5.13) and (5.14) for $i = 1, \dots, n$. Consider the function

$$M(t) = -\int_0^t \int_{-\infty}^{+\infty} H(z,s)dzds,$$

where

$$H(z,t) = \sum_{j=1}^{2} e^{\kappa_j z}\left[(D\bar{u}_{zz} + c\bar{u}_z + F(\bar{u},\bar{\mathbf{v}}))\bar{u}_t + \sum_{i=1}^{n}(c\bar{v}_{i,z} + G_i(\bar{u},\bar{\mathbf{v}}))\bar{v}_{i,t}\right]\chi_j(z)$$

for all $(z,t) \in \mathbf{R}\times\mathbf{R}^+$, $\bar{\mathbf{v}} = (\bar{v}_1, \dots, \bar{v}_n)$, χ_1 is a characteristic function on $(-\infty, 0]$, and χ_2 is a characteristic function on $[0, +\infty)$. Noting that

$$H \equiv 0 \ \text{ for } (z,t) \in \{|z| \le \eta t\}\bigcup\{|z| \ge \eta t + 1\}, \tag{4.10}$$

it follows that $\int_{-\infty}^{+\infty} H(z,s)dz$ converges for all $s \ge 0$. Therefore, $M(t)$ is well defined for all $t \ge 0$. From now on, combining with Lemmas 5.4 and 5.5, we can follow a similar calculation of [10, 5] to complete the proof.

Step 2. *We claim that* $|M(t)|$ *is bounded independently of* t. Indeed, noting that $\bar{u}$, $\bar{v}_i$, a_j, and b_j^i are uniformly bounded for $i = 1, \dots, n$, and $j = 0, 2$, and that ∇F and $\nabla G_i, i = 1, \dots, n$, are continuous, it follows that there exists a constant $C > 0$ such that

$$\begin{aligned} |F(\bar{u},\bar{\mathbf{v}})| &= |F(\bar{u},\bar{\mathbf{v}}) - F(a_j,\mathbf{b_j})| \le C\max_{1\le l\le n}\{|\bar{u}-a_j|, |\bar{v}_l - b_j^l|\},\\ |G_i(\bar{u},\bar{\mathbf{v}})| &= |G_i(\bar{u},\bar{\mathbf{v}}) - G_i(a_j,\mathbf{b_j})| \le C\max_{1\le l\le n}\{|\bar{u}-a_j|, |\bar{v}_l - b_j^l|\} \end{aligned} \tag{4.11}$$

on $\mathbf{R}\times[0,+\infty)$ for $i = 1, \dots, n$ and $j = 0, 2$. Throughout the proof, C always denotes a constant, which may be different from sentence to sentence, but they depend only on D, k_+^i, k_-^i, b_0^i, κ_i, σ_i, μ, and η. From these inequalities, the definitions of $\bar{u}$ and $\bar{\mathbf{v}}$, (4.10), and (5.13)–(5.14), it follows that there exists a positive constant C such that the following inequality holds:

$$\begin{aligned} |M(t)| \le\ & \left[\int_0^t\int_{-\eta s}^{0} e^{\kappa_1 z}(u_t^2(z,s) + \sum_{i=1}^{n} v_{i,t}^2(z,s))dzds\right.\\ &\left. +\ \int_0^t\int_0^{\eta s} e^{\kappa_2 z}(u_t^2(z,s) + \sum_{i=1}^{n} v_{i,t}^2(z,s))dzds\right]\\ &+\ \left[C\int_0^t\int_{-\eta s-1}^{-\eta s}(e^{2\sigma_1 z} + e^{\kappa_1 z - 2\mu t} + 2e^{((\kappa_1/2)+\sigma_1)z-\mu t})dzds\right.\\ &\left. +\ C\int_0^t\int_{\eta s}^{\eta s+1}(e^{-2\sigma_2 z} + e^{\kappa_2 z - 2\mu t} + 2e^{((\kappa_2/2)-\sigma_2)z-\mu t})dzds\right]\\ :=\ & I(t) + II(t). \end{aligned}$$

Noting that $|\kappa_j|\eta - 2\mu = (|\kappa_j|\eta - \mu) - \mu < 0$, $\kappa_j/2 + \sigma_j > 0$, and $\kappa_j/2 - \sigma_j < 0$, $j = 1, 2$, then it follows that $II(t)$ is bounded by some positive constant C. Recalling that $u_t(\cdot, 0) \ge 0$ and $v_{i,t}(\cdot, 0) \le 0$ on $\mathbf{R}$, it follows from Lemma 5.4 that $u_t(z,t) \ge 0$

and $v_{i,t}(z,t) \le 0$ for all $(z,t) \in \mathbf{R} \times \mathbf{R}^+$. Using this fact and Fubini's theorem, we can estimate $I(t)$ as follows:

$$\begin{aligned} I(t) \quad &\le 2C_1 \int_0^t \int_{-\eta s}^0 e^{\kappa_1 z} \left(u_t(z,s) - \sum_{i=1}^n v_{i,t}(z,s) \right) dz ds \\ &\quad + 2C_1 \int_0^t \int_0^{\eta s} e^{\kappa_2 z} \left(u_t(z,s) - \sum_{i=1}^n v_{i,t}(z,s) \right) dz ds \\ &= 2C_1 \left[\int_{-\eta t}^0 e^{\kappa_1 z} \left(\int_{-z/\eta}^t (u_t(z,s) - \sum_{i=1}^n v_{i,t}(z,s)) ds \right) dz \right] \\ &\quad + 2C_1 \left[\int_0^{\eta t} e^{\kappa_2 z} \left(\int_{z/\eta}^t (u_t(z,s) - \sum_{i=1}^n v_{i,t}(z,s)) ds \right) dz \right] \\ &= 2C_1 \left[\int_{-\eta t}^0 e^{\kappa_1 z} \left(u(z,t) - \sum_{i=1}^n v_i(z,t) - u(z,-z/\eta) + \sum_{i=1}^n v_i(z,-z/\eta) \right) dz \right] \\ &\quad + 2C_1 \left[\int_0^{\eta t} e^{\kappa_2 z} \left(u(z,t) - \sum_{i=1}^n v_i(z,t) - u(z,z/\eta) + \sum_{i=1}^n v_i(z,z/\eta) \right) dz \right], \end{aligned}$$

where C_1 is defined in Lemma 5.5. Noting that $\kappa_j < 0$, $\kappa_j/2 + \sigma_j > 0$, $\kappa_j/2 - \sigma_j < 0$, and $|\kappa_j|\eta - \mu < 0$ for $j = 1, 2$, and using the above inequality, (5.13)–(5.14), we obtain that $I(t)$ is also bounded by some positive constant C. Since $I(t)$, $II(t)$ are bounded for all $t \ge 0$, it follows that $|M(t)| \le C$ for all $t \ge 0$ and some constant $C > 0$. This proves our claim.

Step 3. *We claim that* $\lim_{t \to +\infty} |\dot{M(t)} + Q[\bar{u}, \bar{\mathbf{v}}](t)| = 0$, *where*

$$Q[\bar{u}, \bar{\mathbf{v}}](t) = \sum_{j=1}^2 \int_{-\infty}^{+\infty} e^{\kappa_j z} \left[(D\bar{u}_{zz} + c\bar{u}_z + F(\bar{u}, \bar{\mathbf{v}}))^2 + \sum_{i=1}^n (c\bar{v}_{i,z} + G_i(\bar{u}, \bar{\mathbf{v}}))^2 \right] \chi_j(z) dz.$$

Indeed, differentiating $M(t)$, we obtain

$$\dot{M(t)} = -\sum_{j=1}^2 \int_{-\infty}^{+\infty} e^{\kappa_j z} \left[(D\bar{u}_{zz} + c\bar{u}_z + F(\bar{u}, \bar{\mathbf{v}}))\bar{u}_t + \sum_{i=1}^n (c\bar{v}_{i,z} + G_i(\bar{u}, \bar{\mathbf{v}}))\bar{v}_{i,t} \right] \chi_j(z) dz,$$

and so we have

$$\begin{aligned} \dot{M(t)} + Q[\bar{u}, \bar{\mathbf{v}}](t) = &- \int_{-\infty}^0 e^{\kappa_1 z} [(D\bar{u}_{zz} + c\bar{u}_z + F(\bar{u}, \bar{\mathbf{v}}))(L_1[\bar{u}, \bar{\mathbf{v}}] - F(\bar{u}, \bar{\mathbf{v}})) \\ &\qquad + \sum_{i=1}^n (c\bar{v}_{i,z} + G_i(\bar{u}, \bar{\mathbf{v}}))(L_{2i}[\bar{u}, \bar{\mathbf{v}}] - G(\bar{u}, \bar{\mathbf{v}}))] dz \\ &- \int_0^{+\infty} e^{\kappa_2 z} [(D\bar{u}_{zz} + c\bar{u}_z + F(\bar{u}, \bar{\mathbf{v}}))(L_1[\bar{u}, \bar{\mathbf{v}}] - F(\bar{u}, \bar{\mathbf{v}})) \\ &\qquad + \sum_{i=1}^n (c\bar{v}_{i,z} + G_i(\bar{u}, \bar{\mathbf{v}}))(L_{2i}[\bar{u}, \bar{\mathbf{v}}] - G(\bar{u}, \bar{\mathbf{v}}))] dz. \end{aligned}$$

Noting that $L_1[\bar{u}, \bar{\mathbf{v}}] - F(\bar{u}, \bar{\mathbf{v}}) \equiv L_{2i}[\bar{u}, \bar{\mathbf{v}}] - G(\bar{u}, \bar{\mathbf{v}}) \equiv 0$, $i = 1, \ldots, n$, for $(z,t) \in \{|z| \le \eta t\} \bigcup \{|z| \ge \eta t + 1\}$, and using (4.11) and (5.13)–(5.14), we obtain that there

exists a positive constant C such that

$$\begin{aligned}|\dot{M(t)} + Q[\bar{u},\bar{\mathbf{v}}](t)| &\le C\int_{-\eta t-1}^{-\eta t}(e^{2\sigma_1 z} + e^{\kappa_1 z - 2\mu t} + e^{(\kappa_1/2)z+\sigma_1 z-\mu t})dz \\ &\quad + C\int_{\eta t}^{\eta t+1}(e^{-2\sigma_2 z} + e^{\kappa_2 z - 2\mu t} + e^{(\kappa_2/2)z-\sigma_2 z-\mu t})dz \\ &\le C\left(\frac{e^{-2\sigma_1\eta t}}{2\sigma_1} - \frac{e^{-\kappa_1(\eta t+1)-2\mu t}}{\kappa_1} + \frac{e^{-(\kappa_1/2+\sigma_1)\eta t-\mu t}}{((\kappa_1/2)+\sigma_1)}\right) \\ &\quad + C\left(\frac{e^{-2\sigma_2\eta t}}{2\sigma_2} - \frac{e^{\kappa_2\eta t-2\mu t}}{\kappa_2} + \frac{e^{(\kappa_2/2-\sigma_2)\eta t-\mu t}}{(-(\kappa_2/2)+\sigma_2)}\right).\end{aligned}$$

Using this inequality and the fact that $|\kappa_j|\eta - 2\mu < 0$, $\kappa_j/2+\sigma_j > 0$, and $\kappa_j/2-\sigma_j < 0$ for $j = 1, 2$, it follows that the claim holds.

Step 4. *We claim that there exists a sequence* $\{t_p\}_{p\in\mathbf{N}}$ *with* $\lim_{p\to\infty} t_p = +\infty$ *such that*

$$\lim_{p\to\infty} Q[\bar{u},\bar{\mathbf{v}}](t_p) = 0. \tag{4.12}$$

Indeed, noting that $Q[\bar{u},\bar{\mathbf{v}}](t) \ge 0$ for all $t \ge 0$ and that $|M(t)|$ is bounded, it follows that we have $\lim_{t\to+\infty} \sup \dot{M(t)} = 0$. Combining this with Step 3, we obtain (4.12).

Step 5. *We reach our conclusion.* Indeed, Lemma 4.2 implies that there exists a subsequence of $\{t_p\}_{p\in\mathbf{N}}$, say $\{t'_p\}_{p\in\mathbf{N}}$, along which $\bar{u}(\cdot,t'_p)$ and $\bar{v}_i(\cdot,t'_p)$ converge to the limit functions $\hat{u}(z)$ and $\hat{v}_i(z)$ in $C^2(\mathbf{R})$ and $C^1(\mathbf{R})$, respectively, for some functions $\hat{u} \in C^2(\mathbf{R})$ and $\hat{v}_i \in C^1(\mathbf{R})$ and $i = 1,\dots,n$. Set $\hat{\mathbf{v}} = (\hat{v}_1,\dots,\hat{v}_n)$. Using this and (4.12) it follows that for each finite interval $I = [-l, l]$ with $l > 0$, we have

$$\begin{aligned}&\left[\sum_{j=1}^{2}\int_I e^{\kappa_j z}((D\bar{u}_{zz} + c\bar{u}_z + F(\bar{u},\bar{\mathbf{v}}))^2 + \sum_{i=1}^{n}(c\bar{v}_{i,z} + G_i(\bar{u},\bar{\mathbf{v}}))^2)\chi_j(z)dz\right]_{t=t'_p} \\ &\to \left[\sum_{j=1}^{2}\int_I e^{\kappa_j z}((D\hat{u}_{zz} + c\hat{u}_z + F(\hat{u},\hat{\mathbf{v}}))^2 + \sum_{i=1}^{n}(c\hat{v}_{i,z} + G_i(\hat{u},\hat{\mathbf{v}}))^2)\chi_j(z)dz\right] = 0\end{aligned}$$

as $p \to +\infty$. Thus

$$D\hat{u}_{zz} + c\hat{u}_z + F(\hat{u},\hat{\mathbf{v}}) = 0, \quad c\hat{v}_{i,z} + G_i(\hat{u},\hat{\mathbf{v}}) = 0 \ \text{ on } \ \mathbf{R}$$

for $i = 1,\dots,n$. Note that $\hat{u}(-\infty) = a_0$, $\hat{u}(+\infty) = a_2$, $\hat{v}_i(-\infty) = b_0^i$, and $\hat{v}_i(+\infty) = b_2^i$ for $i = 1,\dots,n$. Thus, from the uniqueness of the traveling wave front solution $(\mathcal{U},\mathbf{\Pi})$ of (4.1)–(4.2), it follows that $\hat{u} = \mathcal{U}(z - z_0)$ and $\hat{v}_i = \Pi_i(z - z_0)$, $i = 1,\dots,n$, for some $z_0 \in \mathbf{R}$. Noting that $(u,\mathbf{v}) \equiv (\bar{u},\bar{\mathbf{v}})$ for $|z| \le \eta t$, we obtain that

$$u(z,t'_p) \to \mathcal{U}(z - z_0) \ \text{ and } \ v_i(z,t'_p) \to \Pi_i(z - z_0),\ i = 1,\dots,n,$$

in $C^2(\mathbf{R})$ and $C^1(\mathbf{R})$, respectively, as $p \to \infty$. Finally, an application of Lemma 5.6 with $(\phi(z),\psi_i(z)) = (u(z,t'_p), v_i(z,t'_p))$, $i = 1,\dots,n$, completes the proof. □

5. Appendix.

5.1. The zeros of (3.11). In the following lemma, we will count the positive zero and negative zeros of $p_n(\lambda)$ defined by (3.11).

LEMMA 5.1. *There are only one positive zero and $n+1$ negative zeros for the polynomial $p_n(\lambda)$ which is defined by* (3.11).

Proof. Recall that $p_n(\lambda)$ is a polynomial of degree $n+2$ and is defined by

$$\begin{aligned} p_n(\lambda) &:= p_n(\lambda; k_+^1, \dots, k_+^n, k_-^1, \dots, k_-^n, b_0^1, \dots, b_0^n) \\ &= \det \begin{bmatrix} -\lambda & 1 & 0 & \cdots & 0 \\ -\theta(-a - \sum_{i=1}^n k_+^i b_0^i) & \theta - \lambda & \theta k_-^1 & \cdots & \theta k_-^n \\ -k_+^1 b_0^1 & 0 & -k_-^1 - \lambda & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -k_+^n b_0^n & 0 & 0 & \cdots & -k_-^n - \lambda \end{bmatrix}. \end{aligned}$$

Then, by a careful calculation, we have

$$p_n(\lambda) = (\lambda^2 - \theta\lambda - a\theta) \prod_{i=1}^n (-\lambda - k_-^i) + \sum_{i=1}^n \left[\theta(k_+^i b_0^i) \lambda \prod_{j \neq i}^n (-\lambda - k_-^j) \right]. \tag{5.1}$$

First, we claim that if the off rates $\{k_-^i\}_{i=1}^n$ are different and $n > 1$, then the conclusion of this lemma holds. Indeed, by (5.1), we have the following equalities:

$$\begin{aligned} p_n(0) &= (-1)^{n+1} \theta a \prod_{i=1}^n k_-^i, \\ p_n(-k_-^i) &= -\theta b_0^i k_+^i k_-^i \prod_{j \neq i}^n (k_-^i - k_-^j), \ i = 1, \dots, n. \end{aligned}$$

Set $k_-^0 = 0$. Then, by assumption, we may assume that $0 < k_-^1 < \cdots < k_-^n$, and so we can conclude that $p_n(-k_-^i) p_n(-k_-^{i+1}) < 0$ for $i = 0, \dots, n-1$. Hence we complete the proof of this claim.

Now we turn to the general case; i.e., the off rates $\{k_-^i\}_{i=1}^n$ are not necessarily different. We will use induction to prove it. When $n = 1$, i.e., there is only one buffer, then we observe that $p_1(-\infty) > 0$, $p_1(-k_-^1) = -\theta k_+^1 k_-^1 b_0^1 < 0$, $p_1(0) = \theta a k_-^1 > 0$, and $p_1(+\infty) < 0$, and so we obtain that the conclusion holds for $n = 1$.

Assume that there are only one positive zero and $m+1$ negative zeros for $p_m(\lambda)$ (some zeros of $p_m(\lambda)$ may have multiplicity bigger than 1) for any positive $k_+^1, \dots, k_+^m$, $k_-^1, \dots, k_-^m$, and $b_0^1, \dots, b_0^m$.

Now we consider the case for $n = m+1$. If the off rates $\{k_-^i\}_{i=1}^{m+1}$ are different, then from the above claim it follows that there are only one positive zero and $m+2$ negative zeros for $p_{m+1}(\lambda)$. If the off rates $\{k_-^i\}_{i=1}^{m+1}$ are not necessarily different, then we may assume that $k_-^m = k_-^{m+1}$, and so from (5.1) it follows that

$$\begin{aligned} & p_{m+1}(\lambda) \\ &= p_{m+1}(\lambda; k_+^1, \dots, k_+^{m+1}, k_-^1, \dots, k_-^{m+1}, b_0^1, \dots, b_0^{m+1}) \\ &= (-\lambda - k_-^m) p_m(\lambda; k_+^1, \dots, k_+^m, k_-^1, \dots, k_-^m, b_0^1, \dots, b_0^{m-1}, b_0^m + (k_+^{m+1} b_0^{m+1} / k_+^m)) \\ &= (-\lambda - k_-^m) q_m(\lambda). \end{aligned}$$

By induction hypothesis, $q_m(\lambda)$ has only one positive zero and $m+1$ negative zeros (some of them may have multiplicity bigger than 1). Note that k_-^m is positive. Therefore, $p_{m+1}(\lambda)$ has only one positive zero and $m+2$ negative zeros. The completes the induction, and so the proof is completed. ∎

5.2. Proof of Lemma 4.2. *Plan of the proof of Lemma* 4.2.

The proof of Lemma 4.2 is based on the estimation of the L^∞ norm of $u(\cdot,t)$, $v_i(\cdot,t)$ and their associated partial derivatives. Roughly speaking, we use the invariance principle to show that our solution $(u,\mathbf{v})$ of (4.3)–(4.5) is bounded by the traveling wave solution $(\mathcal{U},\mathbf{\Pi})$ (see Lemma 5.3). Then we use the assumptions of Theorem 3, the L^p-regularity theorem, and Schauder estimates to estimate the partial derivatives of u and v_i for $i=1,\dots,n$ (see Lemma 5.5). Once Lemmas 5.3 and 5.5 are proved, then we can use standard arguments to obtain Lemma 4.2 (see the proof of Lemma 4.6 in Klaasen and Troy [10] for details).

Now we turn to our proof. First, for each $\delta>0$, we define the following two sets:

$$R_\delta^0=\{(u,\mathbf{v})\mid |u-a_0|\le\delta, |v_i-b_0^i|\le\delta \ \text{ for } \ i=1,\dots,n\} \tag{5.2}$$

and

$$R_\delta^2=\{(u,\mathbf{v})\mid |u-a_2|\le\delta, |v_i-b_2^i|\le\delta \ \text{ for } \ i=1,\dots,n\}. \tag{5.3}$$

Then these two sets have the following property.

LEMMA 5.2. *If $a\in(0,1)$, then there exist $\delta_1>0$ and constants α_{11}^i, $\alpha_{11,j}^i$, $\alpha_{12,j}^i$, $\alpha_{21,j}^i$, $\alpha_{22,j}^i$, $i=0,2$, $j=1,\dots,n$, such that for all $\delta\in(0,\delta_1)$, $i=0,2$, and $j=1,\dots,n$, we have*

(1) *$F_u<\alpha_{11}^i=\sum_{j=1}^n\alpha_{11,j}^i<0$, $\alpha_{12,j}^i<F_{v_j}<0$, $\alpha_{21,j}^i<G_{j,u}<0$, and $G_{j,v_j}<\alpha_{22,j}^i<0$ on R_δ^i, where $\alpha_{11,j}^i<0$;*

(2) *$\alpha_{11,j}^i\alpha_{22,j}^i-\alpha_{12,j}^i\alpha_{21,j}^i>0$;*

(3) *if both $(u,\mathbf{v})$ and $(u-q_1,\mathbf{v}+\mathbf{q_2})$ belong to R_δ^i for some $i\in\{0,2\}$, and $q_1>0$, $q_{2j}>0$, $j=1,\dots,n$, then*

$$F(u,\mathbf{v})-F(u-q_1,\mathbf{v}+\mathbf{q_2})\le\alpha_{11}^iq_1-\sum_{j=1}^n\alpha_{12,j}^iq_{2j},$$
$$G_j(u,\mathbf{v})-G_j(u-q_1,\mathbf{v}+\mathbf{q_2})\ge\alpha_{21,j}^iq_1-\alpha_{22,j}^iq_{2j}$$

for $j=1,\dots,n$, where $\mathbf{q_2}=(q_{21},\dots,q_{2n})$.

Proof. For simplicity, we set $K_i=k_-^i/k_+^i$, $i=1,\dots,n$.

(1) By a simple calculation, the quantities

$$F_u(a_0,\mathbf{b_0}),F_{v_j}(a_0,\mathbf{b_0}),F_u(a_2,\mathbf{b_2}),F_{v_j}(a_2,\mathbf{b_2}),$$
$$G_{j,u}(a_0,\mathbf{b_0}),G_{j,v_j}(a_0,\mathbf{b_0}),G_{j,u}(a_2,\mathbf{b_2}),G_{j,v_j}(a_2,\mathbf{b_2})$$

are negative if $a\in(0,1)$. From this it follows that there exist $\alpha_{11}^i<0$, $\alpha_{11,j}^i<0$, $\alpha_{12,j}^i<0$, $\alpha_{21,j}^i<0$, and $\alpha_{22,j}^i<0$, $i=0,2$, $j=1,\dots,n$, such that part (1) of the conclusion is true.

(2) Moreover, noting that

$$F_u(a_0,\mathbf{b_0})=-\sum_{j=1}^n(a/n+k_+^jb_0^j),$$
$$F_u(a_2,\mathbf{b_2})=-\sum_{j=1}^n[(1-a)/n+k_-^jb_0^j/(K_j+1)],$$

the identities

$$(-a/n-k_+^jb_0^j)G_{j,v_j}(a_0,\mathbf{b_0})-F_{v_j}(a_0,\mathbf{b_0})G_{j,u}(a_0,\mathbf{b_0})=ak_-^j/n>0,$$

and

$$[-(1-a)/n - k_-^j b_0^j/(K_j+1)]G_{j,v_j}(a_2,\mathbf{b_2}) - F_{v_j}(a_2,\mathbf{b_2})G_{j,u}(a_2,\mathbf{b_2})$$
$$= (1-a)(k_+^j + k_-^j)/n > 0$$

if $a \in (0,1)$, it follows that we can choose $\alpha_{11}^i < 0$, $\alpha_{11,j}^i < 0$, $\alpha_{12,j}^i < 0$, $\alpha_{21,j}^i < 0$, and $\alpha_{22,j}^i < 0$ such that part (1) of the conclusion and

$$\alpha_{11}^i = \sum_{j=1}^n \alpha_{11,j}^i, \quad \alpha_{11,j}^i \alpha_{22,j}^i - \alpha_{12,j}^i \alpha_{21,j}^i > 0$$

for $i = 0, 2$, and $j = 1, \ldots, n$ hold.

(3) The proof follows from the mean value theorem and part (1). □

Next we estimate the bound of the L^∞ norm of the solution $(u(\cdot,t), \mathbf{v}(\cdot,t))$ of (4.3)–(4.5). We will adapt the method of [10] to prove it.

LEMMA 5.3. *Let $(u, \mathbf{v})$ be the solution of* (4.3)–(4.5). *If $a_2 - \phi_2 > 0$, $\psi_{2i} - b_2^i > 0$, $\phi_0 - a_0 > 0$, and $b_0^i - \psi_{0i} > 0$ are sufficiently small, then there exist constants z_1, $z_2 \in \mathbf{R}$, $\hat{k}_1 > 0$, $k_{2i} > 0$, $i = 1, \ldots, n$, and $\mu > 0$ such that*

$$\mathcal{U}(z - z_1) - \hat{k}_1 e^{-\mu t} \le u(z,t) \le \mathcal{U}(z - z_2) + \hat{k}_1 e^{-\mu t}, \tag{5.4}$$

and

$$\Pi_i(z - z_2) - k_{2i} e^{-\mu t} \le v_i(z,t) \le \Pi_i(z - z_1) + k_{2i} e^{-\mu t} \tag{5.5}$$

for all $(z,t) \in \mathbf{R} \times [0, +\infty)$ and $i = 1, \ldots, n$.

Proof. We prove the left-hand side of (5.4) and the right-hand side of (5.5), since the remaining inequalities follow in a similar way.

The idea is to use the invariance principle to choose suitable functions $\epsilon(t)$, $q_1(t)$, and $\mathbf{q_2}(t)$ such that $\mathcal{U}(z - \epsilon(t)) - q_1(t) \le u(z,t)$ and $\mathbf{\Pi}(z - \epsilon(t)) + \mathbf{q_2}(t) \ge \mathbf{v}(z,t)$ for all $(z,t) \in \mathbf{R} \times \mathbf{R}^+$ and then use the monotone properties of $\mathcal{U}$ and $\mathbf{\Pi}$ to obtain our conclusion. The proof will be divided into three steps.

Step 1. *Construction of $\tilde{u}$ and $\tilde{\mathbf{v}}$.* Recall that the functions $u(z,t)$ and $\mathbf{v}(z,t)$ satisfy

$$L_1[u, \mathbf{v}] \equiv u_t - D u_{zz} - c u_z = F(u, \mathbf{v}),$$
$$L_{2i}[u, \mathbf{v}] \equiv v_{i,t} - c v_{i,z} = G_i(u, \mathbf{v}),\ i = 1, \ldots, n,$$

and

$$u(z,0) = \phi(z), \quad v_i(z,0) = \psi_i(z)$$

for all $z \in \mathbf{R}$ and $i = 1, \ldots, n$. Let $(\underline{u}, \underline{\mathbf{v}}) = (u, \underline{v}_1, \ldots, \underline{v}_n)$ be defined by

$$\underline{u}(z,t) \equiv \mathcal{U}(z - \epsilon(t)) - q_1(t)$$

and

$$\underline{v}_i(z,t) \equiv \Pi_i(z - \epsilon(t)) + q_{2i}(t),\ i = 1, \ldots, n, \quad \text{on } \mathbf{R} \times [0, +\infty),$$

where $\epsilon(t)$, $q_1(t)$, and $q_{2i}(t)$ are positive functions with the properties that

$$\underline{u}(z,t) \ge -\min_{j=1,\ldots,n} \{k_-^j/(2k_+^j)\}, \quad \underline{v}_i(z,t) \ge b_2^i/2 \tag{5.6}$$

for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ and $i = 1,\dots,n$. We remark that $(\underline{u}, \underline{\mathbf{v}})$ will be a subsolution of (4.3)–(4.4). Now we will find the differential equations for which $(\underline{u}, \underline{\mathbf{v}})$ satisfy. Setting $\tau = z - \epsilon(t)$ and using the fact that $D\mathcal{U}'' + c\mathcal{U}' + F(\mathcal{U}, \mathbf{\Pi}) = 0$ and $c\Pi_i' + G_i(\mathcal{U}, \mathbf{\Pi}) = 0$, $i = 1,\dots,n$, we find that for each $i = 1,\dots,n$,

$$\begin{aligned} L_1[\underline{u}, \underline{\mathbf{v}}] &= -\epsilon'(t)\mathcal{U}'(\tau) - q_1'(t) - D\mathcal{U}''(\tau) - c\mathcal{U}'(\tau) \\ &= -\epsilon'(t)\mathcal{U}'(\tau) - q_1'(t) + F(\mathcal{U}(\tau), \mathbf{\Pi}(\tau)) \end{aligned}$$

and

$$\begin{aligned} L_{2i}[\underline{u}, \underline{\mathbf{v}}] &= -\epsilon'(t)\Pi_i'(\tau) + q_{2i}'(t) - c\Pi_i'(\tau) \\ &= -\epsilon'(t)\Pi_i'(\tau) + q_{2i}'(t) + G_i(\mathcal{U}(\tau), \mathbf{\Pi}(\tau)) \end{aligned}$$

for all $\tau \in \mathbf{R}$.

Set $(\tilde{u}, \tilde{\mathbf{v}}) = (u - \underline{u}, \mathbf{v} - \underline{\mathbf{v}})$. Then the variables $(\tilde{u}, \tilde{\mathbf{v}})$ satisfy the following system:

$$\begin{aligned} L_1[\tilde{u}, \tilde{\mathbf{v}}] &= F(u, \mathbf{v}) + \epsilon'(t)\mathcal{U}'(\tau) + q_1'(t) - F(\mathcal{U}(\tau), \mathbf{\Pi}(\tau)) \\ &= [F(u, \mathbf{v}) - F(\underline{u}, \underline{\mathbf{v}})] + [\epsilon'(t)\mathcal{U}'(\tau) + q_1'(t) + F(\underline{u}, \underline{\mathbf{v}}) - F(\mathcal{U}(\tau), \mathbf{\Pi}(\tau))] \\ &\equiv \left[f_1(z,t)\tilde{u} + \sum_{j=1}^{n} f_{1j}(z,t)\tilde{v}_j \right] + N_1(z,t), \end{aligned} \tag{5.7}$$

$$\begin{aligned} L_{2i}[\tilde{u}, \tilde{\mathbf{v}}] &= G_i(u, \mathbf{v}) + \epsilon'(t)\Pi_i'(\tau) - q_{2i}'(t) - G_i(\mathcal{U}(\tau), \mathbf{\Pi}(\tau)) \\ &= [G_i(u, \mathbf{v}) - G_i(\underline{u}, \underline{\mathbf{v}})] + [\epsilon'(t)\Pi_i'(\tau) - q_{2i}'(t) + G_i(\underline{u}, \underline{\mathbf{v}}) - G_i(\mathcal{U}(\tau), \mathbf{\Pi}(\tau))] \\ &\equiv [g_{2i}(z,t)\tilde{u} + \tilde{g}_{2i}(z,t)\tilde{v}_i] + N_{2i}(z,t), \end{aligned} \tag{5.8}$$

together with the initial data

$$\begin{aligned} \tilde{u}(z,0) &= u(z,0) - \underline{u}(z,0), \\ \tilde{v}_i(z,0) &= v_i(z,0) - \underline{v}_i(z,0), \end{aligned}$$

where

$$\begin{aligned} f_1(z,t) &= F_u(\theta_1 u + (1-\theta_1)\underline{u}, \theta_1 \mathbf{v} + (1-\theta_1)\underline{\mathbf{v}})(z,t), \\ f_{1j}(z,t) &= F_{v_j}(\theta_1 u + (1-\theta_1)\underline{u}, \theta_1 \mathbf{v} + (1-\theta_1)\underline{\mathbf{v}})(z,t), \\ g_{2i}(z,t) &= G_{i,u}(\theta_{2i} u + (1-\theta_{2i})\underline{u}, \theta_{2i} \mathbf{v} + (1-\theta_{2i})\underline{\mathbf{v}})(z,t), \\ \tilde{g}_{2i}(z,t) &= G_{i,v_i}(\theta_{2i} u + (1-\theta_{2i})\underline{u}, \theta_{2i} \mathbf{v} + (1-\theta_{2i})\underline{\mathbf{v}})(z,t), \end{aligned}$$

for some $\theta_1 = \theta_1(u, \mathbf{v}, \underline{u}, \underline{\mathbf{v}}) \in (0,1)$, $\theta_{2i} = \theta_{2i}(u, \mathbf{v}, \underline{u}, \underline{\mathbf{v}}) \in (0,1)$, and $i, j = 1,\dots,n$.

Step 2. *We claim that for suitably chosen $\epsilon(t)$, $q_1(t)$, and $q_{2i}(t)$, $i = 1,\dots,n$, the region $\{\tilde{u} \geq 0, \tilde{v}_{2i} \leq 0, i = 1,\dots,n\}$ is invariant under the flow* (5.7)–(5.8). Indeed, from (5.6), Lemma 4.1, and the definitions of F and G_i, it follows that $f_{1i}(z,t) < 0$ and $g_{2i}(z,t) < 0$ for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ and $i = 1,\dots,n$. Therefore, if we can choose $\epsilon(t)$, $q_1(t)$, and $q_{2i}(t)$ satisfying that (5.6) holds and that $N_1(z,t) \geq 0$ and $N_{2i}(z,t) \leq 0$ for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ and $i = 1,\dots,n$, then, by Theorem 14.11 on p. 203 of Smoller [23] we have $\tilde{u}(z,t) \geq 0$ and $\tilde{\mathbf{v}}(z,t) \leq \mathbf{0} = (0,\dots,0)$ for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ if $\tilde{u}(\cdot,0) \geq 0$ and $\tilde{\mathbf{v}}(\cdot,0) \leq \mathbf{0}$ on $\mathbf{R}$.

Next we try to find the desired functions $\epsilon(t)$, $q_1(t)$, and $q_{2i}(t)$, $i = 1,\dots,n$. Indeed, let $\delta \in (0, \delta_1)$ with δ_1 being defined in Lemma 5.2. Also recall the definitions of $R_\delta^i, i = 0, 2$, given by (5.2)–(5.3) and note that $\mathcal{U}' > 0$ and $\Pi_j' < 0$ on $\mathbf{R}$ for $j = 1,\dots,n$. Set $\mathbf{q_2}(t) = (q_{21}(t),\dots,q_{2n}(t))$ and assume $\epsilon' \geq 0$. If for some $i \in \{0, 2\}$

both $(\mathcal{U}(\tau), \mathbf{\Pi}(\tau))$ and $(\mathcal{U}(\tau) - q_1(t), \mathbf{\Pi}(\tau) + \mathbf{q_2}(t))$ belong to R^i_δ, then part (3) of Lemma 5.2 implies

$$\begin{aligned} N_1(z,t) &\geq q_1' - \alpha^i_{11} q_1 + \sum_{l=1}^n \alpha^i_{12,l} q_{2l}, \\ N_{2j}(z,t) &\leq -q_{2j}' - \alpha^i_{21,j} q_1 + \alpha^i_{22,j} q_{2j} \end{aligned} \tag{5.9}$$

for $j = 1, \ldots, n$. On the other hand, from Lemma 5.2 it follows that there exist positive constants μ_0, k_{0j}, $j = 1, \ldots, n$, such that for all $\mu \in (0, \mu_0)$, $i = 0, 2$, and $j = 1, \ldots, n$, we have

$$\frac{\mu}{n} + \alpha^i_{11,j} < 0,\ \mu + \alpha^i_{22,j} < 0,\ \left(\frac{\mu}{n} + \alpha^i_{11,j}\right)(\mu + \alpha^i_{22,j}) > \alpha^i_{12,j}\alpha^i_{21,j},$$

and

$$\frac{\alpha^i_{21,j}}{\mu + \alpha^i_{22,j}} < k_{0j} < \frac{(\mu/n) + \alpha^i_{11,j}}{\alpha^i_{12,j}}.$$

This implies that

$$\begin{aligned} -\mu/n - \alpha^i_{11,j} + k_{0j}\alpha^i_{12,j} > 0, \\ \mu k_{0j} - \alpha^i_{21,j} + k_{0j}\alpha^i_{22,j} < 0 \end{aligned}$$

for all $\mu \in (0, \mu_0)$, $i = 0, 2$, and $j = 1, \ldots, n$. Summing the first inequality from $j = 1$ to n, we obtain that

$$-\mu - \alpha^i_{11} + \sum_{j=1}^n k_{0j}\alpha^i_{12,j} > 0.$$

Hence for all $\mu \in (0, \mu_0)$ and $d > 0$, the functions q_1 and q_{2j} defined by

$$q_1(t) = de^{-\mu t},\ \ q_{2j}(t) = dk_{0j}e^{-\mu t},\ j = 1, \ldots, n, \tag{5.10}$$

satisfy

$$q_1' - \alpha^i_{11} q_1 + \sum_{l=1}^n \alpha^i_{12,l} q_{2l} > 0,\ \ -q_{2j}' - \alpha^i_{21,j} q_1 + \alpha^i_{22,j} q_{2j} < 0 \tag{5.11}$$

for all $t \geq 0$ and $j = 1, \ldots, n$. Therefore, by the above discussion, (5.9), and (5.11), we can choose a sufficiently small $d_0 > 0$ and a sufficiently large $M > 0$ such that if $d \in (0, d_0)$ and $|\tau| > M$, then both $(\mathcal{U}(\tau), \mathbf{\Pi}(\tau))$ and $(\mathcal{U}(\tau) - q_1(t), \mathbf{\Pi}(\tau) + \mathbf{q_2}(t))$ belong to one of R^0_δ and R^2_δ, and $N_1(z,t) > 0$, $N_{2i}(z,t) < 0$ for $i = 1, \ldots, n$.

We focus our attention on the intermediate case: $|\tau| \leq M$. Since $\mathcal{U}' > 0$ and $\Pi_i' < 0$ on $\mathbf{R}$, there exist positive constants β, $\bar\gamma_1$, and $\bar\gamma_{2i}$ such that

$$\begin{aligned} &\mathcal{U}'(\tau) > \beta,\ \ \Pi_i'(\tau) < -\beta, \\ &F(\mathcal{U}(\tau) - q_1(t), \mathbf{\Pi}(\tau) + \mathbf{q_2}(t)) - F(\mathcal{U}(\tau), \mathbf{\Pi}(\tau)) \geq -\bar\gamma_1 q_1(t) - \sum_{l=1}^n \bar\gamma_{2l} q_{2l}(t), \\ &G_i(\mathcal{U}(\tau) - q_1(t), \mathbf{\Pi}(\tau) + \mathbf{q_2}(t)) - G_i(\mathcal{U}(\tau), \mathbf{\Pi}(\tau)) \leq \bar\gamma_1 q_1(t) + \bar\gamma_{2i} q_{2i}(t) \end{aligned}$$

for all $\tau \in [-M, M]$, $t \geq 0$, and $i = 1, \ldots, n$. Thus, for each $i = 1, \ldots, n$, we have

$$N_1(z,t) \geq \epsilon'\beta + q_1' - \bar{\gamma}_1 q_1 - \sum_{l=1}^{n} \bar{\gamma}_{2l} q_{2l},$$
$$N_{2i}(z,t) \leq -\epsilon'\beta - q_{2i}' + \bar{\gamma}_1 q_1 + \sum_{l=1}^{n} \bar{\gamma}_{2l} q_{2l}.$$

Setting $\hat{\gamma}_1 = \bar{\gamma}_1 + \mu$ and $\hat{\gamma}_{2i} = \bar{\gamma}_{2i} + \mu$, $i = 1, \ldots, n$, then from (5.10) it follows that for each $i = 1, \ldots, n$ we have

$$N_1(z,t) \geq \epsilon'\beta - \hat{\gamma}_1 q_1 - \sum_{l=1}^{n} \hat{\gamma}_{2l} q_{2l},$$
$$N_{2i}(z,t) \leq -\epsilon'\beta + \hat{\gamma}_1 q_1 + \sum_{l=1}^{n} \hat{\gamma}_{2l} q_{2l}.$$

Let $\epsilon' = (\hat{\gamma}_1 q_1 + \sum_{l=1}^{n} \hat{\gamma}_{2l} q_{2l})/\beta$ and $\epsilon(0) = z^*$, where z^* is a constant to be determined later. Hence

$$\epsilon(t) = \left[z^* + \frac{d}{\mu\beta} \left(\hat{\gamma}_1 + \sum_{l=1}^{n} \hat{\gamma}_{2l} k_{0l} \right) \right] - \left[\frac{d}{\mu\beta} \left(\hat{\gamma}_1 + \sum_{l=1}^{n} \hat{\gamma}_{2l} k_{0l} \right) \right] e^{-\mu t}.$$

With this choice of $\epsilon(t)$ it follows from the above discussion that $N_1(z,t) \geq 0$ and $N_{2i}(z,t) \leq 0$ for all $(z,t) \in \mathbf{R} \times \mathbf{R}^+$ and $i = 1, \ldots, n$. Now we will choose suitable d such that $\tilde{u}(\cdot, 0) \geq 0$ and $\tilde{\mathbf{v}}(\cdot, 0) \leq \mathbf{0}$. Once these are done, then by the discussion right before finding $\epsilon(t)$, $q_1(t)$, and $\mathbf{q_2}(t)$, we can conclude that

$$\tilde{u}(z,t) \geq 0 \ \text{ and } \ \tilde{v}_i(z,t) \leq 0 \tag{5.12}$$

for all $(z,t) \in \mathbf{R} \times \mathbf{R}^+$ and $i = 1, \ldots, n$. Indeed, let $d_1 \in (0, d_0)$, $a_2 - \phi_2 > 0$, and $\psi_{2i} - b_2^i > 0$ be sufficiently small satisfying that

$$a_2 - d < \phi_2, \quad b_2^i + dk_{0i} > \psi_{2i}$$

and that $\underline{u}(z,t)$ and $\underline{v}_i(z,t)$ satisfy (5.6) for all $(z,t) \in \mathbf{R} \times \mathbf{R}^+$, for all $d \in (0, d_1)$, and $i = 1, \ldots, n$. Hence, if $z^* > 0$ is chosen sufficiently large, it follows that for $i = 1, \ldots, n$, we have

$$\mathcal{U}(z - z^*) - d < \phi(z), \ \ \Pi_i(z - z^*) + dk_{0i} > \psi_i(z) \ \text{ for all } z \in \mathbf{R},$$

and so $\tilde{u}(\cdot, 0) \geq 0$ and $\tilde{\mathbf{v}}(\cdot, 0) \leq \mathbf{0}$. This completes the proof of our claim.

Step 3. *Finally, we will reach our conclusion.* In fact, using (5.12) and noting that $\mathcal{U}$ is monotone increasing and Π_i, $i = 1, \ldots, n$, is monotone decreasing, we obtain that

$$\mathcal{U}(z - z_1) - de^{-\mu t} \leq \underline{u}(z,t) \leq u(z,t) \ \text{ and } \ v_i(z,t) \leq \underline{v}_i(z,t) \leq \Pi_i(z - z_1) + dk_{0i}e^{-\mu t}$$

for all $(z,t) \in \mathbf{R} \times [0, +\infty)$ and $i = 1, \ldots, n$. The proof is completed. □

Before estimating the partial derivatives of the solution $(u, \mathbf{v})$ of (4.3)–(4.5), we need the following lemma.

LEMMA 5.4. *Let* $(u, \mathbf{v})$ *be the solution of* (4.3)–(4.5) *satisfying that* $u_t(z,0) \geq 0$, $v_{i,t}(z,0) \leq 0$, $u_z(z,0) \geq 0$, *and* $v_{i,z}(z,0) \leq 0$ *for all* $z \in \mathbf{R}$ *and* $i = 1, \ldots, n$. *Then*

$u_t(z,t) \geq 0$, $v_{i,t}(z,t) \leq 0$, $u_z(z,t) \geq 0$, *and* $v_{i,z}(z,t) \leq 0$ *for all* $(z,t) \in \mathbf{R} \times [0,+\infty)$ *and* $i = 1, \ldots, n$.

Proof. We prove only that $u_t \geq 0$ and $v_{i,t} \leq 0$, $i = 1, \ldots, n$, on $\mathbf{R} \times [0,+\infty)$, since the remaining inequalities follow in a similar way. Define $p(z,t) = u_t(z,t)$ and $h_i(z,t) = -v_{i,t}(z,t)$, $i = 1, \ldots, n$, on $\mathbf{R} \times [0,+\infty)$. Then p and h_i satisfy the following system:

$$\begin{aligned} L_1[p, h_1, \ldots, h_n] &= p_t - Dp_{zz} - cp_z \\ &= F_u(u, \mathbf{v})(z,t)p - \sum_{j=1}^{n} F_{v_j}(u, \mathbf{v})(z,t)h_j \\ &\equiv N_1(z, t, p, h_1, \ldots, h_n), \\ L_{2i}[p, h_1, \ldots, h_n] &= h_{i,t} - ch_{i,z} \\ &= -G_{i,u}(u, \mathbf{v})(z,t)p + G_{i,v_i}(u, \mathbf{v})(z,t)h_i \\ &\equiv N_2(z, t, p, h_1, \ldots, h_n), \end{aligned}$$

together with the initial data

$$p(z,0) = u_t(z,0) \geq 0 \quad \text{and} \quad h_i(z,0) = -v_t(z,0) \geq 0,$$

where $h_{i,t} = \partial h_i / \partial t$ and $h_{i,z} = \partial h_i / \partial z$ for $i = 1, \ldots, n$. Recall that $F_{v_i}(u, \mathbf{v}) = -(k_+^i u + k_-^i) < 0$ and $G_{i,u}(u, \mathbf{v}) = -k_+^i v_i < 0$ for all $(u, \mathbf{v}) \in [a_0, a_2] \times [b_2^1, b_0^1] \times \cdots \times [b_2^n, b_0^n]$ and that $(u(z,t), \mathbf{v}(z,t)) \in [a_0, a_2] \times [b_2^1, b_0^1] \times \cdots \times [b_2^n, b_0^n]$ for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ and $i = 1, \ldots, n$. Thus $F_{v_i}(u(z,t), \mathbf{v}(z,t)) < 0$ and $G_{i,u}(u(z,t), \mathbf{v}(z,t)) < 0$ for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ and $i = 1, \ldots, n$. Combining this with the fact that $p(z,0) \geq 0$ and $h_i(z,0) \geq 0$ for all $z \in \mathbf{R}$, it follows from Theorem 14.11 on p. 203 of Smoller [23] that $p(z,t) \geq 0$ and $h_i(z,t) \geq 0$ for all $(z,t) \in \mathbf{R} \times [0,+\infty)$ and $i = 1, \ldots, n$. This completes the proof. □

Next we will estimate the partial derivatives of the solution $(u, \mathbf{v})$ of (4.3)–(4.5).

LEMMA 5.5. *Let* $(u, \mathbf{v})$ *be the solution of* (4.3)–(4.5). *Then, under the hypothesis of Theorem* 3, *there exist constants* $\kappa_j < 0$, $\sigma_j > 0$, *and* $C_1 > 0$ *satisfying that* $\kappa_j/2 + \sigma_j > 0$ *for* $j = 1, 2$, *that*

$$|u - a_0|, |u_t|, |u_z|, |u_{zz}|, |b_0^i - v_i|, |v_{i,t}|, |v_{i,z}| < C_1(e^{(-(\kappa_1/2)+\sigma_1)z} + e^{-\mu t}) \tag{5.13}$$

for $z \leq 0$, $t \geq 0$, *and* $i = 1, \ldots, n$, *and that*

$$|a_2 - u|, |u_t|, |u_z|, |u_{zz}|, |v_i - b_2^i|, |v_{i,t}|, |v_{i,z}| < C_1(e^{-(\kappa_2/2+\sigma_2)z} + e^{-\mu t}) \tag{5.14}$$

for $z > 0$, $t \geq 0$, *and* $i = 1, \ldots, n$, *where* μ *is defined in Lemma* 5.3.

Proof. We consider only the case $z \geq 0$ since the case $z < 0$ follows by analogous arguments.

Step 1. *We claim that* $|a_2 - u|$ *and* $|v_i - b_2^i|$, $i = 1, \ldots, n$, *satisfy* (5.14). Linearizing (3.1)–(3.2) around the constant solution π_2, we obtain the equation $d\mathbf{X}/d\xi = A_0\mathbf{X}$, where $\mathbf{X} = (\mathrm{U} - a_2, \mathrm{Z}, \mathrm{V}_1 - b_2^1, \ldots, \mathrm{V}_n - b_2^n)^t$,

$$A_0 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ -F_u/D & -c/D & -F_{v_1}/D & \cdots & -F_{v_n}/D \\ -G_{1,u}/c & 0 & -G_{1,v_1}/c & \cdots & -G_{1,v_n}/c \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -G_{n,u}/c & 0 & -G_{n,v_1}/c & \cdots & -G_{n,v_n}/c \end{bmatrix} \quad \text{with } G_{i,v_j} = \partial G_i / \partial v_j, \tag{5.15}$$

and all the values are evaluated at $(\mathrm{U}, \mathrm{Z}, \mathrm{V}_1, \ldots, \mathrm{V}_n) = (a_2, 0, b_2^1, \ldots, b_2^n)$. And so the associated characteristic polynomial with A_0 is

$$p_n(\lambda) = \det \begin{bmatrix} -\lambda & 1 & 0 & \cdots & 0 \\ -F_u/D & -c/D - \lambda & -F_{v_1}/D & \cdots & -F_{v_n}/D \\ -G_{1,u}/c & 0 & -G_{1,v_1}/c - \lambda & \cdots & -G_{1,v_n}/c \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -G_{n,u}/c & 0 & -G_{n,v_1}/c & \cdots & -G_{n,v_n}/c - \lambda \end{bmatrix}. \tag{5.16}$$

Note that $\partial G_i/\partial v_j = 0$ if $i \neq j$ and $G_{i,v_i}(a_2, \mathbf{b_2}) = -(k_+^i + k_-^i) < 0$ for $i = 1, \ldots, n$. Then, by a careful calculation, we have the following equalities:

$$\begin{aligned} p_n(0) &= -\frac{(1-a)}{c^n D} \prod_{i=1}^{n} (k_+^i + k_-^i), \\ p_n(-G_{i,v_i}(a_2, \mathbf{b_2})/c) &= p_n((k_+^i + k_-^i)/c) \\ &= \frac{b_0^i k_+^i k_-^i}{c^n D} \prod_{j \neq i}^{n} [(k_+^j + k_-^j) - (k_+^i + k_-^i)], \ i = 1, \ldots, n. \end{aligned}$$

Set $k_+^0 = k_-^0 = 0$. Therefore, if we assume that $(k_+^1 + k_-^1) < \cdots < (k_+^n + k_-^n)$, then we have $p_n((k_+^i + k_-^i)/c) p_n((k_+^{i+1} + k_-^{i+1})/c) < 0$ for $i = 0, \ldots, n-1$. Recall that $c < 0$. Therefore, we may assume that the eigenvalues $\lambda_1, \ldots, \lambda_{n+2}$ of A_0 satisfy

$$\lambda_{n+2} < (k_+^n + k_-^n)/c < \lambda_{n+1} < \cdots < \lambda_3 < (k_+^1 + k_-^1)/c < \lambda_2 < 0 < \lambda_1. \tag{5.17}$$

On the other hand, if $\{k_+^i + k_-^i\}_{i=1}^n$ do not satisfy this assumption, then we can use a similar argument as in Lemma 5.1 to obtain that the eigenvalues $\lambda_1, \ldots, \lambda_{n+2}$ of A_0 still satisfy (5.17) (" $<$ " may be replaced with " $=$," but $\lambda_2 < 0 < \lambda_1$ must hold).

Now we rewrite $p_n(\lambda)$ in the factored form $p_n(\lambda) = (\lambda^2 + k\lambda + l) \prod_{i=3}^{n+2} (\lambda_i - \lambda)$; then it follows that $\lambda_1 = -k/2 + \tilde{\sigma}$ and $\lambda_2 = -k/2 - \tilde{\sigma}$, where $\tilde{\sigma} = (k^2 - 4l)^{1/2}/2 > 0$. Since $c < 0$ and $\lambda_{i+2} \leq (k_+^i + k_-^i)/c < 0$ for $i = 1, \ldots, n$, we have

$$\lambda_1 + \lambda_2 = -c/D + \sum_{i=1}^{n} [(k_+^i + k_-^i)/c - \lambda_{i+2}] > 0,$$

and so $k < 0$. Since $\lambda_1 > 0$ and $\lambda_i < 0$ for $i = 2, \ldots, n+2$, we have $(\mathcal{U}, \mathbf{\Pi}) \to (a_2, \mathbf{b_2})$ exponentially fast as $z \to +\infty$. Hence there exist constants $\tilde{C}_1 > 0$, $\kappa_2 < 0$, and $0 < \sigma_2 < \tilde{\sigma}$ such that $\kappa_2/2 + \sigma_2 > 0$ and

$$\max_{i=1,\ldots,n} \{|a_2 - \mathcal{U}|, |\Pi_i - b_2^i|\} < \tilde{C}_1 e^{-(\kappa_2/2 + \sigma_2)z}$$

for all $z \geq 0$. Using this inequality and Lemma 5.3, then the inequalities for $u(z,t)$ and $v_i(z,t)$, $i = 1, \ldots, n$, follow.

Step 2. *We claim that there exists* $m_i < 0$ *such that* $m_i(v_i - b_2^i) \leq v_{i,z} \leq 0$ *on* $\mathbf{R} \times \mathbf{R}^+$ *for* $i = 1, \ldots, n$. Define

$$m_i = \inf_{(u,\mathbf{v}) \in [a_0, a_2] \times [b_2^1, b_0^1] \times \cdots \times [b_2^n, b_0^n]} \left\{ \frac{G_{i,v_i}(u, \mathbf{v})}{-c} \right\}.$$

Since $G_{i,v_i}(u, \mathbf{v}) = -(k_+^i u + k_-^i)$, we have $m_i < 0$ for $i = 1, \ldots, n$. Also recall that

$$G_i(u, \mathbf{b_2}) = k_-^i b_0^i - (k_+^i u + k_-^i)[k_-^i b_0^i/(k_+^i + k_-^i)] = k_-^i b_0^i (1-u)/(K_i + 1) \geq 0$$

for all $u \in [a_0, a_2]$ and $i = 1, \ldots, n$, where $K_i = k_-^i/k_+^i$. Noting that $v_{i,t}(\cdot, 0) \le 0$ on $\mathbf{R}$, it follows from Lemma 5.4 that $v_{i,t}(z,t) \le 0$ for all $(z,t) \in \mathbf{R} \times \mathbf{R}^+$. Therefore, using (4.4), the definition of G_i, and the mean-value theorem, and noting that $v_i \in [b_2^i, b_0^i]$ on $\mathbf{R} \times \mathbf{R}^+$, we obtain

$$\begin{aligned} 0 \ge v_{i,t} &= cv_{i,z} + G_i(u, \mathbf{v}) \\ &= cv_{i,z} + G_i(u, b_2^1, \ldots, b_2^{i-1}, v_i, b_2^{i+1}, \ldots, b_2^n) \\ &\ge cv_{i,z} + G_i(u, b_2^1, \ldots, b_2^{i-1}, v_i, b_2^{i+1}, \ldots, b_2^n) - G_i(u, b_2^1, \ldots, b_2^n) \\ &\ge cv_{i,z} - cm_i(v_i - b_2^i) \end{aligned}$$

on $\mathbf{R} \times \mathbf{R}^+$ for $i = 1, \ldots, n$. Combining this with Lemma 5.4, we obtain

$$m_i(v_i - b_2^i) \le v_{i,z} \le 0 \tag{5.18}$$

on $\mathbf{R} \times \mathbf{R}^+$ for $i = 1, \ldots, n$, since $v_{i,z}(\cdot, 0) \le 0$ on $\mathbf{R}$.

Step 3. *Estimates for the partial derivatives of* v_i. Indeed, (5.18) and the estimate obtained in Step 1 for $|v_i - b_2^i|$ lead to the inequality for $|v_{i,z}|$ for $i = 1, \ldots, n$. Rewrite (4.4) as the following:

$$v_{i,t} = cv_{i,z} + k_+^i(a_2 - u)(v_i - b_2^i) + k_+^i b_2^i(a_2 - u) - (k_+^i + k_-^i)(v_i - b_2^i).$$

Combining this with the estimates for $|a_2 - u|$, $|v_i - b_2^i|$, and $|v_{i,z}|$, we obtain the estimate for $|v_{i,t}|$ for $i = 1, \ldots, n$.

Step 4. *Estimates for the partial derivatives of* u. First, we set up some notation. For sufficiently smooth functions $g(z)$ and $h(z,t)$, and $\Omega \subset \mathbf{R} \times [0, +\infty)$, we define $|g|_0 \equiv \sup_{z \in \mathbf{R}} |g(z)|$, $[g]_\delta \equiv \sup_{x \ne y \in \mathbf{R}} |g(x) - g(y)|/|x - y|^\delta$, and $|g|_{2+\delta} \equiv |g|_0 + |g_z|_0 + |g_{zz}|_0 + [g_{zz}]_\delta$; $|h|_{0;\Omega} \equiv \sup_\Omega |h(z,t)|$, $[h]_{\delta,\delta/2;\Omega} \equiv \sup_{(x,t) \ne (y,s) \in \Omega} |h(x,t) - h(y,s)|/(|x - y|^\delta + |t - s|^{\delta/2})$, $|h|_{\delta,\delta/2;\Omega} = |h|_{0;\Omega} + [h]_{\delta,\delta/2;\Omega}$, and $|h|_{2+\delta,1+\delta/2;\Omega} \equiv |h|_{0;\Omega} + |h_z|_{0;\Omega} + |h_{zz}|_{\delta,\delta/2;\Omega} + |h_t|_{\delta,\delta/2;\Omega}$. Given the set $Q = Q_{z_0,t_0} = [z_0, z_0 + 1] \times [t_0, t_0 + 3/2]$ with $z_0 \in \mathbf{R}$ and $t_0 \ge 0$, set $Q' = Q'_{z_0,t_0} = [z_0 - 1, z_0 + 2] \times [t_0 - 1/2, t_0 + 2]$ with $z_0 \in \mathbf{R}$ and $t_0 \ge 1$ and $Q'' = Q''_{z_0} = [z_0 - 1, z_0 + 2] \times [0, 2]$ with $z_0 \in \mathbf{R}$. Rewrite (4.3) as the following:

$$\begin{aligned} (u - a_2)_t &= D(u - a_2)_{zz} + c(u - a_2)_z - u(u - a)(u - a_2) \\ &\quad + \sum_{j=1}^n [k_+^j(a_2 - u)(v_j - b_2^j) + k_+^j b_2^j(a_2 - u) - (k_+^j + k_-^j)(v_j - b_2^j)] \\ &\equiv D(u - a_2)_{zz} + c(u - a_2)_z + \tilde{f}(z,t). \end{aligned} \tag{5.19}$$

Note that $\tilde{f}(z,t)$, $u_z(z,0)$ are uniformly bounded on $\mathbf{R} \times [0, +\infty)$, $\mathbf{R}$, respectively. Then applying Theorem 6.28 and 6.33 of Lieberman [12] to (5.19) on the set Q, we obtain that there exist positive constants $\alpha \in (0,1)$ and c_1, determined by D, c and independent of (z_0, t_0), satisfying that

$$|u - a_2|_{\alpha;Q} \le c_1(|u - a_2|_{0;Q'} + |v - b_2|_{0;Q'}) \text{ if } t_0 \ge 1 \tag{5.20}$$

and

$$|u - a_2|_{\alpha;Q} \le c_1(|u - a_2|_{0;Q''} + |v - b_2|_{0;Q''} + |u_z(\cdot, 0)|_0) \text{ if } t_0 = 0. \tag{5.21}$$

Finally, (5.20), (5.21), and Schauder estimates (see Theorem 5 on p. 64 and Theorem 4 on p. 121 of Friedman [6]) imply the remaining inequalities for the partial derivatives of $u(z,t)$ for all $(z,t) \in \mathbf{R} \times [0, +\infty)$. Hence the proof is completed. □

5.3. Proof of Lemma 5.6. This lemma is a simple extension of Lemma 4.2 of [5] and is the so-called local stability of traveling wave fronts (in the C^0 norm).

LEMMA 5.6. *Let $(u, \mathbf{v})$ be the solution of (4.3)–(4.5). Then there exists a function $\omega(\eta)$, defined for small positive η, such that the following properties hold:*

(1) $\lim_{\eta \to 0^+} \omega(\eta) = 0$*;*

(2) *if there exists $z_0 \in \mathbf{R}$ such that $|\mathcal{U}(z - z_0) - \phi(z)| < \eta$ and $|\Pi_i(z - z_0) - \psi_i(z)| < \eta$ for all $z \in \mathbf{R}$ and $i = 1, \ldots, n$, then we have*

$$|u(z,t) - \mathcal{U}(z - z_0)| < \omega(\eta) \quad \text{and} \quad |\, v_i(z,t) - \Pi_i(z - z_0)| < \omega(\eta)$$

for all $(z,t) \in \mathbf{R} \times [0, +\infty)$ and $i = 1, \ldots, n$.

Proof. Since the proof is standard, we will briefly describe it. Without loss of generality, we may assume that $z_0 = 0$. Recall the definitions of $\underline{u}(z,t)$ and $\underline{\mathbf{v}}(z,t)$ from Lemma 5.3, i.e.,

$$\begin{aligned} \underline{u}(z,t) &= \mathcal{U}(z - \epsilon(t)) - de^{-\mu t}, \\ \underline{v}_i(z,t) &= \Pi_i(z - \epsilon(t)) + dk_{0i}e^{-\mu t}, i = 1, \ldots, n, \end{aligned}$$

where we set $z^* = 0$ and $\epsilon(t) = d\nu(1 - e^{-\mu t})$ for some constant $\nu > 0$. Also recall from the proof of Lemma 5.3 that there exist $d_1 > 0$, $\mu_0 > 0$ such that if $u(z,0) \geq \underline{u}(z,0)$ and $v_i(z,0) \leq \underline{v}_i(z,0)$, $i = 1, \ldots, n$, for all $z \in \mathbf{R}$, then for all $d \in (0, d_1)$ and $\mu \in (0, \mu_0)$ we obtain that $(\underline{u}, \underline{\mathbf{v}})$ satisfies (5.6), and $u(z,t) \geq \underline{u}(z,t)$ and $v_i(z,t) \leq \underline{v}_i(z,t)$ for all $(z,t) \in \mathbf{R} \times [0, +\infty)$ and $i = 1, \ldots, n$. The key points are the above comparison argument and $\epsilon(t) = O(d)$. Now we define $w_1(\eta) \equiv \max_{1 \leq i \leq n}\{\eta/k_{0i}, \eta k_{0i}\}$ with $\eta \in (0, \min_{1 \leq j \leq n}\{d_1, d_1 k_{0j}\})$. Then using the mean value theorem (or following a similar argument as in [10, 5]), we can reach our conclusion. ∎

SECOND HARMONICS EFFECTS IN RANDOM DUFFING OSCILLATORS*

JUAN A. ACEBRÓN† AND RENATO SPIGLER‡

To George Papanicolaou on his 60th birthday

Abstract. We consider a stochastic model for Duffing oscillators, where the nonlinearity and the randomness are scaled in such a way that they interact strongly. A typical feature is the appearance of *second harmonics* effects. An asymptotic statistical analysis for these oscillators is performed in the *diffusion limit*, when a suitable *absorbing boundary* condition is imposed, according to the underlying physical problem. The related Fokker–Planck equation has been numerically solved to obtain the first two moments of the oscillator's displacement from its rest-position. Dependence on the nonlinearity strength and on the location of the absorbing boundary has also been investigated. Such results have been compared with those computed solving the corresponding stochastic Ito differential equations by a Monte Carlo method, where *quasi-random* sequences of numbers have been efficiently used.

Key words. nonlinear random oscillators, Duffing oscillators, Fokker–Planck equation, diffusions with absorbing boundaries, quasi-Monte Carlo methods

1. Introduction.

Duffing oscillators are among the simplest types of *nonlinear* oscillators. They are governed by second-order ordinary differential equations, describing, e.g., the free motion that a particle performs around its rest-position, subject to a certain nonlinear restoring force. They have been extensively studied (see, e.g., [25]). On the other hand, *random* harmonic (linear) oscillators have also been studied in the literature (see, e.g., [20]).

In [23], a stochastic model for nonlinear oscillators of the Duffing type was considered, in order to investigate the joint effect of nonlinearity and randomness. However, these two mechanisms were scaled in such a way that the effect of the nonlinearity on the underlying linear random oscillator model turned out to be rather insignificant in the behavior over the long run. The topic of nonlinear random oscillators is still an active area of research, especially in connection with applications to engineering; see [5].

In this paper, a stochastic model for a Duffing-type oscillator is considered where the effect of the nonlinearity is much more important than that analyzed in [23]. The model equation is

$$y_\epsilon'' + 2\epsilon^2\lambda(t)y_\epsilon' + \omega_0^2\left[1 + \epsilon\mu(t) + \epsilon w\nu(t)y_\epsilon^2\right]y_\epsilon = 0, \tag{1.1}$$

$$y_\epsilon(0) = y_1, \quad y_\epsilon'(0) = y_2, \tag{1.2}$$

where ϵ represents a small real parameter, w is a real parameter which sizes the nonlinearity, and $\lambda(\cdot)$, $\mu(\cdot)$, $\nu(\cdot)$ are suitable real-valued stochastic processes on some probability space. Therefore, $y_\epsilon(\cdot)$ will be a (real-valued) stochastic process as well. An *absorbing condition* is further imposed to take into account that the representative particle, whose random motion is described by (1.1), is lost whenever its position, $y_\epsilon(t)$, reaches a given value, say $\pm R$. This is the case of the so-called accelerator problem. In fact, when a beam of charged particles turns around in the vacuum, inside a toroidal chamber whose cross section has radius R, being confined by strong static magnetic fields, after a very large number of laps the beam opens up, and some particles are lost when they hit the material wall. We may think that here there is an absorbing boundary, and for a randomly perturbed problem this corresponds to a vanishing probability condition at a certain given radial distance from the center of the chamber. Clearly, such a condition amounts to imposing a boundary condition to the transition probability density obeying the Kolmogorov forward equation (Fokker–Planck). Therefore, the present problem, subject to an absorbing boundary condition, will be shown to possess a diffusion limit solution.

Note that only local existence and uniqueness of solutions to problem (1.1)–(1.2) can be guaranteed. However, the absorbing boundary condition associated to such a problem allows for existence and uniqueness of solutions up to the first time when $y_\epsilon(t)$ attains the value $\pm R$ (for every fixed ϵ and for every chosen realization of the noise terms). On the other hand, as soon as the considered trajectory ends up at the level $\pm R$, the corresponding particle is "killed" and goes out of the problem.

In [23], the nonlinear term $\epsilon w \nu(t) y_\epsilon^2$ was replaced by the "weaker" one, $\epsilon^2 w \nu(\cdot) y_\epsilon^2$, and the solution there was studied in the *diffusion limit*, attained when $\epsilon \to 0$ on a suitably long time scale. As will be shown, the model described by (1.1)–(1.2) exhibits some different features compared to the model in [23]. Among other things, stronger nonlinear effects, such as "second harmonics" effects, can now be observed.

It can be seen that the present problem, without imposing the absorbing boundary condition above, does *not* possess a diffusion limit, since, according to the Feller–Hille theory [7, 9], the formally obtained Kolmogorov forward and backward equations do *not* have *unique* solutions. A comment on this problem is given in section 5.

In section 2, the relevant assumptions on the stochastic processes $\lambda(\cdot)$, $\mu(\cdot)$, and $\nu(\cdot)$ are made. A parabolic differential equation (the Fokker–Planck equation) is then derived, which describes the time evolution of the transition probability density of the limiting-process. Such a process approximates the process y_ϵ in the diffusion limit. From this, the first two moments of the displacement of the oscillator are computed (section 3). In section 4, we describe the numerical treatment performed on such equations to get quantitative information. We also solve the underlying Ito stochastic differential equation for the purpose of comparison. Such a simulation, which is of the Monte Carlo type, has been accomplished by using quasi-random (low discrepancy) sequences of numbers [2, 3, 17]. This choice is an alternative to that of the more common sequences of pseudorandom numbers and here is shown to be effective due to the use of a "scrambling" strategy (a reordering technique [18]). This positive outcome contrasts with the earlier findings of [10], where the authors did not introduce any scrambling; see [1], however. Plots are given to illustrate the dependence of the moments on the various parameters, including the location R of the absorbing barrier and the strength, w, of nonlinearity, and the results are discussed. In section 5, the high points of the paper are summarized.

2. Statistical analysis in the diffusion limit. It is convenient to introduce the van der Pool coordinates, ρ_ϵ, φ_ϵ, defined by

$$y_\epsilon(t) = \rho_\epsilon(t)\cos\left(\omega_0 t + \varphi_\epsilon(t)\right), \quad y'_\epsilon(t) = -\omega_0\,\rho_\epsilon(t)\sin\left(\omega_0 t + \varphi_\epsilon t\right).$$

Note that $\rho_\epsilon^2 = y_\epsilon^2 + \omega_0^{-2} y_\epsilon'^2$ represents the energy of the oscillator. By using this transformation in (1.1)–(1.2), the system

$$\frac{d}{dt}\begin{pmatrix} \rho_\epsilon \\ \varphi_\epsilon \end{pmatrix} = \epsilon \begin{pmatrix} F_1 \\ F_2 \end{pmatrix} + \epsilon^2 \begin{pmatrix} G_1 \\ G_2 \end{pmatrix}, \tag{2.1}$$

where $F_i \equiv F_i(t, \rho_\epsilon, \varphi_\epsilon)$, $G_i \equiv G_i(t, \rho_\epsilon, \varphi_\epsilon)$, is obtained along with the initial conditions

$$\rho_\epsilon(0) = \left(y_1^2 + y_2^2/\omega_0^2\right)^{1/2}, \quad \varphi_\epsilon(0) = -\arctan\left(y_2/\omega_0 y_1\right)^{1/2}, \tag{2.2}$$

where we set, for short,

$$F_1 := \frac{\omega_0}{2}\,\rho_\epsilon\left\{\mu(t)\sin(2\omega_0 t + 2\varphi_\epsilon) + \nu(t)\frac{w}{2}\,\rho_\epsilon^2\left[1 + \cos(2\omega_0 t + 2\varphi_\epsilon)\right]\sin(2\omega_0 t + 2\varphi_\epsilon)\right\},$$

$$F_2 := \frac{\omega_0}{2}\left\{\mu(t)\left[1 + \cos(2\omega_0 t + 2\varphi_\epsilon)\right] + \nu(t)\frac{w}{2}\,\rho_\epsilon^2\left[1 + \cos(2\omega_0 t + \varphi_\epsilon)\right]^2\right\}, \tag{2.3}$$

$$G_1 := -\rho_\epsilon\,\lambda(t)\left[1 - \cos(2\omega_0 t + 2\varphi_\epsilon)\right],$$

$$G_2 := -\lambda(t)\sin(2\omega_0 t + 2\varphi_\epsilon).$$

Below, we shall assume that $\lambda(\cdot)$, $\mu(\cdot)$, and $\nu(\cdot)$ are real-valued, almost surely bounded, wide-sense stationary stochastic processes on some probability space, $(\Omega, \mathcal{A}, P)$. The dependence on the chance variable will be omitted throughout, as is customary. We shall assume that

$$E[\lambda(t)] = \lambda_0, \qquad E[\mu(t)] = 0, \qquad E[\nu(t)] = 0, \tag{2.4}$$

for some constant λ_0, where $E[\cdot]$ denotes taking expected values. Moreover, we shall assume that $\mu(\cdot)$ and $\nu(\cdot)$ satisfy a *mixing* condition in a sufficiently *strong* sense (see, e.g., [19, 21]). As for the stationarity, we shall assume below that $\mu(\cdot)$ and $\nu(\cdot)$ are stationarily correlated (see [4, p. 160], [26, pp. 78–79]), with covariance matrix

$$\begin{pmatrix} E[\mu(s)\mu(\sigma)] & E[\mu(s)\nu(\sigma)] \\ E[\nu(s)\mu(\sigma)] & E[\nu(s)\nu(\sigma)] \end{pmatrix}, \tag{2.5}$$

whose entries will be denoted by $R_{ij}(s - \sigma)$, $i, j = 1, 2$.

Under these hypotheses, we want to investigate whether the process converges weakly to some limiting-process when $\epsilon \to 0$ and $t \to +\infty$, with $\tau := \epsilon^2 t = \text{const.}$, uniformly on $0 \le \tau \le \tau_0$ (diffusion limit). Indeed, under similar hypotheses, this was proved to be true for the Duffing model studied in [23]. In that case, the limiting-process, denoted by $(\rho(\tau), \varphi(\tau))$, turned out to be a Markov process with trajectories continuous with probability 1. Therefore, it could be described by its infinitesimal generator

$$L := \sum_{i,j=1}^{2} a_{ij}(z)\frac{\partial^2}{\partial z_i \partial z_j} + \sum_{i=1}^{2}\left[b_i(z) + c_i(z)\right]\frac{\partial}{\partial z_i}, \tag{2.6}$$

where we set $z := (z_1, z_2)^T$ ($z_1 = \rho$, $z_2 = \varphi$, for us), and a_{ij}, b_i, c_i are given by

$$a_{ij}(z) := \lim_{t\to+\infty} \frac{1}{t} \int_0^t \int_0^s E\left[F_i(s,z)F_j(\sigma,z)\right] ds\, d\sigma, \quad i,j = 1,2,$$

$$b_i(z) := \lim_{t\to+\infty} \frac{1}{t} \int_0^t \int_0^s \sum_{j=1}^{2} E\left[\frac{\partial F_i(s,z)}{\partial z_j} F_j(\sigma,z)\right] ds\, d\sigma, \quad i = 1,2, \tag{2.7}$$

$$c_i(z) := \lim_{t\to+\infty} \frac{1}{t} \int_0^t E\left[G_i(s,z)\right] ds, \quad i = 1,2.$$

Here, we can proceed similarly, taking as quantities F_i, G_i, $i = 1,2$, those defined in (2.3). The result that we shall obtain is of the type of Khas'minskii's [12] (see also [24]), as used in [19, 21].

In our problem, it is possible to evaluate explicitly the quantities in (2.7). Though this is an elementary task, the derivation is quite lengthy; see, e.g., [23]. Therefore, we skip the details and give only the results (obtained using the assumptions on $\lambda(\cdot)$, $\mu(\cdot)$, $\nu(\cdot)$):

$$a_{11}(\rho) = \rho^2 \left[\beta_{11}(2) + \frac{w}{2}\,\rho^2(\beta_{12}(2) + \beta_{21}(2)) + \frac{w^2}{4}\,\rho^4 \left(\beta_{22}(2) + \frac{1}{4}\beta_{22}(4)\right)\right],$$

$$a_{12}(\rho) + a_{21}(\rho) = \frac{w}{2}\,\rho^3(\gamma_{12}(2) - \gamma_{21}(2)),$$

$$a_{22}(\rho) = 2\alpha_{11} + \beta_{11}(2) + \frac{w}{2}\,\rho^2[3(\alpha_{12} + \alpha_{21}) + 2(\beta_{12}(2) + \beta_{21}(2))]$$

$$+ \frac{w^2}{16}\,\rho^4\,(18\alpha_{22} + 16\beta_{22}(2) + \beta_{22}(4)), \tag{2.8}$$

$$b_1(\rho) = \rho \left[3\beta_{11}(2) + \frac{5}{2}\,w\,\rho^2(\beta_{12}(2) + \beta_{21}(2)) + \frac{7}{16}\,w^2\,\rho^4\,(4\beta_{22}(2) + \beta_{22}(4))\right],$$

$$b_2(\rho) = 2\left[\gamma_{11}(2) + w\,\rho^2\,(2\gamma_{12}(2) + \gamma_{21}(2)) + \frac{3}{2}\,w^2\rho^4 \left(\gamma_{22}(2) + \frac{1}{8}\,\gamma_{22}(4)\right)\right],$$

$$c_1(\rho) = -\lambda_0\,\rho, \qquad c_2(\rho) = 0,$$

where the notation

$$\alpha_{ij} := \frac{\omega_0^2}{8} \int_0^{+\infty} R_{ij}(x)\, dx,$$

$$\beta_{ij}(k) := \frac{\omega_0^2}{8} \int_0^{+\infty} R_{ij}(x) \cos(k\omega_0 x)\, dx, \quad k = 2,4, \tag{2.9}$$

$$\gamma_{ij}(k) := \frac{\omega_0^2}{8} \int_0^{+\infty} R_{ij}(x) \sin(k\omega_0 x)\, dx, \quad k = 2,4,$$

has been used.

Remark 2.1. Note that a_{ij}, b_i, c_i depend only on ρ (and not on φ).

Remark 2.2. Observe that in this model there is an effect due to the second harmonics, through the terms $\beta_{22}(4)$, $\gamma_{22}(4)$.

Remark 2.3. In the model studied in [23], $\nu(\cdot)$ had to be "strong enough" in order to be effective, because the nonlinearity was weak (of order $\mathcal{O}(\epsilon^2)$) in comparison to the randomness (of order $\mathcal{O}(\epsilon)$). For example, $E[\nu(\cdot)] \notin L(\mathbf{R}^+)$; $\nu(t) = \text{const.} \neq 0$ was acceptable. However, $E[\nu(\cdot)]$ had to be constant (0 or not) by the assumed stationarity.

In the present model, in some sense, $\nu(\cdot)$ has to be "not too strong," because the nonlinearity term now is considerably more important: A finite second moment, with a correlation function decaying to zero sufficiently fast, is required (by the mixing property), and $E[\nu(\cdot)] \equiv 0$ by the stationarity.

With the infinitesimal generator given by (2.6), (2.8), we can write down the Kolmogorov forward (or Fokker–Planck) equation

$$\frac{\partial p}{\partial \tau} = L^*[p], \tag{2.10}$$

$\tau := \epsilon^2 t$, satisfied by the transition probability density p, L^* denoting the adjoint operator of L (defined in (2.6)–(2.7)). Such an equation should be considered along with the initial value

$$p(\rho, \varphi; 0) = \delta(\rho - \rho_0)\delta(\varphi - \varphi_0), \tag{2.11}$$

where ρ_0 and φ_0 are the initial values of $\rho(t)$ and $\varphi(t)$, and the boundary condition

$$p(R, \varphi, \tau) = 0, \tag{2.12}$$

correspondingly to the absorbing boundary located at $\rho = R$.

We can then evaluate, in particular, the *moments* of the limiting-process $y(\tau) := \rho(\tau)\cos(\omega_0 t + \varphi(\tau))$. It is convenient to write (2.10) in the form

$$\begin{aligned}\frac{\partial p}{\partial \tau_1} = {} & \frac{\partial^2}{\partial \rho^2}\left[\left(1 + A_1 w\rho^2 + A_2 w^2\rho^4\right)\rho^2 p\right] + \frac{\partial^2}{\partial \rho \partial \varphi}\left(B_1 w \rho^3\, p\right) \\ & + \frac{\partial^2}{\partial \varphi^2}\left[\left(C_0 + C_1 w\rho^2 + C_2 w^2\rho^4\right)p\right] - \frac{\partial}{\partial \rho}\left[\left(D_0 + D_1 w\rho^2 + D_2 w^2\rho^4\right)\rho\, p\right] \\ & - \frac{\partial}{\partial \varphi}\left[\left(E_0 + E_1 w\rho^2 + E_2 w^2\rho^4\right)p\right],\end{aligned} \tag{2.13}$$

where

$$\tau_1 := \beta_{11}(2)\,\tau \equiv \beta_{11}(2)\,\epsilon^2 t, \tag{2.14}$$

$$\begin{aligned} A_1 &:= \frac{\beta_{12}(2) + \beta_{21}(2)}{2\beta_{11}(2)}, \\ A_2 &:= \frac{\beta_{22}(2) + \frac{1}{4}\beta_{22}(4)}{4\beta_{11}(2)}, \\ B_1 &:= \frac{\gamma_{12}(2) - \gamma_{21}(2)}{2\beta_{11}(2)}, \\ C_0 &:= 2\frac{\alpha_{11}}{\beta_{11}(2)} + 1, \\ C_1 &:= \frac{3(\alpha_{12} + \alpha_{21}) + 2(\beta_{12}(2) + \beta_{21}(2))}{2\beta_{11}(2)}, \\ C_2 &:= \frac{18\alpha_{22} + 16\beta_{22}(2) + \beta_{22}(4)}{16\beta_{11}(2)}, \end{aligned} \tag{2.15}$$

$$
\begin{aligned}
D_0 &:= 3 - \frac{\lambda_0}{\beta_{11}(2)},\\
D_1 &:= \frac{5(\beta_{12}(2)+\beta_{21}(2))}{2\beta_{11}(2)} \equiv 5A_1,\\
D_2 &:= \frac{7(\beta_{22}(2)+\frac{1}{4}\beta_{22}(4))}{4\beta_{11}(2)} \equiv 7A_2,\\
E_0 &:= 2\frac{\gamma_{11}(2)}{\beta_{11}(2)},\\
E_1 &:= \frac{2(2\gamma_{12}(2)+\gamma_{21}(2))}{\beta_{11}(2)},\\
E_2 &:= \frac{3(\gamma_{22}(2)+\frac{1}{8}\gamma_{22}(4))}{2\beta_{11}(2)}.
\end{aligned}
$$

Note the presence of some "second harmonics" terms (see Remark 2.2), which enter the coefficients above via the quantities $\beta_{22}(4)$, $\gamma_{22}(4)$. Their effect is to increase the value of A_2, C_2, D_2, and E_2 and thus, qualitatively, to increase the nonlinearity size, as $|w|$ would have been increased. Moreover, this happens independently of the sign of w.

Remark 2.4. It is worth noting that the solution to problem (2.10)–(2.12) is not (L^1) norm-increasing. In fact, integrating both sides of (2.13) on the domain $[0, 2\pi] \times [0, R]$ gives

$$
\begin{aligned}
&\frac{\partial}{\partial\tau_1}\int_0^{2\pi}\int_0^R p(\rho,\varphi,\tau_1)\,d\rho d\varphi\\
&= R^2(1 + A_1\,w\,R^2 + A_2\,w^2\,R^2)\int_0^{2\pi}\frac{\partial p}{\partial\rho}(R,\varphi,\tau_1)\,d\varphi, \qquad (2.16)
\end{aligned}
$$

where the absorbing boundary condition in (2.12) has been used. We now observe that $\partial p(R,\varphi,\tau_1)/\partial\rho \le 0$. In fact, such a quantity is nonpositive, given that p is positive inside the domain and zero on the boundary $\rho = R$. Therefore, $dP(\tau_1)/d\tau_1 \le 0$, where

$$
P(\tau_1) := \int_0^{2\pi}\int_0^R p(\rho,\varphi,\tau_1)\,d\rho d\varphi. \qquad (2.17)
$$

The quantity $P(\tau_1)$ represents the *survival probability* of the particle up to time τ_1, which is the probability that the particle does not hit the absorbing barrier before time τ_1. A similar result can be found in [6], where it is shown that, in the presence of an absorbing boundary condition, the norm of any initial data is not preserved.

In the special but important case that $\mu(\cdot)$ and $\nu(\cdot)$ are *uncorrelated* (possibly independent), there are some simplifications. As $R_{12}(\cdot) \equiv R_{21}(\cdot) \equiv 0$ in this case, the partial differential equation in (2.10) reduces to

$$
\begin{aligned}
\frac{\partial p}{\partial\tau_1} &= \frac{\partial^2}{\partial\rho^2}\left[(1 + A_2w^2\rho^4)\,\rho^2 p\right] + \frac{\partial^2}{\partial\varphi^2}\left[(C_0 + C_2w^2\rho^4)p\right]\\
&\quad - \frac{\partial}{\partial\rho}\left[(D_0 + D_2w^2\rho^4)\,\rho\,p\right] - \frac{\partial}{\partial\varphi}\left[(E_0 + E_2w^2\rho^4)\,p\right]. \qquad (2.18)
\end{aligned}
$$

Note that now the coefficients of the equation depend only on w^2, and therefore the results are *independent of the sign* of w. This is not true when $\mu(\cdot)$ and $\nu(\cdot)$ are

correlated. Note also that the effects of the second harmonics depend only on the autocorrelation of $\nu(\cdot)$, $R_{22}(\cdot)$ (in A_2, C_2, D_2, E_2, such an effect enters through $\beta(4)$ and $\gamma(4)$).

3. The time evolution of the moments. As the equation in (2.13) is linear and has coefficients independent of φ, we can perform a Fourier analysis. Expanding p in a Fourier series,

$$p(\rho, \varphi, \tau_1) = \sum_{m=-\infty}^{+\infty} p_m(\rho, \tau_1) e^{i\, m\varphi},$$

we obtain for the mth coefficient

$$p_m(\rho, \tau_1) = \frac{1}{2\pi} \int_0^{2\pi} p(\rho, \varphi, \tau_1)\, e^{-i\, m\, \varphi} d\varphi \tag{3.1}$$

the evolution equation

$$\begin{aligned} \frac{\partial p_m}{\partial \tau_1} &= \frac{\partial^2}{\partial \rho^2} \left[(1 + A_1 w\rho^2 + A_2 w^2 \rho^4)\, \rho^2\, p_m \right] \\ &- \frac{\partial}{\partial \rho} \left[\left(D_0 + (D_1 + i\, mB_1) w\rho^2 + D_2 w^2 \rho^4 \right) \rho\, p_m \right] \\ &+ i\, m \left[(i\, mC_0 - E_0) + (i\, mC_1 - E_1)\, w\rho^2 + (i\, mC_2 - E_2)\, w^2 \rho^4 \right] p_m, \end{aligned} \tag{3.2}$$

with the initial value

$$p_m(\rho, 0) = \frac{1}{2\pi} \delta(\rho - \rho_0)\, e^{-i\, m\, \varphi_0} \tag{3.3}$$

and the boundary condition

$$p_m(R, \tau_1) = 0. \tag{3.4}$$

The boundary point $\rho = R$ is a *regular* boundary, while $\rho = 0$ is a *natural boundary*, according to Feller's classification (see [7, 9]). On a natural boundary, such as $\rho = 0$, no boundary condition is required, while a condition is needed on a regular boundary so that the Fokker–Planck equation has a unique solution. In [7, sect. 23], the boundary value problem for the one-dimensional diffusion equation

$$u_t = \frac{\partial^2}{\partial x^2}(a(x)u) - \frac{\partial}{\partial x}(b(x)u) \tag{3.5}$$

and its adjoint has been considered on the interval $-\infty \le r_1 < x < r_2 \le +\infty$. Depending on the nature of the boundary points r_1, r_2 and the type of data imposed on them to the solution, such equations may or may not have a unique solution. Defining the function

$$W(x) := \exp\left\{ - \int_{x_0}^{x} \frac{b(s)}{a(s)}\, ds \right\}, \tag{3.6}$$

where $x_0 \in (r_1, r_2)$, the boundary points are classified as follows:

- The boundary r_j is *regular* if $W(x) \in L^1(x_0, r_j)$ and $a^{-1}(x) W^{-1}(x) \in L^1(x_0, r_j)$.

- It is an *exit* boundary if $a^{-1}(x)W^{-1}(x) \notin L^1(x_0, r_j)$ and $W(x)\int_{x_0}^{x} a^{-1}(s)W^{-1}(s)\,ds \in L^1(x_0, r_j)$.
- It is an *entrance* boundary if $a^{-1}(x)W^{-1}(x) \in L^1(x_0, r_j)$ and $a^{-1}(x)W^{-1}(x)\int_{x_0}^{x} W(s)\,ds \in L^1(x_0, r_j)$.
- It is *natural* in all other cases.

One may observe that for the heat equation $u_t = u_{xx}$ the boundaries $r_j = \pm\infty$ are both natural, while they are regular when they are finite.

It is straightforward to check that for our problem in (3.2), $r_1 = \rho = 0$ is a natural boundary, while $r_2 = \rho = R$ is a regular boundary. It follows from Feller's theory that our problem possesses a unique solution when the absorbing boundary condition in (3.4) is prescribed, while no condition is imposed on $\rho = 0$.

In the special case of $\mu(\cdot)$, $\nu(\cdot)$ uncorrelated, (2.13) reduces to (2.18) and we get the simpler problem

$$\begin{aligned}\frac{\partial p_m}{\partial \tau_1} &= \frac{\partial^2}{\partial \rho^2}\left[\left(1 + A_2 w^2 \rho^4\right)\rho^2\, p_m\right] + \frac{\partial}{\partial \rho}\left[\left(D_0 + D_2 w^2 \rho^4\right)\rho\, p_m\right] \\ &\quad + i\,m\left[\left(i\,mC_0 - E_0\right) + \left(i\,mC_2 - E_2\right) w^2 \rho^4\right] p_m,\end{aligned}$$

$$p_m(\rho, 0) = \frac{1}{2\pi}\delta(\rho - \rho_0)\, e^{-i\,m\,\varphi_0}, \qquad p_m(R, \tau_1) = 0. \tag{3.7}$$

We are primarily interested in computing the first two moments of the displacement $y_\epsilon(\cdot)$ of the oscillator by approximating it with the limiting-process $y(\cdot)$. For this we have

$$E_{\rho_0,\varphi_0}[y(\tau)] = \operatorname{Re}\left\{e^{i\omega_0 t}\, E_{\rho_0,\varphi_0}[\rho(\tau)\, e^{i\varphi(\tau)}]\right\}, \tag{3.8}$$

$$E_{\rho_0,\varphi_0}[y^2(\tau)] = \frac{1}{2}E_{\rho_0,\varphi_0}[\rho^2(\tau)] + \frac{1}{2}\operatorname{Re}\left\{e^{2i\omega_0 t}\, E_{\rho_0,\varphi_0}[\rho^2(\tau)\, e^{2i\varphi(\tau)}]\right\},$$

where the quantities $E_{\rho_0,\varphi_0}[\rho^k(\tau)\, e^{ik\varphi(\tau)}]$, $k = 1, 2$, and $E_{\rho_0,\varphi_0}[\rho^2(\tau)]$ can be computed by integrating (3.1) (or (3.7)). Recall that $\tau_1 = \beta_{11}(2)\epsilon^2 t$; see (2.14). We obtain

$$E_{\rho_0,\varphi_0}[y(\tau_1)] = 2\pi \operatorname{Re}\left[\int_0^R \rho\, p_1(\rho, \tau_1)d\rho\right]\cos\omega_0 t + 2\pi \operatorname{Im}\left[\int_0^R \rho\, p_1(\rho, \tau_1)d\rho\right]\sin\omega_0 t, \tag{3.9}$$

$$\begin{aligned}E_{\rho_0,\varphi_0}[y^2(\tau_1)] &= \pi\int_0^R \rho^2\, p_0(\rho, \tau_1)d\rho + \pi\left\{\operatorname{Re}\left[\int_0^R \rho^2\, p_2(\rho, \tau_1)d\rho\right]\cos(2\omega_0 t)\right. \\ &\quad \left. + \operatorname{Im}\left[\int_0^R \rho^2\, p_2(\rho, \tau_1)d\rho\right]\sin(2\omega_0 t)\right\}.\end{aligned} \tag{3.10}$$

The problem is clearly affected by *two time scales*, the fast (deterministic) scale, according to the "time" $\omega_0 t$, and the slow scale τ_1, on which nontrivial random phenomena occur in the diffusion limit; see [23]. In fact, it is over long times that the statistical cumulative effect of the small size noise becomes significant.

In the next section, we describe the numerical treatment carried out to solve the aforementioned problems. We give the relevant results in the form of several plots and discuss the observed features.

4. Numerical treatment. We solved numerically problem (3.7) for $m = 0, 1, 2$ on $(0, R) \times (0, T)$, with the boundary condition in (2.12), obtaining the Fourier coefficients $p_m(\rho, \tau_1)$ of the transition probability density $p(\rho, \varphi, \tau_1)$. The covariance matrix $\{R_{ij}(\cdot)\}_{i,j=1,2}$ also had to be specified. In the case above, where $\mu(\cdot)$, $\nu(\cdot)$ are supposed to be uncorrelated, we have only to assign $R_{11}(\cdot)$ and $R_{22}(\cdot)$. Let us choose

$$R_{11}(t) := e^{-\sigma_1|t|}, \qquad R_{22}(t) := e^{-\sigma_2|t|} \tag{4.1}$$

for some positive constants σ_1, σ_2. Then all quantities α_{ij}, β_{ij}, γ_{ij} and hence A_2, D_0, D_2, C_0, C_2, E_0, and E_2 can be computed.

To be more explicit, we get from (2.9)

$$\alpha_{ii} = \frac{\omega_0^2}{8}\frac{1}{\sigma_i}, \quad \beta_{ii}(q) = \frac{\omega_0^2}{8}\,\frac{\sigma_i}{\sigma_i^2 + q^2\omega_0^2}, \quad \gamma_{ii}(q) = \frac{\omega_0^2}{8}\,\frac{q\,\omega_0}{\sigma_i^2 + q^2\omega_0^2}, \quad i = 1, 2, \tag{4.2}$$

and therefore from (2.15)

$$A_2 = \frac{1}{4}\frac{\sigma_2}{\sigma_1}\left(1 + \frac{4\omega_0^2}{\sigma_1^2}\right)\left[\frac{1}{\sigma_2^2/\sigma_1^2 + 4\omega_0^2/\sigma_1^2} + \frac{1/4}{\sigma_2^2/\sigma_1^2 + 16\omega_0^2/\sigma_1^2}\right], \tag{4.3}$$

$$D_0 = 3 - 8\frac{\lambda_0/\omega_0}{\omega_0/\sigma_1}\left(1 + 4\frac{\omega_0^2}{\sigma_1^2}\right), \tag{4.4}$$

$$D_2 = 7A_2, \tag{4.5}$$

$$C_0 = 3 + 8\frac{\omega_0^2}{\sigma_1^2}, \tag{4.6}$$

$$C_2 = \frac{9}{8}\frac{1 + 4\omega_0^2/\sigma_1^2}{\sigma_2/\sigma_1} + \frac{\sigma_2}{\sigma_1}\frac{1 + 4\omega_0^2/\sigma_1^2}{\sigma_2^2/\sigma_1^2 + 4\omega_0^2/\sigma_1^2} + \frac{1}{16}\frac{\sigma_2}{\sigma_1}\frac{1 + 4\omega_0^2/\sigma_1^2}{\sigma_2^2/\sigma_1^2 + 16\omega_0^2/\sigma_1^2}, \tag{4.7}$$

$$E_0 = 4\frac{\omega_0}{\sigma_1}, \tag{4.8}$$

$$E_2 = \frac{3}{2}\left[2\frac{\omega_0}{\sigma_1}\frac{1 + 4\omega_0^2/\sigma_1^2}{\sigma_2^2/\sigma_1^2 + 4\omega_0^2/\sigma_1^2} + \frac{1}{2}\frac{\omega_0}{\sigma_1}\frac{1 + 4\omega_0^2/\sigma_1^2}{\sigma_2^2/\sigma_1^2 + 16\omega_0^2/\sigma_1^2}\right]. \tag{4.9}$$

These expressions make it clear that only the *nondimensional* quantities

$$\frac{\sigma_2}{\sigma_1}, \quad \frac{\omega_0}{\sigma_1}, \quad \text{and} \quad \frac{\lambda_0}{\omega_0} \tag{4.10}$$

play a role and therefore need to be assigned. Another parameter is the ratio of the *two time scales*, which characterize the deterministic oscillations *and* the random fluctuations. We have from (2.14) and (4.2)

$$\tau_1 \equiv \beta_{11}(2)\epsilon^2 t = \frac{\epsilon^2}{8}\,\frac{\omega_0/\sigma_1}{1 + 4\omega_0^2/\sigma_1^2}\,\omega_0 t =: \kappa\omega_0 t \tag{4.11}$$

(note that τ_1 is nondimensional) and, for $\omega_0/\sigma_1 \approx 1$, $\epsilon \approx 0.1$, we get $\kappa \approx 4000$. Note that κ is automatically determined by choosing ϵ and ω_0/σ_1. Therefore, we can assign κ or ϵ, in addition to the previous parameters.

The numerical treatment consists of implementing an *implicit* scheme of finite differences, with forward time differences and space-centered differences (the Crank–Nicholson scheme). We chose $R = 4$ and divided $[0, R]$ into sections of equal length $\Delta\rho = 10^{-3}$; the time-step size we used was $\Delta\tau_1 = 10^{-4}$, and the initial position of

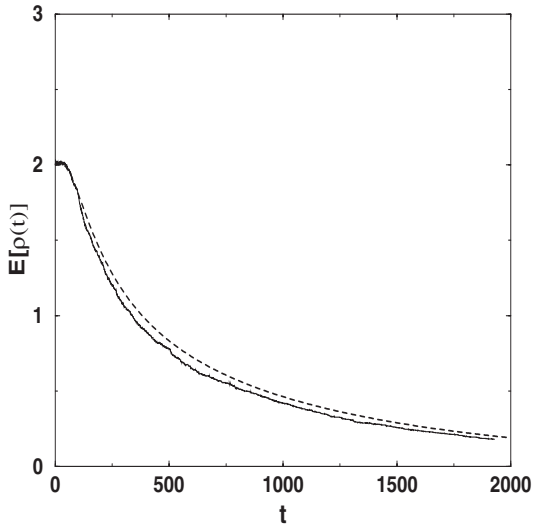

FIG. 4.1. *Time evolution of the expected value of ρ. The nonlinearity size is $w = 0.3$. The dashed line represents the solution obtained through the Fokker–Planck equation; the solid line is obtained by solving the stochastic differential equation. The other parameters are $\epsilon = 0.1$, $\sigma_2/\sigma_1 = 1$, $\omega_0/\sigma_1 = 1$, and $\lambda_0/\omega_0 = 3\beta_{11}(2)/2$.*

the oscillator was $\rho_0 = 2$. The parameters w and λ_0/ω_0 were varied to form several combinations in order to investigate the various effects, while we kept ϵ to the fixed value $\epsilon = 0.1$. The case $\epsilon = 0.5$ was also considered to test the validity of the limiting theory. The first two moments

$$E[\rho^k(\tau_1)] = 2\pi \int_0^R \rho^k p_0(\rho, \tau_1)\, d\rho, \quad k = 1, 2, \tag{4.12}$$

of the oscillator's amplitude, $\rho(\tau_1)$, defined by the van der Pool variables (in the diffusion limit), can then be evaluated. Note that $E[\rho^0] = E[1]$ coincides with the survival probability given by (2.17).

In Figure 4.1, we plotted $E[\rho]$ versus t for $w = 0.3$, $\sigma_2/\sigma_1 = 1$, $\omega_0/\sigma_1 = 1$, and $\lambda_0/\omega_0 = 3\beta_{11}(2)/2$. In Figure 4.2, the time evolution of the second moment $E[\rho^2]$ is shown for the same set of parameters. Recall that $\rho_\epsilon^2 = y_\epsilon^2 + \omega_0^{-2} y_\epsilon'^2$ represents the energy of the oscillator governed by (1.1), and hence $E[\rho^2]$ is the average energy of the oscillator in the diffusion limit. Here we also plotted $E[\rho^2]$ for $w = 0$, that is, for the corresponding linear harmonic oscillator, for the purpose of comparison.

In Figure 4.3, we plotted $E[\rho^2]$ versus τ_1 for the same values of the parameters used above, except that we considered several values of λ_0/ω_0. It is apparent that there is "a threshold" when λ_0/ω_0 goes across a certain value. Above such a value (that is, when the damping is sufficiently strong), $E[\rho^2]$ decreases monotonically in time. Below the threshold value, initially $E[\rho^2]$ grows in time, undergoing a kind of transient behavior, but then it decays in order to match the absorbing boundary condition. Such a threshold is determined by the sign of the coefficient D_0, which takes the values $3, -3, -9$ corresponding to the values $\lambda_0/\omega_0 = 0, 0.15, 0.3$, respectively.

Figure 4.4 shows the time evolution of the survival probability $P(t)$ given by (2.17). This has been computed both from the Fokker–Planck equation and by Monte Carlo simulations to provide mutual validation. The time evolution of two conditional

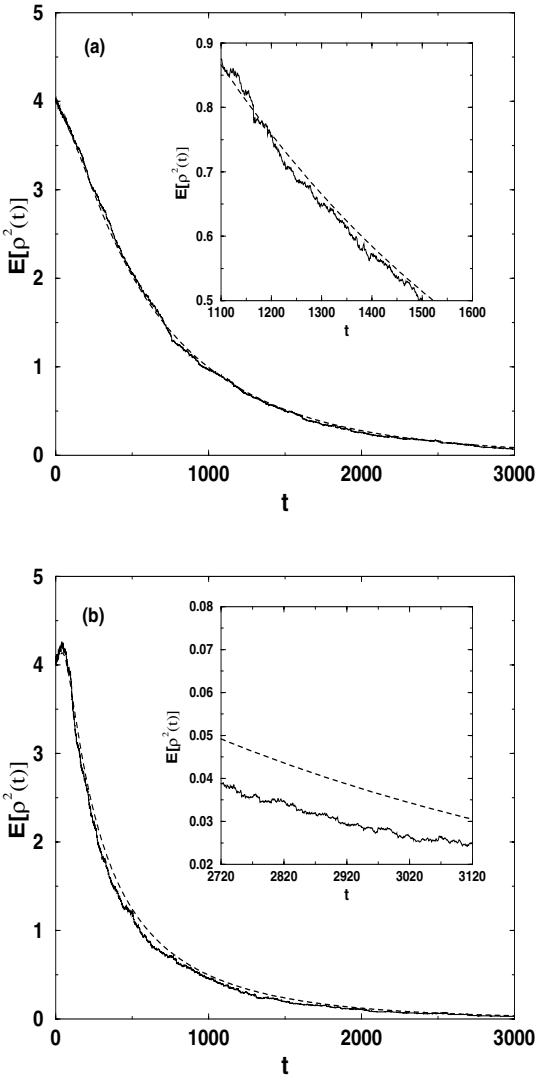

FIG. 4.2. *Time evolution of the expected value of ρ^2 for two different values of the nonlinearity parameter:* (a) $w = 0$ *and* (b) $w = 0.3$. *The other parameters are as in Figure* 4.1. *A magnification of part of the plot is shown in the inset.*

moments of ρ, assuming that the time τ_1 is less than the first hitting time, say τ_R, is plotted in Figure 4.5. Such moments can be obtained knowing the moments $E[\rho^k]$ and the survival probability $P(\tau_1)$ as follows:

$$E[\rho^k | \tau_1 < \tau_R] = \frac{E[\rho^k(\tau_1)]}{P(\tau_1)}. \tag{4.13}$$

These quantities have been computed from the Fokker–Planck equation. The same quantities have been obtained from the corresponding stochastic differential equations by Monte Carlo simulations, for the purpose of validation, and plotted in Figure 4.5 (solid line).

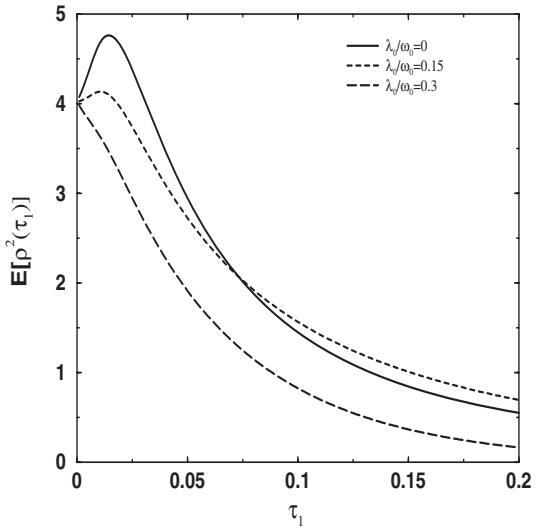

FIG. 4.3. *Time evolution of the expected value of* ρ^2 *for three different values of* λ_0/ω_0*, keeping* w *to the fixed value* 0.3*. The other parameters are as in Figure* 4.1.

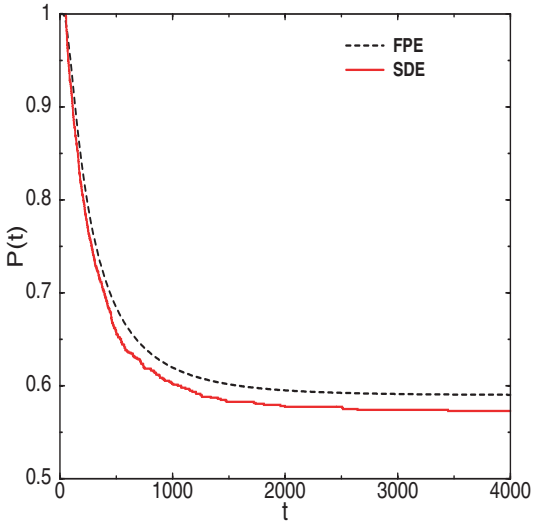

FIG. 4.4. *Time evolution of the survival probability* $P(t)$*, keeping* w *to the fixed value* 0.3 *and* $\lambda_0/\omega_0 = 0.15$*. The other parameters are as in Figure* 4.1.

It is worth noting that the survival probability seems to stabilize around a nonzero value, and the conditional moments of ρ go to zero, when time is sufficiently large. From both such features, the behavior of the surviving particles for a long time can be easily understood. The nonzero value of $P(t)$, say p_∞, would mean that a certain number of particles never exit from the boundary, while, given that the limiting value of the conditional moments when time goes to infinity is zero, it indicates that the surviving particles will be located, with high probability, around $\rho = 0$.

In Figure 4.6, the time evolution of the survival probability, $P(t)$, is plotted for three different values of R. Recall that the parameter R is part of the data of the

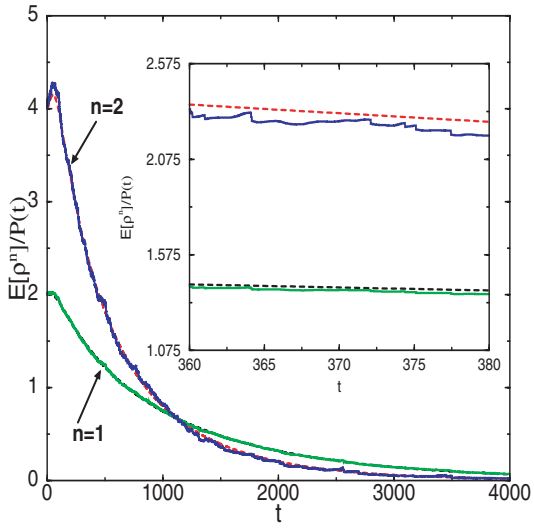

FIG. 4.5. *Time evolution of two conditional moments of ρ with $n = 1, 2$. The parameters are as in Figure* 4.4.

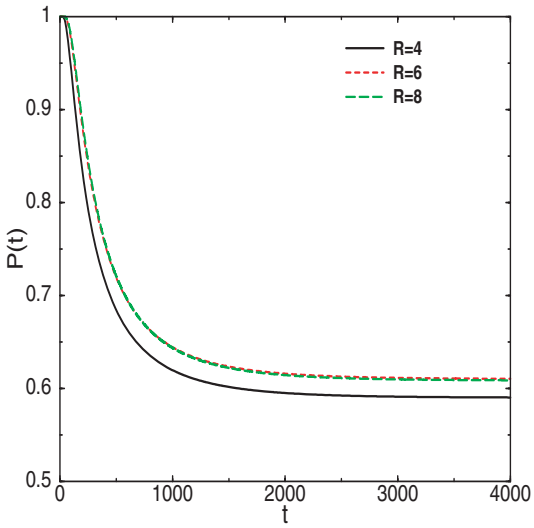

FIG. 4.6. *Time evolution of the survival probability $P(t)$ for three different values of R, obtained by solving the Fokker–Planck equation. The parameters are as in Figure* 4.4.

problem. For instance, in the example of the particle accelerator, R may be the radius of a vacuum chamber. Note that increasing the value of R increases the stationary value of $P(t)$. Clearly, when the boundary R is closer to the initial value $\rho = \rho_0$, the exiting probability of a given particle becomes larger, thus making the survival probability smaller in this case. Nevertheless, for sufficiently large values of R, such a probability seems to become independent of R. However, larger values of R cannot be used in practice to prevent computational overflow, in view of the exponential dependence of some coefficients in the Fokker–Planck equation.

In Figure 4.7, the survival probability has been plotted as a function of time

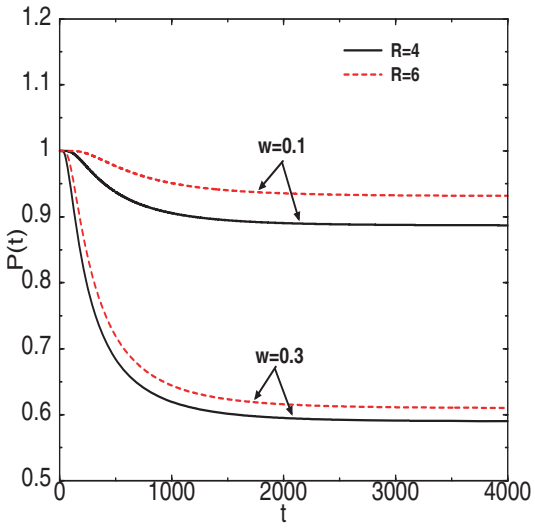

FIG. 4.7. *Time evolution of the survival probability $P(t)$ for two different values of R and the nonlinearity w. The parameters are as in Figure 4.4.*

for two pairs of values of the nonlinearity parameter w and of the location of the absorbing barrier R. These results have been obtained by integrating numerically the Fokker–Planck equation. The numerical simulations seem to show that the survival probability tends to stabilize, after a sufficiently long time, at some nonzero (positive) value. Such a value seems to decrease when the nonlinearity becomes stronger (for any given value of R), while fewer particles tend to be absorbed when the absorbing boundary is located farther from the initial position of the oscillator for any given value of w. In other words, there is numerical evidence that a stronger nonlinearity favors higher absorption of particles, while a more distant barrier makes it more difficult. No claim can be made, however, that the survival probability does indeed tend to a nonzero value when time increases. In fact, the survival probability might decay so slowly that the numerical simulations cannot fully capture its precise behavior.

In Figure 4.8, the full transition probability density, $p_0(\rho, t)$, has been plotted as a function of ρ for several times. The inset in this figure shows the corresponding values of the survival probability obtained for the times when the probability density was plotted. This picture illustrates well what happens to the ρ-profile of $p_0(\rho, t)$ at various times. Such a profile starts smooth and well spread over the full interval $0 < \rho < R = 4$, but as time goes on, it tends to become a Dirac delta function, located at the initial position of the oscillator, $\rho_0 = 0$.

In Figure 4.9, the dependence of the survival probability on two different initial positions of the oscillator, $\rho_0 = 2$ or $\rho_0 = 3$, is shown. It is clear that the closer such an initial position is to the absorbing boundary (located at $\rho = R = 4$), the higher will be the number of the particles absorbed there.

Figure 4.10 displays the dependence of p_∞ on the nonlinearity parameter w. It appears that p_∞ decreases steadily as w increases. Here $R = 4$ was kept fixed. We have also computed the first two moments of the oscillator's displacement, $y(t)$, given by (3.9), (3.10). In Figure 4.11, such moments are shown for the same values of the parameters used in Figures 4.1 and 4.2.

In order to validate the limiting theory, we conducted numerical simulations of

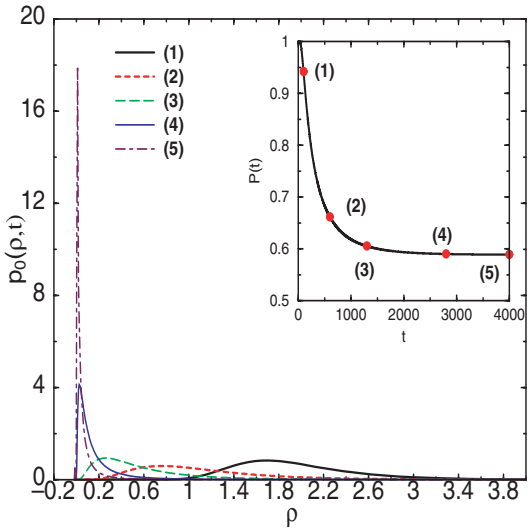

FIG. 4.8. *Transition probability density $p_0(\rho, t)$ versus ρ for several times. The inset shows the corresponding values of the survival probability for these times. The parameters are as in Figure* 4.4.

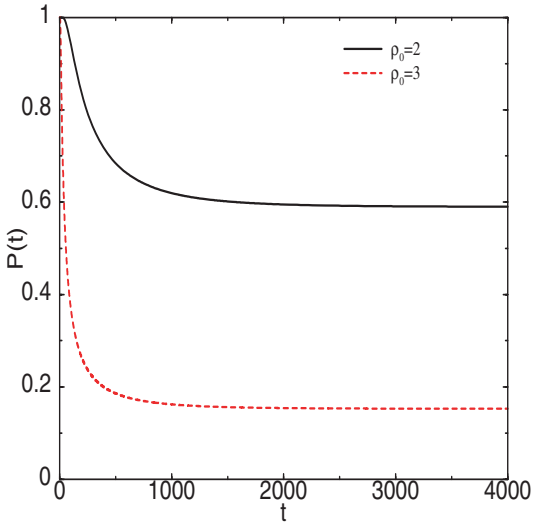

FIG. 4.9. *Time evolution of the survival probability $P(t)$ for two different initial condition data. The parameters are as in Figure* 4.4.

the Monte Carlo type on the stochastic differential equation given in (1.1)–(1.2), with the initial values $y_\epsilon(0) = \sqrt{2}$, $y'_\epsilon(0) = \sqrt{2}$. Our purpose was twofold. First, we took ϵ sufficiently small and t sufficiently large to check to what extent such a model could accurately approximate the original (ϵ-labeled process). On the other hand, the numerical results obtained by solving the stochastic differential equation have an independent interest, because their validity holds true for any size of ϵ and t. Obviously, whenever ϵ is not sufficiently small and/or t is not sufficiently large, we can expect that the resulting functionals of the limiting-process might depart even significantly from those computed on the basis of the stochastic differential equation.

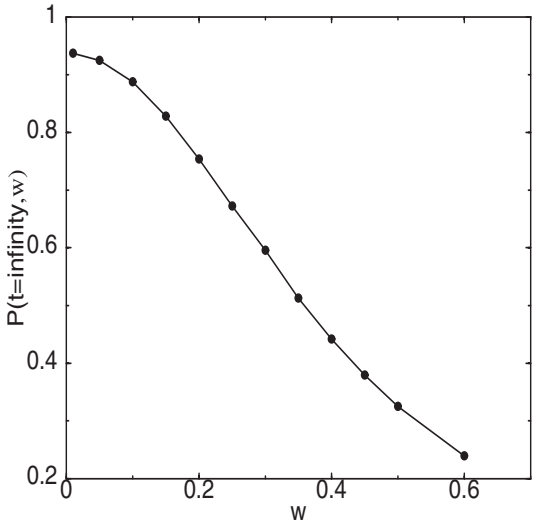

FIG. 4.10. *Long-time value of $p_0(\rho, t)$ obtained in the limit of $t \to \infty$ versus the nonlinearity parameter w. The parameters are as in Figure* 4.4.

The Ito-type system can be written as

$$\begin{cases} d\rho = \left[\epsilon F_1(t;\rho,\varphi;\mu,\nu) + \epsilon^2 G_1(t;\rho,\varphi;\mu,\nu)\right] dt, \\ d\varphi = \left[\epsilon F_2(t;\rho,\varphi;\mu,\nu) + \epsilon^2 G_2(t;\rho,\varphi;\mu,\nu)\right] dt, \\ d\mu = -\sigma_1\,\mu\,dt + \sigma_1\,dW_1, \\ d\nu = -\sigma_2\,\nu\,dt + \sigma_2\,dW_2, \end{cases} \tag{4.14}$$

where we have also displayed the dependence of the functions F_i and G_i on the stochastic processes μ and ν. Since, in the practical simulations, such processes will be colored noise processes with autocorrelations given in (4.1), the system (4.14) includes the last two equations. In fact, according to [11], the colored noise processes above can be evaluated from such Ito equations, driven by the independent standard Brownian motions W_1 and W_2. The process λ in the damping term is taken to be a constant, $\lambda(t) \equiv \lambda_0$.

While the absorbing boundary condition is imposed as a boundary condition on $\rho = R$ for the Fokker–Planck equation (2.10), here we proceed as follows. In correspondence to the first time t^*, when a given realization $\rho(t)$ attains the value R, we ignore the contribution from such a realization in the averages yielding the moments of ρ and y for $t > t^*$. This procedure yields the moments of the particle position at time t, taking into account that such a particle did not hit the absorbing barrier yet. Therefore, only the statistical properties of the particles that have survived up to time t have been included.

In principle, this numerical treatment amounts to a loss of accuracy for larger and larger times, because the sample size (i.e., the number of particles) becomes smaller, thus requiring more realizations when time increases. Numerical results, however, show that the fast decay of the moments computed (from the Fokker–Planck equation) is such that the loss of accuracy mentioned above is felt very little.

As usual, the required Monte Carlo simulations can be based on the generation of sequences of (pseudo-) random numbers, which is routine. Here we chose instead to

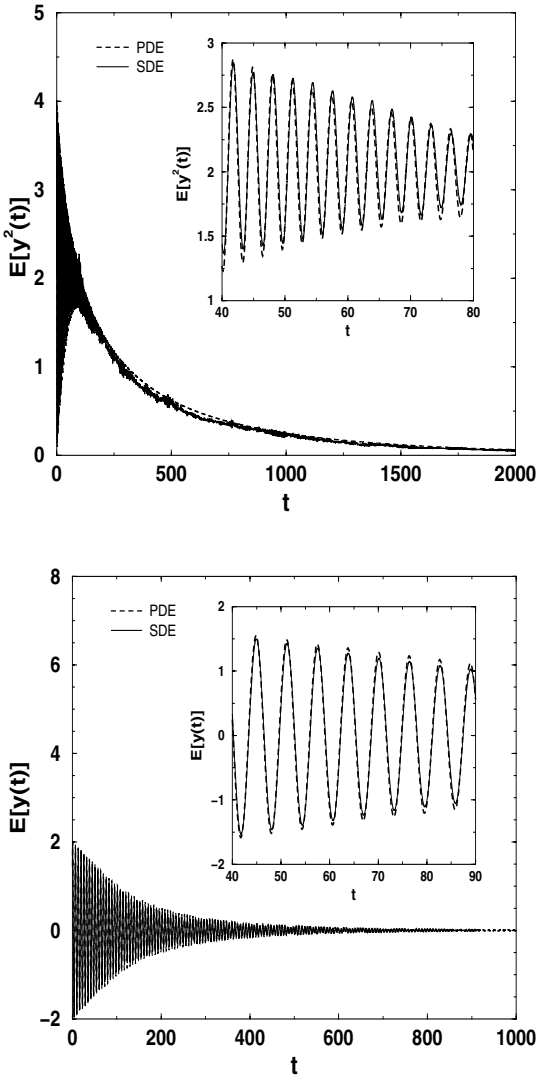

FIG. 4.11. *Time evolution of the first and second moments of the oscillator's displacement, y, keeping w to the fixed value* 0.3. *The other parameters are as in Figure* 4.1.

use the so-called sequences of *quasi-random* numbers (deterministic low discrepancy sequences); see [2, 17]. Such a choice provides a higher accuracy for a given number, N, of realizations, typically involving a deterministic error of order $\mathcal{O}(N^{-1}\log^{d^*-1}N)$ (where d^* is an "effective dimension"; see [1]) instead of the statistical error of order $\mathcal{O}(N^{-1/2})$. Quasi-random number sequences are rather delicate to exploit but have been used successfully in a number of applications; see [2, 3, 14, 15, 18]. Application of quasi-random numbers to the numerical solution of stochastic differential equations has been shown in general to be very inefficient; see [10]. In such a paper, however, no "scrambling" strategy was adopted, which action was actually shown to be important in [14, 15]. Here we have implemented a quasi-Monte Carlo algorithm with a reordering technique, as done in [15], and thus our results turned out to be highly accurate. A more general account of a successful implementation of quasi-random sequences to

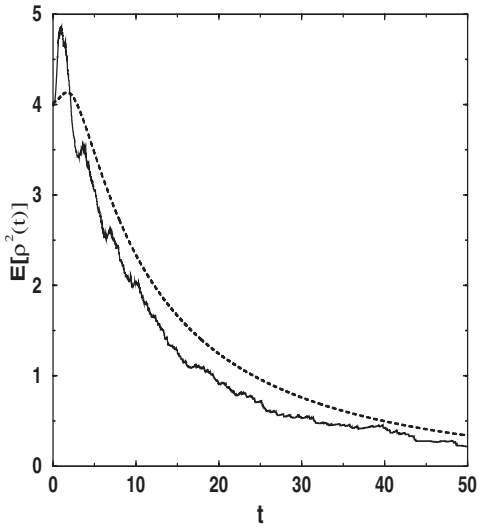

FIG. 4.12. *Time evolution of the expected value of* ρ *for* $\epsilon = 0.5$ *and* $w = 0.3$. *The other parameters are as in Figure* 4.1.

solve stochastic differential equations has been presented in [1].

To solve the system of stochastic differential equations in (4.14), we have implemented a "weak scheme" of order 2 (which reduces to the Heun scheme in the deterministic case); see [13, Chap. 15, sect. 15.1] and [8, 22]. The time-step size used was $\Delta t = 0.01$, with $N = 1000$ realizations. We used Halton sequences of quasi-random numbers [2], being aware that a different choice of numbers, such as Sobol' or Faure numbers, was shown earlier to be essentially irrelevant [16]. In order to simulate random paths to solve the system in (4.14) it is required to generate as many random variables as time steps, which amounts to generating *high-dimensional* quasi-random sequences. This is a sensible issue, in that high-dimensional quasi-random sequences may fail to work appropriately because unwanted correlations can be easily introduced. Such a difficulty was removed in our algorithm by introducing a suitable reordering, as was done in [15, 14]; see also [1]. Using reordering, the effective dimension of the system reduces to the number of dependent variables, ρ and φ. Note that the truncation error will be of order $\mathcal{O}((\Delta t)^2) \approx 10^{-4}$, which is negligible compared to the quasi-Monte Carlo error, which is of order $\mathcal{O}(N^{-1} \log N) \approx 0.9 \times 10^{-3}$.

In Figures 4.1 and 4.2, the continuous line shows the time evolution of the mean value of the oscillator amplitude ρ and of its square ρ^2, and the survival probability, with $\epsilon = 0.1$ and $w = 0.3$. Therefore, a comparison is made with the solution obtained in the diffusion limit. The agreement is very good for all times and also improves when time increases, while instead it gets a little worse in Figure 4.4.

In Figure 4.12, the comparison is made with $\epsilon = 0.5$. All these plots show to what extent the diffusion limit provides a good approximation of the original problem in (1.1)–(1.2). In any case, even when ϵ is not very small, the qualitative agreement gets better for time sufficiently large. In Figure 4.11, the mean values of the oscillator's displacement, y, and of y^2 are depicted versus t (solid line). Again, they are compared with the corresponding results obtained through the Fokker–Planck equation (dashed line).

5. Summary and concluding remarks. In closing, we stress the high points of the paper. A model for a Duffing oscillator with random parameters and subject to an absorbing boundary condition has been analyzed in the diffusion limit, on a scale where the nonlinear term is much stronger than in the model analyzed in [23]. A higher-order nonlinear effect, such as the appearance of second harmonics effects, can be observed here.

A numerical solution of the stochastic differential equation has been obtained, for small fixed ϵ, both for the purpose of validating the diffusion limit theory (when ϵ is sufficiently small and t sufficiently large) and because the problem for finite ϵ and t is meaningful in itself. The dependence on the nonlinearity strength w and on the location R of the absorbing boundary has also been investigated, mostly numerically. We have also shown that quasi-random sequences of numbers can be efficiently used in the Monte Carlo simulation, provided that a reordering strategy is adopted.

It is natural to ask whether the problem in (1.1)–(1.2) is meaningful when no absorbing boundary condition is imposed. The (formal) diffusion problem, say $\mathcal{P}_\infty$, is described by (2.10)–(2.11) on the unbounded space domain $(\rho, \varphi) \in (0, +\infty) \times (0, 2\pi)$. Suppose that we are interested in computing the moments of ρ, among them the mean energy $E[\rho^2]$. According to (4.12), this requires computing $p_0(\rho, \tau_1)$, the solution to (3.7) with $m = 0$, subject to the initial value $p_0(\rho, 0) = \delta(\rho - \rho_0)/2\pi$ on the domain $0 < \rho < +\infty$. It turns out that, according to Feller's classification sketched in section 3, the boundary point $\rho = +\infty$ is an entrance point. Note that in the model studied in [23] the point $\rho = +\infty$ was of a different type, namely, a natural boundary (as for the heat equation). In [6, 7], it was established that when one of the boundaries is natural while the other is an entrance point, no boundary condition should be imposed (on the latter point) and uniqueness is lost. More precisely, several solutions to the problem $\mathcal{P}_\infty$ exist, but only one is characterized by being positive and norm-preserving. Therefore, such a solution is a candidate to be a probability density function. Moreover, such a solution enjoys the property of having its value as well as its flux equal to zero at the same time, at $\rho = +\infty$, so that this boundary can be simultaneously considered an absorbing and a reflecting boundary. All the other solutions, characterized by an arbitrary value of the flux, are instead either negative or norm-increasing.

In order to compute numerically such a solution, $p_0(\rho, \tau_1)$, the problem $\mathcal{P}_\infty$ has to be approximated by the problem $\mathcal{P}_{\rho_{\max}}$, obtained by cutting the unbounded domain to the bounded domain $(0, \rho_{\max})$. Since the boundary $\rho = \rho_{\max}$ now becomes regular, a boundary condition can be imposed on it. Recalling that the unique solution to $\mathcal{P}_\infty$, i.e., that one which is positive and norm-preserving, vanishes along with its space derivative at $\rho = +\infty$, either of these two conditions at $\rho = \rho_{\max}$ can be imposed, provided that $\rho_{\max}$ is sufficiently large. Approximating such a solution to $\mathcal{P}_\infty$ (which has an entrance boundary) by the solutions to problems like $\mathcal{P}_{\rho_{\max}}$ (which has a regular boundary) is a quite delicate task. In fact, on the one hand, a homogeneous Neumann condition is known to preserve the norm of the solution (see (2.16)). On the other hand, as was mentioned before, the solutions to $\mathcal{P}_\infty$ are very sensitive with respect to small departures from the zero value of the space derivative. Indeed one would obtain either negative or norm-increasing solutions. Imposing instead the Dirichlet condition $p_0(\rho_{\max}, \tau_1) = 0$, a much more stable behavior would be observed, but the norm of the solution would not be preserved in this case.

THE KELLER–SEGEL MODEL WITH LOGISTIC SENSITIVITY FUNCTION AND SMALL DIFFUSIVITY*

YASMIN DOLAK† AND CHRISTIAN SCHMEISER‡

Abstract. The Keller–Segel model is the classical model for chemotaxis of cell populations. It consists of a drift-diffusion equation for the cell density coupled to an equation for the chemoattractant. Here a variant of this model is studied in one-dimensional position space, where the chemotactic drift is turned off for a limiting cell density by a logistic term and where the chemoattractant density solves an elliptic equation modeling a quasi-stationary balance of reaction and diffusion with production of the chemoattractant by the cells. The case of small cell diffusivity is studied by asymptotic and numerical methods. On a time scale characteristic for the convective effects, convergence of solutions to weak entropy solutions of the limiting nonlinear hyperbolic conservation law is proven. Numerical and analytic evidence indicates that solutions of this problem converge to irregular patterns of cell aggregates separated by entropic shocks from vacuum regions as time tends to infinity. Close to each of these patterns an "almost" stationary solution of the full parabolic problem can be constructed up to an exponentially small (in terms of the cell diffusivity) residual. Based on a metastability hypothesis, the methods of exponential asymptotics are used to derive systems of ordinary differential equations approximating the long-time behavior of the parabolic problem on exponentially large time scales. The observed behavior is a coarsening process reminiscent of phase change models. A hybrid asymptotic-numerical approach for the simulation of the system is introduced, and the accuracy of this new approach is shown by comparison to numerical simulations of the full problem.

Key words. chemotaxis, hyperbolic limit, entropy solution, exponential asymptotics

1. Introduction.

Chemotaxis, the active motion of organisms influenced by chemical gradients, has been studied both experimentally and theoretically by a large number of authors. The first mathematical model for chemotaxis was derived by Patlak [11] and by Keller and Segel [6]. In its most widely used formulation, the cell density $\varrho(x,t)$ at position $x \in \mathbb{R}^n$ and time $t > 0$ solves the convection diffusion equation

$$\partial_t \varrho + \nabla \cdot (\chi(\varrho, S)\varrho \nabla S - D(\varrho, S)\nabla \varrho) = 0. \tag{1.1}$$

This equation is coupled to an equation for the chemical concentration $S(x,t)$, typically a parabolic or elliptic equation with a reaction term describing production and degradation of the chemoattractant.

The Keller–Segel model has been applied to many different problems, ranging from bacterial chemotaxis to cancer growth or the immune response. For some applications, it turns out that the diffusivity of cells plays only a minor role. In Dolak and Schmeiser [3], a convection equation with a small diffusion term as higher order

correction is derived from a kinetic model for chemotaxis. Taking this case as a motivation, we will study a Keller–Segel model with a small diffusion constant and its limit of vanishing diffusivity. More precisely, we investigate

$$\partial_t \varrho + \partial_x(\chi(\varrho)\varrho\partial_x S) = D\partial_x^2\varrho, \tag{1.2}$$

with $x \in (0, L)$ and $t > 0$. We assume the diffusion D to be constant and the chemotactic sensitivity $\chi(\varrho)$ to be of the form

$$\chi(\varrho) = \chi_0\left(1 - \frac{\varrho}{\varrho_{max}}\right), \tag{1.3}$$

the maximal cell density ϱ_{max} and χ_0 being positive constants. Thus, the chemotactic response of the cells is shut off when a maximal density is reached. Models of this type were first investigated by Hillen and Painter in [5]. In [10], the authors derive a chemotaxis model comprising a chemotactic sensitivity of the above form from a master equation describing a random walk on a one-dimensional lattice, by taking into account the finite size of cells.

The evolution of the chemoattractant S is described by

$$\partial_x^2 S = \beta S - \alpha\varrho. \tag{1.4}$$

This elliptic equation, instead of the more frequently used parabolic equation, is appropriate if we assume that the diffusion rate of the chemoattractant is large in relation to the characteristic time and length scales of the problem.

We nondimensionalize (1.2) and (1.4) by choosing reference values for time, length, cell density, and the chemical concentration, respectively:

$$x_0 = \frac{1}{\sqrt{\beta}}, \quad t_0 = \frac{1}{\alpha\chi_0\varrho_{max}}, \quad \varrho_0 = \varrho_{max}, \quad S_0 = \frac{\alpha\varrho_{max}}{\beta}.$$

By introducing the dimensionless quantities

$$\bar{x} = \frac{x}{x_0}, \quad \bar{t} = \frac{t}{t_0}, \quad \bar{\varrho} = \frac{\varrho}{\varrho_0}, \quad \text{and} \quad \bar{S} = \frac{S}{S_0}$$

and immediately dropping the bars, we obtain the nondimensionalized system

$$\partial_t \varrho + \partial_x(\varrho(1-\varrho)\partial_x S) = \varepsilon\partial_x^2\varrho, \tag{1.5}$$

$$\partial_x^2 S = S - \varrho. \tag{1.6}$$

The only remaining dimensionless parameter is now

$$\varepsilon = \frac{D\beta}{\alpha\chi_0\varrho_{max}},$$

and in the following, we will shall assume $\varepsilon \ll 1$. This corresponds to a situation where the cells react to chemotactic signals strongly enough such that their velocity distribution is significantly biased towards the chemoattractant gradient, as opposed to the case where unbiased reorientation dominates the behavior of individual cells. In the relevant situation, a small diffusion term can be derived as a correction to the purely convective macroscopic limit of a kinetic transport model (see, e.g., [3], as mentioned above).

The initial condition is given by

$$\varrho(x,0) = \varrho_I^\varepsilon. \tag{1.7}$$

We choose homogeneous Neumann boundary conditions, i.e.,

$$\partial_x \varrho(0,t) = \partial_x \varrho(L,t) = 0, \quad \partial_x S(0,t) = \partial_x S(L,t) = 0. \tag{1.8}$$

In the next section, we will analyze the limit $\varepsilon \to 0$ of system (1.5), (1.6). By deriving estimates which are uniformly valid for $\varepsilon > 0$, we will, by a compactness argument, show convergence of ϱ and S to entropy solutions of the corresponding hyperbolic system,

$$\partial_t \bar{\varrho} + \partial_x(\bar{\varrho}(1-\bar{\varrho})\partial_x \bar{S}) = 0, \tag{1.9}$$

$$\partial_x^2 \bar{S} = \bar{S} - \bar{\varrho}, \tag{1.10}$$

with

$$\partial_x \bar{S}(0,t) = \partial_x \bar{S}(L,t) = 0 \tag{1.11}$$

and subject to the initial condition

$$\bar{\varrho}(x,0) = \bar{\varrho}_I. \tag{1.12}$$

As a consequence of (1.11), the characteristics of (1.9) are parallel to the boundary, and no boundary conditions for $\bar{\varrho}$ are needed.

In sections 3 and 4, we study the long-time behavior of solutions of the hyperbolic and the full parabolic system, respectively. In the latter, the formation of so-called pseudostationary or metastable states can be observed. We will use formal asymptotic methods to derive a system of ODEs describing the exponentially slow movement of these patterns. Finally, in section 5, we will investigate the long-time behavior of solutions numerically. The metastability analysis is strongly related to recent work by Potapov and Hillen [13]. However, different scaling assumptions are used there, and consequently, a direct comparison of results is not straightforward.

2. Convergence of solutions. In this section, we investigate the limit $\varepsilon \to 0$ in (1.5), (1.6), (1.7), (1.8). A similar problem from semiconductor physics is considered in Markowich and Szmolyan [8]. There, however, the nonlinearity of the flux is only due to a coupling with an electric field (the equivalent to the chemical concentration here), and the formation of shocks in the hyperbolic problem is not observed.

Equations (1.5) and (1.6) differ from the system analyzed in Hillen and Painter [5] by the fact that an elliptic instead of a parabolic equation for S is considered here. In [5] existence of an invariant region for (ϱ, S) in $\mathbb{R}^2$ and, consequently, global existence of smooth solutions is shown. In our case, the proof (based on a straightforward maximum principle) is much simpler and presented below for completeness.

We make the following assumption on the initial data:

$$0 \le \varrho_I^\varepsilon \le 1, \quad \varrho_I^\varepsilon \in W^{1,1}(0,L), \quad \text{uniformly in } \varepsilon. \tag{A1}$$

THEOREM 2.1. *Let assumption* (A1) *hold. Then there exists a unique, global, smooth solution of* (1.5)–(1.8) *satisfying*

$$0 \le \varrho(x,t),\ S(x,t) \le 1 \quad \textit{and} \quad \int_0^L \varrho(x,t)\,dx = \int_0^L \varrho_I(x)\,dx \tag{2.1}$$

and

$$S \in L^\infty((0,\infty); W^{2,\infty}(0,L)), \tag{2.2}$$

uniformly in ε *as* $\varepsilon \to 0$.

Proof. With Green's function

$$G(x,y) = \frac{1}{2}e^{-|x-y|} + \frac{e^{x+y} + e^{2L-x-y} + e^{x-y} + e^{y-x}}{2(e^{2L}-1)}, \tag{2.3}$$

the chemoattractant density can be computed from (1.6), (1.8) in terms of the cell density:

$$S(x,t) = \mathcal{S}[\varrho](x,t) := \int_0^L G(x,y)\varrho(y,t)dy. \tag{2.4}$$

Using this in (1.5), the resulting equation

$$\partial_t \varrho = \varepsilon \partial_x^2 \varrho - \partial_x(\varrho(1-\varrho)\partial_x \mathcal{S}[\varrho])$$

falls into the class of abstract semilinear parabolic equations. Local existence of unique smooth solutions can be shown by semigroup techniques [12]. Then global existence follows from a comparison principle: writing (1.5) as

$$\partial_t \varrho + (2\varrho - 1)\partial_x S \partial_x \varrho + \varrho(1-\varrho)(S-\varrho) = \varepsilon \partial_x^2 \varrho,$$

it follows immediately that $\varrho = 0$ and $\varrho = 1$ are lower and upper solutions, respectively. A uniform (in time) bound for S is an obvious consequence of (2.4). ∎

We continue with estimates for the derivatives of ϱ.

LEMMA 2.2. *Let assumption* (A1) *hold. Then the solution of* (1.5)–(1.8) *satisfies*

$$\varrho \in L^\infty_{loc}((0,\infty); W^{1,1}(0,L)), \text{ uniformly in } \varepsilon.$$

Proof. Differentiation of (1.5) with respect to x yields

$$\partial_t \partial_x \varrho + \partial_x((1-2\varrho)\partial_x \varrho \partial_x S + \varrho(1-\varrho)\partial_x^2 S) = \varepsilon \partial_x^3 \varrho. \tag{2.5}$$

We define an approximation of the sign function by $\sigma_\delta(z) = \sigma(z/\delta)$, $0 < \delta \ll 1$, with σ smooth and increasing, $\sigma(0) = 0$, and $\sigma(z) = \operatorname{sign} z$ for $|z| > z_0$. Then, with $\operatorname{abs}_\delta(z) := \int_0^z \sigma_\delta(\xi)d\xi$, the convergence of $\operatorname{abs}_\delta(z)$ to $|z|$ as $\delta \to 0$ is uniform in $z \in \mathbb{R}$. Multiplying (2.5) with $\sigma_\delta(\partial_x \varrho)$ and integrating with respect to x yields

$$\begin{aligned} &\int_0^L \sigma_\delta(\partial_x\varrho)\partial_t\partial_x\varrho\,dx + \int_0^L \sigma_\delta(\partial_x\varrho)\partial_x(\partial_x\varrho\partial_x S(1-2\varrho))\,dx \\ &\qquad + \int_0^L \sigma_\delta(\partial_x\varrho)\partial_x(\varrho(1-\varrho)(S-\varrho))\,dx = \varepsilon\int_0^L \sigma_\delta(\partial_x\varrho)\partial_x^3\varrho\,dx. \end{aligned} \tag{2.6}$$

We integrate (2.6) by parts. The boundary terms vanish and we obtain

$$\begin{aligned} &\frac{d}{dt}\int_0^L \operatorname{abs}_\delta(\partial_x\varrho)\,dx - \int_0^L \sigma_\delta'(\partial_x\varrho)\partial_x\varrho\partial_x^2\varrho\partial_x S(1-2\varrho)\,dx \\ &\qquad + \int_0^L \sigma_\delta(\partial_x\varrho)\partial_x(\varrho(1-\varrho)(S-\varrho))\,dx = -\varepsilon\int_0^L \sigma_\delta'(\partial_x\varrho)(\partial_x^2\varrho)^2\,dx \le 0. \end{aligned} \tag{2.7}$$

The function $f_\delta(z) = \sigma_\delta(z)z - \operatorname{abs}_\delta(z)$ satisfies $f_\delta'(z) = \sigma_\delta'(z)z$ and converges to 0 uniformly in $z \in \mathbb{R}$. We integrate the second term in (2.7) by parts, which gives

$$\begin{aligned}\frac{d}{dt}\int_0^L \operatorname{abs}_\delta(\partial_x\varrho)\,dx \le &-\int_0^L f_\delta(\partial_x\varrho)\partial_x(\partial_x S(1-2\varrho))\,dx\\ &-\int_0^L \sigma_\delta(\partial_x\varrho)\partial_x(\varrho(1-\varrho)(S-\varrho))\,dx.\end{aligned} \tag{2.8}$$

The last term can be estimated by

$$\begin{aligned}-\int_0^L \sigma_\delta(\partial_x\varrho)\partial_x(\varrho(1-\varrho)(S-\varrho))\,dx &= -\int_0^L \sigma_\delta(\partial_x\varrho)\varrho(1-\varrho)\partial_x S\,dx\\ -\int_0^L \sigma_\delta(\partial_x\varrho)\partial_x\varrho(3\varrho^2-2\varrho(S+1)+S)\,dx &\le c_1 + c_2\int_0^L |\partial_x\varrho|\,dx.\end{aligned}$$

In the limit $\delta \to 0$, the first term of the right-hand side of (2.8) vanishes, and we obtain

$$\frac{d}{dt}\int_0^L |\partial_x\varrho|\,dx \le c_1 + c_2\int_0^L |\partial_x\varrho|dx. \tag{2.9}$$

The assertion of Lemma 2.2 now follows from the Gronwall inequality. ∎

LEMMA 2.3. *Let* (A1) *hold. Then the solution of* (1.5)–(1.8) *satisfies*

$$\sqrt{\varepsilon}\partial_x\varrho, \partial_t\partial_x S \in L^2_{loc}((0,\infty)\times[0,L]), \quad \textit{uniformly in } \varepsilon.$$

Proof. We write (1.5) as

$$\partial_t\varrho = \partial_x(\varepsilon\partial_x\varrho - \varrho(1-\varrho)\partial_x S). \tag{2.10}$$

Multiplication by ϱ and integration with respect to x leads to

$$\frac{1}{2}\frac{d}{dt}\int_0^L \varrho^2\,dx + \varepsilon\int_0^L (\partial_x\varrho)^2\,dx = \int_0^L \varrho(1-\varrho)\partial_x S\partial_x\varrho\,dx. \tag{2.11}$$

Since the integrand in the last term is in $L^1((0,L))$ uniformly in t and ε by the previous result, we obtain the boundedness of $\sqrt{\varepsilon}\partial_x\varrho$ by integration with respect to t. As a consequence, the flux density $J = \varrho(1-\varrho)\partial_x S - \varepsilon\partial_x\varrho$ is also uniformly bounded in $L^2_{loc}((0,\infty)\times[0,L])$. Differentiating (1.6) with respect to x and t and using $\partial_t\varrho + \partial_x J = 0$, we obtain

$$\partial_t\partial_x^3 S - \partial_t\partial_x S = \partial_x^2 J.$$

Thus, $\partial_t\partial_x S = -\mathcal{S}[\partial_x^2 J]$. Since the expression on the right-hand side is a bounded operator applied to $J \in L^2_{loc}((0,\infty)\times[0,L])$, the proof is complete. ∎

THEOREM 2.4. *Let the assumption* (A1) *hold,* (ϱ, S) *be a solution of* (1.5)–(1.8)*, and* $T > 0$*. Then, as* $\varepsilon \to 0$ *(restricting to subsequences),*

$$\varrho \to \bar\varrho \text{ in } C([0,T];L^1((0,L))) \quad \textit{and} \quad S \to \bar S \text{ in } C([0,T];C^1([0,L])). \tag{2.12}$$

The limit $(\bar\varrho, \bar S) \in L^\infty((0,T);BV((0,L))\times W^{2,\infty}((0,L)))$ *solves* (1.9), (1.10), (1.11)*, where* $\bar\varrho_I \in BV((0,L))$ *is an accumulation point of* ϱ_I^ε*. Moreover,* $\bar\varrho$ *is an entropy solution of* (1.9)*; i.e.,*

$$\partial_t\eta(\bar\varrho) + \partial_x(\psi(\bar\varrho)\partial_x\bar S) + (\bar\varrho(1-\bar\varrho)\eta'(\bar\varrho) - \psi(\bar\varrho))(\bar S - \bar\varrho) \le 0 \tag{2.13}$$

holds in the weak sense for every smooth, convex η *and with* $\psi'(\bar\varrho) = (1-2\bar\varrho)\eta'(\bar\varrho)$.

Remark. Note that the entropy inequality does not give rise to a decaying entropy functional.

Proof. The boundedness of the flux density (proof of Lemma 2.3) gives $\partial_t \varrho \in L^2((0,T);H^{-1}((0,L)))$. Together with Lemma 2.2 this implies that ϱ is in a compact set in $C([0,T];L^1((0,L)))$ (see Simon [15]). From Theorem 2.1, Lemma 2.3, and an anisotropic generalization of the Sobolev embedding of $W^{1,p}$ in $C^{0,1-n/p}$, $p>n$ (see Haskovec and Schmeiser [4]), it follows that $\partial_x S$ is uniformly bounded in $C^{0,1/3}([0,T]\times\bar{\Omega})$, $T>0$. An application of the Arzela–Ascoli theorem concludes the proof of (2.12). The strong convergence of ϱ and $\partial_x S$ allows us to pass to the limit in the weak formulation of (1.5)–(1.8), giving the weak formulation of (1.9)–(1.11) for $\bar{\varrho}$ and $\bar{S}$. The entropy inequality (2.13) follows analogously. ∎

3. Long-time behavior of the hyperbolic system. In this section, we investigate the stability and the asymptotic behavior of entropy solutions of the hyperbolic system. Stationary solutions of (1.9)–(1.11) satisfy

$$\bar{\varrho}(1-\bar{\varrho})\partial_x \bar{S} = 0, \tag{3.1}$$

$$\partial_x^2 \bar{S} = \bar{S} - \bar{\varrho}. \tag{3.2}$$

It can be immediately seen that $\bar{\varrho} = \bar{S} = const$ is a solution.

LEMMA 3.1. *The constant solution, $\bar{\varrho} = \bar{S} = \frac{m}{L}$, where $0 < m < L$ is the total mass, of system* (1.9)–(1.11) *is unstable.*

Proof. We multiply (1.9) by $\bar{S}$ and differentiate (1.10) with respect to t to obtain

$$\frac{1}{2}\frac{d}{dt}\int_0^L (\bar{S}^2 + (\partial_x \bar{S})^2)dx = \int_0^L \bar{\varrho}(1-\bar{\varrho})(\partial_x \bar{S})^2 dx. \tag{3.3}$$

For small nonconstant perturbations, the right-hand side of this equation is positive $\forall t$, and hence $\int_0^L (\bar{S}^2 + (\partial_x \bar{S})^2)dx$ is increasing in time. We rearrange this integral by writing

$$\begin{aligned}\int_0^L (\bar{S}^2 + (\partial_x \bar{S})^2)dx &= \int_0^L \left[\Big(\frac{m}{L} + \bar{S} - \frac{m}{L}\Big)^2 + (\partial_x \bar{S})^2\right] dx \\ &= \frac{m^2}{L} + 2\int_0^L \frac{m}{L}\Big(\bar{S} - \frac{m}{L}\Big)dx + \int_0^L \left[\Big(\bar{S} - \frac{m}{L}\Big)^2 + (\partial_x \bar{S})^2\right] dx. \end{aligned} \tag{3.4}$$

Since the total mass is conserved, we consider only perturbations with mass 0. Thus, we have $\int_0^L \bar{S}\,dx = \int_0^L \bar{\varrho}\,dx = m\ \forall t$, and the second term on the right-hand side vanishes. Hence,

$$\min_{\int \bar{S}dx = m} \int_0^L \Big(\bar{S}^2 + (\partial_x \bar{S})^2\Big)dx = \frac{m^2}{L},$$

which is only achieved for $\bar{S} = \frac{m}{L}$. As the integral on the left-hand side is increasing in time, Lemma 3.1 follows. ∎

LEMMA 3.2. *As $t\to\infty$, $\bar{\varrho}(1-\bar{\varrho})(\partial_x \bar{S})^2 \to 0$ in the following sense:*

$$\int_\tau^\infty \int_0^L \bar{\varrho}(1-\bar{\varrho})(\partial_x \bar{S})^2 dx\,dt \xrightarrow{\tau\to\infty} 0. \tag{3.5}$$

Proof. Integration of (3.3) from $t = 0$ to ∞ shows that

$$\int_0^\infty \int_0^L \bar{\varrho}(1-\bar{\varrho})(\partial_x \bar{S})^2 dx dt < \infty, \tag{3.6}$$

which implies the assertion. ∎

From this, and the steady state equations (3.1), (3.2), we expect convergence to piecewise constant steady states, with $\bar{\varrho} = 0$, $\bar{\varrho} = 1$, or $\bar{S}_x = 0$. Going back to the time-dependent problem (1.9), (1.10) and applying the method of characteristics, we find that along characteristics given by $\dot{x} = (1 - 2\bar{\varrho})\partial_x \bar{S}$, $\bar{\varrho}$ evolves according to $\dot{\bar{\varrho}} = (\bar{\varrho} - \bar{S})\bar{\varrho}(1 - \bar{\varrho})$. It immediately follows that $\bar{\varrho} = \bar{S} = const$, with $0 < const < 1$, is unstable. If $\bar{\varrho}$ gets sufficiently small such that $\bar{S} > \bar{\varrho}$, then $\bar{\varrho} = 0$ is attracting, and a similar argument holds for $\bar{\varrho} = 1$. Hence, we expect solutions to approach (as $t \to \infty$) functions of the form

$$\bar{\varrho}_\infty(x) = \frac{1 - (-1)^{k_i}}{2} \qquad \text{for } x_i < x < x_{i+1}, \tag{3.7}$$

with $0 = x_0 < x_1 < \cdots < x_{M+1} = L$, $k_i = k_0 + i$, and

$$\bar{S}_\infty = \mathcal{S}[\bar{\varrho}_\infty]. \tag{3.8}$$

Plateaus, where $\bar{\varrho}_\infty = 1$, alternate with vacuum regions ($\bar{\varrho}_\infty = 0$). At the left, it starts with a plateau for $k_0 = 1$, or with a vacuum region for $k_0 = 0$. The union of all plateau regions is denoted by

$$P = \bigcup_{k_i \text{ odd}} (x_i, x_{i+1}).$$

It follows from mass conservation that

$$l(P) = \sum_{k_i \text{ odd}} (x_{i+1} - x_i) = \int_0^L \bar{\varrho}_I \, dx.$$

Not all possible stationary solutions $\bar{\varrho}_\infty$ are indeed entropy solutions. For scalar conservation laws the sign of the jump of the density $\bar{\varrho}_\infty$ at an entropic shock is related to the convexity behavior of the flux $\bar{\varrho}_\infty(1 - \bar{\varrho}_\infty)\partial_x \bar{S}_\infty$. This leads to a condition on the sign of $\partial_x \bar{S}_\infty$ at the plateau edges:

$$(-1)^{k_i} \bar{S}_{\infty,x}(x_i) < 0, \quad 1 \le i \le M. \tag{3.9}$$

Formally, $\partial_x \bar{S}_\infty$ would also be allowed to be zero. Such a solution would, however, be unstable, since a small perturbation would lead to a violation of the entropy condition. A possible derivation of (3.9) is given in the following section by the construction of shock profiles for the full parabolic problem, i.e., boundary layer solutions smoothing the jumps of $\bar{\varrho}_\infty$.

Next, we investigate the stability of the stationary solution $(\bar{\varrho}_\infty, \bar{S}_\infty)$ with respect to a particular class of perturbations. We introduce the initial data

$$\bar{\varrho}_I(x) = \frac{1 - (-1)^{k_i}}{2} + \varepsilon u_I(x) \qquad \text{for } x \in (x_i + \varepsilon\xi_i(0), x_{i+1} + \varepsilon\xi_{i+1}(0)) = I_i(0), \tag{3.10}$$

where u_I is a piecewise smooth function and $|\varepsilon| \ll 1$. Then, solutions of (1.9), (1.10) have jumps at $x_i + \varepsilon\xi_i(t)$, and

(3.11)
$$\bar{\varrho}(x,t) = \frac{1-(-1)^{k_i}}{2} + \varepsilon u(x,t) \qquad \text{for } x \in (x_i + \varepsilon\xi_i(t), x_{i+1} + \varepsilon\xi_{i+1}(t)) = I_i(t).$$

The Rankine–Hugoniot jump condition reads

$$\varepsilon\dot{\xi}_i[\bar{\varrho}] = [\bar{\varrho}(1-\bar{\varrho})]\partial_x\bar{S}|_{x=x_i+\varepsilon\xi_i},$$

which, at leading order, yields

$$\dot{\xi}_i(t) = -\left(u(x_i+,t) + u(x_i-,t)\right)\bar{S}_{\infty,x}(x_i).$$

Using (3.11) in (1.9), it follows that $u(x,t)$ approximately satisfies

$$\begin{aligned} &\partial_t u - \partial_x(u\partial_x\bar{S}_\infty) = 0 \qquad \text{in } P,\\ &\partial_t u + \partial_x(u\partial_x\bar{S}_\infty) = 0 \qquad \text{in } Z := (0,L)\setminus P. \end{aligned}$$

By the method of characteristics, we derive

$$\dot{x} = -\partial_x\bar{S}_\infty, \quad \dot{u} = u\partial_x^2\bar{S}_\infty = u(\bar{S}_\infty - 1) \qquad \text{in } P,$$

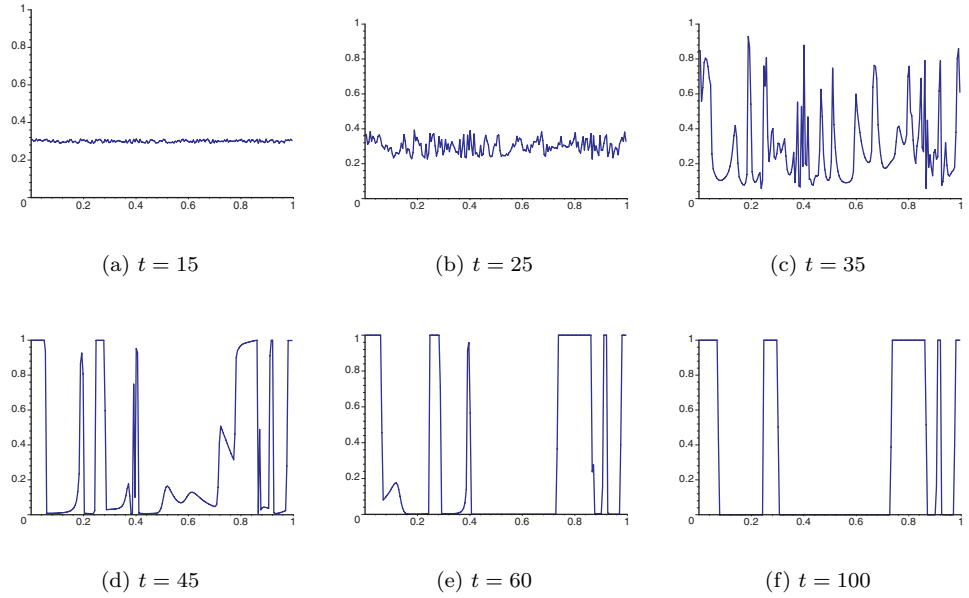
$$\dot{x} = \partial_x\bar{S}_\infty, \quad \dot{u} = -u\partial_x^2\bar{S}_\infty = -u\bar{S}_\infty \qquad \text{in } Z.$$

Since $\bar{S}_\infty$ is concave in P and convex in Z, exactly one extremum $\bar{x}_{i+1/2}$ exists between x_i and x_{i+1} for $1 \le i \le M-1$. Since the derivative of $\bar{S}_\infty$ also vanishes at the boundary points, we introduce the notation $\bar{x}_{1/2} := 0$, $\bar{x}_{M+1/2} = L$. All of the characteristics except those starting at $\bar{x}_{i+1/2}$, $0 \le i \le M$, go into one of the x_i, and u decays along characteristics. The limit of the length of the plateau $I_i(t)$ (k_i odd) as $t \to \infty$ is given by

$$\begin{aligned} l(I_i(\infty)) &= l(I_i(0)) + \varepsilon\int_0^\infty \left(\dot{\xi}_{i+1} - \dot{\xi}_i\right)dt\\ &= l(I_i(0)) + \varepsilon\int_0^\infty [-(u\partial_x\bar{S}_\infty)(x_{i+1}+) - (u\partial_x\bar{S}_\infty)(x_{i+1}-)\\ &\qquad + (u\partial_x\bar{S}_\infty)(x_i+) + (u\partial_x\bar{S}_\infty)(x_i-)]dt\\ &= l(I_i(0)) - \varepsilon\int_0^\infty\int_{x_i}^{x_{i+1}} \partial_x(u\partial_x\bar{S}_\infty)dxdt + \varepsilon\int_0^\infty\int_{x_{i+1}}^{\bar{x}_{i+3/2}} \partial_x(u\partial_x\bar{S}_\infty)dxdt\\ &\quad + \varepsilon\int_0^\infty\int_{\bar{x}_{i-1/2}}^{x_i} \partial_x(u\partial_x\bar{S}_\infty)dxdt\\ &= l(I_i(0)) - \varepsilon\left(\int_{x_i}^{x_{i+1}} u\,dx + \int_{x_{i+1}}^{\bar{x}_{i+3/2}} u\,dx + \int_{\bar{x}_{i-1/2}}^{x_i} u\,dx\right)_{t=0}^{\infty}. \end{aligned}$$

Since $u \xrightarrow{t\to\infty} 0$, we obtain

$$l(I_i(\infty)) = l(I_i(0)) + \varepsilon\int_{\bar{x}_{i-1/2}}^{\bar{x}_{i+3/2}} u_I dx. \tag{3.12}$$



(a) $t = 15$ (b) $t = 25$ (c) $t = 35$

(d) $t = 45$ (e) $t = 60$ (f) $t = 100$

FIG. 3.1. *Temporal evolution of the cell density* $\bar{\varrho}$*, starting from random initial data* $\bar{\varrho}_I \in [0.3, 0.31]$ *and with* $L = 1$.

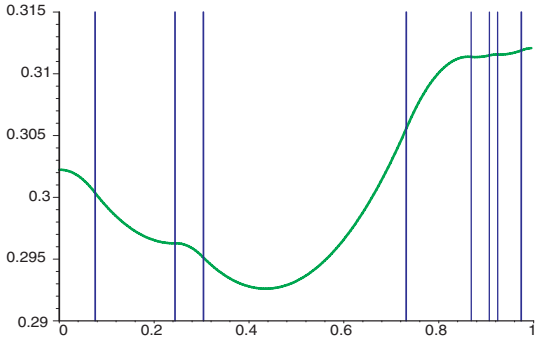


FIG. 3.2. *Cell density* $\bar{\varrho}$ *(dark) and chemical concentration* $\bar{S}$ *(light) at* $t = 100$.

Thus, as $t \to \infty$, each plateau attracts all the mass initially distributed between the neighboring minima of $\bar{S}_\infty$. We can interpret this as a neutral stability of steady states with alternating plateau and vacuum regions with respect to perturbations of the type (3.10).

In Figures 3.1 and 3.2, we solved the problem (1.9)–(1.11) numerically. At each time step, first the new chemical concentration is calculated from the old cell density, and then the cell density is updated using an upwind method. In Figure 3.1, we can observe the formation of shocks and rarefaction waves, until, in the last picture, the stationary state is reached and no further movement of the plateaus can be observed. In Figure 3.2, the corresponding chemical concentration $\bar{S}$ is shown. Note that, as discussed above, the chemical follows the course of the cell density $\bar{\varrho}$, even in the case of the slim plateau on the right-hand side of the domain.

4. Long-time behavior of the parabolic system. In this section, we will be concerned with the stability and the asymptotic behavior of solutions of the full parabolic problem (1.5)–(1.8). All stationary solutions have been characterized by Potapov and Hillen in [13] by a phase plane analysis. They are the restrictions of periodic solutions of the stationary differential equations to the interval $(0, L)$.

The dynamic problem studied in [13] differs from (1.5)–(1.8) by the fact that S is given by a parabolic equation. The authors show that all stationary solutions lie on branches bifurcating from the spatially uniform stationary solution, dependent on a bifurcation parameter inversely proportional to ε. It turns out that the constant solution is linearly stable for large enough diffusivity. After a first bifurcation its stability is transferred to a bifurcating solution. For the model (1.5)–(1.8), the linear stability result can be extended to global nonlinear stability.

LEMMA 4.1. *Let assumption* (A1) *hold, and let* $\varepsilon > \frac{1}{4}$. *Then the solution of* (1.5)–(1.8) *converges to the constant stationary solution as* $t \to \infty$.

Proof. As in the proof of Lemma 3.1, we multiply (1.5) by S and differentiate (1.6) with respect to t to obtain, after integration by parts of the last term on the right-hand side,

$$\frac{1}{2}\frac{d}{dt}\int_0^L (S^2 + (\partial_x S)^2)dx = \int_0^L \varrho(1-\varrho)(\partial_x S)^2 dx - \varepsilon \int_0^L ((\partial_x S)^2 + (\partial_x^2 S)^2)dx. \tag{4.1}$$

We can estimate the left-hand side by

$$\begin{aligned}\frac{1}{2}\frac{d}{dt}\int_0^L (S^2 + (\partial_x S)^2)dx &= \int_0^L \varrho(1-\varrho)(\partial_x S)^2 dx - \varepsilon \int_0^L ((\partial_x S)^2 + (\partial_x^2 S)^2)dx \\ &\le \Big(\frac{1}{4} - \varepsilon\Big) \int_0^L ((\partial_x S)^2 + (\partial_x^2 S)^2)dx. \end{aligned} \tag{4.2}$$

For $\varepsilon > \frac{1}{4}$, the right-hand side of (4.2) is negative. Integration from 0 to t yields

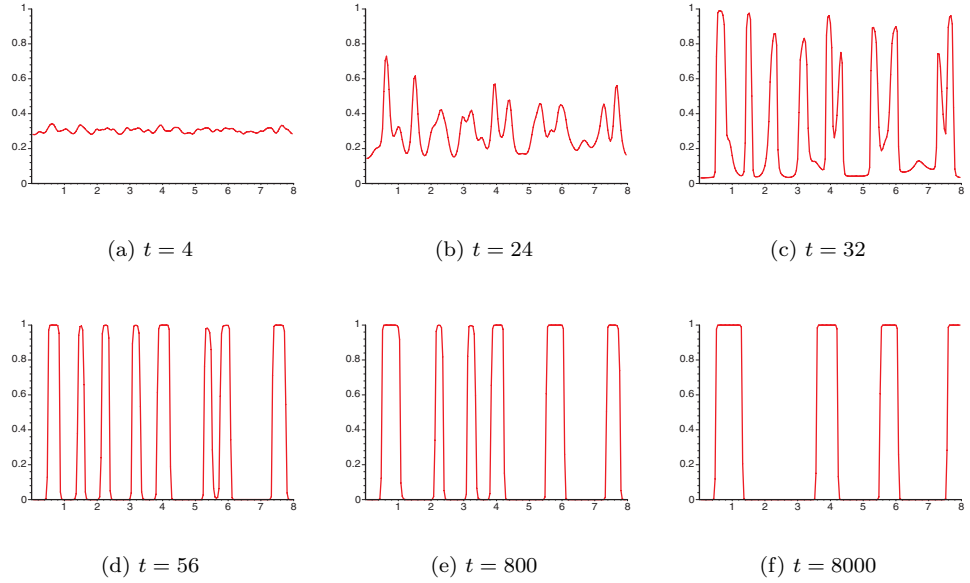
$$\int_0^L (\partial_x S)^2(x,t)\,dx \le \Big(\frac{1}{2} - 2\varepsilon\Big) \int_0^t \int_0^L (\partial_x S)^2 dx + \int_0^L (S^2 + (\partial_x S)^2)dx\Big|_{t=0}.$$

Applying Gronwall's lemma, it follows that $\|\partial_x S\|_{L^2(0,L)} \to 0$ and as a consequence, $S \to const$ as $t \to \infty$. ∎

The result is sharp in the sense that a linear stability analysis yields $\varepsilon = \frac{1}{4}$ as the first bifurcation point, where the constant steady state loses its stability.

We motivate our study of the dynamics for small values of ε by presenting the result of a numerical experiment. Figure 4.1 shows a numerical solution of (1.5)–(1.8) with $\varepsilon = 2 \times 10^{-4}$. We used the same numerical scheme as in the previous section with an explicit discretization of the diffusion term. Starting from homogeneous initial data with small perturbations, a pattern with several plateaus is formed as for the hyperbolic problem. Once this pattern has formed, it remains structurally stable for a long time, with the plateaus moving very slowly. Eventually, neighboring plateaus merge with each other. This merging process occurs on a comparatively fast time scale. The new pattern, now with one peak less, undergoes the same coarsening process.

Experimentally, this so-called metastable behavior is a well-known phenomenon in many fields, for instance solid-state physics. Mathematically, it has been studied in



(a) $t = 4$ (b) $t = 24$ (c) $t = 32$

(d) $t = 56$ (e) $t = 800$ (f) $t = 8000$

FIG. 4.1. *Numerical solution of the parabolic system* (1.5), (1.6) *with random initial data* $\varrho_I \in [0.3, 0.31]$, $L = 10$, *and* $\varepsilon = 2 \times 10^{-4}$.

various contexts such as the movement of viscous shocks [7], [14] or the Cahn–Hillard equation (for instance, [1] and [2]). A chemotaxis model featuring the formation of spike solutions is considered in [16].

The peculiar long-time behavior of system (1.5), (1.6) can be interpreted as follows. Each pseudostationary state of the parabolic system is exponentially close to a stationary entropy solution of the hyperbolic system. In contrast to the latter, however, the small diffusion allows plateaus to communicate with each other, and smaller plateaus are attracted by neighboring larger ones producing more chemoattractant. The whole phenomenon depends on a nonzero diffusion coefficient ε. Eventually, plateaus will get so close to each other that in general, the corresponding stationary solutions of the hyperbolic system cannot satisfy the entropy condition any more. Then a fast transition takes place, and the smaller plateau merges with the larger one. On this fast time scale, solutions behave practically like in the hyperbolic case, and a smoothened version of a rarefaction wave can be observed.

After the two peaks have merged, it is again diffusion that dominates the behavior. The whole process repeats itself, until only one single plateau is left, which will typically move to one of the domain boundaries. Thus, the only stable stationary state seems to be one plateau at the left or right boundary of the domain.

By construction of approximate solutions, it is shown numerically and analytically in [13] that the eigenvalues describing the slow movement of the peaks exponentially approach zero as the length of the domain increases. These exponentially small eigenvalues are typical features of metastable systems. The authors also derive an ODE describing the dynamics of a structure with two plateaus at the domain boundaries. Here, we will use exponential asymptotics to formally derive a system of ODEs describing the slow movement of the plateaus. This method has been successfully used in various applications; see, for instance, Ward [18] and references therein.

Metastable dynamics of the parabolic system. In the following analysis of the long-time behavior of system (1.5), (1.6), now rewritten as

$$\partial_t \varrho + \partial_x J = 0, \qquad J = \varrho(1-\varrho)\partial_x \mathcal{S}[\varrho] - \varepsilon \partial_x \varrho, \qquad J = 0 \quad \text{at } x = 0, L, \tag{4.3}$$

we will assume that the formation of patterns from the initial data has already taken place, and that a quasi-stationary pattern with plateaus (close to (3.7)) has been formed. Our aim is to derive a system of equations describing the evolution of the positions of the plateau boundaries $x_1(t), \dots, x_M(t)$.

A first approximation to a solution of the parabolic problem with plateaus is a stationary entropy solution of the hyperbolic problem $(\bar\varrho_\infty, \bar S_\infty)$ solving (3.7) and (3.8). However, we need a much better approximation $(\tilde\varrho, \tilde S)$ with boundary layer corrections close to the jumps of $\bar\varrho_\infty$. Actually we shall try to solve the parabolic steady state problem

$$\varepsilon \partial_x \varrho - \varrho(1-\varrho)\partial_x \mathcal{S}[\varrho] = 0 \tag{4.4}$$

as precisely as possible. The approximation $\tilde S$ for the chemoattractant density will be constructed such that it is close to $\bar S_\infty$ with the same qualitative behavior. In particular, it has the same monotonicity behavior at the plateau boundaries and extrema $\tilde x_{i+1/2}$ with the ordering $0 = \tilde x_{1/2} < x_1 < \tilde x_{3/2} < \cdots < \tilde x_{M-1/2} < x_M < \tilde x_{M+1/2} = L$ as the extrema $\bar x_{i+1/2}$ of $\bar S_\infty$ introduced above. For the construction of the approximating cell density, we consider the boundary layer problem

$$\varepsilon \partial_x \hat\varrho_i = \hat\varrho_i(1-\hat\varrho_i)\partial_x \tilde S, \qquad \hat\varrho_i(x_i) = \frac{1}{2}, \tag{4.5}$$

where the auxiliary condition fixes the position of the boundary layer. The solution

$$\hat\varrho_i[\tilde S](x) = \left[1 + \exp\left(\frac{\tilde S(x_i) - \tilde S(x)}{\varepsilon}\right)\right]^{-1} \tag{4.6}$$

will be used for $\tilde x_{i-1/2} < x < \tilde x_{i+1/2}$. The shape of $\hat\varrho_i$ depends on the monotonicity of $\tilde S$ in this interval: for increasing $\tilde S$, $\hat\varrho_i(\tilde x_{i-1/2}) \approx 0$ and $\hat\varrho_i(\tilde x_{i+1/2}) \approx 1$, and vice versa for decreasing $\tilde S$. Thus, the boundary layer solution has the appropriate behavior for jumps satisfying the entropy condition (3.9).

The construction of the boundary layer solution is nonstandard from the point of view of singular perturbation theory, where the standard procedure would lead to evaluation of $\partial_x \tilde S$ at $x = x_i$ in (4.5) and, consequently, $\hat\varrho_i[\tilde S](x) = [1 + \exp(\partial_x \tilde S(x_i)(x_i - x)/\varepsilon)]^{-1}$. This is, of course, an approximation of (4.6), obtained by Taylor expansion of $\tilde S$. The better accuracy of (4.6) is needed in the exponential asymptotics here.

By patching together the boundary layer solutions at the points $\tilde x_{i+1/2}$, exponentially small jump discontinuities would be created. By shifting the contributions appropriately, a continuous (actually continuously differentiable) approximate cell density is constructed:

$$\tilde\varrho[\tilde S](x) = \hat\varrho_i[\tilde S](x) - \Delta\varrho_i[\tilde S] \qquad \text{for } \tilde x_{i-1/2} < x < \tilde x_{i+1/2} \tag{4.7}$$

with

$$\Delta\varrho_i[\tilde S] = \sum_{j=1}^{i-1} \Big[\hat\varrho_{j+1}[\tilde S](\tilde x_{j+1/2}) - \hat\varrho_j[\tilde S](\tilde x_{j+1/2})\Big].$$

Note again that these corrections are exponentially small as $\varepsilon \to 0$. There is a certain arbitrariness in their choice. They would also serve their purpose if they would all be shifted by the same constant, which could be fixed by prescribing the total mass, i.e., the total number of cells. However, since our final result will only contain differences of the $\Delta\varrho_i[\tilde{S}]$, this issue is not important for us.

Finally, we require the chemoattractant density to satisfy

$$\tilde{S} = \mathcal{S}[\tilde{\varrho}[\tilde{S}]]. \tag{4.8}$$

This is a highly nonlinear problem whose solvability is not trivial at all. In the appendix we prove, for small ε, existence of a unique solution close to $\bar{S}_\infty$ and satisfying the qualitative assumptions mentioned above. The fact that $(\tilde{\varrho}, \tilde{S})$ is completely determined by the positions $x_1, \dots, x_M$ of the plateau boundaries motivates the notation $\tilde{\varrho} = \tilde{\varrho}(x; x_1, \dots, x_M)$, $\tilde{S} = \tilde{S}(x; x_1, \dots, x_M)$. If these coincide with the points where a stationary cell density takes the value $1/2$, then all the $\Delta\varrho_i$ vanish and $(\tilde{\varrho}, \tilde{S})$ is an exact steady state, since it also satisfies the Neumann boundary conditions $\partial_x\tilde{\varrho} = 0$, $x = 0, L$, by its construction and by the boundary conditions for $\tilde{S}$. In general, however, we obtain the residual

$$R := \varepsilon\partial_x\tilde{\varrho} - \tilde{\varrho}(1-\tilde{\varrho})\partial_x\tilde{S} = \Delta\varrho_i(1 - 2\hat{\varrho}_i + \Delta\varrho_i)\partial_x\tilde{S} \quad \text{in } (\tilde{x}_{i-1/2}, \tilde{x}_{i+1/2}). \tag{4.9}$$

The following procedure is an adaption of the methodology developed by Ward and coworkers for an asymptotic approximation of the metastable dynamics of the Ginzburg–Landau equation, viscous shocks, and the viscous Cahn–Hilliard equation (for an overview see, for instance, [18], [19] and references therein). The term "metastable" can be made more precise by considering the linearization of the problem around the M-parameter family of approximate steady states. The exponential smallness of the residuals leads to expecting M exponentially small eigenvalues. Metastability means that all the other eigenvalues are nonnegative. We do not have any results on the spectral problem, but the assumption of metastability is strongly supported by our numerical experiments and, even more strongly, by the numerical studies of the eigenvalue problem in [13].

We start by introducing a correction term for our approximate solution:

$$\varrho(x,t) = \tilde{\varrho}(x; x_1(t), \dots, x_M(t)) + r(x,t). \tag{4.10}$$

Since the approximate solution satisfies the boundary conditions, we have $\partial_x r = 0$ at $x = 0, L$. Just as in [19], we now consider an approximate version of (4.3), dropping nonlinear terms in r and assuming $|\partial_t r| \ll |\partial_t\tilde{\varrho}|$:

$$\partial_t\tilde{\varrho} + \partial_x J = 0, \qquad \mathcal{L}r + J + R = 0, \qquad J = 0 \quad \text{at } x = 0, L, \tag{4.11}$$

with the linearization of (4.4),

$$\mathcal{L}r = \varepsilon\partial_x r - (1 - 2\tilde{\varrho})\partial_x\tilde{S}r - \tilde{\varrho}(1-\tilde{\varrho})\partial_x\mathcal{S}[r]. \tag{4.12}$$

The nonlocal term $\mathcal{S}[r]$ is one of the major differences between our approach and the work in the above-mentioned references. As a first step, J will be computed by integrating the first equation in (4.11). From the definition of $\tilde{\varrho}$ in $(\tilde{x}_{i-1/2}, \tilde{x}_{i+1/2})$ we have

$$\partial_t\tilde{\varrho} = \frac{\hat{\varrho}_i(1-\hat{\varrho}_i)}{\varepsilon}\left[-\partial_x\tilde{S}(x_i)\dot{x}_i + \sum_{j=1}^{M}\left(\partial_{x_j}\tilde{S}(x) - \partial_{x_j}\tilde{S}(x_i)\right)\dot{x}_j\right] - \sum_{j=1}^{M}\partial_{x_j}\Delta\varrho_i\dot{x}_j.$$

From the differential equation (4.5) for the boundary layer term $\hat{\varrho}_i$ we see that $\hat{\varrho}_i(1-\hat{\varrho}_i)/\varepsilon$ is an approximate Delta-distribution concentrated at $x = x_i$ and with weight $|\partial_x \tilde{S}(x_i)|^{-1}$. The derivatives of the corrections $\Delta\varrho_i$ with respect to the x_j are expected to be exponentially small just as the $\Delta\varrho_i$ themselves. With these observations and (3.9), integration of the first equation in (4.11) gives

$$J(x) \approx \sum_{j=1}^{i} (-1)^{k_j} \dot{x}_j \qquad \text{for } x_i < x < x_{i+1}.$$

Here the boundary condition $J(0) = 0$ has been used. The other boundary condition $J(L) = 0$ leads to the equation

$$\sum_{j=1}^{M} (-1)^{k_j} \dot{x}_j = 0, \tag{4.13}$$

representing conservation of mass.

Now the second equation in (4.11) is multiplied by a test function $\psi(x,t)$ and integrated,

$$\varepsilon \psi r|_{x=0}^{L} + \int_0^L (r\mathcal{L}^*\psi + \psi(J+R))dx = 0, \tag{4.14}$$

with the formally adjoint operator

$$\mathcal{L}^*\psi = -\varepsilon\partial_x\psi - (1-2\tilde{\varrho})\partial_x\tilde{S}\psi + \partial_x\mathcal{S}[\tilde{\varrho}(1-\tilde{\varrho})\psi]. \tag{4.15}$$

In the computation of $\mathcal{L}^*$, the symmetry of Green's function G (see (2.3)) has been used.

The further procedure is motivated by the following observations: With $(\tilde{\varrho}, \tilde{S})$ we have constructed an M-parameter family of approximate solutions of the steady state problem (4.4) producing exponentially small residuals R (see (4.9)). Therefore we expect the linearized operator $\mathcal{L}$ to possess M exponentially small eigenvalues with eigenfunctions approximately given by the derivatives of $(\tilde{\varrho}, \tilde{S})$ with respect to the parameters $x_1, \ldots, x_M$. As a consequence, the inverse of $\mathcal{L}$ will act as a bounded operator on the inhomogeneity $J+R$ in the equation for r only if this inhomogeneity satisfies M solvability conditions characterized by the eigenfunctions of $\mathcal{L}^*$ corresponding to the exponentially small eigenvalues. Since $\mathcal{L}$ is not self-adjoint (the other major difference compared to earlier work for, e.g., the Cahn–Hilliard equation), the computation of approximations for these eigenfunctions is not immediate. We proceed pragmatically by trying to determine candidates for ψ such that the terms involving the unknown r in (4.14) become negligibly small.

The first two terms in (4.15) constitute a singularly perturbed differential operator with turning points (see [9]) close to $x = x_i$ (where $\tilde{\varrho} = 1/2$) and at $x = \tilde{x}_{i+1/2}$ (the extrema of $\tilde{S}$). These turning points are of different character since the sign of the coefficient $(1-2\tilde{\varrho})\partial_x\tilde{S}$ changes from positive to negative close to the x_i and vice versa at the $\tilde{x}_{i+1/2}$. The second group of turning points is interesting for us, since their character allows for spike layer solutions of the differential equation

$$\varepsilon\partial_x\psi + (1-2\tilde{\varrho})\partial_x\tilde{S}\psi = 0.$$

Such spike layer solutions will be the basis for our construction of appropriate ψ's. More precisely, we choose (for $i = 1, \dots, M-1$)

$$\psi_{i+1/2}(x) = c_{i+1/2} \exp\left(-\frac{1}{\varepsilon} \int_{\tilde{x}_{i+1/2}}^{x} (1 - 2\tilde{\varrho}(z)) \partial_x \tilde{S}(z) dz \right)$$

for $x_i \le x \le x_{i+1}$. Outside of this interval we extend $\psi_{i+1/2}$ as a smooth function satisfying

$$\begin{aligned}
&\psi_{i+1/2}(x) = 0 \quad \text{for } 0 \le x \le \tilde{x}_{i-1/2},\\
&|\psi_{i+1/2}(x)| \le \psi_{i+1/2}(x_i) \quad \text{for } \tilde{x}_{i-1/2} \le x \le x_i,\\
&|\psi_{i+1/2}(x)| \le \psi_{i+1/2}(x_{i+1}) \quad \text{for } x_{i+1} \le x \le \tilde{x}_{i+3/2},\\
&\psi_{i+1/2}(x) = 0 \quad \text{for } \tilde{x}_{i+3/2} \le x \le L,
\end{aligned}$$

which is possible under the basic assumption of the whole asymptotic procedure that all the points x_j and $\tilde{x}_{j+1/2}$ are well separated from each other. The constant $c_{i+1/2}$ is chosen such that $\psi_{i+1/2}$ approximately becomes a Delta-family for $\varepsilon \to 0$. This involves the computation of the integral

$$\begin{aligned}
&\int_0^L \exp\left(-\frac{1}{\varepsilon} \int_{\tilde{x}_{i+1/2}}^{x} (1 - 2\tilde{\varrho}(z)) \partial_x \tilde{S}(z) dz \right) dx\\
&\approx \int_{x_i}^{x_{i+1}} \exp\left(-\frac{|\partial_x^2 \tilde{S}(\tilde{x}_{i+1/2})|(x - \tilde{x}_{i+1/2})^2}{2\varepsilon} \right) dx \approx \sqrt{\frac{2\pi\varepsilon}{|\partial_x^2 \tilde{S}(\tilde{x}_{i+1/2})|}},
\end{aligned}$$

leading to

$$c_{i+1/2} = \sqrt{\frac{|\partial_x^2 \tilde{S}(\tilde{x}_{i+1/2})|}{2\pi\varepsilon}}.$$

In this construction we have neglected the last term in the adjoint operator (4.15) so far. Since $\tilde{\varrho}(1 - \tilde{\varrho})\psi_{i+1/2}$ is uniformly exponentially small, the same holds for $\partial_x \mathcal{S}[\tilde{\varrho}(1 - \tilde{\varrho})\psi_{i+1/2}]$, and, thus, also for $\mathcal{L}^* \psi_{i+1/2}$.

Using the functions $\psi_{i+1/2}$ in (4.14), we have to compute

$$\int_0^L \psi_{i+1/2} J \, dx \approx J(\tilde{x}_{i+1/2}) \approx \sum_{j=1}^{i} (-1)^{k_j} \dot{x}_j$$

as well as

$$\int_0^L \psi_{i+1/2} R \, dx.$$

The approximation of the second integral is less straightforward since, by (4.9), the integrand vanishes at $\tilde{x}_{i+1/2}$, where the mass of $\psi_{i+1/2}$ concentrates. We therefore split the integral into four parts A, B, C, and D, corresponding to the subintervals $(0, x_i)$, $(x_i, \tilde{x}_{i+1/2})$, $(\tilde{x}_{i+1/2}, x_{i+1})$, and (x_{i+1}, L), respectively. Using (4.9) and the properties of $\psi_{i+1/2}$, we easily estimate the first and the last terms:

$$\begin{aligned}
&|A| \le c\psi_{i+1/2}(x_i)|\Delta\varrho_i|,\\
&|D| \le c\psi_{i+1/2}(x_{i+1})|\Delta\varrho_{i+1}|,
\end{aligned}$$

with an ε-independent constant c. In a neighborhood of $\tilde{x}_{i+1/2}$, the residual can be approximated up to an exponentially small relative error by $R \approx \Delta\varrho_i(1-2\tilde{\varrho})\partial_x\tilde{S}$ for $x < \tilde{x}_{i+1/2}$, and by $R \approx \Delta\varrho_{i+1}(1-2\tilde{\varrho})\partial_x\tilde{S}$ for $x > \tilde{x}_{i+1/2}$. For the other two subintegrals we therefore obtain

$$\begin{aligned} B &\approx c_{i+1/2}\Delta\varrho_i \int_{x_i}^{\tilde{x}_{i+1/2}} \exp\left(-\frac{1}{\varepsilon}\int_{\tilde{x}_{i+1/2}}^{x}(1-2\tilde{\varrho}(z))\partial_x\tilde{S}(z)dz\right)(1-2\tilde{\varrho}(x))\partial_x\tilde{S}(x)dx \\ &\approx -\varepsilon c_{i+1/2}\Delta\varrho_i \end{aligned}$$

and similarly

$$C \approx \varepsilon c_{i+1/2}\Delta\varrho_{i+1}.$$

Since $\Delta\varrho_i$ is multiplied by the $O(\sqrt{\varepsilon})$-constant $\varepsilon c_{i+1/2}$ in B and by the exponentially small $\psi_{i+1/2}(x_i)$ in A, A is negligible compared to B and, analogously, D is negligible compared to C.

Collecting our results and using that $\psi_{i+1/2}$ vanishes on the boundary, (4.14) with $\psi = \psi_{i+1/2}$ leads to

$$\sum_{j=1}^{i}(-1)^{k_j}\dot{x}_j = \varepsilon c_{i+1/2}(\Delta\varrho_{i+1} - \Delta\varrho_i) \tag{4.16}$$

for $1 \le i \le M-1$. As previously mentioned, a common additive constant in the $\Delta\varrho_i$ would not change this result. From (4.16) with $i = 1$ we obtain an ODE for x_1:

$$\dot{x}_1 = (-1)^{k_1}\varepsilon c_{3/2}(\Delta\varrho_2 - \Delta\varrho_1). \tag{4.17}$$

Equations for x_i, $2 \le i \le M-1$, are derived by taking differences of consecutive versions of (4.16):

$$\dot{x}_i = (-1)^{k_i}\varepsilon\left[c_{i+1/2}(\Delta\varrho_{i+1} - \Delta\varrho_i) - c_{i-1/2}(\Delta\varrho_i - \Delta\varrho_{i-1})\right]. \tag{4.18}$$

Finally, the difference between the mass conservation equation (4.13) and (4.16) with $i = M-1$ gives

$$\dot{x}_M = (-1)^{k_M}\varepsilon c_{M-1/2}(\Delta\varrho_{M-1} - \Delta\varrho_M). \tag{4.19}$$

In principal, this completes the asymptotic procedure, and the dynamics of $x_1(t), \dots, x_M(t)$ is completely determined by (4.17)–(4.19). However, the right-hand sides in (4.17)–(4.19) are given in terms of $\tilde{S}$, the solution of (4.8), which is not known explicitly. On the other hand, it will be shown in the appendix that the explicitly computable $\bar{S}_\infty$ is a good enough approximation (essentially up to $O(\varepsilon^2)$) for $\tilde{S}$ to maintain the accuracy of the leading terms in (4.17)–(4.19). Therefore, the final result of our asymptotics is the system (4.17)–(4.19) with

$$\begin{aligned} \Delta\varrho_{i+1} - \Delta\varrho_i &= \left[1+\exp\left(\frac{\bar{S}_\infty(x_{i+1}) - \bar{S}_\infty(\bar{x}_{i+1/2})}{\varepsilon}\right)\right]^{-1} \\ &\quad - \left[1+\exp\left(\frac{\bar{S}_\infty(x_i) - \bar{S}_\infty(\bar{x}_{i+1/2})}{\varepsilon}\right)\right]^{-1}, \\ c_{i+1/2} &= \sqrt{\frac{|\bar{S}_\infty(\bar{x}_{i+1/2}) - \bar{\varrho}_\infty(\bar{x}_{i+1/2})|}{2\pi\varepsilon}}, \\ \bar{S}_\infty(x) &= \sum_{k_i \text{ odd}} \int_{x_i}^{x_{i+1}} \left[\frac{1}{2}e^{-|x-y|} + \frac{e^{x+y} + e^{2L-x-y} + e^{x-y} + e^{y-x}}{2(e^{2L}-1)}\right] dy. \end{aligned}$$

The whole asymptotic approach is based on the fact that the movement of the boundary layers is exponentially slow. It is valid only as long as x_1 and x_M stay away from the boundaries and an extremal point $\bar{x}_{i+1/2} \in (x_i, x_{i+1})$ of $\bar{S}_\infty$ exists for every pair $x_i < x_{i+1}$. These conditions are equivalent to the requirement that all plateau boundaries satisfy the entropy conditions (3.9). As soon as they are violated, the hyperbolic dynamics starts to dominate.

With the above approximations, the right-hand sides of (4.17)–(4.19) can be evaluated explicitly in terms of $x_1, \dots, x_M$. However, in the general case the formulas are very long and not very instructive. They involve not only the evaluation of the integrals in the last equation above, but also the computation of all the extremal points $\bar{x}_{3/2}, \dots, \bar{x}_{M-1/2}$ of $\bar{S}_\infty$. As an example, we discuss the simplest situation $M = 2$ with $k_0 = 1$, i.e., two plateaus adjacent to the boundaries with one vacuum region in the middle. In this case, the system (4.17)–(4.19) reduces to

$$\dot{x}_1 = \dot{x}_2 = \varepsilon c_{3/2}(\Delta\varrho_2 - \Delta\varrho_1). \tag{4.20}$$

Conservation of the initial mass m implies $x_1 + (L - x_2) = m$, and the system can be reduced to a scalar equation for x_1, substituting $x_2 = L - m + x_1$. The chemoattractant density is given by

$$\bar{S}_\infty(x) = \frac{\sinh(x_1)\cosh(L - x) + \sinh(m - x_1)\cosh(x)}{\sinh(L)}$$

for $x_1 \le x \le x_2$ with one interior minimum at

$$\bar{x}_{3/2} = \frac{1}{2}\log\frac{e^L \sinh(x_1) + \sinh(m - x_1)}{e^{-L}\sinh(x_1) + \sinh(m - x_1)}.$$

Steady states of (4.20) have to satisfy $\bar{S}_\infty(x_1) = \bar{S}_\infty(x_2)$. It is easily seen that $x_1 = m/2$ is the only solution; i.e., the only steady state is the symmetric one, where the mass is distributed equally between the two plateaus. In general, $\operatorname{sign}(x_1 - m/2) = \operatorname{sign}(\bar{S}_\infty(x_1) - \bar{S}_\infty(x_2)) = \operatorname{sign}(\dot{x}_1)$, showing the instability of the steady state. If initially one of the plateaus is bigger, then it will grow at the expense of the smaller one until all the mass is concentrated adjacent to one of the boundaries. This is expected to be the stable stationary state. In the general case $M > 2$, our understanding of the qualitative behavior of (4.17)–(4.19) is less complete. It is easy to see that steady states are characterized by the requirement that $\bar{S}_\infty$ take the same value at the plateau edges $x_1, \dots, x_M$. This implies that all plateaus have the same length and that the same is true for the vacuum regions separating them, with plateaus and/or vacuum regions adjacent to the boundary having half the interior length. This shows that all stationary solutions of the full problem as characterized in [13] are represented. We conjecture that all these solutions are unstable, but a proof is lacking.

About the dynamics we observe that, generically, one of the exponentially small terms $\Delta\varrho_{i+1} - \Delta\varrho_i$ will dominate all the others. As a consequence, effectively only two neighboring plateau edges x_i and x_{i+1} will move (with the same velocity), while the others are approximately stationary.

In Figure 4.2, we compare the numerical solution of the full system (1.5), (1.6) with the solution of system (4.17)–(4.19) by plotting the position of the boundaries of a single plateau situated at $x_1 = 0.6$ and $x_2 = 0.8$ for different values of ε. Light lines represent the solution obtained by solving the full system with an upwind scheme with grid size $\Delta x = \Delta t = 3 \times 10^{-4}$; dark lines were obtained by solving system

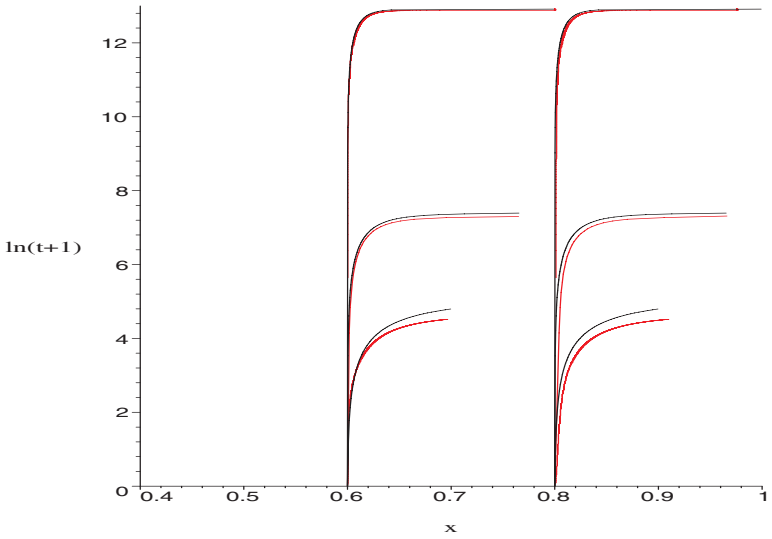


FIG. 4.2. *Comparison of the numerical solution of system* (1.5), (1.6) *with* $\varepsilon = 4 \times 10^{-4}$, 2×10^{-4}, *and* 1×10^{-4} *obtained with an upwind scheme (light) and the numerical solution of the corresponding ODE system (dark). The different lengths of the branches is due to the fact that as* ε *becomes smaller, solutions keep their plateau-like shape even when they get quite close to the boundary, whereas for larger* ε, *the hyperbolic dynamics start to take over much faster.*

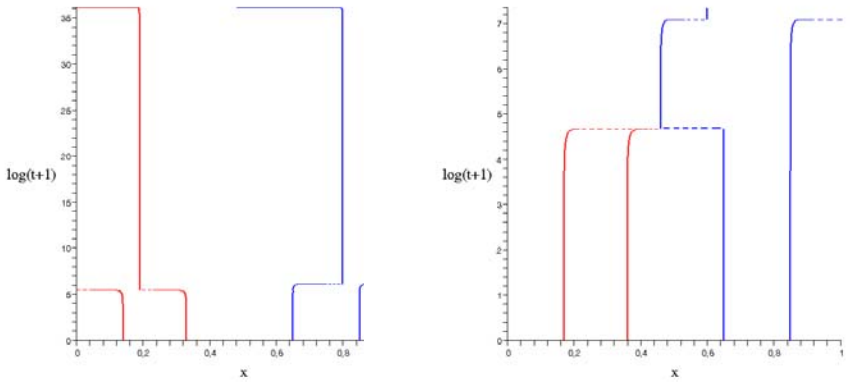
(4.17)–(4.19) for $M = 2$ using the MAPLE routine `lsode` (a Livermore stiff ODE solver). The two lowest branches in the figure correspond to $\varepsilon = 4 \times 10^{-4}$, and it can be observed that the time it takes the plateau to advance towards the boundary calculated by the two different approaches differs slightly. However, as we decrease ε ($\varepsilon = 2 \times 10^{-4}$ for the middle branches, $\varepsilon = 1 \times 10^{-4}$ for the top branches) and thus the error introduced by the approximating assumptions we had to take in order to obtain the ODEs (4.17)–(4.19), the distance between the lines decreases until, for $\varepsilon = 1 \times 10^{-4}$, the trajectories of x_1 and x_2 obtained by the upwind scheme and the ODE system are practically identical.

5. A hybrid numerical-asymptotic approach. Developing a numerical scheme that correctly captures both the short- and the long-time behavior of the parabolic system is a nontrivial task. If we use a standard discretization of (1.5), (1.6) with a grid size that is too large, the long-time behavior of the system will be driven by numerical errors dominating the exponentially small terms responsible for the exact dynamics. Choosing a grid that is fine enough to reduce numerical errors in a sufficient way leads to very large computation times. Another approach is to solve the equations for the positions of the plateau edges (4.17)–(4.19), and then to specify an approximate solution $\tilde{\varrho}$ at each time step according to (4.7). However, this solution is valid only as long as the conditions (3.9) are satisfied.

These observations motivate a combined approach for the numerical solution of (1.5), (1.6): As long as (3.9) holds, we use the asymptotic approximations (4.17)–(4.19). We solve the equations with MAPLE and calculate the corresponding $\tilde{\varrho}$ at each time step. When the velocities of the plateau edges become $\mathcal{O}(\varepsilon)$, we switch to a full numerical solution with the finite difference scheme described above. A similar numerical-asymptotic approach was developed in [17] to solve the viscous Cahn–Hillard equation in one space dimension.



(a) $x_1 = 0.13$, $x_2 = 0.32$ (b) $x_1 = 0.15$, $x_2 = 0.36$

FIG. 5.1. *Solutions of the ODE system* (4.17)–(4.19) *with different initial conditions and* $\varepsilon = 2 \times 10^{-4}$. *The position of the right plateau is* $x_3 = 0.65$, $x_4 = 0.85$ *in all pictures. An animation (obtained with the combined numerical-asymptotic approach described in the text) corresponding to Figure* 5.1(b) *can be found at http://www.ricam.oeaw.ac.at/people/page/dolak/animation.html.*

Example: Behavior near a stationary state. As an example, we investigate the dynamics of the parabolic system when solutions are initially close to an unstable stationary state.

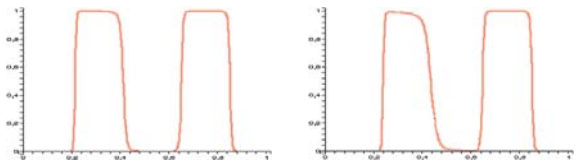
For a given initial mass m, this stationary solution consists of two plateaus of equal mass, with the outer edges being exactly half the distance between the plateaus away from the boundaries. The stationary solution is given by

$$x_1 = \frac{L-m}{4}, \quad x_2 = \frac{L+m}{4}, \quad x_3 = \frac{3L-m}{4}, \quad x_4 = \frac{3L+m}{4}. \tag{5.1}$$

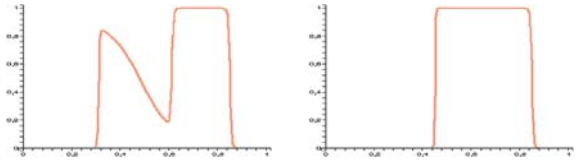
In our experiments, we set $m = 0.4$ and $L = 1$ to obtain the boundary layer positions $x_1 = 0.15$, $x_2 = 0.35$, $x_3 = 0.65$, and $x_4 = 0.85$ from (5.1). Then we choose two different sets of initial conditions close to this stationary point and calculate the temporal evolution of the boundary layers according to (4.17)–(4.19) with $M = 4$. After a plateau has moved to the domain boundary or merged with another plateau, we solve the system for $M = 3$ or $M = 2$, respectively.

In Figure 5.1(a), the left plateau has initially been made smaller and moved towards the left boundary. The evolution proceeds in three steps, as follows. 1. The left plateau moves to the left, until it reaches the boundary. 2. The right plateau moves to the right boundary. 3. The two remaining plateau edges move to the left, meaning that the bigger right plateau attracts cells from the left. The evolution stops after the left plateau has disappeared and one plateau adjacent to the right boundary is left as a stable steady state. As mentioned in the previous section, during each step only one pair of plateau edges moves in parallel.

Figure 5.1(b) features an initial condition, where the left plateau has again been made smaller but now moved towards the center compared to the unstable steady state. We observe a two-step evolution, as follows. 1. The left plateau moves to the right until it loses stability and is absorbed by the bigger right plateau. 2. The remaining plateau moves to the right until it reaches the boundary.



(a) $t = 48000$ (b) $t = 48130$



(c) $t = 48158$ (d) $t = 48165$

FIG. 5.2. *Fast dynamics of the parabolic system, corresponding to the dashed lines in Figure* 5.1(b). (a) *The cell density calculated according to the asymptotic approximations* (4.17)–(4.19) *and* (4.7) *shortly before the hyperbolic dynamics start to dominate.* (b), (c) *A rarefaction wave obtained by solving* (1.5), (1.6) *with an upwind scheme until, in* (d), *only one plateau is left.*

Details of the fast hyperbolic dynamics at the end of step 1 are shown in Figure 5.2. As the left plateau moves towards the right one, a rarefaction wave starts to form when the entropy condition for the corresponding hyperbolic system becomes violated. The outer plateau edge of the right plateau is not affected by this merging process and does not move, since locally the entropy condition is still satisfied. In general, however, it is an open problem to predict the outcome of the hyperbolic evolution because of the nonlocal coupling. After the loss of stability of a plateau edge, the hyperbolic evolution could induce stability losses of other plateau edges. Therefore it cannot be ruled out that several plateaus disappear within one "hyperbolic transition layer."

Appendix. We shall prove solvability of the approximate steady state problem (4.8) and an approximation result for its solution. Recalling the definition (3.7), (3.8) of the plateau state $(\bar\varrho_\infty, \bar S_\infty)$ and of the extremal points $\bar x_{i+1/2} \in (x_i, x_{i+1})$ of $\bar S_\infty$, we define

$$x_{i\pm1/4} := \frac{x_i + \bar x_{i\pm1/2}}{2} \quad \text{for } 1 \le i \le M, \qquad x_{1/4} := 0, \qquad x_{M+3/4} := L,$$

and

$$A_1 := \bigcup_{i=1}^{M} (x_{i-1/4}, x_{i+1/4}), \qquad A_2 := [0, L] \setminus A_1 = \bigcup_{i=0}^{M} [x_{i+1/4}, x_{i+3/4}].$$

Since A_1 stays away from the extremal points of $\bar S_\infty$, and A_2 stays away from its turning points x_i, there exists a $\delta > 0$ such that

$$|\partial_x \bar S_\infty| \ge 2\delta \quad \text{in } A_1, \qquad |\partial_x^2 \bar S_\infty| \ge 2\delta \quad \text{in } A_2.$$

For chemoattractant densities we shall use the Banach space $\mathcal{B}_1 := C^1([0,L]) \cap C^2(A_2)$ with its natural norm

$$\|S\|_1 := \|S\|_{L^\infty((0,L))} + \|\partial_x S\|_{L^\infty((0,L))} + \|\partial_x^2 S\|_{L^\infty(A_2)}$$

and the ball

$$B_\delta := \{S:\ \|S - \bar{S}_\infty\|_1 < \delta\}.$$

Then $S \in B_\delta$ implies

$$|\partial_x S| \geq \delta \quad \text{in } A_1, \qquad |\partial_x^2 S| \geq \delta \quad \text{in } A_2.$$

Therefore, in every subinterval $[x_{i+1/4}, x_{i+3/4}]$ of A_2, S has a unique local extremum $x_{i+1/2}[S]$ of the same character as $\bar{x}_{i+1/2} = x_{i+1/2}[\bar{S}_\infty]$. Consequently $\tilde{\varrho}[S]$ is well defined by (4.7). A fixed point operator for solving (4.8) is now defined on B_δ by

$$F[S](x) := \mathcal{S}[\tilde{\varrho}[S]]. \tag{A.1}$$

Our Banach space for cell densities will be $\mathcal{B}_2 := L^1((0,L)) \cap C(A_2)$ with the norm

$$\|\varrho\|_2 := \|\varrho\|_{L^1((0,L))} + \|\varrho\|_{L^\infty(A_2)}.$$

First we prove that the map $\mathcal{S}$ from ϱ to S given by solving the elliptic S-problem is continuous.

LEMMA A.1. *There exists a $c > 0$ such that, for every $\varrho \in \mathcal{B}_2$, $\mathcal{S}[\varrho] \in \mathcal{B}_1$ holds and $\|\mathcal{S}[\varrho]\|_1 \leq c\|\varrho\|_2$.*

Proof. The result is a consequence of the facts that G and $\partial_x G$ are uniformly bounded and that $S = \mathcal{S}[\varrho]$ solves the differential equation $\partial_x^2 S = S - \varrho$. ∎

Now we are ready to prove the main result of this section.

THEOREM A.2. *For ε small enough, problem (4.8) has a unique solution in B_δ.*

Proof. For every $S \in B_\delta$, $\tilde{\varrho}[S]$ deviates from $\bar{\varrho}_\infty$ only by boundary layer corrections close to the discontinuities $x_1, \ldots, x_M \in A_1$. The thickness of the boundary layers is $O(\varepsilon)$. In A_2, $\tilde{\varrho}[S]$ and $\bar{\varrho}_\infty$ are exponentially close as $\varepsilon \to 0$. This immediately implies $\|\tilde{\varrho}[S] - \bar{\varrho}_\infty\|_2 = O(\varepsilon)$ and, thus, from Lemma A.1, $\|F[S] - \bar{S}_\infty\|_1 = O(\varepsilon)$. This proves that for ε small enough, F maps B_δ into itself.

Now let $S_1, S_2 \in B_\delta$ and set $x^l_{i+1/2} := x_{i+1/2}[S_l]$, $\hat{\varrho}^l_i := \hat{\varrho}_i[S_l]$, $\Delta\varrho^l_i := \Delta\varrho_i[S_l]$, $l = 1, 2$. Assume $\partial_x S_1(x_i), \partial_x S_2(x_i) > 0$ and $x_i < x < \min\{x^1_{i+1/2}, x^2_{i+1/2}\}$. Then we have

$$\begin{aligned}
|\hat{\varrho}^1_i(x) - \hat{\varrho}^2_i(x)| &\leq \left|\exp\left(\frac{S_1(x_i) - S_1(x)}{\varepsilon}\right) - \exp\left(\frac{S_2(x_i) - S_2(x)}{\varepsilon}\right)\right| \\
&\leq \exp\left(\frac{\delta(x_i - x)}{\varepsilon}\right) \frac{1}{\varepsilon} \left|S_1(x_i) - S_1(x) - S_2(x_i) + S_2(x)\right| \\
&\leq \exp\left(\frac{\delta(x_i - x)}{\varepsilon}\right) \frac{x - x_i}{\varepsilon} \|S_1 - S_2\|_1.
\end{aligned}$$

Analogous estimates for $\max\{x^1_{i-1/2}, x^2_{i-1/2}\} < x < x_i$ and for $\partial_x S_l(x_i) < 0$ lead to

$$|\hat{\varrho}^1_i(x) - \hat{\varrho}^2_i(x)| \leq \exp\left(-\frac{\delta|x_i - x|}{\varepsilon}\right) \frac{|x - x_i|}{\varepsilon} \|S_1 - S_2\|_1 \tag{A.2}$$

for $1 \leq i \leq M$ and $\max\{x^1_{i-1/2}, x^2_{i-1/2}\} < x < \min\{x^1_{i+1/2}, x^2_{i+1/2}\}$.

The mean value theorem gives

$$\partial_x S_1(x^2_{i+1/2}) - \partial_x S_2(x^2_{i+1/2}) = \partial_x S_1(x^2_{i+1/2}) = \partial_x^2 S_1(\xi_{i+1/2})(x^2_{i+1/2} - x^1_{i+1/2}),$$

with $\xi_{i+1/2} \in A_2$. Since $S_1 \in B_\delta$,

$$|x^1_{i+1/2} - x^2_{i+1/2}| \leq \frac{1}{\delta} \|S_1 - S_2\|_1 \tag{A.3}$$

follows. Now assume $x^1_{i+1/2} < x^2_{i+1/2}$. Then we can estimate

$$|\hat{\varrho}_i^1(x_{i+1/2}^1) - \hat{\varrho}_i^2(x_{i+1/2}^2)| \le |\hat{\varrho}_i^1(x_{i+1/2}^1) - \hat{\varrho}_i^2(x_{i+1/2}^1)| + |\hat{\varrho}_i^2(x_{i+1/2}^1) - \hat{\varrho}_i^2(x_{i+1/2}^2)|.$$

For the first term on the right-hand side, (A.2) can be used to give a bound of the form $\mathcal{ESST}\|S_1 - S_2\|_1$, where the abbreviation $\mathcal{ESST}$ means "exponentially small term," i.e., a term of the form $\exp(-\kappa/\varepsilon)$ with $\kappa > 0$. For the second term we use (A.3) and the fact that $\partial_x \hat{\varrho}_i^2$ is exponentially small in A_2 to obtain an estimate of the same type. Interchanging the roles of S_1 and S_2, the same can be done for $x_{i+1/2}^2 < x_{i+1/2}^1$. A consequence of these results is

$$|\Delta\varrho_i^1 - \Delta\varrho_i^2| \le \mathcal{ESST}\|S_1 - S_2\|_1 \tag{A.4}$$

for $1 \le i \le M$. Combining (A.2) and (A.4), we have

$$|\tilde{\varrho}[S_1](x) - \tilde{\varrho}[S_2](x)| \le \left[\mathcal{EST} + \exp\left(-\frac{\delta|x_i - x|}{\varepsilon}\right)\frac{|x - x_i|}{\varepsilon}\right]\|S_1 - S_2\|_1, \tag{A.5}$$

for $1 \le i \le M$ and $\max\{x_{i-1/2}^1, x_{i-1/2}^2\} < x < \min\{x_{i+1/2}^1, x_{i+1/2}^2\}$. It remains to consider $\eta_{i+1/2} := \min\{x_{i+1/2}^1, x_{i+1/2}^2\} < x < \max\{x_{i+1/2}^1, x_{i+1/2}^2\}$:

$$|\tilde{\varrho}[S_1](x) - \tilde{\varrho}[S_2](x)| \le |\tilde{\varrho}[S_1](\eta_{i+1/2}) - \tilde{\varrho}[S_2](\eta_{i+1/2})| + \mathcal{ESST}|x - \eta_{i+1/2}|,$$

since $\partial_x \tilde{\varrho}[S_l]$ is exponentially small in A_2. For the first term on the right-hand side we use (A.5) and for the second (A.3), to obtain

$$|\tilde{\varrho}[S_1](x) - \tilde{\varrho}[S_2](x)| \le \mathcal{ESST}\|S_1 - S_2\|_1, \tag{A.6}$$

for $0 \le i \le M$ and $\min\{x_{i+1/2}^1, x_{i+1/2}^2\} < x < \max\{x_{i+1/2}^1, x_{i+1/2}^2\}$. Since the integral of the second term in the bracket in (A.5) is $O(\varepsilon)$, a combination of (A.5) and (A.6) leads to

$$\|\tilde{\varrho}[S_1] - \tilde{\varrho}[S_2]\|_2 \le c\,\varepsilon\|S_1 - S_2\|_1,$$

and, with Lemma A.1,

$$\|F[S_1] - F[S_2]\|_1 \le c\,\varepsilon\|S_1 - S_2\|_1,$$

showing that F is a contraction for ε small enough, and thus completing the proof of the theorem. □

Finally, it will be shown by formal asymptotic arguments that it is asymptotically correct to approximate $\tilde{S}$ by $\bar{S}_\infty$ in the right-hand sides of the ODEs (4.17)–(4.19). It is easily seen that the exponentially small terms in the $\Delta\varrho_i$ are approximated with a $O(\varepsilon)$ relative error if the chemoattractant density $\tilde{S}$ is approximated up to $O(\varepsilon^2)$. This holds for $\bar{S}_\infty$ since

$$\begin{aligned}
\tilde{S}(x) - \bar{S}_\infty(x) &= \int_0^L G(x,y)(\tilde{\varrho}[\tilde{S}](y) - \bar{\varrho}_\infty(y))dy \\
&= \sum_{i=1}^M \int_{\tilde{x}_{i-1/2}}^{\tilde{x}_{i+1/2}} G(x,y)(\hat{\varrho}_i[\tilde{S}](y) - \bar{\varrho}_\infty(y) - \Delta\varrho_i)dy \\
&= \varepsilon\sum_{i=1}^M (-1)^{k_i} G(x,x_i)\left(\int_0^\infty \frac{d\xi}{1+\exp(|\partial_x\tilde{S}(x_i)|\xi)}\right. \\
&\qquad\qquad \left. - \int_{-\infty}^0 \frac{d\xi}{1+\exp(-|\partial_x\tilde{S}(x_i)|\xi)}\right) + O(\varepsilon^2) \\
&= O(\varepsilon^2).
\end{aligned}$$

The third equality is due to the substitution $y = x_i + \varepsilon\xi$ and straightforward Taylor expansion.

TOUCHDOWN AND PULL-IN VOLTAGE BEHAVIOR OF A MEMS DEVICE WITH VARYING DIELECTRIC PROPERTIES*

YUJIN GUO†, ZHENGUO PAN†, AND M. J. WARD†

Abstract. The pull-in voltage instability associated with a simple MEMS device, consisting of a thin dielectric elastic membrane supported above a rigid conducting ground plate, is analyzed. The upper surface of the membrane is coated with a thin conducting film. In a certain asymptotic limit representing a thin device, the mathematical model consists of a nonlinear partial differential equation for the deflection of the thin dielectric membrane. When a voltage V is applied to the conducting film, the dielectric membrane deflects towards the bottom plate. For a slab, a circular cylindrical, and a square domain, numerical results are given for the saddle-node bifurcation value V_*, also referred to as the pull-in voltage, for which there is no steady-state membrane deflection for $V > V_*$. For $V > V_*$ it is shown numerically that the membrane dynamics are such that the thin dielectric membrane touches the lower plate in finite time. Results are given for both spatially uniform and nonuniform dielectric permittivity profiles in the thin dielectric membrane. By allowing for a spatially nonuniform permittivity profile, it is shown that the pull-in voltage instability can be delayed until larger values of V and that greater pull-in distances can be achieved. Analytical bounds are given for the pull-in voltage V_* for two classes of spatially variable permittivity profiles. In particular, a rigorous analytical bound V_1, which depends on the class of permittivity profile, is derived that guarantees for the range $V > V_1 > V_*$ that there is no steady-state solution for the membrane deflection and that finite-time touchdown occurs. Numerical results for touchdown behavior, both for $V > V_1$ and for $V_* < V < V_1$, together with an asymptotic construction of the touchdown profile, are given for both a spatially uniform and a spatially nonuniform permittivity profile.

1. Introduction.

Microelectromechanical systems (MEMS) combine electronics with micro-size mechanical devices to design various types of microscopic machinery. MEMS devices are key components of many commercial systems, including accelerometers for airbag deployment in automobiles, ink jet printer heads, and chemical sensors. Mathematical models of physical phenomena associated with the rapidly developing field of MEMS technology are discussed in [13].

A key component of many MEMS systems is the simple device shown in Figure 1. The upper part of this device consists of a thin deformable elastic membrane that is held fixed along its boundary. This membrane is modeled as a dielectric of a thin, but finite, thickness. The upper surface of this membrane is coated with a negligibly thin metallic conducting film. The thin dielectric membrane lies above a rigid inelastic conducting ground plate. When a voltage V is applied to the conducting film, the thin dielectric membrane deflects towards the ground plate. A similar deflection phenomenon, but on a macroscopic length scale, occurs in the field of electrohydrodynamics. In this context, Taylor [17] studied the electrostatic deflection of two oppositely charged soap films, and he predicted a critical voltage for which the

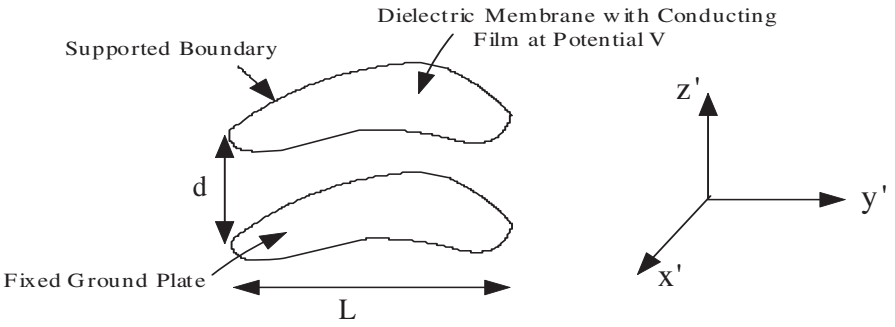

FIG. 1. *The MEMS capacitor. The upper surface of the elastic membrane is coated with an ultrathin conducting film.*

two soap films would touch together.

A similar physical limitation on the applied voltage occurs for the MEMS device of Figure 1 in that there is a maximum voltage, called the pull-in voltage V_*, that can be safely applied to the system. More specifically, if the applied voltage V is increased past V_*, there is no longer a steady-state solution for the membrane deflection (cf. [11], [14]). The existence of such a pull-in voltage was first demonstrated for a lumped mass-spring model of electrostatic actuation in the pioneering study of [10], where the restoring force of the deflected membrane is modeled by a Hookean spring. In this lumped model the attractive inverse square law electrostatic force between the membrane and the ground plate dominates the restoring force of the spring for small gap sizes and large applied voltages. This leads to a touchdown or snap-through behavior whereby the membrane hits the ground plate when the applied voltage is sufficiently large. Although the lumped model qualitatively predicts the existence of a pull-in voltage and the snap-through phenomenon, it cannot quantitatively account for details such as membrane geometry.

A more detailed mathematical model of this phenomena, leading to a partial differential equation (PDE) for the dimensionless deflection u of the membrane, was derived and analyzed in [6], [11], [12], [14], and [15] (see also the references therein). In the damping-dominated limit, and by modeling the thin dielectric as a membrane with zero rigidity, a narrow-gap asymptotic analysis was used in [6] and [14] to derive that u satisfies

$$\frac{\partial u}{\partial t} = \Delta u - \frac{\lambda f(x,y)}{(1+u)^2}, \quad x \in \Omega; \qquad u = 0, \quad (x,y) \in \partial\Omega; \qquad u(x,y,0) = 0. \tag{1.1}$$

An outline of the derivation of (1.1) following that detailed in [14] and [6] is given in the appendix. In (1.1), λ characterizes the relative strength of electrostatic and mechanical forces in the system, and is given by

$$\lambda = \frac{\varepsilon_0 V^2 L^2}{2Td^3}. \tag{1.2}$$

Here V is the applied voltage, d is the undeflected gap size (see Figure 1), L and T are the length scale and tension of the membrane, respectively, and ε_0 is the permittivity of free space. In (1.1), Ω is a bounded domain in $\mathbb{R}^2$, and $f(x,y)$ is the *permittivity*

profile, defined in terms of the dielectric permittivity $\varepsilon_2(x,y)$ of the membrane, by

$$f(x,y) = \frac{\varepsilon_0}{\varepsilon_2(x,y)}. \tag{1.3}$$

The initial condition in (1.1) assumes that the membrane is initially undeflected and that the voltage is applied at time $t = 0$. Mathematically, the pull-in voltage is obtained from (1.2) in terms of the largest possible saddle-node bifurcation value λ_* of λ for which (1.1) has a steady-state solution.

In the actual design of a MEMS device there are several issues that must be considered. Typically, one of the primary device design goals is to achieve the maximum possible stable steady-state deflection, referred to as the *pull-in distance*, with a relatively small applied voltage V. Another consideration may be to increase the stable operating range of the device by increasing the pull-in voltage V_* subject to the constraint that the range of the applied voltage is limited by the available power supply. This increase in the stable operating range may be important for the design of microresonators. For other devices such as microvalves, where touchdown behavior is explicitly exploited, it is of interest to decrease the time for touchdown, thereby increasing the switching speed. One way of achieving larger values of λ_*, and hence larger values of V_*, while simultaneously increasing the pull-in distance, is to use a voltage control scheme imposed by an external circuit in which the device is placed (cf. [12]). This approach leads to a nonlocal problem for the deflection of the membrane (cf. [12]). A different approach, studied theoretically in [14], is to introduce a spatial variation in the dielectric permittivity $\varepsilon_2(x,y)$ of the membrane so that $\varepsilon_2(x,y)$ is largest, and consequently $f(x,y)$ smallest, in the region where the membrane deflection would normally be largest under a spatially uniform permittivity. For a power-law permittivity profile in a slab domain, this approach was shown in [14] to allow for an increase in both the pull-in voltage and the pull-in distance.

The first main goal of this paper is to extend the steady-state analysis in [14] by giving analytical and numerical results for the saddle-node value λ_* and the pull-in distance for (1.1) for some general classes of permittivity profiles $f(x,y)$. For the first class, we assume that $f(x,y)$ is bounded away from zero, so that

$$0 < C_0 \le f(x,y) \le 1, \qquad x \in \Omega. \tag{1.4}$$

For the second class of profile, we allow for part of the membrane to be perfectly conducting, so that

$$0 \le f(x,y) \le 1, \qquad x \in \Omega. \tag{1.5}$$

In Theorem 3.1 of [14], restated below in Theorem 2.1 of section 2, an upper bound for λ_* is obtained for permittivity profiles satisfying (1.4). This bound, however, does not apply to profiles satisfying (1.5). In particular, it does not apply to the power-law permittivity profiles considered in section 4 of [14], which vanish at one point in Ω. To treat this case, in Theorem 2.2 we use a different approach to obtain an upper bound for λ_* for permittivity profiles satisfying (1.5). In section 2.1 we give numerical results for λ_* for a power-law permittivity profile and an exponential permittivity profile, which satisfy (1.5) and (1.4), respectively. The precise forms for these profiles, which each depend on a parameter α, are given below in (2.16). Numerical results for λ_* and the pull-in distance as a function of α are given for a slab domain, a unit disk, and a square domain. For large values of α, these profiles

are such that $f(x,y) \ll 1$ except in a boundary layer near $\partial\Omega$. In this limit, we derive a scaling law for $\lambda*$.

The second main goal of this paper is to analyze and compute time-dependent touchdown behavior for (1.1) for permittivity profiles satisfying either (1.4) or (1.5). The solution u of (1.1) is said to touchdown at finite time if the minimum value of u reaches -1 at some $t = T_* < \infty$. At such a time, the membrane touches the bottom fixed plate. In section 3.1 we determine bounds on λ for which touchdown occurs in finite time. This approach also yields bounds on the touchdown time T_*. The first bound, which is obtained from the method of [6] (see also [16]), applies to a permittivity profile satisfying (1.4). The second bound applies to a permittivity profile satisfying (1.5).

In section 3.2 we analytically construct the local touchdown profile for the constant permittivity profile $f(x,y) \equiv 1$. To do so, we introduce a nonlinear change of variables in a manner similar to that used in [8] to determine the local behavior of the solution to a semilinear heat equation near the blow-up time and blow-up location. This approach leads to a PDE that has smooth solutions near the touchdown point. By constructing a formal power series solution for this PDE, the local form of the touchdown profile is obtained. As discussed in [8], this transformed PDE is also readily amenable to numerical computations. In this way, touchdown behavior is computed numerically. In section 3.3, we briefly construct the local touchdown profile for the constant permittivity profile $f(x,y) \equiv 1$ by using a formal center manifold analysis of a PDE that results from a near-similarity group transformation of (1.1). Such a dynamical systems approach has been used previously in [5] to study quenching behavior in one space dimension and in [4] to study blow-up behavior for a semilinear heat equation in N space dimensions. Another approach for studying quenching behavior is given in [7].

In section 4 we give some asymptotic results for the touchdown profile for spatially variable permittivity profiles. Numerical results of touchdown behavior are also shown. Finally, in section 5, we list a few open mathematical problems.

2. The pull-in voltage: Location of a saddle-node value. In this section we study the steady-state deflection u, which satisfies

$$\Delta u = \frac{\lambda f(x)}{(1+u)^2}, \quad x \in \Omega; \qquad u = 0, \quad x \in \partial\Omega; \qquad u > -1. \tag{2.1}$$

Here we let $x = (x,y)$, and $\Omega \in \mathbb{R}^2$ is a bounded domain. For several domain shapes Ω and permittivity profiles f, we compute the maximum value of λ, labeled by λ_*, for which (2.1) has a solution. This then determines the pull-in voltage from (1.2). Bounds for λ_* are also obtained. The bounds on λ_* derived below are characterized in terms of the smallest eigenvalue $\mu_0 > 0$, with corresponding eigenfunction ϕ_0, of the Dirichlet eigenvalue problem

$$\Delta\phi + \mu\phi = 0, \quad x \in \Omega; \qquad \phi = 0, \quad x \in \partial\Omega. \tag{2.2}$$

The following result for λ_* was proved in [14].

THEOREM 2.1. *Suppose that $f(x)$ satisfies*

$$0 < C_0 \le f(x) \le 1, \quad x \in \Omega. \tag{2.3}$$

Then, there exists a $\lambda_* < \infty$ *such that there is no solution to* (2.1) *for* $\lambda > \lambda_*$. *Moreover, we have the bound*

$$\lambda_* \le \bar{\lambda}_1 \equiv \frac{4\mu_0}{27C_0}. \tag{2.4}$$

Proof. This is Theorem 3.1 of [14]. We only briefly sketch the proof here. We fix the sign $\phi_0 > 0$ in Ω. We multiply (2.1) by ϕ_0, integrate the resulting equation over Ω, and use Green's identity to get

$$\int_\Omega \left(\mu_0 u + \frac{\lambda f(x)}{(1+u)^2}\right)\phi_0\,dx = 0. \tag{2.5}$$

Since $f(x) \ge C_0 > 0$ and $\phi_0 > 0$, the equality in (2.5) is impossible when

$$\mu_0 u + \frac{\lambda C_0}{(1+u)^2} > 0 \quad \text{for all } u > -1. \tag{2.6}$$

Clearly (2.6) holds for λ sufficiently large, which proves that λ_* is finite. A simple calculation using (2.6) shows that (2.6) holds when $\lambda > \bar{\lambda}_1$, where $\bar{\lambda}_1$ is given in (2.4). ∎

As shown below, the bound (2.4) on λ_* is rather good for the constant permittivity profile $f(x) \equiv 1$. However, since this bound relies on the minimum of $f(x)$ on Ω, it cannot be used to estimate λ_* for the power-law permittivity profile $f(x) = |x|^\alpha$ with $\alpha > 0$ considered in [14]. For such a profile, $C_0 = 0$ in (2.3). Therefore, it is desirable to obtain a bound on λ_* that depends on more global properties of $f(x)$. Such a bound is given in the next result.

THEOREM 2.2. *Suppose that* $f(x)$ *satisfies*

$$0 \le f(x) \le 1, \quad x \in \Omega, \tag{2.7}$$

where $f > 0$ *on a set of positive measure. Then, for some* $\lambda_* < \infty$, *there is no solution to* (2.1) *for* $\lambda > \lambda_*$. *Moreover, in terms of the eigenfunction* ϕ_0 *of* (2.2) *normalized by* $\int_\Omega \phi_0\,dx = 1$, *we have the bound*

$$\lambda_* \le \bar{\lambda}_2 \equiv \frac{\mu_0}{3}\left(\int_\Omega f\phi_0\,dx\right)^{-1}. \tag{2.8}$$

Proof. The proof that λ_* is finite follows from (2.5). To obtain the bound (2.8), we take $\phi_0 > 0$ and we normalize ϕ_0 so that $\int_\Omega \phi_0\,dx = 1$. We then multiply (2.1) by $\phi_0(1+u)^2$ and integrate the resulting equation over Ω to get

$$\int_\Omega \lambda f\phi_0\,dx = \int_\Omega \phi_0(1+u)^2\Delta u\,dx. \tag{2.9}$$

Using the identity $\nabla\cdot(Hg) = g\nabla\cdot H + H\cdot\nabla g$ for any smooth scalar field g and vector field H, together with the divergence theorem, we calculate

$$\int_\Omega \lambda f\phi_0\,dx = \int_{\partial\Omega}(1+u)^2\phi_0\nabla u\cdot\hat{n}\,dS - \int_\Omega \nabla u\cdot\nabla\left[\phi_0(1+u)^2\right]\,dx, \tag{2.10}$$

where $\hat{n}$ is the unit outward normal to $\partial\Omega$. Since $\phi_0 = 0$ on $\partial\Omega$, the first term on the right-hand side of (2.10) vanishes. By calculating the second term on the right-hand

side of (2.10), and noting that $u > -1$, we estimate

$$\int_\Omega \lambda f \phi_0 \, dx = -\int_\Omega 2(1+u)\phi_0 |\nabla u|^2 \, dx - \int_\Omega (1+u)^2 \nabla u \cdot \nabla \phi_0 \, dx \tag{2.11a}$$

$$\leq -\int_\Omega \frac{1}{3} \nabla \phi_0 \cdot \nabla \left[(1+u)^3 \right] \, dx. \tag{2.11b}$$

The right-hand side of (2.11b) is evaluated explicitly, with the result

$$\int_\Omega \lambda f \phi_0 \, dx \leq -\frac{1}{3} \int_{\partial\Omega} (1+u)^3 \nabla \phi_0 \cdot \hat{n} \, dS - \frac{\mu_0}{3} \int_\Omega (1+u)^3 \phi_0 \, dx. \tag{2.12}$$

For $u > -1$, the last term on the right-hand side of (2.12) is positive. Moreover, $u = 0$ on $\partial\Omega$, and from (2.2) we get that $\int_{\partial\Omega} \nabla \phi_0 \cdot \hat{n} \, dS = -\mu_0$ since $\int_\Omega \phi_0 \, dx = 1$. Therefore, if (2.1) has a solution, then, from (2.12), we must have that

$$\lambda \int_\Omega f \phi_0 \, dx \leq \frac{\mu_0}{3}. \tag{2.13}$$

This proves that there is no solution to (2.1) for $\lambda > \bar{\lambda}_2$, where $\bar{\lambda}_2$ is given in (2.8). ∎

2.1. Some explicit examples. We now compute λ_* numerically for several choices of the domain Ω and the permittivity profile $f(x)$. In the computations below we consider three choices for Ω,

$$\begin{aligned} &\Omega : [-1/2, 1/2] \quad \text{(slab)}, \quad \Omega : x^2 + y^2 \leq 1 \quad \text{(unit disk)}, \\ &\Omega : [0, \sqrt{\pi}] \times [0, \sqrt{\pi}] \quad \text{(square)}. \end{aligned} \tag{2.14}$$

The unit disk and the square are chosen to have the same area. To compute the bounds $\bar{\lambda}_1$ and $\bar{\lambda}_2$, we must calculate the first eigenpair μ_0 and ϕ_0 of (2.2), normalized by $\int_\Omega \phi_0 \, dx = 1$. A simple calculation yields that

$$\mu_0 = \pi^2, \qquad \phi_0 = \frac{\pi}{2} \sin\left[\pi \left(x + \frac{1}{2} \right) \right] \quad \text{(slab)}, \tag{2.15a}$$

$$\mu_0 = z_0^2 \approx 5.783, \qquad \phi_0 = \frac{z_0}{J_1(z_0)} J_0(z_0 |x|) \quad \text{(unit disk)}, \tag{2.15b}$$

$$\mu_0 = 2\pi, \qquad \phi_0 = \frac{\pi}{4} \sin\left(\sqrt{\pi} x \right) \sin\left(\sqrt{\pi} y \right) \quad \text{(square)}. \tag{2.15c}$$

Here J_0 and J_1 are Bessel functions, and $z_0 \approx 2.4048$ is the first zero of $J_0(z)$. The bounds $\bar{\lambda}_1$ and $\bar{\lambda}_2$ are obtained by substituting (2.15) into (2.4) and (2.8). However, $\bar{\lambda}_2$ must typically be evaluated by a numerical quadrature.

We first consider the constant permittivity profile $f(x) \equiv 1$. For the slab domain, the solution to (2.1) can be reduced to quadrature, and λ_* can be computed from a transcendental equation. To compute λ_* for the unit disk, the scale invariance property of (2.1) can be used as in [11] to reduce the boundary value problem (BVP) (2.1) to an initial value problem, which is then readily solved. Our method for determining λ_* for the disk and the slab uses the BVP solver COLSYS (cf. [1]) with a Newton iteration step to locate λ_*. This approach is similar to that employed in [18]

TABLE 1
Numerical results for the maximum value λ_* of λ for which (2.1) has a solution for the three domains of (2.14). The upper bounds $\bar{\lambda}_1$ and $\bar{\lambda}_2$ on λ_* given in (2.4) and (2.8) are also shown.

Ω	λ_*	$\bar{\lambda}_1$	$\bar{\lambda}_2$
(slab)	1.401	1.462	3.290
(unit disk)	0.789	0.857	1.928
(square)	0.857	0.931	2.094

for Arrhenius nonlinearities and is useful for computing λ_* below for spatially varying permittivity profiles. For the square domain, we compute λ_* using the nonlinear elliptic solver PLTMG (cf. [2]), which uses a finite-element discretization of (2.1) together with path-following methods to compute the solution as λ is varied. This software package allows for the accurate computation of saddle-node bifurcation points. In Table 1 we give numerical results for λ_* for the three domains of (2.14) together with numerical values for the bounds $\bar{\lambda}_1$ and $\bar{\lambda}_2$. Notice that the bound for $\bar{\lambda}_1$ is rather close to λ_*, and is better than that of $\bar{\lambda}_2$. In Figure 2(a) we plot the bifurcation diagram $|u(0)|$ versus λ for the slab domain and for the unit disk. For $\lambda = \lambda_*$, in Figure 2(b) we plot u versus $|x|$ for the slab domain and for the unit disk. In Figure 3(a) we plot the bifurcation diagram for the square domain. For this domain, in Figure 3(b) we show a surface plot of u versus (x, y) when $\lambda = \lambda_*$. The computations were done with 1152 finite elements.

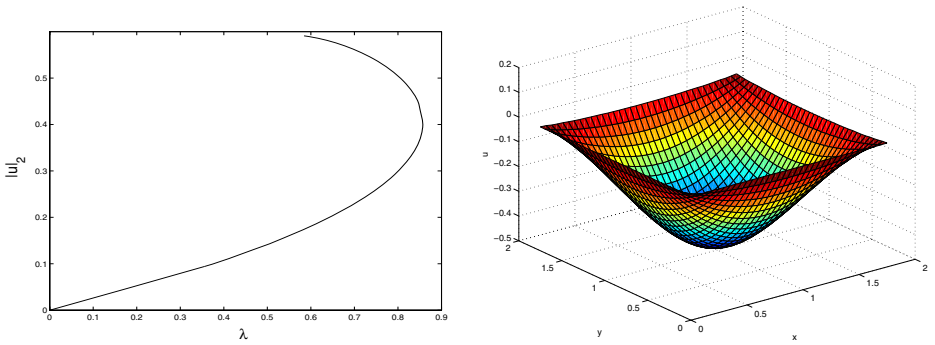
For each of the domains of (2.14), we now calculate λ_* for the following two forms of the permittivity profile $f(x)$:

$$\text{(2.16a)} \qquad \text{(slab)}: \quad f(x) = |2x|^\alpha \quad \text{(power-law)}, \quad f(x) = e^{\alpha(x^2-1/4)} \quad \text{(exponential)},$$

$$\text{(2.16b)} \quad \text{(unit disk)}: \quad f(x) = |x|^\alpha \quad \text{(power-law)}, \quad f(x) = e^{\alpha(|x|^2-1)} \quad \text{(exponential)},$$

$$\text{(2.16c)} \quad \text{(square)}: \quad f(x) = \left(\frac{2}{\pi}\right)^{\alpha/2} |x - x_0|^\alpha \quad \text{(power-law)},$$

$$f(x) = \exp\left(\alpha\left(\frac{2|x - x_0|^2}{\pi} - 1\right)\right),$$



(a) $|u|_2$ versus λ (b) u versus (x, y) at $\lambda = \lambda_*$

where $\alpha > 0$. In (2.16b) and (2.16c), $x \equiv (x, y)$ and $x_0 = (\sqrt{\pi}/2, \sqrt{\pi}/2)$ is the center of the square. For the domains of (2.14), we note that $0 \le f(x) \le 1$ for $x \in \Omega$. In addition, both the power-law and exponential profiles satisfy the property that the minimum of $f(x)$ occurs at the point where the deflection u of the upper membrane in Figure 1 is the largest. This effect leads to larger values of λ_* and, from (1.2), it increases the pull-in voltage. Physically, from (1.3), this corresponds to tailoring the dielectric permittivity ε_2 of the upper membrane so that ε_2 is significantly larger than the free-space permittivity ε_0 in regions where the membrane deflection will be largest. This idea of modifying the dielectric permittivity ε_2 to increase both λ_* and the pull-in distance was first introduced and studied in [14] for the slab and disk domains. For these domains, it was shown in [14] that (2.1) has a scaling invariance property under a power-law profile for $f(x)$. This property, which reduces (2.1) to the study of an ordinary differential equation (ODE), was used in [14] to give a detailed analysis of the bifurcation diagram of (2.1) for the slab and disk domains. Although the power-law profile for $f(x)$ is mathematically very convenient as a result of the scale invariance property, it is not so realistic from a modeling perspective, in that it predicts an infinite dielectric permittivity ε_2 at the center of the membrane. The exponential profile in (2.16) does not have this artifact of an infinite membrane permittivity.

For four values of α, in Figure 4 we plot the bifurcation diagram $|u(0)|$ versus λ for both the power-law and the exponential profiles. The plots are shown for both the slab and the unit disk. The bifurcation diagram of the steady-state problem shown in this figure is typical, in that the transition from existence to nonexistence is due to the first fold. A more detailed study of the bifurcation diagram for a slab geometry under a power-law profile was made in [14]. In [14] it was shown that for $0 \le \alpha < \alpha_c$, where $\alpha_c \equiv -\frac{1}{2} + \frac{1}{2}\sqrt{\frac{27}{2}}$, there is exactly one saddle-node point, and so at most two solutions to (2.1). Alternatively, for $\alpha > \alpha_c$, the bifurcation diagram has an infinite number of fold points, which tend to a common limiting value λ_{*c} as $u(0) \to -1^+$. Although the details of the solution multiplicity obtained in [14] are very interesting, they are not germane to the determination of λ_*.

In Figure 5(a) we plot the saddle-node value λ_* versus α for the slab domain. A

similar plot is shown in Figure 5(b) for the unit disk. The numerical computations were done using COLSYS [1] to solve the BVP (2.1) and Newton's method to determine the saddle-node point. Although Theorem 2.2 guarantees a pull-in voltage for any $\alpha > 0$, λ_* is seen to increase rapidly with α. Therefore, by increasing α, or equivalently by increasing the spatial extent where $f(x) \ll 1$, one can increase the

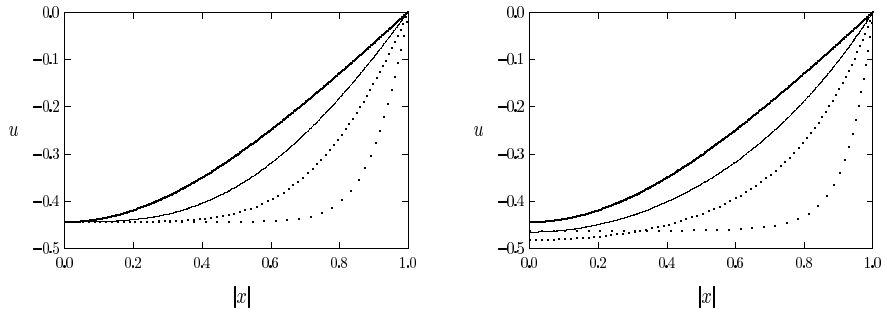
stable operating range of the MEMS capacitor. In Table 2 we give numerical results for λ_* together with the bounds $\bar{\lambda}_1$ and $\bar{\lambda}_2$ for the exponential permittivity profile computed from (2.4), (2.8), (2.15), and (2.16). A numerical quadrature is used to evaluate the integral defining $\bar{\lambda}_2$. From this table, we observe that the bound $\bar{\lambda}_1$ for λ_* is better than $\bar{\lambda}_2$ for small values of α. However, for $\alpha \gg 1$, we can use Laplace's method on the integral defining $\bar{\lambda}_2$ to obtain for the exponential permittivity profile that

$$\bar{\lambda}_1 = \frac{4b_1^2}{27} e^{c_1\alpha}, \qquad \bar{\lambda}_2 \sim c_2\alpha^2. \tag{2.17}$$

Here $b_1 = \pi^2$, $c_1 = 1/4$, $c_2 = 1/3$ for the slab domain, and $b_1 = z_0^2$, $c_1 = 1$, $c_2 = 4/3$ for the unit disk, where z_0 is the first zero of $J_0(z) = 0$. Therefore, for $\alpha \gg 1$, the bound $\bar{\lambda}_2$ is better than $\bar{\lambda}_1$. A similar calculation can be done for the power-law profile. Recall for the power-law profile that $\bar{\lambda}_1$ is undefined. However, by using Laplace's method, we readily obtain for $\alpha \gg 1$ that $\bar{\lambda}_2 \sim \alpha^2/3$ for the unit disk and $\bar{\lambda}_2 \sim 4\alpha^2/3$ for the slab domain.

Next, we compute the pull-in distance for a slab domain for both the power-law and the exponential permittivity profiles. The pull-in distance, defined as the value of $|u(0)|$ at the fold point $\lambda = \lambda_*$, gives the maximum stable steady-state membrane deflection that can be achieved. For the slab domain, in Figure 6(a) we plot $|u(0)|$ versus α for both the power-law and the exponential conductivity profile. For the power-law profile, the plot of $|u(0)|$ versus α is equivalent to that in Figure 5.1 of



(a) power-law profile (b) exponential profile

FIG. 7. (a) *Plots of u versus $|x|$ at $\lambda = \lambda_*$ for $\alpha = 0$, $\alpha = 1$, $\alpha = 3$, and $\alpha = 10$, in the unit disk for the power-law profile.* (b) *Plots of u versus $|x|$ at $\lambda = \lambda_*$ for $\alpha = 0$, $\alpha = 2$, $\alpha = 4$, and $\alpha = 10$, in the unit disk for the exponential profile. In both figures the solution develops a boundary-layer structure near $|x| = 1$ as α is increased.*

[14]. A similar plot of $|u(0)|$ versus α is shown in Figure 6(b) for the unit disk. For the power-law profile in the unit disk we observe that $|u(0)| \approx 0.444$ for any $\alpha > 0$. Therefore, rather curiously, the power-law profile does not increase the pull-in distance for the unit disk. For the exponential profile we observe from Figure 6(b) that the pull-in distance is not a monotonic function of α. The maximum value occurs at $\alpha \approx 4.8$, where $\lambda_* \approx 15.11$ (see Figure 5(b)) and $|u(0)| = 0.485$. For $\alpha = 0$, we have $\lambda_* \approx 0.789$ and $|u(0)| = 0.444$. Therefore, since λ_* is proportional to V^2 from (1.2), we conclude that the exponential permittivity profile for the unit disk can increase the pull-in distance by roughly 9% if the voltage is increased by roughly a factor of four.

For device design purposes one of the primary goals is to maximize the pull-in distance over a certain allowable voltage range that is set by the power supply. To address this problem it would be interesting to formulate an optimization problem that computes a dielectric permittivity $f(x)$ that maximizes the pull-in distance for a prescribed range of the saddle-node threshold λ_*. However, such an optimization problem is beyond the scope of this study.

For the unit disk, in Figure 7(a) we plot u versus $|x|$ at $\lambda = \lambda_*$ for four values of α for the power-law profile. Notice that $u(0)$ is the same for each of these values of α. A similar plot is shown in Figure 7(b) for the exponential permittivity profile. From these figures, we observe that u has a boundary-layer structure when $\alpha \gg 1$. In this limit, $f(x) \ll 1$ except in a narrow zone near the boundary of the domain. For $\alpha \gg 1$ the pull-in distance $|u(0)|$ also reaches some limiting value (see Figures 6(a), 6(b), and 7). For the slab domain with an exponential permittivity profile, we remark that the limiting asymptotic behavior of $|u(0)|$ for $\alpha \gg 1$ is beyond the range shown in Figure 6(a).

For $\alpha \gg 1$, we now use a boundary-layer analysis to determine a scaling law for λ_* for both types of permittivity profiles and for either a slab domain or the unit disk. We illustrate the analysis for a power-law permittivity profile in the unit disk. For $\alpha \gg 1$, there is an outer region defined by $0 \le r \ll 1 - O(\alpha^{-1})$, and an inner region where $r - 1 = O(1/\alpha)$. In the outer region, where $\lambda r^\alpha \ll 1$, (2.1) reduces asymptotically to $\Delta u = 0$. Therefore, the leading-order outer solution is a constant

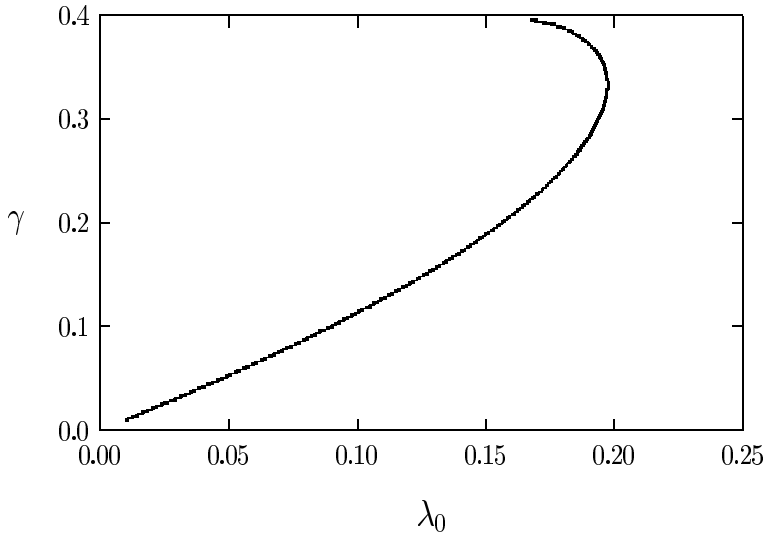


FIG. 8. *Bifurcation diagram of* $w'(0) = -\gamma$ *versus* λ_0 *from the numerical solution of* (2.19).

$u = A$. In the inner region, we introduce new variables w and ρ by

$$w(\rho) = u\left(1 - \frac{\rho}{\alpha}\right), \qquad \rho = \alpha(1 - r). \tag{2.18}$$

Substituting (2.18) into (2.1) with $f(r) = r^\alpha$, using the limiting behavior $(1 - \rho/\alpha)^\alpha \to e^{-\rho}$ as $\alpha \to \infty$, and defining $\lambda = \alpha^2\lambda_0$, we obtain the leading-order boundary-layer problem

$$w'' = \frac{\lambda_0 e^{-\rho}}{(1+w)^2}, \quad 0 \le \rho < \infty; \quad w(0) = 0, \quad w'(\infty) = 0, \qquad \lambda = \alpha^2\lambda_0. \tag{2.19}$$

In terms of the solution to (2.19), the leading-order outer solution is $u = A = w(\infty)$.

We define γ by $w'(0) = -\gamma$, for $\gamma > 0$, and we solve (2.19) numerically using COLSYS [1] to determine $\lambda_0 = \lambda_0(\gamma)$. In Figure 8 we plot $\lambda_0(\gamma)$ and show that this curve has a saddle-node point at $\lambda_0 = \lambda_{0*} \equiv 0.1973$. At this value, we compute $w(\infty) \approx 0.445$, which sets the limiting membrane deflection for $\alpha \gg 1$. Therefore, for $\alpha \gg 1$, the saddle-node value, from (2.19), has the scaling law behavior $\lambda_* \sim 0.1973\alpha^2$ for a power-law profile in the unit disk. A similar boundary-layer analysis can be done to determine the scaling law for λ_* when $\alpha \gg 1$ for the other cases. In each case we can relate λ_* to the saddle-node value of the boundary-layer problem (2.19). In this way, for $\alpha \gg 1$, we obtain

(2.20a)

$$\lambda_* \sim 4(0.1973)\alpha^2, \quad \bar{\lambda}_2 \sim \frac{4\alpha^2}{3} \quad \text{(power-law, slab) or (exponential, unit disk)},$$

(2.20b)

$$\lambda_* \sim (0.1973)\alpha^2, \quad \bar{\lambda}_2 \sim \frac{\alpha^2}{3} \quad \text{(power-law, unit disk) or (exponential, slab)}.$$

Notice that $\bar{\lambda}_2 = O(\alpha^2)$, with a factor that is about 5/3 times as large as the multiplier of α^2 in the asymptotic formula for λ_*. For an exponential profile and a power-law

7.0	56.38	132.6

profile in the unit disk, in Figure 9(a) and Figure 9(b), respectively, we show the close agreement between the full numerical value of λ_* and the asymptotic result (2.20).

For the square domain we use PLTMG (cf. [2]) to compute λ_* as a function of α. In Figure 10(a) we plot λ_* versus α for both the power-law and exponential profiles of (2.16c). In Table 3 we give numerical results for λ_* at different values of α for both

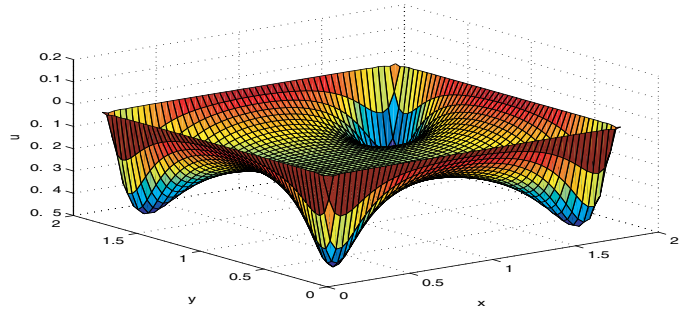

FIG. 11. *Plot of the numerical solution for u in the square domain at the fold point λ_* for the exponential permittivity profile with $\alpha = 8$. The maximum deflection now occurs near each of the four corners of the square, where the dielectric permittivity function f is the largest.*

profiles. The computations were done with 3200 finite elements. From this table we observe that λ_* increases rapidly with α. In Figure 10(b) we plot the pull-in distance $\max|u|$ versus α at $\lambda = \lambda_*$ for the exponential permittivity profile. This curve has the same qualitative shape as for the case of the unit disk shown in Figure 6(b). For the values of α shown in Figure 10(b) the maximum deflection occurs at the center of the square. For the power-law profile our numerical computations (not shown) indicate that, as for the case of the unit disk in Figure 6(a), the membrane deflection at $\lambda = \lambda_*$ is essentially independent of α, provided that α is not too large.

For $\alpha \gg 1$ the solution u under either a power-law or an exponential dielectric permittivity profile develops strong gradients in the localized regions where $f(x, y) \approx 1$. In contrast to the case of the unit disk, where $f \approx 1$ near the boundary $r = 1$, for the square domain we have $f \approx 1$ for $\alpha \gg 1$ only in small neighborhoods near each of the four corners of the square. Away from these corners we have $f \ll 1$ when $\alpha \gg 1$. In Figure 11, where we plot the numerical solution for u in the square domain at the fold point λ_* for the exponential permittivity profile with $\alpha = 8$, we observe that the maximum deflection now occurs near each of the corners of the square.

3. Touchdown behavior. We now study touchdown, or quenching, behavior for (1.1). The solution u of (1.1) is said to touchdown at finite time if the minimum value of u reaches -1 at some $t = T_* < \infty$. In section 3.1 we determine bounds on λ for which touchdown occurs in finite time. In section 3.2 we analytically construct the local touchdown profile for the case $f(x) \equiv 1$. For $f(x) \equiv 1$, in section 3.3 we briefly outline the construction of the local touchdown profile by using a formal center manifold analysis of a PDE, similar to that in [5] and [4], that results from a similarity group transformation of (1.1).

3.1. Bounds on touchdown behavior. Let μ_0 and ϕ_0 be the smallest eigenpair of (2.2). The first result is a minor modification of a key result in [6].

THEOREM 3.1. *Suppose that $f(x)$ satisfies*

$$0 < C_0 \le f(x) \le 1, \quad x \in \Omega, \tag{3.1}$$

and that $\lambda > \bar{\lambda}_1 \equiv \frac{4\mu_0}{27C_0}$. Then, the solution u of (1.1) reaches $u = -1$ at finite time.

Proof. Without loss of generality we assume that $\phi_0 > 0$ in Ω, and we normalize ϕ_0 so that $\int_\Omega \phi_0\, dx = 1$. Multiplying (1.1) by ϕ_0 and integrating over the domain, we

obtain

$$\frac{d}{dt}\int_\Omega \phi_0 u\,dx = \int_\Omega \phi_0 \Delta u\,dx - \int_\Omega \frac{\lambda\phi_0 f(x)}{(1+u)^2}\,dx. \tag{3.2}$$

Using Green's theorem, together with the lower bound in (3.1), we get

$$\frac{d}{dt}\int_\Omega \phi_0 u\,dx \le -\mu_0\int_\Omega \phi_0 u\,dx - \lambda C_0\int_\Omega \frac{\phi_0}{(1+u)^2}\,dx. \tag{3.3}$$

Next, we define an energy-like variable $E(t)$ by $E(t) = \int_\Omega \phi_0 u\,dx$, where $E(0) = 0$, so that

$$E(t) = \int_\Omega \phi_0 u\,dx \ge \inf_\Omega u \int_\Omega \phi_0\,dx = \inf_\Omega u. \tag{3.4}$$

Then, using Jensen's inequality on the second term on the right-hand side of (3.3), we obtain

$$\frac{dE}{dt} + \mu_0 E \le -\frac{\lambda C_0}{(1+E)^2}, \qquad E(0) = 0. \tag{3.5}$$

We then compare $E(t)$ with the solution $F(t)$ of

$$\frac{dF}{dt} + \mu_0 F = -\frac{\lambda C_0}{(1+F)^2}, \qquad F(0) = 0. \tag{3.6}$$

It then follows from standard comparison principles that $E(t) \le F(t)$ on their domains of existence. Therefore,

$$\inf_\Omega u \le E(t) \le F(t). \tag{3.7}$$

Next, we separate variables in (3.6) to determine t in terms of F. The touchdown time T_1 for F is obtained by setting $F = -1$ in the resulting formula. In this way, we get

$$T_1 \equiv \int_{-1}^{0} \left[\mu_0 s + \frac{\lambda C_0}{(1+s)^2}\right]^{-1} ds. \tag{3.8}$$

The touchdown time T_1 is finite when the integral in (3.8) converges. A simple calculation shows that this occurs when $\lambda > \bar{\lambda}_1 \equiv \frac{4\mu_0}{27C_0}$. Hence if T_1 is finite, then (3.7) implies that the touchdown time T_* of (1.1) must also be finite. Therefore, when $\lambda > \bar{\lambda}_1 = \frac{4\mu_0}{27C_0}$, we have that $T_* < T_1$, where T_1 is given in (3.8). □

Recalling Theorem 3.1 in [14], which was summarized in Theorem 2.1, we conclude that not only is there no steady-state solution for (1.1) when $\lambda > \bar{\lambda}_1$, but the corresponding time-dependent solution of (1.1) touches down in finite time. We are not able to obtain any theoretical information on touchdown behavior for the range $\lambda_* < \lambda < \bar{\lambda}_1$. The next result, using the approach of Theorem 2.2, establishes touchdown behavior for more general permittivity profiles $f(x)$, such as the power-law profile, that vanish at certain points in Ω.

THEOREM 3.2. *Suppose that f satisfies* (2.7)*, and that $\lambda > \bar{\lambda}_2$, where $\bar{\lambda}_2$ is defined in* (2.8)*. Then, the solution u of* (1.1) *reaches -1 at finite time.*

Proof. Let ϕ_0 and μ_0 be the smallest eigenpair of (2.2). We fix the sign $\phi_0 > 0$ in Ω, and we normalize ϕ_0 so that $\int_\Omega \phi_0\, dx = 1$. We multiply (1.1) by $\phi_0(1+u)^2$, and integrate the resulting equation over Ω to get

$$\frac{d}{dt}\int_\Omega \frac{\phi_0}{3}(1+u)^3\, dx = \int_\Omega \phi_0(1+u)^2\Delta u\, dx - \int_\Omega \lambda f\phi_0\, dx. \tag{3.9}$$

We calculate the first term on the right-hand side of (3.9) as in the proof of Theorem 2.2 to get

$$\begin{aligned}
&\frac{d}{dt}\int_\Omega \frac{\phi_0}{3}(1+u)^3\, dx \qquad\qquad (3.10a)\\
&\quad = -\int_\Omega \nabla u\cdot\nabla\left[\phi_0(1+u)^2\right]\, dx - \int_\Omega \lambda f\phi_0\, dx\\
&\quad = -\int_\Omega 2(1+u)\phi_0|\nabla u|^2\, dx - \int_\Omega \frac{1}{3}\nabla\phi_0\cdot\nabla\left[(1+u)^3\right]\, dx - \int_\Omega \lambda f\phi_0\, dx \qquad (3.10b)\\
&\quad \le -\frac{1}{3}\int_{\partial\Omega}\nabla\phi_0\cdot\hat{n}\, dS - \frac{\mu_0}{3}\int_\Omega (1+u)^3\phi_0\, dx - \int_\Omega \lambda f\phi_0\, dx. \qquad (3.10c)
\end{aligned}$$

Since $\int_\Omega \nabla\phi_0\cdot\hat{n}\, dS = -\mu_0$ and $u \ge -1$, we further estimate from (3.10c) that

$$\frac{dE}{dt} + \mu_0 E \le R, \qquad R \equiv \frac{\mu_0}{3} - \lambda\int_\Omega f\phi_0\, dx, \qquad E \equiv \frac{1}{3}\int_\Omega \phi_0(1+u)^3\, dx. \tag{3.11}$$

Next, we compare $E(t)$, which satisfies $E(0) = 1/3$, with the solution $F(t)$ of

$$\frac{dF}{dt} + \mu_0 F = R, \qquad F(0) = \frac{1}{3}. \tag{3.12}$$

By standard comparison principles and the definition of E, we obtain

$$\frac{1}{3}\inf_\Omega (1+u)^3 \le E(t) \le F(t). \tag{3.13}$$

Assume that $\lambda > \bar{\lambda}_2$, where $\bar{\lambda}_2$ is defined in (2.8). For this range of λ, we have that $R < 0$ in (3.11) and (3.12). For $R < 0$, we have that $F = 0$ at some finite time $t = T_2$. From (3.13), this implies that $E = 0$ at finite time. Thus, u has touchdown at some finite time $T_* < T_2$. Then, by calculating T_2 explicitly, we get the following bound on T_*:

$$T_* < T_2 \equiv -\frac{1}{\mu_0}\log\left[1 - \frac{\mu_0}{3\lambda}\left(\int_\Omega f\phi_0\, dx\right)^{-1}\right]. \tag{3.14}$$

The operation of a microvalve in MEMS technology explicitly exploits the existence of touchdown behavior in order to open and close a switch (see section 7.6 of [13]). The bounds on the touchdown time above relate to the time it takes to open such a valve, and thereby gives an estimate on the switching speed. To estimate the switching speed as a function of α, we label $I(\alpha) \equiv \int_\Omega f\phi_0\, dx$. For both the power-law and exponential permittivity profiles we calculate that $I'(\alpha) > 0$ and that $I(\alpha) \sim c\alpha^{-2}$ for $\alpha \gg 1$ for some $c > 0$. Therefore, from (3.14) we obtain that T_2 is an increasing function of α and that $T_2'(\alpha) \sim 2\alpha/(3c\lambda)$ for $\alpha \gg 1$. This suggests that the switching speed decreases as α increases. ∎

3.2. The touchdown profile $f(x) \equiv 1$: Transformed problem. We now construct a local expansion of the solution near the touchdown time and touchdown location by adapting the method of [8] used to analyze blow-up behavior. In the analysis below we assume that touchdown occurs at $x = 0$ and $t = T$. In the absence of diffusion, the time-dependent behavior of (1.1) is given by $u_t = -\lambda(1+u)^{-2}$. Integrating this differential equation and setting $u(T) = -1$, we get $(1+u)^3 = -3\lambda(t-T)$. This solution motivates the introduction of a new variable $v(x,t)$ defined in terms of $u(x,t)$ by

$$v = \frac{1}{3\lambda}(1+u)^3. \tag{3.15}$$

Notice that $u = -1$ maps to $v = 0$. In terms of v, (1.1) transforms exactly to

$$v_t = \Delta v - \frac{2}{3v}|\nabla v|^2 - 1, \quad x \in \Omega; \qquad v = \frac{1}{3\lambda}, \quad x \in \partial\Omega; \qquad v = \frac{1}{3\lambda}, \quad t = 0. \tag{3.16}$$

We will find a formal power series solution to (3.16) near $v = 0$ in dimension $N = 1$ and $N = 2$.

As in [8] we look for a locally radially symmetric solution to (3.16) in the form

$$v(x,t) = v_0(t) + \frac{r^2}{2!}v_2(t) + \frac{r^4}{4!}v_4(t) + \cdots, \tag{3.17}$$

where $r = |x|$. In dimension $N = 1$, such a form implies that the touchdown profile is locally even. We then substitute (3.17) into (3.16) and collect coefficients in r. In this way, we obtain the following coupled ODEs for v_0 and v_2:

$$v_0' = -1 + Nv_2, \qquad v_2' = -\frac{4}{3v_0}v_2^2 + \frac{(N+2)}{3}v_4. \tag{3.18}$$

We are interested in the solution to this system for which $v_0(T) = 0$, with $v_0' < 0$ and $v_2 > 0$ for $T - t > 0$ with $T - t \ll 1$. The system (3.18) has a closure problem in that v_2 depends on v_4. However, we will assume that $v_4 \ll v_2^2/v_0$ near the singularity. With this assumption, (3.18) reduces to

$$v_0' = -1 + Nv_2, \qquad v_2' = -\frac{4}{3v_0}v_2^2. \tag{3.19}$$

We now solve the system (3.19) asymptotically as $t \to T^-$ in a manner similar to that used in [8]. We first assume that $Nv_2 \ll 1$ near $t = T$. This leads to $v_0 \sim T - t$ and the following differential equation for v_2:

$$v_2' \sim \frac{-4}{3(T-t)}v_2^2 \quad \text{as } t \to T^-. \tag{3.20}$$

By integrating (3.20), we obtain that

$$v_2 \sim -\frac{3}{4\left[\log(T-t)\right]} + \frac{B_0}{\left[\log(T-t)\right]^2} + \cdots \quad \text{as } t \to T^-, \tag{3.21}$$

for some unknown constant B_0. From (3.21), we observe that the consistency condition that $Nv_2 \ll 1$ as $t \to T^-$ is indeed satisfied. Substituting (3.21) into (3.19) for

v_0, we obtain for $t \to T^-$ that

$$v_0' = -1 + N\left(-\frac{3}{4\left[\log(T-t)\right]} + \frac{B_0}{\left[\log(T-t)\right]^2} + \cdots\right). \tag{3.22}$$

Using the method of dominant balance, we look for a solution to (3.22) as $t \to T^-$ in the form

$$v_0 \sim (T-t) + (T-t)\left[\frac{C_0}{\left[\log(T-t)\right]} + \frac{C_1}{\left[\log(T-t)\right]^2} + \cdots\right], \tag{3.23}$$

for some C_0 and C_1 to be found. A simple calculation yields that

$$v_0 \sim (T-t) - \frac{3N(T-t)}{4|\log(T-t)|} - \frac{N\left(B_0 - 3/4\right)(T-t)}{|\log(T-t)|^2} + \cdots \quad \text{as } t \to T^-. \tag{3.24}$$

The local form for v near touchdown is $v \sim v_0 + r^2 v_0/2$. Using the leading term in v_2 from (3.21) and the first two terms in v_0 from (3.24), we obtain the local form

$$v \sim (T-t)\left[1 - \frac{3N}{4|\log(T-t)|} + \frac{3r^2}{8(T-t)|\log(T-t)|} + \cdots\right], \tag{3.25}$$

for $r \ll 1$ and $t - T \ll 1$. Finally, using the nonlinear mapping (3.15) relating u and v, we conclude that

$$u \sim -1 + \left[3\lambda(T-t)\right]^{1/3}\left(1 - \frac{3N}{4|\log(T-t)|} + \frac{3r^2}{8(T-t)|\log(T-t)|} + \cdots\right)^{1/3}. \tag{3.26}$$

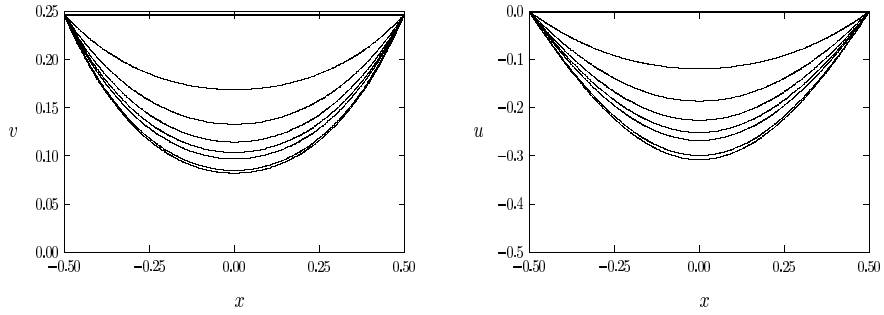
We note, as in [8], that if we use the local behavior $v \sim (T-t) + 3r^2/[8|\log(T-t)|]$, we get that

$$\frac{|\nabla v|^2}{v} \sim \left[\frac{2}{3}|\log(T-t)| + \frac{16(T-t)|\log(T-t)|^2}{9r^2}\right]^{-1}. \tag{3.27}$$

Hence, the term $|\nabla v|^2/v$ in (3.16) is bounded for any r, even as $t \to T^-$. This allows us to use a simple finite-difference scheme to compute numerical solutions to (3.16). With this observation, we now perform a few numerical experiments on the transformed problem (3.16). For the slab domain, we define v_j^m for $j = 1, \ldots, N+2$ to be the discrete approximation to $v(m\Delta t, -1/2 + (j-1)h)$, where $h = 1/(N+1)$ and Δt are the spatial and temporal mesh sizes, respectively. A second-order accurate in space and first-order accurate in time discretization of (3.16) is

$$v_j^{m+1} = v_j^m + \Delta t\left(\frac{\left(v_{j+1}^m - 2v_j^m + v_{j-1}^m\right)}{h^2} - 1 - \frac{\left(v_{j+1}^m - v_{j-1}^m\right)^2}{6v_j^m h^2}\right), \quad j = 2, \ldots, N+1, \tag{3.28}$$

with $v_1^m = v_{N+2}^m = (3\lambda)^{-1}$ for $m \geq 0$. The initial condition is $v_j^0 = (3\lambda)^{-1}$ for $j = 1, \ldots, N+2$. The time-step Δt is chosen to satisfy $\Delta t < h^2/4$ for the stability of the discrete scheme.



(a) v versus x (b) u versus x

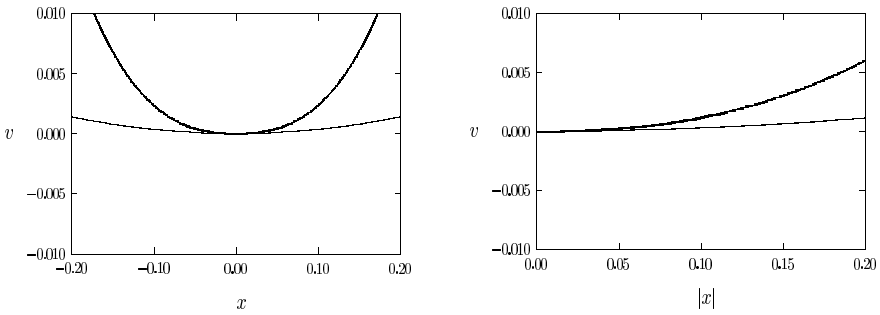
FIG. 13. *Experiment* 2: *for the slab domain and* $\lambda = 1.5 > \lambda_*$ *we plot* v *and* u *versus* x *at times* $t = (0, 0.1, 0.3, 0.5, 0.7, 1.0, 1.04, 1.06, 1.07, 1.07364)$ *from the discrete scheme* (3.28) *with* $N = 200$, *and* $\Delta t = 0.6 \times 10^{-5}$. *For this data, there is touchdown in finite time.*

Experiment 1. We consider the slab domain $|x| \leq 1/2$ with $\lambda = 1.35$. We take $\Delta t = 0.60 \times 10^{-5}$ and $N = 200$, so that $h = 0.49751 \times 10^{-2}$. Since $\lambda < \lambda_* \approx 1.401$ from Table 1, we expect that the time-dependent solution will approach the steady-state solution on the lower branch of the $|u(0)|$ versus λ bifurcation diagram. This is shown in Figure 12(a) and Figure 12(b), where we plot v and $u = -1 + (3\lambda v)^{1/3}$ versus x, respectively.

Experiment 2. Next, we consider the slab domain with $\lambda = 1.5$. From Table 1 we note that $\bar{\lambda}_2 > \lambda > \bar{\lambda}_1 > \lambda_*$. Therefore, Theorem 3.1 guarantees touchdown in a finite time T_* with $T_* < T_1$, where $T_1 = 2.040$ as computed numerically from (3.8). Since $\lambda < \bar{\lambda}_2$, the bound T_2 for the touchdown time, as given in (3.14), is undefined. For the discrete scheme (3.28) we took $\Delta t = 0.60 \times 10^{-5}$ and $N = 200$, so that $h = 0.49751 \times 10^{-2}$. To determine the touchdown time accurately, we took time-steps smaller than this value of Δt when the minimum value of v dropped below some small threshold. In this way, we found that touchdown occurs at $x = 0$ and at $T_* \approx 1.07366$. In Figure 13(a) and Figure 13(b) we plot v and $u = -1 + (3\lambda v)^{1/3}$ versus x, respectively, showing touchdown behavior in finite time.

In Figure 14(a) we compare the numerical approximation for v with the local



(a) slab domain: $t = 1.0736$ (b) unit disk: $t = 0.7228$

FIG. 14. *Plot of discrete approximation for v (heavy solid curve) and the local approximation for v (lighter curve) given in* (3.25). (a) *Slab domain with* $T = 1.07366$. (b) *Unit disk with* $T = 0.722858$.

behavior (3.25) at $t = 1.0736$. In (3.25) we set $N = 1$ and use $T = 1.07366$ for the touchdown time. From this figure we observe that the local asymptotic result (3.25) compares favorably with the numerical result. Note that if we took a coarser mesh with $N = 150$ meshpoints, so that $h = 0.66225 \times 10^{-2}$, and chose $\Delta t = 0.1 \times 10^{-4}$, then the touchdown time would be $T_* \approx 1.07357$.

Experiment 3. Next, we consider the unit disk with $f(x) \equiv 1$ and $\lambda = 1.0$. From Table 1 we note that $\bar{\lambda}_2 > \lambda > \bar{\lambda}_1 > \lambda_*$. Therefore, Theorem 3.1 guarantees touchdown in a finite time T_* with $T_* < T_1$, where $T_1 = 1.140$ as computed numerically from (3.8). Since $\lambda < \bar{\lambda}_2$, T_2 in (3.14) is undefined. A second-order accurate in space and first-order accurate in time discrete approximation to (3.16), with spatial meshsize h, on $0 \le r \le 1$ and $t \ge 0$ is

(3.29a)
$$v_j^{m+1} = v_j^m + \Delta t \left(\frac{\left(v_{j+1}^m - 2v_j^m + v_{j-1}^m\right)}{h^2} + \frac{\left(v_{j+1}^m - v_{j-1}^m\right)}{2hr_j} - 1 - \frac{\left(v_{j+1}^m - v_{j-1}^m\right)^2}{6v_j^m h^2} \right), \quad j = 2, \ldots, N+1,$$

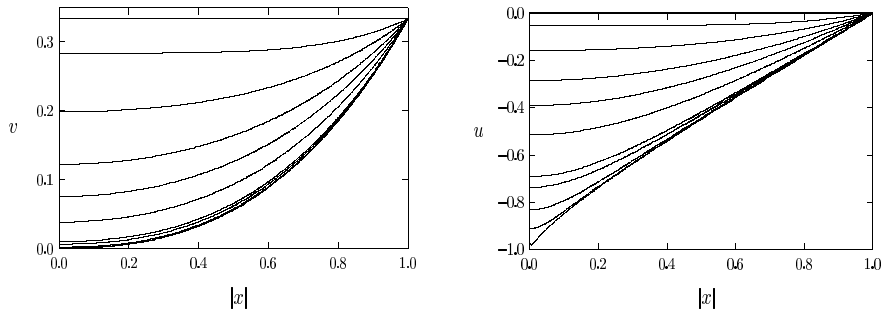
where $r_j = jh$. From [9, p. 50], the discrete approximation for v_1 at the origin $r = 0$ is

(3.29b)
$$v_1^{m+1} = v_1^m + \frac{4\Delta t}{h^2}\left(v_2^m - v_1^m\right).$$

The condition at $r = 1$ is $v_{N+2}^m = (3\lambda)^{-1}$. The results shown below are for $\Delta t = 0.6 \times 10^{-5}$ and $N = 200$, so that $h = 0.49751 \times 10^{-2}$. For these values, the touchdown time is found to be $T_* \approx 0.722858$.

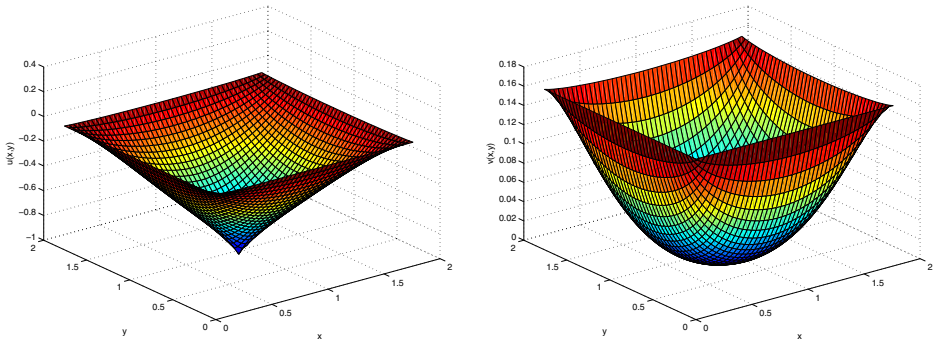
In Figure 15(a) and Figure 15(b) we plot v and $u = -1 + (3\lambda v)^{1/3}$, respectively, versus x, showing touchdown behavior in finite time. In Figure 14(b) we compare the numerical approximation for v with the local behavior (3.25) at $t = 0.7228$. In (3.25) we set $N = 2$ and use $T = 0.722858$ for the touchdown time.

Experiment 4. Finally, we give an example of touchdown behavior in the square domain $[0, \sqrt{\pi}] \times [0, \sqrt{\pi}]$ for the constant permittivity profile $f(x, y) \equiv 1$ with $\lambda = 2.0$. From Table 1 we note that $\bar{\lambda}_2 > \lambda > \bar{\lambda}_1 > \lambda_* \approx 0.857$. Therefore, Theorem 3.1 guarantees touchdown in a finite time T_* with $T_* < T_1$, where $T_1 = 0.2521$ as computed numerically from (3.8). Since $\lambda < \bar{\lambda}_2$, T_2 in (3.14) is undefined.



(a) v versus $|x|$ (b) u versus $|x|$

FIG. 15. *Experiment* 3: *For the unit disk and* $\lambda = 1.0$ *we plot* v *and* u *versus* $|x|$ *at times* $t = (0.05, 0.15, 0.30, 0.45, 0.60, 0.70, 0.71, 0.72, 0.7225, 0.722856)$. *For the discrete scheme* (3.29) *with* $N = 200$, *and* $\Delta t = 0.6 \times 10^{-5}$, *we compute the touchdown time* $T_* \approx 0.722858$.



(a) u versus (x, y) (b) v versus (x, y)

FIG. 16. *Experiment* 4: *For the square* $[0, \sqrt{\pi}] \times [0, \sqrt{\pi}]$ *and* $\lambda = 2.0$ *we show touchdown behavior. For the discrete scheme we used* $N = 150$ *meshpoints in the* x *and* y *directions and a time-step of* $\Delta t = 0.15 \times 10^{-4}$. (a) u *versus* (x, y) *at* $t = 0.1975$. (b) v *versus* (x, y) *at the same time.*

The discretization of (3.16) is similar to that given in (3.28). We use centered differences in x and y to compute discrete approximations to v_{xx} and v_{yy} for Δv. Centered differences are then used in x and y to compute $|\nabla v|^2$. An explicit Euler method is then used for the time integration. For a discretization of 150 meshpoints in each of the x and y directions, and with a time-step of $\Delta t = 0.15 \times 10^{-4}$, which is decreased near touchdown, we compute a touchdown time $T_* \approx 0.19751$. Notice that $T_1 = .2521$ is a reasonably good bound on the touchdown time. The touchdown point $(x_0, y_0) = (.880, .880)$ is at the center of the square. In Figure 16(a) we plot the numerically computed u versus (x, y) for $t = 0.1975$, which is very close to the singularity time. A plot of v versus (x, y) is shown in Figure 16(b).

3.3. The touchdown profile $f(x) \equiv 1$: Center manifold analysis. A different approach to determining the local touchdown profile when $f(x) \equiv 1$ is based on the center manifold analysis of a PDE that results from a similarity group transformation of (1.1). This approach was used in [5] for the case $N = 1$. A closely related method was used in [4] to determine the local blow-up profile for a semilinear heat

equation. We now briefly outline the results that can be derived this way. The first step is to introduce new variables by

$$u = -1 + (T-t)^{1/3} w\,(y,s)\,, \qquad s \equiv -\log(T-t), \qquad y \equiv \frac{x}{\sqrt{T-t}}. \tag{3.30}$$

With this transformation, (1.1) becomes

$$w_s = \frac{1}{\rho}\nabla\cdot(\rho\nabla w) + \frac{w}{3} - \frac{\lambda}{w^2}, \qquad \rho \equiv e^{-|y|^2/4}. \tag{3.31}$$

The touchdown profile as $t \to T^-$ is determined by the large s behavior of (3.31). For $s \gg 1$ and $|y|$ bounded, we have that $w = w_\infty + v$, where $v \ll 1$ and $w_\infty \equiv (3\lambda)^{1/3}$. Keeping the quadratic terms in v, we get

$$v_s = \frac{1}{\rho}\nabla\cdot(\rho\nabla w) + v + \gamma v^2 + O(v^3), \qquad \gamma = -(3\lambda)^{-1/3}. \tag{3.32}$$

As shown in [4] (see also [5]), the nullspace of the linearized operator in (3.32) is three-dimensional when $N = 2$ and is one-dimensional when $N = 1$. By projecting the nonlinear term in (3.32) against the nullspace of the linearized operator, the following far-field behavior of v for $s \to +\infty$ and $|y|$ bounded was obtained (see (1.7), (1.8) of [4]):

$$v \sim \frac{1}{4\gamma s}\left(1 - \frac{y^2}{2}\right), \quad N = 1; \qquad v \sim \frac{1}{2\gamma s}\left(1 - \frac{|y|^2}{2}\right), \quad N = 2. \tag{3.33}$$

The local touchdown profile is then obtained from $w \sim w_\infty + v$, (3.30), and (3.33), which yields

$$u \sim -1 + [3\lambda(T-t)]^{1/3}\left(1 - \frac{N}{4|\log(T-t)|} + \frac{|x|^2}{8(T-t)|\log(T-t)|}\right). \tag{3.34}$$

By making a binomial approximation of (3.26), it is easy to see that (3.26) agrees asymptotically with (3.34). A rigorous derivation of (3.34) for the case $N = 1$, using this type of center manifold analysis, was given in [5]. We also remark that the spatially independent term in (3.34) was proved rigorously in [3].

4. Touchdown behavior: Variable permittivity. In this section we obtain some numerical and formal asymptotic results for touchdown behavior associated with a spatially variable permittivity profile in a slab domain. With the transformation

$$v = \frac{1}{3\lambda}(1+u)^3, \tag{4.1}$$

the problem (1.1) for u in the slab domain, with permittivity profile $f(x)$, transforms exactly to

$$v_t = v_{xx} - \frac{2}{3v}v_x^2 - f(x), \quad |x| < \frac{1}{2}; \qquad v = \frac{1}{3\lambda}, \quad x = \pm\frac{1}{2}; \qquad v = \frac{1}{3\lambda}, \quad t = 0. \tag{4.2}$$

We now use the formal power series method of section 3.2 to locally construct a power series solution to (4.2) near the unknown touchdown point x_0 and the unknown

touchdown time T. We first assume that $f(x)$ is analytic at $x = x_0$ with $f(x_0) > 0$, so that for $x - x_0 \ll 1$ it has the convergent series expansion

$$f(x) = f_0 + f_0^{'}(x - x_0) + \frac{f_0^{''}(x - x_0)^2}{2} + \cdots , \tag{4.3}$$

where $f_0 \equiv f(x_0)$, $f_0^{'} \equiv f^{'}(x_0)$, and $f_0^{''} \equiv f^{''}(x_0)$. Near $x = x_0$, we look for a touchdown profile for (4.2) in the form

$$v(x,t) = v_0(t) + \frac{(x - x_0)^2}{2!}v_2(t) + \frac{(x - x_0)^3}{3!}v_3(t) + \frac{(x - x_0)^4}{4!}v_4(t) + \cdots . \tag{4.4}$$

In order for v to be a touchdown profile, it is clear that we must require that

$$\lim_{t \to T^-} v_0 = 0, \qquad v_0 > 0 \quad \text{for } t < T, \qquad v_2 > 0 \quad \text{for } t - T \ll 1. \tag{4.5}$$

Substituting (4.4) and (4.3) into (4.2), we equate powers of $x - x_0$ to obtain

$$v_0^{'} = -f_0 + v_2, \qquad v_2^{'} = -\frac{4v_2^2}{3v_0} + v_4 - f_0^{''}, \qquad v_3 = f_0^{'}. \tag{4.6}$$

As in section 3.2, we assume that $v_2 \ll 1$ and $v_4 \ll 1$ as $t \to T^-$. This yields that $v_0 \sim f_0(T - t)$ and

$$v_2^{'} \sim -\frac{4v_2^2}{3f_0(T - t)} - f_0^{''}. \tag{4.7}$$

For $t \to T^-$, we obtain from a simple dominant balance argument that

$$v_2 \sim -\frac{3f_0}{4\left[\log(T - t)\right]} + \cdots \quad \text{as } t \to T^-. \tag{4.8}$$

By substituting (4.8) into (4.6) for v_0 and integrating the resulting expression, we obtain

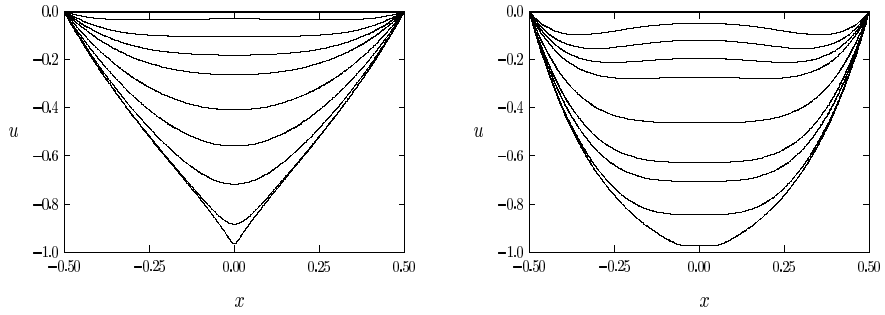
$$v_0 \sim f_0\,(T - t) + \frac{-3f_0(T - t)}{4|\log(T - t)|} + \cdots \quad \text{for } t \to T^-. \tag{4.9}$$

Next, we substitute (4.8), (4.9), and (4.6) for v_3 into (4.4) to obtain the local touchdown behavior

$$v \sim f_0\,(T - t)\left[1 - \frac{3}{4|\log(T - t)|} + \frac{3(x - x_0)^2}{8(T - t)|\log(T - t)|} + \frac{f_0^{'}(x - x_0)^3}{6f_0(T - t)} + \cdots\right], \tag{4.10}$$

for $(x - x_0) \ll 1$ and $t - T \ll 1$. Finally, using the nonlinear mapping (4.1) relating u and v, we conclude that

$$u \sim -1 + [3f_0\lambda(T - t)]^{1/3}\left(1 - \frac{3}{4|\log(T - t)|} + \frac{3(x - x_0)^2}{8(T - t)|\log(T - t)|} + \frac{f_0^{'}(x - x_0)^3}{6f_0(T - t)} + \cdots\right)^{1/3}. \tag{4.11}$$



(a) $\alpha = 2.0$, $\lambda = 5.0$ (b) $\alpha = 10.0$, $\lambda = 22.0$

FIG. 17. *Exponential permittivity profile.* (a) *Plot of u versus x at different times for $\alpha = 2.0$ and $\lambda = 5.0$. The touchdown time is $T_* \approx 0.1332$ and $\lambda_* \approx 2.14$.* (b) *Plot of u versus x at different times for $\alpha = 10.0$ and $\lambda = 22.0$. The touchdown time is $T_* \approx 0.1497$ and $\lambda_* \approx 10.4$. For both cases, the touchdown point is $x_0 = 0$.*

Here $f_0 \equiv f(x_0)$ and $f_0^{'} \equiv f^{'}(x_0)$.

Since $f(x) > 0$ for the exponential profile $f(x) = e^{\alpha(x^2-1/4)}$ of (2.16a), then (4.11) holds for some touchdown point x_0 and touchdown time T. If the touchdown point is at $x_0 = 0$, then (4.11) holds for $f_0 = e^{-\alpha/4}$, and $f_0^{'} = 0$. For two sets of α and λ, in Figure 17 we plot the numerically computed u versus x at different times showing touchdown behavior for the exponential permittivity profile. The bounds T_1 and T_2 on the touchdown time, given in (3.8) and (3.14), together with the numerically computed touchdown time T_* and saddle-node value λ_* are as follows:

(4.12a)

$$\alpha = 2.0, \quad \lambda = 5.0; \qquad \lambda_* \approx 2.14, \quad T_1 = 0.1697, \quad T_2 = 0.4030, \quad T_* \approx 0.1332,$$

(4.12b)

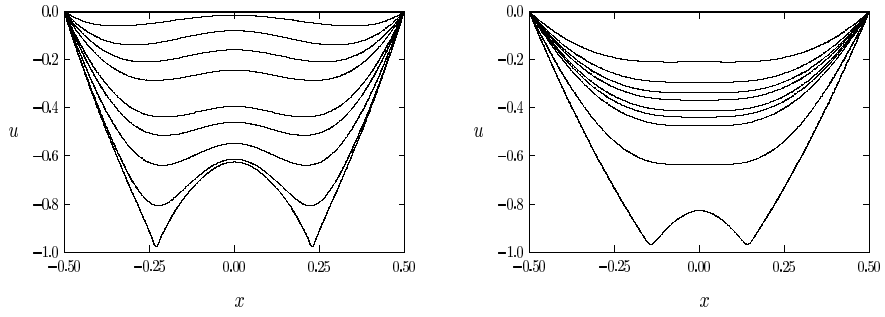
$$\alpha = 10.0, \quad \lambda = 22.0; \qquad \lambda_* \approx 10.40, \quad T_1 = 0.5321, \quad T_2 = 0.3281, \quad T_* \approx 0.1497.$$

In obtaining (4.12) we discretized (4.2) in a similar manner as in (3.28). The discrete approximation to u was then obtained from (4.1). The computations were done with a time-step of $\Delta t = 0.6\times 10^{-5}$ and with $N = 200$ meshpoints, so that $h = 0.4975\times 10^{-2}$. From Figure 17 we observe that touchdown occurs at $x_0 = 0$. For $\alpha = 10$, the touchdown profile is much flatter than that for $\alpha = 2$. This is because $f(0) = e^{-\alpha/4}$ is a decreasing function of α.

We remark that the touchdown profile (4.11) also holds for the power-law profile $f(x) = |2x|^\alpha$ of (2.16a) whenever the touchdown point x_0 is not at the origin, i.e., $x_0 \neq 0$. If this occurs, then (4.11) holds with

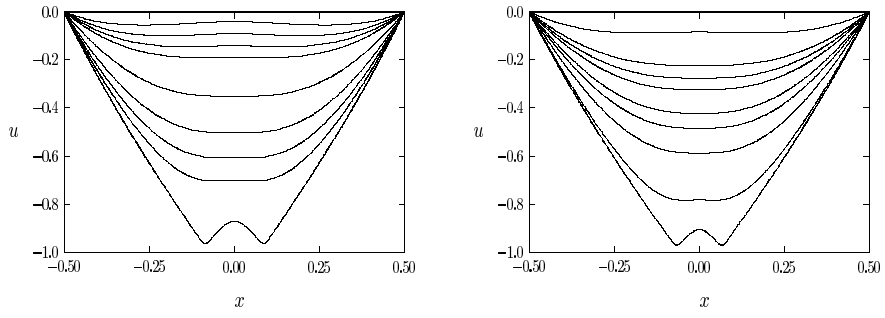
$$f_0 = |2x_0|^\alpha, \qquad f_0^{'} = 2\alpha|2x_0|^{\alpha-1}. \tag{4.13}$$

In Figure 18 we plot the numerically computed u versus x at different times, and for different sets of α and λ, showing touchdown behavior for the power-law profile. In this figure, the touchdown time T_* and the saddle-node value λ_* are shown for each parameter set. From these numerical results we observe that touchdown seems to occur at two points, symmetrically located about the origin. For each of the



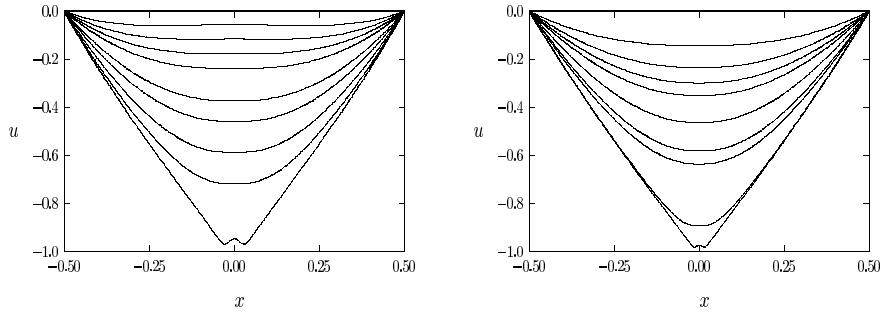
(a) $\alpha = 1.0$, $\lambda = 10.0$

(b) $\alpha = 1.0$, $\lambda = 4.5$



(c) $\alpha = 0.4$, $\lambda = 4.0$

(d) $\alpha = 0.4$, $\lambda = 3.0$



(e) $\alpha = 0.16$, $\lambda = 3.5$

(f) $\alpha = 0.16$, $\lambda = 2.0$

FIG. 18. *Power-law permittivity profile: Plots of u versus x at different times for the values of* α *and* λ *shown in the figure captions. The values for saddle-node point* λ_**, the touchdown time* T_**, and the touchdown points* x_0 *are as follows.* (a) $\lambda_* \approx 4.2$, $T_* \approx 0.1257$, $x_0 = \pm 0.226$. (b) $\lambda_* \approx 4.2$, $T_* \approx 1.887$, $x_0 = \pm 0.147$. (c) $\lambda_* \approx 2.41$, $T_* \approx 0.2366$, $x_0 = \pm 0.087$. (d) $\lambda_* \approx 2.41$, $T_* \approx 0.4857$, $x_0 = \pm 0.067$. (e) $\lambda_* \approx 1.77$, $T_* \approx 0.174$, $x_0 = \pm 0.027$. (f) $\lambda_* \approx 1.77$, $T_* \approx 0.746$, $x_0 = \pm 0.012$.

computations, we have taken $N = 200$ meshpoints, so that $h = 0.4975 \times 10^{-2}$, and a time step $\Delta t = 0.6 \times 10^{-5}$.

Next, we perform a more delicate computational experiment to determine whether touchdown can occur at $x = 0$ for the power-law profile. We take $\alpha = 0.01$ and $\lambda = 2.0$. Since $\alpha \ll 1$, this example represents a small perturbation of the constant

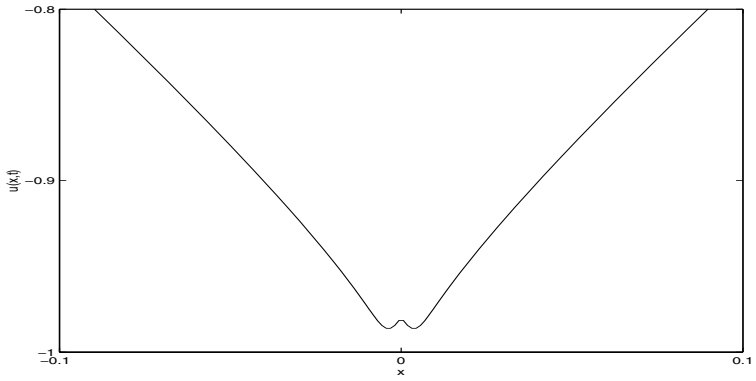


FIG. 19. *Plot of u versus x at $t = 0.34213$ near the touchdown region for the power-law profile with $\alpha = 0.01$ and $\lambda = 2.0$. Touchdown does not occur at $x = 0$, but rather at two points on either side of $x = 0$. The touchdown time is $T_* \approx 0.3422$.*

permittivity profile $f(x) \equiv 1$. Using $N = 800$ meshpoints, in Figure 19 we plot u versus x at $t = 0.34213$ in a neighborhood of the origin. The touchdown time is found to be $T_* \approx 0.3422$. From this figure, we observe that touchdown does not occur at $x = 0$. These computational results suggest the possibility that touchdown cannot occur at a point x_0, where $f(x_0) = 0$. We first investigate this possibility by using a formal power series analysis. Then, at the end of this section we prove a result in this direction. A consequence of this analysis is that touchdown at $x_0 = 0$ is impossible for the power-law profile $f(x) = |2x|^\alpha$.

We first assume that $f(x)$ is analytic at $x = 0$, with $f(0) = 0$ and $f'(0) = 0$, so that $f(x) = f_0 x^2 + O(x^3)$ as $x \to 0$ with $f_0 > 0$. We then look for a power series solution to (4.2) as in (4.4). In place of (4.6) for v_3, we get $v_3 = 0$, and

$$v_0' = v_2, \qquad v_2' = -\frac{4v_2^2}{3v_0} + v_4 - 2f_0. \tag{4.14}$$

Assuming that $v_4 \ll 1$ as before, we can combine the equations in (4.14) to get

$$v_0'' = -\frac{4(v_0')^2}{3v_0} - 2f_0. \tag{4.15}$$

By solving (4.15) with $v_0(T) = 0$, we obtain the exact solution

$$v_0 = -\frac{3f_0}{11}(T-t)^2, \qquad v_2 = \frac{6f_0}{11}(T-t). \tag{4.16}$$

Since the criteria (4.5) are not satisfied, the form (4.16) does not represent a touchdown profile centered at $x = 0$.

A similar calculation can be done for the case where $f(x)$ is analytic at $x = 0$, with $f(0) = 0$ and $f'(0) = f_0 > 0$. From a power series expansion solution centered at $x = 0$, and assuming that $v_4 \ll 1$, we get $v_3 = f_0$ and

$$v_0'' = -\frac{4(v_0')^2}{3v_0}, \qquad v_2 = v_0'. \tag{4.17}$$

In terms of some constant A, the explicit solution to (4.17) with $v_0(T) = 0$ is

$$v_0 = A\,(T-t)^{3/7}\,, \qquad v_2 = -\frac{3A}{7}\,(T-t)^{-4/7}\,. \tag{4.18}$$

Since v_0 and v_2 have opposite signs as $t \to T^-$, the criteria (4.5) do not hold, and we do not have touchdown at $x = 0$. These formal calculations suggest the general result that touchdown cannot occur at a point $x = x_0$, where $f(x_0) = 0$. Without loss of generality, we assume that $x_0 = 0$. Our final result is as follows.

THEOREM 4.1. *Let $u(x,t)$ be a solution of*

$$u_t = u_{xx} - \frac{\lambda f(x)}{u^2}, \qquad |x| \le \frac{1}{2}, \quad 0 < t < T; \qquad u\left(\pm\frac{1}{2}, t\right) = 1, \qquad u(x,0) = 1. \tag{4.19}$$

Here $f(x)$ satisfies (2.7)*, and u touches down at the finite time T. If $f(0) = 0$, then $x_0 = 0$ cannot be a touchdown point of $u(x,t)$ at finite time T.*

Proof. Set $v = u_t$. Then we calculate

$$v_t = v_{xx} + \frac{2\lambda f(x)}{u^3} v, \quad |x| \le \frac{1}{2}, \quad 0 < t < T; \qquad v\left(\pm\frac{1}{2}, t\right) = 0, \quad v(x,0) \le 0. \tag{4.20}$$

Here $\frac{2\lambda f(x)}{u^3}$ is a locally bounded function. By the strong maximum principle, we conclude that

$$u_t = v < 0, \qquad |x| < \frac{1}{2}, \quad 0 < t < T. \tag{4.21}$$

Therefore, since $f(0) = 0$, we have as $t \to T^-$ that $u_{xx} = u_t < 0$ at $x = 0$. From this result, and from the smoothness of $u(x,t)$, we deduce that when $t \to T^-$, there exists an $\bar{x} \neq 0$ such that $u(0,t) > u(\bar{x},t)$. This shows that $x_0 = 0$ cannot be a touchdown point of $u(x,t)$ at finite time T. ∎

5. Conclusion. We have analyzed some properties of the pull-in voltage instability for (1.1) in terms of a spatially variable dielectric permittivity profile for the thin elastic membrane. Bounds on the pull-in voltage were given in section 2, and sufficient conditions for finite-time touchdown were obtained in section 3, together with bounds on the touchdown time. From these bounds, and from numerical computations, it was shown that by appropriately tailoring the dielectric permittivity of the thin membrane the pull-in voltage and the pull-in distance can both be increased. For the special case of a power-law permittivity profile in a slab domain, this conclusion was first obtained in [14]. For voltages that exceed the pull-in voltage threshold, the local touchdown profile was calculated asymptotically in sections 3 and 4 for spatially uniform and spatially nonuniform permittivity profiles, respectively.

An interesting open problem is to formulate an optimization problem for the pull-in distance associated with the steady-state problem (1.1), whereby an optimum permittivity profile f can be computed numerically for a given set of design constraints on both the stable operating range of the applied voltage and maximum value of V that is available by the power supply.

Another way of tailoring the pull-in voltage, without introducing a spatially nonuniform permittivity profile, is to rigidly attach the thin membrane near the

region where the deflection would otherwise be largest. Mathematically this corresponds to considering (1.1) with $f(x,y) \equiv 1$, in a domain Ω punctured by a small patch Ω_ε of area $O(\varepsilon^2) \ll 1$, where $u = 0$ for $x \in \Omega_\varepsilon$. An asymptotic theory for the location of saddle-node bifurcation values for general classes of semilinear problems in such singularly perturbed domains was developed in [18]. For a MEMS device, symmetry-breaking properties of radially symmetric solutions for an annular domain were computed numerically in [15]. For this type of modification of (1.1), it would be interesting to obtain an analytical theory for the pull-in voltage instability.

Finally, it would be interesting to analyze pull-in voltage and touchdown behavior for extensions of the basic model (1.1), whereby the upper surface is modeled by an elastic plate of nonzero rigidity and inertial effects are considered. The resulting model for the deflection of a thin plate that has a spatially uniform permittivity profile involves the Biharmonic operator Δ^2 and takes the following form for some $\beta > 0$ and $\delta > 0$ (see (7.50) of [13]):

$$\beta \frac{\partial^2 u}{\partial t^2} + \frac{\partial u}{\partial t} - \Delta u + \delta \Delta^2 u = -\frac{\lambda}{(1+u)^2}, \quad x \in \Omega; \qquad u = 0, \quad (x,y) \in \partial\Omega; \qquad u(x,y,0) = 0. \tag{5.1}$$

Appendix. Derivation of the membrane deflection equation. Following the analysis in [14] and [6], we now outline the derivation of the membrane deflection equation (1.1). Referring to Figure 1, the electrostatic potential is assumed to satisfy Laplace's equation in the gap between the fixed plate and the lower surface of the membrane. Inside the thin membrane, the dielectric permittivity $\varepsilon_2 = \varepsilon_2(x,y)$ can exhibit a spatial variation. On the upper surface of the membrane, a fixed voltage V is imposed. Therefore, in dimensionless variables, the problem for the electrostatic potential is

$$\frac{\partial^2 \psi}{\partial z^2} + \delta^2 \left(\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} \right) = 0, \quad (x,y) \in \Omega, \quad 0 \le z \le \hat{u} - l, \tag{A.1a}$$

$$\varepsilon_2 \frac{\partial^2 \psi}{\partial z^2} + \delta^2 \left(\frac{\partial}{\partial x}\left(\varepsilon_2 \frac{\partial \psi}{\partial x} \right) + \frac{\partial}{\partial y}\left(\varepsilon_2 \frac{\partial \psi}{\partial y} \right) \right) = 0, \quad (x,y) \in \Omega, \quad \hat{u} - l \le z \le \hat{u} + l, \tag{A.1b}$$

$$\psi = 0, \quad z = 0 \text{ (ground plate)}; \qquad \psi = 1, \quad z = \hat{u} + l \text{ (upper membrane surface)}, \tag{A.1c}$$

together with the continuity of the potential and the displacement fields across $z = \hat{u} - l$. Here ψ is the dimensionless potential scaled with respect to the applied voltage V, x and y are scaled with respect to the length L of the undeformed plate Ω, z is a vertical coordinate scaled with respect to the undeformed gap-size d, $2l$ is the thickness of the membrane, and $\delta \equiv d/L \ll 1$ is the device aspect ratio. The deflection of the membrane is denoted by $\hat{u}$, with $\hat{u} = 1$ on $\partial\Omega$ denoting the undeflected state. Note that $\hat{u} = 0$ corresponds to the touching of the membrane and the lower plate and that $\hat{u}$ is scaled in the same manner as z.

In the small aspect ratio limit $\delta \ll 1$, the asymptotic solution for ψ that is continuous across $z = \hat{u} - l$ is

$$\psi = \begin{cases} \psi_L \frac{z}{\hat{u}-l}, & 0 \le z \le \hat{u} - l, \\ 1 + \frac{(1-\psi_L)}{2l}\left(z - (\hat{u} + l) \right), & \hat{u} - l \le z \le \hat{u} + l. \end{cases} \tag{A.2}$$

To ensure that the displacement field is continuous across $z = \hat{u} - l$ to leading order in δ, we must impose that $\varepsilon_0 \psi_z|_- = \psi_2 \psi_z|_+$, where the plus or minus signs indicate that ψ_z is to be evaluated on the upper or lower side, respectively, of the bottom surface $z = \hat{u} - l$ of the membrane. This condition determines ψ_L in (A.2) as

$$\psi_L = \left[1 + \frac{2l}{\hat{u} - l}\left(\frac{\varepsilon_0}{\varepsilon_2}\right)\right]^{-1}. \tag{A.3}$$

From (A.2) and (A.3), the electric field in the z-direction inside the membrane is independent of z, and is given by

$$\psi_z = \frac{\varepsilon_0}{\varepsilon_2(\hat{u} - l)}\left[1 + \frac{2l}{\hat{u} - l}\frac{\varepsilon_0}{\varepsilon_2}\right]^{-1} \sim \frac{\varepsilon_0}{\varepsilon_2 \hat{u}} \quad \text{for } l \ll 1. \tag{A.4}$$

The coupling of the electrostatic field to the deflection of the membrane was modeled in [6] by a dimensionless damped wave equation of the form

$$\gamma^2 \frac{\partial^2 \hat{u}}{\partial t^2} + \frac{\partial \hat{u}}{\partial t} - \Delta \hat{u} = -\lambda \left(\frac{\varepsilon_2}{\varepsilon_0}\right)\left[\delta^2 |\nabla_\perp \psi|^2 + \left(\frac{\partial \psi}{\partial z}\right)^2\right], \quad (x, y) \in \Omega, \quad \hat{u} - l \le z \le \hat{u} + l. \tag{A.5}$$

Here λ is defined in (1.2), the time t is scaled with respect to the strength of the damping, and $\nabla_\perp$ denotes the gradient in the x- and y-directions only. By substituting (A.4) into (A.5), and letting $\delta \ll 1$, we obtain

$$\gamma^2 \frac{\partial^2 \hat{u}}{\partial t^2} + \frac{\partial \hat{u}}{\partial t} - \Delta \hat{u} \sim -\lambda \frac{\varepsilon_0}{\varepsilon_2 \hat{u}^2}, \quad (x, y) \in \Omega; \qquad \hat{u} = 1, \quad (x, y) \in \partial\Omega. \tag{A.6}$$

We then define $u \equiv \hat{u} - 1$, so that $u = 0$ is the undeflected state. Finally, assuming that the damping force dominates the inertial force so that $\gamma \ll 1$, as was done in [6], (A.6) reduces to the membrane deflection equation (1.1) of section 1.

ON RECOVERING THE SHAPE OF A DOMAIN FROM THE TRACE OF THE HEAT KERNEL*

Z. SCHUSS† AND A. SPIVAK‡

Abstract. The problem of recovering geometric properties of a domain from the trace of the heat kernel for an initial-boundary value problem arises in NMR microscopy and other applications. It is similar to the problem of "hearing the shape of a drum," for which a Poisson-type summation formula relates geometric properties of the domain to the eigenvalues of the Dirichlet or Neumann problems for the Laplace equation. It is well known that the area, circumference, and the number of holes in a planar domain can be recovered from the short-time asymptotics of the solution of the initial-boundary value problem for the heat equation. It is also known that the length spectrum of closed billiard ball trajectories in the domain is contained in the spectral density of the Laplace operator with the given boundary conditions in the domain, from which the short-time hyperasymptotics of the trace of the heat kernel can be obtained by the Laplace transform. However, the problem of recovering these lengths from measured values of the trace of the heat kernel (the "resurgence" problem) is unresolved. In this paper we develop a simple algorithm for extracting the lengths from the short-time hyperasymptotic expansion of the trace. We give an alternative construction of the short-time expansion of the trace by constructing a ray approximation to the heat kernel for a planar domain with Dirichlet or Neumann boundary conditions. We evaluate the trace by introducing the rays as global coordinates.

Key words. heat kernel, trace, short-time asymptotics, eigenvalues

1. Introduction.

The problem of recovering geometric properties of a domain from NMR measurements arises in oil explorations and in noninvasive microscopy of cell structure [1], as well as in other applications. In these measurements the trace of the heat kernel for the initial value problem with reflecting (Neumann) boundary conditions is measured directly. The problem is analogous to "hearing the shape of a drum," where the solution of the wave equation in the domain is measured directly (it is "heard"). This problem consists in recovering geometrical properties of a domain from the eigenvalues of the Dirichlet or Neumann problems for the Laplace equation in a bounded domain.

Much attention has been devoted in the literature to the recovery problem (see [2], [3], [4], [5], [6], [7], [8], [9] for some history and early results; for more recent work see [10], [11] and the references therein). The mathematical statement of the problem is as follows. Green's function for the heat equation in a smooth planar domain Ω, with homogeneous Dirichlet boundary conditions, satisfies

$$\frac{\partial G(\boldsymbol{y},\boldsymbol{x},t)}{\partial t} = D\Delta_{\boldsymbol{y}} G(\boldsymbol{y},\boldsymbol{x},t) \quad \text{for} \quad \boldsymbol{y},\boldsymbol{x}\in\Omega,\ t>0, \tag{1.1}$$

$$G(\boldsymbol{y},\boldsymbol{x},0)=\delta(\boldsymbol{y}-\boldsymbol{x}), \tag{1.2}$$

$$G(\boldsymbol{y},\boldsymbol{x},t)=0 \quad \text{for} \quad \boldsymbol{y}\in\partial\Omega,\ \boldsymbol{x}\in\Omega,\ t>0. \tag{1.3}$$

Since D can be eliminated from (1.1) by scaling it into t, we assume henceforward that $D=1$. The function $G(\boldsymbol{x},\boldsymbol{x},t)\,d\boldsymbol{x}$ is the probability of return to $\boldsymbol{x}\,d\boldsymbol{x}$ at time t of a free Brownian particle that starts at the point $\boldsymbol{x}$ at time $t=0$ and diffuses in Ω with diffusion coefficient 1, with absorption at the boundary $\partial\Omega$. If it is reflected at $\partial\Omega$, rather than absorbed, the Dirichlet boundary condition (1.3) is replaced with the Neumann condition [12]

$$\frac{\partial G(\boldsymbol{y},\boldsymbol{x},t)}{\partial\boldsymbol{\nu}(\boldsymbol{y})}=0 \quad \text{for} \quad \boldsymbol{y}\in\partial\Omega,\ \boldsymbol{x}\in\Omega,\ t>0, \tag{1.4}$$

where $\boldsymbol{\nu}(\boldsymbol{y})$ is the unit outer normal at the boundary point $\boldsymbol{y}$. The trace of the heat kernel is defined as

$$P(t)=\int_\Omega G(\boldsymbol{x},\boldsymbol{x},t)\,d\boldsymbol{x} \tag{1.5}$$

and can be represented by the Dirichlet series

$$P(t)=\sum_{n=1}^{\infty}e^{-\lambda_n t}, \tag{1.6}$$

where λ_n are the eigenvalues of Laplace equation with the Dirichlet or Neumann boundary conditions (1.3) or (1.4), respectively.

It has been shown by Kac [2] that for a domain Ω with smooth boundary $\partial\Omega$, the leading terms in the expansion of $P(t)$ in powers of $\sqrt{t}$ are

$$P_{\text{Kac}}(t)\sim\frac{|\Omega|}{4\pi t}-\frac{|\partial\Omega|}{8\sqrt{\pi t}}+\frac{1}{6}(1-r)+O\left(\sqrt{t}\right) \quad \text{for } t\to 0,$$

where $|\Omega|$ denotes the area of Ω, $|\partial\Omega|$ denotes the arclength of $\partial\Omega$, and r is the number of holes in Ω. The full short-time asymptotic power series expansion of $P(t)$ in the form

$$P(t)\sim\sum_{n=0}^{\infty}a_n t^{n/2-1}$$

can be deduced from the large s expansion of the Laplace transform

$$g(s)=\int_0^\infty\exp\{-s^2t\}\left(P(t)-\frac{a_0}{t}\right)dt, \quad \left(a_0=\frac{|\Omega|}{4\pi}\right)$$

in inverse powers of s. Such an expansion was given by Stewartson and Waechter [3] in the form

$$\hat{g}(s)\sim\sum_{n=1}^{\infty}\frac{c_n}{s^n},$$

where

$$c_n=a_n\Gamma\left(\frac{n}{2}\right). \tag{1.7}$$

The constants c_n are computable functionals of the curvature of the boundary. The full expansion is denoted

$$P_{\mathrm{SW}}(t) \sim \frac{|\Omega|}{4\pi t} - \frac{|\partial\Omega|}{8\sqrt{\pi t}} + \frac{1}{6}(1-r) + \sum_{n=3}^{\infty} a_n t^{n/2-1} \quad \text{for } t \to 0. \tag{1.8}$$

If the boundary is not smooth but has cusps and corners, the expansion contains a term of the order $t^{-\nu}$, where ν is a number between 0 and 1/2.

The Stewartson–Waechter expansion was used in [10] to deduce further geometric properties of Ω by extending $g(s)$ into the complex plane. Examples were given in [10] of the resurgence of the length spectrum of closed billiard ball trajectories in the domain. It was conjectured in [10, eq. (4)] that

$$a_n = \frac{\alpha\Gamma(n-\beta+1)}{\Gamma\left(\frac{n}{2}\right) l^{n-2}}, \tag{1.9}$$

where α and β are constants of order unity and l is the shortest accessible geodesic (as defined in [10]).

The full length spectrum of closed geodesics on a compact Riemannian manifold without boundary Ω appeared in the short-time asymptotic expansion given in [5], [6],

$$P(t) \sim \frac{1}{\sqrt{\pi t}} \sum_{n=0}^{\infty} P_n(\sqrt{t})\, e^{-\delta_n^2/t} \quad \text{for } t \to 0, \tag{1.10}$$

where δ_n are the lengths of closed geodesics on Ω and $P_n(x)$ are power series in x.

Using a different approach, based on the expansion of the spectral density [7], [8], [10]

$$d(s) = \sum_{n=1}^{\infty} \delta(s-\lambda_n) = \bar{d}(s) + d_{\mathrm{OSC}}(s), \tag{1.11}$$

where the nonoscillatory and oscillatory parts are, respectively,

$$\bar{d}(s) \sim \frac{|\Omega|}{\pi}, \quad d_{\mathrm{OSC}}(s) \sim \Re\mathrm{e} \sum_j A_j(s) e^{-il_j\sqrt{s}} \quad \text{for} \quad s \to \infty, \tag{1.12}$$

the second sum extends over the periodic orbits of billiard balls in Ω, and l_j are their lengths. The coefficients $A_j(s)$ depend on the stability of the orbits (see [10, eqs. (11) and (12)]).

Using the identity

$$\int_0^{\infty} \exp\left\{-st - \frac{\delta_n^2}{t}\right\} dt = \frac{2\delta_n K_1(2\delta_l\sqrt{s})}{\sqrt{s}} \sim \frac{\sqrt{\pi\delta_n}}{s} e^{-2\delta_l\sqrt{s}} \quad \text{for} \quad s \to \infty \tag{1.13}$$

and extending formally the asymptotic relation (1.12) to the complex plane, we identify

$$\delta_n = \frac{l_n}{2}. \tag{1.14}$$

In this paper, we adopt a direct approach to the hyperasymptotic short-time expansion of the trace, rather than expanding its Laplace transform. The results can be generalized to higher dimensions in a straightforward manner. We construct the expansion in the form

$$P(t) \sim P_{\rm SW}(t) + \frac{1}{\sqrt{\pi t}} \sum_{n=1}^{\infty} P_n(\sqrt{t})\, e^{-\delta_n^2/t} \quad \text{for } t \to 0, \tag{1.15}$$

where δ_n, ordered by magnitude, are determined directly from the expansion to be related to l_n by (1.14), and $P_n(x)$ are power series in x. Transcendentally small terms may be, in fact, quite large and make a finite contribution to the expansion (1.15) [13]. Indeed, given $P(t)$, e.g., from NMR measurements, we describe a simple numerical algorithm for recovering δ_n from $P(t)$.

To construct the expansion, we use the short-time *ray asymptotic approximation* to the heat kernel [14], [15], [16], [17] to evaluate its trace. Specifically, we use the rays as global coordinates to expand the double integral (1.5) asymptotically beyond all orders for short times. We show that the transcendentally small terms are due to rays reflected in the boundary, much like in the geometric theory of diffraction [18], [19], [20]. In particular, the smallest exponent δ_1 is the width of the narrowest bottleneck in the domain. For the particular case of a circular domain, we find that all diffractive closed trajectories contribute to the transcendentally small terms (see also [10, sect. 3]).

In section 2, we explain the ray approximation and the evaluation of the trace in a one-dimensional example. In section 3, we generalize the ray approximation to higher dimensions, and in section 4 we use it to evaluate the trace for planar domains. In section 5, we work out an algorithm for the numerical evaluation of the exponents δ_n from the given trace $P(t)$. Finally, in section 6 we carry out explicit computations for special domains.

2. The one-dimensional case. The solution of the heat equation in an interval can be constructed by the method of images. Specifically, the Green function of the problem satisfies

$$\frac{\partial G(y,x,t)}{\partial t} = \frac{\partial^2 G(y,x,t)}{\partial y^2} \quad \text{for } 0 < x, y < a,\ t > 0, \tag{2.1}$$

$$G(y,x,0) = \delta(y-x) \qquad \text{for } 0 < x, y < a, \tag{2.2}$$

$$\left(\frac{\partial}{\partial y}\right)^k G(0,x,t) = \left(\frac{\partial}{\partial y}\right)^k G(a,x,t) = 0 \quad \text{for } 0 < x < a,\ t > 0,\ k = 0, 1. \tag{2.3}$$

The method of images gives the representation

(2.4)

$$G(y,x,t) = \frac{1}{2\sqrt{\pi t}} \sum_{n=-\infty}^{\infty} \left[\exp\left\{ -\frac{(y-x+2na)^2}{4t} \right\} - (-1)^k \exp\left\{ -\frac{(y+x+2na)^2}{4t} \right\} \right], \quad (k = 0, 1).$$

Note that if the infinite series is truncated after a finite number of terms, the boundary conditions are satisfied only in an asymptotic sense as $t \to 0$. That is, the boundary

values of the truncated solution decay exponentially fast in t^{-1} as $t \to 0$, and the exponential rate increases together with the number of retained terms.

The trace is given by

$$\begin{aligned}\int_0^a G(x,x,t)\,dx &= \frac{1}{2\sqrt{\pi t}}\int_0^a \sum_{n=-\infty}^{\infty}\left[\exp\left\{-\frac{(na)^2}{t}\right\}+(-1)^k\exp\left\{-\frac{(x+na)^2}{t}\right\}\right]dx\\ &= \frac{1}{2\sqrt{\pi t}}\sum_{n=-\infty}^{\infty}\left[a\exp\left\{-\frac{(na)^2}{t}\right\}+(-1)^k\int_0^a\exp\left\{-\frac{(x+na)^2}{t}\right\}dx\right]\\ &= \frac{a}{2\sqrt{\pi t}}\sum_{n=-\infty}^{\infty}\exp\left\{-\frac{(na)^2}{t}\right\}+\frac{(-1)^k}{2}\\ &= \frac{a}{2\sqrt{\pi t}}+\frac{(-1)^k}{2}+\frac{a}{2\sqrt{\pi t}}\sum_{n\neq 0}\exp\left\{-\frac{(na)^2}{t}\right\},\quad (k=0,1). \qquad (2.5)\end{aligned}$$

On the other hand,

$$\int_0^a G(x,x,t)\,dx = \sum_{n=1}^{\infty} e^{-\lambda_n t}, \qquad (2.6)$$

where $\{\lambda_n\}$ are the eigenvalues of the homogeneous Dirichlet or Neumann problem for the operator d^2/dx^2 in the interval $[0,a]$. Thus

$$\sum_{n=1}^{\infty} e^{-\lambda_n t} = \frac{a}{2\sqrt{\pi t}}+\frac{(-1)^k}{2}+\frac{a}{2\sqrt{\pi t}}\sum_{n\neq 0}\exp\left\{-\frac{(na)^2}{t}\right\},\quad (k=0,1). \qquad (2.7)$$

If instead of a single interval of length a we consider the heat equation in a set Ω consisting of K disjoint intervals of lengths l_j, $(j=1,\dots,K)$, respectively, the resulting expansion is

$$\sum_{n=1}^{\infty} e^{-\lambda_n t} = \frac{\sum_{j=1}^K l_j}{2\sqrt{\pi t}}+(-1)^k\frac{2K}{4}+\sum_{j=1}^K\frac{l_j}{2\sqrt{\pi t}}\sum_{n\neq 0}\exp\left\{-\frac{(nl_j)^2}{t}\right\},\quad (k=0,1). \qquad (2.8)$$

The numerator in the first term on the right-hand side of (2.8) can be interpreted as the "area" of Ω, so we denote it $\sum_{j=1}^K l_j = |\Omega|$. The number $2K$ is the number of boundary points of Ω, which can be interpreted as the "circumference" of the boundary, so we denote it $|\partial\Omega| = 2K$. The exponents in the sum on the right-hand side of (2.8) can be interpreted as the "widths" of the components of Ω. Clearly, for small t, the term containing the smallest width, $r = \min_{1\le j\le K} l_j$, will dominate the sum. Thus we can rewrite (2.8) as

$$\sum_{n=1}^{\infty} e^{-\lambda_n t} = \frac{|\Omega|}{2\sqrt{\pi t}}-\frac{|\partial\Omega|}{4}+\frac{mr}{\sqrt{\pi t}}\exp\left\{-\frac{r^2}{t}\right\}+\sum_{l_j>r}\frac{l_j}{2\sqrt{\pi t}}\sum_{n\neq 0}\exp\left\{-\frac{(nl_j)^2}{t}\right\}, \qquad (2.9)$$

where m is the number of the shortest intervals in Ω.

Equation (2.9) can be viewed as the short-time asymptotic expansion of the sum on the left-hand side of the equation. The algebraic part of the expansion consists of the first two terms, and all other terms are transcendentally small. The geometric information in the various terms of the expansion consists of the "area" of Ω and the

"circumference" $|\partial\Omega|$ in the algebraic part of the expansion. The transcendental part of the expansion is dominated by the term containing the smallest "width" of the domain, r.

The geometric information about Ω contained in the algebraic part is the information given in the "Can one hear the shape of a drum?" expansions [2], [3]. The geometric information contained in the transcendentally small terms in (2.9) can be understood as follows. The terms nl_j in the exponents are the lengths of closed trajectories of billiard balls in Ω, or the lengths of closed rays reflected at the boundaries, as in [7].

The representation (2.4) can be constructed as a short-time approximation to the solution of the heat equation (2.1)–(2.3) by the *ray method* [14]. In this method the solution is constructed in the form

$$G(y,x,t) = e^{-S^2(y,x)/4t} \sum_{n=0}^{\infty} Z_n(y,x) t^{n-1/2}. \tag{2.10}$$

Substituting the expansion (2.10) into the heat equation (2.1) and ordering terms by orders of magnitude for small t, we obtain at the leading order the *ray equation*, also called the *eikonal equation*,

$$\left| \frac{\partial S(y,x)}{\partial y} \right|^2 = 1, \tag{2.11}$$

and at the next orders the *transport equations*

$$\begin{aligned} &2\frac{\partial S(y,x)}{\partial y}\frac{\partial Z_n(y,x)}{\partial y} + Z_n(y,x)\left(\frac{\partial^2 S(y,x)}{\partial y^2} + \frac{2n}{S(y,x)}\right), \\ &\frac{2}{S(y,x)}\frac{\partial^2 Z_{n-1}(y,x)}{\partial y^2}, \quad n = 0,1,\dots . \end{aligned} \tag{2.12}$$

Denoting

$$p(y,x) = \frac{\partial S(y,x)}{\partial y},$$

we write the equations of the *characteristics*, or *rays* of the eikonal equation (2.11), as [15]

$$\frac{\partial y(\tau,x)}{\partial t} = 2p, \quad \frac{dp(\tau)}{dt} = 0, \quad \frac{dS(\tau)}{d\tau} = 2p^2(\tau) \tag{2.13}$$

with the initial conditions

$$y(0,x) = x, \quad p(0) = \pm 1, \quad S(0) = 0.$$

The condition $S(0) = 0$ is implied by the initial condition $G(x,y,0) = \delta(x-y)$. The solutions are given by

$$y(\tau,x) = x + 2p\tau, \quad p(\tau) = \pm 1, \quad S(\tau) = 2\tau = \pm(y-x). \tag{2.14}$$

Thus $S(y,x)$ is the length of the ray from y to x. We denote this solution by $S_0(y,x)$. It is easy to see that the solution of the transport equations corresponding to $S_0(y,x)$

is given by $Z_0(y,x) = \text{const}$, and $Z_n(y,x) = 0$ for all $n \geq 1$. The initial condition (2.2) implies that

$$Z_0(y,x) = \frac{1}{2\sqrt{\pi}}.$$

Combined into (2.10) this solution gives Green's function for the heat equation on the entire line,

$$G_0(y,x,t) = \frac{1}{2\sqrt{\pi t}} \exp\left\{-\frac{(y-x)^2}{4t}\right\},$$

which is the positive term corresponding to $n = 0$ in the expansion (2.4).

The ray from x to y is not the only one emanating from x. There are rays emanating from x that end at y after reflection in the boundary. Thus the ray from x that reaches y after it is reflected at the boundary 0 has length $y + x$. Therefore there is another solution of the eikonal equation, $S_1(y,x)$, which is the length of the reflected ray, given by

$$S_1(y,x) = y + x.$$

The ray from x that reaches y after it is reflected at the boundary a has length $2a - x - y$. The ray from x to 0, then to a, and then to y has length $2a + x - y$. Thus the lengths of all rays that reach y from x after any number of reflections in the boundary generate solutions of the eikonal equation, which are the lengths of the rays, which in turn generate solutions of the heat equation. We denote them by $S_k(y,x)$ with some ordering. The corresponding solutions of the transport equation are

$$Z_{0,k}(y,x) = \frac{C_k}{2\sqrt{\pi}},$$

where C_k are constant. They are chosen so that the sum of all the ray solutions,

$$G_k(y,x,t) = \frac{Z_{0,k}(y,x)}{\sqrt{t}} e^{-S_k^2(y,x)/4t},$$

satisfies the boundary conditions (2.3). Note that for all $k \neq 0$

$$G_k(y,x,t) \to 0 \quad \text{as } t \to 0.$$

This construction recovers the solution (2.4).

3. The ray method for short-time asymptotics of Green's function. The ray method consists in the construction of Green's function $G(\boldsymbol{y},\boldsymbol{x},t)$ (1.1)–(1.3) in the asymptotic form

$$G(\boldsymbol{y},\boldsymbol{x},t) \sim e^{-S^2(\boldsymbol{y},\boldsymbol{x})/4t} \sum_{n=0}^{\infty} Z_n(\boldsymbol{y},\boldsymbol{x}) t^{n-1}. \tag{3.1}$$

The function $S(\boldsymbol{y},\boldsymbol{x})$ is the solution of the *eikonal equation*

$$\left|\nabla_{\boldsymbol{y}} S(\boldsymbol{y},\boldsymbol{x})\right|^2 = 1, \tag{3.2}$$

and the functions $Z_n(\boldsymbol{y},\boldsymbol{x})$ solve the *transport equations*

$$2\nabla_{\boldsymbol{y}} S(\boldsymbol{y},\boldsymbol{x})\cdot\nabla_{\boldsymbol{y}} Z_n(\boldsymbol{y},\boldsymbol{x}) + Z_n(\boldsymbol{y},\boldsymbol{x})\left[\Delta_{\boldsymbol{y}} S(\boldsymbol{y},\boldsymbol{x}) + \frac{2n-1}{S(\boldsymbol{y},\boldsymbol{x})}\right]$$

$$= \frac{2}{S(\boldsymbol{y},\boldsymbol{x})}\Delta_{\boldsymbol{y}} Z_{n-1}(\boldsymbol{y},\boldsymbol{x}) \quad \text{for } n = 0,1,2,\dots. \tag{3.3}$$

The eikonal equation (3.2) is solved by the *method of characteristics* [15]. The characteristics, called *rays*, satisfy the differential equations

$$\frac{d\boldsymbol{y}(\tau,\boldsymbol{x})}{d\tau} = 2\nabla_{\boldsymbol{y}} S(\boldsymbol{y}(\tau,\boldsymbol{x}),\boldsymbol{x}), \quad \frac{d\nabla_{\boldsymbol{y}} S(\boldsymbol{y}(\tau,\boldsymbol{x}),\boldsymbol{x})}{d\tau} = 0, \quad \frac{dS(\boldsymbol{y}(\tau,\boldsymbol{x}),\boldsymbol{x})}{d\tau} = 2. \tag{3.4}$$

The initial condition (1.2) implies that the rays emanate from the point $\boldsymbol{x}$. Thus we choose the initial conditions

$$\boldsymbol{y}(0,\boldsymbol{x}) = \boldsymbol{x}, \quad \nabla_{\boldsymbol{y}} S(\boldsymbol{y}(0,\boldsymbol{x}),\boldsymbol{x}) = \boldsymbol{\nu}, \quad S(\boldsymbol{y}(0,\boldsymbol{x}),\boldsymbol{x}) = 0, \tag{3.5}$$

where $\boldsymbol{\nu}$ is a constant vector of unit length. The solution is given by

$$\boldsymbol{y}(\tau,\boldsymbol{x}) = \boldsymbol{x} + 2\boldsymbol{\nu}\tau, \quad S(\boldsymbol{y},\boldsymbol{x}) = |\boldsymbol{y}-\boldsymbol{x}| = 2\tau, \quad \nabla_{\boldsymbol{y}} S(\boldsymbol{y},\boldsymbol{x}) = \boldsymbol{\nu}. \tag{3.6}$$

The pair $(\tau,\boldsymbol{\nu})$ determines uniquely the point $\boldsymbol{y} = \boldsymbol{y}(\tau,\boldsymbol{x})$ and the value of $S(\boldsymbol{y},\boldsymbol{x})$ at the point. The parameter τ is half the distance from $\boldsymbol{y}$ to $\boldsymbol{x}$ or half the length of the ray from $\boldsymbol{x}$ to $\boldsymbol{y}$. The vector $\boldsymbol{\nu}$ is the unit vector in the direction from $\boldsymbol{x}$ to $\boldsymbol{y}$.

The function $Z_0(\boldsymbol{y},\boldsymbol{x})$ is easily seen to be a constant, $1/4\pi$, and $Z_n(\boldsymbol{y},\boldsymbol{x}) = 0$ for all $n > 0$. This construction recovers the solution of the heat equation in the entire plane and disregards the boundary $\partial\Omega$, because in the plane every point can be seen from every other point by a straight ray. Note that to calculate the function $P(t)$ in (1.5), only the values of $S(\boldsymbol{x},\boldsymbol{x})$ and $Z_0(\boldsymbol{x},\boldsymbol{x})$ are needed. Thus $S(\boldsymbol{x},\boldsymbol{x}) = 0$, and the first approximation to $G(\boldsymbol{x},\boldsymbol{x},t)$ is

$$G(\boldsymbol{x},\boldsymbol{x},t) = \frac{1}{4\pi t};$$

hence the first approximation to $P(t)$ is

$$P_0(t) = \frac{|\Omega|}{4\pi t}.$$

There is another solution of the eikonal equation (3.2) constructed along rays that emanate from $\boldsymbol{x}$ but reach $\boldsymbol{y}$ after they are reflected in $\partial\Omega$ [14]. The law of reflection is determined from the boundary conditions. Dirichlet and Neumann boundary conditions imply that the angle of incidence equals that of reflection [14]. Similarly, there are solutions of the eikonal equation that are the lengths of rays that emanate from $\boldsymbol{x}$ and reach $\boldsymbol{y}$ after any number of reflections in $\partial\Omega$. We denote these solutions $S_k(\boldsymbol{y},\boldsymbol{x})$ with some ordering. Thus the full ray expansion of Green's function has the form

$$G(\boldsymbol{y},\boldsymbol{x},t) \sim \sum_{k=1}^{\infty} e^{-S_k^2(\boldsymbol{y},\boldsymbol{x})/4t} Z_k(\boldsymbol{y},\boldsymbol{x},t), \tag{3.7}$$

where

$$Z_k(\boldsymbol{y},\boldsymbol{x},t) = \sum_{n=0}^{\infty} Z_{n,k}(\boldsymbol{y},\boldsymbol{x}) t^{n-1}.$$

As above, each one of the series

$$e^{-S_k^2(\boldsymbol{y},\boldsymbol{x})/4t} Z_k(\boldsymbol{y},\boldsymbol{x},t)$$

is called a *ray solution* of the diffusion equation. The boundary values of $Z_k(\boldsymbol{y},\boldsymbol{x},t)$ are chosen so that $G(\boldsymbol{y},\boldsymbol{x},t)$ in (3.7) satisfies the imposed boundary condition. In particular, the values of $S_k(\boldsymbol{x},\boldsymbol{x})$ are the lengths of all rays that emanate from $\boldsymbol{x}$ and are reflected from the boundary back to $\boldsymbol{x}$. Note that sums of ray solutions satisfy boundary conditions only at certain points.

To fix the ideas, we consider first simply connected domains. We denote

$$S_0(\boldsymbol{y},\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{y}|$$

and

$$G_0(\boldsymbol{y},\boldsymbol{x},t) = \frac{1}{4\pi t} e^{-S_0^2(\boldsymbol{y},\boldsymbol{x})/4t}.$$

We first consider solutions corresponding to rays that are reflected only once at the boundary and, in particular, rays that are reflected back from the boundary to the points of their origin. Such rays hit the boundary at right angles (see Figure 1 and [14]). If there is only one minimal eikonal $S_1(\boldsymbol{x},\boldsymbol{x}) > 0$, we say that $\boldsymbol{x}$ is a *regular* point of Ω. If there is more than one minimal eikonal $S_1(\boldsymbol{x},\boldsymbol{x})$, we say that $\boldsymbol{x}$ is a *critical* point of Ω. We denote by Γ the locus of critical points in Ω. The eikonal $S_1(\boldsymbol{y},\boldsymbol{x})$ is the length of the shortest ray from $\boldsymbol{x}$ to $\boldsymbol{y}$ with one reflection in the boundary such that the ray from $\boldsymbol{x}$ to the boundary does not intersect Γ. For $\boldsymbol{x} = \boldsymbol{y}$ the eikonal $S_1(\boldsymbol{x},\boldsymbol{x})$ is twice the distance of $\boldsymbol{x}$ to the boundary. We denote by $\boldsymbol{x}'$ the orthogonal projection of $\boldsymbol{x}$ on the boundary along the shortest normal from $\boldsymbol{x}$ to the boundary. When $\boldsymbol{y} = \boldsymbol{x}'$,

$$S_1(\boldsymbol{x}',\boldsymbol{x}) = S_0(\boldsymbol{x}',\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{x}'|\,. \tag{3.8}$$

The function

$$G_1(\boldsymbol{y},\boldsymbol{x},t) = e^{-S_1^2(\boldsymbol{y},\boldsymbol{x})/4t} Z_1\left(\boldsymbol{y},\boldsymbol{x},t\right)$$

has to be chosen so that $G_0(\boldsymbol{x}',\boldsymbol{x},t) - G_1(\boldsymbol{x}',\boldsymbol{x},t) = 0$. In view of (3.8), we have to choose

$$Z_1\left(\boldsymbol{x}',\boldsymbol{x},t\right) = \frac{1}{4\pi t}.$$

When $\boldsymbol{y}''$ is the other boundary point on the normal from $\boldsymbol{x}'$ to $\boldsymbol{x}$, we have

$$G_0(\boldsymbol{y}'',\boldsymbol{x},t) - \ G_1(\boldsymbol{y}'',\boldsymbol{x},t) = \frac{1}{4\pi t} e^{-|x-y''|^2/t} - e^{-\left(|x'-x|+|y''-x'|\right)^2/t} Z_1\left(\boldsymbol{y}'',\boldsymbol{x},t\right). \tag{3.9}$$

Next, we consider in $\Omega - \Gamma$ the minimal among the remaining eikonals $S_k(\boldsymbol{x},\boldsymbol{x}) > S_1(\boldsymbol{x},\boldsymbol{x})$ and denote it $S_2(\boldsymbol{x},\boldsymbol{x})$. This eikonal is twice the length of a ray that emanates from $\boldsymbol{x}$, intersects Γ once, and intersects the boundary $\partial\Omega$ at right angles at a point, denoted $\boldsymbol{x}''$. The eikonal $S_2(\boldsymbol{y},\boldsymbol{x})$ is the length of the ray from $\boldsymbol{x}$ to $\boldsymbol{y}$ with one reflection in the boundary such that the ray from $\boldsymbol{x}$ to the boundary intersects Γ once. When $\boldsymbol{y} = \boldsymbol{x}''$,

$$S_2(\boldsymbol{x}'',\boldsymbol{x}) = S_0(\boldsymbol{x}'',\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{x}''|\,. \tag{3.10}$$

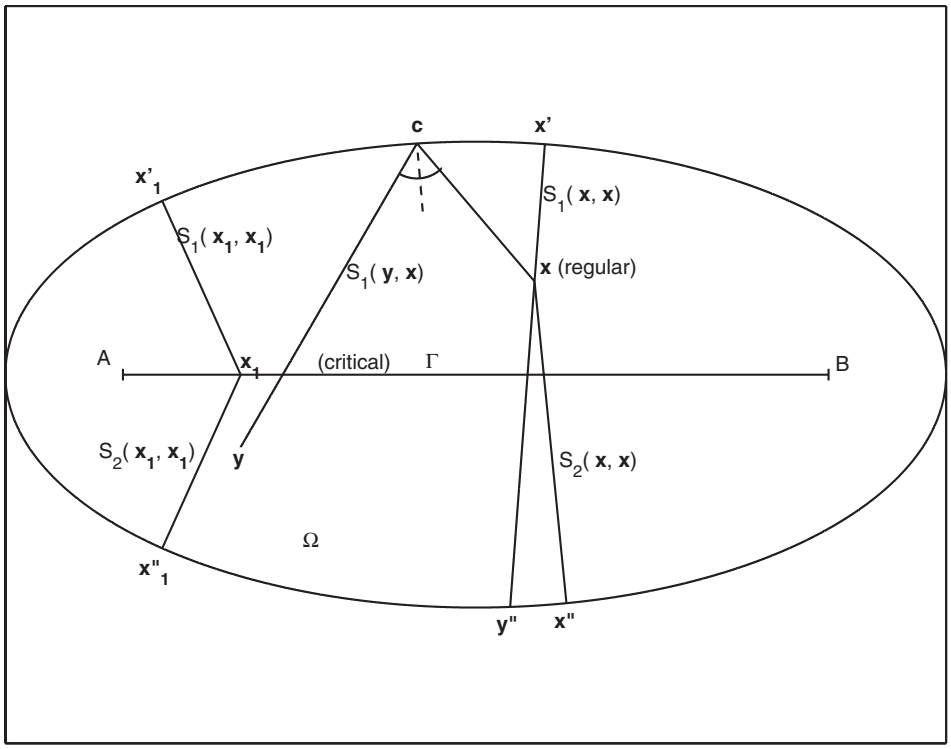

FIG. 1. *The locus of critical points, Γ, is the segment AB. The first eikonal is $S_1(\boldsymbol{y},\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{c}|+|\boldsymbol{c}-\boldsymbol{y}|$. It is defined as the shortest reflected ray from $\boldsymbol{x}$ to $\boldsymbol{y}$, such that $\boldsymbol{x}-\boldsymbol{c}$ does not intersect Γ. For $\boldsymbol{x}=\boldsymbol{y}$ the diagonal values are $S_1(\boldsymbol{x},\boldsymbol{x}) = 2|\boldsymbol{x}-\boldsymbol{x'}|$. The diagonal values of the second eikonal are $S_2(\boldsymbol{x},\boldsymbol{x}) = 2|\boldsymbol{x}-\boldsymbol{x''}|$. The vectors $\boldsymbol{x}-\boldsymbol{x'}$ and $\boldsymbol{x}-\boldsymbol{x''}$ are orthogonal to the boundary. For $\boldsymbol{x}_1\in\Gamma$ the two eikonals are equal.*

When $\boldsymbol{y}'$ is the other boundary point on the normal that emanates from $\boldsymbol{x}''$ (see Figure 2), we have

$$S_2(\boldsymbol{y}',\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{x}''|+|\boldsymbol{y}'-\boldsymbol{x}''|\,.$$

In general, $\boldsymbol{x}'\neq\boldsymbol{y}'$ and $\boldsymbol{x}''\neq\boldsymbol{y}''$. However, if the ray is a 2-periodic orbit (that hits the boundary at only 2 points), $\boldsymbol{x}'=\boldsymbol{y}'$ and $\boldsymbol{x}''=\boldsymbol{y}''$ so that

$$S_2(\boldsymbol{y}'',\boldsymbol{x}) = S_0(\boldsymbol{y}'',\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{y}''|$$

and

$$S_2(\boldsymbol{y}',\boldsymbol{x}) = |\boldsymbol{x}-\boldsymbol{x}''|+|\boldsymbol{y}''-\boldsymbol{x}'|\,.$$

Since

$$|\boldsymbol{x}-\boldsymbol{y}''| < |\boldsymbol{x}-\boldsymbol{x}'|+|\boldsymbol{y}''-\boldsymbol{x}'| < |\boldsymbol{x}-\boldsymbol{x}''|+|\boldsymbol{y}''-\boldsymbol{x}'|$$

for all regular points $\boldsymbol{x}$, the order of magnitude of the boundary error (3.10) decreases if we use the approximation

$$G_0(\boldsymbol{y},\boldsymbol{x},t) \sim G_0(\boldsymbol{y},\boldsymbol{x},t) - G_1(\boldsymbol{y},\boldsymbol{x},t) - G_2(\boldsymbol{y},\boldsymbol{x},t) \tag{3.11}$$

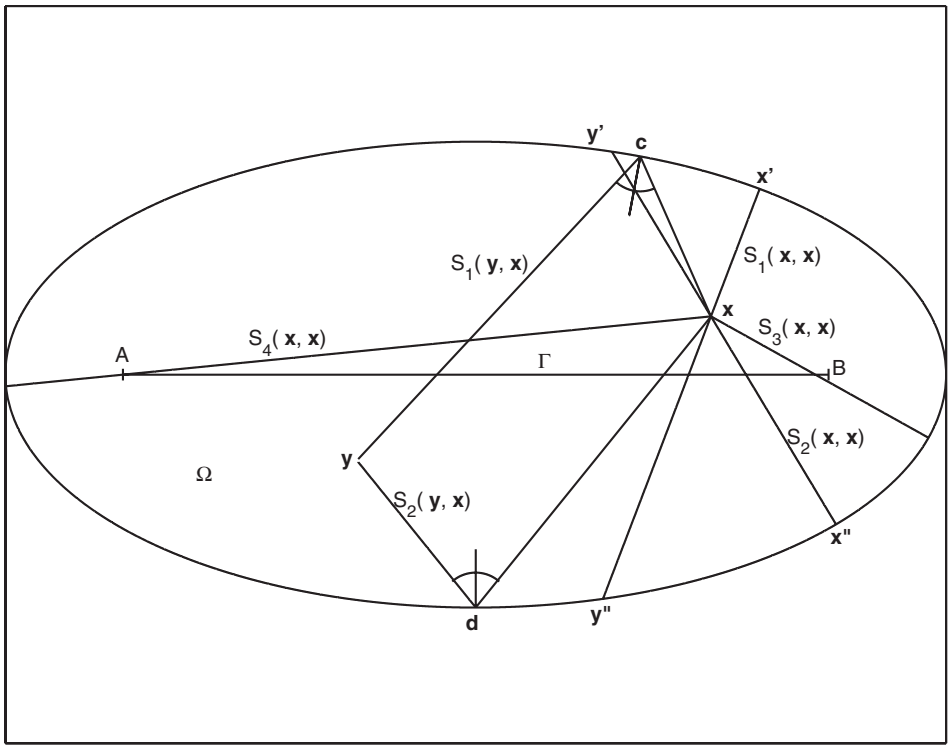

FIG. 2. *The second eikonal* $S_2(\boldsymbol{y}, \boldsymbol{x}) = |\boldsymbol{x} - \boldsymbol{d}| + |\boldsymbol{d} - \boldsymbol{y}|$. *It is defined as the shortest reflected ray such that* $\boldsymbol{x} - \boldsymbol{d}$ *intersects* Γ. *The eikonals* $S_3(\boldsymbol{x}, \boldsymbol{x})$ *and* $S_4(\boldsymbol{x}, \boldsymbol{x})$ *are ordered according to magnitude.*

with

$$Z_2(\boldsymbol{y}'', \boldsymbol{x}, t) = Z_1(\boldsymbol{y}'', \boldsymbol{x}, t) = Z_0(t).$$

4. The trace. To find the short-time asymptotics of the Dirichlet series (1.6), as given in (1.5),

$$P(t) = \int_\Omega G(\boldsymbol{x}, \boldsymbol{x}, t)\, d\boldsymbol{x},$$

we use the ray expansion (3.7) for the evaluation of the integral. We retain in the resulting expansion only terms that are transcendentally small, since all algebraic terms are contained in the expansion (1.8).

4.1. Simply connected domains. We note that according to Sard's theorem, Γ is a set of measure zero and that all points in the domain $\Omega - \Gamma$ are regular. For any point $\boldsymbol{x} \in \Omega$, we denote by $r_1(\boldsymbol{x})$ its distance to the boundary and note that $S_1(\boldsymbol{x}, \boldsymbol{x}) = 2r_1(\boldsymbol{x})$. We also denote by $s_1(\boldsymbol{x})$ the arclength at the boundary point $\boldsymbol{x}'$ (the orthogonal projection of $\boldsymbol{x}$ on $\partial\Omega$ along the shortest normal from $\boldsymbol{x}$ to $\partial\Omega$), measured from a boundary point where the arclength is set to 0 (see Figure 3).

It follows that the change of variables in $\Omega - \Gamma$, given by

$$\boldsymbol{x} \to (r_1(\boldsymbol{x}), s_1(\boldsymbol{x})), \tag{4.1}$$

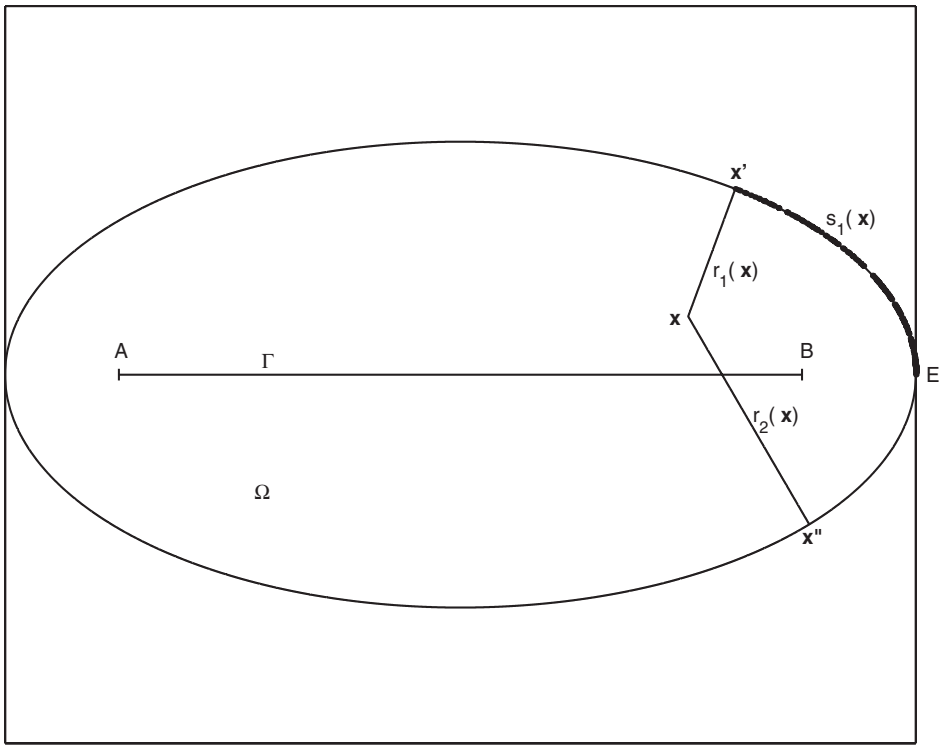

FIG. 3. *The arclength $s_1(\boldsymbol{x})$ is measured from the point E. Both transformations $\boldsymbol{x} \to (r_1(\boldsymbol{x}), s_1(\boldsymbol{x}))$ and $\boldsymbol{x} \to (r_2(\boldsymbol{x}), s_1(\boldsymbol{x}))$ are one-to-one mappings of $\Omega - \Gamma$. The images are given in Figure 4.*

is a one-to-one mapping of $\Omega - \Gamma$ onto a strip $0 \le r_1 \le r_1(s_1)$, $0 \le s_1 \le L$, where $r_1(s_1)$ is the distance from the boundary point corresponding to arclength s_1 to Γ.

We evaluate the integral over Ω separately for each summand k in the expansion (3.7). In this notation, we can write

$$\begin{aligned}
&\int_\Omega G_1(\boldsymbol{x}, \boldsymbol{x}, t)\, d\boldsymbol{x} \\
&= \int_\Omega e^{-[S_1(\boldsymbol{x},\boldsymbol{x})]^2/4t} \sum_{n=0}^{\infty} Z_{n,1}(\boldsymbol{x}, \boldsymbol{x}) t^{n-1}\, d\boldsymbol{x} \\
&= \int_0^L ds \int_0^{r_1(s_1)} e^{-r_1^2/t} J_1(r_1, s_1) Z_1(r_1, s_1, t)\, dr_1,
\end{aligned} \tag{4.2}$$

where $J_1(r_1, s_1)$ is the Jacobian of the transformation and

$$Z_1(r_1, s_1, t) = \sum_{n=0}^{\infty} Z_{n,1}(\boldsymbol{x}, \boldsymbol{x}) t^{n-1}.$$

Note that the Jacobian vanishes neither inside $\Omega - \Gamma$ nor at $r_1 = 0$, because the transformation is one-to-one in $\Omega - \Gamma$; however, it does on Γ.

We set $S_2(\boldsymbol{x},\boldsymbol{x}) = 2r_2(\boldsymbol{x})$ and use it as a coordinate. We use $s_1(\boldsymbol{x})$ as the other coordinate of the point $\boldsymbol{x} \in \Omega - \Gamma$. Note that while $r_2(\boldsymbol{x})$ is the length of the longer normal from $\boldsymbol{x}$ to $\partial\Omega$ (the one that intersects Γ), the other coordinate is the arclength corresponding to the shorter normal from $\boldsymbol{x}$ to $\partial\Omega$ (the one that does not intersect Γ). The transformation

$$\boldsymbol{x} \to (r_2(\boldsymbol{x}), s_1(\boldsymbol{x})) \tag{4.3}$$

maps $\Omega - \Gamma$ onto the strip $r\,(s_1) \le r_2 \le l(s_1),\ 0 \le s_1 \le L$, where $l(s_1)$ is the length of the segment of the normal that starts at the boundary point $r_1 = 0, s_1$ and ends at its other intersection point with the boundary. This mapping is one-to-one as well. It follows that

$$\begin{aligned}
&\int_\Omega G_2(\boldsymbol{x},\boldsymbol{x},t)\,d\boldsymbol{x} \\
&= \int_\Omega e^{-[S_2(\boldsymbol{x},\boldsymbol{x})]^2/4t} \sum_{n=0}^{\infty} Z_{n,2}(\boldsymbol{x},\boldsymbol{x}) t^{n-1}\,d\boldsymbol{x} \\
&= \int_0^L ds_1 \int_{r(s_1)}^{l(s_1)} e^{-r_2^2/t} J_2(r_2,s_1) Z_2(r_2,s_1,t)\,dr_2,
\end{aligned} \tag{4.4}$$

where

$$Z_2(r_2,s_1,t) = \sum_{n=0}^{\infty} Z_{n,2}(\boldsymbol{x},\boldsymbol{x}) t^{n-1}.$$

Note that for $\boldsymbol{x}$ on Γ both transformations, (4.1) and (4.3) are identical and

$$J_2(r_2,s_1)Z_2(r_2,s_1,t) = J_1(r_1,s_1)Z_1(r_1,s_1,t).$$

It follows that (4.2) and (4.4) combine to give

$$\begin{aligned}
&\int_\Omega \left[G_1(\boldsymbol{x},\boldsymbol{x},t) + G_2(\boldsymbol{x},\boldsymbol{x},t)\right]\,d\boldsymbol{x} \\
&= \int_0^L \int_0^{l(s)} e^{-r^2/t} J(r,s) Z(r,s,t)\,dr\,ds,
\end{aligned} \tag{4.5}$$

where $s = s_1,\ r = r_1,\ J = J_1$, and $Z = Z_1$ for $0 < r < r_1(s_1)$, and $s = s_1,\ r = r_2,\ J = J_2$, and $Z = Z_2$ for $r_2(s_1) < r < l(s_1)$. Thus the domain of integration of the function $e^{-r^2/t}J(r,s)Z(r,s,t)$ in (4.5) is the domain enclosed by the s_1-axis and the upper curve in Figure 4. Now, for $t \ll 1$, we write the inner integral on the right-hand side of (4.5) as

$$\begin{aligned}
&\int_0^{l(s)} e^{-r^2/t} J(r,s) Z(r,s,t)\,dr = \sqrt{\frac{\pi t}{2}}\operatorname{erf}\left(\frac{l(s)}{\sqrt{t}}\right) J(0,s)Z(0,s,t)\left(1 + O\left(\sqrt{t}\right)\right) \\
&= \sqrt{\frac{\pi t}{2}}\left(1 - \frac{\exp\left\{-\dfrac{l^2(s)}{t}\right\}\sqrt{t}}{l(s)}\right) J(0,s)Z(0,s,t)\left(1 + O\left(\sqrt{t}\right)\right).
\end{aligned}$$

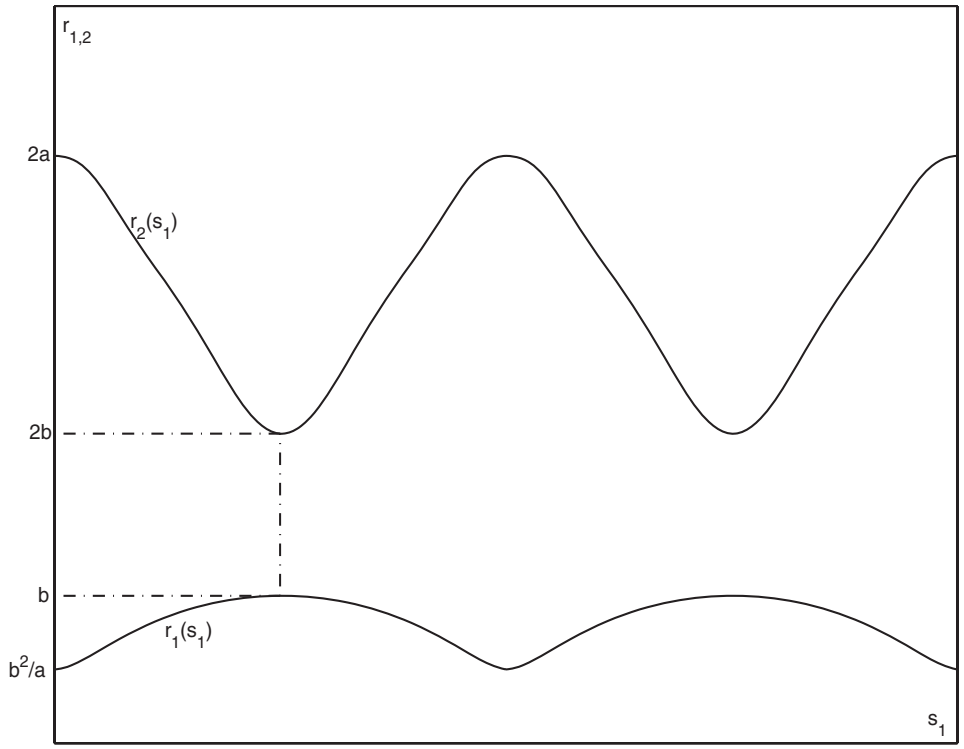

FIG. 4. *The domain* Ω *is the ellipse* $\frac{x^2}{a^2}+\frac{y^2}{b^2}\le 1$. *The domain enclosed between the* s_1*-axis and the lower curve is the image of the ellipse under the transformation* (4.1)*, and the domain enclosed between the upper and the lower curves is its image under* (4.3).

Recall that $J(0,s)Z(0,s,t)\neq 0$. Only the exponentially small terms have to be considered, because the algebraic terms are included in the Stewart–Waechter expansion. Thus

$$\int_0^L\int_0^{l(s)} e^{-r^2/t}J(r,s)Z(r,s,t)\,dr\,ds-\int_0^L\sqrt{\frac{\pi t}{2}}J(0,s)Z(0,s,t)\left(1+O\left(\sqrt{t}\right)\right)\,ds$$

$$=-\int_0^L \exp\left\{-\frac{l^2(s)}{t}\right\}\frac{J(0,s)Z(0,s,t)}{l(s)}O\left(t\right)\,ds\quad\text{for } t\ll 1.$$

Evaluating the last integral by the Laplace method, we find that each point s_i, which is an extremum point of $l(s)$, contributes an exponential term of the form

$$\exp\left\{-\frac{l^2(s_i)}{t}\right\}\frac{J(0,s_i)Z(0,s_i,t)}{l(s_i)}O\left(t^\nu\right), \tag{4.6}$$

where $\nu\ge 0$ and $O\left(t^\nu\right)$ depend on the type of the critical point s_i, and so also on the local behavior of $l^2(s)$ near s_i. The expression (4.6) means that some of the δ_n's in the expansion (1.15) are the extremal values $l(s_i)$ and their multiples. These are half the lengths of the 2-periodic orbits of a billiard ball in Ω (see Figure 5). In particular, the shortest neck is given by

$$\delta_1=\frac{l}{2}. \tag{4.7}$$

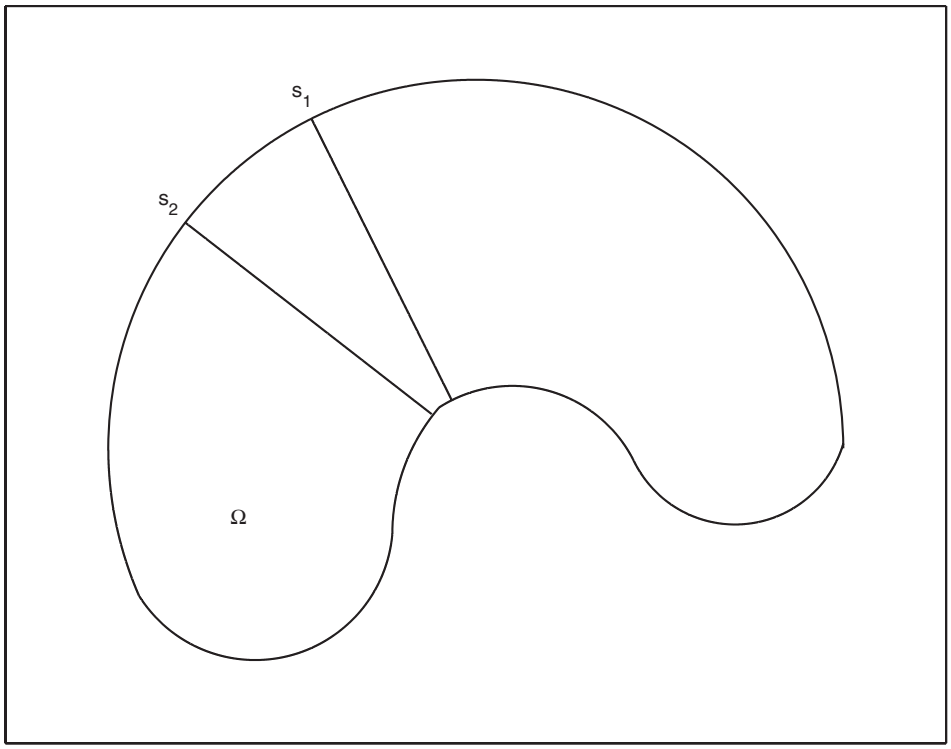

FIG. 5. *The rays emanating from the boundary points s_1 and s_2 are orthogonal to the boundary at both ends. They are 2-periodic orbits.*

The 2-periodic orbits of the ellipse are the major axes, which correspond to the lowest and highest points of the top curve in Figure 4. There are other exponents as well, as discussed below.

The preexponential terms in the expression (4.6) influence the factors $P_n(\sqrt{t})$ in (1.15). For example, if $l'(s_i) = 0,\ l''(s_i) \neq 0$, then $\nu = 3/2$. If the boundary is flatter, then $1 \leq \nu < 3/2$.

In addition to the 2-periodic orbits, there are ray solutions corresponding to rays from $\boldsymbol{x}$ to $\boldsymbol{y}$ that are reflected any number of times in the boundary. There are eikonals from $\boldsymbol{x}$ to $\boldsymbol{y}$ in Ω with $N-1$ different vertices on the boundary, which have N vertices on $\partial\Omega$ if $\boldsymbol{x} = \boldsymbol{y}$ and $\boldsymbol{x} \in \partial\Omega$ (this is a periodic orbit with $N-1$ reflections). Among these periodic orbits, there are eikonals $S_N(\boldsymbol{x}, \boldsymbol{x})$ with extremal length, denoted $S_{N,j},\ (j = 1, \ldots)$. At points $\boldsymbol{x} \in \Omega$ on a 2-periodic orbit the eikonal $S_N(\boldsymbol{x}, \boldsymbol{x})$, which now has $N-1$ vertices on the boundary, may reduce to the 2-periodic orbit with N reflections. Therefore the change of variables $\boldsymbol{x} \to (S_N(\boldsymbol{x}, \boldsymbol{x}), s(\boldsymbol{x}))$ will map the domain into a strip with extremal widths that are the differences between the lengths $S_{N,j}$ and the length of a 2-periodic orbit with N reflections. It follows that the evaluation of the trace by the Laplace method leads to exponents which are the extremal lengths of periodic orbits with any number of reflections.

For example, there is an eikonal in a circle (centered at the origin) that is the ray from $\boldsymbol{x}$ to $\boldsymbol{y}$ with two reflections in the boundary (see Figure 6). For $\boldsymbol{x} = \boldsymbol{y}$ it is the equilateral triangle (see Figure 7) with circumference

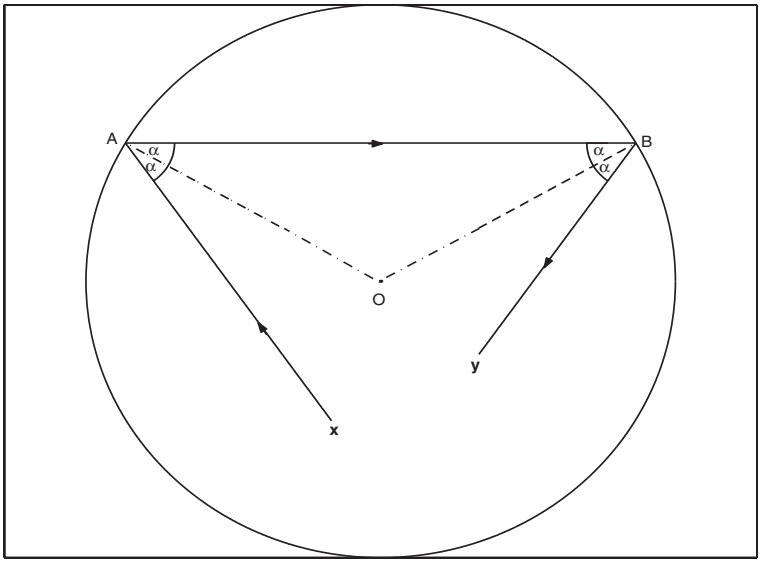

FIG. 6. *The eikonal $S_3(\boldsymbol{y},\boldsymbol{x})$ with two reflections in the circle.*

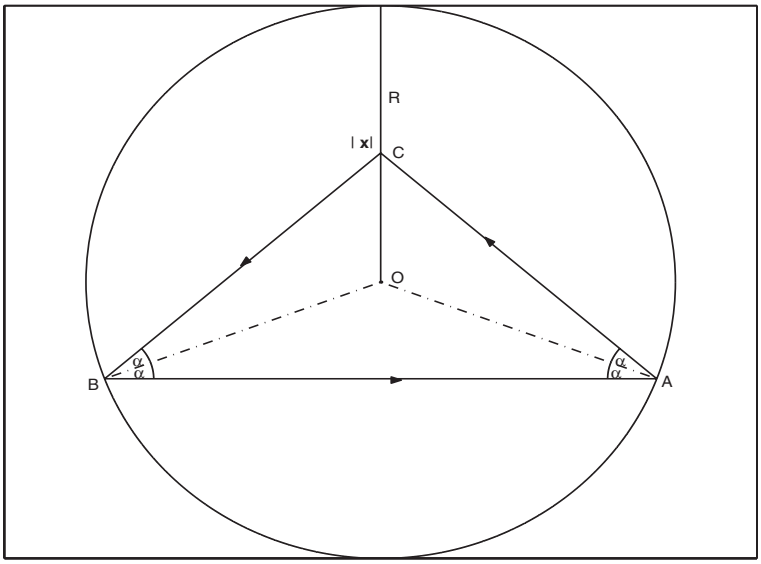

FIG. 7. *The eikonal $S_3(\boldsymbol{x},\boldsymbol{x})$ with two reflections, where $|\boldsymbol{x}| = OC$.*

$$S(\boldsymbol{x},\boldsymbol{x}) = R\left(2\frac{\sqrt{2|\boldsymbol{x}|^2+1+\sqrt{8|\boldsymbol{x}|^2+1}}}{\sqrt{4|\boldsymbol{x}|^2+1+\sqrt{8|\boldsymbol{x}|^2+1}}} + \sqrt{4|\boldsymbol{x}|^2+2+2\sqrt{8|\boldsymbol{x}|^2+1}}\right).$$

The eikonal $S_3(\boldsymbol{x},\boldsymbol{y})$ reduces to a 2-periodic orbit with two reflections if $\boldsymbol{x} = \boldsymbol{y} = 0$ (the center of the circle). If $\boldsymbol{x}$ is on the circumference, the eikonal becomes the isosceles

triangle with one vertex at $\boldsymbol{x}$. To evaluate the contribution of the corresponding ray solution to the trace, we use this eikonal as a coordinate that varies between $4R$, the length of the 2-periodic orbit with two reflections, and $3\sqrt{3}R$, the circumference of the inscribed isosceles triangle. The contribution of this integral to the exponential sum in (1.15) contains exponents that are both lengths. Similarly, the 2-periodic orbit with three reflections has length $6R$, while the periodic orbit with three reflections at three different points has length $4\sqrt{2}R < 6R$. Obviously, if the preexponential factors vanish, these exponents do not appear in the expansion.

4.2. Multiply connected domains. Once again, we first consider rays from $\boldsymbol{x}$ to $\boldsymbol{y}$ that are reflected only once in the boundary. For every connected component of $\partial\Omega$, denoted $\partial\Omega_i$ $(i = 1, \ldots, I)$, a point $\boldsymbol{x}$ in Ω is regular with respect to $\partial\Omega_i$ if there is only one minimal eikonal $S_{i,1}(\boldsymbol{x}, \boldsymbol{x}) > 0$ with one reflection at $\partial\Omega_i$. We denote by Γ_i the locus of the irregular points of Ω with respect to $\partial\Omega_i$.

As above, we define in $\Omega - \Gamma_i$ the minimal eikonal with one reflection in $\partial\Omega_i$ such that $S_{i,2}(\boldsymbol{x}, \boldsymbol{x}) > S_{i,1}(\boldsymbol{x}, \boldsymbol{x})$. We construct an approximation

$$G(\boldsymbol{y}, \boldsymbol{x}, t) \sim G_0(\boldsymbol{y}, \boldsymbol{x}, t) + \sum_{k=1}^{2} \sum_{i=1}^{I} G_{i,k}(\boldsymbol{y}, \boldsymbol{x}, t),$$

where $G_{i,k}(\boldsymbol{y}, \boldsymbol{x}, t)$ are ray solutions with eikonals $S_{i,k}(\boldsymbol{y}, \boldsymbol{x})$ and $Z_{i,k}(\boldsymbol{y}, \boldsymbol{x})$ chosen so as to minimize the boundary values of the sum at the boundary points of rays orthogonal to the boundary, as above. The trace of the double sum is calculated by introducing the change of variables $2r_{i,k}(\boldsymbol{x}) = S_{i,k}(\boldsymbol{x}, \boldsymbol{x})$ and arclength $s_i(\boldsymbol{x})$ in $\partial\Omega_i$, as above. The Laplace evaluation of the integrals produces exponents that are the 2-periodic orbits in Ω.

Eikonals with two or more reflections contribute exponents that are lengths of extremal closed orbits with any number of reflections in the boundary, as in the case of simply connected domains. Thus the exponents δ_n in (1.15) consist of half the lengths of 2-periodic orbits in Ω and their multiples, and extremal lengths of closed periodic orbits with any number of reflections in the boundary and their multiples.

5. Recovering $\boldsymbol{\delta_1}$ from $\boldsymbol{P(t)}$. We denote the sum of $N \geq 3$ terms in (1.8)

$$Q_N(t) \sim \frac{|\Omega|}{4\pi t} - \frac{|\partial\Omega|}{8\sqrt{\pi t}} + \frac{1}{6}(1 - r) + \sum_{n=3}^{N} a_n t^{n/2-1} \quad \text{for } t \to 0. \tag{5.1}$$

To recover the geometrical information from the expansion (1.15), given the (measured) function $P(t)$, we note that

$$|\Omega| = \lim_{t\to 0} 4\pi t P(t), \quad |\partial\Omega| = -\lim_{t\to 0} 8\sqrt{\pi t}\left[P(t) - \frac{|\Omega|}{4\pi t}\right], \tag{5.2}$$

and so on. This way any number of terms in the expansion (1.8) can be determined.

Once $Q_n(t)$ has been determined, we can write

$$t[P(t) - Q_{2n-1}(t)] \sim a_{2n} t^n \left(1 + O\left(\sqrt{t}\right)\right) + \frac{P_1(0)}{\sqrt{\pi}} \left(1 + O\left(\sqrt{t}\right)\right) e^{-\delta_1^2/t}, \tag{5.3}$$

where the first $O\left(\sqrt{t}\right)$ may depend on n. According to (1.9) and to Stirling's formula,

$$a_{2n} = \frac{\alpha}{l^{2n-2}} O\left(\frac{\Gamma(2n)}{\Gamma(n)}\right) = O\left(AB^n n^n\right) \quad \text{for} \quad n \to \infty, \tag{5.4}$$

where

$$A = l^2\alpha, \quad B = \frac{4}{el^2}. \tag{5.5}$$

We will show that for some $\delta > 0$

$$\max_{0\le t\le\delta}\left\{-t\log\left|a_{2n}t^n\left(1+O\left(\sqrt{t}\right)\right)+\frac{P_1(0)}{\sqrt{\pi}}\left(1+O\left(\sqrt{t}\right)\right)e^{-\delta_1^2/t}\right|\right\}\to\delta_1^2 \quad \text{as} \quad n\to\infty.$$

Indeed, setting $b = \frac{P_1(0)}{\sqrt{\pi}}$, assuming $A, B, b > 0$, and defining

$$g(t) = -t\log\left(AB^n n^n t^n + be^{-\delta_1^2/t}\right), \tag{5.6}$$

we set $nt = u$ and rewrite (5.6) as

(5.7)

$$g(t) = -u\log\sqrt[n]{A\left(\frac{4}{el^2}\right)^n u^n + be^{-n\delta_1^2/u}} \to -u\max\left\{\log\frac{4}{el^2}, -\frac{\delta_1^2}{u}\right\} \quad \text{as} \quad n\to\infty$$

$$= \max\left\{\delta_1^2, e\left(\frac{l}{2}\right)^2(-y\log y)\right\},$$

where

$$y = \frac{u}{e}\left(\frac{2}{l}\right)^2.$$

Because

$$-y\log y \le e^{-1},$$

we can write, according to (4.7),

$$\max_{0<t<\delta} g(t) \to \max\left\{\delta_1^2, \left(\frac{l}{2}\right)^2\right\} = \delta_1^2 = \left(\frac{l}{2}\right)^2. \tag{5.8}$$

Note that the maximum is achieved at

$$t_{\max} = \frac{1}{en} \to 0 \quad \text{as} \quad n\to\infty. \tag{5.9}$$

Equation (5.8) implies the following algorithm for determining δ_1 from the given values of $P(t)$. First, use the method of (5.2) to construct $Q_n(t)$ for a given n and then find

$$\max_t\{-t\log|t[P(t)-Q_n(t)]|\} = \delta_1^2 + o(1) \quad \text{as} \quad n\to\infty.$$

This algorithm works quite well with MAPLE.

6. Discussion. We illustrate our expansion for a disk, whose boundary has only one connected component and a single critical point. We consider points $\boldsymbol{x} = (x_1, y_1)$ and $\boldsymbol{y} = (x_2, y_2)$ inside a circle of radius R centered at the origin. The leading-order eikonal is

$$S_0(\boldsymbol{y}, \boldsymbol{x}) = |\boldsymbol{x} - \boldsymbol{y}|.$$

When both $\boldsymbol{x}$ and $\boldsymbol{y}$ are on the x-axis, we have $y_1 = y_2 = 0$ and $S_0(\boldsymbol{y}, \boldsymbol{x}) = |x_1 - x_2|$. Denoting $\boldsymbol{x}_1 = (x_1, 0)$ and $\boldsymbol{x}_2 = (x_2, 0)$, we see that the values of the eikonal on the x-axis are $S_0(\boldsymbol{x}_1, \boldsymbol{x}_2) = |x_1 - x_2|$. We assume that $x_1 > 0$. The boundary values of the eikonal are

$$S_0(\boldsymbol{x}_1, \boldsymbol{x}_2) = R - x_1 \quad \text{at} \quad \boldsymbol{x}_2 = (R, 0)$$

and

$$S_0(\boldsymbol{x}_1, \boldsymbol{x}_2) = R + x_1 \quad \text{at} \quad \boldsymbol{x}_2 = (-R, 0).$$

Thus the leading-order ray approximation to Green's function $G(\boldsymbol{y}, \boldsymbol{x}, t)$,

$$G_0(\boldsymbol{y}, \boldsymbol{x}, t) = \frac{1}{4\pi t} e^{-S_0^2(\boldsymbol{y}, \boldsymbol{x})/4t},$$

misses the boundary conditions when $\boldsymbol{x}$ and $\boldsymbol{y}$ are on the x-axis, giving

$$G_0(\boldsymbol{x}_1, \boldsymbol{x}_2, t) = \frac{1}{4\pi t} e^{-(R - x_1)^2/4t} \quad \text{at} \quad \boldsymbol{x}_2 = (R, 0)$$

and

$$G_0(\boldsymbol{x}_1, \boldsymbol{x}_2, t) = \frac{1}{4\pi t} e^{-(R + x_1)^2/4t} \quad \text{at } \boldsymbol{x}_2 = (-R, 0). \tag{6.1}$$

The next eikonal, denoted $S_1(\boldsymbol{y}, \boldsymbol{x})$, is given on the x-axis by $S_1(\boldsymbol{x}_1, \boldsymbol{x}_2) = 2R - x_1 - x_2$, and its boundary values are

$$S_1(\boldsymbol{x}_1, \boldsymbol{x}_2) = R - x_1 \quad \text{at} \quad \boldsymbol{x}_2 = (R, 0)$$

and

$$S_1(\boldsymbol{x}_1, \boldsymbol{x}_2) = 3R - x_1 \quad \text{at} \quad \boldsymbol{x}_2 = (-R, 0).$$

Thus the approximation of Green's function $G(\boldsymbol{y}, \boldsymbol{x}, t)$,

$$G(\boldsymbol{y}, \boldsymbol{x}, t) \sim G_0(\boldsymbol{y}, \boldsymbol{x}, t) - G_1(\boldsymbol{y}, \boldsymbol{x}, t),$$

corresponding to the ray solutions $G_0(\boldsymbol{y}, \boldsymbol{x}, t)$ and

$$G_1(\boldsymbol{x}, \boldsymbol{y}, t) = Z_1(\boldsymbol{x}, \boldsymbol{y}, t)\, e^{-S_1^2(\boldsymbol{y}, \boldsymbol{x})/4t},$$

will satisfy the boundary condition at (x_1, R) if $Z_1(\boldsymbol{y}, \boldsymbol{x}, t)$ is chosen so that

$$Z_1(\boldsymbol{x}_1, \boldsymbol{x}_2, t) = \frac{1}{4\pi t} \quad \text{at} \quad \boldsymbol{x}_2 = (R, 0).$$

However, this approximation does not satisfy the boundary condition at $\boldsymbol{x}_2 = (-R, 0)$. The error in the boundary values at $\boldsymbol{x}_2 = (-R, 0)$ is

$$\begin{aligned} &G_0(\boldsymbol{x}_1, \boldsymbol{x}_2, t) - G_1(\boldsymbol{x}_1, \boldsymbol{x}_2, t) \\ &= \frac{1}{4\pi t} e^{-(R+x_1)^2/4t} - Z_1(\boldsymbol{x}_1, \boldsymbol{x}_2, t)\, e^{-4(R-x_1)^2/4t} \quad \text{at } \boldsymbol{x}_2 = (-R, 0) \end{aligned}$$

and is of the same order of magnitude as that of the leading-order approximation (6.1). To make up for the missed boundary condition, the further approximation

$$G(\boldsymbol{y}, \boldsymbol{x}, t) \sim G_0(\boldsymbol{y}, \boldsymbol{x}, t) - G_1(\boldsymbol{y}, \boldsymbol{x}, t) - G_2(\boldsymbol{y}, \boldsymbol{x}, t) \tag{6.2}$$

can be used, with

$$G_2(\boldsymbol{y}, \boldsymbol{x}, t) = Z_2(\boldsymbol{y}, \boldsymbol{x}, t)\, e^{-s_1^2(\boldsymbol{y}, \boldsymbol{x})/4t},$$

where on the x-axis

$$s_1(\boldsymbol{x}_1, \boldsymbol{x}_2) = 2R + x_1 + x_2$$

and

$$Z_2(\boldsymbol{x}_1, \boldsymbol{x}_2, t) = \frac{1}{4\pi t} \quad \text{at} \quad \boldsymbol{x}_2 = (-R, 0).$$

This eikonal corresponds to rays with two reflections in the boundary. The approximation (6.2) decreases the error in the boundary condition at $\boldsymbol{x}_2 = (-R, 0)$ to

$$-Z_1(\boldsymbol{x}_1, \boldsymbol{x}_2, t)\, e^{-4(R-x_1)^2/4t}$$

but misses the boundary condition at $\boldsymbol{x}_2 = (R, 0)$ with error

$$\begin{aligned} &G_0(\boldsymbol{x}_1, \boldsymbol{x}_2, t) - G_1(\boldsymbol{x}_1, \boldsymbol{x}_2, t) - G_2(\boldsymbol{x}_1, \boldsymbol{x}_2, t) \\ &= -Z_2(\boldsymbol{x}_1, \boldsymbol{x}_2, t)\, e^{-(3R+x_1)^2/4t} \quad \text{at} \quad \boldsymbol{x}_2 = (R, 0). \end{aligned}$$

This process gives successive approximations to Green's function with errors that decrease at transcendental rather than algebraic rates.

The approximation to the trace produced by $G_0(\boldsymbol{y}, \boldsymbol{x}, t)$ is the first algebraic term in the expansion (1.8). The contributions of the terms $-G_1(\boldsymbol{y}, \boldsymbol{x}, t)$ and $-G_2(\boldsymbol{y}, \boldsymbol{x}, t)$ in the approximation (6.2) of terms that are $O(\sqrt{t}e^{-R^2/t})$ are identical but with opposite signs, and thus they cancel each other. The second term contributes a negative term that is $O(\sqrt{t}e^{-4R^2/t})$. The term $O(\sqrt{t}e^{-R^2/t})$ for small t corresponds to $O(\frac{1}{s}e^{-2R\sqrt{s}})$ for large positive s in the Laplace plane. The number $2R$ is the length of the periodic orbit of a billiard ball bouncing inside a circle with the center removed, that is, inside the domain $\Omega - \Gamma$, where the set of critical points Γ consists of the center. Similarly, the term $O(\sqrt{t}e^{-4R^2/t})$ for small t corresponds to $O(\frac{1}{s}e^{-4R\sqrt{s}})$ for large positive s in the Laplace plane. The number $4R$ is the length of the minimal periodic orbit of a billiard ball bouncing inside a disk. We conclude that the conjecture of [10] should be supplemented with the orbit of length $2R$.

If Ω is an annulus between two concentric circles, of radii a and b, respectively, $(a > b)$, the two connected components of the boundary are the two circles, and there are no critical points in the domain relative to either one of them. In this case $\delta_1 = (a - b)$.

If Ω is the ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} < 1$$

with $a > b$, the locus of critical points relative to the boundary is the segment

$$\Gamma = \left[-\frac{a^2 - b^2}{a}, \frac{a^2 - b^2}{a} \right]$$

on the x-axis. The segment Γ is the short diagonal of the evolute of the ellipse (the asteroid $(ax)^{2/3} + (by)^{2/3} = (a^2 - b^2)^{2/3}$). For the ellipse there are exponents in (1.15) which are $\delta_1 = 2b$ and its multiples and $\delta_2 = 2a$ and its multiples, as well as extremal periodic orbits with any number of reflections in the boundary.

Finally, we observe that if the boundary is reflecting (i.e., a homogeneous Neumann boundary condition), the exponential decay rate of the transcendental terms in the expansion of the trace is the same as in the case of absorbing boundary (homogeneous Dirichlet boundary condition). In this case the second term in the expansion (1.15) changes sign.

Obviously, rays that are reflected from the boundary more than once also give rise to ray solutions. The number of ray solutions needed in the expansion (3.7) is determined by the required degree of asymptotic approximation of the boundary conditions. If only a finite sum of ray solutions satisfies the boundary conditions, the sum (3.7) is finite. Otherwise, additional ray solutions improve the degree of approximation of the boundary conditions, as described in the one-dimensional ray expansion in section 2.

The derivation of the algorithm described in section 5 suggests further conjectures of the type (1.9) [10] concerning the coefficients of the power series $P_n(x)$ in the asymptotic series (1.15). They should relate the rate of growth of the coefficients of $P_1(x)$ to δ_2, and so on. This will make the evaluation of δ_n possible for $n > 1$, as above.

Finally, the asymptotic convergence of the ray expansion follows from the maximum principle for the heat equation in a straightforward manner.

ERRATUM: SINGULARITY FORMATION IN CHEMOTAXIS—A CONJECTURE OF NAGAI*

MATTHEW A. HALVERSON†, HOWARD A. LEVINE†, AND JOANNA RENCŁAWOWICZ‡

Abstract. In [H. A. Levine and J. Rencławowicz, *SIAM J. Appl. Math.*, 65 (2004), pp. 336–360] we considered the problem $u_t = u_{xx} - (uv_x)_x, v_t = u - av$ on the interval $I = [0, 1]$, where $u_x, v_x = 0$ at the end points, $u(x, 0), v(x, 0)$ are prescribed, and $a > 0$. (It was claimed in that article that there were solutions that blow up in finite time in every neighborhood of the spatially homogeneous steady state $(u, v) = (\mu, \mu/a)$ if $\mu > a$.) Here we correct an estimate and reduce Nagai's conjecture to the following statement. Let $\sigma = a/(\mu - a), \rho_1 = 1$. If $\lim_{n\to+\infty} \rho_n$ exists, where for $n \geq 2$, $\rho_n^n \equiv 1/(n-1)\sum_{j=1}^{n-1}(1 + \sigma/j)\rho_j^j \rho_{n-j}^{n-j}$, then the blow up assertion holds.

1. Introduction. In [1] we studied the system $u_t = u_{xx} - (uv_x)_x, v_t = u - av$ on the interval $I = [0, 1]$, where $u_x, v_x = 0$ at the end points, $u(x, 0), v(x, 0)$, are prescribed, and $a > 0$. Nagai and Nakaki [2] showed that there are solutions that are unbounded in finite *or* in infinite time.[1] We claimed that there were initial conditions for which solutions failed to exist for all time. In our proof we used a differential inequality, the derivation of which was unfortunately flawed. We correct this and make more precise the statement proved in [1].

2. Approximate solution. The notation of [1] is in force here. Because system $u_t = u_{xx} - (uv_x)_x, v_t = u - av$ is autonomous, we can assume the initial values are prescribed at $t = 0$ and that the blow up time, when it exists, is positive. As in [1], define, for any sequence $z(t) = \{z_n(t)\}_{n=1}^{\infty}$, $\mathcal{G}_n(z, z') = (1/2)C^2 n\{(\mathcal{M}z * z')_n + n\frac{a}{2}(z*z)_n\}$ and $\mathcal{H}_n(z, z') = (1/2)C^2 n\{[(T_n\mathcal{M}z, z') - (\mathcal{M}z, T_n z')] + an(z, T_n z)\}$, where $\mathcal{M}z(t) = \{nz_n(t)\}_{n=1}^{\infty}$ and $T_k z(t) = \{z_{n+k}(t)\}_{n=1}^{\infty}$. Here $|z| = \{|z_n|\}_{n=1}^{\infty}$ and $(z*w)_n = \sum_{k=1}^{n-1} z_k w_{n-k}$. (The sum is zero if $n = 1$.)

The infinite system of ordinary differential equations for the cosine coefficients $h(t) = \{h_n(t)\}_{n=1}^{\infty}$ is[2]

$$\mathfrak{L}_n h_n \equiv h_n'' + (C^2n^2 + a)h_n' - (\mu - a)C^2n^2h_n = \mathcal{G}_n(h, h') + \mathcal{H}_n(h, h').$$

The infinite system of ordinary differential equations satisfied by the cosine coefficients for the approximate problem, $g(t) = \{g_n(t)\}_{n=1}^{\infty}$, satisfies $\mathfrak{L}_n g_n = \mathcal{G}_n(g, g')$. The

[1]The Nagai conjecture states that if $\mu > a$, there are spatially nonhomogeneous solutions beginning in every small neighborhood of $(\mu, \mu/a)$ which cannot exist for all time.

[2]The spatially homogeneous solution is given by $V(t) = \mu/a + (v_0 - \mu/a)\exp(-at)$, $U(t) = \mu$. One sets $\psi(x, t) = v(x, t) - V(t)$, $u(x, t) = \mu + \psi_t + a\psi$. Then $h(t)$ is the sequence of cosine coefficients for $\psi(x, t)$.

particular sequence $g(t) \equiv \{g_n(t) = a_n e^{n\lambda t}\}_{n=1}^{\infty}$ satisfies this system for $a_1 > 0$, and for $n \geq 2$ and any integer $M > 0$ with $C = 2\pi M$, $\mu > a$ if

$$2\lambda[n - a/(4\pi^2 M^2)]a_n = \frac{1}{n-1}\sum_{k=1}^{n-1}[\lambda(n-k)k + ak]a_k a_{n-k}, \tag{2.1}$$

where λ is the positive root of $\lambda^2 + (4\pi^2 M^2 + a)\lambda - (\mu - a)4\pi^2 M^2 = 0$. There are positive constants a, b, ϵ, δ with $a\epsilon^n \leq na_n \leq b\delta^n$ for all positive integers [1]. From this, it follows that $\liminf_{n\to+\infty}[(-\ln na_n)/(n\lambda)] \equiv \underline{T_b}$ and $\limsup_{n\to+\infty}[(-\ln na_n)/(n\lambda)] \equiv \overline{T_b}$ are finite. Hence there is a subsequence $\{a_{n_k}\}_{k=1}^{\infty}$ such that $\lim_{k\to+\infty}[(-\ln n_k a_{n_k})/(n_k\lambda)] \equiv \underline{T_b}$. For this sequence, $\lim_{k\to+\infty} n_k a_{n_k} \exp(n_k\lambda\underline{T_b}) = 1$. Set $a_n = (A_n/n)\exp(-n\lambda\underline{T_b})$. On the subsequence, $A_{n_k} \to 1$ and

$$\lim_{t\uparrow\underline{T_b}} \sum_{k=1}^{\infty} A_{n_k} e^{-n_k\lambda(\underline{T_b}-t)} = +\infty \text{ and } \lim_{t\uparrow\underline{T_b}} \sum_{k=1}^{\infty} \frac{A_{n_k} e^{-n_k\lambda(\underline{T_b}-t)}}{{n_k}^{1+\delta}} < +\infty \tag{2.2}$$

(for any $\delta > 0$).

Now $\underline{T_b}$ must be the blow up time for the approximate solution $g(t)$ in the space $\ell_1^1(0,\underline{T_b}) \times \ell^1(0,\underline{T_b})$. (A sequence $\{a_n\}$ is in ℓ_1^1 if $\{na_n\}$ is in ℓ^1.) To see this, note that as long as t is in the existence interval,

$$\begin{aligned} \|\mathcal{M}g(t)\|_{\ell^1} + \|g'(t)\|_{\ell^1} &= \sum_{n=1}^{\infty} na_n(1+\lambda)e^{n\lambda t} \geq (1+\lambda)\sum_{k=1}^{\infty} n_k a_{n_k} e^{n_k\lambda t} \\ &= (1+\lambda)\sum_{k=1}^{\infty} A_k e^{-n_k\lambda(T_b - t)}. \end{aligned} \tag{2.3}$$

Consequently, from the first equation in (2.2), $g(\cdot)$ must blow up at some time, possibly earlier than $\underline{T_b}$. If $t < \underline{T_b}$, then $\liminf_{n\to+\infty}[(-\ln na_n)/(n\lambda)] \equiv \underline{T_b} > \underline{T_b} - \delta > t$ for some positive δ. Therefore, for sufficiently large N, $\sum_{n=N}^{\infty} na_n e^{n\lambda t} \leq \sum_{n=N}^{\infty} ne^{-n\lambda(\underline{T_b}-\delta-t)} < \infty$.

Set $\sigma = a/\lambda$. Let $\{\ln[na_n/(2a_1^n)]/n\}_{n=1}^{\infty} = \{\ln A_n/n\}_{n=1}^{\infty} \equiv \{p_n/n\}_{n=1}^{\infty}$. The p_n satisfy $p_1 = -\ln 2$, and for $n \geq 2$, $[1 - a/(4\pi^2 M^2 n)]e^{p_n} = \frac{1}{n-1}\sum_{j=1}^{n-1}(1 + \sigma/j)e^{(p_j + p_{n-j})}$. Then we have the following theorem.

THEOREM 1 (Nagai's conjecture). *Let $\lim_{n\to+\infty}\frac{p_n}{n}$ exist. The corresponding solution of the Nagai problem for which $h_n(0) = g_n(0)$ and $h_n'(0) = g_n'(0)$ for all n cannot both exist and be ℓ^1 regular on $[0,\infty)$. (A solution of the Nagai–Nakaki problem is ℓ^1 regular on an interval $I = [0, T_b)$ if it exists there and if $(\|\mathcal{M}h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1})$ is uniformly bounded on compact subsets I.)*

3. Estimate. Inequality (7.5) of [1] is incorrect. The correct form of the upper bound for the norm of $g - h \equiv w$, $\|\mathcal{M}w(t)\|_{\ell^1} + \|w'(t)\|_{\ell^1}$, is based on the following (infinite) system of ordinary differential equations:

$$\mathfrak{L}_n w_n = \mathcal{G}_n(h-g, h') + \mathcal{G}_n(g, h'-g') + \mathcal{H}_n(h,h') = \mathcal{G}_n(w,h') + \mathcal{G}_n(g,w') + \mathcal{H}_n(h,h') \tag{3.1}$$

and, for some $B > 0$ depending perhaps on τ but not on w, w', h, h', g, g', is given by

(3.2)

$$\|\mathcal{M}w(t)\|_{\ell^1} + \|w'(t)\|_{\ell^1} \le I(t) + J(t) + B\int_0^t \frac{(\|\mathcal{M}h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1})^2}{\sqrt{t-s}}\,ds + B\int_0^t \frac{(\|\mathcal{M}w(s)\|_{\ell^1} + \|w'(s)\|_{\ell^1})(\|\mathcal{M}h(s)\|_{\ell^1} + \|h'(s)\|_{\ell^1})}{\sqrt{t-s}}\,ds,$$

where

$$I(t)+J(t) \equiv \int_0^t \sum_{n=1}^{\infty} \mathcal{M}(|g'|*\mathcal{M}|w|)_n e^{-dn^2(t-s)}\,ds + \int_0^t \sum_{n=1}^{\infty} \mathcal{M}^2(|g|*|w|)_n e^{-dn^2(t-s)}\,ds,$$

and where $d > 0$ is the positive constant in [1, Lemma 1]. We have

$$\begin{aligned}
I(t) &= \int_0^t \sum_{n=1}^{\infty}\sum_{k=1}^{n-1} n(n-k)|g'_k||w_{n-k}|e^{-dn^2(t-s)}\,ds \\
&= \int_0^t \sum_{k=1}^{\infty}\sum_{n=1}^{\infty} n(n+k)|g'_k||w_n|e^{-d(n+k)^2(t-s)}\,ds \\
&\le \int_0^t \sum_{k=1}^{\infty} |g'_k|e^{-(d/2)k^2(t-s)} \left[\sum_{n=1}^{\infty}(n+k)e^{-(d/2)(n+k)^2(t-s)} n|w_n|\right] ds \\
&\le c\int_0^t \frac{\sum_{k=1}^{\infty}|g'_k|e^{-(d/2)k^2(t-s)}}{\sqrt{t-s}}\|\mathcal{M}w(s)\|_{\ell_1}\,ds \\
&\le c\int_0^t \sum_{k=1}^{\infty} A_k e^{-(d/2)k^2(t-s)-\lambda k(T_b-s)}\frac{\|\mathcal{M}w(s)\|_{\ell_1}}{\sqrt{t-s}}\,ds \\
&\le c\int_0^t \left\{\sum_{k=1}^{\infty} A_k e^{-[(d/2)k^2+k\lambda](t-s)}\right\}\frac{\|\mathcal{M}w(s)\|_{\ell_1}}{\sqrt{t-s}}\,ds \equiv c\int_0^t \mathcal{W}(t-s)\frac{\|\mathcal{M}w(s)\|_{\ell_1}}{\sqrt{t-s}}\,ds.
\end{aligned}$$

In the same manner,

$$\begin{aligned}
J(t) &= \int_0^t \sum_{n=1}^{\infty}\sum_{k=1}^{n-1} n^2|g_k||w_{n-k}|e^{-dn^2(t-s)}\,ds \\
&\le \int_0^t \sum_{k=1}^{\infty}\sum_{n=1}^{\infty}(n+k)^2|g_k||w_n|e^{-d(n+k)^2(t-s)}\,ds \\
&\le \int_0^t \sum_{k=1}^{\infty}|kg_k|e^{-(d/2)k^2(t-s)}\left[\sum_{n=1}^{\infty}\frac{(n+k)^2}{kn}e^{-(d/2)(n+k)^2(t-s)}n|w_n|\right] ds.
\end{aligned}$$

From the inequality $(k+l)/kl \le 2$,

$$J(t) \le c'\int_0^t \left\{\sum_{k=1}^{\infty} A_k e^{-[(d/2)k^2+k\lambda](t-s)}\right\}\frac{\|\mathcal{M}w(s)\|_{\ell_1}}{\sqrt{t-s}}\,ds \equiv c'\int_0^t \mathcal{W}(t-s)\frac{\|\mathcal{M}w(s)\|_{\ell_1}}{\sqrt{t-s}}\,ds.$$

In view of (2.2), $\lim_{t\uparrow T_b}\sum_{k=1}^{\infty} A_k k^{-2}e^{-k\lambda(T_b-t)} < +\infty$. Thus $\mathcal{W}(t)$ is in every $L^p[0,T_b]$ space for $1 \le p < \infty$. With $f(t) = \|\mathcal{M}w(t)\|_{\ell^1} + \|w'(t)\|_{\ell^1}$, we see $f(t) \le \int_0^t \mathcal{W}(t-s)f(s)/\sqrt{t-s}\,ds + \Phi(h(t))$. From Hölder's inequality with $1/p+1/r+1/q = 1$

and $1 < r < 2$, there is a constant $K > 0$ such that $f(t) \le K[\int_0^t f(s)^q\, ds]^{1/q} + \Phi(h(t))$ on $[0, T_b)$. From Gronwall's inequality, if h is global, $f(t)$ is bounded on $[0, T_b)$. From the first sum in (2.2) and the triangle inequality, this is impossible.

Other minor errors in [1]. Page 345, equation (5.1): Replace $k(w_k g_{n+k} + h_k w_{n+k})$ by $n(w_k g_{n+k} + h_k w_{n+k})$. Page 349, equation in line 13: $c\sqrt{t}$ should be replaced by $c \sup_{[0,T]} \sqrt{t}$.

THE INVERSE CONDUCTIVITY PROBLEM WITH AN IMPERFECTLY KNOWN BOUNDARY*

VILLE KOLEHMAINEN†, MATTI LASSAS‡, AND PETRI OLA§

Abstract. We show how to eliminate the error caused by an incorrectly modeled boundary in electrical impedance tomography (EIT). In practical measurements, one usually lacks exact knowledge of the boundary. Because of this, the numerical reconstruction from the measured EIT data is done using a model domain that represents the best guess for the true domain. However, it has been noticed that an inaccurate model of the boundary causes severe errors for the reconstructions. We introduce a new algorithm to find a deformed image of the original isotropic conductivity based on the theory of Teichmüller spaces, and we implement it numerically.

1. Introduction.

We consider the electrical impedance tomography (EIT) problem, i.e., the determination of an unknown conductivity distribution inside a domain, for example the human thorax, from voltage and current measurements made on the boundary. Mathematically this is formulated as follows: Let $\Omega \subset \mathbb{R}^2$ be the measurement domain, and denote by $\gamma = (\gamma^{ij})$ the symmetric matrix describing the conductivity in Ω. We assume that the matrix has components in $L^\infty(\Omega)$ and that it is strictly positive definite; that is, for some $c > 0$ we have $\langle \xi, \gamma(x)\xi \rangle \geq c||\xi||^2$ for all $x \in \Omega$. The electrical potential u satisfies in Ω the equation

$$\nabla \cdot \gamma \nabla u = 0. \tag{1.1}$$

To uniquely fix the solution u it is enough to give its value on the boundary. Let this be $u|_{\partial\Omega} = f \in H^{1/2}(\partial\Omega)$, where $H^{1/2}(\partial\Omega)$ is the Sobolev space. Then (1.1) has a unique weak solution $u \in H^1(\Omega)$.

Our boundary data is the map that takes the voltage distribution f on the boundary for all f to the corresponding current flux through the boundary, $\nu \cdot \gamma \nabla u$, where ν is the exterior unit normal to Ω. Mathematically this amounts to the knowledge of the Dirichlet–Neumann map Λ corresponding to γ, i.e., the map taking the Dirichlet boundary values to the corresponding Neumann boundary values of the solution to (1.1),

$$\Lambda_\gamma : u|_{\partial\Omega} \mapsto \sum_{i,j=1}^{2} \nu_i \, \gamma^{ij} \frac{\partial u}{\partial x_j}\bigg|_{\partial\Omega}.$$

§Department of Mathematics and Statistics, Rolf Nevanlinna Institute, University of Helsinki, Helsinki P. O. Box 4, FIN-00014, Finland (Petri.Ola@rni.helsinki.fi).

This defines a bounded operator $\Lambda_\gamma : H^{1/2}(\partial\Omega) \to H^{-1/2}(\partial\Omega)$. The symmetric quadratic form corresponding to Λ_γ,

$$\Lambda_\gamma[h,h] := \int_{\partial\Omega} h\,\Lambda_\gamma h\,dS = \int_{\partial\Omega} \nabla u\cdot\gamma\nabla u\,dx, \tag{1.2}$$

equals in physical terms the power needed to maintain the potential h on $\partial\Omega$.

When γ is a scalar-valued function times an identity matrix, we say that the conductivity is *isotropic*. As usual, conductivities that may be matrix-valued are referred to as *anisotropic* conductivities. The EIT problem is to reconstruct γ from Λ_γ. The problem was originally proposed by Calderón [6] and then solved in dimensions three and higher for isotropic smooth conductivities in [18]. The two-dimensional case that is relevant to us was solved by Nachman [13] for isotropic conductivities assuming $\gamma \in W^{2,p}$, $p > 1$, and then finally for general L^∞-smooth isotropic conductivities by Astala and Päivärinta in a celebrated paper [4].

The conductivity equation is invariant under deformations of the domain Ω in the following sense. If F is a diffeomorphism taking Ω to some other domain $\widetilde{\Omega}$, then $u \circ F^{-1}$ will satisfy the conductivity equation in $\widetilde{\Omega}$ with conductivity

$$\widetilde{\gamma}(x) = \left.\frac{F'(y)\,\gamma(y)\,(F'(y))^t}{|\det F'(y)|}\right|_{y=F^{-1}(x)}, \tag{1.3}$$

where F' is the Jacobi matrix of map F and u is a solution of $\nabla\cdot\gamma\nabla u = 0$ in Ω. We say that $\widetilde{\gamma}$ is the push forward of γ by F and denote it by $\widetilde{\gamma} = F_*\gamma$. Note that all this is well defined for general matrix-valued γ. For us the starting point is the trivial observation that even if γ is isotropic, the deformed conductivity $\widetilde{\gamma}$ will not in general be isotropic. The boundary measurements are invariant: When $f : \partial\Omega \to \partial\widetilde{\Omega}$ is the restriction of $F : \Omega \to \widetilde{\Omega}$, we say that $\widetilde{\Lambda} = f_*\Lambda_\gamma$,

$$((f_*\Lambda_\gamma)h)(x) = (\Lambda_\gamma(h\circ f))(y)|_{y=f^{-1}(x)}, \quad h \in H^{1/2}(\partial\widetilde{\Omega}),$$

is the push forward of Λ_γ in f. As seen in [17], it turns out that $f_*\Lambda_\gamma = \Lambda_{F_*\gamma}$.

The fact that the anisotropic conductivity equation and the boundary measurements are invariant has the important consequence that the EIT problem with an anisotropic conductivity is not uniquely solvable, even though the isotropic problem is; see [17].

In practice, when solving the EIT problem in a given domain Ω, one typically seeks the isotropic conductivity that minimizes

$$||\Lambda_{meas} - \Lambda_\gamma||^2 + \alpha||\gamma||_X^2 \tag{1.4}$$

for γ defined in terms of some triangulation of Ω as, e.g., a piecewise constant function and $||\cdot||_X$ is some regularization norm [10]. Here Λ_{meas} is the measurement of the Dirichlet–Neumann map that contains measurement errors.

In practice, one of the key difficulties in solving the EIT problem is that the domain Ω may not be known accurately. It has been noticed that the use of a slightly incorrect model for Ω, i.e., a slightly incorrect model of the boundary, causes serious errors in reconstructions; see, e.g., [9, 1, 8]. As an example, consider the EIT measurements of pulmonary function from the human thorax. The measurement electrodes are attached on the skin of the patient around the thorax. In principle, an exact parameterization for the shape of the thorax could be obtained from other medical

imaging modalities such as magnetic resonance imaging (MRI) or computerized tomography (CT). However, in most cases this data is not available, and one has to resort to some approximate thorax model. Further, the shape of the thorax varies between breathing states, and it is also dependent on the orientation of the patient. Thus, the thorax geometry is known inaccurately even in best-case scenarios.

In this paper our aim is to propose a method to overcome the problem that the boundary and its parameterization are not exactly known. The set-up of the problem we consider is the following.

We want to recover the unknown conductivity γ in Ω from the measurements of the Dirichlet-to-Neumann map, and we assume a priori that γ is isotropic. We assume that $\partial\Omega$ and Λ_γ are not known. Instead, let Ω_m, called the model domain, be our best guess for the domain, and let $f_m : \partial\Omega \to \partial\Omega_m$ be a diffeomorphism modeling the approximate knowledge of the boundary. As the data for the inverse problem, we assume that we are given the boundary of the model domain, $\partial\Omega_m$, and the map $\Lambda_m := (f_m)_*\Lambda_\gamma$ on $\partial\Omega_m$. Note that we have simplified the problem by assuming that the only error in Λ_m comes from the imperfect knowledge of the boundary.

This set-up is motivated by the fact that the quadratic form corresponding to Λ_m,

$$\Lambda_m[h,h] = \int_{\partial\Omega_m} h\,\Lambda_m h\,dS = \int_{\partial\Omega} (h\circ f_m)\,\Lambda_\gamma(h\circ f_m)\,dS, \qquad h \in H^{1/2}(\partial\Omega_m),$$

represents the power needed to maintain the potential $h \circ f_m$ on $\partial\Omega$.

Since Λ_m usually does not correspond to any isotropic conductivity because of the deformation done when going from the original domain Ω to Ω_m, we obtain an erroneous solution γ when solving the minimization problem (1.4). This means that a systematic error in the domain model causes a systematic error in the reconstruction. In particular, local changes of the conductivity often give rise to nonlocalized changes in reconstructions due to the above systematic error. Thus the spatial resolution of details of reconstructions are often weak. This is clearly seen in practical measurements; see, e.g., [8].

We note that in solving the minimization problem (1.4) one could forget the assumption that γ is isotropic and find the minimizer in the set of anisotropic conductivities. However, the anisotropic inverse problem has a nonunique solution, and as the minimization problem is highly nonconvex, the minimization would be hard; as usual, forgetting existing a priori information makes the solution significantly worse.

To formulate our main results, let us define certain concepts. We start with the maximal anisotropy of an anisotropic conductivity.

DEFINITION 1.1. *Let $\gamma^{jk}(x)$ be an $L^\infty(\Omega)$-smooth matrix-valued conductivity in Ω, and let $\lambda_1(x)$ and $\lambda_2(x)$, $\lambda_1(x) \geq \lambda_2(x)$, be the eigenvalues of matrix $\gamma^{jk}(x)$. We define the maximal anisotropy of a conductivity to be $K(\gamma)$ given by*

$$K(\gamma) = \sup_{x\in\Omega} K(\gamma,x), \quad \textit{where} \quad K(\gamma,x) = \frac{\sqrt{L(x)}-1}{\sqrt{L(x)}+1}, \quad L(x) = \frac{\lambda_1(x)}{\lambda_2(x)}.$$

We call the function $K(\gamma,x)$ the anisotropy of γ at x. Here sup *denotes the essential supremum.*

Sometimes, to indicate the domain Ω, we denote $K(\gamma) = K_\Omega(\gamma)$. As a particularly important example needed later, let us consider the conductivity matrices of the form

$$\widehat{\gamma}(x) = \eta(x) R_{\theta(x)} \begin{pmatrix} \lambda^{1/2} & 0 \\ 0 & \lambda^{-1/2} \end{pmatrix} R_{\theta(x)}^{-1}, \tag{1.5}$$

where $\lambda \geq 1$ is a constant, $\eta(x) \in \mathbb{R}_+$ is a real-valued function, and $R_{\theta(x)}$ is a rotation matrix corresponding to angle $\theta(x)$, where

$$R_\theta = \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix}.$$

We denote such conductivities by $\widehat{\gamma} = \widehat{\gamma}_{\lambda,\theta,\eta}$. These conductivities have the anisotropy $K(\widehat{\gamma}, x) = c_\lambda = (\lambda^{1/2}-1)/(\lambda^{1/2}+1)$ at every point, and thus their maximal anisotropy is $K = c_\lambda$. We call such conductivities $\widehat{\gamma}$ *uniformly anisotropic conductivities.*

THEOREM 1.2. *Let Ω be a bounded simply connected $C^{1,\alpha}$-domain with $\alpha > 0$. Assume that $\gamma \in C^{0,\alpha}(\overline{\Omega})$ is a (possibly) anisotropic conductivity and Λ_γ its Dirichlet–Neumann map. Let Ω_m be a model of the domain satisfying the same regularity assumptions as Ω, and $f_m : \partial\Omega \to \partial\Omega_m$ be a $C^{1,\alpha}$-smooth diffeomorphism.*

Assume that we are given $\partial\Omega_m$ and $\Lambda_m = (f_m)_*\Lambda_\gamma$. Then we have the following:

1. *There is a unique anisotropic conductivity $\widehat{\gamma} \in L^\infty(\Omega_m, \mathbb{R}^{2\times 2})$ such that if γ_1 is an anisotropic conductivity in Ω_m for which $\Lambda_{\gamma_1} = \Lambda_m$, then $K(\gamma_1) \geq K(\widehat{\gamma})$.*
2. *Let $\lambda \geq 1$ be such that $K(\widehat{\gamma}) = (\lambda^{1/2}-1)/(\lambda^{1/2}+1)$. Then there are unique $\theta \in L^\infty(\Omega_m, S^1)$ and $\eta \in L^\infty(\Omega_m, \mathbb{R}_+)$ such that $\widehat{\gamma} = \widehat{\gamma}_{\lambda,\theta,\eta}$.*

Theorem 1.2 can be interpreted by saying that we can find a unique conductivity in Ω_m that is as close as possible to being isotropic. For an isotropic conductivity, the assumption on smoothness of conductivity can be relaxed, as can be seen from the following theorem, which is the main result of the paper.

THEOREM 1.3. *Let Ω, Ω_m, and f_m be as in Theorem* 1.2. *Let $\gamma \in L^\infty(\overline{\Omega})$ be an isotropic conductivity. Assume that we are given $\partial\Omega_m$ and $\Lambda_m = (f_m)_*\Lambda_\gamma$. Then results* 1 *and* 2 *of Theorem* 1.2 *are valid.*

Theorem 1.2 yields immediately the following algorithm for finding $\widehat{\gamma}$.

Remark 1. The conductivity $\widehat{\gamma} = \widehat{\gamma}_{\lambda,\eta,\theta}$ can obtained using the unique solution of the minimization problem

$$\min_{(\lambda,\theta,\eta)\in S} \lambda, \quad \text{where } S = \left\{ (\lambda,\theta,\eta) \in [1,\infty) \times L^\infty \times L^\infty \mid \Lambda_{\widehat{\gamma}(\lambda,\theta,\eta)} = \Lambda_m \right\}. \tag{1.6}$$

Later, in implementation of the algorithm we approximate the problem (1.6) with the regularized minimization problem

$$\min_{(\lambda,\theta,\eta)} ||\Lambda_{\widehat{\gamma}(\lambda,\theta,\eta)} - \Lambda_m||^2_{L(H^{1/2}(\partial\Omega_m), H^{-1/2}(\partial\Omega_m))} + \varepsilon_1 f(\lambda) + \varepsilon_2 ||\theta||^2_{H^1} + \varepsilon_2 ||\eta||^2_{H^1}, \tag{1.7}$$

where $f : [1,\infty) \to \mathbb{R}_+$ is a convex function that has its minimum near $\lambda = 1$ and $\lim_{t\to 1} f(t) = \lim_{t\to\infty} f(t) = \infty$ and $\varepsilon_1, \varepsilon_2, \varepsilon_3 > 0$.

The proof of Theorem 1.2 is based on the theory of quasi-conformal maps. There are several equivalent definitions for these maps, and we will present the one based on a partial differential equation (Beltrami equation) in section 2. However, the quasi-conformal maps also have a geometric definition. Indeed, they are generalizations of conformal maps that take infinitesimal disks at z to infinitesimal disks at $f(z)$, and the radii gets dilated by $|f'(z)|$. Analogously, a homeomorphic map is quasi-conformal on a domain Ω if infinitesimal disks at any $z \in \Omega$ get mapped to infinitesimal ellipsoids at $f(z)$. The ratio of the larger semiaxis to the smaller semiaxis is called the dilation of f at z, and the supremum of dilatations over Ω is the maximal dilation. This

dilatation of infinitesimal discs is in fact the reason why isotropic conductivities change to anisotropic ones in push forwards with quasi-conformal maps.

The crucial fact that we use in proving Theorem 1.2 is a result of Strebel [16] that, roughly speaking, says that among all quasi-conformal self-maps of the unit disk to itself with a given sufficiently smooth boundary value there is a unique one with the minimal maximal dilation. This will yield that corresponding to the given boundary modeling map $f_m : \partial\Omega \to \partial\Omega_m$ there is a unique map $F : \Omega \to \Omega_m$ having the minimal maximal dilation. We will show that this leads to the following result.

PROPOSITION 1.4. *Let Ω, Ω_m, f_m, and an isotropic conductivity γ satisfy the assumptions of Theorem* 1.3. *Then there is a unique map $F : \Omega \to \Omega_m$, depending only on $f : \partial\Omega \to \partial\Omega_m$, such that for the uniformly anisotropic conductivity $\widehat{\gamma}$ corresponding to γ in Theorem* 1.2 *we have*

$$\det(\widehat{\gamma}(x))^{1/2} = \gamma(F^{-1}(x)). \tag{1.8}$$

Proposition 1.4 can interpreted as saying that, solving the minimization problem (1.6), we can find the function $(\det \widehat{\gamma}(x))^{1/2}$ in Ω_m that represents a deformed image of original conductivity γ in the unknown domain Ω, and that the deformation depends only on the error made in modeling the boundary, not on the conductivity in Ω.

In particular, this turns out to be useful as local perturbations of conductivity remain local in reconstruction: If we consider one fixed boundary modeling map $f_m : \partial\Omega \to \partial\Omega_m$ but two isotropic conductivities γ_1 and $\gamma_2 = \gamma_1 + \sigma$ in Ω, then the reconstructions $\widehat{\gamma}_1$ and $\widehat{\gamma}_2$ obtained by Theorem 1.2 corresponding to γ_1 and γ_2 satisfy

$$\det(\widehat{\gamma}_2(x))^{1/2} - \det(\widehat{\gamma}_1(x))^{1/2} = \sigma(F^{-1}(x)).$$

The paper is organized as follows. In section 2 we show how to use isothermal coordinates to push forward an anisotropic conductivity to an isotropic one. There we pay close attention to the smoothness required from γ and Ω and introduce the necessary background from the theory of anisotropic inverse problems. We apply this in section 3 to prove our main results using the existence of a Teichmüller mapping. In section 4 we consider physically realistic measurements, i.e., the so-called complete electrode model. The numerical implementation for the complete electrode model is then described in the last sections.

2. Quasi-conformal maps and solvability of the inverse problem with anisotropic conductivity. It is a classical result that every Riemannian surface is locally conformal to a Euclidean plane: This corresponds to choosing the coordinate system to be *isothermal* [19, section 5.10]. Similarly, every anisotropic conductivity matrix can be transformed into an isotropic conductivity. We identify the plane $\mathbb{R}^2$ with the complex plane $\mathbb{C}$. We use the class $L_{\infty,\alpha}(\Omega)$ that consists of conductivities $\gamma = a\,\sigma$, where $a \in L^\infty(\Omega)$ satisfies $a(x) \geq c > 0$ and σ is a $C^{1,\alpha}(\overline{\Omega})$-smooth symmetric positive definite matrix; i.e., we allow arbitrary L^∞-smooth conformal transformations of $C^{0,\alpha}$-smooth background conductivities. We need the smoothness of the background conductivity above to guarantee the existence of the unique extremal conductivity, but this is a conformally invariant procedure, and hence the smoothness of the conformal factor a plays no role, as we will see below. Notice also that by taking $\sigma = id$, we have an L^∞ isotropic conductivity.

LEMMA 2.1. *Let Ω be a bounded simply connected $C^{1,\alpha}$-domain with $\alpha > 0$. Assume that $\gamma \in L_{\infty,\alpha}(\Omega)$ is an anisotropic conductivity. Then there is a $C^{1,\alpha}$-smooth diffeomorphism $F : \overline{\Omega} \to \widetilde{\overline{\Omega}}$, $\widetilde{\Omega} = F(\Omega) \subset \mathbb{C}$ such that*

$$F_*\gamma = \beta, \tag{2.1}$$

where $F_*\gamma$ is defined by (1.3)*, and β is the identity matrix multiplied by a L^∞-smooth scalar function. Moreover,*

$$\beta = (\det \gamma \circ F^{-1})^{1/2} I.$$

The proof of this result is well known, but as smoothness of F is crucial later, we give the proof for the convenience of the reader.

Proof. The equation (2.1) is a priori a nonlinear system for the derivatives of F. However, in two dimensions this equation completely linearizes and is equivalent to the *Beltrami equation*

$$\overline{\partial} F = \mu \partial F, \tag{2.2}$$

where the complex derivatives are $\partial = \frac{1}{2}(\frac{\partial}{\partial x} - i\frac{\partial}{\partial y})$, $\overline{\partial} = \frac{1}{2}(\frac{\partial}{\partial x} + i\frac{\partial}{\partial y})$ and *the Beltrami coefficient* $\mu = \mu_F(z)$, called also the *complex dilatation*, is given by

$$\mu = \frac{-\gamma_{11} + \gamma_{22} - 2i\gamma_{12}}{\gamma_{11} + \gamma_{22} + 2\sqrt{\gamma_{11}\gamma_{22} - \gamma_{12}^2}}. \tag{2.3}$$

The function μ is invariant in multiplication of the conductivity with a positive scalar function. Thus we see that $\mu \in C^{0,\alpha}(\overline{\Omega})$. The function μ has the crucial property that it is strictly less than one in modulus:

$$\sup_{z\in\Omega} |\mu(z)| < 1. \tag{2.4}$$

Let us extend the conductivity matrix γ (a priori defined only in Ω) to the whole plane to be the identity matrix outside Ω. Similarly, μ is extended outside Ω by zero.

Next we consider how to solve the Beltrami equation, and for this we consider it in the whole plane. In order to have a unique solution we fix the behavior of F at infinity. Thus, consider

$$\begin{aligned} &\overline{\partial} F(z) = \mu(z)\partial F(z) \quad \text{in } \mathbb{C}, \\ &F(z) = z + h(z), \\ &\lim_{z\to\infty} h(z) = 0, \end{aligned} \tag{2.5}$$

where μ is a compactly supported L^∞-function satisfying (2.4). This problem has unique solution $F \in L^p_\delta$ when p is close enough to 2 and $-2/p < \delta < 1 - 1/p$. For the proof of this, see, for example, [2] or [17]. The proof is based on the fact that (2.5) can be written as an integral equation

$$F(z) + \frac{1}{\pi}\int_{\mathbb{C}} \frac{\mu(\zeta)\partial F(\zeta)}{z-\zeta}\, da(\zeta) = z, \tag{2.6}$$

where $da(\zeta)$ is Euclidean area in $\mathbb{C}$ (or $\mathbb{R}^2$). As $||\mu||_\infty < 1$, it turns out that the left-hand side of (2.6) is of the form of the identity plus a contractive operator in Sobolev space $W^{1,p}(\Omega)$, with appropriate p, and thus (2.6) can be solved by an application of the Neumann-series argument.

Using interior Schauder estimates for (2.5), we see that if γ and thus μ are $C^{0,\alpha}$-smooth, the solution F has to be locally $C^{1,\alpha}$-smooth in $\mathbb{C}$, particularly in $\overline{\Omega}$. Using formula (1.3), we see that $F_*\gamma$ is $C^{0,\alpha}$-smooth in closure of $\widetilde{\Omega}$. □

In general, any solution $F : \Omega \to \widetilde{\Omega}$ to the Beltrami equation for μ which satisfies (2.4) and for which $F \in H^1(\Omega)$ is called *quasi-regular*. If a quasi-regular map $F : \Omega \to \widetilde{\Omega}$ is a homeomorphism, it is said to be *quasi-conformal*. The quasi-conformality can be defined also in geometrical terms; see [2, 11].

Next we recall the recent results for inverse problems for anisotropic conductivities γ. Let us consider a class of conductivities in Ω, given by

$$\Sigma(\gamma) = \{F_*\gamma \mid F : \Omega \to \Omega \text{ is a homeomorphism, } F, F^{-1} \in H^1(\Omega; \mathbb{C}), F|_{\partial\Omega} = I\};$$

that is, $\Sigma(\gamma)$ is the equivalence class of the conductivity γ in push forwards with boundary preserving diffeomorphisms. Then $\Lambda_\sigma = \Lambda_\gamma$ for all $\sigma \in \Sigma(\gamma)$. By [3], the converse is true; that is, if σ is a strictly positive definite L^∞-conductivity and $\Lambda_\sigma = \Lambda_\gamma$, then $\sigma \in \Sigma(\gamma)$. In other words, Λ_γ determines the equivalence class $\Sigma(\gamma)$. Note that diffeomorphism $F : \Omega \to \Omega$ such that $F \in H^1(\Omega; \mathbb{C})$ and $F|_{\partial\Omega} = I$ is quasi-conformal.

3. Proof of main results. We start by proving Theorems 1.2 and 1.3. To prove them at the same time, we consider a (possibly anisotropic) conductivity γ in class $L_{\infty,\alpha}(\Omega)$.

First we show that we can assume that Ω_m is the unit disc $\mathbb{D} \subset \mathbb{C}$. To prove this, let $f_m : \partial\Omega \to \partial\Omega_m$ be the boundary modeling map.

Our first observation is that as Ω_m is a simply connected domain, it follows from the Riemann mapping theorem that it can be mapped to unit disc $\mathbb{D}$ conformally. Moreover, as Ω_m is a $C^{1,\alpha}$-smooth domain, it follows from the Kellog–Warschawski theorem [14, Theorem 3.6] that the Riemann map can be chosen to be be a $C^{1,\alpha}$-diffeomorphism $F_0 : \overline{\Omega}_m \to \overline{\mathbb{D}}$ such that $F_0 : \Omega_m \to \mathbb{D}$ is conformal. Thus, if σ is some conductivity in class $L_{\infty,\alpha}(\Omega_m)$, we have that $\sigma_0 = (F_0)_*\sigma$ is a conductivity in class $L_{\infty,\alpha}(\mathbb{D})$.

Second, we observe that the uniformly anisotropic conductivity $\widehat{\gamma}_{\lambda,\theta,\eta}$ of the form (1.5) in Ω_m changes under $(F_0)_*$ to a uniformly anisotropic conductivity $(F_0)_*\widehat{\gamma}_{\lambda,\theta,\eta} = \widehat{\gamma}_{\lambda,\theta_0,\eta_0}$ in $\mathbb{D}$ such that $\eta_0 = \eta \circ F_0^{-1}$.

Third, we see that as $F_0 : \Omega_m \to \mathbb{D}$ is conformal, the maximal anisotropy of $(F_0)_*\sigma$ and σ satisfies

$$K_{\mathbb{D}}((F_0)_*\sigma) = K_\Omega(\sigma);$$

that is, the maximal anisotropy is preserved in conformal transformations for any σ.

Fourth, if $f_0 = F_0|_{\partial\Omega_m}$, then $\Lambda_{\sigma_0} = (f_0)_*\Lambda_\sigma$. Also, we see that our data is invariant in the change of the model domain in the sense that $(\widetilde{f}_m)_*\Lambda_\gamma = (\widetilde{f}_0)_*((\widetilde{f}_m)_*\Lambda_\gamma)$, where $\widetilde{f}_m = f_0 \circ f_m : \partial\Omega \to \partial\mathbb{D}$.

These four observations yield that it is enough to prove the assertion in the case when $\Omega_m = \mathbb{D}$. Indeed, changing Ω_m to $\mathbb{D}$ with F_0 keeps the boundary measurements, the smoothness of objects, the maximal anisotropy, as well as class of uniformly anisotropic conductivities invariant. More precisely, we can replace the boundary modeling map f_m by the map $\widetilde{f}_m = f_0 \circ f_m$. Figure 3.1 will help clarify the argument that follows.

Thus, let us return to proving Theorem 1.2 in the case when $\Omega_m = \mathbb{D}$. Let $f_m : \partial\Omega \to \partial\mathbb{D}$ be the boundary modeling map that is a $C^{1,\alpha}$-smooth diffeomorphism and where γ is a conductivity in class $L_{\infty,\alpha}(\Omega)$, with Dirichlet–Neumann map Λ_γ.

Let F_m be some $C^{1,\alpha}(\overline{\Omega})$-diffeomorphism $F_m : \overline{\Omega} \to \overline{\mathbb{D}}$ such that $F_m|_{\partial\Omega} = f_m$. There are many ways to construct such a map, and for the convenience of the reader

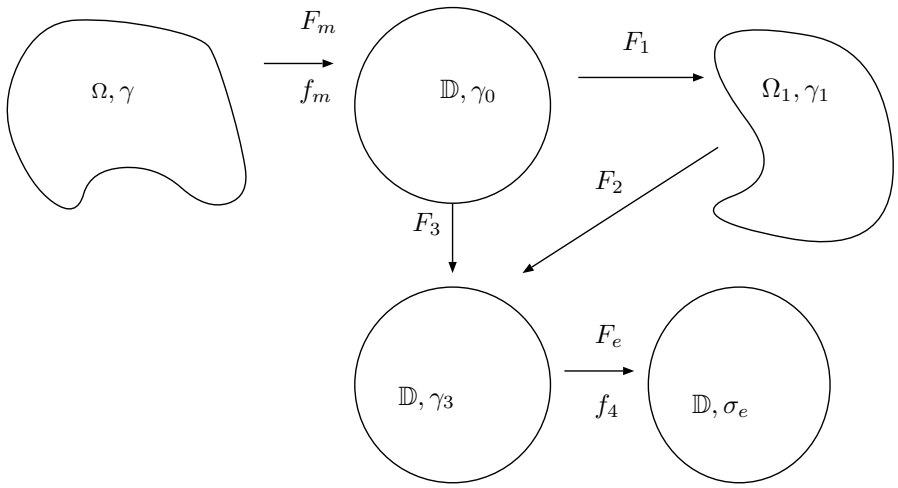

FIG. 3.1.

we present one simple way. Let $G : \Omega \to \mathbb{D}$ be a Riemann map. By [14, Theorem 3.7], G has $C^{1,\alpha}$-extension $G : \overline{\Omega} \to \overline{\mathbb{D}}$. Let $\phi = f_m \circ G^{-1} : \partial\mathbb{D} \to \partial\mathbb{D}$ and $\Phi(z) = |z| \exp(i(|z|^3 \arg(\phi(z/|z|)) + (1 - |z|^3)\arg(z/|z|)))$ be a $C^{1,\alpha}$-diffeomorphism $\mathbb{D} \to \mathbb{D}$ satisfying $\Phi|_{\partial\mathbb{D}} = \phi$. Then F_m can be chosen to be the map $\Phi \circ G$.

Let $\gamma_0 = (F_m)_*\gamma$ be an anisotropic conductivity in $\mathbb{D}$. By Lemma 2.1, there is a $C^{1,\alpha}$-diffeomorphism $F_1 : \overline{\Omega} \to \overline{\Omega}_1$ such that the conductivity $\gamma_1 = (F_1)_*\gamma_0$ is an isotropic $L^\infty(\Omega_1)$-conductivity.

As Ω_1 is a simply connected $C^{1,\alpha}$-smooth domain, by the Kellog–Warschawski theorem cited above there is a conformal map $F_2 : \Omega_1 \to \mathbb{D}$ such that $F_2 : \overline{\Omega}_1 \to \overline{\mathbb{D}}$ is a $C^{1,\alpha}$-diffeomorphism. Let $F_3 = F_2 \circ F_1 : \mathbb{D} \to \mathbb{D}$ and $f_3 = F_3|_{\partial D}$. Note that $(F_3)_*\gamma_0$ is the isotropic conductivity in $\mathbb{D}$, as F_2 is conformal.

The boundary values of quasi-conformal maps $\mathbb{D} \to \mathbb{D}$ are characterized as being the quasi-symmetric maps, that is, homeomorphic maps $f : \partial\mathbb{D} \to \partial\mathbb{D}$ such that $\theta(u) = \arg f(e^{iu})$ satisfy

$$k^{-1} \leq \frac{\theta(u+v) - \theta(u)}{\theta(u) - \theta(u-v)} \leq k \quad \text{for all} \quad u, v \in \mathbb{R}, \tag{3.1}$$

with some $k > 0$; see [11].

Let us consider next the map $f_4 = f_3^{-1} : \partial\mathbb{D} \to \partial\mathbb{D}$. Since f_3 and f_3^{-1} are $C^{1,\alpha}$-smooth, we see that f_4 satisfies

$$\lim_{v \to 0} \frac{\theta(u+v) - \theta(u)}{\theta(u) - \theta(u-v)} = 1 \quad \text{uniformly in } u \in \mathbb{R} \tag{3.2}$$

and is in particular quasi-symmetric. Thus f_4 is the boundary value of at least one quasi-conformal map. What is more, since f_4 satisfies condition (3.2), it follows from the results of Strebel [16] that among all quasi-conformal maps having f_4 as a boundary value there is a unique *extremal* map F_e in the sense that the L^∞-norm of the complex dilatation μ_{F_e} is minimal. More precisely, if $F : \mathbb{D} \to \mathbb{D}$ is a quasi-conformal map such that $F|_{\partial\mathbb{D}} = f_4$, then its Beltrami coefficient satisfies $||\mu_F||_{L^\infty} \geq ||\mu_{F_e}||_{L^\infty}$, and the equality holds only if $F = F_e$. Furthermore, the extremal F_e is a Teichmüller

mapping, i.e., its complex dilatation μ_{F_e} is of the form

$$\mu_{F_e}(z) = ||\mu_{F_e}||_\infty \frac{\overline{\phi(z)}}{|\phi(z)|}, \tag{3.3}$$

where $\phi : \mathbb{D} \to \mathbb{C}$ is holomorphic in $\mathbb{D}$, and thus has a discrete set of zeros. Note that F_e need not even be Lipschitz smooth near zeros of ϕ. Readers should also note that a certain assumption on the regularity of the boundary value f_m is necessary for the existence of extremal maps. This will be discussed after finishing the proof.

Let us now consider how a quasi-conformal map $F : \mathbb{D} \to \mathbb{D}$ with complex dilatation μ_F changes maximal anisotropy of conductivities. When σ is an isotropic conductivity in $\mathbb{D}$, that is, $K(\sigma) = 0$, one sees that for the anisotropic conductivity $\widetilde{\sigma} = F_*\sigma$ we have

$$K(x, \widetilde{\sigma}) = \mu_F(F^{-1}(x)) \quad \text{for } x \in \overline{\mathbb{D}},$$

and hence the maximal anisotropy satisfies $K(\widetilde{\sigma}) = ||\mu_F||_{L^\infty}$.

Let now $\gamma_3 = (F_3)_*\gamma_0$ be an isotropic conductivity in $\mathbb{D}$ and let $\sigma_e = (F_e)_*\gamma_3$ be an anisotropic conductivity in $\mathbb{D}$. Here, $F_e \circ F_3 \circ f_m|_{\partial\Omega} = f_m$. In particular, the above shows that

$$(f_m)_*\Lambda_\gamma = (f_4 \circ f_3 \circ f_m)_*\Lambda_\gamma = (f_4 \circ f_3)_*\Lambda_{\gamma_0} = (f_4)_*\Lambda_{\gamma_3} = \Lambda_{\sigma_e}.$$

In particular, this implies that the inverse problem of finding conductivities σ in $\mathbb{D}$ such that $(f_m)_*\Lambda_\gamma = \Lambda_\sigma$ has a solution $\sigma = \sigma_e$. By section 2, the knowledge of the boundary $\partial\Omega_m = \partial\mathbb{D}$ and the map $(f_m)_*\Lambda_\gamma$ determines the class $\Sigma(\sigma_e)$ of conductivities in $\mathbb{D}$. Now we can write the class $\Sigma(\sigma_e)$ also as

$$\Sigma(\sigma_e) = \{F_*\gamma_3 \ : \ F : \mathbb{D} \to \mathbb{D} \text{ is a homeomorphism, } F, F^{-1} \in H^1(\Omega; \mathbb{C}), F|_{\partial\mathbb{D}} = f_4\}.$$

Since

$$K(F_*\gamma_3) = ||\mu_F||_{L^\infty(\mathbb{D})},$$

we see that the conductivity $\sigma_e = (F_e)_*\gamma_3$ corresponding to the extremal map F_e is the unique conductivity σ in the class $\Sigma(\sigma_e)$ that has the smallest possible value of $K(\sigma)$.

Finally, since $|\mu_{F_e}(z)| = c_0$ is a constant function of $z \in \mathbb{D}$, and $\sigma_e = (F_e)_*\gamma_3$ with isotropic γ_3, we see that the ratio of the eigenvalues of the conductivity matrix $\sigma_e(z)$ is constant for $z \in \mathbb{D}$. Thus σ_e has the form $\sigma_e = \widehat{\gamma}_{\lambda,\theta,\eta}$ with $c_0 = (1-\lambda)/(1+\lambda)$, $\eta = \gamma_3 \circ (F_e)^{-1}$, and some θ. This proves Theorems 1.2 and 1.3 □

Next we prove Proposition 1.4.

Proof of Proposition 1.4. Consider isotropic conductivities γ_1 and γ_2 in Ω. In what follows, we use the notation of the proof of Theorem 1.2. By definition, f_m determines a map F_m. The construction of the map F_1 is based on the Beltrami coefficient of the conductivity. Clearly, the Beltrami coefficients for the conductivities $(F_m)_*\gamma_1$ and $(F_m)_*\gamma_2$ coincide, and thus F_1 and Ω_1 can be taken to be the same for both γ_1 and γ_2. The maps F_2, F_3, and F_e are constructed by using $\partial\Omega_1$ and F_1, and thus they coincide for γ_1 and γ_2. Since in general $\det(F_*\gamma)(x) = \det(\gamma(F^{-1}(x)))$, this proves Proposition 1.4. □

From our assumptions on $\partial\Omega$ and f_m (i.e., that they are in $C^{1,\alpha}$) it follows that the unique extremal exists. For general continuous f_m there are counterexamples,

for instance the so-called Strebel's chimney; see, e.g., [11]. For the sharpest known conditions giving the existence of the unique extremal, see [5].

We note also that if in formula (3.3) the function ϕ has zeros in Ω, then μ_{F_e} has a singularity of type $\overline{(z-z_0)^j}/(z-z_0)^j$, and this could affect the behavior of the reconstruction algorithm we propose in a way to be explained later. However, in all the numerical examples we have tested these difficulties do not appear, probably since our deformations are relatively small.

4. Electrode model. In the numerical simulations below we have used the so-called complete electrode model [15], which is a certain finite-dimensional approximation of Dirichlet-to-Neumann map. This model is chosen because it is an accurate model for the measurements made in practice. As noted before, in experimental measurements one places the measurement electrodes on the boundary, e.g., the skin of the patient, without knowing the exact parameterization of the boundary. Thus this model is a paradigm of the case when the boundary is unknown.

To define the electrode model, let $e_j \subset \partial\Omega$, $j = 1, \dots, J$, be disjoint open paths modelling the electrodes that are used for the measurements. Let u solve the equations

$$\nabla\cdot\gamma\nabla v = 0 \quad \text{in } \Omega, \tag{4.1}$$

$$z_j \nu\cdot\gamma\nabla v + v|_{e_j} = V_j, \tag{4.2}$$

$$\nu\cdot\gamma\nabla v|_{\partial\Omega\setminus\cup_{j=1}^J e_j} = 0, \tag{4.3}$$

where V_j are constants representing electric potentials on electrode e_j. This models the case where electrodes e_j having potentials V_j are attached to the boundary, z_j is the contact impedance between electrode e_j and the body surface, and the normal current outside the electrodes vanish. By [15], (4.1)–(4.3) has a solution $u \in H^1(\Omega)$. The measurements in this model are the currents observed on the electrodes, given by

$$I_j = \frac{1}{|e_j|}\int_{e_j} \nu\cdot\gamma\nabla v(x)\, ds(x), \quad j = 1, \dots, J.$$

Thus the electrode measurements are given by map $E : \mathbb{R}^J \to \mathbb{R}^J$, $E(V_1, \dots, V_J) = (I_1, \dots, I_J)$. We say that E is the electrode measurement matrix for $(\partial\Omega, \gamma, e_1, \dots, e_J, z_1, \dots, z_J)$. Let Ω and $\widetilde{\Omega}$ be $C^{1,\alpha}$-smooth domains. We say that $f : \partial\Omega \to \partial\widetilde{\Omega}$ is length preserving on $\cup_{j=1}^J e_j$ if $||Df(\tau)|| = 1$ for $x \in \cup_{j=1}^J e_j$, where τ is the unit tangent vector of $\partial\Omega$.

PROPOSITION 4.1. *Let Ω and $\widetilde{\Omega}$ be $C^{1,\alpha}$-smooth domains and $F : \overline{\Omega} \to \overline{\widetilde{\Omega}}$ be a $C^{1,\alpha}$-diffeomorphism, $e_j \subset \partial\Omega$ be disjoint open sets, and γ be a conductivity on Ω. Let $f = F|_{\partial\Omega}$, $\widetilde{e}_j = f(e_j) \subset \partial\widetilde{\Omega}$, and $\widetilde{\gamma} = (F)_*\gamma$. Assume that f is length preserving on $\cup_{j=1}^J e_j$. Then the electrode measurement matrices E for $(\partial\Omega, \gamma, e_1, \dots, e_J, z_1, \dots, z_J)$ and $\widetilde{E}$ for $(\partial\widetilde{\Omega}, \widetilde{\gamma}, \widetilde{e}_1, \dots, \widetilde{e}_J, z_1, \dots, z_J)$ coincide.*

Proof. We start with an invariant formulation of electrode measurements E. For this, let R be the Robin-to-Neumann map given by $Rf = \nu\cdot\gamma\nabla u|_{\partial\Omega}$, where u is the solution of

$$\begin{aligned} &\nabla\cdot\gamma\nabla u = 0 \quad \text{in } \Omega, \\ &z\nu\cdot\gamma\nabla v + \eta v|_{\partial\Omega} = h, \end{aligned} \tag{4.4}$$

where $z = z(x)$ is a $C^\infty(\partial\Omega)$ function such that $z|_{e_j} = z_j$ and $\eta = \sum_{j=1}^J \chi_{e_j}(x)$, where χ_{e_j} is the characteristic function of electrode e_j. Note that if the boundary and the

contact impedance are known, the Robin-to-Neumann and the Dirichlet-to-Neumann maps determine each other; that is, they represent equivalent information.

Consider now the bilinear form corresponding to liner maps $E : \mathbb{R}^J \times \mathbb{R}^J \to \mathbb{R}$ and $R : H^{-1/2}(\partial\Omega) \times H^{-1/2}(\partial\Omega) \to \mathbb{R}$ given by

$$E[V, \widetilde{V}] = \sum_{j=1}^{J} (EV)_j \widetilde{V}_j |e_j|, \quad R[h, \widetilde{h}] = \int_{\partial\Omega} (Rh)\, \widetilde{h}\, ds.$$

Let $S = \operatorname{span}(\chi_{e_j} : j = 1, \dots, J) \subset H^{-1/2}(\partial\Omega)$ and define $M : V = (V_j)_{j=1}^J \mapsto \sum_{j=1}^J V_j \chi_{e_j}$ to be a map $M : \mathbb{R}^N \to S$. Then

$$E[V, \widetilde{V}] = R[MV, M\widetilde{V}]. \tag{4.5}$$

Moreover, for $h = MV$ with some $V \in \mathbb{R}^J$, we have

$$R[h, h] = \int_{\partial\Omega} (u + z\nu\cdot\gamma\nabla u)\nu\cdot\gamma\nabla u\, ds = \int_\Omega \gamma\nabla u\cdot\nabla u\, dx + \int_{\partial\Omega} z\,|\nu\cdot\gamma\nabla u|^2\, ds, \tag{4.6}$$

where u solves (4.4). The integral over Ω in (4.6) is invariant in coordinate deformations. Note that in the above formula the integral over the boundary is not coordinate invariant.

Let $\widetilde{E}$ be the electrode measurement matrix for $\widetilde{\gamma}$ in $\widetilde{\Omega}$ with electrodes $\widetilde{e}_j = f(e_j)$, and let $\widetilde{R}$ be the Robin-to-Neumann map for $\widetilde{\gamma}$ defined analogously to (4.4). Since f is length preserving on the electrodes, we see using (1.3) that $\nu\cdot\gamma\nabla u(x) = \nu\cdot\widetilde{\gamma}\nabla\widetilde{u}(f(x))$ for $\widetilde{u} = u \circ F^{-1}$ and $x \in \partial\Omega$, and thus we can see from (4.6) that

$$R[h, \widetilde{h}] = \widetilde{R}[h \circ f^{-1}, \widetilde{h} \circ f^{-1}],$$

for $h, \widetilde{h} \in H^{-1/2}(\partial\Omega)$ supported in the closure of $\bigcup_{j=1}^J e_j$. Thus for the map $\widetilde{M} : V \mapsto \sum_{j=1}^J V_j \chi_{\widetilde{e}_j}$ we have by formula (4.5) that $\widetilde{E}[V, \widetilde{V}] = \widetilde{R}[\widetilde{M}V, \widetilde{M}\widetilde{V}]$. Combining this and (4.5), we obtain

$$E[V, V'] = \widetilde{E}[V, V'].$$

In particular, this implies that the matrices E and $\widetilde{E}$ coincide. ∎

In particular, in the case where $\widetilde{\Omega}$ is the model domain Ω_m and $f = f_m : \partial\Omega \to \partial\Omega_m$ is the model map for the boundary, the assumption that f is length preserving on electrodes means the very natural assumption that in electrode measurements the parameterization of the electrodes is known. Then by Proposition 4.1, the electrode model discretization E of Λ_γ equals the corresponding discretization $\widetilde{E}$ of $(f_m)_*\Lambda_\gamma$. Summarizing, the electrode measurements do not change if we have modeled the geometry of the boundary incorrectly but the electrodes are modeled correctly.

5. Numerical examples. The performance of the proposed method is evaluated by test cases with simulated EIT data. First, in section 5.1 we briefly discuss the discretization and the computational methods that are used, and the results are then given in section 5.2.

5.1. Discretization and notation. The numerical solution of the forward model is based on the finite element method (FEM). The variational formulation and the finite element discretization of the electrode model (4.1)–(4.3) in the case of isotropic conductivities have been previously discussed, e.g., in [10]. The extension of the FEM model to the anisotropic case is straightforward; the details will be given in a subsequent publication.

For the functions $\eta(x)$ and $\theta(x)$ in (1.5) we use piecewise constant approximations that are defined on a lattice of regular pixels. Thus, we have

$$\eta = \sum_{i=1}^{M} \eta_i \chi_i(x), \quad \theta = \sum_{i=1}^{M} \theta_i \chi_i(x), \tag{5.1}$$

where χ_i is the characteristic function of the ith pixel in the lattice. Within the discretization (5.1), the parameters η and θ are identified with the coefficient vectors

$$\eta = (\eta_1, \eta_2, \ldots, \eta_M)^{\mathrm{T}} \in \mathbb{R}^M,$$
$$\theta = (\theta_1, \theta_2, \ldots, \theta_M)^{\mathrm{T}} \in \mathbb{R}^M,$$

and λ is a scalar parameter. Note that as $\widehat{\gamma}_{\lambda,\eta,\theta} = \widehat{\gamma}_{\lambda',\eta,\theta'}$, where $\lambda' = 1/\lambda$ and $\theta'(x) = \theta(x) + \pi/2$, we can assume in looking at the minimizing uniformly anisotropic conductivity that λ gets values $\lambda > 0$.

In practical EIT devices, the measurements are made such that known currents are injected into the domain Ω through some of the electrodes at $\partial\Omega$, and the corresponding voltages needed to maintain these currents are measured on some of the electrodes. Often, voltages are measured only on those electrodes that are not used to inject current. Thus, measurements made give only partial information on the matrix E. To take this into account, we introduce the following notation for the discretized problem. We assume that the EIT experiment consists of a set of K partial voltage measurements, $V^{(j)}$, $j = 1, \ldots, K$. For each measurement, consider a current pattern $I^{(j)}$, $j = 1, \ldots, K$, such that $\sum_{\ell=1}^{J} I_\ell^{(j)} = 0$. Typically, the corresponding measurements are the voltages (potential differences) between pairs of neighboring electrodes. Let us assume that the measurement vector $V^{(j)}$ corresponding to the current pattern $I^{(j)}$ consists of L voltage measurements; i.e., we have $V^{(j)} \in \mathbb{R}^L$. Thus, we write $V^{(j)} = P_j E^{-1} I^{(j)} + \epsilon^{(j)}$, where E is the electrode measurement matrix, random vector $\epsilon^{(j)}$ models the observation errors, and $P_j : \mathbb{R}^J \to \mathbb{R}^L$ is a measurement operator that maps the electrode potentials to measured voltages.

In the inverse problem, the voltage measurements $V^{(1)}, V^{(2)}, \ldots, V^{(K)}$ are concatenated into a single vector

$$V = (V^{(1)}, V^{(2)}, \ldots, V^{(K)})^{\mathrm{T}} \in \mathbb{R}^N, \quad N = KL.$$

For the finite element–based discretization of the forward problem $U : \mathbb{R}^{2M+1} \mapsto \mathbb{R}^N$, we use the notation

$$U(\eta, \theta, \lambda) = (U^{(1)}(\eta, \theta, \lambda), U^{(2)}(\eta, \theta, \lambda), \ldots, U^{(K)}(\eta, \theta, \lambda))^{\mathrm{T}} \in \mathbb{R}^N,$$

respectively. Here, $U^{(j)}(\eta, \theta, \lambda) = P_j E^{-1}(\eta, \theta, \lambda) I^{(j)} \in \mathbb{R}^L$ corresponds to partial voltage measurement, with current pattern $I^{(j)}$ and conductivity $\widehat{\gamma}_{\eta,\theta,\lambda}$.

Using the above notation, we write the discretized and regularized version of our inverse problem as finding the minimizer of the functional

$$F(\eta, \theta, \lambda) = \|V - U(\eta, \theta, \lambda)\|^2 + W_\eta(\eta) + W_\theta(\theta) + W_\lambda(\lambda), \quad \eta > 0, \lambda > 0, \tag{5.2}$$

where the regularizing penalty functionals are of the form

$$W_\eta(\eta) = \alpha_0 \sum_{i=1}^{M} \eta_i^2 + \alpha_1 \sum_{i=1}^{M} \sum_{j \in \mathcal{N}_i} |\eta_i - \eta_j|^2, \tag{5.3}$$

$$W_\theta(\theta) = \beta_0 \sum_{i=1}^{M} \theta_i^2 + \beta_1 \sum_{i=1}^{M} \sum_{j \in \mathcal{N}_i} |e^{i\theta_i} - e^{i\theta_j}|^2, \tag{5.4}$$

$$W_\lambda(\lambda) = \beta_2 \left(\log(\lambda) + \nu^{-2} \log(\lambda)^2 \right) \tag{5.5}$$

and $\mathcal{N}_i$ denotes the usual four-point nearest neighborhood system for pixel i in the lattice.

Our objective is to minimize the functional (5.2) by gradient-based optimization methods. Here we face difficulty due to the positivity constraints. To take the positivity constraint into account we employ the interior point search method [7]. In the interior point search the original constrained problem (5.2) is replaced by a sequence of augmented unconstrained problems of the form

$$\widetilde{F}_j(\eta, \theta, \lambda) = F(\eta, \theta, \lambda) + W_+^{(j)}(\eta), \tag{5.6}$$

where $W_+^{(j)}(\eta)$ is a penalty functional of the form

$$W_+^{(j)}(\eta) = \xi_j \sum_{i=1}^{M} \frac{1}{\eta_i} \tag{5.7}$$

and $\{\xi_j\}$ is a sequence of decreasing positive parameters such that $\xi_j \to 0$ as $j \to \infty$. Using a suitably chosen sequence of penalty functionals $W_+^{(j)}$, the solutions of the unconstrained problems converge (asymptotically) to the solution of the original constrained problem. The positivity constraint for λ can be taken care of with similar techniques. However, it is our experience that the positivity constraint was not needed for λ.

For the minimization of the functionals (5.6) we employ the Gauss–Newton optimization method with an explicit line search algorithm.

5.2. Results. In this section, we evaluate the performance of the proposed method with three different test cases. The first test case is EIT data from an ellipse domain Ω, in the second test case we consider an ellipse domain with a sharp cut, and in the last test case the domain is a smooth Fourier domain which has some resemblance to the cross section of the human body. In all of these cases, we use the unit disk as the model domain Ω_m.

In the simulations, we assume an EIT system with $J = 16$ electrodes. In each of the test cases, the electrodes were located at approximately equally spaced positions at the exterior boundary $\partial\Omega$ of the target domain Ω. The size of the electrodes was chosen such that the electrodes covered approximately 50% of the boundary $\partial\Omega$.

The EIT measurements were simulated using the usual adjacent pair drive data acquisition method. In the adjacent drive method, currents $+1$ and -1 are injected through two neighboring electrodes, say electrodes e_n and e_{n+1}, and the current through other electrodes is zero. The voltages are measured between all J pairs of

neighboring electrodes. However, three of these measurements are typically neglected since they include either one or both of the current feeding electrodes e_n or e_{n+1}. The rationale behind this is that the electrode contact impedances z_j are usually not known accurately. The possible errors in the contact impedance values cause a systematic error between the measured voltage and the forward model for the measurement made on the current feeding electrodes, and this error causes artifacts in the numerical reconstruction; see, e.g., [9]. Thus, with the adjacent pair drive method each partial measurement consists of $L = J - 3$ voltage measurements, and we have $V^{(j)} \in \mathbb{R}^{J-3}$. This data acquisition process is then repeated for all the J pairs of adjacent electrodes, leading to a total of $N = J(J-3)$ voltage measurements for one EIT experiment. Thus, with the $J = 16$ electrode system we have $V \in \mathbb{R}^{208}$.

The simulated EIT measurements were computed using the isotropic EIT model and the FEM. To simulate measurement noise, we added to the data Gaussian random noise with standard deviation of 1% of the maximum value of the simulated voltages. In all of the following test cases we used value $z_\ell = 1$ for the electrode contact impedances. These were assumed known in the inverse problem.

The results for the first test case are shown in Figures 5.1–5.2. The target con-

ductivity is shown in the top left image in Figure 5.1. The target domain Ω is an ellipse with main axes 1.25 in the horizontal direction and 0.8 in the vertical direction. For the simulation of the EIT measurements, the domain was discretized into a finite element mesh that consisted of 1256 nodal points and 2350 triangular elements.

The reconstruction of the conductivity γ with isotropic EIT model in the correct domain Ω is shown in the top right image in Figure 5.1. The reconstruction was obtained by using optimization techniques similar to those explained in the previous section. However, in the case of the isotropic model the unknown parameter vector is the conductivity vector $\gamma \in \mathbb{R}^M$, and the optimization functionals for the interior point search can be written as

$$H_j(\gamma) = \|V - U(\gamma)\|^2 + W_\gamma(\gamma) + W_+^{(j)}(\gamma), \tag{5.8}$$

where $U(\gamma)$ denotes the forward problem for the isotropic model and $W_\gamma(\gamma)$ and $W_+^{(j)}(\gamma)$ are defined by (5.3) and (5.7), respectively. To compute the reconstruction in the top right image in Figure 5.1, the domain Ω was triangulated to a finite element mesh that consisted of 2326 elements with 1244 nodal points. The conductivity was represented in a lattice of $M = 451$ pixels (i.e., $\gamma \in \mathbb{R}^{451}$). The regularization parameters for the penalty functional $W_\gamma(\gamma)$ in (5.8) were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-4}$. When computing the reconstruction in the correctly modeled geometry, the interior point search was kept inactive (i.e., the sequence $\{\xi_j\}$ of interior point search parameters were all zeros). The conductivity vector was initialized to a constant value of one in the optimization process. The Gauss–Newton optimization algorithm was iterated until convergence was obtained.

The image in the bottom left in Figure 5.1 shows the reconstruction of the conductivity with the isotropic model in incorrectly modeled geometry Ω_m. In this case, the computational domain Ω_m was the unit disk, which was triangulated to 2190 elements with 1176 nodal points. The conductivity parameters were represented in a lattice of $M = 437$ pixels (i.e., $\gamma \in \mathbb{R}^{437}$). The regularization parameters for the penalty functional $W_\gamma(\gamma)$ in (5.8) were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 2 \cdot 10^{-4}$. The sequence of interior point search parameters $\{\xi_j\}$ were from $2 \cdot 10^{-5}$ to $5 \cdot 10^{-6}$. The constant vector $\gamma = 1 \in \mathbb{R}^{437}$ was used as the initial guess in the Gauss–Newton optimization.

The image in the bottom right in Figure 5.1 shows the reconstruction of η with the uniformly anisotropic model in incorrectly modeled geometry Ω_m. Here, by the solution in *the uniformly anisotropic model* we mean the optimal solution of the form

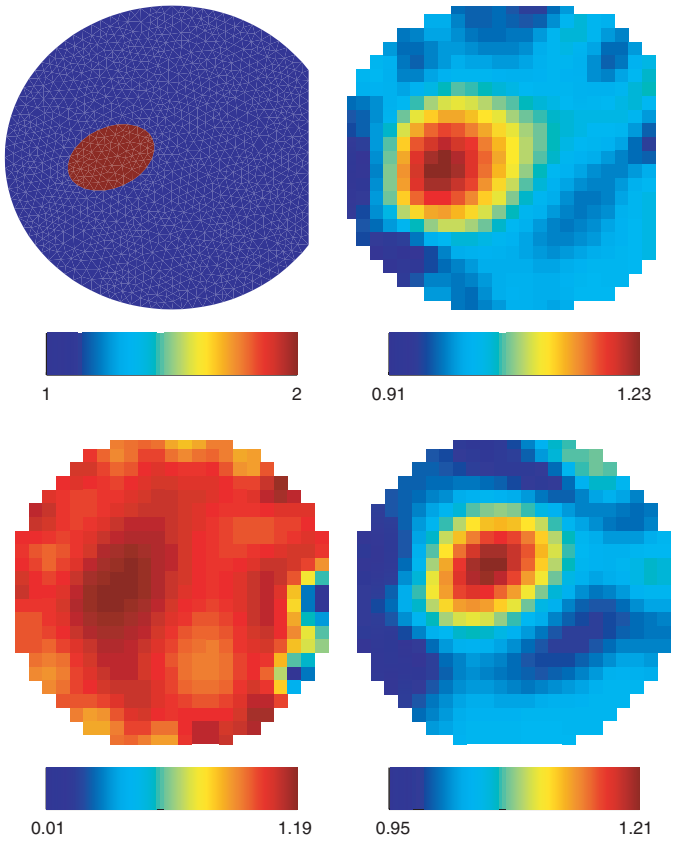

FIG. 5.3. *Test case with EIT data from a truncated ellipse domain Ω with main axes $a = 1.1$ and $b = 0.9$. Top left: Simulated conductivity distribution γ. Top right: Reconstruction of the conductivity γ with the isotropic model in the correct geometry Ω. Bottom left: Reconstruction of γ with the isotropic model in incorrectly modeled geometry. (1.5) of the minimization problem. The reconstruction was obtained by minimizing a sequence of optimization functionals of the form (5.6). The reconstructed angle parameter θ is shown in the left image in Figure 5.2, and the evolution of the parameter λ during the iteration is shown in the right image in Figure 5.2. The computational domain Ω_m was the unit disk. The finite element triangularization and the number of the image pixels were the same as in the isotropic case in bottom left image in Figure 5.1. Thus, the unknowns in the inverse problem are $\eta \in \mathbb{R}^{437}$, $\theta \in \mathbb{R}^{437}$, and $\lambda \in \mathbb{R}$. The parameters for the regularizing penalty functionals $W_\eta(\eta)$ in (5.3) were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-4}$. The parameters for the penalty functionals $W_\theta(\theta)$ and $W_\lambda(\lambda)$ in (5.4)–(5.5) were $\beta_0 = 10^{-8}$, $\beta_1 = 5 \cdot 10^{-6}$, and $\beta_2 = 0$, respectively. The sequence of interior point search parameters $\{\xi_j\}$ was from $1 \cdot 10^{-5}$ to $1 \cdot 10^{-12}$. The Gauss–Newton optimization was started from the constant values $\eta = 1 \in \mathbb{R}^{437}$, $\theta = 0 \in \mathbb{R}^{437}$, and $\lambda = 1$, which correspond to isotropic unit conductivity.

The results for the second test case are shown in Figure 5.3. The simulated conductivity distribution is shown in the top left image. In this case the domain Ω is a

truncated ellipse with main axes 1.1 in the horizontal direction and 0.9 in the vertical direction, respectively. For the simulation of the EIT measurements, the domain was divided into a finite element mesh of 2383 triangular elements with 1240 nodes.

The top right image in Figure 5.3 shows the reconstruction of the conductivity with the isotropic model in the correct geometry. For the reconstruction, the domain Ω was divided into a finite element mesh of 2337 triangular elements with 1217 nodes, and the conductivity was represented on a lattice of $M = 455$ pixels. Thus, the unknown parameter vector was $\gamma \in \mathbb{R}^{455}$. The regularization parameters for the penalty functional $W_\gamma(\gamma)$ in (5.8) were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-4}$. The sequence of interior point search parameters $\{\xi_j\}$ was all zeros. The Gauss–Newton optimization was started from the constant unit conductivity.

The bottom left image in Figure 5.3 shows the reconstructed conductivity with the isotropic model in the incorrectly modeled geometry. The reconstruction domain Ω_m was the unit disk. The finite element mesh and pixel lattice were the same as those used for the unit disk in Figure 5.1. Thus, the unknown conductivity vector was $\gamma \in \mathbb{R}^{437}$. The parameters for the regularizing penalty functional $W_\gamma(\gamma)$ were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-4}$, and the sequence of interior point search parameters $\{\xi_j\}$ was from 10^{-5} to 10^{-8}. The constant unit conductivity was used as the initial guess in the optimization.

The bottom right image in Figure 5.3 shows the reconstruction of η with the uniformly anisotropic model in the incorrectly modeled geometry. The computational domain Ω_m was the unit disk with the same discretization that was used in Figure 5.1. Thus, the unknowns were $\eta \in \mathbb{R}^{437}$, $\theta \in \mathbb{R}^{437}$, and $\lambda \in \mathbb{R}$. The parameters for the regularizing penalty functionals $W_\eta(\eta)$ in (5.3) were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-4}$. The parameters for the penalty functionals $W_\theta(\theta)$ and $W_\lambda(\lambda)$ in (5.4)–(5.5) were $\beta_0 = 10^{-8}$, $\beta_1 = 5 \cdot 10^{-6}$, and $\beta_2 = 0$, respectively. The sequence of parameters $\{\xi_j\}$ was from 10^{-5} to 10^{-12}. The initializations for the parameters in the Gauss–Newton optimization were the constant values $\eta = 1 \in \mathbb{R}^{437}$, $\theta = 0 \in \mathbb{R}^{437}$, and $\lambda = 1$.

The results for the last test case are shown in Figure 5.4. In this case, the target domain Ω is bounded by a smooth Fourier boundary $\partial\Omega$. The true isotropic conductivity distribution within the domain Ω is shown in the top left image in Figure 5.4. For the simulation of the EIT measurements, the domain Ω was divided into a mesh of 2316 triangular elements with 1239 nodes.

The reconstruction of the conductivity γ with the isotropic model in the correct geometry Ω is shown in the top right image in Figure 5.4. The domain was divided into a mesh of 2200 triangular elements with 1181 nodes for the image reconstruction process. The number of pixels was $M = 446$ for the representation of the conductivity image (i.e., $\gamma \in \mathbb{R}^{446}$). The regularization parameters for the penalty functional $W_\gamma(\gamma)$ were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-5}$, and the sequence of parameters $\{\xi_j\}$ was all zeros. The constant unit conductivity was used as the initial guess in the Gauss–Newton optimization algorithm.

The reconstruction of the conductivity γ with the isotropic model in the incorrectly modeled geometry is shown in the bottom left image in Figure 5.4. The reconstruction domain Ω_m was the unit disk. The finite element mesh and the pixel lattice were the same as those used in Figures 5.1–5.3. Thus, the parameter vector in the inverse problem was $\gamma \in \mathbb{R}^{437}$. The parameters in the penalty functional $W_\gamma(\gamma)$ were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 2{\cdot}10^{-4}$, and the sequence of parameters $\{\xi_j\}$ was from $2{\cdot}10^{-5}$ to $5{\cdot}10^{-6}$. The constant unit conductivity was used as the initial guess in the optimization.

The reconstruction of η with the uniformly anisotropic model in the incorrectly

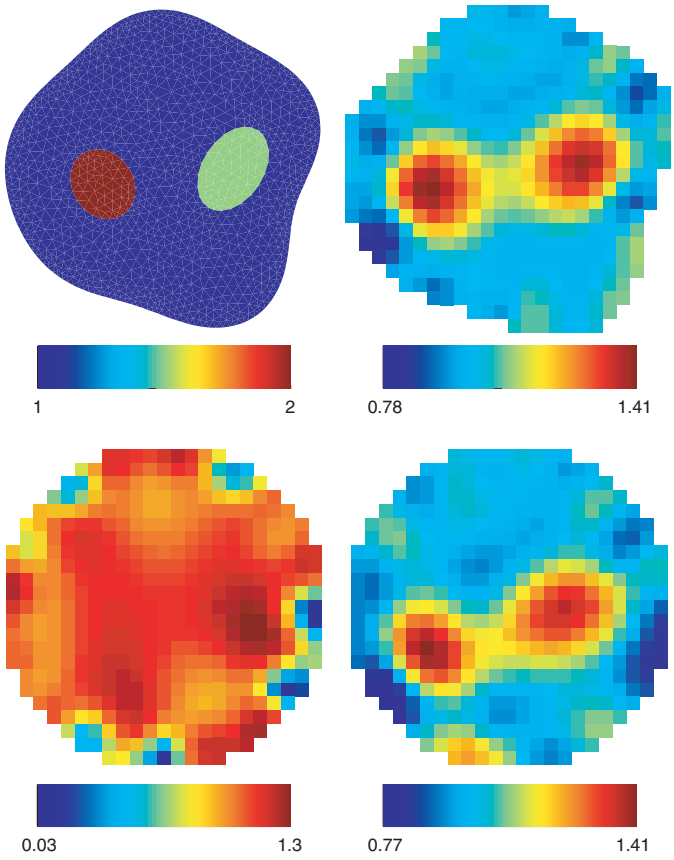

FIG. 5.4. *Test case with EIT data from an arbitrary domain Ω. Top left: True conductivity distribution γ. modeled geometry is shown in the bottom right image in Figure 5.4. The reconstruction domain Ω_m was the unit disk with the same discretization as in Figures 5.1–5.3. Thus, the unknown parameter vectors were $\eta \in \mathbb{R}^{437}$, $\theta \in \mathbb{R}^{437}$, and $\lambda \in \mathbb{R}$. The parameters for the regularizing penalty functionals $W_\eta(\eta)$ in (5.3) were $\alpha_0 = 10^{-8}$ and $\alpha_1 = 10^{-5}$. The parameters for the penalty functionals $W_\theta(\theta)$ and $W_\lambda(\lambda)$ in (5.4)–(5.5) were $\beta_0 = 10^{-8}$, $\beta_1 = 5 \cdot 10^{-6}$, and $\beta_2 = 0$, respectively. The sequence of parameters $\{\xi_j\}$ was from 10^{-5} to 10^{-12}. The initializations for the image parameters were the constant values $\eta = 1 \in \mathbb{R}^{437}$, $\theta = 0 \in \mathbb{R}^{437}$, and $\lambda = 1$.

6. Discussion. As can be seen from Figures 5.1–5.4, the proposed approach gives good results. In all test cases, the traditional reconstructions with the isotropic model are erroneous when the imaging geometry is modeled incorrectly. The effects of erroneous geometry are seen in the reconstructions as distortions and severe artifacts, especially near the boundary. On the other hand, the reconstructions of η with the uniformly anisotropic model in the same erroneous geometry are clear of these artifacts and represent a deformed picture of the original isotropic conductivity. These results

indicate that the proposed method offers an efficient tool to eliminate the difficulties that arise from inaccurately known geometry in practical EIT experiments.

Acknowledgments. The authors are thankful for Prof. Kari Astala and Prof. Seppo Rickman for discussions on quasi-conformal maps that were crucial for the obtained results. Also, thanks to the anonymous referees for valuable comments.

THEORY OF DETONATION WITH AN EMBEDDED SONIC LOCUS*

D. SCOTT STEWART† AND ASLAN R. KASIMOV‡

Abstract. A steady planar self-sustained detonation has a sonic surface in the reaction zone that resides behind the lead shock. In this work we address the problem of generalizing sonic conditions for a three-dimensional unsteady self-sustained detonation wave. The conditions are proposed to be the characteristic compatibility conditions on the exceptional surface of the governing hyperbolic system of reactive Euler equations. Two equations are derived that are necessary to determine the motion of both the lead shock and the sonic surface. Detonation with an embedded sonic locus is thus treated as a two-front phenomenon: a reaction zone whose domain of influence is bounded by two surfaces, the lead shock surface and the trailing characteristic surface. The geometry of the two surfaces plays an important role in the underlying dynamics. We also discuss how the sonic conditions of detonation stability theory and detonation shock dynamics can be obtained as special cases of the general sonic conditions.

1. Introduction.

A detonation wave is a shock wave that triggers exothermic reactions in an explosive as it propagates so that the energy released in the reactions sustains the shock propagation. Modern theories of detonation originate from the theory first developed independently by Zel'dovich, von Neumann, and Doering in the 1940s (ZND theory; see Fickett and Davis [5] for details) that describes the dynamics of a steady one-dimensional planar detonation in a gaseous explosive. The ZND theory is applicable to both self-sustained detonations, that is, autonomous waves whose motion is sustained entirely by the energy released in their reaction zone, and overdriven detonations which require an additional external support to maintain their motion at a nominal speed. In self-sustained steady one-dimensional planar detonations, which are also called Chapman−Jouguet (CJ) detonations, there exists an embedded sonic locus within or at the end of the reaction zone, such that at that point the flow speed is sonic relative to the shock. As a consequence, the lead-shock dynamics is influenced only by the flow between the shock and the sonic locus. In contrast, the lead-shock dynamics of overdriven detonations is influenced by the entire region between the shock and the support (e.g., a piston); no sonic locus exists in such detonations. Without the condition of sonicity, the equations governing the CJ detonation (the mass, momentum, and energy equations) are not closed, since the detonation speed is unknown; the sonicity condition provides the necessary closure. Understanding the nature of the sonic conditions in detonations more general than

planar, one-dimensional, steady detonations of the ZND theory has been difficult to achieve. It is precisely this task of deriving the general sonic conditions and clarifying their nature that is central to our present investigation.

Research that began in the late 1950s and early 1960s (see, e.g., [5, 3]) has shown that most detonation waves, especially in gases, have a multidimensional cellular structure with transversely propagating shock waves in the reaction zone and significant unsteady dynamics. In condensed explosives, the detonation is more often observed to be steady, but importantly it has been known for a long time that high-explosive detonation shocks are almost always curved. Clearly, the ZND theory is too simple to account for the observed structure and must be appropriately modified. There exist conceptual problems that cannot be addressed within the framework of the ZND theory if unsteady and multidimensional detonations are considered. The principal problem has to do with the nature of the sonic condition whose generalization to include unsteady and multidimensional effects has been limited so far to linearized problems and quasi-steady detonations.

In the linear stability theory of detonation, the far-field conditions are commonly referred to as "radiation conditions" or "boundedness conditions" depending on specific circumstances (see [4, 7, 9, 13]). The radiation condition is imposed to filter out incoming acoustic perturbations by considering the far-field acoustic solutions of the governing linearized system and to eliminate the incoming waves by setting their amplitude equal to zero. It follows then that the far-field solutions are linearly dependent and their linear combination forms a far-field constraint on the general solution of the linearized problem. Such a constraint serves as a dispersion relation that allows one to determine the eigenvalues. It turns out (see section 5) that the CJ limit (self-sustained wave) of the radiation condition coincides with the linearized governing equation on the forward characteristic. One can also show that the radiation condition in that case is also a boundedness condition for the solutions of the linearized system at the sonic locus. Thus in the linear stability problem, the general nature of the radiation conditions that provide the dispersion relation is such that they serve as filters of the incoming perturbations and are thus conditions on the forward characteristic surface that acts as an information boundary.

In the theory of detonation shock dynamics (DSD; see the topical review by Stewart [14] for a general discussion and history of the problem), one treats a quasi-steady *curved* detonation and derives sonic conditions (called generalized sonic conditions) that include effects of multidimensionality through the shock curvature term, which is assumed small on the scales of the reaction zone. Originally, the effect of curvature in the sonic conditions was considered by Wood and Kirkwood [17] and later was derived rationally in the works of Bdzil [1] and Stewart and Bdzil [15, 16]. Yao and Stewart [18] considered an extension of the sonic conditions to include asymptotically small unsteady corrections, but their analysis relies partially on the steady concept of a sonic locus by assuming that the flow is sonic relative to the lead shock, which constrains the sonic locus to always be parallel to the shock. The quasi-steady generalized CJ conditions reflect the fact that in a curved detonation, the flow divergence or convergence acts as a sink or source, respectively, of the energy of the lead shock. Thus, for example, in a diverging steady detonation, the sonic condition expresses an exact balance of the heat release and flow divergence, as shown by the equation given in Stewart and Bdzil [16]:

$$(\gamma - 1)\, Q\omega - c^2\, (D + U_n)\, \kappa = 0, \tag{1.1}$$

where Q is the heat release, γ is the adiabatic exponent, ω is the reaction rate at

the sonic point, c is the sound speed, D and U_n are the normal detonation speed and particle velocity at the sonic point relative to the lead shock, and κ is the shock curvature. Equation (1.1) is obtained from the equation (called Master equation)

$$\frac{\mathrm{d}U_n^2}{\mathrm{d}\lambda} = \frac{2U_n^2\left[(\gamma-1)\,Q\omega - c^2\,(D_n+U_n)\,\kappa\right]}{\omega\,(c^2-U_n^2)} \tag{1.2}$$

(λ is the reaction progress variable) that follows directly from the governing equations by a regularity argument, namely, that for the left-hand side of (1.2) to remain finite, the numerator of the right-hand side has to vanish at the sonic point because the denominator vanishes there: $c^2 = U_n^2$.

For unsteady weakly curved detonations, the Master equation can again be written in a form similar to (1.2), but the numerator contains more terms (see [18]):

$$\frac{\partial U_n}{\partial n} = \frac{1}{c^2-U_n^2}\left[(\gamma-1)\,Q\omega - c^2\,(D+U_n)\,\kappa + U_n\left(\frac{\partial U_n}{\partial t}+\frac{\partial D}{\partial t}\right) - v\frac{\partial p}{\partial t}\right], \tag{1.3}$$

where t is time, n is the normal distance from the shock ($n<0$ in the reaction zone), v is the specific volume, and p is pressure. A regularity argument is again invoked that requires that the numerator of (1.3) vanish at the sonic point, *assuming* that the denominator vanishes there as well: $c^2-U_n^2=0$. The latter assumption is one of the key elements that distinguishes the present theory from that of Yao and Stewart [18]—we do not define the sonic locus in the shock-attached frame, so that in our theory, $c^2-U_n^2$ does not necessarily vanish at the sonic locus. In fact, from the characteristic analysis, we find that $c + U_n = \partial n_*/\partial t = \mathcal{D} - D$, where n_* is the distance between the shock and the sonic locus, and $\mathcal{D}$ and D are the speeds of the sonic locus and of the shock, respectively. Thus $c+U_n$ at the sonic locus is equal to the relative speed of the sonic locus and the shock. Therefore, the theory of Yao and Stewart contains an implicit assumption that the sonic locus and the shock are parallel in the characteristic (n,t)-plane. In unsteady detonations, a possible imbalance of the heat release and flow divergence is reflected in the unsteadiness of the curved detonation.

Our generalization of the sonic conditions stems from the following observations. In a general unsteady flow that is sufficiently smooth, with a lead detonation shock, one considers all forward propagating characteristic surfaces, which are the envelopes of the forward propagating acoustic wavefronts. For initial conditions that admit smooth evolution, there may exist a limiting forward characteristic surface that never intersects the shock or intersects the shock only at times that are very long compared to the passage time of particles through the detonation reaction zone. This limiting characteristic is thus identified as a separatrix of the family of forward characteristic surfaces whose motion is toward the shock. On the upstream side of the separatrix, the forward characteristic surfaces flow into the shock in a finite time, while on the downstream side, they flow away from the shock. The region that affects the lead-shock dynamics (the domain of influence) is the region between the shock surface and the limiting characteristic surface so that the evolution of the detonation wave depends only on the data in that region. The limiting sonic surface is then specifically embedded in the reaction zone, usually at a finite distance behind the shock. In Kasimov and Stewart [8], we illustrated the behavior of the sonic locus as a limiting characteristic in one-dimensional detonations by means of a numerical simulation.

Thus a general sonic locus is proposed to be a characteristic surface of the governing hyperbolic equations such that the surface acts as an information boundary that precludes incoming acoustic perturbations from influencing the lead-shock dynamics.

Such a definition is in agreement with the limiting cases of the steady detonation, the unsteady linearized theory, and the weakly curved slowly varying detonation theories that have been derived previously. The new concept clarifies the meaning of the sonic locus by emphasizing its nature as a characteristic surface. In particular, since the sonic locus is a boundary of the domain of influence of the reaction zone, it follows immediately that the detonation problem is, in general, a *two-front problem* with both fronts (the shock and sonic loci) as free boundaries. Therefore, the sonic conditions must be given by *two* equations, a situation that has not been explicitly emphasized but is nevertheless a part of all previous theories of detonation. For example, in the planar CJ detonation, the two equations are (1) the well-known CJ condition, $M_{\rm CJ} = 1$, where $M_{CJ} = -U_n/c$ is the local Mach number relative to the shock and (2) the condition that the sonic point coincides with the end of the reaction zone (for single-step exothermic reaction), $\lambda = 1$. We propose that the sonic conditions for general multidimensional detonations are (1) the condition of local sonicity, that is, for an observer moving with the sonic surface, the particle speed normal to that surface, $\mathcal{U}_n$, is locally sonic,

$$\mathcal{U}_n = -c\,, \tag{1.4}$$

and (2) the compatibility condition in the sonic surface defined as a characteristic surface of the governing reactive Euler equations,

$$\rho c \mathbf{n}_* \cdot \left(\frac{D\mathbf{u}}{Dt} + \frac{1}{\rho}\nabla p \right) + \rho c^2 \nabla \cdot \mathbf{u} + \frac{Dp}{Dt} = \rho c^2 \sigma \omega, \tag{1.5}$$

where $\mathbf{n}_*$ is the unit normal to the sonic surface, $\mathbf{u}$ is the lab-frame particle velocity, $D/Dt = \partial/\partial t + \mathbf{u}\cdot\nabla$ is the material derivative, and σ is the thermicity coefficient. These two conditions are direct consequences of the governing hyperbolic equations and hold therefore under quite general circumstances; no asymptotic ideas are involved.

In section 2 we work out the theory of the characteristic surfaces for general systems of quasi-linear hyperbolic PDEs and derive compatibility conditions in the exceptional surface. The conditions are specialized to reactive Euler equations in section 2.2. In section 3 we discuss the simplest version of the sonic conditions in one spatial dimension to emphasize the connection with the standard theory of characteristics. Section 4 is devoted to two-dimensional detonations where we specialize the sonic conditions to local frames in order to exhibit the connection with the older theories of DSD. The connection of the present work with the theories of detonation stability is a subject of section 5. We conclude in section 6.

2. General theory. This section is divided into two subsections. The first is a general discussion and review of properties of characteristic surfaces defined for systems of hyperbolic PDEs. We quickly specialize to the reactive, compressible flow equations, but the presentation is not restricted to compressible Euler equations and has applications to other hyperbolic systems. The second subsection derives conditions that must be satisfied on a characteristic (sonic) surface, specifically for the reactive Euler equations that are relevant for application to detonation.

2.1. Characteristic surfaces of hyperbolic PDEs and compatibility conditions. The analysis given next closely follows that given in von Mises' treatise [10]. This presentation was developed by G. S. S. Ludford (along with von Mises' wife Hilda Geiringer) to complete the von Mises monograph after his death. Its teaching

was a regular feature of Ludford's famous courses on applied mathematics given at Cornell University. The von Mises reference is one of the few places one can find the general theory of characteristic surfaces written in a succinct and concise manner, and while classical in its form, it is seldom referenced and not widely known. This powerful presentation in fact becomes the basis for our developments and extensions to generate useful and new three-dimensional results for application to detonations in particular. A useful discussion of characteristic surfaces can also be found in Chapman [2]. Another useful reference is Ovsiannikov [12], where one can find a general characteristic form of equations of inert gas dynamics; the conditions on the acoustic characteristic surfaces are found to be similar to ours (see (2.28)), when no chemical reactions take place.

Consider a general system of quasi-linear hyperbolic equations written in the form

$$a_{ij}^k \frac{\partial u_j}{\partial x_k} = b_i \,, \tag{2.1}$$

where the coefficients a_{ij}^k are functions of the state variables u_j, $j = 1, 2, \ldots, J$, index i represents the individual equations of motion, x_k are the independent variables, and b_i are the source terms. Form a linear combination of the equations by multiplying the equations by arbitrary α_i and summing over all equations,

$$\alpha_i a_{ij}^k \frac{\partial u_j}{\partial x_k} \equiv m^k \frac{\partial}{\partial x_k} \, (u_j) = \alpha_i b_i . \tag{2.2}$$

Each term on the left-hand side of (2.2), $\alpha_i a_{ij}^k \, (\partial u_j / \partial x_k)$, is a directional derivative in space with direction tangents, $\mathbf{m}$, whose components, labeled by k, are given by $m^k = \alpha_i a_{ij}^k$. An *exceptional surface* [10] (or more commonly referred to as a characteristic surface) is defined as a surface such that the linear combination (2.2) of directional derivatives expresses changes only in that surface. Then all direction tangents must lie in that surface, and therefore the linear combination (2.2) contains no derivatives normal to the surface. If such an exceptional surface exists, then the unit normal vector $\boldsymbol{\beta}$ to the surface must be orthogonal to all tangent vectors, $\mathbf{m}$ (see Figure 2.1), that is,

$$m^k \beta_k = \alpha_i \beta_k a_{ij}^k = 0 \,. \tag{2.3}$$

This is a system of J homogeneous linear algebraic equations for α_i, with a nontrivial solution if and only if

$$\det |\beta_k a_{ij}^k| = 0 \,, \tag{2.4}$$

which is a Jth order polynomial that determines a constraint on the direction vector $\boldsymbol{\beta}$. Note that only directions in the space of the independent variables are solved for. If one of the independent variables is time, then the constraint on the direction in space time defines the velocity of the characteristic, which we later denote as the *speed relation*.

The *compatibility condition* is simply the differential relation, (2.2), found on the characteristic surface. The first step solves for β_k by solving the characteristic polynomial. The second step is, with a chosen direction, one that expresses the compatibility relation in the characteristic surface. Since the system of equations for α_i is singular, then the solution for α_i is determined up to an arbitrary constant; i.e.,

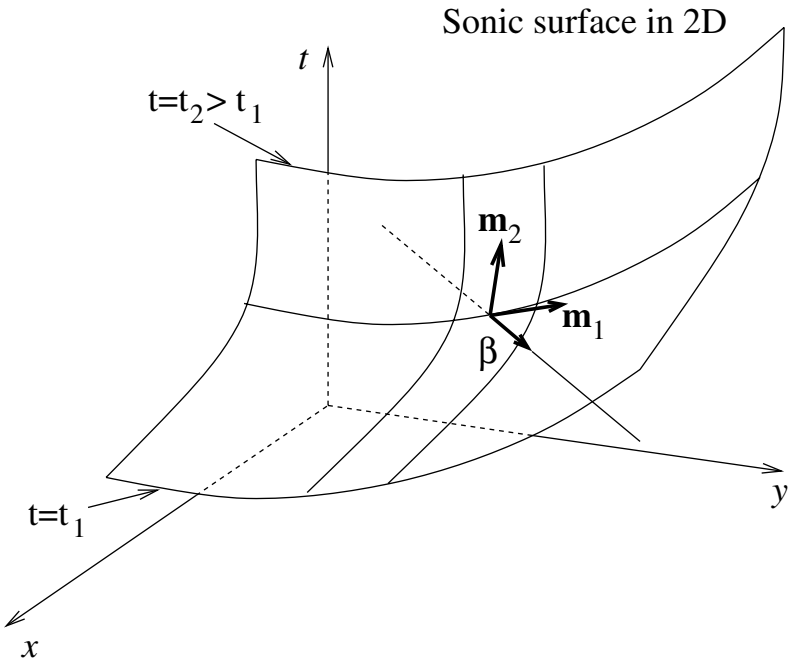

FIG. 2.1. *The sonic surface in* $2+1$ *dimensions, which is generated by time evolution of the two-dimensional sonic locus (a line in the xy-plane) along the third (time t) axis from* $t = t_1$ *to* $t = t_2$.

the ratio between the α_i is determined in terms of the β_k. Say such a direction β_k^* with a corresponding α_i^* is found. Then the *compatibility condition* is specifically

$$\alpha_i^* a_{ij}^k \frac{\partial u_j}{\partial x_k} = \alpha_i^* b_i \,. \tag{2.5}$$

2.2. Compatibility conditions for reactive Euler equations. We now start with reactive Euler equations with a single chemical reaction and closely follow the derivation given in von Mises [10] for the general case of fluid motion for inert flow. Further generalization to a multiple-step chemistry is straightforward. The general equation of state is used in its incomplete form, $e = e(p, \rho, \lambda)$.

Note that a simple device is in use. To simplify the algebraic presentation, the equations of motion are assumed to be analyzed at a point instantaneously aligned with the x-axis, which is taken in the direction of the velocity vector $\mathbf{u} = u\mathbf{i} + v\mathbf{j} + w\mathbf{k}$. Therefore, without loss of generality, the material derivative is $d/dt = \partial/\partial t + u\partial/\partial x$. The general condition for the exceptional surfaces is expressed for this special system and subsequently rewritten in a frame-invariant notation so that any coordinate system can be used. The notion of an exceptional (characteristic) surface is the one that is based on the physical equations and not the coordinates, and it is simply a matter of expressing the equations and directions indicated in those coordinates.

The equations of motion are written as

$$u\frac{\partial u}{\partial x} + \frac{\partial u}{\partial t} + \frac{1}{\rho}\frac{\partial p}{\partial x} = 0, \tag{2.6}$$

$$u\frac{\partial v}{\partial x}+\frac{\partial v}{\partial t}+\frac{1}{\rho}\frac{\partial p}{\partial y}=0, \tag{2.7}$$

$$u\frac{\partial w}{\partial x}+\frac{\partial w}{\partial t}+\frac{1}{\rho}\frac{\partial p}{\partial z}=0, \tag{2.8}$$

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}+\frac{u}{\rho}\frac{\partial \rho}{\partial x}+\frac{1}{\rho}\frac{\partial \rho}{\partial t}=0, \tag{2.9}$$

$$u\frac{\partial p}{\partial x}+\frac{\partial p}{\partial t}-c^2\left(u\frac{\partial \rho}{\partial x}+\frac{\partial \rho}{\partial t}\right)=\rho c^2\sigma\omega, \tag{2.10}$$

$$u\frac{\partial \lambda}{\partial x}+\frac{\partial \lambda}{\partial t}=\omega, \tag{2.11}$$

where p is pressure, ρ is density, λ is the reaction-progress variable, ω is the reaction rate, and c is the frozen sound speed. We have used the definition of the thermicity coefficient given by Fickett and Davis [5],

$$\sigma=-\frac{1}{\rho c^2}\frac{e_\lambda}{e_p}\,, \tag{2.12}$$

and the general expression for the sound speed,

$$c^2=\frac{p-\rho^2 e_\rho}{\rho^2 e_p}, \tag{2.13}$$

where the subscripts of e denote partial differentiation with respect to the arguments.

The state vector u_j is given by $(u_j)=(u,v,w,p,\rho,\lambda)$, with $j=1,\ldots,6$. For the purpose of assigning the a^k_{ij}, we number (2.6) through (2.11) by $j=1,\ldots,6$. The generalized independent coordinates are given by the list $(x_k)=(x,y,z,t)$ with $k=1,\ldots,4$. The equations of motion written in the form (2.1) subsequently identify a^k_{ij} as

$$\begin{aligned}
&[a^k_{11}]=[u,0,0,1]\,,\ a^k_{12}=0\,,\ a^k_{13}=0\,,\ [a^k_{14}]=\left[\frac{1}{\rho},0,0,0\right]\,,\ a^k_{15}=0\,,\ a^k_{16}=0\,,\\
&a^k_{21}=0\,,\ [a^k_{22}]=[u,0,0,1]\,,\ a^k_{23}=0\,,\ [a^k_{24}]=\left[0,\frac{1}{\rho},0,0\right]\,,\ a^k_{25}=0\,,\ a^k_{26}=0\,,\\
&a^k_{31}=0\,,\ a^k_{32}=0\,,\ [a^k_{33}]=[u,0,0,1]\,,\ [a^k_{34}]=\left[0,0,\frac{1}{\rho},0\right]\,,\ a^k_{35}=0\,,\ a^k_{36}=0\,,\\
&[a^k_{41}]=[1,0,0,0]\,,\ [a^k_{42}]=[0,1,0,0]\,,\ [a^k_{43}]=[0,0,1,0]\,,\\
&a^k_{44}=0\,,\ [a^k_{45}]=\left[\frac{u}{\rho},0,0,\frac{1}{\rho}\right]\,,\ a^k_{46}=0\,,\\
&a^k_{51}=0\,,\ a^k_{52}=0\,,\ a^k_{53}=0\,,\ [a^k_{54}]=[u,0,0,1]\,,\ [a^k_{55}]=[-c^2u,0,0,-c^2]\,,\ a^k_{56}=0\,,
\end{aligned}$$

$$a^k_{61}=0\,,\ a^k_{62}=0\,,\ a^k_{63}=0\,,\ a^k_{64}=0\,,\ a^k_{65}=0\,,\ [a^k_{66}]=[u,0,0,1]\,. \tag{2.14}$$

The 6×6 characteristic matrix, $\beta_k a^k_{ij}$, becomes

$$\begin{bmatrix} \beta_0 & 0 & 0 & \beta_1/\rho & 0 & 0 \\ 0 & \beta_0 & 0 & \beta_2/\rho & 0 & 0 \\ 0 & 0 & \beta_0 & \beta_3/\rho & 0 & 0 \\ \beta_1 & \beta_2 & \beta_3 & 0 & \beta_0/\rho & 0 \\ 0 & 0 & 0 & \beta_0 & -c^2\beta_0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \beta_0 \end{bmatrix}, \tag{2.15}$$

where $\beta_0 \equiv u\beta_1 + \beta_4$. Setting its determinant equal to zero results in the characteristic equation

$$-\frac{\beta_0^4}{\rho}\left[\beta_0^2 - c^2(\beta_1^2 + \beta_2^2 + \beta_3^2)\right] = 0. \tag{2.16}$$

A fourfold repeated root is associated with the stream surfaces that form the characteristic surface described by setting $\beta_0 = u\beta_1 + \beta_4 = 0$. In addition, there are two other surfaces associated with the roots of the other factor,

$$\beta_0 = \pm c\sqrt{\beta_1^2 + \beta_2^2 + \beta_3^2}. \tag{2.17}$$

Our focus is on these directions since in a nominally one-dimensional, unsteady flow they would correspond to the forward and backward facing acoustic characteristics (i.e, C_+ and C_-) that are called the "Mach lines." We specifically work out the compatibility relation for both of them, as they occur in a pair, and later we will use the results for the characteristic surface that would correspond to the forward characteristic, as we will explain subsequently.

To display the compatibility relation we need to solve the equations for α_i, namely (2.3). Using the previous definitions, one obtains the six equations

$$\alpha_1\beta_0 + \alpha_4\beta_1 = 0\,, \qquad \alpha_2\beta_0 + \alpha_4\beta_2 = 0\,,$$

$$\alpha_3\beta_0 + \alpha_4\beta_3 = 0\,, \qquad \frac{1}{\rho}\left(\alpha_1\beta_1 + \alpha_2\beta_2 + \alpha_3\beta_3\right) + \alpha_5\beta_0 = 0\,,$$

$$\frac{\alpha_4}{\rho}\beta_0 - c^2\alpha_5\beta_0 = 0\,, \qquad \alpha_6\beta_0 = 0\,. \tag{2.18}$$

The solution of this system is, in terms of α_4 (note that $\beta_0 = u\beta_1 + \beta_4 \neq 0$),

$$\alpha_1 = -\frac{\alpha_4\beta_1}{\beta_0}\,,\ \alpha_2 = -\frac{\alpha_4\beta_2}{\beta_0}\,,\ \alpha_3 = -\frac{\alpha_4\beta_3}{\beta_0}\,,\ \alpha_5 = \frac{\alpha_4}{\rho c^2}\,,\ \alpha_6 = 0\,. \tag{2.19}$$

The compatibility condition (2.2) written out long becomes

$$\alpha_1 a^k_{1j}\frac{\partial u_j}{\partial x_k} + \alpha_2 a^k_{2j}\frac{\partial u_j}{\partial x_k} + \alpha_3 a^k_{3j}\frac{\partial u_j}{\partial x_k} + \alpha_4 a^k_{4j}\frac{\partial u_j}{\partial x_k} + \alpha_5 a^k_{5j}\frac{\partial u_j}{\partial x_k} = \alpha_5 b_5. \tag{2.20}$$

Substituting for the α_i in terms of α_4 leads to

$$\frac{-\alpha_4}{\beta_0}\left[\beta_1 a^k_{1j}\frac{\partial u_j}{\partial x_k} + \beta_2 a^k_{2j}\frac{\partial u_j}{\partial x_k} + \beta_3 a^k_{3j}\frac{\partial u_j}{\partial x_k}\right] + \alpha_4\left[a^k_{4j}\frac{\partial u_j}{\partial x_k} + \frac{1}{\rho c^2}a^k_{5j}\frac{\partial u_j}{\partial x_k}\right] = \frac{\alpha_4}{\rho c^2}b_5. \tag{2.21}$$

The reader is reminded that each of the terms in the equation represents one of the governing equations. Let us introduce the unit vector

$$\mathbf{n} = \frac{\beta_1 \mathbf{i} + \beta_2 \mathbf{j} + \beta_3 \mathbf{k}}{\sqrt{\beta_1^2 + \beta_2^2 + \beta_2^2}}. \tag{2.22}$$

This unit vector is normal to the tangent plane of the Mach cones, and hence normal to the instantaneous realization of the characteristic surface in the physical space.

We also notice that the first three terms in (2.21) represent the first three components of the momentum equation and can be rewritten as

$$\frac{-\alpha_4}{\beta_0}\left(\sqrt{\beta_1^2 + \beta_2^2 + \beta_2^2}\right)\mathbf{n} \cdot \left[\frac{D\mathbf{u}}{Dt} + \frac{1}{\rho}\nabla p\right]. \tag{2.23}$$

The second collection of terms in (2.21) can be rewritten as

$$\alpha_4 \left[\frac{1}{\rho}\frac{D\rho}{Dt} + \nabla \cdot \mathbf{u} + \frac{1}{\rho c^2}\left(\frac{Dp}{Dt} - c^2 \frac{D\rho}{Dt}\right)\right], \tag{2.24}$$

and the right-hand side of (2.21) is

$$\frac{\alpha_4}{\rho c^2} b_5 = \alpha_4 \sigma \omega. \tag{2.25}$$

Putting it all together leads to the frame-invariant expression of the compatibility condition on the characteristic surface (canceling out the common α_4 and the material derivatives of density, and multiplying through by ρc^2),

$$-\frac{\sqrt{\beta_1^2 + \beta_2^2 + \beta_2^2}}{\beta_0}(\rho c^2)\mathbf{n} \cdot \left[\frac{D\mathbf{u}}{Dt} + \frac{1}{\rho}\nabla p\right] + \left[\rho c^2 \nabla \cdot \mathbf{u} + \frac{Dp}{Dt}\right] = \rho c^2 \sigma \omega. \tag{2.26}$$

The characteristic equations (2.17) for the directions show that

$$\frac{\sqrt{\beta_1^2 + \beta_2^2 + \beta_2^2}}{\beta_0} = \pm \frac{1}{c}, \tag{2.27}$$

so that it can be used to write the compatibility condition in the form

$$\mp(\rho c)\mathbf{n} \cdot \left[\frac{D\mathbf{u}}{Dt} + \frac{1}{\rho}\nabla p\right] + \left[\rho c^2 (\nabla \cdot \mathbf{u}) + \frac{Dp}{Dt}\right] = \rho c^2 \sigma \omega. \tag{2.28}$$

The compatibility condition is a differential relation that holds on the characteristic surface. But the other condition is that the motion is confined to be along the space-time characteristic direction defined by *speed relation*

$$u\beta_1 + \beta_4 = \pm c\sqrt{\beta_1^2 + \beta_2^2 + \beta_3^2}\,. \tag{2.29}$$

It is important to interpret (2.29) as well as a frame-invariant relation. The components $(\beta_1, \beta_2, \beta_3)$ can be chosen to be those of a unit normal to the surface, and hence $\sqrt{\beta_1^2 + \beta_2^2 + \beta_3^2} = 1$. Also the term $u\beta_1$ has the meaning $\mathbf{u} \cdot \mathbf{n}$. Finally, β_4 is the velocity of the characteristic surface normal to itself, $\beta_4 = V_n$ (say). Rewriting the expression above leads to

$$V_n = \mathbf{u} \cdot \mathbf{n} \pm c\,. \tag{2.30}$$

In one dimension, this reduces to the familiar equation for the slope of the characteristics $V_n \equiv dx/dt = u \pm c$.

Consider the forward propagating surface that corresponds to the choice of the plus sign in the previous relation (2.30). Note that the particle velocity in the frame of an observer traveling in the forward surface is $u_n - V_n$ and the speed relation can be written as

$$\frac{u_n - V_n}{c} = -1\,. \tag{2.31}$$

This means that on this characteristic surface the local normal Mach number is always unity, which is the conventional definition of sonic.

The compatibility and the speed relation, taken together, are two pieces of information, namely a differential condition in the sonic surface and a scalar speed relation, that determine the motion of the surface. If we include additional reactions and replace λ by λ_q, $q = 1, 2, \ldots, N$, where N is the number of reactions, then in the subsequent derivations only the right-hand side of (2.28) will change since additional reactions generate only additional roots that are multiples of the root associated with the streamline characteristic but not to the acoustics. The right-hand side of the compatibility condition becomes the sum, $\rho c^2 \sigma_q \omega_q$, over $q = 1, \ldots, N$, where

$$\sigma_q = -\frac{1}{\rho c^2}\frac{e_{\lambda_q}}{e_p} \tag{2.32}$$

is the thermicity coefficient and ω_q is the rate of qth reaction. The sound speed in the governing equations is the frozen sound speed and is still given by (2.13).

If we specify the result to a detonation wave that is propagating from left to right in the positive x-direction, then the normal to the characteristic surface embedded in the reaction zone, which can possibly intersect the shock, points forward. Therefore, we select the plus sign in (2.28). Let us denote the unit normal to the characteristic surface $\mathbf{n}_*$ (in general, the subscript $*$ will refer to a quantity evaluated at the sonic surface). The *compatibility condition* for this surface is then

$$\rho c \mathbf{n}_* \cdot \left(\frac{D\mathbf{u}}{Dt} + \frac{1}{\rho}\nabla p\right) + \rho c^2 \nabla \cdot \mathbf{u} + \frac{Dp}{Dt} = \rho c^2 \sigma \omega, \tag{2.33}$$

where it is understood that all terms are evaluated at the sonic surface, although we drop the subscript $*$ in most of the terms for the sake of clarity. The compatibility condition (2.33) holds on the exceptional surface at which the flow is locally sonic; that is, an observer moving with the surface observes that the flow speed normal to the surface is locally sonic:

$$\mathcal{U}_{n*} = \mathbf{u}_* \cdot \mathbf{n}_* - \mathcal{D} = -c_*\,, \tag{2.34}$$

where $\mathcal{D}$ is the normal speed of the sonic surface in the lab frame.

3. One-dimensional sonic conditions. Equation (2.33) simplifies now to

$$\rho c\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + \frac{1}{\rho}\frac{\partial p}{\partial x}\right) + \rho c^2 \frac{\partial u}{\partial x} + \frac{\partial p}{\partial t} + u\frac{\partial p}{\partial x} = \rho c^2 \sigma \omega, \tag{3.1}$$

which can be rewritten as

$$\frac{dp_*}{dt} + \rho_* c_* \frac{du_*}{dt} = \rho_* c_*^2 \sigma_* \omega_*, \tag{3.2}$$

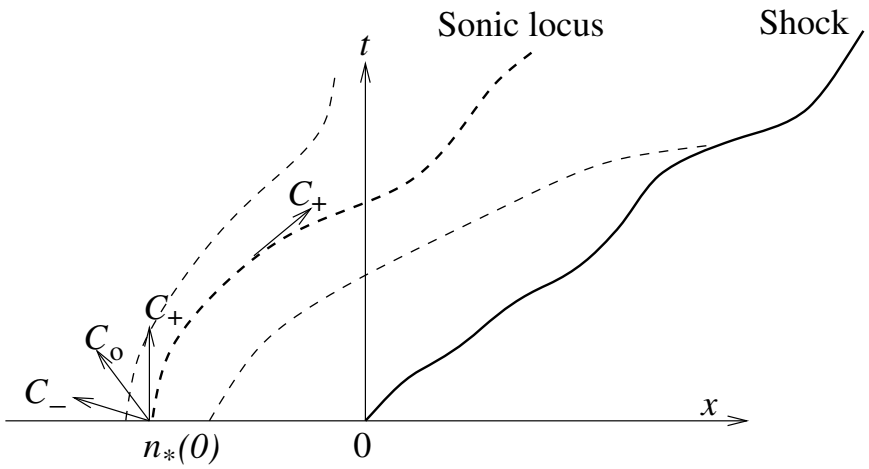

FIG. 3.1. *One-dimensional sonic locus as the C_+ characteristic emanating from the initial steady sonic locus.*

where the spatial and temporal derivatives in (3.1) are combined to form a time derivative along the forward characteristic direction,

$$\frac{d}{dt} = \frac{\partial}{\partial t} + (c_* + u_*)\frac{\partial}{\partial x} = \frac{\partial}{\partial t} + \frac{dx_*}{dt}\frac{\partial}{\partial x},$$

$$\frac{dx_*}{dt} = c_* + u_*. \tag{3.3}$$

As we have mentioned before, the sonic locus is a special characteristic that is a separatrix of two families of characteristic lines, namely those that reach the shock front in finite time and those that do not. It is assumed that the sonic locus exists initially as, for example, in a steady detonation and continues to exist during unsteady evolution. Then the initial condition selects the separatrix from the entire family of forward characteristics for all of which (3.3) and (3.2) hold. It must be pointed out that it is not, in general, possible to identify the separatrix in an arbitrary initial condition.

One can look at (3.2) as a differential equation that does not involve derivatives normal to the characteristic surface. The sonic locus is an (x, t)-curve along a limiting C_+ characteristic (see Figure 3.1), and the derivative $\partial/\partial x$ does not appear. Indeed, the time derivatives in (3.2) are the derivatives along the characteristics; that is, the derivatives lie in the tangent plane of the characteristic surface.

For one-dimensional detonation with point symmetry ($j = 0, 1, 2$ correspond to planar, cylindrical, and spherical symmetry, respectively), one easily finds that the compatibility condition is

$$\frac{dp_*}{dt} + \rho_* c_* \frac{du_*}{dt} + \frac{j}{r}\rho_* c_*^2 u_* = \rho_* c_*^2 \sigma_* \omega_*, \tag{3.4}$$

where r is the radial coordinate, while the speed relation is

$$\frac{dr_*}{dt} = c_* + u_*. \tag{3.5}$$

For a steady one-dimensional planar detonation wave in a mixture with complex reaction network, the compatibility condition reduces to the equation

$$\sigma_q \omega_q = 0 \tag{3.6}$$

that, together with $c_* + U_* = 0$, defines the sonic locus. For a discussion of the condition in applications to multiple-step reactions in detonation waves, see [5].

4. Sonic conditions of detonation shock dynamics. We call (2.33) and (2.34) the *sonic conditions* on the limiting forward characteristic surface, and their application to detonation theory is a main result of this paper. Specifically, we consider initial-value problems where there is an initially prescribed detonation shock locus with states behind it that lead subsequently to smooth evolution in the reaction zone for a self-sustained detonation. In this section, we specialize sonic conditions to one- and two-dimensional detonations. We show that when linearized, the compatibility condition reduces to the *radiation condition* of detonation stability theory (see, e.g., [7, 9, 13]). For the two-dimensional, slowly varying, and weakly curved detonations, the compatibility condition reduces to the *thermicity condition* of detonation shock dynamics (DSD theory; see, e.g., [18]). In both detonation stability theory and DSD, the governing equations are usually written in a frame of reference attached to the shock front since one is often interested in the shock-front dynamics rather than anything else. For the purpose of comparison with the known sonic conditions, we write our sonic conditions in the shock-attached frame. But before doing that, it is instructive to look at the sonic conditions written in the frame of the sonic locus.

4.1. Sonic conditions in the sonic-frame Bertrand coordinates. We express the sonic conditions in two-dimensional surface-attached Bertrand coordinates which use the normal distance to a prescribed front and the arclength to a reference point along the front as the intrinsic surface-based coordinates (see, e.g., [11, 18]). Since the Bertrand coordinates are developed by the sonic surface, they are perfectly suited to simplify the conditions since only derivatives in the surface and normal to that surface appear. Let (η, ζ) be the normal signed distance to the surface and transverse distance measured along the surface (see Figure 4.1). Let $(\mathbf{n}, \mathbf{t})$ be the corresponding unit normal and tangent vectors to the sonic surface. The coordinate transformation from the laboratory frame to the Bertrand frame is defined by

$$\mathbf{r} = \mathbf{r}_s + \eta \mathbf{n}, \tag{4.1}$$

where $\mathbf{r}$ is the lab-frame position of a point in space and $\mathbf{r}_s(\zeta, t)$ is the position of the sonic surface. Then various differential operators in the Bertrand frame are written as follows:

$$\nabla = \mathbf{n}\frac{\partial}{\partial \eta} + \frac{\mathbf{t}}{1 + \eta\kappa_*}\frac{\partial}{\partial \zeta}, \tag{4.2}$$

$$\nabla \cdot \mathbf{u} = \frac{\partial u_\eta}{\partial \eta} + \frac{1}{1 + \eta\kappa_*}\left(\kappa_* u_\eta + \frac{\partial u_\zeta}{\partial \zeta}\right), \qquad \mathbf{u} \cdot \nabla = u_\eta \frac{\partial}{\partial \eta} + \frac{u_\zeta}{1 + \eta\kappa_*}\frac{\partial}{\partial \zeta}, \tag{4.3}$$

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial t} - \mathcal{D}\frac{\partial}{\partial \eta} + \mathcal{S}\frac{\partial}{\partial \zeta}, \tag{4.4}$$

and

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \mathbf{u} \cdot \nabla = \frac{\partial}{\partial t} + (u_\eta - \mathcal{D})\frac{\partial}{\partial \eta} + \left(\mathcal{S} + \frac{u_\zeta}{1 + \eta\kappa_*}\right)\frac{\partial}{\partial \zeta}, \tag{4.5}$$

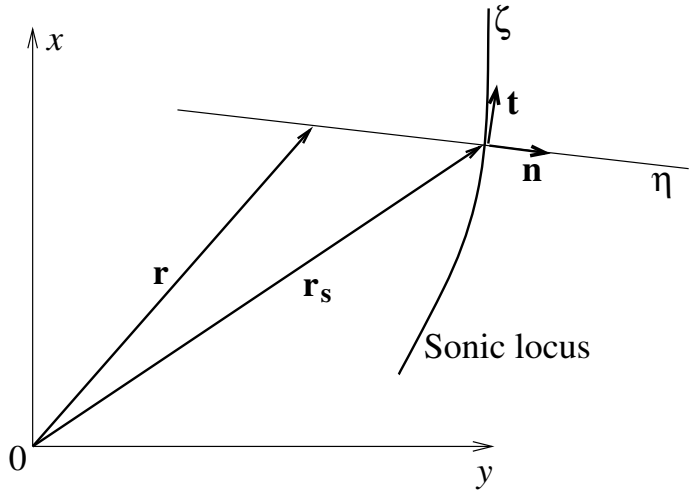

FIG. 4.1. *Bertrand frame attached to the sonic locus.*

where the lab-frame particle speed is $\mathbf{u} = u_\eta \mathbf{n} + u_\zeta \mathbf{t}$, and κ_* is the curvature of the sonic surface. Note that $\eta = 0$ in the sonic surface and that $u_\eta - \mathcal{D} = \mathcal{U}_\eta$ is the normal particle velocity relative to the sonic frame. We introduced the rate of strain of the arclength,

$$\mathcal{S} = \frac{\partial \zeta}{\partial t}, \tag{4.6}$$

and used the fact that

$$\frac{\partial \eta}{\partial t} = -\mathcal{D}. \tag{4.7}$$

Next we calculate the compatibility condition (2.33) in terms of the new coordinates. Clearly, $\mathbf{n} \cdot \nabla p = \partial p / \partial \eta$, and all other terms are also straightforward, except for $\mathbf{n} \cdot D\mathbf{u}/Dt$. To calculate the latter, we write

$$\begin{aligned} \mathbf{n} \cdot \frac{D\mathbf{u}}{Dt} &= \mathbf{n} \cdot \frac{D}{Dt}\left(u_\eta \mathbf{n} + u_\zeta \mathbf{t}\right) = \mathbf{n} \cdot \left(\frac{Du_\eta}{Dt}\mathbf{n} + u_\eta \frac{D\mathbf{n}}{Dt} + \frac{Du_\zeta}{Dt}\mathbf{t} + u_\zeta \frac{D\mathbf{t}}{Dt} \right) \\ &= \frac{Du_\eta}{Dt} + u_\zeta \mathbf{n} \cdot \left[\frac{\partial \mathbf{t}}{\partial t} + (u_\eta - \mathcal{D}) \frac{\partial \mathbf{t}}{\partial \eta} + (\mathcal{S} + u_\zeta) \frac{\partial \mathbf{t}}{\partial \zeta} \right], \end{aligned} \tag{4.8}$$

where we have used (4.5) and $\mathbf{n} \cdot \mathbf{t} = 0, \quad \mathbf{n} \cdot D\mathbf{n}/Dt = 0$. To determine $\mathbf{n} \cdot \partial \mathbf{t}/\partial t$, we differentiate the coordinate transformation, $\mathbf{r} = \mathbf{r}_s + \eta \mathbf{n}$, with respect to time and find

$$0 = \frac{d\mathbf{r}}{dt} = \frac{\partial \mathbf{r}_s}{\partial t} + \frac{\partial \zeta}{\partial t}\frac{\partial \mathbf{r}_s}{\partial \zeta} + \frac{\partial \eta}{\partial t}\mathbf{n} + \eta \left(\frac{\partial \mathbf{n}}{\partial t} + \frac{\partial \zeta}{\partial t}\frac{\partial \mathbf{n}}{\partial \zeta} \right). \tag{4.9}$$

We evaluate the last result in the sonic surface, at $\eta = 0$, to obtain

$$\frac{\partial \mathbf{r}_s}{\partial t} + \mathcal{S}\mathbf{t} - \mathcal{D}\mathbf{n} = 0, \tag{4.10}$$

and differentiate the latter with respect to ζ, and noting that $\mathbf{t} = \partial \mathbf{r}_s/\partial\zeta$, we find, using the Frenet formulas,

$$\frac{\partial \mathbf{n}}{\partial \zeta} = \kappa \mathbf{t}, \qquad \frac{\partial \mathbf{t}}{\partial \zeta} = -\kappa \mathbf{n}, \tag{4.11}$$

that

$$\mathbf{n} \cdot \frac{\partial \mathbf{t}}{\partial t} = \frac{\partial \mathcal{D}}{\partial \zeta} + \kappa \mathcal{S}. \tag{4.12}$$

Then, collecting all terms in (4.8), we find that

$$\mathbf{n} \cdot \frac{D\mathbf{u}}{Dt} = \frac{Du_\eta}{Dt} + u_\zeta \frac{\partial \mathcal{D}}{\partial \zeta} - \kappa u_\zeta^2. \tag{4.13}$$

What is left is to collect terms in (2.33), which results in the following equation:

$$\begin{aligned} &\rho c \left(\frac{Du_\eta}{Dt} + u_\zeta \frac{\partial \mathcal{D}}{\partial \zeta} - \kappa u_\zeta^2 + \frac{1}{\rho}\frac{\partial p}{\partial \eta} \right) \\ &+\rho c^2 \left(\frac{\partial u_\eta}{\partial \eta} + \kappa_* u_\eta + \frac{\partial u_\zeta}{\partial \zeta} \right) + \frac{Dp}{Dt} = \rho c^2 \sigma \omega. \end{aligned} \tag{4.14}$$

Expanding the material derivative according to (4.5) and rearranging derivatives along the same directions, we obtain

$$\begin{aligned} &\frac{\partial p}{\partial t} + \rho c \frac{\partial u_\eta}{\partial t} + \kappa_* \rho c^2 u_\eta + (c + u_\eta - \mathcal{D}) \left(\frac{\partial p}{\partial \eta} + \rho c \frac{\partial u_\eta}{\partial \eta} \right) \\ &+\rho c^2 \frac{\partial u_\zeta}{\partial \zeta} + \rho c u_\zeta \left(\frac{\partial \mathcal{D}}{\partial \zeta} - \kappa_* u_\zeta \right) + (\mathcal{S} + u_\zeta) \left(\frac{\partial p}{\partial \zeta} + \rho c \frac{\partial u_\eta}{\partial \zeta} \right) = \rho c^2 \sigma \omega. \end{aligned} \tag{4.15}$$

An important observation now is that in the sonic surface the flow is locally sonic with

$$c + u_\eta - \mathcal{D} = 0, \tag{4.16}$$

which is the speed relation. Therefore, all normal-derivative terms in the compatibility condition (4.15) drop out, resulting in

$$\frac{\partial p}{\partial t} + \rho c \frac{\partial u_\eta}{\partial t} + \kappa_* \rho c^2 u_\eta = \rho c^2 \sigma \omega - R_*, \tag{4.17}$$

where the terms that explicitly depend on the transverse variation are lumped into R_*, given by

$$R_* = \rho c^2 \frac{\partial u_\zeta}{\partial \zeta} + \rho c u_\zeta \left(\frac{\partial \mathcal{D}}{\partial \zeta} - \kappa_* u_\zeta \right) + (\mathcal{S} + u_\zeta) \left(\frac{\partial p}{\partial \zeta} + \rho c \frac{\partial u_\eta}{\partial \zeta} \right).$$

The reader is reminded that everything in (4.17) is evaluated in the sonic surface.

By definition, the compatibility condition must not contain derivatives along the normal to the characteristic surface in (ζ, η, t)-space. Since our coordinate frame is local, that is, attached to the characteristic surface, then the time derivative in (4.17) does indeed lie in the surface, similar to the time derivative along the C_+

characteristic in one dimension. Furthermore, the ζ-derivative is also in the surface, as ζ is the arclength. The only derivative that is *off* the characteristic surface in (ζ, η, t)-space is $\partial/\partial\eta$, and that derivative is indeed absent in (4.17). If R_* can be neglected, (4.17) is similar to the thermicity condition of the old DSD theories with an important difference that here $\mathcal{U}_\eta$ and $\mathcal{D}$ are the particle velocity in the *sonic* frame and normal speed of the *sonic* surface, respectively; in the older theories of DSD, the same variables are calculated in the *shock-attached* frame. The approximate form that neglects R_* is valid only in the limit of weak curvature, slow time, and small transverse variation. Equation (4.17) is an exact relation that is valid for general two-dimensional detonations with an embedded sonic surface, provided only that the Bertrand coordinates are invertible, which is true if the radius of curvature of the sonic locus is large compared to the length of the reaction zone.

4.2. Sonic conditions of DSD theory: Formulation in the shock-attached frame. The linear stability problem and the DSD problem were originally formulated in shock-attached coordinates: in the first case, this dates back to the first rigorous analysis given by Erpenbeck [4]; in the second case, the shock-attached coordinates were used because the goal of DSD theory is to determine the dynamics of the shock front [16, 18].

Here we revisit the formulation of DSD in the shock-attached coordinates and use Bertrand coordinates attached to the shock. Let (n, ξ) be the normal and transverse coordinates, and let $(\mathbf{n}, \mathbf{t})$ represent the corresponding unit normal and tangent vectors in the shock frame; then the coordinate transformation is given by

$$\mathbf{r} = \mathbf{r}_s(\xi, t) + n\mathbf{n}(\xi, t). \tag{4.18}$$

The time derivative in the shock-attached frame is represented as

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial t} - D\frac{\partial}{\partial n} + S\frac{\partial}{\partial \xi},$$

the velocity in the lab frame is $\mathbf{u} = u_n\mathbf{n} + u_\xi\mathbf{t}$, D is the normal shock speed, $S = \partial\xi/\partial t$ is the stretch rate of the arclength along the shock, and $U_n = u_n - D$ is the normal particle speed relative to the shock. The material derivative is then

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + U_n\frac{\partial}{\partial n} + \left(S + \frac{u_\xi}{1 + n_*\kappa}\right)\frac{\partial}{\partial \xi}. \tag{4.19}$$

Differential operators involving ∇ are similar to those in the sonic frame, (4.2)–(4.3), only now the velocity is expressed in the shock frame. A slight complication arises from the fact that $\mathbf{n}_*$ in (2.33) is the unit normal to the sonic surface, which in general is different from $\mathbf{n}$, the unit normal to the shock. Therefore, the shock-frame compatibility condition will contain terms, proportional to $\mathbf{n}_* \cdot \mathbf{n}$, which need to be evaluated.

Let

$$\mathbf{n}_* = a_n\mathbf{n} + a_\xi\mathbf{t}, \tag{4.20}$$

where the components, $a_n = \mathbf{n}_* \cdot \mathbf{n}$ and $a_\xi = \mathbf{n}_* \cdot \mathbf{t}$, will be determined below (see equations (4.32)). Then, $\mathbf{n}_* \cdot \nabla p = a_n\partial p/\partial n + a_\xi\partial p/\partial\xi$, and

$$\mathbf{n}_* \cdot \frac{D\mathbf{u}}{Dt} = \mathbf{n}_* \cdot \frac{D}{Dt}(u_n\mathbf{n} + u_\xi\mathbf{t}) = \frac{Du_n}{Dt}\mathbf{n}_* \cdot \mathbf{n} + u_n\mathbf{n}_* \cdot \frac{D\mathbf{n}}{Dt} + \frac{Du_\xi}{Dt}\mathbf{n}_* \cdot \mathbf{t} + u_\xi\mathbf{n}_* \cdot \frac{D\mathbf{t}}{Dt}. \tag{4.21}$$

We now calculate each term on the right-hand side of this equation. Consider

$$\mathbf{n}_* \cdot \frac{D\mathbf{n}}{Dt} = a_\xi \mathbf{t} \cdot \frac{D\mathbf{n}}{Dt} = a_\xi \mathbf{t} \cdot \left[\frac{\partial \mathbf{n}}{\partial t} + \left(S + \frac{u_\xi}{1 + n_* \kappa} \right) \frac{\partial \mathbf{n}}{\partial \xi} \right]. \tag{4.22}$$

By time-differentiating the coordinate transformation (4.18) and evaluating the result at the shock, we find that

$$\frac{\partial \mathbf{r}_s}{\partial t} + S\mathbf{t} - D\mathbf{n} = 0. \tag{4.23}$$

Differentiating this result with respect to ξ and using $\mathbf{t} = \partial \mathbf{r}_s / \partial \xi$, we find

$$\frac{\partial \mathbf{t}}{\partial t} + \left(\frac{\partial S}{\partial \xi} - \kappa D \right) \mathbf{t} - \left(\frac{\partial D}{\partial \xi} + \kappa S \right) \mathbf{n} = 0, \tag{4.24}$$

from which it follows that

$$\mathbf{t} \cdot \frac{\partial \mathbf{n}}{\partial t} = -\mathbf{n} \cdot \frac{\partial \mathbf{t}}{\partial t} = -\frac{\partial D}{\partial \xi} - \kappa S \tag{4.25}$$

and

$$\frac{\partial S}{\partial \xi} - \kappa D = 0. \tag{4.26}$$

Using (4.25) and the Frenet formula, $\partial \mathbf{n} / \partial \xi = \kappa \mathbf{t}$, we find that (4.22) results in

$$\mathbf{n}_* \cdot \frac{D\mathbf{n}}{Dt} = a_\xi \left(-\frac{\partial D}{\partial \xi} + \frac{\kappa u_\xi}{1 + n_* \kappa} \right). \tag{4.27}$$

Similarly, we find

$$\mathbf{n}_* \cdot \frac{D\mathbf{t}}{Dt} = a_n \mathbf{n} \cdot \left[\frac{\partial \mathbf{t}}{\partial t} + \left(S + \frac{u_\xi}{1 + n_* \kappa} \right) \frac{\partial \mathbf{t}}{\partial \xi} \right] = a_n \left(\frac{\partial D}{\partial \xi} - \frac{\kappa u_\xi}{1 + n_* \kappa} \right). \tag{4.28}$$

Equation (4.21) becomes

$$\mathbf{n}_* \cdot \frac{D\mathbf{u}}{Dt} = a_n \frac{Du_n}{Dt} + a_\xi \frac{Du_\xi}{Dt} + (u_n a_\xi - u_\xi a_n) \left(-\frac{\partial D}{\partial \xi} + \frac{\kappa u_\xi}{1 + n_* \kappa} \right). \tag{4.29}$$

Collecting all terms, we obtain that the shock-frame compatibility condition is

$$\frac{\partial p}{\partial t} + (c + U_n) \frac{\partial p}{\partial n} + \rho c \left[\frac{\partial u_n}{\partial t} + (c + U_n) \frac{\partial u_n}{\partial n} \right] + \frac{\kappa}{1 + n_* \kappa} \rho c^2 u_n = \rho c^2 \sigma \omega - R, \tag{4.30}$$

where κ (without the * subscript) is the local curvature of the shock, n_* is the normal distance from the shock to the sonic surface, and all terms are evaluated in the sonic surface. By R in the right-hand side of (4.30) we denote the following collection of terms:

$$\begin{aligned} R = & \left(S + \frac{u_\xi}{1 + n_* \kappa} \right) \left(\frac{\partial p}{\partial \xi} + \rho c \frac{\partial u_n}{\partial \xi} \right) + \frac{\rho c^2}{1 + n_* \kappa} \frac{\partial u_\xi}{\partial \xi} \\ & + c (a_n - 1) \left(\frac{\partial p}{\partial n} + \rho \frac{Du_n}{Dt} \right) + c a_\xi \left(\frac{\partial p}{\partial \xi} + \rho \frac{Du_\xi}{Dt} \right) \\ & + \rho c (u_n a_\xi - u_\xi a_n) \left(-\frac{\partial D}{\partial \xi} + \frac{\kappa u_\xi}{1 + n_* \kappa} \right). \end{aligned} \tag{4.31}$$

From the derivations below (see (4.39)), the coefficients a_n and a_ξ in (4.31) are given by

$$a_n = \left[1 + \left(\frac{1}{1+n_*\kappa}\frac{\partial n_*}{\partial \xi}\right)^2\right]^{-1/2}, \qquad a_\xi = -\frac{a_n}{1+n_*\kappa}\frac{\partial n_*}{\partial \xi}, \tag{4.32}$$

so that small transverse variation implies smallness of $a_n - 1$ and a_ξ.

Note that the operator $\partial/\partial t + (c + U_n)\,\partial/\partial n$ in (4.30) in general is *not* the time derivative along the sonic locus, unlike the one in (4.17). In the sonic frame, we had $\mathcal{U}_{n*} = -c_*$ exactly as a speed relation. But now it is no longer true that $c_* + U_{n*} = 0$! In one dimension, we could write $c_* + U_{n*} = dn_*/dt$, in which case the operator $\partial/\partial t + (c + U_n)\,\partial/\partial n$ does indeed become a total derivative along the sonic locus. But in general two-dimensional detonation waves, the derivative $\partial/\partial t + (c + U_n)\,\partial/\partial n$ does not lie in the tangent plane of the sonic locus; only if the transverse variations can be neglected is the derivative in the sonic surface.

The speed relation expressed in the shock-attached coordinates is derived next. Let the equation

$$\psi(x, y, t) = 0 \tag{4.33}$$

represent the level set of the sonic surface in the laboratory frame. Then its unit normal and normal speed are given by

$$\mathbf{n}_* = \frac{\nabla\psi}{|\nabla\psi|} \quad \text{and} \quad \mathcal{D} = -\frac{1}{|\nabla\psi|}\frac{\partial\psi}{\partial t}, \tag{4.34}$$

respectively, so that the general speed relation (2.34) can be rewritten as

$$\frac{\partial\psi}{\partial t} + c\,|\nabla\psi| + \mathbf{u}\cdot\nabla\psi = 0. \tag{4.35}$$

An interesting form of the speed relation is obtained from (4.35) by noting that $|\nabla\psi| = \mathbf{n}_*\cdot\nabla\psi$,

$$\frac{\partial\psi}{\partial t} + (\mathbf{u} + c\,\mathbf{n}_*)\cdot\nabla\psi = 0, \tag{4.36}$$

a transport equation that underscores propagation of the sonic surface in the direction of $\mathbf{u} + c\mathbf{n}_*$ with the normal speed $c + \mathbf{u}\cdot\mathbf{n}_*$. The derivative $\mathcal{L} = \partial/\partial t + (\mathbf{u} + c\mathbf{n}_*)\cdot\nabla$ is a directional time derivative normal to the sonic surface so that (4.36) is an expression of constancy of ψ in the sonic surface.

In the shock-attached frame, (n, ξ, t), the level-set equation can be written as

$$\psi \equiv n - n_*(\xi, t) = 0, \tag{4.37}$$

where n_* is the normal distance from the shock to the sonic surface. Then we obtain that

$$\nabla\psi = \mathbf{n} - \frac{1}{1+n_*\kappa}\frac{\partial n_*}{\partial \xi}\mathbf{t}, \qquad \frac{\partial\psi}{\partial t} = -D - \frac{\partial n_*}{\partial t} - S\frac{\partial n_*}{\partial \xi}, \tag{4.38}$$

and

$$\mathbf{n}_* = \frac{1}{|\nabla\psi|}\left(\mathbf{n} - \frac{1}{1+n_*\kappa}\frac{\partial n_*}{\partial \xi}\mathbf{t}\right). \tag{4.39}$$

Be reminded that in these expressions κ is the curvature of the shock. Substituting these formulas into (4.35), we obtain the speed relation in the shock-attached frame,

$$\frac{\partial n_*}{\partial t} + \left(S + \frac{u_\xi}{1+n_*\kappa}\right)\frac{\partial n_*}{\partial \xi} = U_n + c\sqrt{1+\left(\frac{1}{1+n_*\kappa}\frac{\partial n_*}{\partial \xi}\right)^2}. \tag{4.40}$$

Again, this is an exact relation that expresses the speed relation for the sonic surface written in the shock-attached Bertrand coordinates in terms of the shock properties, that is, the curvature κ and the stretch S, and the flow state in the sonic surface, $n_*(\xi,t)$, U_n, u_ξ, and c. Thus we have two equations, (4.30) and (4.40), that represent the sonic conditions in the shock-attached Bertrand frame.

Equation (4.40) can be rewritten as

$$c + U_n = \frac{\partial n_*}{\partial t} + \left(S + \frac{u_\xi}{1+n_*\kappa}\right)\frac{\partial n_*}{\partial \xi} + c\left[1 - \sqrt{1+\left(\frac{1}{1+n_*\kappa}\frac{\partial n_*}{\partial \xi}\right)^2}\right], \tag{4.41}$$

from which one can see that the speed relation is similar to the equation of the forward characteristic in one dimension, (3.3), which in the shock-attached frame is $c + U_n = dn_*/dt$ but involves more terms, all due to the transverse variation.

Next we make certain approximations in order to simplify the sonic conditions (4.30) and (4.40) and to see their connection with the older formulations of DSD. Let us assume that the shock curvature is small, $\kappa = o(1)$, and the transverse flow speed and transverse variations are also small, $u_\xi = o(1)$, $\partial/\partial\xi = o(1)$. Then retaining only the leading-order terms, from (4.40), we obtain that

$$\frac{\partial n_*}{\partial t} = U_n + c_*. \tag{4.42}$$

Retaining only leading-order curvature terms in (4.30), we obtain that

$$\frac{\partial p}{\partial t} + \rho c\frac{\partial u_n}{\partial t} + \kappa\rho c^2 u_n - \rho c^2\sigma\omega = 0, \tag{4.43}$$

where the time derivative is now

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial t} + (c+U_n)\frac{\partial}{\partial n} = \frac{\partial}{\partial t} + \frac{\partial n_*}{\partial t}\frac{\partial}{\partial n}.$$

The time derivative in (4.43) must be taken along the sonic locus; that is, the state variables, p and u_n, must first be evaluated at the sonic locus, and only then should their derivatives be taken.

5. On the sonic conditions of detonation stability theory. In this section, we show that the linearized version of the compatibility condition reduces to the radiation conditions of detonation stability theory (see, e.g., [7, 9, 13]). Here we derive the one- and two-dimensional radiation conditions.

A one-dimensional radiation condition follows directly from (3.2) by straightforward linearization. Let us denote the steady base state by an overbar and perturbations about the base state by a prime, e.g., $p = \bar{p}(n) + p'(n,t)$, etc. Then the perturbed sonic state is given by

$$p_* = \bar{p}_*(n_*) + p'(n_*,t), \qquad u_* = \bar{u}_*(n_*) + u'(n_*,t), \tag{5.1}$$

$$\rho_* = \bar{\rho}_*(n_*) + \rho'(n_*,t), \qquad \lambda_* = \bar{\lambda}_*(n_*) + \lambda'(n_*,t), \tag{5.2}$$

where we can take $n_* = \bar{n}_*$ in the primed quantities since the correction to the sonic locus, $n'_* = n_* - \bar{n}_*$, that results from the use of the speed relation,

$$\dot{n}'_* = c'_* + U'_{n*}, \tag{5.3}$$

contributes only higher-order terms. But we also expand the leading-order terms about the exact sonic locus to obtain, for example, that

$$\bar{p}_* (n_*) = \bar{p}_* (\bar{n}_*) + \frac{\mathrm{d}\bar{p}_* (\bar{n}_*)}{\mathrm{d}n} n'_*. \tag{5.4}$$

The perturbations such as in the last expression will be absent if the steady-state gradients vanish at the steady sonic locus, which is often the case.

Finally, the linearized compatibility condition is

$$\frac{dp'}{dt} + \bar{\rho}_* \bar{c}_* \frac{du'}{dt} + \left(\frac{\mathrm{d}\bar{p}_*}{\mathrm{d}n} + \bar{\rho}_* \bar{c}_* \frac{\mathrm{d}\bar{p}_*}{\mathrm{d}n} \right) \dot{n}'_* = \bar{\rho}_* \bar{c}_*^2 \bar{\sigma}_* \omega', \tag{5.5}$$

where everything with an overbar is evaluated at $n = \bar{n}_*$. We have also taken into account that $\bar{\omega}_* = 0$; ω' is the perturbation of the reaction rate.

In the special case of an ideal gas, the equation of state is $p = \rho RT$, $e = pv/(\gamma - 1) - \lambda Q$, so that $\rho c^2 \sigma = (\gamma - 1) Q\rho$. For simple-depletion kinetics with $\nu = 1$, the gradients of the steady-state pressure and velocity vanish at the sonic locus, and therefore the term proportional to $\dot{n}'_*$ in (5.5) will drop out. Assuming normal-mode perturbations, $p' = \bar{p}'(n) \exp(\alpha t)$, etc., the radiation condition (5.5) reduces to

$$\alpha (\bar{p}'_* + \bar{\rho}_* \bar{c}_* \bar{u}'_*) + (\gamma - 1) Q \bar{\rho}_* k \exp(-E/\bar{p}_* \bar{v}_*) \bar{\lambda}'_* = 0, \tag{5.6}$$

which is exactly the CJ limit of the radiation condition derived by Lee and Stewart [9].

If the depletion factor is less than unity, that is, $\nu < 1$ in $\omega = k(1 - \lambda)^\nu \exp(-E/pv)$, then the reaction-rate perturbation away from the sonic locus is

$$\omega' = \left(\frac{\partial \bar{\omega}}{\partial \bar{p}} \right) p' + \left(\frac{\partial \bar{\omega}}{\partial \bar{v}} \right) v' + \left(\frac{\partial \bar{\omega}}{\partial \bar{\lambda}} \right) \lambda'. \tag{5.7}$$

As $\bar{\lambda} \to 1$, one finds that $(\partial \bar{\omega}/\partial \bar{\lambda}) \sim (1 - \bar{\lambda})^{\nu - 1} \to \infty$, so the last term in the previous expansion is nonuniform as the sonic locus is approached, clearly a result of the base-state reaction rate vanishing at the sonic locus. Near the sonic locus the reaction rate perturbation is

$$\omega' = \omega (\lambda_*) - \omega \left(\bar{\lambda}_* \right) = k (-\lambda')^\nu \exp(-E/\bar{p}_* \bar{v}_*), \tag{5.8}$$

which is a *nonlinear* function of λ', another indication of the nonuniformity of solutions of the original linearized system of Euler equations. If all perturbations in expansions (5.1) and (5.2) are assumed to be $O(\epsilon)$ with $\epsilon \to 0$, then the left-hand side of (5.5) is also $O(\epsilon)$, while the right-hand side is $O(\epsilon^\nu)$. It follows then that although in the main-reaction layer (i.e., the region behind the shock but away from the sonic locus) the perturbations are $O(\epsilon)$, they are no longer $O(\epsilon)$ as the sonic locus is approached (that is, in the transonic layer). This potential nonuniformity has to be dealt with by considering the linear stability problem separately in the main-reaction layer and the transonic layer, a problem that is beyond the scope of the present paper. Here we indicate only the possibility of essentially nonlinear dynamics in the transonic

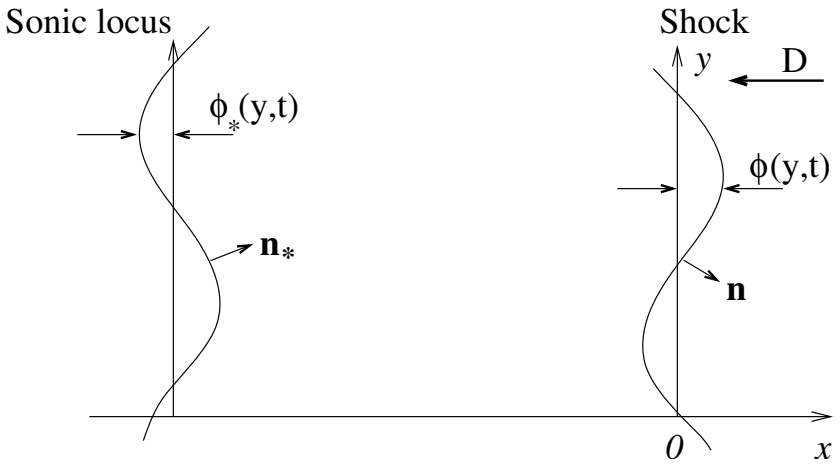

FIG. 5.1. *Perturbation of a two-dimensional steady detonation with an embedded sonic locus.*

layer, a situation common in transonic-flow problems. The linear stability problem of detonation has to be formulated so that this nonlinear character is carefully accounted for, and the solutions in the main reaction layer and transonic layer should be properly matched.

Consider now a two-dimensional detonation wave with an embedded sonic locus subject to a small perturbation of the shock locus, $\phi(y,t)$, as shown in Figure 5.1. Most treatments of detonation stability employ a Cartesian frame of reference attached to the perturbed shock so that the coordinate transformation from the lab frame is

$$x = x^l - Dt - \phi\left(y^l, t\right), \qquad y = y^l. \tag{5.9}$$

Here x^l and y^l are the lab-frame coordinates, D is the steady-state detonation speed, and ϕ is the small shock displacement in the x-direction. Thus the shock is always fixed at $x = 0$ and the reaction zone is at $x < 0$, while the unperturbed medium is at $x > 0$. The differential operators in the moving frame are now

$$\nabla = \frac{\partial}{\partial x}\mathbf{i} + \left(\frac{\partial}{\partial y} - \phi_y \frac{\partial}{\partial x}\right)\mathbf{j} \quad \text{and} \quad \frac{D}{Dt} = \frac{\partial}{\partial t} + U_1\frac{\partial}{\partial x} + u_2\frac{\partial}{\partial y} - u_2\phi_y\frac{\partial}{\partial x}, \tag{5.10}$$

where $U_1 = u_1 - D - \partial\phi/\partial t$ and u_2 are the x- and y- components of the particle speed relative to the perturbed shock, respectively.

Notice that the displacement of the sonic locus, $\phi_*(y,t)$, is not the same as ϕ and therefore, the unit normal, $\mathbf{n}_*$, to the sonic locus differs from $\mathbf{n}$, the unit normal to the shock. To the leading order in the displacements, the unit normals are given by

$$\mathbf{n} = \mathbf{i} - \frac{\partial\phi}{\partial y}\mathbf{j}, \qquad \mathbf{n}_* = \mathbf{i} - \frac{\partial\phi_*}{\partial y}\mathbf{j}. \tag{5.11}$$

One can show that the small transverse component of $\mathbf{n}_*$ contributes only second-order terms to the compatibility condition. Indeed, let $\phi = \phi' = o(1)$, $\phi_* = \phi'_* = o(1)$ and and linearize the state variables about the steady state, as, e.g., $p = \bar{p}(x) + p'(x,t)$, $\mathbf{u} = (\bar{u}_1 + u'_1)\,\mathbf{i} + u'_2\mathbf{j}$, etc., similar to the one-dimensional case; the primed quantities are small corrections to the base state. We have assumed that the gradients of the

steady-state variables vanish at the steady sonic locus. Otherwise one needs to retain terms such as $d\bar{p}/dx\,(\bar{x})\,x'_*$; see earlier in this section. Retaining only linear terms in perturbations, we find that

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \bar{U}_1 \frac{\partial}{\partial x} + \left(U'_1 \frac{\partial}{\partial x} + u'_2 \frac{\partial}{\partial y} \right), \tag{5.12}$$

$$\begin{aligned} \mathbf{n}_* \cdot \frac{D\mathbf{u}}{Dt} &= \left(\mathbf{i} - \frac{\partial \phi'_*}{\partial y} \mathbf{j} \right) \cdot \left[\frac{\partial}{\partial t} + \bar{U}_1 \frac{\partial}{\partial x} + \left(U'_1 \frac{\partial}{\partial x} + u'_2 \frac{\partial}{\partial y} \right) \right] (\bar{u}_1 \mathbf{i} + \mathbf{u}') \\ &= \bar{U}_1 \frac{\partial \bar{u}_1}{\partial x} + \left(\frac{\partial u'_1}{\partial t} + \bar{U}_1 \frac{\partial u'_1}{\partial x} + U'_1 \frac{\partial \bar{u}_1}{\partial x} \right), \end{aligned} \tag{5.13}$$

$$\mathbf{n}_* \cdot \nabla p = \frac{\partial \bar{p}}{\partial x} + \frac{\partial p'}{\partial x}, \qquad \nabla \cdot \mathbf{u} = \frac{\partial \bar{u}_1}{\partial x} + \left(\frac{\partial u'_1}{\partial x} + \frac{\partial u'_2}{\partial y} \right), \tag{5.14}$$

and

$$\frac{Dp}{Dt} = \bar{U}_1 \frac{\partial \bar{p}}{\partial x} + \left(\frac{\partial p'}{\partial t} + U'_1 \frac{\partial \bar{p}}{\partial x} + \bar{U}_1 \frac{\partial p'}{\partial x} \right). \tag{5.15}$$

Before linearization of the compatibility condition, it is convenient to rewrite it as

$$\rho c \left(\mathbf{n}_* \cdot \frac{D\mathbf{u}}{Dt} + c \nabla \cdot \mathbf{u} \right) + \frac{Dp}{Dt} + c \mathbf{n}_* \cdot \nabla p = \rho c^2 \sigma \omega. \tag{5.16}$$

We then find that

$$\mathbf{n}_* \cdot \frac{D\mathbf{u}}{Dt} + c \nabla \cdot \mathbf{u} = \left(\frac{\partial u'_1}{\partial t} + \bar{c} \frac{\partial u'_2}{\partial y} \right) + (c' + U'_1) \frac{\partial \bar{u}_1}{\partial x} \tag{5.17}$$

and

$$\frac{Dp}{Dt} + c \mathbf{n}_* \cdot \nabla p = \frac{\partial p'}{\partial t} + (c' + U'_1) \frac{\partial \bar{p}}{\partial x}, \tag{5.18}$$

so that the linearized compatibility condition becomes

$$\frac{\partial p'}{\partial t} + \bar{\rho}_* \bar{c}_* \frac{\partial u'_1}{\partial t} + \bar{\rho}_* \bar{c}_*^2 \frac{\partial u'_2}{\partial y} = \bar{\rho}_* \bar{c}_*^2 \bar{\sigma}_* \omega', \tag{5.19}$$

or, in terms of the normal modes ($p' \to p' \exp(\alpha t + iky)$, etc.),

$$\alpha \left(p' + \bar{\rho}_* \bar{c}_* u'_1 \right) + ik \bar{\rho}_* \bar{c}_*^2 u'_2 = \bar{\rho}_* \bar{c}_*^2 \bar{\sigma}_* \omega'. \tag{5.20}$$

If one sets the right-hand side of (5.20) to zero, then one obtains the CJ limit of the radiation condition of Short and Stewart [13]. But (5.20) is more general, as it includes a general rate term and holds for a general equation of state. Still the discussion above concerning possible nonuniformities in the transonic layer is obviously important here as well.

5.1. The compatibility condition as a boundedness condition. We now show that for detonations with depletion factor $\nu > 1/2$, the linearized compatibility condition

$$\frac{dp'}{dt} + \bar{\rho}_*\bar{c}_* \left(\frac{dU'}{dt} + \frac{dD'}{dt} \right) - (\gamma - 1)\, Q\bar{\rho}_*\omega' = 0 \tag{5.21}$$

is necessary for the linear stability problem to have solutions bounded at $n \to \bar{n}_*$. Indeed, the one-dimensional Euler equations written in the shock-attached frame

$$v_t + Uv_n - vU_n = 0, \tag{5.22}$$

$$U_t + UU_n + vp_n = -D_t, \tag{5.23}$$

$$p_t + Up_n + \gamma pU_n = (\gamma - 1)Q\rho\omega, \tag{5.24}$$

$$\lambda_t + U\lambda_n = \omega \tag{5.25}$$

can be linearized so that the following set of linear equations is obtained:

$$v'_t + \bar{U}v'_n + \bar{v}_nU' - \bar{v}U'_n - \bar{U}_nv' = 0, \tag{5.26}$$

$$U'_t + \bar{U}U'_n + \bar{U}_nU' + \bar{v}p'_n + \bar{p}_nv' = -D'_t, \tag{5.27}$$

$$p'_t + \bar{U}p'_n + \bar{p}_nU' + \gamma\bar{p}U'_n + \gamma\bar{U}_np' - (\gamma - 1)\, Q\left(\bar{\rho}\omega' + \bar{\omega}\rho'\right) = 0, \tag{5.28}$$

$$\lambda'_t + \bar{U}\lambda'_n + \bar{\lambda}_nU' = \omega', \tag{5.29}$$

where the perturbations are assumed to be small deviations from the corresponding steady-state values. Adding (5.28) and (5.27) multiplied by $\bar{\rho}\bar{c}$, one obtains

$$\begin{aligned} &\left[\frac{\partial}{\partial t} + \left(\bar{U} + \bar{c}\right)\frac{\partial}{\partial n}\right] p' + \bar{\rho}\bar{c}\left[\frac{\partial}{\partial t} + \left(\bar{U} + \bar{c}\right)\frac{\partial}{\partial n}\right](U' + D') - (\gamma - 1)\, Q\bar{\rho}\omega' \\ &\quad + \left(\bar{p}_n + \bar{\rho}\bar{c}\bar{U}_n\right)U' + \gamma\bar{U}_np' + \bar{\rho}\bar{c}\bar{p}_nv' - (\gamma - 1)\, Q\bar{\omega}\rho' = 0. \end{aligned} \tag{5.30}$$

The first two terms are seen to form time derivatives along the steady C_+ characteristic direction, $\partial/\partial t + \left(\bar{U} + \bar{c}\right)\partial/\partial n$, so that the first line of (5.30) tends to the compatibility condition in the limit $n \to \bar{n}_*$ (so that $\bar{U} + \bar{c} \to 0$). All terms in the second line vanish as $n \to \bar{n}_*$, provided that $\nu > 1/2$ (so that the spatial derivatives of the base state vanish at the sonic locus) and that all perturbations remain uniformly bounded. Thus the compatibility condition is necessarily satisfied if perturbations are bounded and $\nu > 1/2$.

6. Conclusions. In this work we have introduced a general definition of a sonic locus for multidimensional unsteady self-sustained detonation waves and discussed its properties under limiting conditions that are relevant to detonation stability theories and asymptotic theories of slowly evolving weakly curved detonations. We have shown that previously known sonic conditions of steady detonation theory, linear stability theory, and DSD are limiting cases of our generalized conditions. Self-sustained detonations are introduced as two-front phenomena with the lead shock and the limiting characteristic surface (as the sonic locus) as free boundaries. The sonic conditions that we have derived can be considered as closure equations that together with the Euler equations and Rankine–Hugoniot conditions complete the set of governing equations for self-sustained detonations.

An important ingredient of the present theory is that the sonic surface is assumed to exist initially; we simply take it as given by the initial conditions. The initial condition could be, for example, a steady detonation wave in which a sonic surface can

be defined unambiguously, and a clear exact case is that of the steady CJ detonation or a weakly perturbed detonation that corresponds to theories relevant to detonation instability or DSDs, both of which are perturbation theories that assume either deviations from a plane CJ state or weak spatial and temporal variation from plane states. Many important initial conditions, for example in initiation problems, will not have an initial sonic locus. But as the detonation forms and becomes a self-sustained wave, the sonic locus will appear somewhere in the flow. From that point on, the detonation dynamics is described by our theory, provided only that the sonic locus persists in the flow, which is the case if the flow evolution is smooth.

Appearance of strong discontinuities within the reaction zone, such as shock waves, can destroy a sonic surface, in which case the present theory may not be applicable. It is indeed the case in gas-phase detonations that strong transverse shock fronts almost always exist which can interact with the sonic surface. Yet, the situation is quite different in condensed explosives, in which smooth reaction zones are more common. In any case, the range of phenomena that the present theory can address is considerable, and even in the case of cellular detonations, the onset of cellular dynamics and propagation of weakly unstable detonations may be phenomena that the present theory is applicable to. Some applications of the theory to weakly curved and slowly evolving detonations can be found in [6] and in forthcoming papers.

THE SPEED LAW FOR HIGHLY RADIATIVE FLAMES IN A GASEOUS MIXTURE WITH LARGE ACTIVATION ENERGY*

JAN BOUWE VAN DEN BERG†, CLAUDE-MICHEL BRAUNER‡, JOSEPHUS HULSHOF†, AND ALESSANDRA LUNARDI§

Abstract. We study a thermodiffusive combustion model for premixed flames propagating in reactive gaseous mixtures which contain inert dust. As observed by Joulin, radiative transfer of heat may significantly enhance the flame temperature and its propagation speed. The Joulin effect is at its most pronounced in the parameter regime where the medium is very transparent while radiative flux dominates convection. In this asymptotic regime, where in the limit the flame temperature achieves its upper bound, we determine the law that describes the relation between the propagation speed of the flame and the control parameters. Finally, we present strong numerical evidence for the validity of the asymptotic analysis.

1. Introduction.

Combustion is one of the important phenomena in our world. It occurs in controlled applications such as rocket engines, energy plants, and cooking on natural gas, as well as in forest fires and mine and tunnel accidents. Experiments in combustion research are both difficult and expensive, which underlines the need for good mathematical models and their analysis.

Combustion models are based on the incorporation of different physical and chemical principles, expressed in the language of mathematics. Simplifying, sometimes heuristic, assumptions are unavoidable to make mathematical treatment possible, be it by numerical, formal asymptotic, or analytical methods. In the latter the modern theory of infinite-dimensional dynamical systems and its application to free boundary problems (FBPs) plays an important role. Such FBPs occur as various flame front models. Asymptotic arguments are strongly intertwined with the derivation of such FBPs from physical and chemical principles.

In this paper we study a thermodiffusive combustion model for premixed flames propagating in reactive gaseous mixtures which contain inert dust that radiates thermal energy. Radiative transfer of heat involves both emission and absorption of radiation and may significantly influence the flame temperature, its propagation speed, and the flammability of the medium itself. This is the so-called Joulin effect [13, 5]: the propagation speed increases compared to a similar flame without radiation, and

there is a temperature overshoot at the flame front. A radiative flame can be ignited at a lower external temperature than a nonradiative flame.

The Joulin effect is at its most pronounced in the parameter regime where the medium is very transparent while radiative flux dominates convection. In this asymptotic regime our goal is to determine the law that describes the relation between the propagation speed of the flame and the control parameters.

In section 2 we will discuss the model in more detail. For now, we just highlight the most important features. Following Buckmaster and Ludford [6, p. 218], we formulate the thermodiffusive model with the thin reactive flame zone replaced by a free boundary. At the free boundary the normal derivative of the (normalized) temperature T is related to the reaction rate ω, which is given by an Arrhenius-type law:

$$\omega = A \exp\left(-\frac{N}{T^*}\right). \tag{1}$$

Here N is a (dimensionless) activation energy, T^* is the (dimensionless) temperature at the free boundary, and A is a so-called preexponential constant, which will be specified and discussed in detail later.

As a model for the radiative field, we take the Eddington equation, which contains two important radiative parameters: the (dimensionless) opacity α and the Boltzmann number β, a measure of the radiative energy flux compared to the convective flux.

Flames will be modelled as travelling waves propagating into the fresh region where the fuel mass fraction and the temperature are constant, Y_- for the fuel mass fraction and T_- for the temperature. A conservation law implies that the temperature T_+ far behind the flame front is given by

$$T_+ = T_- + Y_-.$$

Depending on the opacity of the medium, radiation may significantly influence the flame profile; see [12, 3, 5]. *Radiative flames* are characterized by an overshoot of the flame temperature T^* as well as an enhancement in the burning rate and flame speed μ, which is given by

$$\mu = \frac{\omega}{Y_-}. \tag{2}$$

In [4] it was proved that the flame temperature T^* is bounded by

$$T_- + Y_- < T^* < T_- + 2Y_-.$$

These bounds, which were already conjectured in [5], are achieved in certain limits. The lower bound is in fact the flame temperature in the absence of radiation (the "adiabatic" case), and it is approached as $\alpha \to \infty$ or $\beta \to 0$ (see [4]). In the present paper, however, we focus on the combined asymptotic regime

$$\alpha \to 0, \tag{3a}$$

$$\beta \to \infty, \tag{3b}$$

$$\alpha\beta \to 0, \tag{3c}$$

because in this regime the flame temperature approaches the upper bound, i.e.,

$$\text{in the limit (3):} \qquad T^* \to T_- + 2Y_-, \tag{4}$$

and the radiative effects are most pronounced.

We are going to combine this asymptotic regime of the radiative parameters with the high activation limit; i.e., we take

$$\varepsilon = \frac{1}{N}$$

as the main small parameter. This is very much in the same spirit as the near-equidiffusional flame (NEF) approximation that is frequently used in the absence of radiative effects; see [15]. There the reciprocal ε of the activation energy is coupled with the Lewis number. Here we couple ε with the radiative parameters.

Of primary physical interest are flames that, in this asymptotic regime, propagate with a finite velocity μ. In view of (2), μ is proportional to the reaction rate ω given in (1). Hence, in the high activation limit $N = \varepsilon^{-1} \to \infty$, finite speeds of propagation can be obtained, provided A is of the order $\exp(N/T_c)$, where T_c is a characteristic temperature, to be fixed shortly. Indeed, since in this notation

$$\mu = \frac{1}{Y_-} \exp\left(\frac{1}{\varepsilon}\left(\frac{1}{T_c} - \frac{1}{T^*}\right)\right), \tag{5}$$

the characteristic temperature T_c should equal the asymptotic value of the flame temperature T^*, and hence in view of (4) the only possibility is

$$T_c = T_- + 2Y_-.$$

This is the upper extreme of T^*, and it stands in sharp contrast with the NEF approach, where the suitable choice for T_c is the lower extreme, namely $T_- + Y_-$.

Since we want to look at the asymptotic regime where simultaneously the reciprocal ε of the activation energy tends to zero and the radiative parameters α and β behave as given in (3), we have to couple α and β with ε. Limit condition (3c) suggests it is convenient to introduce the combined parameter

$$\chi \stackrel{\text{def}}{=} \alpha\beta.$$

Our results show that an asymptotically *finite* propagation speed requires

$$\chi = O(\varepsilon) \qquad \text{and} \qquad \beta^{-1} = O(\varepsilon^{1/2}). \tag{6}$$

Since α has a more direct physical meaning than χ, let us give an alternative formulation of these conditions. For simplicity we assume that both α and β are (asymptotically) powers of ε:

$$\alpha \sim \alpha_0 \varepsilon^a \qquad \text{and} \qquad \beta \sim \beta_0 \varepsilon^{-b}.$$

The connection with (6) is made through

$$\chi = \alpha\beta = \alpha_0\beta_0\varepsilon^{a-b} \sim \chi_0 \varepsilon^{a-b}.$$

To obtain a finite flame velocity, one of the following four possibilities must hold (see also Figure 1):

$$\begin{array}{rlll} \text{I:} & a = \frac{3}{2} & \text{and} & b = \frac{1}{2}; \\ \text{II:} & a > \frac{3}{2} & \text{and} & b = \frac{1}{2}; \\ \text{III:} & a = b + 1 & \text{and} & b > \frac{1}{2}; \\ \text{IV:} & a > b + 1 & \text{and} & b > \frac{1}{2}. \end{array}$$

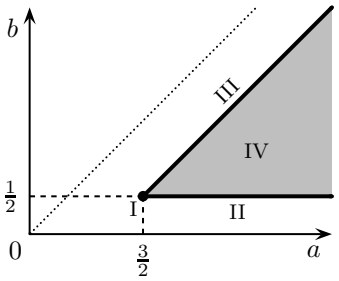

FIG. 1. *The asymptotic regime under consideration in terms of the exponents a and b. The area below the dotted line corresponds to radiation-dominated flames* (3). *Finite wave speeds are found in the shaded region and, more significantly, on its boundary.*

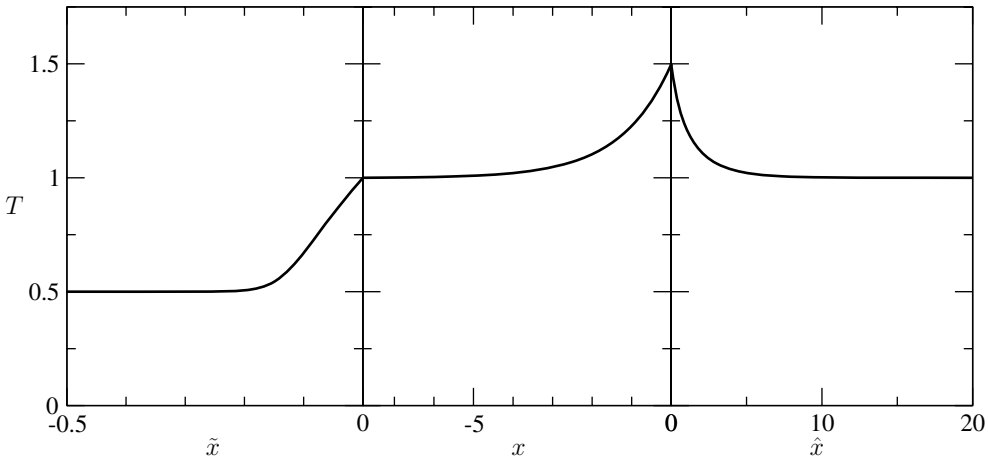

FIG. 2. *In the combined asymptotic limit of high activation energy* $\varepsilon \to 0$ *coupled with the radiative parameters* $\alpha = \alpha_0 \varepsilon^a$ *and* $\beta = \beta_0 \varepsilon^{-b}$ *with* $b \geq \frac{1}{2}$ *and* $a \geq b + 1$, *the solution profile separates into three spatial scales. The numerical solution shown is for* $\varepsilon = 0.001$, $\alpha = 0.3\varepsilon^{3/2}$, $\beta = 0.3\varepsilon^{-1/2}$, *and* $T_- = Y_- = 0.5$. *Notice that the scales are very different in the three regions since on the left the variable is* $\tilde{x} = \alpha\beta^{-1}x$, *in the middle it is* x, *and on the right it is* $\hat{x} = \alpha\beta x$.

We remark that the special scaling $\alpha \sim \alpha_0 \varepsilon^{3/2}$ and $\beta \sim \beta_0 \varepsilon^{1/2}$ in case I was first observed by Joulin and Eudier [13].

In the limit (3) the flame profile naturally separates into three spatial scales (see also Figure 2):

$$x, \qquad \hat{x} = \alpha\beta\, x, \qquad \tilde{x} = \frac{\alpha}{\beta}\, x, \tag{7}$$

where x is the spatial variable in a comoving frame (with speed μ). In section 3 we will perform a matching analysis of these three scales. This enables us to derive a law for the asymptotic speed μ of the front. In the four cases identified above, the speed

law reads (with $T_+ = T_- + Y_-$)

$$\text{(8a)} \qquad \text{I:} \quad \ln(\mu Y_-) = -\frac{\alpha_0\beta_0 T_+^2}{\mu^2} E_1\Big(\tfrac{Y_-}{T_+}\Big) - \frac{\mu^2}{\beta_0^2 T_+^7} E_2\Big(\tfrac{Y_-}{T_+}\Big);$$

$$\text{(8b)} \qquad \text{II:} \quad \ln(\mu Y_-) = - \frac{\mu^2}{\beta_0^2 T_+^7} E_2\Big(\tfrac{Y_-}{T_+}\Big);$$

$$\text{(8c)} \qquad \text{III:} \quad \ln(\mu Y_-) = -\frac{\alpha_0\beta_0 T_+^2}{\mu^2} E_1\Big(\tfrac{Y_-}{T_+}\Big);$$

$$\text{(8d)} \qquad \text{IV:} \quad \ln(\mu Y_-) = 0.$$

Here

$$E_1(s) = \frac{8s + 9s^2 + \frac{16}{3}s^3 + \frac{5}{4}s^4}{(1+s)^2},$$

$$E_2(s) = \frac{3s}{16(1+s)^2} + \frac{3}{4(1+s)^2}\int_0^s \frac{t\,dt}{(1+t)^4 - 1}.$$

It is clear that case I is central to the whole analysis and the other cases are fairly straightforward reductions. On the other hand, in the asymptotic analysis presented in section 3 we will in some sense compute cases II and III and then combine them to obtain case I. The last case, IV, is rather boring, since there is just one finite velocity, namely $\mu = 1/Y_-$. Notice that this corresponds with the maximal flame speed for any of the asymptotic regimes, i.e., $\mu \le 1/Y_-$.

When we compare the four cases we conclude that case I is by far the most interesting, and we will explore it in section 4. Case II leads to a unique flame speed for any set of parameter values, as does case IV (trivially). Case III represents the classical bell-shaped curve of the flame speed versus a heat-loss parameter in nonadiabatic flames (cf. [6, p. 44]).

We remark that in the whole asymptotic regime (3) the profile of any travelling wave with finite speed of propagation (in the asymptotic limit $\varepsilon \to 0$) decomposes into the three different spatial scales (7). The asymptotic analysis in section 3 is thus valid for the whole parameter regime of radiation-dominated flames. In Figure 1 this corresponds to the area below the dotted line. The fact that finite wave speeds occur in only part of this parameter regime is merely a consequence of the way the wave speed is related to T^* and ε (i.e., via (5)).

The organization of the paper is as follows. In section 2 we introduce the mathematical model and make the reduction to a travelling wave problem. In section 3.1 we explain how the matched asymptotic analysis works, while in sections 3.2–3.4 the calculations are performed; i.e., we analyze the profile in three different spatial scales and match these to obtain the full asymptotic picture. This also leads us to the formula for the speed law presented above. Finally, in section 4 we look in more detail at the speed law, we compare with numerical computations, and we draw conclusions about the bifurcation diagrams.

2. Models and equations.

2.1. Premixed flame propagation with constant opacity. We introduce the thermodiffusive combustion model with constant density, simple chemistry, and large activation energy for a premixed flame propagating in a reactive gaseous mixture. We incorporate the flux of the thermal radiative field generated by the radiation of

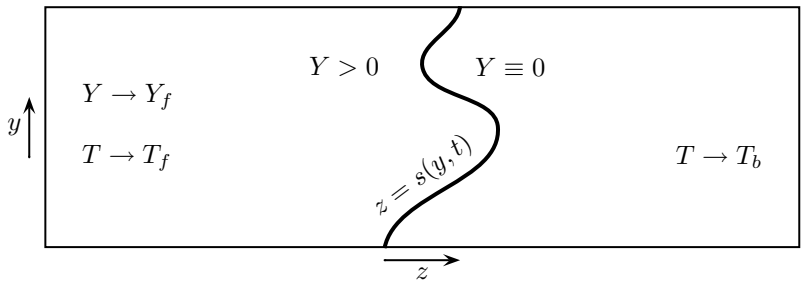

FIG. 3. *The geometric setting of the propagating flame.*

dust particles. The geometric setting is the following (see also Figure 3): the flame propagates into the *fresh* region, where, far ahead of the flame front ($z \to -\infty$), the fuel mass fraction Y and the temperature T are constant:

$$\lim_{z\to-\infty} Y(z) = Y_f \qquad \text{and} \qquad \lim_{z\to-\infty} T(z) = T_f.$$

The region of the flame where the reaction occurs is infinitesimally thin and is located at $z = s(y,t)$, the free boundary of the problem, y being the lateral two-dimensional variable. To the right of the free boundary all fuel has been burnt ($Y(z) = 0$ for $z \geq s(y,t)$), and far behind the flame front the temperature approaches the *burnt* temperature $T_b = \lim_{z\to\infty} T(z)$. The time-dependent system of equations for mass fraction Y and temperature T reads

$$\frac{\partial}{\partial t}(\rho Y) - \nabla(\rho D \nabla Y) = 0, \quad z < s(y,t); \qquad Y = 0, \quad z \geq s(y,t); \tag{9a}$$

$$\frac{\partial}{\partial t}(\rho C_p T) - \lambda \Delta T + \nabla \cdot \mathbf{F_R} = 0, \quad z \neq s(y,t). \tag{9b}$$

The physical parameters are the diffusion constant D, the heat conduction coefficient λ, the specific heat C_p, and the density ρ of the gas (part of which is fuel). The divergence of the radiative energy flux $\mathbf{F_R}$ appears as a loss term in the temperature equation (9b). At the flame front, the jump conditions for the normal derivatives

$$\rho D \left[\frac{\partial Y}{\partial n}\right] = \omega(T); \quad \lambda \left[\frac{\partial T}{\partial n}\right] = -Q\omega(T) \qquad \text{at } z = s(y,t), \tag{9c}$$

are imposed to balance the heat flux coming out of the flame with the mass flux going into the flame, the reaction heat Q being the proportionality constant between the two. These fluxes are also coupled with the chemical reaction rate ω, for which we take a simple Arrhenius law. In the free boundary approximation it reads

$$\omega = A \exp\left(-\frac{E}{2RT^*}\right). \tag{9d}$$

Here T^* denotes the temperature at the flame front, and the other constants are the gas constant R, the activation energy E, and the "preexponential" factor A. Note that the factor 2 in the reaction rate is a consequence of the derivation of the free boundary jump conditions from the reaction-diffusion formulation; see [8]. The appearance of this factor follows from a detailed analysis of the flame in the thin reaction zone,

which leads to (9c), where ω is the square root of the Arrhenius factor in the reaction rate (cf. [8]).

As a law for the radiative flux $\mathbf{F_R}$ we take the Eddington equation

$$-L^2\nabla(\nabla\cdot\mathbf{F_R})+3\mathbf{F_R}+4\sigma_{\rm sb}L\nabla T^4=0, \tag{9e}$$

where $\sigma_{\rm sb}$ is the Stefan–Boltzmann constant and L is the mean free path length of the photons. In astrophysics the Eddington equation is a well-known approximation to the radiative field [11, 17, 16]. It is a good approximation when scattering is nearly isotropic, particularly in a one-dimensional setting. The travelling waves that we use as a model for the propagating flames have indeed a one-dimensional structure. Since the radiative transfer plays a central role in our model, we give some insight in the derivation of the Eddington equation in Appendix A.

We emphasize that the Eddington equation models radiative transfer rather than radiative heat losses. There is, however, an asymptotic limit, discussed in [4, 1], where the radiative flux is given by $\nabla\cdot\mathbf{F_R}=\frac{4\sigma_{\rm sb}}{L}(T^4-T_b^4)$. This asymptotic limit thus looks like heat loss to a reservoir held at $T=T_b$. It can be compared to the usual radiative heat loss models (see [18, sect. 8.2], [6, p. 43]) that are based on the law $\nabla\cdot\mathbf{F_R}=\frac{4\sigma_{\rm sb}}{L}(T^4-T_f^4)$, which differs only in the temperature of the reservoir (T_f instead of T_b).

2.2. Dimensionless variables. We now make the system of equations (9) dimensionless and scale out many of the parameters. We define nondimensional temperature $\hat{T}$, radiative flux $\hat{\mathbf{F}}_\mathbf{R}$, time $\hat{t}$, and spatial coordinate $\hat{\mathbf{r}}$ by comparison with suitable chosen reference quantities indexed by s:

$$\hat{t}=\frac{t}{t_s},\quad \hat{\mathbf{r}}=\frac{\mathbf{r}}{r_s},\quad \hat{T}=\frac{T}{T_s},\quad \hat{\mathbf{F}}_\mathbf{R}=\frac{\mathbf{F_R}}{F_s}.$$

We choose the reference quantities such that they satisfy the following set of equations:

$$\frac{\lambda t_s}{\rho C_p r_s^2}=1,\quad \frac{4\sigma_{\rm sb}T_s^4}{F_s}=1,\quad \frac{\rho D}{Br_s}=1,\quad \frac{\lambda T_s}{QBr_s}=1,$$

that is,

$$F_s=\frac{4\sigma_{\rm sb}Q^4D^4\rho^4}{\lambda^4},\quad T_s=\frac{QD\rho}{\lambda},\quad t_s=\frac{\rho^3C_pD^2}{\lambda B^2},\quad r_s=\frac{D\rho}{B}.$$

Here B is defined by

$$A=B\exp\left(\frac{E}{2RT_C}\right),$$

where T_C is the characteristic temperature. The necessity of this splitting of the preexponential factor A has already been discussed in the introduction. In the high activation energy asymptotics that we are going to employ it is widely used; see, for example, [6, p. 17]. Note that the factor 2 in the reaction rate accounts for B^2, rather than B appearing in t_s.

We have chosen not to rescale the mass fraction Y (which was already dimensionless) because the above choices already simplify the equations as much as we want. Although the additional scaling of Y that we have at our disposal is welcome from a

mathematical point of view, using it obscures the physical role of the control parameters Y_f and/or T_f. Our motivation for the above choices is that we have at hand two important radiative parameters, namely

$$\alpha = \frac{r_s}{L} = \frac{D\rho}{BL},$$

which is a dimensionless opacity, and

$$\beta = \frac{F_s t_s}{\rho C_p T_s r_s} = \frac{4\sigma_{\rm sb} Q^3 D^4 \rho^4}{\lambda^4 B},$$

which is a measure of the radiative flux compared to the convective flux. Furthermore, there is the Lewis number

$$\mathrm{Le} = \frac{r_s^2}{D t_s} = \frac{\lambda}{\rho C_p D},$$

a diffusion parameter. In the new variables the system becomes (where we drop the hats from the notation)

$$\begin{aligned} Y_t - \frac{1}{\mathrm{Le}}\Delta Y = 0, \quad z < s(y,t); \qquad Y \equiv 0, \quad z \geq s(y,t);\\ T_t - \Delta T + \beta\,\nabla\cdot\mathbf{F_R} = 0, \quad z \neq s(y,t);\\ -\nabla(\nabla\cdot\mathbf{F_R}) + 3\alpha^2\mathbf{F_R} + \alpha\nabla T^4 = 0. \end{aligned}$$

The jump conditions at the free boundary $z = s(y,t)$ are

$$\left[\frac{\partial Y}{\partial n}\right] = \mathrm{Le}\,\omega(T) \quad \text{and} \quad \left[\frac{\partial T}{\partial n}\right] = -\omega(T) \qquad \text{at } z = s(y,t),$$

with nondimensional chemical reaction rate (still denoted by ω)

$$\omega(T) = \exp\left(N\left(\frac{1}{T_c} - \frac{1}{T}\right)\right),$$

where

$$N = \frac{E}{2RT_s}$$

is the dimensionless activation energy, and $T_c = T_C/T_s$ is the dimensionless characteristic temperature, the significance of which was already discussed in the introduction.

2.3. Planar travelling waves. We consider flames modelled by planar (one-dimensional) travelling wave solutions, and we thus introduce the travelling wave coordinate $x = z + \mu t$, describing waves travelling at speed μ to the left (into the fresh region). In such a travelling wave the radiative flux has only one component, which we rescale by β for convenience:

$$\mathbf{F_R} = (q/\beta, 0, 0).$$

Also, we introduce the new combined parameter

$$\chi = \alpha\beta.$$

Finally, we may reposition the free boundary at the origin. This leads to the system

$$\mu Y' - \frac{1}{\mathrm{Le}} Y'' = 0, \quad x < 0; \qquad Y \equiv 0, \quad x \geq 0; \tag{10a}$$

$$\mu T' - T'' + q' = 0, \quad x \neq 0; \tag{10b}$$

$$-q'' + 3\alpha^2 q + \chi (T^4)' = 0, \quad x \in \mathbb{R}. \tag{10c}$$

The jump conditions at $x = 0$ are

$$[Y] = [T] = [q] = [q'] = 0, \tag{10d}$$

$$[T'] = -\omega(T), \quad [Y'] = \mathrm{Le}\, \omega(T), \tag{10e}$$

and $\omega(T)$ is still given by

$$\omega(T) = \exp\left(N \left(\frac{1}{T_c} - \frac{1}{T} \right) \right). \tag{10f}$$

Note that the equation (10c) for q implies the continuity of q and q'. The conditions at infinity are

$$T(-\infty) = T_-, \quad Y(-\infty) = Y_-, \quad T(+\infty) = T_+, \quad q(\pm\infty) = 0, \tag{10g}$$

in which $Y_- = Y_f$ is the (dimensionless) "fresh" mass fraction, T_- is the dimensionless fresh temperature, and T_+ is the dimensionless burnt temperature. In fact, direct integration of the equations (see section 3) shows that

$$T_+ = T_- + Y_-. \tag{11}$$

This conservation law (cf. [3, p.221]) reflects the fact that physically only the conditions in the fresh region can be controlled, whereas the temperature in the burnt region is determined by the reaction. The conservation law relating the asymptotic temperatures and fuel mass fraction is independent of the radiation parameters, so that the temperature far behind the flame front is nothing but the adiabatic flame temperature. (In absence of radiation effects, the temperature behind the flame is uniform: $T \equiv T_{ad} = T_- + Y_-$.) The limiting behavior for q at infinity means that radiative equilibrium is achieved at infinity. This follows naturally from (10c); in fact, q may be expressed in terms of T^4 by a convolution formula with a Green's function.

From [4] we know the existence of a travelling wave solution

$$(Y(x), T(x), q(x), \mu)$$

of the system (10) for all (positive) values of the parameters, provided the conservation law (11) is satisfied. Every solution satisfies

$$T_- \leq T(x) \leq T_- + 2Y_-.$$

It is remarkable that this bound is independent of the other parameters.

3. Matched asymptotic analysis.

3.1. Setting the stage. In this section we evaluate the simultaneous asymptotic regime of high activation energy and highly radiative flames. We thus introduce *three* small parameters:

$$\varepsilon = N^{-1}, \tag{12a}$$

$$\delta_1 = \chi = \alpha\beta, \tag{12b}$$

$$\delta_2 = 3\beta^{-2}. \tag{12c}$$

We will couple δ_1 and δ_2 with ε in a moment.

First, we remark that the equation for Y decouples and can be solved explicitly:

$$Y(x) = Y_-(1 - e^{\mathrm{Le}\mu x}), \quad x < 0; \qquad Y(x) = 0, \quad x \geq 0. \tag{13}$$

The jump condition for Y' leads to an expression for the flame velocity:

$$\mu = \frac{1}{Y_-} \exp\left(N\left(\frac{1}{T_c} - \frac{1}{T^*}\right)\right). \tag{14}$$

Since the remaining problem for T, q, and μ is independent of the Lewis number Le, it does not appear in the subsequent asymptotic analysis. However, it plays an important role in the stability analysis, which we discuss in a forthcoming paper [2].

Since Y is given by (13), the system (10a)–(10c) reduces to a set of two equations

$$T'' = \mu T' + q',$$
$$q'' = 3\alpha^2 q + \chi(T^4)'.$$

The first equation can be integrated once, but since T' is discontinuous at $x = 0$, the integration cannot be across the origin. We therefore integrate starting from $x = \infty$ for positive x, while starting from $x = -\infty$ for negative x. This leads to

$$T' = \mu(T - T_\pm) + q \qquad \text{for } x \neq 0.$$

Here and throughout the paper $T_\pm$ stands for T_+ on the right ($x > 0$) and T_- on the left ($x < 0$). We note that we will frequently have to treat the equations separately on the right and on the left.

Using the notation (12) the system reads

$$T' = \mu(T - T_\pm) + q, \tag{15a}$$

$$q'' = \delta_1^2\delta_2 q + \delta_1(T^4)', \tag{15b}$$

with "boundary conditions" at infinity

$$T(-\infty) = T_-, \quad T(+\infty) = T_+, \quad q(\pm\infty) = 0,$$

and at the origin T, q and q' are continuous, while T' satisfies the jump condition

$$\mu(T_- - T_+) = [T'] = -\mu Y_-. \tag{16}$$

The first equality stems from (15a), while the second equality is a consequence of the jump conditions (10e) and the explicit expression (13) for Y. The two equalities in (16) reflect the conservation law

$$T_+ = T_- + Y_-. \tag{17}$$

Here and in what follows we assume that μ is order 1, so that we are dealing with asymptotically finite speeds of propagation. The system (15) now naturally leads to the expansion

$$T \sim T_0 + \delta_1 T_1 + \delta_2 T_2 + \delta_1^2 T_3 + \delta_1\delta_2 T_4 + \delta_2^2 T_5,$$
$$q \sim q_0 + \delta_1 q_1 + \delta_2 q_2 + \delta_1^2 q_3 + \delta_1\delta_2 q_4 + \delta_2^2 q_5.$$

It turns out to be unnecessary to compute the terms of order δ_2^2 to completely determine the leading-order speed law. We will therefore not include those terms in the asymptotic expressions.

In view of (14) our overriding interest is in the temperature at the free boundary. Therefore we introduce the notation $T_i^* = T_i(0)$ for $i = 0, 1, 2$, and hence

$$T(0) = T^* \sim T_0^* + \delta_1 T_1^* + \delta_2 T_2^*.$$

In this new notation the relation (14) between the flame velocity μ and the flame temperature T^* reads

$$\ln(\mu Y_-) \sim \frac{1}{\varepsilon}\left(\frac{1}{T_c} - \frac{1}{T_0^* + \delta_1 T_1^* + \delta_2 T_2^*}\right). \tag{18}$$

There are now several straightforward remarks to make. For the terms on the right and left to balance (i.e., for a finite propagation speed), one needs

$$T_c = T_0^*.$$

This reduces (18) to

$$\ln(\mu Y_-) \sim -\frac{\delta_1}{\varepsilon}\frac{T_1^*}{(T_0^*)^2} - \frac{\delta_2}{\varepsilon}\frac{T_2^*}{(T_0^*)^2}. \tag{19}$$

We anticipate (see below) that $T_1^* < 0$ and $T_2^* < 0$, so the right-hand side of (19) is always nonzero. It is now immediate that we need

$$\delta_1 = O(\varepsilon) \qquad \text{and} \qquad \delta_2 = O(\varepsilon).$$

If both $\delta_1 \ll \varepsilon$ and $\delta_2 \ll \varepsilon$, then we just have $\mu = 1/Y_-$. If δ_1 and/or δ_2 are of order ε, then the left- and right-hand sides balance and the results announced in the introduction follow. Of course, they follow only after we have found the expressions for T_0^*, T_1^* and T_2^*, which are (we will spend the rest of this section establishing this; see (39), (44) and (45))

$$T_0^* = T_+ + Y_-;$$
$$T_1^* = -\mu^{-2}\left(8T_+^3 Y_- + 9T_+^2 Y_-^2 + \frac{16}{3}T_+ Y_-^3 + \frac{5}{4}Y_-^4\right);$$
$$T_2^* = -\frac{\mu^2}{4T_+^5}\int_0^{Y_-/T_+} \frac{t}{(t+1)^4 - 1}\,dt - \frac{\mu^2 Y_-}{16T_+^6}.$$

To calculate T_0^*, T_1^*, and T_2^* we have to match the profile that we obtain on the scale $x = O(1)$ to *two* larger scales. The scale at order $x = O(1)$ we call the inner region, $x = O(\delta_1^{-1})$ is the intermediate region, and $x = O(\delta_1^{-1}\delta_2^{-1})$ is the outer region (see also Figure 4). One may wonder why we do not have a scale $x = O(\delta_2^{-1})$. The

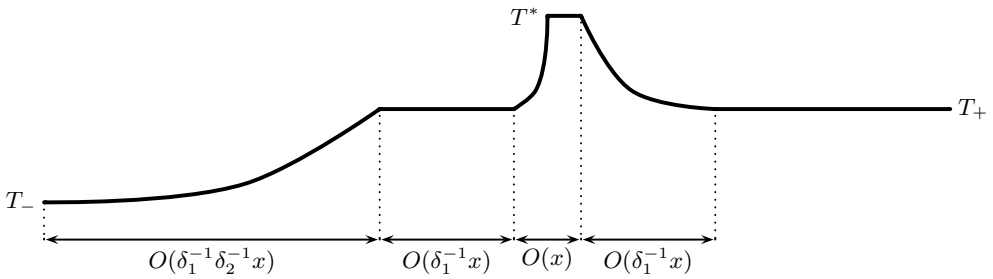

FIG. 4. *The three different scales of the asymptotic problem. The shape of the profiles shown of course uses some a posteriori knowledge which will be collected in the matched asymptotic analysis in sections* 3.2–3.4.

reason is that the profile turns out to be flat at this scale, and therefore no useful information can be extracted. Throughout we calculate with δ_1 and δ_2 as independent quantities. That they are possibly of the same order in ε does not matter whatsoever for the calculations.

In the intermediate and remote regions introduced above, the variables are

$$\begin{aligned} \text{intermediate: } \hat{x} &= \delta_1 x, \qquad \hat{T}(\hat{x}) = T(x) \text{ and } \hat{q}(\hat{x}) = q(x); \\ \text{outer: } \tilde{x} &= \delta_1\delta_2 x, \qquad \tilde{T}(\tilde{x}) = T(x) \text{ and } \tilde{q}(\tilde{x}) = q(x). \end{aligned}$$

(This means $\tilde{x}$ is a factor 3 larger than announced in the introduction, alas.) Although we are eventually interested in the value of T at the origin in the inner region, we start our analysis in the outer region, since there we know the boundary conditions:

$$\lim_{\hat{x}\to\pm\infty} \hat{T}(\hat{x}) = T_\pm \qquad \text{and} \qquad \lim_{\hat{x}\to\pm\infty} \hat{q}(\hat{x}) = 0.$$

We are thus going to work from the outside inward.

3.2. The outer region. The problem in the outer region is

$$\begin{aligned} \delta_1\delta_2\tilde{T}' &= \mu(\tilde{T} - T_\pm) + \tilde{q}, \\ \delta_2\tilde{q}'' &= \tilde{q} + (\tilde{T}^4)', \end{aligned}$$

with boundary conditions

$$\tilde{T}(\pm\infty) = T_\pm \qquad \text{and} \qquad \tilde{q}(\pm\infty) = 0.$$

Of course these equations must be solved on the right and on the left separately, because there are an intermediate as well as an inner region in between. At this outer scale the expansion for $\tilde{T}$ is

$$\tilde{T} = \tilde{T}_0 + \delta_1\tilde{T}_1 + \delta_2\tilde{T}_2,$$

with an analogous expansion for $\tilde{q}$.

The problem for $\tilde{T}_0$ and $\tilde{q}_0$ is

$$\begin{cases} 0 = \mu(\tilde{T}_0 - T_\pm) + \tilde{q}_0, \\ 0 = \tilde{q}_0 + (\tilde{T}_0^4)', \\ \tilde{T}_0(\pm\infty) = T_\pm,\ \tilde{q}_0(\pm\infty) = 0. \end{cases}$$

Combining the equations we get

$$\tilde{T}_0' = \frac{\mu(\tilde{T}_0 - T_\pm)}{4\tilde{T}_0^3}, \qquad \text{with } \tilde{T}_0(\pm\infty) = T_\pm. \tag{20}$$

On the right, the solution is constant:

$$\tilde{T}_0(\tilde{x}) = T_+ \quad \text{and} \quad \tilde{q}_0(\tilde{x}) = 0 \qquad \text{for } \tilde{x} > 0. \tag{21}$$

This follows from the fact that no exponentially growing terms can be present, since it is impossible to match those to the next scale. This argument is silently used several times in what follows.

On the left, we have a choice of the constant solution, an increasing solution and a decreasing solution. As it turns out, the increasing solution will be the one we need. It starts from T_- at $\tilde{x} = -\infty$, and since equation (20) is autonomous, the solution can be translated, and hence the value at the origin is a priori unknown. It has to be determined by matching with the intermediate region. For now, we just introduce the undetermined constant

$$\tilde{T}_0^* \stackrel{\text{def}}{=} \lim_{\tilde{x}\uparrow 0} \tilde{T}_0(\tilde{x}).$$

In order to match with the intermediate region we will need the asymptotic behavior near the origin, which in terms of $\tilde{T}_0^*$ is given by

$$\tilde{T}_0(\tilde{x}) \sim \tilde{T}_0^* + \frac{\mu(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}}\,\tilde{x} \qquad \text{as } \tilde{x} \uparrow 0, \tag{22}$$

and $\tilde{q}_0(\tilde{x}) = \mu(\tilde{T}_0(\tilde{x}) - T_-)$ for $\tilde{x} < 0$.

Next, the problem for $\tilde{T}_1$ and $\tilde{q}_1$ (at order δ_1) is

$$\begin{cases} 0 = \mu\tilde{T}_1 + \tilde{q}_1, \\ 0 = \tilde{q}_1 + (4\tilde{T}_0^3\tilde{T}_1)', \\ \tilde{T}_1(\pm\infty) = 0,\ \tilde{q}_1(\pm\infty) = 0. \end{cases}$$

The limit behavior as $\tilde{x} \to \pm\infty$ is trivial since $T_\pm$ are independent of δ_1 (and δ_2). As it turns out, we need only the solution on the right. There $\tilde{T}_0 = T_+$, so the two equations can be reduced to

$$\tilde{T}_1' = \frac{\mu\tilde{T}_1}{4T_+^3}, \qquad \text{with } \tilde{T}_1(+\infty) = 0,$$

and hence the solution is simply

$$\tilde{T}_1 = \tilde{q}_1 = 0 \qquad \text{for } \tilde{x} > 0. \tag{23}$$

Similarly, the problem for $\tilde{T}_2$ and $\tilde{q}_2$ is

$$\begin{cases} 0 = \mu\tilde{T}_2 + \tilde{q}_2, \\ \tilde{q}_0 = \tilde{q}_2 + (4\tilde{T}_0^3\tilde{T}_2)', \\ \tilde{T}_2(\pm\infty) = 0,\ \tilde{q}_2(\pm\infty) = 0. \end{cases}$$

Again, we need only the solution on the right, which is simply

$$\tilde{T}_2 = \tilde{q}_2 = 0 \qquad \text{for } \tilde{x} > 0. \tag{24}$$

3.3. The intermediate problem. At the intermediate scale the problem reads

$$\delta_1 \hat{T}' = \mu(\hat{T} - T_\pm) + \hat{q},$$
$$\hat{q}'' = \delta_2 \hat{q} + (\hat{T}^4)',$$

with boundary conditions for $\hat{x} \to -\infty$

$$\hat{T}(\hat{x}) = \tilde{T}_0^* + \delta_1 O(\hat{x}^0) + \delta_2 \left[\tfrac{\mu(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}} \hat{x} + O(\hat{x}^0) \right] + o(\delta_1, \delta_2); \tag{25}$$
$$\hat{q}(\hat{x}) = -\mu(\tilde{T}_0^* - T_-) + \delta_1 O(\hat{x}^0) + \delta_2 \left[-\tfrac{\mu^2(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}} \hat{x} + O(\hat{x}^0) \right] + o(\delta_1, \delta_2);$$

and for $\hat{x} \to \infty$

$$\hat{T}(\hat{x}) = T_+ + o(\delta_1, \delta_2); \tag{26}$$
$$\hat{q}(\hat{x}) = o(\delta_1, \delta_2).$$

These boundary conditions are determined by the outer solution; namely, (22) leads to (25), while (21), (23), and (24) imply (26). At the intermediate scale the expansion for $\hat{T}$ is

$$\hat{T} = \hat{T}_0 + \delta_1 \hat{T}_1 + \delta_2 \hat{T}_2,$$

with an analogous expansion for $\hat{q}$.

The problem for $\hat{T}_0$ and $\hat{q}_0$ is

$$\begin{cases} 0 = \mu(\hat{T}_0 - T_\pm) + \hat{q}_0, \\ \hat{q}_0'' = (\hat{T}_0^4)', \\ \hat{T}_0(-\infty) = \tilde{T}_0^*,\ \hat{q}_0(-\infty) = -\mu(\tilde{T}_0^* - T_-), \\ \hat{T}_0(+\infty) = T_+,\ \hat{q}_0(+\infty) = 0. \end{cases}$$

The two equations can be combined into

$$\mu \hat{T}_0'' + (\hat{T}_0^4)' = 0. \tag{27}$$

On the left, we integrate from $\hat{x} = -\infty$ and obtain $\mu \hat{T}_0' + \hat{T}_0^4 - \tilde{T}_0^{*4} = 0$. Since $\hat{T}_0(-\infty) = \tilde{T}_0^*$ the solution on the left is

$$\hat{T}_0(\hat{x}) = \tilde{T}_0^* \quad \text{and} \quad \hat{q}_0(\hat{x}) = -\mu(\tilde{T}_0^* - T_-) \qquad \text{for } \hat{x} < 0. \tag{28}$$

On the right, integration of (27) from $\hat{x} = \infty$ gives

$$\mu \hat{T}_0' = -\hat{T}_0^4 + T_+^4, \qquad \text{with } \hat{T}_0(+\infty) = T_+. \tag{29}$$

This situation is very similar to that in the left outer region. We have a choice of the constant solution, an increasing solution and a decreasing solution, and it is the latter that we need. Since the equation is autonomous, the solution can be translated, and hence the value at the origin is a priori unknown. It has to be determined by matching with the inner region. Again, we introduce an undetermined constant

$$\hat{T}_0^* \overset{\text{def}}{=} \lim_{\hat{x} \downarrow 0} \hat{T}_0(\hat{x}).$$

For the asymptotic behavior near $\hat{x} = 0$ we get, using (27) and (29),

$$\hat{T}_0(\hat{x}) \sim \hat{T}_0^* - \mu^{-1}(\hat{T}_0^{*4} - T_+^4)\,\hat{x} + 2\mu^{-2}\hat{T}_0^{*3}(\hat{T}_0^{*4} - T_+^4)\,\hat{x}^2 \qquad \text{as } \hat{x} \downarrow 0, \tag{30}$$

and of course $\hat{q}_0(\hat{x}) = -\mu(\hat{T}_0(\hat{x}) - T_+)$ for $\hat{x} > 0$.

The problem for $\hat{T}_1$ and $\hat{q}_1$ is

$$\begin{cases} \hat{T}_0' = \mu\hat{T}_1 + \hat{q}_1, \\ \hat{q}_1'' = (4\hat{T}_0^3\hat{T}_1)', \\ \hat{T}_1(\pm\infty) = 0,\ \hat{q}_1(\pm\infty) = 0. \end{cases}$$

On the left, the equation reduces to $\mu\hat{T}_1'' + 4\tilde{T}_0^{*3}\hat{T}_1' = 0$, and hence the solution is constant. The value of the constant is unknown at this point. Since we shortly have to match with the inner region, we use the undetermined limit value at the origin $\hat{T}_1^- \stackrel{\text{def}}{=} \hat{T}_1(0^-)$ to denote the constant:

$$\hat{T}_1(\hat{x}) = \hat{T}_1^- \quad \text{and} \quad \hat{q}_1(\hat{x}) = -\mu\hat{T}_1^- \qquad \text{for } \hat{x} < 0. \tag{31}$$

On the right, one obtains $\mu\hat{T}_1'' = -4(\hat{T}_0^3\hat{T}_1)' + \hat{T}_0'''$. Integrating from 0 to ∞ we get, using (30) and setting $\hat{T}_1^+ \stackrel{\text{def}}{=} \hat{T}_1(0^+)$,

$$\hat{T}_1'(0^+) = -4\mu^{-1}\hat{T}_0^{*3}\hat{T}_1^+ + 4\mu^{-3}\hat{T}_0^{*3}(\hat{T}_0^{*4} - T_+^4). \tag{32}$$

This equation expresses $\hat{T}_1'(0^+)$ in the unknown constant $\hat{T}_1^+$. The behavior of $\hat{q}_1$ near the origin is given by

$$\begin{aligned} \hat{q}_1(\hat{x}) &\sim \hat{T}_0'(0^+) - \mu\hat{T}_1^+ + (\hat{T}_0''(0^+) - \mu\hat{T}_1'(0^+))\,\hat{x} \\ &\sim -\mu^{-1}(\hat{T}_0^{*4} - T_+^4) - \mu\hat{T}_1^+ + 4\hat{T}_0^{*3}\hat{T}_1^+\,\hat{x} \qquad \text{as } \hat{x} \downarrow 0. \end{aligned}$$

The problem for $\hat{T}_2$ and $\hat{q}_2$ is

$$\begin{cases} 0 = \mu\hat{T}_2 + \hat{q}_2, \\ \hat{q}_2'' = \hat{q}_0 + (4\hat{T}_0^3\hat{T}_2)', \\ \hat{T}_2(+\infty) = 0,\ \hat{q}_2(+\infty) = 0, \\ \hat{T}_2'(-\infty) = \frac{\mu(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}},\ \hat{q}_2'(-\infty) = -\frac{\mu^2(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}}. \end{cases}$$

On the left, the equation reduces to $\mu\hat{T}_2'' = -4\tilde{T}_0^{*3}\hat{T}_2' + \mu(\tilde{T}_0^* - T_-)$, with solution, setting as usual $\hat{T}_2^- \stackrel{\text{def}}{=} \hat{T}_2(0^-)$,

$$\hat{T}_2(\hat{x}) = \hat{T}_2^- + \tfrac{\mu(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}}\hat{x} \quad \text{and} \quad \hat{q}_2(\hat{x}) = -\mu\hat{T}_2^- - \tfrac{\mu^2(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}}\hat{x} \qquad \text{for } \hat{x} < 0. \tag{33}$$

On the right, the equation becomes $\mu\hat{T}_2'' = -(4\hat{T}_0^3\hat{T}_2)' + \mu(\hat{T}_0 - T_+)$. Integrating from 0 to ∞ we get, setting $\hat{T}_2^+ \stackrel{\text{def}}{=} \hat{T}_2(0^+)$,

$$\hat{T}_2'(0^+) = -4\mu^{-1}\hat{T}_0^{*3}\hat{T}_2^+ - \int_0^\infty \big[\hat{T}_0(\hat{x}) - T_+\big]\,d\hat{x}. \tag{34a}$$

The last integral involves the function $\hat{T}_0(\hat{x})$, which we have not computed explicitly. The integral can be simplified using equation (29) for $\hat{T}_0$:

$$I_2 \stackrel{\text{def}}{=} \int_0^\infty \left[\hat{T}_0(\hat{x}) - T_+\right] d\hat{x} = -\int_0^{\hat{T}_0^* - T_+} \frac{\hat{T}_0 - T_+}{(\hat{T}_0 - T_+)'}\, d(\hat{T}_0 - T_+)$$

$$= \frac{\mu}{T_+^2} \int_0^{\hat{T}_0^*/T_+ - 1} \frac{t}{(t+1)^4 - 1}\, dt. \tag{34b}$$

We could compute the primitive, but that does not lead to more insight. Finally, the behavior of $\hat{q}_2$ near the origin is given by

$$\hat{q}_2(\hat{x}) \sim -\mu \hat{T}_2^+ + [4\hat{T}_0^{*3}\hat{T}_2^+ + \mu I_2]\,\hat{x} \qquad \text{as } \hat{x} \downarrow 0.$$

3.4. The inner problem. We are getting to the core of the problem. In the inner scale we want to solve

$$T' = \mu(T - T_\pm) + q,$$
$$q'' = \delta_1^2\delta_2 q + \delta_1 (T^4)'.$$

The boundary conditions are for $x \to -\infty$:

$$\begin{aligned} T(x) &= \tilde{T}_0^* + \delta_1 \hat{T}_1^- + \delta_2 \hat{T}_2^- + \delta_1^2 O(x^0) \\ &\quad + \delta_1\delta_2 \left[\tfrac{\mu(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}} x + O(x^0)\right] + o(\delta_1^2, \delta_1\delta_2, \delta_2); \\ q(x) &= -\mu(\tilde{T}_0^* - T_-) - \delta_1 \mu \hat{T}_1^- - \delta_2 \mu \hat{T}_2^- + \delta_1^2 O(x^0) \\ &\quad - \delta_1\delta_2 \left[\tfrac{\mu^2(\tilde{T}_0^* - T_-)}{4\tilde{T}_0^{*3}} x + O(x^0)\right] + o(\delta_1^2, \delta_1\delta_2, \delta_2). \end{aligned} \tag{35}$$

For $x \to \infty$ the boundary conditions look complicated:

$$\begin{aligned} T(x) &= \hat{T}_0^* + \delta_1[-\mu^{-1}(\hat{T}_0^{*4} - T_+^4)x + \hat{T}_1^+] + \delta_2 \hat{T}_2^+ \\ &\quad + \delta_1^2 \hat{T}_0^{*3}\left[2\mu^{-2}(\hat{T}_0^{*4} - T_+^4)x^2 + 4\{-\mu^{-1}\hat{T}_1^+ + \mu^{-3}(\hat{T}_0^{*4} - T_+^4)\}x + O(x^0)\right] \\ &\quad + \delta_1\delta_2[(-4\mu^{-1}\hat{T}_0^{*3}\hat{T}_2^+ - I_2)x + O(x^0)] + o(\delta_1^2, \delta_1\delta_2, \delta_2); \\ q(x) &= -\mu(\hat{T}_0^* - T_+) + \delta_1[(\hat{T}_0^{*4} - T_+^4)x - \mu^{-1}(\hat{T}_0^{*4} - T_+^4) - \mu\hat{T}_1^+] - \delta_2\mu\hat{T}_2^+ \\ &\quad + \delta_1^2[-2\mu^{-1}\hat{T}_0^{*3}(\hat{T}_0^{*4} - T_+^4)x^2 + 4\hat{T}_0^{*3}\hat{T}_1^+ x + O(x^0)] \\ &\quad + \delta_1\delta_2[(4\hat{T}_0^{*3}\hat{T}_2^+ + \mu I_2)x + O(x^0)] + o(\delta_1^2, \delta_1\delta_2, \delta_2). \end{aligned} \tag{36}$$

These conditions follow from the analysis of the intermediate region; e.g., (35) follows from (28), (31), and (33), whereas (36) follows from (30), (32), and (34). Of course the boundary conditions for $T(x)$ and $q(x)$ as $x \to \pm\infty$ are related through the equation $q = T' - \mu(T - T_\pm)$. Furthermore, at the origin q, q' and T are continuous.

We expand T as

$$T \sim T_0 + \delta_1 T_1 + \delta_2 T_2 + \delta_1^2 T_3 + \delta_1\delta_2 T_4,$$

and analogously for q. As mentioned before, terms of order δ_2^2 do not need to be computed. We now solve subsequently the equations at zeroth, first, and second order in the small parameters δ_1 and δ_2.

3.4.1. Zeroth order. The equations for T_0 and q_0 are

$$\begin{cases} T_0' = \mu(T_0 - T_\pm) + q_0, \\ q_0'' = 0, \\ T_0(-\infty) = \tilde{T}_0^*,\ q_0(-\infty) = -\mu(\tilde{T}_0^* - T_-), \\ T_0(+\infty) = \hat{T}_0^*,\ q_0(+\infty) = -\mu(\hat{T}_0^* - T_+). \end{cases}$$

The functions T_0, q_0, and q_0' are continuous across the origin. This means that $q_0(x)$ is constant, and on the right $T_0(x)$ is constant as well. This implies

$$T_0^* \overset{\text{def}}{=} T_0(0) = T_0(+\infty) \qquad \text{and} \qquad q_0(-\infty) = q_0(+\infty),$$

and hence a comparison with the boundary conditions (and (17)) leads to

$$T_0^* = \hat{T}_0^* = \tilde{T}_0^* + T_+ - T_- = \tilde{T}_0^* + Y_-,$$

that is,

$$\hat{T}_0^* = T_0^*, \tag{37a}$$

$$\tilde{T}_0^* = T_0^* - Y_-. \tag{37b}$$

On the left, the solution $T(x)$ decays exponentially to $\tilde{T}_0^* = T_0^* - Y_-$, so

$$T_0(x) = \begin{cases} Y_-(e^{\mu x} - 1) + T_0^* & \text{for } x < 0, \\ T_0^* & \text{for } x \geq 0, \end{cases} \qquad \text{and} \quad q_0(x) = -\mu(T_0^* - T_+).$$

3.4.2. First order. The equations for T_1 and q_1 are (using (37a))

$$\begin{cases} T_1' = \mu T_1 + q_1, \\ q_1'' = (T_0^4)', \\ T_1(-\infty) = \hat{T}_1^-,\ q_1(-\infty) = -\mu\hat{T}_1^-, \\ T_1(x) \sim -\mu^{-1}(T_0^{*4} - T_+^4)x + \hat{T}_1^+ \ \text{ as } x \to \infty, \\ q_1(x) \sim (T_0^{*4} - T_+^4)x - \mu^{-1}(T_0^{*4} - T_+^4) - \mu\hat{T}_1^+ \ \text{ as } x \to \infty. \end{cases}$$

We start by integrating the second equation from $x = -\infty$:

$$q_1'(x) = T_0(x)^4 - T_0(-\infty)^4 = \begin{cases} [Y_-(e^{\mu x} - 1) + T_0^*]^4 - [T_0^* - Y_-]^4, & x < 0, \\ T_0^{*4} - [T_0^* - Y_-]^4, & x \geq 0. \end{cases} \tag{38}$$

We thus have, by comparing with the boundary conditions for q_1 as $x \to \infty$,

$$T_0^{*4} - T_+^4 = q_1'(+\infty) = T_0^{*4} - [T_0^* - Y_-]^4,$$

and hence

$$T_0^* = T_+ + Y_-. \tag{39}$$

Although we now have an expression for T_0^*, we keep using the notation T_0^* in the proceeding for notational convenience.

Another integration of (38) from $x = 0$ in both directions gives

$$\begin{aligned} &q_1(x) \to q_1(0) - I_1 && \text{as } x \to -\infty, \\ &q_1(x) = q_1(0) + (T_0^{*4} - T_+^4)\, x && \text{for } x \geq 0, \end{aligned}$$

where

$$I_1 \overset{\text{def}}{=} \int_{-\infty}^{0} (Y_- e^{\mu x} + T_+)^4 - T_+^4 \, dx = \mu^{-1}\big(4T_+^3 Y_- + 3T_+^2 Y_-^2 + \tfrac{4}{3} T_+ Y_-^3 + \tfrac{1}{4} Y_-^4\big). \tag{40}$$

To obtain $T_1(x)$ on the right we solve $T_1' - \mu T_1 = q_1(0) + (T_0^{*4} - T_+^4)\, x$, and we obtain

$$T_1(x) = T_1^* - \mu^{-1}(T_0^{*4} - T_+^4)\, x \qquad \text{for } x \geq 0, \tag{41}$$

where

$$T_1^* \overset{\text{def}}{=} T_1(0) = -\mu^{-1} q_1(0) - \mu^{-2}(T_0^{*4} - T_+^4). \tag{42}$$

On the left, the limit behavior of T_1 is (using (42))

$$\lim_{x \to -\infty} T_1(x) = -\mu^{-1} q_1(0) + \mu^{-1} I_1 = T_1^* + \mu^{-2}(T_0^{*4} - T_+^4) + \mu^{-1} I_1. \tag{43}$$

Comparing (41) and (43) with the boundary conditions gives the values for $\hat{T}_1^{\pm}$:

$$\begin{aligned} \hat{T}_1^- &= T_1^* + \mu^{-2}(T_0^{*4} - T_+^4) + \mu^{-1} I_1, \\ \hat{T}_1^+ &= T_1^*. \end{aligned}$$

Next, the equation at order δ_2 is

$$\begin{cases} T_2' = \mu T_2 + q_2, \\ q_2'' = 0, \\ T_2(-\infty) = \hat{T}_2^-,\ q_2(-\infty) = -\mu \hat{T}_2^-, \\ T_2(+\infty) = \hat{T}_2^+,\ q_2(+\infty) = -\mu \hat{T}_2^+. \end{cases}$$

Since the equations are satisfied on $\mathbb{R}$ the solution is constant, so $\hat{T}_2^- = \hat{T}_2^+ = T_2(0)$ and

$$T_2(x) = T_2^* \overset{\text{def}}{=} T_2(0) \qquad \text{for all } x \in \mathbb{R}.$$

3.4.3. Second order. The equation at order δ_1^2 reads

$$\begin{cases} T_3' = \mu T_3 + q_3, \\ q_3'' = 4(T_0^3 T_1)', \\ T_3'(-\infty) = 0,\ q_3'(-\infty) = 0, \\ T_3'(x) \sim 4\mu^{-2} T_0^{*3}(T_0^{*4} - T_+^4)\, x + 4\mu^{-3} T_0^{*3}(-\mu^2 T_1^* + T_0^{*4} - T_+^4) \ \text{ as } x \to \infty, \\ q_3'(x) \sim -4\mu^{-1} T_0^{*3}(T_0^{*4} - T_+^4)\, x + 4 T_0^{*3} T_1^* \ \text{ as } x \to \infty. \end{cases}$$

Integrating the second equation from $x = -\infty$ gives

$$q_3'(x) = 4T_0(x)^3 T_1(x) - 4T_+^3 T_1(-\infty),$$

and by using (41) and (43) we obtain for $x \geq 0$

$$q_3'(x) = -4\mu^{-1} T_0^{*3}(T_0^{*4} - T_+^4) x + 4T_0^{*3} T_1^* - 4T_+^3 [T_1^* + \mu^{-2}(T_0^{*4} - T_+^4) + \mu^{-1} I_1].$$

Comparing this with the boundary conditions for $q_3'(x)$ as $x \to \infty$ gives

$$T_1^* = -\mu^{-1} I_1 - \mu^{-2}\big((T_+ + Y_-)^4 - T_+^4\big), \tag{44}$$

with I_1 given in (40).

The equation at order $\delta_1\delta_2$ reads (using (37b))

$$\begin{cases} T_4' = \mu T_4 + q_4, \\ q_4'' = 4(T_0^3 T_2)', \\ T_4'(-\infty) = \frac{\mu Y_-}{4T_+^3},\ q_4'(-\infty) = -\frac{\mu^2 Y_-}{4T_+^3}, \\ T_4'(+\infty) = -4\mu^{-1} T_0^{*3} T_2^* - I_2,\ q_4'(+\infty) = 4T_0^{*3} T_2^* + \mu I_2. \end{cases}$$

Integrating the second equation from $x = -\infty$ to $x = \infty$ gives

$$q_4'(+\infty) - q_4'(-\infty) = 4[T_0^{*3} - T_+^3]T_2^*.$$

On the other hand, the boundary conditions say that

$$q_4'(+\infty) - q_4'(-\infty) = 4T_0^{*3} T_2^* + \mu I_2 + \frac{\mu^2 Y_-}{4T_+^3}.$$

Comparing these expressions for $q_4'(+\infty) - q_4'(-\infty)$ gives

$$T_2^* = -\frac{\mu}{4T_+^3} I_2 - \frac{\mu^2 Y_-}{16 T_+^6}\,, \tag{45}$$

with I_2 given in (34b).

4. The asymptotic law for the velocity. In this section we take a look at what the speed law tells us. We compare the asymptotic formula with numerical computations for small finite values of ε. In particular, we calculate bifurcation diagrams where the radiative parameters α and β are the continuation parameters. For this, the most delicate case where both terms in the right-hand side of (8) are present is the most interesting, i.e., (8a). In this limit the activation energy ε^{-1} is coupled with the radiative parameters via

$$\alpha = \alpha_0 \varepsilon^{3/2} \qquad \text{and} \qquad \beta = \beta_0 \varepsilon^{-1/2}.$$

The relation between the wave speed μ and α_0 and β_0 is thus

$$\ln(\mu\, Y_-) + \frac{\alpha_0 \beta_0 T_+^2}{\mu^2} E_1\Big(\tfrac{Y_-}{T_+}\Big) + \frac{\mu^2}{\beta_0^2 T_+^7} E_2\Big(\tfrac{Y_-}{T_+}\Big) = 0. \tag{46}$$

We note that due to our choice not to scale Y_- (see section 2.2) this expression should be invariant under the scaling

$$Y_- \to sY_-, \quad T_+ \to sT_+, \quad \mu \to s^{-1}\mu, \quad \alpha_0 \to s^{1/2}\alpha_0, \quad \beta_0 \to s^{-9/2}\beta_0,$$

and it is indeed. Furthermore, if one would replace the nonlinear term T^4 in (10c) by a linear approximation, then the solution can be (almost) explicitly calculated for any α and β. In the limit under consideration, an expression for the speed law analogous to (46) is found; see [2]. It is in that context that the stability investigation is being pursued.

The functions E_1 and E_2 depend only on the quotient Y_-/T_+, and since $T_+ = Y_- + T_-$, they thus depend on the ratio of the fuel mass fraction and the dimensionless temperature far ahead of the front. These two functions are plotted in Figure 5.

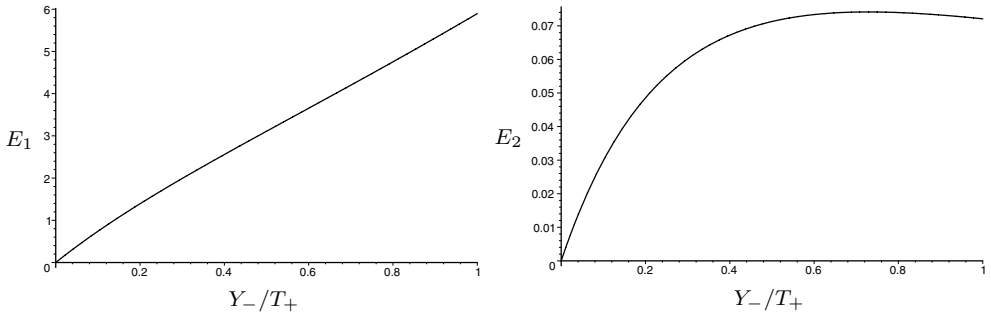

FIG. 5. *The functions* $E_1\left(\frac{Y_-}{T_+}\right)$ *and* $E_2\left(\frac{Y_-}{T_+}\right)$. *Notice that* $T_+ = T_- + Y_-$ *and thus* $0 < \frac{Y_-}{T_+} < 1$.

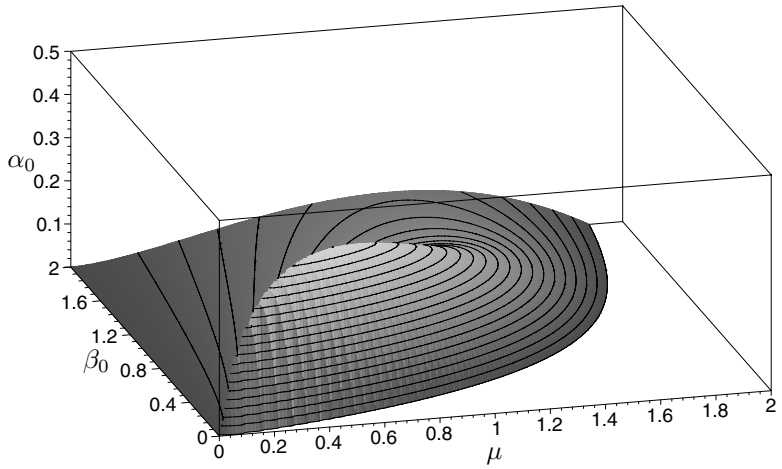

FIG. 6. *The surface in* (μ, α_0, β_0)*-space describing the speed law.*

For the subsequent numerical calculations we need to pick some values for the parameters, and we choose $Y_- = T_- = 0.5$ and hence $T_+ = 1$, throughout. The remaining variables in (46) are thus α_0, β_0, and μ. We can plot the surface most easily by writing α_0 as a function of μ and β_0, and the result is shown in Figure 6. When we fix β_0, then for small α_0 there are two solutions which merge in a saddle-node bifurcation as α_0 increases. On the other hand, when we fix α_0 and use β_0 as the bifurcation parameter we see that the set of solutions forms an *isola* in the (β_0, μ)-plane. This means that β_0 has to be carefully selected, not too large and not too small, for a flame with finite propagation speed to exist. If α_0 is too large, then there are no travelling waves. The maximum value of α_0 for which solutions exist can be calculated to be

$$\alpha_{\max} = \sqrt{\frac{T_+^3}{2e^3 Y_-^2 E_1^2 E_2}}.$$

To compare the asymptotic analysis with numerical computations, we implemented the travelling wave problem in the AUTO software package [7] for the continuation of solutions to ODEs. We treated the three different spatial regions with some care to reflect their respective scaling with ε (or with δ_1 and δ_2 to be more

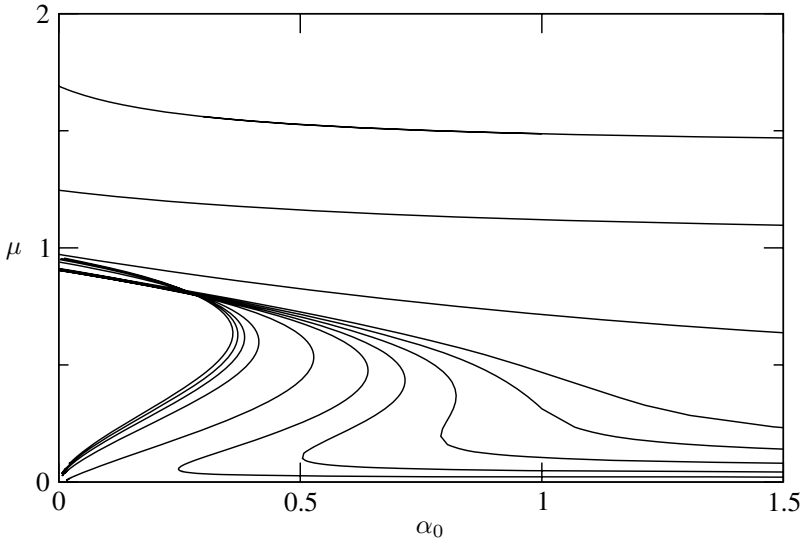

FIG. 7. *The solution curves in the* (α_0, μ)*-plane for fixed* $\beta_0 = 0.3$ *and* $\varepsilon = 1, 0.5, 0.2, 0.11, 0.1, 0.09, 0.08, 0.07, 0.05, 0.02, 0.01, 0.005, 0.001$. *As* ε *decreases, the solution curves shift inwards, i.e., the curve at the top corresponds to* $\varepsilon = 1$.

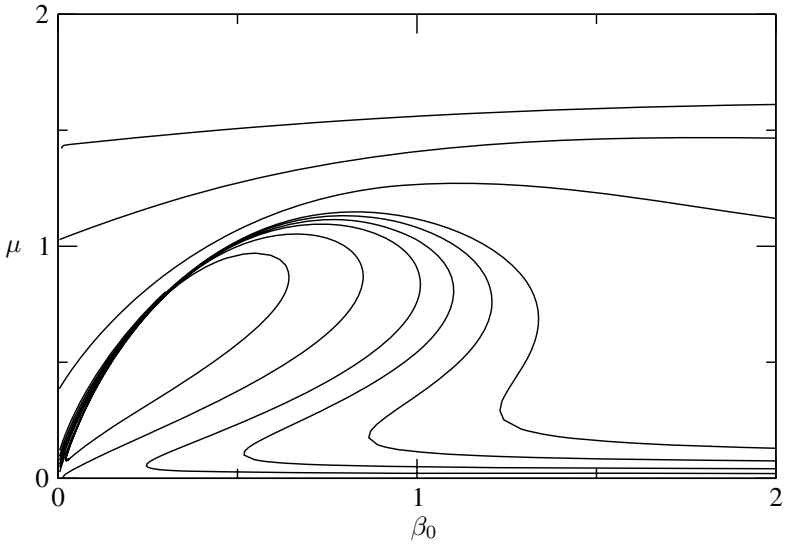

FIG. 8. *The solution curves in the* (β_0, μ)*-plane for fixed* $\alpha_0 = 0.3$ *and the same values of* ε *as in Figure* 7. *As* ε *decreases, the solution curves shift inward.*

precise). We calculated the bifurcation diagram using both α_0 and β_0 as parameters for a set of small values of ε. The resulting pictures are shown in Figures 7 and 8, and one can see how the asymptotic regime is approached. For the (α_0, μ)-diagram the solution curves become S-shaped as ε decreases and then approach a bell-shaped curve as $\varepsilon \to 0$. In the (β_0, μ)-diagram the solution branch curves back more and more and finally closes on itself as ε approaches 0.

To be able to compare with the analytic expression in the limit $\varepsilon \to 0$, we fixed

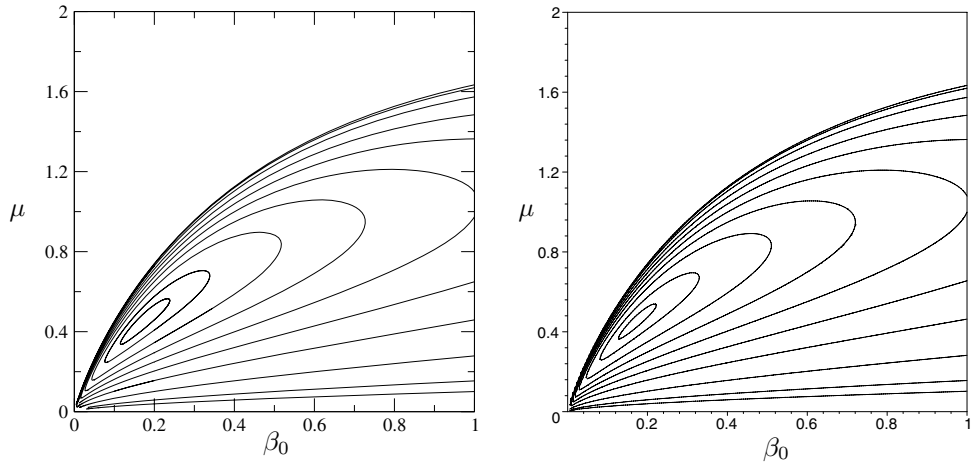

FIG. 9. *On the left is the* (β_0, μ) *bifurcation diagram for* $\varepsilon = 0.001$ *and* $\alpha_0 = 0.01, 0.02, 0.05, 0.1, 0.15, 0.2, 0.25, 0.3, 0.35, 0.375$. *As* α_0 *increases, the curves are moving inward. On the right are, for the same set of* α_0 *values, the contour lines of the surface (see Figure* 6*) describing the asymptotic speed law as* $\varepsilon \to 0$.

$\varepsilon = 0.001$ and computed the (β_0, μ)-diagram for various values of α_0. The resulting curves can thus be compared with the contour lines of the surface in Figure 6. The numerical computations and the contour lines of the analytic expression are depicted in Figure 9 side by side. The agreement is excellent.

5. Conclusion. In a thermodiffusive combustion model we have studied the influence of radiation effects on propagating flames. In particular, radiative heat transfer enhances the flame temperature and its propagation speed. This so-called Joulin effect is at its most prominent when the medium is fairly transparent while the radiative flux dominates convection. In this asymptotic regime the flame temperature approaches its upper bound. We have determined the law that describes the relation between the propagation speed of the flame and the control parameters.

We have arrived at distinguished limits in four cases. Case I exhibits a rich gamut of bifurcation diagrams, such as S-curves in the (α_0, μ)-plane and S-curves and isolas in the (β, μ)-plane. Case III is nothing but the classical bell-shaped curve in nonadiabatic flame models with heat loss. Cases II and IV correspond to straightforward travelling wave dynamics, and we have derived the corresponding laws for the sake of completeness.

Although the matched asymptotic analysis in this paper is fairly cumbersome, we think it would be fruitful to continue the work in the future in two directions. First, a less simplified Arrhenius reaction term will contain the mass fraction Y, leading to a more involved system of three equations instead of two. Second, a more detailed description of the radiative transfer than the Eddington equation can be taken into account. We hope this paper will serve as a guideline for these extensions.

Appendix A. The Eddington equation.

We consider radiative transfer in a medium of opacity κ at temperature T. A photon travelling at the light speed c covers a distance $L = 1/\kappa$ (the mean free path length of the photon) before being absorbed. Loosely speaking, $L = \infty$ ($\kappa = 0$) corresponds to a transparent medium (optically thin limit) and $L = 0$ ($\kappa = \infty$) to an

opaque medium (optically thick limit).

We start from the equation of radiative transfer for the radiative intensity $I = I(\mathbf{r}, \nu, \Omega, t)$,

$$\frac{1}{c}\frac{\partial I}{\partial t} + \Omega \cdot \nabla I = \kappa(\mathcal{B}(T,\nu) - I). \tag{47}$$

Here $\mathbf{r}$ is the position, t the time, ν the frequency, and Ω the unit vector in the direction of propagation. The Planck distribution $\mathcal{B}$ governs the emission of light by the medium and is given by

$$\mathcal{B}(T,\nu) = \frac{2h}{c^2}\frac{\nu^3}{e^{h\nu/(kT)} - 1},$$

where k and h are the Boltzmann and Planck constants.

Since we would like to consider the total amount of radiation, we denote by $\langle\phi\rangle$ the integral of a function ϕ over all frequencies and directions, rescaled with c:

$$\langle\phi\rangle = \frac{1}{c}\int_0^\infty \int_{S^2} \phi(\nu,\Omega)\, d\Omega\, d\nu.$$

Observing that

$$\langle\mathcal{B}(T)\rangle = aT^4 \quad \text{with} \quad a = \frac{8\pi^5 k^4}{15h^3c^3},$$

one obtains from (47) the system [14, 9, 10]

$$\frac{\partial E_R}{\partial t} + \nabla \cdot \mathbf{F_R} = c\kappa(aT^4 - E_R); \tag{48a}$$

$$\frac{1}{c}\frac{\partial \mathbf{F_R}}{\partial t} + c\nabla \mathbf{P_R} = -\kappa \mathbf{F_R}, \tag{48b}$$

for the radiative energy density E_R, the radiative flux $\mathbf{F_R}$, and the radiative pressure $\mathbf{P_R}$, defined by

$$\begin{aligned} E_R &= \langle I\rangle, \\ \mathbf{F_R} &= c\,\langle \Omega\, I\rangle, \\ \mathbf{P_R} &= \langle \Omega \otimes \Omega\, I\rangle. \end{aligned}$$

The factor c is, as usual, included in the definition of $\mathbf{F_R}$ so that it represents an energy flux. Notice that equations (48) do not form a closed system. They are the first members of a hierarchy, and the system still needs to be closed. If the emission and absorption would be isotropic, then we would have

$$\mathbf{F_R} = 0,$$

and also

$$\mathbf{P_R} = \frac{1}{3}E_R\mathbf{Id}. \tag{49}$$

In the so-called P_1-model, which leads to the Eddington equation, (49) is taken as a closure assumption, so that (48) is replaced by

$$\frac{\partial E_R}{\partial t} + \nabla \cdot \mathbf{F_R} = c\kappa(aT^4 - E_R); \tag{50a}$$

$$\frac{1}{c}\frac{\partial \mathbf{F_R}}{\partial t} + \frac{1}{3}c\nabla E_R = -\kappa \mathbf{F_R}. \tag{50b}$$

Since photons travel at light speed we may assume that the radiation is approximately at steady state at the typical time scale of a moving flame; i.e., the system (50) reduces to

$$\nabla \cdot \mathbf{F_R} = c\kappa(aT^4 - E_R); \qquad \frac{1}{3}c\nabla E_R = -\kappa \mathbf{F_R}.$$

It is not difficult to eliminate one of the unknowns, say E_R, by differentiating the first equation, whence

$$c\kappa\nabla E_R = c\kappa a\nabla(T^4) - \nabla(\nabla \cdot \mathbf{F_R}),$$

so that

$$\nabla(\nabla \cdot \mathbf{F_R}) = 4\kappa\sigma_{\rm sb}\nabla T^4 + 3\kappa^2 \mathbf{F_R}. \tag{51}$$

Here $\sigma_{\rm sb} = \frac{1}{4}ac$ is the Stefan–Boltzmann constant.

Equation (51) is the Eddington equation for the radiative flux $\mathbf{F_R}$, which is often written as

$$-L^2\nabla(\nabla \cdot \mathbf{F_R}) + 3\mathbf{F_R} + 4\sigma_{\rm sb}L\nabla T^4 = 0.$$

POROUS MEDIA UPSCALING IN TERMS OF MATHEMATICAL EPISTEMIC COGNITION*

HWA-LUNG YU† AND GEORGE CHRISTAKOS†

Abstract. In this work we revisit the meaning of the term "solution" with respect to a mathematical model representing a physical media upscaling system. A central aim is to combine the science of mind with human mathematical ideas to solve real-world upscaling problems. We propose that in certain cases a (nonconventional) epistemic cognition solution (which assumes that the model describes incomplete knowledge about nature and focuses on conceptual mechanisms and thinking processes) can lead to a more realistic upscaling analysis than a (conventional) ontologic approach (which assumes that the model describes nature as is and focuses on form manipulations). In the present work we apply the epistemic cognition approach to the solution of the two-dimensional bounded porous media upscaling problem. A formal framework is presented, and implementation issues related to the epistemic cognition methodology are considered. Numerical experiments are presented involving effective conductivities in bounded two-dimensional spatial domains, and insight is gained by comparing the results to existing ontologic upscaling solutions. In addition to dealing with new and more general upscaling situations, the proposed approach can reproduce some well-known results, a fact that further demonstrates its power and nesting capabilities.

Key words. upscaling, porous media, epistemic, stochastic

DOI. 10.1137/040614438

1. Introduction.

In the porous media upscaling literature we find various ontologic techniques (analytical and numerical) for deriving useful values of effective hydraulic conductivities; see Cushman (1986), Dagan (1989), King (1989), Deutsch (1989), Rubin and Gomez-Hernandez (1990), Kitanidis (1990), Neuman and Orr (1993), Christakos, Miller, and Oliver (1993), Christakos, Hristopulos, and Miller (1995), Gelhar (1993), Wen and Gomez-Hernandez (1996), Hristopulos and Christakos (1997a and b, 1999), Tartakovsky et al. (2002), and Rubin (2003). Underlying these techniques is an ontologic view of reality, i.e., the organization inherent in the mathematical upscaling model describes nature in a realistic manner and, thus, one is focusing on form manipulations (e.g., extracting from the algebra effective conductivity values so that a system of equations is satisfied).

In an earlier work (Christakos, 2003), an alternative view to porous media upscaling was proposed based on an epistemic cognition approach (ECA), i.e., it involved the epistemically evaluated cognitive integration and processing of various forms of knowledge. The main ECA ideas were developed by Christakos (1992), and since then the approach has been applied with considerable success to a number of physical and life systems (e.g., Christakos, 1998, 2000; Kolovos et al., 2002; D'Or and Bogaert, 2003; Serre et al., 2003a and b; Douaik et al., 2004; Christakos et al., 2005; Quilfen et al., 2004; Parkin, Savelieva, and Serre, 2005). A recent review of the ECA conceptual framework and its various natural applications can be found in Christakos (2005) and references therein. A central aim of the ECA is to combine the science of

mind with human mathematical ideas to solve real-world upscaling problems. One of its basic premises is that an examination of what constitutes a "solution" produces useful tools for physical modelling and suggests greater emphasis on sound scientific reasoning over technical criteria. Unlike the ontologic approach, the ECA seeks effective conductivity values that satisfy a set of epistemic principles (e.g., maximum information and adaptation) subject to all the core knowledge (including the system of equations mentioned above) as well as the various site-specific (and often uncertain) databases available. The term "epistemic" refers to the construction of models of the processes (perceptual and intellectual) by which knowledge and understanding about the physical system are achieved and communicated. In the ECA framework, the contribution of "cognition" is to identify basic knowledge-assimilation and problem-solving processes, which are then examined by means of the evaluative standards of epistemology. The organization structure inherent in the mathematical upscaling model expresses our incomplete knowledge about a real-world situation rather than nature itself, and its solution is neither a fixed nor an absolute matter in the conventional ontologic sense. Instead, an adequate solution is deeply rooted in the process that is concerned with conceptual mechanisms at work—not merely on form manipulations. A distinction is made, e.g., between the individual's way of thinking of a concept and its formal definition, thus distinguishing between mathematical upscaling solution as a mental activity vs. as a formal system.

In this work we apply the ECA to study upscaling in two-dimensional (2-D) porous media situations. A rigorous theoretical definition of the effective hydraulic conductivity (EHC) is given in terms of (2.1) below, which involves stochastic expectation operators. In practice, the EHC is often viewed as a representative conductivity value (spatial average or global property) associated with a porous media scale that is larger than the scale of the available data (Rubin, 2003). The implementation of the ECA starts by distinguishing between two major categories of knowledge, viz., the general knowledge base ($\mathcal{G}$-KB) and the specificatory knowledge base ($\mathcal{S}$-KB). The $\mathcal{G}$-KB may include human constructs like physical equations and stochastic laws, whereas the $\mathcal{S}$-KB consists of site-specific details of the specified porous medium, including exact ("hard") and uncertain ("soft") conductivity data and hydraulic head observations, as well as several secondary information sources. Subsequently, the upscaling reasoning we adopt consists of the following stages (a detailed discussion of the upscaling methodology and the relevant terminology can be found in Christakos, 2003):

1. Structural stage, which transforms the $\mathcal{G}$-KB available into a set of equations in terms of the EHC probability density function (pdf) model, $f_{\mathcal{G}}$. This transformation is achieved by means of a maximum expected information principle $\mathcal{T}$, which can be expressed, e.g., in terms of the Shannon information measures, i.e., $\mathcal{T}$: $\max_{f_{\mathcal{G}}} \overline{\log(f_{\mathcal{G}}^{-1})}$.

2. Specificatory stage, which represents the $\mathcal{S}$-KB in a form suitable for quantitative analysis and processing. Common forms include

(i) Exact numerical values across space (hard data).

(ii) Intervals, i.e., there is not a unique data value available at a spatial location but, instead, an interval of possible values (uncertain data).

(iii) Probability functions, i.e., the datum at the specified location is in the form of a probability distribution (uncertain data).

3. Integration stage, which blends the results of the previous stages by means of an adaptation principle $\mathcal{A}$, thus leading to the final solution in terms of an updated pdf model, $f_{\mathcal{K}}$, for the EHC (the subscript $\mathcal{K}$ denotes the total KB, i.e., the syn-

thesis of the $\mathcal{G}$- and the $\mathcal{S}$-KB). The $\mathcal{A}$ principle may involve Bayesian induction pdf, $f_{\mathcal{K}} = f_{\mathcal{G}}(\text{EHC}|\mathcal{S})$, or stochastic deduction pdf, $f_{\mathcal{K}} = f_{\mathcal{G}}(\mathcal{S} \rightarrow \text{EHC})$ and $f_{\mathcal{K}} = f_{\mathcal{G}}(\mathcal{S} \leftrightarrow \text{EHC})$; the symbols "|," "$\rightarrow$," and "$\leftrightarrow$" denote, respectively, Bayesian conditional (probability of EHC given $\mathcal{S}$), material conditional (probability that $\mathcal{S}$ implies EHC), and material biconditional (probability that EHC if and only if $\mathcal{S}$). In this work, the Bayesian pdf will be used to calculate EHC values.

Hence, there are several possibilities regarding the mathematical formulation of the ECA methodology 1–3 above. For details, see Christakos (2000, 2002, 2005). In the next section a mathematical formulation of the ECA is considered in the 2-D porous media upscaling context.

2. Formulation and solution of the 2-D upscaling problem. Consider the case of effective flow in a 2-D porous domain that is sufficiently characterized by the local mean value law (e.g., Rubin, 2003)

$$\overline{K(\mathbf{s})J_i(\mathbf{s})} = \sum_{j=1}^{2} K_{eff,ij}\overline{J_i(\mathbf{s})} \tag{2.1}$$

$(i = 1, 2)$, where $\mathbf{s} = (s_1, s_2)$ is the spatial location vector, the bar denotes stochastic expectation, $K(\mathbf{s})$ is the random conductivity field at point $\mathbf{s}$, $\overline{J_i(\mathbf{s})}$ is the mean hydraulic gradient in the i direction expressed in terms of boundary conditions (BC) and conductivity statistics, and the $K_{eff,ij}$ are the EHC components sought, i.e., $\mathbf{K}_{eff} = [K_{eff,11}, K_{eff,12} = K_{eff,21}, K_{eff,22}]^T$. The tensorial nature of EHC was established by Tartakovsky et al. (2002). Depending on the porous media flow situation, (2.1) can be associated with different BC. Note that (2.1) constitutes a local law. Nonlocal laws may be considered as well (e.g., for nonhomogeneous situations), but this is beyond the scope of the present work. In addition to the $\mathcal{G}$-KB or core knowledge that is expressed, in this case, by (2.1), in real-world situations a set of conductivity and/or hydraulic gradient measurements is also available at a number of points in space. These measurements constitute site-specific knowledge $\mathcal{S}$-KB that must be also taken into account in deriving meaningful EHC $\mathbf{K}_{eff}$ values.

When talking about "solving" (2.1) in the conventional ontologic sense, we mean extracting from the algebra $K_{eff,ij}$-values at specified points so that the system of (2.1) is satisfied (e.g., Zhang, 2002). In a different spirit, the proposed ECA considers that the intellectual content of a mathematical solution lies in its ideas—not in the symbols themselves—and it seeks $K_{eff,ij}$-values that satisfy a set of epistemic principles ($\mathcal{T}$ and $\mathcal{A}$) subject to all the $\mathcal{G}$-KB and $\mathcal{S}$-KB available. In view of the total KB considered above, $\mathcal{K}$ $(= \mathcal{G} \cup \mathcal{S})$, we can write the stochastic moment equations (2.1) as the following set of equations in a matrix form:

$$\begin{bmatrix} \Lambda_{s_1}[\kappa\zeta_1] \\ \Lambda_{s_1}[\kappa\zeta_2] \\ \vdots \\ \Lambda_{s_n}[\kappa\zeta_1] \\ \Lambda_{s_n}[\kappa\zeta_2] \end{bmatrix} - \begin{bmatrix} \Lambda_{s_1}[\zeta_1] & \Lambda_{s_1}[\zeta_2] & 0 \\ 0 & \Lambda_{s_1}[\zeta_1] & \Lambda_{s_1}[\zeta_2] \\ \vdots & \vdots & \vdots \\ \Lambda_{s_n}[\zeta_1] & \Lambda_{s_n}[\zeta_2] & 0 \\ 0 & \Lambda_{s_n}[\zeta_1] & \Lambda_{s_n}[\zeta_2] \end{bmatrix} \begin{bmatrix} K_{eff,11} \\ K_{eff,12} \\ K_{eff,22} \end{bmatrix} = 0, \tag{2.2}$$

where $\Lambda_{s_q}[\cdot] = \int d\kappa d\zeta_1 d\zeta_2 f_{\mathcal{K}}[\cdot]$ is an operator at each point $\mathbf{s}_q$ $(q = 1, \ldots, n)$ of the 2-D porous domain; the κ and ζ_i denote $K(\mathbf{s})$ and $J_i(\mathbf{s})$ realizations, respectively; and the $f_{\mathcal{K}} = f_{\mathcal{K}}(\mu, \mathbf{g})$ is the integrated pdf, in the sense that it integrates knowledge about the random fields $K(\mathbf{s})$ and $J_i(\mathbf{s})$ $(i = 1, 2)$.

TABLE 2.1

β	$g_\beta(\mathbf{s}_q)$, $q = 1, \ldots, n$
0	$g_0(\mathbf{s}_q) = 1$ (normalization)
1	$g_1(\mathbf{s}_q) = \kappa$
2	$g_2(\mathbf{s}_q) = \zeta_1$
3	$g_3(\mathbf{s}_q) = \zeta_2$
4	$g_4(\mathbf{s}_q) = [\kappa - \overline{K(\mathbf{s}_q)}]^2$
5	$g_5(\mathbf{s}_q) = [\zeta_1 - \overline{J_1(\mathbf{s}_q)}]^2$
6	$g_6(\mathbf{s}_q) = [\zeta_2 - \overline{J_2(\mathbf{s}_q)}]^2$
7	$g_7(\mathbf{s}_q) = [\kappa - \overline{K(\mathbf{s}_q)}][\zeta_1 - \overline{J_1(\mathbf{s}_q)}]$
8	$g_8(\mathbf{s}_q) = [\kappa - \overline{K(\mathbf{s}_q)}][\zeta_2 - \overline{J_2(\mathbf{s}_q)}]$
9	$g_9(\mathbf{s}_q) = [\zeta_1 - \overline{J_1(\mathbf{s}_q)}][\zeta_2 - \overline{J_2(\mathbf{s}_q)}]$

The shape of $f_{\mathcal{K}}$ as well as the form of the vectors μ and $\mathbf{g}$ depend on the principles $(\mathcal{T}, \mathcal{A})$ and the KB $(\mathcal{G}, \mathcal{S})$ of the ECA methodology above (see introduction); e.g., an important case is the exponential form

$$f_{\mathcal{K}} \propto \exp(\mu^T \mathbf{g}), \tag{2.3}$$

which is a general result obtained if we assume a maximum expected information principle (in the Shannon sense) in stage 1, an $\mathcal{S}$-KB consisting of hard (exact) $K(\mathbf{s})$ and $J_i(\mathbf{s})$ data in stage 2, and a Bayesian principle in stage 3. In the 2-D upscaling situation of interest in this work, the $\mathbf{g} = \{g_\beta;\ \beta = 0, 1, \ldots, N\}$ is a vector of functions of the $K(s)$ and $J_i(\mathbf{s})$ fields. For example, in Table 2.1 the g_β functions involve several one-point and two-point spatial statistics so that $N = 9$. In particular, the functions g_1–g_6 are associated with one-point statistics of $K(\mathbf{s})$ and $J_i(\mathbf{s})$ across space, and the g_7–g_9 with the two-point statistics; the g_0 is a normalization constraint (assuring that a mathematically proper pdf $f_{\mathcal{K}}$ is derived). Note that, in principle, any high-order or multiple-point spatial statistics can be incorporated into the upscaling analysis above.

The vector $\mu = \{\mu_\beta\}$ consists of space-dependent coefficients μ_β associated with $\mathbf{g}$ at every point $\mathbf{s}$. In this work these coefficients were calculated as follows: (i) A set of initial values $\mu = \mu^{(0)}$ is selected. (ii) The Bayesian updating of the values of the vector μ is expressed as

$$f(\mu|\mathcal{S}) \propto f(\mathcal{S}|\mu) f(\mu), \tag{2.4}$$

where $\mathcal{S}$ denotes the $K(\mathbf{s})$, $J_i(\mathbf{s})$ data available, as mentioned above, $f(\mathcal{S}|\mu)$ is the likelihood function, and the prior pdf $f_{\mathcal{G}}(\mu)$ is assumed to have a known form (e.g., Gaussian). (iii) The initial $\mu = \mu^{(0)}$ values are updated using (2.4) and the Monte Carlo Markov chain (MCMC), which assures fast convergence to the final $\mu = \mu^{(f)}$ values. These values are substituted into (2.2) and (2.3), which are subsequently solved for the EHC components, $K_{eff,ij}$. Numerical solution of (2.2) at $\mathbf{s}_q$ ($q = 1, \ldots, n$) can be derived by means of a regression technique using the least square criterion. In particular, the regression technique generates $\mathbf{K}_{eff}$ values so that the left-hand side of (2.2) is as close to zero as possible, in the least square sense, at every point $\mathbf{s}_q$ in the porous domain (see, also, Appendix A).

In the next section we discuss a few numerical experiments in an effort to gain insight regarding the performance of the proposed upscaling technique in the case of flow in 2-D bounded porous domains. The ECA is formulated in a way that can reproduce the results obtained by well-established techniques, which are its limiting cases (this property is sometimes called nesting).

3. Numerical experiences.

3.1. Experiment 1. We consider the simple case of uniform flow in a 2-D spatial domain A with an area of 12.8×12.8 units^2; Dirichlet boundary conditions (BC) are assumed on all sides of A; and the distribution of the hydraulic head $H(\mathbf{s})$ values at the boundaries are shown in Figure 1a. Hydraulic head is related to hydraulic gradient $J_i(\mathbf{s})$ by $J_i(\mathbf{s}) = -\partial H(\mathbf{s})/\partial s_i$ $(i = 1, 2)$. A hydraulic conductivity random field $K(\mathbf{s})$ is assumed to be lognormally distributed and exhibits a homogenous/isotropic spatial variation characterized by an exponential covariance model with mean $\overline{\log K} = 1$ unit, variance $\sigma^2_{\log K} = 0.1$ unit^2, and correlation range (length) $\epsilon_{\log K} = 0.8$ units. The above constitute part of the $\mathcal{G}$-KB of the porous media flow situation under consideration. Log-conductivity realizations were generated at $n = 50$ points $\mathbf{s}_q = (s_{q1}, s_{q2})$, $q = 1, \ldots, 50$, using the fast Fourier transform technique of Ruan and McLaughlin (1998). One such realization is plotted in Figure 1b, and then used to obtain hydraulic head values at the 50 points (Figure 1c) by means of a code based on the finite difference technique for solving saturated 2-D flow equations discussed in Wang and Anderson (1982). Using the K and H values at the 50 points as the $\mathcal{S}$-KB, the EHC values were derived by the proposed ECA upscaling technique as follows:

$$\mathbf{K}_{eff} = [K_{eff,11}, K_{eff,12} = K_{eff,21}, K_{eff,22}]^T = [2.83, 0.22, 2.53]^T \tag{3.1}$$

for the entire (bounded) domain A. Note that in a bounded domain the EHC $\mathbf{K}_{eff}$ values generally depend on the distance from the boundaries, although for uniform flow this dependency often dies out within a few correlation lengths from the boundaries. More specifically, the correlation length is defined as $\lambda = \int_0^\infty d\kappa \rho_{\log K}(\kappa)$, where $\rho_{\log K}$ is the correlation function of $\log K$. The λ assesses spatial dependence between hydraulic conductivity values. In this simulation example, the random field is exponentially correlated, in which case the correlation between two points dies out at a distance equal to 4λ (see Figure 2). Note that a similar conclusion concerning the effects of certain boundaries on EHC was presented in Paleologos, Neuman, and Tartakovsky (1996).

3.2. Experiment 2. Assuming a lognormal and statistically isotropic 2-D conductivity field in an unbounded (infinite) 2-D domain, a well-known upscaling result (e.g., Zhang, 2002) leads to the following EHC values:

$$\mathbf{K}_g = [K_g, 0, K_g]^T, \tag{3.2}$$

where K_g is the geometric mean of the $K(\mathbf{s})$ field. Despite certain differences in the underlying assumptions (e.g., bounded vs. unbounded domains), an attempt was made to compare the $\mathbf{K}_{eff}$ values obtained by the proposed upscaling technique with the $\mathbf{K}_g$ result of (3.2). Naturally, such an attempt should require an adequate simulation of the unboundedness condition of the $\mathbf{K}_g$ result, at least approximately. More specifically, in Figure 3 we plot the $K_{eff,11}$ and $K_{eff,22}$ values obtained by the proposed method assuming a series of 2-D conductivity $K(\mathbf{s})$ realizations (the $K_{eff,12}$ values are very close to zero in every realization and, thus, they are not plotted). Two cases were considered in this figure:

(i) Boundary effects were included, in the sense that the $K_{eff,11}$ and $K_{eff,22}$ values were the outcomes of the upscaling technique in Experiment 1 above (K and H values were used at points $\mathbf{s}_q$ located throughout the bounded domain A in Figure 1a).

(ii) Approximately no boundary effects were assumed, in the sense that K and H

FIG. 1. (a) *Domain geometry and BC (hydraulic head distributions),* (b) *log-hydraulic conductivity realization, and* (c) *hydraulic head map.*

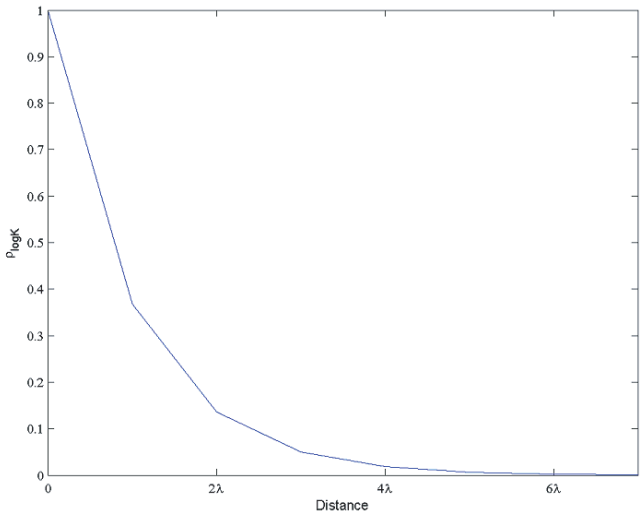

FIG. 2. *Conductivity correlation $\rho_{\log K}$ as a function of spatial distance (in λ units).*

values were used at points $\mathbf{s}_q$ located only within a small subdomain of A and away from its boundaries (in this way the boundary effects were somehow reduced and, hence, a better simulation of the unboundedness condition of the $\mathbf{K}_g$ result was achieved).

As should be expected, the $K_{eff,11}$ and $K_{eff,22}$ values differ for cases (i) and (ii) above. Note that the $K_{eff,11}$ and $K_{eff,22}$ values obtained in case (ii) are, in general, closer to the $\mathbf{K}_g$ values than the $K_{eff,11}$ and $K_{eff,22}$ values of case (i).

3.3. Experiment 3. Some more numerical tests concerning the (approximately) unbounded case (ii) of Experiment 2 above were considered here. More specifically, in Figure 4 we plot the $\mathbf{K}_{eff}$ values as a function of the $\log K$ variance $\sigma^2_{\log K}$. The calculated $K_{eff,11}$ and $K_{eff,22}$ values differ from K_g (since the assumptions of the unbounded K_g case do not exactly apply in the specific experimental setup considered here). Generally, the $K_{eff,11}$ and $K_{eff,22}$ values seem to follow the K_g variation, whereas the $K_{eff,12}$ values fluctuate around zero. Notice that as the $\sigma^2_{\log K}$ increases, the $K_{eff,11}$, $K_{eff,22}$ show larger fluctuations around K_g and the $K_{eff,12}$ larger fluctuations around zero. We subsequently plot the $\mathbf{K}_{eff}$ as a function of $\epsilon_{\log K}$ (Figure 5). For the specific 2-D situation, the calculated $\mathbf{K}_{eff}$ values are very close to the K_g values for $\epsilon_{\log K} < 1$; the $\mathbf{K}_{eff}$ values fluctuate considerably around the K_g values for larger $\epsilon_{\log K}$ values (which may be due to the small size of the domain considered). If the $\epsilon_{\log K}$ is too large, the EHC calculation will seriously depend on the locations from the boundaries. Furthermore, as the $\epsilon_{\log K}$ increases considerably, the EHC field is no longer isotropic ($K_{eff,11}$ exhibits a decreasing trend and $K_{eff,22}$ an increasing trend in Figure 5a). In Figure 6 we plot the $\mathbf{K}_{eff}$ components vs. the number n of points considered within the domain A. As might have been expected, after a certain number, $n = n^*$, further increasing the number n has no significant effect on the magnitude of the fluctuations of the EHC values around the values of the $\mathbf{K}_g$ result.

Several other cases can be handled by the proposed upscaling methodology. For

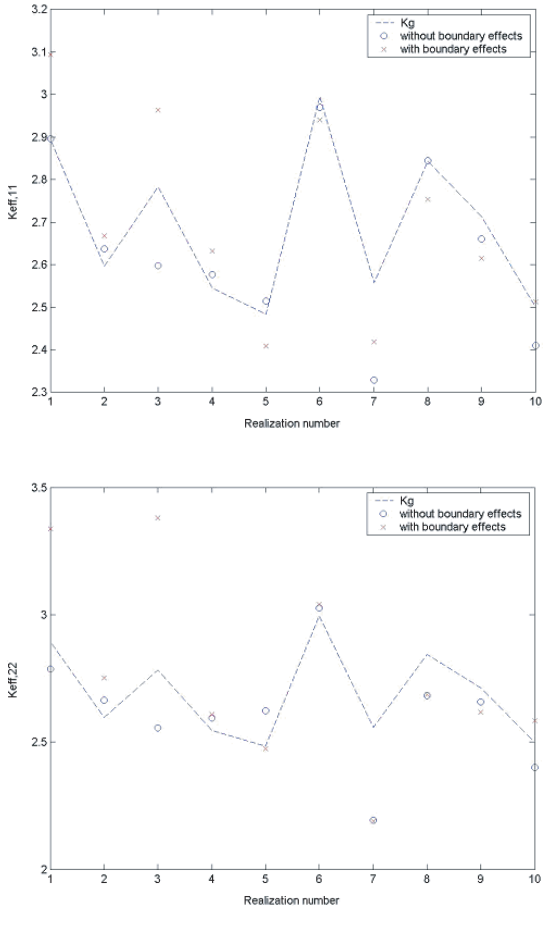

FIG. 3. *Realization number vs.* (a) *calculated* $K_{eff,11}$*, and* (b) *calculated* $K_{eff,22}$*; with boundary effects and without boundary effects. The corresponding* $\mathbf{K}_g$ *result is shown as a dashed line for comparison.*

illustration purposes, another numerical experiment with a different feature (pumping well) from the ones above is investigated next.

3.4. Experiment 4. In this experiment, the same arrangement as in Experiment 1 was considered with regards to the 2-D spatial domain A, the BC, and the hydraulic conductivity random field characteristics. However, in the present case a pumping well is assumed in the center of the domain A with a pumping rate of 100 units/time. Under these conditions, in Figure 7 we plot the log-conductivity field ($K_g = 2.73$) and the corresponding hydraulic head map. In this case, the calculated EHC components were found by the proposed upscaling technique, as follows: $\mathbf{K}_{eff} = [K_{eff,11}, K_{eff,12}, K_{eff,22}]^T = [2.87, 0.20, 2.83]^T$. We would like to conclude by noticing that a variety of different flow situations, BC, domain geometries, etc. can be studied by means of the upscaling technique. The discussion of some of these cases will be the topic of a future publication.

4. Summary. In this short paper, a new epistemic cognition approach was used to formulate and solve a bounded 2-D porous media upscaling problem. An ECA generates mind-based mathematical solutions of the upscaling problem, which do not rely solely on symbolic logic and form manipulations; the cognitive processes involved in the creation and conceptualization of the mathematical solutions are also considered. A systematic stochastic upscaling framework was presented and practical implementation issues were considered. Numerical experiments were discussed involving effective conductivities in 2-D domains, the effects of important flow parameters in the upscaling solution were examined, and comparisons were made with the results of previous ontologic upscaling solutions. Note that, in addition to dealing with new and more general porous media upscaling situations, the proposed approach can reproduce some well-known results, a fact that further demonstrates the

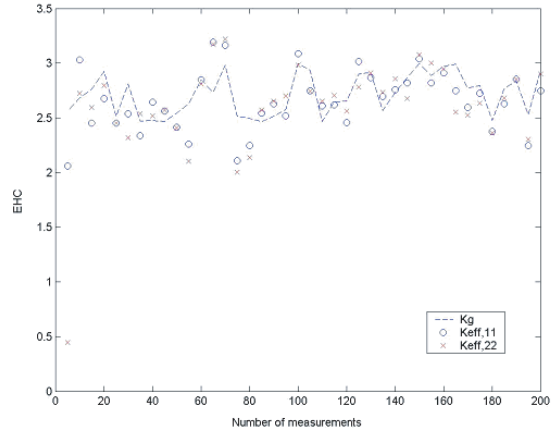
power of the ECA approach. By way of a summary, the ECA-based upscaling results obtained so far are promising, in which case further theoretical and application issues concerning the proposed upscaling technique will be the subject of future research.

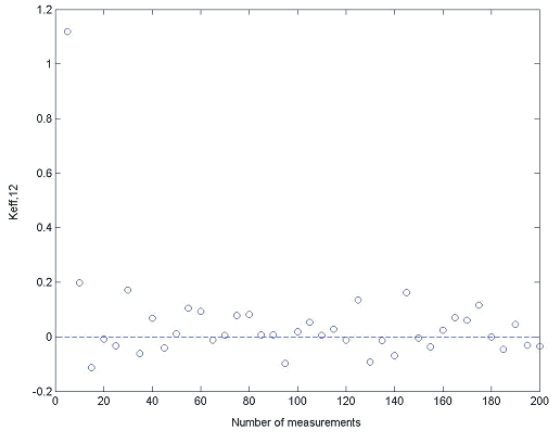
Appendix A.

A.1. The regression technique produces an EHC solution that satisfies (2.2) in the least square sense, at every point of the porous domain. The so-derived solution of (2.2) will have the form

$$\mathbf{K}_{eff} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{Y}, \tag{A.1}$$



(a)



(b)

FIG. 6. *Number n of points vs.* (a) *calculated* $K_{eff,ii}$ $(i = 1, 2)$*, and* (b) *calculated* $K_{eff,12}$*; the corresponding* $\mathbf{K}_g$ *result is shown as a dashed line for comparison.*

where

$$\mathbf{Y} = \begin{bmatrix} \Lambda_{s_1}[\kappa\zeta_1] \\ \Lambda_{s_1}[\kappa\zeta_2] \\ \vdots \\ \Lambda_{s_n}[\kappa\zeta_1] \\ \Lambda_{s_n}[\kappa\zeta_2] \end{bmatrix}, \quad \mathbf{X} = \begin{bmatrix} \Lambda_{s_1}[\zeta_1] & \Lambda_{s_1}[\zeta_2] & 0 \\ 0 & \Lambda_{s_1}[\zeta_1] & \Lambda_{s_1}[\zeta_2] \\ \vdots & \vdots & \vdots \\ \Lambda_{s_n}[\zeta_1] & \Lambda_{s_n}[\zeta_2] & 0 \\ 0 & \Lambda_{s_n}[\zeta_1] & \Lambda_{s_n}[\zeta_2] \end{bmatrix}, \text{ and } \mathbf{K}_{eff} = \begin{bmatrix} K_{eff,11} \\ K_{eff,12} \\ K_{eff,22} \end{bmatrix}.$$

Since the form (A.1) may involve numerical instabilities, it is recommended to reduce it by applying the QR decomposition on the matrix $\mathbf{X}$. The regression technique has been used in a variety of problems (see, e.g., White and Horne, 1987; Wen and Gomez-Hernandez, 1996).

A.2. Note that one set of EHC values is obtained from (2.2) or (A.1) that represents the EHC of the entire field. If, on the other hand, the EHC $\mathbf{K}_{eff}$ values at every point $\mathbf{s}_q$ $(q = 1, \ldots, n)$ within the porous domain are sought, the easiest way to

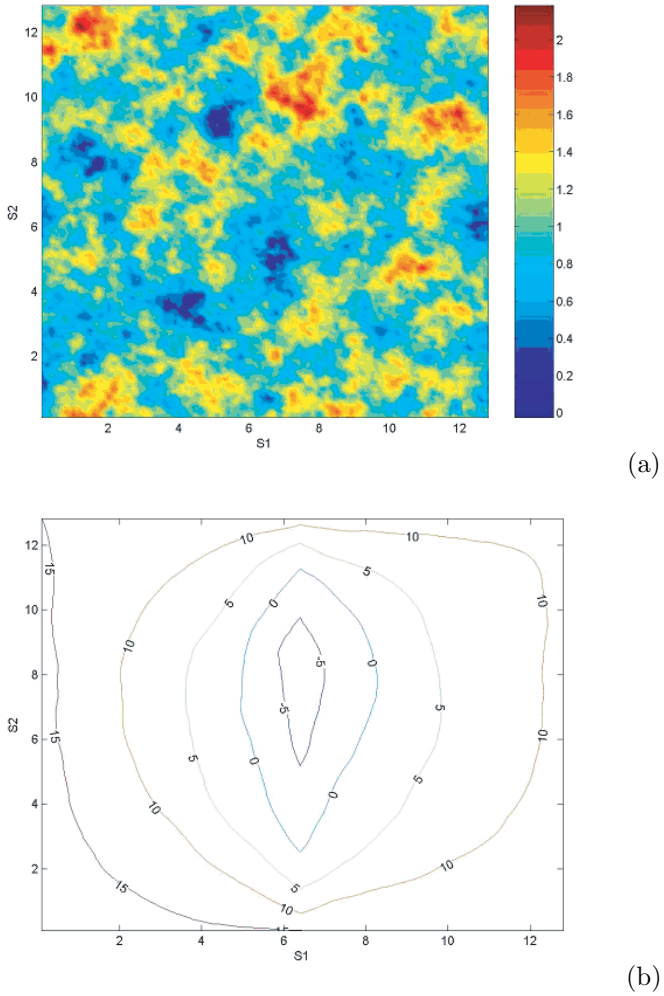


FIG. 7. (a) *Log-hydraulic conductivity realization; and* (b) *hydraulic head map.*

do this is to impose a constraint on (2.2); e.g., by solving (2.2) with the constraint

$$\text{(A.2)} \qquad \begin{cases} \Lambda_{\mathbf{s}_q}[K_{eff,11}\zeta_1 + K_{eff,12}\zeta_2 - \kappa\zeta_1] = 0, \\ \Lambda_{\mathbf{s}_q}[K_{eff,21}\zeta_1 + K_{eff,22}\zeta_2 - \kappa\zeta_2] = 0 \end{cases}$$

at every point $\mathbf{s}_q$, the resulting EHC values will be the local EHC values, $K_{eff,ij}(\mathbf{s}_q)$, at each point $\mathbf{s}_q$. In this case, if a single EHC value for the entire domain A is needed, one should calculate the arithmetic mean of the EHC over all n points, i.e., $\overline{K_{eff,ij}} = n^{-1}\sum_{q=1}^{n} K_{eff,ij}(\mathbf{s}_q)$. Assuming a homogeneous conductivity field $K(\mathbf{s})$, the arithmetic mean $\overline{K_{eff,ij}}$ and the previously obtained solution $K_{eff,ij}$ of (2.2) should be very close to each other.

Acknowledgments. The authors would like to thank the two anonymous referees for their valuable comments and suggestions.

A MIXTURE THEORY FOR THE GENESIS OF RESIDUAL STRESSES IN GROWING TISSUES II: SOLUTIONS TO THE BIPHASIC EQUATIONS FOR A MULTICELL SPHEROID*

ROBYN P. ARAUJO† AND D. L. SEAN MCELWAIN†

Abstract. This is the second paper in the series *A Mixture Theory for the Genesis of Residual Stresses in Growing Tissues*. While the first paper in the series elaborated a general formulation for such a theory, the present paper develops a simple biphasic model of residual stress evolution in a growing multicell spheroid comprising a linear-elastic cellular phase and an inviscid interstitial fluid. Both isotropic and anisotropic growth are considered in this study, highlighting the necessity to incorporate stress relaxation in order to predict an evolution of stresses over a period of growth.

The solutions to the biphasic equations are juxtaposed with the corresponding solutions to the single phase equations, illuminating the approximate nature of the single phase formulation for growing tissues. Moreover, the analysis demonstrates the significance of both interphase drag and the stress-relaxation characteristics of the solid phase in distinguishing between the single phase and multiphase paradigms.

Key words. multicell spheroid, poroelasticity, residual stresses, isotropic growth, anisotropic growth, diffusion, linear elasticity, biomechanics, constitutive equations, porous media

1. Introduction.

The genesis of growth-induced tissue stresses is an important consideration in the study of tumor growth. The experimental studies by Helmlinger et al. [15] on the growth of multicell tumor spheroids in agarose gels, for example, have demonstrated that "solid stress controls tumour growth at both the macroscopic and cellular levels, and thus influences tumour progression and delivery of therapeutic agents." Indeed, an increasing gel stiffness gave rise to smaller equilibrium-size spheroids, in addition to decreasing percentages of proliferating and apoptotic cells and increasing cellular densities. Later experiments by Koike et al. [20] illustrated that solid stress can facilitate the formation of spheroids in cell lines that do not form spheroids in free suspension, in addition to inhibiting their growth. Relieving this stress contributed to a loss of spheroid integrity. Furthermore, the experiments suggested that solid stress increases the synthesis of the extracellular matrix macromolecule, hyaluronan, by tumor cells.

While these two noteworthy experiments varied solid stress by changing the external hydrostatic pressure applied to the tumor spheroids at their outer boundaries, it is important to recognize that any *residual* stresses generated *within* the tumor either add to or relieve these externally applied stresses to increase or decrease the local state of stress. For this reason, an understanding of the evolution of residual stresses in growing tumors is of crucial importance.

Nevertheless, very few mathematical models of residual stress evolution in growing tissues have been proposed. Since residual stresses arise from incompatible growth, a mathematical model of such a phenomenon must consider the tissue's solid charac-

†School of Mathematical Sciences, Queensland University of Technology, Brisbane, Australia (s.mcelwain@qut.edu.au).

teristics via either an elastic or a viscoelastic constitutive law. Significantly, the vast majority of mechanical models of tumor growth employ fluid constitutive laws [5] which either incorporate [9, 11] or neglect [10, 24, 22] viscosity.

The first model to consider an evolution of residual stresses over a period of growth was that proposed by Jones et al. [16], who considered nutrient-regulated isotropic growth of a linear-elastic tissue—a model which highlighted the necessity to incorporate stress relaxation in the tissue's constitutive law in order to maintain boundedness of the solutions. The two models of tumor residual stress evolution proposed since that time have incorporated stress relaxation by various means—MacArthur and Please [21] by viscoelasticity and Araujo and McElwain [6] by anisotropic growth.

Nevertheless, all three mathematical models of residual stress evolution in growing tissues [6, 16, 21] are single phase models. The single phase approach consists of incorporating a source term in the balance of mass and a growth-expansion term in the constitutive equation, so that tissue mass is "created" in regions of cell proliferation and "destroyed" in regions of cell death. While this simple approach represents an excellent tool for studying the effects of the spatial nonuniformity of the growth process and is well suited to incorporating phenomenological relationships between growth and factors such as nutrient concentration and stress-modulated cell proliferation, it must be conceded that the behavior of any extracellular phases, such as the interstitial fluid, cannot be studied using this technique. In addition, a more serious shortcoming of this approach lies in the fact that the "Darcy-like" drag terms are neglected from the equilibrium equation, giving rise to an approximate form of the linear momentum equation which may not be valid in all situations.

The present paper is the second in a series of papers which studies the evolution of residual stresses using multiphase mechanics. The preceding paper in this series [1] (hereafter referred to as "Paper 1") presented a general method of deducing constitutive equations for multiphase materials which undergo a combination of continuous volumetric expansion and interphase mass exchange—a combination which reflects the process of biological growth. In this second paper, the simplest set of multiphase equations which allow residual stresses to develop—the biphasic equations for a linear elastic solid and an inviscid fluid—are solved in spherical polar coordinates in order to model the growth-induced stresses in a multicell spheroid.

Following the framework presented in Paper 1, a number of simplifying assumptions are made—constant volume fractions, intrinsically incompressible phases with equal densities, and a linear-elastic solid phase (regularized by anisotropic growth) with an inviscid fluid phase. While the assumption of constant volume fractions precludes a study of necrosis formation due to the comparatively high fluid content in such regions, the study of nonnecrotic tumors is not without basis. The experiments of Sutherland and Durand [27] demonstrated that multicell spheroids could reach a dormant size without central necrosis, suggesting an alternative cell loss mechanism in these tumors. It was the work of Kerr [18] and Kerr, Wyllie, and Currie [19] which demonstrated that apoptosis can always be detected in malignant neoplasms. The mathematical model by McElwain and Morris [23], which was proposed in response to these important experimental findings, was the first to study a tumor's arrival at a dormant state by incorporating apoptosis as a cell loss mechanism and is an antecedent to much of the subsequent mathematical literature relating to tumor development. It is the purpose of this paper to compare the solutions to these biphasic equations with their single phase counterparts, demonstrating the approximate nature of the single phase formulation for the stresses within the solid phase and illustrating the behavior of the interstitial fluid.

In section 2, the modelling equations underpinning the tissue's growth profile and the associated stress development are presented, with the solution procedure for this suite of equations being given in section 2.2. Numerical solutions are then presented in section 3 and are discussed in section 4. Section 5 presents some concluding remarks and outlines various avenues for future work in this important area of solid tumor growth research.

2. The mathematical model. A spherically symmetric multicell spheroid surrounded by a nutrient-rich medium and consisting exclusively of proliferating/apoptotic cells (the solid phase, with volume fraction ϕ_s) and interstitial fluid (the fluid phase, with volume fraction $\phi_f = 1 - \phi_s$) is considered. Both phases are assumed to be intrinsically incompressible with density ρ on account of the high water content of both phases. Following Jones et al. [16] and Araujo and McElwain [6], it is assumed that the growth of the spheroid is dependent upon the concentration, c, of a key nutrient which is supplied from the well-stirred surrounding medium and diffuses inwards. Assuming the nutrient diffusion to be very rapid, with constant diffusion coefficient, D_c, and the consumption of oxygen to be proportional to the local nutrient concentration, with proportionality constant, m, the nutrient profile maintains a pseudosteady-state distribution which satisfies

$$D_c \boldsymbol{\nabla}^2 c - mc = 0. \tag{2.1}$$

Further, the rate of mass supply to the solid (cellular) phase, Γ_s, due to the uptake of interstitial fluid during cell proliferation and growth is assumed to be proportional to both the nutrient concentration and the cell density ($\phi_s \rho$). Central to the development of the biphasic equations presented in Paper 1 was the assumption that the volume fractions of the two phases were constants, thereby precluding a consideration of necrotic regions which are characterized by a significantly higher porosity than the "live" tumor regions. For this reason, cell death is assumed to occur by apoptosis alone, with the associated rate of mass conversion to the fluid phase assumed proportional to the cell density. Hence,

$$\Gamma_s = \alpha \phi_s \rho c - k \phi_s \rho, \tag{2.2}$$

where α and k are the rate constants associated with cell proliferation and cell death, respectively. Now the balance of mass becomes

$$\boldsymbol{\nabla} \cdot \mathbf{v}_s = \frac{\Gamma_s}{\phi_s \rho} = \alpha c - k, \tag{2.3}$$

where $\mathbf{v}_s$ is the velocity of the solid phase. Recall from Paper 1 that the constitutive equation for the solid phase in the most general case of anisotropic growth is given by

$$\frac{D^s \mathbf{E}_s}{Dt} = \boldsymbol{\nabla} \cdot \mathbf{v}_s \Omega + \frac{1}{2\mu} \left(\frac{D^s \boldsymbol{\sigma}_s}{Dt} - \frac{1}{3} \frac{D^s}{Dt} (\mathrm{tr} \boldsymbol{\sigma}_s) \mathbf{I} + \phi_s \frac{D^s P}{Dt} (3\boldsymbol{\Omega} - \mathbf{I}) \right), \tag{2.4}$$

where $\mathbf{E}_s$ is the infinitesimal strain tensor, $\boldsymbol{\sigma}_s$ is the Cauchy stress tensor, P is the hydrostatic pressure arising due to the intrinsic incompressibility of the phases, $\mathbf{I}$ is the identity tensor, and $\frac{D^s \mathbf{E}_s}{Dt}$ is the material derivative of the strain tensor. Note that the corotational (or Jaumann [8, 17]) derivative of the constitutive equation has reduced to the material derivative in this case because of the assumed spherical symmetry. Note also that (2.4) is a rearrangement of (8.24) in Paper 1 to make the strain tensor

the subject of the equation, rather than the stress tensor. In addition, the anisotropy tensor has the form

$$\mathbf{\Omega} = \begin{bmatrix} \gamma_r & 0 & 0 \\ 0 & \gamma_\theta & 0 \\ 0 & 0 & \gamma_\phi \end{bmatrix}, \tag{2.5}$$

where spherical symmetry requires that $\gamma_\theta = \gamma_\phi$. Thus,

$$\gamma_r = 1 - 2\gamma_\theta, \tag{2.6}$$

since the trace of the anisotropy tensor must be unity (see [2]). Araujo and McElwain [6] have shown that, in order to incorporate stress relaxation via anisotropic growth, the anisotropic strain multipliers, γ_r and γ_θ, must be functions of the difference between the radial and circumferential stress components, $\beta_s = \sigma_{sr} - \sigma_{s\theta}$. Furthermore, a different set of anisotropic multipliers should apply to the two separate growth processes of cell proliferation (represented by αc in (2.3)) and apoptotic cell death (represented by k in (2.3)) since volumetric expansion should occur preferentially in the direction of least compressive stress, while volumetric contraction should occur preferentially in the direction of greatest compressive stress. Thus, the constitutive equation (2.4) becomes

$$\frac{D^s\mathbf{E}_s}{Dt} = \alpha c\mathbf{\Omega}_\eta - k\mathbf{\Omega}_\zeta + \frac{1}{2\mu}\left(\frac{D^s\boldsymbol{\sigma}_s}{Dt} - \frac{1}{3}\frac{D^s}{Dt}(\mathrm{tr}\boldsymbol{\sigma}_s)\mathbf{I} + \phi_s\frac{D^sP}{Dt}(3\mathbf{\Omega}_p - \mathbf{I})\right), \tag{2.7}$$

where

$$\mathbf{\Omega}_\eta = \begin{bmatrix} \eta_r & 0 & 0 \\ 0 & \eta_\theta & 0 \\ 0 & 0 & \eta_\phi \end{bmatrix} \tag{2.8}$$

represents the anisotropy tensor for the process of cell proliferation, and

$$\mathbf{\Omega}_\zeta = \begin{bmatrix} \zeta_r & 0 & 0 \\ 0 & \zeta_\theta & 0 \\ 0 & 0 & \zeta_\phi \end{bmatrix} \tag{2.9}$$

represents the anisotropy tensor for the process of cell death. Moreover, since P is a *hydrostatic pressure* acting on the mixture as a whole as a result of the intrinsic incompressibility of the phases, which is distributed to each phase by its volume fraction, the anisotropy tensor associated with its convected time derivative, $\mathbf{\Omega}_p$, should assume the isotropic value of

$$\mathbf{\Omega}_p = \begin{bmatrix} \frac{1}{3} & 0 & 0 \\ 0 & \frac{1}{3} & 0 \\ 0 & 0 & \frac{1}{3} \end{bmatrix}. \tag{2.10}$$

Following earlier work [6], the forms to be taken for these anisotropic strain multipliers in the present paper will be

$$\eta_r = \frac{1}{2} + \frac{1}{2}\left(\lambda\beta_s + \tanh^{-1}\left(-\frac{1}{3}\right)\right) \tag{2.11}$$

and

$$\zeta_r = \frac{1}{2} - \frac{1}{2}\left(\lambda\beta_s + \tanh^{-1}\left(\frac{1}{3}\right)\right). \tag{2.12}$$

These relations, depicted in Figure 1, allow the multipliers to adopt their isotropic values of $\frac{1}{3}$ when $\beta_s = \sigma_{sr} - \sigma_{s\theta} = 0$, while asymptotically approaching their maximum and minimum values of unity and zero, respectively, as β_s becomes large. Moreover, the stress-relaxation parameter, λ, reflects how readily the anisotropic nature of the growth process responds to the prevailing stresses. (Note that by the convention adopted here, compressive stresses are *negative*.)

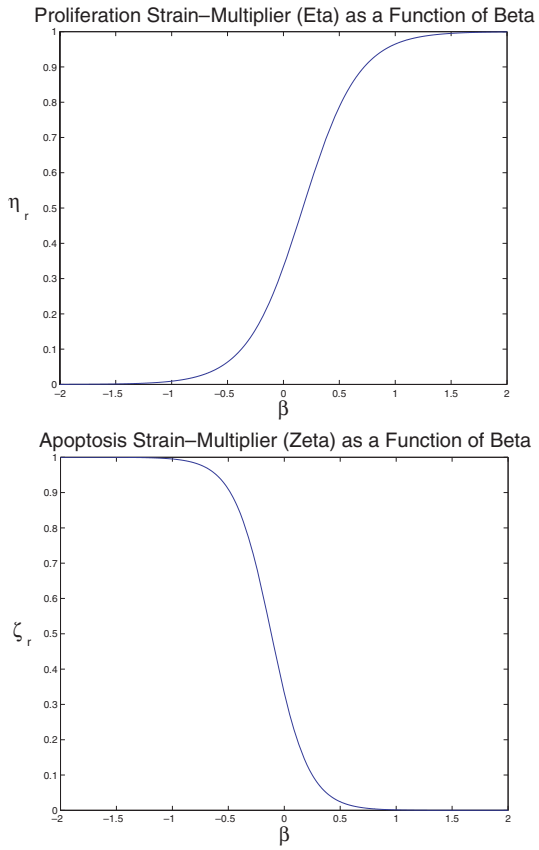

FIG. 1. *The dependence of the growth-strain multipliers on* β $(\lambda = 3)$.

Noting that, in spherical polar coordinates,

$$\frac{D^s\mathbf{E}_s}{Dt} = \begin{bmatrix} \frac{\partial v_s}{\partial r} & 0 & 0 \\ 0 & \frac{v_s}{r} & 0 \\ 0 & 0 & \frac{v_s}{r} \end{bmatrix}, \tag{2.13}$$

where v_s is the radial component of $\mathbf{v}_s$, the radial component of (2.7) is

$$\begin{aligned}\frac{\partial v_s}{\partial r} &= \alpha c\eta_r - k\zeta_r + \frac{1}{2\mu}\frac{D^s}{Dt}\left(\sigma_{sr} - \frac{1}{3}(\sigma_{sr} + 2\sigma_{s\theta})\right)\\ &= \alpha c\eta_r - k\zeta_r + \frac{1}{3\mu}\frac{D^s\beta_s}{Dt}.\end{aligned} \tag{2.14}$$

This equation may also be deduced from a consideration of the circumferential component of (2.7) by recalling that $\eta_\theta = \frac{1}{2}(1 - \eta_r)$. In the special case of isotropic growth, where $\eta_r = \zeta_r = \frac{1}{3}$, (2.14) reduces to

$$\frac{\partial v_s}{\partial r} = \frac{v_s}{r} + \frac{1}{2\mu}\frac{D^s\beta_s}{Dt}. \tag{2.15}$$

Combining (2.1) through (2.14) with the remaining biphasic equations presented in Paper 1 gives rise to the following suite of modelling equations:
Diffusion of nutrient:

$$D_c\boldsymbol{\nabla}^2 c - mc = 0. \tag{2.16}$$

Balance of mass:

$$\boldsymbol{\nabla}\cdot\mathbf{v}_s = \alpha c - k, \tag{2.17}$$

$$\rho\frac{D^s\phi_s}{Dt} = 0, \tag{2.18}$$

$$\boldsymbol{\nabla}\cdot(\phi_s\mathbf{v}_s + \phi_f\mathbf{v}_f) = 0. \tag{2.19}$$

Constitutive equations:

$$\frac{\partial v_s}{\partial r} = \alpha c\eta_r - k\zeta_r + \frac{1}{3\mu}\frac{D^s\beta_s}{Dt}, \tag{2.20}$$

where

$$\beta_s = \sigma_{sr} - \sigma_{s\theta}, \tag{2.21}$$

with

$$\eta_r = \frac{1}{2} + \frac{1}{2}\left(\lambda\beta_s + \tanh^{-1}\left(-\frac{1}{3}\right)\right)$$

and

$$\zeta_r = \frac{1}{2} - \frac{1}{2}\left(\lambda\beta_s + \tanh^{-1}\left(\frac{1}{3}\right)\right),$$

for anisotropic growth and $\eta_r = \zeta_r = \frac{1}{3}$ for isotropic growth,

$$\boldsymbol{\sigma}_f = -\phi_f P\mathbf{I}. \tag{2.22}$$

Momentum equations:

$$\boldsymbol{\nabla} \cdot \boldsymbol{\sigma}_s + \kappa(\mathbf{v}_f - \mathbf{v}_s) = 0, \tag{2.23}$$

$$\phi_f \boldsymbol{\nabla} P = -\kappa(\mathbf{v}_f - \mathbf{v}_s). \tag{2.24}$$

The momentum equations (2.23) and (2.24) may also be combined to give a single equation relating the stress tensor of the solid phase, $\boldsymbol{\sigma}_s$, to the hydrostatic pressure, P,

$$\boldsymbol{\nabla} \cdot \boldsymbol{\sigma}_s = \phi_f \boldsymbol{\nabla} P. \tag{2.25}$$

2.1. Nondimensionalization. The following dimensionless quantities are defined:

$$\hat{\mathbf{r}} = \frac{\mathbf{r}}{L}, \qquad \hat{t} = \frac{t}{T}, \qquad \hat{c} = \frac{c}{C_0}, \qquad \hat{\mathbf{v}} = \frac{\mathbf{v}T}{L}, \qquad \hat{\boldsymbol{\sigma}} = \frac{\boldsymbol{\sigma}}{2\mu}, \qquad \hat{P} = \frac{P}{2\mu},$$

where C_0 is the nutrient concentration at the tumor edge (assumed constant), with $L = \sqrt{\frac{D_c}{m}}$ and $T = \frac{1}{\alpha C_0}$. This transformation allows the modelling equations to be expressed in spherical polar coordinates in the following dimensionless forms:
Nutrient profile:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial c}{\partial r}\right) - c = 0. \tag{2.26}$$

Balance of mass:

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 v_s\right) = c - \epsilon, \tag{2.27}$$

$$\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \phi_s v_s + r^2 \phi_f v_f\right) = 0. \tag{2.28}$$

Constitutive equations:

$$\frac{\partial v_s}{\partial r} = c\eta_r - \epsilon\zeta_r + \frac{1}{3\mu}\frac{D^s \beta_s}{Dt}, \tag{2.29}$$

$$\sigma_{fr} = \sigma_{f\theta} = -\phi_f P. \tag{2.30}$$

Momentum equations:

$$\frac{\partial \sigma_{sr}}{\partial r} + \frac{2\beta_s}{r} + \chi\left(v_f - v_s\right) = 0, \tag{2.31}$$

$$\phi_f \frac{\partial P}{\partial r} = -\chi\left(v_f - v_s\right), \tag{2.32}$$

or

$$\frac{\partial}{\partial r}\left(\sigma_{sr} + \phi_f P\right) + \frac{2\beta_s}{r} = 0, \tag{2.33}$$

where the *hat* notation has been omitted for clarity, with $\epsilon = \frac{k}{\alpha C_0}$ and $\chi = \frac{\kappa L^2}{2\mu T}$. Thus, the parameter ϵ represents the rate of cell death as a proportion of the maximum possible growth rate. For a given diffusion length scale and tumor doubling time, the parameter χ gives a measure of the relative importance of interphase drag in comparison with the elasticity of the tissue.

The suite of equations (2.26) through (2.33) is now to be solved subject to the boundary conditions $v_s = 0$ and c finite at $r = 0$, and $\sigma_{fr} = \sigma_{f\theta} = P = 0$ and $c = 1$ at the tumor's outer boundary.

2.2. Solution procedure. Let $r = a(t)$ denote the position of the tumor boundary at time t, so that the tumor occupies the region $0 \leq r \leq a(t)$. Now, integrating (2.26) subject to the boundary conditions $c(a,t) = 1$ and finite c at $r = 0$ gives

$$c(r,t) = \frac{a \sinh r}{r \sinh a}. \tag{2.34}$$

Substituting (2.34) into (2.27) and integrating subject to the boundary condition $v_s = 0$ at $r = 0$ now gives

$$v_s(r,t) = \frac{a(r\cosh r - \sinh r)}{r^2 \sinh a} - \frac{\epsilon r}{3}. \tag{2.35}$$

Thus, the nutrient-regulated equilibrium size of the tumor is given by $a = a^*$, where

$$\coth a^* - \frac{1}{a^*} - \frac{\epsilon a^*}{3} = 0. \tag{2.36}$$

Now (2.28) may be integrated, noting that $v_f = v_s = 0$ at $r = 0$, to give

$$v_f = -\frac{\phi_s}{\phi_f} v_s = \frac{a\phi_s(\sinh r - r\cosh r)}{r^2 \phi_f \sinh a} + \frac{\phi_s \epsilon r}{3\phi_f}. \tag{2.37}$$

Substituting (2.35) and (2.37) into (2.32) gives

$$\frac{\partial P}{\partial r} = \chi \frac{v_s}{\phi_f^2} = \frac{\chi}{\phi_f^2}\left(\frac{a(r\cosh r - \sinh r)}{r^2 \sinh a} - \frac{\epsilon r}{3}\right), \tag{2.38}$$

which may be integrated subject to the boundary condition $P = 0$ at $r = a$ (i.e., scaling the fluid pressure in the medium surrounding the tumor to zero) to give

$$P = \frac{\chi}{\phi_f^2}\left(\frac{a \sinh r}{r \sinh a} - \frac{\epsilon}{6}\left(r^2 - a^2\right) - 1\right). \tag{2.39}$$

The hydrostatic pressure in the fluid, $\boldsymbol{\sigma}_f$, may now be determined from (2.22), which gives

$$\sigma_{fr} = \sigma_{f\theta} = \sigma_f = \frac{\chi}{\phi_f}\left(1 + \frac{\epsilon}{6}(r^2 - a^2) - \frac{a \sinh r}{r \sinh a}\right). \tag{2.40}$$

In order to proceed, (2.29) must now be solved numerically for $\beta_s = \sigma_{sr} - \sigma_{s\theta}$. In this paper, the integration is performed using the modified Lax–Wendroff scheme presented in [16] for isotropic growth and [6] for anisotropic growth. As noted by Araujo and McElwain [3], this modified scheme "is very useful for a growing domain since it consists of a fixed number of evenly-distributed moving gridpoints. Computing times are significantly reduced when compared with the method of characteristics, the latter method having the additional disadvantages of unequally-spaced gridpoints and the tendency to develop instabilities for solutions at large times." The interested reader is referred to [16] and [6] for the details of this numerical method.

Having determined β_s, (2.31) may then be integrated using a Runge–Kutta scheme (for example) to give the radial stress component in the solid phase, σ_{sr}, subject to the boundary condition $\sigma_{sr} = 0$ at $r = a$. The corresponding circumferential component, $\sigma_{s\theta}$, is then to be determined from the definition of β_s.

Note that residual stresses are those which exist in a solid body in the absence of, or in addition to, the stresses caused by external loads. The assumption of a zero hydrostatic pressure at the periphery of the tumor ($\sigma_r = P = 0$ at $r = a$ being the boundary conditions used to integrate (2.31) and (2.38)) for all time allows the model to emphasize the residual nature of any induced stresses, since they arise in the absence of any external loads.

3. Results. In the solutions to follow, the parameter ϵ will assume the value of 0.1, which implies a low cell death rate in comparison with the maximum possible cell proliferation rate. Jones et al. [16] explain that this assumption gives rise to a tumor structure in which the radius of the tumor boundary at equilibrium (when the processes of cell proliferation and cell death are in balance) is large in comparison with the diffusion length scale, $L = \sqrt{\frac{D_c}{m}}$. Indeed, the nutrient concentration is only significant in a region within a distance of L from the tumor surface, with the equilibrium tumor size being achieved by a large growth rate in the thin region near the tumor surface and a low death rate throughout the tumor. This tumor structure is most representative of experimentally observed multicell spheroids and avascular tumors [12, 13, 14, 18, 19]. Figure 2 depicts the solutions to (2.26), (2.27), and (2.28) based on this assumption.

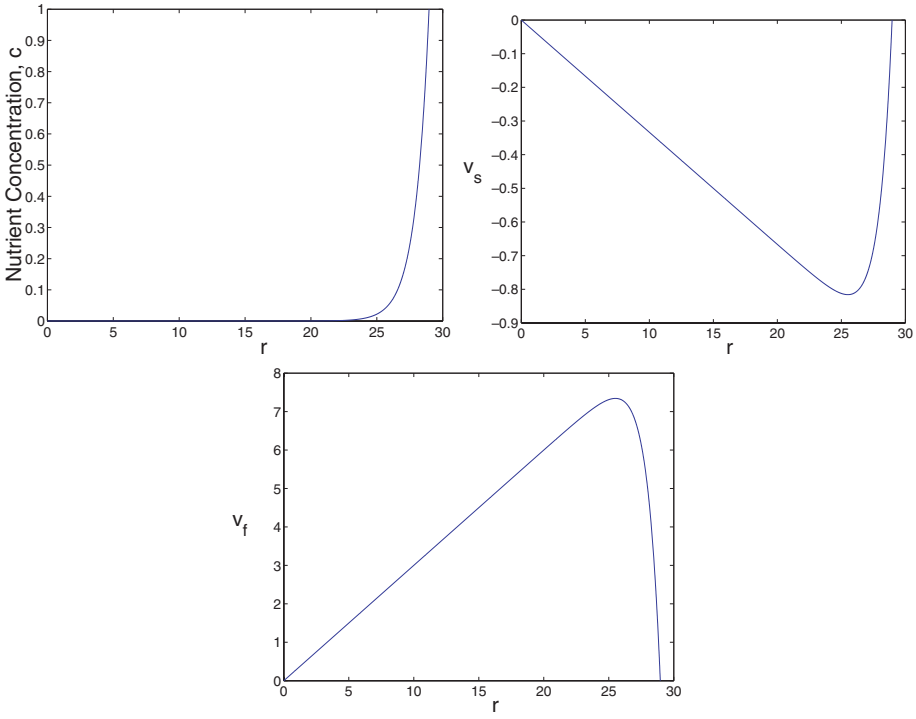

FIG. 2. *Distribution of nutrient, c, velocity profile for the cellular phase, v_s, and velocity profile for the interstitial fluid, v_f.* $\epsilon = 0.1$*;* $\phi_f = 0.1$.

Furthermore, to emphasize the development of growth-induced stresses for large times, most of the solutions for stresses depict the (admittedly artificial) situation in which the tumor begins stress-free at its nutrient-regulated equilibrium size, neglecting

the initial transient period required to attain this size. Figure 10 gives an example of the evolution of stresses in a tumor which begins stress-free at a size much smaller than the equilibrium size.

In addition to presenting the solutions of the biphasic equations developed in the present paper, Figures 3, 4, 7, 8, and 9 present the solutions of the single phase equations developed by Jones et al. [16] (in the case of isotropic growth) and Araujo and McElwain [6] (in the case of anisotropic growth) by way of comparison with the biphasic solutions. These single phase equations were summarized in Paper 1, in juxtaposition with the biphasic equations.

Note that, with the exception of Figure 10, the solutions for β_s are not shown since the difference between the radial and circumferential stress components in the solid phase is unaffected by the choice of single phase or multiphase frameworks.

3.1. Solutions to the stress equations with isotropic growth. Figures 3 and 4 show the solutions to the stress equations for isotropic growth, for which $\mathbf{\Omega}_\eta = \mathbf{\Omega}_\zeta = \frac{1}{3}\mathbf{I}$, or $\eta_r = \eta_\theta = \zeta_r = \zeta_\theta = \frac{1}{3}$, for ascending values of the interphase drag parameter, χ.

These solutions illustrate the problem with the combination of elasticity and isotropic growth—a combination which is unable to impart the crucial property of stress relaxation to the tissue's constitutive law and gives rise to singular behavior in the evolution of the stress profiles. Thus, although this combination is sufficient to give general information about the spatial variations in stresses, the elasticity must be regularized in order to predict the evolution of stresses over a period of growth. This may be accomplished by either incorporating a viscous term into the tissue's constitutive law, giving rise to a viscoelastic constitutive equation, or, as is the case here, by allowing the tissue to expand and contract anisotropically in response to the induced stress field. For anisotropic growth to regularize the elasticity of the tissue, expansion due to cell proliferation must occur in the direction of least compressive stress, while contraction due to cell death must occur in the direction of greatest compressive stress. In the context of spherical symmetry, these directional characteristics of the growth process are conferred by the anisotropy tensor which directs the expansion and contraction into the radial and circumferential principal directions. In this way, anisotropic growth imparts a *pseudoviscoelasticity* to growing tissues.

Nevertheless, these isotropic solutions enable comparisons to be made between the single phase and biphasic mathematical paradigms. As these results illustrate, a value as small as $\chi = 10^{-4}$ gives rise to stress profiles which differ only subtly from their single phase counterparts. By contrast, a larger value of $\chi = 10^{-1}$ affects the stress profiles quite dramatically.

Figures 5 and 6 present the distributions of the hydrostatic pressure, P, as well as the hydrostatic pressure in the fluid, σ_f. Note that these two pressures are unaffected by the choice of isotropic or anisotropic growth.

3.2. Solutions to the stress equations with anisotropic growth. Figures 7 through 9 show the solutions to the stress equations for anisotropic growth, for which $\mathbf{\Omega}_\eta$ and $\mathbf{\Omega}_\zeta$ are as defined by (2.8), (2.9), (2.11), and (2.12), for ascending values of the interphase drag parameter, χ.

These solutions illustrate the stress-relaxation properties of anisotropic growth, enabling steady-state stress profiles to prevail. With the exception of Figure 9, the "moderate" value of $\lambda = 10$ has been used for the stress relaxation parameter. A comparison of the results of the single phase and biphasic equations reveals that

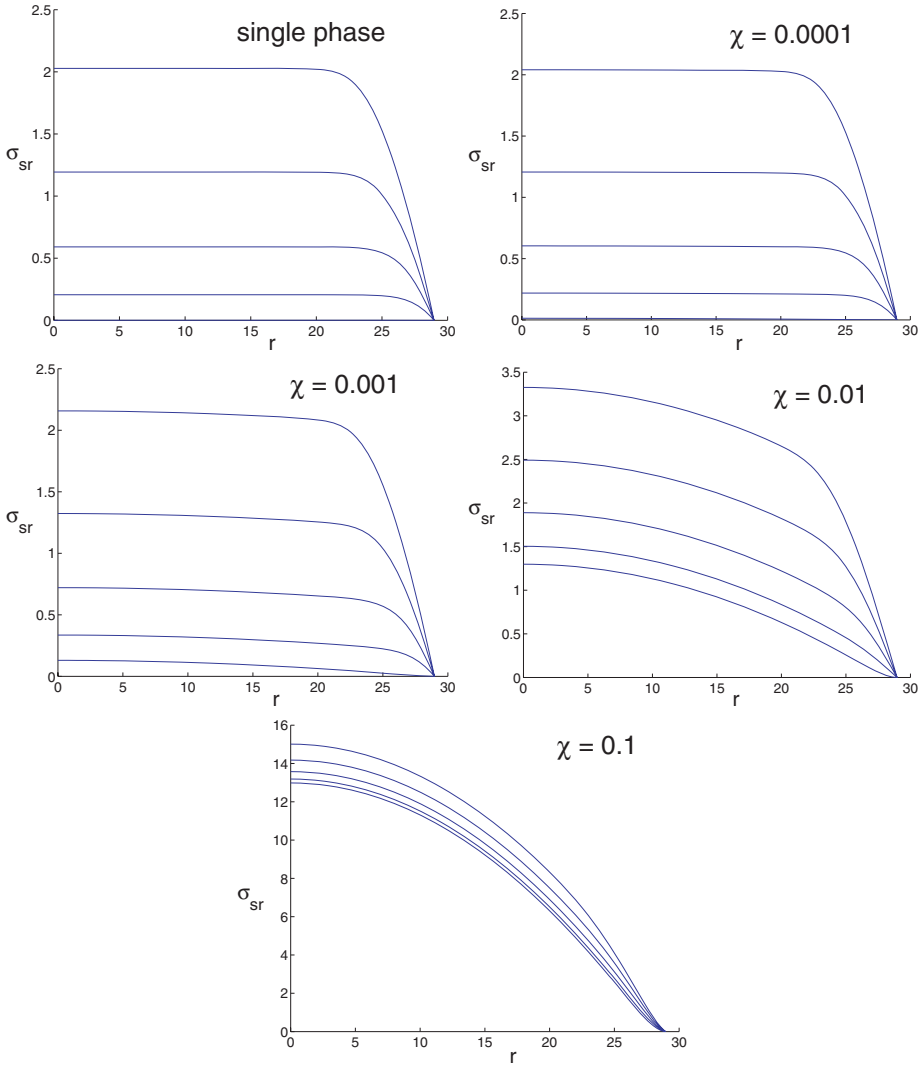

FIG. 3. *The distribution of radial stresses in the solid phase, σ_{sr}, for a single phase model, and for a biphasic model with $\chi = 0.0001, 0.001, 0.01, 0.1$ as labelled, for $t = 0$ to $t = 8$ in equal time increments. Growth is isotropic. The tumor is initially stress-free and at its nutrient-regulated equilibrium size ($a \backsim 29$), with $\epsilon = 0.1$. $\phi_f = 0.1$.*

even extremely small interphase drag, with $\chi = 10^{-4}$, gives rise to stress profiles which differ markedly from the single phase stress profiles. Figure 9 illustrates how this effect is accentuated by the larger stress-relaxation parameter of $\lambda = 100$. This intriguing result will be discussed in the next section. (It is also interesting to note that in Figures 7 and 8, when the comparatively large value of $\chi = 0.1$ has been used, the effect of introducing the second (fluid) phase is so pronounced that the evolution of solid stresses is almost imperceptible in comparison.)

4. Discussion. This paper illustrates the mechanical behavior of a spherically symmetric biphasic model of a growing multicell spheroid comprising a linear-elastic solid phase and an inviscid interstitial fluid phase. The growth process itself, which

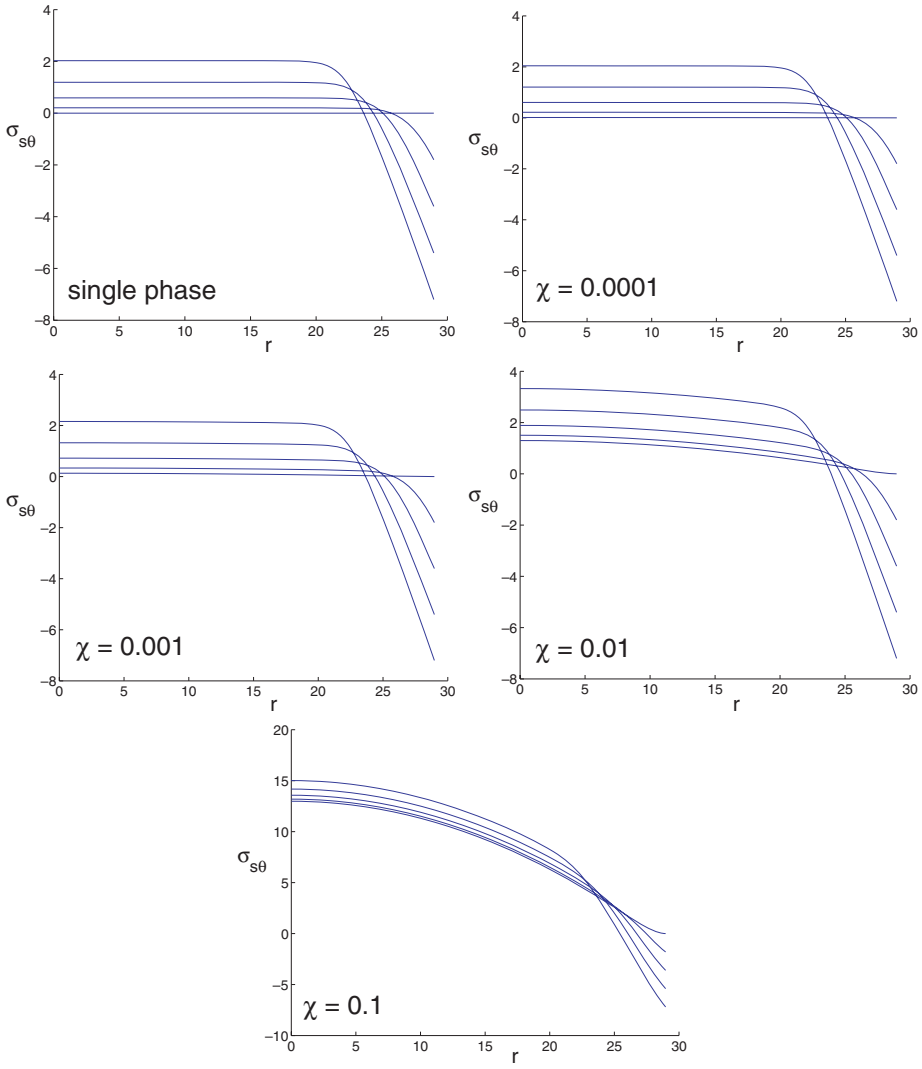

FIG. 4. *The distribution of circumferential stresses in the solid phase, $\sigma_{s\theta}$, for a single phase model, and for a biphasic model with $\chi = 0.001, 0.01, 0.1$ as labelled, for $t = 0$ to $t = 8$ in equal time increments. Growth is isotropic. The tumor is initially stress-free and at its nutrient-regulated equilibrium size ($a \backsim 29$), with $\epsilon = 0.1$. $\phi_f = 0.1$.*

may occur either isotropically or anisotropically, is regulated by an inwardly diffusing nutrient.

The solutions to the modelling equations give information about the distribution of nutrient concentration, c, within the tumor, the tumor's nutrient-regulated dormant radius, a^*, and the behavior of the individual phases—their movement (solid velocity, v_s, and fluid velocity, v_f) and their stress profiles (σ_f in the fluid phase, and σ_{sr} and $\sigma_{s\theta}$ for the radial and circumferential stress components, respectively, in the solid phase, as well as the hydrostatic pressure P acting on both phases). Of these quantities, several are independent of whether a single phase or multiphase modelling approach is taken—c, v_s, and a^*. Moreover, where a biphasic approach is adopted,

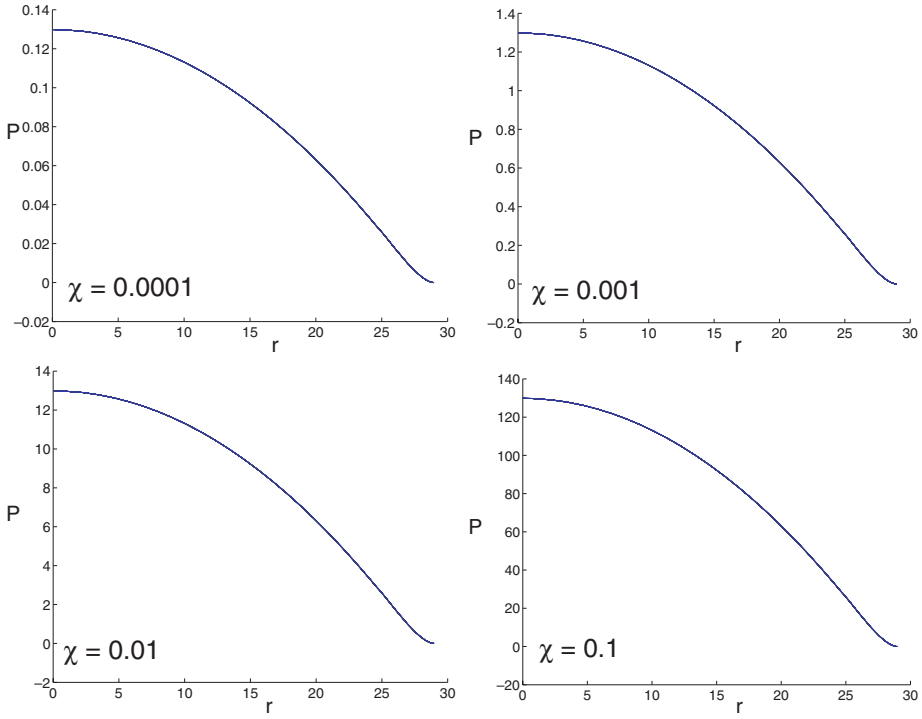

FIG. 5. *The distribution of the hydrostatic pressure acting on the mixture, P, for a biphasic model with $\chi = 0.001, 0.01, 0.1$ as labelled, for $t = 0$ to $t = 8$ in equal time increments. The tumor is initially stress-free and at its nutrient-regulated equilibrium size ($a \backsim 29$), with $\epsilon = 0.1$. $\phi_f = 0.1$.*

the variables associated with the fluid phase are unaffected by the choice of isotropic growth (which neglects stress relaxation) or anisotropic growth (which incorporates stress relaxation)—P, σ_f, and v_f.

The stresses in the solid phase, however, depend crucially on whether a single phase or a multiphase framework is employed. Comparing (2.25) and (2.33) with their single phase counterparts, $\boldsymbol{\nabla} \cdot \boldsymbol{\sigma}_s = \mathbf{0}$ and $\frac{\partial \sigma_r}{\partial r} + \frac{2\beta}{r} = 0$ (see Paper 1), gives some interesting insights into the distinction between the two mathematical paradigms. Whereas in the case of a spherically symmetric single phase solid the radial stress component (see (2.33)) is given by

$$\sigma_r = -\int_0^r \left(\frac{2\beta}{\hat{r}}\right) d\hat{r},$$

the multiphase momentum equation predicts a radial stress of

$$\sigma_{sr} = \phi_f P - \int_0^r \left(\frac{2\beta_s}{\hat{r}}\right) d\hat{r},$$

where β or β_s is determined from compatibility considerations via the constitutive equation (2.29). Thus, the two expressions for radial stress differ by the quantity $\phi_f P$, being the proportion of the hydrostatic pressure P distributed to the fluid phase. This pressure arises from the mechanical interactions between the two phases

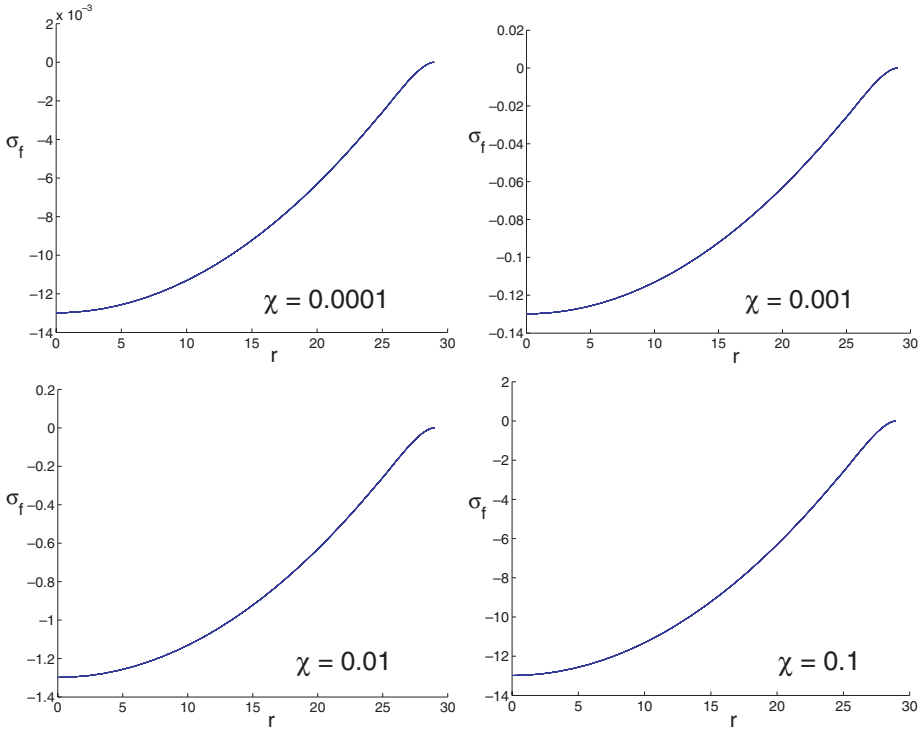

FIG. 6. *The distribution of the hydrostatic pressure in the fluid phase, σ_f, for a biphasic model with $\chi = 0.001, 0.01, 0.1$ as labelled, for $t = 0$ to $t = 8$ in equal time increments. The tumor is initially stress-free and at its nutrient-regulated equilibrium size ($a \backsim 29$), with $\epsilon = 0.1$. $\phi_f = 0.1$.*

and from (2.32) is given by

$$\phi_f P = -\chi \int_0^r (\mathbf{v}_f(\hat{r}) - \mathbf{v}_s(\hat{r}))\, d\hat{r}.$$

Therefore, since the circumferential stress component is given by $\sigma_{s\theta} = \sigma_{sr} + \beta_s$ from (2.21), *both* the circumferential and the radial stress components are augmented by the extra stress created by the relative motion between the phases. Note that this extra stress is directly proportional to the interphase drag parameter, χ.

Thus, in a multiphase model, solid stresses may be decomposed into two components—the temporally constant hydrostatic pressure,[1] $\phi_f P$, and a time-dependent component. Theoretically, if the processes of cell proliferation and cell death (apoptosis) were to cease, the hydrostatic component would vanish, leaving only the (previously) time-dependent component. The existence of the latter in the absence of any externally applied loads attests to its *residual* nature. Thus, the residual stresses in the solid phase are, of themselves, unaffected by the presence of additional phases; nevertheless, they do not occur in isolation but are augmented by a hydrostatic pressure through the presence of additional phases.

[1]Note that P is only constant with time once the tumor has reached its nutrient-regulated equilibrium size. When the tumor size is still evolving, the distribution of P is also evolving (see Figure 10).

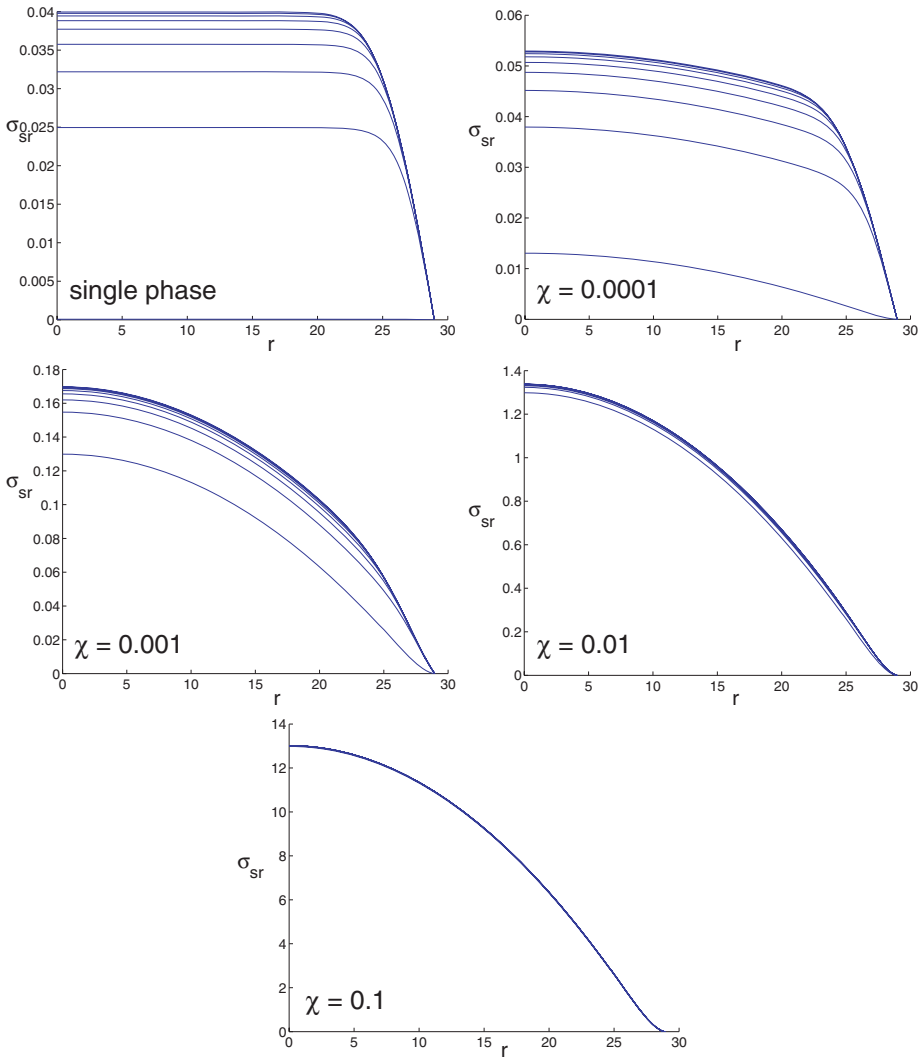

FIG. 7. *The distribution of radial stresses in the solid phase, σ_{sr}, for a single phase model, and for a biphasic model with $\chi = 0.0001, 0.001, 0.01, 0.1$ as labelled, for $t = 0$ to $t = 8$ in equal time increments. Growth is anisotropic with $\lambda = 10$. The tumor is initially stress-free and at its nutrient-regulated equilibrium size ($a \backsim 29$), with $\epsilon = 0.1$. $\phi_f = 0.1$.*

This study also demonstrates the important result that a consideration of multiple phases does nothing to alleviate the singularities associated with the combination of isotropic growth and an elastic constitutive law. Jones et al. [16] had supposed that this measure could resolve the problem, postulating that "in regions of the tumour where the number of live cells is low, the compensatory increase in the number of dead cells and extracellular water should prevent the stress tensor increasing indefinitely over time."

As one would intuitively expect, the magnitude of the interphase drag parameter, χ, strongly influences the extent to which the single phase and multiphase paradigms diverge, as reflected in Figures 3 through 8. In the case of isotropic growth, the

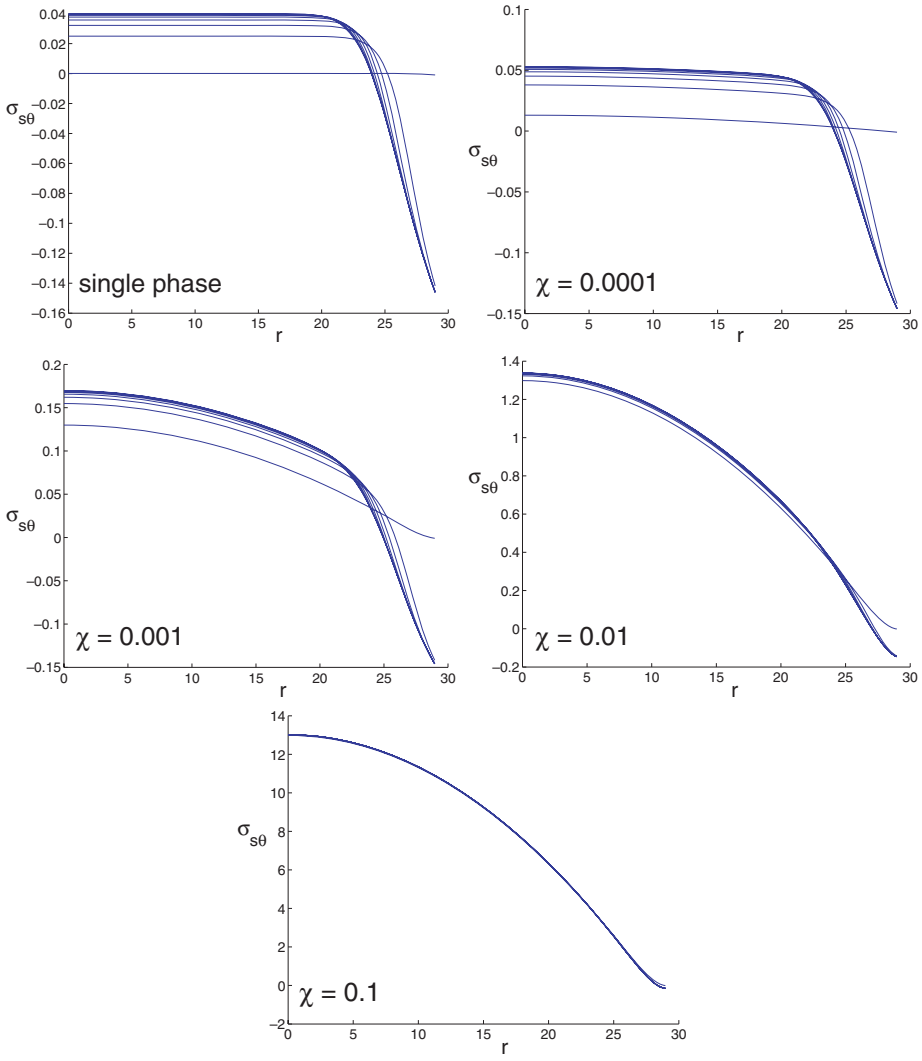

FIG. 8. *The distribution of circumferential stresses in the solid phase, $\sigma_{s\theta}$, for a single phase model, and for a biphasic model with $\chi = 0.0001, 0.001, 0.01, 0.1$ as labelled, for $t = 0$ to $t = 8$ in equal time increments. Growth is anisotropic with $\lambda = 10$. The tumor is initially stress-free and at its nutrient-regulated equilibrium size ($a \backsim 29$), with $\epsilon = 0.1$. $\phi_f = 0.1$.*

solutions are noticeably affected by the choice of modelling framework for $\chi > 0.01$, with $\chi > 0.1$ affecting the stress profiles quite dramatically. Interestingly, as noted in section 3.2, the stress profiles are much more sensitive to the choice of modelling framework when growth is anisotropic, where the biphasic results contrast with their single phase counterparts quite remarkably even with the minute value of $\chi = 0.0001$. This intriguing result may be understood by noting that, when growth is anisotropic, the evolution of residual stresses is gradually arrested in order to permit a steady-state stress profile at the tumor's nutrient-regulated dormant size. The greater the stress relaxation (corresponding to larger values of λ), the smaller are the steady-state stresses, and the shorter the time required to reach the steady-state profile. Therefore,

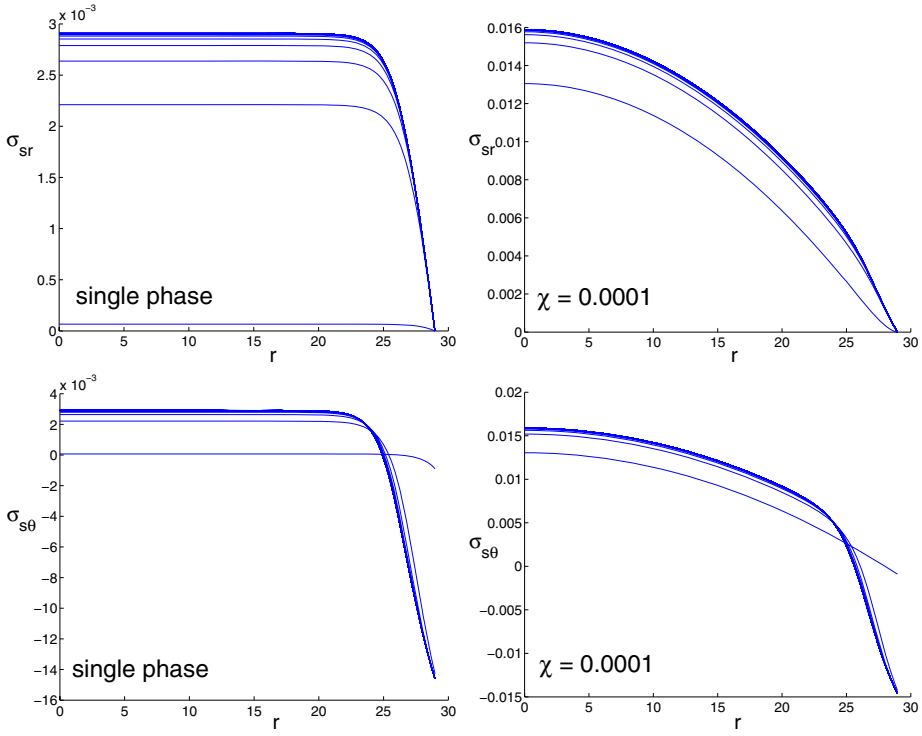

FIG. 9. *Radial stress distributions (top row) and circumferential stress distributions (bottom row) for a single phase model, and a biphasic model with* $\chi = 0.0001$*, as marked. Growth is anisotropic with* $\lambda = 100$*.* $t = 0$ *to* $t = 8$ *in equal time increments. The tumor is initially stress-free and at its nutrient-regulated equilibrium size (*$a \backsim 29$*), with* $\epsilon = 0.1$*.* $\phi_f = 0.1$*.*

the greater the stress relaxation, the more significant is the hydrostatic pressure, P, *in comparison with* the residual stresses. (This is to be compared with the single phase framework in which *only* residual stresses are induced.) As shown by (2.24) and illustrated in Figure 5, P is proportional to χ (all other things being equal), which implies that for a given value of χ, the difference between the stresses predicted by the single phase and multiphase models is more significant for a greater value of the stress-relaxation parameter.

Therefore, it is the combination of stress relaxation (a characteristic of the solid (cellular) phase, which may be associated with either anisotropic growth or viscoelasticity) and interphase drag (associated with the existence of multiple phases) which separates the single phase and multiphase approaches. *Both* properties must be considered in order to determine if single phase techniques give a reasonable approximation to the stresses in the solid phase. This is a most significant outcome of this study, given that stress-relaxation *must* occur in growing biological tissues. As demonstrated by Jones et al. [16] and by Figures 3 and 4 in the present paper, failure to incorporate this crucial property causes stresses to evolve indefinitely, eventually becoming infinite.

Thus, this study deracinates the assertion by Skalak [26] that volumetric growth of biological tissues is entirely analogous to thermal expansion—an analogy which lies at the very heart of the single phase paradigm.

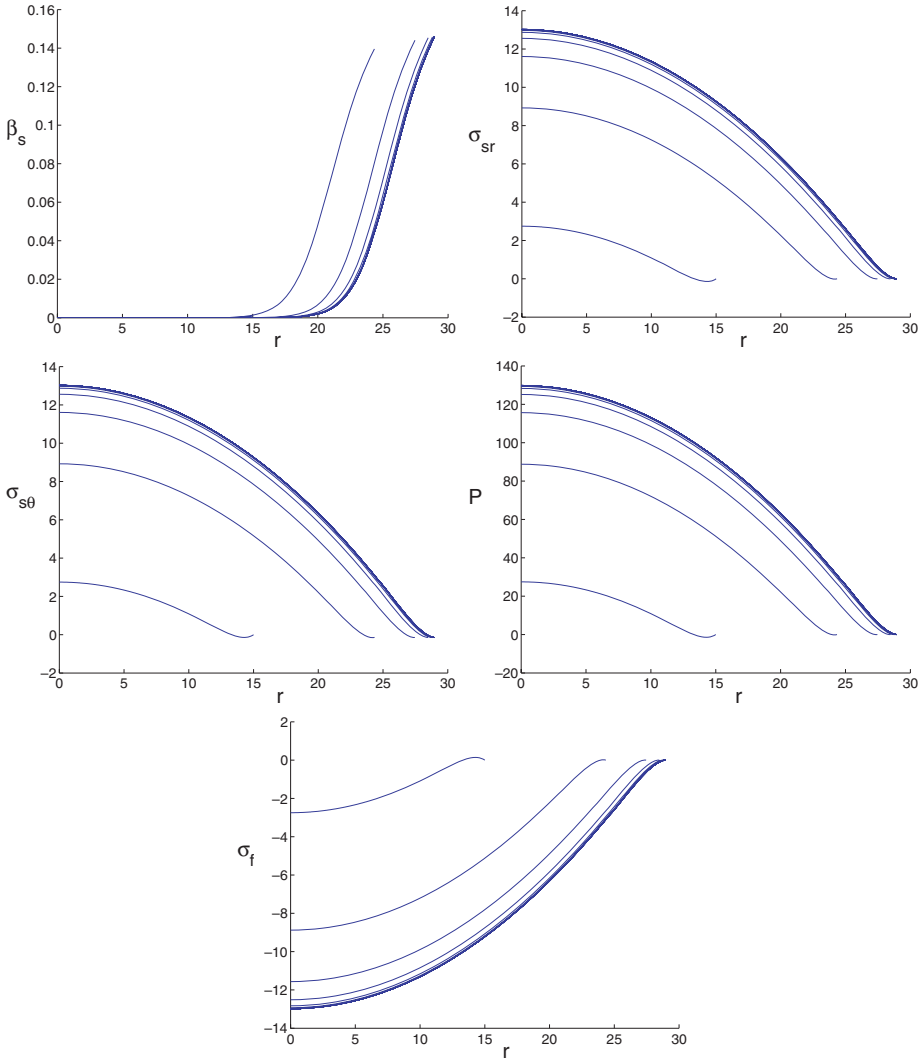

FIG. 10. *Stress distributions for a tumor which begins stress-free and much smaller than its nutrient-regulated equilibrium size,* $a = 15$*, for a biphasic model with* $\chi = 0.1$*. Here,* $t = 0$ *to* $t = 700$ *in time increments of* 35*. The tumor appears to have reached a steady state in both its size and its stress distributions by about* $t = 280$*.* $\phi_f = 0.1$*;* $\epsilon = 0.1$*.*

Caveat. As noted earlier, two distinctly different types of stresses contribute to the total stress in the solid phase—residual stresses, and a hydrostatic mixture stress, P, associated with the pressure in the fluid phase. However, it is essential to bear in mind that, unlike residual stresses, fluid stresses cannot sustain themselves. Therefore, if the growth process were sufficiently slow, the hydrostatic pressure, P, may dissipate. This would have two important implications for mathematical models of stresses in tumors:

1. Multiphase models of residual stresses with only one solid phase (such as the present model) could be replaced by single phase models, since the existence of fluid phases would not influence stresses in the solid phases.

2. Any mathematical model of tumor stresses in which the tissue is composed entirely of fluids would be invalid, since any stresses predicted by the model would dissipate over the timescale of growth. Note that, with the exception of the models by Jones et al. [16], Araujo and McElwain [1, 2, 3, 4, 6, 7], and MacArthur and Please [21], *all* mathematical models of tumor stresses currently in the literature consider the tissue to be composed *entirely of fluids*.

5. Concluding remarks. This paper has studied the evolution of residual stresses in a biphasic model of a multicell spheroid comprising a linear-elastic cellular phase and an inviscid fluid phase. In addition, the solutions to the biphasic equations have been compared with their single phase counterparts, elucidating the approximate nature of the single phase formulation for a growing tissue.

A number of important results have been uncovered by this study. In particular, in view of the minute values of the interphase drag parameter, χ, required to reconcile the single phase and multiphase modelling frameworks (generally $\chi \ll 0.001$), it is likely that single phase models give a poor approximation to the evolving stress profiles in many situations. Most significantly, for a given value of χ, the difference between the two frameworks is more significant for greater values of the stress-relaxation parameter. In the present model, stress relaxation has been imparted via anisotropic growth, with stress relaxation parameter, λ.

While stress relaxation has been addressed qualitatively in both this model and previous models [6, 21], it remains to determine realistic values of stress-relaxation parameters by experimental investigation. It is acknowledged that realistic values of the interphase drag parameter, χ, for real tissues may be somewhat more difficult to determine. Nevertheless, a sustained input by experimental investigators, in complementing these novel theoretical studies, will be the key to continued progress in this important area of tumor growth research.

Furthermore, this study has demonstrated that the consideration of multiple phases alone is unable to alleviate the singularities associated with the isotropic growth of an elastic tissue. Thus, in the context of growth-induced stresses, viscoelasticity and anisotropic growth remain the only two methods of regularizing elasticity.

The model presented here may be extended to consider additional phases such as extracellular matrix and blood vessels, permitting a much wider class of problems to be pursued using these novel theoretical tools. In addition, as discussed in the concluding section of Paper 1, more complicated relationships between interphase mass exchange and solid phase expansion may be proposed, enabling these models to consider the formation of necrotic regions in tumors. Necrosis formation remains a poorly understood aspect of tumor development, and recent investigators [21, 24, 25] have argued that mechanical factors are paramount. Since the formation of necrotic regions appears to correlate with tumor aggressiveness, further insights into this important phenomenon may yield fresh information on tumor invasion and metastasis.

Thus, these new multiphase techniques have the potential to make a powerful contribution to a variety of future projects in cancer research, embryogenesis, and tissue engineering. Indeed, in considering interactions amongst multiple phases, both solid and fluid, the models furnish valuable insights into both the stress profiles within the tissue, as well as the flow of interstitial fluid, permitting a unified study of many diverse aspects of tissue growth. With these techniques, a study of drug delivery may be conducted within an investigation of tumor vascular collapse, for example, where growth-induced stresses compress the weak-walled tumor blood vessels. In addition, the complex relationships between solid stresses and a variety of cellular and molecular

responses in tumors, as illustrated by the experimental work of Helmlinger et al. [15] and Koike et al. [20], may be considered in such theoretical investigations.

Acknowledgment. The authors would like to thank the anonymous referees for their helpful clarifying suggestions that have improved the final version of this paper.

CLASS-D AUDIO AMPLIFIERS WITH NEGATIVE FEEDBACK*

STEPHEN M. COX† AND BRUCE H. CANDY‡

Abstract. There are many different designs for audio amplifiers. Class-D, or switching, amplifiers generate their output signal in the form of a high-frequency square wave of variable duty cycle (ratio of on time to off time). The square-wave nature of the output allows a particularly efficient output stage, with minimal losses. The output is ultimately filtered to remove components of the spectrum above the audio range. Mathematical models are derived here for a variety of related class-D amplifier designs that use negative feedback. These models use an asymptotic expansion in powers of a small parameter related to the ratio of typical audio frequencies to the switching frequency to develop a power series for the output component in the audio spectrum. These models confirm that there is a form of distortion intrinsic to such amplifier designs. The models also explain why two approaches used commercially succeed in largely eliminating this distortion; a new means of overcoming the intrinsic distortion is revealed by the analysis.

1. Introduction.

Class-D audio amplifiers are becoming increasingly popular, particularly at the high end of the hi-fi audio amplification market. The key feature of their design is that they switch their output between two voltage levels at a very high frequency (typically 500kHz), well above the audio range. The audio signal is essentially encoded in the relative durations of the pulses at the two output voltage levels. The discrete nature of the switching then allows the output stage to be highly efficient; the audio signal is recovered by low-pass filtering of the output. Although the concept of class-D amplifiers using this pulse-width modulation technique has been known for at least fifty years [1], it is only much more recently that electronic components have become available that make its practical implementation feasible. Several commercial amplifiers at the high end of the audio market use class-D amplifier technology.

In its simplest manifestation, the class-D amplifier is known to be capable of producing no distortion to audio signals [1, 4, 5], at least when the mathematical model assumes, as we shall do, that electronic components perform in an ideal fashion, and that the circuit is free from noise. (Significant effort has also been applied to devising remedies for the effects of imperfections in the circuit components [2], for example, nonlinearities in a carrier waveform that is generally modeled mathematically as a piecewise-linear (triangular or sawtooth) wave [6].)

Unfortunately, the simplest design is prone to noise (including thermal and output-stage power-supply noise), due to a lack of negative feedback, and so more sophisticated versions of the class-D design have been developed, incorporating such feedback, in an attempt to counter the poor noise performance. While these negative-feedback

designs do indeed have better noise performance, they also significantly distort the output, even with perfect components, and there have been various attempts to develop further negative-feedback designs to counter this *intrinsic* distortion.

Despite the great practical value of the application, and the variety of "engineering" solutions available, there appears to be a dearth of mathematical models for class-D amplifier designs with negative feedback. By contrast, the no-feedback case was analyzed over fifty years ago by Black in his treatise [1] and was shown to allow distortion-free output of sinusoidal input signals. More recently the same problem was reconsidered in greater depth [4, 5], and it was shown that there is no distortion to *any* audio signal, sinusoidal or otherwise. The latter result is significant because the amplifier design is nonlinear, and thus the distortion characteristics of an arbitrary signal cannot be inferred from those of its Fourier components.

We develop mathematical models for class-D amplifiers with negative feedback. The models proceed from the governing differential equations that relate the voltage signals at the various parts of the device, assuming perfect components. The resulting system of equations may be formally integrated to yield what is essentially a set of nonlinear difference equations for the various internal signals at multiples of the switching period. The solution to these equations is then developed in an asymptotic series based on the separation of scales between the (relatively high-frequency) switching stage and the (relatively low-frequency) audio signal. The analysis is continued as far as the first term in the series that reveals the inherent distortion of the system. We then show how two successful commercial approaches to significantly reducing this component of the distortion can be modeled, and confirm what is already known empirically, that they do indeed work. The analysis reveals a third means of reducing the intrinsic distortion. We conclude by briefly considering the effects of nonlinear distortion to the carrier wave upon the audio output.

2. Mathematical model: General considerations. The "classical" class-D amplifier design, without negative feedback, is illustrated in Figure 2.1. The audio input signal is denoted by $s(t)$; generally this signal comprises a Fourier spectrum in the audible range up to 20kHz. This audio signal is added to a triangular carrier wave $v(t)$, with period T, that satisfies

$$v(t) = \begin{cases} 1 - \dfrac{4t}{T} & \text{for } 0 \le t < \dfrac{T}{2}, \\ -3 + \dfrac{4t}{T} & \text{for } \dfrac{T}{2} \le t < T, \end{cases} \tag{2.1}$$

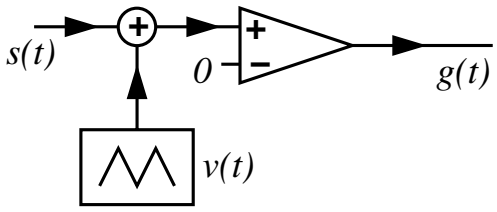

FIG. 2.1. *Classical class-D amplifier (without negative feedback). The audio input signal is* $s(t)$*; this is summed with a high-frequency triangular carrier wave* $v(t)$ *and input to the noninverting input (+) of a comparator, whose inverting input (−) is grounded. The output of the comparator is* $g(t)$*, given by* (2.2).

and $v(t+T) = v(t)$ for all t. Thus $v(nT) = 1$ and $v((n+\frac{1}{2})T) = -1$, for any integer n, and $v(t)$ is piecewise linear between these two values. It will be significant for the analysis that follows that if ω is a typical audio frequency, then $\omega T \ll 1$. The main circuit element is a comparator, which compares the voltage at its noninverting input (denoted by a "+" in the figure) with the voltage at its inverting input (denoted by a "−") and gives an output $g(t)$ that satisfies

$$g(t) = \begin{cases} +1 & \text{if } s(t) + v(t) > 0, \\ -1 & \text{if } s(t) + v(t) < 0. \end{cases} \tag{2.2}$$

Note that the output voltages have been normalized to ± 1; furthermore, we assume throughout this paper that $-1 < s(t) < 1$ for all t. The switching times of $g(t)$ are thus governed by $s(t) + v(t) = 0$; we denote the switching times from $+1$ to -1 by $t = nT + \alpha_n$, with the reverse switchings at times $t = nT + \beta_n$. For the classical design in Figure 2.1 these switching times are governed by

$$0 < \alpha_n = \frac{T}{4}\left(1 + s(nT + \alpha_n)\right) < \frac{T}{2} < \beta_n = \frac{T}{4}\left(3 - s(nT + \beta_n)\right) < T. \tag{2.3}$$

Note that the equations in (2.3) give α_n and β_n only implicitly. We shall consider their solution later.

We now examine how the switching times are used in computing the component of $g(t)$ in the audio spectrum, i.e., the amplifier output.

2.1. Comparator output $g(t)$. In all class-D designs, regardless of the details, the output $g(t)$ takes the form

$$g(t) = \begin{cases} +1 & \text{if } nT < t < nT + \alpha_n \quad \text{or} \quad nT + \beta_n < t < (n+1)T, \\ -1 & \text{if } nT + \alpha_n < t < nT + \beta_n, \end{cases} \tag{2.4}$$

for some switching times $t = nT + \alpha_n$ and $nT + \beta_n$. Thus we may write

$$g(t) = 1 - 2\sum_{n=-\infty}^{\infty} \mathcal{H}_n(t), \tag{2.5}$$

where

$$\mathcal{H}_n(t) = H(t - (nT + \alpha_n)) - H(t - (nT + \beta_n)) \tag{2.6}$$

and where $H(t)$ is the Heaviside step function ($H(t) = 0$ for $t < 0$ and $H(t) = 1$ for $t > 0$). Note that each $\mathcal{H}_n(t)$ has finite support:

$$\mathcal{H}_n(t) = \begin{cases} 1, & nT + \alpha_n < t < nT + \beta_n, \\ 0 & \text{otherwise}, \end{cases} \tag{2.7}$$

so the sum in (2.5) is well defined almost everywhere (i.e., except at the exact switching times). The corresponding Fourier transform

$$\hat{g}(\omega) \equiv \frac{1}{(2\pi)^{1/2}} \int_{-\infty}^{\infty} g(t) \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}t \tag{2.8}$$

is then

$$\hat{g}(\omega) = (2\pi)^{1/2}\delta(\omega) - \frac{2\mathrm{i}}{(2\pi)^{1/2}\omega} \sum_{n=-\infty}^{\infty} \left\{ \mathrm{e}^{-\mathrm{i}\omega(nT+\beta_n)} - \mathrm{e}^{-\mathrm{i}\omega(nT+\alpha_n)} \right\}. \tag{2.9}$$

A formal analysis of this expression allows us to write the output $g(t)$ more usefully in terms of the switching times. We begin by denoting by $\mathcal{S}$ the sum in (2.9). Then

$$\begin{aligned}\mathcal{S} &= \sum_{n=-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega nT}\left(\mathrm{e}^{-\mathrm{i}\omega\beta_n} - \mathrm{e}^{-\mathrm{i}\omega\alpha_n}\right)\\ &= \sum_{n=-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega nT} \sum_{m=1}^{\infty} \frac{1}{m!}(-\mathrm{i}\omega)^m(\beta_n^m - \alpha_n^m)\\ &= \sum_{m=1}^{\infty} \frac{1}{m!}(-\mathrm{i}\omega)^m \sum_{n=-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega nT}(\beta_n^m - \alpha_n^m). \qquad (2.10)\end{aligned}$$

Now we note that

$$\mathrm{e}^{-\mathrm{i}\omega nT}(\beta_n^m - \alpha_n^m) = \int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega t}\left[B^m(t) - A^m(t)\right]\delta(t - nT)\,\mathrm{d}t, \qquad (2.11)$$

where $A(t)$ and $B(t)$ are any smooth functions that satisfy

$$A(nT) = \alpha_n, \qquad B(nT) = \beta_n. \qquad (2.12)$$

We shall refer to $A(t)$ and $B(t)$ as generalized switching-time functions. Substituting (2.11) into (2.10) and using the discrete Fourier transform identity

$$\sum_{n=-\infty}^{\infty} \delta(t - nT) = \frac{1}{T}\sum_{n=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\omega_c nt}, \qquad (2.13)$$

where $\omega_c = 2\pi/T$ is the carrier-wave frequency, we find

$$\begin{aligned}\mathcal{S} &= \frac{1}{T}\sum_{m=1}^{\infty} \frac{1}{m!}(-\mathrm{i}\omega)^m \sum_{n=-\infty}^{\infty} \int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}(\omega - n\omega_c)t}\left[B^m(t) - A^m(t)\right]\,\mathrm{d}t\\ &= \frac{(2\pi)^{1/2}}{T}\sum_{m=1}^{\infty} \frac{1}{m!}(-\mathrm{i}\omega)^m \sum_{n=-\infty}^{\infty} \left[\hat{B}_m(\omega - n\omega_c) - \hat{A}_m(\omega - n\omega_c)\right]. \qquad (2.14)\end{aligned}$$

Here $\hat{A}_m$ and $\hat{B}_m$ are, respectively, the Fourier transforms of A^m and B^m.

Now we use the separation of time scales between the audio signal and the carrier wave to generate a simpler approximation to this expression for $\mathcal{S}$. We begin by noting that since the signal $s(t)$ varies only slowly over a single period of the carrier wave, the switching times α_n and β_n vary only slowly with n. Thus we assume that $A(t)$ and $B(t)$ are chosen to vary only on the relatively slow time scale of the signal and contain no components that vary on the shorter time scale of the carrier wave. (Of course, in practice, this "bandwidth limiting" is only approximate.) The upshot of this assumption is that we take into account only the term $n = 0$ in the sum in (2.14); then, with this approximation,

$$\mathcal{S} = \frac{(2\pi)^{1/2}}{T}\sum_{m=1}^{\infty} \frac{1}{m!}(-1)^m(\mathrm{i}\omega)^m\left[\hat{B}_m(\omega) - \hat{A}_m(\omega)\right]. \qquad (2.15)$$

Correspondingly, from (2.9) it follows that

$$\hat{g}(\omega) = (2\pi)^{1/2}\delta(\omega) + \frac{2}{T}\sum_{m=1}^{\infty} \frac{1}{m!}(-1)^m(\mathrm{i}\omega)^{m-1}\left[\hat{B}_m(\omega) - \hat{A}_m(\omega)\right], \qquad (2.16)$$

and hence, upon inverting the Fourier transform, we obtain for the component of $g(t)$ in the audio spectrum (cf. [4, 5])

$$g_a(t) = 1 + \frac{2}{T}\sum_{m=1}^{\infty} \frac{1}{m!}(-1)^m \frac{\mathrm{d}^{m-1}}{\mathrm{d}t^{m-1}}\left[B^m(t) - A^m(t)\right]. \tag{2.17}$$

This expression applies regardless of the details of the class-D amplifier design: the differences between the various designs lie in the specific relationships between the generalized switching-time functions and the signal $s(t)$; these correspondingly result in different audio outputs $g_a(t)$.

2.1.1. Discussion. The infinite sum in (2.17) should, of course, be viewed with some caution, given the approximations underlying it. Even if $A(t)$ and $B(t)$ are signals whose frequency spectra lie entirely within the audio range, the powers A^m and B^m include successively higher frequencies in their spectra. For example, if A and B are pure sinusoidal signals, each with frequency ω, then A^m and B^m involve frequencies up to $m\omega$. For sufficiently large m, when $|\omega_c \mp m\omega|$ lies in the audio range, terms with $n = \pm 1$ must be included in the sum (2.14), rendering inappropriate our assumption that only terms with $n = 0$ contribute to the output audio spectrum (for larger values of m, additional values of n also become relevant). However, in the analysis that follows we shall consider only the first few terms in (2.17), because these are sufficient to determine the principal distortion characteristics of the amplifier designs; hence for our purposes the difficulty with large values of m in (2.17) is immaterial.

2.2. Alternative expression for $g_a(t)$. This section may be omitted by readers interested only in the class-D amplifier designs with negative feedback, since it is primarily of importance for the classical design without feedback, in which case we shall see below that the equations governing $A(t)$ and $B(t)$ take the form

$$A(t) = \bar{A}(t + A(t)), \qquad B(t) = \bar{B}(t + B(t)), \tag{2.18}$$

for some functions $\bar{A}$ and $\bar{B}$. Clearly some conditions must be imposed upon $A(t)$ and $B(t)$ in order that (2.18) define $\bar{A}$ and $\bar{B}$ uniquely; it is sufficient that $A(t)$ and $B(t)$ should vary sufficiently slowly, i.e., $|A'(t)| < 1$ and $|B'(t)| < 1$ (cf. [5]). It then proves useful to introduce "warped times"

$$t_A = t + A(t), \qquad t_B = t + B(t), \tag{2.19}$$

so that

$$t_A = t + \bar{A}(t_A), \qquad t_B = t + \bar{B}(t_B). \tag{2.20}$$

Now to obtain a simpler expression for $g_a(t)$, we note from the definition of the Fourier transform (2.8) and (2.15) that $\mathcal{S}$ may be written as

$$\mathcal{S} = \frac{1}{T}\sum_{m=1}^{\infty} \frac{(-\mathrm{i}\omega)^m}{m!} \int_{-\infty}^{\infty} [B^m(t) - A^m(t)]\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t, \tag{2.21}$$

and hence, provided the order of the summation and integration may be interchanged,

$$\begin{aligned} \mathcal{S} &= \frac{1}{T}\int_{-\infty}^{\infty} \sum_{m=1}^{\infty} \frac{(-\mathrm{i}\omega)^m}{m!}[B^m(t) - A^m(t)]\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t \\ &= \frac{1}{T}\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega(t+B(t))} - \mathrm{e}^{-\mathrm{i}\omega(t+A(t))}\,\mathrm{d}t, \end{aligned} \tag{2.22}$$

from which it follows that

$$\begin{aligned} \mathrm{i}\omega\hat{g}(\omega) &= \frac{2}{T}\frac{1}{(2\pi)^{1/2}}\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega(t+B(t))} - \mathrm{e}^{-\mathrm{i}\omega(t+A(t))}\,\mathrm{d}t \\ &= \frac{2}{T}\frac{1}{(2\pi)^{1/2}}\left\{\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega t_B}\frac{\mathrm{d}t}{\mathrm{d}t_B}\,\mathrm{d}t_B - \int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega t_A}\frac{\mathrm{d}t}{\mathrm{d}t_A}\,\mathrm{d}t_A\right\} \\ &= \frac{2}{T}\frac{\mathrm{i}\omega}{(2\pi)^{1/2}}\left\{\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega t_B}t(t_B)\,\mathrm{d}t_B - \int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega t_A}t(t_A)\,\mathrm{d}t_A\right\}. \end{aligned} \tag{2.23}$$

Thus, by inverting the Fourier transform, we find that

$$g_a(t) = C_a + \frac{2}{T}\left[g_A(t) + g_B(t)\right], \tag{2.24}$$

where C_a is a constant of integration, $g_A(t_A) = -t(t_A)$, and $g_B(t_B) = t(t_B)$. From (2.20), $t(t_A) = t_A - \bar{A}(t_A)$ and $t(t_B) = t_B - \bar{B}(t_B)$. Thus

$$g_A(t_A) = -t_A + \bar{A}(t_A), \qquad g_B(t_B) = t_B - \bar{B}(t_B), \tag{2.25}$$

or, equivalently,

$$g_A(t) = -t + \bar{A}(t), \qquad g_B(t) = t - \bar{B}(t), \tag{2.26}$$

so that, finally, we obtain from (2.24) and (2.26)

$$g_a(t) = 1 + \frac{2}{T}\left[\bar{A}(t) - \bar{B}(t)\right]. \tag{2.27}$$

The constant of integration $C_a = 1$ has been fixed by noting that for zero input signal ($s(t) \equiv 0$) it follows from (2.2) that $g_a(t) \equiv 0$, while $\bar{A}(t) \equiv T/4$ and $\bar{B}(t) \equiv 3T/4$. Thus when the problem for the generalized switching times is of the form (2.18), the audio output takes a particularly simple form, which does not appear to have been noted previously.

2.3. Classical class-D amplifier. For the classical class-D amplifier illustrated in Figure 2.1, we find from (2.3) and (2.12) that

$$A(nT) = \frac{T}{4}\left[1 + s(nT + A(nT))\right], \qquad B(nT) = \frac{T}{4}\left[3 - s(nT + B(nT))\right]. \tag{2.28}$$

It is then straightforward to extend this definition of $A(t)$ and $B(t)$ appropriately to other times by globally mapping $nT \mapsto t$ in (2.28). Then, in view of (2.18) and (2.27), it follows that

$$g_a(t) = 1 + \frac{2}{T}\left\{\frac{T}{4}\left[1 + s(t)\right] - \frac{T}{4}\left[3 - s(t)\right]\right\} = s(t). \tag{2.29}$$

Thus (as is well known [1, 4, 5]) this amplifier gives no distortion to the signal (given the modeling assumptions).

Note in particular that no assumption has been made regarding the shape of the audio waveform $s(t)$ other than that its spectrum lies entirely in the audio band, well below the carrier-wave frequency; most significantly, the input signal need not be a pure sinusoid. Our derivation of this result differs somewhat from that given recently [4, 5], since we use (2.27) rather than applying a theorem in complex analysis due to Lagrange [4, 5].

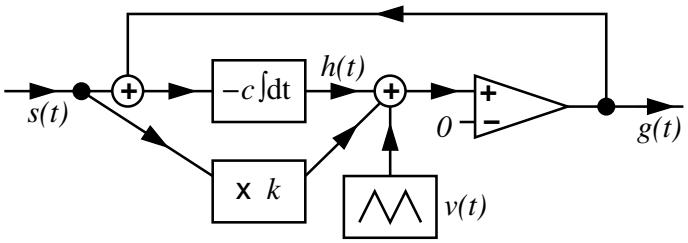

FIG. 3.1. *Class-D amplifier with negative feedback. The signal $s(t)$ is fed into a device that multiplies it by a constant k, and also into an integrator, whose output we denote by $h(t)$. The outputs of the integrator and the multiplier are summed, together with a high-frequency triangular carrier wave $v(t)$ and input to the noninverting input of a comparator whose inverting input is grounded. The output of the comparator is $g(t)$.*

3. Class-D amplifier with negative feedback. With negative feedback, the basic class-D amplifier design is as illustrated in Figure 3.1.

In analyzing the amplifier design, we find it convenient to introduce $f(t)$, the integral of the input signal, defined by $f'(t) = s(t)$; the constant of integration in determining $f(t)$ uniquely is not important in what follows. The triangular carrier wave $v(t)$ again satisfies (2.1) and the periodicity condition $v(t+T) = v(t)$ for all t. The output $g(t)$ of the comparator now satisfies

$$g(t) = \begin{cases} +1 & \text{if } h(t) + ks(t) + v(t) > 0, \\ -1 & \text{if } h(t) + ks(t) + v(t) < 0. \end{cases} \tag{3.1}$$

Finally, the integrator output is given by

$$h(t) = -c \int^t g(\tau) + s(\tau)\,\mathrm{d}\tau. \tag{3.2}$$

The time constant c is such that $cT = O(1)$. Since $-1 < s(t) < 1$, $h(t)$ alternately increases and decreases, when $g(t)$ is, respectively, negative and positive. The relationships between $v(t)$, $g(t)$, and $h(t)$ are illustrated in Figure 3.2. We note that for illustrative purposes the figure shows $h(t)$ as a piecewise linear function of time, which is appropriate only for a constant input signal; otherwise $h(t)$ has a slight nonlinearity.

3.1. Analysis of the model. We analyze the model by first constructing a system of nonlinear implicit difference equations for the switching times α_n and β_n. To do so, we consider a time interval $nT < t < (n+1)T$. Referring to the waveform in Figure 3.2, we see that at the start and end of this interval, $h(t)$ is decreasing; in-between, $h(t)$ is increasing. We define three subintervals:

$$\begin{array}{rll} \text{I:} & nT < t < nT + \alpha_n, & h'(t) < 0 \ [g(t) = 1], \\ \text{II:} & nT + \alpha_n < t < nT + \beta_n, & h'(t) > 0 \ [g(t) = -1], \\ \text{III:} & nT + \beta_n < t < (n+1)T, & h'(t) < 0 \ [g(t) = 1], \end{array} \tag{3.3}$$

and consider each in turn.

Subinterval I. By integrating (3.2) we find

$$h(t) = h(nT) - c[f(t) - f(nT)] - c(t - nT). \tag{3.4}$$

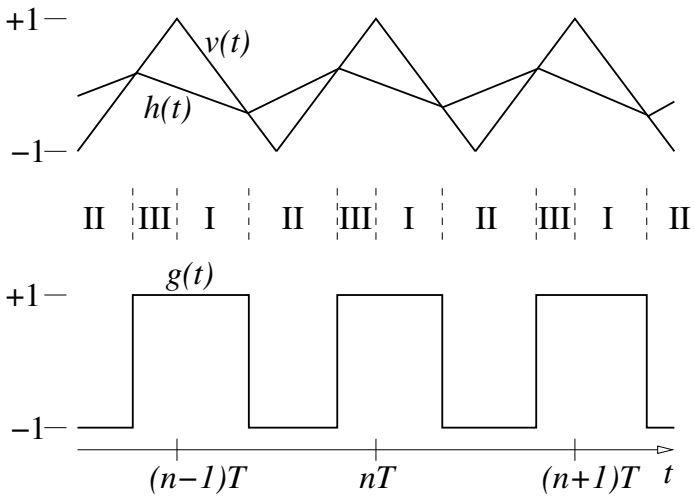

FIG. 3.2. *Diagram showing relationships between $v(t)$, $g(t)$, and $h(t)$ for the class-D amplifier with negative feedback. Note that, although $h(t)$ is drawn here as piecewise linear, it is in fact nonlinear for any nontrivial input signal $s(t)$. The subintervals* I, II, *and* III *are indicated, as defined in* (3.3).

According to (3.1), the value of α_n is defined by

$$h(nT+\alpha_n) + ks(nT+\alpha_n) + v(nT+\alpha_n) = 0; \tag{3.5}$$

that is,

$$h(nT) - c[f(nT+\alpha_n) - f(nT)] - c\alpha_n + ks(nT+\alpha_n) + 1 - \frac{4\alpha_n}{T} = 0. \tag{3.6}$$

Subinterval II. By integrating (3.2) and enforcing continuity of $h(t)$ at time $t = nT + \alpha_n$, we find

$$h(t) = h(nT) - c[f(t) - f(nT)] - c\alpha_n + c(t - nT - \alpha_n). \tag{3.7}$$

From (3.1), the value of β_n is defined by

$$h(nT+\beta_n) + ks(nT+\beta_n) + v(nT+\beta_n) = 0; \tag{3.8}$$

that is,

$$h(nT) - c[f(nT+\beta_n) - f(nT)] + c(\beta_n - 2\alpha_n) + ks(nT+\beta_n) - 3 + \frac{4\beta_n}{T} = 0. \tag{3.9}$$

Subinterval III. By integrating (3.2) and enforcing continuity of $h(t)$ at time $t = nT + \beta_n$, we find

$$h(t) = h(nT) - c[f(t) - f(nT)] + c(\beta_n - 2\alpha_n) - c(t - nT - \beta_n). \tag{3.10}$$

For the remaining analysis, we note that at the end of this subinterval

$$h((n+1)T) = h(nT) - c[f((n+1)T) - f(nT)] + c(2\beta_n - 2\alpha_n - T). \tag{3.11}$$

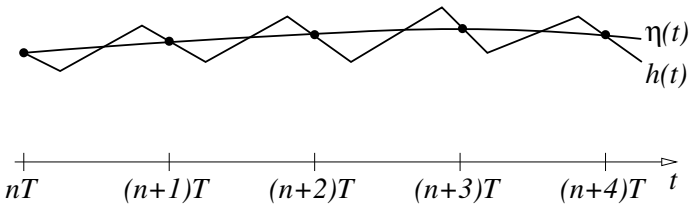

FIG. 3.3. *Diagram showing the relationship between $h(t)$ and $\eta(t)$. The two functions agree at times nT (for integers n), but $h(t)$ varies significantly at intermediate times, whereas η is only slowly varying.*

3.2. Solution of the governing equations. Our goal is to use (2.17) to determine the audio output of the amplifier. To do so we first need to determine the switching times of $g(t)$. Given a signal $s(t)$, we determine these switching times, together with the values of $h(nT)$, from the coupled equations (3.6), (3.9), and (3.11), which are, so far, exact.

We first use (2.12) to substitute the generalized switching-time functions for α_n and β_n; the result is a system of three equations involving $A(nT)$, $B(nT)$, and $h(nT)$. These equations are readily extended to intermediate times by mapping $nT \mapsto t$:

$$\left(\frac{4}{T}+c\right)A(t) = 1 + ks(t+A(t)) + \eta(t) - c[f(t+A(t)) - f(t)], \tag{3.12}$$

$$\left(\frac{4}{T}+c\right)B(t) = 3 - ks(t+B(t)) - \eta(t) + c[f(t+B(t)) - f(t)] + 2cA(t), \tag{3.13}$$

$$\eta(t+T) = \eta(t) - c[f(t+T) - f(t)] + c[2B(t) - 2A(t) - T]. \tag{3.14}$$

Since the functions $A(t)$ and $B(t)$ vary only on the time scale of the audio signal and not on that of the carrier wave, the function $h(t)$ is replaced in these expressions by a slowly varying function $\eta(t)$ such that

$$\eta(nT) = h(nT) \tag{3.15}$$

(see Figure 3.3).

Given the mild restrictions on the form of the input signal $s(t)$ and its first integral $f(t)$, it seems unlikely that a general solution can be found to the coupled nonlinear equations (3.12)–(3.14). Furthermore, it seems unlikely that any solution will be unique, although we are unable to demonstrate nonuniqueness for the system of three equations as posed. (A suggestion of nonuniqueness comes from the following thought experiment. Suppose $A(t)$ and $B(t)$ are known and independent of $\eta(t)$. Then the solution $\eta(t)$ to (3.14) is unique only up to the addition of a function of period T [3]. Note that here the nonuniqueness involves high-frequency components only.)

We find that we are able to construct a solution to (3.12)–(3.14) with frequency spectrum in the audio range, as follows. The derivation is admittedly rather informal. We introduce the small parameter $\epsilon = \omega_{\text{typ}}/\omega_c \ll 1$, where ω_{typ} is a typical audio frequency component of the input. Then we note that (3.12)–(3.14) relate to variations in s, A, B, and η on a time scale $t = O(T)$, and that such variations satisfy

$$\frac{\mathrm{d}^n}{\mathrm{d}t^n} = O(\epsilon^n).$$

We then expand $A(t)$, $B(t)$, and $\eta(t)$ as series

$$A(t) = \sum_{m=0}^{\infty} A_m(t), \qquad B(t) = \sum_{m=0}^{\infty} B_m(t), \qquad \eta(t) = \sum_{m=0}^{\infty} \eta_m(t), \tag{3.16}$$

where the terms in (3.16) satisfy

$$A_m, B_m, \eta_m = O(\epsilon^m).$$

For all functions in (3.12)–(3.14) not evaluated at time t, we make use of Taylor expansions such as

$$\eta(t+T) = \sum_{n=0}^{\infty} T^n \frac{\eta^{(n)}(t)}{n!} \tag{3.17}$$

to write them in terms of functions and derivatives evaluated at time t.

As an aside, we note that an alternative mathematical solution may possibly be developed using the calculus of finite differences [3], where problems such as (3.14), of the form $u(t+T) - u(t) = U(t)$, are examples of the so-called "summation problem." However, the added complication of (3.12) and (3.13) makes a complete explicit solution unlikely. We note, however, that (3.14) has the exact formal solution

$$\eta(t) = -cf(t) + c\sum_{n=1}^{\infty} \left[2B(t-nT) - 2A(t-nT) - T\right].$$

Some of the key terms in the various expansions are

$$\begin{aligned}
f(t+T) - f(t) &= Ts(t) + \tfrac{1}{2}T^2 s'(t) + \tfrac{1}{6}T^3 s''(t) + O(\epsilon^3),\\
\eta(t+T) - \eta(t) &= T\eta_0'(t) + \left[T\eta_1'(t) + \tfrac{1}{2}T^2\eta_0''(t)\right] + O(\epsilon^3),\\
s(t+A(t)) &= s(t) + A_0(t)s'(t) + \left[\tfrac{1}{2}A_0^2(t)s''(t) + A_1(t)s'(t)\right] + O(\epsilon^3),\\
s(t+B(t)) &= s(t) + B_0(t)s'(t) + \left[\tfrac{1}{2}B_0^2(t)s''(t) + B_1(t)s'(t)\right] + O(\epsilon^3),\\
f(t+A(t)) - f(t) &= A_0(t)s(t) + \left[\tfrac{1}{2}A_0^2(t)s'(t) + A_1(t)s(t)\right]\\
&\quad + \left[\tfrac{1}{6}A_0^3(t)s''(t) + A_0(t)A_1(t)s'(t) + A_2(t)s(t)\right] + O(\epsilon^3),\\
f(t+B(t)) - f(t) &= B_0(t)s(t) + \left[\tfrac{1}{2}B_0^2(t)s'(t) + B_1(t)s(t)\right]\\
&\quad + \left[\tfrac{1}{6}B_0^3(t)s''(t) + B_0(t)B_1(t)s'(t) + B_2(t)s(t)\right] + O(\epsilon^3).
\end{aligned}$$

In view of (2.17), we also have the expansion

$$\begin{aligned}
g_a(t) = 1 &- \frac{2}{T}(B_0 - A_0)\\
&+ \frac{1}{T}\left[(B_0^2 - A_0^2)' - 2(B_1 - A_1)\right]\\
&+ \frac{1}{T}\left[-\tfrac{1}{3}(B_0^3 - A_0^3)'' + 2(B_0B_1 - A_0A_1)' - 2(B_2 - A_2)\right] + O(\epsilon^3)
\end{aligned} \tag{3.18}$$

for the audio output. With obvious notation, we write this as

$$g_a(t) = g_0(t) + g_1(t) + g_2(t) + O(\epsilon^3). \tag{3.19}$$

Let us now consider the problem (3.12)–(3.14) at successive powers of ϵ, starting with terms of $O(\epsilon^0)$. In doing so, it proves useful to note that upon adding (3.12) to (3.13) we eliminate the unknown function $\eta(t)$ and arrive at an equation that at $O(\epsilon^n)$ takes the form

$$\{4 - cT\,[1 - s(t)]\}\,A_n(t) + \{4 + cT\,[1 - s(t)]\}\,B_n(t) = P_n(t), \tag{3.20}$$

where $P_n(t)$ is known in terms of quantities calculated at previous stages in the calculation. Furthermore, (3.14) can be written in the form

$$B_n(t) - A_n(t) = Q_n(t), \tag{3.21}$$

where again $Q_n(t)$ comprises known quantities. This system is readily solved to give

$$A_n(t) = \tfrac{1}{8}\left\{P_n(t) - [4 + cT(1 - s(t))]\,Q_n(t)\right\}, \tag{3.22}$$

$$B_n(t) = \tfrac{1}{8}\left\{P_n(t) + [4 - cT(1 - s(t))]\,Q_n(t)\right\}. \tag{3.23}$$

At $O(\epsilon^0)$, we find $P_0 = 4T$ and $Q_0 = \frac{1}{2}T(1 + s(t))$. Correspondingly,

$$A_0 = \tfrac{1}{16}T(1 - s(t))\,[4 - cT(1 + s(t))]\,, \tag{3.24}$$

$$B_0 = \tfrac{1}{2}T + \tfrac{1}{16}T(1 + s(t))\,[4 - cT(1 - s(t))]\,, \tag{3.25}$$

and thus the switching times approximately satisfy

$$\alpha_n = \tfrac{1}{16}T(1 - s(nT))\,[4 - cT(1 + s(nT))]\,, \tag{3.26}$$

$$\beta_n = \tfrac{1}{2}T + \tfrac{1}{16}T(1 + s(nT))\,[4 - cT(1 - s(nT))]\,. \tag{3.27}$$

Of most significance is the result, which now follows from (3.24), (3.25), and (3.18), that

$$g_0(t) = -s(t). \tag{3.28}$$

Thus to this order there is no distortion from signal to output, apart from a sign change, which is unimportant for audio applications. However, in contrast to the classical design, the next orders in the expansion of the audio output reveal distortion inherent in the nonlinear-feedback design. (The minus sign in (3.28) is an artifact of applying the triangular wave input to the noninverting input of the comparator; if it is instead applied to the inverting input, then there is no sign change to the output.)

3.3. Amplifier output. The next steps in the calculation are algebraically cumbersome and shed little further light on the problem, so the full details are not presented here. Our primary interest lies in the audio output, and this turns out to be

$$\begin{aligned} g_a(t) = {} & -s(t) + \frac{1+k}{c}s'(t) \\ & - \frac{1}{48c^2}\left\{[48(1+k) - c^2T^2]s(t) - c^2T^2s^3(t)\right\}'' + O(\epsilon^3). \end{aligned} \tag{3.29}$$

Note that there arises a nonlinear (cubic) distortion term; this term is to leading order independent of k, so it cannot be removed by any choice of this parameter. This nonlinear term represents the "intrinsic" distortion of class-D amplifiers with negative feedback to which we have alluded above.

The linear terms in (3.29) also represent a form of distortion to the signal since they affect different frequency components to different extents. This distortion can be removed by making an appropriate choice of k such that the linear terms in (3.29) form the beginnings of a Taylor series for a slightly delayed signal $-s(t-(1+k)/c)$. It is readily determined that the appropriate value of k satisfies

$$k^2 = 1 - \frac{1}{24}c^2T^2; \tag{3.30}$$

correspondingly, the audio output is then given by

$$g_a(t) = -s\left(t - \frac{(1+k)}{c}\right) + \frac{1}{48}T^2\left(s^3(t)\right)'' + O(\epsilon^3). \tag{3.31}$$

Note that the delay to the output indicated here is independent of signal amplitude and frequency, and thus is entirely benign. Furthermore, $(1+k)/c$ is a time of the order of the carrier-wave period, so the delay to the audio signal is slight. However, the nonlinear distortion term remains.

For the specific case of a sinusoidal input signal $s(t) = s_0 \sin \omega t$, (3.29) becomes

$$\begin{aligned} g_a(t) &= -s_0 \sin \omega t + (1+k)\mu s_0 \cos \omega t \\ &\quad + \frac{\mu^2}{192}\left\{\left[192(1+k) - (4+3s_0^2)c^2T^2\right] s_0 \sin \omega t + 9c^2T^2 s_0^3 \sin 3\omega t\right\} + O(\mu^3), \end{aligned} \tag{3.32}$$

where $\mu = O(\epsilon)$: specifically,

$$\mu = \frac{\omega T}{cT} \ll 1. \tag{3.33}$$

We note from (3.32) that the intrinsic nonlinear distortion manifests itself through both a nonlinear influence on the amplitude of the fundamental and the presence of a third-harmonic term.

3.4. Alternative expression for $g_a(t)$. An alternative expression for the audio output may be derived as follows. First we note that the switching times for $g(t)$ satisfy

$$\begin{aligned} \alpha_n &= \frac{T}{4}\left[1 + h(nT+\alpha_n) + ks(nT+\alpha_n)\right], \\ \beta_n &= \frac{T}{4}\left[3 - h(nT+\beta_n) - ks(nT+\beta_n)\right]. \end{aligned}$$

If we introduce two new slowly varying functions $\eta(t;\alpha)$ and $\eta(t;\beta)$ defined so that

$$\eta(nT+\alpha_n;\alpha) = h(nT+\alpha_n), \qquad \eta(nT+\beta_n;\beta) = h(nT+\beta_n), \tag{3.34}$$

then it follows from (2.29) that

$$g_a(t) = \frac{1}{2}\left[\eta(t;\alpha) + \eta(t;\beta)\right] + ks(t). \tag{3.35}$$

Although this expression does not yield a useful explicit exact formula for $g_a(t)$, it does provide an alternative means of calculating $g_a(t)$. This in turn gives us an independent check on our results, which we have used to verify expressions such as (3.29).

Having highlighted the third-harmonic distortion generated by the simplest class-D amplifier design with negative feedback, we proceed to describe some remedies.

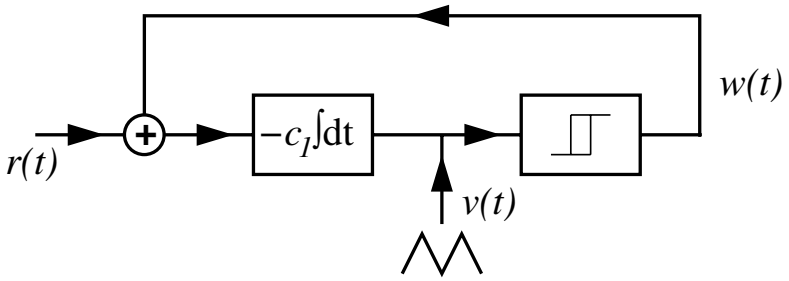

FIG. 4.1. *Circuit diagram for modulation of the carrier wave. The modulation function $r(t)$ is input to an integrator, whose output $v(t)$ is input to a hysteresis loop. The output $w(t)$ of the last device takes the value $+1$ once its input has reached the value $+1$; thereafter $w(t)$ remains at $+1$ until the input $v(t)$ falls to -1, from which point onwards $w(t) = -1$ until the input $v(t)$ reaches $+1$ again, and so on.*

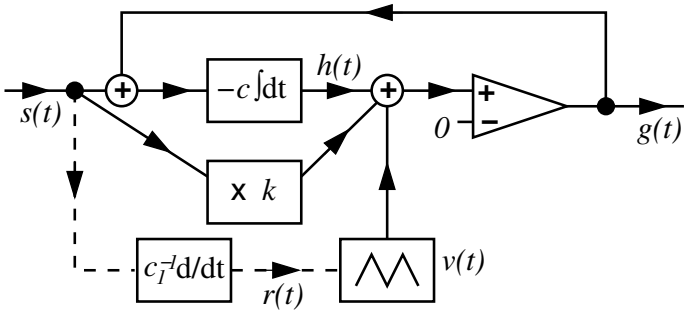

FIG. 4.2. *Class-D amplifier with negative feedback and modulation of the carrier-wave symmetry. Note that the entire circuitry of Figure* 4.1 *is represented by the single box marked "$v(t)$." The appropriate modulation signal $r(t) = c_1^{-1}s'(t)$ is indicated on the diagram, as determined in section* 4.1.2.

4. Modulation of the carrier wave. We now examine one means of eliminating the "intrinsic distortion" term in (3.29). The key to the technique is to modulate the carrier wave in such a way that the switching times of $g(t)$ are slightly altered in a fashion appropriate to countering the distortion. This technique is used successfully for distortion reduction in amplifiers manufactured by Halcro (www.halcro.com).

We suppose that the carrier wave is modulated by a slowly varying input signal $r(t)$, where $r(t) = e'(t)$, for some function $e(t)$; since $r(t)$ involves a first derivative, it is taken to be $O(\epsilon)$ and the modulation of the carrier wave correspondingly slight. The modulation circuit is illustrated in Figure 4.1; the full amplifier circuit is caricatured in Figure 4.2. Now the carrier wave $v(t)$ is governed by

$$v(t) = -c_1 \int^t w(\tau) + r(\tau)\,\mathrm{d}\tau, \tag{4.1}$$

where c_1 is a time constant associated with the integrator in the modulation circuit (see Figure 4.1), and is no longer quite piecewise linear. The signal $w(t)$ is a square wave of variable duty cycle, taking the values $w(t) = \pm 1$, depending on the carrier wave $v(t)$ as follows. First, suppose that $w = -1$; then v is increasing. When v reaches $+1$, w changes to $+1$ and v starts to decrease. Once v has decreased to -1, w changes to -1; then v starts to increase once more, until it reaches $+1$ again, at

which point the cycle starts over.

4.1. Analysis of the model. Suppose that $w(t)$ changes to the value $w = 1$ at times $t = T_n$, and changes to the value $w = -1$ at times $t = U_n$. Then for $T_n < t < U_n$, $w(t) = 1$ and hence

$$v(t) = 1 - c_1[e(t) - e(T_n)] - c_1(t - T_n). \tag{4.2}$$

For $U_n < t < T_{n+1}$, $w(t) = -1$ and

$$v(t) = -1 - c_1[e(t) - e(U_n)] + c_1(t - U_n). \tag{4.3}$$

The time constant c_1 (determined below) is such that $c_1 T = O(1)$. Constants of integration have been chosen so that each of these expressions gives the correct value for $v(t)$ at the start of each time interval. Imposing the appropriate value for $v(t)$ at the end of each time interval then gives the two conditions

$$c_1[e(U_n) - e(T_n)] + c_1(U_n - T_n) = 2, \tag{4.4}$$

$$-c_1[e(T_{n+1}) - e(U_n)] + c_1(T_{n+1} - U_n) = 2. \tag{4.5}$$

For the special case in which $r(t) \equiv r_0$ is constant, the carrier-wave $v(t)$ is time-periodic, with period of oscillation

$$T = \frac{4}{(1 - r_0^2)c_1} \sim \frac{4}{c_1}(1 + r_0^2).$$

Furthermore, in this case

$$U_n - T_n = \frac{2}{(1 + r_0)c_1} \sim \frac{2}{c_1}(1 - r_0).$$

Note that T is in general *increased* by the presence of a nonzero modulation signal (i.e., the frequency of the carrier wave is reduced). In what follows, we shall require corrections to the carrier-wave due to modulation only up to $O(\epsilon)$, and thus, since $r^2 = O(\epsilon^2)$, we may take T as fixed. Then the time constant c_1 must be chosen so that

$$c_1 = \frac{4}{T}. \tag{4.6}$$

With this approximation, it turns out that we may consistently calculate terms in $g_a(t)$ up to $O(\epsilon^2)$, which is sufficient to determine the effects of carrier-wave modulation on the amplifier's distortion characteristics.

If we write the times at which the slope of the triangular wave changes as

$$T_n = nT + a_n, \qquad U_n = nT + b_n, \tag{4.7}$$

where $0 < a_n < b_n < T$, then these times are now governed by

$$\begin{aligned} 0 = {} & h(nT) - c[f(nT + \alpha_n) - f(nT)] - c\alpha_n + ks(nT + \alpha_n) \\ & + 1 - c_1[e(nT + \alpha_n) - e(nT + a_n)] - c_1(\alpha_n - a_n), \end{aligned} \tag{4.8}$$

$$\begin{aligned} 0 = {} & h(nT) - c[f(nT + \beta_n) - f(nT)] + c(\beta_n - 2\alpha_n) + ks(nT + \beta_n) \\ & - 1 - c_1[e(nT + \beta_n) - e(nT + b_n)] + c_1(\beta_n - b_n), \end{aligned} \tag{4.9}$$

rather than by (3.6) and (3.9). As in the absence of modulation, we have (3.14).

The solution technique is just as with no modulation. Again we seek slowly varying generalized switching times $A(t)$ and $B(t)$ of the output $g(t)$, but now we need two further slowly varying functions, $C(t)$ and $D(t)$, such that

$$C(nT) = a_n, \qquad D(nT) = b_n. \tag{4.10}$$

The equations to be solved arise from (3.14), (4.4), (4.5), (4.8), and (4.9), and are

$$c_1[e(t + D(t)) - e(t + C(t))] + c_1(D(t) - C(t)) = 2, \tag{4.11}$$

$$-c_1[e(t + T + C(t + T)) - e(t + D(t))] + c_1(T + C(t + T) - D(t)) = 2, \tag{4.12}$$

$$\begin{aligned} &\eta(t) - c[f(t + A(t)) - f(t)] - cA(t) + ks(t + A(t)) \\ &+ 1 - c_1[e(t + A(t)) - e(t + C(t))] - c_1(A(t) - C(t)) = 0, \end{aligned} \tag{4.13}$$

$$\begin{aligned} &\eta(t) - c[f(t + B(t)) - f(t)] + c(B(t) - 2A(t)) + ks(t + B(t)) \\ &- 1 - c_1[e(t + B(t)) - e(t + D(t))] + c_1(B(t) - D(t)) = 0, \end{aligned} \tag{4.14}$$

$$\eta(t + T) - \eta(t) + c[f(t + T) - f(t)] - c[2B(t) - 2A(t) - T] = 0. \tag{4.15}$$

As with the simpler case of an unmodulated carrier-wave, we expand all unknown functions (here A, B, C, D, and η) as series, as in (3.16), and solve in succession for the terms in these series at the first few orders.

4.1.1. Discussion. When expanded, (4.11) and (4.12) each yield at $O(1)$ and at $O(\epsilon)$ identical equations of the forms

$$D_0(t) - C_0(t) = \frac{1}{2}T, \qquad D_1(t) - C_1(t) = -\frac{1}{2}Tr(t), \tag{4.16}$$

respectively. The fact that only the difference between the times C and D may be determined partly reflects an arbitrariness in the time origin for the circuit that generates the carrier wave. However, if we continue to the next order we find that the two equations for $D_2(t) - C_2(t)$ are in fact inconsistent, reflecting the more serious limitation imposed upon the analysis by our assumption that the mean carrier-wave period is unaltered by the modulation. Fortunately, a consistent calculation of C and D up to terms C_1 and D_1 proves sufficient to determine the audio output of the amplifier up to g_2, which allows us to calculate the elimination of the distortion.

4.1.2. Elimination of the distortion. We find the audio output to be

$$\begin{aligned} g_a(t) = &-s(t) + \frac{1+k}{c}s'(t) \\ &- \frac{1}{3c_1^2c^2}\left\{3c_1c^2(rs^2)' + \left[3(1+k)c_1^2 - c^2\right]s'' - 3c_1c^2r' - c^2(s^3)''\right\} + O(\epsilon^3), \end{aligned} \tag{4.17}$$

where c_1 is given by (4.6). There are two nonlinear distortion terms in this expression, proportional to $(rs^2)'$ and $(s^3)''$. If we set $r = \nu s'(t)$, we may eliminate both of them by choosing $\nu = 1/c_1 = T/4$. Then

$$g_a(t) = -s(t) + \frac{1+k}{c}s'(t) - \frac{1}{12c^2}\left[12(1+k) - c^2T^2\right]s''(t) + O(\epsilon^3). \tag{4.18}$$

Thus all nonlinear distortion is removed, at least to the order calculated. A key result of the present analysis is that the appropriate modulation of the carrier wave is through a derivative of the input signal; this is, in fact, the method used in practice.

Now if we choose $k^2 = 1 - \frac{1}{6}c^2T^2$, then the audio output is of the form

$$g_a(t) = -s\left(t - \frac{(1+k)}{c}\right) + O(\epsilon^3), \tag{4.19}$$

and, to the order calculated, there is no distortion beyond a slight delay to the output.

5. "Sample-and-hold" class-D amplifier with negative feedback. Modulation of the carrier wave is not the only means by which the leading-order nonlinear distortion can be removed from class-D amplifiers with negative feedback. We now describe an alternative means of eliminating this distortion, without carrier-wave modulation. This alternative amplifier design has also been constructed, in prototype, by Halcro and is illustrated in Figure 5.1. There is no modulation of the carrier-wave symmetry.

Now the output of the integrator inputs to a sample-and-hold device, which samples $h(t)$ at times $t = nT$ and $(n + \frac{1}{2})T$; its output $p(t)$ is then a piecewise-constant function. For $nT \le t < (n + \frac{1}{2})T$, $p(t)$ takes the value $h(nT)$, while for $(n + \frac{1}{2})T \le t < (n + 1)T$, $p(t)$ takes the value $h((n + \frac{1}{2})T)$. Aside from this new feature, most details of the model remain essentially unchanged. The triangular wave $v(t)$ again satisfies (2.1) and $v(t + T) = v(t)$ for all t. The output $g(t)$ of the comparator is now $+1$ if $p(t) + ks(t) + v(t) > 0$, and -1 if the inequality is reversed; the switching times thus satisfy

$$p(nT + \alpha_n) + ks(nT + \alpha_n) + v(nT + \alpha_n) = 0,$$
$$p(nT + \beta_n) + ks(nT + \beta_n) + v(nT + \beta_n) = 0.$$

The integrator output $h(t)$ is again given by (3.2). In any interval $nT < t < (n+1)T$, there are three subintervals, as in (3.3); we describe these below. The analysis is somewhat simplified by the sampling.

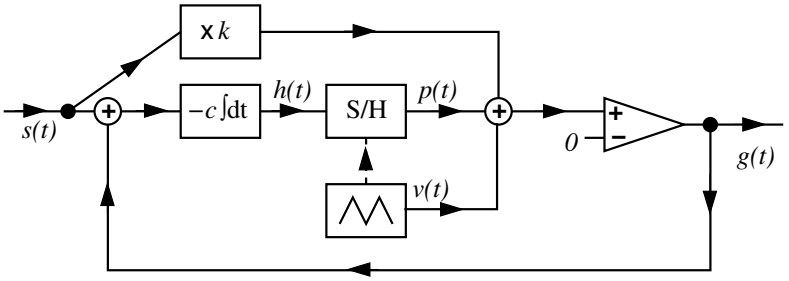

FIG. 5.1. *"Sample-and-hold" class-D amplifier with negative feedback. The sample-and-hold (S/H) device is synchronized with the carrier-wave generator and gives an output $p(t)$ equal to its input $h(t)$ sampled at times $t = nT$ and $t = (n + \frac{1}{2})T$. Thus for $nT \le t < (n + \frac{1}{2})T$, $p(t) = h(nT)$; correspondingly, for $(n + \frac{1}{2})T \le t < (n + 1)T$, $p(t) = h((n + \frac{1}{2})T)$.*

Subinterval I. By integrating (3.2) we find that $h(t)$ is again given by (3.4), but now the value of α_n is defined by

$$p(nT + \alpha_n) + ks(nT + \alpha_n) + v(nT + \alpha_n) = 0; \tag{5.1}$$

that is,

$$h(nT) + ks(nT + \alpha_n) + 1 - \frac{4\alpha_n}{T} = 0. \tag{5.2}$$

Subinterval II. By integrating (3.2) we again find (3.7) for $h(t)$; the value of β_n is defined by

$$p(nT+\beta_n)+ks(nT+\beta_n)+v(nT+\beta_n)=0; \tag{5.3}$$

that is,

$$h((n+\tfrac{1}{2})T)+ks(nT+\beta_n)-3+\frac{4\beta_n}{T}=0. \tag{5.4}$$

Subinterval III. By integrating (3.2) we find (3.10) for $h(t)$; it follows that $h((n+1)T)$ is again given by (3.11).

5.1. Solution of the governing equations. The three governing equations are now

$$\frac{4}{T}\alpha_n = 1+ks(nT+\alpha_n)+h(nT), \tag{5.5}$$

$$\frac{4}{T}\beta_n = 3-ks(nT+\beta_n)-h\left(\left(n+\frac{1}{2}\right)T\right), \tag{5.6}$$

$$h((n+1)T)=h(nT)-c[f((n+1)T)-f(nT)]+c(2\beta_n-2\alpha_n-T). \tag{5.7}$$

Furthermore, by considering subinterval II, we find that

$$h\left(\left(n+\frac{1}{2}\right)T\right)=h(nT)-c\left[f\left(\left(n+\frac{1}{2}\right)T\right)-f(nT)\right]+c\left(\frac{T}{2}-2\alpha_n\right). \tag{5.8}$$

As above, we introduce the slowly varying functions $A(t)$, $B(t)$, and $\eta(t)$, which now satisfy

$$\begin{aligned}
\frac{4}{T}A(t) &= 1+ks(t+A(t))+\eta(t),\\
\frac{4}{T}B(t) &= 3-ks(t+B(t))-\eta(t)+c\left[f\left(t+\frac{T}{2}\right)-f(t)\right]-c\left[\frac{T}{2}-2A(t)\right],\\
\eta(t+T) &= \eta(t)-c[f(t+T)-f(t)]+c[2B(t)-2A(t)-T],
\end{aligned}$$

and solve these equations at successive orders in ϵ. The audio output is eventually found to be

$$\begin{aligned}
g_a(t) = -s(t)+\frac{1+k}{c}s'(t)&\\
+\frac{1}{96c^2(4-cT)}\Big\{&\left[c^3T^3-(28+24k)c^2T^2+192(1+k)cT-384(1+k)\right]s(t)\\
&+\left[cT-4(1+2k)\right]c^2T^2s^3(t)\Big\}''+O(\epsilon^3).
\end{aligned} \tag{5.9}$$

Now the nonlinear distortion term proportional to $(s^3)''$ may be removed from this expression by choosing

$$k=-\frac{1}{2}+\frac{1}{8}cT, \tag{5.10}$$

in which case

$$g_a(t)=-s(t)+\frac{4+cT}{8c}s'(t)-\frac{24-c^2T^2}{48c^2}s''(t)+O(\epsilon^3). \tag{5.11}$$

Once the nonlinear distortion term has been so removed, we may similarly remove linear distortion, so that the audio output suffers only a slight delay, i.e.,

$$g_a(t) = -s\left(t - \frac{\frac{1}{8}(4+cT)}{c}\right) + O(\epsilon^3),$$

by choosing $cT = 12(2\sqrt{3}-1)/11 \approx 2.6881$.

5.2. Alternative means of sampling. Suppose now that the sampling is carried out only at times $t = nT$ (i.e., not also at times $t = (n+\frac{1}{2})T$). Then the equations to be solved for $A(t)$, $B(t)$, and $\eta(t)$ are somewhat simplified:

$$\frac{4}{T}A(t) = 1 + ks(t + A(t)) + \eta(t), \tag{5.12}$$

$$\frac{4}{T}B(t) = 3 - ks(t + B(t)) - \eta(t), \tag{5.13}$$

$$\eta(t+T) - \eta(t) = -c[f(t+T) - f(t)] + c[2B(t) - 2A(t) - T]. \tag{5.14}$$

The audio output is, correspondingly, found to be

$$\begin{aligned} g_a(t) = -s(t) + \frac{1+k}{c}s'(t) + \frac{1}{96c^2}\big\{&-(2k+1)c^2T^2(3s^2(t)+s^3(t))'' \\ &+ \left[-c^2T^2 - 6(1+k)c^2T^2 + 48(1+k)cT - 96(1+k)\right]s''(t)\big\}. \end{aligned} \tag{5.15}$$

In view of the asymmetrical sampling, there are now second and third harmonics at $O(\epsilon^2)$, but these can *simultaneously* be removed by choosing

$$k = -\frac{1}{2}.$$

If this choice is made, then $g_a(t)$ becomes

$$g_a(t) = -s(t) + \frac{1}{2c}s'(t) - \frac{1}{24c^2}\left[12 - 6cT + c^2T^2\right]s''(t) + O(\epsilon^3). \tag{5.16}$$

This is a delayed version of the original signal ($g_a(t) = -s(t - \frac{1}{2}c) + O(\epsilon^3)$) if the choice $cT = 3$ is made.

6. A new class-D amplifier, with reduced distortion. We now describe a third modification to the standard negative-feedback class-D amplifier, which eliminates the intrinsic distortion at $O(\epsilon^2)$. While the two designs described above in sections 4 and 5 were developed first on physical principles and subsequently modeled here mathematically, this new design arose as a consequence of the mathematical models described herein. Prototypes do indeed enjoy significant distortion reduction.

To see how this new design is derived, we consider adding to the noninverting input of the comparator a function $F(t)$ such that $F(t)$ is constant over each interval $nT \le t < (n+1)T$. At present the values taken by this function over each interval are arbitrary; we shall compute the effects of $F(t)$ on the audio output spectrum, then choose it so as to cancel out the intrinsic distortion.

With this additional design feature, the audio output of the amplifier is found to be

$$\begin{aligned} g_a(t) = -s(t) &+ \frac{1}{c}\left[(1+k)s(t) + \theta(t)\right]' \\ &- \frac{1}{48c^2}\left\{\left(48 + 24cT - 3c^2T^2\right)\theta'(t) + \left(48(1+k) - c^2T^2\right)s'(t)\right. \\ &\qquad \left. + 3c^2T^2\left[\theta(t) - s(t)\right]'s^2(t)\right\}' + O(\epsilon^3), \end{aligned} \tag{6.1}$$

where $\theta(t)$ is a slowly varying function that agrees with $F(t)$ at times $t = nT$. The last line of (6.1) represents the nonlinear distortion, and it is clear that this component can be eliminated by choosing

$$F(nT) = s(nT), \tag{6.2}$$

and hence $\theta(t) = s(t)$. Fortunately, no further distortion is introduced by this choice for $F(t)$, and we have

$$g(t) = -s(t) + \frac{2+k}{c}s'(t) - \frac{12(2+k) + 6cT - c^2T^2}{12c^2}s''(t) + O(\epsilon^3), \tag{6.3}$$

which is free from any nonlinear distortion. As in the other models above, it is possible to choose k so that the output is, to the order calculated, a delayed version of the input signal and suffers no further distortion beyond the slight delay.

7. Nonlinearity in the carrier wave. We now consider one way in which imperfect electronic components can introduce distortion into the output. Specifically, we note that it is difficult in practice to generate a high-frequency triangular carrier wave whose slopes are precisely linear. In general the wave comprises sections of exponential functions, which approximate very closely the desired piecewise-linear profile [6]. For instance, let us suppose that instead of (2.1) we have for the carrier wave

$$v(t) = \begin{cases} 1 - \dfrac{2(\mathrm{e}^{t/t_0} - 1)}{\mathrm{e}^{T/2t_0} - 1} \equiv v_1(t) & \text{for } 0 \le t < \dfrac{T}{2}, \\[2ex] -1 + \dfrac{2(\mathrm{e}^{(t-T/2)/t_0} - 1)}{\mathrm{e}^{T/2t_0} - 1} \equiv v_2(t) & \text{for } \dfrac{T}{2} \le t < T, \end{cases} \tag{7.1}$$

and $v(t+T) = v(t)$ for all t. Note that the piecewise-linear profile of (2.1) is recovered as $t_0/T \to \infty$.

7.1. "Classical" class-D amplifier design. Let us first consider the effects of carrier-wave nonlinearity on the classical class-D amplifier design, without negative feedback. Here switching of $g(t)$ takes place whenever $v(t) + s(t) = 0$, i.e., when

$$v_1(nT + \alpha_n) + s(nT + \alpha_n) = 0 \quad \text{or} \quad v_2(nT + \beta_n) + s(nT + \beta_n) = 0. \tag{7.2}$$

These expressions are readily rearranged to give implicit equations for the switching times:

$$\alpha_n = t_0 \log\left\{1 + \tfrac{1}{2}[1 + s(nT + \alpha_n)](\mathrm{e}^{T/2t_0} - 1)\right\}, \tag{7.3}$$

$$\beta_n = \tfrac{1}{2}T + t_0 \log\left\{1 + \tfrac{1}{2}[1 - s(nT + \beta_n)](\mathrm{e}^{T/2t_0} - 1)\right\}. \tag{7.4}$$

It now follows readily from (2.27) that the audio output is

$$g_a(t) = \frac{2t_0}{T} \log \frac{1 + \frac{1}{2}[1 + s(t)](\mathrm{e}^{T/2t_0} - 1)}{1 + \frac{1}{2}[1 - s(t)](\mathrm{e}^{T/2t_0} - 1)}. \tag{7.5}$$

(It is straightforward from this expression to check that $g(t) \sim s(t)$ as $t_0/T \to \infty$, in accordance with (2.29).) Since it follows by Taylor expansion that

$$g_a(t) \sim \frac{4t_0}{T} \sum_{n=0}^{\infty} \frac{1}{2n+1} \left[\frac{(\mathrm{e}^{T/2t_0} - 1)s(t)}{\mathrm{e}^{T/2t_0} + 1}\right]^{2n+1}, \tag{7.6}$$

we may in principle compute the audio spectrum, for instance, due to a sinusoidal input $s(t)$.

We contrast the result here, where $g_a \not\equiv s$ and there is nonlinear distortion of $O(T/t_0)$, with that for a perfectly piecewise-linear carrier wave, where there is no distortion to the output.

7.2. Class-D amplifier with negative feedback. We now consider the effects of carrier-wave nonlinearity on the class-D amplifier with negative feedback (as illustrated in Figure 3.1). It turns out that, provided $T/t_0 \ll 1$, then to leading order in the nonlinearity, the output $g_a(t)$ as given by (3.29) is augmented by a term of the form

$$\frac{T^2}{16t_0}\left(s^3(t) - s(t)\right)'. \tag{7.7}$$

Note that the nonlinear distortion term here (proportional to $(s^3)'$) can be thought of as having a phase different from that inherent in the basic amplifier design (proportional to $(s^3)''$), so one cannot be used to cancel the other.

However, if we modify the design by adding to the comparator input a quantity

$$-\frac{1}{ct_0}h(t) \tag{7.8}$$

sampled at times

$$t = nT \quad \text{and} \quad \left(n + \frac{1}{2}\right)T, \tag{7.9}$$

in addition to the modification proposed in section 6, then the third-harmonic distortion term due to the carrier wave nonlinearity is canceled, and

$$\begin{aligned} g_a(t) &= -s(t) + c^{-1}(2+k)s'(t) \\ &\quad + c^{-2}\left[-\frac{1}{12}\left(12(2+k) + 6cT - c^2T^2\right)s''(t) + t_0^{-1}(2+k)s'(t)\right] + O(\epsilon^3). \end{aligned} \tag{7.10}$$

With an appropriate choice for k, this expression is essentially just a slightly delayed version of the input signal, i.e.,

$$g_a(t) = -s(t - t_1) + O(\epsilon^3). \tag{7.11}$$

To achieve this simplification we take

$$k = -1 + \left(1 + cT - \frac{1}{6}c^2T^2\right)^{1/2};$$

then the delay is

$$t_1 = \frac{2+k}{c}\left(1 + \frac{1}{ct_0}\right).$$

To the order calculated, there is no further distortion; the delay computed here is independent of the signal amplitude or frequency.

8. Conclusions. We have developed mathematical models for a variety of class-D amplifier designs. While models for the classical design with no negative feedback have been known for some time [1, 4, 5], the models presented here appear to be the first to treat in detail the negative-distortion design. One model describes the use of modulation to the carrier wave symmetry in order to reduce the intrinsic distortion of the negative-feedback design; another describes the use of a sample-and-hold device to achieve essentially the same ends. The mathematical analysis has, in each case, given theoretical backing to the design idea and quantitative statements about the parameter sets under which the designs are effective. A new means of reducing the intrinsic distortion has been proposed, on the basis of the mathematical models developed, which involves the use of a sample-and-hold device, but in a manner different from that in the existing design.

One of the authors (BHC) has tested all three designs (i.e., those described in sections 4, 5, and 6) in prototype and found them all to achieve significant reduction in harmonic distortion. The two designs involving a sample-and-hold unit are found not to work as well in practice as the carrier-wave modulation system, and are more expensive to produce. The carrier-wave modulation design is the basis of a successful commercial amplifier manufactured by Halcro.

It should be noted that the models developed here do not reflect a range of important practical issues, such as the noise and stability characteristics of the designs, nor their electromagnetic emissions. The models assume perfect components, an assumption that has particularly significant shortcomings in relation to sample-and-hold devices, for which the errors are relatively severe (in comparison with, say, integrators).

The models developed in this paper appear to be the first to provide an in-depth mathematical treatment of class-D amplifiers with negative feedback, and should be capable of extension to more complicated designs that reflect more accurately actual audio amplifiers.

ACOUSTIC PROPAGATION IN DISPERSIONS IN THE LONG WAVELENGTH LIMIT*

V. J. PINFIELD†, O. G. HARLEN‡, M. J. W. POVEY†, AND B. D. SLEEMAN‡

Abstract. The problem of scattering of ultrasound by particles in the long wavelength limit has a well-established solution in terms of Rayleigh expansions of the scattered fields. However, this solution is ill-conditioned numerically, and recent work has attempted to identify an alternative method. The scattered fields have been expressed as a perturbation expansion in the parameter Ka (the wavenumber multiplied by the particle radius), which is small in the long wavelength region. In the work reported here the problem has been formulated so as to be valid for all values of the thermal wavelength, which varies in order of magnitude, from much smaller to much larger than the particle size in the long wavelength region. Thus the present solution overlaps the limiting solutions for very small thermal wavelength (geometric theory) and very large thermal wavelength (low frequency) previously reported. Close agreement is demonstrated with the established Rayleigh expansion solution.

Key words. Helmholtz equation, scattering theory, ultrasound spectroscopy, dispersions

1. Introduction.

Ultrasound spectroscopy is an increasingly popular technique for characterizing the physical properties of dispersions, emulsions, gels, and solutions of biomolecules. It is a noninvasive technique that can address the extensive range of particle sizes encountered in many particulate systems and can be used with optically opaque materials. The technique has been adopted in manufacturing processes in the food and chemical industries. Ultrasonic instruments may be used to determine particle size distribution and/or concentration of the dispersed particles. In order to do this, it is necessary to use a strong theoretical basis to relate the ultrasound properties, i.e., velocity and attenuation, to the particle size and physical properties of the materials.

The problem of scattering of sound waves by a single spherical object (a fluid droplet) was solved by Rayleigh [1] and later refined by Epstein and Carhart [2]. A similar problem, with solid particles, was addressed by Allegra and Hawley [3]. Their solution is referred to as ECAH. The scattered fields are expanded as spherical harmonics in order to allow the application of boundary conditions at the particle surface. Although the solution is analytically exact, its numerical solution can be troublesome, because the matrix equation is ill-conditioned, and the series does not converge uniformly. In addition, calculation of spherical Bessel functions at large complex arguments is imprecise, and at large distances the Hankel functions oscillate rapidly. Such numerical limitations cause difficulty in applying the ultrasound method in practical applications.

The aim of the present work in this area has been to formulate a numerically stable solution to the single scatterer problem in such a way as to allow its potential extension to multiple scatterers and to nonspherical scatterers. The frequency range of interest is termed the *long wavelength limit*, in which the wavelength of the propagating acoustic wave is much larger than the size of the droplet ($Ka \ll 1$, where K is the wavenumber and a the radius of the particles). In this case, Kleinman's approach can be applied, in which the problem is reformulated to satisfy the radiation condition and uses a perturbation series solution in powers of Ka. At the lowest frequencies, at which the wavelength of the thermal waves produced by scattering is also much larger than the particle radius ($La \ll 1$, where L is the thermal wavenumber), the same technique can be applied to the thermal wave. The method was applied to single particle scattering in the *low-frequency potential scattering theory* (LFPST) previously published (Harlen et al. [4]). A later paper (Harlen et al. [5]) considered the case $La \gg 1$, where the thermal wavelength is much smaller than the particle size, and the Kleinman series expansion in La cannot be used. In this case, a geometric theory method was developed to approximate the solution for the thermal waves while retaining the Kleinman technique for the propagational waves.

In the work reported here, the Kleinman principles have again been used to separate the radiative terms of the waves and to define a series expansion which is convergent for the long wavelength limit ($Ka \ll 1$). The significant difference is that all wave modes are expanded as a series in Ka, leaving dependence on the thermal wavenumber implicit in the coefficients. This avoids assumptions on the size of La.

In the next section, the propagation of sound in fluids is considered in the context of a plane wave incident on a isolated spherical particle. The full ECAH method for the solution of the scattering problem is summarized and the perturbation expansion technique introduced. Sections 3 and 4 define the analytical forms of the wave potentials outside and inside the particle. Section 5 constructs the solution to the scattering problem in the perturbation method, showing the general solution and explicit results for the first few terms. Calculations are presented in section 6 to show that the method agrees with the full Rayleigh expansion method.

2. Sound fields in a fluid. The principles of sound propagation in homogeneous fluids are well documented, and only the most important results are given here. The equations of conservation of mass (continuity equation), momentum (Navier–Stokes equation), and energy, together with some thermodynamic relations, can be simplified by use of a velocity potential, ϕ, such that

$$\mathbf{u} = -\nabla\phi, \tag{1}$$

where $\mathbf{u}$ is the velocity of the fluid. The resulting biharmonic equation is further separated by defining two potentials, one for each of two types of wave mode (propagational and thermal). Propagational modes are the "usual" mode by which sound travels in a fluid. The thermal mode represents heat flow and is dissipative and therefore highly localized. There is an additional solution to the equations resulting from use of a vector potential, which corresponds to shear wave modes. Again these are dissipative with a very short decay length in fluids. In many practical applications of ultrasound, the shear wave modes resulting from scattering at dispersed particles are small. Hence for the subsequent analysis and in the previously published work (Harlen et al. [4], [5]), the vector potential solution is neglected. It was, however, included in the ECAH solutions.

Periodic solutions for the wave potentials have a time dependence defined by a factor $e^{-i\omega t}$, where ω is the angular frequency, which results in two separate Helmholtz equations, one each for the propagational and thermal modes, thus:

$$\left(\nabla^2 + K^2\right)\varphi = 0, \quad \left(\nabla^2 + L^2\right)\psi = 0. \tag{2}$$

The overall velocity potential in the fluid is the sum of the propagational (φ) and thermal (ψ) potentials.

The wavenumbers are given to a very good approximation in fluids by

$$K = \frac{\omega}{v}\left(1 + i\frac{(\gamma-1)\,\sigma\omega}{2v^2}\right), \quad L = \left(\frac{\omega}{2\sigma}\right)^{1/2}(1+i), \tag{3}$$

where γ is the ratio of specific heat capacities, v the speed of sound, and σ the thermal diffusivity, such that $\sigma = \tau/\rho C_p$, where τ is the thermal conductivity, ρ is the density, and C_p is the specific heat capacity at constant pressure.

The common expression for the wavenumber of the propagational mode has the form

$$K = \frac{\omega}{v} + i\alpha, \tag{4}$$

where α is the attenuation. There are many absorption effects in fluids which are not accounted for in the classical thermal and fluid momentum equations used to derive the wavenumber in (3). Hence the measured attenuation should be used instead, as in (4).

The pressure and temperature fluctuations which result from the wave motions are related to the velocity potentials as follows:

$$P = -i\omega\rho\,(\varphi + \psi), \quad T = \Gamma_c\varphi + \Gamma_t\psi, \tag{5}$$

where the thermal factor for each wave mode is

$$\Gamma_c = \frac{-iK^2\,(\gamma-1)}{\beta\,(\omega + i\gamma\sigma K^2)}, \quad \Gamma_t = \frac{-iL^2\,(\gamma-1)}{\beta\,(\omega + i\gamma\sigma L^2)}. \tag{6}$$

Subscript c is used to denote the compressional (or propagational) mode and t the thermal mode. Note that these temperature factors were quoted incorrectly in the previous paper (Harlen et al. [5]).

A useful thermodynamic relation is

$$\gamma - 1 = \frac{v^2\beta^2 T_0}{C_p}, \tag{7}$$

where β is the thermal expansivity and T_0 is the temperature of the system, not the small temperature changes caused by the wave motion.

2.1. Scattering of sound waves by particles. In order to calculate the ultrasound field produced by a dispersion of particles, it is first necessary to consider the effect on a sound wave of a single particle immersed in isolation in an infinite uniform fluid. The most relevant and simple system to study is that of a plane wave of angular frequency ω incident on a spherical particle of radius a. The fluid inside the particle has different physical properties and so will respond in a different way from the fluid surrounding it to the compression and rarefaction of the wave. Scattered waves of

each mode are produced inside and outside the particle. At the surface of the particle certain boundary conditions must be met. These include the requirement that the boundary not be disrupted, i.e., that material immediately inside and outside of the particle move at the same speed, and that temperature and heat flow be continuous (the same either side of the interface). In terms of the wave potentials, the boundary conditions are as follows.

The normal velocity of fluid on both sides of the boundary must be equal to avoid formation of a void:

$$\frac{\partial}{\partial r}\left(\varphi_0 + \varphi + \psi\right) = \frac{\partial}{\partial r}\left(\varphi' + \psi'\right). \tag{8}$$

The pressure must be equal on each side of the boundary:

$$\varphi_0 + \varphi + \psi = \hat{\rho}\left(\varphi' + \psi'\right). \tag{9}$$

The temperature must be equal on each side of the boundary:

$$\Gamma_c\varphi_0 + \Gamma_c\varphi + \Gamma_t\psi = \Gamma'_c\varphi' + \Gamma'_t\psi'. \tag{10}$$

The heat flux must be equal on each side of the boundary:

$$\Gamma_c\frac{\partial}{\partial r}\left(\varphi_0 + \varphi\right) + \Gamma_t\frac{\partial\psi}{\partial r} = \hat{\tau}\left(\Gamma'_c\frac{\partial\varphi'}{\partial r} + \Gamma'_t\frac{\partial\psi'}{\partial r}\right), \tag{11}$$

where primed quantities refer to the inside of the particle,

$$\hat{\rho} = \frac{\rho'}{\rho}, \quad \hat{\tau} = \frac{\tau'}{\tau}, \tag{12}$$

and φ_0 is the potential of the incident wave.

The objective is to determine the amplitude and phase of the scattered propagational mode, which is the only part which is still nonnegligible at a significant distance from the particle (the thermal field having decayed to zero). Other published work is used to determine the wavenumber for a dispersion of particles, by a multiple scattering approach, to obtain the net effect of many particles. For the present work, the aim is to calculate the scattered wave amplitude.

In order to obtain the solution to the scattering problem, a general form for each wave mode must be proposed. The potentials of the scattered fields must be solutions of the appropriate Helmholtz equation (2), whether inside or outside the particle. In addition, the waves inside the particle must be defined at the origin (the center of the particle), and those outside the particle must satisfy the radiation condition. Finally, the boundary conditions at the surface of the particle must be satisfied. In sections 3 and 4 appropriate forms for the solutions are constructed to allow the scattering problem to be resolved.

2.2. ECAH method. The Epstein and Carhart method [2] for the scattering problem expanded the solutions of the Helmholtz equation in spherical coordinates. The solutions are Rayleigh series in the spherical harmonics, that is, a combined series in the spherical Bessel functions (for the radial dependence) and Legendre polynomials (for the angular dependence). The Bessel functions are chosen appropriately for the region in which the wave exists; in the continuous phase the solution must be defined at large distances, so the Hankel function h_n is used, whereas inside the particle the

solution must be defined at the origin, so the j_n function is used. ECAH took the forms for each wave potential to be as follows:

$$\begin{aligned}
\varphi &= \sum_{n=0}^{\infty} i^n (2n+1) A_n h_n (Kr) P_n (\cos\theta), \\
\psi &= \sum_{n=0}^{\infty} i^n (2n+1) B_n h_n (Lr) P_n (\cos\theta), \\
\varphi' &= \sum_{n=0}^{\infty} i^n (2n+1) A'_n j_n (K'r) P_n (\cos\theta), \\
\psi' &= \sum_{n=0}^{\infty} i^n (2n+1) B'_n j_n (L'r) P_n (\cos\theta).
\end{aligned} \tag{13}$$

Similarly the incident field (a plane wave) can be expressed as

$$\varphi_0 = \sum_{n=0}^{\infty} i^n (2n+1) j_n (Kr) P_n (\cos\theta). \tag{14}$$

In the ECAH method, these functions and the relevant derivatives are directly evaluated at the surface of the particle and substituted into the set of boundary conditions. For a spherical particle of radius a the Bessel functions must be determined at $r = a$. In the long wavelength limit, $|Ka| \ll 1$ and $|K'a| \ll 1$, the Hankel and Bessel functions can cause difficulties, and the difference in scale of the values appearing in the boundary equations results in an ill-conditioned matrix equation which must be solved.

In order to avoid these problems, a solution is sought which uses alternative forms for the wave potentials, both to avoid the direct use of the Bessel functions and to produce a direct solution not relying on a matrix inversion for its solution.

2.3. Kleinman method and Poincaré series. In the long wavelength limit, the condition $|Ka| \ll 1$ applies. Kleinman developed a method for solving low-frequency scattering problems (see Harlen et al. [4]) in which he expressed the potentials as a perturbation expansion, i.e., as a series in powers of iKa:

$$\phi = \sum_{m=0}^{\infty} (iKa)^m \phi_m, \tag{15}$$

where ϕ is one of the wave potentials. The series is known to converge rapidly, with an error bounded by $\mathrm{O}\left(|Ka|^{m+1}\right)$ if the mth order solution is used. Thus the problem becomes one of finding the solution to a set of potential functions. Although this may seem to increase the number of equations which must be solved, it avoids the ill-conditioned numerical calculation suffered by the ECAH approach and allows the series to be terminated with some confidence that an accurate result has been obtained. Further details of the method are given in Harlen et al. [4] and [5].

In the present work, *all* potentials are expanded as a series in iKa. The previous low-frequency work (Harlen et al. [4]) expanded each wave potential as a series in its appropriate wavenumber; for example, the thermal wave mode was defined as a series in powers of L. Later, the work on the short thermal wavelength region (geometric theory [5]) introduced combined power series, with positive powers of the

propagational wavenumbers, and inverse powers of the thermal wavenumbers. In the frequency range considered in that work, the values of $|La|$ and $|L'a|$ were large, hence an inverse power series was appropriate. For example, for a scattered propagational mode potential,

$$\phi = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \frac{(iKa)^n}{(iLa)^m} \phi_{nm}. \tag{16}$$

In order to achieve a method which is valid across the entire frequency range in the long wavelength limit, it is appropriate to use only a power series in iKa since this value is by definition small over the entire range, $|Ka| \ll 1$, thus assuring convergence of the series. Series in positive or inverse powers of La are limited in their scope because of the variation in magnitude of this parameter within the long wavelength region. Its value ranges from small at low frequency to very large at the upper frequency limit of the long wavelength region. Hence in the current work, the power series in iKa is applied to each wave potential, with any dependence on other wavenumbers being implicit in the rest of the potential.

3. Solution forms outside the particle. In the continuous phase outside the particle, the solutions of the Helmholtz equation must also satisfy the radiation condition, which restricts its form at large distances from the particle. The Sommerfield radiation condition is as follows:

$$\lim_{r \to \infty} \left[r \left(\frac{\partial \phi}{\partial r} - ik\phi \right) \right] = 0. \tag{17}$$

In physical terms, the condition means that there is no energy radiating inwards from infinity. Thus the solution appears as an outgoing spherical wave at large distances from the particle (cf. Colton and Kress [6, p. 21]).

The spherical Hankel function used in the ECAH method is one such solution, each $h_n(kr)$ including a factor e^{ikr}/r which represents a spherical wave. However, radiating solutions to the Helmholtz equation are not regular at infinity, and it is the exponential part of the function which caused numerical difficulties at large arguments (for the thermal waves).

In general terms, the form of the solution is

$$\phi = \frac{e^{ikr}}{r} \tilde{\phi} = \frac{e^{ikr}}{r} \sum_{l=0}^{\infty} \frac{f_l(\vartheta, \Omega)}{r^l}, \tag{18}$$

where f_l is the angular dependence (Harlen et al. [4]). The function $\tilde{\phi}$ does not suffer from the mathematical difficulties of the overall potential ϕ, and is regular at infinity.

Following the previous method (Harlen et al. [4]), it is therefore appropriate to introduce new potential functions, $\tilde{\varphi}$ and $\tilde{\psi}$, for the propagational and thermal modes, respectively, outside the particle such that

$$\varphi = e^{iK(r-a)} \tilde{\varphi}, \tag{19}$$

$$\psi = e^{iL(r-a)} \tilde{\psi}. \tag{20}$$

The exponential spherical-wave factors have been explicitly taken out, so that the remaining functions $\tilde{\varphi}$ and $\tilde{\psi}$ are regular and differentiable. In addition when applying

boundary conditions for a spherical particle at $r = a$ the exponential factors do not contribute.

Continuing the Kleinman approach, the next step is to express the new potential functions as a series in iKa (see previous section), thus

$$\left(\tilde{\varphi}, \tilde{\psi}\right) = \sum_m (iKa)^m \left(\tilde{\varphi}_m, \tilde{\psi}_m\right). \tag{21}$$

3.1. Propagational mode. Using the spherical harmonic solutions to the Helmholtz equation, the partial fields for the propagational mode can then be written as

$$\tilde{\varphi}_m = \sum_{n=0}^{\infty} \sum_{j=0} A_{nmj} \cdot \frac{r^j}{a^j} \cdot \frac{a^{n+1}}{r^{n+1}} \cdot P_n(\cos\vartheta). \tag{22}$$

This form of the solution is suggested by the results of the LFPST method (Harlen et al. [4]), although it is expressed here as a general series in r. The full wave potential can be constructed using (21) and (19). The Helmholtz equation (2) can then be shown to relate the potentials of consecutive order m by the equation

$$\nabla^2 \tilde{\varphi}_m = -\frac{2}{ar} \frac{\partial}{\partial r} (r\tilde{\varphi}_{m-1}). \tag{23}$$

By substituting the general solution (22) into this form of the Helmholtz equation, and matching powers of (iKa) for each (spherical harmonic) order n, it can be shown that the coefficients are related by the following recurrence relation:

$$A_{n,m,j} = -\frac{2(j-1-n)}{j(j-1-2n)} A_{n,m-1,j-1} \text{ for } j \geq 1. \tag{24}$$

Thus coefficients for the potential of order m are related to those for the previous order. Only the $j = 0$ coefficient remains to be solved from the boundary equations. By definition, all coefficients for orders $m < 0$ are zero. Note that the coefficients are zero for $j \geq n + 1$, and hence the coefficients may be nonzero up to and including $j = n$, i.e., it is a finite series. The solution for the lowest orders (see section 5.6) demonstrates that, excepting $n = 0$, the first (in m) nonzero coefficient is for $m = n$, which implies that at larger orders m the last nonzero term in the j-series will be for $j = m - n$. The result also shows that (22) does give a solution of the Helmholtz equation. Although the propagational mode solution (22) does not appear to have the same form as that required for a radiating solution (18), it is clear that since the coefficients are nonzero only for $j \leq n$, each term in l (18) includes contributions from different m, n, and j combinations, which together give the angular dependence f_l.

The ECAH method expresses the propagational scattered wave in terms of the spherical Hankel functions $h_n(Kr)$. Our result is not simply a power series expansion in Kr of the Hankel function. This is because the wave potential has been written as a power series in iKa, which removes all the K-dependence, leaving a series in r, whose coefficients are to be determined. Contributions from different orders m make up the overall potential series in Kr.

3.2. Thermal mode. In the ECAH method, the thermal wave potential in the continuous phase was based on the spherical Hankel function $h_n(Lr)$. Since the perturbation series expansion (21) is taken in powers of (iKa), rather than in powers

of L, the thermal potential can be expressed simply using the series expansion of the spherical Hankel function. Thus

$$h_n(x) = e^{ix} \sum_{j=1}^{n+1} \frac{h_{nj}}{x^j} \tag{25}$$

(see the appendix for the factors h_{nj}), so that the thermal wave potential takes the form

$$\tilde{\psi}_m = \sum_{n=0}^{\infty} \sum_{j=1}^{n+1} B_{nm} \cdot \frac{h_{nj}}{(Lr)^j} \cdot P_n(\cos\vartheta). \tag{26}$$

All factors of L are taken implicitly as part of the potential function. The spherical Hankel function, in fact, results in a finite series in inverse powers of Lr, whose coefficients are known. These are all included in the appropriate term in the series in powers of $(iKa)^m$.

3.3. The incident wave. The incident wave is a plane wave and can be expressed as a series of spherical harmonics, as in the ECAH method (see (14)). In order to follow the same method as used for the other waves, the spherical Bessel function can be expanded as a power series in (iKa), using the power series expansion of the spherical Bessel function

$$j_n(x) = 2^n x^n \sum_{s=0}^{\infty} \frac{(-1)^s (s+n)!}{s!\,(2s+2n+1)!} x^{2s} \tag{27}$$

(Arfken [7, p. 625]).

Thus the plane wave can be written

$$\varphi_0 = \sum_{n=0}^{\infty} \sum_{s=0}^{\infty} (iKa)^{n+2s} \left(\frac{r}{a}\right)^{n+2s} F_n(s)\, P_n(\cos\vartheta), \tag{28}$$

where

$$F_n(s) = \frac{2^n (2n+1)(s+n)!}{s!\,(2s+2n+1)!}, \tag{29}$$

where n and s are nonnegative integers (F is zero otherwise). For purposes of numerical calculation, the factorial functions suffer from overflow for all but very low orders (n, s). The following recurrence relations can be used for accurate calculation:

$$F_0(0) = 1, \tag{30}$$

$$\frac{F_n(0)}{F_{n-1}(0)} = \frac{1}{(2n-1)} \text{ for } n \geq 1, \tag{31}$$

$$\frac{F_n(s)}{F_n(s-1)} = \frac{1}{2s(2n+2s+1)} \text{ for } s \geq 1. \tag{32}$$

In the low-frequency scattering method (Harlen et al. [4]), the incident field was included in the form of (14), with the $j_n(Kr)$ function retained. Thus the contribution of the incident field was included entirely in the zeroth and first order terms of the perturbation series in (iKa). The later work for the higher frequency region

(Harlen et al. [5]) expressed the incident field through the power series expansion of the exponential form:

$$e^{iKz} = e^{iKr\cos\theta} = \sum_{n=0}^{\infty} \frac{(iKa\cos\theta)^n}{n!}. \tag{33}$$

However, this requires that each of the powers of $\cos\theta$ be expressed in terms of the associated Legendre polynomials $P_n(\cos\theta)$ which appear in the other wave potentials in order to match the angular dependence in the boundary conditions. Hence the expansion used here, (28), appears to be most consistent with the method, since the powers of iKa and the angular dependence $P_n(\cos\theta)$ can be matched directly in the boundary equations.

4. Solution forms inside the particle. Within the particle or droplet, the solutions to the Helmholtz equation need not satisfy the radiation condition, since the waves are in a bounded region. However, the solutions must be defined at the origin ($r = 0$). In spherical coordinates the appropriate solutions for the radial part of the potential are the spherical Bessel functions, j_n, rather than the spherical Hankel functions, h_n, which are not defined at the origin. When the boundary conditions are applied, the Bessel function for the thermal wave must be evaluated for an argument $L'a$ which can have a large imaginary component in the frequency range of interest. Hence, it is again desirable to avoid the use of Bessel functions.

4.1. Propagational mode. There are many different ways of expressing the spherical Bessel functions j_n—for example, as an infinite power series or as a combination of trigonometric functions *sin* and *cos*. For the propagational mode inside the particle, the power series form can be used, since the value $K'a$ (which is the argument of the function used in the boundary equations) is small in the long wavelength region. First, applying the perturbation series expansion as

$$\varphi' = \sum_m (iKa)^m \varphi'_m \tag{34}$$

and then expressing the potential as a series in powers of r gives

$$\varphi'_m = \sum_{n=0}^{\infty} \sum_{j=0} A'_{nmj} \cdot \frac{r^j}{a^j} \cdot \frac{r^n}{a^n} \cdot P_n(\cos\vartheta). \tag{35}$$

The Helmholtz equation (2) can again be used with (34) to relate potentials to those of a different order, and thus

$$\nabla^2 \varphi'_m = \frac{\hat{c}}{a^2} \varphi'_{m-2}, \tag{36}$$

where

$$\hat{c} = \frac{K'^2}{K^2}, \tag{37}$$

which is frequency independent to a very good approximation. Substituting the general solution, (35), into (36) and matching powers of iKa as before results in the following recurrence relation for the coefficients:

$$A'_{n,m,j} = \frac{\hat{c}}{j(2n+j+1)} A'_{n,m-2,j-2} \text{ for } j \geq 2, \tag{38}$$

$$A'_{n,m,j} = 0 \text{ for } j = 1 \text{ and all odd values of } j. \tag{39}$$

As in the case of the propagational mode in the continuous phase, the above equations show that the coefficients $A'_{n,m,j}$ for order m can be calculated from those of a previous order, given that all coefficients for $m < 0$ are zero. Only the $j = 0$ coefficient remains to be determined from the boundary conditions. In this case the limit of the series is determined by the number of nonzero coefficients for the previous order, producing an expanding triangle of coefficients. The solution of the boundary conditions shows that the first nonzero coefficient is for $n = m$, $j = 0$, so that the limit of the series in j would be $j = m - n$, where $m > n$.

4.2. Thermal mode. For the thermal wave, the argument of the function at the boundary, $L'a$, may be small or very large, depending on the frequency. The usual power series expansion of j_n would be inappropriate at large arguments. Similarly an infinite inverse power series in $L'r$, as used by Harlen et al. [5], would be unsuitable at small arguments and is not defined at the origin. Hence, either form is restricted in its frequency range.

The trigonometric form of the Bessel function j_n (e.g., $j_0(x) = \sin x/x$) can be modified by expressing the trigonometric functions as a sum or difference of two exponential terms e^{ix} and e^{-ix}, and thus

$$j_n(x) = e^{ix} \sum_{j=1}^{n+1} \frac{j_{nj+}}{x^j} - e^{-ix} \sum_{j=1}^{n+1} \frac{j_{nj-}}{x^j} \tag{40}$$

(see the appendix for the coefficients).

Hence, the wave potential for the thermal wave in the particle could be written as a sum of modified outward and inward spherical waves. Arfken [7, p. 627] states that "$j_n(x)$ and $n_n(x)$ are appropriate for a description of *standing spherical waves*; $h_n^1(x)$ and $h_n^2(x)$ correspond to *traveling spherical waves*." A standing wave results from a superposition of traveling waves in opposite directions.

Hence the thermal wave inside the particle can be written as

$$\psi' = e^{iL'(r-a)}\tilde{\psi}'_+ - e^{-iL'(r-a)}\tilde{\psi}'_-. \tag{41}$$

Following the previous perturbation series method with each of the new wave potentials,

$$\left\{\tilde{\psi}'_+, \tilde{\psi}'_-\right\} = \sum_m (iKa)^m \left\{\tilde{\psi}'_{+m}, \tilde{\psi}'_{-m}\right\}. \tag{42}$$

And each of the terms has the usual angular dependence; thus

$$\tilde{\psi}'_{+m} = \sum_{n=0}^{\infty} \sum_{j=1}^{n+1} B'_{nm} \cdot e^{2iL'a} \cdot \frac{j_{nj+}}{(L'r)^j} \cdot P_n(\cos\vartheta), \tag{43}$$

$$\tilde{\psi}'_{-m} = \sum_{n=0}^{\infty} \sum_{j=1}^{n+1} B'_{nm} \cdot \frac{j_{nj-}}{(L'r)^j} \cdot P_n(\cos\vartheta). \tag{44}$$

The factor $e^{2iL'a}$ results from the condition that the potential be defined at the origin. All inverse powers of r must cancel at the origin, leaving only a single term from $n = 0$.

The previous work on scattering at the high-frequency end of the long wavelength limit (Harlen et al. [5]) used only the second of the two terms given in (41). When a series solution is used in powers of $L'a$ the only solution for the zeroth order term is a/r (Harlen et al. [5, equation (4.9)]), which results in a function which is not defined at the origin. The result given above avoids this problem.

5. Construction of the solution.

5.1. Pressure and temperature factors. When applying the boundary conditions, terms in the same powers of iKa must be matched, as must the angular dependence $P_n(\cos\theta)$. For consistency, any other parameters which appear in the boundary conditions must be expressed as the appropriate power of iKa. The pressure and temperature changes caused by the different waves were defined in (5). The pressure is related to the wave potential by a factor which includes the frequency and density. Since the frequency is the same for all wave forms, this factor will cancel from the relevant boundary equation. However, the thermal factors (equation (6)) have different frequency dependence for the different wave modes, and these need to be defined in relation to powers of iKa.

For the propagational modes, the thermal factors can be simplified by using the relation

$$\left|\frac{K^2}{L^2}\right| \approx \frac{\omega\sigma}{v^2} \ll 1. \tag{45}$$

The approximation is not limited in frequency range, but relies on the small value of $\omega\sigma/v^2$ which is of order 10^{-5} at 100 MHz in water at 30° C, so that

$$\Gamma_c = \frac{-iK^2(\gamma-1)}{\beta(\omega+i\gamma\sigma K^2)} \approx \frac{K^2(\gamma-1)}{\beta\sigma L^2} \tag{46}$$

and

$$\Gamma'_c = \frac{-iK'^2(\gamma'-1)}{\beta'(\omega+i\gamma'\sigma' K'^2)} \approx \frac{\hat{c}K^2(\gamma'-1)}{\beta'\sigma' L'^2}. \tag{47}$$

The dependence on L is left implicit, whereas the power series in (iKa) requires explicit consideration of powers of K. Hence the K-dependence of thermal factors are expressed by two new parameters, and thus

$$\Gamma_c = (iKa)^2 g_c, \quad \Gamma'_c = (iKa)^2 g'_c. \tag{48}$$

The thermal factors for the thermal wave modes can be simplified,

$$\Gamma_t = \frac{-iL^2(\gamma-1)}{\beta(\omega+i\gamma\sigma L^2)} \approx -\frac{1}{\beta\sigma}, \tag{49}$$

and similarly in the dispersed phase. The temperature factors for the thermal waves can therefore be seen to be approximately independent of frequency, and hence independent of K, which is the power series being used.

5.2. Definitions. The application of the boundary conditions leads to some complicated equations, which can be made easier to read by using some further symbols to define collections of terms. In addition, in numerical calculation, greater accuracy is achieved (avoiding subtraction of nearly equal terms) by using the recurrence relation (24) to write

$$\sum_{j=0} A_{n,m-1,j} + \sum_{j=0}^{m-n} jA_{nmj} = \sum_{j=1}^{m-n} -\frac{j}{(j-2n)} A_{n,m-1,j} + \delta_{n0} A_{n,m-1,0}, \tag{50}$$

where δ_{n0} is a Kronecker delta. The second term on the right-hand side which affects only the $n = 0$ results was omitted in the reported LFPST solution (Harlen et al. [4]).

Other symbols are defined as follows:

$$S_h = \sum_{j=1}^{n+1} \frac{h_{nj}}{(La)^j}, \tag{51}$$

$$S_{dh} = \sum_{j=1}^{n+1} \frac{(iLa - j)\, h_{nj}}{(La)^j}, \tag{52}$$

$$S_j = e^{2iL'a} \sum_{j=1}^{n+1} \frac{j_{nj+}}{(L'a)^j} - \sum_{j=1}^{n+1} \frac{j_{nj-}}{(L'a)^j}, \tag{53}$$

$$S_{dj} = e^{2iL'a} \sum_{j=1}^{n+1} \frac{(iL'a - j)\, j_{nj+}}{(L'a)^j} + \sum_{j=1}^{n+1} \frac{(iL'a + j)\, j_{nj-}}{(L'a)^j}, \tag{54}$$

$$S_{A,m-s} = \sum_{j=0}^{n} A_{n,m-s,j} \text{ for } s = 1, 2, 3, \quad S_{A,m} = \sum_{j=1}^{n} A_{n,m,j}, \tag{55}$$

$$S_{jA,m-s} = \sum_{j=1}^{n} -\frac{j}{(j-2n)} A_{n,m-s,j} + \delta_{n0} A_{n,m-s,0} \text{ for } s = 0, 1, 2, 3, \tag{56}$$

$$S_{A',m-s} = \sum_{j=0}^{m-n} A'_{n,m-s,j} \text{ for } s = 1, 2, 3, \quad S_{A',m} = \sum_{j=1}^{m-n} A'_{n,m,j}, \tag{57}$$

$$S_{jA',m-s} = \sum_{j=1}^{m-n} j A'_{n,m-s,j} \text{ for } s = 0, 1, 2. \tag{58}$$

5.3. Boundary conditions. Having defined the wave potentials in a consistent form, as perturbation series in powers of iKa, and with the Legendre polynomials defining the angular dependence, the boundary conditions can now be applied at the surface of the spherical particle, $r = a$. Each boundary equation consists of summations over orders n, m. The spherical harmonic terms which define the angular dependence are independent and hence must be matched—so all terms in the same n must be matched. In addition, terms in powers of $(iKa)^m$ are matched on each side of the equation, which may arise from various orders of m. If each order m is determined in turn, all coefficients for previous orders, e.g., $m-1$, are already known. In addition, the propagational mode coefficients for order m for $j \geq 1$ can be calculated from the previous order results (see (24) and (38)). Hence, the boundary equations for the n, mth order include four unknowns:

$$A_{nm0},\ A'_{nm0},\ B_{nm},\ B'_{nm}.$$

The four boundary conditions (8)–(11) result in the equations below:

$$mF_n\left(\frac{m-n}{2}\right)+\sum_{j=0}^{m-1-n}A_{n,m-1,j}+\sum_{j=1}^{m-n}(j-n-1)\,A_{nmj}-(n+1)\,A_{nm0}+S_{dh}B_{nm}$$
$$=\sum_{j=1}^{m-n}(j+n)\,A'_{nmj}+nA'_{nm0}+S_{dj}B'_{nm}, \tag{59}$$

$$F_n\left(\frac{m-n}{2}\right)+\sum_{j=1}^{m-n}A_{nmj}+A_{nm0}+S_hB_{nm}$$
$$=\hat{\rho}\sum_{j=1}^{m-n}A'_{nmj}+\hat{\rho}A'_{nm0}+\hat{\rho}S_jB'_{nm}, \tag{60}$$

$$g_cF_n\left(\frac{m-n-2}{2}\right)+g_c\sum_{j=0}^{m-2-n}A_{n,m-2,j}+\Gamma_tS_hB_{nm}$$
$$=g'_c\sum_{j=0}^{m-2-n}A'_{n,m-2,j}+\Gamma'_tS_jB'_{nm}, \tag{61}$$

$$g_c\,(m-2)\,F_n\left(\frac{m-n-2}{2}\right)+g_c\sum_{j=0}^{m-3-n}A_{n,m-3,j}$$
$$+g_c\sum_{j=0}^{m-2-n}(j-n-1)\,A_{n,m-2,j}+\Gamma_tS_{dh}B_{nm}$$
$$=\hat{\tau}g'_c\sum_{j=0}^{m-2-n}(j+n)\,A'_{n,m-2,j}+\hat{\tau}\Gamma'_tS_{dj}B'_{nm}. \tag{62}$$

5.4. Solution. The solution proceeds by stepping through the orders of m starting at $m=0$. All coefficients are zero for $m<0$. For each m the recurrence relations are used to derive any nonzero propagational mode coefficients for order m (equations (24) and (38)). The two thermal boundary conditions, (61) and (62), for the n,mth order include only the unknown thermal coefficients; other terms, being from previous orders $m-2$ and $m-3$, are already known. Hence (61) and (62) can be solved for the thermal coefficients $B_{nm}$and B'_{nm}. These can be substituted into the other boundary equations, (59) and (60), in order to determine the remaining propagational mode coefficients $A_{nm0},\ A'_{nm0}$.

The thermal coefficients for n,m are

$$B_{nm}=\Big[-g_c\,(\hat{\tau}S_{dj}-(m-2)\,S_j)\,F_n\,((m-n-2)/2)$$
$$-g_c\,\{(\hat{\tau}S_{dj}+(n+1)\,S_j)\,S_{A,m-2}-S_jS_{jA,m-3}\}$$
$$+\hat{\tau}g'_c\,\{(S_{dj}-nS_j)\,S_{A',m-2}-S_jS_{jA',m-2}\}\Big]/\Gamma_t\,(\hat{\tau}S_{dj}S_h-S_jS_{dh})\,, \tag{63}$$

$$
\begin{aligned}
B'_{nm} = \Big[& -g_c \left(S_{dh} - (m-2)\, S_h\right) F_n\left((m-n-2)/2\right) \\
& - g_c \left\{\left(S_{dh} + (n+1)\, S_h\right) S_{A,m-2} - S_h S_{jA,m-3}\right\} \\
& + g'_c \left\{\left(S_{dh} - n\hat{\tau} S_h\right) S_{A',m-2} - \hat{\tau} S_h S_{jA',m-2}\right\}\Big] / \Gamma'_t \left(\hat{\tau} S_{dj} S_h - S_j S_{dh}\right).
\end{aligned} \tag{64}
$$

Substituting into the boundary conditions, (59) and (60), thus gives

$$
\begin{aligned}
A_{nm0} = \Big[& (m\hat{\rho} - n)\, F_n\left((m-n)/2\right) \\
& - (n + (n+1)\,\hat{\rho})\, S_{A,m} + \hat{\rho}\left(S_{jA,m-1} - S_{jA',m}\right) \\
& + \left(\hat{\rho} S_{dh} - n S_h\right) B_{nm} - \hat{\rho}\left(S_{dj} - n S_j\right) B'_{nm}\Big] / \left[n + (n+1)\,\hat{\rho}\right],
\end{aligned} \tag{65}
$$

$$
\begin{aligned}
A'_{nm0} = \Big[& (m+n+1)\, F_n\left((m-n)/2\right) \\
& - (n + (n+1)\,\hat{\rho})\, S_{A',m} + \left(S_{jA,m-1} - S_{jA',m}\right) \\
& + \left(S_{dh} + (n+1)\, S_h\right) B_{nm} - \left(S_{dj} + (n+1)\,\hat{\rho} S_j\right) B'_{nm}\Big] / \left[n + (n+1)\,\hat{\rho}\right].
\end{aligned} \tag{66}
$$

Since the thermal boundary equations (61) and (62) include terms in order $m-2$ and lower orders, this implies that the first nonzero thermal field contribution is at second order in iKa.

5.5. Multiple scattering. For practical application of the scattering results, it is necessary to relate the scattering from a single particle to the wavenumber (and corresponding velocity and attenuation) of a dispersion of such particles. The commonly used formulation for multiple scattering is that of Lloyd and Berry [8], whose result was derived in a different way by Waterman and Truell and later works [9], [10]. Taking the limiting form of the solution, (18), in the far field as r approaches infinity, the scattered field takes the form

$$
\varphi \to \frac{e^{iKr}}{r} f(\theta). \tag{67}
$$

In terms of the Legendre polynomials,

$$
f(\theta) = \frac{1}{iK} \sum_{n=0}^{\infty} (2n+1)\, T_n P_n(\cos\theta). \tag{68}
$$

The scattered propagational field, combining (19), (21), and (22), has the form

$$
\varphi = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \sum_{j=0} A_{nmj} (iKa)^m\, e^{iK(r-a)} \cdot \frac{r^j}{a^j} \cdot \frac{a^{n+1}}{r^{n+1}} \cdot P_n(\cos\vartheta), \tag{69}
$$

from which the far field coefficient T_n is

$$
T_n = \frac{e^{-iKa}}{(2n+1)} \sum_{m=0}^{\infty} (iKa)^{m+1} A_{nmn}, \tag{70}
$$

showing that only the terms $j = n$ contribute in the far field. For each spherical harmonic n (except for $n = 0$), the first nonzero term for the $j = 0$ coefficients (from the boundary equations) is for $m = n$ (see, for example, the results in Table 1).

Following the recurrence relation (equation (24)) through the orders m shows that the first nonzero term appearing in the far field (i.e., for $j = n$) will be at order $m = 2n$. So for the $n = 1$ far field coefficient, T_1, the first contribution results from A_{121}; for $n = 2$ the first nonzero term in T_2 corresponds to $m = 4$, i.e., A_{242}. It is very important to include sufficient orders $m \geq 2n$ when an accurate solution for the nth order far field coefficient is required.

The multiple scattering result for the wavenumber of the dispersion, B, is

$$\left(\frac{B}{K}\right)^2 = 1 + \frac{3\phi}{K^2a^3} f(0) + \frac{9\phi^2}{4K^4a^6}\left(f^2(\pi) - f^2(0) - \int_0^\pi d\theta \frac{1}{\sin(\theta/2)}\left(\frac{d}{d\theta} f^2(\theta)\right)\right), \tag{71}$$

which to second order gives

$$\left(\frac{B}{K}\right)^2 = 1 - \frac{3i\phi}{K^3a^3}(T_0 + 3T_1 + 5T_2) - \frac{27\phi^2}{K^6a^6}\left(T_0T_1 + \frac{10}{3}T_0T_2 + 2T_1^2 + 11T_1T_2 + \frac{230}{21}T_2^2\right). \tag{72}$$

Note that here the symbol ϕ refers to the volume fraction of the dispersed particles.

5.6. Explicit solutions for low orders. In order to demonstrate the method of solution and to derive explicit solutions which may be used instead of the general solution, the results are here derived for low orders of n and m. The following parameters are those which are used to obtain the low order solutions:

For $n = 0$

$$h_{01} = -i, \tag{73}$$

$$S_h = -i/(La), \quad S_{dh} = -i(iLa - 1)/(La), \tag{74}$$

$$j_{01+} = j_{01-} = 1/(2i), \tag{75}$$

$$S_j = \left(e^{2iL'a} - 1\right)\Big/(2iL'a), \tag{76}$$

$$S_{dj} = \left\{iL'a\left(e^{2iL'a} + 1\right) - \left(e^{2iL'a} - 1\right)\right\}\Big/(2iL'a), \tag{77}$$

$$F_0(0) = 1, \quad F_0(1) = 1/6, \tag{78}$$

and for $n = 1$

$$F_1(0) = 1. \tag{79}$$

All the nonzero coefficients are given in Table 1 for orders $n \leq 2$ and $m \leq 2$. The method for obtaining these solutions is summarized below.

TABLE 1
Explicit solutions for scattering coefficients at low orders.

	$n=0$	$n=1$	$n=2$
$m=0$	$A'_{000} = 1/\hat{\rho}$		
$m=1$		$A_{110} = \dfrac{(\hat{\rho}-1)}{(2\hat{\rho}+1)}$ $A'_{110} = \dfrac{3}{(2\hat{\rho}+1)}$	
$m=2$	$A'_{022} = \dfrac{\hat{c}}{6\hat{\rho}}$ $B_{02} = \dfrac{\hat{\tau}\,(g'_c - \hat{\rho} g_c)\,S_{dj}}{\hat{\rho}\Gamma_t\left(\hat{\tau} S_{dj} S_h - S_j S_{dh}\right)}$ $B'_{02} = \dfrac{(g'_c - \hat{\rho} g_c)\,S_{dh}}{\hat{\rho}\Gamma'_t\left(\hat{\tau} S_{dj} S_h - S_j S_{dh}\right)}$	$A_{120} = \dfrac{(\hat{\rho}-1)}{(2\hat{\rho}+1)}$ $A_{121} = -\dfrac{(\hat{\rho}-1)}{(2\hat{\rho}+1)}$	$A_{220} = \dfrac{2\,(\hat{\rho}-1)}{3\,(3\hat{\rho}+2)}$ $A'_{220} = \dfrac{5}{3\,(3\hat{\rho}+2)}$
	$A_{020} = \dfrac{(\hat{\rho}-\hat{c})}{3\hat{\rho}} + \dfrac{(g'_c - \hat{\rho} g_c)\left(\hat{\tau}\Gamma'_t - \Gamma_t\right) S_{dj} S_{dh}}{\hat{\rho}\Gamma_t\Gamma'_t\left(\hat{\tau} S_{dj} S_h - S_j S_{dh}\right)}$ $A'_{020} = \dfrac{1}{2\hat{\rho}} - \dfrac{\hat{c}\,(\hat{\rho}+2)}{6\hat{\rho}^2}$ $+\dfrac{(g'_c - \hat{\rho} g_c)\left[\hat{\tau}\Gamma'_t S_{dj}\,(S_{dh}+S_h) - \Gamma_t S_{dh}\left(S_{dj} + \hat{\rho} S_j\right)\right]}{\hat{\rho}^2\Gamma_t\Gamma'_t\left(\hat{\tau} S_{dj} S_h - S_j S_{dh}\right)}$		

By definition, all coefficients for orders $m < 0$ are zero; hence the recurrence relations (equations (24) and (38)) show that all propagational mode coefficients are zero for $j > 0$. There is no incident field contribution to the thermal boundary conditions (equations (61) and (62)) (since $s = (m-n-2)/2 = -1$), so the thermal coefficients are zero:

$$B_{00} = B'_{00} = 0.$$

The velocity and pressure boundary conditions (equations (59) and (60)) include a nonzero contribution from the incident field, such that the zeroth order of the incident field affects the zeroth order propagational mode. The resulting coefficients for the propagational modes are

$$A_{000} = 0, \quad A'_{000} = 1/\hat{\rho}. \tag{80}$$

For $m = 1$ the incident field makes no contribution at the boundary (since the arguments $s = (m-n-2)/2$ or $s = (m-n)/2$ are noninteger). No nonzero coefficients are found from the recurrence relations, so again the thermal field is zero. The propagational coefficients are also zero in this case (by substitution in the boundary equations):

$$A_{010} = A'_{010} = 0. \tag{81}$$

For $m = 2$, the recurrence relations now give a nonzero coefficient, A'_{022}, resulting from the A'_{000} coefficients, as shown in the table.

The summations over coefficients also now have nonzero terms:

$$S_{A',m} = \frac{\hat{c}}{6\hat{\rho}}, \quad S_{jA',m} = \frac{\hat{c}}{3\hat{\rho}}, \quad S_{A',m-2} = \frac{1}{\hat{\rho}}. \tag{82}$$

All coefficients ($j > 0$) of the continuous phase propagational mode are again zero.

The incident field contributes both to the thermal boundary conditions and to the velocity and pressure conditions producing the first nonzero thermal coefficients, B_{02}, B'_{02} (Table 1). These results are consistent with the results in the geometric theory paper (Harlen et al. [5]) for large values of La. The LFPST paper (Harlen et al. [4]) did not assign the incident field to the different orders of Ka, instead assigning it all to the zeroth and first order terms, so analytical comparison is not possible. The propagational coefficients, A_{020}, A'_{020} (Table 1) are found by substituting the thermal coefficients into the velocity and pressure boundary equations. For higher orders in n the process is exactly the same, but there are no thermal contributions up to order $m = 2$, resulting in coefficients which depend only on density.

To obtain the velocity and attenuation of a dispersion using the coefficients up to second order, the relevant far field coefficients, T_n, must be determined. Equation (70) shows that only coefficients for $j = n$ contribute to each T_n. Thus the far field coefficients to second order in m are

$$T_0 = e^{-iKa} (iKa)^3 A_{020}, \quad T_1 = \frac{e^{-iKa}}{3} (iKa)^3 A_{121}, \quad T_2 = 0. \tag{83}$$

Substituting these coefficients into the equation for the wavenumber of the dispersion, B (equation (72)), gives

$$\left(\frac{B}{K}\right)^2 = 1 - 3\phi e^{-iKa} (A_{020} + A_{121}) + 3\phi^2 e^{-2iKa} \left(3A_{020}A_{121} + 2A_{121}^2\right). \tag{84}$$

Since the exponential factors are near unity (Ka being small), and the coefficient A_{121} depends only on density, the particle size and frequency dependence appear almost entirely through the A_{020} coefficient. It is the parameters S_h, S_{dh}, S_j, S_{dj} (equations (74) and (76)) which define the dependence on particle size and frequency through the relationship between the thermal wavelengths and the particle size, expressed by the parameters La and $L'a$. Thus we have an analytical result for the wavenumber of the dispersion which is valid over the entire long wavelength region, and is simple enough to be calculated in a standard spreadsheet. It is, of course, an approximate result, but, as will be demonstrated in the next section, it is a good approximation unless the parameter $Ka > 0.01$. Visco-inertial scattering has not been included in the present theory, so for dispersions with a large density difference between the two components, the results will not be as accurate.

6. Results. Calculations have been carried out using MATLAB for a model system of sunflower oil in water at 30° C. The calculations are straightforward, and take only a few seconds to complete a spectrum of 50 frequency values. The physical properties of the two components are given in Table 2. A particle diameter of 1 μm was chosen so that a complete range of thermal wavelengths could be covered within the long wavelength limit. The concentration (by volume) was 20%. The attenuation of each material was not included in the calculation, so the attenuation determined by

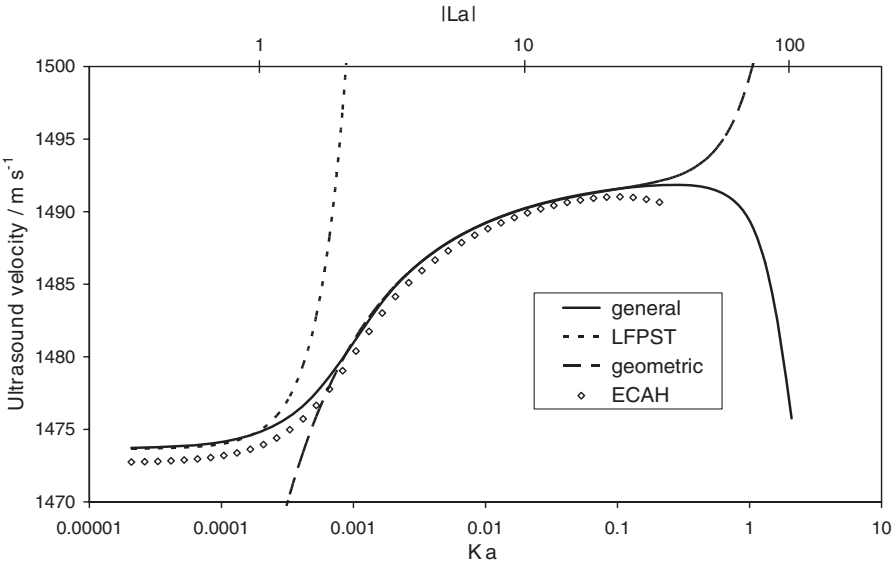

FIG. 1. *Ultrasound velocity as a function of the parameter Ka for* 20% *sunflower oil in water at* 30° *C with a particle diameter of* 1 μm. *Four different calculation methods are shown: the "general" method presented in this paper, the LFPST method (Harlen et al.* [4]*), the geometric theory method (Harlen et al.* [5]*), and the ECAH method (Epstein and Carhart* [2]*). The thermal parameter* $|La|$ *is shown above the plot. The parameters for the dispersed phase are* $|L'a| = 1.24\,|La|$ *and* $K'a = 1.05Ka$.

the scattering calculation is in addition to the nonscattering contribution. Figures 1 and 2 show the velocity and attenuation per wavelength ($\alpha\lambda$) as a function of frequency in the form of the parameters Ka and La. The ultrasound properties have been calculated by four different methods, including ECAH and the general theory results presented here.

It was found that the LFPST theory (Harlen et al. [4]) for low frequencies required orders up to $m = 8$ in order to obtain even the first part of the change in velocity and attenuation as the frequency increases. The theory is very much confined to the lowest frequency range. Similarly the geometric theory (Harlen et al. [5]) (which here was calculated only to second order in m and n) is valid only for high frequencies within the long wavelength region and deviates from the ECAH values as the frequency decreases.

The general theory presented in the current work is valid over the entire frequency range within the long wavelength region. The results for velocity and attenuation match closely those determined using the ECAH method. Visco-inertial scattering,

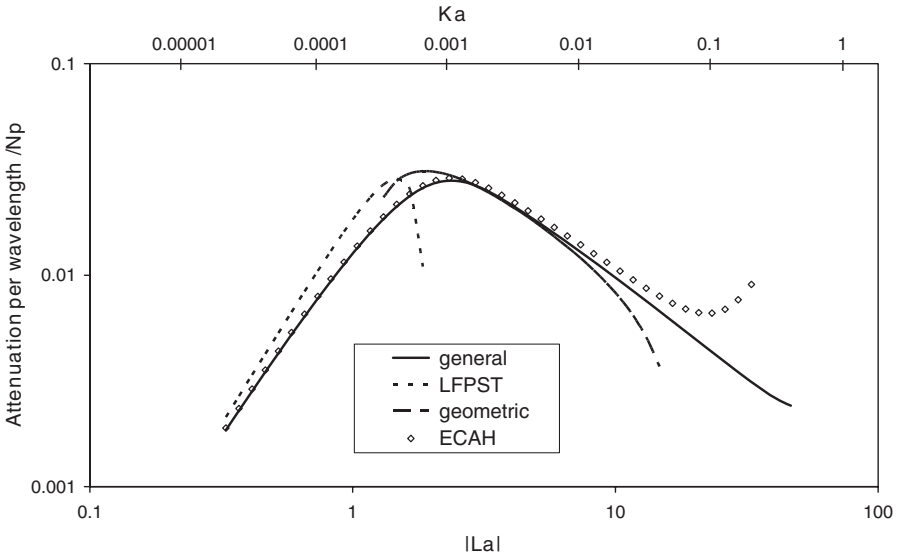

FIG. 2. *Attenuation per wavelength as a function of the parameter* $|La|$ *for* 20% *sunflower oil in water at* 30° *C. Four different calculation methods are shown: the "general" method presented in this paper, the LFPST method (Harlen et al.* [4]*), the geometric theory method (Harlen et al.* [5]*), and the ECAH method (Epstein and Carhart* [2]*). Corresponding values of Ka are shown above the plot. The parameters for the dispersed phase are* $|L'a| = 1.24\,|La|$ *and* $K'a = 1.05Ka$.

which relates to a difference in density between the two components and their viscosity, is not included in the general theory but is included in ECAH. The densities of the two components are similar, but the additional scattering accounts for the difference between the general theory and ECAH results. Terms for $m \leq 4$ were included for the general theory, as higher orders did not significantly change the result. At higher frequencies, the long wavelength criterion ($Ka \ll 1$) is no longer valid, and more and more terms are needed to obtain an accurate result. Figure 3 shows the contribution of including these terms. The second order solution is very accurate for frequencies below the point $Ka = 0.007$. The fourth order solution gives a more accurate result over a much wider frequency range.

7. Conclusions. A method has been presented for the solution of the ultrasound scattering problem in the long wavelength region. The work builds on previously published studies which covered only part of the frequency range, when the thermal wavelength is either much smaller or much larger than the particle size. The technique consists of expressing the scattered fields as perturbation series in the parameter Ka, which is always small in the long wavelength region, and explicitly removing the radiating field factor e^{iKr}. A result has been obtained which covers the complete long wavelength region. The calculation is much more straightforward than the widely used ECAH method, which relies on spherical harmonic expansions and suffers from numerical instability. A simplified analytical version of the result has been produced which enables calculation in an ordinary spreadsheet.

8. Appendix. The thermal wave solutions use expansions of the spherical Bessel functions which are not generally found in mathematical texts. The coefficients can be calculated in the order n by the formula below.

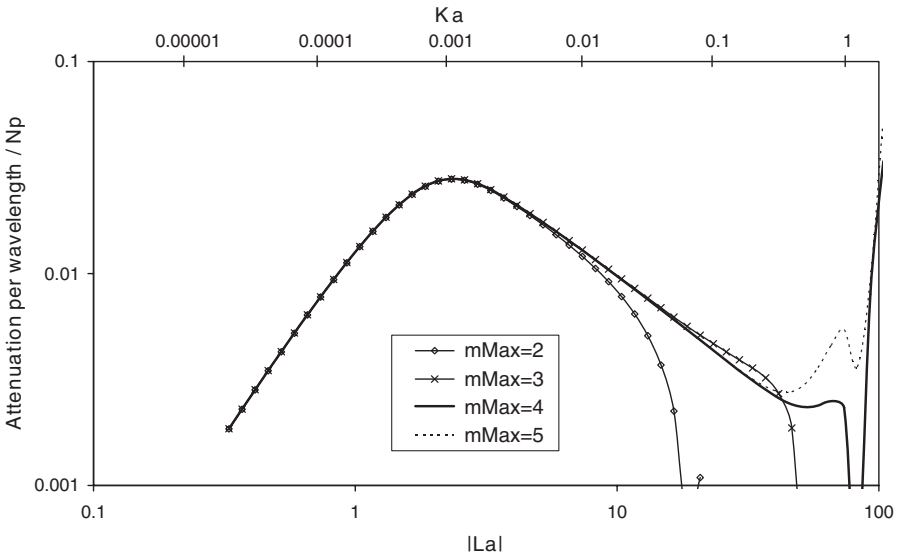

FIG. 3. *General theory results for* 20% *sunflower oil in water at* 30° *C showing the contributions of higher order terms in the series expansion, especially at larger values of* Ka. *The parameters for the dispersed phase are* $|L'a| = 1.24\,|La|$ *and* $K'a = 1.05Ka$.

For the spherical Hankel function,

$$h_{01} = -i \text{ for } n = 0,$$

$$\text{for } n > 0 \quad h_{n,j} = \begin{cases} -ih_{n-1,j} \text{ for } j = 1, \\ -ih_{n-1,j} + (n + j - 2)h_{n-1,j-1} \text{ for } 1 < j < n + 1, \\ (2n - 1)h_{n-1,j-1} \text{ for } j = n + 1. \end{cases}$$

Similarly for the spherical Bessel function, which was defined in two parts, an outgoing and an ingoing traveling wave:

$$j_{0,1+} = 1/2\text{i for } n = 0,$$

$$\text{for } n > 0 \quad j_{n,j+} = \begin{cases} -ij_{n-1,j+} \text{ for } j = 1, \\ -ij_{n-1,j+} + (n + j - 2)j_{n-1,j-1+} \text{ for } 1 < j < n + 1, \\ (2n - 1)j_{n-1,j-1+} \text{ for } j = n + 1, \end{cases}$$

$$j_{0,1-} = 1/2\text{i for } n = 0,$$

$$\text{for } n > 0 \quad j_{n,j-} = \begin{cases} ij_{n-1,j-} \text{ for } j = 1, \\ ij_{n-1,j-} + (n + j - 2)j_{n-1,j-1-} \text{ for } 1 < j < n + 1, \\ (2n - 1)j_{n-1,j-1-} \text{ for } j = n + 1. \end{cases}$$

THE INITIAL SURFACE TENSION–DRIVEN FLOW OF A WEDGE OF VISCOUS FLUID*

J. BILLINGHAM†

Abstract. In this paper, we consider the two-dimensional motion of a viscous, incompressible fluid with a free surface, initially lying inside a wedge. The fluid flows under the action of surface tension, and we analyze its small time motion using the method of matched asymptotic expansions. We show that, in contrast to the case where there is a surrounding fluid with viscosity [M. J. Miksis and J.-M. Vanden-Broeck, *Phys. Fluids*, 11 (1999), pp. 3227–3231], the initial motion is not self-similar but develops over two asymptotic regions: an inner, nonlinear, surface tension–driven Stokes flow region near the tip of the wedge, and an outer, linear, unsteady Stokes flow region, where inertia is important but surface tension is not. The initial velocity of the tip of the wedge is singular, of $O(\log t)$ as $t \to 0$. We calculate numerical solutions of both the inner and outer problem for a general wedge semiangle, α, and also construct asymptotic solutions in the limits $\alpha \to 0$ and $\alpha \to \pi$.

Key words. fluid mechanics, surface tension, matched asymptotic expansions

1. Introduction.

In the time since Keller and Miksis [2] identified a similarity scaling, with lengths scaling like $t^{2/3}$, suitable for the solution of two- and three-dimensional inviscid, surface tension–driven flows in initial configurations with no geometrical lengthscale (for example, wedges and cones), many authors have studied related problems (for example, [3], [4], [5], [6], [7]). Such problems are of relevance to the recoil of fluid sheets and jets after rupture. However, at sufficiently small times, viscosity is always relevant in this type of problem. In order to investigate this, Miksis and Vanden-Broeck [1] studied the two-dimensional, surface tension–driven Stokes flow of two fluids initially lying in four wedges. This canonical problem is relevant to the rupture of liquid sheets (see, for example, [8]), and a similarity scaling is available, with lengths scaling like t. Miksis and Vanden-Broeck [1] solved this similarity problem numerically using the boundary integral method. However, they were unable to find a solution for the case of an inviscid outer fluid and hypothesized that no such solution exists.

In this paper, we consider the problem of the recoil of a single wedge of viscous, incompressible fluid under the action of surface tension. Noting that the solutions studied by Miksis and Vanden-Broeck [1] give the small time asymptotic behavior of the two-fluid problem, we study the small time solution of the single-fluid problem. Drawing on the results given in [4] for the case of an almost flat wedge, we show that inertia is never negligible, and the solution has a two-region asymptotic structure, consistent with the hypothesis of [1] that no similarity solution exists. In an outer region, with size $O(t^{1/2})$, surface tension is negligible and linearized inertia acts at leading order, while in an inner region, with size $O(t)$, inertia is negligible, and the leading order problem is a surface tension–driven Stokes flow, similar to that studied

by Miksis and Vanden-Broeck [1]. The crucial difference is that the tip of the wedge recoils through a distance of $O(t \log t)$ in the single fluid problem that we study here, so that the fluid velocity is singular of $O(\log t)$ as $t \to 0$. The recoil distance is fixed by matching between the inner and outer solutions.

After setting up the initial/boundary value problem in section 2, we detail the asymptotic structure and matching conditions in section 3. We discuss numerical solutions of the outer problem in section 4 and of the inner problem in section 5. Finally, we consider the limiting cases of slender wedges, first of the interior, viscous fluid in section 6, and then of the exterior, inviscid fluid in section 7.

2. The initial/boundary value problem. The dimensionless initial/boundary value problem appropriate to the surface tension–driven recoil of a single wedge of viscous fluid consists of the Navier–Stokes equations for an incompressible, viscous fluid,

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \nabla^2 \mathbf{u} \quad \text{for } y > Y(x,t), \tag{2.1}$$

$$\nabla \cdot \mathbf{u} = 0 \quad \text{for } y > Y(x,t) \tag{2.2}$$

subject to the kinematic condition,

$$\frac{\partial Y}{\partial t} = u_y - u_x \frac{\partial Y}{\partial x} \quad \text{at } y = Y(x,t), \tag{2.3}$$

and the shear and normal stress continuity conditions,

$$\left\{1 - \left(\frac{\partial Y}{\partial x}\right)^2\right\}\left(\frac{\partial u_x}{\partial y} + \frac{\partial u_y}{\partial x}\right) - 4\frac{\partial Y}{\partial x}\frac{\partial u_x}{\partial x} = 0 \quad \text{at } y = Y(x,t), \tag{2.4}$$

$$\begin{aligned} -p - 2\left\{1 + \left(\frac{\partial Y}{\partial x}\right)^2\right\}^{-1} &\left[\left\{1 - \left(\frac{\partial Y}{\partial x}\right)^2\right\}\frac{\partial u_x}{\partial x} + \frac{\partial Y}{\partial x}\left(\frac{\partial u_x}{\partial y} + \frac{\partial u_y}{\partial x}\right)\right] \\ &= -\frac{\partial^2 Y}{\partial x^2}\left\{1 + \left(\frac{\partial Y}{\partial x}\right)^2\right\}^{-3/2} \quad \text{at } y = Y(x,t), \end{aligned} \tag{2.5}$$

where $\mathbf{u} = (u_x, u_y)$ is the velocity field, p is the pressure, and the free surface lies at $y = Y(x,t)$. The initial conditions are

$$\mathbf{u} = 0, \quad Y = \cot \alpha \, x \quad \text{when } t = 0, \tag{2.6}$$

so that the fluid is initially at rest in a wedge of semiangle α, and the far field conditions are

$$\mathbf{u} \to \mathbf{0}, \quad p \to 0 \quad \text{as } x^2 + y^2 \to \infty, \tag{2.7}$$

$$Y - \cot \alpha \, x \to 0 \quad \text{as } x \to \infty. \tag{2.8}$$

The problem has been made dimensionless using the length, time, velocity, and pressure scales,

$$l^* = \mu^2/\sigma\rho, \quad t^* = \mu^3/\sigma^2\rho, \quad u^* = \sigma/\mu, \quad p^* = \rho\sigma^2/\mu^2,$$

where μ, σ, and ρ are the constant viscosity, surface tension, and density of the fluid, respectively. These are the only physical quantities available, since the initial conditions provide no geometrical lengthscale. Note that (2.1) to (2.8) contain just one parameter: the wedge semiangle, α.

3. Asymptotic solution for $t \ll 1$: Structure and matching. We will now construct the small time asymptotic solution of this problem. This has already been done by Miksis and Vanden-Broeck [1] for the equivalent problem with an outer viscous fluid, where a similarity solution of the Stokes flow limit, with lengths scaling on t, provides the solution for $t \ll 1$ of the full Navier–Stokes problem. However, as we noted earlier, no such solution can be found when the viscosity of the exterior fluid is zero. The form of the asymptotic solution of (2.1) to (2.8) when $t \ll 1$ and $|\alpha - \pi/2| \ll 1$ is described in [4], where we found that the solution develops over two asymptotic regions: an inner, surface tension–driven Stokes flow region, where lengths scale with t, and an outer, unsteady Stokes flow region with no surface tension at leading order, where lengths scale with $t^{1/2}$. In addition, the tip of the wedge recoils through a distance of $O(t \log t)$, not simply of $O(t)$, as was the case for a viscous exterior fluid. An explanation for the presence of this logarithm is given by an argument equivalent to one made in [9], which analyzes the coalescence of viscous liquid drops. In [9, section 2], it is shown that the velocity field due to a point force at the tip of a wedge with free boundaries is singular at the tip, and that the velocity there must depend upon the logarithm of the size of an inner region, consistent with the scalings we use here.

The following are appropriate asymptotic scalings:

1. Outer region: $x,\ y = O(t^{1/2}),\ Y = \cot\alpha\, x + O(t),\ p = O(t^{-1/2}),\ u_x,\ u_y = O(1)$.

2. Inner region: $x = O(t),\ y = -Kt\log t + O(t),\ Y = -Kt\log t + O(t),\ p = O(t^{-1}),\ u_x = O(1),\ u_y = -K\log t + O(1)$.

The function $K \equiv K(\alpha)$ is an eigenvalue that must be determined as part of the solution for each value of α.

3.1. Leading order equations and matching conditions. In the outer region, we define the scaled variables

$$x = t^{1/2}\tilde{x},\quad y = t^{1/2}\tilde{y},\quad Y = \cot\alpha x + t\tilde{Y},\quad p = t^{-1/2}\tilde{p},\quad u_x = \tilde{u}_x,\quad u_y = \tilde{u}_y,$$

in terms of which, at leading order for $t \ll 1$, (2.1) to (2.8) become

$$-\frac{1}{2}\tilde{\mathbf{x}}\cdot\tilde{\nabla}\tilde{\mathbf{u}} = -\tilde{\nabla}\tilde{p} + \tilde{\nabla}^2\tilde{\mathbf{u}} \quad \text{for } \tilde{y} > \cot\alpha\,\tilde{x}, \tag{3.1}$$

$$\tilde{\nabla}\cdot\tilde{\mathbf{u}} = 0 \quad \text{for } \tilde{y} > \cot\alpha\,\tilde{x}, \tag{3.2}$$

$$\tilde{Y} - \frac{1}{2}\tilde{x}\frac{d\tilde{Y}}{d\tilde{x}} = \tilde{u}_y - \cot\alpha\,\tilde{u}_x \quad \text{at } \tilde{y} = \cot\alpha\,\tilde{x}, \tag{3.3}$$

$$\left(1 - \cot^2\alpha\right)\left(\frac{\partial\tilde{u}_x}{\partial\tilde{y}} + \frac{\partial\tilde{u}_y}{\partial\tilde{x}}\right) - 4\cot\alpha\,\frac{\partial\tilde{u}_x}{\partial\tilde{x}} = 0 \quad \text{at } \tilde{y} = \cot\alpha\,\tilde{x}, \tag{3.4}$$

$$-\tilde{p} + 2\cos 2\alpha\,\frac{\partial\tilde{u}_x}{\partial\tilde{x}} - \sin 2\alpha\,\left(\frac{\partial\tilde{u}_x}{\partial\tilde{y}} + \frac{\partial\tilde{u}_y}{\partial\tilde{x}}\right) = 0 \quad \text{at } \tilde{y} = \cot\alpha\,\tilde{x}, \tag{3.5}$$

$$\tilde{\mathbf{u}} \to \mathbf{0},\quad \tilde{p} \to 0 \quad \text{as } \tilde{x}^2 + \tilde{y}^2 \to \infty, \tag{3.6}$$

$$\tilde{Y} \to 0 \quad \text{as } \tilde{x} \to \infty. \tag{3.7}$$

These are the equations for unsteady Stokes flow in a wedge, with stress-free boundary conditions. Surface tension does not appear at leading order. The kinematic condition, (3.3), decouples from the other equations and allows $\tilde{Y}$ to be calculated once the velocity field is known. Note that uniform flow in the $\tilde{y}$-direction is a simple solution of these equations, although it does not satisfy the far field boundary condition. The system is forced by the matching conditions as $\tilde{x}^2 + \tilde{y}^2 \to 0$, and we shall determine these below.

In the inner region, we define the scaled variables

$$x = t\bar{x}, \quad y = -Kt\log t + t\bar{y}, \quad Y = -Kt\log t + t\bar{Y}, \quad p = t^{-1}\bar{p},$$

$$u_x = \bar{u}_x, \quad u_y = -K\log t + \bar{u}_y,$$

in terms of which, at leading order for $t \ll 1$, (2.1) to (2.8) become

$$0 = -\bar{\nabla}\bar{p} + \bar{\nabla}^2\bar{\mathbf{u}} \quad \text{for } \bar{y} > \bar{Y}(\bar{x}), \tag{3.8}$$

$$\bar{\nabla}\cdot\bar{\mathbf{u}} = 0 \quad \text{for } \bar{y} > \bar{Y}(\bar{x}), \tag{3.9}$$

$$\bar{Y} - \bar{x}\frac{d\bar{Y}}{d\bar{x}} = K + \bar{u}_y - \bar{u}_x\frac{d\bar{Y}}{d\bar{x}} \quad \text{at } \bar{y} = \bar{Y}(\bar{x}), \tag{3.10}$$

$$\left\{1 - \left(\frac{d\bar{Y}}{d\bar{x}}\right)^2\right\}\left(\frac{\partial\bar{u}_x}{\partial\bar{y}} + \frac{\partial\bar{u}_y}{\partial\bar{x}}\right) - 4\frac{d\bar{Y}}{d\bar{x}}\frac{\partial\bar{u}_x}{\partial\bar{x}} = 0 \quad \text{at } \bar{y} = \bar{Y}(\bar{x}), \tag{3.11}$$

$$\begin{aligned} -\bar{p} - 2\left\{1 + \left(\frac{d\bar{Y}}{d\bar{x}}\right)^2\right\}^{-1}&\left[\left\{1 - \left(\frac{d\bar{Y}}{d\bar{x}}\right)^2\right\}\frac{\partial\bar{u}_x}{\partial\bar{x}} + \frac{d\bar{Y}}{d\bar{x}}\left(\frac{\partial\bar{u}_x}{\partial\bar{y}} + \frac{\partial\bar{u}_y}{\partial\bar{x}}\right)\right] \\ &= -\frac{d^2\bar{Y}}{d\bar{x}^2}\left\{1 + \left(\frac{d\bar{Y}}{d\bar{x}}\right)^2\right\}^{-3/2} \quad \text{at } \bar{y} = \bar{Y}(\bar{x}). \end{aligned} \tag{3.12}$$

These are the equations for steady, surface tension–driven Stokes flow, but with the modified kinematic condition (3.10). We now need to consider the far field behavior of solutions of this inner problem so that we can determine appropriate matching conditions between the two asymptotic regions.

Since we must have $\bar{Y} \sim \cot\alpha\bar{x}$ as $\bar{x} \to \infty$, the flow in the far field lies within a wedge at leading order. By writing the equations in terms of polar coordinates, it is straightforward to show that

$$\bar{Y} \sim \cot\alpha\bar{x} - 2K\log\bar{x} + K\left(b_\infty - 3 + 2\log\sin\alpha\right) \quad \text{as } \bar{x} \to \infty, \tag{3.13}$$

$$\begin{aligned} \bar{p} &\sim 4K\frac{\bar{y}}{\bar{x}^2 + \bar{y}^2}, \quad \bar{u}_x \sim 2K\frac{\bar{x}\bar{y}}{\bar{x}^2 + \bar{y}^2}, \\ \bar{u}_y &\sim -K\log\left(\bar{x}^2 + \bar{y}^2\right) - 2K\frac{\bar{x}^2}{\bar{x}^2 + \bar{y}^2} + Kb_\infty \quad \text{as } \bar{x}^2 + \bar{y}^2 \to \infty. \end{aligned} \tag{3.14}$$

The function $b_\infty(\alpha)$ is, as yet, undetermined.

We can now write the matching condition for the outer problem,

$$\tilde{p} \sim 4K\frac{\tilde{y}}{\tilde{x}^2+\tilde{y}^2}, \quad \tilde{u}_x \sim 2K\frac{\tilde{x}\tilde{y}}{\tilde{x}^2+\tilde{y}^2},$$

$$\tilde{u}_y \sim -K\log\left(\tilde{x}^2+\tilde{y}^2\right) - 2K\frac{\tilde{x}^2}{\tilde{x}^2+\tilde{y}^2} + Kb_\infty \quad \text{as } \tilde{x}^2+\tilde{y}^2 \to 0. \tag{3.15}$$

4. Solution of the outer problem. Since the outer problem is linear and forced by the matching condition (3.15), we can scale the constant K out of the problem and solve to determine b_∞. Once we know b_∞, we have enough information to solve the inner problem. It is also convenient to rewrite the outer problem in streamfunction-vorticity form, so we define the scaled streamfunction ψ and vorticity ω using

$$\tilde{u}_x = K\frac{\partial\psi}{\partial\tilde{y}}, \quad \tilde{u}_y = -K\frac{\partial\psi}{\partial\tilde{x}}, \quad \omega = -\tilde{\nabla}^2\psi.$$

The outer problem then becomes, using the symmetry of the problem about the $\tilde{y}$-axis, in terms of polar coordinates

$$\tilde{\nabla}^2\psi + \omega = 0 \quad \text{for } \pi/2 < \theta < \pi/2+\alpha, \tag{4.1}$$

$$\tilde{\nabla}^2\omega + \frac{1}{2}\frac{\partial}{\partial\tilde{r}}\left(\tilde{r}\omega\right) = 0 \quad \text{for } \pi/2 < \theta < \pi/2+\alpha \tag{4.2}$$

subject to

$$\omega + \frac{\partial^2\psi}{\partial\tilde{r}^2} = 0 \quad \text{at } \theta = \pi/2+\alpha, \tag{4.3}$$

$$\frac{2}{\tilde{r}}\frac{\partial^3\psi}{\partial\tilde{r}^2\partial\theta} + \left(\frac{1}{2}-\frac{4}{\tilde{r}^2}\right)\left(\frac{\partial^2\psi}{\partial\tilde{r}\partial\theta} - \frac{1}{\tilde{r}}\frac{\partial\psi}{\partial\theta}\right) - \frac{1}{\tilde{r}}\frac{\partial\omega}{\partial\theta} = 0 \quad \text{at } \theta = \pi/2+\alpha, \tag{4.4}$$

the symmetry conditions

$$\psi = \omega = 0 \quad \text{at } \theta = \pi/2, \tag{4.5}$$

the far field conditions

$$\psi \to 0, \quad \omega \to 0 \quad \text{as } \tilde{r} \to \infty, \tag{4.6}$$

and the matching conditions

$$\psi \sim 2\tilde{r}\log\tilde{r}\cos\theta - b_\infty\tilde{r}\cos\theta, \quad \omega \sim -\frac{4\cos\theta}{\tilde{r}} \quad \text{as } \tilde{r} \to 0. \tag{4.7}$$

As we noted earlier, a constant flow in the $\tilde{y}$-direction, $\psi = k\tilde{r}\cos\theta$, $\omega = 0$, satisfies the equations and boundary conditions, except for the far field and matching conditions. We can think of b_∞ as the strength of the uniform component of the flow that must emerge from the inner region to ensure that there is no flow at infinity. Note that the singular part of the flow near the origin given by (4.7) is simply a Stokeslet, which

indicates that the outer flow sees a point force and a uniform flow at the tip of the wedge, which is provided by the surface tension–driven inner flow.

Although this is a linear boundary value problem in a wedge, there is no obvious way of solving it analytically using integral transforms. This remains true even when $\alpha = \pi$ and the domain of the solution is a half-plane. However, when $\alpha = \pi/2$, we can use the results given in [4], which show that $b_\infty(\pi/2) \approx 1.869$. We can also consider the limit of a slender wedge, $\alpha \ll 1$, for which a simple asymptotic solution is available, before we discuss the numerical solution of (4.1) to (4.7).

4.1. The slender wedge, $\alpha \ll 1$. When $\alpha \ll 1$, $\theta = \frac{\pi}{2} + O(\alpha)$, so we define the scaled variables

$$\theta = \frac{\pi}{2} - \alpha\bar{\theta}, \quad \psi = \alpha\bar{\psi}, \quad \omega = \alpha\bar{\omega}.$$

Equations (4.1) and (4.2) at leading order then show that $\bar{\psi}$ and $\bar{\omega}$ are linear in θ, and the symmetry conditions give

$$\bar{\psi} = A_0(\tilde{r})\bar{\theta}, \quad \bar{\omega} = B_0(\tilde{r})\bar{\theta}. \tag{4.8}$$

The boundary conditions (4.3) and (4.4) are unchanged by this rescaling and show that

$$B_0 + 2A_0'' = 0,$$

$$\frac{2}{\tilde{r}}A_0'' + \left(\frac{1}{2} - \frac{4}{\tilde{r}^2}\right)\left(A_0' - \frac{1}{\tilde{r}}A_0\right) - \frac{1}{\tilde{r}}B_0 = 0,$$

where a prime denotes a derivative. We can eliminate $B_0(\tilde{r})$ between these equations and arrive at

$$\frac{4}{\tilde{r}}A_0'' + \left(\frac{1}{2} - \frac{4}{\tilde{r}^2}\right)A_0' - \frac{1}{\tilde{r}}\left(\frac{1}{2} - \frac{4}{\tilde{r}^2}\right)A_0 = 0, \tag{4.9}$$

to be solved subject to

$$A_0 \sim 2\tilde{r}\log\tilde{r} - b_\infty(0)\tilde{r} \quad \text{as } \tilde{r} \to 0, \tag{4.10}$$

$$A_0 \to 0 \quad \text{as } \tilde{r} \to \infty. \tag{4.11}$$

Since $A_0 = \tilde{r}$ is an obvious solution of (4.9), which corresponds to the uniform flow solution of the original equations, we can use reduction of order to find the solution in the form

$$A_0 = k_1\tilde{r}\int_{1/16}^{\tilde{r}^2/16} \frac{e^{-u}}{u}du + k_2\tilde{r}.$$

The boundary condition (4.10) then shows that

$$k_1 = 1, \quad k_2 = -b_\infty(0) - \frac{1}{16},$$

and finally, (4.11) shows that

$$b_\infty(0) = \int_{1/16}^{\infty} \frac{e^{-u}}{u}du - \frac{1}{16} \approx 2.194. \tag{4.12}$$

4.2. Numerical solutions. Before attempting to solve (4.1) to (4.7) numerically, it is convenient to subtract out the singularity at the origin by defining

$$\psi = 2\tilde{r}\log\tilde{r}\cos\theta + \hat{\psi}, \quad \omega = -\frac{4\cos\theta}{\tilde{r}} + \hat{\omega}.$$

We then find that

$$\tilde{\nabla}^2\hat{\psi} + \hat{\omega} = 0 \quad \text{for } \pi/2 < \theta < \pi/2 + \alpha, \tag{4.13}$$

$$\tilde{\nabla}^2\hat{\omega} + \frac{1}{2}\frac{\partial}{\partial\tilde{r}}(\tilde{r}\hat{\omega}) = 0 \quad \text{for } \pi/2 < \theta < \pi/2 + \alpha \tag{4.14}$$

subject to

$$\hat{\omega} + \frac{\partial^2\hat{\psi}}{\partial\tilde{r}^2} = 0 \quad \text{at } \theta = \pi/2 + \alpha, \tag{4.15}$$

$$\frac{2}{\tilde{r}}\frac{\partial^3\hat{\psi}}{\partial\tilde{r}^2\partial\theta} + \left(\frac{1}{2} - \frac{4}{\tilde{r}^2}\right)\left(\frac{\partial^2\hat{\psi}}{\partial\tilde{r}\partial\theta} - \frac{1}{\tilde{r}}\frac{\partial\hat{\psi}}{\partial\theta}\right) - \frac{1}{\tilde{r}}\frac{\partial\hat{\omega}}{\partial\theta} = \cos\alpha \quad \text{at } \theta = \pi/2 + \alpha, \tag{4.16}$$

$$\hat{\psi} = \hat{\omega} = 0 \quad \text{at } \theta = \pi/2, \tag{4.17}$$

$$\hat{\psi} \sim -2\tilde{r}\log\tilde{r}\cos\theta, \quad \hat{\omega} \sim \frac{4\cos\theta}{\tilde{r}} \quad \text{as } \tilde{r} \to \infty, \tag{4.18}$$

$$\hat{\psi} \to 0, \quad \hat{\omega} \to 0 \quad \text{as } \tilde{r} \to 0, \tag{4.19}$$

$$\frac{\partial\hat{\psi}}{\partial\tilde{r}} \sim b_\infty\cos\theta, \quad \text{as } \tilde{r} \to 0. \tag{4.20}$$

Note that this rescaled problem contains a forcing term at the boundary in (4.16). We have also written the boundary conditions at the origin in a form that allows us to solve (4.13) to (4.19), and then use (4.20) to determine b_∞.

We solve (4.13) to (4.19) using finite differences on a polar grid. We discretize θ at constant intervals and use a nonuniform grid in the $\tilde{r}$-direction in order to accurately capture the behavior of the solution as $\tilde{r} \to \infty$. By considering solutions on progressively finer grids, we found that we could achieve converged solutions (b_∞ accurate to two decimal places) with 50 equally spaced grid points in the θ-direction, and 275 grid points in the $\tilde{r}$-direction with spacing gradually changing from 0.01 to 1 as $\tilde{r}$ increases to 100. We approximate derivatives using central differences and use three-point formulas at the boundaries. After solving, we obtained b_∞ from (4.20), using a three-point formula to calculate $\partial\hat{\psi}/\partial\theta$ at the origin, and taking the mean value of b_∞ calculated at the half of the discretized values of θ furthest from the boundaries.

Figure 4.1 shows the streamlines, in terms of the original variable, ψ, at various values of α. We can see that the solution has a local maximum of vorticity in the interior for sufficiently large values of α. Figure 4.2 shows the calculated value of b_∞. The numerical solution is in good agreement with the asymptotic solutions for $\alpha = 0$ and $\pi/2$. Note that the form of the scaled equations when $\alpha \ll 1$ indicates that $b_\infty = 2.194 + O(\alpha^2)$, consistent with Figure 4.2. The range of values of b_∞ is not large, with $2.194 > b_\infty > 1.714$. We fitted a cubic spline to the numerically calculated values of b_∞, and used this in the numerical solutions of the inner problem, which we describe below.

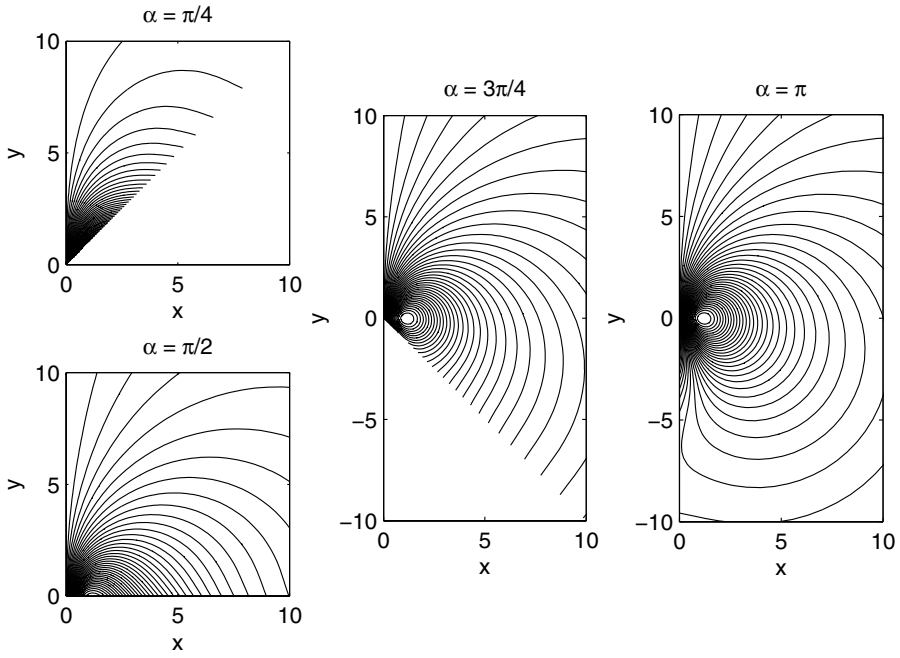

FIG. 4.1. *The streamlines in the outer region when* $\alpha = \pi/4$, $\pi/2$, $3\pi/4$, *and* π.

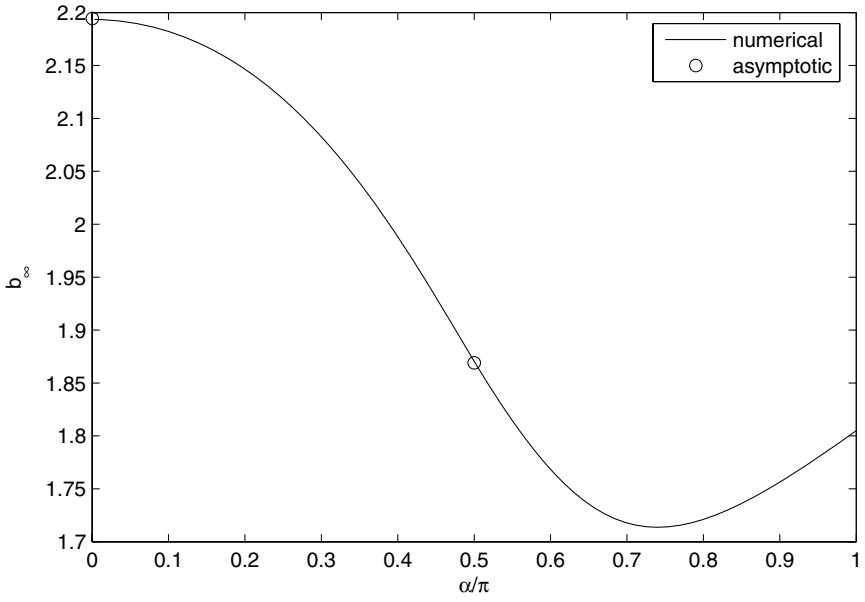

FIG. 4.2. *The numerically calculated value of* b_∞. *Also shown are the known values of* b_∞ *when* $\alpha = 0$ *and* $\alpha = \pi/2$.

5. Solution of the inner problem. Now that we know $b_\infty(\alpha)$, we are in a position to solve the inner problem (3.8) to (3.14). For this free boundary problem, it is natural to use the boundary integral method (see, for example, [10]). For Stokes flow in a bounded domain B,

$$\mathbf{u}(\mathbf{x}_0) = \frac{1}{2\pi}\int_{\partial B}\left\{-\mathbf{f}(\mathbf{x})\log\hat{r} + \frac{\hat{\mathbf{x}}\,(\mathbf{f}\cdot\hat{\mathbf{x}})}{\hat{r}^2} + \frac{4\,(\mathbf{u}\cdot\hat{\mathbf{x}})\,(\mathbf{n}\cdot\hat{\mathbf{x}})\,\hat{\mathbf{x}}}{\hat{r}^4}\right\} ds(\mathbf{x}), \tag{5.1}$$

where $\mathbf{n}$ is the outward unit normal, $\mathbf{f}$ is the force on the free surface, $\mathbf{x}_0$ lies on the free surface, s is arc length, $\hat{\mathbf{x}} = \mathbf{x} - \mathbf{x}_0$, and $\hat{r} = |\hat{\mathbf{x}}|$. We can now proceed by truncating our domain of solution with a circle of radius R_∞, centered on the origin, so that ∂B consists of the free surface, S, and the arc of the circle, S_∞. We discretize the free surface at n points an arc length $s = s_i$, $i = 1, 2, \ldots, n$, from the tip, with $s_1 = 0$ at the tip. At these points, $(\bar{x}, \bar{y}) = (X_i, Y_i) \equiv (X(s_i), Y(s_i))$. We also let $v(s)$ be the tangential fluid velocity at the free surface. We must therefore solve for the $3n + 1$ unknowns X_i, Y_i, $v_i \equiv v(s_i)$, and K.

Equations (3.10) to (3.12) show that

$$\mathbf{f} = (Y'X'' - X'Y'')\,\mathbf{n}, \quad \mathbf{u} = (\mathbf{n}\cdot\mathbf{X} + KX')\,\mathbf{n} + v\mathbf{t} \ \text{ on } S, \tag{5.2}$$

where $\mathbf{X} = (X, Y)$ and $\mathbf{t}$ is the unit tangent vector at the free surface. On S_∞ we assume that $\mathbf{f}$ and $\mathbf{u}$ take their far field values, so that

$$\begin{aligned}\mathbf{u} &= K\,(-2\log R_\infty + b_\infty)\sin\theta\,\mathbf{n} - K\,\{2(1+\log R_\infty) + b_\infty\}\cos\theta\,\mathbf{t},\\ \mathbf{f} &= -\frac{8K\sin\theta}{R_\infty}\mathbf{n} \ \text{ on } S_\infty.\end{aligned} \tag{5.3}$$

We represent the free surface, $(X(s), Y(s))$, and tangential velocity $v(s)$ using cubic splines. We evaluate the normal and tangential components of (5.1) using two-point Gaussian quadrature, collocating at the midpoint of each boundary element, using (5.2) and (5.3) to give the surface force and velocity, and making use of symmetry about the y-axis. We discretized most of S_∞ using equally spaced points. However, close to the point where S_∞ meets S in $x > 0$ we added extra points to resolve the rapid variation of the integrand when collocating at the midpoint of the final element of S. This provides $2n - 2$ nonlinear algebraic equations. We must also enforce the arc length condition

$$(X')^2 + (Y')^2 = 1. \tag{5.4}$$

We do this at the midpoint of each element, which provides a further $n - 1$ nonlinear algebraic equations. We now need four more conditions to close the problem. The far field conditions (3.13) and (3.14) give

$$Y_n = \cot\alpha\, X_n - 2K\log X_n + K(b_\infty - 3 + 2\log\sin\alpha), \tag{5.5}$$

$$v_n = -K\sin\theta_\infty(2\log R_\infty - b_\infty), \tag{5.6}$$

where θ_∞ is the value of θ at the point where S_∞ meets S. At $s = 0$, we imposed the symmetry conditions

$$X_1 = 0, \quad v_1 = 0. \tag{5.7}$$

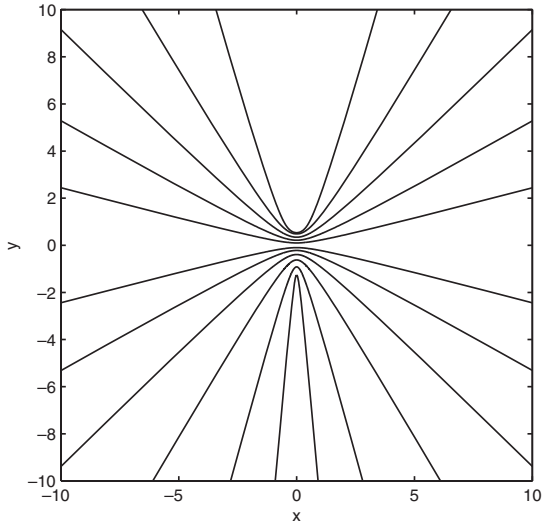

FIG. 5.1. *The numerical solution for* $\alpha = 15°$, $30°$, $45°$, $60°$, $75°$, $105°$, $120°$, $135°$, $150°$, $165°$, *and* $175°$.

We solved this system of $3n + 1$ nonlinear algebraic equations using Newton's method, calculating the Jacobian by numerical differentiation. We started with the known solution for $\alpha = \pi/2$, namely, the flat interface with $K = 0$, and progressively increased or decreased α. In this manner, we were able to obtain converged numerical solutions for $1° \leq \alpha \leq 178°$ or, in radians, $0.0175 \leq \alpha \leq 3.1067$. For $\alpha < \pi/2$, we used $n = 532$ and $s_n = 10^4$, with a grid for which Δs_i progressively increased from $\Delta s_1 = 10^{-2}$. This enabled us to compute down to small values of α for which, as we shall see in section 6, the curvature at the tip is bounded, and changes occur over a long lengthscale. Solutions on coarser grids indicate that the errors in our calculations of K are less than 1%. For $\alpha > \pi/2$, we used $n = 1074$ and $s_n = 50$, with a grid whose spacing became progressively finer for smaller s, with $\Delta s_1 = 5 \times 10^{-4}$. This allowed us to resolve the small region close to the tip, which we shall discuss in section 7. Solutions on coarser grids again indicate that the errors in our calculations of K are less than 1%.

Figure 5.1 shows the solution for various values of $\alpha \geq 15°$. We can see that for α close to π, the curvature of the tip becomes large, but that this does not occur as α approaches zero. The behavior for small α is illustrated in Figure 5.2, which shows that the curvature remains bounded, but that the position of the tip moves off in the negative y-direction as α decreases.

Figures 5.3, 5.4, and 5.5 show how K, the curvature at the tip, and the position of the tip vary with α. Also shown are the linearized predictions for $|\alpha - \pi/2| \ll 1$ given by Billingham [4]. To summarize, these are

$$K \sim -\frac{1}{2\pi}\left(\alpha - \frac{\pi}{2}\right), \quad \kappa(0) \sim -\frac{4}{\pi}\left(\alpha - \frac{\pi}{2}\right),$$

$$Y(0) \sim 0.359\left(\alpha - \frac{\pi}{2}\right) \quad \text{for } |\alpha - \pi/2| \ll 1. \tag{5.8}$$

The numerical and asymptotic solutions are in excellent agreement. We can also see that K is singular as $\alpha \to 0$, as is $Y(0)$, while the curvature remains bounded. As

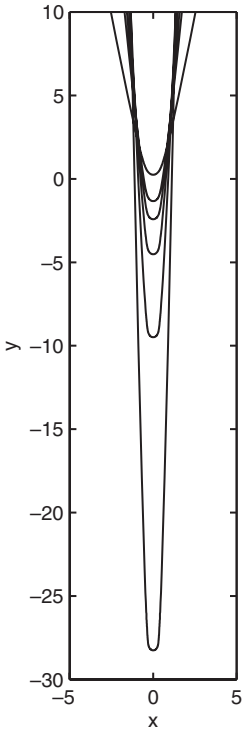

FIG. 5.2. *The numerical solution for* $\alpha = 10°$, $5°$, $4°$, $3°$, $2°$, *and* $1°$.

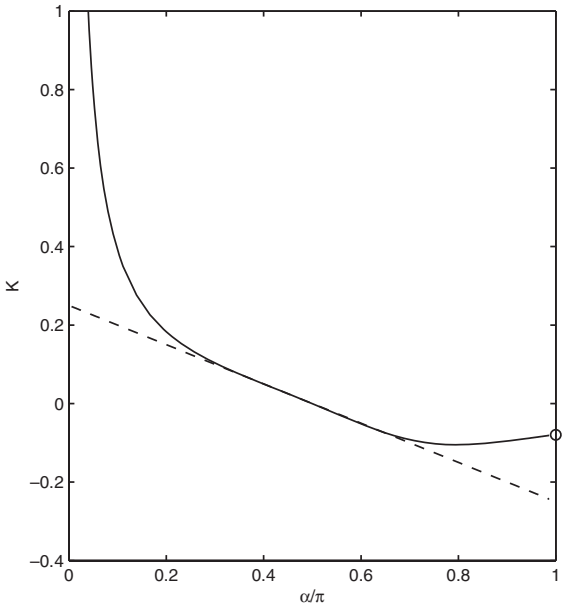

FIG. 5.3. *The numerically calculated value of* K, *along with the asymptotic solution for* $|\alpha - \pi/2| \ll 1$ *(broken line). The value of* K *when* $\alpha = \pi$, *calculated in section 7* ($K = K_0 = -1/4\pi$), *is marked with a circle.*

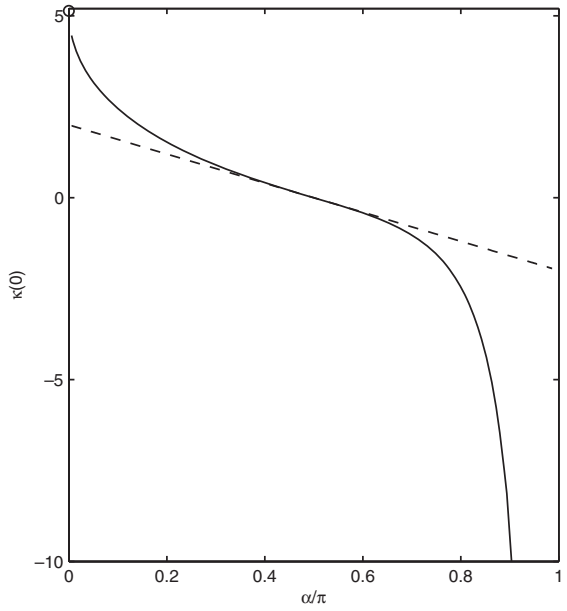

FIG. 5.4. *The numerically calculated value of the curvature at the tip of the recoiling wedge, along with the asymptotic solution for* $|\alpha - \pi/2| \ll 1$ *(broken line). The curvature when* $\alpha = 0$*, calculated in section* 6*, is marked with a circle.*

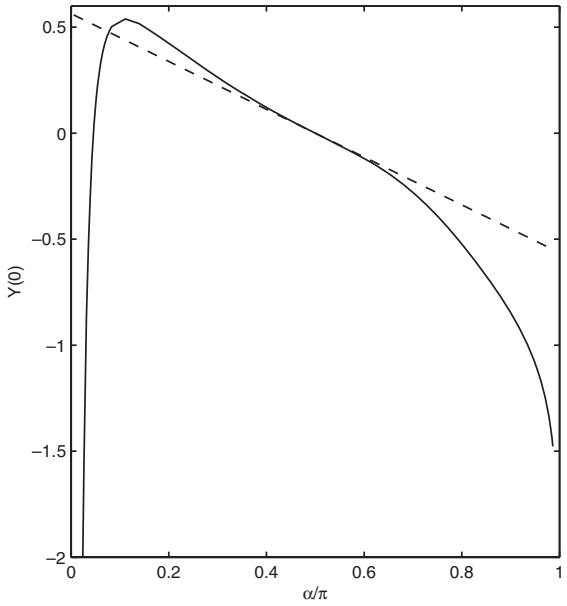

FIG. 5.5. *The numerically calculated value of the position of the tip of the recoiling wedge, along with the asymptotic solution for* $|\alpha - \pi/2| \ll 1$ *(broken line).*

$\alpha \to \pi$, K is bounded, while the curvature is strongly singular, and $Y(0)$ is weakly singular. We will now investigate these cases further using the method of matched asymptotic expansions.

6. Asymptotic solution of the inner problem for $\alpha \ll 1$. In this lubrication limit, it is more convenient to parameterize the free surface as lying at $\bar{x} = \bar{X}(\bar{y})$, in terms of which (3.8) to (3.12) become

$$0 = -\bar{\nabla}\bar{p} + \bar{\nabla}^2\bar{\mathbf{u}} \quad \text{for } 0 < \bar{x} < \bar{X}(\bar{y}), \tag{6.1}$$

$$\bar{\nabla}\cdot\bar{\mathbf{u}} = 0 \quad \text{for } 0 < \bar{x} < \bar{X}(\bar{y}), \tag{6.2}$$

$$\bar{y}\frac{d\bar{X}}{d\bar{y}} - \bar{X} = K\frac{d\bar{X}}{d\bar{y}} + \bar{u}_y\frac{d\bar{X}}{d\bar{y}} - \bar{u}_x \quad \text{at } \bar{x} = \bar{X}(\bar{y}), \tag{6.3}$$

$$\left\{\left(\frac{d\bar{X}}{d\bar{y}}\right)^2 - 1\right\}\left(\frac{\partial\bar{u}_x}{\partial\bar{y}} + \frac{\partial\bar{u}_y}{\partial\bar{x}}\right) - 4\frac{d\bar{X}}{d\bar{y}}\frac{\partial\bar{u}_x}{\partial\bar{x}} = 0 \quad \text{at } \bar{x} = \bar{X}(\bar{y}), \tag{6.4}$$

$$\begin{aligned} -\bar{p} - 2\left\{1 + \left(\frac{d\bar{X}}{d\bar{y}}\right)^2\right\}^{-1}&\left[\left\{\left(\frac{d\bar{X}}{d\bar{y}}\right)^2 - 1\right\}\frac{\partial\bar{u}_x}{\partial\bar{x}} + \frac{d\bar{X}}{d\bar{y}}\left(\frac{\partial\bar{u}_x}{\partial\bar{y}} + \frac{\partial\bar{u}_y}{\partial\bar{x}}\right)\right] \\ &= \frac{d^2\bar{X}}{d\bar{y}^2}\left\{1 + \left(\frac{d\bar{X}}{d\bar{y}}\right)^2\right\}^{-3/2} \quad \text{at } \bar{x} = \bar{X}(\bar{y}), \end{aligned} \tag{6.5}$$

along with the symmetry conditions

$$\bar{u}_x = \frac{\partial\bar{u}_y}{\partial\bar{x}} = \frac{\partial\bar{p}}{\partial\bar{x}} = 0 \quad \text{at } \bar{x} = 0 \tag{6.6}$$

subject to the matching conditions (3.14) and

$$\bar{X} \sim \tan\alpha\left\{\bar{y} + 2K\log\left(\frac{\bar{y}}{\cos\alpha}\right) - K\left(b_\infty(0) - 3\right)\right\} \quad \text{as } \bar{y} \to \infty, \tag{6.7}$$

where $b_\infty(0)$ is given by (4.12).

In order to be able to match the solutions in the two regions that we describe below, we need $K = \hat{K}/\alpha$ with $\hat{K} = O(1)$ as $\alpha \to 0$. We then use a simple lubrication scaling that produces a leading order balance in (6.2), namely,

$$\bar{y} = \hat{y}/\alpha, \quad \bar{x} = \hat{x}, \quad \bar{X} = \hat{X}, \quad \bar{u}_x = \hat{u}_x, \quad \bar{u}_y = \hat{u}_y/\alpha, \quad \bar{p} = \hat{p}.$$

On substituting these scalings into (6.1) to (6.7), we find that, at leading order, $\hat{u}_y \equiv \hat{u}_y(\hat{y})$, $\hat{u}_x = -\hat{x}\hat{u}_y'$, and $\hat{p} = -2\hat{u}_y$, where a prime denotes $d/d\hat{y}$. Equation (6.3) then shows that

$$\frac{\hat{X}'}{\hat{X}} = \frac{1 + \hat{u}_y'}{\hat{y} - \hat{K} - \hat{u}_y}. \tag{6.8}$$

In order to close the problem, we need to consider the tangential stress condition, (6.4), at $O(\alpha^2)$, which shows that

$$\hat{u}_y' = -\frac{2\hat{K}}{\hat{X}}. \tag{6.9}$$

By eliminating $\hat{u}_y$ between (6.8) and (6.9), we obtain an equation for $\hat{X}$, which can be solved analytically to give the implicit solution that satisfies (6.7),

$$\begin{aligned} \hat{y} &= \hat{X} - 2\hat{K}\log\hat{X} + 2\hat{K}\log\alpha - (3 - b_\infty(0))\,\hat{K}, \\ \hat{u}_y &= -2\hat{K}\log\hat{X} - \frac{4\hat{K}^2}{\hat{X}} + 2\hat{K}\log\alpha + \hat{K}b_\infty(0). \end{aligned} \tag{6.10}$$

We will see below why we can justify treating the term of $O(\log\alpha)$ as a constant in this procedure. Note that the leading order shape of the free surface just reproduces the far field boundary condition.

Since $\hat{X}' = \hat{X}/(\hat{X} - 2\hat{K})$, the slope of the free surface becomes unbounded as $\hat{X} \to 2\hat{K}$, and we need an inner-inner region in the neighborhood of $\hat{X} = 2\hat{K}$ in order to complete the solution. Note that $\hat{y} \to \hat{y}_0$ and $\hat{u}_y \to \hat{u}_{y0}$ as $\hat{X} \to 2\hat{K}$, where

$$\hat{y}_0 = (b_\infty(0) - 1)\,\hat{K} - 2\hat{K}\log\left(2\hat{K}/\alpha\right), \quad \hat{u}_{y0} = \hat{y}_0 - \hat{K}. \tag{6.11}$$

By determining the form of the next correction to the asymptotic expansion in the neighborhood of $\hat{y} = \hat{y}_0$, we find that there is a nonuniformity in the expansion when $\hat{y} - \hat{y}_0 = O(\alpha)$.

6.1. Inner-inner region. Appropriate scaled variables in the inner-inner region are[1]

$$\hat{y} = \hat{y}_0 + \alpha\tilde{y}, \quad \hat{x} = \tilde{x}, \quad \hat{X} = \tilde{X}, \quad \hat{u}_x = \tilde{u}_x, \quad \hat{u}_y = \hat{u}_{y0} + \alpha\tilde{u}_y, \quad \hat{p} = \tilde{p}.$$

In terms of the original inner variable defined in section 3, this rescaling just represents a shift of $O(\alpha^{-1})$ in the y-direction along with the removal of a uniform flow of $O(\alpha^{-1})$ in the y-direction. As we would expect, we therefore recover the equations for surface tension–driven Stokes flow. However, the kinematic condition becomes

$$(\tilde{y} - \tilde{u}_y)\,\frac{d\tilde{X}}{d\tilde{y}} = \tilde{X} - \tilde{u}_x, \tag{6.12}$$

which specifies the normal component of the fluid velocity at the free surface, and the far field conditions are given by matching as

$$\tilde{u}_x \sim \tilde{x}, \quad \tilde{u}_y \sim -\tilde{y}, \quad \tilde{p} \to 2, \quad \tilde{X} \to 2\hat{K} \ \text{ as } \tilde{y} \to \infty. \tag{6.13}$$

We can solve this boundary value problem using the boundary element method described in section 5. Note that in this case it is easier to truncate the domain of solution using the straight line $\tilde{y} = \tilde{y}_\infty$, and that we can evaluate the contribution to the integral in (5.1) along this line analytically for the simple far field given by (6.13).

We found the solution by introducing an artificial continuation parameter, β, modifying the far field conditions to be

$$\tilde{X}'\cos\beta - \tilde{Y}'\sin\beta = 0, \quad \tilde{u}_y = -\tilde{y}_\infty\cos\beta \ \text{ at } \tilde{y} = \tilde{y}_\infty.$$

When the continuation parameter β is $\pi/2$, we can converge to a solution from an initial guess with $\tilde{X} = \tilde{u}_y = \tilde{u}_x = 0$, and when $\beta = 0$, we recover the problem whose

[1] We have used tildes here for notational convenience, and note that these variables should not be confused with those used in the outer region.

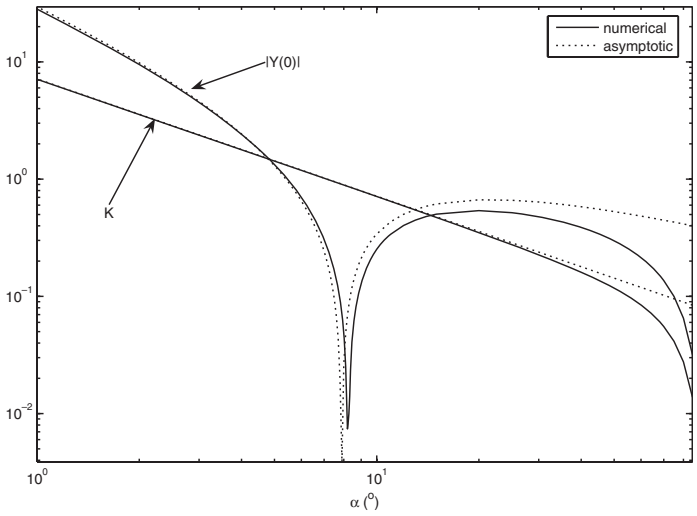

FIG. 6.1. *A comparison between the numerical solution in the inner region and the asymptotic solution for* $\alpha \ll 1$.

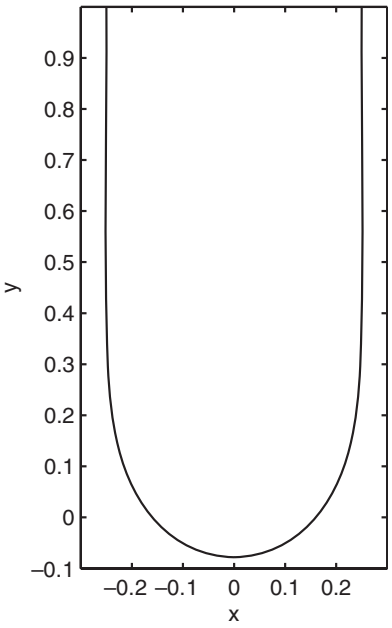

FIG. 6.2. *The asymptotic solution in the inner-inner region for* $\alpha \ll 1$.

solution we are interested in. Starting from $\beta = \pi/2$ and successively solving for smaller values of β, we were able to obtain a converged solution with $\beta = 0$. From the condition that $\tilde{X} \to 2\hat{K}$ as $\tilde{y} \to \infty$, we find that $\hat{K} \approx 0.125$, and hence $K \approx 0.125/\alpha$, and that the curvature at the tip of the fluid is $\kappa(0) \approx 5.13$, consistent with the behavior of the full numerical solution shown in Figure 5.4. Figure 6.1 shows the asymptotic and numerical values of K and $\bar{Y}(0)$, which are in very good agreement.

Note that

$$\bar{Y}(0) = (b_\infty(0) - 1)\, K - 2K \log 2K,$$

so that the logarithmic constant that appears in (6.11) is absorbed into the definition of K. Figure 6.2 shows the asymptotic solution in the inner-inner region, and should be compared to the solutions shown in Figure 5.2. Note that, although $\bar{Y}(0) < 0$ in Figure 5.2, the tip lies at

$$Y(0) \equiv -Kt \log t + t\bar{Y}(0) \sim \frac{\hat{K}t}{\alpha} \log\left(\frac{\alpha^2 e^{b_\infty(0)-1}}{\hat{K}^2 t}\right) \quad \text{as } \alpha \to 0 \text{ for } t \ll 1. \tag{6.14}$$

We conclude that in the double limit $\alpha \to 0$, $t \to 0$ we require that $t \ll \alpha^2$ or $t = O(\alpha^2)$ for this solution to be valid.

7. Asymptotic solution of the inner problem for $\pi - \alpha \ll 1$. As we saw in the previous section, it is more convenient to parameterize the free surface as lying at $\bar{x} = \bar{X}(\bar{y})$. By balancing terms in the equations, we find that the richest asymptotic balance arises when we leave K and all of the variables unscaled, except for $\bar{X}$, which we write as $\bar{X} = \epsilon\bar{\chi}$, where $\chi = O(1)$ for $\epsilon = \pi - \alpha \ll 1$. The region D, where the fluid lies, is given by $\bar{x} > 0$ for $\bar{y} \geq \bar{y}_0$, and $\bar{x} > \epsilon\bar{\chi}(\bar{y})$ for $\bar{y} \leq \bar{y}_0$. The free surface meets the $\bar{y}$-axis at $\bar{y} = \bar{y}_0$, which we need to determine. We must therefore solve

$$0 = -\bar{\nabla}\bar{p} + \bar{\nabla}^2\bar{\mathbf{u}} \ \text{ in } D, \tag{7.1}$$

$$\bar{\nabla} \cdot \bar{\mathbf{u}} = 0 \ \text{ in } D, \tag{7.2}$$

$$\bar{y}\frac{d\bar{\chi}}{d\bar{y}} - \bar{\chi} = K\frac{d\bar{\chi}}{d\bar{y}} + \bar{u}_y\frac{d\bar{\chi}}{d\bar{y}} - \epsilon^{-1}\bar{u}_x \ \text{ at } \bar{x} = \epsilon\bar{\chi}(\bar{y}) \text{ for } \bar{y} < \bar{y}_0, \tag{7.3}$$

$$\left\{\epsilon^2\left(\frac{d\bar{\chi}}{d\bar{y}}\right)^2 - 1\right\}\left(\frac{\partial\bar{u}_x}{\partial\bar{y}} + \frac{\partial\bar{u}_y}{\partial\bar{x}}\right) - 4\epsilon\frac{d\bar{\chi}}{d\bar{y}}\frac{\partial\bar{u}_x}{\partial\bar{x}} = 0 \ \text{ at } \bar{x} = \epsilon\bar{\chi}(\bar{y}) \text{ for } \bar{y} < \bar{y}_0, \tag{7.4}$$

$$\begin{aligned} -\bar{p} - 2\left\{1 + \epsilon^2\left(\frac{d\bar{\chi}}{d\bar{y}}\right)^2\right\}^{-1}\left[\left\{\epsilon^2\left(\frac{d\bar{\chi}}{d\bar{y}}\right)^2 - 1\right\}\frac{\partial\bar{u}_x}{\partial\bar{x}} + \epsilon\frac{d\bar{\chi}}{d\bar{y}}\left(\frac{\partial\bar{u}_x}{\partial\bar{y}} + \frac{\partial\bar{u}_y}{\partial\bar{x}}\right)\right] \\ = \epsilon\frac{d^2\bar{\chi}}{d\bar{y}^2}\left\{1 + \left(\frac{d\bar{\chi}}{d\bar{y}}\right)^2\right\}^{-3/2} \quad \text{at } \bar{x} = \epsilon\bar{\chi}(\bar{y}) \text{ for } \bar{y} < \bar{y}_0, \end{aligned} \tag{7.5}$$

$$\bar{u}_x = \frac{\partial\bar{u}_y}{\partial\bar{x}} = \frac{\partial\bar{p}}{\partial\bar{x}} = 0 \ \text{ at } \bar{x} = 0 \text{ for } \bar{y} > \bar{y}_0 \tag{7.6}$$

subject to the matching conditions (3.14) and

$$\bar{\chi} \sim -\frac{\tan\epsilon}{\epsilon}\left\{\bar{y} + 2K\log\left(\frac{-\bar{y}}{\cos\epsilon}\right) - K\left(b_\infty(\pi) - 3\right)\right\} \quad \text{as } \bar{y} \to -\infty. \tag{7.7}$$

The numerical results presented in section 4 show that $b_\infty(\pi) \approx 1.82$.

We expand $\bar{u}_x = \bar{u}_{x0} + \epsilon \bar{u}_{x1} + O(\epsilon^2)$, and similarly for the other variables. The far field solution, (3.14), is a solution of the full problem at leading order. This solution is singular, which indicates that an inner-inner region will be needed. Since the singularity must be where the free surface meets the $\bar{y}$-axis, the appropriate leading order solution is

$$\bar{p}_0 = 4K_0 \frac{\bar{y} - \bar{y}_0}{\bar{x}^2 + (\bar{y} - \bar{y}_0)^2}, \quad \bar{u}_{x0} = 2K_0 \frac{\bar{x}(\bar{y} - \bar{y}_0)}{\bar{x}^2 + (\bar{y} - \bar{y}_0)^2},$$

$$\bar{u}_{y0} = -K_0 \log\left\{\bar{x}^2 + (\bar{y} - \bar{y}_0)^2\right\} - 2K_0 \frac{\bar{x}^2}{\bar{x}^2 + (\bar{y} - \bar{y}_0)^2} + K_0 b_\infty. \tag{7.8}$$

Note that $\bar{\chi}_0$, the leading order position of the free surface, is not determined by the leading order problem, and is coupled to the solution at $O(\epsilon)$, which satisfies, in terms of a streamfunction in polar coordinates,

$$\bar{\nabla}^4 \psi = 0 \quad \text{for } 0 < \theta < \pi, \tag{7.9}$$

$$\begin{aligned} &- \left[K_0 \left\{b_\infty(\pi) + 1 - 2\log r\right\} - \bar{y}_0 + r\right] \frac{d\bar{\chi}_0}{dr} \\ &+ \left(1 + \frac{2K_0}{r}\right) \bar{\chi}_0 = \frac{\partial \psi}{\partial r} \quad \text{at } \theta = \pi, \end{aligned} \tag{7.10}$$

$$\frac{\partial^2 \psi}{\partial r^2} - \frac{1}{r}\frac{\partial \psi}{\partial r} - \frac{1}{r^2}\frac{\partial \psi}{\partial \theta^2} = 8K_0 \frac{d}{dr}\left(\frac{\bar{\chi}_0}{r}\right) \quad \text{at } \theta = \pi, \tag{7.11}$$

$$-\frac{3}{r}\frac{\partial^3 \psi}{\partial r^2 \partial \theta} + \frac{3}{r^2}\frac{\partial^2 \psi}{\partial r \partial \theta} - \frac{4}{r^3}\frac{\partial \psi}{\partial \theta} - \frac{1}{r^3}\frac{\partial^3 \psi}{\partial \theta^3} = \frac{d^3 \bar{\chi}_0}{dr^3} \quad \text{at } \theta = \pi, \tag{7.12}$$

$$\psi = \frac{\partial^2 \psi}{\partial \theta^2} = 0 \quad \text{at } \theta = 0, \tag{7.13}$$

$$\psi \sim -2K_1 r \log r \sin\theta + \left(K_1 b_\infty(\pi) + K_0 b'_\infty(\pi)\right) r \sin\theta \quad \text{as } r \to \infty, \tag{7.14}$$

$$\bar{\chi}_0 \sim r - \bar{y}_0 - 2K_0 \log r + (b_\infty(\pi) - 3)K_0 \quad \text{as } r \to \infty. \tag{7.15}$$

Note that we have chosen a polar coordinate system with the $\bar{y}$-axis at $\theta = 0$, which is more convenient for the following calculations. We must therefore solve for Stokes flow in the upper half-plane, driven by a stress and normal velocity prescribed on the negative $\bar{y}$-axis, and coupled linearly to the unknown position of the free surface, $\bar{\chi}_0$.

Clearly, the behavior of the solution as $r \to 0$ is crucial, and we investigate this first. If we assume that $\bar{\chi}_0 \sim kr^n$ as $r \to 0$ for some constant k, then the streamfunction must take the form $\psi \sim r^n \log r\, f(\theta) + r^n\, g(\theta)$. If we first consider the terms of $O(r^n \log r)$ and make use of the symmetry condition (7.13), we find that a biharmonic streamfunction has

$$f(\theta) = A_0 \sin n\theta + B_0 \sin(n-2)\theta$$

for some constants A_0 and B_0. On substituting this form into the boundary conditions (7.10) to (7.12), we obtain three linear equations in these two constants. The only

way that we can satisfy these is if n is a half integer. In order for this to be able to match the solution in the inner-inner region, $\bar{\chi}_0$ must be bounded, with nonzero derivative as $r \to 0$, which means that $n = 1/2$ and $\bar{\chi}_0 \sim kr^{1/2}$ as $r \to 0$. This then allows us to fix A_0 and B_0 and obtain

$$f(\theta) = \frac{1}{2}K_0 k \left(3\sin\frac{1}{2}\theta - \sin\frac{3}{2}\theta\right). \tag{7.16}$$

At $O(r^{1/2})$ we obtain

$$g(\theta) = A_1 \sin\frac{1}{2}\theta + B_1 \sin\frac{3}{2}\theta + \frac{1}{2}K_0 k\theta\left(3\cos\frac{1}{2}\theta + \cos\frac{3}{2}\theta\right).$$

On substituting this into the normal stress boundary condition, (7.12), we find that A_1 and B_1 do not appear, so that K_0 is determined at this point in the analysis, with $K_0 = -1/4\pi$. This is in excellent agreement with numerical solutions of the full inner problem, as shown in Figure 5.3. The boundary conditions (7.10) and (7.11) then fix A_1 and B_1, so that

$$\begin{aligned} g(\theta) = k\Bigg[&-\frac{1}{4}\left\{K_0\left(3b_\infty(\pi) - 1\right) - 3\bar{y}_0\right\}\sin\frac{1}{2}\theta + \frac{1}{4}\left\{K_0\left(b_\infty(\pi) + 5\right) - \bar{y}_0\right\}\sin\frac{3}{2}\theta \\ &+\frac{1}{2}K_0\theta\left(3\cos\frac{1}{2}\theta + \cos\frac{3}{2}\theta\right)\Bigg]. \end{aligned} \tag{7.17}$$

It now remains to determine k as a function of $\bar{y}_0$. We could proceed numerically, but, as we shall see in section 7.2, $\bar{y}_0$ is large and negative for $\epsilon \ll 1$, consistent with the behavior shown in Figure 5.5.

7.1. Inner solution for $-\bar{y}_0 \gg 1$. We seek to solve (7.9) to (7.15) when $\bar{y}_0$ is large and negative. Note that since this problem is linear, the results that we obtained above for $r \ll 1$ remain valid when $-\bar{y}_0$ is large. In particular, we must have $\bar{\chi}_0 \sim kr^{1/2}$ as $r \to 0$ and $K_0 = -1/4\pi$. Note also that arbitrary multiples of the solutions of the homogeneous problem, $r\log r\sin\theta$ and $r\sin\theta$, can be added to ψ without affecting the equations satisfied by $\bar{\chi}_0$. We therefore subtract the far field behavior, given by (7.14), from ψ, so that we require $\psi = o(r)$ as $r \to \infty$.

If we define $\delta = -\bar{y}_0^{-1} \ll 1$, we find that we can obtain a suitable leading order balance by defining scaled variables

$$r = \delta^{-1}\tilde{r}, \quad \bar{\chi}_0 = \delta^{-1}\tilde{\chi}, \quad \psi = \delta^{-2}\tilde{\psi}, \quad k = \delta^{-1/2}\tilde{k},$$

in terms of which (7.9) to (7.15) become

$$\bar{\nabla}^4\tilde{\psi} = 0 \quad \text{for } 0 < \theta < \pi, \tag{7.18}$$

$$\begin{aligned} &-\left[K_0\left\{b_\infty(\pi) + 1 - 2\log\tilde{r} + 2\log\delta\right\}\delta + 1 + \tilde{r}\right]\frac{d\tilde{\chi}}{d\tilde{r}} \\ &\qquad + \left(1 + \frac{2K_0\delta}{\tilde{r}}\right)\tilde{\chi} = \frac{\partial\tilde{\psi}}{\partial\tilde{r}} \quad \text{at } \theta = \pi, \end{aligned} \tag{7.19}$$

$$\frac{\partial^2\tilde{\psi}}{\partial\tilde{r}^2} - \frac{1}{\tilde{r}}\frac{\partial\tilde{\psi}}{\partial\tilde{r}} - \frac{1}{\tilde{r}^2}\frac{\partial\tilde{\psi}}{\partial\theta^2} = 8K_0\delta\frac{d}{d\tilde{r}}\left(\frac{\tilde{\chi}}{\tilde{r}}\right) \quad \text{at } \theta = \pi, \tag{7.20}$$

$$-\frac{3}{\tilde{r}}\frac{\partial^3\tilde{\psi}}{\partial\tilde{r}^2\partial\theta}+\frac{3}{\tilde{r}^2}\frac{\partial^2\tilde{\psi}}{\partial\tilde{r}\partial\theta}-\frac{4}{\tilde{r}^3}\frac{\partial\tilde{\psi}}{\partial\theta}-\frac{1}{\tilde{r}^3}\frac{\partial^3\tilde{\psi}}{\partial\theta^3}=-\delta\frac{d^3\tilde{\chi}}{d\tilde{r}^3}\quad\text{at }\theta=\pi, \tag{7.21}$$

$$\tilde{\psi}=\frac{\partial^2\tilde{\psi}}{\partial\theta^2}=0\quad\text{at }\theta=0, \tag{7.22}$$

$$\tilde{\psi}=o(\tilde{r})\quad\text{as }\tilde{r}\to\infty, \tag{7.23}$$

$$\tilde{\chi}\sim\tilde{r}+1-2K_0\delta\log\tilde{r}+2K_0\delta\log\delta+(b_\infty(\pi)-3)K_0\delta\quad\text{as }\tilde{r}\to\infty, \tag{7.24}$$

$$\tilde{\chi}\sim\tilde{k}\tilde{r}^{1/2}\quad\text{as }\tilde{r}\to 0, \tag{7.25}$$

$$\begin{aligned}\tilde{\psi}\sim&-\frac{1}{4}\tilde{k}\left(3\sin\frac{1}{2}\theta-\sin\frac{3}{2}\theta\right)+\frac{1}{2}K_0\tilde{k}\delta\left(3\sin\frac{1}{2}\theta-\sin\frac{3}{2}\theta\right)\tilde{r}^{1/2}\left(\log\tilde{r}-\log\delta\right)\\&+\tilde{k}K_0\delta\left\{-\frac{1}{4}\left(3b_\infty(\pi)-1\right)\sin\frac{1}{2}\theta+\frac{1}{4}\left(b_\infty(\pi)+5\right)\sin\frac{3}{2}\theta\right.\\&\left.+\frac{1}{2}\theta\left(3\cos\frac{1}{2}\theta+\cos\frac{3}{2}\theta\right)\right\}\tilde{r}^{1/2}\quad\text{as }\tilde{r}\to 0.\end{aligned} \tag{7.26}$$

We now expand $\tilde{\psi}=\tilde{\psi}_0+\delta\log\delta\tilde{\psi}_1+\delta\tilde{\psi}_2+o(\delta)$, and similarly for $\tilde{\chi}$ and $\tilde{k}$. At leading order and at $O(\delta\log\delta)$, analytical solutions are available, with

$$\begin{aligned}\tilde{\psi}_0&=-\frac{1}{4}\tilde{k}_0\left(3\sin\frac{1}{2}\theta-\sin\frac{3}{2}\theta\right)\tilde{r}^{1/2},\\\tilde{\chi}_0&=\frac{1}{2}\tilde{k}_0\left\{(\tilde{r}+1)\tan^{-1}\tilde{r}^{1/2}+\tilde{r}^{1/2}\right\},\quad\tilde{k}_0=\frac{4}{\pi},\end{aligned} \tag{7.27}$$

$$\begin{aligned}\tilde{\psi}_1&=-\left(\frac{1}{4}\tilde{k}_1+\frac{1}{2}K_0\tilde{k}_0\right)\left(3\sin\frac{1}{2}\theta-\sin\frac{1}{2}\theta\right)\tilde{r}^{1/2},\\\tilde{\chi}_1&=\tilde{k}_1\tan^{-1}\tilde{r}^{1/2},\quad\tilde{k}_1=\frac{4K_0}{\pi}.\end{aligned} \tag{7.28}$$

At $O(\delta)$ the problem is forced by the leading order solution, and no analytical solution is available directly. Although the problem can be solved, in principle, using Mellin integral transforms, this is not a practical approach, since the Mellin transform of $\tilde{\chi}_0$ is not available analytically. The problem at $O(\delta)$ can be solved numerically, using a technique similar to that used in section 4.2, but, as we shall see, we do not actually need it in what follows. Finally, note that the weak nonuniformity between the terms in the expansion of $\tilde{\chi}$ for $\tilde{r}\gg 1$ is just a reordering and can be ignored.

7.2. The inner-inner region for $\pi-\alpha=\epsilon\ll 1$. Since $\bar{\chi}_0\sim 4\delta^{-1/2}r^{1/2}/\pi$ as $r\to 0$ for $\delta=-\bar{y}_0^{-1}\ll 1$, and we expect a nonuniformity when $\epsilon d\bar{\chi}_0/dr=O(1)$, the inner-inner region has $\bar{y}=\bar{y}_0+O(\epsilon^2\delta^{-1})$, $\bar{x}=O(\epsilon^2\delta^{-1})$. We therefore define scaled variables

$$\bar{x}=\epsilon^2\delta^{-1}\tilde{\bar{x}},\quad\bar{y}=\bar{y}_0+\epsilon^2\delta^{-1}\tilde{\bar{y}},\quad\bar{X}=\epsilon\bar{\chi}=\epsilon^2\delta^{-1}\tilde{\bar{X}},\quad\bar{\mathbf{u}}=\tilde{\bar{\mathbf{u}}},\quad\bar{p}=\epsilon^{-2}\delta\tilde{\bar{p}}.$$

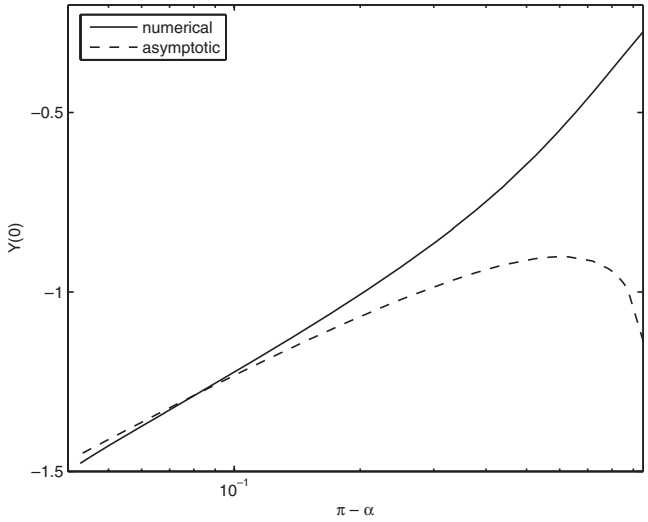

FIG. 7.1. *The numerically calculated value of the position of the tip of the recoiling wedge and the asymptotic approximation given by* (7.30).

At leading order we obtain surface tension–driven Stokes flow, but with kinematic condition

$$\tilde{\bar{u}}_y \frac{d\tilde{\bar{X}}}{d\tilde{\bar{y}}} - \tilde{\bar{u}}_x = (\bar{y}_0 - K_0)\frac{d\tilde{\bar{X}}}{d\tilde{\bar{y}}}. \tag{7.29}$$

By writing the inner solution in terms of these inner-inner variables, we can obtain the matching condition, which gives the inner-inner behavior as $\tilde{\bar{x}}^2 + \tilde{\bar{y}}^2 \to \infty$, in the usual way. Note, however, that we must retain the contribution from the $O(\epsilon)$ correction to $\bar{u}_x$ in the inner region, since it was this that determined the scalings for the inner region. Moreover, we have to be careful with logarithmic terms. The matching condition for $\tilde{\bar{u}}_y$ is

$$\tilde{\bar{u}}_y \sim -2K_0 \log\left(\epsilon^2\delta^{-1}\right) - K_0 \log\left(\tilde{\bar{x}}^2 + \tilde{\bar{y}}^2\right) - \frac{2K_0\tilde{\bar{x}}^2}{\tilde{\bar{x}}^2 + \tilde{\bar{y}}^2} + K_0 b_\infty(\pi) + o(1) \text{ as } \tilde{\bar{x}}^2 + \tilde{\bar{y}}^2 \to \infty.$$

If we define $\tilde{\bar{U}}_y = \tilde{\bar{u}}_y + 2K_0 \log\left(\epsilon^2\delta^{-1}\right)$ and $\tilde{y}_0 = \bar{y}_0 + 2K_0 \log\left(\epsilon^2\delta^{-1}\right) = \bar{y}_0 + 2K_0 \log\left(-\epsilon^2\bar{y}_0\right)$, with $\tilde{\bar{U}}_y$, $\tilde{y}_0 = O(1)$, we can remove the logarithm from the problem. This means that $\bar{y}_0$, the position of the tip, is weakly singular, with

$$\begin{aligned} \bar{y}_0 &\equiv -\delta^{-1} = -4K_0 \log\epsilon - 2K_0 \log\left(4K_0 \log\epsilon\right) + \tilde{y}_0 + o(1) \\ &\equiv \frac{1}{\pi}\log\epsilon + \frac{1}{2\pi}\log\left(-\frac{1}{\pi}\log\epsilon\right) + \tilde{y}_0 + o(1). \end{aligned} \tag{7.30}$$

Figure 7.1 shows that numerical solutions of the full inner problem are consistent with this weak singularity in the position of the tip of the wedge. It now remains to determine $\tilde{y}_0$ by solving the inner-inner problem numerically.

Note that the kinematic condition (7.29) is now

$$\tilde{\bar{U}}_y \frac{d\tilde{\bar{X}}}{d\tilde{\bar{y}}} - \tilde{\bar{u}}_x = (\tilde{y}_0 - K_0)\frac{d\tilde{\bar{X}}}{d\tilde{\bar{y}}}. \tag{7.31}$$

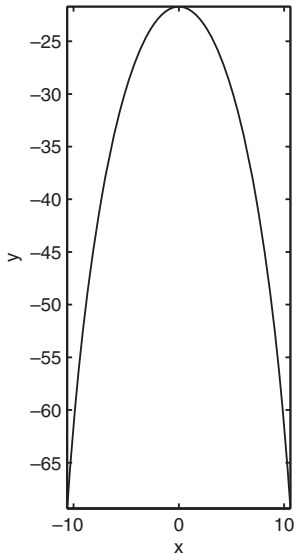

FIG. 7.2. *The numerical solution of the inner-inner problem.*

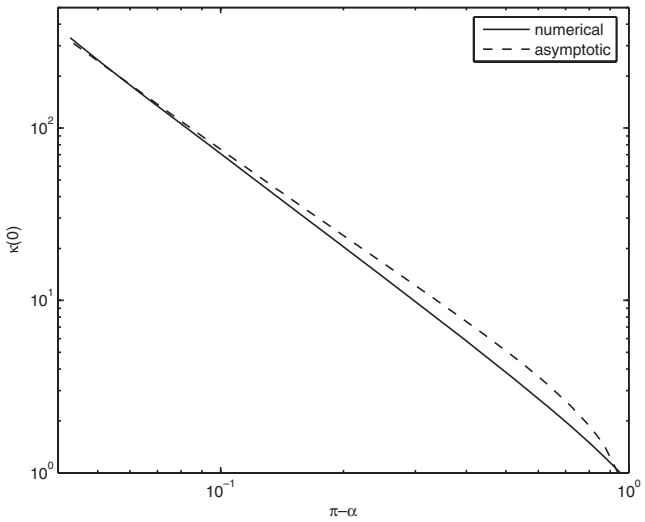

FIG. 7.3. *The numerically calculated value of the curvature at the tip of the recoiling wedge, and our asymptotic estimate for* $\pi - \alpha \ll 1$.

We also have the matching conditions

$$\tilde{\tilde{X}} \sim \frac{4}{\pi}\left(-\tilde{\tilde{y}}\right)^{1/2} \quad \text{as } \tilde{\tilde{y}} \to -\infty, \tag{7.32}$$

and, in terms of a streamfunction and polar coordinates,

$$\tilde{\tilde{\psi}} \sim \frac{1}{2\pi}\tilde{\tilde{r}}\log\tilde{\tilde{r}}\sin\theta - \frac{b_\infty(\pi)}{4\pi}\tilde{\tilde{r}}\sin\theta - \frac{1}{\pi}\left(3\sin\frac{1}{2}\theta - \sin\frac{3}{2}\theta\right)\tilde{\tilde{r}}^{1/2} \text{as } \tilde{\tilde{r}} \to \infty. \tag{7.33}$$

We can solve this boundary value problem using the numerical method described in section 5. Since we were unable to find a suitable artificial continuation parameter,

analogous to β in section 6.1, we used the outer asymptotic solution, (7.27), as our initial guess, from which we were able to obtain a converged solution. We found that $\bar{y}_0 \approx -0.381$, which gives the asymptotic solution for the position of the tip of the wedge shown in Figure 7.1. The numerical solution for the free surface is shown in Figure 7.2, which should be compared to the solutions shown in Figure 5.1. From this, we can calculate the curvature at the tip of the wedge, which is of $O(\delta/\epsilon^2)$. This asymptotic estimate is shown in Figure 7.3.

8. Conclusions. In this paper, we have presented an analysis of the initial motion of a viscous fluid with a free surface under the action of surface tension when the fluid lies in a wedge at $t = 0$. We showed that this is an example of a problem in which inertia is never negligible as $t \to 0$, even though an obvious viscous-dominated similarity scaling exists, since the solution develops over two asymptotic regions: a nonlinear inner region a distance of $O(t \log t)$ from the origin with size $O(t)$ dominated by surface tension and viscous forces, and a linear outer region with size $O(t^{1/2})$ dominated by viscous and inertial forces. The results of [1] show that the addition of an exterior fluid with viscosity much less than that of the interior fluid is a singular perturbation, and the solution can then be described in terms of a region with size $O(t)$, where the flow is dominated by surface tension and viscosity. It would be interesting to investigate the structure of the initial flow in the two-fluid problem when the viscosity ratio is small. Another interesting problem is the case of an initial cone of fluid. The inviscid version of this problem has been studied in [6] and [7].

One reason for attempting this analysis was that it was hoped that the limiting cases presented in sections 6 and 7 would provide some insight into the initial stages of the coalescence of droplets and bubbles. This analogy has proved to be useful in the case of inviscid coalescence (see [11]). However, as discussed in the appendix, this idea does not work here. An analysis of this problem, which shows that $t \log t$-dependence does occur in these coalescence problems, but with coefficients different than those that arise in the wedge problem, is given in [9].

Appendix. Inapplicability to the coalescence of drops and bubbles. Since the asymptotic structure of the solution of the wedge problem indicates that the inner region is small, and that the tip of the wedge lies a distance from the origin much greater than the size of the inner region, we can postulate that the inner flow sees only the local slope of the interface, even if the free surface is actually curved on a much longer lengthscale, an idea that works well for inviscid coalescence (see [11]). Unfortunately, because the separation of scales between the size of the inner region and its distance from the origin is only of $O(\log t)$, we find that this simple idea is not applicable.

A.1. Drops. The wedge solution with $\alpha \ll 1$ indicates that

$$Y(0) \sim \frac{\hat{K}t}{\alpha}\left\{-\log t + \log\left(\frac{\alpha^2 e^{b_\infty(0)-1}}{\hat{K}^2}\right)\right\} \quad \text{as } \alpha \to 0 \text{ for } t \ll 1. \tag{A.1}$$

If initially $x = \epsilon y^2$ with $\epsilon \ll 1$, then, locally,

$$\alpha \sim \frac{dx}{dy} \sim 2\epsilon y \sim -2\epsilon \frac{\hat{K}}{\alpha} t \log t,$$

and hence $\alpha \sim \sqrt{-2\epsilon \hat{K} t \log t}$. However, this means that the two terms inside the braces in (A.1) are of comparable size, and there is no separation of scales.

A.2. Bubbles. The wedge solution with $\pi - \alpha \ll 1$ indicates that

$$Y(0) \sim -\frac{1}{2\pi} t \log t + t \left\{ \frac{1}{\pi} \log(\pi - \alpha) + \frac{1}{2\pi} \log \left(-\frac{1}{\pi} \log (\pi - \alpha) \right) + \tilde{y}_0 \right\} \tag{A.2}$$
$$\text{as } \alpha \to \pi \text{ for } t \ll 1.$$

The same argument as given in the previous subsection indicates that, if initially $x = \epsilon y^2$ with $\epsilon \ll 1$, then $\pi - \alpha \sim -\epsilon t \log t / 2\pi$. The second term in (A.2) is then comparable to the first, and, again, there is no separation of scales.

KINETICS OF MARTENSITIC PHASE TRANSITIONS: LATTICE MODEL*

LEV TRUSKINOVSKY† AND ANNA VAINCHTEIN‡

Abstract. Martensitic phase transitions are often modeled by mixed-type hyperbolic-elliptic systems. Such systems lead to ill-posed initial-value problems unless they are supplemented by an additional kinetic relation. In this paper we explicitly compute an appropriate closing relation by replacing the continuum model with its natural discrete prototype. The procedure can be viewed as either regularization by discretization or a physically motivated account of underlying discrete microstructure. We model phase boundaries by traveling wave solutions of a fully inertial discrete model for a bi-stable lattice with harmonic long-range interactions. Although the microscopic model is Hamiltonian, it generates macroscopic dissipation which can be specified in the form of a relation between the velocity of the discontinuity and the conjugate configurational force. This kinetic relation respects entropy inequality but is not a consequence of the usual Rankine–Hugoniot jump conditions. According to the constructed solution, the dissipation at the macrolevel is due to the induced radiation of lattice waves carrying energy away from the propagating front. We show that sufficiently strong nonlocality of the lattice model may be responsible for the multivaluedness of the kinetic relation and can quantitatively affect kinetics in the near-sonic region. Direct numerical simulations of the transient dynamics suggest stability of at least some of the computed traveling waves.

1. Introduction.

A characteristic feature of martensitic phase transitions in active materials is the energy dissipation leading to experimentally observed hysteresis. The dissipation is due to propagating phase boundaries that can be represented at the continuum level as surfaces of discontinuity. Classical elastodynamics admits nonzero dissipation on moving discontinuities but provides no information about its origin and kinetics. Although the arbitrariness of the rate of dissipation does not create problems in the case of classical shock waves, it is known to be the cause of nonuniqueness in the presence of subsonic phase boundaries (see [7, 13, 20] for recent reviews).

The ambiguity at the macroscale reflects the failure of the continuum theory to describe phenomena inside the narrow transition fronts where dissipation actually takes place. The missing closing relation can be found by analyzing a regularized theory which describes the fine structure of the transition front. When the local curvature effects can be neglected, the problem reduces to the study of a one-dimensional steady-state problem. To formulate the simplest problem of this type it is sufficient to consider longitudinal motions of a homogeneous elastic bar. The total energy of

such bar is the sum of kinetic and potential contributions

$$\mathcal{E} = \int \left[\frac{\rho \dot{u}^2}{2} + \phi(u_x) \right] dx, \tag{1.1}$$

where $u(x,t)$ is the displacement field, $\dot{u} \equiv \partial u/\partial t$ is the velocity, $u_x \equiv \partial u/\partial x$ is the strain, ρ is the constant mass density, and $\phi(u_x)$ is the elastic energy density. The function $u(x,t)$ satisfies the nonlinear wave equation

$$\rho \ddot{u} = (\sigma(u_x))_x, \tag{1.2}$$

where $\sigma(u_x) = \phi'(u_x)$ is the stress-strain relation.

Although in classical elastodynamics (1.2), which is often presented as a first-order p-system, is assumed to be hyperbolic, the hyperbolicity condition $\sigma'(u_x) > 0$ is violated for martensitic materials with nonmonotone stress-strain relation $\sigma(u_x)$ [8]. This makes the initial-value problem associated with the mixed-type equation (1.2) ill-posed; in particular, it leads to the appearance of discontinuities violating the Lax condition (subsonic phase boundaries or kinks, e.g., [16, 17, 31]).

To be more specific, consider a discontinuity moving with velocity V. Let f_- and f_+ denote the limiting values of a function $f(x)$ to the left and to the right of the interface, and introduce the notations $[\![f]\!] \equiv f_+ - f_-$ for the jump and $\{f\} \equiv (f_+ + f_-)/2$ for the average of f across the discontinuity. The parameters on a discontinuity must satisfy both the classical Rankine–Hugoniot jump conditions,

$$[\![\dot{u}]\!] + V[\![u_x]\!] = 0, \quad \rho V[\![\dot{u}]\!] + [\![\sigma(u_x)]\!] = 0, \tag{1.3}$$

and the entropy inequality $\mathcal{R} = GV \geq 0$, where

$$G = [\![\phi]\!] - \{\sigma\}[\![u_x]\!] \tag{1.4}$$

is the configurational (driving) force. Contrary to conventional shock waves, the martensitic phase boundaries usually fail to satisfy the Lax condition $c_+ < V < c_-$, where $c_\pm$ are the values of the sound velocity in front and behind the discontinuity.

One way to remedy the resulting nonuniqueness is to supplement (1.3) by a *kinetic relation* specifying the dependence of the configurational force on the velocity of the phase boundary $G = G(V)$ [1, 30]. Since the nonlinear wave equation (1.2) provides no information about the kinetic relation, the dependence $G(V)$ has often been modeled phenomenologically [1, 29, 30]. An alternative approach has been to derive the kinetic relation from an augmented model incorporating regularizing terms. A typical example is the viscosity-capillarity model, accounting for both dispersive and dissipative corrections [21, 29]. The problem with both approaches is that they introduce into the theory parameters of unclear physical origin.

The aim of the present paper is to obtain the kinetic relation without any phenomenological assumptions at the macroscale by means of direct replacement of the continuum model (1.2) with its natural discrete prototype. Such procedure of going back from continuum to discrete level can be viewed as either regularization by discretization or as a physically motivated account of underlying atomic or mesoscopic microstructure. It is clear that the discrete model must be Hamiltonian to reproduce the conservative structure of the smooth solutions of (1.2). The energy dissipation on the discontinuities can then be interpreted as the nonlinearity-induced radiation of lattice-scale waves which takes the energy away from the long-wave continuum level. This phenomenon is known in physics literature as radiative damping (e.g., [11, 12]).

To regularize (1.2) from "first principles," we consider in this paper fully inertial dynamics of a one-dimensional lattice with bi-stability and long-range interactions. Following some previous work on cracks [22] and dislocations [2], we assume piecewise linear approximation of nonlinearity and construct an explicit traveling wave solution of the discrete problem. There exists an extensive literature on shock waves and solitons in the local and nonlocal discrete systems with convex interatomic potentials (e.g., [9, 10, 19, 27]) and on the semilinear prototypes of the present bi-stable system (e.g., [3, 5, 18]). A discrete quasilinear problem for martensitic phase transitions and failure waves in the chains with nearest-neighbor (NN) interactions was considered in [24, 25, 26, 35]. In the present paper we extend these results to the case of harmonic interactions of finite but arbitrary long range. We show that the local (NN) model is degenerate, find a general solution of the nonlocal model, and provide detailed illustrations for a particular case.

Our analytic solutions demonstrate that the nonlocal model generates a much broader class of admissible solutions than the local model; in particular, it allows the possibility of radiation both in front and behind the moving discontinuity. We also show that sufficiently strong nonlocality may be responsible for the multivaluedness of the kinetic relation and can quantitatively affect kinetics in the near-sonic region. The advantage of the explicit formulas obtained in the paper is that they capture certain details that are difficult or even impossible to detect in numerical simulations, such as singular behavior of solutions near static-dynamic bifurcation and around resonances.

The paper is organized as follows. The piecewise linear discrete model with long-range interactions and the associated dynamical system are introduced in section 2. In section 3 we formulate the dimensionless equations for the traveling waves, the boundary conditions, and the admissibility conditions. An explicit solution for the steady state motion of an isolated phase boundary is obtained by Fourier transform in section 4. In section 5 we obtain static solutions describing lattice-trapped phase boundaries and link them to a nontrivial limit of the dynamic solutions. The energy transfer from long to short waves is studied in section 6, where we obtain a closed-form kinetic relation. In section 7 we illustrate the general theory via the case when the only long-range interactions are due to the second nearest neighbors. Numerical simulations of the transient problem suggesting stability of at least sufficiently fast traveling waves are described in section 8. The last section contains our conclusions.

2. Discrete model. The simplest lattice structure can be modeled as a chain of point masses connected by elastic springs. Suppose that the interactions are of long-range type and that every particle interacts with its q neighbors on each side. If $u_n(t)$ is the displacement of the nth particle, the total energy of the chain can be written as

$$\mathcal{E} = \varepsilon \sum_{n=-\infty}^{\infty} \left[\frac{\rho \dot{u}_n^2}{2} + \sum_{p=1}^{q} p\phi_p\left(\frac{u_{n+p} - u_n}{p\varepsilon} \right) \right], \tag{2.1}$$

where ε is the reference interparticle distance and $\phi_p(w)$ is the energy density of the interaction between pth nearest neighbors. The dynamics of the chain with energy (2.1) is governed by an infinite system of ordinary differential equations:

$$\rho \ddot{u}_n = \frac{1}{\varepsilon} \sum_{p=1}^{q} \left[\phi_p'\left(\frac{u_{n+p} - u_n}{p\varepsilon} \right) - \phi_p'\left(\frac{u_n - u_{n-p}}{p\varepsilon} \right) \right]. \tag{2.2}$$

A continuum system, formally obtained by identifying $u(x,t)$ with a limit of $u(n\varepsilon,t) = u_n(t)$ as $\varepsilon \to 0$, reduces to the nonlinear wave equation (1.2) with a specific macroscopic stress-strain relation

$$\sigma(w) = \sum_{p=1}^{q} p\phi_p'(w). \tag{2.3}$$

When the function $\sigma(w)$ is nonmonotone, (1.2) constitutes an incomplete description of the limit. As we show, in this case the correct limit procedure starting from the discrete problem (2.1), (2.2) must also produce a specific kinetic relation $G = G(V)$. This relation, expressed exclusively in terms of the elastic potentials entering (2.1), provides the desired closure for the macroscopic problem (1.2), (1.3). Here we do not consider the issue of a nucleation criterion, whose discrete prototype was studied in [17].

To obtain analytical results, we consider the simplest potentials allowing for a possibility of a phase transitions: bi-quadratic for local interactions (NN) and quadratic for nonlocal interactions (NNN, NNNN, etc.). Specifically we define

$$\phi_1(w) = \begin{cases} \dfrac{1}{2}\Psi(1)w^2, & w \le w_c, \\ \dfrac{1}{2}\Psi(1)(w-a)^2 + a\Psi(1)\left(w_c - \dfrac{a}{2}\right), & w \ge w_c, \end{cases} \tag{2.4}$$

and

$$\phi_p(w) = \frac{1}{2}p\Psi(p)w^2, \quad p = 2, \dots, q. \tag{2.5}$$

One can see that the nonlinear springs representing NN interactions can be found in two different states depending on whether the strain w is below (phase I) or above (phase II) the critical value w_c. Parameter a defines the microscopic transformation strain (distance between the two linear branches); note that a and w_c are in general independent. For simplicity we assume that the two energy wells of the bi-stable NN potential have equal curvatures $\Psi(1) > 0$.

It is convenient to reformulate the problem using dimensionless variables:

$$\bar{t} = t(\Psi(1)/\rho)^{1/2}/\varepsilon, \quad \bar{u_n} = u_n/(a\varepsilon), \quad \bar{w_c} = w_c/a, \quad \bar{\Psi}(p) = \Psi(p)/\Psi(1), \quad p = 1, \dots, q. \tag{2.6}$$

In terms of these variables with the bars dropped, the energy (2.1) becomes

$$\mathcal{E} = \sum_{n=-\infty}^{\infty}\left[\frac{\dot{u}_n^2}{2} - \frac{1}{2}\sum_{|k-n|\le q} u_n\Psi(k-n)u_k - (u_n - u_{n-1} - w_c)\theta(u_n - u_{n-1} - w_c)\right]. \tag{2.7}$$

By introducing the strain variables $w_n = u_n - u_{n-1}$, we can rewrite the governing equations (2.2) in the form

$$\ddot{w}_n - \sum_{|k-n|\le q}\Psi(k-n)w_k = 2\theta(w_n - w_c) - \theta(w_{n+1} - w_c) - \theta(w_{n-1} - w_c), \tag{2.8}$$

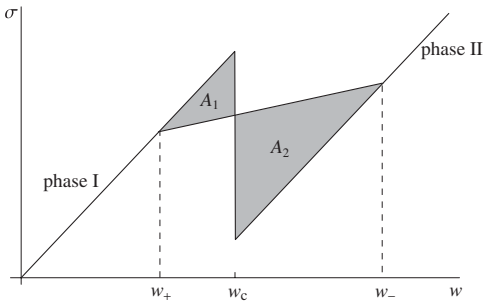

FIG. 2.1. *The bi-linear macroscopic stress-strain law and the Rayleigh line connecting the states at infinity for a traveling wave solution describing an isolated phase boundary. The difference between the shaded areas $A_2 - A_1$ represents the configurational force.*

where

$$\Psi(0) = -2\sum_{p=1}^{q} \Psi(p), \quad \Psi(-p) = \Psi(p), \tag{2.9}$$

and $\theta(w)$ is a unit step function. The macroscopic stress-strain relation (2.3) takes the form

$$\sigma(w) = c^2 w - \theta(w - w_c), \tag{2.10}$$

where

$$c = \left(\sum_{p=1}^{q} p^2 \Psi(p)\right)^{1/2} \tag{2.11}$$

is the dimensionless macroscopic sound speed. The microscopic elastic moduli $\Psi(p)$ must be chosen to ensure that the uniform deformation $w_n = w$ is stable in each of the phases. For this it is necessary and sufficient that all phonon frequencies $\omega^2(k) > 0$, with $\omega(k)$ defined in (3.6) and $k \in (0, \pi]$, are real. This implies, in particular, that the square of the macroscopic sound speed (2.11) is positive. The resulting macroscopic stress-strain relation (2.10) is shown in Figure 2.1.

3. Traveling waves. An isolated phase boundary moving with a constant velocity V can be obtained as a traveling wave solution of (2.8) with $w_n(t) = w(\xi)$, $\xi = n - Vt$. We assume further that in the moving coordinate system all springs in the region $\xi > 0$ are in phase I ($w_n < w_c$), and all springs with $\xi < 0$ are in phase II. The system (2.8) can then be replaced by a single nonlinear advance-delay differential equation:

$$V^2 w'' - \sum_{|p| \le q} \Psi(p) w(\xi + p) = 2\theta(-\xi) - \theta(-\xi - 1) - \theta(1 - \xi). \tag{3.1}$$

The configurations at $\xi = \pm\infty$ must correspond to stable homogeneous equilibria plus superimposed short-wave oscillations with zero average; the averaging is over the largest period of oscillations but can be also defined as

$$\langle w(\xi) \rangle = \lim_{s \to \infty} \frac{1}{s} \int_{\xi}^{\xi + s} w(\zeta)\, d\zeta. \tag{3.2}$$

In terms of the averaged quantities we obtain the following boundary conditions:

$$\langle w(\xi)\rangle \to w_\pm \quad \text{as } \xi \to \pm\infty. \tag{3.3}$$

The nonlinearity of the problem is in the switching condition

$$w(0) = w_c. \tag{3.4}$$

We assume that a solution is admissible if the NN springs in front of the moving interface are still in phase I and behind it already in phase II. This implies that

$$w(\xi) < w_c \quad \text{for } \xi > 0, \qquad w(\xi) > w_c \quad \text{for } \xi < 0. \tag{3.5}$$

Consequently, the mathematical problem reduces to solving (3.1) subject to (3.3), (3.4), and (3.5).

Observe first that the equation (2.8) is linear in each phase ($\xi < 0$ and $\xi > 0$), which means that the solution can be represented as a superposition of linear waves $w_n = \exp(i(kn - \omega t))$. Since the elastic moduli are equal, the dispersion relation

$$\omega^2(k) = 4\sum_{p=1}^{q} \Psi(p) \sin^2 \frac{pk}{2} \tag{3.6}$$

is the same in both phases. For the linear modes to be compatible with the traveling wave ansatz, their phase velocity $V_p(k) = \omega/k$ must be equal to V. This gives the restriction on the admissible wave numbers in the form

$$L(k, V) = 0, \tag{3.7}$$

where

$$L(k, V) = 4\sum_{p=1}^{q} \Psi(p) \sin^2 \frac{pk}{2} - V^2 k^2. \tag{3.8}$$

Among the modes selected by (3.7), the ones with complex wave numbers must be exponentially decaying on both sides of the front. They describe the core structure of the phase boundary. The modes with nonzero real wave numbers correspond to radiation. The waves with $k = 0$ are naturally associated with the macroscopic part of the solution.

4. Exact solution. We solve (3.1) by writing $w(\xi) = h(\xi) + w_-$ and applying the complex Fourier transform

$$\hat{h}(k) = \int_{-\infty}^{\infty} h(\xi) e^{i(k+i\alpha)\xi} d\xi, \quad h(\xi) = \frac{1}{2\pi} \int_{-\infty+i\alpha}^{\infty+i\alpha} \hat{h}(k) e^{-ik\xi} dk,$$

where $\alpha > 0$ is a small parameter which guarantees convergence of the integrals. After inverting the Fourier transform and letting $\alpha \to 0$, we obtain

$$w(\xi) = w_- - \frac{2}{\pi i} \int_\Gamma \frac{\sin^2(k/2) e^{ik\xi} dk}{kL(k, V)}, \tag{4.1}$$

where the contour Γ coincides with the real axis passing the singular point $k = 0$ from below. The singularities associated with nonzero real roots of $L(k, V) = 0$ must

comply with the radiation conditions. Specifically, the modes with group velocity $V_g = \partial\omega/\partial k$ larger than V can appear only in front, while the modes with $V_g < V$ can appear only behind the phase boundary [24]. Using the relation

$$V_g = V + \frac{L_k(k,V)}{2Vk}, \tag{4.2}$$

where $L_k(k,V) = \partial L/\partial k$ and assuming $V > 0$, we obtain that $V_g \gtrless V$ whenever $kL_k(k,V) \gtrless 0$. Therefore, to satisfy the radiation conditions, we need to dent the integration contour in (4.1) in such a way that it passes below the singularities on the real axis if $kL_k(k,V) > 0$ and above if $kL_k(k,V) < 0$.

To compute the integral (4.1) explicitly, we use the residue method closing the contour in the upper half-plane when $\xi > 0$ and in the lower half-plane when $\xi < 0$. The solutions look different in the generic case $q > 1$ and the degenerate case $q = 1$.

For $q > 1$ the Jordan lemma can be applied directly, and by separating the macroscopic part of the solution from the microscopic one, we obtain

$$w(\xi) = \begin{cases} w_- + \displaystyle\sum_{k\in M^-(V)} \frac{4\sin^2(k/2)e^{ik\xi}}{kL_k(k,V)} & \text{for } \xi < 0, \\ w_- - \dfrac{1}{c^2 - V^2} - \displaystyle\sum_{k\in M^+(V)} \frac{4\sin^2(k/2)e^{ik\xi}}{kL_k(k,V)} & \text{for } \xi > 0. \end{cases} \tag{4.3}$$

Here

$$M^{\pm}(V) = \{k : L(k,V) = 0,\ \mathrm{Im}k \gtrless 0\} \bigcup N^{\pm}(V) \tag{4.4}$$

are all roots of the dispersion relation contributing to the solution on either side of the front, with

$$N^{\pm}(V) = \{k : L(k,V) = 0,\ \mathrm{Im}k = 0,\ kL_k(k,V) \gtrless 0\} \tag{4.5}$$

denoting the sets of real roots describing radiation.

For $q = 1$ (NN interactions only) the contribution from a semi-arch at infinity does not vanish at $\xi = \pm 0$ and relations (4.3) must be supplemented by the following limiting conditions:

$$w(\xi) = \begin{cases} w_- + \displaystyle\sum_{k\in M^-(V)} \frac{4\sin^2(k/2)e^{ik\xi}}{kL_k(k,V)} - \frac{1}{2} & \text{for } \xi = -0, \\ w_- - \dfrac{1}{c^2 - V^2} - \displaystyle\sum_{k\in M^+(V)} \frac{4\sin^2(k/2)e^{ik\xi}}{kL_k(k,V)} + \frac{1}{2} & \text{for } \xi = +0. \end{cases} \tag{4.6}$$

In both cases, by applying the boundary conditions (3.3) at infinity we obtain

$$w_+ = w_- - \frac{1}{c^2 - V^2}. \tag{4.7}$$

It is easy to see that (4.7) coincides with the Rankine–Hugoniot relation $V^2[\![w]\!] = [\![\sigma]\!]$, computed for the macroscopic stress-strain relation (2.10). The continuity of $w(\xi)$ at $\xi = 0$ implies that

$$\frac{1}{c^2 - V^2} + \sum_{k\in M(V)} \frac{4\sin^2(k/2)}{kL_k(k,V)} = \begin{cases} 1, & q = 1, \\ 0, & q > 1, \end{cases} \tag{4.8}$$

where $M(V) = M^+(V) \bigcup M^-(V)$. Condition (4.8) is automatically satisfied for $q > 1$ since the sum of residues at all poles (including $k = 0$) equals zero; for $q = 1$ and $\xi = 0$ the integral over a contour at infinity contributes additional unity in the right-hand side of (4.8). The switching condition (3.4) together with (4.8) requires that

$$w_\pm = w_c \mp \frac{1}{2(c^2 - V^2)} + \sum_{k \in N_{\rm pos}(V)} \frac{4\sin^2(k/2)}{|kL_k(k,V)|}, \tag{4.9}$$

where $N_{\rm pos}(V) = \{k : L(k,V) = 0,\ {\rm Im}k = 0, k > 0\} \subset M(V)$ is the set of positive real roots of the dispersion relation. By virtue of (4.7), the two conditions (4.9) are dependent and can be replaced by a single condition:

$$\frac{1}{2}(w_- + w_+) - w_c = \sum_{k \in N_{\rm pos}(V)} \frac{4\sin^2(k/2)}{|kL_k(k,V)|}. \tag{4.10}$$

As we show in section 6, (4.10) represents the desired kinetic relation.

We can use the explicit formulas for $w(\xi)$ to reconstruct the particle velocity profile from $v(\xi) = -Vu'(\xi)$ if we assume that $V \neq 0$. The relation between the velocity and the strain fields reads

$$v(\xi) - v(\xi - 1) = -Vw'(\xi), \tag{4.11}$$

and the right-hand side is already known from (4.3). Solving (4.11) by Fourier transform, we obtain

$$v(\xi) = \begin{cases} v_+ - \dfrac{V}{c^2 - V^2} - 2V \displaystyle\sum_{k \in M^-(V)} \frac{\sin(k/2)e^{ik(\xi + \frac{1}{2})}}{L_k(k,V)} & \text{for } \xi < -\dfrac{1}{2}, \\ v_+ + 2V \displaystyle\sum_{k \in M^+(V)} \frac{\sin(k/2)e^{ik(\xi + \frac{1}{2})}}{L_k(k,V)} & \text{for } \xi > -\dfrac{1}{2}. \end{cases} \tag{4.12}$$

It is easy to check that the average velocities at infinity satisfy the remaining Rankine–Hugoniot condition $(1.3)_1$, which in our case takes the form

$$v_+ - v_- = \frac{V}{c^2 - V^2}. \tag{4.13}$$

Notice that the obtained set of traveling wave solutions is parametrized by the velocity V and the boundary value data $w_\pm$ and $v_\pm$. The average particle velocity v_+ in front can always be set equal to zero due to the Gallilean invariance. If the strain in front of the discontinuity is also prescribed, the remaining three macroscopic parameters are fully constrained by the two classical Rankine–Hugoniot conditions (4.7) and (4.13), plus the nonclassical admissibility condition (4.10).

5. Static solutions. A special consideration is needed when $V = 0$. In this case continuous variable $\xi = n - Vt$ takes integer values, and the strain profile becomes discontinuous at every $\xi = n$. The differential equation reduces to a system of finite-difference equations, and we can replace the continuous Fourier transform by its discrete analogue (see also [6, 11, 23]). First observe that for a piecewise continuous function $w(\xi)$ with discontinuities at integer ξ we have

$$\hat{w}(k) = \int_{-\infty}^{\infty} w(\xi)e^{ik\xi}d\xi = \sum_{n=-\infty}^{\infty} \int_n^{n+1} w(\xi)e^{ik\xi}d\xi.$$

Therefore, assuming that the strain profile $w(\xi)$ converges to $w_0(n)$ as $V \to 0$, we obtain

$$\hat{w}_0(k) = \sum_{n=-\infty}^{\infty} w_0(n) \frac{e^{ik(n+1)} - e^{ikn}}{ik} = \frac{e^{ik} - 1}{ik} \hat{w}_0^{\mathrm{D}}(k), \tag{5.1}$$

where $\hat{w}_0^{\mathrm{D}}(k) = \sum_{n=-\infty}^{\infty} w_0(n) e^{ikn}$ is the discrete Fourier transform of $w_0(n)$. Now we can use (4.1) to obtain

$$\hat{w}_0(k) = 2\pi\delta(k) w_- + \frac{4\sin^2(k/2)}{ik\omega^2(k)},$$

where $\delta(k)$ is the Dirac delta function and $\omega^2(k)$ is given by (3.6). Using (5.1) we can then find $\hat{w}_0^{\mathrm{D}}(k)$ and, applying inverse discrete Fourier transform, obtain a representation of the discrete solution:

$$w_n = \frac{1}{2\pi} \int_{-\pi}^{\pi} \hat{w}_0^{\mathrm{D}}(k) e^{-ikn} dk = w_- - \frac{1}{\pi i} \int_{-\pi}^{\pi} \frac{\sin(k/2) e^{ik(n+1/2)} dk}{\omega^2(k)}.$$

To avoid the singularity at $k = 0$ we must pass it from below; all other roots of the equation $\omega^2(k) = 0$ inside the strip $-\pi \le \mathrm{Re} k \le \pi$ have nonzero imaginary parts. Closing the contour of integration in the upper half-plane for $n \ge 0$ and lower half-plane for $n < 0$, we obtain by residue theorem

$$w_n = \begin{cases} w_- + \displaystyle\sum_{k \in F^-} \frac{\sin(k/2) e^{ik(n+1/2)}}{\omega(k)\omega'(k)}, & n < 0, \\ w_- - \dfrac{1}{c^2} - \displaystyle\sum_{k \in F^+} \frac{\sin(k/2) e^{ik(n+1/2)}}{\omega(k)\omega'(k)}, & n \ge 0, \end{cases} \tag{5.2}$$

where $F^{\pm} = \{k : \omega^2(k) = 0, \mathrm{Im} k \gtrless 0, -\pi \le \mathrm{Re} k \le \pi\}$. Solutions satisfying the admissibility constraints

$$w_n \ge w_c \quad \text{for } n \le -1, \qquad w_n \le w_c \quad \text{for } n \ge 0 \tag{5.3}$$

form a family of lattice-trapped equilibria parametrized by the total stress in the chain $\sigma = c^2 w_- - 1$; the set of such stresses constitutes the *trapping region*.

To specify the trapping region we observe that in our static solutions the phase boundary is pinned at the site $n = -1$. If the strain profile (5.2) is monotone, which occurs, for example, when all long-range interactions are repulsive ($\Psi(p) < 0$ for $p \ge 2$[1]), the constraints (5.3) can be replaced by $w_0 \le w_c$ and $w_{-1} \ge w_c$. The trapping region can then be described explicitly:

$$\sigma_{\mathrm{M}} - \sigma_{\mathrm{P}} \le \sigma \le \sigma_{\mathrm{M}} + \sigma_{\mathrm{P}}, \tag{5.4}$$

where $\sigma_{\mathrm{M}} = c^2 w_c - 1/2$ is the Maxwell stress and

$$\sigma_{\mathrm{P}} = \frac{1}{2} + c^2 \sum_{k \in F^+} \frac{\sin(k/2) e^{ik/2}}{\omega(k)\omega'(k)} \tag{5.5}$$

[1]Since $\Psi(1) = 1 > 0$, the homogeneous phases can still be stable if the negative long-range moduli are sufficiently small.

is the *Peierls stress* (see also [4, 32]). The phase boundary remains trapped until the stress reaches one of the limiting values: $\sigma = \sigma_{\rm M} - \sigma_{\rm P}$, corresponding to $w_{-1} = w_c$ when the interface starts moving to the left ($V < 0$), or $\sigma = \sigma_{\rm M} + \sigma_{\rm P}$, corresponding to $w_0 = w_c$ when the interface starts moving to the right ($V > 0$). The two limiting solutions represent unstable equilibria from which the dynamic solution bifurcates.

6. Kinetic relation. The waves generated in the core of the moving phase boundary carry the energy away from the front without changing the average values of parameters at infinity. At the continuum level these lattice waves are invisible and therefore the associated energy transfer is perceived as dissipation. To evaluate the rate of dissipation, we start with the microscopic energy balance

$$\frac{d\mathcal{E}}{dt} = \mathcal{A}(t),$$

where $\mathcal{E}$ is the total energy of the chain and $\mathcal{A}(t)$ is the power supplied by the external loads. Since the solution of the discrete problem at infinity can be represented as a sum of the macroscopic contribution and the superimposed oscillations, we can split the averaged power accordingly. We obtain

$$\langle \mathcal{A} \rangle = \mathcal{P} - \mathcal{R}, \tag{6.1}$$

where $\mathcal{P} = \sigma_+ v_+ - \sigma_- v_-$ is the macroscopic rate of work and $\mathcal{R}$ is the energy release due to radiated waves which is invisible at the macroscale. While in the general case the expression for $\mathcal{R}$ may contain coupling terms, in the piecewise linear model adopted in this paper, the macroscopic and microscopic contributions decouple (see also [11, 24]). The dissipation rate $\mathcal{R}$ can be written as the sum of the contributions from the areas ahead and behind the front:

$$\mathcal{R}(V) = \mathcal{R}_+(V) + \mathcal{R}_-(V). \tag{6.2}$$

To specify the entries in the right-hand side, we observe that due to the exponential decay of the modes with complex wave numbers, the strain and velocity fields given by (4.3) and (4.12) have the following asymptotic representation at $\xi = \pm\infty$:

$$v(\xi) \approx v_0(\xi) + \sum_{k \in N_{\rm pos}(V)} v_k(\xi), \quad w(\xi) \approx w_0(\xi) + \sum_{k \in N_{\rm pos}(V)} w_k(\xi),$$

where

$$v_0(\xi) = \begin{cases} v_-, & \xi < 0, \\ v_+, & \xi > 0, \end{cases} \qquad w_0(\xi) = \begin{cases} w_-, & \xi < 0, \\ w_+ & \xi > 0, \end{cases}$$

are the homogeneous components and

$$v_k(\xi) = \begin{cases} -\dfrac{4V \sin(k/2)\cos(k(\xi - 1/2))}{L_k(k,V)}, & \xi < 0,\ k \in N^-_{\rm pos}(V), \\ \dfrac{4V \sin(k/2)\cos(k(\xi - 1/2))}{L_k(k,V)}, & \xi > 0,\ k \in N^+_{\rm pos}(V), \end{cases}$$

$$w_k(\xi) = \begin{cases} \dfrac{8\sin^2(k/2)\cos k\xi}{kL_k(k,V)}, & \xi < 0,\ k \in N^-_{\rm pos}(V), \\ -\dfrac{8\sin^2(k/2)\cos k\xi}{kL_k(k,V)}, & \xi > 0,\ k \in N^+_{\rm pos}(V), \end{cases} \tag{6.3}$$

are the oscillatory components. Here $N^{\pm}_{\rm pos}(V) \equiv \{k \in N^{\pm}(V) : k > 0\}$ (recall (4.5)), $N^{+}_{\rm pos}(V) \bigcup N^{-}_{\rm pos}(V) = N_{\rm pos}(V)$. Due to the asymptotic orthogonality of the linear modes, the terms in the right-hand side of (6.2) can be expressed as contributions due to individual modes. Since the energy flux associated with the linear mode k is the product of the average energy density $\langle \mathcal{G}_k \rangle$ and the relative velocity $|V_g - V|$ of the energy transport with respect to the moving front, we can write

$$\mathcal{R}_+(V) = \sum_{k \in N^{+}_{\rm pos}(V)} \langle \mathcal{G}_k \rangle_+ (V_g - V), \qquad \mathcal{R}_-(V) = \sum_{k \in N^{-}_{\rm pos}(V)} \langle \mathcal{G}_k \rangle_- (V - V_g). \tag{6.4}$$

Here $\langle \mathcal{G}_k \rangle_{\pm}$ is the average energy density carried by the wave with the wave number $k \in N^{\pm}_{\rm pos}(V)$. It is given by

$$\langle \mathcal{G}_k \rangle_{\pm} = \lim_{n \to \pm\infty} \frac{1}{2V\tau(k)} \int_{n - V\tau(k)}^{n} \Bigg[v_k^2(\xi) + c^2 (w_k(\xi))^2 - \sum_{p=1}^{q-1} B(p) \{ (w_k(\xi + p) - w_k(\xi))^2 + (w_k(\xi) - w_k(\xi - p))^2 \} \Bigg] d\xi,$$

where $B(p) = \frac{1}{2} \sum_{l=1}^{q-p} l \Psi(l + p)$ and $\tau(k) = 2\pi/\omega(k) = 2\pi/(Vk)$. Using (6.3), we obtain

$$\langle \mathcal{G}_k \rangle_{\pm} = \frac{8V^2 \sin^2(k/2)}{(L_k(k, V))^2},$$

which gives for the total energy flux

$$\mathcal{R}(V) = \sum_{k \in N^{+}_{\rm pos}(V)} \frac{4V \sin^2(k/2)}{k L_k(k, V)} - \sum_{k \in N^{-}_{\rm pos}(V)} \frac{4V \sin^2(k/2)}{k L_k(k, V)} = \sum_{k \in N_{\rm pos}(V)} \frac{4V \sin^2(k/2)}{|k L_k(k, V)|}.$$

Recalling the definition $\mathcal{R}(V) = G(V)V$ we can write the microscopic expression for the configurational force:

$$G(V) = \sum_{k \in N_{\rm pos}(V)} \frac{4 \sin^2(k/2)}{|k L_k(k, V)|}. \tag{6.5}$$

The function $G(V)$ is well-defined since both $L(k, V)$ and $N_{\rm pos}(V)$ depend on V in a known way. Comparing (6.5) with the macroscopic definition of the configurational force (1.4) we obtain

$$G = \frac{1}{2}(w_- + w_+) - w_c, \tag{6.6}$$

which can be interpreted geometrically as the area difference between two shaded triangles in Figure 2.1. Combining (6.5) and (6.6), we obtain exactly (4.10), which shows that (4.10) is indeed the desired kinetic relation and that micro and macro assessments of dissipation are compatible.

7. An example. To illustrate the general solution, consider a special case $q = 2$ (see Figure 7.1). The model is then fully characterized by a single dimensionless parameter,

$$\beta = 4\Psi(2)/\Psi(1),$$

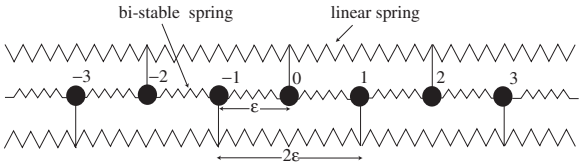

FIG. 7.1. *Discrete chain with nearest and next-to-nearest-neighbor interactions* ($q = 2$).

measuring the relative strength of NNN and NN interactions. The stability constraints (e.g., [36]) give $-1 < \beta \leq \infty$. Recalling that the inequality $\Psi(2) < 0$ is suggested by the linearization of the potentials of the Lennard–Jones type [32, 33], we can further restrict the admissible interval to

$$-1 < \beta \leq 0. \tag{7.1}$$

The total energy of the system can be written as

$$\mathcal{E} = \sum_{n=-\infty}^{\infty} \left[\frac{v_n^2}{2} + \frac{1+\beta}{2} w_n^2 - \theta(w_n - w_c)(w_n - w_c) - \frac{\beta}{4}(w_{n+1} - w_n)^2 \right]. \tag{7.2}$$

One can see that parameter $\beta/(1+\beta)$ characterizes the effect of discreteness: $\beta \sim 0$ corresponds to weak and $\beta \sim -1$ to strong coupling. This identification is compatible with the fact that at $\beta = 0$ the Peierls stress characterizing the size of the lattice-trapping domain takes the largest value (equal to the spinodal limit), while at $\beta = -1$ the Peierls stress is equal to zero.[2]

The energy (7.2) produces the following equation for the traveling waves:

$$\begin{aligned} V^2 w'' - \frac{\beta}{4}\Big(w(\xi+2) - 2w(\xi) + w(\xi-2) \Big) - w(\xi+1) + 2w(\xi) - w(\xi-1) \\ = 2\theta(-\xi) - \theta(-\xi-1) - \theta(1-\xi). \end{aligned} \tag{7.3}$$

The formal solution of this equation has been obtained in section 4. Below we provide detailed illustrations for the physically relevant range of parameters β.

7.1. Dispersion relation. To compute the strain and velocity profiles at a given V we need to find the nonzero roots k of the dispersion relation

$$L(k, V) = 4\sin^2(k/2) + \beta \sin^2 k - V^2 k^2 = 0. \tag{7.4}$$

It is convenient to present the complex roots explicitly as $k = k_1 + ik_2$ and divide them into three categories: real, responsible for radiation; purely imaginary, providing the monotone structure of the core region; and complex with nonzero real part, describing oscillatory contributions to the core.

Since $L(k, V)$ is an even function of k, the real roots appear in pairs $k = \pm k_1$. Assuming positive V, we obtain

$$V(k_1) = \frac{\sqrt{4\sin^2(k_1/2) + \beta \sin^2 k_1}}{|k_1|}.$$

This function is plotted in Figure 7.2(a). An infinite number of local maxima on

[2]The picture emerging in our piecewise linear model is somewhat obscured by the fact that in the limit of strong coupling the macroscopic sound speed tends to zero.

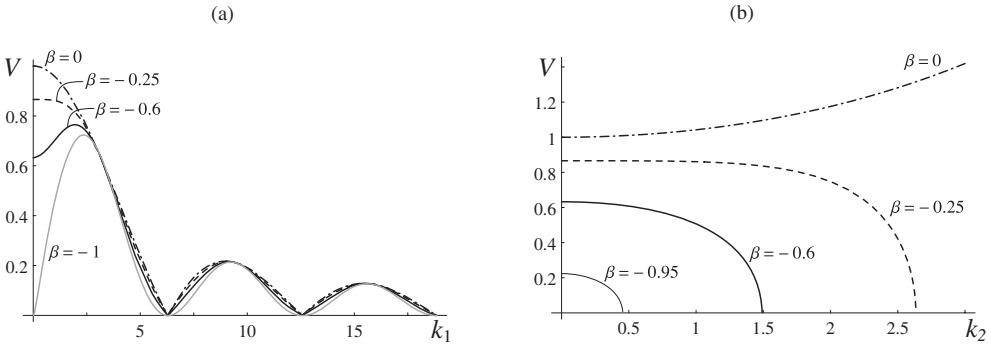

FIG. 7.2. *Real* (a) *and imaginary* (b) *roots of the dispersion relation* $L(k, V) = 0$ *at different* β.

this graph, denoted by $V = V_i$, correspond to resonance velocities: at these points $L_k(k, V) = 0$ and the sums in (4.3), (4.9), and (4.12) diverge. Between the resonance velocities, (7.4) possesses a finite number of positive real roots corresponding to propagating waves. To determine whether these waves propagate ahead or behind the front, we need to check whether $kL_k(k, V) = 2k^3V(k)V'(k)$ is positive or negative. At $V > 0$ the radiation conditions say that the waves with $kV'(k) > 0$ propagate in front of the phase boundary, while the waves with $kV'(k) < 0$ propagate behind.

Changing β affects the function $V(k)$ noticeably only at long waves (small k). A straightforward computation shows that $V(0)$ is equal to the macroscopic sound speed $c = (1 + \beta)^{1/2}$. We also obtain that $V'(0) = 0$ and

$$V''(0) = -\frac{1 + 4\beta}{12\sqrt{1 + \beta}}.$$

At $-1/4 < \beta \le 0$, the function $V(k)$ has a maximum at $k = 0$ while at $-1 < \beta < -1/4$ it has a local minimum implying that sufficiently strong coupling ($\beta < -1/4$) creates the possibility for the lattice waves to move faster than the macroscopic sound speed. The range of supersonic speeds increases as $\beta \to -1$, and in the limiting case $\beta = -1$ all propagating waves are macroscopically supersonic. It is interesting that the critical value $\beta = -1/4$ also emerges in the strain-gradient approximation of the energy (7.2), where it corresponds to the change of sign of the coefficient in front of the strain gradient term [15, 28]. In this approximation the dispersion relation $V(k)$ is replaced by a parabola: for $\beta > -1/4$ (weak nonlocality) the parabola is directed downward and the strain-gradient coefficient is negative while for $\beta < -1/4$ (strong nonlocality) the parabola is upward and the strain-gradient contribution to the energy is positive definite. The latter implies that subsonic phase boundaries can only be dissipation free. To yield a nontrivial kinetic relation in this range of parameters the quasicontinuum model must be augmented by higher-order terms [37].

The purely imaginary roots of (7.4) appear in symmetric pairs and correspond to nonoscillatory modes exponentially decreasing away from the front. By solving $L(ik_2, V) = 0$ for V we obtain

$$V(k_2) = \frac{\sqrt{4\sinh^2(k_2/2) + \beta \sinh^2 k_2}}{|k_2|}.$$

This function is shown in Figure 7.2b. One can show that $V(0) = c$, $V'(0) = 0$, and $V''(0) = (1 + 4\beta)/(12\sqrt{1 + \beta})$. For $-1 < \beta < -1/4$ the maximum of the curve

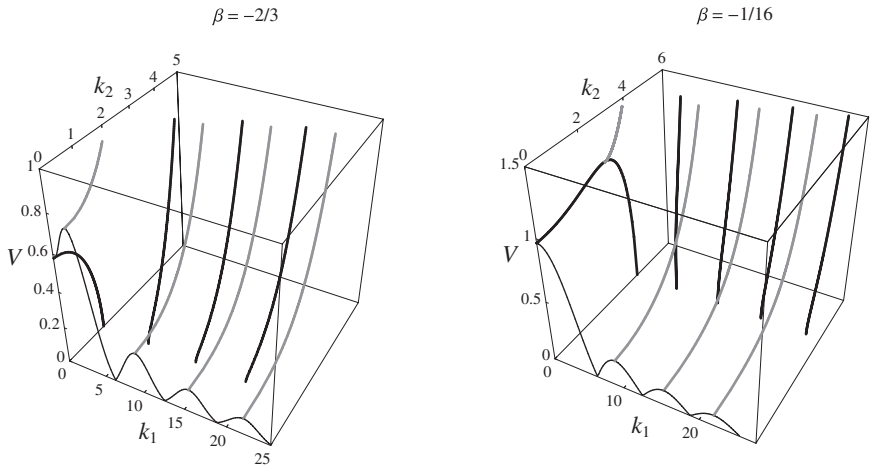

FIG. 7.3. *The structure of nonzero roots of* $L(k,V)=0$ *in the cases of strong* ($\beta=-2/3$) *and weak* ($\beta=-1/16$) *nonlocality. Thin lines: real roots, set N; thick lines: P-roots; gray lines: Q-roots.*

$V(k_2)$ is reached at $k_2=0$, which means that in the case of strong coupling only macroscopically subsonic phase boundaries have monotone contribution to the core structure. Both the value $V(0)$ and the range of available wave numbers decrease as $\beta\to-1$, so that in the limit purely imaginary roots disappear. In the case $\beta=0$ the function $V(k_2)$ is convex and no imaginary roots contribute to the subsonic solution. This is compatible with the fact that in the degenerate NN limit the static interface ($V=0$) is atomically sharp.

Complex roots with nonzero real part contribute to the oscillatory structure of the core region. For the given V the real (k_1) and imaginary (k_2) parts of the relevant wave numbers satisfy the system of two equations: $\mathrm{Re}L(k_1+ik_2,V)=0$ and $\mathrm{Im}L(k_1+ik_2,V)=0$. The set of complex roots contains infinitely many branches that come in symmetric quadruples. The first quadrant of the complex plane is shown in Figure 7.3. The complex roots can be divided into two sets: Q and P. The set Q (thick gray lines), has a purely dynamic nature and contributes to the boundary layers around the front only at nonzero V. The set P, shown in Figure 7.3 by thick black lines, contains purely imaginary branches which intersect the plane $V=0$ and contribute to the static solution: at $V=0$ they are given by

$$k=2\pi n\pm i\lambda,\qquad \lambda=2\mathrm{arccosh}\left[\frac{1}{\sqrt{|\beta|}}\right], \tag{7.5}$$

where n is an integer [33]. As β tends to zero, the imaginary parts of P-roots approach $\pm\infty$; the eventual disappearance of these roots in the limit $\beta\to0$ is responsible for the sharpening of the front in the NN approximation.

7.2. Strain and velocity profiles. Typical profiles of strain $w(\xi)$ and velocity $v(\xi)$ computed for the NNN model from (4.3), (4.12) are shown in Figure 7.4, where $\beta=-0.2$. For this case the first two resonance velocities are $V_1=0.2164$ and $V_2=0.1282$. Accordingly, at $V=0.5>V_1$ we see only one radiative mode propagating behind the phase boundary; at $V_2<V=0.16<V_1$ the solution exhibits two additional radiative modes, one propagating behind and one in front of the phase boundary.

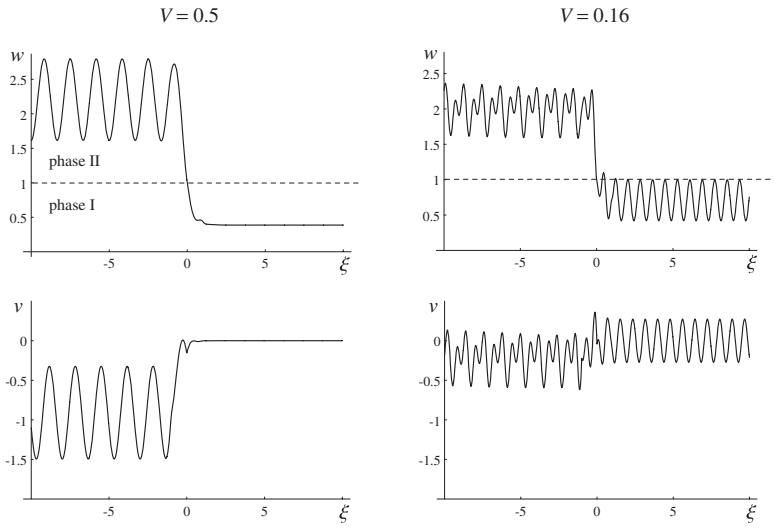

FIG. 7.4. *Strain and velocity profiles at $V > V_1$ and $V_2 < V < V_1$. Here $\beta = -0.2$, $w_c = 1$, $v_+ = 0$.*

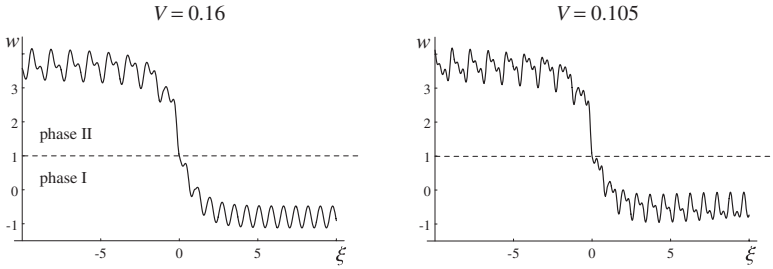

FIG. 7.5. *Strain profiles at $V_2 < V < V_1$ and $V_3 < V < V_2$. Here $\beta = -0.75$, $w_c = 1$.*

A closer inspection of the solutions at $V < 0.266$ reveals a violation of the constraints (3.5): in the strain profile corresponding to $V = 0.16$ in Figure 7.4 the threshold $w = w_c$ is crossed at both $\xi = 0$ and $\xi > 0$. Moreover, for this value of β our numerical computations suggest that the entire velocity interval $(0, 0.266)$ around the resonances has to be excluded as inadmissible. Similar "velocity gaps" also have been detected in [11, 12, 14] for the semilinear Frenkel–Kontorova problem.

At larger β steady interface propagation becomes possible in certain subcritical velocity intervals. For instance, at $\beta = -0.75$ we found admissible traveling wave solutions in the intervals: $[0.24, 0.5]$ (between $V_1 = 0.215$ and $c = 0.5$); $[0.142, 0.19]$ (between V_1 and $V_2 = 0.1279$); $[0.1, 0.11]$ (between V_2 and $V_3 = 0.0912$); $[0.078, 0.08]$ (between V_3 and $V_4 = 0.0708$); and possibly in some shorter intervals at smaller V. Two such solutions are shown in Figure 7.5. The first one corresponds to $V = 0.16$, which is between the first and second resonances; unlike its counterpart at $\beta = -0.2$, this solution is admissible. The second admissible profile corresponds to the value of velocity $V = 0.105$ located between the second and third resonances. In this case there are five radiative modes, two in front and three behind the phase boundary. The appearance of the small-velocity intervals of existence of the traveling wave solutions

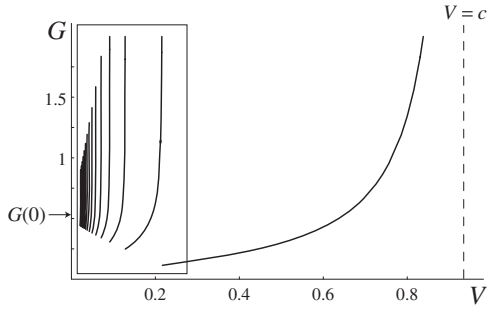

FIG. 7.6. *Kinetic relation $G(V)$ for $\beta = -1/8$. The region inside the rectangle should be excluded because the corresponding solutions violate admissibility constraints* (3.5).

at nonzero β is due to the presence of P-roots at nonzero β: as β grows in absolute value, these roots move closer to the real axis, widening the transition layer and suppressing oscillations due to the Q-roots (see Figure 7.3).

7.3. Kinetic relation. Using (6.5) and the known dispersion spectrum, we can now explicitly evaluate the kinetic relation $G(V)$. A representative example is shown in Figure 7.6. At resonance velocities the configurational force required to move the interface tends to infinity. The singularities are due to equal curvatures of the energy wells ensuring that the energy transport is simultaneously blocked in both phases. The main physical reasons are related to low dimensionality of the model and the absence of microscopic dissipation.

As we discussed above, at sufficiently small β the entire region around the small-velocity resonances has to be excluded because the corresponding solutions violate the admissibility constraints (3.5). With β increasing, some of the small-velocity solutions between the resonances become admissible, as shown in Figure 7.7(b)–(d). Observe also that there is an infinite number of β at which the sonic speed c coincides with one of the resonance velocity. Thus, at $\beta = -0.9539$ we have $c = V_1 = 0.2147$, implying that for $\beta \le -0.9539$ the subsonic region lies below the first resonance (see Figure 7.7(d)). Overall, the total domain of existence of the traveling wave solutions shrinks as $\beta \to -1$, while the domain of admissible traveling waves between the resonances expands.

Zero-velocity limit. To check the compatibility of static and dynamic branches of solutions it is instructive to trace the zero velocity limit of our dynamic theory. At $V = 0$ we can use (5.2) with $F^{\pm} = \{\pm i\lambda\}$, where λ is defined in (7.5). After some algebraic manipulations, the family of lattice-trapped equilibria (5.2) can be represented in the form

$$w_n = \begin{cases} \dfrac{\sigma+1}{1+\beta} - \dfrac{e^{\lambda(n+1/2)}}{2(1+\beta)\cosh(\lambda/2)}, & n < 0, \\ \dfrac{\sigma}{1+\beta} + \dfrac{e^{-\lambda(n+1/2)}}{2(1+\beta)\cosh(\lambda/2)}, & n \ge 0, \end{cases} \tag{7.6}$$

where σ lies in the region (5.4). The solutions (7.6) can be shown to be metastable [32]. The expression for the Peierls stress (5.5) marking the threshold of metastability can now be written explicitly as

$$\sigma_{\mathrm{P}} = \frac{1}{2}\sqrt{1+\beta}.$$

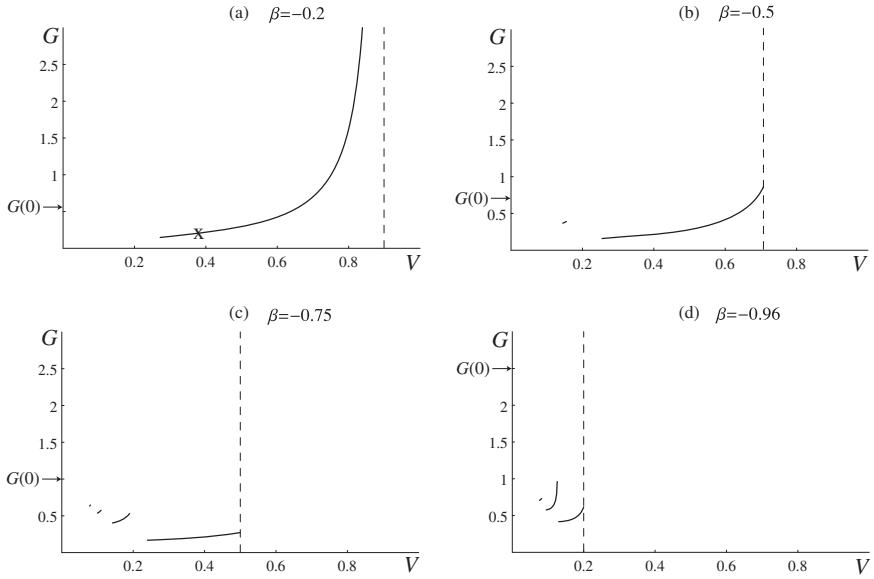

FIG. 7.7. *Kinetic relations $G(V)$ for different β. The point marked by* x *in* (a) *corresponds to the numerical results in Figures* 8.1 *and* 8.2.

Observe that at $\beta = 0$ the Peierls stress coincides with the spinodal stress $\sigma_{\rm S} = 1/2$. As β grows, the trapping region becomes narrower and eventually disappears at $\beta = -1$ ($\sigma_{\rm P} = 0$). The upper boundary of the trapping region (5.4) corresponds to the case when $w_0 = w_c$, which is exactly the condition (3.4). The corresponding saddle-point configuration is given by

$$w_n = \lim_{V\to 0} w(n - Vt) = \begin{cases} w_c + \dfrac{e^{\lambda/2} - e^{\lambda(n+1/2)}}{2(1+\beta)\cosh(\lambda/2)}, & n < 0, \\ w_c + \dfrac{e^{-\lambda(n+1/2)} - e^{-\lambda/2}}{2(1+\beta)\cosh(\lambda/2)}, & n \geq 0. \end{cases} \tag{7.7}$$

Using this solution, we can obtain the value of the configurational force at the depinning limit:

$$G(0) = \frac{1}{2}(w_- + w_+) - w_c = \frac{1}{2\sqrt{1+\beta}}. \tag{7.8}$$

Notice that although the Peierls stress tends to zero when $\beta \to -1$, the corresponding value of the configurational force $G(0)$ tends to infinity. This is, of course, an artifact of our specific assumptions concerning the elastic moduli and is due to the divergence of the macroscopic transformation strain in the limit.

Sonic limit. The qualitative behavior of the function $G(V)$ in the limit $V \to c$ depends on β. If $-1/4 < \beta \leq 0$, and $V \lesssim c$, the wave spectrum contains a single wave number k which approaches zero as $V \to c$. Expanding the expression for the configurational force (6.5) at small k we obtain

$$G \sim \frac{6}{(1+4\beta)k^2},$$

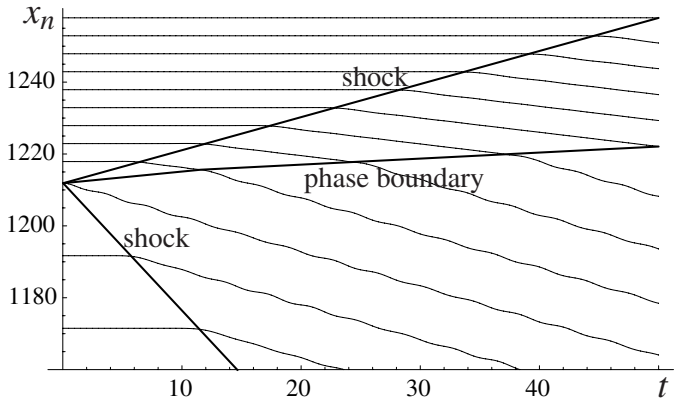

FIG. 8.1. *Positions $x_n(t)$ of every fifth particle in the interval $290 \le n \le 345$ in numerical solution of the Riemann problem with initial data compatible with the traveling wave at $V = 0.375$ at $\beta = -0.2$. The phase boundary is initially placed at $n_0 = 300$, and the problem is solved on the interval $1 \le n \le 600$. The corresponding point on the kinetic relation $G(V)$ is marked by* x *in Figure* 7.7a.

which implies that $G(V) \to \infty$ as $V \to c$ (see Figures 7.6 and 7.7(a)). The picture is qualitatively different when $-1 < \beta < -1/4$. In this case as V approaches c from below, the limit of the corresponding real wave number k is nonzero k_s, and therefore configurational force $G(V)$ remains finite (see Figure 7.7(b)–(d)).

8. Stability of the traveling waves. We now present some numerical experiments aimed at accessing stability of the admissible traveling wave solutions. To simplify the consideration of the transient regimes for the system (2.8), we consider Riemann initial data of the form

$$(w_n, v_n)\big|_{t=0} = \begin{cases} (w_-^0, 0), & n < n_0, \\ (w_c, 0), & n = n_0, \\ (w_+^0, 0), & n > n_0. \end{cases} \tag{8.1}$$

We assume that $w_+^0 < w_c$ and $w_-^0 > w_c$. The analysis of the corresponding continuum problem for the p-system (1.2) suggests the formation of a phase boundary with two shocks in front and behind (e.g., [17]). This is indeed what we see in Figure 8.1, which shows a typical numerical solution of (2.8) obtained using the Verlet algorithm on a large domain.

After a transient period, the phase boundary starts moving with a constant speed. To check convergence of the non-steady-state problem to the admissible traveling wave solution we used the following algorithm. For a traveling wave solution with velocity V, (4.9) provides the average strains at both sides of the discontinuity $w_\pm(V)$. We can then use (4.13) and the Rankine–Hugoniot jump conditions across the shocks to compute the corresponding initial strains $w_\pm^0$ in terms of V and v_+. Without loss of generality, we choose v_+ so that $w_+^0 = 0$ and obtain an explicit formula relating the Riemann data with the observed phase boundary velocity:

$$w_-^0(V) = w_-(V) + w_+(V) + \frac{V}{c(c^2 - V^2)} = 2\left(w_c + \sum_{k \in N_{\rm pos}(V)} \frac{4\sin^2(k/2)}{|kL_k(k,V)|}\right) + \frac{V}{c(c^2 - V^2)}.$$

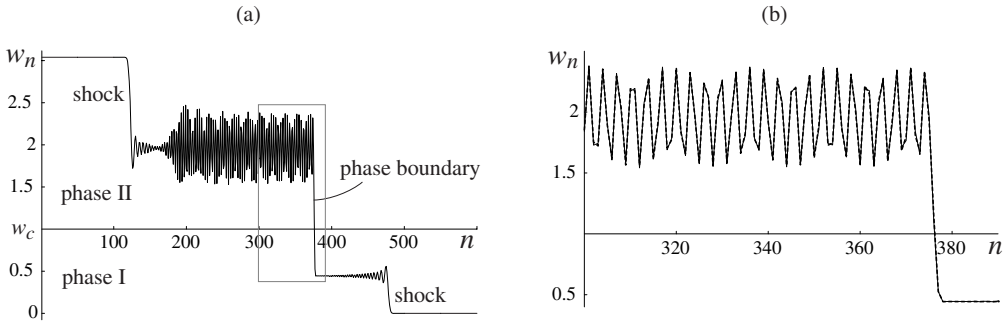

FIG. 8.2. (a) *Strain profile* $w_n(200)$ *for the numerical solution shown in Figure* 8.1. (b) *The same solution (solid line) zoomed in around the phase boundary (inside the rectangle in* (a)*) and compared to the analytical traveling wave solution (thick dashed line).*

Computations based on this relation consistently indicate that the fast branch of the kinetic relation ($V > V_1$) corresponds to traveling wave solutions with a finite domain of attraction. An example corresponding to $\beta = -0.2$ and $V = 0.375$ is shown in Figures 8.1 and 8.2. One can see not only that the generated phase boundary propagates steadily with the predicted velocity but that the strain profile $w_n(t)$ zoomed around the phase boundary (solid line in Figure 8.2(b)) compares perfectly with the analytical solution (4.3) (thick dashed line). The above analysis suggests that the fast branch of the kinetic relation with $V > V_1$, corresponding to traveling wave solutions with a single oscillatory mode behind and monotonic leading edge, is locally stable; proving this conjecture rigorously is highly nontrivial.

Unfortunately, we were not able to find similar evidence of numerical stability for admissible traveling waves with $V < V_1$ exhibiting oscillations both behind and in front of the phase boundary. Numerical simulation for the data expected to converge to the particular traveling wave lead instead to a solution which does not agree with the traveling wave ansatz although the phase boundary propagates steadily (with a slightly smaller velocity). The macroscopic solution is very close to the corresponding traveling wave; the analytical formula captures the core structure but not the oscillations. One can conjecture that while an admissible traveling wave with radiation on both sides of the front is not a global attractor, it is surprisingly close to one.

Finally, we refer to [17] for a related study of the phase boundary stability in the context of a different discretization of the mixed-type p-system.

9. Conclusions. In this paper we used a physically motivated discretization of the p-system to derive an explicit kinetic relation for a one-dimensional theory of martensitic phase transitions. The macroscopic dissipation was interpreted as the energy of the lattice waves emitted by a moving macroscopic discontinuity. By using the simplest piecewise linear model, we obtained an explicit formula for the continuum rate of entropy production which depends only on interatomic potentials. We showed that despite the difference in the structure of micro and macro theories, the assessments of dissipation at different scales are fully compatible. The present study complements previous analyses of related systems in fracture and plasticity framework by including general harmonic long-range interactions.

More specifically, we showed that contrary to the simplest theory with NN interactions, which has a mean field character and is therefore degenerate, strongly nonlocal models produce multivalued kinetic relations with several admissible branches and

rich variety of configurations of emitted lattice waves. In addition to enlarging the domain of existence of steady-state regimes, sufficiently strong long-range interactions significantly alter the structure of mobility curves near sonic speeds. The nonlocality also affects the size of lattice trapping: as long-range interactions become stronger, the trapping region reduces in size in terms of stress. At the same time, it widens in our model in terms of driving forces, which emphasizes an important difference between the physical and configurational descriptions. Although the main effects of nonlocality were illustrated in the paper by the explicit computations for the NNN model, we have also conducted a similar study of the NNNN model which showed qualitatively similar behavior.

The present work was motivated by similar studies of the semilinear discrete Frenkel–Kontorova model (e.g., [11, 12]). While the two models turn out to be equivalent in static and overdamped limits [32, 34], the fully inertial versions are quite different. An additional level of complexity in the quasilinear model considered here is associated with a different structure of nonlinearity that results in the presence of the limiting characteristic velocity, microscopic and macroscopic particle velocities, and the discrete Rankine–Hugoniot jump conditions.

SEMICONDUCTOR SIMULATIONS USING A COUPLED QUANTUM DRIFT-DIFFUSION SCHRÖDINGER–POISSON MODEL*

ASMA EL AYYADI† AND ANSGAR JÜNGEL†

Abstract. A coupled quantum drift-diffusion Schrödinger–Poisson model for stationary resonant tunneling simulations in one space dimension is proposed. In the ballistic quantum zone with the resonant quantum barriers, the Schrödinger equation is solved. Near the contacts, where collisional effects are assumed to be important, the quantum drift-diffusion model is employed. The quantum drift-diffusion model was derived by a quantum moment method from a collisional Wigner equation by Degond et al. [*J. Statist. Phys.*, 118 (2005), pp. 625–665]. The derivation yields an $O(\hbar^4)$ approximation of the equilibrium Wigner function which is used as the "alimentation function" in the mixed-state formula for the electron and current densities at the interface. The coupling of the two models is realized by assuming the continuity of the electron and current densities at the interface points. Current-voltage characteristics of a one-dimensional tunneling diode are numerically computed. The results are compared to those from the three models: quantum drift-diffusion equations, the Schrödinger–Poisson system, and the coupled drift-diffusion Schrödinger–Poisson equations.

Key words. Schrödinger–Poisson system, quantum drift-diffusion model, quantum microscopic-macroscopic coupling, finite differences, resonant tunneling diode, hysteresis

1. Introduction.

Quantum effects in modern semiconductor devices are becoming of increasing importance in VLSI design. Devices which are based on quantum effects, like resonant tunneling diodes, can be used in logic applications [19] and are expected to improve the system performance of multi-GHz circuits in wireless communication systems [27]. Resonant tunneling diodes can be modeled by the Wigner equation [23] or the mixed-state Schrödinger equation [26]. However, the numerical computation of these equations is very expensive, even in one space dimension. Therefore, macroscopic quantum equations like quantum hydrodynamic or quantum drift-diffusion models have been devised [1, 15], whose numerical solution is much cheaper than solving microscopic models [18, 20, 22]. On the other hand, quantum diffusion models do not always give sufficiently physical accurate solutions [7].

In order to meet both demands (physical accuracy and numerical efficiency), *coupled microscopic-macroscopic models* can be employed. In these models, a microscopic quantum description is used in regions with dominant quantum effects, and a macroscopic (fluid-type) model is employed in subregions in which collisional effects are expected to be dominant. In the case of a resonant tunneling diode, it was proposed in [10] to use the stationary mixed-state Schrödinger equation in the (ballistic) channel region and the stationary drift-diffusion equations in the diffusion zones near the contacts. This approach has two advantages. First, the spatial domain in which the Schrödinger equation is solved can be reduced, thus also reducing the computational effort. Second, as the diffusion zone is assumed to be collision dominated, a diffusion

approximation of the Wigner equation leads naturally to a coupling strategy between the quantum and classical equations.

Similar coupling approaches have been proposed in the literature. A coupled kinetic-quantum model was introduced in [4]. More precisely, a Boltzmann equation is solved in the classical zone and the stationary Schrödinger equation is computed in the quantum zone. At the interface between the classical and quantum zones, the boundary conditions for the Boltzmann equation depend on the reflection and transmission coefficients of the Schrödinger solution. The distribution function solving the Boltzmann equation is used as an "alimentation function" in the definition of the electron density in the quantum region. A time-dependent classical-quantum coupling strategy was studied in [5]. Employing the drift-diffusion model with interface conditions from a diffusion approximation leads to the mentioned approach of [10]. The coupled drift-diffusion Schrödinger model was recently extended to include collisions via a Pauli master equation [2]. A model in which a classical transport is assumed in the direction parallel to the electron gas and a quantum description in the transversal direction is analyzed in [6]. In [14] the quantum drift-diffusion model is used in the parallel direction instead of a classical transport description. For other coupling models, see, e.g., [3, 8].

In this paper we propose a slightly different approach compared to [10]. Instead of choosing a classical collision operator in the Boltzmann equation (from which the drift-diffusion model is derived) we start from the Wigner equation with a Bhatganar-Gross-Krook (BGK) collision operator. In [11] it was shown that a diffusion approximation of the Wigner–BGK model leads to the so-called quantum drift-diffusion model (also called the density-gradient model [1]),

$$\frac{\partial n}{\partial t} - \frac{1}{e}\operatorname{div} J = 0, \quad J = \mu_n \left(U_{\mathrm{th}} \nabla n - n \nabla (V + Q[n])\right),$$

where the variables are the electron density $n(x,t)$, the current density $J(x,t)$, and the electrostatic potential $V(x,t)$; the physical constants are the elementary charge e, the electron mobility $\mu_n = e\tau/m$, the effective electron mass m, the momentum relaxation time τ, and the thermal voltage U_{th}. The expression

$$Q[n] = \frac{\hbar^2}{6em} \frac{\Delta\sqrt{n}}{\sqrt{n}}$$

denotes the quantum Bohm potential, where $\hbar$ is the reduced Planck constant. The fourth-order parabolic quantum drift-diffusion model was analyzed and numerically solved in [22].

More precisely, we use the quantum drift-diffusion model in the diffusion region and the mixed-state Schrödinger equation in the ballistic zone. We restrict ourselves to the spatial one-dimensional stationary case in order to avoid complicated topological conditions on the device geometry. The advantage of our approach is that no (artificial) separation of the quantum and classical zones is necessary since a quantum description is employed in the whole device. The coupled model is solved self-consistently with the Poisson equation.

The coupling of the models is realized through connection conditions relating the macroscopic variables, namely, the electron density and the current density, at the interface boundary points. We suppose that the particle and current densities are continuous across the interface. The current density computed from the Schrödinger equation depends on the statistics (or alimentation function) used in the mixed-state

formula. At the interface we assume that the statistics of the incoming particles equal the $O(\hbar^4)$ approximation of the so-called quantum Maxwellian, which is related to the quantum drift-diffusion model. This yields nonlinear boundary conditions for the macroscopic electron density and its derivatives.

The coupled model is numerically implemented using a finite-difference discretization and tested against a test case for a one-dimensional resonant tunneling diode taken from [26]. The numerical results show negative differential resistance in the current-voltage characteristic at room temperature, whereas the quantum drift-diffusion model in the whole domain is not able to reproduce these effects at room temperature (with the physical effective electron mass). Furthermore, hysteresis in the current-voltage curve can be observed in computations from our coupled model but not from the quantum drift-diffusion model. Compared to the numerical solution of the Schrödinger–Poisson (SP) system in the whole domain, the numerical effort of the coupled model is significantly reduced with comparable numerical solutions.

The paper is organized as follows. In the next section, the Schrödinger equation with open boundary conditions is presented and a sketch of the derivation of the quantum drift-diffusion model following [11] is given. Furthermore, the coupling of the two models is explained. Section 3 is concerned with the numerical discretization of the equations and the iteration procedure. Finally, some numerical results for a one-dimensional resonant tunneling diode are presented in section 4.

2. Presentation of the models. The semiconductor is assumed to occupy the interval $\Omega = (0, L)$ in which the ballistic quantum zone $\Omega_s = (x_1, x_2)$ is sandwiched between two quantum diffusion regions $\Omega_q = (0, x_1) \cup (x_2, L)$ and $0 < x_1 < x_2 < L$.

2.1. The Schrödinger model. We consider the Schrödinger equation in the interval (a, b), where $a = 0$, $b = L$ or $a = x_1$, $b = x_2$. In the first case we solve the Schrödinger equation in the whole semiconductor domain; in the latter case we solve only in the ballistic quantum zone.

Let the electrostatic potential $V(x)$ be given and let $\widetilde{V} = V + V_{\rm ext}$ be the sum of electrostatic and external potential ($V_{\rm ext}$ models, for instance, the double barriers). We solve the Schrödinger equation

$$-\frac{\hbar}{2}\frac{d}{dx}\left(\frac{1}{m}\frac{d\psi_p}{dx}\right) - e\widetilde{V}(x)\psi_p = E_p\psi_p, \quad x \in (a,b),\ p \in \mathbb{R}, \tag{2.1}$$

where $\hbar = h/2\pi$ is the reduced Planck constant, m the (generally position-dependent) effective mass of the electrons, e the elementary charge, and E_p is the total energy of the corresponding scattering state ψ_p, given by

$$E_p = \begin{cases} p^2/2m - e\widetilde{V}(a) & : \ p > 0, \\ p^2/2m - e\widetilde{V}(b) & : \ p < 0. \end{cases}$$

Here, $p = \hbar k$ is the crystal momentum and k the wave vector. We use the Lent–Kirkner boundary conditions for (2.1) [16, 24],

$$\hbar\psi_p'(a) + ip\psi_p(a) = 2ip, \quad \hbar\psi_p'(b) = ip_+(p)\psi_b(b) \quad \text{if } p > 0, \tag{2.2}$$

$$\hbar\psi_p'(b) - ip\psi_p(b) = -2ip, \quad \hbar\psi_p'(a) = -ip_-(p)\psi_p(a) \quad \text{if } p < 0, \tag{2.3}$$

where

$$p_\pm(p) = \sqrt{p^2 \pm 2em(\widetilde{V}(b) - \widetilde{V}(a))}. \tag{2.4}$$

These boundary conditions can be derived by solving the above Schrödinger equation in $\mathbb{R}$, extending the potential by the definitions $\widetilde{V}(x) = \widetilde{V}(a)$ for $x < a$ and $\widetilde{V}(x) = \widetilde{V}(b)$ for $x > b$. Then the solutions are plane waves in the intervals $(-\infty, a)$ and (b, ∞), i.e., for $p > 0$ [10],

$$\begin{aligned} \psi_p(x) &= e^{ip(x-a)/\hbar} + r(p)e^{-ip(x-a)/\hbar} \qquad (x < a), \\ \psi_p(x) &= t(p)e^{ip_+(p)(x-b)/\hbar} \qquad (x > b), \end{aligned} \tag{2.5}$$

and for $p < 0$,

$$\begin{aligned} \psi_p(x) &= e^{-ip(x-b)/\hbar} + r(p)e^{ip(x-b)/\hbar} \qquad (x > b), \\ \psi_p(x) &= t(p)e^{-ip_-(p)(x-a)/\hbar} \qquad (x < a). \end{aligned} \tag{2.6}$$

The incoming wave is thus assumed to have amplitude one. The reflection and transmission amplitudes $r(p)$ and $t(p)$ are uniquely determined from the solution (see [10, p. 226]). By elimination of the unknowns $r(p)$ and $t(p)$, the boundary conditions (2.2)–(2.3) are obtained.

From the amplitudes $r(p)$ and $t(p)$ the reflection and transmission coefficients can be computed:

$$R(p) = |r(p)|^2, \quad T(p) = \frac{\mathrm{Re}(p_\pm(p))}{|p|}|t(p)|^2 \quad \text{if } \pm p > 0,$$

where Re denotes the real part of a complex number. It holds $R(p) + T(p) = 1$ for all $p \in \mathbb{R}$ and $T(p) = T(-p_+(p))$ for all $p > 0$ (reciprocity property).

We must introduce some *macroscopic* quantities. The electron density $n_s(x)$ is defined by

$$n_s(x) = \int_{\mathbb{R}} g(p)|\psi_p|^2 dp, \tag{2.7}$$

where $g(p)$ is the statistics of the left reservoir if $p > 0$ and of the right reservoir if $p < 0$ (also called alimentation function), and the current density is given by

$$J_s(x) = \frac{e\hbar}{m}\int_{\mathbb{R}} g(p)\mathrm{Im}(\overline{\psi_p(x)}\psi_p'(x))dp, \tag{2.8}$$

where Im denotes the imaginary part of a complex number. In one space dimension, the expression for the current density can be reformulated. Indeed, using (2.2)–(2.3) and (2.5)–(2.6), we obtain

$$\begin{aligned} \hbar\,\mathrm{Im}(\overline{\psi_p(a)}\psi_p'(a)) &= \mathrm{Im}(ip(1 - |r(p)|)^2) = pT(p) \quad \text{for } p > 0, \\ \hbar\,\mathrm{Im}(\overline{\psi_p(a)}\psi_p'(a)) &= -\mathrm{Im}(ip_-(p)|t(p)|^2) = pT(p) \quad \text{for } p < -p_0, \end{aligned}$$

and $\hbar\,\mathrm{Im}(\overline{\psi_p(a)}\psi_p'(a)) = 0$ if $-p_0 < p \le 0$, where $p_0 = \mathrm{Re}(2em(\widetilde{V}(b) - \widetilde{V}(a)))^{1/2}$. Therefore, since $J_s(x)$ is constant,

$$\begin{aligned} J_s(x) = J_s(a) &= \frac{e}{m}\int_0^\infty g(p)T(p)pdp + \frac{e}{m}\int_{-\infty}^{-p_0} g(p)T(p)pdp \\ &= \frac{e}{m}\int_0^\infty g(p)T(p)pdp + \frac{e}{m}\int_\infty^0 g(-p_+)T(-p_+)pdp \\ &= \frac{e}{m}\int_0^\infty (g(p) - g(-p_+))T(p)pdp, \end{aligned} \tag{2.9}$$

where we have used the substitution $p \mapsto -p_+(p)$ and the reciprocity property of $T(p)$.

The choice of the alimentation function $g(p)$ depends on the choice of a and b. If $a = 0$ and $b = L$, it is taken to be the Fermi–Dirac distribution:

$$g(p) = \frac{mk_BT_0}{2\pi^2\hbar^3} \ln\left\{1 + \exp\left[\frac{1}{k_BT_0}\left(-\frac{p^2}{2m} + E_F\right)\right]\right\},$$

where k_B is the Boltzmann constant, T_0 the lattice temperature, and E_F the Fermi energy computed from the charge-neutrality condition at the left or right reservoir boundary. This formula holds if the system is macroscopically large in its transversal dimensions (see [17, Ch. 9] or [25, Ch. 1.5.2.1]). In the case $a = x_1$ and $b = x_2$ we choose $g(p)$ as an approximation of the so-called quantum Maxwellian (see (2.16) and (2.11)).

2.2. The quantum drift-diffusion model. In order to explain the coupling with the quantum drift-diffusion equations, we need to review its derivation from a Wigner–BGK model as performed by Degond, Méhats, Ringhofer [11, 12]. We start from the collisional Wigner equation in one space dimension,

$$w_t + \frac{p}{m}w_x + \frac{e}{m}\theta[\widetilde{V}] = Q(w), \quad x, p \in \mathbb{R},\ t > 0, \tag{2.10}$$

where w_t, w_x denote the partial derivatives of w with respect to t and x, respectively, and $\theta[\widetilde{V}]$ is a pseudodifferential operator given by

$$(\theta[\widetilde{V}]w)(x,p,t) = \frac{i}{2\pi\hbar}\int_{\mathbb{R}^2}\left[\widetilde{V}\left(x + \frac{\hbar}{2m}\eta\right) - \widetilde{V}\left(x - \frac{\hbar}{2m}\eta\right)\right] \times w(x,p',t)e^{i\eta(p-p')/m}dp'd\eta.$$

(We do not indicate here the time-dependency of $\widetilde{V}$.) The collision operator is assumed to be of BGK type, i.e.,

$$Q(w) = \frac{1}{\tau}(M[w] - w),$$

where τ is the relaxation time and $M[w]$ is the so-called quantum Maxwellian defined as the minimizer of the quantum entropy, subject to the constraint of given particle density [13]. To make this precise, we introduce first the so-called relative quantum entropy.

Let W^{-1} be the inverse Wigner transform (or Weyl quantization):

$$(W^{-1}[w])\phi(x) = \frac{1}{2\pi\hbar}\int_{\mathbb{R}^2} w\left(\frac{x+y}{2}, p, t\right)\phi(y)e^{ip(x-y)/\hbar}dpdy \quad \text{for suitable } \phi(x).$$

The relative quantum entropy for the density matrix $\rho = W^{-1}[w]$ is defined as follows:

$$S(\rho) = \frac{1}{2\pi\hbar}\int_{\mathbb{R}^2} w\left(\mathrm{Ln}(w) - 1 + \frac{H}{k_BT_0}\right)dxdp,$$

where $H = |p|^2/2m - e\widetilde{V}(x)$ is the classical Hamiltonian, $\mathrm{Ln}(w) := W[\ln(W^{-1}[w])]$ is called the quantum logarithm, and $\ln(f)$ is the usual operator logarithm. We wish to find, for given $n(x)$, the minimizer of

$$S(\rho^*) = \min\left\{S(\rho) : \frac{1}{2\pi\hbar}\int_{\mathbb{R}} W[\rho]dp = n(x) \quad \forall x\right\}.$$

The solution (if it exists) is $\rho_a = W^{-1}[w_a]$, where $w_a = \mathrm{Exp}(a(x) - H/k_BT_0)$ and $\mathrm{Exp}(f) := W[\exp(W^{-1}[f])]$ is called the quantum exponential. The function $a(x)$ is such that $\int w_a(x,p)dp/2\pi\hbar = n(x)$. We call w_a a quantum Maxwellian. In other words, for given $w(x,p)$, we define $M[w]$ as the *quantum Maxwellian*

$$M[w] = \mathrm{Exp}\left(b(x) - \frac{|p|^2}{2mk_BT_0}\right)$$

such that $\int (M[w] - w)dp = 0$ and $b(x) = a(x) - e\widetilde{V}(x)/k_BT_0$. We assume that the integral constraint fixes the function $b(x)$ in a unique way [11].

The quantum drift-diffusion model is derived from (2.10) in the diffusion limit. For this, we introduce the scaling $t \to t/\delta$ and $Q(w) \to Q(w)/\delta$, which yields

$$\delta^2 w_t^\delta + \delta\left(\frac{p}{m}w_x^\delta + \frac{e}{m}\theta[\widetilde{V}]\right) = Q(w^\delta).$$

As $\delta \to 0$, the formal limit $w_0 = \lim_{\delta\to 0} w^\delta$ satisfies $Q(w_0) = 0$, hence $w_0 = M[w_0] = \mathrm{Exp}(b_0(x) - |p|^2/2mk_BT_0)$ for some function $b_0(x)$, and $n(x) = \int w_0(x,p)dp/2\pi\hbar$. In [11] it was shown by a Chapman–Enskog expansion method that n satisfies the equation

$$n_t - \frac{1}{e}J_x = 0, \quad J = \frac{\tau e k_BT_0}{m}nb_{0,x} - \frac{\tau e^2}{m}n\widetilde{V}_x,$$

and n and b_0 are related by

$$n = \int_{\mathbb{R}} \mathrm{Exp}\left(b_0(x) - \frac{|p|^2}{2mk_BT_0}\right)\frac{dp}{2\pi\hbar}$$

(see [12, Lemma 6.5]). Furthermore, we can expand $w_0 = \mathrm{Exp}(b_0 - |p|^2/2mk_BT_0)$ and thus n and J in terms of $\hbar$.

LEMMA 2.1. *The following (formal) expansion holds for all $x, p \in \mathbb{R}$ up to order $O(\hbar^4)$:*

$$w_0(x,p) = A_0 e^{-p^2/2mk_BT_0} n\left[1 + \frac{\hbar^2}{12mk_BT_0}\left(1 - \frac{p^2}{mk_BT_0}\right)\left(\frac{(\sqrt{n})_{xx}}{\sqrt{n}} - \frac{(\sqrt{n})_x^2}{n}\right)\right], \tag{2.11}$$

where $A_0 = \sqrt{2\pi\hbar^2/mk_BT_0}$.

Notice that $(\sqrt{n})_{xx}/\sqrt{n} - (\sqrt{n})_x^2/n = (\log n)_{xx}$ but the formulation in (2.11) is more convenient later.

Proof. We use Lemma 5.6 of [11] to obtain

$$\begin{aligned} w_0(x,p) = {} & \exp\left(b_0 - \frac{p^2}{2mk_BT_0}\right) - \frac{\hbar^2}{8mk_BT_0}\exp\left(b_0 - \frac{p^2}{2mk_BT_0}\right) \\ & \times \left[\left(-1 + \frac{p^2}{3mk_BT_0}\right)b_{0,xx} - \frac{1}{3}b_{0,x}^2\right] + O(\hbar^4). \end{aligned} \tag{2.12}$$

This gives

$$n(x) = \int_{\mathbb{R}} w_0(x,p)\frac{dp}{2\pi\hbar} = n_0(x) + \frac{\hbar^2}{24mk_BT_0}n_0(x)(2b_{0,xx} + b_{0,x}^2) + O(\hbar^4),$$

where $n_0 := \exp(b_0)/A_0$. Consequently, $n = n_0 + O(\hbar^2)$ and we can solve the above equation for n_0:

$$n_0 = n - \frac{\hbar^2}{24mk_BT_0} n(2b_{0,xx} + b_{0,x}^2) + O(\hbar^4).$$

Insertion of the above formula into (2.12) yields, after some computations,

$$w_0 = A_0 e^{-p^2/2mk_BT_0} n \left[1 + \frac{\hbar^2}{24mk_BT_0}\left(1 - \frac{p^2}{mk_BT_0}\right) b_{0,xx}\right] + O(\hbar^4).$$

Since

$$b_{0,xx} = 2\frac{(\sqrt{n})_{xx}}{\sqrt{n}} - \frac{n_x^2}{2n^2} + O(\hbar^2) = 2\frac{(\sqrt{n})_{xx}}{\sqrt{n}} - 2\frac{(\sqrt{n})_x^2}{n} + O(\hbar^2)$$

(see [11, sec. 5.3]), we conclude the assertion. □

In [11] it has been shown that we can expand $n = n_q + O(\hbar^4)$, $J = J_q + O(\hbar^4)$, and n_q, J_q in such a way that n_q, J_q satisfy the so-called quantum drift-diffusion equations

$$n_{q,t} - \frac{1}{e} J_{q,x} = 0, \quad J_q = \frac{\tau e k_B T_0}{m} n_{q,x} - \frac{\tau e^2}{m} n_q (\widetilde{V} + Q[n_q])_x, \tag{2.13}$$

where

$$Q[n_q] = \frac{\hbar^2}{6em} \frac{(\sqrt{n_q})_{xx}}{\sqrt{n_q}}$$

is the so-called Bohm potential.

We can rewrite (2.13) by introducing the function $\sigma = \sqrt{n_q}$ and the quantum quasi-Fermi potential

$$F = U_{\rm th} \ln n_q - \widetilde{V} - Q[n_q]$$

(with the thermal voltage $U_{\rm th} = k_BT_0/e$). Then the stationary version of (2.13) becomes

$$(\sigma^2 F_x)_x = 0, \quad F = U_{\rm th} \ln \sigma^2 - \widetilde{V} - \frac{\hbar^2}{6em} \frac{\sigma_{xx}}{\sigma}. \tag{2.14}$$

The current density equals $J_q = (\tau e^2/m)\sigma^2 F_x = e\mu_n \sigma^2 F_x$.

In order to specify boundary conditions for (2.14), we need to distinguish the two cases for the choice of a and b. Let first $a = 0$ and $b = L$. Then, following [22], we assume that the total space charge vanishes and that no quantum effects occur at the boundary (in the sense $(\sqrt{n_q})_{xx} = 0$). Thus

$$n_q(0) = n_D(0), \quad n_q(L) = n_D(L), \quad F(0) = 0, \quad F(L) = -V_a, \tag{2.15}$$

where V_a denotes the applied voltage. The case $a = x_1$ and $b = x_2$ is studied in the next subsection.

2.3. The coupled model. Let $a = x_1$ and $b = x_2$. We solve the Schrödinger equation (2.1) in (a, b) with boundary conditions (2.2)–(2.3) and the quantum drift-diffusion model (2.14) in the intervals $(0, x_1)$ and (x_2, L).

To compute the electron and current densities n_s and J_s, respectively (see (2.7) and (2.8)), we need to specify the alimentation function $g(p)$. We choose $g(p)$ as the $O(\hbar^4)$ approximation (2.11) of the quantum Maxwellian (see Lemma 2.1):

$$g(p) = w_0(a,p) \quad \text{if } p > 0, \quad g(p) = w_0(b,p) \quad \text{if } p < 0. \tag{2.16}$$

Although in general w_0 does not need to be a nonnegative function, we observed in the numerical simulations that $w_0(a,p)$ and $w_0(b,p)$ are always positive. Another idea could be to choose the classical Maxwellian instead of the (approximation of the) quantum Maxwellian w_0 in (2.16). However, this choice did not lead to a converging algorithm. (See section 3 for details on the discretization and the iterative procedure.) A possible explanation could be that the use of the classical Maxwellian is not consistent with the use of the quantum drift-diffusion model.

The coupling of both models is realized through connection conditions relating the macroscopic unknowns (the electron density and the current density) at the two interface points x_1 and x_2. We assume that at the interface, the particle density and the current density are continuous, i.e.,

$$n_q(x_1) = n_s(x_1), \quad n_q(x_2) = n_s(x_2), \quad J_q(x_1) = J_s(x_1), \quad J_q(x_2) = J_s(x_2).$$

Thus, the quantum drift-diffusion model is solved in $(0, x_1)$ with the four boundary conditions

$$n_q(0) = n_D(0), \quad F(0) = 0, \quad n_q(x_1) = n_s(x_1), \quad J_q(x_1) = J_s(x_1). \tag{2.17}$$

On the boundary of the interval (x_2, L) we impose the conditions

$$n_q(x_2) = n_s(x_2), \quad J_q(x_2) = J_s(x_2), \quad n_q(L) = n_D(L), \quad F(L) = -V_a. \tag{2.18}$$

The interface conditions for the current densities can be written in a form which is more convenient for the numerical computations. For this, we remark that we have from (2.16) and (2.9)

$$J_s(x_1) = \int_0^\infty w_0(a,p)T(p)pdp - \int_0^\infty w_0(b,-p_+(p))T(p)pdp$$

and J_s is constant in $[x_1, x_2]$. Insertion of the above formula into $J_q(x_j) = J_s(x_j)$ $(j = 1, 2)$ gives, after some elementary computations, up to order $O(\hbar^4)$,

$$\begin{aligned} J_q(x_2) = J_q(x_1) &= \sqrt{2\pi\theta}A_0\left(n_s(x_1) - e^{-\delta V/2\theta}n_s(x_2)\right)I_1 \\ &+ \sqrt{2\pi\theta}\frac{\hbar^2 A_0}{12}n_s(x_1)\left(\frac{\sigma_{xx}}{\sigma} - \frac{\sigma_x^2}{\sigma^2}\right)_{x=x_1}(\theta I_1 - I_2) \\ &+ \sqrt{2\pi\theta}\frac{\hbar^2 A_0}{12}n_s(x_2)\left(\frac{\sigma_{xx}}{\sigma} - \frac{\sigma_x^2}{\sigma^2}\right)_{x=x_2}e^{-\delta V/2\theta}((\theta - \delta V)I_1 - I_2), \end{aligned}$$

where $\sigma = \sqrt{n_q}$, $\theta = mk_BT_0$, $\delta V = 2em(\widetilde{V}(x_2)\widetilde{-}V(x_1))$, and

$$I_1 = \frac{1}{\sqrt{2\pi\theta}}\int_0^\infty pT(p)e^{-p^2/2\theta}dp, \quad I_2 = \frac{1}{\sqrt{2\pi\theta}}\int_0^\infty p^3T(p)e^{-p^2/2\theta}dp.$$

For the numerical computations we replace the Bohm potential term σ_{xx}/σ by the expression (2.14) in order to avoid the computation of the second derivatives of σ. This gives two nonlinear boundary conditions for the quantum quasi-Fermi potential F:

$$n_s(x_j)F_x(x_j) = f(F(x_1), F(x_2), \sigma_x(x_1), \sigma_x(x_2)), \quad j = 1, 2,$$

where

$$\begin{aligned} f(F(x_1), F(x_2), \sigma_x(x_1), \sigma_x(x_2)) &= \sqrt{2\pi\theta}A_0 I_1 \left(n_s(x_1) - e^{-\delta V/2\theta} n_s(x_2)\right) \\ &+ \frac{em}{2}\sqrt{2\pi\theta}A_0(\theta I_1 - I_2)n_s(x_1)\left(F(x_1) - U_{\rm th}\ln n_s(x_1) + \widetilde{V}(x_1) + \frac{\hbar^2}{6em}\frac{\sigma_x^2(x_1)}{n_s(x_1)}\right) \\ &+ \frac{em}{2}\sqrt{2\pi\theta}A_0 e^{-\delta V/2\theta}((\theta - \delta V)I_1 - I_2)n_s(x_2) \\ &\times \left(F(x_2) - U_{\rm th}\ln n_s(x_2) + \widetilde{V}(x_2) + \frac{\hbar^2}{6em}\frac{\sigma_x^2(x_2)}{n_s(x_2)}\right). \end{aligned}$$

Finally, the electrostatic potential is self-consistently coupled through the Poisson equation

$$\frac{d}{dx}\left(\varepsilon_s\frac{dV}{dx}\right) = e(n - n_D(x)), \quad x \in (0, L),$$

where ε_s is the semiconductor permittivity and the particle density $n(x)$ is given by

$$n(x) = \begin{cases} n_q(x) & : x \in (0, x_1) \cup (x_2, L), \\ n_s(x) & : x \in (x_1, x_2). \end{cases} \tag{2.19}$$

3. Numerical discretization. We discretize the equations by introducing a uniform mesh $\xi_k = k\triangle x$, $\triangle x > 0$, $k = 0, \ldots, K$, and $L = K\triangle x$.

The Schrödinger equation is solved by central finite differences as in [10]. For the convenience of the reader we recall the discretization scheme. We assume that the effective mass is constant in $[x_1, x_2]$ since we wish to compare our results with those from the literature, e.g., [7, 26]. Moreover, a space-dependent effective electron mass leads to quite complicated quantum drift-diffusion models whose numerical solution is delicate [28]. The Schrödinger equation (2.1) with boundary conditions (2.2) for $p > 0$ (the case $p < 0$ can be treated analogously) can be equivalently rewritten as

$$y'' = -\frac{2m}{\hbar^2}(E_p + e\widetilde{V})y \quad \text{in } (x_1, x_2), \quad y(x_2) = 1, \quad y'(x_2) = \frac{i}{\hbar}p_+(p), \tag{3.1}$$

where $p_+(p)$ is defined in (2.4) and y and ψ_p are related by

$$\psi_p(x) = \frac{2ipy(x)}{\hbar y'(x_1) + ipy(x_1)}.$$

With the approximations $y_k \approx y(\xi_k)$ and $\widetilde{V}_k \approx \widetilde{V}(\xi_k) = V_{\rm ext}(\xi_k) + V(\xi_k)$ the discrete problem is

$$\frac{1}{(\triangle x)^2}(y_{k+1} - 2y_k + y_{k-1}) = -\frac{2m}{\hbar^2}(E_p + e\widetilde{V}_k)y_k.$$

This problem is solved as in [10] by Stoermer's method, i.e., writing

$$z_k = \frac{y_{k+1} - y_k}{\triangle x} \quad (k = 0, \dots, K-1), \quad z_K = y'(x_2) - \frac{m}{\hbar^2}(E_p + e\widetilde{V}(x_2))y(x_2)$$

and noticing that z_K is known in view of (3.1), the iteration reads

$$\begin{aligned} z_k &= z_{k+1} - \frac{m}{\hbar^2}\triangle x(E_p + e\widetilde{V}_{k-1})y_{k-1}, \\ y_k &= y_{k+1} - \triangle x z_k, \\ y_0' &= y'(x_1) = z_1 - \frac{m}{\hbar^2}\triangle x(E_p + e\widetilde{V}_0)y_0, \end{aligned}$$

which allows us to calculate z_k and y_k recursively. The algorithm is vectorized and implemented in MATLAB.

The quantum drift-diffusion model (2.14) is approximated by central finite differences as in [22]. The proposed scheme has been proved to be positivity preserving, i.e., the discrete electron density is positive (see [21, 22] for details). Let σ_k and F_k be approximations of $\sigma(\xi_k)$ and $F(\xi_k)$, respectively. Then the discrete problem corresponding to (2.14) is

$$\frac{1}{(\triangle x)^2}\left(\sigma_{k+1/2}^2 F_{k+1} - (\sigma_{k+1/2} + \sigma_{k-1/2})F_k + \sigma_{k-1/2}^2 F_{k-1}\right) = 0, \tag{3.2}$$

$$F_k = U_{\rm th} \ln \sigma_k^2 - \widetilde{V}_k - \frac{\hbar^2}{6em(\triangle x)^2}\frac{\sigma_{k+1} - 2\sigma_k + \sigma_{k-1}}{\sigma_k}, \tag{3.3}$$

where $\sigma_{k\pm1/2} = (\sigma_k + \sigma_{k\pm1})/2$.

Finally, the discrete Poisson equation for $V_k \approx V(\xi_k)$ reads as follows:

$$\frac{\varepsilon_s}{(\triangle x)^2}(V_{k+1} - 2V_k + V_{k-1}) = e(n_k - n_D(\xi_k)) \quad (k = 1, \dots, K-1), \quad V_0 = 0, \quad V_K = U,$$

where we have assumed a constant semiconductor permittivity ε_s, and the electron density is either given by (2.7) (discretized by a standard quadrature formulae) in the interval $[x_1, x_2]$ or by σ_k^2 otherwise.

We describe now the iterative procedures for the various models. We use a fixed-point strategy to solve the SP system in $(0, L)$ (i.e., $a = 0$ and $b = L$). More precisely, we choose the electrostatic potential $V^{(0)}$ of the thermal equilibrium state as an initial guess. This potential is the (discrete) solution of the Poisson equation in which the electron density is replaced by the Thomas–Fermi approximation:

$$\varepsilon_s \frac{d^2V}{dx^2} = e\left(N_c F_{1/2}\left(\frac{\mu - V}{k_B T_0}\right) - n_D(x)\right) \quad \text{in } (0, L), \quad V(0) = V(L) = 0.$$

Here, $N_c = 2(mk_BT_0/2\pi\hbar^2)^{3/2}$ is the effective density of states and $F_{1/2}$ is the Fermi integral of order 1/2 [17, Ch. 9]. The chemical potential μ is a constant in thermal equilibrium and computed from the nonlinear equation $n_D(0) = n(0) = F_{1/2}(\mu/k_BT_0)$ (where we assumed charge neutrality). With this initial potential we solve the discrete Schrödinger problem to obtain the (discrete) scattering states which allow us to compute the discrete electron density from (2.7) and the discrete current density from (2.8). Finally, the update of the electrostatic potential can be computed from the Poisson equation written in the Gummel formulation (see (3.8) in [10]),

$$\varepsilon_s \frac{d^2V^{(j+1)}}{dx^2} + e(V^{(j+1)} - V^{(j)})n^{(j)} = e(n^{(j)} - n_D(x)).$$

The solution of the Schrödinger eigenvalue problem is the most costly part of the iteration. Indeed, we use a uniform grid of 10,000 values for p with grid size $\triangle p = 0.0005\sqrt{mk_BT_0}$. An adaptive mesh size strategy has been proposed for the SP system in the whole domain in [7], but we observed that the adaptive algorithm did not converge for the coupled model.

Another idea to reduce the computing time is to choose different mesh sizes $\triangle x_q$ in the collisional zone and $\triangle x_s$ in the ballistic zone. However, it turned out in our numerical experiments that the computing time is minimized when using the same mesh size in both zones, i.e., $\triangle x = \triangle x_s = \triangle x_q$. We have used $\triangle x = 0.25\,\mathrm{nm}$ (540 grid points).

The quantum drift-diffusion model in the whole interval $(0, L)$ is solved by Newton's method. The initial guess is chosen to be the potential in thermal equilibrium with $V_a = 0$ (see (2.15)). In thermal equilibrium, the quantum quasi-Fermi potential F is constant and, in view of the boundary conditions (2.15), the constant is zero. Then the thermal equilibrium potential is computed by a fixed-point scheme, i.e., we solve first the discrete equation

$$\frac{\hbar^2}{6em(\triangle x)^2}(\sigma_{k+1} - 2\sigma_k + \sigma_{k-1}) = \sigma_k(U_{\mathrm{th}} \ln \sigma_k^2 - \widetilde{V}_k), \quad \sigma_0 = n_D(0), \quad \sigma_K = n_D(L),$$

employing Newton's method and then the linear Poisson equation with homogeneous boundary conditions.

In the case $a = x_1$ and $b = x_2$ we use again a fixed-point-type iteration. More precisely, let an initial guess for the potential be given (namely, the thermal equilibrium potential of the quantum drift-diffusion model). Then compute the scattering states from the discrete Schrödinger equation. The electron and current densities are calculated according to (2.7) and (2.8), where the approximation (2.16) is employed. The quantum drift-diffusion system is solved by Newton's method according to (3.2)–(3.3) using the boundary conditions (2.17) and (2.18), respectively. Finally, an update for the electrostatic potential is obtained through the solution of the Poisson equation using the definition (2.19).

For all models we use the continuation method in the applied voltage, i.e., with the solution for the applied voltage U as an initial guess, we solve the problem applying the potential $V_a = U + \triangle U$ and use this solution again as initial guess for the next applied voltage. For the computations of the next section, we have choosen $\triangle U = 0.005\,\mathrm{V}$.

4. Numerical results. In this section we simulate a simple one-dimensional resonant tunneling diode. We choose the same geometry and data as in [26] (essentially taken from [23]). The tunneling diode consists of highly doped GaAs regions near the contacts and a lightly doped middle region of 35-nm length (see Figure 4.1). The middle region contains a quantum well of 5-nm length sandwiched between two 5-nm AlGaAs barriers. The double barrier heterostructure is placed between two 10-nm GaAs spacer layer with a doping of $5 \cdot 10^{15}\ \mathrm{cm}^{-3}$. These spacers are enclosed by two layers of 50-nm length and with doping $10^{18}\,\mathrm{cm}^{-3}$. The total length is thus 135 nm. The double barrier height is 0.3 eV. The physical effect of the barriers is a shift in the quasi-Fermi potential level, which we model by an additional step function V_{ext} added to the electrostatic potential. The physical constants are chosen as in [26] and are summarized in Table 4.1.

First we present the current-voltage characteristics of the above tunneling diode for four different model equations: the SP model in the whole interval, the coupled drift-diffusion SP (DD-SP) model of [10], the coupled quantum DD-SP (QDD-SP)

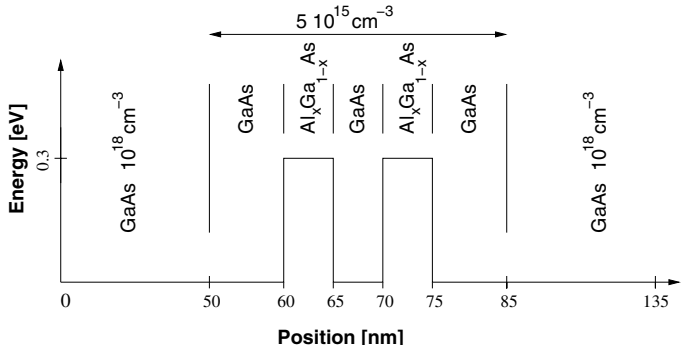

FIG. 4.1. *Geometry of the resonant tunneling diode and external potential V_{ext} modeling the double barriers.*

TABLE 4.1
Physical parameters and their numerical values.

Parameter	Physical meaning	Numerical value
m	electron mass	$0.067 \cdot 9.11 \cdot 10^{-31}$ kg
T	lattice temperature	300 K
ε_s	semiconductor permittivity	$11.44 \cdot 8.85 \cdot 10^{-12}$ As/Vm
τ	relaxation time	10^{-12} s
k_B	Boltzmann constant	$1.36 \cdot 10^{-23}$ J/K
$\hbar$	reduced Boltzmann constant	$1.055 \cdot 10^{-34}$ Js

model presented in this paper, and the quantum drift-diffusion (QDD) model in the whole interval. See [2, 10] for a description of the DD-SP model and its numerical discretization. Figure 4.2 displays the current-voltage curves for the first three models. In all these models, a region of negative differential resistance (NDR), in which the current is decreasing, can be observed. The valley current appears at approximately the same voltage, but the voltage at which the peak current is observed is slightly different in the models. Moreover, the peak-to-valley ratio in the QDD-SP model is smaller than in the SP model. This comes probably from the fact that there are no collisions modeled in the SP system. In [2], a decrease of the peak-to-valley ratio was also observed in simulations from the collisional DD-SP model (compared to the ballistic DD-SP model). The electron density and the electrostatic potential at applied voltage $V_a = 0.25$ V are presented in Figures 4.3 and 4.4, respectively. The results obtained here compare well with those of [2] and [26], where the coupled DD-SP model and the SP model, respectively, were solved.

The current-voltage curve computed from the QDD model does not show any NDR region (Figure 4.5). In fact, the QDD model is too diffusive, thus destroying the quantum resonance behavior (at least at large temperatures). It is known that a nonmonotone behavior of the current-voltage characteristic from the QDD model can be obtained by fitting the effective electron mass. Notice that the values for the current density are overestimated compared to the other models. Since we are using a constant relaxation time model (see section 2.2), the scattering effects are comparable for both temperatures and the current density for $T = 300$ K is larger than that for $T = 77$ K in view of the larger thermal energy.

For comparison, the current-voltage characteristics for the SP, QDD-SP, and DD-SP models at $T = 77$ K are displayed in Figure 4.6. The current-voltage curves of the two coupled models differ significantly from the curve computed from the SP

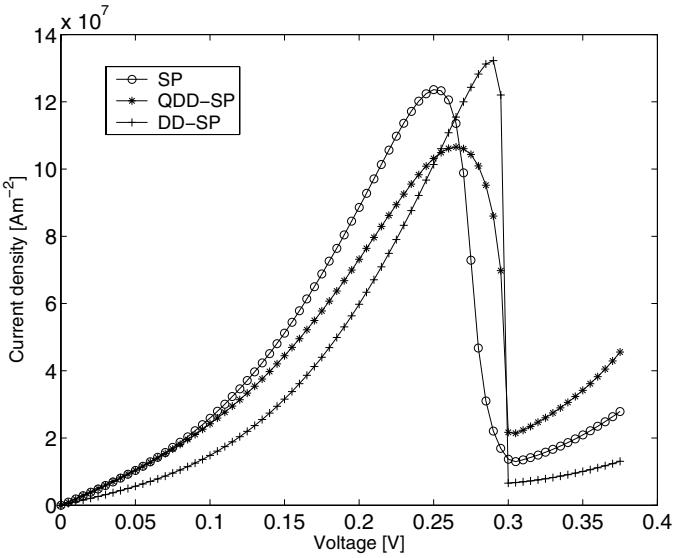

FIG. 4.2. *Current-voltage characteristics for a resonant tunneling diode using the SP, QDD-SP, and DD-SP models.*

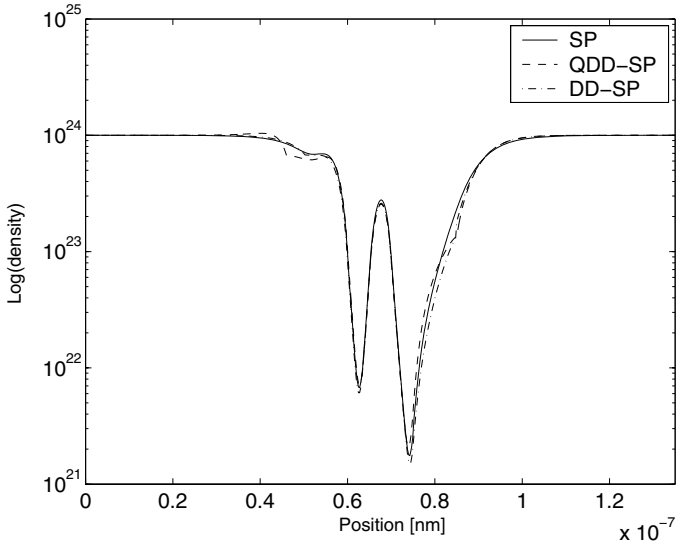

FIG. 4.3. *Electron densities at applied voltage $V_a = 0.25$ V from the SP, QDD-SP, and DD-SP models.*

model. This can be understood by the fact that at this low temperature, collisional effects are expected to be less important such that the use of diffusion models is questionable. Mathematically, the difference of the curves rather comes from the Bohm potential term than from the interface conditions, since a similar difference can be observed comparing the QDD and DD models without coupling to the SP system. The peak current from the QDD-SP model coincides with the peak current from the SP model, whereas the DD-SP model overestimates the peak current. Therefore, for

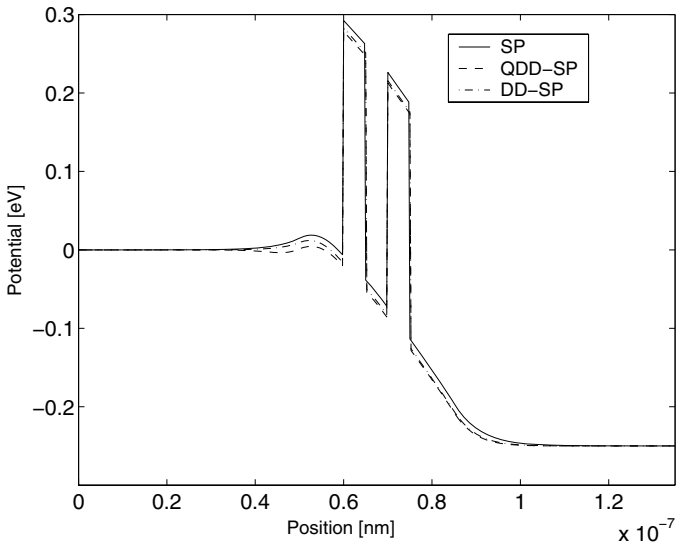

FIG. 4.4. *Potential profiles at applied voltage $V_a = 0.25$ V from the SP, QDD-SP, and DD-SP models.*

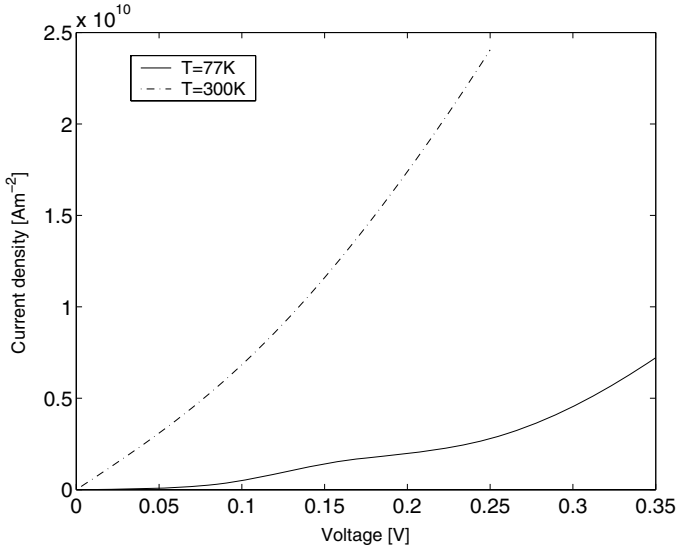

FIG. 4.5. *Current-voltage characteristics for a resonant tunneling diode using the QDD model for two different lattice temperatures.*

low temperature, the QDD-SP model seems to provide more accurate results than the DD-SP model.

In [10] it was observed that the current-voltage values depend quite sensitively on the position of the left interface point $a = x_1$, but the influence of the position of the right interface $b = x_2$ is very small. This observation holds true also for the QDD-SP model (Figures 4.7 and 4.8). When the left interface is too close to the double barrier, the potential in the quantum region cannot reproduce the correct quantum

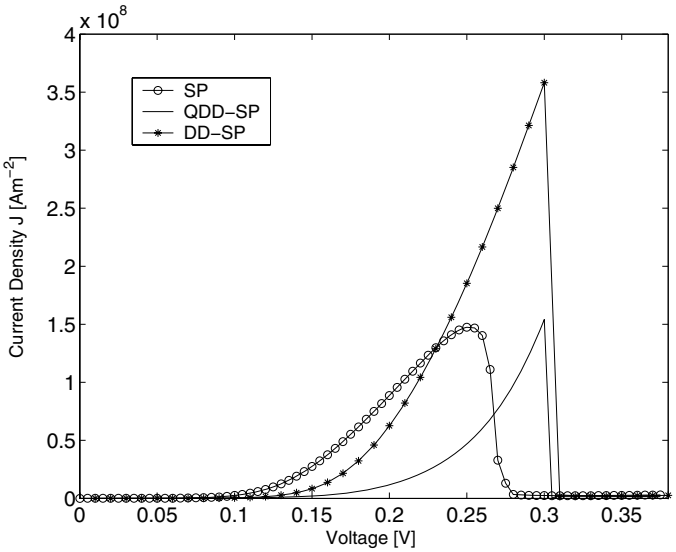

FIG. 4.6. *Current-voltage characteristics for a resonant tunneling diode using the SP, QDD-SP, and DD-SP models at temperature $T = 77\,K$.*

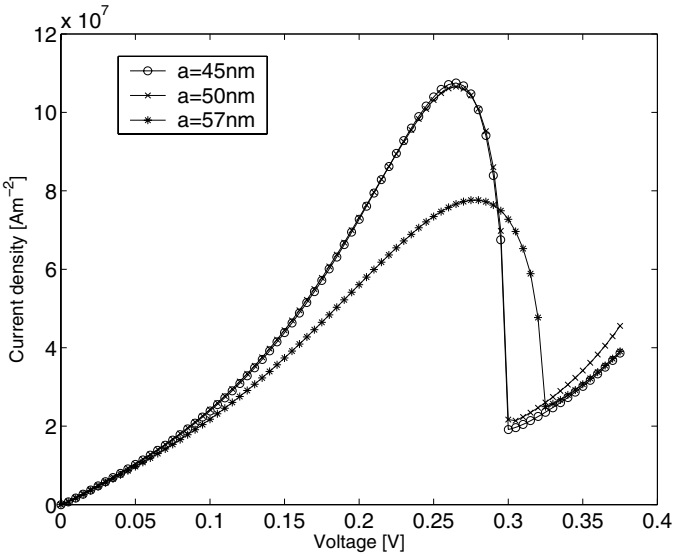

FIG. 4.7. *Influence of changes of the interface $a = x_1$ on the current-voltage characteristics using the QDD-SP model.*

resonances. It is argued in [10] that the insensitivity of the choice of the right interface position comes from the fact that the electrons crossing the double barriers have high energy and can be described equally well by a classical or a quantum model.

We have also investigated the effect of the relaxation time τ on the current-voltage curve. Figure 4.9 shows that the results are insensitive of the choice of τ. This holds true also in the ballistic DD-SP model of [10] (see Figure 4.10). In the collisional DD-SP model of [2], however, the characteristic is very sensitive with respect to τ.

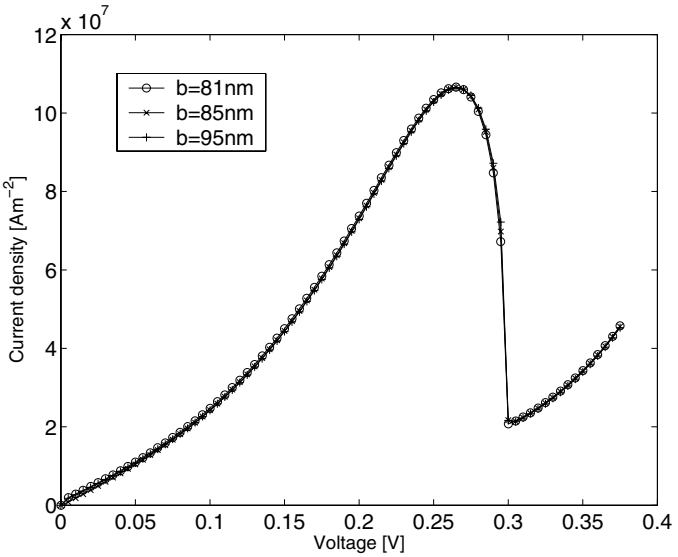

FIG. 4.8. *Influence of changes of the interface $b = x_2$ on the current-voltage characteristics using the QDD-SP model.*

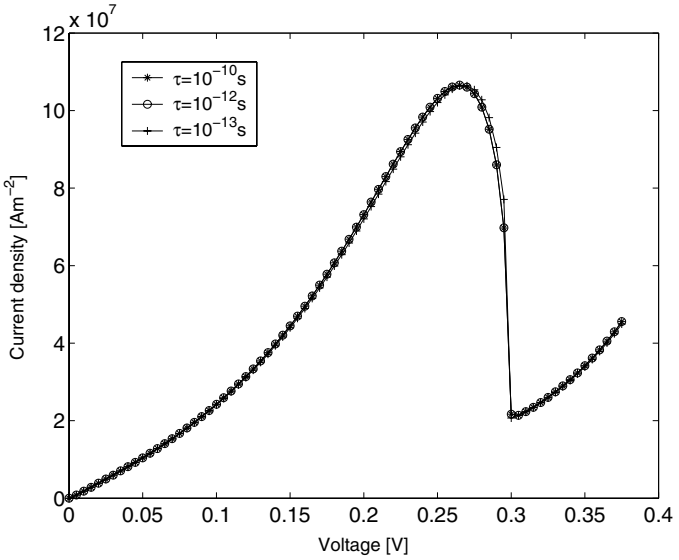

FIG. 4.9. *Influence of the relaxation time on the current-voltage characteristic using the QDD-SP model.*

This seems to come from the collision events in the quantum region modeled by the Pauli master equation. Notice that in the coupled DD-SP and QDD-SP models, no collisions are taken into account in the microscopic quantum region.

It is well known that the current-voltage curve of a tunneling diode exhibits hysteresis, probably resulting from storage effects of the charges in the quantum well [23]. Hysteresis can be found in simulations from the Wigner–Poisson model [23] or from the quantum hydrodynamic equations [9]. It cannot be observed in simulations

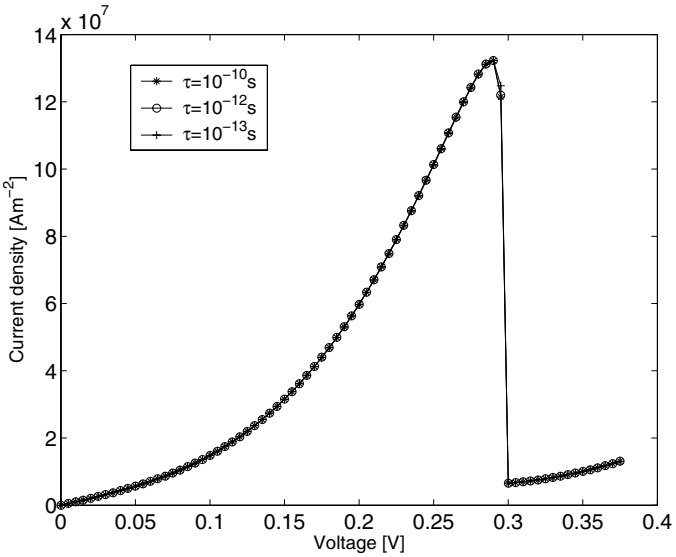

FIG. 4.10. *Influence of the relaxation time on the current-voltage characteristic using the DD-SP model.*

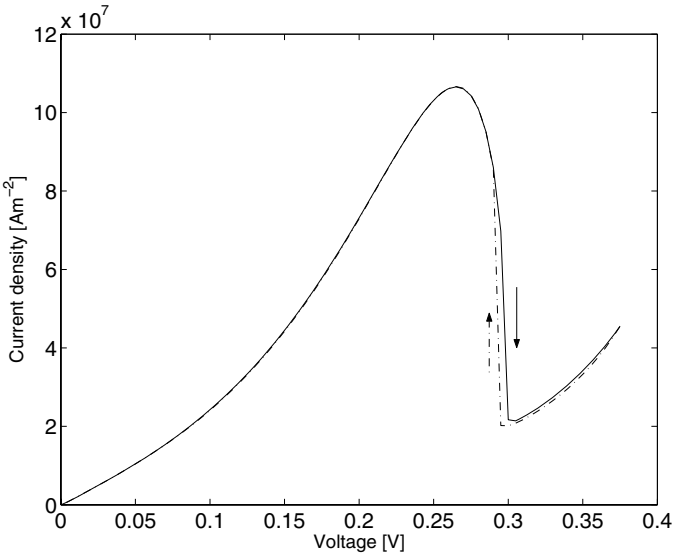

FIG. 4.11. *Hysteresis in the current-voltage characteristic using the QDD-SP model.*

from the QDD model. However, employing the coupled QDD-SP model, the current-voltage characteristic shows hysteresis (Figure 4.11). We notice that also with the DD-SP model, hysteresis effects can be found (Figure 4.12).

Finally, Table 4.2 displays the CPU times (for a 2.4-GHz Pentium 4 processor) needed to compute the current-voltage characteristics in various voltage ranges for the SP, QDD-SP, and DD-SP models. All algorithms are vectorized in the same way such that the CPU times are comparable. The CPU time needed to calculate the current-voltage curve with the QDD model is of the order of a few seconds only;

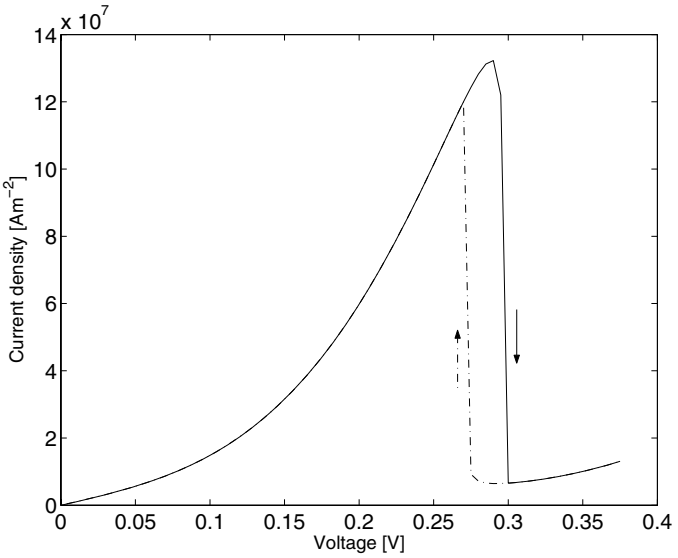

FIG. 4.12. *Hysteresis in the current-voltage characteristic using the DD-SP model.*

TABLE 4.2

CPU times needed to compute the current-voltage characteristic in the indicated voltage ranges, using different models.

model	[0 0.25eV]	[0.25eV 0.3eV]	[0.3eV 0.375eV]	[0 0.375eV]
SP	5776 s	1255 s	1371 s	8402 s
QDD-SP	2305 s	570 s	629 s	3504 s
DD-SP	695 s	187 s	168 s	1050 s

however, the numerical results are not satisfactory. The QDD-SP model needs only about half the CPU time compared to the SP model. This shows that the coupled model allows to reduce significantly the computing time compared to the full SP model. The DD-SP model is even faster; the reduction factor is about 8 compared to the SP model and about 3 compared to the QDD-SP model. The latter model is faster since the current density in the drift-diffusion region can be computed by an analytic expression [2, formula (16)], whereas the current density of the QDD-SP model is a result of the solution of the QDD model. Although the CPU time for the DD-SP model is smaller than for the QDD-SP model, the latter model has the advantage that there is a quantum description in the whole semiconductor device, avoiding any artificial separation of classical and quantum zones. From a more practical point of view, the DD-SP model may be prefered due to the smaller CPU time.

Acknowledgment. The authors thank Dr. Méhats (Toulouse) for very fruitful discussions.

CRITERIA FOR THE CONVERGENCE, OSCILLATION, AND BISTABILITY OF PULSE CIRCULATION IN A RING OF EXCITABLE MEDIA*

H. SEDAGHAT†, C. M. KENT‡, AND M. A. WOOD§

Abstract. A discrete model based on a nonlinear difference equation (equivalent to a coupled map lattice of high dimension) is used to study the dynamics of a circulating pulse in a ring of excitable media, such as cardiac cells. Based on the global and local properties of monotonic restitution and dispersion curves, criteria are obtained for the asymptotic stability of the unique steady state (pulse circulating at constant frequency) as well as for nonconvergent oscillatory behavior of all nonequilibrium trajectories (pulse circulating at variable frequency). We also demonstrate that in certain cases the system is bistable, where an asymptotically stable equilibrium coexists with stable oscillatory solutions.

Key words. difference equation, nonlinear, reentry, restitution, asymptotic stability, persistent oscillations, bistability

1. Introduction.

The periodic contractions of muscles that result in the beating of our hearts are caused by electrochemical signals or excitations called *action potentials* that propagate through chains of cardiac cells. Normally, cardiac cells generate and conduct action potentials in response to excitation by the self-oscillatory pacemaker cells in the heart's sinoatrial and atrioventricular nodes. However, in certain circumstances a closed loop or ring of tissue is formed within the heart that unidirectionally recycles a previously generated action potential. Such a *reentrant circuit* is capable of blocking the much slower pacemaker signals by transmitting its rapid pulses outward through adjacent cell layers, thus taking over the beating of the heart and leading to potentially life-threatening arrhythmias.

Reentry of an action potential pulse in a ring of cardiac cells or other excitable media and the resulting self-sustained propagation is relatively easy to model mathematically because of the simple one-dimensional geometry. The study of such models contributes to our understanding of cardiac arrhythmias, and the results of the study find concrete applications to experimental models of reentrant electrical activity in cardiac muscle. Nevertheless, the mathematical expressions of the manner in which a reentrant pulse propagates in a loop involve complex nonlinear equations whose study requires the application of a variety of different methods from the dynamical systems theory.

In [14] a discrete model of a reentrant circuit is developed based on the *restitution* and *dispersion* properties of cardiac cells. Mathematically, the centerpiece of this

model is a coupled-map lattice whose dimension is equal to the number of cells (or excitable units) in the loop. Close agreement was shown between certain important experimental facts and the model's simulations (using typical exponential-type maps to fit the restitution curve data). The authors discuss a number of issues, including the formation of a unidirectional block. For sustained propagation, they also study local stability and through numerical simulations establish the occurrence of discrete Hopf (or Neimark–Sacker) bifurcations with the variation of a parameter in their dispersion curve. In this way they exhibit the occurrence of almost periodic solutions with multiple incomensurate frequencies.

Two subsequent papers [5], [6] presented equivalent continuous space versions of the above model in terms of a delay differential equation and an integral delay equation, respectively. These papers present a mix of analytical and numerical results. The analytical results establish the occurrence of solutions with multiple frequencies via Hopf bifurcations in the continuous case. The length of the ring is used as the bifurcation parameter in these papers, where the nonconvergent solutions arise when this length is sufficiently reduced. These issues are discussed in greater detail in [6] than in [5]. Notably, the numerical simulations of the delay-differential and the integral delay equation used different versions of the mapping in [14] for their discretizations. These versions are nearly equivalent and one of them is discussed in this paper.

The concepts of restitution and dispersion are well known and have been widely studied in various contexts, both theoretical and experimental; see, e.g., [2], [3], [5], [6], [7], [10], [13], [14], [15], [16], [24], [25], [26]. In this paper we reexamine the dynamical system in [14], limiting our focus to dynamics of sustained reentry. Our purpose is twofold: First, for sustained propagation our results extend those obtained in [14] to include global behavior in a bounded (but not infinitesimal) invariant region of the phase space. In particular, we obtain conditions for (a) the convergence of all orbits within the invariant region to a unique stable equilibrium so that the reentrant pulse circulates at constant frequency; (b) the persistent oscillation (bounded but nonconverging) of all nonequilibrium orbits, resulting in pulse circulation at variable frequency; and (c) the occurrence of bistable behavior with coexisting stable oscillatory and convergent steady states so that it becomes possible to shift from one of these states to another through premature stimulations. Standard methods from the mathematical literature on discrete dynamics (e.g., [1], [8], [12], [17], [18], [19], [20], [23]) are used to advantage in the proofs of Theorems 1 and 2.

Our second goal in this paper is to further generalize various results in previous studies by using *generic* restitution and dispersion curves that satisfy a few minimal conditions. This shows indirectly that the aforementioned qualitatively different types of behavior are general manifestations of the dynamical system under consideration and are not peculiar to a specific class of elementary mathematical functions. This substantial extension of the previously published material is made possible by reliance on rigorous analytical methods that lead to a deeper understanding of the mathematical nature of the model. We limit use of numerical simulations largely to examples to illustrate the main results.

2. The model. We consider a loop of cardiac tissue (or, more generally, of excitable cells) of fixed length L that consists of a fixed number m of cells or, more generally, aggregate units or nodes in the sense of [14]. If the real number $\Delta L_i > 0$ denotes the ith cardiac unit spacing or internodal separation, then $L = \sum_{i=1}^{m} \Delta L_i$. If we denote the average of ΔL_i, $i = 1, 2, \ldots, m$, by ΔL and define

$$\delta_i = \frac{\Delta L_i}{\Delta L}$$

for each i, then

$$\sum_{i=1}^{m} \delta_i = \sum_{i=1}^{m} \frac{\Delta L_i}{\Delta L} = m \quad \text{and} \quad L = m\Delta L. \tag{1}$$

In most published works in the literature the spacings ΔL_i are assumed to deviate negligibly from the average ΔL. In such cases one assumes that $\delta_i = 1$ for all i and considers a *homogeneous loop* in which all nodes are uniformly spaced. This is an important special case which captures all the significant features with a minimum of technical details. Finally, for numerical simulations we arbitrarily take $m = 500$, although much smaller values of m give qualitatively similar outcomes [14].

2.1. Restitution curves.

The action potential duration restitution. The *action potential duration* (APD) is the length of time (usually measured in milliseconds (ms)) that a node or cell is active after excitation by a pulse. After passage of the APD, if no new excitation takes place, the cell enters a recovery period called the *diastolic interval* (DI), also measured in ms. The DI ends only by the arrival of a new excitation and it is only during the DI that a cell can fire or become active again if excited.

Let $\mathrm{APD}_{i,n}$ and $\mathrm{DI}_{i,n}$ denote the APD and DI, respectively, for the cell i in beat n. The most basic temporal relationship that is possible between the APD and the DI may be stated as

$$\mathrm{APD}_{i,n} = A(DI_{i,n-1}), \qquad i = 1, 2, \ldots, m, \tag{2}$$

where A is an increasing single variable function whose graph is called the *APD-restitution curve*.

We use the basic form (2) in this paper but point out that in various papers (e.g., [4], [9], [11], [13], [15], [26]) it has been suggested that in general the function A may contain additional delays or past APD dependence to account for memory effects.

Dispersion and the conduction time (CT) restitution. Each cardiac cell is capable of conducting the action potential pulse through it in a finite amount of time. The speed with which the pulse propagates through a cell is the *conduction velocity* or CV, often measured in cm/sec. If $\mathrm{CV}_{i,n}$ is the conduction velocity through cell i in beat n, then we may express our second restitution hypothesis as follows:

$$CV_{i,n} = V(DI_{i,n-1}), \qquad i = 1, 2, \ldots, m, \tag{3}$$

where V is a nondecreasing single variable function. Its graph is called the *dispersion curve*. With ΔL sufficiently small, we may assume that V does not change from one end of a unit or cell to its other end, so (3) defines a unitwise or cellular *conduction time restitution* as follows:

$$CT_{i,n} = T(i, DI_{i,n-1}) = \frac{\Delta L_i}{V(DI_{i,n-1})} = \frac{\delta_i \Delta L}{V(DI_{i,n-1})}.$$

If we define the function of one variable,

$$C(t) = \frac{\Delta L}{V(t)},$$

then $\mathrm{CT}_{i,n} = \delta_i C(DI_{i,n-1})$ for $i = 1, 2, \ldots, m$. Note that the function C is nonincreasing; we refer to its graph as the *CT-restitution curve*. Except for the factor ΔL the function C is the same as the recovery curve in [14].

2.2. The propagation equation. During sustained reentry the pulse or the excitation front moves from node to node around the loop. The length of each cycle (or beat) n is divided into two distinct periods, the APD followed by DI. The length of each cycle is also the sum of CT for all nodes or cells in the loop. Therefore, we have

$$APD_{i,n} + DI_{i,n} = \sum_{j=1}^{i-1} CT_{j,n+1} + \sum_{j=i}^{m} CT_{j,n}, \qquad i = 1, 2, \dots, m. \tag{4}$$

Since in this setting $i = 1$ is the reference point on the loop where a cycle begins and ends, the split in the sums reflects the fact that for $i > 1$ conduction in cells 1 through $i - 1$ takes place during beat $n + 1$. Using the restitution relations, (4) may be written as the following system:

$$DI_{i,n} = \sum_{j=1}^{i-1} T(j, DI_{j,n}) + \sum_{j=i}^{m} T(j, DI_{j,n-1}) - A(DI_{i,n-1}), \qquad i = 1, \dots, m. \tag{5}$$

Equation (5) is the coupled-map lattice discussed in [14]. It is also a partial difference equation in the spatial variable i and the temporal variable n. See [24] for an adaptation of this argument to a nonloop structure.

Rather than working directly with (5), we first transform it to an ordinary mth-order difference equation by taking advantage of the periodic nature of the loop. Define the combined space-time variable

$$x_{mn+i} = DI_{i,n}$$

and note that

$$A(DI_{i,n-1}) = A(x_{m(n-1)+i})$$

and

$$\sum_{j=1}^{i-1} T(j, DI_{j,n}) + \sum_{j=i}^{m} T(j, DI_{j,n-1}) = \sum_{j=1}^{i-1} T(j, x_{mn+j}) + \sum_{j=i}^{m} T(j, x_{m(n-1)+j}) = \sum_{j=mn-m+i}^{mn+i-1} T(j, x_j).$$

Next, we substitute $k = mn + i$ to get the following:

$$x_k = \sum_{j=k-m}^{k-1} \delta_j C(x_j) - A(x_{k-m}). \tag{6}$$

This equation is the main object of interest in this paper. It is equivalent to (5) provided that we extend the coefficient δ periodically, i.e., $\delta_{i+mn} = \delta_i$ for all positive integers n and each $i = 1, 2, \dots, m$ (a valid assumption since the loop consists of a finite number m of units).

In the homogeneous case where $\delta_i = 1$ for all i, (6) becomes an autonomous difference equation for which a greater number of results exist in the literature. This autonomous version of (6) is the same as that obtained in [6] on a discretization of

their independently developed integral equation (also see [7]). However, no analysis of the discrete case is given in these references.

Each solution of (6) is an infinite sequence $\{x_k\}_{k=1}^{\infty}$ of DI quantities that is generated by a given set of initial values which may be thought of as an initial state vector,

$$\mathbf{DI}_0 = [DI_{1,0}, DI_{2,0}, \dots, DI_{m,0}] = [x_{-m+1}, x_{-m+2}, \dots, x_0].$$

Also, *each subsequent state vector*

$$\mathbf{DI}_n = [x_{m(n-1)+1}, x_{m(n-1)+2}, \dots, x_{mn}], \quad n \geq 0,$$

constitutes the dynamic state of the loop in one cycle. Each such vector determines the DI values for all the cells in the loop within a given cycle, and from the DI values and the restitution and dispersion functions, other quantities such as APD and CV can be computed. Further, plotting the components of $\mathbf{DI}_n$ as functions of the spatial coordinate i, one obtains the spatial profile of the DI values in each cycle (see Figure 2).

Exponential restitution and dispersion curves. Experimental data from pacing experiments as well as data generated by the numerical simulations of the ionic PDE models are typically fitted with exponential maps for numerical studies of pulse propagation. Monotonic maps that are variations of the following two functions appear frequently in the literature on cardiac electrophysiology:

$$A(t) = a - be^{-\sigma t} + pe^{-\gamma(t-\tau)^2}, \quad C(t) = \frac{\Delta L}{c}[1 + de^{-\omega t}], \tag{7}$$

where the parameters a, b, c, d, τ, σ, γ, $\omega > 0$ and p is a real number. We use these representations in our examples and figures below. The parameter c is in fact the limiting (or maximum) value of conduction velocity; i.e., $c = \lim_{t\to\infty} V(t)$. The second exponential term has been added here to the definition of A as a simple device for modifying A locally near the value τ. For small values of $|p|$ the mapping A is strictly increasing and in this paper we shall be concerned with this range of p values only. In particular, if $p = 0$, then A takes the form used in [14]; where the above definition of A is used in the sequel (except for the one on bistability) we assume that $p = 0$.

Using definitions (7) in (6) and rearranging a few terms gives the following:

$$x_k = \frac{d\Delta L}{c} \sum_{j=k-m}^{k-1} \delta_j e^{-\omega x_j} + be^{-\sigma x_{k-m}} - pe^{-\gamma(x_{k-m}-\tau)^2} + \frac{L}{c} - a. \tag{8}$$

Equation (8) defines a complex dynamical system that displays a wide range of behaviors. Nevertheless, it is mathematically a rather special case of (6) in which certain situations do not occur that are possible for (6); e.g., nonconcavity or nondifferentiability. In this paper we generally use the following parameter values in (8), unless otherwise stated:

$$a = 24,\ b = 12,\ \sigma = 0.5,\ \ p = 0,\ c = 6,\ d = 1,\ \omega = 1,\ \Delta L = 0.3. \tag{9}$$

These values are largely arbitrary but not far-fetched; they are within scientifically acceptable ranges and here they are used mainly for numerical verifications of our results in illustrative examples. For the sake of interpretation, $L = m\Delta L = 150$ may be considered to be in millimeters and time units for DI, APD, etc. in various diagrams will be 10 milliseconds each, unless otherwise specified.

3. Dynamics of sustained reentry. A positive solution $\{x_k\}_{k=1}^{\infty}$ of (6), being an infinite sequence, represents *sustained reentry*. As noted above, a partitioning of this sequence into m-dimensional vectors gives the history of the loop's dynamic states in the phase space. In this section we study the qualitative properties of the solutions of (6).

3.1. The existence of a unique equilibrium. We begin with a set of basic assumptions concerning the restitution functions. The functions A, C in (7) in particular satisfy all these hypotheses.

(A1) There is $r_A \geq 0$ such that the APD restitution function A is continuous and increasing on the interval $[r_A, \infty)$ with $A(r_A) \geq 0$.
(A2) There is $r_C \geq 0$ such that the CT restitution function C is continuous and nonincreasing on the interval $[r_C, \infty)$ with $\inf_{x \geq r_C} C(x) \geq 0$.
(A3) There is $r \geq \max\{r_A, r_C\}$ such that

$$mC(r) > A(r) + r.$$

The first two assumptions express basic physiological facts that are commonly attributed to the functions A and C. The third assumption guarantees (via Lemma 1) the existence of a structurally stable equilibrium or steady state. Physiologically, this means that conduction around the ring must be sufficiently slow to achieve the desired effect. Note also that (A1)–(A3) allow for the possibility that the restitution functions may not be monotonic or otherwise well-behaved near the origin.

Next, we define the *auxiliary function* $F = mC - A$ and note that by (A1)–(A3), F is continuous and decreasing on the interval $[r, \infty)$ and satisfies

$$F(r) > r. \tag{10}$$

Let x^* be a steady state solution or *equilibrium* of (6), i.e., a solution of the equation

$$x = \sum_{j=k-m}^{k-1} \delta_j C(x) - A(x) = mC(x) - A(x) = F(x). \tag{11}$$

In particular, x^* is also a fixed point of the auxiliary map F so it is the same in the autonomous case $\delta_i = 1$.

LEMMA 1. *Assume that* (A1)–(A3) *hold.*
(a) *Equation* (6) *has a unique positive equilibrium* $x^* \in (r, F(r))$.
(b) $(x^*, F(r)] = F([r, x^*))$.
(c) $[r, F(r)] = [r, x^*] \cup F([r, x^*))$ *disjointly.*

Proof. (a) Let $f(x) = F(x) - x$ so that by (11) x^* is a zero of f. Then by (10) $f(r) > 0$. Further, since F is decreasing for $x \geq r$, applying F to (10) gives

$$f(F(r)) = F(F(r)) - F(r) < 0.$$

The existence of $x^* \in (r, F(r))$ is now established by applying the intermediate value theorem to the continuous f. The uniqueness of x^* is a clear consequence of the strictly decreasing nature of f.

(b) Let $y \in (x^*, F(r)]$. Then $x = F^{-1}(y) > F^{-1}(F(r)) = r$ and $x < F^{-1}(x^*) = x^*$. Thus $(x^*, F(r)] \subset F([r, x^*))$. The converse is clear.

(c) The disjoint union follows immediately from part (b). ∎

The interval $[r, F(r)]$ represents a *relevant interval* for this model since what happens outside this interval is not relevant to our discussion of sustained reentry. The relevant interval is not generally invariant, although it may contain an invariant interval.

Remark. We are interested only in nonnegative DI values; therefore, if a zero of F occurs in the relevant interval, i.e., if there is $p \in [r, F(r)]$ such that $F(p) = 0$, then $F(x) < 0$ for $x > p$ so the relevant interval reduces to $[r, p]$. We note that since $F(x^*) = x^* > 0$, it must be that $x^* \in (r, p)$.

3.2. The invariant interval. The existence of a nontrivial invariant interval in particular guarantees an open set of bounded solutions for (6) and thus assures the robust occurrence of sustained reentry. An additional hypothesis is required.

(A4) There is $s \in [r, x^*)$ such that $s \le F(F(s)) = F^2(s)$.

LEMMA 2. *Assuming* (A1)–(A4)*, the interval* $I = [s, F(s)]$ *is nontrivial, contains* x^**, and is invariant for* (6)*; i.e., if the initial values* $x_0, \dots, x_{-m+1}$ *are in* I*, then* $x_k \in I$ *for all* $k \ge 1$*. Also* $I \subset [r, F(r)]$*.*

Proof. First, observe that since $s < x^*$ and F is decreasing, then $F(s) > x^* > s$. Hence, the interval I contains x^* and is nontrivial, i.e., it has a nonempty interior. Next, assume that $x_0, \dots, x_{-m+1} \in I$. Then for $j = -m+1, \dots, 0$, $x_j \ge s$, so $A(x_{-m+1}) \ge A(s)$ and $C(x_j) \le C(s)$. Therefore,

$$x_1 = \sum_{j=-m+1}^{0} \delta_j C(x_j) - A(x_{-m+1}) \le mC(s) - A(s) = F(s).$$

Similarly, for $j = -m+1, \dots, 0$, $x_j \le F(s)$ so $A(x_{-m+1}) \le A(F(s))$ and $C(x_j) \ge C(F(s))$. Therefore,

$$\begin{aligned} x_1 &= \sum_{j=-m+1}^{0} \delta_j C(x_j) - A(x_{-m+1}) \\ &\ge mC(F(s)) - A(F(s)) \\ &= F(F(s)) \\ &\ge s. \end{aligned}$$

It follows that $x_1 \in I$. Now, assume inductively that for $k \ge 1$, we have established that $x_{k-1}, \dots, x_{k-m} \in I$. Then repeating the above argument gives $x_k \in I$ and shows I to be invariant. ∎

3.3. Convergence to a stable steady state. In this section we look at a special case of (A4) that implies the asymptotic stability of the equilibrium (convergence of all trajectories in I to a stable steady state). This special case of condition (A4) is stated as follows:

(A4S) There is $s \in [r, x^*)$ such that $F^2(x) > x$ for all $x \in (s, x^*)$.

Figure 1 depicts a case where (A4S) holds with $r = s = 0$. Note in particular that if $A'(x^*) < 1$, then it is easy to see that (A4S) holds, at least when $C'(x^*) = 0$ (although C need not be constant). However, (A4S) is a weaker condition in that the differentiability of A is not required and that if differentiable, then the derivative A' need not be uniformly bounded by 1 in a left-neighborhood of x^* (i.e., small irregularities in the APD curve do not affect the qualitative behavior of the circulating pulse).

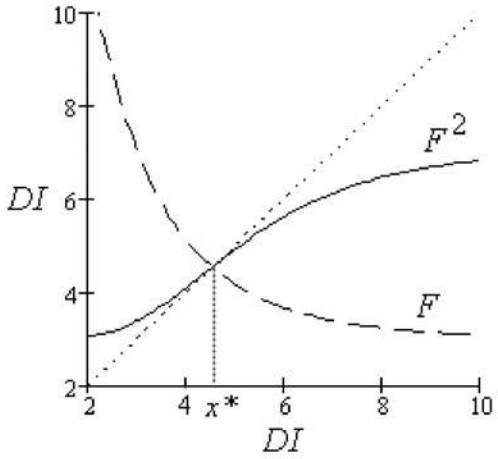

FIG. 1. *Conditions for the stability of the fixed point x^* of the mapping F, which is required in Theorem* 1. *When the graph of $F^2 = F \circ F$ crosses the diagonal going from above it to below it as shown, x^* is asymptotically stable.*

Before Theorem 1 is presented, it is necessary to consider the dynamics of the auxiliary map F under (A4S). It is known [23, sec. 2.1], that condition (A4S) is in fact necessary *and* sufficient for x^* to attract all orbits of F that start in $(s, F(s))$. But since F is a relatively simple mapping, we can be more specific here.

LEMMA 3. *Assume that* (A1)–(A3) *plus* (A4S) *hold. Then for every* $x_0 \in (s, x^*)$

$$s < x_0 < F^2(x_0) < \cdots < x^* < \cdots < F^3(x_0) < F(x_0) < F(s) \tag{12}$$

and

$$\lim_{n\to\infty} F^{2k}(x_0) = \lim_{n\to\infty} F^{2k+1}(x_0) = x^*. \tag{13}$$

Proof. Since F is decreasing, if $x_0 \in (s, x^*)$, then $F(x_0) > F(x^*) = x^*$ and $F(x_0) < F(s)$. Thus

$$x^* < F(x_0) < F(s). \tag{14}$$

Applying F to (14) in the above fashion gives

$$F^2(s) < F^2(x_0) < x^*.$$

Now (12) follows by simple induction. Statements (13) follow from (12) because F has no fixed points in $(s, F(s))$ other than x^* to which the odd and even iterates of F can converge. □

THEOREM 1. *Let* (A1)–(A3) *and* (A4S) *hold. Then the equilibrium x^* is stable and every solution of* (6) *with initial values in $(s, F(s))$ is attracted to x^*.*

Proof. First we establish the attracting nature of x^*. Let $x_0, \ldots, x_{-m+1}$ be in the interval $(s, F(s))$, and define

$$\mu_1 = \min\{x^*, x_0, \ldots, x_{-m+1}\}, \quad \mu_2 = \max\{x^*, x_0, \ldots, x_{-m+1}\}.$$

Since F is continuous, we have $F(x) \to F(s)$ as $x \to s$. Thus we can find $q \in (s, \mu_1)$ sufficiently close to s that $F(q) \in (\mu_2, F(s))$. Next, observe that since $x_0, \dots, x_{-m+1} > q$,

$$x_1 = \sum_{j=-m+1}^{0} \delta_j C(x_j) - A(x_{-m+1}) < mC(q) - A(q) = F(q).$$

Similarly, $x_0, \dots, x_{-m+1} < F(q)$ implies

$$x_1 = \sum_{j=-m+1}^{0} \delta_j C(x_j) - A(x_{-m+1}) > mC(F(q)) - A(F(q)) = F^2(q).$$

If (A4S) holds, then $F^2(q) > q$ so that $x_1 \in (F^2(q), F(q)) \subset (q, F(q))$. Repeating a similar calculation for $x_2, \dots, x_m$ we conclude that

$$x_k \in (F^2(q), F(q)) \subset (q, F(q)), \quad k = 1, \dots, m. \tag{15}$$

Next, we move on to the next cycle and look at x_{m+1}. Since by (15) $x_1, \dots, x_m > F^2(q)$,

$$x_{m+1} = \sum_{j=1}^{m} \delta_j C(x_j) - A(x_1) < mC(F^2(q)) - A(F^2(q)) = F^3(q);$$

further, $x_1, \dots, x_m < F(q)$ gives

$$x_{m+1} = \sum_{j=1}^{m} \delta_j C(x_j) - A(x_1) > mC(F(q)) - A(F(q)) = F^2(q).$$

Since $F^3(q) < F(q)$, this argument can be repeated for $x_{m+2}, \dots, x_{2m}$ to yield

$$x_k \in (F^2(q), F^3(q)) \subset (F^2(q), F(q)), \quad k = m+1, \dots, 2m.$$

Continuing this argument inductively leads to the conclusion that

$$\begin{aligned} x_k &\in (F^{2n}(q), F^{2n-1}(q)), \quad k = m(2n-2)+1, \dots, m(2n-1), \\ x_k &\in (F^{2n}(q), F^{2n+1}(q)), \quad k = m(2n-1)+1, \dots, 2mn. \end{aligned} \tag{16}$$

From these relations and Lemma 3 it is clear that x_k converges to x^* as $k \to \infty$. It remains to show that x^* is stable (dynamically in the sense of Liapunov). Let $\varepsilon > 0$ and use the continuity of F to pick $\delta \in (0, \varepsilon)$ small enough that $F(x^* - \delta) < x^* + \varepsilon$. If $x_0, \dots, x_{-m+1} \in (x^* - \delta, x^* + \delta)$, then it follows from Lemma 3 and (16) that

$$x_k \in (x^* - \delta, F(x^* - \delta)) \subset (x^* - \varepsilon, x^* + \varepsilon), \quad k \geq 1.$$

Hence x^* is stable. □

Remark 1. If x^* is attracting (e.g., conditions of Theorem 1 hold), then the cycle length $mC(x^*)$ may be easily computed as the fixed period T^* (analogous to the *basic cycle length* (BCL)) for the oscillation of the reentrant pulse. Note that

$$T^* = mC(x^*) = \frac{m\Delta L}{V(x^*)} = \frac{L}{V^*},$$

where V^* is steady state conduction velocity in the loop. Similarly, the APD is calculated from the restitution relation as $A^* = A(x^*)$. It may be emphasized that since $F(x^*) = x^*$ we have the cycle period $T^* = A^* + x^* > A^*$ as required.

The frequency $1/T^*$ can be quite high in this sort of reentrant regime. We calculate this frequency in a hypothetical case using (8) subject to the parameter values (9) but with L increased to 162 (from 150 by increasing m to 540). In this case, we obtain the situation depicted in Figure 1 so by Theorem 1 the fixed point $x^* \approx 4.55$ (estimated numerically and interpreted as a steady state DI of 45.5 ms) is globally asymptotically stable (with respect to I).

The fixed cycle length or period of the reentrant pulse is approximately

$$mC(4.55) = \frac{L}{c}(1 + de^{-4.55\omega}) = \frac{162}{6}(1 + e^{-4.55}) = 27.3,$$

which we interpret as 273 milliseconds, corresponding to a frequency of 60000/273 or a rather fast 220 cycles (or beats) per minute.

Remark 2. (A1)–(A3) plus (A4S) are sufficient for the asymptotic stability of the equilibrium but in general they are not necessary. A special case where these hypotheses are both necessary and sufficient for asymptotic stability is when C is constant (see Theorem 2.1.2 in [23]).

3.4. Persistent oscillations. In a series of experiments on animal cardiac tissue by Frame and Simson [10] it was found that the reentrant pulse does not always cycle around a loop with a fixed period. In some cases, the cycle length tended to oscillate without approaching a specific value. In [14] these oscillations were attributed to the appearance of quasiperiodic solutions for (5) due to local bifurcations (Neimark–Sacker or discrete Hopf). In this section we discuss sufficient conditions for oscillations to occur in all nontrivial solutions of (6) within the invariant I^m. Throughout this section we assume that the restitution functions A and C are continuously differentiable and that $\delta_i = 1$ for all i, i.e., the loop is homogeneous.

For the autonomous version of (6), the characteristic polynomial of the linearization at x^* is given as

$$P(\lambda) = \lambda^m + \sum_{i=1}^{m-1} \beta\lambda^i + \beta + \alpha, \quad \alpha = A'(x^*) > 0,\ \beta = -C'(x^*) \geq 0.$$

See, e.g., [18] or [23]. Note that the roots of P are the eigenvalues of the linearization of (6) at x^*. We now list some special properties of P.

LEMMA 4.

(a) *P has no nonnegative (real) roots.*

(b) *If some root of P lies on the unit circle in the complex plane, then $\alpha + \beta = 1$.*

(c) *If $\alpha + \beta = 1$, then for each root λ of P, $1/\lambda$ is also a root.*

(d) *If $\beta = 0$ (even if C is not constant), then either all roots of P are inside the unit disk in the complex plane if $\alpha < 1$ or they are all outside if $\alpha > 1$.*

Proof. (a) This is clear from the facts that $\beta \geq 0$ and $\alpha + \beta > 0$. (b) First we show that (i) implies (iii). Let $\alpha + \beta = 1$. By part (b), roots $\lambda_j = \rho_j \exp(i\theta_j)$ of P must have modulus $\rho_j = 1$ for all $j = 1, \ldots, m$ and thus they are on the unit circle. In particular, the only possible real root of P is -1 which occurs when m is odd.

Next, (iii) trivially implies (ii), so it remains to show that (ii) implies (i). Let λ_1 be a root that is on the unit circle. Then $\lambda_1 = \exp(i\theta_1)$ so the conjugate $\exp(-i\theta_1) =$

$1/\lambda_1$ is also a root. Since $P(\lambda_1) = 0$ it follows that

$$\beta \sum_{i=1}^{m-1} \lambda_1^i = -\lambda_1^m - \alpha - \beta. \tag{17}$$

Also, $P(1/\lambda_1) = 0$ so

$$\begin{aligned} 0 &= \frac{1}{\lambda_1^m} + \beta \sum_{i=1}^{m-1} \frac{1}{\lambda_1^i} + \beta + \alpha \\ &= \frac{1}{\lambda_1^m} \left[1 + \beta \sum_{i=1}^{m-1} \lambda_1^i \right] + \alpha + \beta \\ &= \frac{1 - \lambda_1^m - \alpha - \beta}{\lambda_1^m} + \alpha + \beta \\ &= \left(\frac{1}{\lambda_1^m} - 1 \right) (1 - \alpha - \beta). \end{aligned} \tag{18}$$

Note that $\lambda_1^m \neq 1$, since otherwise the sum of the mth roots of unity in (17) would add up to -1, leaving $-\beta$ on the left but giving $-1 - \alpha - \beta$ on the right. Therefore, by (18) it is the case that $1 - \alpha - \beta = 0$ as required.

(c) If $\alpha + \beta = 1$, then

$$P\left(\frac{1}{\lambda}\right) = \frac{1}{\lambda^m} + \beta \sum_{i=1}^{m-1} \frac{1}{\lambda^i} + 1 = \frac{1}{\lambda^m} \left[\lambda^m + \beta \sum_{i=1}^{m-1} \lambda^i + 1 \right] = \frac{P(\lambda)}{\lambda^m}.$$

(d) This is straightforward since P reduces to the simple equation $\lambda^m + \alpha$ if $\beta = 0$. □

Next, a global oscillation result [23, p. 166] is needed which we quote here as a lemma. We say that a sequence $\{x_n\}_{n=1}^{\infty}$ *oscillates persistently* if it is bounded and has at least two distinct limit points. In particular, persistently oscillating solutions cannot converge to a point.

LEMMA 5. *Consider the general difference equation*

$$x_n = f(x_{n-1}, \ldots, x_{n-m}), \tag{19}$$

where $f : D \to \mathbb{R}$ for a set $D \subset \mathbb{R}^m$. Assume that (19) *has a unique fixed point x^* and that all the eigenvalues of the linearization of* (19) *at x^* (i.e., the roots of its characteristic polynomial) lie outside the unit disk in the complex plane. Further, assume that*

$$f(x^*, \ldots, x^*, x) \neq x^* \quad \text{if} \quad x \neq x^*. \tag{20}$$

Then all nontrivial solutions of (19) *that are bounded oscillate persistently.*

We are now ready for the main result of this subsection.

THEOREM 2. *Assume that* (A1)–(A4) *and one of the following inequalities hold:*

$$A'(x^*) + (m-2)C'(x^*) > 1 \tag{21}$$

or

$$A'(x^*) > 0, \quad C'(x^*) \leq -1. \tag{22}$$

Then x^* is unstable and all nontrivial solutions of (6) *oscillate persistently in the invariant interval I.*

Proof. In the notation of Lemma 4, inequality (21) may be written as

$$\alpha - (m-2)\beta > 1. \tag{23}$$

We first show that if (23) holds, then all roots of the characteristic polynomial P lie outside the unit disk in the complex plane. To this end, define the polynomial

$$Q(\lambda) = \frac{\lambda^m}{\alpha+\beta} P\left(\frac{1}{\lambda}\right) = \lambda^m + \frac{1}{\alpha+\beta}\sum_{j=1}^{m-1} \beta\lambda^j + \frac{1}{\alpha+\beta}$$

and observe that λ_0 is a root of Q if and only if $1/\lambda_0$ is a root of P. Thus if every root of Q is inside the unit disk, then every root of P will be outside as desired. A well-known sufficient condition (e.g., [23, pp. 209, 210]) for all the roots of Q to be inside the unit disk is that the sum of all the coefficients (except for that of the highest power λ^m) be less than unity, i.e.,

$$1 > \sum_{j=1}^{m-1} \frac{\beta}{\alpha+\beta} + \frac{1}{\alpha+\beta} = \frac{(m-1)\beta+1}{\alpha+\beta}. \tag{24}$$

It is easy to see that (24) is equivalent to (23).

Next, assume that (22) holds. Then in the notation of Lemma 4, $\beta \geq 1$ with $\alpha > 0$; in particular, $\alpha + \beta > 1$. If all roots of P are *not* outside the unit disk, then some root

$$\lambda_0 = r_0 e^{i\theta_0} = r_0(\cos\theta_0 + i\sin\theta_0)$$

of P has modulus $r_0 \leq 1$. By Lemma 4(c) we may assume that $r_0 < 1$. Setting $P(\lambda) = 0$ and writing its middle terms in a compact way gives the equation

$$\lambda^m + \beta\frac{\lambda^m - 1}{\lambda - 1} + \alpha = 0. \tag{25}$$

Since by part (a) $\lambda \neq 1$ for any root, the zeros of (25) are precisely those of $P(\lambda) = 0$ and also the same as the nonunit zeros of

$$\lambda^m(\lambda - 1) + \beta(\lambda^m - 1) + \alpha(\lambda - 1) = 0. \tag{26}$$

Inserting λ_0 in (26) and rearranging terms, we get

$$\lambda_0^{m+1} + (\beta - 1)\lambda_0^m + \alpha\lambda_0 = \alpha + \beta. \tag{27}$$

Setting the real parts on the two sides of (27) equal we obtain

$$r_0^{m+1}\cos(m+1)\theta_0 + (\beta-1)r_0^m\cos m\theta_0 + \alpha r_0\cos\theta_0 = \alpha + \beta. \tag{28}$$

For $\beta \geq 1$ and $\alpha > 0$ the left side of (28) is bounded above by the quantity

$$r_0^{m+1} + (\beta-1)r_0^m + \alpha r_0 < 1 + \beta - 1 + \alpha = \alpha + \beta.$$

But this contradicts (28), which was assumed to hold with $r_0 \in (0,1)$ for some θ_0. It follows that λ_0 cannot exist and thus all roots of P must be outside the unit circle.

Having shown that a unique, unstable equilibrium exists in a positively invariant region, the proof can now be concluded by Lemma 5 as soon as we show that (20) holds. For (6), the function f is given by

$$f(u_1, \dots, u_m) = \sum_{j=1}^{m} C(u_j) - A(u_m),$$

so (20) is equivalent to

$$(m-1)C(x^*) + C(x) - A(x) \neq x^* \quad \text{if} \quad x \neq x^*. \tag{29}$$

Since $x^* = F(x^*) = mC(x^*) - A(x^*)$, (29) is equivalent to

$$C(x) - A(x) \neq C(x^*) - A(x^*) \quad \text{if} \quad x \neq x^*.$$

This last inequality is true since the function $C(x) - A(x)$ is strictly decreasing on the invariant interval I. □

Remark 3. Writing (21) in the equivalent form

$$A'(x^*) > 1 + (m-2)|C'(x^*)|$$

we see that for any given value of $A'(x^*)$ larger than 1, persistent oscillations occur by Theorem 2 if $|C'(x^*)|$ is sufficiently small, i.e., if C is sufficiently flat in a neighborhood of x^*. On the other hand, if $A'(x^*) < 1$, then the steepness condition $|C'(x^*)| \geq 1$ is sufficient to guarantee the occurrence of persistent oscillations. Thus in this sense (21) and (22) are complementary conditions.

As an application of Theorem 2, consider (8) subject to the parameter values (9) except with $\omega = 2$ now. Then we may estimate $x^* \approx 3.32$ (DI of about 33.2 ms) and compute

$$A'(x^*) \approx 1.141, \quad 1 + (m-2)|C'(x^*)| \approx 1.065.$$

Thus (21) is satisfied and solutions oscillate by Theorem 2. Figure 2 shows both the spatial and temporal DI profile in six consecutive cycles of a sample trajectory (the thick curve) after the transient effects have dissipated; in addition to its oscillatory nature, this solution is quasi-periodic, a fact that does not follow from Theorem 2 but may be inferred from local analysis.

Alternatively, if we have a CT restitution curve that flattens more quickly (e.g., $\omega = 3$), then we would get the solution shown by the thin curves in Figure 2. In this case, Theorem 2 again confirms that this solution is oscillatory because

$$x^* \approx 3.29, \quad A'(x^*) \approx 1.158, \quad 1 + (m-2)|C'(x^*)| \approx 1.004.$$

We note in passing that although A is independent of ω, if C is not constant, then changes in ω affect x^* and thus the value of the slope $A'(x^*)$.

Remark 4. In [14] it is conjectured that x^* is locally asymptotically stable (or unstable) if the quantity $A'(x^*) - C'(x^*) - 1$ is negative (respectively, positive). Although neither (21) nor (22) implies the positivity of this quantity, numerical simulations and certain results such as Lemma 4 suggest that this conjecture is probably true. In the notation of this paper, we restate this open problem as follows: *All roots of the characteristic polynomial P are inside (respectively, outside) the unit disk if and only if $\alpha + \beta < 1$ (respectively, $\alpha + \beta > 1$).*

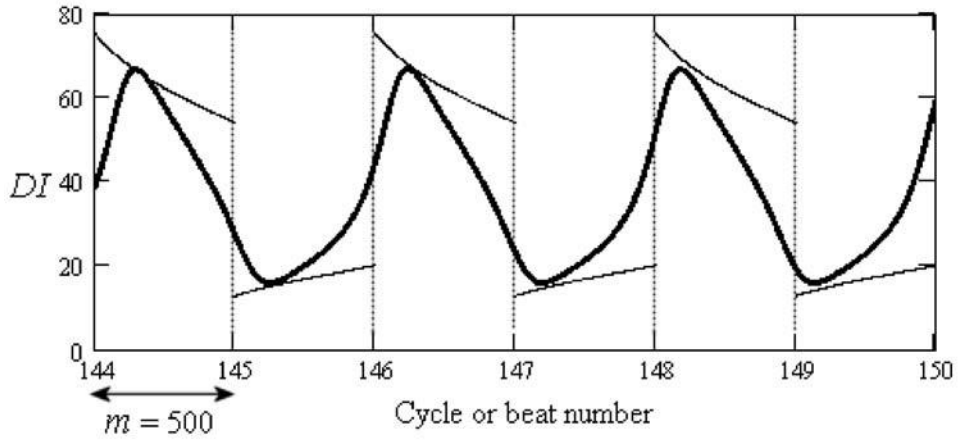

FIG. 2. *Two different types of oscillatory solution: The thick curve shows quasi-periodic oscillations when* $\omega = 2$ *and the thin curves show periodic oscillations when* $\omega = 3$. *Each point on either curve indicates the DI value of a particular unit in a given cycle. Both curves shown are generated from the same initial configuration vector* $DI_0 = [c, \ldots, c]$, *where* c *is a positive constant that may represent, e.g., the dynamic state of the loop in terms of cellular DI values just before the initiation of reentry. In each of the vertial strips each curve indicates the configuration of DI values over the entire ring (*500 *units) in one cycle or beat.*

3.5. Bistability. When cardiac tissue receives a premature stimulus such as an electrical shock of the type imparted by a defibrillator or through electrodes in a lab preparation, this can change its rhythm. In the case of a one-dimensional reentrant circuit, a particular type of behavior such as stably convergent may change to stably persistent oscillatory or conversely. Such changes can occur if (6) is bistable (or, more generally, multistable; note that a premature stimulus in cycle n changes the components of $\mathbf{DI}_n$, thus shifting the orbit in phase space). In this section we use Theorems 1 and 2 to show that a type of bistability that is caused by slight "dents" in the APD curve may exist in a general setting. An advantage of this approach is that the emergence of bistability in the higher-order equation (6) can be observed in a bifurcation diagram of the one-dimensional auxiliary map F even when C is not constant; see Remark 5.

The main idea. Consider a case where the solutions of (6) are persistently oscillatory, e.g., inequality (21) is satisfied at the equilibrium under hypotheses (A1)–(A4). Suppose that now the APD curve is made locally flat (i.e., its slope small) in the vicinity of the unstable equilibrium so that condition (A4S) holds in an interval I_0 containing x^* (A is unaltered or altered negligibly outside I_0). The endpoints of I_0 then represent an unstable 2-cycle for the auxiliary map F. Further, assume that I_0 is small enough to not contain some previously oscillatory solutions (in the sense that the oscillatory orbit in the phase space does not enter the hypercube I_0^m). Then by Theorem 1 solutions that are generated by initial values inside I_0 will converge to a new stable equilibrium without substantially affecting the previously oscillatory solutions that were outside I_0. The resulting system is thus bistable.

We emphasize that the existence of I_0 is sufficient but not necessary for the bistability of (6), unless of course the CT restitution curve C is constant. Let us now illustrate the preceding ideas using (8) subject to the parameter values (9) except that we now set $p = 0.3$ (with $\gamma = 1$, $\tau = 2.5$) to modify the APD curve, and also pick a suitable value for ω to enhance the bistability effect. The graph of $F^2(t) - t$

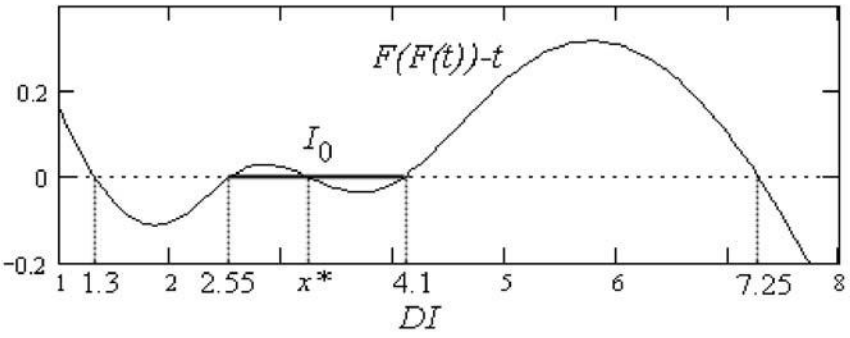

FIG. 3. *The two invariant intervals* $I = [1.3, 7.25]$ *and* $I_0 = [2.55, 4.1]$ *with the latter highlighted as the interval of convergence.*

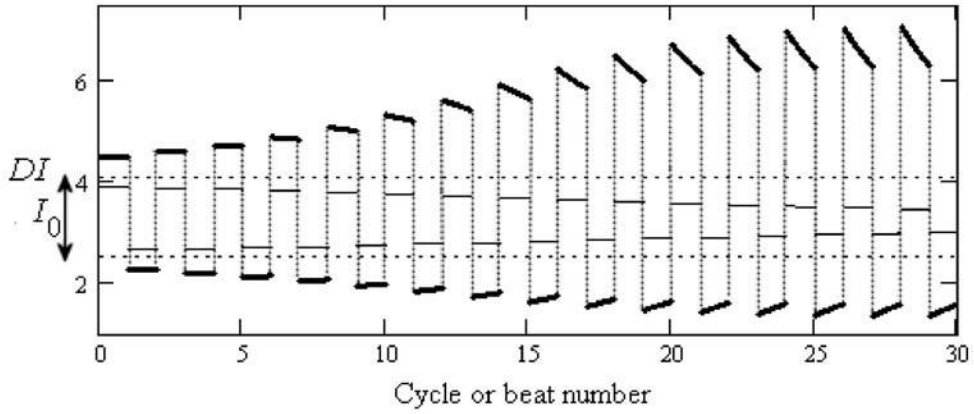

FIG. 4. *Qualitatively different outcomes that result from slightly different initial values. With initial values* $DI_0 = [3.9, \ldots, 3.9]$ *we obtain the convergent solution shown as the thin, square-shaped oscillatory curve, since* 3.9 *is in* I_0. *However, with* $DI_0 = [4.5, \ldots, 4.5]$ *we obtain the divergent, thick oscillatory curve. Note that* 4.5 *is in* I *but not in* I_0. *The horizontal strip between the dotted lines represents* I_0.

in Figure 3 shows the primary invariant interval I discussed previously, as well as the smaller one I_0 for a particular value of ω.

Figure 4 shows the different outcomes that result depending on whether we choose the initial values in I_0 or outside it. Evidently, the divergent oscillatory curve does not enter I_0 in this case. If $\mathbf{DI}_0$ is not constant and its components are only partially in I_0, then the corresponding solution may or may not converge.

More complex types of oscillatory behavior (not shown) where the trajectory may pass through I_0 repeatedly also occur in the above context with different parameter values. In such cases, the occurrence of convergent solutions may again be explained by Theorem 1 if $\mathbf{DI}_0 \in I_0^m$ (even with inhomogeneities). However, explaining the stable occurrence of the nonconvergent orbits requires further extensions of Theorem 2, or perhaps different methods that are global; local arguments and linearization in m dimensions do not apply since the equilibrium is asymptotically stable within I_0^m.

Remark 5. (emergence of bistability). Variations of shapes or changes in the relationship between the CT and APD curves may cause the emergence of bistability

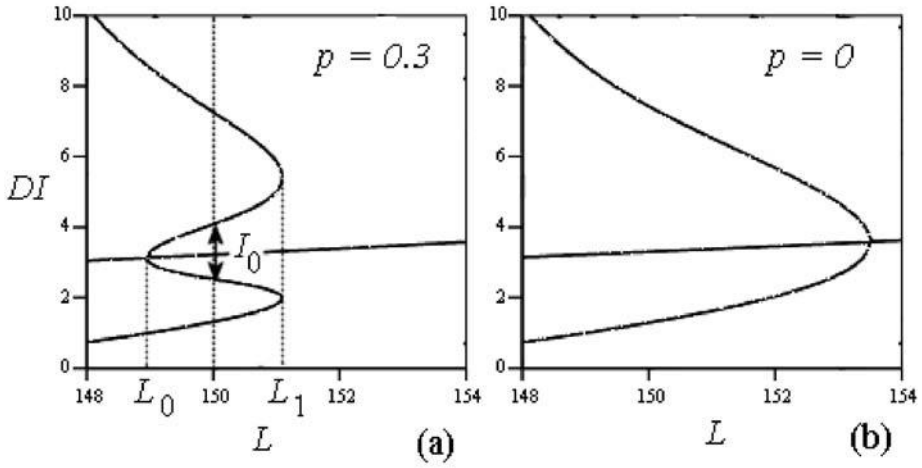

FIG. 5. *As the length L of the ring decreases, bistable behavior emerges in* (a) *but not in* (b). *The occurrences of tangent (or fold) bifurcations in* (a) *create two different period-2 orbits, the inner ones being unstable and enclosing a copy of the interval* I_0 *of Fig.* 3 *between them.*

by bringing x^* close to the region of local flatness for the APD. For illustration, consider (8) again where we change the parameter L (the length of the loop, a common bifurcation parameter). Note that $x^* = \phi^{-1}(L)$ is a strictly increasing function of L, where

$$\phi(x) = \frac{144 + 6x - 72e^{-0.5x} + 1.8e^{-(x-2.5)^2}}{1 + e^{-4x}}, \quad x > 0,$$

is easily obtained by solving (11) for L subject to the functions A, C and their parameter values for Figure 3. Thus we can reduce x^* by decreasing L and examine the effect of local APD flatness on bistability as x^* passes through the region of relative flatness for the APD curve. To visually demonstrate this effect of L on bistability we plot the two variable curve

$$F(L, F(L,x)) = x, \text{ where } F(L,x) = \frac{L}{6}[1 + e^{-4x}] - 24 + 12e^{-0.5x} - pe^{-(x-2.5)^2},$$

for both zero and nonzero (fixed) values of p. Such a bifurcation diagram shows the motion of the equilibrium for (8) as well as the occurrence and development of all period-2 points of the auxiliary map F as L varies. Figure 5 shows a comparison between two cases.

In both of the cases (a) and (b) shown in Figure 5, the nearly horizontal thick curve indicates the path of x^* as L changes. The other thick curve in Figure 5(a) where $p \neq 0$ (local flatness exists in APD) clearly shows the emergence of bistability at $L_1 \approx 151.1$ where tangent (or fold) bifurcations of the auxiliary map F create two period-2 orbits (for F). The two outer curves indicate the stable 2-cycles of F and the inner curves show the unstable 2-cycles which converge to the equilibrium x^* at $L_0 \approx 149$ through a reverse period-doubling (or flip) bifurcation. The interval between the two inner curves exists nontrivially for each $L \in (L_0, L_1)$ and gives the interval $I_0 = I_0(L)$ of bistability (by Theorem 1, x^* is asymptotically stable for all $L \in (L_0, L_1)$.) The line segment with arrows in Figure 5(a) indicates the interval I_0

at the particular value $L = 150$; this is just the interval I_0 that appears in Figures 3 and 4. By contrast, in Figure 5(b) where there is no region of relative flatness for the APD curve, the interval I_0 does not exist. For some related remarks concerning the occurrence of bistable behavior, see Vinet [25]. Vinet also uses a parameter p by which the APD function can be altered. However, the bifurcation diagrams in [25] are based on variation of p rather than L.

4. Concluding remarks. As indicated, many models of reentry in a loop of cardiac tissue or, more generally, of excitable media have been studied in the literature both in continuous and discrete form. In this paper, we refined and extended previous work using ideas and methods that yield global results. But more work remains to be done, especially at the theoretical level. For instance, it is necessary to extend Theorems 1 and 2 to cover a broader range of possibilities that include the relevant ranges of parameters in specific equations like (8), which is likely to be obtained through curve fitting of experimental data.

The interaction between Theorems 1 and 2 is a simple but not sufficiently satisfactory way to explain the occurrence of bistability. For instance, certain oscillatory solutions (periodic or almost periodic ones) repeatedly enter and exit the interval I_0 without converging, although solutions that start inside I_0 do converge (by Theorem 1). This situation requires a more detailed explanation than what is provided here.

The occurrence of almost periodic solutions has a standard description in terms of the Hopf–Neimark–Sacker bifurcation. However, it is less clear why these solutions break up into periodic solutions in some cases as the parameter ω increases from 2 to 3. A more detailed study of both periodic and almost periodic solutions of (6) is certainly desirable.

Beyond the mathematical issues mentioned above and related matters, it is also necessary to study extensions of the model that use more general types of restitution, e.g., to account for beat-to-beat memory, latency, etc. In particular, the addition of latency may lead to the occurrence of complex behavior for small values of DI.

Indeed, one sees that the persistent oscillation exhibited by the solutions of (6) is generally not complicated. (The reasons for the absence of complexity with *monotonic* APD are easy to discern when C is constant.) Can more complex types of persistent oscillations occur, e.g., with higher periods? Can they be possibly chaotic? In certain papers evidence is given that the APD restitution curve A may be nonmonotonic, e.g., be unimodal [24] or contain dents [22] at small DI values. In these works it is shown that chaotic behavior and complex bifurcations may occur whether it is for reentry in a loop [22] or for a regularly paced, nonclosed strip of tissue [24]. These observations may also be confirmed through numerical simulations of (8) with large enough p (not presented here). Such studies indicate the existence of a spatiotemporal form of chaotic behavior that needs further mathematical study and clarification.

THE CONVEX BACK-SCATTERING SUPPORT*

HOUSSEM HADDAR†, STEVEN KUSIAK‡, AND JOHN SYLVESTER§

Abstract. A monochromatic, i.e., fixed-frequency, back-scattering kernel measured at all angles does not uniquely determine the index of refraction in an inhomogeneous medium, nor can it guarantee any upper bound on the support of the inhomogeneity. We show that it is possible to associate with any such kernel its *convex back-scattering support*, a convex set which must be a subset of the convex hull of the support of any inhomogeneity with that back-scattering kernel. For the Born approximation, we further demonstrate that there is an inhomogeneity supported in any neighborhood of the convex back-scattering support which has exactly that back-scattering kernel. Last, we discuss a practical implementation of these results and include a numerical example.

Key words. Helmholtz equation, inverse scattering, back-scattering, acoustic scattering, electromagnetic scattering, far field

DOI. 10.1137/040616231

1. Introduction.

The goal of inverse scattering is to use acoustic or electromagnetic waves to deduce properties of a scatterer from remote observations. Exactly which properties and how well we can deduce them depend on exactly what scattering data we measure. In this paper the measured data are the back-scattered far field at all angles and a single frequency. A back-scattering experiment requires only a single sensor, which acts as both source and receiver. The sensor radiates at a single temporal frequency and measures the amplitude and phase of the resulting time-harmonic field. We can move the sensor to an arbitrary location on a sphere of large radius that surrounds the scatterer and repeat the experiment. The complex field (amplitude and phase) measured at each point on the sphere is the back-scattering data.

We will use the Helmholtz equation as our model for the propagation of time-harmonic waves,

$$(\Delta + k^2 n^2(x))u = 0, \quad x \in \mathbb{R}^d, \quad d \geq 2. \tag{1.1}$$

Here, $n(x) = \frac{c_0}{c(x)}$ is the index of refraction, which is the ratio of the wave speed in the vacuum to that in the medium, while $k = 2\pi/\lambda$ denotes the wave number. It will be convenient to define the scattering potential, $q(x) := k^2(1 - n^2)$, and to rewrite

(1.1) as

$$(\Delta + k^2)u = qu, \tag{1.2}$$

$$u = e^{ik\Theta\cdot x} + u_{sc}, \tag{1.3}$$

$$u_{sc} \sim \frac{e^{ikr}}{r^{\frac{d-1}{2}}} s_q(\Phi, \Theta), \quad |x| = r \to \infty. \tag{1.4}$$

Equation (1.3) expresses the fact that although the sensor, located at $\Theta \in S^{d-1}$, acts as a point source and emits a spherical wave, the sphere is far enough from the scatterer that the incident wave appears to be a plane wave in a neighborhood of the scatterer. Equation (1.4) expresses the asymptotics of the *outgoing* scattered wave.[1] The field measured by an additional dislocated sensor positioned at $\Phi \in S^{d-1}$ is denoted by $s_q(\Phi, \Theta)$. This quantity is called the *scattering kernel*. We define the back-scattering kernel as $s(\Theta) := s_q(\Theta, -\Theta)$. The back-scattering kernel represents the complex time-harmonic scattered field measured at the source position. We will discuss both the back-scattering kernel and what we will call the *Born-back-scattering* kernel. We denote the latter quantity by $b(\Theta) := b_q(\Theta, -\Theta)$ and remark that it is the analogue of $s(\Theta)$ in the Born, or single scattering, approximation. In both cases, a main feature is that the fixed frequency back-scattering data does not uniquely determine the scattering potential $q(x)$. Indeed, the Born-back-scattering kernel is equal to a constant (in Θ) multiple of the Fourier transform of q, restricted to the sphere of radius $2k$, i.e.,

$$b(\Theta) = \frac{k^{d-2}}{2i} \widehat{q}(2k\Theta). \tag{1.5}$$

We learn from (1.5) that as long as $g(x)$ is a smooth compactly supported function, then $\tilde{q} = (\Delta + (2k)^2)g$ has zero Born-back-scattering kernel, so that

$$b_{q+\tilde{q}}(\Theta) = b_q(\Theta). \tag{1.6}$$

The theorems below will relate the back-scattering data to the support of q. A glance at (1.6) makes it clear that it is impossible to produce an upper bound for the $\operatorname{supp} q$. We will, however, compute a lower bound. We will associate (and compute numerically) with $b(\Theta)$, or $s(\Theta)$, its convex back-scattering support, a convex set which must be a subset of the convex hull of the support of any q which produces that back-scattering data. In the Born approximation we will also find a potential supported in any neighborhood of this set that reproduces the data. In this case, the convex back-scattering support is the unique smallest convex set that supports a potential that can produce this data.

We state all our theorems below, and we include only very brief descriptions of the necessary notation here and defer both their detailed discussion and proofs to the following sections. In what follows, the symbol $\sigma_n(2kR)$ denotes the L^2 norm of the d-dimensional Bessel function of order n, and argument $2k|x|$, restricted to the ball of radius R. The number $N = N(n, d) \approx n^{d-2}$ denotes the dimension of the space of spherical harmonics of degree n. For a function $b \in L^2(S^{d-1})$, the functions $b_n^{(c)}(\Theta)$ represent the terms in the *condensed spherical harmonic expansion* (Fourier series expansion in two dimensions) of the function $e^{2i\Theta\cdot c} b(\Theta)$. Additionally, $B_c(R)$ denotes the closed ball of radius R centered at the point $c \in \mathbb{R}^d$.

[1] We will give a more precise mathematical description in the next section.

We now state our main results.

THEOREM 1.1 (linear, born-back-scattering). *Let $q \in L^2(\mathbb{R}^d)$ be compactly supported with Born-back-scattering kernel $b(\Theta)$, i.e.,*

$$b(\Theta) := b_q(\Theta, -\Theta) = \frac{k^{d-2}}{2i}\widehat{q}(2k\Theta), \tag{1.7}$$

and let

$$e^{2ik\Theta\cdot c}b(\Theta) = \sum_{n=0}^{\infty} b_n^{(c)}(\Theta)$$

be its expansion in spherical harmonics centered at c. If the $\operatorname{supp} q \subset B_c(R)$, *then*

$$\sum_{n=0}^{\infty} \frac{||b_n^{(c)}||^2_{L^2(S^{d-1})}}{\sigma_n^2(2kR)} < \infty. \tag{1.8}$$

Conversely, if $b \in L^2(S^{d-1})$ satisfies (1.8), *then there exists a $q \in L^2(\mathbb{R}^d)$ with* $\operatorname{supp} q \subset B_c(R)$ *and Born-back-scattering kernel $b(\Theta)$.*

Moreover, if $b \in L^2(S^{d-1})$ and $\mathcal{B}$ denotes the collection of all balls, $B_c(R)$, for which (1.8) *is satisfied, then for any $\epsilon > 0$, there exists $q \in C^\infty(\mathbb{R}^d)$ with*[2]

$$\operatorname{supp} q \subset \mathcal{N}_\epsilon\left(\bigcap_{B_c(R)\in\mathcal{B}} B_c(R)\right) \tag{1.9}$$

and Born-back-scattering kernel equal to $b(\Theta)$.

THEOREM 1.2 (nonlinear, full back-scattering). *Let $q \in L^p(\mathbb{R}^d)$, where $p > \max(2, \frac{d}{2})$, be compactly supported with back-scattering kernel*

$$s(\Theta) := s_q(\Theta, -\Theta),$$

and let

$$e^{2ik\Theta\cdot c}s(\Theta) = \sum_{n=0}^{\infty} s_n^{(c)}(\Theta)$$

be its expansion in spherical harmonics centered at c. If the $\operatorname{supp} q \subset B_c(R)$, *then, for $n > \max(4R, 2R^2)$,*

$$||s_n^{(c)}||^2_{L^2(S^{d-1})} \le C(q)\ N\sigma_n^2(2kR), \tag{1.10}$$

where $C(q)$ is given explicitly in (4.13).

If we observe that for any $\epsilon > 0$, (1.10) implies (1.8) with R replaced by $R + \epsilon$, we obtain the following corollary.

COROLLARY 1.3. *If the* $\operatorname{supp} q \subset B_c(R)$, *then there is a (complex-valued) $\tilde{q} \in C^\infty(\mathbb{R}^d)$ supported in an ϵ-neighborhood of $B_c(R)$ with Born-back-scattering kernel exactly equal to the full back-scattering kernel of q, i.e.,*

$$b_{\tilde{q}}(\Theta) = s_q(\Theta).$$

[2] $\mathcal{N}_\epsilon(\Omega)$ denotes an open ϵ-neighborhood of Ω, the set of points whose distance from Ω is less than ϵ.

As a consequence of these theorems, we define the convex scattering support to be as follows.

DEFINITION 1.4 (convex scattering support).

$$\mathrm{cS}_k\mathrm{supp}\, b = \bigcap_{B_c(R)\in\mathcal{B}} B_c(R),$$
$$\mathrm{cS}_k\mathrm{supp}\, s = \bigcap_{B_c(R)\in\mathcal{S}} B_c(R),$$

where $\mathcal{B}$ denotes the collection of balls such that b satisfies (1.8) *and $\mathcal{S}$ is the collection of balls such that s satisfies* (1.10).

We record the main property of the convex scattering support below.

THEOREM 1.5. *In both the Born approximation and in the full back-scattering cases, the convex scattering support must be a subset of the convex hull of the support of any potential q with that back-scattering kernel.*

Proof. Note that any point that does not belong to the convex hull of the support of q can be separated from that set by a ball. The Hahn–Banach theorem tells us there is a separating hyperplane, and because this convex set is bounded (q has compact support), a large enough ball will approximate the hyperplane as close as necessary on any compact set and thus accomplish the separation. ∎

In the Born approximation, the linear dependence on q allows a stronger statement.

THEOREM 1.6. *For any $b \in L^2(S^{d-1})$, the convex scattering support of the Born back-scattering kernel b is*

1. *the smallest convex set such that there is a q, supported in every neighborhood of that set, with Born back-scattering kernel b;*
2. *the largest convex set that is contained in the convex hull of the support of every q with Born back-scattering kernel equal to b.*

A simple consequence of Theorem 1.6 is that the convex scattering support of a nonzero Born back-scattering kernel is nonempty. A consequence of Corollary 1.3 is that this same conclusion holds for the full back-scattering kernel.

We introduced the convex scattering support of a far field of a source in [8] and [9]. We extended the notion to include fields scattered by a variation in wave speed or an obstacle, in response to a single incident wave, and described one method to compute it. Different methods that compute roughly the same set have also appeared in [10], [12], [13], [4], [6], and [5].

Our main reason for extending the notion of convex scattering support to back-scattering is that the data are more realistically acquired, and therefore, the methods can be more readily adapted to be of practical use. To measure the far field of a single incident wave requires at least two sensors, one at a fixed position that radiates and another that will move around the scatterer to measure the field. Calibration requires accurate knowledge of the angle between the two devices, while back-scattering simply requires moving a single sensor.

It may appear that a condition like (1.10) is difficult to apply to noisy data. Exactly the opposite is true. The coefficients in a Fourier series or spherical harmonic expansion are easily computed. As we will point out in the final section, the function $\sigma_n(2kR)$, viewed as a function of n at a fixed value of $2kR$, is uniformly large for $n < 2kR$ and rapidly becomes uniformly small when $n > 2kR$. Thus, the norm of the terms in the spherical harmonic expansion for $e^{i2k\Theta\cdot c}s(\Theta)$ undergo a rapid transition

to, and become approximately, zero as n passes through the radius of the smallest ball that contains the convex scattering support. This transition is readily observable and remains so in the presence of appreciable noise.

2. The Herglotz, far field, and scattering operators. For any $\delta > \frac{1}{2}$, the unique $L^2_{-\delta}$ solution[3] of the free (homogeneous) Helmholtz equation, parametrized by α, satisfies

$$(\Delta + k^2)v = 0, \tag{2.1}$$

$$v \sim \frac{e^{ikr}}{r^{\frac{d-1}{2}}}\alpha(-\Theta) + \frac{e^{-ikr}}{r^{\frac{d-1}{2}}}\alpha(\Theta), \quad |x| = r \to \infty, \tag{2.2}$$

and may be expressed in terms of the Herglotz operator

$$v(r\Phi) = (\mathcal{H}\alpha)(r\Phi) := k^{\frac{d-1}{2}} \int_{S^{d-1}} e^{ikr\Theta\cdot\Phi}\alpha(\Theta)d\Theta.$$

The adjoint of the Herglotz operator, which maps $L^2_\delta(\mathbb{R}^d)$ into $L^2(S^{d-1})$, is therefore the Fourier transform (times a power of k), followed by restriction to the sphere of radius k, and may be written as

$$(\mathcal{H}^* f)(\Theta) = k^{\frac{d-1}{2}} \int_{\mathbb{R}^d} e^{-ikr\Theta\cdot\Phi} f(r\Phi) r^{d-1} dr d\Phi = k^{\frac{d-1}{2}} \widehat{f}(k\Theta). \tag{2.3}$$

Here we have simply written $d\Phi$ and $d\Theta$ rather than $dS(\Phi)$ and $dS(\Theta)$ to denote the surface measure on the unit sphere S^{d-1}.

We note that for any right-hand-side $f \in L^2_\delta$, with $\delta > 1/2$, the source problem

$$(\Delta + k^2)u = f \tag{2.4}$$

has a unique *outgoing* solution. Such an *outgoing* solution has asymptotics similar to those in (2.2); however, the second term vanishes. Specifically,

$$u \sim \frac{e^{ikr}}{r^{\frac{d-1}{2}}}\beta(\Theta) + \frac{e^{-ikr}}{r^{\frac{d-1}{2}}} \times 0, \quad |x| = r \to \infty. \tag{2.5}$$

The function $\beta \in L^2(S^{d-1})$ is called the far field of the outgoing solution u. We will use the notation

$$u = Gf$$

to denote the solution operator which solves (2.4). Additionally, we define the far field operator $\mathcal{F}$ as the map between the source f and the far field β, so that

$$\beta = \mathcal{F}f.$$

We will make use of the fact that, except for a factor of $2ik$, the far field operator is the adjoint of the Herglotz operator, as follows.

[3] $||u||_{L^2_\delta(\mathbb{R}^d)} = ||(1+|x|^2)^{\frac{\delta}{2}}u||_{L^2(\mathbb{R}^d)}$. These spaces were first used in the context of the Helmholtz equation in [1] as a means for studying long-range potentials. The existence and uniqueness statements we quote here can be found in [8].

PROPOSITION 2.1.

$$\mathcal{F}f = \frac{1}{2ik}\mathcal{H}^* f = \frac{k^{\frac{d-3}{2}}}{2i}\widehat{f}(k\Theta).$$

Proof. The second equality is a consequence of the first and (2.3). To establish the first, we apply Green's formula to u and v as previously defined in (2.4) and (2.1), i.e.,

$$\begin{aligned}(\mathcal{H}\alpha, f) &= (v, f)\\ &= \int_{\mathbb{R}^d} \overline{v} f\\ &= \int_{\mathbb{R}^d} \overline{v}(\Delta + k^2)u - \overline{(\Delta + k^2)v}u\\ &= \lim_{R\to\infty} \int_{S_R^{d-1}} \left(\overline{v}\frac{\partial u}{\partial \nu} - \frac{\overline{\partial v}}{\partial \nu}u\right) d\Theta,\end{aligned}$$

which becomes, on inserting the asymptotics from (2.2) and (2.5),

$$\begin{aligned}&= 2ik\int_{S^{d-1}} \overline{\alpha}\beta d\Theta\\ &= (\alpha, 2ik\mathcal{F}f). \qquad \square\end{aligned}$$

To define the scattering operator, we return to (1.2),

$$(\Delta + k^2)u = qu,$$

and seek u as an *outgoing* perturbation of the solution of the free Helmholtz equation with the incident field $\mathcal{H}\alpha$ so that

$$u = \mathcal{H}\alpha + u_{sc},$$

where u_{sc} is an outgoing solution. This means that u_{sc} is the unique outgoing solution of

$$(\Delta + k^2)u_{sc} = q\mathcal{H}\alpha + qu_{sc}. \tag{2.6}$$

Such an outgoing field has the asymptotics

$$u_{sc} \sim \frac{e^{ikr}}{r^{\frac{d-1}{2}}}\beta_q(\Theta) + \frac{e^{-ikr}}{r^{\frac{d-1}{2}}} \times 0.$$

This observation allows us to define the relative scattering operator

$$\mathcal{S}\alpha = \beta_q.$$

The Born approximation replaces (2.6) with

$$(\Delta + k^2)u_{born} = q\mathcal{H}\alpha. \tag{2.7}$$

The unique outgoing solution has the asymptotics

$$u_{born} \sim \frac{e^{ikr}}{r^{\frac{d-1}{2}}}\beta_{born}(\Theta) + \frac{e^{-ikr}}{r^{\frac{d-1}{2}}} \times 0$$

and so we define the (relative) Born scattering operator

$$\mathcal{B}\alpha = \beta_{born}.$$

The Born scattering operator is the Fréchet derivative of the relative scattering operator with respect to q, evaluated at $q \equiv 0$. The factorizations below (similar to those in [7]) will enable us to derive useful properties of the scattering operator from analogous properties of the Herglotz operator.

PROPOSITION 2.2. *The full relative scattering operator admits the factorization*

$$\mathcal{S} = \frac{1}{2ik}\mathcal{H}^* q(I - Gq)^{-1}\mathcal{H}, \tag{2.8}$$

$$= \frac{1}{2ik}\mathcal{H}^*(I - qG)^{-1}q\mathcal{H}, \tag{2.9}$$

while the Born relative scattering operator may be decomposed as

$$\mathcal{B} = \frac{1}{2ik}\mathcal{H}^* q\mathcal{H}. \tag{2.10}$$

The kernel of the Born relative scattering operator is

$$b(\Theta, \Phi) = \frac{k^{d-2}}{2i}\widehat{q}(k(\Theta - \Phi)). \tag{2.11}$$

Proof. The proof below relies on the invertibility of $(I - qG)$, the proof of which we defer to Lemma 4.1. We begin with (2.6) and apply G to both sides,

$$\begin{aligned} u_{sc} &= G(q\mathcal{H}\alpha + qu_{sc}), \\ (I - Gq)u_{sc} &= Gq\mathcal{H}\alpha, \\ u_{sc} &= (I - Gq)^{-1}Gq\mathcal{H}\alpha, \\ &= G(I - qG)^{-1}q\mathcal{H}\alpha \end{aligned}$$

so that the far field of u_{sc} is

$$\begin{aligned} \mathcal{S}\alpha &= \mathcal{F}(I - qG)^{-1}q\mathcal{H}\alpha \\ &= \frac{1}{2ik}\mathcal{H}^*(I - qG)^{-1}q\mathcal{H}\alpha, \end{aligned}$$

establishing (2.8). The analogous calculation applied to (2.7) instead of (2.6) establishes (2.10). Once we know that $(I - qG)$ is invertible, the identity

$$(I - qG)^{-1}q = q(I - Gq)^{-1}$$

follows from

$$q(I - Gq) = (I - qG)q,$$

which transforms (2.9) into (2.8). Finally, writing the integral representation of (2.10) as

$$\begin{aligned} \mathcal{B}\alpha &= \frac{k^{d-2}}{2i}\int_{\mathbb{R}^d} e^{-irk\Psi\cdot\Phi}q(r\Psi)\left[\int_{S^{d-1}} e^{irk\Theta\cdot\Psi}\alpha(\Theta)d\Theta\right] r^{d-1}drd\Psi \\ &= \frac{k^{d-2}}{2i}\int_{S^{d-1}}\left[\int_{\mathbb{R}^d} e^{-irk(\Phi-\Theta)\cdot\Psi}q(r\Psi)r^{d-1}drd\Psi\right]\alpha(\Theta)d\Theta \end{aligned}$$

yields (2.11). ∎

3. The Herglotz operator and the spherical harmonics. In this and the next sections, the notation will be slightly less cluttered if we restrict to the case $k = 1$. Because of the representations of the scattering operator in (2.8) and (2.9), the properties of the Herglotz operator will figure prominently into our analysis of the scattering operator. The singular value decomposition of the Herglotz operator in terms of the spherical harmonics and (spherical) Bessel functions will provide a basic tool for all our subsequent calculations. We begin with the expansion of an incident plane wave in spherical harmonics, which for $\Theta, \Phi \in S^{d-1}$ and $0 \leq r < \infty$ is

$$e^{ir\Theta\cdot\Phi} = \sum_{n=0}^{\infty} i^n j_n(r) p_n(\Theta \cdot \Phi).$$

The most useful way to define the functions p_n in our context is as the kernel of the orthogonal projection, $\mathcal{P}_n$, from $L^2(S^{d-1})$ onto the subspace of degree n spherical harmonics, i.e.,

$$\left(\mathcal{P}_n \alpha\right)(\Theta) = \int_{S^{d-1}} p_n(\Theta \cdot \Phi)\alpha(\Phi) d\Phi.$$

The functions $p_n(\Theta \cdot \Phi)$ play a dual role: they act as both kernels of projection operators and are themselves spherical harmonics. When we wish to emphasize their second role we will write

$$p_n^{\Phi}(\Theta) := p_n(\Theta \cdot \Phi).$$

Up to a constant, the function p_n^{Φ} is the unique spherical harmonic that is invariant under rotations about the Φ axis [11]. The constants involved here will be important to us, hence we compute

$$\begin{aligned} \mathcal{P}_n p_n^{\Phi} &= p_n^{\Phi}, \\ \int_{S^{d-1}} p_n^{\Psi}(\Theta) p_n^{\Phi}(\Theta) d\Theta &= p_n^{\Phi}(\Psi), \end{aligned}$$

from which we learn that

$$||p_n^{\Psi}||_{L^2}^2 = p_n^{\Psi}(\Psi)$$

is independent of Ψ and

$$= ||p_n^{\Psi}||_{L^\infty}.$$

If we take the trace of the operator $\mathcal{P}_n$, we see that

$$\begin{aligned} \mathrm{tr}\mathcal{P}_n &= \int_{S^{d-1}} p_n(\Theta \cdot \Theta) d\Theta, \\ N &= p_n(\Theta \cdot \Theta)\ \omega, \end{aligned}$$

where ω denotes the volume of the d-dimensional sphere and $N = N(n, d)$ the dimension of the space of spherical harmonics of degree n. Hence, we conclude that

$$||p_n^{\Phi}||_{L^2}^2 = ||p_n^{\Phi}||_{L^\infty} = p_n^{\Phi}(\Phi) = \frac{N}{\omega}.$$

In terms of the standard Legendre functions, P_n, we have the relation

$$p_n(\Theta \cdot \Phi) = \frac{N}{\omega} P_n(\Theta \cdot \Phi).$$

The Bessel functions $j_n(r)$ are most easily defined in terms of the Herglotz operator acting on the p_n. Recalling that $p_n^\Phi = p_n(\Theta \cdot \Phi)$ acts as both a spherical harmonic and the kernel of a projection, we see that

$$\begin{aligned} \mathcal{H} p_n^\Phi &= \int_{S^{d-1}} e^{ir\Theta\cdot\Psi} p_n(\Theta \cdot \Phi) d\Theta \\ &= \mathcal{P}_n e^{ir\Theta\cdot\Psi} \end{aligned} \tag{3.1}$$

so that $\mathcal{H} p_n^\Phi$, for each fixed r, must again be a spherical harmonic of degree n. We can check that the right-hand side of (3.1) is invariant under rotations about the Φ-axis and thus must be equal to a constant multiple of p_n^Φ itself. Specifically, this constant is i^n times the spherical Bessel function, i.e.,

$$\mathcal{H} p_n^\Phi = i^n j_n(r) p_n^\Phi. \tag{3.2}$$

Because the p_n's act also as projection kernels, we see that any spherical harmonic of degree n may replace p_n^Φ in (3.2). The Herglotz operator is not compact. However, if we compose it with the restriction to the ball of radius R, the composition is compact. We denote the resulting operator by $\mathcal{H}_R$ and describe its singular value decomosition.

$$\begin{aligned} \mathcal{H}_R &= \sum_{n=0}^{\infty} \sigma_n(R) \frac{j_n^R(r)}{||j_n^R||} \mathcal{P}_n \\ &= \sum_{n=0}^{\infty} \sigma_n(R) \mathcal{Q}_n. \end{aligned} \tag{3.3}$$

We have used the notation j_n^R to denote the Bessel function multiplied by the characteristic function of $B_0(R)$, the ball of radius R centered at 0, and defined the singular values

$$\sigma_n^2(R) := ||j_n||^2_{L^2(B_0(R))}.$$

Each projection operator

$$\mathcal{Q}_n := \frac{j_n^R(r)}{||j_n^R||} \mathcal{P}_n$$

is an isometry from the N-dimensional space of spherical harmonics of degree n in $L^2(S^{d-1})$ to an N-dimensional subspace of $L^2(B_0(R))$. In short, we find that the $\mathcal{Q}_n$ simply project onto the spherical harmonics of degree n and then multiply the result by $\frac{j_n^R(r)}{||j_n^R||}$.

Since the singular values all have multiplicity greater than one, this looks a little different from the more familiar version of the singular value decomposition. A compact linear operator K admits the representation

$$\begin{aligned} K &= \sum_{n=0}^{\infty} \lambda_n \Psi_n \otimes \Phi_n \\ &= \sum_{n=0}^{\infty} \lambda_n \tilde{\mathcal{Q}}_n. \end{aligned} \tag{3.4}$$

In this case, Ψ_n and Φ_n are orthonormal basis vectors so that the tensor products $\tilde{\mathcal{Q}}_n = \Psi_n \otimes \Phi_n$ are isometries between one-dimensional subspaces.

The corresponding singular value decomposition for the operator ${\mathcal{H}_R}^*$ is

$$ {\mathcal{H}_R}^* = \sum_{n=0}^{\infty} \sigma_n(R) \mathcal{Q}_n^*, \tag{3.5} $$

and the ranges of the $\mathcal{Q}_n^*$ are exactly the subspaces of spherical harmonics of degree n. Note that as no $\sigma_n(R)$ is zero, ${\mathcal{H}_R}^*$ has dense range in $L^2(S^{d-1})$.

Now, we recall the following.

THEOREM 3.1 (Picard's theorem). *If $K : X \to Y$ is a compact linear operator with dense range in Y and has a singular value decomposition of the form given in* (3.4)*, then*

$$ \alpha = Kf $$

if and only if

$$ \sum_{n=0}^{\infty} \frac{||\mathcal{Q}_n \alpha||^2}{\lambda_n^2} < \infty $$

and $\alpha \in N(K^*)^{\perp}$.

The proof of Theorem 1.1 is now in hand.

Proof of Theorem 1.1. The second equality in (1.7) follows from (2.11) on setting $\Phi = -\Theta$. Now, scaling the Fourier transform gives

$$ b(\Theta) = \frac{1}{2i} \widehat{q}(2\Theta) = 2^{-d} \mathcal{H}^* q(x/2). $$

The Picard theorem applied to $\mathcal{H}_R^*$ tells us that in the case $c = 0$, if the $\operatorname{supp} q \subset B_c(R)$, then b satisfies (1.8). It also tells us the converse, that if b satisfies (1.8), there exists a $q \in L^2(\mathbb{R}^d)$ with $\operatorname{supp} q \subset B_c(R)$ and Born-back-scattering kernel $b(\Theta)$.

The Fourier shift theorem tells us that the Fourier transform—and therefore $\mathcal{H}^*$ and $\mathcal{H}_R^*$—intertwines translation by c and multiplication by $e^{ik\Theta \cdot c}$, i.e.,

$$ e^{ik\Theta \cdot c} \mathcal{H}^* q = \mathcal{H}^* T_c q := \mathcal{H}^* q(x - c), $$

which establishes the corresponding conclusions for arbitrary c.

So far we have shown that every ball for which (1.8) is satisfied supports a q with Born-back-scattering kernel b. We now wish to demonstrate that any open neighborhood of their intersection supports such a q as well. As a consequence of Lemma 3.2, given below, we find that if each of two convex sets support potentials q with corresponding Born-back-scattering kernel b, then so must any neighborhood of their intersection.

LEMMA 3.2. *Suppose the* $\operatorname{supp}\ q_1 \subset \Omega_1$*, the* $\operatorname{supp}\ q_2 \subset \Omega_2$*, and that $\mathbb{R}^d \setminus (\Omega_1 \bigcup \Omega_2)$ is connected and contains a neighborhood of ∞. If*

$$ \mathcal{H}^* q_1 = \mathcal{H}^* q_2 = b, \tag{3.6} $$

then, for any $\varepsilon > 0$, there exists an $q_3 \in C^{\infty}(\mathbb{R}^d)$ with

$$ \operatorname{supp} q_3 \subset \mathcal{N}_{\varepsilon}(\Omega_1 \cap \Omega_2) $$

and

$$\mathcal{H}^* q_3 = b.$$

Proof. A consequence of (3.6) is that the outgoing solutions of

$$\left(\Delta + (2k)^2\right) u_i = q_i, \quad i = 1, 2,$$

$u_1 = Gq_1$, and $u_2 = Gq_2$ have the same far field. According to Rellich's lemma and the unique continuation principle [2], u_1 and u_2 also agree on the $\mathbb{R}^d \setminus (\Omega_1 \bigcup \Omega_2)$. Let $\phi \in C^\infty(\mathbb{R}^d)$ satisfy

$$\phi = \begin{cases} 1, & x \in \mathbb{R}^n \backslash \mathcal{N}_\varepsilon(\Omega_1 \cap \Omega_2), \\ 0, & x \in \mathcal{N}_{\frac{\varepsilon}{2}}(\Omega_1 \cap \Omega_2); \end{cases}$$

then,

$$v = \begin{cases} \phi u_1, & x \in \mathbb{R}^d \backslash \Omega_1, \\ \phi u_2, & x \in \mathbb{R}^d \backslash \Omega_2, \\ 0, & x \in \Omega_1 \cap \Omega_2, \end{cases}$$

is a well-defined C^∞ function and $v = u_1 = u_2$ outside a compact set so that

$$q_3 = (\Delta + (2k)^2) v$$

must also have $\mathcal{H}^* q_3 = b$. ∎

Because the intersection of convex sets is convex, and the complement of the union of two convex sets must be connected, the lemma can be applied repeatedly to produce a $q \in C^\infty$ satisfying the (apparently weaker) analogue of (1.9) with $\mathcal{B}$ replaced by any finite collection of balls, $B_c(R)$, for which (1.8) holds. The following compactness argument shows that (1.9) follows from this analogue. Let R_0 be large enough that $\mathcal{N}_\epsilon(\cap_{B_c(R) \in \mathcal{B}} B_c(R)) \subset B_0(R_0)$, then $B_0(R_0) \setminus \mathcal{N}_\epsilon(\cap_{B_c(R) \in \mathcal{B}} B_c(R))$ is a compact set covered by the relatively open subsets $B_0(R_0) \setminus B_c(R)$, so a finite subcollection, $\mathcal{B}_\mathcal{M}$, of these open subsets suffices to cover that compact set, i.e.,

$$B_0(R_0) \setminus \mathcal{N}_\epsilon\left(\bigcap_{B_c(R) \in \mathcal{B}} B_c(R) \right) \subset \bigcup_{B_c(R) \in \mathcal{B}_\mathcal{M}} \Big(B_0(R_0) \setminus B_c(R) \Big). \tag{3.7}$$

Taking complements of this inclusion yields

$$\mathcal{N}_\epsilon\left(\bigcap_{B_c(R) \in \mathcal{B}} B_c(R) \right) \supset \bigcap_{B_c(R) \in \mathcal{B}_\mathcal{M}} B_c(R),$$

from which we conclude that (1.9) follows from its apparently weaker analogue. This finishes the proof of Theorem 1.1. ∎

4. Estimating the full back-scattering kernel. This section is composed of three main propositions, and a few supporting lemmas, which combine to prove Theorem 1.2. We begin with the following lemma concerning the invertibility of the operator $I - Gq$.

LEMMA 4.1. *Let $q \in L^\infty(\mathbb{R}^d)$ and be compactly supported. Then $q(I-Gq)^{-1}$ is a bounded operator from $L^2(\mathbb{R}^d)$ to itself. Moreover, let $q \in L^p(\mathbb{R}^d)$, with $p > \max(2, \frac{d}{2})$, be compactly supported. Then,*

$$q(I-Gq)^{-1} = q + Gq(I-Gq)^{-1}$$

and $Gq(I-Gq)^{-1}$ and $(I-Gq)^{-1}$ are bounded operators from $L^2(\mathbb{R}^d)$ to itself.

Proof. The lemma is a special consequence of Lemma 12 and Corollaries 13, 14, and 15 of [9]. Roughly speaking, multiplication by q loses $\frac{d}{p}$ L^2-derivatives, while G gains two. This implies that Gq is compact and that $I-Gq$ is Fredholm. If zero were an eigenvalue of $I-Gq$, then the corresponding eigenfunction would be a nonzero outgoing solution to (1.2). An application of Green's formula to this solution and its complex conjugate shows that this outgoing solution would have zero far field. Rellich's lemma and unique continuation imply that any outgoing solution with zero far field is identically zero. Thus zero is not an eigenvalue and $I-Gq$ is invertible. ∎

PROPOSITION 4.2. *If $q \in L^\infty$, the $\operatorname{supp} q \subset B_c(R)$, then scattering operator may be factored as,*

$$\mathcal{S} = e^{-i\Theta\cdot c}\mathcal{H}_R^* B \mathcal{H}_R e^{i\Theta\cdot c}, \tag{4.1}$$

where B is a bounded operator from $L^2(\mathbb{R}^d)$ to itself.

Proof. Because $\mathcal{H}$ intertwines translation by c and multiplication by $e^{ik\Theta\cdot c}$, i.e.,

$$\mathcal{H}e^{-i\Theta\cdot c} = T_c\mathcal{H},$$

it is enough to treat the case $c=0$. We begin with (2.9),

$$\mathcal{S} = \mathcal{H}^*(I-qG)^{-1}q\mathcal{H},$$

then insert a characteristic function of the ball

$$= \mathcal{H}^*(I-qG)^{-1}q\chi_R\mathcal{H}, \tag{4.2}$$

then shift to (2.8)

$$= \mathcal{H}^* q(I-Gq)^{-1}\chi_R\mathcal{H}$$

and again insert another characteristic function

$$= \mathcal{H}^*\chi_R q(I-Gq)^{-1}\chi_R\mathcal{H}, \tag{4.3}$$

which we recognize as

$$= \mathcal{H}_R^* q(I-Gq)^{-1}\mathcal{H}_R. \tag{4.4}$$

Finally, we observe that the operator in the middle is bounded according to Lemma 4.1. ∎

Remark 4.3. The only property of the scattering operator that we will use in the sequel is (4.1). The conclusions of Theorem 1.2 apply to any operator which admits such a factorization.

Remark 4.4. So as not to unnecessarily complicate the subsequent discussion, we will continue working with $q \in L^\infty$ in the rest of this section. Theorem 1.2, however,

remains true for compactly supported $q \in L^p(\mathbb{R}^d)$ with $p > \max(2, \frac{d}{2})$. In this case, the scattering operator is the sum of two operators,

$$\begin{aligned} \mathcal{S} &= \mathcal{H}_R^* q(I - Gq)^{-1}\mathcal{H}_R \\ &= \mathcal{H}_R^* q\mathcal{H}_R + \mathcal{H}_R^* Gq(I - Gq)^{-1}\mathcal{H}_R. \end{aligned} \tag{4.5}$$

The first is the Born scattering operator and the second satisfies (4.1) with a $B = Gq(I - Gq)^{-1}$ which is bounded from $L^2(\mathbb{R}^d)$ to itself.

The factorization (4.1) combines with the singular values of the Herglotz operator to give some natural estimates for the terms in what we might call a *block decomposition* of the scattering operator.

PROPOSITION 4.5. *Let $\mathcal{S}$, mapping $L^2(S^{d-1})$ to itself, admit the factorization (4.1); then $\mathcal{S}_{nm}$, defined as*

$$\mathcal{S}_{nm} = \mathcal{P}_n \mathcal{S} \mathcal{P}_m, \tag{4.6}$$

has an L^∞ kernel $s_{nm}(\Theta, \Phi)$ and satisfies

$$\begin{aligned} ||\mathcal{S}_{nm}|| &\le \sigma_n(R)\sigma_m(R)\ ||B||, \\ |s_{nm}(\Theta, \Phi)| &\le \sqrt{N}\sigma_n(R)\sqrt{M}\sigma_m(R)\ ||B||. \end{aligned} \tag{4.7}$$

Proof. We insert the factorization (4.1) into (4.6),

$$\begin{aligned} \mathcal{S}_{nm} &= \mathcal{P}_n \mathcal{H}_R^* B \mathcal{H}_R \mathcal{P}_m \\ &= (\mathcal{H}_R \mathcal{P}_n)^* B \mathcal{H}_R \mathcal{P}_m, \end{aligned}$$

and use our singular value decompositions, (3.3) and (3.5),

$$= \sigma_n \sigma_m \mathcal{Q}_n^* B \mathcal{Q}_m, \tag{4.8}$$

so that

$$||\mathcal{S}_{nm}|| \le \sigma_n \sigma_m ||B||.$$

Recalling again that the p_n^Θ are kernels of the $\mathcal{P}_n$, we see that the kernel of $\mathcal{S}_{nm}$ is given by

$$\begin{aligned} s_{nm}(\Theta, \Phi) &= \left(p_n^\Theta, \mathcal{S} p_m^\Phi\right)_{L^2(S^{d-1})} \\ &= \left(p_n^\Theta, \mathcal{S}_{nm} p_m^\Phi\right)_{L^2(S^{d-1})}, \\ |s_{nm}(\Theta, \Phi)| &\le ||p_n^\Theta||\ ||\mathcal{S}_{nm}||\ ||p_m^\Phi|| \\ &\le \sqrt{N}\sigma_n(R)\sigma_m(R)||B||\sqrt{M}. \end{aligned}$$

∎

The main conclusion of Theorem 1.2 is the estimate (1.10) of the left-hand side of the identity (4.9) below. We will apply (4.7) to show that the series on the right-hand side is summable and then to prove (1.10).

$$\mathcal{P}_l s(\Theta, -\Theta) = \sum_{n,m} \mathcal{P}_l s_{nm}(\Theta, -\Theta). \tag{4.9}$$

The next proposition tells us that many of the terms in the series are zero.

PROPOSITION 4.6.

$$\mathcal{P}_l(s_{nm}(\Theta,-\Theta)\equiv 0$$

unless the sum of any two indices is greater than or equal to the third.

Proof.

$$\begin{aligned}
s_{nm}(\Theta,-\Theta) &= \left(p_n^{-\Theta},\mathcal{S}p_m^{\Theta}\right)_{L^2(S^{d-1})}\\
&= \left(\int_{S^{d-1}} p_n(\Theta\cdot\Psi_1)p_n^{\Psi_1}d\Psi_1,\mathcal{S}\int_{S^{d-1}} p_m(\Theta\cdot\Psi_2)p_m^{\Psi_2}d\Psi_2\right)\\
&= \int_{S^{d-1}}\int_{S^{d-1}} p_n(\Theta\cdot\Psi_1)p_m(\Theta\cdot\Psi_2)\left(p_n^{\Psi_1},\mathcal{S}p_m^{\Psi_2}\right)d\Psi_1 d\Psi_2\\
\mathcal{P}_l s_{nm}(\tau) &= \int_{S^{d-1}}\int_{S^{d-1}}\left[\int_{S^{d-1}} p_l(\Theta\cdot\tau)p_n(\Theta\cdot\Psi_1)p_m(\Theta\cdot\Psi_2)d\Theta\right]\left(p_n^{\Psi_1},\mathcal{S}p_m^{\Psi_2}\right)d\Psi_1 d\Psi_2.
\end{aligned}$$

The quantities in the square brackets are closely related to the Clebsch–Gordon coefficients [14]. To see that they must be zero, fix Ψ_1 and Ψ_2, and call the quantity in the square brackets $c_{nml}(\tau)$. Since $p_l^\tau(\Theta)=p_l(\Theta\cdot\tau)$ is the kernel of the projection operator $\mathcal{P}_l$ onto degree l spherical harmonics, we see that $c_{nml}(\tau)$ are the degree l spherical harmonics in the condensed spherical harmonic expansion of the product of the two spherical harmonics, $p_n^{\Psi_1}$ and $p_m^{\Psi_2}$, i.e.,

$$p_n^{\Psi_1}(\Theta)p_m^{\Psi_2}(\Theta)=\sum_{l=0}^{\infty}c_{nml}(\Theta).$$

Recalling that every spherical harmonic extends to a homogeneous polynomial of the same degree, we see that the left-hand side extends to the unit ball as a homogeneous polynomial of degree $n+m$ if we replace Θ by $r\Theta$. Since the left-hand side goes to zero as r^{n+m} as $r\to 0$, so must the right-hand side. This is possible only if the c_{nml}, which extend as homogeneous degree l polynomials, are zero for all $l<n+m$. Finally, note that all conclusions remain valid if we permute the indices n, m, and l. ∎

Proof of Theorem 1.2. We start by applying Propositions 4.2 and 4.5 to conclude that

$$|s_{nm}(\Theta,\Phi)|\le ||q(I-Gq)^{-1}||\sqrt{N}\sigma_n(R)\sqrt{M}\sigma_m(R). \tag{4.10}$$

We set $\Phi=-\Theta$ and let $s_{nm}(\Theta)=s_{nm}(\Theta,-\Theta)$.

Now, (4.10) tells us that the terms $|s_{nm}(\Theta)|$ are summable. Hence, we may write

$$s(\Theta)=\sum_{n,m=0}^{\infty}s_{nm}(\Theta)$$

and therefore

$$\mathcal{P}_l s(\Theta)=\sum_{n,m=0}^{\infty}\mathcal{P}_l s_{nm}(\Theta),$$

which is the same as

$$= \sum_{n+m\geq l} \mathcal{P}_l s_{nm}(\Theta)$$

according to Proposition 4.6. Hence

$$||\mathcal{P}_l s||_{L^2} \leq \sum_{n+m\geq l} ||\mathcal{P}_l s_{nm}(\Theta)||_{L^2} \tag{4.11}$$

$$\leq \sum_{n+m\geq l} ||s_{nm}(\Theta)||_{L^2}.$$

Recalling that ω is the area of S^{d-1},

$$\leq \sqrt{\omega} \sum_{n+m\geq l} ||s_{nm}(\Theta)||_{L^\infty} \tag{4.12}$$

$$\leq \sqrt{\omega}||q(I-Gq)^{-1}|| \sum_{n+m\geq l} \sqrt{N}\sigma_n(R)\sqrt{M}\sigma_m(R).$$

Finally, Proposition 4.7, which we state and prove below, estimates the sum on the right-hand side in terms of $\sigma_l(2R)$.

$$\leq ||q(I-Gq)^{-1}|| \frac{\omega\sqrt{2}\, R^{\frac{d}{2}}}{(1-\frac{2R}{l})(1-\frac{R^2}{l+\frac{d}{2}})^2}\ \sqrt{L}\ \sigma_l(2R). \tag{4.13}$$

This completes the proof for $q \in L^\infty$. For $q \in L^p(\mathbb{R}^d)$ with $p > \max(2, \frac{d}{2})$, we return to (4.5) and notice that Theorem 1.2 holds for each of the two terms. It holds for the first because it is a Born back-scattering kernel and for the second because the operator in the middle is bounded. It is not hard to see that the conclusion will persist for the sum. □

The next proposition provides an estimate of the right-hand side of (4.13) and thus yields the last ingredient necessary to establish Theorem 1.2.

PROPOSITION 4.7.

$$\sum_{n+m\geq l} \sqrt{N}\ \sigma_n(R)\sqrt{M}\ \sigma_m(R) \leq \frac{\sqrt{2\omega}\ R^{\frac{d}{2}}}{(1-\frac{2R}{l})(1-\frac{R^2}{l+\frac{d}{2}})^2}\ \sqrt{L}\ \sigma_l(2R). \tag{4.14}$$

Proof. The proof requires several small lemmas. The first allows us to estimate the $\sigma_n(r)$ from above and below by ratios of Γ-functions and powers of r.

LEMMA 4.8.

$$\frac{\Gamma(\frac{d}{2})(\frac{r}{2})^n}{\Gamma(n+\frac{d}{2})}\left(1-\frac{(\frac{r}{2})^2}{n+\frac{d}{2}}\right) \leq j_n(r) \leq \frac{\Gamma(\frac{d}{2})(\frac{r}{2})^n}{\Gamma(n+\frac{d}{2})}, \tag{4.15}$$

$$\frac{\sqrt{\omega}\ 2^{\frac{d-1}{2}}\Gamma(\frac{d}{2})(\frac{r}{2})^{n+\frac{d}{2}}}{\Gamma(n+\frac{d+1}{2})}\left(1-\frac{(\frac{r}{2})^2}{n+\frac{d}{2}}\right) \leq \sigma_n(r) \leq \frac{\sqrt{\omega}\ 2^{\frac{d}{2}}\Gamma(\frac{d}{2})(\frac{r}{2})^{n+\frac{d}{2}}}{\Gamma(n+\frac{d+1}{2})}. \tag{4.16}$$

Proof. The first inequality, (4.15), is just the statement that the spherical Bessel function lies between the first and the partial sum of the first two terms of its alternating power series expansion. The second is obtained from the first by squaring, integrating over the ball of radius r, and making use of (4.18). □

The dimensions N of the spaces of spherical harmonics of degree n also appear on the left-hand side of (4.14). We will estimate them from above and below in terms of Γ-functions as well.

LEMMA 4.9.

$$N(n,d) = \begin{cases} 1, & n = 0, \\ d, & n = 1, \\ \frac{(2n+d-2)(n+d-3)!}{n!(d-2)!} & \text{otherwise}, \end{cases}$$

$$\frac{\Gamma(n+d-1)}{\Gamma(n+1)\Gamma((d-1)} \leq N \leq 2\frac{\Gamma(n+d-1)}{\Gamma(n+1)\Gamma(d-1)}. \tag{4.17}$$

Proof. The first formula follows from the observation that N satisfies the difference equation

$$N(n,d) = N(n,d-1) + N(n-1,d)$$

and the fact that (4.9) holds in the special cases $n = 0$ and $d = 2$. See [11] for a different proof. The inequality (4.17) follows from this formula and

$$n + d - 2 \leq 2n + d - 2 \leq 2(n + d - 2). \qquad \square$$

The ratio $\frac{s!}{(s-1)!} = \frac{\Gamma(s+1)}{\Gamma(s)} = s$. We need to estimate the analogous ratio when one of the arguments is a half integer. For this we state the following lemma.

LEMMA 4.10.

$$\left(s - \frac{1}{2}\right)^{\frac{1}{2}} \leq \frac{\Gamma(s+\frac{1}{2})}{\Gamma(s)} \leq s^{\frac{1}{2}}. \tag{4.18}$$

Proof. Because the gamma function is log-convex [3],

$$\Gamma\left(s + \frac{1}{2}\right) \leq \Gamma(s)^{\frac{1}{2}}\Gamma(s+1)^{\frac{1}{2}},$$
$$\frac{\Gamma(s+\frac{1}{2})}{\Gamma(s)} \leq \frac{\Gamma(s+1)^{\frac{1}{2}}}{\Gamma(s)^{\frac{1}{2}}} = s^{\frac{1}{2}}.$$

Analogously,

$$\Gamma(s) \leq \Gamma\left(s - \frac{1}{2}\right)^{\frac{1}{2}} \Gamma\left(s + \frac{1}{2}\right)^{\frac{1}{2}},$$
$$\frac{\Gamma(s)}{\Gamma(s+\frac{1}{2})} \leq \frac{\Gamma(s-\frac{1}{2})^{\frac{1}{2}}}{\Gamma(s+\frac{1}{2})^{\frac{1}{2}}} = \frac{1}{(s-\frac{1}{2})^{\frac{1}{2}}}. \qquad \square$$

We use Lemma 4.10 to establish a replacement for the binomial theorem involving Γ-functions of half integers rather than just factorials.

LEMMA 4.11.

$$\sum_{n+m=l} \frac{1}{\Gamma(n+\frac{d+1}{2})} \frac{1}{\Gamma(m+\frac{d+1}{2})} \leq \frac{2^{l+d-1}}{\Gamma(l+d)}.$$

Proof. If d is odd, the inequality is an equality which follows from the binomial expansion of $(1+1)^{l+d-1}$. If d is even, we use (4.18),

$$\begin{aligned}\sum_{n+m=l} \frac{1}{\Gamma(n+\frac{d+1}{2})}\frac{1}{\Gamma(m+\frac{d+1}{2})} &\le \sum_{n+m=l} \frac{(n+\frac{d}{2})^{\frac{1}{2}}}{\Gamma(n+\frac{d}{2}+1)}\frac{(m+\frac{d}{2})^{\frac{1}{2}}}{\Gamma(m+\frac{d}{2}+1)}\\ &\le \left(l+\frac{d}{2}\right)\sum_{n+m=l}\frac{1}{\Gamma(n+\frac{d}{2}+1)}\frac{1}{\Gamma(m+\frac{d}{2}+1)}\\ &= \left(l+\frac{d}{2}\right)\frac{2^{l+d}}{\Gamma(l+d+1)}\\ &\le \frac{2^{l+d}}{\Gamma(l+d)}. \qquad \square\end{aligned}$$

The sum in (4.14) is in fact a double summation over the indices n and m. Hence, we first estimate each single sum in Lemma 4.12 and then sum those estimates in Lemma 4.13 to estimate the double summation.

LEMMA 4.12.

$$\sum_{n+m=l} \sqrt{N}\,\sigma_n(R)\sqrt{M}\,\sigma_m(R) \le \frac{\sqrt{2\omega}\,R^{\frac{d}{2}}}{(1-\frac{R^2}{l+\frac{d}{2}})}\sqrt{L}\,\sigma_l(2R).$$

Proof.

$$\sum_{n+m=l} \sqrt{N}\,\sigma_n(R)\sqrt{M}\,\sigma_m(R) \le L\sum_{n+m=l}\sigma_n(R)\,\sigma_m(R). \tag{4.19}$$

We apply (4.15) from Lemma 4.8,

$$\le \omega 2^{d-1}\Gamma^2\left(\frac{d}{2}\right)\left(\frac{R}{2}\right)^{l+d} L\sum_{n+m=l}\frac{1}{\Gamma(n+\frac{d+1}{2})}\frac{1}{\Gamma(m+\frac{d+1}{2})},$$

then Lemma 4.11

$$\le \omega 2^{d-1}\Gamma^2\left(\frac{d}{2}\right)\left(\frac{R}{2}\right)^{l+d} L\frac{2^{l+d}}{\Gamma(l+d)},$$

followed by the left inequality in (4.16) of Lemma 4.8,

$$\le \frac{\sqrt{\omega}\sqrt{L}\sigma_l(2R)}{(1-\frac{R^2}{l+\frac{d}{2}})} \quad \left(2^{\frac{d-1}{2}}\left(\frac{R}{2}\right)^{\frac{d}{2}}\right) \quad \left(\Gamma(\frac{d}{2})\sqrt{L}\frac{\Gamma(l+\frac{d+1}{2})}{\Gamma(l+d)}\right), \tag{4.20}$$

and finally (4.17) to see that the third factor in (4.20) is less than 2,

$$\le \frac{\sqrt{\omega}\sqrt{L}\sigma_l(2R)}{(1-\frac{R^2}{l+\frac{d}{2}})} \quad \left(2^{\frac{d+1}{2}}\left(\frac{R}{2}\right)^{\frac{d}{2}}\right). \qquad \square \tag{4.21}$$

Finally, we complete these estimates with the next lemma.

LEMMA 4.13.

$$\sum_{l=l_0}^{\infty}\sqrt{L}\,\sigma_l \le \frac{\sqrt{L_0}\,\sigma_{l_0}}{(1-\frac{R}{l_0})(1-\frac{R^2}{4l_0+2d})}. \tag{4.22}$$

Proof.

$$\sum_{l=l_0}^{\infty} \sqrt{L}\, \sigma_l \leq \sqrt{L_0}\, \sigma_{l_0} \left(1 + \sum_{l=l_0+1}^{\infty} \sqrt{\frac{L}{L_0}}\, \frac{\sigma_l}{\sigma_{l_0}} \right).$$

According to Lemma 4.9,

$$\leq \sqrt{L_0}\sigma_{l_0} \left(1 + \sum_{k=1}^{\infty} \sqrt{\frac{\Gamma(l_0+k+d-1)\Gamma(l_0+1)}{\Gamma(l_0+d-1)\Gamma(l_0+k+1)}}\, \frac{\sigma_l}{\sigma}_{l_0} \right).$$

Estimating the square root gives

$$\leq \sqrt{L_0}\sigma_{l_0} \left(1 + \sum_{k=1}^{\infty} \left(1 + \frac{d-2}{l_0+1} \right)^{\frac{k}{2}}\, \frac{\sigma_l}{\sigma}_{l_0} \right). \tag{4.23}$$

Next, we apply both upper and lower bounds in (4.16) of Lemma 4.8,

$$\leq \sqrt{L_0}\sigma_{l_0} \left(1 + \sum_{k=1}^{\infty} \left(1 + \frac{d-2}{l_0+1} \right)^{\frac{k}{2}}\, \left(\frac{R}{2} \right)^k \frac{\Gamma(l_0+\frac{d+1}{2})}{\Gamma(l_0+k+\frac{d+1}{2})}\, \frac{1}{1-\frac{R^2}{4l_0+2d}} \right), \tag{4.24}$$

and finally estimate the ratio of Gamma functions, and compare to a geometric series,

$$\begin{aligned} &\leq \sqrt{L_0}\sigma_{l_0} \left(1 + \sum_{k=1}^{\infty} \left(1 + \frac{d-2}{l_0+1} \right)^{\frac{k}{2}}\, \frac{\left(\frac{R}{2}\right)^k}{(l_0+\frac{d+1}{2})^k} \frac{1}{1-\frac{R^2}{4l_0+2d}} \right) \\ &\leq \frac{\sqrt{L_0}\sigma_{l_0}}{1-\frac{R^2}{4l_0+2d}} \left(1 + \sum_{k=1}^{\infty} \left(\frac{(1+\frac{d-2}{l_0+1})^{\frac{1}{2}} r}{l_0+\frac{d+1}{2}} \right)^k \right) \\ &\leq \frac{\sqrt{L_0}\sigma_{l_0}}{1-\frac{R^2}{4l_0+2d}} \sum_{k=0}^{\infty} \left(\frac{r}{l_0}\, \frac{\sqrt{1+\frac{d-2}{l_0+1}}}{1+\frac{d+1}{2l_0}} \right)^k \\ &\leq \frac{\sqrt{L_0}\sigma_{l_0}}{1-\frac{R^2}{4l_0+2d}} \sum_{k=0}^{\infty} \left(\frac{r}{l_0} \right)^k. \end{aligned} \tag{4.25}$$

Hence, (4.22) follows on summing the geometric series. ∎

We need only observe that a combination of Lemmas 4.12 and 4.13 implies (4.14) to finish the proof of Proposition 4.7. ∎

5. Numerical applications. In this section, we illustrate a method for finding the convex back-scattering support with a simple example in two dimensions. Here, our scatterer is rectangle R_q,

$$R_q = \{(x,y) \in \mathbb{R}^2 : -1 \leq x \leq 1, -1/2 \leq y \leq 1/2\},$$

having horizontal sides at $x = \pm 1$ and vertical sides at $y = \pm 0.5$. We computed the full (not the Born) back-scattering kernel numerically, using the Helmholtz equation

$$(\Delta + k^2 n^2(x))u = 0$$

with the wavenumber $k = 5$ and index of refraction given by the formula

$$n^2 = \begin{cases} 2 & x \in R_q, \\ 1 & x \notin R_q. \end{cases}$$

5.1. The forward solution. In this section we explain how we computed the back-scattering kernel that we will use as data to numerically determine the convex back-scattering support for our example to follow.

For each incident wave, we employ a two-step process. First, we solved a discretized version of the Lippmann–Schwinger integral equation (LSIE) for the total field u on (a region slightly larger than) the support of the scatterer, using a Nyström, or collocation, method. Next, we use the product qu as a source and numerically integrate it against the two-dimensional version of the far field operator $\mathcal{F}$, computing only the value of the scattered field in the direction opposite that of the incident wave.

More specifically, we solved the LSIE numerically by discretizing the operator $I - Gq$, and the incident wave u^i, over a large, but finite, number of nodes on a prescribed rectangular region $D = D_x \times D_y$ containing the scatterer q and then solved the ensuing large system of simultaneous equations (of the form $Au = u^i$) for the unknown u on our grid of evaluation nodes. This process was then repeated over a collection of incident directions on the unit circle.

In two dimensions, we use a collection of equally spaced points $(x_{\hat{l}}, y_{\hat{p}}) \in D$, $(l = 1, 2, \ldots, M, p = 1, 2, \ldots, N)$, and then express the LSIE as

$$u(\hat{x}_l, \hat{y}_p) + \int_{D_x} \int_{D_y} K(\hat{x}_l - x, \hat{y}_p - y) u(x, y) dy dx = u^i(\hat{x}_l, \hat{y}_p),$$

where the kernel K is

$$K(\hat{x}_l - x, \hat{y}_p - y) = \frac{i}{4} H_0^{(1)} \left(k \sqrt{(\hat{x}_l - x)^2 + (\hat{y}_p - y)^2} \right) q(x, y)$$

and $H_0^{(1)}$ is the usual Hankel function of the first kind. We discretize the points of integration similarly, defining the additional points (x_l, y_p), at the same points of evaluation of the LSIE. Using the trapezoid rule on this same set of nodes allows us to write the fully discrete version of the LSIE as

$$u_{\hat{l},\hat{p}} + \frac{\Delta x \Delta y}{4} \sum_{\substack{p=1 \\ p \neq \hat{p}}}^{N-1} \sum_{\substack{l=1 \\ l \neq \hat{l}}}^{M-1} (K_{\hat{l},l;\hat{p},p} u_{l,p} + K_{\hat{l},l+1;\hat{p},p} u_{l+1,p} + K_{\hat{l},l;\hat{p},p+1} u_{l,p+1} + K_{\hat{l},l+1;\hat{p},p+1} u_{l+1,p+1}) + w_{\hat{l},\hat{p}} S_{\hat{l},\hat{p}} u_{\hat{l},\hat{p}} = u^i_{\hat{l},\hat{p}}.$$

The notation given above has been abbreviated so that the subscripts indicate the points of evaluation, namely, $u_{\hat{l},\hat{p}} = u(\hat{x}_l, \hat{y}_p)$, $u_{l,p} := u(x_l, y_p)$, and $K_{\hat{l},l;\hat{p},p} = K(\hat{x}_l - x_l, \hat{y}_p - y_p)$. Since the kernel of the integral operator is singular along the diagonal, these terms must be treated separately in the discretization scheme. The term $w_{\hat{l},\hat{p}} S_{\hat{l},\hat{p}} u_{\hat{l},\hat{p}}$ above corresponds to the appropriate trapezoid-rule weighted average of the diagonal terms in the discretization. Specifically,

$$S_{\hat{l},\hat{p}} := \begin{cases} \frac{k^2}{4} \delta^2 q_{\hat{l},\hat{p}} (1 - 2 \log \delta - 4C_k) & \text{if } (\hat{x}_l, \hat{y}_p) \in D, \\ \frac{k^2}{8} \delta^2 q_{\hat{l},\hat{p}} (1 - 2 \log \delta - 4C_k) & \text{if } (\hat{x}_l, \hat{y}_p) \in \partial D, \end{cases}$$

where

$$C_k = \frac{1}{2}\left(\log\frac{k}{2} - \gamma\right) - \frac{i\pi}{4}$$

and γ is the Euler–Mascheroni constant.

In more detail, what we have done is to assume that product qu is nearly constant over some small ball of radius δ and integrated the logarithmic singularity of the kernel on this set to define the appropriate matrix entry in the numerical integration along the diagonal. Provided we take a fine mesh of integration points, this presents a viable way to treat this weakly singular behavior. We use an equispaced grid in both x and y and chose δ to be $\Delta x/2$.

Last, we obtained the back-scattered field by simply computing the discrete sum of the form

$$s_q(\theta) = e^{i\frac{5\pi}{4}}\sqrt{\frac{1}{8k\pi}}\sum_{l=1}^{M-1}\left(A_l(\theta) + A_{l+1}(\theta)\right)\frac{\Delta x}{2},$$

where we define the iterated areas $A_l(\theta)$ and $A_{l+1}(\theta)$ as

$$A_l(\theta) = \sum_{p=1}^{N-1}\left(f(x_l, y_p, \theta) + f(x_l, y_{p+1}, \theta)\right)\frac{\Delta y}{2},$$

$$A_{l+1}(\theta) = \sum_{p=1}^{N-1}\left(f(x_{l+1}, y_p, \theta) + f(x_{l+1}, y_{p+1}, \theta)\right)\frac{\Delta y}{2}$$

and where we used the computed values of the total field u on the grid to compute

$$f(x_l, y_p, \theta) = e^{-ik(x_l\cos\theta + y_p\sin\theta)}q(x_l, y_p)u(x_l, y_p).$$

Again, we ran the above numerical scheme for a rectangular scatterer, i.e., $q = k^2\chi_{R_q}$ with χ_{R_q} the characteristic function of the rectangle

$$R_q = \{(x, y) \in \mathbb{R}^2 : -1 \le x \le 1, -1/2 \le y \le 1/2\}$$

and computed the back-scattering kernel at 100 equispaced points on the unit circle. We used a wavenumber of $k = 5$ and distributed 40 nodes along each of the x and y axes within the bounding region

$$D = \{(x, y) \in \mathbb{R}^2 : -1 \le x \le 1, -1 \le y \le 1\}.$$

Just over 1.5 wavelengths fall within D, so that 40 trapezoid-rule integration nodes (roughly 25 nodes per wavelength) should yield an accurate simulated solution.

5.2. Numerical computation of the convex back-scattering support. In this section, we illustrate how we use the back-scattering data to find only the rectangle.[4] The general outline of our method for locating the rectangle from the back-scattering kernel will be the following:

[4]In general, we can expect to find only the convex back-scattering support of the scatterer, which may be smaller than the convex hull of the scatterer. In the Born approximation, it follows from Theorem 14 of [8] that the convex back-scattering support of a rectangle is exactly the rectangle. We have not proved this for the full back-scattering data, but the numerical computations below suggest that this is the case.

1. Choose a center, $c \in \mathbb{R}^2$ (we take $c = 0$ the first time through), and expand the back-scattering kernel in a Fourier series centered at this point.
2. Find the *support*, i.e., the value of n where these coefficients *rapidly transition to zero*, in order to calculate the radius of the smallest ball centered at c that contains the (convex back-scattering support of the) rectangle. We will explain this in detail below.
3. Choose other centers and repeat the above process to produce other balls.
4. The scatterer, e.g., the rectangle, must be contained in the common intersection of all these balls.

We will illustrate this procedure with the sequence of Figures 2–5 and again with the sequence of Figures 6–9. Before proceeding to the figures, however, we need to explain the logic behind the second step in more detail. We begin by expanding the back-scattering kernel, i.e., the measured back-scattered signal, in a Fourier series centered at c. On the circle, it is more convenient to work with the azimuthal angle $\theta \in [0, 2\pi]$, which is related to the unit vector Θ through $\Theta = (\cos\theta, \sin\theta)$. The Fourier series expansion, centered at c, is

$$e^{ic\cdot\Theta} s(\Theta) = \sum_{n=-\infty}^{\infty} t_n e^{in\theta}.$$

Numerically, we compute a finite sequence $\{t_n\}$ as the discrete Fourier transform of the sequence $\{e^{ic\cdot\Theta_n} s(\Theta_n)\}$, where $\{\Theta_n\}$ are equispaced points on the unit circle. In Theorem 1.2 we expanded in condensed spherical harmonics. In two dimensions, the condensed spherical harmonics of degree n are the linear combinations of $e^{in\theta}$ and $e^{-in\theta}$, i.e., $s_0^{(c)}(\Theta) = t_0$ and

$$s_n^{(c)}(\Theta) = t_n e^{in\theta} + t_{-n} e^{-in\theta}, \quad n \geq 1, \tag{5.1}$$

so that $\|s_0^{(c)}\|_{L^2(S^1)} = |t_0|$ and

$$||s_n^{(c)}||_{L^2(S^1)} = \left(|t_{-n}|^2 + |t_n|^2\right)^{\frac{1}{2}}, \quad n \geq 1. \tag{5.2}$$

Now, if the scatterer, i.e., our rectangle, is contained in the ball of radius R, then the s_n's satisfy the estimate (1.10), which simplifies slightly in two dimensions because $N(n, 2) = 2$. Specifically,

$$||s_n^{(c)}||_{L^2(S^1)} \leq C(q) N \sigma_n(2kR) \leq 2C(q)\sigma_n(2kR).$$

Theorem 1.2 only tells us that if the rectangle is contained in the ball of radius R centered at c, then the s_n's (a shorthand notation for the $||s_n^{(c)}||_{L^2}$) are bounded by a constant times the $\sigma_n(2kR)$'s. We shall operate as if we knew the converse were true as well.[5] The wavenumber k is fixed ($k = 5$ in the example below), so we want to examine the s_n's and find the smallest value of R for which such a bound holds. Our test principle for finding R from the Fourier coefficients will be the following.

TEST PRINCIPLE 5.1. *The s_n's are effectively supported in the interval $(0, N)$ if and only if the the convex back-scattering support is contained in the ball of radius $R = |\frac{N}{2k}|$.*

We expect the s_n's to be effectively supported in the interval $(0, N)$ because the $\sigma_n(2kR)$'s have exactly this property. As a function of n, $\sigma_n(2kR)$ is positive and

[5]For the Born approximation, the converse is part of Theorem 1.1.

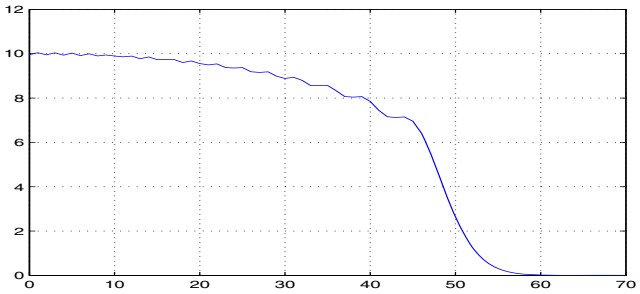

FIG. 1. *$\sigma_n(50)$ plotted as a function of n. Notice that $\sigma_n(50)$ is large (> 6) for $n < 45$ and small (< 0.5) for $n > 55$. If we knew only that this was a plot of $\sigma_n(R)$ for some R, we could have deduced an approximation for R by finding the value of n where the function rapidly transitioned to zero.*

bounded away from zero for $n < |2kR|$ and effectively zero for $n > |2kR|$, with a transition region of width proportinal to $(2kR)^{1/3}$. We see evidence of this behavior in the graph of $\sigma_n(50)$ in Figure 1 and in the asymptotic formulas

$$\sigma_n(2kR) \sim \begin{cases} \sqrt{2}\ \left((2kR)^2 - n^2\right)^{\frac{1}{4}}, & n < |2kR|, \\ \left(\frac{ekR}{n}\right)^{n+1} \sim 0, & n > |2kR|. \end{cases} \tag{5.3}$$

Equation (5.3) follows from classical asymptotics of Bessel functions when at least one of either n or kR is large. We don't yet know a proof when neither is large, but we rely on numerical computations in this case. It can be shown that the two sequences $\sigma_{2n}(2kR)$ and $\sigma_{2n+1}(2kR)$ are monotone decreasing as $n > 0$ increases.

The two sequences of graphs, Figures 2–5 and Figures 6–9, demonstrate that the transitions we witness in the σ_n's are also observed in the back-scattering data as well.

As illustrated in Figures 2–5, our test principle is based on a transition which occurs at a finite value of n, while Theorems 1.1 and 1.2 depend only on large n asymptotics. The strict conditions of these theorems may never be verified experimentally, while the test principle, or any condition that does not include a limit as $n \to \infty$, cannot be a mathematically correct theorem. One can always construct a potential q, supported in the ball of radius R, having any finite number of Fourier coefficients of $\widehat{q}(k\Theta)$ equal to an arbitrary set of numbers. This set of numbers can

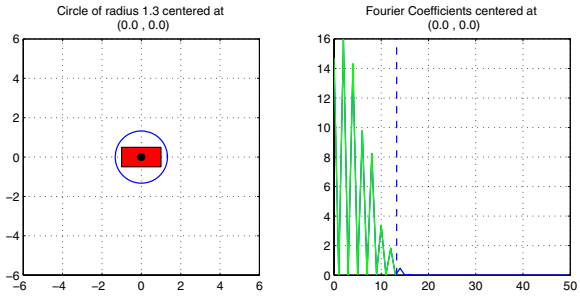

FIG. 2. *We plot the modulus of the Fourier coefficients of the back-scattering kernel on the right and locate the transition to zero at $n = 13$, indicating that value of n by the dashed vertical line. We draw the deduced circle of radius $\frac{n}{2k} = \frac{13}{2\times 5}$ on the left, including the rectangle for comparison.*

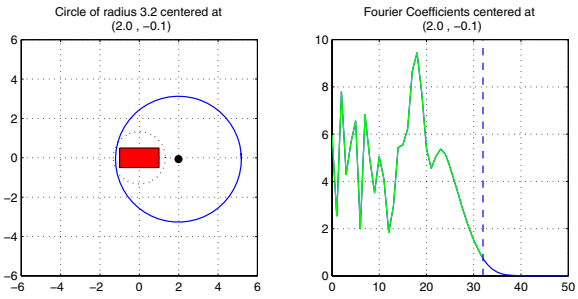

FIG. 3. *We choose a new center, indicated by the black dot in the plot on the left. We compute the modulus of the translated Fourier coefficients, plot them on the right, and locate the transition to zero at* $n = 32$. *We draw the deduced circle of radius* $\frac{n}{2k} = \frac{32}{2\times 5}$ *in the plot on the left. The dashed line represents the circle from Figure* 2.

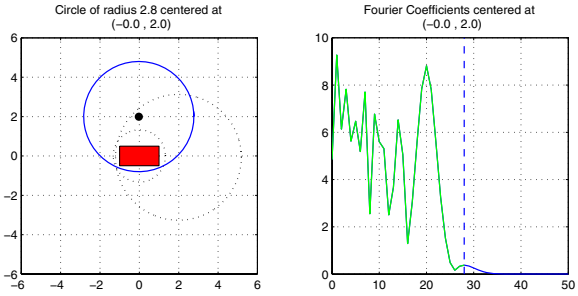

FIG. 4. *We choose another new center, indicated by the black dot. We again plot the modulus of the translated coefficients, locate the transition to zero at* $n = 28$, *and draw the new circle. The dashed lines represents the previous circles from Figures* 2 *and* 3. *Recall that the back-scattering support must lie in their intersection.*

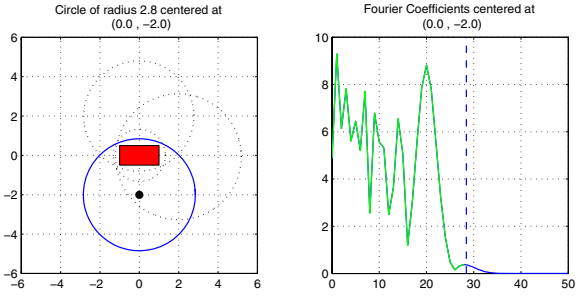

FIG. 5. *We chose the sequence of centers so that we could approximate the rectangle with just a few circles and thus illustrate the method with only a few plots. Of course, we based this choice on a priori knowledge. We don't discuss strategies for efficiently choosing the centers.*

be—somewhat artificially—chosen to be identically zero or to mimic the transition we seek and thus foil our test principle. Nonetheless, such an example would always be exposed by increasing the wave number. Theoretically, we can use a wave of any fixed wavelength to probe any medium—even one which varies very rapidly as a function of position on the scale of that wavelength—to discover its convex back-scattering support. Practically speaking, however, we cannot expect to effectively probe a medium

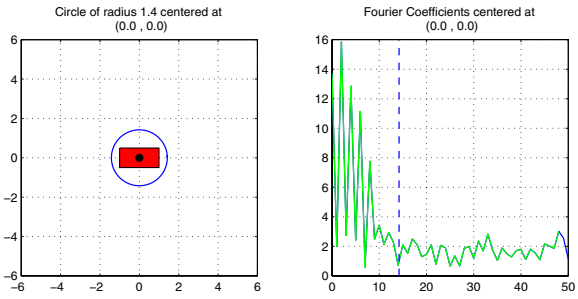

FIG. 6. *The sequence of plots in Figures* 6–9 *uses the same data as the previous sequence, but we have added white noise to both the the amplitude and the phase of the data. We chose the noise level to be* 15% *(i.e., variance equal to* 0.15 *times maximum amplitude* (16) *of the original data for the amplitudes and* $0.15 \times 2\pi$ *for the phases).*

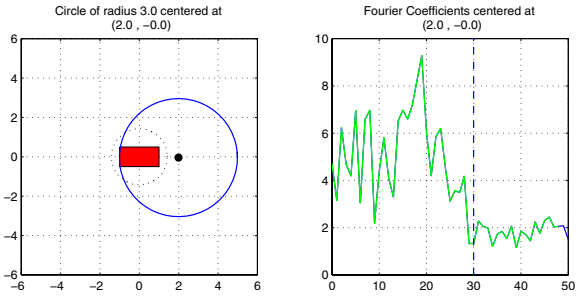

FIG. 7. *We locate the transition to the noise level rather than the transition to zero. If we didn't know that the noise level was* 2.4 *(*0.15×16*), we could readily estimate it from any of the four plots.*

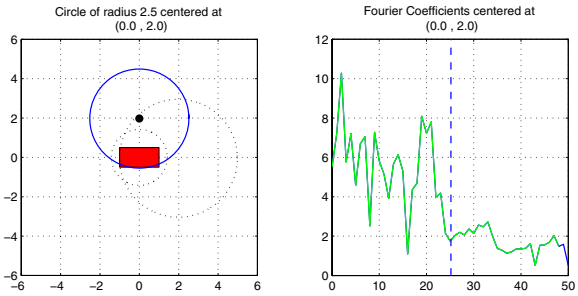

FIG. 8. *Our estimates of the radii in the noisy case are consistently smaller than in the noiseless case.*

whose features vary rapidly on the scale of a wavelength. Some dichotomy between theory and practice is inevitable. One goal for future work will be a more accurate description of those media that we can confidently test with this data and this method.

We should mention that there are certainly other reasonable, and perhaps better, methods for deducing R than our proposed Test Principle 5.1. For instance, one might attempt to sum a regularized version of the series given in (1.8) over various values of R and seek the value of R where the sum becomes bigger than some prescribed threshold. We use Test Principle 5.1 since the very steep transition remained easily visible in the

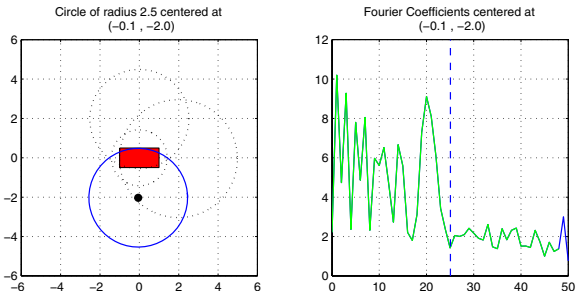

FIG. 9.

presence of noise. This is not a property shared by the partial summations we tried. For our proposed test scheme, we did not need to choose a regularization parameter; however, we did need to decide where the transition to zero, or to the observable noise level, occurred. We found the transition by eye.

NONEXISTENCE OF SYNCHRONOUS ORBITS AND CLASS COEXISTENCE IN MATRIX POPULATION MODELS*

RYUSUKE KON†

Abstract. Existence of synchronous orbits in a general class of matrix population models is considered. Our results show that a matrix population model does not possess a synchronous orbit if the associated directed graph is primitive. Furthermore, it is also shown that if there are no synchronous orbits, then all classes coexist. To illustrate these results, the density dependent Leslie matrix model is analyzed.

Key words. synchronous phenomena, periodic insects, permanence, Leslie matrix models, discrete dynamical systems

1. Introduction.

In this paper, we consider the dynamics of structured populations that are modeled by the following difference equation:

$$\mathbf{x}(t+1) = A_{\mathbf{x}(t)}\mathbf{x}(t), \quad t \in \mathbb{Z}_+, \tag{1}$$

where $\mathbb{Z}_+ = \{0, 1, 2, \dots, \}$, $\mathbf{x}(t) = (x_1(t), x_2(t), \dots, x_n(t))^\top$, and $A_{\mathbf{x}} = (a_{ij}(\mathbf{x}))$ is an $n \times n$ matrix function of $\mathbf{x}$. This equation is a general framework for matrix population models in which a population is divided into n classes (e.g., by chronological age, developmental stage, or habitat position) and the density (or number) of individuals in the ith class is denoted by x_i. Therefore, our interest concentrates on solutions in the nonnegative cone $\mathbb{R}^n_+ := \{\mathbf{x} \in \mathbb{R}^n : x_1 \geq 0, x_2 \geq 0, \dots, x_n \geq 0\}$.

The following equation is a specific example of (1):

$$\begin{pmatrix} x_1(t+1) \\ x_2(t+1) \\ x_3(t+1) \\ \vdots \\ x_n(t+1) \end{pmatrix} = \begin{pmatrix} f_1(\mathbf{x}(t)) & f_2(\mathbf{x}(t)) & \cdots & f_{n-1}(\mathbf{x}(t)) & f_n(\mathbf{x}(t)) \\ p_1(\mathbf{x}(t)) & 0 & \cdots & 0 & 0 \\ 0 & p_2(\mathbf{x}(t)) & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & p_{n-1}(\mathbf{x}(t)) & 0 \end{pmatrix} \begin{pmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \\ \vdots \\ x_n(t) \end{pmatrix}.$$

This equation is the (density dependent) Leslie matrix model for the dynamics of an age-structured population. The variables x_i, $i = 1, 2, \dots, n$, denote the densities (or numbers) of individuals of age i. The functions $f_i(\mathbf{x})$, $i = 1, 2, \dots, n$, denote the numbers of offspring produced by one individual of age i, and $p_i(\mathbf{x})$, $i = 1, 2, \dots, n-1$, denote the probabilities of surviving the ith age-class in one unit of time. This model assumes that the length of life cycle is fixed at n. In addition to the Leslie matrix model, we can find many examples of matrix population models in the literature

[5, 7]. For example, we can find matrix population models incorporating stage or spatial structure (e.g., see [20, 22]).

One of the interesting topics in the study of matrix population models is synchronization. A typical example of synchronous phenomena is found in a density dependent Leslie matrix model with a single reproductive age-class (e.g., see [1, 4, 8, 9, 10, 12, 19, 24]). More precisely, in the Leslie matrix model with $f_1 = \cdots = f_{n-1} = 0$, we can find an orbit $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ such that each $\mathbf{x}(t)$ consists of a single nonzero entry whose position moves to the right in a unit of time (e.g., $\mathbf{x}(0) = (+, 0, 0, \dots, 0)^\top, \mathbf{x}(1) = (0, +, 0, \dots, 0)^\top, \dots$). This kind of behavior is called single year class (SYC) dynamics (e.g., see Davydova, Diekmann, and van Gils [12]) since all but one year class are missing. Recently, the concept of SYC dynamics was extended, and the term "multiple year class (MYC) dynamics" was introduced by Mjølhus, Wikan, and Solberg [19]. Synchronous phenomena are also observed in natural insect populations (e.g., see [14, 17, 18, 21]). Periodical cicadas, inhabiting the eastern United States, are typical examples. Their nymphs remain underground for precisely 17 years (or, in the south, 13 years) before emerging from the ground synchronously and in tremendous numbers. Mature nymphs become adults, mate, lay their eggs, and die within the few weeks (see [17]). Therefore, the lengths of their life cycles are fixed (17 or 13 years), and all individuals in each population have the same age; i.e., all but one year class are missing (this phenomenon corresponds to SYC dynamics). In order to explain this synchronization, the Leslie matrix model with $f_1 = \cdots = f_{n-1} = 0$ has been studied.

Although it is known that the structure of the Leslie matrix with a single reproductive age-class can give rise to synchronous phenomena, it is unknown whether this is the only structure leading to synchronous phenomena. For example, some insect undoubtedly has two or more reproductive age-classes, but it is not clear whether the additional reproductive age-classes dissipate synchronous phenomena. In order to clarify this relationship between the structure of the life cycle and the phenomenon of synchronization, we will investigate a structure that eliminates synchronous phenomena from a general class of matrix population models.

Synchronous phenomena are characterized by an orbit on the boundary of the nonnegative cone $\mathrm{bd}\mathbb{R}^n_+ := \{\mathbf{x} \in \mathbb{R}^n_+ : x_1 x_2 \cdots x_n = 0\}$. Hence, following Cushing [8], we define a synchronous orbit as follows.

DEFINITION 1.1 (synchronous orbits). *An orbit* $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ *of system* (1) *is said to be synchronous if* $\mathbf{x}(t) \in \mathrm{bd}\mathbb{R}^n_+$ *for all* $t \geq 0$. *A synchronous orbit is said to be nontrivial if* $\mathbf{x}(0) \neq 0$.

Notice that a synchronous orbit does not have to be periodic. It is clear that an SYC dynamics pattern does not appear as long as there are no nontrivial synchronous orbits. Moreover, we see that a nontrivial synchronous orbit always includes some missing classes.

In this paper, we will show that, under certain assumptions, the primitivity of the matrix $A_{\mathbf{x}}$ determines the existence of nontrivial synchronous orbits. It is worth mentioning that Cull and Vogt [6] have addressed the primitivity of a density independent Leslie matrix model to study its periodic behavior of age distributions, i.e., the periodicity of $\mathbf{x}(t)/\sum_{i=1}^n x_i(t)$. As in the study by Cull and Vogt [6], the theory of nonnegative matrices is very useful in our study, although we are concerned not with the periodicity of age distributions but with the existence of synchronous orbits. Since our system involves nonlinear terms, unlike the system of Cull and Vogt [6], we will obtain a result on class coexistence with bounded population densities due to the nonlinearity. That is, we will show that, under certain assumptions, nonexistence

of nontrivial synchronous orbits ensures coexistence of all classes in the sense of *c-permanence*, which is defined as follows. (The definition of *p-permanence* is introduced below to distinguish population survival from class coexistence.)

DEFINITION 1.2 (c-permanence). *System* (1) *is said to be c-permanent if there exist positive constants* $\delta > 0$ *and* $D > 0$ *such that*

$$\delta \le \liminf_{t\to\infty} x_i(t) \le \limsup_{t\to\infty} x_i(t) \le D, \quad i = 1, 2, \dots, n,$$

for all solutions $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ *with* $\mathbf{x}(0) \in \mathbb{R}^n_+ \backslash \{(0, 0, \dots, 0)\}$.

The remainder of this paper is organized as follows. In section 2, we introduce some notation and assumptions. That section also includes a new result on the boundedness of solutions, which will be used to prove permanence of a specific matrix population model in section 5. In section 3, we review a known result on permanence for population survival (i.e., p-permanence), which is used to consider c-permanence in the subsequent sections. In section 4, we consider existence of nontrivial synchronous orbits and class coexistence. That section includes the main results of this paper. In section 5, we apply our results to the density dependent Leslie matrix model, which is introduced above, to illustrate our main results. The final section discusses future problems.

2. Preliminaries. In this section, we introduce some notation, assumptions, and preliminary results.

For vectors $\mathbf{x} = (x_1, x_2, \dots, x_n)^\top$ and $\mathbf{y} = (y_1, y_2, \dots, y_n)^\top$, we write $\mathbf{x} \ge \mathbf{y}$ if $x_i \ge y_i$ for all i, and $\mathbf{x} > \mathbf{y}$ if $\mathbf{x} \ge \mathbf{y}$ and $\mathbf{x} \ne \mathbf{y}$. A vector $\mathbf{x}$ is called *nonnegative* if $\mathbf{x} \ge 0$, where 0 denotes the zero vector. A matrix $A = (a_{ij})$ is called *nonnegative* if $a_{ij} \ge 0$ for all i, j. Some important properties of nonnegative matrices are listed in the appendix, which also includes the definitions of *irreducibility* and *primitivity* of matrices and their characteristics. These properties of nonnegative matrices are extensively used in this paper. For matrices $A = (a_{ij})$ and $B = (b_{ij})$, we write $\operatorname{sign}(A) = \operatorname{sign}(B)$ if a_{ij} and b_{ij} have the same sign $-, 0$, or $+$; i.e., the sign pattern of A is identical with that of B. We also write $\operatorname{sign}(\mathbf{x}) = \operatorname{sign}(\mathbf{y})$ for vectors $\mathbf{x}$ and $\mathbf{y}$ if they have the same sign pattern. The set consisting of only the origin is denoted by O.

Throughout this paper, we always assume that system (1) satisfies the following conditions (H1)–(H4):

(H1) each $a_{ij}(\mathbf{x})$ is continuous,
(H2) $A_{\mathbf{x}}\mathbf{x} \ge 0$ for all $\mathbf{x} \ge 0$,
(H3) $A_{\mathbf{x}}\mathbf{x} > 0$ for all $\mathbf{x} > 0$,
(H4) system (1) is *dissipative*; i.e., there exists a positive constant $D > 0$ such that $\limsup_{t\to\infty} \sum_{i=1}^n x_i(t) \le D$ for all solutions $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ with $\mathbf{x}(0) \ge 0$.

Assumption (H1) ensures that the map $f(\mathbf{x}) := A_{\mathbf{x}}\mathbf{x}$, which is the right-hand side of (1), is continuous. Assumption (H2) implies that all solutions of (1) with $\mathbf{x}(0) \ge 0$ are always nonnegative. Hence, the nonnegative cone $\mathbb{R}^n_+$ is forward invariant; i.e., $f(\mathbb{R}^n_+) \subset \mathbb{R}^n_+$. Notice that (H2) holds if $A_{\mathbf{x}}$ is nonnegative for all $\mathbf{x} \ge 0$. Assumption (H3) implies that no points $\mathbf{x} > 0$ are mapped to the origin. Therefore, assumption (H3) ensures that $\mathbb{R}^n_+ \backslash O$ is forward invariant; i.e., $f(\mathbb{R}^n_+ \backslash O) \subset \mathbb{R}^n_+ \backslash O$. We can show that (H3) holds if $A_{\mathbf{x}}$ is nonnegative and irreducible for all $\mathbf{x} \ge 0$ as follows. Since $A_{\mathbf{x}}$ is nonnegative for all $\mathbf{x} > 0$, $A_{\mathbf{x}}\mathbf{x} \ge 0$ holds for all $\mathbf{x} > 0$. Suppose that $A_{\mathbf{y}}\mathbf{y} = 0$ for some $\mathbf{y} > 0$ with $y_k > 0$. The irreducibility of $A_{\mathbf{y}}$ ensures that $a_{ik}(\mathbf{y}) > 0$ for some i. Otherwise, there are no paths from the vertices P_k to the other vertices in

the directed graph of $A_{\mathbf{y}}$. This implies that $A_{\mathbf{y}}$ is not strongly connected and hence not irreducible (see Definition A.3 and Theorem A.4 of the appendix). Therefore, $A_{\mathbf{x}}\mathbf{x} > 0$ holds for all $\mathbf{x} > 0$. Assumption (H4) implies that the total population density does not explode. We can find many matrix population models that satisfy assumptions (H1)–(H4) (e.g., see [5, 7]).

In comparison with (H1)–(H3), it is not always easy to check whether system (1) satisfies (H4). In the rest of this section, we obtain a sufficient condition for the dissipativity of system (1). To obtain the sufficient condition in Theorem 2.2, we need the following lemma on dynamical systems.

LEMMA 2.1 (Hutson [15, Lemma 2.1]). *Let (X, d) be a metric space, and let $f : X \to X$ be a continuous function. Let $\gamma^+(\mathbf{x}) = \{\mathbf{x}, f(\mathbf{x}), f^2(\mathbf{x}), \dots\}$ be a semi-orbit of the discrete dynamical system $f : X \to X$. Let $Y \subset X$ be open, and let N be open with a compact closure $\overline{N} \subset Y$. Assume that Y is forward invariant and that $\gamma^+(\mathbf{x}) \cap N \neq \emptyset$ for every $\mathbf{x} \in Y$. Then $M = \gamma^+(\overline{N})$ is a compact absorbing set for Y; i.e., M is a forward invariant compact subset of Y and $\gamma^+(\mathbf{x}) \cap M \neq \emptyset$ for every $\mathbf{x} \in Y$.*

By using this lemma, under assumptions (H1)–(H3), we can obtain the following theorem of dissipativity.

THEOREM 2.2. *Assume that* (H1)–(H3) *hold. Suppose that there exist positive constants $K > 0$ and $\lambda_\infty > 0$ such that the inequalities $\sum_{i=1}^n a_{ij}(\mathbf{x}) \le \lambda_\infty$, $j = 1, 2, \dots, n$, hold for all $\mathbf{x} \in \mathbb{R}^n_+$ with $\sum_{i=1}^n x_i \ge K$. Then system* (1) *is dissipative if $\lambda_\infty < 1$.*

Proof. Let $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ be a solution of (1) with $\mathbf{x}(0) \in \mathbb{R}^n_+$. Suppose that $\sum_{i=1}^n x_i(t) \ge K$ for all $t \ge 0$. Then, from (1), we have

$$\begin{aligned}\sum_{i=1}^n x_i(t) &= \sum_{i=1}^n \sum_{j=1}^n a_{ij}(\mathbf{x}(t-1))x_j(t-1)\\ &\le \lambda_\infty \sum_{i=1}^n x_i(t-1)\\ &\vdots\\ &\le \lambda_\infty^t \sum_{i=1}^n x_i(0).\end{aligned}$$

Since $\lambda_\infty < 1$, we have $\mathbf{x}(t) \to 0$ as $t \to \infty$. This is a contradiction. Hence, for every $\mathbf{x}(0) \in \mathbb{R}^n_+$ there exists a $T \ge 0$ such that $\sum_{i=1}^n x_i(T) < K$.

Let $X = Y = \mathbb{R}^n_+$ and $N = \{\mathbf{x} \in \mathbb{R}^n_+ : \sum_{i=1}^n x_i < K\}$. Then it is clear that Y is a forward invariant open subset of X, and N is an open set with a compact closure $\overline{N} \subset Y$. By the above argument, we see that $\gamma^+(\mathbf{x}) \cap N \neq \emptyset$ for every $\mathbf{x} \in Y$. Therefore, Lemma 2.1 implies that $\gamma^+(\overline{N})$ is a compact absorbing set for Y, that is, every solution eventually enters the compact set $\gamma^+(\overline{N})$ and remains there. This implies that system (1) is dissipative. □

Remark. It is straightforward to see that this theorem improves a result by Cushing [7] (cf. Theorem 1.2.2 of [7]). In Theorem 1.2.1 of [7], we can find a sufficient condition that ensures global extinction, i.e., $\lim_{t\to\infty} \mathbf{x}(t) = 0$ for all $\mathbf{x}(0) \in \mathbb{R}^n_+$. In this case, the system is certainly dissipative.

3. P-permanence. In this section, we introduce a known result on the *p-permanence* of system (1), which is defined as follows.

DEFINITION 3.1 (p-permanence). *System* (1) *is said to be p-permanent if there exist positive constants* $\delta > 0$ *and* $D > 0$ *such that*

$$\delta \le \liminf_{t\to\infty} \sum_{i=1}^{n} x_i(t) \le \limsup_{t\to\infty} \sum_{i=1}^{n} x_i(t) \le D$$

for all solutions $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ *with* $\mathbf{x}(0) \in \mathbb{R}^n_+\backslash O$.

A result on p-permanence shall be used to consider class coexistence, i.e., c-permanence, in sections 4 and 5. We see that if system (1) is p-permanent, then the total population density $\sum_{i=1}^{n} x_i(t)$ is eventually bounded within some positive interval. Therefore, p-permanence is a mathematical term corresponding to population survival.

The recent study by Kon, Saito, and Takeuchi [16] provides a sufficient condition for the p-permanence of system (1) as follows.

THEOREM 3.2 (see [16]). *Assume that* (H1)–(H4) *hold. Suppose that the matrix* $A_{\mathbf{x}}$ *at the origin, which is denoted by* A_0*, is irreducible. Then system* (1) *is p-permanent if the dominant eigenvalue* λ_0 *of* A_0 *satisfies* $\lambda_0 > 1$.

Remark. Since A_0 corresponds to the Jacobian matrix of (1) evaluated at the origin, $\lambda_0 > 1$ implies that the origin is unstable. Moreover, $\lambda_0 < 1$ implies that the origin is stable, i.e., that system (1) is not p-permanent. Therefore, the magnitude of λ_0 determines whether or not system (1) is p-permanent except in the critical case $\lambda_0 = 1$.

4. Synchronous orbits and class coexistence. In this main section, we consider the existence of synchronous orbits and the possibility of class coexistence, i.e., c-permanence.

The following theorem provides a necessary and sufficient condition for the existence of a nontrivial synchronous orbit.

THEOREM 4.1. *Assume that* (H1)–(H4) *hold. Suppose that* A_0 *is irreducible and* $\mathrm{sign}(A_{\mathbf{x}}) = \mathrm{sign}(A_0)$ *holds for all* $\mathbf{x} \in \mathrm{bd}\mathbb{R}^n_+$. *Then system* (1) *has a nontrivial synchronous orbit if and only if* A_0 *is imprimitive.*

Proof. Suppose that A_0 is imprimitive with index of imprimitivity $h > 1$. Then, by Theorem A.7 of the appendix, A_0^h can be rearranged into quasi-diagonal form by renumbering the indices of rows and columns. So, without loss of generality, we can assume

$$A_0^h = \mathrm{diag}\{B_1, B_2, \ldots, B_h\},$$

where $B_1, B_2, \ldots, B_h$ are primitive matrices. Hence, we can choose a $\mathbf{z} \in \mathrm{bd}\mathbb{R}^n_+\backslash O$ such that $A_0^{kh}\mathbf{z} \in \mathrm{bd}\mathbb{R}^n_+\backslash O$ for all $k \in \mathbb{Z}_+$ (e.g., if B_1 is an $n_1 \times n_1$ matrix, then choose $\mathbf{z} = (z_1, z_2, \ldots, z_n)^\top$ with $z_i > 0$ for $i = 1, \ldots, n_1$ and $z_i = 0$ for $i = n_1 + 1, \ldots, n$). Since A_0 is irreducible and nonnegative, once $A_0^T\mathbf{z} \in \mathrm{int}\mathbb{R}^n_+ := \mathbb{R}^n_+\backslash\mathrm{bd}\mathbb{R}^n_+$ holds for some $T \ge 0$, $A_0^t\mathbf{z} \in \mathrm{int}\mathbb{R}^n_+$ holds for all $t \ge T$. Otherwise, A_0 has a row with only zero entries, so that A_0 is reducible. Therefore, for the $\mathbf{z} \in \mathrm{bd}\mathbb{R}^n_+\backslash O$ chosen above, $A_0^t\mathbf{z} \in \mathrm{bd}\mathbb{R}^n_+\backslash O$ holds for all $t \ge 0$.

It is clear that if $\mathrm{sign}(A) = \mathrm{sign}(B)$ and $\mathrm{sign}(\mathbf{x}) = \mathrm{sign}(\mathbf{y})$ hold for some nonnegative matrices A, B and some nonnegative vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n_+$, then $\mathrm{sign}(A\mathbf{x}) = \mathrm{sign}(B\mathbf{y})$ holds. Therefore, if we let $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ be a solution of system (1) with $\mathbf{x}(0) = \mathbf{z}$, then $\mathrm{sign}(A_{\mathbf{x}(0)}\mathbf{x}(0)) = \mathrm{sign}(A_0\mathbf{z})$ holds, and inductively $\mathrm{sign}(A_{\mathbf{x}(t)}) = \mathrm{sign}(A_0)$ and $\mathrm{sign}(A_{\mathbf{x}(t-1)}\mathbf{x}(t-1)) = \mathrm{sign}(A_0^t\mathbf{z})$ hold for all $t \ge 0$. This implies that $\mathbf{x}(t) \in \mathrm{bd}\mathbb{R}^n_+\backslash O$ for all $t \in \mathbb{Z}_+$, and then $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ is a nontrivial synchronous orbit.

Suppose that A_0 is primitive. Then, by Theorem A.6 of the appendix, there exists an integer $k \geq 1$ such that $A_0^k > 0$. Suppose that there exists a solution $\{\mathbf{x}(t)\}_{t\in\mathbb{Z}_+}$ such that $\mathbf{x}(t) \in \mathrm{bd}\mathbb{R}^n_+ \backslash O$ for all $t \geq 0$. Then we have $A_{\mathbf{x}(k-1)}A_{\mathbf{x}(k-2)}\cdots A_{\mathbf{x}(0)} > 0$. This is a contradiction. Therefore, there are no nontrivial synchronous orbits. □

This theorem ensures that if A_0 is primitive, then there are no orbits remaining in $\mathrm{bd}\mathbb{R}^n_+$; that is, every orbit starting in $\mathrm{bd}\mathbb{R}^n_+$ leaves there and enters the interior of $\mathbb{R}^n_+$ after finite iterations. In the rest of this section, we consider whether or not an interior orbit approaches $\mathrm{bd}\mathbb{R}^n_+$ and show that primitivity implies c-permanence. The following lemma is used below to consider such a problem.

LEMMA 4.2. *Let (X, d) be a compact metric space, and let f and $\gamma^+(\mathbf{x})$ be the same as in Lemma* 2.1. *Let Y be a compact subset of X. Suppose that $\gamma^+(\mathbf{x}) \cap (X\backslash Y) \neq \emptyset$ for every $\mathbf{x} \in X$ and that $X\backslash Y$ is forward invariant. Then there exists a compact absorbing set M for X with $d(M, Y) > 0$.*

Proof. Define $U_t = \{\mathbf{x} \in X : f^t(\mathbf{x}) \in X\backslash Y\}$. Let $\mathbf{x} \in U_t$. Then $f^t(\mathbf{x}) \in X\backslash Y$. By the continuity of f, there exists an open neighborhood $V(\mathbf{x})$ of $\mathbf{x}$ such that $f^t(V(\mathbf{x})) \subset X\backslash Y$. Hence, $V(\mathbf{x}) \subset U_t$. This implies that U_t is open. Since $\gamma^+(\mathbf{x})\cap(X\backslash Y) \neq \emptyset$ for every $\mathbf{x} \in X$, the family of open sets U_t forms an open cover for X. Then, by the compactness of X, there exists a finite subcover $\{U_{t_1}, U_{t_2}, \ldots, U_{t_m}\}$. The forward invariance of $X\backslash Y$ implies $U_t \subset U_{t+1}$. Hence, $X \subset U_T$ holds for $T = \max\{t_1, t_2, \ldots, t_m\}$; i.e., $f^T(X) \subset X\backslash Y$.

Since f is continuous and X is compact, $f^T(X)$ is compact. Let $N = f^T(X)$. Then $\gamma^+(N) = \bigcup_{t=0}^{T-1} f^t(N)$ holds and is compact. Since $\gamma^+(N)$ and Y are compact and $\gamma^+(N) \cap Y = \emptyset$, $d(\gamma^+(N), Y) > 0$ holds. Therefore, we see that $\gamma^+(N)$ is a compact absorbing set for X with $d(\gamma^+(N), Y) > 0$. □

By using this lemma, we can show that if A_0 is primitive, i.e., there are no nontrivial synchronous orbits, then there are no interior orbits converging to $\mathrm{bd}\mathbb{R}^n_+$, as follows.

THEOREM 4.3. *Assume that* (H1)–(H4) *hold. Suppose that $A_{\mathbf{x}}$ is irreducible for all $\mathbf{x} \in \mathbb{R}^n_+$, $\mathrm{sign}(A_{\mathbf{x}}) = \mathrm{sign}(A_0)$ holds for all $\mathbf{x} \in \mathrm{bd}\mathbb{R}^n_+$, and system* (1) *is p-permanent. Then system* (1) *is c-permanent if and only if A_0 is primitive.*

Proof. By Theorem 4.1, the ($\Rightarrow$) part is clear since an imprimitive A_0 leads to a nontrivial synchronous orbit.

Suppose that A_0 is primitive. Since system (1) is p-permanent, by using Lemma 2.1, we can construct a compact absorbing set X for $\mathbb{R}^n_+\backslash O$ such that $X \cap O = \emptyset$. Let $Y = \mathrm{bd}\mathbb{R}^n_+ \cap X$. By Theorem 4.1, for every $\mathbf{x}(0) \in Y$ there exists a $T \geq 0$ such that $\mathbf{x}(T) \in X\backslash Y$. Furthermore, since $A_{\mathbf{x}(t)}$ is irreducible for all $t \geq 0$, $\mathbf{x}(t) \in X\backslash Y$ holds for all $t \geq T$. Otherwise, $A_{\mathbf{x}(t)}$ has a row with only zero entries, and thus $A_{\mathbf{x}(t)}$ is reducible. This fact implies that $X\backslash Y$ is forward invariant. Hence, Lemma 4.2 shows that there exists a compact absorbing set M for X with $d(M, Y) > 0$. This completes the proof. □

Remark. Notice that $A_{\mathbf{x}}$ is assumed to be irreducible not only at $\mathbf{x} = 0$ but also at $\mathbf{x} \in \mathbb{R}^n_+$. If $A_{\mathbf{x}}$ is assumed to be irreducible only at $\mathbf{x} = 0$, then we can construct a matrix function $A_{\mathbf{x}}$ such that (1) has a periodic orbit that visits alternately an interior point and a boundary point. For instance, consider the following example:

$$A_{\mathbf{x}} = \begin{pmatrix} 0 & 16\sigma(x_1, x_2)\exp(-x_1 - x_2) \\ 0.5 & 0.5\sigma(x_1, x_2) \end{pmatrix},$$

where $\sigma(x_1, x_2)$ is the continuous function defined by

$$\sigma(x_1, x_2) = \begin{cases} -x_1x_2 + 1, & 0 \leq x_1x_2 < 1, \\ 0, & x_1x_2 \geq 1. \end{cases}$$

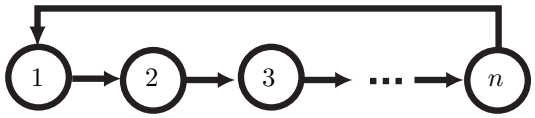

FIG. 1. *The graph of $A_{\mathbf{x}}$ for a semelparous population. This graph has a loop $\{1, 2, \ldots, n, 1\}$, whose length is n. Since there are only loops whose lengths are multiples of n, the greatest common divisor of the lengths are equal to n. Hence, this graph is imprimitive with index of imprimitivity n.*

Note that A_0 is irreducible (and primitive), but $A_{\mathbf{x}}$ is reducible if $x_1 x_2 \geq 1$. Moreover, $\operatorname{sign}(A_{\mathbf{x}}) = \operatorname{sign}(A_0)$ holds for all $\mathbf{x} \in \operatorname{bd}\mathbb{R}^2_+$. We see that $\{(6\ln 2, (3/2)\ln 2), (0, 3\ln 2)\}$ is a periodic orbit of this example.

5. Applications. In this section, we apply the results obtained in the preceding sections to the (density dependent) Leslie matrix model, which was introduced in section 1.

For the functions $f_i(\mathbf{x})$, $i = 1, 2, \ldots, n$, and $p_i(\mathbf{x})$, $i = 1, 2, \ldots, n-1$, we assume the following:

(A1) All $f_i(\mathbf{x})$ and $p_i(\mathbf{x})$ are continuous. $f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_{n-1}(\mathbf{x})$ are nonnegative, and $f_n(\mathbf{x})$ and $p_1(\mathbf{x}), p_2(\mathbf{x}), \ldots, p_{n-1}(\mathbf{x})$ are positive for all $\mathbf{x} \in \mathbb{R}^n_+$.

In order to emphasize that the irreducibility of $A_{\mathbf{x}}$ is determined solely by its sign pattern, in (A1) we do not assume that the functions $p_i(\mathbf{x})$ are less than one. However, from a biological point of view, they must be less than one since they are survival probabilities. In the example studied below, we assume the specific functions $p_i(\mathbf{x})$ that satisfy $0 < p_i(\mathbf{x}) < 1$ for all $\mathbf{x} \in \mathbb{R}^n_+$. It is clear that (A1) ensures that (H1) and (H2) hold. Since $f_n(\mathbf{x})$ and $p_1(\mathbf{x})$, $p_2(\mathbf{x})$, $\ldots$, $p_{n-1}(\mathbf{x})$ are positive for every $\mathbf{x} \geq 0$, the graph $G(A_{\mathbf{x}})$ of $A_{\mathbf{x}}$ has a loop along which we can run through every vertex of the graph (see Figure 1), so that $G(A_{\mathbf{x}})$ is strongly connected (see Theorem A.6 of the appendix). This implies that $A_{\mathbf{x}}$ is irreducible for every $\mathbf{x} \geq 0$. Therefore, (A1) also ensures that (H3) holds. It is clear that dissipativity of the Leslie matrix model is dependent on the forms of the functions f_i and p_i. In fact, if they are all constants, the system becomes linear and hence can exhibit exponential growth. As a nonlinear example, consider the functions $f_i(\mathbf{x})$ and $p_i(\mathbf{x})$:

$$
\begin{aligned}
f_i(\mathbf{x}) &= \frac{\phi_i}{1 + (\sum_{i=1}^n \mu_{ij} x_j)^{\alpha_i}}, \qquad i = 1, 2, \ldots, n, \\
p_i(\mathbf{x}) &= \frac{\sigma_i}{1 + (\sum_{i=1}^n \nu_{ij} x_j)^{\beta_i}}, \qquad i = 1, 2, \ldots, n-1,
\end{aligned} \tag{2}
$$

where the parameters satisfy $\phi_1, \phi_2, \ldots, \phi_{n-1} \geq 0$, $\phi_n > 0$, $0 < \sigma_i < 1$, $\mu_{ij} > 0$, $\nu_{ij} \geq 0$, $\alpha_i > 0$, $\beta_i > 0$ for all i, j. Note that this specific example satisfies the condition (A1) and that $p_1(\mathbf{x}), p_2(\mathbf{x}), \ldots, p_{n-1}(\mathbf{x}) < 1$ hold for all $\mathbf{x} \in \mathbb{R}^n_+$. In this specific case, we can choose $K > 0$ and $0 < \lambda_\infty < 1$ such that

$$
\begin{aligned}
f_1(\mathbf{x}) + p_1(\mathbf{x}) &\leq \lambda_\infty \\
&\vdots \\
f_{n-1}(\mathbf{x}) + p_{n-1}(\mathbf{x}) &\leq \lambda_\infty \\
f_n(\mathbf{x}) &\leq \lambda_\infty
\end{aligned}
$$

hold for all $\mathbf{x} \in \mathbb{R}^n_+$ with $\sum_{i=1}^n x_i \geq K$. Therefore, Theorem 2.2 ensures that the Leslie matrix model with such functions is dissipative; i.e., the assumption (H4) holds.

Let us consider p-permanence of the Leslie matrix model. As shown in Theorem 3.2, the magnitude of the dominant eigenvalue of A_0 plays a crucial role for p-permanence of system (1). The dominant eigenvalue λ_0 of A_0 usually has a strong relationship with the so-called *inherent net reproductive number* $\mathcal{R}_0$, which is defined to be the expected number of offspring per individual per lifetime evaluated by the constant matrix A_0 (see Theorem 1.1.3 of Cushing [7] and Theorem 3 and section 3.1 of Cushing and Yicang [11]). The inherent net reproductive number $\mathcal{R}_0$ of the Leslie matrix is given by

$$\mathcal{R}_0 = \sum_{i=1}^{n} f_i(0) \prod_{j=1}^{i} p_{j-1}(0),$$

where for notational convenience $p_0(0)$ is defined to be 1. For the Leslie matrix model, it is known that $\mathcal{R}_0 > 1$ (resp., $\mathcal{R}_0 < 1$) if and only if $\lambda_0 > 1$ (resp., $\lambda_0 < 1$) (see Cushing [7] and Cushing and Yicang [11]). Therefore, Theorem 3.2 implies that the Leslie matrix model is p-permanent if it is dissipative and $\mathcal{R}_0 > 1$.

Let us consider primitivity of $A_{\mathbf{x}}$ under the assumption (A1). As mentioned above, under the assumption (A1), $A_{\mathbf{x}}$ is irreducible for every $\mathbf{x} \geq 0$. The graph of $A_{\mathbf{x}}$ with $f_1(\mathbf{x}) = f_2(\mathbf{x}) = \cdots = f_{n-1}(\mathbf{x}) = 0$ is depicted in Figure 1. A population with this life cycle is called *semelparous*. In a semelparous population, individuals can reproduce only once in their lives. By Theorem A.5 of the appendix, we see that the index of imprimitivity of $A_{\mathbf{x}}$ for a semelparous population is equal to n, the order of the matrix $A_{\mathbf{x}}$; that is, $A_{\mathbf{x}}$ is not primitive for all $\mathbf{x} \geq 0$. Therefore, Theorem 4.1 ensures that a semelparous population has a nontrivial synchronous orbit. On the other hand, consider the case where $f_1(\mathbf{x}) = f_2(\mathbf{x}) = \cdots = f_{n-1}(\mathbf{x}) = 0$ does not hold. By Theorem A.5, we see that if there are two consecutive fertile age-classes such that $f_i(\mathbf{x}) > 0$ for all $\mathbf{x} \in \mathrm{bd}\mathbb{R}^n_+$, then $A_{\mathbf{x}}$ is primitive for all $\mathbf{x} \in \mathrm{bd}\mathbb{R}^n_+$. Hence, if $f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_n(\mathbf{x}) > 0$ for all $\mathbf{x} \in \mathrm{bd}\mathbb{R}^n_+$, i.e., all age-classes are fertile, then $A_{\mathbf{x}}$ is clearly primitive for all $\mathbf{x} \in \mathrm{bd}\mathbb{R}^n_+$. In such a primitive case, Theorem 4.3 ensures that all age-classes coexist if system (1) is p-permanent.

Figure 2 considers the dynamics of the Leslie matrix model with four age-classes. We use the functions f_i and p_i defined by (2). Figure 2(a) shows the population dynamics of the fourth age-class in an imprimitive Leslie matrix model. From this figure, we see that the orbit converges to a nontrivial synchronous orbit, where all but one year class are missing. If individuals in the third age-class are also fertile, then the orbit stays in the interior of the nonnegative cone. So, we see that all classes coexists as ensured by Theorem 4.3 (see Figures 2(b) and (c)).

6. Discussion. In this paper, we have considered the existence of nontrivial synchronous orbits in a general class of matrix population models. In Theorem 4.1, we showed that the primitivity of the matrix $A_{\mathbf{x}}$ on the boundary $\mathrm{bd}\mathbb{R}^n_+$ is essential for this existence. Furthermore, in Theorem 4.3, we showed that if there are no nontrivial synchronous orbits, then all classes coexist in the sense of c-permanence. By using the specific Leslie matrix model, we confirmed these results in section 5.

Since Theorem 4.1 ensures only existence of a nontrivial synchronous orbit, that orbit's stability is unknown. However, in our example in Figure 2(a), the nontrivial synchronous orbit seems to be stable. It is a future problem to consider the relationship between stability of synchronous orbits and structure of matrix population

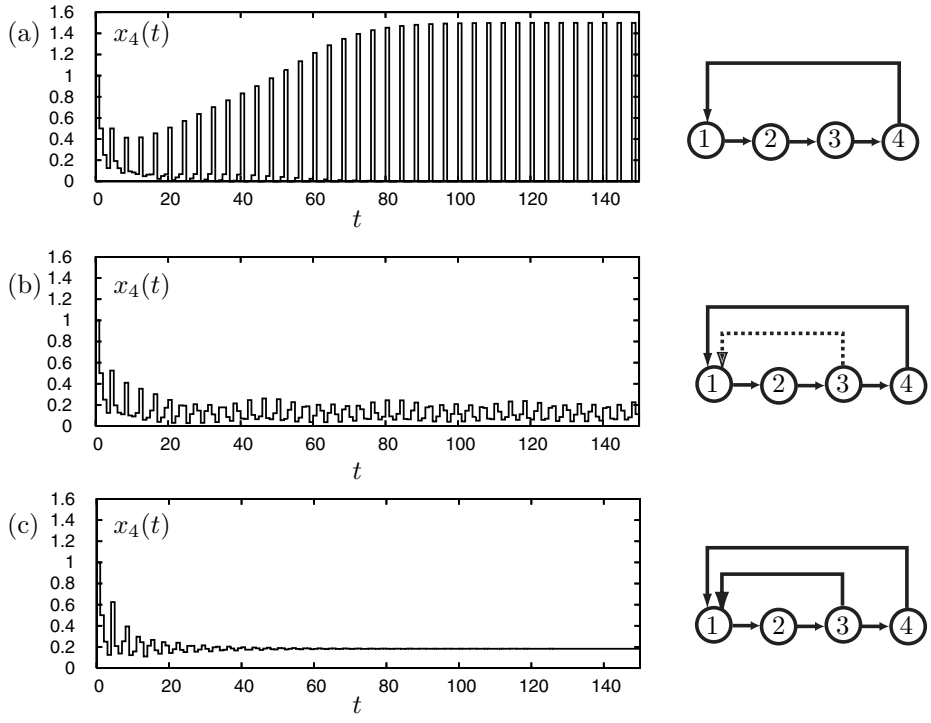

FIG. 2. *The population dynamics of the Leslie matrix model with four age-classes. The left figures show temporal fluctuations of the fourth age-class density. The parameters are* $\phi_1 = 0$, $\phi_2 = 0$, $\phi_4 = 20$, $\sigma_1 = \sigma_2 = \sigma_3 = 0.5$, $\mu_{ij} = \nu_{ij} = \alpha_i = \beta_i = 1$ *for all* i, j, *and the initial condition satisfies* $x_1(0) = x_2(0) = x_3(0) = x_4(0) = 1$. *The parameter* ϕ_3 *is chosen as follows:* (a) $\phi_3 = 0$, (b) $\phi_3 = 1$, (c) $\phi_3 = 5$.

models (see [4, 9, 10, 12, 19, 24] for stability of synchronous orbits in semelparous populations).

In the definition of c-permanence (Definition 1.2), all nonzero orbits are required to be attracted by some compact set in the interior of the nonnegative cone, $\mathrm{int}\mathbb{R}^n_+$. However, we often observe the case where all positive orbits are attracted by some compact set in $\mathrm{int}\mathbb{R}^n_+$ even if the system has a nontrivial synchronous orbit; i.e., the system is not c-permanent. For example, in the Leslie matrix model for a semelparous population, we can find this type of class coexistence. Therefore, it is an important future problem to study class coexistence involving synchronous orbits.

Appendix. In this section, we list some useful theorems of nonnegative matrices. There are several books which discuss the properties of such matrices (e.g., see [2, 3, 5, 13, 23]).

One of the most important properties of nonnegative matrices is irreducibility, which is defined as follows.

DEFINITION A.1 (irreducibility). *A square matrix* A *is said to be irreducible if it can be rearranged into the following form by renumbering the indices of rows and columns:*

$$\begin{pmatrix} B & 0 \\ C & D \end{pmatrix},$$

where B and D are square matrices and 0 *denotes the matrix with only zero entries. Otherwise A is called irreducible.*

An irreducible nonnegative matrix can have multiple eigenvalues whose magnitudes are equal to the magnitude of the dominant eigenvalue λ. By the number of such eigenvalues, irreducible nonnegative matrices are classified as follows.

DEFINITION A.2. *Let A be an irreducible nonnegative matrix that has h eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_h$, whose magnitudes are equal to the magnitude of the dominant eigenvalue $\lambda = \lambda_1$. A is called primitive if $h = 1$, and imprimitive if $h > 1$. h is called the index of imprimitivity of A.*

The theory of nonnegative matrices has a strong relationship with a graph theory.

DEFINITION A.3. *The associated directed graph, $G(A)$, of an $n \times n$ matrix A consists of n vertices $P_1, P_2, \ldots, P_n$, where an edge leads from P_j to P_i if $a_{ij} \neq 0$. A directed graph G is said to be strongly connected if for any ordered pair (P_i, P_j) of vertices of G there exists a path which leads from P_i to P_j. Let $P = \{P_{i_0}, P_{i_1}, \ldots, P_{i_\ell}\}$ be a path in a graph G. Then ℓ is the length of P. P is a loop if $P_{i_0} = P_{i_\ell}$.*

Irreducibility and the index of imprimitivity are characterized by directed graphs as follows.

THEOREM A.4 (e.g., see Theorem 2.2.7 of [3]). *A matrix A is irreducible if and only if $G(A)$ is strongly connected.*

THEOREM A.5 (e.g., see Theorem 2.2.30 of [3]). *Let A be an irreducible nonnegative matrix. The index of imprimitivity of A is equal to the greatest common divisor of the lengths of loops in $G(A)$.*

Remark. This theorem shows that indices of imprimitivity h (like irreducibility) depend only on the pattern of a matrix; i.e., every irreducible nonnegative matrix that has positive entries in exactly the same positions has the same index of imprimitivity.

The following two theorems are utilized in obtaining Theorem 4.1.

THEOREM A.6 (e.g., see Theorem 13.8 of [13]). *A nonnegative square matrix A is primitive if and only if there exists an integer $k \geq 1$ such $A^k > 0$.*

THEOREM A.7 (e.g., see Corollary 13.2 of [13]). *If A is an imprimitive matrix with index of imprimitivity h, then A^h can be rearranged into the following quasi-diagonal form by renumbering the indices of rows and columns:*

$$\operatorname{diag}\{A_1, A_2, \ldots, A_h\} = \begin{pmatrix} A_1 & 0 & \ldots & 0 \\ 0 & A_2 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & A_h \end{pmatrix}, \tag{3}$$

where $A_1, A_2, \ldots, A_h$ are primitive matrices with the same dominant eigenvalue and 0 *denotes the matrix with only zero entries.*

Acknowledgments. I would like to thank two anonymous referees for their helpful comments.

MODELING INTERVENTION MEASURES AND SEVERITY-DEPENDENT PUBLIC RESPONSE DURING SEVERE ACUTE RESPIRATORY SYNDROME OUTBREAK*

SZE-BI HSU† AND YING-HEN HSIEH‡

Abstract. The 2003 severe acute respiratory syndrome (SARS) epidemic came and left swiftly, resulting in more than 8,000 probable cases worldwide and 774 casualties. It is generally believed that quarantine of those individuals suspected of being infected was instrumental in quick containment of the outbreaks. In this work we propose a differential equation model that includes quarantine and other intervention measures implemented by the health authority, including those to prevent nosocomial infections and decrease frequency of contacts among the general public. We also consider the possible behavior change by the general populace to avoid infection, in response to the severity of the outbreak in general and to these intervention measures in particular. Complete analysis is given for the model without quarantine. For the general model with quarantine, a basic reproduction number is derived and full description of its dynamics is provided. We will show that introducing quarantine measures in the model could produce bistability in the system, thus changing the basic dynamics of the model. We give numerical examples of parameter values with which bistable steady states, where one is disease-free and the other endemic, could exist. However, realistic parameter values indicate that, assuming limited imported cases, the occurrence of the stable endemic steady state or bistability is unlikely. The modeling results indicate that for an infectious disease with infectivity and patterns of transmission typical of SARS, the outbreak can always be eradicated by implementing border control of imported cases and limited quarantine, along with the public's social response to avoid infections. Moreover, the results also suggest that quarantine measures will be effective in reducing infections only if the quarantined/isolated SARS patients and their potential contacts can successfully reduce their contact rate and/or transmission probabilities. Hence the effectiveness of quarantine for infectious diseases like SARS, for which no infection is being prevented during the quarantine period, can only be indirect and therefore must be combined with other intervention measures in order to quickly contain the outbreaks.

1. Introduction.

The worldwide severe acute respiratory syndrome (SARS) epidemic outbreak of November 2002–July 2003 accounted for more than 8,000 infections with 774 fatalities directly attributable to SARS [1]. It is generally believed [2] that the experience of affected regions showed that the transmission of SARS-Coronavirus (SARS-CoV) can be effectively controlled by adherence to basic public health measures, including rapid case detection, case isolation, contact tracing, and good infection control such as hand-washing and use of personal protective equipment. Another measure believed to be instrumental in breaking the transmission chain is the quarantine of well but potentially infective individuals to prevent infections [3, 4, 5, 6]. During the outbreak in Taiwan from April to June 2003, the

health authority attempted to quarantine more than 150,000 people who either had possible contact with a suspected SARS case or had just arrived from an affected area as determined by the World Health Organization (WHO). Of these quarantined individuals, only 17 were later officially confirmed as SARS cases. Hence questions remain as to the effectiveness of the quarantine.

During the outbreak, two distinct levels of quarantine were implemented in Taiwan. Level A quarantine, aimed at people suspected of having close contact with a suspected SARS case, was implemented on March 18, 2003. Level B quarantine, aimed at travelers from affected areas, was initiated on April 28 in the aftermath of the first SARS fatality in Taiwan on April 26. Details of the implementation of quarantine measures in Taiwan were described in [7]. By the end of the summer, a total of more than 150,000 people had been quarantined during the SARS outbreak.

There were 346 officially confirmed SARS cases as defined by WHO during the outbreak of 2003 in Taiwan, among which were 37 direct SARS casualties and 36 SARS-related deaths. In addition, 180 patients, who either had a previous negative PCR or antibody test or had been suspected or ruled-out cases, tested SARS antibody positive. However, Level B quarantine detected no confirmed SARS cases, while Level A quarantined persons included 17 officially confirmed SARS cases and 7 suspected or ruled-out cases with positive antibody tests [8]. Using the case data of the 480 laboratory-confirmed SARS cases, [8] showed that, compared to all other patients, previously quarantined persons had a significantly shorter onset-to-diagnosis time, i.e., the time it took a person with onset of symptoms to be diagnosed with suspected SARS and hospitalized. Hence quarantine had at least been useful in attaining more rapid detection and hospitalization of cases.

Rapid case definition also depends on knowledge regarding the clinical and molecular aspect of the disease, an inherently difficult task when facing a newly emerging disease like SARS. Contact tracing and quarantine of the traced contacts is another effective but difficult measure especially in an established democratic society, due to the ethical and legal ramifications [9]. Adherence to infection control, in the hospital or in the community, by the health care workers or the general populace, depends very much on the individual. The personal decision whether to diligently avoid contacts and infection is often based on the circumstances, i.e., whether there is any perceived cause for behavior change by the individual. The increasing severity of an outbreak or the implementation of massive intervention measures, e.g., the images of everyone wearing a face mask while in public places, is surely a cause for behavior change to avoid infection. This perhaps critically important factor will also be considered in our model.

In this work we will focus on three types of interventions evident during the past SARS outbreak: quarantine of potential infectives, isolation of suspected cases, and behavior change of the general public (including health care workers) in response to the increasing severity of the outbreak in an effort to avoid contacts which might lead to SARS infection. The focus is to study the roles played by intervention measures and social response in the quick containment of the outbreak. Previous modeling work of the SARS epidemic includes the early modeling of SARS by [10, 11] to obtain the all-important basic reproduction number for SARS, [12] on modeling the community and hospital transmission of SARS, and [13, 14] on models for data-fitting of SARS in Taiwan. Also see [15] for a review of mathematical models of SARS. Recent modeling work of epidemics with intervention measures (quarantine, vaccination, evacuation, etc.) includes [16, 17, 18, 19, 20] on smallpox, [17] on flu, [21] on bubonic plague, [22] on measles and whooping cough, [23] on optimal intervention strategies, and

[18] on a class of infectious disease models with quarantine.

This article is organized as follows: In section 2 we describe the general model with the intervention measures to be considered and the computation of basic reproduction numbers. In section 3 we give the complete analysis of the model with severity-dependent public response but without quarantine. Section 4 gives analytical results for the full model with quarantine and full description of its dynamics. Finally in section 5 we discuss the biological significance of our results.

2. The model. In this work, we propose a general model with Level A and B quarantines, as well as imported cases who entered the exposed class upon their arrival before April 28, but were quarantined (Level B) as they entered from the affected areas after April 28. The model variables are given as follows; note that the time unit is in days:

S—the number of susceptible individuals at time t;

E—the number of infected asymptomatic persons at time t;

Q_A—the number of asymptomatic infected persons at time t under Level A quarantine;

Q_B—the number of imported asymptomatic infected persons at time t (who were under B quarantine if arriving from affected areas after April 28);

I—the number of infective persons with onset of symptoms not isolated or quarantined at time t;

P—the number of isolated probable SARS cases at time t;

D—the cumulative number of SARS deaths at time t;

R—the cumulative number of discharged SARS patients at time t.

The key assumptions used are as follows:

1. A SARS-infected person is infective after onset of symptoms.

2. A quarantined person is quarantined without symptoms (hence is not infective), becoming infective with reduced contact rates due to quarantine, and is isolated upon diagnosis.

3. An infected person can infect others unless quarantined or isolated as a probable case with reduced contact rate depending on the effectiveness of the isolation. The underlying assumption here is that once diagnosed as a probable SARS case and hospitalized, a patient cannot infect others.

4. A probable case is removed from isolation either by death or discharge.

5. As behavior change by individuals occurs as a result of public response to the severity of the outbreak, the infection rate (or the product of transmission probability and contact rate) decreases with the increasing cumulative number of probable cases. Similarly, the effectiveness of quarantine and isolation also increases with the increasing number of probable cases, resulting in a decreased number of infections. To account for this decrease, we make use of a rational function $\frac{1}{1+a[P(t)+R(t)+D(t)]}$, where $P+R+D$ is the cumulative number of probable cases. We note that the decreasing rational function used, which resembles Holling's functional response in predator-prey models [24], is not the only choice of function to portray the phenomenon in question. A decreasing exponential function, for example, could do just as well.

6. We assume homogeneous mixing with quarantine-adjusted incidence.

7. Quarantine for Level A is proportionate to the number of infected asymptomatic persons.

8. Imported cases are a function of time ($Q(t) = 0$, 1, or 2 as deduced from data), with Level B quarantine after April 28.

The model parameters are as follows:

λ—infection rate due to contact with infective class;

q_1—proportion of recruitment of asymptomatic infected persons for Level A quarantine;

γ_3—isolation rate of infectives not under quarantine;

μ—progression rate from exposure to onset of symptoms;

γ_i, $i = 1, 2$—isolation rates of Q_A and Q_B, respectively;

α_A, α_B, α_P—the proportionate reduction in infectivity of quarantined persons due to Level A and B quarantines (before isolation) and probable cases, respectively;

ρ_i, $i = 1, 2$—respective fatality rates of infective cases and isolated probable SARS patients;

σ_i, $i = 1, 2$—respective discharge rates of infective cases and isolated probable SARS patients;

c—contact rate in absence of an outbreak;

a—the effect of behavior change in reduction of contact due to the cumulative number of probable cases;

β—transmission probability per effective contact.

The flowchart for the model is given in Figure 2.1.

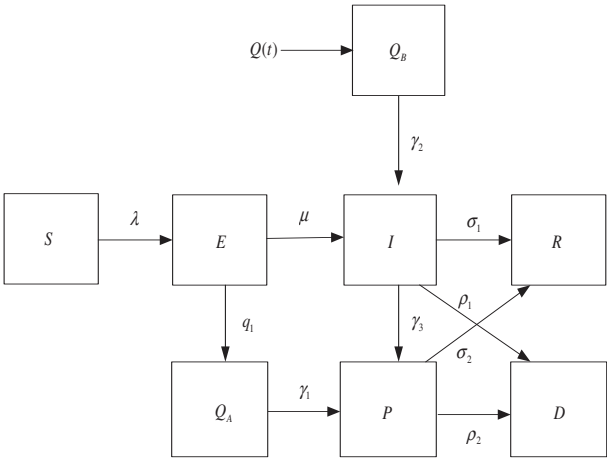

FIG. 2.1. *Flowchart for the model.*

Finally, the model equations with imported cases, Level A and B quarantines, and behavior change are as follows:

$$S' = -\lambda(S, E, I, Q_A, Q_B, P, R, D)S, \tag{2.1}$$

$$E' = \lambda(S, E, I, Q_A, Q_B, P, R, D)S - \mu E - q_1 E, \tag{2.2}$$

$$Q_A' = q_1 E - \gamma_1 Q_A, \tag{2.3}$$

$$Q_B' = Q(t) - \gamma_2 Q_B, \tag{2.4}$$

$$I' = \mu E + \gamma_2 Q_B - (\sigma_1 + \rho_1 + \gamma_3)I, \tag{2.5}$$

$$P' = \gamma_1 Q_A + \gamma_3 I - (\sigma_2 + \rho_2)P, \tag{2.6}$$

$$R' = \sigma_1 I + \sigma_2 P, \tag{2.7}$$

$$D' = \rho_1 I + \rho_2 P, \tag{2.8}$$

where the incidence of infection with quarantine is given by

$$\lambda(S,E,I,Q_A,Q_B,P,R,D) = \beta\frac{c}{1+a(P+R+D)} \times \frac{I+\alpha_A Q_A+\alpha_B Q_B+\alpha_P P}{S+E+I+\alpha_A Q_A+\alpha_B Q_B+\alpha_P P}.$$

Note that $S+E+Q_A+Q_B+I+P+R+D = S_0+I_0$, where S_0 and I_0 are the initial susceptible population sizes. The system is nonautonomous, due to the imported case term $Q(t)$ in the right-hand side of the equation for Q_B'. Brauer and van den Driessche [25] have shown that, if there is a positive flow of infectives into the population, disease-free equilibrium might not exist. However, during the SARS outbreak border control was implemented in Taiwan as well as all other affected areas. Therefore we can reasonably assume that $Q(t)$ has compact support and subsequently the asymptotic properties of the nonautonomous system given in (2.1)–(2.8) are the same as the corresponding autonomous system, i.e., with $Q(t) = 0$. Hence we need only consider the autonomous system hereafter.

For the model without quarantine, the model equations become

$$S' = -\lambda(S,E,I,P,D)S, \tag{2.9}$$

$$E' = \lambda(S,E,I,P,D)S - \mu E, \tag{2.10}$$

$$I' = \mu E - (\sigma_1+\rho_1+\gamma_3)I, \tag{2.11}$$

$$P' = \gamma_3 I - (\sigma_2+\rho_2)P, \tag{2.12}$$

$$R' = \sigma_1 I + \sigma_2 P, \tag{2.13}$$

$$D' = \rho_1 I + \rho_2 P, \tag{2.14}$$

where

$$\lambda(S,E,I,P,R,D) = \beta\left[\frac{c}{1+a(P+R+D)}\right]\frac{I+\alpha_P P}{S+E+I+\alpha_P P}.$$

The disease-free equilibrium (DFE) for the six-dimensional system in (S,E,I,P,R,D) is $(S^*,0,0,0,R^*,D^*)$ with $S^*+R^*+D^* = S_0+I_0$; the endemic equilibrium is $(0,0,0,0,R^{\#},D^{\#})$ with $R^{\#}+D^{\#} = S_0+I_0$.

Making use of the method in [26], we obtain the expression for the basic reproduction number R_0 of this case:

$$R_0 = \frac{\beta c}{(\sigma_1+\rho_1+\gamma_3)[1+a(R^*+D^*)]} + \frac{\beta c\alpha_P\gamma_3}{(\sigma_1+\rho_1+\gamma_3)[1+a(R^*+D^*)](\sigma_2+\rho_2)}. \tag{2.15}$$

Similarly as for the original model with quarantine, we have the more general expression for the effective basic reproduction number with quarantine R_Q, again using the procedure developed in [26]:

$$R_Q = \beta\frac{c}{[1+a(R^*+D^*)]}\left\{\frac{\mu}{(\sigma_1+\rho_1+\gamma_3)[\mu+q_1]}+\frac{\alpha_A q_1}{\gamma_1[\mu+q_1]}\right\} + \beta\frac{c}{[1+a(R^*+D^*)]}\frac{\alpha_P}{(\sigma_2+\rho_2)}\left\{\frac{\gamma_3}{(\sigma_1+\rho_1+\gamma_3)}\frac{\mu}{[\mu+q_1]}+\frac{q_1}{\mu+q_1}\right\}. \tag{2.16}$$

Note that both R_0 and R_Q have very clear biological interpretations which will be discussed in section 5.

3. Analysis for model without quarantine. In this section we provide full analysis for the model without quarantine. To simplify, we let $\alpha_p = 0$. That is, hospitalized and isolated probable cases do not make a significant contribution to the infections, as indicated by the result in a data-motivated modeling study of Taiwan's SARS outbreak in [27]. We note that while it is true that nosocomial infections played a crucial role during the SARS outbreak in all affected, as confirmed by the fact that nearly 80% of SARS infections in Taiwan occurred nosocomially [28], most had occurred *before* the infective individuals had been diagnosed with SARS and hospitalized with adequate isolation. Only a small number of infections in Taiwan as well as in other affected areas have been documented as being caused by a confirmed or probable SARS patient who most likely had been isolated.

Hence the system in (2.9)–(2.14) becomes

$$S' = -\frac{\beta IS}{E+I+S}\frac{c}{1+a(P+R+D)}, \tag{3.1}$$

$$E' = \frac{\beta IS}{E+I+S}\frac{c}{1+a(P+R+D)} - \mu E, \tag{3.2}$$

$$I' = \mu E - (\sigma_1+\rho_1+\gamma_3)I, \tag{3.3}$$

$$P' = \gamma_3 I - (\sigma_2+\rho_2)P, \tag{3.4}$$

$$R' = \sigma_1 I + \sigma_2 P, \tag{3.5}$$

$$D' = \rho_1 I + \rho_2 P, \tag{3.6}$$

with $S(0) = S_0 > 0$, $I(0) = I_0 > 0$, $E(0) = P(0) = R(0) = D(0) = 0$.

We first give the following lemma, the proof of which is in [29].

LEMMA 3.1. *Let f be continuously differentiable. If $f(t) \longrightarrow$ constant as $t \to \infty$ and $|f''(t)| \le M$ for all t, then $f'(t) \to 0$ as $t \to \infty$.*

THEOREM 3.2. *We have the following asymptotic properties: $S(t) \longrightarrow S_\infty \ge 0$, $R(t) \longrightarrow R_\infty > 0$, $D(t) \longrightarrow D_\infty > 0$, and $\lim_{t\to\infty} I(t) = 0$, $\lim_{t\to\infty} E(t) = 0$, $\lim_{t\to\infty} P(t) = 0$.*

Proof. Obviously $S(t)$ is monotone decreasing and bounded below; hence $\lim_{t\to\infty} S(t) = S_\infty \ge 0$, $0 \le S_\infty < S_0$. Moreover, $(E+S)' = -\mu E$, and therefore $E(t)+S(t)$ is monotone decreasing for $t \ge 0$. Hence $E(t) \longrightarrow E_\infty \ge 0$ as $t \to \infty$. Since $S(t)+E(t)+I(t)+P(t)+R(t)+D(t) \equiv N = S_0 + I_0$ for all t, $R' \ge 0$, $D' \ge 0 \Longrightarrow$ $R(t) \longrightarrow R_\infty > 0$, $D(t) \longrightarrow D_\infty > 0$. Obviously $R'' = \sigma_1 I' + \sigma_2 P'$, $|I'|$ and $|P'|$ are bounded, and hence $|R''| \le M$ for some $M > 0$. Consequently by Lemma 3.1 $I(t) \longrightarrow I_\infty = 0$, $P(t) \longrightarrow P_\infty = 0$ as $t \to \infty$.

Claim: $E_\infty = 0$. Suppose $E_\infty > 0$; then $I' = \mu E - (\sigma_1+\rho_1+\gamma_3)I \ge \mu(E_\infty - \varepsilon) - (\sigma_1+\rho_1+\gamma_3)\varepsilon > 0$ for ε small, t large. It follows that $I(t)$ becomes unbounded. This is a contradiction. □

Next, we let $q = \sigma_1 + \rho_1 + \gamma_3$ and $c = 1$ (i.e., β denotes contact rate times transmission probability) for the sake of simplicity. We also, for the moment, assume $a = 0$, i.e., no behavior change. We will return to discuss the case with behavior change later in this section. Subsequently, we consider the following simplified system:

$$S' = -\frac{\beta IS}{E+I+S}, \tag{3.7}$$

$$E' = \frac{\beta IS}{E+I+S} - \mu E, \tag{3.8}$$

$$I' = \mu E - qI, \tag{3.9}$$

with $S(0) = S_0 > 0$, $I(0) = I_0 > 0$, $E(0) = 0$.

Now, we let $W_1 = S/I$, $W_2 = E/I$. Then (3.7)–(3.9) become

$$W_1' = -\frac{\beta W_1}{1 + W_1 + W_2} - W_1(\mu W_2 - q), \tag{3.10}$$

$$W_2' = \frac{\beta W_1}{1 + W_1 + W_2} - \mu W_2 - W_2(\mu W_2 - q), \tag{3.11}$$

with $W_1(0) > 0$, $W_2(0) = 0$.

To study the flow of (3.10)–(3.11) in the W_2W_1-phase plane, we first consider the isoclines $W_1' = 0$ and $W_2' = 0$. Clearly, $W_1' < 0$ if $W_2 > q/\mu$. Moreover,

$$\begin{aligned} W_1' \geq 0 &\Longleftrightarrow q - \mu W_2 \geq \frac{\beta}{1 + W_1 + W_2} \\ &\Longleftrightarrow 1 + W_1 + W_2 \geq \frac{\beta}{q - \mu W_2} \quad \text{for} \quad q - \mu W_2 \geq 0 \\ &\Longleftrightarrow W_1 \geq \frac{\beta}{q - \mu W_2} - (1 + W_2) = f(W_2) \quad \text{for} \quad q - \mu W_2 \geq 0, \end{aligned}$$

and

$$\begin{aligned} W_2' \geq 0 &\Longleftrightarrow \frac{\beta W_1}{1 + W_1 + W_2} \geq [\mu + (\mu W_2 - q)]W_2 \\ &\Longleftrightarrow \beta W_1 \geq [\mu + (\mu W_2 - q)]W_2(1 + W_1 + W_2) \\ &\Longleftrightarrow \beta - W_2[\mu + (\mu W_2 - q)]W_1 > [\mu + (\mu W_2 - q)]W_2(1 + W_2) \\ &\Longleftrightarrow W_1 > \frac{W_2(1 + W_2)[\mu + (\mu W_2 - q)]}{\beta - W_2[\mu + (\mu W_2 - q)]} = g(W_2). \end{aligned}$$

Consequently, it is easy to verify that the curves $W_1 = f(W_2)$ and $W_1 = g(W_2)$ do not intersect.

There are four cases to be considered:

1. $q < \beta$, $q < \mu$.
   Let $\widetilde{W_2}$ be the positive root of
   $$h(W_2) = \beta - W_2[\mu + (\mu W_2 - q)] = 0.$$
   Clearly $h(\frac{q}{\mu}) = \beta - q > 0$. Hence $\frac{q}{\mu} < \widetilde{W_2}$. In the first quadrant of the W_2W_1-phase plane, the isocline $W_1 = 0$, $(W_1 = f(W_2))0 \leq W_2 < \frac{q}{\mu}$, satisfies $f(0) = \frac{\beta}{q} - 1 > 0$ and $f((\frac{q}{\mu})^-) = \infty$. The isocline $\dot{W}_2 = 0 (W_1 = g(W_2))$ satisfies $g(0) = 0$, $g(\widetilde{W_2}-) = \infty$. We note that the isocline $\dot{W}_1 = 0$ is above that of $\dot{W}_2 = 0$. Every trajectory converges to the endemic equilibrium $(S/I, E/I) = (0, 0)$ as $t \to \infty$.
2. $\beta > q$, $\mu < q$.
   There are two equilibria $(0, 0)$ and $(W_2^*, 0)$, where $W_2^* = \frac{q}{\mu} - 1$. Similar to case 1, every trajectory converges to $(W_2^*, 0)$.
3. $\beta < q$, $\mu < q$.
   Clearly $f(W_2^*) = f(\frac{q}{\mu} - 1) = \frac{\beta}{\mu} - \frac{q}{\mu} < 0$. Observe that $h(\frac{q}{\mu}) = \beta - q < 0$ and we have $\widetilde{W_2} < \frac{q}{\mu}$. Since the isocline $\dot{W}_2 = 0$ is above that of $\dot{W}_1 = 0$, it follows that, as $t \longrightarrow \infty$, $h(W_2(t)) \longrightarrow \widetilde{W_2}$, the positive root of $h(W_2) = 0$, and $W_1(t) \longrightarrow \infty$. Moreover, $(W_1(t), W_2(t))$ approaches the curve $W_1 = g(W_2)$, i.e., $W_2 = 0$, as $t \to \infty$.

4. $\beta < q$, $q < \mu$.
   Obviously, this case is similar to the previous case with $W_2(t) \to \widetilde{W_2}$ and $W_1(t) \to \infty$ as $t \to \infty$.

We then have the following theorem.

THEOREM 3.3. *For system* (3.7)–(3.9), *if* $\beta > q$, *then* $S(t) \to 0$ *as* $t \to \infty$. *If* $\beta < q$, *then* $S(t) \to S_\infty > 0$ *as* $t \to \infty$.

Proof. For cases 1 and 2 as described earlier, $\frac{S(t)}{I(t)} = W_1(t) \to 0$ as $t \to \infty$. Since $I(t) \longrightarrow 0$ and $S(t) \longrightarrow S_\infty \geq 0$, we have $S_\infty = 0$. Hence, $\beta > q$ implies $S(t) \longrightarrow 0$ as $t \to \infty$. If $\beta < q$, then, by cases 3 and 4, we have $W_1(t) \longrightarrow \infty$ and $W_2(t) \longrightarrow \widetilde{W_2} > 0$ as $t \to \infty$.

Claim: $S_\infty > 0$. If $S_\infty = 0$, then

$$\int_0^\infty \frac{1}{1 + W_1(t) + W_2(t)} dt = \infty \quad \text{and} \quad \int_0^\infty \frac{1}{W_1(t)} dt \geq \int_0^\infty \frac{1}{1 + W_1(t) + W_2(t)} dt = \infty.$$

Therefore we have $\int_0^\infty \frac{1}{W_1(t)} dt = \infty$.

From (4.10),

$$W_1' = \frac{-\beta W_1}{1 + W_1 + W_2} - W_1(\mu W_2 - q) \geq \frac{-\beta W_1}{1 + W_1 + \widetilde{W_2} - \epsilon} + W_1[q - \mu(\widetilde{W_2} + \epsilon)],$$

where $\widetilde{W_2} - \epsilon < W_2(t) < \widetilde{W_2} + \epsilon$ for $t \geq t_0$.

For $t \geq t_0$,

$$\frac{W_1'}{W_1} \geq \frac{-\beta}{1 + W_1 + \widetilde{W_2} - \epsilon} + [q - \mu(\widetilde{W_2} + \epsilon)].$$

Because $W_1(t) \to \infty$ as $t \to \infty$,

$$\frac{W_1'}{W_1} \geq \frac{1}{2}[q - \mu(\widetilde{W_2} + \epsilon)] > 0 \qquad \text{for } t \geq T, \text{ for some } T \text{ large.}$$

Therefore $W_1 \to \infty$ exponentially, and

$$W_1(t) \geq W_1(T) \exp\left\{\frac{1}{2}[q - \mu(\widetilde{W_2} + \epsilon)](t - T)\right\}.$$

But

$$\infty = \int_T^\infty \frac{1}{W_1(t)} dt \leq \int_T^\infty \frac{1}{W_1(T) \exp\{\frac{1}{2}[q - \mu(\widetilde{W_2} + \epsilon)(t - T)]\}} dt < \infty.$$

This is a contradiction. □

Now we return to consider system (3.1)–(3.6) with behavior change.

THEOREM 3.4. *Let* $\widetilde{\beta} = \frac{\beta c}{1 + aN}$, *where* $N = R_\infty^* + D_\infty^*$.

(i) *If* $q = \sigma_1 + \rho_1 + \gamma_3 > \widetilde{\beta}$, *then the solution of system* (3.1)–(3.6) *satisfies* $S(t) \longrightarrow S_\infty > 0$ *as* $t \to \infty$.

(ii) *If* $q < \widetilde{\beta}$, *then* $S(t) \longrightarrow 0$ *as* $t \to \infty$.

Note that the condition $q < \widetilde{\beta}$ in the above theorem is equivalent to $R_0 > 1$ with R_0 as defined in (2.15) and $\alpha_P = 0$. Hence with this theorem we have shown that the asymptotic result for R_0 is global.

Proof. (i) Suppose not; then $\lim_{t\to\infty} S(t) = S^*_\infty = 0$. Consider the limiting system of

$$S' = -\frac{\beta IS}{E+I+S}\frac{c}{1+a(P+R+D)}a \geq 0, \tag{3.12}$$

$$E' = \frac{\beta IS}{E+I+S}\frac{c}{1+a(P+R+D)} - \mu E, \tag{3.13}$$

$$I' = \mu E - (\sigma_1+\rho_1+\gamma_3)I. \tag{3.14}$$

Since $P(t) \longrightarrow 0$, $R(t) \longrightarrow R^*_\infty$, and $D_(t) \longrightarrow D^*_\infty$ as $t \to \infty$, we have the limiting system as follows:

$$S' = -\frac{\beta IS}{E+I+S}\frac{c}{1+aN}, \quad a \geq 0, \tag{3.15}$$

$$E' = \frac{\beta IS}{E+I+S}\frac{c}{1+aN} - \mu E, \tag{3.16}$$

$$I' = \mu E - (\sigma_1+\rho_1+\gamma_3)I. \tag{3.17}$$

From the analysis of system (3.7)–(3.9) with

$$\widetilde{\beta} = \frac{\beta c}{1+aN},$$

if $q > \widetilde{\beta}$, then $S(t) \to S_\infty > 0$. This is a contradiction.

(ii) Assuming $q < \widetilde{\beta}$, we want to show $\lim_{t\to\infty} S(t) = 0$. If not, then $\lim_{t\to\infty} S(t) = S_\infty > 0$. In this case, we have $R_\infty + D_\infty + S_\infty = N$, where $R_\infty = \lim_{t\to\infty} R(t)$, $D_\infty = \lim_{t\to\infty} D(t)$.

Since $S_\infty > 0$, $D_\infty + R_\infty < N$. The limiting system of (3.12)–(3.14) is system (3.15)–(3.17) with D^*_∞, R^*_∞ replaced by D_∞, R_∞. From the analysis of system (3.7)–(3.9) and the assumption $q < \widetilde{\beta}$, we have

$$\widehat{\beta} = \frac{c\beta}{1+a(D_\infty+R_\infty)} > \frac{c\beta}{1+aN} = \widetilde{\beta} > q;$$

hence $S(t) \longrightarrow 0$ as $t \to \infty$. This is a contradiction. □

4. Analysis for model with quarantine. We now give some analytical results on the model with Level A quarantine only. We then have the system

$$S' = -\lambda(S,E,I,Q_A,P,R,D)S, \tag{4.1}$$

$$E' = \lambda(S,E,I,Q_A,P,R,D)S - \mu E - q_1 E, \tag{4.2}$$

$$Q'_A = q_1 E - \gamma_1 Q_A, \tag{4.3}$$

$$I' = \mu E - (\sigma_1+\rho_1+\gamma_3)I, \tag{4.4}$$

$$P' = \gamma_1 Q_A + \gamma_3 I - (\sigma_2+\rho_2)P, \tag{4.5}$$

$$R' = \sigma_1 I + \sigma_2 P, \tag{4.6}$$

$$D' = \rho_1 I + \rho_2 P, \tag{4.7}$$

where the incidence of infection with quarantine rates is given by

$$\lambda(S,E,I,Q_A,P,R,D) = \beta\frac{I+\alpha_A Q_A}{S+E+I+\alpha_A Q_A}\frac{c}{1+a(P+R+D)}. \tag{4.8}$$

Again $S+E+Q_A+I+P+R+D = S_0+I_0 \equiv N$, where $S(0) = S_0 > 0$, $I(0) = I_0 > 0$.

As in Theorem 3.2, we have $S(t) \longrightarrow S_\infty \geq 0$, $R(t) \longrightarrow R_\infty > 0$, $D(t) \longrightarrow D_\infty > 0$ and $I(t) \longrightarrow 0$, $E(t) \longrightarrow 0$, $P(t) \longrightarrow 0$, $Q_A(t) \longrightarrow 0$ as $t \longrightarrow \infty$.

Next we let $\widetilde{q} = \sigma_1 + \rho_1 + \gamma_3$, $c = 1$, and $a = 0$ and consider the limiting system

$$\begin{aligned} S' &= \frac{-\beta(I + \alpha_A Q_A)}{S + E + I + \alpha_A Q_A} S, \\ E' &= \frac{\beta(I + \alpha_A Q_A)}{S + E + I + \alpha_A Q_A} S - \mu E - q_1 E, \\ Q_A' &= q_1 E - \gamma_1 Q_A, \\ I' &= \mu E - \widetilde{q} I. \end{aligned} \tag{4.9}$$

Let $W_1 = \frac{S}{I}$, $W_2 = \frac{E}{I}$, $W_3 = \frac{Q_A}{I}$. Then we have

$$\begin{aligned} W_1' &= -\frac{\beta(1 + \alpha_A W_3)}{1 + W_1 + W_2 + \alpha_A W_3} W_1 - (\mu W_2 - \widetilde{q}) W_1, \\ W_2' &= \frac{\beta(1 + \alpha_A W_3)}{1 + W_1 + W_2 + \alpha_A W_3} W_1 - (\mu + q_1) W_2 - (\mu W_2 - \widetilde{q}) W_2, \\ W_3' &= (q_1 W_2 - \gamma_1 W_3) - (\mu W_2 - \widetilde{q}) W_3. \end{aligned} \tag{4.10}$$

We note that if $\alpha_A = 0$, $q_1 > 0$, then (4.10) is reduced to the two-dimensional system

$$\begin{aligned} W_1' &= \frac{-\beta W_1}{1 + W_1 + W_2} - (\mu W_2 - \widetilde{q}) W_1, \\ W_2' &= \frac{\beta W_1}{1 + W_1 + W_2} - (\mu + q_1) W_2 - (\mu W_2 - \widetilde{q}) W_2. \end{aligned}$$

As in Theorem 3.4, it can be shown that (i) if $\widetilde{\beta} < \widetilde{q}(\frac{\mu + q_1}{\mu})$, then $S(t) \to S_\infty > 0$ as $t \to \infty$ and (ii) if $\widetilde{\beta} > \widetilde{q}(\frac{\mu + q_1}{\mu})$, then $S(t) \to 0$ as $t \to \infty$.

We give the following equilibria and their respective stability analyses:

1. $E_0 = (0, 0, 0)$ is an equilibrium of (4.10). Then the variational matrix at E_0 is

$$M_0 = \begin{bmatrix} -\beta + \widetilde{q} & 0 & 0 \\ \beta & -(\mu + q_1) + \widetilde{q} & 0 \\ 0 & q_1 & -\gamma_1 + \widetilde{q} \end{bmatrix}.$$

We then have the following trivial lemma.

LEMMA 4.1. *$E_0 = (0, 0, 0)$ is locally asymptotically stable if $\beta > \widetilde{q}$, $\mu + q_1 > \widetilde{q}$, $\gamma_1 > \widetilde{q}$.*

2. $E_{23}^* = (0, W_2^*, W_3^*)$, where

$$\begin{aligned} W_2^* &= \frac{\widetilde{q} - (\mu + q_1)}{\mu} > 0 \Longleftrightarrow \widetilde{q} > \mu + q_1, \\ W_3^* &= \frac{q_1 W_2^*}{(\mu W_2^* - \widetilde{q}) + \gamma_1} > 0 \Longleftrightarrow \gamma_1 > \mu + q_1. \end{aligned}$$

Note that $E_{23}^* = (0, W_2^*, W_3^*)$ exists if $\widetilde{q} > \mu + q_1$, $\gamma_1 > \mu + q_1$.

The variational matrix at E_{23}^* is

$$M^* = \begin{bmatrix} \frac{-\beta(1+\alpha_A W_3^*)}{1+W_2^*+\alpha_A W_3^*} - (\mu W_2^* - q) & 0 & 0 \\ \frac{\beta(1+\alpha_A W_3^*)}{1+W_2^*+\alpha_A W_3^*} & -(\mu+q_1) - (2\mu W_2^* - \widetilde{q}) & 0 \\ 0 & q_1 - \mu W_3^* & -\gamma_1 - (\mu W_2^* - \widetilde{q}) \end{bmatrix}.$$

The local stability result is given below, the proof of which is also trivial.

LEMMA 4.2. *E_{23}^* is locally asymptotically stable if $\beta > \frac{1+W_2^*+\alpha_A W_3^*}{1+\alpha_A W_3^*}(\mu+q_1)$.*

3. $E_\infty = (+\infty, \widetilde{W_2}, \widetilde{W_3})$, where $\widetilde{W_2} < \frac{q}{\mu}$. From the first equation of (4.10), we have $\frac{W_1'}{W_1} \le -(\mu W_2 - \widetilde{q})$. If $\lim_{t\to\infty} W_1(t) = \infty$, then we must have $\widetilde{W_2} < \frac{q}{\mu}$. From the second and third equations of (4.10) and $\lim_{t\to\infty} W_1(t) = \infty$, it can be shown that $(\widetilde{W_2}, \widetilde{W_3})$ is the solution of

$$\begin{aligned} \beta(1+\alpha_A W_3) - (\mu W_2 - \widetilde{q})W_2 - (\mu+q_1)W_2 = 0, \\ (q_1 W_2 - \gamma_1 W_3) - (\mu W_2 - \widetilde{q})W_3 = 0. \end{aligned}$$

By the Poincare transform, $Z_1 = \frac{1}{W_1}$, $Z_2 = \frac{W_2}{W_1}$, $Z_3 = \frac{W_3}{W_1}$. Consequently, system (4.10) becomes

$$\begin{aligned} Z_1' &= \beta Z_1 \frac{Z_1 + \alpha_A Z_3}{1 + Z_1 + Z_2 + \alpha_A Z_3} + \mu Z_2 - \widetilde{q} Z_1, \\ Z_2' &= (1+Z_2)\frac{\beta(Z_1 + \alpha_A Z_3)}{1 + Z_1 + Z_2 + \alpha_A Z_3} - (\mu+q_1)Z_2, \\ Z_3' &= q_1 Z_2 - \gamma_1 Z_3 + Z_3 \frac{\beta(Z_1 + \alpha_A Z_3)}{1 + Z_1 + Z_2 + \alpha_A Z_3}. \end{aligned} \tag{4.11}$$

The local stability of E_∞ for system (4.10) is equivalent to the local stability of $\widehat{E_0} = (0,0,0)$ for system (4.11). The variational matrix of $\widehat{E_0}$ for system (4.11) is computed as

$$\begin{bmatrix} -\widetilde{q} & \mu & 0 \\ \beta & -(\mu+q_1) & \beta\alpha_A \\ 0 & q_1 & -\gamma_1 \end{bmatrix}.$$

From the Routh–Hurwitz criterion, the stability conditions can be rewritten as

1. $\beta < A_1$, $A_1 = \frac{\gamma_1\widetilde{q} + (\mu+q_1)(\gamma_1+\widetilde{q})}{\mu + \alpha_A \widetilde{q}}$.
2. $\beta < A_2$, $A_2 = \frac{(\mu+q_1)\gamma_1\widetilde{q}}{\mu\gamma_1 + \alpha_A q_1 \widetilde{q}}$.
3. $\beta < A_3$, $A_3 = \frac{(\mu+q_1)^2(\gamma_1+\widetilde{q}) + \gamma_1\widetilde{q} + (\mu+q_1)(\gamma_1+\widetilde{q})^2}{\mu(\mu+q_1) + \mu\widetilde{q} + \alpha_A q_1((\mu+q_1)+\gamma_1)}$.

We now have the following trivial results.

LEMMA 4.3. *E_∞ is stable if $\beta < A_2$.*

Proof. By routine computation, we have $A_2 < A_1$, $A_2 < A_3$. ∎

LEMMA 4.4. *If $\gamma_1 > \widetilde{q}$, then $A_2 > \widetilde{q}$.*

Proof. Clearly, $A_2 > \widetilde{q} \Longleftrightarrow \gamma_1 > \alpha_A \widetilde{q}$, $0 \le \alpha_A \le 1$. ∎

Thus, when $\gamma_1 > \widetilde{q}$, we have the stability of E_0 and E_∞ diagramed as in Figure 4.1.

We note that if $q_1 = 0$, $\alpha_A = 0$, then $A_2 = \widetilde{q}$. If $\alpha_A = 0$, then $A_2 = \widetilde{q}\frac{\mu+q_1}{\mu}$. If $0 < \alpha_A < 1$, then

$$A_2 = \gamma_1 \widetilde{q} \frac{\mu + q_1}{\mu\gamma_1 + \alpha_A q_1 \widetilde{q}} \to \frac{\gamma_1}{\alpha_A} \quad \text{as } q_1 \longrightarrow \infty.$$

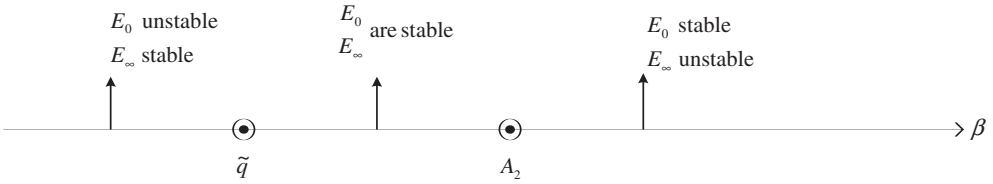

FIG. 4.1. *Stability of E_0 and E_∞ when $\gamma_1 > \widetilde{q}$.*

Thus for the model with quarantine measure, there is a region of bistability. The smaller α_A and larger q_1 give a large region of bistability. According to analysis, if the contact rate $\beta < \widetilde{q}$, we would have only the DFE *no matter if the quarantine measure is implemented or not*. However, if $\beta > A_2$, then we have the endemic case, i.e., $S(t) \longrightarrow 0$ as $t \longrightarrow \infty$.

The following lemma is trivial to prove.

LEMMA 4.5. *If $\mu + q_1 > \widetilde{q}$, $\gamma_1 > \widetilde{q}$, $\widetilde{q} < \beta < A_2$, then both E_0 and E_∞ are locally asymptotically stable. Furthermore, there exists a unique interior equilibrium $E_c = (W_{1c}, W_{2c}, W_{3c})$, $0 < W_{2c} < \frac{\widetilde{q}}{\mu}$.*

Remark. We conjecture that E_c is a saddle point with two-dimensional stable manifold, although we are unable to give a rigorous proof. Instead we will give a full description of the dynamics for the model with quarantine.

Next we consider the case $\widetilde{q} > \mu + q_1$, $\gamma_1 > \mu + q_1$, which guarantees the existence of E_{23}^*. The following inequality is also easy to obtain.

LEMMA 4.6. $A_2 > (\mu + q_1)\frac{1+W_2^*+\alpha_A W_3^*}{1+\alpha_A W_3^*}$.

An illustration of the stability of E_{23} and E_∞ in this case is given in Figure 4.2.

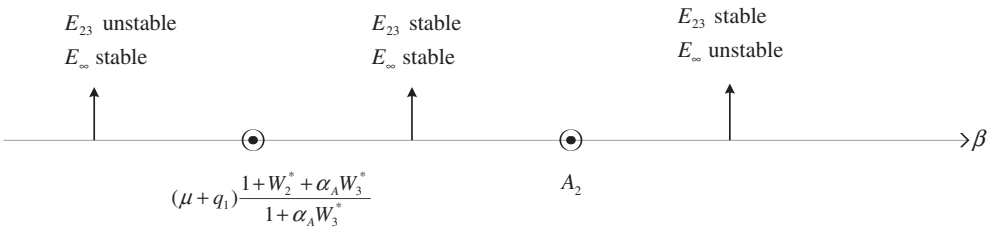

FIG. 4.2. *Stability of E_{23} and E_∞ when $A_2 > (\mu + q_1)\frac{1+W_2^*+\alpha_A W_3^*}{1+\alpha_A W_3^*}$.*

We note that if $\alpha_A = 0$, $q_1 = 0$, then

$$(\mu + q_1)\frac{1 + W_2^* + \alpha_A W_3^*}{1 + \alpha_A W_3^*} = \widetilde{q} \quad \text{and} \quad A_2 = \widetilde{q}.$$

It is also easy to show that

$$(\mu + q_1)\frac{1 + W_2^* + \alpha_A W_3^*}{1 + \alpha_A W_3^*} > \widetilde{q} \Longleftrightarrow \frac{1}{\alpha_A} > \frac{\widetilde{q} - (\mu + q_1)}{\gamma_1 - (\mu + q_1)}.$$

Thus if $\frac{1}{\alpha_A} > \frac{\widetilde{q}-(\mu+q_1)}{\gamma_1-(\mu+q_1)}$ (e.g., if $\gamma_1 > \widetilde{q}$), we have a diagram for the relative sizes of parameters in Figure 4.3.

Thus, for the model with the quarantine measures and the contact rate β, $\widetilde{q} < \beta < (\mu + q_1)(1 + \frac{W_2^*}{1+\alpha_A W_3^*})$ yields the DFE. On the other hand, we would have the

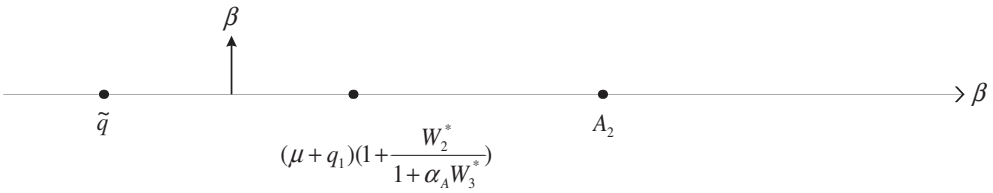

FIG. 4.3. *Diagram for the relative sizes of parameters when* $\frac{1}{\alpha_A} > \frac{\tilde{q}-(\mu+q_1)}{\gamma_1-(\mu+q_1)}$ *(e.g., if* $\gamma_1 > \tilde{q}$*).*

endemic steady state if no quarantine action is taken (i.e., $\beta > \tilde{q} \Longrightarrow$ endemic steady state in the case of no quarantine). The diagram for the case $\frac{1}{\alpha_A} > \frac{\tilde{q}-(\mu+q_1)}{\gamma_1-(\mu+q_1)}$, which is possible if $\gamma_1 < \tilde{q}$, has been deleted for brevity.

For the case $(\mu + q_1)(1 + \frac{W_2^*}{1+\alpha_A W_3^*}) < \beta < \tilde{q}$, E_{23}^* and E_∞ are both stable. Consequently, having quarantine measures implemented might lead to an adverse effect. More precisely, since $\beta < \tilde{q}$, we have the system approaching DFE when there is no quarantine, but with quarantine, we would have the bistable case where the system could approach an endemic steady state, given that the appropriate initial population is in the stability region of the endemic equilibrium.

Remark. In the bistable case, we again conjecture that the interior equilibrium (E_c) exists and (E_c) is a saddle point with two-dimensional stable manifold.

Now we return to the original system (4.1)–(4.7). Consider the limiting system

$$
\begin{aligned}
S' &= -\frac{\beta(I+\alpha_A Q_A)}{S+E+I+\alpha_A Q_A}\frac{cS}{1+a(D_\infty+R_\infty)},\\
E' &= \frac{\beta(I+\alpha_A Q_A)}{S+E+I+\alpha_A Q_A}\frac{cS}{1+a(D_\infty+R_\infty)} - (\mu+q_1)E,\\
Q_A' &= q_1 E - \gamma_1 Q_A,\\
I' &= \mu E - \tilde{q} I.
\end{aligned}
\tag{4.12}
$$

Letting $\widehat{\beta} = \frac{\beta c}{1+a(D_\infty^*+R_\infty^*)}$, we have the following theorem, the proof of which is similar to that of the case without quarantine.

LEMMA 4.7. *If* $W_1(t) \to \infty$ *as* $t \to \infty$*, then we have* $W_2(t) \to \widetilde{W}_2 < \infty$*,* $Z_3 = \frac{W_3}{W_1} \to 0$*, and* $S(t) \to S_\infty > 0$*.*

We now have the main theorem.

THEOREM 4.8. *Let* $\widetilde{\beta} = \frac{\beta c}{1+aN}$*.*

1. *If* $W_1(t) \to \infty$ *as* $t \to \infty$*,* $\widetilde{\beta} < A_2$*, and* E_0, E_{23}^* *are unstable, then* $S(t) \to S_\infty > 0$*.*
2. *If* $W_1(t) \to 0$ *as* $t \to \infty$*,* $\widetilde{\beta} > A_2$*, and one of the two equilibria,* E_0 *or* E_{23}^**, is asymptotically stable, then* $S(t) \to 0$ *as* $t \to \infty$*.*
3. *The bistable case occurs when* $\tilde{q} < \widetilde{\beta} < A_2$*, or* $(\mu+q_1)(1+\frac{W_2^*}{1+\alpha_A W_3^3}) < \widetilde{\beta} < A_2$*.*

Proof.

1. If not, $S(t) \to 0$ as $t \to \infty$, i.e., $S_\infty^* = 0$. Consider the limiting system (4.11) where we have

$$\widehat{\beta} = \frac{\beta c}{1+a(D_\infty^*+R_\infty^*)} = \frac{\beta c}{1+aN} = \widetilde{\beta} < A_2.$$

It follows that $\lim_{t\to\infty} W_1(t) = +\infty$ (assuming the convergence is global) $\Longrightarrow$ $S(t) \to S_\infty > 0$. Hence we have a contradiction.

2. If not, assume $S(t) \to S_\infty^* > 0$. Then $S_\infty^* + D_\infty^* + R_\infty^* = N$. Consequently,

$$\widehat{\beta} = \frac{\beta c}{1 + a(D_\infty^* + R_\infty^*)} > \frac{\beta C}{1 + a(S_\infty^* + D_\infty^* + R_\infty^*)} = \frac{\beta C}{1 + aN} = \widetilde{\beta} > A_2$$

and $\lim_{t\to\infty} S(t) = S_\infty = 0$, again a contradiction. □

Remark. It can be shown that the local stability condition for the effective reproduction number with quarantine $R_Q < 1$ is equivalent to condition 1 of Theorem 4.8, namely, $\widetilde{\beta} = \frac{\beta c}{1+a(S_\infty^* + D_\infty^* + R_\infty^*)} < A_2$.

We further consider the case where $E_0 = (0, 0, 0)$ is unstable and $E_{23}^* = (0, W_2^*, W_3^*)$ does not exist. We note that $E_0 = (0, 0, 0)$ is stable $\iff \beta > \widetilde{q}$, $\mu + q_1 > \widetilde{q}$, $\gamma_1 > \widetilde{q}$ and E_{23}^* exists $\iff \mu + q_1 < \widetilde{q}$, $\gamma_1 > \mu + q_1$.

We consider the case $W_3(t) \to \infty$ as $t \to \infty$. Let $U_1 = W_1$, $U_2 = W_2$, $U_3 = \frac{1}{W_3}$. Then system (4.10) becomes

$$\begin{aligned} U_1' &= \frac{-\beta(U_3 + \alpha_A)}{U_3(1 + U_1 + U_2) + \alpha_A} U_1 - (\mu U_2 - \widetilde{q}) U_1, \\ U_2' &= \frac{\beta(U_3 + \alpha_A)}{U_3(1 + U_1 + U_2) + \alpha_A} U_1 - (\mu + q_1) U_2 - (\mu U_2 - \widetilde{q}) U_2, \\ U_3' &= -q_1 U_2 U_3^2 + \gamma_1 U_3 + U_3(\mu U_2 - \widetilde{q}). \end{aligned} \tag{4.13}$$

We give the equilibria and stability analysis of (4.13):

1. $\widetilde{E_0} = (0, 0, 0)$ always exists.
2. $\widetilde{E_2} = (0, \widetilde{U}_2, 0)$, where $\widetilde{U}_2$ satisfies $-(\mu + q_1)\widetilde{U}_2 - (\mu\widetilde{U}_2 - \widetilde{q})\widetilde{U}_2 = 0$. Therefore $\widetilde{U}_2 = \frac{\widetilde{q} - (\mu + q_1)}{\mu} > 0 \iff \widetilde{q} > \mu + q_1$. Subsequently, $\widetilde{E_2}$ exists if and only if $\widetilde{q} > \mu + q_1$.
3. $\widetilde{E_{12}} = (U_1^*, U_2^*, 0)$.
   From the first equation of (4.13), $U_2^* > 0$ satisfies $-\beta - (\mu U_2^* - \widetilde{q}) = 0$. Therefore $U_2^* = \frac{\widetilde{q} - \beta}{\mu} > 0$.
   From the second equation of (4.13), U_1^* satisfies $\beta U_1^* - (\mu + q_1)U_2^* - (\mu U_2^* - \widetilde{q})U_2^* = 0$. Therefore $U_1^* = \frac{1}{\beta}((\mu + q_1) - \beta)U_2^* > 0$.
   It follows that $\widetilde{E_{12}}$ exists $\iff \widetilde{q} > \beta$, $\mu + q_1 > \beta$.

(i) Stability of $\widetilde{E_0}$. The variational matrix of (4.13) at $\widetilde{E_0}$ is

$$M_0 = \begin{bmatrix} -\beta + \widetilde{q} & 0 & 0 \\ \beta & -(\mu + q_1) + \widetilde{q} & 0 \\ 0 & 0 & \gamma_1 - \widetilde{q} \end{bmatrix}.$$

Thus $\widetilde{E_0}$ is stable $\iff \widetilde{q} < \beta$, $\widetilde{q} < \mu + q_1$, $\gamma_1 < \widetilde{q}$.

(ii) Stability of $\widetilde{E_2}$. The variational matrix of (4.13) at $\widetilde{E_2}$ is

$$\begin{bmatrix} -\beta + (\mu + q_1) & 0 & 0 \\ \beta & -\widetilde{q} + (\mu + q_1) & 0 \\ 0 & 0 & \gamma_1 - (\mu + q_1) \end{bmatrix}.$$

Thus $\widetilde{E_2}$ is stable $\iff \mu + q_1 < \beta$, $\widetilde{q} > \mu + q_1$, $\gamma_1 < \mu + q_1$.

(iii) Stability of $\widetilde{E_{12}}$. The variational matrix of (4.13) at $\widetilde{E_{12}}$ is

$$\begin{bmatrix} 0 & -\mu U_1^* & * \\ \beta & -(\mu + q_1) - 2\mu U_2^* + \widetilde{q} & * \\ 0 & 0 & \gamma_1 + (\mu U_2^* - \widetilde{q}) \end{bmatrix}.$$

The eigenvalue λ satisfies

$$(\lambda - (\gamma_1 + (\mu U_2^* - \widetilde{q})))(\lambda^2 + (\mu + q_1 + 2\mu U_2^* - \widetilde{q})\lambda + \beta\mu U_1^*) = 0, \tag{4.14}$$

$$\gamma_1 + \mu U_2^* - \widetilde{q} = \gamma_1 - \beta \text{ implies } \mu + q_1 + 2\mu U_2^* - \widetilde{q} = \widetilde{q} + (\mu + q_1) - 2\beta.$$

Since $\widetilde{E_{12}}$ exists $\Longrightarrow \widetilde{q} > \beta$, $\mu + q_1 > \beta$, we have $\mu + q_1 + 2\mu U_2^* - \widetilde{q} > 0$ and $\widetilde{E_{12}}$ is stable $\Longleftrightarrow \gamma_1 < \beta$, $\widetilde{q} > \beta$, $\mu + q_1 > \beta$.

Now, when we assume that $E_0 = (0, 0, 0)$ is unstable and E_{23}^* does not exist, there are three cases:

Case 1. $\widetilde{q} > \mu + q_1 > \gamma_1$, and we have three subcases:

Subcase 1. $A_2 > \widetilde{q} \Longleftrightarrow \gamma_1 > \alpha_A \widetilde{q}$.

Subcase 2. $A_2 > \gamma_1 \Longleftrightarrow (\widetilde{q} - \gamma_1) + \widetilde{q} q_1 > \alpha_A q_1 \widetilde{q}$.

Subcase 3. $A_2 > \mu + q_1 \Longleftrightarrow \gamma_1(\widetilde{q} - \mu) > \alpha_A q_1 \widetilde{q}$.

Figure 4.4 illustrates the possibilities for the stability of $\widetilde{E_{12}}$ and E_∞ in Case 1.

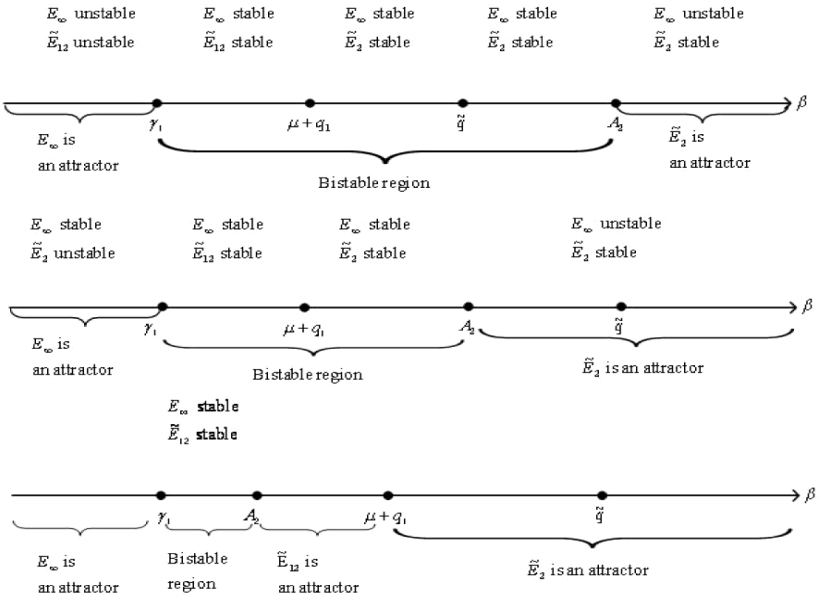

FIG. 4.4. *Stability of* $\widetilde{E_{12}}$ *and* E_∞ *when* $\widetilde{q} > \mu + q_1 > \gamma_1$.

Case 2. $\widetilde{q} < \mu + q_1$, $\gamma_1 < \mu + q_1$, and we have two subcases:

Subcase (i). $\gamma_1 < \widetilde{q}$. The stability of $\widetilde{E_0}$, $\widetilde{E_{12}}$, and E_∞ is as follows.

- $\gamma_1 < q < A_2 < \mu + q_1$.
  If $\beta < \gamma_1$, then E_∞ is an attractor; if $\gamma_1 < \beta < \widetilde{q}$, then $E_\infty, \widetilde{E}_{12}$ are stable; if $\widetilde{q} < \beta < A_2$, then $E_\infty, \widetilde{E}_0$ are stable; if $\beta > A_2$, then $\widetilde{E}_0$ is an attractor.
- $\gamma_1 < \widetilde{q} < \mu + q_1 < A_2$.
  Same as above.
- $\gamma_1 < A_2 < \widetilde{q} < \mu + q_1$.
  If $\beta < \gamma_1$, then E_∞ is an attractor; if $\gamma_1 < \beta < A_2$, then $\widetilde{E}_{12}, E_\infty$ are stable; if $A_2 < \beta < \widetilde{q}$, then $\widetilde{E}_{12}$ is an attractor; if $\beta > \widetilde{q}$, then $\widetilde{E}_0$ is an attractor.

Subcase (ii). $\gamma_1 > \widetilde{q}$. Then $A_2 > \widetilde{q}$. If $\beta < \widetilde{q}$, then E_∞ is an attractor. If $\widetilde{q} < \beta < A_2$, then $\widetilde{E}_0$ and E_∞ are stable. If $\beta > A_2$, then $\widetilde{E}_0$ is an attractor.

Case 3. $\widetilde{q} < \mu + q_1 < \gamma_1$, and $\gamma_1 > \widetilde{q}$. Then $A_2 > \widetilde{q}$, and we have a result similar to that in Subcase (ii).

5. Concluding remarks. For the model without quarantine but with behavior change due to public response to the severity of the disease, we have shown that the local stability condition in Theorem 3.4 is equivalent to the condition that the basic reproduction number R_0 given in (2.15) with $\alpha_P = 0$ is less than 1. If $\beta c > \sigma_1 + \rho_1 + \gamma_3$, the epidemic would persist without public response; however, if the magnitude of public response, as measured by the parameter a, is sufficiently large so that $R_0 < 1$, the reduction of infections through public response will be large enough to drive the epidemic down to a disease-free state.

For the model with both quarantine and behavior change, the dynamics is much more complicated. The effective reproduction number with quarantine R_Q in (2.16) gives local stability of DFE when $R_Q < 1$. However, there are ranges of the parameters which would lead to bistable steady states, i.e., one locally stable DFE and another locally stable endemic equilibrium. In such cases, we conjecture that there is a saddle point with two-dimensional stable manifold. As an illustration, we give the following numerical example.

We let $\alpha_A = 0.1$, $\widetilde{\beta} = 0.5$, $\widetilde{q} = 0.3$, $\gamma_1 = 0.4$, $q_1 = 0.2$, $\mu = 0.2$, and use the initial values of $S(0) = 1$, $E(0) = 0$, $Q_A(0) = 0$, $I(0) = 1$, i.e., one infective case entering a totally susceptible population of one individual so that $(W_1(0), W_2(0), W_3(0)) = (1, 0, 0)$. The result is given in Figure 5.1, where the system goes to the endemic equilibrium.

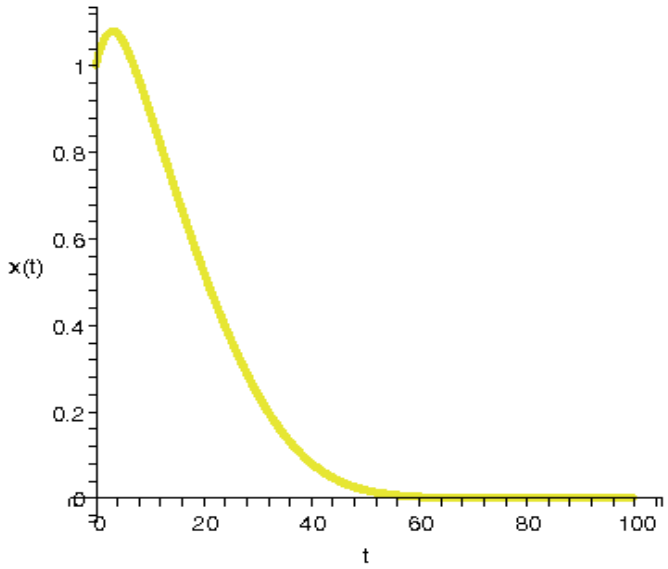

FIG. 5.1. *Numerical example with* $\alpha_A = 0.1$, $\widetilde{\beta} = 0.5$, $\widetilde{q} = 0.3$, $\gamma_1 = 0.4$, $q_1 = 0.2$, $\mu = 0.2$, *and initial population* $S(0) = 1$, $E(0) = 0$, $Q_A(0) = 0$, $I(0) = 1$, *where system approaches endemic equilibrium.* $X(t)$ *is* $W_1(t) = S(t)/I(t)$, *which goes to zero.*

However, if we let the initial values be $S(0) = 10$, $E(0) = 0$, $Q_A(0) = 0$, $I(0) = 1$, i.e., 10 infective cases entering a totally susceptible population of 100 individuals, so that $(W_1(0), W_2(0), W_3(0)) = (10, 0, 0)$, the system will approach DFE as shown in

Figures 5.2 and 5.3. Note that for this set of parameters, $A_2 = 0.56 > \widetilde{\beta} = 0.5 > \widetilde{q} = 0.3$, $\mu + q_1 = 0.2 + 0.2 > \widetilde{q} = 0.3$, $\gamma_1 = 0.4 > \widetilde{q} = 0.3$. Moreover, Case 3 of Theorem 4.8 holds for this data. Therefore we have bistability where both $E_0 = (0, 0, 0)$ and E_∞ are locally stable.

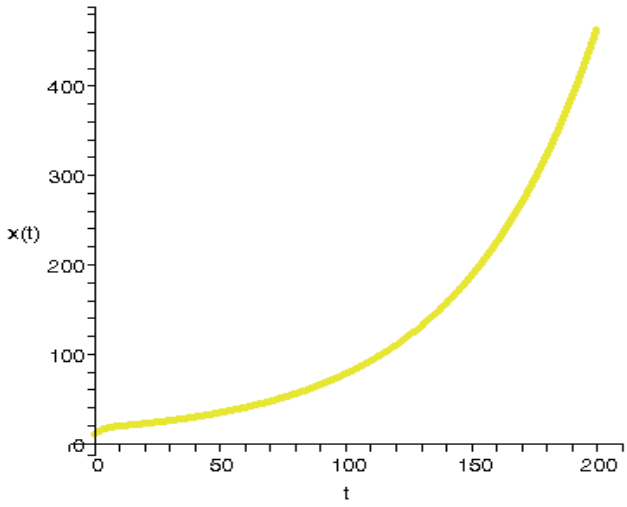

FIG. 5.2. *Numerical example with* $\alpha_A = 0.1$, $\widetilde{\beta} = 0.5$, $\widetilde{q} = 0.3$, $\gamma_1 = 0.4$, $q_1 = 0.2$, $\mu = 0.2$, *and initial population* $S(0) = 10$, $E(0) = 0$, $Q_A(0) = 0$, $I(0) = 1$, *where the system approaches DFE.* $X(t)$ *is* $W_1(t) = S(t)/I(t)$, *which goes to a nonzero equilibrium, and* $S(t) \to 14.58322$.

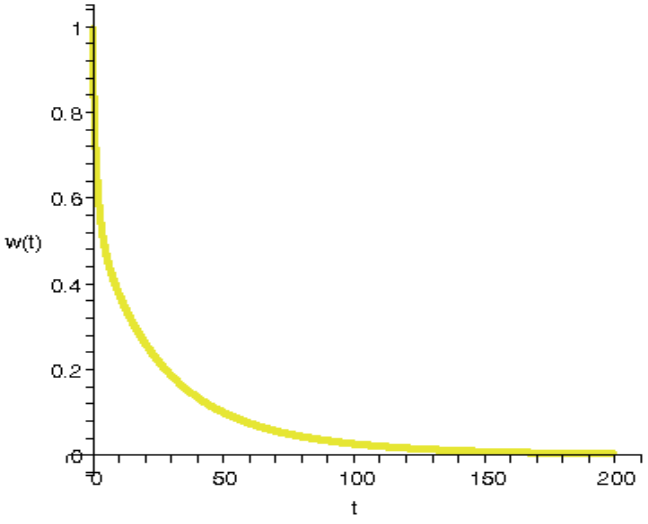

FIG. 5.3. *Numerical example with* $\alpha_A = 0.1$, $\widetilde{\beta} = 0.5$, $\widetilde{q} = 0.3$, $\gamma_1 = 0.4$, $q_1 = 0.2$, $\mu = 0.2$, *and initial population* $S(0) = 10$, $E(0) = 0$, $Q_A(0) = 0$, $I(0) = 1$, *where the system approaches DFE.* $W(t)$ *is* $I(t)$, *which goes to zero.*

The epidemiological interpretation is most interesting. In an epidemic where there is public response to the increasing severity of the epidemic to cut down infections

through individual behavior change, sufficient decrease of the infection rate through the parameter a would be enough to contain the epidemic, *regardless of the initial population sizes at the onset of outbreak.*

Suppose that, in addition to the severity-dependent public response, quarantine is implemented. If the adherence to quarantine to decrease contact rate c and transmission probability β is satisfactory, the effective infection rate $\widetilde{\beta} = \frac{\beta c}{1+aN}$ is sufficiently lowered. Case 1 in Theorem 4.8 will be satisfied along with $\widetilde{\beta} < \widetilde{q}$, and the epidemic can be successfully contained, again regardless of the initial population sizes at the onset of outbreak. If, on the other hand, $\widetilde{\beta}$ is not sufficiently lowered and we have Case 2 of Theorem 4.8, the epidemic will persist and the susceptible population $S(t)$ will be depleted eventually. There is the third scenario, where $\widetilde{\beta}$ is decreased but not sufficiently so, to less than A_2 but greater than $\widetilde{q}$. Then the system could approach either the DFE or the endemic steady state, depending on the initial values of the system.

In the worst case scenario, if the quarantine were not adhered to faithfully, the false sense of security brought about by the quarantine that all infective persons were in quarantine could lead to increased $\widetilde{\beta}$. Thus the quarantine might in fact have an adverse effect by contributing to the persistence of the epidemic. For illustration, we consider the hypothetical case where $\beta < \widetilde{q} = \sigma_1 + \rho_1 + \gamma_3$. Since $\beta > \widetilde{\beta}$ when $c = 1$, from Theorem 3.4 we know the system goes to DFE with no quarantine implemented. However, for Case 1 (Figure 4.4), Subcase 3, when $\mu + q_1 < \beta < \widetilde{q}$ the system will converge to the endemic equilibrium. This demonstrates the (distinct) possibility that, under appropriate parameter values, a quarantine program which is not sufficiently comprehensive ($q_1 < \beta - \mu$) could have the adverse effect of causing a system which would have approached DFE without quarantine to converge to the endemic equilibrium instead.

We should note, however, that $\widetilde{\beta} = \frac{\beta c}{1+aN}$, where N is the constant total population size, which numbers in at least millions whether in Hong Kong, Singapore, Taipei, Beijing, or Toronto. In [27], it was determined that $a = 0.0013$ and $c\beta = 0.429$ for Taiwan's SARS outbreak. Subsequently the real value for $\widetilde{\beta}$ is of the order $0.429/(1+0.0013*10^6) \ll 1$, making it most unlikely for either Case 2 (asymptotically stable endemic equilibrium) or Case 3 (bistability) in Theorem 4.8 to prevail. In other words, the modeling results indicate that for an infectious disease with infectivity and patterns of transmission typical of SARS, the outbreak can always be eradicated by implementing border control of imported cases and limited quarantine, along with the public's social response to avoid infections.

It is also interesting to note that if $\alpha_A = 0$, the stability condition for E_∞ becomes $\beta < \widetilde{q}\mu/(\mu + q_1)$. Hence quarantine is always beneficial and an effective Level A quarantine is always helpful in containing the epidemic. However, if for some disease unlike SARS in its ability to infect during the asymptomatic stage, some fraction of the quarantined population is not fully isolated and can still infect others (i.e., $\alpha_A > 0$), then quarantine might also affect the outbreak adversely. A numerical example of this scenario is as follows: Let $\alpha_A = 0.1$, $\beta = 0.5$, $\mu = 0.5$, $\widetilde{q} = 0.7$, $q_1 = 0.1$, $\gamma_1 = 0.01$, $A_2 = 0.35$. Here $\widetilde{E}_{12} = (0.08, 0.4, +\infty)$ is a global attractor as in Case 1, Subcase 3 in Figure 4.4. However, if there is no quarantine (i.e., $q_1 = 0$ and hence $\alpha_A = 0$), DFE is the global attractor. Additional examples of this type can be observed in Case 1, Subcases 2 and 3 (Figure 4.4), where $\widetilde{E}_2$ can become the global attractor for the appropriate parameter range of β, as well as in Case 2, Subcase (i), where again it is possible for $\widetilde{E}_{12}$ to become a global attractor. Note that

a condition for these cases to emerge is $\widetilde{q} > A_2$ or, equivalently, $\gamma_1/\widetilde{q} < \alpha_A$. Hence if there is a nonzero reduction in the infection rate of the quarantined class α_A which is larger than the ratio of the progression rate of the quarantined persons γ_1 to the removal rate of the unquarantined infectives $\widetilde{q}$, an adverse effect could take place with implementation of quarantine. To keep this possibility from occurring, one would need either (i) significant reduction of infection by the quarantined individuals (small α_A) or (ii) quick isolation of quarantined persons at onset (large γ_1) compared to the removal of the infective class (small $\widetilde{q}$). Similar possible adverse effects of intervention measures have also been observed in other theoretical models of infectious diseases (e.g., [30, 31]).

Going back to the quarantine for SARS, we assume that $\alpha_P = \alpha_A = 0$. If all other pertinent parameters remain the same, we have $R_Q = R_0\mu/(\mu+q_1)$ from (2.15)–(2.16). That is, the implementation of quarantine would give the mean reproduction number of an infective individual a factor of $\mu/(\mu + q_1)$, where q_1 is the effective quarantine rate. That is, through quarantine alone, the mean reproduction number of an infective individual is reduced by a factor of $1 - \mu/(\mu + q_1)$.

In a data-based modeling study where the pertinent parameters were estimated from the Taiwan SARS data [27], the quarantine rate q_1 was estimated to be 0.0277. It was reported by Donnelly et al. [32] that the maximum likelihood estimate for the mean time from exposure to onset of symptoms is 6.37 days. Hence the mean progression rate from exposure to onset is approximately $\mu = 1/6.37 = 0.157$. Making use of the two estimates, we conclude that *if all other parameters remain unchanged*, the quarantine in Taiwan would result in a reduction of 15% ($\mu/(\mu+q_1) = 0.850$) in the mean reproduction number by an infective individual. Given that current studies of SARS indicate that the basic reproduction numbers R_0 in all the SARS-affected areas were greater than 2 at the beginning of the outbreak in 2003, one can conclude that quarantine alone would not have been able to contain the epidemic (i.e., reduce R_0 to less than 1) in Taiwan. For a given affected area with a basic reproduction number R_0, we need to have an effective quarantine rate of $q_1 > q_1^* = 0.157(R_0 - 1)$ for R_Q to be less than 1. Using the estimated values of R_0 for Hong Kong, Toronto, and Taiwan in current literature, we give in Table 5.1 the effective quarantine rate q_1^* needed in the affected areas to reduce the reproduction number to less than 1, if all else remains the same. Note that the estimate for Taiwan [13] assumes that a symptomatic patient is infective from onset to classification as a probable case followed by isolation. If we assume the patient is not infective during the first two days of onset as suggested by some studies (see [2]), the reproduction number is reduced to 3.56 and subsequently $q_1^* = 0.402$.

TABLE 5.1

Affected area	Reproduction number [literature cited]	Effective quarantine rate q_1^* needed to contain outbreak
Hong Kong	2.7 [32]	0.267
	3 [10]	0.314
Toronto	3.3 [33]	0.361
Taiwan	4.23 [13]	0.507

Since the SARS-CoV virus does not appear to be infective before onset of symptoms [2], quarantine does not directly prevent infections by the exposed individuals during the quarantine period. However, studies on SARS quarantine data in Taiwan [8] indicate that quarantined persons are significantly more quickly diagnosed

and hospitalized as compared to the unquarantined individuals. Hence the effectiveness of quarantine for infectious diseases like SARS, for which no infection is being prevented during the quarantine period, can only be indirect and therefore must be combined with other intervention measures in order to fully contain the outbreaks.

Acknowledgments. The authors are grateful for constructive discussions with Roy Anderson, John Glasser, Chwan-Chuan King, and Fred Brauer which helped formulate some of the ideas for this work. Ying-Hen Hsieh would like to thank MITACS (Canada) for their generous financial support while attending the MITACS SARS meetings in Banff, Canada, where several of the abovementioned discussions took place.

IRREVERSIBLE PASSIVE ENERGY TRANSFER IN COUPLED OSCILLATORS WITH ESSENTIAL NONLINEARITY*

GAETAN KERSCHEN†, YOUNG SUP LEE‡, ALEXANDER F. VAKAKIS§, D. MICHAEL McFARLAND¶, AND LAWRENCE A. BERGMAN¶

Abstract. We study numerically and analytically the dynamics of passive energy transfer from a damped linear oscillator to an essentially nonlinear end attachment. This transfer is caused by either fundamental or subharmonic resonance capture, and in some cases is initiated by nonlinear beat phenomena. It is shown that, due to the essential nonlinearity, the end attachment is capable of passively absorbing broadband energy at both high and low frequencies, acting, in essence, as a passive broadband boundary controller. Complicated transitions in the damped dynamics can be interpreted based on the topological structure and bifurcations of the periodic solutions of the underlying undamped system. Moreover, complex resonance capture cascades are numerically encountered when we increase the number of degrees of freedom of the system. The ungrounded essentially nonlinear end attachment discussed in this work can find application in numerous practical settings, including vibration and shock isolation of structures, seismic isolation, flutter suppression, and packaging.

Key words. resonance capture, passive energy transfer, essential nonlinearity, nonlinear energy sinks, energy pumping

1. Introduction.

We study passive and irreversible energy transfer from a linear oscillator to an essentially nonlinear attachment, which, in essence, acts as a *nonlinear energy sink (NES)*; such energy transfer we refer to as *nonlinear energy pumping*. In previous works (Vakakis and Gendelman (2001), Vakakis et al. (2003)) grounded and relatively heavy nonlinear attachments were considered, a feature that limits their attractiveness in practical applications. To eliminate these restrictions, an ungrounded and light nonlinear attachment is considered in this work, which, in addition, possesses the feature of modularity. As shown in Lee et al. (2005), even though the system considered has a simple configuration, it possesses a very complicated structure of undamped periodic orbits, which, in turn, give rise to a complicated

series of transitions and energy exchange phenomena in the damped dynamics. We aim to show that in this system there are at least three different mechanisms for energy pumping, based either on fundamental and subharmonic resonance captures or on nonlinear beat phenomena.

Previous works examined targeted energy transfer in systems of coupled nonlinear oscillators through energy exchanges between donor and acceptor discrete breathers due to nonlinear resonance (Kopidakis, Aubry, and Tsironis (2001), Aubry et al. (2001), Morgante et al. (2002)). In Vainchtein et al. (2004) resonant interactions between monochromatic electromagnetic waves and charged particles were studied, leading to chaotization of particles and transport in phase space. In Khusnutdinova and Pelinovsky (2003) the processes governing energy exchange between coupled Klein–Gordon oscillators were analyzed; the same weakly coupled system was studied in Maniadis, Kopidakis, and Aubry (2004), and it was shown that, under appropriate tuning, total energy transfer can be achieved for coupling above a critical threshold. In related work, localization of modes in a periodic chain with a local nonlinear disorder was analyzed (Cai, Chan, and Cheung (2000)); transfer of energy between widely spaced modes in harmonically forced beams was analytically and experimentally studied (Malatkar and Nayfeh (2003)); and a nonlinear dynamic absorber designed for a nonlinear primary was analyzed (Zhu, Zheng, and Fu (2004)).

In this work we consider the two-degree-of-freedom (DOF) system

$$\begin{aligned} &m_1\ddot{y} + k_1 y + c_1\dot{y} + c_2(\dot{y}-\dot{v}) + k_2(y-v)^3 = P(t) \\ &\qquad\Rightarrow\quad \ddot{y} + \omega_0^2 y + \lambda_1\dot{y} + \lambda_2(\dot{y}-\dot{v}) + C(y-v)^3 = F(t), \\ &m_2\ddot{v} + c_2(\dot{v}-\dot{y}) + k_2(v-y)^3 = 0 \quad\Rightarrow\quad \varepsilon\ddot{v} + \lambda_2(\dot{v}-\dot{y}) + C(v-y)^3 = 0, \end{aligned} \tag{1}$$

where $\omega_0^2 = k_1/m_1$, $C = k_2/m_1$, $\varepsilon = m_2/m_1$, $\lambda_1 = c_1/m_1$, $\lambda_2 = c_2/m_1$, and $F(t) = P(t)/m_1$. Our basic aim is to study the dynamics of irreversible energy transfer ("energy pumping") from the linear oscillator (which will be directly excited) to the nonlinear attachment (which will be assumed to be initially at rest). We show that there are at least three dynamic mechanisms that can initiate or cause such energy transfer in the damped system, and these can be studied and understood by first considering the dynamics of the underlying undamped system.

2. Review of the dynamics of the undamped system (Lee et al., 2005). Since the structure and bifurcations of the periodic orbits of the undamped and unforced system play an essential role in energy transfer phenomena in the damped and forced system, we start with a brief review of the dynamics of system (1) with $\lambda_1 = \lambda_2 = F(t) = 0$; for a more detailed discussion we refer to Lee et al. (2005).

In Figure 1 we present the various branches of periodic solutions in a frequency-energy plot. A periodic orbit is represented by a point in the plot, and a branch, represented by a solid line, is a collection of periodic orbits possessing the same qualitative features. For instance, the branch $S11+$ gathers all the periodic orbits for which the linear and nonlinear oscillators vibrate with the same frequency and in an in-phase fashion. There are two general classes of solutions: *symmetric solutions* $Snm\pm$ correspond to orbits that satisfy the initial conditions $\dot{v}(0) = \pm\dot{v}(T/2)$ and $\dot{y}(0) = \pm\dot{y}(T/2)$, where T is the period, n is the number of half-waves in v, and m the number of half-waves in y in a half-period interval; *unsymmetric solutions* Unm are orbits that fail to satisfy the initial conditions of the symmetric orbits, with the same notation for the two indices. We adopt the following convention regarding the placement of the various branches in the frequency domain: we assign to a specific branch

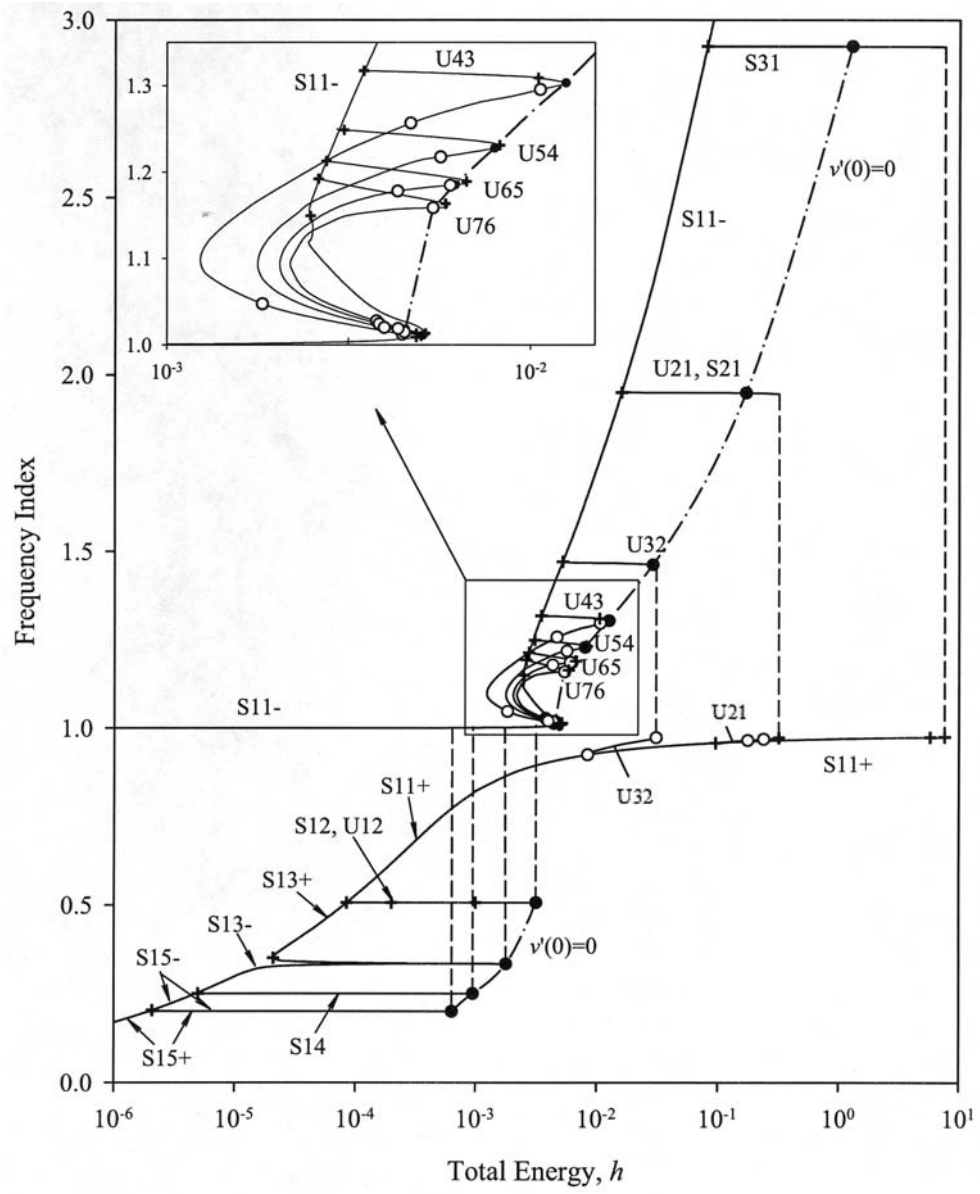

FIG. 1. *Frequency-energy plot of the periodic orbits: for the sake of clarity, no stability is indicated; special orbits are denoted by bullets* (•) *and are connected by dashed-dot lines; other symbols indicate bifurcation points (stability-instability boundaries):* (+) *four Floquet multipliers at* +1*, and* (◯) *two Floquet multipliers at* +1 *and two at* −1 *(see Lee et al.* (2005)*).*

of solutions a frequency index equal to the ratio of its indices; e.g., $S21\pm$ is represented by the frequency index $\omega = 2/1 = 2$, as is $U21$; $S13\pm$ is represented by $\omega = 1/3$; etc. This convention rule holds for every branch except $S11\pm$, which, however, are particular branches forming the basic backbone of the entire plot. On the energy axis we depict the (conserved) total energy of the system when it oscillates in the corresponding periodic motion. Transitions between certain branches seem to involve

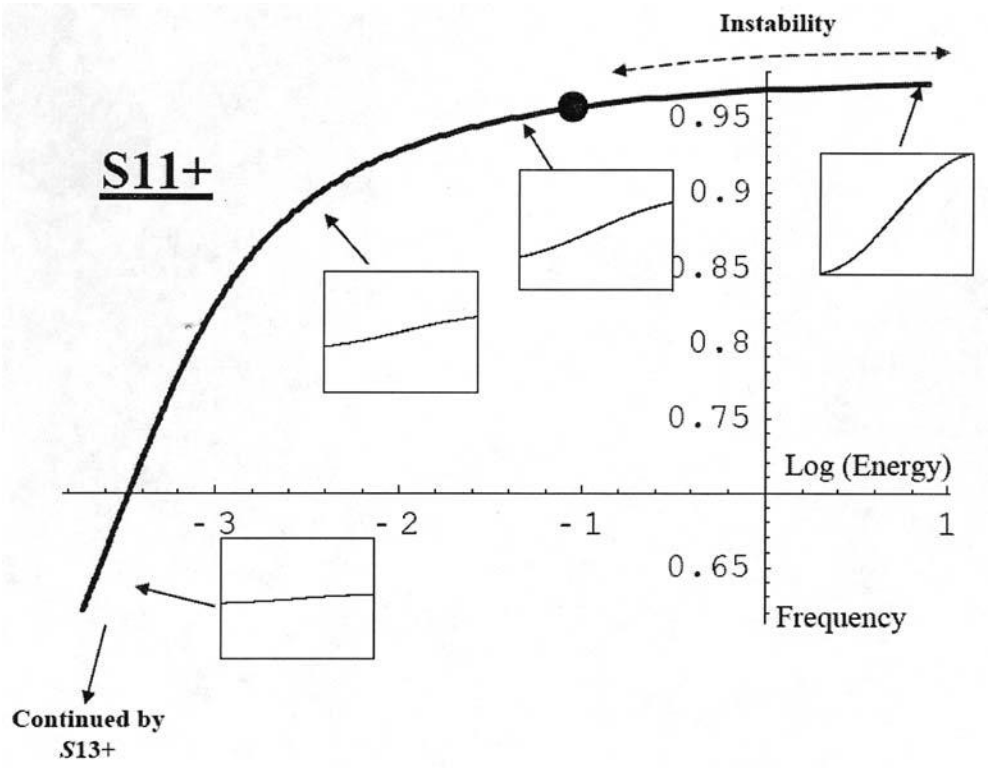

FIG. 2. *Detailed plot of branch* $S11+$ *in the frequency index-logarithm of energy plane. A dot* (•) *represents the initial condition of the motion depicted in Figure* 4. *(At certain points of the branch the corresponding motions in the configuration plane* (y, v) *are depicted.)*

"jumps," but this is only due to the frequency convention adopted, and no actual discontinuities in the dynamics occur. (By definition, branches $S(kn)(km)\pm$, k integer, are identified with $Snm\pm$.) Periodic orbits that correspond to synchronous motions of the two particles of the system, and correspond to curves in the configuration plane (y, v), will be termed *nonlinear normal modes (NNMs)* (Vakakis et al. (1996)).

The main backbone of the frequency-energy plot is formed by the branches $S11\pm$, which represent in- or out-of-phase NNMs possessing one half-wave per half-period. Moreover, the natural frequency of the linear oscillator $\omega_0 = 1$ (which we identify with a frequency index equal to unity, $\omega = 1$) naturally divides the periodic solutions into higher- and lower-frequency modes. A close-up of $S11+$ is presented in Figure 2 together with some modal curves depicted in the configuration plane (y, v) of the system. The horizontal and vertical axes in the plots in the configuration plane are the nonlinear and linear, respectively, oscillator responses, and the aspect ratios in these plots are set so that equal tick mark increments on the horizontal and vertical axes are equal in size, enabling one to directly deduce whether the motion is localized in the linear or the nonlinear oscillator. Figure 2 clearly highlights the energy dependence of the NNMs; the NNMs become strongly localized to the nonlinear attachment as the total energy in the system decreases. This observation shows how useful a frequency-energy plot can be for the interpretation of the dynamics. For the out-of-phase branch $S11-$, the NNMs become localized to y or v as $\omega \to 1+$ or $\omega \gg 1$, respectively.

There is a sequence of higher- and lower-frequency periodic solutions bifurcating

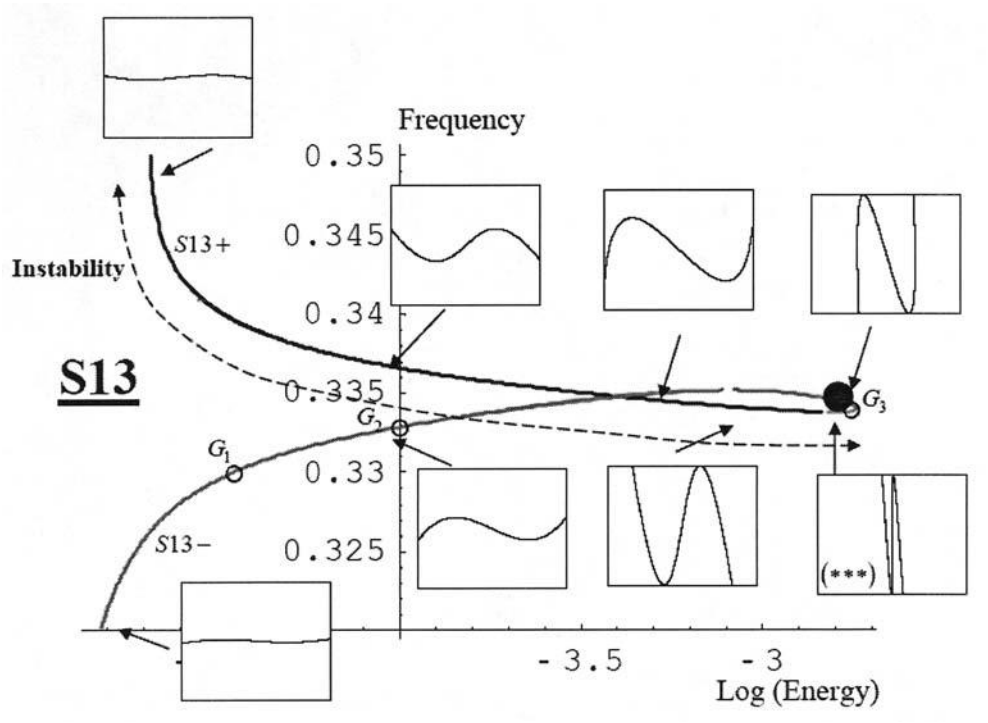

FIG. 3. *Detailed plot of tongues $S13\pm$ in the frequency index-logarithm of the energy plane. Points G_1, G_2, G_3 refer to the text, and the special periodic orbit is represented by triple stars $(***)$; the dot $(\bullet)$ represents the initial condition of the motion depicted in Figure 5. (At certain points of the branch the corresponding motions in the configuration plane (y, v) are depicted.)*

or emanating from branches $S11\pm$, which we will denote as *tongues*. Each tongue occurs in the neighborhood of an internal resonance between the linear oscillator and the nonlinear attachment, and corresponds to either symmetric (S-tongue; e.g., $S13\pm$) or unsymmetric (U-tongue; e.g., $U21\pm$) periodic motion of the system.

Considering first the symmetric solutions, the branches $S1(2k+1)\pm$, $k = 1, 2, \ldots$, appear in the neighborhoods of frequencies $\omega = 1/(2k+1)$, i.e., at progressively lower frequencies with increasing k. For fixed k, each of the two branches $S1(2k+1)\pm$ is linked through a smooth transition with its neighboring branches $S1(2k-1)\pm$ or $S1(2k+3)\pm$ and exists over a finite interval of energy. The pair $S1(2k+1)\pm$ is eliminated through a saddle-node bifurcation at a higher energy value (cf. Figure 3 for branches $S13\pm$). The pairs of branches $S1(2k)\pm$, $k = 1, 2, \ldots$, bifurcate out of $S1(2k+1)\pm$ and exist over finite energy intervals. Branches $Sn1\pm$, $n = 2, 3, \ldots$, appear in the neighborhoods of frequencies $\omega = n$, i.e., at progressively higher frequencies with increasing n; the pair of branches $Sn1\pm$ emanates from $S11-$ and coalesces with $S11+$ through a saddle-node bifurcation. Consider the subharmonic NNMs on tongues $S13\pm$ (similar results hold for the other S-branches), which correspond to motions where the linear oscillator oscillates "three times faster" than the nonlinear attachment. We refer to Figure 3, where a detailed frequency-energy plot for this branch is depicted.

We now discuss the evolution of the motion along $S13-$. As point G_1 is reached in the neighborhood of $\omega = 1/3$, it holds that $v(t) \gg y(t)$, and the nonlinear attachment

vibrates nearly independently, in essence "driving" the linear oscillator; moreover, at that regime of the motion the force generated by the essentially nonlinear coupling spring is approximately equal to that generated by the linear spring. As the energy increases towards point G_2 the nonlinear attachment still "drives" the primary mass, but now the force generated by the linear spring tends to overcome that of the nonlinear spring; this means that the motion of the linear oscillator is less influenced by the motion of the nonlinear attachment. Once point G_2 is reached (with initial displacements $v(0) = 0.0915$, $y(0) = 0.013$ and zero initial velocities), both the linear oscillator and the nonlinear attachment approximately vibrate as a set of *uncoupled linear oscillators* with natural frequencies at ratio 1/3,

$$\ddot{v} + \left(\frac{1}{9}\right) v = 0, \qquad \ddot{y} + y = 0.$$

This means that in the neighborhood of point G_2 of $S13-$ the system oscillates approximately as a system of two uncoupled linear oscillators, a result which explains why the branches $S13\pm$ appear as horizontal straight line segments at frequency index 1/3 of the frequency-energy plot of Figure 1. As energy increases towards point G_3 of Figure 2, the situation is reversed; because the force generated by the nonlinear spring is now negligible compared to that generated by the linear spring, the linear oscillator vibrates nearly independently and drives the nonlinear attachment. Eventually point G_3 is reached, where the periodic motion is approximately given by $y(t) \approx Y \cos \omega t$, $v(t) \approx V \cos \omega t$, and there occurs triple coalescence of branches $S13\pm$ and $S33-$ (which is identical to $S11-$).

Focusing now on the unsymmetric branches, we observe a family of $U(m+1)m$ branches bifurcating from branch $S11-$ that exist over finite energy levels and are eliminated through saddle-node bifurcations with other branches of solutions. The transition of branches $U21$ and $U32$ to $S11+$ seems to involve jumps, but this is only due to the frequency convention adopted, and no actual discontinuities in the dynamics occur. It should be mentioned that periodic motions on the U-tongues are not NNMs because nontrivial phases between the two oscillators are realized. The motion on these tongues is represented by Lissajous curves in the configuration plane, whereas motion on S-tongues corresponds to one-dimensional curves. Localization phenomena are also detected at certain regions of U-tongues (Lee et al. (2005)).

It turns out that certain periodic orbits (termed *special orbits* and depicted by dots in Figure 1) are of particular importance concerning the passive and irreversible energy transfer from the linear to the nonlinear oscillator. These special orbits satisfy the initial conditions $v(0) = \dot{v}(0) = y(0) = 0$ and $\dot{y}(0) \neq 0$, which happen to be identical to the state of the undamped system (1) at $t = 0+$ (being at rest at $t = 0-$) after application of an impulse of magnitude $\dot{y}(0)$ to the linear oscillator. Moreover, certain stable special orbits are localized to the nonlinear oscillator (Lee et al. (2005)) which implies that if the system initially at rest is forced impulsively and one of the stable, localized special orbits is excited, the major portion of the induced energy is channeled directly to the invariant manifold of that special orbit, and hence the motion is rapidly and passively transferred ("pumped") from the linear to the nonlinear oscillator. Therefore, *the impulsive excitation of one of the stable special orbits is one of the triggering mechanisms initiating (direct) passive energy pumping in the system.*

In the following section we discuss in detail three mechanisms for passive energy pumping in system (1). In addition to the mechanism based on excitation of special orbits, we analyze two energy pumping mechanisms that rely on the spatial localiza-

tion of the mode shapes of certain NNMs of Figure 1 as the energy of oscillation of the system decreases due to damping dissipation.

3. Energy pumping mechanisms in the damped system. In this section, the impulsively forced, damped system (1) is considered, and three basic mechanisms for the initiation of nonlinear energy pumping are studied. The first mechanism (*fundamental energy pumping*) is realized when the motion takes place along the backbone curve $S11+$ of the frequency-energy plot of Figure 1, occurring for relatively low frequencies $\omega < \omega_0$. The second mechanism (*subharmonic energy pumping*) resembles the first and occurs when the motion takes place along a lower frequency branch Snm, $n < m$. The third mechanism (*energy pumping initiated by nonlinear beat*), which leads to stronger energy pumping, involves the excitation of a special orbit with main frequency ω_{SO} greater than the natural frequency of the linear oscillator ω_0; in this case energy pumping is initiated by a nonlinear beat phenomenon, as discussed in the previous section. In what follows we discuss each mechanism separately, and provide numerical simulations that demonstrate passive and irreversible energy transfer from the linear oscillator to the nonlinear attachment in each case.

3.1. Fundamental energy pumping. The first mechanism for energy pumping involves excitation of the branch of in-phase synchronous periodic solutions $S11+$, where the linear oscillator and the nonlinear attachment oscillate with identical frequencies in the neighborhood of the fundamental frequency ω_0. Although energy pumping is considered only in the damped system, in order to gain an understanding of the governing dynamics it is necessary to consider the case of no damping.

In Figure 2 we depicted a detailed plot of branch $S11+$ of the undamped system and noted that, at higher energies, the in-phase NNMs are spatially extended (involving finite-amplitude oscillations of both the linear oscillator and the nonlinear attachment). However, *the nonlinear mode shapes of solutions on* $S11+$ *depend essentially on the level of energy, and at low energies they become localized to the attachment.* Considering now the motion in phase space, this low-energy localization is a basic characteristic of the two-dimensional NNM invariant manifold corresponding to $S11+$; moreover, this localization property is preserved in the weakly damped system, where the motion takes place in a two-dimensional damped NNM invariant manifold. This means that when the initial conditions of the damped system are such that they excite the damped analogue of $S11+$, the corresponding mode shape of the oscillation, initially spatially extended, becomes localized to the nonlinear attachment with decreasing energy due to damping dissipation. This, in turn, leads to passive, continuous, and irreversible transfer of energy from the linear oscillator to the nonlinear attachment which acts, in essence, as an NES. The underlying dynamical phenomenon governing fundamental energy pumping was proven to be a *resonance capture on a* 1:1 *resonance manifold* of the system (Vakakis and Gendelman (2001)).

Numerical evidence of fundamental energy pumping is given in Figure 4 for the system with parameters $\varepsilon = 0.05$, $\omega_0^2 = 1$, $C = 1$, and $\lambda_1 = \lambda_2 = 0.0015$. Small damping is considered in order to better highlight the energy pumping phenomenon, and the motion is initiated near the black dot of Figure 2. Comparing the transient responses of Figures 4(a)–(b), we note that the response of the primary system decays faster than that of the NES. The percentage of instantaneous energy captured by the NES versus time is depicted in Figure 4(e) and confirms the assertion that continuous and irreversible transfer of energy from the linear oscillator to the NES takes place; this is more evident by computing the percentage of total input energy that is eventually dissipated by the damper of the NES (cf. Figure 4(f)), which in this

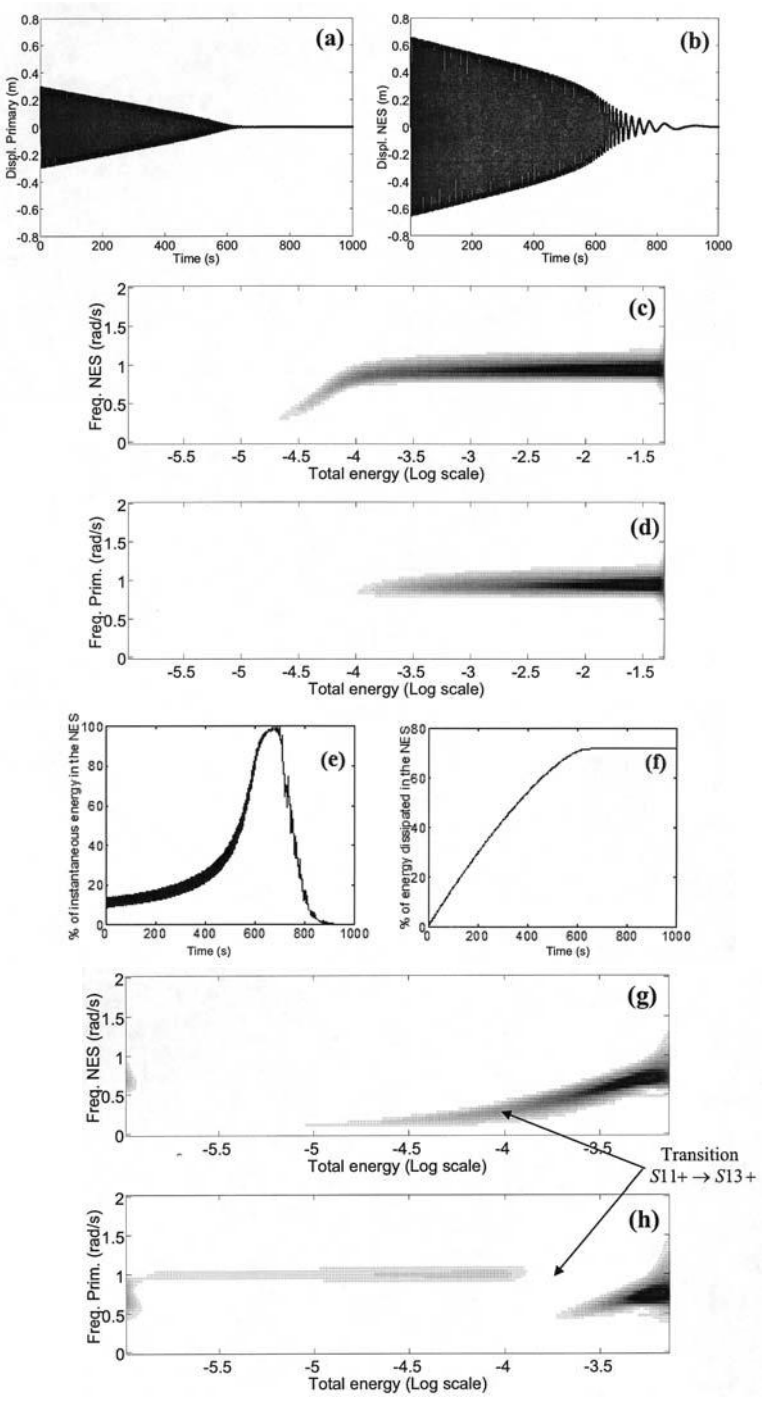

FIG. 4. *Fundamental energy pumping. Shown are the transient responses of the* (a) *linear oscillator and* (b) *NES; WTs of the motion of* (c) *NES and* (d) *linear oscillator;* (e) *percentage of instantaneous total energy in the NES;* (f) *percentage of total input energy dissipated by the NES; transition of the motion from* $S11+$ *to* $S13+$ *at smaller energy levels using the* (g) *NES (observe the settlement of the motion at frequency* 1/3*) and* (h) *linear oscillator.*

particular simulation amounts to 72%; the energy dissipated at the NES is computed by the relation

$$E_{NES}(t) = \lambda_2 \int_0^t \left[\dot{v}(\tau) - \dot{y}(\tau)\right]^2 d\tau.$$

The evolution of the frequency components of the motions of the two oscillators as energy decreases can be studied by numerical wavelet transforms (WTs) (Lee et al. (2005)) of the transient responses, as depicted in Figures 4(c)–(d). These plots highlight that a 1:1 resonance capture is indeed responsible for energy pumping. Below the value of -4 of the logarithm of energy level, the motion of the linear oscillator is too small to be analyzed by the particular windows used in the WT; however, a more detailed WT over smaller energy regimes (cf. Figures 4(g)–(h)) reveals a smooth transition from $S11+$ to $S13+$, in accordance with the frequency-energy plot of Figure 1. This transition manifests itself by the appearance of two predominant frequency components in the responses (at frequencies 1 and 1/3) as energy decreases.

3.2. Subharmonic energy pumping. Subharmonic energy pumping involves excitation of a low-frequency S-tongue. As mentioned previously, by low-frequency tongues we mean the particular regions of the frequency-energy plot where the NES engages in m:n (m, n integers such that $m < n$) resonance captures with the linear oscillator. Another feature of lower tongues is that in these regions the frequency of the motion remains approximately constant with varying energy; as a result, the tongues are represented by horizontal lines in the frequency-energy plot, and the response of system (1) resembles locally that of a linear system (see also discussion about the tongues $S13\pm$ in section 2). In addition, at each specific m:n resonance capture there appears a pair of closely spaced tongues corresponding to in- and out-of-phase oscillations of the two subsystems.

To discuss the dynamics of subharmonic energy pumping we now focus on a particular pair of lower tongues, say $S13\pm$, and refer to Figure 3. As discussed in section 2, at the extremity of a lower pair of tongues, the curve in the configuration plane is strongly localized to the linear oscillator. However, as for the fundamental mechanism for energy pumping, the decrease of energy by viscous dissipation leads to curves in the configuration plane that are increasingly localized to the NES, and nonlinear energy pumping to the NES occurs. In this case, the underlying dynamical phenomenon causing energy pumping is resonance capture in the neighborhood of an m:n resonance manifold of the dynamics. Specifically, for the pair of tongues $S13\pm$, a 1:3 resonance capture occurs that leads to subharmonic energy pumping with the linear oscillator vibrating with a frequency three times that of the NES. It is emphasized that due to the stability properties of the tongues $S13\pm$, subharmonic energy pumping involves excitation of $S13-$ but not of $S13+$.

The transient dynamics when the motion is initiated at the extremity of $S13-$ (cf. the initial condition denoted by the black dot in Figure 3) is displayed in Figure 5. The same parameters as in section 3.1 are considered. Until 500 s, subharmonic energy pumping takes place: despite the presence of viscous dissipation, the NES response grows continuously, with simultaneous rapid decrease of the response of the linear oscillator. A substantial amount of energy is transferred to the NES (cf. Figure 5(e)), and eventually nearly 70% of the energy is dissipated by the NES damper (cf. Figure 5(f)). A prolonged 1:3 resonance capture is nicely evidenced by the WT of Figures 5(c)–(d), and the motion follows the whole lower tongue $S13-$ from the right

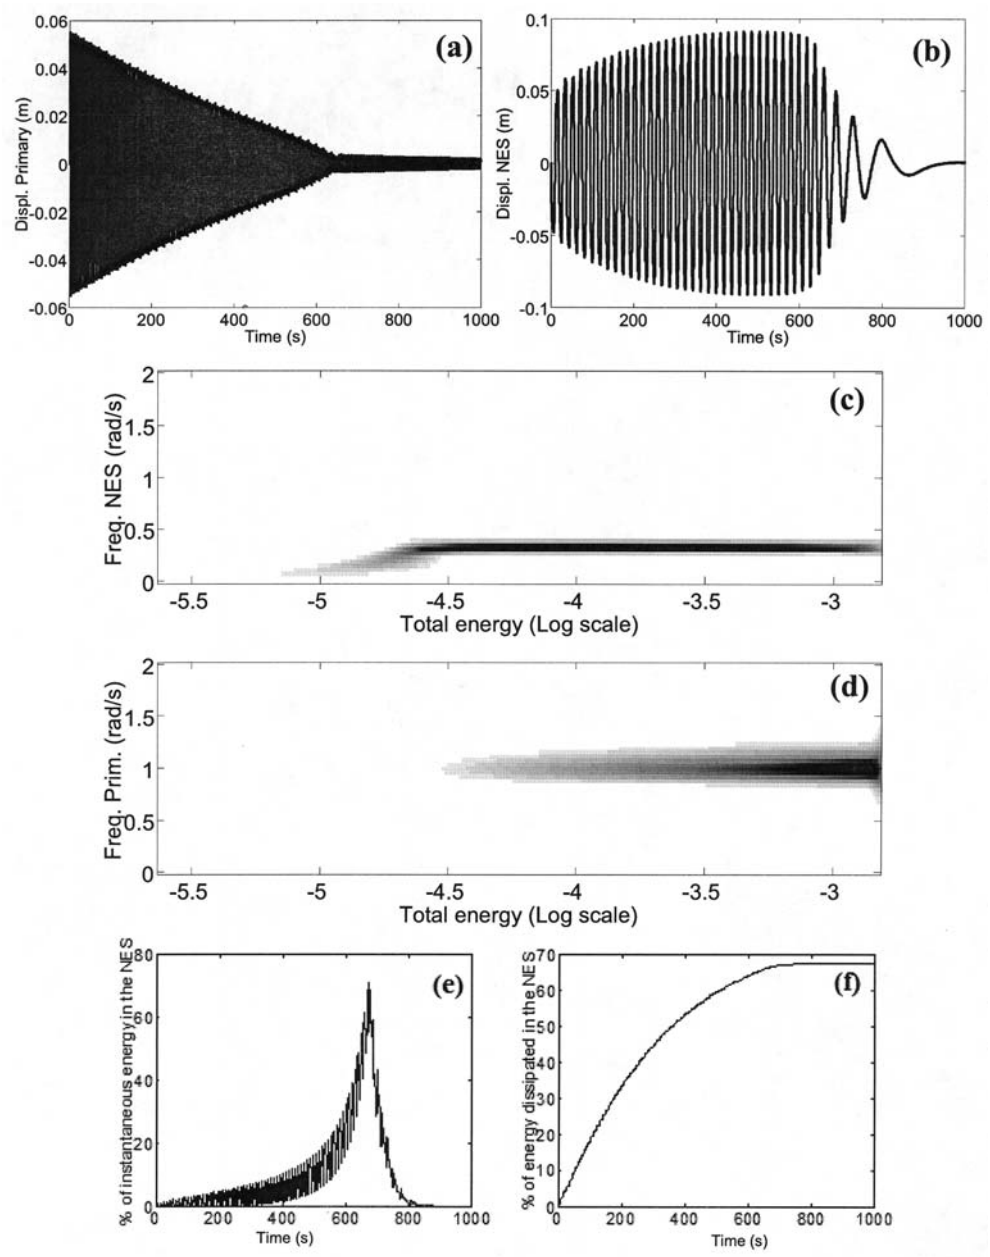

FIG. 5. *Subharmonic energy pumping initiated on S13−. Shown are the transient responses of the* (a) *linear oscillator and* (b) *NES; WTs of the motion of* (c) *the NES and* (d) *the linear oscillator;* (e) *percentage of instantaneous total energy in the NES;* (f) *percentage of total input energy dissipated by the NES.*

to the left. Once escape from resonance capture occurs (around 620–630 s), energy is no longer transferred to the NES.

3.3. Energy pumping initiated by nonlinear beating. The previous two mechanisms cannot be activated with the NES at rest, since in both cases the motion

is initialized from a nonlocalized state of the system. This means that these energy pumping mechanisms cannot be activated directly after the application of an impulsive excitation to the linear oscillator with the NES initially at rest. Such a forcing situation, however, is important from a practical point of view; indeed, this is the situation where local NESs are utilized to confine and passively dissipate unwanted vibrations from linear structures that are forced by impulsive (or broadband) loads.

Hence, it is necessary to discuss an alternative, third energy pumping mechanism capable of initiating passive energy transfer with the NES being initially at rest. This alternative mechanism is based on the excitation of a *special orbit* (as defined and discussed in section 2) that plays the role of a "bridging orbit" for activation of either fundamental or subharmonic energy pumping. Excitation of a special orbit results in the transfer of a substantial amount of energy from the initially excited linear oscillator directly to the NES through a nonlinear beat phenomenon. In that context, the special orbit may be regarded as an initial bridging orbit or trigger, which eventually activates fundamental or subharmonic energy pumping, once the initial nonlinear beat initiates the energy transfer. Indeed, as shown below, *the third mechanism for energy pumping represents an efficient initial (triggering) mechanism for rapid transfer of energy from the linear oscillator to the NES at the crucial initial stage of the motion, before activating either one of the (fundamental or subharmonic) main energy pumping mechanisms through a nonlinear transition (jump) in the dynamics.*

To study the dynamics of this triggering mechanism, we first formulate the following conjecture: *Due to the essential (nonlinearizable) nonlinearity, the NES is capable of engaging in an m:n resonance capture with the linear oscillator, m and n being a set of integers. Accordingly, in the undamped system there exists a sequence of special orbits (corresponding to nonzero initial velocity of the linear oscillator with all other initial conditions zero), aligned along a one-dimensional smooth manifold in the frequency-energy plot.* As a first step to test this conjecture, a nonlinear boundary value problem (NLBVP) was formulated to compute the periodic orbits of system (1) with no forcing and damping, and the additional restriction for the special orbits was imposed. (For a detailed formulation of the NLBVP, we refer to Lee et al. (2005).) The numerical results in the frequency-energy plane are depicted in Figure 6 for parameters $\varepsilon = 0.05$, $\omega_0^2 = 1$, $C = 1$. Each triangle in the plot represents a special orbit, and a one-dimensional manifold appears to connect the special orbits (though a rigorous proof of the existence of this manifold is not given here). In addition, it appears that there exists a countable infinity of special orbits, occurring in the neighborhoods of the countable infinities of internal resonances m:n (m, n integers) of the system, but again no rigorous proof of this conjecture is given in this paper. We note that a subset of high-frequency branches (for $\omega > 1$) possesses two special orbits instead of one (for example, all $U(p+1)p$ branches with $p \geq 3$). To distinguish between the two special solutions in such high-frequency branches we partition them into two subclasses: the a-special orbits, which exist in the neighborhood of $\omega = \omega_0 = 1$, and the b-special orbits, which occur away from this neighborhood (cf. Figure 6); it was numerically proven in Lee et al. (2005) that the a-special orbits are unstable, whereas the b-special orbits are stable. As shown below, it is the excitation of the stable b-special orbits that activates the third mechanism for energy pumping.

Representative special orbits are given in Figure 7. By construction, all special orbits have a common feature; namely, they pass with vertical slope through the origin of the configuration plane (y, v). This feature renders them compatible with an impulse applied to the linear oscillator, which corresponds to a nonzero velocity of the linear oscillator with all other initial conditions zero. The curves corresponding to

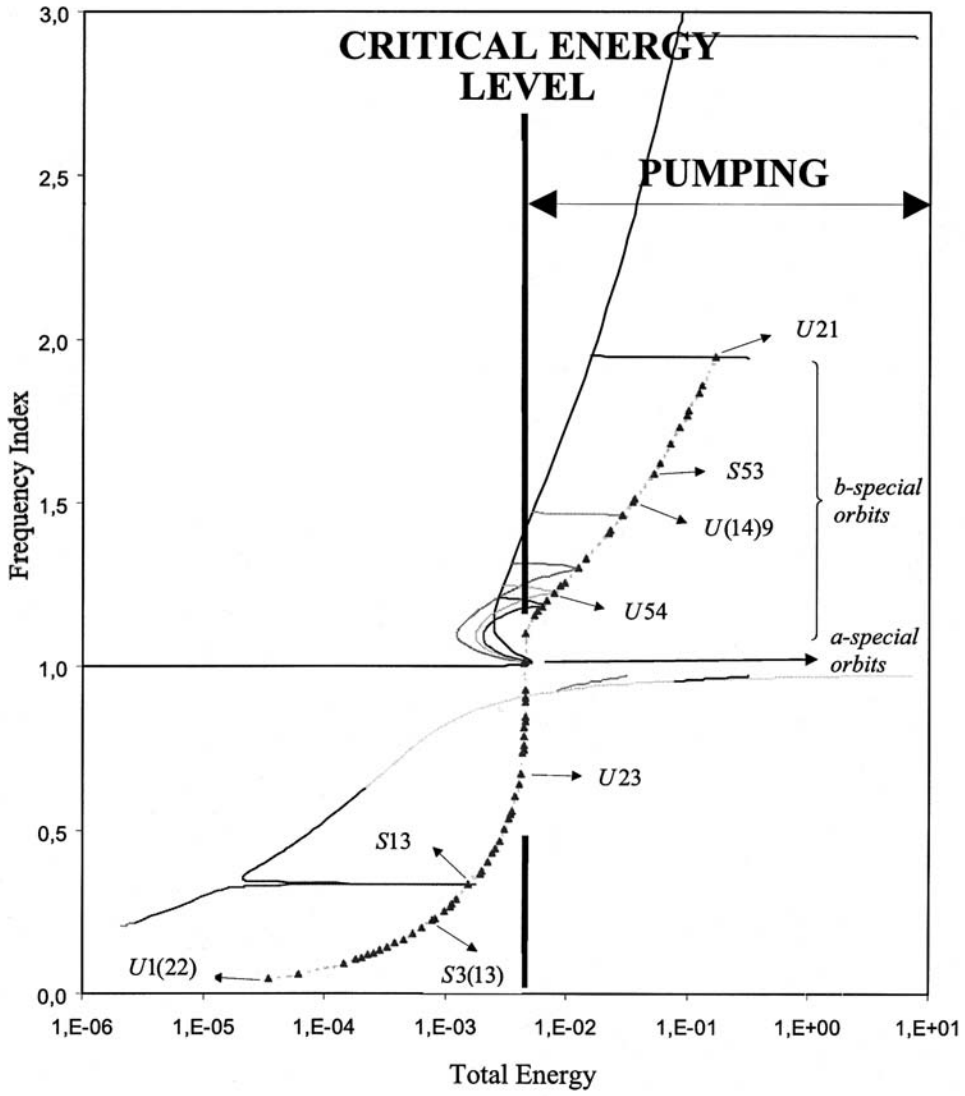

FIG. 6. *Manifold of special orbits (represented by triangles) in the frequency-energy plot.*

the special orbits in the configuration plane can be either closed or open, depending upon the differences between the two indices characterizing the orbits; specifically, odd differences between indices correspond to closed curves in the configuration plane and lie on U-branches, whereas even differences between indices correspond to open curves on S-branches. In addition, higher-frequency special orbits (with frequency index $\omega > \omega_0$) in the upper part of the frequency-energy plot (i.e., $m > n$) are localized to the nonlinear oscillator; conversely, special orbits in the lower part of the frequency-energy plot (with frequency index $\omega < \omega_0$) tend to be localized to the linear oscillator. This last observation is of particular importance since it directly affects the transfer of a significant amount of energy from the linear oscillator to the NES through the mechanism discussed in this section: indeed, there seems to be a well-

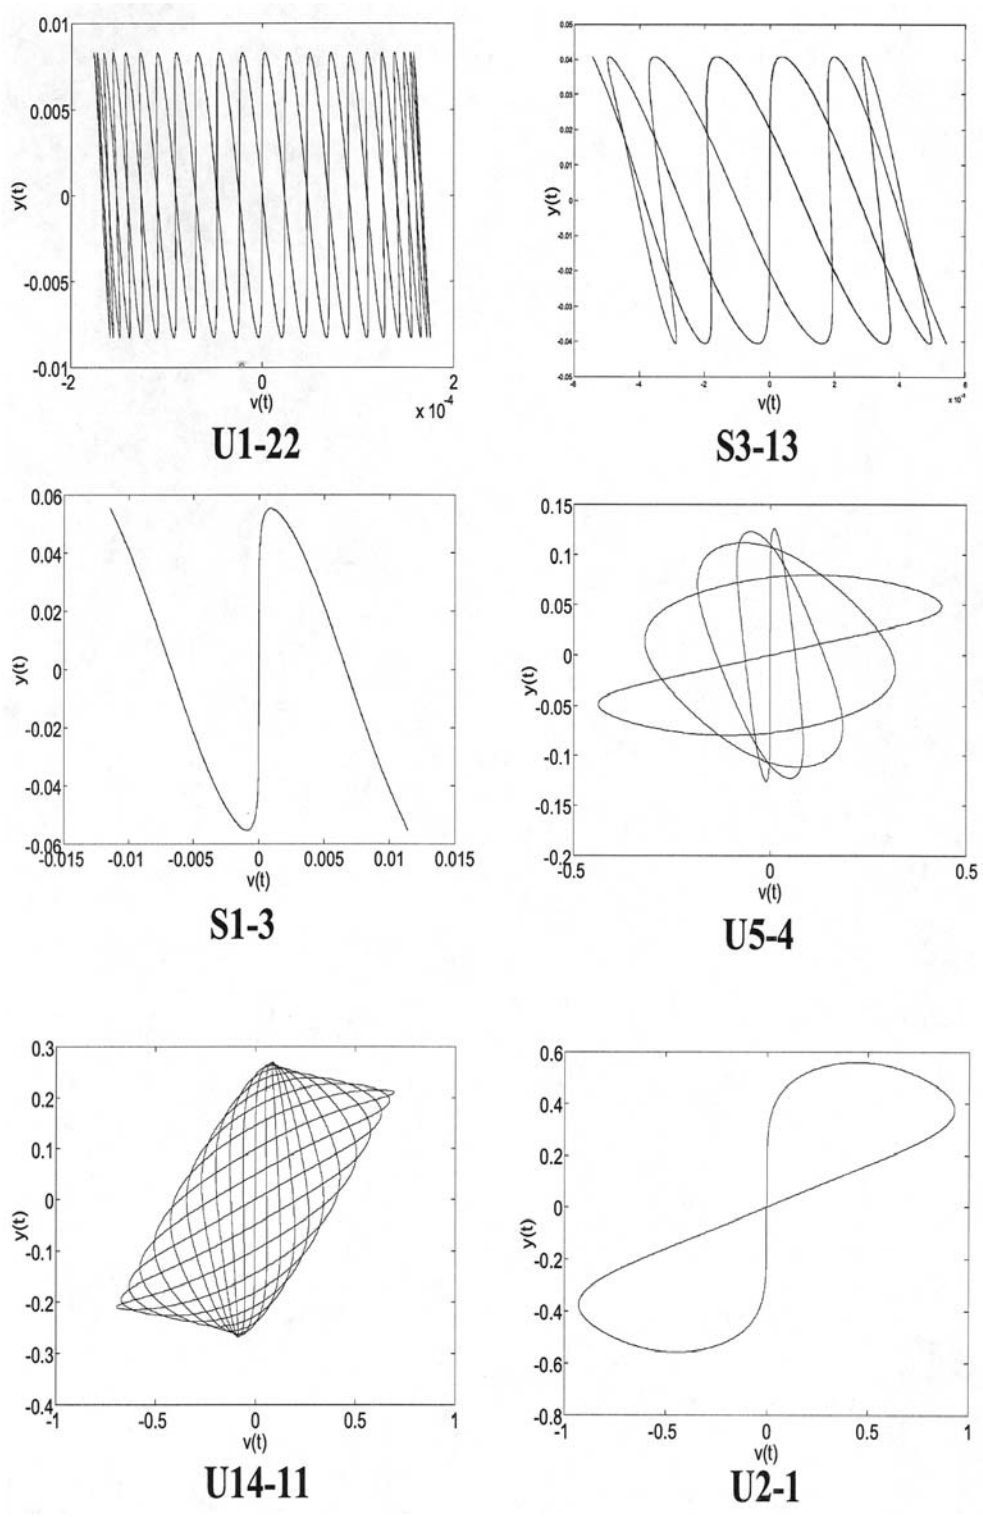

FIG. 7. *Representative special orbits in the configuration plane* (y, v). *Closed curves correspond to special orbits on* U*-branches, and open curves to special orbits on* S*-branches.*

defined critical threshold of energy that separates high- from low-frequency special orbits, i.e., those that do or do not localize, respectively, to the NES (cf. Figure 6). *The third mechanism for energy pumping can be activated only for input energies above the critical threshold*, since below that the (low-frequency) special orbits are incapable of transferring significant amounts of input energy from the linear oscillator to the NES; in other words, the critical level of energy represents a lower bound below which no significant energy pumping can be initiated through activation of a special orbit. Moreover, combining this result with the topology of the one-dimensional manifold of special orbits of Figure 6, it follows that *it is the subclass of stable b-special orbits that is responsible for activating the third energy pumping mechanism, whereas the subclass of unstable a-special orbits does not affect energy pumping.* This theoretical insight will be fully validated by the numerical simulations that follow.

We now proceed to analyze in detail the nonlinear beat phenomenon that takes place when a special orbit is excited by the initial conditions. When the NES engages in an m:n resonance capture with the linear oscillator, a nonlinear beat phenomenon takes place. Due to the essential (nonlinearizable) nonlinearity of the NES and the lack of any preferential frequency, the considered nonlinear beat phenomenon does not require any a priori "tuning" of the nonlinear attachment, since at the specific frequency-energy range of the m:n resonance capture the nonlinear attachment adjusts its amplitude ("tunes itself") to fulfill the necessary conditions of internal resonance. This represents a significant departure from the classical nonlinear beat phenomenon observed in coupled oscillators with linearizable nonlinear stiffnesses (e.g., spring-pendulum systems), where the defined ratios of linearized natural frequencies of the component subsystems dictate the type of internal resonances that can be realized (Golnaraghi (1991), Salemi, Golnaraghi, and Heppler (1997)). As an example, in Figure 8 we depict the exchanges of energy during the nonlinear beat phenomena corresponding to the special orbits of branches $U21$ and $U54$ for parameters $\varepsilon = 0.05$, $\omega_0^2 = 1$, $C = 1$ and no damping. As expected, energy is continuously exchanged between the linear oscillator and the NES, so the energy transfer is not irreversible as is required for energy pumping; *we conclude that excitation of a special orbit can only initiate (trigger) energy pumping, but not cause it in itself.* The amount of energy transferred during each cycle of the beat varies with the special orbit considered; for $U21$ and $U54$, as much as 32% and 86% of energy, respectively, can be transferred to the NES. It can be shown that, for increasing integers m and n with corresponding ratios $m/n \to 1+$, the maximum energy transferred during a cycle of the special orbit tends to 100%; at the same time, however, the resulting period of the cycle of the beat (and, hence, of the time needed to transfer the maximum amount of energy) should increase as the least common multiple of m and n.

We note at this point that the nonlinear beat phenomenon associated with the excitation of the special orbits can be studied analytically using the complexification-averaging method first introduced by Manevitch (1999). To demonstrate the analytical procedure, we analyze in detail the special orbit on branch $U21$ of the system with no damping. In Lee et al. (2005), the periodic motions on this entire branch were studied, and it was shown that the responses of the linear oscillator and the nonlinear attachment can be approximately expressed as

$$\begin{aligned} y(t) &= Y_1 \sin \omega t + Y_2 \sin 2\omega t \equiv y_1(t) + y_2(t), \\ v(t) &= V_1 \sin \omega t + V_2 \sin 2\omega t \equiv v_1(t) + v_2(t), \end{aligned} \tag{2}$$

where

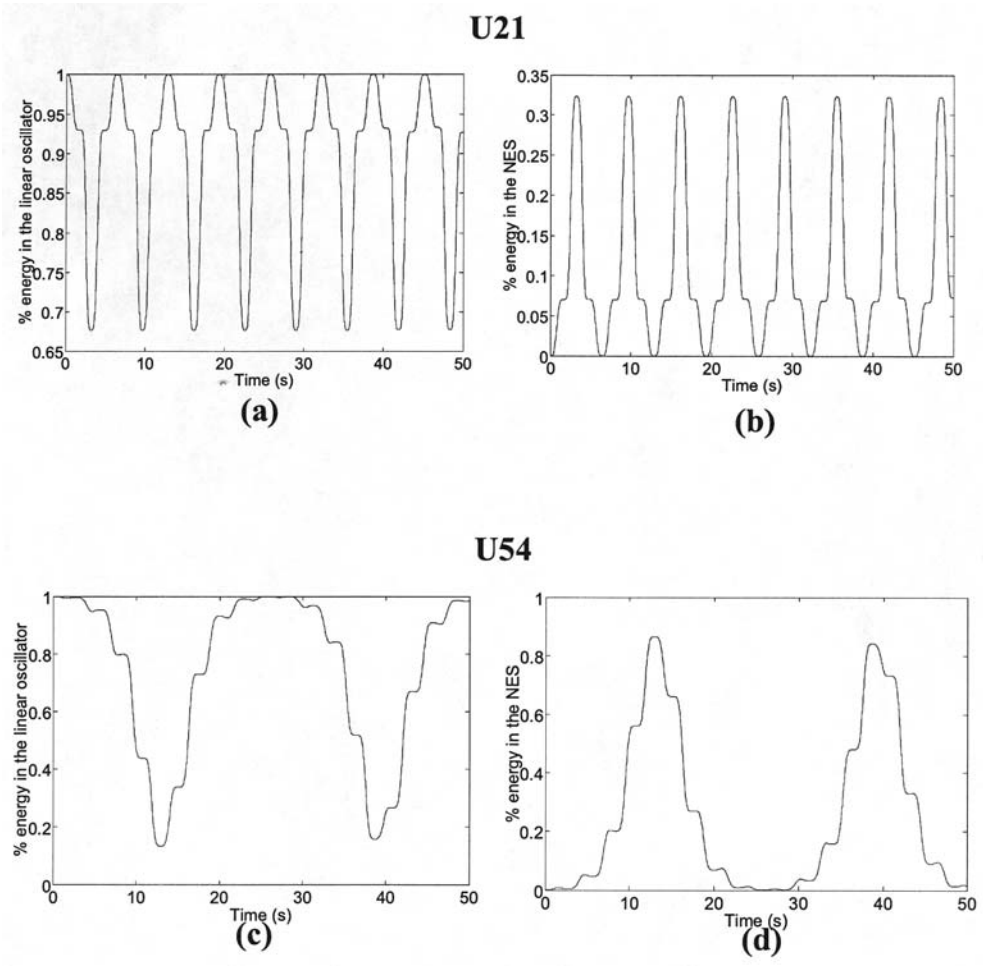

FIG. 8. *Exchanges of energy during nonlinear beat phenomena corresponding to special orbits on* (a), (b) $U21$, *and* (c), (d) $U54$.

$$A = \frac{\varepsilon\omega^2}{\omega_0^2 - \omega^2} B \quad \text{and} \quad D = \frac{4\varepsilon\omega^2}{\omega_0^2 - 4\omega^2} G,$$

$$B = \pm\sqrt{\frac{4\varepsilon\omega^4(Z_2 - 8Z_1)}{9CZ_1^3 Z_2}} \quad \text{and} \quad G = \pm\sqrt{\frac{32\varepsilon\omega^4(2Z_1 - Z_2)}{9CZ_2^3 Z_1}},$$

$$Z_1 = \frac{\varepsilon\omega^2}{\omega_0^2 - \omega^2} - 1 \quad \text{and} \quad Z_2 = \frac{4\varepsilon\omega^2}{\omega_0^2 - 4\omega^2} - 1,$$

$$Y_1 = \frac{A}{\omega}, \quad V_1 = \frac{B}{\omega}, \quad Y_2 = \frac{D}{2\omega}, \quad V_2 = \frac{G}{2\omega}.$$

Hence, a two-frequency approximation is satisfactory for this family of periodic motions. The frequency ω_{SO} at which the special orbit appears is computed by imposing the initial conditions $y(0) = v(0) = \dot{v}(0) = 0$, which leads to the relation

$$B = -2G \qquad \text{(special orbit)}.$$

The instantaneous fraction of total energy in the linear oscillator during the nonlinear beat phenomenon is estimated to be

$$E_{linear}(t) = \frac{\left[(\omega_0^2 - 4\omega_{SO}^2)\sin\omega_{SO}t - 2(\omega_0^2 - \omega_{SO}^2)\sin 2\omega_{SO}t\right]^2}{9\omega_{SO}^2\omega_0^2} + \frac{\left[(\omega_0^2 - 4\omega_{SO}^2)\cos\omega_{SO}t - 4(\omega_0^2 - \omega_{SO}^2)\cos 2\omega_{SO}t\right]^2}{9\omega_0^4}. \tag{3}$$

The nonlinear coefficient C has no influence on the fraction of total energy transferred to the NES during the nonlinear beat; this means that, during the beat, the instantaneous energies of the linear oscillator and the NES are directly proportional to the nonlinear coefficient. Moreover, as the mass of the NES tends to zero, the frequency where the special orbit is realized tends to the limit $\omega_{SO} \to \omega_0$, and, as a result, $E_{linear}(t) \to 1$, and the energy transferred to the NES during the beat tends to zero. However, we note that this is a result satisfied only asymptotically, since, as indicated by the results depicted in Figure 8, even for very small mass ratios, i.e., $\varepsilon = 0.05$, as much as 86% of the total energy can be transferred to the NES during a cycle of the special orbit of branch $U54$.

Considering now the damped system, we will show that following an initial nonlinear beat phenomenon, either one of the main (fundamental or subharmonic) energy pumping mechanisms can be activated through a nonlinear transition (jump) in the dynamics. It was previously mentioned that the two main energy pumping mechanisms are qualitatively different from the third mechanism, which is based on the excitation of a nonlinear beat phenomenon (special orbit); indeed, damping is a prerequisite for the realization of the two main mechanisms, leading to an irreversible energy transfer from the linear oscillator to the NES, whereas a special orbit is capable of transferring energy without dissipation, though this transfer is not irreversible but periodic. This justifies our earlier assertion that the third mechanism does not represent an independent mechanism for energy pumping, but rather triggers it, and through a nonlinear transition activates either of the two main mechanisms. This will become apparent in the following numerical simulations.

The following simulations concern the transient dynamics of the damped system (1) with parameters $\varepsilon = 0.05$, $\omega_0^2 = 1$, $C = 1$, $\lambda_1 = \lambda_2 = 0.0015$ and an impulse of magnitude Y applied to the linear oscillator (corresponding to initial conditions $y(0+) = v(0+) = \dot{v}(0+) = 0$, $\dot{y}(0+) = Y$). By varying the magnitude of the impulse we study the different nonlinear transitions that take place in the dynamics and their effects on energy pumping. The responses of the system to the relatively strong impulse $Y = 0.25$ are depicted in Figure 9. Inspection of the WTs of the responses (cf. Figures 9(c)–(d)), and of the portion of total instantaneous energy captured by the NES (cf. Figure 9(e)), reveals that at the initial stage of the motion (until approximately $t = 120$ s) the (stable) b-special orbit on branch $U32$ is excited (since the NES response possesses two main frequency components at 1 and 3/2 rad/s), and a nonlinear beat phenomenon takes place. (Note the continuous exchange of energy between the two subsystems—reversibility in this initial stage of the motion.) For $t > 120$ s, the dynamics undergoes a transition (jump) to branch $S11+$, and fundamental energy pumping to the NES occurs on a prolonged 1:1 resonance capture (cf. Figures 9(c)–(d)); eventually, 84% of the input energy is dissipated by the damper of the NES (cf. Figure 9(f)).

Lowering the magnitude of the impulse to $Y = 0.11$ gives rise to a different set of nonlinear transitions, as the simulations of Figure 10 indicate. In this case the (stable)

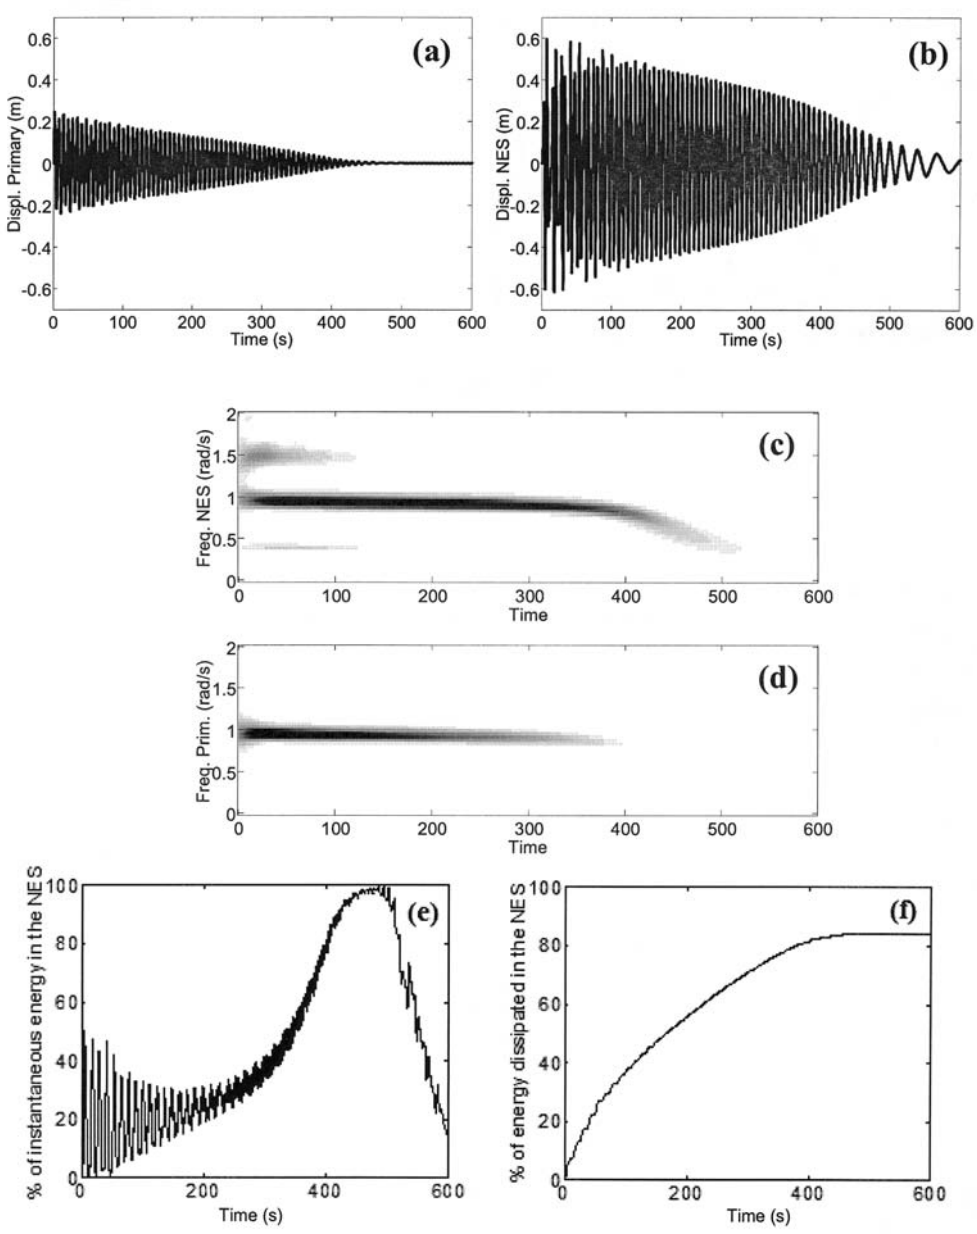

FIG. 9. *Energy pumping by nonlinear beat, transition to* $S11+$. *Shown are transient responses of* (a) *the linear oscillator and* (b) *NES; WTs of the motion of* (c) *NES and* (d) *the linear oscillator;* (e) *percentage of instantaneous total energy in the NES;* (f) *percentage of total input energy dissipated by the NES.*

b-special orbit of branch $U43$ is initially excited, which then activates subharmonic energy pumping through a nonlinear transition to the tongue $S13-$. In other words, the lower tongue appears to act as "bait" and activates energy pumping through 1:3 resonance capture, i.e., by capturing locally the transient dynamics in its domain of attraction. Figure 10(e) reveals that a nonlinear beat phenomenon occurs until

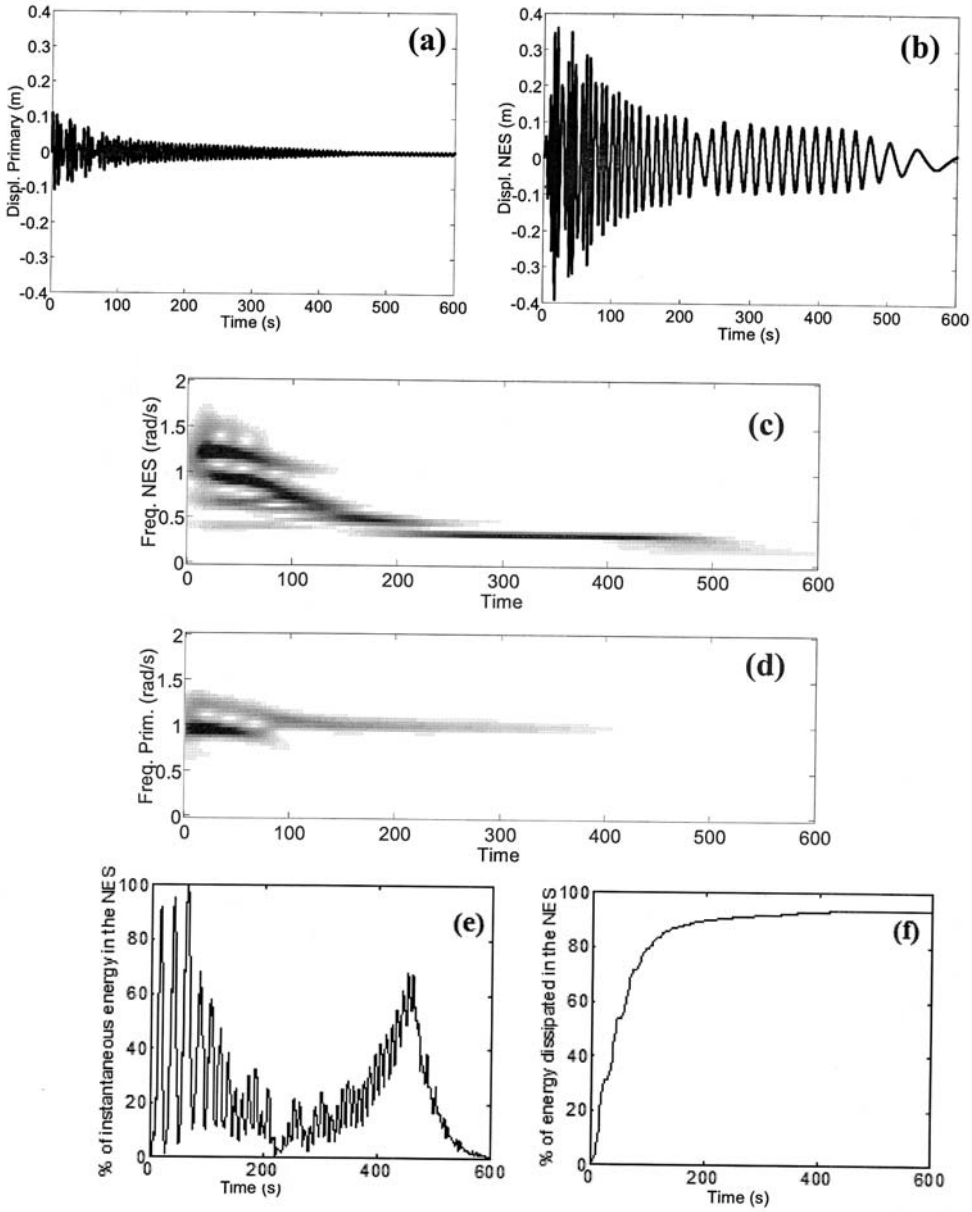

FIG. 10. *Energy pumping by nonlinear beat, transition to* $S13-$. *Shown are transient responses of* (a) *the linear oscillator and* (b) *NES; WTs of the motion of* (c) *NES and* (d) *the linear oscillator;* (e) *percentage of instantaneous total energy in the NES;* (f) *percentage of total input energy dissipated by the NES.*

$t = 150$ s approximately, and in turn activates 1:3 subharmonic energy pumping to the NES (cf. Figures 10(c)–(d)); eventually, 94% of the input energy is dissipated by the NES (cf. Figure 10(f)).

Comparing the two simulations, we conclude that excitation of the *b*-special orbit of $U43$ leads to more effective energy pumping compared to the *b*-special orbit of $U32$. The reason rests with the localization properties of the special orbits, i.e.,

their capacity to transfer a larger fraction of the total energy to the NES during a cycle of the oscillation. Indeed, the localization properties of the b-special orbits of branches $U(p+1)p$ are enhanced as the order p increases, i.e., as their second frequency component, $\omega = (p+1)/p$, approaches that of the first, $\omega = 1$, and the special orbits topologically approach the branch $S11-$ (Lee et al. (2005)). In that context, the b-special orbit of $U43$ is capable of transferring a larger fraction of the input than that being transferred by the b-special orbit of $U32$ (compare Figures 9(e) and 10(e)), and hence the enhanced energy pumping results of the second simulation. We note at this point that the (unstable) a-special orbits of these branches are localized in the linear oscillator and do not affect energy pumping.

We now test the previous theoretical finding that, for sufficiently small impulse magnitudes, no energy pumping can occur, i.e., none of the three aforementioned energy pumping mechanisms can be activated. The simulations for $Y = 0.08$ are depicted in Figure 11. The WT of the NES response of Figure 11(c) shows the presence of a frequency component below $\omega = 1$ at the initial stage of the motion, which indicates excitation of a low-frequency special orbit in the lower part ($\omega < 1$) of the frequency-energy plot (i.e., $U12$). As explained previously, those orbits are localized to the linear oscillator and, as a result, cannot transfer a sufficient amount of energy to the NES in the initial stage of the motion. Accordingly, neither the fundamental nor the subharmonic energy pumping mechanism is eventually activated, leading to a much smaller amount of energy dissipated by the NES (around 45% in this case). This result confirms our previous assertion that energy pumping through nonlinear beat can be activated only above a critical energy threshold (cf. Figure 6).

To demonstrate more clearly the effect of the b-special orbits on energy pumping, in Figure 12 we depict the percentage of input energy eventually dissipated at the NES for varying magnitudes of the impulse for the system with parameters $\varepsilon = 0.05$, $\omega_0^2 = 1$, $C = 1$, $\lambda_1 = \lambda_2 = 0.01$. In the same plot we depict the positions of the special orbits of the undamped system and the critical threshold predicted in Figure 6. We conclude that strong energy pumping is associated with the excitation of b-special orbits of the branches $U(p+1)p$ in the neighborhood above the critical threshold, whereas excitation of a-special orbits below the critical threshold does not lead to rigorous energy pumping. As mentioned previously, in the neighborhood of the critical threshold the b-special orbits are strongly localized to the NES, whereas a-orbits are nonlocalized. We also note from Figure 12 the deterioration of energy pumping as we increase the magnitude of the impulse well above the critical threshold, where high-frequency special orbits are excited; this is a consequence of the fact that well above the critical threshold the special orbits are weakly localized to the NES.

Extending the previous result, in Figure 13 we depict the contours of energy eventually dissipated at the NES, but now for the case of two impulses of magnitudes $\dot{y}(0)$ and $\varepsilon\dot{v}(0)$ applied to both the linear oscillator and the NES, respectively. The system parameters used were identical to those of the previous simulation of Figure 12. Superimposed on contours of energy dissipated at the NES are certain high- and low-frequency U- and S-branches of the undamped system together with their special orbits, in order to confirm for this case the essential role of the high-frequency special orbits in energy pumping. Indeed, high levels of energy dissipation are encountered in neighborhoods of contours of high-frequency U-branches, whereas low values are noted in the vicinity of low-frequency branches. These results agree qualitatively with our earlier theoretical and numerical findings and enable us to assess and establish the robustness of energy pumping when the NES is not initially at rest.

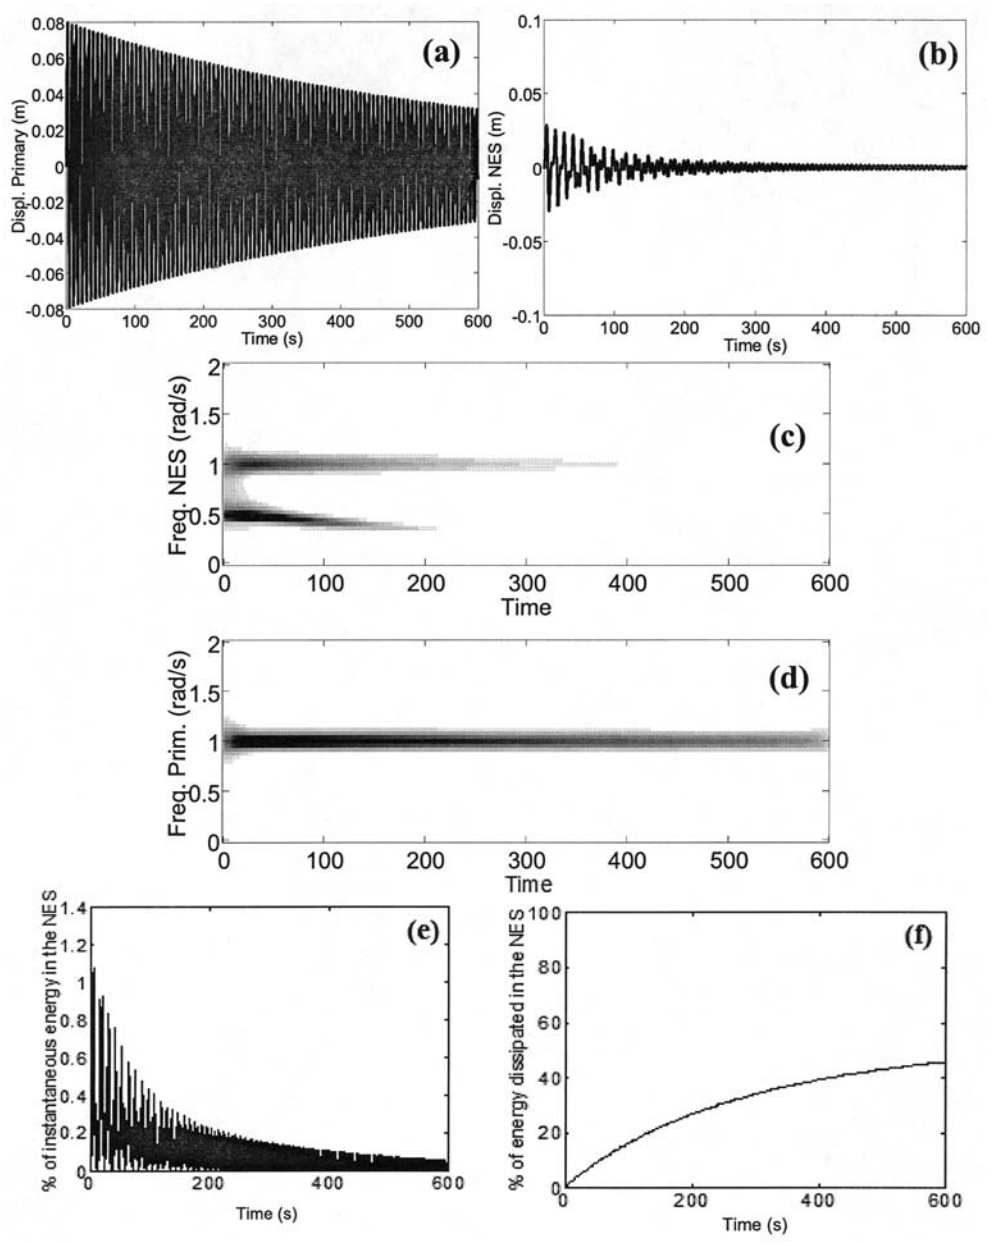

FIG. 11. *Absence of energy pumping for low excitation. Shown are transient responses of* (a) *the linear oscillator and* (b) *NES; WTs of the motion of* (c) *NES and* (d) *the linear oscillator;* (e) *percentage of instantaneous total energy in the NES;* (f) *percentage of total input energy dissipated by the NES.*

In the next section we provide analytical studies of the fundamental and subharmonic energy pumping mechanisms encountered in the damped system; since excitation of nonlinear beats is merely a means for activating the main two energy pumping mechanisms, it will not be analyzed below. We show that in each case we can reduce the governing dynamics of energy pumping to low-order slow-flow dynamical systems.

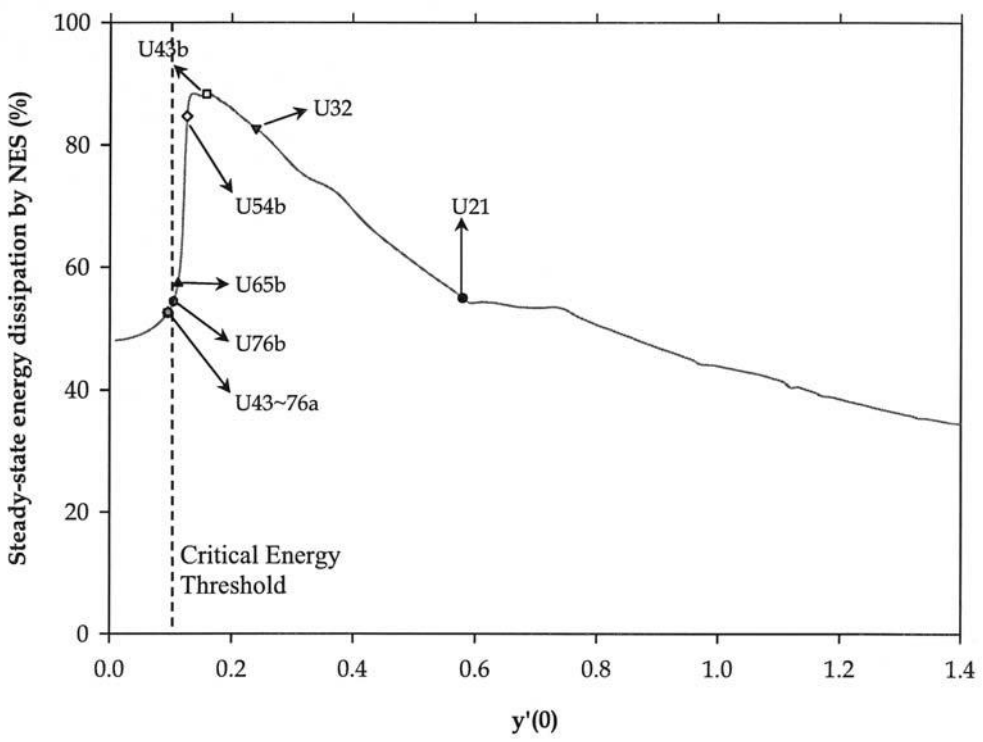

FIG. 12. *Percentage of input energy eventually dissipated at the NES for varying magnitudes of the impulse (the positions of certain special orbits are indicated).*

4. Slow-flow analysis. We now focus on the resonance capture dynamics that governs energy pumping in the damped system. This can be studied by performing a reduction of the dynamics, an approximate partition between slow and fast dynamics, and considering the evolution of the slow-flow dynamics when energy pumping takes place. We show that even though the system of coupled oscillators possesses essential (nonlinearizable) stiffness nonlinearities, analytical modeling of its dynamics at certain motion regimes can still be performed.

The theory of resonance processes for multifrequency systems was developed by Neishtadt (1997), (1999), where capture into and scattering on the resonance were discussed by considering them as random events and computing probabilities of capture and probabilistic distributions of the scattering amplitudes. By assuming small perturbations (e.g., weak nonlinearities), action-angle formulations and the averaging theorem were applied to provide analytical asymptotic validity of the approximations. Also, by introducing a mapping (called the *in-out function*) from a state of resonance capture to that of escape, glued averaging approximation was utilized to analytically describe motions when they are away from, captured into, and escaped from the resonance manifold.

Similar formulations were considered in Vakakis and Gendelman (2001), where the slow-flow equations were established also by the complexification/averaging technique. This method does not necessarily require the perturbations to be small, although it is similar to the (classical) averaging method; once the proper ansatz regarding the frequency content of the response is included, it is numerically verified that the

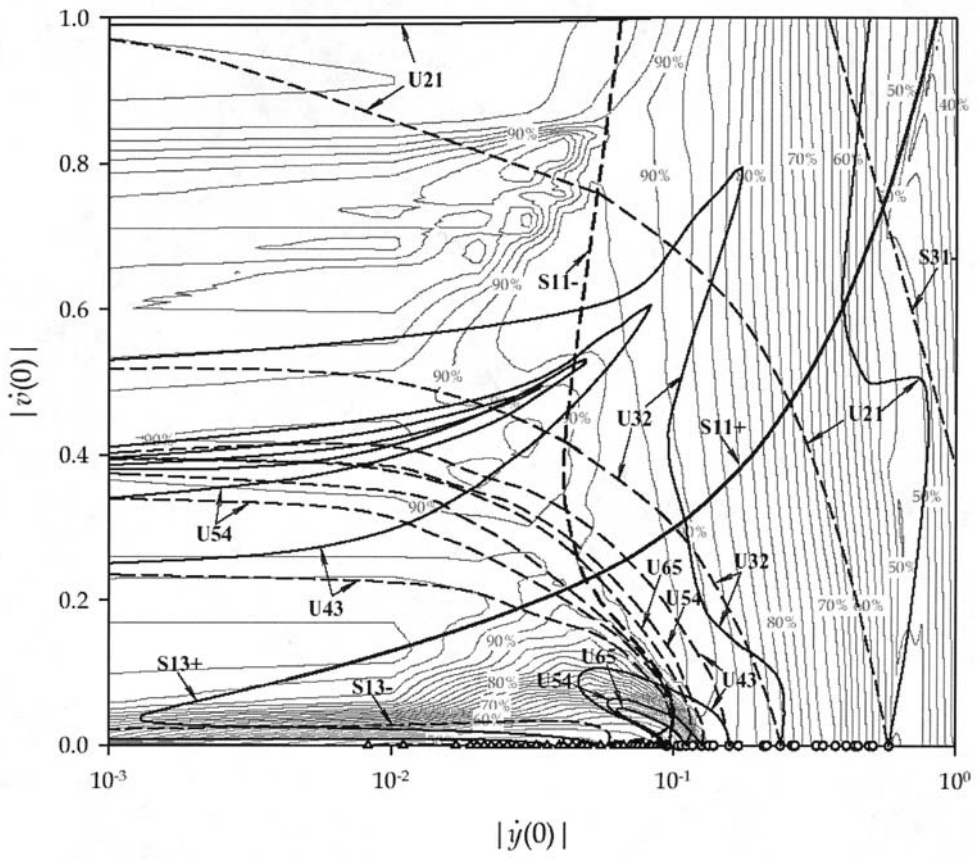

FIG. 13. *Contours of percentages of input energy eventually dissipated at the NES for the case when both oscillators are excited by impulses: superimposed are contours of high- and low-frequency branches of the undamped system (solid line: in phase, dashed line: out of phase branches); special curves in high- and low-frequency branches are denoted by* (◯) *and* (Δ)*, respectively.*

slow-flow model provides good approximation of the original dynamics and the entire resonance processes as well.

In this study, we show that even though the system of coupled oscillators possesses essential (nonlinearizable) stiffness nonlinearities, analytical modeling of its dynamics at certain motion regimes can still be performed by means of the multifrequency complexification/averaging method.

Focusing first on the fundamental energy pumping mechanism, we again consider system (1) and introduce the new complex variables

$$\begin{aligned} \psi_1(t) &= \dot{v}(t) + jv(t) \equiv \varphi_1(t)\, e^{jt}, \\ \psi_2(t) &= \dot{y}(t) + jy(t) \equiv \varphi_2(t)\, e^{jt}, \end{aligned} \tag{4}$$

where $\varphi_i(t)$, $i = 1, 2$, represent slowly varying complex amplitudes and $j = (-1)^{1/2}$. By writing (4) we introduce a partition of the dynamics into slow and fast components and seek slowly modulated fast oscillations at frequency $\omega = \omega_0 = 1$. As discussed previously, fundamental energy pumping is associated with this type of motion in the neighborhood of branch $S11+$ in the frequency-energy plot of the undamped

dynamics. Expressing the system responses in terms of the new complex variables, $y = (\psi_2 - \psi_2^*)/2j$, $v = (\psi_1 - \psi_1^*)/2j$ (where $(*)$ denotes complex conjugate); substituting into (1) with $P(t) = 0$; and averaging over the fast frequency, we derive a set of approximate slow modulation equations that govern the evolutions of the complex amplitudes,

$$\begin{aligned}
&\dot{\varphi}_1 + \left(\frac{j}{2}\right)\varphi_1 + \left(\frac{\lambda}{2}\right)(\varphi_1 - \varphi_2) - \left(\frac{3jC}{8\varepsilon}\right)|\varphi_1 - \varphi_2|^2(\varphi_1 - \varphi_2) = 0,\\
&\dot{\varphi}_2 - \left(\frac{\varepsilon\lambda}{2}\right)(\varphi_1 - \varphi_2) - \left(\frac{3jC}{8}\right)|\varphi_2 - \varphi_1|^2(\varphi_2 - \varphi_1) + \left(\frac{\varepsilon\lambda}{2}\right)\varphi_2 = 0.
\end{aligned} \tag{5}$$

For the sake of simplicity, we have assumed that $\lambda_1 = \lambda_2 = \lambda$ in (1). To derive a set of real modulation equations, we express the complex amplitudes in polar form, $\varphi_i(t) = a_i(t)\, e^{j\beta_i(t)}$, $i = 1, 2$, substitute into (5), and separately set equal to zero the real and imaginary parts. We then reduce (5) to an autonomous set of equations that govern the slow evolution of the two amplitudes $a_1(t)$ and $a_2(t)$ and the phase difference $\phi(t) = \beta_2(t) - \beta_1(t)$:

$$\begin{aligned}
&\dot{a}_1 + \left(\frac{\lambda}{2}\right)a_1 - \left(\frac{\lambda}{2}\right)a_2\cos\phi - \left(\frac{3C}{8\varepsilon}\right)\left(a_1^2 + a_2^2 - 2a_1a_2\cos\phi\right)a_2\sin\phi = 0,\\
&\dot{a}_2 - \left(\frac{\varepsilon\lambda}{2}\right)a_1\cos\phi + \varepsilon\lambda a_2 + \left(\frac{3C}{8}\right)\left(a_1^2 + a_2^2 - 2a_1a_2\cos\phi\right)a_1\sin\phi = 0,\\
&\dot{\phi} + \left(\frac{\lambda}{2}\right)\left[\left(\frac{\varepsilon a_1}{a_2}\right) + \left(\frac{a_2}{a_1}\right)\right]\sin\phi - \left(\frac{1}{2}\right)\\
&+ \left(\frac{3C}{8}\right)\left(a_1^2 + a_2^2 - 2a_1a_2\cos\phi\right)\left\{\left(\frac{1}{\varepsilon}\right)\left[1 - \left(\frac{a_2}{a_1}\right)\cos\phi\right] - \left[1 - \left(\frac{a_1}{a_2}\right)\cos\phi\right]\right\} = 0.
\end{aligned} \tag{6}$$

This reduced dynamical system governs the slow-flow dynamics of fundamental energy pumping. In particular, 1:1 *resonance capture (the underlying dynamical mechanism of fundamental energy pumping) is associated with non–time-like behavior of the phase variable ϕ or, equivalently, failure of the averaging theorem in the slow-flow* (6). Indeed, when ϕ exhibits time-like, nonoscillatory behavior, one can apply the averaging theorem over ϕ and prove that the amplitudes a_1 and a_2 decay exponentially with time and that no significant energy exchanges (energy pumping) can take place. In Figure 14(a) we depict 1:1 resonance capture in the slow-flow phase plane $(\dot{\phi}, \phi)$ for system (6) with $\varepsilon = 0.05$, $\lambda = 0.01$, $C = 1$, $\omega_0 = 1$ and initial conditions $a_1(0) = 0.01$, $a_2(0) = 0.24$, $\phi(0) = 0$. The oscillatory behavior of the phase variable in the neighborhood of the in-phase limit $\phi = 0+$ indicates 1:1 resonance capture (on branch $S11+$ of the frequency-energy plot of Figure 1) and leads to energy pumping from the linear oscillator to the NES, as evidenced by the build-up of amplitude a_1 (cf. Figure 14(b)). Escape from resonance capture is associated with time-like behavior of ϕ and rapid decrease of the amplitudes a_1 and a_2 (as predicted by averaging in (6)). A comparison of the analytical approximation (4)–(6) and direct numerical simulation for the previous initial conditions confirms the accuracy of the analysis.

Considering subharmonic energy pumping, we will focus on energy pumping in the neighborhood of tongue $S13-$ (similar analysis can be applied for other orders of subharmonic resonance captures). Due to the fact that motions in the neighborhood of $S13-$ possess two main frequency components, at frequencies 1 and 1/3, we express

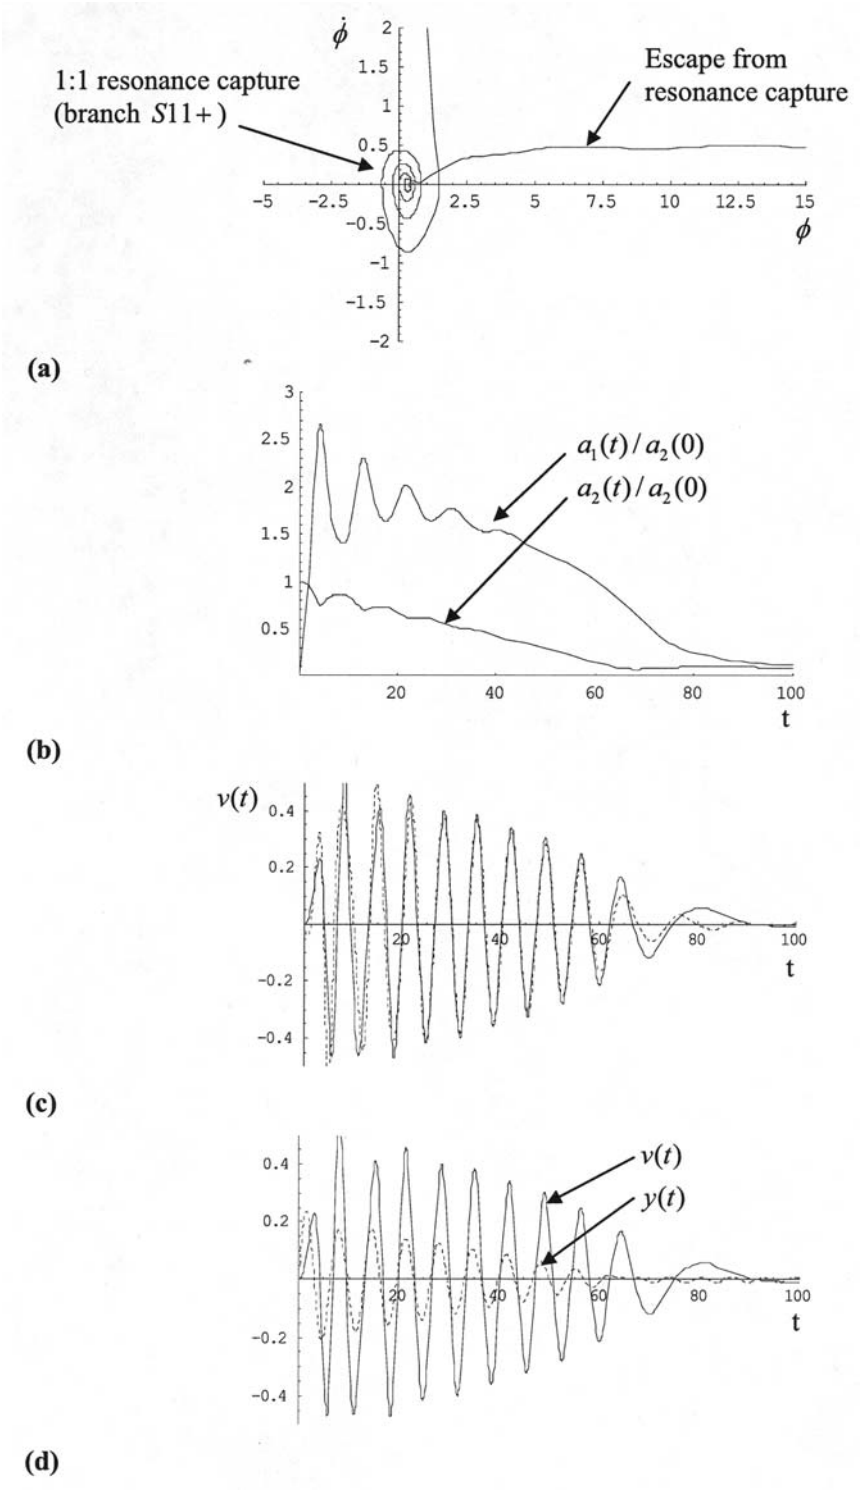

FIG. 14. *Fundamental energy pumping:* (a) 1:1 *resonance capture in the slow flow,* (b) *amplitude modulations,* (c) *comparison between analytical approximation (dashed line) and direct numerical simulation (solid line) for* $v(t)$, (d) *transient responses of the system.*

the responses of system (1) as

$$y(t) = y_1(t) + y_{1/3}(t), \qquad v(t) = v_1(t) + v_{1/3}(t), \tag{7}$$

where the indices represent the frequency of each term. As in the previous case, we introduce new complex variables,

$$\begin{aligned}
&\psi_1(t) = \dot{y}_1(t) + j\omega y_1(t) \equiv \varphi_1(t)\, e^{j\omega t}, \quad \psi_3(t) = \dot{y}_{1/3}(t) + j(\omega/3) y_{1/3}(t) \equiv \varphi_3(t)\, e^{j(\omega/3)t},\\
&\psi_2(t) = \dot{v}_1(t) + j\omega v_1(t) \equiv \varphi_2(t)\, e^{j\omega t}, \quad \psi_4(t) = \dot{v}_{1/3}(t) + j(\omega/3) v_{1/3}(t) \equiv \varphi_4(t)\, e^{j(\omega/3)t},
\end{aligned} \tag{8}$$

where $\varphi_i(t)$ represent slowly varying modulations of fast oscillations of frequencies 1 or 1/3. Expressing the system responses in terms of the new complex variables,

$$y = \frac{\psi_1 - \psi_1^*}{2j\omega} + \frac{3\,(\psi_3 - \psi_3^*)}{2j\omega}, \qquad v = \frac{\psi_2 - \psi_2^*}{2j\omega} + \frac{3\,(\psi_4 - \psi_4^*)}{2j\omega}, \tag{9}$$

substituting into (1) with $P(t) = 0$, and averaging over each of the two fast frequencies, we derive the slow modulation equations that govern the evolutions of the complex amplitudes,

$$\begin{aligned}
&\dot{\varphi}_1 + \left(\frac{j\omega}{2} - \frac{j}{2\omega}\right)\varphi_1 + \left(\frac{\varepsilon\lambda}{2}\right)(2\varphi_1 - \varphi_2) + \left(\frac{jC}{8\omega^3}\right)\Big\{3\Big[9\varphi_3^3 - 27\varphi_3^2\varphi_4 - 9\varphi_4^3\\
&\quad - (\varphi_1 - \varphi_2)\,|\varphi_1 - \varphi_2|^2 + 27\varphi_3\varphi_4^2 - 18\,(\varphi_1 - \varphi_2)\,|\varphi_3 - \varphi_4|^2\Big]\Big\} = 0,\\
&\dot{\varphi}_3 + \left(\frac{j\omega}{6} - \frac{3j}{2\omega}\right)\varphi_3 + \left(\frac{\varepsilon\lambda}{2}\right)(2\varphi_3 - \varphi_4)\\
&\quad + \left(\frac{jC}{8\omega^3}\right)\Big\{-9\Big[\varphi_1\left(2\,(\varphi_3 - \varphi_4)\,(\varphi_1^* - \varphi_2) - 3\,(\varphi_3^* - \varphi_4^*)^2\right)\\
&\quad + \varphi_2\left(2\,(\varphi_4 - \varphi_3)\,(\varphi_1^* - \varphi_2) + 3\,(\varphi_3^* - \varphi_4^*)^2\right) + 9\,(\varphi_3 - \varphi_4)\,|\varphi_3 - \varphi_4|^2\Big]\Big\} = 0,\\
&\dot{\varphi}_2 + \left(\frac{j\omega}{2}\right)\varphi_2 + \left(\frac{\lambda}{2}\right)(\varphi_2 - \varphi_1) - \left(\frac{jC}{\varepsilon 8\omega^3}\right)\Big\{3\Big[9\varphi_3^3 - 27\varphi_3^2\varphi_4 - 9\varphi_4^3\\
&\quad - (\varphi_1 - \varphi_2)\,|\varphi_1 - \varphi_2|^2 + 27\varphi_3\varphi_4^2 - 18\,(\varphi_1 - \varphi_2)\,|\varphi_3 - \varphi_4|^2\Big]\Big\} = 0,\\
&\dot{\varphi}_4 + \left(\frac{j\omega}{6}\right)\varphi_4 + \left(\frac{\lambda}{2}\right)(\varphi_4 - \varphi_3)\\
&\quad - \left(\frac{jC}{\varepsilon 8\omega^3}\right)\Big\{-9\Big[\varphi_1\left(2\,(\varphi_3 - \varphi_4)\,(\varphi_1^* - \varphi_2) - 3\,(\varphi_3^* - \varphi_4^*)^2\right)\\
&\quad + \varphi_2\left(2\,(\varphi_4 - \varphi_3)\,(\varphi_1^* - \varphi_2) + 3\,(\varphi_3^* - \varphi_4^*)^2\right) + 9\,(\varphi_3 - \varphi_4)\,|\varphi_3 - \varphi_4|^2\Big]\Big\} = 0,
\end{aligned} \tag{10}$$

where again it was assumed that $\lambda_1 = \lambda_2 = \lambda$ in (1). To derive a set of real modulation equations, we express the complex amplitudes in polar forms $\varphi_i(t) = a_i(t)\, e^{j\beta_i(t)}$ and derive an autonomous set of seven slow-flow modulation equations that govern the amplitudes $a_i = |\varphi_i|$, $i = 1, \ldots, 4$, and the phase differences $\phi_{12} = \beta_1 - \beta_2$, $\phi_{13} = \beta_1 - 3\beta_3$, and $\phi_{14} = \beta_1 - 3\beta_4$.

The equations of the autonomous slow flow will not be reproduced here, but it suffices to state that they are of the form

$$
\begin{aligned}
&\dot{a}_1 + \left(\frac{\varepsilon\lambda}{2}\right)(2a_1 - a_2) + g_1(a,\phi) = 0,\\
&\dot{a}_3 + \left(\frac{\varepsilon\lambda}{2}\right)(2a_3 - a_4) + g_3(a,\phi) = 0,\\
&\dot{a}_2 + \left(\frac{\lambda}{2}\right)(a_2 - a_1) + \frac{g_2(a,\phi)}{\varepsilon} = 0,\\
&\dot{a}_4 + \left(\frac{\lambda}{2}\right)(a_4 - a_3) + \frac{g_4(a,\phi)}{\varepsilon} = 0,\\
&\dot{\phi}_{12} + f_{12}(a) + g_{12}(a,\phi;\varepsilon) = 0,\\
&\dot{\phi}_{13} + f_{13}(a) + g_{13}(a,\phi) = 0,\\
&\dot{\phi}_{14} + f_{14}(a) + g_{14}(a,\phi;\varepsilon) = 0,
\end{aligned}
\tag{11}
$$

where the functions g_i and g_{ij} are 2π-periodic in terms of the phase angles $\phi = (\phi_{12}\ \phi_{13}\ \phi_{14})^T$ and by a we denote the (4×1) vector of the amplitudes a_i. In this case (as for the fundamental energy pumping mechanism), strong energy transfer between the linear and nonlinear oscillators can occur only when a subset of phase angles ϕ_{ij} does not exhibit time-like behavior; that is, when some phase angles possess oscillatory (nonmonotonic) behavior with respect to time. This can be seen from the structure of the slow flow (11) where, if the phase angles exhibit time-like behavior and the functions g_i are small, averaging over these phase angles can be performed to show that the amplitudes a_i decrease monotonically with time; in that case no significant energy exchanges between the linear and nonlinear components of the system can take place. It follows that *subharmonic energy pumping is associated with non–time-like behavior of (at least) a subset of the slow phase angles* ϕ_{ij} *in* (11).

In Figure 15 we present the results of the numerical integration of the slow-flow (10)–(11) for the system with parameters $\varepsilon = 0.05$, $\lambda = 0.03$, $C = 1$, $\omega_0 = 1$. The motion is initiated on branch $S13-$ with initial conditions $v(0) = y(0) = 0$ and $\dot{v}(0) = 0.01499$, $\dot{y}(0) = -0.059443$ (it corresponds exactly to the simulation of Figure 5). The corresponding initial conditions and the value of the frequency ω of the reduced slow-flow model were computed by minimizing the difference between the analytical and numerical responses of the system in the interval $t \in [0, 100]$: $\varphi_1(0) = -0.0577$, $\varphi_2(0) = 0.0016$, $\varphi_3(0) = -0.0017$, $\varphi_4(0) = 0.0134$, and $\omega = 1.0073$. This result indicates that, initially, nearly all energy is stored in the fundamental frequency component of the linear oscillator, with the remainder confined to the subharmonic frequency component of the NES. In Figures 15(a)–(b) we depict the temporal evolution of the amplitudes a_i, from which we conclude that subharmonic energy pumping in the system is mainly realized through energy transfer from the (fundamental) component at frequency ω of the linear oscillator, to the (subharmonic) component at frequency $\omega/3$ of the NES (as judged from the build-up of the amplitude a_3 and the diminishing of a_1). A smaller amount of energy is transferred from the fundamental frequency component of the linear oscillator to the corresponding fundamental component of the NES (as judged by the evolution of the amplitude a_2).

These conclusions are supported by the plots of Figures 15(c)–(e), where the temporal evolutions of the phase differences $\phi_{12} = \beta_1 - \beta_2$, $\phi_{13} = \beta_1 - 3\beta_3$, and $\phi_{14} = \beta_1 - 3\beta_4$ are shown. Absence of strong energy exchange between the funda-

mental and subharmonic frequency components of the linear oscillator is associated with the time-like behavior of the phase difference ϕ_{13}, whereas energy pumping from the fundamental component of the linear oscillator to the two frequency components of the NES is associated with oscillatory early-time behavior of the phase differences ϕ_{12} and ϕ_{14}. Oscillatory responses of ϕ_{12} and ϕ_{14} correspond to 1:1 and 1:3 resonance captures, respectively, between the corresponding frequency components of the linear oscillator and the NES; as time increases, time-like responses of the phase variables are associated with escapes from the corresponding regimes of resonance capture. In addition, we note that the oscillations of the angles ϕ_{12} and ϕ_{14} take place in the neighborhood of π, which confirms that, in this particular example, subharmonic energy pumping is activated by the excitation of an antiphase branch of periodic solutions (such as $S13-$). The analytical results are in full agreement with the wavelet transforms depicted in Figures 5(c)–(d), where the response of the linear oscillator possesses a strong frequency component at the fundamental frequency $\omega_0 = 1$, whereas the NES oscillates mainly at frequency $\omega_0/3$.

The accuracy of the analytical model (10)–(11) in capturing the dynamics of subharmonic energy pumping is confirmed by the plot depicted in Figure 16, where the analytical response of the NES is found to be in satisfactory agreement with the numerical response obtained by the direct simulation of (1). It is interesting to note that the reduced analytical model is capable of accurately modeling the strongly nonlinear, damped, transient response of the NES in the resonance capture region. The analytical model fails, however, during the escape from resonance capture since the ansatz (7)–(8) is not valid in that regime of the motion. Indeed, after escape from resonance capture, the motion approximately evolves along the backbone curve of the frequency-energy plot; eventually $S15$ is reached, the motion of which cannot be described by the ansatz (7)–(8), thereby leading to the failure of the analytical model.

The results presented so far provide a measure of the complicated dynamics encountered in the two-DOF system under consideration. It is logical to assume that by increasing the degrees of freedom of the system the dynamics will be even more complex. That this is indeed the case is evidenced by the numerical simulations presented in the next section, where resonance capture cascades are reported in multi-degree-

of-freedom (MDOF) linear systems with essentially nonlinear end attachments. By resonance capture cascades we denote complicated sudden transitions between different branches of solutions (modes), which are accompanied by sudden changes in the frequency content of the system responses. As shown in previous works (Vakakis et al. (2003)), such multifrequency transitions can drastically enhance energy pumping from the linear system to the essentially nonlinear attachment.

5. Increasing the DOF of the linear system: Resonance capture cascades. To provide an indication of the complex multifrequency transitions that can take place in coupled oscillators with essentially nonlinear local attachments, we now increase the number of DOF of the linear subsystem to two and examine the system

$$\begin{gathered} \ddot{y}_2 + \omega_0^2 y_2 + \lambda_2 \dot{y}_2 + d(y_2 - y_1) = 0, \\ \ddot{y}_1 + \omega_0^2 y_1 + \lambda_1 \dot{y}_1 + \lambda_3(\dot{y}_1 - \dot{v}) + d(y_1 - y_2) + C(y_1 - v)^3 = 0, \\ \varepsilon \ddot{v} + \lambda_3(\dot{v} - \dot{y}_1) + C(v - y_1)^3 = 0. \end{gathered} \tag{12}$$

The system parameters are chosen as $\omega_0^2 = 136.9$, $\lambda_1 = \lambda_2 = 0.155$, $\lambda_3 = 0.544$, $d = 1.2 \times 10^3$, $\varepsilon = 1.8$, and $C = 1.63 \times 10^7$, with linear natural frequencies $\omega_1 = 11.68$ and $\omega_2 = 50.14$.

In Figure 17(a) we depict the relative response $v(t) - y_1(t)$ of the system for initial displacements $y_1(0) = 0.01$, $y_2(0) = v(0) = -0.01$ and zero initial velocities. The multifrequency content of the transient response is evident and is quantified in Figure 17(b), where the instantaneous frequency of the time series is computed by applying the numerical Hilbert transform (Huang et al. (1998)).

As energy decreases due to damping dissipation, a series of eight *resonance capture cascades* is observed, i.e., of transient resonances of the NES with a number of nonlinear modes of the system. The complexity of the nonlinear dynamics of the system is evidenced by the fact that of these eight captures only two (labeled IV and VII in Figure 17(b)) involve the linearized in-phase and out-of-phase modes of the linear oscillator, with the remaining involving essentially nonlinear interactions of the NES with different low- and high-frequency nonlinear modes of the system. During each resonance capture the NES passively absorbs energy from the nonlinear mode involved, before escape from resonance capture occurs and the NES transiently resonates with the next mode in the series. In essence, *the NES acts as a passive, broadband boundary controller*, absorbing, confining, and eliminating vibration energy from the linear oscillator. Similar types of resonance capture cascades were reported in previous works where grounded NESs, weakly coupled to the linear structure, were examined (Vakakis et al. (2003)). The capacity of the NES to resonantly interact with linear and nonlinear modes in different frequency ranges is due to its essential nonlinearity (i.e., the absence of a linear term in the nonlinear stiffness characteristic), which precludes any preferential resonant frequency.

Finally, we note that the complex nonlinear transitions between modes depicted in Figure 17 can be interpreted and understood by studying the topology and bifurcations of periodic orbits of the corresponding undamped system. As shown in previous sections, the weakly damped, forced dynamics is expected to depend on the periodic dynamics of the underlying undamped system.

6. Concluding remarks. Even though the systems considered in this work possess rather simple configurations and small numbers of DOF, they exhibit interesting passive energy transfer properties. Indeed, under rather general conditions, it is possible to transfer passively, irreversibly, and robustly a significant portion of the energy

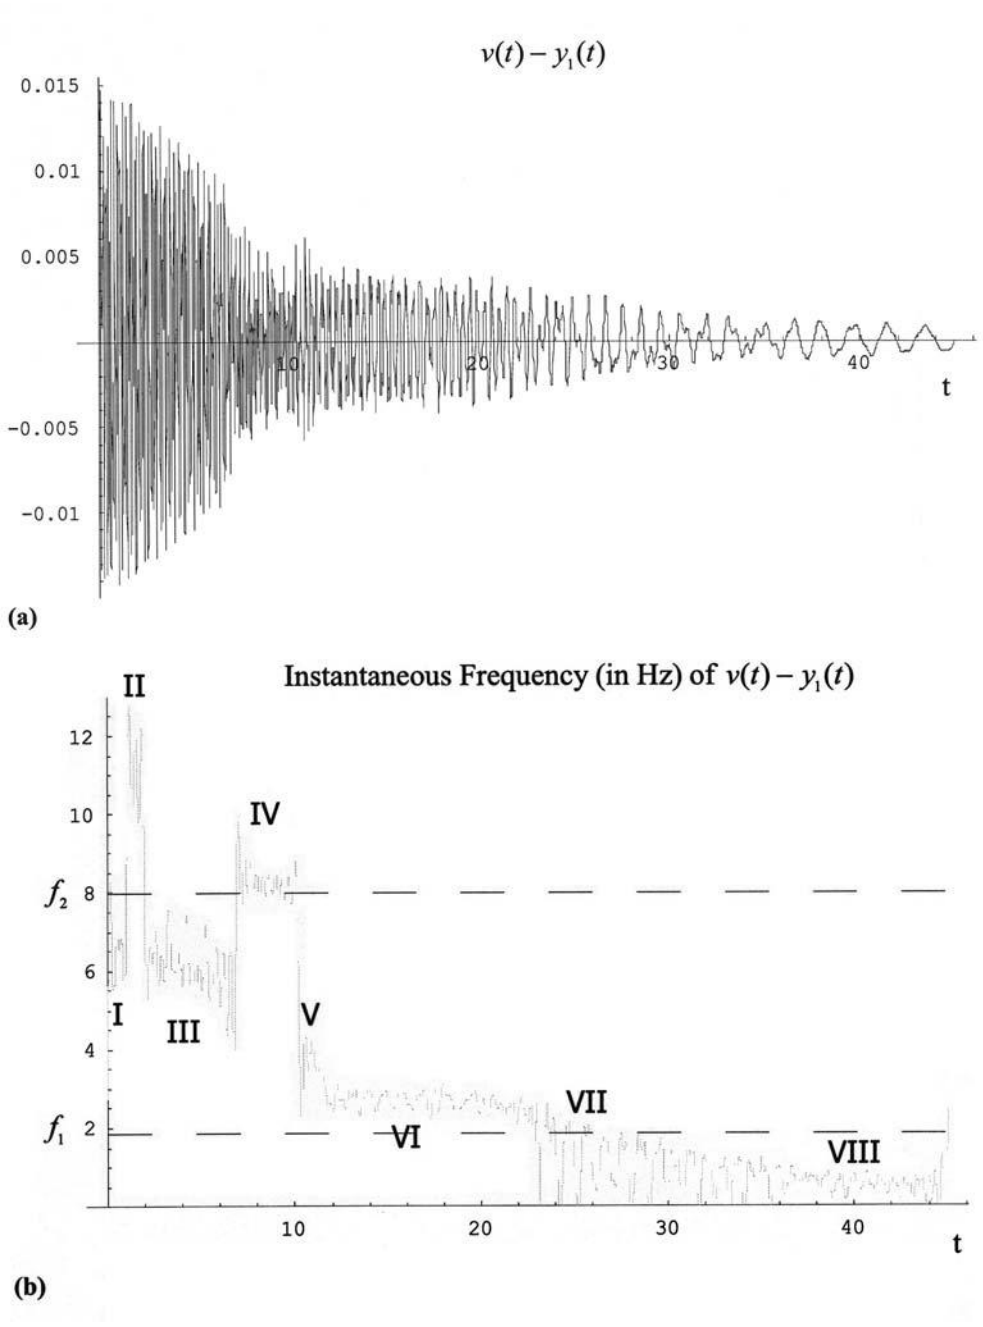

FIG. 17. *Resonance capture cascades in the* 2*-DOF system with nonlinear end attachment:* (a) *relative transient response* $v(t) - y_1(t)$*;* (b) *instantaneous frequency (resonance captures indicated).*

of the linear oscillator to the nonlinear attachment; confine it; and passively dissipate it locally without "radiating back" the transferred energy to the primary system. Moreover, this nonlinear energy pumping occurs over low- as well as high-frequency ranges, and involves broadband disturbances. This last feature clearly distinguishes

the present configuration from previous classical vibration absorber designs, where energy absorption was limited to narrowband disturbances, and the absorbers were effective only in the vicinity of a single frequency.

Three mechanisms for energy pumping were discussed in this work. Two of them rely on resonance capture of the damped dynamics on either fundamental or subharmonic resonant manifolds in phase space. Viewed from a different perspective, in these cases irreversible energy transfer from the linear oscillator to the nonlinear attachment takes place when the dynamics is restricted to a damped nonlinear normal mode invariant manifold, whose mode shape becomes strongly localized to the nonlinear attachment as the energy deceases due to damping dissipation. A third mechanism relies on nonlinear beats to initiate (but not cause) strong energy pumping; these beats act as "bridging orbits" (or "catalysts") for facilitating energy transfer by activating either one of the previously mentioned mechanisms. It is interesting that all these phenomena occur despite the lightness of the nonlinear attachment compared to the linear oscillator and the complete absence of any active (energy source) element in the system.

The considered nonlinear attachment holds promise as an efficient, robust, and modular passive absorbing device for eliminating undesired broadband disturbances of small- or large-scale structures. As such it can find application in diverse problems in engineering and physics, including vibration and shock isolation of machines and structures, seismic mitigation, packaging, and instability (such as limit cycle oscillation or flutter) suppression.

SOLUTIONS TO A MODEL WITH NONUNIFORMLY PARABOLIC TERMS FOR PHASE EVOLUTION DRIVEN BY CONFIGURATIONAL FORCES*

HANS-DIETER ALBER† AND PEICHENG ZHU†

Abstract. We prove the existence of solutions global in time to an initial-boundary value problem for a system of partial differential equations, which consists of the equations of linear elasticity and a nonlinear nonuniformly parabolic equation of second order. The problem models the behavior in time of materials with martensitic phase transformations. This model with diffusive phase interfaces was derived from a model with sharp interfaces, whose evolution is driven by configurational forces, and can be considered to be a regularization of that model. Our existence proof, which contributes to the verification of the model, is only valid in one space dimension.

Key words. nonlinear degenerate parabolic equation, existence of solutions, evolution of phase boundaries, martensitic transformations, configurational forces

1. Introduction.

Two main types of phase transformations in solid materials can be distinguished, diffusion dominated and diffusionless transformations. In this article we study a model for the behavior in time of materials with diffusionless transformations. The model has diffusive interfaces and consists of the partial differential equations of linear elasticity coupled to a quasilinear nonuniformly parabolic equation of second order. It is derived in [2, 3] from a sharp interface model for diffusionless phase transitions and can be considered to be a regularization of that model. The physical background, the sharp interface model, and the derivation of the new model are sketched in the appendix. To verify the validity of the new model investigations are necessary, in which not only must simulations be carried out but also the analytical properties of the model must be determined. We contribute to the verification by showing that in the case of one space dimension an initial-boundary value problem to this model has solutions global in time. We first formulate this initial-boundary value problem in the three-dimensional case, reduce it to the one-dimensional case, and conclude the introduction by stating our main result.

Let $\Omega \subset \mathbb{R}^3$ be an open set. It represents the material points of a solid body. The different phases are characterized by the order parameter $S(t,x) \in \mathbb{R}$. A value of $S(t,x)$ near to zero indicates that the material is in the matrix phase at the point $x \in \Omega$ at time t; a value near to one indicates that the material is in the second phase. The other unknowns are the displacement $u(t,x) \in \mathbb{R}^3$ of the material point x at time t and the Cauchy stress tensor $T(t,x) \in \mathcal{S}^3$, where $\mathcal{S}^3$ denotes the set of symmetric 3×3-matrices. The unknowns must satisfy the following quasi-static equations:

$$-\operatorname{div}_x T(t,x) = b(t,x), \tag{1.1}$$

$$T(t,x) = D\big(\varepsilon(\nabla_x u(t,x)) - \bar{\varepsilon} S(t,x)\big), \tag{1.2}$$

$$S_t(t,x) = -c\big(\psi_S(\varepsilon(\nabla_x u(t,x)), S(t,x)) - \nu\Delta_x S(t,x)\big)|\nabla_x S(t,x)| \tag{1.3}$$

for $(t,x) \in (0,\infty)\times\Omega$. The boundary and initial conditions are

$$u(t,x) = \gamma(t,x), \quad S(t,x) = 0, \qquad (t,x) \in [0,\infty)\times\partial\Omega, \tag{1.4}$$

$$S(0,x) = S_0(x), \quad x \in \Omega. \tag{1.5}$$

Here $\nabla_x u$ denotes the 3×3-matrix of first order derivatives of u, the deformation gradient; $(\nabla_x u)^T$ denotes the transposed matrix; and

$$\varepsilon(\nabla_x u) = \frac{1}{2}\left(\nabla_x u + (\nabla_x u)^T\right)$$

is the strain tensor. $\bar{\varepsilon} \in \mathcal{S}^3$ is a given matrix, the misfit strain, and $D : \mathcal{S}^3 \to \mathcal{S}^3$ is a linear, symmetric, positive definite mapping, the elasticity tensor. In the free energy

$$\psi(\varepsilon, S) = \frac{1}{2}\big(D(\varepsilon - \bar{\varepsilon}S)\big)\cdot(\varepsilon - \bar{\varepsilon}S) + \hat{\psi}(S) \tag{1.6}$$

we choose for $\hat{\psi} \in C^2(\mathbb{R}, [0,\infty))$ a double well potential with minima at $S = 0$ and $S = 1$. The scalar product of two matrices is $A\cdot B = \sum a_{ij}b_{ij}$. Also, ψ_S is the partial derivative, $c > 0$ is a constant, and ν is a small positive constant. Given are the volume force $b : [0,\infty)\times\Omega \to \mathbb{R}^3$ and the data $\gamma : [0,\infty)\times\partial\Omega \to \mathbb{R}^3$, $S_0 : \Omega \to \mathbb{R}$.

This completes the formulation of the initial-boundary value problem. The equations (1.1) and (1.2) differ from the system of linear elasticity only by the term $\bar{\varepsilon}S$. The evolution equation (1.3) for the order parameter S is nonuniformly parabolic because of the term $\nu\Delta S|\nabla_x S|$. Since this initial-boundary value problem is derived from a sharp interface model, to verify that it is indeed a diffusive interface model regularizing the sharp interface model, it must be shown that (1.1)–(1.5) with positive ν have global in time solutions, and that these solutions tend to solutions of the sharp interface model for $\nu \to 0$. This would also be a method to prove existence of solutions to the original sharp interface model.

In this article we contribute to only the first part of this program and show that in one space dimension the initial-boundary value problem has solutions. Whether solutions in three space dimensions exist and whether these solutions converge to a solution of the sharp interface model for $\nu \to 0$ is an open problem not investigated here. The model and therefore the existence result is of interest not only in three dimensions but also in one space dimension. However, we believe that this one-dimensional existence result can also be a basic building block in an existence proof for higher space dimensions, which is sketched at the end of this introduction.

Related to our investigations is the model for diffusion dominated phase transformations obtained by coupling the elasticity equations (1.1), (1.2) with the Cahn–Hilliard equation, which is mentioned in the appendix. This model has recently been studied in [5, 7, 8].

Statement of the main result. We now assume that all functions depend only on the variables x_1 and t, and, to simplify the notation, denote x_1 by x. The set $\Omega = (a,d)$ is a bounded open interval with constants $a < d$. We write $Q_{T_e} := (0,T_e)\times\Omega$, where T_e is a positive constant, and define

$$(v,\varphi)_Z = \int_Z v(y)\varphi(y)\,dy$$

for $Z = \Omega$ or $Z = Q_{T_e}$. If v is a function defined on Q_{T_e}, we denote the mapping $x \to v(t,x)$ by $v(t)$. If no confusion is possible, we sometimes drop the argument t and write $v = v(t)$. We still allow that the material points can be displaced in three directions; hence $u(t,x) \in \mathbb{R}^3$, $T(t,x) \in \mathcal{S}^3$, and $S \in \mathbb{R}$. If we denote the first column of the matrix $T(t,x)$ by $T_1(t,x)$ and set

$$\varepsilon(u_x) = \frac{1}{2}((u_x,0,0) + (u_x,0,0)^T) \in \mathcal{S}^3,$$

then with these definitions (1.1)–(1.3) in the case of one space dimension can be written in the form

$$-T_{1x} = b, \tag{1.7}$$

$$T = D(\varepsilon(u_x) - \bar{\varepsilon}S), \tag{1.8}$$

$$S_t = c\left(T \cdot \bar{\varepsilon} - \hat{\psi}'(S) + \nu S_{xx}\right)|S_x|, \tag{1.9}$$

which must be satisfied in Q_{T_e}. Here we have inserted $\psi_S(\varepsilon, S) = -T \cdot \bar{\varepsilon} + \hat{\psi}'(S)$. Since (1.7), (1.8) are linear, the inhomogeneous Dirichlet boundary condition for u can be reduced in the standard way to the homogeneous condition. For simplicity we thus assume that $\gamma = 0$. The initial and boundary conditions therefore are

$$u(t,x) = 0, \qquad (t,x) \in (0,T_e) \times \partial\Omega, \tag{1.10}$$

$$S(t,x) = 0, \qquad (t,x) \in (0,T_e) \times \partial\Omega, \tag{1.11}$$

$$S(0,x) = S_0(x), \quad x \in \Omega. \tag{1.12}$$

To define weak solutions of this initial-boundary value problem we note that because of $\frac{1}{2}(|y|y)' = |y|$, equation (1.9) is equivalent to

$$S_t - c\nu\frac{1}{2}(|S_x|S_x)_x - c\left(T \cdot \bar{\varepsilon} - \hat{\psi}'(S)\right)|S_x| = 0. \tag{1.13}$$

DEFINITION 1.1. *Let $b \in L^\infty(0,T_e,L^2(\Omega))$, $S_0 \in L^\infty(\Omega)$. A function (u,T,S) with*

$$u \in L^\infty(0,T_e;W_0^{1,\infty}(\Omega)), \tag{1.14}$$

$$T \in L^\infty(Q_{T_e}), \tag{1.15}$$

$$S \in L^\infty(Q_{T_e}) \cap L^\infty(0,T_e;H_0^1(\Omega)) \tag{1.16}$$

is a weak solution to the problem (1.7)–(1.12) *if* (1.7), (1.8), (1.10) *are satisfied weakly and if, for all $\varphi \in C_0^\infty((-\infty,T_e) \times \Omega)$,*

$$(S,\varphi_t)_{Q_{T_e}} - c\nu\frac{1}{2}(|S_x|S_x,\,\varphi_x)_{Q_{T_e}} + c\big(\big(T \cdot \bar{\varepsilon} - \hat{\psi}'(S)\big)|S_x|,\,\varphi\big)_{Q_{T_e}} + (S_0,\varphi(0))_\Omega = 0. \tag{1.17}$$

The main result of this article is the following.

THEOREM 1.1. *For all $S_0 \in H_0^1(\Omega)$ and $b \in C(\overline{Q}_{T_e})$ with $b_t \in C(\overline{Q}_{T_e})$ there exists a weak solution (u,T,S) of the problem* (1.7)–(1.12)*, which in addition to* (1.14)–(1.17) *satisfies*

$$S_t \in L^{\frac{4}{3}}(Q_{T_e}), \quad S_x \in L^{\frac{8}{3}}(0,T_e;L^q(\Omega)) \quad \text{for any } 1 < q < \infty \tag{1.18}$$

and

$$(|S_x|S_x)_x \in L^{\frac{4}{3}}(Q_{T_e}), \qquad S_{xt} \in L^{\frac{4}{3}}(0,T_e;W^{-1,\frac{4}{3}}(\Omega)). \tag{1.19}$$

The remaining sections are devoted to the proof of this theorem. The main difficulty in the proof stems from the fact that the coefficient $\nu|S_x|$ of the highest order derivative S_{xx} in (1.9) is not bounded away from zero and that it is not differentiable with respect to S_x.

To prove Theorem 1.1 we therefore consider in section 2 a modified initial-boundary value problem, which consists of (1.7), (1.8), (1.10)–(1.12) and

$$S_t - (c\nu|S_x|_\kappa + \kappa)S_{xx} - c\big(T\cdot\bar{\varepsilon} - \hat{\psi}'(S)\big)|S_x|_\kappa = 0, \quad x\in\Omega,\ t>0, \tag{1.20}$$

with a constant $\kappa > 0$. Here we use the notation

$$|p|_\kappa := \frac{|p|^2}{\sqrt{\kappa^2+|p|^2}}. \tag{1.21}$$

Since (1.20) is a uniformly parabolic equation, we can use a standard theorem to conclude that the modified initial-boundary value problem has a sufficiently smooth solution $(u^\kappa, T^\kappa, S^\kappa)$. For this solution we derive in section 3 a priori estimates independent of κ.

To select a subsequence converging to a solution for $\kappa \to 0$ we need a compactness result. However, our a priori estimates are not strong enough to show that the sequence S_x^κ is compact; instead, we can show only that the sequence $|S_x^\kappa|S_x^\kappa$, or more precisely an approximation to this sequence, has bounded derivatives and thus is compact. It turns out that this is enough to prove existence of a solution. For the compactness proof in section 4 we use the Aubin–Lions lemma; since one of our a priori estimates for derivatives of the approximating sequence is valid only in $L^1(0,T_e;H^{-2}(\Omega))$, we must use the generalized form of this lemma given by Roubíček [14], which is valid in L^1.

The method of proof is limited to one space dimension, since for the a priori estimates it is crucial that the term $|S_x|S_{xx}$ in (1.9) can be written in the form $\frac{1}{2}(|S_x|S_x)_x$. In the higher-dimensional case the corresponding term $|\nabla_x S|\Delta_x S$ cannot be rewritten in this way. Yet, if in the case of two space dimensions new coordinates (r,χ) are chosen such that r is constant on the level curves of the function $(x_1,x_2)\mapsto S(t,x_1,x_2)$ and such that $\nabla_x S(t,x)$ is a tangential vector to the curve $\chi = \text{const}$, then the evolution equation (1.3) can be written in the form

$$S_t = -c\big(\psi_S(\varepsilon(\nabla_x u),S) - \nu S_{rr}\big)|S_r| + c\nu|S_r|S_r K, \tag{1.22}$$

where K is the curvature of the curve $r = \text{const}$. Applying this formula, it might be possible to prove existence in two space dimensions by iteration: Choose the coordinate system (r,χ) to a known approximate solution $S^{(n)}$ and determine the next iterate $S^{(n+1)}$ by solving the initial-boundary value problem to (1.1), (1.2), (1.22), using the methods of our one-dimensional existence proof and considering $g_n = c\nu|S_r^{(n)}|S_r^{(n)}K$ to be a known right-hand side. A solution would be obtained if convergence of this procedure can be shown. The same idea could also be used in three and higher space dimensions.

2. Existence of solutions to the modified problem. In this section, we study the modified initial-boundary value problem and show that it has a Hölder continuous classical solution. To formulate this problem, let $\chi \in C_0^\infty(\mathbb{R}, [0,\infty))$ satisfy $\int_{-\infty}^{\infty} \chi(t)dt = 1$. For $\kappa > 0$, we set

$$\chi_\kappa(t) := \frac{1}{\kappa}\chi\left(\frac{t}{\kappa}\right),$$

and for $S \in L^\infty(Q_{T_e}, \mathbb{R})$ we define

$$(\chi_\kappa * S)(t,x) = \int_0^{T_e} \chi_\kappa(t-s)S(s,x)ds. \tag{2.1}$$

The modified initial-boundary value problem consists of the equations

$$-T_{1x} = b, \tag{2.2}$$

$$T = D(\varepsilon(u_x) - \bar{\varepsilon}\chi_\kappa * S), \tag{2.3}$$

$$S_t = (c\nu|S_x|_\kappa + \kappa)S_{xx} + c(T\cdot\bar{\varepsilon} - \hat{\psi}'(S))|S_x|_\kappa\,, \tag{2.4}$$

which must hold in Q_{T_e}, and of the boundary and initial conditions

$$u(t,x) = 0, \quad (t,x) \in (0,T_e)\times\partial\Omega, \tag{2.5}$$

$$S(t,x) = 0, \quad (t,x) \in (0,T_e)\times\partial\Omega, \tag{2.6}$$

$$S(0,x) = S_0(x), \quad x \in \Omega. \tag{2.7}$$

To formulate an existence theorem for this problem we need some function spaces: For nonnegative integers m, n and a real number $\alpha \in (0,1)$ we denote by $C^{m+\alpha}(\overline{\Omega})$ the space of m-times differentiable functions on $\overline{\Omega}$, whose mth derivative is Hölder continuous with exponent α. The space $C^{\alpha,\alpha/2}(\overline{Q}_{T_e})$ consists of all functions on $\overline{Q}_{T_e}$, which are Hölder continuous in the parabolic distance

$$\mathrm{d}((t,x),(s,y)) := \sqrt{|t-s| + |x-y|^2}.$$

$C^{m,n}(\overline{Q}_{T_e})$ and $C^{m+\alpha,n+\alpha/2}(\overline{Q}_{T_e})$, respectively, are the spaces of functions, whose x-derivatives up to order m and t-derivatives up to order n belong to $C(\overline{Q}_{T_e})$ or to $C^{\alpha,\alpha/2}(\overline{Q}_{T_e})$, respectively.

THEOREM 2.1. *Let $\nu, \kappa > 0$, $T_e > 0$; suppose that the function $b \in C(\overline{Q}_{T_e})$ has the derivative $b_t \in C(\overline{Q}_{T_e})$ and that the initial data $S_0 \in C^{2+\alpha}(\overline{\Omega})$ satisfy $S_0|_{\partial\Omega} = S_{0,x}|_{\partial\Omega} = S_{0,xx}|_{\partial\Omega} = 0$. Then there is a solution*

$$(u,T,S) \in C^{2,1}(\overline{Q}_{T_e}) \times C^{1,1}(\overline{Q}_{T_e}) \times C^{2+\alpha,1+\alpha/2}(\overline{Q}_{T_e})$$

of the modified initial-boundary value problem (2.2)–(2.7). *This solution satisfies $S_{tx} \in L^2(Q_{T_e})$ and*

$$\max_{\overline{Q}_{T_e}} |S| \le \max_{\overline{\Omega}} |S_0|. \tag{2.8}$$

Proof. Note first that if S is given, then for every t, (2.2), (2.3), (2.5) form a linear elliptic boundary value problem for the unknown function $x \mapsto (u(t,x), T(t,x))$. In

[3] it is shown that the unique solution is given by

$$u(t,x) = u^*\left(\int_a^x (\chi_\kappa * S)(t,y)dy - \frac{x-a}{d-a}\int_a^d (\chi_\kappa * S)(t,y)dy\right) + w(t,x), \tag{2.9}$$

$$T(t,x) = D(\varepsilon^* - \bar\varepsilon)(\chi_\kappa * S)(t,x) - \frac{D\varepsilon^*}{d-a}\int_a^d (\chi_\kappa * S)(t,y)dy + \sigma(t,x), \tag{2.10}$$

where $u^* \in \mathbb{R}^3, \varepsilon^* \in \mathcal{S}^3$ are suitable constants depending only on $\bar\varepsilon$ and D, and where for every $t \in [0,T_e]$ the function $(w(t),\sigma(t)) : \Omega \to \mathbb{R}^3 \times \mathcal{S}^3$ is the solution to the boundary value problem

$$\begin{aligned} -\sigma_{1x}(t) &= b(t),\\ \sigma(t) &= D\varepsilon(w_x(t)),\\ w(t)_{|\partial\Omega} &= 0. \end{aligned}$$

Since by assumption b and b_t belong to $C(\bar Q_{T_e})$, it follows that $(w,\sigma) \in C^{2,1}(\bar Q_{T_e}) \times C^{1,1}(\bar Q_{T_e})$. We insert (2.10) into (2.4) and obtain the equation

$$S_t = a_1(S_x)S_{xx} + a_2\left(t,x,S,S_x,\chi_\kappa * S, \frac{1}{d-a}\int_a^d (\chi_\kappa * S)(t,y)dy\right) \tag{2.11}$$

in Q_{T_e}, where

$$a_1(p) = c\nu|p|_\kappa + \kappa$$

and

$$a_2(t,x,S,p,r,s) = c\big(\bar\varepsilon \cdot D(\varepsilon^* - \bar\varepsilon)r - \bar\varepsilon \cdot D\varepsilon^* s + \bar\varepsilon \cdot \sigma(t,x) - \hat\psi'(S)\big)|p|_\kappa .$$

The equations (2.11), (2.6), and (2.7) form an initial-boundary value problem with nonlocal terms, which is equivalent to the problem (2.2)–(2.7). To prove Theorem 2.1 it therefore suffices to show that this initial-boundary value problem is solvable. This follows from the following claim.

THEOREM 2.2. *Let $T_e > 0$, $M > 0$, and suppose that the coefficient functions $a_1 \in C^1(\mathbb{R},[0,\infty))$ and $a_2 \in C^1(\overline{Q}_{T_e} \times [-M,M] \times \mathbb{R} \times [-M,M]^2, \mathbb{R})$ satisfy the equations and inequalities*

$$a_2(t,x,S,0,r,s) = 0, \tag{2.12}$$

$$\mu_1(1+|p|)^{m-2} \le a_1(p) \le \mu_2(1+|p|)^{m-2}, \tag{2.13}$$

$$\left|\frac{\partial a_1}{\partial p}\right|(1+|p|)^3 + \left|\frac{\partial a_2}{\partial p}\right|(1+|p|) + |a_2| \le \mu_3(1+|p|)^m, \tag{2.14}$$

$$\left|\frac{\partial a_2}{\partial x}\right| \le (\mu_4 + P(|p|))(1+|p|)^{m+1}, \tag{2.15}$$

$$\max\left(\frac{\partial a_2}{\partial S}, \frac{\partial a_2}{\partial r}, \frac{\partial a_2}{\partial s}\right) \le (\mu_4 + P(|p|))(1+|p|)^m, \tag{2.16}$$

where $P(\rho)$ is a nonnegative continuous function that tends to zero for $\rho \to \infty$, $\mu_1, \dots, \mu_4$ are positive constants, and m is an arbitrary number.

If the number μ_4 is sufficiently small, depending on the numbers M, μ_1, μ_2, μ_3, and $\hat{P} = \max_{\rho \geq 0} P(\rho)$, and if the initial data $S_0 \in C^{2+\alpha}(\bar{\Omega}, [-M, M])$ satisfy the compatibility conditions $S_0|_{\partial\Omega} = 0$ and

$$a_1(S_{0,x}(x))S_{0,xx}(x) + a_2(0, x, S_0(x), S_{0,x}(x), r, s) = 0 \tag{2.17}$$

for all $x \in \partial\Omega$ and for all $-M \leq r, s \leq M$, then a solution $S \in C^{2+\alpha,1+\alpha/2}(\overline{Q}_{T_e})$ of the problem (2.11), (2.6), *and* (2.7) *exists. This solution has derivatives $S_{tx} \in L^2(Q_{T_e})$.*

A proof of Theorem 2.2 is obtained by modification of the proof of the analogous Theorem 5.2 in [11, p. 564], which is valid for the quasi-linear parabolic initial boundary value problem

$$\begin{aligned} S_t &= a_1(S_x)S_{xx} + a_2(t, x, S, S_x), \\ S(t, x) &= 0, \qquad (t, x) \in (0, T_e) \times \partial\Omega, \\ S(0, x) &= S_0(x), \qquad x \in \Omega, \end{aligned}$$

which does not contain nonlocal terms. The theorem in [11] states that if the coefficient functions satisfy the conditions (2.12)–(2.16) and if the initial data satisfy compatibility and regularity conditions analogous the ones given above, then this initial-boundary value problem has a solution S with the regularity stated in Theorem 2.2. Actually, in [11] more general coefficient functions are considered. The proof is based on the Leray–Schauder fixed point theorem. We leave the modification, which is technical, to the reader.

End of the proof of Theorem 2.1. It is immediately seen that the coefficients a_1 and a_2 in (2.11) satisfy the relations (2.12)–(2.16) with $m = 3$. In particular, we can choose μ_1, μ_2, μ_3, $\hat{P}$ such that the inequalities (2.15), (2.16) hold for every $\mu_4 > 0$, with a suitable function P depending on μ_4. Moreover, from the assumption $S_0|_{\partial\Omega} = S_{0,x}|_{\partial\Omega} = S_{0,xx}|_{\partial\Omega} = 0$ together with (2.12) it follows that the compatibility condition (2.17) holds. Thus, Theorem 2.2 asserts that a solution $S \in C^{2+\alpha,1+\alpha/2}(\overline{Q}_{T_e})$ of (2.11), (2.6), (2.7) exists with $S_{xt} \in L^2(Q_{T_e})$. The functions T and u with the regularity stated in Theorem 2.1 are obtained from (2.10), (2.9). Finally, since $a_1(0) = \kappa > 0$ and $a_2(t, x, S, 0, r, s) = 0$, we can apply [11, Theorem 2.9, p. 23] to (2.11) and conclude that the estimate (2.8) holds. □

3. A priori estimates. In this section we establish a priori estimates for solutions of the modified problem, which are uniform with respect to κ. We remark that the estimates in Lemma 3.1 and Corollary 1, though stated in the one-dimensional case, can be generalized to higher space dimensions.

In what follows we assume that

$$0 < \kappa \leq 1, \tag{3.1}$$

since we consider the limit $\kappa \to 0$. The $L^2(\Omega)$-norm is denoted by $\|\cdot\|$, and the letter C stands for varies positive constants independent of κ. Supplementing (1.21), we also use the notation

$$[p]_\kappa := \frac{p|p|}{\sqrt{\kappa^2 + p^2}}. \tag{3.2}$$

We start by constructing a family of approximate solutions to the modified problem. To this end let T_e be a fixed positive number, and choose for every κ a function $S_0^\kappa \in C_0^\infty(\Omega)$ such that

$$\|S_0^\kappa - S_0\|_{H_0^1(\Omega)} \to 0, \quad \kappa \to 0, \tag{3.3}$$

where $S_0 \in H_0^1(\Omega)$ are the initial data given in Theorem 1.1. We insert for S_0 in (2.7) the function S_0^κ and choose for b in (2.2) the function given in Theorem 1.1. These functions satisfy the assumptions of Theorem 2.1, and hence there is a solution $(u^\kappa, T^\kappa, S^\kappa)$ of the modified problem (2.2)–(2.7), which exists in Q_{T_e}. The inequality (2.8) and Sobolev's embedding theorem yield for this solution

$$\sup_{0<\kappa\le 1} \|S^\kappa\|_{L^\infty(Q_{T_e})} \le \sup_{0<\kappa\le 1} \|S_0^\kappa\|_{L^\infty(\Omega)} \le C. \tag{3.4}$$

Remembering that σ in (2.10) belongs to $C^{1,1}(\bar{Q}_{T_e})$, we conclude from (3.4) that also

$$\max_{\overline{Q}_{T_e}} |c(T^\kappa \cdot \bar{\varepsilon} - \hat{\psi}'(S^\kappa))| \le C. \tag{3.5}$$

LEMMA 3.1. *There holds for any $t \in [0, T_e]$*

$$\|S_x^\kappa(t)\|^2 + \int_0^t \int_\Omega (\nu |S_x^\kappa|_\kappa + 2\kappa)\, |S_{xx}^\kappa|^2 dx d\tau \le C. \tag{3.6}$$

Proof. Observe first that $S_{tx}^\kappa \in L^2(Q_{T_e})$, by Theorem 2.1, which yields that for almost all t

$$\frac{1}{2}\frac{d}{dt}\|S_x^\kappa(t)\|^2 = \int_\Omega S_x^\kappa(t) S_{xt}^\kappa(t) dx.$$

Using this relation and (3.5), we obtain, by multiplication of (2.4) by $-S_{xx}^\kappa$ and integration by parts with respect to x, where we take the boundary condition (2.6) into account, that for almost all t

$$\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|S_x^\kappa\|^2 + \int_\Omega (\nu |S_x^\kappa|_\kappa + \kappa)\, |S_{xx}^\kappa|^2 dx = \int_\Omega c(\hat{\psi}'(S^\kappa) - T^\kappa \cdot \bar{\varepsilon}) |S_x^\kappa|_\kappa S_{xx}^\kappa dx \\
&\le C \int_\Omega |S_x^\kappa|_\kappa |S_{xx}^\kappa| dx = C \int_\Omega |S_x^\kappa|^{\frac{1}{2}}_\kappa |S_x^\kappa|^{\frac{1}{2}}_\kappa |S_{xx}^\kappa| dx \\
&\le \frac{\nu}{2} \int_\Omega |S_x^\kappa|_\kappa |S_{xx}^\kappa|^2 dx + \frac{2C^2}{\nu} \int_\Omega (|S_x^\kappa|_\kappa)^2 dx. \qquad (3.7)
\end{aligned}$$

We subtract the term $\frac{\nu}{2}\int_\Omega |S_x^\kappa|_\kappa |S_{xx}^\kappa|^2 dx$ on both sides of this inequality and use Gronwall's lemma to derive (3.6) from the resulting estimate, noting also (3.3). ∎

COROLLARY 1. *There holds for any $t \in [0, T_e]$*

$$\int_0^t \int_\Omega (|S_x^\kappa|_\kappa |S_{xx}^\kappa|)^{\frac{4}{3}}\, dx d\tau \le C. \tag{3.8}$$

Proof. By Hölder's inequality, we have for some $2 > p \ge 1$, $q = \frac{2}{p}$, and $\frac{1}{q} + \frac{1}{q'} = 1$

that

$$\begin{aligned}
&\int_0^t \int_\Omega (|S_x^\kappa|_\kappa |S_{xx}^\kappa|)^p \, dx d\tau \\
&= \int_0^t \int_\Omega (|S_x^\kappa|_\kappa)^{\frac{p}{2}} \left((|S_x^\kappa|_\kappa)^{\frac{p}{2}} |S_{xx}^\kappa|^p \right) dx d\tau \\
&\leq \left(\int_0^t \int_\Omega (|S_x^\kappa|_\kappa)^{\frac{pq'}{2}} \, dx d\tau \right)^{\frac{1}{q'}} \left(\int_0^t \int_\Omega (|S_x^\kappa|_\kappa)^{\frac{pq}{2}} |S_{xx}^\kappa|^{pq} dx d\tau \right)^{\frac{1}{q}} \\
&\leq \left(\int_0^t \int_\Omega (|S_x^\kappa|_\kappa)^{\frac{p}{2-p}} \, dx d\tau \right)^{\frac{2-p}{2}} \left(\int_0^t \int_\Omega |S_x^\kappa|_\kappa |S_{xx}^\kappa|^2 dx d\tau \right)^{\frac{p}{2}}. \qquad (3.9)
\end{aligned}$$

Inequality (3.6) implies for $\frac{p}{2-p} \leq 2$, i.e., $p \leq \frac{4}{3}$, that the right-hand side of (3.9) is bounded. □

LEMMA 3.2. *There hold*

$$\int_0^t \int_\Omega \left| ([S_x^\kappa]_\kappa |S_x^\kappa|_\kappa)_x \right|^{\frac{4}{3}} dx d\tau \leq 2^{\frac{8}{3}} \int_0^t \int_\Omega ||S_x^\kappa|_\kappa S_{xx}^\kappa|^{\frac{4}{3}} \, dx d\tau \leq C, \qquad (3.10)$$

$$\int_0^t \| |S_x^\kappa|_\kappa \|_{L^\infty(\Omega)}^{\frac{8}{3}} \, d\tau = \int_0^t \| [S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \|_{L^\infty(\Omega)}^{\frac{4}{3}} \, d\tau \leq C. \qquad (3.11)$$

Proof. We first show that (3.11) is a consequence of (3.10). Equation (3.10) and the Poincaré inequality imply

$$\begin{aligned}
\int_0^t \| \, [S_x^\kappa]_\kappa |S_x^\kappa|_\kappa - \overline{[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa} \|_{L^{\frac{4}{3}}}^{\frac{4}{3}} d\tau &\leq C \int_0^t \int_\Omega \left| ([S_x^\kappa]_\kappa |S_x^\kappa|_\kappa)_x \right|^{\frac{4}{3}} dx d\tau \\
&\leq C, \qquad (3.12)
\end{aligned}$$

where for the function $f = f(t,x)$ we have used the notation

$$\bar{f}(t) = \frac{1}{|\Omega|} \int_\Omega f(t,x) dx.$$

$|\Omega|$ is the volume of the domain Ω. Equations (1.21) and (3.2) imply $|S_x^\kappa|_\kappa \leq |S_x^\kappa|$ and $|\, [S_x^\kappa]_\kappa \,| \leq |S_x^\kappa|$. From Lemma 3.1 we thus conclude

$$\begin{aligned}
\int_0^t \int_\Omega \left| \overline{[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa} \right|^{\frac{4}{3}} dx d\tau &\leq \frac{1}{|\Omega|^{\frac{4}{3}}} \int_0^t \int_\Omega \left(\int_\Omega |S_x^\kappa|^2 dx \right)^{\frac{4}{3}} dx d\tau \\
&= \frac{1}{|\Omega|^{\frac{1}{3}}} \int_0^t \|S_x^\kappa\|^{\frac{8}{3}} d\tau \leq \int_0^t C d\tau \leq Ct. \qquad (3.13)
\end{aligned}$$

Combination of the above two inequalities yields

$$\int_0^t \| [S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \|_{L^{\frac{4}{3}}(\Omega)}^{\frac{4}{3}} \, d\tau \leq C. \qquad (3.14)$$

Invoking (3.10), we assert that

$$[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \in L^{\frac{4}{3}}(0, T_e; W^{1,\frac{4}{3}}(\Omega)),$$

whence by the Sobolev imbedding theorem we obtain

$$\int_0^t \| [S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \|_{L^\infty(\Omega)}^{\frac{4}{3}} d\tau \le C \int_0^t \| [S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \|_{W^{1,\frac{4}{3}}(\Omega)}^{\frac{4}{3}} d\tau \le C. \tag{3.15}$$

Thus (3.11) is proved, and it remains to verify (3.10).

To simplify the notation in the following computation we write $y = S_x^\kappa$. Using that

$$\begin{aligned} ([y]_\kappa |y|_\kappa)_x &= \left(\frac{y^3|y|}{\kappa^2+y^2} \right)_x = \frac{2|y|^3(2\kappa^2+y^2)}{(\kappa^2+y^2)^2} y_x \\ &= |y|_\kappa \frac{2|y|(2\kappa^2+y^2)}{(\kappa^2+y^2)^{\frac{3}{2}}} y_x, \end{aligned} \tag{3.16}$$

we obtain from Young's inequality that

$$\begin{aligned} \left|([y]_\kappa |y|_\kappa)_x\right| &= |y|_\kappa \frac{2|y|(\kappa^2+y^2)}{(\kappa^2+y^2)^{\frac{3}{2}}} |y_x| \\ &\le 2|y|_\kappa \frac{\frac{1}{3}|y|^3 + \frac{2}{3}(\kappa^2+y^2)^{\frac{3}{2}}}{(\kappa^2+y^2)^{\frac{3}{2}}} |y_x| \\ &= 2|y|_\kappa \frac{\frac{1}{3}|y|^{2\,\frac{3}{2}} + \frac{2}{3}(\kappa^2+y^2)^{\frac{3}{2}}}{(\kappa^2+y^2)^{\frac{3}{2}}} |y_x| \\ &\le 2|\,|y|_\kappa\, y_x| = 2|\,|S_x^\kappa|_\kappa\, S_{xx}^\kappa|. \end{aligned} \tag{3.17}$$

Therefore, from (3.8) we have

$$\int_0^t \int_\Omega \left|([S_x^\kappa]_\kappa |S_x^\kappa|_\kappa)_x\right|^{\frac{4}{3}} dx d\tau \le \int_0^t \int_\Omega |2\,|S_x^\kappa|_\kappa\, S_{xx}^\kappa|^{\frac{4}{3}} dx d\tau \le 2^{\frac{4}{3}} C, \tag{3.18}$$

which is (3.10) and completes the proof of this lemma. □

LEMMA 3.3. *The function S_t^κ belongs to $L^{\frac{4}{3}}(Q_{T_e})$, and we have the estimates*

$$\|S_t^\kappa\|_{L^{4/3}(Q_{T_e})} \le C, \tag{3.19}$$

$$\|S_x^\kappa S_{xt}^\kappa\|_{L^1(0,T_e;H^{-2}(\Omega))} \le C, \tag{3.20}$$

$$\| ([S_x^\kappa]_\kappa |S_x^\kappa|_\kappa)_t \|_{L^1(0,T_e;H^{-2}(\Omega))} \le C. \tag{3.21}$$

Proof. From (2.4) and the estimates (3.6), (3.5), and (3.8) we immediately see that $S_t^\kappa \in L^{\frac{4}{3}}(Q_{T_e})$ and that (3.19) holds. Therefore we need to prove only the remaining two estimates.

To prove the first one we show that there is a constant C, which is independent of κ, such that

$$\left|(S_x^\kappa S_{xt}^\kappa, \varphi)_{Q_{T_e}}\right| \le C \|\varphi\|_{L^\infty(0,T_e;H_0^2(\Omega))} \tag{3.22}$$

for all $\varphi \in L^\infty(0,T_e;H_0^2(\Omega))$. This estimate implies (3.20), since $L^1(0,T_e;H^{-2}(\Omega))$ is isometrically imbedded into the dual space of $L^\infty(0,T_e;H_0^2(\Omega))$.

For the proof of (3.22) recall first that $S_{xt}^\kappa \in L^2(Q_{T_e})$, which implies that the right-hand side is well defined. We integrate by parts to get

$$(S_x^\kappa S_{xt}^\kappa, \varphi)_{Q_{T_e}} = (S_t^\kappa, -S_{xx}^\kappa \varphi)_{Q_{T_e}} + (S_t^\kappa, -S_x^\kappa \varphi_x)_{Q_{T_e}} =: I_1 + I_2. \tag{3.23}$$

To estimate I_1 we apply (2.4) and obtain

$$(S_t^\kappa, -S_{xx}^\kappa\varphi)_{Q_{T_e}} = \big((c\nu|S_x^\kappa|_\kappa+\kappa)S_{xx}^\kappa + c\big(T\cdot\bar\varepsilon' - \hat\psi'(S^\kappa)\big)|S_x^\kappa|_\kappa, -S_{xx}^\kappa\varphi\big)_{Q_{T_e}}. \tag{3.24}$$

We estimate the right-hand side of this equation term by term. For the first term we obtain from Lemma 3.1

$$\begin{aligned}\Big|((c\nu|S_x^\kappa|_\kappa+\kappa)S_{xx}^\kappa, -S_{xx}^\kappa\varphi)_{Q_{T_e}}\Big| &\le \|\varphi\|_{L^\infty(Q_{T_e})}\int_{Q_{T_e}}(c\nu|S_x^\kappa|_\kappa+\kappa)|S_{xx}^\kappa|^2 d(x,\tau)\\ &\le C\|\varphi\|_{L^\infty(Q_{T_e})} \le C\|\varphi\|_{L^\infty(0,T_e;H_0^2(\Omega))}.\end{aligned} \tag{3.25}$$

For the second term it follows from (3.5) and (3.8) that

$$\begin{aligned}\big|\big(c\big(T\cdot\bar\varepsilon' - \hat\psi'(S^\kappa)\big)|S_x^\kappa|_\kappa, -S_{xx}^\kappa\varphi\big)_{Q_{T_e}}\big| &\le C\|\varphi\|_{L^\infty(Q_{T_e})}\int_0^{T_e}\| |S_x^\kappa|_\kappa S_{xx}^\kappa\|_{L^1}d\tau\\ &\le C\|\varphi\|_{L^\infty(0,T_e;H_0^2(\Omega))}.\end{aligned} \tag{3.26}$$

The estimates (3.25) and (3.26) together yield

$$|I_1| \le C\|\varphi\|_{L^\infty(0,T_e;H_0^2(\Omega))}. \tag{3.27}$$

Now we estimate I_2. From (2.4) and (3.5) we have

$$\begin{aligned} I_2 &= \big|(S_t^\kappa, S_x^\kappa\varphi_x)_{Q_{T_e}}\big|\\ &= \big|\big((c\nu|S_x^\kappa|_\kappa+\kappa)S_{xx}^\kappa + c\big(T\cdot\bar\varepsilon' - \hat\psi'(S^\kappa)\big)|S_x^\kappa|_\kappa, -S_x^\kappa\varphi_x\big)_{Q_{T_e}}\big|\\ &\le C\int_{Q_{T_e}}\big(|S_x^\kappa|_\kappa|S_{xx}^\kappa| + \kappa|S_{xx}^\kappa| + |S_x^\kappa|_\kappa\big)|S_x^\kappa\varphi_x|d(x,t)\\ &=: C(I_{2,1}+I_{2,2}+I_{2,3}).\end{aligned} \tag{3.28}$$

We are now going to deal with $I_{2,1}, I_{2,2}$, and $I_{2,3}$. Using the Cauchy–Schwarz inequality and invoking the estimates (3.6), (3.8), and (3.11), we arrive at

$$\begin{aligned} I_{2,1} &= \int_{Q_{T_e}}|S_x^\kappa|_\kappa|S_{xx}^\kappa S_x^\kappa\varphi_x|d(x,t)\\ &\le C\int_0^{T_e}\||S_x^\kappa|_\kappa\|_{L^\infty(\Omega)}^{\frac12}\|\varphi_x\|_{L^\infty(\Omega)}\int_\Omega(|S_x^\kappa|_\kappa)^{\frac12}\,|S_{xx}^\kappa S_x^\kappa|dxd\tau\\ &\le C\int_0^{T_e}\||S_x^\kappa|_\kappa\|_{L^\infty(\Omega)}^{\frac12}\,\|\varphi_x\|_{L^\infty(\Omega)}\left(\int_\Omega|S_x^\kappa|^2dx\right)^{\frac12}\left(\int_\Omega\big(|S_x^\kappa|_\kappa|S_{xx}^\kappa|^2\big)\,dx\right)^{\frac12}d\tau\\ &\le C\|\varphi\|_{L^\infty(0,T;H_0^2(\Omega))}\int_0^{T_e}\||S_x^\kappa|_\kappa\|_{L^\infty(\Omega)}^{\frac12}\left\|(|S_x^\kappa|_\kappa)^{\frac12}S_{xx}^\kappa\right\|_{L^2}d\tau\\ &\le C\|\varphi\|_{L^\infty(0,T;H_0^2(\Omega))}\left(\int_0^{T_e}\||S_x^\kappa|_\kappa\|_{L^\infty(\Omega)}d\tau\right)^{\frac12}\left(\int_0^{T_e}\left\|(|S_x^\kappa|_\kappa)^{\frac12}\,S_{xx}^\kappa\right\|_{L^2(\Omega)}^2d\tau\right)^{\frac12}\\ &\le C\|\varphi\|_{L^\infty(0,T;H_0^2(\Omega))}.\end{aligned} \tag{3.29}$$

The other terms are easier to handle. It follows from the estimate (3.6) and the assumption $0 < \kappa \le 1$ that

$$\begin{aligned} I_{2,2} &= \int_{Q_{T_e}} \kappa |S^\kappa_{xx} S^\kappa_x \varphi_x| d(\tau, x) \\ &\le C\kappa^{\frac{1}{2}} \|\varphi_x\|_{L^\infty(Q_T)} \int_{Q_{T_e}} \kappa^{\frac{1}{2}} |S^\kappa_{xx}| |S^\kappa_x| d(\tau, x) \\ &\le C\kappa^{\frac{1}{2}} \|\varphi_x\|_{L^\infty(Q_T)} \left(\int_{Q_{T_e}} \kappa |S^\kappa_{xx}|^2 dx \right)^{\frac{1}{2}} \left(\int_{Q_{T_e}} |S^\kappa_x|^2 d(\tau, x) \right)^{\frac{1}{2}} \\ &\le C \|\varphi\|_{L^\infty(0,T;H^2_0(\Omega))}. \end{aligned} \tag{3.30}$$

Finally, (3.6) and the fact that $|S^\kappa_x|_\kappa \le |S^\kappa_x|$ imply

$$\begin{aligned} I_{2,3} &= \int_{Q_{T_e}} |S^\kappa_x|_\kappa |S^\kappa_x \varphi_x| d(t, x) \\ &\le C \|\varphi_x\|_{L^\infty(Q_{T_e})} \int_{Q_{T_e}} |S^\kappa_x|^2 d(t, x) \\ &\le C \|\varphi\|_{L^\infty(0,T_e;H^2_0(\Omega))}. \end{aligned} \tag{3.31}$$

The estimates (3.28)–(3.31) yield

$$|I_2| \le C \|\varphi\|_{L^\infty(0,T;H^2_0(\Omega))}.$$

This inequality and (3.23), (3.27) together yield the desired estimate (3.22); hence (3.20) follows.

To prove the third statement of the lemma we define

$$\mathcal{R}_\kappa := (c\nu |S^\kappa_x|_\kappa + \kappa) S^\kappa_{xx} + c\big(T \cdot \bar{\varepsilon}' - \hat{\psi}'(S^\kappa)\big) |S^\kappa_x|_\kappa \tag{3.32}$$

and set $y = S^\kappa_x$. Remembering that $S^\kappa_{xt} \in L^2(Q_{T_e})$, we obtain as in (3.16) that

$$([y]_\kappa |y|_\kappa)_t = \frac{2|y|^3(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} y_t. \tag{3.33}$$

Multiply (2.4) by

$$\left(S^\kappa_x \varphi \frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_x = \left(\varphi \frac{|y|^3(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_x,$$

integrate the resulting equation with respect to (x, t) over Q_{T_e}, and note (3.33) to obtain

$$\begin{aligned} 0 &= \left(S^\kappa_t - \mathcal{R}_\kappa, \left(S^\kappa_x \varphi \frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_x \right)_{Q_{T_e}} \\ &= -\left(S^\kappa_{xt}, S^\kappa_x \varphi \frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_{Q_{T_e}} - \left(\mathcal{R}_\kappa, \left(S^\kappa_x \varphi \frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_x \right)_{Q_{T_e}} \\ &= -\frac{1}{2} \left(([S^\kappa_x]_\kappa |S^\kappa_x|_\kappa)_t, \varphi \right)_{Q_{T_e}} - \left(\mathcal{R}_\kappa, \left(S^\kappa_x \varphi \frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_x \right)_{Q_{T_e}} \\ &= -\frac{1}{2} \left(([S^\kappa_x]_\kappa |S^\kappa_x|_\kappa)_t, \varphi \right)_{Q_{T_e}} - \left(\mathcal{R}_\kappa, (S^\kappa_{xx} \varphi + S^\kappa_x \varphi_x) \frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_{Q_{T_e}} \\ &\quad - \left(\mathcal{R}_\kappa, S^\kappa_x \varphi \left(\frac{y|y|(2\kappa^2 + y^2)}{(\kappa^2 + y^2)^2} \right)_x \right)_{Q_{T_e}}. \end{aligned} \tag{3.34}$$

To estimate the last two terms on the right-hand side of this inequality we note that

$$\left(\frac{y|y|(2\kappa^2+y^2)}{(\kappa^2+y^2)^2}\right)_x = \frac{4|y|\kappa^4}{(\kappa^2+y^2)^3}y_x.$$

Thus we have the inequalities

$$\left|\frac{y|y|(2\kappa^2+y^2)}{(y^2+\kappa^2)^2}\right| \le \frac{(y^2+\kappa^2)^2}{(\kappa^2+y^2)^2} = 1$$

and

$$\left|y\left(\frac{y|y|(2\kappa^2+y^2)}{(\kappa^2+y^2)^2}\right)_x\right| = \frac{4y^2\kappa^4}{(\kappa^2+y^2)^3}|y_x| \le \frac{4}{3}\frac{(y^2+\kappa^2)^3}{(\kappa^2+y^2)^3}|y_x| = \frac{4}{3}|S^\kappa_{xx}|,$$

which yield the estimates

$$\begin{aligned}&\left|\left(\mathcal{R}_\kappa, (S^\kappa_{xx}\varphi + S^\kappa_x\varphi_x)\frac{y|y|(2\kappa^2+y^2)}{(\kappa^2+y^2)^2}\right)_{Q_{T_e}}\right| \\ &\le C\int_{Q_{T_e}} |\mathcal{R}_\kappa|\left(|S^\kappa_{xx}\varphi| + |S^\kappa_x\varphi_x|\right)d(\tau,x) \qquad (3.35)\end{aligned}$$

and

$$\left|\left(\mathcal{R}_\kappa, S^\kappa_x\varphi\left(\frac{y|y|(2\kappa^2+y^2)}{(\kappa^2+y^2)^2}\right)_x\right)_{Q_{T_e}}\right| \le C\int_{Q_{T_e}} |\mathcal{R}_\kappa S^\kappa_{xx}\varphi| d(\tau,x). \qquad (3.36)$$

The term $\int_{Q_{T_e}} |\mathcal{R}_\kappa S^\kappa_{xx}\varphi| d(\tau,x)$ coincides with the right-hand side of (3.24), which was estimated in (3.25)–(3.27) by $C\|\varphi\|_{L^\infty(0,T;H^2_0(\Omega))}$. The term

$$\int_{Q_{T_e}} |\mathcal{R}_\kappa S^\kappa_x\varphi_x| d(\tau,x) = \int_{Q_{T_e}} |S^\kappa_t S^\kappa_x\varphi_x| d(\tau,x)$$

was estimated in (3.28)–(3.31) by $C\|\varphi\|_{L^\infty(0,T;H^2_0(\Omega))}$. These results and (3.34)–(3.36) yield

$$\left|\left(([S^\kappa_x]_\kappa|S^\kappa_x|_\kappa)_t\,, \varphi\right)_{Q_{T_e}}\right| \le C\|\varphi\|_{L^\infty(0,T_e;H^2_0(\Omega))},$$

which implies (3.21). □

4. Existence of solutions to the phase field model. In this section we use the a priori estimates established in the previous section to study the convergence of $(u^\kappa, T^\kappa, S^\kappa)$ as $\kappa \to 0$. We shall show that there is a subsequence, which converges to a weak solution of the initial-boundary value problem (1.7)–(1.12), thereby proving Theorem 1.1.

Note first that the estimates (3.6), (3.19), the fact that $S^\kappa(t,x) = 0$ for all $(t,x) \in [0,T_e]\times\partial\Omega$, and Poincaré's inequality imply

$$\|S^\kappa\|_{W^{1,4/3}(Q_{T_e})} \le C\,, \qquad (4.1)$$

for a constant C independent of κ. Hence, we can select a sequence $\kappa_n \to 0$ and a function $S \in W^{1,4/3}(Q_{T_e})$ such that the sequence S^{κ_n}, which we again denote by S^κ, satisfies

$$\|S^\kappa - S\|_{L^{4/3}(Q_{T_e})} \to 0, \qquad S^\kappa_x \rightharpoonup S_x\,, \qquad S^\kappa_t \rightharpoonup S_t\,, \qquad (4.2)$$

where the weak convergence is in $L^{4/3}(Q_{T_e})$.

As usual, since (1.9) is nonlinear, the weak convergence of S_x^κ is not enough to prove that the limit function solves this equation. In the following lemma we therefore show that S_x^κ converges pointwise almost everywhere.

LEMMA 4.1. *There exists a subsequence of S_x^κ (we still denote it by S_x^κ) such that*

$$S_x^\kappa \to S_x, \qquad \text{a.e. in } Q_{T_e}, \tag{4.3}$$

$$[S_x^\kappa]_\kappa \to S_x, \quad |S_x^\kappa|_\kappa \to |S_x|, \qquad \text{a.e. in } Q_{T_e}, \tag{4.4}$$

$$|S_x^\kappa|_\kappa \rightharpoonup |S_x|, \quad [S_x^\kappa]_\kappa \rightharpoonup S_x, \qquad \text{weakly in } L^{\frac{4}{3}}(Q_{T_e}), \tag{4.5}$$

$$[S_x^\kappa]_\kappa |S_x^\kappa|_\kappa \to S_x|S_x|, \qquad \text{strongly in } L^{\frac{4}{3}}(0,T_e;L^2(\Omega)), \tag{4.6}$$

as $\kappa \to 0$.

The proof is based on the following two results.

THEOREM 4.1. *Let B_0 be a normed linear space imbedded compactly into another normed linear space B, which is continuously imbedded into a Hausdorff locally convex space B_1, and $1 \le p < +\infty$. If $v, v_i \in L^p(0,T_e;B_0), i \in \mathbb{N}$, the sequence $\{v_i\}_{i\in\mathbb{N}}$ converges weakly to v in $L^p(0,T_e;B_0)$, and $\{\frac{\partial v_i}{\partial t}\}_{i\in\mathbb{N}}$ is bounded in $L^1(0,T_e;B_1)$, then v_i converges to v strongly in $L^p(0,T_e;B)$.*

LEMMA 4.2. *Let $(0,T_e)\times\Omega$ be an open set in $\mathbb{R}^+\times\mathbb{R}^n$. Suppose functions g_n, g are in $L^q((0,T_e)\times\Omega)$ for any given $1 < q < \infty$, which satisfy*

$$\|g_n\|_{L^q((0,T_e)\times\Omega)} \le C, \qquad g_n \to g \text{ a.e. in } (0,T_e)\times\Omega.$$

Then g_n converges to g weakly in $L^q((0,T_e)\times\Omega)$.

Theorem 4.1 is a general version of the Aubin–Lions lemma valid under the weak assumption $\partial_t v_i \in L^1(0,T_e;B_1)$. This version, which we need here, is proved in [14]. A proof of Lemma 4.2 can be found in [12, p. 12].

Proof of Lemma 4.1. We choose $p = \frac{4}{3}$ and

$$B_0 = W^{1,\frac{4}{3}}(\Omega), \quad B = L^2(\Omega), \quad B_1 = H^{-2}(\Omega).$$

These spaces satisfy the assumptions of the theorem. Since the estimates (3.10) and (3.21) imply that the sequence $([S_x^\kappa]_\kappa|S_x^\kappa|_\kappa)$ is uniformly bounded in $L^p(0,T_e;B_0)$ for $\kappa \to 0$ and $([S_x^\kappa]_\kappa|S_x^\kappa|_\kappa)_t$ is uniformly bounded in $L^1(0,T_e;B_1)$, it follows from Theorem 4.1 that there is a subsequence, still denoted by $([S_x^\kappa]_\kappa|S_x^\kappa|_\kappa)$, which converges strongly in $L^p(0,T_e;B) = L^{\frac{4}{3}}(0,T_e;L^2(\Omega))$ to a limit function $G \in L^{\frac{4}{3}}(0,T_e;L^2(\Omega))$. Consequently, from this sequence we can select another subsequence, denoted in the same way, which converges almost everywhere in Q_{T_e}. Using that the mapping $y \mapsto f(y) := y|y|$ has a continuous inverse $f^{-1} : \mathbb{R} \to \mathbb{R}$, we infer that also the sequence $[S_x^\kappa]_\kappa = f^{-1}([S_x^\kappa]_\kappa|S_x^\kappa|_\kappa)$ converges pointwise almost everywhere in Q_{T_e}.
